Dryers, furnaces, dispersers, pumps, mass and heat exchangers and many other type of equipment can not operate without effective gas scrubbing system. Variety of work conditions and targets necessitates of designing the new removal equipment and of improving their efficiency calculation. Nowadays we have accumulated some experience in solution of these problems. However despite considerable achievements in a theory and a practice of gas scrubbing a series of the problems required new solutions remain.

MATHEMATICAL MODEL

Various theoretical models of a turbulent precipitation of particles on a wall (or a liquid film) of a channels are known. In dependence on the main accepted mechanism these models are divided into five groups:

1) free-inertial subgroup that based on a conception of free inertial ejection of particles from vortexes at the wall;

2) convective inertial subgroup that associates the precipitation with inertial effects at invasion of large vortexes in a boundary layer;

3) rise migration subgroup that associates the precipitation of particles with their rise migration and inertness;

4) effective diffusion subgroup proceeding from a suggestion that a coefficient of turbulent diffusion of the particles is higher than one of a gas in the near-wall region due to the inertness;

5) turbulent migration subgroup that takes into account the turbulent migration of particles to the channel wall caused by a amplitude gradient of pulse cross component of a gas speed.

The turbulent inertial mechanism is the most significant for an experience of the gas scrubbing from a fine dispersion phase. It is assumed that in this case all particles on the distance of the length of an inertial path $l_p = \frac{u_p d_p^2 \rho_p}{18\mu_g}$ are precipitated on the wall and their initial velocity corresponds to quadratic mean velocity of turbulent pulsations $u_p = 0.9u^*$.

It should be noted that a movement of particles in crosswise direction within a flow core occurs due to the turbulent pulsations (turbulent migration mechanism) and near the wall due to decaying turbulent pulsations in the boundary layer (inertial mechanism).

An intensity of the turbulent precipitation is described by the precipitation velocity (by turbulent migration of the particles, m/s): $u_t = j/n$, that is, by amount of the particles precipitated on unit surface for unit time.

It is assumed [1, 2] that for approximate estimation of the intensity of the particle separation on the channel wall (film) concentration of the dispersed phase in the distance from the walls (out of the boundary layer) resulting from turbulent mixing is determined exclusively by the turbulent migration and diffusion.

Let us consider a derivation of the equation for computation of an efficiency of the aerosol removal for nozzle separators. Due to various ways the separation of the dispersed phase occurs when gas with the dispersed particles flows over elements of a nozzle. A film on the nozzle is formed at the liquid aerosol removal.

The turbulent migration affects the non-inertially dispersed particles in the turbulent flow. The inertially dispersed particles do not depend on lines of the liquid stream, they are not entrained by the turbulent pulsation of a medium thus their motion can be considered as rectilinear. The precipitation efficiency of the inertial dispersed particles on the nozzle is determined mainly by their geometrical size. The weak inertial particles can be divided into two groups: (1) the particles that reach the nozzle surface and precipitate in a relaxation time, and (2) the particles entraining by the gas flow. The precipitation efficiency of the second group can be estimated by the following procedure [1, 3].

Let for a time dt the gas flow with the dispersed particles pass a way $dz = u_{av}dt$ and thereby the particle concentration is changed to dn. Then an amount of particles precipitated on the nozzle is

$$dN = -V_g dn dt = -u_{av} S dn dt . \quad (1)$$

For the time dt the nozzle surface is only reached by the particles that are located at a distance not greater then $dr = u_t dt$, thus all particles in the volume dV of a cone of $2dz$ height precipitate on the wall of the section dz.

$$dN = ndV = n\,2\pi R dr dz u_{av} u_t dt^2. \quad (2)$$

If we equate right sides of the equations (1) and (2) and take into account that $V_g = u_{av}\pi R^2$ we can obtain

$$\frac{dn}{n} = -\frac{2u_t}{R}dt = -\frac{4u_t}{d}dt , \quad (3)$$

where R is a channel radius; d is a channel diameter, m.

After an integration of equation (3) with an initial condition $n = n_0$ at $t = 0$ in a range from $t = 0$ to $t = L/u_{av}$ we obtain an equation for calculation of a numerical concentration of the particles in the gas flow at a distance L:

$$n = n_0 \exp\left(-\frac{4}{du_{av}}\int_0^L u_t\, dz\right), \quad (4)$$

or at $u_t = \text{const}$

$$n = n_0 \exp\left(-\frac{4\,Lu_t}{du_{av}}\right) \approx n_0 \exp\left(-\frac{4\,u_t}{d}t_{av}\right) , \quad (5)$$

where $t_{av} \approx L/u_{av}$ is an average residence time.

A part of precipitated particles or the removal efficiency of the weak inertial particles can be expressed by a value of the efficiency of the turbulent precipitation [1, 2]

$$\eta_t = \frac{n_0 - n}{n_0} = 1 - \exp\left(-\frac{4\,Lu_t}{du_{av}}\right). \quad (6)$$

As noted in [1, 2] the exponential dependences of the removal efficiency on the channel length identical to Eq. (6) in form were obtained and used for the efficiency computation of electrostatic precipitators, centrifugal separators, plate dust collectors, Venturi scrubber and other devices with high agitation intensities. The obtained equations are in well accord with an energy theory of wet dust collecting and with results of experimental research.

DETERMINATION OF MODEL PARAMETERS

For computation of the reduced turbulent precipitation velocity $u_t^+ = \frac{u_t}{u^*}$ related to the relaxation time of the particle velocity some empiric and semi-empiric expressions can be stated.

$$\tau_r = \frac{d_p^2 \rho_p}{18\ \mu_g} = \frac{d_p^2 \rho_p}{18 \rho_g \nu_g} , \quad (7)$$

where τ_r is the relaxation time, s.

A dimensionless relaxation time is written as:

$$\tau^+ = \frac{\tau_r u_*^2}{\nu_g} . \quad (8)$$

In [1, 2] the following formulas of various authors are presented:

(1) Liu and Agarwal at $\tau^+ < 10$

$$u_t^+ = 6 \times 10^{-4} (\tau^+)^2 . \quad (9)$$

(2) Mc Coy and Hanratty

$$u_t^+ = 3.25 \times 10^{-4} (\tau^+)^2 \text{ at } \tau^+ \le 22.9, \quad (10)$$

$$u_t^+ = 0.17 \text{ at } \tau^+ > 22.9. \quad (11)$$

(3) Uzhov and Mednikov:

$$u_t^+ = 7.25 \times 10^{-4}\, k \text{ at } k \le 16.6, \quad (12)$$

$$u_t^+ = 0.2 \text{ at } k > 16.6, \quad (13)$$

where

$$k = \left[\frac{\tau_r\, u_*^2}{\nu_g} \left(1 + \frac{\tau_r\, u*}{0.05 d_{equiv}} \right)^{-1} \right]^2. \quad (14)$$

It is evident from equations (9)–(14) that the separation velocity u_t considerably depends on the dynamic velocity value $u*$ or a tangential stress $\tau_w \left(u* = \sqrt{\frac{\tau_w}{\rho_g}} \right)$.

Taking into account a presence of the aerosols in the gas flow at the movement in the channel of various forms we obtain analytically an equation for computation of the dynamic velocity. For this end we use conservative properties of the boundary layer thereby an effects of aerosols and other perturbations can be considered by a parametrical satisfaction to an impulse balance [3, 4].

In applied aero- and gas dynamics for computation of a friction resistance and a heat exchange of bodies with a various surface curvature a technique of an effective wave is employed. In this case an effect of a pressure gradient caused by the curvature of the streamline surface is taken into account by fitting the effective length if thicknesses of the energy losses of gradient and non-gradient boundary layers are equal. At the predetermined effective length characteristics of the boundary layer with the pressure gradient are calculated by appropriate formulas for a flat plate.

This approach based on known properties of conservatism of friction laws within the boundary layer at the presence of the longitudinal pressure gradient in particular on the property that a structure of a mathematical description of elementary act of transfer is invariant with respect to various perturbations and to an apparatus scale. These perturbations do not change the structure of the mathematical description of the boundary layer that enables their parametric consideration. Thus as a theoretical basis for calculation of the average value of dynamic velocity mathematical models can be used of a flat boundary layer avoiding the perturbations (e.g., Karman or Landau–Levich model) and an effect of the various perturbations (the pressure drop, a rough surface, a presence of the dispersed phase) can be considered by integral relations of the impulse balance.

An impulse flow in the turbulent boundary layer is written in a known form:

$$\tau = \rho (\nu + \nu_T) \frac{du}{dy}, \quad (15)$$

where for a turbulent exchange coefficient $\nu_T(y)$ in the viscous sublayer various power functions are used, and out of this sublayer linear functions. For example, according to three layers model a function in the following form is used:

$$\nu_T = \chi\, u_*\, y - \nu, \quad (16)$$

where $\chi = 0.4$ is Prandtl number, σ is a lateral coordinate.

From relations (15), (16) a derivative value follows:

$$\frac{du}{dy} = \frac{u_*}{\chi y}. \quad (17)$$

As it is well known an integration of equation (17) gives a logarithmic distribution of a velocity profile in the turbulent region of the boundary layer.

The tangential stress in the turbulent boundary layer is also written by an averaged values of fluctuating velocity constituents v', and $u'\tau = \rho \overline{u'v'}$.

Hence an average density of the power flow looks like $e = \rho\, u\, \overline{u'v'} = u\tau_w$.

The power flow decreases as it nears to the surface due to an energy dissipation. The derivative de/dy causes the energy dissipation in the unit volume of the medium

$$\varepsilon = \frac{de}{dy} = \tau \frac{du}{dy}. \quad (18)$$

This relation is extensively used for calculation of the dynamic velocity in the turbulent flows when application of other techniques of the calculation of $u*$ is difficult.

If we write the derivative value du/dy in equation (18) as (17) we obtain:

$$\varepsilon = \frac{\rho_g}{\chi\, y} \left(\frac{\tau}{\rho_g} \right)^{\frac{3}{2}} = \frac{\rho_g u_*^3}{\chi\, y}. \quad (19)$$

where ε is a local velocity of the energy dissipation. Evidently at some value of $y = \delta_e$ the local energy dissipation ε will coincide with an average bulk dissipation, thus $\varepsilon = \overline{\varepsilon}$ at $y = \delta_e$.

Let us use an approach from an applied aerodynamics when for determination of some effective length demanding for calculation the average tangential stress

on the surface of the complex geometry the conditions of the equality for the energy loss thicknesses of the gradient and non-gradient boundary layers are written. By this approach we determine thickness value δ_e.

From relation (19) the dynamical velocity value at $y = \delta_e$ is expressed as

$$u_* = \left(\frac{\bar{\varepsilon} \chi \delta_{equiv}}{\rho_g} \right)^{\frac{1}{3}}. \quad (20)$$

In equation (20) main parameters are a velocity of the energy dissipation $\bar{\varepsilon}$, and the thickness of the boundary layer δ_e. The average energy dissipation is found by using the pressure drop in the channels obtained experimentally taking into account the presence of the dispersed phase. An average thickness of the boundary layer is found from the impulse balance.

A resistance to the impulse transfer is written as [3, 4]:

$$\frac{1}{\gamma} = \frac{\rho_g \Delta \bar{u}_\infty}{\tau} = \int_0^{\delta_{equiv}} \frac{dy}{\nu + \nu_T(y)}. \quad (21)$$

where γ is the coefficient of the impulse transfer, m/s; $\Delta\bar{u}_\infty$ is an average driving force of the impulse transfer, m/s.

Assuming the three layers model of the turbulent boundary layer the characteristics of the turbulent transfer is written in the known form taking into account the pulsation dumping in the viscous sublayer (Dissler function):

$$\frac{\nu_T}{\nu} = (0.124\, y^+)^4 \text{ at } y^+ \le 6, \quad (22)$$

$$\frac{\nu_T}{\nu} = \frac{y}{5} \text{ at } 6 < y^+ \le 30, \quad (23)$$

$$\frac{\nu_T}{\nu} = \frac{y}{2.5} - 1 \text{ at } y^+ > 30. \quad (24)$$

Where $y^+ = yu_*/\nu$ is the dimensionless coordinate in the boundary layer.

The resistance to impulse transfer from equations (21)–(24) looks like

$$\frac{1}{\gamma} = \int_0^{\delta_1} \frac{dy}{\nu + \nu(0.124\, y^+)^4} + 5 \int_{\delta_1}^{\delta_2} \frac{dy}{u_* y} + 2.5 \int_{\delta_2}^{\delta_{equiv}} \frac{dy}{u_* y}, \quad (25)$$

where $\delta_1 = 6\nu/u_*$ is the viscous sublayer thickness, m; $\delta_2 = 30\nu/u_*$ is a buffer area thickness of the boundary layer, m.

After an integration of (25) we have obtained:

$$\gamma = \frac{u_*}{13.73 + 2.5\left(\ln\delta_{equiv} - \ln\frac{30\nu}{u_*} \right)}. \quad (26)$$

The boundary layer thickness was found using the flow relation

$$\tau = u_*^2 \rho_g = \rho_g \gamma \Delta \bar{u}_\infty, \quad (27)$$

thereof with the impulse transfer coefficient (26) the following was obtained:

$$\delta_{equiv} = \exp\left[\frac{1}{2.5}\left(\frac{\Delta\bar{u}_\infty}{u_*} - 13.76 + 2.5 \ln\frac{30\nu}{u_*} \right) \right]. \quad (28)$$

In equations (27), (28) $\Delta\bar{u}_\infty$ is the average driving force of the impulse transfer $\Delta\bar{u}_\infty = u_\infty \pm w_p$. A liquid velocity on the interphase surface of a film that is formed on the surface of a separator contact devices is bound with the film thickness and the liquid flow.

Thus set of equations (20), (28) that is solved by an iteration technique was obtained. The average value of the dynamic velocity and the thickness of the turbulent boundary layer are the solution result.

The average energy dissipation in equation (20) is written with introducing the pressure drop:

$$\bar{\varepsilon} = \frac{\Delta PS u_{av}}{V_l} = \frac{\Delta PG}{V_l \rho_g}, \quad (29)$$

Performed test of the mathematical model adequacy revealed a satisfactory agreement of the computed results to the dynamic velocity in the pipe and to the boundary layer thickness on the plate. Comparison of the results obtained with accordance to the known formulas for the pipe and the plate reveals a divergence ±(5–7)%. Therefore an obtained equation set for calculation of the dynamic velocity can be used for the flows with the various perturbations that are taken into account by keeping of the impulse balance, i.e. in the flow relation of the impulse transfer thereby the pressure drop of the apparatus operation area should be used as experimental information about the subject.

Many calculations of u_* for the nozzle separators are generalized with ±18% by a simple equation looking

like

$$u_* = 1.8\left(\frac{\varepsilon \nu_g}{\rho_g}\right)^{1/4} = 1.8\left(\frac{\Delta P u_{av} \nu_g}{L \rho_g}\right)^{1/4}. \quad (30)$$

THE CALCULATION OF THE REMOVAL EFFICIENCY

From (7), (8) and (30) we obtain the dimensionless relaxation time:

$$\tau^+ = 0.18 \frac{d_p^2 \rho_p}{(\rho_g \nu_g)^{1.5}} \sqrt{\frac{\Delta P u_{av}}{L}}. \quad (31)$$

It was established by computations that for meeting the conditions (9) ($\tau^+ < 10$) the particle size in the nozzle separator must be less than 10 μm (Fig. 1). The dimensionless relaxation time of the particles of 0.1 μm size is very small.

The velocity of the turbulent precipitation of the particles for the nozzle separators is expressed as

$$u_t = 0.36\ \text{Ч}10^{-4} \frac{d_p^4 \rho_p^2}{\nu_g^{2.75} \rho_g^{3.25}} \left(\frac{\Delta P u_{av}}{L}\right)^{\frac{5}{4}}, \quad (32)$$

where u_t was written using equation (9).

Using equation (9) we can determine the value of the removal efficiency according to equation (6) in the nozzle apparatus for small particles. We obtain:

$$\eta_t = 1 - \exp\left[1.40 \times 10^{-4} \frac{d_p^4 \rho_p^2 \Delta P^{1.25}}{\nu_g^{2.75} \rho_g^{3.25} d_{equiv}} \left(\frac{u_{av}}{L}\right)^{0.25}\right]. \quad (33)$$

The removal efficiency of large particles regarding equations (6) and (11) (or (13)) is:

$$\eta_t = 1 - \exp\left[-1.44 \frac{1}{d_{equiv}} \left(\frac{L}{u_{av}}\right)^{0.75} \left(\frac{\Delta P \nu_g}{\rho_g}\right)^{0.25}\right]. \quad (34)$$

Equations (33) and (34) enable us to quickly estimate in an explicit form an effect of regime, design features, and physical properties of the gas flow with aerosol particles to the removal efficiency in the apparatus with various nozzles.

Computed results of the removal efficiency of the small and large droplets in the apparatus with Raschig rings and Inzhekhim-2000 nozzles [3] are showed in Figs. 2–4.

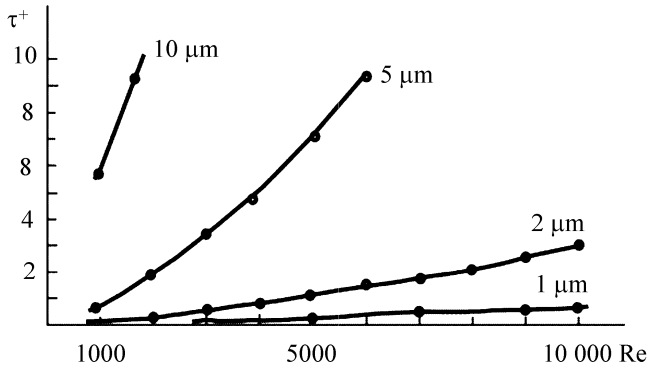

Fig. 1. A dependence of the dimensionless relaxation time on Reynolds number in the nozzle separator with Raschig rings. An operation medium is air-water droplets, d_e = 0.015 m, u_{av} = 1–10 m/s, L = 1 m.

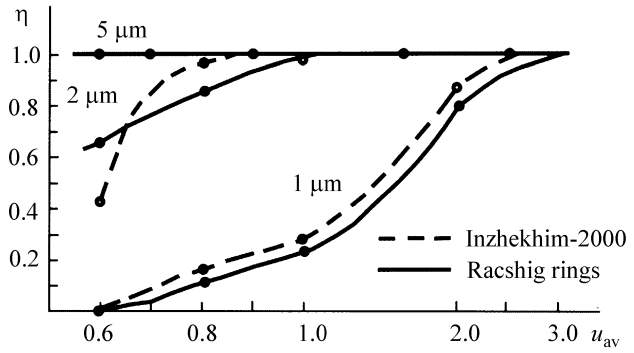

Fig. 2. Dependence of the removal efficiency on the average velocity of the gas flow for particles of a various size. A working media is air–water droplets, d_e = 0.015 m, L = 1 m.

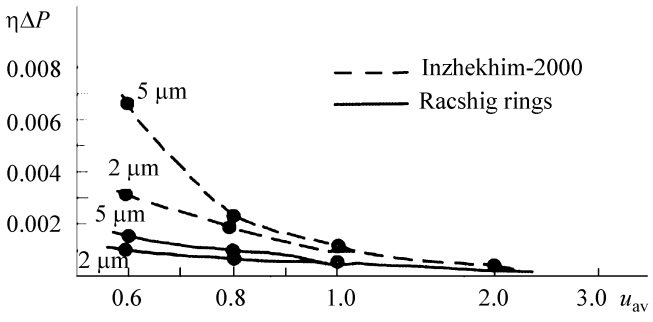

Fig. 3. A relation of the removal efficiency to hydraulic nozzle resistance in a dependence on a fictitious gas velocity.

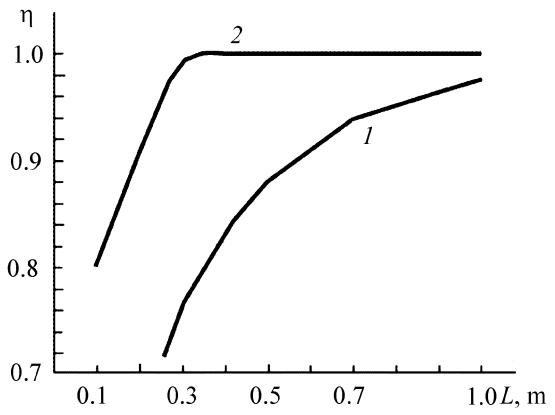

Fig. 4. Dependence of the removal efficiency on the channel length for the large droplets A working media is air, $u_{av} = 2$ m/s, $L = 0.1 \ldots 1$ m, $d_e = 0.015$ m. (*1*) swirling flow motion; (*2*) flow motion in the nozzles.

The removal efficiency in the apparatus with Inzhekhim-2000 nozzles is higher then in the apparatus with Raschig rings. Fig. 4. shows that at a swirl phase motion the removal of the dispersed phase is lower by 6–40% (in dependence on the channel length) than at the removal by the nozzles.

It should be noted that the removal efficiency of the particles with size less than 1 μm is sufficiently small. General removal efficiency of the large and small particles can be calculated in accordance with an additive equation.

The developed mathematical model of the aerosol removal enables estimating the efficiency of nozzles at an improvement and designing of the separators.

USED DESIGNATIONS

u_p is the particle velocity, m/s;
u_{av} is the average gas velocity, m/s;
u_* is the dynamic friction velocity, m/s;
d_p the particle diameter, m or μm;
ρ_p is the particle density, kg/m^3;
ρ_g is gas density, kg/m^3;
μ_g is the dynamic gas viscosity, Pa·s;
n_0 is initial concentration of the particles, 1/m^3;
d_e is equivalent channel diameter, m;
L is the channel length, m;
G is the mass gas flow, kg/s;
V_1 is the operative separator volume, m^3;
ν_g is cinematic gas viscosity, m^3/s;

Abstract—Inhibitors against corrosion of metal surfaces in salt solutions, especially of carbon steel in reference 5% NaCl solution and in suspension fertilizer were selected. We examined a corrosion kinetics, effect of corrosion protection, and also a penetration and a corrosion depth in the presence of various inhibitors.

DOI: 10.1134/S1070427208090437

An efficiency of suspension liquid combined fertilizers (SLCF) is verified by a long-term scientific and practical experience in agriculture. The application of a solid mineral fertilizers does not ensure the homogeneous mixture and its uniform input in soil that leads to an excess consumption of fertilizers, decrease in crop, and an environment pollution. From the point of view expressed [1−3] main requirements to the mineral fertilizers areas follows: increase of concentration of nutrient species, input of necessary micro and macro elements in one operation, an uniform distribution over the area could be satisfied exclusively using SLCF.

We have developed a stable SLCF on the basis of a phosphorite flour, ammophos, carbamide, ammonium sulfate, calcium chloride [4]. These are saturated salt polydispersed solutions in which small particles of soluble and unsoluble salts, stabilizing agents and other materials are dispersed. Due to the presence of the solid particles and also of the concentrated salt solutions in the suspensions their abrasive and corrosion properties increase that leads to an equipment wear at manufacturing, transport, and storing of fertilizers. Despite the noted difficulties the suspensions are the most desired combined fertilizer as confirmed by the international practice.

For establishing of conditions of storage, transport, and input of the suspension fertilizers their corrosion activity schould be studied.

A sheet carbon steel that is applied in the production of bunkers, settlers, flotation devices, crystallizers, screens, cyclones etc. at a potassium chloride manufacturing [5] was selected for an examination. Samples of non-activated steel prepared in the form of 60 × 35.1 × 1 mm plates were used that were preliminary mechanically cleaned, degreased by acetone and then by hexanone, dryed, and weighted. A metal density was 7.87 g/cm^3. Corrosion examinations were carried out at room temperature in polyethylene vessels of 500 cm^3 capacity containing either 5% NaCl (a control experiment) or with addition of the corrosion inhibitors of different concentrations. All solutions were prepared using a distilled water. A weight loss of the samples was defined after removing the corrosion products. A corrosion rate was computed according to the following formula:

$$V_o = \frac{G_r - G_c}{F} 10^4 \times \frac{1}{T},$$

where G_γ is the sample weight before immersion in the solution, g; G_c is the sample weight after the corrosion during in T days; F is a sample area, cm^2; T is a number of days of inhibitor action.

A value of the corrosion protective effect of the inhibitor was computed in accordance with [6] by the formula:

$$Z = [(V_0 - V_1) / V_0] \times 100,$$

where V_0 and V_1 are corrosion rates without inhibiting additive and in its presence.

According to the state standard GOST 13819-68 a corrosion resistance is measured by a thickness of a cor-

roded metal that is defined as the penetration and is expressed in mm per year. A resistance groups are used at a rough estimation, and points at more exact estimation. The metal weight loss is converted in the penetration (the depth value) according to [7] by the formula:

$$\Pi = \frac{8.76 \times K}{\gamma},$$

where Π is the penetration, mm/year; γ is the metal density, g/cm^3; K is the weight loss, g/(m^2·h).

Since the suspension combined fertilizers represents polydispersed saturated salt solutions of urea, potassium chloride, ammophos, ammonium sulfate, an influence of these components upon the carbon steel corrosion should be studied. Results of examinations on the corrosion protection of the steel by the urea are presented in Tables 1 and 2.

The obtained data shows that the urea application decreased the corrosion of the carbon steel, thus the urea reveals inhibiting action relative to the steel. However the corrosion under the action of NaCl solution preoceeds more actively in first 7−14 days and further some decrease in the rate occurs, and the corrosion rate decreases after 21 days (Table 1).

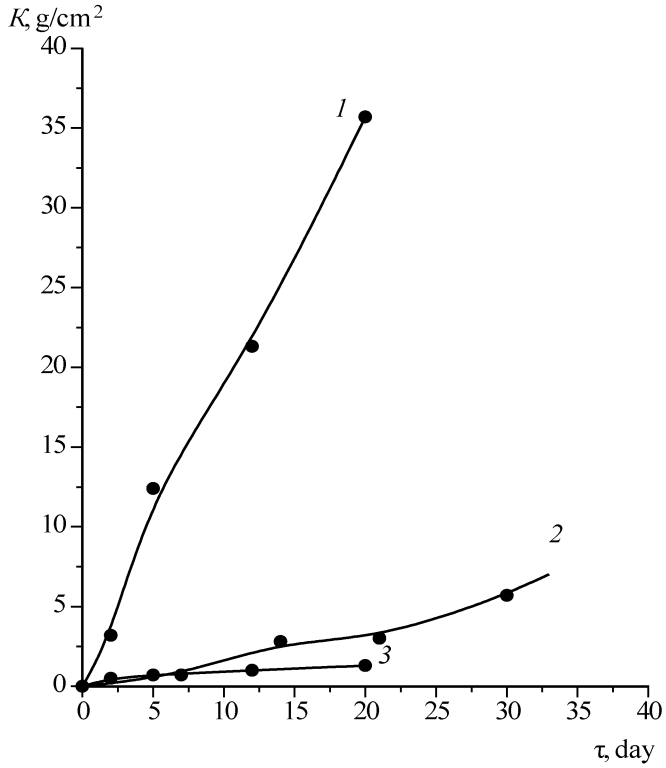
The corrosion protective effect of the urea at 25% concentration of its solutions that approximately corresponds to its content in the suspension, within 42 days on the average is 34−39.6%, within first 7 days 41.7−46%. The penetration equals to 0.041–0.045 mm/year, that is the corrosion resistance of the steel 4. The protective inhibiting action of the urea from a chloric corrosion was established earlier by a stainless steel [8]. Hence the urea use as one of the species of SLCF causes a significant decrease in the corrosion rate of the applied steel equipment at a manufacturing of the suspension fertilizer.

On the contrary a negative influence of the ammophos solutions upon steel occurs that seems unlikely on first sight since compounds of the phosphoric acid are considered as corrosion inhibitors. The ammophos is a double nitrogen phosphor fertilizer, a monoammonium phosphate with an admixture of diammonium phosphate, and compounds of the ammonium salts are as well-known to react with iron forming water insoluble ferroammonium phosphates looking like a uniform film that covers a surface of the steel plates and can be easily washed away. After first 7 days the corrosion rate in the ammophos suspension reaches 10.2−14.1 g cm^{-2} day^{-1}, hereinafter it gradually decreased. The average corrosion value in 35 days, and also the corrosion depth that in concentrated ammophos suspension reached a value of 0.504−0.512 mm/year corresponding to the low group of the metal resistance were measured. Based on the presented data an application of the ammophos as a basic solution for obtaining suspension fertilizers must be restricted.

An influence of the ammonium sulfate solutions upon the corrosion resistance of the steel results in the decrease of the corrosion rate in diluted solutions. In the concentrated solutions of the ammonium sulfate starting from 10% concentration due to decrease of an ammonium sulfate ionicity and reaction with iron ions the steel corrosion essentially falls (0.11 g/m^2 day^{-1} during 22 days).

Hence the presence of the concentrated solutions of the ammonium sulfate in the suspension combined fertilizer also promotes the corrosion protection of steel parts.

The influence of the suspension fertilizer of various compositions (1, 2, 3) upon the corrosion characteristics of the steel was studied.



Composition of the fertilizer 1 is phosphoric flour, ammonium sulfate, ammophos, potassium sulfate in a ratio 9.6:5.6:11.3 % (by dry species). A bentonite clay used as stabilizer is 4 wt% (for all compositions).

Composition of the fertilizer 2 is phosphoric flour, urea, ammophos, potassium chloride in a ratio 10:10.7:8.8%.

Composition of the fertilizer 3 is phosphoric flour, ammonium sulfate, potassium chloride in a ratio 9.4:6.6:12.7%.

Experimental data are presented on the figure. The figure shows that the suspension including carbamide (2) is characterized by lesser corroding action on the steel. The corrosion rate in 5−7 day is 0,10 g/m^2 day. This value corresponds to the corrosion penetration of 0.005 mm/year. Thus the steel in these suspensions is considered as sufficiently resistant with the corrosion resistance of the steel 2 points.

Among the various ways of the metal corrosion protection an application of the corrosion inhibitors: (chemical compounds or their various compositions that in the sufficient concentrations can decrease the corrosion rate of metals), acquires more significance. The inhibitor action is associated with a change of a protected surface state. This can occur due to an adsorption or formation of in soluble compounds with cations of metals. These compounds reduce the active surface area of metals and increase an activation energy of the corrosion. A search of the new high effective inhibitors should be considered as an important problem although nowadays some thousands of substances and their mixtures were tasted.

Corrosion curves of the steel in the SCF of the compositions 1, 2, 3.

An effect of some inhibitors contained in liquid compositions for cold phosphatizing on a chemical corrosion of steel in chloride solutions was studied. Obtained results are presented in Tables 3 and 4.

The presented data show that all studied inhibitors excepting an ammonium molybdate reveal in either measure anticorrosive properties. Thereby the corrosion rate in the corroding solutions gradually decreased with an increase in the residence time of the samples. The best inhibitors are compounds of zinc then sodium silicate,

thiocyanates, sodium phosphate, sodium tetraborate. The corrosion penetration for zinc nitrate is 0.01 mm/year, for sodium silicate 0.02 mm/year. The positive action of the studied inhibitors was caused by both their capability to iron passivation by dissolved oxygen and their capability to form layers of corrosion products, e.g. by ferric and ferrous phosphates in Na_3PO_4 solutions or similar compounds in the sodium silicate solutions or complex compounds of iron with zinc ions. The formed layers of the corrosion products on the iron surface represent effective, anticorrosion, protective diffusive barriers. The protective effect of the corrosion, for instance of the zinc nitrate, in first 8 days of keeping of the steel in NaCl solutions is 97.6%, in sodium silicate solutions 47.3% (Table 3).

A production of inhibitors does not satisfy all industry requirements. An application of waste and inexpasive products of chemical industry is a promising way for extending the amount and decreasing the cost of the corrosion inhibitors.

A phosphate mud (IDG-1 and IDG-3) formed at the phosphatizing the metal surface before a painting was studied as inhibitors for decreasing the corrosion effect of electrolytes on the carbon steel. The zinc and iron phosphates are contained in the chemical composition of the mud. A thin dispersed steady suspension is formed in the salt solution. A presence of the zinc in the inhibitor composition permits a formation of a steady non-porous protective film of the zinc phosphate that promotes an essential decrease in the corrosion of steel devices. Values of the corrosion protective effect of the phosphate mud are presented in Table 5. The inhibitor of 1.0–1.5 wt% provides the corrosion protection 92–93%. Increased inhibitor feed is not required.

Table 5. The corrosion protection of the steel by the phosphate mud

Amount of inhibitor, mas% to NaCl	Corrosion protection effect, %				
	days				
	7	14	21	28	68

IDG-3 (a nitrite–soda melt, "Khimvolokno", Grodno, Ukraine) is a mixture of water-soluble inorganic salts crashed to grains of 10 mm size. pH number of the obtained solution is 8–9. A thin protection film that does not penetrate deep into the steel due to adsorption of nitrate and nitrite ions on the active centers is formed on the metal surface at the application of the melt of the inorganic salts as the inhibitor. An introduction of 2.5–3 wt% IDG-3 in the salt solution significantly decreases the corrosion rate of the steel devices and provides the high value of the corrosion protective effect of the inhibitor on the steel (87–92 %) (Table 6).

Table 6. The values of the corrosion protective effect of the inhibitor (the nitrite–soda melt) on the steel

Amount of inhibitor, mas% to a salt	Corrosion rate, g/(m^2 day)	Protection effect, %
–	5.52	–
0.75	3.06	44.6
1.50	1.95	64.7
2.25	0.81	85.3
2.70	0.56	89.9
3.00	0.44	92.0

The corrosion protection of a metal in result of an introduction of the inhibitor, e.g. the phosphate mud, in the fertilizer 1, is 88%. Thus, we show that the urea using as raw component of SCF, sodium silicate, or liquid glass, using in the phosphate flour manufature as a reagent, the phosphate mud (the zinc and iron phosphate), the nitrite–soda melt, the ammonium and sodium phosphates, sodium thiocyanate are the most efficient compounds studied as the inhibitors of the corrosion for an industry.

CONCLUSIONS

1. High anticorrosion effect of the urea on the steel in the presence of the chorine ions was manifested. The concentrated ammonium sulfate solutions effect similarly on the steel.

2. The phosphate mud and the nitrite–soda melt which are waste products are suggested as the corrosion inhibitors.

3. In the conducted study the carbon steel in the suspension fertilizers containing the urea reveals the sufficient resistance for employing this steel as a structural material of the equipment for the fertilizer preparation and storing without specific corrosion protection.

PROCESSES AND DEVICES OF CHEMICAL MANUFACTURES

Main Reprocessing Ways of Industrial Waste Water on the Local Plants

Abstract—Some ways of wastewater treatment on the local plants are presented. An application of the suggested ways allows reuse of the reprocessed water to reuse and the optimization of the operating costs.

DOI: 10.1134/S1070427208090449

Replacement of technologically used natural fresh water by the treated wastewater allows to avoid a deficiency of a water supply and to prevent an exhaustion of the fresh water. One of the ways is the building of recirculated system of the industrial water supply based on the reuse of the industrial water treated to fit the corresponding requirements of the process water quality.

A definite chemical composition of the water is required for each specific technological process. Hence large amount of the reprocessing ways is known.

A scheme of water treatment must provide minimum discharge of the wastewater into the onsite water, its maximum reuse in technological processes and in the recirculated systems, more complete extraction of valuable admixtures.

Local or community wastewater treatment plants are mainly emplyed in the chemical industry. The latter may include a primary (mechanical), secondary (biological), and tertiary (aftertreatment) wastewater treatment

Local wasterwater treatment plants are applied to decontaminating water immediately after a technologic outlet. The local wasterwater treatment plant is one of the steps of a technological process when as a rule the valuable admixtures are extracted, because usually regenerative processes: sedimentation, flotation, extraction, refining, adsorption, ion exchange, reverse osmosis are used.

Let us consider each of these processes.

SEDIMENTATION

Devices of periodical and continuous operation are used for removal from waste waters of the suspended substances by a settling in response to an external force such as gravity. Settlings of the periodical operation are applied in case of a small flow. They look like a metal or ferroconcrete reservoirs with conic bottom from where water is decanted through a siphon or special gutters. The settlings of continuous operation are used at the large flow. They may be vertical, horizontal, and radial. Also plate (manytier) settlings, pipe settlings with small and steep pipe slope are used [1].

A flocculation is employed for an acceleration of the sedimentation and an efficiency increase of a water clarification and a decoloration That is an enlargement of the colloid and suspended particles caused by clump ing together into flocs under action of adhesion forces. A hydrolysis and a formation of low soluble alkalis occur at a dissolution of coagulants being salts of weak bases and strong acids in water. Aluminium sulfate, ferrous sulfate, ferrous chloride, potassium alum and a mixture of ferrous sulfate and chloride are widely applied as coagulants. In the rare cases salts of magnesium, zinc, and titanium are used [2].

Significant amount of water in the sediment both in various bound states with species and in the free state is a disadvantage of this treatment.

A burial of this bulky wet mud is complicated by rapid increase of a coagulant consumption for the water treatment and conditions of its accumulation do not fit to requirements of a environmental protection. However this problem is solved by the coagulant regeneration by an acid processing that decreases the initial sediment to 15–18 vol% [4].

FLOTATION

The flotation is used for the wastewater treatment from oil waste, products of petroleum processing, fats, oils, gums, latexies, products of organic synthesis, surfactant species, dyes and others. The process is based on a specific utilization of the molecular forces causing the adhering of the suspended admixtures to the bubbles of a finely dispersed gas in water, their carrying to the upper surface, and forming a froth saturated by the separated substances [2].

A main type of devices used for the flotation is the following:

– A foam former where air, wetting and flocculated agents, and also a part of the waste waters are fed;

– A funnel-shape or cylindrical reservoir where a polluted medium slowly passes from a middle to borders of the reservoir, and the suspended particles adhered to the air bubbles are collected as the froth;

– A device for the froth removal;

The best known devices are traps of Wolf and Sawall. A starch, carboxymethyl cellulose, guar gums, polethylene amine, polydimethylaminoethylacrylate, hydrolyzed polyacrylamide are used as flocculating agents [3].

EXTRACTION

The extraction is widely applied to the cleaning from organic admixtures especially phenol waste waters of a thermal processing of the solid fuels. The extraction is available in case of high concentrations of the organic admixtures or of a cost of removed substances. An agitator-settler, and devices of column and rotation types are of commonly applied.

RECTIFICATION

Specificity of the waste water treatment by the rectification is caused by sufficiently small concentraions of the admixtures and by requirement of their practically complete removal. The difference between the rectification in columns in the presence of a superheated water steam, a rectification in the distillation columns, and azeotropic distillation should be considered . The column devices with contact items such as nozzles of various shapes, and plates with downcomer and without the latter. At the azeotropic distillation a separator where a demixing of the azeotropes occurs is added in the scheme.

ADSORPTION

The adsorption by activated carbon is one of more effective ways of the industrial water treatment containing organic admixtures that enables reacting the standard value. The following adsorbents BAU, TNK-AKhB-02,OU, KAD-Iodic, KAD ground, MS-4 are employed. Devices with blade, turbine and propeller agitators, adsorbers of a column type, single-deck adsorber, multideck adsorber with overflow pipes, adsorbers with a divided adsorbent layer are used [1].

Unfortunately the adsorption may be economically available exclusively at repeated uses of adsorbents that can be achieved either by an isolation of an adsorbed valuable substances as products or by a total destruction of compounds and their oxidation to end products: CO_2, H_2O, N_2 etc. [4].

ION EXCHANGE

The waste water treatment by the ion exchange is reduced to a binding of removed ions with forming sparringly or weakly dissociated compounds. In this case chemical reactions are practically irreversible. The ion exchange is used at heavy metals production, an isolation of compounds of a fluorine, radioactive and other elements. The following types of ionites both domestically produced and foreign are used: amberlites (US, Japan), duolites (US, France), dowexes (US), zerolites (UK), levatites, wofatites (Germany), cationites KU-1, KU-2, SG-1, KB-2, KB-4, anionites AV-16, AV-17, AN-1, AN-2F, AN-18, AN-31, EDE-10P (Russia) and others.

REVERSE OSMOSIS

The reverse ocmosis is a continuous process of a molecular separation of solutions by their filtration under pressure through semipermeable membranes that retains completely or partially molecules or ions of a dissolved substance. This process is used for an isolation of saccharides, salts, acids. The membranes of cellulose acetate processed for a water permeability by magnesium perchlorate with a polyelectrolyte film, porous carbonaceous pipes, a porous pipes made of a glass fiber, or also metal or phorphorous filters as a substrates are the most feasible. An equipment of the following types are applied to industry:

– "Filter-press" with a plate chamber filtering elements. Their main disadvantages are an insufficient specific area of a membrane surface and a large metal consumption.

– With tubular filtering elements which characterized by the insufficient specific surface and by a difficult replacement of depreciated membranes

– Filtering elements of a roll or spiral types that are noted for the large specific area of the membrane surface but also characterized by difficult mounting and replacement of the membranes.

– With membranes made of hole fibers. Their advantages are a compactness and a high output but a replacement of the damaged fibers is difficult [1].

It should be noted that an application of a regeneration ways of the treatment enable in many cases repeated use of the treated waste water in the same operation. A return in the technological process of the removed admixtures decreases a loss of a raw material, agents and products and often rises economical efficiency of the waste water treatment.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Diagnostics of the Behavior of Apatite and Its Aggregates with Sphene in Dilute Mineral Acids

A. T. Belyaevskii, A. I. Nikolaev, V. B. Petrov, and Yu. G. Bychenya

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Resources, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received January 22, 2008

Abstract—Behavior of monomineral fractions of apatite and sphene and their aggregates in treatment with dilute solutions of hydrochloric and sulfuric acids was studied by electron microscopy, IR spectroscopy, crystal-optical methods, and X-ray and chemical analyses. The manner in which aggregates of apatite and sphene disintegrate was for the first time visualized by electron scanning microscopy. The efficiency of purification of the apatite concentrate to remove apatite with hydrochloric and sulfuric acid solutions was examined.

DOI: 10.1134/S1070427208100017

The sphene concentrate is produced from wastes formed in dressing of apatite-nepheline ores from Khibiny deposits. The sphene concentrate is regarded as a promising raw material for production of titanium pigments [1, 2] and for use in coatings of welding electrodes [3]. Apatit Open Joint-Stock Company semi-industrially manufactures paints based on titanium dioxide produced from the sphene concentrate. Presence of phosphorus makes lower the recovery of titanium into the pigment titanium dioxide because of the precipitation of titanium phosphate, which remains in the calcium silicate product. In the technical specification for the sphene concentrate, the content of phosphorus is limited to 2 wt % in terms of P_2O_5, and in that for welding electrodes, 0.1 wt % in terms of P_2O_5 or 0.05 wt % in terms of phosphorus. The increasingly stringent requirements to the quality of welding materials necessitate a higher degree of purification of the sphene concentrate to remove phosphorus.

It has been reported [4] that sphene and apatite can form aggregates (via intergrowth of crystals of these minerals), which hinder their separation in the dressing stage. When the ore is crushed, the aggregates partly disintegrate and opened aggregates are formed, which gives reason to believe that sphene can be more fully separated from apatite by other methods. For example, a method of chemical purification, based on decomposition of apatite with mineral acids and, in particular, sulfuric acid, has been suggested for deeper purification to remove phosphorus [4, 5].

A possible obstacle to efficient purification are not-yet-opened aggregates. This hinders removal of phosphorus even upon treatment of the concentrate with rather high-concentration acids. It should be taken into account that treatment with such acids inevitably leads to decomposition of fine fractions of sphene and, accordingly, to loss of titanium. It has been suggested to use diluted (down to 10%) solutions of sulfuric, hydrochloric, and nitric acids for chemical purification of sphene and other concentrates [5].

The aim of the present study was to examine the behavior of apatite, sphene, and their aggregates in their interaction with dilute sulfuric and hydrochloric acids, which can be used in practice for optimizing the purification conditions of the sphene concentrate to remove phosphorus.

EXPERIMENTAL

The experimental procedure consisted in that narrow fractions of sphene and apatite grain size (–0.071...+0.063 mm) and aggregates of the minerals were treated with acids.[1]

[1] Monomineral fractions of sphene and apatite were sampled by V.F. Fedchenko at the Central laboratory of Apatit Open Joint-Stock Company.

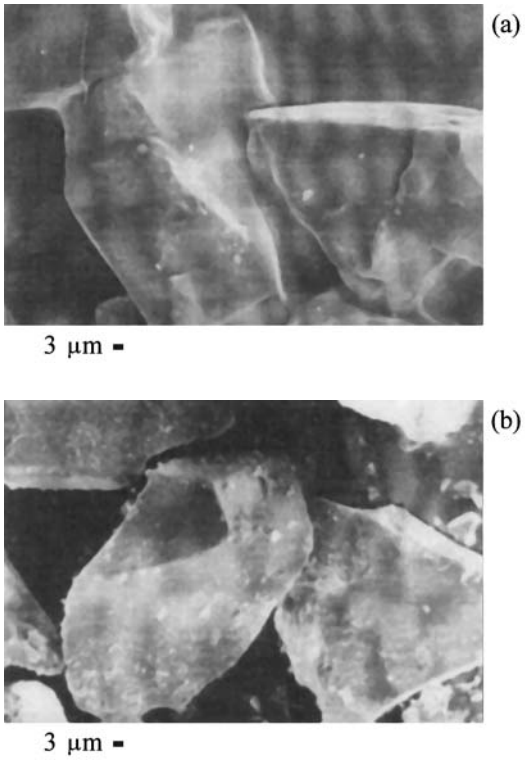

Fig. 1. Micrographs of monomineral particles of (a) sphene and (b) apatite.

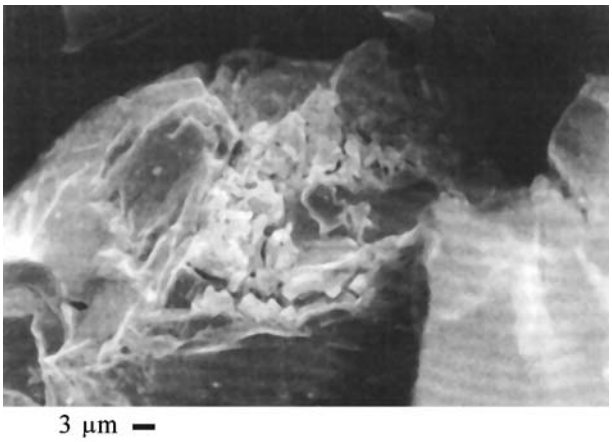

Fig. 2. Micrograph of an aggregate of sphene and apatite.

This fraction fineness was chosen because concentrates with mostly such a grain size are commonly delivered to technological processing. The largest amount of open aggregates of sphene and apatite is concentrated in the sphene concentrate with this grain size. The content of P_2O_5 in the concentrate may vary from 0.8 to 4.5 wt % [4]. Because apatite is rather easily decomposed with acids, the time of treatment of the samples at room temperature was 15 min. In separate experiments with apatite, this time was reduced to 5 min to preclude complete decomposition of apatite particles. After that, the suspension was filtered and the sediment was washed with water.

The products before and after treatment with solutions of sulfuric and hydrochloric acids with various concentrations were examined by digital scanning electron microscopy (SEM) and other techniques: X-ray phase, crystal-optical, and chemical analyses and IR spectroscopy.

With a LEO 420 SEM microscope, the magnification range was 60–30 000. This method makes it possible to trace how the morphology of mineral grains changes in the course of chemical purification of the sphene concentrate and to confirm the existence of sphene and apatite aggregates. The manner in which the aggregates disintegrate under the action of dilute acid solutions was visually represented.

The high stability of sphene against dilute acids suggests that the surface of sphene particles will not change, in contrast to that of apatite. The only exception should be aggregates of sphene and apatite crystals.

Below are presented results obtained in a study of the morphology of narrow fractions of apatite and sphene particles and their aggregates. Figure 1 shows the outward appearance of monomineral fractions of sphene (Fig. 1a) and apatite (Fig. 1b). It can be seen that sphene particles have a clear-cut faceting. It remains unchanged upon treatment with dilute sulfuric and hydrochloric acids. Apatite particles have a rough surface and there are dusty fractions produced in crushing and grinding, which form agglomerates. The agglomerates are constituted by particles less than 28 μm in size and accumulate in energy-strained regions formed at places of crystal breaking [2]. It can be seen at large magnifications that the surface of particles forming the dustlike fractions is amorphized and unstable because of the mechanical activation effect [6–8]. This surface is a product of interaction of apatite with the floating reagent and air medium in the course of crushing and flotation [8].

In the aggregates found, sphene envelops apatite. This suggests that apatite crystallizes earlier than sphene does, with sphene precipitating on the already formed apatite crystals. Figure 2 shows an aggregate of sphene and apatite. It can be seen that apatite is within a sphene crystal. Clearly, phosphorus cannot be removed without opening the crystals-aggregates.

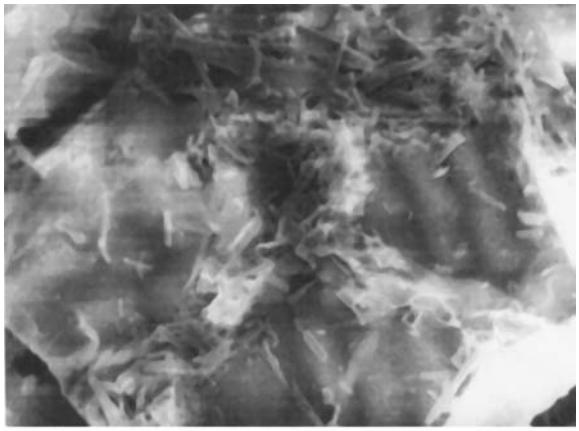

Fig. 3. Micrograph of an aggregate of sphene and apatite, treated with 5% sulfuric acid.

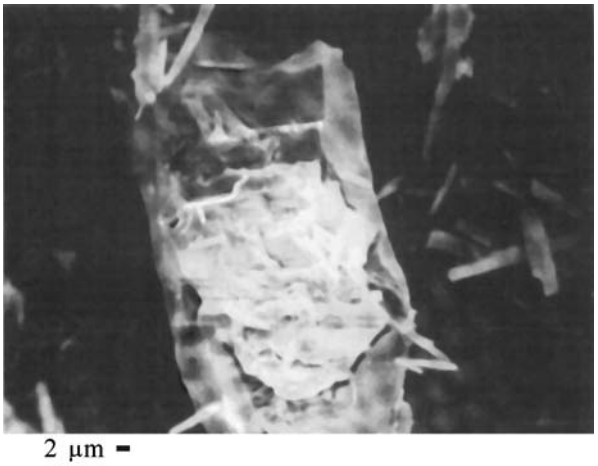

Fig. 4. Micrograph of an aggregate of sphene and apatite, treated with 2% sulfuric acid.

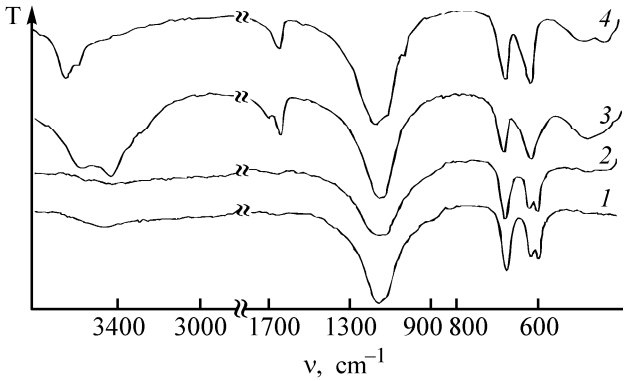

Fig. 5. IR spectra of calcium sulfate isolated in purification of the sphene concentrate. (T) Transmission and (ν) wave number. (*1*) $CaSO_4$, unwashed and dried at room temperature; (*2*) the same at 90°C; (*3*) $CaSO_4 \cdot 2H_2O$, washed and dried at room temperature; and (*4*) $CaSO_4 \cdot 0.5H_2O$, washed and dried at 90°C.

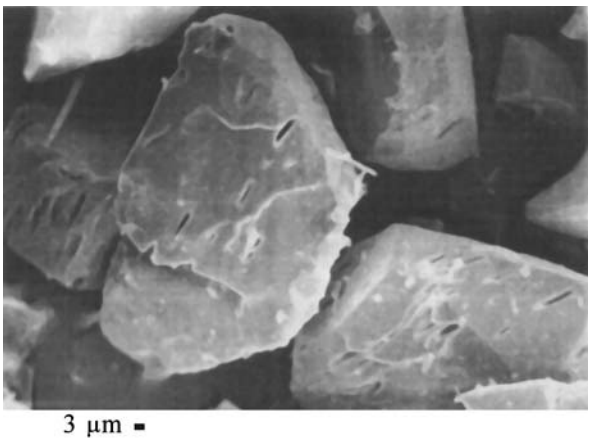

Fig. 6. Micrograph of apatite particles treated with 5% hydrochloric acid.

Figures 3 and 4 show aggregates treated with 5 and 2% sulfuric acid, respectively. Decomposition of apatite yields calcium sulfate crystals covering sphene and partly remaining within the cavern. The crystals (up to 30 μm long) contained within the cavern are strictly oriented. Probably, this occurs because the internal energy of the "mother" crystal orients calcium sulfate crystals. The chaotic arrangement of the outer crystals may be due to agitation of the suspension. Nevertheless, they are bound into druses, which points to their energetic interaction.

Figure 5 shows IR spectra of the forming calcium sulfates. Data furnished by chemical, optical, and X-ray phase analyses and by IR spectroscopy of finely dispersed precipitates isolated by hydroclassification indicate that they are formed by anhydrite, $CaSO_4$. However, washing with water and drying at room temperature and elevated temperatures (up to 90°C) result in that the precipitates are hydrated and transformed first to calcium sulfate semihydrate and then calcium sulfate dihydrate. The absorption at 3400–3700 and 1650 cm^{-1}, which is characteristic of calcium sulfate dihydrate and belongs to hydroxy groups, is observed only for washed samples.

In treatment of apatite with dilute sulfuric acid, there is no reverse formation of calcium phosphates because the main part of calcium is bound into a sulfate and the solubility product for calcium phosphates is not reached [9].

Upon treatment of apatite with 5% hydrochloric acid, the dustlike fraction nearly completely disappears (Fig. 6) and narrow deep elongated etch pits and grooves appear on the surface of the crystals.

According to the monograph [10], the etch pits and grooves are formed because the propagation direc-

tion of the etch front varies with the density of the crystal structure of apatite. In the case under consideration, their formation is facilitated by the presence of impurity elements weakening the structure of pure apatite.

Treatment of aggregates of sphene and apatite with a hydrochloric acid solution can yield calcium fluoride, but this is not observed, possibly because of the low concentration of fluorine. In contrast to the treatment of the aggregates with sulfuric acid, no new phase formation is observed in the given case.

It is noteworthy that the rate of apatite decomposition depends on the acid concentration. A decrease in this parameter within the range studied makes the rate of apatite decomposition lower. As, however, the acid concentration increases, sphene starts to decompose. This circumstance governs the choice of dilute acid solutions for chemical purification of the sphene concentrate to remove the phosphorus impurity. It is preferable to choose hydrochloric acid solutions for this purpose, because poorly soluble calcium sulfate salts, anhydrite $CaSO_4$ and gypsum $CaSO_4 \cdot 2H_2O$, are formed in the case of sulfuric acid. This contaminates the concentrate with sulfur, whose content is strictly limited by technical specifications for welding material components and leads to an increased expenditure of washing water for dissolution of calcium sulfates.

CONCLUSIONS

For a fuller removal of the apatite impurity from the sphene concentrate, it is necessary to perform its chemical purification after grinding to a grain size that provides opening of aggregates of apatite and sphene and thereby simplifies the apatite decomposition with acid solutions and diminishes the content of phosphorus to the concentrations satisfying technical specifications. It is shown that hydrochloric acid solutions are preferable for purification of the sphene concentrate to remove phosphorus and sulfur impurities.

Abstract—Relationship between the distribution of silicon atoms over connectivities in concentrated silicate and silica-containing alkaline solutions differing in chemical composition and preparation methods, on the one hand, and the binding properties of these solutions, on the other, was studied by ^{29}Si NMR spectroscopy.

DOI: 10.1134/S1070427208100029

Silicate and silica-containing alkaline solutions are important representatives of the class of air-hardenable binders: combined with various mineral fillers, they can be cured to give artificial silicate stone. For this purposes, the solutions are used in manufacture of concretes, acid-and heat-resistant articles, coatings, and many other building and special materials [1, 2].

Solutions of alkali metal silicates have a complex polymeric structure [3–5]. ^{29}Si NMR spectroscopy furnishes information about the content of silicon atoms with a particular type of nearest environment in a solution. Depending on the number of siloxane bonds (i.e., bonds with other silicon atoms via oxygen) a particular Si atom has, it can be attributed on the basis of NMR spectroscopic data to one of the following types (connectivity types): Q^0, Q^1, Q^2, Q^3, or Q^4.

In this study, we used NMR spectroscopy on ^{29}Si nuclei to examine the relationship between the distribution of silicon atoms over connectivities in concentrated silicate and silica-containing alkaline solutions differing in chemical composition and preparation methods, on the one hand, and the binding properties of these solutions, on the other.

We considered as objects of study concentrated sodium and potassium silicate solutions prepared by the autoclave method (liquid glasses) or by dissolution of hydrated sodium silicates (products of high-temperature dehydration of liquid glasses) in water under normal conditions. We also used sodium, potassium, lithium, and tetrabutylammonium (TBA) silicate solutions with a silicate modulus, i.e., molar ratio between SiO_2 and R_2O [where R = Na, K, Li, or $N(C_4H_9)_4$], of 2.8–16, produced under laboratory conditions by dissolution of colloid SiO_2 in solutions of the corresponding bases.

EXPERIMENTAL

Table 1 lists parameters of the solutions under study (type of cation R, silicate modulus n, SiO_2 concentration c_{SiO_2}, density ρ, and age τ). Solution nos. 1–5 were prepared by addition (under agitation) of distilled water and NaOH (chemically pure grade) to an industrial sodium silicate solution, sodium liquid glass [Lenstroikeramika Private Company, 32 wt % SiO_2 and 12 wt % Na_2O GOST (State Standard) 13078]. Solution no. 6 is a potassium liquid glass (Ekokhim Private Company, 23.2 wt % SiO_2 and 10.5 wt % K_2O). Solution no. 7 was prepared by dissolution in water of hydrated sodium silicate N28 [Monasil brand, Volkhovskii khimicheskii zavod Private Company, 56.0 wt % SiO_2 and 22.5 wt % Na_2O, calcination loss at 700°C 19.5 wt %, TU (Technical Specification) 2145-001-75 105 538–2005]. Solution nos. 8–13 were prepared by manual mixing of colloid silica solutions SM30 (solution nos. 8–10) and TM40 (solution nos. 11–13) with the corresponding bases (all of chemically pure grade): xLiOH · H_2O, NaOH, KOH, $N(C_4H_9)_4OH$ (30% aqueous solution) and water. The colloid solutions SM30 and TM40 (Ludox brand, Grace Davison Co.) are industrial silica dispersions with 7- and 20-nm SiO_2 particles, respectively, and SiO_2 contents of 30 and 40 wt %, respectively, stabilized with NaOH (Na^+ con-

tent, fractions of a percent). Solution no. 14 is a TM40 dispersion diluted with water.

All the solutions were stored in hermetically sealed plastic vessels under normal conditions. Table 1 lists the ages of the solutions by the instant of time at which their binding properties were tested and NMR spectra were measured.

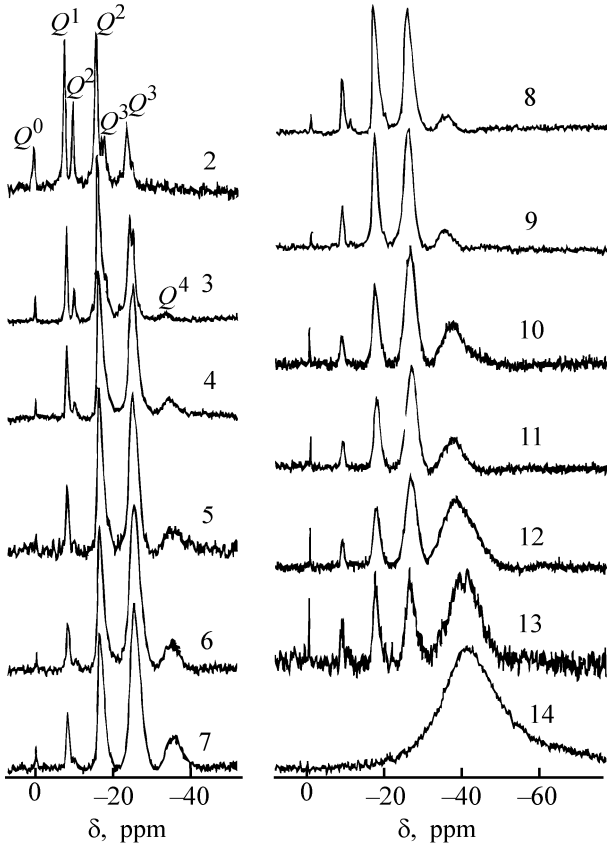

Fig. 1. NMR spectra of silicate solutions. (δ) Chemical shift. *Figures at curves* are solution numbers in Table 1.

The pH values of the solutions were measured with a pH-673.M pH-meter. The solution densities were determined pycnometrically.

^{29}Si NMR spectra of the solutions were measured with a Bruker AM500 spectrometer (99.3 MHz) in standard glass ampules. The spectra were processed using 1D WIN-NMR software (Bruker). Figure 1 shows the solution spectra after subtraction of the spectrum of a water-filled ampule in which the measurements were made. The chemical shifts of the signal are given relative to the position of the Q^0 signal. The content of silicon atoms with different connectivities Q^i (wt % relative to the total content of silicon) was determined by deconvolution and integration of the spectra obtained. The signals were assigned in accordance with the data of [3, 5], where chemical shifts for silicon atoms were presented in relation to the type of their nearest environment. The results of our calculations are shown in Fig. 2 (data from [3] are presented for solution no. 1).

To determine the binding properties, we prepared a mixture of finely ground quartz with particle size less than 100 μm and a solution under study (binder-to-filler mass ratio 0.13). From the paste obtained, we prepared cylindrical samples with a diameter and height of 2 cm by compaction under a pressure of 18 MPa. The samples were stored for 7 days under normal conditions and then their compression strength was deter-

mined. The results obtained in testing the strength of each of the silicate solutions under study are listed in Table 2.

It can be seen in Fig. 2 that, as the molar ratio between SiO_2 and R_2O in solutions becomes lower, the content of Si atoms with low connectivity (Q^0, Q^1, and Q^2) increases, whereas that of Si atoms with connectivities Q^3 and Q^4 simultaneously decreases. Apparently, these changes are due to an increase in the concentration of OH^- ions and depolymerization of large silicate ions (or dissolution of colloid particles), which occurs in this case to give monomers and low-polymer ions:

$$-\overset{|}{\underset{|}{Si}}-O-\overset{|}{\underset{|}{Si}}- + OH^- \rightleftarrows -\overset{|}{\underset{|}{Si}}- + -\overset{|}{\underset{|}{Si}}- + O^-.$$

In this case, solutions with close silicate moduli and SiO_2 concentrations have approximately the same distribution of silicon atoms over connectivities, irrespective of the preparation method.

In high-modulus solutions, a considerable part of silicon atoms have connectivity Q^4 by the time of the experiment, which indicates that the solutions contain high-polymer silica or incompletely dissolved Colloid SiO_2 particles.

Comparison of the data in Table 2 and Fig. 2 shows that the sample strength is higher in the case of low-modulus silicate solutions, in which silicon atoms with low connectivity predominate and the concentration of hydroxide ions is higher (for solution no. 1, it is necessary to take into account the lower total concentration, compared with other solutions). By contrast, colloid SiO_2 solutions and high-modulus silicate solutions, in which the fraction of Q^4 silicon atoms is high, are the least active as binders. Solutions with close distributions of silicon atoms over connectivities have approximately the same binding properties.

When silicate and silica-containing materials are used as fillers, the role of hydroxide ions contained in the binding solution consists in that the particle surface is activated via rupture of Si–O–Si bonds (here and hereinafter, it is assumed that silicon is tetravalent; however, all its four bonds are not shown in all cases for simplicity). As a result, silanol groups Si–OH and charged moieties Si–O^- are formed on the surface of filler grains. The role of silicate ions introduced with silicate binding solutions consists in that new chemical and physicochemical bonds are formed and bind filler particles to give a rigid skeleton. It can be assumed that the activity of a silicate solution toward the filler will be determined by the concentration of SiO^- and SiOH groups, which, in turn, depends on the distribution of silicon atoms in solution over connectivities Q. For example, a silicon atom of Q^1 type has one siloxane bond and, accordingly, three Si–OH or Si–O^-

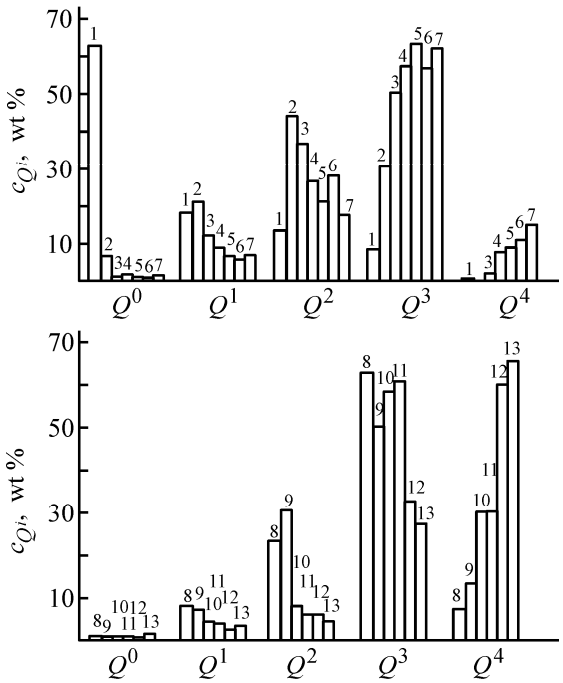
* With account of silanol groups on the surface SiO_2 particles, $S \approx 0.2$ M.



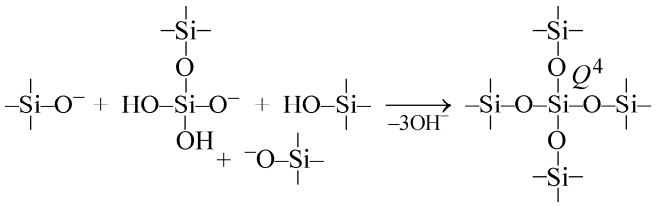


Fig. 2. Contributions of silicon atoms with different connectivities to the total silicon content of a solution. (Q^i) Connectivity of a silicon atom and (c_{Q^i}) contribution of silicon atoms with ith type of connectivity to the total silicon content of the solution. (1–13) Solution numbers in Table 1; the same for Figs. 3, 4.

bonds and can potentially form three new siloxane bonds:

Silicon atoms of Q^0, Q^2, and Q^3 types can be involved in formation of, respectively, four, two, and one siloxane bonds. The Q^4 structural units having no free $Si–O^-$ or Si–OH moieties are not involved in the formation of new siloxane bonds.

Using NMR spectroscopic data, we can calculate the total concentration S (M) of SiO^- and SiOH groups by the formula

$$S = \frac{\rho c_{SiO_2}}{10 M_{SiO_2}} \sum_{i=0}^{4} (4 - i) c_{Q^i},$$

where ρ is the solution density (g cm^{-3}); c_{SiO_2}, SiO_2 content (wt %); M_{SiO_2} = 60, molecular mass of SiO_2 (g mol^{-1}); and c_{Q^i}, content of silicon atoms with ith connectivity type (wt %) (from Fig. 2).

The calculated values of S are listed in Table 2. Apparently, S is the larger, the less structured is a silicate solution. When silica is in the form of colloid particles, S is nearly zero. In accordance with the data in Table 2, the sample strength tends to increase as S becomes larger. Thus, the value of S is a quantitative measure of the polymeric state of silicate ions and, simultaneously, determines the activity of a solution as a binder.

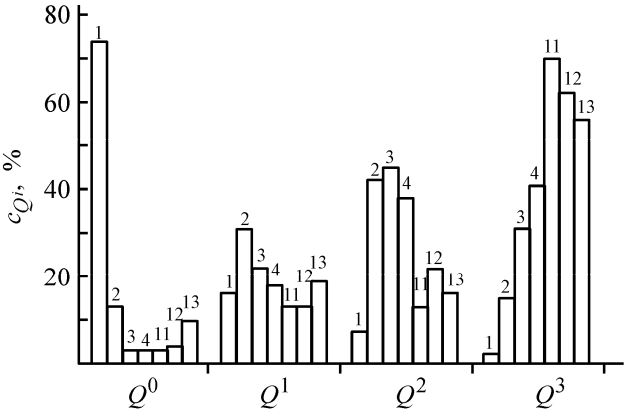

Fig. 3. Contributions of silicon atoms with different connectivities to the total concentration S of SiO^- and SiOH groups. (Q^i) Connectivity of a silicon atom and (c_{Q^i}) contribution of silicon atoms with ith type of connectivity to the total concentration S of SiO^- and SiOH groups.

Figure 3 shows for the example of several solutions under study the contributions (%) of silicon atoms with different connectivities to S, calculated by the formula

$$G_{Q^i} = \frac{(4 - i) c_{Q^i}}{\sum_{i=0}^{4} (4 - i) c_{Q^i}} \times 100.$$

It can be seen in Fig. 3 that the contribution to S from the most reactive species, Q^0 monomers, is noticeable only for low-modulus solutions (nos. 1 and 2) and insignificant in all other cases because of the low concentration of Q^0. For solutions with a modulus exceeding 2.5 (liquid glasses and high-modulus solutions), the contribution of Q^3 structural units is large: their moderate reactivity is compensated by the substantial concentration.

As the silicate modulus becomes higher, the total content of "active" silicon atoms Q^0, Q^1, Q^2, and Q^3 decreases and the fraction of "inactive" Q^4 atoms that cannot form siloxane bonds increases. Table 2 lists ratios between the amounts of active and inactive silicon atoms in the form of the quantity $D = \sum_{i=0}^{3} c_{Q^i} / c_{Q^4}$. It can be seen that the sample strength decreases as D becomes lower.

Using the obtained values of S, we separately estimate the concentrations of SiO^- moieties and silanol groups.

The silicate solutions under consideration contain three types of charged species and moieties: R^+ [R = Na, K, Li, or $N(C_4H_9)_4$], OH^-, $Si–O^-$. The concentration of charged groups $Si–O^-$ can be found on the basis of the solution electroneutrality principle: $[SiO^-] = [R^+] - [OH^-]$,

$$[R^+] = \frac{20 \rho c_{SiO_2}}{n M_{SiO_2}}, \quad [OH^-] = \frac{10^{pH - 14}}{\gamma_{OH^-}},$$

where $[R^+]$ is the cation concentration (M), and γ_{OH^-}, activity coefficient.

For solution nos. 1 and 2, the value of γ_{OH^-} was taken to be 0.26 [6]. In all other solutions, the concentration of hydroxide ions is negligible as compared with $[R^+]$ and $[SiO^-] = [R^+]$.

The concentration of silanol groups is calculated by the formula $[SiOH] = S - [SiO^-]$. It follows from the results of our calculations, listed in Table 2, that the concentrations of SiO^- and SiOH are comparable in order of magnitudewith an increase in the concentra-

tion of one type of groups not leading to a deficiency of groups of the other type.

It can be seen in Fig. 4, which shows how the stone strength depends on the product of the concentrations of the SiO^- and SiOH moieties, that the binding activity of silicate solutions grows with $[SiOH] \cdot [SiO^-]$.

It is known that siloxane bonds are formed both with silanol groups and with charged SiO^- moieties involved by the mechanism of bimolecular nucleophilic substitution S_{N_2} [7]. Accordingly, the formation rate of siloxane bonds is proportional to the product of the concentration of the groups involved in the reaction: $V \propto [SiO^-] \cdot [SiOH]$. Thus, Fig. 4 characterizes the relationship between the kinetics of formation of siloxane bonds and the formation of the stone structure.

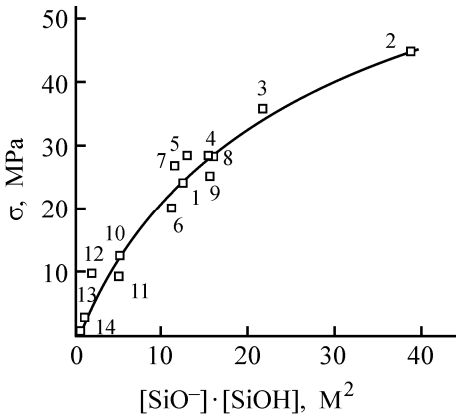

Fig. 4. Compression strength σ of silicate stone vs. the product of the concentrations of the SiO^- and SiOH moieties.

CONCLUSIONS

(1) The strength of structures formed in air curing of silicate solutions with mineral fillers increases with the product of the initial concentrations of the SiO^- and SiOH moieties contained in the solution.

(2) The concentration the SiO^- and SiOH moieties is found from the distribution of silicon atoms over connectivities, which depends on the chemical composition of a solution and is independent of the method of its preparation after the solution attains a nearly equilibrium state.

(3) In solutions with a silicate modulus exceeding 2.5, the main contribution to the formation of the stone structure is made by silicon atoms with a connectivity Q^3. At the same time, the share of inactive Q^4 silicon atoms grows as the silicate modulus becomes higher, which impairs the stone strength.

(4) The method suggested for determining the concentrations of SiO^- and SiOH groups in silicate solutions from the experimentally found (by ^{29}Si NMR spectroscopy) distribution of silicon atoms over connectivities makes it possible to prognosticate the binding properties of silicate solutions on the basis of the dependence of the strength on $[SiO^-]$ + [SiOH] or $[SiO^-] \cdot [SiOH]$.

Received January 22, 2007

Abstract–-Method for determining the total porosity of potassium chloride grains is suggested. The method includes pycnometric measurements of the true and apparent densities of the grains, with kerosene used as a pycnometric liquid.

DOI: 10.1134/S1070427208100030

Grains of potassium chloride are polycrystals produced by compaction of its dispersions into plates and their subsequent crushing and classification to give the commercial fraction –4…+2 mm. In the course of compaction, potassium chloride crystals are arbitrarily oriented with respect to each other and their crystal lattices mostly do not coincide. As a consequence, numerous defects are formed at places of contact between pressed grains, become coarser via recrystallization, and thereby form the porous structure of grains, which largely determines their physicochemical and mechanical properties. The porosity enables diffusion of the surface moisture into grains, which intensifies recrystallization, impairs strength, and raises the caking of the grains.

The nature and value of the porosity depend on technological parameters of the process of grain production (stock dispersity, compaction pressure). In view of the aforesaid, it is important to determine the porosity of grains in various stages of their manufacture, which will enable control over, and wide variation of the consumer properties of grains (strength, moisture absorption, caking).

An analysis of published data demonstrated that there is no scientifically substantiated technique for determining the porosity of potassium chloride grains. Of all the known methods for analysis of the porous structure of solids, the most precise, simple, and reproducible is the liquid-type pycnometric method for porosity measurements [1–3]. Just this method served as a basis for developing a technique for determining the porosity of potassium chloride grains.

The basic parameters characterizing the porous structure of granulated potassium fertilizers is the total pore volume (total porosity) and open pore volume (open porosity). The total pore volume is constituted by the volume of open-pores connected with the outer surface of grains and that of isolated closed pores or ensembles of these.

EXPERIMENTAL

The total porosity was determined by measuring the true and apparent density of grains by the pycnometric method, with kerosene used as a pycnometric liquid. The study was performed with granulate samples from the 1st, 2nd, 3rd, and 4th sylvinite dressing plants (SDP-1–SDP-4) of Belarus'kalii Production Association, Republican Unitary Enterprise. The porosity Π_{gr} (%) of the granulate was calculated by the formula

$$\Pi_{gr} = [(\rho_p - \rho_{gr})/\rho_p] \times 100, \quad (1)$$

where ρ_p is the density of a powdered granulate (true density) (g cm^{-3}), and ρ_{gr} is the density of the granulate (apparent density) (g cm^{-3}).

To determine the true density, a weighed portion of the granulate (4–5 g) ground to a powdered state, dried to constant mass, and sieved (0.08-mm mesh) was placed in a 50-ml pycnometer, and the pycnometer was half-filled with kerosene and heated on a water bath to complete removal of air bubbles from the powder. After that the pycnometer was thermostated at 20 ± 0.1°C, the kerosene level was brought to the graduation mark, and the pycnometer was weighed.

The optimal experimental conditions were as follows: sample heating temperature 75–80°C and heating duration no less than 240 min.

The true density ρ_p of the ground granulate (powder) was calculated by the formula

$$\rho_p = P_p\rho_{ker}^{20}/(P_p + G - F), \quad (2)$$

where ρ_{ker}^{20} is the density of kerosene at 20°C (g cm^{-3}); P_p, mass of the powder (g); F, mass of the pycnometer filled with kerosene (g); and G, mass of the pycnometer with the powder and kerosene (g).

The relative determination error at a confidence probability $P = 0.95$ did not exceed ±1%.

Determining the apparent density ρ_a, which takes into account the volume of open and closed pores, consists in evaluating the geometric volume of a solid body. For samples of arbitrary shape, to which belong products formed in granulation of potassium chloride, the experimental difficulty of such an estimate consists in localization of pore boundaries on the outer surface of a sample.

In the present-day laboratory practice, the most frequently used method is insulation of the grain surface by creating a paraffin film impermeable to the pycnometric liquid (water). However, this method is highly labor-consuming; the results it yields are strongly affected by the thoroughness with which the surface is hermetically insulated and closed air bubbles are removed from the insulating coating itself.

The method of liquid pycnometry was suggested for determining the apparent density of potassium chloride grains. This technique directly measures the volume of kerosene displaced by grains submerged into the liquid.

It was found experimentally that the absorption of kerosene by the granulate is nearly zero during 24–30 h. This gives reason to believe that kerosene does not penetrate into open pores of grains, well wets their surface, and reliably localizes pore boundaries on the outer surface of the samples. Consequently, kerosene can be used as a pycnometric liquid in determining the apparent density of products formed in granulation of potassium chloride (granulate, compacted plates).

The volume of the granulate was measured with a volume meter having the form of a 400-cm^3 conical vessel with a sealed-in tube with an inner diameter of 8–10 mm and a hooked end.

The volume meter was filled with kerosene until the liquid flowed out of the tube and then a weighed sample was submerged into kerosene. The liquid displaced from the volume meter flows out in a short time (2–3 min).

Because the volume of displaced kerosene is equal to the sample volume, $V_{ker} = V_s$, the sample density ρ_s is given by

$$\rho_s = m/V_s, \quad (3)$$

where m is the mass of displaced kerosene (g).

It was found experimentally that stable values of the granulate density are obtained for sample weights of 10–40 g.

It was found that the grain densities measured for separate fractions within the range –4…+2 mm (commercial fraction) are nearly the same. The content of these fractions in the granulate is about 93%. As the granulate is ground to a grain size less than 2 mm, the pore opening occurs and, as a result, the amount of air contained within grains decreases. This reflects on the grain density, whose values approach the experimental values of true density.

The relative error in measuring the apparent density of grains was ±1% at a confidence probability $P = 0.95$.

For comparison, the apparent densities of granulate samples from for SDPs of Belarus'kalii Production Association, Republican Unitary Enterprise, were measured by the known method of insulation (waxing) of the grain surface (I) and by the suggested technique of liquid pycnometry with kerosene (II). The measurement results are listed in Table 1.

These data indicate that the KCl grain densities measured by the two methods nearly coincide.

To assess the applicability of the method suggested, the porosity of products formed in granulation at the dressing plants of Belarus'kalii Production Association, Republican Unitary Enterprise was deter-

mined. The study was carried out with samples of compacted plates and granulates of flotation (SDP-1–SDP-3) and halurgic (SDP-4) types.

The data in Table 2 show that the granulates from the four plants strongly differ in porosity. The lowest porosity is observed for grains of halurgic potassium chloride (SDP-4). The density of powdered grains of this type is also lower than that for flotation KCl, which is due to the absence of clayey-carbonate impurities and metal oxides. The absence of these impurities favors compaction of the halurgic potassium chloride, which reflects on the porosity of the granulate obtained.

The differences in porosity between different production batches of the granulate manufactured at the same plant indicate that granulation conditions affect their porous structure (Table 2).

The porosity of a granulate is related to that of the starting material, plates produced by roll presses. It can be seen for the example of SDP-4 that the compaction conditions of a plate determine its porosity: the plate obtained at a pressure of 80–90 kg cm^{-2} has a lower porosity than that produced at 70–80 kg cm^{-2}.

It follows from a comparison of the data in Table 2 that the porosities of the granulate and plates are in good agreement. This suggests that the method suggested can be used for determining the porosity of products formed in granulation of potassium chloride in various stages of their production. The method shows a sufficiently high precision, yields rapid results, and requires simple apparatus and, therefore, it can be used under industrial conditions of the potassium industry.

CONCLUSIONS

(1) A method was suggested for determining the total porosity of potassium chloride grains, which includes pycnometric measurements of the true and apparent densities of grains, with kerosene serving as a pycnometric liquid. Kerosene well wets the grain surface and reliably localizes pore boundaries on the outer surface of samples.

(2) It was shown that this method can be used to determine the porosity of grains in different stages of their manufacture, which will allow control over the consumer properties of products formed in granulation of potassium chloride at plants of the potassium industry.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Catalytic Conversion of COS and CS_2 under an Excess of Sulfur Dioxide

O. I. Platonov and L. Sh. Tsemekhman

Gipronikel' Institute Limited Liability Company, St. Petersburg, Russia

Received May 19, 2008

Abstract—Conversion of organosulfur components (COS and CS_2) in catalytic processing of a real reduced sulfurous gas was experimentally studied.

DOI: 10.1134/S1070427208100042

At present, about 40 million tons of sulfur is annually produced in the world in purification of discharge gases by the Claus method in natural-gas- and oil-processing industries [1]. It is prognosticated [2] that, with the environment protection regulations becoming increasingly stringent and requiring higher ecological payments, the volume of accompanying sulfur used to manufacture fertilizers will grow via utilization of metallurgical sulfurous gases. The only working technology for processing of these gases into sulfur is reduction with hydrocarbons, followed by catalytic conversion by the Claus method [3]. Because of the specific features of reduced sulfurous gas, its catalytic conversion strongly differs from that in the classical Claus technique [1, 4]. This circumstance determines the topicality of its analysis with account of parameters of a gas being processed.

A characteristic feature of the reduced gas is the increased content of organosulfur compounds (CS_2 and COS) formed from carbon introduced with the reducing agent, which predetermines the priority role of their conversion, traditionally the most difficult stage in catalytic processing by the Claus method [1, 4]. At large contents of sulfur dioxide, characteristic of the reduced sulfurous gas [5], the commonly taken into account mechanism of COS and CS_2 hydrolysis [1, 3] experiences competition from the alternative channel of conversion by reactions of sulfur dioxide reduction:

$$CS_2 + SO_2 = CO_2 + 3/nS_n, \quad (1)$$

$$2COS + SO_2 = 2CO_2 + 3/nS_n, \quad (2)$$

whose contribution can be predominant under an excess of SO_2.

The aim of our study was to experimentally analyze specific features of the conversion of organosulfur components (COS and CS_2) in catalytic processing of a reduced sulfurous gas.

EXPERIMENTAL

We performed tests in the temperature range 220–600°C on a pilot installation with a flow rate of the gas mixture equal to 0.6–0.7 standard $m^3 h^{-1}$ at Gipronikel' Institute Limited Liability Company. We studied two promising vanadium-containing catalysts: titanium oxide catalyst AOK-78-57 with a specific surface area of 145 $m^2 g^{-1}$ (extrudates 4–5 mm in diameter), manufactured by Katalizator Limited Liability Company (Novosibirsk), and a new VA-2 catalyst on an alumina support, developed at the Institute of Catalysis, Siberian Branch, Russian Academy of Sciences, and manufactured by Novomichurinsk Catalyst Plant Private Company in the form of spherical grains 4–5 mm in diameter and active surface area of no less than 240 $m^2 g^{-1}$.

The tests were made in a vertical stainless steel reactor with external electric heating (catalyst-containing cartridge with an inner diameter of 53 mm and height of 175 mm) and a catalyst charge of 0.38 dm^3. The temperature was controlled and recorded in the course of the experiments with a DT-600 digital data-acquisition device [Data Taker Pty. Ltd. (Data Electronics)]. Metran 231-01 Chromel–Alumel thermoelectric transducers (thermocouples) with a sheath diameter of 3 mm were used as temperature sensors. One of the thermocouples, buried to 4/5 of the catalyst bed height, was also used to maintain the reactor temperature; the electric power for heating the reactor and gas heater was varied using TP 403 microproc-

Gas compositions before and after conversion on the VA-2 catalyst

Gas component	Content, vol %

essor heat-control units manufactured by Varta Research and Production Company (St. Petersburg).

The coefficient (degree) of conversion of components of the gas mixture, η_i, was found using the formula [6]:

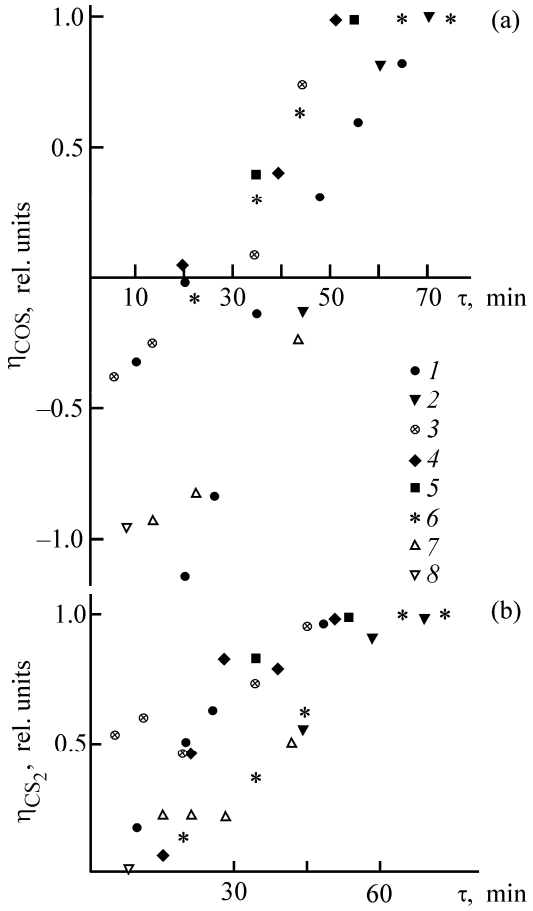

Fig. 1. Relative change in the conversion of (a) carbonyl sulfide, η_{COS}, and (b) carbon disulfide, η_{CS_2}, during tests for a time τ at different temperatures of the VA-2 catalyst. (*6*–*8*) Conversion on the AOK-78-57 catalyst. *T* (°C): (*1*, *6*) 310, (*2*) 340, (*3*, *4*) 380, (*5*) 450, and (*7*, *8*) 250.

$$\eta_i = 1 - \frac{c_i^{out} c_{N_2}^{in}}{c_i^{in} c_{N_2}^{out}}, \quad (3)$$

where c_i^{in} and c_i^{out} are the initial and final concentration of gas component i (i = H_2S, COS, SO_2), and $c_{N_2}^{in}$ and $c_{N_2}^{out}$, the initial and final concentrations of nitrogen in dried gas samples taken at, respectively, the inlet and outlet of the catalytic reactor.

The gas composition was monitored at four points of the pilot installation with an automated analytical complex based on a gas analyzer, EMG 20–1 time-of-flight mass spectrometer manufactured by METTEK Limited Liability Company (St. Petersburg), which can measure the volume concentrations of all the basic components of the gas: H_2S, SO_2, SO_3, COS, CS_2, CO, CO_2, H_2, CH_4, O_2, N_2, and Ar with a threshold sensitivity of 0.01–0.03%. The EMG 20-1 gas analyzer was calibrated against reference gas mixtures prepared at Scientific Instruments Open Joint-Stock Company and Monitoring Limited Liability Company (both from St. Petersburg).

In the course of the tests, a real sulfurous gas reduced in the homogeneous reactor of the pilot installation at a temperature of 1100°C in accordance with the promising technology for processing of metallurgical gases [7] was delivered to the inlet of the catalytic reactor (see table).

In all, the tests were made in 67 operation modes for the VA-2 catalyst and 57 modes for the AOK-78-57 catalysts. The modes differed in temperature at the same initial composition of the gas (see table) and volumetric flow rates W = 1500–1900 h^{-1}.

The results obtained in the pilot tests show that the high efficiency of conversion of organosulfur components on the catalysts under study is high. For example, this is indicated by comparison of the initial composition of the gas with that at the outlet of the catalytic reactor, found from a sample of measurements in 60 modes at a gas flow rate of 11 ± 1.1 standard dm^3 min^{-1} (W = 1600–1900 h^{-1}), also represented in the table.

It can be seen that more than a half, on average, of the organosulfur compounds (CS_2 and COS) is converted in catalytic processing of a reduced sulfurous gas. In the process, the content of carbon dioxide noticeably increases (nearly twice, on average), which points to the decisive contribution of reactions (1) and (2) of sulfur dioxide reduction to the overall conversion.

We observed a rapid variation of the activities of both the catalysts, which is manifested in that the conversion grows during the first hour after a catalyst is put into operation in the on-line mode. This effect is illustrated by Fig. 1, in which the conversion coefficients of sulfur-containing components, η_i, normalized to the maximum conversion of a given component, are arranged in order of increasing time τ elapsed from the beginning of a run. Different symbols in the figure show results of measurements in different runs, on different catalysts, and at different process temperatures.

The activity variation is manifested to the maximum extent in conversion of COS, whose relative conversion coefficient η_{COS} on the alumina catalyst VA-2 changes from –100% to 100% in 1 h (Fig. 1a). The conversion of sulfur dioxide and the overall conversion of sulfur-containing components varies qualitatively similar to η_{CS_2}. The conversion of hydrogen sulfide shows no dynamic effect.

A similar dynamic effect was observed on the titanium oxide catalyst AOK-78-57, on which the conversion of carbonyl sulfide varied under identical process conditions, e.g., at $T \approx 420$°C, from –80 to 76 rel % (Fig. 1).

The statistical scatter of values in the dynamic dependences of the conversion of both the organosulfur components, $\eta_i(\tau)$, is due to uncontrollable specific features of each run (duration of catalyst acidification) at its beginning. Nevertheless, the data scatter σ observed in different runs is noticeably smaller than the variance $\delta\eta_i(\tau)$: $3\sigma < \delta\eta_i(\tau)$, which demonstrates that the dynamic effect is revealed rather reliably.

The activities of the catalysts in CS_2 and COS conversion, determined after 1 h and more of uninterrupted operation, nearly coincide to within the experimental error, even though a tendency is observed for η_{CS_2} to somewhat exceed the conversion of carbonyl sulfide, η_{COS}, under the same conditions.

For illustration, Fig. 2 shows the average, over temperature intervals, conversions of carbonyl sulfide, η_{COS}, and carbon disulfide, η_{CS_2}, on the VA-2 catalyst as functions of temperature in the catalyst bed. The vertical portions correspond to the variances of the averages, and the horizontal portions (defined as variance) are proportional to the width ΔT of the averaging interval.

A possible reason for the appearance of the dynamic dependence of the activities of the catalysts

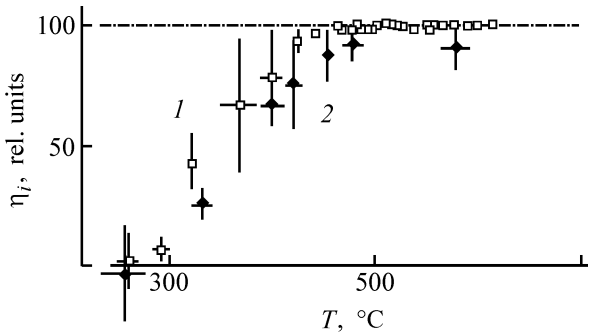

Fig. 2. Conversion η_i of (*1*) carbon disulfide and (*2*) carbonyl sulfide on the VA-2 catalyst vs. temperature T at a volumetric flow rate of 1600–1800 h^{-1}.

tested is their short-term poisoning via sulfation in the warm-up and startup of the installation with the oxygen-containing sulfurous gas. As follows from the results of our tests, the catalyst activity in conversion of organosulfur compounds, low at the beginning of a run, is completely restored during the first hour of on-line operation in the medium of a reduced gas, which contains reducing components (H_2, CO, and H_2S), but is free of oxygen. The differences in the degrees of initial sulfation of a catalyst in each startup predetermine the observed statistical scatter of the empirical values in the dynamic dependences $\eta_i(\tau)$.

As follows from the results of our experiments, CS_2 interacts with SO_2 at least in two stages, with carbonyl sulfide formed in the first of these. The only possible other intermediate in the first stage is, according to the stoichiometric balance of the overall reaction (1), sulfur oxide S_2O, as suggested by the two-stage scheme of the process [6]:

$$CS_2 + SO_2 = COS + [SO_2] = CO_2 + 1/8S_8. \quad (4)$$

In the initial period of operation of a catalyst after its sulfation, carbonyl sulfide is generated, which is manifested in large negative values of its conversion η_{COS} (Fig. 1a). Together with the simultaneously high conversion of carbon disulfide (Fig. 1b), this circumstance suggests that the second stage of carbonyl sulfide conversion is the rate-determining stage, the most sensitive to the catalyst sulfation.

An alternative explanation of the generation of carbonyl sulfide, e.g., that by interaction on the catalyst with sulfur vapor:

$$CO + 1/nS_n = COS, \quad (5)$$

would not do because of the insufficient initial concentration of carbon monoxide (see table). No con-

version of methane (also present in the starting gas), which could serve as a reactant for COS formation, was observed in our experiments within the experimental error limits.

According to the two-stage mechanism of carbon disulfide conversion by reaction (4), with the rate-determining second stage, the conversion of carbon disulfide should be more efficient than that of COS, and this, indeed, was observed in our experiments (Fig. 2). This makes it possible (at least as regards the processing of a reduced sulfurous gas) to reconsider the known paradigm [1, 4] of the more efficient conversion of COS. According to the results of this study, the conversion of organosulfur compounds under an excess of sulfur dioxide predominantly occurs via redox reactions with sulfur dioxide, of which the most efficient is that with CS_2.

The fact that the dynamic effect is observed on catalysts of different types (alumina catalyst VA-2 and titanium oxide catalyst AOK-78-57) means that the conversion of carbonyl sulfide is not directly related to the properties of the active surface, but occurs via adsorption of COS on active basic centers. By analogy with the hydrolysis process [8], the role of centers of this kind can be played by hydroxy groups, which are subject to sulfation in the presence of oxygen.

CONCLUSIONS

(1) If an excess of SiO_2 is present in the gas being processed, the conversion of organosulfur compounds predominantly occurs via their oxidation by sulfur dioxide. An intermediate formed in oxidation of carbon disulfide is carbonyl sulfide, whose further conversion is hindered by sulfation of the active centers of a catalyst. As a result, the conversion of carbon disulfide under an excess of SO_2 is more complete than that of carbonyl sulfide, which predetermines the principal characteristic feature of the catalytic processing of a reduced sulfurous gas.

(2) The experimental data obtained directly confirm for the first time the two-stage mechanism of carbon disulfide conversion by reaction (4) to give COS as an intermediate product of CS_2 conversion.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis and Electrical Properties of Variable-Composition Phases $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ ($0 \le x \le 0.2$; A = Mg, Mn, Co, Ni; R = Sc, Yb, Lu)

N. M. Kozhevnikova and E. P. Ermakova

Baikal Institute of Nature Management, Siberian Branch, Russian Academy of Sciences, Ulan-Ude, Buryatiya, Russia

Received February 8, 2008

Abstract—Subsolidus region of the ternary systems Rb_2MoO_4–$AMoO_4$–$R_2(MoO_4)_3$, in which variable-composition phases $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ crystallizing in the monoclinic system (space group C2) are formed, was studied. Their crystallographic parameters were calculated; temperature dependences of the electrical conductivity, dielectric constant, and dielectric loss tangent were analized.

DOI: 10.1134/S1070427208100054

In the last two decades, an intensive search has been in progress for functional materials with structural skeletons $\{[R_2(ElO_4)_3]^{p-}\}_\infty$, where R is an octahedral cation in phosphate, arsenate, molybdate, tungstate, and sulfate systems [1–8]. Promising in this regard are phases with langbeinite structure, $Sc_2(WO_4)_3$ and $K_2Mg_2(SO_4)_3$, which have bulk cavities partly filled by singly charged cations. They exhibit high conductivity by lithium, sodium, and silver ions [1]. As the radius of a cation increases, its mobility in tunnels and bulk cavities of the structure decreases, which results in a lower conductivity of the phases [4].

In a study of the systems K_2MoO_4–$AMoO_4$–$R_2(MoO_4)_3$ (A = Mg, Mn, Co, Ni; R = Sc, Yb, Lu), variable-composition phases $K_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ ($0 \le x \le 0.5$) belonging to the langbeinite structural type with a conductivity of 10^{-3} $\Omega^{-1}cm^{-1}$ were obtained [4].

The existence of structures with a considerable volume of voids and the presence of centers unpopulated by cations depend on the nature of the cations, their combination, distribution over structural positions, and population of these positions. No data on existence of the ionic conductivity in rubidium phases are available, which is probably due to a decrease in the mobility of a cation with its increasing radius.

The aim of this study was to synthesize variable-composition phases $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ and examine their electrical properties.

EXPERIMENTAL

The starting components for studying the phase formation in the systems Rb_2MoO_4–$AMoO_4$–$R_2(MoO_4)_3$ were Rb_2MoO_4, $AMoO_4$, and $R_2(MoO_4)_3$, preliminarily synthesized by the solid-phase technique from Rb_2CO_3, magnesium, nickel, cobalt, and manganese oxides, molybdenum trioxide of analytically pure grade, and scandium, ytterbium, and lutetium oxides with a content of the main component not lower than 99.99%. Oxides of divalent elements were preliminarily calcined at 650°C for 8 h; Rb_2CO_3 and MoO_3, at 400°C; and R_2O_3, in the temperature range 400–750°C. The reaction mixtures of molybdates of rubidium and di- and trivalent elements were calcined at 450–800°C with multiple intermittent grindings every 20–30 h. The time of calcination at each temperature was 120–150 h. After being annealed, the samples were slowly cooled together with a furnace. Nonequilibrium samples were additionally annealed, with the equilibrium considered to be attained if the phase composition of samples remained constant after two successive annealings. The synthesis products were identified by X-ray phase analysis in an FR-552 chamber-monochromator (Cu_{K_α} radiation, internal standard Ge). The X–ray diffraction patterns were processed using the RENTGEN software. A differential thermal analysis was performed on an MOM OD-103 derivatograph at a heating rate of 10 deg·min^{-1} and sample weight of 0.3–0.4 g.

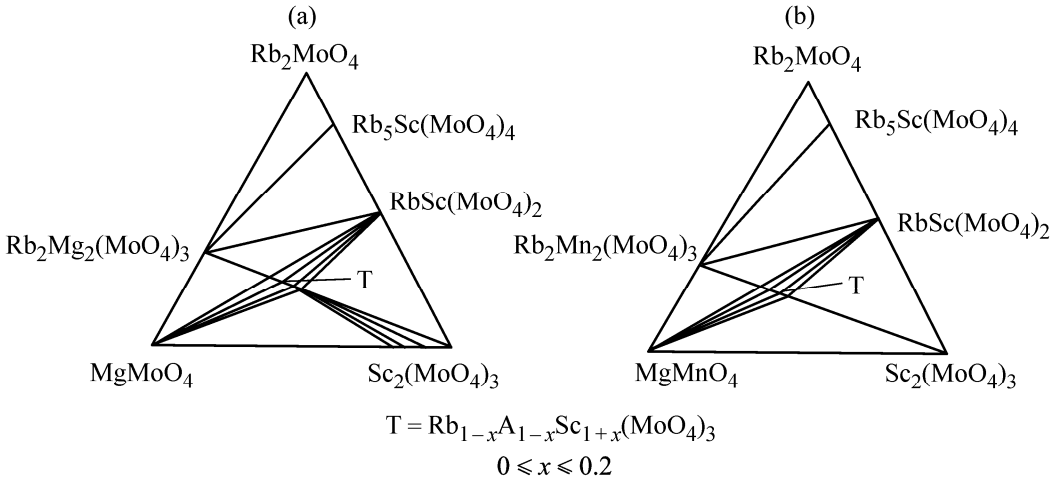

Fig. 1. Phase relationships in the systems (a) Rb_2MoO_4–$MgMoO_4$–$Sc_2(MoO_4)_3$ and (b) Rb_2MoO_4–$MnMoO_4$–$Sc_2(MoO_4)_3$ at 700°C.

Temperature dependences of conductivity σ, dielectric constant ε, and dielectric loss tangent tan δ were studied by Vest and Tallan's polarization technique [6] with densely compacted ceramic samples in the form of pellets 10 mm in diameter and 1–1.5 mm thick, with platinum electrodes. The electrodes were deposited by firing-in a platinum paste. The electrical properties were measured with an E8-4 ac bridge with a P-5025 capacitor box at a frequency of 10^3 Hz (measurement accuracy ±5%). The dc current was recorded with an E6–13A teraohmmeter at a preset voltage of 30–50 mV.

The interaction in the systems Rb_2MoO_4–$AMoO_4$–$R_2(MoO_4)_3$ was examined in the subsolidus region in the temperature range 450–800°C. The study was carried out in two stages. In the first stage, an X–ray study of the phase composition of the samples corresponding to the intersection points of all cuts existing in the systems Rb_2MoO_4–$AMoO_4$–$R_2(MoO_4)_3$ enabled triangulation of the systems. In the second stage, the quasibinary cuts revealed were studied. The formation of ternary molybdates $RbAR(MoO_4)_3$ was observed in the cuts $RbR(MoO_4)_2$–$AMoO_4$ and $Rb_2A_2(MoO_4)_3$–$R_2(MoO_4)_3$ at 600–650°C (Fig. 1). The phases of variable composition $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ are formed in a plane of the triangle Rb_2MoO_4–$AMoO_4$–$R_2(MoO_4)_3$ and along the cut $RbAR(MoO_4)_3$–$R_2(MoO_4)_3$.

Samples with compositions corresponding to the quasibinary cuts were prepared with a step of 2.5–5 mol %, and those intended for refining the composition of the ternary molybdate $RbAR(MoO_4)_3$ being formed and of the homogeneity region of the variable-composition phases $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$, with a step of 1 mol %. The samples were annealed at 450, 550, 600, 650, and 700°C, and those with nickel and cobalt compositions, additionally at 750 and 800°C. Single-phase samples of $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ were obtained at 700–800°C with annealing for 180–200 h. The X–ray diffraction analysis of $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ samples demonstrated that they are isostructural to each other and to the monoclinic modification of $KMgIn(MoO_4)_3$ (space group C2, $Z = 4$). The X–ray diffraction patterns of $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ were indexed in the monoclinic system, using unit cell parameters of the $KMgIn(MoO_4)_3$ single crystal [4]. They melt incongruently in the temperature range 945–1085°C (Table 1).

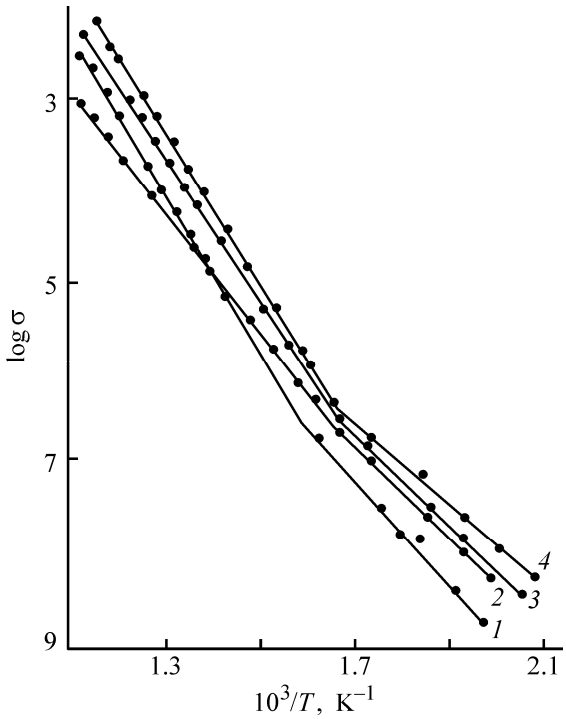

Fig. 2. Temperature dependence of the conductivity σ. (*1*) $RbMgSc(MoO_4)_3$, (*2*) $Rb_{0.8}Mg_{0.8}Sc_{1.2}(MoO_4)_3$, (*3*) $Rb_{0.8}Co_{0.8}Lu_{1.2}(MoO_4)_3$, (*4*) $Rb_{0.8}Mn_{0.8}Yb_{1.2}(MoO_4)$.

The electrical properties of $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ were examined in the temperature range 200–600°C (Figs. 2 and 3). The conductivity σ of rubidium phases varies within the range 10^{-9}–10^{-3} $\Omega^{-1}\,cm^{-1}$ (Fig. 2). They are characterized by mixed ionic-electronic conduction with predominance of the electronic component (t_e = 0.62–0.73) having an activation energy of 0.92–1.28 eV (Table 2).

Table 2. Conductivity σ of $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$, electron transport numbers t_e, and activation energy E_a of conductivity

Composition			300°C		600°C		
A	R	X	$\sigma \cdot 10^8$, $\Omega^{-1}\,cm^{-1}$	t_e	$\sigma \cdot 10^3$, $\Omega^{-1}\,cm^{-1}$	t_e	E_a, eV
Ni	Sc	0.2	0.42	0.68	2.48	0.64	1.15
Ni	Sc	0.2	6.43	0.70	3.14	0.66	1.12
Mg	Sc	0	1.46	0.69	3.67	0.65	1.28
Mg	Yb	0.2	7.51	0.68	5.65	0.64	1.23
Co	Sc	0	7.55	0.69	6.13	0.67	1.05
Co	Sc	0.2	9.83	0.68	7.92	0.64	1.02
Mn	Lu	0	12.2	0.71	5.64	0.63	0.99
Mn	Lu	0.2	36.1	0.70	6.97	0.65	0.95
Mn	Yb	0	7.39	0.69	8.46	0.62	0.96
Mn	Yb	0.2	92.4	0.72	9.77	0.62	0.92

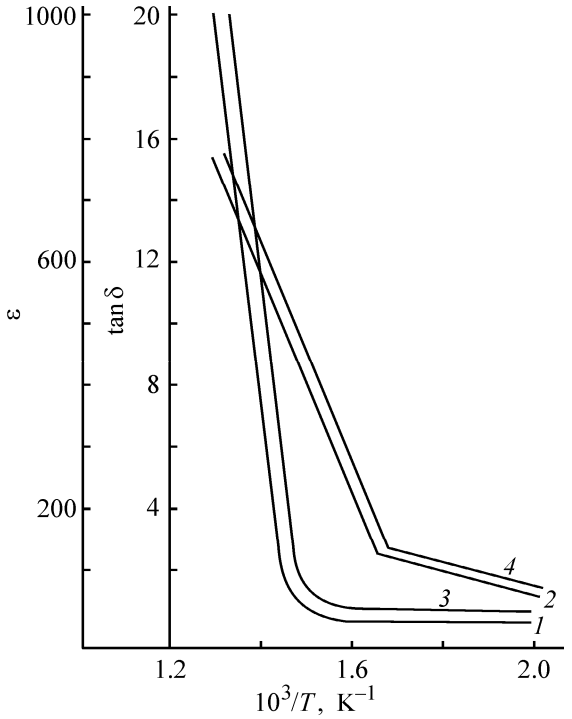

Fig. 3. Temperature dependence of (*2*, *4*) dielectric constant ε and (*1*, *3*) dielectric loss tangent for (*1*, *2*) $RbMgSc \cdot (MoO_4)_3$ and (*3*, *4*) $Rb_{0.8}Mg_{0.8}Sc_{1.2}(MoO_4)_3$.

The dielectric constant ε and the dielectric loss tangent tan δ show an exponential dependence on temperature (Fig. 3). The absence of extrema in the curves for the dielectric constant and dielectric loss tangent indicate that $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ exhibits no phase transitions and ferroelectric properties.

CONCLUSIONS

(1) Variable-composition phases $Rb_{1-x}A_{1-x}R_{1+x} \cdot (MoO_4)_3$ ($0 \le x \le 0.2$), A = Mg, Mn, Co, Ni; R = Sc, Yb, Lu were prepared by the method of solid-phase reactions from rubidium carbonate, magnesium, manganese, cobalt, nickel, scandium, lutetium, and ytterbium oxides, molybdenum trioxide, and also from molybdates of rubidium and di- and trivalent elements.

(2) The $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ samples are isostructural to each other and crystallize in the monoclinic crystal system (space group C2).

(3) The $Rb_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ samples have a mixed ionic-electronic conduction with predominance of the electronic component.

Abstract—Scanning electron microscopy, X-ray diffraction and adsorption structural analyses, and helium pycnometry were used to study the structure of nanoporous carbon produced by chlorination of powdered titanium carbide and carbonitride and of titanium carbide synthesized by chemical-vapor deposition. The results obtained were used to make suggestions about the type of organization of the nanoporous structure of these materials. The evolution of the structure of nanoporous carbon was analyzed in relation to the chlorination temperature. The effect of the chlorination temperature on the structure of the nanoporous carbon obtained and on its pore volume was examined.

DOI: 10.1134/S1070427208100066

Nanoporous carbon (NPC) produced by chlorination of carbides is widely used in various fields of science and technology [1–9]. Structural studies of NPC synthesized from various carbide and carbonitride materials in the form of powders and a compact material at various thermochemical treatment (TCT) temperatures are of particular scientific and practical interest.

In this study, NPC produced from powdered TiC, $TiC_{0.44}N_{0.48}$ and pyrolytic TiC (CVD) was examined. The structure of NPC produced from TiC powder was studied in [10–13]. In [10], NPC produced from powders at chlorination temperatures of 200–1200°C was examined. It was shown that amorphous carbon with a narrow pore size distribution is formed at T = 400–600°C. Raising the synthesis temperature to above 800°C leads to a broader pore size distribution. It was shown in [11–13] that the structure of carbon produced from TiC strongly depends on synthesis temperature and presence of catalytically active metals, such as nickel, cobalt, and iron, in the reaction medium. Addition of an insignificant amount of a metal leads to formation of a turbostratic structure at temperatures as low as 800–900°C.

EXPERIMENTAL

NPC samples were synthesized from the following starting materials: titanium carbide powder (specific surface area by BET 1.3 $m^2 g^{-1}$, pycnometric density 4.87 g cm^{-3}, carbon content 19.5 wt %) by chlorination at temperatures of 400, 600, 800, 1000, 1300, and 1800°C; pyrolytic TiC (in the form of tubes 8 mm in diameter and wall thickness of up to 1.5 mm) produced by chemical vapor deposition (CVD) (pycnometric density 4.84 g cm^{-3}, carbon content 19.8 wt %); and powdered titanium carbonitride of composition $TiC_{0.44}N_{0.48}$ (specific surface area 1.5 $m^2 g^{-1}$, pycnometric density 5.42 g cm^{-3}, carbon content 8.82 wt %, and nitrogen content 11.35 wt %), produced by by chlorination at 800°C. Titanium carbide and carbonitride were charged into an electric furnace with a graphite heater directly heated by passing a current in the atmosphere of argon; chlorine was fed into the reactor heated to a prescribed temperature. The thermochemical treatment was performed in the flow-through mode [14] to complete removal of titanium from the titanium carbide lattice, as indicated by X-ray diffraction analysis (XRD) and elemental analysis by scanning electron microscopy (SEM). No residual amounts of the TiC phase and elementary titanium were found in NPC. To remove the re-sidual content of titanium chloride and chlorine, NPC was additionally dechlorinated at a temperature of 800°C in H_2 for 1 h.

The shape and size of powder particles of TiC and $TiC_{0.44}N_{0.48}$ and of NPC synthesized from powdered TiC and compact material (tube of pyrolytic TiC and NPC produced from pyrolytic TiC) was determined

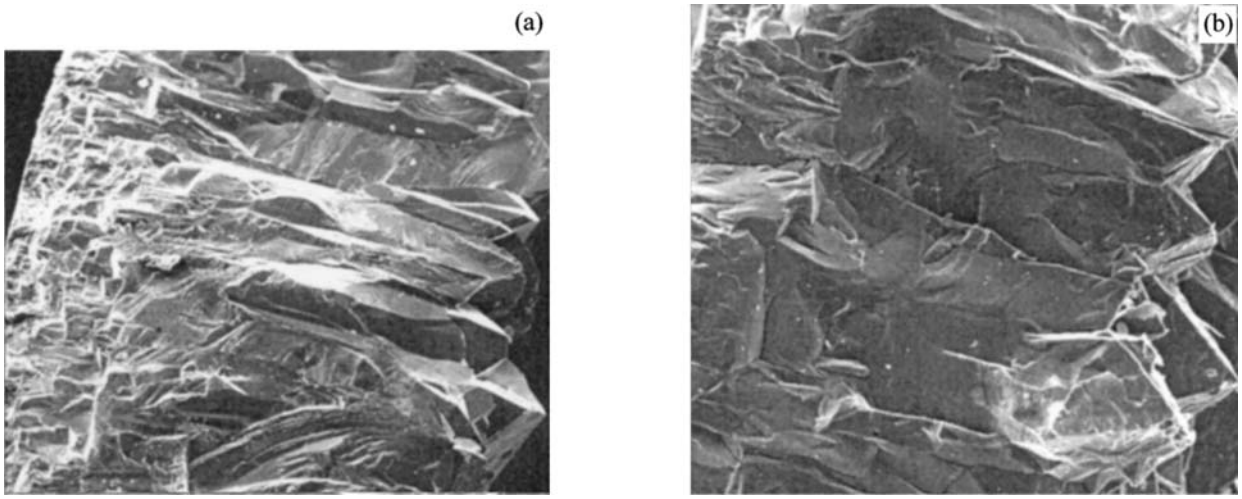

Fig. 1. Fractograms of lateral fractured surface of (a) tube composed of TiC(CVD) and (b) NPC produced from TiC(CVD).

and an elemental analysis was performed with a Quanta 200 scanning electron microscope. The structure was examined by XRD on a DRON-4 X-ray diffratometer with Co_{K_α} radiation. The pycnometric density was measured by gas pycnometry (pycnometric gas He) with a Quantachrome Ultrapycnometer 1000 device. An adsorption-structural analysis (ASA) (measurement of the adsorption–desorption of nitrogen) was performed at liquid-nitrogen temperature (–196°C) on a Micromeritics ASAP 2020 installation.

SEM studies demonstrated that powders of the starting carbide and powders subjected to thermochem-ical treatment at various temperatures have ?the same size and shape of particles?. The pyrolytic TiC has no porosity, which is indicated by results of pycnometric and metallographic studies, and, therefore, used to obtain compact NPC with a monodisperse structure. Figure 1 shows fractograms of a fractured lateral surface of tubes composed of pyrolytic TiC before chlorination (Fig. 1a) and NPC tubes produced from pyrolytic TiC after chlorination (Fig. 1b). As can be seen from these images, the shape, size, and structure of compact NPC before and after chlorination are the same. The pycnometric densities of NPC produced at 400–800°C from TiC and TiC_xN_y powders and pyrolytic TiC fall within the range 2.19–2.25 g cm^{-3}, which is close to the theoretical density of graphite (2.265 g cm^{-3}). At TCT temperatures $T \geq 1000$°C, the pycnometric density gradually decreases (Table 1), with the pore volume for nitrogen simultaneously becoming smaller. This indicates that pores inaccessible to nitrogen (to a greater extent) and helium (to a lesser extent) are formed.

Table 1. Structural parameters of NPC produced from a TiC powder at various temperatures*

* α is the slope of the X-ray diffraction curve at front diffraction angles, which gives the fraction of carbon atoms in the amorphous state; q, number of hexagonal carbon monolayers in microlayers; d_{002}, average interlayer spacing between hexagonal monolayers in a microlayer; L_a, average length of a rectilinear portion of a carbon monolayer; L_c, average thickness of a microlayer; Δa and Δd, average defectiveness of monolayers in the directions a and c, respectively; and ρ_p, pycnometric density.

The structural parameters of NPC were determined using methods described in [15, 16]. An XRD analysis of the structure of NPC synthesized from TiC demonstrated that, as the TCT temperature increases, the structure of the material rather gradually changes from amorphous to paracrystalline and further to turbostratic (Table 1). It should be noted that, in the case of NPC synthesized at 400°C, hexagonal carbon monolayers do not combine into microlayers. The X-ray diffraction pattern of this material contains no (002) reflection (Fig. 2a). As the TCT temperature is raised, the fraction of the amorphous phase decreases to zero. At a TCT temperature of 1800°C, the NPC structure becomes turbostratic, with all carbon monolayers combined into microlayers (q = 100%) (Fig. 2b). The spacing between hexagonal monolayers in microlayers steadily decreases as the TCT temperature is raised and reaches a value of 0.337 nm. The average length L_a of rectilinear portions of carbon monolayers increases from 0.9 to 8.6 nm. For NPC powders produced from TiC (1800°C), in which all monolayers are combined into microlayers, the parameter L_a acquires a meaning of the length of the rectilinear portion of a carbon microlayer. As the TCT temperature is raised, the defectiveness of monolayers in the direction a decreases from 0.05 nm to zero at a temperature of 1300°C. This means that there is no curvature of carbon monolayers across a length L_a.

For NPC powders produced from TiC and subjected to TCT at 400 and 600°C, there are no (002) and (004), and (004) reflections, respectively. Therefore, it is impossible to determine L_c and Δd. The thickness L_c of microlayers is 5.8 nm in NPC produced from TiC (800°C) and increases to 16.4 nm for NPC from TiC (1800°C). The defectiveness of monolayers in the direction c substantially exceeds that in the direction a and decreases from 0.011 to 0.007 nm as the TCT temperature is raised.

The structural parameters of NPC produced from powdered $TiC_{0.44}N_{0.48}$ and compact pyrolytic TiC at 800°C coincide, to within experimental error, with those of NPC synthesized from TiC powders also at 800°C, and, therefore, these data are not presented in Table 1. The structure of NPC produced from TiC varies with the TCT temperature similarly to that of NPC from B_4C [14]. Therefore, a model suggested for NPC produced from B_4C can be adopted for NPC produced from TiC. The NPC synthesized from TiC powders at 400–1000°C contain a large amount of amorphous carbon (α = 34°–11°) with a considerable fraction of carbon monolayers (q = 0–38%). Consequently, a predominantly paracrystalline structure is formed, mostly constituted by single carbon monolayers bound to each other by linear carbine chains. Therefore, it can be stated that the pore structure of NPC synthesized at these temperatures is generated by carbon monolayers. The length and width of these layers, L_a = 0.9–1.2 nm.

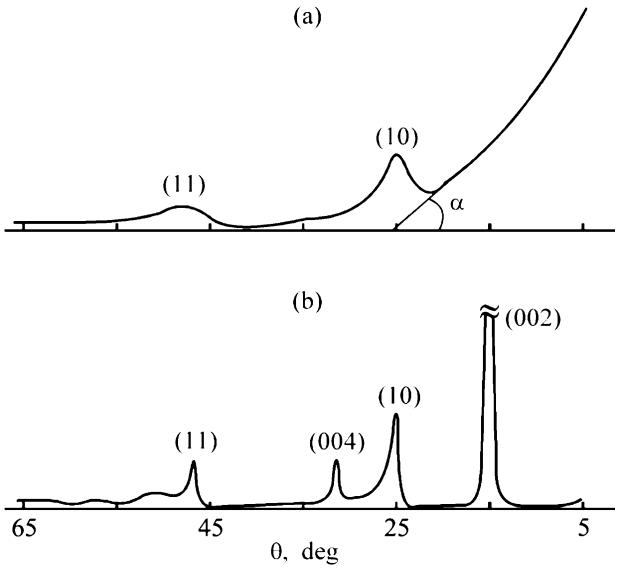

Fig. 2. X-ray diffraction patterns of NPC obtained at (a) 400 and (b) 1800°C from TiC (Co_{K_α}). (θ) Diffraction angle.

At TCT temperatures above 1300°C, the fraction of the amorphous phase decreases to zero, linear carbine chains almost disappear, and a turbostratic carbon structure is formed, with the fraction of monolayers combined into microlayers ranging from 63 to 100%. The pore structure of NPC synthesized from TiC at above 1300°C can be for the most part represented by slits formed between carbon microlayers, and, therefore, a decrease in the specific surface area and pycnometric density is observed for these materials (Table 1). The average sizes of the rectilinear regions of microlayers in NPC produced at a TCT temperature of 1800°C are as follows (nm): L_a = 8.6 and L_c = 16.4. It is apparent that an intermediate structure is formed at TCT temperatures of 1000 to 1300°C. This structure contains pores formed both by carbon monolayers and by intersection of carbon microlayers.

A study of the structure of NPC produced from TiC by high-resolution transmission electron microscopy (HRTEM) demonstrated that the structure of the material is constituted by hexagonal carbon monolayers produced at low chlorination temperatures (Fig. 3a)

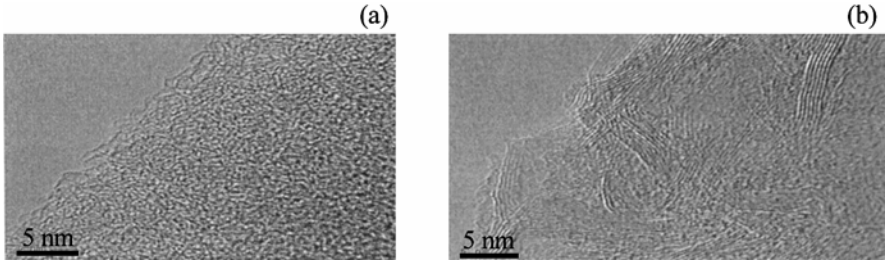

Fig. 3. HRTEM micrographs of NPC produced from α-SiC at T_{TCT} of (a) 600 and (b) 1800°C.

and by carbon microlayers formed at high chlorination temperatures (Fig. 3b).

Titanium carbide has a face-centered cubic (fcc) structure and belongs to interstitial phases formed by introduction of carbon atoms into interstitial positions of the fcc sublattice of titanium atoms. Metal atoms are arranged in densely packed layers, between which carbon layers lie. The lattice constant of TiC is 0.4328 nm. The TCT of carbides is a topochemical reaction, i.e., reaction that occurs in a narrow localized zone at the interface between a solid reagent (carbide in the case in question) and a solid product (NPC), with gradual shift of the reaction front into the carbide and its conversion into carbon. This suggestion was confirmed in chlorination of TiC produced by CVD. With account of the initial structure of TiC and of the chemical nature of the process, an NPC structure with slit-like pores should be formed.

The structure of the NPC samples under study was determined by the ASA method, using the nonlocal density functional theory (NLDFT) adapted to adsorption of nitrogen on amorphous surfaces [17–19]. The surface of ungraphitized carbon black with adsorbed nitrogen served as a reference system. It is noteworthy that the NLDFT variant developed for crystalline surface has been used until now, with graphitized carbon black chosen as a reference system in the case of activated carbons. As a rule, this choice resulted in an insufficiently accurate description of experimental isotherms of nitrogen adsorption on activated carbon and distorted the pore size distribution [18].

The suggestion that the pore wall surface has an amorphous (defective) structure considerably improves the descriptive capacity of the NLDFT and gives a more adequate pore size distribution. The working principle of the approach developed consists in that the adsorbent and adsorbed nitrogen are represented as components of a binary system and the global similarity of these components is in their disordered state. In the original theory, the adsorbate within a limited volume of a pore was understood as a gas or vapor experiencing the action of an external field created by the adsorbent. In the new variant, the adsorbent is not any more a thermodynamically inert, external with respect to the adsorbate, body whose only role is to create an adsorption field. Previously, the NLDFT has been only applied to gases, vapors, or fluids. In the NLDFT version developed in this study, a common procedure is used for the binary system constituted by a solid and a gas (vapor). Even in the case when pores have a slit-like shape, the model suggested here better describes the adsorption isotherm because of the presence of defects in the hexagonal structure of mono- and microlayers.

Particular attention was given to the inversion method used to find the differential pore distribution function from the adsorption isotherm. This problem belongs to the class of ill-posed problems because the results of analysis are rather sensitive to experimental errors. Accidental nonsignificant peaks or dips on the distribution curves are suppressed using the regularization (smoothing) method developed by Tikhonov [20]. A careful choice of the regularization parameter and of the type of the stabilizing functional made it possible to elucidate fine details of the porous structure and the effect of technological parameters on this structure. The pore width H is defined in this study as the distance between the centers of carbon atoms situated on the opposite walls. It is noteworthy that the effective pore width H–Δ (where Δ is the distance between neighboring graphenes in the graphite lattice, 0.335 nm) is used in the literature and software for instruments analyzing the porous structure by the adsorption method. Such a definition has been accepted in order to take into account only pores with width exceeding Δ, accessible to gas molecules. If, in particular, the pore wall is composed of only a single graphene, its wall thickness is considered to be equal to Δ, rather than to zero. In this study, the definition was only used

Table 2. Porous structure parameters of NPC synthesized from TiC at various temperatures*

* V_Σ, V_1, V_2, and V_3 are the total pore volume and volumes of the 1st, 2nd, and 3rd groups of pores; S_Σ, S_1, S_2, and S_3, the total specific surface area and specific surface areas of the 1st, 2nd, and 3rd groups of pores; H_1, H_2, and H_3, widths of the 1st, 2nd, and 3rd groups of pores, respectively.

to calculate the pore volume, because just the volume accessible to molecules of the substance being adsorbed is conventionally understood as the pore volume. However, the concept of the true, geometric pore width was used as the most adequate characteristic when analyzing the pore size distribution function.

The isotherms of nitrogen adsorption on the nanoporous carbon materials studied are shown in Fig. 4. A study of the ASA results demonstrated that, as the TCT temperature increases, the porous structure of NPC changes from microporous with high specific surface area to coarsely mesoporous with low specific surface area (Fig. 5, Table 2). For example, the isotherms of nitrogen adsorption-desorption on NPC samples synthesized at 400, 600, and 800°C show no hysteresis loop characteristic of mesoporous systems and are similar to type-I isotherms, which describe microporous systems in accordance with the IUPAC classification. A hysteresis loop appeared on the isotherm for the NPC produced at 850°C, with the fraction of mesopores equal to 21% of the total pore volume.

The pore size distribution varies with the chlorination temperature At a chlorination temperature of 400–800°C, only pores smaller than 2 nm in size (micropores) are present in NPC; at NPC synthesis temperatures of 850–1200°C, a bidisperse structure (micromesoporous) is formed; whereas chlorination at tem-

peratures $T \geq 1300$°C yields a mesoporous structure. The isotherms of nitrogen adsorption-desorption on NPC samples synthesized at 1000, 1300, and 1800°C and NPC produced from $TiC_{0.44}N_{0.48}$ show a hysteresis loop, which indicates that mesopores are present. For NPC powders produced from TiC at 400–800°C, two groups of micropores are observed, with the following sizes (nm): 1st group, 0.70–0.74; 2nd group, 1.06–1.31 (Fig. 5, Table 2). In the temperature range specified, the volumes and specific surface areas of these two groups of micropores in the NPC obtained change only slightly.

The NPC obtained at 1000°C has already three groups of pores, with the sizes of the first two groups of pores remaining nearly the same, and the average size of pores of the third group equal to 1.71 nm (Fig. 5). The volume of micropores passes through a maximum (0.54 $cm^3\ g^{-1}$) for the NPC obtained at 800°C. Raising the temperature further, to above 800°C, leads to a decrease in the volume of micropores and to a pronounced development of mesopores. The total specific surface area and the specific surface area of micropores show the same tendency. For example, the total specific surface area first increases to 2100 $m^2\ g^{-1}$ at 800°C and then decreases as the temperature is raised further. At a TTCT of 1300°C, a mesoporous NPC structure appears. For TCT at $T \geq 1300$°C, the peaks in the region of micropores are negligible. There is a broad peak in the region of mesopores (Fig. 5) and the specific surface area decreases to 62 $m^2\ g^{-1}$. These NPC materials can be attributed to materials with a mesoporous structure.

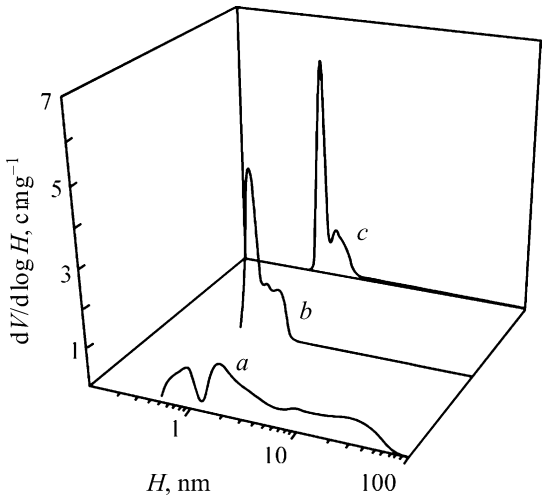

Fig. 6. Pore size distribution for NPC produced from (*a*) $TiC_{0.44}N_{0.48}$, (*b*) TiC (CVD), and (*c*) TiC (powder) in relation to the TCT temperature. ($dV/d\log H$) Change in the pore volume, and (H) pore width.

The results obtained show a good correlation with the results of XRD and refine these data. This gives reason to believe that, at TCT temperatures of 400–800°C, carbon monolayers form a microstructure with two characteristic sizes: 0.70–0.74 and 1.06–1.31 nm (on the assumption of a slit-like model). At a TCT temperature of 1000°C, carbon microlayers start to be formed, with the fraction of pores formed by monolayers becoming smaller and there appearing a new type of pores formed by spaces between microlayers. At TCT temperatures $T \geq 1300$°C, micropores formed by carbon monolayers disappear and mesopores formed by carbon microlayers remain. This yields NPC with a mesoporous structure (Fig. 5).

In this study, NPC produced from TiC powder, compact pyrolytic TiC, and $TiC_{0.44}N_{0.48}$ powder at a chlorination temperature were examined. For TiC powder and compact pyrolytic TiC, the data almost coincide (Table 3, Fig. 6). It can be stated on the basis of the results obtained that the structures of NPC produced under identical conditions are independent of the dispersity of the starting carbide, being the same even for a compact material.

The structure of the NPC produced from $TiC_{0.44}N_{0.48}$ is similar to that of the NPC synthesized from TiC (1000°C) (Figs. 5, 6). A small single peak with an average pore size of 0.96 nm is observed in the region of micropores, and two peaks (~2 and 10 nm), in the region of mesopores. The main difference between these two materials is in the volume and specific

surface area of mesopores (whose size exceeds 2 nm in accordance with the international classification by IUPAC). For example there are no mesopores at all in NPC produced from TiC (1000°C), and the volume and specific surface area of mesopores in NPC produced from $TiC_{0.44}N_{0.48}$ are 0.94 $cm^3 g^{-1}$ and 351 $m^2 g^{-1}$, respectively. The total pore volume in NPC synthesized from $TiC_{0.44}N_{0.48}$ is twice that in NPC produced from TiC (1000°C) (Tables 2, 3). This effect can be attributed to removal of titanium and nitrogen atoms from $TiC_{0.44}N_{0.48}$ by TCT. This yields lager pores.

It should also be noted that the majority of pores in NPC produced from $TiC_{0.44}N_{0.48}$ are formed by hexagonal carbon layers (q = 20%), whereas in NPC synthesized from TiC (1000°C), a substantial part of mesopores are formed by carbon microlayers (q = 38%). The fraction of micropores in NPC produced from $TiC_{0.44}N_{0.48}$ is 24%, and that in NPC synthesized from TiC (1000°C), 100%. This suggests that NPC produced from $TiC_{0.44}N_{0.48}$ belongs to materials with predominantly mesoporous structure, and NPC synthesized from TiC (1000°C), to materials with microporous structure.

CONCLUSIONS

(1) Analysis of the effect of the thermochemical treatment temperature on the structure of nanoporous carbon produced from TiC powders shows that the structure varies from paracrystalline to turbostratic. Depending on the thermochemical treatment temperature, the porous structure of nanoporous carbon varies from microporous (thermochemical treatment temperature 400–800°C) to mesoporous (thermochemical treatment temperature 1300–1800°C).

(2) The structures of nanoporous carbon produced from powdered and compact (pyrolytic) TiC at the same temperature are nearly the same. The structure of nanoporous carbon produced from $TiC_{0.44}N_{0.48}$ is predominantly mesoporous, with a large total volume of pores, including mesopores, which twice exceeds the total pore volume of nanoporous carbon synthesized from TiC.

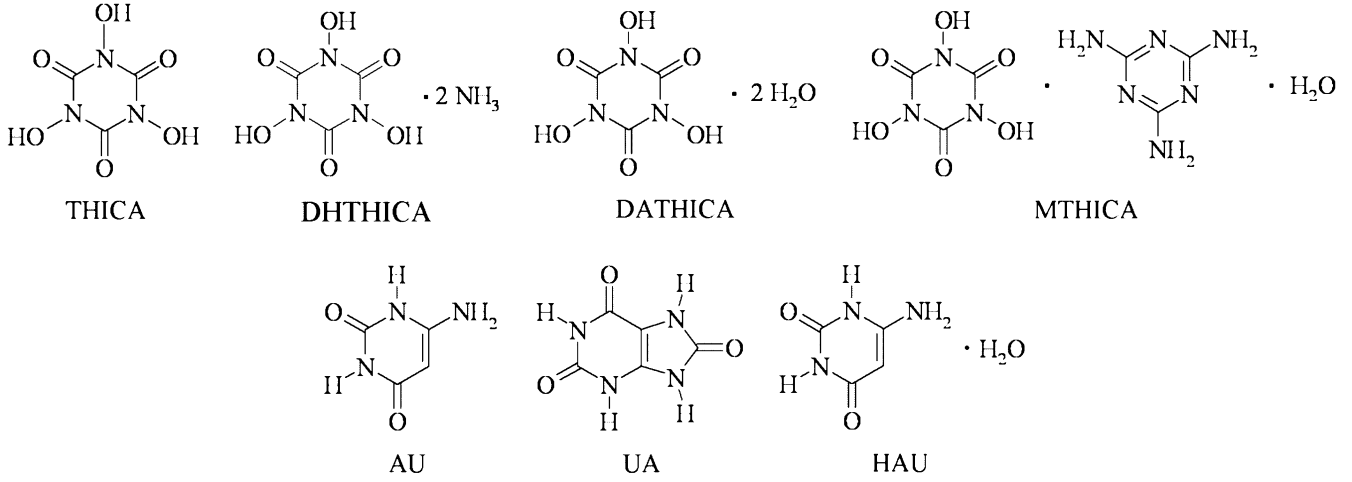
Abstract—Methods for phase stabilization of ammonium nitrate were sought for to substantially extend the application fields of this oxidizing agent in self-combustible formulations for various purposes, including the new generation of gas-generating formulations for automobile safety bags. The phase state of ammonium nitrate alloys with minor additions of organic substances with crystallographic parameters close to those of ammonium nitrate was studied.

DOI: 10.1134/S1070427208100078



Methods for affecting the phase states and phase transformation of crystalline substances, such as introduction of minor amounts (in crystallization from solutions or melts) of modifying substances, are well known and frequently used. The modifiers can affect the phase state in different ways. They can cardinally change the phase transition points, with the thermodynamic range of existence of crystalline modifications extended or narrowed, to the point of stabilization of a substance in one of the phases. For example, ammonium nitrate (AN) can be stabilized in phase III by isomorphic introduction of potassium nitrate into its lattice. At the same time, the effect of other modifiers consists only in the influence on the phase transition kinetics, with the phase transition process substantially decelerated. Some researchers understand such a deceleration as true stabilization, rather than as the actually occurring attainment of a metastable state.

Recently, an increasing attention has been paid to the nature and mechanism of the influence exerted by modifying substances on phase states. The mechanism of the effect of isomorphic introduction of foreign cations or anions into the lattice is more or less clear. This can and must affect the energy of interionic interaction and, consequently, the phase state, too. There are examples of how substances not incorporated into the crystal lattice affect the phase state of substances. It is believed that modifiers of this kind act across the crystallite surface by entering the interblock space.

In recent years, a new group of modifying substances has been discovered. Owing to the crystallochemical similarity to AN (i.e., because of the fullest coincidence of distances between the atomic planes of a modifier with those in AN itself), these modifiers can be incorporated into its lattice. However, their effect on the phase state fundamentally differs from that of ions isomorphically introduced into the lattice [1, 2]: additional intermolecular interactions appear between the incorporated atomic planes of the modifier and the atomic planes of AN. The nature of these intermolecular interactions in the crystal lattice being modified is rather complex: it may involve changes in the electronic state of molecules or ions (to the point of electron transfer and formation of charge-transfer complexes), formation of new hydrogen bonds, and other types of chemical interactions. Performing only crystallochemical studies of the starting crystals and modifier-crystals is insufficient for understanding the nature

and mechanism of the influence exerted by substances of this kind on the phase state. Studies of UV and IR spectra, and possibly of NMR spectra, too, are necessary here, with the nature of intermolecular interactions in individual modifier substances compared with that in the lattice of an object being modified.

This communication reports on continuation and development of our previous studies [1–3]. Results obtained in an analysis of the interaction of planar molecules of unsaturated heterocycles containing carbonyl and amine (or imine) groups with the AN lattice are presented. It follows from quantum-chemical calculations that the planar nitrate anion contains an upper twice-degenerate bonding orbital of the π-type, upper nonbonding orbital of the *p*-type (lies in the plane of the anion), and lower unoccupied orbital of the π-type. the electronic structure of the nitrate ion that the anion can simultaneously act as an electron donor and electron acceptor in its possible intermolecular orbital interactions with the modifier molecule. A number of compounds were studied as modifier molecules: 1,3,5-trihydroxyisocyanuric acid (THICA) $C_3H_3N_3O_6$ (also named 1,3,5-trihydroxyhexahydro–1,3,5-triazine-2,4,6-trione), its dihydrate (DHTHICA) $C_3H_3N_3O_6 \cdot 2H_2O$, its diammonium salt (DATHICA) $C_3H_3N_3O_6 \cdot 2NH_3$, 1,3,5-trihydroxyisocyanuric acid melamine salt hydrate (MTHICA) $C_3H_3N_3O_6 \cdot C_3H_6N_6 \cdot H_2O$ (the last two salts have not been described in the literature), 4-aminouracyl (AU) $C_4H_5N_3O_2$, its monohydrate (HAU) $C_4H_5N_3O_2 \cdot H_2O$, and 2,4,6-trioxypurine (uric acid, UA) $C_5H_4N_4O_3$, suggested as an AN modifier in our previous studies [4, 5]:

Previously, [6], we have performed an X-ray diffraction analysis of DHTHICA, AU, and HAU single crystals and calculated, using the experimental data, the electronic parameters of modifier molecules in order to describe the configuration of the molecules by quantum-chemical methods. To describe the configuration of the UA molecules, we used the results of an X-ray diffraction analysis made in [7]. Our choice of the modifier molecules was governed by the fact that the molecules mentioned above are perfect electron acceptors (owing to the presence of a carbonyl group), on the one hand, and good electron donors (because of the presence of an imine group), on the other. DHTHICA crystals were chosen for an X-ray diffraction analysis; atomic coordinates furnished by the X-ray diffraction analysis were used only for the individual molecule of this acid (THICA); composites with ammonium nitrate were produced using a fine-crystalline powder of DHTHICA.

It has been shown previously as a result of a thorough search for smokeless gas-generating formulations for automobile safety bags that, possibly, one of the best combustibles to be used in pair with AN is THICA [8]. The point is that, in this composition, the low content of AN (40.4%) is combined with the low combustion point (2374 K) and low content of water in combustion products (42.9%). Unfortunately, THICA is a medium-strength acid (pH ~3 for a 10% aqueous solution) (according to the results of spectrophotometric and potentiometric measurements, p*K*(1) 5.23, p*K*(2) 6.32, and p*K*(3) 7.93 [9]). As a consequence, THICA is chemically incompatible with AN (in an attempt to fuse AN with THICA, first signs of interaction were observed at $T \approx 70$°C and decomposition at $T \approx 120$°C).

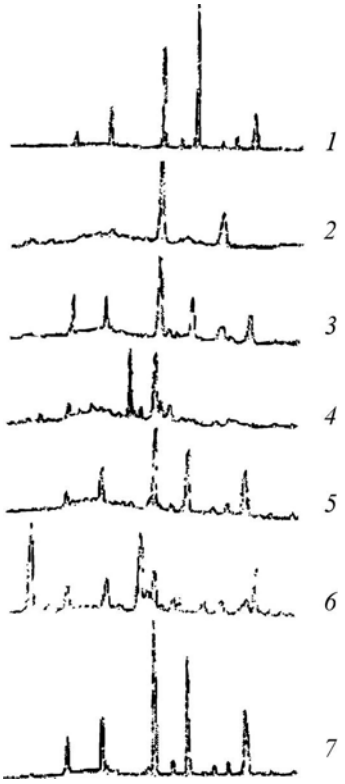


Fig. 1. X-ray diffraction patterns of polycrystalline samples. (λ Cu K_α, 2θ = 10°–50°). (*1*) Ammonium nitrate, (*2*) DATHICA, (*3*) 55.3% AN + 44.7% DATHICA alloy, (*4*) AU, (*5*) 83.8% AN + 16.2% AU, (*6*) UA, and (*7*) 70.4% AN + 29.6% UA.

In a search for THICA derivatives compatible with AN, we synthesized the previously unknown DATHICA and MTHICA. It was found that DATHICA is nearly insoluble in water and organic solvents (a unique situation for ammonium salts of organic acids). The structure of the salts was confirmed by elemental analysis and IR spectroscopy. It was shown by the DTA–TGA technique that both the salts are sufficiently thermally stable and chemically compatible with AN, and DATHICA exhibited modifying properties. Unfortunately, we could not grow single crystals of the DATHICA salt for X-ray diffraction analysis. The crystal-chemical correspondence to the structure of ammonium nitrate is characteristic of both the THICA acid and DATHICA salt.

It follows from the results of an X-ray diffraction analysis of modifier crystals that an intermolecular interaction of the N–H···O=C type, which forms infinite chains of interacting molecules in a crystal, is observed in the crystal structure of 4-aminouracyl. The configuration of the interacting molecules indicates that each modifier molecule acts as a donor of a proton and a lone electron pair of the imine nitrogen atom and as an acceptor of electrons because of the presence of a carbonyl group. It follows from ab initio quantum-chemical calculations based on the X-ray data on the molecular configuration that, being simultaneously electron donors and electron acceptors, modifier molecules form in crystals either chains or 2*D* formations with rather high intermolecular interaction energies. For example, in the structure of AU crystals, the interaction energy of a pair of molecules isolated from the chain is 18 and 10 kcal mol^{-1} before and after optimization, respectively. Such intermolecular interactions in modifier crystals can compete with the energy of the ammonium nitrate structure and be a model of the interactions occurring in the composite. The results of calculations (by GAUSSIAN-03 software) of the electronic energy in the ground singlet state for such modifier molecules as THICA, AU, and UA demonstrated that the highest occupied molecular orbitals (HOMO) of all the three molecules are weakly bonding π-type orbitals and lowest unoccupied molecular orbitals (LUMO) are also of the π-type, with the main contribution to these orbitals made by carbonyl groups and multiple C=N bonds. The LUMO are nonbonding as regards their symmetry, but weakly bonding in their orbital energy. Thus, the modifier molecules can simultaneously act as both electron donors and electron acceptors. The energies of the HOMO and, simultaneously, the energy difference (HOMO–LUMO) can be used to evaluate the acceptor capacity of the chosen three modifiers: the highest acceptor capacity is observed for the UA molecule, a lower capacity, for the AU molecule, and the lowest, for the THICA molecule.

It was demonstrated that, in the case of a crystallochemical similarity of components (modifier and AN), a certain and even, occasionally, large amount of an additive can be introduced into their alloy without any indication of the presence of this additive in the X-ray diffraction pattern of the alloy. The substance introduced into an alloy is distributed as very small clusters over separate crystalline blocks of AN, in which the interplanar spacings coincide with those in the additive. Figure 1 shows comparative X-ray diffraction data for the crystal lattices of AN, modifier substances, and the corresponding alloys.

The most characteristic reflections in the X-ray diffraction pattern of pure AN (Fig. 1, curve *1*, phase IV) to be spanned upon introduction of modifier substances are those corresponding to the interplanar spac-

ings *d* 4.906 and 3.091 Å (the second interplanar spacing is more important because it determines the distance between atomic planes in a stack of planar-parallel anions). Curve *2* in Fig. 1 is the X-ray diffraction pattern of DATHICA crystals with a strong reflection *d* 3.100 Å, and curve *3*, that of the alloy 55.3% AN + 44.7% DATHICA. The X-ray diffraction pattern of the alloy (phase IV of ammonium nitrate) represents a favorable case of an almost full coincidence of the X-ray diffraction patterns of the substances being fused. The X-ray diffraction pattern of the second additive under study, AU, is shown by curve *4* in Fig. 1. This pattern is characterized by coincidence of the interplanar spacings (4.676, 3.151, and 3.077 Å) with the corresponding closely similar spacings in the X-ray diffraction pattern of AN. However, the pattern contains a very strong reflection with *d* = 3.531 Å, which is totally absent in the diffraction pattern of ammonium nitrate in phase IV. In the diffraction pattern of the alloy 83.8% AN + 16.2% AU (Fig. 1, curve *5*), this reflection is not observed, either. Thus, 16.2% AU is fully distributed over the lattice of ammonium nitrate in phase IV. The most significant is the diffraction pattern of the modifier substance UA (Fig. 1, curve *6*). The strongest reflection (with *d* = 6.511 Å) characteristic of this substance is totally absent in the diffraction pattern of individual AN, whereas in the diffraction pattern of the alloy, this reflection appears only at the composition 70.4% AN + 29.6% UA (curve *7*) and it is very weak. Thus, in accordance with the high calculated acceptor capacity of the modifier molecule UA, the ability of this compound to be distributed over the AN lattice is the highest.

It is widely known that pure AN has five polymorphous modifications and, accordingly, shows four phase transformations: VI $\rightleftarrows$ V at –17°C, IV $\rightleftarrows$ III at +32.3°C, III $\rightleftarrows$ II at +84.2°C, and II $\rightleftarrows$ I at +125.2°C. These phase transitions strongly hinder wide use of AN in energetic formulations. The most detrimental is the transition IV $\rightleftarrows$ III (at +32.3°C). A study of the kinetics of this transition demonstrate that it occurs via total disintegration of the starting phase IV. The kinetics of the IV $\rightleftarrows$ III transition in pure ammonium nitrate in the isothermal mode was studied using the method of quantitative X-ray phase analysis of polycrystals. This was done in a specially designed temperature chamber for the DRON-2 diffractometer, which made it possible to record the variation of the phase ratio in the course of time at a constant temperature. We measured the integral intensities of the peaks corresponding to certain phases and normalized the results to an internal standard. The normalized values of the integral intensity at various fixed instants of time were related to the integral intensity at the initial instant of time. Further, kinetic curves of the degree of conversion were plotted. To construct these curves, we examined the variation of three or four reflections for the initial and final phases.

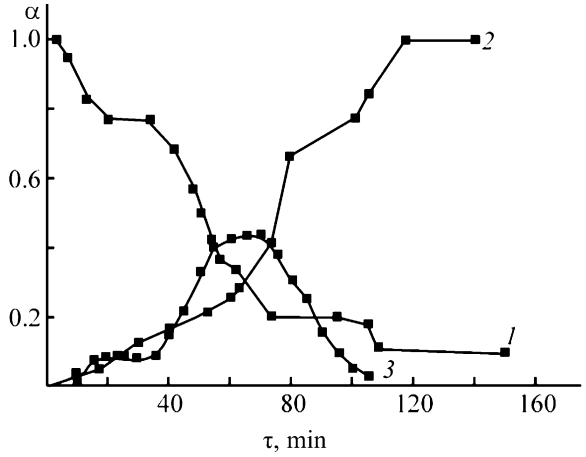

Fig. 2. Direct phase transition IV→III in ammonium nitrate (T = 33°C). (α) Fraction of a given phase relative to the initial amount of phase IV and (τ) time. (*1*) Loss of phase IV, (*2*) gain in phase III, (*3*) kinetics of formation of the intermediate phase X.

Figure 2 shows experimental data on the loss of the initial phase IV and the gain in the final phase III in the course of time at a temperature of 33°C (curves *1* and *2*, respectively). The sum of the relative amounts of the initial and final phases of AN at certain instants of time was substantially smaller than unity. This suggests that an intermediate phase X is formed (Fig. 2, curve *3*). Phase X is not observed in the experimental X-ray diffraction pattern because the substance representing this phase is distributed throughout the sample, rather than being concentrated in clusters of sufficient size, and, presumably, is situated at the interface between the initial and final phases.

Theoretical simulation of the phase transition IV $\rightleftarrows$ III with single-crystal structures gives no way of achieving this transition by minor displacements of ions. Here, a complete disintegration of the initial structure and assembly of a new structure are necessary. Therefore, the transition at +32.3°C is frequently named in the literature the point of "catastrophes." Modification of AN crystals with modifier substances represented in this communication leads to a totally new phase state of the modified product. There are no phase transitions V $\rightleftarrows$ IV and IV $\rightleftarrows$ III in these samples; however, the phase

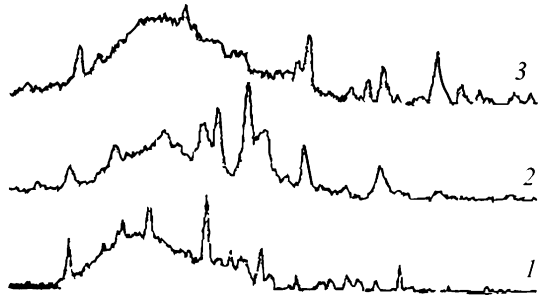

Fig. 3. X-ray diffraction patterns of polycrystalline composites ($\lambda\,Cu_{K_\alpha}$, 2θ = 10°–50°) after a temperature treatment (T = 32.3°C). Alloy: (*1*) 90% AN + 10% DATHICA, (*2*) 83.8% AN + 16.2% AU, and (*3*) 81.1% AN + 18.9% UA.

transition IV $\rightleftarrows$ II remains. The transition IV $\rightleftarrows$ II is also characteristic of pure AN samples if the transition occurs without access of moisture [10, 11].

A study of the kinetics of phase transitions in an alloy of composition 90% AN + 10% UA at temperatures of 53 and 54°C demonstrated that the sum of the initial and final phases is close to unity at any degree of conversion, i.e., the conversion of phase IV to phase II occurs directly from a crystal to crystal, nearly without formation of an intermediate X-ray-amorphous phase. Thus, modification of the product with appropriate organic additives does not lead, in the end, to the final solution of the problem of AN stabilization in the temperature range from –50 to +100°C; the stabilization of the product is limited to the temperature range from –50 to +50°C. As a result of multiple temperature treatments of alloys in the temperature range from –50 to +100°C at different humidities, the phase state of the alloys became stable; after numerous passes along the chosen temperature interval, the transition IV $\rightleftarrows$ II remained unchanged. Nevertheless, we could find conditions of an additional treatment, which consisted in prolonged keeping of samples near the temperature of "catastrophes" at an increased humidity. Such a treatment of the alloy leads to a new state of the substance, previously unknown for alloys of this kind.

Figure 3 shows X-ray diffraction patterns of alloys after their prolonged keeping near the temperature of 32.3°C. The diffraction pattern of the alloy 90% AN + 10% $C_3H_3N_3O_6 \cdot 2NH_3$ (Fig. 3, curve *1*) corresponds to the X-ray-amorphous state of the substance whose particles must be less than 100 nm in size. Even prolonged keeping of X-ray-amorphous alloy samples in a wide temperature range does not change their phase state. The most important circumstance is that the alloy samples are not recrystallized to the initial state (phase IV). X-ray studies of phase transitions in samples with a new phase state demonstrate the total absence of any phase transitions. Calorimetric studies (DTA and DSC) confirm this conclusion.

IR and UV spectroscopies were used to study the intermolecular interaction in composites of ammonium nitrate with DATHICA and AU. To preclude interaction of AN with KBr, samples for spectral studies were prepared as suspensions in Vaseline oil.

It was found that these additives strongly modify the system of hydrogen bonds in alloys with AN. We studied two compositions of AN alloys with DATHICA (44.7 and 10%). The alloy with 10% DATHICA is in the X-ray-amorphous state. IR spectral data indicate that the DATHICA additive is dispersed on the molecular dispersity level in both the composites. For example, the highest-intensity absorption band at 3236 cm^{-1} in the spectrum of the initial modifier DATHICA is observed neither in the spectrum of the alloy of the first composition (3400, 3270, 3196, 3116 cm^{-1}), nor in the spectrum of the alloy of the second composition (in which a single broad band peaked at 3400 cm^{-1} is present). These data point to a very strong interaction of modifier molecules with AN ions. The UV spectra of DATHICA and alloys of the first composition (without special treatment) differ only slightly. However, two broad bands at 240–300 nm appear in the spectrum of the alloy of the second composition (X-ray-amorphous state). Possibly, these bands are due to appearance of intermolecular orbital interactions of the type $\pi(NO_3) \rightarrow \pi^*(C{=}O)$.

The IR spectrum of the AN alloy with 16.2% AU (X-ray-amorphous state of the alloy) contain three absorption bands with comparable intensities in the range of N–H vibrations (3412, 3250, 3192 cm^{-1}), whose frequencies differ from those of the bands in the spectra of 4-aminouracyl (3416, 3396, 3176 cm^{-1}) and ammonium nitrate (3125 and 3015 cm^{-1}). The absence of a simple additivity between the spectra of the alloy and its components may indicate that there is an intermolecular interaction between the modifier molecules and ammonium nitrate ions, which changes the network of hydrogen bonds in the alloy. The IR spectrum of such an alloy, not subjected to any special treatment (not X-ray amorphous), differs from the IR spectrum of the alloy in the X-ray-amorphous state, but is not an additive sum of the spectra of the components, either. The former spectrum is dominated by the strong band

of N–H vibrations at 3180 cm^{-1}, with two weak bands observed on its wing at 3460 and 3344 cm^{-1}. It is noteworthy that a rather strong absorption band appears at 220–230 nm in the UV spectrum of the same alloy (not X-ray amorphous), but is absent in the spectrum of AU. Possibly, this occurs because there appear intermolecular orbital interactions.

EXPERIMENTAL

1,3,5-Trihydroxyisocyanuric acid and DHTHICA were synthesized by the known procedures [12, 13].

Diammonium salt of 1,3,5-trihydroxyisocyanuric acid. To a solution of 0.89 g (5mM) of THICA in 20 ml of methanol was added under agitation a solution of 1.15 g (15 mM) of ammonium acetate in 20 ml of methanol, with an abundant white precipitate formed. The mixture was agitated for 0.5 h at 40°C and for 0.5 h at 20°C. The precipitate was filtered off, washed with methanol (10 ml) and diethyl ether (10 ml), and dried in air at 70°C for 0.5 h. Yield 1.01 g (100%), decomposition point >200°C (without melting).

Found (%): C 17.30, H 4.39, N 32.45.

$C_3H_9N_5O_6$.

Calculated (%): C 17.07, H 4.30, N 33.17.

IR spectrum (KBr), ν, cm^{-1}: 3430, 3236, 3145, 2928, 1776, 1676, 1432, 1400, 1205, 1004, 985, 704. The product obtained is nearly insoluble in water and organic solvents (methanol, ethanol, acetone, DMFA, DMSO, toluene). When boiled in water, the product gradually dissolves because of the hydrolytic cleavage of the ring.

Hydrated melamine salt of 1,3,5-trihydroxyisocyanuric acid. To a solution of 0.89 g (5mM) of THICA in 20 ml of water was added under agitation a warm (~35°C) solution of 0.63 g (5 mM) of melamine in 120 ml of water, with a white precipitate formed. The mixture was cooled to 0°C and agitated at the same temperature for 0.5 h. The precipitate was filtered off, washed with ice water (20 ml), and dried in air. Yield 1.29 g (76%), decomposition point >200°C (without melting).

Found (%): C 22.71, H 3.99, N 40.23.

$C_6H_{11}N_9O_7$.

Calculated (%): C 22.44, H 3.45, N 39.25.

IR spectrum (KBr), ν, cm–1: 3532, 3500, 3400, 3125, 2930, 2870, 2700, 1712, 1672, 1630, 1504, 1440, 1384, 1344, 1212, 1180, 1008, 996, 776, 700.

Minor additions of organic substances were introduced into AN mostly by fusion at a temperature close to the melting point of AN.

The following experimental techniques were used: X-ray phase analysis (computer-controlled DRON-2 diffractometer; phase identification in transformations in the temperature range from –50 to +100°C by analysis of X-ray diffraction patterns, with preliminary calculation of theoretical diffraction patterns of polycrystals of all the phases from atomic coordinates furnished by an X-ray diffraction analysis of single crystals), DTA (MOM derivatograph, Hungary, heating rate 0.6 deg min^{-1}), UV spectroscopy on a Specord M40 spectrophotometer in the range 200–900 nm, and IR spectroscopy on a Specord IR75 spectrophotometer in the range 4000–700 cm^{-1}.

CONCLUSIONS

(1) It was found in a study of ammonium nitrate alloys with minor additions of organic substances that the phase state of the composite is affected only by additives close in crystallochemical parameters to ammonium nitrate.

(2) It was demonstrated that, for an organic substance to exert a stabilizing influence on phase states of ammonium nitrate, a modifier molecule should be an electron acceptor for creating intermolecular orbital interactions and should form new hydrogen bonds with ammonium nitrate ions.

(3) The conditions were found under which an additional temperature treatment of alloys converts them into a new X-ray-amorphous state with a stabilization temperature range from –50 to +100°C.

(4) An analysis of UV and IR spectra demonstrated that the X-ray-amorphous state of the composite is characterized by new intermolecular interactions, which are different from those in the starting components and in freshly prepared composites subjected to a temperature treatment and exposed to moisture.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Modified Method for Synthesis of Detonation Nanodiamonds and Their Real Elemental Composition

V. Yu. Dolmatov

Received March 17, 2008

Abstract—Modified technique for synthesis of detonation nanodiamonds by exploding a charge of high explosives in a water shell is described. Reducing agents are introduced into water. Their use enables solution of a number of problems: the carbon content of nanodiamonds is raised from 90 to 96 wt %, the content of incombustible admixtures is dramatically diminished from 3 to 0.1 wt %, and the yield of detonation nanodiamonds becomes two times higher. A new method for determining the elemental composition is described and the oxidation of nanodiamonds under heating in the presence of atmospheric oxygen is analyzed.

DOI: 10.1134/S107042720810008X

Detonation-synthesis nanodiamonds (DNDs) are the only product of the nanocarbon family (fullerenes, nanotubes, carbine, globular nanocarbon, etc.) produced on the industrial scale in various countries (Russia, China, Ukraine, Belarus, Turkey).

DNDs were discovered and for the first time industrially manufactured [Altai NPO (Research and Production Association), Biisk] in Russia [1–5]. After 15–20 years of studies, researchers came to a conclusion that the optimal explosive formulation for DND synthesis is a ~50 : 50 mixture of TNT and hexogen [2, 4–9]. The synthesis is performed in a detonation chamber in a neutral gas medium in a water or ice shell [6]. At present, use of DNDs in nearly all application fields (plating, polishing, production of oils and lubricants, medicine, biology, polymer technologies, etc.) requires that the DND quality should be improved. DNDs should contain the maximum possible amount of carbon (i.e., they should have a more perfect elemental composition) and should not contain incombustible admixtures (technological contaminations: metal oxides and carbides). This study is an attempt to solve this problem.

EXPERIMENTAL

The TNT–cyclonite alloy containing 40 wt % TNT (TG 40) was exploded in a water shell in a 1-m^3 explosion chamber (charge mass 0.6 kg). The mass ratio between the explosive and water was maintained at 1 : 6; products formed in preceding detonations served as the explosion medium. Readily oxidizable reducing agents (hydrazine hydrate, urotropin, urea, ammonia) were introduced into water at a mass ratio between the explosive and a reducing agent within the range 1 : (0.1–10.0) [10, 11].

The resulting diamond-containing stock (DS, half-product of DND synthesis) was purified with dilute nitric acid at a temperature of 240°C and pressure of about 80×10^5 Pa [12].

The elemental composition of DS and DNDs was analyzed by a new method: a weighed portion of a sample was kept at temperatures of 120–140°C for (DS) or 150–180°C (for DNDs) in a vacuum at a residual pressure of 0.01–10.0 Pa for 3–5 h and then was exposed at 1050–1200°C to oxygen flowing at a rate providing complete combustion of carbon and gasification of heteroatoms (nitrogen and hydrogen) in the course of 40–50 s.

It is known [2–12] that DND particles are complex structural formations that include the following components: crystalline diamond core (75–90% of carbon atoms), transition carbon shell of complex composition around the diamond core, and surface layer of various functional groups (hydroxy, carbonyl, carboxy, amide, and methyl groups). Nitrogen is rather uniformly distributed over all of these layers.

According to [4, 13], the detonation synthesis of DND can be divided into four stages.

In the first stage, the detonation conversion of the explosive mostly occurs within the geometric limits of the charge. The use of a condensed-phase shell (water or ice) confines detonation products (DP) within the geometric dimensions of the charge for an additional time, which enables a more complete conversion of carbon into the diamond prastructure.

After the detonation process is complete, an important role is played by rapid and strong gas-dynamic cooling of DPs to preserve DNDs formed within (or outside [14]) the chemical conversion zone. Just this isoentropic expansion of gaseous explosion products is the second stage.

After reflection of the shock wave (SW) from chamber walls, the third stage of the detonation synthesis of DNDs begins: circulation of the SW and turbulent mixing of the DP with the medium within the chamber.

The maximum attained temperature of the medium within the chamber depends on the mass ratio between the explosive and the gas medium, on the composition of the latter, and on the heat capacity of the gases.

The medium heated by the explosion and confined within a cold shell is intensely cooled (fourth stage). In addition to various gaseous products (CO_2, CO, O_2, H_2, N_2, CH_4, NO, NO_2, NH_3, H_2O), the chamber contains a highly dispersed suspension of carbon particles, which have a strong radiating capacity. Therefore, the process of cooling of such a medium is characterized by combined heat transfer by convection and radiation.

The extent to which condensed carbon is preserved is determined by gas-phase reactions of its gasification by carbon dioxide and water vapor. Therefore, two competing processes occur in the chamber at a high residual temperature in the third and fourth stages: gasification of condensed carbon (primarily nondiamond carbon, which is the most chemically active) and graphitization (or amorphization [14]) of the DNDs formed.

At a constant composition and density of the explosive being exploded, it is impossible to affect the first stage of synthesis, i.e., the DND formation proper, by addition of various substances to the condensed phase enveloping the explosive charge. The processes occurring in the second stage also have hardly enough time to be affected by presence of substances in the condensed phase (water, ice), even with account of the nonideality of the gas-dynamic cooling of DPs in their expansion. By contrast, addition of more readily oxidizable substances (reducing agents) in the third stage (stage of DP turbulization), in which CO_2, H_2O, and other aggressive (under these conditions) gases mostly attack condensed carbon, strongly affects the result of the detonation synthesis. Naturally, the gas medium components (CO_2, H_2O, O_2, NO_2, N_2O_3) are primarily bound with more readily oxidizable reducing agents (in the case in question, with hydrazine, urotropin, urea, ammonia), compared with the rather difficultly oxidizable carbon and, especially, DND. Thus, it would be expected that the yield of DS and DNDs should increase, with the elemental composition of DS and DNDs changed.

In addition, presence of readily oxidizable reducing agents among the DPs also affects the fourth stage of the process by lowering the DP temperature through decomposition of a part of the reducing agent, which favors preservation of DNDs by diminishing their graphitization.

It is known from the literature [16, 17] that, in hot compaction of DNDs ($P \approx 5$–8 GPa, $\tau \approx 1500$–2000°C), volatile products firmly fixed on the DND surface are intensively desorbed. The authors of [16, 17] roughly estimated the amount of volatile admixtures at 10 wt %. Therefore, the real amount of volatile admixtures was determined and a procedure for their removal before performing an elemental analysis of DS and DNDs was developed.

Originally, a sample of a standard DS produced in explosion of TG 40 charges in a water shell (without any additives in water) was dried to constant weight under normal industrial conditions (at 120°C in contact with the atmosphere). Then the air-dry AS was dried in a vacuum (residual pressure ~10 Pa) to constant weight at 200°C (16 h). It was found that the industrial air-dry DS still contains 8 wt % volatile products, including water.

A DS sample obtained by exploding a TG 40 charge with a water shell containing hydrazine has another amount of volatile admixtures. For example, this amount was found to be 13.7 wt % by drying of such an air-dry DS at 200°C (10 Pa).

Thus, depending on the preparation conditions, DS may contain different amounts of volatile admixtures (8–13.7 wt %). This circumstance should be taken into account both in chemical purification of

DNDs contained in DS and in use of DS as a starting product in various formulations.

To determine the real amount of volatiles (including water) in DNDs after nitric acid purification [240°C, $P = (80–100) \times 10^5$ Pa], the product was preliminarily dried by the standard factory method (150°C) to constant weight in contact with the atmosphere. Then, the powder of air-dry DNDs was placed in a vacuum (residual pressure 4–5 Pa) and dried to constant weight at 200°C for 14 h. It was found that air-dry DNDs produced and dried by the standard technique contain about 10 wt % volatiles. Moreover, a sample of such "absolutely dry" DNDs, stored in a desiccator with a humidity of 86%, absorbed 20.6 wt % moisture in 4 h. Its subsequent drying in air at 20°C (relative air humidity 30–35%) for 12 h resulted in a loss of moisture, whose content was 11.8 wt %. Making the drying conditions more severe (200°C, 4–5 Pa, 12 h) led to a residual moisture content of 0.6%.

In an analysis of the elemental composition of DNDs and DS, the annealing time of these products in the atmosphere of oxygen and exposure time were substantially raised (to 1200°C and 50 s). This was necessitated by the rather high resistance of DNDs and DS to combustion and by the incomplete combustion in all the preceding studies. For example, in the known patents obtained by Altai NPO [15, 18], volatiles were not removed and the conditions of DS and DNDs combustion corresponded to combustion of organic compounds (~850–900°C, 4–5 s). This caused a strong data distortion. For DS [15], the elemental composition was as follows (wt %): C 84.0–89.0, H 0.3–1.1, N 3.1–4.3, O 2.0–7.1; incombustible admixtures 2.0–5.0 wt %. For DNDs [18], the elemental composition was the following (wt %): C 75.0–90.0, H 0.8–1.5, N 0.8–4.5, O up to 23.4.

Table 1 presents the elemental composition of DS and the amount of the main impurity interfering with its direct use: incombustible metal oxides and carbides. It can be seen that, on average, the real content of carbon (run nos. 2–10) exceeded by 6–8 wt % that described in the literature (run no. 1). The amount of hydrogen is also, on average, 3 times larger, and that of nitrogen, by contrast, 3–4 times smaller. The amount of oxygen is 3–10 times smaller.

Introduction of reducing agents lowers the amount of incombustibles by 30% in run nos. 3–10 and by a factor of 2 in run nos. 6 and 8, which makes the resulting new DS suitable for direct use in plating, finishing polishing, polymer chemistry, oil formulations, etc. In addition, such a DS is considerably more readily subject to chemical purification.

Although the content of DNDs in DS synthesis with the use of reducing agents increases only slightly (by 2–5 wt %), the total amount of DS increases twice, and, therefore, the yield of DNDs in terms of the starting explosive also increases by a factor of 2.

A study of the elemental composition and impurity content of DNDs produced by chemical purification of the previously described DS (run no. 2) [18] and DS synthesized by the method suggested here (run nos. 3–10) demonstrated that the amount of the main element, carbon, in run no. 2 (Table 2) is actually higher in the standard DS by approximately 5 wt %, compared with published data (Table 2, run no. 1). Introduction of reducing agents can substantially raise the amount of carbon in the DNDs to 96 wt % (run nos. 5, 8) at an appropriate type and amount of a reducing agent. Irrespective of the synthesis conditions, the amount of nitrogen varies within a narrow range, from 2.2 to 2.9 wt %, which indicates that nitrogen is rather uniformly distributed over all DND layers and is introduced into these layers already in the stage of detonation synthesis. At the same time, the amount of hydrogen and oxygen (run nos. 2–10 varies substantially (from 0.4 to 2.4 wt % and from 0.7 to 2.3 wt %, respectively. This shows that these elements are predominantly concentrated in outer layers of a DND particle and their content is strongly affected by detonation synthesis conditions. It can also be seen that the content of oxygen is very strongly overestimated by published data.

The smallest amount of incombustible admixtures is contained in DNDs synthesized in the presence of urotropin. This occurs because urotropin is a rather powerful complexing agent and binds impurity metals (Fe, Ni, Cr, Cu, etc.) into soluble complexes that are easily removed in chemical purification with nitric acid. The low content (0.1–0.3 wt %) of incombustibles (metal oxides and carbides) also enables use of these DNDs in any application field. At the same time, the content of nondiamond carbon in DNDs is rather constant, 0.8–1.4 wt %, and such an amount does not affect any DND application technology. The content of the diamond phase in purified DNDs may be as high as 99.1 wt % in terms of the solid phase of the product.

The available data on the behavior of DNDs under heating in contact with air are rather widely diverse.

For example, it was shown in [19] that, under heating in air at a rate of 10 deg min^{-1}, the DNDs manufactured by Altai NPO start to be intensively oxidized even at a temperature of 430°C, and diamond of ASM 1/0 brand (micropowder of static-synthesis diamond), at 650°C [20].

It should be noted that the content of the main substance in the DNDs manufactured by Altai NPO is

~90% and the onset temperature of intensive decomposition is presumably affected by the large amount of widely diverse impurities in DNDs.

It has been shown previously that heating of DNDs in contact with air causes an exothermic, effect with a decrease in the sample mass at a temperature as low as 250°C and intensive oxidation of carbon to an incombustible residue in the range 500–750°C [4].

However, data on DND oxidation by atmospheric oxygen under heating are scarce and information about the behavior of DS under heating in air is lacking.

Therefore, an attempt was made to thoroughly study the behavior of DS and DNDs (Tables 1, 2) obtained under various conditions under the action of high temperatures in contact with atmospheric oxygen.

On heating DS samples in air (derivatograph, heating rate 5 deg min^{-1}), a minor endothermic effect was observed in the temperature range 30–180°C (Table 3, run no. 5) as a result of desorption of water and volatiles. A set of exothermic effects is observed at temperatures higher than 180°C, which, in the end, leads to complete burning-out of DS at 670°C. These exothermic effects are due to step-by-step oxidation of nondiamond carbon. In this case, the least ordered nondiamond carbon on the very periphery of the diamond-carbon cluster burns-out first, and then, at higher temperatures, oxidation of nondiamond carbon layers closer to the diamond core begins. The DTA curve shows a large number of breaks. As a rule, there are two peaks on the DTA curve. The first of these (at 370°C) represents the oxidation of diamond-like carbon directly at the surface of the diamond core, and the second at ~610°C, the oxidation of the diamond core itself.

In the DTG curve, the loss of DS mass in the temperature range 150–350°C is ~5.0 wt %, i.e., moisture and volatiles are removed and the most disordered peripheral nondiamond carbon component of the diamond-carbon cluster is oxidized. Above ~350°C, the loss of mass rapidly increases to the point of complete burning-out of a sample.

In heating of DND samples in air (derivatograph, heating rate 10 deg min^{-1}), the endothermic effect observed at 40–200°C is due to desorption of adsorbed gases, water, and other volatiles (Table 4, run no. 7). The first, rather slow exothermic effect (200–525°C) is due to destruction of surface functional groups (~200°C) and gasification of the remaining nondiamond carbon on the surface of the diamond core in contact with atmospheric oxygen. The loss of mass by a DND sample (10–17%) corresponds just to the amount of nondiamond (X-ray-amorphous) carbon in DNDs.

At a temperature of 525°C, the diamond core of a DND particle starts to interact with atmospheric oxygen and this interaction ends in ~760°C by complete combustion of DND (peak value at 690°C).

With account of the poor quality of DNDs manufactured by Altai NPO, i.e., of the large amount of nondiamond carbon (up to 30% [18]), the onset of the exothermic effect is shifted to 120°C (Table 4, run no. 8). The large amount of incombustibles (up to 5 wt %) in UDA-B possibly exerts an inhibiting influence on the process of its oxidation and, therefore, only ~50% of a sample burns-out at 770°C.

* Without extreme values.

** UDA-B contains up to 30% nondiamond carbon [18].

Comparison of the oxidation parameters of DNDs (Table 4, run no. 7) and classical diamonds of static synthesis crushed to particle sizes in the range 2–100 nm (run no. 9) shows that the endo- and exothermic effects in these two kinds of diamonds are nearly identical, which points to the high quality of DNDs produced by the new method.

The minor endothermic effect observed in the temperature range 40–200°C for static-synthesis and natural diamonds is due to desorption of adsorbed water (whose amount is as large as 4 wt %).

Comparison of the oxidation processes of carbon in DS and DNDs in air shows that (naturally) DS is more readily oxidized than DND. Because of the mixed type of DS, the exothermic effects have different intensities and contain two peaks (at 370 and 610°C) for nondiamond and diamond carbon, respectively, with complete burning-out of the product at 670°C. High-intensity exothermic effects begin at temperatures as low as ~240°C.

In DNDs, the oxidation process goes smoothly, without breaks in the DTA curve; a strong exothermic effect is observed already at 525°C, with the only peak at 690°C and complete burning-out at 760°C.

As would be expected, pure DNDs are substantially more resistant to oxidation than DS.

CONCLUSIONS

(1) A modified method was developed for detonation synthesis of DNDs and DS in an aqueous medium in the presence of active reducing agents, including hydrazine, urotropin, urea, and ammonia. This method made it possible to raise the content of the main element (carbon), diminish the content of oxygen by a factor of 4 (on average), double the yield of DS and DNDs, lower the amount of incombustible admixture by a factor of 2–3, and vary the elemental composition of DNDs by choosing a reducing agent and its amount.

(2) Two distinct exothermic peaks, at 370°C (oxidation of nondiamond carbon) and 610°C (oxidation of the diamond core), were found in oxidation of new types of DS by oxygen.

(3) One distinct exothermic peak at 690°C, associated with oxidation of the diamond core, was observed in oxidation of new DNDs by atmospheric oxygen.

(4) It was found that, in contrast to the DNDs manufactured by Altai NPO, the new DNDs exhibit the endo- and exothermic effects that are nearly fully identical to those in classical static-synthesis diamonds, which points to the high quality of the new DNDs.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Molecular Layering Method Used to Sensitize Luminescence from Terbium(III) Oxide Nanoparticles in Porous Glass

Abstract—Possibility of obtaining nanoparticles of terbium(III) oxide in a porous glass by impregnating the support with an aqueous solution of $TbCl_3$ and subsequently calcining dried samples in air at 300°C was studied. The molecular layering method was used to modify the surface of encapsulated particles with titanium oxide layers of controlled thickness.

DOI: 10.1134/S1070427208100091

Development of encapsulation methods and analysis of specific structural features of "guest" substances (intercalates) in condensed nanoporous media constitute a rapidly evolving area of research [1, 2]. The internal space of supports acts as a nanoreactor that determines the dimension specifics of processes occurring within and the properties of the materials obtained.

A series of studies in this area has been devoted to synthesis and study of properties of encapsulated phosphors [3–8]. A particular place among the supports used for this purpose is occupied by porous glasses (PGs) having high transparency and chemical resistance, combined with the possibility of purposefully controlling structural parameters and obtaining PGs both as powders and as mechanically strong articles of various configurations [9, 10]. As for intercalates providing luminescence, compounds of rare-earth elements (REE) are reasonable candidates for this function. As a rule, synthesis of luminescent materials on their basis envisages sensitization of luminescence centers by an appropriate environment. This should be done because excitation of REE cations via intrinsic absorption is insufficient both in view of the prohibition imposed by the Laport rule on *f*–*f* transitions in axially symmetric fields and due to screening of valence 4*f*-orbitals by electrons from higher-energy 5*s*- and 5*p* levels [11]. Thus, the role of the nearest environment in luminescence sensitization consists in absorption and transfer of the excitation energy to the radiative states of REE.

This study proceeds with analysis of specific features of the optical properties of REE compounds in porous glasses [6–8] by examining the possibility of sensitization of the photoluminescence (PL) from nanosize Tb_2O_3 intercalates in PGs as a result of synthesis of titanium oxide layers on their surface by the molecular layering method [12].

EXPERIMENTAL

A porous glass obtained in the form of a powder with a particle size of 0.05–0.07 mm, specific surface area S_{sp} = 80 $m^2\ g^{-1}$, pore volume V_p = 0.166 $cm^3\ g^{-1}$, and predominant pore radius r_p = 4.5 nm served as a support [10]. In the first stage, in accordance with the data of [8], terbium(III) chloride was encapsulated in the pore space of the PG by impregnating the support with a 0.8 M aqueous solution of the salt; the content of $TbCl_3$ in samples dried at 120°C was 0.12 ± 0.1 mM g^{-1}, which provided a reliably recorded luminescence [8]. The chloride species were transformed to the oxide form by calcining the $TbCl_3$-modified PG in air at 300°C. To enable further molecular layering [12], the hydroxy cover on the surface of oxide particles was restored via treatment of samples with water vapor at 180°C for 4 h. Trace amounts of adsorbed water were removed at the same temperature with a flow of dry nitrogen and then $TiCl_4$ vapor was fed into the reactor. The reaction occurring on the hydroxylated surface of particles by the scheme

$$n(\text{=Tb−OH})^{s} + TiCl_4^{g} \rightarrow (\text{=Tb−O−})_n TiCl_{4-n}^{s} + n HCl^{g},$$

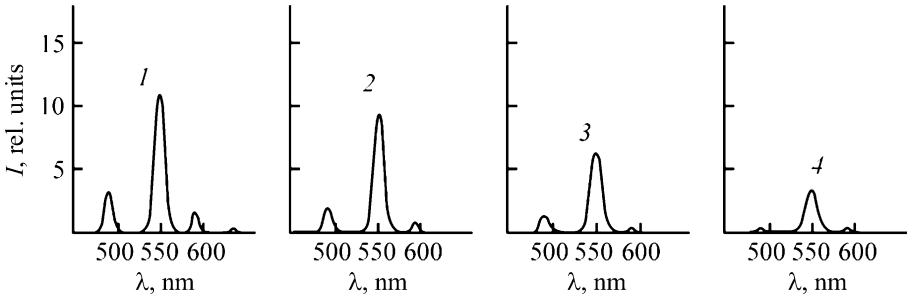

Fig. 1. (*1*) Luminescence from $TbCl_3$ particles and decrease in its intensity *I* as a result of sample calcination at 300°C for (*2*) 10, (*3*) 30, and (*4*) 60 min. (λ) Wavelength; the same for Fig. 2.

yielded a layer of chemically bound oxychloride groups of titanium(IV). The excess amount of $TiCl_4$ in the adsorbed form and the released hydrogen chloride were removed with a flow of dry nitrogen and then the samples were treated with water vapor:

$$(=Tb{-}O{-})_nTiCl^s_{4-n} + (4-n)H_2O^g \rightarrow (=Tb{-}O{-})_nTi(OH)^s_{4-n} + (4-n)HCl^g.$$

As a result, the surface of oxide particles was again covered with OH groups (now bound to titanium atoms) which could serve for further "layering." Thus, titanium oxide layers with increasing thickness (proportional to the number of cycles performed) were formed by cyclic repetition of reactions (1) and (2) [12].

Absorption spectra of modified porous glasses were recorded in reflected diffuse-scattered light, using a Specord M–40 spectrometer with a sphere photometer (pure PG as optical reference). The PL was recorded at room temperature, using an SDL-2 spectrometer with an SVD 120A mercury lamp as excitation source. To record spectra, dry powders (or those with adsorbed water) were placed in hermetically sealed quartz tubes 5 mm in diameter. The luminescence excitation spectra were recorded at the peak λ_{max} = 545 nm of the main emission band of Tb^{3+} cations. The adsorption of water by pure and modified PGs was controlled at relative vapor pressures p/p_0 = 0.1–0.8 set by the desiccator method with the use of sulfuric acid solutions.

The luminescence spectrum of encapsulated chloride particles (Fig. 1) contains, together with the main characteristic band associated with the $^5D_4 \rightarrow {}^7F_5$ transition (λ_{max} = 545 nm), low-intensity bands peaked at 490, 590, and 625 nm, associated with transitions from the lowest excited state $^5D_4$ to levels $F_{6,4,3}$ of the Tb^{3+} cation, respectively [4, 8, 11]. It should be noted that, despite the low content of $TbCl_3$ species in the support, they provide a rather bright, visually observed green emission; nevertheless, they should be converted to the oxide form to enable molecular layering reactions.

It is known that polycrystalline REE chlorides decompose to give oxides at a temperature as low as ~250°C [13]. To the decomposition of encapsulated terbium chloride in thermal treatment at 300°C of glass modified with this compound corresponds gradual decrease in the intensity of luminescence bands (Fig. 1), caused by the possible presence of OH groups on the surface of oxide nanoparticles being formed. The substantial loss of excitation energy is determined in this case by its transfer to high-frequency vibrations ν_{O-H} [11]. It is difficult to judge about the size of encapsulated particles, although it is clear that it is largely determined by pore structure parameters of the support and by the low degree of filling of its surface. For example, a simple estimate made on the assumption of a uniform distribution of the intercalate (in an amount of 0.12 mmol g^{-1}) over the internal surface of the PG (S_{sp} = 80 m^2 g^{-1}) yields approximately one formula unit per area of 1 nm^2 [8]. Thus, there is certain reason to believe that only low-dimension oxide particles with high ratio between the surface area and the volume can appear even under conditions of active aggregation in the course of thermal treatment.

The intrinsic absorption of encapsulated particles is not manifested when recording diffusion reflection spectra. This is due to the small extinction coefficients of the bands corresponding to the $4f \rightarrow 4f$ transitions of Tb^{3+} cations [11] and to the decrease in the transparence of the porous glass in the range 200–250 nm. On raising the number of modifying titanium oxide layers from 1 to 4 (see Fig. 2), the diffusion reflection spectra change, which consists in a long-wavelength shift and in an increase in the intensity of the band associated with the $2p^n(O) \rightarrow 3d(Ti)$ charge transfer from nonbonding orbitals of oxygen to titanium(IV) atoms. It

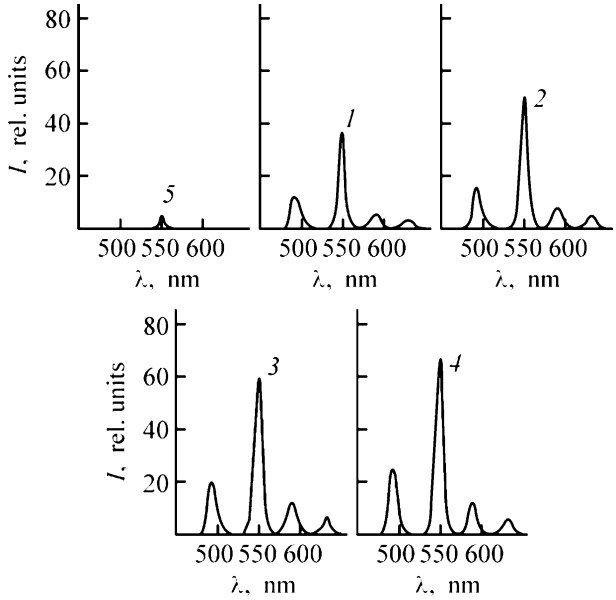

Fig. 3. (*5*) Luminescence from encapsulated Tb_2O_3 particles and its enhancement upon synthesis on their surface of (*1*) 1, (*2*) 2, (*3*) 3, and (*4*) 4 titanium oxide layers. (*I*) Intensity and (λ) wavelength; the same for Fig. 4.

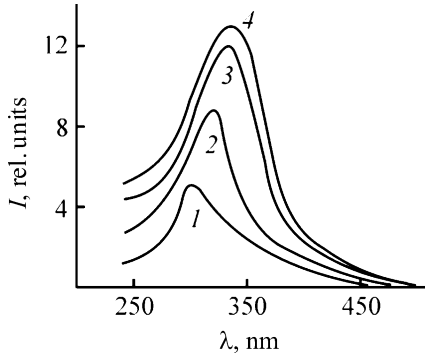

Fig. 4. Luminescence excitation spectra. *Digits at the curves*, number of titanium oxide layers synthesized.

should be noted that, in molecular layering reactions, the modifying layers are synthesized both on the hydroxylated surface of oxide nanolayers and on the free surface of PG. It is significant that, at an effective thickness of the growing titanium oxide of 3–4 monolayers, the spectra of the samples almost coincide and are close to that of the crystalline modification of TiO_2 (rutile).

The formation of =Tb–O–Ti= bonds as a result of a chemical modification of Tb_2O_3 nanoparticles is clearly manifested in luminescence spectra (Fig. 3): a substantial increase in its intensity is recorded already after the first layering cycle. Both further rise in the intensity of green emission, caused by the increase in the thickness of the oxide-sensitizer, and attainment of the maximum efficiency of its action upon synthesis of 3–4 titanium oxide layers (Fig. 3) are in good agreement with the absorption spectra of the samples under study (Fig. 2). Specific features of the sensitization are also reliably reflected in luminescence excitation spectra (Fig. 4). In this case, the increase in the thickness of the titanium oxide layer causes not only the characteristic increase in intensity, but also a pronounced long-wavelength shift in the peak positions of the bands responsible for the sensitization of luminescent centers.

The results obtained suggest that the excited states generated as a result of charge-transfer transitions $2p^n(O) \rightarrow 3d(Ti)$ in the sensitizer layers lie higher than the radiative $^5D_4$ level of the Tb^{3+} cation. The fact that this main condition is satisfied, combined with the possibility of excitation energy transfer to luminescent centers via covalent bond "channels" and the high optical absorption of titanium oxide layers in the UV spectral range, predetermine the luminescence sensitization in the systems under study.

As the thickness of titanium oxide layers synthesized by molecular layering increases, they become considerably denser and can serve as protective coatings [12]. Therefore, there is reason to believe that a titanium oxide shell present on the surface of encapsulated Tb_2O_3 particles will hinder luminescence quenching in the presence of adsorbed water. Figure 5 compares the isotherm of water adsorption by a sample exhibiting the highest emission intensity with the dependence of the intensity I of the main luminescence band on the relative humidity p/p_0. The value of I remains unchanged in a wide range of moderate vapor pressures, which points to a reliable shielding of luminescent centers from water molecules. Moreover, a minor, but reliably recorded increase in the lumines-

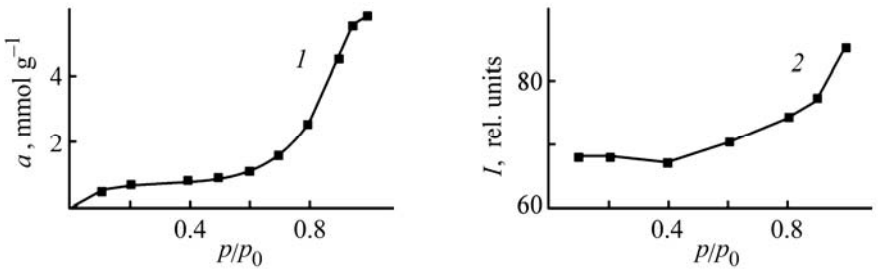

Fig. 5. (*1*) Isotherm of water adsorption *a* by the sample with the highest emission intensity and (*2*) effect of the relative humidity p/p_0 on the intensity *I* of the main band of its luminescence.

cence intensity is observed in the region of capillary condensation of water (at $p/p_0 > 0.6$). The unusual behavior of the system can be regarded, to a first approximation, as a result of luminescence activation caused by the increase in the dielectric constant of the medium [11] upon filling of the pore space by water. A similar, but clearly pronounced effect of luminescence enhancement in the presence of condensed water has been described previously for complex particles $Eu(DBM)_3 \cdot phen$ (DBM, dibenzoylmetane; phen, 1,10-phenanthroline) encapsulated in porous glass.

CONCLUSIONS

(1) It was shown that nanosize Tb_2O_3 particles are formed in a porous glass in thermal decomposition of terbium(III) chloride.

(2) Titanium oxide layers with controllable thickness were synthesized on the surface of oxide particles by the molecular layering method.

(3) It was demonstrated that Tb_2O_3 nanoparticles have a property of luminescence sensitization, which becomes more pronounced as the thickness of the modifying titanium oxide layers increases.

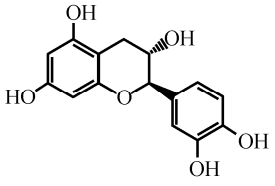
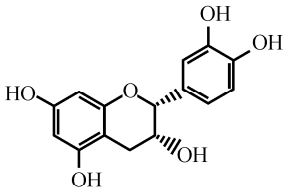
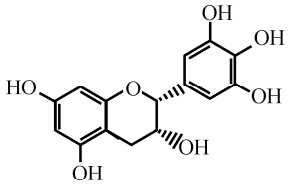
Abstract—The biological activity of catechins, and their interaction with various inorganic [iron(III) salts] and organic (DNA, casein) compounds were examined.



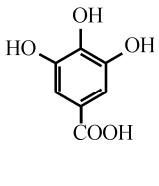
DOI: 10.1134/S1070427208100108



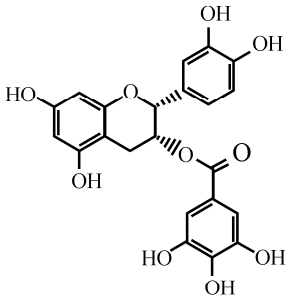
Catechins, or flavan-3-ols, are natural polyphenolic antioxidants contained in vegetables, fruits, grains, and seasonings, as well as in wine and green and black tea (in green tea, in considerably higher concentrations), coffee, and cocoa [1–3].



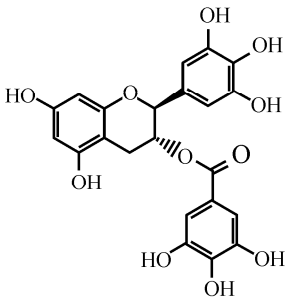
Owing to the high oxidizability of catechins, green and black tea neutralizes the action of free radicals and diminishes the damage inflicted to lipids of membranes, protein, and nucleic acids.



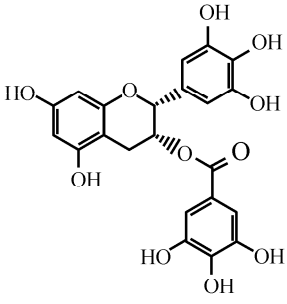
The concentration of catechins in a tea is one of its quality criteria. There exists a correlation between the total content of catechins and the total antioxidant activity of a green tea extract.



The major biologically active components of tea are flavan-3-ols [(+)-catechin, (–)-epicatechin, (–)-epigallocatechin, (–)-epicatechin gallate, (–)-gallocatechin gallate, (–)-epigallocatechin gallate] and gallic acid:



(+)-Catechin (C)



(–)-Epicatechin (EC)

(–)-Epigallocatechin (EGC)

Gallic acid (GA)

(–)-Epicatechin gallate (ECG)

(–)-Gallocatechin gallate (GCG)

(–)-Epigallocatechin gallate (EGCG)

An important property of catechins is their capacity for complexing with metal ions owing to the presence of neighboring phenolic hydroxyls, potential complexing centers, in their molecules. In tea leaves, catechins form complexes with aluminum [4], calcium, magnesium, and manganese [5] ions. This complexing ability makes these compounds suitable for determination of metal ions in biological objects [6]. These processes have been examined with model systems composed of catechins and Fe^{3+} ions [7]. Such studies are extremely important, since the biological activity of catechins is strongly dependent on the form, free or bound, in which they occur [7].

Recently, wide application in analysis of natural objects and biological fluids has been found by the method of capillary electrophoresis (CE) with an ultraviolet detector, also used for determination of polyphenolic compounds in real objects [8–11].

Earlier, we have developed a method for analysis of various brands of green and black tea by micellar electrokinetic chromatography [12]. As a micelle-forming agent served an anionic detergent, sodium dodecyl sulfate (SDS). At concentrations above 8.3 mM (critical micelle concentration), SDS molecules form micelles (pseudostationary phase). This improves the selectivity of separation relative to the capillary zone electrophoresis (CZE) owing to the distribution of analytes between the micelles and the supporting electrolyte solution.

EXPERIMENTAL

The analysis was carried out on a KAPEL' 105 capillary electrophoresis system with a spectrophotometric detector (200–400 nm). We used a quartz capillary with an external polyimide coating (inner diameter 75 μm, effective length 50 cm (total length 60 cm). The working temperature was 20°C. The detection was carried out at a wavelength of 200 nm.

Standard samples of polyphenols [(+)-catechin, (–)-epicatechin, (–)-epicatechin gallate, (–)-epigallocatechin, (–)-gallocatechin gallate, (–)-epigallocatechin gallate and gallic acid], casein, and DNA were available form Fluka and Sigma.

We used hydrochloric acid, sodium hydroxide, sodium dodecyl sulfate, sodium dihydrogen phosphate monohydrate ($NaH_2PO_4 \cdot H_2O$), disodium hydrogen phosphate dodecahydrate ($Na_2HPO_4 \cdot 12H_2O$), sodium chloride (NaCl), and iron(III) chloride (all of chemically pure grade).

To determine catechins, we used a supporting electrolyte based on 0.025 M phosphate buffer (pH 7.0) with addition of SDS in various concentrations (10, 15, 20, 25, 30 mM). The hydrodynamic sample injection was used (30 mbar, 10 s). The analytes were electro-phoretically separated at a positive polarity of +25 kV. Before analysis, the quartz capillary was washed with 1 M hydrochloric acid and distilled water for 10 min and then conditioned successively in 0.5 M sodium hydroxide solution (10 min) and distilled water (10 min). In between analyses, the capillary was washed with the working supporting electrolyte for 3 min.

To study the interaction of caseins with tea catechins, we prepared aqueous solutions of casein and epigallocatechin gallate, taken separately, in concentrations of 150 and 20 mg l^{-1}, respectively. The solution of casein (150 mg l^{-1}) served as the starting solution for preparation of less concentrated solutions of the protein.

We used a high-molecular-weight thymus DNA, whose molecular weight (11.4 MDa) was estimated from the intrinsic viscosity [η] in a 0.15 M NaCl solution: $[\eta] = 6.9 \times 10^{-4} M^{0.7}$. The optical absorption of the DNA solutions was measured on an SF-26 spectrophotometer (Russia). The DNA concentration in solution c was estimated from the UV absorption of the preliminary denaturated DNA [13]. This allowed the condition of the secondary structure of the macromolecule to be monitored before and after the experiment on the basis of the molecular extinction coefficient $E(p) = (31.3D_{260})/c_{DNA}$. We used solutions with $E(p) < 6900$ (hyperchromic effect did not exceed 5%).

The DNA solutions containing catechins in different concentrations were exposed to ^{137}Cs γ-radiation under aerobic conditions on an LMB-γ-I[1] setup at a dose rate of 2.86 krad min^{-1}. The DNA concentration c in all the irradiated solutions was 0.01 g dl^{-1}. As the UV-radiation source we used a 8 W DRB–8 lamp. The DNA solutions were irradiated in quartz cells with a thickness of 0.2 cm. The DNA concentration in all the solutions being irradiated was 0.01 g dl^{-1}. The UV-radiation intensity at a wavelength of 254 nm was 3.4×10^4 J kg^{-1} s^{-1}.

The relative viscosity η_r of the DNA solutions with different concentrations was measured in a modified low-gradient magnetic rotary viscometer [14] at different flow rate gradients g, with the subsequent extrapolation to $g = 0$. The intrinsic viscosity [η] of DNA

[1] The experiments were carried out at the Institute of Cytology, Russian Academy of Sciences, St. Petersburg.

Table 1. Change of the content of catechins in green and black tea, induced by 5% milk addition ($P = 0.95$, $n = 3$)

Analyte	Concentration,* wt %			
	green tea	green tea with addition of milk	black tea	black tea with addition of milk
EGC	1.7 ± 0.1	0.57 ± 0.06	<0.01	<0.01

* The analyte concentrations are given as percent fractions of the weight of tea leave.

was determined by extrapolation of the concentration dependence of the reduced viscosity by the formula

$$[\eta] = \lim_{c\to 0}\left(\frac{(\eta_r - 1)_{g\to 0}}{c}\right). \quad (1)$$

The parameter [η] is proportional to the specific volume of the macromolecule. We took into account the Flory equation [15]

$$[\eta] = \Phi \frac{\left(\overline{h}_0^2\right)^{3/2}}{M}\alpha^3 = \Phi \frac{\left(LA\right)^{3/2}}{M}\alpha^3, \quad (2)$$

where $(\overline{h}_0^2)^{1/2}$ is the root-mean-square distance between the ends of the unperturbed chain; α, linear swelling coefficient of the macromolecule; Φ, Flory coefficient; *L*, hydrodynamic chain length (length of the fully extended macromolecule); *A*, average length of the statistical segment (a secuence of these rigid rod segments models the polymer chain); and *M*, molecular weight.

Based on the results of the experiments, we chose 0.025 M phosphate buffer (pH 7.0) with an SDS additive (25 mM) as the working solution for electrophoretic determination of catechins.

Under these conditions, we obtained comparative characteristic electrophoretic profiles (Fig. 1), quantitatively determinated catechins in various tea samples (Table 1), and elucidated how the detergent concentra-

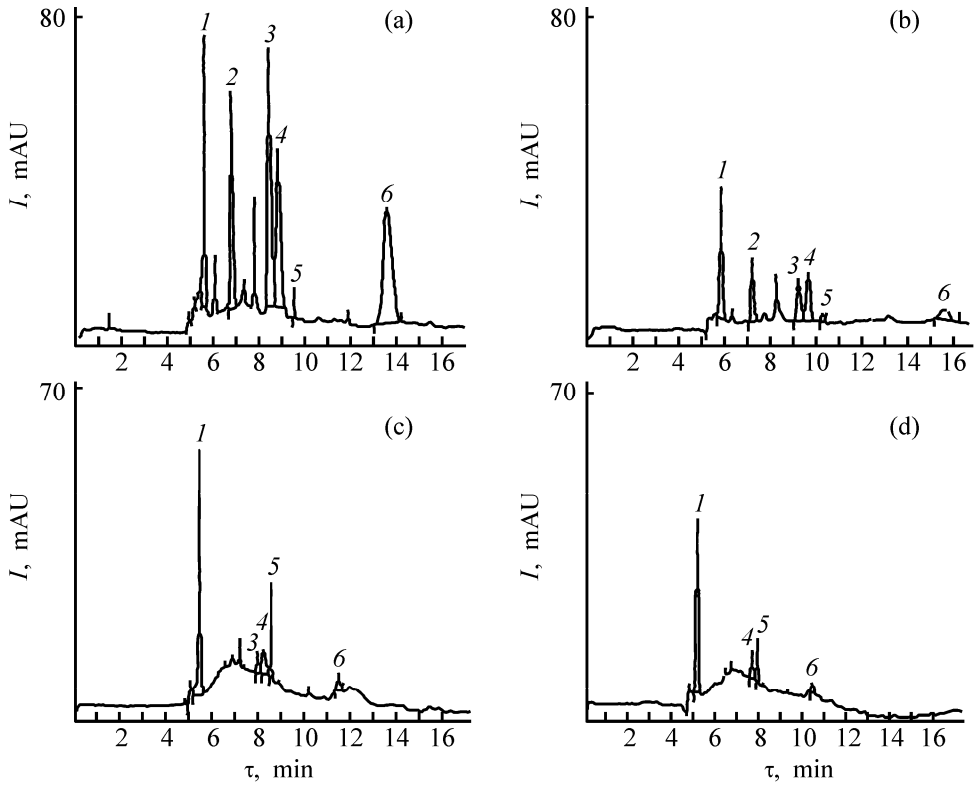

Fig. 1. Electrophoretic profiles of various tea extracts. Conditions: KAPEL' 105; supporting electrolyte: 0.025 M phosphate buffer (pH 7.0), 25 mM SDS; 25 kV; 200 nm. (*1*) Absorption intensity, and (τ) time. (a) Green tea, (b) green tea with 5% addition of milk, (c) black tea, and (d) black tea with 5% addition of milk. tion affects the efficiency and selectivity of separation of the biologically active components of tea (Fig. 2).

Under the optimized conditions, we examined complexing of catechins with casein and Fe^{3+} ions. As the criterion of formation of the corresponding complex served the change in the concentration of the catechins, which was monitored electrophoretically.

We examined in detail the complexing ability of flavan-3-ols for the example of (–)-epigallocatechin gallate. An increase in the proportion of casein (the basic milk protein) in the model mixture composed of EGCG (20 mg l^{-1}) and casein (3 to 15 mg l^{-1}) causes a decrease in the amount of the free form of catechin; at the casein concentration of 15 mg l^{-1} it was estimated at 1 mg l^{-1}. The content of catechins also decreased upon addition of a Fe(III) salt. We found how the concentration of (–)-epigallocatechin gallate varies with the amounts of casein (Fig. 3a) and iron(III) salt (Fig. 3b) introduced.

A similar trend was also observed in quantitative determination of catechins in various samples of green and black tea upon addition of milk (Fig. 1, Table 1).

Also, we examined the radioprotective properties of (+)-catechin and (–)-epicatechin upon exposure of the DNA molecule in solution to ionizing (gamma) and nonionizing (UV light with a wavelength of 254 nm) radiation. An adult human body contains up to 70% water, and water is involved in all the principal biochemical reactions occurring in functioning of DNA. Hence, examination of model systems, aqueous DNA solutions, provides a fairly adequate information about the biological role of various compounds. As is known, ionizing and nonionizing radiations differ in the action mechanisms toward DNA. In the former case, solutions and cells are subjected mainly to indirect action of radiation via reactions of the macromolecule with water radiolysis products, and in the latter case, to direct action, i.e., absorption of photons by the nitrogen bases of DNA [16]. In both cases, this results in disturbance of the DNA structure (single and double breaks of the complementary chains, modification, and elimination of the nitrogen bases, changes in the phosphate group). This can lead to loss of charge by DNA.

It should be noted that the radiation damage is always manifested as a decrease in the volume of the molecular coil in solution, associated with various factors mentioned above. Hence, by estimating the intrinsic viscosity of DNA, [η], proportional to its specific volume, it is possible to determine the radiation damage.

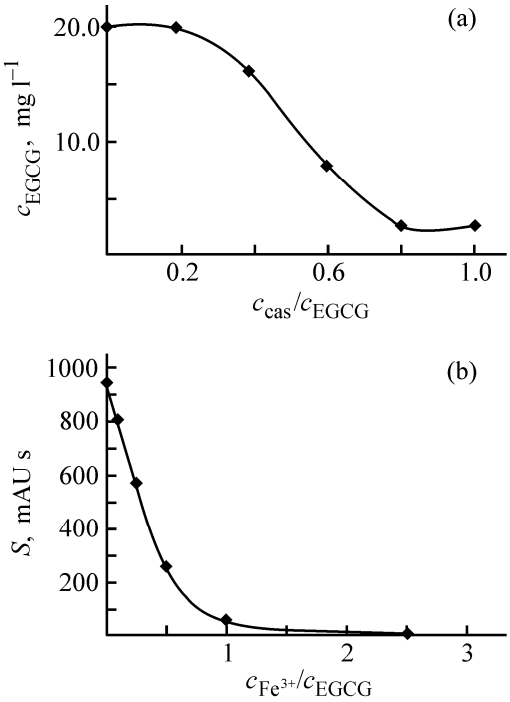

Fig. 3. Change in the concentration of (–)-epigallocatechin 3-gallate upon addition of (a) casein and (b) Fe^{3+} ions. (c_{EGCG}) Concentration of the free form of EGCG, (c_{cas}/c_{EGCG}) casein to EGCG ratio of the initial concentrations, (S) peak EGCG area, and (c_{Fe3+}/c_{EGCG}) molar concentration ratio.

It has been shown earlier that, under γ-radiation exposure of DNA solutions at up to 30 Gy doses and under UV-radiation exposure at several orders of magnitude higher doses (up to 6 ± 10^7 J kg^{-1}), the decrease in the volume of the macromolecule is not accompanied by any appreciable degradation of its secondary structure: No hyperchromic effect associated with

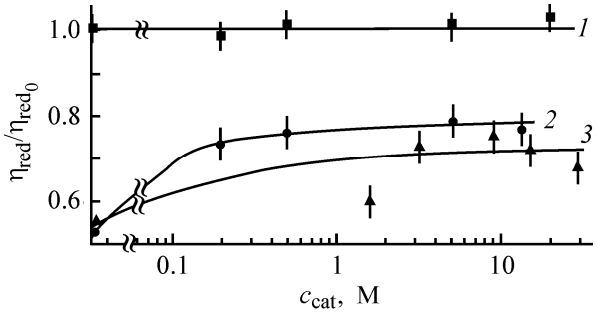

Fig. 4. Relative change in the reduced viscosity η_{red}/η_{red_0} of the DNA solution (c_{DNA}=0.005 g dl^{-1}) vs. (+)-catechin concentration c_{cat} in solution. Solution: (*1*) intact, (*2*) irradiated at a dose of 10 Gy, (*3*) UV-irradiated at a dose of 6.1 × 10^7 J (system kg)$^{-1}$.

the cleavage of hydrogen bonds and stacking interaction of the bases is observed in the UV-absorption spectrum of DNA. There is no change in the flexural rigidity of the double helix, either, which also suggests that the secondary structure of DNA remains unchanged [17–19]. At high irradiation doses these parameters change, which points to a more profound modification of the structure of the macromolecule.

Table 2. Relative change in the intrinsic viscosity of DNA, induced by γ-irradiation*

γ-Radiation dose, Gy	$[\eta]/[\eta]_0 \pm 0.05$		
	$c_{cat} = 0$	$c_{(+)\text{-cat}}$=1.3×10^{-3} M	$c_{(-)\text{-epicat}}$=1.3×10^{-3} M
0	1.00	1.00	0.99
10	0.24	0.61	0.87
30	0.08	0.50	–

* $[\eta]_0$ and $[\eta]$ are the intrinsic viscosities of intact and irradiated macromolecules, respectively.

Also, we elucidated how γ-irradiation at doses of up to 30 Gy affects the DNA molecule in solutions containing various concentrations of flavanoids. Our experiment showed that the $[\eta]$ parameter of DNA tends to sharply decrease with increasing irradiation dose (Table 2). Introduction of (+)-catechin into the solution before the radiation exposure diminishes the damage. An increase in the (+)-catechin concentration up to a certain limiting value results in enhancement of the protective action (Fig. 4). An increase in the (+)-catechin concentration to above 5 × 10^{-5} M does not make this effect more pronounced.

Interestingly, this concentration of (+)-catechin is of approximately the same order magnitude as that in the standard extract of tea tree leaves (2 g of dry tea per 200 ml of boiling water after 5-min infusion). It should be noted that the presence of (+)-catechin only diminishes the γ-radiation damage, rather than provides absolute protection. Thus, our results suggest that (+)-catechin can of protect the DNA molecule against ionizing radiation. In the case of (–)-epicatechin, the radioprotective properties are even more pronounced (Table 2).

We found that, under the experimental conditions, there is no complexing between DNA and the flavan-3-ols examined. This is suggested, in particular, by the fact that the spectral characteristics of both the components in solutions containing different concentrations of DNA and catechins remain identical to those in their solutions taken separately. The volume and the optical anisotropy of the macromolecule remain unchanged. Published data [19] suggest that (+)-catechin and (–)-epicatechin do not intercalate into the double helix of DNA. Our experiment demonstrated the lack of bonding between the catechins and DNA in solution, which suggests that the examined compounds exert the radioprotective action via interception of the free radicals yielded by water radiolysis under γ-radiation exposure.

The exposure to UV light (λ = 254 nm) results in direct action on the macromolecule, rather than in water radiolysis. The wavelength we used is close to the absorption peak of DNA (260 nm) and catechins (280 nm). Despite the different mechanisms by which γ and UV radiations inflict damage, the intrinsic viscosity DNA decreases in both cases. The presence of catechin in solution partly prevents the damage to DNA as well (Fig. 5). A possible reason is that an appreciable portion of the radiation energy is absorbed by catechin, whose absorption spectrum overlaps with that of DNA.

CONCLUSIONS

(1) A micellar electrokinetic chromatographic examination revealed complexing of catechins with Fe^{3+} ions and casein.

(2) It was shown that (+)-catechin and (–)-epicatechin do not react with the DNA molecule in solution, but protect it against the radiation damage by interception of the water radiolysis products.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Supported Metal Catalysts Based on Fibrous Carbon Material for Low-Temperature CO Oxidation

Abstract—A number of supported-metal (Pt, Pd) catalysts based on Karbopon nonwoven carbon fibers were prepared by deposition from hydrosols and by ion exchange. The catalytic activity of the catalysts in low-temperature oxidation of carbon monoxide by atmospheric oxygen was determined. Catalyst samples were studied by transmission electron microscopy.

DOI: 10.1134/S107042720810011X

Purification of air to remove carbon monoxide is an important ecological problem. The only efficient way to remove carbon monoxide from air is catalytic oxidation, and, therefore, extensive studies aimed to develop active catalysts for CO oxidation have been carried out in recent years.

The first practically used low-temperature catalyst for CO oxidation is hopcalite (mixture of copper and manganese oxides). Until recently, catalytic systems of this kind, based on transition metal oxides, have been studied and patented [1–3]. These catalysts are inexpensive and readily available, but rapidly loose activity in the presence of moisture.

Noble metals supported by thermally stable and chemically inert oxides (Al_2O_3, SiO_2) catalyze CO oxidation only at temperatures above 150°C, because, being firmly sorbed on the metal surface at low temperatures, CO hinders adsorption of oxygen [4, 5].

Catalytic systems in the form of a noble metal supported by a reducible oxide (SnO_2, MnO_2, Fe_2O_3) can work at low temperatures [6–10] and are more stable in a humid atmosphere than hopcalite. It is believed [9] that a noble metal makes lower the strength of the M–O bond in the oxide substrate, i.e., it catalyzes the reduction and reoxidation of the oxide. This generates active oxygen for the reaction of CO oxidation.

Because the efficiency of supported-metal catalysts is largely determined by the physicochemical properties of a support, the increasing interest in new types of supports is justified. In particular, a considerable attention has been given recently to carbon materials with fibrous structure. Owing to the electrical conductivity of the carbon support, the supported metal is not electron-deficient, in contrast to the case of supports of acid nature.

Previously, a number of mono- and bimetallic supported-metal catalysts based on Karbopon nonwoven carbon fibers have been synthesized and studied in the reaction of CO oxidation [11]. The catalysts were prepared by impregnation with aqueous solutions of metal salts, followed by heating and reduction. A conclusion was made that platinum-containing catalysts are the most promising for CO oxidation.

Supported-metal catalysts fabricated by the conventional impregnation method have an insufficiently high activity in CO oxidation. Therefore, it was necessary to find a way to obtain a more active catalyst.

The aim of our study was to develop a method for fabrication of an efficient catalyst for low-temperature oxidation of carbon monoxide in the form of a noble metal supported by carbon fibers.

EXPERIMENTAL

We prepared the catalyst from Karbopon carbon fibrous material manufactured by Khimvolokno Production Association (Svetlogorsk, Belarus). The mate-

rial has the following adsorption-structural characteristics: fiber diameter 5–10 μm, sorption volume for water 0.64 $cm^3\ g^{-1}$, average pore diameter 23 Å, and specific surface area S_{sp} (found from nitrogen adsorption) 780 $m^2\ g^{-1}$.

The method for deposition of metals onto supports by adsorption of metallic particles from colloid solutions (sols) is rather simple and convenient. It enables control over the size of metal particles before their deposition. At present, about ten methods for preparing metal sols are known. Of these, the chemical method consisting in treatment of a metal salt solution with a reducing agent is employed the most widely [12–14]. It should be noted that metal sols are unstable without stabilizers (surfactants or soluble polymers), whereas introduction of stabilizers, as a rule, provides stability for strongly diluted metal-containing solutions ($<10^{-3}$ M). With stabilizers used, sols may become unsuitable for fabrication of supported catalysts because either metal particles are not sorbed, or the catalysts produced are inactive due to blocking of a part of the surface by stabilizer molecules.

In view of the aforesaid, we chose sodium citrate as stabilizer for preparing hydrosols. This compound nearly does not hinder sorption of stabilized particles by the carbon fiber and, owing to its polarity, is easily removed by washing with water.

Hydrosols of platinum and palladium were obtained by reduction of aqueous solutions of platinohydrochloric acid and palladium nitrate with 10% hydrazine hydrate. Sodium citrate was used as stabilizer at a 1 : 5 molar ratio between the metal and sodium citrate. The carbon fiber was impregnated with the freshly prepared hydrosol, washed to remove the stabilizer, and dried at room temperature. The samples obtained were studied in CO oxidation both immediately after the drying and upon additional reduction in a flow of hydrogen.

Further, we prepared a number of samples of a platinum-containing catalyst by the ion exchange method. Because the number of exchange centers on the surface of the starting Karbopon is exceedingly small (exchange capacity of about 0.05 mg-equiv g^{-1}), a composite material sulfokarbopon was synthesized and used as a support.

To obtain sulfokarbopon, we grafted a styrene–divinylbenzene copolymer to the starting Karbopon by the radiation-chemical method. In doing so, we varied the composition of the grafting solution by changing the relative amounts of monomers (styrene, divinylbenzene) and a solvent (benzene, methanol) and also the irradiation dose. Karbopon plates (60 × 60 mm) were mounted vertically in a specially fabricated holder, which was placed in a glass vessel filled with the grafting solution and kept there at room temperature for 4 h. Then the solution was discharged, the vessel with the samples was placed in the channel of an RKhM-gamma-20 reactor with a ^{60}Co source, and grafting radiation-chemical copolymerization of styrene and divinylbenzene was performed. The irradiation power was 4.6 kGy h^{-1}.

After the grafting, the samples were dried at 90°C and the mass fraction of the grafted copolymer was found from the difference between the masses of the grafted and starting samples dried under identical conditions. Samples with the grafted styrene–divinylbenzene copolymer were sulfated with concentrated sulfuric acid at 115°C in the course of 3 h. After the sulfation, the samples were washed to remove H_2SO_4 to neutral reaction of the washing water and dried at room temperature. To prepare the Ba-form of sulfokarbopon, an excess amount of a 1 N $BaCl_2$ solution was passed through a column packed with the starting sulfokarbopon (H-form). The resulting sample was washed with distilled water to zero Cl^- concentration in the washing water.

The ion exchange was performed using a platinum(II) ammoniate solution and the barium form of sulfokarbopon. After the exchange, the samples were washed to remove Cl^- ions, dried, and reduced with hydrogen at 180°C. Then the catalysts were activated at 130°C by treatment with a mixture of hydrogen (3%) and air.

To obtain catalysts with different contents of the active component, we varied the number of exchange-reduction cycles.

The activity of the catalysts in oxidation of carbon monoxide was determined in a flow-through reactor at a flow rate of the reaction mixture (0.6 vol % CO in air) of 600 h^{-1}. The starting mixture and the reaction products were analyzed with a Gazokhrom chromatograph at a flow rate of the carrier gas (air) of 100 ml min^{-1}. Samples of the catalysts obtained (ultrathin sections) were examined by transmission electron microscopy on a JEM 100 CX instrument.

The results of experiments on CO oxidation in the presence of hydrosol palladium-containing samples are listed in Table 1. It can be seen that the catalytic activ-

ity grows as the palladium content increases to 3%, and decreases as the palladium content increases further to 5%. An additional treatment of palladium-containing catalysts with hydrogen makes their activity lower.

It is notable that, in the case of platinum-containing catalysts (Table 1), the best result is obtained for sample no. 1, which contains 0.5% metal. In contrast to palladium-containing samples, reduction of platinum-containing catalysts enhances their activity.

It can be concluded that the metal is nearly completely reduced in preparation of a palladium hydrosol. The additional treatment with hydrogen at elevated temperatures probably leads to a certain aggregation of metal clusters and to the corresponding decrease in activity. At the same time, in platinum hydrosols, a part of platinum remains in the unreduced state and additional reduction of the catalyst improves its activity.

Under the experimental conditions ($600\ h^{-1}$), the most active of the palladium- and platinum-containing samples provide the 100% conversion of carbon monoxide at 60 and 68°C, respectively [Table 1, sample nos. 6 (Pd) and 1 (Pt)]. It should be noted that the catalysts become inactive as the CO content of the reaction mixture is doubled. This indicates that the chemisorbed CO blocks the catalyst surface and the reaction becomes only possible after a part of the surface is freed for dissociative adsorption of oxygen.

As can be seen in Table 1, the samples produced by impregnation of the support with hydrosol fail to exhibit high activity in CO oxidation. The apparent reason is that rather coarse metal agglomerates are formed when these samples are synthesized. This is confirmed by an electron-microscopic analysis: the particle size is in the range 5–80 nm (Fig. 1).

Table 2 lists data for platinum-containing catalysts produced by ion exchange, with sulfokarbopon having an exchange capacity (EC) of 0.3–0.6 mg-equiv g^{-1} as a support. The content of platinum in the samples and, accordingly, their activity increases with the number of exchange-reduction cycles (sample nos. 1, 2, 4).

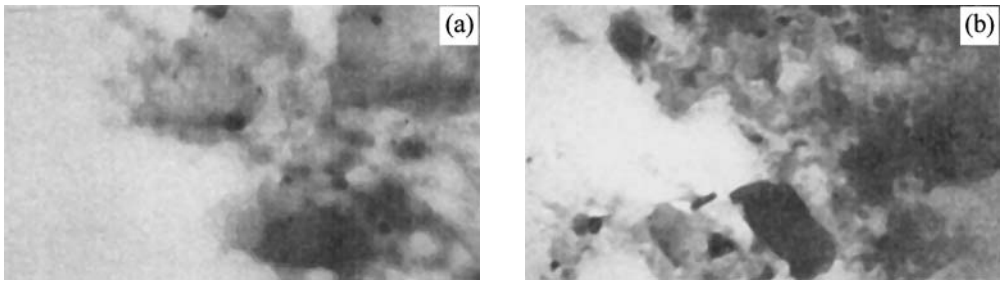

Fig. 1. Electron micrographs of catalysts produced from hydrosols. (a) 0.5% Pt/Karbopon and (b) 1.0% Pt/Karbopon.

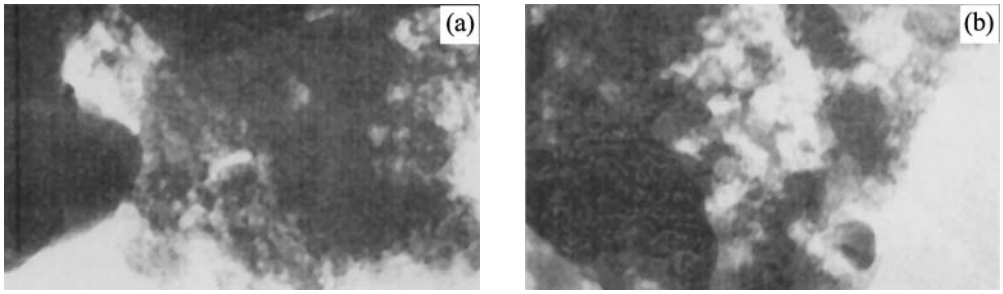

Fig. 2. Electron micrographs of an ion-exchange catalyst (5.4% Pt/sulfokarbopon).

It is notable that sample no. 3 (four exchange–reduction cycles), which contains approximately the same amount of platinum as sample no. 2 fabricated in two cycles, exhibits a substantially higher activity. Thus, the "split" deposition of the metal favorably affects the activity of the catalyst obtained.

The best result was obtained in the presence of the ion-exchange catalyst containing 5.4% Pt (Table 2, sample no. 4). The catalyst provides the 100% conversion of CO at room temperature. A study of this sample by transmission electron microscopy demonstrated that the main part of platinum in this sample is represented by clusters 1–4 nm in size (Figs. 2a, 2b).

Thus, our study demonstrated that the ion-exchange method can produce on a fibrous carbon support a sufficiently efficient platinum-containing catalyst for oxidation of carbon monoxide. It should, however, be noted that even the best of the samples obtained fail to provide a sufficiently high CO conversion in the respiratory mode (at high linear flow velocities of the gas mixture) and contain comparatively large amounts of the expensive noble metal.

CONCLUSIONS

(1) Catalyst samples produced by impregnation of a fibrous carbon support with hydrosols do not exhibit high activity in CO oxidation because of the insufficiently high dispersity of the active material.

(2) Ion-exchange samples containing highly dispersed platinum (particle size 1–4 nm) substantially exceed in activity catalysts synthesized with hydrosols. The best result is obtained in the presence of an ion-exchange sample containing 5.4% Pt. The catalyst provides a 100% conversion of CO under the experimental conditions.

Abstract—Electrochemical process of reduction of Yb(III) ions and oxidation of Yb(II) ions in a molten LiCl–KCl eutectic in the range 723–973 K was studied by linear, cyclic, and square-wave voltammetry and zero-current potentiometry.

DOI: 10.1134/S1070427208100121

The concept of separation and transmutation is considered now as an efficient method for reducing the activity of radioactive waste. It consists in the following: recovery of long-lived fission products from spent nuclear fuel (SNF) and their incorporation into an inert (uranium-free) matrix for subsequent transmutation in appropriate reactors. Pyrochemical separation methods have a number of advantages over hydrometallurgical processes, the main of which are the high radiation hardness of salt melts and the possibility of SNF regeneration with a short cooling-off period [1–3].

Electrochemical methods, such as electrolysis, electrorefining, or reducing extraction, are used in pyrochemical processes for separation of components. The best known of these is the reprocessing of the metallic fuel of the EBR-II reactor [4]. In this process, actinides are electrochemically separated from fission products. Uranium is deposited onto a solid metallic cathode, and plutonium and minor actinides (MA), onto a liquid cadmium electrode [5].

SNF can also be regenerated by reducing extraction on liquid cathodes [6] or electrochemically on solid active electrodes [7].

The purpose of this study was to optimize the efficiency of MA separation and to minimize the content of fission products, and primarily rare earth elements, which are neutron poisons, in these actinides. To solve this problem, it is important to know electrochemical and thermodynamic properties of actinides and lanthanides. These data, obtained using various electrochemical methods for molten chlorides of alkali metals, are ambiguous in some cases [8–22].

Published information about the behavior of ytterbium compounds in chloride melts is scarce. Kinetic data on the behavior of $YbCl_3$ in the molten LiCl–KCl eutectic are entirely absent. Data on the mechanism and kinetics of reduction of trivalent ytterbium ions to the divalent state and on the thermodynamics of $YbCl_3$ formation in CsCl and NaCl–KCl melts were reported in [17, 18]. In [19] the redox potentials of the Yb(III)/Yb(II) system in the LiCl–KCl eutectic melt were measured relative to a 1 M Pt(II)/Pt(0) reference electrode, and its temperature dependence was obtained. The electrochemical behavior of Yb(III) ions on an active electrode (Ni) in the equimolar NaCl–KCl melt was studied at 973 K [20]. It was found that the reaction proceeds in two stages: in the first stage, Yb(II) ions are formed, and in the second, an electrochemical process of alloy formation takes place. The electrochemistry of ytterbium(III) in molten chlorides of alkali metals has been studied by transient methods [21]. The diffusion coefficients of Yb(III) and Yb(II) ions were calculated, and temperature dependences of Yb(III)/Yb(II) conditional standard redox potentials were found. It was assumed that the cationic composition of the solvent-salt affects the value of $E^*_{Yb(III)/Yb(II)}$. In [22], the Yb(III)/Yb(II) conditional standard redox

potentials in molten chlorides of alkali metals were estimated using a correlation between aqueous solutions and chloride melts.

The aim of the present work study was to examine the electrochemical properties of ytterbium compounds in a molten LiCl–KCl eutectic.

EXPERIMENTAL

Electrochemical experiments were carried out in a quartz cell in a glassy carbon crucible in the Ar atmosphere (H_2O <0.5 ppm and O_2 <0.1 ppm) at temperatures of 723–973 K. We used a molten LiCl–KCl eutectic mixture (Aldrich, 99.9%) as a solvent to which calculated portions of $YbCl_3$ (Merck, 99.99%) were added.

The following methods were used to analyze electrochemical processes: cyclic, linear, and square-wave voltammetry and zero-current potentiometry [23–25]. The measurements were carried out with an Autolab PGSTAT 30 (Eco-Chimie) potentiostat-galvanostat with a v.4.9 software. In some cases, a semiintegrated analysis of cyclic voltammograms was carried out with a GPES (Eco-Chimie) software.

A Godfellow tungsten wire (99.9%) 1 mm in diameter was used as a working electrode immersed into the melt to a depth of 3–10 mm. The surface area of the cathode was measured after each experiment. A rod 3 mm in diameter, made of Sofacel S.A. glassy carbon served as a counter electrode. The measurements were made relative to the standard chlorine reference electrode.

Samples for chemical analysis (about 200 mg) were taken from a salt melt and dissolved in a dilute solution of nitric acid. The concentration of ytterbium was determined with an ICP-MS instrument.

The cyclic voltammogram of the background electrolyte, obtained on a tungsten electrode at 723 K, is shown in Fig. 1. In the range of potentials under study, only waves of reduction of lithium ions and oxidation of chloride ions are observed. When ytterbium trichloride is added to the melt, a cathodic current peak at a potential of –1.762 V and an anodic peak at a potential of –1.566 V relative to the chlorine reference electrode appear in the cyclic voltammogram. Potentiostatic electrolysis at potentials of the cathodic current peak did not yield a solid phase on the electrode surface, and the working electrode did not undergo any visual changes. Similar results were obtained when

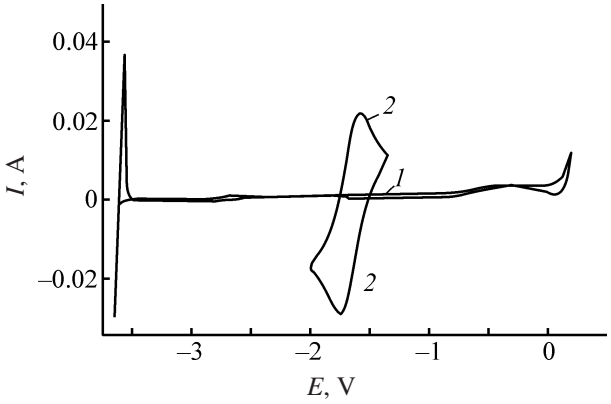

Fig. 1. Cyclic voltammograms of (*1*) background LiCl–KCl eutectic melt and (*2*) LiCl–KCl–$YbCl_3$ melt at a sweep rate of 0.1 V s^{-1} on a tungsten working electrode at 723 K. $m_{YbCl_3} = 9.41 \times 10^{-2}$ mol kg^{-1}; the same for Figs. 2–4. (*I*) current strength and (*E*) potential; the same for Fig. 2.

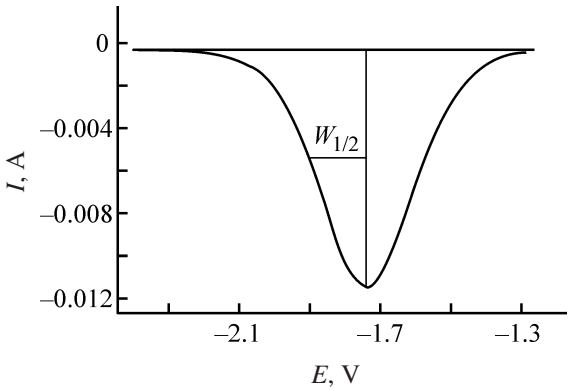

Fig. 2. Square-wave voltammogram of the LiCl–KCl–$YbCl_3$ melt at f = 12 Hz on a W working electrode at 723 K.

studying the electrochemical behavior of ytterbium (III) ions in molten CsCl [17] and in an equimolar NaCl–KCl melt [18].

We determined the number n of electrons involved in the electrode reaction by square-wave voltammetry (Fig. 2), by measuring the half-peak width $W_{1/2}$ (V) in the region in which the current peak is directly proportional to the square root of the signal frequency, according to the equation [23, 25]

$$W_{1/2} = 3.52(RT/nF), \quad (1)$$

where R, T, n, and F are the standard designations.

The calculations demonstrated that the number of electrons involved in the reduction of Yb(III) ions to Yb(II) is 1.00 ± 0.04.

These facts mean that the observed wave is related to the following redox reaction occurring in the melts

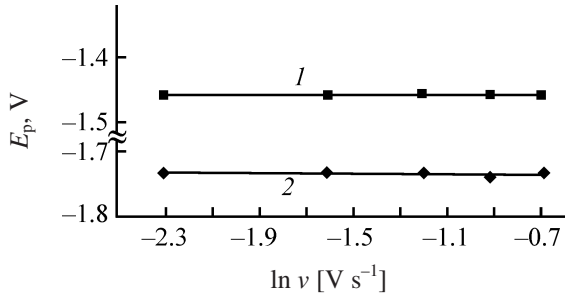

Fig. 3. Dependence of the potential E_p of (*1*) anodic and (*2*) cathodic current peaks on the logarithm of the sweep rate v for LiCl–KCl–$YbCl_3$ melt on a W working electrode at 723 K.

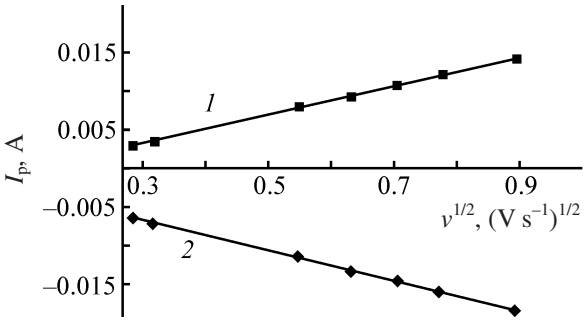

Fig. 4. Dependence of (*1*) anodic and (*2*) cathodic current peaks I_p on the square root of the sweep rate v for LiCl–KCl–$YbCl_3$ melt on a W working electrode at 723 K.

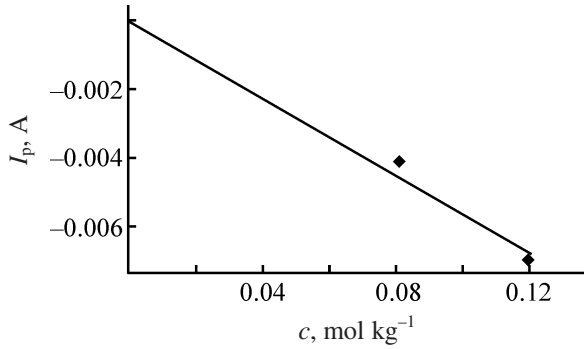

Fig. 5. Cathodic peak current I_p vs. the concentration c of $YbCl_3$ for the LiCl–KCl–$YbCl_3$ melt at 723 K.

$$\text{Yb(III)} + \text{e} \leftrightarrows \text{Yb(II)}. \quad (2)$$

It was found that the potentials of the cathodic and anodic current peaks are independent of the logarithm of the sweep rate (Fig. 3), and the currents of the cathodic and anodic peaks are directly proportional to the square root of the polarization rate in the whole range of potentials under study (Fig. 4). The current of the cathodic peak is directly proportional to the concentration of ytterbium trichloride in the melt (Fig. 5). According to the theory of linear voltammetry, the electrode processes of reduction of the trivalent ytterbium ions to the divalent state and of oxidation of Yb(II) ions to Yb(III) are reversible and are controlled by mass transfer processes.

We found using cyclic voltammetry and chronopotentiometry that the potential of reduction of divalent ytterbium ions to the metal in the molten LiCl–KCl eutectic is not reached, because it lies in the region of more negative potentials than the background decomposition voltage.

It is known [26, 27] that ions of tri- and divalent ytterbium exist in molten chlorides of alkali metals in the form of complex groups $[YbCl_6]^{3-}$ and $[YbCl_4]^{2-}$. The diffusion coefficients of $[YbCl_6]^{3-}$ ions in the molten LiCl–KCl eutectic were calculated by Randles–Shevchick equation

$$I_p = 0.446(nF)^{3/2}c_0S\left(\frac{Dv}{RT}\right)^{1/2}. \quad (3)$$

Here I_p is the peak current (A); S, surface area of the cathode (cm^2); c_0, concentration of electroactive species in the electrolyte bulk (mol cm^{-3}); D, diffusion coefficient (cm^2 s^{-1}); and v, sweep rate (V s^{-1}).

The empirical temperature dependence of the diffusion coefficients of $[YbCl_6]^{3-}$ ions is described by the Arrhenius equation [23]

$$D_{[YbCl_6]^{3-}} = D_0\exp\left(-\frac{E_a}{RT}\right) \pm \Delta. \quad (4)$$

The activation energy E_a of the diffusion process was –38.3 kJ mol^{-1}, and the preexponential factor D_0, 6.2×10^{-3} cm^2 s^{-1}.

According to the theory of linear voltammetry, the following relations are valid for a reversible electrochemical process between the cathodic (E_p^c) and anodic (E_p^a) potentials of the current peaks and the half-wave potential $E_{1/2}$:

$$E_p^c = E_{1/2} - 1.11\frac{RT}{nF}, \quad (5)$$

$$E_p^a = E_{1/2} - 1.11\frac{RT}{nF}, \quad (6)$$

$$\frac{(E_p^c - E_p^a)}{2} = E_{1/2}. \quad (7)$$

Table 1. Diffusion coefficients of $[YbCl_6]^{3-}$ ions, conditional standard potentials of the system Yb(III)/Yb(II), and the basic thermodynamic characteristics of reaction (2) in the LiCl–KCl eutectic melt

T, K	$(D_{[YbCl_6]^{3-}} \pm \Delta) \times 10^5$, $cm^2\ s^{-1}$	$E^*_{Yb(III)/Yb(II)}$, V	$-\Delta G^*_{YbCl_3}$	$-\Delta H^*_{YbCl_3}$	$-\Delta S^*_{YbCl_3}$
			kJ mol^{-1}		
723	1.0 ± 0.2	–1.662	160.93	195.96	0.036
848	2.7 ± 0.2	–1.618	159.13	195.96	0.036
973	5.4 ± 0.2	–1.574	157.33	195.96	0.036

Here,

$$E_{1/2} = E^0_{Yb(III)/Yb(II)} + \frac{RT}{nF}\ln\left(\frac{D_{Yb(II)}}{D_{Yb(III)}}\right)^{1/2} + \frac{RT}{nF}\ln\left(\frac{\gamma_{Yb(III)}}{\gamma_{Yb(II)}}\right). \quad (8)$$

It can be assumed that the activity coefficients in molten salts remain almost constant at concentrations at which the mole fractions N of depolarizer ions do not exceed the value $(3–5)\times 10^{-2}$. Introducing the conditional standard potential $E^*_{Yb(III)/Yb(II)}$, we can write the equation [28]:

$$E^*_{Yb(III)/Yb(II)} = E^0_{Yb(III)/Yb(II)} + \frac{RT}{F}\ln\left(\frac{\gamma_{Yb(III)}}{\gamma_{Yb(II)}}\right). \quad (9)$$

Assuming the diffusion coefficients of tri- and divalent ytterbium ions to be close to each other, we can take that the quantity

$$\frac{RT}{F}\ln\left(\frac{D_{Yb(II)}}{D_{Yb(III)}}\right)^{1/2}$$

is approximately zero.

In view of the aforesaid, we calculated the conditional standard redox potential $E^*_{Yb(III)/Yb(II)}$ by the equations

$$E^*_{Yb(III)/Yb(II)} = E^c_p + 1.11\frac{RT}{F}, \quad (10)$$

$$E^*_{Yb(III)/Yb(II)} = E^a_p + 1.11\frac{RT}{F}, \quad (11)$$

$$E^*_{Yb(III)/Yb(II)} = \frac{(E^c_p - E^a_p)}{2} = E_{1/2}. \quad (12)$$

The overall temperature dependence of the conditional standard redox potential (V) of the system Yb(III)/Yb(II) in the molten LiCl–KCl eutectic is described by the empirical equation

$$E^*_{Yb(III)/Yb(II)} = -(1.915 \pm 0.005) + (3.5 \pm 0.2)\times 10^{-4}T \quad (723–973\ K). \quad (13)$$

The dependence of the change in the conditional standard Gibbs energy of the redox reaction

$$YbCl_{2(s)} + 1/2Cl_{2(g)} \leftrightarrows YbCl_{3(s)} \quad (14)$$

was calculated by the formula

$$\Delta G^*_{YbCl_3} = nFE^*_{Yb(III)/Yb(II)}. \quad (15)$$

Its temperature dependence is expressed by the equation

$$\Delta G^*_{YbCl_3} = \Delta H^*_{YbCl_3} + T\Delta S^*_{YbCl_3}. \quad (16)$$

For the molten LiCl–KCl eutectic mixture this dependence has the following form (kJ mol^{-1}):

$$\Delta G^*_{YbCl_3} = -183.80 + 0.033T \pm 2.46. \quad (17)$$

The results obtained are listed in Tables 1–3 and shown in Fig. 6.

As can be seen in Tables 1 and 2, the diffusion coefficients of trivalent ytterbium ions steadily decrease as the radius of the solvent salt cation increases, which is due to a change in the stability of complex groups. As the temperature is elevated, the diffusion coefficients steadily increase.

As it was shown above, the comparatively high stability of complex ions depends on the composition

CONCLUSIONS

(1) It was shown that the redox electrode reaction (2) in the molten LiCl–KCl eutectic is reversible in the temperature range 723–973 K and is controlled by the mass-transfer process. Its electrochemical parameters were determined and the diffusion coefficients of $[YbCl_6]^{3-}$ ions were calculated.

(2) The temperature dependence of the conditional standard potential of the system Yb(III)/Yb(II) relative to the chlorine reference electrode was obtained.

(3) The basic thermodynamic characteristics of reaction (2) in the LiCl–KCl eutectic melt were calculated and compared with the available published data.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Preparation of Compact Copper from Slurries Formed in Etching of Printed-Circuit Boards

M. N. Bobrov and Yu. P. Khranilov

Vyatka State University, Kirov, Russia

Received January 21, 2008

Abstract—Technological solutions for copper recovery in the form of a compact metal from a slurry formed in etching of printed-circuit boards as a starting material were developed.

DOI: 10.1134/S1070427208100133

In manufacture of printed-circuit boards, a copper-rich slurry is formed at the bottom of etching units. The composition of the slurry depends on that of the etching solution. The slurry formed with a copper–ammonia solution contains copper ammoniates, copper hydroxo chlorides (CHCs), and other copper salts. The high content of copper in slurries of this kind and their large volumes (several hundreds of kilograms annually for a shop of an average output capacity) make promising the recovery of copper in the form of a compact metal.

A large number of technological solutions have been developed for utilization of spent copper-ammonia etching solutions (SESs): electrochemical regeneration, including deposition of excess copper on the cathode and recycling of the etching solution into the technological process [1]; chemical conversion of SESs into CHC to be used for plant pest control [2]; high-temperature treatment of SESs with sodium hydroxide to yield copper(II) oxide as a commercial product [1]; and cementation of copper on iron shavings or iron powder from a preliminarily acidified SES to obtain a copper powder [3]. Owing to its simplicity, the last method has found wide application, although the powder it yields is contaminated with iron.

The problem of slurry utilization has been developed to a lesser extent. Mention can be made of the study [4], in which it was suggested to process the slurry into CHC to be used as an active substance in water-activated power sources. In practice, the slurry is commonly processed together with SES by the cementation method.

The goal of this study was to search for technological solutions for recovery of copper in the compact form from the slurry of copper-ammonia SESs. The total content of copper in the object under study was 40 to 47%; that of chlorine, 35%, on average; and that of ammonium nitrogen, 10 to 12 %. The concentration of copper was determined by iodometry and photocolorimetry (FKF-2 photocolorimetr); concentration of chlorine, by argentometry; and that of ammonium nitrogen, by the formalin method [5].

EXPERIMENTAL

Three procedures for copper recovery were tested experimentally. The first method included dissolution of the slurry in sulfuric acid, followed by electrolytic recovery of copper. A potentiometric titration curve for an aqueous suspension of the slurry (1.5 g of slurry per 50 ml of water) with 1% sulfuric acid is shown in Fig. 1.

Initial suspension has pH 8.5, i.e., it contains an alkaline constituent (copper ammoniates). The upper plateau on the titration curve (at pH 9–8) is due to conversion of ammonia from ammoniates into the ammonium form, and the lower plateau, to dissolution of copper hydroxo chloride by the reaction

$$2CuOHCl + H_2SO_4 \rightarrow CuSO_4 + CuCl_2 + 2H_2O. \quad (1)$$

A solution containing 15.6 g l^{-1} of copper, produced by dissolving a portion of slurry in 10% sulfuric acid (l : s = 30 : 1) , was subjected to a short-time electrolysis with a graphite anode and copper and titanium cathodes. The experiments were performed at current densities of 0.5–2 A dm^{-2}. Figure 2 shows the current efficiencies (CE) at different current densities *i*.

The presence of chlorides in the slurry results in the following. In electrolytic recovery with a copper cathode, the calculated current efficiency by copper somewhat exceeds 100%. This reason is that the surface of the copper cathode (introduced into the electrolyzer at a zero current) interacts with the chloride-containing electrolyte to give a copper monochloride film. This leads to an apparent increase in the CE by copper and to contamination of the cathode deposit. The zero-current potential of the copper electrode in the sulfuric acid solution of the slurry (E = +0.144 V relative to s.h.e.) is close to the value obtained for the equilibrium $Cu + Cl^- \rightarrow CuCl + e$ (E_0 = +0.137 V) in [6], which confirms the explanation suggested. In experiments with the titanium cathode, the CE is lower than 100%, which is due to dissolution of a part of oxygen evolved at the anode in the electrolyte and its subsequent reduction at the cathode. The presence of chlorides in the electrolyte not only contaminates the cathode copper, but also results in evolution of a certain amount of chlorine at the anode, which requires that the electrolyzer should be hermetically sealed and gives no way of using the more convenient lead anodes.

In the second of the tested procedures for copper recovery, copper ions are preliminarily sorbed from a sulfuric acid solution of the slurry onto a strongly acidic KU-2×8 cation-exchange resin. It was found that, to dissolve the slurry prior to the ion exchange, it is necessary to use a sufficiently diluted acid (about 1%). When more acidic solutions (3% and higher) are passed through the column, a breakthrough of copper ions is observed almost immediately. At a solution flow rate of 2–2.5 m h^{-1}, the dynamic exchange capacity for copper ions was 1000–1300 g-equiv m^{-3} of swollen resin.

After the sorption, the ion exchanger was regenerated with 10% sulfuric acid to obtain an eluate containing no Cl^- ions. The concentration of copper in the eluate and the degree of copper return into the eluate depend on the ratio between the volume of the regenerating solution and the mass of sorbed copper (V/m, cm^3/g). On lowering the V/m ratio from 220 to 54 cm^3/g, the copper concentration in the eluate could be raised from 3.9 to 10.8 g l^{-1} however, the degree of copper return decreased from 87 to 58%.

The low concentration of copper in the eluate gives no way of performing the electrolytic recovery at technologically acceptable current densities. The large expenditure of the acid for regeneration makes this copper recovery procedure rather economically inefficient.

The third copper recovery procedure recommended for SESs [1] is based on preliminary thermal

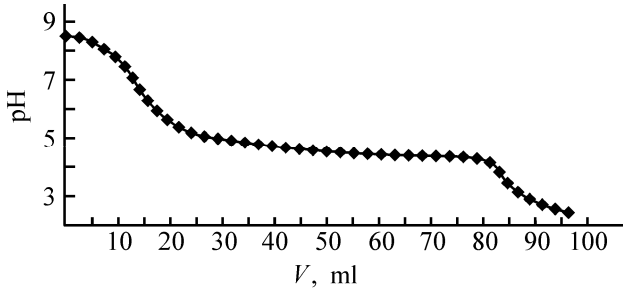

Fig. 1. Curve of pH metric titration of a slurry suspension with 1% H_2SO_4. (V) volume.

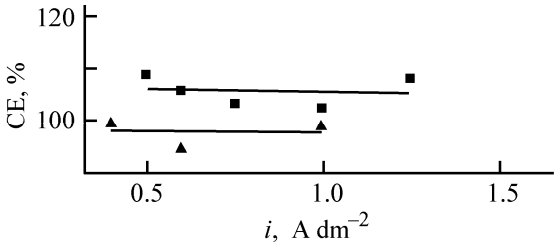

Fig. 2. Effect of the cathode material on the CE by copper. (i) Current density. Cathode: (*1*) copper and (*2*) titanium.

decomposition of ammoniate and chloride complexes of copper(II) by the reactions

$$Cu(NH_3)_2Cl_2 + 2NaOH \rightarrow CuO\downarrow + 2NH_3\uparrow + 2NaCl + H_2O, \quad (2)$$

$$CuOHCl + NaOH \rightarrow CuO\downarrow + NaCl + H_2O. \quad (3)$$

In this study, it is suggested to use this method for thermal decomposition of the slurry to obtain CuO, its dissolution in sulfuric acid, and delivery of the resulting solution to electrolysis. The experiment was performed with an aqueous suspension of the slurry at l : s = 30 : 1, to which a NaOH solution was added to adjust the pH value to 12.5–13. The mixture obtained was heated to 75–80°C. The expenditure of a 5% sodium hydroxide solution is 100–120 ml per 300 ml of the suspension. A copper oxide solution in sulfuric acid served as electrolyte.

To choose the range of the working current densities, the dependence of the limiting current density i_{lim} on the copper concentration (Fig. 3) was determined from cathodic polarization curves recorded in model solutions with a constant concentration of sulfuric acid (50 g l^{-1}) (IPC-PRO potentiostat, potential sweep rate 2 mV s^{-1}).

Various procedures can be used for electrolytic recovery from the sulfuric acid solution obtained. The first of these is based on electrolysis with a ~50% exhaustion of the electrolyte in copper. In this case, the cathode current density is constant and should not exceed

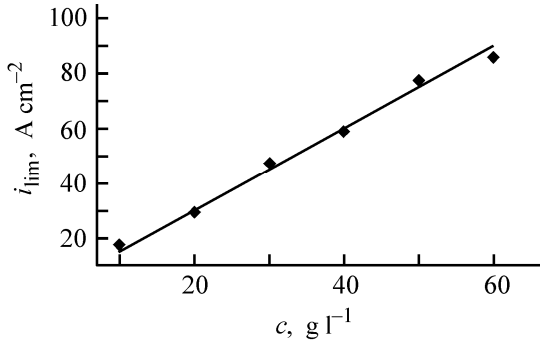

Fig. 3. i_{lim} vs. the copper concentration c.

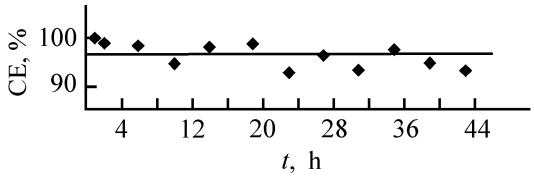

Fig. 4. Variation of the CE by copper in prolonged electrolysis. (t) Time.

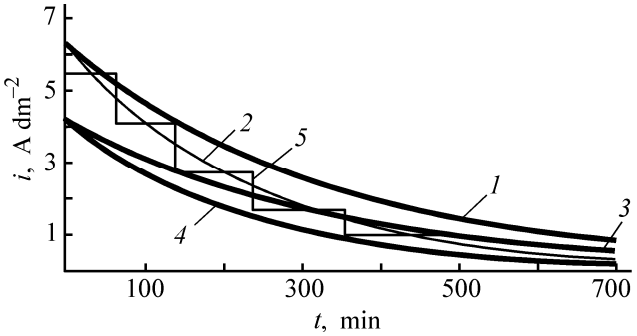

Fig. 5. Calculated working current density i in electrolytic recovery of copper from a sulfuric acid electrolyte vs. time t. (*1*) S/V = 1.5 dm^{-1}, c_0 = 60 g l^{-1}, (*2*) S/V = 2.4 dm^{-1}, c_0 = 60 g l^{-1}, (*3*) S/V = 1.5 dm^{-1}, c_0 = 40 g l^{-1}, (*4*) S/V = 2 dm^{-1}, c_0 = 40 g l^{-1}, (*5*) approximation of curve *2* (stepwise decrease in the current density).

40% of the limiting current density for the starting electrolyte to avoid formation of powdered deposits on the cathode. After about 50% of copper is recovered, a new portion of copper oxide is introduced into the electrolyte and the electrolysis is performed again. A prolonged experiment (about 40 h, with 12 corrections with respect to copper) confirmed that pure copper can be obtained at the cathode in a compact form with a high current efficiency (90–98%) (Fig. 4). According to the results of a spectral analysis (Spec-trolab optical emission spectrometer), the copper content is 99.88%.

Sulfuric acid is only consumed when the electrolyte is initially prepared, with the acid formed at the anode in the course of electrolysis used in the further process. Lead or its alloy with antimony serves as the anode material.

In another procedure for electrolytic recovery, the current density is lowered continuously or in steps in order to avoid formation of powdered deposits upon a decrease in the copper concentration. To calculate how the current density should vary with time, the following starting assumptions were made:

(1) With account of the edge effect, which can result in that spongy, and even powdered deposits can be formed at the edges of the cathode, the working current density i at each instant of time t should not exceed 70% of the limiting current density i_{lim} ($i = 0.7i_{lim}$).

(2) i_{lim} (A dm^{-2}) is proportional to the copper concentration c (g dm^{-3}) in the electrolyte. According to the experimental data of Fig. 3, $i_{lim} = 1.5c$.

(3) At the instant of time t, the copper concentration $c_t = c_0 - \Delta m/V$, where c_0 is the initial concentration (g dm^3); Δm, mass of copper deposited on the cathode in a time t (g); and V, electrolyte volume (dm^3).

(4) The loss of copper mass from the electrolyte during a time t (h) is given by the relation $\Delta m = qi_{av}St\,\mathrm{CE}$, where q is the electrochemical equivalent of copper (1.186 g (A h)$^{-1}$); i_{av}, the average current density over a time t; S, working surface area of the cathode (dm^2); and CE, current efficiency (taken to be 0.95).

With account of the above relations and accepted constants

$$i = 1.05(c_0 - 1.127i_{av}St/V). \quad (4)$$

To construct the i-vs.-t curve, Δm, i_{av}, and i were computed for reasonably short intervals of time t (Δt = 1 min). Selected results are presented in Fig. 5. The ratio S/V = 2.4 dm^3 belongs to a laboratory electrolyzer, and S/V =1.5 dm^3, to the design of an industrial installation with 42 l of electrolyte.

A laboratory experiment with a solution with an initial copper concentration of 60 g l^{-1} and a stepwise decrease in the current density (Fig. 5, curve *5*) yielded a compact deposit with a 75% degree of copper recovery without electrolyte corrections. According to the results of a spectral analysis, this copper was 99.97% pure.

CONCLUSION

Technological solutions for recovery of copper from the slurry formed in etching of printed-circuit boards in copper–ammonia solutions were experimen-

tally substantiated. These are thermal decomposition of the slurry in an alkaline medium to obtain copper(II) oxide, dissolution of copper oxide in sulfuric acid, and electrolytic recovery of copper from the solution obtained, with correction of the electrolyte with respect to copper at regular intervals of time or a stepwise decrease in the current density. The purity of the resulting copper is no less than 99.88%.

Abstract—Effect of the initial electrical conductivity of an electrically isoconducting flow-through electrode made of a fibrous carbon material on the dynamics of copper electrodeposition from a sulfuric acid solution was studied. The distribution of the copper deposit across the electrode thickness and the variation of the electrolysis parameters (copper deposition rate, current efficiency, uniformity of distribution, and mass of a deposited metal per unit mass of the fibrous carbon material) were considered.

DOI: 10.1134/S1070427208100145

Flow-through electrodes made of a fibrous carbon material (FCM) are used in various redox processes, especially in electrodeposition of metals from their low-concentration solutions for electrolytic recovery of metals or metallization of FCM fibers [1–8]. The operation efficiency of a fibrous carbon electrode (FCE) is strongly affected by the relative electrical conductivities of the liquid and solid phases of the electrode [8–14]. However, the available data give no information about the dynamics of metal electrodeposition onto FCE and variation of the deposition parameters in a wide range of electrical conductivities of the electrode and solution for various technological schemes of metal electrodeposition onto FCE (direct-flow, circulatory, circulatory with periodically increasing metal concentration in solution). Such an information is necessary for understanding the fundamental aspects of FCE operation, developing technological processes of electrolytic recovery of metals and their deposition onto FCMs, and designing electrochemical reactors with FCM electrodes.

In this study, the distribution of a deposit across the electrode thickness in the course of electrolysis and the variation of the current efficiency by the metal, deposition rate, uniformity of the metal distribution across the electrode thickness, and amount of the metal deposited on different parts of the electrode were examined in relation to the electrolysis duration for the example of copper electrodeposition from a sulfuric acid solution onto electrically isoconducting FCM electrodes with different initial electrical conductivities.

The experimental scheme simulated the process of electrolytic recovery of metals from solutions in a catching baths at plating shops [7, 8]. A similar scheme can also be applied to metallization of FCM fibers. The electrolyte (500 ml) containing (g l^{-1}): Cu 0.16, H_2SO_4 25, and $(NH_4)_2SO_4$ 80, was circulated between the vessel with a solution (catching bath) and the electrolytic cell (electrolyzer) at a rate of 0.4 cm s^{-1} in accordance with the scheme described in [5, 15]. The electrical conductivity of the solution was 0.101 S cm^{-1}.

The concentration of the me-tal ions being recovered in an electrolyzer was maintained constant within a narrow range, 0.160 ± 0.03 g l^{-1} by adding a solution (10 ml) containing (g l^{-1}): Cu 2.5, H_2SO_4 25, and $(NH_4)_2SO_4$ 80, at regular intervals of time (5–10 min), depending on the rate of copper recovery, with the total volume of the electrolyte remaining constant.

The concentration of copper ions in solution was determined by direct voltammetry on a renewable graphite microelectrode [16].

Copper was electrodeposited in the galvanostatic mode, using a B5–47 dc power supply. The electrolytic cell was described in [15]. A 6-mm thick cathode comprised five FCM layers. A platinum wire served as the anode, and a perforated titanium plate, as the current lead. The solution was delivered to an electrode with a back current lead from the back side with respect to the counter electrode. The back side of the electrode was adjacent to the perforated current lead, and its front side, was the closest to the anode. The electrode thickness was found on the basis of its possibly being assembled from five layers; it was close to the maximum possible thickness used in industry [1, 2, 7, 8].

The properties of FCMs used to assemble electrodes are listed in Table 1. When choosing the materials, the main attention was given to their electrical conductivity χ. It can be seen from the data presented that the electrical conductivities of low- and high-conductivity materials differ by more than a factor of 35. The specific reactive surface accessible to electrolysis is large and differs by less then a factor of 2 between different materials. The profiles of all the FCM fibers are irregular [2, 5], which provides close hydrodynamic conditions in the initial stage of the process.

Each of the FCM layers constituting the electrode was weighed on an analytical balance to within 0.0001 g before and after electrolysis. After electrolysis, the electrode was washed with distilled water and dried at 80°C to constant mass.

The ratio between the masses of the copper deposit and the FCE was calculated for each layer by the formula

$$\delta = m_{Cu}/m_{FCM1}.$$

and that between the total mass of the deposit and the mass of the whole FCM, by the formula

$$\Delta = \frac{\sum_{i=1}^{5} m_{Cu}}{\sum_{i=1}^{5} m_{FCM1}},$$

where m_{Cu} is the mass of the deposited metal (g), and m_{FCM1}, that of the FCM before electrolysis (g). The mass of copper deposited during the time between the delivery of two portions of an electrolyte to a solution in the course of electrolysis (cycle) was determined using the formula

$$m_{Cu} = (c^{add}_{Cu\,i} - c_{Cu\,i+1})V_{el},$$

where $c^{add}_{Cu\,i}$ (g l^{-1}) is the concentration of copper ions in solution upon addition of the adjusting electrolyte in the preceding cycle, and $c_{Cu\,i+1}$ (g l^{-1}), the concentration of copper in solution in the cycle for which the mass of the deposited metal was determined .

We also calculated the rate of copper deposition [U (mg cm^{-2} min^{-1})], current efficiency by copper in a cycle [CE (%)], and total time of electrolysis.

The uniformity of the metal distribution across the FCE thickness was evaluated by the known criterion, root-mean-square deviation [17, 18] calculated by the formulas

$$m_{Cu} = \frac{1}{5}\sum_{i=1}^{5} m_{Cu\,i},$$

$$H_{rms} = \sqrt{\frac{1}{5}\sum_{i=1}^{5} (m_{Cu\,i} - m_{Cu\,av})^2},$$

where $m_{Cu\,av}$ is the average mass of a copper deposited on the FCM layer (g), and $m_{Cu\,i}$, the mass of copper on each FCM layer (g).

All the calculations were carried out using Microsoft Office Excel 2007 software.

Copper was electrodeposited at a current density of 1500 A m^{-2} in the course of 10–460 min. The maximum time of electrolysis was limited by termination of the solution flow or by a substantial decrease in its rate because of the "clogging" of the electrode by the copper deposit. The ratio between the geometric cathode surface area and the solution volume was 0.2 m^2 : 500 l, which corresponded to a real technological process. The current density was chosen taking into account the industrial experience of application of processes with FCE in industry and the possibility of operation

of a considerable part of the electrode at the limiting diffusion current.

We now consider the results obtained on electrodes with a constant electrical conductivity across the electrode thickness and decreasing electrical conductivity of FCM.

Electrode fabricated from high-conductivity FCM (VINN-250). During the first 30 min after the beginning of electrolysis, the copper deposit is rather uniformly distributed across the electrode thickness (Fig. 1a). In the course of time, the deposit is somewhat shifted to the backside of the electrode, and more strongly, to the front side. Further increase in the electrolysis duration results in redistribution of the copper deposit across the electrode thickness to the front side of the electrode. In the central part of the electrode, the minimum (with respect to other electrode areas) amount of copper is deposited. The value of δ varies across the electrode thickness within the range 0.02–35.47. The mass ratio between copper deposited on the whole electrode and the FCM was 13.03 during the entire period of electrolysis. A similar ratio for the front part of the electrode was 35.47. Such a large amount of copper deposit on the FCM has not been obtained previously. It should be noted that the value obtained (13.03 g g^{-1} FCM) rather closely coincides with that characteristic of Cu recovery onto thinner (approximately twofold) electrodes under industrial conditions. The considerable redistribution of the copper deposit to the front side of the electrode characterizes the nonuniformity of copper distribution across the electrode thickness, which grows in the course of electrolysis and, in 460 min, results in a pronounced decrease in the flow rate of the electrolyte (root-mean-square deviation H_{rms} is 320.8).

In the course of electrolysis, the current efficiency considerably increases, from 15% (during the first 10 min of electrolysis) to 90% after 300 min of electrolysis (Fig. 2), and, accordingly, the rate of copper deposition grows from 0.6 to approximately 2.7 mg cm^{-2} min^{-1}. In the course of electrolysis, these parameters decrease by 20–25% from the maximum value. It should be noted that the manner in which the current efficiency by copper and the rate of its deposition varies with time is the same for all the materials studied.

Electrode fabricated from FCM with an electrical conductivity comparable with that of the solution (NTM-100). During the initial period (before 180 min), copper is mainly deposited on the front side of the electrode, and to a lesser extent, on its back side, with the minimum amount of copper deposited in the middle part of the electrode. Further, the mass of copper increases across the entire electrode thickness and the deposit shifts to its front side. For example, the mass ratio between copper and the FCM on the front layer reaches the highest value (37.94), with δ for the entire electrode being the lowest among all of the FCMs studied (Table 2). Therefore, the deposit is distributed the most nonuniformly across the entire electrode thickness (H_{rms} = 328.4). The manner in which the current efficiency and deposition rate vary with time is the same as that for the VINN-250 electrode. The rate of copper deposition gradually increases from 1.2 to 2.4 mg cm^{-2} min^{-1} 300 min after the beginning of electrolysis and decreases to 2.0 mg cm^{-2} min^{-1} in 420 min. Accordingly, the current efficiency increases from 40 to 80% and decreases to 60% by the end of the electrolysis, with the maximum values of CE and *U* being somewhat smaller than those for the VINN-250 electrode. The process of copper deposition is characterized by a smaller difference between the highest and lowest values of CE and *U*. During the whole time of copper deposition, the current efficiency and the deposition rate on the NTM-100 electrode are somewhat smaller than those on the VINN-250 electrode.

Electrode fabricated from FCM whose electrical conductivity is lower than that of a solution (KNM-2). In the initial period (10 min), the distribution of the copper deposit across the electrode thickness is symmetrical with respect to the middle part of the electrode, with a minimum at its center (Fig. 1b). The masses of copper deposited at the front and back sides of the electrode are nearly the same, several times that in its central part. Making the electrolysis duration longer (20–35 min) results in that the distribution of the copper deposit across the electrode thickness becomes more uniform and is further shifted to its front side. In contrast to the cases considered above, a considerable part of copper is deposited on the first and the second layers. As the amount of deposited copper increases, its distribution across the electrode thickness becomes more nonuniform (Fig. 2). In the course of electrolysis, the current efficiency linearly grows in a rather narrow range of variation of these parameters. The rate of copper deposition varies similarly. During 360 min of electrolysis, the deposition rate increases from 1.6 to 1.8 mg cm^{-2} min^{-1}, and the current efficiency by copper, accordingly, grows from 53 to 63%.

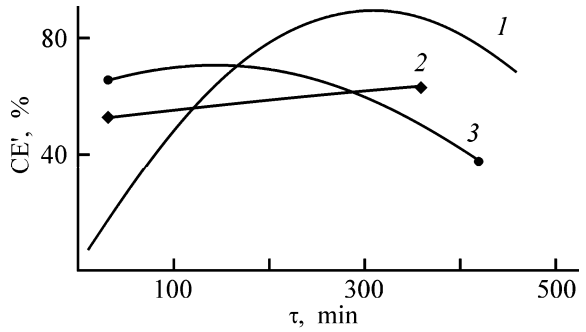

Fig. 2. Current efficiency CE by copper vs. the electrolysis duration τ for (*1*) VINN-250, (*2*) KNM-2, and (*3*) ANM.

The parameters considered above confirm the stable operation of the electrode and show that the influence exerted by the mass of the deposited copper is considerably weaker than that in copper deposition onto other FCEs. As follows from Table 2, the copper deposition rate and the current efficiency are the highest during the full electrolysis time (360 min). The more uniform distribution of copper across the electrode thickness (H_{rms} = 187.8), the higher current efficiency, and smaller changes in *U* and CE in the course of electrolysis on KNM-2 electrode apparently show that the distribution of the potential and local current densities across the electrode thickness is more uniform. The same is indicated by data on the relative mass of copper deposited per unit mass of FCM. For example, δ for the whole electrode differs only slightly from that for VINN-250 and NTM-100 and lies between them, whereas the maximum value of δ for a single layer of the KNM-2 electrode is a factor of 1.6–1.75 smaller

Table 2. Parameters of copper electrodeposition onto FCM electrodes

Material	*U*, mg min^{-1} cm^{-2}	CE', %	δ_{max} for an electrode layer	δ for the electrode	H_{rms}	τ, min
ANM	1.840	59.33	15.56	10.56	110.2	420
KNM-2	1.884	63.57	21.73	10.72	187.8	360
NTM-100	1.815	61.26	37.94	10.08	328.4	420
VINN-250	1.909	62.33	35.47	13.03	320.8	460

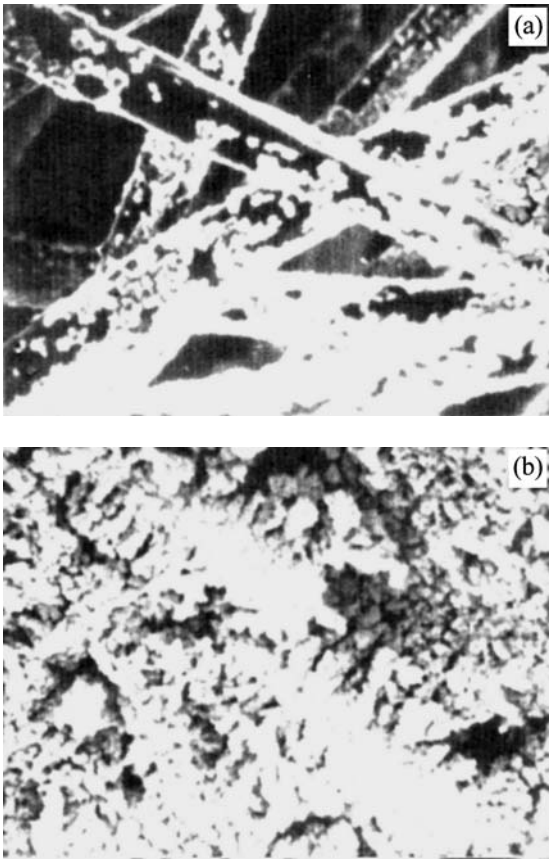

Fig. 3. Electron micrographs of FCM samples. Electrolysis duration (min): (a) 60 (×1000), and (b) 420(×350).

than that for electrodes fabricated from the above FCMs.

Electrodes fabricated from low-conductivity FCM (ANM). The dynamics of the copper distribution across the thickness of an ANM electrode in the course of electrolysis differs from that for the electrodes considered above. During a prolonged electrolysis, the copper deposit is shifted to the back side of the electrode (Fig. 1c). In the course of time, there occurs redistribution of the deposit and its shift to the front side. The current efficiency somewhat increases during 150–200 min of electrolysis, reaches the maximum value, and then decreases (Fig. 2). During the whole time of electrolysis, the integral characteristics U and CE are the lowest (1.84 mg cm^{-2} min^{-1} and 59.33%, respectively) in comparison with those of all the materials considered (Table 2). The ratio between the maximum amount of the copper deposit on a single layer of the ANM electrode (15.56) is also the smallest, but the electrode as a whole is inferior in δ only to VINN-250. Therefore, the distribution of copper across the electrode thickness at the end of the electrolysis is the most uniform (H_{rms}= 110.2).

The time dependences of the Cu distribution across the electrode thickness (Fig. 1c) and the lower U, CE, and δ values are possibly due to the "island" nature of the copper deposit on the FCM during a long electrolysis time. Therefore, the electrode as whole has no continuous current path via the deposited metal having a higher conductivity than the FCM. This suggestion can be confirmed by the shift of the copper deposit to the back side of the electrode. Apparently, the distribution of the copper deposit across the electrode thickness is affected during a rather long time by the initial ratio of the electrical conductivities of the FCM electrode and the solution.

The relative mass of copper deposited on various electrode layers does not exceed 3 g g^{-1} FCM during up to 120 min of electrolysis. Then, this ratio increases, a high-conductivity electrode is formed, and the metal deposition zone shifts to the front side. According to the previously obtained experimental data [15], a solid deposit providing a high electrical conductivity of the electrode is formed upon deposition of 1.0–2.0 g g^{-1} FCM for the case of an island structure and upon deposition of more than 0.2 g g^{-1} FCM for the case of a thin film.

The nature of copper deposition onto FCM fibers is demonstrated by the micrographs (Figs. 3a, 3b) obtained with a JSMT-20 scanning electron microscope. It can be seen that, in the initial period of electrolysis, nuclei are formed on the surface of FCM fibers, gradually grow, and merge to give a solid high-conductivity copper layer. Simultaneously, the growing metallic islands fill the space between the fibers, merge, and form additional current transport paths. All these factors lead to an increase in the electrical conductivity of some parts of the electrode and, as result, to a rise in the electrical conductivity of the electrode as a whole. The electrical conductivity of the electrode becomes considerably higher than that of the solution, which results in a shift of the copper deposit to the front side of the electrode. Apparently, the local current densities will vary in the course of electrodeposition. In the course of copper deposition, the specific reactive surface of the electrode will change, too, which will lead to a change in the mass-transfer coefficient and in the linear flow velocity of the solution. This is confirmed by the calculated values reported in [10, 19]. The results of earlier studies [2, 4, 8] demonstrate that the morphology and nature of "overgrowth" of FCM

fibers with the metal deposit depend on the electrolysis conditions, FCM type, and state of the fiber surface.

Analysis of the data in Table 2 shows that the weight of copper deposited onto the electrode and the maximum mass of the copper deposit in its single layer are in good agreement with the uniformity of the deposit distribution across the entire electrode thickness, which is reflected by the H_{rms} values. For example, the distribution of the copper deposit is the least uniform on the VINN-250 and NTM-100 electrodes (H_{rms} 320.8 and 328.4, respectively). In this case, the ratio between the mass of copper deposited on a single layer and the mass of the FCM layer is somewhat smaller for the VINN-250 electrode, compared with the NTM-100 electrode. At the same time, the ratio for the mass of copper deposited on the entire electrode is larger for the VINN-250 electrode. Rather significant is the deposition of copper onto the ANM material. The value of δ for the layer with the maximum amount of deposited copper is a factor of 2.27 lower for this material than that for VINN-250. At the same time, the value of δ for the whole electrode is only a factor of 1.14 smaller, with H_{rms} for ANM a factor of 2.91 lower than that for VINN-250.

The results of the study show that, from the standpoint of development of processes for electrolytic recovery of metals, in which a considerable amount of metal should be deposited per unit mass of the FCM at a uniform distribution of the metal across the electrode thickness, it is the most reasonable to use electrodes fabricated from a low-conductivity material of the ANM type for the chosen electrolysis conditions and design of the electrode system (back side current lead to FCM and back side delivery of the electrolyte to electrode). To provide a uniform distribution of the copper deposit across the electrode thickness in metallization of FCM fibers, it is necessary to use electrodes fabricated from a material of the KNM-2 type, whose electrical conductivity is several times lower than that of the solution.

The results presented here show, along with the previously obtained data, that the initial electrical conductivity of the electrically isoconducting FCM electrode strongly affects the dynamics of metal deposition, distribution of metal across the electrode thickness, and characteristics of the electrolysis process. For FCM electrodes with various initial electrical conductivities, the distribution of the metal across the electrode thickness can be varied, with high electrolysis characteristics preserved, by changing the electrolysis conditions and process time.

CONCLUSIONS

(1) Copper electrodeposition from a sulfuric acid solution onto electrically isoconducting flow-through electrodes with a thickness of 0.6 cm, fabricated from fibrous carbon materials with various electrical conductivities, under conditions of solution circulation through the electrode volume and by maintaining the copper concentration in solution within the range 0.160 ± 0.03 g l^{-1}) at a current density of 1500 A m^{-2} was studied.

(2) It was shown that, for all of the carbon fibrous electrodes under study, whose electrical conductivity is in the range 0.184–0.0052 S cm^{-1} (electrical conductivity of the solution, 0.101 S cm^{-1}), the copper deposit is redistributed across the electrode thickness in the course of electrolysis and the following parameters vary: current efficiency, deposition rate, uniformity of the distribution across the electrode thickness, and mass of deposited copper per mass of the fibrous carbon material, both across the electrode thickness and for the electrode as a whole.

(3) It was found that the manner in which the parameters vary in the course of copper deposition and their numerical values are determined by the initial ratio between the electrical conductivities of the solution and the electrode material.

(4) It was demonstrated that use of low-conductivity fibrous materials under the chosen electrolysis conditions with backside delivery of a solution to electrode and backside current lead provides the most uniform distribution of the copper deposit across the electrode thickness in the course of electrolysis.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Rare-Earth Metals (Y, La, and Ce) on the Corrosion and Mechanical Properties of Aluminum–Manganese Alloy

Abstract—Effect of some rare-earth metals (yttrium, cerium, and lanthanum) on the corrosion-electrochemical and mechanical properties of an aluminum–manganese alloy of eutectic composition (1.9% Mn) in a neutral medium was studied.

DOI: 10.1134/S1070427208100157

Aluminum–manganese alloys are a well-known construction material that is not hardenable by thermal treatment and is distinguished by high plasticity, good weldability, and high corrosion resistance. However, alloys of the AMts type are subject to pitting corrosion under certain conditions. Previously, the corrosion-electrochemical behavior of Al–Mn alloys has been studied in a wide range of concentrations [1–3].

Multicomponent systems with intermediate phases belong to the most widely used and practically important systems. The phase diagrams of these systems underlie the technology for manufacture of alloys from nonferrous metals and deformable half-products. Therefore, studying these systems and revealing the fundamental aspects of their structure is a topical task.

The aim of this study was to examine the effect of rare-earth metals (REM), such as yttrium, cerium, and lanthanum, on the corrosion-electrochemical behavior of an aluminum–manganese alloy and to analyze its mechanical properties. As a base material was chosen an alloy of eutectic composition (Al + 1.9% Mn) as a construction material with improved physicochemical properties, compared with the industrial AMts alloy.

EXPERIMENTAL

To study the corrosion-electrochemical properties of REM-containing aluminum alloys, addition alloys were prepared from A995 aluminum [GOST (State Standard) 11069–74], and alloys of prescribed compositions, from technical-grade aluminum of A8 brand (GOST 4784–74*) in an SNVL–1.301 vacuum furnace in corundum crucible in the atmosphere of argon at temperatures in the range 800–1000°C. Cylindrical rods 8 mm in diameter and 100 mm long were cast in a graphite mold from the alloys obtained. Before being submerged in an electrochemical cell, the rods were ground, polished, and degreased with ethanol.

The corrosion-electrochemical behavior of alloyed aluminum–manganese alloys was studied using the method described in [1]. The sequence of operations performed when measuring a polarization curve is schematically shown in Fig. 1. The potential sweep rate was 2 mV s^{-1}, a silver chloride electrode served as reference, and the potentials were recalculated to the standard hydrogen scale (s.h.e.). The corrosion rate K, a function of the corrosion current density i_{cor}, was found by the formula

$$K = i_{cor} k,$$

where k is the electrochemical equivalent whose numerical value for aluminum is 0.335 g $A^{-1} h^{-1}$ [4].

* $-E_{fr.cor}$, $-E_{pit}$, $-E^1_{pit}$, $-E_{rpas}$, $-E_{cor}$, and $-E_{pas.on}$ are the potentials of free-corrosion, pitting in the presence and absence of a natural oxide film on the surface, repassivation, corrosion, and passivation onset, respectively; ΔE_{pas}, passivation interval; $i_{d.rpas}$ and i_{cor}, current densities of dissolution in the repassivation region and corrosion.

Because iron is an inevitable accompanying impurity in aluminum alloys, it was of interest to preliminarily consider the joint effect of iron and manganese on the corrosion resistance of aluminum. For this purpose, alloys with a 1 : 1 manganese-to-iron ratio were prepared. With account of the free-corrosion ($E_{fr.cor}$), repassivation ($E_{r.pas}$), and corrosion (E_{cor}) potentials, it was found that the potentials of the alloys in the absence of current are in the passivation region (0.40–0.50 V). At potentials more negative than the pitting potential (E_{pit}), a uniform dissolution of the aluminum–manganese alloys is observed. At more positive potentials, oriented pits appear on the surface. The tendency of an alloy to undergo pitting corrosion can be evaluated by the difference between the pitting and repassivation potentials in a neutral medium. For the case in question, this difference is 0.6–0.9 V.

Iron affects the corrosion resistance of aluminum in diverse ways. As a rule, the effect of iron on the corrosion resistance of aluminum alloys in neutral media is slight. However, its presence in aluminum–manganese alloys leads to a tenfold increase in the corrosion rate. The key role in the corrosion behavior of the given system is played by the $FeAl_3$ phase, because the appearance of pitting is caused by just this phase.

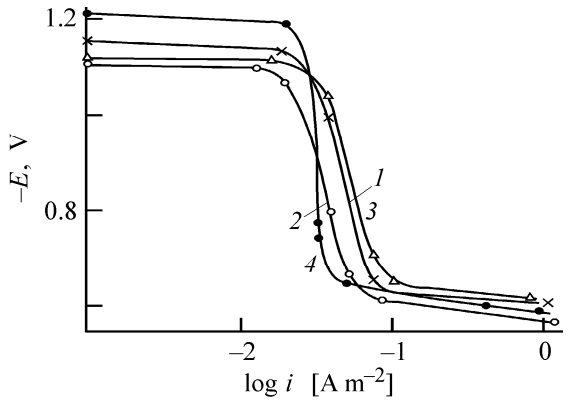

Fig. 2. Anodic polarization curves of Al–Mn (1.9%) alloys alloyed with cerium. (*E*) Potential and (*i*) current density; the same for Figs. 3, 4. Ce content (wt %): (*1*) 0.005, (*2*) 0.05, (*3*) 0.10, and (*4*) 0.50.

It is known that alloying of an aluminum alloy with cerium leads to an increase in the electrical and thermal conductivity of the alloy and improves its rollability in the hot state [5]. However, the influence exerted by cerium on the corrosion-electrochemical behavior of aluminum–manganese alloys remains to be elucidated. Therefore, the corrosion behavior of alloys of the Al–Mn–Ce system was examined in this study. Table 1 lists the results obtained in a study of alloys of this system in a 3% NaCl solution.

It should be noted that presence of manganese in an alloy results in that the aluminum grain becomes somewhat finer. Comparison of the results of the corrosion-electrochemical studies with the data of [5] demonstrates the following specific feature: as the content of cerium increases to 0.5%, the electrochemical parameters vary nonlinearly and reach the minimum values at 0.5% cerium. As the content of cerium increases, the free-corrosion potential shifts to more electronegative values. The corrosion potential E_{cor} first somewhat increases and then, at the maximum content of cerium, slightly shifts into the region of negative values. The passivation interval ΔE_{pas} of the aluminum–manganese alloy insignificantly changes within 0.10 V. It can be seen from the data in Table 1 that microalloying with cerium leads to a decrease in the corrosion rate of the aluminum–manganese alloy. The optimal, in the corrosion regard, amount of the cerium additive is 0.5%. As the content of cerium increases further, the corrosion current grows and, consequently, the corrosion resistance becomes poorer.

(up to 0.5%). It can be seen that the minimum dissolution current in the passivation region corresponds to the alloy with the maximum content of cerium (Fig. 2, curve *4*). The highest passivation-onset potential ($E_{pas.on}$) corresponds to the alloy with the maximum content of cerium. In this case, the passive region is rather stable and an increase in the content of cerium affects its width only slightly.

It is known that, owing to quite a number of properties, yttrium has found wide application in industry, metallurgy, and electronics [6]. Alloying with yttrium causes structural changes and thereby improves the mechanical properties and heat resistance of alloys. The results of a study of the corrosion-electrochemical behavior of an aluminum–manganese alloy (1.9% Mn) alloyed with yttrium are listed in Table 2.

It can be seen from Table 2 that addition of up to 0.1% yttrium to the aluminum–manganese alloy exerts an on the whole positive influence, which is due to the modification effect. The minimum corrosion currents are observed at the yttrium content in the range from 0.005 to 0.1%. The free-corrosion, pitting, repassivation, and corrosion potentials are shifted to more positive values. Alloys of this system have a rather wide and stable passivation region (ΔE_{pas} = 0.50 V). The potentials and corrosion current densities of the alloy of the system Al–Mn (1.9%)–Y (0.5%) nearly coincide with the similar parameters of the base alloy. The difference between the characteristic potentials is 0.10–0.20 V.

Figure 3 shows anodic polarization curves of an aluminum–manganese alloy of eutectic composition, alloyed with yttrium to 0.50 wt %. All the alloys of the compositions considered are well repassivated at potentials in the range 0.520–0.535 V.

It is known that intermetallic compounds (IMC) with structures of the types $ThMn_{12}$, Th_2Zn_{17}, and $LaMnAl_8$ are formed in the Al–Mn–La system. It has been found that binary compounds do not dissolve the third component [7].

Table 3 lists the results obtained in a study of the corrosion-electrochemical behavior of alloys belonging

to the Al–Mn (1.9%) system and alloyed with lanthanum to 0.50 wt %. It can be seen that lanthanum can shift the free-corrosion and pitting potentials to a more positive region. In this case, the corrosion potential remains nearly unchanged and the passivation interval becomes somewhat narrower. The zero-current potentials $E_{fr.cor}$ of alloys of this system are in the passive region, and, consequently, these alloys can be characterized as corrosion resistant. This conclusion is confirmed by the lower dissolution currents in the passivation region. Upon addition of lanthanum in amounts of up to 0.10%, the corrosion current decreases. And only at the maximum content of lanthanum (0.5%), the corrosion current increases and, accordingly, the corrosion rate grows.

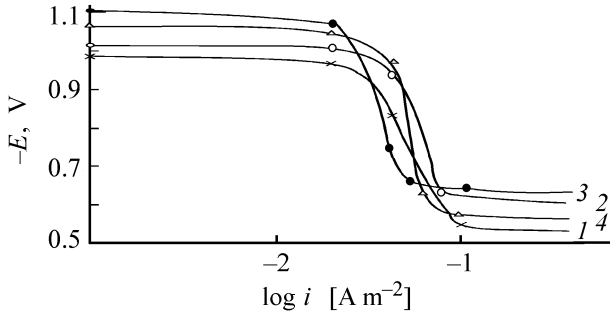

Fig. 4. Anodic polarization curves of Al–Mn (1.9%) alloys alloyed with lanthanum. La content (wt %): (*1*) 0.005, (*2*) 0.05, (*3*) 0.10, and (*4*) 0.50.

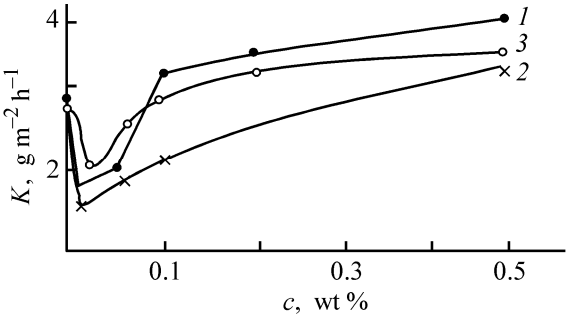

Fig. 5. Effect of the REM content *c* on the corrosion rate *K* of Al–Mn (1.9%) alloys. (*1*) Ce, (*2*) Y, and (*3*) La.

Figure 4 shows anodic polarization curves of an Al–Mn (1.9%) alloy alloyed with lanthanum, measured in a 3% NaCl solution. It can be seen that addition of lanthanum shifts the passivation-onset potential to more negative values. The alloys under study are passivated in the range 0.55–1.10 V, depending on the lanthanum content, and the currents of dissolution in the passivation region decrease as the La content increases.

Figure 5 compares dependences of the corrosion rate K (g m^{-2} h^{-1}) of an aluminum–manganese alloy in a 3% NaCl solution on the content c (wt %) of REM (Y, La, and Ce). It can be seen that all the curves are of the same type, with the minimum corrosion rate observed at a REM content of 0.01%. Further increase in the REM content leads to a rise in the corrosion rate.

The mechanical properties of the alloys were studied: ultimate tensile strength (temporal resistance

σ_t, MPa), yield point σ_y (MPa), and plasticity parameters, relative elongation δ (%) and contraction ratio ψ (%). Tests to determine the mechanical properties were performed on an R-5 tensile machine under a load of 1000–10 000 kg (GOST 1494–84). Table 4 presents the results of these tests. It can be seen that alloying with REM (Y, La, and Ce) does not improve the strength of aluminum–manganese alloys. The REM exert a stronger influence on the yield point, especially in the unannealed state. For example, the maximum value of the yield point is observed for the alloy of composition Al–Mn (1.9%)–Y (0.05%).

In the annealed state, the effect of REM is stronger for alloys alloyed with cerium and weaker for those alloyed with lanthanum. Analysis of plasticity values suggests that the relative elongation is more strongly affected by yttrium and cerium, especially for annealed alloys, and the contraction ratio ψ, by cerium in the concentration range under study.

Thus, the study of the mechanical properties of the alloys demonstrated that the aluminum–manganese alloy modified with yttrium (0.05%) and cerium or lanthanum in the concentration range 0.05–0.5 wt % can be used as a construction material with increased yield point. The effects of REM additives on the plasticity are diverse: the contraction ratio ψ increases upon alloying with 0.5% yttrium, 0.01–0.10% lanthanum, and 0.05–0.5% cerium.

CONCLUSIONS

(1) The free-corrosion potentials of the Al–Mn (1.9%)–Y (La, Ce) system are within the passivation region. Alloying of the aluminum–manganese eutectic with REM (Y, La, and Ce) shifts the $E_{fr.cor}$ and E_{pit} potentials to the region of more positive values.

(2) Alloys alloyed with cerium are repassivated at the same potential of 0.51 V (s.h.e.).

(3) The optimal content of REM (in a pure form or as a misch metal) for achieving an increased corrosion resistance of the aluminum–manganese alloy of eutectic composition is 0.01 to 0.05%. Alloys of these compositions can be recommended as a corrosion-resistant material for use in media causing the pitting corrosion.

(4) The role of REM (Y, La, and Ce) as an alloying additive to aluminum alloys consists in their modifying effect on the structure, which, on the whole, makes it possible to obtain an aluminum-based construction material with enhanced corrosion resistance.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Synthesis Conditions of Pyrocarbon Coatings on Their Corrosion Resistance in H_2SO_4–HNO_3 Oxidizing Mixture

S. D. Kurbakov

Received November 16, 2007

Abstract—Synthesis conditions of pyrocarbon coatings in a fluidized bed via pyrolysis of gaseous hydrocarbons from a CH_4–Ar mixture at temperatures of 1300–2000°C and from C_3H_6–Ar at 1200–1500°C were examined. The corrosion resistance of the pyrocarbon coatings in HNO_3–H_2SO_4 oxidizing mixture was studied.

DOI: 10.1134/S1070427208100169

Pyrocarbon, mostly in the form of coatings, has been of interest during many years. Having been an exclusively reactor material (protective coatings of microfuel elements of high-temperature gas-cooled nuclear reactors [1, 2]) during a long time, the material is gaining steadily expanding application areas: in the first place, these are burial of radioactive wastes, because pyrocarbon coatings show promise for prolonged insulation of a solidified waste from the corrosive effect of the environment [3], and biomedicine, including artificial heart valves [4]. Of particular importance is the role of carbon materials in heterogeneous catalytic processes [5]. The high corrosion resistance of pyrocarbon under the action of numerous chemical reagents places this material on an adequate place among protective coatings for chemical apparatus and matrices of carbon–carbon composites for various purposes [6, 7].

The aim of this study was to choose deposition conditions of pyrocarbon coatings with enhanced resistance to corrosive reagents, such as mixtures of concentrated acids HNO_3–H_2SO_4, which are intercalating agents for most of carbon-graphite materials [8].

Pyrocarbon coatings were produced on spherical zirconium carbide particles 400–600 μm in diameter in a fluidized bed via pyrolysis of gaseous hydrocarbons: from a CH_4–Ar mixture at temperatures of 1300–2000°C and C_3H_6–Ar at 1200–1500°C. The coatings were deposited in a fluidized-bed cylindrical-conical apparatus with a diameter of about 60 mm and a cone opening angle of 40°. The weight of portions of zirconium carbide particles was varied within the range 150–200 g. The overall flow rate of the gas mixture (argon with a hydrocarbon) was chosen so as to provide a bubble mode of particle fluidization (1500 ± 100 l h^{-1}).

Thus, pyrocarbon coatings obtained at 1300–2000°C from a CH_4–Ar mixture (CH_4 content ≤20 vol %) were named conditionally high-temperature (HTP) coatings, and those deposited from a C_3H_6–Ar mixture (C_3H_6 content ≤30 vol %), low-temperature (LTP).

Three basic structural elements are known for pyrocarbon coatings produced by pyrolysis: turbostratic structure, amorphous carbon, and higher-order supraatomic (supramolecular) formations [9, 10]. The main elements of the turbostratic structure are basal planes structurally similar to graphite planes. They are composed of six-membered aromatic rings (hexagons) of carbon atoms with the same interatomic distance (1.415 Å) as that in the graphite plane. A certain number of connected planes form a packet. In contrast to graphite, packets of the turbostratic structure have no mutual orientation of planes in a direction perpendicular to the *c* axis. In the strictly crystallographic sense, the packets cannot be attributed to crystallites as regards their structure, because they have no 3*D* ordering. Thus, the strict order exists for pyrocarbon only in the 2*D* plane. Nevertheless, the turbostratic pyrocarbon structure is conditionally named crystalline in the lit-

erature. According to published data [11–13], the interplanar spacings in packets of pyrocarbon crystallites are 3.36–3.44 Å, which substantially exceeds those in graphite (3.35 Å). The dimensions of turbostratic coherent scattering regions (CSR) (packets) are characterized [12, 13] by the packet thickness L_c and carbon layer width L_a:

$$L_c = 0.9\lambda/(d_{002}\cos\gamma),$$

$$L_a = 1.8\lambda/(d_{110}\cos\gamma),$$

where λ is the radiation wavelength; d_{002} and d_{110}, angular half-width of lines; and γ, Bragg angle.

Pyrocarbon coatings contain a set of packets of various sizes, and, therefore, the experimentally determined values of L_a, L_c, d_{002}, and d_{110} are statistic-average.

To characterize secondary structural formations appearing in the carbon material as a result of mutually matched stacking of carbon planes, the term "supramolecular structure," which reflects the essence of the polymeric organization of pyrocarbon, has been suggested with a rather good substantiation [9, 10].

An X-ray diffraction analysis (DRON-6 diffractometer) of the crystal structure of pyrocarbon demonstrated that the LTP and HTP coatings are polycrystalline. It was found (Fig. 1) that the interplanar spacing d_{002} of HTP coatings is weakly dependent on the deposition temperature. At 1300°C, d_{002} is independent of the CH_4 concentration, and at temperatures higher than 1800°C, a slight decrease in d_{002} is observed at CH_4 concentrations of 1–5 vol %.

For LTP coatings deposited in the range 1200–1500°C, d_{002} is independent of the deposition temperature and C_3H_6 concentration (Fig. 1). It is noteworthy that the absolute values of d_{002} substantially differ between LTP and HTP coatings.

As the deposition temperature of HTP coatings increases, the SCR dimensions L_a and L_c become larger (Fig. 2). L_a and L_c are nearly independent of the concentration. The shape of the SCR markedly changes on raising the deposition temperature. At 1500°C, the SCR diameter exceeds the SCR height, whereas at higher temperatures, the SCR changes and the L_c/L_a ratio increases.

The dimensions of the SCR of LTP coatings are independent of the deposition temperature (in the range 1200–1500°C) and C_3H_6 concentration (Fig. 2)

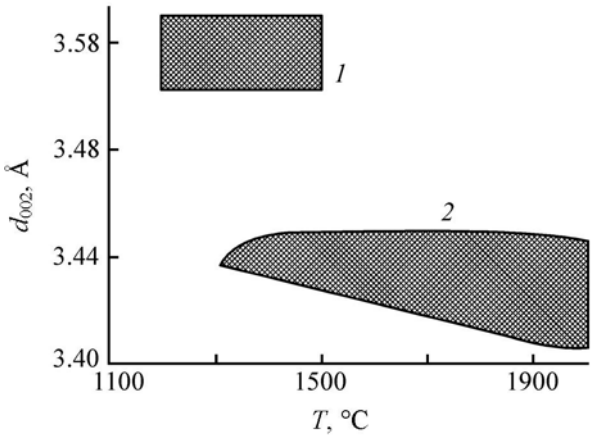

Fig. 1. Effect of the deposition temperature T on the interplanar spacing d_{002} of pyrocarbon coatings. Coating: (*1*) LTP and (*2*) HTP; the same for Figs. 2, 4.

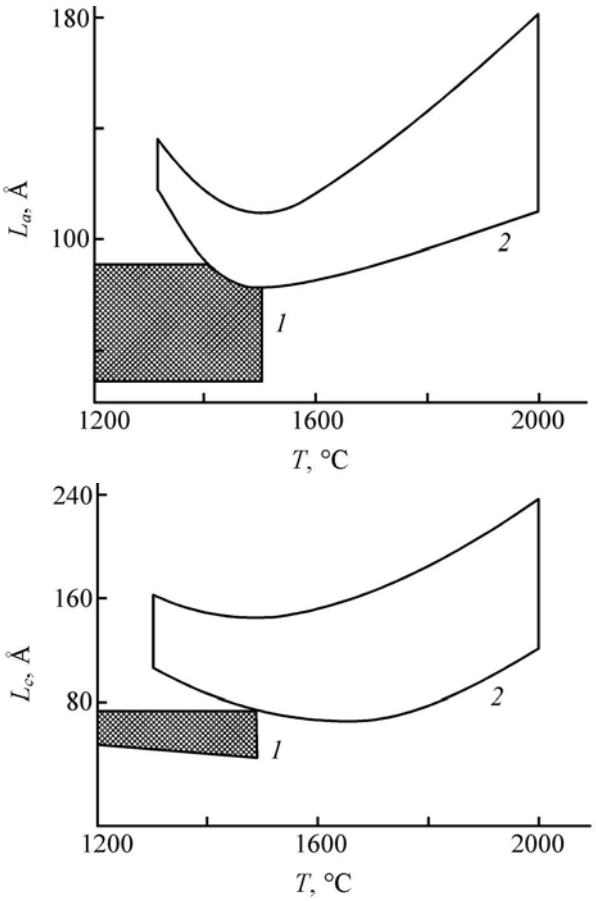

Fig. 2. Dimensions L_a and L_c of the SCR of pyrocarbon coatings vs. the deposition temperature T.

and 3–5 times smaller than those of HTP coatings. For LTP coatings, an SCR shape with $L_a > L_c$ is observed.

The chemical resistance of pyrocarbon coatings was studied under the action of a mixture of concen-

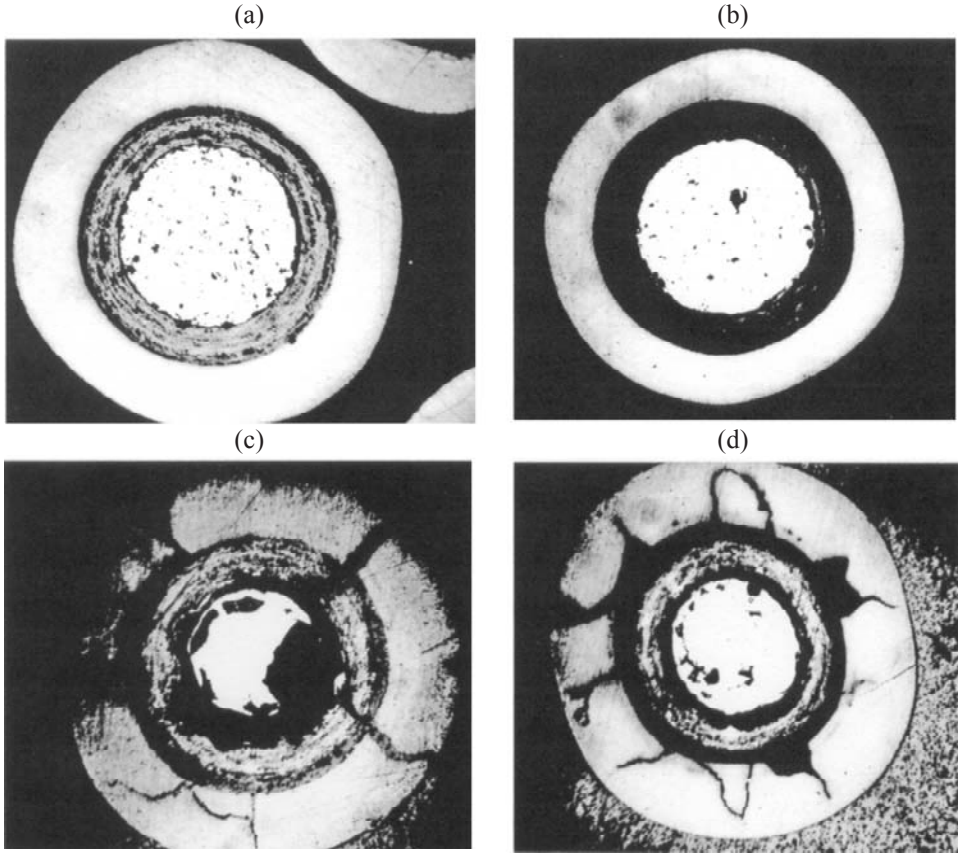

Fig. 3. Macrostructure of particles with LTP and HTP coatings after treatment with an H_2SO_4–HNO_3 oxidizing mixture. Magnification 70. Particles with a LTP layer produced from C_3H_6–Ar: (a) 10 vol % C_3H_6 and (b) 30 vol % C_3H_6; (c, d) particles with an HTP layer produced from C_3H_6. For explanations, see text.

trated acids HNO_3 and H_2SO_4. The oxidizing mixture was composed of 20 volume parts of 98% H_2SO_4 and 1 volume part of 60% HNO_3.

Pyrocarbon coatings were treated with the oxidizing mixture at a temperature of 20–25°C. Microspheres with coatings (150–450 pieces) on a stainless steel grid were placed in the oxidizing mixture and the coating surface was inspected under a microscope at regular intervals of time.

The treatment of most of batches with HTP coatings did not change the surface during the first 2–3 h. Then, particles increased in diameter by approximately 100 μm, after which the coatings cracked. It should be noted that some of samples with HTP coatings sustained a 25-h treatment with the mixture. Particles with LTP coatings did not show any visually observable changes upon an exposure exceeding 70 h. No changes in the morphology and macro-and microstructure of LTP coatings were observed, either (Figs. 3a, 3b).

Two main kinds of damage are characteristic of HTP coatings: formation of radial cracks in those cases when the optical anisotropy coefficient of pyrocarbon, found from the reflection of the plane-polarized light beam, did not exceed 1.20 and planar delamination (fragmentation) when the anisotropy coefficient exceeded 1.20 (Figs. 3c, 3d).

The stability of the coatings was judged from the appearance of first cracks on the particle surface after the beginning of the acid treatment. Figure 4a shows how the optical anisotropy of the coatings affects their resistance. It can be seen that, despite the differences in anisotropy, the LTP coatings are completely stable, whereas the stability of the HTP coating dramatically decreased as the optical anisotropy becomes higher.

The stability of the HTP coatings strongly depends on the deposition temperature (Fig. 4b): for pyrocarbon obtained at CH_4 concentration of 5–25 vol %, it decreases nearly linearly as the temperature is ele-

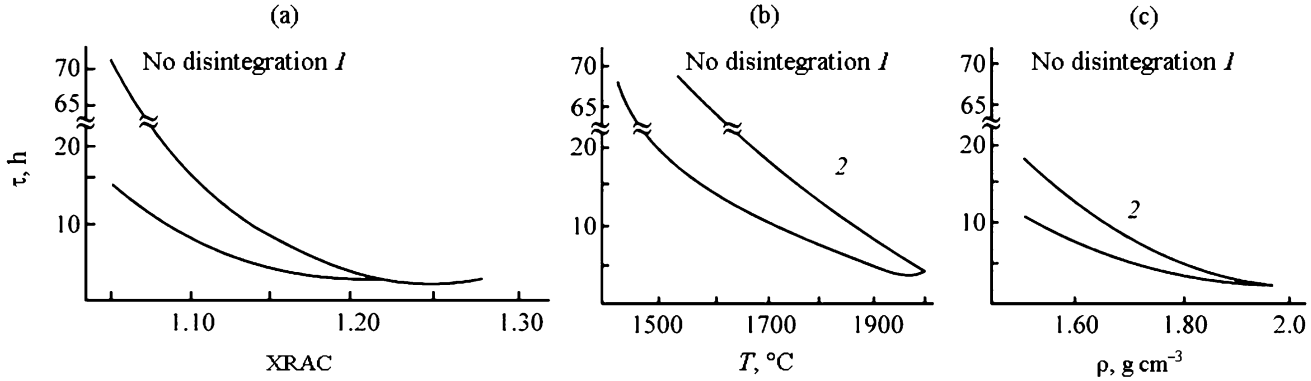

Fig. 4. Resistance of pyrocarbon coatings in an H_2SO_4–HNO_3 oxidizing mixture vs. (a) anisotropy, (b) deposition temperature T, and (c) density ρ. (τ) Time of treatment before cracking and (XRAC) X-ray anisotropy coefficient.

vated. The only exception are coatings deposited at 1500°C and a CH_4 concentration of 1.0 vol %. It should be noted that a clearly pronounced planar texture is characteristic of these coatings. The stability of HTP coatings steadily decreases as their density grows (Fig. 4c), whereas LTP coatings show no dependence of this kind.

The intercalating treatment of graphite, which leads to changes in its volume, was studied in [14]. It was demonstrated that the increase in the volume of a graphite sample upon its interaction with cesium is due to the formation of a number of layered compounds of the C_nCs type, where n = 8, 10, 24, 36, 48, 60, and 72. According to X-ray diffraction data, the process of intercalation of cesium atoms into the space between carbon layers resulted in an increase in the interlayer spacing from 3.35 to 5.94 Å.

The observed increase in the particle size upon an oxidative treatment is due to microscopic changes in pyrocarbon on the crystallite level. Powdered fragments of coatings were used in X-ray structural studies of samples before and after treatment with the oxidizing mixture. The results obtained are listed in the table.

After the treatment, the interplanar spacings d_{002} in HTP coatings (batches 13ts-4/1 and 11ts-4/1) became larger and remained somewhat increased even after coating fragments were annealed at 400°C in a flow of argon. Simultaneously, additional peaks appeared after the annealing. The corresponding interplanar spacings were 3.986 Å for both samples. The parameter d_{100} of the HTP coatings somewhat decreased after the treatment in the oxidizing mixture. The X-ray anisotropy coefficient increased for the 13ts-4/1 batch after all kinds of treatment, whereas for the 11ts-4/1 batch, it decreased from 1.322 to 1.162 after the oxidative treatment and then increased to 1.690 after the annealing. For both HTP coatings the dimensions of the SCR (L_a and L_c) increased after the oxidative and thermal treatments. For fragments of LTP coatings (2tsp batch), no changes in the crystal structure parameters was observed (see table).

In treatment of HTP coatings with the oxidizing mixture, the sulfo group of sulfuric acid can be introduced into the interplanar spacing of pyrocarbon to give the so-called graphite bisulfate. This process can be written as follows

$$nC + 3H_2SO_4 \rightarrow C_n^+[HSO_4]^-2H_2SO_4.$$

With account of the data in the table, analysis of the experimental results suggests the following pattern of structural changes in HTP coatings. In the course of treatment with the mixture of acids, boundaries of the SCR and crystalline formations are etched by nitric acid (oxidizing agent) and then sulfo groups are intercalated into the interplanar spaces of pyrocarbon. This gives rise to stresses, first in crystallites and then in crystalline formations (supramolecular organization of graphite-like carbon). These stresses tend to cleave the surface layer of the material along directions with weak bonds. When these stresses become sufficiently large, the coating suffers an irreversible deformation manifested in cracking.

In the review [15], the lowered hydrostatic compressibility of samples of a layered compound C_8Cs is attributed to a "rigidity" of the cesium bonding to carbon, caused by the strong overlapping of the wave functions of 6*s*-electrons of cesium and π-electrons of graphite along the *c* axis. Here, account should be taken of the fact that cesium is a donor intercalating agent.

The oxidizing mixture H_2SO_4–NHO_3 used in the study is an acceptor intercalating agent. The increased chemical activity of such a mixture will be primarily manifested toward unsaturated surface bonds. It is known that, for carbon-graphite materials in general and pyrocarbon in particular, produced at temperatures lower than 1500°C, the concentration of unsaturated bonds is 1.5–2 orders of magnitude higher than that for materials synthesized, e.g., at 1800–2000°C. Thus, it can be assumed that, collectivizing their "free" electrons with HNO_3, surface carbon atoms of LTP coatings create on the surface a protective layer that hinders penetration of sulfo groups to the material.

Presumably, the graphite structures of LTP coatings, with L_a of about 50 Å and L_c smaller than 80 Å, must exhibit an increased corrosion resistance with respect to the acid mixture H_2SO_4–HNO_3. In this case, the interplanar (interlayer) spacings within a packet of the pyrocarbon coating must be larger than those in graphite, i.e., 3.50 Å and more.

CONCLUSIONS

(1) It was found that high-temperature pyrocarbon coatings synthesized from a CH_4–Ar mixture at pyrolysis temperatures in the range 1300–2000°C are unstable toward the H_2SO_4–HNO_3 oxidizing mixture.

(2) It was shown that low-temperature pyrolytic coatings synthesized from a C_3H_6–Ar mixture at pyrolysis temperatures of 1200–1500°C are stable against the H_2SO_4–HNO_3 mixture, with their resistance increasing at interplanar spacings of 3.50 Å and more.

ACKNOWLEDGMENTS

The author thanks V.N. Kruglov for laborious work in X-ray structural analyses of samples and helpful discussions of the results obtained.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Contact Corrosion of Metals in Aqueous and Aqueous–Glycolic Solutions

V. N. Esenin and L. I. Denisovich

Nesmeyanov Institute of Organoelement Compounds, Russian Academy of Sciences, Moscow, Russia

Received March 13, 2008

Abstract—Corrosion behavior of aluminum, steel, and cast iron both without contact and in short-circuited aluminum–steel, aluminum–cast iron, steel–cast iron, and aluminum–steel–cast iron systems in fresh water, ethylene glycol, and its aqueous solutions of various compositions containing 5 to 95 vol % fresh water was studied.

DOI: 10.1134/S1070427208100170

Designs of various machines, heat exchangers, and other technological equipment include numerous joints of articles made of metals with different electrode potentials and other electrochemical properties. Under the action of the ambient and in the absence of insulation, these joints can work as galvanic cells, which can lead to enhanced "contact" or bimetallic corrosion [1–3] of one of the metals. The main construction metals in modern liquid cooling systems and, in particular, internal combustion engines and various heat-exchange apparatus are steel, cast iron, and aluminum [4], with the role of heat-carrying agents played by aqueous or aqueous-organic formulations [5]. Despite that the problem has long been known and an ample research work has been conducted, the choice and improvement of corrosion inhibitor formulations for purely aqueous and aqueous-organic heat carrying agents remain topical because of the permanently growing integral volume of the problem and increasingly stringent requirements to the quality and, primarily, reliability of the equipment. In this context, a systematic study of the contact corrosion of the metals mentioned above in purely aqueous and agueous–glycolic media was undertaken.

Ethylene glycol (EG) and agueous–glycolic solutions were chosen as organic solvents because EG-based solutions with low content of water are used in Extreme North regions as heat-carrying agents. Also widely applied at present are fire-resistant hydraulic liquids of the HFC class according to the classification by the International Standardization Organization (ISO). These liquids contain, in addition to water (30–50%), a di- or triatomic alcohol (ethylene glycol, most frequently) [6, 7]. It should also be mentioned that EG is frequently transported in the form of 95% aqueous solutions in winter [4], and in regions with warm and moderate climate, solutions of various compositions, with high content of water in EG, are used as heat-carrying agents.

Also important is the theoretical aspect of the study, because the unsystematic nature of hinders the behavior of electrochemically different metals in aqueous-organic media of various compositions research into fundamental understanding of the specific features of the contact corrosion of metals in aqueous-organic media [8].

The aim of the present study was to elucidate the role of the organic component in the corrosion processes under consideration.

EXPERIMENTAL

Planar samples (50 × 25 × 3 mm) of St.3 steel [GOST (State Standard) 380], cast iron GH-190 [VAZ (Volga Automobile Plant) Standard 52205], and aluminum alloy AK6M2 (GOST 1583) were preliminarily polished and degreased. Water from river basins of European Russia was modeled by dissolving 148 mg dm^{-3} of anhydrous sodium sulfate, 165 mg dm^{-3} of sodium chloride, and 138 mg dm^{-3} of sodium bicarbonate in distilled water. The temperature of experiments was 20 ± 2°C.

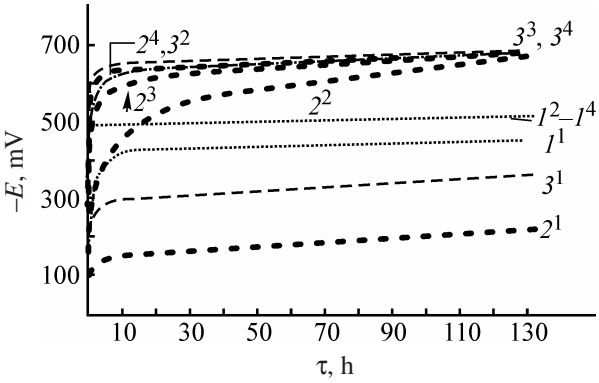

Fig. 1. Metal potentials E in the absence of contact vs. the time τ of testing in aqueous ethylene glycol solutions of various compositions (*1–3*) n. Metal: (*1*) aluminum, (*2*) steel, and (*3*) cast iron. H_2O content n (%): (*1*) 5, (*2*) 30, (*3*) 70, and (*4*) 100.

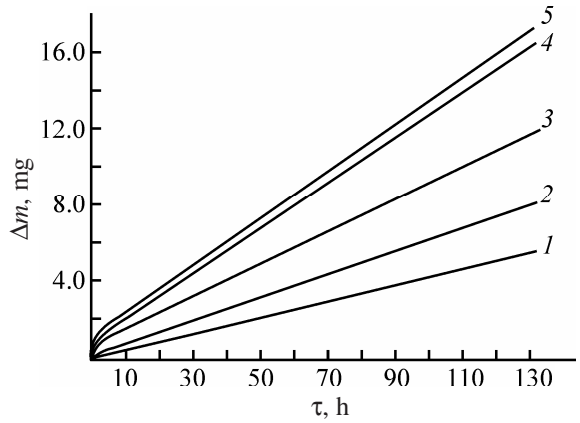

Fig. 3. Corrosion loss Δm by steel in the absence of contact vs. the time τ of testing in aqueous ethylene glycol solutions. H_2O content (%): (*1*) 50, (*2*) 70, (*3*) 85, (*4*) 95, and (*5*) 100.

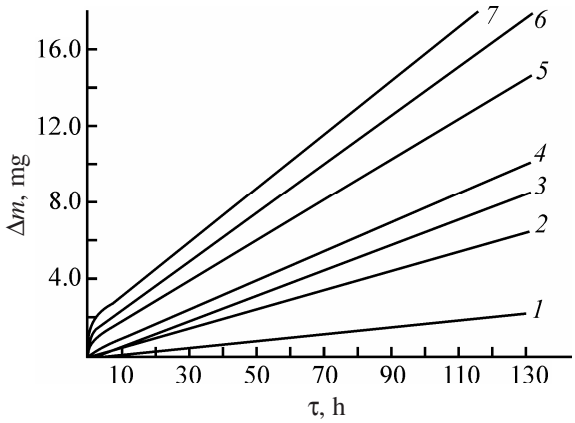

Fig. 4. Corrosion loss Δm by cast iron in the absence of contact vs. the time τ of testing in aqueous ethylene glycol solutions. H_2O content (%): (*1*) 5, (*2*) 30, (*3*) 50, (*4*) 70, (*5*) 85, (*6*) 95, and (*7*) 100.

The corrosion rate was evaluated by a change in the sample mass. The variation of the electrode potentials in the course of tests was monitored using a Shch-1413 high-input-resistance digital voltmeter relative to a silver chloride reference electrode. The electrical contact between metal plates was provided by an external low-resistance conductor. The distance between the electrodes in measurement of the electrode potentials of metals was 20–30 mm, because it has been shown previously [3] that the distance within this range has no effect on the characteristics under study.

In the absence of contact between the metals in purely aqueous and agueous–glycolic solutions, the potential of aluminum remains nearly unchanged in the course of time, and those of steel and cast iron shift to the negative region (Fig. 1), which is apparently due to gradual dissolution of these metals. This shift is the faster, the higher the water content of a solution. In the conditionally anhydrous ethylene glycol[1] and in agueous–glycolic solutions with a water content of up to 30 vol %, the mass of steel samples remained unchanged. Upon further dilution of the solutions studied, a rise in the steel dissolution rate was observed: it steadily increased with the water content and reached the maximum value on passing to the aqueous medium (Fig. 2).

In contrast to steel, cast iron starts to be corroded even upon minor additions of water (<5 vol %). However, on passing to more dilute EG solutions, the corrosion rates of cast iron and steel becomes somewhat closer (Fig. 2). According to mass change data for agueous–glycolic solutions containing EG in amounts of 50 vol % and more, the corrosion rates of steel and cast iron are constant (Figs. 3, 4). At higher water con-

[1] Water content of superior-quality EG should not exceed 0.1 wt % according to GOST 19 710.

Table 1. Initial (V_{in}) and steady-state (V_{st}) corrosion rates of steel and cast iron in purely aqueous and agueous–glycolic solutions of various compositions

Metal	Corrosion rate, g m^{-2} h^{-1}, at indicated H_2O content, vol %							
	70		85		95		100	
	V_{in}	V_{st}	V_{in}	V_{st}	V_{in}	V_{st}	V_{in}	V_{st}
Steel	0.055	0.032	0.090	0.045	0.130	0.063	0.167	0.068
Cast iron	0.070	0.041	0.100	0.051	0.135	0.064	0.185	0.074

centrations, these rates are at a maximum in the initial stage ($\tau \approx 1$–2 h), which corresponds to the also more pronounced change in the potentials of these metals (Fig. 1), and then, the corrosion rates decrease and reach the limiting value (Table 1).

By contrast, a slight increase in mass is observed for aluminum at any water : EG ratio. No traces of pitting were observed in EG and its solution containing 5% water. However, sites of local dissolution of aluminum appear as the content of water increases.

The dependence of the steel corrosion rate on the composition of the mixtures under study for the aluminum–steel and steel–cast iron pairs and for the contact polymetallic system aluminum–steel–cast iron is described by a curve similar to that obtained for individual steel samples (Fig. 5). In all the electrochemical systems studied, steel is not dissolved at water contents lower than 30%.

The rate of steel dissolution in the steel–cast iron pair decreases in a similar way, compared with the individual sample, because of the cathodic polarization of steel by cast iron and increases on passing from the contact polymetallic system aluminum–steel–cast iron to the aluminum–steel pair because of the anodic polarization by aluminum, which is not hindered in this case by the cathodic polarization by cast iron.

A more complicated situation is observed in analysis of the corrosion behavior of cast iron (Fig. 6). Minor additions of water (≤5 vol %) do not cause corrosion of cast iron in aluminum–cast iron and aluminum–steel–cast iron contact systems, but accelerate the dissolution of cast iron in the steel–cast iron pair.

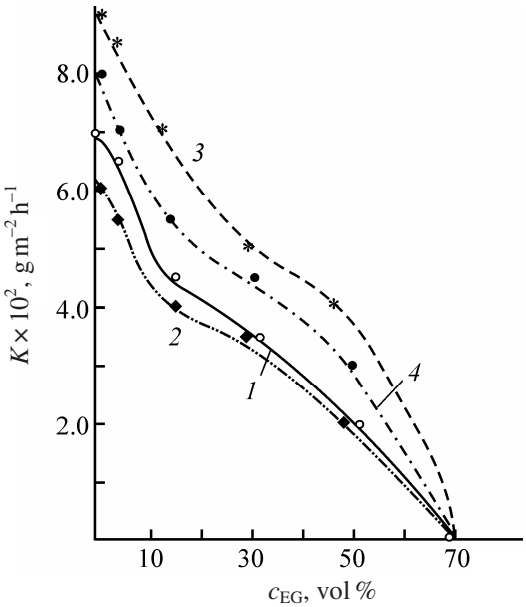

Fig. 5. Corrosion rate K of steel in the absence of contact vs. the composition of aqueous ethylene glycol solutions in various contact pairs. (*1*) Steel (without contact), (*2*) steel–cast iron, (*3*) aluminum–steel, and (*4*) polymetallic system aluminum–steel–cast iron.

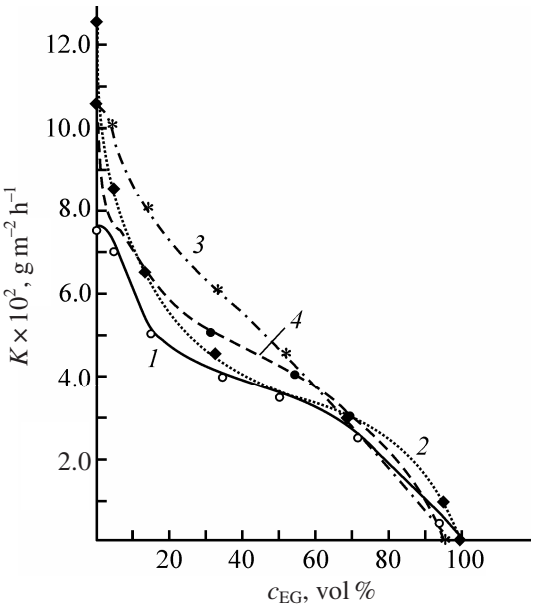

Fig. 6. Corrosion rate K of cast iron in the absence of contact vs. the composition of aqueous ethylene glycol solutions in various contact pairs. (*1*) Cast iron (without contact), (*2*) steel–cast iron, (*3*) aluminum–cast iron, and (*4*) polymetallic system aluminum–steel–cast iron.

Cast iron exhibits such a behavior because it is under cathodic protection by aluminum in concentrated EG solutions, and, in its contact with steel in the absence of aluminum, its dissolution is strongly promoted by the considerable anodic polarization by steel [9]. As the content of water increases, the corrosion rate of cast iron rapidly grows in all the contact systems studied and reaches the maximum value in the purely aqueous electrolyte. It should, however, be noted that an increase in the EG concentration from 30 to 70 vol % affects only slightly the dissolution rate of cast iron in the steel–cast iron pair (Fig. 6, curve *2*). By comparing the corrosion rates for the metals in the contact systems (K_{cont}) and for individual samples (K_{ind}), it is possible to evaluate the extent to which these contacts are hazardous by the acceleration coefficient $K_{acc} = K_{cont}/K_{ind}$ for different compositions of agueous–glycolic solutions. It can be seen in Fig. 7a that the corrosion hazard to steel in the aluminum–steel pair and in the contact polymetallic system aluminum–steel–cast iron increases with the content of EG; however, steel is not corroded in concentrated EG solutions containing 70 vol % and more [9]. The contact with cast iron is not hazardous to steel in the whole range of EG concentrations. By contrast, the acceleration coefficient for the aluminum–steel–cast iron system decreases as the EG concentration increases (Fig. 7b) and becomes zero at EG : H_2O = 95 : 5. The contact with steel is the most hazardous to cast steel in an aqueous solution: K_{acc} = 1.65. As the content of water is lowered to 70%, the acceleration coefficient decreases, passes through a minimum (K_{acc} = 1), and then again increases to reach a value of 1.4 at an EG content of 95%. In the directly opposite way varies the acceleration coefficient in the case of corrosion of cast iron in the aluminum–cast iron pair (Fig. 7b). The dependence has a maximum at an EG content of 15% and then K_{acc} steadily decreases as the EG concentration becomes higher.

The considerable difference in the corrosion behavior of cast iron from that of steel is probably due to its specific "raphitizing" selective corrosion, during which graphite inclusions uncovered upon ferrite dissolution form an increasingly developed system of microcathodes and, accordingly, accelerate the dissolution of the graphite phase to an increasing extent [9].

The high dissolution rates of steel and cast iron in solutions with high water content (Table 1) can be attributed to their surface state and its change on passing

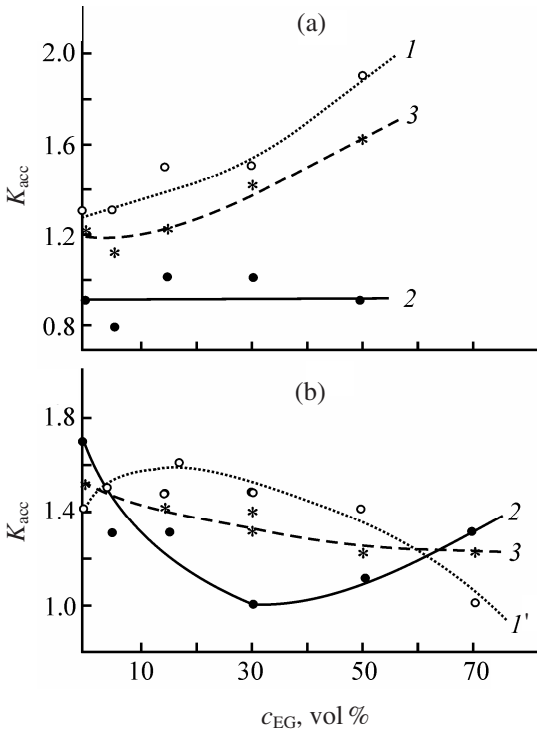

Fig. 7. Acceleration coefficient K_{acc} for (a) steel and (b) cast iron vs. the composition of aqueous ethylene glycol solutions in various contact pairs. (*1*) Steel–aluminum, (*1'*) cast iron–aluminum, (*2*) steel–cast iron, and (*3*) contact system aluminum–steel–cast iron.

from air into solution. It is known that the surface of iron, low-alloyed steels, and cast irons is covered by a thin protective film with an average thickness of 1–4 nm [10–12]. Within this "thickness," the counter gradients of the oxygen and iron concentrations are such that it is possible to state, with a certain degree of conditionality, that the composition and structure of the film pass from, approximately, Fe_2O_3 to Fe_3O_4, and further to FeO on their way to the unoxidized metal [13, 14]. The microheterogeneity of the intrinsic structure of all the three materials under study are of no independent interest in the given case. According to the preferable modern terminology, all of them belong to "mixed electrodes" in the wetted state.

Thus, in corrosion of steel in aqueous solutions, the anodic products (Fe^{3+} ions interact with hydroxide anions formed on the cathodic areas, with the subsequent oxidation of the soluble iron(II) hydroxide into the insoluble iron(III) hydroxide:

$$Fe^{2+} + 2OH^- \rightarrow Fe(OH)_2,$$

$$4Fe(OH)_2 + O_2 + 2H_2O \rightarrow 4Fe(OH)_3.$$

The formation of the insoluble $Fe(OH)_3$ does not hinder the electrochemical corrosion because rust is formed in the solution bulk, rather than on the anodic parts of the surface.

The initial corrosion rates of steel and cast iron in water and dilute EG solutions substantially exceed the steady-state values (by approximately a factor of 2.5 for water). This can be attributed to the adsorption properties of water. The primary interaction of water (having electron-donor properties) with coordination-unsaturated iron atoms yields surface complexes of the donor–acceptor type. For example, water molecules are involved in the anodic process of formation of hydrated iron ions and their transfer into solution, and the important part of this process is the donor–acceptor interaction of water with surface atoms of iron [15].

In the corrosion theory, water is commonly regarded as a reagent composed of separate molecules whose concentration in water and aqueous solutions is high and cannot control corrosion processes in metals, except corrosion under very thin films of purely aqueous electrolytes [16]. Meanwhile, according to the results of [17], liquid water is a structured system that can be regarded as an equilibrium mixture of associates and monomeric water molecules. At the same time, the interaction of water molecules with iron oxide present on the metal surface is considerably stronger than that between the molecules in their own phase. Water as an amphoteric oxide is similar to metal oxides and tends either to form compounds (hydroxides) with these oxides or to be incorporated into their crystal lattices [18].

The formation of an adsorption film of water on the surface of a solid yields dense multilayered associative structures. Owing to the formation of a network of hydrogen bonds, the structuring of water and formation of associates changes the physical properties of water [19]. This is characteristic to the greatest extent of its firmly adsorbed films. Thus, water can affect the corrosion of iron in aqueous solutions in two ways: free water molecules are a corrosion-active agent, whereas dense multilayered structures of water and, in particular, its adsorbed films can hinder the corrosion process to a certain extent via binding of separate molecules into associates and formation of a three-layer aqua-oxide-metallic surface phase [18].

The considerable decrease in the corrosion rates of steel and cast iron in aqueous ethylene glycol solutions (compared with water) is probably due to a change in the structure of the electric double layer upon adsorption of ethylene glycol. Because of the planar position on the electrode surface, ethylene glycol molecules can form a dense screening film [20], which presumably can hinder the corrosion process [21, 22]. The outer layer of iron and aluminum oxides can become thicker via incorporation of ethylene glycol molecules. As a result, a denser layer is formed and, together with the planar-oriented adsorbed layers of ethylene glycol, effectively hinders deterioration of the passive state of a metal [23].

A uniform corrosion of aluminum was observed in all of the contact systems under study in water, as well as for the aluminum–steel pair at a water concentration of 30% and for the aluminum–steel–cast iron contact polymetallic system in an agueous–glycolic solution containing 5% water. Owing to the presence of an oxide film on its surface, aluminum acted in water as a cathode with respect to both ferrous metals, with the result that the continuity of the oxide film was disturbed and aluminum dissolved via chemical interaction with water. Such a behavior of aluminum in water fundamentally differs from that in concentrated aqueous solutions of ethylene glycol, in which, in the end, aluminum undergoes anodic dissolution [9].

In anodic polarization of aluminum, its dissolution is accompanied by oxidation by water present in solution. In a solution containing 30% water, the dissolution rate somewhat exceeds the oxidation rate, whereas in a solution with 5% water, the rates of both processes are close, probably because of the high EG content, and the sensitivity of the analytical balance is insufficient for determining their difference.

The dissolution of aluminum in the steel–aluminum–cast iron contact system can probably be attributed to the considerable anodic polarization of aluminum by both steel and cast iron (Fig. 1). However, no traces of pitting corrosion were observed in any of the contact systems in the whole range of the EG concentrations used. In those cases when an increase in the mass of aluminum was observed, the nearly the same gains in mass in the aqueous electrolyte and aqueous EG solutions can probably be attributed to a low concentration of water, which is only sufficient for a discontinuous (permeable) film of a hydrated aluminum oxide $Al_2O_3 \cdot nH_2O$ ($n \geq 0$) [20, 21].

Under equilibrium conditions, a noticeable amount of coordination-bound hydroxo groups (OH^-) appears in the structure of a low-hydrated oxide. As the content of water increases, aqua groups (OH_2^-) also appear. Such an oxo-hydroxo phase can be regarded as the main

component of the passivating layer, which is in contact with both the metal and a solution under real conditions. The total thickness and the structure of the cover film are determined by the relative rates of the reaction of the metal with proton-containing fragments of water incorporated into the film and the disintegration of the film at the interface [24]. In anhydrous ethylene glycol, no changes in the mass of aluminum were observed under similar conditions. The steady-state corrosion rates of aluminum in purely aqueous and agueous–glycolic solutions containing 5 and 30% water are listed in Table 2.

Comparison of the results describing the corrosion behavior of the metals under study in purely aqueous [29] and agueous–glycolic solutions can reveal the effect of their composition on the corrosion processes. On passing from purely aqueous electrolytes to aqueous EG solutions with EG content of 5 to 95%, the corrosion rates of steel and cast iron decrease in all of the contact systems studied. It can be seen from Figs. 2, 5, and 6 that the corrosion rates of the metals steadily decrease as the EG content of an agueous–glycolic solution increases. In addition, steel does not undergo uniform corrosion in steel–aluminum and steel–cast iron contact pair or in the steel–aluminum–cast iron ternary system at a content of water in ethylene glycol lower than 30% (Figs. 2, 5). In water, aluminum acts as a cathode with respect to both ferrous metals, which led to reduction of its protective oxide film and subsequent dissolution via chemical interaction of aluminum with water. Such a behavior of aluminum in water differs from that in aqueous solutions containing 5 to 50% EG, in which it also serves as a cathode with respect to steel and cast iron and does not undergo uniform corrosion.

A somewhat different behavior was observed for aluminum in pair with steel in 50% EG, in which aluminum underwent a short-time anodic dissolution. It was found that, at 5% water in EG, aluminum behaves in all of the systems studied as an anode with respect to steel and cast iron, but undergoes anodic dissolution only in the aluminum–steel–cast iron contact system. In EG solutions containing 30% water, aluminum also anodically dissolves when in contact with steel.

As already noted, the increase in the mass of aluminum is probably due in all other cases to formation of surface films composed of hydrated aluminum oxide and iron that passed to the metal surface from solution via cathodic reduction of Fe^{2+} cations by aluminum.

Table 2. Steady-state corrosion rate V_{st} of aluminum in purely aqueous and agueous–glycolic solutions of various compositions

Contact system	H_2O content, vol %	Corrosion rate g m^{-2} h^{-1}
No contact	5	0.0
	30	0.0
	100	0.0
Aluminum–steel–cast iron	5	0.007
	30	0.0
	100	0.013
Aluminum–steel	5	0.0
	30	0.003
	100	0.012
Aluminum–cast iron	5	0.0
	30	0.0
	100	0.010

The possible explanation for the increase in the corrosion rates of steel and cast iron with the content of water in agueous–glycolic solutions is that, instead of the dense outer layers of iron oxides formed via incorporation of EG molecules [23], three-layer aqua-oxide-metallic surface phases [18, 25] start to predominate on the surface of steel and cast iron. This favors disruption of the passive state of the metals. In addition, the effect of free water molecules that are not bound yet into dense multilayered structures and, therefore, are corrosion-active agents, starts to be manifested in dilute EG solutions (5–30%) in early stages of metal corrosion. It is the interaction of monomeric water molecules with the iron surface that predetermines the high initial corrosion rate of the metals, compared with the steady-state values in these solutions and water (Fig. 3, curves *2–5*; Fig. 4, curves *4–7*).

CONCLUSIONS

(1) On passing from purely aqueous electrolytes to aqueous solutions containing 5 to 95% ethylene glycol, the corrosion rates of steel and cast iron decrease, and at a <30% content of water in ethylene glycol, steel does not undergo uniform corrosion in any of the contact systems studied.

(2) The most corrosion-hazardous contact systems in the solutions studied are the following: for steel,

aluminum–steel pair in a 50% ethylene glycol solution; for cast iron, aluminum–cast iron and steel–cast iron pairs in dilute aqueous solutions of ethylene glycol (5%); and for aluminum, all the systems under study in aqueous solutions.

(3) In all of the systems studied, aluminum behaves as a cathode in aqueous and dilute solutions of ethylene glycol, and as an anode, in solutions with high content of ethylene glycol.

(4) The difference in the behavior of the metals being tested in purely aqueous and agueous–glycolic solutions of various compositions (5–95% H_2O) is due both to the specific surface state of iron in air and to structural changes in the electric double layer upon adsorption of ethylene glycol whose molecules can form a dense screening film owing to their planar position on the electrode surface.

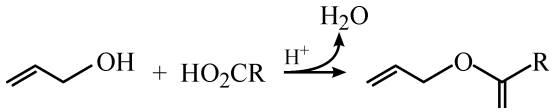
Abstract—Synthesis of norbornenyl methyl esters of a number of haloacetic acids via [4+2] cycloaddition of cyclopentadiene to allyl esters of these acids was examined. The yield and isomer composition of the synthesized compounds were examined in relation to the reaction conditions, and the best conditions for their preparation were found.

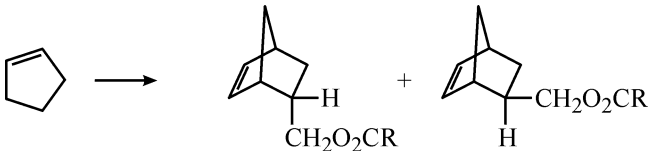


DOI: 10.1134/S1070427208100182

The structure of bicyclo[2.2.1]heptane, or norbornane, is a basis of many important natural compounds like borneal, camphor, etc. [1]. Similarly to norbornane and adamantane moieties, the norbornene moiety is a part of amines, many of which are medical preparations [2].

Significant interest in norbornene compounds also stems from their availability increased due to improvement of diene synthesis techniques. In most cases, this reaction does not involve side processes, which makes it possible to reveal factors governing the rate, direction, and equilibrium of the process with and without catalysts [3].

Halogenated functionally substituted norbornenes are good synthons for preparation of important intermediate halogenated sterically hindered phenols [4–8]. These compounds are also suitable as stanting materials for preparation of α-diketones and γ-lactones [9–12].



This study continues a series dedicated to synthesis of halogen-containing esters of norbornene compounds [13–16]. Here, we prepared bicyclo[2.2.1]-hept-5-enylmethyl esters of a number of haloacetic acids by the reaction of cyclopentadiene (CPD) with allyl esters of haloacetic acids **11–19**. The allyl esters **10–18** were synthesized by the well-known technique of esterification of corresponding acids **1–9** with allyl alcohol

R = CH_2Cl (**1**, **10**); $CHCl_2$ (**2**, **11**); CCl_3 (**3**, **12**); CH_2Br (**4**, **13**); $CHBr_2$ (**5**, **14**); CBr_3 (**6**, **15**); CF_3 (**7**, **16**); CH_3–CHCl (**8**, **17**); CH_2Cl–CH_2 (**9**, **18**).

Table 1 lists the physicochemical parameters of the starting allyl esters (**10–18**).

The target products (**19–27**) were prepared by [4+2] cycloaddition of CPD to allyl esters of haloacetic acids (**10–18**) by the scheme

R = CH_2Cl (**19**), $CHCl_2$ (**20**), CCl_3 (**21**), CH_2Br (**22**), $CHBr_2$ (**23**), CBr_3 (**24**), CF_3 (**25**), CH_3–CHCl (**26**), CH_2Cl–CH_2 (**27**).

The reaction was carried out at temperatures within 100–180°C in the course of 6–10 h at the diene-to-dienophile molar ratio of 1 : (1–4).

Table 2 lists the physicochemical characteristics of the compounds synthesized.

The yield and isomer composition of adducts **19–27** were examined in relation to various reaction parameters (temperature, time, addend ratio). The results are presented in Table 3.

It is seen from Table 3 that, as the temperature increases from 100 to 160°C, the yield of adduct **19** grows from 7.4 to 56.65%. Further increase in temperature (to 180°C) causes a decrease in the yield. A possible reason is formation of a bis-adduct based on compound **19**.

The best conditions for formation of adduct **19** are as follows: temperature 140°C, reaction time 6 h, and diene : dienophile ratio 1:1.5. With increasing temperature, the *endo* selectivity of the reaction of synthesis of adduct **19** decreases from 85 to 61%, which can be associated with conversion of the *endo* isomer to a thermodynamically more advantageous *exo* isomer at a high temperature.

Under similar optimal conditions, we carried out diene condensation of CPD with other allyl esters of haloacetic acids. The yield of the adducts varied within 50.92–87.6%; the highest yield was observed for allyl tri-

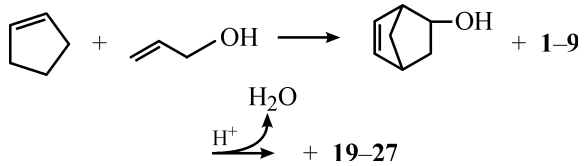

Table 3. Yield and isomer composition of esters **19–27** in relation to the conditions of the reactions of CPD with allyl esters of haloacetic acids **10–18**

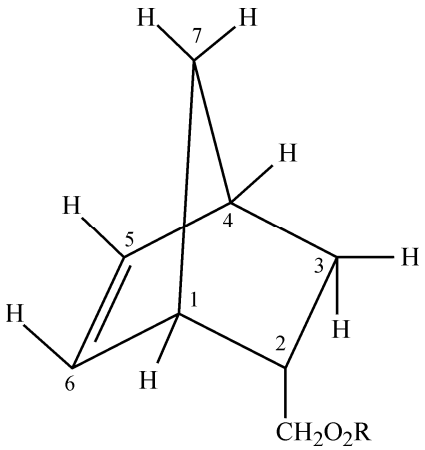
fluoroacetate **16** (87.6%), and the lowest, for allyl ester of tribromoacetic acid **15** (29.63%).

Comparative examination showed that the highest *endo* selectivity was observed in the reaction of CPD with allyl ester of tribromoacetic acid **15** (87%).



The composition and structure of the synthesized compounds **19–27** were proven by counter synthesis. First, by the technique described in [17] we carried out condensation of CPD with allyl alcohol into 2-hydroxymethylbicyclo[2.2.1]hept-5-ene **28** whose esterification with haloacetic acids by the well-known technique yielded the corresponding esters **19–27**:

All the physicochemical data obtained by both techniques for compounds **19–27** are identical.

The composition and structure of adducts **19–27** were confirmed by IR and ^{1}H NMR spectra. The IR spectra of the bicyclic esters synthesized contain characteristic signals of the C=O-group at 1730–1750 cm^{-1} and of the C–O ester group at 1000–1275 cm^{-1}. The bands of the carbon–chlorine bond are observed for chlorine-containing compounds in low-frequency spectral regions: 750, 760, 780, 760, and 770 cm^{-1} for compounds **19–21**, **7**, and **27**, respectively. The IR spectra of bromine-containing esters **22–24** contain intense bands associated with C–Br vibrations at 650–600 cm^{-1}. The ν_{C-F} band of ester **25** is observed near 1050 cm^{-1}. The absorption bands of the ethylene moiety in the norbornene ring lie at 1570–1555 and 3060–3045 cm^{-1} ($\nu_{C=C}$, ν_{C-H}).

The ^{1}H NMR spectra of esters **19–27** contain signals from protons of the double bond in the norbornene ring (H^5, H^6), manifested at 6–6.25 ppm as a multiplet, and are characterized by spin-spin coupling constants $J_{5,6}$ of 7.0 Hz. The H^3 (2H) protons give multiplet signals at high fields with a chemical shift δ of 0.7–1.2 ppm. The multiplet associated with the H^2 proton is observed at δ of 2.5 ppm and is characterized by the constant of spin-spin coupling with the H^3 proton, $J_{2,3}$ of 9.6 Hz. The H^1 and H^4 protons are chemically equivalent and give multiplet signals at δ of 2.70–2.85 ppm. The methylene protons H^8 (CH_2O group) give multiplet signals at δ of 4.15–3.95 ppm:

The isomer composition of esters **19–27** was determined by gas–liquid chromatography.

EXPERIMENTAL

The IR spectra were recorded on a UR-20 spectrophotometer at 4000–400 cm^{-1} for thin films or KBr pellets. The ^{1}H NMR spectra were measured on a BS-487B Tesla radiospectrometer (working frequency 80 MHz) for solutions in CCl_4, with HMDS as internal standard. The chromatographic analysis, as well as determination of the purity of the compounds synthesized, were carried out on an LKhM-8 MD chromatograph with a thermal-conductivity detector on a 300×0.3 cm column packed with 5% PEGS on Dinokhrom; carrier gas helium; flow rate 40 cm^3 min^{-1}; column temperature 155, and evaporator temperature 240°C.

The initial allyl esters of halogenated acetic acids **10–18** were obtained by a well-known technique via esterification in the presence of 5% H_2SO_4 as the catalyst. Upon completion of the reaction, the reaction mixture was washed with water, dried over $MgSO_4$, and distilled.

Bicyclo[2.2.1]hept-5-enyl methyl monochloroacetate 19. A mixture of 14.17 g (0.15 mole) of allyl monochloroacetate **10** and 6.6 g (0.1 mole) of freshly distilled CPD in the presence of hydroquinone was heated at 140°C for 6 h in a sealed ampule. Vacuum distillation yielded 12.69 g (55.25%) of adduct **19**, bp 95°C (1 mm Hg), n_D^{20} 1.4930, d_D^{20} 1.1723. IR spectrum, ν, cm^{-1}: 1735 (C=O), 1100 (C–O), 750 (C–Cl), 1755 (C=C). Elemental analysis:

Found, %: C 59.67; H 6.24; Cl 17.43.
Calculated, %: C 59.95; H 6.48; Cl 17.71.

2-Hydroxymethylbicyclo[2.2.1]hept-5-ene **28** was prepared by condensation of CPD with allyl alcohol by the technique described in [17]. A counter synthesis of esters **19–27** was carried out by esterficiation of bicyclic alcohol **28** with corresponding carboxylic acids **1–9** by the known technique. All the physicochemical characteristics of esters **19–27** prepared by counter synthesis are identical to the data of the same compounds obtained by condensation of CPD with esters **10–18**.

CONCLUSION

Norbornenyl methyl esters of a number of haloacetic acids were synthesized by [4+2] cycloaddition of cyclopentadiene to allyl esters of these acids. With increasing temperature, the total yield of the adducts tends to grow, and the stereoselectivity, to decrease. The best conditions for preparation of the compounds synthesized were found.

Abstract—Descriptive kinetics of synthesis of tetraacetylethylenediamine by acylation of diacetylethylenediamine with acetic acid anhydride was examined. The apparent rate constants of the process were obtained, and a mathematical model adequately describing the process was constructed.

DOI: 10.1134/S1070427208100194

In recent years, the developmental efforts in detergent chemistry have been mainly focused on a search for, and preparation of new composite systems and additives to provide a highly efficient bleaching and removal of contaminations from fabrics at as low temperatures as possible. Among such additives is tetraacetylethylenediamine (TAED), a low-temperature peroxide bleaching activator [1, 2].

Tetraacetylethylenediamine is a typical representative of the class of polyacylated aliphatic diamines, which is produced by acylation of diacetylethylenediamine (DAED) with acetic acid anhydride (AAA). The procedures for preparation of TAED were described in detail in patents [3–5], the mechanism and kinetics of the process were disregarded. At the same time, it is known that acylation of DAED into TAED involves formation of an intermediate, triacetylethylenediamine (TrAED) [6]:

Hence, for simulating the commercial process of DAED acylation, we examined the macrokinetic relationships. To this end, we carried out a series of kinetic experiments with varied DAED : AAA molar ratio (1 : 6.5; 1 : 8.5; 1 : 17) and temperature (120 and 140°C).

EXPERIMENTAL

To study the formal-kinetic aspects of DAED acylation and TAED deacylation, we used a three-necked temperature-controlled flask equipped with a mechanical stirrer, thermometer, and reflux condenser. The structure of the reaction mass was analyzed by gas–liquid chromatography on a Kristall 2000 chromatograph with a flame-ionization detector and a 30 m × 0.53 mm CPS sil-5CB capillary column in the column-temperature-programming mode (initial temperature

100°C, 5 min; heating to 240°C at a rate of 12 deg min^{-1}; final temperature 240°C, 10 min) with nitrogen as carrier gas.

The necessary amount of AAA (or AA in the case of TAED deacetylation) was placed in the flask at room temperature and heated to the desired temperature, whereupon the calculated amount of DAED (or TAED) was introduced under agitation. The instant when mixing of the reactants was complete was taken as the reaction onset time.

At regular intervals of time (15 or 30 min) during 6 h, the reaction mass was sampled and samples were placed in a cooled solvent (dioxane) used in an amount sufficient for terminating the reaction, and the reaction mass was analyzed by gas–liquid chromatography. Using test mixtures, we showed that no side reactions proceed under the chromatographic conditions. Each sample taken was subjected to at least three replicated measurements.

The derived concentration values were used for plotting the primary kinetic curves and calculating the apparent rate constant of the reaction.

The kinetic data were processed by the regression analysis procedure using Table Curve Windows V1.10 software.

Statistical processing of the measurements results was carried out by the least-squares and regression analysis procedures; the confidence interval (error corridor) was calculated under a homogeneous reproducibility condition [7].

Using the concentration values derived at different molar ratios of the reactants [DAED : AAA = 1 : (6.5–17)] and temperatures (120–140°C), we plotted the primary kinetic dependences $c = f(\tau)$, one of which is shown in Fig. 1.

An analysis of the processed experimental data (Figs. 2, 3) showed that the DAED acylation by acetic acid anhydride can be described by the pseudo-first order reaction model.

As can be seen from Fig. 3, the semilogarithmic anamorphoses are straight lines with breaks. This pattern indirectly evidences that the DAED acylation by acetic acid anhydride includes two stages. The first stage consists in the formation of TrAED, and the second, in the acylation of TrAED to TAED; the rate of the first stage exceeds that of the second stage.

Analysis of the primary experimental curves (Fig. 1) suggests that the stage of acylation of TrAED to

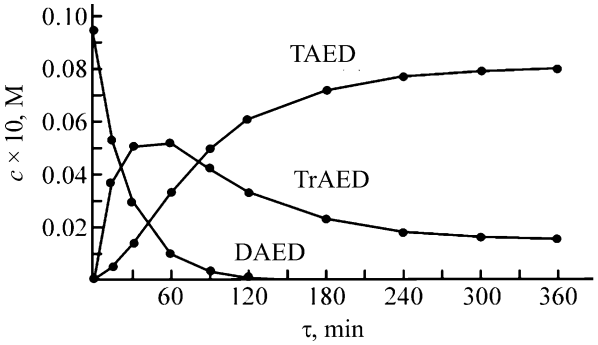

Fig. 1. Primary experimental curves of the DAED acylation by acetic acid anhydride at 140°C and initial molar ratio DAED : AAA = 1 : 8.5. (*c*) Concentration and (τ) time.

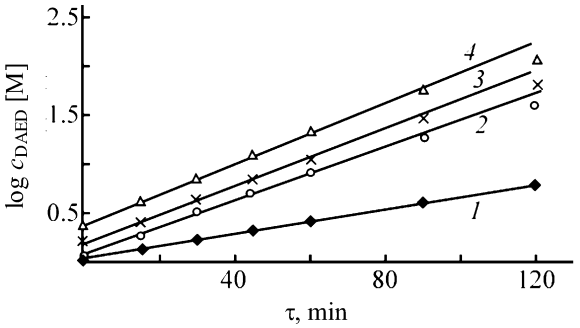

Fig. 2. Semilogarithmic plot of c_{DAED} vs. time τ. Initial molar ratio DAED : AAA, *T*, °C: (*1*) 1 : 8.5, 120; (*2*) 1 : 8.5, 140; (*3*) 1 : 6.5, 140; and (*4*) 1 : 17, 140; the same for Fig. 3.

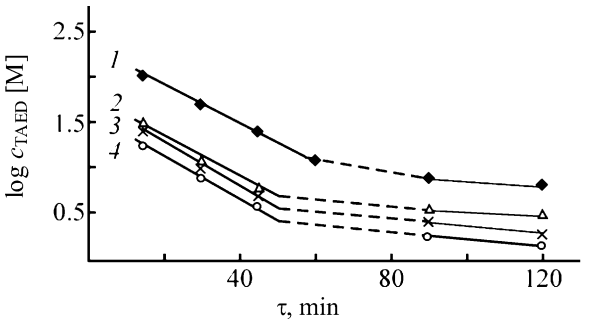

Fig. 3. Semilogarithmic plot of c_{TAED} vs. time τ.

TAED is reversible, and chemical equilibrium is eventually attained in the acylation reaction. Our experiments were carried out under nearly industrial conditions, for which reason we used 97% acetic acid anhydride. In the experiments carried out under a 8.5-fold molar excess of acetic acid anhydride over DAED, the molar ratio of the components of the DAED : AAA : AA reaction system at the initial instant of time was 1 : 8.5 : 0.4 mole, respectively. After the equilibrium was established in the system, the molar ratio of the components of the reaction mixture TrAED : TAED : AAA : AA was 0.2 : 0.8 : 6.7 : 2.2. This can

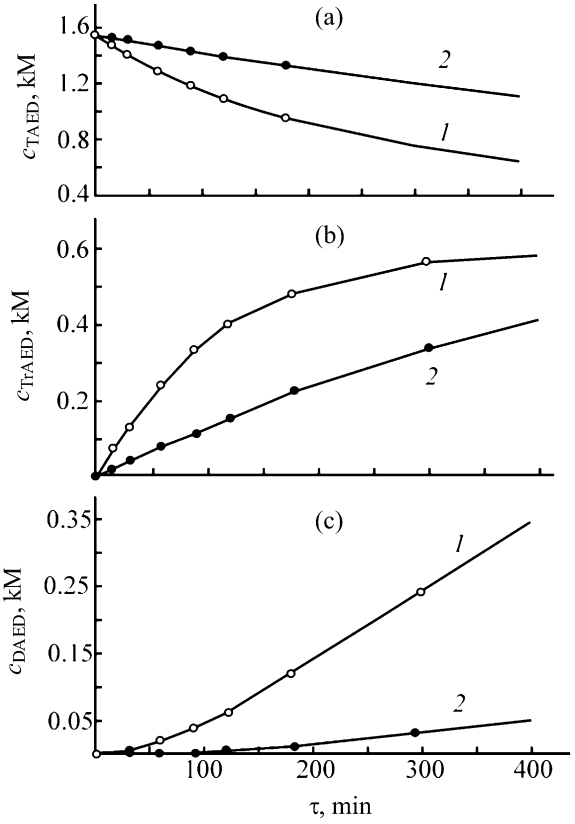

Fig. 4. Variation of the concentration c of (a) TAED, (b) TrAED, and (c) DAED with time τ. T, °C : (*1*) 125 and (*2*) 110.

be attributed to occurrence of a reverse reaction between the TAED acylation product and acetic acid formed during the reaction.

The reversibility of the reaction in the case of TrAED acylation by acetic acid anhydride was confirmed experimentally by the appearance of the peak of acetic acid anhydride in the chromatogram recorded for the reaction of TAED with acetic acid.

Thus, the DAED acylation by acetic acid anhydride is a two-stage process; the second stage of acylation of TrAED to TAED is reversible, which is responsible for the not very high (≤84%) yield of the reaction product, TAED. Naturally, each of the stages includes a series of chemical transformations. Therefore, it is expedient to describe the kinetics in terms of the concentration and yield of the target product, using the known dependences for two first-order reactions of the type

$$A \xrightarrow{k_1} B \underset{k_3}{\overset{k_2}{\rightleftarrows}} C.$$

The variation of the concentration of the substances can be described by the dependences [8]

$$a_0 = c_A + c_B + c_C,$$

$$c_A = a_0 e^{-k_1 t},$$

$$c_B = c_{B\infty} + (k_2 + k_3 - k_1)^{-1}\{a_0(k_1 - k_3)e^{-k_1 t} - [k_2 c_{B\infty} - c_{C\infty}(k_3 - k_1)]e^{-(k_2 + k_3)t}\},$$

$$c_C = c_{C\infty} - (k_2 + k_3 - k_1)^{-1} \times \{a_0 k_2 e^{-k_1 t} - [k_2 c_{B\infty} - c_{C\infty}(k_3 - k_1)]e^{-(k_2 + k_3)t}\},$$

where a_0 is the initial concentration of substance A, M; c_A, c_B, c_C, running concentrations of the initial, intermediate, and final compounds, respectively, M; and $c_{B\infty}$, $c_{C\infty}$, equilibrium concentrations of the intermediate and final compounds, respectively, M.

Analysis of the plots suggests that these dependences cannot adequately describe the experimental data. This is apparently due to the occurrence of a more complex process that cannot be described by dependences for first-order reactions.

For more detailed description of the acylation process, we performed a set of kinetic experiments on TAED deacylation by acetic acid at temperatures of 110–125°C under a significant excess of acetic acid (TAED : AA = 1 : 7). Figure 4 presents the primary experimental curves for the upper and lower limits of the temperature range examined.

A kinetic description of the DAED acylation by acetic acid anhydride is a mathematically complex procedure. Hence, we applied a special software, namely, DesK-Pro software available from Khiminform Private Company [9], used for construction of descriptive kinetic models and reactor modeling.

Descriptive kinetic models are suitable for reactions proceeding in batch, semicontinuous, or continuous reactors operating under various heating conditions and for simulation and optimization of processes.

The construction of these models requires that the initial hypothesis about the chemical nature of the reactions should be formulated, experimental data on the concentration responses be available, and basic properties of substances (thermal capacity and density as functions of temperature and molecular weight) be known.

Descriptive concentration models describe the reaction mechanism in detail. These models are based on the generalized law of mass action (GLMA) which states that the rate of a stage is proportional to the product

of the concentrations raised to arbitrary powers (orders). A special case of the law of mass action is the exact law of mass action (ELMA), in which the orders coincide with the stoichiometric coefficients.

A multi-stage reaction is described by the stoichiometric scheme

$$\sum_{i=1}^{N}(\beta_{ji}-\nu_{ji})A_{ji}=0;\quad j=1,...,M, \tag{1}$$

where the rate of jth stage is set by the expression

$$r_j=k_j\prod_{(i)}[\mathrm{A}_{ji}]^{\nu_{ji}}\quad\text{for GLMA and}$$

$$r_j=k_j\prod_{(i)}[\mathrm{A}_{ji}]^{n_{ji}}\quad\text{for ELMA;}$$

$$j=1,\ ...,\ M, \tag{2}$$

and the rate at which the concentration of ith component changes is described by the equation

$$\frac{\mathrm{d}[\mathrm{A}_i]}{\mathrm{d}t}=\sum_{(j)}(\beta_{ji}-\nu_{ji})r_j, \tag{3}$$

where ν, β are stoichiometric coefficients; r, rate of a stage, mol m^{-3} s^{-1}; k, rate constant of the stage, $k(T) = k_0\exp(-E/RT)$; k_0, pre-exponential coefficient; E, activation energy, kJ mol^{-1}; R, gas constant, J mol^{-1} K^{-1}; [A], concentration of substance A, mol m^{-3}; and t, time, s.

The model is supplemented by the appropriate initial conditions and observation model, a set of equations relating the rates of stages to the observed responses (concentration, heat or gas evolution, etc.) :

$$\frac{\mathrm{d}Q}{\mathrm{d}t}=\sum_{(j)}Q_j^{\infty}r_j;$$

$$\frac{\mathrm{d}G}{\mathrm{d}t}=\sum_{(j)}G_j^{\infty}r_j;$$

$$[A_{ji}], \tag{4}$$

where Q is the specific heat evolution, kJ mol^{-1}; Q^{∞}, specific heat effect of a stage, kJ mol^{-1}; and G^{∞}, specific final gas evolution in the stage, mol mol^{-1}.

A specific feature of complex kinetic models is that they are substantially nonlinear in the parameters. Hence, the general approach to solving the inverse kinetic problem (estimating the model parameters) is based on nonlinear optimization.

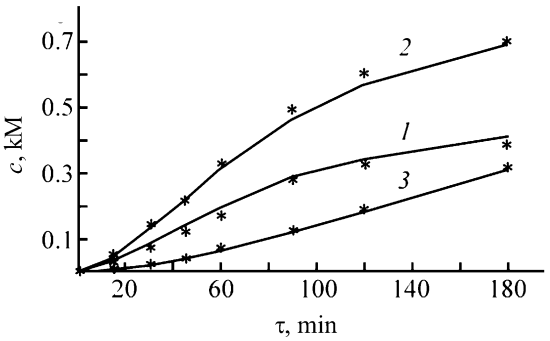

Fig. 5. Variation of the TAED concentration c with time τ. (*Line*) DesK-Pro program model and (*points*) experimental data. Initial molar ratio DAED : AAA, T, °C : (*1*) 1 : 17, 140; (*2*) 1 : 8.5, 140; and (*3*) 1 : 8.5, 120.

To solve the inverse problem means to find the kinetic parameters that best fit the experimental data. For this purpose, a certain measure of residuals between the experimental and simulated responses is minimized. Most of nonlinear optimization algorithms are based on the least-squares procedure which utilizes to this end the sum of the squared residuals. The parameter vector $\mathbf{P}_r$ is estimated by minimization of the target function SS :

$$\mathrm{SS}(\mathbf{P})=\frac{1}{2}\sum_{(i)}\left(\frac{Y_{\exp}(t_i)-Y_{\mathrm{sim}}(\mathbf{P},t_i)}{\varepsilon_i}\right)^2$$

$$\rightarrow \min = \mathrm{SS}(\mathbf{P}_r), \tag{5}$$

where SS(**P**) is the weighted sum of the squared residuals; i, experimental point number; e, experimental error at the point; and $Y_{\exp}$ and Y_{sim}, experimental and calculated responses, respectively.

The condition for the minimum SS is set by a system of the nonlinear algebraic equations

$$\frac{\partial SS(\mathbf{P})}{\partial P_j}=0;\quad j=1,...,L, \tag{6}$$

where P_j is jth component of the parameter vector.

The target function is extended by inclusion of the data derived from several multi-response experiments. Simultaneous processing of the results of several experiments and responses of varied physical nature allows use of different kind of information on the reaction and provides more adequate resulting kinetics.

A primary program processing of the experimental data (Fig. 5) showed that synthesis of TAED is satisfactorily described by the model of two successive

Rate constants and activation energies of the DAED acylation reaction

Stage no.	Activation energy E, kJ mol^{-1}	Pre-exponent, l mol^{-1} s^{-1}	Rate constants $k \times 10^{-5}$	
			120°C	140°C
1	62.3	6.02×10^3	3.2	8.1
2	87.1	2.92×10^6	0.2	1.3
3	103.3	1.69×10^8	0.8	2.8
4	112.9	2.46×10^9	0.3	1.5

reversible second-order bimolecular reactions in accordance with the general scheme.

$$\mathrm{DAED + AAA} \underset{k_3}{\overset{k_1}{\rightleftarrows}} \mathrm{TrAED + AA},$$

$$\mathrm{TrAED + AAA} \underset{k_4}{\overset{k_2}{\rightleftarrows}} \mathrm{TAED + AA}.$$

The rate constants and activation energies are listed in the table.

CONCLUSIONS

(1) Diacetylethylenediamine is acylated by acetic acid anhydride in two stages.

(2) Tetraacetylethylenediamine is deacylated by acetic acid to diacetylethylenediamine via a triacetylethylenediamine intermediate. Hence, the acylation of diacetylethylenediamine is described by successive reversible second-order equations.

(3) The formal kinetics of acylation of diacetylethylenediamine by acetic acid anhydride was examined, which allowed determination of the activation energies and the functional temperature dependences of the apparent rate constants of the reaction k_1–k_4 for two successive reversible stages of the process.

(4) The kinetic data obtained allow construction of an adequate mathematical model for industrial apparatus.

Abstract—Thermodynamic and kinetic features of the reaction of aminoguanidine with malonic acid in aqueous solutions at pH 0.5–1.3 to give mono- and diguanylhydrazides of malonic acid were examined, and the reaction mechanism was suggested.

DOI: 10.1134/S1070427208100200

The reaction of aminoguanidine (AG) with dicarboxylic acids is the synthetic route to 5-amino-1,2,4-triazole-3-carboxylic (**I**) and 5-amino-1,2,4-triazol-3-ylacetic (**II**) acids [1–3] and to bis(5-amino-1,2,4-triazol-3-yl)alkanes (**III**) [4]. These compounds are used in production of drugs and biologically active substances [5–7], dyes [8], corrosion-protecting formulations [9], and polymers [10], and also in biological studies [11]. The reactions of AG with dicarboxylic acids are usually performed in aqueous solutions. According to [1–3], the reaction occurs via formation of guanylhydrazides of the corresponding acids, which, when heated subsequently in an alkaline medium, cyclize into aminotriazoles **I–III**:

I, $n = 0$
II, $n = 1$

III

The procedure reported in [1] allows preparation of acid **I** in a yield of about 80% and is well reproducible. An experimental check of the protocols from [2, 3] showed that the yield of **II** is very sensitive to slight changes in the solution acidity and reactant ratio in the step of synthesis of malonic acid guanylhydrazide. It should be kept in mind that reactions of carboxylic acids with nitrogen nucleophiles in aqueous solutions are usually reversible, and the position of the equilibrium and the reaction rate strongly depend on the solution temperature and acidity [12–15]. Until recently, the effect of these factors on the thermodynamics and kinetics of the reactions of AG with carboxylic acids has received virtually no researchers' attention. In this study, we examined the thermodynamic and kinetic features of the reaction of AG with malonic acid (MA) in aqueous solutions at pH 0.5–1.3.

EXPERIMENTAL

Aminoguanidinium hydrocarbonate (Lancaster) contained no less than 98% main substance. The other chemicals were of analytically pure grade. Aqueous solutions were prepared using double-distilled water.

Kinetic experiments were performed in a 250-ml three-necked glass flask with a reflux condenser and a mercury thermometer. The temperature in the reactor was maintained to within ±0.5°C, using an ESR^C thermostat. The solution acidity was determined using a pH-150M with device an ESL-63-07 glass electrode and an EVL-1M3 reference electrode.

A calculated amount of aminoguanidinium hydrocarbonate was suspended in 50 ml of H_2O, after which 6 M HCl was added until the hydrocarbonate completely dissolved and the gas evolution ceased. The resulting solution was heated to the required temperature and brought to the required pH and volume of 100 ml by adding 6 M HCl and H_2O. Malonic acid was dis-

solved in 70 ml of H_2O, and the solution was heated to the required temperature and brought to the required pH and volume of 100 ml by adding 6 M HCl and H_2O. The resulting solutions of AG and MA were mixed in the reaction flask, and the time counting was started.

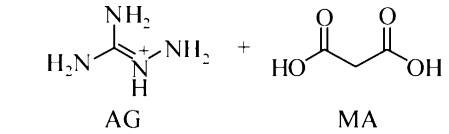
The AG concentration in reaction mixtures c_{AG} (M), was determined by iodatometric titration [16]. At definite time intervals, a 1-ml sample of the reaction mixture was withdrawn and dissolved in 20 ml of distilled water in a conical flask. To the resulting solution we added 30 ml of 2.5 M H_2SO_4 solution and 30 ml of 0.1 N KIO_3 solution. The flask was closed and kept for 3 min at room temperature, after which an excess amount of a saturated KI solution was added, and the released I_2 was titrated with a 0.1 N $Na_2S_2O_3$ solution. The quantity c_{AG} was calculated by the formula

$$c_{AG} = \frac{V_0 - V}{V_s} \times 0.02497,$$

where V_0 and V are the volumes of sodium thiosulfate solution spent in the blank experiment and in titration of the sample, respectively (ml), and V_s is the volume of a sample of the reaction mixture (ml).

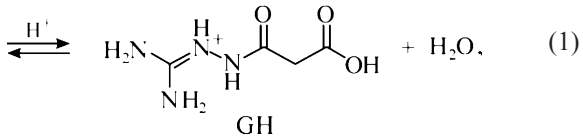
The concentrations of guanylhydrazide (GH) c_{GH} (M) and diguanylhydrazide (DGH) c_{DGH} (M) of malonic acid were determined chromatographically after their cyclization in alkaline solution to acid **II** and bis(5-amino-1,2,4-triazol-3-yl)methane **III**, respectively. To this end, we took a 5-ml sample of the reaction mixture at definite time intervals, mixed it with 7 ml of 2 M NaOH, and heated for 30 min on a boiling water bath, after which we cooled the sample, neutralized it with concentrated HCl to pH 6–7, added 25 ml of a 0.05 M aqueous KH_2PO_4 solution, and brought the solution volume to 50 ml. The resulting sample was chromatographed on a Milikhrom-5.3 chromatograph equipped with a UV detector and an 80 × 2-mm column packed with Separon C_{18}. The mobile phase was a 0.025 M aqueous KH_2PO_4 solution; elution rate 80 μl min^{-1}, detection at a wavelength of 220 nm, sample volume 6 μl, temperature of the chromatographic column 35°C. The retention time of acid **II** was 2.9 min, and that of compound **III**, 4.0 min. The concentrations c_{GH} and c_{DGH} in the reaction mixtures were assumed to be equal to the chromatographically determined concentrations of compounds **II** and **III** after the sample treatment with an alkali. The reliability of the procedure is confirmed by the fact that the difference between the AG concentrations determined by iodatometric titration and calculated by the equation

$$c_{AG} = c_{AG0} - c_{GH} - 2c_{DGH}$$



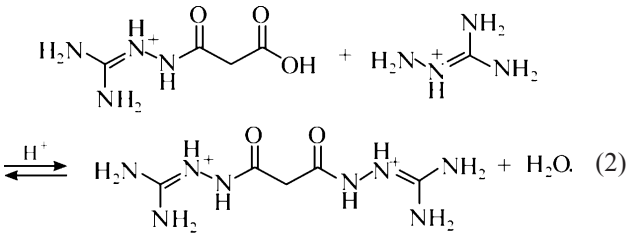
(c_{AG0} is the initial concentration of AG in the reaction mixture) did not exceed 1.6%.

The MA concentratoin c_{MA} was calculated by the formula



$$c_{MA} = c_{MA0} - c_{GH} - c_{DGH},$$

where c_{MA0} is the initial MA concentration.



A chromatographic analysis of the reaction mixtures showed that the reaction of AG with MA involves successive formation of GH and DGH of malonic acid:

AG MA

GH (1)

DGH (2)

The equilibrium constants of the formation of GH (K_{GH}) and DGH (K_{DGH}) were calculated by the formulas

$$K_{AG} = \frac{[GH]}{[MA][AG]}, \quad (3)$$

$$K_{DGH} = \frac{[DGH]}{[GH][AG]}, \quad (4)$$

where [GH], [DGH], [MA], and [AG] are the equilibrium concentrations of the corresponding compounds, M.

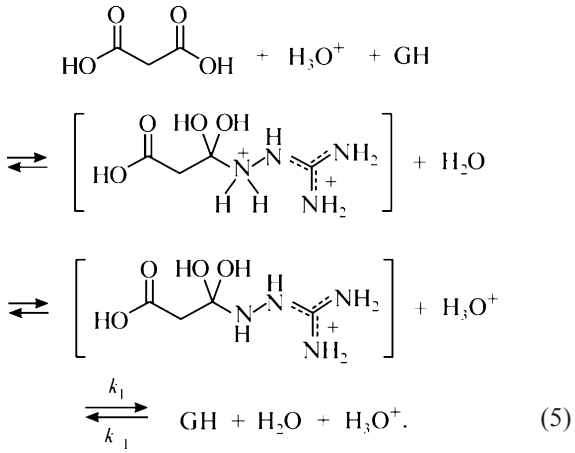
It should be noted that, in acid-catalyzed reactions of carboxylic acids with nitrogen nucleophiles, e.g., amines, the position of the equilibrium and the reaction

rate are, as a rule, governed by the concentrations of the nonprotonated form of the nucleophile and nondissociated form of the acid [13]. Equations (3) and (4) should seemingly include the concentration of the nonprotonated form of AG. However, this concentration is negligible in the examined pH range, because AG is a strong base (pK_a 11.5 [17]). At the same time, it is known that, even in the protonated form, AG exhibits fairly high nucleophilicity and can react with electrophiles, because the proton in the aminoguanidinium cation is bonded to the guanidine moiety, with the lone electron pair of the amino group of the hydrazine moiety remaining free [17, 18]. Therefore, most probably, AG enters into the reaction in the form of the aminoguanidinium cation [reactions (1), (2)]. In the pH interval examined, the concentration of this form is actually equal to the analytical concentration, and specifically this quantity was taken into account in formulas (3) and (4), as well as in the further rate equations. The concentration of the nondissociated form of MA, c'_{MA}, was calculated by the equation

$$c'_{MA} = \frac{10^{-pH}}{10^{-pH} + 10^{-pK_a}} c_{MA},$$

where pK_a is equal to 2.86 [19].

The concentrations [AG], [MA], [GH], and [DGH] in Eqs. (3) and (4) were determined by analyzing the composition of the reaction mixtures afer the attainment of equilibrium. The equilibrium was attained from the sides of both forward and reverse reactions until the analyzed concentrations coincided within the experimental error. The reaction mixtures required for studying the reverse reaction were prepared by heating AG, MA, and HCl in a minimal volume of water at 60°C for 3 h. Under these conditions, the yield of guanylhydrazides was considerably higher than the equilibrium yield in dilute solutions. Then the resulting mixture was diluted with water to the required volume, and the hydrolysis of GH and DGH was studied.



The equilibrium constants K_{GH} and K_{DGH} obtained at 50–71°C are given in Table 1. At higher temperatures, it was impossible to determine K_{GH} and K_{DGH} with acceptable reliability because of the gradual decarboxylation of MA. Varying the acidity within the interval examined did not lead to noticeable changes in K_{GH} and K_{DGH}. The good linear dependence of the logarithms of these constants on the reciprocal temperature allowed us to apply the van't Hoff isobar equation and calculate the thermal effects of the reactions of GH (1) and DGH (2) formation: $\Delta H_{GH} = -27.5 \pm 2.0$ and $\Delta H_{DGH} = -34.6 \pm 5.3$ kJ mol^{-1}. Notably, these values are close to the enthalpy of the related reaction of aniline acylation with formic acid in acidic solution (–27.5 kJ mol^{-1} [13]).

Table 1. Equilibrium constants K_{GH} and K_{DGH}

T, °C	K_{GH}	K_{DGH}
	l mol^{-1}	
50	8.9 ± 0.1	1.29 ± 0.05
60	6.1 ± 0.2	0.90 ± 0.05
63	5.4 ± 0.2	0.84 ± 0.07
71	4.9 ± 0.2	0.58 ± 0.05

To elucidate the mechanism of formation of malonic acid guanylhydrazide, we studied the kinetics of reaction (1) in the reactant concentration range 0.1–1.2 M and pH 0.5–1.3. The course of reaction (1) was monitored by variation of the AG and GH concentrations. We failed to study the kinetics of reaction (2) of DGH formation, because determination of the DGH concentration in the initial portions of the kinetic curves involved large errors due to the low degree of conversion of MA to DGH.

Because the reaction of AG with MA is similar to the reactions of carboxylic acids with amines under the conditions of acid catalysis [12–14], it is reasonable to assume that its mechanism is also similar:

The limiting step can be both the acid-catalyzed addition of AG to the carboxy group of MA with the formation of a tetrahedral intermediate (TH) and the TH

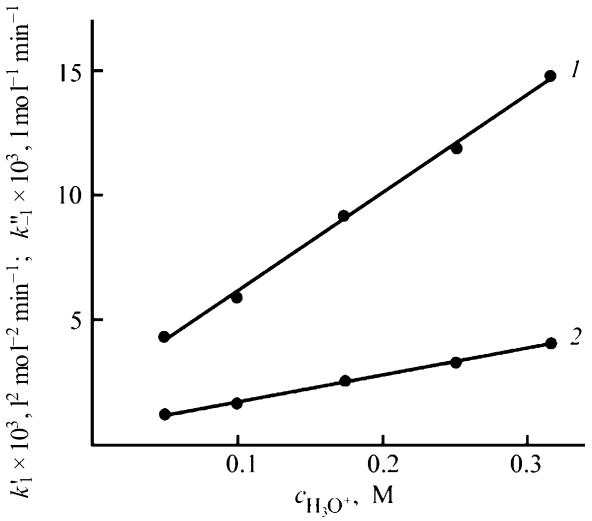


Fig. 1. Apparent rate constants of the (*1*) forward (k'_1) and (*2*) reverse (k''_{-1}) reactions at 80°C vs. the solution acidity. ($c_{H_3O^+}$) Concentration of hydroxonium ions.

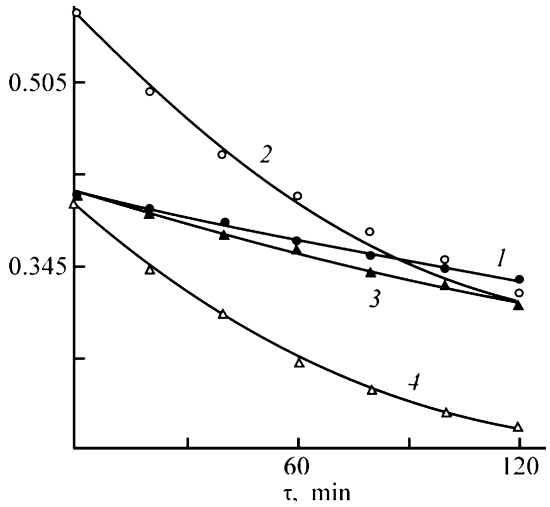

Fig. 2. Kinetic curves of AG consumption at pH 1.0. (c_{AG}) AG concentration and (τ) time. T (°C), c_{MA0} (M): (*1*) 60, 0.6001; (*2*) 80, 0.8000; (*3*) 70, 0.6004; and (*4*) 90, 0.6000. *Lines* are calculated kinetic curves, and *points*, experimental data.

dehydratoin [12–14]. In both cases, the rate of GH formation is described by the rate equation

$$\frac{dc_{GH}}{d\tau} = k_1 c_{AG} c'_{MA} c_{H_3O^+} - k_{-1} c_{GH} c'_{H_2O} c_{H_3O^+}, \qquad (6)$$

where k_1 and k_{-1} are the rate constants of the forward and reverse reactions, respectively.

As the reaction is performed in dilute aqueous solutions, it has pseudo-zero order with respect to H_2O. Therefore, the rate constant of the reverse reaction can be expressed as

$$k'_{-1} = k_{-1} c_{H_2O}.$$

At a constant pH, Eq. (6) will take the form

$$dc_{GH}/d\tau = k'_1 c_{AG} c'_{MA} - k''_{-1} c_{GH},$$

where $k'_1 = k_1 c_{H_3O^+}$ and $k''_{-1} = k_{-1} c_{H_3O^+}$ are the effective rate constants of the forward and reverse reactions, respectively.

Table 2. Rate constants k_1 and k'_{-1}

T, °C	k_1, l^2 mol^{-2} min^{-1}	k'_{-1}, l mol^{-1} min^{-1}
60	0.026 ± 0.001	0.0042 ± 0.0002
70	0.035 ± 0.003	0.0074 ± 0.0003
80	0.060 ± 0.007	0.0170 ± 0.0020
90	0.088 ± 0.004	0.0310 ± 0.0020

The constant k' was calculated by the linear least-squares method using the integral form of the rate equation for a reversible bimolecular reaction [20]:

$$\tau = \frac{1}{k'_1}\left\{\frac{1}{X_1 - X_2}\ln\left[\frac{(c_{AG_0} - X_1)(c_{AG} - X_2)}{(c_{AG_0} - X_2)(c_{AG} - X_1)}\right]\right\}, \qquad (7)$$

where X_1 and X_2 are the quantities calculated by the formulas

$$X_{1,2} = \frac{-[K_{GH}(c'_{MA} - c_{AG_0}) + 2c_{AG_0}]}{2(K_{GH} - 1)} \pm \frac{\sqrt{[K_{GH}(c'_{MA} - c_{AG_0}) + 2c_{AG_0}]^2 + 4(K_{GH} - 1)c^2_{AG_0}}}{2(K_{GH} - 1)}.$$

The rate constant of the reverse reaction k''_{-1} was obtained from the relationship $k''_{-1} = k'_1/K_{GH}$. The equilibrium constants K_{GH} at 80 and 90°C were calculated by the van't Hoff equation.

Figure 1 shows the dependence of the apparent rate constants k'_1 and k''_{-1} on the concentration $c_{H_3O^+}$. The linear dependence of k'_1 and k''_{-1} on $c_{H_3O^+}$ allows determination of the true rate constants k_1 and k'_{-1}, whose values at various temperatures are listed in Table 2.

Figure 2 shows the experimental concentrations c_{AG} and the calculated kinetic curves obtained by Eq. (7). The coincidence of the experimental and calculated data within the experimental error confirms the adequacy of the kinetic model we chose.

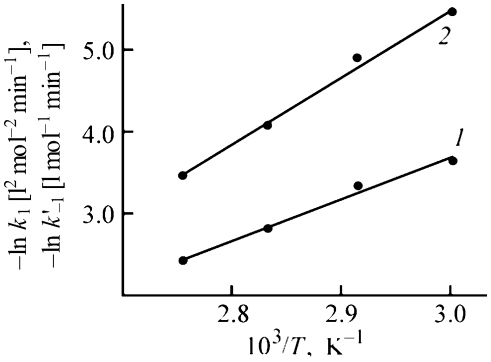

Fig. 3. Temperature dependence of the logarithms of the rate constants of the (*1*) forward (k_1) and (*2*) reverse (k'_{-1}) reactions.

The linear dependence of the logarithms of the rate constants k_1 and k'_{-1} on the reciprocal temperature (Fig. 3) allows calculation of the parameters of the Arrhenius equation $k = A\exp(-E_a/RT)$:

Rate constant	A	E_a, kJ mol^{-1}
k_1	$9.93 \pm 0.1 \times 10^4$	42.1 ± 3.0
k'_{-1}	$3.33 \pm 0.48 \times 10^8$	69.6 ± 3.5

Notably, the activation energy of hydrolysis of malonic acid guanylhydrazide is close to E_a of hydrolysis of hydroxamic acids [21] and of carboxylic acid amides and polyamides [22–24] under the conditions of acid catalysis (66–90 kJ mol^{-1}), which occur by the same mechanism. Thus, the kinetic data are consistent with the suggested mechanism of reaction (5).

The thermodynamic and kinetic data we obtained can be used for development of an improved procedure for preparing 5-amino-1,2,4-triazol-3-ylacetic acid **II** and bis(5-amino-1,2,4-triazol-3-yl)methane **III**.

CONCLUSIONS

(1) The reaction of aminoguanidine with malonic acid in acidic aqueous solutions yields not only guanylhydrazide, but also diguanylhydrazide of malonic acid. In the temperature range 50–71°C, both reactions are reversible and exothermic. The equilibrium constant of formation of malonic acid guanylhydrazide is, on the average, seven times that of formation of malonic acid diguanylhydrazide.

(2) A kinetic model was suggested for the formation of malonic acid guanylhydrazide, which adequately describes the experimental data in the range pH 0.5–1.3. The reaction of aminoguanidine with malonic acid follows the mechanism characteristic of acid-catalyzed reactions of carboxylic acids with the amine, but the role of a nucleophile in this process is played by the protonated, rather than neutral form of aminoguanidine. This fact allows synthesis of guanylhydrazides in fairly acidic media providing high reaction rate.

Abstract—Swelling of sodium acrylate-based polyelectrolytic hydrogels with various degrees of cross-linking (from 300 to 50 acrylate units per cross-link) was studied over the solution pH range from 2 to 12.

DOI: 10.1134/S1070427208100212

Polyelectrolytic polymeric hydrogels based on chemically cross-linked acrylic (PAA) or methacrylic (PMAA) acid have been intensively studied in the last two decades, because of their great scientific and practical interest. In particular, such hydrogels show promise in development of new prolonged-action drug carriers. The interaction of hydrogels with low-molecular-weight electrolyte solutions has been rather well studied [1–9].

In most of these studies, the authors theoretically and experimentally examined the equilibrium in the system hydrogel–solution, as influenced by the pH, ionic strength, and nature of solvent. For systems with controlled and directed transport of drugs in human body, the drug release rate was experimentally demonstrated to be dependent not only on the pH and ionic strength of the medium, but also on such factors as the chemical structure, charge density, swelling kinetics, and degree of cross-linking of the hydrogel [1, 3]. Shefer et al. [7] studied the effect of the solution pH on the swelling of the gel based on PAA variously cross-linked with tris(4-isocyanatophenyl)methane. However, the swelling in hydrogels has not been systematically studied over wide ranges of the cross-linking density and pH.

In this study, we examined the behavior of sodium polyacrylate (Na-PAA) hydrogels with various cross-linking densities over a wide pH range in both acidic and alkaline solutions.

EXPERIMENTAL

The hydrogels were prepared by radical copolymerization of sodium acrylate with *N*,*N*'-methylenebisacrylamide as a cross-linking agent [5] and ammonium persulfate as an initiator. The monomers were completely neutralized with NaOH. The degree of cross-linking was controlled by the initial component ratio. We prepared a series of hydrogels with *N* 50, 100, 150, 200, and 300 monomer unites per cross-link. The monomer to cross-linking agent molar ratios used in the experiments are listed in the table. The monomer concentration in the initial solution was 25%. The resulting gels were thoroughly washed and vacuum-dried to constant weight.

The equilibrium degree of swelling of the hydrogels in water and acidic and alkaline solutions was determined gravimetrically to within 10%. A weighed portion of a dry gel (~0.02 g) was poured over with 30 ml of distilled water or with HCl or NaOH solutions. The initial pH was varied from 2 to 12. The hydrogel samples were allowed to stand to reach equilibrium swelling, which was monitored gravimetrically. The degree of swelling, Q, was calculated as the ratio of the weight of the swollen hydrogel to its dry weight. The solution pH was measured with an ANION-410V pH meter.

It has been demonstrated previously [10] that, at a low Na^+ concentration in the system Na-PAA–low-molecular-weight acid, no redistribution of the H^+ ions occurs between the hydrogel and the solution, so that the solution pH remains practically unchanged after contact with the hydrogel. To meet this condition in our experiments, the solution to dry gel weight ratio was 1500. In this case, the polymer concentration recalculated to the total system volume was about 10^{-5} M, and the volume fractions V_2 of the polymer in the swollen gel, calculated as

Degree of swelling of hydrogels, Q, and volume fraction of the polymer in swollen gels, V_2, at various cross-linking densities N and cross-linking agent to monomer molar ratios X

$$V_2 = (1 + \rho_2 Q/\rho_1)^{-1}, \quad (1)$$

where ρ_2 and ρ_1 are the polymer and solvent densities [8], ranged from 0.003 (N 300, water) to 0.071 (N 50, pH 2) (see table).

To optimize the experimental conditions (swelling time, sample weight),we examined in preliminary experiments the swelling kinetics of Na-PAA hydrogel with N 300 at various pH values. First, we compared the swelling kinetics for the samples with the same weight, but different surface areas. Monolithic and crushed samples demonstrated different swelling kinetics, and the finer the sample, i.e., the larger its surface area, the faster the swelling kinetics. The time of establishment of equilibrium swelling in the crushed samples was lower by about an order of magnitude as compared to the monolithic sample of the same weight (2 and 24 h, respectively). In this case, the equilibrium swellability of the samples was the same. In further experiments, we used crushed gel samples. As an example, Fig. 1 shows the swelling kinetics of crushed hydrogel with N 300 at pH 4.6, 6.0, and 8.3. As an ordinate, we used the relative swelling Q_t/Q_{eq}, where Q_t and Q_{eq} are the current and equilibrium swellings, respectively. As can be seen, the equilibrium in the system is established in 2 h, irrespective of pH. Therefore, in our further experiments, the swelling time was selected to be 3 h.

The pH dependences of the equilibrium swellability Q pass through a maximum at pH 3.5–9.0. Figure 2 shows such a dependence for the hydrogel with N 300. As can be seen, the swellability is low in strongly acidic solutions, which can be attributed to replacement of Na^+ by H^+. Acrylic acid is characterized by a lower degree of dissociation as compared to Na-PAA, which results in a considerable contraction of the macromolecular chains. At low initial pH values, we observed slight increase (by 6–7%) in the equilibrium solution pH by virtue of replacement of Na^+ by H^+.

Raising the pH to 6–7 enhances swelling by a factor of 4–5. Previously, this effect has been observed for gels based on cross-linked PAA [1, 7] and copolymer of *n*-alkyl hydrogen itaconates with *N*-acrylamide [11]. Swelling of Na-PAA gels in strongly alkaline solutions is affected both by condensation of the counterions and

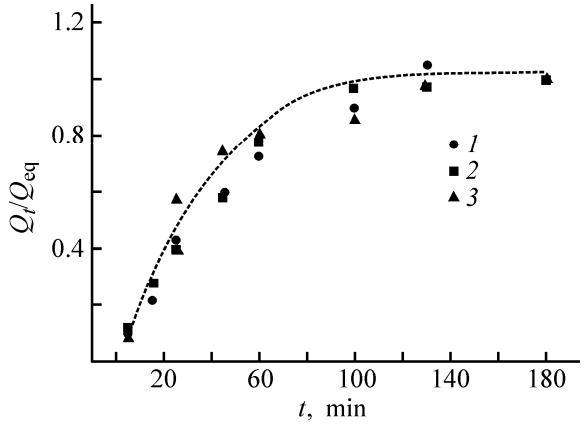

Fig. 1. Swelling kinetics of Na-PAA hydrogel. pH: (*1*) 4.6, (*2*) 6.0, and (*3*) 8.3. (Q_t) Current swelling, (Q_{eq}) equilibrium swellability, and (t) time.

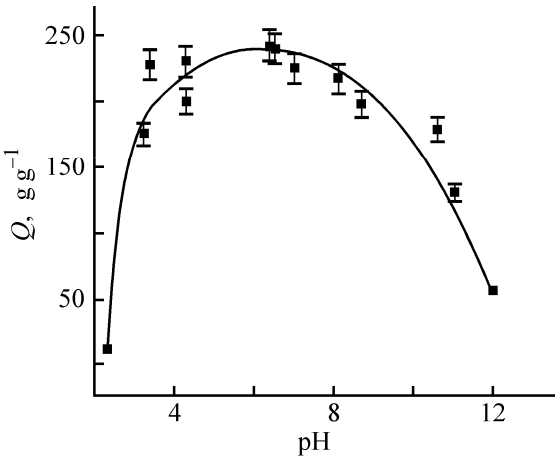

Fig. 2. pH dependence of the degree of swelling, Q, of the hydrogel with N 300.

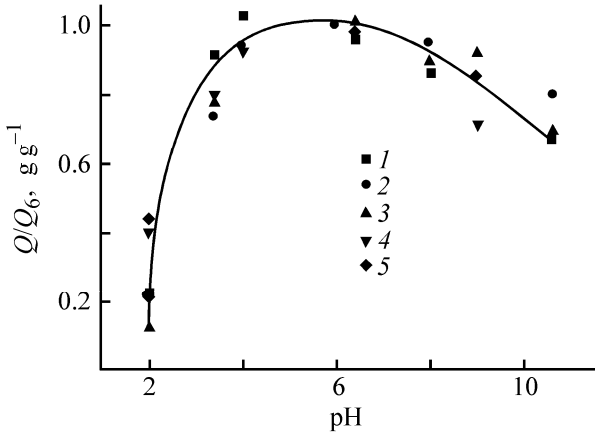

Fig. 3. pH dependence of the relative degree of swelling of the hydrogel Q/Q_6. (Q) Equilibrium degree of swelling at fixed pH and (Q_6) that at pH 6. N: (*1*) 300, (*2*) 200, (*3*) 150, (*4*) 100, and (*5*) 50.

by shielding of charges by excess Na^+ ions, suppressing polyelectrolytic swelling. In this case, the degree of swelling of the hydrogel decreases as compared to that in neutral solutions (pH 4–8), being although higher than that in acidic solutions.

At high initial pH, we observed a slight acidification of the solution [Δ(pH) <0] by no more than 6–7%. Similar results were obtained for samples with other cross-linking densities. The equilibrium swellabilities of all the hydrogels studied at pH 2.0, 6.0, and 10.6 are listed in the table. The absolute value of Q_{max} becomes about an order of magnitude lower as the distance between cross-linking sites decreases from 300 to 50 monomer units.

The pH dependence of the relative swellability Q/Q_6 (ratio of the equilibrium swelling at a fixed pH to that at pH 6) is independent of the degree of cross-linking (Fig. 3) and can be described by a common invariant curve. A similar invariant curve was obtained for the increase in the degree of swelling as a function of pH over the pH range up to pH 11 for PAA gels with various degrees of cross-linking [7]. However, no compaction of the gels in alkaline solutions was observed in this case. The invariant curve can be used as a calibration curve for preliminary estimation of changes in the size of any Na-PAA hydrogel samples with changing pH.

CONCLUSIONS

(1) pH dependences of the degree of swelling of hydrogels with various cross-linking densities (from 300 to 50 sodium acrylate units per cross-link) pass through a maximum at pH 3.5–9.0.

(2) pH dependence of the relative swellability of gels (ratio of the equilibrium swelling at a fixed pH to that at pH 6) is independent of the degree of cross-linking of hydrogels over the entire experimental pH range and can be described by a common invariant curve.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

"Dormant" Inhibitors of Urethane Type as Controllers of Temperature Modes of Styrene Polymerization

A. L. Aleksandrov, E. R. Badamshina, G. A. Gorbushina, A. A. Grishchuk, A. S. Dzhalmukhanova, V. V. Komratova, I. S. Kochneva, A. I. Kuzaev, V. P. Lodygina, E. V. Stovbun, T. N. Fedotova, and Ya. S. Estrin

Abstract—Urethanes based on a series of monoisocyanates and phenolic inhibitors of styrene radical polymerization, which release the initial phenolic inhibitor at elevated temperatures, were prepared and characterized. Some of these compounds meet the requirements to "dormant" inhibitors: they sharply decelerate thermally initiated high-temperature polymerization of styrene and do not noticeably affect the rate of low-temperature polymerization in the presence of an inhibiting substance. The possibility of preventing uncontrollable emergency situations by adding these compounds to the initial monomer was confirmed experimentally.

DOI: 10.1134/S1070427208100224

One of the most extensively used procedures for preparing polystyrene is polymerization in the bulk in large reactors, which is characterized by the complex behavior owing to the nonlinear dependence of the reaction rate on the temperature and reactant concentrations. The exothermic heat effect of polymerization has a positive feedback, i.e., both the reaction rate and heat release increase with temperature, which, in turn, causes further use in temperature. As a result, unstable states of the process and emergency situations arise, which are accompanied by an uncontrollable rise in the temperature of the reaction mass by tens of degrees and by a significant excess of the monomer conversion over the level permissible for the reactor.

In the commercial production of polymers, various mathematical models of the reactors are used, which allows development of automatic control systems providing the maximal productivity of the process. However, owing to the risk of uncontrollable emergency situations, the process is frequently performed under modes that are far from the optimum. Continuous polymerization of styrene is carried out in a cascade of reactors (with the volume of tens of cubic meters) to provide a gradual increase in temperature as the content of the monomer in the reaction mixture decreases [1]. The greatest danger of uncontrollable emergency situations is typical of the first reactor owing to the highest monomer concentration in the reaction mixture. Three main procedures are used to prevent the emergency with an uncontrollable temperature increase in the reactor: cooling of the reaction mixture by lowering the coolant temperature in the reactor jacket, addition of inhibitors that sharply decrease the polymerization rate, and emergency discharge of the reaction mixture into an external vessel with a solvent.

However, all the above procedures are noticeably inertial, i.e., they are characterized by slow elimination of the thermal and concentration gradients in the large reactor. Owing to the high inertia, prevention of the emergency situations in the case of local overheating may become impossible. The use of so-called "dormant" inhibitors (DIs) added to the reaction mixture before polymerization can be probably the optimal solution to this problem.

The effect of these inhibitors is as follows. A DI is inert at the polymerization temperatures. Upon an uncontrollable rise in the temperature above the permissible level, a DI exhibits the inhibition activity via its decomposition to components among which at least one component acts as a polymerization inhibitor or isomerization to give an active inhibitor. In this case, it is not necessary to supply the inhibitor to the over-

heated area because DI is uniformly distributed in the reaction mixture from the very begining.

DIs were first suggested for controlling the photoinitiated polymerization of methyl methacrylate (MMA) in the form of large blocks [2]. As DIs were studied various compounds, such as nitroso compounds, hydrazine derivatives, saturated and unsaturated halogen derivatives, nitrites, and ammonium salts, which are activated and then inhibit polymerization even at 50–60°C. However, these compounds cannot be used in the case of styrene, because its polymerization is carried out at temperatures no less than 50°C at which all the above compounds act as polymerization inhibitors lowering the process rate and molecular weight of the polymer.

As is known, phenols and polyphenols (in particular, di- and triphenols) are efficient inhibitors of radical polymerization of styrene [3–5]. The inhibiting effect of these compounds is due to the fact that propagating polystyrene radicals detach a labile hydrogen atom from the hydroxy group of the inhibitor molecule and are thereby transformed into "dead" polymer molecules. The resulting oxyphenyl radicals do not interact with the monomer and thus cannot initiate the propagation of new polymer chains. If active hydrogen in the inhibitors can be blocked so that it will be activated only at relatively high temperatures, then its reactivity with respect to the polymer radicals at lower temperatures will be suppressed.

The most appropriate blocking procedure is conversion of phenols into urethanes in the reaction with isocyanates (DI of urethane type). The reaction of urethane formation can be represented as follows:

$$RNCO + HOR' \leftrightarrows RNHC(O)OR'. \quad (1)$$

At elevated temperatures, the reaction equilibrium is shifted to the left, and the temperature at which the equilibrium concentrations of isocyanate and phenol become noticeable depends on the structure of radicals R and R' [6].

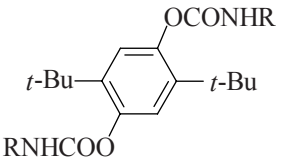
Hydrogen atoms are more strongly bound with nitrogen atoms in the urethane group than with oxygen atoms in phenols. Hence, urethanes should not exhibit significant inhibiting activity at moderate temperatures [7].

Here, we describe the synthesis of some promising DIs of the urethane type and present characteristics of the resulting compounds and data on their effect on the kinetics of styrene polymerization under the isothermal conditions and on the thermal modes under the conditions of restricted heat exchange which model parameters of the heat exchange in large-volume reactors.

EXPERIMENTAL

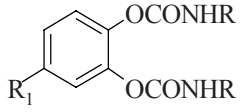
Styrene containing 99.9% main compound and stabilized with *p-tert*-butylpyrocatechol (0.001%) was washed to remove the inhibitor with a 10% NaOH solution (4 : 1 weight ratio). Then the monomer was washed with distilled water to neutral reaction. Washed styrene was dried over anhydrous $CaCl_2$. The dried monomer was distilled in a vacuum (44–45°C, 20 mm Hg) and stored in an argon atmosphere at –18°C. The monomer purity was determined by the kinetic method [8]. The reaction order of styrene polymerization with respect to initiator was found to be 0.5, which corresponds to the pure monomer.

Phenyl isocyanate (I-**I**), *m*-chlorophenyl isocyanate (I-**II**), *o*-chlorophenyl isocyanate (I-**III**), 2-ethylphenyl isocyanate (I-**IV**), 2,6-dimethylphenyl isocyanate (I-**V**), *o*-tolyl isocyanate (I-**VI**), and 6-chlorohexyl isocyanate (I-**VII**), all purchased from Aldrich, were distilled in a vacuum and stored in sealed glass ampules.



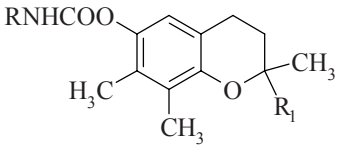
In this study, we used the following phenols: 2,5,7,8-tetramethyl-2-(4',8',12'-trimethyltridecyl)-6-chromanol (α-tocoferol) (P-**I**) purchased from Aldrich, was used without additional purification; 2,2,5,7,8-pentamethyl-6-chromanol, pure grade (P-**II**), mp 94–96°C, was recrystallized from petroleum ether; 1,2-dihydroxybenzene (pyrocatechol), pure grade (P-**III**), and 1,3-dihydroxybenzene (resorcinol), pure grade (P-**IV**), were sublimed in a vacuum at 100°C, mp 105–106 and 109–110°C, respectively; 1,4-dihydroxybenzene (hydroquinone), pure grade (P-**V**), was successively recrystallized from xylene, water, and acetonitrile, mp. 173.5–175.0°C, 1,4-dihydroxy-2,5-di-*tert*-butylbenzene (2,5-di-*tert*-butylhydroquinone), pure grade (P-**VI**), was precipitated with water from methanol and reprecipitated from ether with toluene, mp 217–219°C; and 4-*tert*-butyl-1,2-dihydroxybenzene (*p-tert*-butylpyrocatechol), pure grade (P-**VII**), was recrystallized from petroleum ether, mp 55–56°C.

Urethanes were prepared by the reaction of monoisocyanates with hydroxy compounds by reaction (1), using two standard procedures: (a) at [NCO]=[OH] at room temperature to complete consumption of



NCO groups and (b) at threefold excess of the isocyanate groups in the melt at 170°C, with subsequent distillation of excess isocyanate in a vacuum. In both procedures, the reaction was carried out in an inert gas atmosphere in the presence of 10^{-5} M urethane-forming catalyst (dibutyltin dilaurate, DBTDL). The resulting compounds were analyzed by IR spectroscopy for the reaction completeness judged from the absence of an intense absorption band at 2270 cm^{-1}, characteristic of the free isocyanate group. These compounds are crystalline compounds with mp from 20 to 271°C, except U-**IIIb** (Table 1). Urethanes were purified by recrystallization from toluene, the degree of purification was analyzed by reversed-phase chromatography.

The IR spectra were recorded on a Specord M-82 spectrophotometer: the spectra of compounds U-**Ia**–U-**Id**, U-**IIa**–U-**IIf**, and U-**IIIa**, in KBr pellets and those of compounds U-**IIIb** and U-**IIIc**, in capillary films prepared from solutions in chloroform.



The structures of the resulting urethanes are as follows:

U-(**Ia–Id**):
R = 3-ClPh (a),
2-ClPh (b),
2-EtPh (c),
2,6-$(Me)_2$Ph (d)

U-(**IIa–IIf**):
R = Ph, R_1 = H (a);
R = Ph, R_1 = *t*-Bu (b);
R = 3-ClPh, R_1 = *t*-Bu (c);
R = 2-ClPh, R_1 = *t*-Bu (d);
R = 2-MePh, R_1 = *t*-Bu (e);
R = 6-Cl$(CH_2)_6$, R_1 = *t*-Bu (f)

U-(**IIIa–IIIc**):
R = 3-ClPh, R_1 = CH_3 (a);
R = 3-ClPh, R_1 = $[CH_2CH_2CH_2CH(CH_3)]_3CH_3$ (b);
R = 2,6-$(Me)_2$Ph, R_1 = $[CH_2CH_2CH_2CH(CH_3)]_3CH_3$ (c)

The characteristics of the urethanes prepared are listed in Table 1.

The chromatographic analysis of the initial compounds, urethanes, and diurethanes was carried out on a Milikhrom chromatograph equipped with a UV detector, using the reversed-phase procedure (2 × 80-mm column packed with Separon SGX C18, 6 μm, 5500 TP performance) with a water-methanol mixture as eluent. The optimal composition of the eluent providing determination of the maximal number of impurities at a sufficiently high resolution of the peaks was determined for each compound in the gradient mode, and analysis was carried out in the isocratic mode. Depending on the polarity of the compounds analyzed, the methanol : water ratio in the isocratic mode was varied from 30 : 70 to 90 : 10 at a flow rate of the eluent of 100 μl min^{-1}. The concentration of the compound analyzed in solution (in eluent or methanol) was up to 10 mg ml^{-1} at a sample volume of 8 μl. The detection was performed in the single- or double-wave mode at 210 and 260 nm. For preliminarily identification of the impurities (if necessary), the spectra of each chromatographic peak in the 190–360 nm range were recorded in the stopped-flow mode.

The effect of potential DIs was preliminarily evaluated from the data on the kinetics of styrene polymerization at 50–70°C with azobis(isobutyronitrile) (AIBN) initiator and at 125 and 150°C without initiator (thermal initiation), in the presence of DI and without it. The measurements were carried out in isothermal calorimeters of the Tian–Calvet type. The reaction mixture in glass ampules was thoroughly degassed, sealed, and placed in calorimeter cells [9]. The signals of the calorimeters were recorded on a computer using an E-24 analog-digital converter (ADC); the signal from the E-24 ADC was recorded using a BEG program developed by Yu.A. Sokolov.

Nonisothermal thermal modes of the styrene polymerization under the conditions of restricted heat exchange in the absence and in the presence of DI were studied on a minireactor with restricted heat removal. The monomer containing either an initiator only or the initiator and DI was degassed and poured in a vacuum into a glass ampule 30 mm in diameter, equipped with a thermocouple well. The ampule was filled with argon, sealed off, and placed in the installation preliminarily heated to the temperature of an experiment. The thermal electromotive force of the copper–constantan thermocouple, whose cold ends were placed in a Dewar vessel containing an ice–water mixture, was recorded with E-24 ADC.

Nonisothermal thermal modes of the styrene polymerization were also simulated using 1- and 8-liter metallic reactors equipped with a stirrer and modified so as to provide the conditions of restricted heat exchange; the ratio of the heat-exchange area to the volume of the reaction mixture was about 1.5 m^{-1}, whereas

for 15 m^3 industrial reactors this ratio is close to 2 m^{-1}. Experimentally, we selected the conditions at which the system passes into the high-temperature mode in the absence of DI. In the nonisothermal tests we also used AIBN initiator at a common concentration of 0.02 M.

In all the cases, unless otherwise indicated, the concentrations of the inhibitors and potential DIs were also 0.02 M.

The molecular-weight distribution (MWD) of polystyrenes was determined at 25°C on a Waters chromatograph with a refractometric detector [10] and a tetrahydrofuran eluent at 1.2 ml min^{-1} flow rate. The volume of the sample was 2 ml, and the concentration of the compound being analyzed in solution was 0.3–0.4 wt %. We used three Styrogel columns (10 × 1000 mm) calibrated using polystyrene references with a porosity of 3×10^3, 3×10^4, and 3×10^5 Å.

A distinctive feature of styrene is that it is capable of thermally initiated polymerization at a rather high temperature (above 90–100°C) [11, 12]. This means that, if the control over the process (performed at moderate temperatures in the presence of initiating substance) is lost, further polymerization and, thus, uncontrollable temperature increase can occur even after complete consumption of the initiator. Just in these cases the use of DIs may become the only way to avoid uncontrollable emergency situations.

Apparently, DIs of the urethane type can be synthesized only from such proton-donor compounds that rather effectively decelerate radical polymerization. Therefor, we estimated the inhibiting power of a series of phenols.

It should be noted that polymerization of styrene is, as a rule, accompanied by the gel effect, which is manifested in a manyfold increase in the reaction rate in the course of the process passing from the bimolecular chain termination to the diffusion-controlled stage. Transition of the polymerization to the high-temperature uncontrollable mode is the most probable just in the step of the gel effect, when the polymerization rate is the highest, whereas the intensity of the heat exchange decreases owing to the rapid increase in the viscosity of the reaction mixture [13]. Therefore, the inhibiting power of the compounds in question was evaluated using two parameters: $\varphi_0 = W_0/W_{0x}$ and $\varphi_m = W_m/W_{mx}$, where W_0 and W_{0x} are the reduced initial rates of polymerization and W_m and W_{mx} are the maximal reduced rates of polymerization (at similar conversions of the inhibitor, respectively. The parameters of the inhibiting power of phenols in styrene polymerization are listed in Table 2.

Table 2. Inhibition parameters φ_0 and φ_m of phenols in styrene polymerization

Potential inhibitor	φ_0		φ_m	
	at indicated temperature, °C			
	60	125	60	125
P-**I**	1.05	2.5	a*	20.6
P-**II**	2.03	1.5	61.2	15.2
P-**III**	2.08	1.40	26.32	3.0
P-**IV**	1.35	0.9	0.4	1.1
P-**V**	1.68	1.2	4.3	1.3
P-**VI**	b**	2.0	b**	10.0
P-**VII**	b**	1.5	b**	7.1

* Reaction is terminated at the conversion $\alpha = 0.3$.

** Strong inhibition, almost no polymerization is observed.

As can be seen, phenols P-**IV** and P-**V** do not noticeably inhibit polymerization of styrene at temperatures of 60°C and higher. Compounds P-**III**, P-**VI**, and P-**VII** more strongly inhibit the process in the case of initiated polymerization at 60°C, whereas at thermally initiated polymerization (125°C and higher) chromanols P-**I** and P-**II** are the most effective.

Based on the data on the inhibiting power of the above compounds (Table 2), we chose phenols P-**I**–P-**III**, P-**VI**, and P-**VII** for the synthesis of urethane-type DIs.

As shown above, the decomposition of urethane-type DIs with liberation of the active inhibitor should occur in a certain temperature range. We have shown previously [14] that neat urethanes based of phenols start to decompose to the initial components at a noticeable rate [reaction (1)] at temperatures higher than 200°C. Apparently, such compounds cannot be used as DIs. At the same time, as shown in [14], decomposition of these compounds with water [reactions (2)–(4)] or aliphatic alcohols [reaction (5)], especially in the presence of tin-containing organic catalysts (e.g., DBTDL), can occur at significantly lower temperatures with the release of the initial phenol. In these reactions, the isocyanates are converted into urea derivatives (reaction with water) or alkyl urethanes (reaction with alcohols), and reactions (2)–(5) are almost irreversible.

Table 3. Parameters of inhibition of styrene polymerization with urethanes at 60°C

Compound	φ_0	φ_m	Compound	φ_0	φ_m
U-**Ia**	1.11	1.43	U-**IId**	1.78	4.35
U-**Ib**	1.08	1.23	U-**IIe**	1.04	1.98

U-**Id**	1.39	2.80	U-**IIIa**	1.0	1.54
U-**IIa**	1.25	1.85	U-**IIIb**	1.1	>100*
U-**IIb**	1.11	2.56	U-**IIIc**	1.0	>100*
U-**IIc**	1.07	1.33			

* Polymerization is virtually terminated at 30–35% conversion.

$$RNHCOOAr + H_2O \rightarrow RNHCOOH + ArOH, \quad (2)$$

$$RNHCOOH \rightarrow CO_2 + RNH_2, \quad (3)$$

$$RNHCOOAr + RNH_2 \rightarrow RNHCONHR + ArOH, \quad (4)$$

$$RNHCOOAr + HOR' \rightarrow RNHCOOR' + ArOH. \quad (5)$$

Taking into account that the monomers for radical polymerization are not thoroughly dried to remove moisture, we assumed that the activation of DIs can occur, depending on their structure and operation conditions, in the acceptable temperature range.

The inhibiting activity of DIs was evaluated by two procedures. In the first procedure, we compared the isothermal kinetics of polymerization of the polymer (in particular, styrene) in the presence and absence of a compound in question. The ideal DI should not affect the process at moderate temperatures, but should decelerate polymerization at elevated temperatures.

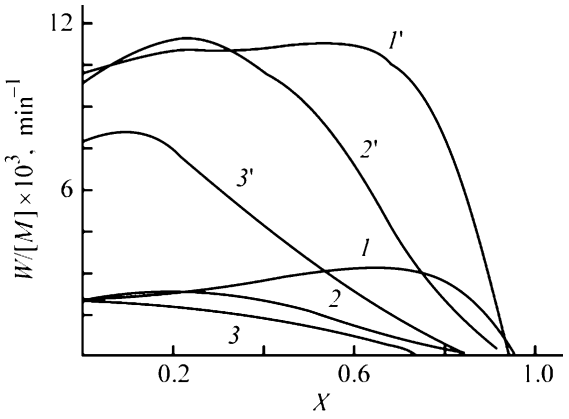

Fig. 1. Reduced rate of thermal polymerization of styrene $W/[M]$ vs. conversion X (*1*, *1'*) in the absence of additives and in the presence of urethanes (*2*) U-**IIIc**, (*3*) U-**IIIb**, (*2'*) U-**IIIa**, and (*3'*) U-**IIIb**; concentration of urethanes 2×10^{-2} M. Temperature, °C: (*1*–*3*) 125 and (*1'*–*3'*) 150.

The second procedure requires that similar comparative experiments should be performed in reactors with restricted heat exchange, in which nonisothermal modes of polymerization are provided and uncontrollable emergency situations are simulated. In this case, polymerization in the presence and absence of DIs should be performed in similar thermal modes of polymerization in a comparatively low-temperature range. In the high-temperature range, a certain decrease in temperature should be observed in styrene polymerization in the presence of DI as compared to the control experiment.

The inhibition parameters of styrene polymerization at 60°C for the urethanes prepared are listed in Table 3. As can be seen, at 60°C almost all the urethanes only slightly affect the initial and maximal rate of polymerization, except urethanes U-**IId**, U-**IIIb**, and U-**IIIc**. For example, urethane U-**IId** suppresses the gel effect and does not noticeably affect the initial polymerization rate, whereas urethanes U-**IIIb** and U-**IIIc** do not affect the initial rate and strongly inhibit polymerization at a conversion of about 30%. Nevertheless, the thermal polymerization of styrene in the presence of urethanes U-**IIIb** and U-**IIIc** was also studied.

The data on the effect of urethanes U-**IIIb** and U-**IIIc** on thermal polymerization, presented in Fig. 1, indicate that compound U-**IIIb** more effectively inhibits styrene polymerization at 125°C than does compound U-**IIIc**; it permanently decreases the polymerization rate and completely terminates the process at a 70% conversion. The inhibiting power ofprocess at urne U-**IIIb** is greater than that of U-**IIIa** at 150°C.

Our experimental data show that, at 125°C, urethanes U-**IIc** and U-**IId** do not noticeably affect the initial rate and noticeably decelerate the polymerization in the course of the process, whereas compound U-**IIa** only slightly affects the reaction rate throughout the process. Urethane U-**IIb** at elevated temperatures first significantly raises the initial rate, but after a 30% conversion is attained, it does not noticeably affect the polymerization rate. Hence, urethanes U-**IIa** and U-**IIb** are unsuitable as DIs. Compound U-**IIf** does not affect the initial rate of styrene polymerization, but it suppresses the gel effect, and the highest conversion attained in this case is 85%.

As noted above, the decomposition of urethanes with the release of the free inhibitor at temperatures

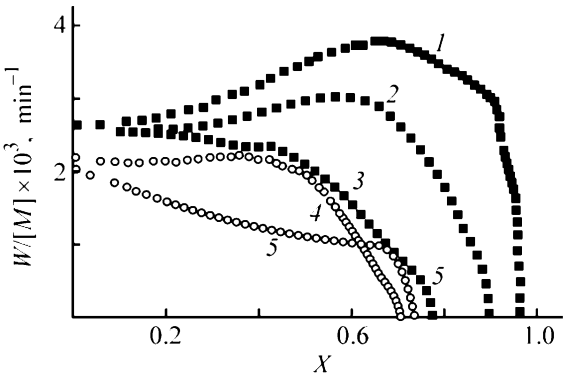

Fig. 2. Reduced rate of thermal polymerization of styrene $W/[M]$ vs. of conversion X (*1*) in the absence of additives and in the presence of (*2*) urethane U-**Id**, (*3*) inhibiting formulation based on urethane U-**Id**, (*4*) urethane U-**IIc**, and (*5*) inhibiting formulation based on urethane U-**IIc**. T = 125°C, [U] = [BuOH] = 2×10^{-2} M, [DBTDL] = 10^{-5} M.

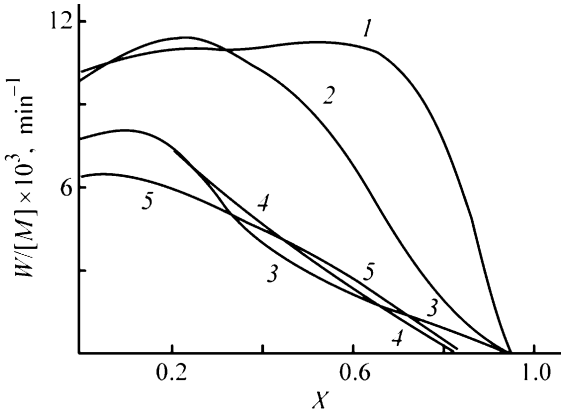

Fig. 3. Reduced rate of thermal polymerization of styrene $W/[M]$ vs. conversion X (*1*) in the absence of additives and in the presence of (*2*) urethane U-**IIIa**, (*3*) inhibiting formulation based on urethane U-**IIIa**, (*4*) urethane U-**IIe**, and (*5*) inhibiting formulation based on urethane U-**IIe**. T = 150°C, [U] = [BuOH] = 2×10^{-2} M, [DBTDL] = 10^{-5} M.

lower than 200°C proceeds at a significant rate only in the exchange reactions with proton-donor compounds and, in particular, with water and alcohols. This fact suggests that the inhibiting effect of urethanes on the styrene polymerization at 125–150°C is probably due to the exchange reactions with water present in the monomer.

The temperature at which inhibitors of the phenolic type are liberated from urethanes can be additionally lowered (i.e., the DI performance can be improved) by using the "inhibiting formulation" containing a urethane-type DI, a proton-donor compound, and a catalyst.

To confirm the above assumption, we studied the isothermal polymerization of styrene as influenced by the inhibiting compositions based on urethanes U-**Id**, U-**IIc**, U-**IIe**, and U-**IIIa**, containing *n*-butanol (BuOH) taken in equimolar amount to urethane (~0.02 M) and DBTDL (~10^{-5} M). At 60°C, these inhibiting formulations do not noticeably affect the initial rate of polymerization, but slightly diminish its maximal rate (i.e., decrease the gel effect).

The data on the inhibiting effect of some of the above formulations at 125 and 150°C (Fig. 2, curves *2* and *3*, *4* and *5*; Fig. 3, curves *2* and *3*) show that, compared to urethanes, they are actually more effective DIs of the isothermal polymerization of styrene. At the same time, under the given experimental conditions, urethane U-**IIe** exhibits the highest activity in the absence of proton donor, which does not noticeably affect the performance of this urethane (Fig. 3, curves *4*, *5*). Our special tests showed that, under the isothermal conditions in the absence of urethanes, neither *n*-butanol nor DBTDL affect the rate of styrene polymerization in the entire temperature range studied (60–150°C).

Since the MWD parameters are the decisive factors affecting the polymer properties, we studied the effect of some inhibitors and urethane-type DIs on the molecular weight (MW) of the resulting polystyrene (Table 4). As can be seen, the additives inhibiting the styrene poly-

T_0 = 75°C, [AIBN] = 2.2×10^{-2} M, [U] = [BuOH] = 2×10^{-2} M, [DBTDL] = 10^{-5} M. (*1*'–*3*') Reaction mixture before experiment was rapidly heated to 75°C; (*1*–*3*) initial temperature of the reaction mixture was 20°C.

merization reduce the polymer MW and this effect is the most pronounced for polymerization at elevated temperatures. At 125°C, the effect of the dormant inhibitors on M_n of the resulting polystyrene is significantly weaker as compared to the initial inhibitors, and at 60°C they cause even a slight increase in the polymer molecular weight.

Thus, our experimental data on styrene polymerization under isothermal conditions suggest that urethanes U-**Id**, U-**IIc**, U-**IIe**, U-**IIf**, and U-**IIIa** or their mixtures with alcohol and a catalyst of exchange reactions can be promising DIs. However, the effect of DI can be demonstrated only in the experiments simulating uncontrollable transition of the polymerization process to the high-temperature mode.

Under the conditions of restricted heat exchange, initiated polymerization of styrene can proceed in three different modes, depending on the initial conditions. At a coolant temperature T_0 lower than a certain critical value, the process occurs in the low-temperature mode at which the difference between the temperatures of the reaction mixture and thermostat, $T - T_0$, is small and the temperature curve exhibits a flat maximum. At T_0 higher than the critical temperature, $T - T_0$ rapidly increases to tens degrees and the temperature curve is characterized by a sharp maximum. Rapid decrease in the temperature after passing the maximum is due to the consumption of the initiator and termination of initiation. This is the mode of high-temperature initiated polymerization. However, if the temperature in the reactor reaches the values providing relatively rapid thermal initiation of polymerization, the system can pass into the high-temperature mode of thermal initiation.

The thermal curves of styrene polymerization, recorded using sealed glass ampules at various T_0 on the installation with restricted heat exchange, are shown in Fig. 4. All the three modes are observed in this figure: low-temperature mode (T_0 59.0 and 60.5°C), high-temperature mode of initiated polymerization (T_0 62, 65, and 70°C), and high-temperature mode of thermal polymerization (T_0 75°C). The dependence of the maximal temperature in the ampule on T_0, which is shown in the inset, indicates that transition from one mode to another occurs in a narrow T_0 range, especially in the region of thermally initiated polymerization.

The effect of DI on the styrene polymerization was studied under the conditions nearly critical (T_0 75°C). As can be seen from Fig. 5 (curves *1*' and *2*', *3*'), which illustrates the typical results of the experiments on the effect of DI on polymerization of styrene under conditions of an uncontrollable reaction, addition of the inhibiting formulation based on urethane U-**IIc** appreciably depresses the temperature of maximal overheating of the reaction mixture in the step of thermal polymerization and does not noticeably affect the process at

lower temperatures. In this case, the degree of polymerization is significantly smaller in the presence of DI than that in its absence and the reaction mixture remains fairly fluid.

A similar behavior was observed for the inhibiting formulation based on urethane U-**IIe**. As can be seen, the kinetics of polymerization in the presence of this formulation is close to the kinetics of uninhibited polymerization at temperatures of up to 145°C. At higher temperature, polymerization sharply decelerates and the maximal temperature in the reactor decreases by 35° as compared to the uninhibited process.

Under the nonisothermal conditions, the highest performance is exhibited by urethane U-**IIIb**, which lowers the maximal temperature in the reactor by 50° at a concentration of 0.02 M as compared to the control experiment. At the same time, up to transition to the high-temperature mode, this urethane does not noticeably affect the reaction rate. Additions of BuOH and DBTDL do not appreciably affect the inhibiting activity of this DI (Fig. 5, curves *2* and *3*).

The data on the effect of the urethane-type DI on styrene polymerization, determined under the conditions of restricted heat exchange using glass ampules, were qualitatively confirmed by the experiments carried out in 1- and 8-l metallic reactors equipped with stirrers. The reactors were modified so as to provide the minimal ratio of the heat exchange surface to the volume of the reaction mixture, which allowed us to find the conditions at which the initiated polymerization passes to the high-temperature mode.

Initially we found that, at a constant coolant temperature of 90°C, the system passes to the high-temperature mode as the temperature of the reaction mixture increases to 140–150°C. However, further passing to the high-temperature mode of thermal initiation (similar to that in glass ampules) was not observed. This is probably due to a sharp increase in the heat loss through the nonthermostated inlet for the stirrer in the reaction lid. Hence, it is impossible to evaluate the DI performance under these conditions. As a result, the thermal mode of the process was changed so that after attainment of 90°C in the reactor, the temperature of the thermostat was switched to 120°C. In this case, the system passed to the high-temperature mode of thermal polymerization of styrene as the temperature of the reaction mixture increased to more than 200°C (Fig. 6, curve *1*). As a result, the degree of the monomer conversion was close to unity and the resulting mass could be unloaded from the reactor.

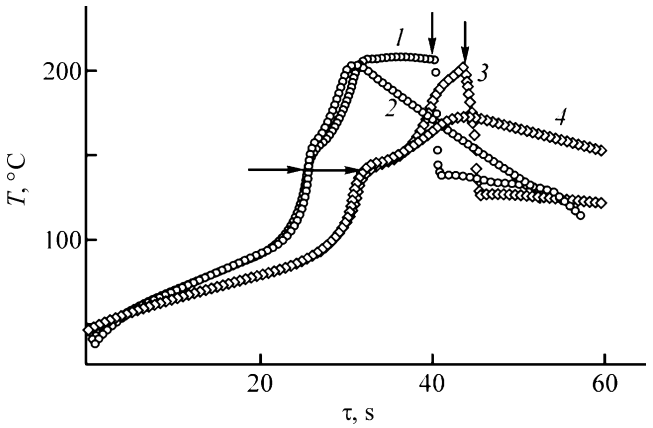

Fig. 6. Temperature curves of styrene polymerization in a 1-l metallic reactor (*1*) without additives and (*2*) in the presence of urethane U-**IIIb**, and in an 8-l metallic reactor (*3*) without additives and (*4*) in the presence of an inhibiting formulation based on urethane U-**IIIa**. (*1*, *2*) [AIBN] = 2.2×10^{-2} M, (2) [U] = 1.4×10^{-2} M; (*3*, *4*) [DIA] = 2×10^{-2} M, (*4*) [U] = [BuOH] = 1.5×10^{-2} M, [DBTDL] = 10^{-5} M. Amount of the monomer loaded, ml: (*1*, *2*) 500 and (*3*, *4*) 5000. Moments of the addition of the cold solvent in the control experiments are shown by the arrows.

Under the same conditions, we performed experiments with DI additives that were tested previously using glass ampules (Fig. 6, curve *2*). As can be seen, urethane U-**IIIb** is less efficient under the given conditions than in the case of the ampule experiments. In its presence, the rate of thermal polymerization even somewhat increases as compared to the control experiment. However, even in this case, the temperature maximum is lower by 5° than that in the control experiment, and, after attainment of the maximum, the temperature of the reaction mixture sharply decreases and the polymerization virtually terminates. The final product is fluid, and it can be discharged from the reactor without dilution with a solvent, as in the control experiment.

The results obtained for a 1-l reactor were taken into account when choosing the process modes of styrene polymerization in an 8-l reactor. This reactor was also modified to diminish the heat exchange in order to provide the possibility of attainment of the high-temperature mode of thermal polymerization. In these experiments, the temperature control unit of the thermostat was switched from 90 to 120°C when the temperature of the reaction mixture reached 150°C. The thermal modes in the course of styrene polymerization in an 8-l reactor are shown in Fig. 6 (curves *3*, *4*).

In the control experiment, when the temperature in the reactor exceeded 200°C, cold xylene was poured to lower the temperature of the reaction mixture and to

prevent uncontrollable emergency situation. Otherwise, the stirrer could be blocked and it could become impossible to unload the reaction mixture from the reactor because of the high viscosity at a conversion close to 100%. In the experiments with addition of the inhibiting formulation based on U-**IIIa**, the maximal temperature decreased by no less than 30° as compared to the control experiment, especially if we take into account that the control experiment was terminated at the temperature of the reaction mixture of 202°C, before the maximal temperature was attained.

CONCLUSIONS

(1) Dormant inhibitors of the urethane type (phenolic inhibitors blocked with isocyanates) prevent uncontrollable emergency situations in the course of styrene polymerization.

(2) In the presence of dormant inhibitors, the maximal temperature in the reactor strongly decreases and the resulting reaction mixture is a viscous mass at a conversion of about 75%, whereas in their absence the conversion reaches almost 100%.

(3) The performance of dormant inhibitors of the urethane type can be controlled by addition of proton-donor compounds accelerating liberation of the phenol inhibitor from urethane at elevated temperatures. The majority of urethanes tested do not significantly affect both the kinetics of low-temperature polymerization and the molecular-weight characteristics of the resulting polymer.

Abstract—Kinetics of radical polymerization of individual components of the ethyl acrylate–ethylene glycol dimethacrylate–chain-transfer agent system and their mixtures in toluene was studied.

DOI: 10.1134/S1070427208100236

Previously [1], we have discussed the prospects for using branched poly(methyl methacrylates) as polymers with increased molecular mobility in rigid glassy matrices (e.g., PMMA) to decelerate photochromic transformations of spiropyran. This discussion was encouraged by the increased segmental mobility of the branched macromolecules, as indicated by their glass-transition point T_g. The glass-transition point of these compounds depends on their macromolecular structure and on the content of branching and chain-transfer agent units and is lower than that of PMMA by more than 20–40°C [2]. However, our further studies showed that this level of molecular mobility of the polymer matrix is insufficient for significantly affecting the kinetics of photochromic transformation of spiropyrans.

For this purpose, linear acrylic polymers whose T_g in some cases is lower by 100°C than that of PMMA are the most suitable [3]. Branched polyacrylates are even more preferable than the linear polymers. Since these polymers are characterized by a high concentration of terminal chains and branching sites in the shell and in the core of the macromolecule [5], they can sorb molecules of a functional compound [5] (e.g., spiropyran) to form a nanocontainer, thus insulating it from the glassy matrix.

The aim of this study was to prepare branched ethyl acrylate (EA) copolymers suitable for producing sites with increased molecular mobility in organic glasses and to determine the molecular-weight distribution (MWD) and intrinsic viscosity of these copolymers and the content of residual C=C bonds in them.

EXPERIMENTAL

Branched poly(ethyl acrylates) were prepared by one-step highly efficient procedure [6] based on 3*D* radical copolymerization of EA with various multifunctional monomers [ethylene and triethylene glycol dimethacrylates (EGDM, TEGDM), 1,4-butanediol diacrylate (BDDA), and pentaerythritol triacrylate (PETA)] as branching agents. The copolymerization was controlled by 1-decanethiol (DT) as chain-transfer agent.

Monomers, EA, EGDM, TEGDM, BDDA, PETA (all Aldrich), and toluene (chemically pure grade) were used as received. Copolymerization was performed in a three-necked flask with a reflux condenser and thermometer in an argon flow for 5.5 h at T = 88°C maintained with a thermostat. The amounts of the branching agent and DT corresponded to 0.05 mol of EA. The content of the reactants in a toluene solution was approximately 20 wt %. The concentration of the initiator, 2,2'-azobis(isobutyronitrile) (AIBN), was 2×10^{-2} M.

The concentration of the branching agents and DT was varied in a wide range, with their equimolar ratio being constant. The EGDM content in EA–EGDM–DT mixtures was 2, 5, 12, and 20 mol % with respect to EA. The content of TEGDM, BDDA, and PETA in the reaction mixtures was 5, 12, and 20 mol %. After the reaction completion, the unchanged comonomers and toluene were removed in a vacuum. The polymers were dried to constant weight at T = 60°C in a vacuum.

The polymer yield determined gravimetrically was 90–95%.

The (co)polymerization kinetics of EA–EGDM–DT mixtures was studied by precision isothermal calorimetry on a DAK-1-1 calorimeter. The reaction mixture was subjected to repeated freezing–pumping–thawing and then was polymerized at T = 60°C in evacuated sealed glass ampules. The polymerization kinetics of 100 : 0 : 0, 100 : 12:0, 100 : 0 : 12, and 100 : 12 : 12 EA–EGDM–DT mixtures in toluene in the presence of 4×10^{-4} M 2,2',6,6'-tetramethylpiperidine-1-oxyl (TEMPO) was studied. The conversion *C* of C=C bonds and the reduced (co)polymerization rate *w*/[M] were calculated by the procedure described in [7] from the heats of polymerization of EA and MMA, equal to 78.7 and 58.8 kJ mol^{-1}, respectively.

The content of residual C=C bonds in the copolymers was determined by ozonolysis [8] using ADS-4M double bond analyzer. For this purpose, solutions of (co)polymers in CCl_4 were prepared. Stilbene was used as a reference compound.

The average molecular weight of the copolymers and their MWD were determined by exclusion chromatography (EC) on a Waters liquid chromatograph equipped with a differential refractometer. We used Silasorb SGH 600 and Nucleosil 300 columns connected in tandem (Set B) or a Silasorb SGH 600 column (Set A), which provide linear calibration for PS references with M ~200–(5×10^5). The columns were eluted with THF at a flow rate of 0.3 ml min^{-1}. The column temperature was 35°C. To calculate MW, we used calibration curves for the PS references. The chromatograms were recorded and treated with the aid of Millennium-32 software.

The rheological properties of linear PEA and branched EA-EGDM, EA-TEGDM, EA-BDDA, and EA-PETA copolymers were studied with an Ubbelohde viscometer. The time of toluene outflow is $t_0 \approx 70$ s. The intrinsic viscosity [η] was determined by extrapolation of the dependence of the reduced viscosity on the polymer concentration in toluene to the zero concentration. The Huggins constants *k*' were calculated from experimental [η] values and from the slope of the dependence of the reduced viscosity on the polymer concentration in the solution.

Uncontrolled propagation of polymer chains in the course of 3*D* (co)polymerization of multifunctional monomers results in intra- and intermolecular chemical cross-linking to form an insoluble cross-linked polymer [4]. To prevent cross-linking, chain-transfer agents (e.g., thiols) terminating the chain propagation by the reaction

$$R_n^{\cdot} + RSH \rightarrow R_nH + RS^{\cdot},$$

$$RS^{\cdot} + M \rightarrow RSR_n.$$

are added.

3*D* radical copolymerization (in particular, copolymerization of EA with functionalized monomers) in the presence of chain-transfer agents yields branched macromolecules with different degrees of polymerization, which increase with the content of the branching agent [9]. The formation of small rings by the reaction of the C=C bonds of adjacent chains or by intrachain interaction may interfere with branching of the polymer chains [4]. However, this process can be minimized by varying the ratio of the chain-transfer agent to the branching agent in the system.

At *T* = 20°C, the copolymers are in the hyperelastic or viscous-flow state and are soluble in many organic solvents (benzene, toluene, chloroform, acetone). Their molecular structure (content of EA and branching agent units and their distribution in the macromolecule) is determined by the monomer reactivity and the composition of the reaction mixture. For example, copolymer with a random distribution of the monomer units is formed by radical copolymerization of EA (r_1 = 0.5) with dimethacrylates (r_2 = 2) [10]. In this case, unlike diacrylates, the copolymer enriched in EGDM or TEGDM is formed in the initial steps and the copolymer containing mainly the acrylate units is formed at high monomer conversions. This, in turn, increases the chain-transfer efficiency, since the chain-transfer coefficient C_s in the case of chain termination on the acrylate radical is higher than that on the methacrylate radical [11].

The formation of branched EA copolymers in kinetically controlled. We studied first the kinetics of radical polymerization of the components of the EA–EGDM–DT system and of their mixtures in toluene. The kinetic curves of polymerization of 100 : 0 : 0, 100 : 12 : 0, 100 : 0 : 12, and 100 : 12 : 12 EA–EGDM–DT mixtures are shown in Fig. 1. It can be seen (curve *1*) that EA polymerization in toluene is accompanied by a weak gel effect (acceleration of the reaction due to a raise in the viscosity of the reaction mixture upon an increase in the monomer conversion). As a result, the termination of the propagating macroradicals becomes hindered, and the constant of chain termination

of the macromolecules decreases [4]. The reaction exhibits an autoinhibiting effect in a wide conversion range, i.e., the polymerization decelerates owing to the diffusion control of the chain propagation. Introduction of EGDM results in the conventional 3*D* radical copolymerization and inhibits the reaction which is autocatalytic (gel effect) at low conversions and autoinhibited at $C > 50\%$ (curve *2*). Introduction of DT into the re-action system shifts the gel effect to high conversions and decreases it (cf. curves *1* and *3*). The features of radical polymerization of 100 : 12 : 12 EA–EGDM–DT mixtures are described by curve *4*. The reaction is autocatalytic at $C > 30\%$ and autoinhibited at $C > 60\%$ and yields a water-soluble EA–EGDM copolymer.

The average lengths of primary polymer chains $\bar{P}$ for branched EA–BDDA and EA– PETA copolymers were calculated from the kinetic data by the equation [4]

$$\overline{P} = \frac{k_p[M_1 + M_2]}{\sqrt{w_i k_t + k_{tr}[P]}} \approx \frac{k_p[M_1 + M_2]}{k_{tr}[P]}$$

(where k_p, k_t, and k_{tr} are the rate constants of chain propagation, termination, and transfer, respectively; $[M_1]$ and $[M_2]$, the concentrations of EA and branching agent; [P], DT concentration; and w_i, initiation rate equal to approximately 10^{-6} mol l^{-1} s^{-1}) taking into account that $(w_i k_t)^{1/2} << k_{tr}[P]$. The propagation of the primary polymer chains was initiated by a single event of generation of the R_i initiator radical by the reaction $I \rightarrow R_i$. $\bar{P}$ was calculated using $C_s = k_{tr}/k_p = 1.7$. The longest primary polymer chains ($P = 12$) are formed from 100 : 5 : 5 mixtures. $\bar{P}$ for copolymers prepared in the presence of 12 and 20 mol % of BDDA and PETA and equimolar amounts of DT decreases to 6 and 4 units, respectively, which suggests shortening of the inter-cross-link segments and terminal chains.

To obtain additional information on the copolymer structure, we used the critical conversion C_{cr} (gel point) calculated by the equation of the gelation theory [4]:

$$C_{cr} = 0.5k_p[P]/k_p\Phi_{22}(0) = 0.5k_{tr}[P]/k_p 2[M_2],$$

where $\Phi_{22}(0)$ is the second moment of functional istribution of the initial monomer molecules at the instant of time $t = 0$.

The fact that C_{cr} of EA–BDDA and EA–PETA copolymers is 42.5% suggests that the high copolymer yields (which are higher by a factor of more than 2 than C_{cr}) are due to the contribution of cyclization, which shifts C_{cr} to high conversions [4]. Hence, the branched macromolecules contain cyclic fragments.

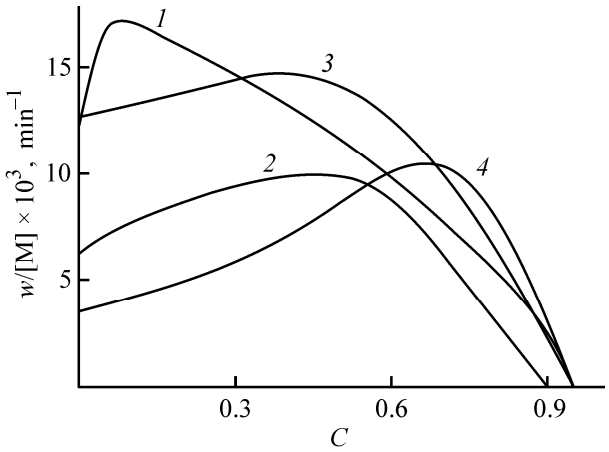

Fig. 1. Kinetic curves of polymerization of (*1*) 100 : 0 : 0, (*2*) 100 : 12 : 0, (*3*) 100 : 0 : 12, and (*4*) 100 : 12 : 12 EA–EGDM–DT mixtures in toluene. [AIBN] = 0.02 M, $T = 60°C$, [TEMPO] = 4×10^{-4} M, [toluene] = 80 wt %. (w/[M]) Reduced polymerization rate and (C) conversion.

Since the hydrodynamic volumes of linear and branched macromolecules differ, the molecular-weight parameters of the branched polymers are underestimated as compared to the absolute values calculated from the data of EC and multiple-angle light scattering. However, the MWD of branched polymers can be semiquantitatively estimated by the conventional EC method using an interferometer-reflactometer and calibration curves for linear polymers [6]. The number-average molecular weight (M_n), weight-average molecular weight (M_w), and polydispersity coefficients (M_w/M_n) of linear PEA and branched copolymers are listed in the table. MWD curves for linear PEA and branched copolymers prepared from mix-tures of different compositions are shown in Fig. 2. The MWD curve of linear PEA consisting of approximately 70 EA units is unimodal (Fig. 2, curve *1*), whereas the MWD curve (Fig. 2, curve *2*) of the copolymer prepared from a mixture of 2 mol % EGDM and DT is broadened owing to the presence of a low-molecular-weight fraction. The MWD curve of the co-polymer prepared in the presence of 12 mol % EGDM and DT is pronouncedly bimodal (Fig. 2, curve 3): the amount of the low-molecular-weight fraction is comparable to that of the high-molecular-weight fraction. M_n and M_w/M_n of the high-molecular-weight fraction ares 8×10^3 and 1.3, respectively. The molecular-weight distribution of the copolymer prepared from 20 mol % EGDM and DT is polymodal. As the EGDM content

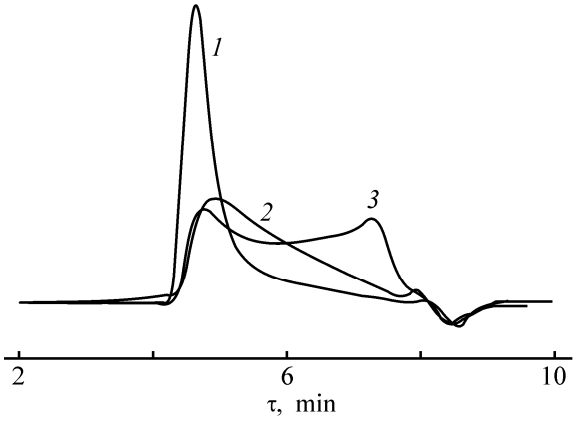

Fig. 2. MWD curves of (*1*) linear PEA and branched copolymers prepared from EA–EGDM–DT reaction mixtures of the compositions (*2*) 100 : 2 : 2 and (*3*) 100 : 12 : 12. (τ) Time.

in the reaction mixture increases from 2 to 20 mol % and hence the content of EGDM units in the copolymer grows, M_w/M_n ratio becomes larger (see table), i.e., the copolymer becomes more nonuniform in MW.

Comparison of MWD of EA–EGDM and EA–TEGDM copolymers shows that a change in the length and flexibility of the oligomeric branching agent block makes M_w and M_w/M_n of the copolymer smaller (see table). By contrast, use of BDDA as a branching agent leads to an increase in M_w and M_w/M_n of the EA–BDDA copolymers. The amount of the high-molecular-weight fraction in the MWD curves of these copolymers increases with the BDDA content in the reaction mixture from 5 to 20 mol %.

As can be seen from the table, the MWD of the copolymers depends on the content of C=C bonds in the branching agent. For example, the MWD of EA–PETA is broader than that of EA–BDDA. This fact is consistent with the data of Slark et al. [12], who showed that M_w and M_w/M_n of branched poly(methyl methacrylates) increased with the number of the functional groups of the branching agent. The number-average molecular weight (M_n) of the high-molecular-weight fraction is in the range $(13.6–21.3) \times 10^3$ and M_w/M_n, increases from 1.6 to 2.2 as PETA content becomes higher.

Thus, the MWD of the copolymers is determined by the composition of the reaction mixture, chemical structure of the branching agent, and its functionality. Our experimental data show that EA copolymers are macromolecules with different molecular weights.

Molecular weight and rheological parameters of linear and branched EA (co)polymers

(Co)polymer	Composition of EA–P*–DT mixture	MWD			[η], dl g^{-1}	k'

* Branching agent.

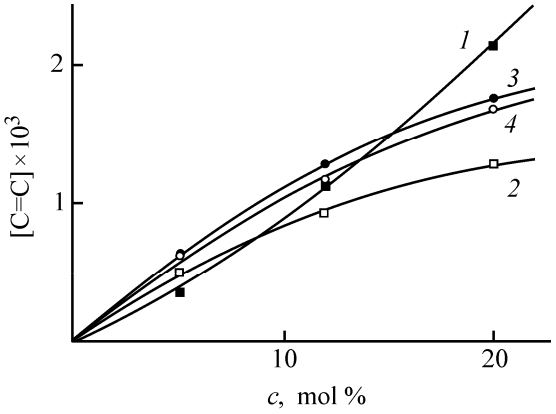

Fig. 3. Content of residual C=C bonds in 1 g of branched copolymers (*1*) EA–EGDM, (*2*) EA–TEGDM, (*3*) EA–BDDA, and (*4*) EA–PETA vs. the content *c* of the branching agent and DT.

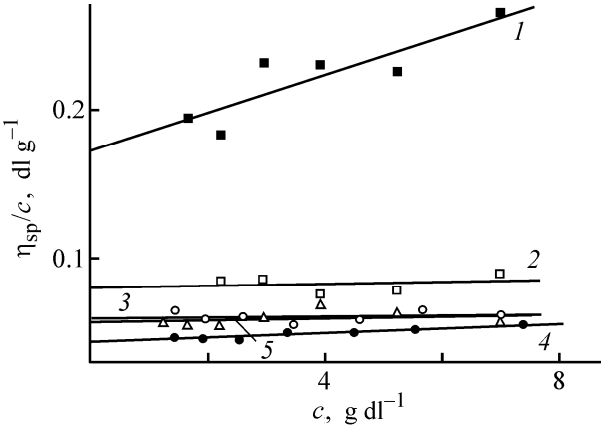

Fig. 4. Reduced viscosity η_{sp}/c vs. the concentration *c* of (*1*) linear PEA polymer and branched EA–EGDM copolymers prepared from (*2*) 100 : 2 : 2, (*3*) 100 : 5 : 5, (*4*) 100 : 12 : 12, and (*5*) 100 : 20 : 20 EA–EGDM–DT mixtures. Toluene, 20°C.

The dependence of the content of residual C=C bonds in the copolymers on the concentration of the branching agent and DT in the initial mixtures is shown in Fig. 3. The content of C=C bonds in the copolymers prepared in the presence of 20 mol % branching agent is the highest. As can be seen from Fig. 3 (curves *1*, *2*), the content of residual C=C bonds in the EA–TEGDM copolymer is a factor of 1.4 higher than that in EA–EGDM at a 5% dimethacrylate content in the reaction mixture. The content of residual C=C bonds in the EA–TEGDM copolymers prepared in the presence of 12 and 20 mol % dimethacrylates is lower than that in the corresponding EA–EGDM copolymers. This is probably due to involvement of the residual C=C bonds of TEGDM in branching and intrachain cyclization. In going from dimethacrylates to BDDA, the residual unsaturation of the copolymers grows (Fig. 3, curve *3*). As the functionality of the branching agent increases, the content of the residual C=C bonds in the copolymer (EA–PETA compared to EA–BDDA) slightly decreases.

The branching structure of copolymers can be readily confirmed by viscometry [13, 14]. The copolymer structure can be indirectly determined from the rheological properties of the copolymers and their comparison with those of the linear analogs of similar molecular weight. The typical dependences of the reduced viscosity η_{sp}/c of linear PEA and EA–EGDM copolymers of various compositions on their concentration *c* in the solution are shown in Fig. 4. These dependences were analyzed by the Huggins equation

$$\eta_{sp}/c = [\eta] + k'[\eta]^2 c,$$

where k' is the Huggins constant characterizing the thermodynamics of polymer–solvent interaction and the hydrodynamic behavior of the copolymer solutions.

We obtained the similar dependences for solutions of the other copolymers.

The intrinsic viscosities [η] and the Huggins constants k' of the copolymers examined are summarized in the table. As can be seen from the table, the rheological properties of these copolymers differ from those of the linear polymer. Since the conformation of branched copolymer macromolecules is compact, their [η] is low. In addition, the slope of the $\eta_{sp}/c = f(c)$ dependence for these copolymers suggests a weaker dependence of the reduced viscosity on the copolymer concentration (Fig. 4).

Important data on the behavior of branched copolymer in a solution were obtained from the analysis of the Huggins constants k'. As can be seen from the table, $k' < 0.5$ for linear PEA, i.e., toluene is a comparatively good solvent. Introduction of the EGDM and DT units into the macromolecule decreases k', i.e., the solvent quality becomes better. The exception is EA–EGDM copolymer (composition of the reaction mixture 100 : 12 : 12) which has $k' > 0.5$. This fact means that macromolecules of this copolymer form small dense balls in toluene, thus decreasing the viscosity of the copolymer solution. As also can be seen from the table, the interaction of EA–EGDM copolymer with the solvent varies in a wide range. The copolymer prepared in the presence of 12 mol % TEGDM is characterized by the best thermodynamic compatibility. Macromolecules of the copolymer prepared in the presence

of 20 mol % TEGDM weakly interact with the solvent. In this case, toluene becomes a bad solvent.

The branched copolymers prepared from 100 : 5 : 5 and 100 : 20 : 20 EA–BDDA–DT mixtures have similar thermodynamic affinities for toluene, whereas the interaction between the solvent and macromolecules of this copolymer prepared in the presence of 12 mol % branching agent becomes weaker. The dependence of k' on the composition of EA–PETA–DT reaction mixture is inverse. In this case, according to k', the interaction between the solvent and the branched copolymer macromolecules prepared in the presence of 12 mol % PETA and DT is the strongest.

An analysis of the experimental [η] and Huggins constants k' of EA copolymers showed no correlation between their rheological properties and the composition of the reaction mixture, the branching agent structure, and its functionality. This is due to the formation of branched copolymer by 3*D* random radical copolymerization controlled by the chain-transfer agent.

CONCLUSIONS

(1) Branched copolymers were prepared by one-step 3*D* radical copolymerization of ethyl acrylate with multifunctional comonomers of different chemical structures in toluene. The process is controlled by 1-decanethiol.

(2) The molecular-weight properties of the copolymer were determined by exclusion chromatography, and the content of residual C=C bonds in their molecules, by ozonolysis.

(3) The rheological properties of the branched copolymer in toluene were studied, the intrinsic viscosities of these solutions were measured, and the Huggins constants were calculated.

Abstract—Formation of nanocomposites in the sol–gel systems $RSiX_3$ [R = CH_3 (**I**), C_6H_5 (**II**), X = Cl; R = $ClCH_2$ (**III**), X = OC_2H_5]–polyvinylazole [$(–CH_2–C(Y)H–)_n$, Y = pyrazolyl, imidazolyl, 4-pyridinyl, 2-methyl-5-pyridinyl], and also **I**–1-vinyl-4,5,6,7,-tetrahydroindole using was studied. The composition and structure of the resulting nanocomposites were analyzed.

DOI: 10.1134/S1070427208100248

Sol–gel technique employing tetraalkoxysilanes SiR_4 (R = OC_2H_5, OCH_3) and organic low- and high-molecular-weight compounds is being intensively developed as a method for preparing organoinorganic composite materials and, in particular, nanocomposites [1–5]. To expand the range of such materials and to improve their performance characteristics, various polymers are introduced into the sol–gel process [6–8]. An extension of this approach is use of organyltrichloro- or organyltrialkoxysilanes [$RSiX_3$; X = Cl, OCH_3, OC_2H_5; R = CH_3, C_6H_5, $CH{=}CH_2$, $(CH_2)_3NH_2$, etc.] instead of tetraalkoxysilanes, e.g., vinyltriethoxysilane, phenyltriethoxysilane, 3-aminopropyltriethoxysilane, etc. [9–11]. In this case, the structure and properties of the resulting copolymers are governed by the nature of a substituent R and by the conditions of the sol–gel process (hydrolysis of silanes) [12, 13].

For example, a specific feature of the hydrolysis product of chloromethyltriethoxysilane, poly(chloromethylsilsesquioxane) $[ClCH_2SiO_{1.5} \cdot nH_2O]_m$, is that it contain in the bulk and at the surface chloromethyl groups capable of donor–acceptor interaction with compounds basic in nature. In ethanol, a macroporous product with high content of mesopores (total volume 1.37 $cm^3\ g^{-1}$) and large specific surface area (155 $m^2\ g^{-1}$) is formed [13].

The hydrolytic polycondensation of methyltrichlorosilane in aqueous and aqueous-organic solutions is accompanied by the formation of hydrated poly(methylsilsesquioxane) $[CH_3SiO_{1.5} \cdot nH_2O]_m$. The resulting solid product is characterized by a high specific surface area (394–1204 $m^2\ g^{-1}$) and microglobular (prevalent globular size 1–2 nm) lamellar or folded structure with a highly developed system of micro- and mesopores [14, 15]. The process is rapid and gives poly(methylsilsesquioxane) in nearly 100% yield via three parallel independent mechanisms of formation of Si–O–Si groups: hetero- and homofunctional polycondensation, and generation and further transformation of silanone intermediates [16, 17].

Preparation of cross-linked phenyltrichlorosilane-based 3*D* polymers is sterically hindered by the bulky phenyl groups. Poly(phenylsilsesquioxanes) $[C_6H_5SiO_{1.5}]_m$ synthesized by any method demonstrate poor thermal stability and low solubility in water and organic solvents [13].

The goal of this study was to synthesize hybrid copolymers based on organosilicon monomers using sol–gel technique. We performed a comparative analysis of the formation, structure, and properties of nanocomposites based on $RSiX_3$ (X = CH_3, C_6H_5, CH_2Cl), on the one hand, and polyvinylazoles, on the other hand.

The following polyvinylazoles were studied: poly(1-vinylpyrazole) (PVP), poly(1-vinylimidazole) (PVI), poly(4-vinylpyridine) (PVSP), poly(2-methyl-5-vinylpyridine) (PMVP), and 1-vinyl-4,5,6,7-tetrahydroindole) (VTHI).

EXPERIMENTAL

Poly(1-vinylpyrazole), poly(1-vinylimidazole), poly(4-vinylpyridine), poly(2-methyl-5-vinylpyridine), and 1-vinyl-4,5,6,7-tetrahydroindole) were prepared using the known procedures [18–20]. Commercial chloromethyltriethoxysilane (CMTEOS), methyltrichlorosilane, and phenyltrichlorosilane were used.

An elemental analysis of reaction products was carried out on a Thermo Finnigan gas analyzer. IR spectra were recorded on an IFS-25 spectrometer using KBr pellets and Nujol mulls. ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ on a Bruker DPX-400 instrument (400.13 MHz) using TMS as an internal reference.

The surface structure of the organoinorganic copolymers was examined on a Philips-525M scanning electron microscope.

The specific surface area of the composites was estimated by measured the nitrogen adsorption at various temperatures and pressures in a graduated high-vacuum cell.

TG curves were recorded on a Paulik–Paulik–Erdey derivatograph (MOM, Hungary) in air at a heating rate of 5 deg min^{-1}. The maximal temperature was 700°C, and the DTA sensitivity, 1/5 to 1/10.

The sorption of Ag(I), Pd(II), and Pt(IV) on the copolymers was carried out from solutions containing 0.2–5 (mg metal) l^{-1}. Stock solutions were prepared using $AgNO_3$, $PdCl_2$, and $H_2PtCl_6 \cdot 6H_2O$ (chemically pure grade), and distilled water. The metal concentrations in solutions were determined photometrically with a KFK-2 photocolorimeter [21].

The base hydrolysis of CMTEOS in the presence of nitrogen polybases was carried out at room temperature as follows. CMTEOS (1.0 g) and 0.1 M aqueous NaOH (2.55 ml) were successively added to the nitrogen polybase (0.3 g) dissolved in ethanol (5 ml). On adding aqueous NaOH, the resulting mixture first became turbid and gel-like, and then an insoluble hybrid composite copolymer precipitated. This precipitate was multiply washed with water and vacuum-dried in a desiccator to constant weight. Carrying out the hydrolysis in alkaline medium provides a 3*D* condensation of poly(chloromethylsilsesquioxane) [12, 13], whose rigid structure makes the product insoluble in water and organic solvents and thermally stable (Table 1).

The hydrolysis of MTCS in the presence of nitrogen polybases or VTHI was performed similarly, but

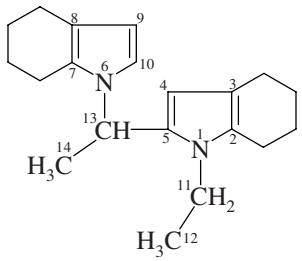
without base catalysis. The hydrolysis of MTCS in accordance with Eq. (1) does not require base catalysis [12, 13], being accompanied by a considerable increase in the solution acidity as a result of formation of HCl, along with methylsilanetriol, in the first stage:

$$n\mathrm{CH_3SiCl_3} + 3n\mathrm{H_2O} \rightarrow n\mathrm{CH_3Si(OH)_3} + 3n\mathrm{HCl},$$

$$n\mathrm{CH_3Si(OH)_3} \rightarrow (\mathrm{CH_3SiO_{1.5}})_n + 1.5n\mathrm{H_2O}. \quad (1)$$

The process is rapid, and gives finely dispersed low-molecular-weight poly(methylsilsesquioxane). Such composites are stable up to 195–325°C (Table 1).

Similarly to the case of tetraethoxysilane-based systems studied previously [22], we found in this study no correlations between the hybrid copolymer composition and the basicity of the nitrogen polybase (pK^+_{BH} of 1-vinylpyr-azole, 1-vinylimidazole, 4-vinylpyridine, and 2-methyl-5-vinylpyridine is 1.7, 7.52, 5.62, and 5.67, respective-ly). In these systems, the fraction of nitrogen polybases in the composite increases in the order PVP < PVI < PVSP < PMVP. The composition of the CMTEOS-based copolymers ($\mathrm{ClCH_2SiO_{1.5}}$: N-polybase unit) is as follows: 4.2 : 1 (PVP), 4.0 : 1 (PVI), 2.9 : 1 (PVSP), and 1.9 : 1 (PMVP) (Table 1). In the MTCS-based systems, the $\mathrm{CH_3SiO_{1.5}}$: N-polybase unit ratios were 1.4 : 1 (PVP), 0.8 : 1 (PVI), 0.7 : 1 (PVSP), and 0.5 : 1 (PMVP) (Table 1).



In the copolymers formed in the system phenyltrichlorosilane–nitrogen polybase, the fraction of the polybase decreases as its basicity increases. In this case, the $\mathrm{C_6H_5SiO_{1.5}}$: N-polybase unit ratios are 1 : 1 (PVP), 1.7 : 1 (PVSP), 2.5 : 1 (PMVP), and 3.7 : 1 (PVI) (Table 1).

The case with VTHI is somewhat special. In the presence of HCl, formed as a hydrolysis product of methyltrichlorosilane, VTHI tends to dimerize. As a result, the resulting composite contains VTHI dimer, but not monomeric VTHI or its polymerization product poly(1-vinyl-4,5,6,7-tetrahydroindole), and the composition of this copolymer is $\mathrm{CH_3SiO_{1.5}}$: $(\mathrm{VTHI})_2$ = 1.8 : 1.

The formation of VTHI dimer in synthesis of this composite is confirmed by the IR and ^{1}H and ^{13}C NMR spectra.

The IR spectrum of the sample under study contains pyrrole absorption bands at 690, 912, 1200, 1300, 1380, 1490, and 1540 $\mathrm{cm^{-1}}$.

The ^{1}H and ^{13}C NMR spectra of this composite show resonances typical of the dimer:

^{1}H NMR, δ, ppm: 1.77, 2.66 (cyclohexane fragment); 5.84, 6.19 (pyrrole ring); 5.17, 1.54 (=CH–CH_3). ^{13}C NMR: δ, ppm: 128.99 ($C^{2,7}$), 116.69 ($C^{3,8}$), 106.99 (C^4), 129.04 (C^5), 108.67 (C^9), 117.50 (C^{10}), 49.87 (C^{11}), 24.23 (C^{12}), 47.94 (C^{13}), 22.64 (C^{14}).

Therefore, one could suggest the following dimerization mechanism. First, HCl formed in hydrolysis reacts with 1-vinyl-4,5,6,7-tetrahydroindole to give the immonium cation. Second, electrophilic attack of the immonium cation at the pyrrole ring of the copolymer macromolecule yields VTHI dimers.

Among the MTCS-based copolymers, the composite with VTHI has the best thermal stability, highest specific surface area (Table 1), and smallest globule size (predominant particle size 86–97 nm).

Among the CMTEOS-based composites, the smallest particle size (30–50 nm) was found for the copolymers with PVP. The particle size of the corresponding copolymers with PVI is 300 nm. The products obtained in the sol–gel process with PVSP and PMVP are polydisperse crystal-like substances.

The IR spectra of all the copolymers under consideration contain strong absorption bands at 1010–1150 $\mathrm{cm^{-1}}$, typical of Si–O–Si stretching vibrations. The protonation causes a high-frequency shift of the stretching vibrations of the pyridine nitrogen from 1615 $\mathrm{cm^{-1}}$ in the initial polybases to 1650 $\mathrm{cm^{-1}}$. Weak absorption bands of the protonated pyrazole and imidazole rings are observed at 1530–1570 $\mathrm{cm^{-1}}$.

The fact that the nitrogen atoms of the heterocycles in the composites retain their chemical activity was confirmed by sorption data. The sorption activity of the copolymers of CMTEOS and MTCS with nitrogen polybases was examined with respect to Ag^+ in nitric acid solutions and to Pd(II) and Pt(IV), in HCl solutions, in which these metals exist as anionic complexes $[PdCl_4]^{2-}$ and $[PtCl_6]^{2-}$ (Table 2). Data on the static sorption capacity (SSC) and distribution coefficient D (in 1 M acid solutions) revealed no correlation between the sorption activity, polybase nature, and

Table 2. Static sorption capacity SSC and limiting sorption capacity LSC of copolymers for noble metals, and distribution coefficient *D* of noble metals between copolymers and aqueous solutions

Copolymer	SSC, mg g^{-1} / LSC, mg g^{-1}			D, cm^3 g^{-1}		
	Pd(II)	Pt(IV)	Ag(I)	Pd(II)	Pt(IV)	Ag(I)

$CH_3SiO_{1.5}$: PMVP	803/690	850/1270	–	2500	1400	–

sorbate nature. However, the observed high sorption capacities suggest that the nitrogen donor atoms in the composites retain their complexing power. The formation of metal–nitrogen bonds is demonstrated by the appearance of the bands at 400–300 cm^{-1} in the IR spectra of the metal-saturated copolymers.

CONCLUSIONS

(1) Hydrolysis of chloromethyltriethoxysilane, methyltrichlorosilane, and phenyltrichlorosilane in the presence of poly(*N*-vinylazoles), poly(vinylpyridines), and 1-vinyl-4,5,6,7-tetrahydroindole gives organoinorganic copolymers.

(2) The resulting copolymers are characterized by high thermal and chemical stability, highly dispersed structure, and highly developed surface area.

(3) The hybrid copolymers efficiently sorb noble metal ions from acidic solution.

Abstract—Synthesis of polyvinyl formal from a mixture of polyvinyl alcohol and formaldehyde under microwave irradiation was studied. The syntheses of polyvinyl formal under microwave irradiation and thermal treatment were compared. The yield of polyvinyl formal was examined in relation to the irradiation power, initial component concentration, and reaction time. The polyacetals were characterized by elemental analysis and IR spectroscopy.

DOI: 10.1134/S107042720810025X

One of promising approaches to development of efficient power-saving chemical processes is based on application of microwave irradiation (MWI). Therefore, the study of effects of microwave irradiation on chemical systems is an topical problem.

The published data show that microwave irradiation is an efficient technique for pretreatment of samples in analytical chemistry [1] and synthesis of low-molecular-weight organic compounds [2, 3]. The preparation of nanostructures from nanoparticles of silver, platinum, palladium, ruthenium, and other metals in the presence of polymeric stabilizers in combination with reducing agent, such as glycerol, hydrazine, dimethylformamide, and polyalcohols, has been extensively studied recently [4, 5]. It was found that, under microwave irradiation, polymeric methyl acrylate nanostructures are formed in situ from methyl acrylate monomers in the presence of silver nanoparticles [6]. The selective absorption of microwave radiation by polar components incorporated in a nonpolar polymeric matrix can improve composites. Owing to the higher efficiency of microwave heating as compared to thermal treatment, this technique can be used for dehydration of fuels (e.g., coal) [7, 8].

The number of studies concerned with the effect of microwave irradiation on foodstuffs steadily increases [9, 10]. In particular, it has been found that physicochemical characteristics of gel-like starch treated with microwave radiation strongly differ from those of thermally treated gel-like starch [11]. The problem of utilization of polymeric wastes can be solved by their microwave treatment. For example, the efficiency of decomposition and/or dehydrochlorination of polyvinyl chloride grows in the presence of components absorbing microwave radiation (activated carbon, iron) and also with increasing radiation power and irradiation time [12].

It should be noted that microwave irradiation can not only substantially accelerate slow reactions, but also make possible new processes. Therefore, the modern chemistry is characterized by growing application of microwave irradiation.

In this study, we examined the effect of microwave irradiation on synthesis of polyvinyl formal (PVF) by the reaction of polyvinyl alcohol (PVA) with formaldehyde (F). The features of PVA acetalization under these conditions are analyzed. In modern chemistry, PVF is prepared either from polyvinyl acetate or, more preferably, by heterogeneous acetalization of PVA. This reaction is commonly performed in aqueous solutions containing formaldehyde and acid catalyst (e.g., hydrochloric or sulfuric acid) at elevated temperatures in the course of several hours. The resulting insoluble product is separated, repeatedly washed, and then dried [13].

Table 1. PVF preparation under microwave treatment ([PVA] = 1.4 M, [F] = 2.0 M)

Run no.	Power, W (time, min)	$M_{PVA} \times 10^{-3}$	HCl concentration, %	PVF yield, %

EXPERIMENTAL

In this study, both low- (M = 25 000) and high-molecular-weight (M = 100 000) PVA were used. Other chemicals were aqueous formaldehyde (Formalin) 40% and aqueous hydrochloric acid.

Low-molecular-weight PVA was of Laverna 16/1 brand [GOST (State Standard) 10 779–78, the acetate group content does not exceed 2%]. High-molecular-weight PVA was of Sandinil 2499M brand (Netherlands) (the acetate group content did not exceed 1%].

The PVA acetylation under microwave irradiation was carried out in a Teflon beaker at various ratios of the starting reactants.

The reaction mixture was irradiated in microwave ovens (Samsung GP90, China, 2.45 GHz; MDS-2000, CEM Corp., USA, 2.45 GHz). The resulting polymeric products were characterized by IR spectroscopy (Bruker, EGUINOX-55, Germany) and elemental analysis. The solubility of PVF in various solvents was determined both at room and elevated temperatures.

The PVF synthesis under thermal treatment was carried out as follows. An 8% aqueous solution of PVA (10 ml) was placed in a reaction flask, and then formaldehyde (2.1 ml) and concentrated acid (0.2–0.4 ml) were added. The reaction mixture was heated for 1.5 h, with the temperature gradually increasing from 60 to 90°C.

Polyacetal samples prepared under both thermal treatment and microwave irradiation were thoroughly washed with warm water (35–40°C) and then dried to constant weight. The polyacetal yield was calculated as the ratio of the weight of the final product after its contact with hot water (80°C) for 30 min to the total weight of the initial PVA and formaldehyde.

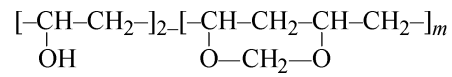
In this study, we examined how the radiation power, irradiation time, acid concentration, and molecular weight of the starting PVA affect the PVF yield. We found that MWI caused the temperature of the reaction mixture to increase to 53–55 (180 W, 3 min) or 65–70°C (300 W, 3 min). Table 1 shows that, with increasing radiation power and irradiation time, the PVF yield grows. At the irradiation time exceeding 10 min, the reaction mixture strongly warms up and is carbonized. With the HCl concentration in the reaction mixture increasing from 0.37% (pH 1.14) to concentrated HCl (pH 0.63), the PVF yield grows. It was found that the PVA molecular weight insignificantly affects the polyacetal yield.

In this study, PVF was prepared in an open reaction vessel. Under these conditions, the PVF synthesis is accompanied by gradual evaporation of the solvent (water) and increase in the reactant concentrations. As a result, the final product is formed as a swollen film. In preparing PVF in a closed reaction vessel, water formed as one of by-products is not noticeably removed from the reaction mixture. We believe that the presence of water, all other factors being the same, makes lower the PVF yield as compared to synthesis in an open reaction vessel (Table 1).

Table 3. PVF interaction with solvents at 25°C (24 h) and 85–90°C (1 h)

Solvent	Treatment method			
	thermal		MWI	
	25°C	85–90°C	25°C	85–90°C
Dioxane	w	s	w	s
DMF	w	s	w	s
Acetic acid	s	sol	s	sol
Pyridine	s	s	s	s
Benzyl alcohol	s	sol	s	sol

* (w) Weakly swelling, (s) strongly swelling, and (sol) dissolves.



The PVF yield was examined in relation to the concentration and ratio of the starting components. Table 2 shows that, with the PVA to formaldehyde ratio varied from 1 : 0.3 to 1:6, the PVF yield is maximal when this ratio is approximately 1 : 1.5.

For comparison, PVF was also prepared by the common technique with stepwise heating of the reaction mixture: 60°C (30 min) + 75°C (30 min) + 90°C (30 min). In these experiments, the temperature of the reaction mixture was comparable to, or even higher than that in synthesis under microwave irradiation, and the reaction vessel was equipped with a reflux condenser preventing the solvent evaporation. After treatment of the reaction mixture for 1.5 h, the PVF yield was about 28%. Under these conditions, the yield remained virtually unchanged with increasing reaction time. In going to synthesis under thermal treatment in an open reaction vessel, the PVF yield changed insignificantly.

The IR spectra of PVA and formaldehyde substantially differ from the spectra of polyvinyl formal obtained under microwave or thermal treatment. The intensity of absorption bands of the hydroxo groups of polyvinylformal (3300–3600 cm^{-1}) decreases and new absorption bands at 2805 and 2885 cm^{-1} appear, presumably due to vibrations of the CH_2 groups in the O–CH_2–O fragments. Furthermore, the acetylation is accompanied by a significant change in the intensity of four absorption bands belonging to the C–O groups (1000–1200 cm^{-1}), present in the spectrum of PVA [14, 15]. It was also found that the IR spectrum of the sol prepared by extraction of PVF with hot water is almost identical to that of the initial PVA except for a weak change in the intensity of absorption bands in the range 1000–1200 cm^{-1}. This effect can be caused by the low degree of acetalization of the water-soluble fraction of polyacetal.

It is known [13] that the solubility of PVF decreases as the content of vinyl acetate groups in the starting PVA becomes lower. The solubility of PVF prepared in this study was determined in toluene, dimethylformamide, acetic acid, pyridine, benzyl alcohol, and nitrobenzene, i.e., in solvents commonly used for dissolution of polyacetals. The PVF samples were kept in these solvents either at room temperature for 24 h or at elevated temperature (85–90°C) for 1 h. Table 3 shows that the solubility of polyacetals is essentially independent of the method of their preparation. The similarity of the chemical compositions of polyacetals prepared under microwave irradiation and thermal treatment was confirmed by elemental analysis.

The carbon and hydrogen content of the polyacetals (wt %) was, respectively, 56.10–57.05 and 8.57–8.71 for samples prepared under microwave irradiation (Table 1, run no. 7) and 56.80–58.24 and 8.60–8.80 for samples prepared under thermal treatment. The calculated carbon and hydrogen content was 54.54 and 9.1% for PVA and 60 and 8% for PVF. Based on these data, we suggest the following formula of the polyacetal:

where $n = 4$ and $m = 1$.

It is known [13] that, when preparing acetals under thermal treatment, a product with a low degree of acetalization is formed. We believe that, in this case, the acetalization of PVA is deteriorated due to the fact that incompletely acetalized PVA is poorly soluble and precipitates in the form of a dense precipitate, and its further reaction with formaldehyde becomes hindered. The product with a more uniform composition can be prepared by makes larger the solid–liquid interface area. Apparently, MWI also provides some possibilities for raising the degree of acetalization.

CONCLUSIONS

(1) Polyacetals are efficiently formed under microwave irradiation of the reaction mixture containing polyvinyl alcohol and formaldehyde.

(2) At identical concentrations of the starting components and equal reaction temperatures, the yield of polyvinyl formal is 50–57% (reaction time 4–6 min) under microwave irradiation and 28–30% (reaction time 1.5 h) under thermal treatment.

(3) The yield of polyvinyl formal is maximal at a 1 : 1.5 molar ratio of polyvinyl alcohol and formaldehyde, and under microwave irradiation the reaction time decreases by a factor of 10–15 as compared to thermal treatment.

(4) Polyvinyl formal samples prepared from reaction mixtures of identical composition under microwave irradiation and thermal treatment have identical chemical composition.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation of a Block Copolymer of Polymethyl Methacrylate with Polymethacrylic Acid by Radical Polymerization

Abstract—Amphiphilic block copolymers of methacrylic acid with prepolymers of polymethyl methacrylate, functionalized with both silicon hydride and methacrylic terminal groups, were synthesized.

DOI: 10.1134/S1070427208100261

Recently, the interest in telechelates (polymers containing reactive terminal groups selectively reacting with functional groups of another molecule) has considerably increased. Such polymers can be used as cross-linking agents, chain extenders, and precursors for synthesis of block and graft copolymers and macromolecules with star-shaped and dendritic architecture. Macromonomers with terminal unsaturated bonds (telechelates) occupy an important place among such precursors.

The preparation of these macromonomers by radical polymerization is usually based on use of chain-transfer agents, polyfunctional initiators, or high concentrations of initiator [1–4], when side reactions of chain transfer to the initiator are absent. In the last case, azo initiators are used most frequently. Their nitrile groups are converted by hydrolysis into carboxy groups, and then, in the course of reaction of the terminal COOH groups with, e.g., glycidyl metacrylate, the polymer acquires unsaturated bonds. The same method for preparing macromonomers by radical polymerization is used with carboxyl-containing chain-transfer agents, such as iodoacetic [5], 3-mercaptopropionic [6], and thioglycolic [7, 8] acids.

Previously, we have reported [9, 10] a new versatile approach to synthesis of macromonomers via chain transfer to a tetrafunctional organosilicon hydride, dimethyldisilane, in radical polymerization of methyl methacrylate (MMA) and styrene, with the subsequent hydrosilylation of dimethacrylate with the telechelate containing terminal Si–H bonds. At the same time, in the synthesis of a block copolymer, both macromonomer and telechelate (which contains silicon hydride groups capable of chain transfer) can be used.

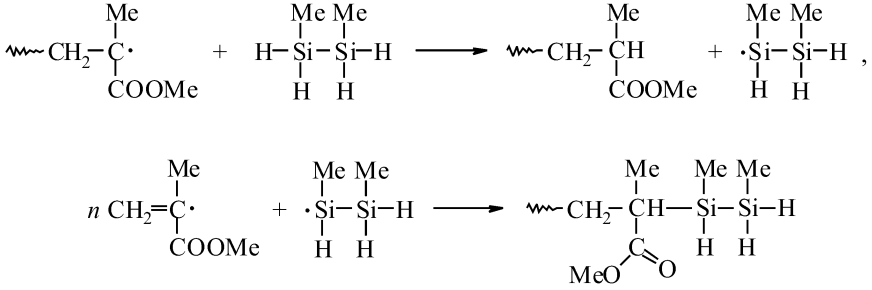
In this study, we examined the possibility of preparing polymethyl methacrylate (PMMA)–polymethacrylic acid (PMAA) block copolymers by radical polymerization, with PMMA precursors of both types involved.

EXPERIMENTAL

Methyl methacrylate was purified by vacuum condensation; methacrylic acid (MAA) was separated from water by repeated refreezing and distilled under reduced pressure. 1,3-Dimethacryloyloxymethyl-1,1,3,3-tetramethyldisiloxane (DMDSO) was prepared from 1,3-bis(chloromethyl)-1,1,3,3-tetramethyldisiloxane and potassium methacrylate [11]. Dimethyldisiloxane (DS) was synthesized by the method described in [12, 13]. Azobis(isobutyronitrile) (AIBN) purified by recrystallization from isopropyl alcohol (IPA) was used as initiator. Acetonitrile, toluene, and cyclohexane were used without additional purification. Methanol and dimethylformamide (DMF) were purified by the known methods [14].

Polymethyl methacrylate with a silicon hydride terminal group (prepolymer A) was prepared by radi-

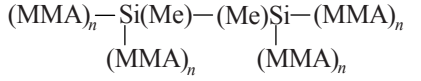
cal polymerization of MMA in the bulk at 60°C in the presence of 0.005 M AIBN and 2.5 wt % DS in sealed tubes to the maximum accessible conversion of 80%, which was checked gravimetrically. The polymer prepared was purified by twofold reprecipitation from acetone into petroleum ether and dried to constant weight in a vacuum. To obtain the macromonomer (prepolymer B), DMDSO was hydrosilylated with prepolymer A dissolved in toluene (1 g in 10 ml) at 3 : 1 molar ratio at 80°C for 15 h in the presence of a 5×10^{-5} M solution of hexachloroplatinic acid in IPA (Speier catalyst). The macromonomer was isolated from the solution in toluene by solvent evaporation.



The synthesis of A-PMAA and B-PMAA block copolymers in the 50 : 50 wt % reaction mixture was performed in DMF in the presence of 0.05 M AIBN at 60°C to deep conversion. The mixtures prepared, consisting of prepolymer solution in DMF (1 g in 10 ml) and MAA, were placed in ampules, deoxygenated by threefold freezing–pumping–thawing, and sealed. After the polymerization was complete, the hybrid products obtained were purified by precipitation from solutions in DMF with diethyl ether and dried in a vacuum to constant weight. The reference PMAA sample was synthesized by radical polymerization of MAA under the same conditions as those in synthesis of block copolymers: 1 g of MAA in 10 ml of DMF, 0.05 M AIBN, 60°C.

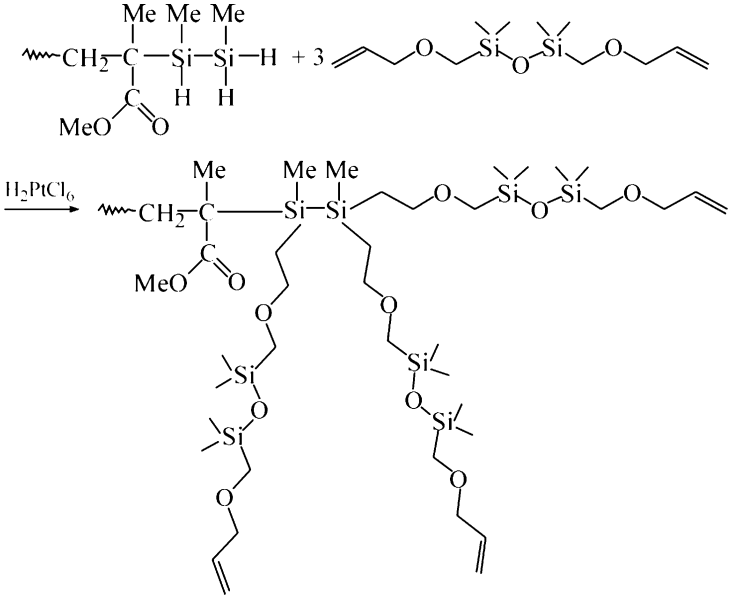
The content of MAA units in copolymers was estimated by potentiometric titration of acid groups with a 0.1 M KOH solution in methanol on a TV-6L1 device. The molecular-mass distribution (MMD) of the polymers preliminarily methylated by the method described in [15] was determined by gel-permeation chromatography (GPC) on a Waters chromatograph (USA) with a set of five Styrogel chromatographic columns with the pore diameters of 10^5, 3×10^4, 10^4, 10^3, and 250 Å. An R-403 Waters differential refractometer was used as a detector. Tetrahydrofuran was used as an eluent. The block copolymers were fractionated in methanol with separation of the insoluble and soluble fractions.

The IR spectra of A and B prepolymer films cast on NaCl discs from solutions in chloroform were recorded on a Perkin–Elmer-577 spectrophotometer. The surface profile of polymer samples was studied with a set of Solver Pro scanning probe microscopes (NT-MDT, Zelenograd, Russia). Standard silicon cantilevers produced by NT-MDT and MicroMash (Tallinn, Estonia) with a typical curvature radius of the working part of the probe of about 10–15 nm were used. Measurements were performed in the contact and tapping modes. In the case of the tapping mode, NSG11 cantilevers (resonance frequencies 150–250 kHz) were used. The sample films were applied onto silicon plates from methanol–acetone solution.



The polymeric films for determining the limiting wetting angles were prepared by dipping of quartz plates into polymer solutions in 50 : 50 vol % IPA : acetone mixtures, followed by drying in a vacuum desiccator.

Two types of PMMA precursors were used in the synthesis of PMMA–PMAA block copolymers. Prepolymer A was prepared by radical polymerization of MMA in the presence of a tetrafunctional organosilicon hydride, dimethyldisiloxane, as a chain-transfer agent:



Prepolymer A

In the course of chain transfer, prepolymer A macromolecule acquires one to three terminal Si–H bonds. At the same time, the formation of completely substituted, nonfunctionalized macromolecules with the branched structure, though in substantially smaller amount, is also probable:

Therefore, in the synthesis of prepolymer B, which is a macromonomer, we proceeded from the presence of three terminal Si–H bonds in prepolymer A and performed the hydrosilylation reaction between prepolymer A and DMDSO at threefold excess of the latter:

Prepolymer B

The presence of Si-H functional groups in prepolymer A and unsaturated vinyl groups in prepolymer B is confirmed by IR spectroscopy (Fig. 1). Weak and medium bands at 2075 and 810 cm^{-1}, associated with stretching and bending vibrations of Si–H bonds, respectively, and a band at 798 cm^{-1} characteristic of the Si–Me group, in spectrum *1* and a new band at 1610 cm^{-1} due to ν(C=C) in spectrum *2* are clearly seen.

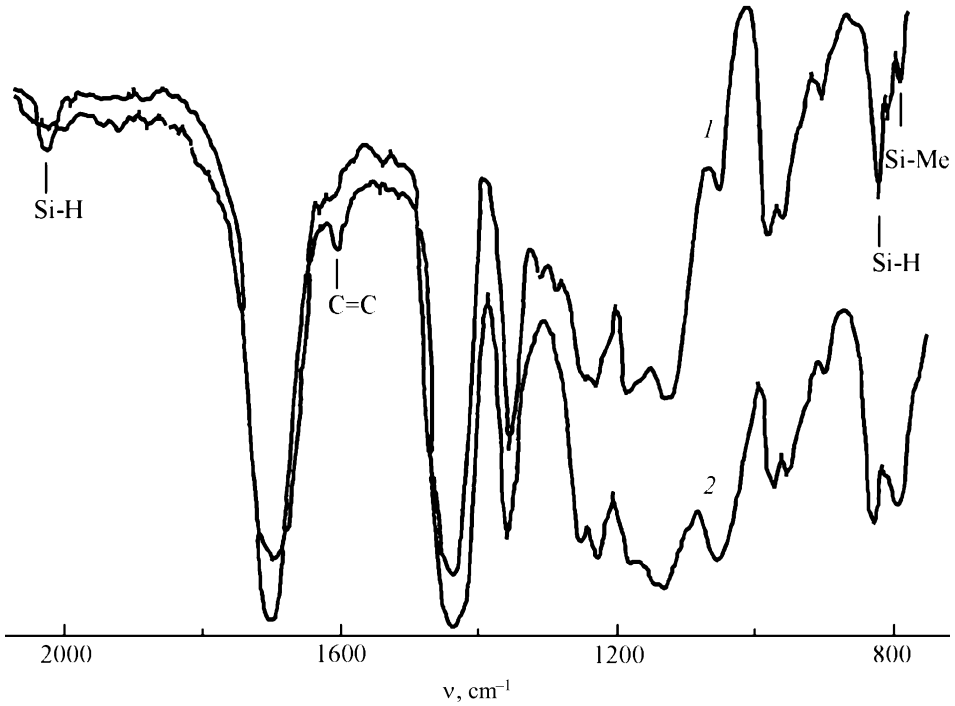


Fig. 1. IR spectra of prepolymers (*1*) A and (*2*) B. (ν) Wavenumber.

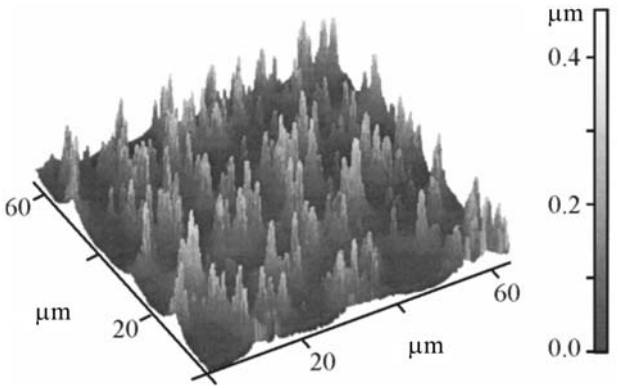

Fig. 2. AFM image of the surface of a film of A–PMAA hybrid product, first fraction.

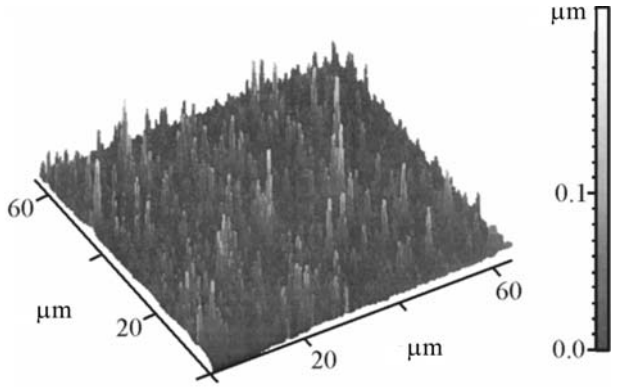

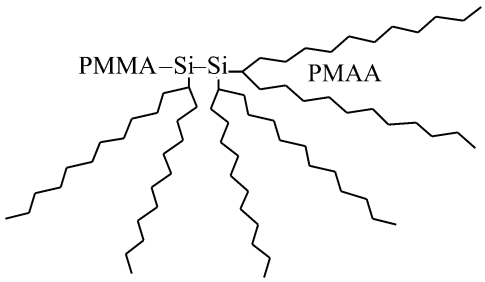

Fig. 3. AFM image of the surface of a film of B-PMAA hybrid product, second fraction.

The difference in the chemical structure of the terminal groups of prepolymers A and B suggests different mechanisms of formation of block copolymers with MAA. In the first case, due to chain transfer to the remaining three Si–H bonds, the maximum possible number of PMAA blocks grafted to prepolymer A is three. In the second case, due to addition of MAA macroradicals to prepolymer B, block copolymer B–PMAA can have six PMAA blocks, with all of its terminal unsaturated groups involved in the reaction:

The data on the synthesis of both types of block copolymers are listed in Tables 1 and 2 as characteristics of the composition and molecular weights of fractions isolated from methanol: insoluble (first fraction) and soluble (second fraction). It follows from the composition data that these fractions are not homopolymers. Since methanol is a hard precipitant for PMMA and a good solvent for PMAA, the first fraction can contain MAA, and the second fraction, MMA only in the PMMA–PMAA block copolymer. In other words, the first fraction contains the block copolymer and PMMA, and the second fraction, the block copolymer and PMAA. In systems of this kind, the supramolecular structures are formed by aggregation of blocks and macromolecules having the same chemical structure proceeds. In particular, it follows from this fact that amphiphilic block copolymers can be used as components of formulations containing a homopolymer similar to one of the blocks.

Sample	θ, deg
Prepolymer A	62
PMAA	0
A–PMAA:	
first fraction	23
second fraction	0
B–PMAA:	
first fraction	28
second fraction	0

The surfaces of the polymeric films of the fractions separated from hybrid products A-PMAA and B-PMAA were studied. An examination of the film surface topography showed that, in almost all the cases, structures with pronounced peaks are formed. As can be seen from AFM images in Figs. 2 and 3, the height of peaks in the first fractions is several times that in the second fractions and is comprable with the contour length of the PMMA prepolymer. It follows from this fact that peaks are formed on the basis of the "crown" consisting of blocks and PMMA macromolecules of the first fraction. The wetting angles with water of the block copolymer films and films of the corresponding homopolymers are listed in Table 3. As follows from these data, drops spread on PMAA films and films of the second fractions, whereas on films of the first fractions equilibrium drops wetting the surface are formed in both cases. This fact indicates that the surface formed by peaks (bristle) is substantially enriched in blocks and macromolecules of PMMA, and the smaller wetting angles in comparison with PMMA films are caused by the admixture of PMAA blocks and probably by surface roughness, which, as a rule, gives better wetting.

CONCLUSIONS

(1) Synthesis of block-copolymers by radical polymerization proceeds through precursors with both terminal silicon hydride and unsaturated groups.

(2) Fractionation of polymethyl methacrylate–poly-methacrylic acid hybrid products with methanol gives two fractions. Each of these contains the homopolymer with the block copolymer enriched in the related block.

(3) The developed compositions containing amphiphilic block copolymers polymethyl methacrylate–poly-methacrylic acid are of interest as modifiers of the surface of polymeric materials based on polymethyl methacrylate.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Stabilization of the Oleic Acid–Water Emulsion with Various Kraft Lignins

Abstract—The influence of the initial wood species and polymolecular characteristics on the characteristics of the surface of solid-phase lignin was estimated, and the correlation of these parameters with the ability of kraft lignins to stabilize the oleic acid–water emulsion was examined. The kinetics of breakdown of emulsions stabilized with kraft lignin was studied.

DOI: 10.1134/S1070427208100273

Industrial pulp is produced today predominantly by the kraft procedure. Lignin derivatives formed in this procedure are soluble in alkalis, whereas in going to acidic solutions they pass into the solid state. Solid particles of kraft lignins have a large specific surface area (up to 20 $m^2 g^{-1}$) and contain a large number of polar groups (up to 14 mg-equiv g^{-1}) [1]. They have high sorption power with respect to many classes of substances and also efficiently stabilize oil-in-water emulsions [1, 2].

In particular, a stable lignin–tall emulsion is formed in synthesis of tall oil, by-product of kraft cellulose manufacture (Fig. 1). As shown previously [3–5], this emulsion is stabilized by kraft lignin.

It is well known [6, 7] that the stabilization mechanism of emulsions depends on hydrophilicity and lipophilicity of the solid emulsifier and, in particular, kraft lignin. Taking into account that kraft lignins recovered from liquors formed in cooking of deciduous and coniferous wood differ in topological structure and chemical composition [8, 9] and, at the same time, they are polydisperse and polyfunctional compounds, it is reasonable to expect that the nature of their surface and, accordingly, the ability to stabilize emulsions should depend on the initial wood species and also on the molecular weight and molecular-weight distribution. Although this statement is obvious, there are no published data on the behavior of fractionated lignins in the systems water-oil-lignin.

In this study, we examined the behavior of kraft birch and spruce lignins and evaluated the influence of their molecular weights on the stability of the oleic acid–water system simulating the lignin–tall emulsion.

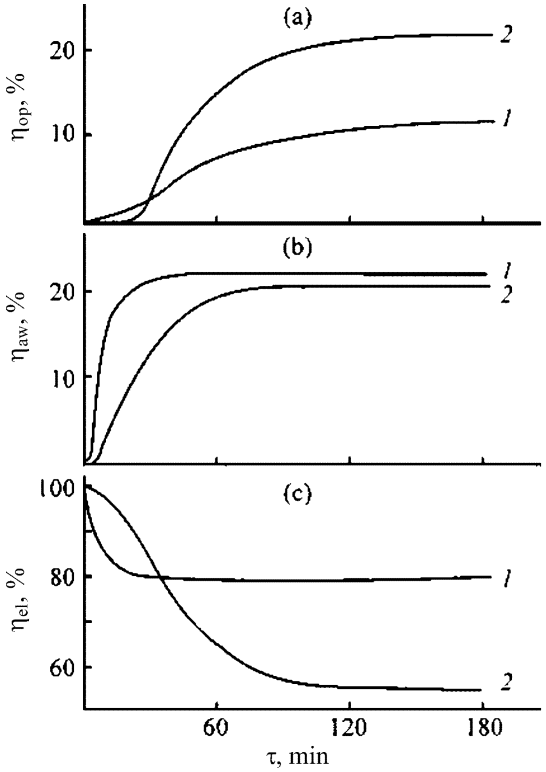

Fig. 1. Relative yields of (a) oil phase (η_{op}), (b) acidic water (η_{aw}), and (c) emulsified layer (η_{el}) vs. the settling duration τ in production of tall oil by degradation of (*1*) deciduous and (*2*) coniferous sulfate soap.

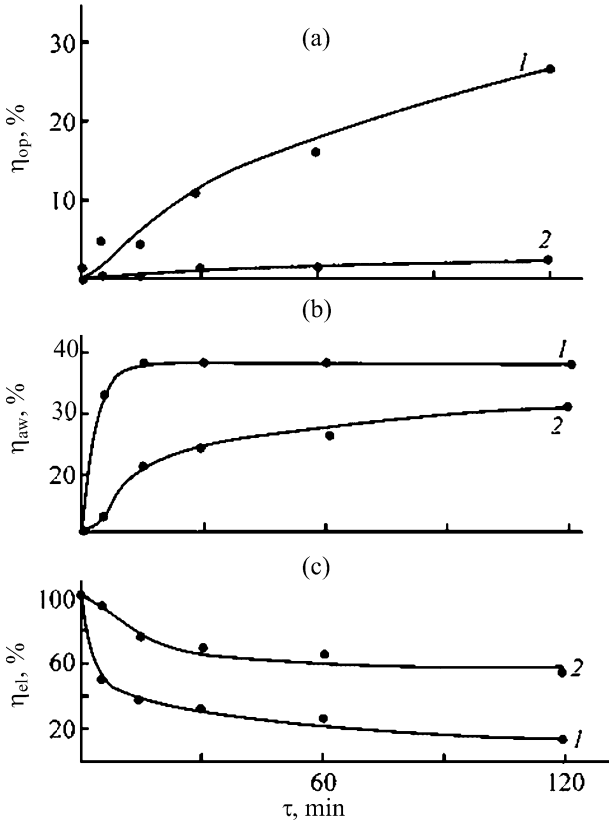

Fig. 2. 1. Relative yields of (a) oil phase (η_{op}), (b) acidic water (η_{aw}), and (c) emulsified layer (η_{el}) vs. the settling duration τ of oleic acid–water emulsion in the presence of (*1*) birch and (*2*) spruce lignins.

EXPERIMENTAL

For studies, we used the model systems prepared by successive neutralization of lignin and oleic acid (main component of tall oil) samples with a 10% solution of sodium hydroxide to pH 11. The oleic acid : water weight ratio in the system under study was 1 : 1. The amount of lignins added to the model systems was 5% relative to the weight of oleic acid. The samples were thermostated at 95 ± 2°C and treated with 30% sulfuric acid with vigorous stirring to pH 2.2–2.5. The stability of the emulsions formed was quantitatively characterized by the variation of the volume of the separated phases at certain intervals of time.

The characteristics of the lignin surface were varied by changing the initial wood species and the fractional composition of the samples.

It has been shown previously that hydrophilic–oleophilic characteristics of kraft lignin also depend on the con-tent of extractive resinous substances and precipitation pH [10]. Therefore, to study the influence of the initial wood species on the stability of emulsions we chose the lignin samples isolated by precipitation at pH 1.5 from black sulfate liquors formed in laboratory cooking of deresined spruce and birch wood.

The resulting lignin samples differ in the composition and in polymolecular and hydrophilic–oleophilic characteristics. Differences in the ratio of guaiacyl-, syringyl-, and *p*-hydroxyphenylpropane units in deciduous and coniferous lignins are manifested in a higher content of Clason lignin in the sample prepared from birch wood (93.4% in comparison with 88.2% for spruce lignin) and in a lower content of oxygen (26.2% in comparison with 31.1%); furthermore, spruce lignin has a higher molecular weight (M_w 9700) than birch lignin (M_w 2800). Adsorption of hexane vapor with spruce lignin (0.41×10^{-3} mol g^{-1}) is higher than that with birch lignin (0.29×10^{-3} mol g^{-1}) by 26%. The sorption power of birch lignin with respect to water vapor is 8.90×10^{-3} mol g^{-1}, and that of spruce lignin, 8.32×10^{-3} mol g^{-1}, i.e., it differs by 7%. This fact suggests that the hydrophilicity of birch lignin is higher.

The kinetic dependences of separation of oil (Fig. 2a) and aqueous (Fig. 2b) phases under static conditions at 80 ± 1°C and of breakdown of emulsions stabilized with birch (Fig. 2c, curve *1*) and spruce (Fig. 2c, curve *2*) lignins show that the system is more stable in the presence of spruce lignin. In both cases, breakdown of the emulsion proceeds in two stages: in the first 5–10 min, an aqueous layer is formed, and then the volume of this layer varies insignificantly. The oil layer is formed at approximately the same rate untill the equilibrium state, which is reached in the presence of spruce lignins in approximately 1 h and in the presence of birch lignins, in 1.5–2 h.

As can be seen from Fig. 2, in the presence of the more hydrophilic birch lignin, the model system is separated into layers more completely than in the presence of the higher-molecular-weight and more hydrophobic spruce lignin. The yield of the oil phase is 90% of the theoretical value in the first case and 18% in the second case.

It is well known that low-molecular-weight fractions of kraft lignins contain a larger number of phenolic hydroxyls and are more hydrophilic in comparison with the high-molecular-weight fractions [11]; therefore, the revealed relationships were studied in more detail in stabilization of the oleic acid–water emulsion with lignins differing in molecular weight. The molecular weights of lignins were determined by the gel-permeation chromatography [12]. Dimethyl sulfoxide

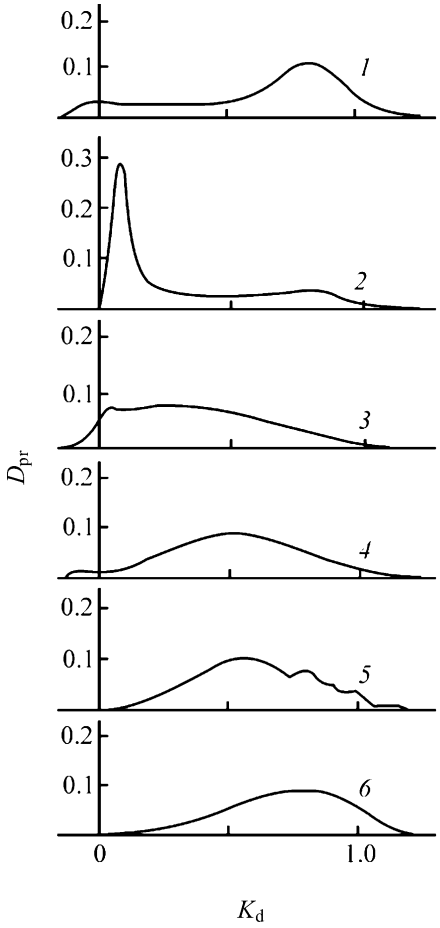

Fig. 3. Gel chromatograms of fractions of kraft birch lignin. (D_{pr}) Gravimetric concentration and (K_d) retention volume. (*1*) Nonfractionated lignin (M_w 2800); fraction: (*2*) no. 1 (M_w 36 000), (*3*) no. 2 (M_w 14 600), (*4*) no. 3 (M_w 8300), (*5*) no. 4 (M_w 4000), and (*6*) no. 5 (M_w 2400).

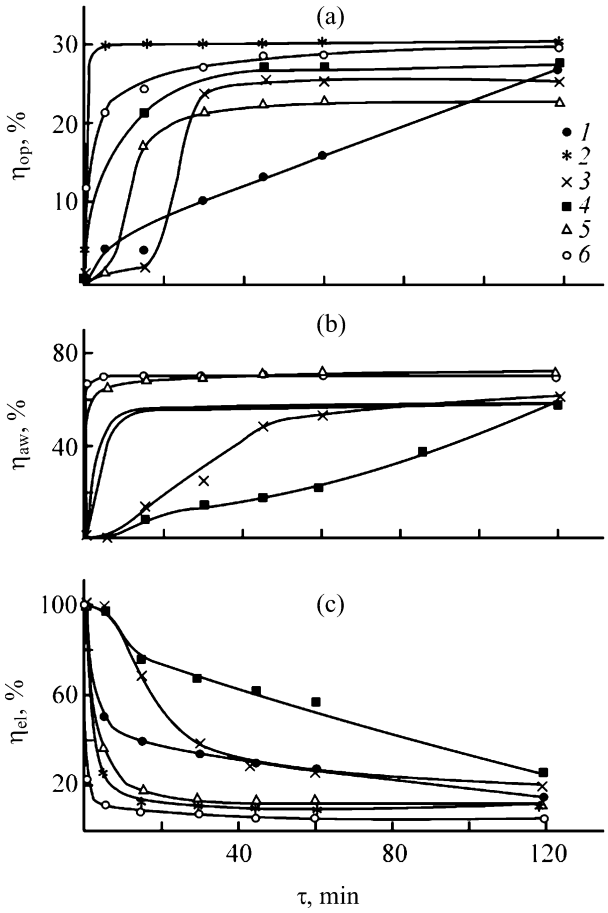

Fig. 4. Relative yield of (a) oil phase η_{op}, (b) acidic water η_{aw}, and (c) emulsified layer η_{el} vs. the settling duration τof the oleic acid–water emulsion in the presence of the (*1*) initial birch lignin and (*2–6*) fractionated lignins. Fraction: (*2*) no. 1 (M_w 36 000), (*3*) no. 2 (M_w 14 600), (*4*) no. 3 (M_w 8300), (*5*) no. 4 (M_w 4000), and (*6*) no. 5 (M_w 2400).

(freezing point 16°C) was used as an eluent. The solutions with lignin concentration of 0.5% were prepared a day before determination.

Lignin fractions prepared by fractional precipitation with benzene from a solution of birch lignin in dioxane differ significantly in the shape of chromatograms (Fig. 3). The weighted-average molecular weights of the recovered fractions vary in the range from 2400 to 36 000 and fairly completely represent the range of variation of this parameter, typical of kraft lignins [11–15].

The separation of the oleic acid–water emulsion (Fig. 4c) stabilized with lignin fraction nos. 1 (M_w 36 000) and 5 (M_w 2400) into layers is complete within 15–20 min, no. 2 (M_w 14 600) and no. 4 (M_w 4000), within 50–70 min, and no. 3 (M_w 8300), within 2 h. In this case, the highest yield of the oil phase (Fig. 4a) is observed in the presence of fractions with the lowest (M_w 2400, fraction no. 5), and highest molecular weight (M_w 36 000, fraction no. 1). With the other lignin fractions, this value is 9–13% lower.

Using the data obtained for the breakdown of the oleic acid–water emulsion in the presence of fractionated lignins, we calculated the formation rates ω of the oil layer:

$$\omega = \frac{\Delta n_i}{S\Delta\tau_i},$$

where Δn_i is an increase in the oil layer volume, mol; *S,* surface area of the phase boundary, cm^2; and $\Delta\tau_i$, time interval between measurements, min.

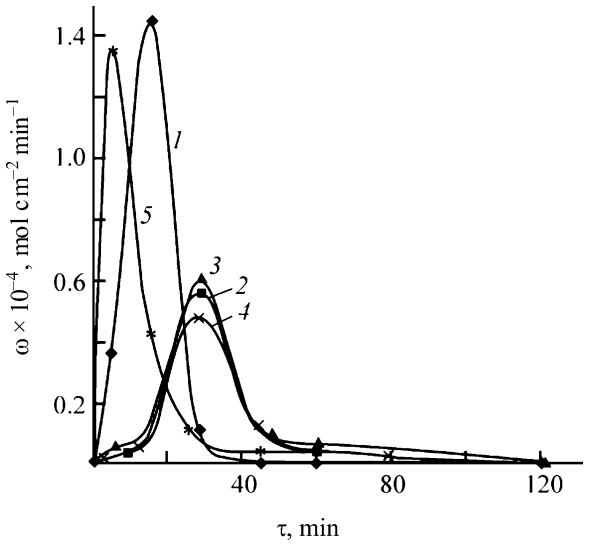

Fig. 5. Rate of oil phase separation from the emulsion, ω, vs. the settling duration τ in the presence of fractionated lignins. Fraction: (*1*) no. 1 (M_w 36 000), (*2*) no. 2 (M_w 14 600), (*3*) no. 3 (M_w 8300), (*4*) no. 4 (M_w 4000), and (*5*) no. 5 (M_w 2400).

The dependences of the rate of oil phase separation on time (Fig. 5) pass through a maximum for all the fractions. The peaks in the kinetic curves for the medium-molecular-weight fractions (4000–14 000) are observed at a settling time of 30–40 min, whereas for fraction nos. 1 and 5 (M_w 2400) they are shifted to shorter time intervals (15–20 and 3–5 min, respectively).

In interpretation of the data obtained, it should be borne in mind that lignins were recovered from the preliminary deresined wood. In addition, in estimation of the ability of lignins to stabilize oil-in-water emulsions, the differences in the composition of deciduous and coniferous tall oil and, in particular, the presence of resin acids, the specific component of the latter, were not considered. As a result, the revealed trends do not fully correspond to published results of the laboratory studies and to the practice of wood-chemical production at pulp-and-paper plants, according to which tall oil is recovered from coniferous soap more completely and faster than from deciduous soap [4, 16]. Despite this fact, the data obtained allow us to state that the breakdown of the emulsion in the presence of both deciduous and coniferous lignins proceeds in similar ways and the influence of lignins on the stability of oil–water emulsions is caused by the hydrophilic-oleophilic characteristics of their surfaces.

The relationships obtained in studying the influence of polydisperse characteristics of lignins on the stability of emulsions can be interpreted as follows. Lignins promote dispersion of oil drops in an aqueous medium. On adding fractionated lignins with a molecular weight of 4000 to 14 600, separation of the emul-sion into layers in the initial period of time becomes slower in comparison with macromolecular and low-molecular-weight fractions. Due to high hydrophobicity of the surface of solid particles surrounding the oil drop aggregates, lignins with a molecular weight of 36 000 and higher fairly rapidly pass from the aqueous phase into the oil phase. Fractions with intermediate molecular weights prevent separation of the emulsion into layers, as indicated by the broad peak and low rate of oil separation. Lignins with molecular weights lower than 4000 are more hydrophilic and, accordingly, have higher affinity for the aqueous phase. Therefore, oil drops dispersed by this fraction fairly rapidly pass into the aqueous phase and thereby provide a high rate of emulsion breakdown. In the absolute value, the rates of phase evolution for fraction nos. 1 (M_w 36 000) and 5 (M_w 2400) exceed those for the other fractions by a factor of 3.

Comparison of the peak positions and amplitudes of the rates of phase separation depending on the process duration, with the molecular weights of the samples suggests that the breakdown of the emulsion stabilized with kraft lignin proceeds in two kinetically different steps. In the first step, separation of dispersion medium (aqueous solution) predominates. In parallel, as the process develops, conditions arise for the coalescence of oil drops and formation of an oil layer with simultaneous separation of an aqueous layer. After separation of water that is not bound with lignin, the emulsion brealdown occurs only owing to the coalescence of oil drops and the process rate steadily decreases. In this case, in the course of emulsion breakdown, the low-molecular-weight fractions characterized by increased hydrophilicity will be concentrated in the aqueous phase. The hydrophobic high-molec-ular-weight fraction of lignin should have high affinity for the oil phase and, hence, should assist transfer dispersed oil particles from the emulsified layer into the oil layer. The medium-molecular-weight fractions characterized by the balance of hydrophobic and hydrophilic parts of molecules exhibit affinity for both oil and aqueous phases. The equality of hydrophilic and hydrophobic characteristics of medium-molecular-weight fractions of lignins accounts for the emulsifying effect in the oil–water–lignin systems.

CONCLUSIONS

(1) The ability of lignins to stabilize oil–water emulsions is governed by their hydrophilic–lipophilic ratio.

(2) Hydrophobic macromolecular lignins have high affinity for the oil phase and promote transfer of oil particles dispersed in water into the oil layer. Samples of medium molecular weights (M_w 4000–15 000) are characterized by the balance of hydrophilic–oleophilic characteristics. They exhibit affinity for both the oil and aqueous phases and, as a result, efficiently stabilize an oil-in-water emulsion. Hydrophilic lignins of low molecular weight ($M_w < 4000$) are concentrated in the aqueous layer, which accounts for the efficient separation of the emulsion in the presence of these lignins.

(3) The breakdown of the heterogeneous system oil–water stabilized with kraft lignin occurs in two kinetically different steps: the first fast step in which intense separation of an aqueous layer is observed and the second slow step characterized by formation of an oil layer. Separation of the dispersion medium in the first step provides conditions for coalescence of oil drops and separation of the dispersed phase to form an

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Acylation of Lignocellulose Material with Aliphatic Amino Acids

A. A. Beushev, V. V. Kon'shin, N. A. Chemeris, and M. M. Chemeris

Polzunov Altai State Technical University, Barnaul, Russia

Received April 17, 2006

Abstract—A lignocellulose material was acylated with a thionyl chloride–aliphatic amino acid–trifluoroacetic acid mixture at 30–50°C with the aim to obtain cellulose esters of aliphatic amino acids.

DOI: 10.1134/S1070427208100285

Numerous cellulose esters of carboxylic acids, including mixed esters, are known [1, 2]. Studies of the synthesis of cellulose esters of amino acids have been performed for a long time [3]. The starting materials were samples of cellulose included by various procedures and cellulose alcoholate prepared by exchange of cellulose with sodium isoamylate dissolved in xylene. The acylating agents were chlorides of *N*-substituted amino acids: *N*-carbobenzoxyglycine, *N*-carbobenzoxyaminoenanthoic acid, *N*-phthalylglycine, and *N*-phthalylaminoenanthoic acid. The esters obtained contained 3.84–4.50% nitrogen. The degree of substitution with the amino acid was 1.06–1.44.

The same research team [4] developed a procedure for preparing cellulose esters of α-amino acids, based on the substitution of the residue of a sulfonic acid (*p*-toluenesulfonic, methylsulfonic) with an amino acyl residue.

A disadvantage of the above-described procedures for preparing cellulose esters of aliphatic amino acids is that they use cellulose (recovery of cellulose from wood is a time-consuming, expensive, and environmentally harmful process) or various cellulose-based included samples, and also chlorides of various *N*-substituted amino acids as acylating agents. The multistep procedure for preparing the starting reactants increases the cost of production of the final products. Preparation of cellulose esters of amino acids requires long time (from 44 to 100 h) or high temperatures (for example, the residues of methylsulfonic acids are completely substituted by glycine and alanine residues only at 155°C).

The interest in cellulose derivatives acylated with amino acids is due to their potential biological activity. It is well known that α-, β-, and γ-amino acids play a particular role in metabolism, being precursors of hormones, creatine, and energetic substrates). Recently, amino acids have found use as drugs in psychology, neurology, and oncology (glycine, β-alanine, γ-aminobutyric acid) [5].

It is known that the most active acylating agents in synthesis of mixed cellulose esters are anhydrides and chlorides of various carboxylic acids. It has been shown previously that carboxylic acid chlorides can be prepared using a thionyl chloride–carboxylic acid mixture in trifluoroacetic acid (TFAA) [6, 7]. To simplify the procedure for preparing cellulose esters of carboxylic acids, modified wood (lignocellulose material, LCM) can be used instead of cellulose [8, 9].

In this context, it seemed interesting to examine the possibility of preparing mixed cellulose esters of α-, β-, and γ-amino acids from LCM by using a mixture of thionyl chloride (TC) with aliphatic amino acid in TFAA as acylating agent. As LCM, we chose prehydrolyzed aspen wood.

EXPERIMENTAL

In the course of this study, we performed the reactions of prehydrolyzed aspen wood (LCM containing 64.8% cellulose, as determined by the Kürschner method, and 35.2% lignin, as determined by the Komarov method [10]) with aminoacetic acid (glycine), β-alanine (BAL), and γ-aminobutyric acid (GABA) in TFAA in the presence of TC, following the procedure described in [11]. Prehydrolyzed aspen wood was prepared from sawdust of size 0.40–0.75 mm, extracted with an alcohol–benzene mixture (to remove extractive substances) and treated with a 0.5–1.0% H_2SO_4 solution (to remove hemicelluloses). LCM was acylated in

a round-bottom flask into which we introduced an aliphatic amino acid and TFAA. The mixture was kept at a definite temperature, after which TC was added, and the mixture was kept at the same temperature until the aliphatic amino acid chloride was formed. To the resulting acylating mixture we added LCM.

The product obtained after the reaction was complete was a mixture of a solution of the cellulose ester with undissolved LCM particles (at a synthesis time from 1 to 5 h) or a homogeneous solution of the ester (at a synthesis time of 6 h). To isolate the product, it was precipitated into acetone, water, or ethanol (for LCM containing glycine, BAL, and GABA residues, respectively), after which it was washed and air-dried.

LCM derivatives were synthesized by the following scheme:

$$NH_2(CH_2)_nCO_2H + CF_3CO_2H + SOCl_2$$

$$\xrightarrow[-SO_2,\ -HCl]{} [NH_3(CH_2)_nCOCl]^{\oplus} + LCM\text{–}OH$$

$$\xrightarrow[-HCl,\ -CF_3CO_2H]{} NH_2(CH_2)_nC(=O)\text{–}O\text{–}LCM,$$

where n = 1–3.

An analysis of the acylated LCMs for residual lignin showed that the products were almost pure cellulose esters (lignin content 2–3%). The product yield relative to the weighed portion of the starting LCM was 70–178%, and the degree of substitution with the amino acid was 0.20–1.82.

Because the acylation of LCM with a TC–aliphatic amino acid mixture in TFAA is an example of topochemical reactions, we can calculate the rate constant by the Erofeev–Kolmogorov equation [12] which can be represented in our case in the following form:

$$\ln [-\ln(1 - \alpha)] = \ln k + n\ln \tau, \quad (1)$$

where α is the degree of conversion of hydroxy groups into ester groups; k, reaction rate constant; and τ, synthesis time.

The degree of conversion is calculated by the formula

$$\alpha = C_{OH(am)\tau}/C_{OH(am)max}, \quad (2)$$

where $C_{OH(am)\tau}$ is the amount of LCM OH groups substituted by acyl residues of amino acids by the time τ (calculated by the procedure from [13]), and $C_{OH(am)max}$ is the maximal amount of OH groups of cellulose (31.5%).

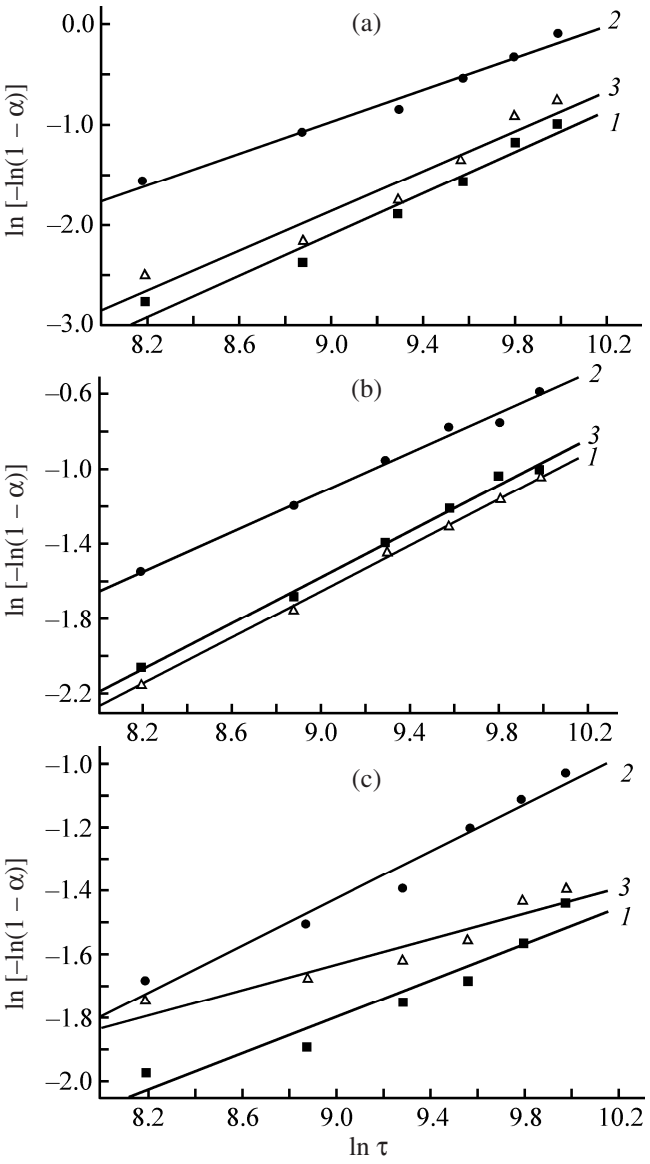

Fig. 1. Kinetic curves of the acylation of LCM with (a) glycine, (b) BAL, and (c) GABA at (*1*) 30, (*2*) 40, and (*3*) 50°C, plotted in the coordinates of the Erofeev–Kolmogorov equation. (α) Degree of polymerization and (τ) synthesis time.

The rate constant k of LCM acylation with a mixture of TC with aliphatic amino acid in TFAA, calculated by the Erofeev–Kolmogorov equation, is a dimensionless quantity. To convert the k values obtained to the rate constant K of dimension, s^{-1}, we used the Sakovich equation [12]

$$K = nk^{1/n}. \quad (3)$$

To determine k, we plotted the dependences of ln[–ln(1 – α)] on ln τ for the acylation of prehydrolyzed aspen wood with glycine, BAL, and GABA (Figs. 1a–1c).

Rate constants K of acylation of LCM with glycine, BAL, and GABA

Amino acid	pK_a	$K \times 10^5$, s^{-1}, at indicated temperature, °C		
		30	40	50
Glycine	2.36	1.70	3.14	2.15
BAL	3.55	0.58	0.92	0.59
GABA	4.23	0.07	0.11	0.08

The highest rate constant K of acylation of LCM with aliphatic amino acids in the examined temperature range (30–50°C) is observed at 40°C. The decrease in K at temperatures exceeding 40°C is due to the evaporation and decomposition of thionyl chloride. As a result, the yield of the amino acid chloride decreases. Furthermore, hydrogen chloride liberated in the process causes strong degradation of wood [14]. It should be noted that at high temperatures the product undergoes hydrolytic degradation, which leads to dissolution of LCMs acylated with amino acids and to a decrease in the yield of the target product and in the content of chemically bound nitrogen in it. To confirm the occurrence of hydrolytic degradatoin, we evaluated the degree of polymerization of cellulose isolated from LCM acylated with β-alanine.

Because the products obtained were insoluble in available solvents, we evaluated viscometrically the degree of polymerization of cellulose obtained by saponification of cellulose esters [11].

The solution viscosity was measured with an Ubbelohde viscometer at 20°C, with iron–tartaric acid–sodium complex as solvent. The viscometer was immersed in an ultrathermostat in which the temperature was maintained with an accuracy of ±0.02°C.

From the data obtained, we calculated the relative (η_{rel}) and specific (η_{sp}) viscosities:

$$\eta_{rel} = \tau/\tau_0, \quad (4)$$

$$\eta_{sp} = \eta_{rel} - 1, \quad (5)$$

where τ and τ_0 are the outflow times of the solution and solvent, respectively.

The intrinsic viscosity [η] ($cm^3\ g^{-1}$) was calculated by the formula

$$[\eta] = \frac{\eta_{sp}/c - K_1}{1 + K_2\eta_{sp}}, \quad (6)$$

where η_{sp} is the specific viscosity of the polymer solution; c, concentration of the polymer solution ($g\ l^{-1}$); and K_1 and K_2, coefficients equal to 0.25 and 0.1, respectively.

The degree of polymerization of cellulose was calculated by the Staudinger empirical equation

$$DP = \frac{[\eta]}{8.14 \times 10^{-4}}, \quad (7)$$

where [η] is the intrinsic viscosity of the polymer solution.

The degrees α of polymerization of cellulose isolated from LCM that has been acylated with β-alanine (acylation time 3 h) at various synthesis temperatures are given below:

T, °C	α
30	1150
40	800
50	450

These data show that, with increasing temperature, the degree of polymerization of cellulose derivatives acylated with BAL dereases, which confirms the occurrence of hydrolytic degradation of cellulose.

The main kinetic relationships of acylation do not change significantly in going from α- to β- and γ-amino acids.

The table shows how the rate constant K of LCM acylation correlates with pK_a of the corresponding amino acid.

It can be seen that, in going from α- to γ-amino acids at the same temperature, the rate constant of LCM acylation decreases as the strength of the amino acid becomes lower, which is in certain contradiction with published data for the acylation of cellulose with aliphatic acids in TFAA [15]. This may be due to the presence of NH_2 groups in amino acids, which presumably form additional hydrogen bonds with LCM. These bonds, in combination with the steric factor, hinder the acylation.

CONCLUSIONS

(1) In acylation of a lignocellulose material with an aliphatic amino acid–thionyl chloride–trifluoroacetic acid mitxure, cellulose esters of α-, β-, and γ-amino acids with the degree of substitution of 0.20–1.82 are formed at 30–50°C within 1–6 h.

(2) In the temperature range 30–50°C, the acylation rate is maximal at 40°C.

BRIEF COMMUNICATIONS

Prognostication of Properties of Molecular Inorganic Fluids from the Stoichiometric Formula of a Compound

I. B. Sladkov

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received June 6, 2008

Abstract—A method is suggested for prognosticating the physicochemical properties of molecular inorganic fluids in the total absence of experimental information about the properties of a substance under study. The method makes it possible to determine quite a number of properties on the basis of only the stoichiometric formula of a compound.

DOI: 10.1134/S1070427208100297

At present, prognostication of properties of molecular inorganic fluids requires information about at least a single experimental characteristic of a substance under study, its boiling point [1, 2]. Methods for prognostication of the boiling point itself cannot be found in the literature, and, therefore, "blind" prognostication of physicochemical properties, i.e., that in the total absence of input information about the substance under study, is also impossible.

In this communication, a method for prognostication of the boiling point and a number of other properties of molecular inorganic fluids is suggested. This method doers not require any evidence about the compound under study, except its stoichiometric formula.

The first step in the development of the technique was a search for a correlation that could be used for estimating the boiling points of molecular inorganic fluids. It was found that this can be done using the correlation between two determinative criteria of thermodynamic similarity. One of these was described in detail in [3]:

$$\psi = 0.1\ln T_b - 0.122\ln V_b + 0.006, \quad (1)$$

and the other, in [4]:

$$f = \ln T_b - 1.1\ln \Pi - 4, \quad (2)$$

where T_b is the standard boiling point (K); Π, parachor ($J^{1/4}\,cm^{5/2}\,mol^{-1}$) calculated by an additive method from the stoichiometric formula of a compound [3]; and V_b, molar volume of the fluid at the boiling point ($cm^3\,mol^{-1}$).

A set of compounds, constituted by several tens of molecular inorganic compounds, was used to establish a correlation between the criteria mentioned above:

$$f = 6.8\psi + 0.21. \quad (3)$$

Relation (3) served as a basis of an iteration that enables calculation of the boiling point and quite a number of physicochemical properties of the substance. This correlation includes a set of the following formulas taken from [3, 4].

Initially, a first approximation to the boiling point T_1 ($T_1 = 200$) and molar volume of the fluid at the boiling point V_1 ($V_1 = 27\Pi$) are set.

Then, two determinative criteria of thermodynamic similarity, f and ψ, are calculated by formulas (1) and (2).

Further, the boiling point is found in a second approximation and a number of physicochemical properties are calculated:

$$T_b = \exp[6.8\psi + 1.1\ln \Pi + 4.21],$$

$$T_{cr} = 1.5\,T_b,$$

$$V_b = (-6.2f + 31.2)\Pi^{0.94},$$

$$b = 1.27V_b - 6,$$

$$P_{cr} = 1.039T_{cr}/b,$$

Table 1. Accuracy of property prognostication for ReF_6 and $SiHCl_3$

Property	Value of a property					
	ReF_6 (Π = 3.17)			$SiHCl_3$ (Π = 3.67)		
	calculation	experiment	discrepancy, %	calculation	experiment	discrepancy, %
T_b	303.3	306.9	–1	342.9	305.2	12
V_b	84.1	85.4	–2	97.3	102.8	–5
T_{cr}	455.0	479.0	–5	514.3	479.0	7
V_{cr}	228.1	230.0	–1	263.8	268.0	–2
P_{cr}	4.69	4.81	–3	4.54	4.17	9
b	100.8	103.5	–3	117.6	119.4	–1
Z_{cr}	0.283	0.278	2	0.280	0.281	–1
ΔH_b	26 600	28 300	–6	29 500	26 700	10
ρ_{293}	3.625	3.633	–0.2	1.484	1.345	10

Table 2. Effect of the error in the boiling point on the accuracy of prognostication of other properties

Substance	Calculation error (in absolute value), %								
	T_b	V_b	T_{cr}	V_{cr}	P_{cr}	b	Z_{cr}	ΔH_b	ρ_{293}
ReF_6	1	2	5	1	3	3	2	6	1
$TiCl_4$	2	1	2	1	6	5	6	1	2
NpF_6	2	5	6	2	4	2	1	4	5
$SnBr_4$	5	2	1	1	1	1	2	6	2
$PSCl_2F$	6	2	2	1	4	2	2	7	4
$SbCl_5$	9	1	5	2	3	2	1	10	3
$SiBr_4$	10	2	6	1	6	1	1	8	5
$ReCl_4O$	12	3	15	2	13	3	1	12	7
$SiHCl_3$	12	5	7	2	9	1	1	10	10
$GeCl_4$	14	4	11	2	14	3	1	13	8
$SiBrCl_3$	16	6	14	6	16	2	4	14	9

$$V_{cr} = V_1(2.69 + 0.05f),$$

$$\Delta H_b = T_1[73 + 2.09\ln(T_1M/V_b)],$$

$$Z_{cr} = P_{cr}V_{cr}/(8.314T_{cr}),$$

$$\rho_{293} = (M/V_b)[1 + 0.46(1 - 293/T_b)],$$

where T_{cr} is the critical temperature (K); V_{cr}, critical volume ($cm^3\ mol^{-1}$); P_{cr}, critical pressure (MPa); Z_{cr}, critical compressibility factor ($P_{cr}V_{cr}/RT_{cr}$); b, van der Waals constant ($cm^3\ mol^{-1}$); ΔH_b, enthalpy of evaporation at the boiling point ($J\ mol^{-1}$); M, molar mass ($g\ mol^{-1}$); and ρ_{293}, density of the fluid at 293 K ($g\ cm^{-3}$).

At the end of the iteration follows the test for the prescribed accuracy (0.1 K), $|T_b - T_1| < 0.1$. If the condition is satisfied, the calculation is terminated; otherwise, the preceding value T_1 is replaced with a new one, $T_1 = T_b$, and the calculation is repeated beginning with Eq. (1).

All the data for determining the error of prognostication of the substance property under consideration were taken from the reference book [3]. The prognostication accuracy is mostly determined by the error in determining the boiling point. Table 1 lists errors of calculation of various properties for two substances with different T_b determination errors: small (ReF_6) and large ($SiHCl_3$).

The effect of the error in prognostication of the boiling point on the calculation error for other properties is illustrated in more detail by Table 2. It can be seen from the data in Table 2 that, as the calculation error of the boiling point increases, so does that for other properties; however, the errors in calculation of

some properties (V_b, V_{cr}, Z_{cr}, b) remain comparatively small.

The precision of the method was determined on a set of 80 compounds of elements from Groups III–VIII of the Periodic system. The set included hydrides, fluorides, chlorides, bromides, iodides, mixed halides, and oxyhalides. The average (in absolute value) errors in property prognostication were the following (%): T_b 8, V_b 3, ΔH_b 10, T_{cr} 8, V_{cr} 3, P_{cr} 10, b 4, Z_{cr} 2, and ρ_{293} 5. With account of the fact that the prognosis is made without any preliminary information about the properties of a substance under study, the prognostication accuracy should be considered quite satisfactory. The data for the prognostication accuracy refer to nonpolar and weakly or moderately polar substances. For strongly polar substances (NH_3, H_2O), the prognostication error is substantially larger.

If the boiling point is known, a calculation by the same formulas [beginning with Eq. (2), but without iteration] has a two times higher accuracy.

CONCLUSION

A method for prognostication of properties of molecular inorganic fluids on the basis of only the stoichiometric formula of a compound was suggested.

BRIEF COMMUNICATIONS

Sorption Ability of *N*-Vinylpyrrolidone–Trimethoxyvinylsilane Copolymers

M. N. Gorbunova and E. A. Sazonova

Institute of Technical Chemistry, Ural Branch, Russian Academy of Sciences, Perm, Russia

Received April 9, 2008

Abstract—Sorption ability of *N*-vinylpyrrolidone–trimethoxyvinylsilane copolymers was studied. Cross-linked *N*-vinylpyrrolidone–trimethoxyvinylsilane copolymers sorb Ni(II) and Cu(II) from ammonia solutions and can find use for wastewater treatment to remove these metal ions.

DOI: 10.1134/S1070427208100303

Polymeric sorbents of various classes are widely used in analysis and preconcentration of metals [1, 2]. In particular, cross-linked copolymers based on *N*-vinylpyrrolidone (VP) are used as sorbents. For example, VP–divinylbenzene copolymer is used in solid-phase extraction to determine phenoxyalkanoic acids and other herbicides in water and in the environment [3]. The copolymer of VP with 2-(vinyloxyethoxy)methylthiirane is a sulfur-containing sorbent of Ag(I) and Hg(II) ions [4]. Sorbents of a 3*D* structure, used as stabilizers for food and perfume liquids, were prepared by copolymerization of VP with triethylene glycol dimethacrylate [5, 6].

With the aim to prepare new potential sorbents, we synthesized cross-linked copolymers of *N*-vinylpyrrolidone with trimethoxyvinylsilane (TMVS) and examined their sorption activity.

EXPERIMENTAL

N-Vinylpyrrolidone (Lancaster) was dried over KOH and vacuum-distilled, with collection of the fraction with bp 65°C (1.5 mm Hg), $n_D^{20} = 1.5117$.

Trimethoxyvinylsilane (chemically pure grade) was purified by vacuum distillation, with collection of the fraction with bp 123°C, $d_4^{20} = 0.9700$, $n_D^{20} = 1.390$.

Copolymerization of VP with TMVS was performed in the bulk and in solution in a vacuum in the presence of AIBN initiator.

The pH dependence of the sorption ability of the VP–TMVS copolymer toward nonferrous and heavy metal ions was determined by the static sorption method at the initial concentration of the metal ions of 0.015 ± 0.005 M, temperature of 20 ± 2°C, polymer : salt solution ratio of 1 : 200, and phase contact time of 24 h.

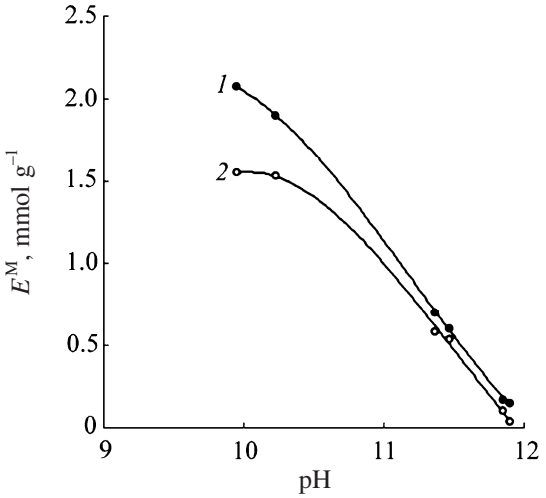
Solutions of metal salts were prepared by dissolving a weighed portion of appropriate salt $CuCl_2 \cdot 2H_2O$, $NiCl_2 \cdot 6H_2O$, $Pb(NO_3)_2$, or $Sc(SO_4)_3$ in HNO_3 solutions of required concentration or in ammonia solutions. The metal concentrations in solutions were determined by complexometric titration with Na_2EDTA. The static sorption capacity for a metal, E^M, was determined from the difference between the metal concentrations in the solution before and after sorption, with an error not exceeding 5%.

VP–TMVS copolymers were prepared by radical polymerization [7].

The copolymers obtained are colorless solids soluble in ethanol, acetone, and DMSO. However, after reprecipitation and drying, the copolymers lose the solubility in organic solvents because of the formation of siloxane cross-links, in agreement with published data [8].

We examined the dependence of the sorption ability of the cross-linked VP (80 mol %)–TMVS (20 mol %) copolymer (content of active groups, according to elemental analysis, 8.64 mmol g^{-1}) toward certain transi-

Table 1. Static sorption capacity E^M and distribution coefficients K_d of nonferrous and heavy metals



Metal	Acidity of initial solution	E^M, mmol g^{-1}	K_d, cm^3 g^{-1}

	pH 0.44	0.36	37.50
	1 M HNO_3	0.02	1.54

Table 2. Static sorption capacity E^M and distribution coefficients K_d of nonferrous and heavy metals in ammonia solutions

Metal	pH of initial solution	E^M, mmol g^{-1}	K_d, cm^3 g^{-1}
Ni(II)	5.78	0.96	56.47
	9.95 (0.1 M NH_3)	2.07	350.85
	11.47 (1 M NH_3)	0.60	29.13
	11.85 (3 M NH_3)	0.17	6.83
Cu(II)	5.78	0.96	77.42
	10.23 (0.1 M NH_3)	1.53	228.36
	11.37 (1 M NH_3)	0.58	35.80
	11.90 (3 M NH_3)	0.04	1.85

tion metal ions on the initial acidity of the solution (Table 1) and of that toward Cu(II) and Ni(II) ions on pH of the initial ammonia solution (figure, Table 2). We found that, with an increase in the solution acidity, the sorption ability of this polymer toward metal ions steadily decreases (Table 1) as a result of protonation of the nitrogen atom in the pyrrolidone ring.

In ammonia solutions, the sorption capacities for Cu(II) and Ni(II) and the distribution coefficients of these ions are considerably higher than those in acid solutions. With an increase in pH of ammonia solutions, the sorption capacity of the polymer with respect to Ni(II) and Cu(II) ions decreases as a result of the formation of stable metal ammine complexes in solution (figure, Table 2).

Sorption capacity E^M of cross-linked VP–TMVS copolymer for (*1*) Ni(II) and (*2*) Cu(II) as a function of pH of the initial ammonia solution.

Thus, cross-linked VP–TMVS copolymers quantitatively sorb Ni(II) and Cu(II) ions from ammonia solutions and can be used for wastewater treatment to remove these metal ions and for recovery of Cu(II) ions from ammonia solutions used in electronics production.

Oxidation of 4-Hydroxytoluene with an Ozone–Oxygen Mixture in Acetic Acid

A. G. Galstyan, A. I. Tarasenko, and Yu. A. Shumilova

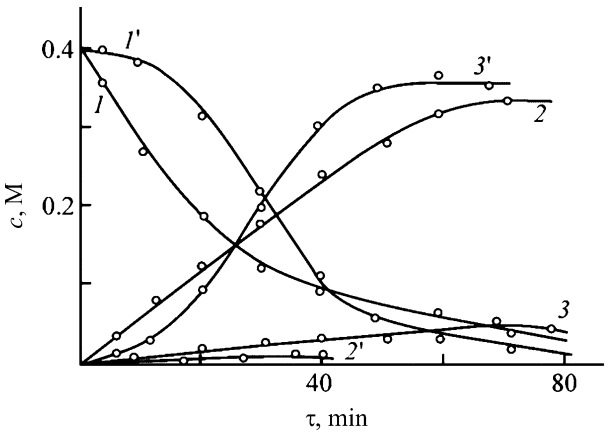
Institute of Chemical Technologies, Dal' East-Ukrainian National University, Rubezhnoe, Lugansk oblast, Ukraine

Received February 5, 2008

Abstract—Liquid-phase oxidation of 4-hydroxytoluene by ozone to 4-hydroxybenzoic acid in the presence of cobalt(II) acetate as a catalyst was studied. The optimal oxidation conditions were found.

DOI: 10.1134/S1070427208100315

4-Hydroxybenzoic acic (4-HBA) is widely used in production of drugs and pharmaceuticals, as conservant for foodstuffs, and for preparation of liquid crystal compounds [1, 2]. In industry, this acid is mainly produced by carboxylation of potassium phenolate [3] and oxidation of 4-hydroxytoluene (4-HT) with Pb, Mn, and Fe oxides [4]. The drawbacks of these procedures are the process complexity in the first case and formation of large amounts of toxic wastewater in the second case.



In this study we examined oxidation of 4-HT by an ozone–oxygen mixture with the aim to develop a low-waste process for 4-HBA production.

Published data on ozonation of 4-HT in acetic acid are lacking. It is only known [5–7] that, in tetrachloromethane, ozone rapidly attacks methylphenols at the lone electron pair of the OH group, which is followed by breakdown of the aromatic ring. Products of methyl group oxidation are not formed under these conditions.

The results of preliminary studies of the reaction of ozone with 4-HT in acetic acid do not differ noticeably from those described in [5–7]: The reaction rate constant at 20°C is 2.2×10^3 l mol^{-1} s^{-1}, and only aliphatic peroxides are detected in the oxidate after exhaustive oxidation of the substrate.

With the aim to protect the OH group of the 4-HT molecule from the attack by ozone, it was acylated.

The kinetic experiments showed that the reactivity of acylated 4-HT in reactions with ozone is considerably lower than that of nonacylated 4-HT, as indicated by the apparent rate constant obtained at 20°C: k_{app} = 0.74 l mol^{-1} s^{-1}. A drastic decrease in the rate constant of the reaction of ozone with 4-acetoxytoluene (4-AT), compared to 4-HT, suggests a change in the oxidation mechanism. Apparently, in this case, ozone attacks not the OH group but, in accordance with the classical concept of the reaction of ozone with alkylbenzenes [7, 8], predominantly the double bonds of the aromatic ring (86.8%) and, to a lesser extent, the methyl group (12.9%) (see figure). At 20°C, 1.15 mol of ozone is consumed per mole of 4-AT.

Variation of the concentration c of reaction mixture components in oxidaiton of 4-AT by an ozone–oxygen mixture in CH_3COOH at (*1*–*3*) 20 and (*1*'–*3*') 95°C in the presence of cobalt(II) acetate. $[4\text{-AT}]_0 = 0.4$, $[O_3]_0 = 4.8 \times 10^{-4}$, $[Co(OAc)_2] = 0.18$ M; $v_{air} = 8.3 \times 10^{-3}$ l s^{-1}. (*1*, *1*') 4-AT, (2) peroxides, (*2*') 4-ABAl, and (*3*, *3*') 4-ABA. (τ) Time.

Influence of the concentration of cobalt(II) acetate on the selectivity of 4-AT oxidation at the methyl group ($[O_3] = 4.8 \times 10^{-4}$, [4-AT] = 0.4 M; $v_{air} = 8.3 \times 10^{-3}$ l s^{-1}; $T = 95$°C)

$[Co(OAc)_2]$, M	Selectivity with respect to CH_3 group, %
0.06	43.9
0.10	58.4
0.14	71.0
0.18	87.0
0.22	87.1

The major product of 4-AT oxidation at the methyl group is 4-acetoxybenzoic acid (4-ABA) (see figure). In early steps of the oxidation, we also identified 4-acetoxybenzaldehyde (4-ABAl) whose concentration in solution does not exceed 10^{-4} M.

The selectivity of oxidation at the side chain increases on introducing into the system an oxidation catalyst, cobalt(II) acetate. Under the experimental conditions, the reaction is fast, and its major product is 4-ABA (see figure). The oxidation selectivity depends on the catalyst concentration, and, at a cobalt(II) acetate concentration of 0.18 M and temperature of 95°C, the oxidation is complete in 1 h, and the selectivity with respect to the methyl group is 87% (see table).

Selective oxidation at the methyl group in the presence of cobalt(II) acetate becomes possible as a result of two-step oxidation by ozone. Under the experimental conditions, ozone predominantly reacts with Co^{2+} [reaction (1)] ($k_1 = 9.7 \times 10^2$, $k_{AcOArCH_3 + O_3} = 0.74$ l mol^{-1} s^{-1}) to give active Co^{3+} species which involve 4-AT at a high rate [reaction (2)] in selective oxidation at the methyl group [9]:

$$Co^{2+} + O_3 + H^+ \rightarrow Co^{3+} + HO + O_2, \quad (1)$$

$$AcOArCH_3 + Co^{3+} \rightarrow AcOArCH_2 + Co^{2+} + H^+. \quad (2)$$

To ensure the occurrence of reaction (1), ozone should be continuously supplied to the oxidation system. Interruption of its supply impedes the process to the point of its complete cessation. This fact additionally confirms the assumption that the active form of the catalyst is mainly formed by reaction (1). Under the experimental conditions, the concentration of molecular oxygen in the gas mixture is one and a half orders of magnitude higher than the ozone concentration. Therefore, the acetoxybenzyl radical generated in the system [reaction (2)] reacts mainly with an oxygen molecule [reaction (3)] to form a peroxy radical which subsequently recombines [reaction (4)] to give the reaction products:

$$AcOArCH_2 + O_2 \rightarrow AcOArCH_2O_2, \quad (3)$$

$$AcOArCH_2O_2 \rightarrow \text{products}. \quad (4)$$

EXPERIMENTAL

In the experiments, we used glacial acetic acid (analytically pure grade) purified by vacuum distillation from potassium permanganate. Crystalline 4-HT was purified by repeated recrystallization from water, and liquid 4-AT, by repeated distillation. Cobalt(II) acetate (analytically pure grade) was used without additional purification.

Acylation was performed in a three-necked flask. Acetyl chloride was added dropwise at room temperature over a period of 30 min to the calculated amount of 4-HT dissolved in an equivalent amount of acetic acid. Then the reaction mixture was carefully diluted with water to a 1 : 1 ratio, with continuous stirring until the HCl evolution fully ceased. After that, the mixture was separated in a separating funnel, and the organic layer was washed with a 5% alkali solution and distilled.

The reactor (glass column with a porous partition for dispersing the ozone–air mixture) was charged with 10 ml of glacial acetic acid, 0.4 M 4-AT, and a calculated amount of the catalyst, after which the installation was thermostated and, after the ozonizer attained the steady-state operation mode, the ozone–oxygen mixture containing 4.8×10^{-4} M ozone was passed at a rate of 30 l h^{-1}.

After the oxidation was complete, the mixture was poured into water with ice (1 : 3 ratio). The precipitated 4-ABA was filtered off and dried. If necessary, 4-ABA can be readily hydrolyzed to 4-HBA. For this purpose, to 4-ABA we added 10 ml of concentrated HCl, 20 ml of water, and 4 ml of ethanol, refluxed the solution for 1 h, and then cooled it to 10°C. The 4-HBA precipitate was filtered off and dried. Yield 79% based on the loaded 4-AT.

The ozone content of the gas phase was determined spectrophotometrically from the absorption at 254–290 nm. The oxidation products in solution were identified and quantitatively determined by GLC on a chromatograph equipped with a flame ionization detector and a column 2 m long and 4 mm in diameter,

packed with Chromaton N-AW impregnated with SE-30, under the following conditions: vaporizer temperature 250°C, column temperature 180°C, flow rates, l h^{-1}: carrier gas (nitrogen) 1.8, hydrogen 1.8, air 18. As internal reference we used 4-nitrochlorobenzene.

The running concentration of 4-ABA was determined by potentiometric titration with alkali. To this end, we took from the reaction mixture a sample (0.5 ml) from which we distilled off the solvent. Then we dissolved the dry residue in 30 ml of 50% ethanol neutralized with respect to phenolphthalein and titrated it with 0.05 N NaOH.

CONCLUSIONS

(1) Noncatalytic oxidation of 4-hydroxytoluene by ozone in acetic acid occurs at a high rate predominantly at the lone electron pair of the heteroatom, without formation of products of methyl group oxidation. Acylation of the hydroxy group allows preparation under these conditions of 4-acetoxybenzoic acid in a yield of about 13%.

(2) The selectivity of 4-acetoxytoluene oxidation to 4-acetoxybenzoic acid increases to 87% at 95°C in the presence of a catalyst, cobalt(II) acetate. This acid, if necessary, can be readily hydrolyzed to 4-hydroxybenzoic acid. The yield of 4-hydroxybenzoic acid based on the loaded 4-acetoxytoluene is 79%.

BRIEF COMMUNICATIONS

Influence of Finely Dispersed Granite Dust on the Composition and Properties of Asphalt

D. A. Rozental', N. V. Maidanova, and V. A. Kulikova

St. Petersburg State Institute of Technology (Technical University), St. Petersburg, Russia

Received May 13, 2008

Abstract—Changes in the composition and properties of asphalt upon contact at 160°C with granite dust whose concentration in a mixture with asphalt was 40, 60, 70, and 85 wt % were examined.

DOI: 10.1134/S1070427208100327

The majority of materials based on petroleum asphalt contain mineral fillers. Their content varies from 15–20% in mastics and roofing materials to 94–96% in asphalt concrete. Although the effect of fillers on various properties of asphalts has been extensively studied [1–5], many aspects of the problem are still poorly understood.

In this study, we examined the influence exerted on the composition and properties of BDUS 70/100 asphalt by granite dust with a particle size less than 0.071 mm.

Previous studies [6, 7] has shown that, with a coarsely dispersed filler (fractions 2–3 and 3–5 mm), a part of the asphalt is adsorbed by granite. This fraction depends on the time of heating the asphalt–mineral mixture at 160°C, and the adsorption causes changes in the asphalt composition. The optimal time required to attain the adsorption equilibrium under these conditions is 3–5 h. Changes in the asphalt composition in the spaces between the filler grains consist in a decrease in the content of aromatic oils and a certain increase in the content of resins and asphaltenes. Apparently, the amount of adsorbed asphalt is proportional to the surface area of the filler and to its adsorption power.

It is known from Levchenko's studies [6, 7] that hot centrifugation (5 min, 5000 rpm) of a mixture consisting of 90 wt % granite and 10 wt % asphalt of BDUS 70/100 grade, thermostated for 5 h at 160°C, allows recovery of 16% of the introduced asphalt. Its composition and properties are listed in Table 1.

This study was performed with granite dust sieved through a 0.071-mm sieve and having the specific surface area of 1 $m^2 g^{-1}$, i.e., 10 000 $cm^2 g^{-1}$. We prepared mixtures containing 40, 60, 70, 85, and 95 wt % granite dust with asphalt of BDUS 70/100 grade. These mixtures were thermostated at 160°C for 5.5 h (4 h with stirring and 1.5 h without stirring). The results are presented in Table 2.

Table 2 shows that, with an increase in the dust content in the mixture with asphalt, its penetration considerably decreases and the softening point grows. We could not determine the softening point of the mixture

asphalt	81	65	54	33	13
Dust : asphalt volume ratio	0.23	0.54	0.85	2.03	6.7

with 85% dust, because it was a set of granules of different sizes. Comparison of changes in the group composition of asphalts (Tables 1 and 2) shows that these changes are considerably more pronounced in the asphalt that was brought in contact with coarsely grained granite. This can be attributed to the limited capacity of the method for determining the component composition, suggested by VNII NP–SoyuzdorNII, as applied to mix-tures of asphalt with dust.

Dust particles having a microscopic volume and small weight are involved in the Brownian movement and are nearly uniformly distributed over the bulk of asphalt. In hexane extraction of ashpaltenes, the initial material is a mixture of asphalt with granite dust, rather than pure asphalt. In the course of the extraction, the major fraction of the adsorbed asphalt is washed out with the solvent. Therefore, the compositions of the initial asphalt and that thermostated with granite dust differ insignificantly. For the mixtures containing more than 60% dust, the analytical errors are too large.

For the convenience of the analysis of the effect exerted by the granite dust concentration on the composition and properties of asphalt, the mixture compositions were converted from wt % to vol %. The results are listed in Table 3.

It can be seen that the dust content of asphalt at weight concentrations of the dust of 40 and 60% is low: 19 and 35 vol %, respectively. Dust particles are for apart from each other and are surrounded by a solvation shell of asphalt components present in these mixtures in excess. In these mixtures, the dust particles are in the freely dispersed state and do not form a continuous structure in the bulk of asphalt.

Because the range of adhesion forces of dust particles is tens of nanometers, it whould be expected that the interaction can occur only when the particles approach each other to such a distance. Starting from a 70 wt % concentration of dust, at which the volume ratio of the dust and asphalt becomes close to unity, the dust particles can combine into a continuous framework in the bulk of the asphalt. The compound becomes a hard monolith. At a higher content of dust in the mixture with asphalt, the amount of asphalt becomes insufficient for the formation of a monolith, and

the mixture is broken to separate granules. At a 95% content of the dust, the mixture remains powdered and is only slightly black colored.

Thus, it can be concluded that, at a large specific surface area of the mineral filler and its high concentration, all the asphalt components are adsorbed. As a result, the material becomes nonmonolithic and friable. This is possible only with a finely dispersed material in which the interparticle distances are comparable with the range of the effect of the adhesion energy field. Apparently, in asphalt concrete, the voids between filler grains should be larger in size than the range of the effect of the energy field of the filler. This would allow a certain amount of asphalt to be retained in the state insignificantly differing from the initial state, with preservation of its plastic properties.

CONCLUSIONS

(1) When present in concentrations of 40 and 60 wt %, granite dust affects the asphalt composition insignificantly, but noticeably increases its softening point and decreases the penetration. At a dust concentration of 70%, a solid monolith is formed, and at 85% dust content its mixture with asphalt is broken down to separate lumps. At high concentrations of dust, it adsorbs all the asphalt components.

(2) Finely dispersed filler (in contrast to coarsely dispersed one) can form a 3*D* condensation structure in the bulk of asphalt. This is possible if dust particles approach each other to a distance comparable with the range of their adhesion energy field. A high content of dust in asphalt concrete can lead to premature destruction of the road pavement.

(3) At a dust concentration exceeding the above level, the mixture is broken down to separate particles, in the limit equal in size to dust particles. This fact indicates that, under definite conditions, all components of asphalt are adsorbed on the mineral filler.

Received May 16, 2008

Abstract—Reasons for formation of the liquid phase in operation of fire-extinguishing aerosol generators were examined. The amount of the melt formed depends on the particle size and on the inclination angle and length of the cylindrical generator.

DOI: 10.1134/S1070427208100339

Fire safety is currently a pressing problem. Despite the overall decrease in the number of fires in the past three years, the total damage, according to the Emergency Ministry data, increased by more than 20%. One of the most efficient and economical means for fire control is the use of fire-extinguishing aerosol generators. However, they have certain drawbacks. In particular, formation of not only a solid, but also a liquid phase in the course of generator operation impairs the generator performance and causes additional damage to the materials being treated. The goal of this study was to elucidate the reasons for formation of the liquid phase.

Experiments were performed in a model cylindrical generator with an outer diameter of 0.85 and an inner diameter of 0.8 m, made of St.10 steel [GOST (State Standard) 8733–74]. We used two cylinders of different lengths, 0.82 and 1.64 m. Charges were prepared by dead pressing on a PSU-125 hydraulic press at a compaction pressure of 200 MPa. Charges of two types were used: with an internal channel 0.04 m in diameter and without it. The charge length in both cases was 0.20 m, and the outer diameter, 0.078 m. To protect the generators from burning-through of the side surface, the charges were twice coated with a mixture of liquid glass and iron(III) oxide. To prevent an uncontrollable increase in the combustion rate, the charge was wrapped with a 0.002-m layer of a heat-insulating material (mica).

To measure the temperature, we used standard TKhA thermocouples in a porcelain sheath [Chromel (90.5% Ni + 9.5% Cr)–Alumel (94.5% Ni + 5.5% Al, Si, Mn, Co)], 0.001 m in diameter, with the upper temperature measurement limit of 1300 K. The junctions of some of the thermocouples were fixed at hollows on the generator housing, and some of the thermocouples were inserted through apertures in the housing to record the aerosol temperature.

The model generator was tested on a special installation consisting of a computer, analog–digital converter, amplifier, and thermocouples. The installation allows on-line monitoring of changes in the temperatures of both the generator walls and the aerosol flow. Data obtained in the course of the tests were treated with a computer in the Microsoft Windows 2000 environment and were recorded using a specially developed software. The test results are listed in Table 1.

Table 1. Results of generator tests

Experimental series	Pipe length, m	Charge weight, kg	Charge length, m	T_{max}, K		Average combusiton time, s	Melt weight, wt %
				walls	aerosol		
Charge without channel	0.83	1.2	0.22	983	1083	69	5
	1.63	1.2	0.22	798	943	77	0

Charge with channel	1.63	1.5	0.42	943	1054	145	0

Table 2. AFC composition and energy characteristics (charge weight m_c = 2.1 kg, fuel density ρ = 994.7 kg m^{-3}, combustion velocity U_l = 0.00284 m s^{-1})

Component	Empirical formula	Content, wt %	ΔH_f^0(298.15), kJ kg^{-1}
Iditol (phenol–formaldehyde resin)	$C_{13}H_{12}O_2$	15	–2964
Dicyandiamide (DCDA)	$C_2H_4N_4$	10	221
Potassium nitrate	KNO_3	75	–4660

As the experiments showed, the amount of the melt formed in combustion of the aerosol-forming composition (AFC) in the generator depends on the extent to which the generator wall is heated, charge weight, and pipe length. To elucidate this dependence more accurately, we constructed a mathematical model of the gravity sedimentation of the liquid melt on the inner surface of the pipe of an aerosol fire extinguisher. The input data for calculating the properites of AFC combustion products and AFC energy characteristics are given in Table 2.

Thermodynamic calculations of the aerosol composition, performed according to [1], showed that the fuel composition we chose provides the combustion temperature (T = 1591 K) at which almost the whole amount of KOH, which is the main condensed product, is in the liquid state; its weight fraction Z is 0.396 (mole fraction of liquid KOH_l 0.244 and that of gaseous KOH_g 0.33×10^{-2}), i.e., the condensed phase is fully formed near the combustion surface and then undergoes only coagulation, fragmentation, and adhesion to the channel walls.

At an enthalpy of the system changed by 5%, possible fluctuations of the charge combustion temperature due to variation of the external conditions cannot significantly affect the thermodynamic characteristics of the aerosol. The condensed phase present in the aerosol is polydispersed [2].

At an initial instant of time, the condensate can fall out on a cold channel wall and even solidify. As the structure is heated to 633–678 K (melting point of KOH), the melt entrained by the gas flow will be transferred along the internal generatrix of the channel to the open end of the pipe and will be ejected to the environment in the form of coarse drops and clots.

In the suggested mechanism of deposition of the liquid melt on the channel walls, each particle of the melt is involved in two motions: to the side surface of the channel under the action of the gravitation and in the opposite direction from the channel wall under the action of the aerodynamic force.

The gravitational force acting on a particle was calculated as follows:

$$F_g = mg\cos\alpha,$$

where F_g is the force acting on a particle (N); g, free-fall acceleration; α, inclination angle of the generator axis relative to the horizon (deg); and m, particle weight (kg).

The particle weight, in turn, was calculated by the formula

$$m = V\rho_p,$$

where V is the particle volume (m^3), and ρ_p, particle density (kg m^{-3}).

The aerodynamic force acting on the particle was calculated as

$$F_a = C_y \frac{\rho W_y^2}{2} S,$$

where W_y is the particle velocity relative to the gas flow across the channel or, in other words, sedimentation velocity (m s^{-1}); ρ, gas phase density (kg m^{-3}); and S, cross-section area of the particle (m^2).

The aerodynamic resistance coefficient C_y for the turbulent flow is chosen according to [3]. The Reynolds number for the system under consideration is

$$\mathrm{Re} = \frac{\rho W_y d_z}{} > 10^4,$$

where d_z is the mean diameter of the melt particle (m) and ν is the viscosity (Pa s).

Accordingly, the aerodynamic resistance coefficient C_y will be equal to 0.4–0.5 for this system. Then the equation of the particle motion along the Y axis, determining the deposition of particles on the walls, can be written as

$$m\frac{dW_y}{dt} = mg\cos\alpha - C_y \frac{\rho W_y^2}{2} S.$$

Because the particle size is small (mean particle diameter, according to experimental data [2], is 20 μm), it can be assumed that, in motion along the X axis, $W_{xg} = W_{xm}$ (m refers to melt, and g, to gas). This

assumption will not bring about any fundamental quantitative changes to the final result and, primarily, will not affect the residence time of particles in the pipe, which is determined by the formula $\tau = L/W_x$.

Let us assume that the mean size of melt particles is d_z. Then Eq. (1) will take the form

$$\frac{dW_y}{dt} = g\cos\alpha - \frac{3}{4} C_x \rho W_y^2 \frac{1}{\rho_z d_z},$$

and the total scheme for calculation of the particle sedimentation will be as follows:

$$dx = W_x \Delta t,$$

$$dy = W_y \Delta t, \quad W_{y_i} = W_{y_{i-1}} + \left(\frac{dW_y}{dt}\right)_{i-1} \Delta t,$$

$$x + dx, \quad y = y + dy,$$

The total residence time of the aerosol in the pipe does not exceed 3 s. Therefore, to provide a sufficient calculation accuracy in the numerical integration, Δt was assumed to be 10^{-3}. To calculate the residence time of an aerosol particle in the pipe, we used the quantities calculated by the following formulas.

Generator performance (aerosol expenditure):

$$m_{as} = \rho_T F_{ch} U_l,$$

where m_{as} is the aerosol weight (kg); ρ_T, aerosol density at a current temperature (kg m^{-3}); U_l, linear velocity of combustion (m s^{-1}); and F_{ch}, charge surface area (m^2).

The charge surface area is given by

$$F_{ch} = \pi d_p^2/4.$$

The amount of the melt supplied to the fire-extinguisher pipe as a result of combustion

$$m_m = m_{as} Z,$$

where Z is the weight fraction of the melt (%).

The amount of the melt deposited on the channel walls is

$$m_{mw} = (m_m/F) dy L_x,$$

where F is the wall surface area (m^2) and L_x is the channel length.

Table 3. Melt weight in relation to the generator inclination angle and particle size

Mean particle diameter $d_z \times 10^{-6}$, m	Melt weight, kg, at indicated inclination angle of the generator, deg			
	0	30	45	60
10	1.04×10^{-2}	8.99×10^{-3}	7.34×10^{-3}	5.19×10^{-3}
20	4.13×10^{-2}	3.58×10^{-2}	2.92×10^{-2}	2.07×10^{-2}
30	0.111	8.63×10^{-2}	6.5×10^{-2}	4.6×10^{-2}
40	32.5	26	18.7	10.6
60	0.719	0.619	0.481	0.301
80	–	–	0.8	0.593
100	–	–	–	0.805

The results of a calculation of the weight of the melt formed are listed in Table 3.

CONCLUSIONS

(1) At a particle size $d_z < 10$ μm, melt is not deposited on the channel walls to any noticeable extent; with an increase in the aerosol particle size, the fraction of the melt deposited on the channel walls grows.

(2) With a decrease in the inclination angle of the fire extinguisher axis, the fraction of the melt condensing on the channel wall increases.

(3) To reduce the melt discharge along the side surface of a fire extinguisher, it can be recommended to decrease the length of the cylindrical channel and increase the inclination angle of the fire extinguisher relative to the horizon.

BRIEF COMMUNICATIONS

Coulometric Determination of the Moisture Content, Using Modified Fischer Reagent with Epichlorohydrin

G. F. Nichugovskii

Prikladnaya Khimiya Russian Scientific Center, St. Petersburg, Russia

Receivd April 22, 2008

Abstract—Application of a coulometric method of water titration in the medium of a modified Fischer reagent in which epichlorohydrin is used to shift the equilibrium of sulfur dioxide oxidation by iodine was experimentally substantiated.

DOI: 10.1134/S1070427208100340

In a new modification of the Fischer reagent, it is suggested to use, instead of pyridine, epichlorohydrin (ECH), which rapidly and quantitatively reacts with HI, for shifting the equilibrium of sulfur dioxide oxidation by iodine. Certain conditions and results of using this reagent for quantitative determination of water in the volumetric titration mode, with isopropyl alcohol as solvent, have been reported previously.

Interest in the coulometric mode is caused by its two major advantages: absolute character of measurements (no calibration is required) and high sensitivity [1]. It is also important that different companies presently produce a large number of industrial coulometric installations. Apparently, coulometric titration is only possible in a conducting solution containing a certain minimal concentration of iodide ions to obtain elemental iodine at the anode. However, the suggested reagent based on ECH does not contain such a source of iodide ions. Hence, to implement a coulometric procedure, these ions should be introduced into the electrolyte in advance in the form of an appropriate salt.

EXPERIMENTAL

All the studies were performed on an experimental coulometric installation including generator and indicator units and a gas cell with a filter. For iodine indication, we used a bipotentiometric system with an additional 30 kΩ resistor in the indicator electrode circuit [2]. Preliminarily, we prepared a solution of SO_2 in ECH by passing the gas through the solvent until saturation. The SO_2 concentration was about 3 M. As a solvent for preparing the working electrolyte we used methanol with less than 0.1% moisture content. The cell was charged with 20 ml of methanol and 2–3 ml of a solution of SO_2 in ECH, after which argon dried over P_2O_5 was fed at a rate of 30–50 ml min^{-1}, and crystalline iodine was added in portions until its persistent color appeared. Initially, colored jets of an iodine solution rapidly decolorized owing to the reaction with H_2O in the immediate vicinity of the crystals, after which, with the progress of dehydration, these jets increased in length and gradually reached the surface. In the process, the indicator signal became maximal, and the potential difference at the indicator electrodes became close to zero. A similar pattern is observed with the common Fischer reagent. This fact indirectly suggests that the rate of the main chemical reaction of iodine with water in both reagents is similar.

The cathodic chamber is filled with the resulting solution containing a small excess of iodine through a filter by the principle of communicating vessels. In the course of the experiments, the solution level in the cathodic chamber should be necessarily kept below its level in the anodic chamber, to exclude ingress into the working chamber of interfering impurities accumulating in the near-cathode space.

In the first step of the studies, we used CsI as a source of iodide ions. However, its solubility in methanol in the presence of 10–20% ECH is less than 0.1 M.

Furthermore, the salt probably exists in solution mainly in the form of neutral ion pairs. Therefore, the electrolytic conductivity of the solution is relatively low: We failed to raise the generator current even to 2 mA. Characteristically, as products of the reaction of iodine with water and SO_2 in the presence of ECH are accumulated, the generator current at a given voltage noticeably increases, but no iodine generation is observed at the anode. This fact suggests accumulation in solution of methylsulfuric acid, which does not react with ECH but provides comparatively high conductivity.

Ammonium iodide NH_4I appeared to be the most efficient source of iodide ions. Its advantage is in the high solubility in methanol, which provides a high conductivity of the solution. However, due to its acidic properties, it slowly reacts with ECH, which leads to a gradual decrease in the concentration of iodide ions, and, at a certain critical level, the current efficiency of the electrochemical generation of molecular iodine becomes lower than 100% at a given current density. This critical concentration in the traditional Fischer reagent is about 0.1 M at a current density of about 10 mA cm^{-2}. Furthermore, the indicator current ceases to be proportional to the iodine concentration at very low concentration of iodide ions, and the sensitivity of the indicator system drastically decreases. Apparently, when iodide ions are fully absent, it is impossible to attain the final titratoin point, although the generator current does not change noticeably. The first sign of an irreversible change in the electrolyte composition, at which it becomes unsuitable for coulometric titration, is a well-defined increase in the results in successive analyses of the same sample. We found that this problem can be readily solved by intermittent introduction of additional amounts of NH_4I into the electrolyte.

As already noted, the main condition for applicability of the coulometric method is the 100% efficiency of titration. The simplest way to find this parameter is to perform titration of known amounts of water in accordance the introduced–found principle. To this end, we introduced with a syringe portions of a solvent with known amounts of water into a cell with the electrolyte. These amounts were calculated by a common procedure using the Faraday formula, taking into account equimolar ratio between iodine and water. Some of the results obtained are listed in Table 1.

These data show that the suggested electrolyte based on the modified Fischer reagent with ECH is quite suitable for coulometric titration of water at its content exceeding 0.01%. It is important that the stoichiometry of the reaction between the major components does not change in the process. The analytical error, as a rule, does not exceed 3 rel %. The relatively high error of the results, according to our observations, is due, firstly, to hydrodynamic flows of the catholyte and anolyte through the glass filter and, secondly, to electromigration transport of interfering products from the cathodic space into the working anodic space. Among these products, we should primarily note the di-thionite ion $S_2O_4^{2-}$ formed at the cathode by electrochem-ical reduction of SO_2 and quantitatively oxidized by iodine. In the common Fischer reagent, this process occurs with 100% efficiency. This fact served as the basis for coulometric back-titration of water [3].

Table 1. Efficiency of coulometric titration of water, using modified Fischer reagent with epichlorohydrin ($\alpha = 0.95$)

Solvent	H_2O introduced, %	H_2O found, %	Error, rel %	n
Isopropanol	–	0.052 ± 0.004	–	7
	0.48*	0.47 ± 0.06	–2.1	3
	0.80	0.78 ± 0.03	–2.5	–
DMF	–	0.218 ± 0.009	–	5
	0.38*	0.39 ± 0.02	+2.6	4
	0.78	0.79 ± 0.09	+1.3	4
Chloroform	–	0.020 ± 0.001	–	4

* Taking into account the initial moisture content.

Table 2. Efficiency of the electrochemical reduction of sulfur dioxide on a cathode in the modified Fischer reagent with epichlorohydrin ($n = 3$, $\alpha = 0.95$)

Current density, mA cm^{-2}	Time, s		t_c/t_a ratio, %
	anodic process, t_a	cathodic process, t_c	
6	200	200 ± 12	100 ± 6
10	200	196 ± 8	98 ± 4
16	200	110 ± 50	55 ± 25

We found that a similar pattern is observed in the electrolyte based on the modified reagent with ECH (Table 2). As can be seen, with an increase in the current density, the time required for the reduction of elemental iodine accumulated in the working chamber in the course of the anodic process sharply decreases. This result can be attributed to two factors: low current

Table 3. Stoichiometry of the reaction between water and iodine in modified Fischer reagent with epichlorohydrin ($\alpha = 0.95$)

Water		Iodine		$K = \frac{n_{H_2O}}{n_{I_2}}$
weight, g	*n*, mol	weight, g	*n*, mol	
0.034	0.00189	0.500	0.00197	0.96
0.022	0.00122	0.320	0.00126	0.97
0.017	0.00094	0.236	0.00093	1.01
				$K_{av} = 0.98 \pm 0.06$

efficiency by iodine at the anode (i.e., other electrochemical reactions occur along with the main reaction) and considerable electromigration transport into the working space of $S_2O_4^{2-}$ ions lowering the initial concentration of molecular iodine. Apparently, with accumulation of these ions in the cathodic space, the contribution of this process (and hence the determination error) will increase.

It is interesting that introduction into the electrolyte of chloroform, whose dielectric constant is considerably lower (4.7) than that of methanol (32.6), to a concentration of 20 vol % does not noticeably decrease the solution conductivity, but apparently improves the sensitivity of iodine indication. It is quite likely that addition of chloroform appreciably decreases the rate of the reaction of ECH with NH_4I. In this case, it is appropriate to add this amount of chloroform to the methanol-based electrolyte in advance.

The previously made conclusion that the ratio between iodine and water in the modified reagent with ECH is equimolar can be readily confirmed by direct gravimetric titration of weighed portions of pure water with crystalline iodine (Table 3). These data, as previously [4], can serve as a basis for gravimetric determination of the moisture content of substances and formulations containing up to 100% water.

CONCLUSIONS

(1) A new modification of the Fischer reagent, with epichlorohydrin used for shifting the equilibrium of the oxidation of sulfur dioxide with iodine, is suitable for coulometric titration of water, provided that ammonium iodide as a source of iodide ions is intermittently added to the methanol-based electrolyte.

(2) In the modified reagent in the presence of excess epichlorohydrin, iodine and water react in an equimolar ratio. The same ratio was confirmed by direct gravimetric titration of water with crystalline iodine.

OBITUARY

Vladimir Aleksandrovich Krol' (1923–2008)

DOI: 10.1134/S1070427208100352

Vladimir Aleksandrovich Krol', a prominent scientist in the field of synthetic rubber production, doctor of chemical sciences, professor, winner of the Lenin and State Prizes, eldest staff member of the Lebedev Research Institute of Synthetic Rubber (VNIISK), died on June 7, 2008, at the age of 84, after serious sickness. A gifted man with a heroic fate passed away.

Krol' was born on November 16, 1923, in Omsk into a family of hereditary physicians. In June 1941, at the age of 17, he graduated with excellent marks from secondary school no. 37 of Omsk and hoped to continue the job of his parents. However, his destiny was different. Since the autumn of 1941, Krol' worked as a turner at a military plant in Novosibirsk. In May 1942, he volunteered into the Red Army and participated in battles. He was wounded twice (for the second time, heavily). After demobilization in the autumn of 1944, he entered the Lensovet Institute of Technology. After the second year, he passed to the University and graduated from the Chemical Faculty with honor in 1949. His specialization was organic synthesis. All the further activities of Krol' are associated with VNIISK. In 1953, he defended his Candidate's dissertation "Activity of Free Radicals in Connection with the Polymerization Process." In 1963, he became a senior researcher. Under the guidance of Prof. B.A. Dolgoplosk (Academician since 1964), Krol' actively participates in studies concerning the problem of butadiene polymerization. For a series cycle of studies on catalytic systems for the synthesis of *cis*-polybutadiene, Krol' was awarded in 1961 a Diploma of the Mendeleev All-Union Chemical Society, and for a series of papers "Development of *cis*-Polybutadiene Rubber" he, together with co-workers, received the Lebedev prize of the Presidium of the USSR Academy of Sciences. In 1967, Krol' and co-workers were awarded a Lenin Prize "For a Series of Studies on the Development of Regular Rubbers and of a Process for Their Commercial Production." The development and mastering of the production of two new kinds of rubber on a number of plants was at that time a major achievement of the Soviet science and engineering. The contribution of Krol' to this success is very large.

In 1972, Krol' very successfully defended his Doctoral (Chemistry) dissertation. It concerned the polymerization of butadiene and the development and commercial implementation of a procedure for producing SKD (*cis*-1,4-polybutadiene) rubber. In 1973, Krol' became a professor, and in 1978 he was awarded a State Prize for his studies.

From 1985 to 1989, Krol', along with heading a laboratory in VNIISK, occupied a professor's post at the Chair of Macromolecular Compounds of the Leningrad State University. He delivered the course of chemical technology of polymers and supervised diploma works. In the period from 1965 to 1990, twelve candidate's dissertations were defended under the guidance of V.A. Krol'.

Vladimir Aleksandrovich Krol' was a very good and comprehensively gifted person, a talented scientist, an excellent experimenter, and a tireless traveler. He enjoyed deserved universal esteem. Krol' spent the last period of his life in Israel, but he remained the Russian citizen and visited St. Petersburg every year.

Staff members of the Research Institute of Synthetic Rubber, colleagues, and friends

BOOK REVIEWS

Ananichev, V.A., *Ob"emnaya dilatometriya khal'kogenidnykh stekloobraznykh materialov* (Volumetric Dilatometry of Chalcogenide Glassy Materials),

St. Petersburg: Izd. Politekhnicheskogo Univ., 2007, 166 pp.

DOI: 10.1134/S1070427208100364

The discovery of semiconducting glasses by N.A. Goryunova and B.T. Kolomiets in the middle of the XX century stimulated studies of the whole set of physicochemical properties of these materials. Ananichev's book summarizes and analyzes methods and results of studying the thermal expansion of chalcogenide glasses and their melts in a wide temperature range.

The book consists of an introduction, eight chapters, and an appendix. In the brief Introduction (pp. 6–7), the author formulates the goal of the book and the problems considered. Very short Chapter 1 (pp. 8–18) presents the general relationships determining the cubic expansion coefficient of solids and liquids and, in particular, of chalcogenide glass melts. Chapter 2 (pp. 19–30) describes devices developed by V.A. Ananichev and co-workers for studying the thermal expansion of chalcogenide materials. Chapters 3 (pp. 31–72) and 4 (pp. 73–92) analyze experimental data on the thermal expansion of glasses and melts in chalcogenide and halogenide–chalcogenide systems. Chapter 5 (pp. 93–107) discusses, using specific examples, the features of isotherms expressing the composition dependence of the molar volume. It is noted that the maximal deviations from the additivity, suggesting the occurrence of ordering, in the isotherms of the molar volume of melts and glasses correspond to the compositions of compounds formed in the chalcogenide system and known from the phase diagrams. Chapter 6 (pp. 108–122) concerns the stability of chalcogenide glasses with respect to crystallization. The method of volumetric dilatometry, developed by the author, is sensitive to crystallization and furnishes useful information. Chapters 7 (pp. 123–136) and 8 (pp. 137–146) report the results of studying the vitrification of melts of chalcogenide and halogen–chalcogenide systems, obtained by volumetric dilatometry. When discussing the results, the author proceeds from the fact that chalcogenide glasses are inorganic polymers and that the trends in variation of their properties in the glass transition range are satisfactorily described in terms of the fluctuation free volume theory.

In the Appendix (pp. 147–164), the author presents tabulated data on the density of glasses and melts for nine chalcogenide systems containing arsenic. The monograph is based on original experimental studies performed by the author. V.A. Ananichev developed devices allowing chalcogenide systems to be studied in a wide temperature range with high reliability. These devices are intended for measuring the cubic expansion coefficients both for melts of chalcohenide systems in the liquid and high-viscosity states and for solid chalcogenide materials. They allow determination of the crystallization parameters and density of glasses. All these devices, protected by Inventor's Certificates, were developed on the basis of simple and available measuring devices. The book is well written, it includes ample reference material. The lists of references are given to each chapter separately. Ananichev's book is included in the series "Chemistry in the Polytechnic University." The book can be useful for a wide range of researchers dealing with physicochemical studies of both chalcogenide systems and other objects. The presentation is very intelligible. The polygraphic quality of the book is very high.

Received February 5, 2008

Abstract—Joint reduction of iron group metals in aqueous solutions on a dispersed aluminum matrix was studied. The powders obtained were examined by X-ray phase analysis and electron scanning microscopy.

DOI: 10.1134/S1070427208110013

The development of new generations of structural and functional materials is a topical problem. A possible way to solve this problem is variation of the composition of a system used a precursor.

It is well known that evolution of any physicochemical systems occurring under nonequilibrium conditions can lead to formation of fractal structures and nanocomposites [1]. For example, dendritic structures of frequently formed, e.g., in the course of nonequilibrium electrolytic deposition of metals and solidification of alloys under the conditions of strong supercooling, or in the course of phase decomposition. These methods can be considered as formation of nanostructures in the bulk of a matrix under the conditions of its chemical modification. This process allows the parameters of the particles in the matrix to be controlled in the step of their formation and varied in the course of material operation.

Much researchers' attention is attracted today by synthesis of metallic composites with elemental aluminum or its compounds as a matrix [2–6]. Owing to unique combination of the protective properties of surface oxide–hydroxide layers and intrinsic chemical activity, aluminum under definite conditions chemically reacts with the environment to form products exhibiting a set of specific properties [7, 8]. According to the results of numerous studies, the chemical activity of finely dispersed aluminum powders toward water and aqueous solutions of chemical compounds considerably exceeds the chemical activity of the compact metal [9, 10]. Many authors believe [7, 9, 10] that this is due to the developed surface of the powders and to the strongly defective state of the surface oxide–hydroxide coatings of the particles, and also to intense heating of the solid phase in the course of the oxidation [10]. These factors can strongly affect the extent and character of the interaction of compact and dispersed aluminum matrices with an aqueous solution containing metal ions. Of particular interest is contact deposition of iron group metals on a dispersed aluminum matrix. This process may lead to the development of powdered systems with variable composition and properties, showing promise as precursors of compact materials and coatings.

Alloys and composites based on iron and aluminum occupy a particular place among intermetallic systems promising from both theoretical and applied standpoint. They exhibit a unique set of physicochemical, mechanical, magnetic, and corrosion properties. However, iron aluminides are not still demanded by the industry because of the lack of a relatively simple and cheap procedure for their preparation. Today Fe–Al systems are prepared by mechanochemical methods which are not always efficient and are power-consuming.

It was proposed previously to prepare alloys and composites based on the Fe–Al binary system from aqueous solutions by contact exchange of metals on aluminum microparticles [11]. This process occurs in solution under normal conditions and is accompanied by the release of a large amount of heat, mainly due to ionization of aluminum. The deposition of Fe(0) from such solutions occurs in two steps: Fe(III) → Fe(II) → Fe(0), with simultaneous ionization of the aluminum

base and formation of an α-Fe layer on its surface. As a result, dendritic spherical particles with large internal cavities and pores are formed, which determines the low bulk density of the powder [11]. In the process, threadlike nuclei of submicrometer cross section can be formed in particle pores.

EXPERIMENTAL

Experiments were performed with close-cut fractions of dispersed aluminum (85 ± 15 μm, purity no less than 99.0%), with a specific surface area of 260 $cm^2\ g^{-1}$. The chemicals we used were $FeCl_3 \cdot 6H_2O$, $NiCl_2 \cdot 6H_2O$, and $CoCl_2$ (analytically pure grade). The molar ratio of the starting aluminum powder and precursor was 1.5 : 1 in all the experiments.

To study the process kinetics, we took samples at regular intervals of time and examined them by X-ray fluorescence analysis on a VRA-20L installation (Carl Zeiss) under the following conditions: LiF 200 analyzer crystal, voltage 55 kV, current 35 mA, X-ray tube with a tungsten anode, collimator 2, SZ counter, discriminator 1.0 V, and sensitivity 3×10^4–1×10^5 counts $s^{-1}\ cm^{-2}$. The degree of precursor reduction to metal was estimated from variation of the concentration of ions of the corresponding elements in solution. The experimental error was governed by the methods used and amounted to 5%.

The chronopotentiograms in a suspension of dispersed aluminum were recorded with an EPV-1 platinum electrode and an EVL-1MZ-1 silver chloride reference electrode.

The samples we obtained were analyzed with a DRON-2 X-ray diffractometer to determine their chemical and phase composition. To reduce the background from scattering of the primary X-ray beam in air, we used long-wave FeK_α radiation with a β-filter. The diffraction patterns were recorded in the following mode: voltage 30 kV, current 15 mA, recording range 2θ 10°–160°. The diffraction patterns were processed with MAUD 1.999 multifunctional software [12, 13]. As a reference for comparing the line profiles (to determine the size of coherent scattering regions and microstresses), we used annealed copper foil.

Analysis and recording of microscopic images of the initial aluminum and powders obtained were performed with a Philips SM XL-30 TMP scanning electron microscope at the following parameters: ΔE scale 10 keV (0–500), acquisition time T = 100 s, E_{probe} = 30 keV. The size of the microanalysis area was varied from 20 × 30 to 50 × 75 μm.

Electrolytic codeposition of two or several metals is of particular interest because of the mutual influence of the jointly reduced ions on the rate of electrochemical processes [14]. It is known [14–17] that, in joint reduction of Fe(II) and Ni(II) ions, the electrochemical reaction is conjugate, i.e., the rate of discharge of their ions differs from the rate at which these ions are reduced separately. It was shown in a number of papers [14, 17] that the rate of reduction of Fe(II) ions increases by a factor of almost 3 in joint electrodeposition with Ni(II). On the contrary, the rate of reduction of Ni(II) in joint deposition with Fe(II) decreases by a factor of approximately 8. In the course of nickel electrodeposition, hydrogen is released at a considerably higher rate than in joint deposition of iron and nickel, because of the lower overvoltage of hydrogen on nickel.

The experiments performed [18] suggest that the reactions of Fe(III) and Ni(II) reduction when these ions are present in solution simultaneously are conjugate, i.e., the successively occurring steps Fe(III) → Fe(II) → Fe(0) initiate the reaction Ni(II) → Ni(0).

Both conjugated reduction reactions can be adequately described by first-order rate equations

$$c(Fe^{3+}) = c_0(Fe^{3+}) \exp(-kt),$$

$$c(Ni^{2+}) = c_0(Ni^{2+}) \exp(-kt).$$

Previously, in studying joint deposition of Fe and Ni on an Al surface, we showed [18] that Ni metal is mainly deposited on the surface of the iron formed, with a certain part of iron undergoing oxidation and passing into the solution. In joint deposition of Fe(III) and Ni(II), a dark gray ferromagnetic powder is formed. The reaction is accompanied by considerable (to 373 K) heat-up of the reaction mixture. In joint deposition of Fe and Ni on Al, the powder is enriched in the less noble component [18]. The similar effect observed in electrodeposition is attributed in [19] to a shift of the metal deposition potentials when the metals are present simultaneously and to possible formation of passive films on the iron surface, preventing the deposition of Ni. Hydrogen evolution occurs simultaneously with the metal codeposition.

Similar process is observed in the Fe(III)–Co(II) system. When the cobalt and iron ions are present simultaneously, they are reduced somewhat more slowly

compared to the separate reduction. At equal content of the Fe(III) and Co(II) ions in the initial solution, the deposition of both metals is virtually simultaneous (electrolytic alloy formation), and high degrees of iron and cobalt deposition are attained (Fig. 1). Apparently, electrolytic alloy formation may take place in the course of contact exchange when the metals are deposited simultaneously. Karbasov et al. [20, 21] reported on the alloy formation in the course of contact exchange and proved the existence of various kinds of alloys by X-ray diffraction analysis and electron microscopy.

Both conjugate reactions in joint reduction of iron and cobalt can be adequately described by first-order rate equations

$$c(Fe^{3+}) = c_0(Fe^{3+}) \exp(-kt),$$

$$c(Co^{2+}) = c_0(Co^{2+}) \exp(-kt).$$

According to reference data [22], joint reduction of Fe(III), Co(II), and Ni(II) with Al to the metals is thermodynamically possible, because the redox potential of the Al(III)/Al(0) couple is more negative than those of the corresponding couples involving Fe, Co, and Ni. However, the process is stongly complicated by the presence of the natural oxide film on Al and high overvoltage of the reduction of iron ions.

Joint Fe–Ni–Co deposition is a still more complex process and is determined both by the state of the surface of dispersed Al and by the concentration of the ions of these metals in solution. Iron and cobalt are deposited at approximately equal rate, and nickel, at a somewhat lower rate (Fig. 2). In ternary solutions, iron and cobalt are deposited virtually synchronously (Fig. 2, curves *1* and *3*), but cobalt is deposited more completely (98%, against 90% for Fe). In the case of Ni, the deposition rate increases after the lapse of 90 s, at the time by which iron and cobalt have been 50% reduced. This result is consistent with the previous data on the joint deposition of iron and nickel [18].

The results of studying joint deposition of metallic iron, nickel, and cobalt showed that the reactions of the Fe(III), Ni(II), and Co(II) reduction are conjugate, i.e., the consecutive reactions with iron ions initiate the reactions with the cobalt [Co(II) → Co(0)] and nickel [Ni(II) → Ni(0)] ions. The conjugate reduction reactions can be described by first-order rate equations (Fig. 2).

Deceleration of the reduction of Ni ions in joint deposition with Fe and Co may be due to increased adsorption of hydroxy compounds on the alloy surface, compared to deposition of the individual metals. The observed deceleration of the reduction of Ni ions indicates that the discharge of the ions is not facilitated by the alloy formation. Deceleration of the ion discharge in the course of the joint reduction can be largely attributed to a change in the concentration of the ions being discharged in the electrical double layer.

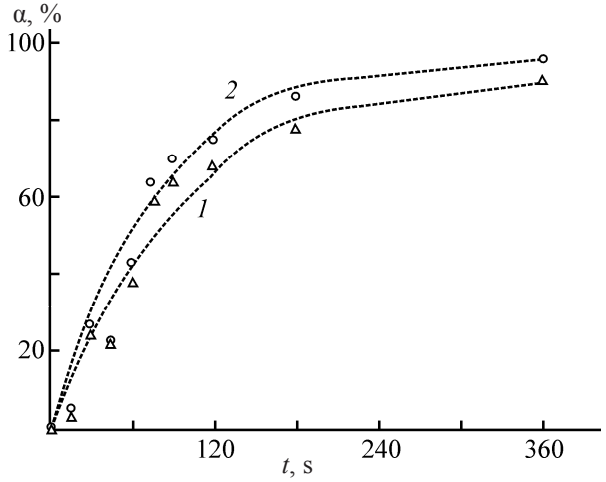

Fig. 1. Kinetic curves of joint deposition of (*1*) Fe and (*2*) Co from a 0.5 M $FeCl_3$ + 0.5 M $CoCl_2$ solution. Points refer to experimental data, and lines, to calculation; the same for Fig. 2. (α) Degree of deposition and (*t*) deposition time; the same for Fig. 2.

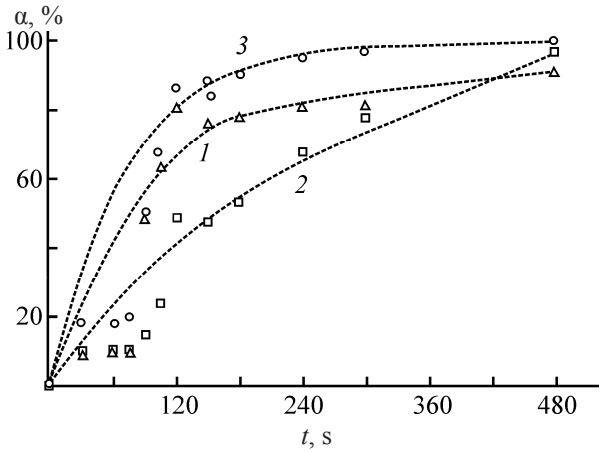

Fig. 2. Kinetic curves of joint deposition of (*1*) Fe, (*2*) Ni, and (*3*) Co from a 0.7 M $FeCl_3$ + 0.6 M $CoCl_2$ + 0.7 M $NiCl_2$ solution.

The reduction process can be illustrated by the chronopotentiograms obtained for dispersed aluminum suspended in the working solution (Fig. 3). Comparison of the chronopotentiogram (Fig. 3) obtained with a platinum electrode in the reaction mixture containing Al with the kinetic curves (Fig. 2) shows that, in the

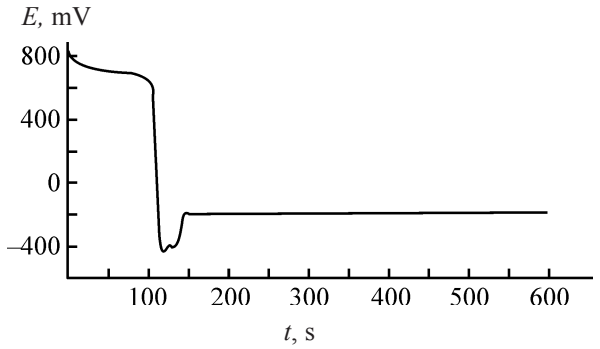

Fig. 3. Redox potential E as a function of time t in deposition of iron group metals (0.7 M $FeCl_3$ + 0.6 M $CoCl_2$ + 0.7 M $NiCl_2$).

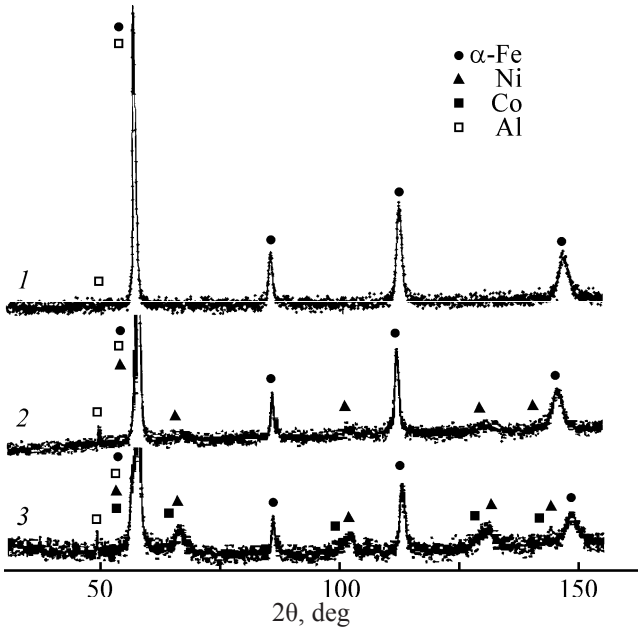

Fig. 4. Diffraction patterns of dispersed (*1*) Fe–Al, (*2*) Fe–Ni–Al, and (*3*) Fe–Ni–Co–Al samples. (2θ) Bragg angle.

course of the first 90 s, the potential smoothly decreases and the degree of metal deposition grows, also smoothly. The length of this portion of the curves strongly depends on the concentration of the starting reactants and is primarily caused by the presence of an oxide film on the aluminum particle surface. Furthermore, the potential does not decrease significantly until the nickel deposition starts. After the drop toward the negative region, the potential fairly actively shifts toward more positive values and then gets stabilized. It is known [23] that a metal being reduced can fully plug the pores of the powder, which leads to termination of the contact exchange. In the process, the electrode potential becomes close to the equilibrium potential of the more electropositive components (Fe, Ni, Co) in the solution. The chronopotentiogram (Fig. 3) indicates that the deposit fully blocks the aluminum surface. According to [20, 21], plateaus in the chronopotentiograms correspond to the formation of solid solutions or intermetallic compounds in the surface layer.

According to the results of X-ray phase analysis (Fig. 4) and local microanalysis, the powders obtained are mechanical mixtures of crystallites of iron group metals and aluminum, like the Fe–Al samples obtained previously [11, 24]. The amount of residual Al can be readily controlled by treating the powder with an alkali solution and can be reduced to tenth fractions of percent. When the powder is not kept in an alkali, an amorphous phase (probably pseudoboehmite) is detected, and with time bayerite crystals formed from metastable products of aluminum dissolution also appear [25]. In accordance with the results of X-ray structural and phase analysis and of local microanalysis, it can be concluded that the systems under consideration can be classed with substitution solid solutions with atoms of the major components (iron group elements) partially substituted in the crystal lattices by aluminum atoms. Furthermore, intermetallic phases of iron group elements are also detected. The process kinetics is strongly affected by the size and state of the surface of the aluminum particles.

Electron microscopic examination of particles taken from the solution after the metal deposition shows that they are virtually always spherical with the size similar to that of the starting Al particles (Fig. 5). This fact allows control of the properties of the synthesized particles by varying the parameters of the initial Al matrix. The presence of a large number of nuclei on the surface of coarse particles, in combination with the systems of cracks and pores, promotes the development of the metal surface, which may be very important in the possible use of such powders as heterogeneous catalysts. Furthermore, an important feature of the powders obtained is the presence of internal cavities.

It should be noted that, virtually in all the experiments, we clearly observed the formation of nanostructures in the form of whiskers (Fig. 5). However, on the surface of particles obtained in the Fe–Co system, there are also conical flaky individuals with a mean size of 100–200 nm (Fig. 5). Such a structure of the surface, in combination with the phase composition of the objects, is responsible for the specific properties of the Al–M systems (M = Fe, Ni, Co) obtained from aqueous solutions.

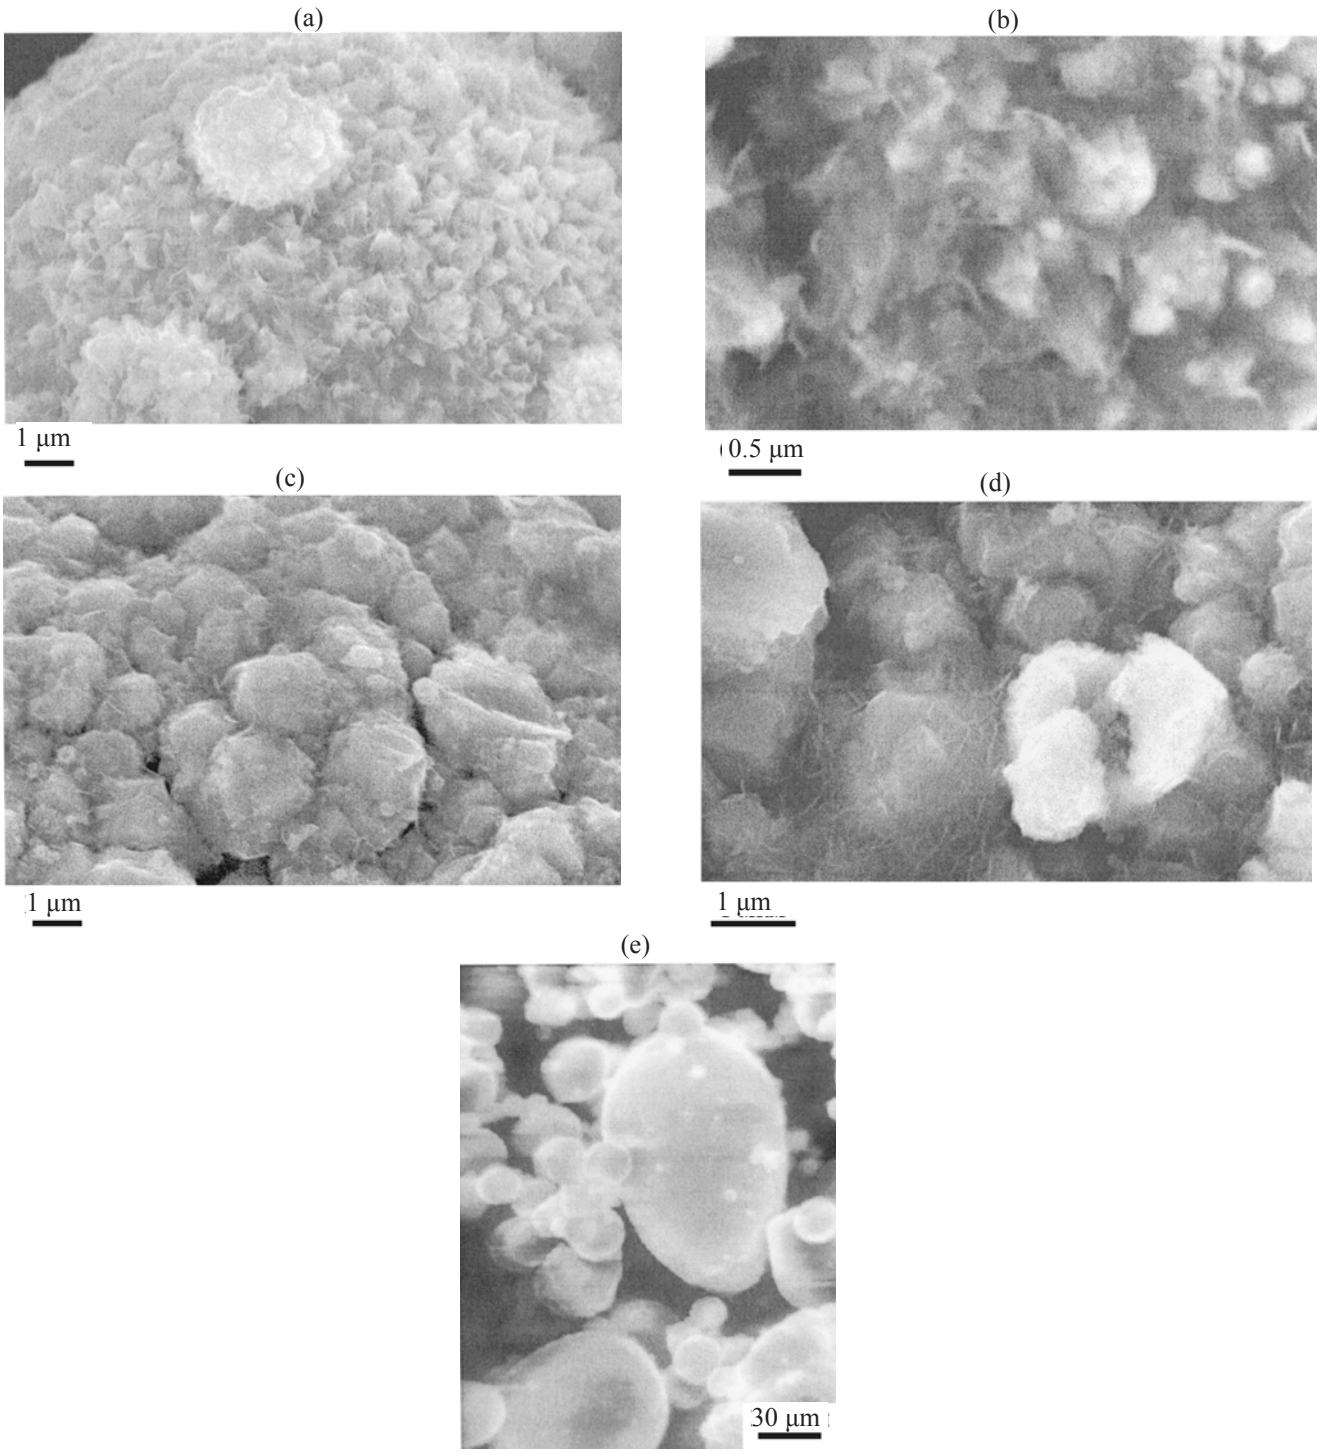

Fig. 5. Electron micrographs of disperse systems (a) Fe–Co, (b) Fe–Co–Al, (c) Fe–Co–Ni, (d) Fe–Co–Ni–Al, and (e) Al.

CONCLUSIONS

(1) Kinetic features of the formation of Fe–Co and Fe–Co–Ni deposits on dispersed aluminum matrix were elucidated.

(2) The reactions of Fe(III), Ni(II), and Co(II) reduction are conjugate and are adequately described by first-order rate equations with close rates of iron and cobalt deposition and lower rate of nickel deposition.

(3) It was found by X-ray phase analysis that the

precipitates obtained contain phases of aluminum and of individual iron group metals.

(4) Electron microscopic examination revealed nanosized whiskers and conical formations on the deposit surface.

Abstract—The results of microwave (at a frequency of 2.45 GHz) synthesis of $BaTiO_3$, $SrZrO_3$, and $NaIn(WO_4)_2$ are compared with those of the common solid-phase synthesis.

DOI: 10.1134/S1070427208110025

Single-phase finely dispersed (desirably nanocrystalline) powders of barium metatitanate and strontium metazirconate are required for the production of multilayer ceramic capacitors.

Previously [1] we examined the solid-phase synthesis of powdered barium titanate with titanium oxide and oxyhydroxide and barium carbonate, nitrate, and hydroxide as starting compounds. Because the intensity of the solid-phase synthesis and the quality of the final product largely depend on the perfection of the mixture of the starting powders, this mixture was subjected to ultrasonic mechanical activation in an inert organic liquid. We found that single-phase $BaTiO_3$ containing no Ba_2TiO_4 and $BaCO_3$ impurities is formed from a mixture of titanium oxyhydroxide and barium nitrate upon treatment at 650°C for 2 h.

The drawback of this process is high content of the residual organic liquid in the filtered and dried mixture of the starting components. Calcination of such a mixture is accompanied by formation of pyrolytic carbon, and, to ensure its complete burn-out, it is necessary to increase the calcination temperature to 700–750°C, which leads to coarsening of the final product particles. The specific surface area of the samples obtained did not exceed 0.5 $m^2\ g^{-1}$. To obtain single-phase $NaIn(WO_4)_2$ by common solid-phase synthesis, a mixture of the starting compounds (WO_3, In_2O_3, Na_2CO_3) is pelletized and calcined at 950°C for 50 h [2]. It follows from the aforesaid that, to prepare these substances, it is necessary to accelerate solid-phase processes so as to decrease the calcination temperature and/or time.

Microwave heating is widely used today for accelerating various processes, including sintering, dehydration, and decomposition of salts and hydroxides [3]. Microwave radiation is a nonionizing electromagnetic radiation with a frequency from 0.3 to 30 GHz. As stipulated by the international agreement, laboratory and household microwave ovens use frequencies of 0.915 and 2.45 GHz. As shown in [4], the latter frequency is preferable for the synthesis of ceramic materials.

In microwave solid-phase synthesis, the direct reaction of powdered components occurs only if at least one of them efficiently interacts with microwaves. If the starting substances are poor microwave acceptors, a secondary acceptor is added. This additive should be chemically inert, should efficiently absorb microwave radiation, and should be readily separable from the synthesis products after the process completion.

The commonly used absorbing additive is high-purity powdered graphite (particle size about 7 μm). To perform the synthesis, a mixture of the starting compounds is pelletized, pellets are placed in a quartz test tube and covered with graphite powder, and the mixture is irradiated in a microwave oven. Owing to the high microwave susceptibility, graphite lights up and heats pellets, initiating the decomposition of nitrates or carbonates. It was found that a hot oxide mixture well interacts with microwaves, which provides rapid reaction to obtain the required product [5].

In the course of microwave heating of a sample, correct measurement of temperature is very difficult.

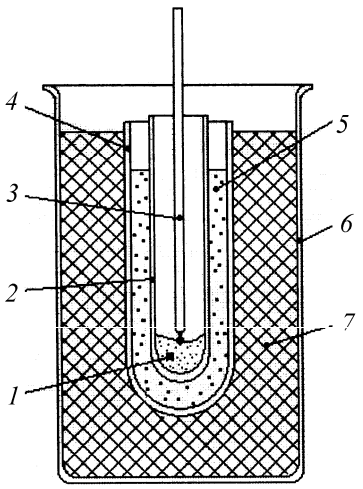

Fig. 1. Cell with a secondary heater: (*1*) initial charge, (*2, 4*) quartz test tube, (*3*) thermocouple, (*5*) WO_3, (*6*) glass beaker, and (*7*) quartz wool.

The use of common bimetallic thermocouples in microwave heating is impossible, because high-frequency electromagnetic field generates additional currents in the thermocouple and induces interference in measuring devices. Furthermore, introduction of a metallic object into the cavity alters the distribution of the microwave field power, which may lead to local overheatings. The only solution of this problem is the use of a shielded thermocouple grounded to the cavity wall. A 0.02-mm-thick platinum foil is used as a shield [6].

The aim of this study was to prepare $BaTiO_3$, $SrZrO_3$, and $NaIn(WO_4)_2$ in the form of finely dispersed powders by solid-phase microwave synthesis.

EXPERIMENTAL

The starting substances were chosen taking into account the following facts. It is known that TiO_2 and ZrO_2 are relatively poor microwave acceptors [6], whereas WO_3 absorbs microwaves very efficiently [7]. In nitrates, the high dipole moment of the nitrate ion should actively interact with a microwave field. Therefore, nitrates readily melt in their water of crystallization, and aqueous solutions always absorb microwave radiation well. Furthermore, large volume of gases released in the course of nitrate decomposition should favor disaggregation of the oxide powders being synthesized. Therefore, to prepare $BaTiO_3$ we used titanium oxyhydroxide $TiO(OH)_2$ and $Ba(NO_3)_2$; to prepare $SrZrO_3$, $ZrO(NO_3)_2{\cdot}6H_2O$ and $Sr(NO_3)_2$; and to prepare $NaIn(WO_4)_2$, we took WO_3, $Na_2WO_4{\cdot}2H_2O$, and In_2O_3.

The corresponding stoichiometric mixtures were prepared by grinding and mixing of the starting compounds in a TEFAL 6797 Magiclean household mixer. The resulting blend was charged into a quartz test tube. In first experiments, the test tube was placed in a wide glass beaker packed with quartz wool to ensure good heat insulation. The assembled cell was placed in a Samsung M192DNR microwave oven operating at 2.45 GHz, with an output power of 1 kW. The mixture temperature was measured with a Chromel–Alumel thermocouple protected with 0.04-mm-thick silver foil.

Preliminary studies showed that, in synthesis of $BaTiO_3$ or $SrZrO_3$, the mixture temperature first increased to 120–140°C and then remained essentially constant at the oven power varied from 0.3 to 1 kW. Apparently, this temperature is determined by the absorbing power of reaction mixture components and by the intensity of the heat removal from the sample surface. In the synthesis of $NaIn(WO_4)_2$, the maximal temperature of the mixture was 400°C, which was insufficient for the formation of $NaIn(WO_4)_2$.

Further experiments were performed in a cell with a secondary heater (Fig. 1). The initial charge *1* was placed in a quartz test tube *2*, which was inserted into another quartz test tube *4* packed with WO_3 (*5*). Test tube *4* was placed in a glass beaker *6* packed with quartz wool *7* as heat-insulating material. WO_3 layer *5* is intended for the primary heating of the initial charge. The mixture temperature was monitored with a thermocouple *3*. We found that the mixture temperature depends on the preset microwave oven power and on the irradiation time and can be increased to 700–900°C. Synthesis was performed in the temperature range 600–800°C. The isothermal heating time was varied from 15 min to 1 h. The final products were obtained as finely dispersed powders. The phase composition of the powders was determined by X-ray phase analysis with a DRON-2 diffractometer (CuK_α radiation, graphite monochromator, scanning rate 2 deg min^{-1}). The phases were identified using JCPDS database. The specific surface area of powdered samples was determined by thermal desorption of nitrogen with a FlowSorb II 2300 electronic laboratory device for measuring the specific surface area and porosity. The particle size was calculated by the formula

$$d = K/\Omega r,$$

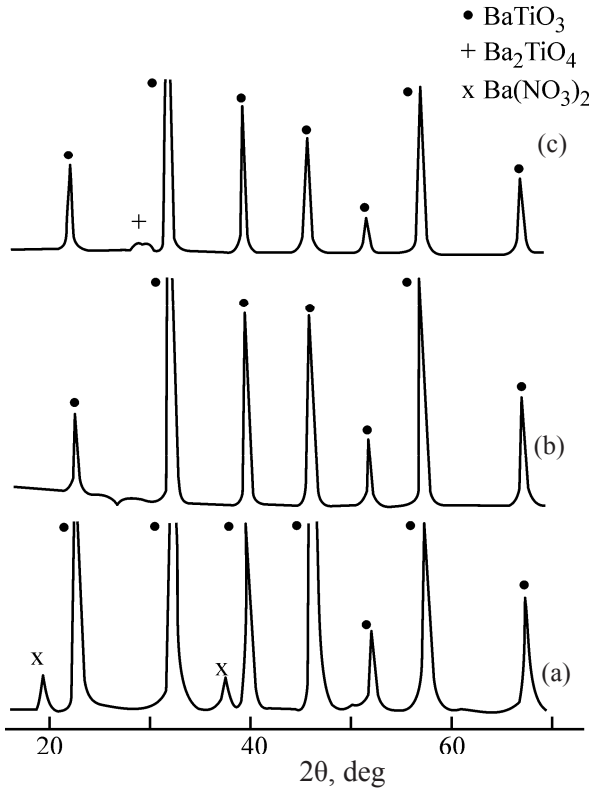

Fig. 2. Diffraction patterns of $BaTiO_3$ samples. (2θ) Bragg angle; the same for Figs. 4 and 5. Temperature (°C) and synthesis time: (a) 600, 1 h; (b) 650, 0.5 h: and (c) 720, 20 min.

where *d* is the mean particle diameter; *K*, form factor equal to 6 for spherical and cubic particles; Ω, specific surface area; and *r*, substance density.

It follows from the diffraction patterns of products obtained in synthesis of $BaTiO_3$ that (1) synthesis at 600°C for 1 h yields a product with an impurity of $Ba(NO_3)_2$, i.e., is incomplete (Fig. 2a); (2) synthesis at 650°C for 0.5 h yields single-phase $BaTiO_3$ (Fig. 2b); (3) at 720°C, the synthesis of $BaTiO_3$ is complete in 20 min, but the final product contains an impurity of Ba_2TiO_4 (Fig. 2c).

Powdered $BaTiO_3$ prepared at 650°C has a specific surface area of 2.56 $m^2\ g^{-1}$, which corresponds to a mean particle size of 380 nm.

The time–temperature dependences plotted in Fig. 3 show that microwave solid-phase synthesis of $BaTiO_3$ is more efficient than the common solid-phase synthesis from the viewpoint of both time and power consumption.

The diffraction patterns of the products obtained in synthesis of $SrZrO_3$ show that (1) synthesis at 600°C for 1 h yields $SrZrO_3$ with an impurity of $Sr(NO_3)_2$,

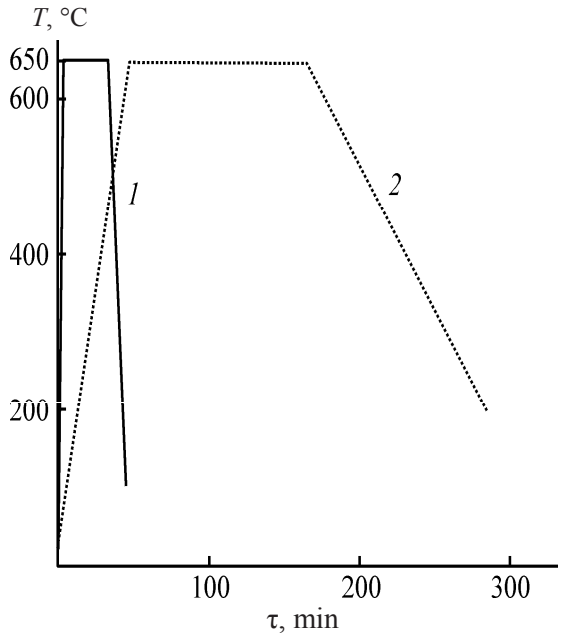

Fig. 3. Temperature *T*–time τ dependence for (*1*) microwave and (*2*) common solid-phase synthesis of $BaTiO_3$.

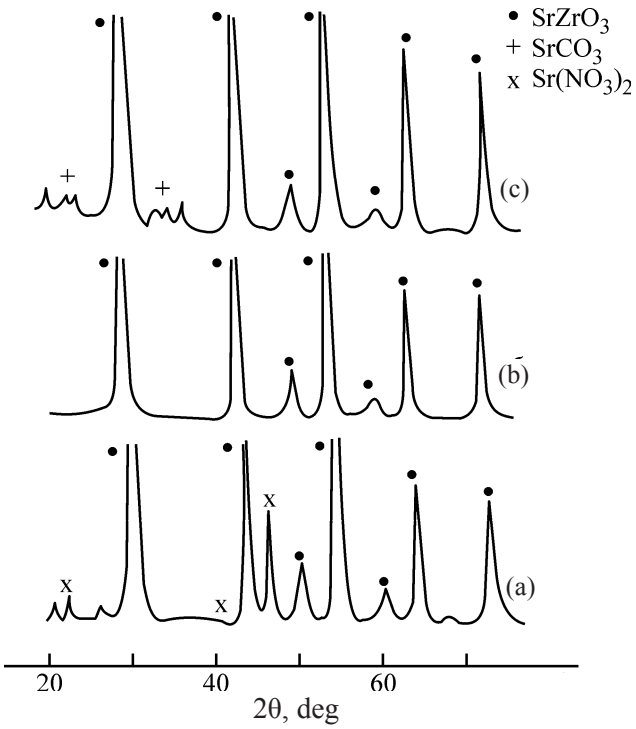

Fig. 4. Diffraction patterns of $SrZrO_3$ samples. Synthesis temperature (°C) and time: (a) 600, 1 h; (b) 650, 0.5 h; and (c) 700, 15 min.

i.e., the reaction is incomplete (Fig. 4a); (2) synthesis at 650°C for 0.5 h yields single-phase $SrZrO_3$ (Fig. 4b); (3) at 700°C, the synthesis of $SrZrO_3$ is complete in 15 min, but the final product contains an impurity of $SrCO_3$ (Fig. 4c).

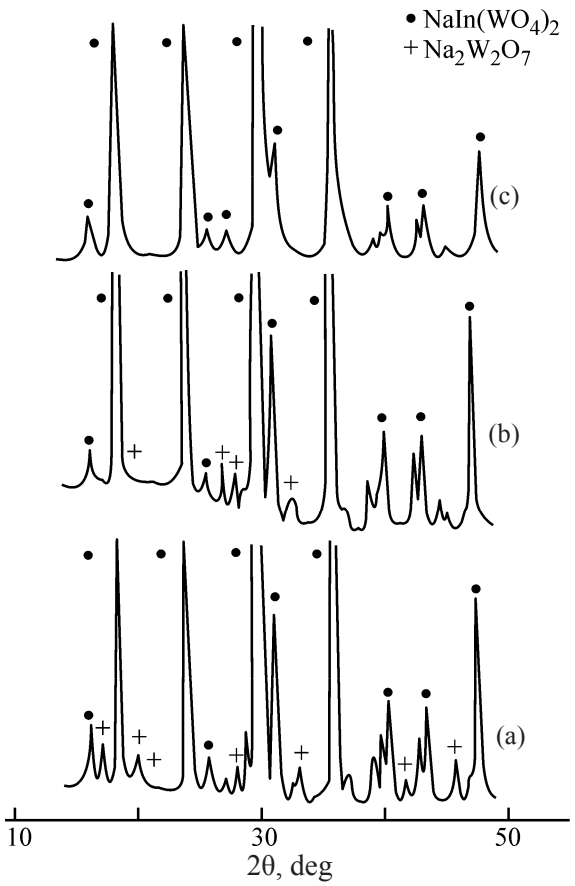

Fig. 5. Diffraction patterns of $NaIn(WO_4)_2$ samples. Synthesis conditions: (a) 600–800°C, 1 h; (b) 750°C, two steps; and (c) 750°C, 1 h, from a stoichiometric mixture of Na_2WO_4 and $In_2(WO_4)_3$.

Powdered $SrZrO_3$ prepared at 650°C has a specific surface area of 2.4 $m^2 g^{-1}$, which corresponds to a mean particle diameter of 460 nm.

The diffraction patterns of the products obtained in synthesis of $NaIn(WO_4)_2$ show that the synthesis at 600–800°C for 1 h yields $NaIn(WO_4)_2$ with an impurity of sodium tungstate $Na_2W_2O_7$ (Fig. 5a). Despite the absence of In_2O_3 reflections in the diffraction patterns, it was concluded that In_2O_3 reacted with WO_3 incompletely. To perform the synthesis with preliminary binding of WO_3 into $Na_2W_4O_{13}$, synthesis of $NaIn(WO_4)_2$ at 750°C was divided in two steps. In the first step, a stoichiometric mixture of Na_2WO_4 and WO_3 was treated for 0.5 h to obtain $Na_2W_4O_{13}$, and in the second step, a stoichiometric mixture of $Na_2W_4O_{13}$ and In_2O_3 was treated for 1 h. However, in this case also the final product contained an impurity of sodium tungstate $Na_2W_2O_7$ (Fig. 5b). It follows from these experiments that the use of WO_3, $Na_2WO_4 \cdot 2H_2O$, and In_2O_3 does not ensure preparation of single-phase $NaIn(WO_4)_2$. Therefore, we decided to replace WO_3 and In_2O_3 by indium tungstate $In_2(WO_4)_3$.

Indium tungstate was prepared by the reaction

$$3Na_2WO_4 \cdot 2H_2O(soln) + 2In(NO_3)_3 \cdot 4.5H_2O(soln) = In_2(WO_4)_3(solid) + 6NaNO_3(soln).$$

For this purpose, solutions containing equivalent amounts of $Na_2WO_4 \cdot 2H_2O$ and $In(NO_3)_3 \cdot 4.5H_2O$ were simultaneously added to a beaker with water with vigorous stirring. The $In_2(WO_4)_3$ precipitate was centrifuged off, thoroughly washed with water on the filter to remove NO_3^-, and dried at 150°C.

The diffraction pattern (Fig. 5c) of the product obtained by the treatment of a stoichiometric mixture of Na_2WO_4 and $In_2(WO_4)_3$ at 750°C for 1 h exhibits reflections of $NaIn(WO_4)_2$ only, which indicates that the product is single-phase. The specific surface area of the resulting powdered product is 1.45 $m^2 g^{-1}$, which corresponds to the mean particle size of 580 nm. At synthesis temperatures lower than 750°C, preparation of the single-phase product requires longer time of isothermal heating.

CONCLUSIONS

(1) Microwave solid-phase synthesis of complex oxides has significant advantages over the common solid-phase synthesis. It was shown by the example of $BaTiO_3$ that the time of isothermal heating required to obtain the single-phase product decreased from 2 to 0.5 h and that the specific surface area of the powder increased from 0.5 to 2.56 $m^2 g^{-1}$. Furthermore, comparison of the time–temperature dependences unambiguously indicates that the microwave process is less power- and time-consuming.

(2) Microwave solid-phase synthesis provides preparation of finely dispersed single-phase $BaTiO_3$ and $SrZrO_3$ at 650°C, at an isothermal heating time of 0.5 h.

(3) Microwave synthesis of single-phase $NaIn(WO_4)_2$ from Na_2WO_4 and $In_2(WO_4)_3$ allows the synthesis temperature to be decreased to 750°C, with 50 times shorter isothermal heating time. Furthermore, pelletizing of the initial charge becomes unnecessary.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Stability of Metallic Materials in Aqueous and Aqueous–Glycol Solutions

V. N. Esenin and L. I. Denisovich

Nesmeyanov Institute of Organometallic Compounds, Russian Academy of Sciences, Moscow, Russia

Received May 26, 2008

Abstract—The corrosion behavior of aluminum, steel, and pig iron in fresh water, ethylene glycol, and water–glycol mixtures containing 5–95 vol % fresh water in the temperature range 20–100°C was studied. The influence of temperature on the corrosion rate of the metals was examined in relation to the composition of aqueous ethylene glycol solutions.

DOI: 10.1134/S1070427208110037

This work continues our systematic studies of the corrosion of aluminum alloys, steel, and pig iron in aqueous and aqueous–glycol solutions with the aim to find how the composition of the aqueous–organic solution affects the corrosion. The choice of the metals, organic solvent, and composition of aqueous–organic solutions is governed by the fact that in modern liquid cooling systems, in particular, in internal combustion engines, in various heat-exchange apparatuses, and in hydraulic equipment the main structural materials are the above-mentioned metals. Aqueous ethylene glycol (EG) solutions of various compositions are used as heat carriers in various climatic zones of Russia. In the previous papers we reported the results of studying the corrosion of the above metals in model fresh water [1] and in aqueous EG solutions [2]. Available data on the corrosion behavior of electrochemically dissimilar metals in aqueous–alcoholic media of various compositions are scarce [3–6] and, to certain extent, contradictory. Here we report the results of examining the effect of temperature on the rate of corrosion of the above metals in aqueous and aqueous–glycol solutions. There are almost no published data [7] on this matter.

EXPERIMENTAL

Corrosion tests were performed in a temperature-controlled cell. Flat samples of St.3 steel [GOST (State Standard) 380], GH-190 pig iron (VAZ 52 205 normal), and AK6M2 aluminum alloy (GOST 1583) of size 50 × 25 × 3 mm were preliminarily polished and degreased. The corrosion rate was estimated from the sample weight loss. Experiments were performed at 20–100°C. The pH values were measured with a pH-150M pH meter. Ethylene glycol (GOST 19 710, supreme grade) was used without additional purification. Simulation of fresh water by adding into distilled water sodium sulfate, sodium chloride, and sodium hydrogen carbonate to their typical concentrations was described elsewhere [1].

Published data on the influence of temperature on the rate of metal corrosion in aqueous–glycol solutions are scarce [7]. Therefore, it seemed important to evaluate the effect of the temperature factor on the corrosion behavior of the metals under consideration. Tests of steel, pig iron, and aluminum were performed in 50% aqueous–glycol solution in the temperature range 20–100°C and in EG solutions containing 5 to 100 vol % water at 20 and 70°C. The corrosion rates of steel and pig iron at 20–90°C during the test period are constant (Fig. 1). Figure 2a shows how the temperature affects the corrosion rate of steel and pig iron. The corrosion rates of both metals sharply increase (by a factor of more than 5) in the range 20–50°C and then linearly increase up to 90°C. The temperature dependences of the rate constants of dissolution of steel and pig iron are satisfactorily linearized in the coordinates of the Arrhenius equation in the temperature range 50–90°C (Fig. 2b). From the straight lines obtained, we determined the apparent activation energies of metal dissolution in this temperature range, which amounted to 2.1 kcal mol^{-1} for steel and to 1.6 kcal mol^{-1} for pig iron.

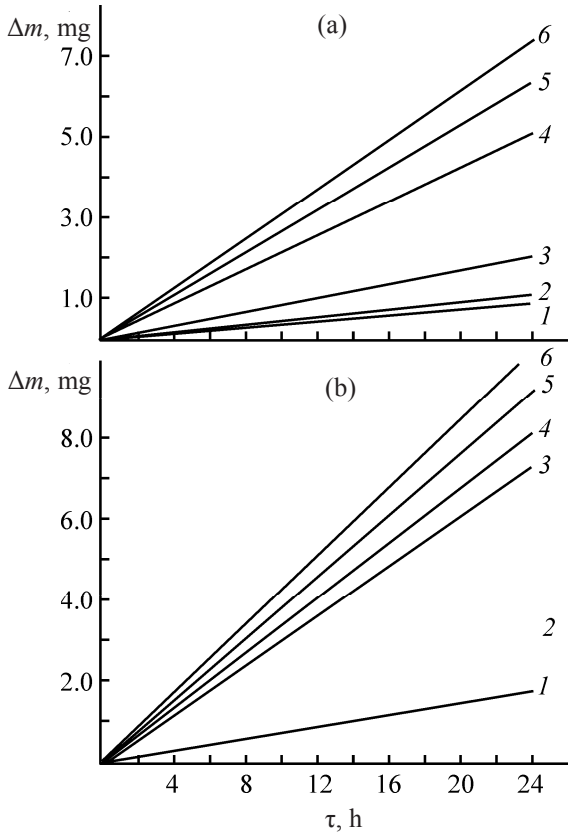

Fig. 1. Corrosion loss Δm of (a) steel and (b) pig iron as a function of testing time τ in 50% aqueous EG solution at various temperatures. T, °C: (*1*) 20, (*2*) 30, (*3*) 40, (*4*) 50, (*5*) 70, and (*6*) 90.

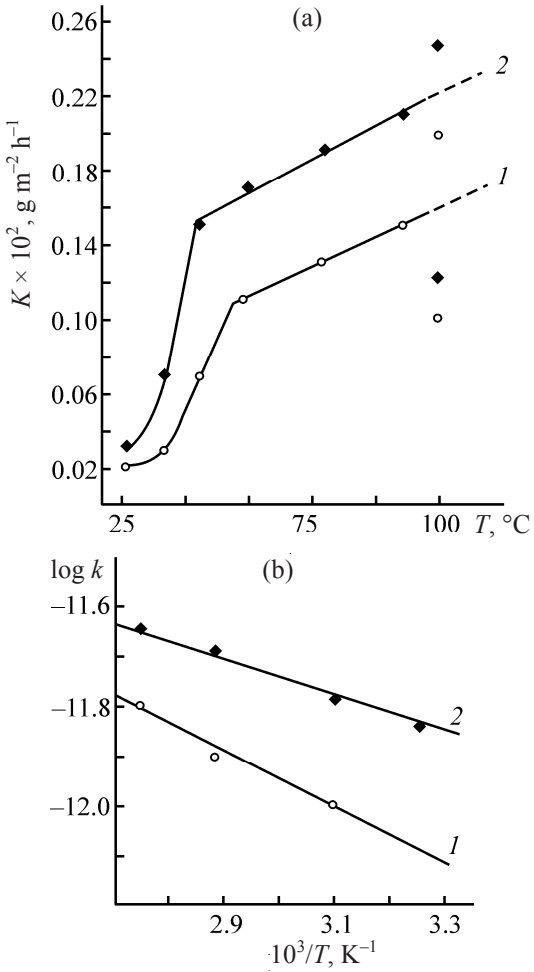

Fig. 2. Temperature dependences of the (a) corrosion rate K and (b) dissolution rate constant k (Arrhenius coordinates) of (*1*) steel and (*2*) pig iron in 50% aqueous EG solution.

At 100°C, the kinetics of dissolution of both metals is more complex: The corrosion rates of steel and pig iron samples are maximal in the initial period (τ ~2 h) and then decrease, reaching steady-state values (Fig. 3). It should be noted that these rates differ significantly from those obtained by approximation of the linear portions of the corresponding curves (Fig. 2a). In the case of aluminum samples, at all the examined temperatures, in a 50% EG solution we noted slight increase and traces of pitting corrosion. The extent of local damage of the surface increased with temperature, reaching a maximum at 50–70°C. At higher temperatures, the number of pittings decreased, and at 100°C virtually no pittings were observed.

The nonmonotonic trend in the corrosion behavior of steel and pig iron in relation to the electrolyte temperature (Fig. 2a) can be attributed to several factors. A considerable increase in the dissolution rate of both metals in the temperature range 20–50°C is apparently due to an increase in the efficiency of the diffusion steps of cathodic processes, caused by a decrease in the dynamic viscosity of the electrolyte from 5 to 1.5 cP [8, 9]. With an increase in the temperature (50–90°C), the viscosity of the aqueous–glycol solution varies less significantly (1.5–0.8 cP), and the dissolution rate of the metals starts to be controlled by formation of difficultly soluble films of secondary corrosion products hindering the diffusion processes [10]. Linear portions of the kinetic curves of the dissolution of both steel and pig iron (Fig. 2a) suggest the diffusion control of these processes. A decrease in the metal corrosion rate by a factor of more than 2 (including the disappearance of traces of pitting corrosion of aluminum) in the course of tests at 100°C is apparently due to formation of denser layers of iron and aluminum oxides, as suggested by the oxidation tint of the surface.

The kinetics of dissolution of pig iron and steel at 70°C in EG solutions is similar to that of the process at

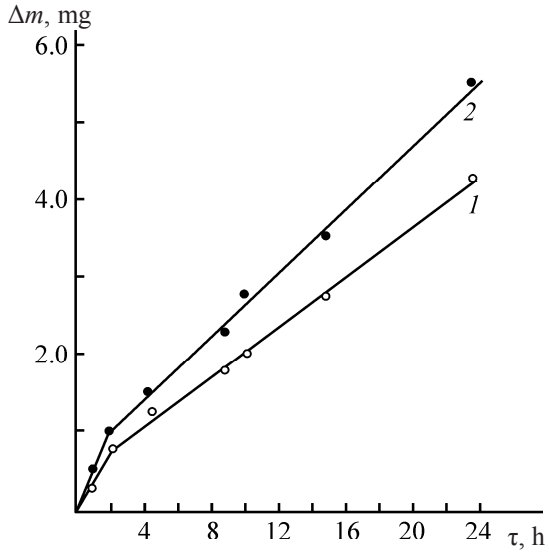

Fig. 3. Corrosion loss Δ*m* of (*1*) steel and (*2*) pig iron as a function of testing time τ in 50% aqueous EG solution at 100°C.

room temperature, examined previously [2]. At a water content of 5–50%, the corrosion rates are constant, and in solutions with a higher water content and in aqueous solution they are maximal in the initial period (τ ~1 h) and then become constant (Fig. 4, Table 1). The dependences of the steady-state rates of steel and pig iron corrosion at 70°C on the composition of the aqueous–glycol solution are shown in Fig. 6.

Comparison of the rates of steel and pig iron dissolution at room temperature (Fig. 6, curves *1*', *2*') and 70°C (curves *1*, *2*) reveals significant differences in the behavior of these metals. At 70°C, steel starts to dissolve at a water content slightly exceeding 5%, whereas at room temperature even at a water content of 30% steel does not undergo corrosion. At the same time, pig iron, irrespective of temperature, starts to dissolve at a very low water content (less than 5 vol %). It should also be noted that the maximal acceleration of the corrosion of both metals at 70°C, in contrast to room temperature, is observed at lower concentrations of water. An increase in the temperature leads to a decrease in the EG adsorption on the electrode surface, which disturbs the passive state of the metals. Thus, appearance of defects in the dense shielding film of

Table 1. Initial (V_{in}) and steady-state (V_{st}) rates of steel and pig iron corrosion in aqueous and aqueous–glycol solutions of various compositions at 70°C

flat-oriented layers of adsorbed EG [11, 12] and formation of a metal aqua oxide surface phase [1, 13] occur at a lower water content of the solution.

In the case of aluminum samples, in all the examined aqueous–glycol solutions at 70°C, a slight weight gain and traces of pitting corrosion were observed. The extent of local damage of the surface increased with the EG concentration in solution. It should be noted, however, that in the individual components (EG and fresh water) we observed no pitting corrosion of the aluminum alloy.

High corrosion activity toward metals is typical of water and all water-containing liquids. According to [14, 15], in the presence of glycols many metals undergo corrosion at a considerably higher rate than in water. This fact is attributed to the corrosion activity of a mixture of organic acids (in particular, aggressive formic acid) formed by thermal oxidation of glycol. Ethylene glycol can be readily oxidized with various oxidants at relatively low temperatures. For example, potassium permanganate and periodic acid readily oxidize EG at 30–35°C to give formaldehyde and formic acid [16]. With potassium bichromate in an acid solution, EG is exhaustively oxidized to carbon dioxide [17]. Ozonation of glycols at slight heating, followed by oxidation with oxygen at 50–100°C, leads to the formation of the corresponding dicarboxylic acids. Similar reaction also occurs on treatment of aqueous–glycol solutions with nitrogen(IV) oxides [18]. Despite the fact that glycols are susceptible to autooxidation, i.e., to spontaneous oxidation with atmospheric oxygen at relatively low temperatures, an attempt to oxidize ethylene glycol at 60–95°C in a wide range of partial pressures of oxygen, in contrast to the similar reaction with diethylene glycol [19], failed [20]. Carboxylic acids were detected in EG oxidation products only after its heating at 150°C for 1000 h with continuous air bubbling [8]. However, the possibility of EG autooxidation in its aqueous solutions on contact with variable-valence metals, in particular, with iron whose soluble corrosion products efficiently initiate radical reactions [21], cannot be ruled out. The mechanism of the action of these compounds consists in acceleration of the decomposition of hydroperoxides and in an increase in the amount of free radicals participating in the chain propagation:

$$ROOH + M^{3+} \rightarrow ROO^{\cdot} + M^{2+} + H^{+},$$

$$ROOH + M^{2+} \rightarrow RO^{\cdot} + M^{3+} + OH^{-}.$$

To check the validity of this assumption, we attempted to oxidize EG in its 50% aqueous solution at the boiling point of the solution (108°C at atmospheric pressure) under various conditions. The reaction progress was monitored by variation of pH. The conditions and results of the experiments are given in Table 2.

Table 2 shows that neither the conditions favoring formation of variable-valence metal ions nor addition of 2,2'-azobis(isobutyronitrile) (AIBN) as initiator of radical reactions lead to the appearance of acidic products.

Thus, either EG is not oxidized under the experimental conditions or final products of its transformation are nonacidic products.

CONCLUSIONS

(1) A study of the corrosion behavior of aluminum, steel, and pig iron in fresh water, ethylene glycol, and its aqueous solutions showed that the corrosion rates of steel and pig iron increase with increasing temperature and water content of aqueous–glycol solutions, reaching a limit in the aqueous electrolyte.

(2) In the case of aluminum, traces of pitting corrosion appear at 30–90°C in water–glycol mixtures at any component ratios. The extent of the local damage of the metal surface increases with an increase in the ethylene glycol concentration and with temperature, reaching a maximum at 50–70°C.

(3) The apparent activation energies of steel and pig iron dissolution in the temperature range 50–90°C were estimated: 2.1 kcal mol^{-1} for steel and 1.6 kcal mol^{-1} for pig iron.

(4) Ethylene glycol in aqueous–glycol solutions is not oxidized even in the presence of initiators of radical reactions, or final products of its oxidation are not acidic.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Decomposition of Ozone in Water at pH 4–8

B. G. Ershov and P. A. Morozov

Frumkin Institute of Physical Chemistry and Electrochemistry, Russian Academy of Sciences, Moscow, Russia

Received March 4, 2008

Abstract—A systematic study of the ozone decomposition in water in the pH range 4–8 was carried out.

DOI: 10.1134/S1070427208110048

At present ozone is widely used to disinfect and oxidize impurities when preparing potable water [1–3]. It is a very strong oxidant (E^0 = 2.07 V), which is second in this regard only to the hydroxy radical (E^0 = 2.80 V) and substantially exceeds chlorine (E^0 = 1.36 V). Ozone reacts with water to give oxygen. The rate of this reaction noticeably grows as pH is raised, which is due to the catalyzing effect of hydroxide ions OH^-. The mechanism includes a chain of successive reactions yielding H_2O_2, O_3^-, and $^{\cdot}OH$ and $HO_2^{\cdot}$ radicals [4–8]. The radical products initiate chain decomposition of ozone. The disinfecting and oxidizing efficiency of ozone in water depends on its concentration, which is, in turn, determined by the rate of its decomposition. Therefore, it is important to elucidate the fundamental aspects of the kinetics of ozone decomposition in water and the effect of various factors on the rate of this process. Studies in this area have been already carried out during several decades. However, the results obtained are rather contradictory. For example, different orders of the reaction of ozone decomposition in water, including first [9, 10], first-and-a-half [11, 12], and second [13], and markedly different rate constants have been reported.

EXPERIMENTAL

Experiments were performed with triple-distilled water subjected to a preliminary treatment with ozone to decompose the possibly present organic impurities. The pH value was adjusted with $HClO_4$ and NaOH (Merck). Ozone was produced using an ozonizer (designed by LOT Limited Liability Company) with a capillary discharge chamber yielding an ozone–oxygen mixture (OOM) with a high concentration of ozone (up to 200 mg l^{-1}). The concentration of O_3 in OOM was determined with an optical UV analyzer to be approximately 166 mg l^{-1}. Solutions with a preset pH value were ozonized for 1–3 min to reach a concentration of approximately 3×10^{-4} to 8×10^{-4} M. After that, a solution was placed in hermetically sealed cylindrical glass cells connected by a sealed-in glass tube (d = 5 mm, l = 15 cm) to a quartz cell (1 × 1 × 4 cm). The concentration of ozone was measured on the basis of its absorption at the peak of the optical band at λ_{max} = 258 nm (ε = 2950 l mol^{-1} cm^{-1}) [14] with an SF-2000 spectrophotometer.

All experiments except those aimed to determine the activation energy of the reaction were carried out at 19 ± 1°C.

As can be seen in Fig. 1, the rate of ozone decomposition substantially grows as pH increases from 4 to 8. After the complete decomposition of ozone and attainment of the equilibrium with ambient air, the initial pH value of the solution is recorded. It was found that $\tau_{0.5}$ (time in which the concentration of ozone in water decreases by a factor of 2 in the course of its decomposition) depends on the initial concentration of ozone. For example, for water with pH 6.0, $\tau_{0.5}$ was 190, 330, and 600 s at ozone concentrations of 7.6×10^{-4}, 4.3×10^{-4}, and 2.4×10^{-4} M, respectively. The observed change in $\tau_{0.5}$ precisely corresponded to that expected for ozone decomposition by a second-order reaction, for which the following relation is valid:

$$\tau_{0.5} = 1/(c_0 k),$$

where c_0 is the initial concentration (M), and k is the reaction rate constant (l mol^{-1} s^{-1}).

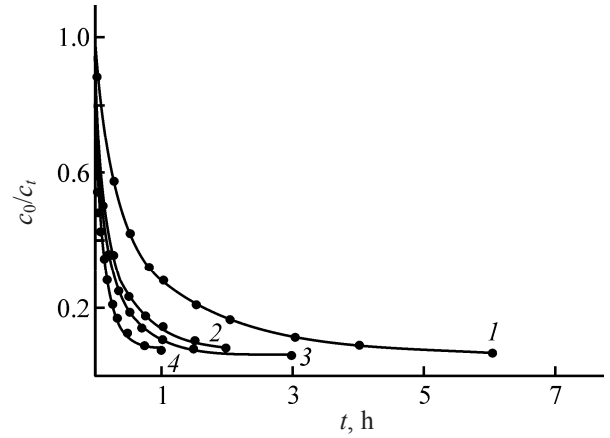

Fig. 1. Ozone decomposition in water at various pH values. (c_0, c_t) Initial and running concentrations of ozone in water and (t) time. pH: (*1*) 4.7, (*2*) 6.0, (*3*) 6.8, and (*4*) 7.9; the same for Fig. 2.

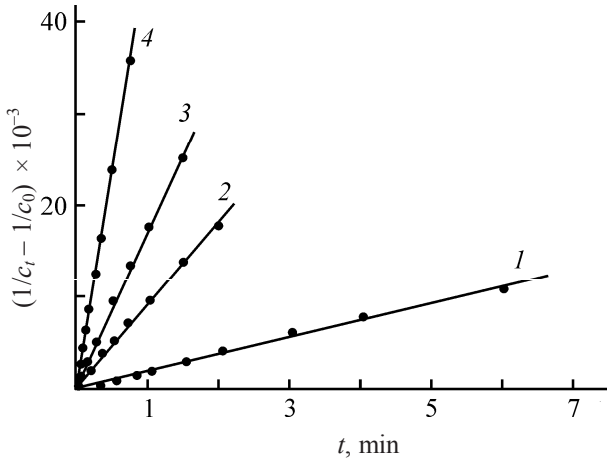

Fig. 2. Kinetic curves of ozone decomposition, plotted in the coordinates of the second-order rate equation. (c_0, c_t) Initial and running concentrations of ozone in water and (t) time.

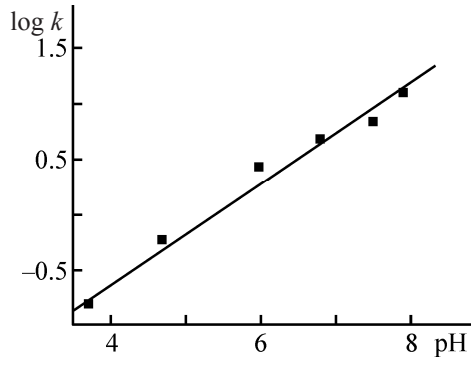

Fig. 3. Logarithm of the rate constant k vs. pH.

It is, indeed, seen that there is a strictly inversely proportional relationship between $\tau_{0.5}$ and c_0.

Figure 2 shows how the ozone decomposition kinetics depends on the pH value in the range 4–8. The process is described with high precision by a second-order rate equation

$$c_t^{-1} - c_0^{-1} = kt, \qquad (1)$$

where c_t and c_0 are the running and initial concentrations of ozone in water, and t is time.

Analysis of the kinetic dependences shows that, in all cases, the reaction order n of ozone decomposition, calculated by the least-squares method, is within the range 1.9 ± 0.2. The reaction order remains unchanged almost until the complete decomposition of ozone. This means that the mechanism is the same within the entire pH range studied. The fact that the decomposition reaction is second-order with high accuracy makes it possible to determine the reaction rate constant from the slopes of the straight lines in Fig. 2. Figure 3 shows how log k depends on pH at 19°C. In the pH range 4–8, this dependence is linear and well described by the equation

$$\log k_{(\mathrm{pH})} = \log k_{(\mathrm{pH}\,4)} + (0.49 \pm 0.03)(\mathrm{pH} - 4), \qquad (2)$$

where $k_{(\mathrm{pH})}$ is the sought-for rate constant at pH 4–8, and $k_{(\mathrm{pH}\,4)}$ is the rate constant at pH 4.0, equal to 0.2 l mol^{-1} s^{-1} (accordingly, $\log k_{(\mathrm{pH}\,4)} = -0.7$).

The decomposition of ozone is catalyzed by OH^- ions and occurs by the scheme [4–8]

$$O_3 + OH^- \rightarrow HO_2^- + O_2,$$

$$O_3 + HO_2^- \rightarrow \dot{O}_2^- + \dot{O}H + O_2,$$

$$O_3 + \dot{O}_2^- \rightarrow \dot{O}_3^- + O_2,$$

$$\dot{O}_3^- + H_2O \rightarrow \dot{O}H + OH^- + O_2.$$

The reaction of O_3 with OH^- leads to the loss of additional two molecules of ozone and regeneration of the OH^- ion. The chain process of ozone decomposition occurs as a result of reactions involving $\dot{O}H$ and $HO_2^{\cdot}$ radicals. The chain is terminated by their recombination. In [13], a second-order reaction of ozone decomposition in water was observed in the pH range 6.0–9.5. The study was carried out in the presence of 0.1–1.0 M of a borate or phosphate as a buffering additive, rather than in pure water. The values of the constants, measured at the same pH values as those in the present study, strongly depended on the additive used

and its content in solution and differed by one to two orders of magnitude. All these circumstances indicated that the additives are involved in the ozone decomposition.

The decomposition of ozone becomes faster as temperature is elevated. Figure 4 shows how the rate constant of the second-order reaction of ozone decomposition in water at pH 4.7 depends on temperature in the Arrhenius coordinates. In the temperature range 9–37°C, this dependence is described by the equation

$$k(T) = k_{19} \exp\{76.0[(T - 292)/292RT]\}, \quad (3)$$

where k_{19} is the rate constant at a temperature of 19°C, and R is the universal gas constant (8.314 J mol^{-1} K^{-1}). The activation energy of ozone decomposition was 76.0 ± 8.3 kJ mol^{-1}, which coincides within experimental error with the value of 79.5 kJ mol^{-1}, measured in [8] for ozone solutions with pH 0–4. The temperature coefficient of the reaction (reaction acceleration factor upon an increase in temperature by 10°C) is approximately 3. Thus, the results of the present study indicate that the kinetics of ozone decomposition in water is described by the equation of a second-order reaction with respect to the ozone concentration in the pH range 4–8. The linearly proportional relationship between log k and pH [Eq. (3)] makes it possible to calculate the reaction rate constants at different pH values:

pH	k, l mol^{-1} s^{-1}
4.0	0.20
4.5	0.35
5.0	0.62
5.5	1.08
6.0	1.91
6.5	3.35
7.0	5.90
7.5	10.4
8.0	15.2

It follows from the data obtained that the rate constant at 19°C grows by a factor of approximately 3 (±10%) upon an increase in pH by a single unit.

Thus, the kinetics of ozone decomposition in water is well described by the second-order reaction equation $O_3 + O_3 \rightarrow 3O_2$ and is catalyzed by hydroxide ions. The measured kinetic dependences make it possible to calculate the dynamics of concentration decrease in the course of time and evaluate the effect of pH and temperature. Potable water is disinfected with ozone concentrations on the order of 1 mg l^{-1} (or ~2 × 10^{-5} M). The time in which the ozone concentration is halved, $\tau_{0.5}$, can be calculated by Eq. (1). With the value of k at 19°C taken from the table, the values of $\tau_{0.5}$ at pH 5.0, 6.0, and 7.0 are approximately 22.2, 7.2, and 2.4 h, respectively. The time in which the ozone concentration decreases by a factor of 10 can be calculated using the equation $\tau_{0.1} = 9\tau_{0.5}$. At a temperature lower by 10°C, the time of ozone decomposition becomes approximately a factor of 3 longer, and at a 10°C higher temperature it is, accordingly, shorter by the same factor.

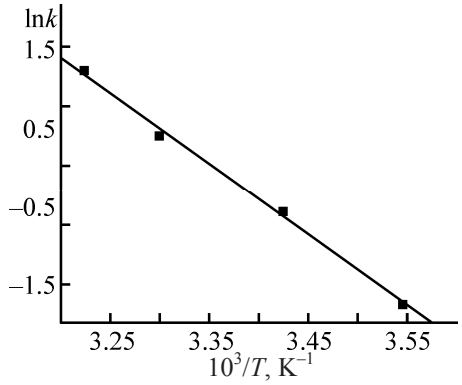

Fig. 4. Temperature dependence of the rate constant k of ozone decomposition in water (pH 4.7) in the coordinates of the Arrhenius equation.

The key factor in the ozone decomposition in water and aqueous solutions is the presence of readily oxidizable substances. This is particularly important in treatment of wastewater and process solutions with ozone. In this case, it is desired to saturate these substances with ozone to the maximum possible extent, with concentrations as high as 20–40 mg l^{-1} reached. As a result, the self-decomposition of ozone is intensified and $\tau_{0.5}$ decreases by, correspondingly, a factors of 20–40 as compared to the values presented above.

For effective decomposition of impurities (S) in aqueous solutions, it is necessary that the inequality $c_0 k << c_S k_S$ should be satisfied (here, c_0 and k are the concentration of ozone and rate constant of its self-decomposition in water; c_S and k_S, concentration of the solute and the rate constant of its interaction with ozone). If this condition is satisfied, ozone is preferentially consumed for oxidative decomposition of impurities. This relationship also makes it possible to estimate the impurity concentration at which there occurs preferential self-decomposition of ozone. It is given by the equation $c_S \le c_0(k/k_S)$. It follows from this equation that, for deeper decomposition of impurities in ozona-

tion of aqueous solutions, it is necessary to gradually lower the concentration of the dissolved gas, which also provides a decrease in its expenditure.

CONCLUSIONS

(1) In the pH range 4–8, the kinetics of ozone decomposition in water is well described by the second-order rate equation. As pH increases, the rate of ozone decomposition becomes higher.

(2) The dependence of the rate constant of ozone decomposition on pH at 19°C corresponds to Eq. (2) at $\log k_{(pH\,4)} = -0.7$. The activation energy of ozone decomposition is 76.0 ± 8.3 kJ mol^{-1}.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Amorphous Calcium Barium Monophosphate and Its Dehydration in Air at Room Temperature

V. A. Sinyaev, E. S. Shustikova, L. V. Levchenko, R. A. Karzhaubaeva, and G. A. Tokseitova

Bekturov Institute of Chemical Sciences, Ministry of Education and Science of Kazakhstan Republic, Almaty, Kazakhstan

Received March 4, 2008

Abstract—The change in the state of chemical bonds during dehydration of amorphous calcium barium monophosphate was studied. The monophosphate was obtained by precipitation from an aqueous phosphate solution under the action of a binary solution containing simultaneously calcium and barium chlorides in the atomic ratio Ba/Ca ~0.2.

DOI: 10.1134/S1070427208110050

As a basis for new materials for medicines, amorphous calcium monophosphates (orthophosphates) close in the chemical composition to hydroxyapatite $Ca_5(PO_4)_3OH$ and to tricalcium phosphate $Ca_3(PO_4)_2$ attract growing researchers' attention [1–8]. These compounds are also of interest as precursors of technical ceramics [4]. The composition of precursors and conditions of their treatment are the main factors determining the microscopic structure of the forming ceramics. Salts of the metals that are analogs of calcium in the periodic table, namely, of magnesium, strontium, and barium, are of interest as agents for controlling the porosity of ceramics. High performance of Mg^{2+} ions as inhibitors of the crystallization of calcium phosphates has been shown in a number of studies [4, 9–15]. Later the effect of these ions on the microscopic structure of calcium phosphate ceramics was described [16, 17]. The Sr^{2+} ions are much more poorly studied [8, 18] in this respect, though the procedure for preparing strontium-containing calcium phosphate bioceramics has been described [19]. As to barium, in spite of the presence of its traces in apatites of biological origin [9, 20], the role of Ba^{2+} cations in the crystallization of calcium monophosphates is understood still more poorly.

Here we briefly describe the synthesis of amorphous calcium barium monophosphate and its transformations at room temperature.

EXPERIMENTAL

To synthesize the compounds under consideration, we used analytically pure grade sodium phosphate $Na_2HPO_4 \cdot 12H_2O$ and hydroxide NaOH, and also pharmacopoeia grade calcium and barium chlorides. 5% aqueous solutions of sodium phosphate were treated with solutions of the same concentration, containing calcium and barium chlorides in various proportions. The solutions of chlorides were added to a phosphate solution dropwise with vigorous stirring at room temperature. Preliminarily the phosphate solution was alkalized to pH 9 and was maintained at this pH level during the reaction. The precipitated substances were separated from the solution of salts by decantation, dispersed in distilled water with pH 8 taken approximately in a 10-fold excess, settled for 2–3 h, and again separated from the solution. The operation was repeated up to the absence of Cl^- ions in the wash water. The acidity of the water used for washing was adjusted with an ammonia solution. The washed products were filtered in vacuum on a Corning Nylon porous filter with a pore size of 0.2 μm.

To characterize the precipitated phosphates and to study their dehydration, we used X-ray phase and differential thermal analyses, and also IR Fourier spectroscopy. The phase analysis was carried out on a DRON-3 diffractometer with CoK_α radiation. The IR spectra were recorded on an FT-IR Nicolet 5700 spectrometer, using the attenuated total internal reflection technique on a ZnSe single crystal at a resolution of 4 cm^{-1}, measuring accuracy of ±0.5 cm^{-1}, and scan number 32. The dehydration process was monitored by recording the IR spectra with a periodicity of approximately 10 min. The thermal analysis was carried out on a Mettler Toledo TGA/SDTA 851 thermoanalyzer

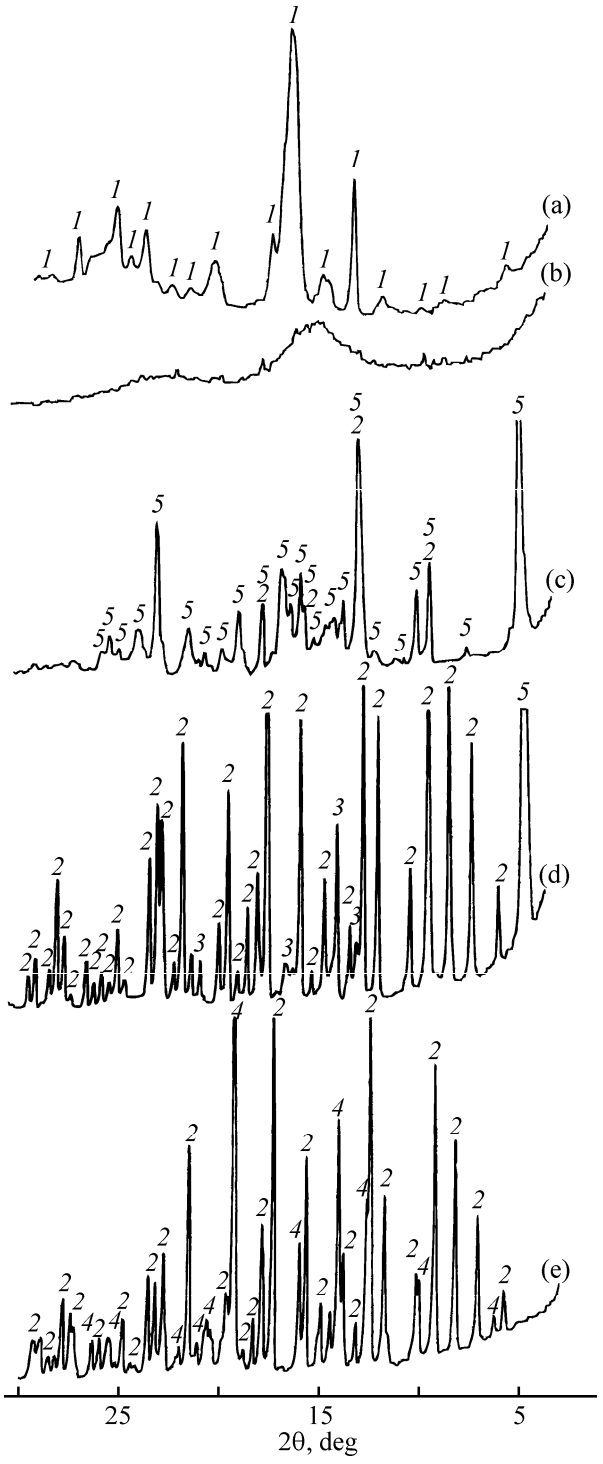

Fig. 1. Diffraction patterns of substances precipitated under the action of binary chloride solutions with various $BaCl_2$ content. (2θ) Bragg angle. $BaCl_2$ content, (mol %): (a) 0, (b) 10–20, (c) 40, (d) 60–80, and (e) 100. Individual phosphate in precipitated substances: (*1*) $Ca_5(PO_4)_3OH$, (*2*) $NaBa(PO_4)\cdot 9H_2O$, (*3*) $Ba_2Ca(PO_4)_2$, and (*4*) $Ba_3(PO_4)_2$; (*5*) not identified.

in open corundum crucibles with a weighed sample of about 100 mg at a constant temperature of 25°C.

The substances precipitated from the phosphate solution under the action of only one chloride, $CaCl_2$ or $BaCl_2$, are crystalline (Fig. 1). The calcium salt crystallizes in the form of hydroxyapatite, and the barium salt, in the form of $Ba_3(PO_4)_2$. In presence of both chlorides, either amorphous substances or a mixture of crystal phases are formed. The former appear at the Ba/Ca atomic ratio close to 1/4, which is slightly less than in the case when magnesium ions are used for the same purpose [14, 15]. At the ratio Ba/Ca > 1/4, crystalline sodium barium monophosphate $NaBa(PO_4)\cdot 9H_2O$, barium calcium monophosphate $Ba_2Ca(PO_4)_2$, and barium monophosphate $Ba_3(PO_4)_2$, usually in the form of a mixture, are formed. Among the products we have found a substance that is difficult to identify reliably. However, proceeding from Fig. 1, we can assume that it is a calcium-rich barium-containing phosphate salt.

Amorphous calcium barium phosphate (ACBP) in which components should be "intermixed" at a level close to molecular is of the greatest interest as a ceramics precursor; therefore, it became the object for the further study.

Pasty character of ACBP suggests that it is hydrated. In fact, the bands related to the main vibrations of O–H bonds in water molecules dominate in its IR spectrum in the ranges 1500–1800 and 2800–3700 cm^{-1} (Fig. 2). There is also a weak absorption at 2000–2300 cm^{-1} connected with a combination of vibrations (δ + ω)(OH) [21]. A fairly strong band at lower frequencies corresponds to the vibrations of P–O bonds in the phosphate anion PO_4^{3-} [8, 25, 26].

The comparison of the spectra of ACBP, crystalline hydroxyapatite [8], and also of amorphous calcium and calcium magnesium monophosphates described earlier [27] suggests that water in all the four substances is in the same state. However, judging from the state of P–O bonds, ACBP can be considered as a substance with less homogeneous in energy (in strength) chemical bonds and, probably, with a stronger amorphous character (Fig. 3).

Similarly to other amorphous calcium phosphates, ACBP is stable at room temperature when stored in a sealed vessel. In air it changes the consistency and rapidly erodes. The thermal analysis data show that the substance first undergoes an endothermic transformation accompanied by a weight loss at a gradually decreasing rate (Fig. 4a). After 2 h, the weight loss rate

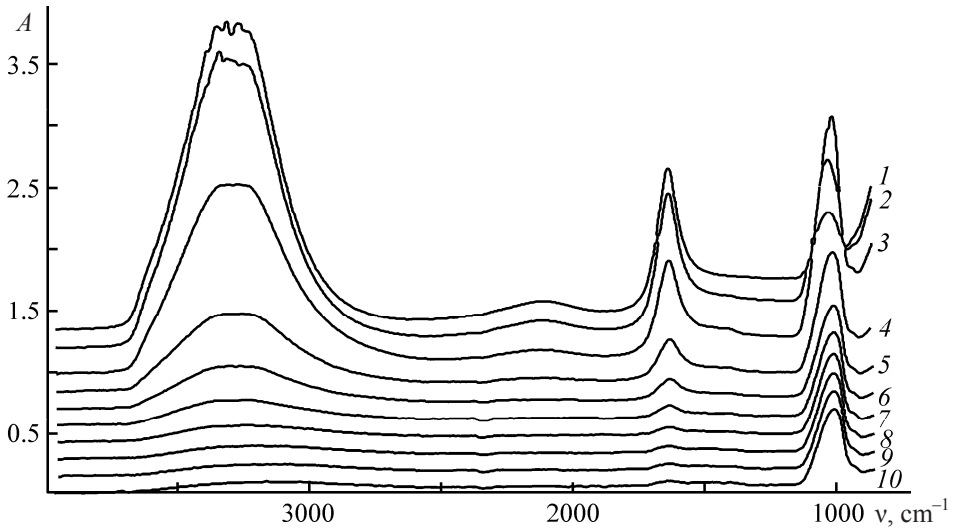

Fig. 2. Variation of the ACBP IR Fourier spectra on keeping the substance in air at room temperature for various times. (*A*) Absorbance and (ν) wavenumber; the same for Fig. 3. τ, min: (*1*) 0, (*2*) 34, (*3*) 54, (*4*) 59, (*5*) 64, (*6*) 69, (*7*) 74, (*8*) 79, (*9*) 84, and (*10*) 118.

becomes considerably lower but constant, and finally it rapidly decreases and the process stops. The shape of the TG and DTA curves indicates that the process consists of at least three steps.

The ACBP weight loss is due to dehydration. In fact, the ratio of intensities of ν(OH) and ν(PO) bands in the IR spectra of the products formed gradually decreases with time (Fig. 4b). Within 80 min, the I_{OH}/I_{PO} value reaches the lowest, though not "zero," level, suggesting retention of residual moisture in the substance. The amount of such water found from the total weight loss is close to 20%.

The dehydration should be accompanied by changes in chemical bonding in the phosphate. According to the IR spectra of the products of ACBP dehydration, despite a large water loss in the first 30–50 min, the intensities of the ν(OH) and δ(OH) bands did not decrease noticeably, whereas the intensity of the ν(PO) band appreciably increased (Fig. 4c). This is due to the fact that, in the initial dehydration step, the density of the substance increases owing to its shrinkage and hence the phosphate concentration grows. After 50 min, because of cracking and reduction of the surface area from which the spectra are recorded, all the IR bands start to rapidly weaken. After a period slightly exceeding 1 h, the values of the spectral maxima get stabilized on the same level, suggesting completion of the water removal.

In the course of ACBP dehydration, not only the intensities of bands in the IR spectra of the products but also their frequencies change. During the period of rapid weakening of all bands, the frequency of the δ(OH) band increases first smoothly, then stepwise, and finally is stabilized (Fig. 4d). As to the stronger ν(OH) maximum, it is impossible to determine reliably its frequency because the peak is smeared. Nevertheless, judging from the general profile of the spectral band, we can assert that ν(OH) behaves in the opposite way, shifting to the low-frequency region. The trend is the most significant in the period of weakening of this band. The ν(PO) band also sharply shifts to lower frequencies at the moment of a decrease in its intensity; however, after reaching a minimum its frequency again starts to grow (Fig. 4e). It is impossible to account for such a behavior simply by the progress of changes in the substance composition due to the dehydration. Therefore, we shall interpret this effect after consider-

ing how the composition of dehydration products affects the state of chemical bond in ACBP.

Whereas the dynamics of the δ(OH) vibrations can be used only as an evidence of stepwise transformations in a substance in a certain dehydration step, the other two types of vibrations furnish more detailed information. The point is that the strength of chemical bonds correlates with the frequency of the corresponding stretching vibrations in the spectra. Such a dependence was used earlier to account for the shift of Raman bands of amorphous (vitreous) polyphosphates depending on their composition [28, 29]. It was concluded that, as the electronegativity of the nearest environment of phosphate anions increases, the P–O vibration frequency becomes higher and the bonds become stronger and more polar. Applying a similar approach to ACBP, we can attribute a decrease in the frequency of ν(OH) and ν(PO) bands in the spectra of the dehydration products to a decrease in the content of water as the most electronegative component. As a result, the polarizing action of the environment on PO_4^{3-} anions decreases, which results in weakening and, apparently, depolarization of the P–O bonds. Due to the same effect, O–H bonds in the molecules of residual water also become weaker, but probably more polar.

Coming back to an increase in the frequency of P–O bonds at the end of the ACBP dehydration (Fig. 4e) and using the above approach (the higher the electronegativity of the environment, the higher the vibration frequencies), we can assume that, in this step, the electronegativity of the substance does not decrease, but suddenly starts to grow. It is possible if the phosphate absorbs a component more electronegative than ACBP and water from air. Such a component can be carbon dioxide which was detected in the IR spectra of the products in final dehydration steps.

As water is removed, the shape of spectral bands also changes. In particular, the ν(OH) band becomes broader and weaker. The ν(PO) band becomes even slightly narrower when its frequency decreases, but when it is again shifted to higher frequencies, its width increases again. The broadening of bands suggests appearance of chemical bonds different from the main bonds and increase in structural disorder. Thus, it is possible that the residual moisture in ACBP is less organized than in the mother substance. Similarly, pure phosphate substance in the final step of dehydration is disordered to almost the same extent as in the initial paste, though in the products of partial dehydration P–O bonds are more uniform.

CONCLUSIONS

(1) The reaction of monophosphate anions PO_4^{3-} with Ca^{2+} and Ba^{2+} cations present in a solution simul-

taneously in the atomic ratio Ba/Ca ~0.2 yields amorphous calcium barium monophosphate. At other Ba/Ca ratios, crystalline products are precipitated.

(2) Amorphous calcium barium monophosphate contains 80% water. The substance is stable when stored in a sealed vessel, but in air it rapidly loses in three steps the main part of moisture, remaining, however, amorphous and, probably, becoming still more disordered.

(3) Dehydration leads to weakening of O–H chemical bonds in the molecules of remaining water. The P–O bonds also become weaker, but in the final dehydration step they are noticeably strengthened, possibly due to the absorption of carbon dioxide from air.

Abstract—Potentialities of low-temperature (300–500°C) chlorination to remove the aluminum cladding of fuel elements and separate uranium and aluminum were studied.

DOI: 10.1134/S1070427208110062

Fuel elements with an aluminum cladding and based on alloys with uranium and aluminum are widely used in nuclear reactors of various types. Water-based methods for processing of such fuel elements are multistage and produce a large amount of radioactive waste [1, 2].

This study is concerned with the possibility of using low-temperature chlorination of aluminum (removal of the cladding) and U–Al alloys (separation of uranium and aluminum). As prerequisites served low sublimation points of aluminum trichloride (182.7°C) and comparatively high boiling points of uranium tetrachloride (775°C) and especially uranium trichloride (1789°C).

The reaction of aluminum with chlorine $2Al + 3Cl_2 = 2AlCl_3$ is accompanied by a noticeable heat effect ($\Delta H^0_{298} = -695.85$ kJ mol^{-1}) and is characterized by a substantial negative change in the Gibbs energy ($\Delta G^0_{298} = -637.65$ kJ mol^{-1}) [3]. The thermodynamic characteristics show that the chlorination of aluminum must occur without any hindrance. However, aluminum is always covered, because of its high chemical activity, with a dense film of an oxide whose crystal lattice constants are very close to the lattice constants of aluminum itself. This provides a rather high corrosion resistance of aluminum in a wide temperature range. The reaction of chlorine with aluminum oxide becomes noticeable only at sufficiently high temperatures. For the reaction

$$Al_2O_3 + 3Cl_2 = 2AlCl_3 + 1.5O_2, \quad (1)$$

calculations of changes in the Gibbs energy on the basis of the data from [3] for temperatures of 500, 1000, and 1500 K give ΔG_r values of 156 808, 65 883, and –19 694 J mol^{-1} Al_2O_3, respectively.

It can be seen that reaction (1) becomes thermodynamically possible only at temperatures close to 1500 K. Therefore, effective chlorination of metallic aluminum with gaseous chlorine is only possible upon disintegration of the oxide film.

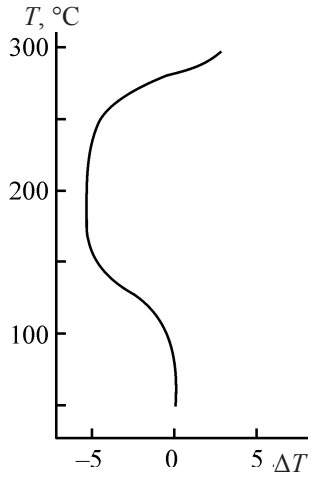
The aim of the study was to determine the minimum chlorination temperature of metallic aluminum, chlorination rate, extent of chlorine utilization, and completeness of uranium and aluminum separation in chlorination.

EXPERIMENTAL

The chlorination was carried out with aluminum of chemically pure grade (≥99.9%) in the form of grains ~1 cm in diameter and 0.3–0.4 cm thick, or as shavings or a foil, which had a substantially larger specific surface area than grains. As an apparatus for chlorination served a quartz or ceramic test tube tightly closed with a cover through which chlorine was introduced and volatile chlorination products, including unchanged chlorine, were removed. The breakthrough of chlorine was determined with an indicator, potassium iodide

solution, whose reaction with chlorine

$$2KI + CI_2 = 2KCl + I_2 \quad (2)$$



yields elemental iodine making the indicator paper brown. A weighed portion of aluminum was 5–15 g, and the charge bed height, 5–10 cm.

Chlorine was produced by electrolysis of lead chloride in a chlorine-producing unit. After being purified to remove trace amounts of moisture (bubbling through concentrated sulfuric acid) and solid dust sublimates (filtration through glass wool), chlorine was delivered via a ceramic tube into the experimental cell. The rate of chlorine supply was controlled by varying the current strength through the chlorine unit. The chlorination process was carried out with an excess of chlorine, determined from its breakthrough with the indicator, which enabled estimation of the chlorination rate.

The minimum temperature at which aluminum chlorination begins was determined using a differential thermocouple that measured the temperature difference between the exterior and interior of the chlorinator. Because the heating elements of the furnace were outside the chlorinator, the temperature of a heated chlorinator remained 5–10°C lower. The reaction of aluminum with chlorine, accompanied by a strong heat effect, results in that the negative difference between the internal and external temperatures first decreases in magnitude and then, after the chlorination is intensified and a considerable amount of heat is released, becomes positive. This was methodologically achieved by gradual heating of the furnace at a constant chlorine delivery into the chlorinator. The temperature difference ΔT was recorded with a RECORDER self-recorder. The thermogram obtained is plotted in the ΔT–T coordinates in the figure. As can be seen in the thermogram, a noticeable heat release in aluminum chlorination is observed at a temperature close to 250°C, and just this temperature is the minimum chlorination temperature.

The chlorination was mostly performed using granulated aluminum with an average grain mass of 0.4–0.6 g and surface area of about 2.5–3 cm^2. To have a larger specific surface area, aluminum foil (Table 1, run no. 10) or freshly prepared shavings (run no. 11) were used in separate experiments.

The chlorination temperature was varied from 200 to 500°C. The flow rate of chlorine delivery (in terms of the current through the chlorine unit) was within the range 2–3 A, which provided an excess of chlorine

Thermogram of aluminum chlorination.

relative to the amount consumed at the actual chlorination rate in all the experiments. The chlorination duration was 1 to 5 h. Data on the conditions and results of chlorination without preliminary treatment of the grain surface are summarized in Table 1.

As a rule, chlorination at 200–300°C fails to yield positive results: aluminum is either not chlorinated (Table 1, run nos. 1 and 2) or the chlorination rate is low and does not exceed 2 mg cm^{-2} h^{-1} (run nos. 10, 11). The best result is obtained in chlorination of freshly prepared shavings. An increase in temperature to 350–500°C raises the chlorination rate of aluminum to the maximum value of 9–12 mg cm^{-2} h^{-1}. However, no clearly pronounced temperature dependence of the chlorination rate was observed. The maximum value of 12 mg cm^{-2} h^{-1} (Table 1, run no. 4) was observed at 350°C, whereas at 450°C (run no. 8), the chlorination rate was lower, 8.2 mg cm^{-2} h^{-1}. The chlorination rate did not exhibit any pronounced dependence on the process duration, either. The best result was obtained at 350°C (Table 1, run no. 4) in a 1-h-long experiment (12 mg cm^{-2} h^{-1}), and at a duration of 4–5 h (run nos. 6, 9), the chlorination rate was two times lower.

The chlorination rate is presumably low because the oxide film is not effectively removed from the aluminum surface at the process parameters (temperature, duration) used. At the same time, an interesting type of behavior was observed: in all the runs with the highest chlorination rates, some grains (1 to 2–3 grains) lost 50 to 90% of mass, whereas parameters of all the others (15–20 grains) remained almost unchanged. Thus, the average chlorination rate is determined by chlorination of only a part of aluminum grains (~10%), with the

[a] Treating solution: run no. 1, NaOH; run no. 2, $ZnSO_4$ + NaOH; run nos. 3–5, $Hg(NO_3)_2$; run nos. 6–8, $CuCl_2$; run no. 9, HCl.

chlorination rate of these grains exceeding the average value by at least an order of magnitude, i.e., it is not lower than 100 mg cm^{-2} g^{-1}. Interestingly, no chlorine breakthrough through the cell was observed in these experiments, i.e., as the intense chlorination of separate grains begins, the whole amount of passed chlorine is consumed by these grains to give aluminum chloride, which suggests that an even higher chlorination rate is possible.

The observed behavior indicates that the effective chlorination of metallic aluminum is limited by the stage of disintegration of the protective oxide film.

The following solutions were tested in decomposition of the protective film: 2 N NaOH solution, alkaline solution of zinc sulfate, and dilute (0.05 N) solutions of mercury nitrate and copper(II) chloride. The results obtained are listed in Table 2.

The stripping of the aluminum surface in alkaline solutions is based on the reaction

$$Al_2O_3 + 2NaOH = 2NaAlO_2 + H_2O, \quad (3)$$

which gives sodium aluminate well soluble in water. Prior to chlorination, aluminum grains were placed for several minutes in a 2 N NaOH solution and then

charged into the chlorinator. The chlorination was performed at 300°C. No changes in the mass of aluminum were observed. Presumably, aluminum oxide is not removed from the aluminum surface under the conditions specified.

The highest efficiency was observed in the case of triple short-time (0.5–1 min) wetting of aluminum grains with dilute solutions of mercury nitrate and copper(II) chloride.

The grains were treated with a 0.05 N $Hg(NO_3)_2$ solution three times for 0.5–1 min. Chlorination was performed after each treatment. As can be seen in Table 2, amalgamation produces a positive effect. At 300°C, the chlorination occurs at an acceptable rate, with each subsequent treatment of the aluminum surface leading to an increase in the chlorine utilization efficiency and in the chlorination intensity. The chlorination rate increased from 6.2 to 12.2 mg cm^{-2} h^{-1}, and the chlorine utilization efficiency, from 36 to 67%.

The advisability of using mercury and its salts is limited by their high toxicity. It was of interest to try other activating agents. A triple treatment of aluminum grains with a dilute copper chloride solution yielded a positive result. Upon a triple treatment, the chlorination rate at 300°C and the chlorine utilization efficiency increased from 1.3 to 12.5 mg cm^{-2} h^{-1} and from 8 to 66%, respectively.

Presence of uranium in aluminum alloys must markedly accelerate the chlorination process for two reasons. First, the fact that uranium has several stable valence states substantially accelerates delivery of the chlorinating agent to the metal surface. Uranium trichloride is stable in contact with aluminum, and uranium tetrachloride and even pentachloride, in contact with gaseous chlorine, and these uranium compounds are effective transporters of chlorine to the surface of aluminum and its alloys. Second, the protective properties of the surface oxide film are considerably impaired in the presence of uranium in aluminum.

To verify these assumptions, experiments on low-temperature chlorination of uranium–aluminum alloys were carried out. The alloys were chlorinated at 350°C in a small Alundum test tube. After chlorination for approximately 1 h, the cooled solid residue was weighed before and after the salts were removed by washing. An analysis of the resulting solutions demonstrated that they are nearly fully composed of uranium chlorides (mostly UCl_3). The conditions and results of chlorination are listed in Table 3.

Table 3. Conditions and results of the low-temperature (350°C) chlorination of uranium–aluminum alloys

Parameter	Passed quantity of electricity, A h	
	1.0	1.4
Mass of alloy, g:		
initial	1.088	0.182
after chlorination:		
before washing	1.042	0.121
after washing	0.900	0.045
Content of uranium U in alloy, %:		
initial	39.5	31.8
after washing	34.0	31.8
Mass loss, g:		
U	0.124	0.053
Al	0.064	0.072
Quantity of electricity consumed for chlorination, A h:		
U	0.042	0.018
Al	0.191	0.215
Cl_2 utilization efficiency, %	23.3	23.3
Content in fumes:		
U, mg	25.4	5.3
U, %	20	10
Al, mg	57.6	65.3
Al, %	70	92
Mass of solid residue, g:		
found from ΔP	0.142	0.076
found from difference	0.143	0.069

The contents of uranium in the starting and final, washed alloy and the differences of their masses were used to find the loss of mass by uranium and aluminum in the course of chlorination (Δm_i); the quantities of electricity required for this purposes are given by the equation $Q_i = \Delta m_i/q_i$, where q_{Al} and q_U are 0.3355 and 2.96 g A^{-1} h^{-1}, respectively; the chlorine utilization efficiency $\eta = (Q_U + Q_{Al})/Q$, where Q is the total quantity of electricity passed.

An analysis of the sublimates demonstrated that they mostly contain aluminum chloride (≥90%) and 10 to 30% uranium chlorides. The mass of the salt residue after the chlorination, found from difference of the masses of the alloy before and after its washing, almost coincides with that calculated from the difference of masses after the chlorination and sublimation of uranium (in terms of its trichloride), which additionally confirms that most of aluminum chloride is removed into sublimates.

The rate of low-temperature chlorination of uranium–aluminum alloys (200–300 mg cm^{-2} h^{-1}) substantially exceeds (by factors of tens and hundreds) the

chlorination rate of pure aluminum. Despite that the weighed portions of the alloys were small, the chlorine utilization efficiency was considerable (>20%).

The considerable loss of uranium with the fumes is presumably observed because a part of uranium is chlorinated to its tetrachloride, which has a noticeable vapor pressure. Therefore, by passing the vapor through a reducing packing (e.g., aluminum shavings), it is possible to deposit uranium trichloride reduced from the tetrachloride on this packing, with loss of uranium with the fumes precluded. It is recommended to condense aluminum chloride vapor at 240–260°C on lumps or ingots of sodium chloride to obtain molten $NaCl–AlCl_3$ mixtures containing up to 60 mol % $AlCl_3$ [4].

CONCLUSIONS

(1) The onset temperature of chlorination of pure aluminum by gaseous chlorine is close to 250°C.

(2) The existence of a dense oxide film on the metal surface results in low chlorination rates (<10 mg cm^{-2} h^{-1}) and chlorine utilization efficiencies (<20%). Upon disintegration of the oxide film at least on a part of the sample surface, the chlorination rate increases by more than an order of magnitude, with the chlorine utilization efficiency reaching 60%.

(3) The highest efficiency in disintegration of the oxide film on aluminum upon its wetting before chlorination was observed for an alkaline solution of zinc sulfate, 0.05 N solution of mercury nitrate, and 0.05 N solution of copper(II) chloride.

(4) In chlorination of solid uranium–aluminum alloys (39.5% uranium) at 350°C, the presence of uranium in an alloy provides high chlorination rates (up to 300 mg cm^{-2} h^{-1}) and high chlorine utilization efficiencies. Almost the whole amount of chlorinated aluminum and part of uranium are removed into sublimates. To preclude the loss of uranium, the gas flow should be passed through aluminum shavings reducing the volatile uranium tetrachloride to the considerably less volatile trichloride.

Abstract—Possibility of obtaining nanodispersed copper-containing powders by electrochemical cathodic deposition from aqueous and water–isopropanol solutions of copper dichloride was examined.

DOI: 10.1134/S1070427208110074

In the last decade, the researchers' interest in synthesis and properties of nanosystems of varied nature has been swiftly increasing [1–3]. Nanopowders of copper and its oxides are widely used among nanostructures, and their large specific surface area and high energy content open up wide opportunities for their application in various fields of science and technology. Highly selective catalysts used in manufacture of ammonia, methanol, and caprolactam are being developed on the basis of nanopowders of copper and its compounds [4, 5]. Introduction of nanosize copper-containing powders into plastic lubricants considerably improves their tribotechnical properties and makes it possible to prolong the service life of machine and device elements owing to the slower wear of friction units [6, 7]. Nanosize copper powders intercalated into a polymeric matrix exhibit a biocide effect against a number of microbes and bacteria [8].

A still topical issue is synthesis of ultradispersed powders with required physicochemical properties. Use of electrochemical methods allows control and wide variation of the process parameters to obtain the required particle size distribution. The environmental safety of the technology for synthesis of nanosize metal-containing powders and the simplicity of the apparatus used make electrosynthesis advantageous over other methods for production of materials of this kind [9–11].

Previously, the effect of isopropyl alcohol on the cathodic reduction of ultradispersed copper-containing powders from water–isopropanol solutions of copper dichloride ($CuCl_2$) has been studied [12]. It was shown that addition of low-molecular-weight surfactants to aqueous electrolyte solutions lowers the limiting cathode current, enhances the cathodic polarization, and promotes formation of ultradispersed metal-containing deposits.

The aim of this study was to determine the chemical composition of electrodeposited ultradispersed copper-containing powders produced under various electrolysis conditions.

EXPERIMENTAL

Cathodic deposits containing ultradispersed copper and its compounds were deposited onto a preliminarily trimmed cylindrical steel cathode (working area S = 0.16 dm^2) at a constant electrode potential. Ruthenium oxide–titanium plates served as the anode. Aqueous and water–propanol solutions of copper dichloride were used as the electrolyte. The mole fraction of i-C_3H_7OH was 0.04, and the concentration of $CuCl_2$, 0.1 mol kg^{-1}. This electrolyte composition is the optimal: it corresponds to the maximum current efficiency and provides a high dispersity of the copper-containing powder [12]. The experimental installation and the synthesis procedure of ultradispersed copper-containing powders were described in detail in [13].

After the electrolysis was complete, the deposit obtained was detached from the electrode, thoroughly washed with distilled water to constant electrical con-

(*I*) Current strength and (*E*) potential relative to the silver chloride electrode.

ductivity of the mother liquor, and dried to powdered state.

Polarization curves of the cathodic reduction of copper were measured with a PI-50-1 potentiostat equipped with a PR-8 programming unit. The potential sweep rate was 5 mV s^{-1}. A copper disc (working area $S = 8.55 \times 10^{-4}$ dm^2) was used as the working electrode in polarization studies. A platinum electrode served as the auxiliary electrode, and a saturated silver chloride electrode, as reference.

Information about the size and shape of particles of the powders obtained was furnished by transmission electron microscopy on an EMV-100 L electron microscope in the high-resolution mode. For reliable construction of histograms characterizing the dispersion composition of the powders, electron micrographs of different parts of a sample were obtained at numerous magnifications. To determine the chemical composition, X-ray diffraction patterns of an object of study and reference sample were compared [14].

X-ray diffraction analysis was carried out on a DRON-3M diffractometer with CuK_α radiation.

The key influence on the physicochemical (including size) properties of powder particles is exerted by the electrolysis conditions and electrolyte composition. If electrolysis is performed with the maximum current density, the discharge of copper ions is diffusion-controlled, which results in the appearance and initial development of crystalline nuclei of a loose cathode deposit. Introduction of surfactants enhances the cathodic polarization and makes lower the surface energy of the powders, which leads to a higher nucleation probability. Being adsorbed on the surface of nuclei, surfactants inhibit their growth. As a result, the potential of the lateral faces of a growing crystal reaches a value sufficient for new crystalline nuclei to be formed.

Figure 1 shows results of polarization studies of the deposition of metal-containing compounds. On the plateaus in the overvoltage region ($-E \approx 0.3$–0.5 V), the current strength is independent of the voltage applied. In this case, the rate of ion delivery to the electrode surface is constant within this range and its maximum value is determined by the rate of steady-state diffusion. Introduction of an organic cosolvent into the electrolyte solution makes lower the dielectric constant and electrical conductivity of this part of the solution and, as a consequence, leads to a decrease in the limiting cathode currents and an increase in the cathodic polarization. It has been reported that, at a mole fraction of isopropyl alcohol of 0.04, the limiting cathode currents favor synthesis of highly dispersed deposits to the greatest extent [12].

The potential jump (component of the Galvani potential) caused by the preferential orientation of organic solvent dipoles adjacent to the electrode will be equal to the surface potential of the solution, –0.28 V [15] (i.e., the surface potential of neat isopropyl alcohol), for compositions with the mole fraction of isopropyl alcohol of 0.04–0.08 in the aqueous–organic mixture. It can be suggested on these grounds that the near-electrode space at the electrode/solution interface will be nearly fully composed of alcohol molecules at the alcohol mole fraction of 0.04. This hypothesis has been scientifically substantiated by Yakushevskii et al. [16], who demonstrated by using the direct immersion method that, in the water–ethanol system, the surface of the metallic electrode is fully blocked by molecules of the organic solvent. As an indirect confirmation of this fact can serve the results of [17, 18], where the surface properties of aqueous–organic electrolyte solutions were analyzed by the method of voltaic potential differences.

Addition of low-molecular-weight surfactants to aqueous electrolyte solutions makes smaller the limiting currents and raises the magnitude of the cathodic polarization $\Delta\eta$, which favors formation of highly dispersed deposits. The cathode deposit produced by electrosynthesis was a spongy formation (Fig. 2).

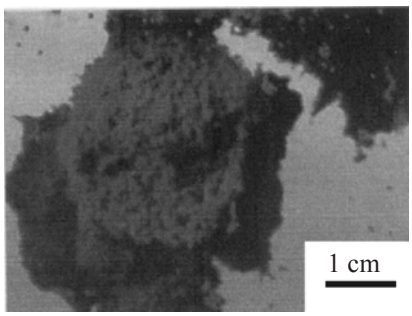

Fig. 2. Image of the spongy cathode deposit.

The results of an analysis of micrographs of the copper-containing powder produced by electrodeposition from aqueous (Fig. 3a) and water–isopropanol (Fig. 3b) solutions of 0.1 M copper dichloride are presented in the form of histograms in Fig. 4. The nanoparticle size distributions are different. In the first case, the main part (~76%) is constituted by nanosize particles (100 to 300 nm). These are mostly irregular aggregates formed by cohesion of finer particles. In the presence of *i*-C_3H_7OH, the size distribution of powder particles changes: the main part (~85%) is constituted by nanoparticles 20 to 100 nm in size. The share of coarser formations is smaller.

According to the results of an X-ray phase analysis (Fig. 5), the product obtained is multicomponent and contains unoxidized copper and copper(I, II) oxides. The structure of nanoparticles can be characterized as a druse of polycrystalline copper with an oxidized surface (Fig. 6).

The predominance of an oxide of a certain type in the powder is determined by the growth dynamics of dendrites and by the nature of the overvoltage accompanying the discharge of the metal. Powders produced from aqueous electrolytes contain a large amount of Cu and CuO. Upon addition of *i*-C_3H_7OH, the content of Cu_2O in the powder increases. This is indicated by the higher intensity of the line of cuprous oxide, with interplanar spacings d = 2.46, 2.12, 3.00, and 1.51 nm (Fig. 5).

The average particle size was calculated by the formula

$$D = k\lambda/(\beta \cos \theta),$$

where D is the crystal size; θ, Bragg angle of a reflection (deg); k, coefficient dependent on the shape of the crystal (k = 1 for spherical particles, and k = 0.9 for particles of other shapes); λ, wavelength (nm); and β, width at half-maximum of the reflection (rad).

Processing of the X-ray diffraction patterns demonstrated that the average size of copper crystallites in the copper-containing powder (50 ± 10 nm) is independent of the electrolyte composition. The average size of copper oxide (CuO and Cu_2O) crystallites is 50 ± 10 nm.

When comparing results of an X-ray diffraction analysis and electron microscopic data, it should be taken into account that X-rays are scattered on volume elements. In this case, in determining the average crystallographic size of a crystallite, a major contribution will be made by particles whose share in the total volume of a sample is the largest. The volume accounted for by particles with an average diameter d is proportional to the product of the number N of particles of this size by cubed linear size d^3.

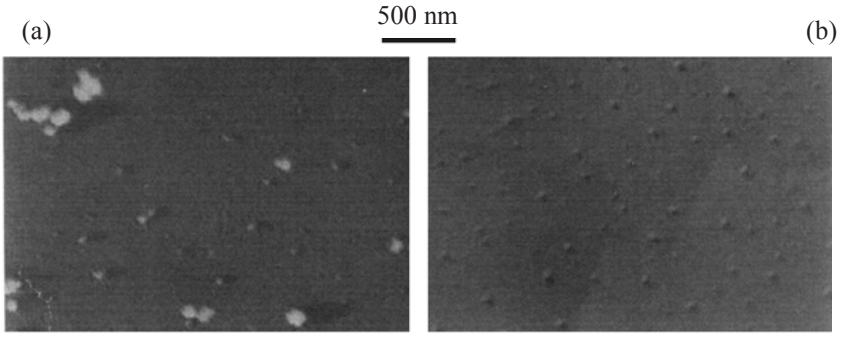

Fig. 3. Micrographs of nanosize copper-containing powders produced by electrodeposition from (a) aqueous and (b) water–isopropanol solutions of copper dichloride. *i*-C_3H_7OH mole fraction 0.04 (micrograph b), $CuCl_2$ concentration 0.1 mol kg^{-1}; the same for Fig. 5.

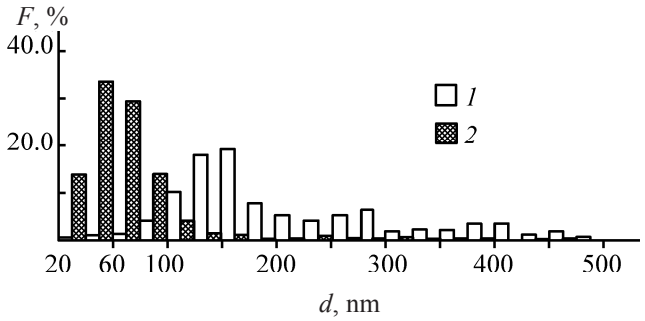

Fig. 4. Size distribution histograms of nanosize copper-containing particles in powders produced by electrodeposition from (*1*) aqueous and (*2*) water–isopropanol solutions of copper dichloride. (*F*) Fraction of particles and (*d*) particle size.

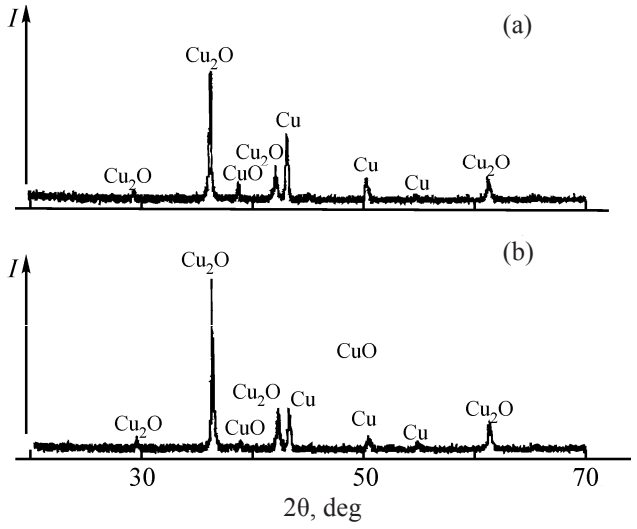

Fig. 5. X-ray diffraction patterns of nanosize copper-containing particles in powders produced by electrodeposition from (a) aqueous and (b) water–isopropanol solutions of copper dichloride. (*I*) Intensity and (2θ) Bragg angle.

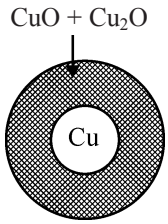

Fig. 6. Suggested structure of a nanoparticles.

In the case of spherical particles, the total volume V_d of particles with an average diameter d can be estimated using the relation

$$V_d = \pi N d^3/6.$$

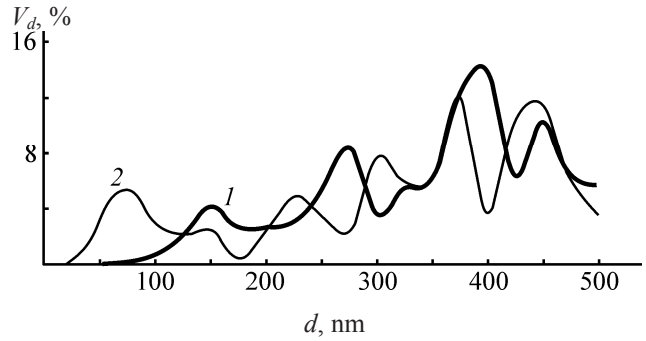

Fig. 7. Volume fraction V_d of particles corresponding to various diameters d for powders produced from (*1*) aqueous and (*2*) water–isopropanol solutions of copper dichloride.

To compare powders obtained under different conditions, the dependence of V_d on the particle size d was normalized. The total volume of particles of a powder under study (taken to be 100%) was used as the normalization parameter. The dependence of the total volume of particles in a powder on their size is shown in Fig. 7.

A characteristic feature of the dependences for powders produced from aqueous and aqueous–organic media is the appearance of periodically repeated maxima (Fig. 7). In the case of the water–isopropanol medium, the first maximum lies at 75–80 nm, which suggests that the powder contains a noticeable amount of particles composed of single crystallites. The periodicity of the maxima (70, 150, 225, 300, 375, and 450 nm) yields a sequence in which grows the number of crystallites in the cross-section of a particle. In the case of electrocrystallization from an aqueous medium, the first maximum is shifted to sizes of about 150 nm and is repeated with a period close to 120 nm, which corresponds to the sum of the average sizes of crystallites of copper and its oxide. Possibly, this occurs because the electrocrystallization of copper from aqueous solutions is accompanied by more intense oxidation processes and formation of the oxide phase, together with reduced copper. This is also indicated by the higher intensity of the reflection corresponding to copper oxide CuO in this sample.

CONCLUSIONS

(1) Introduction of isopropanol additives into the aqueous electrolyte changes both the granulometric and chemical composition of the powders obtained. Addition of isopropyl alcohol shifts the relative amounts of components in the powders obtained to-

ward a higher content of copper(I) oxide.

(2) Use of organic solvents as additives to water in electrolysis from aqueous–organic electrolyte solutions enables control over the size and chemical composition of particles constituting the powders obtained.

Abstract—Adsorption of DAFS-25 (1,5-diphenyl-3-selenapentane-1,5-dione) from dilute solutions in various solvents on various adsorbents was studied by UV spectrophotometry. The experimental data were interpreted thermodynamically by the method of excess Gibbs quantities.

DOI: 10.1134/S1070427208110086

Active development of the chemistry of 1,5-diketones is stimulated by their capability to form various heterocyclic compounds with valuable properties. The presence of a selenium heteroatom in the diketones not only strongly affects their chemical properties, but also imparts to them specific biological activity [1]. Therefore, the chemistry of these compounds attracts researchers' attention. DAFS-25 (1,5-diphenyl-3-selenapentane-1,5-dione) containing 25% Se contains a center with reducing properties. Therefore, this diketone can be considered as potential antioxidant reacting both with hydroperoxides and with organic radicals.

Today DAFS-25 is used for prophylaxis of white muscle disease, massive hepatic necrosis, and exudative diathesis [1]. It is synthesized by the reaction of acetophenone with $SeOCl_2$ [2]. After performing biological tests [2], the compound was put into commercial production. Its trade name is diacetophenonyl selenide. The compound contains two aromatic rings, which determines a specific adsorption mechanism:

1,5-Diphenyl-3-selenapentane-1,5-dione

A topical problem is the development and application to medical practice of combined enterosorbents based on two or several materials of different groups, which considerably expands the spectrum of the sorption activity and, as a result, the efficiency of the therapeutic effect of the adsorbable agent. Published data on adsorption of organoselenium compounds are virtually lacking. Dallakyan and Kiselev [3] studied the adsorption of S- and Se-containing aromatic compounds on graphitized thermal carbon black and showed that Se-containing compounds were adsorbed more strongly than their S-containing analogs, according to the atom–atom potentials. Therefore, in the development of high-quality enterosorbents, the adsorption of Se-containing 1,5-diketones on the solid surface is not only of theoretical interest but also of practical importance for the development of effective drugs.

This study concerns the adsorption of DAFS-25 from binary solutions on sorbents of various chemical nature and is aimed at further development of combined enterosorbents.

EXPERIMENTAL

For taking the adsorption isotherms, we used an HP A 8452 spectrophotometer. The optical density was recorded in the region of the absorption maximum. Using the calibration dependences of the optical density on the initial solution concentration, we determined the composition of the equilibrium solution and calculated the excess adsorption [4, 5]. The temperature was controlled with a TZh-TS-01/16-150 thermostat. As adsorbents we used calcium carbonate, silica gels ASK and MSK, NaX zeolite, and activated carbon

Physicochemical characteristics of adsorbents

Adsorbent	Micropore volume w_0, $cm^3\ g^{-1}$	Mesopore volume w_s, $cm^3\ g^{-1}$	Characteristic energy E_0, kJ mol^{-1}	Mesopore surface area S, $m^2\ g^{-1}$
SKT-2B activated carbon	0.39	0.42	25.8	43
NaX zeolite	0.320	0.342	14.2	–
Chalk, chemically precipitated $CaCO_3$	–	–	–	2.2
ASK silica gel	–	–	10.9	300

(AC), and as sorbents, diisopropyl ether (DIPE) and toluene. The choice of the adsorbents was governed by the need for examining the adsorption of DAFS-25 on both microporous and macroporous adsorbents. Interest in studying the adsorption of DAFS-25 on activated carbons is caused by the need for elucidating the mechanisms and specific features of the transfer of this compound through membranes, including biological ones. A study of the sorption kinetics will allow in the future understanding of the behavior of this agent in real biological objects and evaluation of the possibility of using activated carbons as enterosorbents.

The other demands were that the adsorbate should not chemically react with adsorbents chosen and should be infinitely soluble in the solvents chosen. Some physicochemical characteristics of the adsorbents are given in the table.

Prior to experiments, coarsely porous ASK silica gel was subjected to prolonged refluxing in HCl solution to remove iron ions, after which it was washed with distilled water to remove chloride ions and dried at 175°C in an oven to constant weight. Just before experiments, silica gel was dried for 2 h at 200°C. The concentration of OH^- groups in silica gels was 7.0–0.5 μmol m^{-2}, or 4.2–5.7 OH^- groups per 100 $Å^2$. At equal degree of hydration, the properties of the unit surface for nonporous and coarsely porous (pore size about 50 $Å^2$) silica gels coincide.

Prior to adsorption tests, activated carbon was calcined for 2 h at 120°C. Zeolite NaX was dehydrated at 500–550°C for 5 h.

Figure 1 shows the adsorption isotherms of DAFS-25 from DIPE on activated carbons, silica gels ASK and MSK, calcium carbonate, and NaX zeolite. All the adsorption isotherms in the region of dilute solutions have a similar shape. The adsorption starts to steeply increase from the very beginning. The largest excess adsorption of DAFS-25 is observed on activated carbon. On silica gels MSK and ASK and on NaX zeolite it is lower, and on calcium carbonate it is the lowest. Such features of adsorption can be attributed to the structure of the diketone molecule. In this molecule, some peripheral fragments bear high electron density (π bonds, lone electron pairs).

Fairly high values of adsorption of DAFS-25 on silica gels are caused by the presence on the surface of silanol grops ≡Si–OH capable to form hydrogen bonds with electron-donor molecules. Owing to the polarity of the OH bond, hydroxylated silica gels have local positive charges on the surface. As already noted, the properties of the unit surface for nonporous and coarsely porous (pore size about 50 $Å^2$) silica gels coincide at equal degree of hydration. Therefore, the character of adsorption of DAFS-25 on ASK and MSK is essentially similar. In this case, we can assume the adsorption due to interaction with surface hydroxy groups of silica gel with electron-donor groups which are centers of specific molecular adsorption.

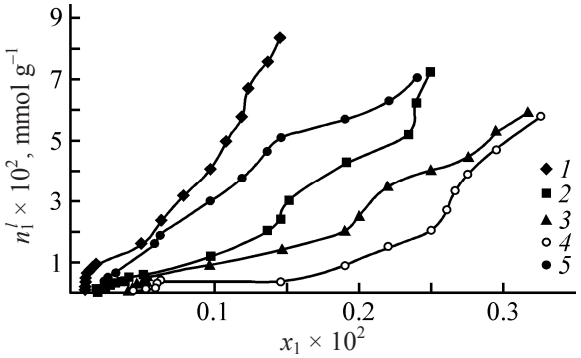

Fig. 1. Isotherms of DAFS-25 adsorption from DIPE on AC, NaX zeolite, ASK and MSK silica gels, and calcium carbonate at 298 K. (n_1^l) Amount of adsorbed DAFS-25 and (x_1) mole fraction of DAFS-25 in solution; the same for Figs. 2 and 3. (*1*) AC, (*2*) ASK, (*3*) NaX, (*4*) $CaCO_3$, and (*5*) MSK.

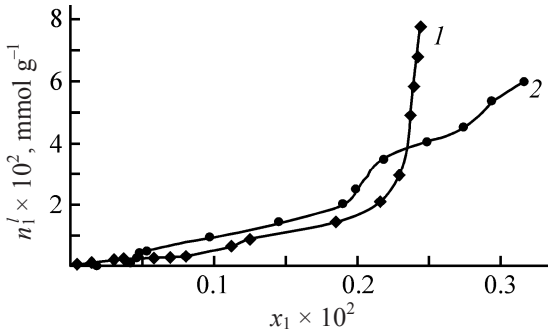

Fig. 2. Isotherms of DAFS-25 adsorption from (*1*) DIPE and (*2*) toluene on NaX zeolite at 298 K.

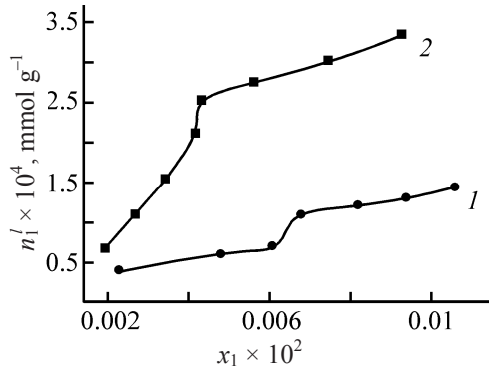

Fig. 3. Isotherms of DAFS-25 adsorption from dilute solutions in DIPE on calcium carbonate at (*1*) 293 and (*2*) 313 K.

Among possible adsorption mechanisms, chemisorption is the most probable. In this case, the polar groups of the adsorbate molecules should be oriented toward the surface, and their hydrocarbon chains, toward the solution. Presumably, a major role in the adsorption mechanism on silica gels is played by the effective volume, with carbonyl groups exerting a significant influence.

As seen from Fig. 1, the adsorption on the zeolite occurs to a considerably lesser extent than on activated carbon and silica gel. Aluminum in the zeolite is in the form of negatively charged AlO_4 tetrahedra. The compensating positive charge is localized in exchangeable cations of smaller radius. Therefore, cationized zeolites are specific molecular adsorbents of type II after Kiselev, i.e., adsorbents bearing on the surface localized positive charges (small cations) arranged near large complex anions. The presence of cations in zeolite cavities is responsible for manifestation of all the forms of adsorption interaction, from electrostatic to dispersion. As the specific features of adsorption on zeolites as heteropolar adsorbents are determined by the electrostatic interaction, it is manifested the more strongly, the more asymmetrical are adsorbate molecules. Apparently, the diketone is adsorbed on cations with the participation of the aluminosilicate framework. The diketone molecules containing peripheral electron-donor fragments are capable of strong specific interaction with zeolite cations. The major role in the process is played by localization of the electron density on specific bonds. In joint adsorption of molecules of different electronic structures, the mutual displacement is largely determined by the geometric structure.

Figure 1 shows that the adsorption isotherm on activated carbon is steeper, which is apparently due to increased adsorption potential of the micropores, compared to that of wider pores of the other adsorbents. The thin pores are filled with adsorbate molecules already at their relatively low concentration in solutions.

Analysis of the experimental isotherms of DAFS-25 adsorption from DIPE and toluene on NaX zeolite shows that, at low DAFS-25 concentrations, the adsorption is insignificant, apparently because of the competing effect of the solvent (Fig. 2).

The adsorption from toluene increases uniformly, whereas from DIPE up to the mole fraction $x_1 = 0.22$ there is a sharp bend with a characteristic increase in the excess adsorption from 2×10^{-2} to 8×10^{-2} mmol g^{-1}. The solvent effect in adsorption of DAFS-25 on ASK silica gel is manifested in that the adsorption monotonically increases with the adsorbate concentration and occurs from DIPE more actively than from toluene. These facts suggest the occurrence of the competing adsorption. On calcium carbonate at low concentrations, the adsorption isotherms have similar shape up to $x_1 = 0.2$, after which they sharply ascend. From toluene, DAFS-25 is adsorbed worse than from DIPE. Thus, on all the types of adsorbents DAFS-25 is adsorbed from DIPE better than from toluene.

The highest values of DAFS-25 adsorption from binary solutions are observed on activated carbon, which is consistent with the theory of adsorption on adsorbents of various chemical structures. The adsorption of DAFS-25 from binary solutions increases with temperature (Fig. 3). Apparently, in the adsorption system DAFS-25–calcium carbonate the interaction of solvent molecules with the adsorbent and, correspondingly, their competing effect become weaker with increasing temperature. As all the solutions are strongly dilute and the solute solubility is limited to low mole fraction, the isotherm of variation of the solution com-

position transforms into an individual isotherm of the solute adsorption, despite the possibility of the adsorption of a large amount of the solvent.

The adsorption isotherms of the DAFS-25–solvent–adsorbent systems, obtained in [4, 5], do not give a true pattern of the adsorption on the sorbent surface. Therefore, it is interesting to perform thermodynamic calculations of the adsorption equilibrium [6]. For the thermodynamic consideration of adsorption systems we used the method of excess Gibbs quantities allowing calculation of the main thermodynamic characteristics of sorption systems as a whole from the experimentally determined excess adsorption values. The change in the chemical potential of the sorbent was determined from the equation

$$-\Delta\Phi = -(\Phi x_1 - \Phi x_2) = RT \int_0^{x_1 y_1} \frac{n_1^l}{x_2 x_1 \gamma_1} \mathrm{d}(x_1 y_1),$$

where γ_1 is the activity coefficient of component 1 in the bulk of solution.

To determine the quantities $\Phi x_1 - \Phi x_2$, it is necessary to have information on the concentration dependence of the activity coefficient of bulk solution and excess adsorption n_1^l. The quantity $-\Delta\Phi$ was determined by graphical integration, namely, by calculation of the area under the curve

$$\frac{n_1^l}{x_2 x_1} = f(x).$$

The change in the free energy of the sorption system was calculated by the equation

$$\Delta G = Gx_1 - Gx_2 = -(\Phi x_1 - \Phi x_2) - \sum n_{i0}(\mu_{i0} - \mu_i),$$

where $\Phi x_1 - \Phi x_2$ is the change in the chemical potential of the sorbent, and $\mu_{io} - \mu_i$, change in the chemical potential of the bulk solution.

Figure 4 shows the concentration dependences of $\Delta\Phi$ and ΔG of the adsorption systems DAFS-25–toluene–NaX zeolite, DAFS-25–toluene–ASK silica gel, DAFS-25–toluene–activated carbon, DAFS-25–toluene–calcium carbonate, and DAFS-25–toluene–MSK silica gel. The largest values of $\Delta\Phi$ and ΔG are observed in adsorption from toluene on activated carbon, which is consistent with the excess adsorption values, and the smallest values, on calcium carbonate.

The concentration dependences of $\Delta\Phi$ and ΔG in adsorption of DAFS-25 from DIPE on NaX zeolite,

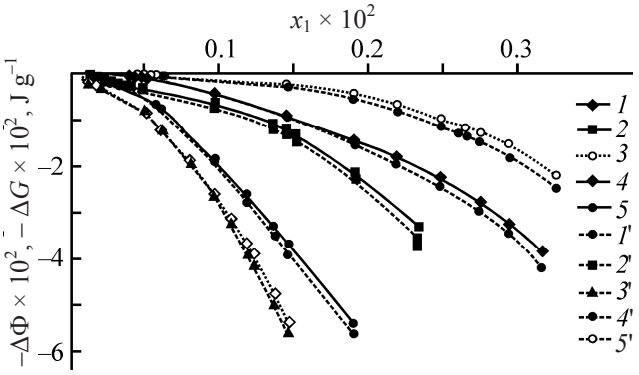

Fig. 4. Concentration dependences of the changes in the (*1*–*5*) chemical potential $\Delta\Phi$ of sorbents and (*1*'–*5*') Gibbs free energy ΔG of DAFS-25 adsorption from toluene at 298 K. (x_1) Mole fraction of DAFS-25 in solution; the same for Figs. 5 and 6. (*1*, *1*') NaX, (*2*, *2*') ASK, (*3*, *3*') AC, (*4*, *4*') $CaCO_3$, and (*5*, *5*') MSK.

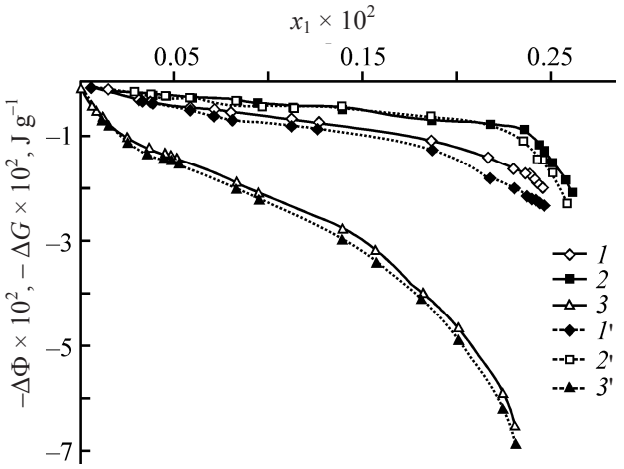

Fig. 5. Concentration dependences of the changes in the (*1*–*3*) chemical potential $\Delta\Phi$ of sorbents and (*1*'–*3*') Gibbs free energy ΔG of DAFS-25 adsorption from DIPE at 298 K. (*1*, *1*') NaX, (*2*, *2*') $CaCO_3$, and (*3*, *3*') ASK.

calcium carbonate, and ASK silica gel, shown in Fig. 5, indicate that these quantities are comparable on NaX zeolite and calcium carbonate and are considerably larger on ASK silica gel.

The thermodynamic functions allow us to trace the solvent effect more reliably. The quantities $\Delta\Phi$ and ΔG in adsorption of DAFS-25 from toluene and DIPE on ASK silica gel are plotted in Fig. 6a. They indicate that the adsorption from DIPE is higher than from toluene. On NaX zeolite, the solvent effect in adsorption of DAFS-25 is insignificant.

The concentration dependences of $\Delta\Phi$ and ΔG in adsorption of DAFS-25 on calcium carbonate (Fig. 6b) show that the adsorption is considerably more efficient

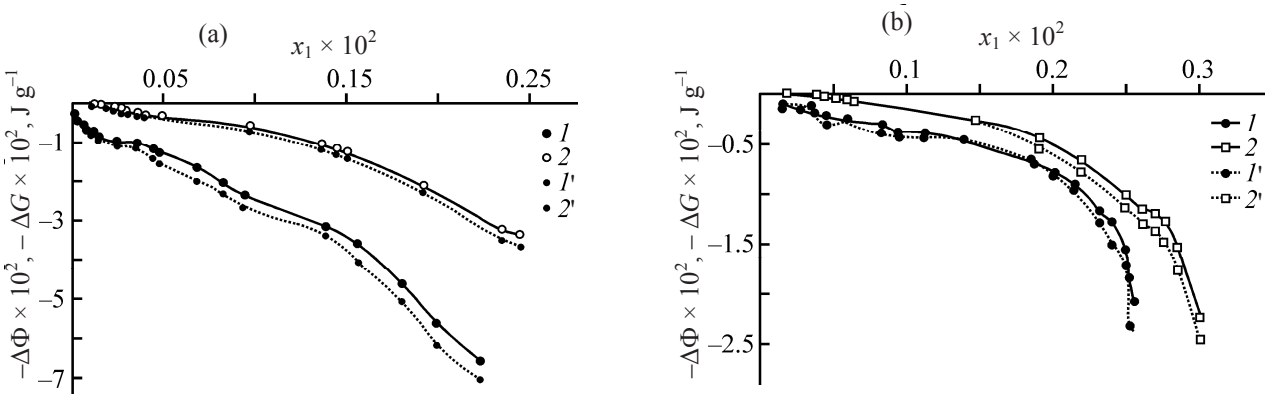

Fig. 6. Concentration dependences of the changes in the (*1*–*3*) chemical potential $\Delta\Phi$ of sorbents and (*1*'–*3*') Gibbs free energy ΔG of DAFS-25 adsorption from (*1*, *1*') DIPE and (*2*, *2*') toluene at 298 K. Adsorbent: (a) ASK silica gel and (b) $CaCO_3$.

from DIPE. The results we obtained suggest competition of the solvent with the solute for the adsorption centers of the surface. The surfaces of the adsorbents under consideration are chemically nonuniform, as they contain different centers with high and low adsorption energies and with polar and nonpolar groups.

Thus, a study of DAFS-25–solvent–adsorbent systems shows that the adsorption of DAFS-25 is the most efficient from DIPE on activated carbon. The experimental data were interpreted by the method of excess Gibbs quantities, and the concentration dependences of the chemical potential $\Delta\Phi$ and Gibbs free energy ΔG were analyzed. The character of adsorption from solutions depends not only on the properties of the bulk solution but also on the chemical nature of the surface and pore size of the sorbent.

It can be surely concluded that biologically active substances based on DAFS-25 will readily penetrate through cell membranes and, with coal used as enterosorbent, this substance and its metabolites and decay products will be sorbed or removed from the living body. The data we obtained can be used for the development of new enterosorbents with antioxidant properties, suitable for preventing poisoning with various toxicants.

CONCLUSIONS

(1) The adsorption isotherms were obtained for the systems DAFS-25–toluene–NaX zeolite, DAFS-25–toluene–ASK silica gel, DAFS-25–toluene–activated carbon, DAFS-25–toluene–calcium carbonate, DAFS-25–toluene–MSK silica gel, DAFS-25–diisopropyl ether–NaX zeolite, DAFS-25–diisopropyl ether–calcium carbonate, and DAFS-25–diisopropyl ether–ASK silica gel.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Fluidization of Cation Exchangers with Regenerating Sulfuric Acid Solution

A. V. Mamchenko and I. M. Kosygina

Dumanskii Institute of Colloid and Water Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received April 18, 2007

Abstract—Dependences of the bed expansion of cation exchangers (weakly acidic Lewatit CNP 80 and strongly acidic KU-2×8) on the flow velocity, temperature, and concentration of the regenerating sulfuric acid solution were determined. An equation describing the dependence of the bed expansion of cation exchangers on the flow velocity, temperature, and concentration of sulfuric acid, common to the two ion exchangers, was derived, which allows a priori determination of the extent of bed expansion in regeneration of cation exchangers in the fluidization mode.

DOI: 10.1134/S1070427208110098

Regeneration of cation exchangers in a fluidized bed diminishes the threat of deposition of contaminants impairing the process efficiency onto their grains [1–3]. This primarily refers to the case of regeneration of cation exchangers with sulfuric acid, in which a solid phase of calcium sulfate can be formed on grains and in the gel phase of ion exchangers [1–7].

In this context, the aim of the study was to find a generalized dependence of the bed expansion of a cation exchanger on the linear flow velocity, temperature, and concentration of a sulfuric acid solution, which is necessary for determining the process conditions but is not available from the literature.

As objects of study we chose a weakly acidic cation exchanger Lewatit CNP 80 [5, 8] and a strongly acidic cation exchanger KU-2×8 [9]. Prior to experiments, the cation exchangers were washed first with a 2 wt % sulfuric acid solution to total absence of sodium ions in the filtrate and then with distilled water.

The experimental procedure was as follows. A temperature-controlled column was charged with 200 cm^3 of a cation exchanger. The bed height was 80–82 cm, which corresponds to the minimum admissible height of the cation exchanger charge of filters according to recommendations of manufacturers of ion-exchange materials [3–5, 8]. The temperature of the regenerating solution was varied within the range 20–60°C, which broadly overlaps the temperature range in which the regeneration process is carried out. In regeneration of the strongly acidic cation exchanger, the concentration of the sulfuric acid solution was varied within the range 2–8 wt % with a step of 2%. This concentration range corresponds to recommendations for regeneration of strongly acidic cation exchangers [4, 7, 8]. Because carboxy cation exchangers show high selectivity with respect to hardness ions in the working cycle [10–12] and to hydroxonium ions in the course of regeneration, the probability of gypsum formation in the ion exchanger bed substantially grows. Therefore, dilute sulfuric acid solutions with a concentration not exceeding 0.8% are used in the water treatment technology for regeneration of the weakly acidic cation exchanger [1–6, 8, 10, 13]. In view of this circumstance, experiments with the Lewatit CNP 80 cation exchanger were carried out with the sulfuric acid concentration in solution varied within the range 0.2–0.8 wt % with a step of 0.2%. A prepared regenerating solution with a prescribed concentration was delivered from bottom to top with an SP 311/6 peristaltic pump. The feed rate was varied so that the bed expansion was within the range 10–100% relative to the initial height, with a step of 10%. The linear flow velocity of the solution supplied was determined at a fixed bed height.

Cation exchangers in the H form show lower swelling than those in the salt form [8, 14, 15]. Therefore, the experiments were performed with the H form of the cation exchangers in order to determine the maxi-

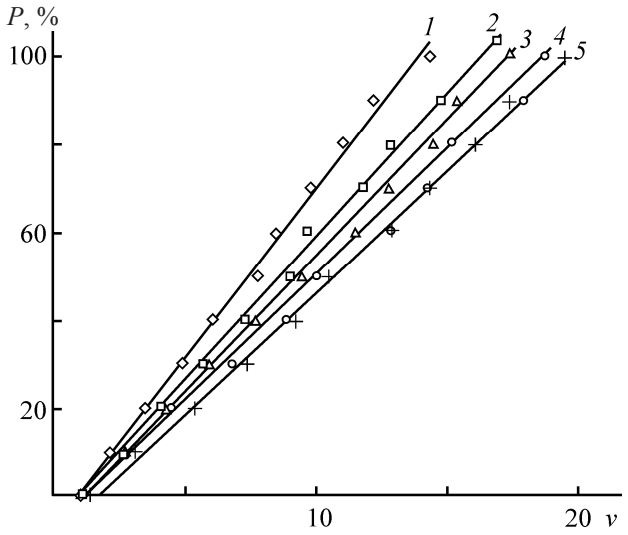

Fig. 1. Extent of bed expansion, P, of the Lewatit CNP 80 ion exchanger vs. the linear flow velocity v of the regenerating solution at different temperatures and constant concentration. Temperature, °C: (*1*) 20, (*2*) 30, (*3*) 40, (*4*) 50, and (*5*) 60.

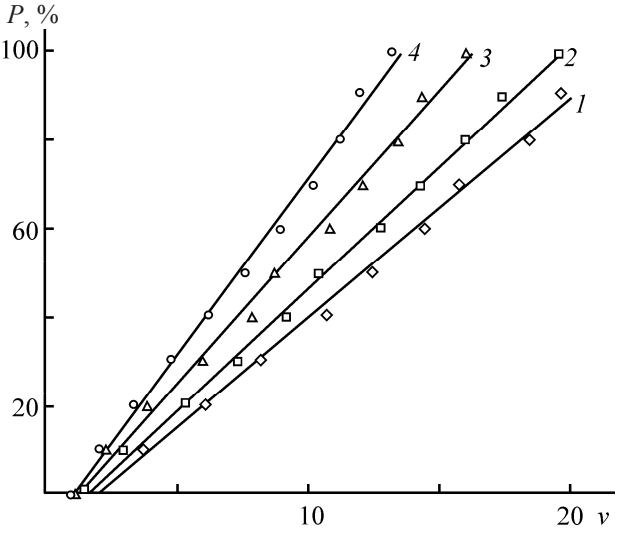

Fig. 2. Extent of bed expansion, P, of the Lewatit CNP 80 ion exchanger vs. the linear flow velocity v of the regenerating solution at different concentrations and constant temperature. Concentration, wt %: (*1*) 0.21, (*2*) 0.39, (*3*) 0.59, and (*4*) 0.81.

mum possible bed expansion in the course of their regeneration. The viscosities of sulfuric acid solutions were determined with a VPZh 2 viscometer.

Figure 1 shows as an example how the extent P of bed expansion of the Lewatit CNP 80 cation exchanger depends on the linear flow velocity v with which the regenerating solution is passed at a constant concentration c and varied temperature T. It can be seen that the extent of bed expansion of the Lewatit CNP 80 cation exchanger strongly depends on the solution temperature.

Figure 2 compares dependences of P on v for the same ion exchanger at a constant temperature T and different concentrations c. It can be seen that the extent of bed expansion of the ion exchanger also strongly depends on c. Similar results were obtained for the KU-2×8 cation exchanger.

The dependences $P = f(v)$ are affected by T and c because the densities of the solution (ρ) and ion exchanger grains (ρ_i), radius r of ion exchanger particles, and solution viscosity η vary with these parameters [16–20]. In a fixed bed, there is a free space between particles, which is characterized by the bed porosity ε_0. For identical spherical particles [18],

$$\varepsilon_0 = (V_b - V_i)/V_b = 1 - V_i/V_b = 0.44, \quad (1)$$

where V_i is the ion exchanger volume, and V_b, bed volume.

According to manufacturers' data, the ion exchangers are characterized by a comparatively uniform granulometric composition [8, 9, 21]. For example, the average diameter d_g of grains of the Lewatit CNP 80 ion exchanger is 0.48 ± 0.05 mm, and that of KU-2×8, 0.45 ± 0.1 mm [8, 9, 21]. Therefore, ε_0 was taken to be equal to the theoretical value.

In the theory [16–20], a fluidized bed is characterized by its porosity ε calculated by Eq. (1), where V_b is taken to be equal to the volume of the fluidized bed.

According to the definition of the quantities P (%) and ε, the following equation is valid:

$$P = 100(\varepsilon - \varepsilon_0)/(1 - \varepsilon). \quad (2)$$

It was shown in [16–19] that the dependence of ε on v is expressed by the Richardson–Zaki equation

$$\varepsilon^z = v/v_f, \quad (3)$$

where v_f is the linear velocity of a flow around particles (hovering velocity), and z is the exponent which is a function of the d_g/D ratio (D is column diameter) and Reynolds number $Re_t = vd_g\rho/\eta$.

The value of z for spherical particles is found using the following empirical equations [16, 19]:

$$z = 4.65 + 20d/D \text{ at } Re_t < 0.2, \quad (4)$$

$$z = (4.4 + 18d/D)Re_t^{-0.03} \text{ at } 0.2 < Re_t < 1, \quad (5)$$

$$z = (4.4 + 18d/D)\mathrm{Re}_t^{-0.1} \text{ at } 1 < \mathrm{Re}_t < 500, \quad (6)$$

$$z = 4.4\mathrm{Re}_t^{-0.1} \text{ at } 200 < \mathrm{Re}_t < 500, \quad (7)$$

$$z = 2.4 \text{ at } \mathrm{Re}_t > 500. \quad (8)$$

The calculated values of Re_t for the experimental conditions were within the range 1–80, which corresponds, according to Eq. (6), to z = 3.1–4.8.

Because a settling suspension and a fluidized bed are hydrodynamically similar [18], the velocity of a flow around particles is given by the Allen equation [22]

$$v_f = 51.53r[(\rho_i - \rho)/\rho]^{2/3}(\rho/\eta)^{1/3}. \quad (9)$$

Substitution of Eq. (9) into (3) gives the dependence of ε on v, η, ρ, r, and ρ_i:

$$\varepsilon = (v/v_i)^{1/z}\{(v/51.53r)[\rho\eta/((\rho_i - \rho)^2]^{1/3}]^{1/z}$$

$$= \{v^3\rho\eta/[51.53^3r^3(\rho_i - \rho)^2]\}^{1/3z} \equiv E. \quad (10)$$

From Eqs. (10) and (2) follows

$$P = [(E - \varepsilon_0)/(1 - E)] \times 100\%. \quad (11)$$

According to relation (11), P depends on v, η, ρ, r, and ρ_i. All the parameters, except ρ_i, are known from independent experiments, manufacturers' information [8, 9, 21], and tabulated data [23].

To find ρ_i from the dependences of $P(\varepsilon)$ on v and ρ at a given temperature T, Eq. (10) is transformed to

$$\rho_i = [\rho_1\rho_2(v_2^3\eta_2 - v_1^3\eta_1) + (\rho_1 - \rho_2)(v_1^3v_2^3\eta_1\eta_2\rho_1\rho_2)^{1/2}]$$

$$\times (v_2^3\eta_2\rho_2 - v_1^3\eta_1\rho_1)^{-1}, \quad (12)$$

where subscripts 1 and 2 correspond to two solutions with different concentrations at the same temperature.

Equation (12) was derived on the assumption that ρ_i and r are independent of c at small variations of this parameter. In addition, account was taken of the fact that, according to Eq. (10), equal values of ε and, consequently of P, too, are obtained at different v with regenerating solutions with two different concentrations c, because η and ρ of these solutions are not the same.

Equation (12) was used to calculate ρi from data obtained at close concentrations c and the same temperature T. The resulting values are close to those provided by the manufacturers [8, 21].

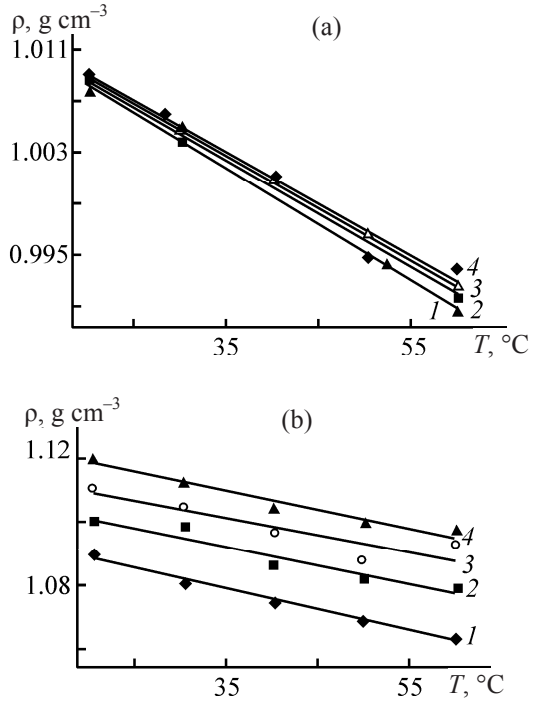

Fig. 3. Density ρ of (a) Lewatit CNP 80 and (b) KU-2×8 cation exchangers vs. temperature T of the sulfuric acid solution. Concentration, wt %: (a) (*1*) 0.21, (*2*) 0.39, (*3*) 0.59, and (*4*) 0.81; (b) (*1*) 2.06, (*2*) 4.04, (*3*) 5.93, and (*4*) 8.26.

Figures 3a and 3b shows how ρ_i varies with T. It can be seen that the dependences of ρ_i on T at different c almost coincide for the Lewatit CNP 80 cation exchanger and are markedly different for KU-2×8. Apparently, this is so because the sulfuric acid concentrations and the step of their variation differ by an order of magnitude for these two cation exchangers. The dependences are linear and are described by the equation

$$a\rho_i = dT + f. \quad (13)$$

The table lists values of the constants d and f of these dependences. It can be seen that the constants for Lewatit CNP 80 coincide at different c within the determination errors $S(d)$ and $S(f)$ (S is the standard deviation). For the KU-2×8 ion exchanger, the constant f depends on c, whereas d is constant. The fact that the density of the KU-2×8 ion exchanger increases with c is due to the nonexchange sorption of the electrolyte [24]. In the case of the Lewatit CNP 80 ion exchanger, such an effect is insignificant because of the small values of c.

If ρ_i is known, all the dependences of P on v can be represented as a generalized curve because the parame-

Constants of Eq. (13) describing the dependence of the ion exchanger density on the temperature of the regenerating solution

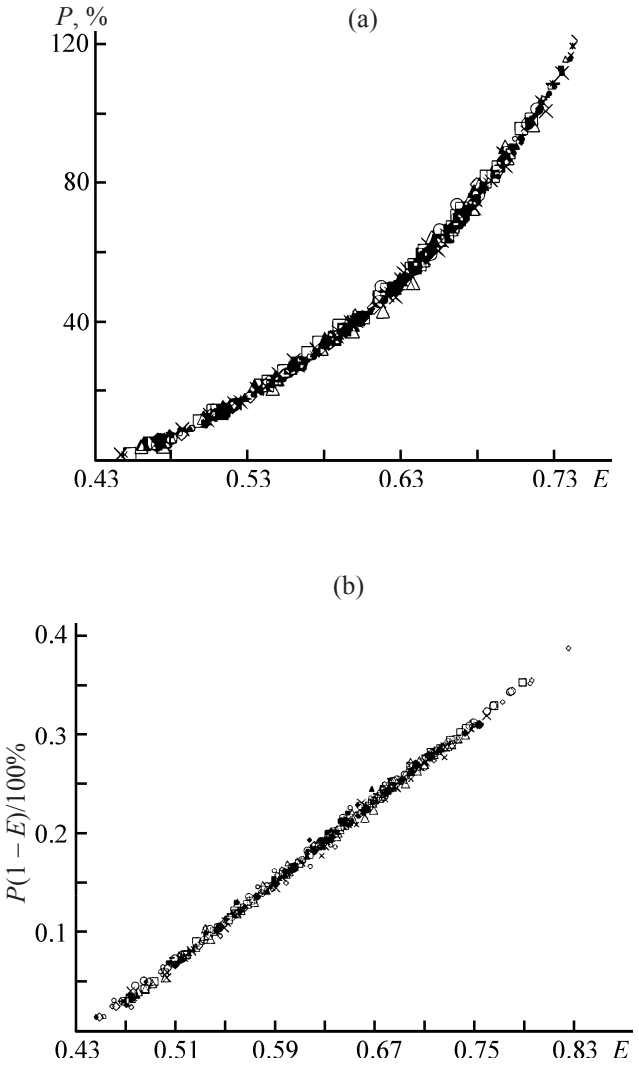

Fig. 4. Dependences of (a) P and (b) $P(1 - E)/100\%$ on E, calculated by Eq. (11). Bed expansion of a cation exchanger.

ter E in Eq. (10) can be a priori calculated. A dependence of this kind is shown in Fig. 4a. It can be seen that the dependences for the two ion exchangers merge into a single curve, in agreement with the basic assumptions of the theory.

According to Eq. (11), the dependence of $P(1 - E)/100\%$ on E should be linear and must intersect the ordinate axis at a point ε_0 at its theoretical value of –0.44, with the slope rate of the straight line equal to unity. As follows from Fig. 4b, this requirement of the theory is, indeed, satisfied. It was found from the dependence in Fig. 4b that $\varepsilon_0 = 0.43 \pm 0.003$, slope rate is 0.987 ± 0.004, and $R^2 = 0.9975 \pm 0.0011$.

CONCLUSIONS

(1) The density of an ion exchanger strongly depends on the temperature of the regenerating solution and is independent of the solution concentration at its minor variations. When the range within which the concentration varies is extended by an order of magnitude, the density of the ion exchanger grains changes only slightly.

(2) Equation (11) satisfactorily describes the dependence of the bed expansion of an ion exchanger on parameters of the regenerating solution. Consequently, if the flow velocity, temperature, concentration, density, and viscosity of the regenerating sulfuric acid solutions are known, together with dependences of the ion exchanger density on temperature and solution concentration, the bed expansion of the ion exchanger can be found in relation to the linear flow velocity of the regenerating solution.

(3) Use of this equation for calculating the bed ex-

pansion of the ion exchanger will enable a priori determination of the regeneration mode of ion exchangers in a fluidized bed, which is necessary for industrial implementation of this technology.

Abstract—Sorption of phenol on cellulose from water–dimethyl sulfoxide and water–acetonitrile mixtures was studied. Different shape of the isotherms of phenol sorption from these mixtures is due to different character of phenol solvation in different concentration regions of water–dimethyl sulfoxide and water–acetonitrile mixtures.

DOI: 10.1134/S1070427208110104

Study and prediction of the properties of systems consisting of a polymer and an aqueous–organic solvent is necessary for solving problems related, in particular, to the development of sorbents based on composites of natural and synthetic polymers for water treatment to remove aromatic hydrocarbons and petroleum products [1–4].

To understand the nature of the interaction of low-molecular-weight liquids with a polymer, it is necessary to elucidate the physicochemical features of the interaction of a polymer with components of an aqueous–organic solution and the correlation of these features with the solution structure. The solvation effect shows a nonlinear dependence on the component ratio, owing to the fact that the solvation shell around a solute molecule or around functional groups of a polymer differs in the composition from the bulk of the binary solvent. Deviations from a thermodynamically ideal binary system arise when molecules of water and organic solvent are mixed nonhomogeneously on the level of clusters. Hence, in such nonideal binary systems the preferential solvation occurs more readily. The molecular cluster formation in binary solvents determines the solvation of solutes. This preferential solvation may be a key moment in sorption on a polymer.

In this study we examined the sorption of phenol on cellulose from water–dimethyl sulfoxide (DMSO) and water–acetonitrile (AN) mixtures.

The choice of the solvents (DMSO, AN) is governed by the fact that their mixtures with water are examples of two nonideal binary systems with different properties. It can be expected that the solvation of a solute (e.g., phenol) in these systems would be essentially different.

The shape of the composition dependences of the physicochemical properties of water–DMSO and water–AN binary mixtures indicates that the systems strongly deviate from the ideal behavior owing to various intermolecular interactions.

Certain information on intermolecular interactions in binary systems is furnished by deviations of the partial vapor pressures of mixture components over the solution from Raoult's law. If molecules in a mixture interact less strongly than those in a pure substance, the partial pressures over the solution have positive deviations from Raoult's law. It should be noted that, in the range of acetonitrile mole fractions $0.5 < x_{AN} < 0.8$, the partial pressure of both components is virtually independent of the concentration. This means that each of the molecules of the mixture interacts with molecules of the same kind more efficiently than with molecules of the other kind. This situation is possible if water molecules form three-dimensional hydrogen-bonded clusters surrounded by acetonitrile molecules. The AN molecules behave as a "solvent" and can be oriented toward water clusters owing to dipole–dipole interactions [5].

The water–DMSO system belongs to systems in which the partial pressure of one of the components (water) shows negative deviations from Raoult's law and the partial partial of DMSO shows sign-variable deviations. The latter fact suggests not only the occurrence of complex intermolecular interactions in the water–DMSO system but also variation of the mean size of associates with an increase in the DMSO mole fraction.

The cluster formation in water–DMSO and water–AN systems was studied in [5–9] using a special mass-spectrometric procedure of direct cluster isolation from a solvent mixture. The effect of additions of various substances, e.g., phenol, on the cluster composition was also examined. It is believed in [5–9] that, in water–DMSO and water–AN mixtures, phenol shows a stronger tendency to interact with the clusters already formed in the solution than with individual molecules.

According to the data of these authors, in the water–DMSO system water clusters exist only up to a concentration $x_{DMSO} < 0.07$. At $0.07 < x_{DMSO} < 0.1$, the size of water clusters sharply decreases and that of DMSO clusters increases. The same trend, though less pronounced, is observed in the range $0.1 < x_{DMSO} < 0.28$ [6]. The hydrogen bond network of water is broken, and DMSO exists in the form of dimers or "small" clusters in which the DMSO molecules are held together in the antiparallel fashion by S=O dipole–dipole interactions [6, 10]. In such dimers, the hydrophobic CH_3 groups are located on the periphery, and DMSO clusters exhibit hydrophobic properties. The hydrophobicity of DMSO in this concentration interval is confirmed by X-ray diffraction analysis [10]. In the range $0.28 < x_{DMSO} < 0.6$, the size of DMSO clusters increases, and at $x_{DMSO} > 0.6$, DMSO molecules form clusters of the same structure as in pure DMSO.

In the water–AN system, on adding AN into water in the concentration range $0 < x_{AN} < 0.2$, the number of free water molecules considerably decreases. In other words, the fraction of water clusters increases with an increase in the AN concentration. Wakisaka et al. [5, 8] believe that addition of AN to water stabilizes the hydrogen bond network of water, increasing the lifetime of large clusters. At $x_{AN} > 0.2$, a large number of AN molecules stabilize water clusters, restricting the thermal motion of water molecules owing to a strong bond network. Water clusters exist up to AN mole fraction of ~0.8, after which the hydrogen bond network is broken. At $x_{AN} > 0.8$, AN clusters consisting only of AN molecules are formed [9].

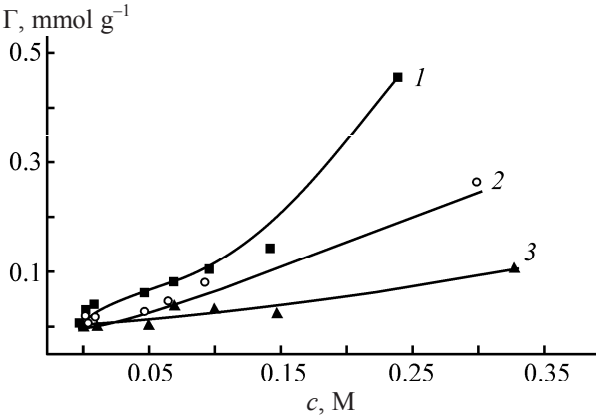

Fig. 1. Isotherms of phenol sorption Γ from water at various temperatures. (*c*) Phenol concentration; the same for Figs. 2 and 4. *T*, K: (*1*) 283, (*2*) 298, and (*3*) 313; the same for Figs. 2 and 4.

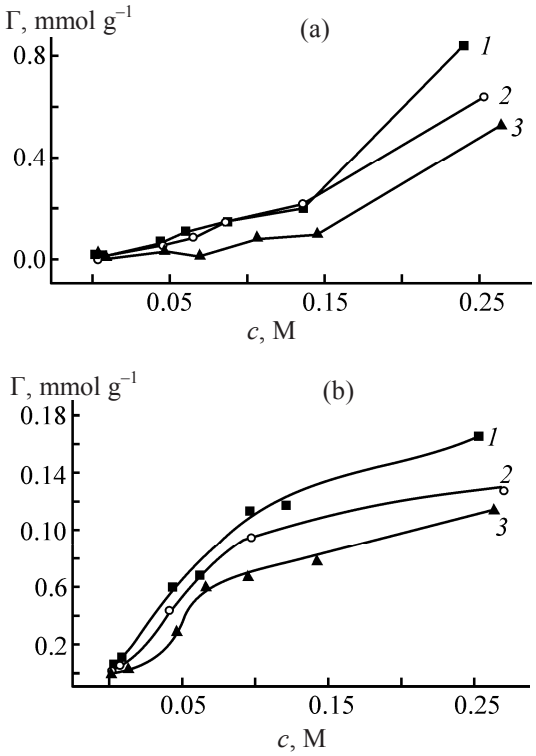

Fig. 2. Isotherms of phenol sorption Γ from water–DMSO solutions at various temperatures. x_{DMSO}: (a) 0.05 and (b) 0.3.

EXPERIMENTAL

Isotherms of phenol sorption from water and from water–DMSO and water–AN mixtures were obtained by the isothermal saturation method in the phenol concentration range 5–350 mM at 283, 288, and 313 K. To

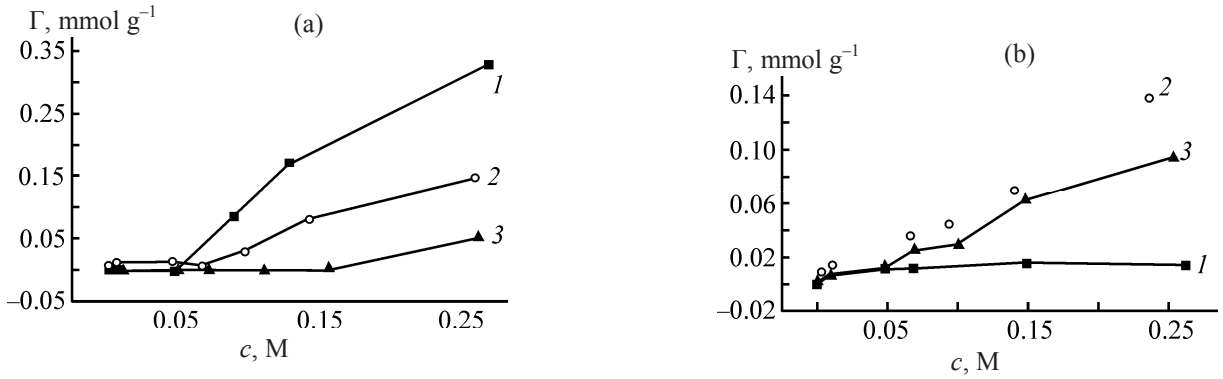

Fig. 4. Isotherms of phenol sorption from water–AN solutions at various temperatures. x_{AN}: (a) 0.05 and (b) 0.3.

a 0.8-g adsorbent sample, we added 10 ml of a phenol solution and thermostated for 48–56 h. The phenol concentration in solution before and after the adsorption was determined spectrophotometrically at λ = 271 nm. The adsorption was calculated by the formula

$$\Gamma = (c_0 - c_{eq})V/m,$$

where c_0 and c_{eq} are the initial and equilibrium concentrations of phenol (M); V, solution volume (l); and m, sample weight (g).

As adsorbent we used sulfite wood cellulose [GOST (State Standard) 3914–89].

The isotherms of phenol sorption from water and water–DMSO mixtures at three temperatures are shown in Figs. 1 and 2. It can be seen that the shapes of the sorption isotherms at x_{DMSO} = 0.05 and x_{DMSO} = 0.3 are different. At x_{DMSO} = 0.05, the shape of the sorption isotherm is similar to that obtained in pure water. The sorption value is approximately two times higher than from pure water. The isotherms of phenol sorption from the water–DMSO mixture at x_{DMSO} = 0.3 are curves with saturation. Presumably, different shape of the isotherms is due to different character of the phenol solvation in these concentration ranges of the water–DMSO mixture.

Indeed, as shown in [6], phenol at these DMSO concentrations is solvated differently. At x_{DMSO} = 0.05, phenol is mainly solvated by water clusters, and at x_{DMSO} = 0.3, by DMSO clusters, which leads to different shapes of the isotherms.

It can be seen from the previously obtained [11] individual isotherms of water and DMSO sorption on cellulose that, in the concentration range up to x_{DMSO} ~0.1, the sorption of water is larger than that from pure water (Fig. 3). The presence of a maximum at x_{DMSO} ~0.1 is associated with the existence of DMSO in the form of hydrophobic dimers. In the same concentration interval, the phenol sorption is larger than from pure water. Presumably, phenol is sorbed in the hydrated form.

A more complex pattern is observed in sorption of phenol from water–AN mixtures (Fig. 4). Sorption of

phenol from a water–AN mixture at $x_{AN} = 0.05$ decreases with increasing temperature, and at $x_{AN} = 0.03$ the temperature dependence of the sorption is anomalous: At 283 K, sorption of phenol is smaller than at 298 and 313 K.

In the concentration range $0 < x_{AN} < 0.2$, phenol mainly interacts with water clusters [8]. At $x_{AN} > 0.2$, water clusters and phenol are solvated by AN molecules, so that the water–phenol interaction is hindered. With an increase in temperature, more active thermal motion destroys the solvation shell consisting of AN molecules, and the water–phenol interaction becomes possible. Specifically this fact is responsible for an increase in the phenol sorption on cellulose at 298 K. Further increase in the temperature to 313 K leads to a decrease in the phenol sorption, which is due to the overall exothermic character of the sorption. A combination of these two factors, break of the solvation shell of molecules being adsorbed (determined by structural organization of the solution) and exothemic character of the sorption, leads to appearance of a sorption maximum at a definite temperature.

CONCLUSIONS

(1) Sorption of phenol on cellulose from water–dimethyl sulfoxide and water–acetonitrile binary mixtures is mainly determined by the hydration of phenol.

(2) Introduction of an organic component can lead both to an increase in the phenol sorption relative to the sorption from water, as in the case of the water–dimethyl sulfoxide mixture ($x_{DMSO} = 0.05$), and to a decrease in the sorption, as in the case of water–acetonitrile mixtures.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Colloid-Chemical Properties of Sodium and Calcium Salts of α-Alkyl-Substituted Dicarboxylic Acids

V. A. Ivanova, G. V. Mitrofanova, and T. N. Perunkova

Mining Institute, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received January 16, 2008

Abstract—Surface activity and micelle formation ability in aqueous solutions of Na and Ca salts of α-alkyl-substituted dicarboxylic acids was studied in relation to the length of the hydrocarbon radical, total length of the hydrocarbon chain of the molecule, and mutual position of carboxy groups. The results obtained are compared with properties of saturated monocarboxylic and unsaturated oleic acids.

DOI: 10.1134/S1070427208110116

Previous studies have demonstrated the possibility of using α-alkyl-substituted dicarboxylic acids (DAs) as reagents-collectors for flotation of a number of sulfide-free ores. It was shown that the collecting properties of DAs depend on the composition and structure of a molecule, and primarily on the mutual position of carboxy groups. The observed changes are due to differences in their physicochemical and surface properties manifested both in the liquid phase of the flotation sludge and at water–air and water–mineral particle interfaces.

The capacity of surfactants for association in the solution bulk, determined by the critical micelle concentration (CMC), is an important parameter of colloid solutions and can characterize their capacity for structuring at the water–mineral interface in the formation of an adsorption hydrophobic layer. Properties of branched DAs are poorly understood. The available published evidence about their surface activity and micelle formation are limited to data for Na salts of DAs with 1,1- 1,2-, and 1,3-positions of carboxy groups [3, 4]. The CMC values and the relationships based on these values are contradictory and widely vary between different authors.

The aim of this study was to examine the surface activity and micelle formation ability in aqueous solutions of Na and Ca salts of a wide variety of DAs, which will make it possible to understand processes occurring in the liquid phase of the flotation sludge and to substantiate the choice of DAs with the optimal structure as collectors.

EXPERIMENTAL

Dicarboxylic acids (Table 1) of the general formula $HOOC–(CH_2)_{m-1}–CHR–COOH$ (where R is an alkyl radical, from $C_3H_7–$ to $C_{18}H_{37}–$, and m = 1–11) were synthesized by the known methods [5, 6], twice recrystallized from benzene, and identified by acid–base titration and melting points. The content of the main substance, determined by TLC and elemental analysis, was no less than 97%. The properties of DAs were compared with those of monocarboxylic saturated acids (lauric, myristic, palmitic, and stearic) and unsaturated (oleic) acid of chemically pure grade.

Solutions of Na and Ca salts of the acids mentioned above were prepared with distilled water. The Na salts were synthesized by saponification of the acids with NaOH, followed by dilution to required concentrations. Solutions of the Ca salts were prepared immediately before measurements by mixing equivalent amounts of a Na salt of the acid and $CaCl_2$ in the course of 1 min and then were thermostated at 30 or 40°C for 3 min. To prevent hydrolysis of the salts, the pH values of the solutions were maintained at 10.2–10.5.

The surface activity of the DA salts under study and the micelle formation in aqueous solutions were evaluated using isotherms of surface tension σ, measured by the Du Nouy method at solution temperatures of 30 and 40°C. As a result, the CMC values were found, adsorption isotherms were constructed, and the area per molecule of an acid in the limiting adsorption layer

Table 1. Composition and properties of the DAs under study

Acid	R	C_{n-m}-DA[a]	mp, °C	Acid number, mg KOH/g substance	
				calculated	found
Dodecylmalonic	$C_{12}H_{25}$	C_{13-1}-DA	115–117	412.0	402.0

[a] n is the number of carbon atoms in the total hydrocarbon chain of DA and m, the number of carbon atoms between carboxy groups.

at the water–air interface was calculated by the Shishkovskii equation [7].

It can be seen from the surface tension isotherms of solutions of Na salts of α-alkylsuccinic acid (C_{n-2}-DA), shown in Fig. 1a and characteristic of all the other DAs, that the run of the curves is typical of solutions of micelle-forming surfactants: as the concentration is raised, the surface tension first decreases and then, after the CMC is reached, takes a constant value. As in the case of other homologous series of DAs (C_{n-1}, C_{n-4}, C_{n-11}), the surface activity steadily increases as the alkyl radical R in the DA molecule becomes larger, and the total hydrocarbon chain, longer.

The surface tension isotherms of aqueous solutions of Na salts of DAs with the number of carbon atoms in the total hydrocarbon chain close to, or somewhat exceeding that in the molecule of oleic acid (C_{17}), shown in Fig. 1b, demonstrate that the Na salts of DA have at

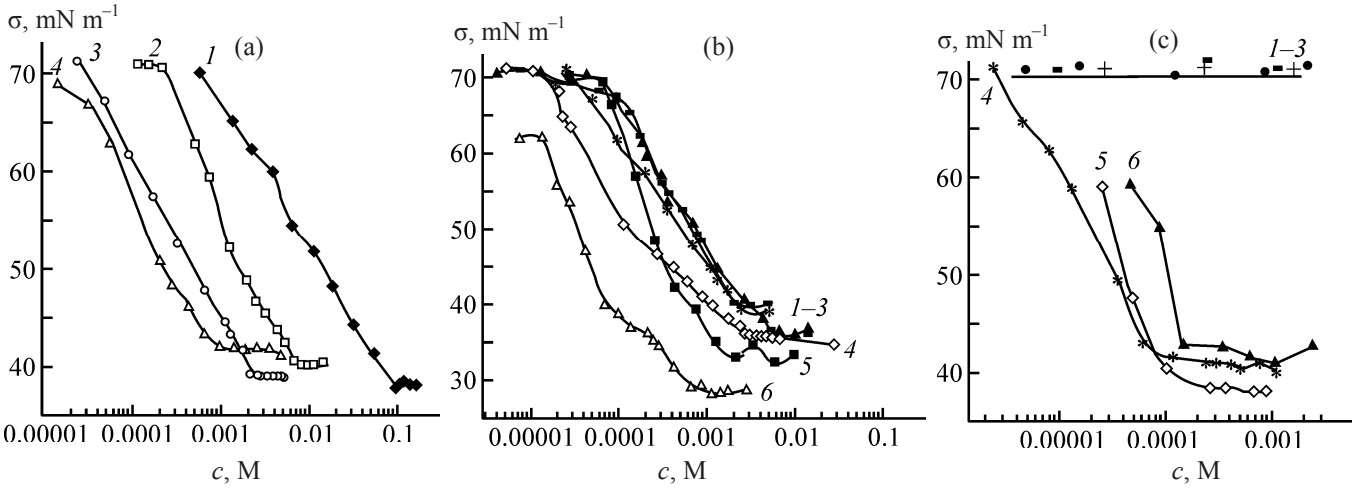

Fig. 1. Isotherms of the surface tension σ of aqueous solutions of sodium salts of (a) alkylsuccinic and (b) carboxylic acids and (c) of calcium salts of carboxylic acids at 30°C and pH 10.2–10.5. (c) DA salt concentration. Acid: (a) (*1*) C_{10-2}-DA, (*2*) C_{16-2}-DA, (*3*) C_{18-2}-DA, and (*4*) C_{20-2}-DA; (b) (*1*) C_{17-1}-DA, (*2*) C_{17-3}-DA, (*3*) C_{18-2}-DA, (*4*) C_{19-11}-DA, (*5*) C_{18-4}-DA, and (*6*) oleic; (c) (*1*) C_{17-1}-DA, (*2*) C_{18-2}-DA, (*3*) C_{17-3}-DA, (*4*) oleic, (*5*) C_{21-7}-DA, and (*6*) C_{18-4}-DA.

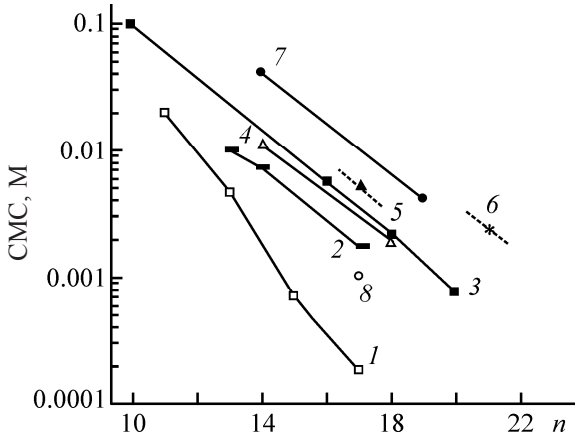

Fig. 2. Semilog plots of CMC vs. the total number n of carbon atoms in the hydrocarbon chain of sodium salts of mono- and dicarboxylic acids at (*1*) 40 and (*2–8*) 30°C, pH 10.2–10.5. Carboxylic acid: (*1*) $C_nH_{2n+1}COOH$, (*2*) C_{n-1}-DA, (*3*) C_{n-2}-DA, (*4*) C_{n-4}-DA, (*5*) C_{n-3}-DA, (*6*) C_{n-7}-DA, (*7*) C_{n-11}-DA, and (*8*) oleic.

low concentrations a noticeably weaker surface activity than sodium oleate. The minimum value of the surface tension, reached in this case, is 27–28 mN m^{-1} for sodium oleate and 38–40 mN m^{-1} for Na salts of DAs.

The CMC values found from the surface tension isotherms for Na salts of DAs are shown, in comparison with monocarboxylic acids, in Fig. 2 in the form of the known dependence on the number n of carbon atoms in the hydrocarbon chain: $\log CMC = A - Bn$. It can be seen that an increase in the length of the total hydrocarbon chain in the homologous series of DA leads, as in the case of monocarboxylic acids, to a steady decrease in the CMC.

However, the CMC of the Na salt of a DA substantially exceeds that of the Na salt of the monocarboxylic acid with the same number of carbon atoms in the hydrocarbon chain and depends on the distance between the carboxy groups. As the distance between COOH groups in the DA molecules increases within the range 1–11 carbon atoms, the micelle-forming ability passes through a maximum value presumably corresponding, in a series of acids with the same total hydrocarbon chain, to a position of the second carboxy group in the middle of the chain (Fig. 2). In this case, the carbon chains between the COOH groups and the alkyl substituent R become comparable and the molecule is branched to the greatest extent.

Table 2. Parameters A and B of the dependence $\log CMC = A - Bn$ for Na salts of carboxylic acids

Acid	A		B	
	30°C	40°C	30°C	40°C
$C_nH_{2n+1}COOH$	–	2.18	–	0.35
C_{n-1}-DA	0.56	0.78	0.20	0.20
C_{n-2}-DA	1.09	1.28	0.21	0.22
C_{n-4}-DA	0.71	0.88	0.19	0.20
C_{n-11}-DA	1.40	1.37	0.20	0.20

The DA structure can be regarded as a result of substitution of a hydrogen in the hydrocarbon chain of a saturated monocarboxylic acid with a carboxy group. In this regard, the effect of a substitution of this kind is the most pronounced for high-molecular-weight saturated acids: the solubility of Na salts of DAs steeply increases and their micelle-forming ability decreases. Comparison of the CMC of Na salts of mono- and dicarboxylic acids with 17 carbon atoms in the total chain shows (Fig. 2) that the effect of the second carboxy group on micelle formation exceeds that of the unsaturated bond (for the example of oleic acid).

The parameters A and B of the semilogarithmic dependence $\log CMC = A - Bn$, calculated from experimental data to be 2.18 and 0.35, respectively, for Na salts of dicarboxylic acids (Table 2), are in agreement with published data [3, 4]. The value obtained for the parameter B for homologous series of DA is 1.5 times lower, which is graphically manifested in the smaller slope of the $\log CMC = f(n)$ straight lines (Fig. 2). This behavior agrees with the theoretical concept about the effect of polar substituents in hydrocarbon chains of surfactants on their micelle-forming ability [4]. A shift of the carboxy group along the hydrocarbon chain of DA does not lead to any noticeable change in the parameter B.

The considerable difference of the CMC obtained for Na salts of some C_{n-1}-, C_{n-4}-, and C_{n-3}-DAs from published data [3] is presumably due to the experimental conditions and, in particular, to the pH of the solutions under study. For example, according to the data obtained, a decrease in pH from 10.2–10.5 to 9.0–9.5 causes an order-of-magnitude decrease in the CMC, which suggests noticeable hydrolysis of the salts.

The areas per DA molecule in the limiting adsorption layer at the interface are listed in Table 3. It can be seen that these values are close for DA molecules of the same homologous series (C_{n-1}-, C_{n-2}-, and C_{n-4}-DA). The exception is provided by members of the homologous series C_{n-2}-DA and C_{n-11}-DA, which have

Table 3. Area per molecule of alkyldicarboxylic acid in the surface layer

Na-DA	Area per molecule, Å^2
C_{13-1}-DA	42.0
C_{14-1}-DA	42.7
C_{17-1}-DA	43.7
C_{10-2}-DA	59.5
C_{16-2}-DA	49.5
C_{18-2}-DA	50.7
C_{20-2}-DA	49.5
C_{17-3}-DA	52.96
C_{14-4}-DA	52.1
C_{18-4}-DA	54.4
C_{21-7}-DA	59.3
C_{14-11}-DA	56.1
C_{19-11}-DA	62.4

Table 4. CMC of Ca salts of carboxylic acids

Acid	CMC, M (50°C)
Oleic	0.75×10^{-4}
C_{14-4}-DA	8.0×10^{-4}
C_{18-4}-DA	1.4×10^{-4}
C_{21-7}-DA	1.2×10^{-4}
C_{19-11}-DA	3.2×10^{-4}

a small alkyl substituent (C_3H_7, C_8H_{17}) and form loose adsorption layers because of the weak hydrophobic interaction. The area for DA molecules with close sizes of the alkyl substituent (C_{14-1}-, C_{16-2}-, C_{17-3}-, C_{18-4}-, and C_{21-7}-DA) grows with the distance between the functional groups. This behavior and comparison with the areas for monocarboxylic acids [7] indicate that DAs have the following molecular orientation in the adsorption layer: R is oriented perpendicularly to the interface, both the functional groups face the aqueous phase, and the hydrocarbon chains between these groups are parallel to the adsorbing surface. The increase in the area per C_{21-7}- and C_{n-11}-DA molecules with respect to C_{n-4}-DA is substantially smaller than it would be expected. Presumably, another possible molecular orientation takes place in these cases: similar to that of high-molecular-weight α,ω-DAs [8] in which the hydrocarbon chains between carboxy groups are bent and lie above the interface.

Figure 1c shows surface tension isotherms of aqueous solutions of Ca salts of oleic acid and DAs with comparable hydrocarbon chains, but different distances between carboxy groups. It can be seen that solutions produced by equivalent mixing of solutions of Na salts of DAs with 1,1-, 1,2-, and 1,3-positions of carboxy groups with $CaCl_2$ exhibit zero surface activity (curves *1–3*). This is accounted for by formation, similarly to first members of the homologous series of α,ω-DAs (from oxalic to glutaric), of poorly soluble complex compounds of cyclic structure with ions of alkaline-earth metals [9].

Similarly to calcium oleate, Ca salts of DAs with more than three carbon atoms between carboxy groups (C_{18-4}-, C_{21-7}-, and C_{19-11}-DA) are surface-active (Fig. 1c, curves *4–6*), with the CMC values (Table 4) an order of magnitude smaller than the CMC for their Na salts (Fig. 2).

It should be noted that opalescence was observed for each Ca salt at a premicellar concentration, and a precipitate was formed at concentrations exceeding CMC.

CONCLUSIONS

(1) For all the homologous series of dicarboxylic acids considered in the study, the parameter *B* in the logarithmic dependence of the critical micelle concentration of Na salts of α-alkyl-substituted dicarboxylic acids on the number of carbon atoms in the total hydrocarbon chain of the molecule, dependent on the decrease in the free energy per methylene group in micelle formation, is 1.5 times smaller than that for the series of saturated monocarboxylic acids.

(2) Presence of a second carboxy group in the saturated hydrocarbon chain of dicarboxylic acids makes lower the micelle-formation ability of their Na salts, compared with monocarboxylic acids.

(3) The extent of this decrease depends on the position of the carboxy group nonmonotonically, with the maximum for dicarboxylic acids with the same total chain length corresponding to the middle position of the COOH group.

(4) Presence of a second carboxy group in the hydrocarbon chain of a saturated carboxylic acid leads to a stronger decrease in the micelle-forming ability than does the unsaturated bond.

(5) Ca salts of dicarboxylic acids with 1,1–1,3-positions of carboxy groups exhibit zero surface activity at the water–air interface. At 1,4–1,11-positions of carboxy groups, Ca salts are surface-activity. Their critical micelle concentration is an order of magnitude

lower than that of the Na salts of these acids and exceeds that of calcium oleate by a factor of 2–4.

Abstract—The recovery of platinum(II) and platinum(IV) chloro complexes from hydrochloric acid and chloride solutions with a new heterochain S,N-containing sorbent, MITKhAT, was studied. The suggested mechanism of formation of platinum(II) mercapto–thio ether complexes in the course of sorption was confirmed by DFT calculations. The results of group and selective recovery of platinum metals with MITKhAT sorbent from simulated and real industrial solutions are reported.

DOI: 10.1134/S1070427208110128

Granulated and fibrous complexing S,N-containing sorbents have been widely used in the past decades for separation, preconcentration, and determination of platinum and other platinum metals (PMs) [1–3]. Early studies on the use of such sorbents, in particular, of thioamidated copolymers of cellulose with acrylonitrile (Mtilon-T) and of vinyl alcohol with acrylonitrile (MSPVS), were discussed in reviews [2–5].

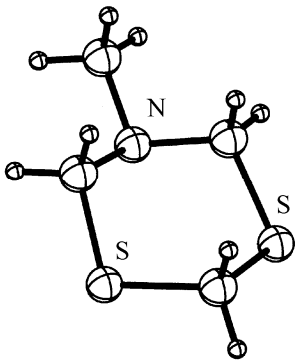
For improving the procedures for sorption preconcentration of PMs, it is extremely important to know the composition and structure of complexes formed by interaction of platinum metals with functional groups of sorbents as polymeric ligands, and also to understand the effect exerted by the polymeric matrix of the sorbents on their kinetic and capacity characteristics [2, 3, 5]. As S,N-containing functional groups grafted to matrices of various sorbents used for sorption recovery of PMs, we tested diethyldithiocarbamate, thiourea, thiosemicarbazide, 8-mercaptoquinoline, and other groups. The chemical transformations occurring in the course of sorption recovery of Pd(II) with such sorbents are discussed in [6].

It was found [7] that the sorption recovery of platinum(II) chloro complexes with Tiopan-2 sorbent, which is a copolymer of acrylonitrile with grafted polyglycidyl methacrylate, containing diethyldithiocarbamate groups, is accompanied by formation in the fiber phase of platinum complexes *cis*-$[Pt(RS_2CN(C_2H_5)_2)_2Cl_2]$ in which the polymeric ligand is coordinated with Pt via sulfur atom. In sorption of platinum(II) chloro complexes with Tiopan-6 sorbent, formation of the complex *cis*-$[Pt(Rpy)_2Cl_2]$ was detected, in which the 8-mercaptoquinoline group acts as a monodentate ligand coordinated with Pt(II) via N atom. It should be noted that the reaction of platinum(II) chloro complexes with a monomeric ligand, sodium 8-quinolinethiolate (QuinS), yields bischelate complexes of the composition $[Pt(QuinS)_2]$ [8].

A study of the sorption of platinum(II) and platinum(IV) chloro complexes from hydrochloric acid and chloride solutions with a fibrous sorbent based on polyacrylonitrile modified with thiosemicarbazide (RThscH) (Glipan-1) showed that the complex $[(RThscH)_2PtCl_2]$ is formed in the fiber phase, with the polymeric ligand coordinated to the platinum atom in the bidentate fashion via N and S atoms [9, 10]. In the process, Pt(IV) is reduced to Pt(II) [10].

S,N-Containing water-soluble polyelectrolytes were suggested for the recovery of a series of platinum metals, including Pt(II) in the form of chloro complexes [11]. These agents allow quantitative recovery of $[PtCl_4]^{2-}$ from hydrochloric acid and chloride solutions containing 1–50 mM platinum. The polyelectrolytes interact with platinum(II) chloro complexes mainly

by the ion-exchange mechanism, and the forming sparingly soluble compounds have the composition $(R_4N)_2[PtCl_4]$. The possible formation of a sparingly soluble complex $[Pt(R_2S)_2Cl_2]$ in which the polymeric ligand is coordinated via S atom was noted [11].



Thus, the above examples show that the interaction of platinum complexes with S,N-containing sorption materials in the course of sorption recovery depends on the nature of functional groups and matrix of the sorbent.

The preconcentration of platinum metals from process solutions and secondary raw materials for the subsequent determination of these elements by physical methods is performed, in particular, with heterochain polymeric sorbents. The matrix of such sorbents contains S and N atoms forming polymer chains in which the sorption centers and the matrix are a single whole [12–14]. Among such sorbents, the most known are those prepared by polycondensation of piperazine with formaldehyde and hydrogen sulfide [12, 13] and those containing aminoethylenepiperazine and dimethyl sulfide groups [14].

New sorbents of the polycondensation type, containing in the backbone alternating methylene and methylene sulfide groups and tertiary nitrogen atoms, have been prepared recently [15, 16]. It was found that the new S,N-containing sorbents allow recovery of microamounts of platinum group metals, gold, and silver at room temperature from solutions in dilute mineral acids in the presence of macroamounts of nickel, iron, and copper [16–19]. Procedures were developed for sorption preconcentration of platinum metals with a new S,N-containing sorbent from solutions containing macrocomponents of secondary and artificial raw materials, with the subsequent determination of PMs by atomic absorption spectrometry [16, 17]. Thiomethylation of amines as a procedure for preparing S,N-containing heterochain oligomers and polymers usually yields a mixture of products. Samples of new heterochain S,N-containing polymers KDM-2 and KPU-2 are commercially produced and used in practice [17], but for studying complexing properties of the sorbents it is preferable to use low-molecular-weight compounds.

This study concerns sorption recovery of platinum(II) and platinum(IV) chloro complexes from hydrochloric acid and chloride solutions with MITKhAT low-molecular-weight S,N-containing oligomer [15–18].

The MITKhAT sorbent, aminomethylene sulfide, contains in its chain alternating methylene and methylene sulfide groups and tertiary nitrogen atoms (~12 wt % N and ~47 wt % S). Its molecular weight is 135. It is a colorless crystalline powder stable in 6 M HCl and 3 M HNO_3:

This sorption material is insoluble in water but soluble in hydrochloric acid and chloride solutions. It was confirmed in special experiments that the sorbent does not degrade in the course of dissolution. The IR spectra of the initial sorbent before and after precipitation from hydrochloric acid solution in the range 400–3000 cm^{-1} are fully identical.

Platinum(II) and platinum(IV) chloro complexes K_2PtCl_4 and K_2PtCl_6 were prepared by well-known procedures [20]. The sorption was performed under static conditions with continuous stirring on a Unipan type 358 S laboratory shaker at room temperature in 0.1–4 M HCl and 0.1–4 M NaCl. The starting solutions were prepared by dissolving weighed portions of K_2PtCl_4 and K_2PtCl_6. The working volume of the solutions was 20 ml, and the sorbent weighed portion, 0.1 g. The platinum concentration in solutions before and after sorption was determined spectrophotometrically with tin(II) chloride [21]. The platinum concentration in the solution was varied from 1 to 60 mM. The electronic absorption spectra of solutions were measured on a Specol 11 spectrophotometer, and the IR spectra of samples, on a Shimadzu IR-435 spectrometer. The X-ray photoelectron spectra (XPS) were measured on a Perkin–Elmer PHI-5400 spectrometer with excitation by monochromatic AlK_α X-ray radiation (energy 1486.6 eV). The calculation of the atomic concentrations and resolution of separate XPS lines into components were performed by standard procedures. The binding energy was determined with an accuracy of 0.1 eV, and the quantitative analysis was made with 10% accuracy. The spectra were calibrated against C 1*s* line.

As the sorbent dissolves in hydrochloric acid and chloride solutions, actually the interaction of MITKhAT with platinum(II) and platinum(IV) chloro complexes under these conditions involves chemical reactions yielding difficultly soluble platinum compounds.

In contrast to sorption of iridium(III) and iridium(IV) chloro complexes [22], platinum chloro complexes are efficiently recovered at room temperature. Typical kinetic curves of the recovery of platinum(II) and platinum(IV) chloro complexes from 0.5 M HCl solutions at room temperature are shown in Fig. 1.

As seen from Fig. 1, the apparent equilibrium in the distribution of both platinum(II) and platinum(IV) chloro complexes between the solution and precipitate is attained at 20°C within 2.5–3 h. It is seen from the kinetic curves (Fig. 1) that 93% of platinum is recovered from a 0.5 M HCl solution (c_{Pt} = 3 mM) already in 1 h. In all the subsequent experiments, the time of contact of solutions with MITKhAT sorbent at room temperature was 3 h.

It is important that variation of the platinum concentration in solution (from 1 to 10 mM) and of the solution composition (0.1–4 M HCl and 0.1–4 M NaCl) does not noticeably affect the rate of recovery of platinum chloro complexes at room temperature. On heating the solutions to 50°C, the rate of recovery of platinum(II) and platinum(IV) chloro complexes increases by a factor of approximately 2.

The color of the products obtained after the sorption recovery depends on the platinum oxidation state. The precipitates obtained with Pt(IV) are brown, and those with Pt(II), yellow. With an increase in the metal concentration in solutions, the color becomes more intense.

Figure 2 shows that MITKhAT sorbent exhibits high sorption capacity (SC) toward platinum(II) chloro complexes, which reaches 6.5 mmol g^{-1} even at room temperature.

The steep ascent of the isotherm of recovery of platinum(II) chloro complexes shows that MITKhAT should be recommended primarily for recovering microamounts of platinum. In the range of initial platinum(IV) concentrations from 1.0 to 20 mM, platinum(IV) chloro complexes are virtually quantitatively recovered into the precipitate at room temperature (SC ~4.0 mmol g^{-1}).

The dependence of the SC on the composition and concentration of HCl and NaCl solutions is shown for platinum(II) as example (Fig. 3). In a wide range of HCl and NaCl concentrations, both the rate of Pt(II) recovery and SC remain constant.

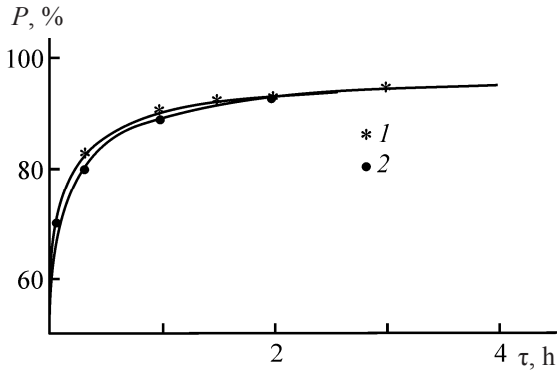


Fig. 1. Kinetic curves of the sorption of (*1*) K_2PtCl_4 and (*2*) K_2PtCl_6 with MITKhAT from 0.5 M HCl at 20°C. Platinum concentration 3 mM. (*P*) Degree of platinum recovery and (τ) time.

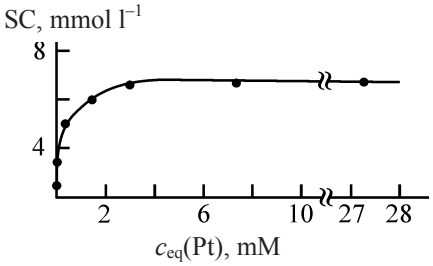

Fig. 2. Sorption capacity SC of MITKhAT sorbent in 0.5 M HCl at 20°C as a function of the equilibrium concentration c_{eq}(Pt) of Pt(II).

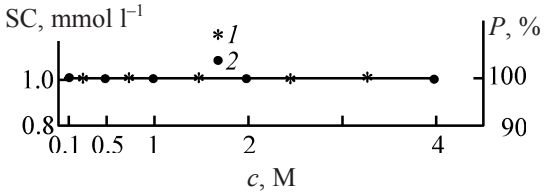

Fig. 3. Sorption capacity SC of MITKhAT sorbent for K_2PtCl_4 and K_2PtCl_6 as a function of the concentration *c* of (*1*) HCl and (*2*) NaCl. (*P*) Degree of platinum recovery.

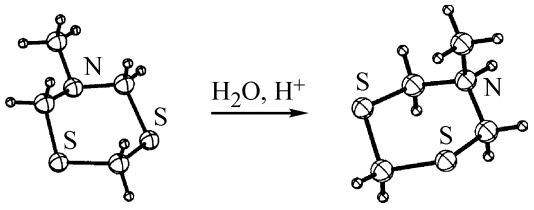
Similar pattern is observed with platinum(IV) chloro complexes. Thus, the kinetic and capacity characteristics of MITKhAT toward platinum(II) and platinum(IV) chloro complexes are preserved in both hydrochloric acid and neutral chloride solutions.

Platinum cannot be recovered from the difficultly soluble compounds formed even by treatment with 6–10 M HCl. Platinum can be transferred into solution

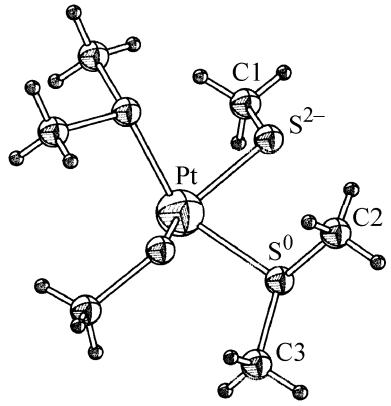


only by "wet combustion," i.e., by treatment with concentrated nitric acid or aqua regia.

The absence of any effect of the solution composition on the recovery of platinum(II) and platinum(IV) chloro complexes suggests similar mechanism of their recovery.

Elemental analysis revealed no nitrogen in the compounds isolated after the sorption of K_2PtCl_6 and K_2PtCl_4. The IR spectra of the isolated compounds differ from that of the initial sorbent in the range of ν(C=S) stretching vibrations (1450–1300 cm^{-1}) and the adjacent range of δ(CH) bending vibrations (1400–1300 cm^{-1}) [23]. Certain changes are also observed in the range of ν(C–S) stretching vibrations (700–600 cm^{-1}) [23]. In the far-IR range (400–140 cm^{-1}), the metal–halogen stretching vibration bands [24] are absent. All these facts suggest that the complexation reactions in the course of sorption recovery of platinum involve formation of Pt–S bonds.

It was shown by XPS that, after sorption of both K_2PtCl_6 and K_2PtCl_4, only Pt(II) is identified in the isolated compounds. In the spectra of the samples after recovery of both Pt(II) and Pt(IV), E_b for the Pt $4f_{7/2}$ line is 73 eV, which corresponds to Pt(II) [25, 26]. The recovery of platinum(IV) chloro complexes with MITKhAT sorbent is accompanied by reduction of Pt(IV) to Pt(II) and oxidation of sulfide sulfur to S^0 (E_b for S^0 $2p_{3/2}$ 164.0 eV) [25, 26].



The whole set of data of elemental analysis, XPS, and IR spectroscopy indicates that the compounds isolated after sorption are mercapto–thio ether complexes of Pt(II). In hydrochloric acid solutions, the first step of the sorption involves, along with the redox reaction (in solution, with MITKhAT), also protonation of the tertiary nitrogen atom of the sorbent and formation of the onium compound by the scheme

$$2CH_3N(CH_2)_2S_2CH_2 \cdot HCl + [PtCl_4]^{2-}$$

$$\rightarrow [CH_3NH(CH_2)S_2CH_2]_2[PtCl_4].$$

The subsequent transformations involve decomposition of the onium compound, heterolytic cleavage of the C–N and C–S bonds, and inner-sphere coordination of the ligand to the Pt(II) ion with the formation of polymeric mercapto–thio ether complexes of Pt(II):

To predict the possibility of formation and the strength of platinum mercapto–thio ether complexes, we performed quantum-chemical calculations of the electronic structure of the ligand $CH_3N(CH_2)_2S_2CH_2$ (L), its protonated form $[CH_3NH(CH_2)_2S_2CH_2]^+$, and the model complex *trans*-$[Pt(DMS)_2(SCH_3)_2]$, where DMS is $S(CH_3)_2$. The calculations were performed with full geometry optimization by the DFT B3LYP method with the 6-31 G** basis set for transition metals and HW effective core potential for the Pt atom [27], using the GAMESS-2007 program package [28].

The results obtained indicate that the nitrogen atom in ligand L has an effective negative charge, whereas the S atom is charged positively: $q(N) = –0.30$ e, $q(S) = 0.13$ e. However, the electron density of the highest occupied MO (HOMO) of this ligand with an energy of –6.20 eV is concentrated on the S atom. These facts indicate that the ligand L is potentially ambidentate.

According to the Klopman's approach [29] and the Pearson's concept of hard and soft acids and bases [30], an acceptor that is a hard Lewis acid in coordination with an ambidentate ligand will "choose" the atom that bears the largest negative charge, i.e., the coordination will be charge-controlled. An acceptor that is a soft Lewis acid will "choose" in this ligand the center with the highest charge density on HOMO. The HOMO should have an energetically favorable high energy (or, in other words, low molecular ionization energy). That is, the coordination will be orbital-controlled.

From this viewpoint, the protonation of ligand L should be charge-controlled, i.e., it should occur at the

nitrogen atom bearing the largest negative charge. Calculation of the protonated ligand $[CH_3NH(CH_2)_2S_2CH_2]^+$ showed that in this species, as compared to the neutral compound, the –N–CH_2– bonds are weakened and the adjacent –CH_2–S– bonds are strengthened: $R(N–C)_L$ = 1.415, $R(N–C)_{L^+}$ = 1.526, $R(C–S)_L$ = 1.836, $R(C–S)_{L^+}$ = 1.804 Å. The Mayer bond orders n [31] are as follows: $n(N–C)_L$ = 0.89, $n(N–C)_{L^+}$ = 0.75. The calculation results demonstrate why protonation of the N atom promotes decomposition of the ligand.

Interaction of ligand L with platinum ions, which are soft Lewis acids, should be orbital-controlled: This ligand with a very low ionization energy can coordinate with Pt via S atoms whose electrons are concentrated on HOMO.

The DFT calculations of the electronic structure of the Pt(II) complexes with the $S(CH_3)^-$ and $S(CH_3)_2$ ligands simulating the decomposition products of the $CH_3NH(CH_2)_2S_2CH_2$ ligand showed that the anionic ligand $S(CH_3)^-$ is an efficient donor of the electron density. The average value of the $S(CH_3)^- \rightarrow$ metal electron transfer in the complexes under consideration is 0.77 e. Each of these ligands forms strong bonds with the central ion: The mean Mayer order of the M–$S(CH_3)^-$ bond [31] is 0.81. The $S(CH_3)_2$ ligands are also good donors. However, they donate only about 0.37 e to the metal, and the mean order of the M–$S(CH_3)_2$ bonds formed, 0.56, is lower than with the anionic ligands.

Thus, quantum-chemical calculations support the suggested scheme of the heterolytic cleavage of the C–N bonds with the formation of polymeric mercapto–thio ether complexes of Pt(II) in the course of the sorption.

The MITKhAT sorbent was tested for group recovery of metals from a model solution containing platinum metals and gold in amounts typical of an industrial process. It was found (see table) that the sorbent recovers from the solution almost 100% of Pd and Au, about 93% of Ir and Pt, and 76.5% of Rh.

MITKhAT was also tested for recovering palladium and platinum from hydrochloric acid solutions obtained in reprocessing of catalysts for exhaust gas treatment. From the solution containing (g l^{-1}) Pd 0.414, Pt 0.074, and Al 1.02, it is possible to recover 99.9 and 98.0% of Pd and Pt, respectively.

Commercial samples of S,N-containing heterochain polymers KDM-2 and KPU-2, analogs of MITKhAT, were tested for group recovery of Pt, Pd, and Rh from spent automobile catalysts after their acid breakdown, with the subsequent atomic absorption determination. Based on the results obtained, procedures were developed for sorption–atomic absorption determination of platinum metals in multicomponent samples (in the presence of Ti, Al, Zr, Sn, Co, Ni, Fe, Cu) [32].

Sorption of platinum metals from a model hydrochloric acid (3 M HCl) solution (3 h, 18°C)

Metal	Concentration in solution, μg ml^{-1}		Recovery, %
	before sorption	after sorption	
Au	4.14	0.08	98.0
Ir	4.00	0.3	92.5
Pt	10.05	0.65	93.5
Pd	53.76	0.18	99.7
Rh	12.40	2.91	76.5

CONCLUSIONS

(1) Optimal conditions were found for recovering platinum(II) and platinum(IV) chloro complexes from hydrochloric acid and chloride solutions with MITKhAT heterochain S,N-containing sorbent at room temperature. The maximal sorption capacity toward platinum(II) and platinum(IV) chloro complexes is 6.5 and 4 mmol g^{-1}, respectively.

(2) As shown by elemental analysis and by IR and X-ray photoelectron spectroscopy, the recovery of platinum(II) and platinum(IV) chloro complexes from hydrochloric acid and chloride solutions is accompanied by formation of mercapto–thio ether complexes of Pt(II).

(3) The DFT calculations of the electronic structure of aminomethylene sulfide, its protonated form, and a model Pt(II) complex, *trans*-$[Pt(DMS)_2(SCH_3)_2]$, where DMS = $S(CH_3)_2$, confirm the formation of platinum mercapto–thio ether complexes in the recovery process.

(4) Heterochain S,N-containing sorbent MITKhAT can be suggested for group recovery of platinum metals from multicomponent solutions.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Use of Activated Carbon Materials for Wastewater Treatment to Remove Ni(II), Co(II), and Cu(II) Ions

Abstract—The sorption activity of UVIS-AK activated carbon fiber with respect to the Co(II), Ni(II), and Cu(II) cations was studied. The possibility of using this fiber for industrial wastewater treatment to remove heavy metal ions was examined.

DOI: 10.1134/S107042720811013X

Many heavy metals exhibit high toxicity even in trace quantities and are concentrated in living bodies. In contrast to organic compounds, which undergo degradation, metals are only redistributed between natural media and are gradually accumulated in them. Therefore, further research and development of new methods for wastewater treatment to remove heavy metal ions are necessary. The most widely used methods involve precipitation of difficultly soluble heavy metal hydroxides and sulfides using appropriate reagents [1]. Such methods are simple, but involve introduction of new chemicals into the wastewater. Furthermore, the hydrated precipitates formed in the process are voluminous. Fine water purification is commonly performed with zeolites [2], cation-exchange resins [3], or activated carbons [1]. For the recovery of heavy metal ions, much promise is shown by fibrous carbon materials, as they combine filtration and sorption properties and have high specific surface area and developed porosity [4, 5].

In this study we evaluated the sorption activity of activated carbon fibers toward Co(II), Ni(II), and Cu(II) cations with the aim of its use for the treatment of wastewater contaminated with these metal ions.

EXPERIMENTAL

For the sorption of heavy metal ions, we used activated carbon fiber (ACF) of UVIS-AK brand, oxidized activated carbon fiber (OACF), and activated birch charcoal (BAU-A).

The sample of oxidized carbon fiber was prepared by refluxing ACF for 1 h in concentrated HNO_3, with the subsequent washing with double-distilled water.

The specific surface area of adsorbents S was determined by thermal desorption of nitrogen, and the limiting adsorption pore volume for ethanol vapor V_Σ, by the desiccator method [6]. The mean pore diameter r_m was calculated by the formula

$$R_m = 2 \times 10^4 V_\Sigma / S.$$

The total acidity of carbon adsorbents was determined by titration with a 0.1 N NaOH solution. The content of functional groups on the surface of carbon adsorbents was determined by the Boehm method [7] from the sorption of the solutes from 0.05 N $NaHCO_3$, Na_2CO_3, and NaOH solutions. Some characteristics of the carbon adsorbents are given in Table 1. As can be seen, the specific surface area of the sorbents is fairly high, from 660 to 1300 $m^2 g^{-1}$, with the prevalence of micropores with a mean diameter of 6–14 Å. Oxidation of the initial carbon fiber led to an increase in the micropore size by a factor of more than 2, a decrease in the specific surface area, and a considerable increase in the cation-exchange capacity.

The sorption of metal cations was performed from solutions of their chemically pure grade salts in the

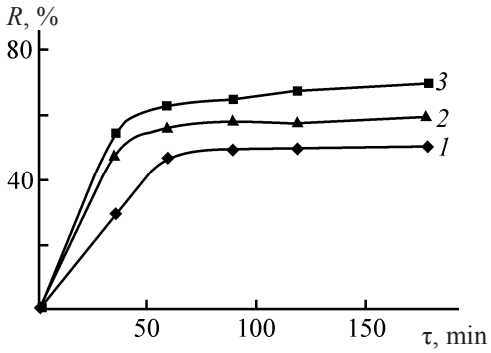

Fig. 2. Degree of recovery R of Cu^{2+} ions in the presence of Na^+ ions (600 mg l^{-1}) as a function of time τ. $C_{Co^{2+}}$ = 32 mg l^{-1}, $V_{solution}$ = 50 ml, m = 0.1000 g. ACF: (*1*) initial, (*2*) oxidized, and (*3*) impregnated with nitroso-R-salt.

static mode at room temperature with continuous stirring. Weighed portions of the adsorbents brought to constant mass (from 0.0200 to 0.1000 g) were placed in model solutions (25 ml) containing (mg l^{-1}) 6–60 cobalt(II) sulfate, 0.01–0.8 copper(II) nitrate, and 0.8–4.0 nickel(II) sulfate. The mixture was kept for a time required to attain the sorption equilibrium. The major fraction of Ni(II), Cu(II), and Co(II) cations is sorbed by the fiber within 2 h, 2.5–3 h, and no less than 1.5 days, respectively. The concentration of metal ions was determined photocolorimetrically with nitroso-R-salt for Co(II), sodium diethyldithiocarbamate for Cu(II), and dimethylglyoxime for Ni(II) [8].

Table 2. Degree of recovery R of Co(II), Ni(II), and Cu(II) ions ([Na^+] = 920 mg l^{-1})

Sorbent	R, %, without Na^+			R, %, with Na^+		
	Co^{2+}	Ni^{2+}	Cu^{2+}	Co^{2+}	Ni^{2+}	Cu^{2+}
BAU-A	30	35	83	29	35	87
ACF	41	40	98	26	30	98
OACF	100	100	93	100	100	94

One of the major factors controlling the ion exchange between an adsorbate and an adsorbent containing weakly acidic and weakly basic groups is pH of the solution. The pH was adjusted by adding small volumes of HCl and NaOH solutions. Figure 1 shows how the degree of metal ion recovery with the carbon fiber depends on the solution acidity. The Ni^{2+} and Co^{2+} ions are quantitatively recovered at pH 7 within 1.5 days and 2 h, respectively, and the Cu^{2+} ions, at pH 5–6 within 3 h. Further increase in pH is not appropriate because of the possible binding of metal cations into insoluble hydroxides and basic salts.

As wastewaters to be treated to remove heavy metal ions are usually mineralized, we examined the effect of sodium sulfate on the degree of removal of Cu^{2+}, Co^{2+}, and Ni^{2+} from water. The results of treatment to remove these metal ions from aqueous solutions containing up to 920 mg l^{-1} Na^+ ions are given in Table 2. It can be seen that the presence of sodium ions does not noticeably affect the recovery of Cu^{2+} with the carbon sorbents, whereas the recovery of Co^{2+} and Ni^{2+} cations with ACF somewhat decreases. However, in all cases OACF shows high selectivity toward heavy metal ions in the presence of sodium ions.

The selectivity of the sorption treatment with the oxidized fiber increases owing to an increase in the concentration of active acid centers responsible for the ion exchange. In particular, the concentration of carboxy groups increases by a factor of 2.5 (Table 3). Figure 2 shows the dependences of the degree of Cu^{2+} recovery from a solution containing up to 600 mg l^{-1} Na^+ on the contact time for the initial fiber, that modified with nitroso-R-salt, and that oxidized with nitric acid. As can be seen, treatment of the fiber with the reagent forming a stable complex with cobalt ions also considerably increases the efficiency and selectivity of the sorption. The complex is formed by coordination of the cobalt ion with the nitroso group atoms and phenolic oxygen. As a result, the degree of Co^{2+} recovery increases by 10%.

Figure 3 shows as example the adsorption isotherms of Cu^{2+}, obtained by the method of varied weighed portions at 25°C. The sorption isotherms on BAU and ACF have the shape described by the Langmuir equation. The shapes of the sorption isotherms are similar because of similarities in the structure of the carbon skeleton and in the surface chemistry of these adsorbents. The adsorption isotherm on the carbon fiber at a low degree of filling of the surface is steeper than that on activated carbon, which suggests

Table 3. Content of functional groups on the surface of carbon adsorbents

Adsorbent	Content of functional groups, mg-equiv g^{-1}		
	carboxy	phenolic	lactone
BAU-A	0.15	0.81	0.31
ACF	0.97	0	0
OACF	2.38	1.24	0.64

Table 4. Degree of sorption treatment of wastewater to remove Cu(II) ions

Sorbent	*R*, %
BAU-A	70
ACF	88
OACF	90

higher microporosity of the carbon fiber. Adsorption of metal ions on carbon adsorbents mainly occurs by the ion-exchange mechanism, as follows from a decrease in pH of the solution by 0.2–0.6 after the contact with the adsorbents. The total content of acidic functional groups on BAU is higher than that on ACF by a factor of 1.3 (Table 1), but the content of carboxy groups responsible for the ion exchange is lower by a factor of more than 6. This fact is, apparently, responsible for faster attainment of the sorption equilibrium of salt solutions with the fiber than with the charcoal. The sorption isotherms of metal cations on OACF are steeply ascending, which is due to considerably enhanced cation-exchange power of the fiber.

Under the optimal conditions, we performed static sorption treatment of wastewater containing up to 2.5 mg l^{-1} Cu(II), 0.02 wt % ethyl acetate, and 0.04 wt % ethanol. The results of the sorption treatment to remove Cu(II) cations are given in Table 4. The degree of removal of Cu(II) cations from water

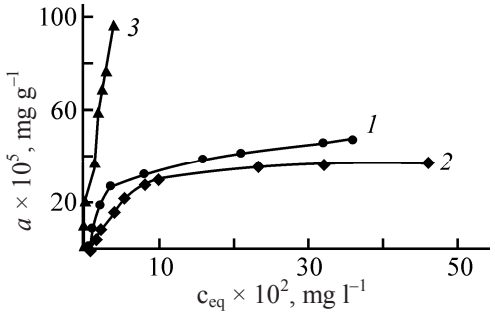

Fig. 3. Isotherms of adsorption of copper ions on (*1*) ACF, (*2*) BAU-A, and (*3*) OACF at 25°C. (*a*) Adsorption and (c_{eq}) equilibrium concentration of Cu(II) ions.

increases in the order BAU < ACF < OACF. The sample of a catalytically oxidized sulfide–alkaline wastewater containing petroleum products (25 mg l^{-1}), phenols (100 mg l^{-1}), sulfates (2300 mg l^{-1}), and Co^{2+} (20 mg l^{-1}) was treated only with ACF. After the treatment, no Co^{2+} was detected in the solution.

CONCLUSIONS

(1) Comparative estimation of the sorption activity of activated carbon fiber UVIS-AK and activated charcoal BAU-A with respect to Cu^{2+}, Co^{2+}, and Ni^{2+} ions was made. The UVIS-AK fiber exhibits higher sorption characteristics than BAU-A owing to its high permeability and higher content of active adsorption centers.

(2) The recovery of Cu^{2+}, Co^{2+}, and Ni^{2+} ions depends on pH, degree of water mineralization, and texture of carbon adsorbents (grained or fibrous).

(3) Modification of activated carbon fibers by oxidation in nitric acid appreciably enhances the efficiency of the recovery of heavy metal ions from highly mineralized water. The degree of recovery is as high as 93–94% for Cu^{2+} and 100% for Co^{2+} and Ni^{2+}.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Rate of Energy Dissipation in Apparatus with High-Intensity Agitation

A. N. Verigin and A. V. Pelevin

St. Petersburg State Institute of Technology (Technical University), St. Petersburg, Russia

Received May 12, 2008

Abstract—Flow nature in rotary mills is considered and a mathematical description of the energy dissipation rate under high-intensity agitation is given.

DOI: 10.1134/S1070427208110141

In recent years, a considerable progress has been made in the field of basic research into the hydrodynamics and transport processes in apparatus with mechanical agitators. Studies by V.V. Kafarov, P.G. Romankov, F. Strenk, V.G. Ushakov, V.M. Barabash, N.N. Kulov, and other scientists provided insight into the physical mechanism of agitation and enabled analysis of its various aspects from the common theoretical standpoint.

However, there exists a gap between achievements in synthesis of new materials and development of technologies, on the one hand, and potentialities of their implementation on the existing equipment, on the other. This primarily refers to high-intensity processes (especially those in potentially hazardous media) and complex reactions in heterogeneous media. The increasingly stringent requirements to the quality of the products obtained entail increased requirements to the quality and rate of agitation. Just this circumstance makes important studies aimed to develop apparatus that can control the process intensity. To apparatus of this kind can be attributed rotary reactors providing a high agitation intensity.

Solving this problem requires an in-depth study of the influence exerted by the macro- and microstructure of turbulence on the fundamental aspects of agitation and efficiency of the apparatus being designed. Although the influence exerted by stable coherent formations and fractal structure of turbulent flows on transfer processes is considered in the theoretical hydrodynamics, it still has no engineering applications. In this context, studies concerned with the mechanisms of agitation in rotary apparatus at high energy dissipation rates and with application of achievements of the theoretical hydrodynamics to development of scientifically substantiated methods for their calculation remain rather topical.

The aim of our study was to examine the energy dissipation in rotary apparatus under agitation, to compare amounts of energy dissipation in laminar and turbulent agitation modes, and to select and theoretically substantiate a procedure for calculating the energy dissipation in accordance with experimental data.

Theoretical studies of transfer processes that occur under agitation in rotary apparatus have been performed using a unified approach based on the energy dissipation rate as the key parameter. A method employing elements of the theory of dissipative systems has been suggested for analyzing the fundamental aspects of energy dissipation in various hydrodynamic flow modes. An expression for calculating the energy dissipation rate in a turbulent flow can be found from the concept of the fractal nature of turbulence. Methods for experimentally estimating the fractal dimension of the energy dissipation field and determining the local rate of energy dissipation have been substantiated.

The lack of a sufficiently complete theory of turbulence makes difficult an engineering description of agitation in turbulent flows. The relations known from the literature are either purely empirical or refer to flow types rarely occurring in apparatus. It is apparent that theoretical foundations for an engineering description of turbulence in apparatus should be related both to parameters characterizing an apparatus and to pa-

rameters determining the fundamental properties of turbulence: characteristic size of turbulent pulsations, local energy dissipation rate, and fractal dimension of the dissipation field.

Theoretical studies are devoted to description of the fundamental aspects of energy dissipation in laminar, transition, and turbulent flow modes in rotary apparatus and to calculation of the power consumed for agitation on this basis.

At present, the most complete in theoretical regard and best substantiated by practical results is A.N. Kolmogorov's theory of locally isotropic turbulence. According to this theory, the turbulence is a hierarchy of vortices (i.e., perturbations or heterogeneities) of various characteristic sizes, in which vortices of a given size appear as a result of stability loss by larger vortices and "borrow" energy from these vortices, and, in turn, losing stability, give rise to pulsations of a smaller characteristic size, to which they transfer their energy. Energy passes from larger vortices to smaller pulsations, almost with zero dissipation. It can be considered that there occurs a continuous energy flow from large- to small-scale turbulent formations. This flow dissipates, i.e., the kinetic energy is transformed into heat, in the smallest-size vortices. In this case, the stationary state of the flow is provided by an external source (agitator), which continuously transfers energy to the large-scale motion. As a result of the chaotic nature of this energy transfer, the orienting effect of the medium-scale flow must become weaker in any transition to finer perturbations. Therefore, this orienting influence should not affect the turbulence properties on a sufficiently small scale. Generally speaking, the medium-scale flow and the largest vortices of real turbulent flows are anisotropic, but the statistical mode of small-scale pulsations can be considered isotropic. It is characterized by the existence of a certain averaged energy inflow (W kg^{-1}) to the largest perturbations and the equal energy dissipation into heat under the action of viscous-friction forces in the smallest perturbations. In this case, the dissipation rate is given by

$$\varepsilon \sim \nu^3/\lambda^4, \quad (1)$$

where ν is the kinematic viscosity and λ is the scale of vortices in which the energy dissipation proper occurs.

Based on dimension considerations, we can demonstrate that

$$\lambda \sim L/\mathrm{Re}^{3/4}, \quad (2)$$

where the Reynolds number $\mathrm{Re} = UL/\nu$ is expressed in terms of the characteristic velocity U and characteristic size L of the entire flow.

Relations (1) and (2) can be transformed into an equality by introducing a Reynolds number for pulsations of characteristic size λ and the corresponding velocity $U\lambda$. Then we obtain at $\lambda = [(L\mathrm{Re}_0)/\mathrm{Re}]^{3/4}$:

$$\varepsilon = \nu^3 L^{-4}(\mathrm{Re}/\mathrm{Re}_0)^{-3}. \quad (3)$$

The flow in formations of characteristic size λ is laminar and energy dissipations occurs under the action of viscous forces, with the following condition to be satisfied:

$$\varepsilon^* \sim \nu U_\lambda^3 \lambda^{-2}, \quad (4)$$

where ε^* is the local energy dissipation rate in a formation of characteristic size λ.

Converting (4) into an equality, we obtain

$$\varepsilon^* = \nu^3 \gamma \mathrm{Re}_0^2 \lambda^{-4}. \quad (5)$$

A relationship between ε^* and the energy dissipation rate ε space-averaged over the apparatus can be determined by using the concept of the fractal dimension of the energy dissipation field [1–5].

The quantity ε^* is a characteristic of the local energy dissipation, and for the flow as a whole, the following condition should be satisfied:

$$\varepsilon = \varepsilon^* N^*/N. \quad (6)$$

According to expression (6), the number N^* of formations in which the energy dissipation ε^* occurs may differ from the maximum possible number N of formations of characteristic size λ. It is apparent that $N = (L/\lambda)^3$. The value of N^* depends on the fractal dimension d of the energy dissipation field. Considering the dissipation field in a rotary apparatus to be monofractal, we can write down that $N^* = (L/\lambda)^d$. Substituting expressions for N and N^* into (6), we obtain

$$\varepsilon^* = \varepsilon(L/\lambda)^{3-d}. \quad (7)$$

Simple rearrangements can give an expression relating the energy dissipation rate to the fractal dimension

$$\varepsilon = \nu^3 L^{-4}(\gamma \mathrm{Re}^2)^{12/(17-3d)}, \quad (8)$$

where γ is the proportionality coefficient.

It can be seen from expression (8) that $\varepsilon \sim \mathrm{Re}^3$ only in the case when the fractal dimension of the dissipation field is equal to the Euclidean dimension of the field ($d = 3$), i.e., the turbulent formations of the small-

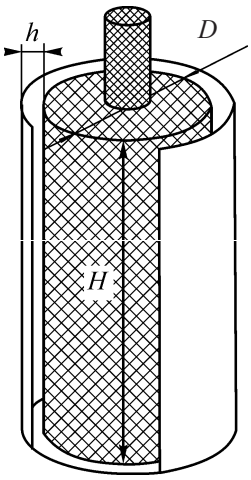

Fig. 1. Schematic of apparatus with a smooth rotor.

est size should occupy the whole flow volume. This situation rarely occurs in technological apparatus, and, therefore, the turbulence in such apparatus should be considered nonuniformly locally isotropic.

Although the thus introduced dimension d can be fractal only within a certain physical interpretation, such as capacitive (metric) dimension in the given case, rather than in the strictly mathematical understanding of this word, it is very convenient and effective for describing agitation in the apparatus under consideration.

The presently available data suggest that the fractal dimension of the energy dissipation field for flows that can be obtained in practice is within the range 2.5–3.

Let us consider two extreme cases. If $\gamma \to 1$ and $d \to 3$, i.e., the spatial scale of minimum pulsations and the corresponding Reynolds number are small. This situation corresponds to a uniform isotropic turbulence, which is observed, e.g., in a flow below a grid. If $\gamma << 1$ and $d \to 3$, the characteristic size of turbulent pulsations is large. In this case, a strongly nonuniform hydrodynamic situation is probable: a turbulent core exists, with the rest of the apparatus volume remaining laminar. Knowledge of γ and d makes it possible to judge about the structure of the turbulent flow in an apparatus. Expressions (7) and (8) enable description of transfer processes in a turbulent flow.

It was found in processing and analysis of experimental data for apparatus with different gaps that the fractal dimension d is a function of the Reynolds number:

$$D = 2 + (\mathrm{Re}/B)^n, \quad (9)$$

where B and n are found experimentally.

The suggested equations contain the quantity γ dependent on specific features of the flow in minimum turbulent pulsations. In some cases, theoretical estimation of its value is possible. In accordance with the data of [3], reasons for flow turbulization can be conditionally divided into two groups. To the first group belong specific features of the flow as a whole, which lead to loss of stability by the laminar flow at a certain critical value of the Reynolds number. From the practical standpoint, it is also necessary to take into account the effect of the existing initial fluctuations of hydrodynamic parameters in the flow, wall vibration and roughness, and chemical heterogeneity. These features constitute the second group, conditionally named the background. As shown in [2], the rather small values of the parameters characterizing the background are as important for the appearance and development of turbulence as the boundary (initial) conditions commonly taken into account in analyses of flows. In the case of a developed turbulence, when the background effects already exert no influence on the flow, a theoretical estimate of γ is possible. The value of Re_0 is 2.5, to which corresponds $\gamma = 0.16$. It would be expected that γ should be of the same order of magnitude for all types of industrially used rotors.

The main distinctive feature of rotary apparatus is the agitating device in the form of a cylindrical rotor whose diameter and height are comparable with the diameter and height of the apparatus casing. The working zone in rotary apparatus is the annular gap of width h between the casing and the surface of the rotating rotor.

We used in experiments an apparatus with a smooth rotor (Fig. 1). Its basic parameters are as follows: rotor length H 150 mm, rotor diameter D 150 mm, gap (fluid layer thickness) h = 8, 15, 18, 24, 30, 37, and 58 mm.

The parameters of the working media are listed in the table.

If the rotor of radius R rotates with angular velocity ω, then, in the case of a laminar flow, the energy dissipation rate in the annular gap is given by

$$\varepsilon = \nu(\mathrm{d}U/\mathrm{d}T)[(\mathrm{d}U - U)/(\mathrm{d}r - r)], \quad (10)$$

where U and r are the running values of the velocity and radius, respectively.

Upon rearrangements, we obtain

$$\varepsilon = \nu^3 A \mathrm{Re}^2/h^4. \quad (11)$$

The geometrical parameter A is defined as

$$A = [3(1 + h/R)^2 + 1](R + h)^2(2R + h)^{-2}. \quad (12)$$

It is known [5] that the rotary motion of a fluid in the annular gap is unstable. At $\mathrm{Re} \approx 41.3(R/h)^{0.5}$, a flow of another type is formed, constituted by toroidal vortices (Taylor vortices) regularly arranged over the length of the cylinders. At $\mathrm{Re} \approx 1000(R/h)^{0.5}$, the fluid flow becomes turbulent, but coherent structures, toroidal macrovortices remain the flow.

Let us consider qualitative features of the energy dissipation in this transition. It is suggested to use the gap width h between the casing wall and the rotor surface as the characteristic size L of the maximum pulsation when describing the turbulence in the apparatus under consideration.

From the energy dissipation standpoint, the fluid flow can be regarded as a bistable system one of whose equilibrium states corresponds to a streamline flow with a dissipation rate $\varepsilon_s(\mathrm{Re})$, and the other, to a vortex-type flow with dissipation $\varepsilon_v(\mathrm{Re})$. The streamline flow must be preserved while the whole amount of input energy can be dissipated. The appearance of a turbulence will become possible at Re_{cr}, i.e., at $\varepsilon_s(\mathrm{Re}_{cr}) = \varepsilon_v(\mathrm{Re}_{cr})$. At Reynolds numbers exceeding Re_{cr}, turbulent pulsations may appear in the medium, with a part of its volume occupied by the laminar flow, and a part by a turbulent flow. Then the dissipation rate can be represented as

$$\varepsilon = K_s\varepsilon_s(\mathrm{Re}) + K_v\varepsilon_v(\mathrm{Re}), \quad (13)$$

where K_s and K_v are the ratios of the flow volume that remained laminar (turbulent) to the whole volume of the system, which are defined as

$$K_{s(v)} = V_{v(s)}/V_\Sigma, \quad (14)$$

where $V_{v(s)}$ is the volume of the vortex-type (streamline) flow, and V_Σ, the total flow volume.

K_s and K_v are related by $K_s + K_v = 1$. Upon rearrangements, formula (13) will take the form

$$\varepsilon = K_s\varepsilon_s(\mathrm{Re}) + (1 - K_s)\varepsilon_v(\mathrm{Re}). \quad (15)$$

Having found the expression for the energy dissipation rate, we can determine the power expended for agitation:

$$N = \varepsilon\rho V_a,$$

Properties of working media (20°C)

Medium	Density, kg m^{-3}	Viscosity, m^2 s^{-1}
Water	1002	10^{-6}
Glycerol	1280	1.18×10^{-3}
Glycerol solution, 70%	1208	6.55×10^{-5}
Acetone	896	3×10^{-7}

where ρ is the density of the medium in the apparatus, and V_a is the apparatus volume.

An annular layer adjacent to the walls of the immobile cylinder (casing) must remain laminar. The power dissipated in the streamline flow can be calculated by the formula

$$\varepsilon_s = \nu^3 h^{-4} A(\mathrm{Re})^2, \quad (16)$$

and that for the vortex-type flow, by the formula

$$\varepsilon_s = \nu^3 h^{-4}(\gamma\mathrm{Re})^{12/(17-3d)}, \quad (17)$$

where ν is the kinematic viscosity of the medium being treated.

To find K_s, it was suggested to use the function of the type

$$K_s = 1 - \exp(-\mathrm{Re}/\mathrm{Re}_{cr})^m, \quad (18)$$

where Re_{cr} is the critical value of the Reynolds number (in our case, $\mathrm{Re}_{cr} = 4$), and m is an empirical coefficient equal to 1.5.

The calculated values of the energy dissipation rate are in good agreement with experimental data. The best agreement of the theory with the experiment is observed at the following values of the basic parameters: $\gamma = 0.5$, $n = 0.107$, $m = 1.5$, and $B = 2.1 \times 10^7$. The root-mean-square discrepancy between the calculation and the experiment does not exceed ±12%.

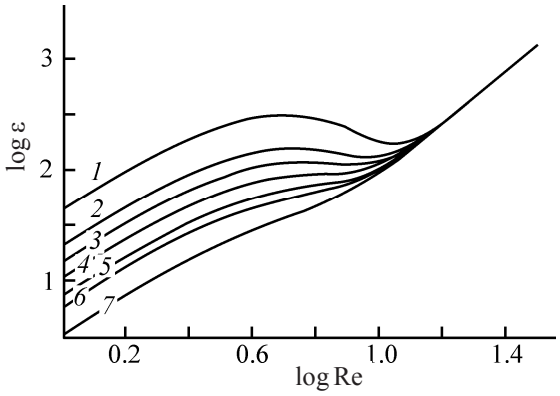

Fig. 2. Energy dissipation rate ε vs. the Reynolds number Re in the transition region. Gap width h, mm: (*1*) 58, (*2*) 37, (*3*) 30, (*4*) 24, (*5*) 18, (*6*) 15, and (*7*) 8.

The mathematical dependence we obtained enables prediction of the behavior of the system at small values of the Reynolds number in the laminar and transition flow modes (Fig. 2).

CONCLUSIONS

(1) An equation for calculating the average (over the mass of the medium in the apparatus) energy dissipation rate in the developed turbulent mode was derived.

(2) The nonuniformity of the turbulent flow can be taken into account by introducing the fractal dimension of the dissipation field.

(3) Taking into account the nonuniformity of the dissipation field by determining the corresponding fractal dimension is of use in simulation of substance and heat transfer processes in apparatus under study.

Abstract—Possibility of preferential dissolution of uranium or aluminum from U–Al alloys in salt electrolytes was examined by performing thermodynamic calculations and experimentally.

DOI: 10.1134/S1070427208110153

Heat-releasing fuel elements based on uranium–aluminum alloys are widely used in research and transport reactors. Fabrication and regeneration of fuel elements of this kind make necessary fine control over their composition.

Our study is concerned with the possibility of solving this problem by electrochemical methods. For this purpose, the possibility of separating uranium and aluminum in anodic dissolution of U–Al alloys in various salt electrolytes was assessed theoretically and compositions of these alloys for preferential dissolution of uranium or aluminum were determined.

The efficiency of the separation process is characterized by the separation coefficient, the quotient of the ratios between the atomic fractions of the metals M1 and M2 being separated in the electrolyte, c_1 and c_2, and in the alloy, x_1 and x_2:

$$\theta = c_1x_2/(c_2x_1). \quad (1)$$

The separation coefficients of uranium and aluminum in their anodic dissolution in various salt melts were estimated using the previously derived [1] relation

$$\ln\theta = (3F/RT)\{E^*(Al^{3+}/Al) - E^{**}[U^{3+}/U(Al)]\}, \quad (2)$$

where $E^{**}[U^{3+}/U(Al)]$ is the conditional standard potential of U–Al alloys in a certain melt, and $E^*(Al^{3+}/Al)$, the conditional standard potential of aluminum in the same melt.

$E^{**}[U^{3+}/U(Al)]$ is calculated from the conditional standard potential of uranium, $E^*(U^{3+}/U)$, and the activity coefficient of uranium in uranium-lean liquid aluminum alloys, γ_U:

$$E^{**}[U^{3+}/U(Al)] = E^*(U^{3+}/U) \times (2.3RT/3F)\log\gamma_U. \quad (3)$$

The dependence of the separation coefficient of uranium and aluminum on the composition of the salt melt and temperature was analyzed using the equation [2]

$$\Delta E_i = E_i^0 = -0.096 + 0.0897(I_i/I) + [0.029 - 0.044(I_i/I)] \times 10^{-3}T, \quad (4)$$

where I_i and I are the ionic moment of uranium or aluminum cation and that of the solvent salt [3], and E_i^0 are standard potentials of uranium and aluminum.

Equation (4) is rather precise (correlation coefficient 0.96) and convenient for analysis. Close relations were obtained for molten fluorides, chlorides, bromides, and iodides of mono-, di-, tri-, and tetravalent elements from results of both electrochemical and calorimetric measurements.

Analysis of our results and published data [4] demonstrated the possibility of calculating the conditional standard potentials E^* of the Al^{3+}/Al system in molten chloride electrolytes of arbitrary composition from the previously measured temperature dependences of the standard potential ($E^0 = -2.290 + 5.53 \times 10^{-4}T$) and ΔE_i values [Eq. (4)].

Table 1. Estimates by Eq. (9) of the separation coefficients of uranium and aluminum in various salt solvents

Solvent	I, nm^{-1}	$\ln\theta = a - b/T$		θ at indicated T, K	
		a	b	1000	1100
LiCl	14.7	10.56	4300	523	773
LiCl–KCl	10.6	11.51	6228	196	346
NaCl–KCl	8.66	12.27	7780	89	180
NaCl	10.2	11.64	6500	126	235
KCl	4.5	12.91	9089	46	104
CsCl	6.06	14.05	11 415	14	39
$MgCl_2$	27	9.44	2022	1670	2000

For mixed solvents, we found the effective ionic moment as an additive function of products of mole fractions by ionic moments of cations of individual chlorides, $I = \Sigma_i c_i I_i$. This yielded for the temperature dependence of the conditional standard potential of aluminum, E^*, the expression

$$E_2^* = -2.290 + 0.553 \times 10^{-3}T + 0.096 - 0.0897(I_2/I) - [0.029 - 0.044(I_2/I)] \times 10^{-3}T. \quad (5)$$

A similar dependence has been obtained [5] for the conditional standard potential of uranium in chloride melts:

$$E_1^* = -2.79 + 0.56 \times 10^{-3}T + 0.096 - 0.0897(I_1/I) - [0.029 - 0.044(I_1/I)] \times 10^{-3}T. \quad (6)$$

According to [1], the activity coefficient of uranium in liquid aluminum in the temperature range 934–1150 K is independent of the solution composition and varies with temperature by the equation

$$\log\gamma_U = 3.672 - 7266/T. \quad (7)$$

Substituting expressions (6) and (7) into Eq. (3), we obtain the generalized equation for calculation of the conditional standard potential of the U–Al alloy:

$$E^{**}[U^{3+}/U(Al)] = -2.31 + 0.32 \times 10^{-3}T + 0.096 - 0.0897(I_1/I) - [0.029 - 0.044(I_1/I)] \times 10^{-3}T. \quad (8)$$

By including relations (5) and (8) into Eq. (2), with account of the ionic moments of U^{3+} ($I_1 = 29.13$ nm^{-1}) and Al^{3+} ions ($I_2 = 52.13$ nm^{-1}), we obtain the generalized expression for calculation of the separation coefficients of uranium and aluminum as functions of the temperature and ionic moment I of the solvent-salt cation:

$$\ln\theta = 696/T + 8.11 - 73\,390/IT + 36/I. \quad (9)$$

The results of calculation by Eq. (9) are listed in Table 1.

Depending on the nature of the solvent salt, the separation coefficient of uranium and aluminum varies by more than two orders of magnitude. An increase in the ionic moment of the solvent-salt cations and in temperature favors more complete separation of uranium and aluminum. The maximum values of the separation coefficient are observed with molten $MgCl_2$ used as a solvent. However, pure magnesium chloride has high viscosity (469 cP), low electrical conductivity (1.58 Ω^{-1} cm^{-1}), high melting point (712°C), and increased hydrolysis susceptibility. Therefore, we used as the solvent a melt containing 20 mol % NaCl and 80 mol % $MgCl_2$ ($I = 23.64$ nm^{-1}). For this solvent, the temperature dependence of the separation coefficient has the form

$$\ln\theta = 9.63 - 2408/T, \quad \theta_{1000\,K} = 1370, \quad \theta_{1100\,K} = 1704. \quad (10)$$

EXPERIMENTAL

The anodic dissolution of an aluminum alloy with 27.4 wt % uranium was performed in purified argon at 750°C in an electrolyte composed of $MgCl_2$ + 20 mol % NaCl, with liquid aluminum electrodes as a cathode and a reference electrode. As the alloy is depleted of uranium, the anode current density was lowered from 0.03 to 0.007 A cm^{-2}. Two experiments were performed.

In the first of these, the anodic dissolution of the alloy was performed for 50% recovery of uranium in a small alundum crucible whose walls served as a diaphragm separating the catholyte from the anolyte. In the process, magnesium ions discharged at the anode to give a magnesium–aluminum alloy. At the same time, uranium and aluminum dissolving at the anode accumulated in the anolyte. As seen from Fig. 1a, this leads to a pronounced polarization of the anode.

The second mode of anodic dissolution of the same alloy for 80% recovery of uranium was performed without separation of the anode and cathode spaces. In this case, the anodic polarization became considerably weaker. A 70% amount of aluminum was dissolved with the maximum current density of 0.03 A cm^{-2}

Table 2. Results of anodic dissolution of the U–Al alloy in the $MgCl_2$ + 20 mol % NaCl electrolyte at 750°C

Mode	Anode/U weight, g		U content of anode, %		Weight loss, g/fraction, %			Amount of electricity, A h/ fraction of current, %			U recovered, %
	initial	final	initial	final	anode	U	Al	anode	U	Al	
1	1.580/0.433	1.368/0.231	27.4	16.9	0.212/100	0.202/95.3	0.010/4.7	0.098/100	0.0682/69.6	0.298/30.4	46.7
2	1.902/0.521	1.617/0.152	27.4	9.4	0.372/100	0.3688/99.14	0.0032/0.86	0.134/100	0.1245/92.9	0.0095/7.1	70.8

(Fig. 1b). The amount of dissolved uranium and aluminum was found from the total loss of mass by the anode and the quantity of passed electricity.

The final content of uranium in the alloy was confirmed by chemical analysis. The results of two experiments are listed in Table 2.

On changing the conditions of alloy dissolution, the anodic current efficiency by uranium was raised to 92.9%, the fraction of dissolved uranium increased from 95.3 to 99.1%, and the recovery of uranium from the anode alloy was 70.8%, which made it possible to lower the uranium content of the alloy from 27.4 to 9.4% (0.0116 mole fraction). According to Eq. (10), $\theta_{1023\,K} = 1445$. Substituting this value of θ and the concentrations of uranium (0.0116) and aluminum (0.9884) in the final alloy into Eq. (1), we obtain the ratio between the near-electrode concentrations of U^{3+} and Al^{3+} ions:

$$c_1/c_2 = \theta x_1/x_2 = 1445(0.0116/0.9884) = 17,$$

which is in good agreement with the experimentally obtained ratio between the fractions of current expended for dissolution of uranium and aluminum (92.9/7.1 = 13).

The results of these calculations (Table 1) indicate that the fraction of current expended for ionization of aluminum in dissolution of U–Al alloys increases as the ionic moment of the solvent-salt cation decreases, with complex ions formed in the salt melt becoming more stable. However, in all purely chloride melts, the salt phase is enriched in uranium (θ > 1).

The situation fundamentally changes on passing to mixed chloride–fluoride melts. In these melts, aluminum is in the form of complex anions AlF_4^- and AlF_6^{3-} [6], whose stability substantially exceeds that of similar complex uranium ions. For example, the instability constants of hexafluoride complexes at 1000 K are 3.2×10^{-21} for aluminum [6] and 7.8×10^{-15} for uranium [7]. As a result, preferential dissolution of aluminum from U–Al alloys becomes possible in chloride–fluoride melts. This can be done by using the three-layer method, in which the anode alloy is at the electrolyzer bottom owing to the higher density than that of aluminum, and aluminum forms the upper (third) layer floating on the electrolyte surface. For this purpose, the electrolyte density should have an intermediate value between the densities of aluminum and its alloys with uranium. Table 3 lists the densities of aluminum and uranium–aluminum alloys in relation to temperature and the uranium content. The density of the U–Al alloys was estimated by the additivity

method, and that of aluminum was calculated by the formula [8]

$$d_{Al} = 2.382 - 0.000273(T - 659).$$

The three-layer refining of aluminum employs the electrolyte containing (wt %): 53–60 $BaCl_2$, 12–17 NaF, 22–24 AlF_3, and 2–4 NaCl; cryolite ratio 1.4–1.5, melting point 670–700°C, and density 2.65–2.70 g cm^{-3} at 770°C. The data in Table 3 demonstrate that this electrolyte can be used in processing of the uranium–aluminum alloy with a uranium content of no less than 3–4 wt %. To extend the concentration range, the content of barium chloride was lowered to 35–40%, and 7% lithium chloride was introduced instead of 2–4% sodium chloride to raise the electrical conductivity. The density of this electrolyte is 2.5 g cm^{-3}, and its melting point, 670°C.

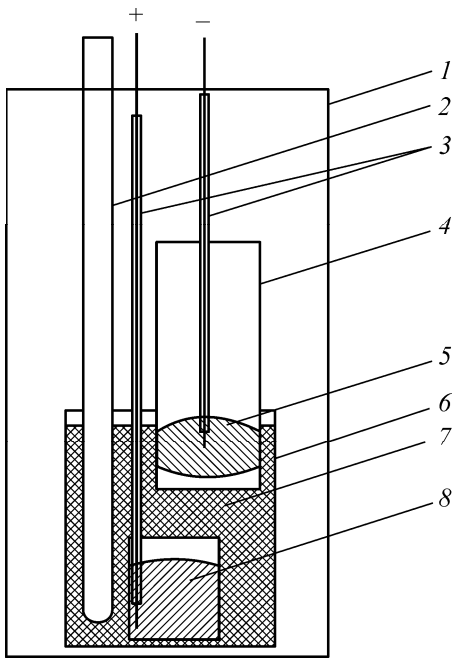

Fig. 2. Schematic of the electrolytic cell: (*1*) metallic container, (*2*) thermocouple sheath, (*3*) current leads, (*4*) alundum tube, (*5*) aluminum cathode, (*6*) alundum crucible, (*7*) electrolyte, and (*8*) U–Al alloy (anode).

The first set of experiments was performed at a current density of 0.5 A cm^{-2} at 780–800°C. The course of the process was monitored by the counter electromotive force, which included the anodic and cathodic polarizations. At the chosen ratio of the cathode and anode current densities [1 : (7–10)], the cathodic polarization is insignificant and the counter electromotive force is almost equal to the anodic polarization.

The electrolytic cell we used is schematically shown in Fig. 2. A preliminarily prepared electrolyte was melted in air in a large crucible, and then a weighed portion (15–20 g) of the U–Al alloy was placed in a small crucible and a molybdenum current lead was introduced. The cathode (aluminum) was lowered from above into the electrolyte in an alundum tube on a molybdenum rod, which served as a current lead after aluminum melted. After the required temperature was reached, a dc current from the power source was switched on. The current was monitored by readings of the stabilized power source and an ammeter. The voltage and counter electromotive force across the cell were measured with a digital voltmeter and *X–Y* self-recorder. The counter electromotive force was measured at the instant of switching-off the current. After the electrolysis, the current leads were removed and the cell was cooled to room temperature. The cathode and anode washed to remove the electrolyte were weighed and analyzed for the content of uranium by atomic-emission spectroscopy with inductively coupled plasma.

The results of these experiments are listed in Tables 4 and 5, and the manner in which the voltage and

counter electromotive force vary is shown in Figs. 3 and 4.

In all the experiments, the loss of mass by the anode is larger, and that by the cathode, smaller, than those calculated from the quantity of passed electricity, which is accounted for by the noticeable corrosion of aluminum in the chloride–fluoride melt. The degree of anodic dissolution of aluminum in the first set was 70–85%, with the maximum enrichment of the anode in uranium of up to 15 wt %.

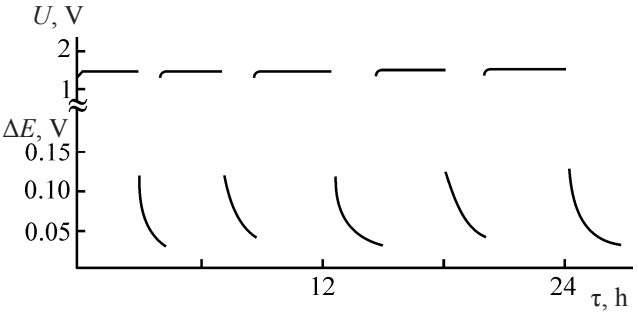

Fig. 3. Variation of the voltage U and anodic polarization ΔE in electrorefining of the U–Al alloy at a current density of 0.5 A cm^{-2}.

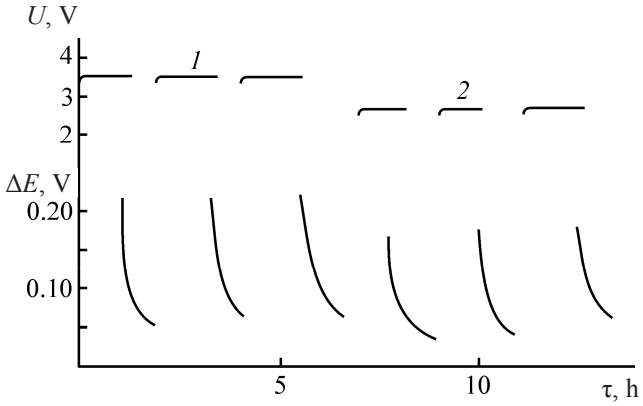

Fig. 4. Variation of the voltage U and anodic polarization ΔE in electrorefining of the U–Al alloy at a current density of (*1*) 1.3 and (*2*) 1.0 A cm^{-2}.

In the second set, the initial anode current density was raised to 1.3 A cm^{-2}, and the final current density was lowered to 1 A cm^{-2}.

It can be seen in Fig. 4 that, on raising the current density, the anode polarization increased by 0.05–0.1 V.

In the first run, uranium was hardly ionized and remained in the anode residue despite the higher anode current density. The content of uranium in the cathode product was at the sensitivity level of chemical analysis. In the second experiment at the same current densities, the degree of anodic dissolution of aluminum was raised to 80.9%. As a result, 30 mg of uranium (5.9% of the initial amount) passed to the cathodic aluminum. The reason is that the limiting current density of aluminum ionization is exceeded at the end of electrolysis because of the decrease in the anode surface area and increase in the uranium concentration in the anode.

CONCLUSIONS

(1) An equation for estimating the separation coefficients as functions of temperature and ionic moment of the solvent-salt cation was suggested.

(2) It was shown that, depending on the nature of a chloride used as a solvent, the separation coefficient varies by more than two orders of magnitude. The maximum values of the separation coefficient (2000) are observed in the $MgCl_2$ melt.

(3) Uranium was dissolved from the Al + 27.4 wt % alloy in a melt composed of 20 mol % NaCl + 80 mol % $MgCl_2$ at 750°C to a final uranium content

of 9.4 wt %. In this case, the current expended for dissolution of aluminum is 13 times smaller than that expended for dissolution of uranium, in good agreement with the theoretical estimate.

(4) The electrolyte composition and parameters of anodic dissolution of U–Al alloys in chloride–fluoride melts, with selective extraction of 80–85% of aluminum from the alloys and uranium concentration in the anode residue from 2.57 to 14–15 wt %, were substantiated.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Synthesis of Electrolytic Manganese Dioxide on Fibrous Carbon Electrodes and Its Use in Voltaic Cells

Received April 9, 2008

Abstract—Selected problems of electrosynthesis of manganese dioxide, with a fibrous carbon material used as anodes and cathodes, were considered. The quality of the product as a cathode material for manganese dioxide–zinc chemical power cells with an alkaline electrolyte was examined.

DOI: 10.1134/S1070427208110165

Owing to a large number of technological and economical factors, the main contribution to the saturation of the market of chemical power cells (CPCs) is made by cells of the MnO_2–Zn system (MTs cells) [1]. The best electrical characteristics among the cells of this kind are observed for those with an alkaline electrolyte [2, 3]. At the same time, they are more sensitive than salt cells to the quality (and in particular, to purity) of the active component of the cathode mixture, MnO_2 [4]. Consequently, one of ways to improve CPCs of this system is to obtain electrolytic manganese dioxide (EMD) under conditions that would provide penetration of a lesser amount of detrimental impurities into the electrosynthesis product.

Severe synthesis conditions of EMD (high temperature and acid medium) restrict the number of materials that can be used as electrode materials. At the same time, anodes and cathodes used in the industry have disadvantages: passivation under inappropriate electrolysis conditions (titanium anodes), poor mechanical stability and nonreusable nature (graphite and lead anodes), difficult fabrication and high cost (combined titanium-based anodes, steel and copper cathodes), contamination of the target process by the electrode material (most of the electrodes mentioned above, to some extent), and large size and the resulting decrease in the volume current density (graphite anodes and cathodes). Compared with other electrochemical processes, electrosynthesis of MnO_2 has low output capacity resulting from the low anode current density [5–8].

To eliminate or diminish the consequences of some of the disadvantages mentioned above, fibrous carbon materials (FCMs) have been tested as anodes and cathodes. These materials are fabricated by thermal treatment of organic fibers and petroleum products in a certain mode and are manufactured as threads, fabric, bundles, and felt [9, 10]. Such a wide range of products predetermine the broad design opportunities furnished by FCMs These materials are 85–95% composed of graphite, which leads to their good electrical conductivity, high porosity, large specific surface area, and stability in severe chemical and thermal conditions. These properties have aroused a considerable interest in use of FCMs in various fields of technology and, in particular, in applied electrochemistry [11–13]. The electrode characteristics of FCM can be improved by various, including electrochemical, methods [14, 15].

Previously, an FCM has been used in EMD synthesis only as an anode and the product obtained has been tested in MTs cells with salt electrolyte [16]. The cells were fabricated with FCM as an electrically conducting additive to the cathode mixture and as a current-lead support in electrochemical preparation of cathodes for voltaic cells [17].

EMD was synthesized with FCM anode and cathode from an acidified $MnSO_4$ solution in cylindrical electrolyzers (2 l) at a current of 1.1 A. The electrodes had the form of rectangular frames made of a nonconducting material (polypropylene) with parallel vertical lines of a bundle-like FCM. The current lead to the electrodes was provided by a pair of titanium (for the

anode) and copper (for the cathode) plates. Figure 1 shows cathodic and anodic polarization curves measured on FCM electrodes under the conditions of EMD synthesis, commonly used for metallic and graphite electrodes [5, 6]: concentration (M): $MnSO_4$ 0.8 and H_2SO_4 0.25; solution temperature 94 ± 1°C. The electrode potentials were measured relative to a calomel reference electrode and recalculated to the hydrogen scale. The measurements were made after 3 h of electrolysis, when the surface area of the anode with a deposited EMD could be measured with sufficient precision. Under these conditions, the cathodic potentials of the FCM (curve *1*) lie within the range of potentials characteristic of other materials used in EMD synthesis [18] up to a current density of 11–13 mA cm^{-2} and further increase (in absolute value) to a lesser extent.

The range 16–19 mA cm^{-2} was chosen as the optimal cathode current density. Further increase in this parameter is limited by the comparatively steep rise in the voltage across the electrolyzer bath, caused by an increase in the ohmic resistance of the solution because of the high degree of its filling with the evolving hydrogen. In the case of anodic polarization, an electrode fabricated from any material becomes a MnO_2 electrode (M–MnO_2, graphite–MnO_2, FCM–MnO_2) after a solid layer of the EMD deposit is formed. Consequently, the anodic polarization curve *2* (Fig. 1) for the FCM differs only slightly from that for other materials [5]. Therefore, a principal criterion in choosing the optimal anode current density is the current efficiency (CE) by the product.

Figure 2 shows how the current efficiency by EMD depends on the anode current density at a constant solution acidity (0.25 M H_2SO_4) (curve *1*) and on the acid concentration at a constant anode current density (10 mA cm^{-2}) (curve *2*). The current efficiency by EMD has a conditional value because it is commonly calculated from the mass of a processed and dried electrolysis product containing (%): MnO_2 90–91, Mn_2O_3 up to 8, hygroscopic moisture up to 4, sulfates up to 1.3, residues insoluble in HCl up to 2, and admixtures of various metals, in trace amounts [5, 19]. The data in Fig. 2 suggest that the optimal anode current density is 9–11 mA cm^{-2}, and the optimal concentration of sulfuric acid, 0.25–0.35 M. Further decrease in the H_2SO_4 concentration is limited by the fact that the spent solution is used for leaching-out of manganese from a reduced ore concentrate, envisaged by the technology of EMD synthesis [5, 8]. Below are given parameters of EMD synthesis on FCM electrodes.

Anode current density, mA cm^{-2}	10
Cathode current density, mA cm^{-2}	17.5
Volume current density, A m^{-3}	650
Voltage, V	2.61
Temperature, °C	94 ± 1
$MnSO_4$ concentration, M	0.8
H_2SO_4 concentration, M	0.30
Current efficiency, %	103.5
Electric power expenditure, kW h kg^{-1}	1.51

It is noteworthy that the voltage across the electrolyzer bath remains unchanged in the course of time, 2.6 V. It is known [5, 7, 8] that, with cylindrical titanium anodes, the electrolysis voltage varies under the influence of three factors: thickening of the titanium oxide layer under the EMD deposit, thickening of the EMD layer, and decrease in the current density because of the increase in the anode diameter. Naturally, the first factor is unimportant for FCM, and it can be believed that the increase in the electrical resistance of

the EMD deposit layer and decrease in the polarization resistance cancel each other.

Synthesis of EMD at a volume current density of 650 A m^{-3} (calculated from the electrolyzer volume) corresponds to intensification of the process by approximately 30%. This occurs for the following reasons: titanium and combined titanium-based cylindrical anodes are 1.8–2.5 cm in diameter; graphite anodes and cathodes, 2.0–3.0 cm in diameter [5, 6, 8]; and anodes made of bundle-like FCM take the form of a cylinder 0.3 cm in diameter (in the initial stage of the process). This causes a decrease in the volume occupied by the electrodes, which makes it possible to raise the volume current density at the same interelectrode spacing. The value of one of the principal parameters of electrolysis, energy expenditure of 1.51 kW h, is rather small for the process under consideration. In contrast to the case of metallic anodes, the EMD obtained cannot be detached from FCM and, therefore, the product with the anode material was subjected to chemical processing, drying, and grinding in accordance with the production specification [5, 8, 19]. The content of FCM in the product was approximately 0.15%.

The following can be said about the economic aspect of application of nonreusable anodes and reusable cathodes fabricated from FCM. Obtaining 1 m^2 of the anode surface area in manufacture of EMD requires 21–23 kg of rod titanium (D = 2.0 cm), 22–24 kg of lead strips (4.0 × 0.4 cm), or 16–17 kg of cylindrical (D = 3.0 cm) electrode grade graphite [5, 6]. The same surface area was obtained in this study with only 74–76 g of FCM. Here is meant the FCM surface area accessible to electrochemical deposition of EMD, rather than the substantially larger true surface of FCM [9]. Although the cost of FCM exceeds that of titanium by approximately an order of magnitude, the expenditure of the former is 280 times smaller than that of the latter. According to the experiments performed, this advantage can be well utilized in engineering practice. With account of the fact that the cathode current density used is 1.75 times the anode current density, the FCM expenditure is even smaller than those of lead and graphite, by factors of 530 and 320, respectively. In the authors' opinion, an important role in determining the economic feasibility of industrial use of FCM as electrodes can be played by the improvement of the EMD obtained in this case.

The electrolytic manganese dioxide obtained on FCM was used in MTs cells with alkaline electrolyte. The aim of the experiment was to find the optimal ratio between the masses of the EMD produced under the conditions mentioned above and the carbon materials (graphite and carbon black) added to the cathode mixture of power cells to raise its electrical conductivity. A model cell intended for determining the EMD quality [20, 21] was used as the CPC of the MnO_2–Zn system with alkaline electrolyte. The composition of the dry cathode mixture corresponded to the widely occurring cylindrical power cells of this system (%): EMD 84, elemental graphite 12.5, and acetylene black 3.5. In a cell of this kind, the paste-like anode mass containing high-purity powdered zinc is taken in an excess, and, therefore, CPC parameters fully depend on the EMD quality. A 12.5 KOH solution was used as electrolyte. Eight batches of CPC were fabricated (each with four cells) with the following contents of EMD in the dry cathode mixture (wt %): batch no. 1, 75; no. 2, 78; no. 3, 81; no. 4, 84; no. 5, 87; no. 6, 90; no. 7, 93; and no. 8, 96. The mass ratio between graphite and acetylene black was the same (12.5 : 3.5) for all the batches. To obtain their electrical characteristics, the CPCs were discharged at room temperature via a constant external resistance of 20 Ω in the continuous mode to a final voltage of 0.9 V.

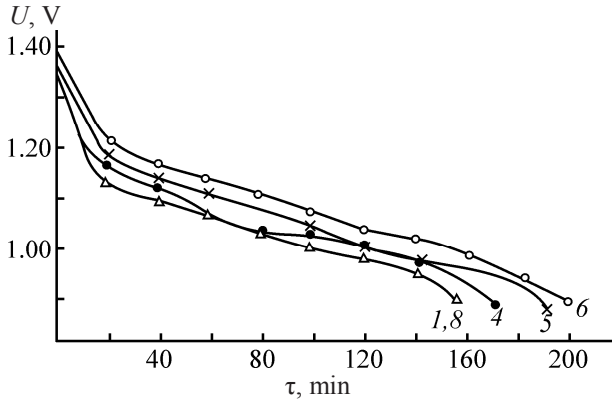

Fig. 3. Discharge curves of model MTs power cells. (U) Voltage and (τ) time. Digits at curves are numbers of power cell batches.

Figure 3 shows discharge characteristics of some batches of MTs power cells tested under the conditions specified (curves *1* and *8* almost coincide). The discharge time of the best of the cells, including that with the existing standard composition (curve *4*), corresponds to that for high-quality EMD samples [20, 21].

Figure 4 shows dependences of the electrical capacity of the power cells (curve *1*) and of the reagent utilization coefficient (RUC) (curve *2*) on the EMD content of the dry cathode mixture. It can be seen that, as the EMD content increases, the RUC first varies only

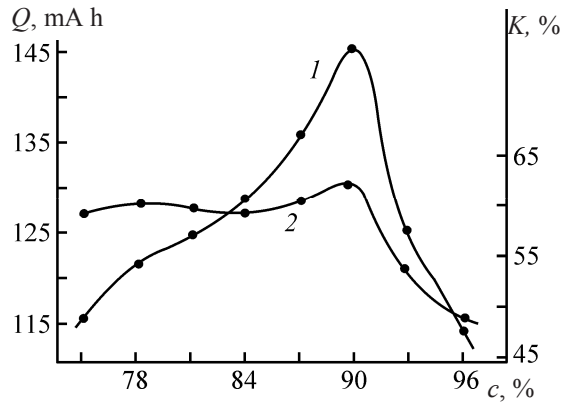

Fig. 4. (*1*) Electrical capacity Q of model MTs power cells and (*2*) reagent utilization coefficient K vs. the EMD content c of the dry cathode mixture.

slightly and the capacity of the power cells grows because the amount of the active substance (MnO_2) becomes larger. On reaching a maximum at 90% EMD, RUC steeply falls, which causes a dramatic decrease in the electrical capacity of the power cells. This is probably due to an increase in the internal resistance of the cells as a result of a decrease in the content of electrically conducting materials in the cathode mixture.

According to Figs. 3 and 4, the optimal EMD content of the dry cathode mixture is approximately 90%, which exceeds by 6% the standard value. It should be noted that, when the EMD obtained on FCM anode was tested in MTs power cells with a salt electrolyte, its optimal content was lower than the standard value [16]. It is suggested that the high quality of the EMD synthesized on FCM electrodes is due to two factors: elimination of electrode impurities (Ti, Pb, Cu, Fe) and presence of an admixture of the material of the FCM anodes in the product. If a salt electrolyte is used, the second factor is important [17]. In the case under consideration, the amount of FCM contained in the product is small, and, therefore, the purity of the EMD is of key importance in the improvement of its quality.

CONCLUSIONS

(1) Use of fibrous carbon materials as cathodes and anodes improves some technical (materials consumption, volume current density, specific electric power expenditure) parameters of MnO_2 electrosynthesis.

(2) Absence of admixtures of metallic electrode materials in electrolytic MnO_2 improves its quality as a cathode material for power cells of the MnO_2–Zn system with an alkaline electrolyte.

Abstract—Structural changes in humic acids from various soils, produced by acid hydrolysis, are studied by elemental and thermal analyses and by IR and NMR spectroscopy.

DOI: 10.1134/S1070427208110177

According to the modern views of the structure of a humic acid (HA) macromolecule, it consists of two major parts, a core built by aromatic fragments interlinked by aliphatic chains and a periphery consisting of readily hydrolyzable oxygen-containing fragments such as polysaccharides, ethers, polyphenols, and amino acids. Orlov [1] noted that the terms "periphery" and "core" are not quite adequate and that it would be more correct to designate these parts as hydrolyzable and nonhydrolyzable, which, however, appears to be inconvenient, and no adequate alternative for the above-mentioned terms has been found yet.

The use of hydrolytic methods for analysis of HAs originates from routine procedures employed for analysis of complex protein molecules. However, in contrast to proteins, none of HAs ever extracted have been fully decomposed via hydrolysis. The hydrolyzates were intensively studied, including their amino acid composition [2–10], polysaccharide fraction [11–15], and other components [10, 15].

The goals of this study were to examine the changes in the composition and structure of HAs, produced by acid hydrolysis, and to compare nonhydrolyzable fractions of HAs from soils of different genesis, using such methods as elemental and thermal analyses, IR, and NMR.

EXPERIMENTAL

We studied HAs extracted from tundra soils of the Tyumen oblast [cold soils: gley podzolic sandy loam (sample no. 1) and surface-gley clay loam (sample no. 2)] and dry-steppe zone of the Altai krai [warm soils: southern chernozem (sample no. 3) and chestnut soil (sample no. 4)].

The experiments on acid hydrolysis of HAs were carried out as follows [16]. A weighed portion (about 100 mg) of a sample was heated in a specially designed flask with 2.5 ml of 6 M HCl for 18 h at 120°C (sand bath) under helium. The residue was filtered off, washed with distilled water to remove the chloride ions, and air-dried to constant weight.

Carbon, hydrogen, and nitrogen were determined on a Carlo Erba Model 1106 elemental analyzer and also using the standard C,H analysis procedure for organic substances.

To measure NMR spectra, a 20–50-mg sample was dissolved in 0.5 ml of $NaOH/D_2O$ and placed into an ampule with an outer diameter of 5 mm. The ^{13}C NMR spectra were recorded on a Bruker DRX-500 instrument operating at 125.76 MHz. To exclude the nuclear Overhauser effect, the ^{13}C NMR spectra were recorded with proton decoupling in the INVGATE mode. Tetramethylsilane (TMS) was used as external reference. The spectra were recorded at 1-s pulse delay.

The IR spectra were recorded over the range 400–4000 cm^{-1} on a Vector-22 FTIR spectrometer (Bruker) using KBr technique (1:150).

Thermal analysis was carried out on an STA 409 PC Luxx thermoanalyzer (Netzsch) in a platinum cru-

cible in air. Samples were heated from 20 to 1000°C at a rate of 10 deg min^{-1}. The sample weight was determined to within 2 μg. The limit of intrinsic relative error of determination of the thermal effects was ±3%.

The elemental composition of the HA samples before and after hydrolysis is given in Table 1. It appears of particular significance to analyze the changes in the H/C, C/N, and O/C atomic ratios.

The H/C ratio is a significant parameter characterizing the aromaticity of humic acids. As can be seen, for chernozem and chestnut soil, hydrolysis does not affect this parameter. For the tundra soils, it slightly decreased after hydrolysis, being most strongly decreased for sample no. 2 (by more than 20%), suggesting increase in the fraction of aromatic fragments in nonhydrolyzable residue. However, in this case, the resulting H/C ratio (1.11) is still higher by a factor of 1.6 than that of HAs extracted from chernozem (0.71), suggesting a significant difference in the core structure of humic acids from tundra (cold) soils and steppe (warm) soils.

The observed considerable increase in the C/N ratio after hydrolysis, particularly, for HAs of tundra soils (by factors of 3 and 2.5 for sample nos. 1 and 2, re-

spectively), reveals that these HAs are characterized by high content of amino acid residues, which pass into solution in the course of hydrolysis along with the most part of nitrogen atoms. The remaining nitrogen is included into the heterocycles or fixed via other, stronger bonds. In HAs extracted from warm soils, the hydrolyzability of nitrogen is lower: C/N increases by a factor of 1.5 for HAs from chernozem and only 1.2 for HAs from chestnut soil.

The decrease in the relative oxygen content (O/C) after hydrolysis is observed only for HAs of tundra soils, the decrease being less pronounced as compared to that in C/N. For HAs extracted from chernozem and chestnut soils, the O/C ratio remains unchanged within the determination error. Therefore, under the experimental conditions, hydrolysis of the peptide bonds prevails over that of the ester and glycoside bonds.

No significant differences were observed between the IR spectra of HAs of steppe soils and their nonhydrolyzable residues. Furthermore, their spectra in the range 400–1800 cm^{-1} are identical to those of nonhydrolyzable residue of HAs from tundra soils. However, the IR spectra of HAs from cold and warm soils differ in the range from 1800 to 4000 cm^{-1} in that the strong bands due to stretching vibrations of methylene groups (2927 and 1854 cm^{-1}) are observed in spectra of HAs from tundra soils. Neither the intensity nor the position of these bands change after hydrolysis, evidencing the presence of the methylene chains in the nonhydrolyzable residue, i.e., in the core of HAs of tundra soils.

The DSC curves obtained in heating HAs in air are shown in Figs.1a–1c. The nonhydrolyzable residue obtained after hydrolysis of HAs of tundra soils is characterized by more distinctly pronounced low-temperature (<400°C) and high-temperature (400–700°C) thermal effects, the maximum of the high-temperature exothermic effect being shifted toward higher temperatures. For HAs of steppe soils, the low-temperature exothermic effect is no longer observed after hydrolysis, and the maximal decomposition temperature increases.

Data on the weight loss of the HA samples in the course of heating are given in Table 2. All the samples are characterized by low ash content, the total weight loss being about 90%. The periphery to core (P/C) ratio is slightly below 0.5 for HAs of steppe soils. For all HA samples studied, this ratio remains practically unchanged after hydrolysis, except for the sample of gley-podzolic soil, in which the core fraction considerably increases. The total thermal effects of decomposition of HAs of tundra soils are higher than those of HAs from steppe soils, which can be attributed to different mechanisms of oxidative decomposition of HAs of cold and warm soils.

ple weight and carbon content (at. %), we estimated the hydrolyzability of particular structural fragments of HAs (Table 4). As expected, the most sensitive to hydrolysis are polysaccharide fragments. Their hydrolyzability was demonstrated to be independent of the soil nature, being about 70% for both HAs of tundra soils and chernozem. Thus, about 30% of polysaccharide fragments remain in the nonhydrolyzable residue.

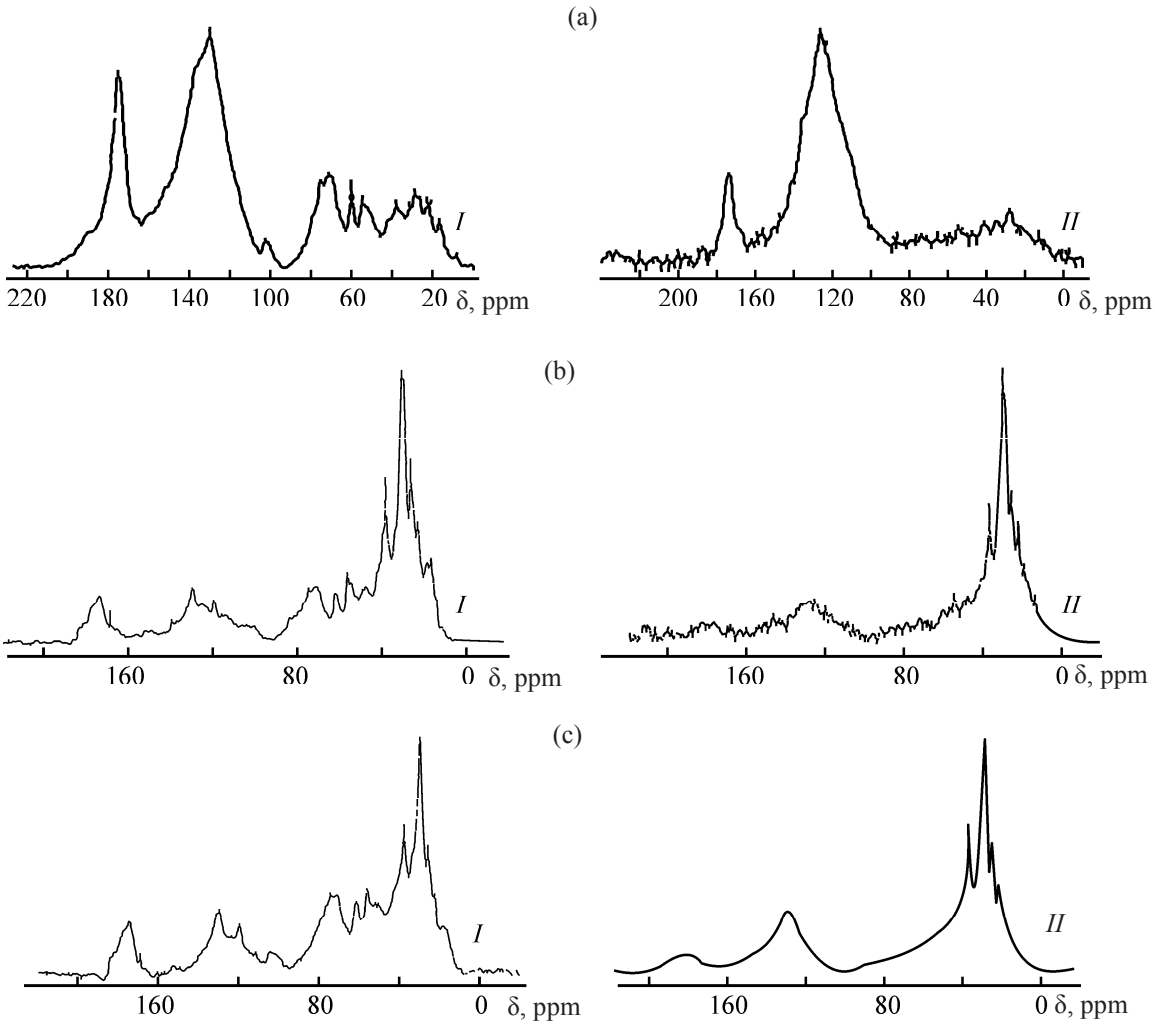

Fig. 2. ^{13}C NMR spectra of (*I*) initial HAs and (*II*) nonhydrolyzable residue after treatment with 6 M HCl. (δ) Chemical shift. Sample no.: (a) 3, (b) 1, and (c) 2.

Sample no.	Aromatic fragments, %			Polysaccharide fragments, %			Aliphatic fragments, %		
	initial	nhr	hydrolyzed, %	initial	nhr	hydrolyzed, %	initial	nhr	hydrolyzed, %
1	6.3	4.4	30.3	3.8	1.2	68.2	20.9	17.3	17.2
2	5.7	5.4	4.9	5.5	1.8	66.7	18.9	14.3	24.2
3	22.8	20.3	10.9	4.8	1.2	74.2	8.9	2.84	68.1

They are bound via ether bonds, which are stable under the experimental hydrolysis conditions.

The hydrolyzability of aromatic fragments depends on the soil kind. In this relation, the difference between two samples of tundra soils appeared to be particularly unexpected. The hydrolyzability of aromatic fragments of HAs of gley-podzolic sandy loam soil (sample no. 1) is 30%, whereas that of surface-gley clay loam soil (sample no. 2), only 5%. This value for chernozem is 11%. However, the absolute values of the loss of aromatic fragments in sample nos. 1 and 3 are very similar. It is about 2–2.5% of aromatic fragments that are bound to the macromolecule via bonds unstable under the experimental conditions.

There is a similarity in the hydrolyzability of the carboxy fragments of HAs of chernozem (sample no. 3) and gley-podzolic soil (sample no. 1): about a half of these fragments passed in the hydrolyzate (52 and 53%, respectively), in contrast to surface-gley clay loam soil (sample no. 2) initially containing small amount of carboxy fragments, and only about a quarter of them (26%) is hydrolyzed. As a result, the nonhydrolyzable residues of HAs of tundra soils contain practically equal amount (1.5%) of carboxy fragments.

The hydrolyzability of aliphatic fragments differs depending on the climatic zone. It is about 20% for tundra soils (sample nos. 1 and 2), and 70% for HAs of southern chernozem (sample no. 3).

CONCLUSIONS

(1) Under the experimental acid hydrolysis conditions, the peptide, glycoside, and ester bonds in humic acids extracted from various soils are cleaved, which affects their elemental and group composition.

(2) Hydrolyzability of the polysaccharide fragments is independent of the soil nature, while that of the aliphatic fragments depends on the climatic zone.

(3) Nonhydrolyzable fractions (core) of humic acids extracted from tundra and steppe soils differ significantly in their composition. In the core of humic acids extracted from tundra soils, aliphatic chains dominate, whereas in steppe soils, aromatic fragments prevail.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Solvent Effect on Epoxidation of Allyl Chloride with Hydrogen Peroxide on Titanium-Containing Silicalite

Abstract—The solvent effect on liquid-phase epoxidation of allyl chloride with an aqueous solution of hydrogen peroxide on TS-1 titanium-containing silicalite was examined. 1-Butanol, 2-butanol, 1-propanol, isopropanol, methanol, ethanol, water, acetone, methyl ethyl ketone, and 1-pentanol were tested as solvents.

DOI: 10.1134/S1070427208110189

Epichlorohydrin is an important product of basic organic synthesis. It is highly reactive owing to the presence of an epoxy group and a labile chlorine atom. Epichlorohydrin readily reacts with compounds of various classes, which allows preparation of many valuable products from it (epoxy resins, lacquers, paints, adhesives, synthetic fibers, ion-exchange resins, rubbers characterized by high oil and heat resistance and impermeability to gases). However, despite diversity of products prepared using epichlorohydrin, the major area of its application is production of epoxy resins (68% of the whole amount of epichlorohydrin produced) [1].

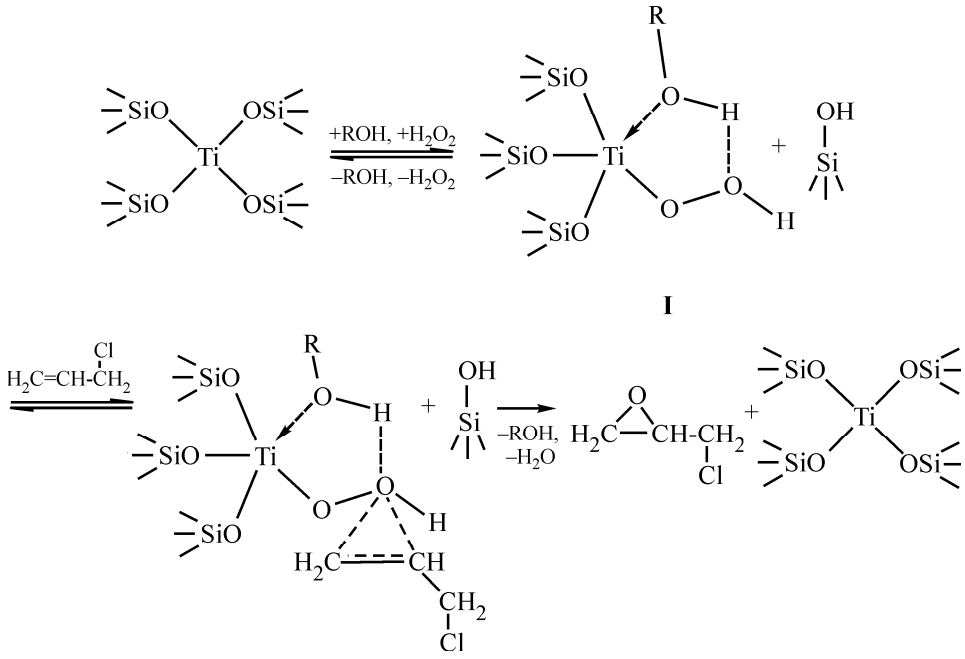
Today epichlorohydrin is produced on the large-tonnage scale (the annual world production exceeds 1.3 million tons [1]). In Russia, the demand for products based on epichlorohydrin increases by 4–5% annually, and the major fraction of epichlorohydrin is imported.

With the steadily growing demand for epichlorohydrin, it becomes necessary to put into operation new facilities capable of producing a competitive product. Our analysis of procedures for epichlorohydrin production [2] showed that the most promising procedure is liquid-phase oxidation of allyl chloride with hydrogen peroxide in an organic solvent on a heterogeneous catalyst, titanium-containing zeolite TS-1 [3]. However, published data on the solvent effect on the process are virtually lacking.

Here we report the results of studying the solvent effect on liquid-phase oxidation of allyl chloride with an aqueous solution of hydrogen peroxide on TS-1 titanium-containing catalyst.

In our study we used the following chemicals. Solvents: 1-butanol, 2-butanol, 1-propanol, isopropanol, methanol, ethanol, water, acetone, methyl ethyl ketone of pure or analytically pure grade, distilled and dehydrated before use; epichlorohydrin of pure grade, GOST (State Standard) 12 844–74; 33–34% hydrogen peroxide of ultrapure grade [TU (Technical Specification) 2611-069-05 807 977–2006]; and allyl chloride (TU 6-01-753–77). The catalyst, titanium-containing zeolite, was prepared by the procedure described in [3] (Ti content counting on TiO_2 3.16%). Experiments were performed on a batch laboratory installation at 30°C, allyl chloride : hydrogen peroxide molar ratio of 3.0, and solvent : allyl chloride weight ratio of 9.1. The content of the titanium-containing zeolite remained the same in all the experiments (8.0 g l^{-1}).

The reaction mixture components were analyzed by GLC on a Tsvet 500 chromatograph under the following conditions: 2000 × 3-mm metallic column; stationary phase Carbowax 6000 (15 wt % on Chromaton N-AW); flame ionization detector; carrier gas nitrogen, flow rate 50 ml min^{-1}; vaporizer and column temperatures 180 and 130°C, respectively. Hydrogen peroxide was determined by iodometric titration.



Epoxidation of allyl chloride is usually performed with aqueous solutions of hydrogen peroxide in an organic solvent. In the process, the solvent acts as a homogenizer of allyl chloride and hydrogen peroxide, providing their reaction on the surface of a solid cata-

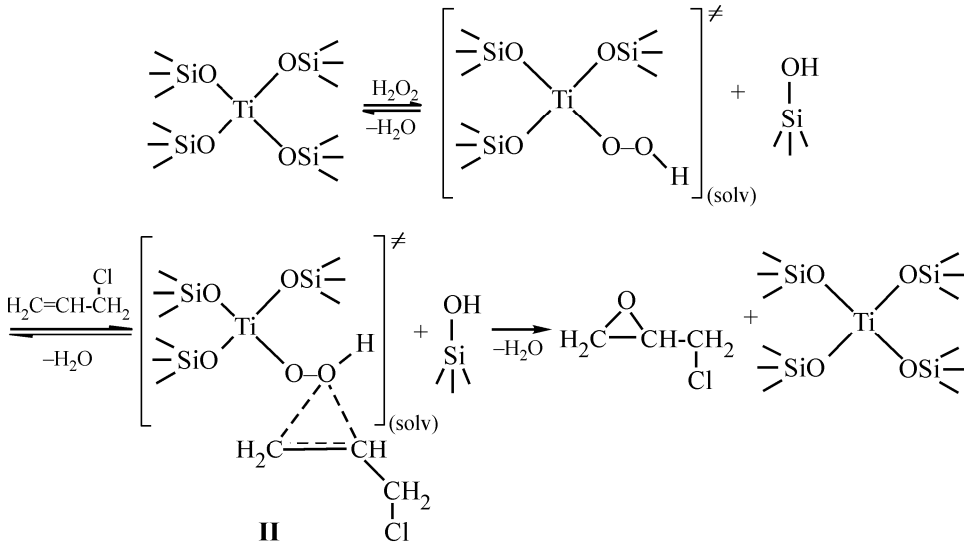
Solvent effect on the initial rate of hydrogen peroxide conversion and on the yield of epichlorohydrin. 30°C, 8.0 g l^{-1} catalyst, catalyst : hydrogen peroxide molar ratio 3.0, solvent : allyl chloride weight ratio 9.1

Solvent	Initial rate of H_2O_2 conversion, mol l^{-1} min^{-1}, $\times 10^2$	Yield of propylene oxide at 50% conversion of H_2O_2, %
Methanol	1.61	49.6
Ethanol	0.66	45.7
Isopropanol	0.47	43.4
1-Propanol	0.37	42.4
Acetone	0.33	42.9
2-Butanol	0.29	25.9
Methyl ethyl ketone	0.16	–
1-Butanol	0.7	–
Water	0.5	–

lyst. Therefore, the solvent should meet certain requirements. It should exhibit good solvency (toward both allyl chloride and hydrogen peroxide) and be sufficiently inert under the reaction conditions. Among diverse available solvents, we chose 1-butanol, 2-butanol, 1-propanol, isopropanol, methanol, ethanol, water, acetone, methyl ethyl ketone, and 1-pentanol. The results are given in the table.

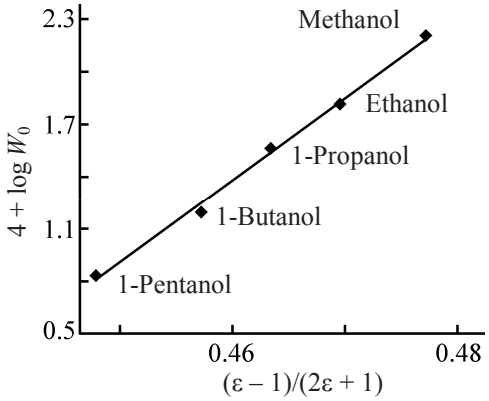
The table shows that the yield of epichlorohydrin decreases in the order methanol, ethanol, 2-propanol, acetone, 1-propanol. In the other solvents (methyl ethyl ketone, 1-butanol, 1-pentanol, water), 50% conversion of hydrogen peroxide was not attained in 180 min. Also, the solvent strongly affects the initial rate of hydrogen peroxide conversion. This solvent effect can be understood taking into account the mechanism of allyl chloride epoxidation with hydrogen peroxide in a proton-donor organic solvent on titanium-containing silicalite [4]:

Epoxidation of allyl chloride with hydrogen peroxide occurs on titanium atoms in the four-coordinate state [5] via formation of an active five-membered cyclic complex **I** in which the hydrogen peroxide molecule contains an active oxygen atom attacking the allyl chloride molecule [6].



Thus, the solvent not only acts as a homogenizer of the mixture of the starting reactants but also actively participates in the stabilization of the Ti peroxo complex **I** formed by a hydrogen peroxide molecule on a titanium center of the catalyst. Such stabilization is possible owing to coordination of a solvent molecule with a titanium center and formation of a hydrogen bond with a hydrogen peroxide molecule.

It should be noted that an increase in the size of the alkyl radical R in an alcohol molecule and, correspondingly, in the size of the transition complex **I** complicates the approach of an olefin molecule to the activated complex and thus hinders the oxygen transfer. Therefore, the yield of epichlorohydrin is the highest when methanol is used as solvent. Certain authors believe [7] that, along with the steric factor, a decrease in the yield of epichlorohydrin in the series methanol, ethanol, 2-propanol, acetone, 1-propanol, 2-butanol may be due to the fact that the binding energy of the solvent molecule in the transition complex increases in the order 2-butanol, 1-propanol, acetone, 2-propanol, ethanol, methanol. This leads to a decrease in the reactivity of the five-membered complex **I** and, as a result, to a decrease in the rate of oxygen transfer from the hydrogen peroxide molecule to allyl chloride. However, this hypothesis has not yet been confirmed experimentally.



Furthermore, owing to an increase in the volume of the solvent molecule, the rate of diffusion of the solvent and reaction products in catalyst pores decreases, which leads to a decrease in the process selectivity.

Numerous studies were aimed to examine the structure of the five-membered active complex, but its structure is still unclear because of the instability of the complex consisting of a titanium atom incorporated in the framework of titanium-containing silicalite, a solvent molecule, and hydrogen peroxide [8, 9]. Attempts are made [10, 11] to elucidate the structure of the five-membered complex by quantum-chemical calculations.

It is important that complex **I** is formed only in proton-donor solvents and is not formed in aprotic solvents. However, the Ti–OOH species exists in both systems [12]. The mechanism of epoxidation of allyl chloride with hydrogen peroxide in an aprotic organic solvent on a titanium-containing zeolite is as follows:

In this case, the effect of the aprotic solvent on the epoxidation of allyl chloride can be interpreted from the standpoint of the solvent polarity. Transition states observed in the course of the reaction are characterized by certain charge separation, i.e., they are more polar than the starting reactants. This should lead to variation of the epichlorohydrin yield with variation of the solvent permittivity. The higher the solvent permittivity, the lesser the extent to which the polar transition state is stabilized by solvation and the weaker the effect of internal factors on the reaction rate. Thus, an increase in the solvent polarity facilitates the cleavage

Correlation of the initial reaction rate W_0 with the permittivity function (ε – 1)/(2ε + 1) in oxidation of allyl chloride in various solvents. 30°C, catalyst content 8.0 g l^{-1}, allyl chloride : hydrogen peroxide molar ratio 3.0, solvent : allyl chloride weight ratio 9.1.

of the peroxy bond in complex **II** and the oxygen transfer to allyl chloride. In particular, the yield of epichlorohydrin increases as the solvent polarity grows in going from acetone to methyl ethyl ketone. Similar trends are observed in proton-donor solvents. The figure shows how the initial rate of allyl chloride epoxidation correlates with the dielectric constant of the medium within the same homologous series of alcohols (methanol, ethanol, 1-propanol, 1-butanol, 1-pentanol). For solvents of different classes, it is impossible to construct a correlation between the initial rate and solvent permittivity because of the growing role of steric factors.

In view of the trends revealed for organic solvents, it could be expected that the use of water as solvent would lead to an increase in the epoxidation rate. However, despite the absence of steric hindrance caused by large molecular volume of organic solvents and high polarity (ε = 78.5) of water, it is a poor solvent for performing the process. This may be caused by the fact that the concentration of the five-membered active complex in catalyst pores will be very low because of hydrophobicity of the titanium-containing silicalite [5]. This conclusion is consistent with the fact that in other processes the catalyst also shows lower activity with water as solvent [4].

Vankelecom et al. [13] suggested to perform oxidation on titanium-containing silicalite without a solvent in a three-phase system. Unfortunately, it is difficult to judge the efficiency of such a procedure because of the lack of experimental data on epoxidation of olefins. However, it is undesirable to perform the process under such conditions because of hazard associated with the use of concentrated hydrogen peroxide solutions.

It is important that, in the synthesis of epichlorohydrin, the desired reaction can be accompanied by side reactions, in particular, by oxidation of the solvent (of methanol to formaldehyde, of ethanol to acetaldehyde, of isopropanol to acetone). It was found that the reactivity of lower alcohols increases with an increase in their molecular weight. When the experiments were performed under the same conditions, formaldehyde was not detected (trace amounts), whereas in isopropanol the yield of acetone reached several percents. Aprotic solvents (acetone, methyl ethyl ketone) do not undergo such side transformations under the reaction conditions. However, the use of acetone or other ketones as solvents is undesirable, because in the presence of hydrogen peroxide they can form dangerously explosive organic peroxides [14].

CONCLUSION

Methanol is the most suitable as solvent for epoxidation of allyl chloride with hydrogen peroxide on the commercial scale.

Abstract—Physicomechanical and rheological properties of isotactic polypropylene modified with a high-molecular-weight amorphous polymer, polyoctene, were studied. Modification of polypropylene with polyoctene allows the impact resilience and relative elongation to be increased relative to the initial polypropylene and the processing temperature to be decreased.

DOI: 10.1134/S1070427208110207

Polyolefins are the main commercial thermoplastics, thanks to a set of their valuable propertries [1]. In particular, isotactic polypropylene (PP) exhibits high strength, high wear and chemical resistance, low water vapor and gas permeability, and good dielectric characteristics. At the same time, PP is brittle, and its frost resistance is poor (–15°C). This fact significantly restricts its application area.

The PP application area can be expanded by its modification allowing preparation of composite materials with improved processing and service characteristics.

Use of plasticizing polymeric additives as PP modifiers is well known. Among such additives are rubbers (butadiene–styrene, butyl rubber, copolymers of ethylene with propylene and/or with higher α-olefins) and thermoelastoplastics (block copolymers of butadiene with styrene) [1–3]. Introduction of an elastomer into a brittle polymer yields a product that is considerably more resistant to failure than the initial polymer. The impact resilience, breaking elongation, and rupture work increase, and the material becomes less brittle. Some parameters, however, inevitably become worse: the elastic modulus and breaking tensile stress somewhat decrease, the transparency is lost, and the melt becomes more viscous. Nevertheless, all these losses are insignificant compared to the gain in the resistance to failure.

Modification of PP can be performed both in the course of the synthesis and by mixing the homopolymer with an elastomer in the melt. The latter procedure, performed in an extruder, is widely used today. The extruder acts as a reactor in which the steps of the dispersion of ingredients and a chemical reaction between them can be combined [4]. The extrusion mixing combines functionalization of the ingredients in situ and formation of block or graft copolymers on the phase boundary. These copolymers act as compatibilizers, enhancing the specific intermolecular interaction of chains and making the ingredients better compatible [5].

In this paper we analyze the results of PP modification with high-molecular-weight polyoctene (HMWPO) exhibiting elastomeric properties (HMWPO is a comb-shaped flexible-chain polymer which can itself act as compatibilizer owing to the presence of labile pendant groups).

EXPERIMENTAL

As modifier for polypropylene of 21 270D grade containing 95 wt % isotactic fraction, we used a high-molecular-weight amorphous polymer, polyoctene, prepared as described in [6]. The viscosity-average molecular weight M of polyoctene was determined viscometrically [7] in tetrahydrofuran at 20°C by the formula

$$[\eta] = 2.32 \times 10^{-4} M^{0.69},$$

where [η] is the intrinsic viscosity.

The modifier was introduced into the compound in

a Brabender mixer at 180°C for 5 ± 0.5 min. The composition of the initial PP compound modified with high-molecular-weight polyoctene was as follows (wt %):

Polypropylene of 21 270D grade	Up to 100
HMWPO	16.0
Carbon black concentrate KTU-30PP	1.4
Irganox 1010	0.2
Calcium stearate	0.1

The melt flow index (MFI) of samples was determined on a Ray–Ran extrusion plastometer in accordance with ASTM 1238 standard under the following conditions: capillary diameter 2.095 ± 0.005 mm, temperature 230°C, load 2.16 kg.

The melting and crystallization points of substances were determined by differential scanning calorimetry (DSC) on a Mettler Toledo device in the automatic mode (heating rate 20 deg min^{-1}), in accordance with ASTM D 3418 standard.

Flow curves were obtained with a Brabender plasticorder at 200°C (shear rate 228–5750 s^{-1}).

Reference samples for physicomechanical tests of the initial and modified PP were prepared by pressure casting with a Negri–Bossi machine.

The physicomechanical and thermal properties of PP and its compounds were evaluated either by standardized Russian protocols in accordance with GOST (State Standard) 26 996 or by American standards, namely: bending elastic modulus, according to ASTM D 790; Izod impact resilience, according to ASTM D 256; ultimate tensile strength at yield point and relative elongation, according to ASTM D 638.

Mixed shock-resistant plastics are composite materials consisting of a rigid matrix with a relatively high melting point and a disperse phase of an elastomer with a low glass transition point. The adhesion between the phases should be sufficiently strong, and the elastomer should be uniformly dispersed in the polymer matrix. Specific character of physicomechanical properties depends on specific features of the elastomer used [3, 8]. As crystallographic studies of polyolefins and their copolymers show [1], the use of bulky comonomer units in production of an elastomer, such as 1-octene, is more preferable than the use of propylene and 1-butene, because the latter units are inserted into crystalline formations and destroy them, whereas 1-octene units remain in amorphous regions. Therefore, the use of polyoctene as an elastomeric phase in a compound may be more efficient than the use of ethylene–propylene copolymers.

Table 1. Melting and crystallization points of modified polypropylene

HMWPO content, wt %	T_m, °C	T_{cr}, °C
0	160.0	116.0
8	159.5	117.1
14	158.5	117.2
20	157.5	116.3

As the difference between the melting point of isotactic PP and polyoctene is almost 200°C [1], it was interesting to examine the effect of HMWPO on temperature characteristis of the compound. The HMWPO content was varied from 8 to 20 wt %.

The results obtained by DSC (Table 1) show that the melting and crystallization points of PP compounds remain essentially the same.

One of important parameters for estimating the mechanical properties of the polymer is Izod impact resilience. The experimental data (Fig. 1) show that introduction of elastomeric HMWPO into the compound increases its impact resilience compared to the initial PP.

It should be noted that the impact resilience of modified samples, determined in the region of negative temperatures, increases insignificantly, whereas at room temperature the impact strength of the compound increases by a factor of almost 2 at 14 wt% and higher content of the modifier.

Along with the Izod impact resilience, the mechanical properties of PP are characterized by the stretch

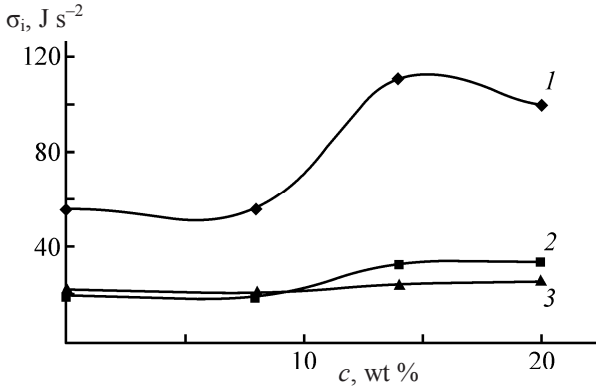

Fig. 1. Izod impact resilience σ_i as a function of the content c of HMWPO modifier in PP samples. Temperature, °C: (*1*) +23, (*2*) –20, and (*3*) –40.

Table 2. Deformation–strength properties of polypropylene–polyoctene compounds

HMWPO content, wt %	Bending elastic modulus, MPa	Ultimate tensile strength at yield point, MPa
0	1635	34
8	1170	29
14	885	24
20	666	19

diagram. At a tensile strain of a PP article, only the initial portion of the diagram is important. The "service suitability" of PP is evaluated by the yield point, i.e., by the maximum in the stretch diagram, corresponding to definite values of stress and relative elongation. The PP behavior in tensile tests is determined, according to published data, by the ratio of the crystalline and amorphous fractions in a sample. With an increase in the content of the atactic fraction playing the role of an elastomeric phase, the tensile elastic modulus decreases, the relative elongation, as a rule, increases, and the ultimate tensile strength at yield point somewhat decreases [2].

Experimental data show that this character of variation of the above characteristics is also observed with HMWPO: With an increase in the modifier content in the PP compound, the relative elongation increases (Fig. 2), and the tensile elastic modulus and the ultimate tensile strength decrease (Table 2). This is apparently associated with the elastomeric nature of the modifying additive, which can be used in production of specific articles in some branches of industry.

The effect of elastomers on the properties of the base polymer is manifested not only in the solid state but also in a melt, because the rheological properties of the melt change. For example, the viscosity associated with an increase in the hyperelastic strain appreciably increases, which is accompanied by swelling of the extrudate jet [9]. The latter fact is important for the modern high-speed casting processes. The behavior of HMWPO and PP melts is of doubtless interest in this respect.

Primary evaluation of the modifier effect on the viscosity properties of the melt was made by measuring MFI of samples at a load of 2.16 kg and a temperature of 230°C. The test results are shown in Fig. 3. It can be seen that modification of PP with elastomeric polyoctene leads to a significant increase in the melt flow index, which is apparently due to good compatibility of the components and strong plasticizing effect of the modifier.

The melt flow index of the polymer, by which the viscosity properties of melts are usually evaluated in technological practice, correspond to only one point in the flow curve in the region of relatively low shear stresses. Samples with the same MFI can strongly differ in the processing properties, owing to the sensitivity of the viscosity to the variation of the shear rate [10]. Therefore, for more complete evaluation of the rheological properties of modified PP, we used the flow curves. The results of rheological tests are given in Fig. 4.

[a] (GOST) State Standard and (TU) Technical Specification.

Figure 4 shows that an increase in the modifier content in the compound favors a decrease in the shear stress with increasing shear rate.

Thus, analysis of the rheological properties of modified PP shows that, to intensify the PP processing, flexible-chain comb-shaped polyoctene is a promising modifier allowing not only an increase in the processing rate in production of composite materials, but also a decrease in the processing temperature.

In addition, we compared the main physicomechanical and thermal properties of 21 270 D grade polypropylene modified with polyoctene ([η] = 12.0) and of commercial frost- and shock-resistant PP modified with ternary ethylene–propylene–diene copolymer SKEPT50. The amount of modifiers in the compound was 16 wt % (Table 3).

The data we obtained show that the impact resilience and other physicomechanical characteristics of the experimental sample are no worse or appreciably better than those of the compound with SKEPT-50. At the same time, the relative elongation at break increased by 34% and MFI, by a factor of 3.

CONCLUSIONS

Polyoctene, a high-molecular-weight polymer derived from a higher α-olefin, when used as an elastomeric component of a shock- and frost-resistant polypropylene-based compound, shows certain advantages as compared to the known elastomers and quite real prospects for practical use.

MACROMOLECULAR COMPOUNDS AND POLYMERIC MATERIALS

Influence of the Nature of Curing Agents on Properties of Polyetherurethanethiol Composites

Abstract—The effect of the nature of curing agents on the properties of sealants based on polyetherurethanethiols was examined.

DOI: 10.1134/S1070427208110219

HS-Terminal oligomers are widely applied for preparing mastics and sealants used in machine and ship building, aviation industry, and construction [1–4]. However, preparation of such oligomers, Thiokols, is extremely hazardous for the environment. Production of 1 t of Thiokol involves formation of 60 t of highly toxic aqueous–organic salt solutions requiring utilization. Therefore, of increased interest are procedures for preparing SH-containing oligomers that do not involve formation of so large amounts of wastewater. Principally, such routes exist. For example, the reaction of polyetherdiols or –triols with diisocyanates yields preisocyanates:

$$–OH + O=C=N–R–N=C=O \rightarrow \sim O–CO–NH–R–N=C=O.$$

The reaction of preisocyanates with mercapto alcohols allows preparation of polyetherurethanethiols (PEUTs):

$$\sim O–CO–NH–R–N=C=O + HO–CH_2–CH_2–SH$$

$$\rightarrow \sim O–CO–NH–R–NH–CO–O–CH_2CH_2–SH.$$

These compounds contain terminal mercapto groups, which can be oxidized to disulfide groups or converted to metal mercaptides. In so doing, the material will be cured with the formation of a 3D structure. This procedure is environmentally clean. The PEUT synthesis process is single-step. All these advantages attract attention. However, until now, only scarce patent information concerning this approach was available, and there are virtually no data on the properties of sealants based on PEUT [5, 6].

The goal of this study was to examine the properties of sealants prepared on the basis of PEUT, in particular, to reveal the dependences of the physicomechanical properties of the vulcanizates on the nature of the curing agents, because it is well known that this factor strongly affects the properties of sealants [1–4, 7].

EXPERIMENTAL

The substances used in this study met the requirements indicated in Table 1.

Laprol used for preparing PEUT was preliminarily dried in a vacuum at a residual pressure of 2600 Pa and

a temperature of 90–100°C for 4 h. Then the hydroxyl number of the dry polyether was determined in accordance with GOST (State Standard) 25 261–82. The preisocyanate was synthesized in a four-necked flask equipped with a power-driven stirrer, a thermometer, and a reflux condenser with a calcium chloride tube and a tube for introducing an inert gas (nitrogen or argon). First the dried polyether and toluylene diisocyanate (T-80 grade) were charged to the flask with stirring at 40–45°C. The reactant ratio should correspond to the HO : NCO ratio of 1 : 2. An inert atmosphere was provided by feeding nitrogen at excess pressure. The flask contents were heated to 80 ± 5°C, and this temperature was kept for no less than 2 h with stirring of the reaction medium. The reaction completion was judged from the attainment of a constant content of isocyanate groups in the reaction medium. The amount of isocyanate groups in aliquot portions was determined in accordance with TU (Technical Specification) 38.103 137–78.

Mercaptoethanol can react with isocyanates via both hydroxy and mercapto groups. When performing this step, we took into account the results of a thermodynamic analysis of the reaction of phenyl isocyanate with methanol and methyl mercaptan [8], which showed that thiourethanes at 100°C virtually completely decompose into the starting reactants, whereas urethanes remain stable at this temperature. Our experiments showed that, when this reaction step is performed at temperatures below 100°C, the reaction mixture rapidly transforms into a rubber-like mass.

The preisocyanate from the previous step was mixed with mercaptoethanol at 60–70°C. The molar ratio of the isocyanate and hydroxy groups was kept equal to 1 : 1. Then the reaction mixture temperature was increased to 100 ± 5°C, and the mixture was stirred in an inert atmosphere for no less than 6 h up to complete exhaustion of the isocyanate groups. The resulting PEUT is a viscous colorless liquid at room temperature. The content of SH groups in PEUT was determined in accordance with TU 38.103 636–87 to be 2.30 wt %. The IR spectrum of PEUT (film on KBr, Perkin–Elmer 16PC–FT-IR device) contains amide absorption bands (1720, amide I; 1540, amide II; 1280 cm^{-1}, amide III), a band of N–H stretching vibrations (3335 cm^{-1}), bands of antisymmetric and symmetric vibrations of C–H bonds in methyl and methylene groups (2960, 2940, 2970, 2860 cm^{-1}), bands of bending vibrations of C–H bonds in methylene and methyl groups (1470, 1350 cm^{-1}), a strong absorption band of C–O–C antisymmetric stretching vibrations (1150 cm^{-1}), and a weak bond of H–S stretching vibrations (2560 cm^{-1}).

The vulcanizates of PEUT-based sealants were prepared by mixing the base paste with a curing paste containing curing agents. The compositions of the base and curing pastes are given in Table 2.

To reveal the influence of the curing agent content in the sealant compound on the physicomechanical properties of the vulcanizates, we varied the relative amounts of the base and curing pastes in the compound. The preparation of the vulcanizates consisted of the following steps.

(1) Preparation of the base paste by manually mixing the components in a porcelain mortar with a putty knife, according to the formula given in Table 2.

(2) Preparation of the curing paste by manually mixing the components in a porcelain mortar with a putty knife, according to the formula given in Table 2.

(3) Preparation of vulcanizates by manually mixing the base and curing pastes in a porcelain mortar with a putty knife and keeping the compound for 1 day at room temperature and for 3 h in an oven at 70°C. The samples obtained were kept for 1 day at room temperature, and their physicomechanical parameters were determined.

The physicomechanical parameters of the vulcanizates were determined in accordance with the procedures given in TU 5772-042-05 766 764 "Building Sealant 1m." The tensile strength σ, stresses at 100 and 300% elongation σ_{100}, σ_{300}, relative elongation ε, and elongation set ε_{set} were determined with a 2166R-55 tensile-testing machine, and the Shore hardness (scale A), with a TIR hardness meter, GOST 7761–55.

The working life of sealant compounds was determined at room temperature as the time within which the compound can be uniformly applied to any surface. The water absorption of sealant vulcanizates was determined by the procedure described in [9].

We studied the vulcanization of PEUT-based sealant compounds under the action of manganese dioxide, sodium bichromate, and zinc oxide. The first two agents are oxidative curing agents, and the third is a salt-forming agent.

The use of manganese dioxide for vulcanization of oligomers with HS fragments is based on the reaction [1–4, 7]

$$2\ {\sim}SH + MnO_2 \rightarrow {\sim}S{-}S{\sim} + Mn(OH)_2. \quad (1)$$

This reaction step is catalyzed by bases. For this purpose, diphenylguanidine is added to the curing paste. The resulting white manganese(II) hydroxide is then readily oxidized to brown manganese(III) oxyhydroxide and then to manganese(IV) hydroxide [10, 11]:

$$2Mn(OH)_2 + O_2 \rightarrow 2MnO(OH) + H_2O, \quad (2)$$

$$4MnO(OH) + 6H_2O + O_2 \rightarrow 4Mn(OH)_4. \quad (3)$$

The occurrence of the last two steps requires the presence of water, which is introduced into the curing paste. Manganese(III) compounds are less powerful oxidants than Mn(IV) compounds [10]. Principally, oligomers containing HS groups could be vulcanized by catalytic amounts of manganese dioxide. However, in this case the process becomes too long, which is unacceptable. Therefore, in practice manganese dioxide is introduced into sealant compounds in increased amounts (>2 wt %). The vulcanization mainly occurs owing to the direct reaction of mercapto groups with manganese dioxide [reaction (1)]. We made experiments to determine what amounts of manganese dioxide should be introduced into PEUT-based compounds to attain the best physicomechanical parameters of the sealing agents under the common vulcanization conditions.

Bichromates are six-electron oxidants, and in the presence of water Cr(VI) compounds are readily reduced to Cr(III) compounds [11]:

$$6\ {\sim}SH + Na_2Cr_2O_7 + H_2O \rightarrow 3\ {\sim}S{-}S{\sim} + 2Na[Cr(OH)_4]. \quad (4)$$

The reaction of aromatic [12] and aliphatic [13] mercaptans with zinc oxide is a preparative route to zinc mercaptides:

$$2\ {\sim}SH + ZnO \rightarrow ({\sim}S)_2Zn + H_2O. \quad (5)$$

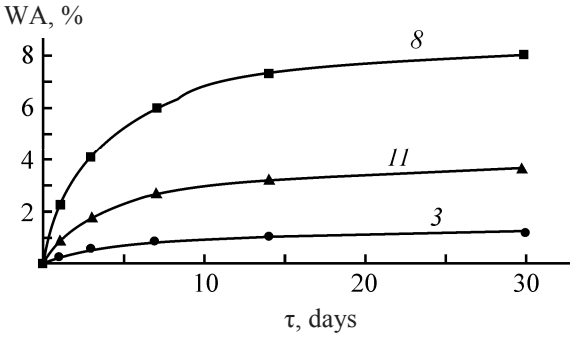
In the latter two cases, it was also necessary to elucidate the influence of the amount of curing agents on the properties of the sealants obtained.

The physicomechanical properties of sealants cured in the presence of curing agents of different chemical nature are given in Table 3.

As seen from the data obtained, the physicomechanical parameters of the vulcanizates in all the cases increase with an increase in the content of the curing agents in the compounds. For complete exhaustion of mercapto groups in vulcanization of the sealant compound in accordance with Eq. (1), the required content of MnO_2 is 2.63%; that of sodium bichromate [Eq. (4)], 1.51%; and that of zinc oxide [Eq. (5)], 5.30%.

The use of zinc oxide leads to formation of vulcanizates with unsatisfactory properties. Introduction into the compound of superstoichiometric amounts of zinc oxide failed to give a positive result. We believe that this fact is due to a weak oxidizing action of ZnO on SH groups.

Sodium bichromate is a more effective curing agent than manganese dioxide. Good properties of the sealants are attained when the bichromate is taken in a substantially smaller amounts relative to the stoichiometry [Eq. (4)]. This fact suggests that chromium in higher valence states can be formed from Cr(III) under the action of atmospheric oxygen. Indeed, Cr(III) compounds are oxidized with atmospheric oxygen to Cr(IV) compounds, and these reactions are catalyzed by variable-valence heavy metal ions [14, 15]. Note that an increase in the sodium bichromate concentration in the compound leads to substantial changes in the physicomechanical parameters of the vulcanizates: the tensile strength and hardness increase and the elongation set decreases. Similar trends are observed in vulcanization with manganese dioxide.



The consumer's properties of sealants are determined by their behavior toward water. Low water ab-

sorption is the necessary condition of their practical use. Therefore, we evaluated the water absorption of the sealants. In so doing, we examined samples whose properties, from our viewpoint, are the best in the series. The results are shown in the figure.

The sealant obtained with manganese dioxide exhibits the lowest water absorption. It is two times lower than that of the common Thiokol sealants. Vulcanizates based on zinc oxide exhibit moderate water absorption. The highest water absorption is observed with the sealants vulcanized with sodium bichromate. Only in the latter case, both the curing agent and its transformation products are water-soluble. Presumably, the increased water absorption in this case is due to formation of solvation shells around species formed in transformations of sodium bichromate.

Water absorption WA of vulcanizate samples as a function of the exposure time τ. Figures at curves are sample nos. in Table 3.

Thus, sealants with acceptable service properties can be prepared on the basis of PEUT. Their production is simple and waste-free. Therefore, the new oligomers show much promise for practical use.

CONCLUSIONS

(1) Vulcanization of polyetherurethanethiol-based sealant compounds can be effected by oxidative (manganese dioxide, sodium bichromate) and condensation (zinc oxide) types. The best results are obtained with oxidative curing agents.

(2) Sodium bichromate is a more effective cross-linking agent for polyetherurethanethiol-based compounds than manganese dioxide.

(3) The water absorption of polyetherurethanethiol-based sealants depends on the nature of the curing agent used. The use of agents capable of solvation with water increases the water absorption of the vulcanizates.

MACROMOLECULAR COMPOUNDS AND POLYMERIC MATERIALS

Oxidation of Polyethylene Inhibited with a Phenolic Antioxidant under the Conditions of Contact with Metallic Zinc

D. G. Lin, E. V. Vorob'eva, and N. V. Marchenko

Skorina Gomel State University, Gomel, Belarus

Received March 25, 2008

Abstract—The inhibiting power of a phenolic antioxidant upon introduction into polyethylene contacting with metallic zinc was examined. Conditions at which zinc enhances the inhibiting effect of the antioxidant were determined, and the mechanism responsible for this effect was suggested.

DOI: 10.1134/S1070427208110220

It is well known that many variable-valence metals accelerate oxidation of noninhibited polyethylene (PE) owing to the transfer of soluble metal-containing compounds formed by contact reactions [1, 2]. These compounds exhibit high catalytic activity and transfer the oxidation process from the layer adjacent to the metal into the bulk of the polymeric material. Therefore, for successful operation of metal–polymer materials and articles containing active metals, it is necessary to ensure deactivation of the catalytic surface of metal-containing compounds which in the course of oxidative transformations migrate in a polymeric binder. One of the ways to solve this problem is introduction into a polymer of antioxidant (AO) additives. The most common of them are amine and phenolic additives. Previous studies [3–5] showed that the use of such AOs for inhibiting the oxidation of polymers that are in contact with active metals can lead to quite unexpected results. For example, Irganox 1010, an effective AO for PE, in oxidative contact of the polymer with copper (e.g., in case of a PE coating on a copper support or of PE filled with dispersed copper) is rapidly consumed, and the induction period of the oxidation (IPO) decreases by a factor of more than 7 [4, 5]. On the contrary, relatively weak amine AO, Neozon D, under the similar conditions becomes more effective, and IPO of the polymer increases [3]. Below we briefly describe the mechanism [4] of the copper effect on the inhibiting power of amine and phenolic AOs.

With a phenolic AO, the decisive factor is transfer of copper-containing compounds from the zone of adhesion contact to the bulk of the polymer [4–6]. This transfer apparently occurs even during the IPO. The transferred copper compounds catalyze the generation of primary radicals which, in turn, accelerate the AO consumption. In this step of the oxidation process, stable oxidation products (namely, carbonyl-containing compounds) are not detected yet, and, according to IR monitoring, this period can be considered as IPO. After the majority of AO is consumed, the oxidation becomes autocatalytic, and specifically this moment is fixed as the end of IPO.

Enhancement of the performance of an amine AO in the presence of copper is attributed [3, 7] to direct reaction of AO with copper (support surface or filler particles) with the formation of stable nitroxyl radicals whose inhibiting power is higher than that of the initial AO. Effective oxidation inhibitors arising in the contact zone suppress the formation and transfer of copper-containing compounds. As a result, the onset of the autocatalytic step of the oxidation process is delayed, and IPO becomes longer.

As can be seen, the use of AOs of different classes under the conditions of contact oxidation of PE on copper can lead to opposite results. Therefore, solution of the problem of suppressing the catalytic effect of active metals that are components of metal–polymer materials and of articles based on them will remain for a long time on the level of experimental search and discoveries. In this connection, we examined in this study the oxidation of PE inhibited by a phenolic AO and occurring in contact with metallic zinc.

EXPERIMENTAL

In the experiments we used powdered nonstabilized high-density PE prepared under the industrial conditions at a low pressure on complex organometallic catalysts [GOST (State Standard) 16 338–85, 20 306-005 grade). As oxidation inhibitor we used a phenolic antioxidant Irganox 1010 [pentaerythrityl tetrakis-3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propionate]. The AO was introduced into PE by wetting of the polymer powder with a solution of a dosed amount of AO in acetone (GOST 2603–79), followed by complete solvent evaporation at room temperature.

Two kinds of inhibited polymer samples were examined: PE films on a zinc support and films of PE filled with zinc powder (Ts 1 grade, GOST 18 843–73, particle size 2–7 μm). Zinc powder was introduced by mixing it with a powder of the inhibited polymer. From the binary (PE + AO) and ternary (PE + AO + ZnO) mixtures, we prepared films by hot pressing (150°C, 30 s). These films were used in the studies. Films of binary compounds were oxidized on zinc supports, and films of ternary compounds, on KBr plates (material transparent in the IR range [8]). It is known [9] that KBr is inactive with respect to PE oxidation. The samples were oxidized in air in ovens at 150 and 175°C.

As modifier for inhibited PE we also used zinc stearate [TU (Technical Specification) 6-09-17-316–96] to simulate the effect of zinc-containing compounds formed by contact oxidation of PE on zinc supports. Zinc stearate was introduced together with AO by treating the polymer powder with a solution of the modifiers in acetone. The films obtained after the solvent evaporation were then oxidized on KBr plates.

In our tests we used films of oxidized PE in which we estimated the extent of the polymer oxidation and the content of the transferred zinc in the polymer.

The extent of PE oxidation was characterized by the extinction factor, namely, by the ratio of the optical density at 1720 cm^{-1} in the IR spectra of the polymer to the film thickness in centimeters. To record the spectra of films oxidized on zinc supports, they were separated from the metallic base; films oxidized on KBr plates were subjected to IR measurements directly on the supports. The IR spectra were recorded on a Vertex 70 Fourier spectrophotometer (Bruker, Germany, 2004).

To determine the concentration of zinc transferred into the PE film in the form of compounds with polymer oxidation products, we used polarographic analysis [10]. When preparing working solutions for polarography, we used the ash residue of the polymer film oxidized on a zinc support. Ashing was performed by two-step heat treatment of the polymer samples under the conditions given in [11]. The ash residue was dissolved in a supporting electrolyte. The pH of samples was monitored with an EV-74 pH meter. The working solutions were examined with a PU-1 device using a mercury dropping electrode; the metal content of the solutions was determined from calibration plots. The results were converted to the metal concentration referred to the initial polymer weight.

Figure 1 shows data on the accumulation of carbonyl groups in PE films inhibited by Irganox 1010 and oxidized on KBr and zinc supports (curves *1*–*3*). The result was unexpected: The zinc support, promoting oxidation of nonstabilized PE, in this case acted as an additional oxidation inhibitor. The IPO of PE films oxidized on zinc appeared to be longer than that of the films contacting in the course of oxidation with an inert support, KBr. The effect of the additional suppression of the polymer oxidation on zinc depends on the polymer film thickness. With an increase in the film thickness, the support effect is enhanced and IPO increases (Fig. 1, curves *2*, *3*). The revealed effect of the zinc support on the oxidation of PE inhibited by Irganox 1010 was also observed with inhibited PE filled with zinc powder (Fig. 1b). As can be seen, introduction of zinc into the polymer makes IPO longer (Fig. 1, curves *1*, *5*–*8*).

With an increase in the concentration of the zinc filler, as well as with a decrease in the thickness of an unfilled PE film oxidized on a zinc support, IPO becomes longer. In both cases, the ratio of the surface area of the zinc support to the polymer weight increases. As a result, the effect exerted by zinc on the oxidation process becomes stronger. Apparently, a similar result can be obtained by decreasing the particle size of the zinc filler in the polymer, instead of increasing the filler concentration. In so doing, the total surface area of the filler particles and correspondingly the ratio of the filler surface area to the polymer weight will increase.

Additional prolongation of the IPO on adding dispersed zinc into inhibited PE is observed in a fairly wide range of oxidation temperatures. Figure 2 shows how IPO at 150 and 175°C depends on the concentration of the zinc filler. As can be seen, in both cases IPO of PE increases with an increase in the filler con-

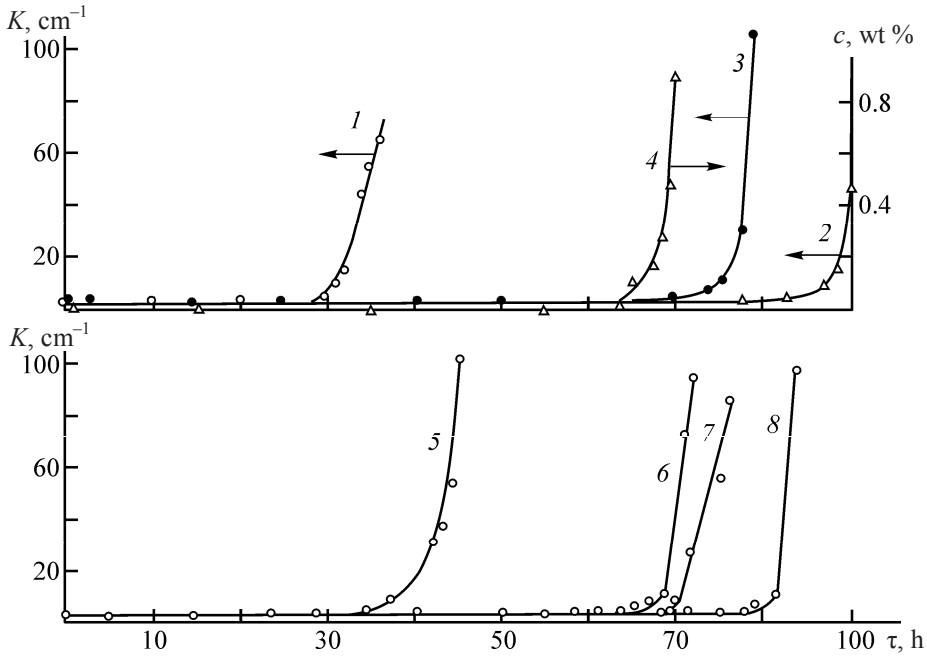

Fig. 1. Influence of the polymer oxidation time τ on (*1–3*, *5–8*) extinction factor K at 1720 cm^{-1} in the IR spectra of films and (*4*) zinc concentration c in films. centration. On introduction of the same amount of zinc, 15 wt %, into PE inhibited by 0.1% Irganox 1010, IPO at 150 and 175°C increased by a factor of 2.5 and 2.0, respectively.

Our further experiments were aimed to elucidate the possible mechanism by which zinc enhances the efficiency of PE inhibition with Irganox 1010.

Let us first assume that, in the polymer–AO–zinc system, direct interaction of AO with the zinc support does not appreciably affect its inhibiting power. Then it can be expected that the effect of the metal support is mediated by formation of microamounts of zinc-containing compounds and their participation in redox transformations in the polymer layer adjacent to the support. In this connection, it was necessary to estimate the activity of zinc-containing compounds formed by contact thermal oxidation. Because it is difficult to isolate such compounds from the bulk of the polymer being oxidized, we performed experiments with zinc stearate simulating such compounds.

Figure 3 shows that zinc stearate catalyzes the oxidation of inhibited PE, and the higher the concentration of the additive in the polymer, the shorter the IPO. For the viscous medium of a PE melt, it can hardly be expected that direct interaction of AO and zinc stearate molecules is the decisive factor in AO transformations. Most probably, these substances in the polymer affect the oxidation process separately, each accomplishing its own functions. Being an oxidation catalyst, zinc stearate catalyzed the oxidation, whereas Irganox 1010 tends to suppress oxidation by terminating the oxidation chains. Repeated participation of the metal (zinc) ion in catalytic events leads to accelerated consumption of AO and, correspondingly, to IPO shortening.

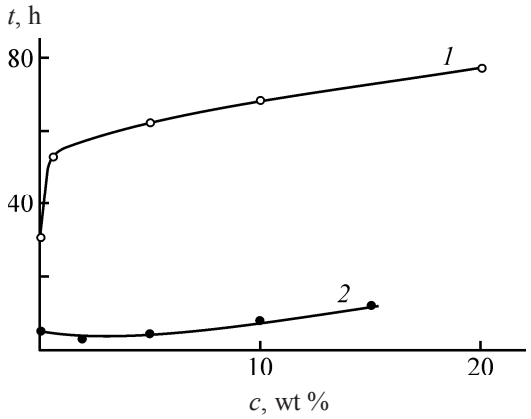

Fig. 2. Influence of the zinc powder content in the polymer c on the IPO duration t for PE films inhibited with 0.1 wt % Irganox 1010 and oxidized at (*1*) 150 and (*2*) 175°C on KBr plates. Film thickness 100 μm; the same for Figs. 3–5.

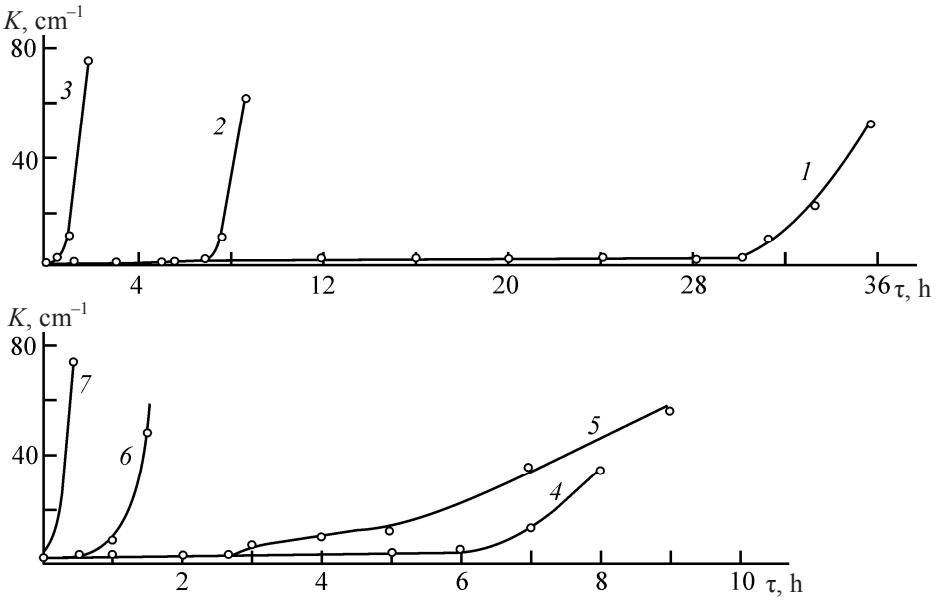

Fig. 3. Influence of the oxidation time τ of the polymer on KBr plates at (*1–3*) 150 and (*4–7*) 175°C on the extinction factor *K* at 1720 cm^{-1} in the IR spectra of PE films inhibited with 0.1 wt % Irganox 1010. Zn content in the form of metal stearate, wt %: (*1*, *4*) 0, (*5*) 0.05, (*2*, *6*) 0.5, (*7*) 1, and (*3*) 2.

Therefore, the diffusion transfer into the polymer of zinc-containing compounds formed by contact reactions should seemingly accelerate the oxidation. Actually, however, zinc enhances the inhibiting effect of Irganox 1010 introduced into the polymer. This means that, when studying the mechanism of the zinc action in inhibited PE, the consequences of the direct reaction of the metal with AO should be taken into account.

To elucidate this question, we performed the following experiments. In the first of them, we examined how the inhibiting power of Irganox 1010 changes upon its heat treatment in contact with a zinc support.

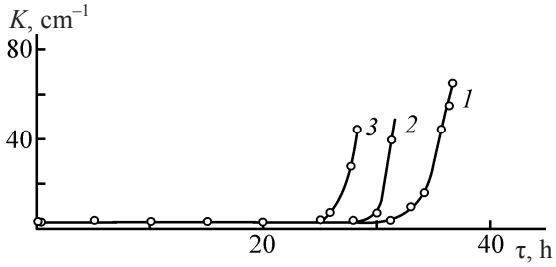

Fig. 4. Influence of the oxidation time τ of the polymer on KBr plates on the extinction factor *K* at 1720 cm^{-1} in the IR spectra of PE films inhibited with 0.1 wt % Irganox 1010. Temperature 150°C; the same for Fig. 5. Prior to introduction into the polymer, the AO was heat-treated at 123°C on the zinc surface for (*1*) 0, (*2*) 4, and (*3*) 10 h.

For this purpose, a thin (0.5 mm) layer of the AO was applied onto a zinc foil and heat-treated in air at 123°C for different times. After the heat treatment, the AO was dissolved in acetone and then introduced into PE (the Irganox 1010 concentration in the polymer was also 0.1%). Figure 4 shows that, upon heat treatment of the AO in contact with zinc support, its inhibiting power decreases. In other words, direct reaction of the initial AO with zinc cannot lead to an additional increase in IPO under the conditions of contact of inhibited PE with the metal (Fig. 4).

In the second experiment, we compared the efficiency of PE inhibition at two different modes of AO introduction into the polymer. In procedure I, the AO amount required for the inhibition was first applied onto the surface of the polymer filler, and then the filler with the antioxidant additive was introduced into the polymer. For this purpose, before introduction into the polymer, a dosed volume of the filler was wetted with a solution of AO in acetone. The resulting suspension was dried until complete evaporation of the solvent, after which the filler was mixed with the polymer powder. In this procedure, the AO distribution in the polymer was nonuniform. Virtually the whole amount of AO was on the surface of the filler particles. Naturally, in the course of the tests AO passed into the polymer melt and provided its oxidation protection. In

procedure II, a mechanical mixture of polymer and filler powders was wetted with an AO solution. After that, the solvent was evaporated and the composite obtained was used in the experiments. This procedure ensured uniform distribution of the AO in the bulk of the polymer, with only very small amount of AO deposited on the metal surface.

Figure 5 shows data on the oxidation of PE compounds prepared by procedures I and II. We found that, when the AO is introduced by procedure I, the presence of filler has virtually no effect on the heat resistance of the composite. In this case, the IPO of the samples (Fig. 5, curve *1*) is almost the same as IPO of the inhibited PE containing no zinc filler (Fig. 1, curve *1*). Hence, blocking of the filler surface with an antioxidant additive prevents participation of the metal in the additional prolongation of the IPO. Therefore, it can be assumed that the zinc surface in the course of oxidation favors regeneration of the spent AO and its reuse. If the amount of AO on the zinc surface is small and the filler surface is not blocked (procedure II), the zinc surface participates in the process more actively and IPO of the composites increases (Fig. 5, curve *2*).

Denisov et al. [12, 13] indicate that variable-valence metal ions can repeatedly terminate chains of oxidative transformations in oxidation of low-molecular-weight hydrocarbons and alcohols. The chain termination reactions occur between alcohol oxidation products and transition metal ions [13]:

$$>C(YH)OO^{\cdot} + M^{n+} \rightarrow C(YH)OO^{-} + M^{n+1},$$

$$>C(YH)OO^{\cdot} + M^{n+1} \rightarrow C{=}Y + O_2 + H^{+} + M^{n+}.$$

In the system PE–zinc–phenolic AO, such processes are quite probable. Firstly, the required substances, transition metal (Zn) and low-molecular-weight organic substance with an alcoholic group (AO), are available in the system. Secondly, multiple chain termination starts upon accumulation of the direct participants of the process: zinc ions (metal-containing compounds formed by contact reactions and zinc oxide on the surface of the support or filler) and oxidized form of AO (product of inhibitor oxidation by reactions with peroxy radicals, oxygen, and hydroperoxide [13]). This conclusion is convincingly confirmed by the following experiment.

Polyethylene films containing 0.1% Irganox 1010 were first heat-treated in air in contact with zinc supports, after which the process was terminated, and the films were separated from the supports and transferred onto KBr plates for further oxidation at the same temperature. The time of film preoxidation in contact with zinc did not exceed the IPO duration, i.e., the transition of the oxidation process to the autocatalytic step was observed only in the course of film oxidation on KBr plates. The data below show how the time of the preliminary heat treatment of the films in contact with zinc affects an increase in IPO (difference between the IPO values in combined heat treatment on zinc and KBr supports and in heat treatment on KBr plates only, without contact with zinc).

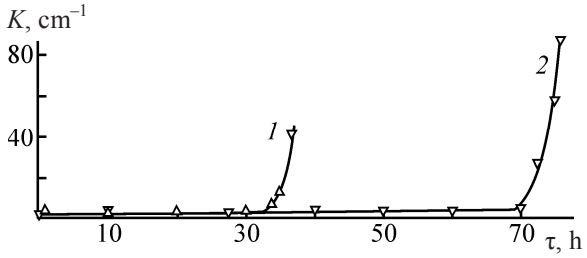

Fig. 5. Influence of the oxidation time τ of the polymer on KBr plates and procedure of the AO introduction on the extinction factor K at 1720 cm^{-1} in the IR spectra of PE films inhibited with 0.1 wt % Irganox 1010. (*1*) AO is first applied onto the surface of filler particles, which are then introduced into the polymer; (*2*) AO is uniformly introduced into a mixture of the polymer with the filler.

Influence of the time of the preliminary heat treatment of PE films in contact with zinc on an increase in IPO (PE films inhibited with 0.1% Irganox 1010, oxidation temperature 150°C, oxidation of films on KBr plates after contact with zinc)

Time of preliminary heat treatment on zinc, h	Increase in IPO, h
0.0	0.0
10.0	11.0
15.0	20.0
20.0	30.0
27.5	36.5
35.0	40.0
45.0	43.3
60.0	46.0
67.5	51.5

As can be seen, the longer the preliminary heat treatment of the films in contact with zinc, the more pronounced is an increase in IPO.

CONCLUSIONS

(1) The contact of zinc metal with polyethylene inhibited by Irganox 1010 phenolic antioxidant enhances the resistance of the polymer to thermal oxidative degradation.

(2) An increase in the performance of the phenolic antioxidant in the presence of zinc is associated with regeneration of the spent antioxidant in the presence of zinc ions. As a result, the antioxidant becomes capable of repeatedly participating in termination of oxidation chains, and the induction period of the polymer oxidation becomes longer.

MACROMOLECULAR COMPOUNDS AND POLYMERIC MATERIALS

Effect of the Content of Unmodified Nanosilica with Varied Specific Surface Area on Physicomechanical Properties and Swelling of Epoxy Composites

Received January 22, 2008

Abstract—Strength characteristics of polyepoxy formulations with different contents and dispersities of Aerosil nanosilica were studied. The effect of silica on the swelling of epoxy-polymeric composite in water was examined.

DOI: 10.1134/S1070427208110232

Nanodispersed silica (NS) of the Aerosil type is a highly dispersed powder with spherical nanosize primary particles susceptible to self-aggregation. As is known, NS is capable of self-organization of its structures in polymeric matrices and affects the structure of polymeric chains, which makes it possible to improve the strength, thixotropic, and other properties of polymers. Therefore, NS is used as a filler and thickener of industrial epoxy resins in manufacture of joint fillers, glues, filled floors, and glass-reinforced plastics [1–3]. Its most readily accessible unmodified forms are frequently used in these processes. Both in practical use and in scientific studies, the problem of the influence exerted by the physical characteristics of Aerosils (specific surface area, physically adsorbed water, aggregation capacity, etc.) is frequently disregarded. In particular, not only the concentration, but also the dispersity of silica should affect the basic characteristics of the composite. Information about the nature of this influence arouses permanent interest [4–13].

In this study, we examined the possibility of controlling the physicomechanical properties and water absorption of epoxy composites by varying the concentration and specific surface area of unmodified Aerosil.

EXPERIMENTAL

Experiments were performed with an epoxy polymer based on ED-20 resin (manufactured by Ufakhimprom) with varied content of silicas A-50, A-100, A-175, A-300, and A-455 (manufactured by the Institute of Surface Chemistry, National Academy of Sciences of Ukraine; the number is the specific surface area in square meters per gram), cured by introduction of 12.5 wt % polyethylenepolyamine (PEPA) at room temperature with aftercure at 110°C for 3 h. The composites were tested in accordance with GOST (State Standard) for compression (GOST 4651–68, stubs 12 mm in diameter and 15 mm high), bending (GOST 4848–71, 2 × 25 × 80 mm plates), and shearing (GOST 17 302–71, 30-mm overlap of 10-mm-wide glass-reinforced plastic plates, layer thickness not exceeding 1 mm). The measurement error was 1–2% for compression tests and 5–10% for shearing and bending tests. Separately, the swelling of composite samples (10 × 5 × 2 mm plates) in water in the course of 100 days was studied. The swelling was evaluated by the gain in mass. Samples 1 cm in diameter and 2–3 mm thick were placed in test tubes with water. After each withdrawal, the samples were thoroughly dried with a lignin blanket and were allowed to stay for 40–50 min before weighing under normal conditions (18–22°C). Atomic-force microscopy (AFM) and scanning electron microscopy (SEM) were used to obtain images of the samples by the standard procedure. IR reflection spectra of pure powders of epoxy polymers were measured with a Nicolett instrument (USA–EU) without addition of potassium bromide.

It can be seen from the results obtained (Fig. 1) that, in some cases, minor additions of NS noticeably

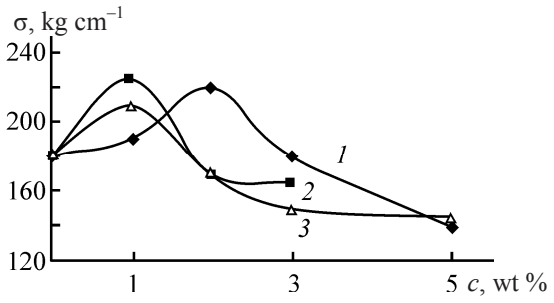

Fig. 1. Shearing strength σ of composites filled with Aerosils with different specific surface areas. (*c*) Aerosil content. (*1*) A-100, (*2*) A-175, and (*3*) A-455.

affect the physicomechanical properties of the epoxy polymer. The strongest reinforcing effect is observed for the shearing strength σ (with the composite in the form of a thin layer between plates). In the range 1–2 wt % filler, this parameter may grow by 15–25%. Further increase in the Aerosil concentration results in that σ falls. It can be concluded that its concentration strongly affects the shearing strength of the epoxy polymer in the form of a thin layer.

At the same time, the compression and bending strengths change only slightly for bulk (~1 cm^3) samples in their filling with silica. It can be seen from the table that, at best (for A-50 and A-100 NS), the increase in the compression strength does not exceed 5–10%. This weak effect is only observed within a narrow range near 1 wt %, in agreement with published data [6, 7]. Analysis of the results obtained and published data [4–12] suggests that the effect of composite strengthening upon NS introduction becomes weaker as the sample thickness grows. Possibly, this occurs because of the multiplication of bulk macroscopic defects, e.g., microcracks, heterogeneities, and air bubbles.

Compression and bending strength of composites filled with Aerosils with different specific surface areas

c, wt %	Compression strength, kg cm^{-2}				Bending strength, 10^4 kg cm^{-2}	
	A-50	A-100	A-300	A-455	A-100	A-300
0	1300	1300	1300	1300	3.3	3.3
0.1	–	–	–	–	3.4	3.3
0.5	–	–	–	–	2.9	3.0
0.7	–	–	–	–	2.8	–
1.0	1430	1340	1340	1310	2.6	3.0
1.5	–	–	–	–	2.9	–
2.0	–	1330	1300	1260	–	–
3.0	–	1360	1300	1300	–	–
5.0	–	1360	1300	1220	3.1	–

The most stable enhancing influence is exerted on the strength characteristics under study by NS with small specific surface area (with large particles): A-50, A-100, and A-175 Aerosils (see table, Fig. 1). Aerosils with large specific surface affect the strength parameters of the composite only slightly. This can be attributed to the observed effect of increasing self-aggregation and agglomeration capacity of NS at its larger specific surface area. It is also probable that, in this case, its negative effect not only on the homogeneity of the composite, but also on the structure (defect formation, loosening) of the polymer network is enhanced. It is noteworthy that the effect of an Aerosil is weakened (but not eliminated) upon modification of its surface with silanes and other organic substances (which may lead to loss of clear meaning by the notion of the specific surface area of an Aerosil).

Swelling curves are shown in Fig. 2. The negative value of the degree of smelling, *q* (%), near the beginning of the process reflects the rapid washing out that occurs immediately after a sample is submerged in water. The effect of silica on the composite swelling can be assessed as rather unambiguous. Introduction of Aerosils leads, on the whole, to a decrease in the rate and degree of swelling in water in all stages of the process. For all the composites studied (>20 samples), the swelling is 1.5–2.0%. It follows from Fig. 2 that structural changes occur even at small fillings (1 wt %). As the degree of filling grows, penetration of water molecules into the polymer network becomes increasingly difficult, which is possibly due to densification of the polymeric network upon introduction of nanoparticles. This is confirmed by SEM studies: According to Fig. 3, even upon introduction of 1 wt % Aerosil, the number of pores on the polymer surface decreases dramatically (cf. Fig. 3a).

The effect of the specific surface area on the swelling process can be estimated as comparatively insignificant. At the same time, Aerosils can be conditionally divided into two groups as regards their influence on swelling: low- and high-dispersed. As seen from Fig. 2, for the low-dispersed A-50 and A-100 (and, to a certain extent, for A-175), low concentrations (~1 wt%) of a filler do not exert any significant influence. In these cases, the swelling curves for 0 and 1 wt %

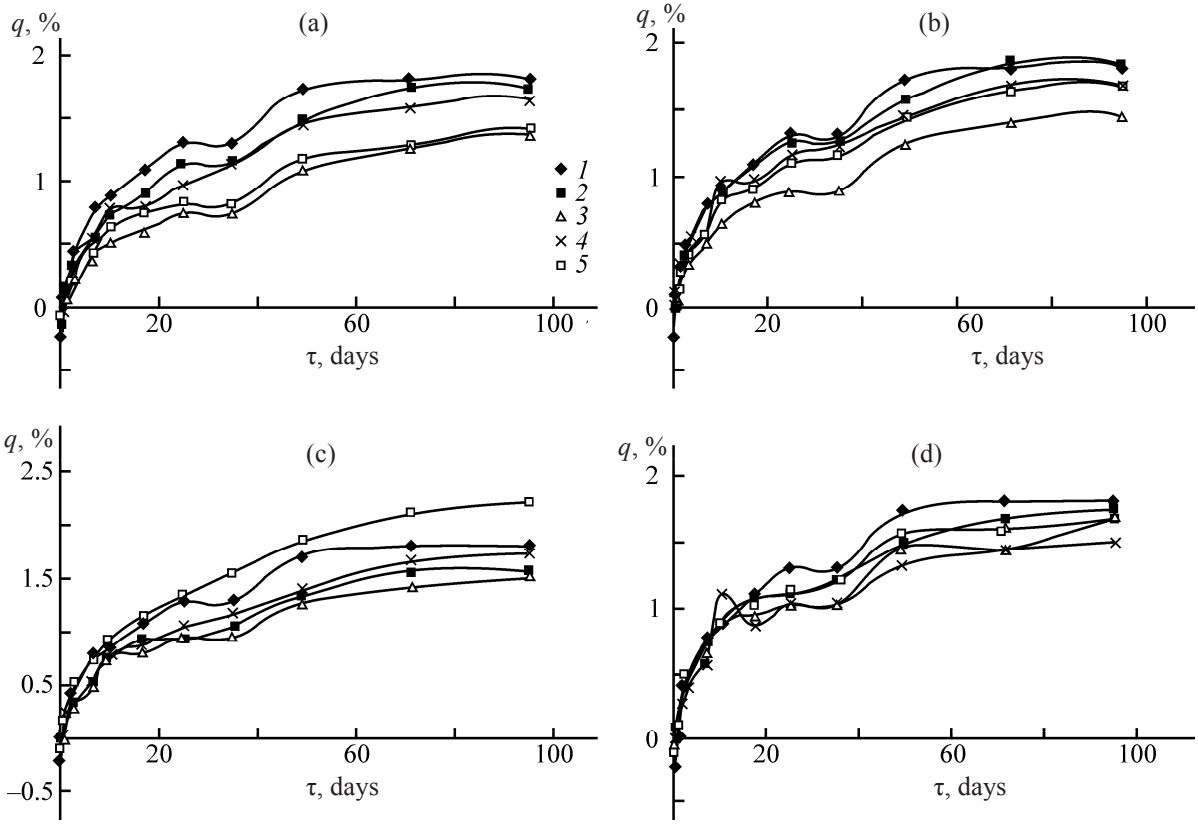

Fig. 2. Degree of swelling in water, q, of epoxy polymers with Aerosils with different specific surface areas vs. time τ. (a) A-100, (b) A-175, (c) A-300, and (d) A-455. Degree of filling, %: (*1*) 0, (*2*) 1, (*3*) 5, (*4*) 10, and (*5*) 20.

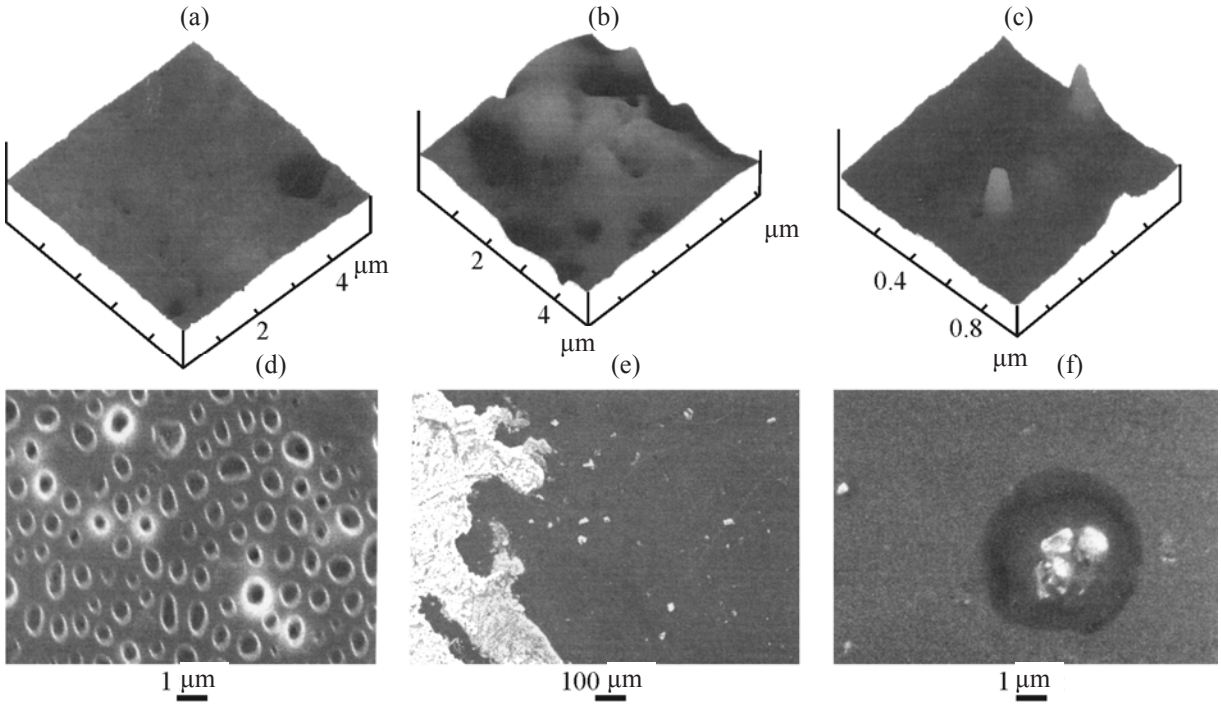

Fig. 3. AFM images of the surface of a film of an epoxy polymer (a) unfilled and (b, c) filled with 3.5 wt % A-300 Aerosil, and also SEM images of a film of an epoxy polymer (d) unfilled and (e, f) filled with 1 wt % A-100 Aerosil.

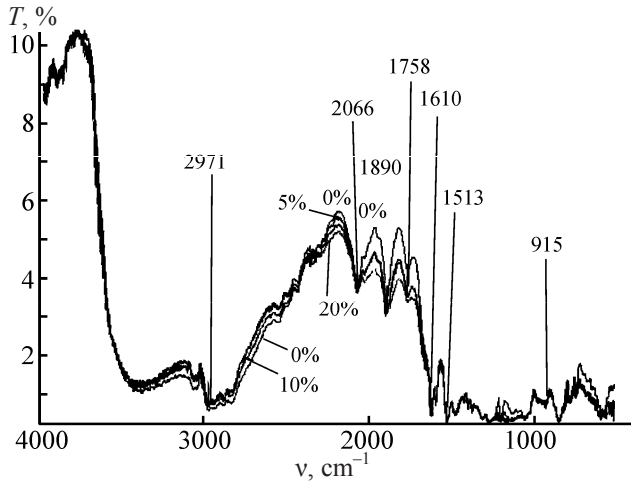

Fig. 4. IR spectra of epoxy polymers filled with 0, 5, 10, and 20 wt % A-100 Aerosil. (*T*) Transmission and (ν) wavenumber.

are very close. For the group of highly dispersed A-300 and A-455, 1 wt % of a filler has a more pronounced effect (Fig. 2).

For the low-dispersed group of Aerosils, the differences in the degree of swelling, dependent on the filler concentration, may be as large as 0.4–0.6%, i.e., approximately up to a quarter of the average degree of swelling. For the Aerosils of the highly dispersed group, these differences are substantially smaller, within the range 0.2–0.4%.

Thus, as the specific surface area of Aerosils decreases, the effect of their concentration on the swelling becomes more pronounced, with the differences in the degree of swelling being considerably less dependent on the NS concentration for highly dispersed Aerosils.

As an additional specific feature of the influence exerted by highly dispersed Aerosils can be regarded the faster saturation period, within 50–60 days. For low-dispersed aerosils, this time is substantially longer. Hence follows that the NSs of the highly dispersed group affect the composite structure to a somewhat lesser extent, whereas low-dispersed Aerosils change it so that the penetration of solvent molecules occurs during a longer time.

It was a priori assumed that there should be a more or less simple relationship between the NS concentration and degree of swelling. It was found that, most frequently, this dependence is not linear or, at least, monotonic. For example, a rather clearly pronounced correlation between the decreasing degree of swelling and increasing NS concentration is observed only for A-455 Aerosil with the largest specific surface area (i.e., smallest particles). In the other cases, the swelling nonlinearly depends on the Aerosil content and decreases near 5 wt % (Fig. 2). This means that, irrespective of the specific surface area of an NS, at its certain concentrations it can form a specific structure characterized by an increased density of the polymer network.

According to IR data (Fig. 4), introduction of unmodified NS does not change the chemical nature of the epoxy composite. All the absorption bands characteristic of epoxy polymers and (in most cases) their intensities remain unchanged even at high degrees of filling (Fig. 4). The band at 915 cm^{-1}, characteristic of oxirane groups of the epoxy resin, is almost not observed, which points to a high conversion of the composite in all cases. No changes are revealed in the intensity of the band at 1605–1610 cm^{-1}, which is standard for epoxy polymers and is characteristic of stretching vibrations ν(CH–CH) of benzene rings. True, a certain decrease is observed in the intensity of overlapping bands in the region 3100–3500 cm^{-1}, characteristic of OH groups of the polymer and adsorbed water. This may indicate that their number slightly decreases upon filling. It is noteworthy that, even at an Aerosil content of 20 wt %, its characteristic absorption band at 3750 cm^{-1}, associated with vibrations of isolated surface OH groups, is not observed. This may point to a strong physicochemical interaction (hydrogen bonds) of these groups with fragments of the polymer chain, which results in that this band disappears, or, more precisely, is shifted to lower wavelengths, to the region 3100–3500 cm^{-1} difficult for band assignment.

The data obtained suggest that regions of denser macromolecule packing, e.g., in the adsorption and orientation layer that is near-surface with respect to Aerosil particles, and a framework constituted by filler particles are formed in the filled composite [8–14]. At the same time, various defects impairing the strength characteristics are also formed. An important role in the weakening of the reinforcement effect as a result of filling may also be played by nonoptimal aggregation (e.g., clustering, rather than framework formation) and combination of particle aggregates in the polymer. The latter is frequently observed visually and is confirmed by microscopic data (Fig. 3), which can serve to make some conclusions about the structure of the epoxy

composites. For example, the AFM image (Fig. 3c) clearly shows "islets" of aggregated silica. It can be seen in smaller-scale images (Figs. 3a and 3b) that pores become coarser and sparser as a result of filling. The same effect is observed in the SEM image: Figures 3d and 3f show that pores become coarser and less in number, and islets of silica aggregates may appear in the pores. On the whole, Aerosil can form, even at small degrees of filling (1 wt %), large bodies of the intrinsic phase neighboring the polymer phase, which, in turn, includes small Aerosil aggregates (Fig. 3e).

CONCLUSIONS

(1) Addition of unmodified silica affects the strength of polymers in different ways, depending on the silica concentration and a parameter under study. A weak tendency toward an increase in the strength parameters is observed at 1–2 wt % content of Aerosil, as well as a tendency toward weakening of the effect of Aerosil on the strength parameters with its increasing specific surface area (as a result of a higher self-aggregation capacity). At the same time, introduction of nanodispersed silicas of the Aerosil type can improve the shearing strength (substantially, by 15–25%) and compression strength (insignificantly, by up to 5–10%).

(2) Changing the Aerosil concentration noticeably affects the swelling of filled epoxy polymers. In the range up to 20 wt %, filling with unmodified Aerosil makes the degree of swelling lower, with the decrease at concentrations of ~5 wt % being the most pronounced. Irrespective of their specific surface area, silicas affect the swelling in similar ways, but low-dispersed silicas (conventionally up to 200 $m^2 g^{-1}$) exert a stronger influence on the swelling (and, consequently, on the structure) of the epoxy polymer than do highly dispersed silicas.

(3) The IR spectra demonstrate that no chemical changes occur in the epoxy polymer upon introduction of unmodified Aerosils. Together with the AFM and SEM images obtained, this fact suggests that filling with unmodified nanosilica substantially changes only the physical conditions of structuring in the composite.

ACKNOWLEDGMENTS

The author is grateful to S. Golovan' (Institute of Macromolecular Compounds, National Academy of Sciences of Ukraine) for assistance in obtaining SEM images and to O. Litvin (Lashkarev Institute of Semiconductor Physics, National Academy of Sciences of Ukraine) for organizing the acquisition of AFM images of the samples. The strength tests were carried out with participation of A.G. Girchenko (Chuiko Institute of Surface Chemistry, National Academy of Sciences of Ukraine).

Abstract—Changes in the functional composition of chitosan films in the course of storage under ambient conditions were examined by conductometric titration and IR spectroscopy. The deformation–strength and thermal properties of the films were studied, and their supramolecular structure was analyzed by X-ray diffraction.

DOI: 10.1134/S1070427208110244

Chitosan film materials find growing use in medicine, as membranes of various purposes, as coatings, and as packaging films. Such films can be readily prepared by dry forming from solution in a readily available nontoxic solvent, dilute acetic acid. Installations for continuous forming with drying by air preheated to a definite temperature have been developed long ago, and therefore chitosan films can be produced in required amounts. Their cost will be chiefly determined by the market price of chitosan.

Despite such advantages as biocompatibility and bactericidal and fungicidal properties, freshly formed chitosan films have a significant drawback: They dissolve or strongly swell in aqueous media. Ways to overcome this drawback are well known: cross-linking, hydrophobization by surface treatment, and heat treatment. The first two procedures are not always acceptable, in particular, when the films are used in medicine, because of introduction of toxic substances or chemical groups. Heat treatment does not give rise to toxic products in films. Although this procedure was used in numerous studies and in practice, the chemical nature of transformations occurring in the course of heat treatment did not receive due researchers' attention until recently.

Vikhoreva and Zotkin [1–3] were the first to examine how the forming at elevated temperatures or heat treatment affects the composition of functional groups of chitosan films prepared from solutions in aliphatic carboxylic acids. They revealed a decrease in the amount of amino groups and acids depending on the solvent used and then proved by IR and NMR spectroscopy the reaction pathways: amidation and formation of Schiff bases, with the result that the films lose solubility.

The loss of the solubility of chitosan films in the course of drying at elevated temperature was noted in preparation of films for electrical engineering [4]. Later on, attention was given to the fact that the films also lose solubility in the course of prolonged storage under ambient conditions, with a simultaneous increase in the strength. This phenomenon was attributed to gradual volatilization of acetic acid used as solvent, with the amino groups of chitosan becoming free. It was interesting to examine more thoroughly the chemical nature of processes occurring in chitosan films in the course of their storage.

EXPERIMENTAL

To form films, we used chitosan prepared from crab shells, with the following characteristics: ash residue 0.35%, solubility in 2% acetic acid 99.7%, content of primary amino groups N_{am} = 8.48%, degree of deacetylation (DD) 0.98, intrinsic viscosity [η] = 9.0 dl g^{-1} (in 2% acetic acid with addition of 0.5 M NaCl), and molecular weight 200.5 kDa (calculated by the formula from [5]).

Films were formed on a glass support from 2% solutions in 2% acetic acid using a slot die and were dried under ambient conditions. The film thickness was 12 μm. Then some of the films were stored in the rolled-up state under ambient conditions, and the other films were kept in a vacuum, also at room temperature. At definite intervals (2 weeks during the first 2.5 months, 1 month during the subsequent period, maximal storage time 3 years), the amounts of primary amino groups and acetic acid in the films were determined by conductometric back-titration, the solubility in water and 2% acetic acid was evaluated, the IR spectra were taken, the deformation–strength and thermomechanical properties were determined, and the thermal gravimetric and X-ray diffraction analyses were performed.

Conductometric titration was performed with an EC 215 conductometer (Hanna Instruments, Germany). The IR spectra were recorded with a Bruker IFS-88 spectrometer (Germany).

The mechanical tests of film samples were performed in the uniaxial extension mode on a UTS 10 universal installation for mechanical tests (Germany). We determined the elastic modulus E, tensile strength σ_t, plasticity limit σ_p, and breaking elongation ε_b.

Thermomechanical tests were performed with a UMIV-3 installation in the uniaxial extension mode under the action of a constant tensile load of 0.25 MPa, with sample heating at a rate of 5 deg min^{-1}.

Thermal gravimetric analysis (TGA) was performed with a laboratory thermal balance. Samples weighing about 50 mg were heated in a self-generated atmosphere at a rate of 5 deg min^{-1}.

X-ray diffraction analysis was performed on a DRON-2 diffractometer with Ni-filtered CuK_α radiation.

Figure 1 shows how the quantitative composition of films with respect to amino groups and acetic acid varies in the course of 1-year storage. The most pronounced changes are observed in the first 50 days of storage: N_{am} decreases by a factor of 2, and acetic acid content, by 30%; the solubility decreases by a factor of 2. In the subsequent period, the content of amino groups and acetic acid decreases insignificantly, and the solubility continues to decrease: to 3.5% in 150 days and to 3% in 1 year.

The calculated AcOH/chitosan molar ratio in the forming solution (Fig. 2) is 2.74, and in the freshly

formed film after drying in air it is 2.9 (according to the results of conductometric titration). In the course of the film storage, the ratio gradually decreases to 2.0 in 150 days. Then both the ratio and the solubility in water change slowly, but by the moment of the complete loss of the solubility this ratio is still 1.5. At such an excess of the acid, the film should, seemingly, at least swell in water. The lack of swelling suggests partial conversion of the amino groups of chitosan into amide groups, i.e., reacetylation of the amino groups owing to the condensation with acetic acid. The degree of deacetylation of chitosan, calculated from the conductometric data, after 150 days of storage is 0.42 at the initial DD of 0.97, i.e., 0.55 mol of acetic acid is bound to 1 mol of chitosan units. Hence, a part of acetic acid volatilizes in the course of storage. At the same time, the films remain soluble in 2% acetic acid for a year. Hence, the remaining free amino groups provide the degree of protonation sufficient for the dissolution.

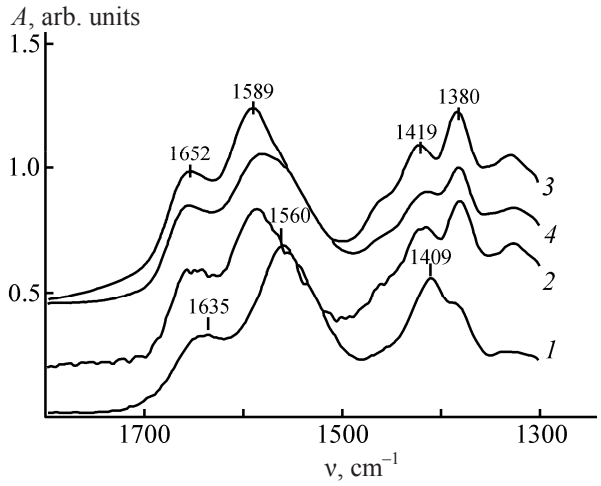

Fig. 3. IR spectra of chitosan films, (*1*) freshly prepared and stored under ambient conditions for (*2*) 2 weeks, (*3*) 2 months, and (*4*) 3 years. (*A*) Absorption and (ν) wavenumber.

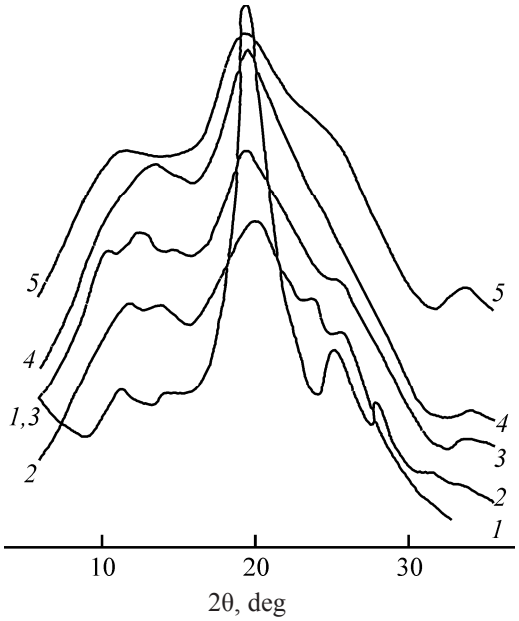

Fig. 4. X-ray diffraction patterns of (*1*) initial chitosan and chitosan films, (*2*) freshly prepared, (*3*) washed with ethanol to remove acetic acid, (*4*) heated at 120°C for 3 h, and (*5*) stored under ambient conditions for 3 years. (2θ) Bragg angle.

And only the film stored for 3 years does not dissolve in acetic acid. The DD of such film decreases to 0.20, i.e., the film material is partially deacetylated chitin.

The IR Fourier spectroscopic data confirm the quantitative results we obtained (Fig. 3). The IR spectra of the freshly formed film contain absorption bands at 1559 and 1409 cm^{-1}, corresponding to the vibrations of carboxylate groups. With an increase in the storage time, the band at 1409 cm^{-1} transforms into a shoulder but remains even in the spectrum of the film stored for 3 years. A broad band at 1559 cm^{-1} obscures the absorption bands of the amide (amide II, 1555 cm^{-1}) and amino (1560–1600 cm^{-1}) groups. Therefore, it is impossible to monitor by IR spectroscopy the variation of their amount with time. In the course of storage, the band maximum at 1559 cm^{-1} is shifted toward higher frequencies, and a shoulder at 1652 cm^{-1} (amide I) becomes more pronounced, suggesting formation of acetamide groups.

For comparison, we recorded the spectra of a freshly formed film washed with ethanol to remove acetic acid and of a film heated at 120°C for 3 h. In the IR spectrum of the washed film, the intensity of the absorption bands at 1559 and 1409 cm^{-1} considerably decreases, and in the spectrum of the heated film, the intensity of the shoulder at 1652 cm^{-1} (amide I) increases.

In the IR spectra of the films stored in a vacuum, the changes are similar to those in the spectra of the films stored in air: weakening of the absorption bands of carboxylate groups and slight increase in the intensity of the amide I band. After storage in a vacuum for 3 months, the films partially dissolve in water and fully dissolve in 2% acetic acid, i.e., atmospheric oxygen does not appreciably affect the processes occurring in the course of storage in air, at least for 3 months.

The results of X-ray diffraction analysis of chitosan films subjected to various treatments are shown in Fig. 4. The freshly formed film and the same film washed with ethanol to remove excess acetic acid give essentially similar X-ray diffraction patterns: Against the background of an amorphous halo, weak reflections are observed at 2θ 13.5° and 20° (these reflections are characteristic of the crystal structure of chitosan), and also at 2θ 24.5° and 26° (curves *1*–*3*). The diffraction patterns of the film heated at 120°C for 3 h and of that stored for 3 months (curves *4*, *5*) also have much in common: The reflections characteristic of chitosan at 2θ 13.5° and 20° are still less pronounced, and those at 2θ 24.5° and 26° are absent, which indicates that the films are more amorphous. Further distortion of the supramolecular organization may be caused by the appearance of bulky acetamide groups whose random distribution along macromolecules favors cleavage of intermolecular hydrogen bonds.

The results of determining the deformation–strength properties of films in the course of storage (see table) show no well-defined trends. Rather, they

Variation of the properties of chitosan films in the course of storage under ambient conditions

36 months	5.06	122	118	13	11.7	247	

fluctuate in a certain range, and it is impossible to correlate these fluctuations with the storage time or functional composition of the film. Only determination of the moisture content W of the films by TGA revealed certain correlations: E, σ_p, and strength characteristics (σ_t) vary in opposite directions with the moisture content (Fig. 5). At the same time, breaking elongation shows no definite trend, probably because of larger scatter of the corresponding data.

It should be particularly noted that examination of the sample stored for 3 years revealed no deterioration of the mechanical properties of the material and no appreciable changes in the qualitative characteristics of its deformation behavior.

A study of the thermal properties of the films stored for different periods showed that the shape of the DTA and TGA curves was similar for all the samples. Figure 6 shows as examples the curves for a film stored for 6 months. However, the temperature T_1 of the inflection point in the thermomechanical curves, above which the sample rigidity grows in the course of heating, gradually increases in the course of storage. This temperature corresponds to the onset of degradation processes in the material. Indeed, the temperatures T_1 are virtually identical to the parameters τ_1 determined from the TGA curves, namely, to the temperatures of 1% weight loss (Fig. 6). The parameter τ_1 tends to shift toward higher temperatures with the sample storage, which may be due to gradual transformation of amino groups into acetamide groups. Comparison of the thermomechanical curves with the TGA curves allows a conclusion that the failure of chitosan films in the course of thermomechanical tests occurs at temperatures at which the weight loss amounts to 50% and more. This means that the molecular "skeleton" capable of standing a mechanical load is preserved up to these high degrees of degradation. For films of the ma-

jority of known polymeric materials, the failure on heating at the same tensile loads is observed already at 10–15% degradation.

Thus, the results we obtained show that amidation of the amino groups in chitosan films gradually occurs in the course of storage, and after storage for 3 years chitosan virtually transforms into chitin. This reaction also occurs in the course of heating the films at 120°C [1]. At the same time, formation of Schiff bases leading to cross-linking of macromolecules and characteristic of heated films is not observed, because in films stored in air excess acid preventing formation of azomethine bond is preserved. The IR spectra of the examined films do not contain a C=N bond at 1676 cm^{-1}.

The deformation–strength properties of the films in the course of prolonged storage under ambient conditions change insignificantly, and these changes are determined to a greater extent by the air humidity rather than by the storage time. The results we obtained suggest that, if a sample is stored at a constant temperature and constant humidity, prolonged storage will not affect the suitability of chitosan films as a packaging material and the properties of chitosan coatings. At the same time, the observed changes in the functional composition, especially a decrease in the amount of amino groups, can make worse the quality of films used for accelerated wound healing.

CONCLUSIONS

(1) Storage of chitosan films under ambient conditions results in slow reacetylation of amino groups. As a result, the films lose solubility in water and acetic acid.

(2) The appearance of aminoacetyl groups fully distorts the system of hydrogen bonds and leads to the film amorphization.

(3) The deformation–strength properties of films remain essentially unchanged after prolonged storage. Slight changes are due to fluctuations of the humidity of the ambient atmosphere.

(4) A DTA and TGA study of the thermal properties of the films revealed a gradual increase in the temperature of the decomposition onset with an increase in the storage time.

Abstract—Possibility of obtaining cellulose–iron(II, III) oxide composites with various component ratios was studied. The specific magnetization of the material was determined in relation to the mass fraction of the magnetic component in the composite.

DOI: 10.1134/S1070427208110256

Development and synthesis of polymeric composites with prescribed functional (including magnetic), electrical, and other properties is a topical task for modern materials science. The undiminishing researchers' interest in composite polymeric materials is due to the fact that, in some cases, additives introduced into polymers provide a fundamental change in their properties. Because of the combination of properties of a polymer and filler, the composite as a whole becomes a new material suitable for some practical applications.

It is known that such a natural polymer as cellulose can be used to create salt-containing composites and convert them by pyrolysis into, depending on the medium, metal–carbon materials [1], fibers of refractory oxides [2], and complex oxide compounds [3], which can serve as intermediates for obtaining practically important materials.

In this study, a cellulose composite containing iron(II, III) oxide of the magnetite modification was prepared. Owing to the magnetic properties of the oxide component, the composite may find direct practical application. Some aspects of solid-phase thermal transformations of the cellulose composite in a vacuum and in air were studied.

EXPERIMENTAL

The cellulose composite with inclusion of finely dispersed iron(II, III) particles is prepared by carrying out a number of successive procedures. First, cellulose is impregnated with a solution of iron(II) sulfate and iron(III) chloride salts mixed in a 1 : 2 molar ratio, with the concentrations of the salts equal to 0.75 and 1.5 M, respectively, at a solid–liquid impregnation ratio of 2 ml g^{-1}. Then follows treatment of the salt-containing cellulose with a concentrated sodium hydroxide solution; washing of a sample with distilled water to remove the unchanged alkali, sodium chloride and sulfate formed in the reaction, and excess amount of iron oxide not fixed on the fabric; and drying. The starting cellulose was preliminarily subjected to mercerization with a 17% sodium hydroxide solution at 18°C for 30 min.

The content of iron oxide (Fe_3O_4) in the cellulose composite obtained using the above scheme was found gravimetrically after thorough washing and drying of the samples and on a Netzsch STA 449C combined thermal analyzer (Germany) by thermal gravimetric analysis (TG) from the mass of the residue formed on burning a sample in an oxygen atmosphere. In addition to measuring the mass change on the thermal analyzer, heat effects were determined by differential scanning calorimetry (DSC) on heating the samples in the temperature range from room temperature to 600°C.

The phase composition of the samples was analyzed with a DRON-3.0 X-ray diffractometer with iron-filtered CoK_α radiation (λ = 1.6208 Å). The morphology of the cellulose–Fe_3O_4 composite was analyzed by scanning electron microscopy (LEO-906 E, FRG).

The magnetic properties (specific magnetization) of samples were determined on a Faraday balance. A cotton fabric was chosen as the starting cellulose

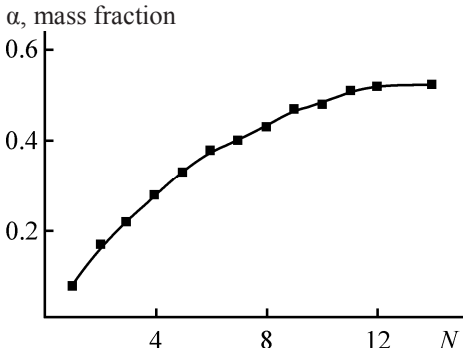

Fig. 1. Fe_3O_4 content α in the iron oxide–cellulose composite vs. the number *N* of sorption–deposition cycles.

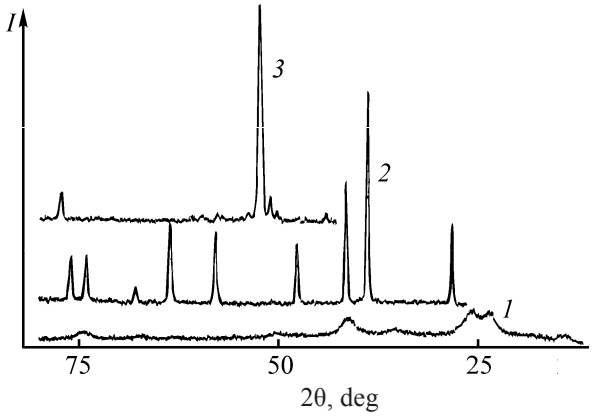

Fig. 2. X-ray diffraction patterns of (*1*) iron oxide–cellulose composite with a Fe_3O_4 mass fraction of 0.27 and of products of its thermal transformations (*2*) in air and (*3*) in a vacuum. (*I*) Signal intensity and (2θ) Bragg angle.

material. Its mercerization with a sodium alkali in the first stage was performed to impart a developed internal sorption surface. It is known that alkaline hydrolysis of a mixture of salts of bi- and trivalent iron with a molar ratio of, respectively, 1 : 2, yields Fe_3O_4 (magnetite) [4]. After impregnation of the cellulose fabric with a stoichiometric mixture of the iron salts and treatment of the iron-containing cellulose with sodium hydroxide, the gain weight due to Fe_3O_4 in a sample is about 80 wt %. However, the X-ray diffraction pattern of the sample contains only reflections at Bragg angles of 14.0°, 23.5°, and 25.3°, which are characteristic of cellulose II and appear upon treatment of natural cellulose (cellulose I) with a concentrated alkali in the first stage [5]. A similar result, lack of an X-ray diffraction evidence of the inorganic phase deposited onto the polymeric matrix, has been observed for cellulose structurally modified with 68% nitric acid and impregnated with an organic salt [3]. This fact is attributed to formation of isolated X-ray amorphous iron oxide particles within the internal system of pores and capillaries and on the fiber surface.

The amount of magnetite capable of being retained in the cellulose matrix without any noticeable washing-out and desorption was raised by performing multiple cycles of impregnation of the cotton fabric with a mixture of salts of bi- and trivalent iron, taken in a prescribed ratio, and an alkaline treatment of the salt-containing cellulose. As the number of these cycles increases, the sorption equilibrium in the system approaches saturation (Fig. 1). In this case, the maximum mass fraction of magnetite in the composite reaches 0.54. In the X-ray diffraction pattern of a sample subjected to three sorption–deposition cycles (Fig. 2, curve *1*), there appear reflections characteristic of magnetite at 2θ = 35.1°, 41.4°, 50.4°, 67.2°, and 74.1°. The average crystal size *L* found by the Scherrer formula [6] is 5.0 nm. As follows from electron micrographs (Fig. 3), magnetite deposited onto cellulose in the initial cycles rather uniformly covers fabric fibers, and only upon the saturation of the surface with magnetite, separate crystals start to be formed. The specific magnetization of the samples grows with the number of sorption–deposition cycles. As seen from the table, it reaches 14.0 A m^2 kg^{-1} at room temperatures in a magnetic field with a strength 3.97×10^5 A m^{-1}.

The cellulose–iron(II, III) composite obtained acquires magnetic properties and retains mechanical properties characteristic of cellulose, primarily elasticity and ability to take on a prescribed shape, which enables its direct use as elastic magnetic shields against electromagnetic radiation [7].

A study of the solid-phase thermal transformations of the cellulose composite in a vacuum and in air revealed a number of specific features of its thermal decomposition, compared with cellulose. The thermal treatment in a vacuum was performed at a residual pressure of 1.3 Pa with the temperature raised at a rate of 10 deg min^{-1}; after the final temperature of annealing was reached, the samples were kept under isothermal conditions for 60 min.

Our experiments showed that annealing of composite samples with varied content of Fe_3O_4 without admission of air up to temperatures of 800°C led to transformation of cellulose fibers to carbon fibers and of Fe_3O_4 particles to Fe particles. As a consequence, the specific magnetization of the samples substantially increased and exceeded by approximately an order of

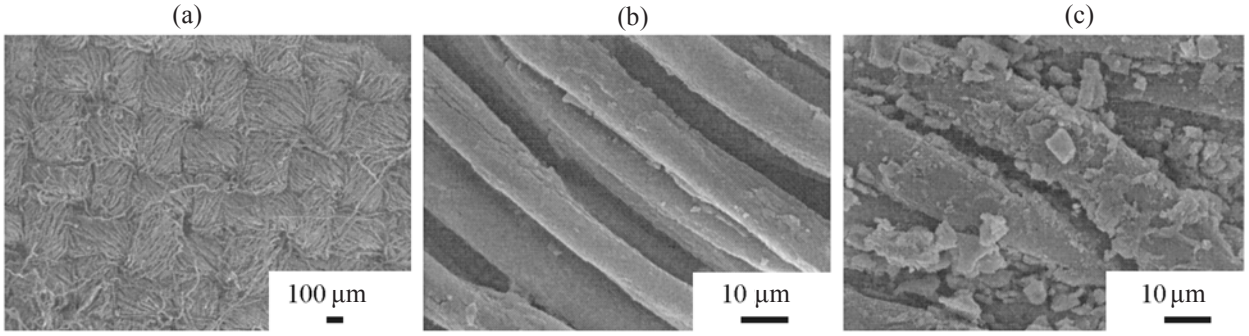

Fig. 3. SEM micrograph of iron oxide–cellulose samples. (a) General view of the composite material; Fe_3O_4 mass fraction in the composite: (b) 0.27 and (c) 0.54.

magnitude the maximum magnetization of the starting cellulose–oxide composite. The specific magnetization of the samples also grows with the number *N* of sorption–deposition cycles to reach 160.3 A m^2 kg^{-1}.

The formation of the iron phase in the carbon composite matrix is confirmed by the X-ray diffraction pattern of a sample with Fe_3O_4 mass fraction of 0.27, thermally treated in a vacuum (Fig. 2, curve *3*). Figure 2 shows that the X-ray diffraction pattern contains basic α-Fe reflections, with a crystallite size of approximately 30.0 nm. According to a calculation, the content of iron in this sample is 65 wt %. In the cellulose–iron oxide sample with a Fe_3O_4 mass fraction of 0.54, subjected to a similar treatment, the mass fraction of iron reaches 1.0. The sample composed of a purely iron phase retains the structure of the precursor composite and, upon annealing in a vacuum at 1050°C, transforms into a high-strength metallic fabric-grid. In thermal transformations of the oxide–cellulose composite in a vacuum, the iron phase is apparently formed in the same way as it does in thermal treatment of cellulose impregnated with salts of variable-valence inorganic cations, as a result of a chain of transformations: $Fe_3O_4 \rightarrow FeO \rightarrow Fe$ [8]. The procedure described in [8] is intended for synthesis of iron–carbon fibrous materials that contain approximately 10 wt % iron, exhibit important magnetic and catalytic properties, and are pyrophoric.

It should be noted that fully porous metallic fibrous structures can be produced from salt-containing cellulose [9]. However, as noted in [10], their synthesis requires a considerable change in the experimental conditions: in particular, the thermal treatment of salt-containing cellulose should be performed in the medium of ammonia decomposition products at 900–1000°C. As follows from the results obtained, by setting a certain content of Fe_3O_4 in a composite, it is possible to obtain upon its thermal treatment either an iron–carbon composite or a nearly single-phase product that is composed of α-Fe and reproduces the fabric texture of the precursor composite. The specific magnetization of the single-phase product exceeds by an order of magnitude that of the oxide–cellulose precursor composite.

The main aspects of thermal transformations of oxide–cellulose samples in air were found by analysis of their TG and DSC curves. Figure 4a shows TG curves of thermal decomposition of cellulose modified with a 17% sodium hydroxide solution. It can be seen that the thermal degradation of cellulose subjected to an activating treatment with the alkali occurs in two stages. In the first stage of intensive thermal decomposition, which involves with the main loss of mass, the tarry fraction burns out in a narrow temperature range, with the maximum of the exothermic effect at 340°C. The second, low-intensity stage of smoldering of the carbon residue ends at 520°C. The thermal decomposition of the oxide–cellulose composite almost ends at a temperature 200°C lower than that for cellulose. Accord-

Specific magnetization of the iron(II, III) oxide–cellulose composite, σ, and iron–carbon composite, σ', at room temperature at a field strength of 3.97×10^5 A m^{-1}

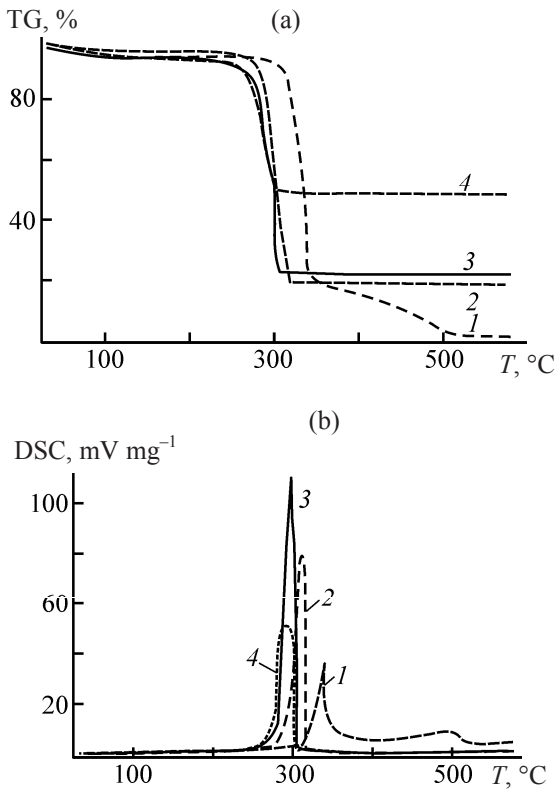

Fig. 4. (a) TG and (b) DSC curves: (*1*) cellulose activated with a 17% aqueous solution of sodium hydroxide and (*2–4*) cellulose–iron oxide composites with Fe_3O_4 mass fraction of 0.21, 0.27, and 0.54, respectively. (*T*) Temperature.

ing to the DSC data in Fig. 4b, the thermal decomposition of the composite occurs with a higher total heat release and the maximum of the exothermic effect lies at 295–313°C depending on the Fe_3O_4 content of a composite, i.e., lower than the low-temperature peak associated with the decomposition of the cellulose matrix (340°C). The second stage of the process, the smoldering of the carbon residue, is not separated by a time–temperature interval from the first stage. Apparently, the intensification of the thermal decomposition of the cellulose matrix in the composite is due not only to the catalytic effect of the filler, but also to the occurrence of the exothermic reaction

$$Fe_3O_4\ (FeO, Fe_2O_3) \rightarrow \alpha\text{-}Fe_2O_3.$$

In all probability, the metal phase is not formed in thermal decomposition of the oxide–cellulose composite in air, in contrast to the case of its thermal treatment in a vacuum. This is indicated by the fact that the X-ray diffraction pattern of an oxide–cellulose composite subjected to thermal treatment at temperatures lower than the onset temperature of the exothermic effect (260°C) contains no iron phase.

As follows from the DSC data, the magnitude of the exothermic effect, found from its area, in thermal decomposition of samples with Fe_3O_4 mass fraction of 0.21, 0.27, and 0.54 is 10 940, 13 990, and 15 730 J g^{-1}, respectively, in terms of the cellulose base, which exceeds the corresponding value for cellulose (7600 J g^{-1}). In other words, the cellulose–iron oxide composite is a more efficient energy carrier than cellulose. In this context, an attempt was made to subject the composite to thermal treatment by its initiated firing. The experiments performed demonstrated that, in initiated firing of oxide–cellulose composites with varied weight fraction of Fe_3O_4 (including the maximum mass fraction of 0.54), the cellulose base completely burns out at the combustion front to give $\alpha\text{-}Fe_2O_3$ with L = 30.0 nm according to X-ray diffraction data (Fig. 2, curve *2*). The annealed sample reproduces the texture of the starting fabric and, on being touched, crumbles without special dispersion into a dark red, loose soft, by touch, powder of anisotropic particles, microfibers. This circumstance is important, e.g., when oxides are used as pigments for polymers [10] or as synergists of fire-retardant additives to polymers [11], because, in this case, oxide microfibers arranged along chains of polymer macromolecules impair the performance characteristics of the polymer to a lesser extent than do spherical particles of oxides [12].

Thus, the oxide–cellulose composite, which is a microheterogeneous system with numerous phase boundaries, is less thermally stable than cellulose. Serving as a carrier matrix in the composite, modified cellulose fibers execute in combustion, because of the vigorous gas evolution, an additional function of a dispersant and homogenizer of the forming final degradation product, oxide stock. The thermal transformations of the composite in air are accompanied by a stronger exothermic effect than those in the case of cellulose. This circumstance enables synthesis of finely dispersed $\alpha\text{-}Fe_2O_3$ in the self-propagating combustion mode, similar to the known self-propagating high-temperature synthesis [13].

CONCLUSIONS

(1) A cellulose–iron(II, III) oxide composite material was synthesized. The material combines the magnetic properties characteristic of Fe_3O_4 with the elastic-

ity of cellulose, which enables its use as magnetic shields.

(2) The relative amounts of cellulose and Fe_3O_4 in the composite, necessary for its complete transformation in thermal treatment in a vacuum into an almost single-phase product having the form of α-Fe with the fabric texture of the precursor composite, were determined. The specific magnetization of the single-phase product is an order of magnitude higher than that of the composite.

(3) The possibility of conversion of the composite into α-Fe_2O_3 in air at the self-propagating combustion front was demonstrated.

Abstract—The effect of Cr(III), Fe(III), Co(III), and Ni(II) acetylacetonates on epoxy–anhydride polycondensation in preparation of unmodified polymeric materials based on UP-650T epoxy resin and isomethyltetrahydrophthalic anhydride and of epoxy–siloxane hybrid composites was examined The resistance of the materials obtained to high-temperature oxidation and thermal oxidative degradation was evaluated.

DOI: 10.1134/S1070427208110268

Materials based on epoxy oligomers are widely used in industry owing a set of valuable properties: high adhesion to many materials, low shrinkage in the course of curing, good dielectric properties, chemical resistance, high strength, and low creep under a load [1]. Much attention has been given recently to a new direction in the chemistry and technology of polymeric epoxy materials, the development of hybrid composites based on epoxy resins and alkoxides of silicon, titanium, zirconium, etc. In such materials, the inorganic "phase" is formed by the sol–gel process consisting in hydrolysis of alkoxy compounds followed by polycondensation of the hydrolysis products and gelation of the system [2, 3].

The properties of epoxy–inorganic composites depend on many factors, including the procedure for curing epoxy oligomers. The most widely used procedures for forming the epoxy constituent of hybrid composites are cationic polymerization and amine curing. Studies in which dicarboxylic acid anhydrides are used for preparing epoxy–silica composites are extremely few. There are data on modification of an anhydride-curable epoxy composite material with nanodispersed silica particles [4]. Such materials exhibit enhanced heat resistance and improved mechanical properties compared to unfilled materials. Mascia and Tang [5] reported on preparation by the sol–gel procedure of keramers based on Bisphenol A epoxy resin and methylnadic anhydride.

To decrease the temperature and time of curing of unmodified epoxy–anhydride systems, various accelerators, in particular, metal acetylacetonates [6–9], are used. These agents allow preparation of materials with high dielectric properties and variation of the life of uncured composites at room temperature by varying the central atom in the chelate [9]. The most widely used are acetylacetonates of Fe(III) [9], Co(III), Co(II), Mn(III) [6, 7, 9], and Cr(III) [8]. However, as shown previously, transition metal compounds (including acetylacetonates) can both accelerate and inhibit thermal oxidative degradation of epoxy polymers [10–14]. The mechanism of the accelerating or inhibiting effect of metal acetylacetonates on thermal oxidation processes in epoxy polymers is poorly understood, and it is impossible to determine a priori what metal acetylacetonates can be used as polycondensation accelerators without decreasing the stability of the materials obtained to thermal oxidative degradation. Metal acetylacetonates were used as accelerators of reactions of dicarboxylic acid anhydrides with epoxy compounds only in simple (unmodified) systems. In preparation of hybrid composites by the sol–gel process, the system inevitably contains water, alcohols, organic solvents, and mineral acids. The presence of even small amounts

of these components and the formation of finely dispersed polysiloxane particles can affect in the general case both the curing process catalyzed by metal acetylacetonates and the heat resistance of the resulting hybrid materials.

The goal of this study is comparative evaluation of the accelerating effect of metal acetylacetonates on formation of anhydride-curable epoxy polymers and hybrid composites based on them and prepared by the sol–gel method, and also analysis of the effect exerted by metal acetylacetonates on the resistance of polymers and composites to thermal oxidative degradation and the choice of an accelerator ensuring high heat resistance of the resulting materials.

EXPERIMENTAL

As investigation objects we chose an unmodified epoxy–anhydride polymer (hereinafter, epoxy polymer) and a hybrid composite prepared by modification of the initial system by products of hydrolytic polycondensation of ethoxysilanes (hereinafter, hybrid composite). Epoxy polymers and hybrid composites were prepared on the basis of 1,1-dimethylol-3-cyclohexene triepoxide (UP-650T) and isomethyltetrahydrophthalic anhydride (*iso*-MTHPA). The curing accelerators were metal acetylacetonates $M(acac)_n$, where M = Fe(III), Co(III), Cr(III), or Ni(II), taken in an amount of 0.75 wt % relative to the epoxy resin. In preparing hybrid composites, we performed the preliminary step of the hydrolytic polycondensation of tetraethoxysilane (TEOS) and epoxypropxypropyltriethoxysilane (ES-1), taken in 2 : 1 molar ratio, in the presence of UP-65-T resin, solvent (methyl ethyl ketone, volume ratio to ethoxysilanes 1 : 2), and curing accelerator. The total content of ethoxysilanes in the initial composite was 10 wt %.

The thermograms of epoxy–anhydride polycondensation in the presence of metal acetylacetonates were recorded by differential scanning calorimetry (DSC) with a DSM-2M microcalorimeter at a heating rate of 2, 4, 8, and 16 deg min^{-1}. The sol fraction yield was determined from the weight loss of the film samples after prolonged (3 days) extraction of low-molecular-weight products with methanol. The extraction was performed at 50°C with repeated replacement of the extractant. The glass transition point of polymers and composites was determined by the thermomechanical method. Oxidation of polymeric and composite materials was performed on a gas-volumetric unit at 200°C in oxygen at a partial pressure of 1 atm. Thermogravimetric studies were performed with a Q-1500 D derivatograph (MOM, Hungary) in the dynamic mode in air at a heating rate of 10 deg min^{-1}.

All the acetylacetonates studied exert a catalytic effect on the epoxide–anhydride polycondensation in preparation of epoxy polymers and hybrid composites. With these chelates, the maximum in the DSC patterns shifts toward lower temperatures by 10 to 50°C depending on the nature of the central atom in the chelate. The temperatures of the maxima in the thermograms for the unmodified systems and hybrid composites with the same accelerator are very close. Hence, preliminary step of the hydrolytic polycondensation of ethoxysilanes and the presence of polysiloxane particles in the composites exert no significant effect on the polymerization of the organic constituent.

To evaluate the efficiency of the catalytic action of acetylacetonates, we determined from the DSC data the activation energy of curing of epoxy–anhydride polymers and composites. The dependence of the temperature of the maximum T_{max} on the heating rate V is well linearized in the coordinates $\ln V$–$1/T_{max}$ (Fig. 1). The linear correlation coefficients r vary in the range 0.9915–0.9995. This fact allowed us to calculate by the formula

$$E_a = -R\mathrm{d}(\ln V)/\mathrm{d}(1/T_{max}) \quad (1)$$

the apparent activation energy of curing of epoxy oligomers [15] in the cases of formation of epoxy polymers and hybrid compounds. The dependence of T_{max} on the heating rate is also well linearized in the coordinates

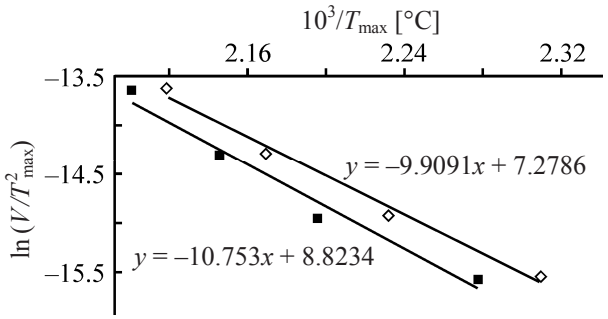

Fig. 2. Temperature of the maximum T_{max} in the DSC curves as a function of the heating rate V (deg min^{-1}) in the coordinates of the Kissinger method.

$$\ln(V/T^2_{max})–1/T_{max}$$

(Fig. 2). In this case, the activation energy was additionally calculated by the Kissinger method [16] developed for the process of cross-linking of filled epoxy polymers (Table 1). The activation energy is related to the temperature of the maximum and the heating rate by

$$E_a = –R\mathrm{d}(V/T^2_{max})/\mathrm{d}(1/T_{max}). \quad (2)$$

We found that the activation energies determined by the two methods differ by no more than 10%, which may be caused by relatively low concentration of polysiloxane particles in the composite. Counting on silicon oxide, the concentration of the products of hydrolytic polycondensation of ethoxysilanes is 3 wt %.

All the acetylacetonates used decrease by a factor of 1.3–2 the apparent activation energy of curing of epoxy–anhydride compounds and organo–inorganic hybrids. This is consistent with the published data for unmodified polymers cured in the presence of manganese and iron acetylacetonates [9]. In the systems under consideration, the most pronounced decrease in the activation energy is observed with cobalt(III) and nickel(II) acetylacetonates. Studies aimed to elucidate the mechanism of the catalytic effects of metal acetylacetonates and the factors causing differences in their activity are being continued. In this stage, it should be noted that the activation energies for the epoxy polymers and hybrid composites are approximately equal. This fact confirms the previously made assumption that the preliminary step of formation of a sol of polysiloxane particles does not appreciably affect the epoxy–anhydride polycondensation and makes it possible to compare the effect of acetylacetonates on formation of epoxy polymers and composites.

Taking into account the DSC data, we chose the optimal curing conditions allowing preparation of polymers and composites with the glass transition point as high as possible: 4 h at 160°C and 6 h at 180°C. Further increase in the curing temperature or time is not appropriate, because this may lead to the development of degradation. We obtained transparent film samples and determined their glass transition point and sol fraction content (Table 2). It can be seen that introduction of ethoxysilanes into the starting formulation decreases the glass transition point of the composites both at noncatalytic curing of the epoxy resin and at catalysis of the polycondensation with all the metal acetylaceto-

nates studied. The plasticizing effect of polysiloxane particles in epoxy polymers prepared by cationic polymerization and anhydride curing is due to formation of topological defects in the structure of the epoxy polymer [17, 18]. In the systems under consideration, increased defectiveness of the structure of the epoxy constituent of the composites is manifested in higher yield of the sol fraction.

Table 2 shows that the sol fraction content in epoxy polymers and in hybrid composites prepared using $Cr(acac)_3$ is lower compared to the samples prepared with the other acetylacetonates. On the whole, the glass transition points and sol fraction yields for the polymers and composites prepared with different accelerators are randomly scattered. This is apparently due to the fact that the final steps of curing of the polymeric material may be accompanied by the onset of degradation processes whose influence on the sol fraction content and glass transition point may be different and may depend on particular accelerator.

We examined the effect of Fe(III), Co(III), Cr(III), and Ni(II) acetylacetonates on the rate of high-temperature oxidation of polymeric film samples in the medium of molecular oxygen. Because of the limited solubility of acetylacetonates and the negative effect of high chelate concentrations on the resistance of unmodified films to thermal oxidative degradation [19], we chose for a detailed study epoxy polymers and hybrid composites obtained at an accelerator concentration of 0.75 wt % relative to the resin.

Typical curves of oxygen uptake by polymeric films are shown in Fig. 3. The maximal oxidation rates at 200°C, taken as a criterion of the relative stability of polymers and composites to thermal oxidative degradation, are given in Table 3. We found that the oxygen uptake by hybrid composites is slightly faster than by epoxy polymers with the same content of the polymerization accelerator in the system. This can be accounted for, firstly, by the fact that the hybrid films, compared to unmodified films, contain a larger amount of the more readily oxidizable sol fraction. Secondly, the structure of the organo-inorganic composite is more defective, which facilitates the oxygen diffusion inside the film sample. It can also be seen that all the acetylacetonates except $Fe(acac)_3$ at the given concentration exert virtually no effect on the resistance of the material to high-temperature oxidation. Higher oxidation rates for the films prepared with $Fe(acac)_3$ are due to higher activity of this compound in the decomposition of hydroperoxides (with a high yield of active radicals), which leads to considerable acceleration of the radical-chain oxidation [20].

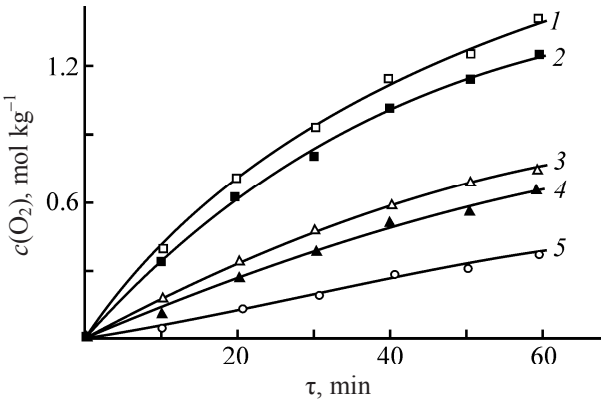

Fig. 3. Kinetic curves of oxidation of (*2*, *4*, *5*) epoxy polymers and (*1*, *3*) hybrid composites. ($c(O_2)$) Oxygen uptake and (τ) time. Accelerator: (*1*, *2*) $Fe(acac)_3$, (*3*, *4*) $Cr(acac)_3$, and (*5*) none.

As shown in [21], silica particles incorporated in epoxy polymers enhance their heat resistance as estimated from the temperatures of the onset and completion of degradation of polymer samples, temperature corresponding to maximal weight loss rate, and temperatures of 5 and 10% weight loss in the dynamic heating mode. For the systems considered in this study, we evaluated the resistance to thermal oxidative degradation by thermal gravimetric analysis (Table 4). It can be seen that introduction of all the examined acetylacetonates into unmodified epoxy–anhydride polymers decreases their heat resistance (to different extents depending on the central atom in the chelate). The less resistant to thermal oxidative degradation are the materials cured with $Fe(acac)_3$ and $Co(acac)_3$, which is due to high yield of active radicals in hydro-

[a] (T_{on}, T_{end}) Temperatures of the onset and end of degradation; (T_5, T_{10}) temperatures of 5 and 10% weight loss; (T_{max}) temperature corresponding to the maximal weight loss rate.

peroxide decomposition reactions activated by these chelates [20]. However, the use of acetylacetonates in preparation of hybrid composites allows the heat resistance to be preserved on the initial level or even enhanced. The strongest stabilizing effect is exerted by Cr(III) acetylacetonate: The temperature of 5 and 10% weight loss increases by 26–27°C.

CONCLUSIONS

(1) The examined acetylacetonates can be used as accelerators of epoxide–anhydride polycondensation in preparation of organo-inorganic composites. The apparent activation energy decreases relative to the noncatalytic process to the same extent as in curing of the unmodified polymers. The step of the hydrolytic polycondensation of ethoxysilanes and formation of a sol of polysiloxane particles exerts virtually no effect on curing of hybrid composites.

(2) At 0.75 wt % concentration of acetylacetonates relative to the resin, the high level of the heat resistance of the materials, characteristic of anhydride-cured epoxy polymers, is preserved.

(3) Among the tested catalysts for curing of epoxy–anhydride systems, the most effective is chromium(III) acetylacetonate. Epoxy polymers and hybrid composites prepared with this catalyst exhibit the best set of properties: low sol fraction content, high glass transition point, and resistance to thermal oxidative degradation.

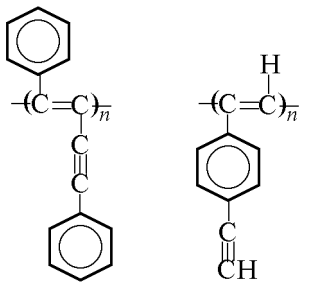
Abstract—Diphenyldiacetylene and *p*-diethynylbenzene homopolymers and copolymers exhibit high resistance to heat and thermal oxidation. Their composites with commercial oligomers were examined.

DOI: 10.1134/S107042720811027X

It is well known that substituted polyacetylenes exhibit a set of unique physicochemical properties allowing preparation on their basis of diverse materials for electronics, information recording, and catalysis [1–3]. Within the class of substituted polyacetylenes, polydiphenyldiacetylene (poly-DPD) and poly-*p*-diethynylbenzene (poly-DEB) exhibit high resistance to heat and thermal oxidative degradation [1, 4]. Furthermore, there are indications that polyconjugated polymers inhibit thermal and thermal oxidative degradation of various substances and polymeric materials [4, 5]. However, these studies dealt with samples of polyconjugated polymers that had been prepared under the conditions causing formation of defective structures of macrochains. The polymers were insoluble and contained virtually no reactive functional groups. Furthermore, the suggested procedures for preparing the polymers were difficult to implement in industry.



For example, in thermal polymerization of DPD in the bulk, the insoluble fraction content was as high as 61%. Macromolecules of the polymer contained both polyene and polyacene fragments [6, 7]. Polymerization of DPD in the presence of coordination initiators [6, 8, 9] led to the formation of polyenes of low molecular weight with a low conversion.

In thermal polymerization of DEB, both ethynyl groups of the monomer opened. This led to the formation of a nonmelting insoluble colored polymer of three-dimensional network structure [10]. In the presence of coordination initiators [11–16], thickly crosslinked insoluble polyphenylenes or branched oligophenylenes containing no more than 2–4 –C≡CH groups were obtained.

Later the synthesis of DPD [17] and DEB [18, 19] homopolymers and of their random copolymers [20] under mild conditions (anionic initiators, temperature lower than 60°C) allowed preparation for systematic studies of polymers in which the chains were nondefective and had proved intramolecular structure. Here we demonstrate for the first time the possibility of using these polymers for the modification of commercial oligomers of various classes.

EXPERIMENTAL

All the synthesized polyconjugated polymers were powders readily soluble in organic solvents. Thermoplastic poly-DPD and thermosetting poly-DEB had the structure of substituted polyenes. These units were also present in thermosetting random copolymers of DEB and DPD in 3 : 1 (CPL-1) and 1 : 3 (CPL-2) ratios.

Poly-DPD Poly-DEB

To prepare a carborane-containing polymer (poly-DEB-B), to a toluene solution of poly-DEB we added toluene solutions of decaborane and dimethylaniline. The reaction mixture was washed with HCl and water,

and the product was precipitated into hexane. The boron content was 20%.

Thermal gravimetric and differential thermal analyses were performed on an OD-2 derivatograph (MOM, Hungary) and a VTV-1 device (in a vacuum) with continuous heating at a rate of 5 deg min^{-1}.

When heated in air to 300°C, poly-DPD underwent virtually no changes. At 500°C, the weight loss was 18%. Above 500°C, degradation of the polymers became progressive, and at 800°C it was complete (Fig. 1).

The weight loss of poly-DEB in a vacuum was 20% at 700°C (Fig. 2). With increasing temperature, the rate of the weight loss decreased, and a significant amount of a coke residue formed. In air, poly-DEB also showed high resistance to thermal oxidation. No noticeable weight loss was observed on heating it in air to 370°C (Fig. 2a). In the DTA curve of the polymer (Fig. 2b), there was an exothermic peak at about 170°C, associated with oxidation of C≡C bonds in ethynyl groups –C≡CH. Preliminary heat treatment in a vacuum for 6 h of poly-DEB at 100 (poly-DEB-100) and 200°C (poly-DEB-200) led to a decrease and subsequent disappearance of this exothermic peak in the DTA curve. Simultaneously, in the IR spectra the vibration bands of the C≡C bonds in –C≡CH groups decreased in intensity and then disappeared.

Noticeable degradation of DPD–DEB random copolymers in air started at 350–400°C (Fig. 1). An increase in the DPD content in the copolymer led to a decrease in the extent of thermal oxidative degradation (curves *2*, *3*) owing to a decrease in the amount of readily oxidizable –C≡CH groups. The samples completely burned out at 700–750°C.

Comparison of the resistance of homo- and copolymers of DEB and DPD to thermal oxidative degradation revealed the following trend. The homopolymer poly-DEB was the least stable. With an increase in the DPD fraction in the copolymer, the resistance to thermal oxidative increased (Fig. 1), and poly-DPD appeared to be the most stable. The temperatures corresponding to 40% weight loss, $T_{40\%}$, determined from the TGA data, varied in this series of polymers from 500 to 610°C. Boron-modified poly-DEB appeared to be still more resistant to thermal oxidative degradation (Fig. 2, curve *6*). At 800°C, poly-DEB-B lost only 18% of its weight. The weight gain observed with poly-DEB-B in the range 500–600°C can be accounted for by formation of oxygen-containing boron compounds [21] and B_2O_3 [22].

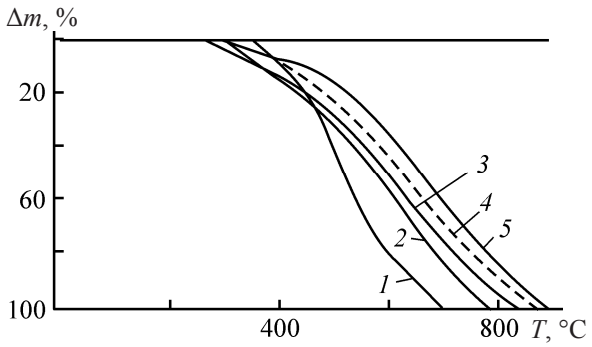


Fig. 1. TGA curves in air for DEB and DPD homo- and copolymers. (Δ*m*) Weight loss and (*T*) temperature; the same for Figs. 2 and 3. (*1*) Poly-DEB, (*2*) CPL-1, (*3*) CPL-2, (*4*) CPL-2 after vacuum thermolysis at 200°C for 6 h, and (*5*) poly-DPD.

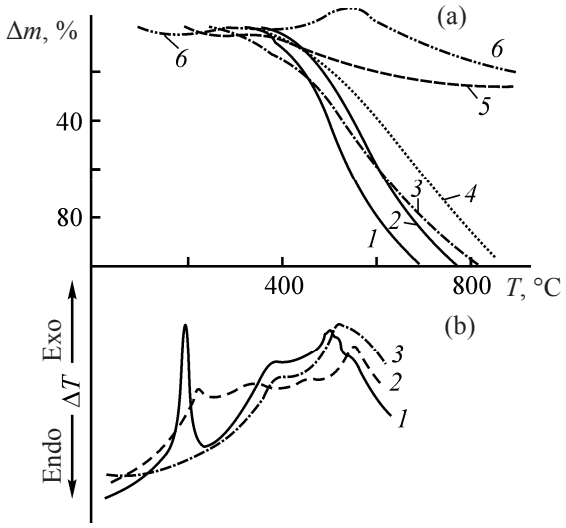

Fig. 2. (a) TGA curves (*1–4*, *6*) in air and (*5*) in a vacuum; (b) DTA curves in air. (a) (*1*) Poly-DEB, (*2*) poly-DEB-200, (*3*) CPL-2, (*4*) poly-DPD, (*5*) poly-DEB, and (*6*) poly-DEB-B; (b) (*1*) poly-DEB, (*2*) poly-DEB-100, and (*3*) poly-DEB-200.

Thus, DPD and DEB homopolymers and their copolymers exhibit high resistance to thermal and thermal oxidative degradation. Therefore, the polymers should not make a negative contribution to the degradation when used in composites with commercial oligomers.

In the production of carbon–carbon composite materials, the following procedures are used: impregnation of a fibrous carbon materials with a liquid curable resin; curing of the liquid resin to obtain a solid sam-

Table 1. Effect of additions of poly-DPD and copolymer on the yield of the pyrolyzate of EN-6 polymeric resin

35	35	0.64	30	78.43	66.49

ple; pyrolysis of the sample in the absence of oxygen, with the major fraction of the resin degrading and volatilizing and the sample becoming porous; repeated impregnation of the fibrous carbon material with a liquid resin; repetition of the impregnation–pyrolysis cycles to attain the required characteristics of the sample.

One of the main steps is pyrolysis. The larger the amount of the substance (coke residue) remaining after the pyrolysis, the smaller the number of repeated impregnation–pyrolysis cycles required. It is clear that the process is more efficient and cost-saving if the coke residue is large. Therefore, increasing the coke residue was always an important problem. To accomplish this goal, we examined the modification of widely used commercial resins.

Epoxy–novolac resin EN-6 [TU (Technical Specification) 6-05-1585–77] and novolac-type phenol–formaldehyde resin SF-010 [GOST (State Standard) 18 694–80] were modified by two procedures: in solvents (acetone, furfural) and in melts. As modifiers we used poly-DPD and DPD–DEB copolymer. The SF-010 resin was cured with *p*--toluenesulfonic acid (*p*-TSA). Then the samples of the cured modified resins were heated in a nitrogen atmosphere at various temperatures, and the amount of the remaining pyrolysis products (amount of coke residue) was determined.

Analysis of the results obtained (Tables 1, 2) showed the following: (1) introduction of 10–30 wt parts of DPD homo- and copolymer into EN-6 epoxy–novolac resin leads to the resin curing without special addition of curing agents; (2) poly-DPD is better combined with the resins in solvents with the formation of a stable composite binder; (3) introduction of 10–30 wt parts of DPD homo- and copolymer into resins increases the yield of the solid pyrolysis products by 21–33% for EN-6 resin and by 17–19% for SF-010 resin; (4) in coking of EN-6 resin, addition of the copolymer is more effective than addition of the same amount of poly-DPD; apparently; this is due to the presence in copolymer macromolecules of a large amount of reactive –C≡CH groups favoring formation of a 3D network in pyrolysis.

Thus, addition of polyconjugated polymers considerably (by 17–33%) increases the coke residue in pyrolysis of various modified commercial resins.

[a] Cumene hydroperoxide. [b] *tert*-Butyl hydroperoxide. [c] Azobis(isobutyronitrile). [d] Product of reaction of glycidyl methacrylate with boric acid.

It is known that formulations based on polyfunctional oligomeric compounds of the acrylic series exhibit poor heat resistance. Therefore, a topical problem is to enhance the heat resistance and strength of 3D polymers of various commercial oligoether acrylates at elevated temperatures. For this purpose, into the initial liquid oligoether acrylates we added 10–35 wt % poly-DEB. We also introduced oxyalkylene–organosiloxane block copolymer KEP2 as foam regulator. As references we prepared samples to which, instead of poly-DEB, we added another polyconjugated polymer, polyphenylacetylene (poly-PA), having the structure –(HC=CPh)$_n$–. It differs from the poly-DEB structure in that there are no reactive –C≡CH groups at –Ph substituents. The storage conditions and storage time for the oligoether acrylate compounds obtained were the same as for the initial oligoether acrylates. The resulting compound was cured with common radical polymerization initiators at 100–110°C. The heat resistance of the samples in air was estimated by TGA. As reference quantities in comparing the resistance of the samples to thermal oxidation we used the temperatures at which the weight loss reached 10, 50 and 75%: $T_{10\%}$, $T_{50\%}$, and $T_{75\%}$, respectively.

The results given in Fig. 3 and Table 3 allow the following conclusions: (1) addition of poly-PA does not noticeably enhance the resistance of cured TGM-3 to thermal oxidation (run nos. 16–18); (2) for all the types of oligoether acrylates studied, additions of poly-DEB in an amount of 6 wt % appreciably enhance the

15	2.3	0.75	0.62	0.62	0.75
16	2.5	0.30	0.10	0.05	0
17	2.4	0.25	0.10	0.05	0
18	2.4	0.90	0.20	0.65	0
19	–	–	–	–	–

heat resistance of cured oligoether acrylates in air; (3) the use of poly-DEB in an amount exceeding 35 wt % led to a considerable increase in the compound viscosity, which complicated its handling; furthermore, the strength characteristics of the cured composite materials got somewhat worse; (4) the heat resistance in air of cured oligoether acrylates increases with an increase in the amount of poly-DEB added (run nos. 3, 4, 9, 10); (5) a decrease in the sample weight loss (run nos. 2–11) relative to the reference sample (run no. 11) is the most significant at the highest temperatures: $T_{10\%}$ increased by 105°C, whereas $T_{75\%}$ increased by up to 280°C; (6) an increase in the KEP-2 content can make the resistance to thermal oxidation lower (run nos. 9, 11); (7) the type of the radical polymerization initiator does not affect the heat resistance of the cured samples (run nos. 5–7); (8) with poly-DEB-B, the weight loss by TGM-3 at 850°C was only 60%.

The compounds obtained were tested as sealants in a bolt–nut joint in simulation of high-temperature operation. For this purpose, the compounds obtained were applied to the threads, the nuts were screwed, and the compound was cured. After curing, the mean torque in unscrewing by one turn was measured. The strength tests were performed at 20, 150, 200, 250, and 300°C.

It follows from the results given in Table 4 that (1) addition of poly-PA decreases the strength characteristics of cured TGM-3 (run nos. 16–18); (2) for all the types of oligoether acrylates studied, addition of poly-DEB (10–35 wt %) enhanced the strength properties of the cured compounds; (3) an increase in the amount of poly-DEB added leads to enhancement of the strength characteristics; (4) the observed effect is more significant for TGM-3 oligomer than for OKM-2 and GBK oligomers; (5) for OKM-2 (run nos. 12, 13) and GBK (run nos. 14, 15) oligomers, no strength enhancement is observed up to 150°C, whereas at higher temperatures (200–300°C) the effect is significant.

On the whole, our results show that it is appropriate to use as modifying additive polyconjugated poly-DEB forming an additional 3D network. The modifying addition of poly-DEB enhances the resistance of all the types of oligoether acrylates studied to thermal oxidation and improves the strength properties of the cured compounds at high temperatures. Addition of poly-PA not only does not enhance the resistance of oligoether acrylate to thermal oxidation but also deteriorates the strength of the cured compounds at high temperatures.

It should be emphasized that, by varying the composition of DPD–DEB copolymers, it is possible to control their thermal oxidation resistance and thermal reactivity, and hence their modifying ability.

CONCLUSIONS

(1) Homopolymers and copolymers of phenylacetylene and *p*-diethynylbenzene exhibit high resistance to heat and thermal oxidation.

(2) The coke residue of commercial resins considerably increases upon modification of the resins with additions of polydiphenylacetylene and diphenylacetylene–*p*-diethynylbenzene copolymer.

(3) Additions of polydiethynylbenzene to oligoether acrylates enhance their resistance to thermal oxidation and the strength properties of the cured compounds at high temperatures.

(4) Polymers and copolymers of diphenyldiacetylene and *p*-diethynylbenzene can be used in industry

for improving the properties of cured polymeric materials.

Abstract—The hydrodynamic and conformational properties of silicon-containing polynorbornene prepared by metathesis polymerization of 5-trimethylsilylnorbornene in the presence of Grubbs Ru carbene complex were studied by viscometry, isothermal translation diffusion, and centrifugal sedimentation. For the ten-sample homologous series of the polymer, Mark–Kuhn–Houwink relationships correlating the hydrodynamic characteristics of the molecules in toluene with their molecular weight were obtained.

DOI: 10.1134/S1070427208110281

Polymers of bicyclo[2.2.1]hept-2-ene, more commonly known as norbornene, can be prepared by various procedures, in particular, by polymerization following the metathesis (with ring opening, *m*) [1, 2] and additive [with double bond opening, *a*] [3, 4] schemes. Polymerization of norbornene by the isomerization scheme (*i*) [5, 6] is also possible:

Metathesis and additive polynorbornenes are commercial products. Both exhibit a set of practically important properties [3, 4, 7, 8]. The best studied is metathesis polymerization (the term ROMP, ring opening metathesis polymerization, is also used) of norbornenes [1, 2]. Owing to the development of highly active catalysts tolerant to functional groups: Grubbs, Schrock, Hoveyda, Grela carbine complexes [9–11], norbornenes with bulky functional groups can be successfully involved in metathesis polymerization.

It was shown recently that introduction of trimethylsilyl groups $-SiMe_3$ as side substituents into both additive and metathesis polynorbornenes substantially improves the gas-transport properties of films of these polymers compared to unmodified analogs [12, 13]. Additive poly(trimethylsilylnorbornene) (*a*-PNB-$SiMe_3$) is one of the most permeable to gases among glassy polymers. At the same time, its isomer, metathesis poly(trimethylsilylnorbornene) (*m*-PNB-$SiMe_3$), exhibits considerably lower permeability coefficients [13].

m-PNB-$SiMe_3$

In our previous study [14] we found what conformational and microstructural properties of *a*-PNB-$SiMe_3$ chains are responsible for specific morphology of films of this polymer. In this study, using hydrody-

namic methods of isothermal translation diffusion, centrifugal sedimentation, and viscometry, we examined for the first time the molecular characteristics of *m*-PNB-$SiMe_3$ and revealed its significant difference from *a*-PNB-$SiMe_3$ in molecular properties.

The specific goals of our study were as follows: (1) determination of the molecular weight (MW) of a homologous series of *m*-PNB-$SiMe_3$ samples by two independent procedures: absolute method of diffusion–sedimentation analysis [15, 16] and gel permeation chromatography [17]; (2) determination of Mark–Kuhn–Houwink relationships correlating the hydrodynamic characteristics of the macromolecules with their MW [16]; (3) determination of the equilibrium rigidity (Kuhn segment length) as a basic conformational characteristic of the polymer of a new structure; (4) simulation of *m*-PNB-$SiMe_3$ decamers by PM3 quantum-chemical semiempirical method to reveal the microstructural features of the polymer chains.

We compared the molecular conformational characteristics of silicon-substituted polynorbornenes of two types with the aim to determine why *m*-PNB-$SiMe_3$ samples are less suitable materials for gas-permeable films than their additive analogs. Our study is connected with the urgent problem of the search for new heat-resistant polymers for high-performance gas-transport membranes.

EXPERIMENTAL

In this study, the metathesis polymerization of 5-trimethylsilylnorbornene was performed for the first time in the presence of the Grubbs Ru carbene complex of the first generation, $Cl_2(PCy_3)_3Ru{=}CHPh$, which allowed variation of the molecular weight of the polymer in a wide range by varying the [Monomer]/[Cat] ratio (Table 1).The polymerization occurred at room temperature. The monomer prepared by high-temperature diene condensation of dicyclopentadiene with vinyltrimethylsilane by the procedure described in [18] was an equimolar mixture of the *exo* and *endo* isomers.

A solution of Grubbs catalyst in absolute toluene (0.04 M) was prepared in an inert atmosphere just before the polymerization. A 10-ml glass ampule equipped with a magnetic stirrer was charged under argon with a catalyst solution and with the calculated amount of the monomer. In the course of the polymerization, the solution color changed from violet to yellow-brown or pale yellow. The reaction was stopped by adding into the ampule a 3 M solution of ethyl vinyl ether in toluene, after which the oxidation inhibitor, 2,2'-methylenebis(6-*tert*-butyl-4-methylphenol), was added, and the polymer was precipitated with methanol. Then the polymer was reprecipitated from a toluene solution with methanol and vacuum-dried to constant weight. The ^{13}C NMR spectra for the sample series obtained were identical, which allowed this series to be considered as homologous. Taking into account virtually quantitative yield of the polymers, it can be concluded with confidence that they contain equal amounts of *exo*- and *endo*-monomeric units. Complex character of the spectra does not allow accurate determination of the ratio of the *cis* and *trans* double bonds. It is known, however, that polynorbornenes prepared on Ru catalysts contain, as a rule, mainly *trans* double bonds [1, 2].

Table 1. Conditions of synthesis of *m*-PNB-$SiMe_3$ samples

Sample no.	[Monomer]/[Cat], mol/mol	[Cat] × 10^4, M	Reaction time, h	Polymer yield, %
2[a]	7000	0.7	19	95
3	5000	1.6	19	92
4	3000	1.0	24	95

7	2000	3.4	0.7	99.3
8	1000	7.5	0.8	95.7
9	500	7.5	24	94.3
10	250	7.5	1	94.5

[a] Sample no. 1 was prepared under the conditions similar to those for the synthesis of sample no. 2 but with different catalytic complex; for the synthesis of sample nos. 2–10, we used the Grubbs Ru carbene complex of the same composition.

All the hydrodynamic studies of *m*-PNB-$SiMe_3$ samples were performed under similar conditions in toluene solutions at 25°C. At this temperature, the solvent had the following characteristics: density 0.863 g cm^{-3}, viscosity 0.55 cP, and refractive index 1.4945.

The viscometric measurements were performed in an Ostwald capillary viscometer with the solvent outflow time of 89.2 s. The intrinsic viscosity [η] was determined after Huggins [16] from the plot

$$[\eta] = \lim_{c \to 0}(\eta_{sp}/c), \quad (1)$$

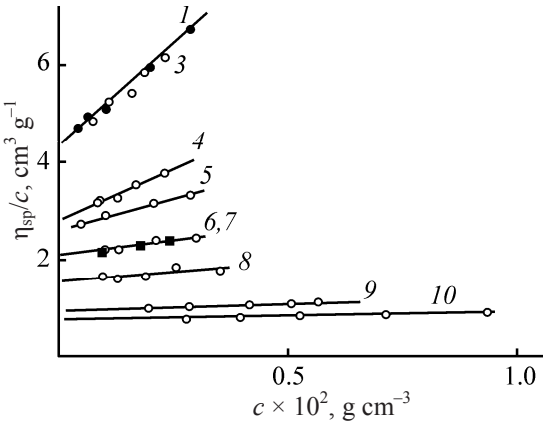

Fig. 1. Plots of η_{sp}/c vs. solution concentration c for *m*-PNB-SiMe$_3$ samples. Figures at straight lines are sample nos. in Tables 1–3.

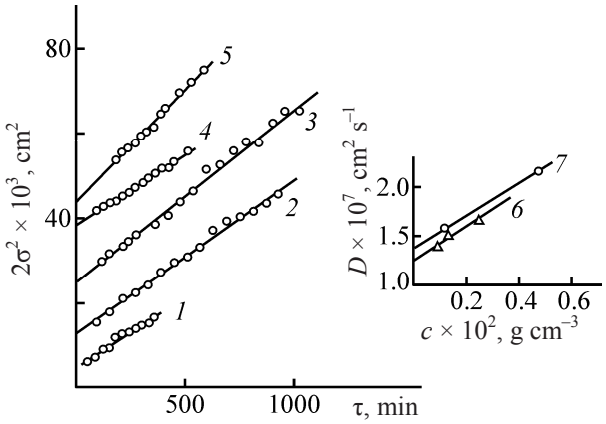

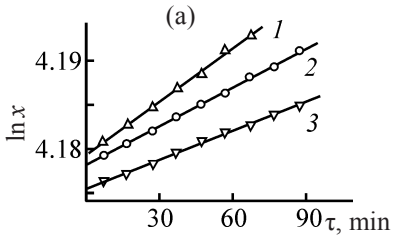

Fig. 2. Doubled variance of the diffusion curve $2\sigma^2$ as a function of time τ for sample no. 1 at solution concentrations of (*1*) 0.094, (*2*) 0.13, and (*3*) 0.248 × 10^{-2} g cm^{-3}, and for sample no. 2 at solution concentrations of (*4*) 0.0119 and (*5*) 0.475 × 10^{-2} g cm^{-3}; (*6*, *7*) concentration dependences of the diffusion coefficient *D* for sample nos. 1 and 2, respectively.

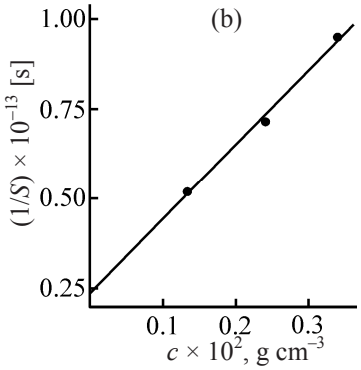

Fig. 3. (a) Logarithm of the shift of the sedimentation boundary ln x as a function of time τ at solution concentrations c of (*1*) 0.34, (*2*) 0.24, and (*3*) 0.13 × 10^{-2} g cm^{-3}; (b) the corresponding concentration dependence of the sedimentation coefficient 1/S for sample no. 4.

where $\eta_{sp} = (\eta - \eta_0)/\eta_0$ is the reduced viscosity of the solution, η and η_0 are the viscosities of the solution and solvent, and c is the polymer concentration in the solution.

For sample no. 7, we measured the temperature dependence of [η] in the range 16–35°C and determined the temperature coefficient of the viscosity $d \ln[\eta]/dT$ = 0.016. Its sign and value are typical of flexible-chain polymers [16].

The isothermal translation diffusion of polymers was studied in a Tsvetkov diffusometer [16]. The diffusion boundary was formed by layering of the solvent onto the solution and was recorded at definite intervals. The procedure is described in detail in [15, 16], and the installation parameters are given elsewhere [14].

The translation diffusion coefficients D (Fig. 2) were determined from the slope of the experimental dependences of the diffusion curve variance σ^2 on time, after which they were extrapolated to zero solution concentration c: $\lim_{c \to 0} D = D_0 + k_D c$ (Figs. 3a, 3b). For macromolecular sample nos. 1–4, we used the mean experimental value k_D = 1.75, and for the other samples in the concentration range $c[\eta] < 1$ the concentration dependence of D was not observed.

Centrifugal sedimentation of macromolecules was studied on an MOM 3180 analytical ultracentrifuge at 40 × 10^3 rpm in a two-sector cell with an artificially made concentration boundary of the layering type [15]. The ultracentrifuge was equipped with a polarization-interferometric attachment; the spar doubling value

[a] The slopes of the experimental dependences $\eta_{sp}/c = f(c)$ [formula (1), Fig. 2] varied within 0.3–0.44.

[b] (dn/dc) Increment of the refractive index of the solution from diffusion data.

[c] Mean experimental value of the hydrodynamic invariant $A_0 = D_0(M_{SD}[\eta])^{1/3}/RT$ for the given polymer–solvent system is $(3.3 \pm 0.1) \times 10^{-10}$, which is typical of flexible-chain polymers [16].

was 0.0545 cm [15, 16]. Figure 3a shows how the logarithm of the shift of the sedimentation boundary, $\ln x$, depends on time τ for sample no. 4. From the slopes of the straight lines $\ln x = f(\tau)$, we determined the sedimentation coefficients S in the range of solution concentrations (0.18–0.55) $\times 10^{-2}$ g cm^{-3}. The sedimentation coefficients S obtained were extrapolated to zero solution concentration (Fig. 3b) in accordance with the equation $1/S = (1/S_0)(1 + k_s c)$, where S_0 is the limiting sedimentation coefficient at $c = 0$ and k_s is the concentration coefficient of the sedimentation [15, 16]. Such dependences were also obtained for the other samples, except sample nos. 3, 5, and 7, for which the coefficients S were obtained only at a single concentration and the limiting sedimentation coefficients S_0 were calculated by the above equation using k_s for sample no. 4. In the examined homologous series we revealed the dependence of k_s on MW of the polymer, which can be described by an empirical relationship $k_s = 0.965 S_0^{1.49}$.

The molecular weight of the polymers M_{SD} was determined by the Svedberg formula [15, 16]

$$M_{SD} = [RT/(1 - v\rho_0)](S_0/D_0), \quad (2)$$

where R is the universal gas constant; T, absolute temperature; $(1 - v\rho_0)$, buoyancy factor; v, specific partial volume of the polymer; and ρ_0, solvent density.

The specific partial molar volume was determined pycnometrically wth 5- and 10-ml pycnometers. The mean buoyancy factor for sample nos. 5–7 was $(1 - v\rho_0) = 0.156 \pm 0.005$.

All the hydrodynamic characteristics obtained for the examined *m*-PNB-$SiMe_3$ samples are given in Table 2.

The weight-average molecular weight M_w and polydispersity parameter M_w/M_n of *m*-PNB-$SiMe_3$ samples were determined by exclusion GPC with a Waters chromatograph equipped with styrogel columns and replaceable detection units. The sample was calibrated with polyisoprene references from the All-Russian Research Institute of Synthetic Rubber (St. Petersburg), and toluene was used as eluent. The elution rate was 1 ml min^{-1}. The GPC data for the samples studied are given in Table 3.

Decamers of *m*-PNB-$SiMe_3$ were examined by PM3 [19] semiempirical calculations using Hyperchem program [20].

As follows from the results of diffusion–sedimentation analysis (Table 2), variation of the synthesis conditions (Table 1) allowed preparation of *m*-PNB-$SiMe_3$ samples in a relatively wide (12-fold) interval of molecular weights M_{SD}, which is principally important for obtaining adequate molecular characteristics of the

polymer [16]. It is important that *m*-PNB-$SiMe_3$ samples, according to GPC data (Table 3), are characterized by close polydispersity parameters M_w/M_n, despite significant variations in synthesis conditions. This fact, along with spectral data, additionally confirms that the series under consideration is homologous. The mean polydispersity parameter of the samples studied is close to 2.

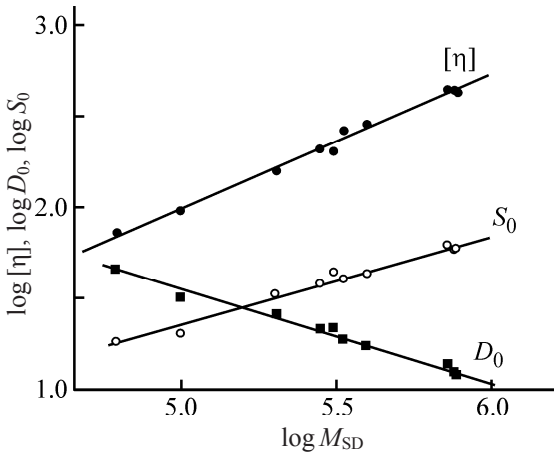

Fig. 4. Intrinsic viscosity [η] and diffusion (D_0) and sedimentation (S_0) coefficients as functoins of M_{SD} for *m*-PNB-$SiMe_3$ samples in toluene at 25°C) (log–log plots).

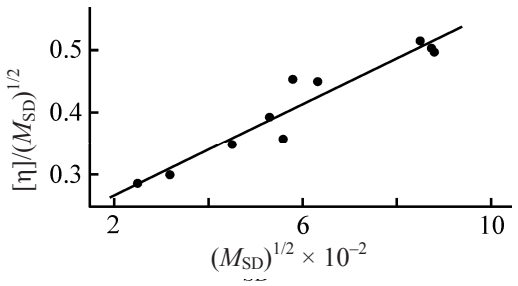

Fig. 5. Plot of [η]/$(M_{SD})^{1/2}$ vs. $(M_{SD})^{1/2}$ for the homologous series of *m*-PNB-$SiMe_3$.

Despite polydispersity, the molecular weights of *m*-PNB-$SiMe_3$ samples determined by two different methods agree with each other, as can be seen from comparison of M_{SD} (Table 2) and M_w (Table 3). This fact shows that the choice of specifically polyisoprene references for chromatograph calibration in our study was correct.

From the logarithmic plots of the intrinsic viscosity [η], D_0, and S_0 vs. M_{SD} (Fig. 4), we obtained the following Mark–Kuhn–Houwink relationships for *m*-PNB-$SiMe_3$ in toluene at 25°C:

$$[\eta] = 1.89 \times 10^{-4}(M_{SD})^{0.74\pm0.05},$$
$$D_0 = 1.11 \times 10^{-4}(M_{SD})^{-0.50\pm0.05}, \quad (3)$$
$$S_0 = 6.93 \times 10^{-16}(M_{SD})^{0.50\pm0.05}.$$

Relationships (3) are similar in the numerical coefficients and exponents to those obtained for polymers of the diene series (like polyisoprene or polybutadiene) in thermodynamically good solvents [21]. Therefore, high exponent in the equation for [η] indicates that the solvent used is thermodynamically good for *m*-PNB-$SiMe_3$ also.

In view of the latter fact, construction of the dependences $[\eta]/(M_{SD})^{1/2} = f(M_{SD})^{1/2}$, according to the Stockmayer–Fixman theory of thermodynamic properties of worm-like chains in good solvents [22], allowed us to determine the equilibrium rigidity of the *m*-PNB-$SiMe_3$ chain, $A = 21 \pm 2$ Å. This construction, in which the Kuhn segment length A is determined from the portion intercepted on the ordinate, is shown in Fig. 5. The corresponding equation of the theory [22] is given below:

$$[\eta]/M^{1/2} = \Phi_\infty(A/M_L)^{3/2} + 0.51\Phi_\infty BM^{1/2}, \quad (4)$$

where $\Phi_\infty = 2.87 \times 10^{23}$ mol^{-1} is the Flory constant for chains with strong hydrodynamic interaction, B is the numerical coefficient of the theory [22] depending on the thermodynamic quality of the solvent, A is the length of the Kuhn statistical segment, and $M_L = M_0/\lambda$ ($M_0 = 166.18$ is the molecular weight of the monomeric unit and λ is the length of its projection onto the chain propagation direction) is the molecular weight of the chain length unit, which for *m*-PNB-$SiMe_3$ at *trans* configuration of the double C=C bond and maximally stretched chain (λ = 6.2 Å) is equal to 27×10^8 g mol^{-1} cm^{-1}.

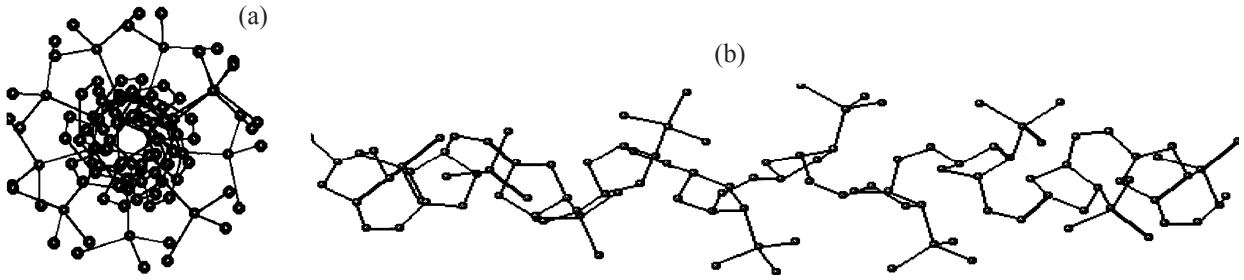

Fig. 6. PM3-optimized structure of the *exo* decamer of *m*-PNB-$SiMe_3$ containing C=C bonds in the *cis* configuration only. Projections: (a) perpendicular to $^{1}9$ axis of the helix corresponding to the conformation of the given decamer and (b) along the helix axis.

The obtained length of the Kuhn segment in *m*-PNB-$SiMe_3$ can be compared with the corresponding characteristic of the structurally related backbone of poly-2-*tert*-butylbutadiene (one double and three single C–C bonds per monomeric unit), whose equilibrium rigidity in a thermodynamically good solvent, *n*-octane, according to formula (4) is 13 Å [23]. Such comparison allows a conclusion that the presence of trimethylsilyl side substituents, which are bulkier than alkyl groups, affects the equilibrium conformational properties of chains with double C=C bonds, enhancing their rigidity. However, like poly-2-*tert*-butylbutadiene, *m*-PNB-$SiMe_3$ should be classed with typically flexible-chain polymers, as the statistical segment of these polymers contains no more than four monomeric units A/λ.

Examination of the molecular properties of *a*-PNB-$SiMe_3$ synthesized by the additive (vinyl) route of 5-trimethylsilylnorbornene polymerization, showed that the equilibrium rigidity of the chains in this polymer is considerably higher than in *m*-PNB-$SiMe_3$. The statistical Kuhn segment of *a*-PNB-$SiMe_3$ chains in toluene at 298 K is 47 Å long and consists of approximately 18 monomeric units [14]. It was also shown that the specific feature of the microstructure of *a*-PNB-$SiMe_3$ chains is their nonuniformity due to the presence of spiral fragments whose length is determined by the correlation length and hence does not exceed 47 Å. Helical segments, as the most energetically favorable, are formed and fixed in the course of *a*-PNB-$SiMe_3$ synthesis owing to steric interaction of closely located bulky trimethylsilyl groups only for regular sequences of monomeric units (e.g., head-to-tail, where the tail is the $–SiMe_3$ group). The helical fragments are randomly arranged in the chains of, on the whole, atactic *a*-PNB-$SiMe_3$, according to spectral data [13].

In the *m*-PNB-$SiMe_3$ chains, the trimethylsilyl side substituents are remote from each other, and therefore, in contrast to *a*-PNB-$SiMe_3$, they cannot cause appreciable enhancement of correlation interactions. As a result, *m*-PNB-$SiMe_3$ is two times less rigid than its additive analog.

Furthermore, as shown by quantum-chemical simulation of *m*-PNB-$SiMe_3$ decamers, helical fragments can appear only at regular repetition of the *cis* configurations of the C=C bonds (Fig. 6). With *trans* configurations only, or with alternating *trans* and *cis* configurations of C=C bonds, decamers of *m*-PNB-$SiMe_3$ take the conformation of random coils.

As the catalyst that we used for preparing *m*-PNB-$SiMe_3$ samples, according to the NMR spectra, provides incorporation of C=C bonds in the chain mainly in the *trans* configuration (~80%), it can be concluded that the microstructural nonuniformity, characteristic of the silicon-substituted additive-type polynorbornene, principally cannot be obtained in *m*-PNB-$SiMe_3$ chains. This difference in the microstructure and equilibrium rigidity of chains should lead to different morphology of *m*-PNB-$SiMe_3$ and *a*-PNB-$SiMe_3$ films and to significant difference in their gas-transport properties. Just for this reason, the gas permeability parameters given in [12] for *m*-PNB-$SiMe_3$ films are two orders of magnitude lower than those for the additive analogs.

The main conclusion following from our analysis is that the gas-transport properties of *m*-PNB-$SiMe_3$ can probably be improved by modification of the catalytic system used, with the aim to increase in the 5-trimethylsilylnorbornene polymerization product the content of C=C bonds in the *cis* configuration. The principal possibility of improving the gas-transport properties of films by this way was noted in [12, 24, 25], where other types of metathesis polymerization catalysts were used.

CONCLUSIONS

(1) With respect to hydrolytic characteristics and equilibrium rigidity of chains, the new silicon-substituted polynorbornene is a typical representative of the polydiene series.

(2) Polymerization of 5-trimethylsilylnorbornene by the metathesis route yields a more flexible (in the thermodynamic sense) polymer compared to the polynorbornene synthesized by the additive scheme. The thermodynamic equilibrium rigidity (Kuhn segment length) of the new polymer is low, about 12 ± 2 Å.

(3) Metathesis poly(trimethylsilylnorbornene) has no nanosized nonuniformities of the chain microstructure, characteristic of additive-type silicon-substituted polynorbornene, which is responsible for essential difference in the gas-transport properties of films of this polymers.

Abstract—Synthesis in a hexamethylenediamine–guanidine hydrochloride melt was carried out at different monomer ratios and synthesis temperatures.

DOI: 10.1134/S1070427208110293

Polyhexamethyleneguanidine hydrochloride (PHMG) prepared by polycondensation in a hexamethylenediamine (HMDA)–guanidine hydrochloride (GHC) melt [1] is a water-soluble polymer containing amino groups, which makes it suitable as antiseptic [2], fungicide, and flocculant for removing iron from potable water [3]. Good water solubility, coupled with lack of odor and of aggressiveness towards various materials and with film formation capability, is responsible for wide application of this polymer in national economy. At the same time, the relationships in formation of the macromolecules of this polymer and its structure are poorly understood.

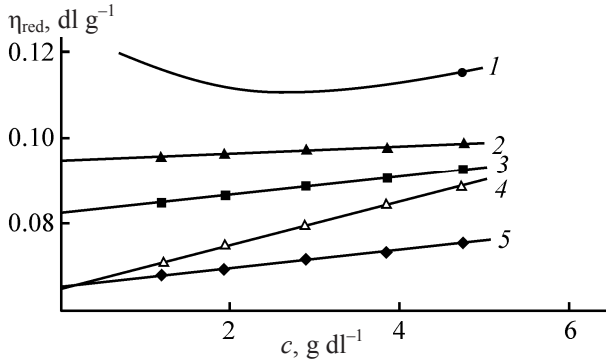
In this study we elucidated the conditions of formation of the PHMG macromolecules by polycondensation of bi- and trifunctional monomers and also determined the constants for the Mark–Kuhn–Houwink equation.

EXPERIMENTAL

The polycondensation reaction between bifunctional HMDA and trifunctional GHC monomers allowed changing, along with the synthesis temperature and time, the reactant ratio, from equimolar to stoichiometric. The synthesis temperature was varied from 165 to 250°C. Gembitskii et al. [4] showed that ammonia ceases to evolve 9 h after the start of the reaction, and this time was chosen as the polycondensation time. The polymers synthesized were dissolved in distilled water and filtered through a Schott filter no. 4; the resulting gel was dried in a desiccator to constant weight. The concentration of the soluble fraction of the polymer was determined by vaporization of 2 ml of the solution, followed by drying to constant weight.

Linear polymers and sol fractions of selected samples were fractionated chromatographically. To this end, we used a 1 m × 10 mm glass column packed with Sephadex-G-50. The column top was filled with 20% solution of the polymer, and the fractions were eluted with distilled water supplied until exhaustive washing of the polymer out of the column. Fractionation yielded from 10 to 15 fractions; the loss was estimated at 1.4–5%.

The intrinsic viscosities of the sol fractions were determined in a suspended-level capillary Ubbelohde viscometer [5] at the thermostat temperature of 25 ± 0.05°C**.** Because of polycationic nature, the synthesized samples exhibit the polyelectrolyte effect in viscosity measurements, i.e., a nonlinear concentration dependence of the reduced viscosity. To suppress the polyelectrolyte effect, we used NaCl solutions with different ionic strengths as solvents (Fig. 1).



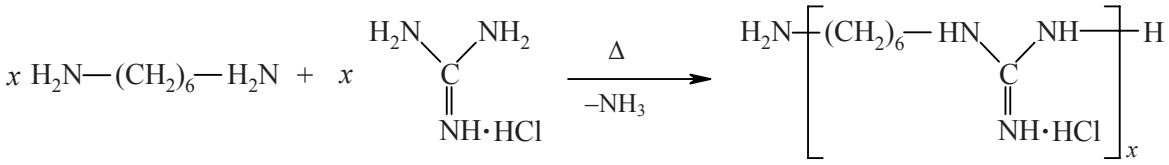


Fig. 1. Reduced viscosity $\eta_{red} = \eta_{sp}/c$, of PHMG in aqueous NaCl solutions with different ionic strengths vs. NaCl concentration c. (*1*) Pure water, (*2*) 0.2 N NaCl, (*3*) 0.3 N NaCl, (*4*) 0.4 N NaCl, and (*5*) 0.5 N NaCl.

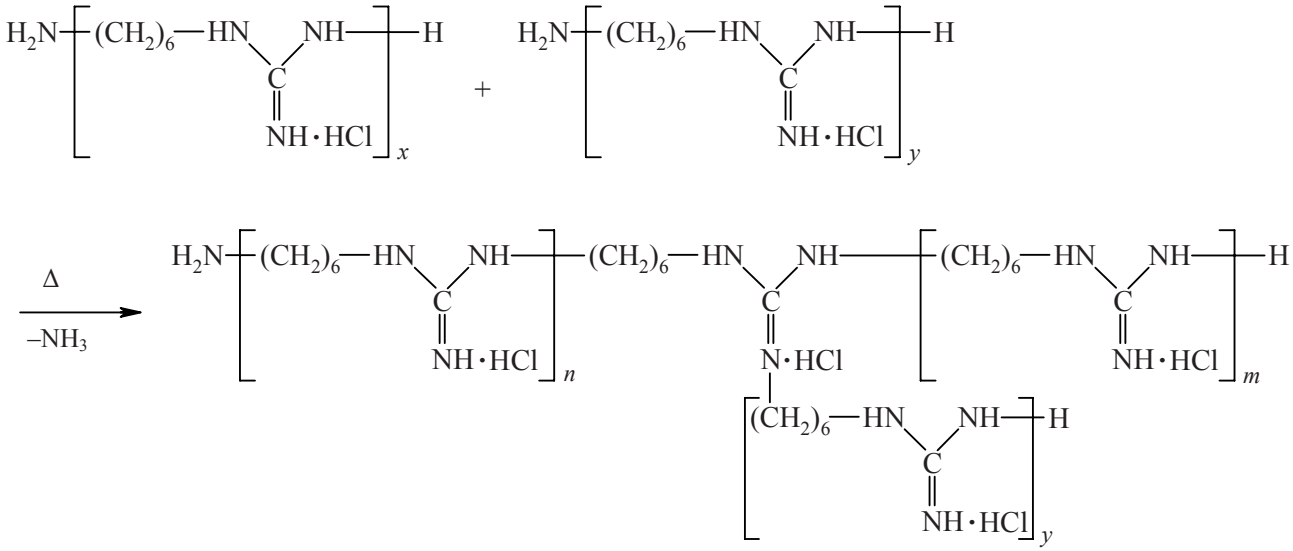

Figure 1 shows that, in 0.2 N NaCl solution, the reduced viscosity is virtually independent of the concentration; in 0.3 N NaCl solution, a positive concentration dependence is observed; and for 0.4 and 0.5 N NaCl solutions the reduced viscosities are virtually identical. In 1 N aqueous NaCl, the solution becomes turbid, which suggests precipitation of the polymer. For this reason, the solvents in our subsequent experiments were 0.3 and 0.5 N aqueous NaCl solutions, i.e., those with a minimal ionic strength at which the polyelectrolyte effect is suppressed to a sufficient extent. The viscosity was measured at concentrations within 0.5–5 g dl^{-1} for 4–6 different concentrations of the polymer in 0.3 and 0.5 N aqueous NaCl solutions. The weight-average molecular weights $\bar{M}_w$ of selected samples and selected fractions were calculated by the nonestablished equilibrium method [6] using the sedimentation data obtained in 0.3 and 0.5 N NaCl solutions on an MOM 3180 (Hungary) ultracentrifuge at a rotor temperature of 25 ± 0.1°C.

The syntheses at equimolar ratio of the reactants in argon and air at 165 ± 2°C yielded polymers with identical intrinsic viscosities, which, most likely, suggests that thermal oxidative degradation does not proceed at this temperature. The intrinsic viscosity of the polymer prepared in argon at 190°C is lower than that of the sample synthesized in air because of removal of the monomers from the argon reaction medium; for this reason, polycondensation was carried out in air. The reaction at 100°C yielded a polymer with a low intrinsic viscosity (0.029 dl g^{-1}). Therefore, we chose for our experiments the following synthesis temperatures: 165, 180, 200, and 250°C.

Formation of a linear polymer in the polycondensation reaction at the equimolar ratio of HMDA to GHC is described by the following scheme:

Since GHC is a trifunctional monomer, a branched polymer can be formed:

where $n + m + 1 = x$.

Table 1 presents the intrinsic viscosities of the linear and branched polymers, their weight-average molecular weights $\bar{M}_w$, number-average molecular weights $\bar{M}_n$, and the polydispersity index $\bar{M}_w/\bar{M}_n$. The $\bar{M}_w \times 10^{-3}$ parameters were calculated using the sedimentation data [6], and the $\bar{M}_n \times 10^{-3}$ parameters, using the mo-

lecular-weight distribution curves plotted on the basis of the results of fractionation of the polymers by the technique described in [7].

Table 1 suggests that, with increasing ratio of the amounts of bifunctional to trifunctional component (HMDA/GHC = a), the intrinsic viscosities of the samples and their molecular weights tend to increase (sample nos. 1–3), and the polydispersity index also increases. An increase in temperature for sample nos. 1, 11, and 18 synthesized at equimolar ratio of the reagents (a = 1) also causes the molecular-weight characteristics to increase, which contradicts the theory of three-dimensional polycondensation proposed by Flory [8]. In the framework of this theory, the basic characteristics of the reaction products depend on the compo-

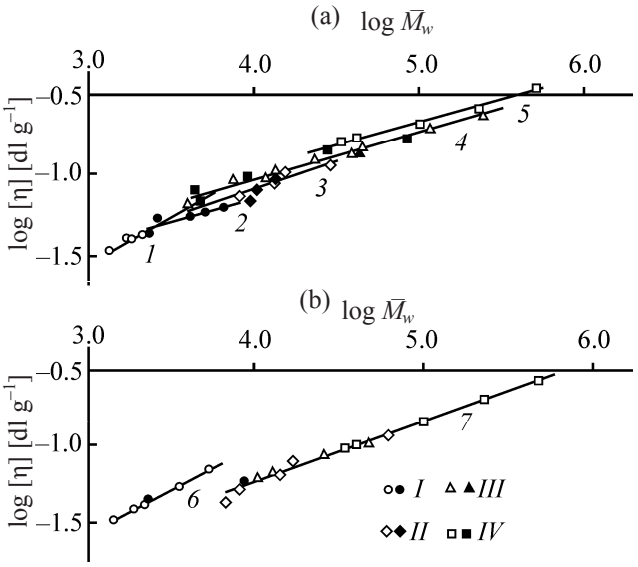

Fig 2. log–log plots for [η], vs. $\bar{M}_w$, measured in (a) 0.3 N and (b) 0.5 N aqueous NaCl solutions for the PHMG samples obtained at different temperatures and at a = 1. T, °C: (*I*) 165, (*II*) 180, (*III*) 200, and (*IV*) 250. (*1–7*) For explanations, see text.

sition only and are temperature-independent. The limiting yield of gel is also temperature-dependent. Each synthesis temperature has its corresponding limiting equilibrium amount of gel**,** which is independent of increase in the content of the bifunctional monomer. In terms of the Flory's theory, polycondensation of bi- and trifunctional monomers, taken in the stoichiometric ratio, results in 100% gelation.

The intrinsic viscosities and weight-average molecular weights of the fractions and nonfractionated polymers were used for constructing the log–log plots for the intrinsic viscosities vs. the molecular weights for two solvents, 0.3 N and 0.5 N aqueous NaCl solutions (Figs. 2a, 2b).

In Fig. 2, filled symbols correspond to the initial polymers, and hollow symbols, to the fractions of the PHMG samples. Table 2 presents the Mark–Kuhn–Houwink equation parameters corresponding to these dependences.

Figure 2 and Table 2 show that, in 0.3 N aqueous NaCl solution, the experimental points corresponding to the samples obtained at different temperatures and a = 1 fall on different straight lines (Fig. 2, straight lines *2–5*). In this solvent, the dependence of the viscosity on the molecular weight of narrow fractions tends to weaken with increasing synthesis temperature, which is typical for branched polymers. In 0.5 N NaCl, the experimental points for the PHMG samples obtained at 180, 200, and 250°C are described by a uniform dependence (Fig. 2, straight line *7*), which is not valid for the sample obtained at 165°C (Fig. 2, straight line *6*). In both solvents, the sample synthesized at 165°C (Fig. 2, straight lines *1*, *6*) exhibits an exponential dependence with the exponent lying in the range 0.5–0.8 typical for linear polymers. Thus, polycondensation of bi- and trifunctional monomers yields a linear polymer, which also contradicts the Flory theory.

Table 2. Mark–Kuhn–Houwink equation parameters for the PHMG samples, determined in aqueous NaCl solutions at four different temperatures

T, °C	a	0.3 N NaCl		0.5 N NaCl	
		$K\times10^{-3}$	α	$K\times10^{-3}$	α
165	1	0.46	0.59	0.53	0.57
180	1	2.08	0.39	1.79	0.38
200	1	4.88	0.32	1.79	0.38
250	1	8.46	0.28	1.79	0.38

CONCLUSIONS

(1) Polycondensation of hexamethylenediamine with guanidine hydrochloride in a melt at different temperatures and monomer ratios yields linear and branched polymers with different molecular weights and also cross-linked polyhexamethyleneguanidine hydrochloride samples.

(2) Polycondensation of bi- and trifunctinal monomers exhibits deviations from the Flory theory: The molecular-weight characteristics and the limiting yield of gel depend on the synthesis temperature, and the reaction gives a linear polymer.

ACKNOWLEDGMENTS

The molecular weights of the polymers were determined at the Laboratory of Physical Chemistry of Polymers, Nesmeyanov Institute of Organoelement Compounds, Russian Academy of Sciences, headed by Cand Sci. (Chem.) G.I. Timofeeva.

Abstract—The kinetics of the formation of cationic starch ethers under the action of 3-chloro-2-hydroxypropyltrimethylammonium chloride is studied in relation to the reactant molar ratio, temperature, and concentration of the starch suspension. Comparative data on how the content of the introduced catoinic groups depends on the origin of native starch are presented. The efficiency of starch cationization and the physicochemical properties of the synthesized samples are examined by chemical analysis, scanning electron microscopy, X-ray diffraction analysis, and thermal gravimetric analysis.

DOI: 10.1134/S107042720811030X

Starch derivatives containing cationic groups (amino, ammonium, sulfonium, phosphonium, etc.) in ether substituents are important commercial products widely used ad effective additives in pulp-and-paper, textile, cosmetic, and other industries. The most widely used are cationic starches with tertiary amino and quaternary ammonium groups in ether substituents [1], which have been efficiently used in the past decades in production of paper and cardboard to increase the retention of the fiber and filler, decrease dust formation, and enhance the surface and tearing strength of paper and its resistance to fracture [2].

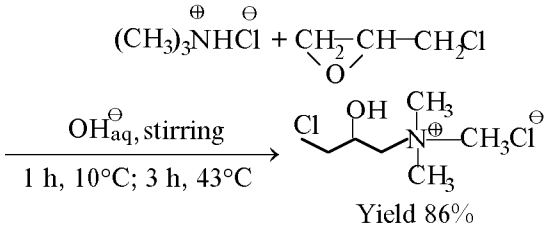
Such cationic starches can be prepared by different procedures (dry, wet, extrusion), by introducing into the starch macromolecule functional groups bearing a positive charge [3–5]. The range of reagents used for this purpose is fairly wide, and the most widely used are 3-chloro-2-hydroxypropyltrimethylammonium chloride (CHPTMAC) and 2,3-epoxypropyltrimethylammonium chloride (EPTMAC).

Cationic starch ethers are prepared by the reaction of native starch (potato, corn, waxy corn, etc.) with a cationic reagent (CHPTMAC or EPTMAC) under various conditions, following the general scheme

Wet cationization procedures involve heterogeneous reactions of starch grains in a suspension and homogeneous reactions of gelatinized starch in the paste [6]. Products of these reactions should be washed and dried before use. The main requirement to the starch intended for use in paper industry is its good retention

by fiber. Depending on the degree of substitution of starch with cationic groups and its natural base, it is retained differently. As the initial substrate for cationization it is preferable to use potato starch, as it was determined experimentally that, at a degree of substitution from 0.030 to 0.040, potato starch is retained on the fiber to more than 95%, against 60% for corn starch and 50% for native starch. Cationic starch is retained and fixes adhesive particles on the fiber only at a degree of substitution higher than 0.020.

Along with these commonly used processes, there are two more methods which can be used for preparing cationic starches. For example, in the dry procedure [5], an aqueous solution of an alkali and a cationic reagent is sprayed onto starch, and then this mixture is heat-treated. The products thus obtained can be used directly, without any additional treatment.



In the extrusion method, the reagent is added to a dry mixture of starch and NaOH in the course of extrusion [7, 8]. The reaction occurs under the conditions of high shear stresses and high temperatures (up to 170°C). Therefore, cationic starches prepared by this method, in contrast to other starches, are soluble in cold water, which largely facilitates manipulations with them in the course of paper and cardboard production. As in the dry procedure, extrusion cationic starches can be used directly, but in both processes the final product can contain salts, residual reagents, and by-products.

The physicochemical properties of cationic starches strongly depend on the production procedure, type of cationic groups, and degree of substitution. Variations in the properties of starches in relation to the botanical origin, cationic substituents introduced [9–12], or degree of substitution [13] are described in numerous papers. For example, Manelius et al. [9] and Vihervaara et al. [14] suggest that dry cationization of potato starch involves predominantly surface modification of the granules, whereas in wet cationization starch granules are also modified in the bulk. However, Hamunen [10] showed that the difference in the distribution of nitrogen from cationic groups in modified starches prepared by the dry and wet procedures was insignificant. Generally, in the dry procedure the native structure of starch granules strongly affects the process, in contrast to the wet procedure. In turn, the degree of crystallinity of starch was lower after dry cationization [9], but did not change noticeably after wet cationization [12, 13] compared to the crystallinity of native starch grains. Introduction of cationic groups into the structure of the polysaccharide leads to a decrease in the temperature and enthalpy of paste formation from starch granules [9, 12, 13] but increases their dispersibility and swelling [11].

In this study we examined the effect of various factors (reactant molar ratio, temperature, starch concentration in suspension, reaction time, origin of native starch) on synthesis and properties of cationic starch ethers, with 60 wt % aqueous solution of 3-chloro-2-hydroxypropyltrimethylammonium chloride synthesized by the specialy developed procedure used as cationic reagent.

EXPERIMENTAL

As investigation objects we used potato starch [GOST (State Standard) 7699–78; content, %: amylose 23.8, P 0.08, N 0.044, ash residue 0.31, moisture 12.0] and also, for comparison, corn, waxy corn, and wheat starches. All the chemicals used in this study were of chemically pure or analytically pure grade. The cationic reagent was prepared by the scheme

Yield 86%

Alkylation of starch with the cationic reagent. A 500-ml round-bottomed flask equipped with a power-driven stirrer, a dropping funnel, and a thermometer and placed on a water bath was charged with 81.0 g (0.50 mol) of starch, 200 ml of distilled water, and 25 g of NaCl (to prevent starch gelatinization in the course of the reaction). The resulting suspension was stirred at room temperature, and the required amount of a 10% aqueous NaOH solution was slowly added from a dropping funnel. In so doing, the water bath temperature was raised to the required level with continuous stirring. After that, a calculated amount of the cationic reagent was slowly added. In the course of the reaction, at definite intervals, ~10-ml samples of the suspension were withdrawn and transferred into a beaker with 200 ml of distilled water preliminarily acidified with 0.2 ml of 25% HCl. Then the precipitate of cationic starch was separated by decantation and washed on the filter with a water–isopropanol mixture (1 : 1) until the qualitative reaction for Cl^- in wash waters became negative. After that, the precipitate was washed with an additional 50-ml portion of isopropanol and dried in an oven at 50°C. The cationic starch prepared is sized in hot water. We determined by the

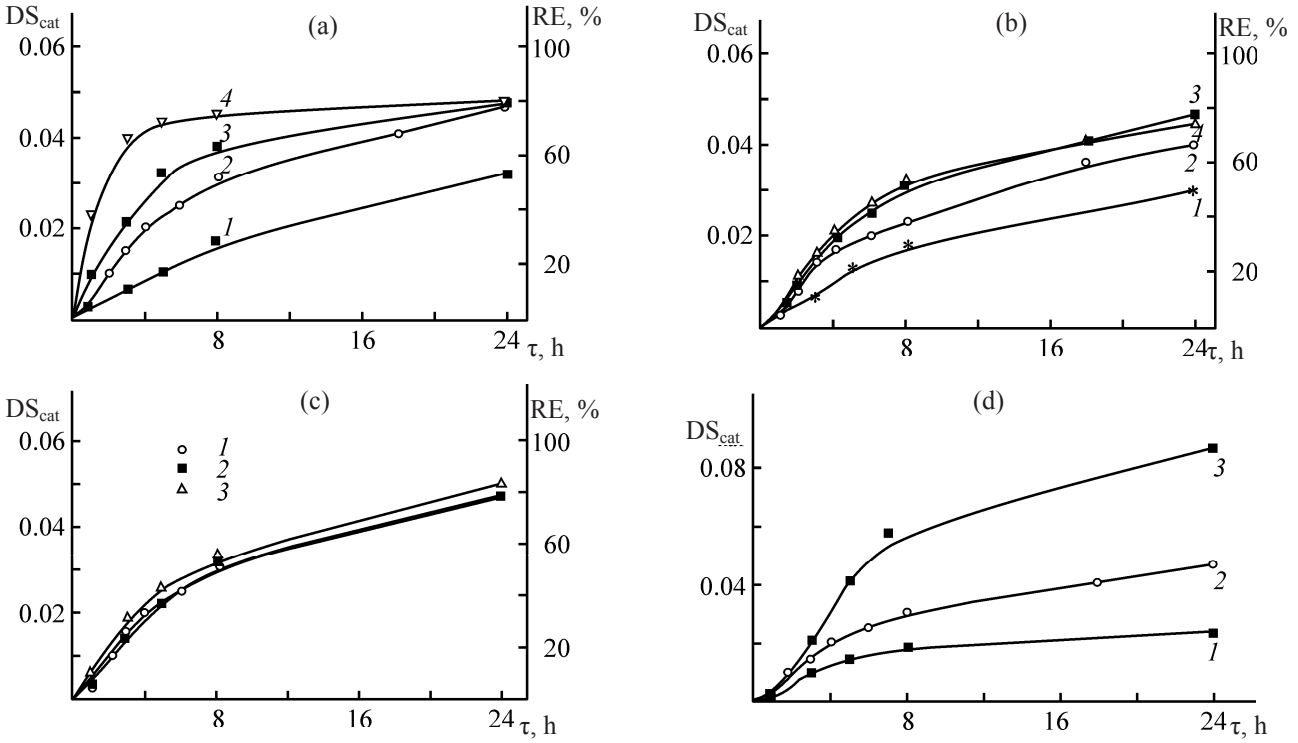


Fig. 1. Kinetic curves of cationization of potato starch. (DS_{cat}) Degree of substitution with cationic groups, (RE) reaction efficiency, and (τ) time. (a) Concentration of aqueous starch suspension 33%; molar ratios NaOH/CHPTMAC = 2.8, CHPTMAC/AGU = 0.06; temperature of reaction medium, °C: (*1*) 25, (*2*) 35, (*3*) 45, and (*4*) 55. (b) Concentration of aqueous starch suspension 33%; 35°C; molar ratio CHPTMAC/AGU = 0.06; molar ratio NaOH/CHPTMAC: (*1*) 1.6, (*2*) 2.2, (*3*) 2.8, and (*4*) 3.3. (c) 35°C: molar ratios NaOH/CHPTMAC = 2.8, CHPTMAC/AGU = 0.06; concentration of aqueous starch suspensoin, %: (*1*) 24, (*2*) 33, and (*3*) 42. (d) 35°C; concentration of aqueous starch suspension 33%; molar ratio NaOH/CHPTMAC = 2.8; molar ratio CHPTMAC/AGU: (*1*) 0.03, (*2*) 0.06, and (*3*) 0.12.

Kjeldahl method the nitrogen content N (%), and from the gain in the nitrogen content after cationization we calculated the degree of substitution DS_{cat} and the reaction efficiency RE_{cat} by the formulas

$$DS_{cat} = 162.1N_{cat}/(1401 - 151.6N_{cat}),$$

$$RE = (DS_{cat}/DS_{theor}) \times 100\%,$$

where $N_{cat} = N - N_{init}$; $DS_{theor} = n_{CHPTMAC}/n_{AGU}$; N_{cat} is the content of nitrogen introduced into starch with cationic groups (%); N, nitrogen content in cationic starch (%); N_{init}, nitrogen content in native starch (%); DS_{theor}, theoretical degree of substitution with cationic groups (2-hydroxypropyltrimethylammonium chloride groups); $n_{CHPTMAC}$, amount of CHPTMAC in the modifying agent added in the course of the reaction (mol); AGU, anhydroglucopyranose unit; and n_{AGU}, amount of starch taken for cationization (mol AGU).

The diffraction patterns were recorded with an HZG-4A X-ray diffractometer (Carl Zeiss, Jena, Germany), CuK_α radiation, Ni filter, point-by-point recording. The samples were prepared by cold pressing of the polymer in the form of monolithic round pellets 2 mm thick and 18 mm in diameter. The morphology of structural elements constituting particles of native potato starch and of the prepared samples of cationic starch was examined with an LEO 1420 scanning electron microscope (Germany). Thermal decomposition of the samples was studied on an STA 449C synchronous thermal analyzer (Netzsch, Germany) in a dynamic nitrogen atmosphere at a nitrogen feed rate of 22 cm^3 min^{-1}; heating rate 5 deg min^{-1}, sample weight 50 mg; freshly calcined aluminum oxide was used as reference.

RESULTS AND DISCUSSION

The performance of the cationic reagent was estimated by studying the kinetics of the preparation of cationic ethers of potato starch using the synthesized reagent in the temperature range 25–55°C at various molar ratios of the components and various solid-to-liquid ratios. It can be seen (Fig. 1a) that the rate of

alkylation of potato starch with 3-chloro-2-hydroxypropyltrimethylammonium chloride (main active substance in the cationic reagent) regularly increases with temperature. However, at $T > 45°C$, despite the presence of NaCl, cationization of starch leads to its gelatinization in alkaline solution, which severely complicates isolation of the final product and its washing to remove salts.

It should be noted (Fig. 1b) that, at the NaOH : CHPTMAC molar ratio in the range 2.2–3.3, the reaction rate in the initial period is essentially the same. It can also be seen that the highest rate and the highest degree of starch cationization are attained already at the NaOH/CHPTMAC molar ratio of 2.8. Hence, further increase in the amount of alkali is not appropriate. In turn, the deficiency of NaOH in the reaction mixture does not allow the desired results to be attained, even in a prolonged reaction.

We found that preparation of cationic ethers depends on the starch suspension concentration insignificantly. When this parameter was varied in the range 24–42%, at a constant stirring rate, we found no significant differences in the reaction rate and maximal degree of substitution with cationic groups (Fig. 1c).

As can be seen (Figs. 1a–1c), it is quite appropriate to use the synthesized modifying agent for preparing cationic starches, because its use allows attainment of high reaction efficiency (RE = 70–80%) which, in turn, shows that the major fraction of CHPTMAC is spent for binding with starch rather than for formation of by-products.

A strong influence on both the reaction rate and the limiting degree of substitution is exerted by the CHPTMAC/AGU molar ratio (Fig. 1d). As this ratio is increased, with the solution volume remaining constant, the CHPTMAC concentration in the solution increases. As a result, the starch alkylation rate increases. An increase in the CHPTMAC/AGU molar ratio also leads to a proportional increase in the limiting content of cationic groups in the polysaccharide.

Preliminary studies showed that introduction of a quaternary ammonium group into the anhydroglucopyranose unit of starch decreases the temperature of paste formation. Solutions prepared from modified starch are stable even at low pH values and are not prone to retrogradation, which is important for their further practical use.

Alkylation of starch with 3-chloro-2-hydroxypropyltrimethylammonium chloride in an alkaline solution

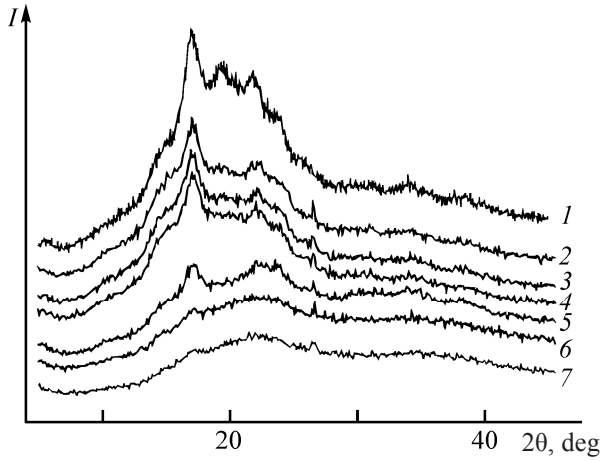

Fig. 2. Diffraction patterns of (*1*) native potato starch and (*2–7*) cationic potato starch samples differing in the cationic group content and preparation temperature. (*I*) Relative intensity and (2θ) Bragg angle. *T*, °C: (*2–5*) 35, (*6*) 45, and (*7*) 55.

can involve significant changes in the supramolecular structure of the polysaccharide, depending primarily on the process temperature. For example, the diffraction patterns shown in Fig. 2 (curves *6*, *7*) indicate that the degree of crystallinity of starch after its cationization at temperatures leading to gelatinization of starch in the reaction mixture considerably decreases, and the extent of these changes is the greater, the higher the reaction temperature. It can be seen that the main reflections characteristic of native potato starch (2θ 17.0°, 19.5°, and 22.1°) are virtually lacking in the patterns of cationic starch (Fig. 3, curves *6*, *7*) prepared at $T \geq 45°C$. As under such conditions of starch modification not only amorphous but also crystalline regions of the structure are involved in the process, the introduced 2-hydroxypropyltrimethylammonium chloride groups are, apparently, distributed fairly uniformly.

The diffraction patterns of cationic starch samples with different degrees of substitution (Fig. 2, curves *2–5*), prepared at 35°C, are characterized by the lack of the reflection at 2θ = 19.5° and the presence of well-defined peaks at about 17.0° and 22.1°. However, calculation of the relative degree of crystallinity (DC) of these cationic starches shows that DC for sample nos. 2 and 3 is higher, and for sample nos. 4 and 5, lower than that of the native starch (Table 1). Such character of changes in the degree of crystallinity of modified starch samples may be due to the fact that, in washing with a water–isopropanol mixture, the more soluble (amorphous) fraction of the modified polysaccharide remains in the filtrate. Therefore, the fraction of crystalline regions in the isolated and studied cationic

Table 1. Degrees of crystallinity (DC) of the examined samples

Sample no.	Starch sample	DC, %
1	Native potato	33.2
2	Cationic (DS_{cat} = 0.0041)	39.5
3	Cationic (DS_{cat} = 0.021)	36.5
4	Cationic (DS_{cat} = 0.047)	32.4
5	Cationic (DS_{cat} = 0.035)	28.0
6	Cationic (DS_{cat} = 0.061)	X-ray amorphous
7	Cationic (DS_{cat} = 0.045)	″

starch sometimes increases, which leads to a certain increase in DC. Also, as seen from the data obtained, by varying the cationization temperature it is possible to prepare cationic starch samples with a close content of 2-hydroxypropyltrimethyammonium chloride groups but with different degreese of crystallinity (Fig. 2, curves *4*, *7*), which can ultimately lead to differences in the physicochemical properties. The numerical values of the relative degree of crystallinity of the samples studied are given in Table 1.

As seen from Fig. 3a, granules of native potato starch are very nonuniform in the size and shape. Among them are both very small granules (d < 5 μm) of predominantly round shape and very large granules (d > 60 μm) of oval shape. The breaking effect of NaOH whose ions under definite conditions can induce the gelatinization of starch in solution is well consistent with the observed changes in the morphological structure of starch granules (Fig. 3): With an increase in the synthesis temperature, starch granules undergo more and more pronounced changes. Cavities, fractures, and folds appear in starch granules, and all these changes are enhanced with increasing temperature. For example, at 35°C, when starch cationization throughout the reaction occurs in a suspension (without gelatinization), granules of cationic starch insignificantly differ from the initial granules in the shape and size: only small cavities and surface defects are observed (Figs. 3a, 3b). At $T \geq 45$°C, in the alkaline solution, the reaction occurs under the conditions of starch gelatinization when the granules strongly swell and are destroyed. As a result, in the electron micrographs of cationic starch more significant granule defects are observed (Fig. 3c, 3d): large cavities and even through holes, as well as fine fragments of granules.

Nonisothermal thermogravimetric (TG) curves of native potato starch and three samples of cationic potato starch are shown in Fig. 4. As can be seen, introduction into starch macromolecule of 2-hydroxypropyltrimethylammonium chloride groups exerts a signifi-

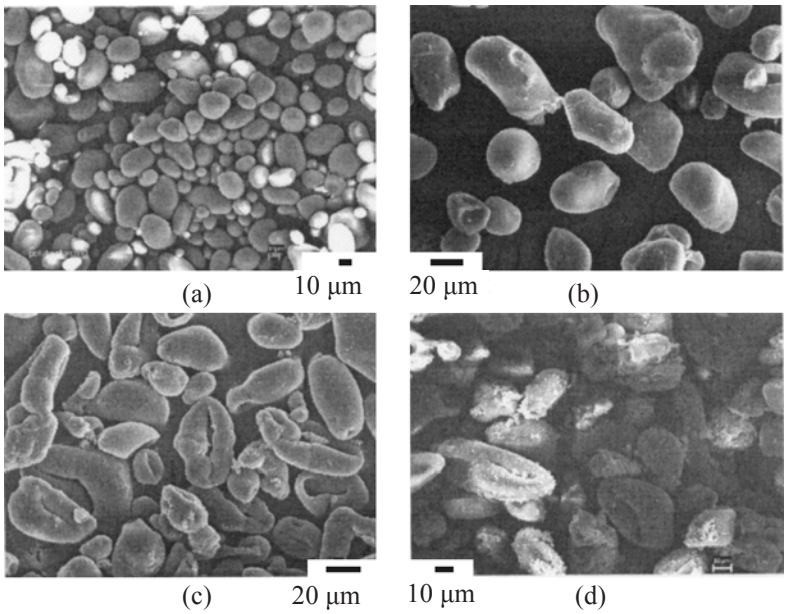

Fig. 3. Scanning electron micrographs of granules of (a) native potato starch and (b–d) cationic potato starch samples prepared at (b) 35, (c) 45, and (d) 55°C.

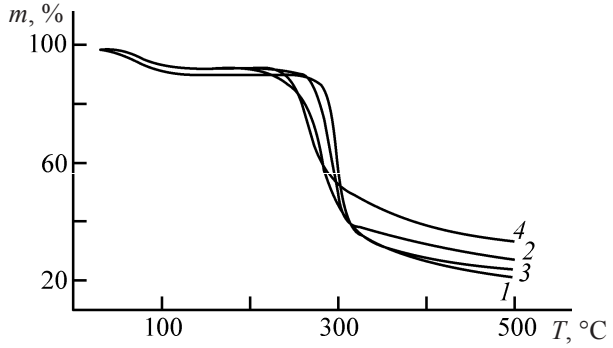

Fig. 4. TG curves of (*1*) native potato starch and (*2–4*) cationic potato starch samples prepared at various temperatures. (*m*) Sample weight and (*T*) temperature. Preparation temperature, °C: (*2*) 35 (DS_{cat} = 0.035), (*3*) 45 (DS_{cat} = 0.061), and (*4*) 55 (DS_{cat} = 0.045).

cant effect on the thermal characteristics of starch, mainly on the onset temperature and mechanism of its degradation. All the examined samples lose weight in two steps: The first step (T = 70–100°C) involves removal) of adsorbed moisture, and the second step (T = 220–287°C) involves degradation proper, with carbonization. Carbonization of all the samples of cationic starch starts at lower temperatures (Table 2) compared to native starch. As seen from Table 2, for all the cationic starches the weighed of the carbonized residue at 500°C is higher compared to the native starch, and with an increase in the content of cationic groups the carbonization temperature decreases. At the same time, the temperature at which the samples lose 50% of their weight is independent of the degree of substitution of cationic starch. Table 3 shows that the use for cationization of starches isolated from different sources allows preparation of cationic starch ethers with close degrees of substitution, i.e., the origin of native starch, other conditions being the same, affects the content of cationic groups insignificantly. The observed insignificant differences in DS_{cat} are apparently associated with differences in the molecular weight and amylose content of the initial starches.

Table 2. Quantitative characteristics of thermal degradation of starch samples[a]

Waxy corn	0.032
Wheat	0.028

CONCLUSIONS

(1) The use of the synthesized modifying agent, 3-chloro-2-hydroxypropyltrimethylammonium chloride, allows efficient cationization of various starches.

(2) The examined conditions of starch alkylation ensure preparation of cationic starches with the preset degree of substitution (DS_{cat} = 0.01–0.06) and high reaction efficiency (RE = 80%).

(3) The structure and properties of cationic starch strongly depend on the temperature conditions of the modification of native starch.

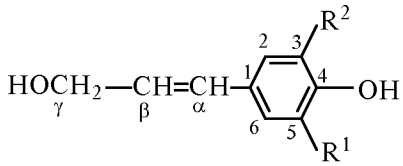
Abstract—The hydrodynamic and conformational properties of the macromolecules of lignins derived from *Secale sp.* rye straw and *Hordeum sp.* barley straw were examined in dimethylformamide solutions. The molecular weights, centrifugal sedimentation coefficients, translational diffusion coefficients, and intrinsic viscosities of the polymers were determined. The fractal dimensions and Mark–Kuhn–Houwink scaling indices were calculated.

DOI: 10.1134/S1070427208110311



Lignins are biopolymers widely occurring in plants. As a polymer, lignin substantially differs from other macromolecular compounds, both natural and synthetic [1]. A unique feature of lignins is that their macromolecules consist of a multitude of variable microstructural units [2], which is responsible for their highly diversified topological structure. We showed earlier [3, 4] that softwood deciduous (birch, aspen) lignins can be classed with regularly branched star-shaped polymers, and the macromolecules of coniferous species (pine, larch) have a configuration corresponding to the topology of randomly branched polymers. Herbaceous lignins distinguished by extremely high species diversity received insufficient research effort, and their topological structure still remains to be elucidated.

Research activities dedicated to lignins, in particular, those of annual cereals, are urgent in view of the importance of these polymers in chemical processing of plant biomass. Specifically, the choice of technology for preparation of cellulose and other chemical products from non-woody plant materials is dictated, above all, by the structural organization and physicochemical properties of lignins.

EXPERIMENTAL

The initial plant materials were *Secale sp.* rye straw and *Hordeum sp.* barley straw (Komi Republic). Component composition of the rye straw, %: lignin 20.5, cellulose 49.0, easily hydrolyzable polysaccharides 17.4, ash 2.6. Component composition of barley straw, %: lignin 22.2, cellulose 41.3, easily hydrolyzable polysaccharides 19.5, ash 2.5. Lignin samples prepared from rye (RSL) and barley straw (BSL) were isolated by 2-h treatment with aqueous dioxane in the presence of HCl (0.7%) at the boiling temperature. The respective yields of RSL and BSL are 19 and 22% of the lignin content in the initial material (as determined by Komarov's method). Elemental composition [Hewlett–Packard analyzer (USA)]: RSL, C 58.7, H 5.5, O 35.8%; BSL, C 60.5, H 5.6, O 33.9 %. Content of methoxy groups, %: RSL 15.8, BSL 15.7. Averaged empirical formula (C_9 formula) of the monomer unit in the samples: RSL $C_9H_{10.3}O_{3.6}(OCH_3)_{1.05}$, BSL $C_9H_{10.0}O_{3.2}(OCH_3)_{1.01}$. Major absorption bands in the IR absorption spectra (Specord M-80), cm^{-1}: 3440, 1720, 1610, 1520, 1470, 1430, 1365, 1335, 1270, 1130, 1035, 840.

The macromolecules of both lignins are composed of phenylpropanoid units (PPUs) of three basic types: guaiacyl (G), syringyl (S) and *p*-coumaryl (H), linked to one another by various types of intermonomer bonds (β-O-4, α-O-4, γ-O-α, β-β, 5-5, β-5):

where R^1 = H, R^2 = H is *p*-coumaryl alcohol (H-unit); R^1 = H, R^2 = OCH_3, coniferyl alcohol (G-unit); and R^1 = OCH_3, R^2 = OCH_3, sinapyl alcohol (S-unit).

Chemical shifts of the characteristic resonance signals in the carbon spectra (^{13}C NMR, Bruker AM-300 spectrometer), ppm: G-PPE, 119.1 (C^6); S-PPE, 152.1–152.4 (C^3, C^6); H-PPE 131.4–131.5 (C^2, C^6), 160.1 (C^4).

The lignins were subjected to fractional precipitation in dioxane–benzene system. The unaccounted loss in fractionation was no larger than 5–7 %. Each fraction, as well as the nonfractionated sample, was examined by the molecular hydrodynamics method with DMF as solvent. The measurements were carried out at 298 K; η_0 0.78×10^{-2} Pa, ρ_0 0.9473 g cm^{-3}. The $\Delta n/\Delta c$ parameters for the BSL and RSL samples in DMF were estimated at 0.14–0.02.

The diffusion coefficients *D* were determined on an MOM-3180 analytical ultracentrifuge. We used the dependence of the dispersion of the concentration boundary in a two-sector polyamide cell in which an artificial boundary was formed (insert height in the beam propagation direction 12 mm). The solution–solvent boundary was recorded using standard Philpot–Svensson optical unit at the phase-contrast plate angle of 30°, rotor rotation rate of 5×10^3 rpm, and temperature of 298 K. The dispersion was calculated by the standard maximal ordinate and area method using the equation $\Delta^2 = 0.5(S/H_{max})^2\pi^{-1} = 2Dt$. The corresponding diffusion coefficients were calculated by the formula $D = (S/H_{max})^2/4\pi t$, where *S* and H_{max} are the area and the maximal ordinate of the diffusion profile, respectively. The concentration of the solutions was ca. 3×10^{-3} g cm^{-3}. We neglected the concentration dependence of the coefficients *D* in view of the dilution criterion $c[\eta] \le 1$.

The centrifugal sedimentation coefficients *S* were measured on an MOM-3180 ultracentrifuge in a two-sector polyamide cell in which an artificial boundary was formed at 48 000 rpm. The insert height was 12 mm, experiment time 50 min, and temperature 298 K. The measurements were carried out at one concentration of solutions, 3×10^{-3} g cm^{-3}. We neglected the concentration dependence of the sedimentation coefficient in view of the Debye criterion $c[\eta] \le 1$. The sedimentation coefficients were calculated by the formula

$$S = (\Delta \ln x/\Delta t)\omega,$$

where $\omega = 2\pi n$, ω is the angular rotation rate, rad s^{-1}, of rotor; *n*, centrifuge rotor rotation rate (rpm); and *x*, coordinate of the sedimentation boundary maximum.

The viscosity of the solutions was measured by the classical method in an Ostwald capillary viscometer with the solvent outflow time of 52.0 s at 298 K. The concentration of the solutions was varied within 0.02–0.08 g cm^{-3}, for which range the $c[\eta] \le 1$ and $\eta_{rel} > 1.1$ inequalities are valid. The intrinsic viscosity $[\eta]$ was calculated by the standard technique using the Huggins equation, corrected for the density of the solutions: $[\eta] = [\eta]_{meas}/\rho_0$, as substantiated by Pavlov et al. [5]. The relative error in determination of $[\eta]$ is ca. 1%.

The hydrodynamic examination of dilute solutions of lignins allows determination of the macromolecular characteristics, in particular, the molecule size, molecular weight (MW), scaling parameters, and fractal dimensions. By analogy to chemical criteria taken for lignin, Karmanov [6] introduced the macromolecular criteria according to which the basic characteristics of woody lignins as polymers include: (1) compactness of the macromolecules, responsible for their high diffusion mobility in solutions; (2) abnormally low intrinsic viscosity under normal conditions, which tends to further decrease under heating of solutions (negative temperature coefficient for $[\eta]$); (3) variability of the hydrodynamic invariants, depending on the nature and background of lignins; (4) high values and complex (random) pattern of variation of the Huggins coefficients with MW; and (5) ranking of fractal and other scaling parameters of lignins depending on the botanical origin of the plant species.

Our experimental results suggest that these criteria are also valid for nonwoody lignins of cereals, rye and barley.

The quantity M_{SD} was calculated using the experimental data for each of the lignin fractions analyzed:

$$M_{SD} = S_0RT(1 - \bar{v}\rho_0)D_0,$$

where $(1 - \bar{v}\rho_0)$ is the Archimedes buoyancy factor for the polymer–solvent system, which was estimated pycnometrically at 0.3380 and 0.3315 for RSL–DMF and BSL–DMF systems, respectively.

By contrast to high-molecular-weight fractions, for which the MW was determined with the use of Svedberg relationship, for low-molecular-weight fractions we used the equation

$$M_{D\eta} = A_0^3([D]^3[\eta])^{-1},$$

where $[D] = \eta_0 D_0/T$, and A_0 is hydrodynamic invariant estimated from the data obtained in examination of the

high-molecular-weight fractions by sedimentation–diffusion analysis, $A_0 = (R[S][D]^2[\eta])^{1/3}$, $[S] = S\eta_0/(1 - \bar{\nu}\rho_0)$.

Table 1 lists the molecular weights and hydrodynamic parameters for the fractions. The molecular weight of the fractions of the examined lignins varies within $(7–25) \times 10^3$. Published data [3–6] suggest that, for dioxane lignins, the typical scaling region is $(3–5) \times 10^3$ to 30×10^3. The upper limiting value of the molecular weight is associated with the specific conditions of lignin biosynthesis in cellular shells of the plants. The low-molecular-weight fractions [MW lower than $\sim(3–5) \times 10^3$] usually are not used for conformational analysis, since a decrease in the molecular weight down to the indicated values is accompanied by escape from the scaling region, more correctly, by changing to the area where there can exist other scaling parameters. The reason is a finite value of the thermodynamic flexibility of real macromolecules.

It should be emphasized that the size and MW of the molecules of lignins derived from annual cereals RSL and BSL are comparable with those of lignins from perennial, in particular, woody plants. The macromolecules of all lignins (at least, those we examined) have fairly small hydrodynamic dimensions in any solvent known for lignin. In dilute solutions they are distinguished by small values of the translational friction coefficients, which is responsible for high values of the experimentally determined diffusion coefficients. As shown by analysis of the hydrodynamic data, the examined lignins are characterized by fairly high density of the macromolecular coils, measurable with the so-called globularity. For the RSL and BSL samples, the globularity was estimated at 20% and over, whereas

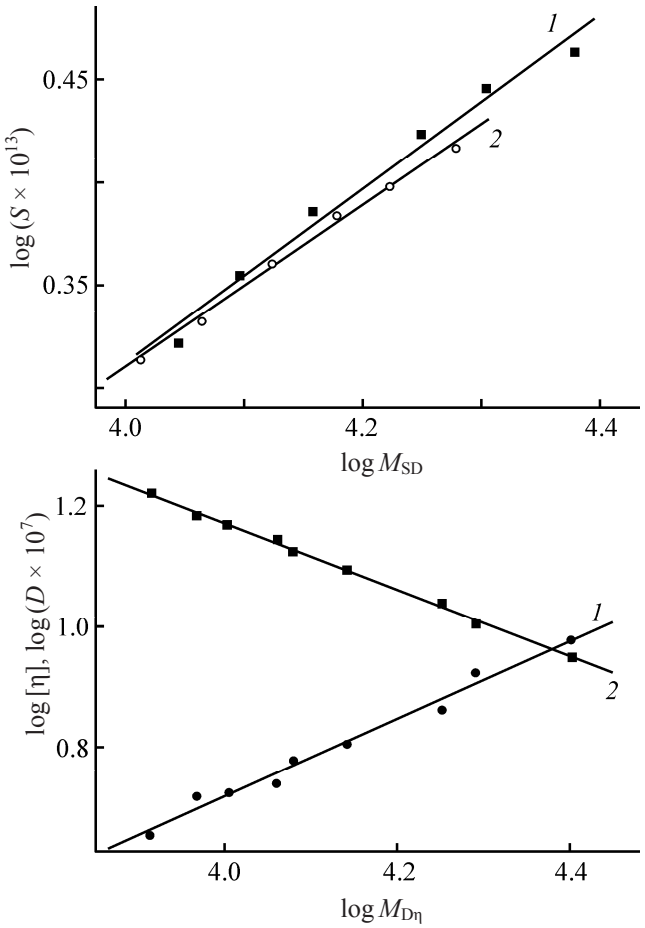

Fig. 1. Sedimentation coefficient S vs. M_{SD}, translational diffusion coefficient D vs. $M_{D\eta}$, and intrinsic viscosity [η] vs. $M_{D\eta}$ for (*1*) RSL and (*2*) BSL samples. Solvent DMF.

for typical linear flexible-chain polymers it is usually less than 10%. Another measure of compactness of the macromolecules can be found in the coefficient $q = 0.4[\eta_0]/\overline{\nu}$ [7]. The calculated q values for the RSL and BSL samples are 4.2 ± 1.5 and 3.8 ± 1.5, respectively. Synthetic linear polymers are characterized by much higher q values.

The validity of the scaling principle in the case of interest suggests the topological uniformity of the polymers, both synthetic and natural. The fact that the plots constructed in the coordinates of the Mark–Kuhn–Houwink (M–K–H) equation for lignin–DMF system are linear (Fig. 1) suggests the molecular-weight scaling of the hydrodynamic parameters for the RSL and BSL samples, which implies scale invariance of the macromolecules. The dependences for S, D, and [η] on M_{SD} can be approximated by power law equations of the M–K–H type:

$$[\eta] = K_\eta M^a,\ S = K_S M^c,\ D = K_D M^b.$$

Table 2 lists the values of scaling M–K–H indices and their corresponding K_D, K_S, K_η coefficients. In connection with analysis of the scaling indices we will note that the $|b| = (a + 1)/3 = 1 - c$ relationship is valid, which suggests that our calculations are correct and that hydrodynamic dimensions estimated from the rotational and translational friction effects reasonably agree. The values of the M–K–H parameters for RSL and BSL correspond to those of linear polymers in the conformation of a swollen nonpercolating coil**.** It should also be mentioned that these indices decrease in the following order: $a > |b| > c$, which corresponds to the trend in variation of the sensitivity of the corresponding hydrodynamic parameters to the change in the MW, typical for linear polymers.

Comparison of the values of scaling indices, in particular, of parameter a, for lignins of different origins is of interest. Certainly, it cannot but depend on the thermodynamic quality of the solvent. However, most of studies concerned with the hydrodynamic properties of lignins were carried out for systems with thermodynamically good solvents, DMF or DMSO. Karmanov [6] estimated this parameter at 0.15–0.30 and 0.5–0.65 for coniferous and deciduous lignins, respectively; for herbaceous lignins $a \geq 0.7$. For the herbaceous lignins that we examined, the index a was estimated at 0.71 ± 0.04 and 0.72 ± 0.03 for the RSL and BSL samples, respectively.

Various polymers can be characterized and compared with one another using the Tsvetkov–Klenin parameter A_0 [8], which is an invariant reflecting the probability of self-similar behavior for fractions with different molecular weights both in good solvents and θ-solvents. The differences in the A_0 values can depend

Table 2. Conformational parameters of RSL and BSL lignins

Lignin	a	c	b	K_η, cm^3 g^{-1}	K_S, s	K_D, cm^2 s^{-1}	K_θ, cm^3 g^{-1}	d_f
RSL	0.71 ± 0.04	0.42 ± 0.03	–0.58 ± 0.03	7.6×10^{-3}	4.4×10^{-15}	3.2×10^{-4}	0.25×10^{-1}	1.76/1.72
BSL	0.72 ± 0.03	0.37 ± 0.02	–0.63 ± 0.02	7.2×10^{-3}	6.6×10^{-15}	4.9×10^{-4}	0.35×10^{-1}	1.77/1.64

on the thermodynamic flexibility of the chain and, probably, should be governed by the specific features of the topological structure (all other conditions being the same). For RSL and BSL samples, this parameter was estimated at $(3.1–3.2) \times 10^{-10}$ erg K^{-1} $mol^{-1/3}$, which coincides with the available published data for A_0 in synthetic linear polymers with flexible chains. Rigid-chain polymers are characterized by higher average values of the Tsvetkov–Klenin invariant, $(3.6 \pm 0.4) \times 10^{-10}$ erg K^{-1} $mol^{-1/3}$.

By contrast to typical polymers, for lignins the invariant A_0 varies with the lignin type. The available data suggest that the parameter A_0 takes the smallest value of $\sim 2.7 \times 10^{-10}$ erg K^{-1} $mol^{-1/3}$ in the case of guaiacyl–syringyl lignin (deciduous woody species); for guaiacyl (coniferous) lignins $A_0 = (2.9–3.0) \times 10^{-10}$, and for lignins of annual plants, $A_0 \sim 3.2 \times 10^{-10}$ erg K^{-1} $mol^{-1/3}$.

A characteristic feature of lignin–solvent polymeric systems is that the Huggins coefficient k_H for them takes fairly high values, irrespective of the nature of lignin, the extraction method, and the chosen solvent. In the low-molecular-weight region, k_H randomly varies in changing from one fraction to another, typically within 1–5. Table 1 suggests that, for the BSL–DMF system, the Huggins coefficient varies within a narrow range 0.74–1.53, which, however, lies well beyond the measurement error; it is impossible to reveal any trend in variation of k_H with the MW. For the LSR–DMF system, k_H varies within 1–1.25. Of principal importance are the fractal dimensions for individual fractions of lignins, determined by the method proposed by Kozlov et al. [9], which relies on the Huggins coefficient values. Table 1 suggests that the fractal dimensions of all the fractions are virtually identical (1.76 ± 0.05) and coincide with the d_f parameter calculated with the use of the M–K–H scaling indices (Table 2). At the same time, the k_H values for fraction nos. 1 and 8 differ more than twofold. This suggests that, in the case of interest, the Huggins coefficients were reliably estimated, although it is known that the k_H values for linear polymers in good solvents typically do not exceed 0.2–0.3.

This casts doubts on the validity of a simple linear structure of the RSL and BSL lignin macromolecules, as suggested by analysis of the M–K–H scaling indices and fractal dimension d_f (Table 1). In this context, estimation of the so-called *g*-factor can be attempted. For natural polymers with complex topological and chemical structures, for which it is difficult or impossible to find a linear analog of the polymer examined, a calculation procedure was developed for estimating the *g*-factor, including the calculation of the intrinsic viscosity of a hypothetical linear macromolecule in terms of the Stockmayer–Fixman equation. By this method, the viscosity of a linear chain can be calculated by the equation

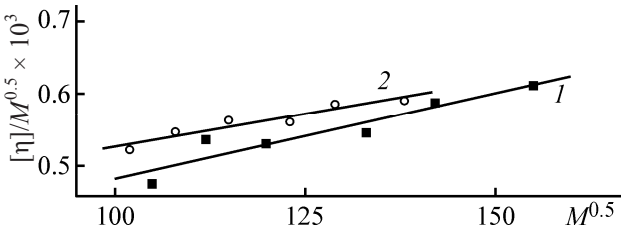

Fig. 2. Stockmayer–Fixman plot for (*1*) RSL and (*2*) BSL samples in DMF.

$$[\eta]_{lin} = K_\theta M^a,$$

where K_θ is a parameter estimated by extrapolation of the experimental data plotted in the $[\eta]/M^{0.5}$ vs. $M^{0.5}$ coordinates, and a, experimentally established M–K–H viscometric index in the solvent used.

The $[\eta]_{exp}/[\eta]_{lin}$ ratio, commonly called the g_η-factor, gives an idea of the average number of the branching sites per macromolecule. For any type of branched polymers, the g_η-factor is less than unity, and its dependence on the MW is determined by that of the number of the branching sites on MW. As shown earlier [10], with increasing MW of the fractions of randomly branched polymers the *g*-factor tends to decrease according to a certain law (provided that the configuration parameters remain unchanged), which is associated with an increase in the number of branching sites per macromolecule. For coniferous lignins, specifically this law is valid [11]. For the guaiacyl–syringyl lignins, derived from birch, aspen, white acacia, and apple-tree wood, $[\eta]_{exp}/[\eta]_{lin}$ = const; specifically, this ratio was estimated at 0.7–0.8. This allowed a presumption that the macromolecules of the abovementioned lignins are compact star-shaped structures whose hydrodynamic behavior is governed by the linear topology of the branches, no larger than 4 in number [12].

Figure 2 presents the experimental data for the examined samples, plotted in the Stockmayer–Fixman equation coordinates, which suggest $K_\theta^{RSL} = 0.25 \times 10^{-1}$ and $K_\theta^{BSL} = 0.35 \times 10^{-1}$ cm^3 g^{-1}. Using the K_θ values obtained, as well as the values of scaling index a and the molecular weight of the fractions, we determined the $[\eta]_{lin}$ values and further the desired *g*-factor values.

The calculations showed that the *g*-factors for the BSR fractions are virtually identical, 0.26; for the RSL sample the *g*-factor slightly increases with increasing MW, from 0.28 to 0.32. Our data, first, can serve as an argument in favor of branching of the RSL and BSL macromolecules, since otherwise the *g*-factor would be equal to unity; second, they allow the random (chaotic) nature of branching of the macromolecules to be unequivocally rejected, since in that case the g_η-factor should asymptotically decrease. Also, it is impossible to attribute the RSL and BSL macromolecules to comb-shaped or ladder regularly branched polymers. Based on the elimination method, we can choose the dendrimeric or star-shaped topology of the macromolecules. Indeed, certain hydrodynamic properties of dendrimers resemble those of lignins, in particular, a fairly low viscosity and the observed values of the Huggins coefficient, but the actual values of the scaling indices (Table 2) make us to reject this presumption.

As a working hypothesis we also can take a star-shaped structure of the RSL and BSL macromolecules. Actually, a number of features characteristic for star-shaped topology can be observed in our case [13], namely, the Mark–Kuhn–Houwink scaling indices typical both for linear and star-shaped polymers and compactness of the macromolecules, probably associated with the occurrence of the branching sites. It should be noted that, for single-center star-shaped macromolecules, the *g*-factor does not decrease with increasing MW and, on the contrary, should tend to increase, since the number of the branching sites remains unchanged and the degree of branching tends to decrease. If the MW of the fractions varies within a narrow range, we can expect for the *g*-factor either invariance or a weak tendency for increase, as is the case. Nevertheless, it would be premature to draw final conclusions. The analysis of the hydrodynamic behavior of real star-shaped polymers and model stars allows, as shown by Lavrenko and Vinogradova [14], estimation of the number of branches in the macromolecules. The results of calculations using the viscometric data and the estimated values of the *g*-factor allow estimation of the number of branches in the RSL macromolecules at 16, and that in BSL macromolecules, at 17. Taking into account the molecular weight of the examined lignins, we should recognize that the values obtained are unrealistically high. Thus, the presumption concerning a star-shaped structure requires sounder argumentation than that provided in this study.

Analysis of the whole set of our experimental data make us to once again resort to the concept of the linear structure of the chains, whose validity is naturally proven by the values of the scaling and fractal indices. Baranov et al. [15] showed that a linear macromolecule in a thermodynamically good solvent takes a conformation of a coil characterized by the fractal dimension of 1.67 (5/3). For the RSL sample, the fractal dimension, as averaged for the viscometric and sedimentation–diffusion data, was estimated at 1.73, and for the BSL sample, at 1.66.

As known [10], the Tsvetkov–Klenin hydrodynamic invariant for branched polymers is appreciably lower than those for linear polymers (20%). For the samples we examined, $A_0 = 3.2 \times 10^{-10}$ erg K^{-1} $mol^{-1/3}$, i.e., it coincides with that for linear flexible-chain polymers.

As found previously [6], the Stockmayer–Fixman dependences for branched macromolecules, in particular, for coniferous lignins, have a negative slope. For the polymers we examined, this dependences do not differ essentially (Fig. 2) from those for linear polymers. Among few experimental data that, to a certain extent, are inconsistent with the hypothesized linear topology of the BSL and RSL macromolecules are the Huggins coefficient values. Without overestimating the role played by this parameter which, moreover, characterizes above all the polymer–solvent interactions, rather than the topology of the polymers, we must recognize the linear structure of the macromolecules of the examined lignins as the most substantiated version.

CONCLUSIONS

The analysis of the hydrodynamic, scaling, and conformational properties of straw lignins in dimethylformamide suggests that these biopolymers can be attributed to the universal class of linear macromolecular compounds.

BRIEF COMMUNICATIONS

Synthesis of Silver Nanoclusters in Starch Aqueous Solutions

E. A. Venediktov and V. A. Padokhin

Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia

Received January 21, 2008

Abstract—The capability of aqueous starch solution for reduction of Ag^+ ions and stabilization of metallic silver nanoparticles was examined. Kinetic parameters of formation of Ag nanoparticles were determined.

DOI: 10.1134/S1070427208110323

Nanodispersed silver particles have unique physicochemical and biomedical properties and are of interest for a number of fields of science, engineering, chemical engineering, and medicine [1–3].

The reducing mineralization with carbohydrates as reductants [1, 3–5] is one of methods for the synthesis of Ag nanoparticles [1–6]. The use of starch for this purpose was not reported, though there is an information on its application for stabilization of aqueous solutions of Ag nanoparticles [3–5]. At the same time, the study of starch as a reductant-stabilizer opens the way for developing environmentally safe nanocomposite materials of a wide functionality based on Ag particles [1–3].

The present work is devoted to the study of certain kinetic relationships of the synthesis of Ag nanoparticles stable in aqueous solutions using starch. As strong interaction with light is a specific feature of silver particles [1–6]; the spectrophotometric method allows reliable monitoring of their synthesis.

As model compounds we used water-soluble starch-indicator (Khimmed, Russia), silver nitrate prepared by dissolution of metallic Ag in concentrated nitric acid with its subsequent precipitation, and single-distilled water.

The order of the preparation of the starch aqueous solution was as follows. A 6-g portion of starch was dissolved in 400 ml of water with vigorous stirring in the course of 15 min at 55–80°C (the temperature region of starch gelatinization) up to the formation of a homogeneous system. Then the resulting solution was left at room temperature for 15 h. During this period, it separated into two fractions. In the experiments we used the upper, most stable, fraction of starch which could be stored in air for two weeks without visual indications of a precipitation process. Furthermore, it appeared to be the most convenient medium for the spectrophotometric study of the formation of metal particles owing to its relatively low light scattering coefficient. Then 2 ml of this solution was sampled and transferred into a 1 × 1 cm square quartz cell of total volume 4 ml, placed in a temperature-controlled chamber of a spectrophotometer. To optimize the process, after reaching the required temperature, from 0.009 to 0.18 ml of 0.028 M $AgNO_3$ solution was added to this volume with vigorous stirring for 15 s, so that the concentration of the solution became from 1.24×10^{-4} to 2.4×10^{-3} M with respect to the salt, respectively. Then electronic absorption spectra of these solutions were measured against an aqueous starch solution without $AgNO_3$ at the same temperature, using a Specord M-40 spectrophotometer. A constant temperature was maintained with an accuracy of ±0.2°C. The kinetic data were treated by the least-squares method.

It is known [4] that the concentration of a starch aqueous solution should be no less than 0.17% to stabilize silver nanoparticles. However, as preliminary experiments have shown, this starch concentration does not provide their efficient synthesis under conditions of dilute $AgNO_3$ solutions ($\leq 2.4 \times 10^{-3}$ M) and low temperatures (<50°C). Partly this problem is eliminated if a starch concentration in solution is increased to 1.5% and the solution temperature, to 50°C. However, even under these conditions the light absorption of the solution associated with the synthesis of Ag particles changes extremely slowly. Nevertheless, the aqueous solution of starch containing 2.4×10^{-3} M $AgNO_3$ appeared to be optimal for the experiments in a relatively wide temperature range.

A typical dependence of the optical density of a starch solution containing $AgNO_3$ on time is shown in Fig. 1. It is seen that an absorption band appears with a maximum in the region of 413 nm and a half-width $\lambda_{1/2}$ of ~96 nm. This band, which can be assigned to the absorption of separated Ag particles preferentially surrounded by starch molecules [5], is close in its parameters to the absorption band of Ag particles with the effective diameter d = 5.3 nm (λ_{max} = 419, $\lambda_{1/2}$ ~122 nm) [4].

According to the data from [3], there is a linear correlation between the absorption band maximum and the effective diameter of Ag particles. Using this approximation and the spectrophotometric data, we have found that the size of the obtained Ag particles does not exceed 37 nm. Thus, the presented data suggest that Ag^+ ions are mineralized in the aqueous solution of its salt in presence of starch and that nanoparticles of this metal are formed.

Published data [3] show that the reducing synthesis of silver particles is a complicated process involving, at least, reduction of metal ions and formation of clusters from its atoms. In the case under study, it is necessary to expect a complication of the kinetics of this process because it involves the formation of the aldehyde form of reducing glucose residues of this polysaccharide, as only these species have a sufficient reduction potential [7]. To find what kinetic factors affect the synthesis of Ag particles, we examined the influence of temperature on the process rate.

It is seen from Fig. 1 that the intensity of the solution absorption band grows with time, its maximum and half-width remaining practically constant at 86°C for at least the first 2 h. The same relationships can also be noted at other, lower, temperatures. The variation of the optical density of the absorption band of Ag particles in time follows a linear law; therefore, this dependence can be used for determining the initial process rate.

It is seen from Fig. 2 that the temperature dependence of the rate of formation of Ag particles is well fitted by the Arrhenius equation (r = 0.9987). The activation energy calculated from these data is 96 ± 1 kJ mol^{-1}. It significantly exceeds the activation energy of the diffusion in water (~18.8 kJ mol^{-1} [8]) and of the viscous flow of aqueous solutions of gel-like starch (~16.7 kJ mol^{-1} [9]), but is considerably lower than the activation energy of the starch hydrolysis (no less than 209 kJ mol^{-1} in highly basic media [10]). At

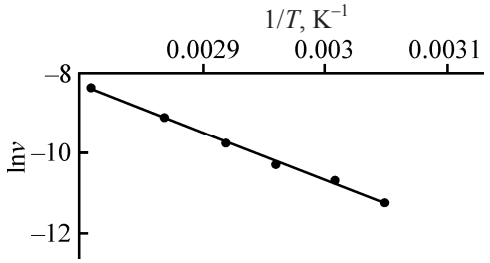

Fig. 2. Temperature dependence of initial rate v of the formation of Ag particles in starch aqueous solution ($[AgNO_3] = 2.4 \times 10^{-3}$ M).

the same time, the value we found is close to the activation energy of glucose mutarotation in water (approximately 71.1 kJ mol^{-1} [11]). It follows from the aforesaid that one of the factors controlling the formation rate of Ag particles is mutarotation of reducing residues of starch glucose.

A similar process occurs in a gel-like solution of potato starch, though less effectively. Taking into account the nature of starches, it can be accounted for by the difference in specific concentrations of glucose reducing residues.

And finally, we found that liquid-phase composites based on Ag and starch nanoparticles are stable in air for at least 1 month.

CONCLUSIONS

(1) The possibility of reducing synthesis and stabilization of silver nanoparticles in an $AgNO_3$ aqueous solution using starch was shown.

(2) One of the factors controlling the kinetics of their formation is the mutarotation of reducing glucose residues of this polysaccharide.

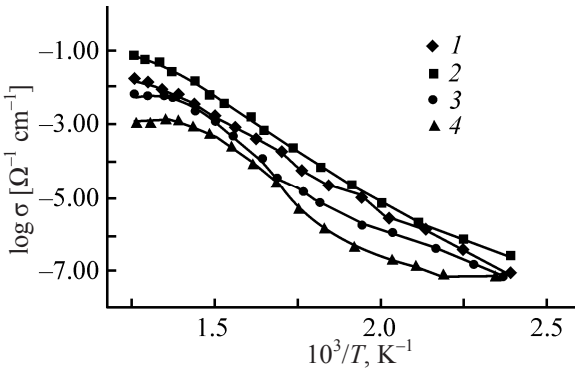
Abstract—Triple molybdates of the compositions $Rb_5LnHf(MoO_4)_6$ (5 : 1 : 2) and $Rb_2LnHf_2(MoO_4)_{6.5}$ (2 : 1 : 4), Ln = Ce–Lu, were prepared by solid-phase reactions. The temperature dependence of the electrical conductivity of the compounds $Rb_5LnHf(MoO_4)_6$ (5 : 1 : 2) at 200–500°C was studied.

DOI: 10.1134/S1070427208110335

Increased interest in complex molybdenum oxide compounds is caused by their diverse physicochemical (piezoelectric, ferroelectric, optical, and catalytic) properties [1].

The aim of this study was to synthesize triple molybdates $Rb_5LnHf(MoO_4)_6$, Ln = Ce–Lu, and to examine their electrical conductivity.

EXPERIMENTAL



Triple molybdates of these compositions were prepared from neutral molybdates (except for cerium) by solid-phase reactions in the temperature range 500–600°C within 70–100 h. Attainment of the equilibrium was monitored by X-ray diffraction with a Bruker D8 Advance diffractometer (CuK_α radiation, graphite monochromator, interval of angles 10°–40° with a step of 0.02°).

Samples for measuring electric properties were pellets approximately 1 mm thick and 10 mm in diameter. The pellets were prepared by pressing powder samples with the subsequent annealing at a temperature of 2/3 T_m of the corresponding compound.

The temperature dependences of the conductivity σ, permittivity ε, and dielectric loss tangent tan δ were studied on a pilot installation according to the Vest–Tallan procedure [2]. The quantity σ was measured on alternating current with an E8-4 capacitance meter with the connection of a P-5025 capacitor box allowing the interval of measuring tan δ in the samples to be increased. The direct current was measured with an E6-13A teraohmmeter at fixed voltages of 30 and 60 mV. The quantity t_e was determined as the ratio of the electronic conductivity measured on direct current to the total conductivity measured on alternating current: $t_e = \sigma_{=}/\sigma_{\sim} = \sigma_e/(\sigma_e + \sigma_i)$.

We have studied the temperature dependence of the conductivity of triple molybdates in the temperature range 200–500°C. The dependence of the total conductivity of triple molybdates on reciprocal temperature in the coordinates $\log\sigma$–$10^3/T$ is shown in the figure.

The ordinate values give the conductivity at a certain temperature. We determined the activation energies of ionic and electronic conductivity E_a(i) and E_a(e) from the line slopes. The calculated activation energies of the conductivity E_a(i) and E_a(e) and the conductivities σ of triple molybdates are given in the table.

Temperature dependence of the electrical conductivity σ of (*1*) $Rb_5GdHf(MoO_4)_6$, (*2*) $Rb_5LuHf(MoO_4)_6$, (*3*) $Rb_5PrHf\cdot(MoO_4)_6$, and (*5*) $Rb_5TmHf(MoO_4)_6$.

Electrophysical properties of triple molybdates (450°C)

$Rb_5YbHf(MoO_4)_6$	1.1	0.59	
$Rb_5LuHf(MoO_4)_6$	9.0		0.45

According to the electronic transport numbers t_e obtained, the mixed electronic-ionic conduction is observed in the samples of triple molybdates at relatively low temperatures (200–400°C). At the same time, at a higher temperature, the electrical conductivity of the molybdates containing lanthanides (Ce, Pr, Nd, Sm, Eu, Tb, Dy, Ho, Er, Tm, and Yb) is mainly ionic. The predominantly ionic character of conductivity was observed also in the previously studied triple molybdates containing lanthanide atoms, but with another ion (K^+) apparently participating in conduction [3].

It should be noted that the ionic conductivity of molybdates is independent of the ionic radii of rare-earth elements. This is attributable to the fact that the ionic radii in the series of rare-earth elements vary only slightly as their atomic weight increases. The crystal structure of the molybdates $Rb_5LnHf(MoO_4)_6$ [4] is a three-dimensional mixed framework consisting of alternating Mo tetrahedra and (Ln, Hf)O_6 octahedra sharing common O vertices. In large cavities of the framework, two types of rubidium cations are arranged, which basically determine the transport of conduction ions.

According to the electronic transport numbers t_e, preferentially electronic conduction was detected in the molybdates $Rb_5GdHf(MoO_4)_6$ and $Rb_5LuHf(MoO_4)_6$ at temperatures above 400°C. This is apparently caused by intrinsic electronic conductivity of the molybdates containing Gd and Lu atoms with the electronic configuration $4f^7 5d^1 6s^1$ and $4f^{14} 5d^1 6s^2$, respectively. According to the data of [5], the presence of the $5d^1$ levels in the electronic structure of rare-earth atoms determines the intrinsic conductivity of molybdates. The conductivities σ at 450°C of the molybdates $Rb_5GdHf(MoO_4)_6$ and $Rb_5LuHf(MoO_4)_6$ are noticeably higher than those of the other ternary molybdates exhibiting mostly ionic conductivity at the same temperatures. The fact of intrinsic electronic conductivity in the molybdates containing Gd ions is confirmed by a higher electronic conductivity found for $Gd_2Zr_3(MoO_4)_9$ as compared to double molybdates exhibiting only the impurity electronic conductivity [6].

CONCLUSIONS

(1) The triple molybdates $Rb_5LnHf(MoO_4)_6$ (Ln series except for Gd and Lu) exhibit ionic conductivity. Its value is independent of particular lanthanide.

(2) $Rb_5GdHf(MoO_4)_6$ and $Rb_5LuHf(MoO_4)_6$ exhibit predominantly electronic conductivity caused basically by the electronic configurations of Gd and Lu atoms.

Abstract—The Mark–Kuhn–Houwink relationship was obtained for solutions of poly-*N*-methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate in 1 M $NaNO_3$ from the light scattering and viscometric data. The Kuhn segment length for this polymer was estimated.

DOI: 10.1134/S1070427208110347

Molotkov et al. [1] compared two procedures for preparing water-soluble poly-*N*-methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate (PDMAEM·DMS). The synthesis was performed by the radical mechanism with the Co(III)–glycine redox system and with acid-catalytic initiation. It was shown that the intrinsic viscosities [η] and molecular weights M_w of all the samples well fit in a common relationship $\log [\eta] = f(\log M_w)$. However, the range of MW did not allow the Mark-–Kuhn–Houwink (MKH) relationship $[\eta] = KM_w^a$ (where K and a are constants characterizing the specific polymer–solvent system) to be obtained reliably [2]. It should be noted that such an equation, which would allow determination of MW by the readily available viscometric method, is demanded by wide use of PDMAEM·DMS in practice and research.

In this study, we supplemented the available data by new data on viscosity and molecular weights, which allowed us to obtain the MKH relationship for a relatively wide MW range and to estimate the Kuhn segment length for this polymer.

EXPERIMENTAL

To prepare PDMAEM·DMS of a lower molecular weight, we developed a radical polymerization procedure with azobis(isobutyronitrile) (AIBN, 0.5–2 wt % relative to monomer) as polymerization initiator. The reaction was performed in ethanol or isopropanol at a monomer concentration of 10–25 mol % and a temperature of 65°C. Solutions of the initiator and monomer were prepared separately and combined at room temperature. The prepared working solution of the monomer with the initiator of the required concentration was placed in a thermostat. The reaction was performed in an argon flow with gradual heating to 65°C. After the reaction completion (18 h, ~90% conversion of the monomer), the polymer was dissolved in distilled water and purified by dialysis with a cellulose membrane. The degree of conversion was determined from the concentration of the polymer solution obtained, by weighing the dry residue. The dry polymer was isolated from the aqueous solution by freeze drying.

Viscometric measurements for determining the intrinsic viscosity [η] were performed in 1 M aqueous $NaNO_3$ at 20°C in an Ostwald viscometer with a solvent outflow time of about 100 s. The molecular weights M_w of the polymers were determined by the light scattering method with a Fica diffusometer at the wavelength of the incident vertically polarized light of 546 nm in the concentration range $c \sim (0.01–1.0) \times 10^{-2}$ g cm^{-3}; the device was calibrated against benzene. The solutions and solvent (1 M aqueous $NaNO_3$) were treated to remove dust by centrifugation at 15 000 rpm for 1.5 h. The results were processed by the Debye method taking into account asymmetry of scattering at 45° and 135° [3]. The refractive index increment dn/dc was determined with an IRF-23 refractometer. For PDMAEM·DMS in 1 M aqueous $NaNO_3$, dn/dc = 0.15 cm^3 g^{-1}.

Synthesis conditions, degree of conversion, and molecular characteristics of PDMAEM·DMS with AIBN used as polymerization initiator (65°C)

[M], wt %	AIBN, % of [M]	Solvent	τ, h	Conversion, %	[η],[a] ml g^{-1}	$M_w \times 10^{-3}$
20	1	Ethanol	18	73.3	20	95
20	1	Isopropanol	18	83.0	44	300
10	2	Ethanol	18	79.3	8	30
20	1	″	9	87.3	28	190
20	1	″	6	78.7	19	100

[a] In 1 M $NaNO_3$.

The synthesis conditions, degrees of conversion, intrinsic viscosities [η], and weight-average molecular weights M_w of PDMAEM·DMS samples obtained with AIBN initiator at 65°C are given in the table.

From the results of this study and the values of [η] and M_w for ultrahigh-molecular-weight PDMAEM·DMS samples prepared in [1] with acid-catalytic initiation, we constructed the dependence of $\log[\eta]$ on $\log M_w$ (Fig. 1). In the entire examined range of M_w, it corresponded to the MKH equation of the form

$$[\eta] = 5.24 \times 10^{-3} M_w^{0.71}.$$

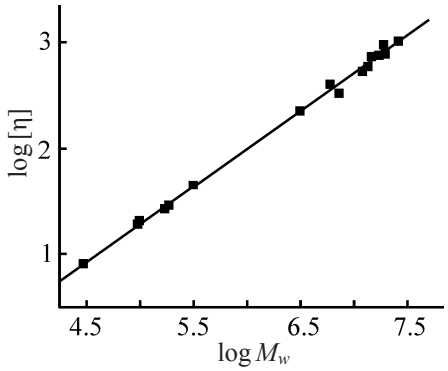

Fig. 1. Plot of $\log[\eta]$ vs. $\log M_w$ for poly-*N*-methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate in 1 M $NaNO_3$.

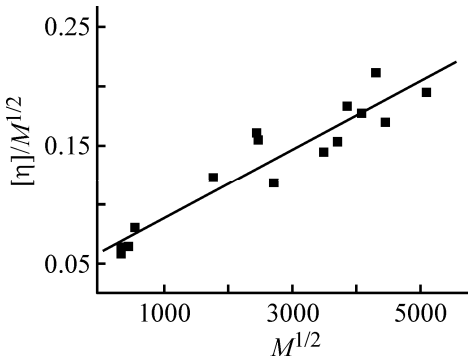

Fig. 2. Stockmayer–Fixman plot for poly-*N*-methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate in 1 M $NaNO_3$.

To exclude the influence of volume effects and determine the Kuhn segment *A* of the macromolecule, we used the Stockmayer–Fixman relationship [4]

$$[\eta]/M^{1/2} = K_0 + 0.51\Phi_0 BM^{1/2} = \Phi_0(Al/M_0)^{3/2} + 0.51\Phi_0 BM^{1/2}.$$

By extrapolation of the relationship $[\eta]/M^{1/2} = f(M^{1/2})$ (Fig. 2), we obtained the Kuhn segment $A = 4.1 \pm 0.5$ nm (at the Flory coefficient $\Phi_0 = 2.51 \times 10^{23}$ mol^{-1}, length of monomeric unit projection $l = 0.252$ nm, and molecular weight of the monomeric unit of the polymer $M_0 = 283$).

The obtained Kuhn segment length *A*, despite large value, nevertheless does not allow PDMAEM·DMS to be classed with moderately rigid-chain polymers ($5 \le A \le 20$ nm, according to [5]). The exponent in the MKH equation (0.71) is also typical of flexible-chain polymers in good solvents ($a = 0.7$–0.8 [6]).

CONCLUSIONS

(1) A relationship between the intrinsic viscosity of poly-*N*-methacryloyloxyethyl-*N*,*N*,*N*-trimethylammonium methyl sulfate in 1 M $NaNO_3$ solution and its molecular weight M_w was constructed on the basis of light scattering and viscometric data. This relationship corresponds to the Mark–Kuhn–Houwink equation in the form $[\eta] = 5.24 \times 10^{-3} M_w^{0.71}$.

(2) The Kuhn segment length was estimated: $A = 4.1 \pm 0.5$ nm.

Abstract—Formulations of protective polymeric coatings for sea craft, which contain natural aluminosilicates (zeolite and vermiculite from Primor'e deposits) as fillers and polyheterosiloxanes, oxides, and fluorides of some metals and mixtures of these as modifiers of binding resins, were developed.

DOI: 10.1134/S1070427208110359

It is known that polymeric coatings are widely used in ship building for corrosion protection of metals [1]. It has been shown previously that high-quality polymeric coatings can be obtained using formulations containing natural zeolite from the Chuguev deposit as a filler and polychromoorganylsiloxane as modifier of the binding polymer [2].

For a more systematic and broader-scope study of the protective properties of coatings, formulations based on perchlorovinyl (PCV) and polystyrene (PS) were developed, which contain zeolite or vermiculite as a filler and polychromophenylsiloxane, polyphenylborophenylsiloxane, iron(III) and copper(II) oxides, and antimony trifluoride as modifiers.

EXPERIMENTAL

Polymeric coatings were deposited from the formulations under study as follows: a 5% solution of polystyrene in toluene was prepared, the aluminosilicate filler was added (10, 20, 30, and 40% relative to the mass of the resin solution), and then the modifier was introduced (3% relative to the mass of the preceding solution). Prior to deposition of the coatings, St.3 steel samples were polished to remove corrosion products, degreased with toluene, and treated with a 10% sulfuric acid solution with addition of thiourea.

A polymeric coating was deposited with a brush onto a prepared and dry sample. After triple deposition, the coating was dried in air to constant mass.

The corrosion of St.3 steel was studied by submerging plates with protective coatings in seawater for a long time. At certain intervals of time, seawater was sampled and the content of iron ions was determined. The corrosion rate was also determined gravimetrically from the loss of mass by a sample, with subsequent recalculation to the corrosion depth index (mm year^{-1}) by the formula

$$\nu = \Delta m \times 10 \times 365/(\rho St),$$

where Δm is the loss of mass by a sample (g); ρ, metal density (g cm^{-3}); S, sample surface area (cm^2); and t, exposure time (days).

The interaction in the aluminosilicate–polymer system was studied by IR spectroscopy. The IR spectrum of aluminosilicate show characteristic absorption bands associated with Si–OH (3630 cm^{-1}) and OH bonds (H_2O_{assoc}) (3460–3380 cm^{-1}). The presence of bound water is also indicated by bending vibrations at 1630 cm^{-1}. In the PCV–aluminosilicate–PS systems, these bands are completely absent, which points to interactions associated with removal of water. Such an interaction enhances the cohesion of the composite and improves the coating. In the aluminosilicate–polyheterosiloxane system, the bands related to OH vibrations have a lower intensity, but do not disappear completely [2]. Probably, the interaction proceeds in this system to a lesser extent, and, accordingly, the composite is strengthened less.

The effect of the content of the filler-pigment intro-

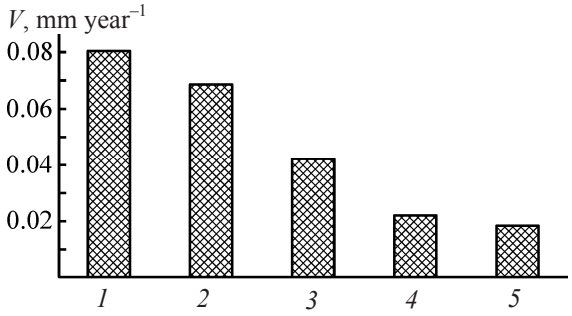

Fig. 1. Dependence of the corrosion rate V of St.3 steel in seawater on the coating composition. (*1*) No coating; coating: (*2*) PS, (*3*) PS + 10% zeolite, (*4*) PS + 20% zeolite, and (*5*) PS + 40% zeolite.

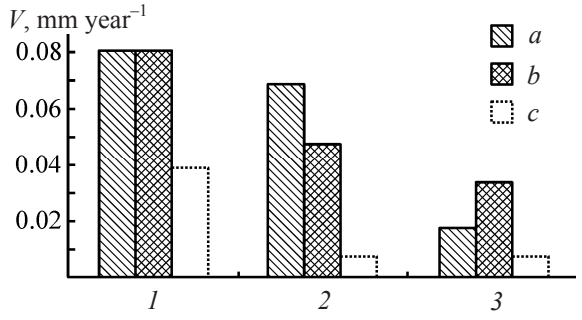

Fig. 2. Dependence of the corrosion rate V of (*a*, *b*) St.3 steel and (*c*) bronze in seawater on the nature of a polymeric binder in the coating. (*1*) No coating; coating: (*2*) (*a*) PS and (*b*, *c*) PCV; (*3*) (*a*) PS + 40% zeolite and (*b*, *c*) PCV + 40% zeolite.

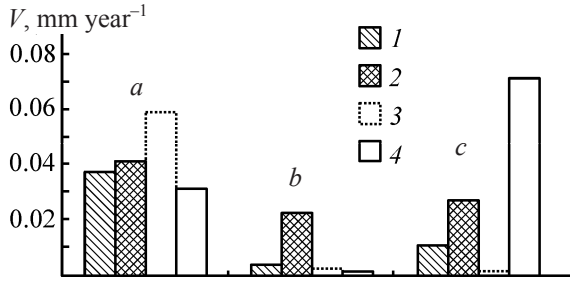

Fig. 3. Influence exerted on the corrosion rate V by addition to the coating of modifiers of various binders. Modifier: (*1*) Cu_2O + vermiculite; (*2*) Cu_2O, SbF_3, PPBPS + zeolite; (*3*) Cu_2O + zeolite; and (*4*) PPBPS + zeolite. Binder: (*a*) PCV, (*b*) PCV + PE, and (*c*) PCV + PE + PS.

duced into the coating on the corrosion rate of St.3 steel in seawater at 20°C is illustrated by Fig. 1. It can be seen that, at a zeolite content exceeding 20%, the corrosion rate remains nearly unchanged. The lowest corrosion rate was observed for the composite containing 40% zeolite. In this case, the corrosion rate decreased by a factor of 4.7, compared with the starting steel sample, whereas deposition of a filler-free polystyrene film diminished the corrosion rate by only a factor of 1.1.

Using a polystyrene coating instead of that composed of perchlorovinyl leads to an increase in the corrosion rate by a factor of 1.2. The same result was observed upon introduction of 40% zeolite. Passing from PCV to PS makes the corrosion rate 1.8 times lower. The results obtained are confirmed by Fig. 2, which points to a denser structure of the polystyrene coating with zeolite, compared with the structure of the perchlorovinyl coating with the same amount of aluminosilicate.

The influence exerted on the corrosion rate by introduction of binder modifiers, such as polyphenyl borophenyl siloxane (PPBPS), copper(II) oxide, antimony trifluoride, and mixture of antimony trifluoride, copper(I) oxide, and polyphenyl borophenyl siloxane, and also by replacement of zeolite with vermiculite is illustrated by Fig. 3.

Making the coating composition more complex results in the appearance of chemical interactions. The most pronounced effect of this interaction is observed on mixing perchlorovinyl resin and polyepoxide (PE). Also rather important is the influence of the aluminosilicate structure. The lowest corrosion rate is observed upon introduction of vermiculite, because the lamellar structure of its particles provides the highest coating density at the same modifier (CH_2O).

The highest corrosion rate was observed upon introduction of Fe_2O_3 as a filler pigment in the case of a three-component polymer mixture (PCV + PE + PS). Presumably, this is due to the effect of the polystyrene component, because the corrosion rate is substantially lower in the absence of this component.

CONCLUSION

A study of the corrosion in seawater with the coatings obtained demonstrated that introduction of zeolite and vermiculite diminishes the corrosion rate by factors of 4.5 and 10, respectively. Introduction of heterosiloxanes strongly affects the corrosion rate, which depends on the nature of an element in the heterosiloxane.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of the Substrate Nature on the Formation of Thin Titanium Dioxide Films by Molecular Layering

Abstract—Results of structural studies of titanium dioxide films synthesized on glass, silicon, and mica substrates by molecular layering are presented. An analysis of data furnished by electron and X-ray diffraction analyses and atomic-force microscopy of the samples in different growth stages revealed the effect of the substrate nature on the structure of the titanium oxide coatings synthesized.

DOI: 10.1134/S107042720812001X

Finding the factors that affect the structure of titanium oxide films formed by molecular layering (ML) is of not only theoretical, but also practical interest. It is known that titanium dioxide finds use in optical, pigment, catalytic, sorption, etc. coatings [1–9]. Depending on the functional purpose, and important factor is the phase state of titanium dioxide, which can be in the form of anatase, rutile, and brookite.

As shown by previous studies, the substrate nature strongly affects the phase composition of the nanolayer being formed in synthesis of titanium oxide nanostructures on the surface of porous silicon and aluminum oxide particles [2, 3]. The surface of aluminum oxide favors formation of a rutile-like modification of titanium oxide, whereas on silicon dioxide, mostly an anatase-like system is produced.

A study of the properties of ML products revealed such structural-dimensional characteristics as effects of a monolayer, substrate coverage, and structural matching between the substrate surface and layer being grown [2, 7, 8]. It can be assumed that, as the thickness of a growing layer increases, the substrate will exert lesser influence on its structure, but in the initial stages of synthesis, in a thin (several monolayers) coating, the matrix is known to have the most pronounced effect (monolayer effect). In turn, the structure of the coating formed in the initial stages of synthesis, can affect that of thicker layers.

The initial stages of synthesis of titanium oxide nanolayers on the surface of semiconductor silicon and glass by the ML method, with up to 20 treatment cycles, have been studied by ellipsometry and atomic-force microscopy (AFM) [1, 7, 8, 10, 11]. At the same time, integrated studies of thicker (with several hundreds or thousands of treatment cycles, which provides film thicknesses of 100 nm and more) titanium oxide layers, their phase composition on the surface of various substrates, and the influence exerted by the matrix nature on the structure of coatings being formed have not been widely reported in scientific publications.

The aim of this study was to examine the influence exerted by the nature of the solid-phase matrix (glass, mica, silicon) on the structure of the titanium oxide layer formed on the substrate surface in molecular layering (beginning with 500 treatment cycles and more).

As substrates were used plates (20 × 20 mm) of polished sodium-calcium-silicate glass, Si(III) silicon, and mica (muscovite), treated, prior to synthesis, with a surfactant [$CH_3(CH_2)_{10}$–SO_3Na + 0.5 wt % NaOH] and then washed with distilled water and dried in a vacuum at 500 K for 15 min.

The fact that the silicon surface commonly contains a thin (up to several nanometers) layer of silicon oxide and results of an analysis of published data suggest that hydroxy groups bonded to silicon atoms are the main reaction centers on the surface of substrates treated with water and dried.

The synthesis was performed by alternate treatments of the starting matrices with $TiCl_4$ and H_2O vapors, followed by removal of the excess amount of the starting reagent and gaseous reaction products to a residual pressure in the reactor of ≤1 Pa.

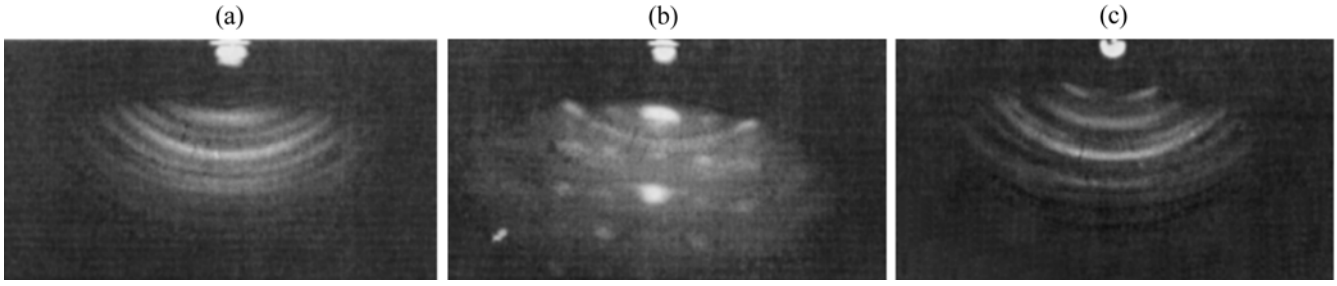

Fig. 1. Typical electron diffraction patterns of titanium oxide films after 500 ML cycles on (a) glass, (b) mica, and (c) silicon.

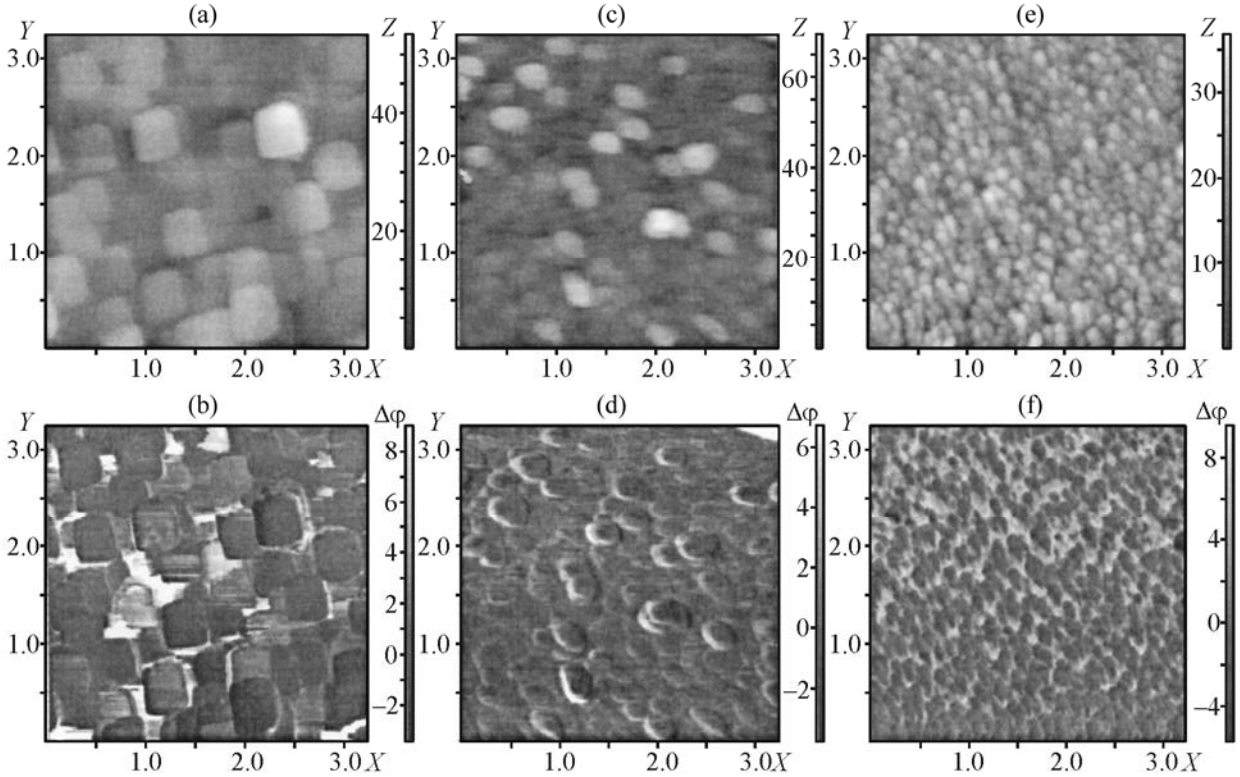

Fig. 2. AFM images of the surface of titanium oxide films after 500 ML cycles in the topographic and phase-contrast modes on (a, b) glass, (c, d) mica, and (e, f) silicon.

Each ML cycle, carried out after a preliminary evacuation of the reactor to a residual pressure of about 1 Pa, included the following stages: letting-in of a titanium chloride vapor, keeping the substrate in this vapor, pumping-out of titanium chloride and the gaseous reaction product (hydrogen chloride), letting-in water vapor, keeping the substrate in this vapor, and pumping-out of the excess amount of the reagent and gaseous reaction products. Further, the procedure was repeated for a prescribed number of times. The substrate temperature in synthesis was $T_s = 493$ K.

Titanium oxide films produced by 500–2000 cycles of molecular layering were studied.

The crystal structure of the films was analyzed with an EMR-100 electron diffractometer and Difrey DNR diffractometer.

The morphology of the titanium oxide coatings was examined with a Solver P47 Prof scanning probe microscope (NT-MDT, Russia) by the AFM method in the tapping mode in air. Samples were studied in two modes: by topographic measurements and by scanning in the phase-contrast mode, which enables evaluation of qualitative changes in the phase composition of separate areas of the sample surface by changes in the shift $\Delta\varphi$ of the amplitude-frequency characteristic of the AFM probe, caused by adhesion interactions. The main results of the study are shown in Figs. 1–5.

As follows from the electron diffraction patterns (Fig. 1), the films produced by 500 ML cycles on glass and silicon have a polycrystalline structure, and those produced on the mica surface, a crystalline structure of the "smeared texture" type.

The AFM images of the samples (Fig. 2) indicate that the surface morphology of the layer being grown strongly depends on the nature of the substrate used in synthesis. On the glass surface (Fig. 2a), titanium oxide microcrystallites of regular shape (squared at base, with a side of 350–500 nm and height of up to 15–20 nm) are formed. Despite the complete coverage of the starting substrate by TiO_2 crystallites, they are formed not only on the matrix surface, but also on lower-lying crystallites to give a coating that has a nonuniform thickness, but is solid. Scanning in the phase-contrast mode (Fig. 2b) indicates that the properties of the titanium oxide nanostructures are uniform; the differences in the image, obtained in the phase-contrast mode, are presumably due to the topographic nonuniformity of the layer being synthesized.

Performing the synthesis under the same conditions on mica (Fig. 2c) yields similar structures with a lateral size of 200 to 400 nm and height of 20 nm, which have, in contrast to those formed on glass, a rectangular shape with rounded corners. The surface image obtained in the phase-contrast mode (Fig. 2d) indicates, as in the preceding case, that the substrate is completely covered and the properties of the nanostructures formed are uniform. At the same time, the titanium oxide structures formed on mica are more closely packed than those on glass, without gaps between separate crystallites.

Synthesis on Si(III) yields on the matrix surface a solid uniform coating composed of rounded crystallites with a later size of 50–100 nm and height of 10–15 nm (Fig. 2e). In this case, scanning in the phase-contrast mode does not reveal any significant differences from the characteristics of the already considered titanium oxide coatings (Fig. 2f).

Figure 3 shows electron diffraction patterns of titanium oxide films synthesized on mica and silicon substrates after 1000 ML cycles. Comparison with the electron diffraction patterns of thinner films (Fig. 1) shows that the crystal perfection of the films becomes better in the course of synthesis. At the same time, electron diffraction analysis shows that films grown on glass retain their polycrystalline structure as the thickness increases. However, the crystal structure of the films formed on a glass substrate does change in the course of synthesis. This is indicated by Fig. 4, which shows X-ray diffraction patterns of samples in different growth stages (curves *2* and *3*) in comparison with the starting substrate (curve *1*). It follows from Fig. 4 that, in all stages, the films contain an anatase structure in addition to the amorphous phase. The crystal struc-

ture of anatase is oriented in the (101) direction in the film studied. In Fig. 4, the reflection from this plane is designated as A101. Its intensity grows with the film thickness.

The evolution of the surface morphology of titanium oxide films in the course of synthesis can be assessed using the data in Fig. 5, which shows AFM images of silicon samples after 500, 1000, and 2000 ML cycles. As the thickness of the film formed on Si(III) grows, the AFM images show that the shape of surface structures changes via fusion of separate closely spaced TiO_2 crystallites and the length of the final structure increases from 50–100 nm (characteristic lateral size of a separate TiO_2 crystallite in Fig. 5a) to 300–500 nm (Fig. 5c) at its almost unchanged width (50–100 nm). As the thickness of the growing titanium oxide layer increases, a texture appears in the layer after 500 ML cycles, which is clearly seen in Fourier transforms of the AFM images of the coatings under study [12].

Comparative analysis of the results obtained shows that the substrate nature strongly affects the shape and size of crystallites formed in the titanium oxide film in the course of synthesis. In going from glass, to mica, and to silicon substrates (Fig. 2), the size of the crystallites decreases and their shape changes from rather distinctly squared on glass (Fig. 2a) to squared with rounded corners on mica (Fig. 2c) and rounded on silicon (Fig. 2e). The fact that the crystallinity of the starting substrate increases in the same order suggests that a more perfect coating structure is formed on silicon already in the first monolayers and is preserved in further growth. In the case of the amorphous glass matrix, the crystallinity of the layer starts to increase only in sufficiently thick layers, when the effect of the matrix is insignificant. Mica occupies an intermediate position between the above two types of substrates.

The experimental results of this study correlate to a certain extent with data on synthesis of titanium oxide films on silicon by a method similar to the ML [13]. The authors of [13] varied the concentration of hydroxy groups on the silicon surface by their partial replacement with hydride groups, with the surface hydrophobicity thereby raised, and analyzed changes in the structure of the forming titanium oxide films. In the end, they came to a conclusion that mostly single hydroxy groups are present on a hydrophobic silicon surface and reaction (1) occurs to give finer crystallites (as in the case shown in Figs. 2e and 5); on a hydrophilic surface, the concentration of hydroxy groups is higher and the synthesis occurs predominantly by reaction (2) to give coarser crystallites (as in Figs. 2a and 2c):

$$\geq Si{-}O{-}H + Cl_2Ti(Cl)_2 \rightarrow \geq Si{-}O{-}TiCl_3 + HCl, \quad (1)$$

$$O(\geq Si{-}O{-}H)_2 + Cl_2Ti(Cl)_2 \rightarrow O(\geq Si{-}O{-})_2TiCl_2 + 2HCl. \quad (2)$$

With account of the aforesaid, it can be suggested that the growth on glass begins with the formation of an amorphous layer (compare curves *1* and *2* in Fig. 4), and then there appears a coarsely grained structure containing anatase (as indicated by A101 peak in curve *2*). In further growth, the crystallinity of this structure grows with the film thickness (as indicated by the increase in the intensity of A101 reflection with the film thickness).

The growth process on silicon begins with the appearance of fine crystals (Fig. 2e), which increase in size via fusion (Fig. 5).

CONCLUSIONS

(1) The structural study of titanium oxide films produced by molecular layering on substrates of varied nature demonstrated that the matrix nature strongly affects the size and shape of crystallites in the titanium oxide film. In passing from glass, to mica, and to silicon substrates, the crystallite sizes decrease in all stages of synthesis and their shape changes from rather distinctly squared on glass to squared with rounded corners on mica, and to rounded on silicon.

(2) In the initial stage of film formation (up to 500 molecular layering cycles), the structure of the films is largely determined by the substrate nature: an amorphous layer is formed on amorphous glass; an oriented crystalline structure, on mica; and crystalline film. on silicon.

(3) As the thickness of a film increases (to 2000 cycles of molecular layering), its crystal structure becomes more perfect.

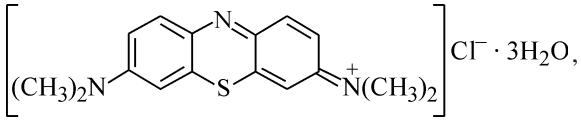
Abstract—Photodestruction and adsorption of dyes in aqueous suspensions of nanopowders of titanium dioxide of anatase modification was studied. The photocatalytic activity of titanium dioxide nanopowders was examined in relation to the dispersity of particles and pH of the medium.

DOI: 10.1134/S1070427208120021

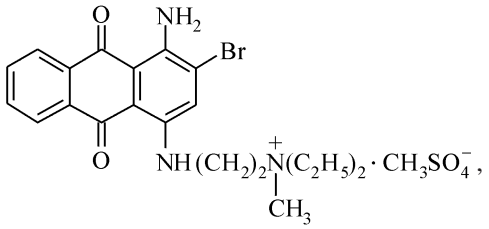
Development of new optically active nanocrystalline materials and technologies of their effective application has become particularly important in recent years. This is due both to the need to search for new power sources (solar light convertes in the case in question) and to the ecological safety of the technologies employed.

Of particular scientific and applied interest in this context are studies in the field of synthesis and analysis of properties of semiconducting nanopowders, oxides of transition metals, including titanium dioxide. Owing to the excellent combination of physicochemical, optical, and catalytic properties, fields of its application are rather extensive. In particular, use of TiO_2 in heterogeneous catalytic oxidation processes for destruction of chlorine- and nitrogen-containing compounds, acids, dyes, surfactants, pesticides, and herbicides was described in [1].



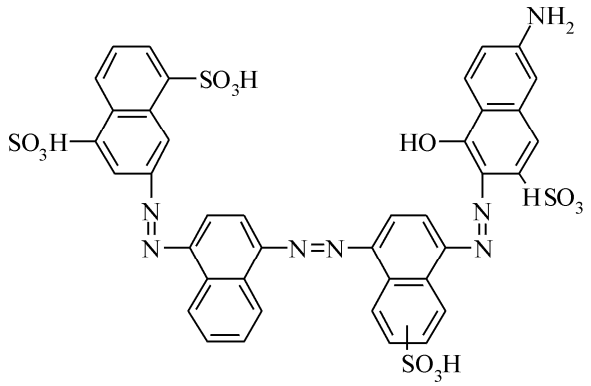
However, certain aspects of heterogeneous processes of this kind are insufficiently understood because of their multifactor and multistage nature. This is largely due to very complex chemical and structural features of the surface of TiO_2 powders, which includes basic and acidic centers, hydroxy groups, and hydroxy and oxygen radicals generated by photocatalytic processes [2]. The situation is made even more complicated in the case of nanosize TiO_2 particles having large specific surface area, mesoporous structure, and high interparticle interaction energy. Of particular interest in this case are TiO_2–dye systems with varied chemical composition and structure, which, in addition, can exhibit sensitizing properties [3].

EXPERIMENTAL



The communication reports on a study of the photocatalytic activity of TiO_2 nanopowders with different particle sizes in photodestruction of dyes of varied chemical nature and structure in aqueous solutions under UV irradiation.

As objects of study were chosen the following TiO_2 powders: of anatase crystalline modification with a particle size of 5 nm and specific surface area of 140 $m^2 g^{-1}$ (Aldrich) (TiO_2-I); of rutile modification with a particle size of <5 nm and specific surface area of 2.7 $m^2 g^{-1}$ (TiO_2-II); of anatase modification with a particle size of 20–25 nm and specific surface area of 108 $m^2 g^{-1}$, synthesized at the Institute of Material Science Problems, National Academy of Sciences of Ukraine (TiO_2-III); and a powder of AV-01-SF brand (Precheza) with a particle size of 100–120 nm and specific surface area of 15.5 $m^2 g^{-1}$ (TiO_2-IV).



The interaction of titanium dioxide with the following dyes was studied: Methylene Blue (MB) of the thiazine series {analytically pure grade, TU (Technical Specification) 6-09-29–76 [4]}

Cationic Violet 4S (CV) of the anthraquinone series (TU 6-00-49222775-07–2001 [5])

and Direct Blue 2S polyazo dye (DB), GOST (State Standard) 22849–77 [5]

The photocatalytic activity of the TiO_2 powders was determined in 40 mg l^{-1} aqueous solutions of the dyes. The manner in which the optical density and the residual concentration of a dye in solutions vary with the type of TiO_2, pH of the medium (3.2–9.2), and duration of contact between the components (5–60 min) with and without UV irradiation was analyzed. The pH value of dye solutions was adjusted by addition of hydrochloric acid and sodium tetraborate. The optical density of the dye solutions was measured with a KFK-2MP photoelectric colorimeter at wavelengths of 540 (for CV and DB solutions) and 590 nm (for MB solutions) and solution layer thickness of 0.5 cm. The wavelengths corresponded to the absorption peaks. After being brought in contact with TiO_2 powders, the dye solutions were subjected to centrifugation at 8000 rpm for 15 min and their optical density was measured. The residual dye concentrations were found using optical density–dye concentration calibration plots obtained at the corresponding wavelengths. The UV irradiation of dye solutions and suspensions was performed using an SVD-120A high-pressure mercury lamp at an intensity of 18.9 W m^{-2} in the wavelength range 200–400 nm.

The photocatalytic activity of TiO_2 powders is mostly due to the presence of oxygen vacancies and Ti^{3+} ions in the crystal lattice and is manifested upon irradiation with photons with energies of no less than 3.0 and 3.2 eV for the rutile and anatase TiO_2 modifications, respectively. The anatase form of TiO_2 exhibits a higher activity in photoreactions [6–9]. In heterogeneous photocatalytic processes in aqueous media, electron–hole pairs are generated in TiO_2 crystals in the presence of oxygen under the action of UV light, with the subsequent formation of $O_2^{\cdot}$, $O_3^{\cdot}$, $HO^{\cdot}$, and $HO_2^{\cdot}$ radicals [1] having a strong oxidizing effect. In this case, changes in the pH of the medium can strongly affect the concentration of $HO^{\cdot}$ radicals and destruction of organic substances and, in particular, synthetic dyes.

The UV irradiation of TiO_2 suspensions in MB solutions at pH 9.2 is accompanied by an initially, during the first 5–10 min, steep and then insignificant decrease in the residual concentration of the dye (Fig. 1). The discoloration process has the highest intensity in systems containing photocatalyst nanopowders with the smallest particle size, TiO_2-I and TiO_2-III. As the particle size increases, the rate of the discoloration process becomes substantially lower. For example, for powders with particle sizes of 5 and 100–120 nm, the residual dye concentration reaches in 5 and 60 min values of 9 and 2, and 35 and 22 mg l^{-1}, respectively. The process of MB discoloration by TiO_2 nanopowders in the first 5–10 min can be attributed, in accordance with the data of [3], to zeroth-order photoreaction. A similar kinetic dependence of the residual con-

Table 1. Residual dye concentration c and the degree G of adsorption of MB dye in TiO_2 suspensions at pH 6.1 upon UV irradiation for 10 and 60 min

Sample	c, mg l^{-1}		G, %	
	10 min	60 min	10 min	60 min
TiO_2-I	38	35	2.5	6.3
TiO_2-II	38	23	2.5	2.5
TiO_2-III	40	29	0	6.3
TiO_2-IV	35	32	12.5	15.0

centration of a fungicide, fanarimol, has been observed when the role of a photocatalyst was played by TiO_2 of P-25 brand (Degussa) with a specific surface area of 50 $m^2 g^{-1}$, which is a mixture of the anatase (70–85%) and rutile (15–30%) modifications of TiO_2 [7].

As the pH value of the MB solution is lowered to 6.1, the degree of discoloration dramatically decreases (Table 1), with this effect being characteristic of all TiO_2 powders; the relative positions of the kinetic curves is preserved, as also for dye suspensions with pH 9.2.

Because the optical density of MB solutions remains almost unchanged as pH is lowered from 9.2 to 6.1 and upon UV irradiation for 1 h, the steep decrease in the photocatalytic activity of TiO_2 powders can be attributed to changes in the properties of the photocatalyst itself, whose isoelectric point is 6.7 [10]. The adsorption of OH^- ions on the surface of TiO_2 particles makes larger their negative charge. As a result, the concentration of highly reactive $HO^{\cdot}$ radicals generated by the reaction OH^- + electron vacancy → $HO^{\cdot}$ increases, too. As the pH of TiO_2 suspensions decreases, these factors become less important and the aggregation of TiO_2 particles increases, primarily for the nanosize catalyst, which makes lower the degree of discoloration of the dye solution.

Undoubtedly, an important role is played in the mechanism of photocatalytic discoloration and destruction of a dye by adsorption of its molecules on the surface of TiO_2 particles, which is the initial event of this process. The dynamic nature of the adsorption–desorption of dye molecules and products of their destruction has the key importance for the effective course of the whole photocatalytic process.

As follows from Fig. 2, the run of the kinetic curves in the case of a dark contact of TiO_2 particles with dye solutions is similar to that for irradiated suspensions. As the size of particles decreases and their specific surface area becomes larger, the degree of dye adsorption grows. For example, for TiO_2-I, TiO_2-II, and TiO_2-IV powders brought in contact with MB solutions with pH 9.20 for 1 h, the degree of adsorption reaches values of 70, 50, and 18%, respectively, relative to the initial dye concentration. These values are substantially lower than the residual concentrations of the dye in its photocatalytic discoloration. Substantially lower degrees of MB adsorption on TiO_2 powders were observed for the suspensions at pH 6.10 (Table 1). The interaction of dye molecules with the surface of TiO_2 particles may occur as a result of electrostatic attraction between positively charged cations

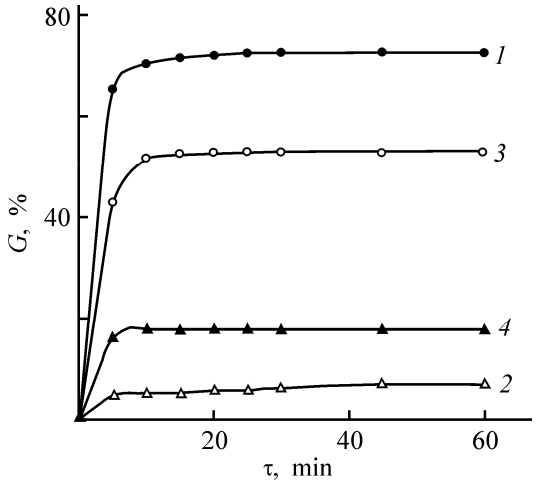

Fig. 2. Kinetics of Methylene Blue dye adsorption in suspensions containing TiO_2 powders at pH 9.20. (G) Degree of dye adsorption and (τ) adsorption duration; the same for Fig. 4.

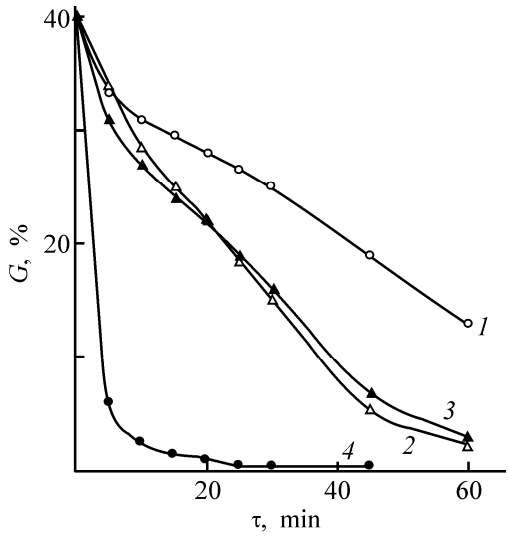

Fig. 3. Kinetics of discoloration of Cationic Violet 4S dye solutions in suspensions containing TiO_2 powders at pH 6.10.

of the dye and negatively charged TiO_2 particles and formation of π-bonds involving electrons of the conjugated system of bonds of the dye, hydrogen bonds, and van der Waals bonds [11].

Thus, there exists a direct relationship between the photocatalytic activity of TiO_2 powders, their dispersity, and adsorption of a dye on the surface of photocatalyst particles, which is noticeably manifested in the difference between the kinetic curves of discoloration of MB and carbonyl-containing CV (Table 1, Fig. 3). It should also be kept in mind that, being a comparatively strong oxidizing agent, CV itself exhibits a certain photosensitivity in the spectral range of the UV irradiation, which is expressed in a decrease in its residual concentration to 32 mg l^{-1} upon exposure for 60 min. As the solution pH increases, the coloration intensity noticeably decreases and almost completely disappears at pH 9.2.

As follows from Fig. 3, the rate of CV discoloration and destruction in TiO_2 suspensions markedly exceeds that for the thiazine dye. Noteworthy is the very high photocatalytic activity of the TiO_2-IV powder, which has the coarsest particles (100–120 nm) among TiO_2 nanopowders. This may be due to the minimum particle aggregation of this photocatalyst and to the maximum degree of adsorption of CV dye on its particles (Fig. 4). All the other TiO_2 powders also exhibit a rather high catalytic activity, compared with that in MB solutions at pH 6.1. This should be particularly emphasized for the TiO_2 powder of the rutile modification, with a particle size of less than 5 μm, for which the particle aggregation effect is the least pronounced. For example, the residual concentration of the dye in CV solutions reaches for TiO_2-I and TiO_2-II, upon 5 and 60 min of UV irradiation, values of 31 and 13 mg l^{-1} and 33 and 2.5 mg l^{-1}, respectively. In most cases, the degree of CV adsorption is smaller than that for MB, especially for the TiO_2-IV powder. Thus, the anthraquinone dye is less stable against UV irradiation as compared with the thiazine Methylene Blue.

The pH of the medium strongly affects the photocatalytic activity of TiO_2 powders. Rather important in the interaction of a dye with surface OH groups of TiO_2 is the formation of hydrogen bonds [12] involving carbonyl groups of the dye, which is accompanied by its discoloration. The nature of kinetic dependences and the absolute values of the residual concentration of the dye under UV irradiation in the course of interaction between CV and TiO_2 powder suggest the following. In given case, there is a favorable combination of the spectral sensitivity of the photoreaction of discoloration and destruction of the anthraquinone dye and the spectral excitation of the photocatalyst, which promotes high-intensity generation of electron–hole pairs and leads to an increase in their lifetime before recombination and thereby enables their involvement in the photochemical reaction.

Table 2. Residual DB dye concentration c in TiO_2 suspensions upon UV irradiation for 60 min

Sample	c, mg l^{-1}, at indicated pH		
	3.2	6.7	9.2
TiO_2-I	0.6	5/0*	35
TiO_2-II	32	29/23*	32.5
TiO_2-III	22	20/3*	34
TiO_2-IV	24	30/18*	32

* After contact in the dark between the dye solution and TiO_2 powder for 10 min and subsequent UV irradiation for 30 min.

The key role in evaluation of the catalytic activity of TiO_2 particles is played by the intrinsic photoactivity of the dye used for this purpose. As shown by studies of the photostability of the acid polyazo dye, Direct Blue 2S, its aqueous solutions are stable in the pH range studied, and only at pH 3.2 and UV irradiation, the residual concentration decreases by 10%. The nature of kinetic dependences of the residual concentration of DB in TiO_2 suspension is nearly the same as that for cationic dyes. As in the case of MB, the highest catalytic activity is exhibited by the TiO_2-I powder at any of the pH values studied (Table 2). For example, at pH 3.2 and UV irradiation duration of 60 min, the re-

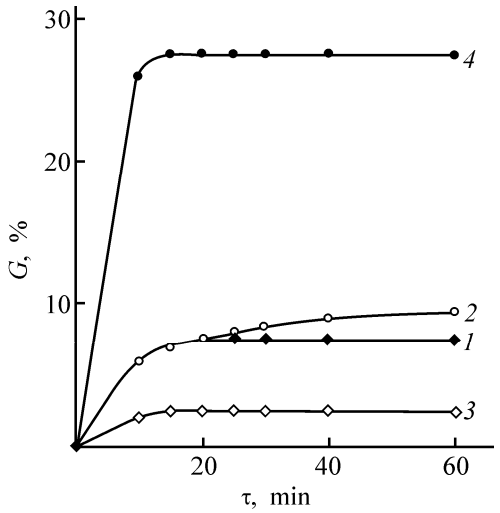

Fig. 4. Kinetics of Cationic Violet 4S dye adsorption in suspensions containing TiO_2 powders at pH 6.10.

Table 3. Residual dye concentration c and total carbon content [C] of MB and DB solutions upon UV irradiation of TiO_2-I suspensions

Suspension no.	Dye	pH	Duration of UV irradiation, min	c, mg l^{-1}	[C], mg l^{-1}
1	MB	9.2	10	4.0	6.3
2			60	2.5	7.9
3*			60 + 60	10.0	16.5
4**			60 + 60 + 60	17.5	18.6
5	DB	3.2	20	0.6	5.2
6		6.7	60	5.0	8.7

* Suspension no. 3 was produced from suspension no. 2 after a UV irradiation for 60 min, centrifugation, dispersion of the sediment in the same volume of a fresh dye solution, and UV irradiation for 60 min.

** Suspension no. 4 was produced from suspension no. 3 on performing the same procedures as those with suspension no. 2.

sidual concentration of DB reaches a value of 0.6 mg l^{-1}. In this case, the higher the dispersity of a TiO_2 powder, the stronger its catalytic activity, with this tendency becoming weaker at higher pH values and the dye discoloration being only slightly manifested at pH 9.2. In contrast to the cationic dyes, the TiO_2–DB system is characterized by a smaller difference between the residual concentrations of the dye in its discoloration via adsorption of photocatalyst particles and UV irradiation, with the correlation between these concentrations for different TiO_2 powders preserved. The degree of adsorption after a dark contact of the components for 60 min at pH 9.2 reaches a value of 70% for the TiO_2-I powder and 51% for TiO_2-III, whereas the residual concentrations of DB are 5 and 20 mg l^{-1}, respectively. This points to a considerable contribution of the adsorption of the dye to its discoloration under UV irradiation in the presence of TiO_2 powders. At the same time, the results of experiments with preliminary contact (adsorption) of the components for 10 min and subsequent UV irradiation and those with continuous UV irradiation of the suspensions for 60 min demonstrate that the residual concentration of the dye is substantially lower in the first case. These data suggest that the discoloration of the dye under UV irradiation of the suspensions studied is of dynamic nature.

A specific feature of the discoloration and destruction of DB under UV irradiation in the presence of TiO_2 powders is that this process can occur by the mechanism of photoreduction or photooxidation, as it has been observed for other azo dyes [3]. Presumably, one or the other mechanism will be observed, depending of the pH value of TiO_2 suspensions. In an aqueous medium in the presence of oxygen and low pH values, it is possible that the nitrogen atoms of nitro groups are protonated and the dye is discolored to give amines as a result of destruction of the backbone of dye molecules and oxidation by atmospheric oxygen and by ozone formed in its ionization. As the pH of the medium increases, the concentration of hydrogen ions decreases and the intensity of complexation of azo groups, dye discoloration, and destruction of dye molecules to give products with various degrees of oxidation becomes higher. Simultaneously, the negative charge of the surface of TiO_2 particles increases, the degree of ionization of acid-dye molecules grows, the electrostatic repulsion between TiO_2 particles and dye molecules becomes stronger, the adsorption decreases, and the catalytic activity of TiO_2 powders declines.

Analysis of dye solutions after the UV irradiation in the presence of TiO_2-I powder (Table 3) shows that their total carbon content markedly exceeds that corresponding to the residual concentration of a dye. This may indicate that, together with the disruption of the system of conjugated bonds, there occurs chemical destruction of the dyes to give low-molecular-weight compounds with various degrees of oxidation.

It should be kept in mind, when analyzing the results obtained, that the total carbon concentrations in the starting solutions of MB and DB are 20.6 and 20.2 mg l^{-1}, respectively. Comparison of the absolute values of the residual concentrations of the dyes and the total carbon content of solutions subjected to UV irradiation in the first 10–60 min shows that a considerable amount of volatile products is formed in photodestruction of MB and DB.

A repeated use of the TiO_2 nanopowder as a photocatalyst (suspension nos. 3 and 4) demonstrated that, in this case, the residual concentration of the dye and

the total carbon content in solution increase. The decrease in the photocatalytic activity of the TiO_2 powder in its repeated use may be due not only to "poisoning" of the catalyst, associated with blocking of active centers on the surface of its particles as a result of chemisorption of products formed in dye destruction, but also to impossibility of restoring the initial dispersity of particles of the photocatalyst in its redispersion.

Thus, the photocatalytic activity of highly dispersed TiO_2 powders in dye-containing aqueous suspensions strongly depends not only on the physicochemical properties of photocatalyst particles, but also on the chemical composition and structure of dye molecules and their mutual influence on the process of discoloration and destruction of an organic substance under UV irradiation of the system constituted by TiO_2 and an aqueous solution of a dye.

CONCLUSIONS

(1) A correlation was revealed between the kinetics of discoloration, destruction, and adsorption of a polyazo dye and thiazine and anthraquinone dyes in aqueous suspensions of titanium dioxide powders of anatase modification, with particle size of 5–120 nm.

(2) It was demonstrated that the kinetics of photodiscoloration and adsorption of aqueous solutions of the dyes studied shows the highest rate in the first 5–10 min and is largely determined by the type of interaction of their molecules with the surface of titanium dioxide particles.

(3) It was shown that the photocatalytic activity of titanium dioxide nanopowders increases with the dispersity of their particles and strongly depends on the pH of the medium, which markedly affects both the stability of synthetic dyes and the activity of titanium oxide photocatalysts.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Stock Dispersity on Properties of Ceramic Materials

A. A. Nesterov, K. S. Masurenkov, and E. V. Karyukov

Southern Federal University, Rostov-on-Don, Russia

Received January 21, 2008

Abstract—Powdered ceramic piezoelectric phases of fixed chemical composition and prescribed particle size in the range from 15 to 350 nm were obtained using a unified synthesis technique. The dependence of their electrical parameters on the granulometric composition of the stock was studied.

DOI: 10.1134/S1070427208120033

Nanopowders of ferroelectric phases can be obtained using condensation (gel-technique, cryogenic method, cooling of vapors at high supersaturations) and dispersion methods (grinding in colloid mills, thermal or mechanical impact). Despite the different types of physicochemical processes that occur when highly dispersed phase are formed, they yield highly defective particles with a considerably higher internal energy, compared with microparticles. Therefore, all the possible phase transitions in nanodispersed systems occur at lower temperatures, compared with microscopic systems. As the crystallite size decreases, the volume, symmetry, and space groups of the unit cells of the phases being synthesized change and materials on their base acquire new properties or loose those already existing [1–3].

In this study, prospects for use of nanopowders of ferroelectric phases in synthesis of ceramic piezoelectric materials were considered. Powders of phase with a perovskite structure of compositions ABO_3, $A^1_{1-x}A^2_xBO_3$, $AB^1_{1-x}B^2_xO_3$, and $A^1_{1-x}A^2_xB^1_{1-y}B^2_yO_3$ (A^1 and $A^2 = Ca^{2+}$, Sr^{2+}, Ba^{2+}, Pb^{2+}; B^1 and $B^2 = Ti^{4+}$, Zr^{4+}, Sn^{4+}, Mn^{4+}) were produced by interaction of gels of Ti(IV), Zr(IV), Sn(IV), and Mn(IV) hydroxides (Fig. 1) with oxides or hydroxides of calcium, strontium, barium, and lead [4–7]. The method enables control over the dispersity of the final crystalline product within the range from 15–20 to 2000 nm and synthesis of powders with close particle sizes. This dramatically diminishes the rate of secondary crystallization in sample sintering and thereby makes it possible to fabricate ceramics with grain sizes that begin with 50–80 nm. These specific features of the method enable assessment of the influence exerted by the size of particles of the starting powder and grains of ceramics prepared from this powder on the electrical properties of finished articles.

EXPERIMENTAL

The starting forms of Ti(IV), Zr(IV), Sn(IV), and Mn(IV) hydroxides were precipitated from nitrate solutions of compounds of these elements at 5–10°C with 10% aqueous ammonia (final pH 8). Then, Pb(II) and (or) hydroxides of alkaline-earth metals were added in a prescribed ratio. The occurrence of exchange processes in the system [between active forms of M(IV) hydroxides (Fig. 1) and M(II) oxides (hydroxides)] in the surface layer of the gel yields an intermediate amorphous reaction product [5–7]. To raise the reaction rate (renewal of the reaction zone), the suspension was ground for 1 h and dried at 80–100°C. The resulting finely dispersed powder was pelletized under a pressure of 50–70 MPa and the pallets were calcined at 300–900°C with a step of 50°C (isothermal keeping at each temperature for 1 to 10 h).

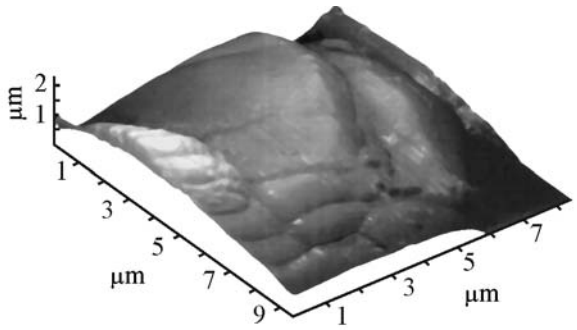

Fig. 1. Micrograph of Ti(IV) hydroxide precipitated from a nitrate solution with a 10% solution of NH_3.

Calcined samples were subjected to X-ray phase (XPA) and diffraction (XRD) analyses (DRON-2.0 diffractometer, Cu$K_{\alpha 1}$ radiation, Ni-β filter). The lattice constants were found from the (220) and (202) reflections, and sizes of the coherent-scattering regions (CSR) and microstrains ($\Delta d/d$) in the [200] direction, from the (100) and (200) reflections by the approximation method [reference and experimental diffraction profiles described by functions of the type $y = A\exp(-\alpha^2 x^2)$] [8, 9]. The rms displacements $(\bar{u}^2)^{1/2}$ of atoms from their ideal positions, caused by vacancies and interstitial atoms, were determined in the [111] and [200] directions in accordance with the pseudo-thermal multiplier $\exp[8\pi^2\bar{u}^2(\sin\theta/\lambda)^2]$ (θ is the Bragg angle, and λ, X-ray wavelength). The absolute error in determining the unit cell parameters was 0.0003 nm, and the relative error of $D_{[200]}$, $(\Delta d/d)_{[200]}$, and $(\bar{u}^2)^{1/2}$ did not exceed 15%.

The surfaces were visualized and the particle size distribution were found using a Solver Pro-M scanning probe microscope (NT-MDT).

The stocks synthesized at different temperatures by the conventional ceramic technology [1, 2] (sintering temperature 1050–1150°C, duration 2–6 h, modes monitored by the maximum density) were used to fabricate ceramic samples 10 mm in diameter and 1 mm high (Ag electrodes deposited by firing-in, polarization in silicone oil with a field of up to 50 kV cm^{-1} at 100–120°C). The electrical properties of these samples were determined in accordance with GOST (State Standard) 12370–80.

According to XPA data, the powders synthesized at 5–260°C are X-ray amorphous. The sizes of the coherent-scattering regions of cubic crystalline phases formed upon calcination of the primary amorphous product at 300–350°C for 2 h are 15–25 nm; $[(\Delta d/d)_{[200]}\times10^3 =$ 3.2 to 2.7, respectively, at $(\bar{u}^2_{[111]})^{1/2} = 0.036$–$0.039]$. The ceramic fabricated from this stock (calcination at 1100°C for 2 h) has grains with diameters of 40–60 nm (according to probe microscopy) (Figs. 2, 3), separated by wide regions of, presumably, a glassy phase. These ceramic samples have an anomalously high dielectric constant (3–5 times that of samples of the same composition, with grain sizes of several micrometers), the phase remains cubic, the material has no piezoelectric properties, the electrical conductivity of the samples widely varies, the maximum density of the ceramic does not exceed 70% of the theoretical value, and the article density cannot be raised by raising the sintering temperature and duration.

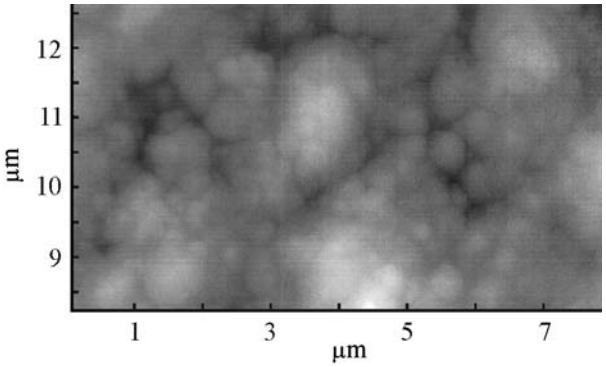

Fig. 2. Micrograph of the surface of a ceramic sample produced by the gel technique.

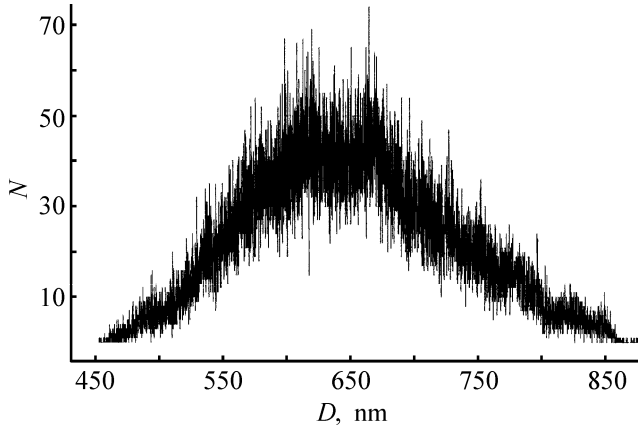

Fig. 3. Particle size distribution for the ceramic synthesized by the gel technique. (*N*) Relative number of particles and (*D*) particle diameter.

Elevating the stock synthesis temperature from 400 to 600°C leads to a gradual increase in the crystallite size, and, at a particle CSR of 70–90 nm $(\Delta d/d)_{[200]}\times10^3$ equal to 2.1 and 2.7, respectively, $(\bar{u}^2_{[111]})^{1/2} = 0.016$–$0.028]$, the cubic structure of a number of phases and solid solutions on their base ($PbTiO_3$, $BaTiO_3$, $PbZrO_3$) is transformed to a tetragonal or rhombohedral phase (Figs. 4, 5), depending on their chemical composition. These changes in the structure and size of stock particles result in that the ceramics synthesized from this stock acquire piezoelectric properties on the background of a decrease in the dielectric constant (Fig. 6).

According to probe microscopy, raising the synthesis temperature of the molding powder (up to 900°C) results in an increase in the particle size from 110 to 155 nm and, accordingly, in the grain diameter of the ceramic produced from this powder. As the grain diameter of the ceramic grows within the range 150–350 nm, its $\varepsilon^T_{33}/\varepsilon_0$ continues to decrease and the elec-

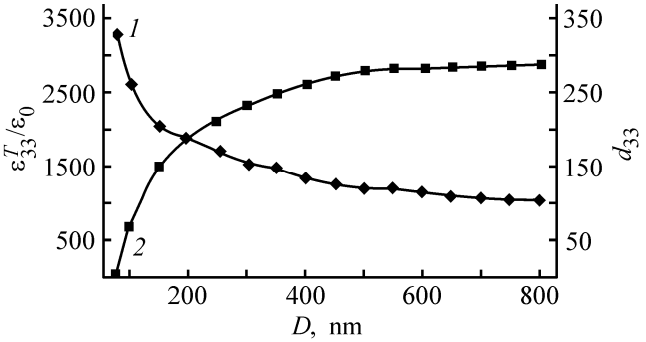

Fig. 6. Variation of the electrical properties of a ceramic sample with the average grain diameter D. (*1*) $\varepsilon_{33}^T/\varepsilon_0$ and (*2*) d_{33}.

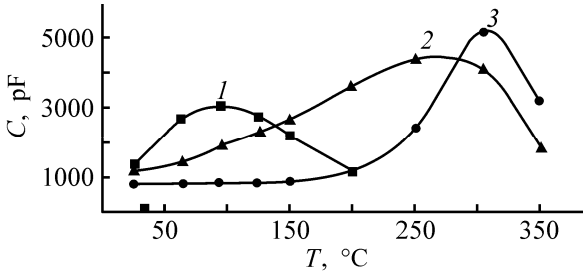

Fig. 7. Capacitance C of standard ceramic samples (h = 1 mm, d = 10 mm) vs. temperature T. Sample density is not lower than 87% of the theoretical value. Average grain size (nm): (*1*) 150, (*2*) 280, and (*3*) 600.

tromechanical coupling coefficients and piezoelectric moduli grow severalfold. Further increase in the grain size in the samples (400–600 nm) changes $\varepsilon_{33}^T/\varepsilon_0$ only slightly (tendency toward a minor decrease), whereas their K_p, K_t, and piezoelectric moduli grow by 20–30% (Fig. 6). It should also be noted that, as the grain diameter of the ceramic increases from 150 to 600 nm, the Curie point of the materials grows from 96 to 319°C (Fig. 7), in good agreement with experimental data on the decrease in $(\Delta d/d)_{[200]}$ and $(\bar{u}^2_{[111]})^{1/2}$ of the piezoelectric phase as the grain diameter becomes larger.

Analysis of the results obtained shows that the dispersity of powdered ferroelectric phases and the defectiveness of their separate particles can be rather widely varied by changing the formation conditions of the pow-

ders. An increase in the ratio between the surface area of a particle to its volume leads to a rise in the fraction of surface unit cells and, as a consequence, to a higher total energy of the system. An increase in the isobaric-isothermal potential of the phases gives rise to a number of negative, as regards the quality of piezoelectric materials, phenomena. For example, a decrease in the degree of distortion of perovskite phases makes weaker the spontaneous polarization of the samples (the factor diminishing the electromechanical coupling coefficients and piezoelectric moduli) and leads to lowering of the temperature of phase transition to the cubic modification (Curie point): e.g., at a grain size of the ceramic of less than 80 nm, the Curie point of the materials is below 0°C. In addition, the conductivity of the samples increases as the grain diameter of the ceramic decreases within the range 50–150 nm, which gives no way of performing their effective polarization. The results of the study indicate that the piezoelectric ceramic with grain sizes in the range from 200 to 800 nm is of interest from the practical standpoint. By varying the grain diameter within these limits, it is possible to fabricate materials that can effectively operate in both the reception and emission modes and articles with different temperature stabilities of separate parameters by varying the Curie point of piezoelectric phases and, consequently, to considerably extend the application fields of piezoelectric transducers fabricated from a certain phase.

CONCLUSIONS

(1) The size effect (or effect of phase defectiveness) is observed in piezoelectric materials in a wide range of granulometric compositions of the samples, which makes it possible to obtain piezoelectric ceramics with various combinations of electrical parameters from a substance of fixed composition.

(2) Of practical interest is a piezoelectric ceramic based on perovskite phases with a grain diameter in the range from 200 to 800 nm, whose piezoelectric and dielectric properties and Curie point depend on the grain size.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis and Properties of Zirconium-containing Materials Produced Using Calcium Aluminates

M. A. Kruglova and M. P. Yaroshenko

NIIAP-Katalizator Limited-Liability Company, Novomoskovsk, Tula oblast, Russia

Received March 25, 2008

Abstract—Highly dispersed zirconium-alumocalcium oxide materials were synthesized with calcium aluminates. The phase composition and surface properties of the samples obtained were analyzed in relation to temperature. Texture characteristics and acid properties of the surface of the materials synthesized were examined in relation to the relative amounts of the components.

DOI: 10.1134/S1070427208120045

The expansion of the application field of zirconium oxide compounds as sorbents, supports, and catalysts for various processes [1–4] makes topical the interest in development and studies of highly dispersed systems based on ZrO_2. The key factor in application of zirconium dioxide as a component of catalysts and supports is the stabilization of its low-temperature metastable phases (amorphous, tetragonal, or cubic), to whose presence are attributed such important characteristics as the high dispersity and developed surface [5, 6] of the material. The attention of numerous researchers has been given to stabilization of the ZrO_2 structure in the low-temperature modifications by introduction of various cations: Ca^{2+}, Sr^{2+}, Ba^{2+}, Y^{3+}, La^{3+}, Fe^{3+} [7, 8], as well as Al^{3+} [9–11], in synthesis of M–Zr–O binary oxide systems. It has been noted that properties of the zirconium-containing materials synthesized depend on the preparation method and conditions. Apparently, the development of new catalytic materials containing nanosize zirconium dioxide is associated with a search for new ways of their synthesis and control over their properties.

The best presently known methods for synthesis of materials containing nanosize zirconium dioxide are the coprecipitation from metal nitrate or chloride solutions [11, 12] and the sol–gel technique using metal alkoxides [10]. Another approach to synthesis of systems of this kind may consist in that the zirconium dioxide structure is formed on the surface of solid materials under the conditions that favor interaction of the forming ZrO_2 with a carrier compound. It has been shown previously [13] that precipitation from a zirconyl nitrate solution in the presence of γ-Al_2O_3 leads to stabilization of the low-temperature phases of zirconium dioxide in the product obtained because of the interaction observed in a wide range of ZrO_2/Al_2O_3 ratios.

This study is concerned with the possibility of using calcium aluminates as a carrier compound. This compounds can serve as a "supplier" of Al^{3+} and Ca^{3+} cations for modification of the zirconium dioxide structure. At the same time, owing to their binding properties, calcium aluminates enable production of the material in various geometric configurations and sizes, with a developed surface and high mechanical strength. A specific feature of the method suggested is that, instead a solution of zirconium salts, it uses a solid hydrated zirconium oxide, which can adsorb ions produced in hydration of calcium aluminates. The combination of these factors in the synthetic procedure suggested here seems to be useful for obtaining an oxide system containing nanosize zirconium dioxide. The aim of this study was to examine the formation of the structure of zirconium dioxide in the samples synthesized and the texture characteristics of the materials obtained for their subsequent use as catalysts for methanol dehydration.

EXPERIMENTAL

Zirconium-aluminocalcium samples were obtained as follows: hydrated zirconium oxide was thoroughly mixed and ground with a calculated amount of a high-alumina cement having the form of a mixture of calcium mono- and dialuminate with a $CaAl_2O_4/CaAl_4O_7$ ratio of 0.3. The mechanical mixture was mixed with a molding solution and the paste obtained was molded on a laboratory molder into extrudates, which were subjected to a humid-air treatment at a temperature of 25°C for 24 h. Then the samples were kept in water at 90°C for 3 h. The thus obtained extrudates were dried at 120°C for 5 h. The samples were calcined in air at temperatures of 300 to 1000°C. For comparison, an aluminocalcium sample containing no zirconium component was produced under similar conditions. Samples calcined at 400°C were treated with a 20% CH_3COOH solution for 30 min and then washed with water [14]. The compositions of the samples obtained are listed in Table 1.

X-ray studies were performed on DRON-3 and DRON-3m diffractometers (CuK_α radiation, with a graphite monochromator in the reflected beam). Phases were identified using the JCPDS database. The average size of coherent-scattering regions (CSR) was found from broadening of diffraction peaks by the Selyakov–Scherrer formula. The content of the tetragonal phase of zirconium dioxide was determined from the relation [15]:

$$X_t = \frac{I_t(111)}{I_m(111) + I_m(11\bar{1}) + I_t(111)},$$

where I_m and I_t are the integral intensities of the diffraction peaks associated with the monoclinic and tetragonal ZrO_2 phases.

A differential-thermal analysis (DTA) was carried out on a Q-1500D derivatograph at a heating rate of 5 deg min^{-1}. The specific surface area, pore volume, and pore size distribution were found from the low-temperature adsorption of nitrogen at 77 K on a Micrometrics ASAP 2010N instrument. The acidity of the surface of samples calcined at 400°C was examined by the method of thermally programmed desorption of ammonia (TPD NH_3)[1]. After a preliminary treatment, saturation with ammonia mixed with nitrogen, and blowing-out of the excess ammonia, the experiment was performed in a He flow at a heating rate of 8 deg min^{-1}; the evolving ammonia was recorded with a heat-conductivity detector.

According to the results of X-ray phase analyses (XPA), the resulting zirconium-aluminocalcium samples (ZAC) and the starting sample of hydrated zirconium oxide (Z) contain, after being dried at 120°C, an X-ray-amorphous zirconium oxide phase. Calcination in air at different temperatures revealed strong differences in the formation of crystallized zirconium dioxide in the samples studied. If follows from the XPA data in Table 1 that the X-ray-amorphous phase exists in the sample of individually precipitated zirconium dioxide (Z) up to 300°C, and after calcination at 400°C, the sample contains two crystalline phases: tetragonal (t-ZrO_2) and monoclinic (m-ZrO_2). As the calcination temperature is raised from 400 to 1000°C, the integral intensities of

the diffraction lines associated with t-ZrO_2 and m-ZrO_2 are redistributed, which points to transformation of the metastable low-temperature tetragonal modification of ZrO_2 to the stable monoclinic modification.

In contrast to Z, crystallization of ZrO_2 in ZAC samples was observed after calcination at 600°C and higher, with t-ZrO_2 being the only crystalline zirconium dioxide phase recorded in the whole range of calcination temperatures. An analysis of the integral intensities of the corresponding diffraction lines made it possible to evaluate the content of t-ZrO_2 in the samples studied. It was found that the crystallization onset temperature and the ratio between the crystallized and amorphous zirconium dioxide phases depend on the sample composition at certain temperatures (Table 1). For example, in ZAC25 sample, t-ZrO_2 crystallizes at 600°C by approximately 80%, whereas in ZAC50 sample, the X-ray-amorphous phase is preserved at the same temperature in an amount of up to 50%. In samples with a higher content of calcium aluminates, ZAC75 and ZAC90, only the X-ray-amorphous phase is observed under these conditions and its crystallization begins after calcination at 700°C. The fully formed t-ZrO_2 phase is observed in all ZAC samples at calcination temperatures in the range 800–1000°C. The existence of this metastable modification of ZrO_2 after treatment at so high temperatures is not characteristic of individual zirconium dioxide and can be accounted for by the presence in its structure of foreign ions that hinder the transformation of the tetragonal lattice into the monoclinic one [5].

According to X-ray data (Fig. 1), the position of the (111) line of t-ZrO_2 for ZAC samples at various temperatures noticeably differs from that in the X-ray diffraction pattern of Z sample, which can be regarded as evidence in favor of the incorporation of foreign ions into the tetragonal ZrO_2 lattice. Apparently, this results from interaction of calcium aluminates with hydrated zirconium oxide under the conditions of the synthesis.

The occurrence of such an interaction can be confirmed by comparing the results obtained for a sample of a mechanical mixture Z + AC (50 wt %) and the synthesized ZAC50 sample. The XPA data in Table 1 demonstrate that, upon calcination at 400°C, the sample of a mechanical mixture contains M-ZrO_2 and t-ZrO_2 in approximately the same ratio as that for sample Z, in contrast to ZAC50, in which the X-ray-amorphous phase is present. This is in good agreement with the DTA data. Figure 2 shows derivatograms of the samples, which demonstrate that a clearly pronounced exothermic effect at 390°C, which corresponds to ZrO_2 crystallization in Z sample, is also observed for a sample of the mechanical mixture, but is absent for ZAC50 sample and other synthesized samples containing calcium aluminates. The exothermic effect accompanying

** Trace amounts.

the crystallization of zirconium dioxide in the ZAC system is shifted to higher temperatures and extends over a wider temperature range. This effect may be superimposed by endothermic effects corresponding to decomposition of products formed in hydration of calcium aluminates. In particular, the derivatogram of ZAC50 sample shows a pronounced endothermic effect associated with calcium carbonate decomposition (770°C), with the related loss of mass being about 4 wt %. It is noteworthy that such a pronounced endothermic effect was observed in this temperature range neither for the mechanical mixture, nor for a separately dehydrated AC, for which the loss of mass in the temperature range 600–1000°C was about 1.5–2 wt %. This points to a higher degree of dehydration (and of subsequent carbonization in air) of calcium aluminates in ZAC50 sample, compared with AC and Z + AC samples, which may result from interaction of its starting components under the synthesis conditions.

Pronounced indications that calcium aluminates interact with hydrated zirconium oxide are observed in analysis of the phase composition of products formed in hydration of the starting calcium aluminates (Table 2) It is known [16, 17] that the contact of calcium monoaluminate $CaAl_2O_4$ and dialuminate $CaAl_4O_7$ with water and atmospheric CO_2 yields phases of $Ca_3Al_2(OH)_{12}$, $Al(OH)_3$, and calcium carboaluminate $Ca_4Al_2(OH)_{12}CO_3 \cdot 6H_2O$. It is these phases, and also residual amount of $CaAl_4O_7$, that were observed in an X-ray phase analysis of uncalcined AC and Z + AC samples, with $Al(OH)_3$ present in these samples only in the form of gibbsite. In contrast to the preceding samples, the phase composition of uncalcined ZAC50 includes, in addition to the X-ray-amorphous zirconium-containing phase, a considerable amount of $CaCO_3$ and $Al(OH)_3$, represented by two modifications, bayerite and gibbsite. For ZAC50 sample, the loss of mass (related to the endothermic effect at 270 and 280°C), associated with decomposition of aluminum hydroxide, was 12.6 wt %; for Z + AC sample (with the same content of calcium aluminates, it was about 7.5 wt %.

A comparison of the XPA and DTA data demonstrated that, in the set of ZAC samples studied, the fraction of phases of aluminum hydroxide (gibbsite and bayerite) and calcium carbonate (calcite and aragonite) steadily increases as the ZrO2 content of the system is raised to 50 wt %, i.e., the presence of hydrated zirconium oxide in the samples results in a higher degree of hydration of calcium aluminates under the synthesis conditions. This may occur via removal of Ca^{2+} and $Al(OH)_4^-$ ions appearing when calcium aluminates are brought in contact with water from the reaction zone on the particle surface, which stimulates continued hydration of calcium aluminates to give phases of $Al(OH)_3$ and $Ca(OH)_2$ converted in contact with atmospheric CO_2 into $CaCO_3$.

Analysis of the phase composition of samples calcined at different temperatures (Table 2) shows, together with the above changes in structural modifications of ZrO_2, certain differences in the composition of products formed in thermolysis of the aluminocalcium component of the system. For example, the main phases in AC sample in the temperature range 400–800°C are $CaAl_4O_7$ and $12CaO \cdot 7Al_2O_3$, and also a certain amount of γ-Al_2O_3 and $CaCO_3$. ZAC50 sample containes no $12CaO \cdot 7Al_2O_3$ phase and the best represented products of hydration and thermolysis of calcium aluminates were $CaCO_3$ and γ-Al_2O_3. Upon calcination at 1000°C, the composition of AC sample is primarily represented by phases of $CaAl_2O_4$ and $CaAl_4O_7$, with trace amounts of CaO and $Ca(OH)_2$. The same phases were also observed in ZAC90 sample. However, ZAV75 and ZAC50 samples calcined at 1000°C contain, in contrast to the preceding samples, $CaAl_4O_7$ and δ-Al_2O_3 phases.

Thus, unbound CaO is observed in the final products of AC thermolysis (1000°C), whereas ZAC samples, by contrast, contain unbound Al_2O_3. Apparently, in the case of AC sample, the fraction of $CaAl_4O_7$ increases as compared with that in the initial composition, and part of calcium remains "free," in the form of CaO (or $CaCO_3$). The presence of "excess" aluminum oxide in ZAC50 sample can be attributed, taking into account that $CaAl_4O_7$ is the only observed aluminocalcium phase, to removal of a part of calcium from the sphere of the possible reactions, e.g., in the stage of hydration. This fact, as well as the above indications of an increase in the degree of hydration of the starting aluminates in uncalcined ZAC samples, indicates that hydrated zirconium oxide is involved to a certain extent in the conversion of the aluminocalcium component of the system.

In the conditions of a close contact between the surface of particles of calcium aluminates and hydrated zirconium oxide (after the molding procedure) and presence of water, the components of the ZAC system interact at the solid–liquid–solid double interface. The fact that Ca^{2+} and $[Al(OH)_4]^-$ ions are present in the liquid phase as a result of dissolution of calcium aluminates enables their involvement in the interaction

with the surface of zirconium hydroxide. On the one hand, zirconium hydroxide has a certain ability to adsorb various cations and anions and, consequently, can remove a part of ions from solution, thereby stimulating further adddissolution of calcium aluminates. On the other hand, the surface of zirconium hydroxide particles can provide additional nucleation centers for the $Al(OH)_3$ and $Ca(OH)_2$ (eventually $CaCO_3$) phases being formed in the course of hydration. The formation of phases of this kind on the surface of zirconium hydroxide particles also stimulates continued dissolution of calcium aluminates and their deeper hydration. By contrast, hydration of calcium aluminates in AC sample occurs to give a surface layer of new hydrate formations on each grain [18]. These formations hinder diffusion and thereby restrict the degree of hydration of aluminocalcium cements.

The increase in the degree of hydration of calcium aluminates, which leads to a rise in the content of hydration products, favors development of the surface of the material, and this does occur in samples of the ZAC system, with the maximum values of this parameter obtained for ZAC50 sample (Fig. 3).The specific surface area of AC sample calcined at 400°C is 88 $m^2 g^{-1}$, whereas ZAC50 sample is characterized under the same conditions by a specific surface area of 228 $m^2 g^{-1}$.

As a result of the interaction in the ZAC system, zirconium hydroxide can apparently be enriched in calcium and aluminum cations both via sorption in the initial stage of hydration and via formation on the surface of its particles of aluminum and calcium hydroxide phases, which are converted in subsequent thermolysis into the corresponding oxides, with –Zr–O–Al– and –Zr–O–Ca– bonds formed in the boundary region. Also, it is not improbable that hydrated zirconium oxide can be partly reprecipitated under the synthesis conditions, with incorporation of calcium and aluminum cations present in the reaction system. The considerable increase in the ZrO_2 crystallization point, observed in ZAC samples, and the stabilization of its tetragonal phase at high calcination temperatures may result from modification by Ca^{2+} and Al^{3+} cations of the structure of zirconium dioxide being formed. The increase in the disprosity of ZrO_2 can also be attributed to the influence of this factor.

Determination of the CSR size demonstrated (Fig. 4) that crystallites of the tetragonal ZrO_2 phase in ZAC samples at calcination temperatures in the range 600–800°C are noticeably smaller in size (6–12 nm) than those in Z sample (13–24 nm) used as a starting component in synthesis of the ZAC system.

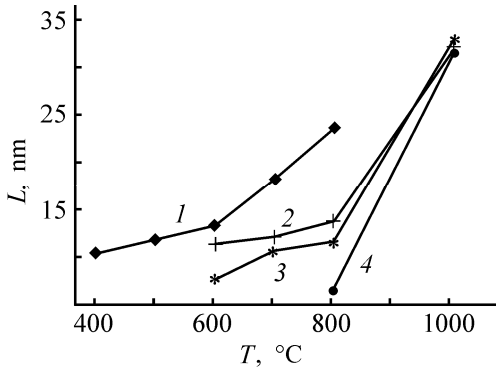

Fig. 4. CSR size L for the tetragonal ZrO_2 phase vs. the sample calcination temperature T. Sample: (*1*) Z, (*2*) ZAC25, (*3*) ZAC50, and (*4*) ZAC75.

The interaction of calcium aluminates and zirconium hydroxide under the synthesis conditions affects both the phase composition and texture characteristics of the samples obtained. It can be seen from the data in Table 3 that the pore volume increases with the ZrO_2 content of the system and reaches the maximum value (0.19 $cm^3 g^{-1}$) for ZAC50 sample. In this case, the pore size distribution markedly changes (Fig. 5). In contrast to the starting Z sample, whose pores are mostly distributed within the range 2–20 nm, ZAC samples show a considerable increase in the volume of the narrowest pores (2–3 nm) and a certain increase in that of coarse pores. The average pore diameter tended to steadily decrease as the ZrO_2 content of the ZAC system increased (from 0 to 50 wt %) and reached the maximum value for ZAC50 sample (3.36 nm), so that this sample differed in all the parameters presented above from the texture characteristics of hydrated zirconium oxide (Z) and calcium aluminates (AC), which are the starting components of the system synthesized. It is noteworthy

* Data for a sample calcined at 400°C, without treatment with acetic acid.

that, because of the low content of calcium aluminates, ZAC25 sample had a mechanical strength insufficient for further study of its characteristics.

Molded grains of the samples, calcined at 400°C, were treated with an aqueous solution of acetic acid, which resulted in a 1.3–1.6-fold increase in their specific surface area (Table 3). The total pore volume of the samples increased by 20–60%. The pore size distribution preserved a bimodal shape characteristic of calcium aluminates, with the exception of ZAC50 sample, in which pores with a diameter exceeding 100 nm appeared and the volume of 2–3-nm pores decreased. The changes in the texture characteristics of the samples upon their treatment with acetic acid are due to partial dissolution of products formed in hydration of calcium aluminates. According to XPA data, the content of $CaCO_3$ and γ-Al_2O_3 phases decreased in all the samples and $12CaO \cdot 7Al_2O_3$ completely disappeared from AC and ZAC90 samples, which provided the most pronounced increase in their specific surface area and pore volume (by 60%).

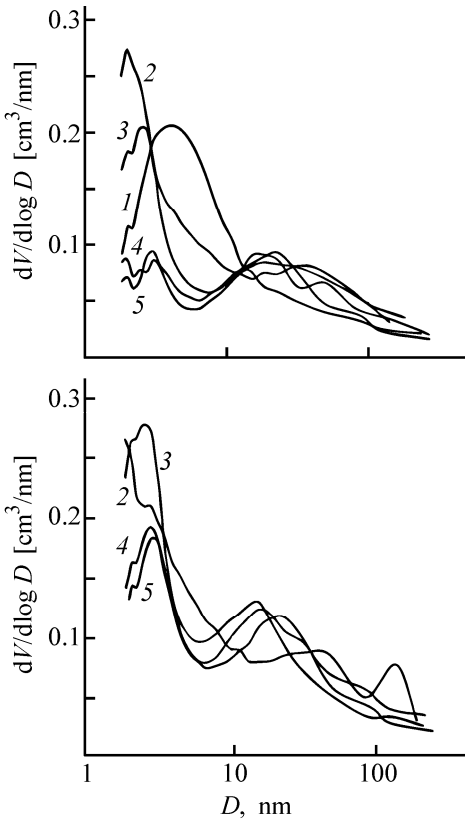

Fig. 5. Pore size distribution for samples calcined at 400°C (a) untreated and (b) treated with 20% CH_3COOH. (*V*) Pore volume and (*D*) pore size. Sample: (*1*) Z, (*2*) ZAC50, (*3*) ZAC75, (*4*) ZAC90, and (*5*) AC.

A study by the TPD NH_3 method demonstrated that the acid properties of the surface of the samples synthesized in the ZAC system and treated with acetic acid markedly differ from the surface properties of the individually synthesized zirconium dioxide (Fig. 6). As follows from the data of [13], ZrO_2 has strong acid centers, to which correspond two high-temperature desorption peaks peaked at 490 and 580°C, and a certain amount of weak acid centers manifested in ammonia desorption in the temperature range 100–400°C. For all the zirconium-containing aluminocalcium samples, the peak at 490°C, which has the highest intensity among those characteristic of ZrO_2, was completely absent in thermal desorption curves, whereas the other high-temperature peak shifted to higher temperatures (600–640°C). At the same time, the intensity of the desorption peaks in the low-temperature region, related to weak acid centers, substantially increased. According to the data obtained (Table 3), the total number of acid centers increased in the set of ZAC samples with the fraction of ZrO_2; the density of acid centers was the highest for ZAC50 and ZAC75 samples. As shown in [19], weak and medium acid centers play a key role in methanol dehydration to dimethyl ether, which suggests that the zirconium-aluminocalcium materials under consideration should exhibit a high activity and selectivity toward dimethyl ether.

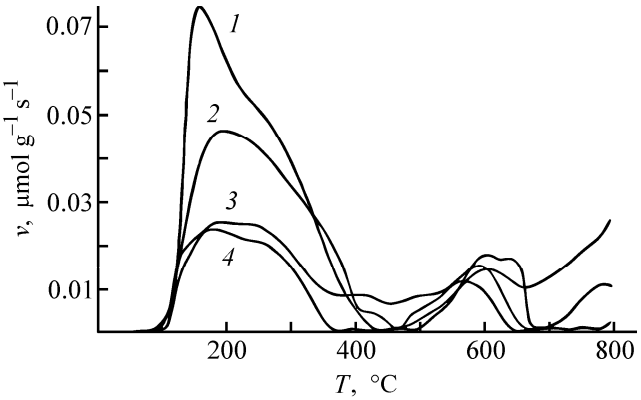

Fig. 6. Results of TPD NH_3 for samples calcined at 400°C and treated with CH_3COOH. (*v*) NH_3 desorption rate and (*T*) temperature. (*1*) ZAC50, (*2*) ZAC75, (*3*) AC, and (*4*) ZAC90.

The catalytic properties of the ZAC samples were studied in methanol dehydration. ZAC50 and ZAC75 samples exhibited an activity comparable with that of γ-Al_2O_3, successfully used in this process, and surpassed it in selectivity toward dimethyl ether.

CONCLUSIONS

(1) Materials containing nanosize zirconium dioxide stabilized in low-temperature phases, amorphous and tetragonal, were obtained using calcium aluminates. The fact that the zirconium–aluminocalcium system contains amorphous ZrO_2 up to calcination temperatures of 500–600°C and tetragonal ZrO_2 in the temperature range 600–1000°C was attributed to modification of the zirconium dioxide structure by Ca^{2+} and Al^{3+} cations. It was shown that hydrated zirconium oxide interacts with calcium aluminates in the stage of their hydration in a wide range of component ratios.

(2) It was found that the texture characteristics and acid properties of the surface of the materials synthesized are controlled by the component ratio. The largest pore volume and specific surface area are observed for a system containing 50 wt % ZrO_2. The system with 25 wt % ZrO_2 has the maximum density of acid centers.

(3) It was shown that the materials synthesized can find use as supports and catalysts. Tests of these materials in methanol dehydration demonstrated that their use as catalysts for synthesis of dimethyl ether is promising.

Abstract—Stability of $(NH_4)_2SO_4 \cdot H_2O_2$ aqueous solutions and some structural changes in ammonium sulfate in the course of its solvation and subsequent desolvation were studied.

DOI: 10.1134/S1070427208120057

The ability of ammonium sulfate to be solvated by hydrogen peroxide was first mentioned in [1]. The composition of the peroxo solvate was found by studying the solubility of ammonium sulfate in anhydrous hydrogen peroxide and by determining the H_2O_2 content of the solid phase being crystallized [2]. In [3], the optimal conditions of synthesis, stabilization, and storage of ammonium sulfate monoperoxo solvate were reported, which provide that the sulfate retains hydrogen peroxide for more than 100 days. The fact that efficient stabilizers have been found among chemical compounds of various classes for other peroxo solvates [2] suggests that the stable state of $(NH_4)_2SO_4 \cdot H_2O_2$ can be substantially prolonged.

Ammonium sulfate peroxo solvate combines in itself an effective nitrogen fertilizer and a disinfectant in the form of coordinated hydrogen peroxide. Practical use of this compound in general disinfection science, plant growing, and, possibly, other fields requires data on its solubility and stability in aqueous solutions, because, apparently, a dry preparation is less suitable for these purposes.

This communication reports on study of the solubility and stability of $(NH_4)_2SO_4 \cdot H_2O_2$ aqueous solutions. In separate experiments, we examined precipitation of ammonium sulfate, whose X-ray diffraction patterns markedly differ in line intensity from those of the starting sulfate.

EXPERIMENTAL

Ammonium sulfate peroxo solvate was synthesized using sodium diphosphate as stabilizer [3]. Solutions for study (nearly saturated) were prepared by gradual addition of a dry solvate to water until there appeared indications of turbidity. After 24 h of keeping, no precipitate was observed. The thus obtained solutions, both undiluted and diluted to appropriate concentrations, were kept in closed polymeric containers at 20 ± 2°C. At regular intervals of time, the solutions were analyzed for the content of hydrogen peroxide by permanganatometric titration. The decomposition rate constants were calculated by the equation

$$\ln c_0/c = k(\tau - \tau_0).$$

The precipitates formed during storage of the solutions were removed, squeezed between two sheets of a filter paper, dried in air, analyzed for the content of H_2O_2, and subjected to X-ray diffraction analysis.

The X-ray diffraction patterns of powders were recorded on an ADP-2-01 diffractometer (CuK_α radiation, Ni filter) using the software for automation of data acquisition, processing, and analysis, developed for DRON X-ray diffractometers.

The values of the solubility and stability of $(NH_4)_2SO_4 \cdot H_2O_2$ in water are listed in Table 1.

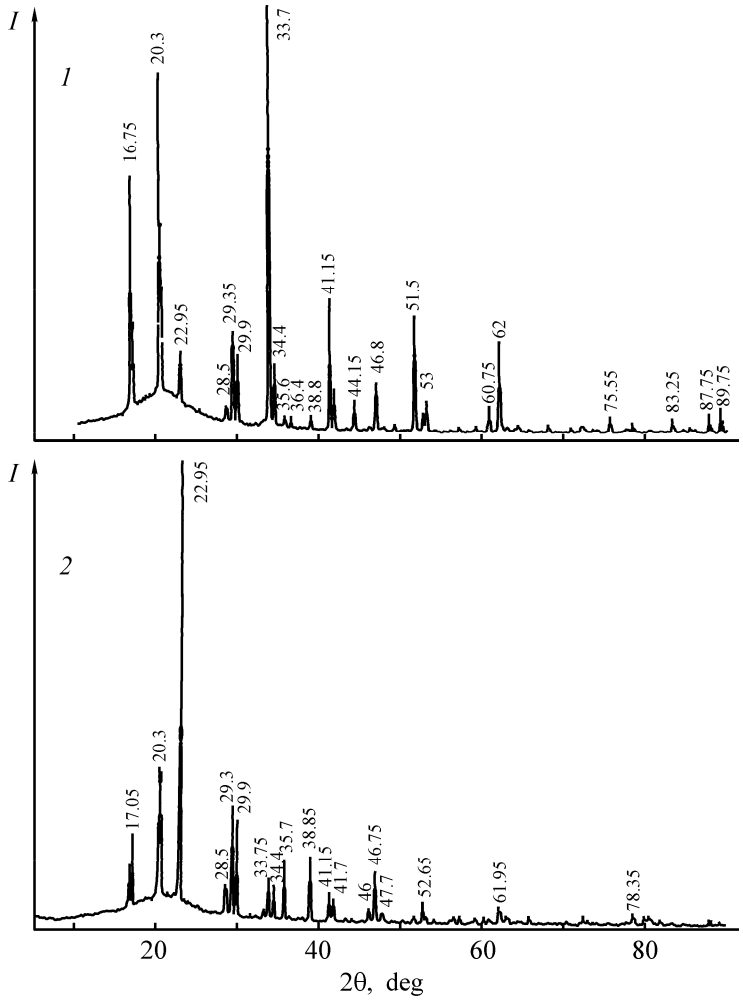
As can be seen from Table 1, the decomposition of hydrogen peroxide occurs uniformly at an initial H_2O_2 concentration of 8.24% in solution at an average constant rate $k = 2.7 \pm 1.5$, which corresponds to 40.2% $(NH_4)_2SO_4 \cdot H_2O_2$, with 36.2% loss of H_2O_2 relative to the starting solution. The content of hydrogen peroxide remaining in solution is 5.34%, which makes it suitable for further use. Similar results were also obtained for a solution containing 4.66% H_2O_2.

However, the following deviation was found in a solution containing 2.51% H_2O_2. After 9 days of storage, a hardly noticeable precipitation of crystals from solution commenced, with the H_2O_2 concentration increasing from 1.96% (in 9 days) to 2.48% (in 30 days). In further storage of the solution, the amount of the precipitate became lower and the H_2O_2 concentration gradually decreased. These data were the reason why the experiments were repeated.

We prepared the second set of solutions containing 9.57 and 3.89% H_2O_2. In a solution containing 9.57% H_2O_2, the concentration of H_2O_2 started to gradually increase from the first days of storage (Table 2) and a precipitate containing 1.02% H_2O_2 was formed in 8 days. In the second solution, the hydrogen peroxide concentration also increased and a precipitate containing 1.07% H_2O_2 was formed after 8 days of storage. No other outward changes (intense gas evolution, change of solution color) were observed. The content of SO_4^{2-} in the precipitate was 71.4%, and that of NH_4^+, 26.9%. For $(NH_4)_2SO_4$, values of 72.7% and 27.3%, respectively, were calculated. Apparently, ammonium sulfate was precipitated.

The content of $(NH_4)_2SO_4$ in the first starting solution was 37.2% in terms of hydrogen peroxide. Thus, the amount of the liquid phase was (100 – 37.2)% = 62.8%. Taking into account that the solution contains 5.34% H_2O_2, the content of the aqueous solution of hydrogen peroxide is 62.8% per 37.2% ammonium sulfate.

The solubility of $(NH_4)_2SO_4$ in water is 70.1 g per 100 g water at 0°C [4] and that in anhydrous H_2O_2 at 0°C, 70.4% [2].



It seems unlikely that an unchanged ammonium sulfate precipitated in the initial state at such a high solubility in water and hydrogen peroxide. Because no outward changes in the system $(NH_4)_2SO_4 \cdot H_2O_2$–solvent were revealed, it is natural to suggest that ammonium sulfate precipitated in another crystalline form, which is less soluble in aqueous hydrogen peroxide.

X-ray diffraction patterns of $(NH_4)SO_4$. (*I*) Intensity and (2θ) Bragg angle. (*1*) Starting sample, (*2*) Precipitate.

The results of an X-ray phase analysis demonstrate that, being identical to the starting ammonium sulfate in interplanar spacings *d*, the precipitated $(NH_4)_2SO_4$ sharply differs in relative reflection intensities I_{rel} (see figure). Therefore, the precipitate cannot be identified as the known ammonium sulfate. At the same time, it was already mentioned that the sets of interplanar spacings for these compounds are the same, which demonstrates that their lattices are identical. The unexpectedly strong differences in the relative intensities of the X-ray reflections of the starting ammonium sulfate and the precipitate initiated measurements of X-ray diffraction patterns of all the precipitates. It was shown (Table 3) that the differences we observed cannot be accounted for by measurement errors. It should be accepted as established facts that (i) the precipitate retains the unit of the starting ammonium sulfate and (ii) the lattice cell undergoes a structural change and this rearrangement is preserved upon decomposition of hydrogen peroxide. The results obtained suggest that, under the action of solvation and subsequent desolvation of hydrogen peroxide, the arrangement of atoms in the unit cell of $(NH_4)_2SO_4$ changes and differs from that in the unit cell of the known ammonium sulfate.

New α-form		β-form		β-form		β-form	

It should be noted that, when coordinated to certain salts, e.g., to KF, hydrogen peroxide itself undergoes the following transformation: the H–O bond forms an acute angle with the O–O bonds, which confirms the formation of an intramolecular hydrogen bond [5]. It can be suggested that, in the given case too, the change in positions of atoms in the bound H_2O_2 molecule results in displacement of other atoms within the unit cell and this rearrangement is retained after the decomposition of hydrogen peroxide, i.e., ammonium sulfate is converted to another form. It is impossible to give without additional structural studies any other explanation for the decrease in the solubility of ammonium sulfate in aqueous hydrogen peroxide, apart from the gradual conversion $(NH_4)_2SO_4(\alpha) \rightarrow (NH_4)_2SO_4(\beta)$.

The $(NH_4)_2SO_4(\alpha) \rightarrow (NH_4)_2SO_4(\beta)$ conversion and precipitation of the less soluble β-form of ammonium sulfate can be represented by the following sequence of reactions:

$$(NH_4)_2SO_4(\alpha) + H_2O_2 \rightarrow (NH_4)_2SO_4 \cdot H_2O_2, \quad (1)$$

$$(NH_4)_2SO_4 \cdot H_2O_2 + H_2O \rightarrow 2NH_4^+ + [SO_4 \cdot H_2O_2]^{2-}, \quad (2)$$

$$[SO_4 \cdot H_2O_2]^{2-} \rightarrow SO_4^{2-} + H_2O_2, \quad (3)$$

$$SO_4^{2-} + 2NH_4^+ = (NH_4)_2SO_4(\beta)\ \text{(precipitate)}. \quad (4)$$

The degree of conversion of the soluble $(NH_4)_2SO_4 \cdot H_2O_2$ into a less soluble $(NH_4)SO_4(\beta)$ is determined by the equilibrium of reaction (3), i.e., by the degree of dissociation of $[SO_4 \cdot H_2O_2]^{2-}$ anion with release of the SO_4^{2-} ion. It has been shown previously [6] that potassium fluoride peroxo solvate dissociates in aqueous solution with partial preservation of the solvated $[F...H_2O_2]^-$ ion, i.e., there exists the equilibrium

$$2KF \cdot H_2O_2 = 2K^+ + F^- + [F...H_2O_2]^- + H_2O_2. \quad (5)$$

Therefore, with account of the fact that solvated $[A...H_2O_2]^-$ ions are preserved in peroxo solvate aqueous solutions, we have that a difficultly soluble $(NH_4)SO_4(\beta)$ is precipitated when the equilibrium of reaction (3) is shifted to the right, and the soluble form, $(NH_4)_2SO_4 \cdot H_2O_2$, is preserved in the solution when the equilibrium of reaction (3) is shifted to the left. Reasons for such shifts of the equilibrium of reaction (3) remain unclear.

The suggested polymorphic conversion of ammonium sulfate, which occurs as a consequence of the coordination and subsequent release of hydrogen peroxide, is not the only example of the above conversion.

It has been shown previously [7] that another compound, potassium fluoride, undergoes a more pronounced polymorphic transformation under the action of hydrogen peroxide. It was found that, if the desolvation of $KF \cdot H_2O_2$ occurs slowly (during about a year at 20°C), the X-ray diffraction pattern is a set of bands associated with $KF \cdot 2H_2O$ formed by the reaction $2KF \cdot H_2O_2 = KF + KF \cdot 2H_2O + O_2$ and a set of bands that does not coincide with published data for KF [8] and with our data for anhydrous potassium fluoride obtained by dehydration of $KF \cdot 2H_2O_2$ or by heating of α-KF to 100–140°C (Table 4).

Table 5. Relative intensities I_{rel} of $(NH_4)_2SO_4$ precipitates at various temperatures

d, Å		I_{rel} for a chosen d					
$(NH_4)_2SO_4$	precipitate	$(NH_4)_2SO_4$ at 20°C	precipitate				Average I_{rel}
			20°C	46°C	100°C	180°C	
5.193	5.200	55	13	10	16	4	11 ± 3
4.375	4.375	76	35	22	40	17	28 ± 9
3.875	3.875	12	100	100	100	100	100 ± 0
2.659	2.656	100	14	11	11	8	11 ± 1

In this case, however, other values are observed not only for the relative intensities, but for the interplanar spacings as well. The low-temperature form, α-KF, obtained in $KF \cdot H_2O_2$ decomposition upon prolonged storage (at 20°C), is transformed to its common β-form at 100–140°C (Table 4). In the case of ammonium sulfate, the crystallographic change in I_{rel} in the precipitated sulfate is also preserved in the sulfate at higher temperatures (Table 5).

The results of this study can be understood on the assumption that hydrogen peroxide can change the structure of a solvated compound.

CONCLUSIONS

(1) Aqueous solutions of $(NH_4)_2SO_4 \cdot H_2O_2$ are rather stable in a wide range of concentrations, up to 40.2%. Such solutions containing simultaneously a fertilizing soil and disinfecting components, can be used first of all in plant growing. Owing to the full ecological safety, they are also suitable for use in general disinfection.

(2) In some cases, $(NH_4)_2SO_4$ precipitates from solution. According to tentative results of an X-ray phase analysis, this is due to the $(NH_4)_2SO_4(\alpha) \rightarrow (NH_4)_2SO_4(\beta)$ phase transition that occurs under the influence of the solvation and subsequent desolvation of the sulfate. In this case, $(NH_4)_2SO_4(\beta)$ less soluble in hydrogen peroxide is precipitated.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Extraction of Sulfuric and Hydrochloric Acids with Macromolecular Aliphatic Alcohols of Varied Structure

A. G. Kasikov and A. M. Petrova

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Resources, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received June 18, 2008

Abstract—Extraction of HCl and H_2SO_4 with isomers of monoatomic aliphatic alcohols C_7–C_{10} was studied. The distribution coefficients of the acids were determined in relation to their concentration in the system, length of the hydrocarbon chain of an aliphatic alcohol, and nature of an acid being extracted. It was found that the alcohol nature affects the rate of phase stratification in aqueous re-extraction of the acids.

DOI: 10.1134/S1070427208120069

Aliphatic alcohols containing 7–10 carbon atoms in the chain are a promising type of industrial oxygen-containing extractive agents that can selectively recover some elements from acid solutions with a complex salt composition [1]. There are data on application of extractive agents of the class of aliphatic alcohols to recovery of rare (Nb, Ta, Re), platinum, and noble metals (Au, Os, Ru), and also arsenic, iron, vanadium, and some other elements [1]. In extraction with aliphatic alcohols from solutions of acids, there occurs, in addition to the recovery of the target component, co-extraction of a mineral acid, and this process noticeably affects the extraction of an element. Therefore, studying the extraction of mineral acids with various aliphatic alcohols is a topical task.

By now, a considerable body of data on extraction of inorganic acids with aliphatic alcohols has been accumulated [1–14]. First reports in this field appeared in the country in the early 1960s and were devoted to analysis of the extractive properties of low-molecular-weight alcohols (amyl, butyl) [2–5], which are for the most part applicable in analytical practice. Later, researchers focused attention on higher-molecular-weight aliphatic alcohols (C_7–C_{11}) because of the possibility of their use in the technological process [6–14]. In particular, an extractive method for recovery of sulfuric acid from solutions produced at copper-nickel shops, with octanols used as extractive agents, have been developed and tested on the laboratory scale in recent years [12–14].

Most of studies failed to pay due attention to the influence exerted by the structure of aliphatic alcohols on their extracting capacity toward acids, although it is known that their extracting capacity toward some complex metalloacids strongly depends on the position of the hydroxy group [15–19]. The present study is concerned with the influence exerted by the structure of aliphatic alcohols C_7–C_{10} on the extraction of sulfuric and hydrochloric acids.

EXPERIMENTAL

As extractive agents were used higher aliphatic alcohols of domestic manufacture: 1-heptanol, 4-heptanol, 1-octanol, 2-*DL*-octanol, 1-nonanol, 2-nonanol, 4-nonanol, 1-decanol, 4-decanol, and 5-decanol of pure grade, and of foreign made: 2-heptanol and 3-heptanol of "Purum, ≥99.0% (GC)" grade and 3-octanol of "97.8 %, for synthesis" grade without additional dilution. Model acid solutions were prepared using HCl and H_2SO_4 of chemically pure grade.

The acids were extracted from their individual solutions in 0.05-l volumetric cylinders with a ground stopper at o : w = 1 : 1 and manual shaking for 5 min, which is sufficient for equilibrium to be attained in alcohol–HCl and alcohol–H_2SO_4 systems. The extraction was performed at room temperature (18 ± 2°C), and the phase stratification, with thermostating at 20 ± 1°C for 10–20 min. Experiments devoted to the effect of temperature on the extraction of acids were carried out

in a thermostated 0.25-l round-bottomed flask with a mechanical stirrer.

The acid concentrations in aqueous solutions were determined by titrimetry in the presence of phenolphthalein. The acid concentrations in the organic phase were calculated from the difference between their contents in the aqueous phase before and after extraction, with account of changes in the phase volumes. The distribution coefficients were calculated by the formula

$$D_{HX} = [c_{HX}]_{org}/[c_{HX}]_{aq}.$$

The table lists the distribution coefficients of H_2SO_4 and HCl in extraction from 3 and 6 M solutions of the acids, and Figs. 1 and 2 show extraction isotherms of these acids with isomers of aliphatic alcohols C_7–C_{10}. As can be seen in Figs. 1 and 2, the distribution curves of both acids ascend for all the alcohols studied as the acid concentration in the system becomes higher. This is natural because the extraction of

HCl and H_2SO_4 with aliphatic alcohols occurs by the hydrate-solvate mechanism [5, 9], which can be represented in the general form by the scheme

$$mH_3O^+ + nH_2O + qS_o + X^{m-} = [(H_3O^+)_m \cdot (H_2O)_n \cdot qS_o]^{m+}X^{m-},$$

where X^{m-} is the anion of an acid being extracted, and S_o, molecule of the extractive agent in the organic phase.

Apparently, in accordance with the scheme, any increase in the concentration $[H_3O^+]$ in the aqueous phase will favor a shift of the equilibrium to the right.

The extraction isotherms of HCl and H_2SO_4 with secondary and primary isomers of aliphatic alcohols with the same molecular mass differ only slightly, although the distribution coefficients in extraction of microscopic amounts (~10^{-3} M) of some elements with isomers of octyl alcohol on the background of these acids differ severalfold [15–19]. In all cases, the primary alcohols extract acids somewhat better than do secondary alcohols, despite the higher basicity of the latter [20]. Probably, the key role in the extraction of acids from rather concentrated solutions (>1 M) is played by steric hindrances that diminish the distribution coefficients in extraction with secondary alcohols whose functional group is less accessible than the OH group of primary alcohols.

As the molecular mass of the extractive agent increases, the extraction of the acids, on the whole, somewhat decreases because of the "hydrocarbon dilution effect" [7]. However, the decrease in the distribution coefficients of H_2SO_4 and HCl in the series $C_7 \rightarrow C_{10}$ is insignificant, and in some cases, this kind of behavior is not observed at all (see table). The latter presumably occurs because, as the hydrocarbon radical becomes longer, the polarity of an alcohol and its capacity for self-association decrease, and, accordingly, the number of active functional groups in the phase of the extractive agent increases [7], which partly compensates for the hydrocarbon dilution effect.

As already noted, the extraction of HCl and H_2SO_4 with aliphatic alcohols depends on the acid concentration in the system, with this dependence being pronounced for H_2SO_4. For example, HCl is extracted noticeably better than H_2SO_4 at a low acidity, and the distribution coefficients of the acids become comparable at a high acidity. Thus, the structure of aliphatic alcohol more strongly affects the extraction of H_2SO_4, compared with HCl, which is presumably due to specific forms of existence of the acids in solutions. Hydrochloric acid is a strong monobasic acid ($pK_a \approx -7$); in an aqueous solution, it is nearly completely dissociated and contains only hydrated ions H_3O^+ and Cl^- at any acidity. Sulfuric acid is weaker and, moreover, dibasic. HSO_4^- and SO_4^{2-} ions are present in sulfuric

acid solutions, with their relative amounts dependent on the acid concentration in solution [21]. At $c_{H_2SO_4}$ < 5–6 M, the equilibrium concentrations of HSO_4^- and SO_4^{2-} are comparable; as, however, $c_{H_2SO_4}$ increases further, HSO_4^- becomes the predominant species in solution [21]. Different ionic forms of sulfuric acid are differently extracted with aliphatic alcohols. It has been found previously that doubly charged anions are considerably more poorly extracted with alcohols, compared with those singly charged [18, 19]. Thus, the small distribution coefficients of H_2SO_4 in weakly acidic and moderately concentrated solutions can be attributed to a low concentration of the well-extractable HSO_4^- anion, as well as to the insignificant extraction of the doubly charged SO_4^{2-} anion. The higher values of $D_{H_2SO_4}$ in strongly acidic solutions, which occasionally even exceed D_{HCl}, are associated with the extraction of the singly charged HSO_4^- anion.

In addition to the aforesaid, the extraction isotherms of H_2SO_4 have a specific feature: at H_2SO_4 concentrations exceeding 4 M, the experimental values in the isotherm strongly fluctuate, which leads to considerable deviations of the corresponding points from the approximating line. Presumably, this is due to the variable composition of hydrate-solvate complexes formed in the organic phase; these complexes can contain both HSO_4^- and other ionic forms of H_2SO_4 present in strongly acid solutions. The content of water and alcohol in the complex may vary with the form being extracted, which also affects the extraction equilibrium. In addition, there are data on chemical transformations of an alcohol in extraction of H_2SO_4 [11]. An IR spectral study of sulfuric acid octanol extracts containing up to 0.9 M H_2SO_4 demonstrated that the intensity of the peak associated with the hydroxy group decreases,

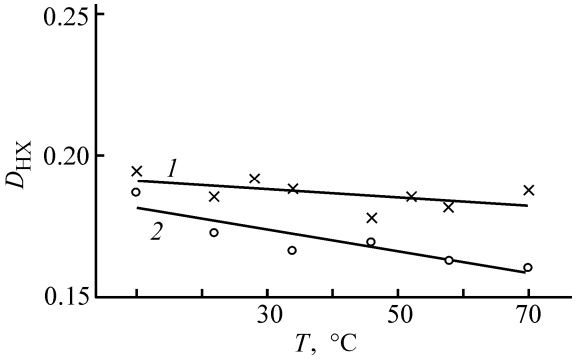

Fig. 3. Effect of temperature T on the distribution coefficients D_{HX} of sulfuric and hydrochloric acids in extraction with 2-octanol from 6.0 M solutions of the acids. (*1*) H_2SO_4, (*2*) HCl.

which is probably due to partial esterification of the alcohol to give unstable fatty alcohol sulfates, whose extracting properties differ from those of alcohols.

The effect of temperature on the extraction with aliphatic alcohols was studied for the example of H_2SO_4 and HCl recovery with 2-octanol from 6 M solutions of the acids. It follows from Fig. 3 that, for both acids, an increase in temperature leads to a certain decrease in the distribution coefficients, although the thermodynamic distribution constant is temperature-independent [6]. The authors of [6] attribute this dependence to a decrease in the degree of acid hydration in the organic phase, observed as temperature is elevated.

HCl and H_2SO_4 can be readily re-extracted from the phase of an aliphatic alcohol with distilled water. In doing so, more than 99% of an acid contained in extracts is recovered in a single stage at o : w = 1 : 1 for all the alcohols considered. It should, however, be noted that the phase stratification becomes poorer in re-extraction from extracts that are based on primary aliphatic alcohols and are concentrated in acid, as the chain length increases. For example, in re-extraction from 1-heptanol and 1-octanol containing 1.5–2 M HCl or H_2SO_4, the aqueous–organic mixture stratifies in 3–5 min, whereas in the case of concentrated acid extracts based on 1-nonanol and 1-decanol and shaking with distilled water for 5 min, the mixture turns cream-like and stratifies in 10–30 min (C_9) or in several hours (C_{10}). The stratification time depends on the type of an acid: systems containing H_2SO_4 stratify in a considerably longer time, compared with HCl. Probably, this phenomenon is due to formation of unstable solid acid-containing hydrate-solvate associates with emulsifying properties in the phase of the extractive agent upon introduction of H_2O into the extract.

In re-extraction of acids from secondary alcohols, 5–10 min was sufficient for stratification of aqueous-organic mixtures in all cases. Emulsification in re-extraction of acids with water is not characteristic of secondary aliphatic alcohols C_9–C_{10}, presumably because of their lower capacity for self-association.

CONCLUSIONS

(1) In extraction of HCl and H_2SO_4 with primary and secondary aliphatic alcohols of the C_7–C_{10} series, the extraction of HCl and H_2SO_4 mostly increases as the hydrocarbon chain becomes shorter and the concentration of the acids in the aqueous phase grows,

with the primary aliphatic alcohols extracting the acids somewhat better than secondary alcohols do.

(2) An increase in the process temperature in extraction of HCl and H_2SO_4 leads to a decrease in the distribution coefficients of the acids.

(3) Deep re-extraction of the acids from the organic phase is provided by water, with the degree of extraction in a single stage being no less than 99% at o : w = 1 : 1 in all cases.

(4) In aqueous re-extraction from concentrated extracts (1.5–2 M H_2SO_4 or HCl) based on primary alcohols, the phase stratification becomes poorer as the molecular mass of the extractive agent increases, which is not characteristic of acid extracts based on secondary alcohols.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Extractive Recovery of Gallium(III) from Acid Sulfate Solutions with Primary Amines

A. A. Geidarov

Institute of Chemical Problems, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

Received January 29, 2008

Abstract—Liquid extraction of Ga(III) ions with technical-grade aliphatic amines from sulfate media at a temperature of 20 ± 5°C was studied. The composition of the complex being extracted was determined and the equation of the reaction of Ga(III) extraction with primary amines was derived. The equilibrium constant of the reaction of gallium(III) extraction from acid sulfate solutions was found.

DOI: 10.1134/S1070427208120070

Gallium(III) is a typical scattered element and its concentration in raw materials and technological industrial products from which gallium compounds are recovered is low. Therefore, a key task of the gallium (III) technology is its primary recovery and concentration. A successful solution of this problem should be promoted by wide introduction of extractive and sorption processes previously employed for recovery, concentration, and purification of numerous rare and nonferrous metals [1–4] into the chemical technology of gallium(III). Despite that the number of studies devoted to extraction of gallium(III) is sufficient, they are mostly concerned with its recovery from alkaline media [5] and chloride solutions [6]. Information about extraction of gallium(III) from neutral and acid sulfate solutions is rather scarce. The possibility of using aliphatic amines for extraction of gallium(III) was described in [1, 2, 6–10]. Gallium(III) is recovered from acid chloride solutions via the reaction of $GaCl_4^-$ anions with the ammonium cation:

$$RNH^+_{3org} + GaCl^-_{4aq} \rightarrow RNH_3GaCl_{4org}.$$

The possibility of gallium(III) recovery from sulfate solutions with primary, secondary, and tertiary alkylamines in chloroform was first described by Shevchuk [10]. It was shown that gallium(III) can exist in the organic phase as acido complexes [$Ga(SO_4)_2^-$, $Ga(SO_4)_3^{3-}$, $Ga(SO_4)_4^{5-}$] and chloroform solutions of di-*n*-ionylamine and tri-*n*-octylamine hardly extract gallium(III) at all from acid sulfate solutions.

This communication reports on a study of the extraction of gallium(III) ions from sulfate solutions with technical-grade primary aliphatic amines.

EXPERIMENTAL

We carried out the study with the use of technical-grade mixture of primary aliphatic amines (ANPO) produced from liquid paraffins of general formula

$$CH_3(CH_2)_m—\underset{\displaystyle NH_2}{\underset{|}{CH}}—(CH_2)_n—CH_3,$$

where $m + n$ = 10 to 16 carbon atoms, manufactured by Deneprodzerzhinsk chemical combine; bp = 240–345°C, extractive agent density 0.899 g cm^{-3}, refractive index 1.51, average molecular mass 185 g mol^{-1}. Burning kerosene served as a diluent.

Our preliminary experiments demonstrated that a 5-min mixing with aqueous and organic phases by shaking is sufficient for equilibrium to be attained. The complete phase stratification is achieved in 1–3 min. The phase ratio was $V_o : V_w = 1 : 2$ in all the experiments. The content of gallium(III) in the aqueous and organic phases was found by photocolorimetry [11], and the concentration of sulfate ions in equilibrium organic phases, by gravimetry, in the form of $BaSO_4$.

We prepared the starting aqueous Ga-containing solutions [Ga(III) = 7.2×10^{-4} M] from $Ga_2(SO_4)_3 \cdot 18H_2O$ produced using the method described in [11].

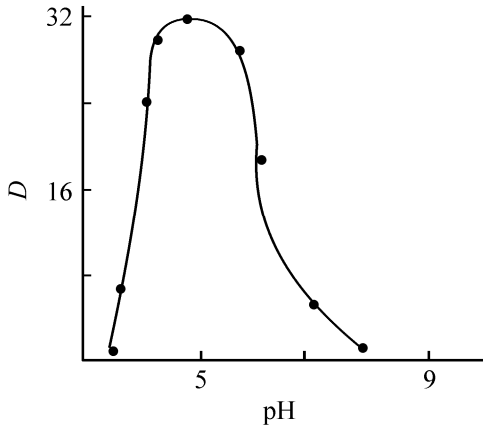

Fig. 1. Effect of the acidity of the aqueous phase on the extraction of gallium(III) ions with a 0.5 M solution of ANPO in kerosene. $c_{Ga} = 7.2 \times 10^{-4}$ M; the same for Fig. 3. (*D*) Gallium(III) distribution coefficient.

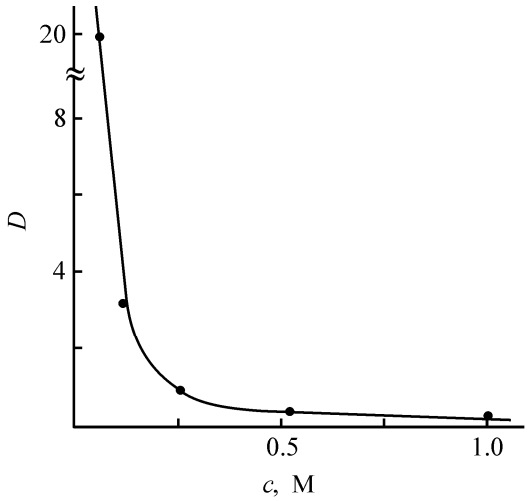

Fig. 2. Gallium(III) distribution coefficient *D* vs. H_2SO_4 concentration *c* in solution.

For this purpose, an appropriate weighed portion was dissolved under heating in water and then the solution was acidified to a required pH. IR spectra were recorded with a Specord 75-IR spectrometer in the range 400–4000 cm^{-1}.

The acidity of the aqueous phase most strongly affects the degree of gallium(III) recovery with a primary aliphatic amine (Fig. 1). It follows from the results obtained that the maximum extraction of Ga(III) ions lies in the weakly acid, nearly neutral region (pH 4–6). The maximum recovery of gallium(III), with a distribution coefficient of about 32, is observed at pH ~4.8.

In the extraction, the amine reacts with sulfuric acid in accordance with the equation $2RNH_2 + H_2SO_4 \rightarrow (RNH_3)_2SO_4$. The salt formed is distributed among the aqueous and organic phases. To study the extraction of gallium(III) from aqueous solutions, we examined the distribution of the amine salt among the aqueous and organic phases in relation to the sulfuric acid concentration. The experiments demonstrated that the ammonium salt is almost insoluble in kerosene.

Further, we studied the effect of the sulfuric acid concentration on the extraction of gallium(III) from aqueous solutions with a primary amine. It can be seen from Fig. 2 that the maximum distribution constant is observed at an H_2SO_4 concentration of 0.05 M in the starting solution. As the sulfuric acid concentration increases, the distribution coefficient of gallium(III) steeply decreases. The possible reason is that, as a result of appearance of an excess amount of sulfuric acid, H_2SO_4 is bound with ammonium ions and displaces the anion from the organic phase via competitive extraction. Ammonium sulfate is co-extracted with gallium(III) into the organic phase.

This is indicated by the results of the following experiments. The extraction was performed from a 0.05 M aqueous solution of H_2SO_4 in the absence of gallium(III), and the content of the ions in the organic phase was determined. Then, we carried out the same experiment in the presence of gallium(III). The difference between the contents of SO_4^{2-} ions in the extract was used to judge about the form of gallium being extracted, whose ions are contained in the organic phase. The experimental data are listed in the table.

Determination of the Ga^{3+}/SO_4^{2-} ratio in the extract under study

SO_4^{2-}, Ga(III)	Content, g	ν, mol
SO_4^{2-}:		
in the $Ga_2(SO_4)_3$ solution before extraction	0.0615	0.0006406
in the aqueous phase after extraction	0.009306	0.0000969
in the organic phase after extraction	0.0265	0.000276
in the organic phase after extraction from H_2SO_4	0.0156	0.0001625
in the organic phase after extraction from $Ga_2(SO_4)_3$	0.0101	0.0001052
Ga(III) in the organic phase after extraction	0.0050	0.0000717

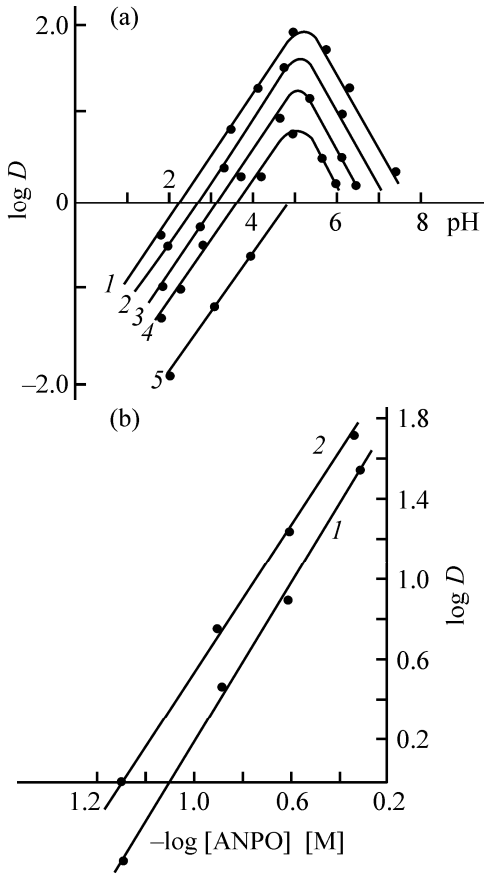

Fig. 3. Gallium(III) distribution coefficient D vs. (a) pH of the medium and (b) ANPO concentration. (a) c_{ANPO} (M): (*1*) 1, (*2*) 0.5, (*3*) 0.25, (*4*) 0.125, and (*5*) 0.05. (b) pH: (*1*) 45 and (*2*) 5.0.

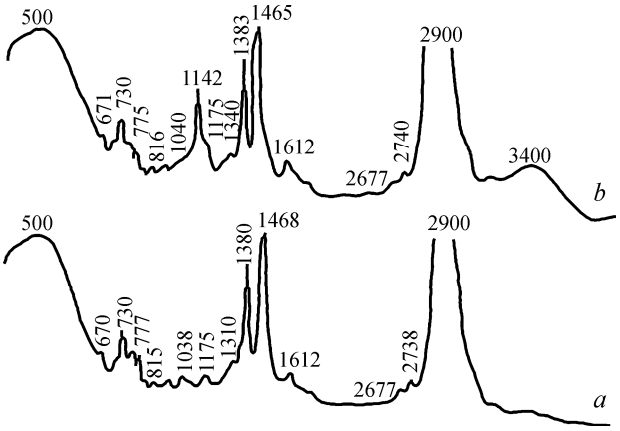

Fig. 4. IR absorption spectra. (*a*) Extractive agent and (*b*) extract.

Theoretically, it follows from the composition $Ga_2(SO_4)_3$ that 1 mg of Ga^{3+} corresponds to 2.06 mg SO_4^{2-}. The ratio experimentally found in the organic phase is 5 mg Ga^{3+} to 10.1 mg SO_4^{2-}, i.e., gallium(III) exists in the organic phase in the form of $Ga_2(SO_4)_3$.

At any of the amine concentrations studied in the organic phase, the maximum distribution coefficient corresponds to pH 4.8 (Fig. 3a).

To determine the stoichiometry of the components in the composition of the compounds being extracted, we analyzed the dependence of the distribution coefficient of gallium(III) at a constant concentration of the metal ion (0.05 g l^{-1}) and varied content of the amine in the organic solvent (Fig. 3b). In recovery of gallium (III) from weakly acid sulfate media, this dependence is represented by a straight line (Fig. 3b) with a slope approaching 2. This means that two amine molecules are associated with a single gallium(III) atom, at least within that range of amine concentrations in which the organic phase remains ideal.

To obtain additional evidence about the extractive agent and compounds being extracted, we examined their IR spectra in the range 400–4000 cm^{-1} (Fig. 4). It can be seen in Fig. 4 that the spectra of the extractive agent generally reproduce the IR spectra of a 1 M ANPO solution in kerosene, but with certain distinctions. It was demonstrated that vibrations of the following bonds appear in both the spectra: N–H (775, 1310, 3100–3200 cm^{-1}), C–N (1380 cm^{-1}), S–O (670, 1038, 1142 cm^{-1}), and O–H (1612, 3200–3700 cm^{-1}). In contrast to the IR spectrum of the reagent, the IR spectrum of the extractive agent shows a noticeable peak at around 1142 cm^{-1}, which can be attributed to stretching vibrations of the SO_4^{2-} group. The presence of a weak band in the region of deformation vibrations of water molecules (1612 cm^{-1}) can be attributed to the hygroscopic nature of the compounds studied, which is presumably due to the possibility of formation of $AmH^+\cdots OH_2$ hydrogen bonds [12].

A broad absorption band at 3100–3700 cm^{-1}, peaked at 3400 cm^{-1} and associated with deformation vibrations of OH groups of molecular water, appears in IR spectra of the extractive agent saturated with gallium(III). The absence of narrow absorption bands in the range of stretching vibrations of OH^- (3500–3700 cm^{-1}) [13] indicates that this extract contains no hydroxy groups.

In the presence of sulfuric acid, the complexation capacity of gallium(III) is manifested to a lesser extent, compared with in weakly acid sulfate media in which the $GaSO_4^+$ complex is formed [14]. Other possible sulfate acido complexes [$Ga(SO_4)_2^-$, $Ga(SO_4)_3^{3-}$, $Ga(SO_4)_4^{5-}$ are only formed in the presence of organic solvents (acetone, *n*-propanol, dioxane) [15]. Therefore, the mechanism described in the literature [10] is unlikely and

was studied for analytical purposes. We believe that gallium exists in the organic phase as $n[(RNH_3)_2SO_4] \cdot Ga_2(SO_4)_3$, as also does Fe(III) described in [2].

With account of the aforesaid, the extraction of gallium(III) from sulfuric acid solutions can be expressed by the equation

$$2Ga^{3+}_{aq} + 4(RNH_3)^{+}_{aq} + 5SO^{2-}_{4aq} \rightleftarrows 2[(RNH_3)_2SO_4] \cdot Ga_2(SO_4)_{3org},$$

with the reaction constant

$$K_{ex} = \frac{\{2[(RNH_3)_2SO_4] \cdot Ga_2(SO_4)_3\}_{org}}{[Ga^{3+}]^2_{aq}[SO^{2-}_4]^5_{aq}[(R(NH_3)_7]^4_{aq}}.$$

Based on the data obtained for the pH range 3.5–4.9, we calculated the concentration constants of gallium extraction $\log K_{ex} = 5.82 \pm 0.88$.

The fact that the calculated values of the extraction constants are invariable confirms the validity of the equation we suggested.

Gallium(III) was quantitatively re-extracted with a 1 : 1 NH_4OH ammonia solution from the organic phase, the pH value of whose equilibrium aqueous phase was 9–10, in agreement with the available recommendation for re-extraction of gallium(III) from amines [1]. In re-extraction of gallium from the organic phase with an ammonia solution, 80–85% of gallium(III) passes to the aqueous phase in a single stage.

CONCLUSIONS

(1) Ga(III) is extracted from sulfate acid solutions with primary aliphatic amines in the form of a complex compound $2[(RNH_3)_2SO_4] \cdot Ga_2(SO_4)_3$, whose composition was determined by the extraction method and analysis of the organic phase.

(2) The maximum degree of extraction is achieved in the weakly acid region at pH 4.8–5.4. Gallium(III) is quantitatively re-extracted from the organic phase with a 1 : 1 NH_4OH solution.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Characterization of the Amphotericity of Oxides and Hydroxides of Group-IIIA Elements in Aqueous Media

E. V. Shkol'nikov

St. Petersburg State Forestry Academy, St. Petersburg, Russia

Received June 11, 2008

Abstract—Dependences of the molar solubility of M_2O_3 solid oxides on the pH of aqueous media at 25°C and also the constants of acid-base equilibria in aqueous media for stable crystalline M_2O_3 oxides and for crystalline and dissolved $M(OH)_3$ hydroxides (M = In, Al, Ga, In, and Tl) were calculated by the thermodynamic method with account of the formation of hydroxo complexes.

DOI: 10.1134/S1070427208120082

Previously, the effect of pH on the molar solubility of solid hydroxides of the Group-IIIA elements in aqueous alkaline and acid media has been calculated by the thermodynamic method [1]. Of interest are a thermodynamic calculation of solubility of solid oxides M_2O_3 in water and aqueous media and calculation of acid–base equilibria [2] for oxides and hydroxides of group-IIIA elements.

Crystalline and amorphous oxides M_2O_3 are widely used in production of special glasses, ceramics, enamels, catalysts, and sorbents; in metallurgy; laser technology; radio engineering; and electronics [3–6]. Being products of a real dehydration of hydroxides, solid oxides can be obtained by heating of hydroxides and metahydroxides in an inert atmosphere. Anhydrous oxides M_2O_3 are obtained by burning elementary substances M in oxygen (ozone) and by thermal decomposition of nitrates and sulfates [4–6]. Polymeric oxides M_2O_3 form rather difficultly soluble (B_2O_3) or nearly water-insoluble amorphous and crystalline modifications whose reactivity depends on their structure and preparation method and conditions [3–7].

The amphotericity of M_2O_3 oxides has been little studied, and quantitative data on their solubility in aqueous media are rather scarce and frequently contradictory. For example, according to [5], B_2O_3 is an acid oxide, Al_2O_3 is a typical amphoteric oxide, and, in the series $Ga_2O_3 \rightarrow In_2O_3 \rightarrow Tl_2O_3$, indications of acidity become weaker, basicity increases, and solubility in acids grows. According to the data of [3, 5], the acid and basic functions of Ga_2O_3 and $Ga(OH)_3$ are exhibited approximately to the same extent, whereas according to [6, 8], the acid properties are more pronounced than the basic properties. The basic properties of $In(OH)_3$ predominate over its acid properties, and for thallium(III) hydroxide and oxide, the acid function is expressed very weakly [5]. According to [3], brown thallium(III) hydroxide and oxide are peptized by alkalis to give a sol, but do not dissolve in alkalis and form no thallates. The oxide Tl_2O_3 is obtained in the form of an amorphous powder on heating the $Tl_2O_3 \cdot mH_2O$ precipitate, and the oxide and its hydrate react with acids and do not dissolve in ammonia water and solutions of strong alkalis [4, 7]. However, hydrated thallium(III) oxide dissolves to a noticeable extent in concentrated solutions of strong alkalis to give readily hydrolyzed thallates [6].

Light yellow amorphous and yellow cubic In_2O_3 modifications react with acids under heating, but do not dissolve in dilute solutions of alkaline hydroxides [4, 6, 7]. The hydrate $In_2O_3 \cdot mH_2O$ is peptized in aqua ammonia and dissolves in acids and in concentrated solutions of strong alkalis to give unstable indates [3, 4, 6]. The oxides Ga_2O_3 and Al_2O_3 form several crystalline modifications. Moderate heating of a $Ga(OH)_3$ or GaO(OH) gel yields a metastable hexagonal α-Ga_2O_3 [4] soluble in acids and alkalis to give gallium(III) salts and gallates, respectively [6, 7]. The stable mono-

clinic modification β-Ga_2O_3 is formed as a white powder upon a stepwise heating of gallium(III) nitrate or hydroxide at 250°C and then at 600°C for 12 h [6]. After being calcined at above 600°C, Ga_2O_3 reacts with molten alkalis and ceases to be soluble in acids and aqueous-alkaline media, similarly to Al_2O_3 [4, 6, 7].

Amorphous porous oxide Al_2O_3 (aluminogel) and the tetragonal modification γ-Al_2O_3, produced by calcination of aluminum hydroxides at 550°C, are rather hygroscopic and chemically active and react with solutions of acids and alkalis [4, 6, 7]. The stable rhombohedral modification α-Al_2O_3 (corundum), produced from diaspore AlO(OH) at 500–600°C, does not react with water and reacts with solutions of acids and alkalis under heating. The reactivity and solubility of Al_2O_3 strongly decrease as its preparation temperature is raised [6]. Natural corundum and α-Al_2O_3 calcined above 1200°C are very hard, nonhydroscopic, and chemically inert under ordinary conditions [3–6].

Unlike other M_2O_3 oxides, B_2O_3 is easily vitrified and reacts with water with strong warming up [4] to give weak orthoboric acid with a limited solubility in water [1, 6]. A stable hexagonal modification of B_2O_3 is obtained by cautious heating of α-HBO_2. Boron(III) oxide and boric acids react with NaOH solutions to give $Na[B(OH)_4]$, $Na_2B_4O_7$, and $NaBO_2$ [4, 6]. Fusion of B_2O_3 and other M_2O_3 oxides with sodium oxide yields hydrolyzed oxo compounds of the $NaMO_2$ type [3–6].

Because the heterogeneous reaction

$$0.5M_2O_3(s) + 1.5H_2O(l) = M(OH)_3(g)$$

does not occur to a noticeable extent for the solid oxides under consideration ($\Delta G^0_{298} > 0$, except for boron oxide), formation of $M(OH)_3$ solid hydroxides was disregarded when calculating the solubility of oxides. In an aqueous solution saturated with the poorly soluble oxide $MO_{1.5}$ ($0.5M_2O_3$), heterogeneous chemical equilibrium (1) is attained.

$$MO_{1.5}(s) + 1.5H_2O(l) \rightleftarrows M^{3+}(sol) + 3OH^-(sol). \qquad (1)$$

Its thermodynamic constant is given, similarly to $M(OH)_3$ hydroxides [1], by the expression

$$K^0_s = SP^0 = a_{M^{3+}}\, a^3_{OH^-} = \text{const}(T),$$

where $a_{M^{3+}}$ and a_{OH^-} are the activities of M^{3+} and OH^- ions.

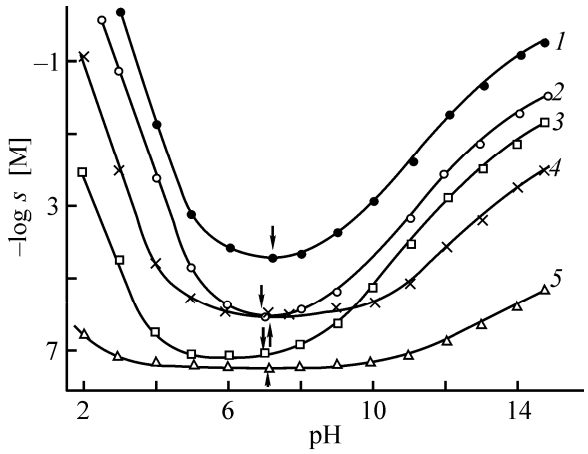

Fig. 1. Dependence of the solubility s of crystalline oxides on the pH of the aqueous medium at 25°C. (*1*) γ-Al_2O_3, (*2*) α-Al_2O_3, (*3*) β-Ga_2O_3, (*4*) In_2O_3, (*5*) Tl_2O_3.

The thermodynamic calculation of K^0_s for equilibrium (1) was performed using the procedure described in [1]. The required standard values of ΔG^0_f of ion formation in aqueous solutions were taken from [9], and values of ΔG^0_f for solid oxides at 298 K, from the reference books [7, 10, 11]. The molar solubilities of the oxides (except $BO_{1.5}$) were calculated taking into account the ionic strength of the solutions and the formation of mononuclear hydroxo complexes in accordance with the generalized equation

$$s = c_M = \frac{K^0_s}{f_{M^{3+}} f_{OH^-}} \sum_{i=0}^{n} \beta_i [OH^-]^{i-3}.$$

Here, the constant K^0_s characterizes the heterogeneous equilibrium (1); $f_{M^{3+}}$, f_{OH^-} are the molar activity coefficients of M^{3+} and OH^- ions; $\beta_0 = 1$; β_1, β_2, β_3, and β_4 are the total stability constants of MOH^{2+}, $M(OH)^+_2$, $M(OH)_3$, and $M(OH)^-_4$, found from averaged data of [8, 11–13].

The equilibrium concentration of free OH^- anions and the pH^0 values of saturated aqueous solutions of oxides in pure water (shown by arrows in Fig. 1) were found by solving a system of six equations [1], using the Ferrari, Cardano, or Newton method.

We estimated the molar solubility of the stable hexagonal modification of $BO_{1.5}$ in pure water at 25°C by using the intrinsic solubility of a rather weak orthoboric acid exothermally formed in accordance with the reaction equation [4]

$$BO_{1.5}(cr) + 1.5H_2O(l) = H_3BO_3(cr) + 38\ kJ,$$

Table 1. Thermodynamic parameters of dissolution of crystalline oxides in water and aqueous media at 25°C

* Amorphous powder.

with its dissolution in water being, however, an endothermic process [1, 4]. Analysis of the data from the reference book [13] shows that the temperature dependence of the solubility of the solid oxide B_2O_3 in water in the temperature range 0–100°C can be represented by the equation

$$\ln s = 9.983(\text{cr}) + 2694/T.$$

Here s is the solubility of B_2O_3 (g/100g of H_2O), and T is absolute temperature.

The graphically found standard enthalpy of dissolution, $\Delta H_s^0 = 22.4$ kJ mol^{-1}, hardly differs from the value of ΔH_s^0 for H_3BO_3 [1]. The results of our calculation are listed in Table 1, where $pK_s^0 = -\log K_s^0$, s^0 is the total molar solubility of solid oxides $MO_{1.5}$ in pure water, and $[M(OH)_3]$ is the equilibrium molarity of neutral complexes in aqueous solutions of oxides at 25°C. It is seen from Table 1 that pK_s^0 values calculated in this study satisfactorily agree with the data from [14]. For some of the oxides, the calculation was carried out for the first time. The solubility of amorphous M_2O_3 oxides, as also that of $M(OH)_3$ hydroxides [1], substantially exceeds the solubility of crystalline modifications. The solubility of these latter noticeably depends on structure and decreases on passing to the stable modifications α-Al_2O_3 and β-Ga_2O_3. The solubility of M_2O_3 oxides in pure water is determined by the content of dissolved neutral $M(OH)_3$ complexes (from 89% for aluminum oxides to approximately 100% for Tl_2O_3).

It is seen from Table 1 that saturated solutions of B_2O_3 and Ga_2O_3 in pure water are slightly acidic, those of thallium(III) are neutral, and solutions of aluminum and indium(III) oxides are weakly alkaline (pH 7.02–7.2). The isoelectric point of the dispersed system was found to be at pH 6.8 [3] and 8.0 [4], respectively, for $Ga(OH)_3$ and γ-Al_2O_3.

The calculation of the average ligand number n in the hydroxo complexes (Bjerrum function) at pH 15 gives a value of ~4 for all the oxides and hydroxides of Group-IIIA elements, which indicates that the amphotericity condition $n > 3$ is satisfied for these compounds. No thermodynamic data are available for the small B^{3+} cation with a high polarizing power and for its hydroxo complexes in aqueous solutions of B_2O_3 and H_3BO_3, with the exception of $\Delta G_{f\,298}^0$ for $B(OH)_4^-$ and $B(OH)_3$ [1, 10]. The calculated ratio of total stability constants β_4 and β_3 of these hydroxo complexes is 6×10^4, which provides that the amphotericity condition is satisfied and the homogeneous equilibrium

$$H_3BO_3(\text{sol}) + OH^-(\text{sol}) \rightleftarrows B(OH)_4^-(\text{sol})$$

is shifted to the right at pH > 9.2, with $B(OH)_4^-$ complexes formed.

The minimal solubility of M_2O_3 oxides is observed at the optimal concentration of OH^- ions, when the mole fraction of neutral $M(OH)_3$ complexes in aqueous solutions is at maximum. We found from this condition, similarly to [1], first pH_{opt} and then s_{min}. The values of $ps_{min} = -\log s_{min}$ at 25°C are listed in Table 1 and in part shown in Fig. 1, whence follows that there is no negative effect of OH^- on the solubility of both M_2O_3 oxides and $M(OH)_3$ hydroxides in alkali

[1]. Analysis shows that the conditions for the absence of this effect for oxides and hydroxides of Group-IIIA elements are the following: high values of the total stability constant β_3 of the neutral $M(OH)_3$ complex and of its mole fraction in a purely aqueous saturated solution, in contrast to, e.g., CdO, CuO, and FeO oxides with a strong negative effect of common OH^- ions [2].

For a comparative quantitative estimate of amphoterism of the oxides, we used, as before [2], the ratio ($A > 1$) of their molar solubilities in an alkaline medium with pH 14.7 (5 M NaOH solution) and in pure water. The amphotericity parameter is determined by the chemical nature of an oxide and varies over a wide range, from 3.1 for B_2O_3 to 3.3×10^6 for Ga_2O_3 (Table 1). The molar solubility of stable crystalline M_2O_3 oxides in 1 and 5 M NaOH solutions is determined by $M(OH)_4^-$ complexes and steadily decreases as the element M is replaced in the series B→Al→Ga→In→Tl coinciding with the order in which the ionic radius of M^{3+} increases in Group IIIA and the ionicity P_i of the M–O chemical bond grows from 46 (B–O) to 67% (Tl–O) in oxides, according to an estimate of P_i from Pauling's curve [5]. The solubilities of stable B_2O_3 and β-Ga_2O_3 with predominant acid properties in 5 M NaOH and 10^{-3} M $HClO_4$ are lower than those of the stable H_3BO_3 and H_3GaO_3 acids. A different relationship between the solubilities is observed in Group IIIA for other stable oxides and hydroxides with predominant basic properties.

In an acid medium with pH 3 (upon addition of $HClO_4$) the solubility of Tl_2O_3 is intrinsic [1], as also that of the very weak electrolyte $Tl(OH)_3$; the solubilities of gallium(III), indium(III), and aluminum oxides are determined, respectively, by $GaOH^{2+}$ complexes and Ga^{3+} cations, by In^{3+} cations and $InOH^{2+}$ complexes, and by free Al^{3+} cations. The molar solubility of stable $M(OH)_3$ hydroxides in the acid medium (pH 3) decreases as the element M is replaced in the following order: B→Al→Ga→In→Tl.

Despite the large value of the main amphotericity parameter A, the solubility of the stable hydroxides γ-$Al(OH)_3$, $In(OH)_3$, $Tl(OH)_3$ and the oxides In_2O_3 and Tl_2O_3 in 5 M NaOH is low (1.8, 0.03, 4×10^{-4}, 2×10^{-4}, and 1×10^{-5}, respectively) because of the small values of s^0 (Table 1) and the influence of other parameters (Fig. 2 and Table 2), which supplement the amphotericity characteristics of the hydroxides and oxides. Figure 2 shows on a logarithmic scale how the ratio of the molar solubilities of the stable crystalline oxides (hydroxides) under study in aqueous alkaline (acid) media and in pure water depends on the pH of the medium at 25°C.

Table 2. Amphotericity parameters* of stable crystalline hydroxides and oxides in aqueous media at 25°C

Compound	A	pH_b	B	C_b	C_b
γ-$Al(OH)_3$	1.07×10^6	7.6	0.5	1.0	2.8
α-$AlO_{1.5}$	1.08×10^6				
$Ga(OH)_3$	3.46×10^6	7.1	0.3	1.0	2.2
β-$GaO_{1.5}$	3.3×10^6				
$In(OH)_3$	7.39×10^3	8.9	1.9	0.8	2.5
$InO_{1.5}$	7.4×10^3				
$Tl(OH)_3$	1.42×10^2	10.5	3.5	0.5	1.2
$TlO_{1.5}$	1.4×10^2				

* $A = s(\text{pH } 14.7)/s^0$, pH_b at $s_b = s^0$, $B = pH_b - pH^0$, $C_b = |\Delta p s_b/\Delta pH|$, $C_a = \Delta p s_a/\Delta pH$.

Table 2, compiled using the data in Fig. 2, contains, in addition to A parameter, pH_b values above which the solubility s_b in alkali exceeds the solubility s^0 in water upon addition of NaOH. The lower the pH_b value, the smaller additions and the lower alkali concentrations are necessary for the solubility of a hydroxide (oxide) to start to increase as compared with the solubility in pure water. The lowest pH_b values were found for the typically amphoteric gallium and aluminum hydroxides (oxides) having the largest values of the main parameter A, and the highest pH_b values were obtained for $Tl(OH)_3$ and Tl_2O_3 with weak indications of amphotericity (Table 2). The parameter B, equal to $(pH_b - pH^0)$, determines the pH range in which $s < s^0$ is at a minimum for gallium(III) hydroxide and at a maximum for thallium(III) hydroxide and oxide upon addition of

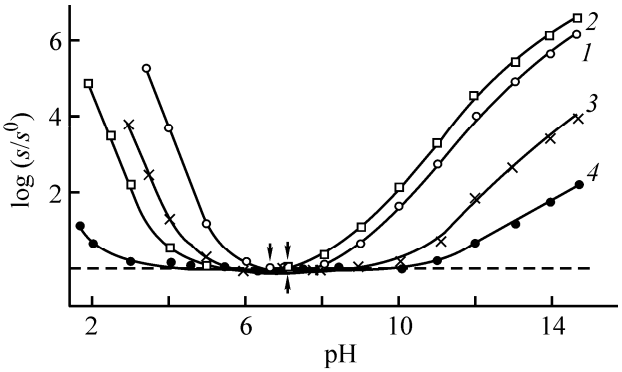

Fig. 2. Dependence of the ratio of molar solubilities of stable oxides and hydroxides in aqueous medium s and in pure water s^0 on the pH of the medium at 25°C. (*1*) α-Al_2O_3 and γ-$Al(OH)_3$, (*2*) β-Ga_2O_3 and $Ga(OH)_3$, (*3*) In_2O_3 and $In(OH)_3$, (*4*) Tl_2O_3 and $Tl(OH)_3$.

Table 3. Thermodynamic constants of heterogeneous equilibria for stable crystalline hydroxides and oxides in water (2)–(6) and in acid (7)–(9) and alkaline (10) media

Compound	pK_{298} for equilibrium								
	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)

$Tl(OH)_3$	32.52	19.51	7.24	–	18.94	5.52	4.54	3.94	4.95
H_3BO_3	–	–	0.066	9.22	9.28	–	–	–	–4.70
$BO_{1.5}$	–	–	0.13	7.41	6.52	–	–	–	–7.97
α-$AlO_{1.5}$	23.45	14.12	6.09	13.86	14.36	–0.78	–4.52	–9.52	0.39
β-$GaO_{1.5}$	27.45	16.89	7.22	12.58	13.76	2.66	–0.64	–3.24	–0.23
$InO_{1.5}$	25.05	15.07	5.92	14.51	15.36	1.11	–2.70	–6.69	1.37
$TlO_{1.5}$	32.40	19.80	7.41	–	18.40	4.97	4.00	3.39	4.41

the alkali (Fig. 2 and Table 2). The parameters C_b and C_a (Table 2) characterize the rate at which the solubility increases as the pH changes upon addition of NaOH ($pH > pH_b$) or $HClO_4$ ($pH < pH^0$). The typical amphoteric aluminum and a gallium(III) oxides and hydroxides with increased C_a and C_b parameters and with low pH_b (Table 2) readily dissolve in the amorphous state in dilute acids and alkalis [3–6]. Indium (III) oxide and hydroxide with increased C_a, B, and pH_b parameters readily dissolve in acids, but hardly do so in concentrated alkalis [3–7]. Anhydrous and hydrated thallium(III) oxides with small C_b parameter (pH 11→14), medium value of C_a parameter (pH 3→1), and increased pH_b and B are soluble in acids, but difficultly and rather poorly soluble in strongly concentrated alkalis [5, 6].

Similarly to hydroxides [1], amphoteric oxides with M–O chemical bonds close in ionicity to O–H bonds can shift the water dissociation equilibrium and add hydroxide ions or protons in aqueous media to give the corresponding ions. Therefore, we supplemented the comparative characterization of the acid-base properties of stable crystalline hydroxides and oxides with a calculation of the thermodynamic parameters ΔG^0_{298} and pK_{298} (K is the equilibrium constant) of heterogeneous reactions in a saturated aque-

$$M(OH)_3(cr) \rightleftarrows MOH^{2+}(sol) + 2OH^-(sol), \quad (2)$$

$$M(OH)_3(cr) \rightleftarrows M(OH)_2^+(sol) + OH^-(sol), \quad (3)$$

$$M(OH)_3(cr) \rightleftarrows M(OH)_3(sol), \quad (4)$$

$$M(OH)_3(cr) \rightleftarrows H^+(sol) + H_2MO_3^-(sol), \quad (5)$$

$$M(OH)_3(cr) + H_2O(l) \rightleftarrows H^+(sol) + M(OH)_4^-(sol). \quad (6)$$

The corresponding heterogeneous equilibria (2)–(6) for stable oxides differ from equilibria (2)–(6) for hydroxides in that the $M(OH)_3(cr)$ phase is replaced by two phases: $MO_{1.5}(cr) + 1.5\ H_2O(l)$. The values of pK_{298}, calculated using the data of [6–14], are listed in Table 3, which shows that, with account of equilibria (2) and (3), the basic properties are predominant and are the most pronounced for γ-$Al(OH)_3$ and α-Al_2O_3, and the least pronounced for $Tl(OH)_3$ and Tl_2O_3. According to the pK_{298} values for equilibria (5) and (6), the acid properties are characteristic of H_3BO_3 and B_2O_3, predominate over basic properties for gallium (III) hydroxide and oxide, and are the least pronounced for thallium(III) oxide and hydrated oxide. The same conclusion follows from a calculation of pK_{298} for chemical equilibria in the acid and alkaline media for stable hydroxides

$$M(OH)_3(cr) + H^+(sol) \rightleftarrows M(OH)_2^+(sol) + H_2O(l), \quad (7)$$

$$M(OH)_3(cr) + 2H^+(sol) \rightleftarrows M(OH)^{2+}(sol) + 2H_2O(l), \quad (8)$$

$$M(OH)_3(cr) + 3H^+(sol) \rightleftarrows M^{3+}(sol) + 3H_2O(l), \quad (9)$$

$$M(OH)_3(cr) + OH^-(sol) \rightleftarrows M(OH)_4^-(sol). \quad (10)$$

and for the corresponding equilibria (7)–(10) for stable oxides. It can be seen from Table 3 and Figs. 1 and 2 that boron(III) and gallium(III) oxides and hydroxides are the best soluble in alkalis, and aluminum and indium(III) oxides and hydroxides, in acids.

Table 4 lists the thermodynamic constants of basicity ($K_{b,1}$, $K_{b,2}$, and $K_{b,3}$) and acidity ($K_{a,1}$, $K_{a,2}$, and $K_{a,3}$) of $M(OH)_3$ ampholytes dissolved in water in

Table 4. Stepwise thermodynamic basicity constants $K_{b,1}$, $K_{b,2}$, $K_{b,3}$ and acidity constants $K_{a,1}$, $K_{a,2}$, $K_{a,3}$ of hydroxides in the form of neutral complexes $M(OH)_3$ dissolved in water at 25°C

Compound	$pK_{b,1}$	$pK_{b,2}$	$pK_{b,3}$	$pK_{a,1}$	$pK_{a,2}$	$pK_{a,3}$	$pK^*_{a,1}$

the form of neutral complexes. The $pK_{a,1}$ values correspond to the ionization equilibrium

$$M(OH)_3(sol) + H_2O(l) \rightleftarrows H^+(sol) + M(OH)_4^-(sol)$$

in an aqueous solution, which is rather probable for H_3BO_3 [3, 4, 6]. Along with the values calculated from the data of [8–13], Table 4 lists the pK values from [3–6, 11]. It can be seen that the inequalities $K_{a,1} > K_{b,1}$ and $K_{a,2} > K_{b,2}$ are valid not only for the weak acid H_3BO_3, but also for neutral complexes of gallium(III) hydroxide in solutions. For other dissolved $M(OH)_3$ ampholytes, the basic properties ($K_{b,1} > K_{a,1}$) predominate, being the most pronounced for $Al(OH)_3$ and the weakest for $Tl(OH)_3$.

CONCLUSIONS

(1) The molar solubility of solid oxides $MO_{1.5}$ (M is a Group-IIIA element) in water, mainly determined by neutral $M(OH)_3$ complexes, is rather low (10^{-8}–10^{-5} M at 25°C, except for $BO_{1.5}$) and depends on the composition and structure, becoming considerably lower on passing from the amorphous to the stable crystalline modification.

(2) The thermodynamic method was used to calculate the effect of pH on the solubility of solid oxides M_2O_3 in aqueous alkaline and acid media at 25°C and to find the amphotericity parameter $A > 1$, which increases in the order B→Tl→In→Al→Ga. The values of pH of an acid medium, below which M^{3+} cations are not bound into hydroxo complexes, were found.

(3) The minimum solubility and the pH values corresponding to the most complete precipitation of amphoteric aluminum, gallium, indium, and thallium(III) oxides were calculated with account of the formation of hydroxo complexes.

(4) The calculation of the thermodynamic constants of heterogeneous acid–base equilibria in aqueous media and of the stepwise basicity and acidity constants of neutral $M(OH)_3$ complexes points to the acid nature of boron oxide and hydroxide, predominance of weak acid properties over weak basic properties for gallium(III) oxide and hydroxide, and predominance of basic properties, the most pronounced for aluminum oxide and hydroxide and the weakest for thallium(III) oxide and hydroxide.

Abstract—Equilibrium and kinetics of absorption of samarium(III) ions from sulfate solutions by a natural clinoptilolite-containing tuff were studied. The kinetic parameters of the sorption process were determined.

DOI: 10.1134/S1070427208120094

Compounds of rare-earth elements (REE), and especially those of the first representatives of this series: lanthanum, cerium, neodymium, and samarium, exhibit an enhanced biological activity and are used as fertilizers [1]. Lanthanum sulfate catalyzes the fixation of atmospheric nitrogen by Azobacter in legume crops, sulfates and nitrates of neodymium and samarium are involved in humus accumulation and activate the nitrogen and carbohydrate metabolism [2, 3].

The biological activity of REE compounds can be enhanced by introduction of their ions into the zeolite matrix by the sorption technique, with natural zeolites used as sorbents [1]. It has been shown that the sorption technology is the most rational way to obtain lanthanum- and neodymium-containing microfertilizers stimulating the production process in the soil–plant system and diminishing the possible migration of microelements in soils with light granulometric composition [4, 5].

The ion-exchange properties of natural zeolites with respect to rare-earth elements are insufficiently understood; the sorption of lanthanum and neodymium ions by mordenite and clinoptilolite tuff has been studied [1, 4, 5]; data on sorption of samarium ions by natural zeolites are lacking, but are necessary for evaluating the influence exerted by the nature of REE on the equilibrium and kinetics of sorption and require a deeper analysis. This study is devoted to analysis of the sorption of samarium(III) ions from sulfate solutions by a clinoptilolite tuff in relation to the solution concentration, sorbent grain size, and solid-to-liquid mass ratio.

EXPERIMENTAL

A clinoptilolite-containing tuff with the following content of components was used (wt %): SiO_2 68.11, Al_2O_3 12.84, Fe_2O_3 1.08, FeO 0.35, Mn 0.08, P_2O_5 0.05, TiO_2 0.58, CaO 4.17, MgO 2.65, K_2O 2.47, Na_2O 2.87, CuO 0.003, F 0.002; Si/Al = 5.25. The content of the zeolite in the rock was found by X-ray diffraction analysis with PTsL-2 [6] to be about 60%.

Grain fractions with sizes of 0.25–0.5 and 1–2 mm were taken for analysis by the sieving method. The sorption equilibrium was studied under static conditions in sorption from samarium sulfate solutions in the concentration range 0.0003–0.025 M of the ion being determined at s : l ratios of 1 : 10 and 1 : 50.

The kinetic parameters were calculated from Q–τ curves, where Q is the sorbed amount of samarium ions (mmol g^{-1}) and τ is time, by the procedure reported for sorption on zeolites [7]. For the initial period of time, when sorption occurs on the sorbent surface and the process goes under the control of the outer-diffusion mechanism, the rate constant of R of the outer-diffusion process was calculate by the equation

$$R = \mathrm{d}Q/\mathrm{d}\tau(1/cK_\mathrm{d}), \quad (1)$$

where c is the concentration of the ion being exchanged in solution (M); K_d, equilibrium distribution coefficient (ml g^{-1});

$$K_\mathrm{d} = (c_0 - c_\mathrm{eq})V/c_\mathrm{eq}m, \quad (2)$$

Solution*	τ_∞, min	$dQ/d\tau \times 10^5$, mmol g^{-1} min^{-1}	K_d, ml g^{-1}	$R \times 10^4$, s^{-1}	$B \times 10^4$, s^{-1}	$D \times 10^8$, cm^2 s^{-1}
I	1550	3.8	52.8	24.7	9.8	4.9
II	1580	3.3	46.4	23.9	10.1	5.3
III	2060	1.6	29.7	10.3	6.5	2.7

c_0 and c_{eq}, initial and equilibrium samarium ion concentrations in solution; V, solution volume (ml); and m weighed portion of the zeolite (g).

As the time of contact increases, the amount of absorbed ions is determined by the exchange rate within a sorbent grain. The effective diffusion coefficient D and the rate constant B of the inner-diffusion process, which characterize the inner-diffusion mechanism, were calculated using the relations derived for spherical particles:

$$F = \frac{Q\tau}{Q_\infty} = \frac{6\sqrt{Dr}}{r\pi}, \quad (3)$$

$$B = \pi^2 D/r^2, \quad (4)$$

where F is the degree of absorption of samarium ions, and r is the average radius of sorbent grains.

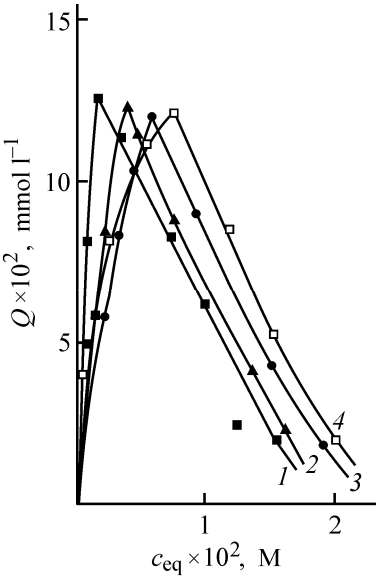

Fig. 1. Equilibrium curves of samarium sorption from $Sm_2(SO_4)_3$ solution. (Q) Sorbed amount of ions and (c_{eq}) concentration of the ion being exchanged in solution. Grain size d (mm), s : l ratio: (*1*) 0.25–0.5, 1 : 50; (*2*) 0.25–0.5, 1 : 10; (*3*) 1–2, 1 : 50; and (*4*) 1–2, 1 : 10.

The content of samarium ions was determined photometrically with arsenazo (III) [8]. The absorption capacity was calculated from the difference of the samarium ion concentrations before and after sorption, found in three parallel runs. The experimental results are listed in the table and shown in Figs. 1–3.

The equilibrium curves of samarium sorption on the clinoptilolite-containing tuff indicate that samarium is quantitatively recovered from dilute solutions (Fig. 1). With clinoptilolite grains with sizes of 1–2 mm (at s : l = 1 : 10) and 0.25–0.5 mm (at s : l = 1 : 50), samarium ions are more completely recovered at initial solution concentrations of up to 0.002 M.

As the solution concentration increases, the equilibrium curves pass through a maximum, which is followed by a decrease in the exchange capacity (EC) of the tuff. The maximum EC is 0.124–0.137 mmol g^{-1}. The appearance of the extremum in the isotherm may be due to existence in solution of intermediate reaction products to which the sorbent exhibits an increased capacity [9]. Samarium has a high capacity for complexation; in neutral and acid aqueous solutions, samarium ions are in the form of aqua complexes of the type $[Sm(H_2O)_n]^{3+}$ or $[Sm(H_2O)_nOH]^{2+}$, where n = 5–8 [10].

In samarium sulfate solutions, the formation of complexes with composition $[Sm(SO_4)_n]^{3-2n}$, where n = 1–3, was also observed. At low concentrations of sulfate ions (<0.02 M), $[SmSO_4]^+$ cations predominate [10], although anion complexes can also be formed under these conditions [4, 5, 11, 12]. Before the extremum point, aqua and hydroxo complexes of samarium are presumably sorbed, because the increased selectivity of the zeolite toward samarium ions in the initial portion of the equilibrium curve, when the ions are nearly completely absorbed, is due to the large charge carried by the ion. In [12], a mechanism of sorption of lanthanum aqua complexes on synthetic zeolite was described; the suggested mechanism is confirmed by the reversal of the sorbent selectivity toward samarium ions after their certain concentration in solution is reached. This fact is associated with a manifestation of electroselectivity, because, according to the theory [9], dilution of the solution in the solution–sorbent system shifts the equilibrium toward an increase in the sorption of an ion with a larger charge and concentration leads to full selectivity reversal.

The absorption of samarium ions is accompanied by a decrease in the solution pH by 0.7–0.9 units. The pH is 6.3 for a 0.005 M samarium sulfate solution and 6.1 for a 0.001 M solution. The grain size and the s : l

ratio affect the position of the maximum in the isotherms (Fig. 1). The maximum of EC on grains with d = 0.25–0.5 mm and s : l = 1 : 50 (Fig. 1, curve *1*) is shifted to lower equilibrium concentrations, as the grain size increases (d = 1–2 mm) at s : l = 1 : 10, the maximum lies at higher concentrations (Fig. 1, curve *4*). Thus, low solution concentrations are sufficient for reaching the highest EC on fine grains, which is important for making a rational choice of the mode of zeolite saturation with samarium ions when obtaining a modified form of the clinoptilolite-containing tuff.

It was found that a nearly equilibrium state is attained in 28 h on 0.25–0.5-mm grains and in 35 h on 1–2-mm grains, after which a certain desorption within 1.5–2.0% is observed (Fig. 2). Analysis of kinetic parameters (see table) shows that the sorption of samarium occurs under mixed-diffusion control because the rate constants of outer- (R) and inner-diffusion processes (B) are on the same order of magnitude. The run of the dependence of the degree of filling of the zeolite phase (F) on $\tau^{1/2}$ (τ is time, s), whose initial portions are linear up to high values of F (Fig. 3), points to a considerable contribution from the inner-diffusion mechanism.

An increase is observed both in the sorption rate of samarium, $dQ/d\tau$, from a dilute solution on 0.25–0.5-mm grains under the outer-diffusion control and in the equilibrium distribution coefficient K_d. The acceleration of the process is due to an increase in the dispersity of tuff grains. The values of the effective diffusion coefficient D are in agreement with those from [7]. The high values of D, compared with the data obtained for mono- and divalent metals, are accounted for by the Helfferich principle [13], according to which more mobile ions are decelerated and less mobile ions are accelerated in an exchange of a mixture of ions.

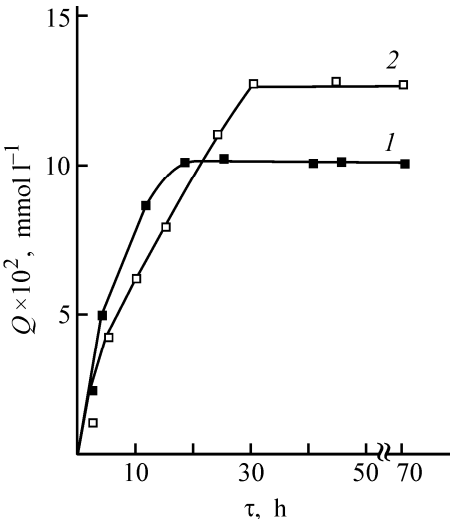

Fig. 2. Kinetic curves of samarium sorption from (*1*) 0.001 and (*2*) 0.005 M $Sm_2(SO_4)_3$ solutions by the clinoptilolite-containing tuff. (Q) Sorbed amount of ions and (τ) time. d (mm), s : l: (*1*) 0.25–0.5, 1 : 50; and (*2*) 1–2, 1 : 10; the same for Fig. 3.

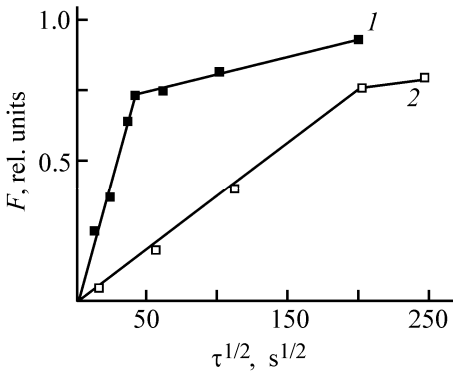

Fig. 3. F–$\tau^{1/2}$ dependence for samarium sorption from (*1*) 0.001 and (*2*) 0.005 M $Sm_2(SO_4)_3$ solutions. (F) Degree of filling of the zeolite phase and (τ) time.

CONCLUSIONS

(1) The equilibrium in the system constituted by a clinoptilolite-containing tuff and samarium(III) was studied and it was found that the sorbent can recover samarium ions from aqueous solutions. At low concentrations (<0.002 M), samarium ions are recovered quantitatively; as the concentration increases, the sorption capacity of the clinoptilolite-containing tuff becomes lower. The sorption isotherms show a maximum, which is due to the complex nature of the interaction between the components of the system.

(2) It was demonstrated that the sorption kinetics of samarium(III) ions by the natural clinoptilolite-containing tuff is controlled by the mixed-diffusion sorption mechanism. The pronounced contribution of the inner-diffusion sorption mechanism was confirmed. It was found that the rate of absorption of samarium ions from a dilute solution on 0.25–0.5-mm grains by the outer-diffusion mechanism increases and the equilibrium distribution coefficient grows as the solution concentration becomes lower.

Abstract—Correlation between the chemical composition, structure, and ion-exchange properties of tin(II) hydrophosphate was studied.

DOI: 10.1134/S1070427208120100

Inorganic ion exchangers of the zirconium(IV) phosphate type, characterized by high selectivity and chemical stability, are promising for separation of elements with closely similar properties and for preparation of special-purity inorganic salts. For example, it is advisable to use tin(IV) hydrophosphate for recovery of microscopic amounts of potassium from sodium salts [1]. The structure and ion-exchange capacity of this compound have been studied in sufficient detail and a correlation between these characteristics has been demonstrated [2–7]. Data on the ion-exchange properties of tin(II) phosphate are scarce and contradictory. In [8], a conclusion was made that, despite the lamellar structure and the same type of the crystal systems and space symmetry group of $Sn(HPO_4)_2 \cdot H_2O$ and $SnHPO_4$, the replacement of protons in the latter compound by other cations is impossible. At the same time, data obtained in analysis of the synthesis conditions and the ion-exchange interaction in the case of this sorbent have been reported [9, 10]. These contradictions are probably due to differences in the synthesis conditions, chemical composition, and structure of the tin(II) phosphate samples studied.

This communication reports on a study of the structural features of tin(II) hydrophosphate in sorption of elements with closely similar properties in relation to synthesis conditions.

EXPERIMENTAL

An X-ray phase analysis (XPA) (powder technique) of tin(II) phosphate samples was made on DRON-3 and DRON-3M diffractometers (CoK_α and CuK_α radiation), using the PDF database [11] for phase identification. IR spectra of samples in the form of suspensions in vacuum-treated Vaseline oil were recorded in the range 4000–400 cm^{-1} on a Specord M-80 spectrometer. A thermogravimetric analysis was performed on an MOM derivatograph (Hungary), with aluminum oxide as reference. An ion exchanger for physicochemical analysis was prepared and stored under the conditions providing the minimum contact with air. The acid–base properties of the samples were examined by potentiometric titration of separate weighed portions. The rest of the methods of study are similar to those used in [9,10].

The parameters of tin(II) hydrophosphate samples, synthesized in accordance with [10] at a varied P : Sn molar ratio in the starting products, and the distribution coefficients in sorption of alkali metal cations are listed in Table 1.

It can be seen in Table 1 that, as the P : Sn molar ratio in the starting products increases within a wide range, this ratio in the sorbents also becomes larger, and the distribution coefficients K_d of K^+, Rb^+, and Cs^+ ions first increase and then decrease. Consequently, the chemical composition of the ion exchangers strongly affects their ion-exchange properties. Under the given conditions, Na^+ ions are not sorbed. As the P : Sn ratio increases, the yield of the sorbent decreases because of a rise in the solubility of the ion exchanger being synthesized.

* Relative intensity of the rest of the peaks is less than 10.

According to the results of an X-ray phase analysis of tin(II) phosphate sample nos. 2–5 (Table 2), all ion exchangers are crystalline compounds, and, as the P : Sn ratio increases, the intensities of the X-ray reflections become higher, i.e., the crystallinity, on the whole, grows.

Comparison with published data shows that all samples are composed of tin(II) hydrophosphate $SnHPO_4$. However, the best agreement is characteristic of ion exchanger no. 3, synthesized at P : Sn = 4. For tin(II) hydrophosphate synthesized at this P:Sn ratio, the sorption parameters are at a maximum (Table 1).

It should be noted, when comparing the XPA data for tin(II) and tin(IV) hydrophosphates, that the first ion exchanger is prepared in the crystalline form directly by low-temperature precipitation, whereas the second is amorphous upon low-temperature precipitation and crystalline samples are synthesized by high-temperature precipitation, e.g., by treating the system in boiling orthophosphoric acid [5, 6]. A submicrocrystalline structure of the X-ray amorphous tin(IV) hydrophosphate is only recorded by electron diffraction analysis [5].

The interplanar spacing in tin(II) hydrophosphate is 6.815 Å, and that in the crystalline tin(IV) phosphate, 7.8 Å. Therefore, according to the similar ion-exchange mechanism based on the ion-sieve principle, the sorption parameters of tin(II) phosphate having a lower interplanar spacing must be poorer. However, it has been found experimentally that tin(II) hydrophosphate sorbs Cs^+, Rb^+, and K^+ ions from acid solutions, whereas crystalline tin(IV) hydrophosphate does not sorb the first two ions having larger radii than the K^+ ion under the same conditions [6]. On the whole, it is probable that, despite the same monoclinic crystal system of the ion exchangers, their packing and layer

540–550	0.245	0.297	0.325	0.340	0.439	0.445
580	0.046	0.184	0.195	0.246	0.318	0.418
620	0.200	0.130	0.101	0.056	0.032	0.028

* A_0 is the intensity of the band at 1015 cm^{-1}.

binding may be different and the size of channels in $Sn(HPO_4)_2$ structure will be larger than that in $SnHPO_4$. For example, for crystalline zirconium(IV) hydrophosphate, the channels in the cavity are 2.61 Å wide, which makes impossible sorption from an acid solution for ions larger than unhydrated K^+. For tin(II) hydrophosphate, the size of channels between separate oxygen atoms is 3.27 Å, and, therefore, this ion exchanger will sorb larger cations [3, 12, 13].

The IR spectra of all the tin(II) hydrophosphate samples studied (Fig. 1) show that the results obtained are, on the whole, consistent with published data for tin(II) hydrophosphate [14]. The IR spectra contain bands at 3190 and 1230 cm^{-1}, associated with stretching [ν(OH)] and deformation vibrations [δ(OH)] of the HPO_4^{2-} ion. At the same time, the spectra contain bands at 3440 and 1640 cm^{-1}, associated with vibrations of water molecules. Bands in the region 915–970 cm^{-1} correspond to vibrations of the tin–oxygen skeleton. As the P : Sn ratio increases, the crystallinity of the samples becomes higher, with sample no. 1 not only being the least crystalline, but also containing a larger amount of other impurities.

Analysis of the IR spectra of sample nos. 1–5 shows that, as the P : Sn ratio increases, the content of tin(IV) phosphate becomes lower, and that of tin(II) phosphate, higher. A comparative estimate of the amounts of tin(II) and tin(IV) in the IR spectra of the samples studied is presented in Table 3. The band at 1015 cm^{-1} served as reference.

The data of Table 3 also confirm the conclusion that Sn(II) content increases with the P : Sn ratio: the relative intensity of the 580 and 540–550-cm^{-1} bands, which characterizes the content of tin(II) hydrophosphate, increases, whereas the relative intensity of the 620-cm^{-1} band, determined by the tin(IV) content, decreases. Consequently, in synthesis of ion exchangers at a small P : Sn ratio, the known chemical reaction of Sn(II) with the acid and water to give tin(IV) probably occurs [15].

A chemical analysis of various forms of tin present in the ion exchangers under study was made with account of the high importance and probability of transition of tin to the Sn(IV) state under certain conditions. It was shown that the content of tin(IV) in sample nos. 3, 4, and 5 is 1.3, 1.1, and 0.9 wt %, respectively, and that in sample nos. 1 and 2, several times higher, with the content of this impurity in sample no. 5 being equal to that in the starting $SnCl_2 \cdot 2H_2O$. Consequently, presence of minor amounts of tin(IV) will affect only slightly the sorption properties, which confirms the previously made conclusion about the optimal value of the P : Sn ratio in the starting reagents.

The results of a thermogravimetric analysis of the ion exchangers under consideration are, on the whole, similar, with some specific features. The results of a study by the DTA method are listed in Table 4 for all the sorbent samples.

As can be seen from Table 4, the ion exchangers under study are tin(II) hydrophosphates [8, 16]. The first endothermic effect at 60–250°C corresponds to removal of occluded water, and the second endothermic effect at 260–460°C, to condensation of acid phosphate groups into $SnHPO_4$. Sample no. 1 shows endothermic effects at 360–550°C and 550–660°C, which are probably due to removal of constitution water and presence of Sn(IV) ions and other impurities. Sample no. 5 shows an endothermic effect in the high-temperature region, 470°C to 670°C, which is associated with the condensation of phosphate groups or even, according to [16], with the melting of tin(II) diphosphate. Thus, sample nos. 2–4 correspond to tin(II) hydrophosphate to the greatest extent. It is noteworthy that the amount of water in the samples studied is small (0.1 mole at the optimal P : Sn ratio of 4).

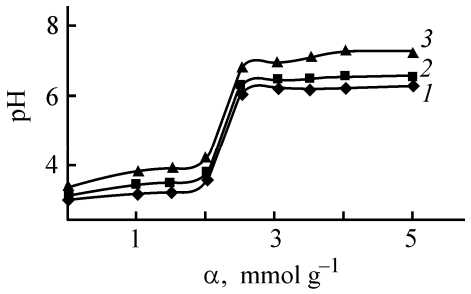

Fig. 2. Results of potentiometric titration of tin(II) phosphate. Titrant 0.1 M KOH + 0.1 M KCl. (α) Amount of OH^- per gram of sorbent. Digits at curves, sample nos. in Tables 1 and 2.

The acid–base properties of sample nos. 1–3, which differ in the P : Sn ratio to the greatest extent, were compared using potentiometric titration of their separate weighed portions. As titrants served 0.1 M KOH and 0.1 M KCl (Fig. 2).

The titration curves are identical, which points to similarity of the ion-exchange groups. The titration curves have two horizontal portions. In the first of these, K^+ ions are sorbed upon addition of KOH in amounts of up to 2 mmol g^{-1} of sorbent. The zero slope of the dependence indicates that all the released hydrogen ions are neutralized by the alkali introduced. Upon addition of 2–2.5 mmol KOH per 1 g of sorbent, pH sharply increases and, as the content of KOH is raised further (in the second horizontal portion of the curve), K^+ ions are not sorbed and excess OH^- groups favor occurrence of other reactions, e.g., hydrolysis of the ion exchanger. As follows from Table 3, the P : Sn ratio in the ion exchanger affects the maximum amount of sorbed K^+ ions only slightly.

The methods considered above were used to study the influence exerted on synthesis of tin(II) hydrophosphate by the pH of gelation, gelation duration, pH of ion exchanger washing, and concentration of orthophosphoric acid. At a pH structure gelstion equal to 0.8, the sorbent best corresponds to tin(II) hydrophosphate. All other synthesis parameters studied here af-

fect the resulting structure of the ion exchanger only slightly, and the efficiency of the ion-exchange interaction in sorption will be directly determined by the sorption parameters [10].

Consequently, the ion-exchange properties are affected by the chemical composition and structure of tin(II) phosphates. In tin(II) phosphate synthesized under the optimal conditions, the P : Sn molar ratio is 1.52. Therefore, if only phosphate-containing constituents of the ion exchangers are considered, monosubstituted tin(II) phosphates are probably present along with a disubstituted phosphate. The ratio between phosphates with different degrees of substitution will determine the P : Sn ratio in the sorbents, with other impurities also apparently present in sample no. 1.

Comparison of the data in Table 1 with the results of [5, 6, 17] shows that tin(II) hydrophosphate is of interest for separation of K^+, Rb^+, and Cs^+ ions and for purification of sodium salts to remove potassium.

CONCLUSIONS

(1) Tin(II) hydrophosphates synthesized by low-temperature precipitation, with interaction of tin(II) chloride and orthophosphoric acid, are crystalline compounds with composition $SnHPO_4$. The optimal P : Sn molar ratio in the starting reagents is 4, and the pH for maturing of the gel structure, 0.8.

(2) Tin(II) hydrophosphate exhibits ion-exchange properties related to its chemical composition and structure. The crystalline tin(II) hydrophosphate obtained sorbs Rb^+ and Cs^+ ions from acid solutions. This indicates that cavities in its structure are larger than those in crystalline tin(IV) hydrophosphate, which does not recover these ions under similar conditions.

Abstract—Kinetic features and the mechanism of photooxidative decomposition of sodium dodecyl sulfate in an aqueous solution under the action of pulsed short-wavelength UV light with a continuous spectrum upon introduction of hydrogen peroxide was studied.

DOI: 10.1134/S1070427208120112

Surfactants are widely used in the industry and households. They belong to the most widely occurring contaminants contained in wastewater.

An efficient way to purify wastewater to remove surfactants is their oxidative decomposition to CO_2 and H_2O. Ozone is most frequently used for this purpose (oxidation potential 2.07 V) [1]. However, ozone rather effectively oxidizes nonionogenic surfactants, but is considerably less efficient with anion-active surfactants (AAS) [2].

The hydroxy radical $^{\cdot}OH$ is a stronger and more effective oxidizing agent (oxidation potential 2.8 V). In contrast to ozone, it is not a selective oxidizing agent and equally effectively interacts with all organic substances, including surfactants [3].

After the appearance of pulsed xenon lamps with a continuous spectrum, it became possible to generate $^{\cdot}OH$ radicals in the reaction $H_2O_2 + h\nu \rightarrow 2^{\cdot}OH$ [4].

The method of photochemical oxidation in the presence of hydrogen peroxide has been used to deactivate EDTA-containing solutions [5], and the mode of nearly complete decomposition of the complexone was found.

The aim of the present study was to examine specific features of decomposition of sodium dodecyl sulfate (an AAS) in aqueous solutions by hydroxy radicals formed in H_2O_2 photolysis under irradiation with a xenon lamp.

EXPERIMENTAL

Al'fa-02 pulsed UV installation with an average electric power applied to the lamp equal to 200 W (pulse width 100 μs, pulse repetition frequency $f = 2$ Hz) was used in the experiment. Samples were irradiated in an open quartz cell with an IFP 1200 Xe lamp with a flash energy of 100 J. The cuvette with a solution was placed at a distance of 1 cm from the lamp and was cooled with an air flow in the course of irradiation. The volume of the reaction mixture was 10 ml.

The pulsed Xe lamp provides a continuous-spectrum light over the entire UV spectral range (200–400 nm). The light intensity was measured using the procedure described in [6]. The intensity I of the light flux incident on the cuvette was 3.8×10^{16} photons s^{-1}. The operation stability of the xenon lamp was monitored in the course of the study.

Sodium dodecyl sulfate (SDS, $C_{12}H_{25}OSO_2ONa$) was chosen as object of study. The aqueous solutions contained up to 100 mg of SDS per liter of a solution. The SDS concentration was found using the extraction-photometric determination with Methylene Blue by the procedure described in [7].

The degree of AAS decomposition was evaluated by measuring the chemical oxygen demand (COD) [7, 8].

The reaction course was also monitored by changes in optical spectra. The absorption spectra of the solutions in the UV and visible spectral ranges were recorded with an SF-2000 spectrophotometer in a quartz cuvette with an optical path length of 1 cm.

The hydrogen peroxide concentration in the solutions was determined from the concentration of the peroxide complex $[TiO \cdot H_2O_2]^{2+}$ [9, 10].

Figure 1 shows kinetic dependences of SDS decomposition at various initial concentrations. It can be seen that the AAS concentration almost linearly decreases in the course of irradiation. Despite the high power of the UV irradiation, the degree of decomposition is low: 20.1, 34.8, and 50.6% for SDS solutions with concentrations of 100, 50, and 25 mg l^{-1}, respectively, upon 20 min of irradiation. In the course of irradiation, the solution pH changes from 6.3 to approximately 5.0.

Figure 2 compares the kinetic dependences of SDS decomposition (100 mg l^{-1}) with and without H_2O_2 (100 mg l^{-1}). Introduction of H_2O_2 intensifies the decomposition of SDS. It almost completely decomposes after 20 min of irradiation, with about 50 mg l^{-1} of H_2O_2 consumed.

Preliminary experiments revealed that the presence of H_2O_2 in solution does not cause decomposition of SDS (8 days) if the solution is not subjected to UV irradiation.

The exposure to UV light gives rise to free $^{\cdot}OH$ radicals as a result of homolytic decomposition of H_2O_2. It is known [3] that $^{\cdot}OH$ radicals have high reactivity toward organic compounds RH of varied nature (commonly, $k_{^{\cdot}OH+RH} > 10^7$ M s^{-1}). As a result, organic compounds undergo oxidative decomposition. Thus, the oxidation in the case in question occurs in the combined mode, with an oxidizing agent (H_2O_2) and its activation with UV light.

It can be seen in Fig. 3 that the SDS decomposition rate increases with the H_2O_2 content of a solution. As a result of oxidative decomposition of SDS, the solution ceases to foam and pH changes to approximately 3–4.

Comparison of curves *1* and *2*, *4* and *5* shows that raising the initial pH value from 6.3 to 9.6 leads to a certain increase in the SDS decomposition rate.

To determine the relative qualitative composition of the aqueous solution after photooxidation, the generalized water-quality parameter, COD, was measured (Fig. 4). The irradiation of an SDS solution (100 mg l^{-1}) in the presence of 50 and 200 mg l^{-1} of H_2O_2 led to a decrease in COD, which is the more pronounced, the higher the H_2O_2 concentration. For a solution with 200 mg l^{-1} of H_2O_2, the COD decreased by 28% in 20 min after a residual SDS concentration of 0.4 mg l^{-1} was reached. This means that only 28% of SDS decomposed to CO_2 and H_2O. For a solution with 50 mg l^{-1} of H_2O_2, the decrease did not exceed 13.5% after 35 min of irradiation, with the residual SDS concentration of 7.5 mg l^{-1}.

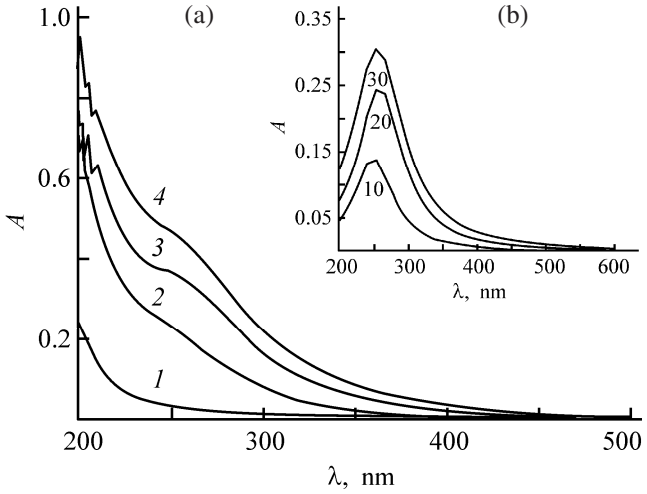

Fig. 6. (a) Absorption of SDS (100 mg l^{-1}) and H_2O_2 solutions (200 mg l^{-1}) subjected to UV irradiation and (b) absorption spectra in the spectral range 250–280 nm computed from the spectra in Fig. 6a. (A) Optical absorption and (λ) wavelength. (a) Irradiation time (min): (*1*) 0, (*2*) 10, (*3*) 20, and (*4*) 30.

It was found that the kinetics of SDS decomposition is well described by a first-order reaction equation. In accordance with this equation, the variation of the SDS concentration with time is linearized in the coordinates $-\ln(c_t/c_0)$–t, where c_0 and c_t are the SDS concentrations at the initial and running instants of time, and t is time. The experimental data well fall on the straight lines (Fig. 5), which confirms the validity of the suggested kinetic equation. The slopes of these lines were used to calculate the relative (related to the intensity of the UV light source used and experimental conditions) rate constants of SDS decomposition, k_{AAS}. The values of k_{AAS} (0.077, 0.1813, and 0.313 min^{-1} for H_2O_2 concentrations in solution of 50, 100, and 200 mg l^{-1}, respectively) almost linearly increase with the SDS concentration. This means that SDS decomposes under conditions in which $^{\cdot}OH$ radicals are generated at a constant rate proportional to the H_2O_2 concentration, because the efficiency of H_2O_2 photodecomposition is, in turn, proportional to the energy of UV light absorbed by hydrogen peroxide, i.e., to the H_2O_2 concentration in solution. This fact is confirmed by the data in Fig. 2 (curve *2*).

An analysis of the absorption spectra of SDS solutions enabled a suggestion about the possible products of its photodecomposition. Figure 6a shows absorption spectra of a solution irradiated for different times. It can be seen that the absorption spectrum of the solution changes, compared with the initial spectrum, after photooxidation.

Particularly pronounced changes are observed below 200 nm and in the range 250–280 nm. The absorption in the second range increases, which further gives rise to a new band. A computer processing of the spectra revealed a new optical absorption band peaked at 250–280 nm (Fig. 6b). It can be seen that the intensity of this band increases almost proportionally to the time of the UV irradiation. The absorption above 250 nm can be attributed to presence of carbonyl-containing oxidation products formed as a result of interaction with .OH radicals. An absorption typical of carbonyl compounds is observed at 190 nm and above 250 nm (ε_{190} = 1900 mol^{-1} cm^{-1}, ε_{280} = 1500 mol^{-1} cm^{-1}) [11]. However, quantitative characterization of the forming photoproducts by their spectra is impossible because, as it would be suggested, the composition of products containing a carbonyl group is rather complex.

In [12], products of this kind were observed upon treatment of SDS with both ozone and $^{\cdot}OH$ radicals specially generated under the action of radiation in a so-

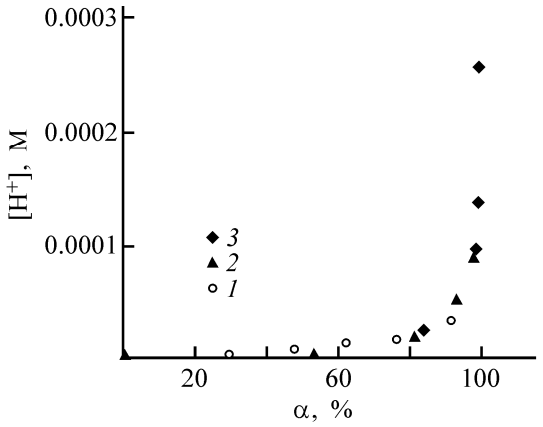

Fig. 7. Concentration of H^+ ions vs. the degree α of SDS decomposition under photooxidation. SDS concentration 100 mg l^{-1}. H_2O_2 concentration (mg l^{-1}): (*1*) 50, (*2*) 100, and (*3*) 200.

lution saturated with N_2O. It was found that $^{\cdot}OH$ radicals react with the hydrocarbon chain of SDS and oxidize carbon in this chain, with carbonyl groups randomly introduced along the entire hydrocarbon chain.

The presence of a peak at ~190 nm in spectra with a characteristic gentle slope is typical of carboxylic acids. The pH values of the solutions also point to an increase in the concentration of H^+ ions. As the exposure duration increases, the visible variation of the concentration of H^+ ions with the degree of SDS conversion in solution passes through a kind of induction period after the onset of SDS conversion and then noticeably grows (Fig. 7). Products of the carbonyl type formed in the first stage of SDS decomposition are oxidized to give carboxy-containing products in the subsequent stage.

Comparison of the data obtained (Figs. 3, 6, and 7) distinguishes two stages of the SDS decomposition. In the first stage, an almost 95% destruction of SDS occurs, which does not lead to any noticeable change in the pH of the medium. This initial period of SDS photooxidation is accompanied by splitting-off of the OSO_2ONa^- group by an SDS molecule and by loss of surface-active properties. Presumably, the role of $^{\cdot}OH$ radicals consists in this stage in the formation of carbonyl-containing intermediates. Further occurs the stage in which there exists a narrow range of SDS conversion, with the solution acidity substantially increasing as a result of the subsequent intense oxidation to give carboxy compounds. Further deeper destruction of the forming organic products, to the point of CO_2 and H_2O formation, proceeds at a considerably slower rate (Fig. 4).

CONCLUSIONS

(1) Sodium dodecyl sulfate decomposes in an aqueous solution under the action of high-intensity continuous-spectrum light emitted by a Xe lamp. The decomposition efficiency substantially increases upon addition of H_2O_2 to a solution. The decomposition kinetics of sodium dodecyl sulfate is described by a first-order equation, and the decomposition rate constant is proportional to the H_2O_2 content of the solution.

(2) In the initial stage of sodium dodecyl sulfate decomposition ($\alpha \approx 80\%$), sulfo groups are split-off and carbonyl compounds are formed, with the surface-active properties disappearing in the process. In the subsequent stage, the products of sodium dodecyl sulfate decomposition are deeply oxidized, compounds with carboxy groups are formed, and the solution acidity substantially increases.

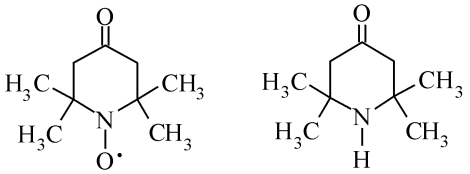
Abstract—Effect of a paramagnetic substance on the crystallization of calcium carbonate in magnetic water was studied.

DOI: 10.1134/S1070427208120124



Numerous studies have been devoted to elucidation of the diminishing influence exerted by magnetic fields (MF) on the rate of scale formation on walls of heat equipment [1–4], with attempts made to explain this phenomenon on the basis of theoretical concepts. The main drawback of these studies was that the role of the experimental factor was underestimated. In this communication, we suggest a new, more perfect concept of the antiscale magnetic treatment of water, based on real experimental data.

Analysis of the scale formed on apparatus walls shows that it is mainly composed of trigonal calcite and leaf-like vaterite, whereas the needle-shaped modification of calcium carbonate, aragonite, remains in solution [5]. Having low adhesion to vessel walls and poor cohesion to each other, the needle-shaped crystals of aragonite are easily carried away by water into setting tanks, wherefrom they are periodically removed [5]. Therefore, the scale formation can be considerably diminished by forcing calcium carbonate to crystallize in the form of aragonite. Application of MF by itself promotes directed crystallization of calcium carbonate in the form of aragonite [1]. Furthermore, it has been shown [6] that the amount of aragonite sharply increases when dissolved oxygen is present in magnetic water. This fact was observed for the first time. However it remained unclear whether the observed effect is due to the paramagnetism of oxygen or to its microbubbles [2, 7] whose influence cannot be excluded a priori. As to the role of paramagnetic substances, no studies have been peerformed in this area, with the exception of an analysis of the influence exerted by ferromagnetic inclusions [4, 8, 9].

The aim of the present study was to examine the effect of paramagnetic impurities on the crystallization of calcium carbonate with and without MF application.

EXPERIMENTAL

We chose for the study paramagnetic substances of varied nature: gaseous nitrogen oxide (NO), readily water-soluble organic radical 2,2,6,6-tetramethylpiperidine-4-on-*N*-oxyl (TEMPON) (**I**), and its nonparamagnetic analogue 2,2,6,6-tetramethyl-4-piperidine (**II**), close in structure and molecular weight:

I **II**

Distilled water used to prepare solutions was preliminarily boiled to remove carbon dioxide. In the process, the pH value of distilled water increased from 5.6 to 7.0. Water was cooled to room temperature without access of air and 5 mg-equiv dm^{-3} of calcium chloride was dissolved in it. Then sodium hydrocarbonate was added with shaking until the solution pH reached a value of 8.3. During 15 min before each experiment and over the whole period of the experiment, air or argon was

bubbled through the solution. The resulting aqueous solutions were passed through a magnetic field with a strength of 60 kA m^{-1} and 75-mT remanent induction at a flow velocity of 0.15 m s^{-1}. Four pairs of permanent magnets were arranged with unlike poles on opposite sides of the hy-draulic channel at a distance of 7 mm from each other. In this arrangement, each succeeding pair of magnets repulsed from a preceding pair. The combination of a uniform magnetic field inside each pair of magnets with a "magnetic shock" in the gap between the pairs enhanced the magnetic treatment effect.

Nitrogen oxide was obtained by adding 7 M H_2SO_4 to copper shavings in a glass apparatus without access of air. For pressure equalization, the lower reaction part of the apparatus was connected by a glass tube to a separatory funnel situated in the upper part. NO was purified to remove trace amounts of NO_2 by passing the gas mixture through a Tishchenko flask filled with a 0.1 N sodium hydroxide solution. A solution under study was saturated with nitrogen oxide for 5 min, and then the NO feed was switched off. The mass concentration of TEMPON and its analogue was 5 mg l^{-1}. These concentrations of dissolved salts and a paramagnetic substance were chosen in accordance with the results of preliminary experiments as corresponding to the best manifestation of the magnetic treatment effect.

To accelerate the crystallization, we heated a glass flask with magnetic water on a water bath to 80–100°C and cooled it without access of air to room temperature. Calcium carbonate formed on heating the solution gathered in the bottom part of the flask. Upon settling of the solutions, the excess amount of water was decanted and the remaining suspension was observed and photographed with a Polyvar optical microscope equipped with a Vision video camera.

The conditions of magnetic treatment of the water type under study (arrangement of magnets and magnetic field strength, shape of the hydraulic clearance, and water flow velocity) were chosen experimentally, because it is known from the literature that the dependence of the magnetic treatment effect on these factors is of polyextremal nature and cannot be calculated.

It is known [5] that, in the absence of MF, calcium carbonate precipitates from aqueous solutions in three crystallographic modifications: calcite, vaterite, and aragonite, with predominance of calcite and vaterite. Application of a magnetic field changes the mechanism of calcium carbonate crystallization both in the presence of air (Fig. 1) and in an argon atmosphere (Fig. 2). The amount of vaterite and calcite decreases,

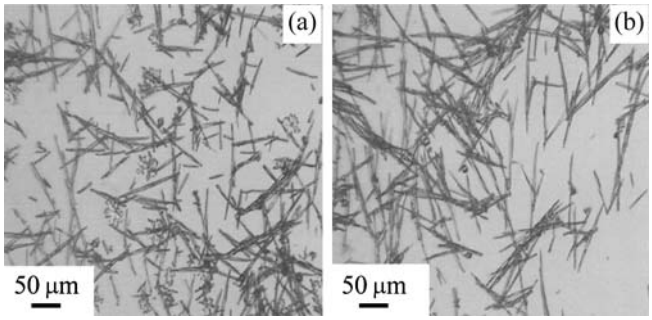


Fig. 1. Micrographs of $CaCO_3$ crystals (×140) obtained (a) without magnetic treatment and (b) with magnetic treatment of calcium hydrocarbonate water containing dissolved air.

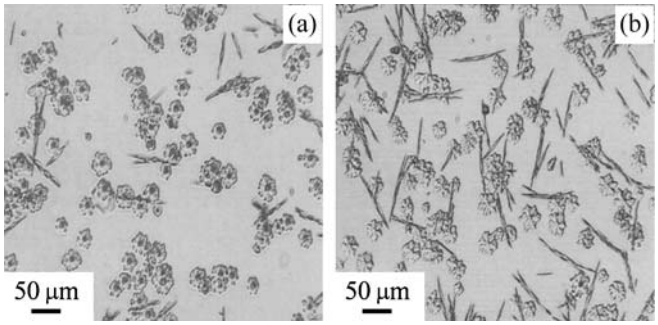

Fig. 2. Micrographs of $CaCO_3$ crystals (×140) obtained (a) without magnetic treatment and (b) with magnetic treatment of calcium hydrocarbonate water saturated with argon.

and that of aragonite increases. The larger number of aragonite crystals in air is accounted for by the presence of paramagnetic atmospheric oxygen [6], which enhances the magnetic treatment effect. The amount of needle-shaped aragonite crystals increases; the crystals become longer and thicker.

The assumption that the process of calcium carbonate crystallization is affected just by the paramagnetism of dissolved gases, rather than by their microbubble structure, was confirmed by the experiments with nitrogen oxide. Introduction of paramagnetic NO into a solution (Fig. 3a) noticeably raises the amount of

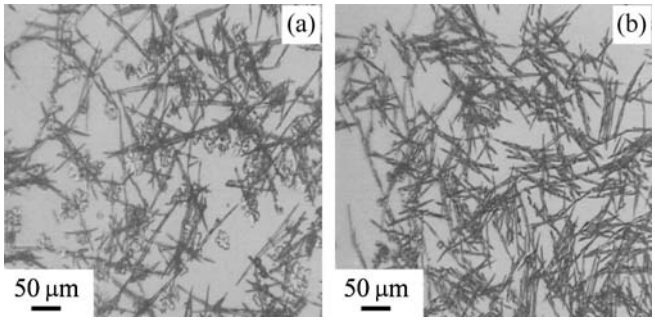

Fig. 4. Micrographs of $CaCO_3$ crystals (×140) obtained (a) without magnetic treatment and (b) with magnetic treatment of calcium hydrocarbonate water containing 5 mg l^{-1} of TEMPON.

aragonite in a precipitate, compared with control experiments in the presence of argon (Fig. 2). When MF is applied to a solution containing NO, the amount of aragonite strongly increases (Fig. 3b). In the process, leaf-like vaterite crystals completely disappear, but separate crystals of trigonal calcite appear. It can be assumed that the application of the field promotes conversion of the metastable vaterite to a more stable calcite. The slightly weaker effect of the magnetic treatment in the presence of NO (presence of calcite inclusions), compared with O_2 [6], can be attributed to the lower magnetic susceptibility of nitrogen oxide. According to the data of [10], the specific magnetic susceptibility of O_2 is 1.335 $m^3 kg^{-1}$, and that of NO, 0.62 $m^3 kg^{-1}$.

The effect of a paramagnetic substance on the process of crystallization of calcium carbonate can be explained as follows. It is known that, on applying MF, paramagnetic substances are pulled in a magnetic field and are arranged along magnetic force lines, whereas diamagnetic substances, water among them, are pushed out. Under the action of MF in the absence of a paramagnetic substance, the hydrate shells of calcium ions situated along magnetic force lines are deformed. In a water flow, partly hydrated calcium ions can approach to a distance at which the Van der Waals attraction forces exceed the electrostatic repulsion forces, and formation of crystalline nuclei becomes possible. First, short chains or planar monomolecular layers can be formed, and their further agglomeration yields a solid phase. Thus, the increased concentration of partly hydrated ions along the MF force lines is the main condition for directed crystallization of calcium carbonate in the form of needle-shaped aragonite.

There are two reasons for the enhancement of the magnetic treatment in the presence of a paramagnetic substance. On the one hand, a paramagnetic arranged along MF lines weakens the hydration of the surrounding ions. On the other hand, having an unpaired electron and an energetically nonuniform surface, the paramagnetic radical can by itself initiate the crystallization process [5]. The effect of a paramagnetic substance on the directed crystallization of calcium carbonate seems to consist in weakening of the hydration of calcium ions along the magnetic force lines. In principle, the direct crystallization of $CaCO_3$ on paramagnetic centers is not impossible, but the probability of such a process is rather small. In view of the aforesaid, we can suggest that, in a sense, the paramagnetic substance reminds in operation mechanism a catalyst, which accelerates a reaction without entering into the composition of its products. This refers to the same extent to all the paramagnetic substances studied.

The strongest influence on the directed crystallization of calcium carbonate was exerted by introduction of a paramagnetic organic radical TEMPON into a solution (Figs. 4a and 4b). Comparison of the micrographs in Figs. 3 and 4 shows that TEMPON substantially exceeds gaseous nitrogen oxide in the effect on the $CaCO_3$ crystallization. This is attributable to the difficulty of retaining gaseous NO molecules along magnetic field lines. Indeed, when a sufficient number of NO molecules join into a bubble, Archimedes forces can exceed the orienting action of MF, and the bubble will float-up to the surface of a liquid. The freed place will be primarily filled by neighboring water molecules and calcium ions, whose concentration is considerably higher than that of NO. Eventually, the labile NO molecules will displace diamagnetic water molecules and calcium ions to the periphery of the MF force lines, and the process will repeat from the very beginning. Periodic fluctuations of the paramagnetic NO somewhat diminish its influence on the process of calcium carbonate crystallization.

Fluctuations of this kind are not characteristic of the organic radical TEMPON. The crystallization of calcium carbonate occurs in more undisturbed conditions, which reflects on the properties of the resulting precipitates.

According to Fig. 4a, the precipitates of calcium carbonate formed in solution in the presence of TEMPON without magnetic treatment mainly consist of aragonite and vaterite. Trigonal calcite crystals are absent in this case. When magnetic field is applied, metastable vaterite crystals disappear and almost the whole amount of calcium carbonate crystallizes in the form of the needle-shaped aragonite (Fig. 4b). Taking into ac-

count the absence of calcite crystals in magnetic water, we can conclude that the paramagnetic radical TEMPON is as good as, or even better than, one of the strongest paramagnetic substances, molecular oxygen, in the efficiency of antiscale treatment [6].

As additional evidence in favor of our concept can serve the results of experiments with a close analogue of TEMPON, nonparamagnetic 2,2,6,6-tetramethyl-4-piperidine. According to the data obtained, calcium carbonate crystallizes in the presence of the nonparamagnetic analogue, as it also does in the case of argon, mainly in the form of leaf-like vaterite. Even though application of a magnetic field leads to a slight increase in the amount of needle-shaped aragonite, the main part of crystals retains in the leaf-like shape characteristic of vaterite.

CONCLUSIONS

The presence of paramagnetic nitrogen oxide, atmospheric oxygen, and the organic paramagnetic radical 2,2,6,6-tetramethylpiperidine-4-on-*N*-oxyl in magnetic water promotes directed crystallization of calcium carbonate in the form of a needle-shaped aragonite.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Effect of Hydroacoustic Treatment on Chitosan Dissolution in Aqueous Acetic Acid Solutions

I. M. Lipatova and L. I. Makarova

Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia

Received May 13, 2008

Abstract—Effect of a hydroacoustic treatment in a rotary-pulsatory apparatus on the dissolution rate and the achievable limiting solubility of chitosan in aqueous acetic acid solutions of various concentrations was studied. The rheological properties of solutions produced by the conventional method and with mechanical activation were compared.

DOI: 10.1134/S1070427208120136

Chitosan is an ionogenic polysaccharide with a set of rather valuable properties. The technological convenience of chitosan, related to its solubility in weakly acid aqueous media, makes it possible to produce from this polymer microspheres, microcapsules, coupling agents, and membranes, as well as carrier matrices in manufacture of medicinal preparations. Many structurally sensitive properties of these materials and articles are preset already in the stage of preparation of starting solutions from commercial chitosans manufactured in the form of powders or scales.

The properties of chitosan solutions have been described more than once [1–4], but either the method of solution preparation was not mentioned at all, or only the dissolution duration was specified. The solvent most frequently used for chitosan is 2% acetic acid. The duration of dissolution in this solvent under laboratory conditions is 4–16 h for different samples, depending on their molecular mass and degree of deacetylation [3, 4]. It was found in a study of the solubility of various brands of chitosan [5] that all the samples studied dissolve in 1% acetic acid; however, complete dissolution was reached for some of these samples only in 24 h. In addition, we found that solutions of chitosan with a molecular mass exceeding 400 kDa are inhomogeneous because of the presence of a gel fraction, which adversely affects the quality of films formed from these solutions. With the expansion of the field of industrial application of chitosans, the problem of fast preparation of their solutions without additional filtration becomes increasingly pressing.

A rather effective method for intensification of various technological processes performed in liquid media is hydroacoustic treatment in high-speed rotary-pulsatory apparatus [6]. The main distinctive design feature of these apparatus is the presence of alternating immobile and rotating cylinders with slits. In these apparatus, the most important factors activating the liquid media being treated are ultrasonic vibrations and, accordingly, cavitation, and also high shear stresses to which the liquid is subjected in narrow (0.1–0.5 mm) gaps between the rotor and stator elements.

The aim of our study was to examine the effect of a hydroacoustic treatment in rotary-pulsatory apparatus on the dissolution rate and achievable limiting solubility of chitosan in aqueous acetic acid solutions of various concentrations. In addition, we intended to compare the rheological properties of solutions produced in the conventional way and those obtained with mechanical activation.

EXPERIMENTAL

As objects of study served three chitosan samples with M = 360 (Kh-360), 470 (Kh-470), and 500 kDa (Kh-500).[1] The degrees of deacetylation (DD) of the chitosans were 0.82, 0.79, and 0.60, respectively. In the air-dry state, the chitosans were in the form of flat scales 0.5–2 mm in size.

[1] Chitosan samples were provided by Bioprogress Private Company.

We used as solvents aqueous acetic acid solutions with an acid concentration varied within the range 0.2–2 wt %. Weighed portions of chitosans (1 g dl^{-1}) were dissolved in the aqueous acetic acid solutions at a temperature of 25°C under agitation until the process termination was analytically determined.

The thus obtained suspensions were mechanically treated in a laboratory rotary-pulsatory apparatus (RPA) in the recycle mode. The thermostated working chamber of the apparatus is formed by the rotor and stator whose cylindrical rings have rectangular channels. The average gap between the rotating and immobile members of the working chamber was 0.3 mm. The rotor rotation rate was 5000 rpm, to which corresponds a shear rate gradient of 17.4×10^4 s^{-1}. The treatment duration was varied within the range 4–40 s.

The dissolution rate of chitosans was determined by sampling the dispersion medium of the suspensions under study at regular intervals of time. The samples, transparent solutions, were analyzed for the content of chitosan by performing the reaction with Ninhydrin dye by the procedure described in [7], with the optical density of the resulting stained solutions measured on a Specol 11 spectrophotometer at a wavelength of 565 nm. Taking into account that the result of the analysis depends on the degree of deacetylation, a separate calibration plot was measured for each sample.

The content of the gel fraction in the chitosan solutions was found gravimetrically. A weighed portion of a solution was passed through preliminarily weighed sieves with 0.8×0.8-mm mesh, after which the sieves with the gel fraction they retained were again weighed and the volume fraction of the gel fraction was calculated, with the solution density taken to be 1 g cm^{-3}.

The viscosity of the solutions was determined on a Brookfield rotation viscometer (LVDV-1+) with a cylindrical rotor (6 rpm) at 25 ± 0.5°C at shear rates in the range 0.1–132 s^{-1}.

The characteristic viscosity of dissolved chitosan samples was determined at 25°C in an Ubbelohde viscometer (capillary diameter 0.73 mm) by successive dilution with 2% acetic acid. A 0.2 M solution of sodium acetate was introduced as a supporting electrolyte.

Chitosan is a polyaminosaccharide having an apparent dissociation constant of a conjugated acid, pK_a = 6.3–6.7, and dissolving in water only at pH < 6. As solvents can be used dilute solutions of monobasic organic and inorganic acids. The dissolution is preceded by protonation of NH_2 groups to give a salt adduct. Solutions are most frequently prepared using acetic acid with a concentration of 2 wt %, with the solution pH taking values of 3.3–3.6 upon complete dissolution. The so low pH values are undesirable in some cases and, in particular, in use of chitosan for immobilization of proteins and certain medicinal preparations. However, the decrease in the acid concentration strongly hinders the dissolution.

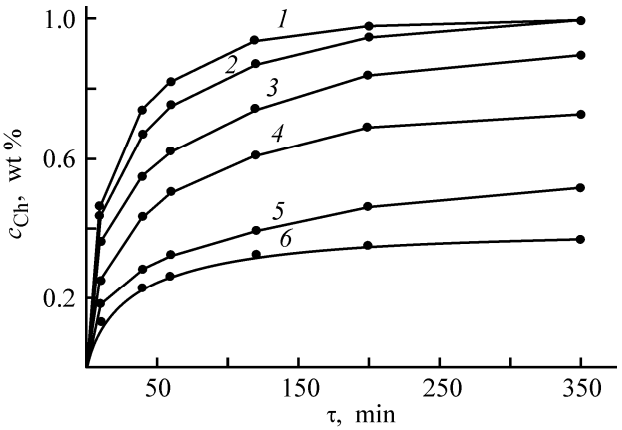

Fig. 1. Concentration c_{Ch} of Kh-360 chitosan in solution vs. the dissolution duration τ at a hydromodulus of 1 : 100. Acid concentration in solution (wt %): (*1*) 2, (*2*) 1, (*3*) 0.8, (*4*) 0.5, (*5*) 0.3, and (*6*) 0.2.

In this study, we used acetic acid solutions with concentrations of 0.2, 0.3, 0.5, 0.8, 1, and 2% as a medium for chitosan dissolution. Kinetic curves of Kh-360 chitosan dissolution in these media under ordinary conditions are shown in Fig. 1. The run of the kinetic curves indicates that the dissolution rate steeply decreases as the process duration becomes longer and the kinetic curves take a nearly horizontal position, although, according to analytical data, the process continues for several more hours until its completion.

Such a nonuniform course of the dissolution process is presumably due to structural inhomogeneity and molecular polydispersity of chitosan. The time in which the limiting concentration of chitosan is reached steadily increases as the acid concentration in the solvent decreases. For example, as indicated by analytical data and visual inspection, the process was complete in 5–6 h at acid concentrations of 1 and 2%, whereas at concentrations of 0.2 and 0.4%, the chitosan concentration in samples of the dispersion medium ceased to increase 20–22 h after introduction of chitosan into the solvent and, in this case, the solution contained a noticeable amount of undissolved particles.

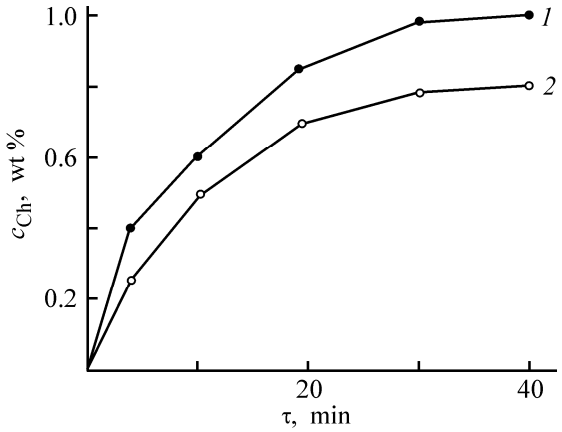

Fig. 2. Concentration c_{Ch} of Kh-360 chitosan in solution vs. the dissolution duration τ for the process performed in an RPA at a hydromodulus of 1 : 100. Acid concentration in solution (wt %): (*1*) 1 and (*2*) 0.8.

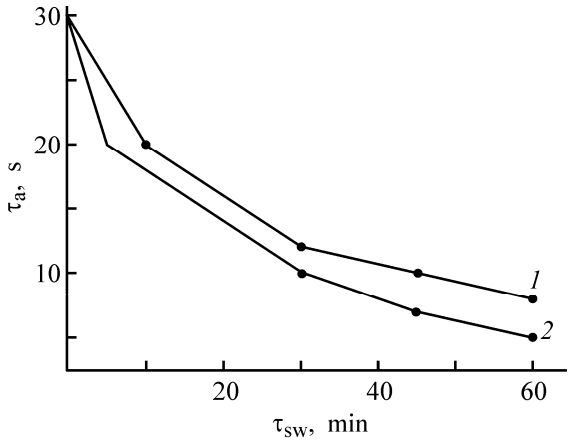

Fig. 3. Effect of the preliminary swelling time τ_{sw} on the dissolution duration τ_a of (*1*) Kh-470 and (*2*) Kh-360 chitosans in 2% acetic acid under mechanical activation in an RPA.

In the case of chitosan dissolution directly in the working chamber of RPA, sampling during treatment is impossible because of the too short process duration. To measure the rate of mechanically activated dissolution of chitosan, we prepared as many starting suspensions as the number of points to be obtained in the kinetic curve. The suspensions were activated one after another, with the treatment duration increasing each time, after which the undissolved fraction was separated and the solutions were analyzed for the content of chitosan. The kinetic curves obtained for the process of Kh-360 chitosan dissolution under hydroacoustic treatment are shown in Fig. 2 (curves *1*, *2*).

Comparison of the data in Figs. 1 and 2 points to a high efficiency of RPA application to intensification of the chitosan dissolution in the aqueous media under study. For example, a 80% dissolution of chitosan is reached under ordinary agitation by a mechanical stirrer at acid concentrations of 1 and 0.8% in 90 and 210 min, respectively, whereas in dissolution in an RPA, the same occurs in 17 and 35 s, respectively. The efficiency of mechanical activation in dissolution substantially increases if a suspension is treated in an RPA after a certain time, i.e., after a preliminary swelling of particles in the solvent, rather than immediately upon its preparation. Figure 3 shows how the time of mechanical treatment of a chitosan suspension (samples Kh-360 and Kh-470) in an RPA, necessary for complete dissolution of the polymer, becomes shorter as the time of preliminary swelling of the chitosan suspension increases.

It should be noted that, even with thermostating of the working chamber of the RPA, the solution warmed-up to 30–32°C. The heat released because of the internal friction in media being processed is apparently an additional factor that intensifies the dissolution. In this study, the duration of treatment in RPA did not exceed 40 s, because at longer durations it was impossible to preclude a considerable warming-up of the media being processed and a noticeable destruction of the polymer [8]. For Kh-500 chitosan, treatment in an RPA of a suspension without preliminary treatment does not lead to complete dissolution in 40 s. A total visually indicated dissolution is achieved only in activation of the suspension after a preliminary swelling for 2 h. In this case, too, the total process duration is substantially shorter than that in dissolution without activation. In addition, a solution obtained with mechanical activation is more homogeneous and contains no gel fraction.

The achieved effect of accelerated dissolution is accounted for by the simultaneous action of a number of factors on suspensions being processed under hydroacoustic treatment. The dissolution of solid particles in a liquid under treatment in RPA occurs simultaneously with the dispersion and, consequently, with the development of the phase-contact surface. The particles being dissolved are subjected to a multifactor treatment including turbulent pulsations of the liquid flow velocity, spherical shock waves in pulsations of cavitation bubbles, and cumulative action upon the collapse of these bubbles. Chaotic turbulent fluctuations of various layers of the liquid create strong shear stresses on the surface of a solid particle, which favors a decrease in the thickness of the diffusion layer, enhances its mobility, and provides an inflow of a fresh liquid to the surface of a particle being dissolved.

It was of interest to find whether it is possible to raise the limiting solubility of chitosan at low acetic acid concentrations by hydroacoustic treatment. According to the data of [9], the chitosan dissolution occurs at a degree of protonation equal to 0.5, i.e., 50% of amino groups are to be ionized for a macromolecule to pass into solution. According to the results of the same study, the 0.5–0.7 degree of protonation is reached only at the equimolar CH3COOH : chitosan ratio. The authors of [10] found that, irrespective of the acid concentration in the starting solutions, the residual amount of acetic acid in films formed from chitosan solutions in aqueous acetic acid is 24–27%, which corresponds to an approximately equimolar ratio between the acid and amino groups of the polymer. Upon introduction of 1 wt % chitosan into a solution, the equimolar ratio between the acid and amino groups is reached by the system at an acid concentration as low as 0.4%.

Thus, the complete dissolution can theoretically be reached at acid concentrations substantially lower than 2%, or even 1%, relative to the solution mass. As, however, follows from the experimental data obtained, only 73% of Kh-360 chitosan is dissolved even on raising the process duration to 24 h if the acid concentration is lowered to 0.5%. This result indicates that the solubility of chitosan is determined not only by the acid concentration of a solution, but, apparently, also by the degree of chemical and structural nonuniformity of a sample, i.e., by the quality of the raw material used.

Chitosan is produced by alkaline deacetylation of chitin. The incomplete course of this process is due to the presence of residual acetyl groups whose distribution in chitosan depends on the degree of crystallinity or on the relative amounts of the crystalline and amorphous regions of the starting chitosan, because the deacetylation reaction more easily proceeds in amorphous regions. The nonuniform distribution of the residual acetyl groups presumably predetermines that less soluble blocks are present in the chitosan structure, which alternate with regions of a nearly completely deacetylated polysaccharide. These latter cause a strong swelling of structural units in protonation in solution via electrostatic repulsion [11].

Under a hydroacoustic treatment, the combination of the above-mentioned factors must lead to disintegration of strongly swollen particles and to rupture of hydrogen bonds, which, in turn, must favor transfer of macromolecules with a sufficient degree of protonation to the solution. Figure 4 shows how the limiting solubility depends on the acetic acid concentration in an aqueous solution for the cases of conventional chitosan dissolution and that in the working chamber of RPA in the course of 40 s. It can be seen that, at low acid concentrations, the effect of the mechanical activation is manifested in that the limiting solubility increases, on average, by 25–45%.

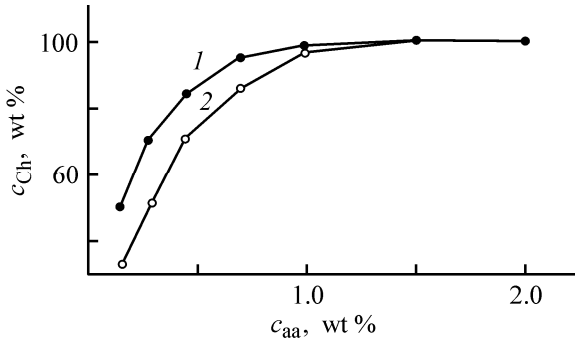

Fig. 4. Limiting solubility c_{Ch} of Kh-360 chitosan at a hydromodulus of 1 : 100 vs. the acetic acid concentration c_{aa} for the process performed (*1*) with mechanical activation in RPA and (*2*) with a mechanical stirrer at 25°C.

In mechanically activated dissolution with the use of RPA, not only the process duration changes, but also the quality of the solution obtained; in particular, the content of the gel fraction substantially decreases. Numerous publications concerned with properties of chitosan solutions do not mention presence of a gel fraction. We found that, after centrifugation of visually homogeneous solutions produced by prolonged dissolution in 2% acetic acid, their lower part with a higher viscosity can be separated by decantation. When these solutions are sieved, a viscous, gel-like part of the solution, in which spherical transparent particles ("gellites") can be seen, remains on the sieve. This primarily refers to samples with high molecular mass and low degree of deacetylation. For example, on keeping a Kh-500 sample (DD 0.6) in 2% acetic acid under periodic agitation for 18 h, complete dissolution was visually observed. However, an analysis demonstrated that the content of the gel fraction at the instant of complete visual dissolution was 11 vol %. On further keeping of the solution for additional 4 and 8 h, the content of the gel fraction decreased to 8.5 and 6.2 vol %, respectively, but it did not disappear completely even on keeping the solution for two days.

The gel fraction is present because the polymer incompletely passes into solution even at acid concentrations and process durations at which complete dissolution must occur according to published data. The rea-

Effect of hydroacoustic treatment on the duration of chitosan dissolution in 2% acetic acid and properties of the solutions obtained (c_{Ch} = 1 wt %)

Parameters of a solution	Kh-360		Kh-470	
	without activation	with RPA	without activation	with RPA
Dissolution duration	5 h	20 s	8 h	30 s
Dynamic viscosity, mPa s^{-1}	580	370	780	410
DSS	11.3	18.6	12.7	20.7
[η], dl g^{-1}	7.2	6.8	8.2	7.6
Huggins constant	0.62	0.48	0.72	0.55

sons for such a behavior are apparently related to the prehistory of a sample and to the presence of fractions with a lower degree of deacetylation. As a result, strongly swollen transparent agglomerates remain, although visual observation shows complete dissolution. Films formed from these solutions have an uneven, hummocky surface. In solutions prepared using RPA, no gel fraction was found by the method used in this study. Films formed from mechanically treated solutions are homogeneous and have a smooth surface.

It has been found previously that hydroacoustic treatment on chitosan solutions leads to a decrease in their viscosity because of the occurrence of mechanically initiated structural and chemical transformations, with a certain contribution to the observed decrease in the viscosity made by activated hydrolytic destruction of the polymer, whose extent increases with temperature [8]. In this context, a goal of the present study was to compare the rheological properties of solutions prepared by the conventional method and with mechanical activation. To evaluate the extent of mechanically initiated destruction, we measured in parallel the characteristic viscosity related to the molecular mass of the polymer. The data obtained are listed in the table.

It can be seen from the table that solutions produced by the mechanical method have a lower viscosity and are less structured than solutions prepared by ordinary dissolution. The decrease in the characteristic viscosity, indicative of the mechanical destruction of the polymer, is 5–7%. The decrease in the degree of structuring of the mechanically treated solutions is indicated by an increase in the dynamic stability of their structure (DSS), whose values were calculated using rheological data by the formula

$$DSS = (90 - \alpha)/(\alpha - 45),$$

where α is the slope rate of the linear portions of the dependences of the shear rate on shear stress, plotted in log–log coordinates.

The degree of structuring of the solutions presumably decreases via disintegration of stable aggregates of associated chitosan macromolecules in the mechanical field. The decrease in the Huggins constant, which characterizes the interaction of the polymer with the solvent, also points to a less important role of polymer–polymer contacts and increased role of polymer–solvent interactions in mechanically treated solutions. In other words, it can be stated that mechanical activation favors a more complete dissolution of chitosan.

Thus, it was shown that hydroacoustic treatment can diminish the duration of chitosan dissolution from several hours to several seconds. Solutions produced using mechanical activation are distinguished by lower viscosity and by better structural uniformity as compared with solutions of the same concentration, prepared in the conventional way. A decrease in the viscosity of chitosan solutions without any change in its concentration may be of practical interest in some cases and, in particular, for deposition of uniform films by spilling, synthesis of composite materials and impregnating solutions, and thin-layer dressing of various surfaces, and for other purposes.

CONCLUSIONS

(1) Use of hydroacoustic treatment in a rotary-pulsatory apparatus for intensification of chitosan dissolution in aqueous acetic acid solutions diminishes the process duration from several hours to 20–40 s.

(2) Mechanical activation of chitosan suspensions in acetic acid solutions with concentrations lower than 1% raises the limiting solubility of the polymer by 30–45%.

(3) Solutions produced using mechanical activation are distinguished by lower shear viscosity and molecular mass and by better structural uniformity, compared with solutions of the same concentration, prepared by the conventional method.

Abstract—The possibility of preparing new composite materials from acetylated wood and aluminum, aluminum chloride, and aluminum hydroxide as mineral fillers was examined.

DOI: 10.1134/S1070427208120148

Acylation of vegetable raw materials is an effective route of their chemical modification. Polymeric acylation products (esters of lignocarbohydrate materials) are soluble in organic solvents, exhibit hydrophobic and thermoplastic properties, and are biostable. These physicomechanical properties determine the possible applications of acylated lignocarbohydrate materials [1].

The use of acylated wood as a thermoplastic binder for preparing composite materials with mineral and wood fillers allows fabrication of boards with good physicomechanical parameters and hydrophobic properties. This is favored by the high thermoplasticity of acylated wood and its good adhesion to mineral and organic fillers [2].

Procedures have been developed for preparing esters from wood mechanochemically activated in the presence of catalysts, involving acylation of wood with a mixture of acetic anhydride with aliphatic carboxylic acid at 100–130°C for 4–6 h [3, 4]. These procedures have significant drawbacks: long process time (4–6 h), high temperature (100–130°C), and high consumption of acylating agents (3–10 mol).

The known procedure for preparing wood–mineral composite materials involves preparation of a cellulose-containing vegetable filler, its treatment with chemical additives (water glass, aluminum sulfate, calcium chloride), combination with a mineral binder (e.g., Portland cement of grade 400–500), forming of the composite, pressing, heat treatment, storage, and drying of the finished item [5]. However, the physicomechanical parameters of the resulting articles and their strength and water resistance are poor.

In this study, we prepared composite materials based on acetylated wood and aluminum and its compounds. We examined the strength properties and electrical conductivity of these materials.

EXPERIMENTAL

For activation of wood prior to the acetylation, it was subjected to cavitation pretreatment on a rotary cavitation apparatus at a rotor rotation rate of 3000 rpm. A 500-g portion of air-dry aspen sawdust (fraction 1–3 mm) was placed in a 50-l glass vessel and poured over with 8 l of water. The treatment was performed at 60°C for 30 min. Then the treated wood was filtered off with a linen filter, washed with water to neutral reaction, squeezed on the filter, and air-dried to constant weight.

The acetylation of activated aspen wood was performed as follows. A 3.0-g portion of air-dry activated sawdust was placed in a 250-ml round-bottomed flask equipped with a reflux condenser and placed on an oil bath (thermostat). Then a suspension of ammonium sulfate (20 wt % relative to wood) in 3 mol of acetic anhydride was added. The mixture was heated at 125°C for 4 h. Then the flask was cooled to room temperature, and 100 ml of distilled water was added. The mixture was filtered off on a glass frit (pore class 160) and washed with distilled water to remove acetic acid and the catalyst to neutral reaction and absence of sul-

fate ions (check with $BaCl_2$). The content of bound acetyl groups was determined by saponification of samples of acetylated wood with a 0.5 N solution of NaOH in alcohol, followed by conductometric back-titration of excess alkali with 0.5 N HCl [4]. The content of bound acetyl groups in the product obtained was 46 wt %.

The composite materials were prepared as follows. Into the matrix (acetylated aspen wood, AAW) we introduced aluminum, aluminum hydroxide, and aluminum chloride in an amount of 10–90 wt %. The resulting blends were charged into test tubes and heated for 2 h at 120°C. Then the samples of the composite materials were compacted into pellets 1 cm in diameter under a load of 15 kN (Table 1).

The phase composition of the samples was determined with a DRON-2.0 diffractometer with a cobalt anode ($\lambda Co K_{\alpha(mean)}$ = 1.7902 Å) at a rotation rate of 1 deg min^{-1} and on a X'Pert Pro diffractometer (Philips, Netherlands) with a copper anode and a nickel filter, at a tube voltage of 40 kV. The substances were identified using JCPDS data file.

The IR spectra of samples were measured on a Specord IR-82M spectrometer using KBr technique. The electrical conductivity of the polymeric composites was studied with an MO-62 dc bridge of class 0.1. Copper plates were used as electrodes, and samples of composite materials were placed between them. The limits of resistance measurements were chosen assuming that the polymer is an insulator and the filler content is varied from 10 to 90%. Accordingly, the resistance measurement range was from 10 to 10^6 Ω. The corresponding voltage was set at 36 V.

As can be seen from Table 1, the optimal content of all kinds of fillers is 30–70%. The strength of the composites reaches 21.0 MPa, which is comparable with the strength of known composites based on acetylated wood and mineral fillers [2, 5, 6].

We found that the materials have a relatively high ultimate strength, up to 21.0 MPa for the sample with Al, but the strength of the materials with aluminum chloride and aluminum hydroxide fillers is lower.

As can be seen from Table 1, composites with the same filler at its content of 70 and 90% have closely similar strengths exceeding that of unfilled AAW. Thermograms (Table 2) demonstrate a relatively high (up to 200°C) heat resistance of the composites containing 70% filles.

Table 1. Ultimate strength of composite materials based on AAW and aluminum compounds

Sample no.	Material composition	Filler content, %	Ultimate strength σ ± 0.3, MPa	Sample no.	Material composition	Filler content, %	Ultimate strength σ ± 0.3, MPa	Sample no.	Material composition	Filler content, %	Ultimate strength σ ± 0.3, MPa

Table 3. Results of an X-ray phase analysis of composite samples containing 90 wt % mineral filler

Composite	d, Å	I_{rel}, %	Composite	d, Å	I_{rel}, %
AAW–$Al(OH)_3$	4.90	100	AAW–Al	4.82	1
	4.30	81		2.37	100
	2.34	1		2.05	45
	1.85	9		1.44	15
	1.42	1		1.22	11

Two exothermic peaks in the range 210–480°C in the case of decomposition of the binder are due to degradation of acetylated components of aspen wood. A sample of a composite material containing aluminum chloride hydrate as a filler exhibits three endothermic peaks associated with the removal of water and cleavage of hydrogen bonds occurring as the filler complexes decompose, and also one exothermic peak with a considerable weight loss, characterizing the main degradation reactions of acetylated components of wood in the temperature range 200–278°C. The samples containing aluminum and aluminum hydroxide as fillers exhibit only one peak in the DTA curve in the temperature ranges 200–414 and 264–493°C, respectively.

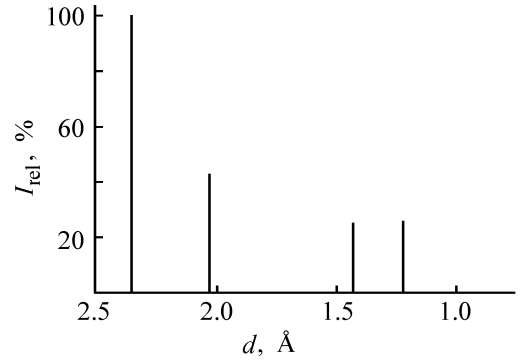

Fig. 1. X-ray diffraction pattern of a composite material based on acetylated wood with Al filler (70 wt %). (I_{rel}) Relative intensity and (d) interplanar spacing; the same for Fig. 2.

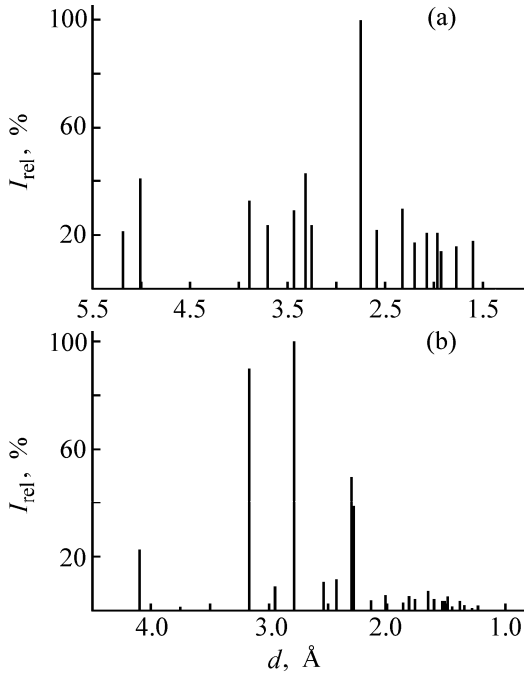

Fig. 2. X-ray diffraction patterns of a composite material based on acetylated aspen wood with aluminum chloride hydrate as filler. Filler content, wt %: (a) 70 and (b) 90.

An examination of the composite samples by X-ray phase analysis showed that the diffraction patterns of the composite material containing 70 wt % aluminum hydroxide exhibit only one reflection ($2\theta = 20.65°$) characteristic of AAW. The lack of reflections from the inorganic filler indicates that it is X-ray amorphous. The diffraction pattern of the composite material containing 90% aluminum hydroxide shows reflections from two modifications of the filler: σ-$Al(OH)_3$ (one reflection at $d = 4.30$ Å) and nordstrandite (four reflections) (Table 3).

The X-ray diffraction patterns of the materials containing 70 (Fig. 1) and 90 wt % (Table 3) Al unambiguously demonstrate the presence of the Al phase.

The AAW–$AlCl_3 \cdot 6H_2O$ composite material exhibits 16 reflections in the diffraction pattern, one of which ($d = 5.01$ Å) corresponds to AAW, and the others, to aluminum chloride hydrate (Fig. 2a).

X-ray phase analysis of the composite containing 90% $AlCl_3 \cdot 6H_2O$ (Fig. 2b) reveals the presence of two phases: aluminum chloride hydrate and AlO(OH).

The qualitative composition of the samples was determined from the characteristic IR absorption bands. The IR spectra of the materials containing aluminum chloride and hydroxide as fillers do not differ significantly from that of acetylated aspen wood.

The main absorption bands of composite components are present in all the spectra. The spectra of the samples containing 70 and 90% aluminum chloride

hydrate differ from the spectrum of unfilled AAW in that, in the range 3550–3100 cm^{-1} corresponding to vibrations of hydroxy groups, there are two bands indicative of the formation of an additional hydrogen bond between OH groups of AAW and aluminum chloride hydrate.

Conductivity measurements showed that the materials containing aluminum and aluminum hydroxide as fillers are dielectric (their resistivity exceeds 10^6 Ω cm), whereas the samples filled with aluminum chloride show weak conductivity: Their resistivity decreases to 10^5 Ω cm at a filler content of 70% and to 10^4 Ω cm at a filler content of 90%.

CONCLUSIONS

(1) Composite materials containing 30–70% acetylated wood and mineral fillers (aluminum, aluminum chloride, aluminum hydroxide) were prepared.

(2) The composites have a strength of up to 21.0 MPa, are heat-resistant up to 200°C, and can be used as finishing materials.

Abstract—Coalescence of KHA-30 compressor oil microdroplets on a carbon fabric, aimed to remove them from air and water streams used for compressor cooling, was examined.

DOI: 10.1134/S107042720812015X

Compressors [1, 2] can be responsible for contamination of air, water, and soil with hydrocarbon oils which severely affect the hygienic characteristics of these media. This is of special relevance to finely dispersed compressor oils (COs). Oil trapping filters fail after a certain period, so that oil gets into air, water, and soils.

The removal of microscopic droplets of KHA-30 compressor oil from water, which is specifically the subject of this study, is not a simple task. This oil brand is not toxic for humans, but poses a serious threat to aquatic biota, because of the extremely low maximum permissible concentrations set for KHA-30 oil in water (0.05 mg l^{-1}). The major procedure used for removing microconcentrations from water is adsorption. However, this method, efficient for molecules, is inefficient in trapping substances in the form of micro- and nanodroplets. In this case, it seems expedient to subject water to heterogeneous hydrodynamic coagulation–coalescence (HHC) treatment to be followed by adsorption. The HHC method is highly promising for removal of microdroplets from water, as demonstrated by experiments with food fats and technical oil [3] and by simulations of this process [4–6].

Water treatment by the HHC procedure to remove oil microdroplets can also be termed adagulation [7], but this term does not cover all the processes of formation and growth of clusters, as well as detachment of the coalesced fragments of the latter. In this context, we consider two processes: 1) preparation of quasistable CO emulsions in water and 2) degradation of these emulsions. We apply the term "quasistable" to emulsions that preserve no less than 70% of the optical transparency for 1 day. The breakdown (coalescence) of emulsions can also be regarded as water treatment to remove CO microdroplets. The removal of CO emulsions can be monitored by the variation of their optical absorbance A.

Tarasov et al. have shown [8] that the kinetics of water treatment to remove oil microdroplets is described by the Eley–Rideal equation [8], modified by Tarasov [3–5]. As is known, this process is named the SV process [8]; its principal kinetic characteristic is the slope φ of the straight line $\Delta(t) = 1/A - 1/A_0$, which determines the heterogeneous coagulation rate coefficient (HCRC, s^{-1}). The heterogeneous coagulation is a first-order process with respect to the concentration of the substance in the aqueous phase, which is characterized by a variable order (ranging from unity to zero) with respect to the microdroplet concentration on the surface [3–5]. In this case, the corresponding line is described by a $\Sigma(t)$ function, namely, $\Sigma(t) = \ln(A_0/A) + (1/A - 1/A_0) = f(t)$ [3–5], where A_0 and A are the light absorbances at the onset of the process and at any other instant of time, respectively. Another variable is the degree of removal of microdroplets from the emulsion, $E = f(t)$, %.

Here, we examined the water treatment to remove KHA-30 CO microdroplets by HHC with the use of a carbon fabric.

EXPERIMENTAL

The procedure for examination of the coagulation–coalescence of compressor oil microdroplets is nearly identical to that described by us earlier [4, 5] with two essential exceptions: The reactor walls are coated with a carbon fabric layer, and the operation of the rotor with disks in the coagulator-coalescer is started and stopped with an electronic circuit. The choice of a carbon fiber fabric was due to the specific conditions of wetting of the fabric with CO (see [3–5]). The close proximity of the fabric to the walls prevents the emulsion from filtration through the carbon fabric, which, in turn, precludes the mechanism operating in filter cartridges, with all its inherent drawbacks.

The KHA-30 compressor oil has a kinematic viscosity of 28–32 $mm^2 s^{-1}$ at 50°C, or 120 $mm^2 s^{-1}$ at 25°C. Its flash point in an open crucible is 185°C, the solidification point, –38°C; and density, 905 kg m^{-3} [9].

The setup used to prepare quasistable emulsions consisted of an IKA DI25 disperser equipped with an S25N–18G sprayer and a 500 cm^3 glass vessel with a rectangular cross section. The operation of the IKA DI25 disperser is based on interruption of an emulsion stream at a frequency of 1333–4000 Hz. The disperser rotor rotation rate was fixed at 133, 158, 225, 342, and 400 s^{-1}. The emulsions were used for testing the HHC method developed (coalescence of droplets). From the hydrodynamic viewpoint, these emulsions can be regarded as homogeneous liquids, since they are sensitive solely to minor hydrodynamic pulsations [10].

Figure 1 presents as an example the number- and volume-fraction size distributions of the CO emulsion microdroplets, obtained at 133 s^{-1}. It should be noted that similar patterns were obtained for rotation rates of up to 400 s^{-1}. The particle radius determined by computer-aided photomicrography is within 0.4–7.6 μm. All the distributions are oblique (asymmetric), because they lie at the edge of the visible spectral range. At 133 s^{-1} (Fig. 1), the w(r) distribution exhibits a distinct maximum, which disappears at 158 and, the more so, at 400 s^{-1}. However, distributions the maxima are preserved in the $\alpha = f(r)$; they are observed at 0.8–1.4 μm for all the disperser rotor rotation rates used in our experiments. The volume fractions are much more sensitive to the presence of individual large particles, since they are proportional to the cubed radius. This is specifically responsible for the fact that the maxima are preserved in the $\alpha = f(r)$ distributions at all the stirring intensities used in the experiments.

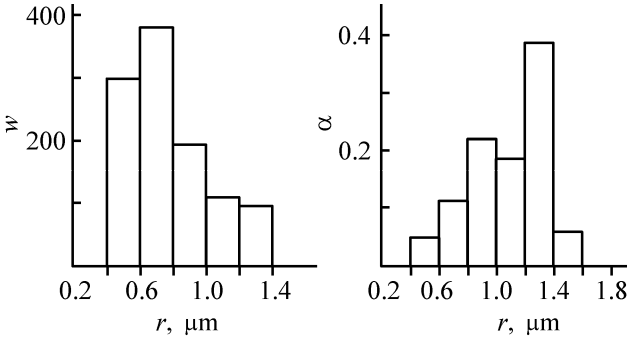

Fig. 1. Number-fraction and volume-fraction size distributions for droplets at the disperser rotor rotation frequency m=133 s^{-1} (8000×10/60 = 133.3 Hz). (w) Number, (α) volume fraction, and (r) radius of droplets.

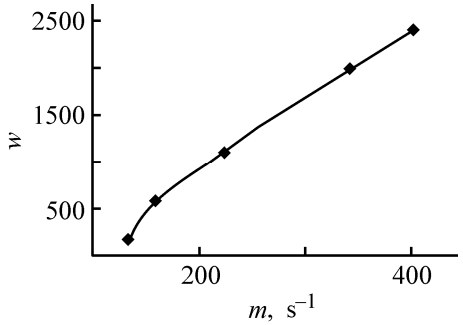

Fig. 2. Number of droplets w vs. disperser rotor rotation frequency m.

The change of the disperser rotor rotation rate m causes a nearly proportional increase in the number of droplets w (dimensionless parameter) (Fig. 2). The abscissa in Fig. 2 is the disperser rotor rotation rate m, and the ordinate, the number of the droplets, w, corresponding to the significant domain of the distribution (95% of the total area), recalculated for one image.

Importantly, not only the maxima are preserved in the $\alpha = f(r)$ distributions, but also fairly long (up to 7.6 μm) "tails" appear in the right segment of the distributions, probably due to the transverse axis vibration.

The setup for HHC treatment of water to remove microdroplets consisted of a reactor whose walls were coated with a carbon fabric, a PE–8100 stirrer with an electronic control circuit for the electric motor, a central shaft with a set of smooth polypropylene disks, and a temperature-control system (for the setup design, see [3]). There exists a direct proportionality between the CO droplet concentration in the emulsion and the light absorbance A measured on a KFK instrument. The basic kinetic parameter Δ is a function of three parameters:

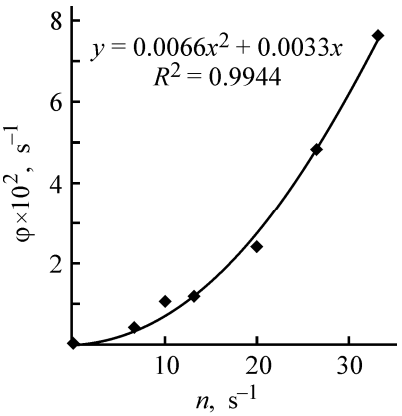

Fig. 3. Variation of the slope φ of the Δ(*t*) function with the coagulator–coalescer rotor rotation frequency *n* at a constant *m* = 225 s^{-1} (2250 Hz).

m, n, and *t*, where *m* and *n* are rotor rotation rates of the disperser and coagulator, respectively. In the case of interest, three alternatives are possible: $\Delta(t)_{m,\,n}$ = const, $\varphi(m) = \Delta(m)/t_n$ = const, and $\varphi(n) = \Delta(n)/t_m$ = const.

For all the 18 replicated experiments the $\Delta(t)_{m=225,\,n=16.7}$ function was linear with the approximation reliability factor of 0.9987. We confirmed for the first time that there exists a strict direct proportionality between the Δ(*t*) and $\Sigma(t) = \ln(A_0/A) + (1/A - 1/A_0)$ functions [3–6], the slope rate of a such function being close to unity. The approximation reliability factor for the $\Sigma = 1.1789\Delta$ equation is $R^2 = 0.9975$. Previously, this situation has been presumed, but not confirmed experimentally.

Tarasov et al.have shown [5, 6] that the Δ(*t*) function may be parabolic, $\Delta = 0.102t^2 + 0.0221t$, with the approximation reliability factor $R^2 = 0.9982$. However, the Σ(*t*) plot is represented by a straight line $\Sigma = 1.1761t$, with the approximation reliability factor $R^2 = 0.9941$ [5, 6]. Probably, this is possible only at not very large, though appreciable departures from unity of the logarithmic term of the sum (about several first ten units). As to trends in variation of the Δ(*t*) function, the function changes in the selected cases from parabolic to linear, as demonstrated and interpreted earlier [5, 6].

The $E = f(t)$ kinetic curves show that, within 2–6 min, 98–100% of compressor oil can be coagulated and even coalesced. Naturally, this specific proportion depends on the rotation rate of coagulator reactor disks.

Despite a threefold variation of the rotation frequency *m* of the disperser rotor (from 133 to 400 s^{-1}), the coagulation–coalescence rate is almost independent of *m* (see table). This is most clearly demonstrated by the microdroplet coalescence data for tri-*n*-butyl phosphate, used confirm the assumption that the microdroplet coalescence rate coefficients do not vary with *m.* The rate coefficients φ(*m*) for the CO coagulation–coalescence [4] are also listed in the table. They exhibit a weak and nonmotonic variation with *m*. It can be seen that the number of the droplets in the image varies from 166 to 2310 (nearly 14-fold). This suggests an efficient disintegration and reduction in size of the droplets. It was subsequently shown that a regular dependence of $\varphi(m) = \Delta/t$ on *m* is not observed for other objects, either. The invariance of φ(*m*) is not indicative of the kinetic control, for which φ(*m*) = const for all the rotation rates *n*.

If we accept for φ(*m*) a uniform value with a fairly large rms deviation, 0.025 ± 0.006, this can imply the invariance of φ(*m*), rather than that of the coagulation–co-alescence mechanism. In the case of a process occurring in a coagulator–coalescer, the mechanism of surface interaction with clusters becomes operative. This process is completely irreversible, and each collision of droplets with clusters results in their coalescence. In some cases, the slope of the φ(*m*) functions is zero, and in other cases, *m* tends to substantially decrease with increasing rotation rate of the disperser rotor. In the case of coalescence of the CO microdroplets, the rate-determining stage is a process characterized by a variable order (from two to unity), which results in attachment of the microdroplets attacking the surface clusters from the bulk. This stage is specifically responsible for the invariance of φ(*m*) at invariantable *n*. Hence, the size of turbulent pulsations [10] in the coagulator–coalescer bulk strongly exceeds the size of the resulting droplets. However, coalescence proceeds on the surface, rather in the volume of the coagulator–coalescer, and even minor changes in position relative to the wall coated with the fabric can be sufficient to strongly affect the behavior of droplets, which is specifically responsible for the pattern displayed in Fig. 3.

The coalescence in the coagulator–coalescer at *n* varying within 6.7–33.3 s^{-1} provides on exhaustive removal of the CO microdroplets. This result has not been achieved earlier; it suggests the irreversibility of the process. Now, the stirring intensity for the coagulator rotor with disks can be raised to ≥33.3 s^{-1} without exposing the system to a redispersion risk (Fig. 3). Even at the highest *n* values, the known maximum [11] was not achieved, which suggests complete suppres-

sion of the redispersion in the case of interest. No repeated disintegration of droplets is observed because of their high viscosity and prolonged resistance to breakdown of coalesced droplets. Apparently, it takes an appreciable time for a droplet to break down into two fragments.

The experimental $\varphi(n)$ curve at m = const = 225 s^{-1} is parabolic, $\varphi(n) = 0.0066n^2 - 0.0033n$, with the approximation reliability factor $R^2 = 0.9953$. Hence, validation of any mode should rely on variance or invariance of the process rate with respect to n, rather than on invariance of the coalescence rate coefficient φ with respect to m.

Our results suggest that the rate of coalescence of compressor oil microdroplets can be affected by introduction, in advance, of a minor amount of a diluent, such as diesel fuel (DF). The viscosity of DF at 20°C is 1.5–3.0 $mm^2 s^{-1}$, which is much lower than that of CO (140 $mm^2 s^{-1}$).

It could be expected that a decrease in viscosity would cause an increase in the coagulation–coales-cence rate coefficient $\varphi = \Delta/t$. However, even a minor decrease in viscosity caused initially a nearly fivefold decrease in the coagulation rate coefficient, and only subsequently, a minor increase in φ. A possible reason is that adding even a minor amount of diesel fuel causes a decrease in the stickiness (adhesion) of CO droplets to each other and to clusters. Therefore, the coalescence of microdroplets is decelerated by DF addition (Fig. 4).

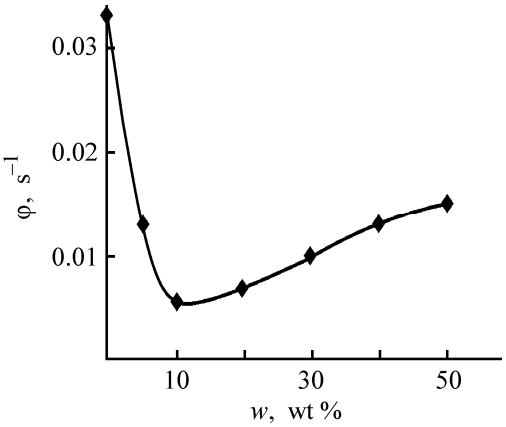

Fig. 4. Slope φ of the $\Delta(t)$ function vs. concentration w of diesel fuel additives (m = 225 s^{-1}, n = 16.7 s^{-1}).

CONCLUSIONS

(1) The coalescence of compressor oil microdroplets is an irreversible and fairly efficient process, which provides an exhaustive (nearly 100%) removal of 0.8–7.6-μm microdroplets within no longer than 480 s.

(2) An examination of the coalescence of microdroplets showed that, at invariant rotation frequency of the coagulator–coalescer rotor, the coalescence rate coefficient is nearly independent of the rotation rate of the disperser rotor. Rotation of the coagulator–coalescer rotor favors coalescence of microdroplets by a parabolic law.

(3) In the case of coalescence of compressor oil microdroplets, the rate-determining stage is a first-order process with respect to the concentration of microdroplets in the aqueous phase, which is characterized by a variable order with respect to the concentration of microdroplets on the solid surface. Adding the less viscous diesel fuel causes a nearly fivefold decrease in the rate constant coefficient of coalescence of compressor oil microdroplets.

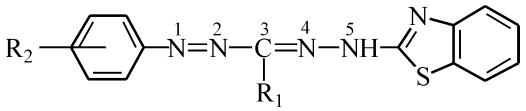
Abstract—New iron(II) coordination compounds with 1-aryl-5-(benzothiazol-2-yl)formazans were prepared. Their compositions and structures were determined by electronic spectroscopy, mass spectrometry, single crystal X-ray diffraction analysis, and magnetochemical measurements.



DOI: 10.1134/S1070427208120161

Iron coordination compounds with polydentate nitrogen-containing heterocyclic ligands are unique chemical systems. The specific features of their properties and structure are determined by the nature of the coordination core and by the steric arrangement of side functional groups.

Iron chelates has demonstrated good performance as effective catalysts of not only industrial (synthesis of ammonia, dehydrogenation of hydrocarbons, etc.) [1–3] but also biochemical processes [4]. Many of these compounds are characterized by exchange interactions of both ferro- (ferri-) and antiferromagnetic type, which lead under the action of certain external factors (temperature, pressure, irradiation at a definite wavelength) to transitions into a magnetically ordered state or to spin transitions $S = 5/2 \rightleftarrows S = 1/2$ [5–7] and make the iron complexes attractive objects for molecular electronics. In this context, synthesis and study of structural features of new coordination compounds of iron with ambidentate ligands are of both scientific and practical interest.

Among such ligands are, in particular, hetarylformazans, for which both bridging and chelate coordination is typical. The polydenticity and high flexibility of the formazan molecule, as well as the ability of such compounds to act as both bi-, tri-, and tetradentate ligands and also the possibility of controlling their properties through the substituent effect make them attractive for design of organometallic complexes with required stereochemistry [8, 9].

This study is concerned with synthesis of iron coordination compounds with formazans **I–V** and with the substituent effect on the composition, structure, and spin state of the metal complexes.

I–V

EXPERIMENTAL

The compounds were prepared from $FeCl_3 \cdot 6H_2O$ of analytically pure grade. 1-Aryl-5-benzothiazol-2-ylformazans were synthesized by the procedures described in [10–13]. The purity of the metal complexes was verified by TLC on Silufol UV-254 plates.

Iron 1-(4-sulfophenyl)-3-methyl-5-(benzothiazol-2-yl)formazanate (IFe). A solution of 0.3 mmol of iron (III) chloride in 15 ml of water was added dropwise with continuous stirring at 40 ± 5°C to a solution of 0.9 mmol of formazan in 100 ml of aqueous ethanol (1 : 1). The resulting mixture was stirred for 30 min and evaporated to a volume of 10 ml. The precipitate

was filtered off, washed with a small amount of distilled water, and dried in air.

Iron 1-phenyl-3-(propen-1-yl)-5-(benzothiazol-2-yl)-formazanate (IIFe). A solution of 0.3 mmol of iron(III) chloride in 15 ml of acetone was added dropwise with continuous stirring at 40 ± 5°C to a solution of 0.9 mmol of formazan in 100 ml of acetone. The resulting mixture was stirred for 30 min and evaporated to a volume of 10 ml. The precipitate was filtered off, washed with warm distilled water and ethanol, and dried in air. Iron formazanates **III**Fe, **IV**Fe, and **V**Fe were prepared similarly. The compositions of the ligands and complexes obtained are listed in Table 1.

The electronic absorption spectra of the ligands and their metal complexes in aqueous ethanol (1 : 1) for **I** or acetone for **II–V** were recorded on a Beckman UV-5260 double-beam spectrophotometer in the wavelength range 350–800 nm. The compositions of the complexes and equilibrium concentrations were determined from the plots of the optical densities of solutions vs. the volume of the salt solution added. The equivalence point corresponded to the salt solution volume required to attain the saturation. From these data, the stoichiometric composition of the complexes formed was calculated.

An elemental analysis was performed on a CHN PE2400SII automatic analyzer (Perkin–Elmer Instruments, the United States). The metal content was determined by express gravimetric analysis with a device produced by Khimlaborpribor Joint-Stock Company (Klin, Moscow oblast, Russia).

The IR spectra of the ligands and complexes obtained were recorded with a Specord 75-IR spectrophotometer in KBr pellets in the range 400–4000 cm^{-1}.

Mass spectra of iron formazanates were measured in the electron impact ionization mode on an MAT-ZPA device (Varian) with the reverse configuration in the design of magnetic and electrostatic analyzers, which allowed the spectra of metastable ions to be obtained directly. The spectra were measured under standard conditions: accelerating voltage 3 kV, cathode emission current 300 μA, and ionizing electron energy 70 eV. The samples were introduced into the ion source using the direct inlet system.

The magnetic characteristics of the compounds were measured with a Quantum Design 5-XL SQUID magnetometer in the temperature range 0–300 K in magnetic fields of strength 30 and 50 kOe.

Single-crystal X-ray diffraction analysis of complex **IV**Fe was performed at 295(2) K with an Xcalibur 3 autodiffractometric system equipped with a CCD detector. Crystals of **IV**Fe ($C_{36}H_{36}N_{10}O_2S_2Fe$, red prisms) belong to the monoclinic system. Unit cell parameters: a = 10.3951(18), b = 21.968(2), c = 15.9281(16) Å; α = 90.00°, β = 99.347(11)°, γ = 90.00°; V = 3589.0(8) $Å^3$; ρ_{calc} = 1.408 g cm^{-3}; M = 760.72; Z = 4; space group $P2(1)/n$. The experiment completeness at $\theta \le 26.38°$ was 99.5% (ω-scanning at 1° step and 10-s exposure per frame, crystal–detector distance 50 mm). A total of 7299 unique reflections were measured, including 2515 reflections with $I > 2\sigma(I)$. The absorption correction was ne-

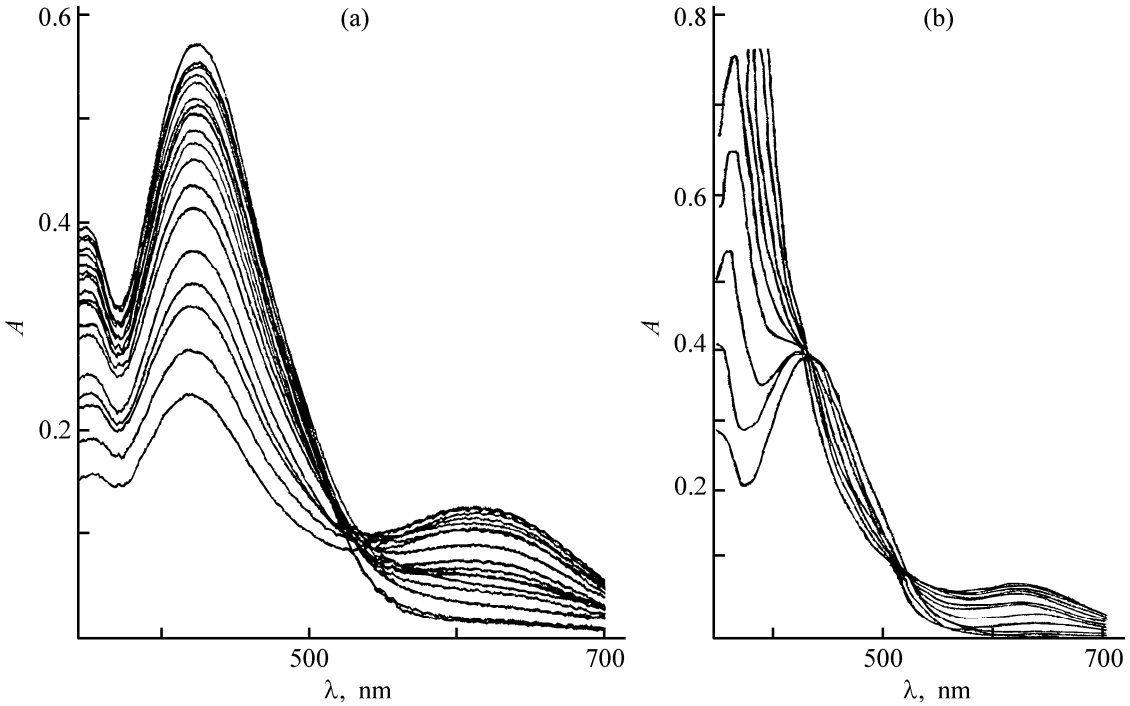

Fig. 1. Electronic spectra of formazan **IV** in acetone, recorded in the course of titration with a solution of (a) nickel(II) nitrate ([**IV**] = 2.85×10^{-5}, [$Ni(NO_3)_2$] = 10^{-3} M) and (b) iron(III) chloride ([**IV**] = 2.85×10^{-5}, [$FeCl_3$] = 1×10^{-2} M) in acetone. (*A*) Absorption and (λ) wavelength.

glected because of its insignificance (μ = 0.585 mm^{-1}). To collect and edit the experimental data and refine the unit cell parameters, we used the CrysAlis CD program [14]. The structure was solved by the direct method using the SHELX-97 program package [15]. The hydrogen atoms were placed in calculated positions and included in refinement in the rider model with dependent thermal parameters. The structure was solved by the least-squares method in the anisotropic approximation for nonhydrogen atoms and isotropic approximation for H atoms. The final divergence factors were R_1 = 0.0670, wR_2 = 0.0803 [$I > 2\sigma(I)$] at goodness-of-fit S = 0.994.

Depending on the structure of the initial formazan group, the ligands can coordinate M^{2+} and M^{3+} ions either in the tridentate fashion via N^1 and N^4 atoms of the formazan chain and nitrogen atom of the heteroring to give complexes ML_2 with a nitrogen-containing coordination core, or, if the aryl fragment contains an additional *o*-OH or *o*-COOH group, in the tridentate or tetradentate fashion to give complexes ML_2 or ML with N_xM or N_xO_yM coordination cores, depending on the synthesis conditions [8].

The variations in the mode of coordination of hetarylformazans in their complexes with metal ions, to give coordination compounds with diverse structures and properties are determined not only by the set of donor atoms in the ligand structure, but also by the electronic configuration of the central metal ion.

For example, in complexation of tridentate formazan **IV** with nickel(II) nitrate in an acetone solution, the intensity of the absorption band of the starting formazan at λ_{max} = 430 nm gradually decreases, and an absorption band of the metal complex appears at λ_{max} = 630 nm. The spectral pattern is characterized by the presence of one isobestic point, which suggests that only two formazan species are involved in the process: the starting formazan and the forming nickel(II) formazanate.

With iron(III), a metal ion with a variable oxidation state, the spectral pattern (Fig. 1) observed in the course of titration is more complicated. A decrease in the intensity of the absorption band of formazan is mainly associated with its tranformation into a product with λ_{max} < 350 nm. Apparently, formazan is oxidized into a tetrazolium salt (a well-known reaction of formazans [8]), with Fe(III) acting as oxidant. A weak absorption band appearing at 625 nm can be assigned to Fe(II) formazanate. This behavior has been already noted for complexation of some benzazolylformazans with Fe(III) and Mn(III) ions [16, 17].

The reactions of ethanol solutions of iron(III) chloride with benzothiazolylformazans **I–V** yielded

Table 2. Data furnished by electronic spectroscopy, mass spectrometry, and magnetochemical measurements for iron (II) complexes

Complex	*M*	*m/z* (*I*, %)	λ_{max}, nm	μ_{eff}, μ_B (μ^2_{eff})
IFe	858.64	–	670, 490	2.09 (4.4)
IIFe	696.72	696 (32.26)	675, 510	1.97 (3.9)
IIIFe	700.76	700 (100)	670, 520	0.22 (0.05)
IVFe	760.82	760 (100)	675, 490	0.45 (0.2)
VFe	768.78	768 (100)	680, 495	1.18 (1.4)

crystalline iron complexes **I**Fe–**V**Fe, which have, according to the analytical data (Table 1), electronic spectra, and mass spectra (Table 2), the composition L_2Fe.

For formazanate **I**Fe, we failed to detect the molecular ion and recorded only weak peaks of fragmentation ions.

In the electronic spectra of the iron-containing complexes, we observed, along with the major absorption bands at 670–680 nm, weak bands at 490–520 nm.

In the IR spectra of the iron formazanates, absorption bands assignable to ν(Fe–N) vibrations [18, 19] appear at about 745 and 500 cm^{-1}. In the IR spectra of the initial ligand, these bands are lacking.

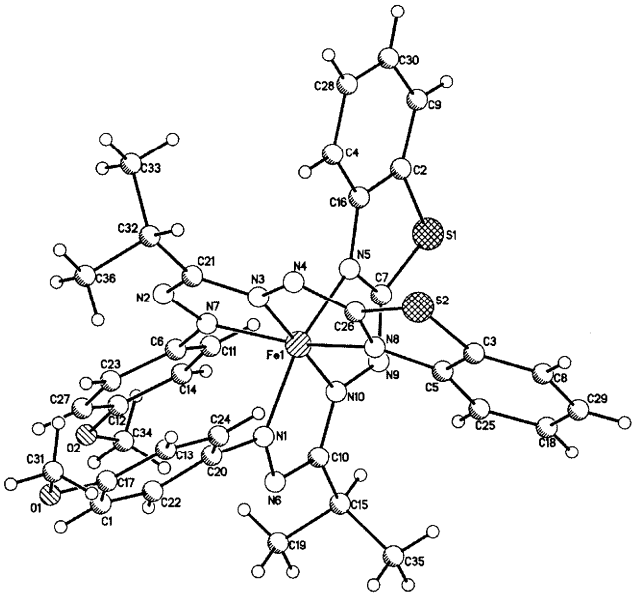

Fig. 2. Structure of iron 1-(4-methoxyphenyl)-3-isopropyl-5-(benzothiazol-2-yl)formazanate **IV**Fe. Selected bond lengths, Å: Fe(1)–N(1) 1.933(4), Fe(1)–N(5) 1.997(4), Fe (1)–N(10) 1.850(4), N(5)–C(7) 1.313(5), N(6)–N(1) 1.321 (4), N(6)–C(10) 1.364(6), N(9)–C(7) 1.346(5), N(10)–N(9) 1.366(5), N(10)–C(10) 1.332(6), N(5)–C(16) 1.373(5), C (7)–S(1) 1.745(5), C(10)–C(15) 1.500(6), N(1)–C(20) 1.411(5). Selected bond angles, deg: N(3)–Fe(1)–N(7) 79.27(18), N(3)–Fe(1)–N(8) 78.48(19), N(10)–Fe(1)–N(1) 78.80(18), N(10)–Fe(1)–N(5) 78.81(19).

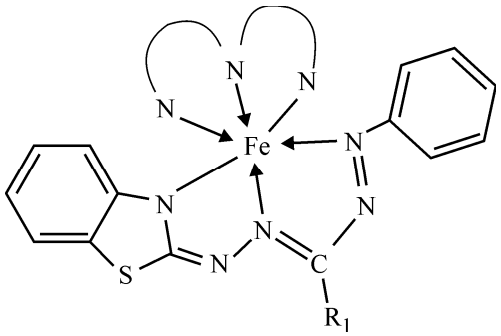
The measured effective magnetic moments μ_{eff} of the metal complexes **III**Fe, **IV**Fe, and **V**Fe, containing bulky substituents in the 3-position of the formazan molecule, are as low as 0.22, 0.45, and 1.18 μ_B, respectively, which suggests formation of Fe(II) complex compounds predominantly in the low-spin (LS) state [20, 21].

For the metal complexes **I**Fe and **II**Fe containing alkyl substituents in the 3-position of the formazan molecule, μ_{eff} was 2.09 and 1.97 μ_B, respectively, which, according to [21], can be attributed to the presence of low- and high-spin (HS) iron(II) complexes and an admixture of Fe(III) complexes. Formazans with the alkyl substituent at the C^3 atom are oxidized to the tetrazolium salt somewhat more difficultly. Therefore, the probability of formation of impurity iron(III) complexes is higher.

The structure of the metal chelate core formed in complexation of formazans **I–V** with iron(III) chloride solutions was finally confirmed by single-crystal X-ray diffraction analysis for **IV**Fe as an example.



The general view of the molecule of **IV**Fe is shown in Fig. 2. The structure of **IV**Fe is, on the whole, similar to that of 1,3-diphenyl-5-(benzothiazol-2-yl) formazanate **V**Fe prepared previously [16].

The molecule of the iron complex occupies a special position on a twofold axis. Two formazan ligands are coordinated in the tridentate fashion via N^1 and N^4 atoms of the formazan chain and nitrogen atom of the heteroring to form the metal complex L_2Fe with the N_6Fe coordination core. The angle between the planes of the formazan ligands in the complex is 81.93°.

The N(8)FeN(7) (157.77°) and N(5)FeN(1) (157.66°) angles correspond to the meridional (*mer*) isomer; in the facial (*fac*) isomer this angle would be 90°. The iron coordination polyhedron is a distorted octahedron. Despite that all the vertices of the coordination polyhedron are occupied by nitrogen atoms, the Fe–N bonds noticeably differ in the length and can be subdivided into three groups, each with two bonds. The shortest Fe–N bonds, 1.850 and 1.856 Å, are formed by the N(10) and N(3) atoms occupying the vertex positions, i.e., the octahedron is compressed along the N(10)···N(3) axis. The intermediate-length Fe–N bonds, 1.933 and 1.942 Å, are formed with the N(1) and N(7) atoms, and the N(5) and N(8) atoms are the most remote from the Fe atoms: 1.997 and 2.003 Å, respectively.

The hetaryl nitrogen atom involved in the coordination behaves like an additional complexing group. The complexation leads to changes in the electronic structure of the initial ligand, which is in the amino form with the *EEZ* configuration of the formazan ring. The molecular configuration also changes significantly: in the formazanate, the ligand is in the imino form, with the open *EZE* configuration.

The above spectral data suggest that compounds **III**Fe–**V**Fe are metal complexes containing Fe(II) predominantly in the LS state with the coordination configuration similar to that in **IV**Fe:

CONCLUSION

In the course of synthesis of coordination compounds from tridentate benzothiazolylformazans and solutions of iron(III) chloride, formazan is oxidized to tetrazolium salts, iron(III) is reduced, and, as a result, iron(II) formazanates are formed with various spin states of Fe(II).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Generation of Resin–Asphaltene Substances in the Luminescent Concentrate under Irradiation

Abstract—The effect of photoirradiation on the luminescent concentrate of heavy gas oil produced by catalytic cracking (>400°C) was examined.

DOI: 10.1134/S1070427208120173

Secondary heavy petroleum residue finds limited use today. Recent studies have shown that luminescent concentrates, i.e., petroleum luminophores that are recovered from heavy gas oil produced by catalytic cracking (HGCC), can be used in various branches of science and technology. Petroleum and synthetic luminophores are widely used in luminescence flaw detection, as photosensitizers of decomposition of organic compounds, as dyes for polymeric materials, and as working substances for information recording, storage, and processing [1–3].

These processes involve, to a certain extent, the action of atmospheric oxygen, radiation, illumination, and heating on petroleum products, which leads to their diverse photochemical and thermal oxidative transformations deteriorating their quality.

The available data mainly refer to thermal oxidative transformations [4–7]. Previous studies of photochemical oxidative transformations of petroleum products have not revealed their mechanism, because they did not use appropriate low-temperature techniques allowing the rate of photochemical processes to be considerably reduced and their elementary steps to be revealed. Also, nearly no attention has been given to the problem of the contribution of one- and two-photon photochemical processes to transformations of petroleum products undergoing photochemical (in particular, photooxidative) transformations under illumination in a wide spectral range covering the UV range and a considerable part of the visible solar radiation.

Petroleum fractions thoroughly purified to remove resin–asphaltene substances (RASs) exhibit paramagnetism upon heat treatment [4–7] due to generation of RAS free radicals (FRs). However, until recently, FRs generated by photoirradiation of oils and their processing products have not been detected.

In this study, we examined the results of UV irradiation of the luminescent concentrate (LC) recovered from HGCC (>400°C). The high content of fused polycyclic aromatic hydrocarbons (PACs) efficiently absorbing light allowed preparation from this substance of multicomponent high-performance petroleum luminophores used in nontraditional (for petroleum products) branches of science and technology.

EXPERIMENTAL

The main physical methods we used were ESR, UV, and IR spectroscopy. The procedures for performing experiments and recording ESR spectra have been described previously [8]. As a light source we used a DRSh-500 mercury lamp with UFS-5 and ZhS-10 color filters. The ESR spectra were recorded with an RE-1306 radiospectrometer under the conditions of minimal saturation, using Mn^{2+} ($S = 5/2$) as a reference for the magnetic field. The IR spectra were recorded on a Specord M-80 spectrophotometer, and the UV/visible spectra, on a Specord UV Vis spectrophotometer in the range 200–700 nm at room temperature.

The LC of HGCC (>400°C) is a multicomponent substance composed of naphthene–paraffin (NPH) (57–58 wt %), polycyclic aromatic (40 wt %), and olefin (2–3 wt %) hydrocarbons. Their content was determined by fluorescence–indicator analysis (FIA) [9].

A UV study of the structural-group composition of PAHs revealed the presence of naphthalene (226 nm), anthracene (294 nm), phenanthrene (255 nm), chrysene (270 nm), 1,2-benzanthracene + 3,4-benzofluorene (295 nm), pyrene (340 nm), and perylene (430 nm) hydrocarbons, which are well-known initiators of photochemical processes [10].

Figure 1 shows how the FR concentration (in absolute units) varies with time of RAS irradiation (the ESR spectra of these radicals consist of a single line with ΔH = 0.7–0.8 mT and g-factor of ~2.0023). It can be seen that, for the LC, accumulation of radicals starts from zero. Two steps of FR accumulation are observed in the course of LC photoirradiation: the step of relatively rapid growth (~1 h) followed by the step of slow, nearly linear growth (2.5 h).

As already noted, LC consists of NPHs, PAHs, and olefins. Nevertheless, the pattern of FR generation under photoirradiation of LC is typical of RASs (Fig. 1). Therefore, it seems appropriate to examine the possible role of the initial steps of photochemical processes in RAS generation under photoirradiation for each LC component.

We assumed that PAHs in LC can photosensitize the decomposition of naphthene–paraffin hydrocarbons (NPHs), as it was observed upon addition of small amounts (10^{-7} M) of PAHs to aliphatic alcohols and liquid paraffins [11–13]. In LCs with a relatively high PAH content (~10 wt %), the concentration of RAS FRs generated in NPHs is very low, apparently because PAHs absorb the exciting light in the surface layer. The ESR spectra observed in this case are, on the whole, similar, but a new line appears (ΔH_{tot} = 2.8 mT) with signs of the hyperfine structure characteristic of $PAH^{+\cdot}$ radical cation [14].

To examine the primary and intermediate steps of photosensitized transformations in the LC under consideration, and also the role of molecular oxygen in the RAS FR generation mechanism, we studied the phototransformations of NPHs from HGCC, sensitized by PAHs from LC. As many photochemical processes in LC are extremely fast, which complicates elucidation of the phototransformation mechanism in detail because of the short lifetime of the generated excited molecules and intermediates, the photolysis was performed at –196°C.

Figure 2 shows the ESR spectra of frozen photoirradiated NPH solutions with PAH addition. A detailed analysis of the ESR spectra allowed identification of

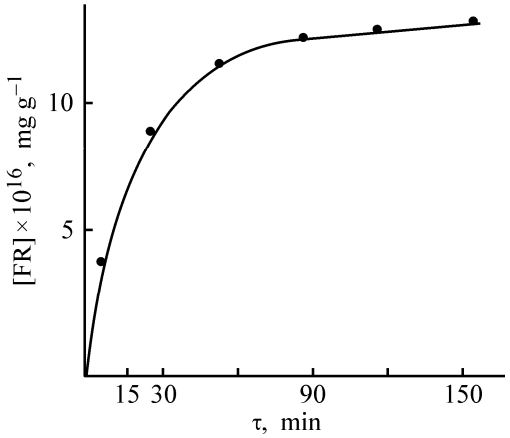

Fig. 1. Kinetic curve of a rise in the absolute concentration of RAS free radicals [FR] in the course of irradiation of LC HGCC (>400°C). (τ) Exposure time.

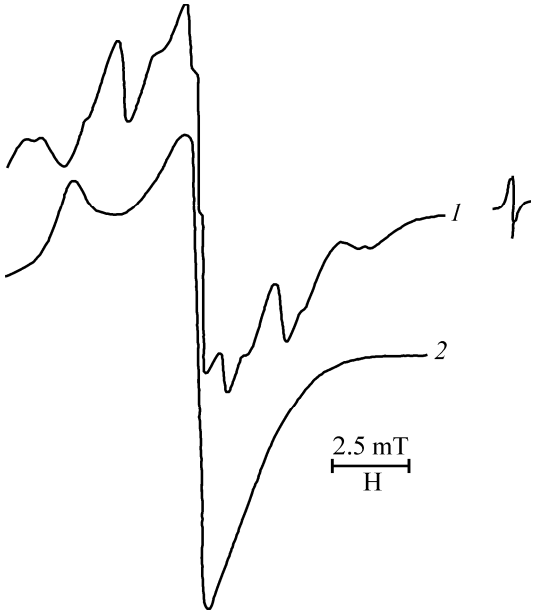

Fig. 2. ESR spectra of photoirradiated frozen (–196°C) naphthene–paraffin hydrocarbon with PAH added (10^{-7} M). Exposure time 2 h. T, °C: (*1*) –196 and (*2*) –108. To the right of curve *1* is one of the components of the ESR spectrum of atomic hydrogen.

most of the generated radicals: $R_1^{\cdot}$(–CH_2–$\dot{C}$H–CH_2–) with ΔH_{tot} = 12.5 mT, g = 2.0020; $R_2^{\cdot}$(CH_3–$\dot{C}$H–CH_2–) with ΔH_{tot} = 11.0 mT, g = 2.0018; and atomic hydrogen with ΔH_{tot} = 50 mT [14]. The other signals were not fully identified. Most likely, these are a narrow $R_3^{\cdot}$ singlet (ΔH_{tot} =1.4 mT) from phenyl-type radicals of an aromatic hydrocarbon and $R_4^{\cdot}$ signal (ΔH_{tot} = 2.8 mT) from an unresolved doublet. Overlapping with the $R_1^{\cdot}$ and $R_2^{\cdot}$ patterns, these signals distort the central components of the observed ESR spectra.

Thermal annealing of the deoxygenated samples results in a decrease in the intensity of the ESR lines, without changes in the spectrum shape. An apparent decrease in the intensity of the $R_3^{\cdot}$ is also observed in the course of solution storage under ambient conditions [11]. When the sample containing dissolved oxygen is warmed, the ESR spectrum considerably changes, starting from –108°C, and shows an asymmetric pattern characteristic of the peroxy radical $ROO^{\cdot}$, which fully decays at 17°C.

The essential role of O_2 in RAS formation has been noted in numerous papers. It was, in particular, shown [4] that the presence of oxygen in oil leads to an increase in concentration and to disproportionation of RAS radicals at a relatively low temperature (40–100°C). In the absence of oxygen, even at high temperatures (450–480°C), the radicals are not formed, which points to the important role of molecular oxygen in the mechanism of RAS generation.

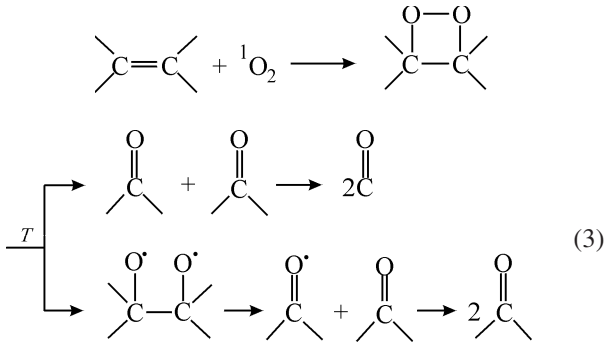
Formation of RASs in LC was also observed upon slight heating (≥30°C) under conditions when the formation of excited molecules and radicals generated by photoirradiation is impossible [7]. It was shown that the necessary condition of RAS formation in the samples was the presence of molecular oxygen and a hydrocarbon.

It should be noted that there are hardly any studies in which the joint action of light and oxygen on petroleum products would be examined using methods of low-temperature photolysis. At the same time, in most cases, such an action is one of major factors affecting the properties of petroleum products, including LC [15].

Upon photoirradiation of LC with monochromatic light in the region of PAH absorption bands, no free radicals are detected. This fact suggests that the generation of radicals in the luminescent concentrate is initiated by two-photon absorption [16] by PAH molecules acting as photosensitizers, with their transition to the highly excited triplet state PAH*(T*). In this case, the energy $h\nu_1$ of the first photon may be insufficient for cleavage of the C–H and C–C[1] bonds in PAH. However, the long lifetime of the triplet excited state of molecules of aromatic compounds, such as naphthalene, phenanthrene, etc., allows absorption of one more photon $h\nu_2$ with transition to the highly excited triplet level. The excitation energy of PAH molecule (~5 eV) is in this case sufficient for cleavage of the C–H bond in an NPH and can be transferred to an NPH molecule, causing its decomposition to free radicals. Thus, simultaneous generation of alkyl radicals and H atoms from NPHs may occur by the two-photon mechanism, as it has been observed in photosensitized decomposition of organic compounds (alcohols and unsaturated paraffins) in luminescent concentrate [11–13]:

$$\begin{aligned} &\mathrm{PAH(S)} \xrightarrow{h\nu_1} \mathrm{PAH^*(S^*)} \longrightarrow \mathrm{PAH^*(T)} \\ &\xrightarrow{h\nu_2} \mathrm{PAH^*(T^*) + RH} \longrightarrow \mathrm{PAH(S) + RH^*} \\ &\longrightarrow \mathrm{PAH(S) + R^{\cdot} + H}, \end{aligned} \qquad (1)$$

where S, S* and T, T* are the ground and excited singlet and triplet states of PAH molecules, respectively.



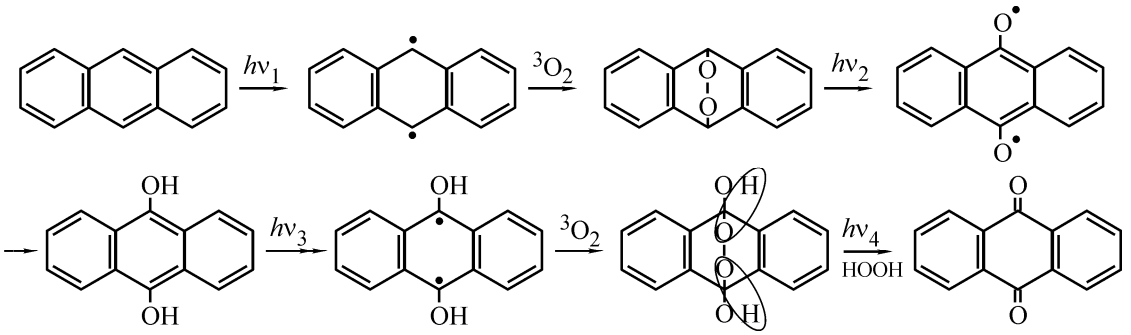
The H atoms react with hydrocarbons RH, $H + RH \rightarrow R^{\cdot} + H_2$, to form a radical $R^{\cdot}$ and a hydrogen molecule. The formation of H_2 as one of major products of chemical cleavage of oils and petroleum residues was noted in [17]. The formation of H_2 in petroleum hydrocarbons upon photolysis and radiolysis has been confirmed by gas-chromatographic analysis [18].

The radicals $R^{\cdot}$ generated in reaction (1) readily react under common conditions with molecular oxygen to form $ROO^{\cdot}$. Then the process can develop by the chain mechanism.

Polycyclic aromatic hydrocarbons initiate photochemical reactions of other LC components, olefins, which do not directly absorb UV light from the source used, but react with singlet oxygen $^1O_2$ generated by excited PAH molecules:

$$\mathrm{PAH^*(T) + {}^3O_2 \rightarrow PAH(S) + {}^1O_2}. \qquad (2)$$

It should be noted that singlet oxygen can arise only in selective excitation of PAH molecules. The same is true for dioxetanes, which are formed by reactions of olefins with $^1O_2$ and subsequently decompose thermally to form ketones or biradicals [15, 19]:



(3)

[1] Although the energy of the C–C bond is lower than that of the C–H bond, in fused aromatic systems C–H bonds are cleaved preferentially, because of the cage effect [16].

In the course of photoirradiation, the most stable LC–PAH components acting as photosensitizers in photochemical reactions also undergo, according to the IR spectra, various transformations with formation of endoperoxides (820–885 cm^{-1}), quinones (1700 cm^{-1}), and phenols (3300–3400 cm^{-1}). The formation of PAH endopexorides is associated with PAH transition from the excited singlet to triplet state:

$$PAH(S) \xrightarrow{h\nu} PAH^*(S^*) \longrightarrow PAH^*(T),$$

The reaction of PAH*(T) with molecular oxygen leads to sensitized formation of $^1O_2$ by reaction (2). The IR spectra show that the above-noted diamagnetic molecules are formed from PAHs under the action of light and molecular oxygen. The scheme of their formation (for anthracene as example) is shown below.

(4)

Anthraquinone formed in reaction (4) (along with other aromatic ketones) is also a photooxidation sensitizer. This is particularly true for LC components containing labile hydrogen (certain isoparaffins, alkylnaphthenes, etc.). In this case, anthraquinone acts as a chemical sensitizer [16].

Thus, PAHs apparently play a major role in photochemical and photooxidation reactions occurring in LC. PAHs are involved in the generation from all major LC components of a series of primary ($R_1^{\cdot}$, $R_2^{\cdot}$, $R_3^{\cdot}$, $R_4^{\cdot}$) and intermediate ($ROO^{\cdot}$) radicals and of other labile products upon irradiation with light in the UV and visible parts of the solar spectrum. These species undergo diverse transformations (oxidation, condensation) to form RASs of complex composition and structure, which have not been reliably identified yet.

Recently, Salmanova is examined [20] the dependence of the optical density of LC with 2 wt % additions of antioxidants (RASs HGCC) on the irradiation time. She showed that the presence of RASs leads to a decrease in the optical density at the carbonyl absorption wavelength (1720 cm^{-1}) throughout the irradiation period. She found that RASs of the cracking origin exerted a more efficient stabilizing effect and that the inhibiting activity of asphaltenes was higher than that of the resin.

Our results are also consistent with the results of an early study [21] which revealed generation of stable free radicals with an ESR spectrum characteristic of RASs in lubricating and motor oils under the conditions of heat treatment and oxidation with atmospheric oxygen. As stated in [21], the presence of FRs makes longer the induction period of motor oil oxidation. The autostabilization of the oil in an engine is attributed to the accumulation of FRs inhibiting the oxidation of hydrocarbons.

Thus, analysis of our and published data shows that one of the major components of heavy petroleum residue (in particular, HGCC), RASs, inhibit photosensitized photooxidative transformations of another major HGCC component, LC.

Reactions (1), (3), and (4) of photosensitized decomposition of organic compounds can find wide use in new technologies for reprocessing of petroleum raw materials into valuable petroleum intermediates for organic synthesis.

CONCLUSIONS

(1) Primary and intermediate radicals and other labile products are generated in all major components of luminescent concentrate with participation of aromatic hydrocarbons under the action of UV and visible light.

(2) Fast complex reactions involving molecular oxygen lead to oxidation and condensation of the luminescent concentrate to give resin–asphaltene substances.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Polycondensation of Naphthalene and Its Alkyl Derivatives

Abstract—Polycondensation of naphthalene and its alkyl derivatives (stripping oil, 2,5-dimethylnaphthalene) in the presence of aluminum halides was performed. Under the action of an ultrasonic field on a benzene solution of naphthalene in the presence of the catalyst, intermolecular condensation and benzene addition are observed.

DOI: 10.1134/S1070427208120185

The formation of tarry by-products from aromatic hydrocarbons at elevated temperatures and in the course of alkylation in the presence of catalysts has been described in the literature [1, 2]. In some cases, tars can act as target products, rather than as contaminating components. In particular, this occurs in preparation of a binder for composite anodes in aluminum production. It seemed appropriate to examine the possibility of transformation of naphthalene and its alkyl derivatives into more complex products under the influence of catalysts and to evaluate the degree of conversion. To accelerate the condensation, we used ultrasonic activation instead of prolonged heating. Aluminum halides were tested as catalysts. It should be noted that the effect of ultrasound on fused aromatic hydrocarbons is poorly understood. It has been reported [3] that, under cavitation treatment, naphthalene undergoes cleavage with the formation of the simplest gaseous compounds.

EXPERIMENTAL

Liquid stripping oil was prepared by distillation of coal tar pitch; its boiling point is about 300°C. An ultrasonic source (UZDN-2T device, nominal power 400 W, generator working frequency 22 kHz) was immersed in a vessel with stripping oil containing 10% $AlBr_3$. In the process, the temperature of the mixture increased to 200°C. After keeping for 30 min and cooling to room temperature, the mixture solidified. To remove aluminum bromide, the mixture was poured over with water and boiled, after which it was extracted with benzene. After removing the solvent, we obtained a viscous tar. The results of its analysis by gas chromatography–mass spectrometry (GC/MS) are listed in Table 1.

We found that heating of naphthalene for 0.5 h at 180°C in the presence of 10% aluminum chloride does

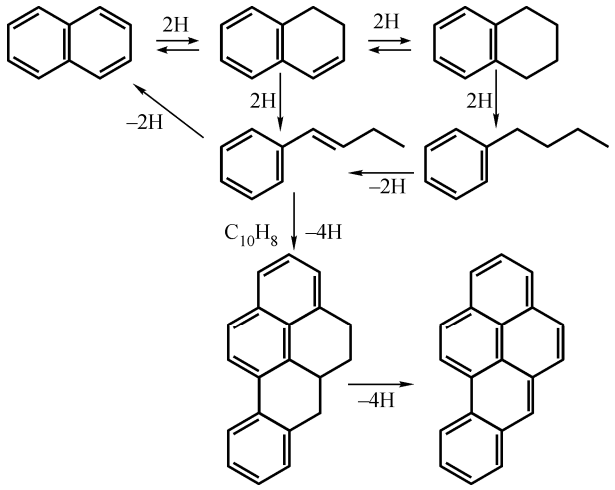
Octahydrobenz[*a*]pyrene	260	0.3

not chromatographically detectable changes. Therefore, we performed a combined cavitation-catalytic treatment of naphthalene. The procedure was as follows.

A glass beaker was charged with 1 g of naphthalene and 20 ml of benzene, after which 0.1 g of $AlBr_3$ was added. A plate-type emitter was immersed, and the UZDN-2T device was switched on. The temperature increased in the course of the treatment from 20 to 60°C. In the process, the mixture was bubbled with air for 30 min at a rate of 200 ml min^{-1}. After the treatment completion, water was added, the mixture was shaken, the aqueous solution was separated, and the tar precipitated on the beaker walls was washed out with benzene and acetone. The organic solutions were combined, dried over $CaCl_2$, filtered, and vacuum-evaporated. The yield was quantitative. To evaluate the contribution from benzene condensation to the tar formation, we subjected a solution of aluminum bromide in benzene to ultrasonic treatment. No significant amount of tar was formed upon 30-min treatment. The results of GC/MS analysis of the tar are listed in Table 2.



The tar composition was determined on an HP 6890A gas chromatograph equipped with an HP 5972A mass-selective detector, using NIST CSD database (275000 compounds). We used an HP-5MS quartz column, 30 m long, 0.25 mm i.d., coated with a 0.3-μm layer of 5% diphenyl–95% dimethylsiloxane copolymer.

Conditions of GC/MS analysis: initial column temperature 70°C, 4 min; linear heating at a rate of 100 deg min^{-1}; final temperature 300°C, 5 min; vaporizer temperature 280°C; sample volume 1 μl. The mass spectra were recorded with electron impact ionization (70 eV). The scanning rate was 1 scan per second, and the scanning range, 40–600 amu.

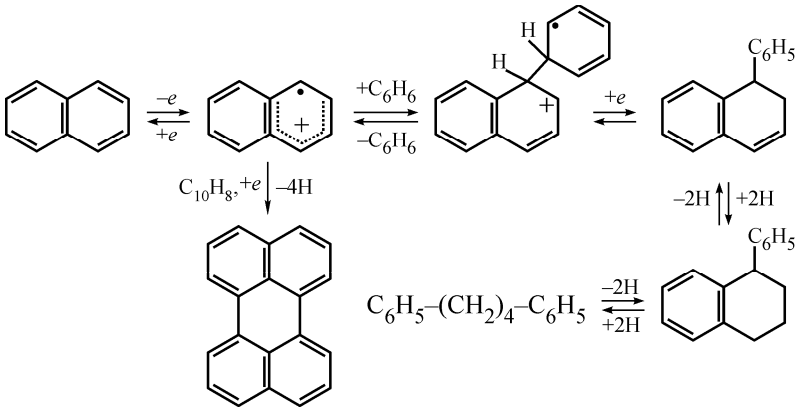
The organic compounds were identified by comparison of the experimental mass spectra with those from the NIST CSD database using the ChemStation standard system for GC/MS data processing. Polycyclic aromatic hydrocarbons (PAHs) were analyzed in the mode of selective detection of individual ions, with identification by characteristic ions and retention times, using solutions of reference substances.

According to the chromatogram, the stripping oil contained (%) naphthalene 18.7, alkylated naphthalenes 45, dibenzofuran 11.5, acenaphthene 7.6, and fluorene about 2. High-boiling carcinogenic compounds were absent (Table 1).

After the cavitation treatment, the oil composition changed considerably: The amount of naphthalene and methylnaphthalenes decreased, and di- and trimethylnaphthalenes virtually disappeared. At the same time, the amount of 2-ethylnaphthalene and dibenzofuran increased, which suggests their relative inertness under the experimental conditions. The appearance of benz[*a*]pyrene in the reaction mixture points to the occurrence of polycondensation. Apparently, benz[*a*]pyrene is

Scheme 1.

formed by a sequence of reactions involving naphthalene (Scheme 1).



According to Scheme 1, for the formation of benz[*a*]pyrene to be formed, naphthalene should add a fragment consisting of phenyl residue and a radical with four carbon atoms. Such a fragment can be formed after hydrogenation of naphthalene to dihydronaphthalene or tetralin. The ring opening in these compounds will lead to formation of fragments required for "assembling" benz[*a*]pyrene.

If the naphthalene transformation follows this pattern, its polycondensation should lead to formation of tetrahydrobenz[*a*]pyrene and benz[*a*]pyrene. According to the chromatogram, the naphthalene tar contains more than 50 substances. The major components identified using the database on polycyclic compounds are listed in Table 2.

Indeed, heating of a benzene solution of naphthalene in the presence of $AlBr_3$ at 60°C for 0.5 h under the action of cavitation leads to formation, along with other substances, of benz[*a*]pyrene and its hydrogenated analogs: tetrahydro- and octahydrobenz[*a*]pyrenes. The occurrence of this reaction pathway is also confirmed by the detection of 1,4-diphenylbutane among reaction products.

At the same time, it should be noted that methylated naphthalenes losing methyl substituents under the conditions of acid catalysis can also be precursors of benz[*a*]pyrene. To evaluate the possibility of this route, we heated 2,5-dimethylnaphthalene with 10% aluminum chloride at 180°C for 0.5 h. By liquid chromatography, we detected among reaction products acenaphthene, 2-methylnaphthalene, benz[a]pyrene, and dibenz[*a*,*h*]anthracene (40.5, 28.1, 5.8, and 1.8%, respectively).

Along with undergoing disproportionation and condensation, naphthalene also reacts with benzene to form 1- and 2-phenylnaphthalenes, 1,2- and 1,7-diphenylnaphthalenes, and their hydrogenation products. Also, naphthalene undergoes self-condensation to form dinaphthyl and perylene. The formation of the above products can be described by Scheme 2 involving radical cations. According to Scheme 2, the reaction mixture should also contain dihydro- and tetrahydro-1-phenylnaphthalenes, which were, indeed, detected (Table 2). The formation of carboxylic acids (2-phenylacetic, hexadecanoic, oleic) is attributable to the presence of air in the reaction medium.

Scheme 2.

CONCLUSIONS

(1) Naphthalene and its methyl derivatives transform in the course of acid catalysis of the polycondensation into a complex mixture of products, some of which are carcinogenic (e.g., benz[*a*]pyrene).

(2) Ultrasonic treatment of a solution of naphthalene in benzene in the presence of aluminum halides leads to considerable tarring and formation of numerous high-molecular-weight polyaromatic derivatives.

Abstract—The enthalpies of solution of cytisine derivatives (phosphoric acid cytiside dimethyl ester, cytisinovinyloxyethylaminothiourea) in 96% ethanol at various dilutions were determined by isothermal calorimetry. Equations describing the dependences $\Delta H_s^0 = f(m^{1/2})$ (m is the molal concentration) were obtained. The standard enthalpies of solution, combustion, melting, and formation (at 298.15 K) of the compounds were calculated.

DOI: 10.1134/S1070427208120197

Biologically active substances (BASs) isolated from vegetable raw materials are active agents of drugs and are of particular importance for human vital functions. Revealing a correlation between the structure and physicochemical properties of BASs is of both theoretical and applied importance [1].

Calorimetry is widely used for studying the thermodynamics of biochemical processes. Particular attention is given to studies of solute–solvent interactions and elucidation of the role of hydration and solvation in biological functions of molecules [2].

Alkaloids are natural biologically active substances with base properties, which mostly occur in plants and are considerably more seldom in animal bodies. The majority of alkaloids exhibit pronounced antiarhythmic, arythmogenic, local anesthetic, spasmolytic, antiphlogistic, muscle relaxant, psychotropic, and antitoxic action [3].

Cytisine occupies a particular place among alkaloids. It was first isolated from *Cytisis laburnum* and *Thermopsis lanceolata* seeds. Today it is widely used in medicine as 0.15% aqueous solution under the name of *Cytitonium* [3–7].

Studies of thermochemical and thermodynamic properties of alkaloids as an extremely important class of biologically active substances are of theoretical and applied interest for purposeful synthesis of their derivatives and for standardization and certification of drugs based on them. For this purpose, we have previously studied the thermochemical properties of cytisine [8]. As a continuation of these studies, we calorimetrically measured the enthalpies of solution of new cytisine derivatives, phosphoric acid cytiside dimethyl ester $C_{13}H_{19}N_2O_4P$ and cytisinovinyloxyethylaminothiourea $C_{16}H_{21}N_3O_2S$, in 96% ethanol and estimated the standard heats of their formation, combustion, and melting.

The enthalpies of solution of the compounds were measured on a DAK-I-IA isothermal calorimeter (T = 25°C) at three dilutions [1 : 9000, 1 : 18 000, 1 : 36 000 (mole compound : mole solvent)]. The device characteristics are as follows: working temperature range 25–200°C, error of measuring the heat release energy within 20 μV. The calorimeter operation is based on measuring the integral thermal flux going from an ampule with substances through differentially arranged thermoelectric batteries and a massive central block of the microcalorimeter. The heat is released or absorbed in the working cell. Inside the cylindrical passive thermostat, there is a massive calorimetric unit with two calorimetric cells. The calorimetric cell consists of a sleeve and a thermostat block with vertical grooves and thermopiles arranged between them. The thermo-

piles are welded into two differentially arranged thermoelectric batteries: measuring and compensating.

The metallic ampule with a sample was placed in the internal sleeve with a calibration heater. The sample (weighed on an analytical balance with an accuracy of 0.1 mg) was placed in a screen cup of the stopper which was then inserted into the sleeve. The sleeve with the metallic ampule and a bar was assembled. The ampule volume was 8 cm^3, and the solvent amount, 5 ml. The ampule was warmed to the experimental temperature (25°C) and introduced into the calorimetric cell. The preliminary thermostating was performed for 2 h. After the attainment of a thermal equilibrium between the calorimetric cells, monitored with a KSP-4 recorder, the "experimental zero" was set. By pressing the bar button, the stopper was ejected and the heat release energy was recorded with an IP-4 precision integrator in the automatic heat–compensation mode. The reaction course was monitored with a KSP-4 recorder.

At each dilution, we performed five replicate measurements. Their results were averaged and statistically processed. For each averaged value of ΔH_s^0, we calculated the random error using Student's test. The homogeneity of variance was checked using Cochran's test [9]. The hypothesis of the homogeneity of variance was accepted with a 5% significance level.

The device operation was checked by measuring the heat of solution of triply recrystallized KCl at 1 : 1600, 1 : 2400, and 1 : 3200 dilutions (mole salt : mole water). Our value of the mean heat of solution of KCl in water, 17640 ± 320 J mol^{-1}, is well consistent with the recommended and reference data: 17577 ± 34 [10] and 17489 ± 371 J mol^{-1} [11].

The enthalpies of solution of the cytisine derivatives in 96% ethanol at three dilutions are listed in Tables 1 and 2.

It can be seen that phosphoric acid cytiside dimethyl ester and cytisinovinyloxyethylaminothiourea dissolve in 96% ethanol with the energy absorption. The experimental values of ΔH_s^0 were extrapolated to infinite dilution using the dependence $\Delta H_s^0 \sim f(m^{1/2})$ (where m is the molal concentration) [12]. The following equations were obtained (with ΔH_s^0 in kJ mol^{-1}):

$$\Delta H_s^0 (C_{13}H_{19}N_2O_4P) = -8.58 + 677.89(m^{1/2}), \quad (1)$$

$$\Delta H_s^0 (C_{16}H_{21}N_3O_2S) = 11.51 + 461.88(m^{1/2}). \quad (2)$$

Table 3. Calculated thermodynamic characteristics of cytisine derivatives

Compound	ΔH^0_{comb}, kJ mol^{-1}			ΔH^0_m, kJ mol^{-1}	$-\Delta_f \Delta H^0_{298.15}$, kJ mol^{-1}	
	after Karash	after Frost	average		liquid	solid
$C_{13}H_{19}N_2O_4P$	7329	7793	7561	82.0	1021.6	1103.6
$C_{16}H_{21}N_3O_2S$	8637	9373	9005	97.4	593.1	690.5

From Eqs. (1) and (2), we calculated the basic thermochemical quantities, standard enthalpies of solution of $C_{13}H_{19}N_2O_4P$ and $C_{16}H_{21}N_3O_2S$ in 96% ethanol at infinite dilution. We obtained the values of –8.58 ± 0.14 and 11.51 ± 0.18 kJ mol^{-1}, respectively.

Then we estimated the standard enthalpies of combustion, melting, and formation of the compounds. It should be noted that, as the experimental data on these thermochemical characteristics of complex biologically active substances, such as cytisine derivatives, are lacking, even their estimated or calculated values are of certain theoretical and practical interest for purposefully performing chemical transformations of these compounds. Therefore, the calculations were performed by different methods, namely, by Karash's and Frost's methods which supplement each other (if contributions of certain functional groups to the heat of combustion disregarded by one method, they are taken into account by the other) [13].

The heats of combustion calculated by these two methods and their averaged values are listed in Table 3.

From the calculated heats of combustion, we calculated using the Hess law and considering the reactions

$$4C_{13}H_{19}N_2O_4P_{(l)} + 72O_{2(g)} = 52CO_{2(g)} + 38H_2O_{(l)} + 4N_{2(g)} + P_4O_{10(s)} - \Delta H^0_{comb}, \quad (3)$$

$$2C_{16}H_{21}N_3O_2S_{(l)} + 42.5O_{2(g)} = 32CO_{2(g)} + 21H_2O_{(l)} + 3N_{2(g)} + 2SO_{2(g)} - \Delta H^0_{comb}, \quad (4)$$

the standard enthalpies of formation of $C_{13}H_{19}N_2O_4P$ and $C_{16}H_{21}N_3O_2S$ in the liquid (molten) state (Table 3). It should be noted that Karash's and Frost's methods are applicable to liquid compounds only. The required data for calculating $\Delta_f H^0_{298.15}$ of $C_{13}H_{19}N_2O_4P_{(l)}$ and $C_{16}H_{21}N_3O_2S_{(l)}$ by schemes (3) and (4), except ΔH^0_{comb}, were taken from [14–17]. As both compounds are crystalline at 298.15 K, it was necessary to calculate their ΔH^0_{comb} for the solid state. For this purpose, we calculated ΔH^0_m by the Gambill equation [18]

$$\Delta H^0_m / T_m = 20.72 \times 10^{0.00324M}. \quad (5)$$

The values of ΔH^0_m of $C_{13}H_{19}N_2O_4P$ and $C_{16}H_{21}N_3O_2S$, found by Eq. (5), are listed in Table 3.

From the equations

$$\Delta_f \Delta H^0_{298.15}(C_{13}H_{19}N_2O_4P_s) = \Delta_f \Delta H^0_{298.15}(C_{13}H_{19}N_2O_4P_l) - \Delta H^0_m, \quad (6)$$

$$\Delta_f \Delta H^0_{298.15}(C_{16}H_{21}N_3O_2S_s) = \Delta_f \Delta H^0_{298.15}(C_{16}H_{21}N_3O_2S_l) - \Delta H^0_m \quad (7)$$

we calculated the standard enthalpies of formation of $C_{13}H_{19}N_2O_4P$ and $C_{16}H_{21}N_3O_2S$ in the crystalline state (Table 3).

The results obtained in this study are important for estimating the probability and direction of reactions involving related natural biologically active substances. These are primary data for inclusion into databases and reference books on thermodynamic constants of natural substances and their derivatives.

Abstract—Supramolecular inclusion complexes, polyrotaxanes, derived from γ-cyclodextrin and polydimethylsiloxane modified with terminal epoxy groups were studied. The dependence of the structure, morphology, and thermal properties of polyrotaxanes on the molecular weight of the linear polymer, molar ratio of γ-cyclodextrin and polymer, and presence of free γ-cyclodextrin in the complexes was examined.

DOI: 10.1134/S1070427208120203

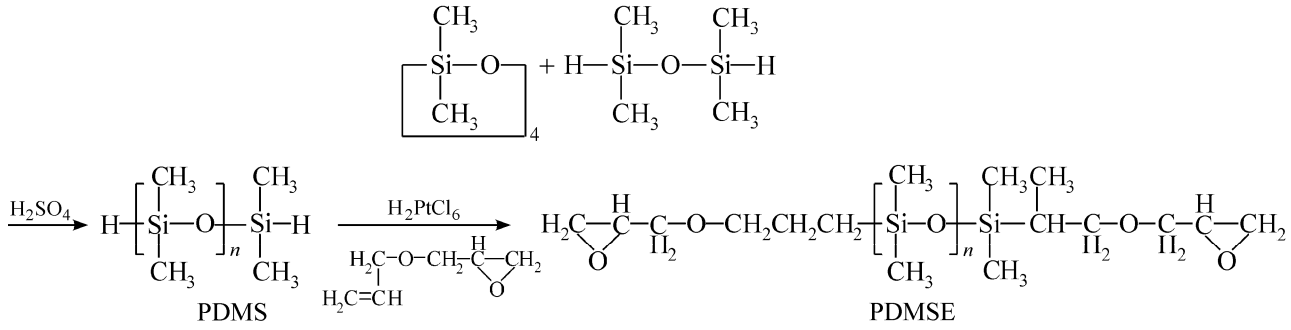
Polyrotaxanes (PRots) are supramolecular inclusion complexes (SMICs) formed by macrocycles (host) strung on linear macromolecules (guest) [1–3]. Cyclodextrins (CDs), cyclic oligosaccharides consisting of *D*-glucopyranose units linked with α-1,4-glucoside bond [4], are frequently used as macrocyclic components in PRot preparation. The CD molecules have the shape of a truncated cone with a length of about 7.9 Å and inner diameter from 4.5 to 9.5 Å, depending on the number of structural units in the macroring (six, seven, or eight glucose residues in the ring; α-, β-, and γ-CD, respectively) [4, 5]. The internal hydrophobic surface of the cavity of the CD molecule can include molecules of appropriate size and functionality, whereas the external hydrophilic surface makes the resulting inclusion complex soluble in water.

PRots are usually prepared from linear components that have two hydrophilic terminal groups and a hydrophobic central part. When both components are dissolved in a polar solvent (e.g., water), the hydrophobic moiety of a linear macromolecule gets inside the CD cavity, whereas the hydrophilic moieties remain outside the cyclic components. Thus, the driving force of the complexation in this case is the hydrophobic interaction of polymer chain components with internal fragments of the macroring [2–4].

Polyrotaxanes are promising materials for various branches of technology as controllable molecular switches [2, 6, 7] and as supports for silicate materials with pH-dependent pore size [8], and also for targeted transport of medical preparations [9]. Polyrotaxanes of more complex architecture can be used for development of nanoscopic analogs of bearings, units, motors, rotors, pistons, and macroscopic ensembles consisting of centralized mechanical parts [10]. Owing to their unique properties, PRots have also been suggested as smart materials for production of sensors [11] and devices for information accumulation and storage [10, 12].

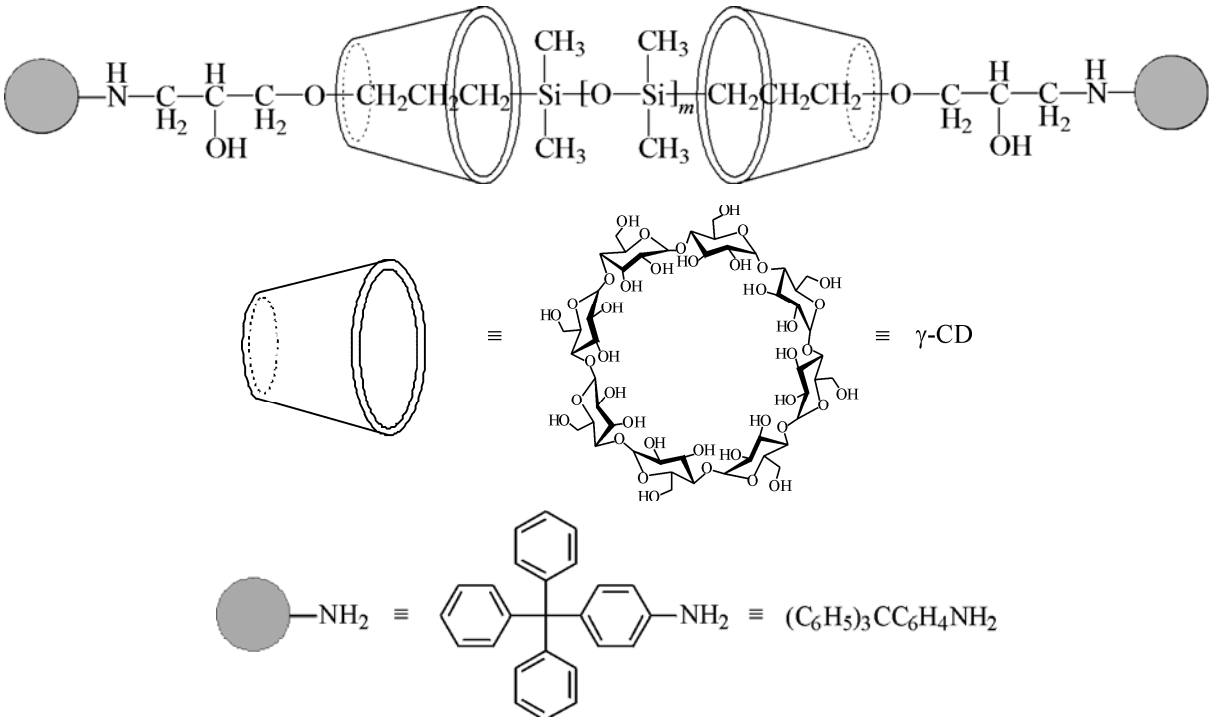
Polyrotaxanes based on γ-CD and polydimethylsiloxane (PDMS) were prepared for the first time by Harada et al. [13–15]. It was shown that, owing to the small inner diameter of its molecules (4.5 Å), α-CD cannot form inclusion complexes with PDMS macromolecules having a large cross section. At the same time, β-CD can form PRots with PDMS of low molecular weight (M_n < 700), and γ-CD can be strung on PDMS macromolecules of higher MW (up to M_n = 3300). The resulting complexes have been examined by ^{1}H and ^{13}C NMR spectroscopy, gel permeation chromatography, and IR Fourier spectroscopy [13, 15], but have not been subjected to a comprehensive structural and physicochemical study.

In this study we examined the structure, morphology, and thermal properties of PRots based on γ-CD and PDMS modified with functional epoxy groups (PDMSE) in relation to the PDMSE molecular weight, γ-CD/PDMSE molar ratio, and presence of γ-CD unbound with PDMSE.



EXPERIMENTAL

The major component of the inclusion complex, linear polymer PDMSE, was prepared by two-step synthesis (Scheme 1).



In the first step, we prepared PDMS samples of various molecular weights with the active terminal Si–H groups by the reaction of octamethylcyclotetrasiloxane with 1,1,3,3-tetramethyldisiloxane. PDMS was synthesized at room temperature within 4 h at an H_2SO_4 concentration of 2 vol %.

In the second step, PDMS dissolved in toluene (50 wt %) was brought into the hydrosilylation reaction with allyl glycidyl ether in the presence of Speier's catalyst (2% H_2PtCl_6 in isopropanol). The reaction was performed at 100–110°C for 6 h and yielded PDMSE. The precipitated polymer was purified to remove impurities and the unchanged components by heating to 150°C at 0.1 mm Hg. PDMSE samples differing in molecular weight were prepared (M_n = 1250 and 2100, according to exclusion chromatographic data).

The PRot was prepared (Scheme 2) in accordance with the data of [16, 17].

Scheme 1. PDMSE preparation.

Scheme 2. Structure of PRot derived from γ-CD and PDMSE.

Saturated solutions of γ-CD in DMF with PDMSE were stirred for 72 h at 65°C. The crude compounds PRot-1250c and PRot-2100c were prepared by reactions of the terminal epoxy groups with 4-aminophenyltriphenylmethane (8 h). The resulting suspension was poured into water, and the precipitate was filtered off, washed with ethanol, and dried for 8 h at 40°C to constant weight. To remove unchanged PDMSE, the precipitate was stirred overnight as a suspension in diethyl ether, after which it was filtered off and dried for 8 h at 40°C. Free γ-CD was removed by additional precipitation of the samples from a 50% aqueous DMF into water (samples PRot-1250p and PRot-2100p).

To study the effect of the PRot component ratio on their structure and physical properties, we examined samples with γ-CD/SiO molar ratios of 1/1.57 (PRot-1250c), 1/4.8 (PRot-1250p), 1/1.55 (PRot-2100c), and 1/4.6 (PRot-2100p). The above ratios were calculated from the ^{1}H NMR spectra per Si–O bond. It is noteworthy that, according to [13–15], the maximal γ-CD/SiO ratio for PRot derived from γ-CD and PDMS is 1.5. The characteristics of PDMSE and PRot are listed in Table 1.

X-ray diffraction studies of γ-CD and PRot were performed on a DRON-3 installation (Burevestnik Research and Production Association, Russia) in the scattering angle range 2θ = 3°–37° with Ni-filtered CuK_α radiation (λ = 1.54 Å). Thermal properties of the samples were studied with a DSM-2M differential scanning calorimeter (Special Designing Office of Instrument Making, Pushchino, Moscow oblast, Russia) at a scanning rate of 16 deg min^{-1}. Morphological studies were performed with a Tesla BS-300 scanning electron microscope (Czechia).

Figure 1 shows the X-ray diffraction patterns of hydrated samples of γ-CD, PRot-1250c, PRot-1250p, PRot-2100c, and PRot-2100p. The experimental interplanar spacings d (Å) are listed in Table 2. All the PRots examined are crystalline substances with a structure differing from that of the initial γ-CD.

Comparison of d values for the initial γ-CD used for PRot synthesis with published data shows that γ-CD has a cage-type packing arrangement [18, 19]. The crystal structures have been studied previously for inclusion complexes of γ-CD with aromatic linear polymers [19] and polyethylene oxide (PEO) [20]. It was shown that the initial hydrated inclusion complexes have a columnar-type crystal structure of molecular "necklaces" with a characteristic peak at 2θ ≈ 7.5 Å (d ≈ 12 Å) in the diffraction patterns. The crystals of the complexes have a shape of rectangular parallelepipeds and a tetragonal unit cell with the parameters $a = b = 23.75$, $c = 22.92$ Å [19] or $a = b = 16.88$, $c = 23.13$ Å [20].

Table 1. Synthesis conditions and characteristics of PDMSE and PRot samples

M_n of PDMSE	Polyrotaxane	γ-CD/SiO molar ratio	Free γ-CD, %	Yield, %
1250	PRot-1250c	1/1.6	57	–
1250	PRot-1250p	1/2.8	0	81
2100	PRot-2100c	1/1.6	58	–
2100	PRot-2100p	1/3.3	0	75

Table 2. Interplanar spacings in γ-CD and PRot samples

Sample	d, Å
γ-CD*	17.1, 14.4, 11.6, 9.40, 8.66, 7.75, 7.14, 6.31, 5.73, 5.46, 4.97, 4.73, 4.27, 4.10, 3.87, 3.59
PRot-1250c*	11.8, 7.46, 5.97, 5.62, 5.34, 4.64, 4.36, 4.09, 3.77, 3.36
PRot-1250p*	15.3, 12.0, 7.66, 6.13, 5.79, 5.48, 4.54, 4.18, 3.84, 3.42, 3.22
PRot-2100c*	15.0, 11.6, 7.59, 6.02, 5.58, 5.29, 4.59, 4.36, 4.13, 3.78, 3.38
PRot-2100p*	14.8, 10.6, 7.18, 5.98, 5.28, 4.02
PRot-2100p**	14.8, 10.5, 7.40, 6.04, 5.23, 4.10

* Experimental data. ** Calculated data.

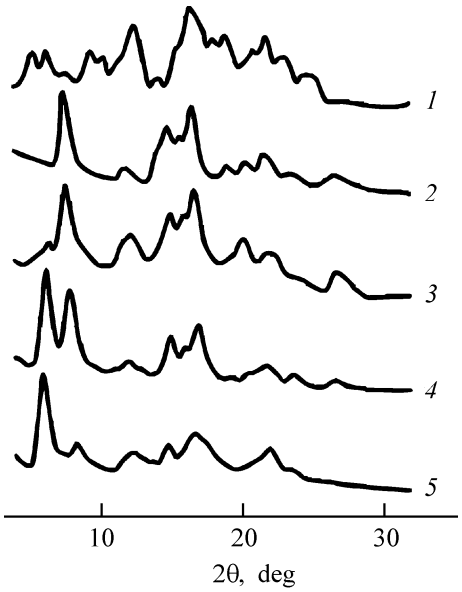


Fig. 1. X-ray diffraction patterns of (*1*) γ-CD, (*2*) PRot-1250c, (*3*) PRot-1250p, (*4*) PRot-2100c, and (*5*) PRot-2100p. (2θ) Scattering angle.

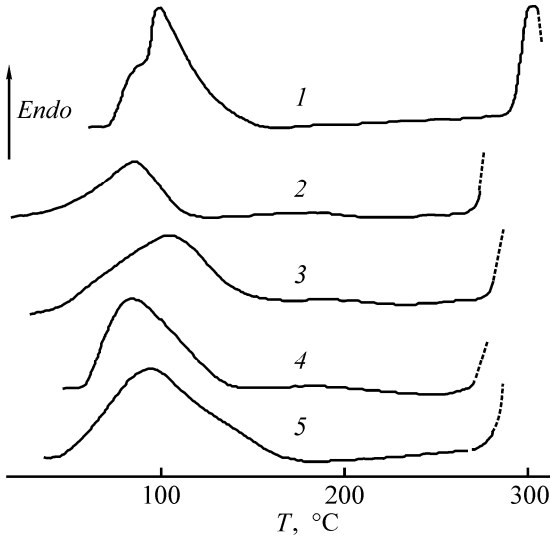

Fig. 2. DSC curves: (*1*) γ-CD, (*2*) PRot-1250c, (*3*) PRot-1250p, (*4*) PRot-2100p, and (*5*) PRot-2100c. (*T*) Temperature.

The interplanar spacings that we obtained for the complexes PRot-1250c and PRot-1250p (Table 2) well coincide with the results reported in [20]. This fact suggests that PRot-1250c and PRot-1250p have a columnar-type crystal structure with a tetragonal packing of molecular necklaces.

The diffraction pattern of the purified complex PRot-2100p (γ-CD/SiO = 1/4.6) (Fig. 1, curve *5*) differs from those of the PRot-1250c and PRot-1250p samples (Fig. 1, curves *2*, *3*) with lower molecular weights. A calculation of the interplanar spacings for PRot-2100p by formulas for quadratic lattices [21] showed good coincidence with the experimental values (Table 2) for the cubic system. Therefore, the structure of PRot-2100p can be described most adequately by the cubic lattice with unit cell parameters $a = b = c =$ 14.8 Å. Comparison of the interplanar spacings for PRot-2100c containing excess γ-CD (γ-CD/SiO = 1/1.55) (Fig. 1, curve *4*; Table 2) with the other PRot samples shows that this sample is a mixture of crystals with tetragonal and cubic packing of molecular necklaces.

Table 3. DSC data for γ-CD and PRot samples

Sample	T_{max}, °C	ΔH, J g^{-1}
γ-CD	103	237.5
PRot-1250p	95	160.0
PRot-1250c	90	224.1
PRot-2100p	85	156.0
PRot-2100c	100	206.9

Thus, the γ-CD/SiO molar ratio, molecular weight of the linear polymer PDMSE, and presence of free γ-CD in the complexes affect the crystal structure of the PRots being formed.

Figure 2 shows thermograms of γ-CD (curve *1*) and PRot (curves *2–4*), recorded in air. In the temperature range 50–170°C, γ-CD exhibits a broad endothermic peak with a shoulder in the low-temperature region, caused by dehydration of the initial γ-CD. This peak is not observed in repeated scanning of the same temperature range. Further heating leads to melting of γ-CD with simultaneous degradation. The onset of melting is observed at 280°C. Similar dependences (two endothermic effects) are observed in heating of PRot samples with different molecular weights (curves *2–4*). In the thermograms of the complexes, there is a broad endothermic peak in the range 50–150°C with a maximum at about 100°C, caused by release of bound water. As shown in [19, 20, 22], water is an important component of the complexes. It plays the role of bridges in the formation of a system of hydrogen bonds between γ-CD molecules along PRot molecular necklaces.

The enthalpies ΔH and peak temperatures T_{max} of dehydration of the systems studied are listed in Table 3. It should be noted that the enthalpy of dehydration is at a maximum for pure γ-CD. In addition, it follows from Table 3 that purification of PRot to remove γ-CD leads to a decrease in ΔH. At temperatures above 270°C, PRot melts with simultaneous decomposition.

Figure 3 shows electron micrographs of the initial γ-CD (a, b) and synthesized PRot samples (c–h). As can be seen from Fig. 3a (general view), γ-CD consists of crystalline aggregates of various shapes with a size varying in a wide range (μm): length, from 3 to 45, and width, from 2 to 12. It should be noted that both rodlike crystalline particles and platelike rhombic aggregates can be seen in the micrographs, i.e., γ-CD consists of crystals of different structures. At a higher magnification (Fig. 3b), a lamellar morphology of the majority of crystalline particles is clearly seen. A looser porous structure is observed on the surface of some particles.

Figure 3c shows a micrograph of the complex PRot-1250c containing free (unbound) γ-CD (γ-CD/SiO = 1/1.57). It can be seen that, in contrast to pure γ-CD,

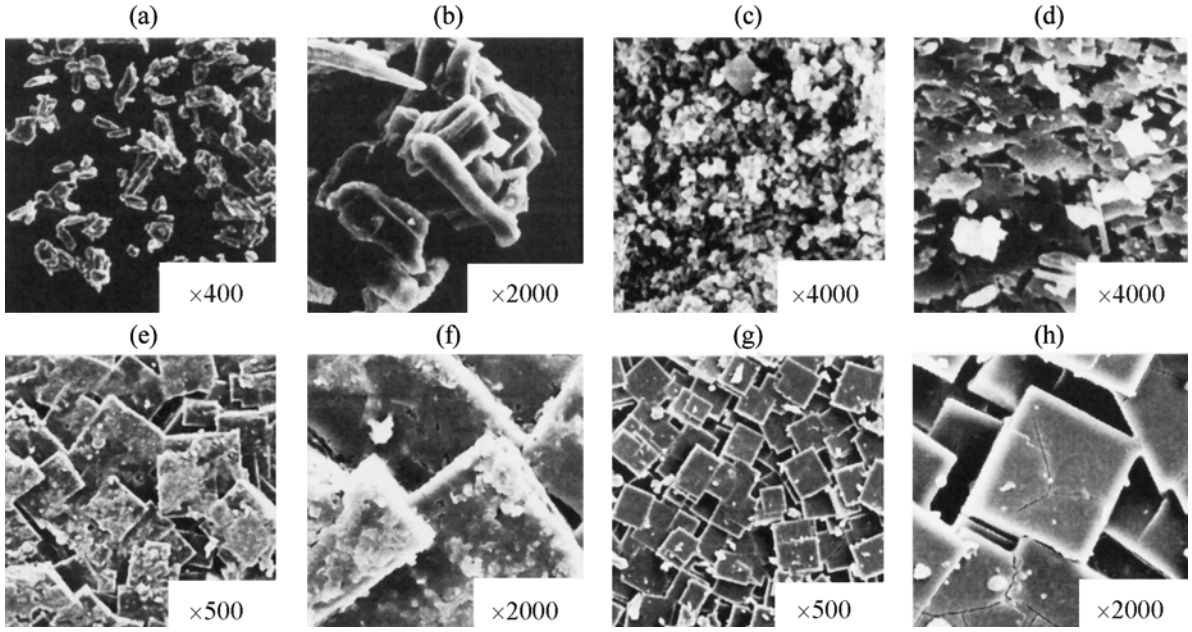

Fig. 3. Electron micrographs of (a, b) γ-CD, (c) PRot-1250c, (d) PRot-1250p, (e, f) PRot-2100c, and (g, h) PRot-2100p.

crystalline formations of the complex are close-packed and consist of small (<2 μm) aggregates having the shape of tetragonal parallelepipeds (Fig. 3c). By contrast, crystals of the purified sample PRot-1250p containing no free γ-CD (γ-CD/SiO = 1/4.8) have a lamellar morphology and consist of thin rectangular plates and a minor amount of crystals of rhombic shape (Fig. 3d). At higher magnifications, stacks of lamellas formed by self-assembling of columnar molecular necklaces of PRot can be seen.

The morphology of the complex PRot-2100c (Figs. 3e, 3f) containing excess γ-CD (γ-CD/SiO = 1/1.55) strongly differs from that of low-molecular-weight samples. The electron micrograph Fig. 3e shows that coarse crystals are formed as cubes and parallelepipeds in this case, with the face size of 30–120 μm. On the crystal surfaces, there is a thin precipitated layer apparently formed by the unchanged starting components, γ-CD and PDMSE.

Figures 3g and 3h show micrographs of the purified PRot-2100p sample (γ-CD/SiO = 1/4.6). It can be seen that, in the absence of free γ-CD, crystals are formed in the system as coarse cubes of regular shape with the face size from 20 to 100 μm. The surface of PRot-2100p crystals is clean. This fact reveals cracking of crystals (Fig. 3h), caused by dehydration of the sample in the course of preparation (evacuation) and examination in the scanning electron microscope.

It is interesting that the same crystal shape was found when [20] in studying the crystal structure and morphology of SMICs based on γ-CD and PEO with MW = 1500 and chain length of 94.7 Å. The crystals of the complex γ-CD/PEO also had the shape of rectangular parallelepipeds, but the mean face size was considerably smaller, about 15 μm.

Previously, we have studied [16] the morphology of PRots derived from PDMSE of various molecular weights and β-CD having a smaller diameter of the internal cavity compared to γ-CD. We showed that, with β-CD as a host, an increase in the molecular weight M_n of PDMSE from 1250 to 3300 makes lower the probability of formation of crystalline SMIC particles of regular shape. By contrast, in the case of the complex with γ-CD, an increase in M_n of the linear component, PDMSE, from 1250 to 2100 led to the formation of coarser and more perfect highly crystalline particles having the shape of tetragonal parallelepipeds and cubes.

CONCLUSIONS

(1) The crystal structure and morphology (packing character, crystal shape and size) of polyrotaxanes depend on the molecular weight of the linear polymer, molar ratio of γ-cyclodextrin and modified polydimethylsiloxane, and presence of free γ-cyclodextrin in the system.

(2) An increase in the molecular weight of modified polydimethylsiloxane leads to formation of polyrotaxanes in the form of coarser and well-faceted highly crystalline particles.

Abstract—Specific features of modification of an alicyclic polyimide with polyaniline were examined. The thus obtained new polymeric composites exhibit better capability for silver plating.

DOI: 10.1134/S1070427208120215

Polymeric materials, both individual polymers and multicomponent systems, attract growing researchers' interest. Modification of polymers with various low- and high-molecular-weight additives allows preparation of composites with valuable properties, making them suitable for application in microelectronics, radio engineering, and space industry [1, 2]. Of particular interest are composites of nanosize polyaniline, polypyrrole, and polythiophene, which, thanks to the high electrical conductivity and stability in redox processes have found use in high-capacity batteries; supercapacitors; corrosion-protecting, reflecting, and absorbing coatings; and power-converting and power-saving devices [3, 4]. Among conducting polymers, the most widely used are polyaniline (PANi) and its derivatives [5, 6]. Homogeneous defect-free composites with high electrical conductivity and good mechanical properties, prepared by forming PANi layers on the surface of aliphatic polymers (polyethylene, polypropylene), have been described [6–8]. It was of interest to evaluate the effect of electroactive polymers on heat-resistant polymers and, in particular, polyimides.

In this study, we examined specific features of formation and the main properties of composites based on a nanosize polyaniline and an alicyclic polyimide derived from tricyclodecenetetracarboxylic dianhydride and 4,4'-diaminodiphenyl ether:

EXPERIMENTAL

The starting compounds and solvents were purified by standard procedures. N,N'-Dimethylacetamide (DMAA) was additionally dried over 4-Å molecular sieves. Acetone, methanol, and 4,4'-diaminodiphenyl ether (DADPE), all of chemically pure grade, were used without additional purification. Polyimide (PI) was prepared in the presence of catalytic amounts of triphenyl phosphate in a DMAA solution. The polyimide was prepared in an inert atmosphere by the following procedure: A three-necked flask was charged with 13.70 g (0.05 mol) of the dianhydride, 10.00 g (0.05 mol) of DADPE, and 1.18 g (5 wt % relative to the sum of the monomers) of triphenyl phosphate, after which 70.0 ml of DMAA was added. The mixture was heated for 20 min at 70°C, after which the temperature was raised to 120°C, and the mixture was stirred for additional 4.0 h. From the resulting solution, in which, according to the IR spectra, the degree of imidization of the polymer was 94–96%, we cast films or precipitated the polymer into acetone. The products obtained were washed with two portions of acetone and dried in a vacuum oven at 80–90°C to constant weight.

The polyimide films were prepared by casting the reaction solutions or a 25% solution of the precipitated polyimide in DMAA onto glass surfaces. To remove the solvent, the films were dried at 80°C for 0.3 h, after which they were additionally heat-treated in the temperature range 80–250°C in air for 1.0 h. Silver plat-

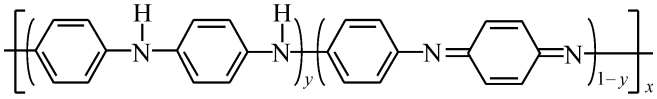
* In concentrated H_2SO_4.



ing of the polyimide films was performed as described in [9].

Polyaniline was prepared by oxidative polycondensation of a solution of aniline in 1 M HCl with potassium persulfate [10]. The product obtained as an emeraldin salt was additionally purified by successive extraction with methanol and acetone for 24 h and treated with a 10% solution of ammonium hydroxide, after which it was dried in a vacuum oven at 50°C for 5 h. The bulk electrical conductivity of emeraldin and the emeraldin salt was 10^{-10} and 0.45 Ω^{-1} cm^{-1}, respectively. The molecular weight of the emeraldin form of PANi in concentrated sulfuric acid was 35 000. The fibril size, according to an electron-microscopic examination, was 150–220 nm [11].

The reduced viscosity was measured in an Ubbelohde viscometer at 25°C for 0.5% solutions of the polyimide in DMF and for solutions of PANi in concentrated H_2SO_4. The thermal gravimetric analysis of PI and composites was performed with a Mettler Toledo TGA SDTA device at a heating rate of 8 deg min^{-1}. The temperatures of the decomposition onset, $T_{d.o}$, and 50% weight loss for the polymers were calculated from the TG curves. The tensile strength σ_t, relative elongation l, elastic modulus E, dielectric loss tangent tan δ, relative permittivity ε, and bulk and surface resistivities ρ_v and ρ_s of 40–45-μm-thick films were measured under standard conditions [12, 13]. The electrical properties of the metal-modified films were measured in the dc mode at a field istrength of 20 mV cm^{-1}, using sputtered silver electrodes. The temperature dependence of the surface resistivity was studied in the range 25–200°C. The reflection coefficient $R(\lambda)$ was determined in the wavelength range 400–750 nm for samples with a surface area of 2.2 cm^2 on an SF-1201 spectrophotometer. The determination error was ±0.05% for ρ_v and ρ_s, and ±1% for R. The IR spectra of 3–5-μm-thick films were measured on an IR-25 device. Polymer blends with nanosize polyaniline were prepared by homogenization of 0.1–2.0 wt % PANi in a polyimide solution at 20–25°C. After settling, films were cast and dried in air for 1.0 h at 80–250°C.

The surface morphology of the composite systems was studied with a Jeol JSM-1800 scanning electron microscope (Japan) equipped with an Oxford MathScan attachment.

The first step in studying the specific features of modification of the alicyclic polyimide with the conducting polymer was to examine the effect of PANi samples of the general formula

$x = y = 0.5$

on the PI viscosity. In contrast to the known PE–PANi composite systems prepared by successive deposition of PANi layers on the surface of polyethylene films [6], composites of alicyclic polyimide and polyaniline were prepared by mechanical mixing of the starting polymers. The experimental results obtained show that the systems remain homogeneous and transparent at a PANi content of up to 2.0 wt %, and above this concentration the solution becomes turbid, the system undergoes phase separation, and high-quality films are not obtained. In the presence of conducting polymer additives, the viscosity of the PI solution somewhat increases: from 1.54 to 1.80 dl g^{-1}. The viscosity reaches a maximum in the presence of 1.5 wt % PANi and then does not change noticeably (Table 1). This fact can be attributed to the plasticizing effect of PANi, apparently leading to loosening of the structure of the initial polyimide.

As can be seen from Table 1, the thermal stability of the polyimide–polyaniline systems is relatively high and, at the PANi content examined, it is determined, on the whole, by the structure of the polyimide.

Analysis of the spectral characteristics of the polymeric system with PANi shows that the IR spectra do not change noticeably in the presence of relatively low amounts of the conducting polymer. We only observe an increase in the intensity of the absorption bands of the aromatic rings at 1500 cm^{-1} and a shift of the imide ring band from 1375 to 1385 cm^{-1}. The positions and intensities of the other bands remain essentially unchanged.

To evaluate the stability of mechanical properties of films with different PANi contents, we measured their tensile strength and elongation. As can be seen from Table 1 for unmodified PI, the mean values of σ_t and l are 140 MPa and 32%, respectively, and the elastic modulus is 4200 MPa. For the samples with PANi, these characteristics vary as follows: the tensile strength remains nearly unchanged, and the elasticity decreases (e.g., for the sample with 2% PANi, by a factor of 1.8 relative to the initial sample); the elastic modulus increases practically to 400 MPa, i.e., the system becomes appreciably more rigid. This fact, which is on the whole expected, can be attributed to structurization of the polyimide chains with a rigid PANi framework (according to [6–8], PANi is cross-linked in the temperature range 160–200°C).

The optical and electrical properties change in the presence of PANi more significantly. As can be seen from Fig. 1, as the polyaniline concentration is raised from 0.1 to 1.5 wt %, the optical reflection coefficient of the metal-plated composites increases. An evaluation of the residual silver content by TGA showed that an increase in the PANi content leads to a rise in the sorption capacity of the composite for silver ions by a factor of 1.1–1.5. It is also seen from Fig. 1 that the shape of the curve of the optical reflection coefficient of the metal-plated PI vs. wavelength (curve *1*) differs from the corresponding curves for the systems with PANi, characterized by stabilization of this parameter at λ = 550–600 nm.

On the whole, it can be noted that, as the polyaniline content of the composite is raised (within the examined range), the metal content also increases. A similar trend has been observed previously for alicyclic polyimide–poly(ethylene terephthalate) composites [14], but for the composites with the electroactive component the effect is more significant.

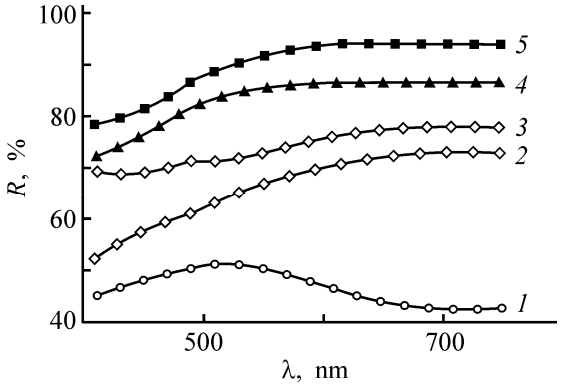


Fig. 1. Influence of the polyaniline concentration on the optical reflection coefficient R of (*1*) PI, (*2–4*) PI + PANi, and (*5*) Ag films. (λ) Wavelength. PANi concentration, wt %: (*2*) 0.1, (*3*) 0.5, and (*4*) 1.5.

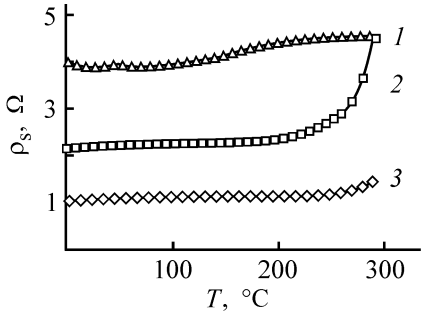

Fig. 2. Temperature dependence of the surface electrical resistivity ρ_s of (*1*) PI and (*2*, *3*) PI + PANi films. PANi concentration, wt %: (*2*) 0.5 and (*3*) 1.5.

For the metal-free polymeric composites, the bulk resistivity increases by two orders of magnitude (Table 2). Introduction of PANi into the polyimide also leads to appreciable changes in the surface resistivity of metal-plated films. Figure 2 shows that, with an increase in the polyaniline content, the surface resistivity ρ_s decreases. Thus, active properties of polyaniline are manifested not only on the surface, as noted

Table 2. Electrical properties of polymeric composites based on alicyclic polyimide and PANi

Polymer	tan δ	ε	ρ_v, Ω m
PI	0.001	2.82	$(1–3)\times10^{15}$
PI + PANi, %:			
0.5	0.003	1.30	$(2–4)\times10^{15}$
1.0	0.009	1.33	$(2–3)\times10^{14}$
1.5	0.020	1.32	$(2–3)\times10^{14}$
2.0	0.024	1.28	$(2–4)\times10^{13}$
2.5	0.030	1.30	$(2–4)\times10^{13}$
PANi	0.25–12*	1.40	222

* Depends on temperature and doping level.

in [7, 8], but also in the bulk of the polymer, i.e., these composites can be characterized by both bulk and surface conductivity.

Analysis of the properties of alicyclic polyimide + polyaniline composites shows that PANi enhances the capability of the composites for metal plating by favoring formation of larger silver clusters, compared to metal particles in the polyaniline-free polyimide (Fig. 3). It should also be noted that the thus obtained metallic layer is tightly impregnated in the polymer base, with the formation of a more uniform metal layer in the surface layer of the polyimide as compared to the individual polymer.

CONCLUSIONS

(1) Specific features of modification of the polyimide derived from tricyclodecenetetracarboxylic dianhydride and an aromatic diamine with polyaniline were examined. The components are well compatible at conducting polymer concentrations of up to 2.0 wt %.

(2) Introduction of small amounts of polyaniline leads to formation of polymeric composites with a more rigid structure, compared to the initial polyimide, and improved capability for metallization, which is reflected in the optical and electrical properties of the composites: for silver-plated films, the optical reflection coefficient increases and the surface electrical resistivity decreases.

(3) In the presence of a conducting polymer, silver clusters of larger size, compared to metal particles in the polyaniline-free polyimide, are formed.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Nanodispersed Silica (Aerosil) on the Thermal and Chemical Resistance of Photocurable Polyacrylate Compounds

D. L. Starokadomskii

Chuiko Institute of Surface Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received November 8, 2008

Abstract—The effect of filling of a photopolymeric composite based on oligoacrylates (OKM-2, TGM-3) with highly dispersed silicas (Aerosils) was examined. Thermograms recorded in the range 20–900°C were analyzed in detail. A scheme of the effect of silica on the polymer structure, accounting for the filler effect on the thermal and chemical resistance of the composites, was suggested.

DOI: 10.1134/S1070427208120227

Introduction of nanodispersed silicate particles is a commonly used method for modification of the physicochemical and mechanical characteristics of polymeric materials, as well as for thickening of polymers and for making the materials cheaper [1]. However, the effect of inorganic nanoparticles on the stability (e.g., heat resistance) of composites under the conditions of extreme external actions is not always taken into account. At the same time, natural and social calamities, becoming more and more frequent, make particularly topical the problem of enhancing the strength of composite polymeric structures.

It has been noted in numerous papers that highly dispersed particles of silica and aluminosilicates have a certain effect on the thermal degradation and chemical resistance of polymers [2–7]. In some cases, these properties of polymers change essentially [3, 4], whereas in other cases, the effect of nanoparticles is ambiguous or insignificant [2, 5]. It is still poorly understood how a silicate nanofiller can affect the thermal and chemical resistance of photocurable polyacrylates.

In this study, we examined the effect of Aerosil nanosilica samples with various specific surface areas on the resistance of photocurable polyacrylates to heat and aggressive liquids. Aerosil is a widely used filler (thickener, modifier) for polymers, and therefore elucidation of the in fluence it exerts on the thermal degradation and chemical resistance is of both scientific and practical interest. In so doing, we assumed that the decisive factors could be the specific surface area and the concentration of Aerosils.

EXPERIMENTAL

We prepared composites based on OKM-2 oligo (carbonate methacrylate) produced by the Dzerzhinsk Research Institute of Polymers, Federal State Unitary Enterprise. As photoinitiator we used benzil dimethyl ketal produced by Ciba (Switzerland). For filling of photopolymers, we used highly dispersed silicas (analogous to Aerosils produced by Degussa), of A-100, A-300, and A-455 brands (specific surface area 100, 300, and 455 $m^2 g^{-1}$, respectively), produced by the Kalush Pilot Plant (Ukra-ine). The filled composites were prepared in a dark room at ambient temperature by mixing the components weighed on an analytical balance. The compounds containing 0.6 wt % photoinitiator were applied in the form of 2–3-mm-thick layers onto a mirror glass support and cured for 5 min. The cured compounds were then milled in an Ardenna vibrator. The thermal degradation was studied with a Q-1500D derivatograph (MOM, Hungary) TG, DTG, and DTA curves recorded. The measurements were performed in the range 20–1000°C at a heating rate of 10 deg min^{-1}.

The mass spectra were measured on an MKh-7304A mass spectrometer (Selmi Joint-Stock Company) in the temperature range 20–800°C at a residual pressure of 10^{-5} mm Hg.

Table 1. Temperature characteristics of thermal oxidative degradation of photopolymeric composites based on OKM-2* (Aerosil filler)

Aerosil, wt %	Temperature, °C, of processes				Dry residue, wt %
	low-temperature		high-temperature		
	T_1/T_1^*(DTA)	t_1 (DTG)	T_2 (DTA)	t_2 (DTG)	
–	300/400	430	565	565	1.35
A-100:					
10	280/360	360	620	620	11.11

20	280/350	350	580	585	20.81
A-455, 20	270/340	340	575	575	19.79

* Temperature T_1^* corresponds to the maximum of the low-temperature process, and T_1, to its completion.

The stability of polymeric composites in alkaline solutions was studied using 0.1 N KOH. Samples of size 0.2 × 0.5 × 10 mm were placed in an alkaline solution. At regular intervals, during a period of 1 month, the samples were withdrawn, dried in air for 40–60 min under normal conditions, and weighed on an analytical balance. From the data obtained, we plotted the dependence of the weight loss on the time of keeping in alkali.

Table 1 and Fig. 1 show typical results obtained when studying the thermal oxidative degradation of the filler (Aerosil, Fig. 1a), unfilled photopolymer (Fig. 1b), and filled photopolymer (Fig. 1c).

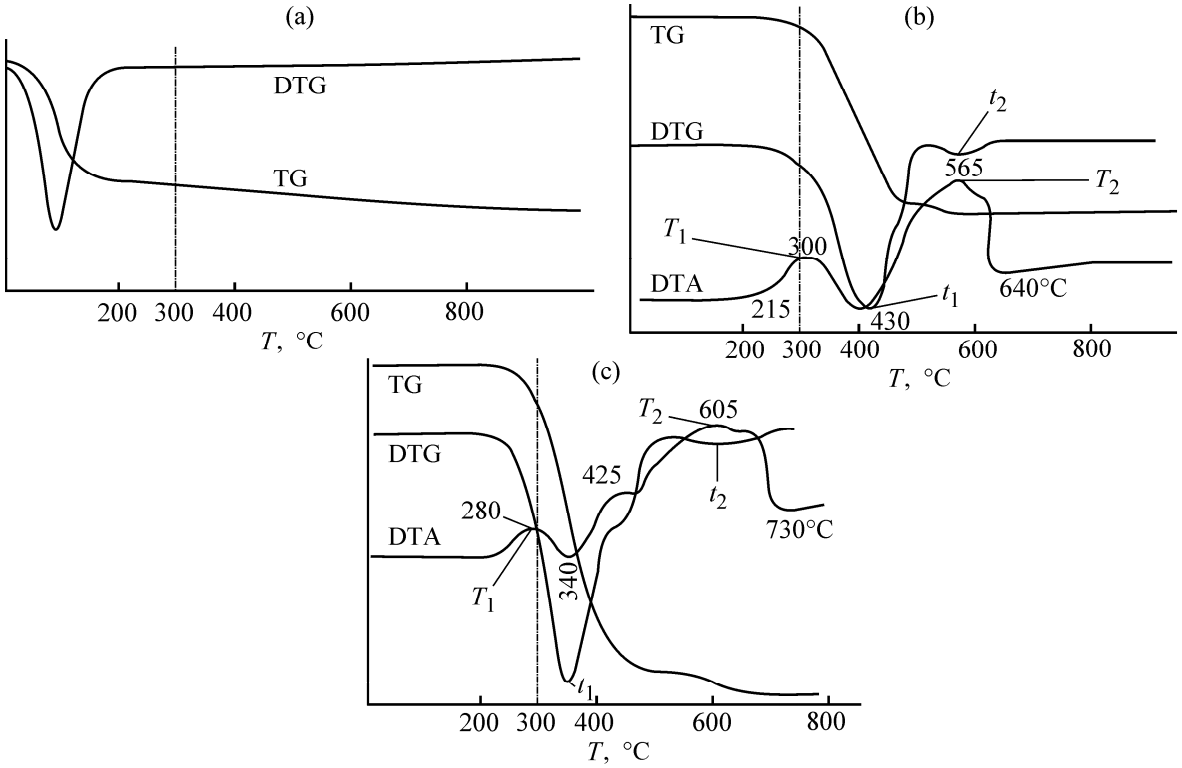

Fig. 1. Derivatograms of (a) A-300 silica, (b) cured unfilled oligo(carbonate methacrylate) (+0.6 wt % benzil dimethyl ketal), and (c) the same with 10 wt % A-300 filler. (*T*) Temperature.

It is well known that the thermogram of free unmodified Aerosil reflects only the water evaporation. This process has the highest intensity in the range 50–150°C, with the maximal weight loss rate at 100°C (Fig. 1a, DTG curve). The DTA curve corresponding to this process is, as a rule, characterized by a weak peak at 350–400°C.

Despite the considerable concentration of Aerosil (10–20 wt %), features of its thermogram are not manifested in the thermogram of the photopolymer filled with it. Apparently, the polymer surrounding silica particles shifts the water evaporation peak to higher temperatures. The filler effect was examined by comparative analysis of the experimental data before and after filling. To obtain a more objective pattern, the studies were simultaneously performed by two methods: in air (thermograms) and in a vacuum (mass spectrometry).

The unfilled polymeric compositeis, as a rule, characterized by a multistep course of thermal degradation. The TG curves of unfilled polymers, recorded in the course of heating in air, have several steps, with the corresponding extrema in the DTG and DTA curves. These features are due to various thermal oxidation processes [3, 7, 9]. The unfilled composite under consideration (Fig. 1, curve *6*; Table 1) also exhibits two extrema in the DTG curves: at $t_1 = 430$ and $t_2 = 565$°C. These extrema are due to two main types of processes giving peaks in the DTA curves at points T_1 and T_2 (Fig. 1b). Let us denote the processes occurring in the temperature range 200–450°C as low-temperature processes (with the extrema at t_1 and T_1 in the DTG and DTA curves, respectively), and the processes at temperatures above 450°C, as high-temperature processes (with extrema at t_2 and T_2 in the DTG and DTA curves, respectively).

The major fraction of the composite degrades in the low-temperature region. In the TG curve (Fig. 1b, Table 1), there is a portion of intense weight loss starting at 215°C. Its rate reaches a maximum at $t_1 = 430$°C (Fig. 1b, DTG curve). The main thermal degradation process is manifested as a peak in the DTA curve with a maximum at $T_1 \approx 300$°C (with 10% weight loss). This maximum is due to thermal oxidation of the composite. Mass-spectrometric analysis (Table 2) shows that the maximal weight loss in thermal degradation in a vacuum is observed at approximately 270°C. It follows from the mass spectra (Table 2) that, in the low-temperature process, the main thermal degradation products are water ($m/z = 18$) and carbon dioxide ($m/z = 44$).

The high-temperature process starting at 450°C is exothermic. It is accompanied by a slight weight loss and reaches the maximal intensity in the thermogram at $T_2 = 565$°C (Fig. 1b, Table 1). Recent published data also show that there may be an exothermic effect in the high-temperature region. For example, according to [3], divinylbenzene–styrene polymers also decompose in two steps, at 300–400 and 600–800°C, with the second step characterized by an exothermic effect. Bolbukh et al. [3] assign these effects, respectively, to products of primary and secondary decomposition of divinylbenzene copolymers with styrene or acrylates. As can be seen from the mass spectra we obtained, in thermal decomposition in a vacuum, the high-temperature step is ill-defined, though intensification of certain processes at 600–900°C is noticeable. As can be seen from Table 2, the major decomposition products in this case are water ($m/z = 18$) and carbon monoxide ($m/z = 28$), with the latter prevailing at high temperatures (900°C). The carbon dioxide peak, prevailing in low-tempera-ture processes (200–300°C), is not manifested at high temperatures.

After the filling, the general pattern of oxidative thermal degradation (shapes of the thermogram and mass spectra) does not change essentially. The influence of filler characteristics (concentration, specific surface area) is manifested in quantitative changes in some parameters (Fig. 1; Tables 1, 2).

Filling of the polymers under consideration with Aerosils leads in all the cases to a noticeable (by 20–50°C, i.e., by 10–15%, Table 1) shift of the exothermic effect of the low-temperature process (T_1) toward lower temperatures (DTA curve) and to a more pronounced (by 70–90°C) decrease in the temperature t_1 of the maximal rate of weight loss (DTG curve). The thermograms of samples filled with Aerosils that differ essentially in the dispersion and character of aggregation, such as A-100 and A-455, are on the whole similar. The only difference is that, as the dispersity increases, the high-temperature maximum (T_2) shifts toward still higher temperatures (Table 1).

It follows from our data that filling with Aerosils impairs the heat resistance (temperature of the maximal intensity of the primary decomposition process) of the polymeric composite. According to the data obtained, variation of the specific surface area and concentration in the range examined affects the heat resistance only slightly. An essentially similar conclusion (decrease in the heat resistance by 10°C) was made by Syrovatka et al. [2] for polyacrylate filled with another filler.

In this case, however, both steps were observed in the temperature range 200–450°C (in our case, only the first step), and the thermal degradation was studied only by mass spectrometry.

A study of the mass spectra of the composites showed that, after filling, thermal degradation of the composites in a vacuum (apparently corresponding to the low-temperature processes in the derivatograms) have a considerably higher intensity and occurs at lower temperatures. For all the composites, the main processes start earlier and occur faster than in air (200–300°C, Table 2, against 300–500°C in air, Fig. 1). The release of thermal degradation products is the most intense at approximately 270°C from the unfilled composites and at 230°C from the filled samples (Table 2). Thus, in the case of anaerobic thermal degradation, filling with unmodified nanosilica also diminishes the heat resistance of the composite by 10–15% (Table 1).

Comparison of the mass spectra (Table 2) shows that filling makes appreciably richer the set of peaks detected in the spectrum. The decrease in the degradation temperature and the richer set of degradation products released at 200–400°C from the filled polymer are apparently due to two possible factors: decrease in the activation energy of thermal degradation due to filling and/or richer chemical composition of the polymerization products formed in the presence of the filler. The latter factor is nontrivial and inconsistent with some recent data for other fillers. For example, when an antifriction filler (probably aluminosilicate) is introduced into polyacrylate, the intensity of the release of the volatile products (the main of which are the same: H_2O, m/z = 18; CO, m/z = 28; CO_2, m/z = 44), by contrast, decreases [2]. This means that the effect of the nanodispersed filler is ambiguous and difficult to predict.

One more distinctive feature of the filled composites examined in this study is that the evolution of CO and H_2O at high temperatures (600–900°C) is considerably less pronounced than that in the unfilled composite (Table 2). This fact suggests that filling facilitates complete decomposition of the polymeric component at lower temperatures, below 400°C.

The effect of Aerosil on the high-temperature process is opposite to that on the low-temperature process. Namely, T_2 and t_2 increase. The greatest increase is observed with 10 wt % A-100 and A-300. In this case, T_2 increases by 50–60°C (by approximately 10%) relative to the unfilled composite. With a further increase in the degree of filling, T_2 decreases, but it does not reach the value observed for the unfilled sample (Table 1). This trend is the more pronounced, the larger the surface area of Aerosil (Table 1). With an increase in the silica dispersity, the "afterdegradation" temperature (T_2, t_2, Table 1) decreases to a greater extent than T_1 and t_1, i.e., filling thermodynamically facilitates the "afterdegradation," with the magnitude of this effect depending on the concentration and specific surface area of Aerosil.

The high-temperature process in thermal degradation of polymers apparently involves secondary degradation products (let us term it afterdegradation). The mass spectra (Table 2) show that, at 600–900°C, in contrast to the range 200–400°C, the filled composite gives fewer peaks. This fact points to more active "early afterdegradation" of the filled composite and suggests that, with an increase in the specific surface area of Aerosil, less ordered surface layers and denser regions are formed.

It should be noted that a dry residue (1–1.5% relative to the initial polymer weight) remains after complete degradation of even the unfilled polymer. Apparently, its presence leads to intensification of the afterdegradation at high temperatures. In filled composites, the weight of the dry residue, as a rule, corresponds to the weight of Aerosil, exceeding it by no more than 0.8% (Table 1). In all the cases, these are carbon-like formations with a size of fractions of a millimeter. This fact confirms the conclusion that filling with Aerosil favors complete degradation of the polymer in the earlier steps.

As can be seen from our results and data of [3], Aerosil strongly affects the afterdegradation processes characterized by the second extremum (T_2, t_2) in the DTA and DTG curves. It should be assumed that these processes involve more stable (compared to the amorphous part) denser structures of the polymer and its surface layers at the filler particles. Afterdegradation can also involve degradation of structurally nonuniform zones of the polymer phase, which should apparently have a higher degradation temperature than the main part of the polymer. Based on this reasoning, we can suggest a scheme of the effect of nanosilicas on the structures of network polyacrylates (based on the previously published model [8]). According to this scheme, denser surface layers of the polymer are formed around filler particles. These layers should be more resistant to degradation than inhomogeneities of the unfilled amorphous polyether acrylate.

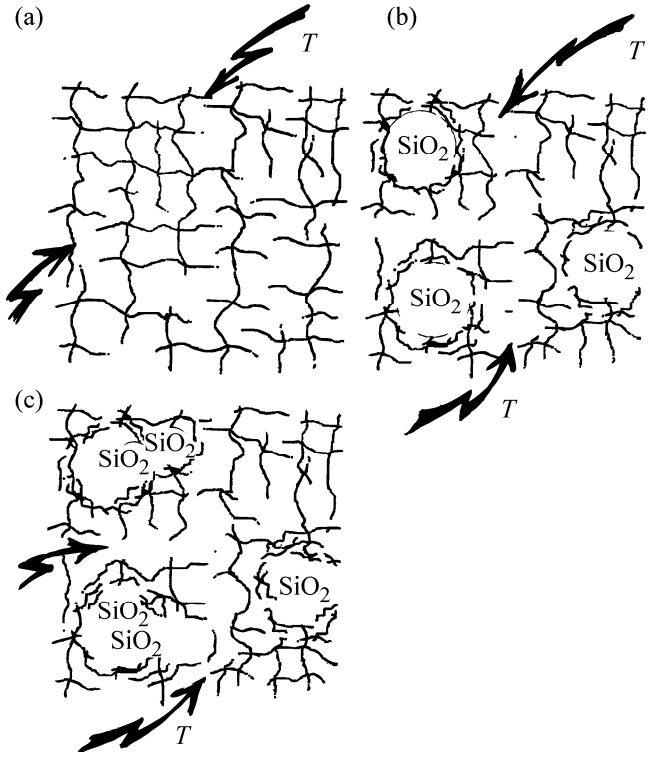

Fig. 2. Schematic illustration of the possible influence of the surface area, size, and aggregation of silica particles on the structure of a network polymer. Polymer: (a) unfilled, (b) filled with coarsely dispersed silica (A-50, A-100), and (c) filled with finely dispersed silica (A-300, A-455). Arrows symbolize the temperature effect on the polymer degradation.

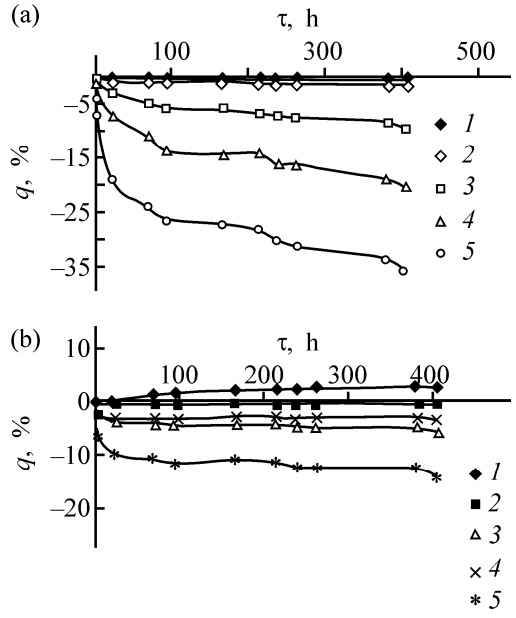

Fig. 3. Weight loss q of samples with time τ of keeping in 0.1 N KOH of composites based on (a) OKM-2 and (b) TGM-3, filled with 0–20% A-300 silica. Filler content, wt %: (*1*) 0, (*2*) 1, (*3*) 5, (*4*) 10, and (*5*) 20.

In remote areas of the adsorbed surface layer of the polymer, there are zones of increased strain of polymer chains and loose packing of macromolecules, which undergo thermal degradation first (Fig. 2, arrows). Thus, filling raises the density in the surface layer but distorts the integral structure of the network polymer, promoting appearance of breaks, loosenings, and weak regions. This leads to an increase in the temperature t_2 of the high-temperature process in the derivatograms. Apparently, the particle size (specific surface area) of silica is not a decisive factor in the formation of these loose layers; therefore, the specific surface area does not affect the temperature T_1 of primary degradation.

Variation of the filler concentration within the range 10–20 wt % also affects the amount, but not the quality of these "weak areas." This fact apparently accounts for the weak dependence of the temperature interval of the main thermal degradation process on the silica concentration. Indeed, degradation starts in weak areas irrespective of their amount (Fig. 2). The richer chemical composition of the degradation products in the case of the filled polymer can also be attributed to the formation of "weak areas" (Table 2).

Our conclusions are, on the whole, consistent with published data for other polymer–filler systems [3, 7, 9]. Bolbukh et al. [3] believe that the decrease in the activation energy of the thermal degradation of divinylbenzene–styrene or divinylbenzene–acrylate copolymers upon filling with silica containing trimethylsilyl groups is due to the formation of strained and rigid chains near the surface of Aerosil particles.

It follows from the above scheme that filling with Aerosil should also diminish the resistance of photopolyacrylate composites, e.g., in aggressive liquid media. Examination of the swelling curves for various composites in alkali solutions confirmed this conclusion. Figure 3 shows the typical curves of the weight loss with time, $q(t)$, on filling of various photopolymeric matrices with Aerosil. They demonstrate a well-defined, though not always linear (Fig. 3b), decrease in the resistance of the composite with increasing silica concentration.

From the suggested scheme and experimental data, we can make certain conclusions about the influence of the specific surface area and the concentration of Aerosil on the thermal and chemical resistance of the polymer. For example, the resistance of the composite in alkali solution strongly depends on the Aerosil concentration. The dependence may be either linear (with OKM-2) or nonlinear (with TGM-3) (Fig. 3).

In particular, of interest is the concentration of about 10 wt % at which the weight loss of the composite based on TGM-3 in alkali is lower than that with 5 and 20 wt % filler (Fig. 3).

As for the heat resistance, two cases should be considered. In the low-temperature region, there is no noticeable effect of the specific surface area of Aerosil on the temperature T_1 of primary thermal degradation: Only a slight decrease in T_1 and t_1 is observed as the surface area increases (Table 1). The Aerosil concentration affects these parameters insignificantly. In the high-temperature region (>450°C), the afterdegradation temperature ($T_2 = t_2$) strongly depends on the filling conditions: it whereases as the surface area and concentration of Aerosil decrease (Table 1). The maximal afterdegradation temperature is attained at 10 wt % filler content (Table 1), a concentration frequently mentioned in published papers. For example, according to [10], the formation of ordered supramolecular structures becomes hindered at a filler concentration exceeding 10 wt %, and according to [8], at 10 wt % filler content the polymer conversion in the composite appreciably increases. This fact suggests that the best ordered structures of surface layers, which are the most resistant to thermal degradation, are formed at a filler content of up to 10 wt %, whereas further increase in the filler concentration leads to their disordering.

CONCLUSIONS

(1) Introduction of nanosilicas into photopolymeric acrylate composites diminishes their heat resistance by 10–20%, but does not noticeably affect their thermal degradation. The effect is the stronger, the smaller the specific surface area of the silica and the lower the filler concentration (within the range examined). The decrease in the resistance to alkali solutions clearly correlates with the increase in the filler content.

(2) Upon filling of the composites, the spectrum of thermal degradation products in the temperature range 200–400°C becomes richer, and in the range 600–900°C, poorer, which indicates that the filling affects the polymer degradation at lower temperatures.

(3) The thermal degradation correlates with the level of ordering of surface layers of the polymer in the filled composite, which, in turn, is associated with the effect of nanosilica on the structures of the network polyacrylate.

Abstract—Gelation in the system sodium lignosulfonate–hexavalent chromium salt was studied. Isothermal phase diagrams were constructed, and the critical gelation concentrations of the polymer and cross-linking agent were determined. The time evolution of the elastic modulus of the gels was examined.

DOI: 10.1134/S1070427208120239

Raising the productivity of oil and gas wells is a pressing problem today. For this purpose, secondary and tertiary oil recovery processes are used, e.g., flooding with polymer solutions. This technique comprises injection of a polymer solution of increased viscosity through injection wells. However, injection of a polymer solution is not always an effective tool for raising the formation pressure. In this case, there is a need for systems with advanced mechanical characteristics, e.g., hydrogels, which could be prepared through gelation of the polymer via interaction of its functional groups with cross-linking agents [1].

Oil and gas industry employs various water-soluble polymers, such as polyacrylamide and its copolymers and cellulose ethers [2]. Previously, we have performed a rather thorough study of the gelation in hydroxyethyl cellulose and sodium carboxymethyl cellulose solutions, including syneresis and dynamics of viscoelastic properties of these gels, and also the effect of pH and alkali metal salts on their characteristics [3–5]. It has been shown that Sodium lignosulfonate (NaLS) is the most promising as a polymer for use in oil and gas industry [6]. Being a by-product of sulfite cellulose manufacture, this polymer is inexpensive and readily available. It forms coordination cross-linked gels in the presence of transition metal salts [7, 8]. The use of such gels in oil and gas industry facilitates solution of at least two problems, one of which is environmental (utilization of wastes from pulp-and-paper industry) and another, economic (reducing the cost of reagents for oil and gas production).

There is only limited published information on NaLS-based gels [9].

In this study, we examined the gelation in NaLS solutions in the presence of $Cr_2O_7^{2-}$ ions. The formation of such gels has been studied earlier, but therehave been no comprehensive studies because of the complexity of the process and problems arising in its practical implementation. Also the effects of alkali and alkaline-earth metal salts on the critical gelation concentration and mechanical characteristics of the resulting gels have been studied. These effects are of great practical significance in view of the fact that these salts are always present in formation water.

EXPERIMENTAL

In the study, we used commercial solid NaLS from Solikamsk Pulp and Paper Combine.

In gelation experiments, we used 40–50 wt % NaLS solution in distilled water and 10–50 wt % solutions of potassium ($K_2Cr_2O_7$) or sodium dichromate ($Na_2Cr_2O_7 \cdot 2H_2O$). Initially we prepared the gels in the presence of potassium dichromate. However, its solubility in water is only 12.5 g/100 g H_2O, which is much lower than that of the sodium salt (180.0 g/100 g H_2O, 20°C). Therefore, all the subsequent experiments were performed with sodium dichromate.

To examine the effect of alkali and alkaline earth metal salts on gelation, 0.5–3.0 M NaCl and 0.5 M $MgSO_4 \cdot 7H_2O$ were introduced into the system.

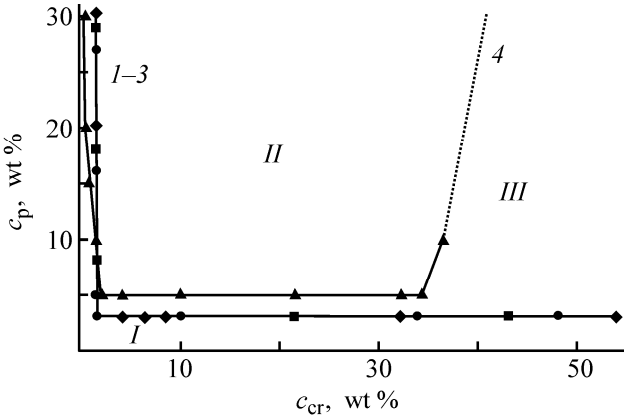

Fig. 1. c_p vs. c_{Cr} isotherm of the system NaLS–dichromate. (c_p) Polymer concentration and (c_{Cr}) sodium dichromate concentration. [NaCl], M: (*1*, *3*) 0, (*2*) 0.5, and (*4*) 3.0. [$MgSO_4 \cdot 7H_2O$], M: (*1*, *2*, *4*) 0 and (*3*) 0.5. Regions: (*I*) solutions, (*II*) gels, and (*III*) heterogeneous systems.

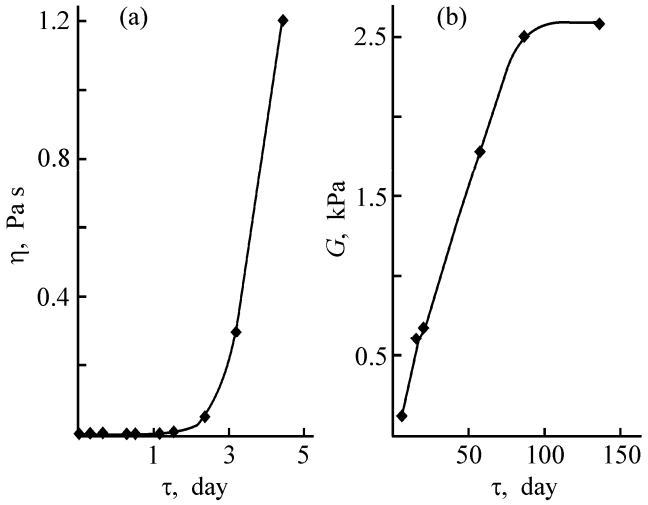

Fig. 2. (a) Viscosity η and (b) elastic modulus G vs. time τ. c_p = 10 wt %, c_{Cr} = 3.0 wt %.

The critical gelation concentrations, i.e., the minimal concentrations of the polymer and cross-linking agent that provide gelation, were fixed visually by the loss of solution flowability under gravity at the instant of turning over the vial containing the polymer and chromium salt solutions [10].

The viscous characteristics of the system before the flowability loss were measured on a BH-2 Höppler (falling ball) viscometer (Prüfgeräte–Werk Medingen, Dresden, Germany).

The elastic modulus was measured by the penetration method using spherical indenters of various radii (2–3 mm, depending on the elasticity of the gel) [11] and also by the tangential plate displacement method using a specially designed analytical balance. Following the Hertz theory, the elastic modulus of a test material is estimated in the spherical indentation case as

$$G = \frac{3}{16}\frac{F}{h^{3/2}R^{1/2}},$$

where F is the force applied to the spherical indenter of radius R, and h, indentation depth.

Experimental data on the critical gelation concentrations in the system NaLS–hexavalent chromium salt are presented in Fig. 1 as isotherms plotted in the coordinates polymer concentration vs. cross-linking agent concentration.

There are three regions in the isotherm bounded by curves corresponding to the minimal and maximal component concentrations at which gels are formed. The component concentrations in region *I* are below the critical gelation concentrations. Region *II* corresponds to formation of gels stable for a long time, and region *III*, to heterogeneous systems.

From this diagram, we estimated the critical polymer concentration (c_p = 3.0 wt %) and critical cross-linking agent concentration (c_{Cr} = 1.4 wt %) below which gelation does not occur at any concentration of the other component.

Our examination of the resulting gels revealed no visual water bleeding. In fact, however, syneresis takes place, though at a low rate: with time, the gels undergo shrinkage and compaction, keeping their shape.

Furthermore, as can be seen from Fig. 1, introduction of 0.5 M NaCl or $MgSO_4 \cdot 7H_2O$ into the system has nearly no effect on the critical polymer and cross-linking agent concentrations. However, with a simultaneous increase in the component concentrations, only two regions are found in the diagram, corresponding to solutions and gels.

Raising the NaCl concentration to 3 M leads to an increase in the critical gelation concentration with respect to the polymer to 5 wt %. Moreover, at high NaCl concentration, the range of gels is abruptly reduced, and the region of heterogeneous systems is found in the diagram, i.e., at sodium dichromate concentrations above curve *4*, no gelation occurs, but two-phase systems (solution and solid precipitate) are formed. In this case, salting-out of the polymer occurs, i.e., its solubility decreases with increasing salt concentration.

Our kinetic results show that the gelation in the system NaLS–sodium dichromate is characterized by a clearly pronounced induction period. Therefore, we measured the viscosity of the system before gelation and the elastic modulus after the loss of flowability (Fig. 2). The results show that, initially, the viscosity does not

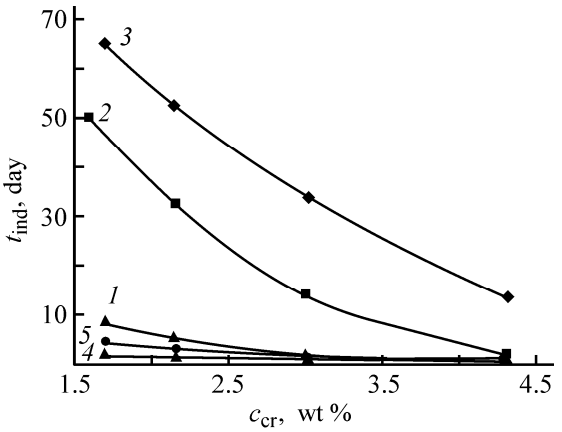

Fig. 3. Induction period t_{ind} vs. the dichromate concentration c_{Cr}. c_p, wt %: (*1*) 20.0, (*2*, *4*, *5*) 10.0, and (*3*) 5.0. [NaCl], M: (*1–3*, *5*) 0 and (*4*) 3.0. [$MgSO_4 \cdot 7H_2O$], M: (*1–4*) 0 and (*5*) 0.5.

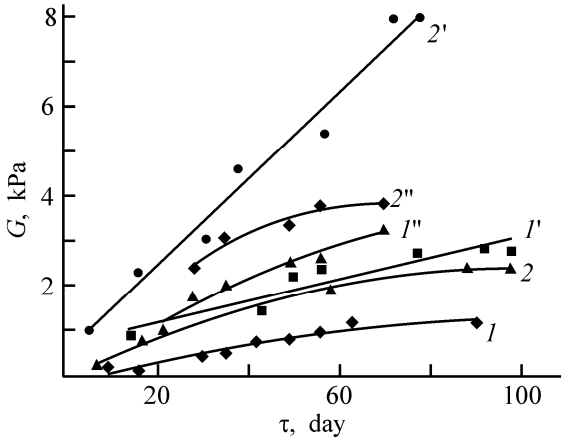

Fig. 5. Effect of alkali and alkaline-earth metal salts on the elastic modulus of the gels. c_p, wt %: (*1*, *1'*, *1"*) 5 and (*2*, *2'*, *2"*) 10. c_{Cr}, wt %: (*1*) 6.5 and (*2*) 2.2. [NaCl], M: (*1*, *2*) 0 and (*1'*, *2'*) 3. [$MgSO_4 \cdot 7H_2O$], M: (*1*, *2*) 0 and (*1"*, *2"*) 0.5.

change noticeably. Then it dramatically increases to the point of loss of flowability ($\eta \to \infty$), i.e., a gel is formed with the minimal elastic modulus (Fig. 2), which increases with time to the equilibrium value. This phenomenon can be attributed to a redox reaction between the dichromate ion and functional groups of the macromolecules, resulting in partial reduction of Cr(VI) to Cr(III). The occurrence of this reaction is confirmed by the fact that, in the course of gelation, pH changes from the acid range (pH 3.7) to the weakly alkaline range (pH 7.1).

According to the analyses in [12, 13], both Cr(III) polynuclear complexes and dichromate ions, forming cyclic structures with the guaiacyl groups of NaLS, are involved in the formation of the coordination network.

Our results show that the induction period of gelation decreases as both the polymer and the dichromate concentrations increase (Fig. 3). Addition of alkali and alkaline-earth metal salts has a more pronounced effect on the decrease of the induction period than changing in the polymer concentration. Thus, introduction of 0.5 M $MgSO_4 \cdot 7H_2O$ (Fig. 3, curve *5*) or 3.0 M NaCl (curve *4*) affects the induction period more strongly than does doubling of the polymer concentration (curves *2* and *1*).

The elastic modulus G of the gel is a rheological characteristic directly associated with the coordination network density, i.e., with the degree of structurization of the system. We studied the time evolution of G in the course of formation of gels of various compositions (Fig. 4). In all cases, the elastic modulus increases during a certain time, approaching the limiting (equilibrium) value (1–40 kPa, depending on the system composition).

Figure 4 shows that the elastic modulus of the resulting gels is controlled by the component concentrations in the system: G increases with the concentrations of the polymer (curves *1*, *3*) and dichromate (curves *1*, *5*). Deficit of both NaLS and dichromate considerably deteriorates properties of the gels: in this case, inelastic loose systems are formed.

The elastic modulus also increases upon introduction of alkali and alkaline-earth metal salts (Fig. 5). For example, addition of 3 M NaCl or 0.5 M $MgSO_4 \cdot 7H_2O$ cases an increase in G by about an order of magnitude, the effect being even more pronounced at higher polymer concentrations (Fig. 5).

Finally, our studies of the gelation in NaLS solu-

tions revealed some interesting features, which advantageously distinguish this system from those studied earlier. Gelation proceeds not instantly, but with some induction period caused by the redox reaction between the dichromate ions and macromolecules. Furthermore, addition of considerable amounts of alkali metal salts and even alkaline-earth metal salts does not interfere with the gelation; instead, it promotes formation of higher-molecular-weight gels, in contrast to the previously studied systems.

These features are important for practical appli-

CONCLUSIONS

(1) The dichromate ion is an efficient cross-linking agent for 5–30 wt % sodium lignosulfonate solutions. In this case, gels with an elastic modules G = 1–40 kPa are formed, and the gelation is characterized by clearly pronounced induction period.

(2) The elastic modulus of the resulting gels is in direct proportion to the polymer and cross-linking agent concentrations, whereas the induction period is in inverse proportion.

(3) Alkali and alkaline-earth metal salts hardly affect the critical gelation concentrations, but their addition makes the induction period several times shorter and raises the limiting (equilibrium) elastic modulus by several orders of magnitude.

St. Petersburg State University, St. Petersburg, Russia

Received April 9, 2008

Abstract—Efficiency of the stage of pre-electrolysis in inversion-voltammetric measurements was examined in relation to the hydrodynamic modes used.

DOI: 10.1134/S1070427208120240

The pre-electrolysis stage is a constituent of several electrochemical methods of analysis: inversion voltammetry (IVA), controlled-potential coulometry (CPC), and zero-reference combined electrochemical technique [1–3]. It is known that the electrolyte agitation efficiency strongly affects the sensitivity of the methods mentioned above, because in all of them, the deposition current is inversely proportional to the diffusion layer thickness δ, the parameter that characterizes the intensity of mass transfer.

Traditionally, IVA measurements are carried out with a rotating disk electrode (RDE), whose theory has been developed by Levich [3]. The same hydrodynamic system was employed in [1, 5, 6] in a zero-reference electrochemical method in which the pre-electrolysis efficiency is determined by the coulometric constant:

$$K = DS/(\delta V), \quad (1)$$

where D is the diffusion coefficient; S, electrode area; δ, diffusion layer thickness; and V, volume of the solution under study in the cell.

It follows from Eq. (1) that the constant K depends not only on δ, but also on the working electrode area S. The dependence of K on the volume has been studied previously [1, 6]. In the RDE method, it is not always possible to make larger the working electrode area at a fixed solution volume, which is necessary for using the zero-reference method. Another hydrodynamic model, a rotating cylindrical electrode (RCE), is possible, which allows use of large electrodes at small solution volumes [6].

The limiting diffusion current to the RDE is given by the equation [3]

$$i_d = 0.62nFc_0\omega^{0.50}\nu^{-0.167}D^{0.667}, \quad (2)$$

where n is the number of electrons involved in the electrode reaction; F, Faraday number; c_0, solution concentration in the cell; ν, kinematic viscosity; ω, angular rotation rate; and D, diffusion coefficient.

The limiting diffusion current to the RCE can be found using the equation [6, 7]

$$i_d = 0.0791nFc_0\omega^{0.70}d_i^{-0.30}\nu^{-0.344}D^{0.667}, \quad (3)$$

where d_i is the electrode diameter.

Equation (2) is satisfied for the RDE in a wide range of rotation rates [3]. For the RCE (the general scheme of the electrode is shown in Fig. 1a), there exist three fluid flow modes resulting from different electrode rotation rates.

(1) Simple laminar flow with concentric current lines, observed at low cylinder rotation rates. This flow merely sets the substance in a circular motion, without any increase in the mass-transfer rate.

(2) Flow with Taylor vortices, a cellular flow with a velocity component directed from one cylinder toward the other. This flow is also regular, laminar, and stable; it requires a higher electrode rotation rate and contributes to the mass-transfer rate.

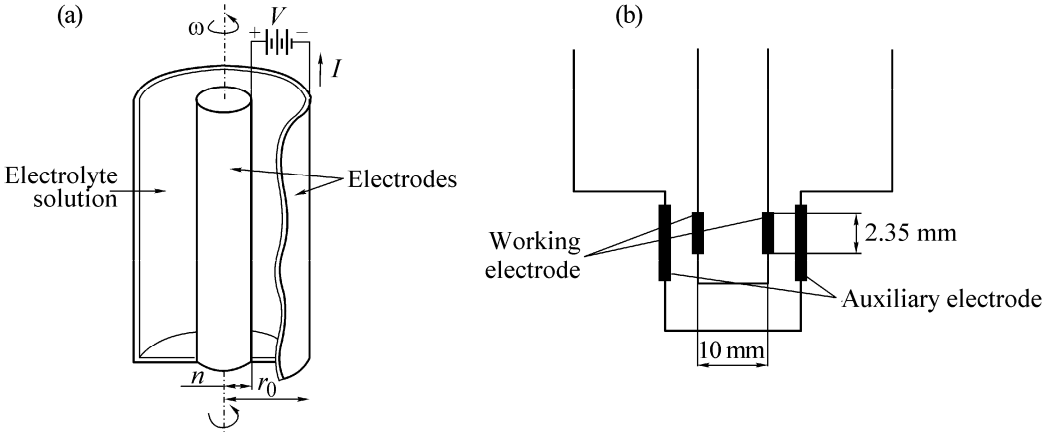

Fig. 1. (a) General scheme of a rotating cylindrical electrode and (b) schematic of the working cell: ω is the angular rotation rate of the cylindrical electrode; r, radius of the inner electrode; r_0, radius of the outer electrode; and V, voltage applied across the electrodes.

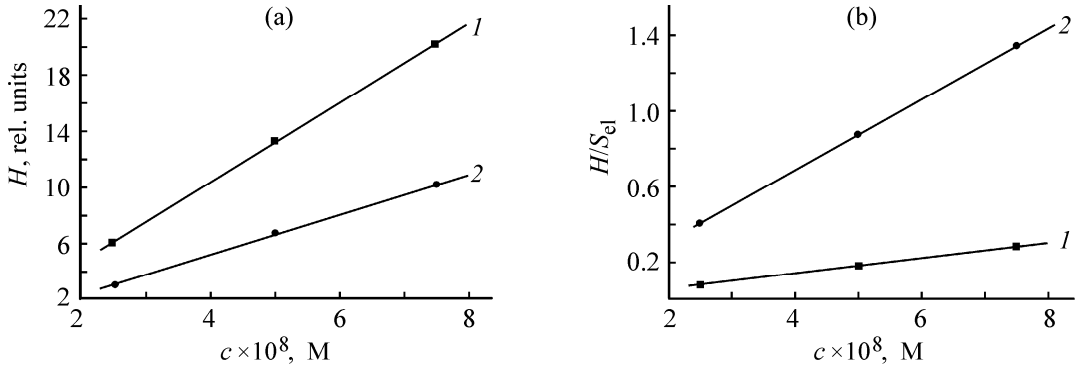

Fig. 2. (a) Height H of the ionization peak and (b) ratio between the analytical signal and the electrode area, H/S_{el}, vs. the solution concentration c in the working cell. Electrode rotation rate 1200 rpm. Electrode: (*1*) cylindrical and (*2*) disc-type; the same for Fig. 3.

(3) Turbulent flow characterized by rapid random fluctuations of velocity and pressure. Here is also included a fluctuating velocity component that is directed from one cylinder to the other and provides a substantial increase in the mass-transfer rate, which is uniform over the cylinder surface. This flow provides an effective agitation and requires the largest rotational moment.

Equation (3) is satisfied for the turbulent motion mode in a wide range of electrode rotation rates [6].

In this communication, the efficiencies of electrolysis with RDE and RCE are compared.

EXPERIMENTAL

The electrolysis efficiency was studied by the IVA method on a PLS-1 polarograph (Belarus) with an AKV-07 transducer (Akvilon NPKF, Moscow) in the ac mode. A solution of lead ions, with a concentration of 10^{-3} M, was prepared from a solution of a State standard sample (1 mg cm^{-3}) (SSS 7252–96). Solutions with concentrations of 10^{-5} and 10^{-6} M were prepared by dilution of the 10^{-3} M solution. The solutions were prepared from reagents of chemically pure and analytically pure grades and twice-distilled water. The measurements were made on a thin-film mercury-graphite electrode, with the electrode rotation rate in the accumulation stage varied from 1200 to 1800 rpm. The choice of the range of rotation rates was determined by the agitation intensity used in the IVA. All the potentials are given relative to a saturated silver chloride reference electrode. Platinum foil rolled-up in the form of a cylinder and placed along the inner wall of the lower part of the cup served as the auxiliary electrode. A solution of the following composition (M) was used as a supporting electrolyte: 1×10^{-4} $Hg(NO_3)_2 + 5 \times 10^{-2}$ HCl + 1×10^{-4} HNO_3. The preelectrolysis was carried out at a potential of –0.9 V. To satisfy the condition of a full dissolution of the metal from the amalgam, a low potential sweep rate was used (5 mV s^{-1}) [1]. The solution volume was constant (4 ml); the areas of the disc-type and cylindrical electrodes were 7.5 and 73.8 mm^2, respectively. The experiments were carried out in the quartz cell shown in Fig. 1b.

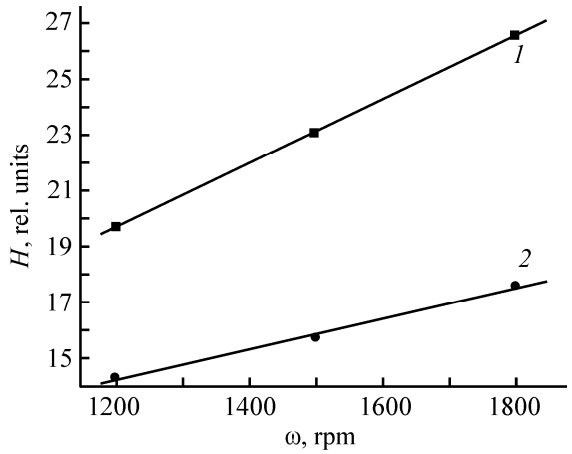

Fig. 3. Height H of the ionization peak vs. the electrode rotation rate ω.

The dependence of the current of Pb(II) dissolution from the amalgam on RDE and RCE in a solution at its different concentrations is shown in Fig. 2. The observed dependence is linear, in good agreement with Eqs. (2) and (3). The dependence of the dissolution (and, accordingly, deposition) current on the electrode rotation rate is shown in Fig. 3. At electrode rotation rates in the range 1200–1800 rpm, the dependence is almost linear in both cases and has slope rates $b_1 = 0.5$ for RDE and $b_2 = 0.7$ for RCE, also in good agreement with Eqs. (2) and (3). The value of b_2 equal to 0.7 indicates that a turbulent fluid motion occurs in the given case at the rotation rates studied.

The dependences of the currents of lead ionization from the amalgam on the rate of RDE and RCE rotation in the accumulation stage indicate that, at the electrode rotation rates within the range studied, the efficiency of electrolysis in the cell with RCE exceeds that in the cell with RDE. The efficiency of electrolysis with RCE is higher because of the larger electrode area, compared with RDE, in agreement with the data in Fig. 2b, which shows how the ratio between the height of the peak of lead ionization from the amalgam and the electrode area depends on the Pb(II) concentration in solution. The run of the dependence points to a higher efficiency of mass transfer in a cell with RDE, compared with RCE, at the electrode rotation rates within the range under study. Thus, the RDE provides a higher mass-transfer rate, compared with RCE, but the efficiency of electrolysis is higher with RCE because of its larger area at the given cell design.

CONCLUSIONS

It was shown that the efficiency of electrolysis in an electrochemical cell with a rotating cylindrical electrode exceeds that in a cell with a rotating disc electrode because of the possibility of using a larger-area cylindrical electrode at the same volume of a solution under study.

Abstract—The possible synergistic effect in the manifestation of the wear resistance and antifriction properties of nickel–Teflon composite electrolytic coatings was analyzed. The results of calculations of the diagnostic properties of the coatings in terms of the "concentration-wave" model are discussed in comparison with the corresponding experimental data.

DOI: 10.1134/S1070427208120252

It is well known [1] that nickel–boron–Teflon composite electrolytic coatings (CECs) exhibit a synergistic effect: Their wear resistance and antifriction properties are better than those calculated in terms of the additive model. The synergism of the solid and lubricating components consists in that the lubricating Teflon phase is concentrated on the friction surface, thus enhancing the antifriction characteristics and wear resistance of the solid phases of the coatings, and that the coatings contain nanoparticles of certain solid phases (probably borides Ni_3B and Ni_2B). These nanoparticles have a spherical or cylindrical shape with a cross section diameter of 1.2–2.5 nm; they apparently exhibit the properties of solid lubricants [1].

To verify the assumption that nanoparticles of only low-boron nickel phases contribute to the overall synergistic effect observed with nickel–boron–Teflon CECs, we examined boron-free nickel–Teflon CECs. In this case, the possible synergism would be exclusively due to the first factor, concentration of Teflon microparticles on the friction surface.

The calculated data for the linear wear I^0_{lin} and friction coefficient f^0 of nickel–Teflon CECs in the CEC/CEC friction couple were obtained within the two-component approximation of the "concentration-wave" model [2] by the formulas:

$$I^0_{lin} = \alpha\langle I^0_{lin,\,solid}\rangle + (1-\alpha)\langle I^0_{lin,\,lub}\rangle + \delta(\langle I^0_{lin,\,solid}\rangle - \langle I^0_{lin,\,lub}\rangle), \quad (1)$$

$$f^0 = \alpha\langle f^0_{solid}\rangle + (1-\alpha)\langle f^0_{lub}\rangle - \delta(\langle f^0_{solid}\rangle - \langle f^0_{lub}\rangle), \quad (2)$$

where $\alpha = \alpha_{solid}$ and $(1-\alpha) = \alpha_{lub}$ are the volume fractions of the solid and lubricating components of CEC, respectively; $\delta = 4(1-\alpha)\alpha^2[1-k(1-k_n)]$, relative synergistic effect; k, size parameter characterizing the dispersity of the solid component of CEC: the ratio between the mean size of microparticles r_{solid} of solid phases in the surface later and the thickness of this layer Δx, i.e., $k = r_{solid}(r_{solid} + \Delta x)^{-1}$ (at $r_{solid} \to \Delta x$ $k \to 0.5$); k_n, nanostructure parameter of the solid component of CEC: the volume fraction of solid phase nanoparticles of spherical or cylindrical shape in the surface layer Δx ($0 \le k_n < 1$); $\langle I^0_{lin,\,solid}\rangle$, $\langle f^0_{solid}\rangle$, $\langle I^0_{lin,\,lub}\rangle$, and $\langle f^0_{lub}\rangle$ are the mean values of the corresponding individual characteristics in the solid and lubricating components of CEC [2].

In accordance with the data of Kryachko et al. [3], the influence of the characteristics of counterbody (CB) material (St45 steel in our case) on the CEC properties was taken into account as follows:

$$I_{lin} = I^0 + (\Delta\alpha - \Delta\delta)(I^0_{solid} - I^0_{lub}) + (\alpha + \delta)(I_{CB} - I^0_{solid}), \quad (3)$$

$$f = f^0 + (\Delta\alpha - \Delta\delta)(f^0_{solid} - f^0_{lub}) + (\alpha + \delta)(f_{CB} - f^0_{solid}), \quad (4)$$

where $\Delta\delta \cong 2\alpha(3\alpha - 2)\Delta\alpha$ is the change in the relative synergistic effect [3]; $\Delta\alpha = \alpha^* \cong (\alpha I^0_{solid} + I_{CB})\times$

Table 1. Phase composition and concentration of components of composite coatings

Coating	CEC component	Phase composition	Weight fraction	Volume fraction	α
			%		
Ni	Solid	Ni	100	100	1.00
	Lubricating	–	0	0	
Ni–Teflon	Solid	Ni	99.1	95.4	0.954
	Lubricating	Teflon	0.9	4.6	
	Solid	Ni	98.3	91.6	0.916
	Lubricating	Teflon	1.7	8.4	
	Solid	Ni	96.9	85.6	0.856
	Lubricating	Teflon	3.1	14.4	

$(I^0_{solid} + I_{CB})^{-1} - \alpha = (1 - \alpha)I_{CB}(I^0_{solid} + I_{CB})^{-1}$ is the change in the volume concentration of solid phases in going from CEC to wear products of the CEC/CB couple (for the CEC/CEC friction couple, $\Delta\alpha$ is formally equal to zero) [3]; $(\alpha + \delta) = \alpha[1 + 2\alpha(1 - \alpha)(1 + k_n)]$; I^0_{lin} and f^0 are the linear wear rate and CEC friction coefficient in the CEC/CEC friction couple, determined by formulas (1) and (2).

Composite electrolytic coatings with Teflon volume fractions of 4.6, 8.4, and 14.4% were prepared from an electrolyte of the following composition ($g\,l^{-1}$): nickel chloride hexahydrate 200–250, nickel sulfate heptahydrate 2.5–5.0, boric acid 25–40, Chloramine B 0.5–2.5, and F-4D-E (Teflon) emulsion 10–20. Electrolysis conditions: pH 1.0–5.5, temperature 18–30°C, cathode current density 0.5–9 $A\,dm^{-2}$.

From the data on the phase composition and concentration of CEC components (Table 1), using the calculation procedures described in [2, 3], we obtained the concentration dependences $I_{lin}(\alpha)$ and $f(\alpha)$ at fixed values of the parameter k_n = 0, 0.05, 0.1, 0.15, and 0.2 for the CEC/CEC and CEC/St45 friction couples.

Note that the individual characteristics of the solid and lubricating CEC components that we used in the calculations, namely, for nickel, $I_{lin,\,solid}$ = 1.1 $\mu m\,h^{-1}$, f_{solid} = 0.25; for Teflon, $I_{lin,\,lub}$ = 7.5 $\mu m\,h^{-1}$, f_{lub} = 0.03; and for St45 steel, $I_{lin,\,St45}$ = 1.2 $\mu m\,h^{-1}$, f_{St45} = 0.24, corresponded to the stationary step of the mode of dry friction of two identical materials at a specific load of 3 MPa and a friction velocity V = 0.048 $m\,s^{-1}$.

Analysis of the $I_{lin}(\alpha)$ dependences for CEP in the case of friction over the identical material showed that the minimum of the linear wear rate, 0.673 $\mu m\,h^{-1}$, at k_n = 0 is attained at α = 0.86. As the nanostructure parameter increases to 0.20, the minimum of the linear wear rate decreases to 0.401 $\mu m\,h^{-1}$ at α = 0.83. In the case of friction over St45 steel, $(I_{lin})_{min}$ = 0.520 $\mu m\,h^{-1}$ for k_n = 0 is attained at α = 0.80, and with an increase in k_n to 0.20, this value decreases to 0.356 at α = 0.75. Apparently, the observed quantitative changes in $I_{lin}(\alpha)$ dependences are due to a rise in the contribution of nickel nanoparticles to the synergistic effect of the CECs.

An analysis of the $f(\alpha)$ dependences revealed a regular decrease in the friction coefficient with an increase in the volume fraction of Teflon and decrease in f_{CB} in the entire range of α. However, the maximal synergistic effect, i.e., the maximal deviation of the dependences $f(\alpha)$ from the values calculated in terms of the corresponding additive model, is attained at α = 0.72 ± 0.02.

It should be noted that the calculated data can be used for determining the compositions of Ni–Teflon CECs with prescribed wear resistance and antifriction properties. From the same data, we can determine the optimal composition of a wear-resistant antifriction coating, i.e., a formulation with the minimal value of $(I_{lin}f)|k_n$. For example, at k_n = 0, the minimal value of this parameter is attained for CECs (friction over St45 steel) at the Teflon volume fraction of about 0.25.

Experimental data on the wear resistance of CECs in friction couples with St45 steel are in reasonable agreement with the calculated data at k = 0.5 and k_n = 0.07 (Table 2). The nanostructure parameter equal to 0.07 was used for obtaining predictable data on the other tribological characteristics of the CECs (Table 2).

Thus, the concentration-wave model with the parameters k = 0.5 and k_n = 0.07 allows satisfactory interpretation of the experimental data on the linear wear rate of Ni–Teflon CECs in friction over St45 steel and prediction of the corresponding friction coefficients. Within the framework of the model we used, the quantity $k_n > 0$ means not only a high dispersity of micro-

Table 2. Wear and antifriction properties of nickel and composite coatings in a friction couple with St45 steel

	0.835	0.434	0.42	0.155	0.15

particles of Ni and γ-Fe phases, but also the presence among them of spherical or cylindrical nanofragments enhancing the effect of the CEC lubricating component.

It should be noted that the experimental data on the linear wear rate and friction coefficient for the nickel–boron–Teflon CEC, reported in [1] (Table 2), were satisfactorily described by the concentration wave model with a higher nanostructure parameter $k_n = 0.17$. In so doing, it was assumed [1] that, along with Teflon concentration on the surface of the CEC/St45 friction couple, nanoparticles of the specific shape were formed only from boron-containing phases.

The data we obtained suggest that, in nickel–boron–Teflon CECs, not only Ni_3B and Ni_2B, but also Ni and γ-Fe phases act in friction as lubricating components along with Teflon. On the whole, the role of boron-containing phases consists in that the wear resistance of the coatings is enhanced owing to their individual charactetistics I^0_{lin} and the friction coefficient of the surface decreases owing to the formation of the corresponding nanoparticles.

CONCLUSIONS

(1) Ni–Teflon composite electrolytic coatings show a synergistic effect consisting in enhancement of their wear resistance and antifriction properties, compared to the additive values.

(2) The synergism of the solid and lubricating components of the composite electrolytic coatings under consideration consists in concentration of Teflon on the wear surface, enhancing the antifriction properties and wear resistance of nickel, and in the presence of spherical or cylindrical nickel nanoparticles acting as solid lubricants.

Diffusion of Tl-204 Isotope and Ionic Conductivity in Tl_4HgI_6 Membrane Material for Chemical Sensors

D. S. Kalyagin, Yu. E. Ermolenko, and Yu. G. Vlasov

St. Petersburg State University, St. Petersburg, Russia

Received October 27, 2008

Abstract—Method for solid-phase synthesis of Tl_4HgI_6 was developed and the diffusion coefficients of thallium-204 isotope were determined for this compound for the first time. Data on the ionic conductivity and diffusion of thallium ions were obtained and used to calculate the defect concentration and mobility in the thallium sublattice.

DOI: 10.1134/S1070427208120264

The topicality of this study is due to a search for new crystalline inorganic materials that would be promising as materials for ion-selective membranes for chemical sensors. Studies of the structure and transport characteristics of these materials are highly important for determining the possibility of their use in development of new sensors [1, 2]. This communication presents results obtained in measurements of the ionic conductivity and the diffusion coefficients of thallium-204 isotope in the compound Tl_4HgI_6 and data on the mobility coefficients and concentration of defects in the thallium sublattice of this compound at various temperatures.

EXPERIMENTAL

As starting substances for solid-phase synthesis of the compound Tl_4HgI_6 were chosen TlI and HgI_2 preliminarily precipitated from aqueous solutions, with $TlNO_3$, $Hg(NO_3)_2$, and KI of special-purity grade used as starting reagents. The thallium and mercury iodide salts with grain sizes $d \leq 30$ μm, dried in an inert atmosphere, were taken in the relative amounts of 80 mol % TlI + 20 mol % HgI_2, thoroughly mixed, and ground in an agate mortar to full homogeneity. The resulting mixture was placed in a steel mold and compacted into cylindrical briquettes 6 mm in diameter and 8–10 mm high at a specific pressure of 1.5 ton cm^{-2}. Then the briquettes were annealed in a dry inert atmosphere at 200°C for 3 h.

After a slow cooling, the samples were ground and again compacted to perform the second cycle of the solid-phase reaction at the same temperature (200° C). An X-ray phase analysis performed after two cycles of the solid-phase reaction demonstrated the presence of the only phase with a tetragonal unit cell (a = 9.26 Å, b = 9.45 Å, space group $P4/mnc$) corresponding to Tl_4HgI_6. For measurements of the electrical conductivity and diffusion coefficients, the resulting compound was again compacted at a residual pressure of 3 ton cm^{-2} into cylindrical samples 6 mm in diameter and 6–10 mm high.

The total electrical conductivity was measured with graphite contacts in the ac mode at frequencies of 0.3–20 kHz in the temperature range 80–200°C. The experimental setup comprised an E 8-2 resistance-capacitance bridge, F 582 zero indicator, GZ-56/1 low-frequency generator, electric furnace, and nitrogen-filled measuring cell. An analysis of the frequency dispersion of the resistance revealed an insignificant variation in the frequency range 5–20 kHz. Despite this circumstance, the conductivity data obtained were extrapolated to an infinite frequency.

Figure 1 shows temperature dependences of the electrical conductivity of Tl_4HgI_6 samples for different numbers of cycles of the solid-phase reaction. Within the experimental error, all the straight lines obtained are well reproducible both in absolute values of conductivity and in activation energies. However, all fur-

ther experiments used samples obtained after two cycles of the solid-phase reaction, because samples subjected to a single cycle contained trace amounts of unreacted thallium and mercury iodides.

Experiments aimed to estimate the electronic component of the conductivity in Tl_4HgI_6 were carried out by Wagner's polarization method in the dc mode with one reversible and one inert electrodes [3, 4]. With the method used to synthesize the Tl_4HgI_6 compound in the temperature range 80–200°C, the electronic component was 1.5–2.0 orders of magnitude lower than the total electrical conductivity. Thus, the graphical dependences log σ–T (Figs. 1, 2) with activation energy E_a eV can be assumed to represent only the ionic component σ_{ion}. It should be noted that only strict observation of the stoichiometry, well developed synthesis technology, and purity of the starting reagents make it possible to obtain the Tl_4HgI_6 compound with nearly purely ionic conductivity in the temperature range specified (80–200°C).

The adequacy of the experimental procedure and measuring techniques chosen in this study is confirmed not only by the good reproducibility of results for different numbers of cycles of solid-phase synthesis (Fig. 1), but also by their rather good agreement with data obtained by a number of other authors [5, 6] (Fig. 2).

The main part of the experimental study consisted in measuring the diffusion coefficients of thallium-204 radioactive isotope ($T_{1/2}$ = 3.78 yr, E_β = 763 keV) in the Tl_4HgI_6 ionic conductor and in comparing the results obtained in studies of the diffusion and ionic conductivity. The experiments were performed by the method of diffusion from an "infinitely" thin $TlNO_3$ layer, with the subsequent sectioning of a sample and measurements of the β-activity of ground-off layers on an end-window counter.

The diffusion annealing of the samples was performed in the temperature range 120–200°C for 900 s. The resulting linear dependences of the activity logarithm on the squared distance from the starting deposited active layer (A–x^2) are shown in Fig. 3. The experimental straight lines plotted in the coordinates log A–x^2 without any peaks of residual activity near $x \to 0$ point to diffusion from an infinitely thin layer and to the bulk nature of the process.

The diffusion coefficients were calculated using the formula for the distribution of radioactive ions in a sample for the case of diffusion from a thin layer:

$$\log A = \text{const} - (0.1086/D^*t)x^2,$$

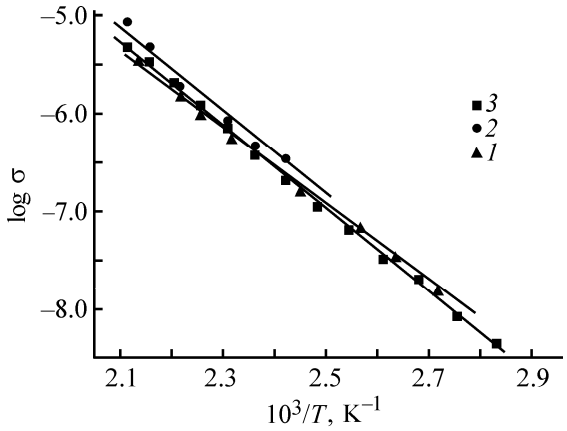

Fig. 1. Dependence of the electrical conductivity σ of Tl_4HgI_6 samples after one, two, or three cycles of the solid-phase reaction on temperature T. (*1–3*) Number of cycles of the solid-phase reaction.

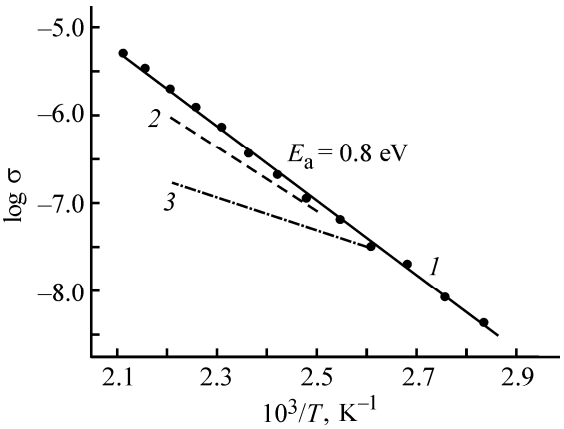

Fig. 2. Dependence of the electrical conductivity σ of Tl_4HgI_6 samples on temperature T in comparison with data of various authors. (*1*) Results of this study; published data: (*2*) [5] and (*3*) [6].

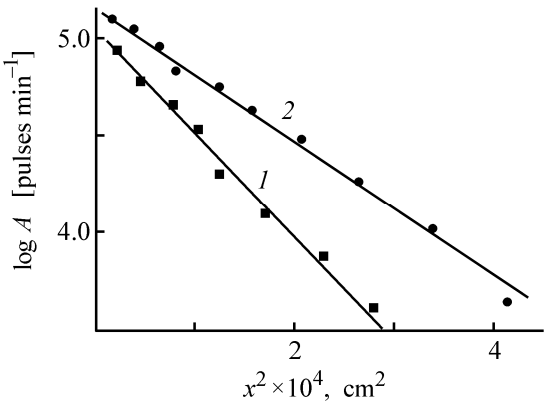

Fig. 3. Diffusion profiles of Tl_4HgI_6 samples for temperatures of (*1*) 182 and (*2*) 188°C. (*A*) Activity of a section and (*x*) distance from the active surface.

where A is the activity of a ground-off section (pulses min^{-1}); x, distance from the active surface (cm); t, time of sample annealing (s); and D^*, diffusion coefficient (cm^2 s^{-1}).

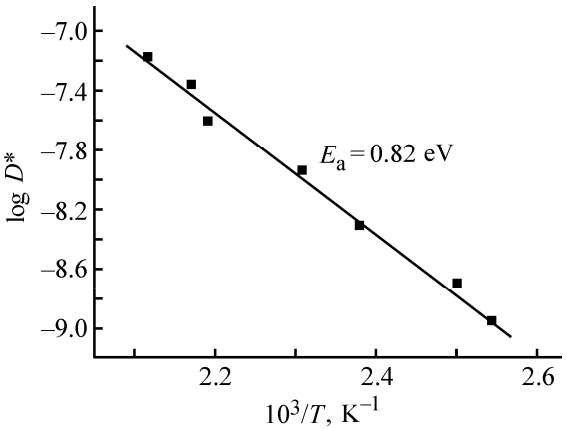

Fig. 4. Dependence of the diffusion coefficients D^* of thallium-204 isotope in the Tl_4HgI_6 compound on temperature T.

Figure 3 shows as an example the diffusion profiles for annealing temperatures of 182 and 188°C. Experiments on determining D^* were carried out for ten samples in the temperature range 120–200°C; data for seven of these are presented in Fig. 4. It is important to note that the activation energy found for diffusion of thallium ions, E_{diff} = 0.82 eV, well correlates with the activation energy of ionic conductivity, E_{cond} = 0.84 eV in Tl_4HgI_6.

The data on the diffusion of Tl-204 isotope in Tl_4HgI_6 samples can be used to calculate the mobility μ of thallium ions at various temperatures by the Nernst–Einstein equation:

$$D^*/\mu = kT/e,$$

where e is the charge of the ion (C); k, Boltzmann's constant (J deg^{-1}); μ, mobility of the ion (cm^2 V^{-1} s^{-1}); and T, absolute temperature.

For example, $\mu_1 = 5.8\times10^{-8}$ cm^2 V^{-1} s^{-1} and $\mu_2 = 1.6\times10^{-6}$ cm^2 V^{-1} s^{-1} at temperatures of 127 and 199°C, respectively.

As an additional important characteristic of the ion transport in Tl_4HgI_6 samples can serve the concentration of thallium defects in the cation sublattice, calculated from the data obtained. The total concentration of Tl^+ ions can be found ($N = 7.6\times10^{21}$ ions cm^{-3}). from the measured density of polycrystalline thallium hexaiodomercurate samples, ρ = 5.6 g cm^{-3}. Also, these concentrations can be found, e.g., for temperatures of 127 and 199°C, to be $\eta_1 = 1.1\times10^{19}$ s cm^{-3} and $\eta_2 = 1.8\times10^{19}$ s cm^{-3} on the assumption that $\sigma_{ion} = e\eta_i\mu_i$, where η is the concentration of carriers (defects).

Thus, the effective fraction of ion carriers in the temperature range in question can be estimated as (1.5–2.4) $\times10^{-3}$. The high value of the ionic component of the conductivity makes it possible to regard Tl_4HgI_6 as a promising material for chemical sensors.

CONCLUSIONS

(1) The diffusion coefficients D^* and the ionic electrical conductivity σ were found for Tl_4HgI_6 in the temperature range 80–200°C, and the concentrations of defects in the thallium sublattice and their mobilities were determined.

(2) A quantitative study of ionic transport characteristics in thallium hexaiodomercurate demonstrated the advisability of its use for development of membranes for chemical sensors for the thallium ion.

Preparation of Fluorinated Esters of Abietic Acid

I. N. Gaidukov and L. M. Popova

St. Petersburg State Technological University of Vegetable Polymers, St. Petersburg, Russia

Received July 28, 2008

Abstract—The reaction of abietic acid chloride with sodium salts of 1*H*,1*H*-dihydrotrifluoroethanol, 1*H*,1*H*,3*H*-trihydrotetrafluoropropanol, 1*H*,1*H*,5*H*-trihydrooctafluoropentanol, and pentafluorophenol was studied. The main reaction products are the corresponding fluorinated alkyl (aryl) abietates.

DOI: 10.1134/S1070427208120276

One of the ways to modify rosin is its esterification. The resulting products, depending on the kind of the rosin and alcohol used, show promise in production of synthetic resins, ester plasticizers, hot-melt adhesives, varnishes, paints, adhesives for food package, etc., meeting the most stringent environmental requirements. As compounds with long-chain fluoroalkyl group exhibit surface activity [1], esters of rosin and fluorinated alcohols can be valuable hydro- and oleophobizing agents for fibrous composite materials. Therefore, development of procedures for preparing such esters is a topical problem.

This work continues our studies devoted to development of new fluorinated surfactants [2, 3] and is aimed to devise of a procedure for preparing previously unknown esters of abietic acid (model compound of oleoresin rosin) and fluorinated alcohols: 1*H*,1*H*-dihydrotrifluoroethanol, 1*H*,1*H*,3*H*-trihydrotetrafluoropropanol, 1*H*,1*H*,5*H*-trihydrooctafluoropentanol, and pentafluorophenol.

Esterification of resin acids, the major component of rosin, is complicated by the steric shielding of the carboxy group located at the tertiary carbon atom [4] and by the low acidity (pK_a 6.4) [5] of compounds of this class. This results in a decrease in the rate of esterification of resin acids in the presence of common acid catalysts (H_2SO_4, H_3PO_4, etc.). Performing the esterification under harsh conditions (in the presence of aggressive acid agents and at elevated temperatures) gives rise to undesirable side reactions, such as dimerization of abietic-type acids and their disproportionation, which diminishes the yield of the target product and complicates its isolation [3]. Therefore, the reaction of resin acids with alcohols in the presence of acid catalysts is an extremely inefficient route to esters.

In some reports, alternative procedures for preparing resin acid esters have been suggested. For example, it is recommended to prepare methyl abietate by the reaction of abietic acid with diazomethane [6] or of silver abietate with methyl iodide on heating [7]. Halbrook and Lawrence [8] prepared rosin monoesters of ethylene or 1,3-propylene glycol by the reaction of rosin with ethylene or propylene oxide at elevated temperatures. The reactions of alkali metal resinates with alkyl halides also yield esters; by this route, Zandersons and Tardenaka [9] prepared glycidyl abietate. As reported by Bardyshev [4], methyl, ethyl, and phenyl abietates are formed by reactions of the corresponding alcohols with abietic anhydride. It was also noted that these reactions occur at elevated temperatures in the presence of a catalyst. Johnston [10] prepared ethyl abietate by the reaction of abietic acid chloride with ethanol.

Kryachko et al. [3] reported that esterification of abietic acid with 1*H*,1*H*,5*H*-trihydrooctafluoropentanol in the presence of *p*-toluenesulfonic acid yields 1*H*,1*H*,5*H*-trihydrooctafluoropentyl dehydroabietate, i.e., the esterification is accompanied by disproportionation of abietic acid. The same ester has been prepared by esterification of dehydroabietic acid with concentrated H_2SO_4 as catalyst [2].

In the present study, esters of abietic acid and fluorinated alcohols were prepared by reactions of sodium salts of the corresponding alcohols and abietic acid chloride synthesized as described in [4, 11–14]. The reactions between the alcoholates and acid chlo-

Analytical and NMR data for products of reactions of abietic acid chlorides with sodium salts of 1H,1H-dihydrotrifluoroethanol, 1*H*,1*H*,3*H*-trihydrotetrafluoropropanol, 1*H*,1*H*,5*H*-trihydrooctafluoropentanol, and pentafluorophenol (products **I–IV**, respectively)

ride were performed in toluene in the course of 3–6 h, at the reactant molar ratio of 1 : 1.25. The choice of the alcoholate instead of the corresponding alcohol was governed by the facts that the reaction in this case is faster and that the second product is sodium chloride, which is insoluble in toluene and can be readily removed from the reaction mixture, i.e., isolation of the desired product is simplified. The products obtained were yellow-brown resinous noncrystallizing sub-

EXPERIMENTAL

The ^{1}H and ^{19}F NMR spectra of the products were recorded on a Bruker WH-400 spectrometer (400 MHz) from 5% solutions in acetone-d_6. The chemical shifts were determined relative to internal TMS (^{1}H NMR) and trifluoroacetic acid (^{19}F NMR).

To evaluate the purity of the initial abietic acid and monitor the reaction progress, we used TLC on Silufol UV 254 plates (eluent hexane–methylene chloride–acetone, 1 : 1 : 0.5).

Abietic acid was isolated from oleoresin rosin of the Wg brand according to [6]. The solvents were purified by the standard procedures [15].

Sodium alcoholates were prepared by reactions of the corresponding fluorinated alcohols with sodium metal in ether or toluene, following the procedures described in [16–19].

Abietic acid chloride. To a solution of 5.00 g (16.5 mmol) of abietic acid in 100 ml of toluene, 0.74 g (5.5 mmol) of PCl_3 was slowly added at room temperature with stirring. The reaction mixture was stirred for 20 h, after which H_3PO_3 was filtered off. Abietic acid chloride was used immediately after preparation, without isolation.

Reaction of abietic acid chloride with sodium 1H,1H-trifluoroethylate. To 5.30 g (16.5 mmol) of abietic acid chloride in 100 ml of toluene, a suspension of 2.51 g (20.6 mmol) of sodium 1*H*,1*H*-dihydrotrifluoroethylate was added with vigorous stirring at room temperature. The mixture was stirred for 3 h, after which the NaCl precipitate was filtered off, the toluene solution was washed with water and dried over calcined $MgSO_4$, and the solvent was separated. The tarry residue was dried in a vacuum over P_2O_5. The yield of the product (**I**) was 90%.

1*H*,1*H*,3*H*-Trihydrotetrafluoropropyl (product **II**), 1*H*,1*H*,5*H*-trihydrooctafluoropentyl (product **III**), and pentafluorophenyl (product **IV**) esters of abietic acid were prepared similarly from 5.30 g (16.5 mmol) of abietic acid chloride and 3.17 g of sodium 1*H*,1*H*,3*H*-trihydrotetrafluoropropylate, 5.23 g of sodium 1*H*,1*H*,5*H*-trihydrooctafluoropentylate, and 4.24 g of sodium pentafluorophenolate, respectively; the reaction time was 6 h. The yields of fluorinated alkyl (aryl) abietates **II–IV**, evaluated by ^{1}H NMR, were 60–85% (see table).

The TLC data suggest the presence of a minor impurity of abietic acid in all the reaction mixtures. The formation of esters is also confirmed by the acid and iodine numbers of the resulting products (see table).

An NMR analysis of reaction mixtures from synthesis of **I–IV** revealed the presence of the major component, fluoroalkyl (fluoroaryl) abietate. For example, in the ^{1}H NMR spectra of **I–III**, there are multiplets with δ 4.46 (I), 4.59 (II), and 4.75 ppm (**III**), corresponding to the $-OCH_2-$ protons of the fluoroalkyl moiety. The olefinic protons in I–IV give rise to signals at 5.37, 5.78 (I), 5.25–5.6, 5.78 (**II**, **III**), and 5.37, 5.78 ppm (**IV**). In addition, in the spectra of **II** and **III** there are proton signals from terminal $-CF_2H$ groups (triplet of triplets) with δ 6.37 ($^2J_{HF}$ 52.7 Hz) (**II**) and 6.73 ppm ($^2J_{HF}$ 51.2 Hz) (**III**).

In the ^{19}F NMR spectrum of **I**, there is a single signal at –72.26 ppm, belonging to fluorine nuclei of the $-CF_3$ group. The presence of the $-^2CF_2-^3CF_2-$ group in the molecule of **II** is confirmed by the signals with δ_F –123.6 (s, $^2CF_2$) and –136.4 ppm (d, $-^3CF_2-$). In the spectrum of product **III** containing the residue of the telomeric alcohol with $n = 2$, there are the following signals: –119.5 (s, $-^2CF_2-$), –124 (s, $-^3CF_2-$), –131 ppm (s, $-^4CF_2-$), and a doublet of $-^5CF_2H$ (–138 and –137.3 ppm). For the pentafluorophenyl fragment, we observed signals from the fluorine atoms of the aromatic ring at –170.8 (γ-$C_{ar}F$), –165.1 (β-$C_{ar}F$), and –161.9 ppm (α-$C_{ar}F$).

The chemical shifts and integral intensities of the proton and fluorine signals correspond to the presumed structures of the fluorinated alkyl (aryl) abietates.

CONCLUSION

Fluorinated alkyl (aryl) abietates were prepared in 60–90% yields by the reactions of abietic acid chloride with sodium salts of 1*H*,1*H*-dihydrotrifluoroethanol, 1*H*,1*H*,3*H*-trihydrotetrafluoropropanol, 1*H*,1*H*,5*H*-trihydrooctafluoropentanol, and pentafluorophenol under mild conditions (toluene, room temperature, 3–6 h). Abietic acid does not disproportionate under these conditions.

Esters of Amylose, Cellulose, and Tall Oil Fatty Acids

A. V. Kurzin, A. N. Evdokimov, O. S. Pavlova, and V. B. Antipina

St. Petersburg State Technological University of Vegetable Polymers, St. Petersburg, Russia

Received May 14, 2008

Abstract—The possibility of preparing amylose and cellulose esters by esterification and acylation with chlorides of tall oil fatty acids was examined.

DOI: 10.1134/S1070427208120288

Esters of carbohydrates and higher fatty acids (HFAs), the so-called liposaccharides, are promising and valuable nonionic surfactants used in various branches of industry and in medicine [1]. Polysaccharide esters form a particular group of liposaccharides. The main procedures for their preparation are based on acylation with HFAs under the conditions of acid or base catalysis, and also on ester interchange of alkyl esters of acids with polysaccharides [1–4].

A promising renewable source of fatty acids is tall oil, a by-product from kraft pulp production. The main components of tall oil fatty acids (TOFAs) are unsaturated C_{18} acids: oleic, linoleic, and linolenic [5]. A search for new applications of tall products is a topical problem of pulp-and-paper and resin industry. Previously, we have prepared liposaccharides from sucrose [6], xylitol [7], and tall oil fatty acids.

The goal of this study was to prepare TOFA esters of amylose and cellulose.

Use of strong Brønsted acids as acylation catalysts leads to formation of dark tarry products. A more efficient synthetic route to polysaccharide esters is the reaction of activated polymers with acid chlorides in the presence of tertiary amines.

Chlorides of higher unsaturated acids are usually prepared by treatment of the acids with phosphorus halides or thionyl chloride, but side processes occur in the latter case. For the experiments, we chose phosphorus trichloride, which is successfully used in synthesis of chlorides of higher fatty unsaturated acids, including TOFAs [8].

Among the catalysts reported in the literature for esterification of carbohydrates with HFAs, a particular place is occupied by anhydrides and chlorides of acetic acid derivatives (methoxyacetic, chloroacetic, trifluoroacetic acids). Positive results have also been obtained with free trichloroacetic acid used as catalyst (impeller).

The degree of substitution of the reaction product was calculated from the difference between the saponification number and acid number. For the amylose ester prepared with TOFA chlorides, it was 0.38, and for the ester prepared using trichloroacetic acid, 0.45. The low acid numbers (less than 1 mg KOH/g product) show that the product hardly contains any amount of starting fatty acids. The appearance of new ester bonds is also confirmed by comparison of the IR spectra of the starting amylose and its esterification products. Absorption bands characteristic of stretching vibrations of ester C=O groups (1730 cm^{-1}) and of double bonds in hydrocarbon residues of TOFAs (1680–1620 cm^{-1}) appear in the IR spectra, whereas bands of the reagents used, including C–Cl stretching vibration bands (800–600 cm^{-1}), are absent.

The polymers obtained are structurally similar to surfactants widely used today for stabilization of dispersions and control over rheological properties (Emulsan etc.) [9].

EXPERIMENTAL

TOFAs (A grade, Segezha Pulp-and-Paper Combine, Joint-Stock Company) were additionally purified by vacuum distillation, with the fraction boiling at 170–205°C/1 mm Hg collected. Bleached coniferous pulp (Kotlas Pulp-and-Paper Combine, Joint-Stock Company) was disintegrated to separate fibers. TOFA

chlorides were prepared by the reaction of the acids with phosphorus trichloride according to [7]. In our study we used edible-grade amylose and dehydrated trichloroacetic acid (chemically pure grade). Pyridine (chemically pure grade) was dried over KOH and distilled. The acid and saponification numbers were determined by the standard procedures [10]. The IR spectra of the esters were recorded on a Shimadzu FTIR-8400S spectrophotometer from Nujol mulls.

Esters of polysaccharides and TOFAs were prepared as follows.

(1) A mixture of 20 g (0.12 mol) of the polysaccharide (cellulose was preliminarily kept in 50 ml of pyridine for 2 days in a flask with a tightly ground-in stopper), 80 ml of pyridine, and 100 ml of toluene was stirred for 20 min. To this mixture, 150 ml (0.5 mol) of TOFA chlorides was added, and the mixture was heated with a reflux condenser at 55°C for 8 h. Then 100 ml of methanol was added, the mixture was filtered, and the precipitate was washed with methanol (2×50 ml) and petroleum ether (50 ml) and dried in air.

(2) Trichloroacetic acid (210 g, 1.3 mol) was mixed with 105 ml (0.36 mol) of TOFAs, after which 50 g of pyridine was added. The mixture was stirred for 20 min. To this solution, 20 g (0.12 mol) of the polysaccharide was added (cellulose was preliminarily kept in 50 ml of pyridine for 2 days in a flask with a tightly ground-in stopper), and the mixture was heated with a reflux condenser at 40°C for 8 h. Then 150 ml of methanol was added, the mixture was filtered, and the precipitate was washed with two portions of a methanol–hexane mixture (1 : 1, 50 ml) and dried in air.

The resulting amylose esters are weakly colored solid amorphous substances, and cellulose esters are pale yellowish fibrous materials.

CONCLUSION

Polysaccharides can be acylated with tall oil fatty acids or acid chlorides in the presence of pyridine or with the free acids in the presence of trichloroacetic acid.

Abstract—A procedure was developed for preparing a carbon–silica composite by thermolysis of powdered cellulose in the presence of tetraethoxysilane. The resulting composite was studied in model processes of trimethylhydroquinone oxidation and hydrogen peroxide decomposition.

DOI: 10.1134/S107042720812029X

Carbon–mineral composite materials find growing use in various branches of science and technology [1–7]. Modification of carbon fibers with a silicon dioxide xerogel is accompanied by changes in the physicochemical (in particular, sorption) properties of the material, which expands the possibilities of its use as catalyst support, enterosorbent, hemosorbent, adsorbent for chromatography, etc. However, practical use of carbon composites is largely restricted by their relatively high cost. Therefore, a topical task is development of new methods for preparing such materials with the required set of consumer's properties from cheap and renewable raw materials. One of the most readily available materials for producing these composites is cellulose. Of most interest for this purpose is powdered cellulose, whose preparation procedures have been developed in detail [8–10], because it is characterized by higher homogeneity, compared to common (fibrous) cellulose.

The goal of this study was to prepare carbon–silica materials based on carbon fibers formed by thermolysis of powdered cellulose and to study the properties of these materials. As inorganic component, we used hydrolysis products of tetraethoxysilane (TES).

EXPERIMENTAL

Powdered cellulose (PC) was prepared by hydrolysis of kraft pulp from Baikal Pulp-and-Paper Combine [TU OP (Pilot Technical Specification) 13-027 94 88-08–91] in 2.5 N HCl at 100°C. The hydrolysis was performed for 2 h. The resulting product was washed on the filter with distilled water to neutral pH of the aqueous extract, squeezed on the vacuum filter to a moisture content of 60 wt %, and compacted into granules 4 mm in diameter, which were dried at 100°C to constant weight and impregnated with tetraethoxysilane. The PC–TES sample was placed in a desiccator in an atmosphere of NH_3 and water vapor (10% aqueous ammonia solution) and kept there to ensure TES hydrolysis. The sample was dried at 100°C. Thus, we prepared a material of the composition PC–16% SiO_2, which was subsequently subjected to thermolysis at 350°C in a reactor equipped with a hydroseal. The material was heated at a rate of 2 deg min^{-1} and kept at the final temperature for 3 h.

The yield of the solid thermolysis product was 43%. The material had the composition C–36 wt % SiO_2. The resulting composite was impregnated to saturation with TES and kept in a desiccator in an atmosphere of NH_3 and water vapor. After the hydrolysis was complete, the material was dried at 100°C. The resulting material had the composition C–46 wt % SiO_2. Then the impregnation was repeated, and the final composition was C–65 wt % SiO_2. Granules of the composite were boiled for 3 h in water, with its intermittent replacement. Figure 1 shows a micrograph of the surface of the composite obtained.

The IR spectra of the solid powder were recorded on a Perkin–Elment Spectrum One IR Fourier spec-

trometer in the range 4000–370 cm^{-1} using a diffuse reflection attachment (DRA).

The bands were assigned on the basis of data from [11]. The spectra were processed, with calculation of the band intensities, using special programs from the software supplied with the spectrometer.

Kinetic experiments on oxidation of trimethylhydroquinone (TMHQ) and decomposition of hydrogen peroxide were performed in a temperature-controlled reactor equipped with a reflux condenser. The aqueous-methanol solution (water : methanol = 1 : 1 by volume) was agitated by air bubbling. Air was fed at a rate of 2.1 $1h^{-1}$. The oxidation of TMHQ was performed at 50°C; the temperature was maintained with an accuracy of ±0.2°C. The component concentrations were as follows: substrate 66 mM, $CuCl_2 \cdot 2H_2O$ 6 mM; the amount of the composite was 0.1–0.4 g. TMHQ was quantitatively determined performed by GLC with a Chrom-4 chromatograph [12]. The decomposition of hydrogen peroxide was studied at 50°C. The initial concentration of H_2O_2 was 5.7 mM, and the amount of the composite, 0.007–0.5 g. Kinetic measurements were performed by stopping the reaction and determining the content of the starting substance.

Sorption of carbon monoxide by the composite was studied with a BI-SORBchemo-2 device. A sample was placed in a quartz reactor and heated in a helium flow to 200°C at a rate of 10 deg min^{-1}; after being kept at the final temperature for 1 h, the sample was cooled to room temperature. The pulse titration with the sorbate gas was performed. The amount of the sorbed CO was determined with a thermal conductivity detector. The CO sorption was 0.041 cm^3 per gram of C–SiO_2. The carbon matrix sorbs CO in an amount of 0.49 $cm^3\ g^{-1}$.

For comparison, we performed sorption of CO on commercial activated birch charcoal BAU-A (S_{sp} = 750 $m^2\ g^{-1}$) and on BAU-A sample subjected to a single impregnation with TES and subsequent hydrolysis as described above, BAU-A–43 wt % SiO_2. No CO sorption on the reference samples was observed. Thus, the presence of silicon dioxide in the carbon granule leads to a considerable decrease in the sorption capacity for CO, apparently, because active sorption centers become less accessible to the sorbate. The total porosity of the sample was 0.7 $cm^3\ g^{-1}$.

The carbon–mineral composite was examined by IR spectroscopy. The IR spectrum of C–SiO_2 contains an absorption band at 3647 cm^{-1}, corresponding to stretching vibrations of O–H bonds in isolated hydroxy groups; a broad band at 3385 cm^{-1}, assigned to vibrations of adsorbed water and bound OH groups; bands at 2900–2800 cm^{-1}, assigned to stretching vibrations of methylene and methyl groups (weak absorption due to incomplete hydrolysis of TES); a band at 1700 cm^{-1}, assigned to C=O vibrations in carboxy groups of the carbon matrix, formed by thermal oxidative degradation of pyranose rings of PC [13]; a band at 1593 cm^{-1}, corresponding to the superposition of the stretching bands of ethylene groups (–CH=CH–) [13] and δ_{H-O-H} (1629 cm^{-1}). It should be noted that the presence of strong bands at 1593 and 1442 cm^{-1} may also suggest the presence of conjugated –C=C– bonds in fused aromatic structures [14] arising from PC degradation. The lack of the corresponding =C–H stretching bands at 3100–3000 cm^{-1} may be due to their being obscured by the low-frequency wing of the ν_{OH} band. The peaks between 1250 and 1000 cm^{-1} are assigned to the Si–O–Si vibrations.

Fig. 1. Microstructure of the surface of the composite material (×4000).

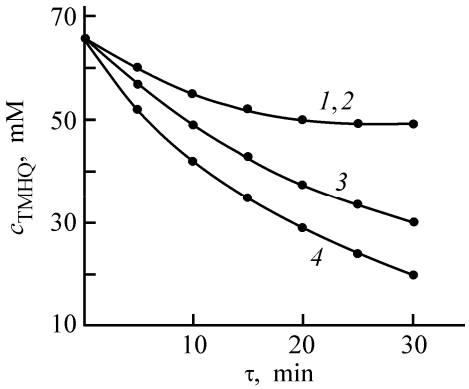

Fig. 2. Kinetic curves of oxidation of trimethylhydroquinone with atmospheric oxygen in the presence of various substances: (*1*) no substance added, (*2*) composite, (*3*) $CuCl_2$, and (*4*) $CuCl_2$ + composite. (c_{TMHQ}) Trimethylhydroquinone concentration amd (τ) time.

A study of the effect exerted by the composite on the decomposition of hydrogen peroxide showed that H_2O_2 remains stable in the presence of the composite in a wide range of substrate/C–SiO_2 ratios.

The composite material was tested in a model reaction of liquid-phase oxidation of TMHQ to trimethyl-1,4-benzoquinone. The results are shown in Fig. 2. Introduction of C–SiO_2 (sample weight 0.05–0.4 g) does not affect the course and parameters of oxidative dehydrogenation of TMHQ with atmospheric oxygen. When the reaction is performed with a catalyst, $CuCl_2 \cdot 2H_2O$, the presence of the composite leads to an increase in the TMHQ oxidation rate at the ratios of 0.15–0.2 mmol Cu^{2+}/g C–SiO_2. A previous ESR study have shown [15] that, depending on the Cu^{2+}/SiO_2 ratio, several types of Cu(II) complexes are formed in the SiO_2 phase: mononuclear complexes, Cu(II) hydroxide, and polynuclear bridged compounds. The last kind appeared to be the most reactive. Thus, the effect observed in the presence of the composite is due to complexation of Cu(II) ions with the oxide constituent of the composite, which leads to formation of the most catalytically active Cu(II) species on the surface of silicon dioxide in the examined range of Cu^{2+}/C–SiO_2 ratios.

CONCLUSIONS

(1) A granulated carbon–silica composite acting as sorbent and catalyst support was prepared by thermolysis of powdered cellulose in the presence of tetraethoxysilane.

(2) It was shown that the C–SiO_2 composite used as catalyst support in the model process of oxidative dehydrogenation of trimethylhydroquinone enhances the catalytic activity of Cu(II).

Abstract—The photolysis kinetics was studied, and methods were suggested for photostabilization of complexes of europium with β-diketones and europium cinnamates and quinaldates in polyvinyl chloride.

DOI: 10.1134/S1070427208120306

Preparation and study of the photochemical properties of polymeric materials doped with coordination compounds of rare-earth elements is a topical problem because of the possible applications of such materials in agriculture and medicine. The spectral characteristics and high quantum yields of fluorescence of lanthanide complexes allow their use as additives to polymeric materials [1, 2]. The thus obtained light-trans-forming polymeric materials enhance the photobiological conversion of solar light and raise the plant productivity [1, 3]. Therefore, of high importance are studies devited to preparation of photostable composites based on *f*-element compounds and organic luminophores showing strong luminescence in a wide spectrum range [4, 5]. Novel light-transforming polymeric materials with promising fluorescent and photochemical properties can be developed on the basis of these composites [6–8].

Polyvinyl chloride (PVC), a widely used polymer, exhibits high mechanical and radiation resistance and is transparent (90–95%) in the visible range [9]. However, PVC is extremely unstable when subjected to energetic actions, which nearly excludes its reprocessing and use without additional stabilization. This polymer contains a number of thermostabilizers and plasticizers, which break down a luminescent additive already in the course of preparation of the polymeric composite and initiate the photodecomposition of the luminescent additive. Therefore, photostabilization of luminophores based on europium complexes in polyvinyl chloride matrix is a topical problem [10].

In this study, we examined the kinetics of photodecomposition of luminescent europium compounds in PVC in the presence of a series of UV absorbents. As luminophores introduced into PVC we chose europium complexes that show the strongest luminescence: β-diketonates $Eu(\beta\text{-dik})_3 \cdot Phen$, where β-dik is an anion of acetylacetone (AA), thenoyltrifluoroacetone (TTA), or hexafluoroacetylacetone (HFAA); cinnamates $Eu(Cin)_3 \cdot L$, where L = H_2O, hexamethylphosphoramide (HMPA), 1,10-phenanthroline (Phen); quinaldates of monomolecular $[Eu(Qiun)_3 \cdot L$, where L = H_2O, Phen, benzimidazol-2-ylguanidine (BG)] and polymeric $\{[Eu(Quin)_3 \cdot H_2O]_n$, where Quin is anion of quinaldic acid$\}$.

As UV absorbents we chose quinaldic and cinnamic acids and the complex of europim chloride with 1,10-phenanthroline.

EXPERIMENTAL

The complexes were prepared as described in [11]. The luminescent compounds were introduced into an optically transparent polymer, polyvinyl chloride, which contained, along with commercial PVC proper, also thermostabilizers (Ba and Cd stearates), a plasticizer (dialkyl phthalate, DAP), lubricating additives (ESM soybean oil), and Ionol. The content of

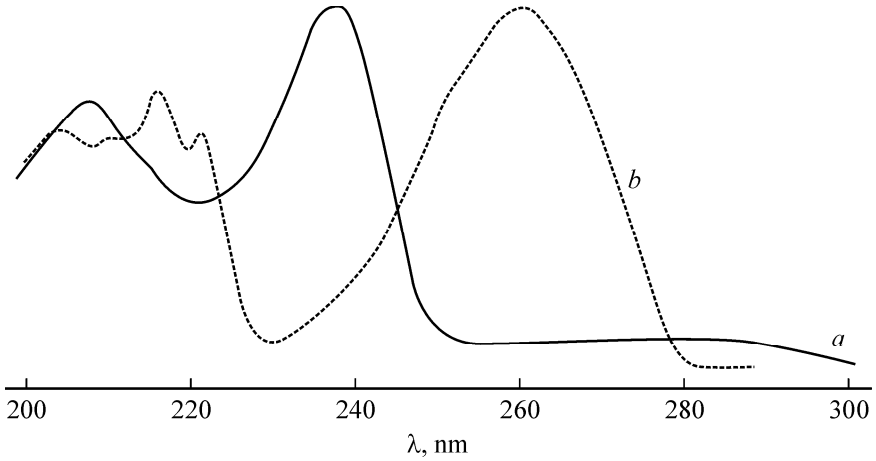

Fig. 1. Electronic absorption spectra of (*a*) quinaldic and (*b*) cinnamic acids. (λ) Wavelength.

the luminescent additive in the polymer was 0.1 wt %. The ratio of the luminophore and UV absorber in the polymer film was 1 : 1. For preparing luminescent composites, a mixture of PVC powder with the luminescent additive and UV absorber was thoroughly mixed and compacted on a hydraulic press. The electronic absorption spectra of the compounds in chloroform were recorded on an M-40 spectrometer. The luminescence spectra of polymeric compounds were recorded on an SDL-1 spectrophotometer. The polyvinyl chloride films were irradiated with the unfiltered light of a DRT-250 mercury lamp. The photodecomposition was monitored by variation of the luminescence intensity in the head line of the $^5D_0$–$^7F_2$ transition of the Eu ion with the time of the UV irradiation.

A comparative study of the absorption and luminescence spectra and photochemical properties of polymeric compounds with Eu complexes allowed us to choose the highest-intensity luminophores for further studies. Some of the examined luminophores and UV absorbers fully cease to luminesce already in the preparation step, or the intensity of their luminescence is very low. Therefore, for studying the photodegradation we chose the Eu(III) compounds that exhibited a high luminescence intensity in the polyvinyl chloride matrix.

Analysis of the spectral data shows that the composition and structure of luminescent compounds are preserved on their introduction into polyvinyl chloride. This is confirmed by the presence of a single line from the singlet $^5D_0$–$^7F_0$ transition, three Stark components assigned to the magnetic-dipole $^5D_0$–$^7F_1$ transition, and five components of the $^5D_0$–$^7F_2$ transition, as well as by only slight changes in the positions of the peak andin the distribution of the intensities of the Stark components.

Among the compounds examined, the complex of europium thenoyltrifluoroacetonate with 1,10-phenanthroline and polymeric europium quinaldate hydrate showed the strongest luminescence. Therefore, we chose these compounds for the photolysis experiments.

For photostabilization of europium complexes, we used a series of UV absorbers: cinnamic and quinaldic acids and a complex of europium chloride with 1,10-phenanthroline.

The electronic absorption spectrum of quinaldic acid is shown in Fig. 1, curve *a*. The absorption bands of the acid lie at 208–210, 240, and 282 nm. As compared to quinaldic acid, cinnamic acid shows higher extinction for some bands, i.e., it is a stronger UV absorbent (Fig. 1, curve *b*). The complex $EuCl_3 \cdot 2Phen$ has absorption bands at 220–230 and 260–270 nm.

Figure 2 illustrates the kinetics of photodecomposition of the luminescent complexes. The luminescent compounds we chose, introduced into the polyvinyl chloride film, cease to luminesce after UV irradiation for less than 1 h (Fig. 2a, curve *1*).

Introduction of quinaldic acid into the polymeric composite with $Eu(TTA)_3 \cdot Phen$ leads to a slight stabilization. The polymeric film ceases to luminesce after UV irradiation for 1.5 h (Fig. 2a, curve *2*). Cinnamic acid is a stronger UV absorbent than quinaldic acid,

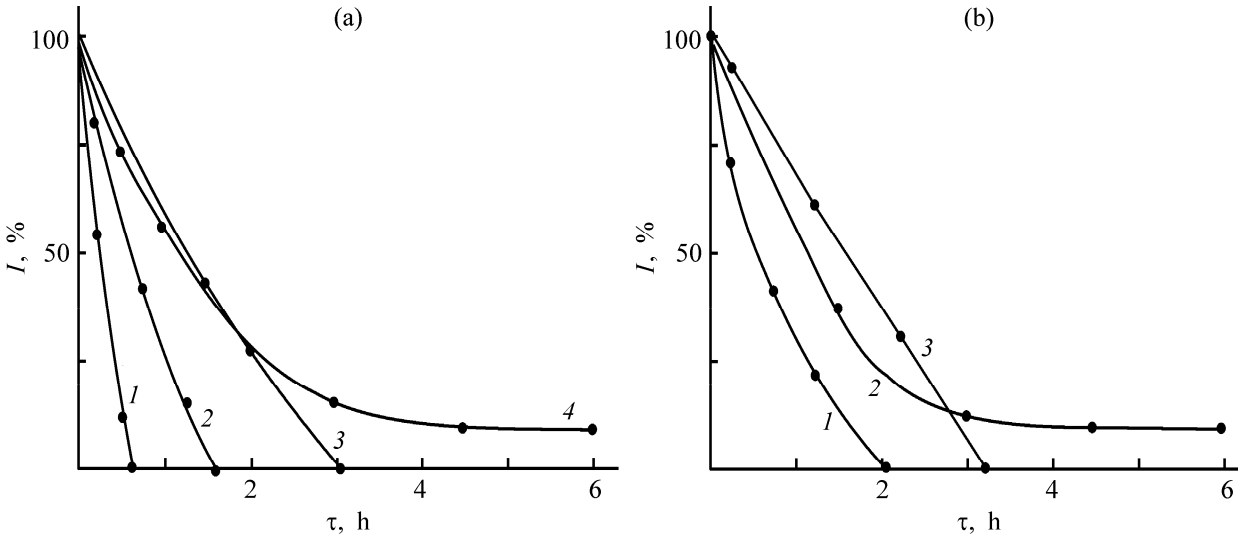

Fig. 2. Kinetic curves of photodegradation of complex compounds in the presence of UV absorbers. (*I*) Intensity and (τ) time. (a) (*1*) $Eu(TTA)_3 \cdot Phen$, (*2*) $Eu(TTA)_3 \cdot Phen + Quin$, (*3*) $Eu(TTA)_3 \cdot Phen + Cin$, and (*4*) $Eu(TTA)_3 \cdot Phen + EuCl_3 \cdot 2Phen$; (b) (*1*) $[Eu(Quin)_3 \cdot H_2O]_n$, (2) $[Eu(Quin)_3 \cdot H_2O]_n + EuCl_3 \cdot 2Phen$, and (*3*) $[Eu(Quin)_3 \cdot H_2O]_n + Cin$.

and its absorption bands cover a wider range of the spectrum. Introduction of cinnamic acid into the composites with europium thenoyltrifluoroacetonate and quinaldate hydrate leads to an increase to 3–4 h in the UV irradiation time in which the luminescence decreases to zero (Fig. 2a, curve *3*).

Figures 2a (curve *4*) and 2b (curve *2*) illustrate the kinetics of photodecomposition the complex compounds of $Eu(TTA)_3 \cdot Phen$ and $Eu(Quin)_3 \cdot H_2O$ in the presence of a UV absorbent, $EuCl_3 \cdot 2Phen$. Addition of $EuCl_3 \cdot 2Phen$ to europium β-diketonates and quinaldates results in photostabilization of the Eu^{3+} luminescence. Despite a sharp decline in the first hours, the luminescence intensity remains constant during the subsequent irradiation for a long time (>10 h).

It is well known that polyvinyl chloride degrades with the elimination of HCl molecules and formation of a polyene structure with conjugated double bonds [10]. Apparently, the release of HCl is one of the major factors leading to decomposition of both the luminophore and the UV absorbent. Hence, to provide a more efficient stabilization of the luminophore, it is necessary to choose a UV absorbent that would be more resistant to HCl, i.e., a compound inhibiting dehydrochlorination by blocking active centers of the polymer. Under certain conditions, some metal chlorides, which are usually active dehydrochlorination catalysts, inhibit the PVC degradation [10]. The presence of chloride anions in $EuCl_3 \cdot 2Phen$ as UV absorbent can make it more resistant, compared to the tested carboxylic acids (quinaldic, cinnamic), to the action of HCl released upon photoirradiation of polyvinyl chloride and can lead to stabilization of the luminophore.

CONCLUSIONS

(1) The photostabilizing effect of quinaldic acid, cinnamic acid, and complex of europium chloride with phenanthroline on the luminescence of Eu(III) in a polymeric composite was revealed. The stabilizing effect of the UV absorbents increases in the order quinaldic acid < cinnamic acid < $EuCl_3 \cdot 2Phen$.

(2) It was shown that the chlorine-containing UV absorbent $EuCl_3 \cdot 2Phen$ exerting the strongest photostabilizing effect on the examined luminophores inhibits the dehydrochlorination of polyvinyl chloride.

DOI: 10.1134/S1070427208120318

In 2002, a team of authors constituted by S.S. Naboichenko, L.P. Ni, Ya.M. Shneerson, and L.V. Chugaeva published a fundamental monograph *Avtoklavnaya gidrometallurgiya tsvetnykh metallov* (Autoclave Hydrometallurgy of Nonferrous Metals) (946 pp.), which considered physicochemical foundations of hydrometallurgical processes carried out at elevated pressures and temperatures. The authors described examples of application of autoclave processes in manufacture of alumina, nickel, cobalt, zinc, copper, noble, and rare metals and discussed the instrumentation of autoclave technologies. In contrast to the single-volume first edition, the authors considered it appropriate to present the material of the second edition of the monograph in three volumes, with account of the progress made in autoclave metallurgy in recent years.

The already published first volume comprises an introduction and eight chapters grouped in two parts. The introduction (pp. 11–32) presents biographic evidence about domestic scientists who promoted the appearance and development of autoclave technologies, from N.N. Beketov (1826–1911) to B.I. Laskorin (1915–1997). The introduction also discusses the history of implementation of the autoclave technologies abroad and in Russia.

The first part of the monograph (pp. 33–179, chapters 1–4) is devoted to specific features of equilibria in hydrothermal systems that include the gaseous, liquid, and solid phases. The first chapter (pp. 33–68) presents the general principles underlying the autoclave metallurgy and considers typical solvents used in technological processes, reaction gases, and oxidizing agents. The chapter discusses methods for preparation of raw materials for autoclave leaching, various types of processes employed in leaching of sulfide raw materials (alkaline, neutral, and sulfuric acid leaching), and effect of various factors on parameters of the autoclave leaching. A special section of the first chapter considers various physicochemical methods used to study properties of hydrothermal solutions and slurries (conductometric, potentiometric, spectrophotometric methods, autoclave differential-thermal analysis, etc.)

The second chapter of the monograph (pp. 69–118) contains information necessary for a thermodynamic description of autoclave processes and potential–pH diagrams (Pourbet diagrams) for a large number of systems that are of interest for hydrometallurgical technologies. It also discusses the effect of various factors on the solubility of difficultly soluble compounds. The small third chapter (pp. 119–135) discusses the solubility of gases in various aqueous solutions. The fourth chapter (pp. 136–179) is devoted to the solubility of metal salts at elevated temperatures and considers sulfate, ammoniacal, and alkaline systems.

The second part of the first volume of the monograph (pp. 180–373, chapters 5–8) contains information about the theory of dissolution of minerals, metals, and metal alloys under the autoclave conditions, with mostly kinetic issues considered. The fifth chapter (pp. 180–277) analyzes the available published data on the dissolution of metal chalcogenides: sulfides of copper, nickel, cobalt, zinc, lead, and molybdenum; sulfides and arsenides of rare metals; selenides and tellurides of nonferrous metals. In the sixth chapter (pp. 278–334), the authors analyze the occurrence of by-processes in autoclave oxidation of sulfide concentrates. In particular, they consider the behavior of elementary sulfur and various sulfur- and oxygen-containing ions (thiosulfate and polythionate ions), specific ki-

netic features of the oxidation of pyrrhotine concentrates, and some other issues.

The seventh (pp. 335–354) and eighth (355–370) chapters are devoted to the dissolution kinetics of metals, metal alloys, and oxide materials in various media, with the effect of various factors on the process rate considered for the most part.

Each chapter is provided with a bibliographic list, with a total of 493 references. A prominent place in the whole body of the experimental material is occupied by the results of studies carried out by the authors of the monograph. The presented material is, on the whole, rather understandable; only the third chapter somewhat falls out because of a number of inaccuracies. Chapter 2 pays a considerable attention to Pourbet diagrams, but this evidence is insufficiently used in the succeeding chapters of the first volume. The polygraphic design of the monograph is very good.

INFORMATION

Bio&Polymers—New Polymer Technologies with Water Biannual Meeting of the German Chemical Society, Macromolecular Chemistry Division

DOI: 10.1134/S107042720812032X

The conference "Bio&Polymers—New Polymer Technologies with Water" (Biannual Meeting of the German Chemical Society, Macromolecular Chemistry Division) was held in Aachen from September 28 to 30, 2008.

The conference focused on the exchange of new results on the interface of classical polymer science with biological systems and on the importance of developing new water-based technologies. This includes topics ranging from "Polymers from Biomass," "Chemical and Physicochemical Transformations in Water" to the "Development of Novel Bioinspired Macromolecular Systems and Biohybrids." With the common theme expressed by the subtitle "New Polymer Technologies with Water," the Conference spanned topics starting from application-oriented research in water-based polymers to engineering polymers from biomass, and to highly specific and novel biofunctional polymers.

The limited resources of water, energy, and materials cause a growing need for new concepts in materials science and its ecological integration. Water technology and resource management are central factors not only in environmental protection, health care, and agriculture, but also in energy production and use of biomass as a material source. Within Polymer Science, this requires an adoption of a "biological view" on polymer synthesis, application, and the fate of polymer materials after use. Here, a key to the future advancement is the ability to deal with water and to take advantage of its unique properties. Due to its dielectric properties, amphoteric nature, and capacity for hydrogen bonding, water is certainly the most powerful solvent we know. It imposes enthalpic and entropic forces on other molecules that form an essential base for the richness in structure formation found in nature and the molecular functions in living systems. Hence, very topical scientific and technological challenges open up upon mastering water-based self-organization of polymers: responsiveness, switching of water solubility for water insolubility, and hybridization of synthetic components with biological systems.

The Conference program included five plenary lections and 44 presentations divided into five sessions.

Plenary lectures covered the most topical problems discussed at the Conference. The lecture presented by Dr. Stefan Marcinowski (Germany) was entitled "Renewable Raw Materials—a Novel Approach in Polymer Chemistry." J.M. Frechet (the United States) devoted his lecture to water-compatible polymer carriers for therapeutics. B.D. Ratner (the United States) entitled his lecture "Water and Biomaterials: Hydrogels, Healing and Non-Fouling." B. Rieger (Germany) reported on carbon dioxide as a building block of novel polymer architectures. Finally, R. Melhaupt (Germany) outlined data on preparation, characterization, and applications of biofunctional materials.

Session "Bioinspired Polymers" included eleven presentations covering such topics as natural polymeric composites with mechanical function, macromolecular oxidation catalysts based on miniemulsion polymerization, synthesis of bioinspired polymers, etc.

Session "Bio-medical Polymers" included presentations entitled Functionalized Nanoparticles and Nanocapsules as Markers and Nanocarriers in Biomedical Applications, Smart Hydrogels for Biomedical Applications, Injectable Biodegradable Hydrogels for Protein and Cell Delivery, Biodegradable Polymers for Biomedical Applications, Design and Function of DNA and Protein Nanoparticles, and some others.

Within the scope of Session "Polymers from Biomass", the participants discussed topical problems of production (synthesis) of polymers from biomass, including such aspects of the problem as sustainability

assessment of polymers based on renewable resources, biomass-based polyesters and polycarbonates for coating and engineering plastic applications, vegetable oils as renewable resources in polymer science, etc.

Session "Biofunctional Polymers" covered such topics as Biocompatible and Bioactive Polymers Containing Saccharide Functionality, Design and Mechanisms of Antimicrobial Polymers, Microcapsules and Nanoparticles for Controlled Delivery and Repair, Smart Nanocarriers for Bioseparation and Responsive Drug Delivery Systems, etc.

Lectures presented at Session "Waterborne Polymers" covered such topics as Synthesis of Smart Nano-Hydrogels, pH- and Temperature-Sensitive Microgels for Stimuli Controlled Emulsion Stabilization, Industrial Application of Mini-Emulsion Polymerization in the Coating Field, etc.

The Conference also included the Poster Session at which about 40 posters were presented.

The conference participants were about 100 scientists from 11 countries including Austria, China, Finland, Germany, India, Netherlands, Poland, Russia, Sweden, Switzerland, and the United States.

Generally, the Conference has demonstrated that the biopolymer research takes a great part of polymer science today.

The next Bio&Polymers Conference will be held in 2010.

The packed columns are of wide use in the chemical and relative branches of industry. A nozzle packed in column is for enhancing the heat and mass transfer by an increase of a contact surface and by improving an agitation of flows.

Absorption, rectification, cooling (heating) with simultaneous contact of phases are the processes that occur in the largest scale in packed columns. Nowadays these processes are employed both as technological steps and increasingly more for solution of problems of environmental protection.

A volume of mass exchange equipment in the modern chemical industry is very large. This equipment is industry-leading (about 60%) in metal consumption. The nozzle apparatus size reaches quiet often significant value: up 100 meters in hight, and of several meters in diameter.

Thus enhancement of the nozzle column operation that can decrease their size, and, therefore, an equipment investment, and power inputs for overcoming hydraulic resistance, is the topical problem.

To the present day an application capacity of irregular nozzles prevails despite a growth in employing regular nozzles especially in a vacuum rectification. Therefore the enhancement problems of the columns with the irregular nozzles should be examined first of all.

We assume that several ways occur for intensifying the columns. First there are developments that are ready after some refining or ready for use. They are based on earlier conducted numerous studies, on present engineering designs, and also on an experience of the running plants relative to examination of the following effects: an increase of the operation gas flow, change in a management of the adsorption–desorption, use of combined nozzle devices, lowering the scale effect.

As should be expected designing new more effective construction of the main technological item, the nozzles, results in essential efficiency increase. Finally a trend that necessitates further examination is the effects of physical factors on the enhancement of the mass transfer.

In designing the apparatus with the nozzles in most of cases a value of the operation rate equaled to 60% of the rate at the point of flood w_f beginning is used as the maximum accessible operation rate w_p [1–5] since (1) w_p occurs in a region of a film regime where hydrodynamic and mass exchange characteristics are more steady; (2) an effect of the gas (vapor) flow to the hydraulic resistance of the nozzle layer ΔP increases significantly at the rates that exceed the rate of suspension beginning w_s; (3) it is required to avoid the device flood at the possible technologic regime failures (an unscheduled load increase).

The conditions noted above are considerable in the case of manual management but nowadays at computer-automated management when a given regime is supported steadily the process should be executed at the operation rate w_p more close to the value of w_f.

In accordance with Fig. 6 we suggest [6] to assign $w_p = w_n$, where w_n is point A that as rule is found in a range of 0.8–0.9 w_f, and the obtained favorable results are shown in the table. Here ΔP_{RM} is hydraulic resistance per a running meter of the nozzle layer; β_{lp} is volume mass transfer coefficient relative to the liquid phase; H is the height of the nozzle layer.

Evidently assuming $w_p = w_n = 0.885$ instead of $w_p = 0.6w_f$ and conserving the apparatus diameter D = const

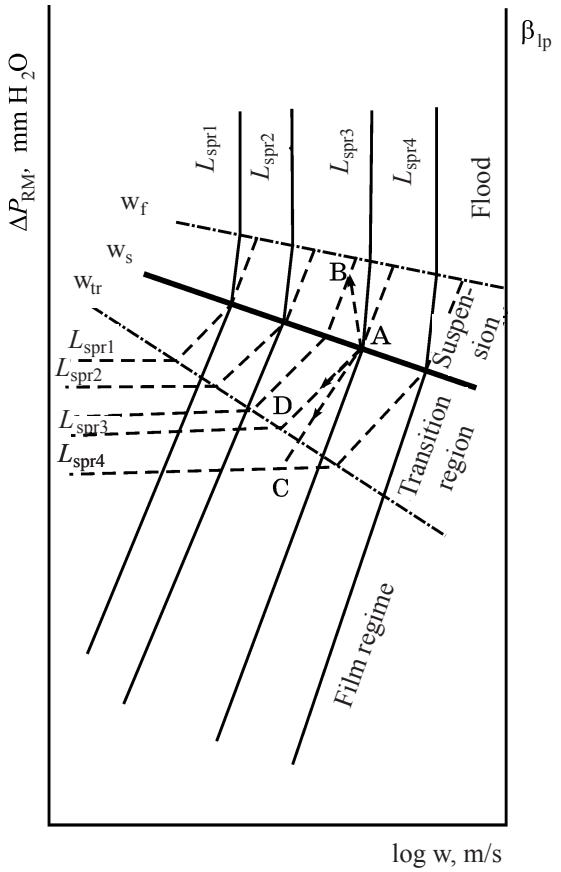

Fig. 1. Hydrodynamic and mass exchange features of a nozzle: $\Delta P_{RM} = f(w)$ and $\beta_{lp} = f(w)$.

an output can be increased to 30% and on the contrary keeping the output we can decrease the height of the nozzle layer to 24% and the diameter D to 18%.

We pictured the results of hydraulic and mass exchange studies of the nozzle characteristics on the combined diagrams (Fig. 1) that facilitated a thorough choice of the operation rate for the computation of the nozzle devices and estimation of their efficiency [7].

A significant change of the gas and liquid amount over the apparatus height caused by bleeding and feed of gas or liquid, significant temperature change, a phase transfer of the large amount of extracted components occurs sufficiently often in the nozzle columns. If in this case the apparatus diameter does not vary over the height then the noted changes on the flow amount result to increase or decrease (on the proper apparatus sections) of the gas rate and a sprinkle density. Since the apparatus diameter is computed according to the maximum loads relative to gas then lowering the rate in comparison with initial rate w_p, e.g. equaled to w_n providing the maximum value of the mass transfer coefficient β_{lp}, occurs on the sections where gas amount decreases. Also lowering the sprinkle liquid flow L_{spr} on the sections, where liquid bleeding occurs, results in increase of β_{lp}.

Therefore the column diameter should be varied over the height, if possible providing w_p = const and L_{spr} = const on the all sections of the column, to achieve maximum efficiency over the column height.

Some simplest ways of distribution of the gas and liquid flows in the apparatus of the constant and variable section are presented on Fig. 2.

According to IIa the lowering of w_p in the bottom section of the device causes a decrease of β_{lp} (in direction from A to D, Fig. 1) that leads to growth of the nozzle layer height. At the same distribution of the flows (IIb), when w_p is kept constant and L_{spr} increases in the bottom section of the apparatus, β_{lp} growths (in direction from A to B, Fig. 1). That is achieved by decrease in D at simultaneous diminishing H.

According to IIIa the lowering of L_{spr} and w_p in the top section of the apparatus (in direction from A to C) causes an essential increase of β_{lp} that leads to growth of H. A narrowing D in the top apparatus section allows supporting initial values of w_p, and L_{spr} and, therefore, the nozzle layer height.

Some technological processes necessitate presence of three or more different diameters over their height as that is presented on Fig. 2.

Evidently despite columns with different diameters over their height have more complex design their metal

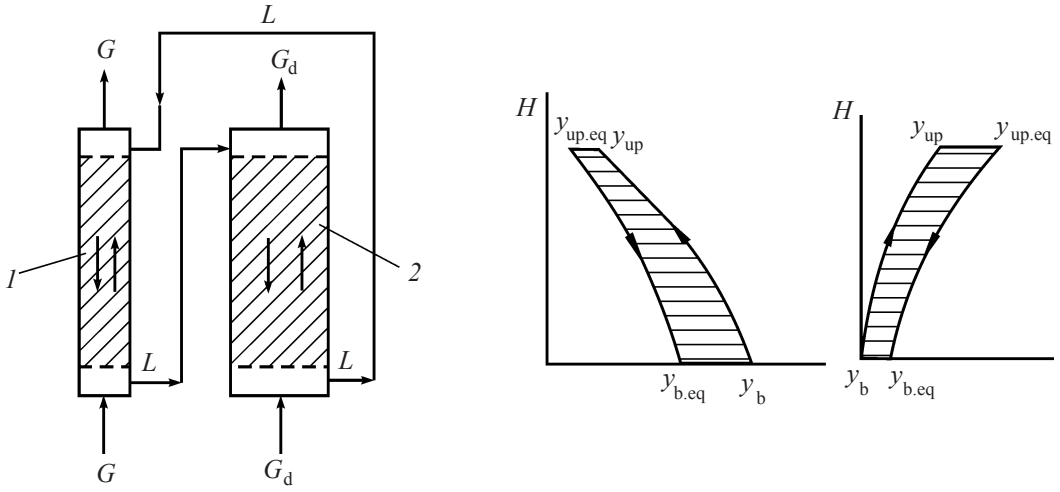

Fig. 3. Countercurrent phase movement in adsorber and in desorber: (a) scheme with countercurrent phase movement: (1) absorber, (2) desorber. G is the gas for absorption, G_d is the gas for desorption, (L) absorbent; (b) distribution of concentration over absorber height, y_{in} and y_{out} input and output concentrations of extracted component in gas, $y_{in.eq}$ and $y_{out.eq}$ input and output equilibrium concentrations. (c) the same in desorber.

consumption decreases significantly especially for adsorbers where processes are performed under high pressure. Moreover consumption of nozzles decreases.

In should be noted that the presented evident ways are already used in some industries with positive results. For example, diameter of the top section of absorber for cleaning feed gas from CO_2 in ammonia synthesis plant according to "Karsol" scheme is 2.2 m and of the bottom section, 3.4 m. And the top section of the desorber is of 4.5 m diameter, its bottom section, of 3.7 m diameter.

Placing on the different trays the nozzles of the same design but of various sizes can provide constant β_{lp} value at a single diameter of a column with variable values of flows. The small- size nozzles that are of higher efficiency should be used in the case of decrease in the gas or liquid flow.

Some advances in the efficiency of the nozzle devices can result from the combination of the nozzles of the

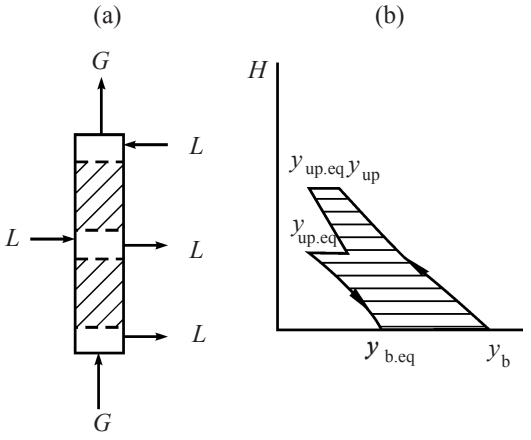

Fig. 4. Countercurrent absorber with input of live absorbent: (a) scheme of the flow movement; (b) distribution of the concentrations over absorber height.

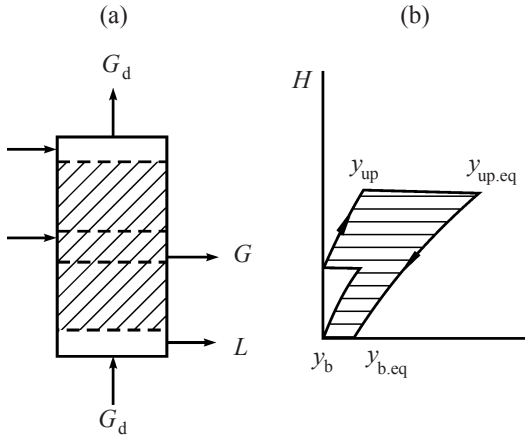

Fig. 5. Countercurrent desorber with input of live desorbent: (a) scheme of the flow movement; (b) distribution of the concentrations over absorber height.

different design. For example, an efficiency increase can be expected if the nozzle placed in the top section of the nozzle layer provides the better distribution of an inlet liquid or if a negative lengthwise mixing is lowered by a rational combination of the nozzles. In this case a target of a study is to reveal the best combination of the nozzles, a search of their optimum positional relationship, and also an optimum ratio of the layer heights made of the nozzles of different designs.

The mass transfer equation $M = \beta_{lp}\ v_{nl}\ \Delta y_{av}$, where v_{nl} is the volume of the nozzle layer reveals that an amount of a transferred substance M is defined both by value of β_{lp} and by a driving force of the process: a difference between operation and equilibrium concentration of the transferred substance (and vice versa) Δy_{av}.

Figs. 3b and 3c show the character of change of the extracted component concentration along the height nozzle layer height in the absorber and the desorber with countercurrent movement of gas and liquid according to the scheme (Fig. 3a).

Change of the concentrations over the absorber height with an additional input of a live absorbent according to the scheme (Fig. 4a) is showed on Fig. 4b.

Change of the concentrations in the desorber at an additional input of a live gas according to the scheme (Fig. 5a) is showed on Fig. 5b.

The driving force in the top section of the absorber of Fig. 4b is not practically changed in comparison with one on Fig 3b. Δy is significantly increased in the bottom section of the absorber (lower than a input point of the additional absorbent) respectively lowering a height of this section of the apparatus and the whole absorber.

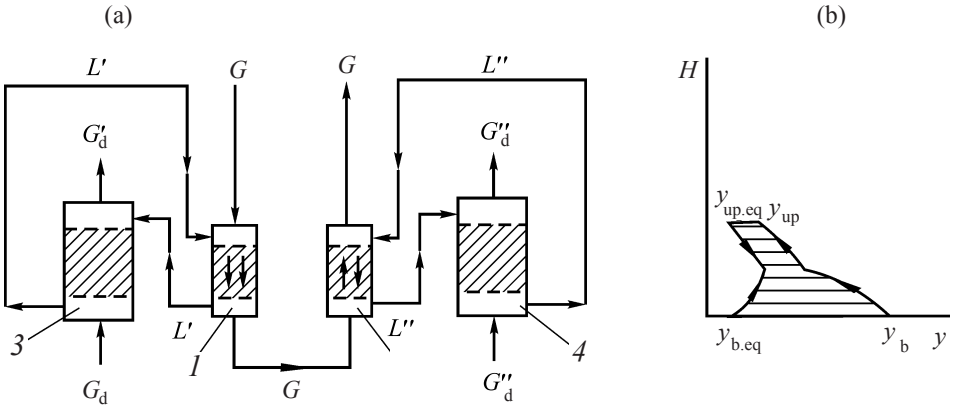

Fig. 6. Forward and countercurrent flow absorber with input of the live absorbent: (a) scheme of the absorption–desorption plant: (*1*) bottom section of absorber operating at forward flow; (*2*) upper section of absorber operating at countercurrent flow; (*3*) desorber serving to the bottom section of absorber; (*4*) desorber serving to the upper section of absorber. Ratio of the flows: $G'_d + G''_d = G$, $L' + L'' = L$. (b) Distribution of concentration over absorber height.

The additional input of the live desorbing gas in the desorber can respectively increase the driving force in its top section (Fig. 5b) and reduce the height of the whole apparatus. However an economic efficiency of such schemes where the absorbent flows and the desorbing gas are increased is doubtful though in particular cases they can be reasonable.

A number of the schemes is possible for supporting permanent values of G and L, but with a stepped input of one or another flow. An estimation of economic efficiency of the stepped inputs of gas and liquid should be carried out for each concrete case. Thereby an optimum height of the nozzle layer in a place of the additional inputs, the extracted component concentrations in the place of the inputs etc. should be determined. In this case rich facilities of the process manipulation occur for reaching the maximum performance.

Even greater lowering the apparatus size can be expected in the case of a forward movement of phases. In these apparatus operating at large gas velocities (to 10 m/s), impossible at the countercurrent movement due to the flood, the mass transfer enhances, the sizes of the devices decrease, the hydraulic resistance is significantly smaller then at the countercurrent flow [7–9]. An application of the forward flow nozzle devices is reasonable in the case when the direction of the phase movement does not significantly affect the driving force [2].

Let us consider one possible scheme of designing the forward flow in the nozzle apparatus (Fig. 6).

The forward flow occurs in the upper section of the absorber and a parallel flow of the gas and liquid phases at simultaneous feeding the live absorbent in the bottom section of apparatus takes place. However producing these two regimes of the movement in one body is difficult hence apparently both absorber and desorber should be divided in two apparatus (Fig. 6a). The height of the nozzle layer and the distribution of the concentration in the upper section of the absorber, where the countercurrent occurs, are kept approximately analogous to the picture presented on Figs. 3a and 3b. However the height of the nozzle layer on the forward flow section of the absorber decreases in comparison with the nozzle height in the same section of the absorber operating according to the schemes on Figs. 3a and 4a due to the risen driving force (let us compare Δy on the Figs. 3b, 4b, and 6b). Besides the significant increase of the value of β_{lp} in the bottom section of the apparatus that provides longer contact of each elementary volume of gas and liquid also promotes the decrease in the height of the nozzle layer. Therefore summary height of the nozzle in two absorbers (Fig. 6a) is essentially less than one in the absorber according to scheme in Fig. 3a. Also an essential decrease in the device diameter occurs in the section where the countercurrent flow takes place.

Working according this scheme the gas flow fed to each desorbers is lesser then one that feeds to desorber according to the scheme on Fig. 3a ($G'_d+G''_d = G_d$), since in both desorbers summary amount of the desorbed gas is equale to a gas amount that desorbed in one desorber in accordance with the scheme noted above. Hence supporting the permanent gas flow in the desorbers, i.e. lowering their diameter, L_{spr}, and therefore, β_{lp} increase that must result in reducing the summary height of the nozzle in two desorbers according to the scheme on Fig. 6a in comparison with the nozzle height in the desorber according to the scheme on Fig. 3a. The noted lowering of the summary nozzle height in all apparatus results in the decrease within ΔP which in certain measure

Fig. 7. Pall ring: (a) types of Pall ring: metal rings (flexiring, Koch Engineering Co.), (b) polymeric ring; (c) ceramic ring (Rschig Gmbh).

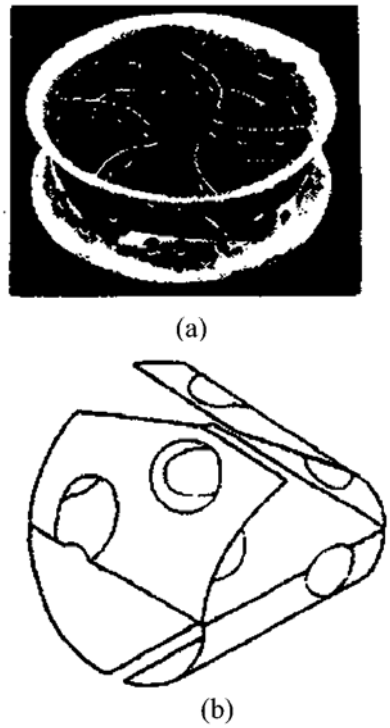

Fig. 8. Metal nozzles: (a) cascade mini-rings (Mass Transfer Inc.,), (b) semiring nozzle (GIAP-NZ) [11].

can compensate additional power consumption for the absorbent flow transfer.

We mark again that the rich facilities of the process manipulation occur for reaching the maximum performance by manipulating the values of flows, the position of the additional inputs both of the gas and of the liquid, the direction of the flow movements in apparatus, and also an engineering design of processes.

A special place in the enhancement of the nozzle apparatus efficiency must be given to development of new effective nozzles. Development of a new nozzle design with high capacity results in decrease in the diameter device, and the enhanced efficiency diminishes the height of the nozzle layer and of the whole apparatus, lower hydraulic resistance reduces the power consumption.

Some trends in the new irregular nozzle development are considered in [20, 25]. An improvement of the nozzles with the optimum shape is assumed to be the most reasonable. These are the ring and saddle nozzles [11], e.g. Pall rings, semi-ring nozzle (GIAP-NZ) (Fig. 8b), mini-ring nozzle (Fig. 8a), and saddle nozzle (Fig. 9).

Objective predicted decrease of the growth of efficiency and other parameters at the development of the new designs is noted. Consideration of the economic parameters: ease of production and low cost of mass-production is prescribed. Ways of reducing the consumption of time and resources for perfection of the new nozzle designs were considered in [21]. As first step the air blowing of single sample through an engine jet to estimate aerodynamic parameters is recommended [21]. Production of a pilot lot and its testing should begin only after required corrections of the design and reaching the optimum indices for a single nozzle constituent.

As noted above the enhancement of the mass transfer may be caused by physical factors. One of the ways, whose execution in available nozzle columns is quite possible, is producing the pressure pulsation in the gas flow that causes alternate deceleration and acceleration of the flow.

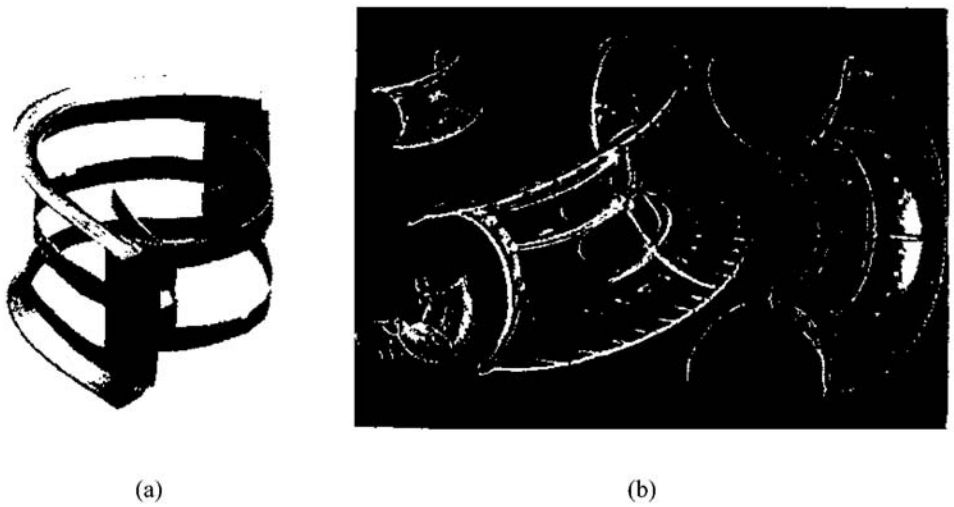

Fig. 9. Saddle nozzles: (a) metal nozzle (Norton Inc.,), (b) saddle from polymere (Flexisaddle, Koch Engineering Co.).

Effects caused by flow deceleration are analogous to an effect in a diffuser where tearing a boundary layer off a channel wall and formation of vortices occur. Under these conditions an increase in heat resistance and in the mass transfer resistance, i.e. enhancement of the heat and mass transfer, should be expected. Forming the boundary layer on the next phase occurs. However it does not finish to the point of the start of the recurring deceleration in the case of sufficiently large pulse rate. The enhanced heat and mass transfer should be expected at this stage since the boundary layer thickness is not yet large.

The longitudinal pulsation of the gas at the countercurrent two-phase movement of the flows in the nozzle apparatus must lead to an increase in the resistance to mass transfer of the boundary layer at the gas–liquid boundary. That is especially important if the processes are limited by the resistance in the gas phase. Simultaneously this pulsation must promote an additional turbulization of the liquid flowing down toward the gas over the nozzle. Thus, the physical effects of the pressure pulsation must promote the mass transfer enhancement.

The studies of the pulsation influence on the transfer efficiency mainly were conducted with respect to the heat transfer. Kosterik et al. [12] established an increase in the heat radiation coefficient of the gas α up to 50%. West et al. [13] found 60–80% increase at heating water in a pipe. Draiswamy et al. [14] established 130% increase of α at moderate value of Reynolds number (Re = 5000) and 30% increase of α at Re = 20 000.

Taking into account an analogy between heat and mass exchanges the efficiency of the mass transfer including the nozzle apparatus should be also expected as result of the pulsation. However the pressure pulsation of the flow inevitably leads to growth of the hydraulic resistance. Linke [15] examined a relation of the heat transfer growth and ΔP. He assumes that use of the pressure pulsation for enhancing the heat transfer is reasonable if a demand of device compactness prevails over one of the power consumption. However it should be taken into account that some additional power consumption is required for producing the pulsations.

A possible significant enhancement of the mass transfer in the nozzle devices, especially regarding exclusively large sizes of the absorption–desorption apparatus in some industries, necessitates an execution of a fundamental investigation on the pressure pulsation employment in mass exchange nozzle devices. Results of first such investigation reported in [22] showed, for example, that exclusively using a layer of the regular nozzle with a variable structure and geometry over a column height about 25% increase of the heat and mass exchange characteristics can be obtained. Regarding this result the studies that were performed in Moscow State University of Engineering Ecology proceed further in this direction.

Development of the new effective structured nozzles is also conducted in FGUP "Applied Chemistry" [10], and in Kazan State Energy University [26]. Sidorov et al. [24] note that a developed new nozzle in "Applied Chemistry" surpasses in the mass exchange intensity well-known nozzles of SULZER both VKH and SU.

Obviously certain effect on the mass transfer efficiency in the nozzle columns can be caused by vibration that can lead to decrease of a held liquid amount, to lowering the thickness of the gas and liquid boundary layer. The vibration like the pulsation must promote enhancement of a transversal mixing, increase in an irregular flow distribution in the transversal section of the nozzle columns and that must result in a decrease in a negative effect of the scale factor in the nozzle devices. However producing the vibration in the large dimension columns is sufficiently a difficult problem.

Other possible way of the mass transfer enhancement can be an ultrasound vibration. As in the case of the vibration the ultrasound effect is mainly studied relative to the heat transfer enhancement. Tret'yakov et al. [16] established that at heating the liquid in a pipe 30% increase of the heat radiation coefficient is defined at the one-sided effect, and 80% increase at two-sided effect of the ultrasound vibrations. Therewith the flow, physical properties of the liquid, the geometry and material of the channel, the frequency, and intensities of the vibrations produce an effect on the increase of the heat radiation coefficient α. The like results were obtained by Robinson et al. [17]. The results of an effect of the sound pulsation of ultrasonic frequency on the heat transfer under conditions of the free and forced convection were examined by Lemlich [18]. The influence of acoustic vibration in the ultrasonic range on a waste treatment was analyzed by Krivoborodova et al. [23].

Taking into account the analogy between the heat and mass transfer the positive effect of the ultrasonic vibrations also on the mass transfer in the nozzle column should be expected. Realization of the ultrasonic vibration in chemical engineering devices is possible to design. Details of such devices are discussed on [19].

We assume that the positive effect in the mass transfer also will be revealed further by other ways. Obviously that the enhancement ways of a directed movement of molecules of the extracted component both in fluid and in gas phases, and also at the phase boundary by sufficiently well examined physical phenomena, such as electromagnetic fields etc., will be found in the course of development of applied research. In the course of development of basic research, and knowledge about physical phenomena the facilities of the mass transfer enhancement will be extended.

Abstract—An algorithm for a calculation of indices at separation of suspensions with non-Newtonian properties, two-step flotation in hydrocyclone with application of a regression model was developed. An analysis of an influence of governing similarity criteria that describe the suspension separation by two-step flotation in the hydrocyclone and of rheological constants of a separated media on a distribution of a recovery efficiency of solid particles from a suspension over an operation height of a hydrocyclone was carries out.

DOI: 10.1134/S1070427208120343

An extraction of suspension particles of the smallest fraction and essential increase of the separation indices may be realized by separation of a solid phase by a pressure flotation in an area of centrifugal force of a hydrocyclone. During the pressure flotation in a regime of a film flow of the highly viscous non-Newtonian fluid in the hydrocyclone the carrying of a particle−bubble group to the film surface is the limiting stage. The two-stage pressure flotation in the hydrocyclone that enables essential intensifying the process and practically complete extraction of particles of solid fraction from the suspension applied in some cases to reduce the time of carrying the particle−bubble groups to the film surface.

Several attempts were performed for developing semiempirical and empirical relations describing some points of a device hydrodynamics in well-known studies [1] on hydrocyclones. However these relations are not used in practice due to their complexity in a definition of integral indices of separation in the hydrocyclones.

It was established in [2, 3] that an amount of collisions of particles and bubbles is increased owing to the presence of the centrifugal force area, and also a dependence of the collision number on a centrifugal acceleration was indicated.

Developed calculation methods for separation of nonhomogeneous fluid systems by the flotation in the hydrocyclones [4–6] based on a solution of a differential equation for the particle−bubble movement are not utilizable for separation at the film flow of highly viscous non-Newtonian fluid in the centrifugal force area where separation is essentially enhanced.

Nowadays wide industrial implementation of the suspen-sion separation by the pressure flotation in the centrifugal force area at the film regime of the flow is hampered by the absence of a science-based algorithm of an engineering computation of such apparatus giving good results. Thus developing this algorithm is actual and practically important task.

Tasks of separation for nonhomogeneous non-Newtonian fluid system by the two stage flotation in film flow regime in a cylindrical and cylinder-conic hydrocyclones were solved in [7, 8]. Developing the algorithm on engineering computation of the hydro-cyclones for the separation of the nonhomogeneous non-Newtonian fluid systems by the two-stage flotation may be carried out on the base of results of these studies.

The hydrocyclone (Fig. 1) includes a cylinder chamber in which suspension is fed through an inlet (*1*) fixed in the upper section, and in a conic section (an angle of the conic section α) is fed tangentially at increased pressure (until 0.8 MPa). If α = 0 the hydrocyclone is cylindrical. The fed suspension flows down over the wall forming a revolving film with peripheral V_φ, axial

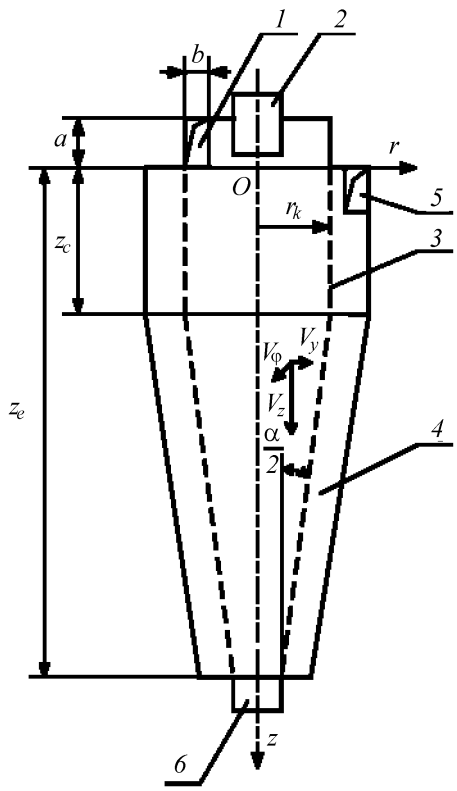

Fig. 1. Scheme of the suspension separation by the two-stage flotation in the cylinder-conic hydrocyclone: (*1*) the inlet fitting, (*2*) the upper outlet fitting, (*3*) the penetrate wall, (*4*) the manifold; (*5*) the gas feed jet, (*6*) the emptying fiitting in the bottom.

V_z, and radial V_r velocity components. An oversaturation of a solute gas and "boiling up" of the suspension are produced at decreasing the pressure to atmospheric. The particles of the solid phase move to the hydrocyclone body wall under the centrifugal force action, and the gas bubbles under the action of the buoyancy centripetal Archimedean force move towards them to the film surface. Floto groups carrying the particles of the solid phase toward the film surface in a froth layer, that is removed through the upper outlet jet (*2*) are formed on first stage of the pressure flotation at the collision of the particles of the solid phase with the gas bubbles. Besides the particles of the solid phase serve immediate centers of a formation of gas bubbles evolving at the pressure decrease that leads to essential growth of a kinetic coefficient of the pressure flotation in the first stage. The bubbles of a secondary gas input through a penetrate wall (*3*) of the hydrocyclone body from a ring manifold (*4*) to which gas is fed through the jet (*5*) with 10-fold larger diameter then the gas bubbles evolving from suspension at the pressure decrease, possess significantly larger rate of floating to the film surface than the formed particle–bubble group. In the second stage of the flotation the bubbles of the secondary gas colliding with the particle–bubble group form with them secondary group where the particle is a bridge between the bubbles [9] that quickly rush to the film surface. Since carrying the particle–bubble group to the film surface is the limiting stage [7, 8] the input of the secondary gas in the hydrocyclone through the penetrate wall leads to essential flotation enhancement. A clarified suspension is removed from the apparatus through a bottom outlet (6).

An index of quality for the separation of non-homogeneous fluid system by the two-stage flotation is a mean integral recovery efficiency of the of the solid particles S that is mean dimensionless volume part of free particles of the solid phase and the particles of the solid phase, associated in the groups in the suspension at a given film section (at $Z = const$).

With the help of the mean integral recovery efficiency of the solid particles S the effect of the governing similarity criteria and the rheological properties of the dispersion media in the efficiency of the two-stage pressure flotation in the hydrocyclone may be estimated.

The mean integral recovery efficiency of the solid particles S is calculated in accordance with equation (1):

$$S = \frac{\int_{R_K(Z)-\Delta(Z)}^{R_K(Z)} (C_p + C_{pc})\, H_p(R, Z)\, R\, dR}{C_{p0} \int_{R_K(Z)-B}^{R_K(Z)} H_{p0}(R, Z) R\, dR}.$$

Calculating according to Eq. 1 by numerical method an axial component of the velocity of the free particles and associated in group ones $H_p(R, Z)$ was assumed equaled to an axial component of the velocity of the dispersion environment $H_l(R, Z)$ since an inertia of the free particles and the particle-bubble groups in the axial direction was not taken into account [7, 8]. Relations for an approximation of the axial component of the velocity $H_l(R, Z)$ are reported in [10].

The separation by the pressure flotation in the hydrocyclone of the nonhomogeneous fluid non-Newtonian systems that can be described by an exponential equation of Ostwald-de Waele is characterized by the following governing similarity numbers [7, 8]:

$$Fr = \frac{U_0^2}{g r_k}; \quad Re_n = \frac{\rho_l r_k^n U_0^{2-n}}{k}; \quad Q_0 = \frac{a b}{\pi r_k^2};$$

$$Re_{np} = \frac{\rho_l d_p^n U_{0p}^{2-n}}{k}; \quad Re_{nc} = \frac{\rho_l d_{b1}^n U_{0c}^{2-n}}{k};$$

$$Fl_1 = \frac{A_1 c_{b1} r_k}{U_0}; \quad Fl_2 = \frac{A_2 c_{b2} r_k}{U_0}.$$

Kinetic coefficients of first and second stages of the flotation A_1 and A_2 are determined according to [7].

Let's assume that the particles of the solid phase and the bubbles of the primary phase evolved at the pressure decreasing in course of input in the hydrocyclone, and also the bubbles of the secondary gas feed through the penetrate wall of the hydrocyclone are monodisperse. If it is necessary to perform computations for the separation of polydisperse mixtures of solid particles by the two-stage flotation a given recovery efficiency S can be provided assuming a computed diameter of a solid particle equals to a particle diameter of the smallest fraction.

A distribution of the recovery efficiency of the solid particles S over the height of an operation region of the hydrocyclone at the given geometric and regime parameters of the cylinder-conic and cylindrical devices for separation of the nonhomogeneous fluid system by the two-stage flotation in the area of the centrifugal force may be simulated by an equation of regression that is written as:

$$S = \sum_{i=0}^{4} \frac{K_i + L_i[\tan(\alpha/2)]^{H_i} + M_i Fl_2^{T_i}}{Z^j}$$

$$\times Fr^{A_i} n^{B_i} Re_n^{C_i} Q_0^{D_i} Re_{np}^{E_i} Re_{nc}^{F_i} Fl_1^{G_i},$$

where $j = i$ is an exponent index of the axial coordinate Z.

Items that contain tg $2(\alpha/2)$ and Fl_2 are introduced in the regression equation additively to coefficients K_i so that errors of determination of small values of tg $(\alpha/2)$ and Fl_2 at $\alpha \to 0$ and $c_{b2} \to 0$ could not affect the accuracy of computation by the regression equation (3).

For determination of the coefficients of Eq. 3 we carried out calculation of the suspension separation by the two-stage flotation [7, 8] for the most common case in the flotation when a volume part of gas bubbles in the device is essentially higher then that of the solid particles. The calculations were conducted changing the dimensionless quantities and the rheological constants of the dispersed medium in a wide range according to a fractional factorial design [11]. Computed distribution values of the recovery efficiency S in the dependence on the coordinate Z at various values of the dimensionless quantities and the rheological constants of environment were recorded in the *SPSS* database and executing the nonlinear regression

The coefficients of the regression equation for the suspension separation by two-stage flotation in the area of the centrifugal forces into the cylinder-conic and cylindrical hydrocyclones

procedure at an iteration convergence 1×10^{-8} the coefficients of Eq. 3 were determined.

A correspondence between the values of S obtained by the simulation model [7, 8] and computed according to the regression equation (3) was evaluated with a squared correlation index $R_{squared}$ from *SPSS* [12]. Its value computed by executing a non-linear regression procedure was 0.953 and thus was evidence that the obtained regression equation described correctly the computed data. The regression coefficients of Eq. 3 are presented in the table.

At $\alpha = 0$ Eq. 3 should reduce to equation of regression for cylindrical hydrocyclone and at $Fl_2 = 0$ it should simulate single stage pressure flotation (without the secondary gas feeding). In *SPSS* instead of zero values of α and Fl_2 we have used $tg(\alpha/2) = 1 \times 10^{-7}$ and $Fl_2 = 1 \times 10^{-7}$ as no computation is possible at negative values of exponents H_i and T_i. Thus at $tg(\alpha/2) = 1 \times 10^{-7}$ in Eq. 3 we obtain the equation for simulation of the suspension separation by the two-stage pressure flotation in the cylindrical cyclone, and $Fl_2 = 1 \times 10^{-7}$ the equation for simulation of the suspension separation by the single stage pressure flotation in the cylindrical and cylinder-conic cyclones. These equations result in quiet feasible computation accuracy at given geometrical and regime parameters of the hydrocyclones.

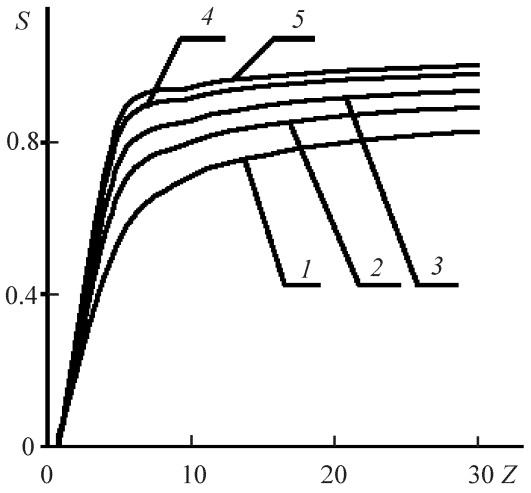

Fig. 2. A dependence of the recovery efficiency of the solid particles S by the two-stage flotation in the cylindrical hydrocyclone on Z coordinate at various values of numbers Fr; $n = 0.8$; $Re_n = 9000$; $Q = 0.12$; (*1*) $Fr = 30$, $Re_{np} = 1.27$ Ч 10^{-6}, $Re_{nc} = 7.02 \times 10^{-3}$, $Fl_1 = 1.88 \times 10^{-2}$, $Fl_2 = 1.23$; (*2*) $Fr = 50$, $Re_{np} = 4.17 \times 10^{-6}$, $Re_{nc} = 2.31 \times 10^{-2}$, $Fl_1 = 3.41 \times 10^{-2}$, $Fl_2 = 2.24$; (*3*) $Fr = 70$, $Re_{np} = 9.15 \times 10^{-6}$, $Re_{nc} = 5.07 \times 10^{-2}$, $Fl_1 = 5.05 \times 10^{-2}$, $Fl_2 = 3.32$; (*4*) $Fr = 100$, $Re_{np} = 2.10 \times 10^{-5}$, $Re_{nc} = 1.17 \times 10^{-1}$, $Fl_1 = 7.66 \times 10^{-2}$, $Fl_2 = 5.03$; (*5*) $Fr = 120$, $Re_{np} = 3.22 \times 10^{-5}$, $Re_{nc} = 1.78 \times 10^{-1}$, $Fl_1 = 9.48 \times 10^{-2}$, $Fl_2 = 6.22$.

Using MathCAD and substituting the coefficient values form the table in the non-linear regression equation (3) we performed simulation for the distribution of the recovery efficiency of the solid particles over the operating section of the hydrocyclone varying the dimensionless quantities and values of the rheological constants of a dispersed media in a wide range.

The main calculation results are shown in Figs. 2–4.

Considering a feature of the distribution of the recovery efficiency along Z coordinate two distinctive region of the curves may be notes: the region of fast growth of S where the most portion of the particles is separated and that finished at $Z = 9–12$, and the region of slow growth of S over Z. A presence of these regions is caused by the large volume part of the solid particles associated in groups that quickly floated to the film surface in the froth due to high values of peripheral component of the velocity of the dispersed media $V_{\varphi l}$. In the course of further increase of Z coordinate the volume part of the solid particles in the suspension sharply decreases as a result of removal of the particle–bubbles group in the froth, and the values of the peripheral component of the velocity $V_{\varphi l}$ decrease due to its damping towards the axial coordinate.

A length of the S fast growth region is reduced as Fr number increases from $Z = 12$ at $Fr = 30$ to $Z = 7$ at $Fr = 120$ due to the rise of the peripheral component of the velocity $V_{\varphi l}$, and the decrease in its damping aver Z coordinate [7].

Fig. 2 shows that the recovery efficiency of the solid particales S growths as Froude number increases.

An analysis of the distribution on the Fig. 2 shows that the recovery efficiency of the solid particles S grows as Froude number Fr increases because of thickening the suspension film and an increase in the peripheral velocity of the dispersed medium $V_{\varphi l}$ [7] at the rise of the radial velocity component of the solid phase, of the primary and secondary gas bubbles, and of the particle–bubble groups relative to the fluid and the their way in the radial direction at the appropriate increase in the collision number and in the kinetic coefficients of the first and second flotation stages A_1 and A_2, and groups Fl_1 and Fl_2.

A dependence of the recovery efficiency of the solid particles S by the rwo-stage flotation in the cylindrical

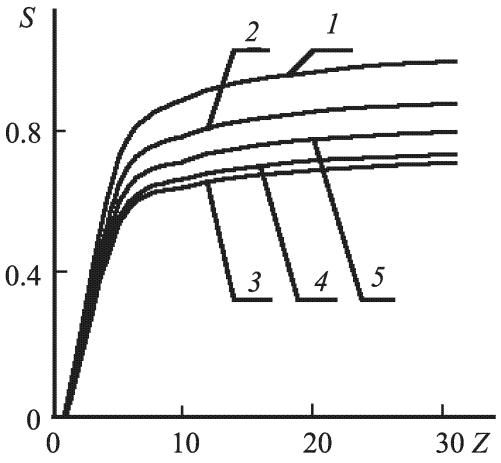

Fig. 3. A dependence of the recovery efficiency of the solid particles S by the rwo-stage flotation in the cylindrical hydrocyclone starting on the axial coordinate Z at various Re_n; n = 1.2, Fr = 200, Q = 0.04, $Re_{np} = 1.06 \times 10^{-4}$, $Re_{nc} = 5.87 \times 10^{-1}$, $Fl_1 = 1.72 \times 10^{-1}$, $Fl_2 = 1.42$; (*1*) Re_n = 500; (*2*) Re_n = 1000; (*3*) Re_n = 2000; (*4*) Re_n = 4000; (*5*) Re_n = 9000.

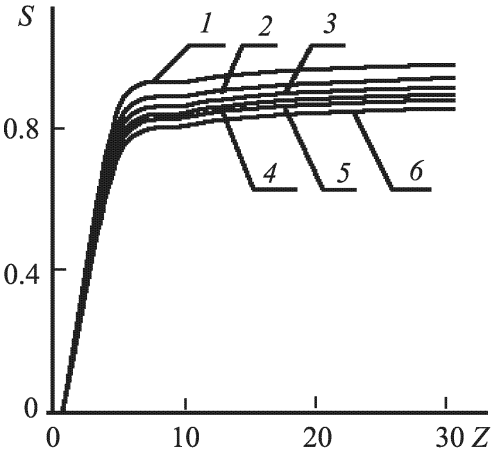

Fig. 4. The dependence of the recovery efficiency of the solid particles S by the two stage flotation in the cylindrical hydrocyclone on the axial coordinate Z at the various values of a flow dimensionless Q; n = 1, Fr = 100, Re_n = 2000, $Re_{np} = 2.10 \times 10^{-5}$, $Re_{nc} = 1.17 \times 10^{-1}$, $Fl_1 = 7.66 \times 10^{-2}$, $Fl_2 = 6.31 \times 10^{-1}$; (*1*) Q = 0.02; (*2*) Q = 0.03; (*3*) Q = 0.04; (*4*) Q = 0.05; (*5*) Q = 0.06; (*6*) Q = 0.08.

hydrocyclone starting on the axial coordinate Z at various Re_n is shown on Fig. 3.

Curves presented on Fig. 3 show that the recovery efficiency of the solid particles grows at the increase of Re_n owing to increase of the peripheral velocity component of the dispersed medium $V_{\varphi l}$ [7], rise of radial velocity component of the solid particles, of the primary and secondary gas bubbles, and the bubble–particle groups relative to the fluid and their path in the radial direction at rising collision number of the solid particles and the gas bubbles, and also of the secondary gas bubbles and the bubble–particle groups thereby the kinetic constants of the first and second flotation stages A_1 and A_2 growth and the orresponding rise in the groups Fl_1 and Fl_2.

A dependence of the recovery efficiency of the solid particles S by the two stage flotation in the cylindrical hydrocyclone on the axial coordinate Z at various values of a flow dimensionless parameter Q.

Comparing the data presented on Fig. 4 for various values of the dimensionless parameter Q we can conclude that the recovery efficiency of the solid particles S diminishes whilst the value of Q rises owing to the thickening the suspension film [7] and to the growth of the bubble–particle group path to the film surface. Hence the value of the flow dimensionless parameter Q at the hydrocyclone designing should be as small as possible small.

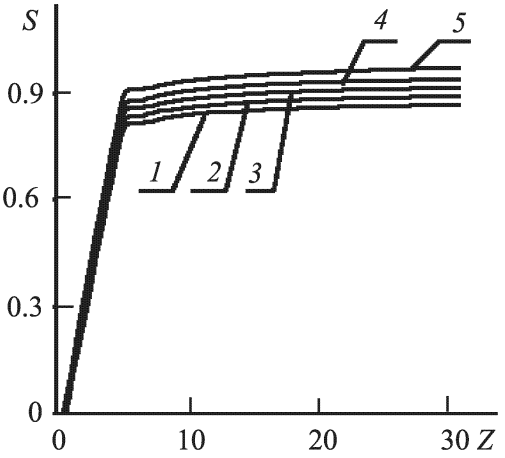

Fig. 5. Dependences of the recovery efficiency of the sold particles S by two stage flotation in the cylindrical hydrocyclone on the axial coordinate Z at the various values of a non-linearity index n; Fr = 50, Re = 4000, Q = 0.08, $Re_{np} = 4.17 \times 10^{-6}$, $Re_{nc} = 2.31 \times 10^{-2}$, $Fl_1 = 3.41 \times 10^{-2}$, $Fl_2 = 2.81 \times 10^{-1}$; (*1*) n = 0.6; (*2*) n = 0.8; (*3*) n = 1; (*4*) n = 1.2; (*5*) n = 1.3.

Fig. 5 shows dependences of the recovery efficiency of the solid particles S by two stage flotation in the cylindrical hydrocyclone on the axial coordinate Z at various values of a non-linearity index n.

Comparing the dependencies for the various value n it follows that the recovery efficiency of the solid particles S diminishes as non-Newtonian anomaly decreases (at rise of n). It is caused by damping the peripheral velocity

component of the dispersed medium $V_{\varphi l}$ towards the axial direction [7] and also by appropriate decrease in the radial velocity components of the solid particles, gas bubbles, the particle–bubble groups, and the secondary groups leading to decrease in the kinetic coefficients of the first and second flotation stages A_1 and A_2.

The obtained equation of regression well describes the computed data resulting from the simulation of the two-stage flotation in the wide range of values of the governing dimensionless criteria and the rheologic properties of dispersed medium, and also with its help constructional and regime parameters of hydrocyclones at a developing stage can be computed.

$$U_{0c} = \left\{ \frac{1}{18} d_{b1}^{n-2} d_p^3 \left[\rho_l \left(1 + \left(\frac{d_{b1}}{d_p} \right)^3 \right) - \rho_p \right] \frac{U_0^2}{f(n) r_k k} \right\}^{\frac{1}{n}}$$

$\times \Phi(c_{c0})$ is coefficient that used to determine high-density movement of the solid particles computed according to equation of Prof. V.I. Sokolov;

$F(c_{p0}) = 10^{-1.82 c_{p0}}$ is coefficient that used to determine non-Newtonian properties of the dispersed medium [10];

$$f(n) = 3^{1.5(n-1)} \frac{2 + 29\ n - 22 n^2}{n(n+2)(2n+1)}$$

is a function describing a cross braking of the groups at their co-floating to the film surface computed according to Brunner equation;

Q is the suspension flow in the hydrocyclone inlet, m^3/s;

U_0 is the average speed in the hydrocyclone inlet, m/s;

V_{zl} is the axial velocity component of the dispersed medium, m/s;

V_{zl0} is the axial velocity component of the dispersed medium in the initial film section, m/s;

$V_{\varphi l}$ is the peripheral velocity component of the dispersed medium, m/s;

V_{zp} is the axial velocity component of the solid particle, m/s;

r, z is the radial and axial coordinates, m;

r_k is radius of the cylindrical hydrocyclone body, m;

ρ_p is density of the solid particles, kg/m^3;

ρ_l is density of the dispersed medium, kg/m^3;

a, b is the height and wide of the hydrocyclone inlet, m;

d_p is the particle diameter of the solid phase, m;

d_{b1} is diameter of the primary gas bubble escaped in the suspension at the pressure decrease, m;

d_{b2} – is diameter of the secondary gas bubble feed through the penetrate porous wall of the hydrocyclone body, m;

$\delta(z)$ is thickness of the suspension film, m;

z_c is cylindrical body height of the hydrocyclone, m;

α is angle of the conic section of the hydrocyclone body, deg;

c_{pc} is volume fraction of the solid particles bonded in groups, m^3/m^3;

c_p is volume fraction of the free particles of the solid phase, m^3/ m^3;

c_{p0} is volume fraction of the free particles of the solid phase in the hydrocyclone inlet, m^3/ m^3;

c_{b1} is volume fraction of the primary gas bubbles escaped in the suspension at the pressure decrease, m^3/ m^3;

c_{b2} is volume fraction of the secondary gas bubbles feed through the penetrate porous wall of the hydrocyclone body, m^3/ m^3;

c_{p0} is volume fraction of the particles of the solid phase in the hydrocyclone inlet, m^3/ m^3;

indeces: p is solid phase; c is particle–bubble group; b is gas bubbles; l dispersed medium.

MODELING AND CALCULATION OF TECHNOLOGICAL PROCESSES

Mathematical Simulation of the Evaporation in Operation Area of a Bubble Evaporator

Z. D. Reipnazarova and A. A. Artikov

Tashkent Chemical Engineering Institute, Tashkent, Uzbekistan

Received August 15, 2008

Abstract—Simulation of evaporation in operation area of an evaporator is considered. We obtained a formalized model of this process and optimum conditions of an engineering system on the basis on the analysis.

DOI: 10.1134/S1070427208120355

Evaporation is a process in chemical engineering when concentration of process liquor increases due to evaporation of a part of a solvent.

There are surface evaporators where the heat transfers from a heat-carrier to the solution through a wall, and contact evaporators where the heat-carrier simultaneously touches the solution [1].

The contact evaporators have wide application especially due to an enhancement of a chemical fertilizers industry. A large surface of interaction between gas (heat-carrier) and liquid (solution) phases is obtained in these devices. Evaporation of solutions in them occurs without heating spirals. Thus reliability of evaporation plants rose along with their design and work simplification.

In this paper we simulate an active plant on evaporation of a pulp for computation of the optimum conditions of their operation.

In our plant suspensions are evaporated in an operation area of a bubble evaporator (BE).

We consider the operation area of the evaporator as a large system that first is divided into two subsystems: a liquid phase, and a gas phase. Besides we assume that a hydrodynamic structure of the fluid flows is as ideal mixture and then the liquid phase is a continuum where evaporation occurs (Fig. 1).

Water vapor removes from the liquid phase and transfer in a vapor phase. The gas phase is of discrete form, i.e. the gas leaving a bubbler or an exhaust into upper section of liquid, and dividing into small bubbles go up one by one.

Mainly in this case the gas phase is described by the laws of displacement of an ideal gas [3]. Generalizing a mathematical model the liquid phase can be simulated by a differential equation of the first order, and gas phase by a partial differential equation.

In this case for the liquid phase we use the heat-balance equation at non-steady state. Then a heat change of some elementary *i*th area of the liquid phase depends on a heat leaving this area of the liquid, and besides a heat of the gas

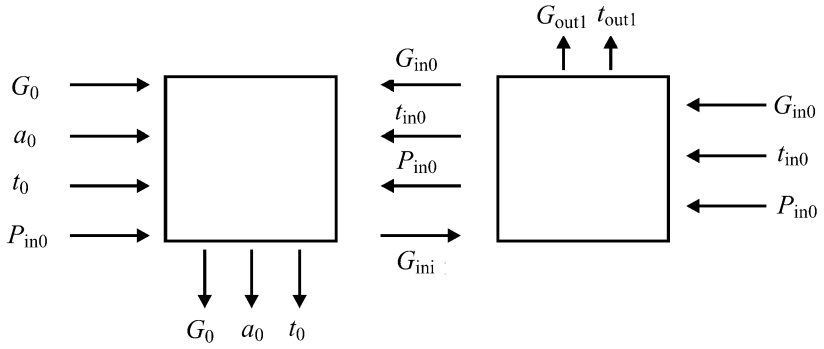

Fig. 1. Block-scheme of the evaporating process into the operation area.

phase influences this liquid. The heat-balance equation [4] for the liquid phase can be written as:

$$\frac{dQ_1}{d\tau} = q_{\text{in1}} - q_{\text{out1}} + \Delta q_i \ , \quad (1)$$

where q_{in} is heat input to the liquid; q_{out} is heat leaving the liquid; Δq_i is heat of the water vapor form.

The heat input in the elementary ith area of the liquid phase is computed by the following equation:

$$q_{\text{in1}} = G_{l0}\, c_{l0}\, t_{l0}\,, \quad (2)$$

where G_l is heat consumption by the liquid, kg/s; c_l is heat capacity of the liquid, kJ kg^{-1} K^{-1}; c_l is liquid temperature, °C.

The heat leaving the area is computed by Eq. 3.

$$q_{\text{out1}} = G_l\, c_l\, t_l\,. \quad (3)$$

An output of the water vapor can be computed by Eq. 4:

$$Q_{\text{in1}} = \Delta G_2\, I, \quad (4)$$

where I is standard enthalpy of the water vapor, kJ/kg;

As the heat is transferred by means of the gas we use a volume heat-transfer coefficient then an equation for calculation of the heat transferred by the gas phase looks as

$$\Delta q_{2i} = K \Delta V_m\, (t - t_1)\,, \quad (5)$$

where K is heat-transfer coefficient.

The heat input by the water vapor and earlier evaporated in a previous elementary area is described by equation (6).

$$\Delta q_1 = \left(\frac{1}{a_1 - 2} - \frac{1}{a_i - 1} \right) G_0\, a_0\,. \quad (6)$$

Taking into account the equation of the heat balance for the gas phase (7)

$$\frac{dQ_2}{d\tau} = q_{\text{in2}} - q_{\text{out2}} - \Delta q_i\,, \quad (7)$$

where q_{in2} is heat of the input gas and air; q_{out2} is heat of the gas removed from a furnace; Δq_i is heat that was formed in the furnace as a result of methane oxidation in the oxygen environmental, we can compute the heat input by the gas with the help of equation (8)

$$q_{\text{in2}} = G_{20}\, c_{20} t_{20}\,. \quad (8)$$

The heat removed form this elementary area can be expressed by the following equiation

$$q_{\text{out}} = G_2\ \ c_2\ t_2\,, \quad (9)$$

where G_{20}, G_2 are heat consumption of the gas and air, kg/s; c_{20}, c_2 are heat capacity of the gas and air, respectively, kJ/ kg^{-1} K^{-1}; t_{20}, t_2 are temperature of the gas and air, respectively, °C.

Thus we determine main items of the heat balance both for the liquid phase and for the vapor phase.

Assuming that at evaporation of non-volatile liquids the flow is permanent we write an equation of the mass balance

$$a_0 \cdot G_0 = a_1 \cdot G_1, \quad (10)$$

or the liquid flow in the elementary area

$$G_1 = \left(\frac{a_0}{a_1} \right) G_{10}\,. \quad (11)$$

Then an amount of the water transformed to the vapor is computed by equation (12):

$$\Delta G_i = G_{10} - G_1 = \left(\frac{1}{a_i - 1} - \frac{1}{a_i} \right) G_{10}\, a_0\,. \quad (12)$$

Boiling point is an important characteristics at the solution evaporation. In most cases accessible range of the temperature change in an ammophos industry is considered relative to an ammophos pulp. The boiling point in this case can be described by the following linear equation:

$$t = b_0 + K_{\text{t}}\, a. \quad (13)$$

Then we calculate the liquid heat in the elementary area by equation (14)

$$Q = m\, c_1\, t_1. \quad (14)$$

However the liquid weight depends on the volume and density of the liquid:

$$m = V_{\text{m}}\, S_{\text{m}}\,, \quad (15)$$

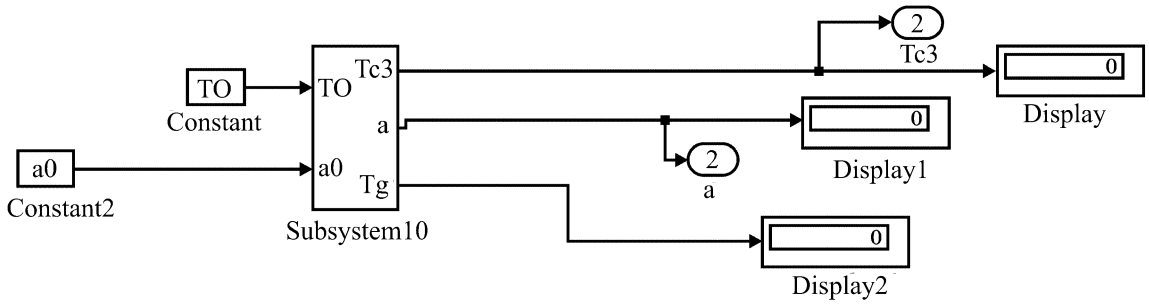

Fig. 2. One-step elementary area of the computer model for BE at ideal mixture of the flows in the liquid phase and gas displacement according to the law for ideal gas in the vapor phase.

where V_m and S_m are volume and density of the liquid, respectively.

Earlier it was established for the bubble evaporator that in the case of good operation of the bubble plant the vapor volume occupied two thirds of the device volume and the liquid phase, one third, therefore we can write equation (16)

$$V_l = \frac{1}{3} V_{ap}, \quad (16)$$

and taking into account equations (15) we can compute the heat of the liquid phase for the elementary area

$$Q = \frac{1}{3} V_{am} S_m t_1, \quad (17)$$

Substituting Eq. 13 we obtain equation (18)

$$Q = \frac{1}{3} V S_m t_1 = \frac{1}{3} V S_m (b_0 + K_t a), \quad (18)$$

and after differentiation of the heat of the elementary area we have equation (19) that described change in the concentration with respect to time.

$$\frac{dQ}{d\tau} = \frac{1}{3} V S_m K_0 \frac{d_a}{d\tau}, \quad (19)$$

Using Eq. (11) we can compute the heat removed from the elementary area

$$q_{out1} = \frac{a_0}{a_1} G_{10} c_1 t_1. \quad (20)$$

After some conversion we obtain a set of equations that characterized dynamics of processes in the liquid phase.

$$\frac{da_i}{d\tau} = \frac{3}{VpK_t}\left[G_0 c_{i-1} t_{i-1} - \frac{a_0}{a_i}\right] G_{10} c_i t_i - \left(\frac{a_0}{a_i - 1} - \frac{a_0}{a_i}\right) G_{10} I + \left(\frac{1}{a_i - 2} - \frac{1}{a_i - 1}\right) G_0 a_0 I_i + KV(t_{2i-2} - t_{i-1}), \quad (21)$$

$$t_i = (G_0 + K_t c_i), \quad (21.1)$$

$$I = (I_0 + K_i (t_2 - t_{20})), \quad (21.2)$$

$$c_1 = (c_{10} + Kc_1 (t_1 - t_{10})), \quad (21.3)$$

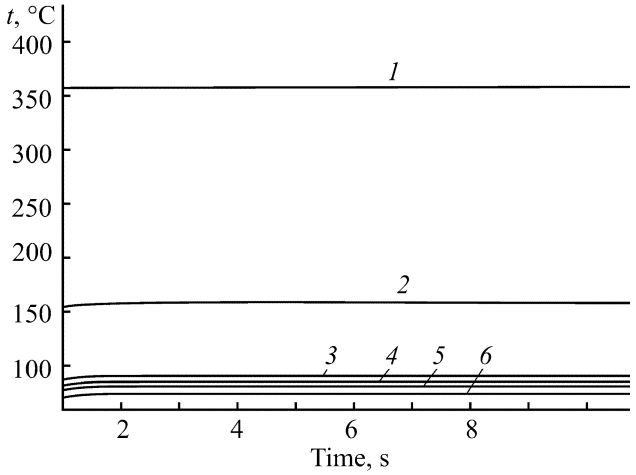

Fig. 3. Distribution of the gas temperature on liquid quasilayers in the apparatus.

where Eq. 21.1 describes the change of the concentration, Eq. 21.1 the liquid temperature in the elementary area, Eq. 21.3 the heat of vapor.

Then we developed a block-scheme for simulation of the process in the operation area on the basis of the set of equations using principles presented in [5] (Fig. 2).

Computation results on the basis of an actual plant data are presented in the table.

Numerical experiments were carried out for the initial data (no. 4): $G_1 = 8.33$ kg/s (pulp), $G_{2t} = 9.94$ kg/s (hot gas); temperature of the input pulp $t = 100°C$; initial concentration of the pulp $a_0 = 0.35$ %; the furnace temperature $t = 500°C$, heat transfer coefficient $\alpha = 9$ kJ/m^{-3} deg^{-1}. The results that depict the temperature distribution of the gas mixture along the liquid layers in the evaporator are shown in Fig. 3.

The presented mathematical model of the pulp evaporation can be used for optimum designing of new devices and for the control of this process on the actual plants.

Abstract—In the recent years owing to growing necessity of raw material and energy economy and solution of ecological problems, a significant interest by the chemistry thechnologists is paid to the microsystem technology. One of directions in the development of microsystem technology is creation and application of microstructural reactors (microreactors). Currently world market proposes many samples of microstructural installations and even full-value chemical units for, in part, of organic synthesis. In Russia the microsystem technology is included to the list of priority directions of development of science and technology in 2001–2010 years.

DOI: 10.1134/S1070427208120367

The life whole sense consists in the infinite conquest of unknown, in the everlasting effort to get know more.

Emile Zola

INTRODUCTION

Microtechnology is developed in many branches of science and technology. In the recent decade have been created the microstructural units providing more effective conducting of chemical and biochemical reactions. Their performance is demonstrated in many publications [1, 2, 3–8].

An original patent has been issued in the former DDR in 1986 that protected the main principles of construction of microstructural systems and properties that they should possess for their optimal application [9]. To 1989 in the research institute Forschungszentrum Karlsruhe (Germany) has been constructed the first micro heat exchanging unity [10]. Since 1993 began analogous development in the Pacific Northwest National Laboratory (PNNL), USA [11].

In 1995, the application of microsystems for chemical and biochemical reactions has been discussed at the symposium in Mainz (Germany), that started development of microreaction technology for over the world [12]. In 1997 was arranged the first conference on microtechnology (International Conference on Micro-reaction Technology, IMRET-1), that since that time is held yearly in Europe and USA alternatively. To the year 2001 in cooperation with DECHEMA has been created industrial platform for the modeling the systems of microchemical technology (MicroChemTec) aimed at the industrial manufacturing and application of the microsystems [13].

Today the world market proposes a wide choice of microstructural units and even complete chemical installations (in part, for organic synthesis) [14]. Many companies, e.g., Ehrfeld Mikrotechnik BTS GmbH, Syrris Ltd., Micronit Microfluidics BV and others produce such units. Many research institutions and universities carry out research in this area, arrange scientific conferences and publish books and articles. In part, a great attention to the microsystem technology is paid in the Institute of Technical Chemistry of Drezden Technical University. Investigations were carried out on the enhancing efficiency of liquid phase catalytic process of phenylacetonitrile alkylation under phase transfer conditions [15, 16], and study in the area of bioreactions in the microstructural reactors [17]. In the Institute have been arranged scientific educational courses on microreactor technology in June 2006 and May 2007

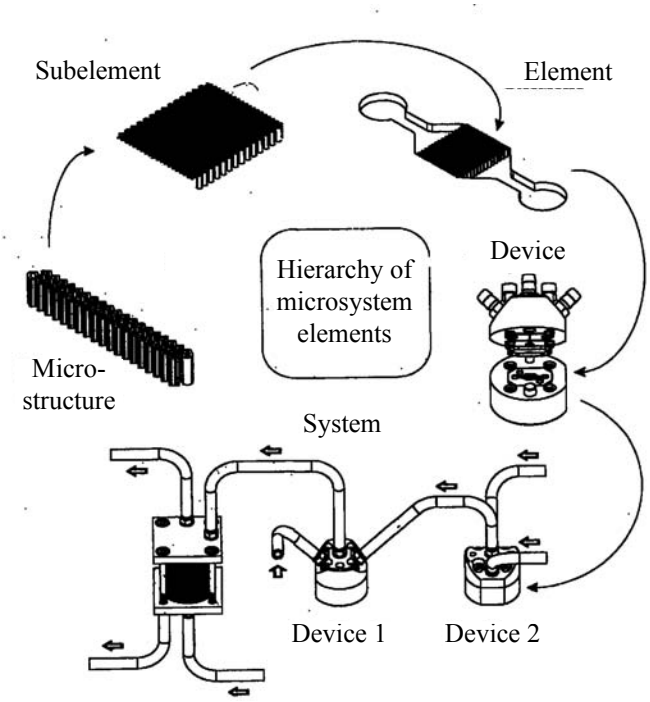

Fig. 1. Hierarchy of the elements of microsystem units on the example of micromixers [2].

(GDCh-Fortbildungskurs "Praeparative Chemie in Mikroreaktoren").

It is obvious that due to advantage of microstructural reactors in the respects of saving space, energy and material resources they will be more and more applied both for pilot installations and in general technology, under the slogan: "The reactor is as small as necessary" [1].

1. MICROSTRUCTURAL REACTORS: TERMINOLOGY

In correspondence with the widely used term "Microsystems," the term "microstructural reactor" is used for denoting a miniature system for carrying out chemical reactions, that are constructed with at lest partial application of the methods of microtechnology. The term "microstructural reactor" can be reduced to "microreactor" taking in mind that it is assumed a special microtechnology that is applied at their producing, rather than laboratory analogs of industrial reactors. The typical size of internal channels in the microstructural reactors fall to the range from microns to millimeters (Table 1). Sometimes one can meet terms "nanoreactor" or "milli/mini-reactor". These terms denotes the units with the size respectively below or higher than the above range [2].

2. STRUCTURAL HIERARCHY OF MICROREACTORS

Commonly the microreactors are produced in correspondence with the hierarchy principle, that is, they are assembled from a set of elements that includes in turn sub-elements and so on. Such approach is based on the so-called "concept of sequence" [19]. The aim of this concept is definition of various elements allowing modular producing a microsystem unit and selecting those the most often used in the installations [2].

A most miniature systems for the realization of flows, the so-called "microstructure" consist of a number of channels (Fig.1), which have the flow inlet and outlet. Single channel or a set of such channels that form a complete object is denoted as "sub-element." In some cases a sub-element can contain additional microstructures, e.g., pores [2].

A set of sub-elements combined with joined channels constructed of the same material form an "element". For increasing their input-output characteristics, the elements can be joined to form a row, e.g., a row of catalytic plates in the chamber of a gas-phase microreactor. Alternatively, identical units can be parallely connected on a plate.

Units and chambers can not work separately, that is means that they are not a microreactor till they have no body or at least upper and down plates used for the transfer of a flow to the additional units. An element becomes a unit when it is plased into a body or between two panels. A complicated system can be constructed by means of integration of severalunits in one body.

3. FUNCTIONAL CLASSIFICATION OF MICROREACTORS

By the purpose of application the microreactors can be classified as follows:

Analytical units and equipment for research

Table 1. Comparison in size of internal channels of macro-, micro-, and nano-units [2,18]

Parameter	Macro	Micro	Nano
Size range	$(1\ldots10^{-3})$ m	$(10^{-3}\ldots10^{-6})$ m	$(10^{-6}\ldots10^{-9})$ m
Measuring unit	1 mm	1 μ	1 nm
Surface area to volume ratio	100–1000 m^2/m^3	10000–50000 m^2/m^3	~100000 m^2/m^3

Some of microreactors are used presumably for analytical purposes, in biochemistry in particular, other have found application in chemical technology, although these areas obviously are very different. In view of construction of analytical and technological equipment, some of microreactors can be used in both these areas.

By the type of the processes in a microreactor they can be classified as:

Units for catalytic and non-catalytic reactions

Depending on the presence or absence of a catalyst and on the type of catalyst the microreactor construction can differ. In some systems the catalyst covers the microchannel wall, in others is applied as a powder, or can be absent at all.

Units for homogenous and heterogenous processes

Some of microreactors are specialized for homogenous, or heterogenous processes. In the first ones it is sufficient to provide well mixing of the components; the second ones should provide necessary interphase surface area.

Units for certain system types, e.g., gas–liquid,liquid–liquid, gas–gas, photochemical reactions, etc.

To provide maximal process intensification, a reactor can be developed for a certain type of the system.

Many units with micro channels have been developed in the end of 80-th for the research purposes. When one unit provided conducting several types of processes, e.g., filtration, mixing, separation and analysis in the same unit, such a system commonly had been assigned to general microanalytical type (mTAS) [20].

By analogy with technological processes, the microreactors can be classified by the type of their action, that is, a reactor can be of continuous or periodical operating. Most of used microreactors are of continuous operating.

4. DIFFERENCE BETWEEN ANALYTICAL AND REACTION SYSTEMS

Analytical systems are commonly designated for the information acquisition and estimation, e.g., analysis of water samples from a lake. Reaction systems differ from the analytical ones in that they designated for producing or processing materials or substances. For microsystems this difference vanishes because diminishing in the unit size leads to decrease in the amount of processed matter to the level of analytical systems. Such a mycrosystem can be used for fine organic synthesis and for the initial step of developing a process. In both the cases measuring technique should be applied for finding optimal parameters of the process and for testing quality of the obtainedtt product. Such measuring units are similar to analytical ones. However, they differ by the purpose of using the obtained information. In the analysis, the information obtained is the final product, e.g., determination of the ozone concentration in a certain layer of atmosphere is an important information for ecological studies. In distinct, the information obtained in the microreaction systems is used for the optimization of both laboratory synthesis and large scale complicated process. There is a significant difference between miniature analytical systems and microreactors [2].

5. PRINCIPAL ADVANTAGE OF MICROREACTORS

Despite small size of microreactors, their internal volume is too large to provide interaction of reagents on the molecular level. The main advantage of microreactors is improving the regime of flow and providing intensification of mass and heat transfer. Basically, the contribution of microreactors concerns the microscale section of chemical engineering rather than chemical aspect of reactions, reaction mechanism and kinetics.

5.1. *Diminishing of Linear Size*

Diminishing of linear size of a closed system increases respective gradient of a given parameter of process. This concerns such parameters as pressure, temperature and concentration that are the most important for conducting a process in the reactor and for data acquisition and treatment. Due to diminished linear size of the system, the moving force of mass and heat transfer or of diffusion flow per volume of surface unit increases when microreactors are applied.

These simple theoretical assumptions are confirmed by investigations in the area of mass and heat transfer. Most modern microreactors contain microchannels whose width falls to the range 50–500 μm and the wall thickness between the channel of reaction and channel of heat transfer can be diminished to the size in the range 20–50 μm which leads to increase in the heat transfer coefficient to 25000 W m^{-2}. Such value of this coefficient in the micro units at least by one order of magnitude larger than the value for commonly used heat exchange units [3]. In micromixers, the thickness of liquid layer can be diminished to the value of several tens microns and in

some cases to nanometers. As a result, the time of mixing in the micromixers falls to milliseconds and in some cases to nanoseconds [4], which is hardly available in the apparatus with stirrer or other traditional mixing units.

5.2. *Increase in the Surface–Volume Ratio*

Due to diminished linear size of microchannels the surface to volume ratio increases noticeably. As shown in Table 1, specific surface of the micrireactor channels is 50 times over than those of standard units. Besides the above mentioned advantage in heat transfer, increase in the surface area of apparatus can be used for intensification of processes, e.g., in catalytic gas phase reactors, where internal surface of the apparatus is covered by active substance.

Similar advantage of microreactors occurs in the case of multiphase processes when thickness of at least one of liquid phase layers has size of nanometers. Both theoretical and experimental investigations have confirmed that interphase surface in the microreactors are in the range 5000–30000 m^2/m^3. To the moment the best achieved interphase surface in the down draining film microreactors is 25000 m^2/m^3 [5]. For standard bubbling columns this value is below 100 m^2/m^3. In some cases, e.g., for ring regime of (two-phase) flow in microbubbling column the specific surface area can achieve approximately the same value as the surface in microchannels [6].

Due to decrease in the linear size the microreactor volume diminishes to several microliters. This difference as compared with common industrial units becomes ever more emphasized when together with diminishing in the reactor size the industrial process that includes stirring is replaced by continuous process in microreactor. In te case of organometallic reactions a receiver 6000 liters volume can be replaced by five miniature mixers several milliliters volume each [7]. Diminished volume provides the process safety and due to diminished duration of residence increases the process selectivity.

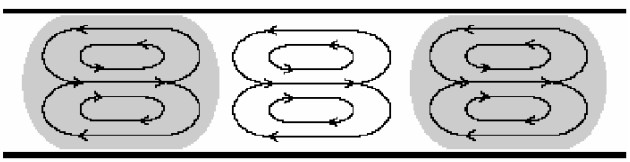

Fig. 2. Additional circular motion in a microchannel.

5.3. *Flow Regimes in Microchannels*

Another advantage of microreactors is a specific hydrodynamics of flow, which is a significant feature of microliquids. The flow is commonly laminar, directed and very symmetrical [8]. In addition, multiphase flows often demonstrate good phase separation [21]. This is connected with the formation of so-called Tailor flow ("slug-flow") in the microchannels. In this case occurs secondary circulation inside the liquid drops due to friction between the segmented liquid and microchannel wall (Fig. 2).

5.4. *Multiple Increase in the Number of Elements*

A typical feature of microstructural units is multiple repeating of basic elements (Fig. 3). They can work consecutively, as is common for the units of preliminary sampling, or being connected in parallel, with common feeding pipe, that is applied for the purposes of manufacturing [2].

In the recent time significantly extended application of combinatory strategy, beginning from the producing of drugs [22] and ending by preliminary sampling of inorganic materials, catalysts and polymers [23]. To the moment have been tested many inorganic materials and some of catalyst for their application in the microreactors [24]. For this purpose, separate sections of a microchannel were covered by a thin layer of corresponding substance using a technology of thin film covering. The investigations were carried out on the examples of standard processes with the purpose of choice of local concentration profile and therefore of given properties of materials.

However, such direct approach is restricted, especially in respect of development of new catalysts and polymers. A necessity of maintaining porosity in the first case and long reaction duration in the second are the main reasons for application standard tubular type continuously operating reactors [25].

5.5. *Versatility of Manufacturing*

In distinct to the classical industrial installations, increase in productivity of microreactors is achieved by increase in the number of units rather then in size [19]. Functional units in a microsystem, e.g., mixers, are duplicated several times. Connection of such units is achieved by using channels and sections with equal flow distribution. Increase in the number of units in a great extent provides retaining the same desired characteristics

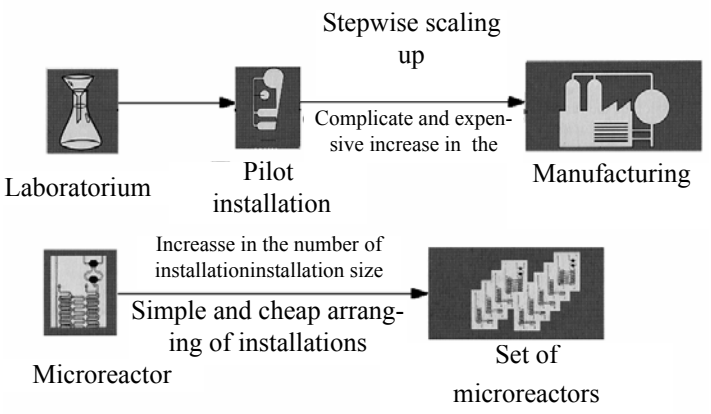

Fig. 3. A simplified scheme reflecting the principles of stepwise scaling up an industrial installation and increasing in the number of microreactors [2].

of main unit at the increase in the whole system volume [19]. In the ideal case the measuring units used in some steps of development of the process remain similar and consist of identical components. The results of application of such units have been demonstrated by comparison of efficiency of mixing in the system consisting of 10 mixers with that in one unit [26]. It should be noted also that uniformity of flow distribution is important for the productivity of general type reactors. In addition, application of great number of units allows easily change the amount of product if there is a possibility to switch on or off some units in the whole set. Such sectional projecting gives a possibility of ease modification of an installation for several reactions. By introducing changes in pipe lines, an installation can be adapted to the synthesis of various products using microreactor modules with the principle of "LEGO" system. Such flexibility is confirmed additionally by the possibility of these systems to work in a wide range of working conditions.

6. POSSIBILITY OF EXPLOITATION OF MICROREACTORS

Above mentioned fundamental advantage of microreactors allows at their application to provide the following:

– Fast transfer from research step to manufacturing at low expenses.

– Simple increase in the amount of product

– Less plant area for the manufacturing

– Less cost of transport, materials and energy

– More flexible response to the market demand

The fast transfer from research to manufacturing is possible due to the possibility of fine changing working conditions and obtaining more accurate data and information that is not available in other cases, e.g., in respect of new regimes of a process [7, 27]. In addition, simple practical aspects make application of microreactors attractive, e.g., easiness and flexibility of assembling and disassembling experimental installation, low consumption of materials and enhanced safety.

Besides the purposes of investigation, there are other potential areas of application of microreactors related to manufacturing. Now is effected production of hydrogen in miniaturized reforming installations for its further using in fuel cells. This is the most promising direction because it really requires application of light and compact microreactors.

Considering yield of product we have to note that the process productivity is connected directly with the volume of reaction system. Hence, the product cost should increase when the reactor size decreases [28]. Moreover, the ratio of amount of material needed for creating apparatus is very large for microreators because they consist of many microchannels separated by dividing walls in the apparatus. This unfavorable ratio makes supposedly unprofitable manufacturing in microreactors. However, have special aspects been revealed that either allow to increase general productivity of microreactors, or due to other factors their micro volume leads to economy in the product cost. Below are considered some of these aspects.

– Replacement of periodically loaded reactor by continuous process

– Process intensification

– Safety

– Creation of distributed manufacturing

– Ecological aspects

6.1. *Replacement of Periodical Reactor by Continuous Process, the Process Intensification*

In many cases the processes are carried out in periodical reactors, e.g., at the use of reactor with stirrer. Sometimes the reaction duration becomes too long due to slow mass and heat transfer in the system with low specific surface of contact. Continuous process in microreactor where owing to thickness of liquid layer the mass and heat transfer in microchannels is much faster leads to significant shortening of reaction duration. In addition, conversion and selectivity also can be increased, as have been described for organometallic reactions [5]. Hence, yield of the final product in microreactor can be higher than in a periodical reactor. Moreover, due to application of microreactor can be changed reaction conditions. For example, a process in a periodical reactor requiring cooling can proceed in a microreactor enough effectively without cooling.

Due to the possibility of intensification of heat transfer in micro reactor, carrying out of high temperature autothermal reactions in such reactors can lead to increased conversion [27]. Calculations show that with a technology of continuous manufacturing in microreactor the amount of catalyst for a given chemical process can be decreased approximately by the factor of 1000. Besides, by decreasing ratio between volume and cost of apparatus can be enhanced productivity of microreactors. Despite much smaller size of continuous microreactor, its advantage over traditional reactors for solving this problem becomes obvious.

6.2. Safety of Microreactors

Microreactors allow much simpler control over the process parameters (temperature, pressure, duration, etc.) due to small volume of the reaction system. Reactions proceeding at high pressure or with application of hazard chemicals proceed more safely. There are many examples of application of microreactors that demonstrate their work under the explosion safe regimes [29]. On the contrary, at classical development of a process aimed at increase in the reactor volume the work under such regimes becomes impossible. Obviously in such cases should be applied the principle of multiplicity, that is, to use several identical units while each unit remains small. The possibility to work in so-called “remote” or “hindered” regimes extends flexibility of continuous microreactors. However, for real estimation of the possibility of working in such regimes should be carried out additional investigation of model reactions.

6.3. *Creation of Distributed Manufacturing*

Currently manufacturing is carried out in big fabrics and occurs a tendency of their extension. Concerning petroleum chemistry where the essence of natural raw material is transported for treatment on large distances to the central plant where it is worked up for obtaining valuable products, then small amount and distant location of the source of raw material can lead to unprofitable manufacturing because laying of pipe or constructing of a new plant are not profitable economically. In this case manufacturing with the use of microreactors can become cheaper than application of traditional equipment. Construction and dismounting of microreactors can be carried out enough quickly and their productivity is high, in particular when the principle of multiple repeating of micro units is applied.

6.4. *Ecological Aspects*

There is an opinion that producing of microreactors requires much more energy and materials than is needed for making common continuously operating reactors due to application of stainless still, and hence they in greater extent promote environment pollution. Moreover, the time limit of application of microreactors can be shorter due to possibility of their contamination and hence they should be produced more often. Karlish and co-workers [30] have compared time limits of operation of traditional and micro reactors under the conditions of strongly exothermal organic reaction. The results of investigation showed that despite shorter time limit for the microreactors in certain processes (e.g., production of tetrahydrofuran) their application can increase yield of the targeted product and thus to decrease consumption of energy. Taking all these pluses of microreactors, one can reliably say that the necessity of often renewing in the case of microreactor plays secondary role.

7. PRINCIPAL TYPES OF MICROREACTORS

Now there are many microreactors that are used in the various types of reaction systems. Research institutes develop new technologies for producing the microsystem unities and compare them with the existing ones. All research and development in this area is directed to intensification of the processes and increase of their safety compared to traditional reactors and related economical preferences for industry.

Figure 4 depicts distribution over the types of reactions studied in laboratories. One can see that homogenous

reactions in the liquid–liquid systems are carried out most often, that is explained by their relative simplicity and by a large number of the installations for the reactions of this type.

Below we consider a construction and working principles of several microreactors for various types of reaction systems.

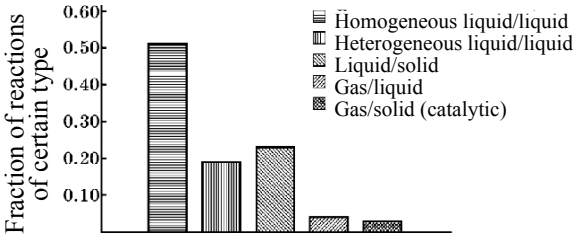

Fig. 4. Distribution over the types of the reactions carrying out in laboratories [31].

7.1. *Microreactors for Liquid Phase Processes*

In traditional reactors for liquid phase processes the components commonly are stirred by a stirrer, while in the microreactors this process in most cases is conducted through diffusion [29] which, depending on the reaction rate, can begin even in the mixer on the inlet [32].

There are different methods for mixing liquids. A simple and therefore often applied principle is the principle of multilayer [29], which is applied, e.g., in the mixers of IMM firm [29, 32] depicted in Fig. 5 and of the firm MGT, Mikroglas Technik AG [33] in Fig. 6; both companies are located in Mainz, Germany.

The specific geometry of the mixers favors so-called "focusing", that provides mixin in several milliseconds [34]. Contact of non-mixing liquids [33] or gas–liquid [35] is of more complicated nature. Various types of mixing chambers are used depending whether the flow regime is laminar or turbulent [36].

Fig. 7 depicts a mixer developed by Micronit Microfluidics BV (The Netherlands), operating on the principle of split-recombination technique. The idea of this technique is generation of multilaminar layers by splitting and recombination of liquid flows. Often due to high flow rate in such mixers is provided turbulent regime of the second stream. Thus, most of important from the practical viewpoint streams can be joined to provide a regime between laminar and turbulent ones. These additional streams in a general case are favorable for the process of mixing, but they decrease duration time and diminish a possibility of modeling the process. As compared with the counter-split mixers, the mixers of

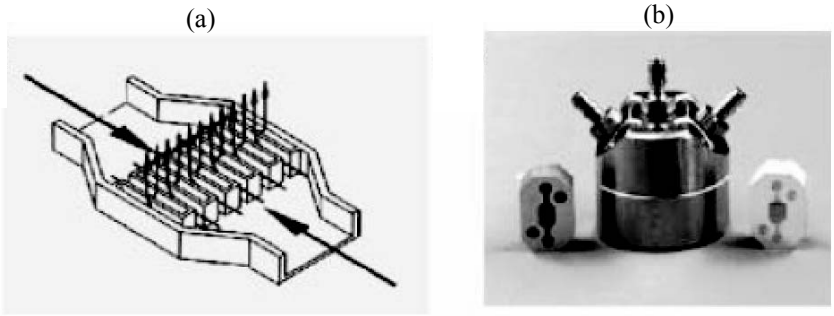

Fig. 5. Opposite gap type mixer: (a) working principle; (b) general view (made of metal and stainless steel); produced by IMM, Mainz [29].

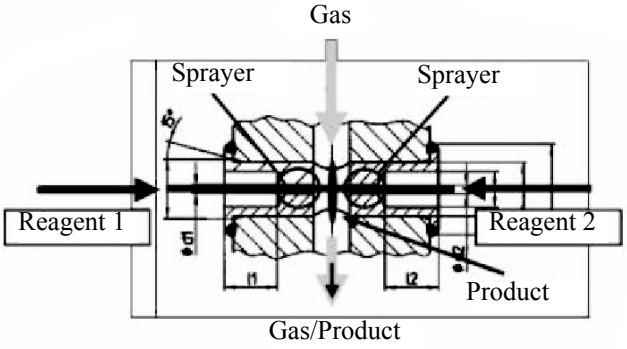

Fig. 8. Microstructural mixer (source: Synthesechemie GmbH, Heusweiler [37]).

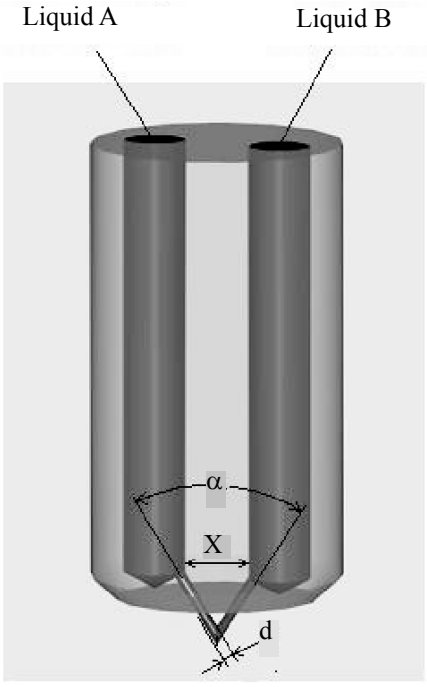

Fig. 9. Mixer of jet-collision type (source: IMM [38]).

split-recombination type can provide less pressure drop due to relatively larger internal size. Therefore the split-recombination mixers allow to work at higher rates of liquid streams that being not significant for the reliability decreases probability of depositing substances [36].

The phenomenon of turbulence is also applied at the mixing of liquids in micromixers at high stream rates. Figure 6 depicts a micro-jet mixer developed by Synthesechemie (Heusweiler, Germany) [37], where the reagents are pulverized through diamond or sapphire sprayer (with holes 60–350 m), collide in the mixer chamber and are intensively stirred. A gas input from top is responsible for removing the mixture from the chamber.

A jet-collision mixer depicted in Fig. 9 (developed by IMM) operates along the same principle [38], that is, the liquids are joined out of the mixer and are mixed in a short period.

Both the above described mixers were developed for the reaction that can lead to formation of a precipitate and as a sequence to the stoppage. Stoppage of these mixers is impossible because the reagents are stirred not in the microchannel but in open chamber and then are moved by gas flow.

To the moment a series of modular reactor systems has been developed. Figure 11 depicts a microstructural reactor (MGT, Mikroglas Technik AG), where are integrated: a mixer, a module of duration control and a cooling system [39].

More complicated microstructural reactor that has been projected by IMM for BASF is intended for two-phase reactions in a liquid-liquid system [40]. The microsystem joins three modules: mixer, duration control module and heat exchanger (Fig. 12).

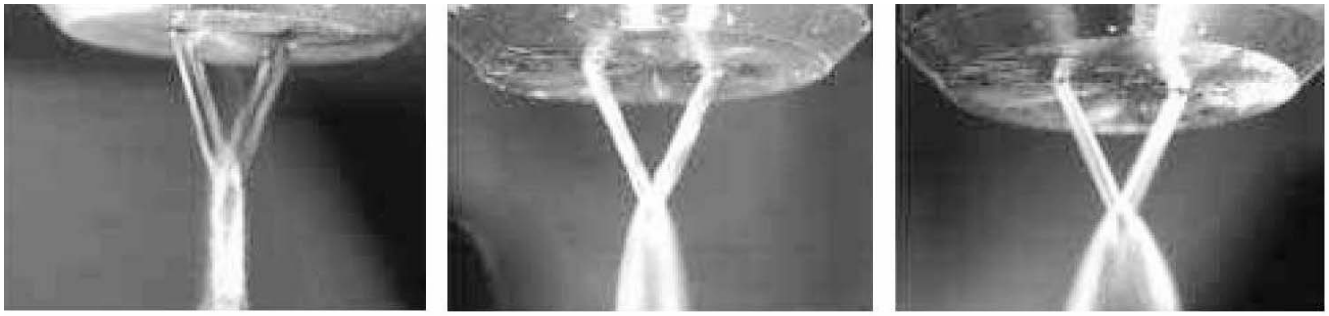

Fig. 10. Mixing regimes of the jet-collision type mixer (source: IMM).

Complete installations that include pumps, microstructural reactors, duration control modules, probes and real time analytical systems have been proposed by such producers as Cellular Process Chemistry Systems GmbH (CPC, Frankfurt), MGT Mikroglas Technik AG and IMM. Basically, these installations operate along the principle of micromixing in channel and are applied for investigations in the area of organic synthesis in laboratory.

For optimal carrying out certain chemical reaction the respective microstructural reactor installation should be assembled selectively for a given purpose. Such installations operate in many research institutions and universities in Germany.

7.2. *Microreactors for Gas–Liquid Processes*

In the recent years the interest to the investigations in the area of microreactor technique for the processes in the systems of gas–liquid increased. Two microstructural reactors for gas–liquid reactions have been developed by IMM in cooperation with other firms [41, 42]. Figure 13 depicts a principle of operation of a reactor with down draining film [41, 42]. The reactor consists of four components: bottom with integrated heat exchanger, reaction plate, seal at contact zone and a head with chamber. The central element of this microstructural reactor is reaction plate with the channels 100–1200 m width and 100–600 m depth. In the microreactor head there is a reaction channel through which the liquid drains down, that contains a rectangular gas chamber where reaction gas is passed through a distributing unit. The gas outlet hole is constructed like a gas diffuser to provide uniform distribution. Size of cooling channels depend on the width and depth of reaction channels.

To confine reaction space by the cooling volume of the reactor, the reaction plate is covered by a contact zone seal to prevent the contact with the gas in the not-cooling space.

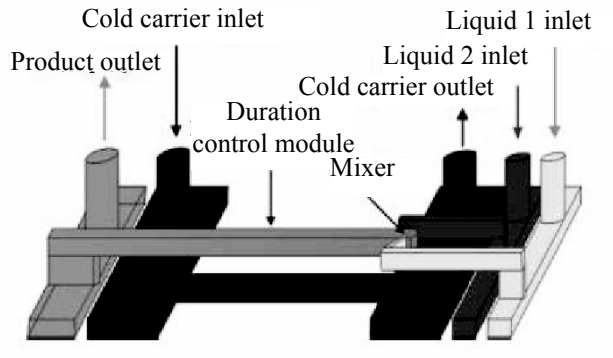

Fig. 11. Microstructural reactor with mixer, duration control module and heat exchanger (source: MGT, Mikroglas Technik AG [39]).

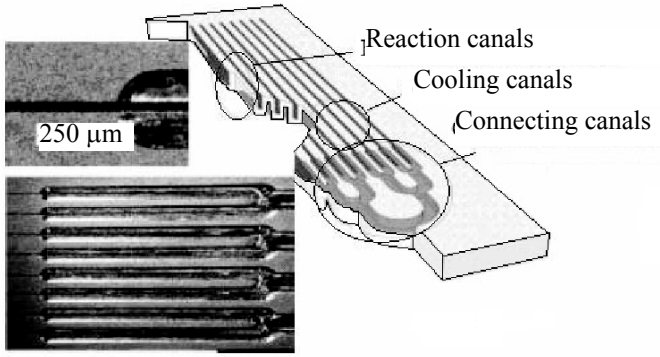

Fig. 12. Microstructural reactor with mixer, duration control module and heat exchanger (source: IMM [40]).

Figure 14 depicts a reactor with down draining film constructed of stainless steel, containing an inspection window. Good mass and heat exchange can be improved by thickening the liquid layer in microchannels. Liquid films up to 15 m thickness can have interphase space up to 20 000 m^2m^{-3}, that is approximately 10-fold over than in analogous systems, e.g., in the jet-collision type unit.

Close results have been achieved in a microbubbling column which operating principle is shown in Fig. 15 [41,

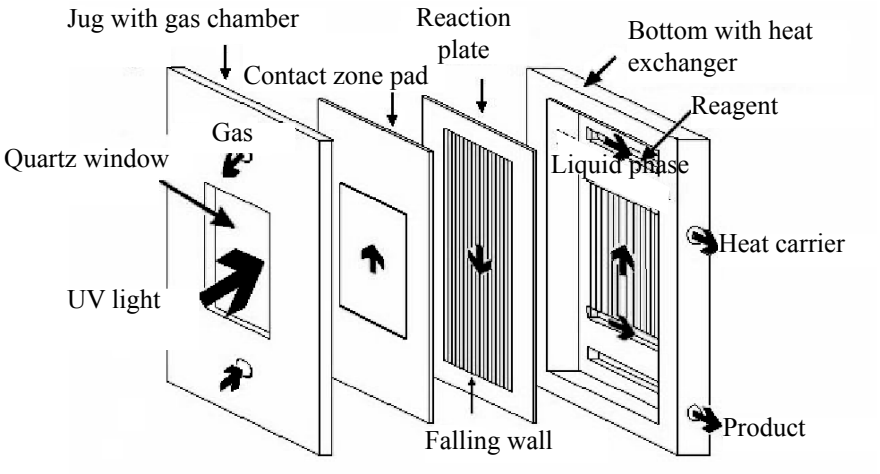

Fig. 13. Structure of the down draining film reactor (source: IMM [43]).

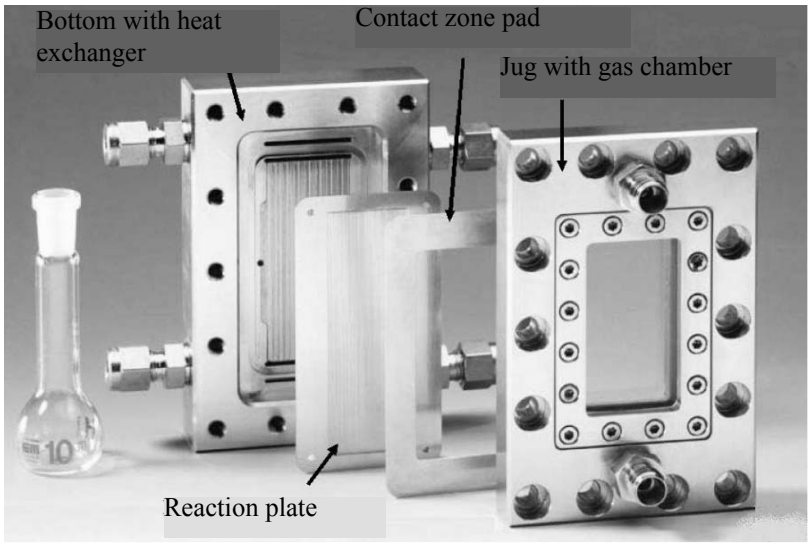

Fig. 14. Down draining film reactor with inspection window (source: IMM [43]).

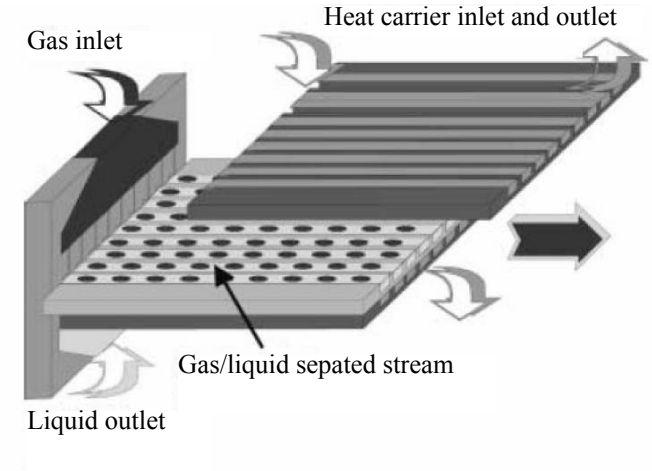

Fig. 15. Construction of microbubbling column (source: IMM [43]).

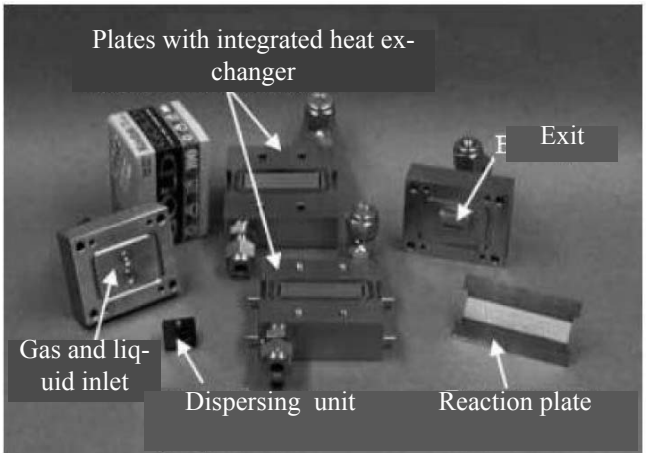

Fig. 16. Construction of microbubbling column (source: IMM [43]).

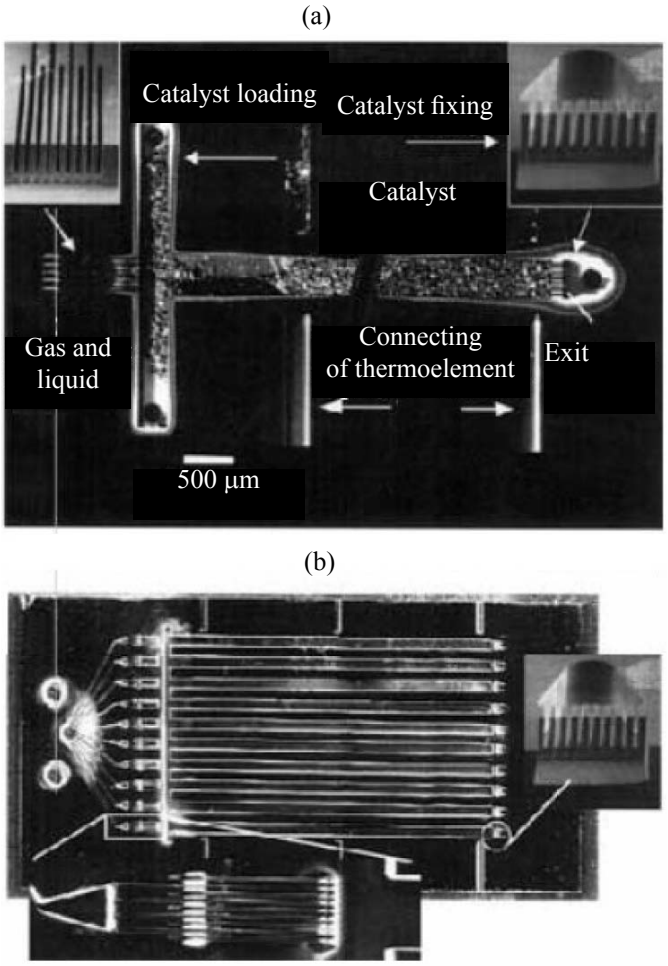

Fig. 17. Microreactor with immovable catalyst: (a) one reactor (b) ten reactors with a unit for distribution of liquid (source: MIT, Cambrige [45]).

42]. The microbubbling column is a reactor developed for providing fast contact between liquid and gas.

A central element of the microbubbling column is dispersion unit made of copper-nickel alloy. Uniform distribution of gas and liquid flows is achieved by small size of the microdispersion channels that the reagents are passed under the pressure at feeding. The channels for gas phase size is 5 m or less, for liquid phase 20 m. The channels are constructed in a metallic sheet. Effective temperature control is achieved by a heat carrier flowing through small channels as a counterflow to the reagents. Some details of the microbubbling column are shown in Fig. 16.

Figure 17 depicts a microreactor for the system of gas–liquid–solid developed in MIT (USA). Its microchannels contain powdered catalyst [44, 45]. This reactor with immovable catalyst was successfully applied for the process of hydrogenation of conjugated olefins and

selective oxidation of benzyl alcohol to benzaldehyde.

Figure 18 depicts a glass vortex mixer [35]. It consists of 11 equal elements that contain sprinklers of two types. A sprinkler for gas inlet is of 30 m, for liquid of 50 m width. In the reaction space for gas phase is formed a helix-like cloud, for liquid phase analogous circulating turbulent flow. Such flows are typical of the formed in two-phase mixers. In the reaction space from bubbles

and foam are formed separate bubbles that are combined together in the microchannels. Such type of reactors is appropriate for providing effective contact of catalyzed suspension with gas phase, although for this purpose the sprinkler should be extended to 150 m.

A microreactor constructed by Chamber et al. [46] is developed in particular for the strong exothermal reactions of fluorination (Fig. 19).

Liquid and gas are passed through a channel with a rate providing formation of ring type flow. Thanks to this the liquid is distributed as a thin layer on the microchannel wall while gas is passed through the middle space of the channel. Similar conditions of flow and interphase surface occur in the reactor with a down draining film.

7.3. *Microreactors for Gas Phase Reactions*

Gas phase reactions are the most studied processes in respect of application of microreactors. Even omitting economical aspect and scientific importance of such investigations, microreactors remains the most appropriate for such reactions from the viewpoint of technology. Wцrz [40] in his works affirms that the processes proceeding with a high rate and with significant heat liberation should be carried out in microreactors.

Most gas phase reactions are carried out in the presence of heterogenous catalysts , that is, a two-phase system (solid and gas) is formed, which is particularly appropriate for conducting in microreactors. In industry and in laboratory many gas phase reactions are conducted in the reactors of replacement type which by the principle of their work are analogous to microreactors. On the other side, they differ by the technology of introducing catalyst. In the replacement reactors the catalyst is commonly used in the form of balls or tablets (immobile technology) or as a well stirred dust (pseudoliquid layer). The catalyst as a thin layer on the reactor wall is applied exclusively in the microreactors. Therewith, for the fixation of the catalyst on the microchannel wall is applied technique of grounding analogous to those applied in monolithic reactors. The ground by means of wet chemical impregnation is coated by the catalyst. To the microreactors can not be placed friable materials because this leads to loss in pressure and destroys laminar regime of flow.

7.3.1. Staple multiplate reactors. The most often applied type of microreactors for the gas phase systems is a microreactor constructed of many plates assembled into staples. Each plate has parallel microchannels [48, 49]. Such plates are either fastened by external welding seam (Fig. 20) [50], or joined under end shield (Fig. 21), [51], have joining plates (Fig. 20), [52] or placed in a body (Fig. 22) [48, 49].

(a) (b)

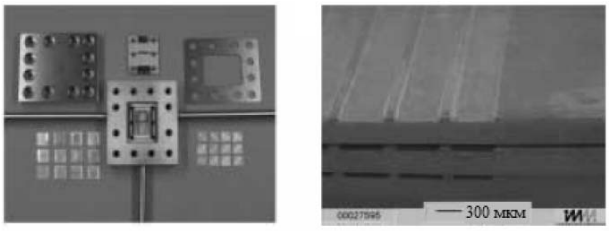

Fig. 23. Staple multiplate reactor with body, consisting of two parts: (a) construction elements; (b) zoomed view of one plate (source: IMM [2]).

When necessary, the plates can be separated into sections and mutually isolated by the sealers made of graphite or other material [52]. The body often has reinforcing screws that provide uniform pressure on the plate edges. The microstructural plates can also be joined by laser or diffusion welding [50]. The plates joined by diffusion welding should be placed into a body. Schubert and co-workers [51] have optimized the diffusion welding of the microreactor plates to provide perfect heat exchange without placing them into a body. Such configuration is quite compact one because large working surfaces are formed by joining small volumes.

A sample of such reactors is two-channel microstructural reactor that can be used for the operations with counterflows. In such reactor an exothermal reaction can be used for heating the flow of reagents. Thus, endothermic and exothermic reactions can be carried out simultaneously [52] and autothermal regime can be arraned.

Wolfart, Renken and co-authors [54] have created a microreactor that operates without microchannels. Instead of the microchannels it has a small chamber with separators that passes the flow along a constrained channel thus forming miniaturized active surfaces in each part of the chamber wall.

Among other examples of staple multiplate microreactors there are the reactors for oxidation of ammonia developed by Schouten et al. [55]. Richter et al. [48] have developed a reactor for the synthesis of ethylene oxide, Kaminos et al. [56] a reactor for methanol reforming in a steram.

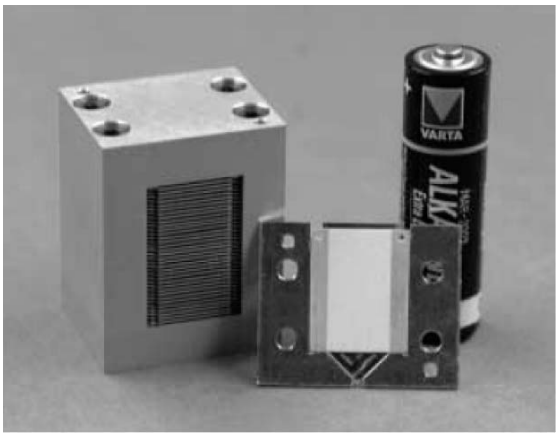

Fig. 24. Module of staple microreactor consisting of 35 plates (Source: Universitдt Chemnitz; IMM [59]).

7.3.2. Staple multiplate reactors for parallel testing of catalysts. A special form of multiplate microreactors allows parallel testing of several catalysts, each applied to certain plate. Zech and Нцnicke [57] in cooperation with IMM developed a multiplate reactor (35 plates). Central component of this installation is a capillary 300 м width that automatically collects samples from each plate (Fig. 24). More recently, Kolb et al. [58] has constructed a reactor consisting of 10 groups. Such reactor can operate consecutively or parallely, depending on the connection of its plates. In such reactor also possible to carry out optimization without changing the reactor structure and geometry of its channels.

7.3.3. A microreactor constructed of one plate and one channel. The microreactor consisting of one plate has an advantage over the staple multiplate reactors

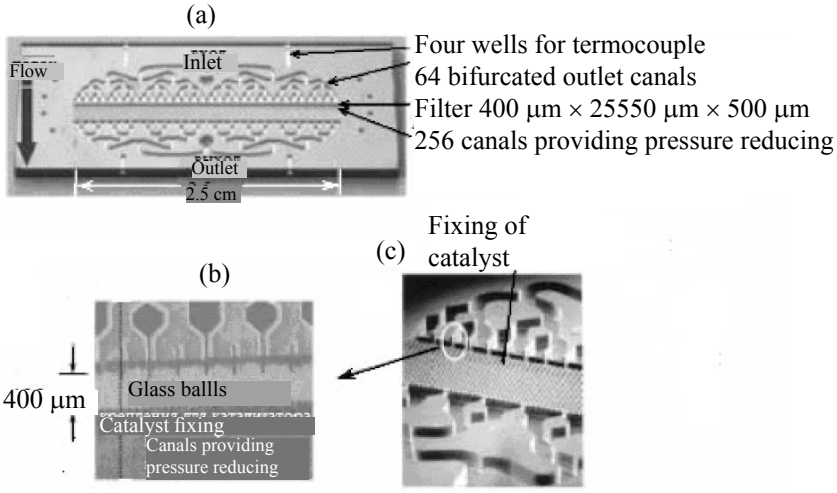

Fig. 25. Silicon microstructural reactor: (a) crtoss flow scheme; (b) microreactor filled with 50 m glass balls; (c) Microstructural reactor zoomed image obtained with an electron microscope (source: MIT [62]).

because there is no necessity of distribution between several microchannels. This special type of microreactors is created by Veser and co-authors [60]. It consists of two plates of which one contains channel and fasteners for assembling with the second plate. The plates are assembled and fastened by appropriate method.

Ajmera et al. [61] have described a monochannel microreactor that allows to use powdered catalyst and ever can work with a fabricated catalyst. The reactor has a channel of certain length where the particles are located as a bifurcated cascade to provide averaging by size and uniform flow at the both sides of the reactor.

7.3.4. Membrane type microstructural reactor. Membrane type microstructural reactors with impregnated membranes can be applied for the reactions where more favorable equilibrium conditions are provided due to continuous drain off the reaction product through a membrane wall.

Franz et al. [63] and Jensen et al. [64] have proposed a monochannel microstructural membrane type microreactor with many built in pressure and temperature probes along whole reaction zone.

The microstructural reactor is sealed at the top by hermetical membrane containing a thin film of platinum catalyst (Fig. 26). The reactor can operate at various regimes depending on the membrane material strength and ability of heat distribution. To start separation of the reaction product gas flow from the reaents the membrane should be open, that is, the plate should be removed [65].

7.3.5. Microstructural chip-reactors. Many microstructural reactors are projected using the concept and methods of manufacturing applied in microelectronics. The systems on chips commonly are formed of two or more silicon (glass) disks (Fig. 27) [63, 64]. In some cases one can meet multilayer systems where each layer possess its own function, e.g., the newest silicon microchip system developed in MIT in cooperation with DuPont, Delaware, is shown in Fig. 27 [66].

The microreactor depicted in Fig. 28 consists of two layers of borosilicate glass. Such microreactor can include one or several mixing chambers. Operating temperature in such reactor can achieve 400°C, pressure up to 100 bar. The channel length can be in the range from 332 to 676 mm depending on the modification used [67].

Among recent samples developed by Micronit Microfluidics BV (The Netherlands) is a laboratory on the microchip (Fig. 29).This system consists of the body containing a standard reactor on microchips. The body

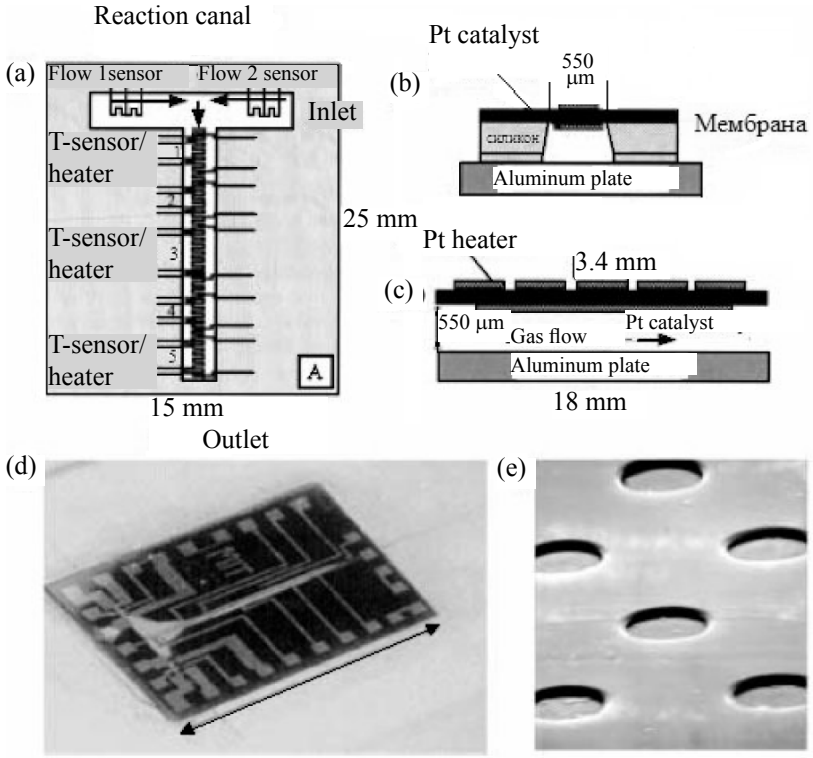

Fig. 26. Membrane type microstructural reactor : (a) top view; (b) cross section of reaction channel; (c) axial section of reaction channel; (d) microreactor general view; (e) uniformly distributed holes in the membrane (source: MIT Cambridge [45]).

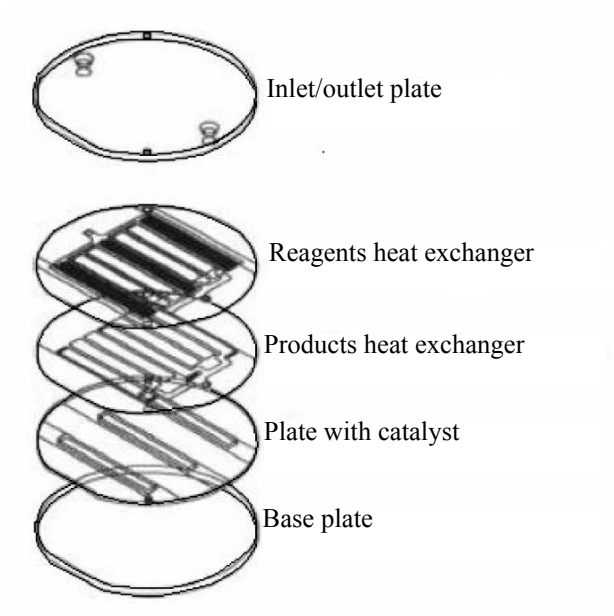

Fig. 27. Extended scheme of construction of integrated silicon reaction microsystem (source: DuPont, Delaware [66]).

provides more convenient and reliable connection of capillary tubes, has inspection window through which the processes in the reactor can be observed with a microscope. The principal advantage of the system is providing reliable operation at high pressure and ability to use various chip reactors by disassembling–assembling the installation [60].

Another interesting project of DuPont and MIT [31] is a complete microstructural installation for simultaneous conducting several reactions (Fig. 30).

Such automatized system is built basing on the principles used in microelectronics. The system block is filled with so-called mother boards analogous to those used at manufacturing computers. Each such microscheme possess microreactors, microseparators, probes and other units ("Lab on a Chip"). Inside the each mother board there is a system of microchannels that provide connection between the units. The whole system is controlled by a program which, depending on a given task can optimize the process by varying the process conditions. Due to parallel operating of the mother boards the system allows to carry out either one reaction simultaneously on several boards, or several different reactions. In the former case at the outlet of the microsystem installation the reaction product can be obtained in a higher amount.

7.3.6. The systems for fixing catalyst for gas phase reactions in microchannels. There are many techniques

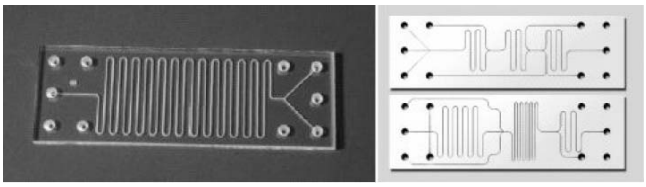

Fig. 28. Reactors on microchips (source: Micronit Microfluidics BV).

(a)

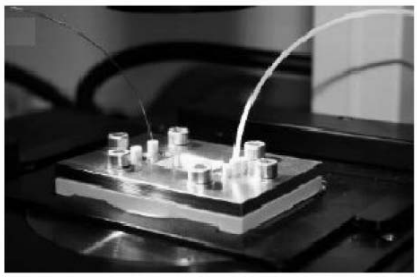

Fig. 29. Laboratory on glass microchip: (a) disassembled; (b) at the operation process (source: Micronit Microfluidics BV).

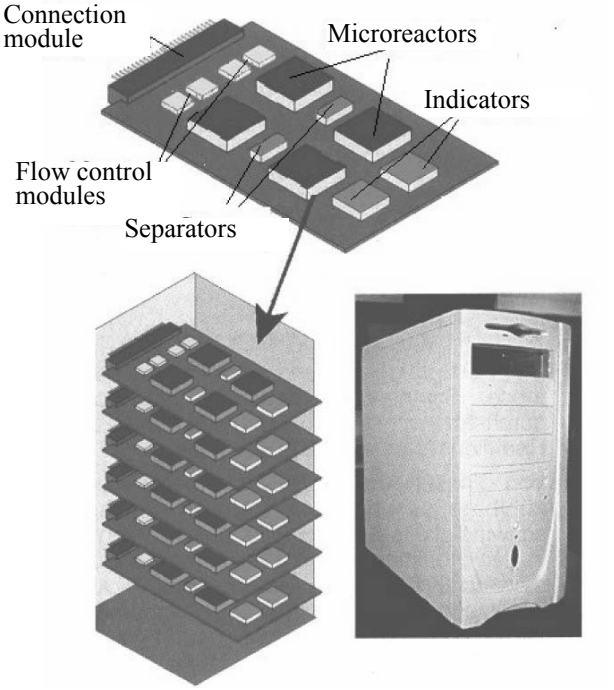

Fig. 30. A system for ssimultaneous testing of several catalysts [31].

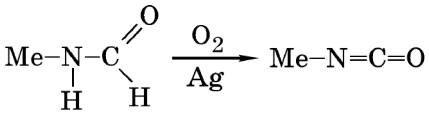
for introducing and fixing catalyst in a microchannel. The simplest one is covering the material used for the microchannels with a layer of catalyst: then no carrier is needed for the catalyst [48, 51]. In this mode the microchannel walls act as the catalyst, but the catalyst surface is restricted to the area of the microchannel walls, that is, only small contact area is available. Therefore such type of fixing the catalyst is applied for fast reactions or for the technological processes with low rate of moving the flow along the channel.

Mostly, covering the microchannels is achieved by the method of grounding followed by wet chemical imprenation [52].

Zeolites, an important class of industrial catalysts, can be synthesized directly in the microchannel [68]. There are other types of the systems of fixing catalyst: covering with a catalyst by pulverization [63], sol-gel technique, and plasma jet electrochemical treatment [36].



8. INDUSTRIAL APPLICATION OF MICROSTRUCTURAL REACTORS

In 1995 the microreaction technique was first applied in industrial chemical laboratories. Wцrz et al. [40, 69] have described incomplete oxidation of alcohol to aldehyde, the process that BASF developed on the industrial scale. The purpose was, on the one hand, to study a possibility of application the information obtained with the microreactors for the optimization of the process in the classical reactors, and, on the other hand, to apply the microreactors themselves for enhancing the process selectivity. Such direct comparison of the reactors allows estimate the potential of the microreactor technique for their industrial application.

8.1. *Synthesis of Methylisozyanate*

Lerou et al. [66] conducted in the DuPont laboratories a series of catalytic gas phase reactions. They studied high-temperature, dangerous, catalytic and photochemical gas phase processes. The microreactor consisted of several silicon plates assembled together. Each plate had its own function, such as heat exchanger and others. The catalyst was introduced as small particles by analogy with miniature immovable layer. On the example of synthesis of methylisocyanate from formamide in microreactor, it has been shown that conversion was the same as in traditional reactor, but selectivity was lower, due probably to not ideal temperature profile in the reaction zone [36]. The reaction scheme is shown in the Scheme 1.

Scheme 1. Synthesis of methylisocyanate from formamide [36].

To the current moment many similar investigations have been carried out. Many of them have not been published owing to their industrial significance.

Now almost each chemical firm has at least small installation related to the microreaction technique. The firms conducting fine organic syntheses are the most interested in such technology. It is expected that industrial application of microreactors will grow [70].

8.2. *Industrial Application of the Microreactor StarLam 30 (IMM)*

A recent example of successful industrial application of microreactors in the existing installation for producing chemicals was presented by Kirschneck and Tekautz (Fig. 31) [71]. The process consisted of two steps that were realized in a 10 m^3 periodical reactor. The first step is strongly exothermic, therefore the reactor should be cooled due to volatility of one reagent. The second step is endothermic, and the installation should be heated for several hours. The process is slow enough, thus productivity provided was only 1.8 ton per hour (the whole process scheme is not divulged by producer). It was decided to carry out one step in a microreactor of continuous operation, with the purpose to increase the product yield to 3.6 ton per hour.

This installation has been launched in June 2005, and after 10 months work it was studied completely in respect of corrosion. No traces of rust have been found.

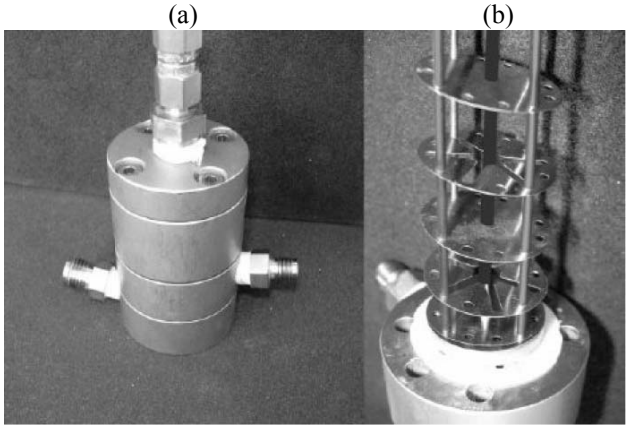


Fig. 31. Microreactor StarLam 30 produced by IMM: (a) general view, (b) inside construction [71].

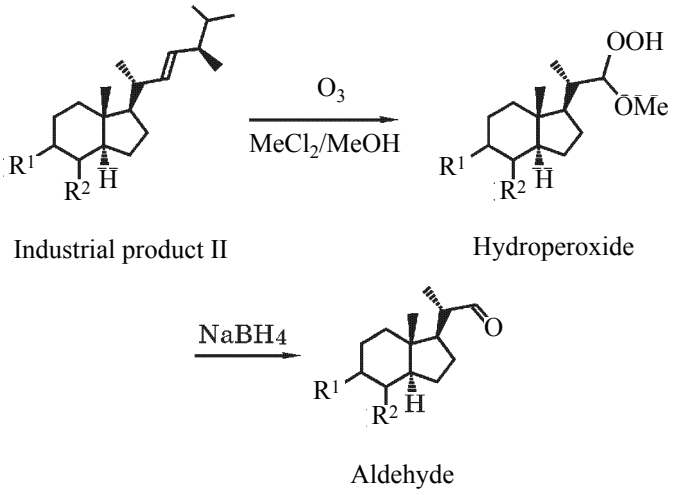
The authors note a fact that control over the microreactor operations did not create any problem and that the cost of analogous reactor for periodical operations was much higher. Introduction of the microreactor led also to the economy in energetic resources for cooling because cooling was not needed in the continuously operating microreactor.



8.3. *Synthesis of Sterouids in Microreactor*

The next example of successful application of microreactors was demonstrated by Schering Company. This company performs develpment in the area of microreaction technique. One of directions of the development is seventeen steps synthesis of steroids for producing analog of Vitamin D [72]. The reaction scheme is shown in Scheme 2. Application of microreactor for this process became very actual after the explosion in DSM Fine Chemicals plant in Linz in 2004.

Commonly for this process was used a reactor of semi-continuous operation. For producing 15 kg of the product needed 13 loadings of initial mixture. It was decided to test ability of carrying out this synthesis in the reactors of three types: a microreactor with down draining film (productivity 130 g per day), a mini-reactor with down draining film (productivity 1.5 kg per day) (Fig. 32), and a mini-reactor of continuous operation (productivity 1.5 kg per day) (Fig. 33). The principal characteristics of the reactors are listed in Table 2.

It is clearly seen that the reactor of semi-continuous operations is disadvantageous as compared with other reactors both in respect of safety and by productivity. The most productive was found the microreactor with down draining film that left behind other reactors. Its productivity achieves 10 kg of steroid per day and at multiplication to whole volume 1 liter even 520 kg. This fact is explained by effective proceeding the process in account of microchannels that leads to significant increase in productivity.

Scheme 2. Synthesis of steroids for the producing of Vitamin D analog [72].

8.4. *The process of Gas Phase Propylene Epoxidation in Microreactors (Demis^T)*

Concern Degussa also leads development in the area of microreaction technique. In cooperation with other firms, research institutes and universities of Germany its researchers have developed a microstructural microreactor for the process of gas phase propylene epoxidation.

The reactor consists of special plates forming reaction chambers at butt-joining (Fig. 34). The plates can be of different length (up to 5 m) depending on the size of the apparatus. The plate internal wall is covered by catalyst. The manufacturing becomes more flexible due to modular type of this unit. Compared to the reactors commonly used for such process, this technology allows to carry out the process at higher pressure and to control the possibility of explosion. In Fig. 35 are depicted such reactors of two types: (a) laboratory unit, (b) industrial reactor.

After completing investigation, a pilot plant installation that consisted of one module and provided productivity ~1 kg of propylene oxide per hour was started up; it worked about 250 h. More recently was effected an installation consisting of three reactor modules and three evaporators, with productivity ~3 kg of propylene oxide per hour. This installation worked about 350 h in testing regime (3 periods). During the work its regime state was very stable, and was noted reproducibility of the obtained results. The catalyst that has been synthesized specially for this process showed in the pilot plant installation the same results as at the testing. The system of microstructural reactor and the new catalyst allowed obtaining results better than with all the known analogs (Fig. 36).

CONCLUSION

In the recent years due to extension in application of microstructures in various areas of chemistry, physics, biology, materials technology, etc., began intense study of microreaction technique. In literature appear more and more examples of their industrial application. Therewith, while in the beginning of development of microreaction technique the principal works were carried out only for liquid and gas phase systems, in the recent time the technology becomes more complicated, and research and development concern also heterogenous, solid phase systems and photochemical and electrochemical reactions. A wide development concerns also so-called "Lab on a chip" systems that allow to carry out in miniature scale parallel analysis of several reactions simultaneously. Intensity of all these works is dictated by the interest of industry, because application of the microreaction technique leads to increase in the yield of final products owing to the changes in the process conditions, economy in space and energetic resources. It is ecological and economical advantage of the microreaction technique over classical reactors that explain the fact of particularly intense application of microstructural reactors in chemical technology.

Development of microreaction technique in the industrial scale still is aimed at the substitution of traditional reactors by microreaction technique in the existing industrial installations rather than at the creation of full-value microreaction systems. Therewith a principle of multiple repeated microreactors is commonly applied. Thus, we can state that modern development of microreaction technique allows to transfer "micro-approach" to the "macro-world" retaining therewith all advantages of the miniaturization.

Industrial producing of butanol began in 1916. That time was used a method of ABE fermentation (ABE abbreviates acetone, butanol and ethanol) with bacteria *Clostridia acetobutylicum*. This microorganism was first isolated by Weizman (US Patent 1 315 585), a student of Luis Paster; the microorganism produces acetone. In the time of First World War, England asked the young microbiologist to resign the right for producing by this method of acetone for further manufacturing smokeless powder cordit. This process was used up to 1920th exclusively for producing acetone. However, at the fermentation, yield of each pound of acetone is accompanied by formation of two pounds of butanol. Somebody once mixed nitrocellulose with butanol and thus obtained quickly drying lacquer. Three years later, automobile industry changed whole market completely, and to 1927 butanol became the main product of ABE process. In the time of Second World War it was used for producing synthetic rubber.

So, in the first half of 20th century biobutanol was produced from corn and molasses by fermentation. This process affords acetone, butanol and ethanol (therefore it is denoted as ABE process). However with growing demand for butanol its producing by fermentation began to fall because since 1954 the price of petroleum becomes below those of sugar because USA lost cheap sugar supply from Cuba.

Now butanol is produced starting with petroleum via hydrolysis of haloalkanes or hydration of alkenes.

Butanol can be produced from biomass and from mineral fuel. The butanol from biomass is conveniently denoted as biobutanol despite the fact that it has the same characteristics as the butanol from petroleum.

First of all, butanol is used as industrial solvent. World market for this product is estimately 350 million gallons per year, of which 220 million gallon/year is the fraction consumed by USA. Butanol can be used instead of gasoline even in higher degree than ethanol due to its physical properties, economy, safety and because it can be applied without remodeling car engine.

Progress in the area of biotechnology allows to use corn and other biomass as economically effective source of biobutanol.

The main reason that nobody know butanol as an alternative fuel is the fact that its producing has never been suggested economically reasonable. As mentioned above, this product is used mainly as industrial solvent and costs triple compared to gas. Traditional process of fermentation allows to produce from one bushel of corn (or 35 pounds of sugar) only 1.3 gallons of butanol, 0.7 gallons of acetone, 0.33 gallons of ethanol and 0.62 pounds of hydrogen. Such manufacturing of butanol can not compete with the technology of producing ethanol that yelds 2.85 gallons of the product per bushel.

The alcohol based fuel including butanol and ethanol is partially oxidized (compared to hydrocarbons) and therefore mixture for engine should be more enriched than in the case of gasoline.

As compared with ethanol, butanol can be used as a mixure with gasoline in higher proportion and thus can be used in currently working cars without modification of their system for the formation of air–fuel mixture.

The alcohol based fuel contains less energy per unit of weight or volume than gasoline and its mixture with air should be more enriched. Per one cycle of engine running, butanol liberates more pure energy than ethanol

or methanol and approximately by 10% more than gasoline.

Owing to appearance of new highly effective technologies for producing biobutanol, now butanol from corn attracts more attention of specialists than ethanol. There are several advantages of butanol over ethanol:

1. Butanol contans by 25% more energy than thanol: 110 000 Britain heat units per gallon as compared with 84 000 Britain heat units per one gallon of ethanol. Energy content of gasoline is about 115 000 Britain heat units per gallon.

2. Butanol is more safe because is evaporated six times less than ethanol and by factor 13.5 less volatile than gasoline. Its vapor pressure by Reid is 0.33 pounds per squire inch, the same characteristic of gasoline is 4.5 pounds per squire inch, of ehanol 2.0 pounds per squire inch. This makes butanol safe at its application as oxygenate, and need no significant changes in the mixture proportion at summer and winter application. Now it is used as oxygenate in the states Arizona, California and others.

3. Butanol is much less aggressive substance than ethanol and therefore it can be transported with currently used fuel pipes, while ethanol should be transported by rail way transport.

4. Bitanol can be mixed with gasoline.

5. Butanol can be used instead of gasoline, while ethanol can be used as additive to benzene with content of the latter in the mixture not less than 85% and requires significant modernization of engine. Currently predominantly are used mixtures with content of ethanol 10%.

6. Producing of butanol can simultaneously solve problems connected with the infrastructure of supplying hydrogen.

7. Butanol provides higher yield of energy (10 Wt-h/g) than ethanol (8 Wt-h/g).

8. At combustion, butanol does not produce sulfur and nitrogen oxides that is advantageous from the ecology wievpoint.

Thus, biobutanol allows to solve a part of problems retarding fast application of biofuel over the world, in part, it is compatible with existing car fuel and with infrastructure of logistics. Low vapor pressure of biobutanol and its low sensitivity to the presence of water in its mixture with gasoline extend its versatility. It can be mixed with gasoline to higher concentration than existing biofuels without modernization of engines, economically it is preferred than the mixture of ethanol with gasoline, it improves efficiency of cars in respect of fuel and increases run per a unit of consumed fuel.

Also, biobutanol can enhance productivity of ethanol–gasoline mixture, in part, in account of decreasing the effect of ethanol on the vapor pressure of the mixed fuel (a serious problem restricting wide application of ethanol).

Like ethanol, fuel biobutanol contains "green" carbon that allows decreasing emission of hotbed gases.

In USA, the fuel biobutanol as suggested can decrease dependence of the country on foreign supply of petroleum and increase development of agriculture.

Biobutanol is produced from the same raw material as ethanol: corn, sugar beet, sorghum, manioc, corn stem and other biomass, but in can replace gasoline at use in the same volume.

US patent 5 753 474 "Continuous two-step anaerobic fermentation process for producing butanol and other organic solvents using two different bacterial strains", owned by Environmental Energy Co., proposes a technology that makes producing of butanol effective and economically reasonable. Using by the company of paired bioreactors with immobilized cells of continuous application increases yield of butanol to 2.5 gallons from one bushel of corn plus gives 0.6 pounds of hydrogen as a side product.

Fermentation ABE with bacteria *Clostridium acetobutylicum* is one of the earliest processes applied to industrial fermentation for producing butanol. By the yield of product, it is second to yeast fermentation for producing ethanol. With the mentioned anaerobic microorganisms first in the world was created such branch of industry as microbiological manufacturing. One of the biggest microbiologicasl plants belonged to Commercial Solvents International company in the state Indiana. However fermentation remained a complicated and hardly controlled process at creation of new technology by Environmental Energy company.

At the typical ABE fermentation, initially *C. acetobutylicum* bacteria produce butyric, propionic, lactic and acetic acids (the step of producing acid), the pH value of the culture decreases and metabolic shift to the step of producing solvent is initiated, resulting in formation of butanol, acetone, isopropanol and ethanol.

The shift is initiated at increase in butyric acid concentration to more than 2 g/l and decrease in pH

below 5. At the commonly used ABE fermentation, yield of butanol from glucose is as low as 15%, and hardly can be achieved more than 25% (1.3 gallons per one bushel). The butanol producing is restricted because at the concentration 1.0–2.0% it blocks substantially the cell growing and can lead to cancelling fermentation. Therefore concentration of butanol in the common ABE process is not higher than 1.3%.

Efforts in the last over than 20 years allowed only to obtain butanol with concentration below 2.0% at productivity 4.46 g/l per hour and butanol yield less than 25% on the glucose weight.

Optimization of the process of ABE fermentation and synthesis of butanol via butyric acid from carbohydrates allowed considerably increase the butanol yield, productivity per volume unity and concentration. Application by Environmental Energy company of immobilized cultures *Clostridium tyrobutyricum* and *Clostridium acetobutylicum* allows to achieve optimal productivity of butanol 4.64 g/l per hour and yield 42% on the glucose weight or 2.5 gallons per bushel of corn (35 pounds of starch–lactose–sugar).

As compared with traditional ABE process, the technology of Environmental Energy company allows to avoid producing of undesirable products including acetic, lactic and propionic acids, acetone, isopropanol and ethanol, thus to save carbon and to producce only carbon dioxide, butyric acid and butanol. This process increases twice yield of butanol per bushel of corn from 1.3 to 2.5 gallons.

As compared with this process, the process of yeast fermentation for producing ethanol gives 2.5 gallons of ethanol per bushel of corn at concentration 10–15%. It is therefore ethanol was considered as the most promising candidate for alternative fuel.

The technological process patented by Environmental Energy Inc. can produce 2.5 gallons of butanol per bushel of corn, without formation of acetone and ethanol. Thus, butanol can be really nominated for using as alternative fuel. Besides, the new technology gives hydrogen as a side product that also can be applied as alternative fuel. With accounting for the hydrogen, the new technology allows to obtain by 42% more energy than traditional synthesis of ethanol, of which 25 % belongs to butanol and 18 % to hydrogen.

It is important to understand that even in the absence of technical base for application of hydrogen as the alternative source of energy, it remains to be valuable chemical product used in many subbranches of chemical industry.

Raw biomass initially is mixed with bacteria *Clostridium tyrobutyricum*, that leads to conversion of large fraction of the raw material into butyric acid and hydrogen. In the second step, the butyric acid formed is mixed with bacteria *Clostridium acetobutylicum* and is converted into butanol. This technology produces much less side products, only hydrogen, butyric acid and carbon dioxide.

This new process has been still demonstrated in laboratory scale only.

In summer 2006 the company has studied efficiency of this process on a pilot plant installation B-100 with productivity 100 gallons of butanol per week.

Theoretical calculations of specialists showed that the cost of butanol from corn will be 1.20 US dollar per gallon, excluding side hydrogen. This is comparable with the cost of producing ethanol (about 1.28 USD per gallon). Taking into account higher energetic value of butanol, this gives 105 000 Britain heat units per one dollar in the case of butanol against 84 000 Britain heat units per dollar at producing ethanol, the cost of corn is taken 2.50 dollars per bushel. For comparison, the cost of producing butanol from petroleum is about 1.35 dollars per gallon.

The process developed by Environmental Energy Inc. will become ever more effective at using agricultural by-products instead of corn: then the cost of one gallon will be 0.85 dollars.

Environmental Energy Inc. now is one of a few companies in USA that works on the creation of experimental installation for producing biobutanol which, by their opinion, can be produced from everything that grows on the globe.

Initially the Environmental Energy Inc. company is intended to arrange biobutanol manufacturing for the market of solvents, but further will produce and sale it as alternative fuel.

The company has developed and patented its own method for producing butanol by fermentation, that is more economical as compared with known petrochemical methods. This technology was developed thanks to support by federal grant of USA Ministry of Energetics in the framework of program of development small business, in cooperation with Dr. S.T. Yang, Ohio State University, who submit to the company his patented bioreactor.

Never before in the world was known any technology that could provide effective producing butanol from biomass. Therefore butanol manufactured earlier was of low concentration and its yield was lower than that of ethanol. Earlier ABE technology allowed to produce acetone, ethanol and butanol in the ratio 3 : 6 : 1, that is, from one bushel of corn it was possible to obtain 1.3 gallon of butanol (with concentration 1–2%), 0.7 gallon of acetone and 0.13 gallon of ethanol. As far as biobutanol and ethanol are produced from the same raw material, existing facilities for producing ethanol can easily be rearranged for producing biobutanol.

Companies DuPont, British Petroleum and British Sugar Corporation are intended to reassign a plant in Great Britain that produces bioethanol for manufacturing biobutanol. It is assumed that the first line of the project will produce from sugar beet 30 000 ton or 9 millions gallon of butanol per year using currently existing technology.

The difference in producing ethanol and butanol first of all is defined by features of their distillation. Therewith, both technologies use the same raw material: sugar beet, maize wheat and manioc corn, as well as straw and maize stems. As DuPont company claimed, current facilities for producing butanol can be easily rearranged for biobutanol.

On June 20, 2006 DuPont and British Petroleum (BP) announced creation of strategic partnership for development, producing and realization of next generation of biofuel. This partnership should comprise achievements of DuPont company in the area of biotechnology and great experience and know-how of BP in the area of fuel technology and market. Owing to this cooperation these companies will became world leaders in development and manufacturing of biofuel.

Since year 2003, the two companies worked jointly on the overcoming of disadvantage of existing biofuels. Now they are intended to present to world market their first jointly developed product, the biobutanol, that is planned to be introduced in Great Britain as biocomponent additive to gasoline in 2007. For organization of its producing the companies BP and DuPont cooperate with British Sugar company, a branch of Associated British Foods plc that now rearranges its first plant for producing ethanol by fermentation to the facility for producing biobutanol. At further development of respective market it is planned to create additional facilities for manufacturing this product in various countries. Now BP and DuPont in cooperation with British Sugar develop study of techno-economical validity of the project for the revealing a possibility of building in Great Britain of more powerful plants.

Initially was planned to create manufacturing of biobutanol on the ground of currently existing technologies. However, would the current research and development in the area of enhancing productivity of this process be completed successfully, in the plant will be applied the biotechnologies that allow to make efficiency of producing biobutanol comparable with that of ethanol. As a raw material is planned to use sugar cane or beet, maize, wheat and manioc, and further cellulose raw material from grace or agricultural by-products (straw and maize stems).

Biobutanol is advantageous over petroleum fuel like other types of biofuel, in part, by low emission of hotbed gases.

In April 2006 on the conference in the Illinois State University denoted to bioenergy professor Hans Blaschek, who is specialist on food microbiology in that university, has reported on a significant progress in its research on the biobutanol technology. Using patented by him genetically modified microorganism *Clostridium beijerinkii* he successfully transformed maize corn into butanol. For initiation of the fermentation process he used obtained by him genome map of this microorganism. He plans further to use result of genome analysis to produce next, more effective, generation of *C. Beijerinckii* microorganism.

C. beijerinckii has been chosen for gene mapping by USA Energy Ministry in в 2004. This research has been carried out in United Genome Institute in California.

Besides, professor Blaschek has developed grounds for the technology of synthesis butanol from gas. This butanol will be cheap and not contaminated with admixtures that are possible at application of technology based on the use of membranes.

The scientists suggests that butanol has large potential as alternative fuel because it has higher octane number than ethanol and is not mixed with moisture contained in pipe lines. Butanol also can be used as chemical raw material for producing polymers and plastics.

Increase of butanol demand leads to necessity of producing additionally 400 millions bushels of corn per year or of equivalent volume of agricultural biomass in USA, thus stimulates development of agriculture.

The scientist is planning to scale the fermentation process of producing butanol using existing strain *C. beijerinkii*, to select appropriate corn raw material and type of corn fibers for producing butanol and to create next generation of microorganisms.

In Russia first facility for producing biobutanol (biofuel of second generation) will begin to work at Spetember 2008 on the ground of Tulun hydrolysis plant. This has been confirmed at the presentation of the project on creation of new biotechnological complex on the plant. In May 2008 administration of Irkutsk region and noncommercial organization "Fuel-Energetic Union" signed the Intention Record announcing this project.

The plant stopped to work at May 2008 and soon has been claimed its bankruptcy. Note that crisis situation is characteristic of all the hydrolysis industry of Russia: all 68 hydrolysis plants were stopped, and their facilities were mostly sold out.

After transfer the packet of shares to regional ownership, the Priangar'e administration makes efforts for attracting investors to revive the plant. In early December 2007 the "Fuel-Energetic Union" has bought the plant property on the open auction. Now here is created a modern facility for manufacturing the principally new product, biobutanol, a fuel of second generation, that can be distributed at world market. The project is supported by Open join stock company "United Industrial Corporation of Defence Industry" (Oboronprom, Russia). For its realization is created Open join stock company "East Siberian Holding of Biotechnology."

New owners have planned investment 500 millions RUR and attract qualified specialists, including those formerly employed at hydrolysis plant. After initiation of the plant the number of employed will be 500 people and will be created additional jobs in agriculture and forest branch.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Physicochemical Modification of Nanodiamonds

I. I. Obraztsova and N. K. Eremenko

Received June 18, 2007

Abstract—Thermal modification of nanodiamonds in the atmosphere of argon and hydrogen and their chemical modification with oleum and chlorine at different temperatures were studied. The effect of the modification conditions on the catalytic activity of palladium catalysts supported by nanodiamonds in the reaction of nitrobenzene hydrogenation and on the adsorption properties of nanodiamonds with respect to benzene, chloroform, and water was analysed.

DOI: 10.1134/S107042720804006X

The increased scientific and practical interest in synthesis and study of substances in the nanostate is due to the fact that they possess new functional properties because the size of nanoparticles is in the range 10^{-9}–10^{-7} m, which is comparable with that of molecules. An object of this kind are nanodiamonds (ND) produced by detonation synthesis with explosives having a negative oxygen balance in a nonoxidative medium, which yields a carbon stock containing the diamond fraction.

The recovery and purification of ND or, as they are also named, utradispersed diamonds (UDD) can be divided into the gas- and liquid-phase methods. Oxygen and air are used in the first case, and oxidizing mixtures (H_2SO_4–HNO_3, HNO_3–$HClO_4$, HNO_3–H_2SO_4–$H_2S_2O_7$, etc.), in the second [1–4]. In the process, new functional groups are added to those already present on the UDD surface, depending on the recovery technique.

The presence of functional groups with various chemical compositions on the surface of ND predetermines their widely diverse and unique properties. Therefore, methods used to modify ND may be of key importance for various applications.

At present, nanodiamonds are used in electrodeposited metal–diamond coatings, antifriction additives, various lubricants, lubricating-cooling fluids for physical modification of ferrolacquer coatings of magnetic tapes and disks, as composite materials in polymeric films and membranes, in various rubbers, and as carriers of biological and medicinal preparations [5, 6].

Development of methods for controlling the chemical composition of the nanodiamond surface by varying the amount and nature of functional groups opens the way to their modification for creating new types of ND, including those with a multifunctional surface composition.

In this study, thermal and chemical modification of nanodiamonds was carried out in order to expand the application fields of UDD.

EXPERIMENTAL

ND recovered from a detonation diamond stock by the previously developed technique [4, 7] and additionally dried in air at 150°C was used in the study.

ND were thermally treated for 4 h in a quartz reactor similar to that used for determining carbon and hydrogen in organic compounds [8]. Argon or hydrogen served as a carrier gas. Prior to an experiment, the system was purged with carrier gas for 10 min. The released water was absorbed with anhydrone and its amount was found from the increase in the mass of this drying agent. Carbon dioxide was absorbed with a $Ba(OH)_2$ solution of a known concentration (with subsequent titration with 0.2 N HCl). The amount of the released carbon monoxide was found by its absorption with an acetone solution of palladium(II), with metallic palladium recovered and the unreacted Pd^{2+} gravimetrically determined with dimethylglyoxime [9].

Table 1. Amounts of released products in relation to the thermal treatment conditions of nanodiamonds

T, °C	Concentration, mmol g^{-1} ND				
	CO_2		H_2O		CO
	Ar	H_2	Ar	H_2	Ar
200	0.19 ± 0.01	0.30 ± 0.01	1.73 ± 0.10	2.20 ± 0.12	–
400	1.85 ± 0.07	1.00 ± 0.03	2.03 ± 0.04	3.83 ± 0.25	0.38 ± 0.02
600	7.00 ± 0.16	1.23 ± 0.03	5.60 ± 0.03	5.31 ± 0.06	4.44 ± 0.12
800	4.81 ± 0.08	0.98 ± 0.04	0.86 ± 0.03	7.53 ± 0.07	6.01 ± 0.09

To study the adsorption properties of ND, a weighed portion of ND was calcined at a prescribed temperature for 4 h, cooled in a desiccator over $CaCl_2$, weighed, and placed in a desiccator with various solvents (water, benzene, and chloroform) at 21°C. The amount of an adsorbed reagent was found from the increase in the weighed portion of ND and then the procedure was repeated many times to constant weight of the sample.

The time in which equilibrium was attained was, for all the samples, 14 days in chloroform, 28 days in water, and 21 and 2 days in benzene for samples modified in argon and hydrogen, respectively.

Samples were sulfated by boiling in oleum at 180°C for 20 h. ND were chlorinated with molecular chlorine in a flow-through quartz reactor at 400 and 600°C. Chlorine and sulfur in the samples was determined by the procedure described in [8].

Nitrobenzene was hydrogenated under an atmospheric pressure of hydrogen. The method used to synthesize palladium catalysts and nitrobenzene (NB) hydrogenation conditions were the same as those in [10], but, in some cases, the catalyst was prepared without triphenylphosphine.

IR spectra were measured on a Bruker Tensor-27 IR Fourier spectrometer with a diffuse-reflection attachment.

In thermal treatment of nanodiamonds in inert (Ar) and reducing (H_2) atmospheres, the products are formed in different relative amounts (see Table 1).

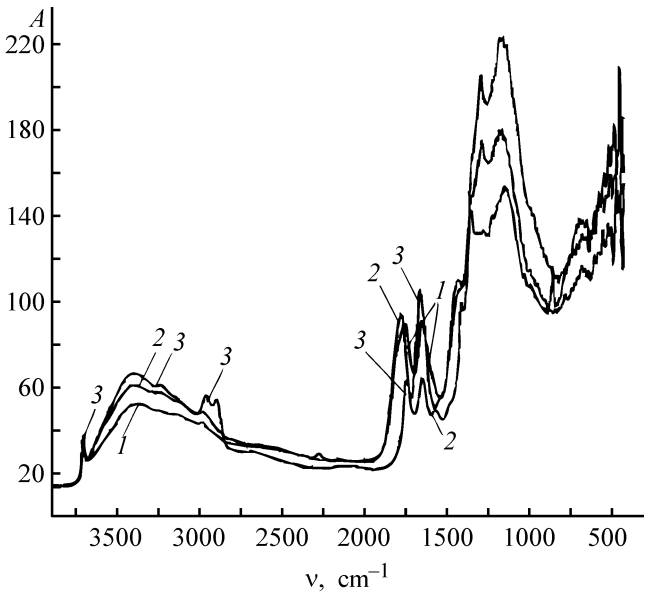
The amount of carbon dioxide formed in the inert atmosphere of argon exceeds that produced in the reducing atmosphere of hydrogen. This occurs because mainly decarbonization of various carbonyl-containing groups (=C=O, –COOH, =COH) and removal of –OH groups and adsorbed water from, the ND surface occur in Ar at temperatures below 600°C. At temperatures of 600–800°C, processes in which carbon monoxide is released start to predominate, which is accompanied by a decrease in the released amounts of CO_2 and H_2O (0.89 mmol g^{-1} ND at 800°C). The formation of CO can be attributed to interaction of carbon dioxide and water with the surface carbon of nanodiamonds. The release of CO commences in the temperature range 300–400°C and its amount increases with temperature.

In the reducing atmosphere, the modifying gas interacts with the ND surface in a different way. It can be seen that the amount of released water grows and reaches the maximum value at 800°C, whereas in the argon atmosphere, it sharply decreases.

All these phenomena are accounted for by the occurrence of reducing reactions with hydrogen on the nanodiamond surface. As it is believed by the authors of [11], hydrogen is adsorbed on the ND surface at treatment temperatures below 300°C. However, this temperature is sufficient, as also in the case of thermal desorption in a flow of Ar, for the decarbonization and dehydration processes to commence. As the modification temperature is raised further (in the range 300–600°C), hydrogen reacts with oxygen-containing groups, which results in that the amount of water released in thermal treatment below 600°C exceeds that of carbon dioxide. At temperatures of 600–800°C, hydrogen continues to react with the ND surface, which results in the maximum release of water at 800°C. The decrease in the amount of CO_2 formed in H_2 at this temperature is possibly also due to the reaction of carbon dioxide with the surface, but it is impossible to determine the amount of CO released, because, in the method used, palladium acetate is reduced by the modifying hydrogen gas to metallic palladium.

The assumptions that chemical reactions occur on the ND surface in the course of modification at various temperatures are in agreement with IR spectroscopic data obtained in this study and previously [11, 12]. The modification leads to pronounced changes in the position and intensity of absorption bands associated with carbonyl groups (see figure). Treatment at 400°C in argon shifts the peak of the band at 1730 cm^{-1} to the range 1780–1790 cm^{-1}, which indicates that –C(O)–O–C(O)– structures are formed. Modification with hydrogen gives rise to an absorption band associated with isolated –OH groups (~3680 cm^{-1}) and to absorption bands at 2938 and 2867 cm^{-1}, which point to the presence of C–H bonds at the carbon atom. The changes in the IR spectra confirm that the modification of nanodiamonds change the chemical state of their surface.

After treatment with oleum, the content of sulfur in the samples modified in hydrogen and argon was 0.26 and 0.30%, respectively. A more prolonged sulfation (up to 100 h) did not lead to any increase in the content of sulfur in the samples. Probably, these conditions are insufficient for complete sulfation of nanodiamonds; however, the IR spectra obtained after treatment with oleum clearly show a new band at 620 cm^{-1}, characteristic of sulfo groups.



Various ND samples were chlorinated at 400 and 600°C. The results obtained are listed in Table 2.

It can be seen that chlorination of the starting sample and that modified in argon at 600°C results in that the content of chlorine increases with the chlorination temperature, whereas for samples modified in hydrogen, the content of chlorine remains constant and is independent of the ND treatment conditions and chlorination temperature.

The effect of the ND surface modification conditions on the catalytic activity of palladium catalysts supported by nanodiamonds was studied in the reaction of NB hydrogenation, chosen as the model reaction. The results obtained are listed in Table 3.

Modification of the ND surface affects the catalytic activity of nanodiamond-supported palladium catalysts in the reaction of NB hydrogenation. The relative amounts of surface groups vary with the modification conditions [13], and this circumstance is responsible for the difference in the average reaction rates. In thermal treatment, CO_2 and H_2O are removed from the surface the most easily, and phenol, ketone, and lactone groups, more difficultly [13].

As can be seen in Table 3, the highest activity is observed for the catalyst treated in a flow of argon at

IR diffuse reflection spectra of nanodiamonds. (*A*) Reflectance and (ν) wave number. (*1*) Starting sample and (*2*, *3*) that treated at 400°C with (*2*) argon and (*3*) hydrogen.

400°C (sample no. 2). As the treatment temperature is raised to 800°C, the activity of the samples modified in the atmosphere of argon somewhat falls, but remains twice that for the starting sample (sample no. 1).

Modification of nanodiamonds in the atmosphere of hydrogen (sample nos. 5–7) does not change the catalytic properties, compared with the starting ND (sample no. 1). In the case of treatment with argon, functional groups are removed and the nanodiamond surface is freed for NB adsorption, whereas in hydrogen, presumably only the chemical composition of the surface is changed (see figure).

Table 2. Effect of nanodiamond chlorination conditions on the chlorine content

ND treatment conditions	Chlorination temperature, °C	Chlorine content, %
Starting	400	11.0 ± 0.3
	600	16.0 ± 0.5
Ar, 600°C	400	8.8 ± 0.3
	600	12.0 ± 0.5
H_2, 600°C	400	10.6 ± 0.4
	600	10.6 ± 0.3
H_2, 800°C	400	10.6 ± 0.4

Table 3. Catalytic activity of catalysts produced in different support modification conditions (reaction conditions: 10 ml of ethanol, 0.3 ml of NB, weighed portion of nanodiamonds 50 mg, content of palladium 2%, temperature 40°C)

Sample no.	ND treatment conditions	W_{av},* l H_2/(g Pd min)	Sample no.	ND treatment conditions	W_{av},* l H_2/(g Pd min)
1	Starting	7.3 ± 0.2	8	600°C, oleum: Ar	13.5 ± 0.3
2	Ar: 400°C	17.5 ± 0.3	9	H_2	10.0 ± 0.2
3	600°C	16.8 ± 0.3	10	Cl_2: 400°C	13.7 ± 0.3
4	800°C	14.0 ± 0.2	11	600°C	11.0 ± 0.3
5	H_2: 400°C	4.3 ± 0.1	12	Ar, 600°C/Cl_2, 400°C	12.3 ± 0.3
6	600°C	5.3 ± 0.1	13	H_2, 600°C/Cl_2, 400°C	11.1 ± 0.2
7	800°C	6.4 ± 0.2	14	H_2, 800°C/Cl_2, 400°C	12.6 ± 0.2

* Average rate of NB hydrogenation.

Table 4. Effect of ND modification conditions on the amount of adsorption

Solvent	Adsorption, mmol g^{-1} at indicated modification temperature, °C								
	Starting ND	200	400	600	800	200	400	600	800
		Ar				H_2			
Benzene	12.3	12.6	12.7	13.2	13.6	11.4	12.1	18.7	24.9
Chloroform	13.5	14.0	14.2	14.5	14.9	14.3	14.5	14.7	15.8
Water	41.6	–	57.1	60.2	64.6	–	55.4	53.4	50.8

It can also be seen in Table 3 that modification of ND with sulfo and chloro groups makes the catalyst activity higher.

Thus, it can be concluded that the most efficient way to modify nanodiamonds is their thermal treatment in argon, which makes it possible to raise the rate of NB hydrogenation by more than a factor of 2, with ND used as a support for palladium catalysts. The nature of the support surface affects the formation of active centers in palladium catalysts and, accordingly, their catalytic activity.

A property important for various applications of nanodiamonds is their adsorption capacity. It was pointed out in [5] that UDD has a high adsorption capacity, 9 to 14 mmol g^{-1} for benzene vapor and 10.5 to 17 mmol g^{-1} for chloroform vapor, depending on a UDD brand. The adsorption properties of modified nanodiamond forms were studied. The adsorption capacity of ND for benzene, chloroform, and water vapors was determined (with an average determination error not exceeding 3 wt %). The results obtained are listed in Table 4.

It can be seen that the adsorption of chloroform is independent of the nanodiamond modification conditions and is virtually constant. Its average value is 14.55 mmol g^{-1}. The adsorption of benzene vapor on the surface of the starting nanodiamond and that modified in an inert atmosphere at various temperatures is also virtually constant, with its average value equal to 12.88 mmol g^{-1}.

Thus, the chemical composition of the ND surface (presence of functional groups of different types) weakly affects its adsorption properties. Presumably, the factor responsible for the adsorption of benzene and chloroform is the presence in a sample of sufficiently narrow pores, because nanodiamonds form stable aggregates from particles 4–5 nm in size. It should, however, be noted that the adsorption capacity for benzene vapor increases for samples modified in a flow of hydrogen, and, at the maximum thermal treatment temperature (800°C), the amount of adsorption is 24.9 mmol g^{-1}, which is more than two times the adsorption capacity of the starting ND and that modified in an inert atmosphere. Presumably, this is so because reduction reactions occur in the atmo-

sphere of hydrogen at high thermal treatment temperatures and, as a result, oxygen-containing groups are virtually absent on the nanodiamond surface and alkyl functional groups appear.

It should be noted that the maximum adsorption capacity for benzene vapor is reached in only 48 h for samples treated in a flow of hydrogen, and in 21 days for all other samples.

As can be seen in Table 4, the adsorption of water on the ND surface is two to three times that of benzene and chloroform. The adsorption capacity of samples treated in a flow of argon increases with the modification temperature and, at 800°C, exceeds that of the starting ND by a factor of 1.5. A somewhat different situation is observed for samples treated in a flow of hydrogen: the adsorption capacity slightly decreases as the sample modification temperature increases, but the amount of adsorption also exceeds that of the starting nanodiamonds. Probably, this is due to occurrence of reducing reactions in the course of thermal treatment in the atmosphere of hydrogen, with a large number of oxygen-containing groups reduced to hydrocarbon radicals at the maximum temperature (800°C). However, the adsorption capacity of samples treated in hydrogen is higher than that of the starting ND because, probably, adsorption occurs in this case at the remaining functional groups with which water forms hydrogen bonds and at active centers that appeared on the surface because of the desorption of other functional groups (amino groups, sulfo groups, etc.).

The high adsorption capacity of nanodiamonds for water can be attributed to the formation of hydrogen bonds with carboxy and hydroxy groups contained on the ND surface. Formation of strong chemical bonds between water and the ND surface is unlikely [14], which is confirmed by experiments on desorption of water from the surface with calcium chloride. Samples that absorbed water were placed in a desiccator with calcium chloride, and, after 4 days, the mass of the weighed portion of nanodiamonds took its original value. This experiment shows that a chemical interaction with the ND surface is unlikely, because chemisorption is a virtually irreversible process [15].

Thus, the higher (by a factor of 3–4.5) adsorption capacity of nanodiamonds for water, compared with chloroform and benzene, can be noted. Comparison of the amounts of adsorbed water (>100 wt %) rather unambiguously points to the physical mechanism of water adsorption in nanodiamond pores.

CONCLUSIONS

(1) Quantitative characteristics of thermal transformations of functional groups on the surface of nanodiamonds in their modification in various atmospheres were determined. It was found that a larger amount of carbon dioxide and water is released in thermal treatment of nanodiamonds in an inert atmosphere, and the maximum amount of carbon monoxide, at 800°C. In thermal treatment in a reducing atmosphere, the amount of released water exceeds that of carbon dioxide.

(2) The conditions of modification of the nanodiamond surface affect the catalytic activity of supported palladium catalysts in the reaction of nitrobenzene hydrogenation. Nanodiamonds thermally treated in the atmosphere of argon were found to be the best support for these catalysts (with the rate of nitrobenzene hydrogenation increasing by more than a factor of 2).

(3) A study of the effect of the modification conditions on the adsorption properties of nanodiamonds with respect to benzene, chloroform, and water demonstrated that the adsorption of chloroform vapor is independent of the conditions in which the nanodiamond surface is modified. The adsorption capacity for benzene vapor is independent of the modification temperature for samples treated in argon and increases with this temperature for samples treated in hydrogen. The adsorption capacity of nanodiamonds for water vapor is two to three times that for benzene and chloroform vapors.
