Abstract—Effect of introduction of sulfuric acid and sodium cations into phosphoric acid at 70°C on the solubility of lanthanides was studied.

DOI: 10.1134/S1070427208010011

In the dihydrate process of sulfuric acid decomposition of the Khibiny apatite concentrate, a noticeable part of lanthanides is contained in the wet-process phosphoric acid (WPPA) [1, 2]. Compared to the initial lanthanide composition of the apatite concentrate, these lanthanides are enriched in yttrium and elements from the middle of the lanthanide group [1], which predetermines the interest in a search for methods of their recovery.

Although the content of lanthanides in the apatite concentrate is rather constant, data on their distribution among WPPA and phosphogypsum are widely diverse. According to different reports, 20 to 40% of lanthanides pass from the Khibiny apatite concentrate into WPPA. For example, 34.6–53.0% of yttrium passes from the apatite concentrate into WPPA according to [1], and 80.6%, according to [2]. In WPPA samples from the Volkhov aluminum plant, the total content of lanthanides ΣLn_2O_3 varies from 1.42 to 2.3 g l^{-1}. The reasons for so different distributions of lanthanides among WPPA and phosphogypsum have not been analyzed.

Neutralization of the production WPPA with ammonia causes precipitation of phosphate concentrates containing the sum of lanthanides in an amount of 2.1–2.2 wt % [3]. Recovery of lanthanides from these concentrates is economically unfeasible. Therefore, a noticeable attention is being paid to the development of methods for crystallization of lanthanides directly from WPPA.

It has been suggested to crystallize the phosphate concentrate of lanthanides by thermal treatment of defluorinated WPPA in an autoclave at 200°C for 1 h [4]. This method is based on the fact that the solubility of lanthanide phosphates in phosphoric acid solutions decreases as temperature is elevated. The precipitate formed contained, on washing with a fivefold amount of water and drying, 15–24 wt % ΣLn_2O_3 and 15 wt % P_2O_5 and was strongly contaminated with calcium. The recovery of rare-earth elements (REE) into the precipitate was as high as 98%. Industrial application of this technique is unlikely because of the high energy expenditure and necessity for intricate apparatus.

According to the data of [5], lanthanides form in WPPA supersaturated solutions. Table 1 lists the calculated lanthanide concentrations that can be present in WPPA on the assumption that lanthanides from the

apatite concentrate completely dissolve in WPPA. The composition of the sum of lanthanides from the apatite concentrate is given according to [6]. The calculated lanthanide concentrations substantially exceed those experimentally found in WPPA from the dihydrate process at Ammofos Open Joint-Stock Company [1]. However, the data in Table 1 cannot serve as evidence that WPPA is supersaturated with lanthanides.

It has been reported that lanthanides can be recovered from WPPA by spontaneous crystallization on seeds composed of lanthanide phosphates or fluorides [7–9]. It has been shown that neutral lanthanide phosphate hemihydrates crystallize on phosphate seeds, and anhydrous lanthanide fluorides, on fluoride seeds. It has been found in tests of these techniques that the seeds are rapidly "poisoned" and the crystallization of lanthanides first becomes slower and then ceases at all [10, 11]. No satisfactory explanations of this effect have been found. It should be noted that hydrates of the types $YPO_4 \cdot 2H_2O$ [12], $LaPO_4 \cdot 2H_2O$ [13], and $CePO_4 \cdot xH_3PO_4 \cdot yH_2O$ [14], rather than hemihydrates, crystallize from aqueous orthophosphoric acid solutions corresponding in concentration to WPPA at 70–80°C.

To develop methods for recovery of lanthanides from WPPA by crystallization, it is necessary to study the fundamental aspects of the solubility of lanthanide compounds in phosphoric acid solutions.

The aim of our study was to examine the influence exerted by the concentrations of sulfuric acid and sodium ions on the solubility of lanthanides in phosphoric acid solutions at 70°C, the average temperature at which the apatite concentrate is subjected to hemihydrate decomposition, and to use the data obtained for recovery of a lanthanide concentrate from WPPA.

EXPERIMENTAL

We used a solution containing 38.5 wt % H_3PO_4 as a "base" solution. The solubility was studied at 70°C because the dihydrate process is commonly carried out at 70±5°C [15]. Chemicals of grade no worse than analytically pure were used. To a solution containing 38.5 wt % H_3PO_4 we added concentrated (96.5 wt %) H_2SO_4 and sodium sulfate, so that the prescribed concentrations of H_2SO_4 and Na_2SO_4 were reached. Lanthanide sulfates were introduced into the solution prepared. The resulting mixtures were kept in hermetically sealed vessels at 70±1°C until equilibrium was attained (≥168 h), which was judged from constancy of the results of analyses of liquid samples. The content of lanthanides in a separated liquid phase was found by oxalate gravimetry and atomic-emission spectroscopy with inductively coupled plasma on a Perkin–Elmer Plasma 400 instrument. The results of the analyses were in satisfactory agreement. The sodium concentration was determined by the atomic absorption method in an acetylene–air flame (Carl Zeiss AAS-30 instrument, Jena). The experimental data we obtained are listed in Tables 2 and 3.

It is known [16–23] that the solubility of lanthanide phosphates in sulfuric acid solutions depends on the kind of a lanthanide, phosphoric acid concentration, and temperature. At room temperature, the solu-

bility of phosphates of the cerium-group lanthanides is considerably lower than that of yttrium and yttrium-group lanthanides at all H_3PO_4 concentrations (Fig. 1).

The solubility of yttrium [12], lanthanum [13], cerium [14, 24], and europium [25] phosphates in phosphoric acid becomes lower as temperature is elevated. It has been shown that the solubility of yttrium, lanthanum, and cerium phosphates at 70–80°C grows as the concentration of phosphoric acid increases from 10 to 50–65 wt % [12–14, 24]. As the acid concentration increases further, the solubility varies only slightly. For a solution containing 38.6 wt % H_3PO_4, the solubility was, according to different reports, 0.15–0.20 g l^{-1} La_2O_3 for lanthanum phosphate at 70°C and about 0.48 g l^{-1} Ce_2O_3 for cerium phosphate at 80°C. The solubility of $EuPO_4 \cdot 0.5H_2O$ in boiling phosphoric acid of various

concentrations increases as the concentration of phosphoric acid is raised in the range 0.5–4 M and, accordingly, its boiling point grows in the interval 100.5–104°C [25].

At the same content of phosphoric acid, not exceeding 40 wt %, raising the temperature from 25 to 70–80°C reduces the solubility of lanthanide phosphates by a factor of 5–100. In more concentrated solutions, the temperature dependence becomes less pronounced.

The values obtained for the solubility of lanthanum and cerium in a sulfuric acid solution are in good agreement with the data of [13, 14, 24]. Table 2 shows that the solubility of samarium, europium, gadolinium, dysprosium, and erbium in phosphoric–sulfuric acid solutions at 70°C noticeably exceeds that of cerium-group lanthanides in solutions of the same composition. A similar dependence was also observed at 101°C [25]. It can be seen that the solubility of lanthanide phosphates hemihydrates in 2 M H_3PO_4 at 101°C increases with the atomic number of a rare-earth element and, for heavy elements, is hundreds of times the solubility of lanthanum phosphate [25]:

Lanthanide	c, g l^{-1}	Lanthanide	c, g l^{-1}
La_2O_3	0.0033	Dy_2O_3	0.186
Pr_2O_3	0.023	Ho_2O_3	0.264

Sm_2O_3	0.031	Yb_2O_3	0.453
Eu_2O_3	0.031	Lu_2O_3	0.597
Gd_2O_3	0.094		

Introduction of sulfuric acid into a phosphoric acid solution even in an amount of 0.5 wt % makes the solubility of lanthanides substantially higher (Table 1). It rapidly grows as the content of H_2SO_4 is raised to 10 wt % and becomes comparable with, or higher than that of lanthanide sulfates in water and aqueous sulfuric acid solutions containing H_2SO_4 in the same concentration (Tables 4, 5). This fact suggests that, under the conditions studied, lanthanides can exist in phosphoric–sulfuric acid solutions as sulfuric–phosphoric acid complexes whose solubility exceeds the solubility of not only hydrated phosphates, but also lanthanide sulfates.

Table 3 shows that sulfuric acid affects the solubility of lanthanides in a phosphoric acid solution in the presence of sodium sulfate in another way: an increase in the concentration of sulfuric acid favors a dramatic decrease in the solubility of the lanthanides studied. An increase in the concentration of sodium ions in solutions with equal concentrations of phosphoric and sulfuric acids also lowers the solubility of lanthanides. When sodium ions are present, the solubility of cerium-group lanthanides is also considerably lower that the solubilities of the other lanthanides studied.

The observed decrease in the sodium content of the solutions indicates that double lanthanide sodium sulfates can be formed in phosphoric–sulfuric acid solutions. The formation of double sulfates $NaLn(SO_4)_2\cdot H_2O$ (Ln = La, Ce, Pr, Nd, Sm, Eu, Gd) was confirmed by an X-ray phase analysis of bottom phases. It was found that, at a sulfuric acid content of up to 10 wt %, yttrium, erbium, and dysprosium are present in the bottom phase as a mixture of sulfates and double sulfates (Fig. 2). At higher sulfuric acid concentrations, X-ray phase analysis revealed only double sulfates. However, in this case too, presence of minor admixtures of sulfates that are difficultly determinable because of the close similarity of crystal structures is possible.

Thus, sodium present in phosphoric–sulfuric acid solutions promotes formation of double lanthanide

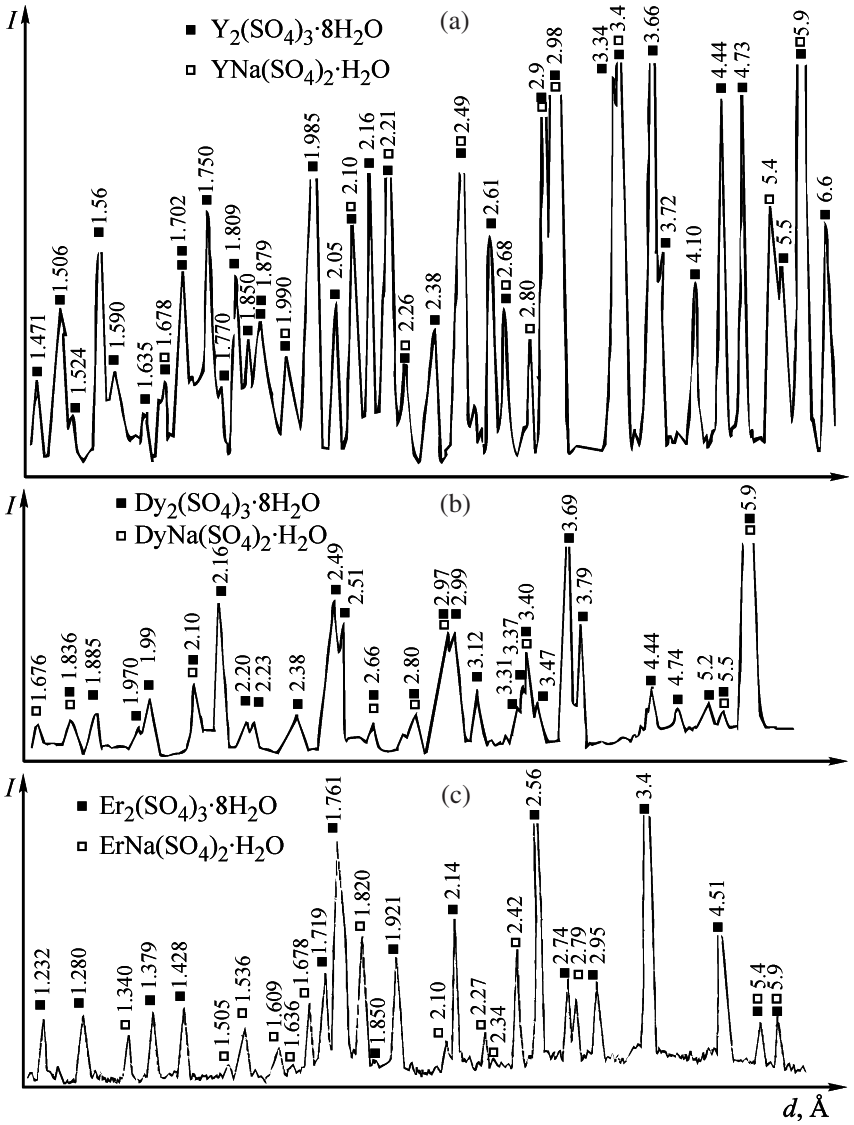

Fig. 2. X-ray diffraction patterns of bottom phases containing (a) yttrium, (b) dysprosium, and (c) erbium at $c_{H_2SO_4} < 10$ wt %. (*I*) Intensity and (*d*) interplanar spacing.

sulfates that are poorly soluble not only in sulfuric acid [27], but in phosphoric acid as well.

If it is assumed that double lanthanide sulfates dissociate by the reaction

$$NaLn(SO_4)_2 \longrightarrow Na^+ + Ln^{3+} + 2SO_4^{2-}, \quad (1)$$

then the solubility product (SP) is given by the equation

$$SP = [c_{Na^+}][c_{Ln^{3+}}][c_{SO_4^{2-}}]^2. \quad (2)$$

We used Eq. (2) and experimental data from Table 3 to calculate, taking into account that $c_{H_2SO_4}$ in Eq. (2) is found by summation of the concentration of the sulfuric acid introduced with that of sulfate ions of the dissolved lanthanide sulfates, the solubility products in sulfuric–phosphoric acid solutions in which the bottom phase is composed of only $NaLn \cdot (SO_4)_2 \cdot H_2O$ (Table 6). When calculating the volume concentrations of the components, we found the solution densities ρ by additive summation of the densities of 38.5 wt % H_3PO_4 and 96.5 wt % H_2SO_4.

The dihydrate decomposition of the apatite concentrate is commonly performed at 65–77°C. The WPPA concentration varies between different plants in the range 38.6–44 wt % [15]. The observed fluctuations of the content of lanthanides in the production WPPA from the dihydrate process cannot be attributed to

changes in the solubility of lanthanide phosphates at rather small differences in the concentration and temperature of WPPA.

However, the results obtained indicate that the solubility of lanthanides in a phosphoric acid solution is strongly affected by the concentration of sulfate ions and sodium cations always present in WPPA produced from the Khibiny apatite concentrate. Presumably, their varying content is the main reason why the distributions of lanthanides among WPPA and phosphogypsum are different in [1, 2].

We carried out a pilot study of the precipitation of lanthanides from WPPA (produced at Volkhov aluminum plant) with a concentration of 42.86 wt % and density of 1.276 g cm^{-3}, which contained (g l^{-1}): 2.30–2.65 ΣLn_2O_3, 19.3–22.3 CaO, 1.90 Na_2O, 0.80 K_2O, 1.82 TiO_2, 8.8 SiO_2, 6.7 Al_2O_3, 2.9 Fe_2O_3, and individual lanthanides 0.254 Y_2O_3, 0.59 La_2O_3, 0.93 CeO_2, 0.196 Pr_2O_3, 0.47 Nd_2O_3, 0.069 Sm_2O_3, 0.028 Eu_2O_3, 0.057 Gd_2O_3, 0.007 Tb_4O_7, 0.0275 Dy_2O_3, 0.0046 Ho_2O_3, 0.012 Er_2O_3, 0.008 Yb_2O_3. The experimental conditions and the data obtained are listed in Table 7.

Table 7. Residual concentration of lanthanides and calcium in WPPA in relation to increasing content of H_2SO_4 (T = 70°C)

Solution composition, wt %		Residual concentration, g l^{-1}	
H_2SO_4	H_3PO_4	ΣLn_2O_3	Ca(Sr)O
0	42.86	2.30	19.3
5	40.59	1.03	2.77
10	38.30	0.23	1.3
15	36.03	≤0.001	0.9

The composition of WPPA in the pilot study noticeably differed from that commonly obtained, but it made it possible to assess whether lanthanides can be recovered in principle. Table 7 shows that 90% of lanthanides precipitated at 70°C as the H_2SO_4 content of WPPA was raised to 10 wt % and the precipitation was complete as it was raised to 15 wt %. Thus, first, the residual content of lanthanides in WPPA containing 15 wt % H_2SO_4 was negligible and, second, not only the cerium-group lanthanides precipitated, but also the other lanthanides, whose concentration in WPPA was considerably lower than their solubility limit, i.e., a synergic effect was observed, in which more soluble double sulfates (possibly, sulfates or sulfatophosphates) cocrystallized with less soluble double sulfates. This is favored by the close crystal structures of these compounds.

It is noteworthy that the presence of 10–15 wt % H_2SO_4 in the recycle WPPA results in that 2–3 wt % H_2SO_4 is contained in the recycle sludge, which should not hinder its use for apatite decomposition, because this corresponds to the concentration range in which a well filterable phosphogypsum is obtained in the dihydrate process [15].

CONCLUSIONS

(1) Introduction of sulfuric acid into a phosphoric acid solution leads to a significant increase in the solubility of lanthanides, and introduction of sodium

cations causes a dramatic decrease in the solubility. This is due to the formation of double sulfates of lanthanides and sodium.

(2) The solubility products of double sulfates of lanthanum, cerium, praseodymium, neodymium, samarium, europium, and gadolinium in sulfuric–phosphoric acid solutions at 70°C were determined.

(3) The observed differences in the distribution of lanthanides among the liquid and solid phases can be attributed to differences in the content of free sulfuric acid and sodium cations in the wet-process phosphoric acid.

(4) Lanthanides are effectively precipitated from wet-process phosphoric acid if its content of H_2SO_4 is raised to 10–15 wt %.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Specific Features of Sulfuric Acid Leaching-out of Lanthanides from Phosphohemihydrate

E. P. Lokshin and O. A. Tareeva

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received February 6, 2007

Abstract—Effect of raising in the range 75–95°C the temperature at which hydrated lanthanide phosphates are synthesized on the degree of their chemical activity and, accordingly, on specific features of the sulfuric acid leaching was studied. The mechanism of restoration of the chemical activity of lanthanide compounds was considered.

DOI: 10.1134/S1070427208010023

Processing of the Khibiny apatite concentrate by the hemihydrate method to obtain wet-process phosphoric acid yields dump waste calcium sulfate hemihydrate [technical name of the product is phosphohemihydrate (PHH)], from which lanthanides can be effectively leached-out with sulfuric acid solutions containing up to 30 wt % H_2SO_4 [1].

However, a study of the leaching-out of lanthanides from PHH taken directly from filters (untreated PHH) demonstrated that the process developed is efficient for the product obtained at Voskresenskie Mineral'nye Udobreniya (Voskresensk Mineral Fertilizers) Open Joint-Stock Company (OAO) (the recovery of the sum of lanthanides into solution was as high as 83.9% under the optimal conditions) but inefficient for an untreated PHH manufactured by Ammofos OAO (Table 1). As seen from Table 1, the content of alkali metal impurities in the product is low and they could not prevent the leaching-out of lanthanides by forming double sulfates poorly soluble in sulfuric acid solutions [2].

Making longer the time during which the untreated PHH manufactured by Ammofos OAO is kept in a humid medium leads to conversion of calcium sulfate hemihydrate into its dihydrate (CSD), with the leaching-out of lanthanides with sulfuric acid solutions becoming more efficient (Table 2).

According to the information provided by the Research Institute of Chemical Fertilizers and Insectofungicides (NIUIF OAO), the processing technology of the apatite concentrate is the same at both plants. Therefore, it was necessary to understand why similarly obtained products behave so differently. It was suggested that the differences in the leaching-out of lanthanides from PHH produced at these plants may be due to the following. First, this may occur because of differences in the physicochemical properties of PHH, associated with different temperatures of decomposition of the apatite concentrate and(or) different sulfuric acid introduction modes. The second reason may consist in different chemical activities of hydrated lanthanide phosphates, caused by differences in the decomposition temperatures of the apatite concentrate.

According to the first hypothesis, grains formed in the phosphoric–sulfuric acid sludge and containing celestite and lanthanide phosphates, in which form main part of lanthanides are present in PHH [3], may be encapsulated in $2CaSO_4 \cdot H_2O$ crystals at Ammofos OAO because of a slightly different mode of the acid

Table 1. Kinetics of leaching-out of lanthanides from the untreated PHH from Ammofos OAO. $c_{H_2SO_4} \approx 23$ wt %, l : s = 2 : 1

τ, min	Concentration in solution, g l^{-1}					Recovered ΣLn_2O_3, %
	ΣLn_2O_3	CaO	Na_2O	K_2O	H_3PO_4

15	0.46	0.86	0.21	0.065	6.0	16.7
25	0.61	0.84	0.25	0.072	6.5	22.2
35	0.29	0.81	0.38	0.082	6.5	10.6
45	0.25	0.80	0.38	0.080	6.8	9.1

decomposition of apatite. As a result, they become inaccessible to the sulfuric acid solution. When PHH is stored in a humid medium, $CaSO_4 \cdot 0.5H_2O$ is transformed to $CaSO_4 \cdot 2H_2O$ with a noticeable increase in volume, which could lead to disruption of the integrity of the protective crust of calcium sulfate, which hinders contact with the sulfuric acid solution.

However, no more than 60 min is required for washed PHH to be completely converted to $CaSO_4 \cdot 2H_2O$ [4, 5]. Table 2 shows that this time is incomparably longer than that required to restore the "chemical activity" of lanthanide compounds present in PHH from Ammofos OAO.

The second hypothesis is based on the known fact that the chemical activity of lanthanide phosphates decreases as the degree of their hydration becomes lower. For example, anhydrous lanthanide phosphates are very chemically stable and are only sulfated at 180–200°C by concentrated H_2SO_4 [6]. In addition, the solubility of hydrated phosphates $LnPO_4 \cdot 1.5H_2O$ (Ln = La, Ce, Nd) in 1.5–5 M nitric acid solutions decreases upon partial dehydration of orthophosphate sesquihydrates at 200°C and becomes very low upon total dehydration [7].

It has been shown that hydrated crystalline lanthanide orthophosphates can be divided, as regards their thermal behavior, into two groups [8]. The first group, to which belong hexagonal orthophosphates of La to Tb and orthorhombic dysprosium orthophosphate, shows two dehydration-related endothermic effects at temperatures lower than 300°C. The second group includes tetragonal orthophosphates of yttrium and lanthanides from Ho to Tm, for which dehydration occurs in a wide temperature range 100–600°C. The onset temperatures of their dehydration are listed in Table 3.

The data in Table 3 should be considered tentative, because the products were synthesized by precipitation from boiling 2 M H_3PO_4 (bp 101°C [9]).

In the technique developed by NIUIF, the Khibiny apatite is commonly decomposed by the hemihydrate method at 90–97°C [10]. Table 3 demonstrates that partial dehydration of the hydrated phosphates $LnPO_4 \cdot H_2O$ is, in principle, possible at such temperatures.

Thus, a possible reason for differences in the behavior of lanthanides in sulfuric acid leaching is the certain difference between the temperatures of acid decomposition of the apatite concentrate at these plants, which leads to a decrease in the degree of hydration and, as a consequence, in the chemical activity of hydrated lanthanide phosphates as well.

Table 2. Efficiency of recovery of lanthanides at different storage times of PHH from Ammofos OAO. l : s = 2 : 1, leaching duration 25 min, $c_{H_2SO_4}$ = 25 wt %

The aim of our study was to analyze reasons for the decrease in the efficiency of the sulfuric acid leaching-out of lanthanides from the untreated phosphohemihydrate from Ammofos OAO, compared with the similar product from Voskresenskie Mineral'nye Udobreniya OAO, and reasons for the improvement of leaching-out of lanthanides in dump storage of phosphohemihydrate from Ammofos OAO.

EXPERIMENTAL

We used hydrated phosphates of lanthanum, cerium, and neodymium, because these elements largely determine the composition of the sum of lanthanides in the Khibiny apatite concentrate and, according to Table 3, the onset temperatures of their dehydration noticeably differ.

Hydrated lanthanum, cerium, and neodymium orthophosphates were precipitated at 900°C from aqueous solutions of their nitrates with 20% orthophosphoric acid, taken in a 20% excess with respect to

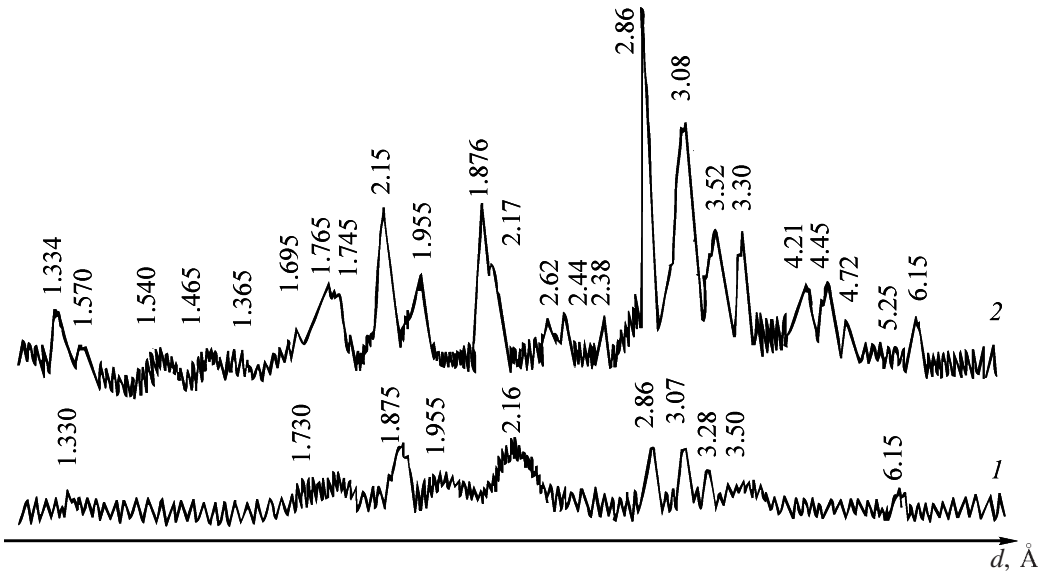
* Wet products kept in this state for 4 months.

the stoichiometry, by the reaction

$$Ln(NO_3)_3 + H_3PO_4 \rightarrow LnPO_4 + 3HNO_3. \quad (1)$$

After 12 h of keeping, gel-like precipitates were separated by centrifugation, thoroughly washed with water to remove nitrate ions and the excess amount of phosphoric acid, dried in a vacuum at 200°C, and ground in a mortar. The untreated products were amorphous. The products calcined at 900°C were orthophosphates $LnPO_4$ according to X-ray phase (XPA) and chemical analyses. According to the results of a thermogravimetric analysis (TGA), the phosphates synthesized were $LaPO_4 \cdot 1.5H_2O$, $CePO_4 \cdot 1.5H_2O$, and $NdPO_4 \cdot H_2O$.

The phosphates were additionally wetted with 70 wt % H_3PO_4 and subjected to thermal treatment at 25, 75, 85, and 95°C, with moisture not allowed to evaporate (mode 1). We assumed that this yields hydrated orthophosphates whose degree of hydration corresponds to that of orthophosphates formed in the untreated PHH under different thermal conditions of its synthesis (75, 85, and 95°C).



The products synthesized were subjected to various additional treatments. First, wet products thoroughly washed with water to remove orthophosphoric acid were kept for 1 month at room temperature in hermetically sealed vessels, without evaporation of the moisture that they contain (mode 2).

In addition, wet products washed with water to remove phosphoric acid in a hermetically sealed vessel for 1 month were mixed either with phosphogypsum and K_2SiF_6 taken in a mass ratio of 1 : 4 : 0.9, or only with K_2SiF_6 at a mass ratio of 1 : 0.9, or only with phosphogypsum wetted with 2 wt % H_3PO_4, taken in a mass ratio of 1 : 4. These mixtures were also kept at room temperature in hermetically sealed vessels, to give products processed in modes 3, 4, and 5, respectively.

Weighed portions were leached for 25 min with a solution containing 26 wt % H_2SO_4 and 1.5 g l^{-1} Na_2O. The solution composition and the leaching time corresponded to the optimal conditions used in sulfuric acid leaching of PHH. The s : l ratio was sufficient for providing the solubility of double lanthanide sulfates that could be formed in leaching. The amount of lanthanides that passed into solution was determined by methods described in [2]. The experimental results are listed in Table 4.

It is known that the solubility of hydrated Ce, La, and Nd orthophosphates in HNO_3 solutions with concentrations of 1.5–5 M noticeably decreases as the content of crystal hydrate water becomes lower, which is provided by elevating the thermal treatment temperature [7].

Table 4 shows that the solubility of hydrated phosphates thermally treated at 75–95°C is substantially lower than that of hydrated phosphates obtained at 25°C. We assumed that, for samples obtained in modes 1 and 2, the decrease in the solubility of hydrated phosphates thermally treated at 75–95°C, compared with the solubility of the product synthesized at 25°C, indirectly characterizes the change in the number of water molecules bound to $LnPO_4$.

X-ray diffraction patterns of hydrated cerium phosphate prepared at 75°C in mode 2. The product was (*1*) stored in a humid atmosphere for 1 month and (*2*) ground in a porcelain mortar during a short time. (*d*) Interplanar spacing.

As the thermal treatment temperature is raised from 75 to 95°C, the solubility of the phosphates in sulfuric acid solutions decreases (run nos. 2–4). The most pronounced decrease in the solubility (by a factor of 4) was observed for lanthanum and cerium phosphates. The solubility of neodymium phosphate decreases to a somewhat lesser extent, although its dehydration onset temperature is the lowest [8].

The solubility of wet products washed to remove phosphoric acid and kept for 1 month was even lower (run nos. 6–9), with an increase in the keeping time to 4 months further impairing the solubility of hydrated lanthanum and neodymium phosphates (run no. 7). The XPA data in the figure suggest that the decrease in solubility is due to aging, upon which amorphous products start to crystallize (X-ray diffraction pattern *1*). Short-term grinding of the aged products in a porcelain mortar resulted in a dramatic acceleration of the crystallization of the hydrated phosphates studied (diffraction pattern *2*).

Thus, the "spontaneous" restoration of the chemical activity of lanthanide phosphates, assumed to possibly proceed because the degree of hydration of lanthanide phosphates returns to its initial value upon their prolonged storage in a humid medium, does not occur. Consequently, the chemical activity is restored via chemical interaction of lanthanide phosphates with the PHH components. We believe that the most important of these components is phosphoric acid or SiF_6^{2-} ions present in noticeable concentrations in the dump waste PHH.

The effect of impurity components of PHH on the restoration of the chemical activity of lanthanide phosphates was studied on the least soluble samples obtained by thermal treatment at 85 and 95°C.

Phosphoric acid may find its way into dump waste PHH by two channels. First, PHH contains minor amounts of H_3PO_4 unremoved by washing. Second, silicofluorides contained in dump waste PHH are hydrolyzed if the acidity of the aqueous decreases, with the formation of hydrofluoric acid by the reactions

$$Na_2SiF_6 + (2 + n)H_2O = SiO_2 \cdot n\,H_2O\downarrow + 4HF + 2NaF, \quad (2)$$

$$K_2SiF_6 + (2 + n)H_2O = SiO_2 \cdot n\,H_2O\downarrow + 4HF + 2KF. \quad (3)$$

It can be assumed that, in storage of PHH, hydrofluoric acid reacts with $CaHPO_4$ or residual undecomposed apatite in accordance with the equations

$$CaHPO_4 + 2HF = CaF_2\downarrow + H_3PO_4, \quad (4)$$

$$Ca_5(PO_4)_3F + 9HF = 5CaF_2\downarrow + 3H_3PO_4. \quad (5)$$

As the concentration of H_3PO_4 increases, it interacts with hydrated lanthanide phosphates to give acid phosphates that are more soluble in acids by the reaction

$$LnPO_4 \cdot m\,H_2O + xH_3PO_4 = LaPO_4 \cdot x\,H_3PO_4 \cdot m\,H_2O. \quad (6)$$

However, the solubility of the samples obtained in mode 5 (run no. 12) became even lower, compared with the results of run no. 9. Thus, free phosphoric

acid does not favor restoration of the chemical activity of hydrated lanthanide phosphates.

A processing in modes 3 and 4 resulted in a substantial increase in the solubility of the hydrated phosphates. However, the solubility of cerium phosphate increased to a lesser extent, compared with lanthanum and neodymium phosphates. The results of run nos. 10 and 11 suggest that it is the hydrolysis of SiF_6^{2-} ions that restores the chemical activity of hydrated lanthanide phosphates, because the activity of the lanthanide phosphates was not restored upon storage for the same time of preliminarily dried mixtures of the same composition. Therefore, the most probable mechanism improving the solubility of the hydrated phosphates processed in modes 3 and 4 is associated with the occurrence of the reaction

$$LnPO_4 \cdot xH_2O + 3HF = LnF_3\downarrow + H_3PO_4 + xH_2O. \quad (7)$$

Lanthanide fluorides are fairly well soluble in sulfuric acid solutions. For example, the solubility of LaF_3 in 2.3 M H_2SO_4 at room temperature is 1 g l^{-1} (in terms of La_2O_3) [11] and the solubilities of CeF_3 and NdF_3 in terms of oxides are approximately 0.7 and 3 g l^{-1}, respectively.

Although the XPA method failed to confirm the formation of MF_3, probably because of the ultradispersity of the particles being formed, the fractions of lanthanides that passed into solution in run nos. 10 and 11 correlate with the above solubilities of lanthanide fluorides, which confirms this hypothesis.

CONCLUSIONS

(1) In thermal treatment of wet lanthanide orthophosphates $LnPO_4 \cdot (1–1.5)H_2O$ (Ln = La, Ce, or Nd) in the presence of 70 wt % H_3PO_4 (conditions of their formation in hemihydrate decomposition of the apatite concentrate), raising the thermal treatment temperature from 75 to 95°C lowers their solubility in a sulfuric acid solution by a factor of 3–4, probably because of a decrease in the degree of their dehydration. Consequently, a slight increase in the temperature of the hemihydrate process of phosphoric acid decomposition of the Khibiny apatite may lead to a pronounced decrease in the chemical activity of hydrated lanthanide orthophosphates.

(2) Prolonged keeping in a humid atmosphere of the hydrated lanthanide orthophosphates synthesized hinders their dissolution in a sulfuric acid solution to an even greater extent, which is due to their "aging" and the onset of crystallization of the amorphous product.

(3) Presence of SiF_6^{2-} ions in a mixture of low-active lanthanide phosphates with phosphohemihydrate or K_2SiF_6, stored for a long time in a humid medium, leads to an increase in the efficiency of sulfuric acid leaching-out of lanthanides.

(4) The results obtained make it possible to explain the experimentally observed decrease in the efficiency of sulfuric acid leaching-out of lanthanides from the untreated phosphohemihydrate from Ammofos OAO, compared with the product manufactured in a similar way at Voskresenskie Mineral'nye Udobreniya OAO, and the improvement of the leaching-out of lanthanides upon prolonged storage of the phosphohemihydrate from Ammofos OAO.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Oxidation of Hydrogen Chloride with Hydrogen Peroxide in Aqueous Solution

V. I. Skudaev, A. B. Solomonov, A. I. Morozovskii, and N. A. Isakov

Perm State Technical University, Perm, Russia

Received June 20, 2005; in final form, October 2007

Abstract—Evolution of chlorine into the gas phase upon mixing of aqueous solutions of hydrogen chloride and hydrogen peroxide was studied. The threshold hydrogen chloride concentration corresponding to the onset of the chlorine evolution was determined.

DOI: 10.1134/S1070427208010035

From the standpoint of use of chlorine raw materials and in the environmental respect, utilization of exhaust (abgas) hydrogen chloride is one of the problems of industrial organochlorine synthesis. The basic methods for processing abgas hydrogen chloride are its deep purification and processes of hydrochlorination and oxidative chlorination [1, 2]. Certain success has been achieved in the development of chemistry and technology of the latter methods. Application of oxidative chlorination is impeded by low productivity of the method itself, which in most cases is limited by oxidation of hydrogen chloride with oxygen or air. The most commonly applied catalysts are copper(I) and copper(II) chlorides. Attempts to develop a more effective catalyst based on compounds of other metals did not ensure process intensification to an extent at which the oxidation rate of hydrogen chloride and the chlorination rate of an organic compound are comparable [3].

In this connection, efforts are made to intensify the process by applying other oxidants that are more effective than oxygen. Among the compounds tested are nitrogen(II) and nitrogen(IV) oxides, chromium(VI) oxide, ozone, and chlorine(I) and chlorine(IV) oxides. An undoubted advantage of the above oxidants is that they ensure the required rate of the hydrogen chloride oxidation even at a temperature close to 300 K. The oxidative chlorination of olefins from C_2 to C_6 and of aromatic hydrocarbons in the HCl–H_2O_2 system with the HCl conversion exceeding 70% was reported [4]. At the same time, the limiting stage of the process involving the oxidation of hydrogen chloride with hydrogen peroxide remains unknown. Therefore, for the subsequent development of the process control it is urgent to establish the formal kinetic features of chlorine evolution into the gas phase.

EXPERIMENTAL

In a temperature-controlled glass reactor with the temperature set in the range 298–348 K, 30% hydrogen peroxide (pure grade) was mixed with water, after which hydrochloric acid was added. This sequence of introducing the components ensured their fast mixing owing to high density of the latter component [5]. The released chlorine and a potassium iodide solution reacted in an absorber to form iodine, which was used for titrimetric determination of the amount of the released chlorine [6]. The oxygen formed was collected in a gas meter via rheometer to obtain data on the dynamics and amount of the released gas. The initial concentration of hydrogen peroxide before mixing with hydrochloric acid was determined by iodometric titration, and that of hydrochloric acid, by the density at 293 K. In most cases, the hydrogen chloride concentration exceeded by more than an order of magnitude the concentration of hydrogen peroxide, which made its control in the course of the reaction unnecessary. The measurements were performed only at the beginning and at the end of the experiment. Initially, when testing the procedure, we simultaneously performed the chemical analysis.

After the experiment was complete, chlorine dissolved in a solution was removed from the reactor with a gas flow and was absorbed with a potassium iodide solution. In this case, the possibility of the

oxidation of iodide ion with concomitant gases was checked when testing the procedure. In the blank experiments involving bubbling of nitrogen through a hydrogen peroxide solution and then through a solution of potassium iodide, no iodine was detected. Bubbling of oxygen through a potassium iodide solution did not result in the formation of iodine either.

Table 1 illustrates how the concentrations of hydrogen chloride c_1 and hydrogen peroxide c_2 vary with time of oxidation of hydrogen chloride with hydrogen peroxide in aqueous solution. The reaction rates are given in Table 2. The current concentrations of hydrogen chloride and hydrogen peroxide were calculated from the amounts of the forming chlorine and oxygen. The rate of chlorine evolution into the gas phase was determined as the ratio of the chlorine amount trapped by the absorber to the solution volume and time. The reaction orders, as purely formal quantities that can be used for the mathematical description of variations of rate with the concentration of the initial substances, were calculated by the Correlia 2005 computer program from data of Table 2. Four parameters can be determined simultaneously: two partial orders of reaction, activation energy, and preexponential factor [7]. The activation energy was calculated from the results of the experiments at different temperatures (Table 2). The satisfactory character of the mathematical description obtained is confirmed by good coincidence of the calculated rates with the experimental values. The rate equation obtained can be used for the analysis of variations of the rate of chlorine formation with hydrogen chloride concentration at a given concentration of hydrogen peroxide. Also, it illustrates the occurrence of the threshold hydrogen chloride concentration in a solution, below which chlorine is not released. The calculation shows that at a hydrogen chloride concentration c_1 lower than 5 M there is virtually no chlorine liberation. The formal kinetic order with respect to hydrogen chloride, estimated from these data, is larger than 8. Therefore, it may be suggested that only the concentration that is in excess over a threshold value must be put in the rate equation: $c_e = c_1 - c_0$. The experimental threshold concentration c_0 lies within 4–5 M, whereas the value calculated from the reaction order corresponding to the lowest error is 5.2 M. The activation energy E is 100 kJ mol^{-1}. The derived formal rate equation has the form

$$\nu = 4.8 \times 10^{13} \exp(-E/RT) c_e^{1.1} c_2^{2.3} \text{ mol l}^{-1} \text{ s}^{-1},$$

where c_2 is the concentration of hydrogen peroxide in solution.

329	6.13	0.363	6.53	5.615
329	6.5	0.363	7.83	8.116
329	7.02	0.363	10.8	11.752
317	7.02	0.363	2.67	2.943
337	7.02	0.363	41.4	28.002
347	7.02	0.363	60.5	78.362

Evidently, the reaction studied is complex. The obtained formal rate equation allows us to suggest the stages that account for the experimental results. First of all, this refers to the presence of the threshold concentration of hydrochloric acid:

$$H_2O_2 + HCl \rightleftarrows H_2O_2 \cdot HCl, \quad (1)$$

$$H_2O_2 \cdot HCl \rightarrow H_2O + HOCl, \quad (2)$$

$$HOCl + HCl \rightleftarrows H_2O + Cl_2, \quad (3)$$

$$HOCl + H_2O_2 \rightarrow H_2O + HCl + O_2, \quad (4)$$

$$H_2O_2 + Cl_2 \rightarrow 2HCl + O_2 \quad (5)$$

The fact that the complex $H_2O_2 \cdot HCl$ can be

formed in the stage of the oxidation of hydrochloric acid in HOCl was reported elsewhere [5, 8].

The rate of chlorine formation by reaction (3) depends on the concentrations of hydrogen chloride and hydrogen peroxide. The dissolved chlorine is hydrolyzed by reverse reaction (3) and reduced by reaction (5).

The rate of the above reactions is proportional to chlorine concentration in the solution, which is limited by the solubility. When the solubility is exceeded, chlorine is released into gas phase. The rate of the chlorine formation in the steady-state mode is equal to the rate of its consumption up to a certain value of the HCl concentration. At a higher concentration, chlorine starts to evolve into the gas phase.

CONCLUSIONS

(1) The oxidation of hydrogen chloride with hydrogen peroxide at common temperature with the evolution of chlorine into the gas phase occurs at a hydrogen chloride concentration in a solution exceeding the threshold value (5.2 M).

(2) The obtained formal rate equation for the oxidation of hydrogen chloride with hydrogen peroxide makes it possible to calculate the rate of the chlorine evolution into the gas phase. The results are accounted for from the standpoint of the occurrence of the threshold concentration of hydrogen chloride.

Abstract—Molybdate phosphates $Na_{1-y}Zr_2(MoO_4)_y(PO_4)_{3-y}$ (y = 0, 0.25, 0.5) having the $NaZr_2(PO_4)_3$ structure were prepared by the sol–gel method. The catalytic properties of the molybdate phosphates in dehydration and dehydrogenation of methanol in inert and oxidizing atmospheres were studied.

DOI: 10.1134/S1070427208010047

Framework phosphates that are structural analogs of sodium dizirconium orthophosphate $NaZr_2(PO_4)_3$ (NZP) have a flexible structure allowing iso- and heterovalent substitutions in both cationic and anionic positions without significant changes in the crystallographic characteristics of the basis lattice [1].

Wide isomorphism of various types of cations leads to disbalance of charges in the structure, caused by geometric features of the arrangement of the adjacent polyhedra, and to appearance of local and cooperative distortions. Thus it becomes possible to control the concentration and strength of both Brønsted and Lewis acid centers. Therefore, such phosphates show promise as heterogeneous catalysts for many acid–base (isomerization, dehydration) and redox (selective oxidation of paraffins, dehydrogenation) processes [2–11]. They are also convenient model objects for studying the correlations between the activity and chemical composition of a catalyst, structural characteristics, ionic charges and radii, surface area, acidity, etc.

Previously [12] we considered crystal-chemical features of the incorporation of Mo into various crystallographic positions of the NZP structure depending on the synthesis conditions. We noted that Mo(IV) occupies octahedral positions of the NZP framework, and Mo(VI), tetrahedral positions. In the latter case, molybdate phosphates are formed under the conditions of free air access at relatively low temperatures (873 K), and they are chemically stable. The structure of alkali metal zirconium molybdate phosphates $A_{1-y}Zr_2(MoO_4)_y(PO_4)_{3-y}$, where A = Na ($0 \le y \le 0.6$), K ($0 \le y \le 0.3$), Rb ($0 \le y \le 0.2$), Cs ($0 \le y \le 0.1$), crystallizing in the NZP structural type, was simulated in [13] by minimization of the interatomic interaction energy. The results of computer simulation of the structure were confirmed experimentally.

In this study we examined the possibility of using molybdate phosphates $Na_{1-y}Zr_2(MoO_4)_y(PO_4)_{3-y}$ as convenient objects for model studies of their catalytic properties in methanol transformations in inert (Ar) and oxidizing (air) atmospheres. The dehydration and dehydrogenation of methanol can yield dimethyl ether (promising additive to diesel fuel), formaldehyde, hydrogen, carbon oxides, and other products. Our goal was to prepare the molybdate phosphates $Na_{1-y}Zr_2 \cdot (MoO_4)_y(PO_4)_{3-y}$ (y = 0, 0.25, 0.5), characterize their surface properties, and examine their catalytic activity in methanol transformations in the inert and oxidizing atmospheres.

EXPERIMENTAL

The molybdate phosphates $Na_{1-y}Zr_2(MoO_4)_y \cdot (PO_4)_{3-y}$ were prepared from the following chemically pure grade chemicals: zirconium oxochloride $ZrOCl_2 \cdot 8H_2O$, phosphoric acid H_3PO_4, sodium chloride NaCl, and ammonium paramolybdate $(NH_4)_6 \cdot Mo_7O_{24} \cdot 4H_2O$. Weighed portions of ammonium paramolybdate were dissolved in a small amount of water, and 1 M solutions of sodium chloride and zirconium oxochloride were added in stoichiometric

Table 1. Results of microprobe analysis, surface area, and acidity of molybdate phosphates $Na_{1-y}Zr_2(MoO_4)_y(PO_4)_{3-y}$

amounts. Then a stoichiometric amount of 1 M H_3PO_4 was added with continuous stirring at 343 K. The resulting gel was dried at 363 and 473 K and then heat-treated with free access of air at 873 and 923 K for no less than 24 h in each step, with intermediate grindings to ensure homogenization of the mixtures. The optimal mode of the heat treatment was chosen in accordance with the previous data [12].

The chemical composition and homogeneity of the molybdate phosphate samples were monitored with a CamScan MV-2300 scanning electron microscope (VEGA TS 5130MM), equipped with YAG detectors of secondary and reflected electrons and a Link INCA ENERGY 200C energy-dispersive X-ray microanalyzer with a Si(Li) semiconductor detector. When calculating the composition, we used the PAP correction method. The results of the microprobe analysis confirmed the homogeneity of the samples and were consistent with the theoretical composition (Table 1). The molybdate phosphates were polycrystalline powders with the prevalent crystallite size of 1–10 μm.

The phase composition of the samples was determined by X-ray phase analysis (XPA) with a DRON 3M diffractometer using Ni-filtered CuK_α radiation in the angle range $2\theta = 10°–50°$. The patterns were recorded at a rate of 2 deg min^{-1}. X-ray diffraction data for the synthesized $Na_{1-y}Zr_2(MoO_4)_y(PO_4)_{3-y}$ samples show that the positions and intensities of the diffraction maxima are close to those given in [11] and that the samples belong to the NZP structural type. The calculated unit cell parameters of the molybdate phosphates are given in Table 2.

The specific surface area of the molybdate phosphates was calculated from the adsorption–desorption isotherms obtained with a Micrometritics ASAP 2020 installation by the method of capillary condensation of nitrogen at 77 K. The acidity of the samples was calculated from the curves of temperature-programmed desorption of ammonia. The calculation results are given in Table 1. An increase in the molybdenum content of the samples led to their sintering in the course of the synthesis and to a decrease in the surface area and acidity.

The catalytic properties of the molybdate phosphates in methanol transformations were studied in a flow-through reactor in argon or air flow at atmospheric pressure in the temperature range 450–700 K. A 0.300-g portion of molybdate phosphate was mixed with quartz (mean particle size 1 mm). Saturated methanol vapor from a temperature-controlled bubbler was fed into the reactor in a flow of a carrier gas (Ar or air) at a total rate of 1.2 l h^{-1}. The ratio of the space velocities of methanol and oxygen was 1 : 4.6. The reaction products were analyzed with an LKhM-5 chromatograph equipped with a thermal conductivity detector and with columns packed with activated carbon and Porapak T. The chromatograms were processed with a computer. From the results of the analysis, we calculated the methanol conversion x (%), selectivity S (%), and yields of target products A (mmol h^{-1} g^{-1}) by the formulas

$$x = \frac{(\varphi_0 - \varphi_1)}{\varphi_0} \times 100, \quad S = \frac{\varphi_t}{(\varphi_0 - \varphi_1)} \times 100, \quad A = \frac{FxS}{W},$$

where φ_0 and φ_1 are the initial and running volume fractions of methanol; φ_t, fraction of methanol consumed in the target reaction; F, rate of feeding methanol vapor (mmol h^{-1}); and W, catalyst weight (g).

The calculated amounts of methanol consumed and products formed in all the catalytic experiments agree with the material balance within the measurement error (±3%).

In the series of $Na_{1-y}Zr_2(MoO_4)_y(PO_4)_{3-y}$ samples, the phosphate $NaZr_2(PO_4)_3$ ($y = 0$) showed the

highest catalytic activity and nearly 100% selectivity in the dehydration of methanol to dimethyl ether (DME) in an argon flow:

$$2CH_3OH \rightleftarrows CH_3OCH_3 + H_2O. \quad (1)$$

The methanol conversion is close to the equilibrium value, 89%, at 600 K. The phosphate $NaZr_2(PO_4)_3$ well competes as methanol dehydration catalyst with other phosphates $AZr_2(PO_4)_3$ (A = K, Rb, Cs, $Mg_{0.5}$, $Ca_{0.5}$, $Ba_{0.5}$, $Zr_{0.25}$) [6], synthetic aluminosilicates, aluminophosphates, composites based on oxides of aluminum and titanium or titanium and zirconium, and commercially produced DME–FCAT catalyst (Haldor Topsoe). It shows higher productivity and ensures almost equilibrium conversion at 2–5 times higher loads (Table 3). The activity of catalysts in methanol dehydration is associated with their acid properties, which are determined by Brønsted acid centers (–OH) present on the surface of the compounds and by coordination-unsaturated cations having high charge, exerting a strong polarizing effect, and thus acting as electron density acceptors (Lewis acid centers) [15]. It was shown [5] that on the surface of the phosphate $Zr_{0.25}Zr_2(PO_4)_3$ (NZP structural type) there are strong (Zr–OH) and weak (P–OH) Brønsted acids centers and Lewis acid senters (Zr^{4+}). The schemes of formation of the adsorption complexes of methanol with acid centers of zirconium-containing phosphates are, presumably, as follows:

$$Zr–OH + O(H)CH_3 \rightleftarrows Zr–OH\text{---}O(H)CH_3,$$

$$Zr^{4+} + O(H)CH_3 \rightleftarrows Zr^{4+}\text{---}O(H)CH_3.$$

Apparently, higher activity (with respect to converted methanol) of zirconium-containing phosphates in the dehydration of methanol, compared to known alcohol dehydration catalysts, is due to higher concentration and optimal strength of acid centers on the surface.

The methanol conversion on molybdate–phosphate catalysts in an Ar atmosphere reached 93% (Fig. 1). This value is higher than the equilibrium conversion

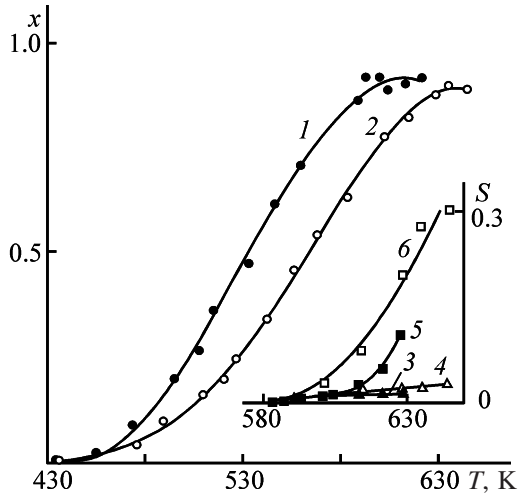

Fig. 1. (*1*, *2*) Conversion x and selectivity S of (*3*, *4*) dehydrogenation and (*5*, *6*) methanol decomposition in an inert atmosphere on molybdate phosphates $Na_{1-y}Zr_2(MoO_4)_y \cdot (PO_4)_{3-y}$ with (*1*, *3*, *5*) y = 0.25 and (*2*, *4*, *6*) y = 0.5, as functions of temperature T.

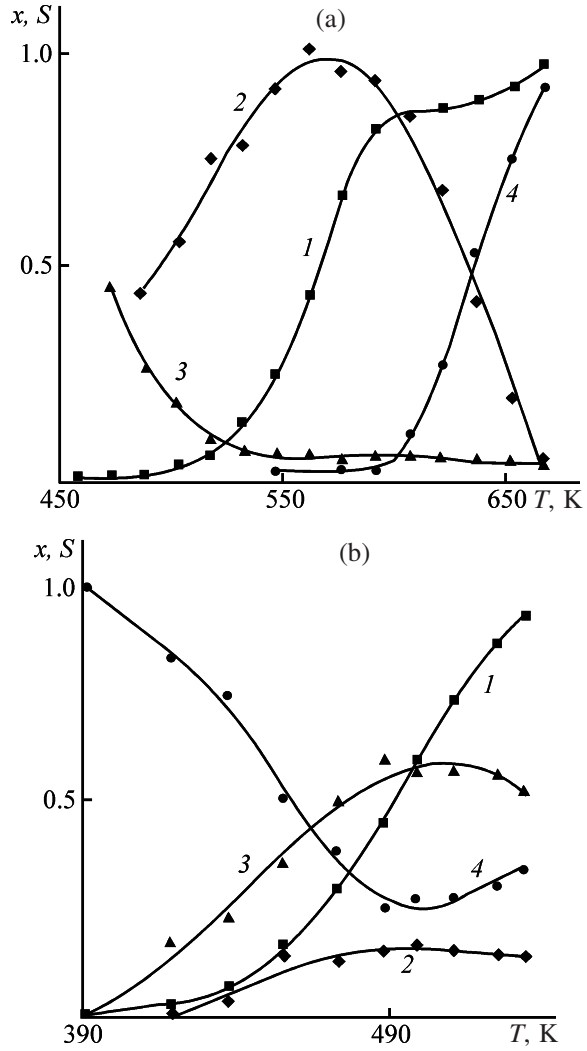

FIg. 2. (*1*) Conversion x and selectivity S of (*2*) dehydration, (*3*) dehydrogenation, and (*4*) decomposition of methanol on (a) $NaZr_2(PO_4)_3$ and (b) $Na_{0.5}Zr_2(MoO_4)_{0.5}(PO_4)_{2.5}$ in oxidizing atmosphere, as functions of temperature T.

of methanol in the dehydration (88–90%) in the examined temperature range, which is due to parallel occurrence of the dehydration (selectivity 66–100%), dehydrogenation to formaldehyde, and decomposition to carbon oxides. At temperatures above 620 K, the selectivity of methanol dehydrogenation and decomposition reached 3 and 30%, respectively (Fig. 1). With respect to the methanol conversion on molybdate phosphates at the same temperature, the most active catalyst was $Na_{0.75}Zr_2(MoO)_{0.25}(PO_4)_{2.75}$ (y = 0.25), and $Na_{0.5}Zr_2(MoO)_{0.5}(PO_4)_{2.5}$ (y = 0.5) was less active. The difference in the alcohol conversion was 20–25%. The molybdate phosphate with y = 0.25 is more active than that with y = 0.5 in methanol dehydration but less active in methanol dehydrogenation. For the sample with y = 0.25, the maximal amount of methanol converted along the dehydration pathway at 593 K was 6.5 mmol h^{-1} g^{-1}, and the dehydrogenation selectivity was 1%; for the sample with y = 0.5, the respective quantities were 4.9 mmol h^{-1} g^{-1} and 3% at the same temperature. This difference is attributable to larger specific surface area and acidity of the former sample and its lower molybdenum content, as the methanol dehydration is a typical acid-catalyzed reaction, whereas the components responsible for dehydrogenation are transition metal (Mo) atoms.

In all the experiments, the hydrogen yield was 2–10 times lower than the value corresponding to the amounts of the dehydrogenation and decomposition products. Furthermore, the hydrogen yield decreased with an increase in the molybdenum content of the catalyst. These facts are apparently due to the reduction of the Mo(VI) ions in the molybdate phosphates with the formation of water. This assumption also accounts for the observed decrease with time of the activity of the molybdate phosphates in the methanol dehydrogenation and an increase in the dehydration selectivity in the course of catalytic experiments, and also for the fact that the amount of water formed exceeds (by ~6%) the quantity corresponding to the amount of dimethyl ether formed.

When the catalytic experiments with the molybdate phosphates (y = 0.25 and 0.5) were performed in an oxidizing atmosphere, among methanol transformation products we also detected formaldehyde and carbon oxides, along with dimethyl ether and water. The temperature dependence of the selectivity of the methanol dehydration [reaction (1)] on $NaZr_2(PO_4)_3$ passes through a maximum (97%) at 570 K and gradually decreases to 5% at 670 K (Fig. 2a).

Simultaneously with a decrease in the selectivity of the methanol dehydration, the yield of water and selectivity of formation of carbon oxides increase (the latter, to 92%). The maximal conversion of methanol reached 96%, at the catalyst activity with respect to converted methanol of 7.2 mmol h^{-1} g^{-1}. We believe that the observed trend is due to the occurrence of exhaustive oxidation of both methanol [Eq. (2)] and its dehydration product, dimethyl ether [Eq. (3)]:

$$CH_3OH + 1.5O_2 \rightleftarrows CO_2 + 2H_2O, \quad (2)$$

$$CH_3OCH_3 + 3O_2 \rightleftarrows 2CO_2 + 3H_2O. \quad (3)$$

Reactions (2) and (3) are characterized by a definite ratio of the amounts of the converted reactants and formed products; therefore, to determine the tempera-

ture ranges of the occurrence of reactions (2) and (3), we plotted the ratios of the methanol consumption and product formation.

Below 550 K, according to the experimental data, the H_2O/CO_2 ratio is less than 1.5, which contradicts Eqs. (2) and (3) and suggests the occurrence of an additional pathway of the formation of carbon oxides. Apparently, such a pathway is conversion of methanol with water vapor:

$$CH_3OH + H_2O \rightleftarrows CO_2 + 3H_2, \quad (4)$$

with water formed by dehydration of methanol [reaction (1)]. Simultaneous occurrence of reactions (3) and (4) can lead to the H_2O/CO_2 ratio less than 1.5. When calculating the amount of methanol consumed for the formation of dimethyl ether that burnt out in reaction (3), we took into account the amounts of methanol consumed in reactions (2) and (4) and of water released in these reactions. In so doing, we took into account the molar ratios of the participants of reaction (1): $CH_3OH/CH_3OCH_3 = 2$, $CH_3OCH_3/H_2O = 1$.

The maximum of the formation of dimethyl ether (560–580 K) corresponds to the ratio $H_2O/CO_2 = 1.5$, suggesting the occurrence of reaction (3). With a further increase in the temperature, this ratio increased to 2, and the CH_3OH/CO_2 and CH_3OH/H_2O ratios simultaneously approached 1 and 0.5, respectively, suggesting the occurrence of reaction (2).

The selectivity of $NaZr_2(PO_4)_3$ with respect to formaldehyde formation in an oxidizing atmosphere was virtually constant, about 6%. As this phosphate contains no metals that can change the oxidation state and thus act as possible active centers of methanol dehydrogenation, the formation of formaldehyde can be accounted for as follows. On the surface of zirconium-containing phosphates there are Lewis acid centers Zr^{4+} [5]. The Zr^{4+} ion is coordination-unsaturated and has vacant 4*d* orbitals owing to which it can adsorb oxygen having free 2*p* electrons. The reaction of such adsorbed complex with a methanol molecule apparently yields formaldehyde with the regeneration of the Zr^{4+} ion:

$$Zr^{4+}O_{ads} + CH_3OH \rightarrow Zr^{4+} + CH_2O + H_2O. \quad (5)$$

The low yield of the dehydrogenation products is due to the low capability of the Zr^{4+} ion for oxygen adsorption.

On molybdate phosphates with $y = 0.25$ and 0.5 in an oxidizing medium, the rate of methanol dehydrogenation increases. The complete conversion of methanol occurs at temperatures 100 K lower than in an inert atmosphere. $Na_{0.5}Zr_2(MoO_4)_{0.5}(PO_4)_{2.5}$ is the most active (3.6 mmol h^{-1} g^{-1} of formaldehyde) and selective (56–60%) in methanol dehydrogenation, with the dehydration selectivity being less than 16% (Fig. 2b). Increased yield of the dehydrogenation products on molybdate phosphates in an oxidizing atmosphere is due to permanent regeneration of active centers, Mo(VI), whereas in an inert atmosphere, as shown above, their amount and the catalyst activity decrease with time.

CONCLUSIONS

(1) Framework molybdate phosphates of the $Na \cdot Zr_2(PO_4)_3$ structural type, $Na_{1-y}Zr_2(MoO_4)_y(PO_4)_{3-y}$ ($y = 0$, 0.25, 0.5), were prepared by the sol–gel method and characterized by X-ray diffraction, electron microprobe analysis, capillary condensation of nitrogen, and temperature-programmed desorption of ammonia.

(2) Molybdate phosphates were studied in methanol transformations in inert (Ar) and oxidizing (air) atmospheres. The main products formed in an inert atmosphere are dimethyl ether and water. In the process, $NaZr_2(PO_4)_3$ well competes with the known catalysts of methanol dehydration. Oxidative dehydrogenation of methanol in the presence of air yielded formaldehyde with up to 60% selectivity.

(3) The activity of molybdate phosphates in the dehydration and dehydrogenation of methanol depends on the surface properties and concentration of molybdenum ions in the phosphate structure.

Abstract—The polythermal solubility of fullerene C_{60} and a fullerene mixture (60 wt % C_{60} + 39 wt % C_{70} + 1 wt % higher fullerenes C_n, n = 76, 78, 84, 90...) in valeric and caproic acids was studied in the temperature range 20–80°C. The solubility diagrams are presented and characterized.

DOI: 10.1134/S1070427208010059

The paper completes a series of studies devoted to the polythermal solubility of fullerene C_{60} and a fullerene mixture (C_{60} + C_{70} + C_n, n = 76, 78, 84, 90...) in saturated monocarboxylic acids $C_{n-1}H_{2n-1}COOH$ (n = 1–9) that are liquid at room temperature [1–3].

Studies of the solubility of fullerenes are of primary importance for developing the crystallization and extraction methods of separation of fullerenes from a fullerene-containing carbon black, for studying chemical reactions with participation of fullerenes, and for developing methods of chromatographic and prechromatographic separation of a fullerene mixture into individual fullerene components [4–6].

EXPERIMENTAL

In the experiments we used fullerene C_{60} of 99.9% purity containing about 0.07 wt % C_{70}, a fullerene mixture 60 wt % C_{60} + 39 wt % C_{70} + 1 wt % C_n (n = 76, 78, 84, 90...) from ILIP (Innovations of Leningrad Institutes and Enterprises) Private Company (St. Petersburg), *o*-xylene (analytically pure grade), and caproic and valeric acids (chemically pure grade).

Experimentally, the polythermal solubility of both the individual fullerene C_{60} and a fullerene mixture was studied by the isothermal saturation method in the temperature range 20–80°C on a temperature-controlled shaker [1–3].

The concentrations of C_{60} and a fullerene mixture after each step of saturation were determined spectrophotometrically on a Specord M-32 spectrophotometer at λ 335.5 and 472.0 nm. The method of the analysis is reported in [7].

Hereinafter, the presence of minor amounts (about 1 wt %) of higher fullerenes C_n (n = 76, 78, 84, 90...) in the analysis was neglected.

The solvent content of crystal solvates was determined as follows. The solid phase that just precipitated from a carboxylic acid solution was washed twice with ethanol, dried at 20°C for 30 min, and weighed. Then, the resulting solid was repeatedly refluxed with ethanol in a Soxhlet apparatus (78°C, 1 atm), vacuum-dried at 200°C (0.1 mm Hg) for 1 h, and weighed again. The solvent content of the initial crystal solvate (or solid solution of fullerenes on its basis) was determined as the weight loss.

Figure 1 shows the electronic absorption spectra of the individual fullerene C_{60} and a fullerene mixture in caproic acid. Similar spectra were obtained in valeric acid. It is easily seen that the recorded spectra are stable and fully correspond to the absorption spectra of light fullerenes in one-component aromatic solvents (benzene, toluene, *o*-xylene, and *o*-dichlorobenzene) [7], so that the use of empirical relationships from [7] for calculating the concentrations of light fullerenes is quite reasonable in the given case.

Figure 2 shows six solubility polytherms of C_{60} and fullerene mixture in caproic and valeric acids.

20	184.4	423.5	303.2
30	196.7	405.1	290.9
40	186.1	344.3	275.0
50	170.4	315.4	262.6
60	146.3	310.3	257.6
70	135.2	241.2	254.3
80	127.1	257.8	315.2

The table lists experimental polythermal data on the solubility of individual C_{60} and of C_{60} and C_{70} from the fullerene mixture in these acids.

The temperature dependences of the C_{60} solubility in these acids are close: a slight monotonic increase with temperature at relatively low temperatures, then singular break point, and a monotonic decrease at high temperatures. Thus, the solubility diagrams for C_{60} in both acids consist of two solubility branches: a low-temperature branch (crystallization of fullerene monosolvate C_{60}–$C_{60} \cdot C_{n-1}H_{2n-1}COOH$) and a high-temperature branch (crystallization of unsolvated C_{60}). All diagrams contain one nonvariant through-pass point [8, 9], which corresponds to simultaneous saturation with both solid phases. This run of the polythermal dependences (Fig. 2) is rather typical of C_{60} and is in satisfactory agreement with the solubility data available from the literature [10]. Similar run is also observed for the solubility of light fullerenes C_{60} and C_{70} from the fullerene mixture in both acids. As in the previous case, each diagram consists of two solubility branches and has one nonvariant break point.

Figure 3 shows how the content (wt %) of C_{60} in a mixture of light fullerenes C_{60} + C_{70} in the saturated liquid solution varies with temperature. It can be readily seen that valeric and caproic acids exert the opposite effects. In valeric acid, the liquid phase is

always enriched in fullerene C_{60} relative to a solid solution at all temperatures, whereas in caproic acid, the liquid phase is always depleted of this fullerene. It is also seen from Fig. 3 that, with increasing temperature, the liquid phases based on both acids become richer in a more polarizable fullerene C_{70}, with the liquid solution based on caproic acid at 80°C enriched by more than 15 wt % relative to the initial solid solution being dissolved. This effect can be used in practice in cascade recrystallization for prechromatographic isolation of fullerene C_{70}.

CONCLUSIONS

(1) The solubility diagrams of the binary systems C_{60}–valeric acid and C_{60}–caproic acid were obtained; the temperature dependences of the solubility are nonmonotonic, which corresponds to the solvation mechanism of dissolution.

(2) In the case of valeric acid, the liquid phase is enriched in fullerene C_{60} in comparison with the solid solution at all temperatures, whereas in the case of caproic acid, the liquid phase is always enriched in fullerene C_{70}.

(3) The prospects for using valeric and caproic acids as solvents for prechromatographic isolation of light fullerenes were demonstrated.

Abstract—The kinetics of decomposition of hydrogen peroxide in the liquid phase of the ternary system $LiOH–H_2O_2–H_2O$ was studied in the presence the solid phase of $Li_2O_2 \cdot H_2O$ and without it. The main kinetic parameters of the processes studied were determined.

DOI: 10.1134/S1070427208010060

To prepare peroxides of alkali and alkaline-earth metals (principal components of products for chemical regeneration of air in closed volumes), hydrogen peroxide and a hydroxide of the corresponding metal are commonly used as starting components. Peroxo solvates of varied chemical composition, obtained by crystallization from the solution, are then dehydrated to form dry peroxides (Li, Na, Ca, Ba) and superoxides (K, Rb, Cs) [1–8]. In this case, to prepare the products containing the maximum amount of the main substance, water must be removed during dehydration as quickly as possible, and its amount should be as low as possible, to avoid the reaction of the formed peroxides or superoxides with water vapor [9]. At the same time, to choose the optimal process parameters, it is necessary to determine the temperature and concentration conditions ensuring the crystallization of peroxo solvates of varied chemical composition from the $MOH–H_2O_2–H_2O$ ternary systems (M is alkali metal), which is complicated by the known experimental difficulties associated with instability of liquid and solid phases. The catalytic decomposition of peroxy compounds, occurring in the process under the action of hydroxide anions, is exothermic, which affects the temperature conditions of the study. Owing to relatively high solubility of the forming peroxo solvates, a fast shift of figurative points along the solubility curve toward lower hydrogen peroxide concentrations is observed as a consequence of the above phenomena. The decomposition rate of hydrogen peroxide solutions in the presence of hydroxides of alkali and alkaline-earth metals increases in the order $LiOH–NaOH–KOH–Ca(OH)_2–Ba(OH)_2$ [2].

At the same time, in the development of a process for the synthesis of lithium peroxide from lithium hydroxide and hydrogen peroxide [10], stabilization of a liquid phase of the ternary system $LiOH–H_2O_2–H_2O$ by the solid phase of $Li_2O_2 \cdot H_2O$ was revealed. This work continues our previous studies and concerns the kinetic parameters of the above interesting phenomenon.

EXPERIMENTAL

In all experiments, we used lithium hydroxide and 50% hydrogen peroxide (ultrapure grade). The effect exerted by the solid phase on the kinetics of decomposition of the liquid phase of the ternary system $LiOH–H_2O_2–H_2O$ was estimated experimentally in the temperature range from 21 to 33°C (hydrogen peroxide concentrations in the liquid phase 1.56–5.67 and 1.82–6.43 wt %, respectively), because the solid phase of the composition $Li_2O_2 \cdot H_2O$ crystallizes under these conditions, which was confirmed previously by chemical and qualitative X-ray phase analyses of the $LiOH–H_2O_2–H_2O$ system studied by the solubility method [10].

It is well known that the catalytic decomposition of hydrogen peroxide and peroxide-containing products in a liquid phase involves two constituents: homogeneous catalysis by ions present in the solution and heterogeneous catalysis by the reactor walls and solid phases constituting the system studied [11, 12]. To make experiments identical, all reactors had the same shape (Pyrex glass cylinders, $r = 4$ cm). In the course

of the experiments, the ratio of the surface area in contact with the liquid phase of the systems studied to their volume was the same ($S/V \approx 0.67$ cm^{-1} = const). This ensured constant contribution of the hydrogen peroxide decomposition on the reactor walls in all experiments [13].

Prior to performing the main experiments, all reactors were passivated with a solution under study at 70–75°C for 24 h. The kinetic data became reproducible after three preliminary passivations.

It was established [14] that hydrogen peroxide is accumulated in the solution in air owing to more intense evaporation of water (at 20°C, the water vapor pressure is 17.5 mm Hg, and hydrogen peroxide vapor pressure is 1.36 mm Hg). Therefore, to prevent removal of water from the solution studied and thus to decrease the experimental error, the reactors with the samples studied were closed and equipped with reflux condensers. With these precautions, the loss of water due to incomplete condensation in the examined range of temperatures was as low as 0.3 wt % throughout the experiment.

In the experiments, to hydrogen peroxide, which was thermostated on a water bath to within ±0.2°C, we added a required amount of lithium hydroxide at a rate chosen so as to avoid temperature changes exceeding 0.5°C. Thus, we prepared simultaneously two samples. Sample no. 1 was used as prepared, whereas from sample no. 2, the solid phase was separated on a Büchner funnel at the experimental temperature (the composition of the solid phase corresponded to the formula $Li_2O_2 \cdot H_2O$, as indicated by chemical and X-ray phase analyses). Samples under study were placed in a thermostat, and the kinetics of decomposition of hydrogen peroxide in the liquid phase was studied. The thermostat was in a dark room throughout the experiment. The mass of the reactors with the samples studied was also measured throughout the experiment. The liquid phase in the systems studied was analyzed by permanganatometric titration over a certain period of time, and the content of hydrogen peroxide in it was determined with an accuracy of ±0.01% [15].

Figure 1 shows the kinetics of the hydrogen peroxide decomposition in the LiOH–H_2O_2–H_2O ternary system containing 6.09 wt % hydrogen peroxide in the liquid phase at T = 30°C. The shapes of the kinetic curves of decomposition of the liquid phase in the LiOH–H_2O_2–H_2O system in the presence of the solid phase of $Li_2O_2 \cdot H_2O$ and without it at the above temperatures and concentrations are similar.

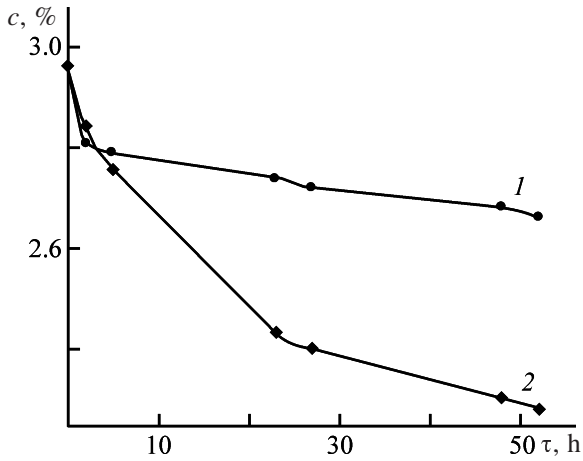

Fig. 1. Kinetic curves of decomposition of the liquid phase of the LiOH–H_2O_2–H_2O system (*1*) in the presence of the solid phase of $Li_2O_2 \cdot H_2O$ and (*2*) without it. (*c*) Content of available oxygen and (τ) time.

Curve *1* characterizes the decomposition of hydrogen peroxide in the liquid phase in the system containing the solid phase of $Li_2O_2 \cdot H_2O$, and curve *2*, the decomposition of hydrogen peroxide in the liquid phase after filtering the solid phase off. The initial section of curve *1*, wherein the concentration of available oxygen in the liquid phase of the LiOH–H_2O_2–H_2O ternary system decreases from 2.96 to 2.81% at constancy of its mass, corresponds to attainment of the phase equilibrium. The equilibrium state (compositions of liquid and solid phases are constant) can be considered to be attained 2 h after mixing the initial components. Similar results were obtained for the studied system containing from 2 to 6 wt % hydrogen peroxide in the liquid phase in the temperature range 21–33°C.

The obtained kinetic curves of the decomposition of hydrogen peroxide in the liquid phase of the LiOH–H_2O_2–H_2O system were treated by the equation for monomolecular reaction:

$$\ln(c_0/c) = k(\tau - \tau_0), \quad (1)$$

where c_0 and c are the contents of available oxygen in the solution studied at times τ_0 and τ, respectively.

In calculating the constants of hydrogen peroxide decomposition in the liquid phase of the system studied in the presence of the solid phase, the time of attainment of the phase equilibrium was assumed to be the initial point.

The temperature dependence of the rate constants of the processes studied k within the temperature

Kinetic parameters of decomposition of the liquid phase of the $LiOH–H_2O_2–H_2O$ ternary system in the presence of the solid phase of composition $Li_2O_2 \cdot H_2O$ (sample no. 1) and without it (sample no. 2)

Sample no.	T, °C	$k \times 10^{-5}$, min^{-1}	Average temperature coefficient γ	Activation energy E_a, kJ mol^{-1}, as calculated by	
				formula (4)	formula (3)
1	21	0.612	3.252	86.12	90.69
	26	1.17			
	30	1.83			
	33	2.52			
2	21	3.98	2.326	62.54	66.02
	26	5.75			
	30	8.37			
	33	10.96			

range 21–33°C is described by the Arrhenius equation

$$k = Ae^{-E_a/RT}, \quad (2)$$

where A is the Arrhenius coefficient for the given reaction, proportional to the number of collisions of active molecules, and E_a, apparent activation energy of the process.

The temperature dependence of the rate constants in Arrhenius coordinates for the decomposition of hydrogen peroxide in the liquid phase is shown in Fig. 2. The activation energy of the processes was calculated, using the presented plots, by the formula [16]

$$E_a = 19.11 \tan\alpha\xi, \quad (3)$$

where $\tan\alpha$ is the slope of the straight line and ξ, the abscissa-to-ordinate scale ratio.

The activation energy of the processes studied was also calculated using the temperature dependence of the time in which the conversion reaches a given value. For the static mode of the experiment, this method of determination of the activation energy yields more correct E_a values in comparison with the calculation based on the reaction rate constants [16, 17]. In the calculation, we used the equation

$$E_a = 4.58 \log(\tau_{T_1}/\tau_{T_2})(1/T_1 - 1/T_2)^{-1}, \quad (4)$$

where T_1 and T_2 are experimental temperatures; τ_{T_1} and τ_{T_2} are times in which 20% of hydrogen peroxide in the liquid phase of the system studied decomposes at temperatures T_1 and T_2, respectively.

The results obtained, as calculated from three replicate experiments, are listed in Table 1.

For the temperature range considered, we calculated, using formula (5), the average temperature coefficients of the rates of decomposition of hydrogen peroxide in the liquid phase of the $LiOH–H_2O_2–H_2O$ ternary system in the presence of the solid phase of $Li_2O_2 \cdot H_2O$ and without it:

$$\log k_{T_1}/k_{T_2} = \log\gamma(T_2 - T_1)/10, \quad (5)$$

where k_{T_1} and k_{T_2} are the rate constants of the reactions at temperatures T_1 and T_2, respectively.

The average temperature coefficients that we found are also listed in Table 1.

Table 1 shows that the solid phase of $Li_2O_2 \cdot H_2O$ in the $LiOH–H_2O_2–H_2O$ ternary system inhibits the decomposition of hydrogen peroxide in the liquid phase. The fact that the activation energies of decomposition of hydrogen peroxide in the liquid phase, obtained by different methods, are virtually the same

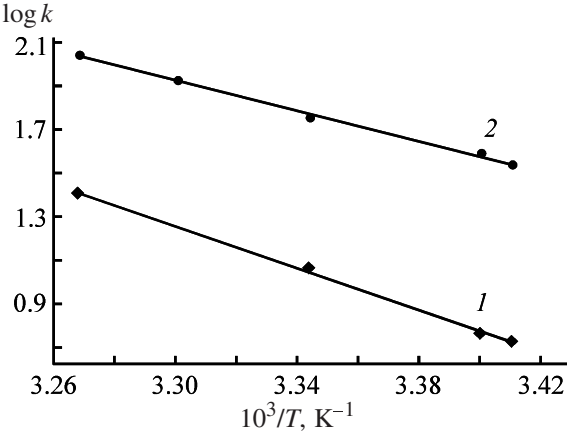

Fig. 2. Temperature dependence of rate constants k of liquid phase decomposition in the $LiOH–H_2O_2–H_2O$ system (*1*) in the presence of the solid phase of $Li_2O_2 \cdot H_2O$ and (*2*) without it.

shows that the suggested rate equation for the reaction is correct.

CONCLUSIONS

(1) The kinetics of decomposition of the liquid phase of the ternary system $LiOH–H_2O_2–H_2O$ in the temperature range from 21 to 33°C (hydrogen peroxide concentrations in the liquid phase 1.56–5.67 and 1.82–6.43 wt %, respectively) can be described by the equation for monomolecular reaction.

(2) The solid phase of the composition $Li_2O_2 \cdot H_2O$ inhibits the decomposition of peroxides in the liquid phase.

(3) The average temperature coefficients for the decomposition rate of hydrogen peroxide in the liquid phase of the $LiOH–H_2O_2–H_2O$ system in the presence of the solid phase of $Li_2O_2 \cdot H_2O$ and without it in the 21–33°C temperature range are 3.25 and 2.32, respectively.

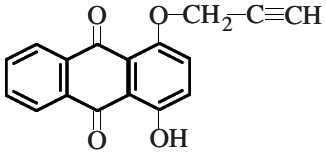
Abstract—The enthalpies of solution of a series of anthraquinone derivatives in dioxane at various dilutions were determined by isothermal calorimetry.

DOI: 10.1134/S1070427208010072



Thermodynamic and thermochemical properties of compounds are of interest for simulation of processes for preparing substances with preset properties. In this study, we determined calorimetrically the enthalpies of solution of anthraquinone derivatives: 1-hydroxy-1-(2-propyn-1-yloxy)-9,10-anthraquinone ($C_{17}H_{10}O_4$) (**I**), 1-hydroxy-2-(1-methyl-2-oxoprop-1-yloxy)-9,10-anthraquinone ($C_{18}H_{14}O_5$) (**II**), and 4-hydroxy-1-(2-propyn-1-yloxy)-9,10-anthraquinone ($C_{17}H_{10}O_4$) (**III**), and estimated their standard enthalpies of combustion ΔH^0_c, melting ΔH^0_m, and formation $\Delta_f H^0_{298.15}$:

I

II

III

The enthalpies of solution of the compounds in dioxane were measured with a DAK-I-IA isothermal calorimeter at three dilutions: 1 : 3000, 1 : 9000, and 1 : 18000 (mole of compound per mole of solvent). The experimental procedure is described in detail elsewhere [1–4]. At each dilution, we performed five replicate measurements. Their results were averaged and statistically treated. For each averaged value of the enthalpy of solution ΔH^0_s we calculated the random error using Student's test and the homogeneity of variance using Cochran's test [5]. The hypothesis of the homogeneity of variance was taken with 5% significance level.

The operation of the device was checked by measuring the enthalpy of solution of triple-recrystallized potassium chloride at dilutions of 1 : 1600, 1 : 2400, and 1 : 3200 (mole of salt per mole of water). The average enthalpy of solution of KCl in water, 17640 ± 320 J mol^{-1}, is well consistent with the recommended and reference data, J mol^{-1}: 17577 ± 34 [6] and 17489 ± 371 [7].

The enthalpies of solution of anthraquinone derivatives in dioxane at three dilutions are given in Table 1.

The obtained enthalpies of solution were extrapolated to infinite dilution using the least-squares method. Based on the known relationship $\Delta H^0_s = f(m^{1/2})$ (m is the molal concentration) [8], we obtained the following equations for each compound (kJ mol^{-1}):

$$\Delta H^m_s(\mathbf{I}) = 405.7 - 6428.8m^{1/2}, \quad (1)$$

$$\Delta H^m_s(\mathbf{II}) = 372.2 - 4437.8m^{1/2}, \quad (2)$$

$$\Delta H^m_s(\mathrm{III}) = 681.0 - 10181.4m^{1/2}, \quad (3)$$

from which we determined the standard enthalpies of

		$\Delta\bar{H}_3^0 = 293.67 \pm 0.76$			$\Delta\bar{H}_3^0 = 201.21 \pm 0.70$			$\Delta\bar{H}_3^0 = 493.57 \pm 0.90$	

solution of **I–III** in dioxane, equal to 405.7 ± 1.5, 372.2 ± 2.0, and 681.0 ± 2.2 kJ mol^{-1}, respectively.

Then the quantities ΔH_c^0 and ΔH_m^0 were determined for **I–III** using the equations suggested in [9, 10]. The results are given in Table 2.

Using the Hess cycle

$$C_{17}H_{10}O_{4(l)} + 17.5O_{2(g)} = 17CO_{2(g)} + 5H_2O_{(l)} - \Delta H_c^0, \quad (4)$$

$$C_{18}H_{14}O_{5(l)} + 19O_{2(g)} = 18CO_{2(g)} + 7H_2O_{(l)} - \Delta H_c^0, \quad (5)$$

we calculated the standard enthalpies of formation of compounds in the liquid (molten) state (Table 2). The required quantities $\Delta_f H_{298.15}^0[CO_2(g), H_2O(l)]$ were taken from [11, 12].

Table 2. Enthalpy characteristics (kJ mol^{-1}) of **I–III**

Compound	$-\Delta H_c^0$	ΔH_m^0	$-\Delta_f H_{298.15}^0$	
			liquid	solid
I	7726	78.6	398.3	472.0
II	8407	89.5	683.1	772.1
III	7726	76.6	398.3	475.0

Using ΔH_m^0, we calculated the standard enthalpies of formation of solid (crystalline) **I–III** (Table 2):

$$\Delta_f H_{298.15(s)}^0 = \Delta_f H_{298.15(l)}^0 - \Delta H_m^0. \quad (6)$$

Thus, using experimental and calculation methods of thermochemistry, we determined the previously unknown ethalpies of solution of anthraquinone derivatives in dioxane ΔH_s^0 and the enthalpies of their combustion ΔH_c^0, melting ΔH_m^0, and formation $\Delta_f H_{298.15}^0$.

CONCLUSIONS

(1) The standard enthalpies of solution of anthraquinone derivatives in dioxane were determined, and their standard enthalpies of formation, combustion, and melting were calculated.

(2) The results obtained are primary data for inclusion into data banks and handbooks of thermodynamic constants. They are of interest for physicochemical simulation of reactions involving these compounds and their analogs.

Abstract—Sorption of nonferrous metal ions under static conditions by a composite sorbent based on titanium phosphate was studied. The distribution coefficients and exchange constants for Cu(II), Ni(II), and Co(II) were calculated from the experimental data. The kinetics of the sorption of multiply charged ions from dilute hydrochloric acid solutions was studied, and the diffusion coefficients of exchanging ions were determined.

DOI: 10.1134/S1070427208010084

One of serious problems of plants dealing with hydrometallurgical and electrochemical productions is treatment of the wastewater containing a significant amount of heavy nonferrous metals. Harmful chemical elements penetrating in water reservoirs deteriorate their sanitary state and necessitate special deep water treatment before its household and production use.

Traditional water treatment methods, such as settling, coagulation, and flotation, do not provide the required quality of tail waters. This fact makes necessary the inclusion of a sorption refining stage in the flowsheet. As a rule, this is the final stage in a process, which makes it possible to achieve a demanded purity without application of additional chemicals.

Synthetic inorganic sorbents having certain advantages over organic resins find increasing application today for treatment of various types of polluted water. Such materials can almost completely bind metal ions in solutions with concentrations of the order of several milligrams per liter, and the possibility of their regeneration allows the ion exchanger operation life to be considerably increased.

At present, a great number of both universal and selective synthetic ion exchangers for wastewater treatment are known. Titanium phosphates of the general formula $TiOHPO_4 \cdot nH_2O$ are among highly selective ion-exchange materials. The synthesis and properties of such inorganic sorbents have been described in [1–4]. We have developed a technology of producing a new composite sorbent based on titanium phosphate [5, 6]. As a raw material we used waste from the integrated processing of apatite–nepheline ores, which considerably reduces the cost price of the end product. In this study we examined the ion-exchange properties of such sorbent in relation to ions of nonferrous metals (Cu^{2+}, Co^{2+}, and Ni^{2+}). To optimize the sorption process using the new ion exchanger, we studied the kinetics of the uptake of multiply charged ions from dilute chloride solutions under static conditions, obtained the sorption isotherms, and determined the sorption characteristics of the ion exchanger. The results obtained demonstrate the possibility for effective removal of ions of polyvalent metals.

EXPERIMENTAL

The synthetic ion exchanger used in this study has the composition $TiO_2 \cdot 0.75P_2O_5 \cdot 0.16SiO_2 \cdot 2.75H_2O$, with particles of hydrated silicon oxide fairly uniformly distributed in a titanyl phosphate matrix of a larger weight. The pH-metric titration data show that acid residues in such compound, i.e. phosphate groups, are bifunctional, and their capacity determined as described in [7] is 0.7 for strong acid groups and 3.4 mg-equiv g^{-1} for weak acid groups. Apparently, the major fraction of the sorbent is a mixture of mono- and disubstituted titanyl phosphate $TiO(HPO_4) \cdot TiO \cdot (H_2PO_4)_2 \cdot nH_2O$. Such phosphates have a layered structure with the staggered arrangement of phosphate groups of neighboring layers, forming zeolite cavities [8, 9]. One part of P–OH groups forms hydrogen bonds with phosphate groups of the neighboring layers, and another part forms hydrogen bonds with

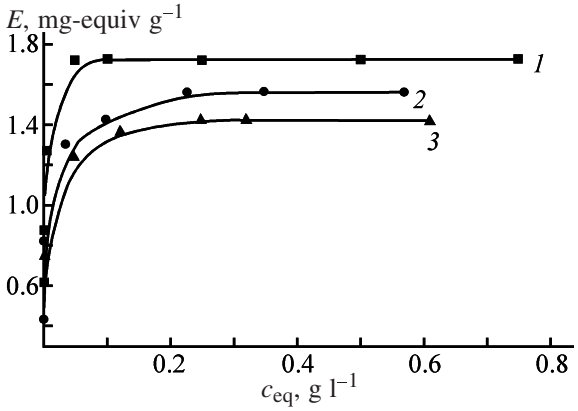

Fig. 1. Isotherms of sorption E of nonferrous metal ions by the composite sorbent. (c_{eq}) Equilibrium concentration. (*1*) Cu, (*2*) Ni, and (*3*) Co; the same for Fig. 2.

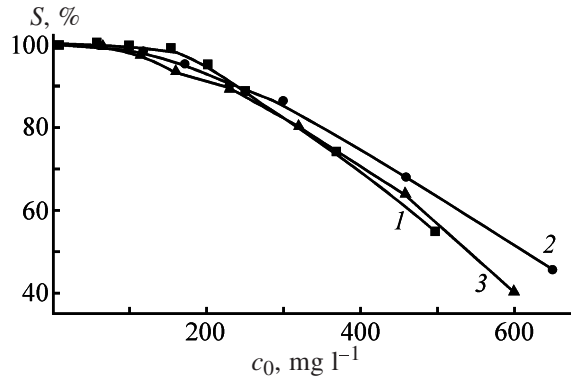

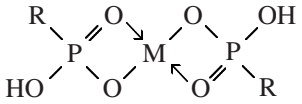

Fig. 2. Degree of sorption S as a function of metal ion concentration c_0 in the starting solution.

water molecules. In the course of an ion exchange, protons in P–OH groups bound with water molecules are replaced first, and then protons in the phosphate groups bound with the neighboring layers are replaced [10]. If ions of polyvalent metals take part in ion-exchange reactions, the following complex compounds are formed:

The relative sorbability of polyvalent metal ions, other things being equal, will be defined by the stability constant of the complex formed [11].

When studying sorption of Cu^{2+}, Co^{2+}, and Ni^{2+} ions under static conditions, 0.5 g of an ion exchanger sample in the Na^+ form was poured over with 0.01–1 g l^{-1} solutions of metal chlorides, providing the solid to liquid phase ratio of 1 : 200, and kept with intermittent stirring at 22°C until an equilibrium was attained. The pH value of starting aqueous solutions was 6–6.5. After ion exchanger removal, the equilibrium liquid phase was analyzed for the sorbate content with a Perkin–Elmer FT-IR 200 spectrophotometer. From the data obtained, the sorbent capacity (mg-equiv g^{-1}) for an ion under determination was calculated. The distribution coefficient K_d (ml g^{-1}) was calculated by the formula

$$K_d = \frac{(c_0 - c_{eq})V}{c_{eq}m},$$

where c_0 and c_{eq} are the initial and equilibrium concentrations of a metal ion in a solution; V, solution volume (ml); and m, ion exchanger sample weight (g).

To determine the concentration constant of Na^+–M^{2+} exchange, samples of the ion exchanger in the Na^+ form were poured over with 1 M NaCl solution containing certain amounts of MCl_2. After reaching an equilibrium the solution and the solid phase were analyzed for Na^+ and M^{2+}, and the exchange constants were calculated. The kinetics of sorption from MCl_2 solutions (containing 100 mg l^{-1} of M^{2+}) was studied at 20°C by the limited volume method [12]. The volume of the solution contacting with the sorbent was 50 ml, and the sorbent sample weight was 0.25 g.

Figure 1 shows that the ion exchanger under study has a good sorption capacity for nonferrous metal ions. The amount of sorbed metal cations increases as their content in the starting solution increases to 350–400 mg l^{-1}, and then it remains constant, which is due to the hindered transfer of metal cations through a product layer formed on the sorbent surface.

According to the degree of sorption (Fig. 2), the ion exchanger under study provides practically complete removal of nonferrous metal ions from solutions with an initial concentration of up to 100–150 mg l^{-1}.

All the isotherms are characterized by steep ascent in the region of low equilibrium concentrations of metal ions and by a saturation limit which allows estimation of the static sorbent capacity under the chosen conditions. The average value of the distribution coefficient at cation concentrations in the solid phase of up to 0.6 mg-equiv g^{-1} is 3×10^4 ml g^{-1} (Table 1).

It follows from the dependence of the distribution coefficient K_d of exchanging ions on their concentration in the liquid phase that a decrease in the initial concentration of metal ions in a solution favors an increase in the sorption of multiply charged ions. The K_d value decreases with increasing degree of ion exchange. This is due to the fact that large cations of

polyvalent metals, occupying surface reactive centers, block channels in the ion exchanger structure. This results in a decrease in the cation mobility and hinders the subsequent exchange in the interlayer space.

The material under study has the highest sorption capacity for the least hydrated ion, Cu^{2+}. The higher selectivity of the ion exchanger to the Ni^{2+} ion, which is more hydrated than the Co^{2+} ion, is caused by the presence of active centers of hydrated silicon oxide in the sorbent [13]. Thus, the selectivity series for sorption of nonferrous metal cations on the composite ion exchanger is as follows: $Cu^{2+} > Ni^{2+} > Co^{2+}$.

To study the exchange of these ions in more detail, we determined the Na^+–M^{2+} exchange constants by the static method at pH 5.8 (Table 1). The exchange constant allows quantitative estimation of the preferential sorption of one of two exchanging ions. The concentration exchange constants were calculated according to the exchange reaction

$$M^{2+} + 2R\text{–}Na \rightleftarrows R_2M + 2Na^+,$$

whre R is the ion exchanger matrix on which an ion is fixed,

$$K_{ex} = \frac{\bar{c}_M^{1/2} c_{Na}}{\bar{c}_{Na} c_M^{1/2}},$$

$\bar{c}_{Na}$ and $\bar{c}_M$ are concentrations of ions in the ion exchanger (mg-equiv g^{-1}), and c_{Na} and c_M are concentrations of ions in the solution (mg-equiv ml^{-1}).

The data obtained show that the exchange constant depends on the ionic composition of the ion exchanger. In the case of the Na^+–M^{2+} exchange in the region of solid phase compositions with the equivalent fraction $N_M < 0.4$, the exchange constant is practically independent of the ion exchanger ionic composition, whereas at $N_M > 0.4$ K_{ex} sharply decreases. This trend is caused by steric hindrance to entrance of cations into the interlayer space and to the action of repulsive forces between similarly charged counterions.

Apart from selectivity, sorption materials should provide a high rate of ion extraction. Kinetic characteristics of ion exchangers, which depend on their structure, play a decisive role in the choice of sorption conditions.

Time dependences of the sorption of Cu^{2+} and Co^{2+} ions are presented in Fig. 3 as semilog plots. Two linear portions (two stages) where sorption proceeds at different rates can be distinguished. In the first stage the sorption occurs on energetically

favorable reactive centers located on the ion exchanger surface. Then the ion exchange is accompanied by a number of processes: rupture of hydrogen bonds between phosphate groups of neighboring layers, hydration, dehydration of a cation entering into the ion exchanger, and coordination of the cation inside the ion exchanger matrix [14]. All this requires appreciable energy expenditure, and the process rate decreases. As transition metal ions are considerably hydrated and their penetration into the sorbent bulk is hampered, the sorption as a whole proceeds rather slowly, and the equilibrium is reached in approximately 8 h.

The ion exchange kinetics is known to be controlled by either external or internal diffusion [15]. To determine the limiting stage of the sorption process, we used the interruption technique [16]. We found that after the process interruption the rate of ion absorption increases. Such a phenomenon is characteristic of gel kinetics, which is the case when the sorption rate depends on the diffusion of ions inside sorbent grains. Another indication of the gel kinetics is the linear dependence of the degree of equilibrium attainment F on $t^{1/2}$ (Fig. 4).

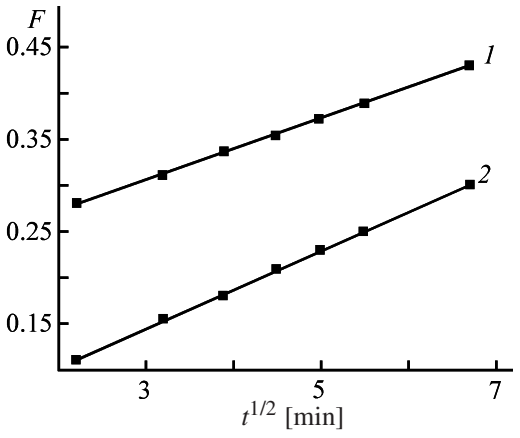

Fig. 4. Relative rate of sorption of nonferrous metals on the composite oin exchanger. (F) Degree of ion exchanger filling and (t) time.

The degree of equilibrium attainment was calculated by the formula $F = SEC_t/SEC_\infty$, where SEC_t and SEC_∞ (mg l^{-1}) are the amounts of sorbed ions at instant t and on reaching the maximal sorption. To estimate ion-exchange kinetic parameters, we used Boyd's equation for internal-diffusion processes [17]:

$$F = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}(1/n^2)\exp(-Dt\pi^2n^2/R^2),$$

where t is time (s); R, radius of ion exchange particles (m); D, diffusion coefficient ($m^2\ s^{-1}$); and n, natural numbers from 1 to infinity.

This series relatively rapidly converges at high degrees of filling. Having determined experimentally the degree F of equilibrium attainment for a specified time t and using the reference value of Bt [18], we calculated the diffusion coefficients D (Table 2) by the formula

$$D = \frac{Btr^2}{t\pi^2},$$

where r is the radius of sorbent particles (m).

The average radius of sorbent particles determined with a Shimadzu Sald-201V instrument is 1 mm.

It follows from Table 2 that sorbents based on titanium phosphate sorb nonferrous metal ions at a moderate rate. The diffusion coefficient of Co^{2+} cations is by an order of magnitude lower than that of Cu^{2+} cations, which is indicative of slower diffusion processes

Table 3. Sorption of nonferrous metal cations under dynamic conditions (initial concentration of metal ions in solution 100 mg l^{-1})

M^+	pH	DEC, mg-equiv g^{-1}	c_M at column outlet, mg l^{-1}
Cu^{2+}	4.98	2.27	<0.002
Ni^{2+}	6.03	1.94	<0.004
Co^{2+}	5.58	1.75	<0.005

in the case of the $Na^+ \rightarrow Co^{2+}$ exchange. This is caused by steric hindrances to the migration of more hydrated cobalt ions in the ion exchanger matrix. The value of D depends on the radius of sorbent particles. As a rule, particles of inorganic ion exchangers are agglomerates of irregular shape, consisting of nonuniform clusters of microparticles. Therefore, the diffusion takes place both in channels between microparticles and inside them. As the true size of microparticles is much smaller than the effective size of agglomerates, the measured actual diffusion rate is also lower. However, it is most probable that the established dependence between the diffusion rate and the kind of the cation will be preserved.

The results obtained can be used in the industrial practice of the sorption of nonferrous metals. Performing the sorption under dynamic conditions (flow rate 2 ml h^{-1}) allowed us to efficiently remove impurities of nonferrous metal ions from solution (Table 3).

CONCLUSIONS

(1) The ion exchanger under study provides practically complete removal of nonferrous metal ions from dilute hydrochloric acid solutions at their initial concentrations of up to 100–150 mg l^{-1} with the selectivity varying in the order $Cu^{2+} > Ni^{2+} > Co^{2+}$.

(2) The rate of ion exchange of transition metal ions is controlled by internal diffusion. The diffusion coefficient for Co^{2+} cations is by order of magnitude lower than that for Cu^{2+} cations, which is caused by steric hindrance to the migration of the more hydrated cobalt ions in an ion exchanger matrix.

Abstract—Isotherm of OH^-/GeO_3^{2-} ion exchange on a synthetic sorbent is studied. The limiting sorption of the germanate ion and the apparent constant and Gibbs energy of ion exchange are estimated.

DOI: 10.1134/S1070427208010096

In non-ferrous metallurgy, particularly, in zinc and lead production, germanium-containing process solutions are formed, which should be reprocessed. Since germanium is a rare element, and its application field is being steadily extended, integrated processing of complex ores is a quite topical problem. Germanium is recovered from aqueous solutions by such methods as sorption, solvent extraction, precipitation, evaporation, and flotation. The decision on the technology is determined primarily by the germanium concentration and speciation in solution. Ion exchange is believed to be the most cost-efficient and practically feasible process. It is applicable over a wide Ge concentration range from 0.01 to 3 g l^{-1}, whereas other chemical methods are efficient only at a Ge concentration above 0.5 g l^{-1}.

Sorption of germanium on cation-exchange resins has been extensively studied. Shostak et al. [1] have demonstrated that germanium forms complexes with heterocyclic nitrogen bases, diazo compounds, aliphatic amines, phenylfluorone, dihydric phenols, carboxy derivatives of polyhydric phenols, polyhydric alcohols, and hydroxy acids. However, in practice, cation-exchange resins have no significant sorption capacity for germanium occurring in solutions, and the most of commercial cation exchangers are unsuitable for this purpose [1]. Small amounts of germanium can be sorbed from acidic solutions on KB-4P and ROAS cation exchangers (most likely via complexation), and from weakly acidic solutions on KU-21 and KU-1G cation exchangers in the presence of hydroxylamine, but not from neutral solutions. Therefore, it is advisable to use cation exchangers for treatment of Ge-containing solutions to remove concomitant metals [2]. Thus, it was recommended to use cation-exchange resins for recovery of iron, copper, lead, and zinc from acidic and sodium alkaline Ge-containing solutions. In this case, germanium practically totally remains in solution. Many methods for treating Ge-containing acidic solutions to remove Al(III), Cu(II), and some other metal cations are based on this approach [3].

Sorption of germanium from solutions on activated carbon impregnated with tartaric, oxalic, and citric acids was reported in [4–6]. Germanium complexes with tartaric and oxalic acids appeared to be readily sorbed on activated carbon. In sorption of germanium on activated carbon impregnated with tartaric acid, a germanium tartrate complex is readily formed on the sorbent surface. On the contrary, modification of activated carbon with an oxalic acid solution reduces its sorption capacity for germanium. At the same time, a germanium oxalate complex formed in a solution is readily sorbed on activated carbon. Impregnation of activated coal with citric acid considerably increases its sorption capacity for germanium, which can be attributed to the fact that, unlike the smaller tartaric acid molecules penetrating into micropores of the sorbent, bulkier citric acid molecules may penetrate only into macropores, and, as a result, they are practically totally involved in chemisorption with formation of a germanium citrate complex.

Germanium sorption on anion-exchange resins has been most thoroughly studied. Germanium dioxide speciation in solutions was determined from data on the sorption of the germanate anions on Amberlite IRA-400 strongly basic anion exchanger in the presence of chloride. Germanium is sorbed on this resin at pH 4–13, and the maximal sorption is observed at pH 9–9.2. At pH < 6 and pH > 11, germanium is only insignificantly sorbed. At pH 6.9–9.4, germanium is sorbed in the form of the pentagermanate ions $Ge_5O_{11}^{2-}$. The decrease in the germanium sorption at lower pH

is due to the formation of the monogermanate ions $HGeO_3^-$ and GeO_3^{2-}. At pH > 9.4, the adsorbed species are germanate ions of lower degree of polymerization than in $Ge_5O_{11}^{2-}$.

Meleshko and Dubrovskaya [7] reported data on the sorption of germanium from aqueous solutions on EDE-10P, AV-16G, AV-17, and AV-31G anion-exchange resins. The experiments were carried out at pH 6.0–10.0 and various Ge concentrations in solution. Regardless of the resin type, the maximal sorption was observed at pH 9.3–9.4. It was demonstrated also that, with increasing Ge concentration in solution, the exchange capacity of the resins abruptly increases by virtue of the formation of the pentagermanate ions and the fact that the large size of this ion has no negative effect on the sorption kinetics [8].

Among a number of sorbents studied, AN-31 weakly basic anion-exchange resin was found to be the most selective sorbent for germanium, and its use allowed considerable increase in the Ge recovery [3]. Furthermore, it was demonstrated that this sorbent is suitable for recovering Ge from leaching solutions formed in processing such kinds of raw materials as ashes and sublimates of power plant coal, iron ore, and nonferrous metallurgical dusts [8]. Thanks to the high selectivity of AN-31, germanium may be recovered from multicomponent solutions containing high concentrations of such elements as zinc, lead, molybdenum, arsenic, iron, etc.

EXPERIMENTAL

We studied Ge sorption on D-403 anion-exchange resin. This is a macroporous polystyrene-based weakly basic chelating resin. Its color is milk-white, and the granule size is 0.4–1.25 mm. The functionality of the resin is caused by the tertiary nitrogen atom with the hydroxy substituents in the β-, γ-, and δ-positions. The hydroxy groups reduce the mobility of the unshared electron pair of nitrogen by virtue of the negative inductive effect. The anion exchanger was converted into the OH form prior to use. The resin was charged into a column and eluted first with 2 N H_2SO_4 and then with 1 N NaOH. Finally, the resin was washed with distilled water to pH 6.

In the sorption experiments, we used the method of variable volumes in which the same samples of the resin were shaken with different volumes of the solution with a fixed element concentration. The static sorption Γ (mol kg^{-1}) of germanate ions was determined at various liquid to solid phase ratios from the difference between the initial and equilibrium solution concentrations ($c_0 - c_\infty$):

$$\Gamma = (c_0 - c_\infty)V/m.$$

The resin samples (5 ml; bulk weight of the sorbent in the swollen state 0.738 g ml^{-1}) were placed into 250-ml conical flasks, poured over with 25–100 ml of a Ge-containing solution (0.05 M with respect to Ge), and shaken until equilibration. The starting Ge solution was prepared by dissolving germanium oxide (chemically pure grade) in 5 wt % NaOH (pH 14). The time of establishment of the sorption equilibrium was 6 h. After this time elapsed, the solution was decanted, and the equilibrium germanate concentration was determined photometrically with ammonium molybdate [9]. An aliquot portion of the solution (2 to 5 ml depending on the germanate concentration) was placed into a 25-ml flask, and 5% ammonium molybdate (10 ml) and 2 N H_2SO_4 (2 ml) were added. Finally, water was added to the mark. Germanium was determined by the intensity of the adsorption band of the molybdate complex at a wavelength of 428 nm.

The equivalence of the exchange of the OH^- ions for germanate was confirmed by satisfactory agreement between the total dynamic exchange capacity (TDEC) with respect to the alkali and germanate ions. The resin was charged into a column with the sorbent bed height of 300 mm and diameter of 16 mm (sorbent volume 60 ml). A solution containing 0.04 M germanium and 5% NaOH was passed through the column at a rate of 0.5–1 ml min^{-1} using a peristaltic pump. The TDEC for Ge was determined from the Ge concentration in the eluate (50-ml samples of the eluate were analyzed by X-ray fluorescence method). Then the resin was regenerated, washed with water to pH 6, and eluted with 0.1 N NaOH. The OH^- concentration in the eluate was determined volumetrically. The TDEC for Ge was found to be 0.82 ± 0.01 equiv l^{-1}, which was well consistent with that for the OH^- ions (0.76 ± 0.01 equiv l^{-1}). These values are well consistent with the certificate data for D-403 resin (0.9 equiv l^{-1}). Therefore, not the pentagermanate ions $Ge_5O_{11}^{2-}$, but monogermanate ions $HGeO_3^-$ and GeO_3^{2-} are sorbed, since, with increasing OH^- concentration, the equilibrium

$$5GeO_3^{2-} + 4H_2O \rightleftarrows Ge_5O_{11}^{2-} + 8OH^-$$

shifts to the left. The elution curves of the OH^- and germanate ions are shown in Figs. 1a and 1b.

Figure 2 shows the isotherm of Ge sorption on the synthetic sorbent, based on data of the table. The table summarizes data on the equilibrium germanate concentrations c_∞, germanate sorption Γ and its reciprocal

values $1/\Gamma$, degree of Ge recovery ε, and mean ionic activity coefficients $\gamma_\pm$ for Na_2GeO_3 and NaOH from [10].

The thermodynamic analysis of the OH^-/GeO_3^{2-} exchange was performed on the assumption of ideality of the solid phase, i.e., without taking into account the activity coefficients of the adsorbed ionic species. The Langmuir-type equation was linearized using the procedure described in [11]. The law of mass action for the ion-exchange reaction

$$2ROH_s + 5GeO_{3aq}^{2-} \rightleftarrows R_2GeO_{3(s)} + 2OH_{aq}^-$$

takes the form

$$K = \frac{\Gamma_{GeO_3^{2-}} a_{OH^-}^2}{\Gamma_{OH^-}^2 a_{GeO_3^{2-}}}, \quad (1)$$

where K is the apparent exchange constant; $\Gamma_{GeO_3^{2-}}$ and Γ_{OH^-} are the sorptions of the ions (mol kg^{-1}); and $a_{GeO_3^{2-}}$ and a_{OH^-}, ionic activities in the solution (m).

The limiting sorption of the ions Γ_∞ (equiv kg^{-1}) is written as

$$\Gamma_\infty = \Gamma_{OH^-} + 2\Gamma_{GeO_3^{2-}}.$$

Equation (1) can be rearranged to obtain Eq. (2):

$$K = \frac{\Gamma_{GeO_3^{2-}} [OH^-]^2 \gamma_{\pm(NaOH)}^2}{\Gamma_{OH^-}^2 [GeO_3^{2-}] \gamma_{\pm(Na_2GeO_3)}}$$

$$= \frac{\Gamma_{GeO_3^{2-}} [OH^-]^2 \gamma_{\pm(NaOH)}^2}{(\Gamma_\infty - 2\Gamma_{GeO_3^{2-}})^2 [GeO_3^{2-}] \gamma_{\pm(Na_2GeO_3)}}. \quad (2)$$

Equation (2) was rearranged to Eq. (4), whose form is similar to that of the Langmuir equation (3):

$$\Gamma = \Gamma_\infty Ka/(1 + Ka), \quad (3)$$

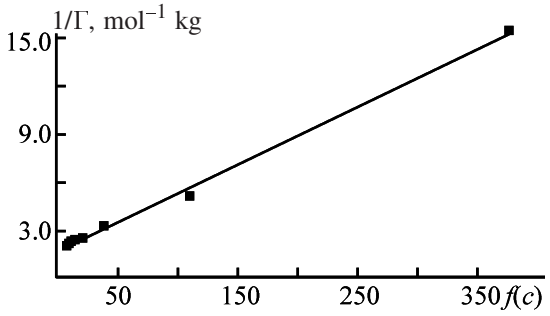

Fig. 3. Linearized isotherm of OH^-/GeO_3^{2-} ion exchange. (1/Γ) Reciprocal sorption of GeO_3^{2-} and $f(c) = [OH^-] \cdot \gamma_{\pm(NaOH)}\{\Gamma_{GeO_3^{2-}}[GeO_3^{2-}]\gamma_{\pm(Na_2GeO_3)}K\}^{-1/2}$.

$$\Gamma = \Gamma_\infty \frac{(\Gamma_{GeO_3^{2-}})^{1/2}\{[GeO_3^{2-}]\gamma_{\pm(Na_2GeO_3)}K\}^{1/2}}{[OH^-]\gamma_{\pm(NaOH)} + 2\{\Gamma_{GeO_3^{2-}}[GeO_3^{2-}]\gamma_{\pm(Na_2GeO_3)}K\}^{1/2}}. \quad (4)$$

The linearized form of Eq. (4),

$$\frac{1}{\Gamma_{GeO_3^{2-}}} = \frac{2}{\Gamma_\infty} + \frac{[OH^-]\gamma_{\pm(NaOH)}}{\Gamma_\infty\{\Gamma_{GeO_3^{2-}}[GeO_3^{2-}]\gamma_{\pm(Na_2GeO_3)}K\}^{1/2}}, \quad (5)$$

is similar to the linearized Langmuir equation (6):

$$1/\Gamma = 1/\Gamma_\infty + 1/\Gamma_\infty Ka. \quad (6)$$

In Fig. 3, the reciprocal sorption of the germanate ion $1/\Gamma_{GeO_3^{2-}}$ is plotted against $f(c)$. The linear approximation of this relationship is written as $1/\Gamma_{GeO_3^{2-}} = 0.0356f(c) + 1.6759$ (R^2 0.997). The ionic activity coefficients were determined by extrapolating the tabulated data to the Na_2GeO_3 and NaOH concentrations corresponding to a given ionic strength [10]. The ionic strength was estimated as $I = 0.5([Na^+] + 4[GeO_3^{2-}] + [OH^-])$.

Finally, the limiting sorption of GeO_3^{2-} anions was estimated to be 1.19 ± 0.01 equiv kg^{-1} (or 0.88 ± 0.01 equiv l^{-1}, taking into account the bulk density of the sorbent); apparent ion-exchange constant, $K_{OH^-/GeO_3^{2-}} = 2216$; and Gibbs energy of the exchange of the OH^- ions from the resin phase for the germanate ions from the solution, $\Delta G^0_{298} = -19.1$ kJ mol^{-1}. A negative value of the Gibbs energy reflects the selectivity of D-403 resin to germanium. The estimated limiting sorption of the germanate ions $\Gamma_\infty = 0.88 \pm 0.01$ equiv l^{-1} is above TDEC (0.82 ± 0.01 equiv l^{-1}), which can be attributed to the fact that this theoretical value is unattainable in the dynamic sorption mode.

CONCLUSIONS

(1) Capacitive characteristics of sorbent D-403 with respect to germanium are as follows (equiv l^{-1}): dynamic exchange capacity to breakthrough 0.53 ± 0.01 and total dynamic exchange capacity 0.82 ± 0.01. The total dynamic exchange capacity for germanium is consistent with that for the OH^- ions (0.76 ± 0.01 equiv l^{-1}).

(2) The isotherm of OH^-/GeO_3^{2-} ion exchange is described by a Langmuir-type relationship, which can be linearly approximated ($R^2 = 0.997$). The limiting sorption of the GeO_3^{2-} ions $\Gamma = 1.19 \pm 0.01$ equiv l^{-1}, apparent ion exchange constant $K_{OH^-/GeO_3^{2-}} = 2216$, and Gibbs energy of the exchange of the OH^- ions from the resin phase for the germanate ions from the solution $\Delta G^0_{298} = -19.1$ kJ mol^{-1}.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Sorption of Neodymium(III) Ions by Natural Mordenite-Containing Tuff

N. M. Kozhevnikova and N. L. Tsybikova

Baikal Institute of Nature Management, Siberian Branch, Russian Academy of Sciences, Ulan-Ude, Buryatia, Russia

Received September 26, 2006; in final form, August 2007

Abstract—Equilibrium in the system constituted by a mordenite-containing tuff and neodymium(III) was studied in a wide range of concentrations (10^{-5}–10^{-2} M) in sorption from neodymium sulfate solutions. Isotherms of absorption of neodymium ions were constructed and kinetic parameters of the sorption process were determined.

DOI: 10.1134/S1070427208010102

Natural zeolites modified with ions of rare-earth elements (REE) are promising for manufacture of microfertilizers and biologically active preparations [1–3].

The kinetics and equilibrium of sorption of lanthanum(III) ions by mordenite- and clinoptilolite-containing tuffs have been studied previously. It has been shown that sorption isotherms of lanthanum typically show a peak resulting from the complex nature of the interaction in the system constituted by a zeolite and lanthanum(III) ions [4]. It is of interest to study the influence exerted by the nature of REE on the equilibrium and kinetics of sorption. The insufficient understanding of the ion-exchange properties of natural zeolites with respect to REE hinders their application. For this purpose, we studied the sorption of neodymium ions by a mordenite-containing tuff in relation to the solution concentration, sorbent grain size, and solid-to-liquid mass ratio.

EXPERIMENTAL

We used as sorbent a mordenite-containing tuff from the Mukhor-Talinskoe perlite–zeolite deposit (Buryatia), with the following content of components (wt %): SiO_2 70.96, Al_2O_3 11.97, MgO 0.18, CaO 0.92, Na_2O 2.38, K_2O 5.22 [4]. The [Si]/[Al] ratio was 5.2. The content of zeolite in the rock was found by X-ray diffraction analysis with PTsL-2 [2] to be 62 wt %. To study the kinetics and equilibrium of absorption of neodymium(III) ions, the mordenite-containing tuff was crushed, grain fractions with diameters of 0.25–0.65 and 1–2 mm were selected by sieving, dust was removed, grains were dried at room temperature for 24 h, and a weighed sample was taken. The drying time of 24 h was chosen on the basis of triple control weighing every 3 h of drying.

The equilibrium was studied under static conditions in aqueous solutions of $Nd_2(SO_4)_3 \cdot 8H_2O$ by the constant-mass method [6, 7]. The content of neodymium(III) ions was determined by photometry with Arsenazo III, which is a highly sensitive and selective method [8]. The absorption capacity was calculated from the difference of the neodymium(III) ion concentrations before and after sorption, measured in three parallel runs with a relative error not exceeding 3%.

The absorption kinetics of neodymium ions was studied by the limited-volume method at s : l = 1 : 10 and 1 : 50 in sorption from neodymium(III) sulfate solutions with concentrations of 0.001–0.003 M under continuous agitation. The time of contact between a solution and the sorbent was varied from 5 min to 6 days. The effect of the sorbent grain size was studied on grains of diameters 0.25–0.5 and 1–2 mm.

The kinetic parameters were calculated from Q–τ curves [Q is the amount of sorbed neodymium(III) ions (mmol g^{-1}), and τ is time (s)] by the procedure described for the case of sorption on zeolites in the monograph [9]. For the initial period of time, when sorption occurs on the zeolite surface under outer-diffusion control, the rate constant of the outer-diffusion process, R, is calculated by the equation

$$R = dQ/d\tau(1/cK), \quad (1)$$

where c is the ion concentration in solution (M), and K is the equilibrium distribution coefficient (ml g^{-1}).

As the time of contact increases, the amount of absorbed ions is determined by the rate of exchange within a grain. The effective diffusion coefficient D and the rate constant B of the inner-diffusion process, which characterize the inner-diffusion mechanism, were calculated by the following equations derived for spherical particles:

$$F = Q_\tau/Q_\infty = (6/r)(Dr/\pi)^{1/2}, \quad (2)$$

$$B = \pi^2 D/r^2, \quad (3)$$

where F is the degree of absorption of neodymium(III) ions, and r is the average radius of sorbent grains (cm).

The results obtained are listed in the table. The equilibrium of sorption of neodymium ions on a mordenite-containing tuff was studied in a wide concentration range (10^{-5}–10^{-2} M), which made it possible to reveal changes in the initial and final portions of the equilibrium curves.

Figure 1 shows equilibrium curves for neodymium(III) ions in sorption from neodymium sulfate solutions on a natural zeolite, measured for grains with different diameters (~0.25–0.5 and 1–2 mm) at s : l = 1 : 10 and 1 : 50.

The equilibrium curves are similar and reflect a certain pattern in the nature of interaction between neodymium ions and the zeolite phase. The isotherms show an extremum, which may occur because intermediate products of the chemical reaction, toward which the sorbent exhibits an increased selectivity, are formed in solution. The processes of hydration, hydrolysis, polymerization, and complexation are characteristic of the state of aqueous solutions of neodymium(III). In neutral and acid aqueous solutions, neodymium ions form aqua and hydroxoaqua complexes of the following types: $[Nd(H_2O)_n]^{3+}$ and $[Nd(H_2O)_nOH]^{2+}$, where n = 5–8 [10, 11]. At low concentrations of sulfate ions (<0.03 M), $[Nd(SO_4)]^+$ cations are predominant [12], although anion complexes can also be formed under the same conditions [13].

The absorption of neodymium(III) ions is accompanied by a decrease in the solution pH by 0.4–0.6 unit. To find out why pH decreases, we performed control runs in which the mordenite-containing tuff was poured over with distilled water. During 20–24 h of contact, a decrease in pH also by 0.4–0.6 unit was recorded in all experiments, and this occurred via exchange between Na^+ and H^+ ions present in zeolites [10], irrespective of whether or not neodymium ions were absorbed. Possibly, the decrease in pH in contact of mordenite with distilled water occurs via hydrolysis of aluminum(III), magnesium(II), and iron(III) ions by the scheme

Kinetic parameters of sorption of neodymium(III) ions from sulfate solutions by natural mordenite-containing tuff

Parameter	Solution concentration, M		
	0.001*	0.002**	0.003**
τ, min	1540	1870	1630
$dQ/d\tau \times 10^{-5}$, mmol g^{-1} s^{-1}	5.8	3.7	4.7
K, ml g^{-1}	49.3	40.5	56.8
$R \times 10^{-4}$, s^{-1}	4.2	3.4	4.4
$D \times 10^{-8}$, cm^2 s^{-1}	4.2	2.1	3.5
$B \times 10^{-4}$, s^{-1}	8.9	7.3	8.6

* d = 0.25–0.5 mm, s : l = 1 : 50.
** d = 1–2 mm, s : l = 1 : 10.

$$M^{n+} + 2H_2O \rightleftarrows [MOH]^{(n-1)+} + H_3O^+, \quad (4)$$

$$M^{n+} = Al^{3+},\ Mg^{2+},\ Fe^{3+}.$$

The pH values for 0.005 and 0.001 M solutions of neodymium(III) sulfate are 6.4 and 6.2, respectively.

As the solution concentration increases to the point of extremum, aqua and hydroxoaqua complexes of neodymium(III) are sorbed, because these complexes have a larger ion charge and the zeolite shows an increased selectivity with respect to them. The size of windows and channels of the zeolite under study are 6–7 Å, which markedly exceeds the size of aqua and hydroxoaqua complexes of neodymium(III) and suggests that neodymium(III) is sorbed in the form of aqua and hydroxo complexes. The suggested mechanism of exchange sorption via substitution of Na^+, K^+, and H^+ by Nd^{3+} confirms the data of [7].

The grain size and s : l ratio affect the position of the peak in the isotherms in Fig. 1. The maximum of the exchange capacity (EC) on grains with d = 0.25–0.5 and s : l = 1 : 50 (Fig. 1, curve *1*) is shifted to lower equilibrium concentrations. For larger grains (d = 1–2 mm) and s : l = 1 : 10, the maximum EC lies at higher concentrations (Fig. 1, curve *2*).

Thus, the maximum CE is achieved on small-size tuff grains at a lower expenditure of the reagent.

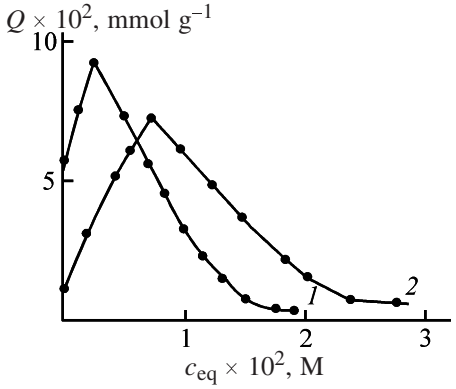

Fig. 1. Isotherms of neodymium sorption from neodymium sulfate solutions. (Q) Amount of sorbed neodymium(III) ions and (c_{eq}) equilibrium Nd(III) concentration in solution. (*1*) d = 0.25–0.5 mm, s : l = 1 : 50; (*2*) d = 1–2 mm, s : l = 1 : 10.

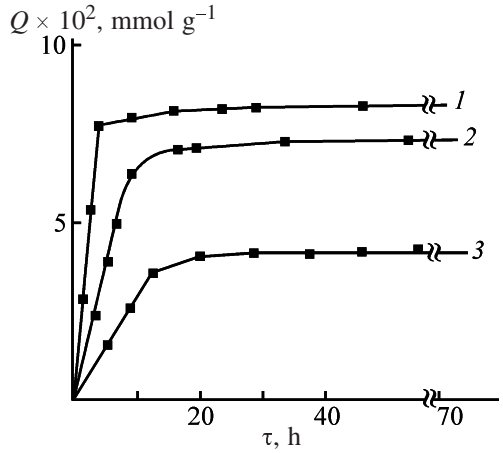

Fig. 2. Kinetic curves of neodymium(III) sorption from aqueous solutions by mordenite-containing tuff. (Q) Amount of sorbed neodymium(III) ions and (τ) sorption time. (*1*) 0.001 M, d = 0.25–0.50, s : l = 1 : 50; (*2*) 0.003 M, d = 1–2 mm, s : l = 1 : 10; and (*3*) 0.01 M, d = 1–2 mm, s : l = 1 : 10.

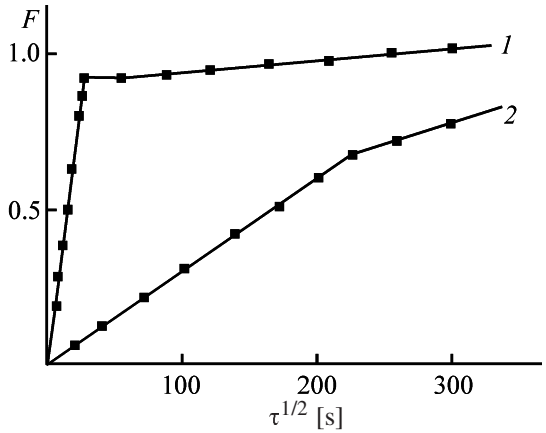

Fig. 3. Degree of exchange F vs. time τ. (*1*) 0.005 M, d = 0.25–0.50, s : l = 1 : 50; (*2*) 0.01 M, d = 1–2 mm, s : l = 1 : 10.

The kinetic curves of absorption of neodymium(III) ions are similar (Fig. 2).

The linear dependence of the degree of filling F of the zeolite phase on time τ (s), F–$(\tau)^{1/2}$, in Fig. 3 confirms the rather high contribution of the inner-diffusion sorption mechanism [7, 10].

The kinetic parameters listed in the table indicate that the absorption rate of neodymium(III) ions depends on the grain size of the mordenite-containing tuff and on the solution concentration. A decrease in the sorbent grain size leads to an increase in the surface area, which results in that the absorption rate $dQ/d\tau$ by the outer-diffusion mechanism increases. As the concentration of neodymium(III) sulfate solutions is raised, the time in which equilibrium is attained, τ_∞, becomes shorter, and the rate constants of outer- (R) and inner-diffusion (B) processes, distribution coefficient K, and effective diffusion coefficient D become larger. The constants R and B are of the same order of magnitude, which confirms that Nd^{3+} ions are sorbed by the mordenite-containing tuff by a mixed mechanism.

CONCLUSIONS

(1) The isotherms of neodymium(III) sorption by the mordenite-containing tuff exhibit a peak, which is due to the complex nature of the interaction. As the concentration of the aqueous solution increases, the selectivity of the mordenite-containing tuff with respect to neodymium(III) ions changes and its sorption capacity decreases.

(2) The sorption rate of neodymium(III) ions on the mordenite-containing tuff depends on the grain size, solution concentration, and s : l ratio. The results obtained open up prospects for production of effective microfertilizers and medicinal preparations by the sorption technology.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Dealuminated Zeolites in Sorption Treatment of Industrial Liquid Wastes to Remove Alkylbenzenesulfonates

Abstract—Comparative study of the fundamental aspects of the kinetics and statics (equilibrium) of sorption of alkylbenzenesulfonates from aqueous solutions and liquid wastes on industrial AV-17-OH and KAD-iodine sorbents and deeply dealuminated synthetic zeolites NaY and NaX was carried out. The kinetic curves and adsorption isotherms obtained were processed using the classical equations of the diffusion kinetics and the known Langmuir and Nikol'skii equations for equilibrium sorption processes.

DOI: 10.1134/S1070427208010114

It is known that ionic surfactants can be subdivided into anionic, cationic, and ampholytic [1, 2]. Anionic and cationic surfactants are most widely used in industry and households. In particular, alkylbenzenesulfonates (ABS) as representatives of anionic surfactants serve as a basis for fabrication of foaming and wetting agents and emulsifiers [2] and are used as detergents under the trade mark Sulfonols. In contrast to linear polymers, alkylbenzenesulfonates are rather toxic and, when they find way into natural water basins together with wastewater from various industries, they are a hazard to the flora and fauna [3].

It is recommended to purify industrial wastewater to remove ABS using, together with various physicochemical methods [4], sorption methods with solid sorbents, which are efficient and provide deep purification of water in conformity with modern regulations.

A sorption-based method for wastewater treatment to remove surfactants of various classes with activated carbons of various brands has been developed and implemented in practice [4]. A disadvantage of this technique is that these processes use only a minor fraction of the specific surface area of some of the activated carbons tested (~25–30%). Taking into account this circumstance, we consider it appropriate to use activated carbons for treatment of wastewater containing low concentrations of surfactants or, in some cases, for additional purification of wastewater after another purification method.

Solid sorbents of the class of aluminosilicates (bentonite and kaolinite clays, mixed aluminosilicate sorbent, ash from oil shales) have been successfully tested in sorption treatment of wastewater to remove ABS [2, 4–7]. Although the clays used exhibit high sorption activity with respect to ABS, their strong swelling in aqueous media prevented their wide use in wastewater treatment on sorption columns.

It is of interest to develop effective sorbents based on natural and synthetic zeolites by modification of their surface in order to remove alkylbenzenesulfonates from liquid industrial wastes. It should be noted that natural and synthetic zeolites have not been used previously to remove alkylbenzenesulfonates from liquid media because of their rigid framework and narrow-pore structure and of the lack of swelling and strong hydrophilicity in aqueous media.

Samples of natural zeolites (clinoptilolite and mordenite), modified with methylamine hydrochloride, were used for treatment of liquid wastes to remove toxic organochlorine compounds (dichloroethane, trichloroethylene, chloroform), with high sorption capacities obtained (12.0–14.5 wt %) [8].

Here we report on a study of the sorption purification of liquid industrial wastes to remove alkylbenzenesulfonates with dealuminated zeolites and on an analysis of the fundamental aspects of the kinetics and statics (equilibrium) of the process.

EXPERIMENTAL

To modify the surface by dealumination, we took natural zeolites, clinoptilolite from the Ai-Dag deposit

and mordenite from Chananab deposit (Azerbaijan), and synthetic zeolites, NaX and NaY zeolites and Na-mordenite. Samples of these zeolites were treated under dynamic conditions at room temperature with aqueous solutions of HCl (or H_2SO_4) with various concentrations (0.5–2.0 N) to give samples with various degrees of dealumination. This degree was 3 to 95–98% for NaX and NaY zeolites and 3 to 30–35% for natural clinoptilolites and mordenite.

Samples of synthetic and natural zeolites with different degrees of dealumination were preliminarily tested in wastewater treatment at a number of Sumgait detergent-manufacturing plants to remove alkylbenzenesulfonates present in a concentration of about 700 mg l^{-1} (for comparison we took commercial solid sorbents, activated carbon of KAD-iodine brand and AV-17-OH highly basic anion exchanger). Weighed portions (2 g) of sorbents (zeolites with different degrees of dealumination, KAD-iodine activated carbon, and AV-17-OH anion exchanger) were placed in glass tubes a wastewater solution was passed through these tubes, and to complete saturation of the ABS sorbents. After that, the capacities of the samples for alkylbenzenesulfonates were calculated (mg g^{-1}).

The results of experiments with dealuminated samples of synthetic zeolites NaX and NaY are listed in Table 1. For the other of the sorbents tested we obtained the following capacities for ABS (mg g^{-1}) (degrees of dealumination are given in parentheses): synthetic mordenite 27.0 (32.0), natural mordenite 28.0 (30.0), natural clinoptilolite 30.5 (35.0), KAD-iodine activated carbon 55.7, and AV-17-OH 58.2.

In accordance with the results of the experiment (Table 1), the synthetic zeolites NaY and NaX with degrees of dealumination of 63.6 and 86.4%, respectively, which exhibited high sorption activity, and natural KAD-iodine and AV-17-OH sorbents were chosen for a comparative study of the fundamental aspects of the kinetics and equilibrium of ABS sorption from a solution with concentration c_0 = 1000 mg l^{-1}. In wastewater from detergent-manufacturing plants in Sumgait, the ABS concentration varies within the range 500–1000 mg l^{-1}, which is many times the maximum permissible concentration MPC (0.1 to 5.0 mg l^{-1}, depending on a particular region) [3, 4].

The kinetic pattern of ABS sorption on the chosen sorbents was studied by the limited-volume method at l : s = 100 : 1 and temperatures of 298, 308, and 328 K. Weighed portions (0.5 g) of the sorbents were placed in flasks and poured over with 50 ml of an ABS solution with a concentration of 1000 mg l^{-1}. The flasks were transferred to a thermostat shaker and the ABS concentrations in the flask were determined at certain intervals of time by the known procedure [9]. Kinetic curves of sorption were plotted in the a_t–t coordinates, where a_t is the amount of sorbed ABS (mg g^{-1}) and t is the sorption time (s).

Isotherms of ABS sorption from a solution with a concentration of 1000 mg l^{-1} on the sorbents under study were obtained by the variable-volume method. For this purpose, 0.5-g portions of the sorbents were placed in 250-ml flasks and poured over with different volumes (20, 40, 60, 80, 100, and 120 ml) of the solution with the concentration specified above. The mixtures were agitated for 8 h (which is sufficient for the sorption equilibrium to be attained), the ABS concentrations in the equilibrium solutions were determined, and sorption isotherms were plotted in the a–c_{eq} coordinates.

It is known that, being associated in solutions, the radicals of alkylbenzenesulfonates form micelles of colloid sizes if the solution concentration exceeds a certain value named the critical micelle concentration (CMS) [2]. Formation of micelles noticeably affects the course of sorption processes, which complicates obtaining reliable values of kinetic parameters. Therefore, we processed the results of kinetic experiments at the beginning of the process (for short t) at solution concentrations below the CMC (~200–

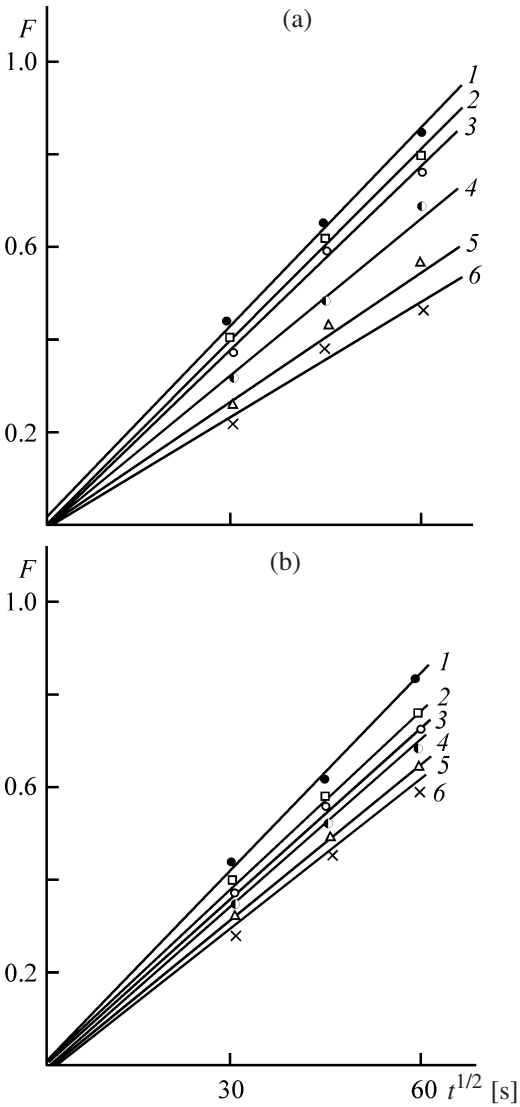

Fig. 1. Sorption parameter $F = a_t/a_\infty$ vs. t for the sorbents under study under different conditions. (t) Sorption time. Temperature, K: (*1, 2*) 323, (*3, 4*) 308, and (*5, 6*) 298. Sorbent: (a) (*1, 4, 6*) AV-17-OH and (*2, 3, 5*) KAD-iodine; (b) (*1, 3, 6*) NaY and (*2, 4, 5*) NaX.

300 mg l^{-1}) by the formula [10]

$$F = a_i/a_\infty = 6(D_{\text{eff}}t/\pi)^{1/2}r^{-1}, \quad (1)$$

where r is the average radius of sorbent particles (cm); D_{eff}, effective diffusion coefficient for alkylbenzenesulfonate ions (cm^2 s^{-1}); and a_∞, maximum equilibrium capacity of the sorbents for ABS (mg g^{-1}).

In Figs. 1a and 1b, the dependences described by formula (1) are plotted for the beginning of the process (for short t) in the coordinates F_∞–$t^{1/2}$. These dependences are linear, which made it possible to determine D_{eff}, using the known Arrhenius formula $D_{\text{eff}} = D_0 e^{-E_a/RT}$, and calculate the activation energies of diffusion for all of the sorbents under study (Table 2). Table 2 also lists values of the thermodynamic functions ΔH^0 and ΔS^0 for the diffusion stages and ΔG^0 for the equilibrium stage of the sorption process, calculated from the results of the kinetic experiments performed at different temperatures.

* For AV-17-OH anion exchanger, E_a, ΔH^0, and ΔG^0 are expressed in kJ g-ion^{-1}, and ΔS^0, in J K^{-1} g-ion^{-1}.

from a solution with a concentration of 1000 g l^{-1} on the sorbents under study (KAD-iodine, NaX, and NaY) and on AV-17-OH anion exchanger, respectively.

Assuming that the sorption of ABS from solutions on KAD-iodine, NaX, and NaY sorbents must be molecular, we carried out a theoretical processing of the isotherms in Fig. 2 for the portions with $c_{eq} \leq 200$ mg l^{-1} (henceforth CMC) by the known Langmuir equation:

$$a = a_\infty K c_{eq}/(1 + K c_{eq}). \quad (2)$$

or, in linear coordinates,

$$c_{eq}/a = 1/(a_\infty K) + c_{eq}/a_\infty, \quad (3)$$

where K is the sorption equilibrium constant.

In Fig. 4, the portions with $c_{eq} \leq 200$ mg l^{-1} of the isotherms of ABS sorption on the KAD-iodine, NaX, and NaY sorbents (Fig. 2) are replotted in the coordinates (c_{eq}/a)–c_{eq} of Eq. (3). The maximum sorption capacities a_∞ of the sorbents for ABS were found from the slopes of the linear isotherms, and then the sorption equilibrium constants K were calculated (Table 3).

It is known that the sorption of alkylbenzenesulfonate ions on the surface of AV-17-OH anion exchanger in a solution is of ion-exchange nature [2, 4, 6] and occurs by substitution of mobile OH^- ions of the sorbent by the larger $C_nH_{2n+1}C_6H_4SO_3^-$ (n = 10–18) ions of the anionic surfactant. We used in experiments the fraction with an average molecular weight M = 376 g mol^{-1} (n = 14).

The isotherm in Fig. 3 was theoretically processed for the portion of isotherm with $c_{eq} \leq 5 \times 10^{-4}$ mg-equiv ml^{-1} (~200 mg l^{-1}) with the use of the Nikol'skii equation for single-charged ions [11]:

$$a_1/a_2 = K_{1.2} c_1/c_1. \quad (4)$$

On applying the exchange-equivalence law a_1 =

Sorbent	K	a_∞	TDSC
		mg g^{-1}	
AV-17-OH	0.3334	54.170 (0.1430)*	58.204 (0.1548)*
KAD-iodine	0.0461	54.300	55.704
NaX	0.0163	56.820	57.950
NaY	0.0246	62.500	63.420

* Values of a_∞ and total dynamic sorption capacity (TDSC) for AV-17-OH anion exchanger are expressed in parentheses in mg-equiv g^{-1}.

$a_\infty - a_2$ and $c_1 = c_0 - c_2$ for the alkylbenzenesulfonate ion appearing with index 2, at $a_2 = a$ and $c_2 = c_{eq}$, Eq. (2) takes the form

$$(a_\infty - a)/a = K(c_0 - c_{eq})/c_{eq}. \quad (5)$$

Equation (5) was used in this form to find the ion-exchange equilibrium constant K. For this purpose, we determined from the data in Fig, 3, for the portion with $c_{eq} \le 5 \times 10^{-4}$ mg-equiv cm^{-3}, the maximum equilibrium ion-exchange capacity a_∞ of AV-17-OH anion exchanger for the alkylbenzenesulfonate ion. Taking several values of c_{eq} and the corresponding values of a (Fig. 3), we plotted the dependence of $(a_\infty - a)/a$ on $(c_0 - c_{eq})/c_{eq}$. In accordance with formula (5), this dependence is linear, which enabled us to find the ion-exchange equilibrium constant K. The values obtained for a_∞ and K are listed in Table 3. The same table lists TDSC values for ABS sorption on the sorbents under study, found in separate experiments at a solution concentration of 1000 mg l^{-1}.

As the temperature increases, the rate of ABS sorption on the sorbents under study grows, which leads to a steady decrease in the time t_∞ in which the equilibrium is attained. Simultaneously, the diffusion of alkylbenzenesulfonates in solution and in sorbent pores becomes faster (Table 2). It is known that sorption from solutions occurs on porous solid sorbents, including zeolites, under the mixed-diffusion control [12]. Table 2 shows that, in the case of the narrow-pore unswelling sorbents NaX and KAD-iodine, ABS is mostly adsorbed from solutions on the hydrophobic (as a result of deep dealumination for NaX) outer surface of the sorbents via mixed diffusion with prevalence of the outer diffusion. There also occurs, under inner-diffusion control, sorption in mesopores in the carbon and in secondary pores in the zeolite. This inner-diffusion hindrance in pores weakens diffusion processes to a certain extent, which is confirmed by the values of D_{eff} on the order of 10^{-7} cm^2 s^{-1}, listed in Table 2.

In contrast to the narrow-pore NaX, the synthetic zeolite NaY used in the experiment is broad-pore powder-like ($r \le 0.01$ cm) sorbent that has a developed sorption surface and is highly hydrophobized because of deep dealumination. In this case, the sorption process also occurs under mixed-diffusion control, with a noticeable influence of the inner-diffusion hindrance caused by diffusion penetration of large ABS anions into macropores of the sorbent (D_{eff} on the order of 10^{-9} cm^2 s^{-1}). Presumably, the high sorption activity of NaY (Table 3, high static and dynamic sorption capacities) with respect to large organic radicals results in that the adsorbate structure is formed early, long before the CMC region is formed [13]. In addition, aluminum hydroxide is deposited on the surface of NaY sorbent from aqueous solutions of aluminosilicates, to which NaY zeolite also belongs. ABS molecules having long hydrocarbon radicals with high van der Waals interaction energy are adsorbed not only on hydrophobic areas of the surface, but also on strongly hydrophilic areas of the powder surface with aluminum hydroxide [6, 14]. Therefore, our processing of the isotherm of ABS sorption on NaY in terms of the Langmuir equation yielded increased values of capacity, listed in Table 3.

In contrast to KAD-iodine, NaX, and NaY sorbents, on which molecular ABS is sorbed, the ABS sorption on the swelling broad-pore anion exchanger AV-17-OH is of the ion-exchange nature. It occurs in internal pores of the sorbent, where the inner-diffusion kinetics plays the most important part. In static experiments, 90.0–92.0% of the TDSC of the sorbent for alkylbenzenesulfonates could be utilized.

The values of the thermodynamic functions ΔH^0, ΔG^0, and ΔS^0, listed in Table 2, refer to the diffusion stage of the process. Therefore, they do not noticeably differ between unswelling sorbents (KAD-iodine, NaX, NaY), on which sorption mainly occurs on the outer surface of the sorbents via mixed diffusion with prevalence of the outer-sphere diffusion. Only for the broad-pore and swelling anion exchanger AV-17-OH, the substitution of the smaller hydroxide ion by the larger ABS ion is accompanied by a decrease in the content of water in the pores of the anion exchanger and, accordingly, by an increase in entropy.

The deeply dealuminated synthetic zeolites NaY and NaX, which compare well in capacity with the

commercial sorbents KAD-iodine and AV-17-OH, can be recommended for use in sorption treatment of various liquid wastes to remove toxic ions of a number of anionic surfactants.

CONCLUSIONS

(1) It was found that, among the zeolites tested, deeply dealuminated NaY and NaX compare well in capacity for alkylbenzenesulfonates (57.0–60.0 mg g^{-1}) with the commercial sorbents studied (54.0–58.0 mg g^{-1}).

(2) A theoretical processing of the kinetic curves and sorption isotherms obtained demonstrated that the sorption on the narrow-pore and unswelling sorbents NaX and KAD-iodine occurs on the hydrophobic external surface of the sorbents via mixed diffusion with prevalence of the outer-sphere diffusion, whereas the sorption on the broad-pore, powder-like, and highly hydrophobized NaY occurs also under mixed-diffusion control, but with a noticeable influence of the inner-diffusion hindrance.

(3) It was shown that, in contrast to the three sorbents mentioned above, the sorption on the swelling broad-pore anion exchanger AV-17-OH is of the ion-exchange nature and occurs in internal pores of the sorbent, where the inner-diffusion kinetics is the most important.

(4) The thermodynamic functions ΔH^0, ΔG^0, and ΔS^0 related to the diffusion stage of the sorption process were calculated.

Abstract—The catalytic activity exhibited in turpentine oxidation at elevated pressure by cobalt coordination compounds, some transition metal compounds, in particular, polyoxometallate with spherical nanoclusters (Mo_{132}), vanadium oxide bronze, and cobalt complexes immobilized on AN-241 anion exchanger was studied.

DOI: 10.1134/S1070427208010126

It is known that oxidation of α-pinene with molecular oxygen leads to allyl oxidation products and oxygen-containing compounds formed by oxidation of the methyl group adjacent to the double bond; epoxidation products are also formed [1]. The ratio of the oxidation products can be apparently controlled by choosing appropriate catalysts. Catalytic oxidation of α-pinene still attracts researchers' attention [2–4]. At the same time, today the main source of α-pinene is sulfate turpentine, which is mainly used as solvent. Therefore, to extend the possibilities of preparing practically important α-pinene derivatives, it is appropriate to study its oxidation using as substrate commercial turpentine. Proceeding with studies in this field [5], we examined the activity of a series of homogeneous and heterogeneous catalysts in the oxidation of turpentine at elevated pressure of molecular oxygen (~1.3 atm). Apparently, slightly elevated oxygen pressure should lead to a decrease in the oxidation temperature (in contrast to [6] where the reaction was performed at reduced pressure) and in the yield of high-boiling oxidation products. As catalysts we used homogeneous complexes, including those capable of reversible oxygen binding and suitable for oxidation of sulfate turpentine because of no need in their regeneration. We also tested a series of heterogeneous catalysts containing transition metals (Cu, V, Mo, Co), taking into account successful use of these compounds, in particular, of vanadium oxide bronzes (VOBs) $Cu_{0.6} \cdot V_2O_5$ [7], for liquid-phase peroxide oxidation of aromatic compounds.

EXPERIMENTAL

The reaction mixture was analyzed with a Chrom-5 chromatograph equipped with a thermal conductivity detector and a 1.5-m glass column with DC-550 stationary phase. Carvone was used as internal reference.

Experiments were performed, in accordance with [5], in a setup with a temperature-controlled reactor fixed in a high-speed rocker. Experiments were performed at 300 rockings per minute at elevated pressure (1.3 atm) and a temperature of 50°C. We used turpentine [GOST (State Standard) 1571–82] as substrate, acetonitrile as solvent, and various homogeneous and heterogeneous catalysts.

Samples of the reaction mixture were taken at regular intervals and subjected to chromatographic analysis, and the kinetic curves of α-pinene oxidation were plotted. For each kinetic curve, we determined the initial rate by extrapolation of the measurement results after completion of the induction period, using a pseudo-first-order equation [5].

In addition, we determined the specific oxidation rate. The complexes $Co(acac)_2$ and CoSalen were prepared by procedures described in [5]. The catalyst activities were evaluated by the rate of α-pinene consumption in the reaction mixture. The α-pinene content was determined by gas chromatography. The dependence $\log c = f(t)$ is linear (see figure).

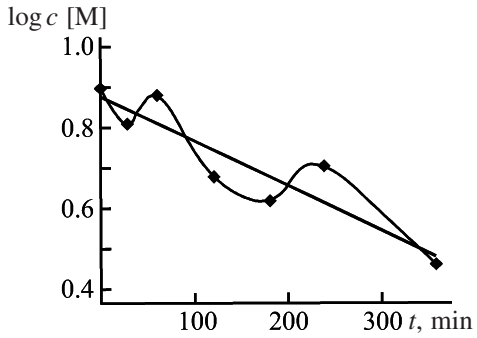
The common criterion of performance of homogeneous and heterogeneous catalysts under the examined conditions is the specific oxidation rate. This quantity is defined as the ratio of the initial rate of α-pinene oxidation to the molar concentration of the catalyst, $V_{sp} = V_0/[Cat]$ (see table).

Among the heterogeneous catalysts tested, the highest initial oxidation rate was observed with vanadium oxide bronze of the composition $Cu_{0.6}V_2O_5$.

Oxidation of α-pinene in the presence of homogeneous and heterogeneous catalysts. T = 500°C, P = 1.3 atm, solvent acetonitrile

Sample no.	Catalyst	Sample weight, g	Molar ratio α-pinene : solvent* : catalyst	V_0, mol l^{-1} min^{-1} for α-pinene	V_{sp}
	–	–	1 : 11.05 : 0	-0.00219	–
1	AN-251 + $CoCl_2$**	0.0242	1 : 11.05 : 0.0000837	-0.0217	19 700
2	$Co(acac)_2$	0.0395	1 : 11.05 : 0.0117	-0.0186	122
3	CoSalen	0.0497	1 : 11.05 : 0.0117	-0.0724	473
4	$Cu_{0.6}\cdot V_2O_5$	0.0337	1 : 11.05 : 0.0152	-0.0684	334
5	$(NH_4)_{42}[Mo^{VI}_{72}Mo^{V}_{60}O_{372}(HCO_2)_{30}\cdot (H_2O)_{72}]\cdot 30HCO_2Na\cdot 250H_2O$**	0.0337	1 : 11.05 : 0.0001169	-0.0567	37 000

* For calculation simplicity; actually the solvent also contained other turpentine components (apart from α-pinene and its oxidation products).



** In calculation of V_{sp} for sample nos. 1 and 5, the molecular weights of both catalysts were taken equal, 22 000.

This catalyst can be used repeatedly. Along with the compounds synthesized previously, we tested in turpentine oxidation polyoxometallate with spherical nanoclusters of the composition $(NH_4)_{42}[Mo^{VI}_{72}\cdot Mo^{V}_{60}O_{372}(HCO_2)_{30}(H_2O)_{72}]\cdot 30HCO_2Na\cdot 250H_2O$ [8].

It should be noted that the resistance of the spherical molybdenum complex to atmospheric oxygen was evaluated in [9] by spectrophotometry and by photovoltaic effect measurement, and the tendency of the complex to gradual oxidation and degradation, accelerating under the action of light, was revealed. At the same time, the oxidation of α-pinene without solvent in the presence of the polyoxometallate was slow.

A heterogeneous analog of Co(II) picoline complex, prepared by sorption of Co(II) ions on AN-251 anion exchanger, proved to be the least active among the heterogeneous catalysts, despite the fact that the corresponding homogeneous catalyst showed high selectivity in oxidation of α-pinene to verbenone [10].

According to GLC data, elevated pressure appreciably increases the α-pinene conversion. The α-pinene conversion reached 78% (at 45% conversion, the selectivity of verbenone formation was about 12%), at the highest oxidation rate, with the homogeneous Co(Salen) catalyst. It is appropriate to use this catalyst for oxidation of sulfate turpentine, as it is a one-use catalyst.

α-Pinene concentration c as a function of time t. Oxidation in the presence of $Co(acac)_2$. $\log c = -0.0011t + 0.8715$; $R^2 = 0.8375$.

CONCLUSIONS

(1) The conditions chosen for sulfate turpentine oxidation (P ~1.3 atm) ensure increased conversion of α-pinene and confirm the necessity of searching for compounds generating radical oxygen species as catalysts for α-pinene oxidation to verbenol and verbenone.

(2) The presence of other terpene hydrocarbons, along with α-pinene, in turpentine reduced the negative effect of the most active radical species on the initial oxidation process.

(3) Heterogeneous catalysts are appropriate for oxidation of oleoresin turpentine, because this raw material contains no sulfur compound and there is no risk of catalyst poisoning.

ACKNOWLEDGMENTS

The authors are grateful to V.L. Volkov for the sample of VOB of the composition $Cu_{0.6}\cdot V_2O_5$ and to V.P. Fedin for the sample of the polyoxometallate $(NH_4)_{42}[Mo^{VI}_{72}Mo^{V}_{60}O_{372}(HCO_2)_{30}(H_2O)_{72}]\cdot 30HCO_2Na\cdot 250H_2O$.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

A Sonoluminescent Method for On-Line Monitoring of the Natural Water Quality

A. M. Worontsov, A. P. Patsovskii, M. N. Nikanorova, and G. B. Krivtsova

Scientific Research Center for Ecological Safety, Russian Academy of Sciences, St. Petersburg, Russia

Abstract—Ultrasonic impact on natural waters was applied to identify hydrochemical anomalies from the changes in the characteristics of sonoluminescence generated by ultrasonic cavitation in a flowing water sample. Sonoluminescence excitation spectra characteristic for various natural water pollutants were obtained for the first time. The suitability of changes in the sonoluminescence intensity and in the shape of the sonoluminescence excitation spectra as indicators of hydrochemical anomalies was elucidated.

DOI: 10.1134/S1070427208010138

The overwhelming majority of methods for water pollution assessment are based on comparison of the measured chemical composition, physical properties, and microbiological characteristics with the corresponding aquatic environment quality standards. Such pair-by-pair component-by-component assessment is not only awkward and hard to comprehend but also fails to meet (in ever growing extent with time going) the environmental safety requirements in the context of the hazard of chemical water pollution: There exist standards for no more than 6000 substances, while a total of 88 mln compounds were synthesized by the end of 2006 [1].

Multicriterial estimation [2] based on information compression and elimination of dimensionality of the resulting values is not suitable as an alternative to the pair-by-pair component-by-component assessment, since the resulting generalized (total property of a substance) and integrated (total amount of a substance) indicators are calculated using the results of the same single measurements of the same standardized parameters that were used previously [3]. This concerns above all such, now conventional, indicators as the water pollution index, atmosphere pollution index, soil pollution index, and waste toxicity index. Recent years have witnessed ever more extensive use of test methods for aquatic environment monitoring [4]. They can be subdivided into selective (qualitative or semiquantitative analysis of one substance) and nonselective (analysis of the total content of a substance or the total property of the medium) methods.

Clearly, nonselective test methods, in fact, provide integrated or generalized indicators without calculation of the corresponding indices. A combination of test methods with the screening methodology (elimination of obviously "blank" samples) is in line with the new analytical monitoring paradigm [5].

Development of new test methods should be focused on the search for hydrochemical anomalies, based on the "yes/no" qualitative criterion, rather than on measurement of water quality indicators (individual, generalized, or integrated). This allows designing nonselective sensors of hydrochemical anomalies, raising alarm in cases when the composition of the medium exhibits any significant deviation from the statistically normal value. These are environmental alarm sensors (EASs) which can be regarded as functional and cost analogs of widely used fire and security alarm sensors [6].

Among test methods promising for designing EASs is that based on monitoring of the total content of dissolved organic matter (DOM) in natural waters and wastewaters from ozone chemiluminescence. This method is underlain by the interrelation between the amount of DOM being ozonized in a flowing water sample and the chemiluminescence intensity [7].

Also promising is the method based on sonoluminescence (SL) effect whose intensity exhibits nonselective dependence on the content of an infinitely broad spectrum of possible components of water objects: biotic and anthropogenic dissolved organic matter of different nature, inorganic ions, dissolved

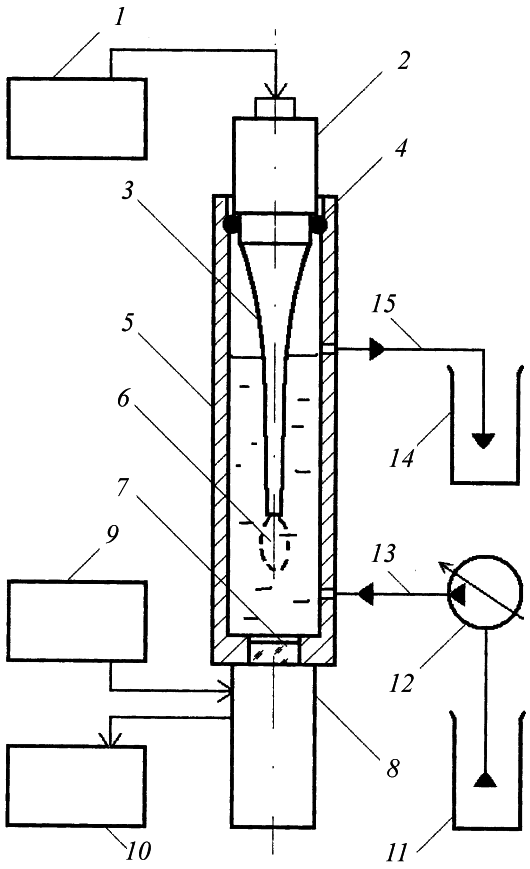

Fig. 1. Experimental setup for recording sonoluminescence in a flowing water sample (this is a functional scheme; see designations in the text).

gases, colloid particles, any kind of sonoluminescence and chemiluminescence quenchers and catalysts, and substances containing UV/Vis-absorbing chromophore groups.

Ultrasonication of water and aqueous solutions results in formation of a multibubble cavitation zone (cavitation cloud) in which specific sonochemical reactions proceed and SL arises. It has been known for already half a century that the SL intensity is proportional to the electrolyte content of water and depends on the composition and amount of dissolved gases and also that dissolved organic alcohols decrease the SL intensity [8, 9]. It is generally recognized that virtually all the dissolved organic substances act as SL quenchers, but it was recently demonstrated [10, 11] that the luminescence of aqueous solutions exhibits a complex dependence on the concentration of soluble substances.

The first examinations of sonoluminescence in a natural water flow date back to 2000 [12], when we showed that the SL effect can underlie the development of EASs. Since then, the research methodology and experimental setups were improved [13–16], which allowed us to attempt formulating the basic principles of the new method of analysis, sonoluminescence excitation spectroscopy, to underlie designing equipment to reveal chemical anomalies in the aquatic environment, in particular, sonoluminescence-based EASs.

EXPERIMENTAL

The main specific feature of the experimental setup for examination of SL in a flowing water sample (Fig. 1) is that the ultrasonication energy at a fixed ultrasonic frequency can be varied, so that the characteristic dependences of the SL intensity on the SL-exciting energy can be derived for model and natural aqueous solutions.

The setup was assembled from standard units of analytical and medical instruments. As the source of ultrasonication responsible for formation in a water flow of a multibubble cavitation zone we used a SUZA commercial medical apparatus developed in Russia [17, 18] *1* comprising one-half-wave piezo converter *2* and ultrasonication energy concentrator *3*. This system allows the specific density of acoustic energy in the ultrasonication zone to be varied discretely (in 9 steps) from 4.92 to 15.62 J cm^{-3} at a fixed frequency of 22 kHz. The ultrasonication energy concentrator *3* is introduced through shock-absorbing sealing ring *4* into the case of flow cell *5* (d_{in} = 20 mm). Ultrasonication results in formation near the end face of the concentrator of multibubble cavitation zone *6*, in which SL is generated; it passes through KU-1 melted quartz window *7* onto the photocathode of photodetector *8* (FEU-85). High-voltage board *9* supplies up to 1100 V voltage to the photomultiplier; the photocurrent comes to signal amplification and recording system *10*. Hose pump *12* with a feeding volume of 35 cm^3 min^{-1} supplies a natural water sample from reservoir *11* through line *13* (nominal diameter 2 mm) into flow cell *15*, from whence it flows down into receiver *14* through line *15* (nominal diameter 8 mm). It should be noted that this small-sized (weighing 6.5 kg) setup is essentially an SL excitation spectrometer.

A spectrometer measures the distribution function (spectrum) of some physical quantity f with respect to parameter x. Here we report on the development of a spectrometer for determination of the $f(x)$ distribution, where f is the SL intensity, and x, energy of the ultrasonication responsible for this SL (in a similar

manner, e.g., spectral fluorescence instruments record the fluorescence excitation spectra).

The SL excitation spectra of aqueous solutions were recorded at different concentrations of dissolved organic and inorganic substances, salinities, and amounts of dissolved gases. Figure 2 presents the SL excitation spectrum of a background object, distilled water (Fig. 2a) and the most characteristic excitation spectra of aqueous solutions of the substances that are important indicators of the aquatic environment quality. These include humates (Fig. 2b) whose concentration largely determines the water object quality; NaCl, whose concentration governs the water environment salinity (Fig. 2c); and Ponceau 4R dye, a model natural water pollutant of organic origin (Fig. 2d).

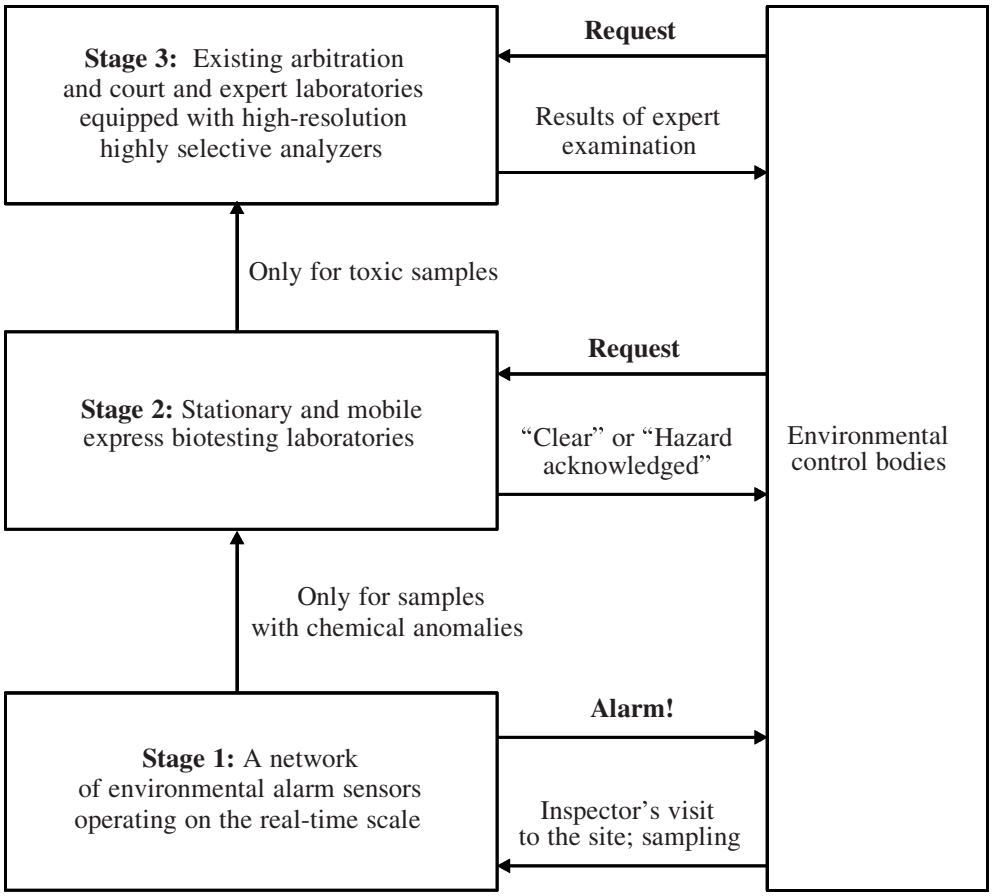
luminescence excitation spectrum of an aqueous NaCl solution.

Figure 3 shows how the SL intensity varies with time; in this case, the revealed hydrochemical anomalies were associated with the appearance in the aquatic environment of an organic (Fig. 3b) and inorganic (Fig. 3c) substance.

To check the consistency of the results of measurements and determine the action limits (the hydrochemical anomaly detection level) we used control Schuhart maps (*R*-diagrams) [19].



The Schuhart map is a plot of the values of certain characteristics of subgroups vs. their numbers. The map has the central line corresponding to the reference value of a characteristic. This is a long-term value of the characteristic or its nominal value derived from the previously available information about the process of interest. Schuhart maps have two statistically determined control limits relative to the central line, an upper and a lower limit.

The control limits on Schuhart maps are separated from the central line by a distance of 3σ. The ±3σ limits suggest that ca. 99.7% of the values of the subgroup characteristic will fall within these limits, provided that there will be no significant systematic errors.

The analytical application of the SL method is exemplified by Fig. 4 demonstrating the results of examinations carried out by the Laboratory of Hyphenated Methods of Environmental Control, Scientific Research Center for Ecological Safety, Russian Academy of Sciences, in the period April 1–30, 2007. The subjects of these examinations were water samples taken from Chernaya Rechka river to check the consistency of the data on the content and properties of the dissolved matter. This was done by daily analyzing three aliquots of the water sample under replication conditions. In calculation of the central line and control limits we used the coefficients from [19].

The mapped data evidence inconsistency of the

A hierarchic system of on-line environmental monitoring of water objects

results of measurements, associated with anomalies in the content of the dissolved matter: One point in the map exceeds the action limit, and the data derived from three series of measurements, each comprised of seven or more results, are located above the central line. These and similar anomalies can evidence emergent or illegal dumping or utilizing inadequate treatment technologies in water supply systems of settlements, i.e., the events that can be detected by EASs whose operation is underlain by the SL effect.

However, an EAS is able of informing only about a chemical anomaly which can be associated with natural processes and be quite harmless. Therefore, the sample taken at the time when a sensor raised an alarm needs to be promptly tested for toxicity. An ideal choice for Stage 2 can be found in simple biotesting instruments and methods suitable for identifying new and inadequately studied pollutants of unknown type and composition from the change in the total toxicity of the sample.

Only samples for which a chemical anomaly was revealed and subsequently a toxicity was identified in a biotest should be taken for analysis in Stage 3, i.e., for detailed expert examinations in laboratories equipped with expensive high-resolution highly selective instruments (chromatographs, chromato-mass-spectrometers, atomic absorption spectrometers, inductively coupled plasma atomic emission analyzers), serviced by highly skilled personnel.

This makes it possible to sharply decrease the number of expensive analytical procedures and conduct environmental monitoring at a small number of the best available arbitration and expert and criminological laboratories.

The environmental control system we proposed (see scheme) is an open hierarchic structure which can be comprised of the available components and, as soon as appropriate funding is obtained (mostly through application of the results achieved), be supplemented with new components.

CONCLUSIONS

(1) A method was proposed for the search of anomalies in the chemical composition of natural

waters, based on the sonoluminescence effect which was not earlier used for these purposes.

(2) The search for anomalies in the chemical composition using the sonoluminescence method can underlie development of a new type of environmental alarm sensors to be applied in the first stage of the natural water quality control system. Rising an alarm by such a sensor allows promptly responding to possible chemical threats, and further analytical procedures will apply only to those samples for which hydrochemical anomalies were revealed in time (stationary environmental alarm sensor in a water flow or "on the pipe") and in space (a mobile sensor onboard an over- or underwater vessel).

(3) A small-sized setup (sonoluminescence excitation spectrometer) was developed for recording the sonoluminescence intensity vs. the ultrasonication energy for a natural water flow; characteristic sonoluminescence excitation spectra of model and natural water samples were recorded.

(4) A sonoluminescence excitation spectrometer was described in a detail sufficient for replication by other research laboratories.

Abstract—The electrothermal method for control over the combustion velocity of energetic condensed systems based on ammonium nitrate oxidizing agent at the intrachamber pressure of the gas phase of combustion products varied in the range 1–6 MPa was examined as applied to controllable solid-fuel power installations.

DOI: 10.1134/S107042720801014X

It is known that the combustion velocity of energetic condensed systems (ECS) is a function of several variables:

$$u = F[\chi,\ P_c,\ T_0,\ \nu,\ a_g],$$

where χ is the chemical composition of ECS; P_c, gas phase pressure in the combustion chamber as a function of temperature T_c; T_0, initial temperature of ECS; ν, gas-dynamic factor, e.g., the "erosion" effect determined by the Pobedonostsev criterion; and a_g, the accelerative force acting on the ECS in accelerated motion of the charge.

Because of the existence of the electrothermal effect [2, 3], which has been experimentally confirmed under atmospheric pressure, one more factor can be added to the functional dependence: power N (W) released in the reaction zone of the condensed phase (c-phase) when current flows through a continuously burning fuel.

With account of the fact that $N = IU = I^2R_x$, where I is the current strength in the reaction zone and U is the voltage across the charge, the dependence of the combustion velocity on pressure and current strength, $u(P_c, I)$, can be studied at a constant chemical composition and other factors mentioned above. The current strength obeying in steady-state combustion Ohm's law depends on the resistance related to the chemical composition and geometric dimensions of the electrically conducting zone by $R_x = \rho_0 L/S$, where ρ_0 is resistivity; L, interelectrode distance; and S, area of the conducting cross section of the reaction zone of ECS.

The electrothermal control over the combustion velocity is executed with a system of metallic electrodes built in a solid-fuel charge. These electrodes serve to pass electric current through the reaction zone of ECS from an external voltage source. All other conditions (chemical composition, initial temperature of the fuel, temperature and pressure in the chamber, etc.) being the same, the combustion velocity of a condensed system will be a function of the current flowing through the electrically conducting layer. Electrodes made of a thin metallic foil can be involved in chemical reactions as a fuel burning-out in the gas phase.

EXPERIMENTAL

To study the dependences $u(P_c, I[U, R_x])$, the procedure was chosen in which the pressure in the chamber and the current strength steadily increase in the course of combustion. In this case, the results obtained will depend on the variation rates (derivatives with respect to time) of the factors and, in the process, will become increasingly related to intrachamber transient processes and different from the results obtained under steady-state conditions $u(P_c = \text{const}_i,\ I = \text{const}_j)$.

A difficult issue is the choice of the value of the derivative dP_c/dt at which the processes occurring in the gas phase and in the reaction zone of ECS can be conditionally considered steady-state. The derivative with respect to pressure is the most important for solid fuels with a large ballistic exponent in the power law of combustion, $[u(P_c) = u_0 P_c^{\nu}]$ [1, 4]. Probably,

the dynamic properties of the reaction zones of the c-phases should be considered low-inertia, because otherwise it would be impossible for anomalous acoustic effects, such as resonant combustion of ECS at frequencies from 100 Hz to 10 kHz and more, to appear and to be maintained. For example, at harmonic pressure oscillations in the chamber, with an amplitude A = 0.1 MPa at a frequency f = 100 Hz, the absolute value of the pressure variation rate is as high as $dP_c/dt = 2\pi Af$ = 62.8 MPa s^{-1}. Therefore, the rate of the monotonic rise in pressure in the experiments was chosen to be $dP_c \le 1$ MPa s^{-1} at a free volume of the chamber equal to 1.5–1.7 l.

Under the electrothermal control, the thermal power of the electric current is released directly within the c-phase of the reaction zone of the solid fuel without any intermediate physical conversion stages or high-inertia processes and is independent of the current frequency (up to $f \le 20$ kHz).

A computerized multichannel measuring system [5] was used to record the experimental values of the chamber pressure and of the voltage and current in the

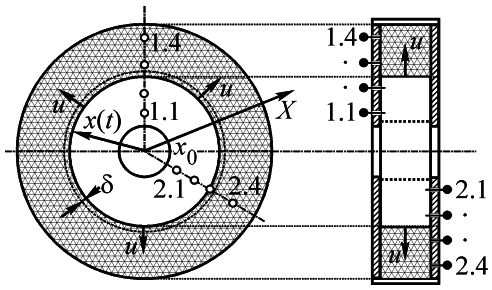

Fig. 1. Schematic of charge combustion in the inner channel. (X) Axis of radial coordinates of combustion front sensors (1.1–2.4), (u) combustion velocity vector, (δ) thickness of the reaction zone of ECS, (x_0) initial radius of the channel, and [$x(t)$] channel radius as a function of time.

reaction zone of the c-phase as functions of time and the instants of time when the ECS combustion front passed control coordinates (electrodes of the combustion front sensors, CFS). The oscillograms obtained were used to determine the values of $P_c(t)$ and $I(U, t)$ at any instant of time t in order to construct joint dependences. The function describing the combustion velocity, $u(t_i)$, was found from the derivative dx/dt of the approximated (by the least-squares method) dependence of the channel radius on time, $x(t)$, which is originally obtained in a discrete form $x(t_i)$ (at instants of time at which the control coordinates are passed by the combustion front), using CFS with known coordinates. The procedure used to determine the ECS combustion velocity has proved to be efficient in similar measurements under atmospheric pressure [6].

In the experiments, model formulations (see table) of mixed solid fuels (MSF) were used in the form of cylindrical charges (diameter 85 mm, thickness 11–12 mm) with progressive combustion in the inner channel (Fig. 1). The fuels were based on pure ammonium nitrate (AN) with addition of powdered aluminum ASD-4 (10%) at a constant content of the binder (15% ED-22 epoxy resin with urotropin as curing agent).

If the combustion front of an ECS charge is a cylindrical surface expanding in an axially symmetric manner, then the electrical resistance of the reaction zone of the c-phase can be described as a function of the channel radius x by the formula

$$R(x) = \rho_0 L/\pi(2\delta x - \delta^2), \quad (1)$$

where ρ_0 is the resistivity of the reaction zone and L is the charge thickness.

Thus, information about the ECS combustion dynamics in a wide range of automatic variation of the pressure and current strength determined by the electrical conductivity of the c-phase and the effective (const) voltage across the charge can be obtained in one experiment.

The fabrication technology of the charges included production of dried (100–200-μm) fraction of the oxidizing agent, mechanical mixing with an epoxy binder, and compaction of fuel pastes (93–100 g) in special molds under a pressure of 8 ± 0.5 MPa and polymerization of articles in a continuous mode at 75–80°C for 18–20 h. The initial diameter of the inner (cylindrical) combustion channel was x_0 = 15 mm.

A scheme illustrating the procedure used to measure the combustion velocity of the charge [5, 6], current strength, and voltage is shown in Fig. 2. The

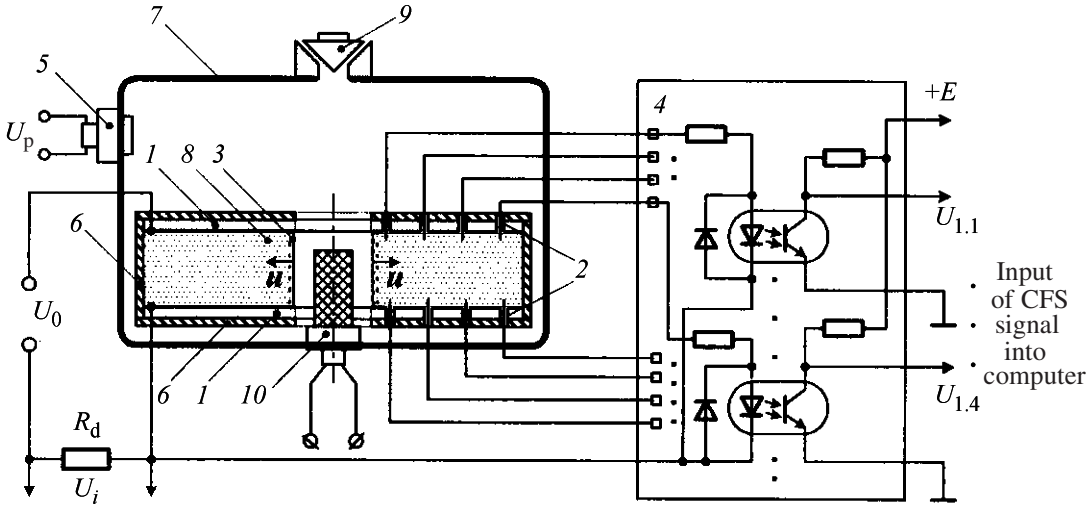

Fig. 2. Measuring unit of the experimental setup. (*1*) Electrode discs with copper foil, (*2*) CFS wire electrodes, (*3*) reaction zone (front) of combustion, (*4*) converter interface for a computer, (*5*) pressure transducer, (*6*) thermal insulation (restriction) of the charge, (*7*) combustion chamber, (*8*) MSF, (*9*) gas pressure-relief valve, (*10*) ignition device (ID), (U_p) the pressure transducer voltage, (U_0) input voltage, and (U_i) voltage across the divider R_d for measuring the current strength in the charge.

MSF charge was adhesively attached on two sides to the copper foil of round plates of foiled textolite (1) connected to a source of electric voltage U_0. These electrode discs have apertures along their radii in two directions, in which wire electrodes (2) of thickness 0.4 mm are mounted without electric contact with the copper foil. The coordinates of these electrodes (away from the longitudinal axis of the charge) and the distances x_i between them were measured with an MBS-10 microscope in the fabrication stage. Under normal conditions, when there is no adsorbed moisture on the surface of the inner channel, the fuel paste has a resistance of more than 30 MΩ (measured with V7-38 device), i.e., the resistivity of ECS is no less than 10^9 Ω cm.

Under the combustion conditions, the moving front of the electrically conducting reaction zone (3) in the condensed phase of the fuel successively passes across the wire electrodes. When touching the combustion surface (zone of molten NH_4NO_3), the electrodes are connected to the voltage source ($\sim U_0$), which opens optoelectronic switches in the electronic unit (4) of the combustion front sensors and the signals are fed via a multichannel analog-data-input interface into a computer. The dependence of the radial coordinates of the electrodes on the instants of their actuation is approximated with a continuous function $x(t)$, whose first derivative gives numerical values of the instantaneous combustion velocity in the time interval under study.

At fully closed valve, the pressure in the combustion chamber reached 10–11 MPa. Therefore, radial arrangement of CFSs was chosen in accordance with their actuation in the pressure range 1–8 MPa at the pressure derivative $dP_c/dt \leq 1$–1.2 MPa s^{-1}.

The igniting devices (ID) had the form of powder charges 12 mm in diameter, made of compacted (at pressures of up to 600 MPa) black powder, with computer-controlled electric-coil ignition. Under the action of the ID and additional powder charges, the starting gas-phase pressure of 0.8–1.0 MPa with a 30–50% excess was created in the chamber. The intrachamber gas-phase pressures were measured with a PD-150-0.4 commercial low-inertia tensoresistive transducer with the working range 0.1–15 MPa (relative error 0.4%).

Figure 3 shows prognosticated pressure dependences of the combustion velocity of an ECS with a cylindrical channel at different charge voltages U_n

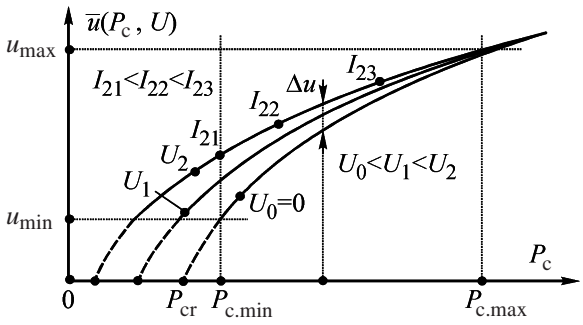

Fig. 3. Prognosticated pressure dependence of the combustion velocities, $u(P_c, U_n)$, in the pressure range under study $[P_{c.min}, P_{c.max}]$ at different voltages applied to the charges (U_1–U_3).

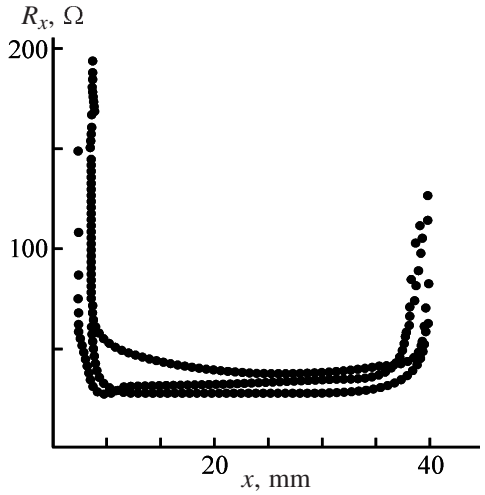

Fig. 4. Electrical resistance R_x of the reaction zones a1–a5 of ECS (85% AN + 15% ED-22) vs. the radius x of the charge combustion channels.

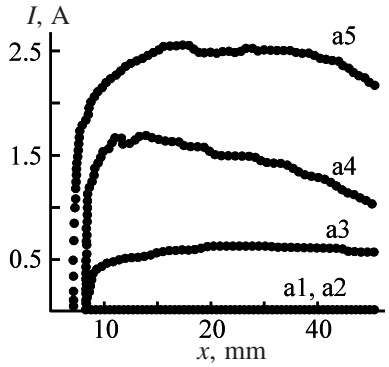

Fig. 5. Current strength I in the reaction zone of ECS vs. the radius x of the charge combustion channel.

and current strengths I_n in the reaction zone. The expected characteristics $u(P_c,\ I[U, R_x])$ are associated with the advanced rise in the mass expenditure rate of the fuel with respect to that in the electric power and with the accordingly gradually decreasing specific power (W kg^{-1} s = J kg^{-1}) in the c-phase. It is possible in this case that, as the mass expenditure rate increases, the electrothermal effect Δu will decrease and the combustion velocity will asymptotically approach its normal value under the current thermodynamic conditions, $u(P_c, 0)$.

Originally, experiments devoted to analysis of the amplitude–frequency characteristics of the c-phase were performed. For this purpose, a GZ-110 programmed sinusoidal voltage generator was used as a U_0 voltage source. This enabled multiple changes of frequency within a certain range in the course of an experiment at U_0 = const and control over the resistance of the reaction zone. At frequencies of 0–20 kHz, no changes in electrical conductivity within 5% were observed, and, therefore, both dc and ac voltages were used in experiments. This indicates that the electronic conduction predominates in the viscous-liquid (liquid-viscous) surface layer of the c-phase of ECS and the capacitive and inductive components are insignificant.

Figure 4 shows superimposed plots of the resistance of the reaction zones of five ECS (85% AN + 15% ED-22) against the combustion channel radii. The nearly rectangular shape of the curves and the increase in resistance before the complete burning-out possibly indicate that the shape of the inner channel deviates from the cylindrical [hyperbolic dependence in formula (1)] toward formation of a convex surface by the end of combustion.

These known "edge" effects [4] associated with an increase in the ECS combustion velocity in the near-wall zones probably occur in the cases in question due to the additional heating of the edge surface of the fuel across the copper foil (40–50 μm) of the electrode discs and to an increase in the initial temperature of the fuel. This factor was disregarded in data processing and its manifestation was considered to be the same in all cases and to have no effect on the general pattern of relative changes in the ballistic characteristics of ECS.

Figure 5 shows superimposed plots of the effective values of the current strength in the reaction zones of five charges (85% AN + 15% ED-22) against the combustion channel radii. At constant voltages, the currents are proportional to changes in the conductivities of the charges.

The instantaneous values of the intrachamber pressures, known from the oscillograms, and the pressure dependences of the combustion velocity, calculated for each charge, were used to obtain combustion equations for the ECS under study: $u(P_c, U)$. Figure 6 shows superimposed plots demonstrating how the ballistic characteristics of ECS vary with intrachamber pressure and discrete voltages on the charges, constructed for two experimental series (see table).

The ECS combustion equations (Fig. 6) have the form

$$u(\text{a1}) = 0.84(P_c - 10.88)^{0.405} - 0.86,$$

$$u(\text{a2}) = 0.75(P_c - 8.52)^{0.423} - 0.88,$$

$$u(\text{a3}) = 0.40(P_c - 8.99)^{0.484} - 0.01,$$

$$u(\text{a4}) = 1.03(P_c - 9.06)^{0.285} - 0.84,$$

$$u(\text{a5}) = 0.87(P_c - 12.59)^{0.240} - 0.22,$$

$$u(\text{b1}) = 0.90(P_c - 6.36)^{0.448} - 0.93,$$

$$u(\text{b2}) = 0.77(P_c - 9.22)^{0.438} - 0.23,$$

$$u(\text{b3}) = 0.74(P_c - 6.33)^{0.450} - 0.45,$$

$$u(\text{b4}) = 0.95(P_c - 8.22)^{0.315} - 0.07.$$

It is appropriate to formulate tentative conclusions based on the results obtained if the stationary model of ECS combustion, for which the characteristics shown in Fig. 6 are considered static, is adopted. In the pressure range in question, the rate of pressure buildup, dP_c/dt, did not exceed 1.0–1.2 MPa s^{-1} ($\leq$0.5 MPa s^{-1} at 1 MPa $< P_c <$ 4 MPa).

To substantiate the results (Fig. 6), it is necessary to consider comprehensively the possible processes in the gas and condensed phases. It follows from the plots that, for both ECS compositions (AN + ED-22 and AN + Al + ED-22), the functional dependences of the combustion velocity on pressure and charge voltages are similar. Metallization of ECS leads to an increase in the fuel combustion velocity, which can be attributed to a rise in the temperature of the gas phase and to the corresponding acceleration of the initial stages of the heterogeneous reactions in the viscous-liquid layer of the c-phase.

The increase in the ECS combustion velocity under the action of electric current at pressures $P_c <$ 2.5 MPa is, on the whole, in agreement with the prognosticated dependences (Fig. 3) and with the results obtained in similar studies under atmospheric pressure. The thermal power released by the electric current within the reaction zone additionally accelerates the stages of ECS decomposition and the heterogeneous reactions in accordance with the Arrhenius law. This increase in the internal energy of the reaction zone in the c-phase, independent of the inflow of heat from the gas phase, possibly corresponds to the state of the c-phase at the intrachamber pressure exceeding the current value. That is, the acceleration of the reaction kinetics in the c-phase under the action of an external source of voltage is probably equivalent to an increase in the pressure (temperature) in the gas phase in the chamber. Of interest in this case are the overall decrease in the ballistic exponent ν of the ECS, which becomes a quantity that is variable (controllable) within certain limits, and the decrease in the threshold pressures of stable combustion, P_{cr}, on raising the working voltages.

The decrease in the combustion velocity of the MSF formulations in question under the action of electric current and voltages at pressures exceeding

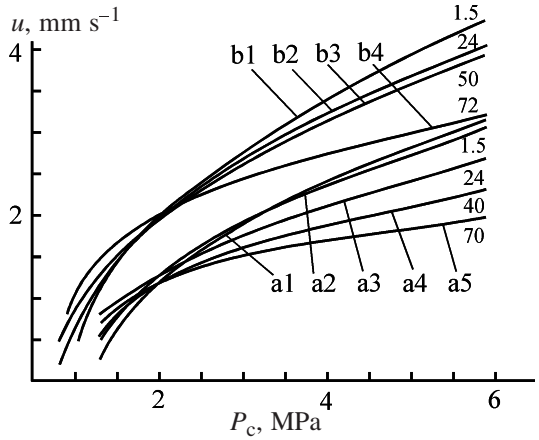

Fig. 6. ECS combustion velocity u vs. the intrachamber pressure P_c at different effective voltages on the charges. Figures at curves are charge voltages (V).

3 MPa can be, probably, accounted for by the effect of the following (one or several) factors.

(1) The decomposition rate of ammonium nitrate grows, which leads to an increase in the mass fraction of ammonia that has not enough time to react in the c-phase and is transferred into the gas phase, thereby lowering the temperature of the surface zone of the flame. The inhibiting effect of NH_3 in ammonium nitrate oxidizing agents was noted in [7].

(2) As the pressure becomes higher, the gas content of the reaction zone grows, which is accompanied by foaming (onset of boiling) of the viscous-liquid layer and by an increase in its volume, with the result that its density and, accordingly, thermal conductivity decrease and, therefore, the preliminary stages, decomposition of the oxidizing agent and thermal degradation of the binder, are decelerated. In similar experiments performed under atmospheric pressure, an intense discharge of foam-like fragments of the viscous-liquid layer of the c-phase in the form of a multitude of drops were observed at higher currents in the charge. In this case, the combustion velocity ceased to increase and its dependence on he current strength became strongly nonlinear.

(3) The decrease in the combustion velocity reflects processes that occur in natural way for these MSF formulations at considerably higher pressures (10–15 MPa), with different equivalent P_c corresponding to different voltages. Then the crossing point of the characteristics may correspond to the beginning of the exponent sign reversal ($\nu < 0$).

These effects and their possible reasons may depend on the existence (magnitude) of an intra-

chamber gas flow along the charge combustion surface and on other gas-dynamic factors.

CONCLUSIONS

(1) The increase in the combustion velocity of energetic condensed systems based on ammonium nitrate under the action of an electric current flowing in the reaction zone of the c-phase is in agreement with the prognosticated results at low intrachamber pressures of up to 2 MPa.

(2) The ballistic exponent of the energetic condensed systems (in the power law of combustion) and the critical pressure decrease under the action of an electric current. This means that the dependence of the reaction processes at the combustion surface on the inflow of heat from the gas phase becomes weaker and, accordingly, their stability at lower pressures decreases.

(3) Metallization with aluminum (10%) of mixed solid fuels based on NH_4NO_3 leads to a decrease in the conductivity of the reaction zone of the c-phase by 30–40%. This possibly means that aluminum particles are not involved in electrical conduction because, being present in the solid phase in the viscous-liquid layer, they are coated with Al_2O_3.

(4) The electronic conduction predominates in the reaction zones of the c-phases of the energetic condensed systems studied; the frequency-dependent ionic conduction of a pure ammonium nitrate melt is not manifested.

(5) The combustion velocity of the mixed solid fuel formulations studied decreases under the action of an electric current at pressures exceeding 3 MPa.

(6) The changed thermal state of the reaction zone of the c-phase, in which an electric current flows, possibly corresponds to processes that occur without any electrothermal action at higher pressures.

(7) Measurements of the electrical conductivities of the reaction zones of the c-phases of charges that should burn in strictly calculated ranges in uncontrolled modes can serve as an additional method for monitoring the intrachamber processes and revealing various deviations: appearance of acoustic oscillations, cracking (disintegration) of charges or their asymmetric burnout, and other anomalous modes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Cerium on Electrochemical and Mechanical Properties of Aluminum–Iron Alloys

Abstract—Effect of cerium on the corrosion-electrochemical and mechanical properties of aluminum alloys with an iron content of up to 3% was studied in order to use secondary aluminum in development of sacrificial formulations.

DOI: 10.1134/S1070427208010151

According to the fundamentals of metal science, aluminum–iron alloys are not classed with any type of alloys, being related neither to deformable, nor to castable alloys. At the same time, alloys of the Al–Fe system are of particular interest as a structural material because iron is always present in aluminum: as an impurity from the steel equipment used in melting and casting or as an alloying additive introduced to improve the heat resistance of an alloy. It is known that each percent of iron raises the modulus of elasticity by 25%, and the shear modulus, by 3%; iron improves to a certain extent the machinability of aluminum by cutting and gives rise to a damping capacity [1].

The aim of the present study is to convert off-grade aluminum to a structural material by alloying. It is known that addition of cerium in an amount of 0.25–0.5% to an alloy containing aluminum and iron leads to a decrease in the grain size and improves the hot rolling capacity [2].

EXPERIMENTAL

Because secondary aluminum may contain up to 3% iron, we preliminarily examined the effect of iron on the corrosion-electrochemical properties of aluminum. Alloys based on aluminum brands with different degrees of purity were synthesized: special-purity of A6N0 brand (TU-ANT-006–88), high-purity of A995 brand [GOST (State Standard) 11 069–74], and technical-grade of A8, A6, and A5 brands (GOST 4784–74*), whose chemical composition is listed in Table 1.

A molten aluminum alloy was poured into a steel mold to obtain cylindrical rods. The electrode thus obtained was ground, polished to mirror shine, washed, and degreased with ethanol.

Corrosion-electrochemical studies were performed on a PI 50-1 potentiostat with a PR-8 programming unit in a 3% NaCl solution at a potential sweep rate of 2 mV s^{-1} [3, 4]. A silver chloride electrode was used as reference, and the potentials given were recalculated to the standard hydrogen scale.

The corrosion current i_{corr} as the basic electrochemical characteristic of the corrosion process was calculated from the cathodic curve (with account of the slope of the Tafel portion, b_c = 0.12 V), because the pitting corrosion in neutral media is mostly controlled by the cathodic reaction of oxygen ionization [5]:

$$O_2 + 2H_2O + 4e \rightarrow 4OH^-.$$

The corrosion rate K, which is a function of the corrosion current density, was found using the formula

$$K = i_{corr}k,$$

where k is the electrochemical equivalent, equal to 0.335 g A^{-1} h^{-1} for aluminum [6].

The results of the corrosion-electrochemical tests are listed in Table 2. Rare-earth metals (REM) have specific properties and are widely used for improving the structure and properties of alloys, among which the corrosion resistance should be mentioned. For these reasons, cerium was chosen as an additional alloying component. It was introduced as a 7% alloy into an aluminum–iron melt at a temperature of 900°C.

To choose the optimal content of cerium in the

alloy, we examined the electrochemical, mechanical, and technological properties of the system, which are insufficiently understood for this group of alloys. The results of a corrosion-electrochemical study of alloys of the system Al–Fe–Ce in a 3% solution of sodium chloride are listed in Table 3.

The mechanical properties were tested on a P-5 tensile machine at loads of 1000–10000 kg. The hardness of the alloys, HB, was determined by the Brinell method; strength and plasticity [ultimate strength σ_t (MPa) and relative elongation δ (%), respectively] were found in accordance with GOST 1494–84. The

* Studies performed by I.T. Amonov.

results obtained in tests of cerium–modified aluminum–iron alloys of a eutectic composition (2.18%) are listed in Table 4.

It is known that one of the most reliable, available, and effective methods for control of electrochemical corrosion of metallic structures is sacrificial protection. Among the presently existing industrial sacrificial alloys based on zinc, magnesium, and aluminum, the most effective material as regards the amount of absorbed energy per unit mass is aluminum. In addition, zinc-based industrial sacrificial alloys have strict limitations on the content of impurities. A 3% NaCl solution served as the working solution, and St.3 steel rods were the protected objects. The test duration was 100 h at a current density $I = 1.5$ A m^{-2}.

The utilization coefficient (UC) of the sacrificial material was calculated using the procedure described in [7].

Table 5 lists the results of galvanostatic tests of aluminum alloys containing up to 1.5% iron and up to 1.0% Ce (cerium misch metal). Manganese has a negative equilibrium potential ($E = -1.1$ V) and its presence in an alloy reduces the adverse effect of impurities via formation of intermetallic compounds (Mn,Fe)Al and other compounds having negative electrode potentials.

It follows from the results obtained (Table 2) that iron present in amounts of up to 0.15 wt % does not affect the corrosion rate of aluminum significantly. As the amount of aluminum is raised to 15 wt %, the corrosion currents strongly increase. The free-corrosion, pitting, corrosion, and repassivation potentials are shifted to more positive values as the content of iron increases. The passivation interval ΔE_{pass} is 0.30–0.36 V.

Table 3 illustrates the effect of cerium on the corrosion-electrochemical properties of aluminum with high content of iron. For example, comparison of the characteristics of the first two alloys shows that modification with cerium shifts the free-corrosion, pitting, and corrosion potentials to more positive values. Modification with minor amounts of cerium of an alloy composed of aluminum and 1% iron reduces the corrosion rate by a factor of 3–4. Raising the content of iron to 2.18% (eutectic composition) shifts the free-corrosion, pitting, and corrosion potentials to more negative values. The passivation interval increases insignificantly. The corrosion rate of this alloy with a microscopic addition of cerium (0.005–0.05%) decreases by a factor of 2 to $(6.2–6.7) \times 10^{-4}$ g m^2 h^{-1} (Table 3). The optimal, in the corrosion regard, composition of this group of alloys is that of the alloy Al–2.18Fe–0.01Ce.

A study of the aluminum alloy with the maximum content of iron (3%) demonstrated that alloying with 0.5% cerium shifts the free-corrosion, pitting, and corrosion potentials to more positive values. In this case, the passivation interval remains unchanged, whereas the corrosion rate decreases by a factor of 2.5.

Table 5. Characteristics of aluminum alloys recommended as sacrificial materials

Alloy no.	Alloy component, wt %			$-E_w$, V	UC, %	i_{corr}, A m^{-2}
	Fe	Mn	Ce (misch metal)			
1	0.15	–	–	0.545	86.2	0.15
2	0.15	0.35	–	0.560	86.9	0.12
3	0.15	0.35	0.1	0.610	77.2	0.10
4	1.0	1.0	–	0.520	58.2	0.28
5	1.0	1.0	0.1	0.580	98.1	0.20
6	1.5	–	–	0.500	84.5	0.50
7	1.5	–	0.1	0.540	97.8	0.23

* The corrosion current densities were found from a cathodic polarization curve obtained under a sacrificial protection.

It should be noted, when analyzing the mechanical properties (hardness, strength, and plasticity) of the Al–2.18Fe alloy, that alloying with cerium exerts the strongest influence on the plasticity. The relative elongations of these alloys increase 2.5–3-fold at the same or somewhat increased hardness of the samples. The maximum hardness HB = 270 is observed for the alloy Al–2.18Fe–0.20Ce.

With account of the low electrochemcial equivalent of aluminum and aluminum-based alloys (0.335 g A^{-1} h^{-1}) and their comparatively low cost and toxicity, the possibility of further use of secondary aluminum with 0.005–0.2% cerium as low-alloy material for anodes can be considered. Table 5 shows that, at low content of iron (on the impurity level), addition of manganese affects the protective properties of technical-grade aluminum only slightly. At equal contents of iron and manganese (1 wt %), introduction of REM (cerium misch metal) into an aluminum melt results in a significant increase in the UC of the sacrificial material (to 98.1%). At the maximum content of iron (1.5%) in the absence of other components, the UC of the aluminum anode is rather high (84.5%), whereas alloying with cerium misch metal raises its value to 97.8%. Among disadvantages of these alloys can be mentioned the insufficiently negative working potential of the sacrificial material. Therefore, according to the results of this study, use of aluminum with high content of iron (up to 1.5%) as a sacrificial material is only possible if activators, such as tin, indium, or gallium, are additionally introduced, which noticeably shifts the working potential of the sacrificial material to more electronegative values [8]. For example, addition of 0.2 wt % indium to alloy nos. 3, 5, and 7 (Table 5) shifts the working potential of the sacrificial material by 300–340 mV.

CONCLUSION

The results obtained in the study enable development of alloys with enhanced corrosion resistance and plasticity on the basis of secondary aluminum with addition of cerium (cerium misch metal). These alloys can also be recommended as a sacrificial material for protection of steel from corrosion damage in aqueous chloride-containing media.

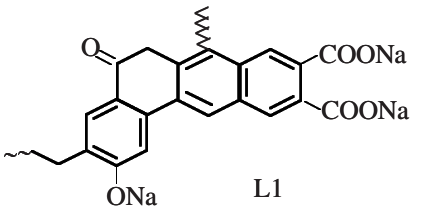
ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Nickel(II) and Copper(II) Complexes with Humic Acid Anions and Their Derivatives

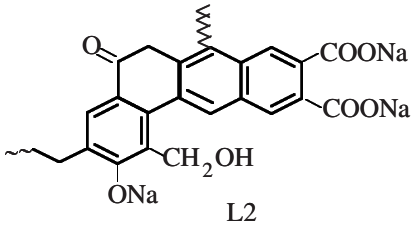
I. N. Ryabova

Institute of Organic Synthesis and Coal Chemistry, Karaganda, Kazakhstan



Received March 16, 2007; in final form, October 2007

Abstract—Complexation of Ni(II) and Cu(II) in aqueous solutions with anions of humic acids, extracted from naturally oxidized coal, and with their hydroxymethyl derivatives is studied spectrophotometrically and potentiometrically. The complexation stoichiometry and the stability constants of the complexes are determined.



DOI: 10.1134/S1070427208010163

Humic acids (HAs) and their hydroxymethyl derivatives are insoluble in water. However, their sodium salts are water-soluble, opening the door for studying their complexation in aqueous solutions. Chuveleva et al. [1] studied complexation of HAs with Ca(II) using potentiometric titration of their aqueous suspensions. It was demonstrated that, at pH ~4, CaL and CaL_2 complexes are formed.

In this study we determined the stoichiometry and stability constants of Ni(II) and Cu(II) complexes with humic acid sodium salt L1, obtained from naturally oxidized coal, and with their hydroxymethyl derivatives L2 in aqueous solutions. The solubility of the humates in water is 0.125–0.150 M. According to the available analytical data, the structural units of L1 and L2 can be represented as follows:

L1

L2

The complexation was studied by the spectrophotometric and potentiometric methods. The electronic absorption spectra of Ni(II) and Cu(II) complexes with L1 and L2 in aqueous solutions show strong absorption bands with a maximum at 440–445 nm.

The solution pH values 4.7 and 4.2 were found to be optimal for studying complexation of Ni(II) and Cu(II) with L1, and pH values 5.4 and 5.2, with L2, respectively (Fig. 1). The stoichiometry of the complexes, formed in dilute aqueous solutions, was determined spectrophotometrically at a constant ionic strength (1 M NaCl) [2, 3].

Within the metal concentration range 1×10^{-5}–1×10^{-4} M, at a fivefold excess of the ligand, 1 : 1 complexes were found to form in the systems L1–Cu(II) and L2–Ni(II), and also 1 : 2 complex in the system L2–Cu(II). No complex was found in the system L1–Ni(II). Similar results were obtained poten-

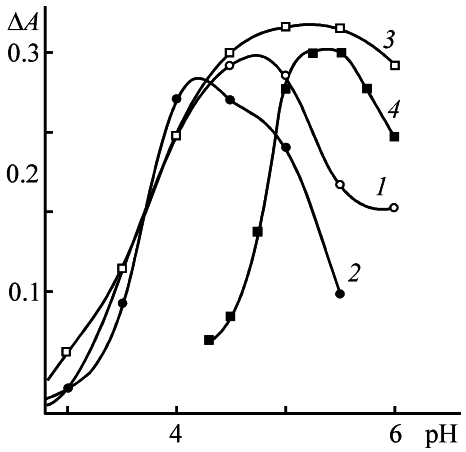


Fig. 1. Optical density ΔA as a function of the solution pH. Solution composition: (*1*) Cu(II)–L1, (*2*) Ni(II)–L1, (*3*) Cu(II)–L2, and (*4*) Ni(II)–L2 (λ = 440 nm, l = 1 cm).

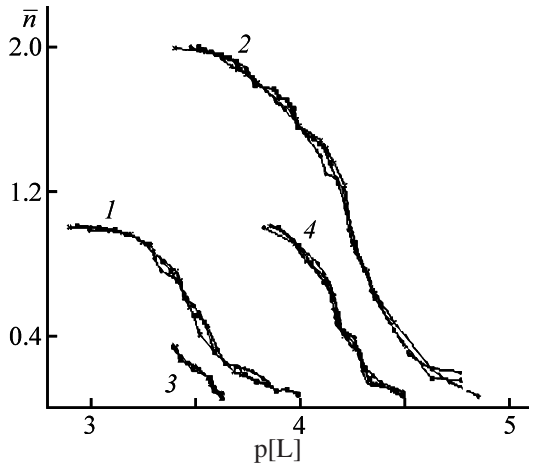

Fig. 2. Mean coordination number $\bar{n}$ as a function p[L] (negative logarithm of the concentration of ionized carboxy groups) in the systems (*1*) Cu(II)–L1, (*2*) Cu(II)–L2, (*3*) Ni(II)–L1, and (*4*) Ni(II)–L2.

tiometrically at the same ionic strength, but at the reagent concentrations 10–30 times higher than in the spectrophotometric experiments. It follows from Fig. 2 that L1 and L2 form 1 : 1 and 1 : 2 complexes with Cu(II) and Ni(II). Our previous results [4] demonstrate that, at pH < 5.5, L1 and L2 complexes exist in aqueous solutions in the form of H_nL^-. Therefore, the equilibrium ligand concentrations were estimated taking into account the first dissociation constant only (k_{a1} 4.74 and 4.53 for L1 and L2, respectively [5]).

The stoichiometry and stability constants of the complexes were estimated from the potentiometric titration curves, obtained with 0.1 M NaOH in the absence and in the presence of Ni(II) and Cu(II), using Eq. (1),

$$\bar{n} = [\mathrm{COOH}]_b/c_M, \quad (1)$$

where c_M is the initial metal concentration (M).

The results are given in the table.

The concentration of carboxy groups $[\mathrm{COOH}]_b$ bound to the metal was determined as the difference between their total concentration and the sum of the concentrations of ionized and free carboxy groups [3]. The total carboxy group concentration in the humate was estimated from the titration curve in the absence of the complexing cations. From the volume of the titrant consumed and pH, we estimated the concentration of ionized carboxy groups $[\mathrm{COO}^-]$ and then the concentration of free carboxy groups [COOH], using the Henderson–Hasselbach equation:

$$\mathrm{pH} = \mathrm{p}K - m\log\frac{1-\alpha}{\alpha}, \quad (2)$$

where m is the empirical coefficient (m 2.19 and 2.79 for L1 and L2, respectively [4]).

In the investigated systems, mononuclear complexes are essentially formed, as demonstrated by similar shapes of the curves obtained at various ligand concentrations (Fig. 2).

The stability constants were estimated from the semi-integer values of n using the least-squares method. The formation of metal hydroxo complexes within the experimental pH range was neglected. The estimated stability constants β were validated by substituting them in the Bjerrum equation [6]:

$$\bar{n} = \sum_0^N n\beta_n[\mathrm{L}]^n / \sum_0^N \beta_n[\mathrm{L}]^n$$

Our results show (see table) that Cu(II) forms medium-stability complexes with L1 and L2 (β 6.59 and 6.52, respectively). Ni(II) forms no complex with L1, but Ni(L2) is formed even at high Ni concentration in the solution (0.024 M). The stability of Ni(L2) is well comparable with that of $Cu(L2)_2$.

The mean number of the HA carboxy groups bound to Cu(II) is 1–2, which is slightly lower than the mean basicity of HA and its derivatives (2.6–2.8), as estimated by the Ostwald method [4]. Most likely, the incomplete saturation of the Cu(II) coordination sphere with the humic ligands results in formation of mixed-ligand complexes with participation of the water molecules.

Parameters of complexation of Ni(II) and Cu(II) with L1 and L2

Cation	L1		L2	
	$\bar{n}$	log β	$\bar{n}$	log β
Cu^{2+}	1	6.59	2	6.52
Ni^{2+}	–	–	1	6.46

EXPERIMENTAL

Humates L1 and L2 were synthesized from naturally oxidized coal of the Oikaragaiskoe field (Kazakhstan) using the method described in [7]. The unit molecular weight of humic acids M_r was determined ebulliometrically to be 374. The content of carboxy and phenolic hydroxy groups was 5.6 and

2.75 mg-equiv g^{-1}, respectively.

Found, wt %: C 67.81, H 3.80.
$C_{22}H_{14}O_6$.
Calculated, wt %: C 70.59, H 3.74.

IR (KBr), ν, cm^{-1}: 3450–3300, 3030, 1710, 1660–1610, 1250, 1205, 1063.

The spectrophotometric and potentiometric measurements were carried out at constant ionic strength [μ = 1 (NaCl)] and temperature (20.0±0.5°C). The spectrophotometric measurements were performed on a Shimadzu UV-2401 PC instrument, and potentiometric titration, using a Jenway 3345 ion meter. For each metal ion, the titration was carried out at three concentrations (0.8×10^{-2}, 1.6×10^{-2}, and 2.4×10^{-2} M) at a fivefold excess of the ligands.

CONCLUSIONS

(1) Humic acids and their hydroxymethyl derivatives form 1 : 1 and 1 : 2 complexes with Cu(II).

(2) Ni(II) forms a 1 : 1 complex with L2, but no complex with L1.

(3) Copper(II) forms medium-stability complexes with L1 and L2 (β 6.59 and 6.52, respectively). The stability of Ni(L2) is well comparable with that of $Cu(L2)_2$.

Abstract—Antioxidant properties of sulfides derived from 2-propylphenol and of their aminomethyl derivatives were studied in a model reaction of cumene oxidation. The kinetic parameters of the reactions of these compounds with cumylperoxy radicals and cumyl hydroperoxide were determined.

DOI: 10.1134/S1070427208010175

In the modern oil-refining technology, there is a need for the development of advanced processes for production of petroleum products, including fuel and lubricating oils of optimal hydrocarbon composition, to meet the modern engineering and environmental requirements. At the same time, the use of petroleum fuels and lubricating oils is impossible without additives having various functional effects.

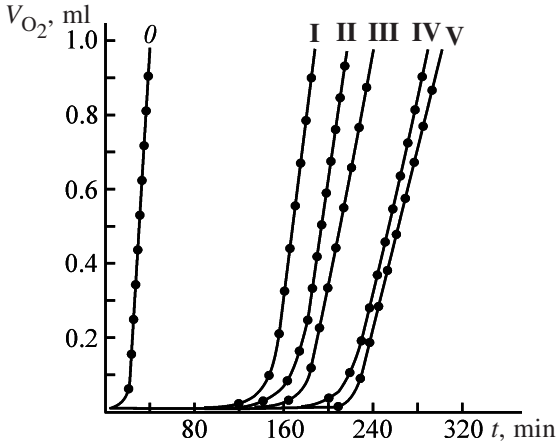
Among the most widely used additives to fuels and lubricating oils are alkylphenols and their various sulfur-, nitrogen-, and phosphorus-containing derivatives [1, 2].

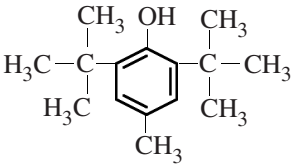
As antioxidant properties of additives are associated with the presence of definite functional groups, it is particularly interesting to prepare organic compounds containing two or more functional groups in the molecule and to study the mechanism of their antioxidant effect, because such compounds may combine useful properties of different types of antioxidants.

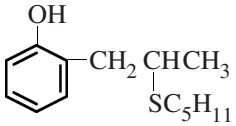
Studies on the synthesis and mechanism of the antioxidant effect of compounds containing in their molecules a sulfide sulfur atom in combination with phenolic fragment (phenolic sulfides), aromatic amine (amino sulfides), and phenolic fragment + aromatic amine (aminophenolic sulfides) showed that these compounds not only combine the capabilities of sulfides to decompose hydroperoxides and of phenols and amines to terminate oxidation chains in reactions with peroxy radicals, but also exhibit a new property: They are capable to catalytically decompose hydroperoxides into molecular products [3–7].

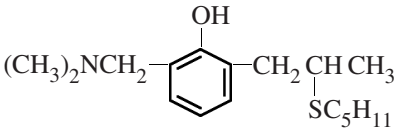
With the aim to develop a scientific basis for the purposeful synthesis of an antioxidant of an optimal structure, exhibiting high performance, we examined in this study the antioxidant properties of new phenolic sulfides derived from 2-propylphenol and of their aminomethyl derivatives. The phenolic sulfides were prepared by homolytic thiylation of 2-propenyl- and 2-allylphenols with amyl and benzyl mercaptans, and the aminomethyl derivatives were synthesized by the Mannich condensation of the resulting phenolic sulfides with formaldehyde and dimethylamine [8–10].

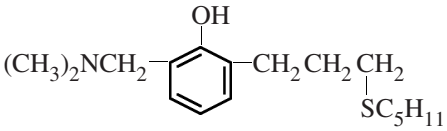
Antioxidant properties of the compounds were evaluated by the well-known kinetic method based on inhibition of certain key reaction. As a model hydrocarbon we chose cumene.

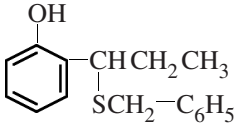












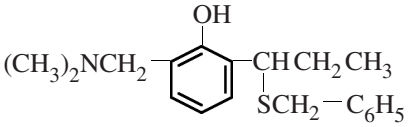


Fig. 1. Kinetic curves of cumene autooxidation (*0*) without additives and in the presence of compounds **I**–**V**. 110°C; [InH] = 5×10^{-5} M. (V_{O_2}) Oxygen uptake and (*t*) time; the same for Fig. 2.

Kinetic parameters of the reactions of **I**–**V** with cumylperoxy (CP) radicals (60°C, [AIBN] = 2×10^{-2} M) and cumyl hydroperoxide (CHP) (110°C), and induction periods of cumene autooxidation in the presence of these compounds (110°C, [InH] = 5×10^{-5} M)

Compound	Formula	CP radicals		CHP		τ, min
		f	$k_7 \times 10^{-4}$, l mol^{-1} s^{-1}	k, l mol^{-1} s^{-1}	ν	
Ionol		2.00	2.10	–	–	150
I		1.68	2.18	31	36 000	150
II		1.87	2.18	40	40 000	170
III		2.0	2.94	41	40 000	180
IV		2.88	2.85	39	45 000	220
V		2.90	2.86	40	45 000	225

Experiments on cumene autooxidation at 110°C in the presence of **I**–**V** showed (Fig. 1) that these compounds efficiently inhibit the oxidation, as judged from the long induction periods τ (see table). For comparison, we performed under the same conditions autooxidation of cumene in the presence of a widely used phenolic antioxidant, Ionol (2,6-di-*tert*-butyl-4-methylphenol). As seen from the table, only compound **I** is similar to Ionol in the induction period, whereas all the other compounds surpass Ionol. The longest induction periods are observed with **IV** and **V**.

To evaluate the capability of compounds to terminate oxidation chains in reactions with peroxy radicals, we performed initiated [with azobis(isobutyronitrile), AIBN] oxidation of cumene in the presence of these antioxidants. The reaction was performed on a manometric unit; the oxidation kinetics was monitored by the oxygen uptake in a definite time interval. The reaction temperatrue was 60°C, and initiator concentration, 2×10^{-2} M. The concentrations of **I**–**V** were varied in the range 1×10^{-4}–5×10^{-5} M. From the kinetics of the oxygen uptake, we calculated the rate constant of the reaction of the antioxidants with the cumylperoxy radicals k_7, and from the induction period, the stoichiometric coefficient of inhibition f, equal to the number of oxidation chains terminated on one molecule of the antioxidant and its transformation products [11]. The experiments showed that all the compounds tested inhibit the initiated oxidation of cumene by reacting with cumylperoxy radicals.

Figure 2 shows the kinetic curves of the initiated oxidation of cumene in the presence of **I**–**V**.

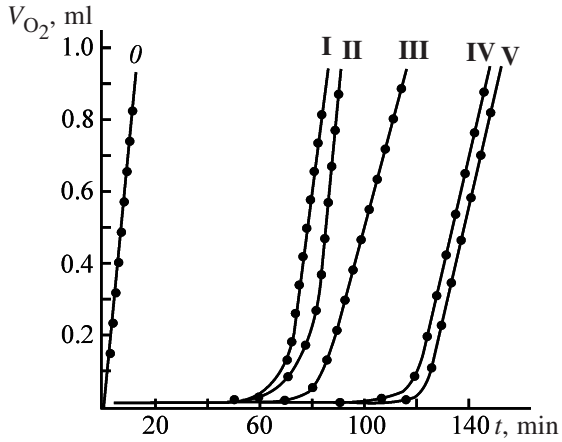

Fig. 2. Kinetic curves of the initiated oxidation of cumene (*0*) without additives and in the presence of **I**–**V**. 60°C; [AIBN] = 2×10^{-2} M.

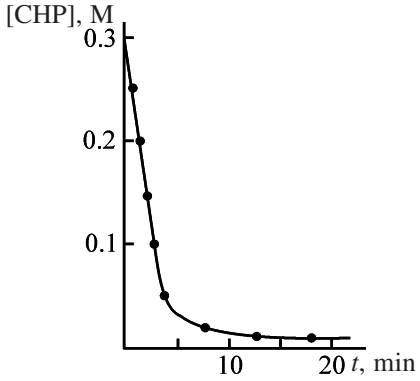

Fig. 3. Kinetic curves of CHP decomposition under the action of **I**. 110°C; [InH] = 1×10^{-4} M. (*t*) Time.

The kinetic curves of the initiated oxidation of cumene show that the rate of cumene oxidation in the presence of compounds **IV** and **V** after the end of the induction period is lower than the rate of cumene oxidation without inhibitors (curve *0*). This fact indicates that the products of the transformation of **IV** and **V** in the reaction with cumylperoxy radicals also exhibit an inhibiting effect, i.e., secondary inhibition is observed.

The kinetic parameters of the reactions of the antioxidants with the cumylperoxy radicals are given in the table. The data for Ionol, obtained under similar conditions, are also given for comparison.

It is known that for alkylphenols $f \approx 2$ [12–14], i.e., they terminate two oxidation chains. For Ionol also $f = 2$. For compounds **I**–**III**, $f \leq 2$, and for **IV** and **V** f approaches 3. The latter fact is attributable to the secondary inhibition, i.e., to partial termination of oxidation chains by products formed from **IV** and **V** in the reactions with cumylperoxy radicals. It should also be noted that, in contrast to compounds **I**–**III** with an alkyl substituent at the S atom, in **IV** and **V** the S atom is benzyl-substituted. With respect to the rate constant, compounds **I** and **II** are comparable with Ionol, and compounds **III**–**V** somewhat surpass it.

Thus, as regards the capability to terminate oxidation chains in reactions with peroxy radicals, compounds **I**–**V** behave as typical alkylphenol antioxidants. At the same time, as regards the reactivity toward peroxy radicals and the number of terminated oxidation chains, compounds **IV** and **V** surpass alkylphenolic antioxidants.

The reactions of the antioxidants with CHP were performed in chlorobenzene at 110°C in a nitrogen atmosphere at various reactant ratios. All the antioxidants studied were found to catalytically decompose CHP (Fig. 3).

The following kinetic parameters of the reaction of the antioxidants with CHP are given in the table: rate constants k and catalytic factor ν (number of CHP molecules decomposing under the action of one antioxidant molecule). It is known that dialkyl sulfides inhibit the oxidation of hydrocarbons by reacting with hydroperoxides; one sulfide molecule decomposes two hydroperoxide molecules [15]. The catalytic factors ν obtained for **I**–**V** show that one molecule of **I**–**V** is capable to decompose several tens thousands of CHP molecules. As in the reaction with cumylperoxy radicals, the highest activity in the reaction with CHP is shown by phenolic sulfide **IV** in which the sulfur atom is linked to the C atom in the α-position to the benzene ring of the phenolic fragment, and also by its aminomethyl derivative **V**.

Thus, our studies showed that sulfides derived from 2-propylphenol and their aminomethyl derivatives efficiently inhibit the oxidation of hydrocarbons and demonstrate a combined antioxidant effect: They terminate oxidation chains by reacting with peroxy radicals and catalytically decompose hydroperoxides.

CONCLUSIONS

(1) Kinetic studies of a model reaction of cumene oxidation revealed high antioxidant properties of sulfides derived from 2-propylphenol and of their aminomethyl derivatives.

(2) The mechanism of the antioxidant effect of these compounds involves termination of oxidation chains in reactions with peroxy radicals and catalytic decomposition of hydroperoxides.

(3) Among the compounds studied, the highest activity in reactions with cumylperoxy radicals and

cumyl hydroperoxide is shown by the phenolic sulfide in which the S atom is bonded to the C atom in the α-position to the benzene ring of the phenolic fragment and by its aminomethyl derivative.

(4) Introduction of the aminomethyl fragment into the molecule of phenolic sulfides somewhat enhances their antioxidant activity.

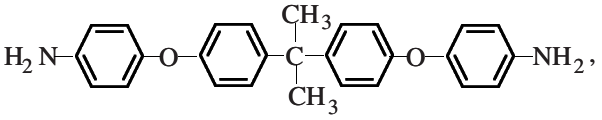
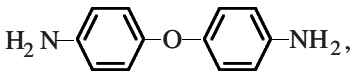
Abstract—The specific interaction of aromatic and aliphatic diamines with benzoic acid without a solvent was studied by IR spectroscopy and phase diagram analysis.



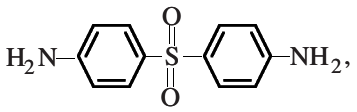
DOI: 10.1134/S1070427208010187

We have shown previously [1, 2] that a benzoic acid (BA) melt at 140–150°C can be used as catalytically active medium in the synthesis of polyimides (PI) by one-step high-temperature polycyclocondensation of diamines and dianhydrides of aromatic and tetracarboxylic acids [3, 4]. A study of this process in BA melt revealed a series of interesting kinetic features untypical of the reaction of diamines and dianhydrides under other conditions. In particular, the total rate of polycondensation in BA melt only slightly depends on the basicity of the amino group in the diamine, whereas in low-temperature polycondensation this dependence is strongly pronounced [5–7]. One of possible explanations of this effect is that the acid medium specifically interacts with the amino group and changes its reactivity. In view of these facts, in this study we examined the specific interaction of some diamines strongly differing in the basicity with molten BA in binary systems diamine–BA by phase diagram analysis in combination with IR spectroscopy.



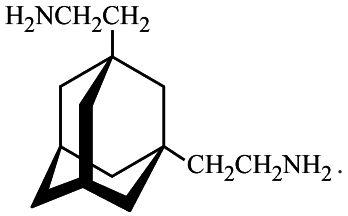
EXPERIMENTAL

The following aromatic and aliphatic diamines strongly differing in the basicity were the objects of our study:



2,2-bis[4-(4-aminophenoxy)phenyl]propane (BAPP)

4,4'-diaminodiphenyl oxide (DADPO)



4,4'-diaminodiphenyl sulfone (DADPS)

1,6-hexamethylenediamine (HMDA)

$H_2N–(CH_2)_6–NH_2$,

1,3-bis(2-aminoethyl)adamantane (ADA)

Benzoic acid (technical grade, Russia) was recrystallized from water–ethanol mixture and dried in a vacuum at 50°C, mp 122°C; BAPP (technical grade) was purified by recrytallization from isopropyl alcohol, mp 129°C; DADPO (technical grade, Russia) was purified by sublimation in vacuum, mp 190°C; DADPS (technical grade) was purified by recrystallization from isopropyl alcohol, mp 175°C; HMDA (Aldrich) was double-distilled in a vacuum, mp 44–45°C; and ADA was distilled in a vacuum, mp 129°C.

Phase diagrams of binary mixtures were constructed from data of differential scanning calorimetry (DSC), obtained on a DTAS-1200 device (Russia) at

a heating rate of 16 deg min^{-1}. For each composition, the temperature corresponding to endothermic peak on a DSC thermogram was determined and plotted on the phase diagram. Samples for DSC were prepared by grinding in agate mortar of mixtures of the required composition, preliminarily melted and cooled to 20°C.

In the general case, interaction of nitrogen-containing organic bases with carboxylic acid can involve the dissociation of carboxylic acid dimer and formation of hydrogen-bonded complexes and even products of complete proton transfer from the acid to the base [7, 8]. To elucidate the chemical composition of products obtained by alloying the BA–diamine mixtures (in the absence of diluent), we compared the IR spectra of melts and individual components.

The IR spectra of solid binary systems containing BA and BAPP, DADPO, and DADPS are superpositions of the spectra of the individual components.

The DSC thermograms for the BA–DADPO binary system with the molar ratios of 0.9 : 0.1 (curve *1*) and 0.16 : 0.84 (curve *2*) are shown in Fig. 1. Two endothermic peaks are observed in these thermograms; the first of them is located at 108°C irrespective of the mixture composition. The temperature of the second peak depends on the composition and varies from 108°C to the melting points of the individual components. The DSC data for binary systems BA–diamine were used for construction of the corresponding phase diagrams (Figs. 2–4). In the phase diagrams of BA–BAPP (Fig. 2) and BA–DADPO (Fig. 3) systems, two curve branches bounding the homogeneity area connect the melting points of the individual components with the eutectic point. Such a pattern is characteristic of binary systems with limited mutual solubility in the absence of pronounced specific interaction. In contrast to the first two systems, in the phase diagram of the BA–DADPS system (Fig. 4) the liquidus curve for mixtures enriched in BA is the line practically parallel to the composition axis. This shape of the diagram shows that, below the BA melting point, 122°C, the components of the mixtures enriched in BA (the part of the diagram to the left of the eutectic point) are practically incompatible and crystallize separately. Above 122°C, the components are compatible at all ratios except the region bounded by the liquidus and solidus curves at compositions to the right of the eutectic point.

The phase diagrams and IR spectra of binary systems containing highly basic aliphatic diamines, BA–HMDA and BA–ADA, are essentially different. In the IR spectra of the BA–HMDA (Fig. 5) and BA–

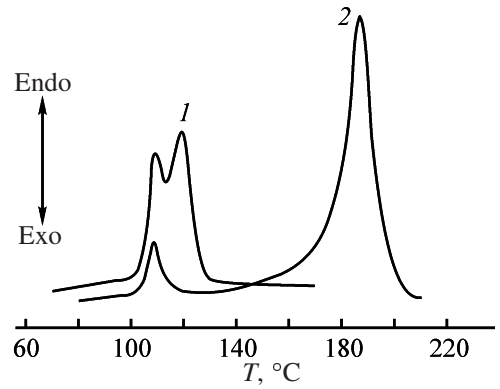


Fig. 1. DSC thermogram of BA–DADPO binary system with the component molar ratio of (*1*) 0.9 : 0.1 and (*2*) 0.16 : 0.84. (*T*) Temperature; the same for Figs. 2–4, 7, and 8.

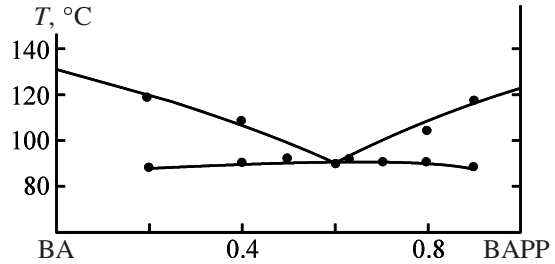

Fig. 2. Phase diagram of the BA–BAPP binary mixture (mole fraction scale).

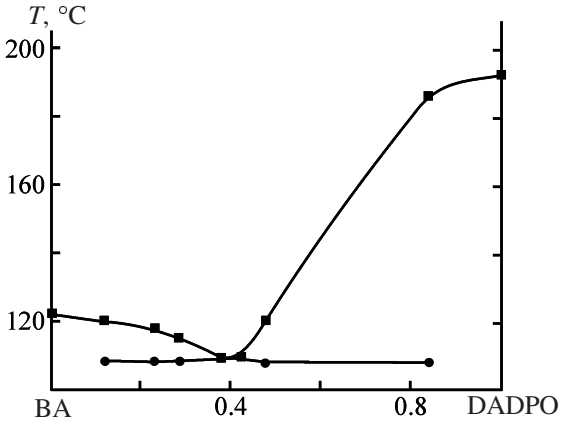

Fig. 3. Phase diagram of the BA–DADPO binary mixture (mole fraction scale).

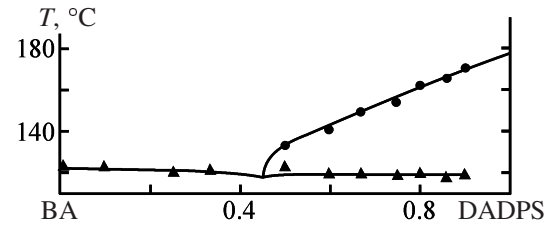

Fig. 4. Phase diagram of the BA–DADPS binary mixture (mole fraction scale).

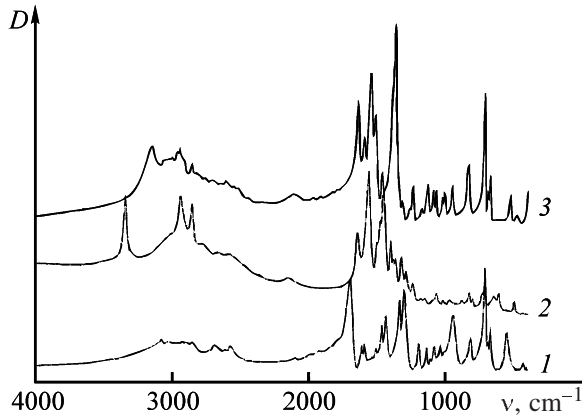

Fig. 5. IR spectrum of the BA–HMDA binary mixture with the component molar ratio of 0.7 : 0.3. (*D*) Optical density and (ν) wavenumber; the same for Fig. 6. (*1*) BA, (*2*) HMDA, and (*3*) mixture.

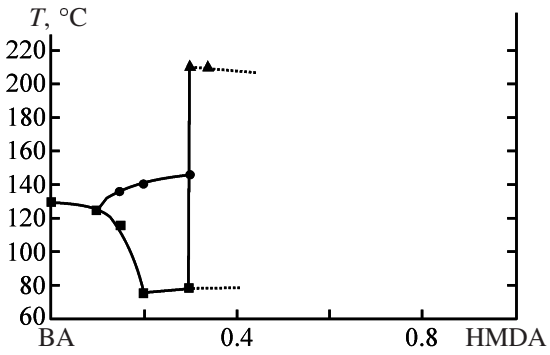

Fig. 7. Phase diagram of the BA–HMDA binary mixture (mole fraction scale).

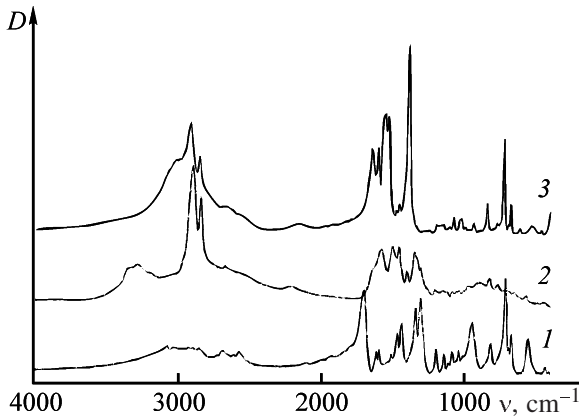

Fig. 6. IR spectrum of BA–ADA binary mixture with component molar ratio of 0.7 : 0.3. (*1*) BA, (*2*) ADA, and (*3*) mixture.

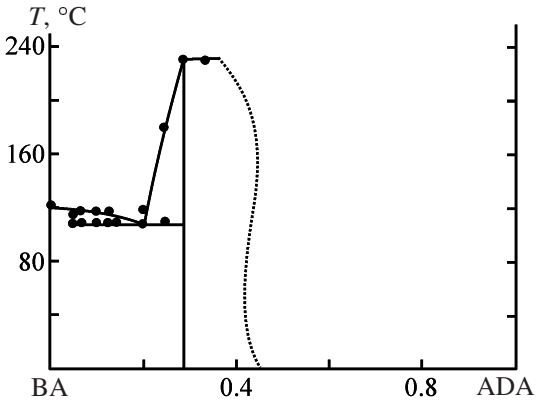

Fig. 8. Phase diagram of the BA–ADA binary mixture (mole fraction scale).

ADA systems (Fig. 6), at 2 : 1 molar ratio in both cases, new absorption bands are observed at 3154 and 3023 cm^{-1} (N–H stretching vibrations in alkylammonium ion of HMDA and ADA, respectively) and at 1550 and 1382 cm^{-1} (symmetric and antisymmetric C–O stretching vibrations of benzoate ion, respectively). At the same time, characteristic bands of the initial diamines at 3347 (N–H stretching vibrations of amino group in HMDA spectrum) and 3286 cm^{-1} (ADA) and of BA at 1690 cm^{-1} (C=O stretching vibrations) are absent.

Influence of diamine basicity on type of interaction with benzoic acid without a solvent. BA : diamine molar ratio 2 : 1

Diamine	pK_1	pK_2	Product type
HMDA	10.93	9.83	Dibenzoate salt
ADA	10.67*	9.61	Dibenzoate salt
BAPP	4.63**	4.22**	Physical mixture
DADPO	4.75	3.74	Physical mixture
DADPS	2.01	1.02	Physical mixture

* Calculated from data measured in nitromethane (pK_{a1} 17.75, pK_{a2} 16.36) using the equation $pK_a(H_2O) = 0.76pK_a(CH_3NO_2) - 2.82$.

** Data for double-hinged diamine, 4,4'-diaminodiphenoxyhydroquinone [9], structurally related to BAPP.

In phase diagrams of binary systems BA–HMDA and BA–ADA (Figs. 7 and 8, respectively), congruent point at 2 : 1 molar ratio is indicative of the formation of diamine dibenzoate.

The data in the table allow us to correlate the chemical structures of solid binary systems obtained by the reactions of diamines with BA in the absence of the solvent with the basicity of the initial diamines expressed in pK_a units (in water).

As seen from the table, only highly basic diamines with $pK_a \geq 9.5$ form BA–diamine binary systems with strong interaction, in which after melting and subsequent cooling products with complete proton transfer are formed. The resulting compounds form their own crystalline phase whose melting point is higher

than that of the initial components (congruent point). Aromatic diamines with $pK_a \leq 4.7$ show only "weak interaction" with BA. It stops in the step of formation of intermolecular complexes with amine–acid hydrogen bond in equilibrium with the initial components. On cooling of such a system, crystallization of the components can decompose the BA–amine intermolecular complex. Therefore, in the IR spectra of solid BA–aromatic diamine systems, intermolecular complexes are not manifested. With low-basic aromatic diamines with pK_a ~2, the specific interaction in the melt is virtually completely absent, and in the region of compositions rich in BA the presence of the diamine does not affect the BA melting and crystallization.

CONCLUSIONS

(1) The diamines studied can be subdivided into two groups differing in the type of the specific interaction with benzoic acid in two-component solid systems.

(2) Highly basic aliphatic diamines ($pK_a \geq 9.5$) react with benzoic acid in the melt to form products of complete proton transfer (benzoate salts), which are individual chemical compounds soluble in benzoic acid melt.

(3) Moderately and low-basic aromatic diamines with $pK_a \leq 4.7$ do not form with benzoic acid products with complete proton transfer; the phase diagrams have a shape typical for mixtures of chemical components without interaction and partial mutual or unilateral solubility.

Abstract—The possibility of synthesis of soluble copolymers by radical copolymerization of 1,2-dichlorovinyl propyl ketone with styrene in the presence of azobis(isobutyronitrile) was studied. The polymerization constants were determined and the probabilities of formation of various sequences of comonomer units were evaluated. The structure of the copolymers was studied by IR and ^{13}C NMR spectroscopy, and some characteristics of the copolymers were determined.

DOI: 10.1134/S1070427208010199

Chlorovinyl ketones are very important and promising intermediates for synthesis of numerous polyfunctional highly reactive and heterocyclic compounds [1]. Copolymers containing keto group in the backbone (polyketones, which are alternating copolymers of carbon monoxide with acyclic and cyclic olefins, dienes, styrene, and its derivatives) are thermally stable and readily processable materials and have specific gas-permeability characteristics. For example, with respect to its barrier characteristics (permeability to N_2, O_2, and CO_2), the copolymer based on carbon monoxide and ethylene is intermediate between high-density polyethylene and polyvinyl chloride, and with respect to moisture permeability it is close to polyurethane [1, 2]. The ready compatibility of polyketones with other materials (Nylon, polycarbonate, and polyvinyl alcohol) and also their chemical resistance make these substances particularly attractive in use as protective coatings and chemical containers. Due to strong adhesion to organic and inorganic materials, polyketones can be used for fabrication of structural materials. A low friction coefficient and high strength allow these polymers to be recommended for use in various gearings and similar structures [2, 3]. These copolymers containing carbonyl groups and styrene fragments can be synthesized using palladium-containing complexes as catalysts [4].

Here we suggest the simplest and convenient route to such copolymers: direct copolymerization of 1,2-dichlorovinyl propyl ketone (DCVK) and styrene (ST).

It is well known that homopolymers based on methyl 2-chlorovinyl ketone, synthesized by polycondensation under heating or in the presence of Friedel–Crafts catalysts [5, 6], are catalytically active in oxidation and dehydrogenation of alcohols [5], have extremely interesting and unusual electrical and magnetic characteristics [6], and tend to chemical transformations at elevated temperatures. There is only one paper in which the synthesis of a polymer based on phenyl 2,2-dichlorovinyl ketone in the presence of $AlCl_3$ was reported; however, the characteristics of this polymer was not studied [7]. Thus, the reactivity of chlorovinyl ketones in (co)polymerization practically was not studied.

Among the wide variety of chlorovinyl ketones, only 1,2-dichlorovinyl ketones are fairly stable. They do not become dark in storage for 1 month under ordinary conditions and are not dehydrochlorinated with formation of pyrones in prolonged storage. The presence of two chlorine atoms in the vicinal positions of vinyl and carbonyl groups in 1,2-dichlorovinyl propyl ketone offers wide possibilities for numerous polymer-analogous reactions with N-, O-, and S-nucleophiles, for dehydrochlorination, and for crotonic condensation. These transformations can lead to functionalized, polyconjugated, or aromatic condensation polymers.

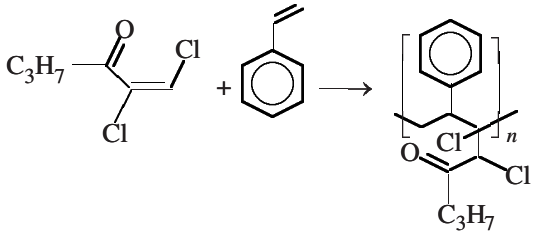
EXPERIMENTAL

1,2-Dichlorovinyl propyl ketone was prepared from butyryl chloride and *cis*-1,2-dichloroethylene in the presence of aluminum chloride at 35°C within a period of 40 h. The yield of the reaction product is 90%, bp 68–70°C (9 mm Hg), n_D^{20} 1.4900, which is in good agreement with published data [8]. Styrene was purified according to the procedure described in [9]. Azobis(isobutyronitrile) (AIBN) was purified by double recrystallization from methanol.

Copolymerization of DCVK and ST was performed in hermetically sealed ampules in the bulk at 60°C in the presence of AIBN in an argon medium. The resulting reaction mixture was dissolved in DMF, and the copolymer was precipitated with methanol. Copolymers were reprecipitated two times. The copolymer composition was evaluated by the elemental analysis for chlorine using the standard procedure [9]. The turbidimetric titration was performed on a KFK-2 spectrophotometer at λ = 670 nm. DMF was used as a solvent for titration, and ethanol, as a precipitant.

The IR spectra were recorded on a Specord IR-75 spectrophotometer in KBr pellets. The ^{13}C NMR spectra were recorded on a Varian VXR-500S spectrometer (125.5 MHz, relaxation delay 2.5 s, 90° pulse, solvent DMSO-d_6). Chromium tris-acetylacetonate (0.02 M) was used as a relaxant and HMDS, as an internal reference.

The specific surface area of copolymers was determined by measurement of the volume of a gas (nitrogen) adsorbed on the surface of this solid at various pressures. The measurements were performed in a calibrated high vacuum (ASAP-2000).



The intrinsic viscosity was determined on an Ubbelohde viscometer in DMF at 20°C; the initial concentration of the solutions was 2.6 g in 100 ml.

The copolymerization constants of monomers were evaluated by the procedure described in [10, 11] using the linear integral method modified according to [12]. The softening point (SP) was determined with a Boëtius heating table.

The radical copolymerization of DCVK and ST in the presence of AIBN was studied. Powdered products readily soluble in aromatic hydrocarbons, DMF, and DMSO and insoluble in alcohols were obtained. Homopolymerization of DCVK does not proceed under similar conditions. Variation of the reaction conditions (heating and increased AIBN concentration) does not result in formation of DCVK homopolymer. This fact can be explained by low rate constants of chain propagation in homopolymerization as a result of steric hindrance produced by two chlorine atoms.

Copolymerization via the double bond is proved by the results of turbidimetric titration and by IR and NMR (^1H, ^{13}C) data. In the IR spectra of the synthesized copolymers, there are no absorption bands typical for vinyl group, but there are characteristic bands caused by skeleton vibrations of the aromatic ring at 1601, 1584, 1500, and 1451 cm^{-1} and also stretching modes of the carbonyl group at 1695 cm^{-1}. The absorption band at 680 cm^{-1} can be assigned to the C–Cl bond. In the ^{13}C NMR spectra of copolymers, there are broad signals corresponding to carbon atoms of carbonyl (192.95 ppm), CH_2 (32.27 ppm), CH_3 (7.57 ppm), and CHCl (56.7–60.0 ppm) groups.

Based on the IR and NMR data and elemental analysis, the synthesis of the copolymer can be described by the following scheme:

As seen from Table 1, the yield and intrinsic viscosity of the resulting samples decrease with increasing concentration of DCVK in the initial mixture; however, at the equimolar ratio of comonomers in the initial mixture, the intrinsic viscosity increases to 0.165 dl g^{-1}. The dependence of SP on the copolymer composition is not linear. The turbimetric titration curve has a smooth shape corresponding to a single-component structure (Fig. 1).

From data on variation of the composition of copolymers with variation of the initial ratio of monomers in the reaction mixture (Table 1), we evaluated the copolymerization constants to be $r_{DCVK} = 0.039 \pm 0.002$ and $r_{ST} = 0.598 \pm 0.01$. As seen from the copolymerization constants, ST is by an order of magnitude more active than DCVK, which is in good agreement with the experimental data (Fig. 2). At $r_1 < 1$, $r_2 < 1$, and $r_2 \gg r_1$ a trend toward alternation of monomeric units is observed. The composition curve intersects the diagonal of the composition diagram and in the intersection point the copolymer composition is equal to the composition of the monomer mixture. In addition, the r_1 and r_2 values suggest lower activity of radicals formed from comonomers in

homopolymerization than that of radicals formed in cross chain propagation.

The distribution of monomer units in the copolymer chain was evaluated by the common statistic methods using r_1 and r_2 parameters (Table 2). At virtually all compositions of the initial mixture, alternating copolymers are formed and only at 10% content of DCVK in the reaction mixture formation of block copolymers is possible.

The reactivity of DCVK was quantitatively characterized by the Alfrey–Price method [13]; the quantities Q and e were evaluated from the experimental r_1 and r_2 values. It should be noted that the parameter e characterizing the polar properties of DCVK suggests electron-acceptor characteristics of the chlorine-containing monomer or the corresponding radical. For ST we took $Q = 1$ and $e = -0.8$. For DCVK, the calculated values are $e = 1.132$ and $Q = 0.356$.

The specific surface area S_{sp} and pore volume V_{por} of the synthesized copolymer containing 16.47 mol % DCVK (Table 1, sample no. 2) are 11.11 m^2 g^{-1} and 2.55 cm^3 g^{-1}, respectively. For comparison, we determined the similar values for emulsion polyvinyl chloride (PVC) to be $S_{sp} = 1.22$ m^2 g^{-1} and $V_{por} = 0.28$ cm^3 g^{-1}. Polyvinyl chloride had the following characteristics: Fickentscher constant $K_F = 62–63$, $T_{decomp} = 120$°C. For polystyrene in a wide range of concentration of the initial solutions, the specific surface area was found to be 20–25 m^2 g^{-1} [14].

The specific surface area of the copolymer based on DCVK and ST is intermediate between those of polystyrene and PVC. It should be noted that the polymer studied was reprecipitated two times. This

fact is very important in determination of the specific surface area and pore volume.

CONCLUSIONS

(1) A new convenient procedure for the synthesis of copolymers containing carbonyl groups and styrene fragments without using expensive catalysts was suggested.

(2) Copolymers based on 1,2-dichlorovinyl propyl ketone and styrene were synthesized by radical copolymerization. The copolymerization constants were determined to be $r_{DCVK} = 0.039 \pm 0.002$ and $r_{ST} = 0.598 \pm 0.010$.

(3) The probabilities of formation comonomer unit sequences M_1M_2, M_2M_2, and $M_1M_2 = M_2M_1$ were evaluated.

Abstract—Two-layer film corona-electrets based on low-density polyethylene and copolymers of ethylene with vinyl acetate of various brands were studied. The dependence of the electret characteristics of two-layer corona-electrets on the percentage content of polar groups in the copolymer constituting the bottom layer was analyzed. Data on thermally stimulated depolarization and thermally stimulated relaxation of the surface potential served as a basis for suggesting a mechanism of depolarization of two-layer corona-electrets.

DOI: 10.1134/S1070427208010205

The wide use of polymeric electrets in numerous electric instruments and devices, friction and sealing units, and gas and liquid filters [1, 2] predetermines the unremitting interest in studies of the electret effect in polymeric insulators. Particular attention is given to a search for new electret materials by combining the already known materials, i.e., by obtaining composites, to which belong multilayer electrets whose layered structure can give rise to specific features uncharacteristic of single-layer materials [3–9].

A practical application of two-layer films is their use as anticorrosive coatings whose quality is determined both by the electret properties of polymeric films and by the adhesion between a film and a metallic substrate. As shown in [6, 7], presence of a surface charge improves the anticorrosive properties of a coating, whereas an increase in the content of polar groups in the lower layer improves the adhesion, but impairs the electret properties of corona-electrets. Thus, studies of the stability of the electret state and elucidation of the depolarization mechanism are of interest and can determine the optimal content of polar groups in the lower layer to provide the best quality of anticorrosive coatings.

EXPERIMENTAL

As objects of study were chosen low-density polyethylene (LDPE) of 11503-070 brand [GOST (State Standard) 16337–77] and ethylene–vinyl acetate copolymers (EVAC) with varied content of vinyl acetate (VA) groups, of 11106-030, 11306-075, 11507-070, 11808-240 [TU (Technical Specification) 6-05-1636–78], 12306-020, and 12506-150 (TU 301-05-56–90) brands. The characteristics of the polymers are given in Table 1.

Single-layer films of thickness 0.25 mm were prepared by compaction in accordance with GOST 12019–66 at 170±5°C and compaction time of 5 min. The films were doubled at 170±5°C in a restricting frame of height 0.5 mm in the absence of pressure for 10 min. Then, the composites obtained were heated at 90°C for 10 min and cooled in the field of a negative corona discharge. The corona discharge was created with an electrode comprising 196 pointed needles evenly arranged over an area of 49 cm^2 in the form of a square. The polarization voltage and time were 35 kV and 60 s.

The electret characteristics were measured daily with an IPEP-1 meter whose working principle is based on a periodic shielding of the measuring probe situated at a certain distance from the electret surface. The error in measuring the surface potential V_e, electric field strength E, and surface density σ_{eff} of electric charges did not exceed 3%.

Spectra of thermally stimulated currents (TSC) were measured under heating at a constant rate of 5 deg min^{-1} in a special measuring cell equipped with blocking aluminum electrodes and a fluoroplastic spacer.

The films were also studied by the method of ther-

mally stimulated relaxation of the surface potential (TSRSP), with the surface potential measured with a dynamic electrometer. The samples studied were preliminarily charged in the field of a negative corona discharge at room temperature for 60 s. After that, the samples were heated at a constant rate of 5.4 deg min^{-1}, with the temperature and the surface potential simultaneously measured. Also, temperature dependences of the potential were obtained for the same samples polarized in the field of the negative corona discharge for 60 s after preliminary heating at 90°C for 10 min.

Being a nonpolar polymer, low-density polyethylene is well electretized in a corona-discharge field. According to the phenomenological theory, the effective surface charge density is constituted by a homocharge σ_p and heterocharge P:

$$\sigma_{eff} = \sigma_p - P.$$

The homocharge in polyethylene corona-electrets is due to injected carriers (electrons and ions) and macroions (including radical ions) formed in treatment of a polymer in a corona discharge. It is quite possible that a contribution to the homocharge is made by the dipole polarization of groups (mostly oxygen-containing groups) formed on the surface of the polymeric film under the action of the corona discharge. The heterocharge is due to the dipole polarization of groups contained in the polymer itself (for polyethylene, these are "anomalous" vinylidene, vinyl, and other groups in an amount of 4–6 groups per 1000 C atoms [10]).

Ethylene–vinyl acetate copolymers are polar polymers. Their polarity is due to the presence of dipole vinyl acetate groups whose mass content varies between different EVAC brands (Table 1). It was shown in [1] that the stability of corona-electrets based on EVAC decreases as the content of vinyl acetate groups in these copolymers increases. This would be expected because depolarization involves transfer of charge to the polymer surface and relaxation of this charge. These processes are governed by the bulk resistivity ρ_v of the material, and the ρ_v of EVAC is one to three orders of magnitude lower than that in LDPE, and it is the lower, the larger the content of polar vinyl acetate groups in a polymer (Table 1). Moreover, as the mass content of vinyl acetate in EVAC increases, the degree of crystallinity decreases (Table 1), and, consequently, so does the area of the phase boundary between the amorphous and crystalline phases, which acts as a trap for injected carriers. Undoubtedly, the decrease in the number of traps leads to smaller values of the electret parameters of polymers [11].

In electretization with preliminary heating of two-layer films based on LDPE and EVAC of various brands, values of the electret parameters decrease as the content of polar groups in the lower layer increases (Table 2). This seems to be reasonable: if the amount of the homocharge remains virtually unchanged, the amount of heterocharge grows.

It should be noted that, when revealing specific features of the electret effect, two-layer LDPE + EVAC films are to be compared with cohesively connected LDPE and EVAC films, rather than with single-layer films of these types. It was shown in [12] that spectra of thermally stimulated depolarization (TSD) of polyethylene films show two positive peaks: at 80–85 and 110–115°C, which appear upon disintegration of some type of traps for injected carriers. The first of these corresponds to Vicat's softening point, and the second lies near the melting point of LDPE. At the softening point of polyethylene, the mobility of its macromolecules dramatically increases and the appearance of the TSC peak is due to the relaxation of the Maxwell–Wagner polarization at phase boundaries. At the melting point, ordered supramolecular formations constituting the crystalline phase of LDPE are thermally disintegrated and the appearance of the TSC peak is attributed to release of carriers from traps at the phase boundary between the amorphous and crystalline phases of polyethylene [12].

Table 2. Electret properties of two-layer films

It was found in an analysis of TSD data for a cohesively connected two-layer polyethylene film that the first, low-temperature TSC peak lies in the negative region (Fig. 1, curve *1*). On replacing the lower polyethylene layer with that of EVAC, a new low-temperature negative peak appears, and the peak at 80–85°C again becomes positive. As the fraction of vinyl acetate in EVAC increases, the position and intensity of the low-temperature negative peak change: it is shifted to lower temperatures and the thermally stimulated current increases (Fig. 1).

The data obtained can be readily understood if account is taken of the fact that there is no injected charge in EVAC and the dipole polarization can give rise to homo- and heterocharge in polymeric films. The lowered softening point of EVAC, compared with LDPE, results in that macromolecules of the copolymer become flexible to an extent sufficient for displacement of their groups and segments at lower temperatures than in the case of LDPE macromolecules. Under heating, dipole groups of the copolymer are oriented in the field of the nonequilibrium homocharge of the upper polyethylene layer. This process can be termed additional orientation, because part of the dipoles was possibly oriented in the course of electretization of two-layer films, although the time of action of the corona discharge field is short (60 s). This phenomenon is manifested in TSD spectra in the appearance of the negative peak. It can be seen (Fig. 1) that the higher the content of vinyl acetate groups in the copolymer, the lower the temperature at which the additional orientation of dipoles occurs in two-layer corona-electrets and the higher the intensity of this process.

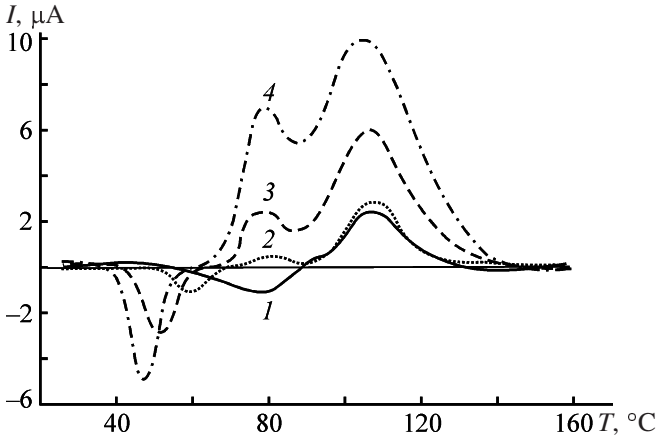

Fig. 1. Spectra of thermally stimulated depolarization currents in two-layer corona-electrets. (*I*) Current and (*T*) temperature. (*1*) LDPE + LDPE, (*2*) LDPE + EVAC-6, (*3*) LDPE + EVAC-17, and (*4*) LDPE + EVAC-27.

Then, upon further heating, there occurs the Maxwell–Wagner relaxation, which gives rise to the TSC peak at 80–85°C. An increase in the fraction of polar films in the lower layer results in that a larger amount of charge is captured at the phase boundary. It is quite probable that a part of the injected charge is released at this temperature.

When two-layer corona-electrets are heated to the melting point of LDPE, a complete charge relaxation

occurs because of the release of injected carriers from structural traps. It is the loss of the homocharge that is responsible for the final disorientation of dipole groups throughout the film volume.

The above considerations suggest that the presence of the negative peak in the spectra of the cohesively connected polyethylene films is due to the additional orientation of dipole groups present in a certain amount on the surface of polymeric films. Their presence is due to oxidation of the polymer surface, which occurs at elevated temperatures in fabrication of the two-layer structures. Connecting two LDPE films leads to appearance of an oxidized polyethylene "spacer" in the bulk of the structure, and just this spacer gives rise to the negative peak at 80–85°C.

These conclusions are confirmed by TSRP data. Figure 2 shows temperature dependences of the surface potential at a heating rate of 5.4 deg min^{-1} for two-layer films LDPE + LDPE, LDPE + EVAC-17, and LDPE + EVAC-27, preliminarily heated at 90°C for 10 min and charged in the field of a negative corona discharge. The surface potential remains unchanged up to 65–70°C and then starts to decrease (Fig. 2, curve *1*). The potential does not decrease at a constant rate as the temperature increases, and this range can be conditionally divided in two: at a temperature of 100–105°C the curve has an inflection after which the rate at which the surface potential decreases becomes higher. Comparison of the TSRP and TSD data shows that the first portion of the TSRP curve corresponds to the temperature range of the first peak of thermally stimulated currents, and the second, to the region of the high-temperature TSD peak.

A somewhat different pattern is observed for two-layer LDPE + EVAC films: the region in which the potential decreases can now be divided in three (Fig. 2, curves *2* and *3*). For example, for the LDPE + EVAC-17 film (Fig. 2, curve *2*), the first, second, and third portions lie at 50–65, 65–90, and 90–120°C. The decrease in the potential in the temperature range from 50 to 65°C is due only to the additional orientation of the dipole groups of EVAC in the lower layer and, therefore, the rate of this decrease is low. The second portion, in which the rate is the highest, corresponds to charge relaxation both in the upper polyethylene layer and in the lower layer formed by the ethylene–vinyl acetate copolymer. The third portion ends with a complete relaxation of the surface potential of two-layer corona-electrets.

Figure 3 shows how the potential depends on temperature at a heating rate of 5.4 deg min^{-1} for the same samples polarized in the field of a negative

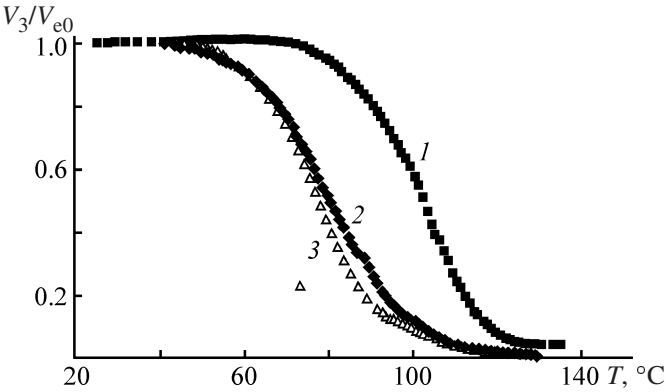

Fig. 2. Surface potential V_e/V_{e0} vs. temperature T for two-layer films charged in the field of a negative corona discharge after preliminary heating at 90°C. (*1*) LDPE + LDPE, (*2*) LDPE + EVAC-17, and (*3*) LDPE + EVAC-27.

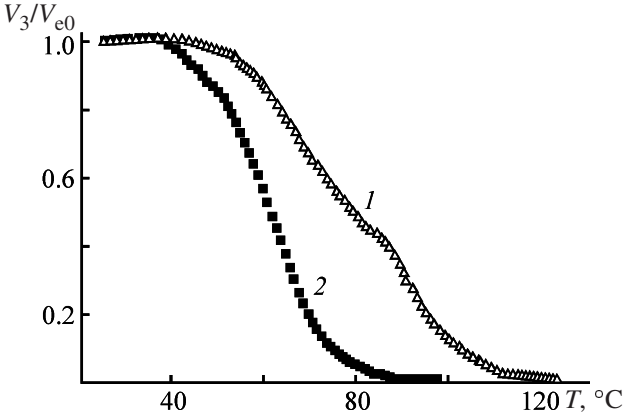

Fig. 3. Surface potential V_e/V_{e0} vs. temperature T for two-layer films charged at room temperature in the field of a negative corona discharge. (*1*) LDPE + LDPE and (*2*) LDPE + EVAC-27.

corona discharge for 60 s, but without preliminary heating. Comparison of the decaying portions of the surface potential for preliminarily heated and unheated films (Figs. 2, 3) shows that the stability of the electret state in samples preliminarily heated at 90°C before polarization exceeds that for samples polarized at room temperature. The possible reason is that, at elevated electretization temperatures, the Maxwell–Wagner polarization partly shields the field of the homocharge, which hinders the additional orientation of the polar groups of the copolymer.

The patterns revealed open up opportunities for practical use of two-layer polymeric corona-electrets based on polyethylene and an ethylene–vinyl acetate copolymer. Among the known applications are two-layer sleeves for anticorrosive insulation of edge joints of oil and gas pipelines. These sleeves are composed of polyethylene and a thermoplastic adhesive, whose role is frequently played by ethylene–vinyl acetate copolymers, and are made heat-shrinkable [13]. If the

polyethylene surface is electretized in a corona discharge, the polar groups of the polymeric adhesive will be additionally oriented in thermal treatment, which will enhance the adhesion of the sleeves to edge joints because of the contribution of electrostatic forces to the work of adhesion [14]. Undoubtedly, this suggestion needs practical verification.

CONCLUSIONS

(1) The surface potential, electric field strength, and surface electric charge density of two-layer corona-electrets based on low-density polyethylene and ethylene–vinyl acetate copolymers of various brands are adversely affected by an increase in the content of polar groups in the lower layer. This occurs because of the increase in the fraction of heterocharge.

(2) The spectra of thermally stimulated depolarization of two-layer corona-electrets based on low-density polyethylene and ethylene–vinyl acetate copolymers show three peaks: at the softening points of a copolymer and low-density polyethylene and at the melting point of the latter. The first peak points to orientation of dipole groups of the copolymer in the field of the nonequilibrium homocharge of the upper polyethylene layer (additional orientation). The second peak is indicative of the Maxwell–Wagner relaxation. The full relaxation of the charge, caused by release of carriers from structural traps that disintegrate upon melting of low-density polyethylene, gives rise to the third peak of thermally stimulated currents.

(3) Data on the thermally stimulated relaxation of the surface potential in two-layer corona-electrets confirm that the electret parameters decay in three stages corresponding to those revealed by analysis of thermally stimulated depolarization data.

(4) The stability of the electret state in two-layer corona-electrets based on low-density polyethylene and ethylene–vinyl acetate copolymers, preliminarily heated before polarization, exceeds that of samples polarized at room temperature.

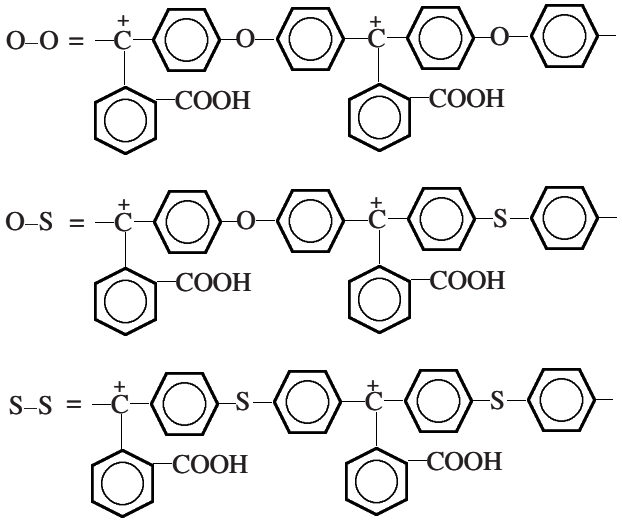
Abstract—Two-step copolycondensation of 3-chloro-3-(4-phenoxyphenyl)phthalide and 3-chloro-3-(4-phenylthiophenyl)phthalide was studied. The influence exerted by the sequence of loading the comonomers on the order of incorporation of the monomer residues into the polymer chain and on the microstructure of the resulting copolyarylenephthalides was examined.

DOI: 10.1134/S1070427208010217

Among new classes of polymers synthesized in the recent years, of much interest are polyarylenephthalides, card aromatic polymers prepared by electrophilic substitution reactions involving pseudomono- and pseudodichlorides of *o*-keto carboxylic acids [1–3]. Polyarylenephthalides combine high softening point, high heat resistance, and high chemical stability with good solubility in organic solvents and unusual electrophysical properties [1, 4].

It was demonstrated previously by the examples of 3-chloro-3-(4-phenoxyphenyl)phthalide **I** and 3-chloro-3-(4-phenylthiophenyl)phthalide **II** that pseudomonochlorides of *o*-keto carboxylic acids are capable of not only self-condensation but also copolycondensation [5]. One-step copolycondensation of these monomers yields random copolymers [6, 7].

In this study we performed two-step copolycondensation of **I** and **II**, prepared polyblock copolyarylenephthalides with different lengths of (4,4'-oxydiphenyl)phthalide and (4,4'-thiodiphenyl)phthalide sequences, and determined the microstructure and some properties of the synthesized polymers:



EXPERIMENTAL

Nitrobenzene and dimethylformamide were purified according to [7, 8]. $InCl_3$ was purchased from Aldrich. 3-Chloro-3-(4-phenoxyphenyl)phthalide and 3-chloro-3-(4-phenylthiophenyl)phthalide were synthesized according to [3].

Copolycondensation of **I** and **II** was performed by a two-step scheme using two procedures. In the first procedure, a 50-ml four-necked flask equipped with air-cooled reflux condenser with a bubble counter and a power-driven stirrer with a hydroseal was charged in an argon flow with 3.8 ml of a 2 M solution of **I** in nitrobenzene. Then the reaction mixture was heated with stirring to 110°C, and 0.2212 g of $InCl_3$ was added (10 mol % relative to the functional groups in both monomers). After 10, 30, or 180 min (in three different runs), 3.5 ml of a 2 M solution of **II** was added, and the synthesis was continued for 10 h. Samples of the reaction mixture (0.1–0.2 ml) were taken after 5, 10, 20, 40, 60, and 90 min. The products were isolated from the intermediate samples and final reaction mixture by precipitation into methanol. The precipitated polymers were dissolved in dimethylformamide and reprecipitated into methanol, after which they were washed with methanol and dried in air at 120°C for 24 h.

The second procedure was similar except that the self-condensation of **II** was performed first, after which compound **I** was added.

The electronic absorption spectra of sulfuric acid solutions of copolyarylenephthalides were recorded on a Shimadzu UV-3100 spectrophotometer. The optical density was measured at 533.5, 587.5, and 638.5 nm (absorption bands of the OO, OS, and SS diads, respectively):

The mole fractions of the diads in the polymer chain were determined according to [10, 11]. The experimental mole fractions of the diads P_{OO}, P_{SS}, and P_{OS} were used for calculating the microheterogeneity coefficients K_m, content of (4,4'-oxydiphenyl)phthalide (P_O) and (4,4'-thiodiphenyl)phthalide (P_S) units in the copolymer, and length of the (4,4'-oxydiphenyl)phthalide (L_O) and (4,4'-thiodiphenyl)phthalide (L_S) sequences [11]:

$$K_m = \frac{P_{OS}}{P_{OS} + P_{SS}} + \frac{P_{OS}}{P_{OS} + P_{OO}}, \quad (1)$$

$$P_O = P_{OO} + P_{OS}/2, \quad P_S = P_{SS} + P_{OS}/2,$$

$$L_O = 2P_O/P_{OS}, \; L_S = 2P_S/P_{OS}. \quad (2)$$

The softening onset temperature of the copolyarylenephthalides was determined with a thermomechanical installation at a load of 30 g mm^{-2} and a heating rate of 3 deg min^{-1}. The reduced viscosity of the polymers was measured in chloroform at 25°C and copolymer concentration of 0.5 g per 100 ml of solvent.

The microstructure of the copolyarylenephthalide prepared from **I** and **II** by two-step polycondensation depends on numerous factors: the relative reactivity of **I** and **II**, the comonomer taken in the first step for preparing the oligomeric block, the molecular weight of this block, and the time of the copolymer synthesis.

Analysis of the microstructure of the copolymers formed in the first minutes after adding the second comonomer shows that the sequence of addition of the monomeric (or oligomeric) fragments to the propagating polymer chain in the first and second procedures is different (see table).

In the first procedure (more active comonomer **I** is introduced first), the self-condensation of **I** apparently continues after addition of the second, less active comonomer **II**. This reaction is accompanied by the reactions yielding structures in which (4,4'-oxydiphenyl)phthalide units alternate with (4,4'-thiodiphenyl)phthalide units and, as the reaction goes on, with longer blocks of (4,4'-thiodiphenyl)phthalide units. This is indicated by the fact that K_m of the final copolyarylenephthalide is independent of the time of the selfcondensation of **I** (Fig. 1), and the content of heterodiads at the beginning of the copolycondensation is higher than by the end of the synthesis (see table). Thus, apparently, in the first procedure of the copolycondensation of **I** and **II** the macromolecules of the forming copolyarylenephthalide have a diagonal structure. One end of the copolymer molecule is enriched

* Time of synthesis of the oligomeric block.
** Time of synthesis of copolyarylenephthalide after loading the second comonomer.

in (4,4'-oxydiphenyl)phthalide blocks separated by (4,4'-thiodiphenyl)phthalide units, and on the other end there are (4,4'-thiodiphenyl)phthalide blocks that are longer than in the middle of the macromolecule:

$$[-(O)_pO-S-O-(O)_p-]-[-(S)_p(O)_p-(S)_p-(O)_p-]-[-S]_q,$$

where O is (4,4'-oxydiphenyl)phthalide unit; S, (4,4'-thiodiphenyl)phthalide unit; $q > p$.

In the second synthesis procedure, after adding more active second comonomer **I**, it first undergoes self-condensation, which is followed by alternation of (4,4'-oxydiphenyl)phthalide and (4,4'-thiodiphenyl)-phthalide sequences of various lengths. This is indicated by very low content of heterodiads in the sample taken 5 min after the start of the copolymer synthesis and by gradual increase in the heterodiad content with the progress of the reaction. As the time of the self-condensation of **II** in the first step of the synthesis is increased from 10 to 30 and 90 min, K_m regularly decreases from 0.14 to 0.08 and 0.04, suggesting an increase in the mean length of the forming blocks (Fig. 2). The longer the self-condensation (i.e., the longer the oligomeric block formed in the first step of the synthesis), the lower the amount of heterodiads at block junctions and the lower the microheterogeneity coefficient of the forming copolymer (see table). It should be emphasized that the OS heterodiads (in contrast to the first procedure) are apparently localized only at block junctions. Alternation of (4,4'-thiodi-

Oligomer prepared in the first step: (a) oligo[(4,4'-oxydiphenyl)phthalide] and (b) oligo[(4,4'-thiodiphenyl)phthalide]. Second comonomer added (*1*) 10, (*2*) 30, and (*3*) 180 min after the start of the first step. Catalyst $InCl_3$, 10 mol %; 110°C; comonomer concentration 2 M; time of synthesis after adding the second comonomer 10 h; the same for Fig. 2. (τ) Time.

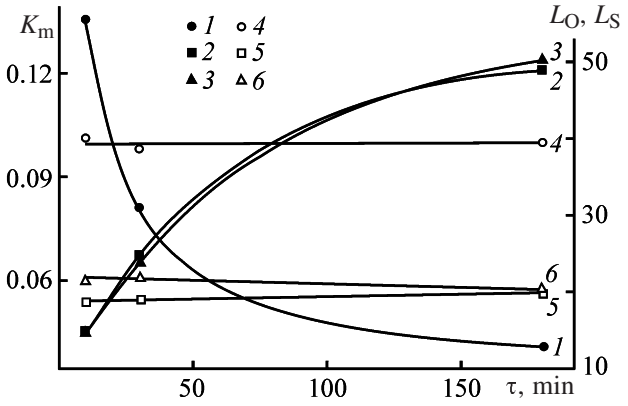

Fig. 2. (*1*, *4*) Microheterogeneity coefficient K_m and mean lengths of (*2*, *5*) (4,4'-oxydiphenyl)phthalide and (*3*, *6*) (4,4'-thiodiphenyl)phthalide blocks in copolyarylenephthalides as functions of the synthesis time τ of the oligomeric block. Procedure: (*1*–*3*) first and (*4*–*6*) second.

phenyl)phthalide units and (4,4'-oxydiphenyl)phthalide blocks with the formation of SOS triads is improbable because of the low activity of **II** and low concentration of chloride (diphenyl oxide) groups in oligo(4,4'-oxydiphenyl)phthalide.

The synthesized block copolyarylenephthalides are readily soluble in a wide range of organic solvents (chloroform, methylene chloride, tetrachloroethane, *N*-methylpyrrolidone, cyclohexanone, nitrobenzene) and form colorless transparent films (η_r = 0.45–0.64 dl g^{-1}). The flow point of copolyarylenephthalides is independent of their microstructure and amounts to 250–255°C.

CONCLUSIONS

(1) The sequence of loading the comonomers in the two-step copolycondensation of 3-chloro-3-(4-phenoxyphenyl)phthalide and 3-chloro-3-(4-phenylthiophenyl)phthalide **II** affects the order of incorporation of the monomeric fragments into the polymer chain and the microstructure of the resulting copolyarylenephthalides.

(2) The more regular structure of block copolyarylenephthalides is obtained when the less active comonomer is loaded first.

(3) Variation of the time of oligoarylenephthalide synthesis in the first step of the copolycondensation allows preparation of block copolyarylenephthalides with controllable block length.

ACKNOWLEDGMENTS

The study was financially supported by the Program no. 8 of Basic Research of the Presidium of the Russian Academy of Sciences and by the Foundation for Support of Leading Scientific Schools (project NSh-9342.2006.3).

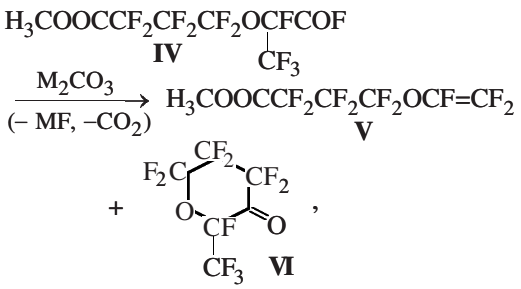
Received September 12, 2006; in final form, October 2007

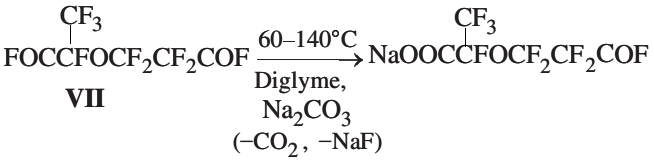
Abstract—Formation of cyclic structures under the conditions of pyrolytic decarboxylation of perfluorooxaalkanedicarboxylic acids was studied.

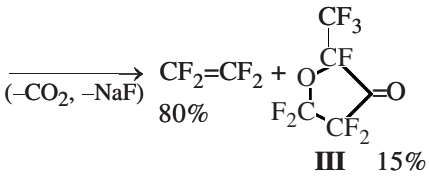


DOI: 10.1134/S1070427208010229

Pyrolytic decarboxylation of salts of perfluoro-2-alkoxypropionic acids is a known route to perfluorinated alkyl vinyl ethers [1]. However, the direction of pyrolytic processes may vary depending on the reaction conditions and substrate structure [2]. In particular, pyrolysis of perfluorooxaalkanedicarboxylic acids containing six- and seven-membered structures yields cyclic compounds.

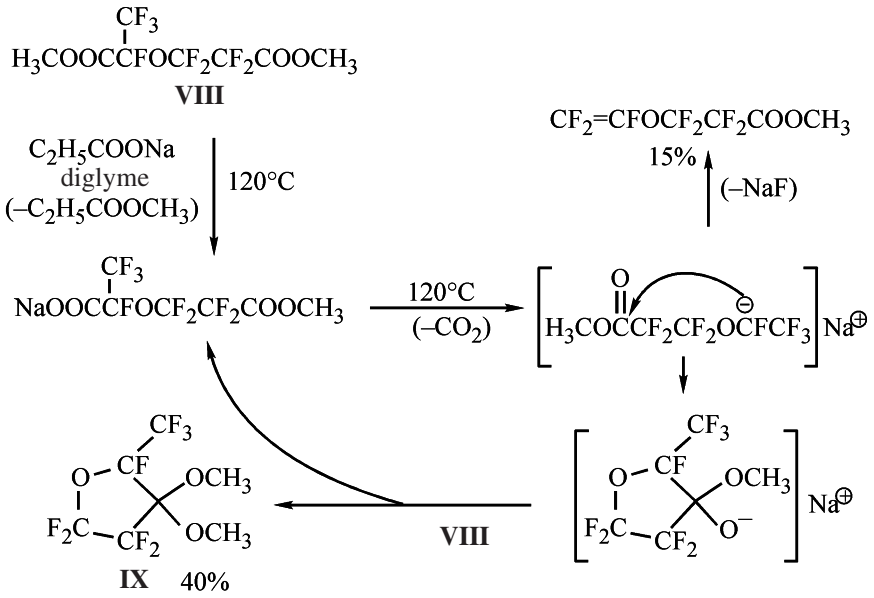
Pyrolysis of sodium pefluoro-4-oxaheptane-1,7-dioate at 250°C gives in less than 3% yield perfluoro-3-vinyloxypropionyl fluoride **II**, which partially isomerizes under the action of CsF even at room temperature to form a cyclic product, perfluoro-2-methyloxolan-3-one **III** [3]:





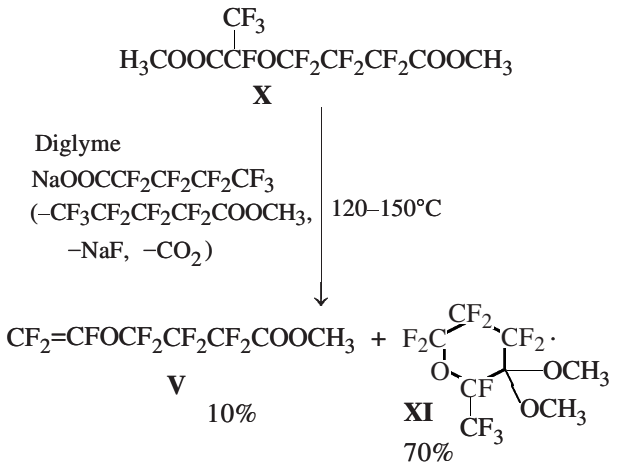
Pyrolysis of sodium and potassium salts derived from methyl perfluoro-6-methyl-5-oxa-7-oxoheptanoate **IV** yields, along with the major product, vinyl ether **V**, also perfluoro-2-methylpyran-3-one **VI** [4]:

where M = K or Na.



Pyrolysis of an isomer of **I**, perfluoro-2-methyl-3-oxahexane-1,6-dioyl fluoride **VII**, in diethylene glycol dimethyl ether (diglyme) at 120°C in the presence of an equimolar amount of sodium carbonate resulted in direct formation of perfluoro-2-methyloxolan-3-one **III** in approximately 15% yield [2]:

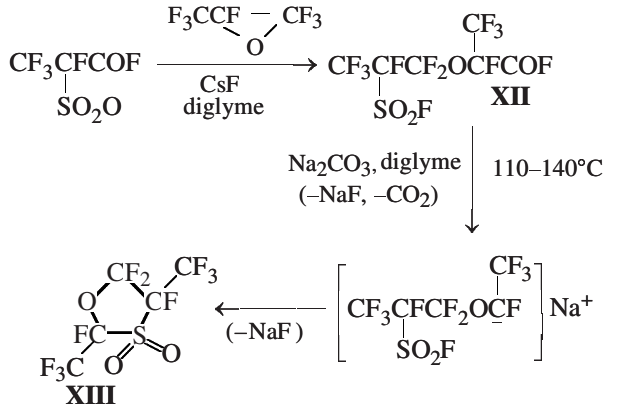
Compound **III** was identified by ^{19}F NMR spectroscopy from the characteristic signals of the magnetically nonequivalent geminal fluorine atoms with coupling constants of 125 Hz for the $–CF_2I–$ group and 295 Hz for the $–CF_2C(O)–$ group. The ^{19}F NMR spectrum also contained the signals of the –OCF< and $–CF_3$ groups (see table).



With the aim to prevent such cyclization, dimethyl perfluoro-2-methyl-3-oxahexane-1,6-dioate **VIII** was subjected to pyrolytic decomposition in diglyme in the presence of an equimolar amount of sodium perfluoropropionate [5]. At 120°C, active decarboxylation with the CO_2 evolution was observed along with the ester interchange yielding methyl perfluoropropionate. In the ^{19}F NMR spectrum of the major pyrolysis product boiling at 106°C, we failed to find the characteristic signals of the trifluorovinyl group and difluoromethylene group adjacent to the carboxyl, expected for methyl perfluoro-3-vinyloxypropionate. We managed to identify this compound only by comparing the ^{19}F NMR, ^1H NMR, and mass spectra; this compound is 3,3-dimethoxyperfluoro-2-methyloxolane **IX**. Apparently, under these conditions, stabilization of the intermediate carbanion by intramolecular cyclization with charge transfer is preferable. Apparently, the forming adduct reacts with the starting substrate **VIII**, nucleophilically attacking the ester group by the S_N2 mechanism [6] to give product **IX**, with the regeneration of the salt derived from **VIII**:

Similar results were obtained when the pyrolysis was performed in the presence of sodium perfluorobutyrate. Pyrolysis of analogs of **VIII**, diethyl (**VIIIa**) and diisopropyl (**VIIIb**) esters, yielded the corresponding cyclic ketals **IXa** and **IXb**.

An attempt to perform the pyrolysis of the related *tert*-butyl ester, di-*tert*-butyl perfluoro-2-methyl-3-oxahexane-1,6-dioate **VIIIc**, failed because of the thermal instability of this ester. Even at 80°C, compound **VIIIc** decomposes to give isobutylene, with the decarboxylation and formation of 1,2'-dihydroperfluorodiethyl ether [7].



To exclude the possibility of cleavage of the C–O bond in the course of pyrolysis, characteristic of perfluoro-3-alkoxypropionic acid derivatives [2], we performed pyrolysis experiments with dimethyl perfluoro-2-methyl-3-oxaheptane-1,7-dioate **X** under similar conditions in the presence of sodium perfluorobutyrate. Along with methyl perfluorobutyrate, we obtained in approximately 10% yield methyl perfluoro-4-vinyloxybutyrate **V** and in approximately 70% yield a six-membered cyclic product boiling at 144°C and identified by the ^{19}F and ^1H NMR spectra as 3,3-dimethoxyperfluoro-2-methyloxane **XI**:

The cyclic ketals obtained are heavy liquids very resistant to acids, alkalis, and halogens under UV irradiation. Their NMR spectra are given in the table.

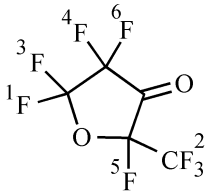
Without solvent, the cyclization in the course of pyrolysis occurs at a higher temperature (180–200°C), and in the case of compound **VIII** boiling below 180°C it does not occur at atmospheric pressure, probably because of the above-mentioned cleavage of the C–O bond with the elimination of tetrafluoroethylene. However, the pyrolysis of **X** gives cyclic ketal **XI** and methyl perfluoro-4-vinyloxybutyrate **V** in equal yields (~40%).

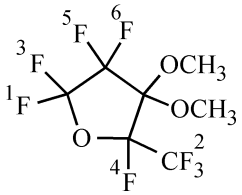
Perfluorooxaacyl fluorides containing a sulfonyl fluoride group instead of one of the carbonyl fluoride groups also underwent cyclization in the course of pyrolysis under the same conditions. For example, perfluoro-5-fluorosulfonyl-3-oxa-2-methylhexanoyl fluoride **XII** yielded exclusively perfluoro-3-oxa-2,4-dimethylsulfolane **XIII** by the scheme

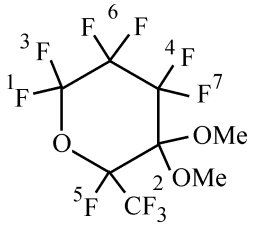
The structure of **XIII** suggests the possibility of the *cis* and *trans* arrangement of the CF_3 groups relative to the ring plane, which is in agreement with the ^{19}F NMR data (see table) and corresponds to the spectrum of the isomer mixture in 1 : 1 ratio.

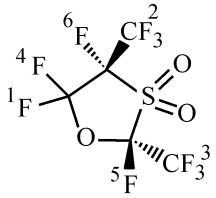
EXPERIMENTAL

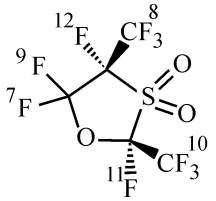
The pyrolysis products were analyzed chromatographically with an LKhM-8MD chromatograph [model 5, thermal conductivity detector, programmed heating from 30 to 200°C at a rate of 6 deg min^{-1}, 3000 × 3 mm columns, solid support Celite-545 (0.16–0.2 mm, packing density 0.30–0.01 g cm^{-3}), stationary phase SKTFT-50 (15 wt %), carrier gas helium (40 ml min^{-1})].











The ^{19}F NMR spectra were recorded on a Bruker Spectrospin AM-500 spectrometer at a frequency of 470.572 MHz using hexafluorobenzene or hexafluoro-*p*-xylene as internal reference and $CDCl_3$ as solvent. The ^{19}F chemical shifts were recalculated relative to CCl_3F. The ^1H NMR spectra were recorded on the same spectrometer at a frequency of 500 MHz with HMDS as external reference. The mass spectra were taken on a Chromass Varian CH-7M device.

Dimethyl, diethyl, and diisopropyl perfluoro-2-methyl-3-oxahexane-1,6-dioates were prepared by alcoholysis of perfluoro-2-methyl-3-oxahexane-1,6-dioyl fluoride **VII** with the corresponding alcohols (compound **VII** was prepared as described in [7]). Dimethyl perfluoro-2-methyl-3-oxaheptane-1,7-dioate **X** was prepared similarly.

Perfluoro-2-fluorosulfonyl-4-oxa-5-methylhexanoyl fluoride **XII** was prepared by condensation of hexafluoropropene oxide with the isomerization product of hexafluoropropene sultone [9], following the known procedure [10].

Pyrolysis of dimethyl perfluoro-2-methyl-3-oxahexane-1,6-dioate VIII. A 250-ml four-necked round-bottomed glass flask equipped with a stirrer, a thermometer, a dropping funnel, and a column (d = 10 mm, h = 40 cm) with Levin spiral packing and a reflux head was charged with 33 g (0.11 mol) of **VIII** and 50 ml of absolute diglyme. The mixture was heated to 120°C, and a solution of 19 g (0.1 mol) of sodium perfluoropropionate in 50 ml of diglyme was added dropwise with stirring over a period of 2 h. In so doing, methyl perfluoropropionate was distilled off. After adding the whole amount of sodium perfluoropropionate, the mixture was rerfluxed at 120–150°C for 6 h, and the pyrolysis products were collected successively in a receiver and in a trap cooled to –50°C. Finally the gas phase was passed through a trap with bromine, in which tetrafluoroethylene formed in small amounts was converted into 1,2-dibromoperfluoroethane. The pyrolyzate was combined, washed to remove diglyme, dried over Na_2SO_4, and subjected to fractional distillation. 3,3-Dimethoxyper-

fluoro-2-methyloxolane **IX** was obtained; yield 13.2 g (41%), bp 106°C, d_4^{20} 1.51 g cm^{-3}, n_D^{20} 1.3265.

Mass spectrum, *m/e* (I_{rel}, %): 290 (7.3) M^+; 271 (2.0) $M^+ – F$; 259 (10.8) $M^+ – OCH_3$; 231 (1.7) $M^+ – CO_2CH_3$; 197 (1.5) $M^+ – CF_2CO_2CH_3$; 193 (2.4) $M^+ – CF_3CO$; 181 (5.1) $M^+ – CF_2CO_2CH_3$; 174 (100) $M^+ – OCFCF_3$; 169 (7.3) $C_3F_7^+$; 159 (10.1) $C_2F_4CO_2CH_3^+$; 147 (2.9) $C_2F_5CO^+$; 143 (5.3) $C_2F_3 \cdot C(OCH_3)_2^+$; 131 (10.6) $C_3F_5^+$ [$C_2F_4OCH_3^+$]; 129 (28.4) $C_2F_4CHO^+$; 124 (21.9) $C_4F_4^+$ [$CF_2C(OCH_3)_2^+$]; 121 (7.3) $C_2F_2CO_2CH_3^+$; 119 (4.7) $C_3F_7^+$; 109 (8.9) $CF_2 \cdot CO_2CH_3^+$; 101 (20.0) $C_2F_4H^+$; 100 (16.0) $C_2F_4^+$; 97 (15.0) $C_2F_3O^+$; 93 (6.7) $C_3F_3^+$; 81 (40.0) $C_2F_3^+$; 74 (19.0) $C(OCH_3)_2^+$; 69 (24.0) CF_3^+; 59 (41.0) $CO_2CH_3^+$.

3,3-Diethoxyperfluoro-2-methyloxolane **IXa** (yield 45%), bp 136°C, d_4^{20} 1.50 g cm^{-3}, n_D^{20} 1.3276), 3,3-diisopropoxyperfluoro-2-methyloxolane **IXb** (yield 35%, bp 88°C/90 mm Hg, d_4^{20} 1.49 g cm^{-3}, n_D^{20} 1.3298), and 3,3-dimethoxyperfluoro-2-methyloxane **XI** (yield 70%, bp 144°C, d_4^{20} 1.60 g cm^{-3}, n_D^{20} 1.3315) were prepared similarly.

Pyrolysis of dimethyl perfluoro-2-methyl-3-oxaheptane-1,7-dioate X. The reactor similar to that described above was charged with 38.4 g (0.1 mol) of **X** and 28.6 g (0.1 mol) of dry sodium perfluorobutyrate. The stirring was switched on, and the mixture was heated to 180–200°C over a period of 6 h, with collection of the pyrolysis products in a receiver and a trap cooled to –60°C. The pyrolyzate was combined and subjected to fractional distillation. We isolated 13 g (40%) of 3,3-dimethoxyperfluoro-2-methyloxane **XI** and 12 g (40%) of methyl perfluoro-4-vinyloxybutyrate **V**, bp 129°C, d_4^{20} 1.57 g cm^{-3}, n_D^{20} 1.3180.

Pyrolysis of perfluoro-2-fluorosulfonyl-4-oxa-5-methylhexanoyl fluoride XII. The similar installation was charged with 22 g (0.2 mol) of dry Na_2CO_3 and 50 ml of absolute diglyme. The reaction mixture was heated with stirring to 70°C on an oil bath, and 0.79 g (0.2 mol) of **XII** was added dropwise. After the CO_2 evolution ceased, the mixture was heated to 120°C, and 56 g of the product with bp 64°C, d_4^{20} 1.64 g cm^{-3}, and n_D^{20} 1.3107 was distilled into a receiver. According to the GLC data, the content of perfluoro-3-oxa-2,4-dimethylsulfolane **XIII** was 98%. The total yield of **XIII** was 83%.

CONCLUSIONS

(1) Pyrolysis in a solvent (diglyme) of sodium salts of α,ω-perfluorooxaalkanedioic acids with the chain length n = 6–7 mainly yields five- and six-membered cyclic structures.

(2) Depending on the structure of the compound subjected to pyrolysis (fluorides or esters of perfluorooxaalkanoic acids), cyclization yields oxalanone or ketal structures.

(3) On replacement of a fluorocarbonyl group in the perfluorooxaalkanedioic acid molecule by the fluorosulfonyl group, pyrolysis also occurs along the cyclization pathway, yielding perfluoro-3-oxa-2-methylsulfolane ring.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Spontaneous Polymerization of Acrylamide in Preactivated Glycerol

Abstract—Spontaneous polymerization of acrylamide in acrylamide–glycerol mixture was studied.

DOI: 10.1134/S1070427208010230

It is commonly believed that spontaneous polymerization of monomers is initiated by random formation of active centers (radicals, ions, etc.) caused by various factors. The polymerization can also be initiated by impurities present in monomers and solvents. These impurities can form specific compounds capable of decomposing under certain conditions to form active intermediates. For example, the presence of hydroperoxide impurities in monomers can induce spontaneous formation of polysulfones [1, 2].

We reported previously [3] that spontaneous polymerization of acrylamide was observed in acrylamide–glycerol mixture on adding finely dispersed acrylamide monomer to glycerol without any initiatior. In this study we examined the mechanism of formation of active centers initiating the spontaneous polymerization of acrylamide in glycerol.

EXPERIMENTAL

Acrylamide recrystallized from acetone was ground in an agate mortar to 100-μm particles. Glycerol (analytically pure grade, main substance content 99.3%) was used without additional purification. The main impurities in glycerol were iron, lead, and silver sulfates and chlorides, and also fatty acid esters. Glycerol was irradiated with light [$\lambda \geq 236$ nm (intensity 7.6×10^{17} quanta $cm^2\ s^{-1}$) and $\lambda \geq 360$ nm (intensity 4.1×10^{17} quanta $cm^2\ s^{-1}$)] and with γ-rays (^{60}Co, radiation dose rate 0.5 Gy s^{-1}).

Finely dispersed acrylamide monomer (20%) was added to glycerol, and the resulting suspension was thoroughly stirred. Since dissolved atmospheric oxygen does not affect the acrylamide polymerization, the acrylamide–glycerol suspension was not degassed. After the polymerization completion, the reaction mixture was washed with ethanol to remove glycerol, and then ethanol was removed by evacuation. The ESR spectra were recorded on an EPR-21 radiospectrometer at 77 K (wavelength 3 cm, UHF field power about 10^{-4} W). The electronic absorption spectra were recorded on a Specord-40 M spectrophotometer in a 1-cm optical cell. The gaseous products of photolysis were analyzed on an MI-1201 mass spectrometer. The peroxy compounds were determined by iodometric titration.

Experiments on spontaneous polymerization of acrylamide in glycerol of various batches showed that this phenomenon was poorly reproducible. Since in glycerol of some batches polymerization was not observed, we suggested that it is the glycerol activity that is responsible for spontaneous polymerization of acrylamide. In particular, it is possible that commercial glycerol contains active species inducing polymerization. These active species can be either complexes of glycerol with impurities or other compounds formed in glycerol in its production and storage under the action of light, irradiation, heating, and other factors.

We found that glycerol is activated with both the daylight and γ-ray irradiation, and this effect occurs at small radiation doses and short exposure time. As seen from Fig. 1, the maximal yield of the polymer (70%) is reached at the irradiation dose of about 0.5 kGy or upon photolysis ($\lambda \geq 360$ nm) for 30 min. Hence, both the photolysis and radiolysis of glycerol are accompanied by formation of stabilized active intermediates initiating polymerization of acrylamide.

Figure 2 shows the dependence of the polymer yield on the wavelength of light used for preactivation

of glycerol. It is seen that commercial glycerol (analytically pure grade) used in our experiments is activated by light within wavelength range from 260 to 450 nm. It should be noted that glycerol must be optically transparent in this optical region since the C–C, C–H, C–O and OH groups absorb only in the vacuum ultraviolet range. Therefore, we believe that photoactivation of glycerol is due to photosensitizing effect of impurities. Iron, lead, and silver sulfates and chlorides, and also fatty acid esters present in commercial glycerol as impurities can acts as sensitizers. The absorption band at λ_{max} = 275 nm in the electronic absorption spectrum of glycerol (Fig. 2, curve *2*) can be caused by impurities present in glycerol.

The mechanism of activation of glycerol was examined by a common technique based on inhibition of the radical reactions by adding 2,2,6,6-tetramethylpiperidineoxyl stable radicals (nitroxyl radical, NR). The nitroxyl radicals were added to initial glycerol at 293 K and their concentration was monitored by ESR. We found that NR added to glycerol disappeared completely after irradiation for 30 min and acrylamide added to irradiated glycerol did not polymerize. Thus, in the presence of nitroxyl radicals, the active species formed in irradiation are not stabilized. The decay of NR suggests that, in irradiation of glycerol, free radicals such as $R^{\bullet}$, $HO^{\bullet}$, and $H^{\bullet}$ are formed. The peak corresponding to molecular weight 2 present in the mass spectrum of gaseous products of irradiated glycerol can be assigned to molecular hydrogen formed by rupture of CH groups in glycerol molecules. The above radicals, when reacting with glycerol molecule, generate active species.

The rate of generation of active species v in irradiation of glycerol with light ($\lambda \geq 236$ nm and $\lambda \geq 360$ nm) was determined by the inhibition technique from the experimental dependence of the active species concentration on the exposure time. The v values determined in these experiments at $\lambda \geq 236$ nm and $\lambda \geq 360$ nm were 2×10^{12} and 4.2×10^{11} $cm^{-3}\ s^{-1}$, respectively. The rate of accumulation of radicals in glycerol in the course of its irradiation at $\lambda \geq 360$ nm, determined from the initial portion of the curve of decay of nitroxyl radicals, was 4.2×10^{16} $cm^{-3}\ s^{-1}$). Thus, the fraction of the active species relative to the total amount of photolytically formed radicals was about 10^{-5}.

The active species were characterized by spectroscopic and kinetic methods. Although irradiated glycerol contained 1.4×10^{17} cm^{-3} of active species, we failed to detect paramagnetic particles by ESR spectroscopy allowing detection of 10^{14} spin cm^{-3}.

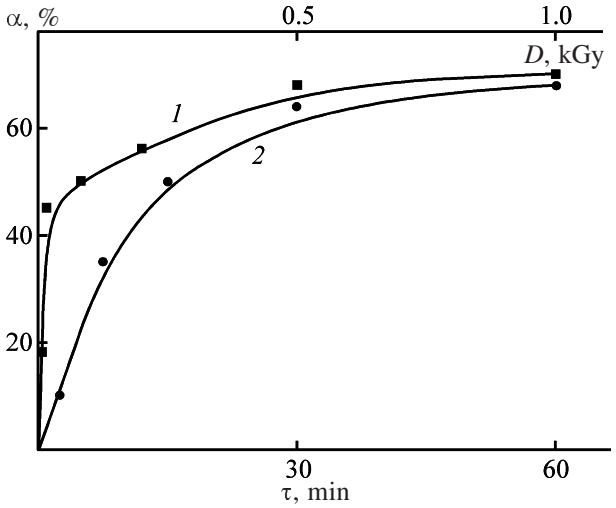

Fig. 1. Yield of polymer α in irradiation of glycerol with (*1*) light ($\lambda \geq 360$ nm) and (*2*) γ-rays vs. the exposure time and dose, respectively.

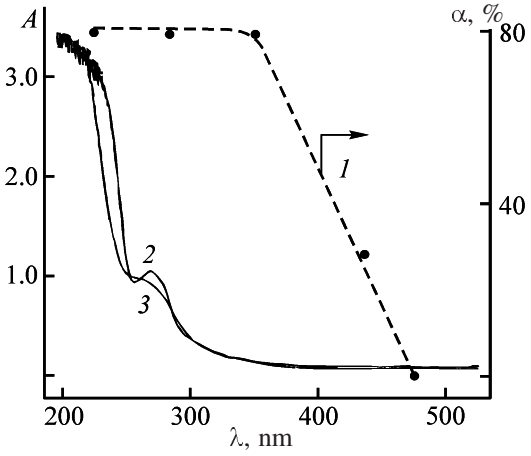

Fig. 2. Dependence of the (*1*) polymer yield α and (*2, 3*) optical absorption A (1-cm optical cell) of the (*2*) initial and (*3*) preactivated glycerol on the light wavelength λ.

The electronic absorption spectra of irradiated glycerol in the absorption range of active species (200–500 nm) also contained no additional absorption bands. These results showed that the active species are diamagnetic molecular compounds capable of dissociating to radicals initiating polymerization of acrylamide. To elucidate how the active species dissociate to induce polymerization, the nitroxyl radicals were added to a suspension of acrylamide in preactivated glycerol. We found that, under these conditions, NR rapidly disappeared, and the polymerization did not develop. This means that the active species dissociate to form radicals.

Since irradiation of glycerol generates unstable active species, they start to spontaneously decompose after the irradiation completion or on addition of

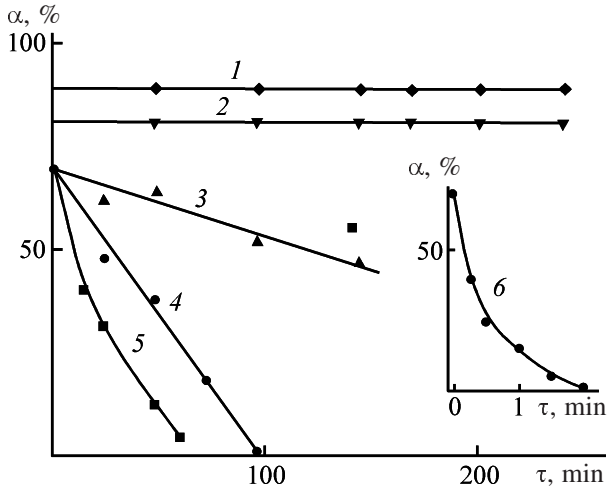

Fig. 3. Dependence of the polymer yield α on the time (τ) of keeping preactivated glycerol under temperature-controlled conditions. (*1, 2*) λ ≥ 236 nm and (*3–6*) λ ≥ 360 nm. Irradiation time, h: (*2–6*) 1 and (*1*) 5. Temperature, K: (*1–5*) 298 and (*6*) 318.

acrylamide. The initial rate of decomposition of the active species was estimated as follows. Figure 3 shows how the yield of the polymer depends on the time and temperature of keeping glycerol after completion of its photolysis. In these experiments, glycerol was irradiated with light (λ ≥ 236 nm and λ ≥ 360 nm) for different times. Since both the polymerization rate and polymer yield are in proportion with the initial content of the active species in glycerol, the decrease in the polymer yield with increasing keeping time, observed in our experiments, is apparently caused by decomposition of active species. We found that both the increase in keeping temperature of preactivated glycerol and the addition of foreign solvents (e.g., H_2O) accelerate the decomposition of the active species. The initial concentration of active species in irradiated glycerol was about 1.5×10^{15} cm^{-3}. The rate of decomposition of active species ($cm^{-3}\ s^{-1}$) increases with temperature: 273 K, 6.2×10^{8}; 293 K, 4.3×10^{9}; and 318 K, 1.7×10^{12}. On addition of water to irradiated glycerol, the rate of spontaneous decomposition of the active species was found to be 7.0×10^{9} $cm^{-3}\ s^{-1}$. The activation energy of spontaneous decomposition of active species, calculated from our experimental results, was 24 kcal mol^{-1}. This value is consistent with low thermal stability of these species.

In irradiation of glycerol by light with λ ≥ 236 nm, the polymer yield remains constant irrespective of the keeping time. At the maximal keeping time of 240 h, the concentration of active species was more than 10^{15} cm^{-3}. We suggested that under these conditions only a small portion of the active species participated in the polymerization. This hypothesis is consistent with the fact that, on removal of polymeric and monomeric acrylamide from the reaction mixture after the polymerization completion, the recycled glycerol, similar to the initial preactivated glycerol, induced effective polymerization of acrylamide (80% polymer yield).

To polymerize acrylamide in glycerol to 70% at the factor of chain transfer ~10^4 [3], the concentration of active species in the reaction mixture must be no less than 10^{14}–10^{15} cm^{-3}. In the course of polymerization for 60 min, approximately 10^{13} cm^{-3} of active species decompose in the reaction mixture. This amount is insufficient to ensure the 70% degree of polymerization of acrylamide even at complete consumption of the active species. Therefore, apparently, the spontaneous polymerization of acrylamide occurs not only due to thermal decomposition of the active species. We believe that the main amount of active centers (10^{14}–10^{15} cm^{-3}) is generated from the active species due to forces of the molecular stress caused by the concentration gradient at the solid acrylamide–glycerol interface in dissolution of acrylamide monomer.

Thus, based on the spectroscopic and kinetic data, we can suggest that the active species formed in glycerol are diamagnetic molecules slowly decomposing at room temperature with the activation energy equal to ~24 kcal mol^{-1} to give free radicals. The decomposition of active species is accelerated in dissolution of solid acrylamide monomers in glycerol. We assume that the active species are peroxy compounds. To check this hypothesis, the glycerol samples thoroughly evacuated to remove atmospheric oxygen were irradiated with light (λ ≥ 236 nm) for 20 h and then analyzed by iodometric titration for the hydroperoxy groups. These experiments showed that irradiated glycerol contains the hydroperoxy groups in the amount of ~1.2×10^{17} cm^{-3}, which is very close to the content of the active species in this system, determined by the inhibition technique (~1.4×10^{17} cm^{-3}). Thus, the irradiation of glycerol is accompanied by formation of the hydroperoxy groups, and their yield is insensitive to dissolved oxygen. On adding acrylamide to preactivated glycerol, the ROOH groups decompose to form radicals initiating the propagation of polymer chains.

The formation of the hydroperoxy groups can be described by the following scheme. On irradiation of glycerol, the impurity species absorb photons and pass

into an excited state (M)*. The excess energy of these excited species is transferred to glycerol molecules, breaking bonds in them. As a result, hydrogen atoms and glycerol radicals are formed. Although these active species rapidly decompose, a small fraction of radicals (approximately 0.001%) has time to react with glycerol to form the hydroperoxy groups ROOH.

$$(M) + UV \rightarrow (M)^* + Gl \rightarrow Gl^* + M \rightarrow R^\bullet + H^\bullet(HO^\bullet), \quad (1)$$

$$CH_2OH–CHOH–CH_2OH + H^\bullet \rightarrow CH_2OH–CHO^\bullet–CH_2OH + H_2, \quad (2)$$

$$CH_2OH–CHO^\bullet–CH_2OH + HO^\bullet \rightarrow CH_2OH–CHOOH–CH_2OH(ROOH), \quad (3)$$

$$ROOH\,(\text{decomposition}) \rightarrow RO^\bullet + HO^\bullet, \quad (4)$$

$$RO^\bullet(HO^\bullet) + \text{acrylamide(AA)} \rightarrow R_0^{AA}\,(\text{initiation}), \quad (5)$$

$$R_0^{AA} + AA \rightarrow R_p\ldots\ (\text{chain propagation}). \quad (6)$$

Since glycerol is widely used in medicine, biology, food and cosmetic industries, for producing explosives, etc., the possibility of activation of glycerol under natural factors (for example, by daylight) is important from practical viewpoint. The reaction of the photolytically induced peroxy groups with additives introduced into glycerol can produce radicals stimulating undesirable side reactions. This is particularly important for medicinal, perfume, and food products in connection with the effect of free radicals on the malignant tumor growth, aging, etc. Therefore, the production and storage of glycerol must meet stringent requirements to exclude the formation of peroxy impurities. Furthermore, in production of glycerol and glycerol-containing mixtures (pastes, creams, and solutions for medical and perfume applications), sensitizing additives should also be inadmissible because the illumination of glycerol can induce formation of peroxides and products of their spontaneous decomposition initiating undesirable radical reactions.

Thus, the development of techniques for production of glycerol free of sensitizing impurities and for purification of glycerol to remove undesirable impurities is an urgent problem. Our studies show that the determination of the degree of polymerization of acrylamide in glycerol preactivated by illumination or γ-ray irradiation is a simple, sensitive, and reliable method for determining the sensitizer content of glycerol.

CONCLUSIONS

(1) Spontaneous polymerization of acrylamide in glycerol preactivated by illumination or γ-ray irradiation is initiated by hydroperoxides formed in activated glycerol due to its photolysis (radiolysis) sensitized by trace impurities.

(2) The use of sensitizer-containing glycerol for preparing medicinal, cosmetic, and food composites can induce undesirable side reactions and formation of products dangerous to health.

(3) A method for determining the content of sensitizing impurities in glycerol was suggested.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Reaction of Polyvinyl Chloride with Calcium and Magnesium Oxides

O. V. Rudometova, Zh. A. Vnutskikh, A. A. Fedorov, and Yu. S. Chekryshkin

Institute of Technical Chemistry, Ural Division, Russial Academy of Sciences, Perm, Russia

Received September 17, 2007

Abstract—Reaction of polyvinyl chloride with calcium and magnesium oxides was studied. The dependence of binding with metal oxides of hydrogen chloride formed by polyvinyl chloride dehydrochlorination on the oxide to polymer weight ratio and on temperature was examined. The activation energies and specific rates of formation of the corresponding metal chlorides were calculated. Conditions of complete chloride binding into environmentally safe products were found.

DOI: 10.1134/S1070427208010242

The use of plastics grows at appreciably higher rate compared to other materials, which results in accumulation of enormous amounts of the polymeric waste (both household and industrial). The traditional methods of waste incineration or disposal are extremely unhealthy from the environmental point of view because of penetration into the atmosphere, water, and soil of toxic substances, dioxins, which are strong carcinogens. The method of deep oxidation of solid polymeric materials containing halogens by heating these materials mixed in the finely ground state with oxides and hydroxides of calcium, magnesium, and barium with formation of harmless products has been reported [1].

The dehydrochlorination of polyvinyl chloride (PVC) (which is the primary reaction of PVC thermal degradation), producing polyene sequences in the degraded polymer, and the secondary reaction of crosslinking of macrochains, proceeding parallel-successively, are fairly comprehensively studied [2, 3]. At the same time, the data on PVC reaction with inorganic compounds are very limited. The effect of copper(I) chloride on formation of polychlorinated dibenzo-*p*-dioxins and polychlorodibenzofurans in the course of PVC incineration was noted [4]. The PVC pyrolysis in the presence of zinc and barium chlorides decreases the dehydrochlorination temperature and formation of high-molecular-weight products [5]. The 11%, on the average, increase in the efficiency of hydrogen chloride trapping at PVC reprocessing with sorbents based on calcium carbonate, hydroxide, and acetate was reported in [6].

The goal of this study is determination of the effect of calcium and magnesium oxides on PVC dehydrochlorination, examination of the kinetics of PVC reaction with calcium and magnesium oxides under isothermal conditions, and optimization of conditions of complete binding of PVC chlorine into the corresponding metal chlorides.

EXPERIMENTAL

Powder of emulsion PVC of E-6250Zh brand and analytically pure grade calcium and magnesium oxides were used. The reaction of the components was studied by differential-thermal and thermogravimetric methods on a Q-1500D derivatograph in alundum crucibles at a heating rate of 2.5 deg min^{-1}. The reaction kinetics was studied under isothermal conditions by introduction of polymer and metal oxide mixture (taken in definite weight ratio) into a crucible heated to preset temperature. The samples were prepared by prolonged trituration of the suspension of the components in acetone in an agate mortar. The content of alkaline-earth metal chlorides was determined by volumetric Mohr titration after dissolution of the mixture sample in distilled water. Similarly, the chlorine content of the gas phase was determined after absorption of hydrogen chloride with water.

The degree of binding of polymer chlorine α was calculated as the ratio of chlorine weight in metal chloride to chlorine weight in the initial PVC sample.

It was found that the thermal oxidative degradation of PVC and reaction of the degradation products with

calcium and magnesium oxides occur step by step within the range 200–500°C interval and involve PVC dehydrochlorination, the subsequent reaction of hydrogen chloride with metal oxide, and oxide carbonation.

The PVCh dehydrochlorination, irrespective of the composition of the gas phase, starts at 200°C, and a maximal rate of the weigh loss is observed at 250°C (Fig. 1 a). At 280°C, 90% of chlorine contained in PVC is eliminated. An endothermic effect at 255°C corresponding to reaction [7, 8]

$$[CH_2–CHCl]_n \rightarrow [–CH=CH–]_n + HCl$$

is observed in the derivatogram.

Within the range 280–340°C, two processes occur: The PVC dehydrochlorination is complete, and gradual decomposition of the hydrocarbon residue starts. Above 340°C, the decomposition is accompanied by oxidation of the decomposition products, which is confirmed by exothermic effects at 425 and 500°C. In an inert gas (nitrogen, helium) flow, the thermal effects corresponding to oxidation substantially decrease.

The reaction of PVC with magnesium oxide is complex and multistage (Fig. 1b). Similarly to thermal degradation of straight PVC, the first stage is PVC dehydrochlorination with the maximal rate of hydrogen chloride evolution at 250°C. The released hydrogen chloride reacts with magnesium oxide, as indicated by disappearance of the endothermic effect of HCl release at 255°C and appearance of an exothermic peak in the DTA curve at 270°C. At MgO/PVC ratio increased from 2 to 3, the reaction surface area increases, which accounts for the difference in the weight loss associated with the larger amount of magnesium chloride formed. Within the range 300–400°C, the PVC degradation products decompose. The exothermic effect within the range 410–470°C corresponds to carbonation of magnesium oxide [9]. The further increase in the temperature leads to reverse reaction of magnesium carbonate decomposition, which is accompanied by an endothermic effect in the DTA curve (this effect is not detected at low heating rates). The analysis of the residue after heating the reaction mixture to 500°C showed the absence of magnesium carbonate.

The behavior of PVC–CaO mixture at heating substantially differs from that of the mixture with MgO (Fig. 1c). After the stage of dehydrochlorination and subsequent reaction of HCl with calcium oxide, the sample weight increases. This feature is also observed

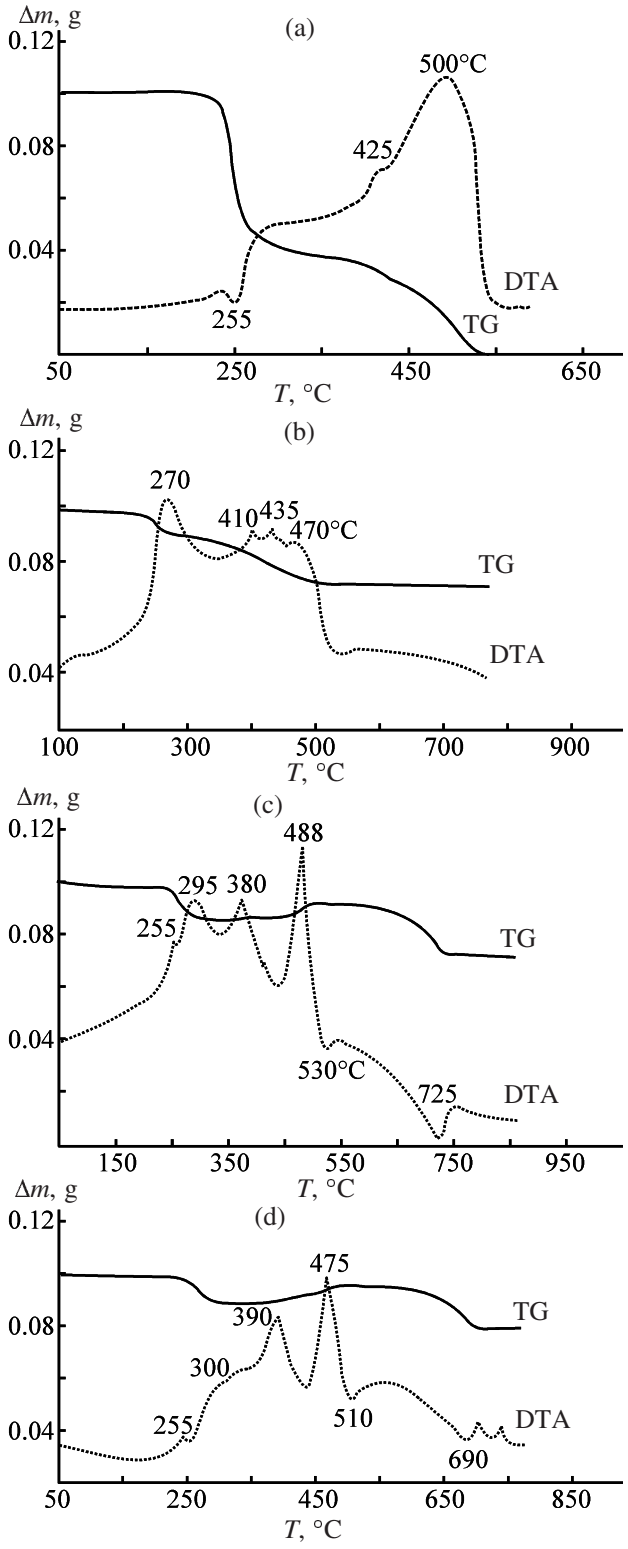

Fig. 1. DTA and TG curves of (a) PVC, (b) PVC + MgO, and (c, d) PVC + CaO. Heating: (a–c) in air and (d) in helium atmosphere. M = 3. (Δm) Weight loss and (T) temperature.

Table 1. Degree of chlorine binding and activation energies of formation of calcium and magnesium chlorides in reaction of PVC with CaO and MgO. Temperature 290°C, contact time 6 min

Oxide	Degree of PVC chlorine binding α, %		Activation energy, kJ mol^{-1}			
			α = 15%		α = 20%	
	M = 2	*M* = 3	*M* = 2	*M* = 3	*M* = 2	*M* = 3
CaO	25.9	37.6	86.2 ± 13.3	88.8 ± 7.1	93.9 ± 11.5	92.7 ± 6.8
MgO	21.0	35.4	44.8 ± 1.7	38.7 ± 0.6	48.3 ± 3.1	42.5 ± 1.6

when the experiment is performed in a flow of an inert gas (Fig. 1d). This fact suggests probable formation in this stage of calcium hydroxide and carbonate in the reaction of PVC degradation products with CaO. The decrease in the sample weight at the temperature higher than 500°C is due to dehydration of $Ca(OH)_2$ and decarbonation of $CaCO_3$, which is confirmed by endothermic effects at 530 (510) and 725 (690)°C in air (helium). The degree of polymer carbon binding amounts to 55%.

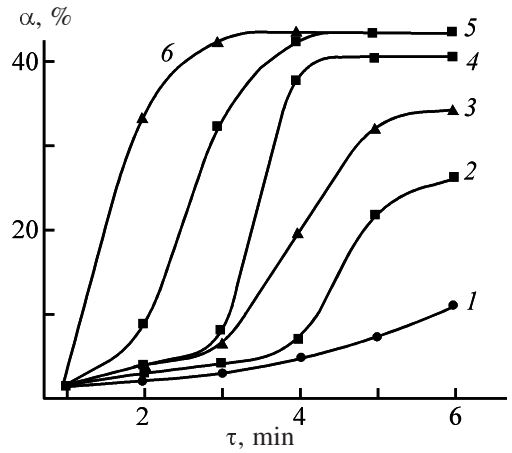

Fig. 2. Time dependence of the degree of PVC chlorine binding α. Heating with MgO (*M* = 3). Temperature, °C: (*1*) 274, (*2*) 290, (*3*) 300, (*4*) 310, (*5*) 320, and (*6*) 350.

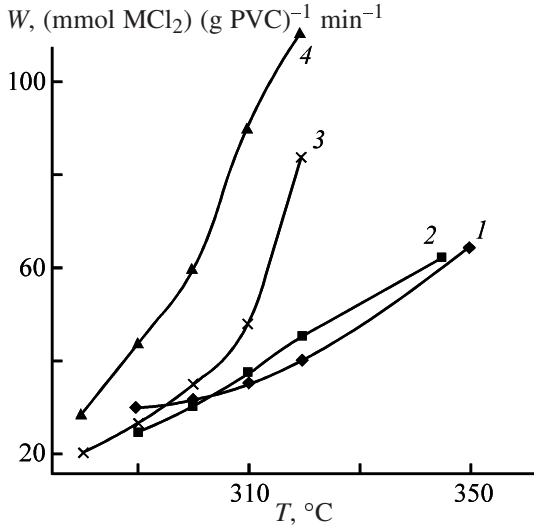

Fig. 3. Temperature dependence of the specific rate of calcium and magnesium chloride formation *W* in mixtures: (*1*) PVC : MgO = 1 : 3, (*2*) PVC : MgO = 1 : 2, (*3*) PVC : CaO = 1 : 2, and (*4*) PVC : CaO = 1 : 3.

The kinetics of formation of metal chlorides was studied within the range 270–350°C at metal oxide/polymer weight ratio *M* 2 and 3. The dependence of the degree of the polymer chlorine binding on time has double-bend shape (Fig. 2), demonstrating acceleration of formation of metal chlorides in the initial period, caused by autoacceleration of PVC dehydrochlorination [7].

The calculated values of the degree of PVC chlorine binding in the reactions with calcium and magnesium oxides are listed in Table 1. They show that, with increasing oxide/polymer weight ratio, the degree of PVC chlorine binding increases and that the degree of PVC chlorine binding in the mixture with CaO under any conditions is higher than that in the PVC–MgO mixture. The specific rates of formation of metal chlorides per gram of PVC (initial amount in the mixture) were calculated for the period up to reaction deceleration. The dependence of the specific rate of metal chloride formation on the temperature at 20% binding of PVC chlorine is shown in Fig. 3. With increasing temperature, the rate of metal chloride formation increases, and the specific rate of calcium chloride formation is in all cases higher than that of magnesium chloride formation.

From data obtained, we calculated the effective activation energy of the formation of calcium and magnesium chlorides at the degree of PVC chlorine binding α equal to 15 and 20% (Table 1). As can be seen, the activation energy is independent of the metal oxide/polymer weight ratio. At the same time, the activation energy increases in going from magnesium to calcium.

In experiments on optimization of conditions of

Table 2. Chlorine amount in the solid (metal chlorides) and gas (HCl) phase in reaction of PVC reaction with CaO and MgO. Temperature 290°C, M = 3

Reaction mixture	Phase	Chlorine amount, %
PVC + CaO	Solid	94.6
		99.3*
	Gas	5.3
		1.5*
PVC + MgO	Solid	72.1
		96.8*
	Gas	18.2
		3.1*

* PVC–oxide mixture, 0.2 g + oxide, 0.1 g.

PVC chlorine binding into the corresponding metal chlorides, to increase the time of contact of HCl formed with the solid phase, a sample of the reaction mixture was introduced into a narrow reactor (inner diameter 4 mm) heated to a required temperature, and then the air flow was passed. The results of calculation of α are listed in Table 2. As can be seen, α is fairly high, 95% for calcium oxide, while for magnesium oxide this value is 72% under the similar conditions.

To additionally increase α, a bed of pure metal oxide of equal weight was charged over the reaction mixture bed. As follows from Table 2, in this case 99% of PVC chlorine can be bound with calcium oxide and 97%, with magnesium oxide.

CONCLUSIONS

(1) The reactivity of calcium oxide with respect to PVC chlorine binding under conditions of PVC dehydrochlorination is higher than that of magnesium oxide.

(2) At 290–300°C, the metal oxide/polymer weight ratio equal to 3, and time of the contact of HCl formed with the solid phase of 6 min, PVC chlorine reacted with CaO or MgO to form the corresponding chlorides to 97–99%.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Lyophilizing Power of the Polymer Chain on the Relationships in Formation of Polyelectrolyte–Surfactant Complexes

Abstract—Viscometry and turbidimetry were applied to examine the relationships in formation of complexes by poly-1,2-dimethyl-5-vinylpyridinium methyl sulfate, poly-*N,N,N,N*-trimethyl(methacryloyloxyethyl)ammonium methyl sulfate, and poly[*N*-benzyl-*N,N*-dimethyl-*N*-(methacryloyloxyethyl)]ammonium chloride with sodium dodecyl sulfate.

DOI: 10.1134/S1070427208010254

Complexes formed by polyelectrolytes (PEs) with oppositely charged surfactants, polymer–colloid complexes (PCs), belong to a special class of amphiphilic compounds with variable lyophilic–lyophobic balance controllable by varying the composition of the complex [1]. Numerous studies of PCs showed that complexing is driven by electrostatic interactions of oppositely charged ions of PEs and surfactants, as well as by hydrophobic interactions of the alkyl moieties of surfactants, responsible for micellization in the body of the macromolecule [2]. The critical association concentration (CAC) of surfactants in the presence of PE is by 1.5–2 orders of magnitude lower than the critical micellization concentration (CMC) of surfactants in water [1]. Depending on the composition and reaction conditions, PCs can be soluble or insoluble in water and water–salt media. The solubility of complex species is provided by free PE units which are not bound to the surfactant ions [1]. When the content of surfactant in the complex species exceeds some critical level, so-called limiting composition of soluble complexes, the lyophilizing power of the free segments of the polymer chains proves to be insufficient, and phase segregation occurs in the system [3]. Thus, the range of existence of soluble complexes is determined by the hydrophilic–hydrophobic balance of the PC species, which, in turn, depends both on the hydrophobicity of the components of the complex (e.g., length of the aliphatic moiety of the surfactant) and on the lyophilizing power of the macromolecule. The lyophilizing power of the PE is governed by the effective charge of the polymer chain, as well as by the polar and nonpolar groups in the composition of the macromolecule, which can cause the lyophilizing power to increase or decrease.

The growth of interest in PCs is dictated by the fact that they contain surfactant micelles linked to the polymer coil by salt bonds and exhibiting a significant solubilizing power with respect to different classes of organic compounds [4]. This makes them suitable for solving various environmental, medicinal, and engineering problems. In particular, high-performance flocculants for wastewater treatment can be synthesized from PCs.

We examined here complexation of polyelectrolytes with sodium dodecyl sulfate (DDS) as influenced by their lyophilizing power.

EXPERIMENTAL

Polymerization of monomers, 1,2-dimethyl-5-vinylpyridinium methyl sulfate (M-1), *N,N,N,N*-trimethyl(methacryloyloxyethyl)ammonium methyl sulfate (M-2), and [*N*-benzyl-*N,N*-dimethyl-*N*-(methacryloyloxyethyl)]ammonium chloride (M-3), was carried out in aqueous solutions at 20 ± 0.5°C by the ampule method. To this end, the initiator in the form of an aqueous solution with the concentration of 0.001–0.1 M was introduced into the monomer solution of

* $[M_0]$ is the initial concentration of the monomer, and $[\eta]$, intrinsic viscosity of the PE solution in 0.05 M NaCl at 30°C.

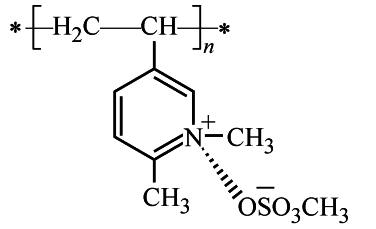
a definite concentration. The initial monomers were purified by recrystallization from organic solvents. Polymerization was run to 96–98% conversion, whereupon the polymerization product was dissolved in methanol and precipitated with diethyl ether. The polymers were additionally purified by reprecipitation from methanol solutions with diethyl ether and vacuum-dried (p_{res} = 1.5–2.0 mm Hg, T = 20 ± 0.5°C) to constant weight. The polyelectrolytes with different molecular weights (MWs) were synthesized using *tert*-butylperoxy-2-propanol (TBPP) as initiator and ethanol or hydroquinone as the chain-transfer agent [5, 6]. Table 1 presents the synthesis conditions for the polyelectrolytes.

The surfactant, sodium dodecyl sulfate available from Merck, was used without additional purification.

The PC solutions were prepared by mixing the initial solutions of the PE and DDS in 0.05 M aqueous solution of a low-molecular-weight electrolyte (sodium chloride, sodium bromide, sodium fluoride, or potassium iodide). To this end, a DDS solution of the known concentration was added dropwise to a PE solution under vigorous stirring. The properties of the solutions were examined no earlier that 1 day after the preparation. The composition of the complexes was presumed to be identical to that of the reaction mixture Z, expressed through the ratio of the molar concentrations of DDS and PE in the system.

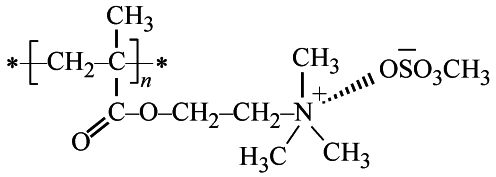
The molecular-weight characteristics of the PE were determined by static laser light scattering. The scattered light intensity was measured on a PhotoCor (PhotoCor, USA) wide-angle laser light scattering photometer using a PhotoCor 280-channel logic correlometer. The increment of the refractive index of the solutions dn/dc was determined on a Chromatix KMX-16 (Milton Roy) differential refractometer with a He–Ne laser (2 mW power, wavelength 630 nm) as the light source. The reference solution in measurements of dn/dc was the solvent brought into the dialysis balance with the solution. The weight-average molecular weight M_w was determined by the Zimm's double extrapolation method accurately to within 15%. Before measurements, the solutions were thoroughly freed from dust by filtering through Millipore membrane filters with the pore size of 0.45 μm.

The intrinsic viscosity $[\eta]$, dl g^{-1}, of the solutions of the polymers was measured in an Ubbelohde viscometer at 30°C in 0.05 M aqueous solution of a low-molecular-weight salt (sodium chloride, sodium bromide, sodium fluoride, or potassium iodide). The intrinsic viscosity was determined by double extrapolation of the specific viscosity η_{sp} and the logarithm of the ratio of the relative viscosity η_{rel} to the polymer concentration c, g dl^{-1}, to the zero concentration of the polymer. The η_{sp} parameter of the polymer solutions in the presence of different amounts of DDS was determined as the ratio of the times of flow of the corresponding solution of the polymer τ and of the solvent τ_0.



To determine the limiting compositions of the complexes, dilute solutions of the PEs were titrated with a DDS solution of the known concentration, which was added dropwise under vigorous stirring. After each portion of DDS was added, the optical density of the solution A was measured at the wavelength of 490 nm on a KFK-3 photoelectrocolorimeter. The turbidity of the solutions D was calculated by the formula $D = 2.3A/l$, where l = 3 cm is the cell length. We presumed that the limiting composition of the reaction mixture at which the system remains transparent (the

Table 2. Molecular-weight characteristics of the initial polyelectrolytes



Polyelectrolyte	$M \times 10^{-6}$	$A_2 \times 10^4$, cm^3 mol g^{-2}	R_g, nm	α	*a*

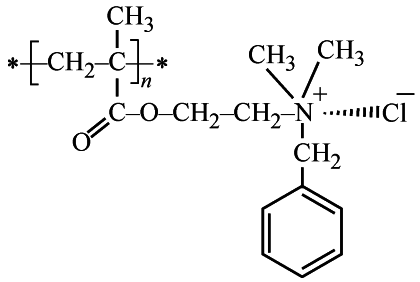
turbidity is close to zero) corresponds to the limiting composition of water-soluble complexes, i.e., to the maximal content of DDS in the system at which the complexes remain soluble in aqueous media.



The limiting composition of soluble PCs corresponds to the maximal content of the ions of surfactants in the bulk of the macromolecule and is determined by the hydrophilic–lipophilic balance of the complex species. When the composition of the complex exceeds the limiting level, phase segregation occurs in the system. We examined here the complexes formed by a series of polymers with the same surfactant; hence, the hydrophilic–lipophilic balance of the complex species can be largely determined by the lyophilizing power of the polymer chain, which depends both on the hydrophobicity of the polymer backbone and the degree of binding of the counterions. To examine the structure and properties of the resulting PCs as influenced by the chemical structure of the PEs, we synthesized a series of polymers with essentially different structures of the lateral substituents, namely: poly-1,2-dimethyl-5-vinylpyridinium methyl sulfate (P-1), poly-*N,N,N,N*-trimethyl(methacryloyloxyethyl)ammonium methyl sulfate (P-2), and poly[*N*-benzyl-*N,N*-dimethyl-*N*-(methacryloyloxyethyl)]ammonium chloride (P-3):

P-1

P-2

P-3

This choice was dictated by the excellent flocculation properties exhibited by these polymers with respect to various model and real disperse systems [7, 8]; some of them are produced commercially (P-1 under the trade name KF-91, and P-2–acrylamide copolymer, KF-99).

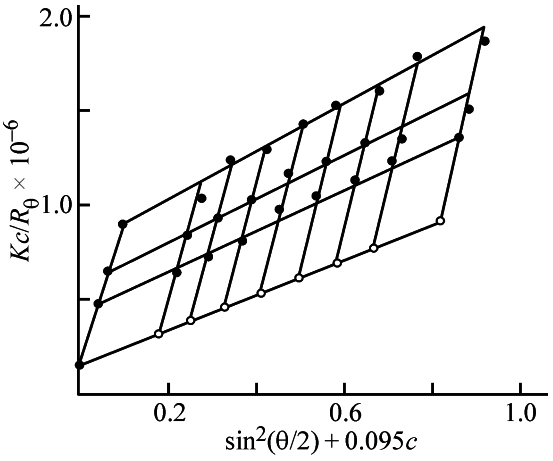


Fig. 1. Zimm's diagram for P-2-2. [NaCl] = 0.05 M, T = 20°C.

The characteristics of the PEs synthesized were derived from the static light scattering data. Figure 1 presents as an example the Zimm's diagram for P-2-2, and Table 2, the basic molecular-weight characteristics of the PEs.

It is seen from Table 2 that the PEs have high molecular weights M_W. Positive values of the second virial coefficients A_2 suggest that 0.05 M solution of sodium chloride is a thermodynamically good solvent for all the PEs. Also, they suggest that the PE macromolecules occur in solution as swollen coils. This is confirmed by the rms radii of gyration R_g of the macromolecules of the polymers examined [9]. Not-

* k_H is the Huggins constant, T = 30°C.

ably, the A_2 coefficient for P-3 is much smaller than those for P-1-2 and P-2-2. The unit of this polyelectrolyte contains a bulky hydrophobic benzyl substituent; hence, the hydrophobic interactions for P-3 are presumably stronger than those for P-1-2 and P-2-2.

Based on the known relationship between A_2 and the intrinsic viscosity of the solution, we can estimate the coefficient of polyelectrolyte swelling of the coils α. It can be used, in turn, for determining the exponent a at the molecular weight in the Mark–Kuhn–Houwink equation from the relationship [10]

$$\ln[1 + \pi^{1/2}(\alpha^2 - 1)/2] = \frac{27\Phi}{(32)^{1/2}\pi N_a}\frac{M_w A^2}{[\eta]},$$

$$a = \frac{4\alpha^2 - 3}{5\alpha^2 - 3},$$

where $\Phi = 2.1 \times 10^{21}$ mol^{-1}.

The calculated parameters α and a are also presented in Table 2. It is seen that, for P-3, the polyelectrolyte swelling coefficient is also much smaller than those for P-1-2 and P-2-2.

The conformation assumed by the macromolecular coil in a dilute solution is determined, on the one hand, by the electrostatic interactions associated with the occurrence in the polymer chain of charged units, and, on the other, with intramolecular interactions, characteristic for PEs whose macromolecules comprise hydrophobic groups. An increase in the concentration of a low-molecular-weight electrolyte will result in shielding of the electrostatic interactions. Hence, the size of the macromolecules will be determined to a greater extent by hydrophobic interactions. The intensity of the intramolecular interactions in the macromolecule can be estimated by examining how the intrinsic viscosity and the Huggins constant vary with increasing concentration of the low-molecular-weight electrolyte (Table 3). It is seen that, with increasing ionic strength, the intrinsic viscosity of the PEs examined naturally tends to decrease, and the Huggins constant, to increase.

Another way to characterize the lyophilicity of the macromolecular chain is via changing the nature of the low-molecular-weight electrolyte (Table 4). By varying the nature of the low-molecular-weight anion without changing essentially the nature of the cation, it is possible to elucidate the influence exerted by the degree of binding of the low-molecular-weight counterions with the macromolecular chain.

As known, the strength of binding of halide ions with the polycation containing a quaternized nitrogen atom decreases as $I^- > Br^- > Cl^- > F^-$ [11]. Table 4 shows that the increase in the degree of binding of counterions with the polymer chain tends to decrease the lyophilizing power of PE, thereby decreasing the intrinsic viscosity of their solutions.

Thus, combined analysis of the viscometric and

light-scattering data suggests that the contribution from the hydrophobic interactions to the size of the macromolecules varies for the PEs examined as P-2-2 ≪ P-1-2 ≈ P-3. It can be expected that different lyophilizing powers of the macromolecules will be manifested in the features of in their interaction with the surfactant ions.

Examination of the complexation of P-1-2 and P-2-2 with DDS revealed common relationships for these PCs. For example, Fig. 2 shows that, starting from some critical DDS concentration of about 10^{-5}–10^{-4} M, the viscosity of the solutions of the polymers sharply decreases due to binding of the DDS ions by the PE macromolecules. The CAC of sodium dodecyl sulfate in the presence of the polymers is by nearly two orders of magnitude smaller than the CMC of sodium dodecyl sulfate in water (8×10^{-3} M), which reasonably agrees with the published data [1].

It should be noted that the DDC concentration range within which the viscosity is reduced because of complexation is enclosed in Fig. 2 by two points, of which one corresponds to CAC, and the other, to the limiting composition of the soluble complex. A decrease in viscosity of the PE solutions with further increase in Z is associated with a decrease in the polymer concentration in the system.

Indeed (Fig. 3), up to a certain composition of the reaction mixture, the turbidity of the system remains virtually unchanged. An increase in Z beyond this value sharply increases the turbidity of the system owing to formation of insoluble complexes. It should be noted that the P-2-2 solution remains transparent up to Z = 0.5, while P-1-2 and P-3 are characterized by an appreciable change in the turbidity starting from Z = 0.1–0.15.

The reason for this substantial difference in the limiting compositions of the complex can be found in the molecular weight of the polymer. However, examination of the limiting composition as influenced by the molecular weight of the PE showed that the limiting composition of soluble complexes is virtually unaffected by the degree of polymerization of the PE over a wide range of molecular weights (Table 5).

The limiting composition of the complex is also determined by the effective charge of the macromolecule. In real solutions, a significant proportion of the counterions in PE is condensed on a macromolecule, and the remaining ionized units determine its effective charge and, hence, the lyophilizing power. Table 6 shows that, in the series of salts NaF → NaCl → NaBr → KI, the limiting composition of the water-

Table 6. Limiting compositions of the PCs in water–salt media of different nature

P-1-2	0.30	0.15	0.15	N/f*
P-3	0.25	0.10	0.10	N/f

* (N/f) Water-soluble complexes are not formed.

soluble complexes tends to decrease with decreasing degree of binding of the anions in the series I > Cl > Br > F. The degree of binding of the iodide ions with P-3 and P-1-2 proves to be so high that, in the presence of NaI, soluble complexes are not formed. This is consistent with the measured viscosities of the solutions of the polyelectrolytes in solutions of these salts. The fact that the limiting composition remains unaffected by the change from NaCl to NaBr for all the PEs examined is explained by comparable degrees of binding for the chloride and bromide anions.

Evidently, a decrease in the lyophilizing power of the polymer chain causes the range of existence of water-soluble complexes to narrow, and in the case of hydrophobic PEs water-soluble complexes are not formed.

CONCLUSION

The lyophilizing power of a polyelectrolyte affects substantially the relationships in formation of water-soluble complexes. In the presence of hydrophobic moieties in the composition of the polyelectrolyte macromolecules, the limiting composition of the complexes decreases owing to a decrease in the lyophilizing power of the macromolecular chain.

Abstract—Formation of bifunctional xerogels containing $-NH_2$, –SH, $-P(O)(OEt)_2$, and $-NHP(O,S)(OEt)_2$ complexing groups in the surface layer was studied using sol–gel method (fluoride ion catalyst, ethanol solvent) and three-component systems.

DOI: 10.1134/S1070427208010266

The possibility of using multicomponent systems is a principal advantage of sol–gel synthesis of functionalized polysiloxane materials. This makes it possible to vary the nature and ratio of both cross-linking [$E(OR)_n$, E = Si, Al, Ti, etc.] and functionalizing agents [in the simplest case, trifunctional silanes $(RO)_3SiR'$]. In the latter case, polysiloxane xerogels with a complex surface layer containing various functional groups R' can be prepared in one step. The possibility of changing conditions of hydrolytic polycondensation allows, to a large extent, direct control of the properties of the final xerogels, primarily their structural-sorption characteristics. Thus, using sol–gel method, one can control the design of both the resulting materials and their surface.

However, whereas the use of one- and two-component systems for preparing monofunctionalized xerogels with complexing groups has been studied rather extensively [1–3], there are only a few papers on preparing bifunctional polysiloxane xerogels using three-component systems. In these papers [4–7] the procedures of sol–gel synthesis of such materials are developed and their structures are studied by spectral methods. It should be noted that the design of polyfunctional surface layer suggests a finer effect on the xerogel properties (e.g., sorption) by changing both the nature and ratio of the functional groups in this layer [7–9]. At the same time, apparently, participation of alkoxysilanes with ligand groups of various chemical and steric structures in the hydrolytic polycondensation will strongly affect both the structure of the resulting xerogels and their surface. Therefore, it becomes necessary to determine the decisive factors affecting the composition, structure, and properties of xerogels with a bifunctional surface layer. In this study we attempted to analyze some of these factors using as example xerogels containing both (thio)phosphoryl and amine (or thiol) functional groups in the surface layer.

EXPERIMENTAL

In our study we used tetraethoxysilane $Si(OC_2H_5)_4$ (TEOS, 99%, Aldrich), diethoxyphosphorylethyltriethoxysinlane $(C_2H_5O)_3Si(CH_2)_2P(O)(OC_2H_5)_2$ (DPTS, 95%, Gelest), 3-aminopropyltriethoxysilane $(C_2H_5O)_3Si(CH_2)_3NH_2$ (APTES, 98%, Aldrich), 3-mercaptopropyltrimethoxysilane $(CH_3O)_3Si(CH_2)_3 \cdot SH$ (MPTMS, 95%, Aldrich), ammonium fluoride NH_4F (Fluka, ≥98%), and absolute ethanol. Diethyl 3-(triethoxysilyl)propylphosphoramidate $(C_2H_5O)_3 \cdot Si(CH_2)_3NHP(O)(OC_2H_5)_2$ (DEPPA) and *O,O'*-diethyl 3-(triethoxysilyl)propylphosphoramidothioate $(C_2H_5O)_3Si(CH_2)_3NHP(S)(OC_2H_5)_2$ (DEPPAT) were prepared by the procedure given elsewhere [10]. The procedures of the xerogel synthesis were as follows.

DO-1. DPTS (0.025 mol), APTES (0.025 mol), and TEOS (0.1 mol) were dissolved in 12.5, 12.5, and 10 ml of ethanol, respectively. Then, a solution of ammonium fluoride (0.0463 g, 0.00125 mol) in water (4.28 ml, 0.2375 mol) was added dropwise with stirring to a DPTS solution cooled on an ice bath. After stirring for 5 min, solutions of APTES and TEOS were added dropwise. After formation of a clear solu-

tion, the stirring was terminated. A gel formed in 1 min, which was confirmed by opalescence. After aging for 24 h, the gel was dispersed and dried in a vacuum at room temperature for 1 h, and then at 50 and 105°C for 1 and 4 h, respectively. Then, the resulting xerogel was ground in an agate mortar, washed with water (800 ml), and dried by the above procedure. A white compound was obtained, yield 13.67 g.

DO-2. Compound was prepared by the above procedure, using MPTMS (0.005 mol) instead of APTES (0.02 mol of TEOS, 0.005 mol of DPTS). The reaction was performed using a solution of ammonium fluoride (0.0093 g, 0.00025 mol) in water (0.86 ml, 0.0525 mol). The gel was formed in 5 min; the yield of the xerogel was 2.73 g.

DO-3. The xerogel was prepared by the procedure given for DO-1 using TEOS (0.03 mol), DPTS (0.005 mol), and APTES (0.005 mol) dissolved in ethanol (2.5 ml in each solution) and a solution of ammonium fluoride (0.0148 g, 0.0004 mol) in water (1.35 ml, 0.075 mol). The gel was formed in 1 min; the yield of the xerogel was 2.87 g.

DO-4. The xerogel was prepared by the procedure given for DO-3 using MPTMS instead of APTES. The gel was formed in 5 min; the yield of the xerogel was 3.28 g.

DO-5. The xerogel was prepared by the procedure given for DO-1 using DEPPA (0.01 mol) instead of DPTS, TEOS (0.04 mol), and APTES (0.01 mol) dissolved in ethanol (5 ml in each solution) and a solution of ammonium fluoride (0.0222 g, 0.0006 mol) in water (1.98 ml, 0.11 mol). The gel was formed in 1 min; the yield of the xerogel was 5.06 g.

DO-6. The xerogel was prepared by the procedure given for DO-5 using MPTMS instead of APTES. The gel was formed in 1 h; the yield of the xerogel was 5.66 g.

DO-7. The xerogel was prepared by the procedure given for DO-5 using DEPPAT instead of DEPPA. The gel was formed in 1 min; the yield of the xerogel was 5.36 g.

DO-8. The xerogel was prepared by the procedure given for DO-6 using DEPPAT instead of DEPPA. The gel was formed in 20 min; the yield of the xerogel was 6.12 g.

DO-9. The xerogel was prepared by the procedure given for DO-3 using DEPPA (0.01 mol) instead of DPTS, APTES (0.01 mol), and TEOS (0.06 mol) dissolved in ethanol (12.5, 12.5, and 10 ml in each solution, respectively) and a solution of ammonium fluoride (0.0296 g, 0.0008 mol) in water (2.71 ml, 0.15 mol). The gel was formed in 5 min; the yield of the xerogel was 6.84 g.

DO-10. The xerogel was prepared by the procedure given for DO-9 using MPTMS instead of APTES. The gel was formed in 10 min; the yield of the xerogel was 7.18 g.

DO-11. The xerogel was prepared by the procedure given for DO-9 using DEPPAT instead of DEPPA. The fine gel was formed immediately on mixing; the yield of the xerogel was 5.97 g.

DO-12. The xerogel was prepared by the procedure given for DO-11 using MPTMS instead of APTES. The gel was formed in 10 min; the yield of the xerogel was 7.36 g.

DO-13. The xerogel was prepared by the procedure given for DO-12 using 0.08 mol of TEOS and 0.001 mol of ammonium fluoride. The gel was formed in 5 min; the yield of the xerogel was 6.12 g.

The composition of the resulting xerogels was determined in the analytical laboratory (Institute of Organic Chemistry, National Academy of Sciences of Ukraine). The particle shape and size were determined using a Tesla BS301 scanning electron microscope. The thermal analysis was performed on an MOM Q-15000 derivatograph (Hungary) in the 20–1000°C range at a heating rate of 10 deg min^{-1}. The sensitivity of the thermal balance was ± 0.1 mg, and the sensitivities of DTA, DTG, and TG were 1/5, 1/5, and 100, respectively. The IR spectra were recorded on a Nicolet NEXUS FTIR spectrophotometer in the 400–4000 cm^{-1} range in the reflection mode with 4 cm^{-1} resolution. The IR spectra of the initial alkoxysilanes were recorded from thin film between RS-5 plates. The solid-state NMR spectra were recorded on a Bruker Avance spectrometer (300 MHz); the ^{13}C and ^{29}Si CP/MAS NMR (cross-polarization under fast magic angle spinning) spectra were recorded at 121.6 and 59.7 MHz, respectively. The rate of spinning of the ampule with the sample was 7–8 kHz, and the scan number was 1024–4096. Tetramethylsilane and 85% orthophosphoric acid were used as references.

The structural and sorption characteristics of the resulting xerogels were calculated using the isotherms of low-temperature adsorption of nitrogen (Kelvin-1042). The samples were preliminarily degassed in a helium flow at 100°C for 2 h. The specific surface area of the sorbents was studied by the BET procedure [11], and the size distribution were determined by

* Amount of functional groups: $c^1_{f.gr}$, calculated from the data of chemical analysis; $c^2_{f.gr}$, calculated from the reactant ratio (a, b, and c refer to PO(S), NH_2, and SH groups, respectively).

** Calculated from the Gurvich equation ($d_{eff} = 4V_{sorb}/S_{sp}$) [13].

BJH method [12] and from the Gurvich equation ($d_{eff} = 4V_{sorb}/S_{sp}$) [13].

Our preliminarily experiments showed that hydrolytic polycondensation proceeds rather rapidly in most of the three-component systems studied. Therefore, the reaction was performed at decreased temperature using ethanol. Without ethanol solvent, heterogeneous gelation was often observed in these systems. As catalyst we used fluoride ion [6, 10] (F/Si ratio 1/100), which hinders breakdown of the sulfur-containing ligand groups:

$$Si(OEt)_4 + (EtO)_3Si(CH_2)_2L + (MO)_3Si(CH_2)_3L' \xrightarrow[-EtOH,\ -MOH]{+H_2O/F^-} [(SiO_2)_x(O_{3/2}Si(CH_2)_2L/O_{3/2}Si(CH_2)_3L')],$$

where L = $-3P(O)(OEt)_2$ and $-CH_2NHP(O,S)(OEt)_2$; and L' = $-NH_2$ and $-SH$.

After vacuum drying we obtained white powder compounds; some sulfur-containing compounds were yellowish. As a rule, all the xerogels are easily suspended in air.

The content of the functional groups in the resulting xerogels, determined from the data of chemical analysis, is given in the table. As can be seen, the contents of the phosphorus-containing, amino, and mercapto groups vary within 1.0–1.9, 1.3–1.7, and 1.0–1.5 mmol g^{-1}, respectively, which is determined by the ratio of TEOS and trifunctional silane in the initial mixture. With increasing relative content of TEOS, it naturally decreases. It should also be noted that the molar ratio of trifunctional silanes in the initial solution (1 : 1) is, as a rule, preserved in the final xerogel. The C/P ratio in the final samples in most cases is often slightly higher than that calculated from the ratio of the initial componenta (see table). This is due to the presence of residual alkoxysilyl groups (no chemical analysis was performed for virtually nonporous materials). Analysis of the Si/P ratio and comparison of the content of the introduced groups with their content in xerogels (chemical analysis) suggests that only an insignificant amount of oligomeric siloxanes is removed by washing.

The thermogravimetric curves for samples DO-3, DO-4, DO9, and DO-11 are shown in Fig. 1. As can

be seen, the DTA curves for all the samples exhibit small endothermic effect at 80–130°C, which can be due to the loss of water (and residual solvent). The exothermic effects observed at higher temperatures (270–600°C) suggest degradation of the surface layer. The weight changes at 220–400°C are primarily due to the removal of ethoxy groups and oxidation of the sulfur-containing fragments. Two exothermic effects with smaller weight changes can be due to oxidation of NH and CH groups. It is obvious that samples DO-3, DO-4, and DO-9 are more thermally stable than DO-11, because intense weight loss for these samples is observed only above 200°C, whereas in the case of sample DO-11 breakdown of the surface layer starts already at 160°C. This is probably due to the different composition of substituents at the phosphorus atom in the functional groups. In the 440–460°C range, for all the samples an exothermic effect is observed, which is not accompanied by a significant weight loss (Fig. 1). This effect is probably due to exothermic intrastructural processes. Analysis of the TG curves shows that, for all the samples, the weight loss in the range 160–700°C is 22–28%, which agrees with the data of chemical analysis assuming that nonvolatile phosphates are formed upon burn-out of the organic fraction of the gel.

The composition and structure of the surface layer in the samples were first studied by IR spectroscopy. The IR spectra of all the samples (Fig. 2) contain weak bands at 1350–1490 cm^{-1} and three medium-intensity bands at 2800–3000 cm^{-1}. The latter bands are typical of the stretching vibrations $\nu_{s,as}(CH)$, whereas the absorption bands at 1364–1372, 1392, 1442–1446, and 1478 cm^{-1} belong, respectively, to the vibrations $\omega(CH_2)$, $\delta_s(CH_3)$, $\delta_{as}(CH_3)$, and $\delta(CH_2)$ of the ethoxy groups bound to the phosphorus atom [14]. The absorptions bands of the fragments $\equiv Si(CH_2)_2-$ [and/or $\equiv Si(CH_2)_3-$] occurring in the same region are weak, except the absorption band of $\delta[(Si)CH_2]$ [14] at 1409–1417 cm^{-1} (Fig. 2). The absorption band of $\nu(P=O)$, which in the IR spectra of individual trifunctional silanes is observed at 1240 (DPTS) [15] and 1233 cm^{-1} (DEPPA) [10], in the corresponding xerogels shifts toward lower frequencies and is observed as either a pronounced shoulder or as a separate strong band at ~1200 cm^{-1} (Fig. 2). This fact suggests that the phosphoryl group participates in formation of a hydrogen bond.

The IR spectra of the samples prepared using DEPPAT contain a weak band at 556–642 cm^{-1}, belonging to the $\nu(P=S)$ vibration (Fig. 2). The IR spectra of the xerogels prepared using such trifunctional silanes as DEPPA and DEPPAT contain two strong bands at 790–800 and 960–965 cm^{-1} belonging probably to $\nu_s(PN)$ and $\nu_{as}(PN)$, respectively [10]. The IR spectra of samples DO-2, DO-4, DO-6, DO-8, DO-10, DO-12, and DO-13 have a weak absorption band at 2565 cm^{-1} belonging to $\nu(SH)$ (Fig. 2).

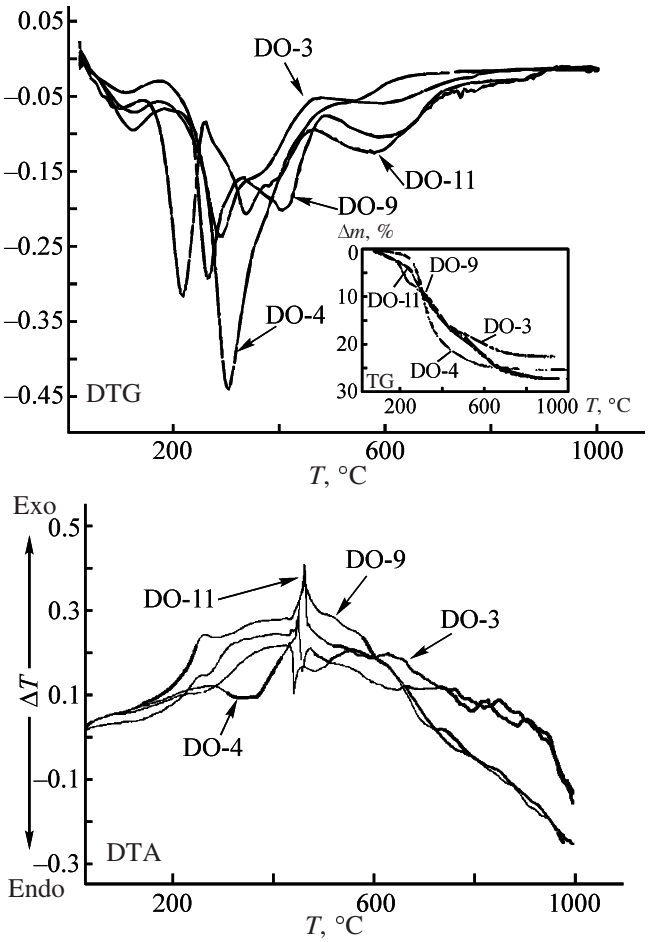

Fig. 1. Thermogravimetric curves of xerogels. (Δm) Weight loss and (T) temperature.

It should be noted that the IR spectra of all the samples exhibit the strongest absorption band at 1045–1065 cm^{-1}, which suggests formation of a three-dimensional system of the siloxane bonds [16]. The presence of water in the samples is confirmed by IR absorption bands at 1630 and 3100–3400 cm^{-1} [14]. In the 3100–3400 cm^{-1} range, the absorption bands $\nu(OH)$ overlap with the absorption band $\nu(NH)$, which is fairly strong in the IR spectra of the initial amides (DEPPA and DEPPAT). As for APTES, the absorption bands $\nu_{s,as}(NH)$ occurring in the same region are weak and are not observed in the IR spectra of the resulting xerogels (Fig. 2). At the same time, the absorption band $\delta(NH_2)$ at 1540 cm^{-1} suggests the presence of amino groups participating in formation of

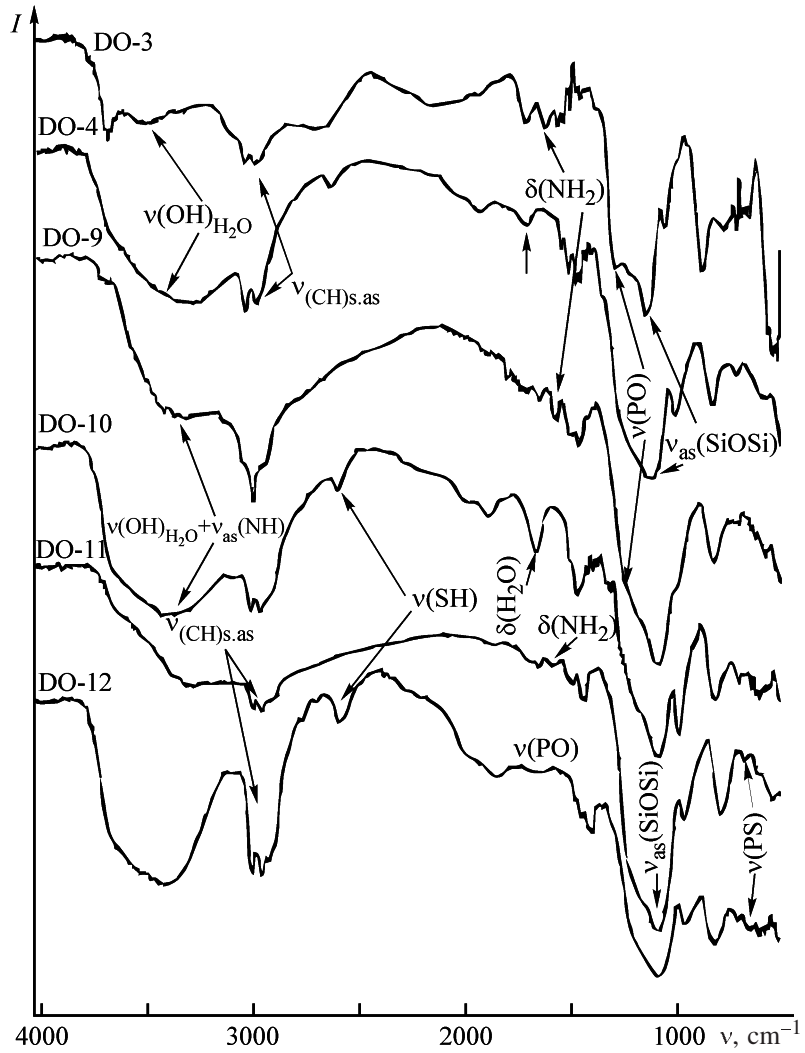

Fig. 2. IR spectra of xerogels prepared at the ratio TEOS : phosphorus-containing alkoxysilane : APTES (or MPTMS) = 6 : 1 : 1. (*I*) Intensity and (ν) wavenumber.

a hydrogen bond (in the IR spectra of neat APTES, this absorption band is observed at 1600 cm^{-1}). It should be noted that the IR spectra of the xerogels studied exhibit a broad shoulder at 3635–3660 cm^{-1}, which probably belongs to the stretching vibrations of the silanol groups. Thus, the IR data confirm the presence of the introduced functional groups, water, silanol groups, and polysiloxane bonds in the resulting xerogels.

The ^{13}C CP/MAS NMR spectra of xerogels DO-3 and DO-4 are shown in Fig. 3. Both spectra exhibit a signal at 5 ppm, which belongs to the carbon atom of the ethyl chain directly bound to the silicon atom ≡Si$\underline{C}H_2$–CH_2–P(O)= [17]. The signal of the second carbon atom in this chain, which is bound to the phosphorus atom and should be observed at 16 ppm, was not identified because it is obscured by the signal of the methyl carbon atom of the ethoxy group. The presence of the ethoxy groups in DO-3 and DO-4 is also confirmed by the signal at 62 ppm belonging to the methylene carbon atom of these groups (Fig. 3). The ^{13}C CP/MAS NMR spectra of sample DO-3 also exhibit three signals at 9.9, 19.8, and 42.6 ppm, which belong to the carbon atom of the propyl fragment (≡$SiCH_2$–, –C[CH_2]C–, and –CH_2NH_2, respectively [18]). The signal of the middle carbon atom of the propyl group at 20–23 ppm suggests that the amino group participates in formation of a strong hydrogen bond [19], which agrees with the conclusion based on the IR data. As for sample DO-4, only two signals of the propyl fragment were identified in its ^{13}C CP/MAS NMR spectrum (Fig. 3), which is typical for the 3-mercaptopropyl fragment [18] and is due to

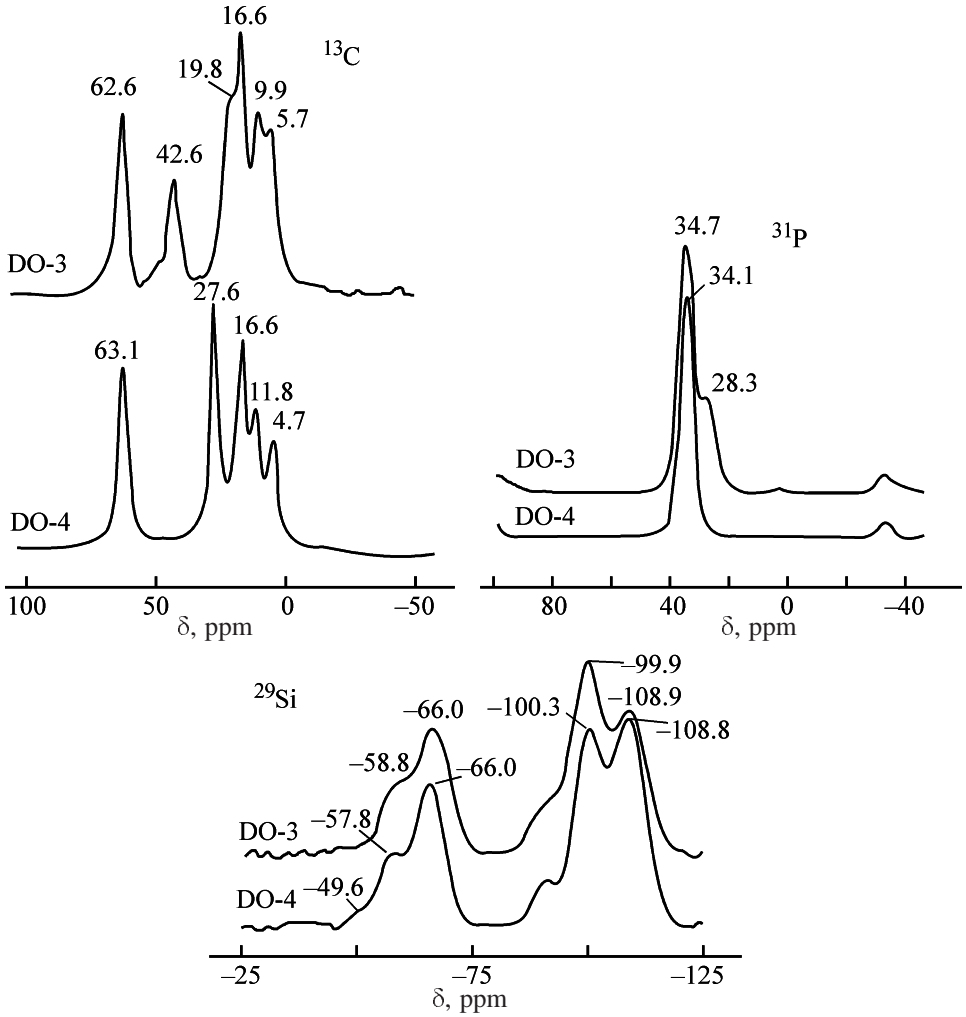

Fig. 3. CP/MAS NMR spectra of samples DO-3 and DO-4. (δ) Chemical shift.

the overlap of the signals of two carbon atoms: –C[$\underline{C}H_2$]C– and –$\underline{C}H_2NH_2$.

As seen from Fig. 3, the ^{13}C CP/MAS NMR spectra of the samples prepared under similar conditions differ from each other. For example, for sample DO-4 only one signal is identified at 34 ppm, whereas for sample DO-3, along with a strong signal at 35 ppm, an additional weaker signal at 28 ppm is observed. This second signal is probably due to interaction of the phosphorus-containing group with the xerogel surface with the formation of bridges like ≡Si$(CH_2)_2$P(O)–(OC_2H_5)OSi≡, which can appear in the course of prolonged drying of the samples under reduced pressure. In other words, one of the ethoxy groups bound with the phosphorus atom interacts with the silanol group to form ethanol, which is removed from the sample upon drying. A similar phenomenon was observed for xerogels with a monofunctional surface layer [20, 21].

The ^{29}C Si/MAS NMR spectra of samples DO-3 and DO-4 are similar, and their shapes are typical of polysiloxane xerogels (Fig. 3). In the range from –45 to –70 ppm, the spectrum of sample DO-3 exhibits only two signals, which are due to the presence of structural units T^2 and T^3 in the xerogel [18]. Thus, the xerogel surface layer contains no readily hydrolyzable structural units of T^1 type, i.e., there are no structural units which are linked to the polysiloxane skeleton by a single siloxane bond. However, the signal of this structural unit is observed in the ^{29}Si CP/MAS NMR spectrum of sample DO-4 (Fig. 3). Three other signals in the range from –90 to –110 ppm belong to the structural units of Q^n type (n = 2, 3, or 4) [22]. Thus, the data of solid-state NMR spectroscopy not only confirm but also supplement the conclusions based on the IR data.

The isotherms of the low-temperature adsorption–desorption of nitrogen on porous xerogels are shown

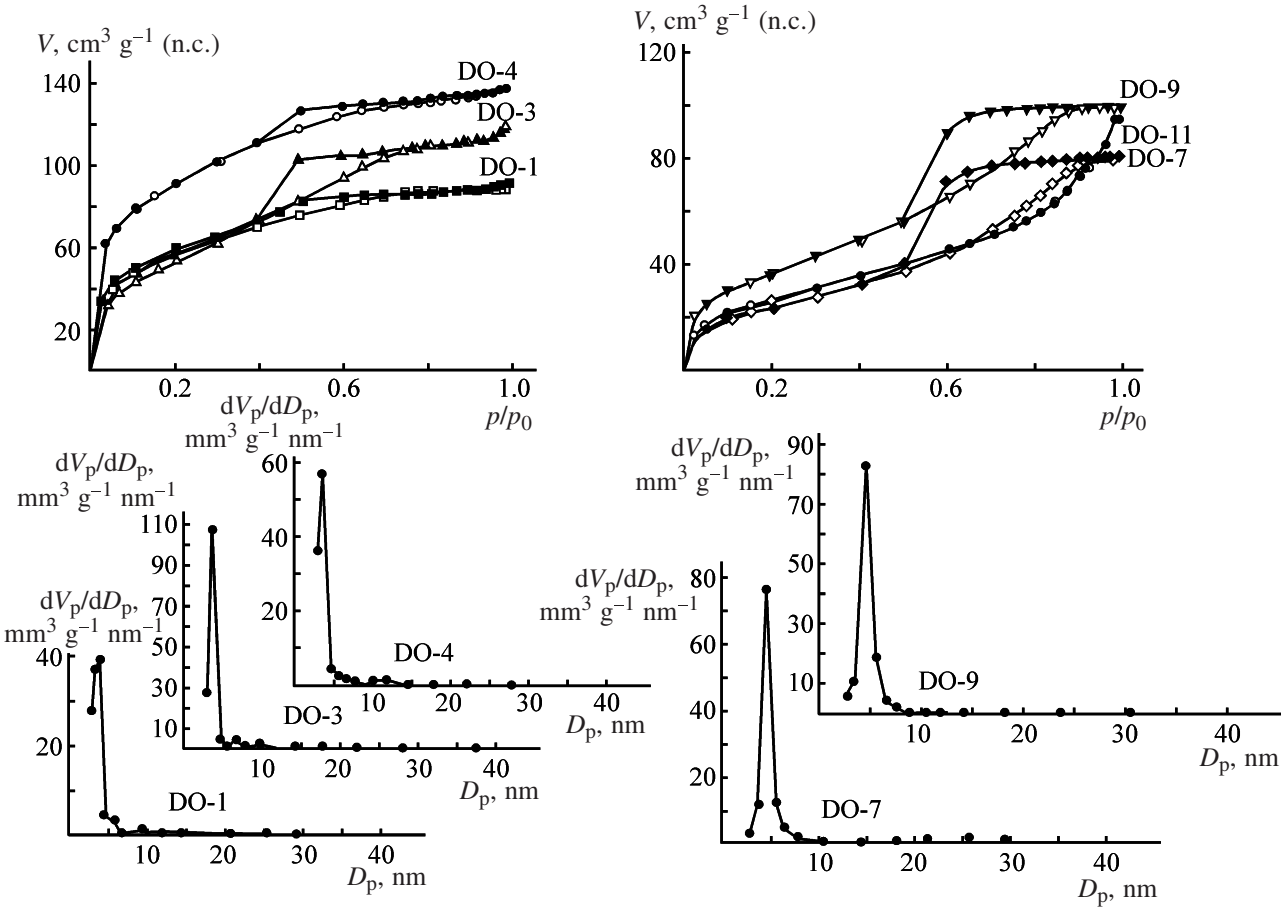

Fig. 4. Sorption–desorption isotherms of nitrogen and pore size D_p distribution dV_p/dD_p of the xerogels studied. (V) Volume of adsorbed nitrogen and (p/p_0) relative pressure.

in Fig. 4. The isotherms of samples DO-1, DO-3, DO-4, DO-7, and DO-9 belong to type IV in accordance with the IUPAC classification [23] and exhibit a hysteresis in the relative pressure range 0.4–0.8. They are also characterized by relatively narrow pore diameter distribution (Fig. 4). The pore sizes evaluated from these curves (see table) suggest that all the xerogels studied have the mesopore structure. The shape of the sorption isotherm of sample DO-11 differs from that of the above samples (Fig. 4); this also concerns the pore structure parameters (see table). This result can be attributed to the fact that in the course of synthesis of the given xerogel a precipitate rather than a gel is formed throughout the solution bulk.

The structural and adsorption parameters given in the table allow the following conclusions. In the systems prepared using DPTS at the molar ratio TEOS : trifunctional silanes = 2 : 1 (0.5 + 0.5), porous xerogel was formed only on addition of the amino group (sample DO-1). With increasing molar ratio to 3 : 1 (0.5 + 0.5), porous xerogels were formed on introduction of both 3-aminopropyl and 3-mercaptopropyl groups (samples DO-3 and DO-4). It should be noted that the xerogels prepared in [15] at the TEOS : DPTS ratios of 2 : 1 and 3 : 1 were nonporous. However, the conditions for preparing these samples and those described above were similar. The same phenomenon was observed for xerogels containing thiourea group $\equiv Si(CH_2)_3NHC(S)NHC_3H_7$-$n$ in the surface layer [6]. This fact confirms our previous conclusion on the noticeable effect of the size of the introduced functional groups on the structural and sorption parameters of the resulting xerogels. In general, the parameters of the pore structure of samples DO-5–DO-8 do not contradict this conclusion (see table). For example, replacement of DPTS by DEPPA and DEPPAT with bulkier functional groups (molar ratio of the reacting alkoxysilanes 2 : 1) provides formation of almost nonporous or weakly porous (in the case of DO-7) samples. With an increase in this ratio to 3 : 1, a xerogel with the developed surface containing additional amino group (sample DO-9) was prepared. With the amino group replaced by the

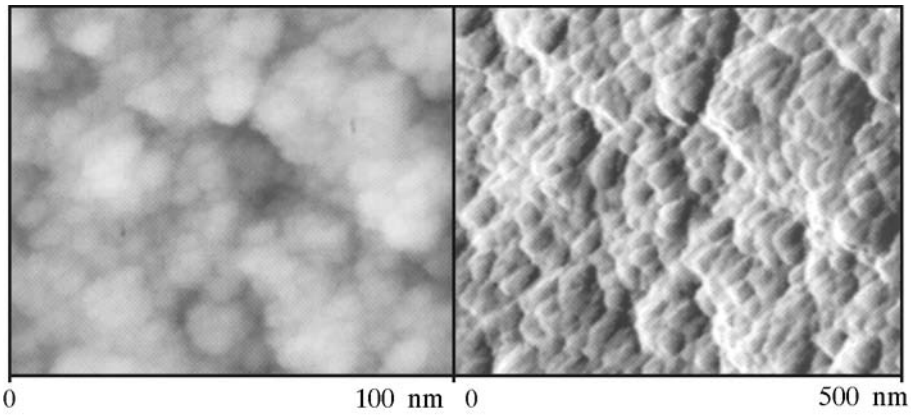

Fig. 5. Photomicrographs of xerogel DO-4, obtained by atomic force microscopy.

mercapto group, only nonporous samples were prepared at any molar ratio (2 : 1–4 : 1) of the reactants (see table). Probably, in this case the pore structure parameters are determined not only by an increase in the size of functional groups, but also by changes in the medium in which the hydrolytic polycondensation occurs (it changes from alkaline to nearly neutral).

The photomicrographs of xerogel DO-4 shown in Fig. 5 indicate that the sample surface is nonuniform. As can be seen, the xerogel particles are nearly spherical and they are probably aggregates of primary particles (globules). As we found, the sizes of these aggregates are similar and vary within 40–50 nm.

CONCLUSIONS

(1) The sol–gel procedure allows one-step preparation of the xerogels with a bifunctional surface layer and a relatively high total content of functional groups (3.6 mmol g^{-1}).

(2) The replacement of such complexing groups as $\equiv Si(CH_2)_3P(O)(OC_2H_5)_2$ by bulkier functional groups such as $\equiv Si(CH_2)_3NHP(O)(OC_2H_5)_2$ and $\equiv Si(CH_2)_3 \cdot NHP(S)(OC_2H_5)_2$ leads to the formation of nonporous compounds.

(3) The replacement of 3-aminopropyl groups in the bifunctional surface layer by 3-mercaptopropyl groups does not lead to the formation of porous xerogels even when the ratio of the reacting alkoxysilanes (tetraethoxysilane/mixture of trifunctional silanes) reaches $4 : 1(0.5 + 0.5)$. This fact suggests that the pore structure is determined not only by the size of functional groups but also by changes in the medium in which the hydrolytic polycondensation occurs.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Modification of High-Density Polyethylene with Binary Mixtures of ε-Caprolactone and ε-Caprolactam

R. Z. Khairullin and V. P. Arkhireev

Kazan State Technological University, Kazan, Tatarstan, Russia

Received August 13, 2007

Abstract—Modification of high-density polyethylene with binary mixtures of ε-caprolactone and ε-caprolactam was performed. The composition–property diagrams reflecting the dependences of the physicomechanical, rheological, and optical properties of the resulting polymeric compounds on the content of modifying mixture components were constructed, and the thermal oxidative degradation of the blend samples was studied. Based on the results obtained, the optimal modifier concentrations were suggested.

DOI: 10.1134/S1070427208010278

Progress of engineering requires the development of new types of polymeric materials with a set of properties that are not exhibited by the known plastics. This problem can be largely solved by modification of polymers with the aim to adjust their properties to a level required by the conditions of processing and operation. Much success has been gained in the modification of polymers. Diverse modifying compounds were tested, either as fillers or as chemically active additives, in a wide concentration range with virtually all the known commercial polymers [1].

Modification of polymers with individual compounds allows improvement of many of their processing and service characteristics. However, in some cases the use of binary mixtures leads to an effect significantly exceeding that produced by the components taken separately, i.e., to a synergistic effect [2]. From this viewpoint, modification with binary systems opens wide prospects for improving the properties of polymeric materials. At the same time, it is difficult to find among the diversity of chemical compounds the components that would enhance the effect of each other.

In this study we chose as modifying additives the heterocyclic compounds that are capable to chemically react with each other to form various copolymers and with the polymer subjected to modification (high-density polyethylene, HDPE) at temperatures close to that of HDPE processing. The products formed in these reactions can significantly affect the properties of the modified polymer.

We chose HDPE as one of large-tonnage products of polymer chemistry. In the world production of polymerization plastics, polyethylene (PE) occupies the first place thanks to a combination of valuable properties with the feasibility of processing by all the known highly productive methods used in the technology of thermoplastics. In addition, PE is one of the cheapest polymers, which also makes its use economically sound.

The goal of this study was to evaluate the efficiency of HDPE modification with ε-caprolactam (ε-CLM) and ε-caprolactone (ε-CLN) taken both separately and as binary mixtures, and also to determine the optimal concentrations of the modifying additives.

EXPERIMENTAL

Experiments were performed with HDPE of 277-73 brand [GOST (State Standard) 16338–85], produced by the Organicheskii Sintez Joint-Stock Company (Kazan) and widely used for production of various articles. The modifying additives were ε-CLN and ε-CLM, widely used as monomers for the commercial production of the corresponding polyesters and polyamides.

The components were compounded in a melt on a Brabender rotary mixer at 170°C, with simultaneous introduction of the modifying components. Additionally, 0.1 wt % 2,4-toluene diisocyanate, an activator of anionic polymerization of ε-CLN and ε-CLM, was introduced into the melt.

To optimize the search for effective compositions of modifying mixtures, we used the simplex–lattice experimental design [3–5]. As approximating polynomial we chose third- (maximal content of the addi-

tive 3 wt %) and fourth-order (maximal content of the additive 12 wt %) Scheffe models. To construct the composition–property diagrams, we used the program developed at the Kazan State University.

The mid-IR spectra of the reaction products of HDPE and the binary mixture were recorded on a Bruker FT-IR spectrophotometer from the preliminarily prepared films. Quantitative treatment of the IR spectra was performed with an internal reference [6].

The physicomechanical characteristics were determined in accordance with GOST (State Standard) 11262–80 at 20±2°C (samples of type 1) on an Inspekt mini tensile-testing machine (Trilogica) at a clamp velocity of 100 mm min^{-1}. Samples were cut out from plates prepared by direct hot pressing in accordance with GOST 12019–66.

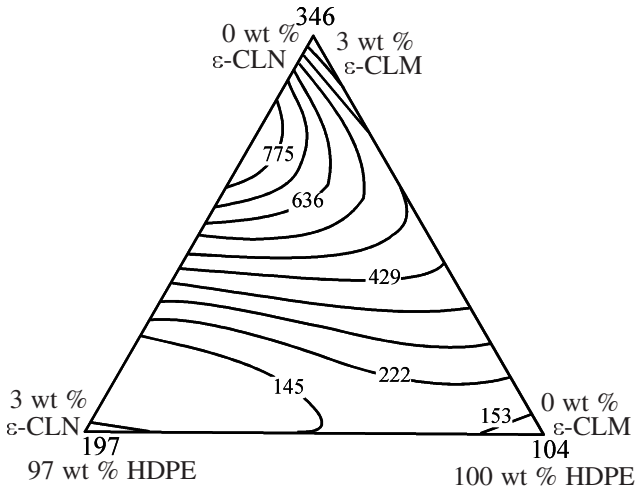

Fig. 1. Isolines of ε of the system HDPE–ε-CLN–ε-CLM.

The melt flow index (MFI) was determined in accordance with GOST 11645–83 on an IIRT-type capillary viscometer at 190°C and a load of 5 kg.

The optical density of polymer samples, preliminarily pressed and having equal thickness, was measured with an SF-2000 spectrophotometer.

To evaluate the stabilizing effect of the modifiers, we studied the autooxidation of HDPE. The method is based on the determination of the amount of oxygen taken up by the polymer at high temperatures. Tests were performed on an installation consisting of differential manometers to which the test tubes containing the modified samples were connected. The test tubes were placed in a thermostat kept at 200°C. The amount of oxygen taken up by the polymer was evaluated from the pressure change.

It is known that ε-CLM and ε-CLN copolymerize to form the corresponding poly(amido esters) (PAEs) [7]. The composition of the copolymers depends on the content of the monomers in the starting mixture. The activators of the anionic polymerization of these compounds are isocyanates, and the reaction rate increases in the presence of lactamates of various alkali metals [8].

It was of certain interest to examine the effect of the modifiers and their transformation products on the whole set of HDPE properties, and also to estimate how sodium lactamate (SL) acting as accelerator of the anionic polymerization affects the properties of the polymeric compounds. For this purpose, we additionally examined the effect of SL on the properties of modified HDPE. We obtained two series of polymeric compounds, one of which contained SL in catalytic concentrations and ther other was prepared without the catalyst.

The physicomechanical tests showed that the catalyst exerts a certain effect on the properties of the polymeric compound (Table 1). It should be noted that, on the whole, there is no rigorous relationship between the presence of SL in the polymeric compound and the physicomechanical properties. This result can be accounted for by the fact that the presence of SL favors more complete passing of both homo- and copolymerization of ε-CLM and ε-CLN and that the copolymers formed in the process strongly affect the physicomechanical properties of HDPE.

It should be noted that the alkali metal present in the HDPE matrix may somewhat accelerate the thermal oxidative degradation of HDPE. Therefore, our further experiments were performed with the samples containing no catalyst.

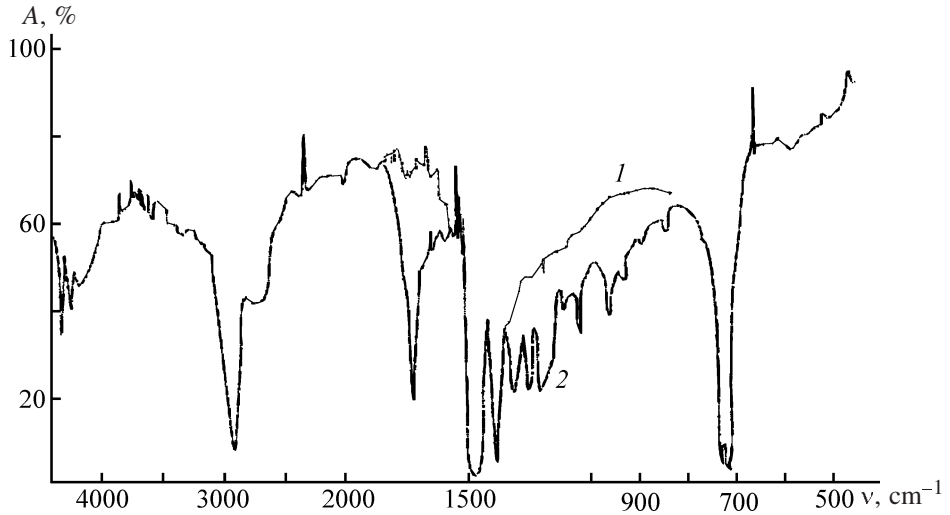

Fig. 2. IR spectra of (*1*) initial HDPE and (*2*) HDPE modified with a binary mixture of ε-CLM and ε-CLN. Molar ratio of the modifiers 1 : 1. (*A*) Absorption and (ν) wavenumber.

We should also note a considerable incrase in the relative breaking elongation ε upon modification of HDPE with small concentrations of ε-CLN and ε-CLM. However, the highest ε is observed with the binary mixtures, rather than with the individual modifiers (Fig. 1). For example, modification of HDPE with a binary mixture of 1 wt % ε-CLN and 2 wt % ε-CLM increased ε by a factor of more than 8, compared to unmodified HDPE, with the strength properties remaining on the same level as for straight HDPE.

Our results can be attributed to the occurrence of the anionic polymerization in the course of compounding at elevated temperatures, with opening of the lactam ring of ε-CLM and lactone ring of ε-CLN. As a result, poly(amido esters) are formed, which interact with defects of the HDPE amorphous phase, altering its structure and ultimately increasing ε. The occurrence of the copolymerization was confirmed by comparison of the IR spectra of the initial and modified HDPE (Fig. 2).

Figure 2 shows that new bands appear at about 1730 (vibrations of ester carbonyl group), 1470 (methylene C–H bending vibrations), and 1170 cm^{-1} (C–O stretching vibrations). These facts show that ε-CLM and ε-CLN undergo anionic copolymerization with opening of the corresponding heterorings.

The formation of PAEs can also be indirectly confirmed by an increase in the optical density *D* of the modified polymeric compounds. The products formed from ε-CLN and ε-CLM are incompatible with HDPE because of their essentially different polarity, and it can be expected that they will form a separate phase and thus increase *D* to the greater extent, the more heterogeneous is the polymer blend. In our case, the highest optical densities are observed with HDPE modified specifically with binary mixtures of ε-CLN and ε-CLM. This fact suggests that the forming copolymers are less compatible with HDPE than the homopolymers of ε-CLN and ε-CLM. Data on *D* of the HDPE-based polymeric compounds are given in Table 2.

One of the main processing characteristics of a polymer is the melt flow index. This quantity deter-

mines the feasibility and optimal procedure of plastic deformation (extrusion, die casting, etc.) for polymer processing. A decrease in the viscosity of the polymer melt, with the other characteristic preserved, allows considerable saving of power for heating the equipment and reduction of the equipment wear.

Measurement of the rheological characteristics of HDPE blend modified with binary mixtures of ε-CLM and ε-CLN demonstrated the efficiency of these substances as additives decreasing the temperature of polymer processing (Fig. 3).

A study of the effect of modifiers on the viscosity of the HDPE melt showed that the maximal decrease in the melt viscosity is also provided by binary mixtures of ε-CLN and ε-CLM. Addition of even small amounts of the modifiers (Fig. 3a) leads to a noticeable decrease in the melt viscosity. A stronger effect is observed with larger amounts of the modifiers. The most pronounced decrease in the viscosity is provided by the binary mixture of 3 wt % ε-CLN + 9 wt % ε-CLM. When introduced into HDPE, this mixture increases its MFI to 23.4 g/10 min, i.e., by a factor of almost 2 relative to staight HDPE.

The effects observed can be accounted for by the fact that the PAEs formed from ε-CLN and ε-CLM exhibit a certain plasticizing effect.

One of the main causes of limited use of polymers as structural materials is aging, namely, changes in the polymer characteristics with time under the action of various factors of the environment. From this viewpoint, it is important to enhance the resistance of a polymer to these factors.

To evaluate how the additives in hand affect the resistance of the polymer to thermal oxidative aging, we examined HDPE samples modified with binary mixtures of ε-CLN and ε-CLM. The results are given in Fig. 4. It was found that the oxidation curves have a combined shape, i.e., both the induction period and autoacceleration are obseved. It should be noted that the oxidation curves of HDPE samples modified with ε-CLN, ε-CLM, and their binary mixtures lie below the oxidation curve of staight HDPE. Thus, ε-CLN and ε-CLM at high temperatures exhibit a certain stabilizing effect.

CONCLUSIONS

(1) The use of binary mixtures of ε-caprolactone and ε-caprolactam as modifiers for high-density polyethylene is preferable over separate use of these modifiers.

(2) Modification of high-density polyethylene with binary mixtures of ε-caprolactone and ε-caprolactam, on the one hand, appreciably decreases the viscosity of the polymer melt and, on the other hand, increases the relative breaking elongation, with the breaking tensile stress remaining essentially the same as for straight high-density polyethylene.

(3) The effects observed are associated with the occurrence of the anionic copolymerization of ε-caprolactone and ε-caprolactam at elevated temperature in the presence of isocyanate activator. The poly(amido esters) formed, interacting with defects of the amorphous phase of high-density polyethylene, alter its structure, causing a sharp increase in the relative breaking elongation.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Antimicrobial Polymeric Composite Films for Medical Use

N. A. Gushchin, G. U. Ostrovidova, and E. A. Sosnov

St. Petersburg State Institute of Technology (Technical University), St. Petersburg, Russia

Received June 28, 2007

Abstract—Preparation of prolonged-action antimicrobial polymeric films based on polyvinyl alcohol and carboxymethyl cellulose sodium salt (Na-CMC), modified with chlorohexidine, is studied. The effects of Na-CMC on the adsorption capacity, degradability, and specific weight of the electrodeposited film are examined.

DOI: 10.1134/S107042720801028X

Modification of polymers with bioactive compounds (BACs) has attracted a great interest in view of the development of immobilized biocatalysts, bioregulators, and prolonged-action drug dosage forms.

Many up-to-date therapeutic agents are characterized by a short durability because of ineffective drug formulation. Therefore, one has to repeatedly take a medicine, increasing the hazard of overdose and side effects [1].

The use of BACs immobilized on biocompatible polymers allows solution of this problem by increasing duration of prolonged action through controlled degradation of the polymeric support, by ensuring desired BAC liberation kinetics via control of the chemical composition of the carrier, and by providing a convenient drug dosage form via optimization of the polymer matrix.

The existing methods for modification of polymeric films with BACs do not always provide a prolonged effect of the immobilized BACs. For example, polyvinyl alcohol (PVA) films modified with immobilized protease C and polyhexamethyleneguanidine hydrochloride lose their enzymatic activity in 2–3 h and antimicrobial activity, in a day [2].

Electroforming shows promise as a method for preparing films of water-soluble polymers with simultaneous immobilization of bioactive components [3]. The method allows thickness-controlled preparation of film coatings of a complex composition. Furthermore, this is a time-saving method, which can be realized under mild conditions. The latter is particularly significant for BACs, as they are sensitive to elevated temperature and immobilization time.

Water-soluble polymers commonly used for film formation showed themselves for many years in medicine and pharmaceutics as nontoxic and highly biocompatible materials [4–6].

Here we report on preparation and characterization of prolonged-action antimicrobial polymeric films based on polyvinyl alcohol (PVA) and carboxymethyl cellulose.

EXPERIMENTAL

Polymeric films were prepared from polyvinyl alcohol [PVA, 16/1 grade; MW ~40000; GOST (State Standard) 10779–78] and carboxymethyl cellulose sodium salt [Na-CMC, Kamtsel-0 grade; MW ~120 000; TU (Technical Specifications) 2231-002-50277563-00]. Boric acid (GOST 9656–75) was used as a cross-linking agent. To impart antimicrobial activity, chlorohexidine (CH) (000 P no. 000734/01) was introduced into the formulation. The hydrogel was electroformed on a Si(111) support.

Chlorohexidine is widely used in medicine [7–9]. This antiseptic agent, taken in a concentration above 0.01%, demonstrates a strong bactericidal activity against most gram-positive and gram-negative aerobes and anaerobes, and fungicidal and antiviral activities as well.

The CH concentration was determined spectrophotometrically at $\lambda = 253$ nm. The antimicrobial activity of immobilized CH was measured in the agar-diffusion test [10] using *Staphylococcus citreus* as a test culture.

To improve the elastic characteristic of the films, 3 wt % glycerol (GOST 6259–75) was added into the formulation as a plasticizer [11].

The basic film-forming component is PVA [12, 13]. The film cannot be electroformed from a formulation containing only Na-CMC.

The presence of Na-CMC considerably increases the specific weight of the film deposited on the electrode (Fig. 1, curves *2, 3*). In aqueous Na-CMC, asso-

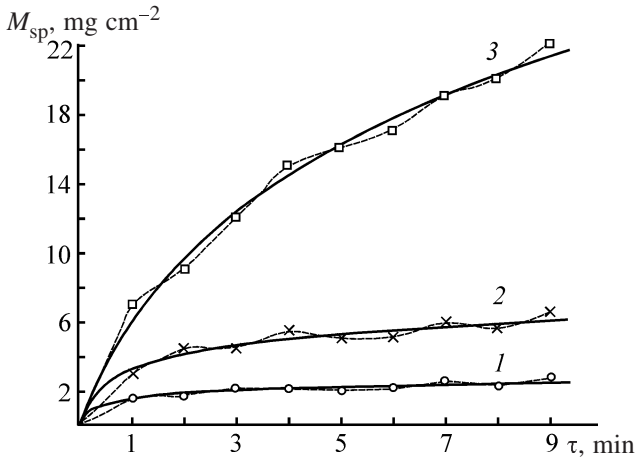

Fig. 1. Specific weight of the electroformed film M_{sp} as a function of the deposition time τ: (*1*) 1% CMC, (*2*) 3% PVA, and (*3*) 1% CMC + 3% PVA.

ciation of macromolecules occurs through intermolecular hydrogen bonding [6]. Evidently, similar interactions take place in the composite solution between free hydroxy groups of Na-CMC and PVA. In the electric field, the resulting associates move to the cathode to form a polymeric film. Na-CMC, used in this study, has a molecular weight three times that of PVA, thus increasing the specific weight of the electroformed film.

It was experimentally demonstrated that addition of Na-CMC increases the adsorption capacity of the resulting material with respect to chlorohexidine by virtue of electrostatic binding of the CH cations to COO^- groups of the Na-CMC molecules [14, 15] (Fig. 2).

The films were formed in the electric field of a 15–20 V cm^{-1} strength for 1–5 min. All the components of the composite solution are involved in the electrophoretic motion. On the cathode, a hydrogel of PVA, cross-linked with boric acid, is formed. Na-CMC also enters the composition of the hydrogel, but via hydrogen bonding with the hydrogel network. The chlorohexidine cation also moves to the cathode, which allows control of its concentration in the hydrogel by changing the film formation time (Fig. 2) [8].

The degradability of the polymeric films was characterized by the sample weight loss in water (Fig. 3). Addition of Na-CMC to the starting composite solution facilitates degradation. The reason is that Na-CMC does not form a strong chemical bond with the PVA hydrogel, but disturbs its structure, thus promoting degradation of the film. Heat treatment at 50°C improves the adhesion of the film to the electrode surface, decelerating the degradation (Fig. 3). In this case, the bioactivity of CH remains unchanged [8].

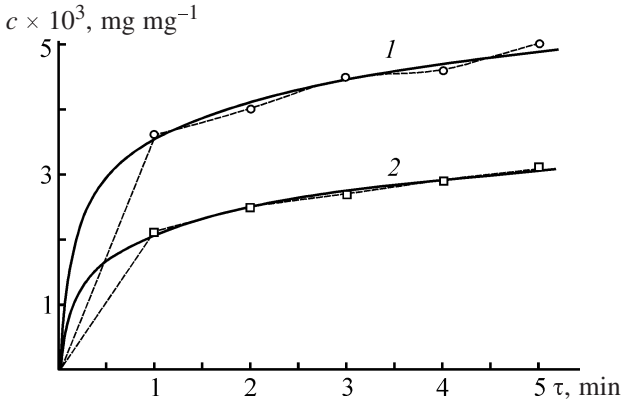

Fig. 2. Chlorohexidine content of the film as a function of the deposition time τ: (*1*) CMC + PVA and (*2*) PVA. CH content of the initial solution 0.01%.

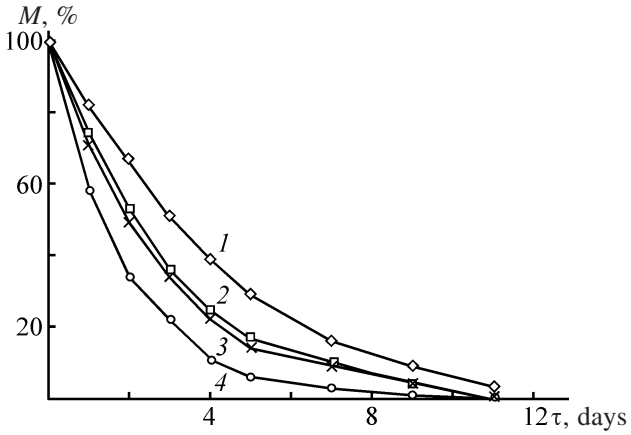

Fig. 3. Kinetic curves of the film degradation. (*M*) Weight loss and (τ) time. (*1*) 6% PVA, heat-treated; (*2*) 6% PVA, (*3*) 1% CMC + 6% PVP, heat-treated; and (*4*) 1% CMC + 6% PVA.

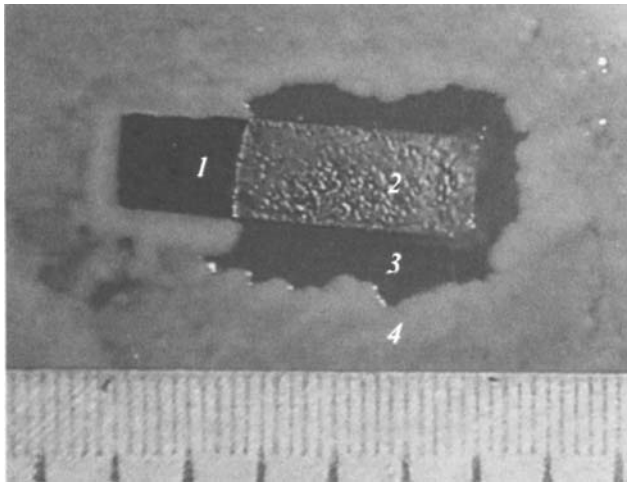

Fig. 4. Inhibition zone against the growth of *Staphylococcus citreus*. Chlorohexidine content about 0.005 mg mg^{-1}. (*1*) Coating-free electrode, (*2*) antimicrobial film, (*3*) growth inhibition zone, and (*4*) test culture of *Staphylococcus citreus* (3-day age).

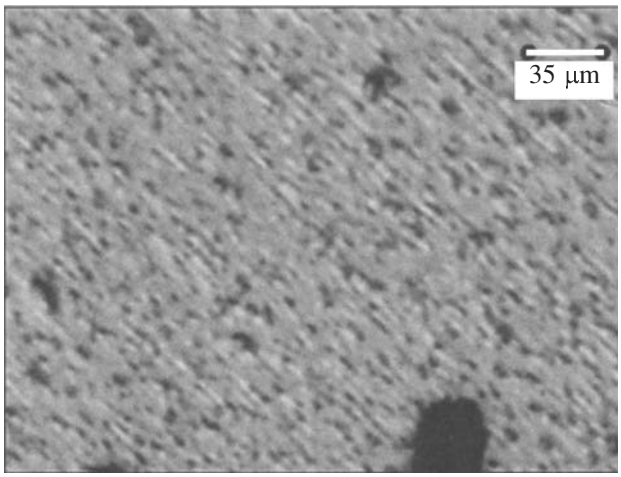

Fig. 5. Optical image of the film surface (cantilever width 35 μm).

The antimicrobial activity of the CH-doped films was demonstrated to be high even at a relatively low CH concentration (about 0.005 mg mg^{-1}) [7]. The inhibition zone against the test microorganisms was at least 15 mm (Fig. 4, zone *3*). The antimicrobial durability of the film was at least 7 days.

The surface morphology of the polymeric films was examined using a scanning tunneling microscope (Optem Int.) with an atomic-force probe. Figure 5 shows that the film surface is oriented (textured).

Finally, taking into account the biocompatibility of the polymeric matrix of the film and bactericidal properties of chlorohexidine, one may recommend the investigated films for use in local treatment of coverlets and mucous coats, particularly, for disinfection of postoperative stitches, wounds, and other injuries; and for treatment and infection prophylaxis of the oral cavity and parodentium [7–9].

CONCLUSIONS

(1) Modification of polyvinyl alcohol based films with carboxymethyl cellulose sodium salt improves their performance, including the specific weight of the film, adsorption capacity for bioactive substances, and degradability.

(2) The degradability of the films can be controlled by changing the composite formulation and by heat treatment.

(3) The films doped with chlorohexidine demonstrate a prolonged antimicrobial effect. The chlorohexidine content of the film can be controlled by changing the film electroforming parameters. The efficiency and duration of the antimicrobial action depend on the concentration of immobilized chlorohexidine and degradability of the matrix. The duration of the antimicrobial effect of the investigated films was at least 7 days.

Abstract—To modify properties of polyvinyl chloride, its chlorine atoms were substituted using sodium salts of pyrazole, 3,5-dimethylpyrazole, and 2-mercaptobenzimidazole.

DOI: 10.1134/S1070427208010291

Polyvinyl chloride (PVC) is one of the most important polymers produced on a large scale. High cost efficiency of production and application of PVC in different branches of industry caused fast growth in its production in many countries, which is due to availability and low cost of the initial raw material, valuable physical and physicochemical properties of materials and articles made of PVC, and advances in stabilization of PVC and its processing.

However, PVC has a number of significant drawbacks. The most serious drawback is that the straight polymer cannot be processed. The presence of C–Cl bonds determining many properties of PVC is the main cause of its poor solubility in organic solvents, very high viscosity of its melts, and low thermal stability at temperatures required for its effective processing.

The most widely used method for modifying PVC properties is copolymerization of vinyl chloride (VC) with one or several monomers. The PVC properties can also be improved by nucleophilic substitution of chlorine atoms in the polymer. Copolymerization of VC was extensively studied [1, 2], whereas substitution of chlorine in PVC was given much less attention.

In this study we examined nucleophilic substitution of chlorine atoms in PVC. For this purpose we used sodium salts of pyrazole (pz), 3,5-dimethylpyrazole (dpz), and 2-mercaptobenzimidazole (mbi).

EXPERIMENTAL

Commercial pz, dpz, and mbi were recrystallized from ethanol.

Sodium and potassium salts of pz, dpz, and mbi were prepared as follows. The initial pz, dpz, or mbi (1 mol) were dissolved in ethanol (30 ml). To this solution, an aqueous solution of NaOH or KOH (1 mol) was added. The reaction mixture was kept for 3 h at room temperature. The solvent was removed and the resulting salt was dried by azeotropic distillation with benzene. The purity of the salt was determined by potentiometric titration.

Substitution of chlorine atoms was performed in solvents purified by known methods [3]. To a 4% PVC solution, Na or K salts of pz, dpz, and mbi were added in portions at a definite temperature. The salts were isolated by dialysis or precipitation into water. The product was filtered off, washed with water, and dried. The viscosity of polymer solutions was measured on an Ubbelohde viscometer at 25°C. Elemental analysis of the reaction products was performed on a Thermo Finnigan gas analyzer.

The IR spectra of the copolymers in the form of KBr pellets or mulls in mineral oil were recorded on a Specord IR-75 or Bruker IFS-25 spectrophotometer. The ^{13}C NMR spectra of the copolymers were taken on a Varian VXR-500S spectrometer operating at 125.5 MHz with relaxation delay of 2.5 s and 90° pulse in DMSO-d_6 solutions. Chromium(III) acetylacetonate (0.02 M) was used as a relaxation agent. The relative integration error was 3%. The ^{1}H NMR spectra were recorded on a Bruker DPX-400 spectrometer operating at 400.13 MHz in C_6D_6 and DMSO-d_6. The concentration of the polymer solutions was 1%.

The specific surface area of the composites was de-

termined by nitrogen adsorption at different pressures. The measurements were performed in a graduated high vacuum.

We used emulsion PVC soluble in dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and cyclohexanone (CH). The polymer has the following properties: Fickentscher constant K_F = 62–63, T_{dec} = 120°C, and specific surface area of 1.81 $cm^2 g^{-1}$.

Nucleophilic substitution of chlorine atoms in PVC with pz and dpz anions in the form of sodium and potassium salts was performed in different solvents at temperatures from 0 to 45°C. The presence of nitrogen in the reaction products confirms substitution of chlorine atoms. The results are presented in Table 1.

As seen from Table 1, reaction of PVC with sodium and potassium salts of pz and dpz at temperatures above 0–2°C yields insoluble products. It is known

Scheme 1.

[2] that the chromophore effect is observed after elimination of only 0.1–0.2% of HCl. Substitution of chlorine atoms in PVC is accompanied by dehydrochlorination: signals of the ~CH=CH– fragment (128.03–127.58 ppm) appear in the ^{13}C NMR spectra of the examined solutions, and a new band at 1640 cm^{-1} appears in the IR spectra. Substitution of chlorine atoms in PVC is described by Scheme 1.

Double bonds of the macromolecule form cross-links, which makes the polymer insoluble. The maximal nitrogen content is approximately 4% (Table 1, run nos. 3, 5, and 11). At low temperature (0–2°C), the substitution is insignificant (the maximal nitrogen content is as low as 1.48%, Table 1, run no. 1). However, PVC modified under these conditions is soluble in DMF and DMSO. The degree of chlorine substitution under the similar reaction conditions depends on the solvent: the maximal nitrogen content (2.04 %) is observed in a DMSO solution (Table 1, run no. 9; cf. samples modified in DMF, run no. 8). As the Na-pz concentration is increased by a factor of 2, insoluble samples are formed even when the modification is performed at 0–2°C (Table 1, run no. 5).

Nucleophilic substitution of chlorine in PVC is accompanied, as a rule, by cyclization and cross-linking [1, 2]. For example, the polymer treated with lithium or potassium contains small amount of chlorine, cyclopropane rings, and cross-links.

It is known that reactivity of the –SNa group in nucleophilic substitution is higher that that of the >NH group. To check this fact, we studied the reac-

tion of PVC with sodium salt of 2-mercaptobenzimidazole. The results are presented in Table 2.

The reaction in CH yields only soluble products, whereas in DMF both soluble and insoluble polymers are formed. As the reaction temperature increases from 80 to 100°C, the nitrogen content of the polymers increases from 7.52 to 10.86% (Table 2, run nos. 1–5). At 120°C, the nitrogen content of the samples does not increase further (Table 2, run no. 6).

The presence of strongly broadened signals of CHCl and CH_2 groups of PVC (4.0–5.0 and 2.0–2.9 ppm, respectively [4]) and signals of H-4,7 and H-5,6 atoms of mbi (7.6 and 7.1 ppm, respectively [5]) suggests formation of the copolymer by the reaction of PVC with sodium salt of mbi (Table 2, run no. 5). Broadened strongly overlapped lines in the resonance region of hydrogen atoms of olefin fragments (5.0–6.7 ppm [6]) are also present in the ^{1}H NMR spectrum.

The presence of olefin fragments in the copolymer structure was confirmed by ^{13}C NMR spectroscopy. Significantly overlapped strong signals of carbon atoms of the olefin fragments HC=CH are observed in the range 128–138 ppm along with signals of carbon atoms of vinyl chloride fragments (58.0–64.0 and 46.0–48.4 ppm for CHCl and CH_2 groups, respectively) and broad signals of 2-mercaptobenzimidazole [110–118 (C-4,7); 122 and 126 (C-5,6); ~140 (C-8,9); and 142–150 ppm (C-2)].

The results of quantitative analysis of the ^{1}H and ^{13}C NMR spectra of the copolymer are presented in Table 3. The ratio of the main structural elements in the copolymer calculated from these data is mbi : VC : (HC=CH) = 1 : 1.32 : 1.

The elemental composition of the copolymer, calculated from the ^{13}C NMR data and results of chemical analysis, is presented in Table 4. It is seen that

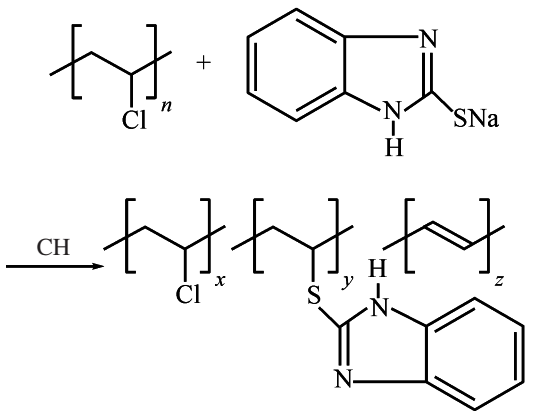

Table 4. Elemental composition of the copolymer (Table 2, run no. 5) calculated from the ^{1}H and ^{13}C NMR data and the results of chemical analysis

Element	Content, wt %	
	NMR data	chemical analysis
C	58.9	58.34
H	4.9	5.53
N	10.6	10.86
S	12.1	11.65
Cl	13.4	13.62

the data obtained by two different methods are well consistent.

Thus, nucleophilic substitution of chlorine atoms in PVC under the cation of sodium salt of mbi can be described by the Scheme 2:

Scheme 2.

The decomposition temperature of the reaction products of PVC with mbi (Table 2, run nos. 4–6) is as high as 160–180°C. Relatively strong and stable composite films are formed by application of solutions of these compounds to metal or polyethylene surface. The specific surface area and pore volume of the VC copolymers are higher by a factor of 6.7 (8.23 $m^2 g^{-1}$ and 1.89 $cm^3 g^{-1}$, respectively, Table 2, run nos. 4 and 5) than those of the initial PVC.

This is of fundamental importance for plasticization of VC copolymers.

Thus, nucleophilic substitution of chlorine atoms in polyvinyl chloride is one of the most interesting reactions from the theoretical and practical viewpoints, allowing improvement of physical properties of PVC polymers. To obtain polymers with required properties, the influence of different factors on the reaction course should be studied.

ACKNOWLEDGMENTS

This study was financially supported by the Russian Foundation for Basic Research (project no. 06-08-00320-a).

CONCLUSIONS

(1) Only insignificant fraction of chlorine atoms is substituted in polyvinyl chloride by the reaction with sodium pyrazolate or sodium 3,5-dimethylpyrazolate. The maximal nitrogen content of the soluble reaction products is 5.90%.

(2) When sodium salt of 2-mercaptobenzimidazole is used as a nucleophile, the degree of substitution of chlorine atoms increases and the nitrogen content of the reaction products reaches 7.52–10.86%.

(3) The ratio of the main structural fragments of the copolymer was calculated from the ^{1}H and ^{13}C NMR data.

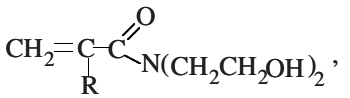
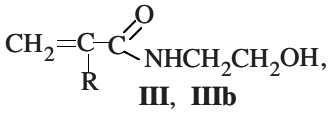
Abstract—The selectivity with respect to N-acylation of the reactions of *N*,*N*-bis(2-hydroxyethyl)amine and *N*-methyl(2-hydroxyethyl)amine with acryloyl and methacryloyl chlorides was examined.

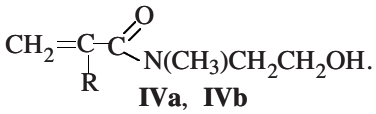


DOI: 10.1134/S1070427208010308

The majority of polymers derived from acrylamides are water-soluble. Aqueous solutions of these polymers, in particular, of poly(*N*-isopropyl)acrylamide, can be sensitive to external effects. For example, variation of the temperature in a narrow range strongly affects their solubility. Therefore, such polymers are widely used in various branches of engineering and medicine [1, 2]. Expansion of the assortment of such polymers and study of their behavior are of both scientific and practical interest. This particularly concerns acrylamide polymers containing hydroxyalkyl groups in monomeric units. For example, Laschewsky et al. [3] studied in detail the phase equilibria in solutions of polymers and copolymers of mono-, di-, and trihydroxyalkyl(meth)acrylamides: *N*-(2-hydroxypropyl)methacrylamide **I**, *N*,*N*-bis(2-hydroxyethyl)acrylamide **IIa**, *N*-tris[(hydroxymethyl)methyl]acrylamide, and their partially and fully acylated derivatives.



The synthesis and polymerization of *N*-hydroxyalkyl(meth)acrylamides (HAAs), namely, of *N*-(2-hydroxyethyl)acrylamide **IIIa**, *N*-(2-hydroxyethyl)methacrylamide **IIIb**, *N*-methyl-*N*-(2-hydroxyethyl)acrylamide **IVa**, and *N*-methyl-*N*-(2-hydroxyethyl)methacrylamide **IVa** were described for the first time in patents [4, 5]:



I

IIa, **IIb**

III, **IIIb**

IVa, **IVb**

where R = H (**IIa**–**IVa**) or CH_3 (**IIb**–**IVb**).

Procedures for preparing **IIa** and **IIIa** are also given in a patent [6], and the synthesis and polymerization of **I** are described in [7]. A modified procedure for preparing amide **IIa** in a tetrahydrofuran (THF) solution is given in [3]. In all the cases, HAAs were prepared by the reactions of appropriate hydroxyalkylamines [2-hydroxyethylamine (ethanolamine), 2,2'-bis(hydroxyethyl)amine (diethanolamine, **V**), *N*-methyl-*N*-(2-hydroxyethyl)amine **VI**] with acryloyl chloride **VIIa** or methacryloyl chloride **VIIb** in acetonitrile or in THF at low temperature. At the same time, Mohamed and Abd El-Hai [8] reported on the preparation of **IIa** by the reaction of diethanolamine with acrylic acid **VIII** in refluxing xylene with azeotropic distillation of water.

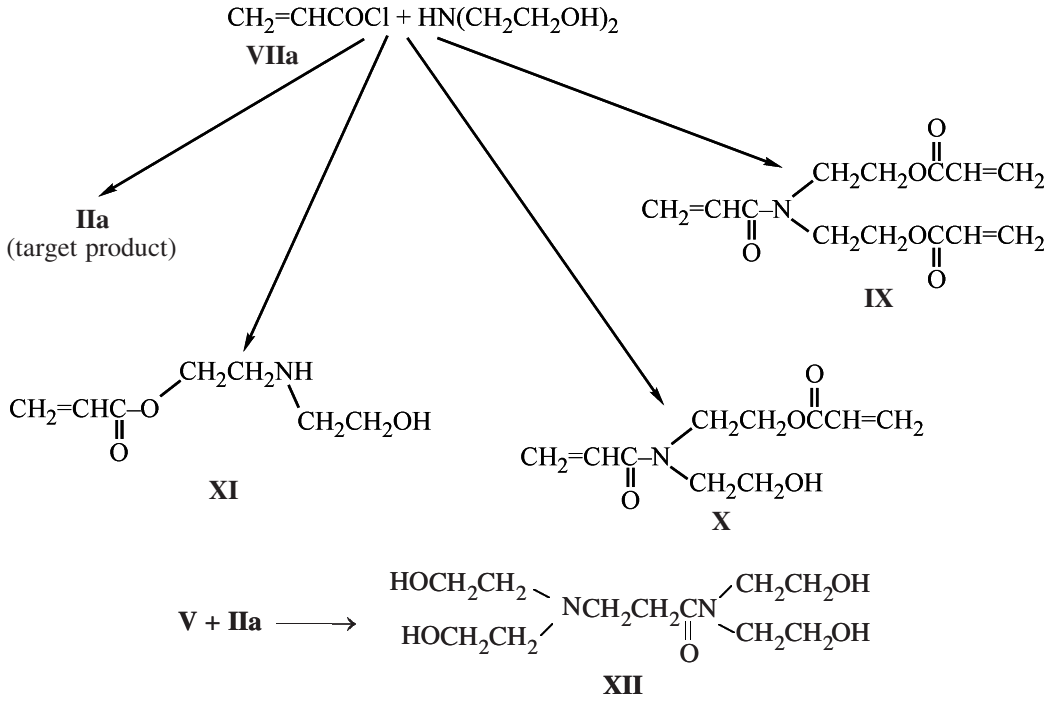
In patent [4], the monomers were isolated by vacuum distillation and characterized by the boiling point, refractive index, density, and nitrogen content. Product **I** was isolated by low-temperature crystallization from acetone and was characterized by the melting point only [7]. In all these cases, the target product yield did not exceed 60%. In the other cases, the monomers were used for the subsequent polymeriza-

tion without isolation and purification; therefore, their physicochemical characteristics were not given (amide **IIa** was characterized only by the ^{1}H NMR spectrum [3]). Data on the composition of the reaction mixture obtained were not reported either.

At the same time, the presence in hydroxyalkylamine molecules of two or three centers capable of reacting with acylating agents creates prerequisites for the occurrence of the reaction along more than one pathway, as both N- and O-acylation are possible. Hence, evaluation of the selectivity of such syntheses and of the purity of the monomers obtained is a topical problem. It is particularly important to determine whether the reaction mixture contains compounds polyfunctional with respect to double bonds (ester amides), as such compounds can cause undesirable gelation due to cross-linking of the macromolecules. Furthermore, along with undesirable O-acylation, addition of the amine across the acrylate double bond (Michael reaction [9, 10]) is also possible.

The goals of this study were to evaluate the selectivity of various methods for HAA synthesis, determine the content of undesirable impurities, find possible ways of their removal, and develop procedures for preparing the monomers of the required high purity.

N-Hydroxyalkyl(meth)acrylamides are a particular case of N-substituted amides which are usually prepared by the following procedures [11]: (1) condensation of primary or secondary amines with acyl chlorides in the presence of bases (tertiary amines or inorganic bases) as HCl acceptors; (2) oxidation of Schiff bases formed by reactions of primary amines with aromatic aldehydes; (3) addition of alcohols to nitriles; (4) amide interchange in reactions of primary or secondary amides with esters at elevated temperature, with the release of the corresponding alcohol; (5) condensation of primary or secondary amines with carboxylic acids at elevated temperature, usually with azeotropic distillation of water; (6) alkylation of primary amides with alcohols or alkyl halides at elevated temperature (up to 180°C).



The synthesis procedure via Schiff bases is by no means suitable for preparing (meth)acrylamides. Addition of alcohols to nitriles is also a specific route, hardly suitable for this purpose. The amide interchange (fourth route) readily occurs only in cases when esters derived from relatively acidic alcohols (e.g., nitrophenol) react with highly basic amines. With (meth)acrylates as starting esters, the Michael reaction will be the major pathway, especially with low-basicity amines such as hydroxyalkylamines. Furthermore, this route, like all the other routes starting from the fourth route, requires, as a rule, elevated temperatures significantly exceeding 100°C. The same is true for the synthesis of *N*-hydroxyalkyl- or *N*,*N*-dihydroxyalkylamines by reactions of epoxides (ethylene oxide, epichlorohydrin, glycidyl alcohol) with primary amides (acetamide, formamide) at 140–150°C in the presence of base or acid catalysts [12, 13]. Apparently, in synthesis of (meth)acrylate derivatives under these conditions, it is virtually impossible to prevent the polymerization of both the starting compounds and the target products. Although in [8] the polymerization in the course of the synthesis of **IIa** seems to be avoided, our attempt to reproduce this procedure led to oligomers as major products (see below).

Thus, the first route seems to be the only suitable for preparing HAAs, and we chose this route in our experiments.

Amines very rapidly react with acyl halides at low temperatures, which allows the polymerization to be excluded. However, the polyfunctional structure of both reagents gives rise to certain problems in the selective synthesis of HAAs. Indeed, the starting hydroxyalkylamines contain not only amino groups but also hydroxy groups, which are also capable of acylation. (Meth)acryloyl chlorides contain, along with the reactive acyl chloride group, fairly active C=C bonds. In our case, apparently, the major side reaction will be O-acylation (formation of esters), occurring instead of, or along with N-acylation. As for the Michael reaction, it probability, at first glance, is low when the reaction is performed quickly and at low temperature, but it cannot be fully ruled out a priori. Thus, the reaction of (meth)acryloyl chloride with HAA may yield a mixture of products, as illustrated in Scheme 1 by the example of **VIIa** and **V**.

An ingenious procedure for preparing **IIa**, circumventing the problem of selectivity in the acylation step, was used by Miyabe et al. [14]: Diethanolamine **V** was exhaustively acylated with acryloyl chloride **VIIa** at the reactant molar ratio of 1 : 3 in the presence of triethylamine (TEA), after which the ester groups in acryloyliminodiethane-1,1'-diyl bisacrylate **IX** thus obtained (Scheme 1) were subjected to base alcoholysis with a saturated solution of Na_2CO_3 in methanol. However, whereas the yield of the target product based on the starting amine **V** is about 95%, the yield based on the starting chloride **VIIa** does not exceed 32%. This procedure apparently deserves at-

Scheme 1. Possible side processes in reactions of hydroxyalkylamines with acryloylchloride

tention as a preparative route, but for the synthesis of large amounts of monomers it is preferable to use a one-step procedure with the minimal consumption of expensive acid chlorides.

To elucidate how the condensation conditions affect the reaction selectivity, we studied the products of the reaction of **V** with **VIIa**, performed under different conditions. The relative contributions of the N- and O-acylation pathways can be readily evaluated by IR spectroscopy. Formation of ester groups leads to appearance of a strong absorption band of the carbonyl group in the range 1740–1720 cm^{-1} and of bands at about 1180 and 1120 cm^{-1} (C–O–C vibrations), whereas the amide C=O groups absorb at approximately 1600 cm^{-1} [15].

The reaction of amine **V** with equimolar amounts of acid chloride **VIIa** and TEA was performed in toluene (in this case, the system was heterogeneous, as compound **V** is insoluble in toluene), 1,4-dioxane (DO), and THF. In all the cases, along with bands at 1640 (vibrations of C=C bond in acrylic derivatives) and ~1610 cm^{-1} (vibrations of amide C=O group), the IR spectrum of the reaction mixture contained strong bands at 1740, 1180, and 1120 cm^{-1}, belonging to ester groups (Fig. 1, spectrum *1*). The same result was obtained when the reaction was performed in the phase-transfer mode, when a toluene solution of **VIIa** was added dropwise with vigorous stirring to an aqueous solution of amine **V** and sodium carbonate.

A different IR pattern is obtained when the reaction is performed with excess amine **V** (and not TEA) as HCl acceptor, both in DO and in THF. The bands at 1740, 1180, and 1120 cm^{-1} become weak, whereas the bands at 1640 and ~1600 cm^{-1} are fairly strong (Fig. 1, spectrum *2*). Spectrum *3* in Fig. 1 belongs to

The IR spectrum of the latter product is shown in the insert. Products **X** and **XI** were identified by retention times and UV spectra.

the same product after purification. The bands at 1740, 1180, and 1120 cm^{-1} in the latter spectrum are fully absent, but a doublet band at 1605–1590 cm^{-1} belonging to the C=O groups of the disubstituted amide can be observed. Hence, under these conditions N-acylation is the major reaction pathway. The reaction mixture after adding a solution of chloride **VIIa** to a solution of amine **V** in a 1 : 2 ratio is a low-viscosity turbid solution over a highly viscous precipitate. The yield of crude **IIa** after distilling off the solvent is approximately 60% based on converted chloride **VIIa**.

Similarly, we prepared *N*,*N*-bis(2-hydroxyethyl)-2-methacrylamide **IIb** by the reaction of a twofold excess of amine **V** with chloride **VIIb** in THF. The yield of the crude product was up to 90% based on **VIIb**. By reactions of a twofold excess of amine **VI** with chlorides **VIIa** and **VIIb** in THF, we prepared amides **IVa** and **IVb**; the yields of the crude products were 67 and 95%, respectively.

To evaluate the reaction selectivity, the composition of the reaction mixture was determined by reversed-phase HPLC. It should be noted that chromatography (especially in combination with spectroscopic methods) is the most efficient, sensitive, and reliable method for determining compositions of complex mixtures. Chromatograms of crude (pattern *1*) and purified (pattern *2*) amide **IIa** are shown in Fig. 2 (their IR spectra are given in Fig. 1). Chromatogram *3* (Fig. 2) belongs to the product obtained by condensation of amine **V** with an equimolar amount of acrylic acid **VIII** in refluxing xylene with azeotropic distillation of water, as described in [8].

Crude product **IIa** contains as major impurity approximately 2–5% 2-[acryloyl(2-hydroxyethyl)amino]ethyl acrylate **X**, the product of simultaneous N- and O-acylation. This impurity is undesirable, as it can cause formation of an insoluble gel in the course of synthesis of linear polymers. Fortunately, compound **X**, in contrast to amide **IIa**, is better soluble in organic solvents than in water. Chromatogram *2* (Fig. 2) belongs to a sample of amide **IIa** isolated after treatment of its aqueous solution with methylene chloride. In this case, the content of the target product is approximately 96.5%. However, a small peak with a retention time of 4.3 min does not disappear after the extraction with methylene chloride. This peak apparently belongs to the O-acylation product, 2-[(2-hydroxyethyl)amino]ethyl acrylate **XI**, which is similar in polarity to **IIa**. The UV spectra of amide **IIa** (major peak) and product **X** (peak with a retention time of about 8 min) have maxima at 220 and 246 nm, characteristic of acrylamides [16]. Product **XI** (peak

with a retention time of 4.3 min) has a UV spectrum with only one maximum at approximately 220 nm, characteristic of acrylic acid ester [17]. The peak at 2.86 min was not identified. This product shows no UV absorption, i.e., it is neither an esters nor an amide and is apparently a nonreactive water-soluble impurity in **V**. The exhaustive acylation product **IX** shown in the scheme present in trace amounts or absent at all in the reaction mixture and is absent in the purified product.

Chromatogram *3* in Fig. 2 essentially differs from chromatograms *1* and *2*. The product prepared by condensation of amine **V** with acrylic acid **VIII** in refluxing xylene following the procedure from [8] is a dark semisolid mass consisting of numerous compounds (most likely polymers or oligomers). Peaks of several individual substances can be seen against irregular background. The content of target amide **IIa** (identified by the retention time) in this mixture is as low as 10%. The IR data also show that N-acylation is not the major reaction pathway under these conditions: The spectrum given in [8] is almost identical to the spectrum of the product obtained in our experiment but differs essentially from the spectrum of pure amide **IIa** in the range of vibrations of carbonyl groups and C=C double bonds (see insert in Fig. 2).

The IR spectrum and chromatogram of amide **IIb** prepared by condensation of chloride **VIIb** with a twofold excess of amine **V** in THF are shown in Figs. 3 and 4. Similar results were obtained in the reactions of **VIIa** and **VIIb** with excess **VI** in THF, as seen from the IR spectra and chromatograms of products **IVa** and **IVb** (Figs. 3 and 4, respectively). All these spectra contain a C=C absorption band at 1644 (for methacrylic derivatives) or 1640 cm^{-1} (for acrylic derivatives), and also bands at 1600 cm^{-1} belonging to C=O groups in unsaturated amides. Crude products were purified by extraction of less polar impurities containing two C=O bonds with methylene chloride from aqueous solutions in all the cases except **IVb**. Compound **IVb** was fairly pure (~95%) without additional treatment. According to the IR spectra (Fig. 3, spectrum *3*, lack of absorption at ~1720 cm^{-1}) and chromatograms (Fig. 4, pattern *4*, lack of peaks after the major peak), it contains no impurities of O-acylation products.

Thus, with a twofold excess of hydroxyalkylamine in the absence of other HCl acceptors, the N-acylation selectivity exceeds 90% for amine **V** and reaches almost 100% for amine **VI**. Specifically this procedure, suggested and substantiated for the first time in

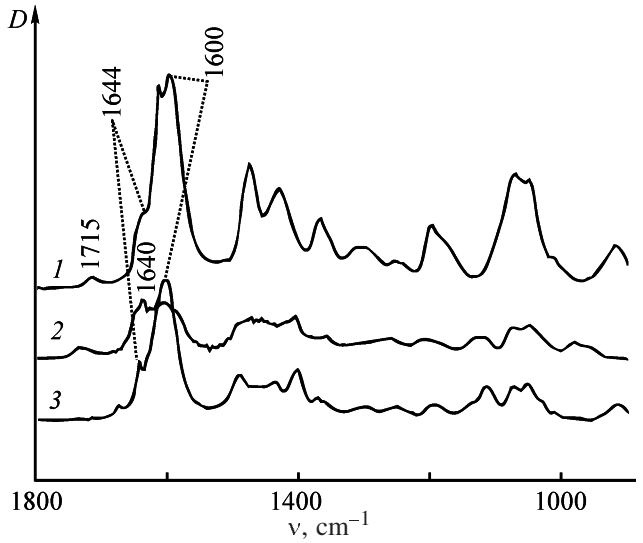

Fig. 3. IR spectra of crude amides (*1*) **IIb**, (*2*) **IVa**, and (*3*) **IVb**.

[4], was subsequently used by other authors for preparing the corresponding HAAs whose polymerization yielded water-soluble polymers. An exception is patent [6] whose authors prepared amide **IIa** by the reaction of amine **V** with acid chloride **VIIa** in the presence of TEA in THF. The solution after separation from the precipitate of triethylamine hydrochloride was used, without isolating the target product, for preparing polymers and copolymers. The polymers described in [6] are insoluble in water and become soluble only after boiling in aqueous NaOH. Apparently, in this case the reaction yields a mixture of N- and O-acylation products with a high content of bi- and, possibly, trifunctional (with respect to double bonds) compounds (Scheme 1). Dissolution of polymers prepared from such a mixture occurs under the action of alkali, apparently due to hydrolysis of cross-links formed via ester groups.

Nevertheless, partial O-acylation takes place even when an HAA is prepared with excess of the amine component. Isolation and complete identification of the by-products were beyond the scope of this study. However, data on the structures of the starting compounds and the reactivities of their functional groups suggest that the main by-products in the synthesis of HAAs are formed by simultaneous N- and O-acylation. These are amido esters (compound **X** and its analogs) containing two double bonds in the molecule and aminoalkyl acrylates (compound **XI** and its analogs). This conclusion follows from the IR spectra and chromatograms of the crude products (presence of absorption bands of ester carbonyl groups

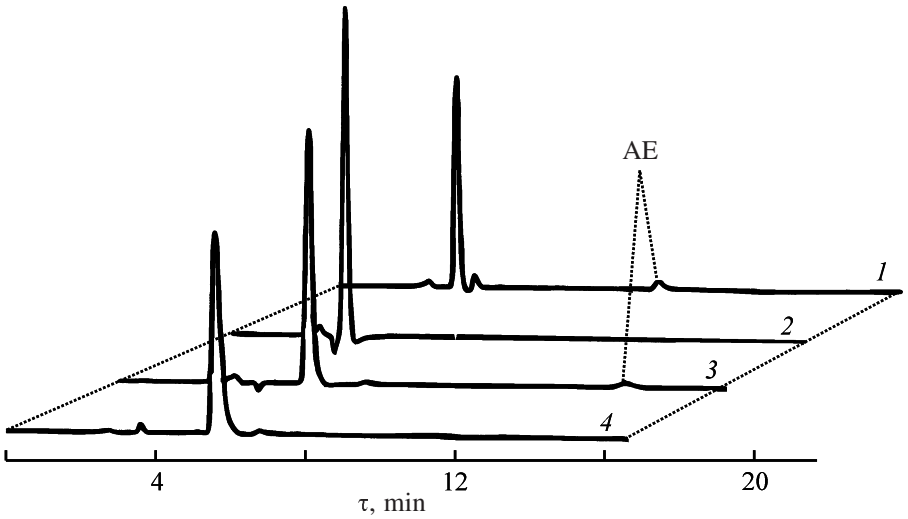

Fig. 4. Chromatograms of (*1*) crude **IIb**, (*2*) purified **IIb**, (*3*) crude **IVa**, and (*4*) crude **IVb**. (AE) Impurities of amido esters.

and of minor peaks that have longer retention times and hence belong to less polar, compared to the target products, compounds), and also from the characteristic UV spectra of the impurities.

Along with side O-acylation, the Michael reaction also takes place, especially with acrylamides. This conclusion is based on the following observations. First, the yields of amides **IIb** and **IVb** are almost quantitative, whereas the yields of **IIa** and **IVa** are considerably lower. Second, the volume of the salt precipitate formed in the course of the reaction is considerably larger in the case of the synthesis of **IIa**, compared to **IIb**. It is known that acrylic derivatives add primary and secondary amines after Michael considerably faster than do methacrylic derivatives. If the rate of the Michael reaction is sufficiently high, the reaction of amide **V** with chloride **VIIa** can yield a large amount of 3-[bis(2-hydroxyethyl)amino]-*N*,*N*-bis(2-hydroxyethyl)propanamide **XII** (Scheme 1), because the free amine is present in the reaction mixture almost up to the end of the process along with growing concentration of the target product **IIa**. Apparently, the Michael reaction can occur in the synthesis of acrylamides to a greater extent than in the synthesis of methacrylamides. It should be noted that, even if the target product contains an impurity of the product of this reaction, its amount is very low, because by the end of the reaction it virtually fully transforms into the hydrochloride insoluble in THF. Furthermore, this impurity should not affect the polymerization of the monomers, because it contains no double bonds. An additional evidence for the possible formation of this adduct is the fact that, on mixing equimolar amounts of **V** and **IIa** at room temperature, the IR spectrum of the mixture rapidly takes the form shown in Fig. 5. The spectrum does not contain the absorption band of the C=C bond at 1640 cm^{-1} but contains a strong band at 1610 cm^{-1}, belonging to the amide group [15].

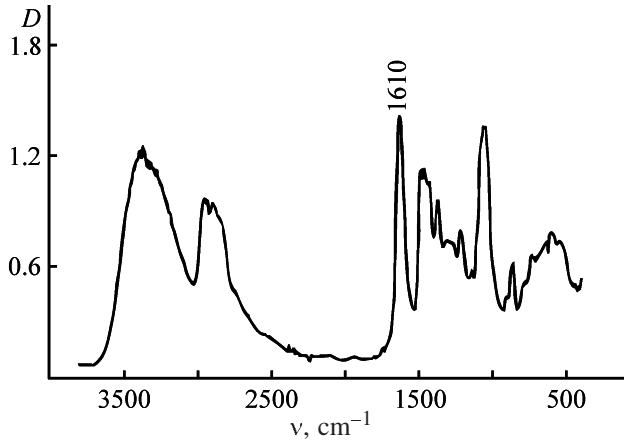

Fig. 5. IR spectrum of the product formed by the reaction of equimolar amounts of **V** and **IIa** at room temperature.

One more evidence for the noticeable contribution of the Michael reaction in the case of acrylamides is the fact that, at a threefold excess of the amine, the yield of the target product under the same conditions does not exceed 20%. Apparently, the major fraction of amide **IIa** formed subsequently adds the unchanged amine.

Thus, addition of amines **V** and **VI** to amides **IIa** and **IVa**, respectively, occurs fairly actively, despite

low temperature and relatively short reaction time (taking into account the fact that the yields of amides **IVa** and **IIa** are considerably lower than the theoretical value, in contrast to amide **IVb**). Acylation of amines with acid chlorides is strongly exothermic. Therefore, the reaction time is determined by the rate of addition of acid chloride solution to the amine solution, which should not be high to avoid overheating of the reaction mixture. Thus, to reduce the contribution of the Michael reaction and increase the yield of the target products, it is necessary to perform the reaction in an apparatus providing efficient heat removal.

The high selectivity of N-acylation of hydroxyalkylamines with acid chlorides in the absence of a "foreign" hydrogen chloride acceptor is apparently due to the fact that the first step of the reaction is formation of complexes of acid chlorides with bases present in the reaction mixture. If an amine containing an N–H bond is used as a base, the second step predominantly occurs as an intramolecular rearrangement with the formation of the C–N bond and release of HCl. If a more basic tertiary amine is present in the system, specificially this component forms the related complex in the first step. In the second step, this complex reacts along a bimolecular pathway with any proton-donor groups present in the reaction mixture. The reaction either is nonselective or predominantly involves more acidic (in particular, hydroxy) groups. Thus, without tertiary amine, O-acylation of hydroxyalkylamines is improbable, whereas in the presence of a tertiary amine it becomes even more probable than N-acylation.

The suggested mechanism can also account for the higher contribution of O-acylation in the synthesis of acrylamides, compared to methacrylamides. Indeed, as shown above, the occurrence of the Michael reaction with the acrylic derivative leads to the formation of a large amount of tertiary amine **XII**, which becomes a "foreign" HCl acceptor and thus decreases the reaction selectivity.

EXPERIMENTAL

Diethanolamine **V** (Aldrich, 98.5%) was distilled in a vacuum, bp 115–118°C/1 mm Hg. Acryloyl chloride **VIIa** (Aldrich, 96%) and methacryloyl chloride **VIIb** (Aldrich, 80%) were distilled at atmospheric pressure with the addition of tetramethylpiperidine-*N*-oxyl (TEMPO) as inhibitor. Triethylamine (Aldrich, 99%) and *N*-methylhydroxyethylamine **VI** (Aldrich, 99%) were used without additional purification. The solvents DO, THF, and toluene were distilled from KOH (THF), P_2O_5 (DO), or Na (toluene) and were then stored over CaH_2 (THF, under argon). Xylene was distilled without drying. Methylene chloride (Aldrich, 99.6%) was distilled just before use.

The reaction of diethanolamine **V** with acryloyl chloride **VIIa** in the presence of TEA was performed as follows.

(a) Compound **VIIa** (0.6 ml) was slowly added to a mixture of 1 ml of TEA, 0.5 g of amine **V**, and 10 ml of toluene under vigorous stirring with a magnetic stirrer. The solution was filtered to remove the precipitate, and the solvent was distilled off. The remaining viscous nonvolatile liquid has an IR spectrum shown in Fig. 1 (spectrum *1*).

(b) Acryloyl chloride **VIIa** (0.5 ml) was slowly added under vigorous stirring with a magnetic stirrer to a mixture of 2.5 ml of TEA, 0.76 g of amine **V**, and 10 ml of DO. The solution was filtered to remove the precipitate, and the solvent was evaporated. The remaining viscous nonvolatile liquid has an IR spectrum similar to that in procedure (a).

To perform phase-transfer condensation of diethanolamine **V** with acryloyl chloride **VIIa**, a solution of **VIIa** (0.5 ml) in toluene (7 ml) was added dropwise under vigorous stirring with a magnetic stirrer to a mixture of 0.65 g of **V** and 0.7 g of Na_2CO_3 in 10 ml of water. After the reaction completion, the aqueous layer was separated, KCl was added to the aqueous solution to obtain a saturated salt solution, and the organic products were extracted with diethyl ether. The IR spectrum of the viscous nonvolatile residue after distillation of the solvent was similar to those in procedures (a) and (b).

The condensation of diethanolamine **V** with acrylic acid **VIII** in xylene was performed under the same conditions as in [8], except that NaA zeolite treated with 1 N HCl and washed with water to neutral reaction was used as catalyst instead of mordenite.

Amides IIa, IIb, IVa, and IVb. Amine **V** (31.1 g, ~0.3 mol) was placed in a three-necked flask equipped with a thermometer, a dropping funnel, and a power-driven stirrer. Then the flask was charged with 200 ml of THF, and the mixture was cooled to 8–10°C on a water–ice bath. A solution of 12.5 g (~0.14 mol) of acid chloride **VIIa** in 20 ml of THF was added dropwise with vigorous stirring over a period of 12 min. In the process, the temperature of the reaction mixture did not exceed 15°C. The resulting solution was decanted from the viscous residue. The precipitate was extracted with 200 ml of THF, the second solution

was also decanted, and both solutions were combined. The mixture, which had alkaline reaction, was acidified to weakly acidic reaction by dropwise addition of concentrated sulfuric acid. The solution was filtered, TEMPO was added, and the solvent was distilled off. Crude amide **IIa** was obtained in an amount of 12.5 g (0.078 mol, yield 56%). The product was dissolved in 120 ml of water; the solution was extracted with seven 100-ml portions of methylene chloride. After distillation of water, 10.1 g of the purified product (yield 45% based on acid chloride **VIIa**) was obtained; d_4^{20} = 1.163, n_D^{20} = 1.5135.

Found, %: C 51.33, H 8.18, N 8.46.
$C_7H_{13}NO_3$.
Calculated, %: C 52.82, H 8.23, N 8.80.

The same procedure was used for preparing amide **IIb**. From 0.28 mol of amine **V** and 0.12 mol of acid chloride **VIIb**, 19 g (0.11 mol, yield >90%) of crude amide **IIb** was obtained. Yield of the purified product after extraction with methylene chloride 15.0 g (72% based on acid chloride **VIIb**); d_4^{20} = 1.135, n_D^{20} = 1.497.

Found, %: C 55.30, H 8.60, N 7.76.
$C_8H_{15}NO_3$.
Calculated, %: C 55.47, H 8.73, N 8.09.

Similarly, from 28.3 g (0.377 mol) of amine **VI** and 17.3 g (0.191 mol) of acid chloride **VIIa** in 200 ml of THF at 7–10°C, we prepared 16.6 g (0.128 mol) of amide **VIa** (67% based on acid chloride **VIIa**). After single extraction of an aqueous solution of crude **IVa** with methylene chloride, 11.0 g (0.085 mol) of pure amide **IVa** was obtained; d_4^{20} = 1.099, n_D^{20} = 1.5015.

Found, %: C 54.23, H 8.50, N 9.83.
$C_6H_{11}NO_2$.
Calculated, %: C 55.80, H 8.58, N 10.84.

By adding a solution of 20.3 g (0.194 mol) of acid chloride **VIIb** in 20 ml of THF to a solution of 30.7 g (0.409 mol) of amine **VI** in 200 ml of THF at 8–10°C, we obtained 26.2 g (0.183 mol) of amide **IVb** (94.3% based on acid chloride **VIIb**); d_4^{20} = 1.0645, n_D^{20} = 1.4879.

Found, %: C 58.37, H 8.44, N 8.69.
$C_7H_{13}NO_2$.
Calculated, %: C 58.72, H 9.15, N 9.78.

The IR spectra were recorded on a Specord M82 spectrophotometer from neat substances as thin films between KBr plates.

Liquid chromatography was performed with a Waters chromatograph equipped with a refractometric detector and a spectrophotometric detector with a photodiode matrix. Column Diaspher 110 C18, 250 × 4 mm; eluent water–methanol, 30 : 70 for **IIa** and **IVa**, 40 : 60 for **IIb** and **IVb**, 0.7 ml min^{-1}; column temperature 35°C. The chromatograms were recorded and processed with Millennium 32 software.

CONCLUSIONS

(1) The use of liquid chromatography in combination with spectroscopic methods shows that, in reaction of carboxylic acid chlorides of the acrylic series with hydroxyalkylamines, the selectivity with respect to N-acylation exceeds 90% and can reach virtually 100% provided that the amine reagent acts as the only acceptor of hydrogen chloride. Correspondingly, the contribution of the side O-acylation reaction can be reduced to a minimum.

(2) The possibility of virtually complete removal of impurity O-acylation products and preparation of 95–97% pure monomers was demonstrated.

(3) In the synthesis of acrylamides, in contrast to methacrylamides, Michael addition of the amine across the double bond occurs fairly actively, leading to a substantial decrease in the target product yield.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Adhesion of Butyl Methacrylate Copolymers to Cellulose Fabrics

N. V. Volkova, D. N. Emel'yanov, and A. A. Molodova

Abstract—The influence of physicochemical properties of polyacrylate binder on adhesion properties of cellulose fabrics glued by its melt was examined.

DOI: 10.1134/S107042720801031X

A common step of restoration of paintings and applied art pieces made of fabric is their bonding to a new fabric with the aid of adhesives. These substances should strongly glue the initial and backing material at minimal pressure and temperature but should be free of solvents that dissolve paint, should not deform the article being restored owing to shrinkage in the course of formation of the adhesive joint, and should not change the elasticity and strength of the joint in the course of prolonged storage [1]. Adhesives most widely used in the world for fabric-to-fabric bonding are water-base acryl dispersions and an analog of Beva 371 wax–resin formulation [composite of ethylene–vinyl acetate (VA) copolymer, Keton N resin, paraffin, benzine, and toluene]. Bonding with both adhesives is performed at elevated temperature and pressure on a vacuum apparatus equipped with a heater [1]. Frequently, foreign methods cannot be used in Russian restoration practice because of economic and technical reasons. Therefore, development of new Russian adhesives and procedures for their application is an urgent problem.

The aim of this study was to prepare butyl methacrylate (BMC) copolymers with a number of vinyl monomers, whose melts would be suitable for gluing canvases of paintings and cotton fabric with a backing material.

EXPERIMENTAL

We used BMC as the main component for preparing copolymers. This choice is caused by the fact that its homopolymer, poly(butyl methacrylate) (PBMA), is widely used in Russian restoration practice for preservation and restoration of masterpieces, including those on a fabric base [2, 3]. The copolymer composition is presented in Table 1. The copolymers were prepared by radical polymerization at 80°C in a solution of isopropanol which is a chain-transfer agent. Low-molecular-weight copolymers with flow points T_f below 100°C were prepared. Melts of these copolymers can be used to glue fabrics. The molecular weight M of these copolymers was estimated by comparison of the intrinsic viscosity $[\eta]$ (dl g^{-1}) of their acetone solutions with that of a solution of PBMA in the same solvent. The flow point of the copolymers was determined on a Hoeppler consistometer.

Fabrics, coarse calico produced in Ivanovo [GOST (State Standard) 29298–92], were glued (bonded) as follows. Copolymer solutions of definite concentration were applied with a brush to a fabric sample. Then the second and third polymer layers were applied onto the first layer at intervals of 1 h. The sample was dried to constant weight by convection exchange at ambient temperature. Thus we obtained a sample of backing fabric. The sample of backing fabric was put by the polymer-coated side onto the sample of the initial fabric. The fabrics were glued at a small force for 3 min with the aid of an iron heated to 120°C. The glued fabrics were cooled under a load of 0.8 kg. The viscosity $[\eta]$ (mPa s) of copolymer solutions applied onto the backing fabric was measured with the aid of a Hoeppler ball viscometer at 23°C; the viscosity of melts η_m (kPa s) was measured with a modified device for measuring thermoplastic melt indices (TMIM). The tensile strength σ_t (Pa) and relative elongation ε (%) were measured on an RMI-5 tensile-testing machine. The main parameter determining the suitability of the copolymers as

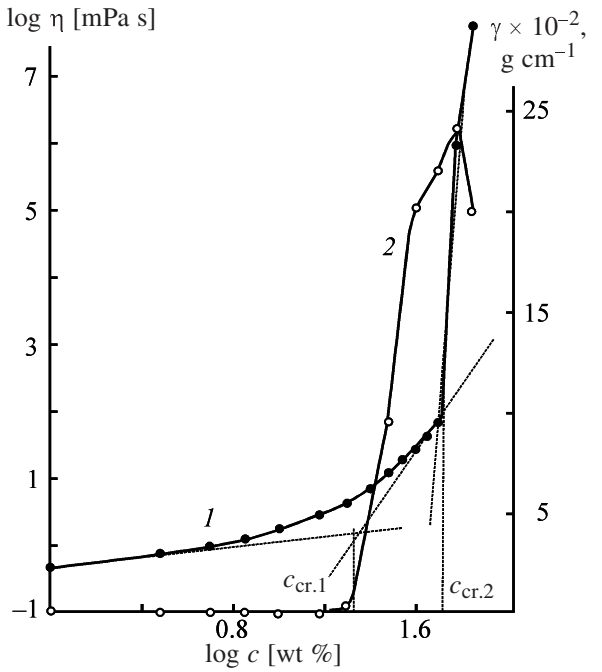
adhesives is their adhesion to the fabric. To estimate the adhesion of the copolymers used for restoration of fabric articles, the plybond strength γ (g cm^{-1}) [4] was measured at room temperature on an RMI-5 tensile-testing machine at an extension rate of 50 mm min^{-1}.

It is known [4, 5] the adhesion of macromolecular compounds containing polar functional groups to a macromolecular substrate also containing such groups is high. Therefore, vinyl polymers containing along with BMA polar (μ, D) units should exhibit the maximal adhesion to polar cellulose fibers [4–6]. This is confirmed by the data presented in Table 1. As seen from Table 1, the adhesion of copolymers to the fabric is also determined by the viscosity of their melts during gluing. The lower the viscosity of a copolymer melt, the higher the adhesion to the fabric. This is due to the fact that a low-viscous copolymer melt penetrates faster and deeper from the backing fabric into interthread cells and into the threads of the doubled fabric, thus providing deeper junction. However, if the viscosity of the melt is too low, it can penetrate into the paint layer of the article being restored, which is strictly forbidden by the requirements to adhesives used in restoration. Hence, an adhesive should have good fluidity and high adhesion but should be held on the internal side of the doubled fabric. For this purpose, a higher-molecular-weight copolymer should be used. Indeed, the main components of adhesive melts are high-molecular-weight polymers providing sufficiently high cohesion strength of the adhesive [5]. However, as M of the copolymer increases, the fluidity of its melt decreases and hence the adhesion of the polymer to the fabric decreases (Table 1).



To increase the fluidity of a polymer melt, waxes (e.g., paraffin) are added to the adhesive [5]. As seen from Table 2, the adhesion of adhesive compound to the fabric sharply decreases after introduction of

paraffin. The lower M of the copolymer and the higher the paraffin content of the compound, the lower the plybond strentgh. To prevent sharp decrease in the plybond strength with a low-molecular-weight copolymer adhesive, the more concentrated solution should be used or the number of polymer layers applied to the backing fabric should be increased.

Fabric fibers are porous. The pore volume of natural cellulose fibers of cotton is 35–45% of the fiber volume. In addition, there is a space between threads of the first and second twists [4]. Therefore, interaction of a polymer adhesive with a textile substrate is controlled by diffusion and is determined by the adhesive amount. The larger the adhesive amount in the glue joint, the larger amount of the adhesive can penetrate into fabric interstice. The adhesive amount on the backing fabric can be increased either by an increase in the concentration of a polymer solution applied to the fabric or by application of several layers of the polymer solution. As seen from Table 3, both methods increase the adhesion.

(*1*) Viscosity η of a solution of 85 BMA–10 VA–5 BA copolymer with [η] = 0.20 dl g^{-1} and (*2*) plybond strength γ of glued coarse calico as functions of the polymer concentration c in the solution. Three layers of the copolymer solution were applied to the backing fabric.

As seen from the figure, the fabrics are glued with a measurable adhesion when the polymer concentration in the solution reaches $C_{cr.1}$ = 20 wt %. At this concentration, a Newtonian liquid transforms into a structured-viscous liquid [8]. In the latter case, macromolecular associates are formed. Penetration of large associates into fiber interstice of the backing fabric is complicated, and these associates are located on the fiber surface to form an adhesive layer. Therefore, solutions in the structured-viscous rheological state should be applied onto the backing fabric. As seen from the figure (curve *2*), the adhesives prepared from solutions with a concentration close to $C_{cr.2}$ (50–60 wt %) have the best adhesive properties. At higher concentration, the solution transforms from the structured-viscous to hyperelastic state [8]. At $c \cong c_{cr.2}$, the associates are closely packed in the solution. A polymer film prepared from this solution shrinks to a lesser extent. In this case, the internal stresses in the adhesive film decrease and the adhesion-strength properties are improved. At $c > c_{cr.2}$, a fluctuation network of macromolecular contacts is formed [8]. When a continuous fluctuation network of contacts is formed in a solution, its viscosity sharply increases (Fig. 1, curve *1*). This solution is difficult to apply to a fabric. It does not noticeably penetrate into pores of fabric fibers and is located on the filament surface. As a result, adhesion of the composite decreases owing to poor adhesion of the polymer molecules to fibers of both backing and doubled fabric, since the structure of the polymer solution is retained in the film prepared from this solution [9].

It is known than the unfolded conformation of the polymer chain is favorable for interaction of the polymer with the substrate surface, whereas the globular conformation formed, e.g., in a "bad" solvent prevents formation of sufficiently large number of contacts, thus decreasing the adhesion. As seen from Table 4, the adhesion of the copolymer applied from a solution in a bad solvent (isopropanol) is lower. The quality of solvents with respect to the copolymers was estimated

* $\delta_{COP} = \Sigma \delta_i \varphi_i$, where φ_i is the volume fraction of the monomer in the copolymer and δ_i is the solubility parameter of the homopolymer [10].

** δ for propanol.

by comparison of the solubility parameters of the copolymer and solvent [10]. As seen from Table 4, the viscosity of a solution in a bad solvent is higher than that in a good solvent (ethyl acetate). As noted above, the more structured solution is nonuniformly applied onto the fabric and lower amount of the polymer penetrates into pores of fabric fibers.

CONCLUSIONS

(1) To increase the adhesion to cellulose fabric (coarse calico) of butyl methacrylate copolymer applied from a copolymer melt, hydroxyl-containing vinyl acetate and acrylic units should be introduced into the copolymer macromolecules, the copolymer molecular weight should be higher, the polymer amount in the adhesive layer should be larger, and the viscosity of the adhesive melt should be lower.

(2) The structural rheological state of a copolymer solution applied to the backing fabric affects the adhesion of cellulose fabrics glued by copolymer melts. Adhesive melts prepared from solutions being in the transition from the structured-viscous to hyperelastic states have the best adhesion to cellulose fabrics.

(3) Copolymer solution in solvent good for the copolymer should be used to prepare adhesives with high adhesion to fabrics.

Abstract—The influence of various factors on degradation of wood cellulose with Lewis acids was studied. The physicochemical characteristics of the resulting products were analyzed.

DOI: 10.1134/S1070427208010321

Reactions of monosaccharides catalyzed by Lewis acids (MX_n) are well studied and widely used [1]. In chemistry of polysaccharides, Lewis acids are used less extensively. They are mainly used as highly effective catalysts for cellulose degradation. Previously [2, 3] conversion of cotton cellulose in the presence of Lewis acids was studied and possible application fields for the synthesized powder celluloses were outlined. The use of water-free procedures is a promising pathway for production of powder celluloses. The use of organic solvents in the course of the reaction and their subsequent regeneration allows a decrease in the expenditure of pure water and in the volume of wastewaters.

Wood cellulose differs from cotton cellulose by the presence of residual hemicelluloses and lignin. It is used for production of powder cellulose for technical purpose. For this purpose, it is degraded in an aqueous medium at a high liquid-to-solid ratio and an excess of sodium hypochlorite. The use of Lewis acids and anhydrous media for production of powder celluloses can essentially improve the product purity. The use of wood raw materials for this purpose can significantly reduce the cost of the process and impart new properties to the cellulose material.

Here we studied the influence of various factors on degradation of wood cellulose with the use of Lewis acids and analyzed physicochemical characteristics of the resulting products.

EXPERIMENTAL

The object of the study was deciduous kraft bleached cellulose produced by the Syktyvkar Timber Industry Association, Joint-Stock Company. Before treatment, the cellulose was separated into single fibers to provide the highest homogeneity in size. Aluminum chloride, aluminum bromide, and titanium tetrachloride were used as Lewis acids (MX_n). $AlCl_3$ and $AlBr_3$ were synthesized by the standard procedure [4]. Before use, the sample stored for more than one year was purified by sublimation at atmospheric pressure. The sample stored for more than two years was purified by simple distillation. To prepare $TiCl_4$ we used commercial titanium tetrachloride of pure grade, which was purified by simple distillation at atmospheric pressure [4]. The reaction was performed in anhydrous organic solvents (carbon tetrachloride, hexane, and ethanol) at their boiling points. A weighed portion of cellulose dried at 105°C was placed into a conical flask and poured over with a solution of freshly prepared Lewis acid for a certain period of time. Aluminum chloride: a 1.99-g weighed portion of cellulose was treated with 50 ml of 0.1–0.005% solution in CCl_4. Titanium chloride: a 1.65-g weighed portion of cellulose was treated with 100 ml of 1.0–0.005% solution in CCl_4. Depending on the concentration of Lewis acid in the solution, the weight ratio MX_n : cellulose was from 1 : 2.5 to 1 : 500 (Table 1). After a lapse of time, cellulose was transferred onto a glass frit, the solution was filtered, and the residual catalyst was washed out with the same solvent, included with ethanol, and dried in an oven. The degree of degradation was judged from variation of the average degree of polymerization (DP) of the samples determined from their viscosity in aqueous solutions of Cadoxen [5].

In the experiments we varied the concentration of Lewis acids, treatment duration, weight ratio

Table 1. Influence of the concentration of Lewis acid on the degree of polymerization of cellulose

$AlCl_3$–C_2H_5OH, 78.3	120	150	230	330	420	–
$TiCl_4$–C_2H_5OH, 78.3	160	240	360	–	–	–
$AlBr_3$–C_2H_5OH, 78.3	240	330	–	–	–	–

MX_n : cellulose, and conditions of drying the samples. Data on the influence of Lewis acid concentration on the degree of polymerization of cellulose powders (treatment duration 120 min) are presented in Table 1. The degree of polymerization of the initial cellulose was 580.

All systems of metal halides with a concentration of 1.0% exhibit high catalytic activity. The degree of polymerization of cellulose is 180–240, which corresponds to the limiting value for microcrystalline cellulose prepared by the "classic" procedure [6]. After treatment the cellulose samples are in the form of powders.

At low concentrations of the catalysts (0.01–0.10%), the most active degrading agents are metal chlorides: $AlCl_3$ in CCl_4 and $TiCl_4$ in C_6H_{14}. The less active catalyst is $AlBr_3$ in C_2H_5OH: at its concentration lower than 1.0% the attempts to prepare powder cellulose failed, because at DP higher than 330 the cellulose particles preserved the structure of microfibers and were not friable.

The solvent significantly affects cellulose degradation (Table 1). The DP reaches the smallest values in nonpolar solvents (C_6H_{14} and CCl_4) and the largest values, in a protic solvent (C_2H_5OH). These results are in good agreement with data for cotton cellulose [7].

The kinetic curves of cellulose degradation are presented in Fig. 1. For comparison, data on degradation of the same raw materials in hydrolytic treatment are also presented. These data suggest that the degree of cellulose degradation, compared to the hydrolytic treatment, is higher in nonpolar solvents and lower in polar solvents.

It was shown previously [8] that an increase in the contact time of cellulose with Lewis acid leads to a certain increase in the product weight, because washing of the samples with solvent does not ensure complete removal of the catalyst from cellulose. In subsequent additional drying of cellulose in an oven, metal chlorides induce its further degradation. This fact made it necessary to study the effect of metal chlorides on the degradation process. As follows from Table 2, the choice of drying conditions significantly affects DP of cellulose. An increase in DP was observed for the samples obtained as a result of cellulose degradation in CCl_4 and then subjected to drying in a chamber with removal of the $AlCl_3$ residue.

Washing with the solvent decreases DP of cellulose with subsequent drying in a chamber. The use of additional heating for the powders obtained after cellulose treatment in the $AlCl_3$–CCl_4 medium at two levels of the catalyst concentration increased the degree of degradation by a factor of 2, and samples with very low values of DP (60 and 100) were obtained. In the systems with ethanol, DP of the samples decreased at any modes of additional heating.

The reuse of the catalytic solution after filtration showed that the reagent dissolved in nonpolar solvents

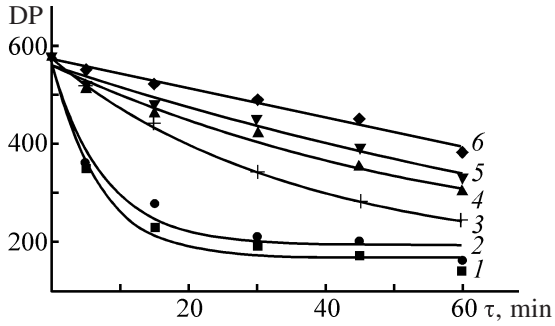

Fig. 1. Degree of polymerization of powder cellulose DP as a function of conditions of catalytic degradation. (τ) Time. 	120	200	400	100	540
1.0% $AlCl_3$ in C_2H_5OH	30	320	280	190	340
	60	240	200	150	300
	120	120	180	110	260
0.1% $AlCl_3$ in C_2H_5OH	30	420	380	340	460
	60	300	220	170	420
	120	150	200	120	400

is consumed practically completely, whereas the reagents dissolved in ethanol react significantly more slowly and in reuse the system exhibits weak catalytic activity, probably due to dehydration of the treated polysaccharides.

Whiteness is a significant factor of the cellulose quality. The results of studying the influence of temperature on the DP and whiteness of the powder cellulose samples obtained in anhydrous organic media after washing off the acid catalyst are presented in Table 3. For comparison, data on cellulose subjected to hydrolytic treatment are presented. The whiteness of cellulose was measured on an FKTsSh-M double-beam photometer. Under these conditions, the hydrolysis duration does not noticeably affect the whiteness of powder cellulose, and additional heating at 100°C has virtually no effect on its DP.

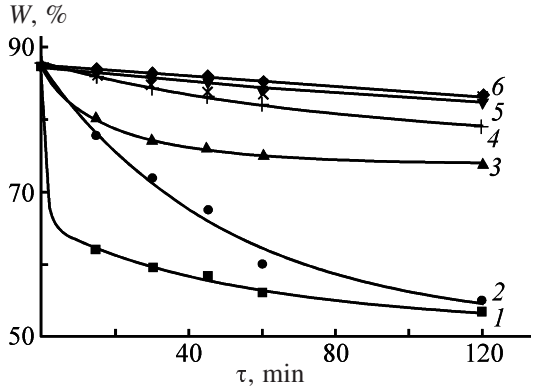

Fig. 2. Whiteness of powder cellulose W as a function of treatment duration τ. Catalytic system (content 0.1 wt %), temperature, °C: (*1*) $TiCl_4$–CCl_4, 76.7; (*2*) $AlCl_3$–CCl_4, 76.7; (*3*) $TiCl_4$–C_6H_{14}, 68.8; (*4*) $AlCl_3$–C_2H_5OH, 78.3; (*5*) $TiCl_4$–C_2H_5OH, 78.3; and (*6*) $AlBr_3$–C_2H_5OH, 78.3.

As a rule, in treatment of cellulose with Lewis acids, its degradation is accompanied by decrease in whiteness. This trend is particularly pronounced for the samples of powder cellulose prepared with using $TiCl_4$. The apparent change in color can be explained by formation of the complex MX_n–cellulose. The decrease in whiteness of cellulose as a result of the action of $TiCl_4$ and $AlCl_3$ is particularly significant with catalysts in CCl_4. This is illustrated by Fig. 2.

An increase in the MX_n concentration from 0.01 to 1.00 wt% is favorable for faster and deeper decrease in cellulose whiteness. The darkest samples of cellulose powders were obtained after treatment of cellulose in the $TiCl_4$–CCl_4 medium throughout the entire range of catalyst concentrations (Fig. 3).

To evaluate the influence of Lewis acid expenditure on the DP of cellulose, we varied the liquid-to-solid ratio ($cm^3\ g^{-1}$) at the initial concentration of $TiCl_4$ in C_6H_{14} equal to 0.1%. The reaction was carried out in a thermostat at the boiling point of the solvent. In one case, the weighed portion of cellulose (1.65 g) was placed into a conical flask containing 100 ml of degrading solution, and, in the other case, a weighed portion of cellulose (0.34 g) was placed

Table 3. Influence of additional thermal treatment on the depth of degradation and whiteness of cellulose powders in various catalytic systems

Degrading medium	Treatment time, min	Degree of polymerization of samples		Whiteness,* %

* After treatment and drying in air.

into an ampule and impregnated with 1 ml of the degrading solution. In this case, the liquid-to-solid ratios were 60 : 1 and 3 : 1, and the ratios MX_n : cellulose were 1 : 25 and 1 : 500, respectively (Fig. 4).

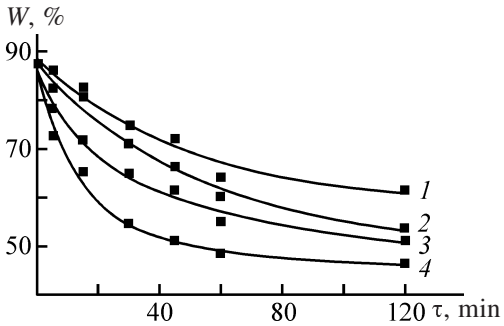

Fig. 3. Whiteness of powder cellulose W as a function of treatment duration τ in the system $TiCl_4$–CCl_4 at various catalyst concentrations c. Degradation at T = 76.7°C, the samples were dried at T = 100.0°C for 120 min. Catalyst concentration, wt %: (*1*) 0.01, (*2*) 0.10, (*3*) 0.30, and (*4*) 1.0.

Figure 4 shows that an increase in the liquid-to-solid ratio is favorable for significant decrease in the DP of cellulose. The minimum value of DP reaches 85 (curve *1*) and 390 (curve *2*).

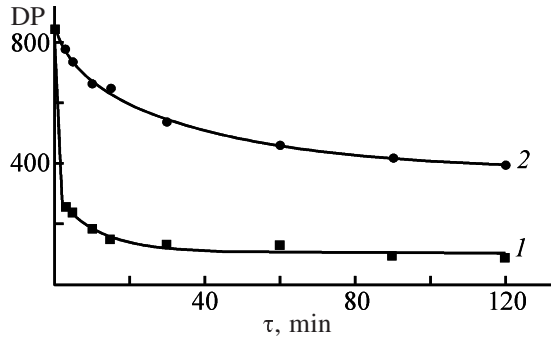

Fig. 4. Degree of polymerization DP of powder celluloses as a function of duration τ of treatment with 0.1% $TiCl_4$ in hexane at liquid-to-solid ratio of (*1*) 60 : 1 and (*2*) 3 : 1.

CONCLUSIONS

(1) Lewis acids $AlCl_3$ and $TiCl_4$ in CCl_4 and C_6H_{14} exhibit high catalytic activity at catalyst concentration of 0.01–0.1 wt%. As a result of treatment of cellulose in nonpolar solvents for a short time, products with the degree of polymerization two times lower than that after acid hydrolysis can be obtained.

(2) In drying of the samples, excess Lewis acid leads to an increase in the degree of polymerization due to probable cross-linking of cellulose chains. The formation of the complex MX_n–cellulose is accompanied by darkening of the product and depends on the acid concentration.

Received July 3, 2007

Abstract—Spatial distribution of gold nanoparticles obtained by vacuum deposition on the surface of amorphous polymers was studied within the limits of the cluster lattice model.

DOI: 10.1134/S1070427208010333

The formation of condensed phase particles on a solid surface can be random, independent of the topological structure of the substrate, or can preferentially occur on active centers of the surface interacting with adsorbed particles [1, 2]. Such centers can be presented by structural defects of the surface and also sites with an enhanced energy and noncompensated electric charge, where, as a rule, essential local fluctuations of electron density take place [2]. The preferential formation of particles on active centers results in decoration of the substrate surface, i.e., special features of its microstructure are revealed. This finds use in the analysis of the topology of solid surfaces [3].

Of special interest is the use of vacuum deposition of gold for the decoration of the surface of amorphous and semicrystalline polymers [4]. The decoration of nano- and microdefects on the surface of polymers favors revealing both well pronounced irregularities of a geometrical microrelief, e.g., dislocations on a surface of polymeric crystals [5], and heterogeneity of an energy microrelief, e.g., impurity inclusions, sites of localization of reactive functional groups, density fluctuations of macromolecular packing, etc. [4].

At present, structural microheterogeneity of amorphous polymers is associated either with density fluctuations or with a cluster structure of an object [6]. Usually by clusters are meant fractal aggregates of structural units (in case of polymers, blocks of segments of macromolecules) having a higher local density compared to an average density of a substance [7, 8]. Amorphous films obtained from solutions of flexible-chain polymers are characterized by heterogeneity of the supramolecular scale, caused by density fluctuations arising owing to the irreversible transition from a solution to a solid state of the polymer [9]. Density fluctuations have a scale-invariant character and can be described within the limits of the model of fractal clusters [10, 11].

Cluster microheterogeneous structure of amorphous polymers causes the heterogeneous character of the surface energy microrelief and substantially influences initial stages of the formation and growth of decorating gold particles [12, 13]. Most of defects of amorphous polymers are associated with density fluctuations of packing of macromolecules and are localized on boundaries of the clusters [8]; therefore, the topography of decorating particles is connected with the profile of a planar density distribution on the polymeric support surface.

The character of the adsorption defines the dependence of density fluctuations $\langle\sigma^2\rangle/\langle N\rangle$ of a spatial distribution of adsorbed particles on the degree of filling of the substrate surface with these particles [14]. The dependences of $\langle\sigma^2\rangle/\langle N\rangle$ on the fraction θ of the surface area covered by adsorbed particles were determined by computer simulation of various mechanisms of the adsorption of dispersed phase particles on a solid surface [14, 15]. The random surface filling with the particles corresponds to the random adsorption (RA) model [16], for which dependence [14] is valid:

$$\langle\sigma^2\rangle/\langle N\rangle = 1 - 4\theta + 3^{1/2}/\pi\theta^2 + o(\theta^3), \qquad (1)$$

where $o(\theta^3)$ is a value of the third infinitesimal order.

This dependence was confirmed experimentally by studying the adsorption of small particles of polymeric latexes from dilute solutions on a solid substrate [15].

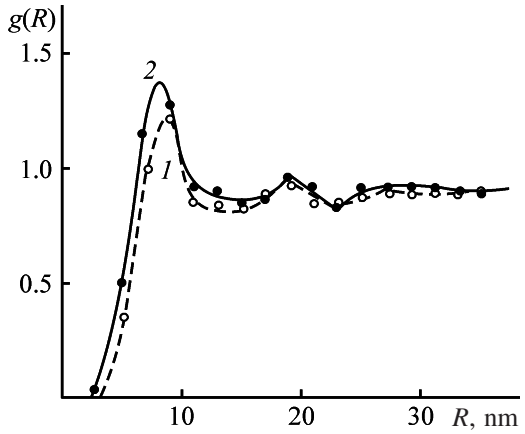

Fig. 1. Distribution functions $g(R)$ of gold nanoparticles on the surfaces of (*1*) PS and (*2*) CTA films.

In the case of adsorption in an external potential field, e.g., the adsorption of heavy particles in a gravitational field, the ballistic adsorption model [17] is valid. According to this model, the dependence of $\langle\sigma^2\rangle/\langle N\rangle$ on θ is of form (2) [14]:

$$\langle\sigma^2\rangle/\langle N\rangle = 1 - 3.16\theta^3 + 2.3\theta^4 + o(\theta^5). \qquad (2)$$

In this study we used the cluster lattice model to study the spatial distribution of gold nanoparticles of size 1–15 nm, obtained by vacuum deposition on a surface of films formed from polystyrene (PS) and cellulose triacetate (CTA) solutions. The aim of the study was to examine the effect of the cluster structure of the polymer surface in the steps of the formation and growth of decorating gold particles.

EXPERIMENTAL

In the work we used samples of X-ray amorphous PS and CTA films of 60 μm thickness. The films of linear atactic PS (molecular weight $M_n = 9 \times 10^6$) and partially hydrolyzed CTA (degree of polymerization 300, degree of substitution 2.85) were obtained from solutions of the polymers in chloroform (PS concentration 0.72 g dl^{-1}) and in a 9 : 2 methylene chloride : ethanol mixture (CTA concentration 10 wt %) on a leveled plate glass at 298 K. According to the capillary viscometry, the concentration of polymers in the solution corresponded to the formation of a continuous fluctuational network of macromolecular contacts [18].

Polystyrene belongs to typical flexible-chain polymers, whereas CTA macromolecules, in turn, are rigid-chain polymers and form anisotropic ordered assemblies of the microdomain type in boundary layers [19].

Single vacuum depositions of gold (vacuum 0.00133 Pa, flux level 10^{15}–10^{16} cm^{-2} s^{-1}, effective layer thickness 0.4 nm) were carried out on the surface of films formed on the boundary with air. Gold particles, which were separated from the films using supporting carbon replicas, were studied with an EMV-100L electron microscope. The electron micrographs for computer treatment were obtained at a 500 000 magnification.

The radial distribution function $g(R)$ of gold nanoparticles was determined by step-by-step scanning of the density ρ of particle distribution (at δ = 2 nm steps) on a micrograph [4, 12].

Aggregates of gold nanoparticles on the surface of films were represented as clusters on a two-dimensional lattice [10] with an interstitial distance corresponding to the most probable distance r between particles. The coordination number m of the quasilattice was determined from the $g(R)$ functions as an average number of the nearest neighbors around an arbitrarily selected particle [20].

According to [13], the relative distribution function ρ_l of m for points of a two-dimensional regular lattice is expressed as

$$\left.\begin{aligned} \rho_l &= 0.77/r^2 \text{ for } m = 3, \\ \rho_l &= 1/r^2 \text{ for } m = 4. \end{aligned}\right\} \qquad (3)$$

The functions $g(R)$ for the distribution of gold nanoparticles on the surfaces of PS and CTA films are shown in Fig. 1. The coordination number m of the two-dimensional quasilattice takes the value m = 3 for PS (hexagonal lattice) and m = 4 for CTA (square lattice). The density ρ of the distribution of the complete ensemble of nanoparticles practically corresponds to the density ρ_l of two-dimensional regular lattice points calculated by relationships (3), which allows us to use the lattice model for the description of the spatial distribution of particles.

In this study we have carried out a computer simulation of the process of sequential filling of a lattice (surface) with gold nanoparticles as their size increases. For this purpose an ensemble of particles on micrographs was separated into classes according to their maximum linear size l at 1-nm intervals. For each group of classes limited by a value of l, we calculated the degree $\rho_s(l)$ of filling of a two-dimensional quasilattice with particles, or the lattice density of clusters: $\rho_s(l) = \rho(l)/\rho$, where $\rho(l)$ is the density func-

tion of particles with sizes not exceeding l, and ρ is the density function of the complete ensemble of particles.

To analyze the character of surface filling with gold nanoparticles, we used the scheme of the percolation along bound circles with centers located in particles [20]. Figure 2 shows the dependences of the weight-average size $\langle n^2\rangle/\langle n\rangle$ of the clusters of bound circles with centers in particles on the dimensionless radius of circles $R\rho(l)^{1/2}$. These dependences were obtained for isolated groups of separated classes of particles. At l = 1–11 nm for a PS sample and l = 1–5 nm for CTA, the semilog plots of $\langle n^2\rangle/\langle n\rangle$ vs. $R\rho(l)^{1/2}$ have a break point which shows that gold nanoparticles are distributed on the substrate surface as separate aggregates, i.e., discrete clusters. At $l \geq 12$ (PS) and $l \geq 6$ nm (CTA), infinite clusters of particles exist, and the dependences monotonically ascend according to the law $\langle n^2\rangle/\langle n\rangle \sim (R_p - R)^{-\gamma}$, where n is the number of circles in a cluster; R_p, radius of a circle corresponding to the percolation cluster; the critical exponent $\gamma = 2.4 \pm 0.2$ [21].

The transition from finite clusters to an infinite cluster takes place at the $\rho_s(l)$ value equal to the percolation threshold p_c. For the lattice clusters of gold nanoparticles on the PS film surface (m = 3), the percolation threshold, $p_c \approx 0.65$, corresponds to that in the case of the random filling of a hexagonal lattice [10]. In the case of CTA sample, $p_c \sim 0.75$. This value is higher than the percolation threshold at random filling of the square lattice (p_c = 0.59 [10]). In this case, the positions of "point" gold nanoparticles of a size $l \leq 5$ nm are correlated with each other (nanoparticles are localized as separate chains) and form discrete fractal clusters with the correlaton radius $\xi \approx 20$ nm and fractal dimension $D = 1.25 \pm 0.05$.

The fractal dimension D of clusters was calculated from the slope of the log–log plot of the average lattice density $\rho_s(l, R)$ of gold nanoparticle clusters in a circle of radius R with the center in the particle vs. R. Such dependences obtained for separate groups of classes of particles with sizes limited by the l value are shown in Fig. 3. The density of the lattice clusters decreases as the radius R of a scale increases according to the law $\rho_s(l, R) \sim R^{D-2}$. The scale value of R corresponding to the position of the break point of the dependences fits the average correlation radius ξ of clusters [10].

Clusters of the "point" gold nanoparticles are localized inside a set of homogeneously distributed larger particles. The presence of clusters (chains) of

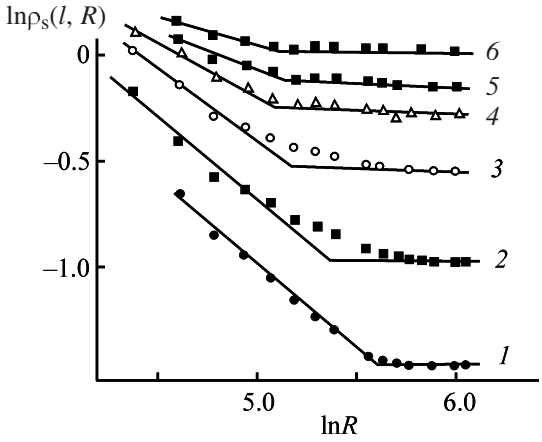

Fig. 3. Dependence of the lattice density $\rho_s(l, R)$ of clusters of gold nanoparticles on the scale R in log–log coordinates for the CTA film surface. l, nm: (*1*) 2, (*2*) 3, (*3*) 4, (*4*) 5, (*5*) 6, and (*6*) 8.

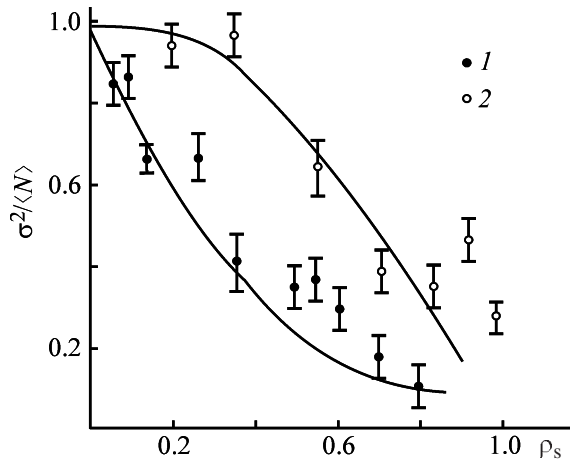

Fig. 4. Dependence of fluctuations $\langle\sigma^2\rangle/\langle N\rangle$ of the density function of gold nanoparticle on the degree ρ_s of lattice filling with the particles for the films of (*1*) PS and (*2*) CTA. Lower line: dependence (*4*) for the RA adsorption model; upper line: dependence (*5*) for the ballistic adsorption model.

point gold nanoparticles is caused by their preferential formation on the structural defects located on boundaries of close-packed aggregates of macromolecules or microdomains with the average size of about 20 nm. This size of microdomains corresponds to the size of scattering particles in the CTA film (16–26 nm), calculated from the data of small-angle X-ray scattering [22]. The size of microdomains is close to the value of Kuhn's segment for cellulose acetates (25–30 nm [23]). Defects on the polymer surface stabilize gold nanoparticles formed by vacuum deposition and hinder their further coalescence.

The value of fluctuations $\langle\sigma^2\rangle/\langle N\rangle(l)$ of the density function of particles for each set of the separated classes was calculated by the procedure from [14], and, to compare the resulting dependences of $\langle\sigma^2\rangle/\langle N\rangle(l)$ on $\rho_s(l)$ with model dependences (1) and (2), these latter were reduced to the form $\langle\sigma^2\rangle/\langle N\rangle(\rho_s)$ as follows. When the relationships $\theta/\theta_{max} = \rho_s$ (θ_{max} is the maximal degree of coverage of the surface by adsorbed particles), $\theta_{max} = 0.547$ for the RA model, and $\theta_{max} = 0.611$ [14, 15] for the ballistic adsorption model are taken into account, dependences (1) and (2) take forms (4) and (5) for RA and ballistic models, respectively:

$$\langle\sigma^2\rangle/\langle N\rangle = 1 - 2.19\rho_s + 1.32\rho_s^2, \quad (4)$$

$$\langle\sigma^2\rangle/\langle N\rangle = 1 - 0.72\rho_s^3 + 0.32\rho_s^4. \quad (5)$$

The dependences of the fluctuations $\langle\sigma^2\rangle/\langle N\rangle(l)$ of the density of the spatial distribution of gold nanoparticles on the degree $\rho_s(l)$ of the filling of PS and CTA film surfaces with these nanoparticles are shown in Fig. 4. The dependence of $\langle\sigma^2\rangle/\langle N\rangle(l)$ on $\rho_s(l)$ for the PS film corresponds to the RS adsorption model and random filling of the surface with particles. In the case of the CTA film, this dependence corresponds to the ballistic adsorption model in an external potential field. Such a field is the potential field of the surface defining the character of the interaction of adsorbed gold nanoparticles with CTA macromolecules. Deviations from model dependences (4) and (5) in Fig. 4 appear when the size of gold nanoparticles increases. They are caused by a change of the mechanism of their growth during the vacuum deposition of the metal on transition from the particle–adsorbed atom interactions to the particle–particle interactions, resulting in the coalescence of particles.

CONCLUSIONS

(1) The profile of the energy microrelief of the amorphous polymer surface, defined by its cluster microheterogeneous structure, predetermines the features of the spatial distribution of decorating gold nanoparticles obtained by vacuum deposition on the surface under study. The ballistic adsorption mechanism and the cluster type of the spatial distribution of particles correspond to the preferential formation of nanoparticles on active surface centers (structural defects).

(2) The mechanism of the adsorption of decorating nanoparticles defines the character of the dependence of density fluctuations of nanoparticle ensembles selected according to their values on the degree of filling of the surface with these nanoparticles.

(3) The smoothed energy microrelief of a polymer surface leads to random adsorption and random distribution of nanoparticles, which was shown by the example of a polystyrene film. In this case, to reveal in detail the topology of the cluster surface structure, a modification of the surface by additional active centers of the decorating particle formation is required.

Abstract—Chemical purification of cobalt powders to remove iron, silicon, copper, and sodium with complexing oxalate ions was studied.

DOI: 10.1134/S1070427208010345

Modern industrial processes employing powdered cobalt impose stringent requirements to its purity. Therefore, development of processes for cobalt purification to remove iron, silicon, manganese, copper, sodium, and calcium is exceedingly important. Most frequently, processes of this kind are employed in reprocessing of secondary raw materials (worked-out hard-alloy tools, catalysts, contaminated powders, etc.).

The known, in hydrometallurgy of cobalt, practice of cobalt treatment to remove iron, with lime or soda used to neutralize acid solutions and atmospheric oxygen serving as an agent that oxidizes Fe(II) [1], cannot be employed to obtain an ultrapure cobalt powder because of its contamination with sodium and calcium. Moreover, oxidation of iron with atmospheric oxygen is prolonged and inefficient.

The known technique for processing of secondary raw materials to obtain a cobalt powder employs soda for neutralization of the working solution [2]. In [3], the procedure by which powders were obtained from worked-out cobalt cathodes in deposition of iron and manganese used sodium chlorate and hypochlorite, caustic soda, and soda ash. In this case, the final product is also contaminated with sodium. In the techniques developed, iron is separated from solution in the form of a poorly filterable Fe(III) hydroxide, which poses certain technological difficulties. In addition, the freshly precipitated Fe(III) hydroxide sorbs cobalt from solutions, which leads to its loss.

This study was devoted to a search for new ways to solve the problem of cobalt refining. A possible way was to use complexing agents. Substances of this kind make it possible to obtain complex metal compounds with widely diverse physicochemical properties. It was necessary to determine whether Co can be recovered from an acid solution by choosing such a complexing agent with which Fe and other impurities would remain in solution, i.e., by reversing the order in which two basic procedures of the process are performed. This cannot be done using the hydroxide technique, whereas complexing agents can probably provide the desired effect.

It was found that the complexing agents best suitable for resolving this problem are carboxylic acids and their salts, e.g., oxalic acid and ammonium oxalate. These compounds cannot contaminate the cobalt powder with sodium, and Fe(III) oxalate is a stable complex well soluble in water. Carbon monoxide released in thermal reduction of cobalt oxalate to a metallic powder is involved in the reduction process, which saves hydrogen.

To perform the process, it was necessary to choose an oxidizing agent appropriate for Fe(II) oxidation to Fe(III) in an acid medium. Hydrogen peroxide was found to be the best suitable. Comparison of the standard potentials of the redox reactions

$$H_2O_2 + 2H^+ + 2e \rightarrow 2H_2O, \quad E_0 = 1.77\ V, \quad (1)$$

$$Fe^{2+} \rightarrow Fe^{3+} + e, \quad E_0 = 0.77\ V, \quad (2)$$

$$Co^{2+} \rightarrow Co^{3+} + e, \quad E_0 = 1.81\ V \quad (3)$$

shows that hydrogen peroxide is an effective agent for Fe(II) oxidation in an acid medium, with the potential of Co(II) → Co(III) oxidation not reached. Furthermore, hydrogen peroxide does not contaminate the final product and its excess amount is easily removed from solution. If oxalate ions are used as a complexing agent, it is important to analyze the state and mutual influence of the forming oxalates CoC_2O_4 and $Fe_2(C_2O_4)_3$.

Content of impurity elements in the starting cobalt powder and that after refining

Powder	Precipitant	Content of impurities, wt %				
		Fe	Ni	Si	Cu	Na
Starting	–	3.5	≤0.01	0.01	0.03	0.04
After refining	$(NH_4)_2C_2O_4$	<0.01	≤0.01	≤0.05	Trace amounts	Not found
	$H_2C_2O_4$	<0.01	≤0.01	≤0.05		

It is known that CoC_2O_4 is a poorly soluble substance (SP = 6.3×10^{-8}), whereas $Fe_2(C_2O_4)_3$ is well soluble in water [4]. Therefore, the former precipitates, whereas the latter remains in solution. Presence of free oxalic acid in solution makes lower the solubility of cobalt oxalate in an acid medium [5]. It should be noted that, in an acid medium, oxalic acid is a weak reducing agent:

$$H_2C_2O_4 + 6H^+ + 6e \rightarrow 2H_2O + CH_3COOH,\ E_0 = 0.31\ V, \quad (4)$$

but in the presence of a strong oxidizing agent (H_2O_2) it cannot reduce Fe(III) to Fe(II). For the same reason, the photochemical reaction of Fe(III) reduction by $C_2O_4^{2-}$, used in manufacture of photographic paper, is impossible. Hydrolysis of Fe^{3+} ions does not occur, either, because of the sufficiently acid medium and the stability of the complex $Fe_2(C_2O_4)_3$.

If secondary cobalt is contaminated with manganese, it can be seen from a comparison of the solubility products of their oxalates, equal to 2.0×10^{-6} and 6.3×10^{-8}, respectively, that the solid phase of cobalt oxalate will be the first to precipitate from solution, and the relative content of Mn in the solid phase will be lower than that in solution.

These facts demonstrate that cobalt can be purified by using oxalate ions as a complexing agent and hydrogen peroxide as an oxidizing agent. A test in cobalt refining confirmed this suggestion.

A cobalt powder contaminated with iron was chosen as object of study. The contents of impurities are listed in the table.

The experiments wee carried out as follows. Weighed portions of cobalt (10.0 g), containing 3.5 wt % Fe, were dissolved in 85 ml of HCl (1 : 1) under agitation with a magnetic stirrer. After complete dissolution, 2.5 ml of a 30% hydrogen peroxide solution was added to each sample and the mixtures were agitated and kept for 0.5 h (solution 1). Then, 16.7 g of ammonium oxalate was dissolved in hot water (solution 2), which constitutes a 20% excess with respect to stoichiometry (in terms of Co and Fe), and solution 2 was slowly poured into a solution 1, heated to 80 ± 5°C. The cobalt oxalate precipitate formed was filtered off on a nutsch filter and thrice washed first with water acidified with oxalic acid and then with pure warm water, and dried at 120 ± 5°C for 0.5 h. The precipitate obtained was thermally reduced in hydrogen at 750 ± 20°C. The final product was finely dispersed pure cobalt powder, whose impurity content is presented in the table. It can be seen that the procedure developed allows cobalt purification to remove iron, silicon, copper, and sodium to residual concentrations lower than those regulated by GOST (State Standard) 9722–97 for a powder of PK-1u brand, which makes it possible to class the product with ultrapure powders. The content of nickel cannot be lowered because the solubility product of its oxalate is two orders of magnitude smaller than that of cobalt oxalate.

CONCLUSIONS

(1) A technique for chemical refining of cobalt with complexing oxalate ions was developed.

(2) The technique does not use any sodium- or calcium-containing reagents that could contaminate cobalt.

(3) The cobalt refining is performed in two steps, which simplifies it to the maximum possible extent.

Abstract—Possibility of using electrodialysis for controlling the content of ions in structuring of silk fibroin in a shear flow was studied.

DOI: 10.1134/S1070427208010357

Fibrous wastes of fibrillar proteins can be processed into polymeric materials in solutions in the presence of ions of salts, acids, and alkalis [1]. However, presence of ions in solution hinders formation of bonds between macromolecules when a three-dimensional structure of proteins is formed in a flow. The ions can be subsequently removed from the solutions by electrodialysis, and application of this technique is of practical interest [2].

The present study was concerned with the effect of electrodialysis of salt ions on the structuring of fibrillar proteins in a shear flow for the example of the fibroin of real silk.

EXPERIMENTAL

An installation for carrying out the experiments was fabricated on the basis of the Rheotest-2 instrument (Germany) with a cylinder–cylinder working unit (Fig. 1). A cylindrical cellulose hydrate membrane (*2*) was mounted between carbon electrodes (*1, 1'*) fixed in parallel in a glass cylinder. A glass cylinder (*3*) rotated by electric motor (M) was coaxially mounted within the membrane cylinder. The spacing between the cylinders, filled with a solution of silk fibroin (*4*), was about 3 mm. A polarization beam was passed through this space in order to determine the macromolecule orientation factor β in the flow with a polarization microscope (PM):

$$\beta = (\Delta n/\Delta n_\infty)^{0.5}, \quad (1)$$

where Δn is the current birefringence, and Δn_i, the maximum possible birefringence [3].

The direction in which ions *6* move across the membranes toward the electrodes submerged in the dialyzate coincides with the direction in which protein molecules are deformed by the centrifugal force $F_c = V\rho\omega^2 r$ (V is the volume of the solution; ρ, its density; ω, angular rate of rotation; and r, distance from the rotation axis).

The fluidity ρ_r of the fibroin solution was found by the Margules formula [2], with the rate of cylinder rotation controlled by the electric motor

$$\tau_r = 1/\eta_r \approx 2\pi\omega h R^3/bM, \quad (2)$$

where η_r is the solution viscosity; h, cylinder height; $R = (R_1 + R_2)/2$, hydrodynamic cell parameter (R_1 is the radius of the inner glass cylinder, and R_2, that of the outer membrane cylinder); b, distance between the cylinders; and $M = rF_c$, torque.

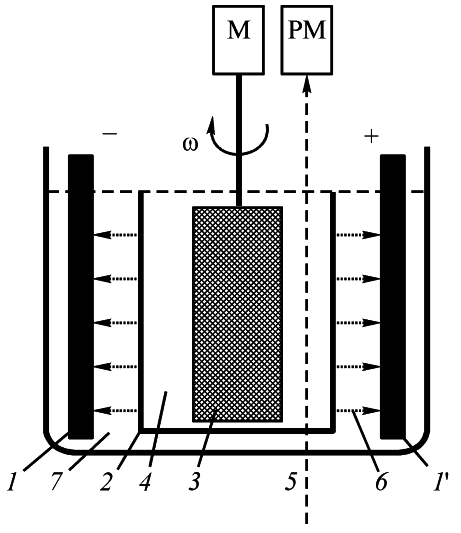

Fig. 1. Schematic of electrodialysis of ions in a shear flow of ion-containing solutions of fibrillar proteins. For explanations, see text.

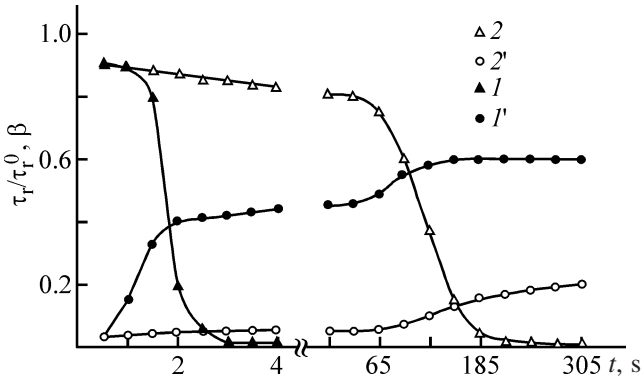

Fig. 2. (*1, 2*) Relative fluidity τ_r/τ_r^0 and (*1'*, *2'*) orientation factor β vs. time *t* of (*1, 1'*) electrodialysis and (*2, 2'*) dialysis of ions in a shear flow of the fibroin solution.

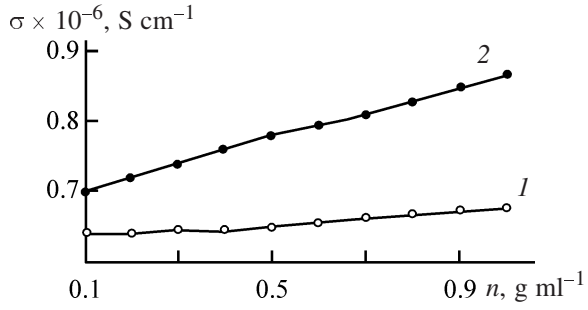

Fig. 3. Electrical conductivity σ vs. concentration *n* of residal ions in gel-plastics of fibroin at (*1*) 25 and (*2*) 50°C.

The variation of the dynamics of solution fluidity was found by comparison with the initial fluidity τ_r^0. The ratio $\tau_r/\tau_r^0 \to 0$ characterizes the loss of the independent flow of solutions on their transformation to the gel-like state.

The electrodialysis was performed for a 10% solution of fibroin in 2.5 M LiCl–DMF, with water used as a dialyzate. The efficiency of electrodialysis was evaluated by comparison with an ordinary dialysis of ions in a flow.

Figure 2 shows how the relative fluidity τ_r/τ_r^0 and the orientation factor β depend on the electrodialysis time. The curves are S-shaped, which is characteristic of a non-Newtonian flow of the solutions.

It was found that, in the course of electrodialysis ($I \approx 5$ mA) of solutions ($V \approx 50$ cm^3) subjected to a permanent shear stress (100 N m^{-2}), the fluidity steeply decreases in the time interval 100–150 s, to become zero at $t > 180$ s (Fig. 2). The results of birefringence measurements demonstrated that the macromolecule orientation factor starts to grow considerably earlier in the case of electrodialysis of ions (curves *1'*), compared with ordinary dialysis (curves *2'*). Consequently, electrodialysis accelerates the formation of intermolecular interactions of the chains being deformed in the shear field, with a controlled content of ions in solution.

Because the gelation of the solutions in electrodialysis of ions develops in the course of 120 min, the value $\beta \approx 0.4$, reached during this time, indicates that macromolecules are contained in gels in a rather ordered state. Further action of the shear field markedly raised the degree of deformation-induced ordering of proteins and resulted in that a value $\beta \approx 0.6$ was reached, with phase separation occurring in the solution. A compressed gel-like phase was formed near the membrane wall as a gel-plastic. This sample preserved its structure after the shear flow was stopped. The content of residual ions in the gel-plastics was found by extraction in a Soxhlet apparatus. It was found that 0.1 to 1 g of residual ions is contained in 10 ml of the gel plastic and this amount depends on the dc current passed in electrodialysis.

The residual ions make gel-plastics electrically conducting. The results obtained when determining the electrical conductivity at different temperatures are presented in Fig. 3. It can be seen that the electrical conductivity is higher for samples containing residual ions in a larger amount. An increase in temperature to 50°C results in that the curves are linearly shifted to higher σ. The shifts and electrical conductivities observed are characteristic of ion-containing polymeric formulations [5]. The electrical conduction mechanism is mixed, with both the ionic and electronic components, because ions are readily separated from the proteins under the action of the electric field.

CONCLUSIONS

Electrodialysis enables control over the content of ions in structuring of fibrillar proteins in a flow. The gel-plastics obtained are ion-containing electrically conducting formulations with a medium degree of chain ordering.

Abstract—Optimal conditions for obtaining activated carbons from pine nutshells were determined. Their sorption properties were studied.

DOI: 10.1134/S1070427208010369

Solving the problems associated with integrated processing of the vegetable biomass into valuable food and technological products is a particularly topical issue for the Siberian region, on whose territory is situated up to 19% of world's resources of wood. The resources of cedar in East Siberia are vast, with cedar forests occupying 18.7 million hectares. Purely cedar forests (kedrachs) cover the territory of Tyva, Krasnoyarsk krai, Altai, and Buryatia [1]. Annually, more than one million tons of pine nuts are harvested in Siberia, so that large amounts of wastes in the form of nutshells, which constitute 51–59% of the mass of nuts, will be accumulated at places of industrial processing of the nuts. Nutshells are a valuable raw material for obtaining nutritional substances and tanning agents (tannins), essential oils, and activated carbons (AC). So far, the problem of large-tonnage utilization of pine nutshells (PNS) has not been resolved. The PNS belong to renewable raw materials and are an environmentally cleaner product than artificial polymers and natural coals. Moreover, the availability of the raw material and the low content of mineral admixtures, comparatively high strength, and developed porous structure of the resulting AC make nutshells a promising material for manufacture of low-cost high-quality carbon sorbents [2].

EXPERIMENTAL

Activated carbon was produced from the starting pine nutshells and shells extracted with an aqueous–alcoholic solution (PNSE) to recover tanning agents (tannins). Removal of extractive substances leads to additional opening of pores in solid nutshell residues, which allows further use of extracted nutshells to obtain activated carbons.

PNS and PNSE crushed to 0.1–0.2 mm were used. To intensify the recovery of tannins from PNS, a microwave electromagnetic field (MEF) was additionally used, with aqueous solutions of highest-purity ethanol of Ekstra brand serving as an extractive agent [3]. This kind of treatment gives rise to cooperative processes in the system: rapid bulk warming-up of the reaction mixture, formation of micropores, and release of extractive substances because of the appearing temperature gradient and excess pressure. After drying, the tannins obtained have the form of a dark brown powder with a specific odor of pine nuts.

Carbon adsorbents were produced from PNS and PNSE by the conventional technology including stages of carbonization and steam activation.

The carbonization and activation of pine nutshells were performed in a tubular reactor placed in a shaft furnace. The installation enables gradual heating of samples under study to 1200°C. First, the carbonization was carried out with heating to 550°C at a rate of 2–3 deg min^{-1} and keeping at this temperature for 30 min. The carbonizate yield was 78–88 wt % relative to the starting weighed portion. The carbonizate obtained was steam-activated at 750–800°C for 30 min. After the activation was complete, the activated carbon was cooled in the reactor to room temperature. The burn-off mass loss X_m (%) was found as the ratio $(m_0 - m)/m_0$, where m_0 and m are the initial and final masses of the product [4], and the carbon yield R (%) after thermal treatment stages was determined.

The sorption properties of the AC obtained were determined with respect to iodine, benzene, and Methylene Blue by the standard methods [5]. As a ref-

Properties of carbonizates and activates produced from PNS and PNSE

Parameter	Carbonizate at 550°C		Activate at 800°C		Activated carbon (pellets)

erence sample was used commercially available activated carbon (in pellets) conforming to the requirements of FS (Pharmacopoeia Item) 42-3246–95 "Activated Carbon Pellets."

It is known that PNS (PNSE) belongs to the class of cellulose materials [6], contains more than 90% carbohydrates (of which 38.6% is cellulose), and possesses an "open" porous structure and enhanced adsorption properties. Additional treatment with selective removal of a part of components enables purposeful development of, and control over the porous structure of the carbon material and manufacture of a product with high specific surface area.

The loss of mass in carbonization of PNS (PNSE) (Fig. 1) occurs for the most part because of the release of carbon-containing low-molecular-weight volatile compounds and heavy tarry products during pyrolysis [1].

The main loss of mass occurs in the temperature range 200–250°C, being accompanied by vigorous gas evolution. The gas evolution is complete at 550°C, with the mass loss of 75–88%.

The lower yield of AC from the starting nutshells, compared with ethanol-treated nutshells, is due to removal, in the course of thermal treatment at elevated temperatures, of a large amount of tarry substances and the corresponding decrease in the yield of the final carbon product.

Preliminary removal of extractive substances from PNS leads to a slight increase in the pore volume in the material obtained from 0.01 to 0.02 $cm^3\ g^{-1}$. After the carbonization, the total pore volume for benzene increases to 0.12 and 0.07 $cm^3\ g^{-1}$ for the nutshells subjected to extraction and the initial nutshells, respectively. In the course of carbonization, there occurs loss of mass: by 65 and 70.5% by PNSE and starting PNS, respectively.

After activation of the carbonizate from PNSE to a mass loss of 81.0%, the resulting AC has a pore volume for benzene of 0.38 $cm^3\ g^{-1}$ and its yield is 19.0%. The yield of the activate from the starting nutshells is 16.6% and its pore volume for benzene is 0.23 $cm^3\ g^{-1}$.

When tannins are recovered from PNS with MEF, cellulose degrades to give oxycellulose containing carboxy groups. Thermolysis of oxycellulose is typically accompanied by an increase in the number of phenol and carboxy groups on the nutshell surface.

Carbonization and activation of the starting and preliminarily extracted nutshells yielded samples whose properties are listed in the table in comparison with those of activated carbon (FS 42-3246–95).

The table shows that the pore volume of the carbonizate increases in the stage of carbonization of materials obtained both from the initial PNS and from the preliminarily extracted PNSE. The activation stage introduces strong differences in the properties of materials obtained from PNS and PNSE. For example, the yields of the activate from PNSE and PNS are 19.5 and 1.66%, respectively.

After preliminary extraction, nutshell samples have a large BET specific surface area (800 $m^2\ g^{-1}$) [8].

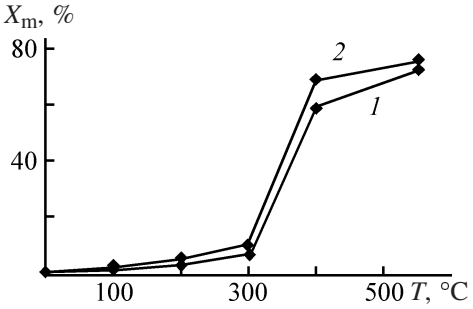

Fig. 1. Mass loss X_m by nutshells vs. carbonization temperature T. (*1*) Extracted PNSE and (*2*) unextracted PNS.

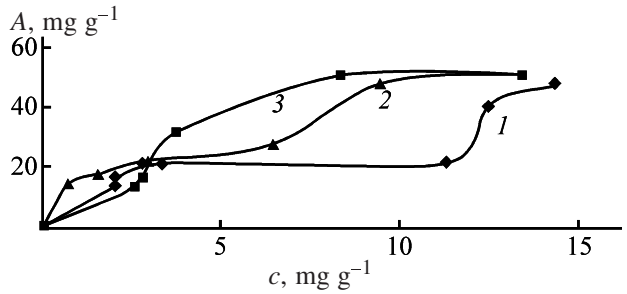

Fig. 2. Sorption isotherm of Fe(III) ions at different temperatures. (*A*) Sorption capacity and (*c*) concentration. *T*, °C: (*1*) 20, (*2*) 40, and (*3*) 60.

The adsorption capacity of the resulting activated carbons for iodine varies within the range 62.0–79.0%. These values correspond to parameters of modern industrial carbon sorbents [9]. The sorption properties of the activate produced from PNSE are comparable with those of pelletized activated carbon, a known enterosorbent.

The sorption properties of the activated carbons obtained from PNSE were studied by the method of sorption of iron(III) ions under static conditions at various temperatures. It has been found that, in sorption on microporous sorbents of substances whose molecular sizes are close to the effective pore sizes, the penetration of these molecules into the pores is temperature-dependent. At a sufficient temperature, sorbate molecules penetrate into pore windows and are sorbed, otherwise there occurs only a slight absorption on the surface of meso- and macropores. In the case in question, the maximum sorption capacities were obtained at 40°C (Fig. 2).

The spent activated carbon was regenerated after the sorption with 0.1 N HCl. On being treated with the acid, a sample was washed with distilled water to neutral reaction. The sorption capacity of the regenerated carbons for benzene was 0.20 $cm^3 g^{-1}$.

CONCLUSIONS

(1) The possibility of obtaining high-porosity activated carbons from pine nutshells and residues of their extractive processing was demonstrated.

(2) It was found that preliminary separation of extractive substances from nutshells can yield activated carbons with better sorption properties. These activated carbons have properties satisfying the requirements to modern industrial carbon sorbents.

Abstract—Possibility of sorption-precipitation purification of wastewater to remove admixtures of fluorine with titanium compounds was studied.

DOI: 10.1134/S1070427208020018

Previously, it has been suggested to purify wastewater containing F^- ions by using titanium compounds [1, 2]. However, a number of plants (e.g., those manufacturing mineral fertilizers from an apatite concentrate, metallic aluminum by electrolysis, etc.) produce wastewater in which fluorine can be present in the form of fluorosilicate and fluoroaluminate complexes.

The goal of this study was to examine the possibility of removing fluorine in the form of complexes with silicon and aluminum from wastewater.

EXPERIMENTAL

Wastewater can be purified if fluorine contained in the anionic complexes SiF_6^{2-} or AlF_6^{3-} can be bound into poorly soluble more stable hydroxo fluoride complexes with titanium or zirconium. We took into account published data according to which the stability of complex fluorides in solution increases in the order: $FeF_6^{3-} < SiF_6^{2-} < AlF_6^{3-} < BF_4^- < BeF_6^{4-} < ZrF_6^{2-}$ [3] and also the results of our earlier study [1] which demonstrated that F^- anions can be effectively removed from wastewater with titanium compounds.

The results of a potentiometric titration of H_2SiF_6, Na_3AlF_6, K_2TiF_6, and K_2ZrF_6 solutions are shown in Fig. 1. It can be seen in Fig. 1a that hydrolysis of H_2SiF_6 occurs without formation of stable intermediate complexes and is complete at pH about 7 at an initial concentration $c_{SiF_6^{2-}} = 0.003258$ N.

A stepwise change in pH is observed in the initial stage of titration in the curve of Na_3AlF_6 titration (Fig. 1b), which points to an increased hydrolytic stability of the AlF_3 species predominant at this concentration of fluorine [4]. At pH exceeding 7, hydrolysis readily occurs without formation of stable intermediate complexes, being complete at pH ~8.4.

In potentiometric titration of a K_2TiF_6 solution (Fig. 1c), a break is observed at pH 4.7–4.8, which may indicate, judging from the NaOH consumption corresponding to this break, that $TiOF_2 \cdot nH_2O$ is formed. The hydrolysis is complete at pH ~8.

In titration of more concentrated K_2TiF_6 solutions (0.0104–0.0208 N) with sodium or ammonium hydroxide, precipitation of $TiO(OH)F \cdot nH_2O$ at pH 5.75–6.48 was also observed, together with the formation of $TiOF_2 \cdot nH_2O$ at pH 5.3–5.75. The hydrolysis was complete at pH 10.45 [5].

The titration of K_2ZrF_6 occurs similarly to that of K_2TiF_6 (Fig. 1d). Here, a break is also observed, which indicates that an intermediate form $ZrOF_2 \cdot nH_2O$ is formed. The hydrolysis is complete at pH 8.6.

Effective purification to remove an admixture of fluorine is possible under conditions for preferential hydrolysis of complex fluorine-containing anions of silicon and aluminum to give F^- ions, whereas poorly soluble variable-composition hydroxide complexes of fluorine with titanium or zirconium are still stable.

Therefore, we carried out a preliminary study of the hydrolytic behavior of SiF_6^{2-}, AlF_6^{3-}, TiF_6^{2-}, and ZrF_6^{2-} anions in solutions. We used solutions with an equivalent fluorine concentration of 10 mg l^{-1}, because the total concentration of fluorine in various

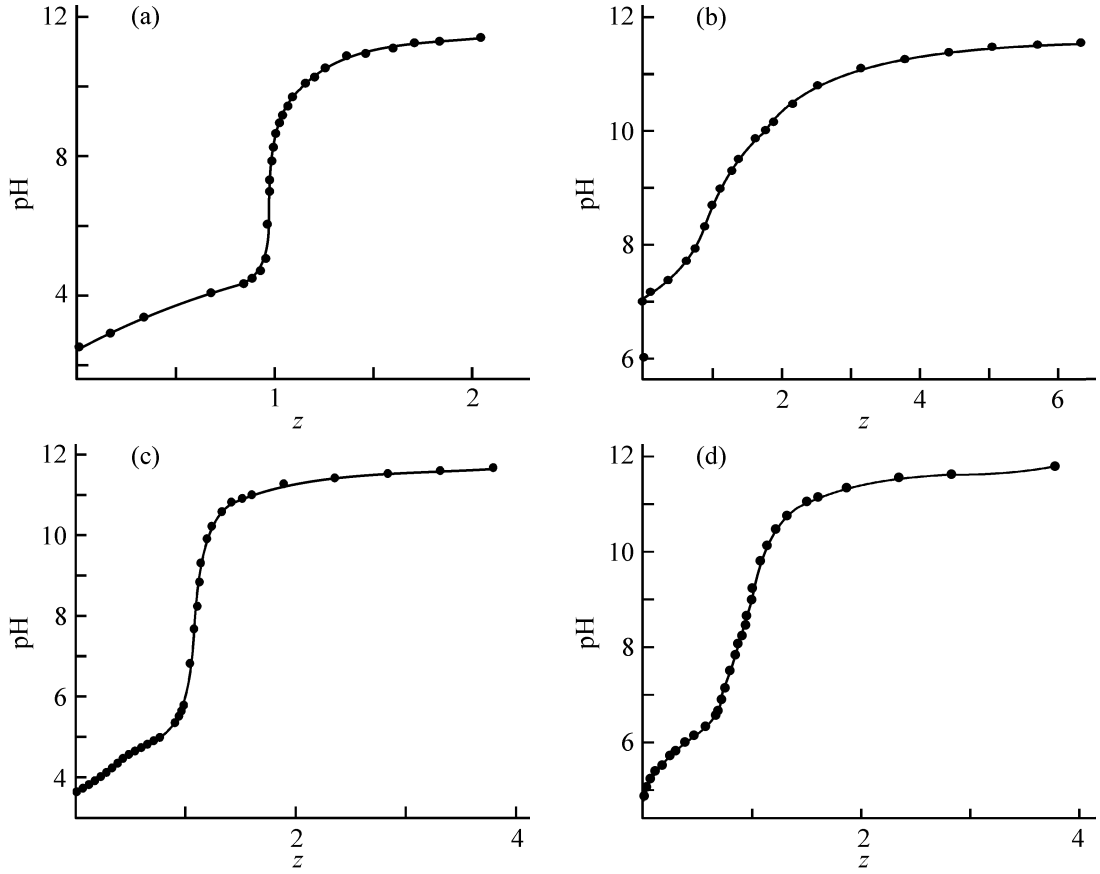

Fig. 1. Titration curves of (a) 0.003258 N H_2SiF_6, (b) 0.000263 N Na_3AlF_6, (c) 0.000438 N K_2TiF_6, and (d) 0.000441 N K_2ZrF_6 solutions with a 0.01 N NaOH solution. (z) Ratio between gram-equivalents of NaOH and F^-.

anionic forms in wastewater from numerous factories and fluorine-contaminated underground water from artesian wells does not exceed this value.

We determined the dependence of the degree of hydrolysis on the solution pH by the ionometric method, with the concentrations of H^+ and F^- ions measured using an I-160 ionometer with an ESL-43-07 electrode and a Volta-3000 fluorine-selective electrode, respectively. It was found that, on adding a next NaOH portion, equilibrium was attained in 15 min.

According to the data [6], the hydrolysis of SiF_6^{2-}, AlF_6^{3-}, TiF_6^{2-}, and ZrF_6^{2-} anions is described by the reactions

$$SiF_6^{2-} + 2H_2O = \downarrow SiO_2 + 4H^+ + 6F^-, \quad (1)$$

$$AlF_6^{3-} + 3H_2O = \downarrow Al(OH)_3 + 3H^+ + 6F^-, \quad (2)$$

$$TiF_6^{2-} + 3H_2O = \downarrow TiO(OH)_2 + 4H^+ + 6F^-, \quad (3)$$

$$ZrF_6^{2-} + 4H_2O = \downarrow Zr(OH)_4 + 4H^+ + 6F^-. \quad (4)$$

Experimental dependences of the degree x of hydrolysis at room temperature on pH are listed for the ions SiF_6^{2-}, AlF_6^{3-}, TiF_6^{2-}, and ZrF_6^{2-} in the table.

We calculated the hydrolysis constants K from the experimental data. The calculation scheme is presented for the example of the SiF_6^{2-} ion.

If the fraction of hydrolyzed SiF_6^{2-} ions is x, the amount of SiF_6^{2-} ions remaining in solution is $(1 - x)$, and that of F^- ions formed, $6x$. On the assumption that the activities of ions in dilute solutions are equal to their concentrations, we obtain the following expression for calculating the hydrolysis constant:

$$K = \frac{6^6 x^6 a_{H^+}^4 a_{SiF_6^{2-}}^5}{1 - x}. \quad (5)$$

Equation (5) is also applicable to calculation of the hydrolysis constants of reactions (3) and (4). Similar reasoning for the equilibrium constant of reaction (2) leads to Eq. (6).

$$K = \frac{3^3 6^6 a_{H^+}^3 x^6 c_{AlF_6^{3-}}^5}{1-x}. \quad (6)$$

Hydrolysis constants K calculated by Eqs. (5) and (6) are listed in the table, which shows that K depends on pH. The hydrolysis constants for the SiF_6^{2-} anion markedly differ from the values 8.3×10^{-28}–1.7×10^{-27} reported in [6]. It can be assumed that the scatter of the hydrolysis constants K is due to the fact that the solubility of metal hydroxides (oxohydroxides) formed in the hydrolysis was disregarded in the calculations.

The solubility of amorphous silica at room temperature in the pH range 2–9 is 0.1–0.15 g l^{-1} SiO_2, with the minimum solubility observed at pH ≈ 7 [7]. It is assumed in this case that the monomer $Si(OH)_4$ is formed in solutions.

At low concentrations of the SiF_6^{2-} ion, examined in this study, the maximum concentration of the hydrated form of silica in solution was 0.007 g l^{-1}. It can be considered that hydrolysis of anions occurs by the reaction

$$SiF_6^{2-} + 2H_2O = Si(OH)_4 + 4H^+ + 6F^-, \quad (7)$$

and the equilibrium constant is given by

$$K_1 = \frac{a_{Si(OH)_4} a_{H^+}^4 a_{F^-}^6}{a_{SiF_6^{2-}}}. \quad (8)$$

If we assume that the activity coefficient of the hydrated form of silica in the solutions under study is unity, then $a_{SiO_2} = x a_{SiF_6^{2-}}$ and the expression for the equilibrium constant takes the form

$$K_1 = \frac{6^6 x^7 a_{H^+}^4 a_{SiF_6^{2-}}^6}{1-x}. \quad (9)$$

It can be seen in the table, which lists K_1 values calculated by Eq. (9), that the K_1 value for SiF_6^{2-} anions is sufficiently invariable and equal to $(3.1 \pm 1.2) \times 10^{-32}$.

The solubilities of $Al(OH)_3$, $TiO(OH)_2$, and $Zr(OH)_4$, estimated using the data of [8–10], are 0.0034, 0.0061, and 0.001 mg l^{-1}, respectively. Therefore, it seems justified to neglect these solubilities when calculating the equilibrium constants of reactions (2)–(4). Presumably, the scatter of the K values for the reactions of hydrolysis of the AlF_6^{3-} and TiF_6^{2-} anions indicates that the forming $Al(OH)_3$, $TiO(OH)_2$, and $Zr(OH)_4$ react in parallel with sodium cations even at low concentrations of reagents:

$$Al(OH)_3 + xNa^+ \rightarrow Al(OH)_{3-x}(ONa)_x + xH^+, \quad (10)$$

$$TiO(OH)_2 + xNa^+ \rightarrow TiO(OH)_{2-x}(ONa)_x + xH^+, \quad (11)$$

$$Zr(OH)_4 + xNa^+ \rightarrow Zr(OH)_{4-x}(ONa)_x + xH^+, \quad (12)$$

which affect the equilibria in solutions.

Effect of pH on the degree of hydrolysis of the SiF_6^{2-}, AlF_6^{3-}, TiF_6^{2-}, and ZrF_6^{2-} ions and the hydrolysis constants K and K_1 (c_{F^-} = 10 mg l^{-1})

* pH of the starting solution.

It can be seen from the table that, at room temperature and equal initial concentrations in solution, the SiF_6^{2-}, AlF_6^{3-}, TiF_6^{2-}, and ZrF_6^{2-} anions are completely hydrolyzed at pH 4.35, 7.70, 5.25, and 7.20, respectively. Therefore, the hydrolytic stability series differs, at least at low concentrations, from that found

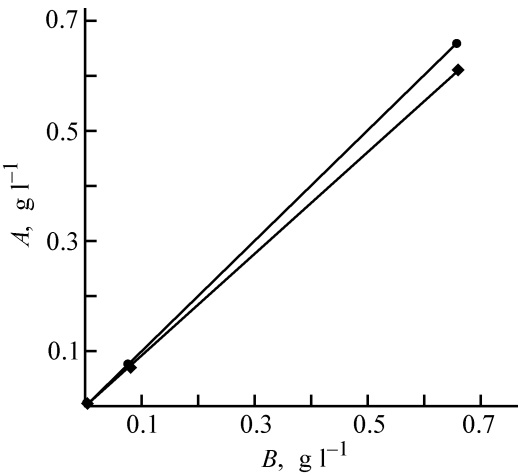

Fig. 2. Effect of impurity anions on the efficiency of fluorine determination in solutions of alkali element fluorides by the ionometric method. (*A*) Fluorine found and (*B*) fluorine introduced. Impurity anion: (*1*) Cl^-, NO_3^- and (*2*) SO_4^{2-}.

previously [9], and aluminum, rather than zirconium, is the strongest fluorine acceptor among the anions under study.

Thus, effective precipitation of fluorine from the AlF_6^{3-} anion with titanium or zirconium compounds cannot be reached.

We studied water purification to remove fluorine present in the form of SiF_6^{2-} with titanium sulfate compounds. Model solutions containing 8.77×10^{-5} M K_2SiF_6 (10 mg l^{-1} of fluorine) were used. A prescribed amount of a titanium-containing reagent (titanyl sulfate dihydrate $TiOSO_4 \cdot 2H_2O$) was introduced into fluorine-containing solutions. The pH value was maintained in the interval 4–4.5 by addition of a concentrated sodium hydroxide solution and, upon agitation, the precipitate formed was separated by centrifugation. The degree of fluorine removal was estimated from the residual content of fluorine in the solution and from the amount of fluorine in the precipitate, found as follows.

The fluorine concentration in a solution after treatment was measured by ionometry at pH 4 and 8. The precipitate was treated with a sodium hydroxide solution, the solid and liquid phases were separated by centrifugation, and then the fluorine concentration in the resulting alkaline solution was measured by the ionometric method.

The fluorine-selective electrode used in the study is suitable for operation in solutions with pH 4–8. Therefore, the alkaline solution was preliminary neutralized with hydrochloric or nitric acid, because it was found that the ionometric determination of fluorine with sulfuric acid gives a content approximately 7.5% lower than the actual value (Fig. 2). Consequently, a part of fluorine is present in sulfate solutions, together with the F^- ion determined by ionometry, in the form that cannot be determined with a fluorine-selective electrode. Probably, this form is the complex fluorosulfate anion FSO_4^{3-}. It has been shown previously [11–13] that this anion exists at 50–75°C in solutions containing 44–60 wt % H_2SO_4 and 6–10% HF and appreciable concentrations of lanthanides and titanium, with the phases $LnFSO_4 \cdot nH_2O$ (Ln = Y, Ce, Nd) isolated from the solutions.

The increased solubility of LaF_3 and YbF_3 fluorides at room temperature in sulfate solutions of lower concentrations (9.5–20 wt %), compared with their solubility in monobasic acids, was attributed to formation of FSO_4^{3-} ([14]).

When $TiOSO_4 \cdot 2H_2O$ (800 mg l^{-1}) was added to a K_2SiF_6 solution containing 10 mg l^{-1} of fluorine, the residual concentration of fluorine in the treated solution was 0.64 at pH 4 and 2.7–2.8 mg l^{-1} at pH 8. This suggests that the remaining fluorine is in a complex form in solution. The solutions produced by alkali treatment of the precipitate contained 7.2–7.32 mg of fluorine, which points to a good agreement of the results obtained. Upon introduction of an additional amount of $TiOSO_4 \cdot 2H_2O$ (200 mg l^{-1}) into the solution, the residual concentration of fluorine was 0.75 mg l^{-1}.

The results of a calculation show that the $TiO_2 : F^-$ molar ratio in the precipitate is 10.5 and its composition can be represented by the formula $TiO(OH)_{1.905}F_{0.095} \cdot nH_2O$.

CONCLUSIONS

(1) It was shown that the hydrolytic stability in dilute solutions increases in the order $SiF_6^{2-} < TiF_6^{2-} < ZrF_6^{2-} < AlF_6^{3-}$. Therefore, use of titanium compounds for efficient wastewater purification to remove fluorine in complexes with aluminum is unpromising.

(2) The hydrolysis constant of the SiF_6^{2-} anion was found to be $(3.1 \pm 1.2) \times 10^{-32}$ at room temperature. It was shown that a scatter of the calculated values of hydrolysis constants for the AlF_6^{3-}, TiF_6^{2-}, and ZrF_6^{2-} is observed. This is due to the necessity for taking into account the interaction of the alkaline element cation with the forming hydroxides (oxohydroxides).

(3) It was found experimentally that wastewater containing up to 10 mg l^{-1} of fluorine in the form

of the complex anion SiF_6^{2-} can be purified with titanium sulfate compounds to satisfy regulations concerning the content of fluorine in fish-farming ponds. In the presence of sulfate ions, fluorine forms complex fluorosulfate anions.

Abstract—Absorption of hydrogen by carbon-magnesium composites synthesized by mechanochemical treatment and arc spraying was studied and methods for optimization of the process of hydrogen absorption were suggested.

DOI: 10.1134/S107042720802002X

Owing to the high content of hydrogen (7.66 wt %), magnesium hydride (MgH_2) is one of the most promising materials for accumulation of hydrogen. However, the high temperature of hydrogen absorption and release hinders its practical use [1].

Intermetallic compounds of magnesium, primarily with nickel and rare-earth metals, obtained by classical metallurgical methods, exhibit a high rate of interaction with hydrogen. However, the mass content of hydrogen in these compounds markedly decreases because of the increase in their density, caused by introduction of heavy elements.

An alternative to the conventional metallurgical methods for improvement of the properties of most of the hydride-forming metals is their mechanochemical treatment in high-energy ball mills.

Mechanochemical treatment of a mixture of magnesium and graphite has been used to obtain carbon-magnesium composites [2]. Composites of this kind are hydrogenated at lower temperatures (the hydrogenation temperature decreases by nearly 200°C). A subsequent analysis of a thermal desorption spectrum allowed the authors to record a shift of the hydrogen evolution onset to lower temperatures, compared with pure magnesium hydride [1].

The authors of [3] obtained carbon-magnesium composites with nanosize particles by grinding metallic magnesium in liquid hydrocarbons. It was found that hydrogenation occurs at a higher rate on nanosize magnesium particles. Already in the first cycle, magnesium absorbs hydrogen at a rate of 6 wt % per hour, which exceeds by a factor of 1.5 that for magnesium ground together with graphite to only a micrometer size (4 wt % per hour). This value is 60 times that for magnesium with nanosize particles, unmodified with graphite (0.1 wt % per hour).

Use of graphite instead of heavy elements, combined with mechanochemical treatment, made it possible to obtain magnesium-based composites that have lower density and can be hydrogenated (dehydrogenated) at lower temperatures.

In [4], a nickel-magnesium alloy was ground in a solution of fullerenes in toluene. It was found that the time of hydrogen desorption from the composite obtained decreased by a factor of 2–3, compared with composites produced by grinding in the presence of graphite.

One more method for dispersion of various materials is, in addition to mechanical grinding, their evaporation in an electric arc. It is known that this method of dispersion of carbon materials and, in particular, graphite can yield carbon nanostructures: fullerenes, nanofibers, and nanotubes. The application of this technique in the present study yielded a carbon-magnesium composite in a highly dispersed state.

The goal of the study was to determine how methods for dispersion of magnesium together with carbon, namely, joint grinding with graphite and sputtering of a magnesium-graphite composite in a dc arc, affect the activation of the carbon-magnesium composites obtained. The composites were also compared with the starting magnesium and magnesium ground without carbon additives.

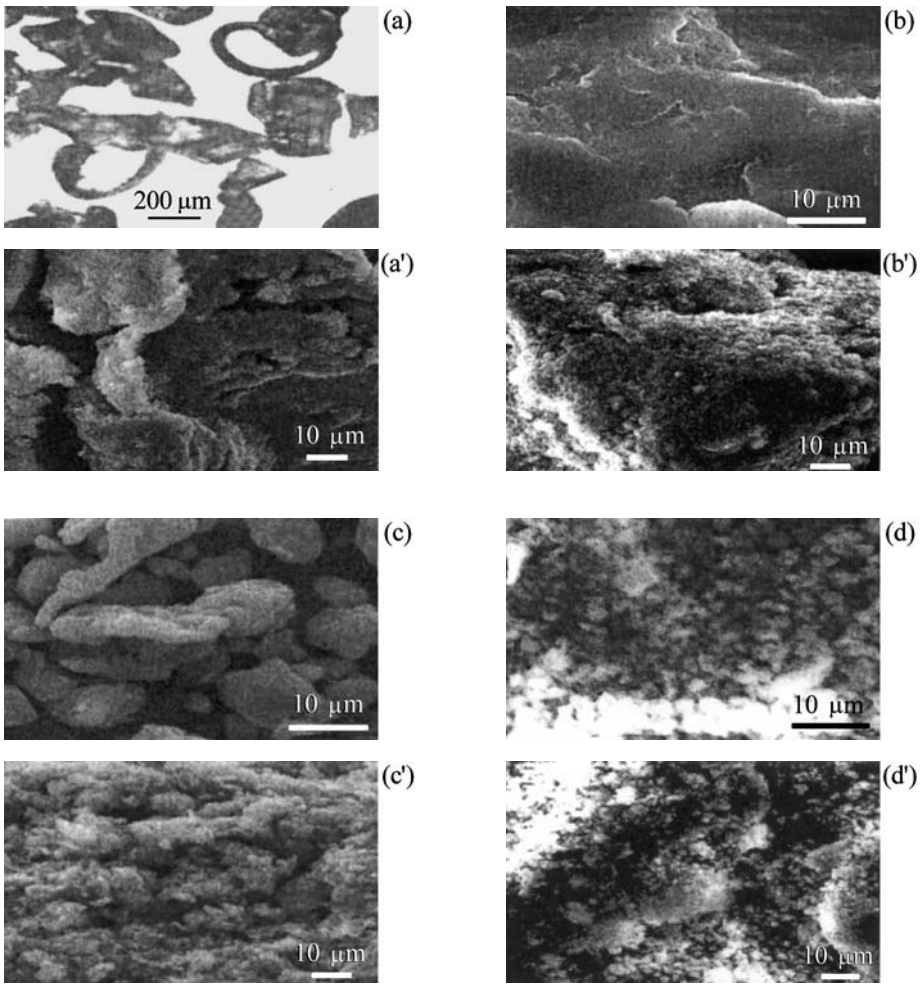

Fig. 1. Particles of a material (a–d) before and (a'–d') after five cycles of hydrogenation. Material: (a, a') starting magnesium powder, (b, b') ground magnesium, (c, c') ground magnesium with graphite), and (d, d') magnesium sputtered in an arc with carbon. (b–d, a'–d') Electron microscopy and (a) optical microscopy.

EXPERIMENTAL

The mechanochemical synthesis was performed with powdered magnesium (99.98%) with particles having an average size of 100 μm and low-ash medium-grain graphite of GMZ brand [5]. Graphite had the following properties: density 1.6 g cm^{-3}, compression strength 300 kg cm^{-2}, bending strength 120 kg cm^{-2}, electrical resistivity 10 Ω mm^2 m^{-1}, porosity ≤25%. The grinding was carried out in an IVCh vibration grinder. The grinding time was 30 min.

A composite magnesium-carbon electrode was sputtered in an electric arc on the installation described in [6]. The composite electrode was fabricated by compaction of a mixture of magnesium (70 wt %) and novolak with addition of urotropin (30 wt %) at 180°C under a pressure of 200 kg cm^{-2}.

The electrode was calcined in a graphite charge in a muffle furnace at 500°C. The heating rate was 0.5 deg min^{-1}. The composite electrode was sputtered in the atmosphere of helium at a pressure of 13.33 kPa and temperature of 2000°C. The content of carbon in the sputtered sample, found from the difference of sample masses before and after dissolution of magnesium in hydrochloric acid, was 13.2 wt %.

The processes of hydrogenation and dehydrogenation were studied using hydrogen of purity 99.9999%. The amount of absorbed gas was measured on a volumetric installation at 350°C and a constant pressure of 65 atm. The amount of absorbed hydrogen was found from the decrease in pressure in the measuring

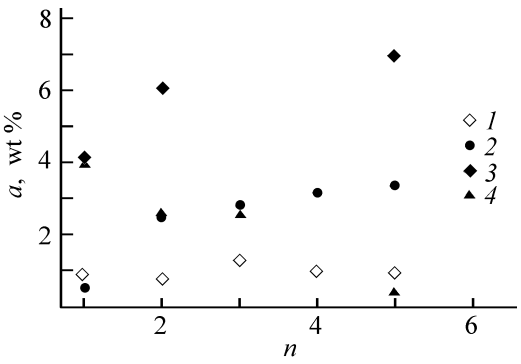

Fig. 2. Amount of hydrogen absorbed by magnesium vs. the number *n* of cycles at 350°C (*a*) Amount of absorbed hydrogen per 1 g of Mg; the same for Fig. 3. Magnesium: (*1*) starting powder, (*2*) ground, (*3*) with 10 wt % graphite, and (*4*) obtained in arc discharge.

volume of the installation, and that of released hydrogen, from the volume of water displaced from the gas meter under the ambient pressure. The absorption of hydrogen by each sample was examined in five cycles of hydrogenation–dehydrogenation. The samples were vacuum-treated at 1.33 Pa before the first cycle, and taken without vacuum treatment in the subsequent cycles.

The particle size of the materials obtained was measured with a Polyvar-Met optical microscope with a Quantimet analytical system and by electron microscopy.

The amount of absorbed hydrogen was measured for the following samples: unground (starting) magnesium, ground magnesium without carbon additives, and magnesium ground with graphite and modified with carbon by sputtering in an electric arc. According to optical-microscopic data, the starting magnesium powder was composed of irregularly shaped particles 200 to 600 μm in size (Fig. 1a).

According to electron-microscopic data, magnesium particles had an average size of about 145 μm after grinding in a vibration grinder (Fig, 1b). Upon grinding of magnesium together with graphite (10 wt %), the particle size decreased to 10 μm (Fig. 1c).

It can be seen in Figs. 1a and 1c that some particles of ground magnesium are agglomerates composed of finer particles. Introduction of graphite in the grinding stage makes smaller both the agglomerates themselves and the particles constituting these agglomerates. The magnesium powder produced by arc sputtering is composed of spherical particles of size not exceeding 1–2 μm (Fig. 1d).

It is known that, in hydrogenation of magnesium, its absorption capacity does not reach maximum values immediately. Of high importance in this case are the duration and temperature of hydrogenation.

Figure 2 shows how the number of hydrogenation–dehydrogenation cycles in activation of samples affects their absorption capacity. It can be seen that, at 350°C, the maximum amount of absorbed hydrogen by the unground (starting) magnesium powder reaches a value of about 1–1.5% relative to the mass of magnesium and remains virtually unchanged during five repeated cycles of hydrogenation-dehydrogenation. The amount of hydrogen absorbed by ground magnesium increases, compared with the starting magnesium. It reaches a value of 3 wt % in the third cycle and slightly increases (to 3.5 wt %) in the fourth and fifth hydrogenation–dehydrogenation cycles.

The volume of hydrogen absorbed by a sample produced by grinding of magnesium together with graphite reaches the maximum value of 7 wt %, close to that theoretically possible, already by the fourth cycle.

The hydrogenation of a sample produced by arc sputtering markedly differs from that of other samples. The volume of absorbed hydrogen, which varies from cycle to cycle, reaches a certain maximum value by the third cycle (approximately 3 wt %) and then substantially decreases to less than 1 wt %.

Figure 3A shows how the amount of hydrogen absorbed in the first cycle depends on the hydrogenation time. It can be seen that, initially, all the samples are hydrogenated at a high rate, with the limiting values rapidly reached. In this case, all the samples containing no graphite absorb a substantially smaller volume of hydrogen, compared with samples containing graphite.

In the second cycle (Fig. 3B), the rate of hydrogenation in the initial stage still remains high; however, the maximum volume of absorbed hydrogen increases only for samples ground in the vibration grinder. It decreases to 2 wt % for the sample produced by the arc method and remains unchanged for unground magnesium.

In the fifth cycle, magnesium ground together with graphite reaches the maximum capacity, and the sample produced by the arc method absorbs an even smaller amount of hydrogen than that in the preceding cycles (Fig. 3C).

These data suggest that, in grinding with graphite, the oxide film hindering the hydrogenation process is disintegrated. The cyclic hydrogenation–dehydrogenation at a sufficiently high temperature also improves the absorption capacity of magnesium.

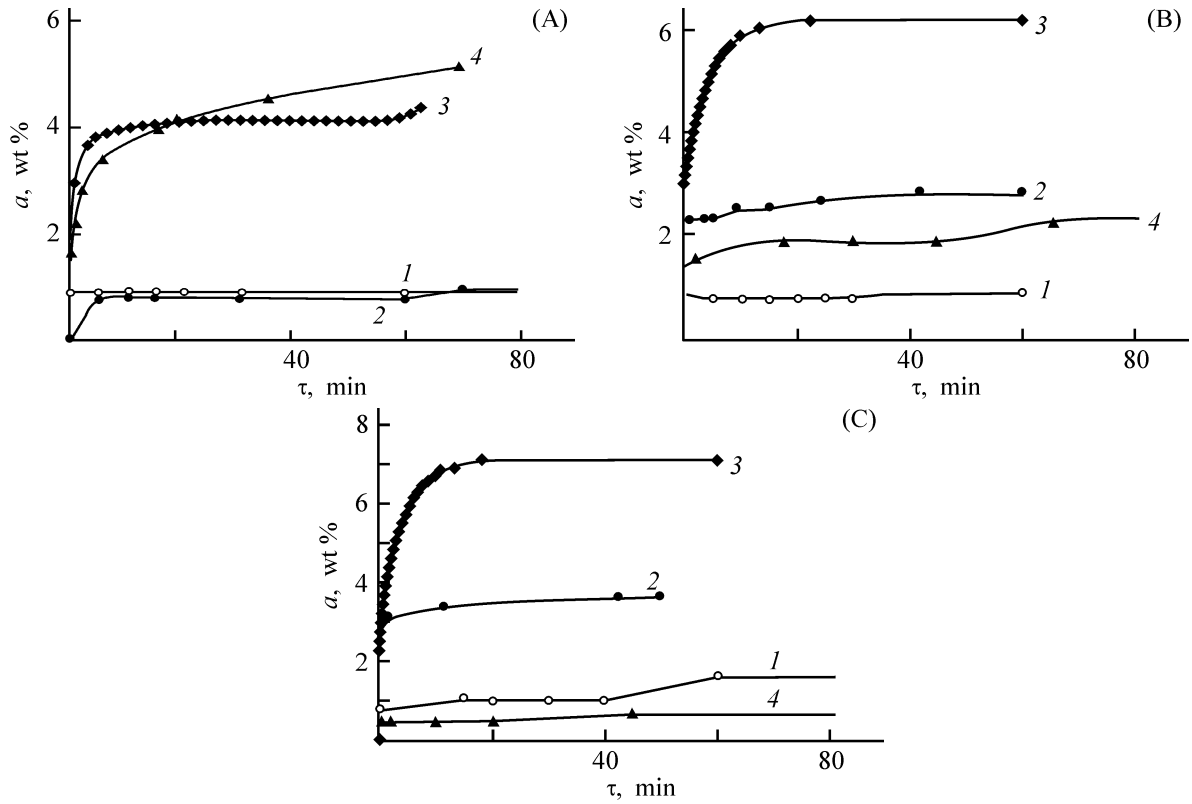

Fig. 3. Amount of hydrogen absorbed by various composites vs. the hydrogenation time τ in (A) first, (B) second, and (C) fifth cycles.

The sample produced by arc sputtering possibly contains not only magnesium, but also its carbides. As a consequence, carbide particles are shifted, from cycle to cycle in hydrogenation and dehydrogenation processes, from the bilk of a sample to its surface. It is these carbide particles that prevent further hydrogenation of magnesium and, accordingly, its dehydrogenation.

The surface morphology of samples subjected to hydrogenation-dehydrogenation cycles (Figs. 1a'–1d') shows that strong changes are observed for all the samples except that produced by arc sputtering (Fig. 1d'). Changes for a sample produced in an electric arc are difficult to observe because of the insufficient resolution of the microscope.

CONCLUSIONS

(1) Grinding of magnesium strongly affects the hydrogenation rate and is a necessary stage in magnesium preparation for use in hydrogen accumulators.

(2) A sample with a particle size of about 0.02 μm, produced by sputtering in an electric arc, is deactivated already after the second cycle and ceases to absorb hydrogen, whereas the composite produced by grinding in a vibration grinder to a particle size of several tens of micrometers, retains its absorption and desorption capacity.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Colored Cobalt-containing Shell Powders from Silicon Oxide Particles

G. V. Bychko, V. D. Koshevar, and I. P. Kazhuro

Institute of General and Inorganic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

Received April 10, 2007

Abstract—Possibility of synthesizing core microstructures composed of a core-forming material (silicon dioxide micrograins) and shell of cobalt oxides, formed as a result of precipitation of the corresponding hydroxides from a cobalt(II) chloride solution and their subsequent thermal decomposition, was studied.

DOI: 10.1134/S1070427208020031

Synthesis of core microstructures of the "core in the shell" type is an efficient method for controlling the surface properties of composite materials, which enables wide variation of their physicochemical and service properties. It consists in deposition of inorganic, organic, and polymeric shells onto inert carriers, cores [1, 2]. This is a way to obtain colored powders that can be used as pigments-fillers for decorative and protective coatings for various purposes, with a considerable amount of nonferrous maetals saved [3, 5].

The goal of this study was to examine whether core microstructures can be produced using silicon dioxide particles synthesized from wastes formed in manufacture of orthophosphoric acid at Gomel chemical combine [TU (Technical Specifications) RB 00 203 714.006] as a core-forming material, and hydrated cobalt(II)oxide obtained from a salt solution by chemical precipitation, as a shell.

Silicon dioxide particles have a large surface energy content and readily form cellular coagulation structures. The potential of an aqueous dispersion of such SiO_2, ξ, is –12.2 mV, and the average particle radius, 5 μm. Silanol groups of the acid type are present on the surface of SiO_2 micrograins. These groups can dissociate in water and enter into ion-exchange reactions with metal cations. In synthesis at pH 8–9, metal hydroxides are poorly soluble compounds and, therefore, the equilibrium is shifted toward their precipitation in solution and on the active surface of SO_2 as an X-ray-amorphous hydroxo complex. Positively charged adsorbed metal complexes electrostatically interacting with negatively charged SO_2 particles can further undergo hydrolysis and polymerization localized in the surface layer. The polymerization presumably occurs between bulk and surface complexes by the polycondensation mechanism [6]. The final stages of shell formation on the particles are drying and thermal treatment. In dehydration of hydroxo compounds of metals and removal of bound water, the cohesion of the shell with the surface of carrier-core particles increases.

The components forming the outer shell are used in the given case in amounts of 5–25% relative to the mass of the carrier core, which is economically profitable because nonferrous metals are saved. Thus, formation of shell powders of this composition is of scientific and practical interest.

EXPERIMENTAL

The synthesis process was studied by FTIR spectroscopy on a Midac M200 spectrophotometer (USA). The IR spectra were recorded in the spectral range 4000–400 cm^{-1} (resolution 4 cm^{-1}) and processed using GRAMSS/32 software (Galactic, USA). A differential-thermal analysis (DTA) was made on an MOM derivatograph (Hungary), with calcined aluminum oxide as reference and a heating rate of 5 deg min^{-1}. An X-ray phase analysis (XPA) was performed on a DRON-2 instrument with a Cu anode. The granulometric composition of the powders was determined on a FSKh-4 photosedimentometer. A computer unit calculated, using a specially developed software, the integral and differential size distribution functions of the mass and number of particles and a number

Color characteristics of the powders synthesized in relation to the $CoCl_2$ concentration

of statistical parameters of the distributions. The reflectances of the colored powders at various wavelengths in the visible spectral range were measured with a FMSh-56M photoelectric sphere photometer, with the subsequent calculation by the method of weighted ordinates of color characteristics [6].

In the first stage of synthesis, silicon dioxide micrograins were dispersed, for purification, in water at room temperature on an LDU-3MPR laboratory installation at a cutter rotation rate of 500 rpm for 30 min. After filtration and drying, 0.5–2 M solutions of cobalt(II) chloride were added to the resulting SiO_2 powder at s : l = 1 : 2 or 1 : 10. In the second stage, the precipitating agent (NaOH, 50 g l^{-1}) was added to the resulting suspension under heating (80°C) and constant agitation, with the pH of the mixture brought to 8–9. The precipitate obtained was subjected to centrifugation, filtration, multiple decantation with water, and drying at 60°C and then was thermally treated at 200–800°C for 1–3 h.

To optimize the synthesis, the dependence of the color tone of the powders of the given system on the concentration of the $CoCl_2$ solution, precipitation pH, ratio between the amounts of the core-forming (SiO_2 particles) and shell-forming phases [cobalt(II) chloride solution], temperature, and calcination duration was studied. The data obtained are listed in the table and presented in Fig. 1.

As follows from the data in the table, a higher cobalt(II) chloride concentration favors, irrespective of the phase ratio, formation of powders with an increasing fraction of the green color component. At a phase ratio of 1 : 2 and calcination temperature of 800°C, blue powders are formed, with the intensity of their coloration decreasing as the SiO_2 content becomes higher. If the concentration of the $CoCl_2$ solution is lowered at the same solution volume and components ratio (composition nos. 7–10), the intensity of the color tone decreases. At a high content of $CoCl_2$ (>25%), black powders was synthesized (composition no. 11). Raising the calcination temperature from 600 to 800°C is accompanied in most cases by an increase in the coloration intensity.

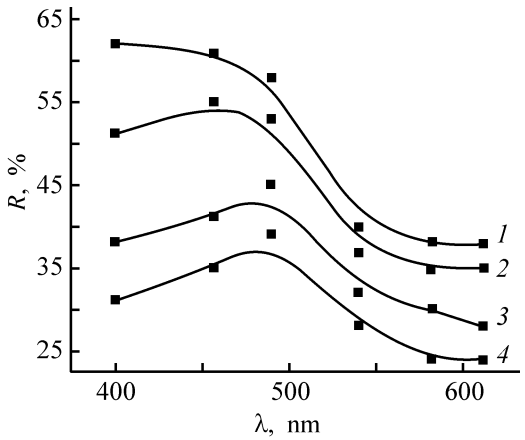

Fig. 1. Reflectance curves for cobalt-containing core powders. (R) Reflectance and (λ) wavelength in the visible spectral range. Co(II) content (wt %): (*1*) 5, (*2*) 10, (*3*) 15, and (*4*) 20.

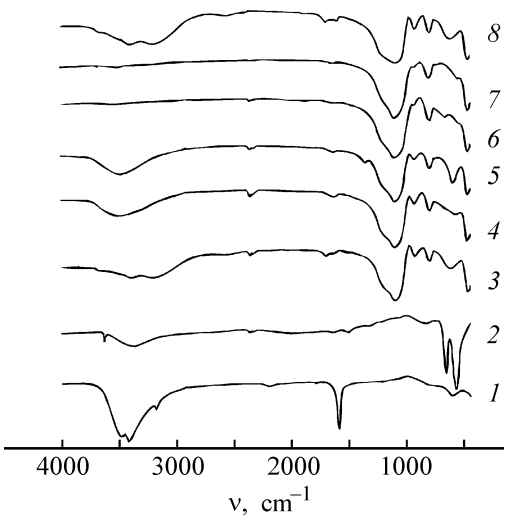

Fig. 2. IR spectra of individual substances and core powders. (ν) Wave number. (*1*) Starting $CoCl_2 \cdot 5H_2O$; (*2*) experimentally obtained CoOOH; (*3*) starting SiO_2; (*4*) SiO_2 : CoOOH (aqueous ammonia as precipitating agent); (*5*) SiO_2 : CoOOH (NaOH as precipitating agent); (*6*) SiO_2 : CoOOH, calcination at 800°C for 1 h; (*7*) mechanical mixture of SiO_2 and $CoCl_2$, calcination at 800°C for 1 h; and (*8*) mechanical mixture before calcination.

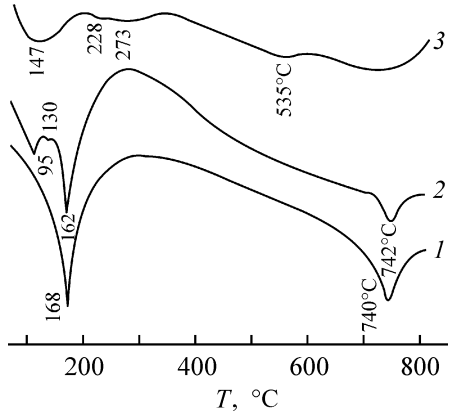

Fig. 3. DTA curves of the starting SiO_2 and powders produced by impregnation or precipitation. (*T*) Heating temperature. (*1*) Starting SiO_2, (*2*) SiO_2 impregnated with a cobalt(II) chloride solution, and (*3*) SiO_2 : CoOOH (NaOH as precipitating agent).

As the content of the shell-forming phase increases, the reflectance curves of the powders (Fig. 1) are characterized by a gradual shift of the maximum reflectance from the blue part of the visible spectral range (465 nm) to the blue-green part (496 nm). At wavelengths of 540–660 nm, there appears a strong absorption of Co(II) ions in the tetrahedral coordination. As a result, the powder color changes from light blue to blue-green.

Powders synthesized at low $CoCl_2$ solution pH (1.2, 4.0, 5.0) form no colored precipitates before and after thermal calcination. This occurs because hydroxo forms of the $[CoOH(H_2O)_5]^+$ type and, possibly, $–Si–OH \cdot Co(OH)_2$ or $–Si–OCo(OH)_2$ complexes are formed in solution only at pH 9.0. It was found that raising the calcination time from 1 to 3 h at a fixed temperature does not exert any further noticeable influence on the intensity of the color tone.

It follows from the IR spectra in Fig. 2 that the samples under study are characterized by the following absorption bands (AB): 3100–3500 cm^{-1}, deformation vibrations of molecular and adsorbed water and hydroxo groups incorporated into the layer from solutions; 1400–1500 cm^{-1}, deformation vibrations of bonds of OH^- groups contained in cobalt hydroxide; and 500–700 cm^{-1}, stretching vibrations of the Co–O bond. The absorption bands at 1100–1110 cm^{-1} are identified as Si^{4+}-related stretching vibrations, and AB at 927–933 and 472–475 cm^{-1} can presumably be assigned to vibrations of Si–O groups (bonds with a nonbridging oxygen atom) and deformation vibrations of Si–O–Si, respectively.

As is known [7], $Co(OH)_2$ formed in precipitation exists in two forms: unstable blue and stable pink, which appears at a high alkalinity and elevated temperatures (80°C). This form is intensively oxidized in air, to give CoOOH as a result of aging. This compound characteristically shows AB in the form of shoulders at 578 and 662 cm^{-1}, associated with stretching vibrations of Co–O groups. Comparison of the spectra of the individual CoOOH (spectrum *2*) and of the resulting core powders before their calcination (spectra *4*, *5*) shows that the AB at 568, 599, and 668 cm^{-1}, which are presumably associated with vibrations of the Co–O bond, are somewhat shifted under the action of the energy field of SiO_2. XPA data also confirm the presence of CoOOH (weak peak at 2θ = 22.56°). These AB (spectrum *8*) are not present in the spectrum of a mechanical mixture SiO_2 : $Co(OH)_2$. The observed doubled AB at 3391–3486 and 3181–3196 cm^{-1} in the range of stretching vibrations of H_2O and AB at 1699 and 1602 cm^{-1} in the range of deformation vibrations of H_2O suggest that, in the case in question, $CoCl_2 \cdot 3Co(OH)_2 \cdot [Co(OH)_{1.5}Cl_{0.5}]$ is formed in addition to $Co(OH)_2$. After thermal treatment of the powders at 800°C, all the AB in the spectra lie in the range 400–1200 cm^{-1} (spectrum *6*) because of the removal of OH^- groups, and are shifted to higher frequencies.

Figure 3 shows DTA data for the starting SiO_2 powder and that impregnated with a cobalt(II) salt solution, and for the product obtained by precipitation of cobalt(II) hydroxide on the surface of SiO_2 particles. The starting SiO_2 shows two endothermic ef-

fects: strong at 168°C, associated with desorption of adsorbed water, and that of medium intensity, related to removal of surface OH^- groups. In this case, the loss of mass was 8 and 19% in the first and second stages, respectively. The following changes were observed for SiO_2 impregnated with a cobalt(II) chloride solution: weak endothermic effect at 95°C, which is probably due to partial loss of the hydration water of the aqua complex of cobalt; medium-intensity effect at 162°C, associated with desorption of water adsorbed by the SiO_2 surface; and endothermic effect related to loss of surface hydroxides. This suggests that the impregnation of SiO_2 with a $CoCl_2$ solution is not accompanied by any chemical transformations. For shell powders (curve *3*), the endothermic effect associated with transformations of hydrated water is shifted to higher temperatures (117°C), the endothermic effect associated with desorption of water bound to the SiO_2 surface decreases in intensity and is shifted by nearly 100°C, and a slight endothermic effect corresponding to loss of surface OH^- groups is observed. These changes indicate that the energy state of the SiO_2 surface affects thermal processes occurring in the given product.

Thus, the differences observed in the IR absorption spectra of the mechanical mixture $SiO_2 : Co(OH)_2$ and the synthesized shell powders, as well as the differences in the derivatograms, confirm that cobalt hydroxo compounds interact with active surface centers of SiO_2 particles and these centers are involved in the control over the color tone of colored products. XPA data demonstrated that these powders are X-ray-amorphous. However, X-ray diffraction patterns of the samples synthesized by precipitation from concentrated $CoCl_2$ solutions (composition nos. 7 and 8) and thermally treated at 800°C for 2 h show reflections associated with CoO (2θ 21.2, 36.8°) and Co_3O_4 (2θ 18.45, 19.30, 22.4, 29.7°). Just this circumstance can account for the fact that black powders are obtained.

The most intense coloration is observed for powders synthesized at pH 9 at s : l = 1 : 10 from a 0.5 M $CoCl_2$ solution and calcined at 800°C for 1 h. The calculated photometric chromaticity coordinates *X*, *Y*, *Z* and the dominant wavelength λ (nm) and color purity *P* (%), found from the color triangle, have the following values: $X = 32$, $Y = 37$, $Z = 31$, $\lambda = 558$, and $P = 30$ for green powders and $X = 26$, $Y = 30$, $Z = 44$, $\lambda = 490$, and $P = 10$ for blue powders. The granulometric composition of the colored powders synthesized does not change significantly, compared with the starting aerosil particles (average particle diameter 2–5 μm). As regards their service characteristics, the powders have a satisfactory chemical stability against water (the color purity does not change on keeping the powders in water for 30 days or boiling for 1 h), hiding power of 60 g cm^{-2} [GOST (State Standard) 8784–75], and oil absorption of 37 g per 100 g of oil (GOST 211 119.8–75, section 1). The powders are easily dispersed in aqueous media to give comparatively stable suspensions.

CONCLUSIONS

(1) Shell powders with various color tones were produced by precipitation of cobalt(II) hydroxo compounds on the surface of SiO_2 particles. The main factors affecting the coloration of the powders is the concentration of a cobalt(II) salt in solution, ratio between the solid and liquid phases, and calcination temperature.

(2) It was found that, during precipitation, cobalt(II) hydroxo compounds interact with active centers of the surface of silicon dioxide particles. This gives rise to a "prestructure" of the future material with a shell in the form of an X-ray-amorphous hydroxo complex.

(3) It was shown that the colored powders synthesized are somewhat inferior in coloration intensity to cobalt pigments produced by the conventional methods. However, the process of their synthesis is less energy-intensive and saves expensive cobalt salts. Powders of this kind may be of interest as filler pigments in manufacture of paint-and-varnish materials, ceramics with magnetic properties, and various products for building purposes.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Fluorination of Beryllium Concentrates with Ammonium Fluorides

A. A. Andreev, A. N. D'yachenko, and R. I. Kraidenko

Tomsk Polytechnic University, Tomsk, Russia

Received August 30, 2007

Abstract—New method for processing of beryllium ores to beryllium oxide was suggested and studied. The method is based on decomposition of bertrandite or phenacite with ammonium chloride, with the subsequent leaching of ammonium tetrafluoroberyllate and precipitation from a beryllium hydroxide solution. The thermodynamic characteristics were calculated and a thermogravimetric analysis of the process was made. The kinetics of beryllium oxide fluorination with ammonium fluoride was experimentally studied. A technological scheme of a closed cycle for processing of beryllium-containing raw materials with ammonium fluoride was suggested.

DOI: 10.1134/S1070427208020043

Russia possesses vast resources of beryllium ores [1], but beryllium is not manufactured in our country. The only plant manufacturing beryllium plants on the CIS territory is Ul'ba metallurgical plant (Ust'-Kamenogorsk, Kazakhstan). At present, work is in progress on restoring the mining and smelting combine at the Ermakovskoe deposit (Buryatiya), where mining of the beryllium concentrate is to be resumed. Two kinds of beryllium ore are predominant at the Ermakovskoe deposit, bertrandite $Be_4[Si_2O_7](OH)_2$ and phenacite Be_2SiO_4.

The most widely used method for processing of beryllium concentrates is their sulfuric acid decomposition, followed by recovery of beryllium compounds from solution. The main technological procedures used in processing of beryllium concentrates have been described in the literature [2–4]. The applicability of these methods to the concentrate from the Ermakovskoe deposit is limited because this concentrate contains a large amount of fluorite (calcium fluoride), which is the carrier rock. Fluorite reacts with sulfuric acid to give gaseous hydrogen fluoride and gypsum (calcium sulfate). Present-day problems of, and prospects for processing of the beryllium concentrates from the Ermakovskoe deposit were described in [5–7].

The goal of this study was develop a virtually waste-free industrial technology for decomposition of fluorite-beryllium concentrates with ammonium fluorides. In [8–10], physicochemical foundations of the processes of fluoroammonium processing of mineral substances, such as zircon, ilmenite, and topaz were described; the same procedures were used when studying the interaction of beryllium-containing minerals with ammonium fluorides.

Melts of ammonium fluoride (NH_4F) and ammonium hydrofluoride ($NH_4F \cdot HF$) are strong fluorinating agents with reactivity exceeding that of fluorine and hydrogen fluoride. The fluorinating capacity is exhibited by these substances in melts in the temperature range 126–240°C. At room temperature, ammonium fluorides are nonvolatile and sufficiently ecologically safe crystalline substances.

Processing of silicon-containing minerals {Be_2SiO_4, $Be_4[Si_2O_7](OH)_2$}, is hindered by their chemical stability. The quartz component of the mineral can be decomposed under the action of fluoride ions. Ammonium fluorides form with silicon oxide a complex compound $(NH_4)_2SiF_6$. The convenience of use of ammonium hexafluorosilicate in the technology consists in its physicochemical properties. At temperatures above 320°C, this compounds sublimes and leaves the reaction mass; in another apparatus, ammonium hexafluorosilicate can be condensed and subjected to ammonia hydrolysis, with the regenerated ammonium fluoride recycled and a commercial product, silicon oxide of "carbon white" brand, obtained [11–13].

Thermodynamic characteristics of the process of phenacite fluorination with NH_4F and $NH_4F \cdot HF$

Reaction	ΔG, kJ mol^{-1} K^{-1}, at indicated T, K						ΔH_{298}, kJ mol^{-1}
	298	400	500	600	700	800	
(1)	20	–181	–384	–588	–793	–999	32
(2)	–224	–297	–353	–394	–424	–443	620

The thermodynamic probability of the occurrence of reactions was calculated for the interaction of components of a beryllium concentrate (phenacite) with ammonium fluorides

$$Be_2SiO_4 + 14NH_4F = 2(NH_4)_2BeF_4 + (NH_4)_2SiF_6 + 8NH_3 + 4H_2O, \quad (1)$$

$$Be_2SiO_4 + 7NH_4F \cdot HF = 2(NH_4)_2BeF_4 + (NH_4)_2SiF_6 + NH_3 + 4H_2O. \quad (2)$$

The results of the thermodynamic calculation are listed in the table.

The calculated temperature dependence of the Gibbs energy suggests that the reaction of phenacite NH_4F fluorination [reaction (1)] proceeds toward formation of ammonium hexafluoroberyllate at temperatures exceeding 400 K, and $NH_4F \cdot HF$ interacts with phenacite by reaction (2) at room temperature and above. As the temperature is elevated, the completeness of fluorination increases for both the reactions in proportion to the decrease in the Gibbs energy of the processes.

After the thermodynamic possibility of the fluorination reaction was confirmed, a thermogravimetric study of the process was performed. In this experiment, ammonium hydrofluoride was used instead of ammonium fluoride to eliminate the heat-flux DTA peaks corresponding to melting of ammonium fluoride and its conversion to ammonium hydrofluoride, with ammonia released. The peak corresponding to this conversion overlapped in the DTA curve with the peaks related to reactions between the components. After melting and decomposition of ammonium fluoride, the reaction occurs just with ammonium hydrofluoride. The experiments were carried out on an SDT Q600 combined TGA/DSC/DTA analyzer-derivatograph, with data processing by TA instruments Universal v. 4.2E software. The samples were heated at rate of 1 deg min^{-1} in a flow of air.

Figure 1 shows gravimetric (TG) and differential-thermal (DTA) dependences for the interaction of beryllium oxide with ammonium hydrofluoride introduced in a twofold excess with respect to stoichiometry.

The reaction starts to proceed at room temperature to give a fluoroammonium complex of beryllium, $(NH_4)_2BeF_4 \cdot nNH_4F$, with release of gaseous ammonia and water. Upon further heating, the fluoroammonium complex of beryllium decomposes. At 126°C, ammonium hydrofluoride melts. At 200°C, $(NH_4)_2BeF_4 \cdot NH_4F$ is formed, which decomposes to $(NH_4)_2BeF_4$ on heating to 240°C. As the temperature is elevated to 280°C, $(NH_4)_2BeF_4$ decomposes to NH_4BeF_4, which, in turn, decomposes to BeF_2 at 385°C. The fluoroammonium complexes decompose with release of gaseous ammonia and hydrogen fluoride.

The thermogravimetric study of the reaction of beryllium oxide with ammonium fluoride yielded the same results, but the thermograms obtained were complicated by peaks related to decomposition of ammonium fluoride to the hydrofluoride.

The results of an analysis of the thermogravimetric data suggest the following scheme of chemical trans-

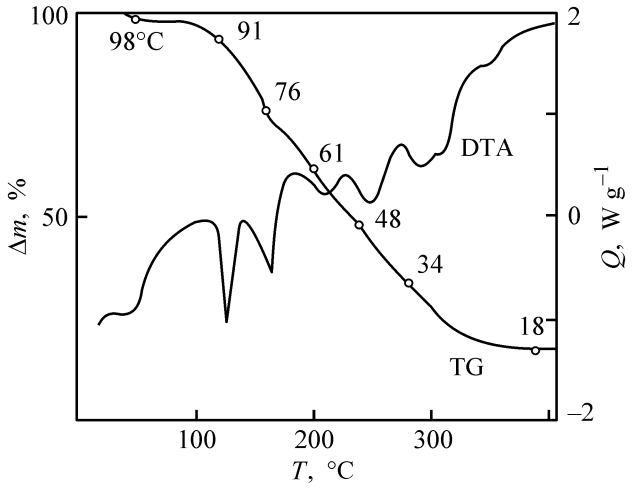

Fig. 1. Thermogram of the interaction of beryllium oxide with ammonium hydrofluoride. (Δm) Change in mass, (Q) heat flux, and (T) temperature.

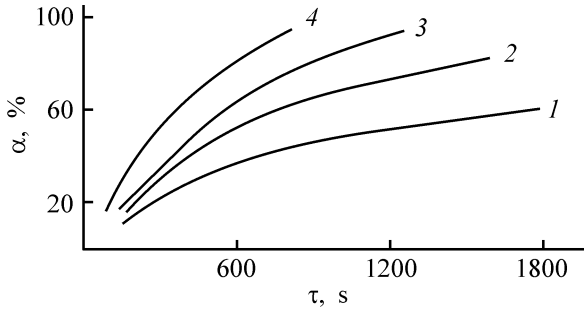

Fig. 2. Kinetic curves of the reaction between beryllium oxide and ammonium fluoride. (α) Degree of conversion and (τ) time. Temperature (°C): (*1*) 140, (*2*) 160, (*3*) 180, and (*4*) 200.

formations that occur in the reaction of beryllium oxide with ammonium fluoride and hydrofluoride:

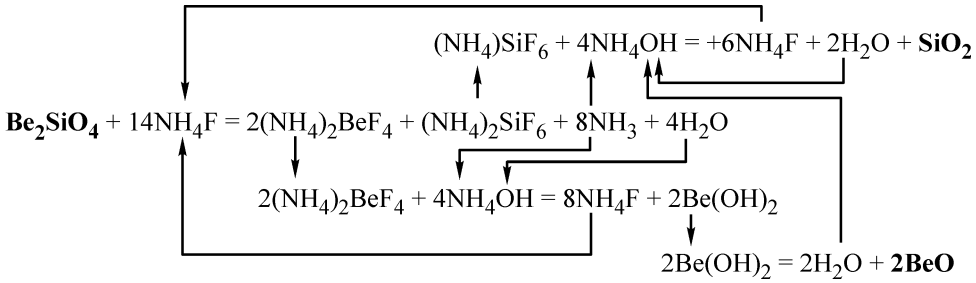
$$BeO + NH_4F \cdot nHF \xrightarrow{200^\circ C} (NH_4)_2BeF_4 \cdot NH_4F$$

$$\xrightarrow{240^\circ C} (NH_4)_2BeF_4 \xrightarrow{280^\circ C} NH_4BeF_3 \xrightarrow{385^\circ C} BeF_2.$$

The thermogravimetry of the reaction between silicon oxide (as the second component of phenacite) with ammonium fluorides was described in detail in [15].

The results of thermodynamic and thermal analyses of the system under consideration, which confirmed the theoretical possibility of the process, made necessary a study of the rate of beryllium oxide fluorination by ammonium fluoride

$$BeO + 4NH_4F = (NH_4)_2BeF_4 + 2NH_3 + H_2O. \quad (3)$$



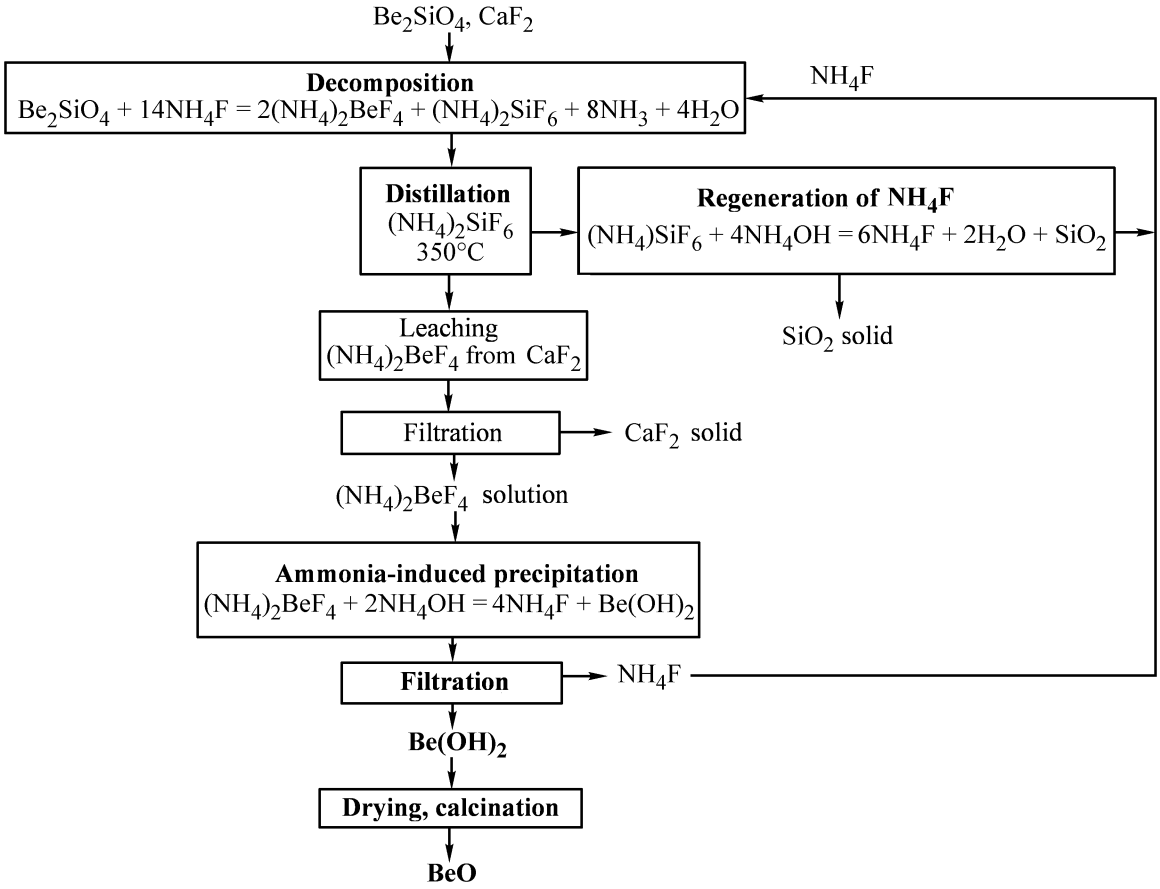
A kinetic experiment was performed by uninterrupted weighing of the reacting mixture, with automatic recording of the mass. The mass loss determined by the formation of gaseous ammonium and water was used to find the degree of conversion. Preliminarily, the decomposition rate of ammonium hydrofluoride at these same temperatures was experimentally determined, with appropriate corrections introduced into the final results. The kinetic curves of beryllium oxide decomposition are shown in Fig. 2.

The experimental data are described with sufficient accuracy by the equation of a contracting sphere, and the following dependence of the conversion α on time τ and temperature T was derived:

$$\alpha = 1 - \left(1 - 1.8e^{\frac{31\,000}{8.31T}}\tau\right)^3.$$

The rate constant of the chemical reaction is 1.8 s^{-1}. The activation energy of the process was 31 kJ mol^{-1}, which indicates that the reaction occurs under mixed diffusion and kinetic control. This means that not only temperature, but also the intensity of agitation of the reaction mass affect the rate of the chemical reaction. The kinetic study demonstrated that more than 95% of beryllium oxide decomposes in 20 min at 200°C.

The general scheme of a closed fluoroammonium cycle of phenacite decomposition into silicon oxide and beryllium oxide, with ammonium fluoride regenerated, is as follows:



(4)

Scheme (4) clearly demonstrates that the flows are closed and the material balance are equal. A scheme of a closed fluoroammonium cycle of beryllium oxide decomposition by ammonium hydrofluoride can be composed in the same way.

The calculated and experimental data presented here suggest the technological sequence of operations in the fluoroammonium method for beryllium oxide recovery from the fluorite-phenacite concentrate (see scheme).

In accordance with the technological scheme suggested, the starting fluorite-phenacite concentrate (phenacite content 30%) is mixed with ammonium fluoride and heated to 200°C. Phenacite reacts with

Technological scheme of fluoroammonium processing of the fluorite-phenacite concentrate.

ammonium fluoride to give ammonium fluoroberyllate and ammonium hexafluorosilicate, with gaseous ammonium and water released in accordance with reaction (1). After the hydrofluorination, the resulting mixture of fluorides is heated to 320°C, with silicon sublimed in the form of gaseous ammonium hexafluorosilicate $(NH_4)_2SiF_6$. Thus, silicon is removed from the mixture as ammonium hexafluorosilicate. Ammonium tetrafluoroberyllate and unfluorinated fluorite remain in the solid fraction. Leaching-out of ammonium tetrafluoroberyllate with water enables its complete recovery from the carrier rock, because the solubility of $(NH_4)_2BeF_4$ is as high as 32% and calcium fluoride is virtually insoluble. After the ammonium tetrafluoroberyllate solution is separated, it is purified to remove admixtures of aluminum and iron by the method of ammonium-induced increase in the solution pH to 8.5. At pH 8.5, aluminum and iron hydroxides precipitate from the solution. The separation of aluminum impurity by ammonium precipitation enables application of the fluoroammonium technique in processing of beryl ($2BeO \cdot Al_2O_3 \cdot 6SiO_2$), too. As the solution pH is raised further to 12, beryllium hydroxide precipitates. Beryllium hydroxide separated by filtration is converted to the oxide form after calcination.

An important economical factor of the process is the possibility of regeneration of a major part of ammonium fluoride from ammonium hexafluorosilicate. The sublimed ammonium hexafluorosilicate was subjected to ammonia hydrolysis:

$$(NH_4)_2SiF_6 + 4NH_4OH = SiO_2\downarrow + 6NH_4F + 2H_2O. \quad (5)$$

Ammonium tetrafluoroberyllate is also subjected to ammonia hydrolysis with regeneration of ammonium fluoride:

$$(NH_4)_2BeF_4 + 2NH_4OH = Be(OH)_2 + 4NH_4F. \quad (6)$$

Thus, the fluorite-phenacite rock is decomposed using ammonium fluoride and beryllium hydroxide is recovered and separated from impurities.

The advantages of the method suggested are the following: possibility of complete regeneration of

ammonium fluoride or hydrofluoride, virtually waste-free mode, and possibility of using the standard chemical apparatus for setting-up commercial production.

CONCLUSIONS

(1) A thermodynamic analysis of the reactions of phenacite with ammonium fluorides demonstrated that the reaction equilibrium is shifted toward product formation.

(2) A thermogravimetric analysis revealed the mechanism of beryllium oxide fluorination by ammonium fluorides. The fluorination occurs to give intricate fluoroammonium complexes, which decompose to beryllium difluoride at temperatures exceeding 380°C.

(3) The kinetic study demonstrated that more than 95% of beryllium oxide is fluorinated in 20 min at 200°C. The rate constant of the chemical reaction is 1.8 s^{-1}, and the activation energy of the process, 31 kJ mol^{-1}.

(4) A technological scheme was suggested for fluoroammonium processing of the fluorite-phenacite concentrate, with ammonium fluoride recycled and beryllium oxide, silicon oxide, and calcium fluoride recovered.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Use of Polysulfides of Alkali and Alkaline-Earth Metals To Obtain Highly Dispersed Sulfur

I. A. Massalimov, I. N. Vikhareva, and M. S. Kireeva

Research Institute of Low-Tonnage Chemical Products and Reagents, Ufa, Bashkortostan, Russia

Received May 15, 2007

Abstract—Possibilities of obtaining polysulfides of alkali and alkaline-earth metals in aqueous solutions were considered. The composition of the polysulfides and their concentration in solutions were found. The efficiencies of application of highly dispersed sulfur, produced from calcium polysulfide, and colloid sulfur as a fungicide were compared.

DOI: 10.1134/S1070427208020055

Sulfur widely occurs in nature in a free state, in various sulfide ores, and as various sulfates, such as gypsum ($CaSO_4$), barite ($BaSO_4$), etc. The diversity of the application fields of sulfur is due to its bactericide and fungicide properties. Brimstone deposits had been industrially developed beginning in the XIX century till mid-XX century [1, 2]. However, the intensive exploitation of sulfur-containing-oil and -gas fields yielded a new source of sulfur. The amount of sulfur in wastes from oil-and-gas processing plants started to rapidly increase. By now, the accumulated resources of these products are so vast that considerable amounts of high-quality raw materials remain unused. In this context, a search for new ways to use elementary sulfur is a rather topical task.

The effective utilization of its bactericide properties can be achieved by grinding sulfur in various devices, micronizers and colloid mills [3]. A prolonged mechanical treatment with addition of various surfactants can yield sulfur with micrometer particles, which is commonly used under the name "colloid sulfur" as a means for plant protection [4]. It has been found that the activity (chemical, catalytic, and biological) of highly dispersed substances markedly increases on passing to submicrometer, nanosize particles [5]. The preparative chemistry employs various precipitation methods that can yield sulfur in a sufficiently dispersed submicrometer state. However, these methods of sulfur isolation (with hydrochloric acid from calcium sulfide and sodium thiosulfate solutions) can only be used to obtain chemically pure sulfur in comparatively small amounts [6].

According to published data [7], ammonium, potassium, sodium, barium and calcium polysulfides have been tested at different times as chemical means of plant protection, but failed to find use because of the lack of preparative forms convenient for practical purposes.

The aim of our study was to examine the possibility of obtaining stable compounds of sulfur with alkali (sodium, potassium) and alkaline-earth (calcium, strontium, barium) metals with subsequent isolation of high-dispersity (submicrometer) sulfur from these compounds. The efficiency of practical application of sulfur recovered from solutions of its compounds and colloid sulfur was tested by comparison of their fungicide properties.

We chose as a basis the polysulfide form containing a comparatively large amount of sulfur, from which, as demonstrated by experiments, highly dispersed sulfur can be produced. We examined the possibility of obtaining polysulfides of varied chemical nature in aqueous solutions and determined their composition. We analyzed, for the example of calcium polysulfide, the possibility of converting sulfur into the polysulfide form by its mechanical activation in a disintegrator and tested it as a plant protection means.

EXPERIMENTAL

Polysulfides of alkali and alkaline-earth metals were synthesized in aqueous solutions in a flask with

a reflux and stirrer. To prevent the possible evolution of hydrogen sulfide, the outlet of the reflux was connected with a solution of lead acetate.

To a weighed portion of a metal hydroxide or oxide was added a certain amount of water, with the mixture heated to boiling. Separately, we prepared a hand-ground sulfur powder, from which a paste was prepared by addition of water and mixed with the boiling solution of the metal hydroxide. Them the mixture was boiled and then cooled and filtered. The filtrate is a dark cherry liquid whose coloration intensity grows as the solution concentration increases. The solution concentration can be controlled in the subsequent evaporation of water. Being subjected to a nucleophilic attack by ions of hydroxide-containing compounds, chains of sulfur molecules are ruptured to give S_n^{2-} ions of various lengths, with polysulfides of the corresponding metals formed as a result.

It was found that elementary sulfur is converted to the polysulfide form in aqueous solutions in different ways in all cases (see table). The synthesis of polysulfides is the easiest for alkali metals:

$$10S + 6NaOH = 2Na_2S_4 + Na_2S_2O_3 + 3H_2O.$$

The process goes rapidly, in 1–1.5 h; by the end of an experiment, the reaction mass contains in the precipitate only sulfur taken in an excess (10% with respect to the stoichiometry) and the content of the target polysulfide reaches high values (35–40 wt % dry substance).

A different situation is observed when alkali metal polysulfides are obtained. For example, in the reaction of synthesis of calcium polysulfide

$$10S + 3CaO = 2CaS_4 + CaS_2O_3,$$

with the use of hand-ground sulfur, the main part (70–75%) of the starting reagents enters into the reaction in the course of 3–4 h of thermal treatment at 100°C. At the same time, a considerable part (up to 25–30%) of the starting reagents is not involved in the reaction even upon prolonged thermal treatment (up to 60–70 h). To obtain a concentrated (with 20% dry substance and more) solution, it is necessary to evaporate water and add stabilizers [8].

It is known that preliminary mechanical treatment of reagents [9] leads to a substantial acceleration of chemical reactions in solid and liquid phases. To improve the synthesis of calcium polysulfide, we used a disintegrator that, as shown previously, strongly changes the thermodynamic [10] and structural characteristics [11, 12]. We obtained in our study samples with different numbers of treatments in the disintegrator and subjected these samples to an X-ray diffraction analysis. The samples were used in the reaction of synthesis of calcium polysulfide. With sulfur once treated in the disintegrator, the time of boiling of a mixture of sulfur and calcium hydroxide decreased from 3–4 to 1 h, and the amount of the precipitate, from 30 to 5%. It was also found that use of sulfur twice treated in the disintegrator leads to complete interaction of the starting reagents. Thus, intensive mechanical treatment changes the equilibrium solubility of sulfur, enables full use of the starting reagents, and markedly facilitates preparation of its concentrated aqueous solutions in the form of polysulfides. Synthesis of calcium polysulfide with mechanically activated sulfur and polysulfide stabilizers (glycerol, sugar, ethylene glycol, etc.) can give concentrated solutions with density $\rho = 1.18–1.32$ g cm^{-3}.

To study how the particle size and structural parameters vary in mechanical treatment, we performed sedimentation and X-ray diffraction analyses of the starting and mechanically treated sulfur samples. Because the disintegrator is a flow-through grinding device, the duration of the mechanical treatment was varied by carrying out repeated treatments.

The particle size distribution (Lumosed sedimentograph) demonstrated that the process of sulfur particle grinding virtually ceased after two treatments. The particle size of the starting hand-ground powder was in the range 0.1–3 mm; immediately after the first treatment the particle size distribution corresponded to the range 1–12 μm.

The integral intensities and diffraction angles were measured on a DRON-3M diffractometer. The experimental results were processed using a special-purpose software package developed at Moscow Institute of Steel and Alloys. It was found that the X-ray diffraction patterns of the starting and mechanically treated samples exhibit reflections that correspond only to the orthorhombic phase of elementary sulfur, but their parameters (width and position) change in the course of mechanical treatment. The basic parameter characterizing deviations of the crystal lattice from the ideal order is the integral linewidth. It is known [9, 11, 12] that just this quantity is correlated with practically important parameters, such as the solubility and chemical activity of solid substances.

The figure shows how the integral linewidth for reflections from the (313), (135), and (026) planes depends on the treatment duration. It should be noted that sample 2 corresponds to the stage of a double

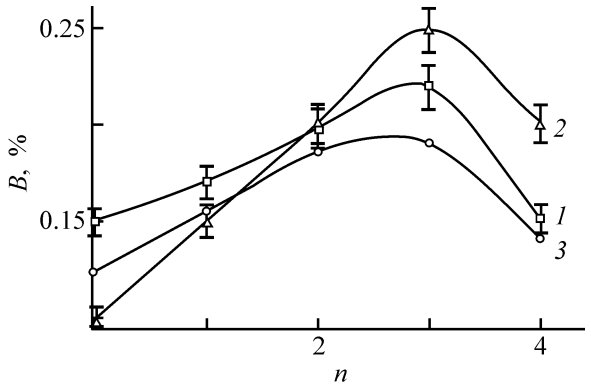
* The weighed portion of sulfur corresponds to the mass of sulfur with account of the stoichiometric coefficients in the equation describing the synthesis of a polysulfide.



treatment, in which the grinding process is complete. It can be seen from the figure that, despite the grinding is complete, the linewidth increases as the treatment duration becomes longer, untill the third treatment, and the linewidth slightly decreases for sample 4. Thus, these dependences demonstrate that the level of structural disruption within particles (samples 3 and 4) changes even in the absence of comminution. Comparison of the results of X-ray studies with data on dissolution of elementary sulfur in a calcium hydroxide solution shows that a gradual increase in the linewidth is correlated with a rise in the solubility of sulfur. In this case, the increase in the linewidth, observed for sample 2, is sufficient for complete dissolution of sulfur.

It was found experimentally that a 20–30-fold dilution of the starting solution with density ρ = 1.18–1.20 g cm^{-3} results in that the solution loses transparence and a precipitate composed of finely dispersed sulfur and calcium carbonate, hydroxide, and thiosulfate is formed in 24 h. A sedimentation analysis of the precipitate demonstrated that 95% of precipitate particles are less than 1 μm in size, and 80%, less than 0.1 μm. Thus, the method of sulfur isplation from a calcium polysulfide solution can give highly dispersed sulfur, which is difficult to obtain by mill grinding.

Further, we performed a chemical analysis of the solutions obtained. In samples of polysulfide solutions, the amount of ions of alkaline-earth metals was determined by chelatometry, and that of alkali metals, by acid-base titration.

The amount of sulfur in the thiosulfate form was found by iodometric titration after separating the polysulfide and sulfide sulfur in the form of cadmium sulfide and sulfur. A part of sulfur, which is in the sulfide form, was determined by back redox titration with iodine [13], with the subsequent subtraction of the previously found amount of thiosulfate sulfur. The content of sulfur in the polysulfide form was found by conversion of the polysulfide sulfur to thiosulfate under the action of a sodium sulfite solution, separation of the sulfide sulfur in the form of cadmium sulfide, and titration with iodine thiosulfate in an acid medium [14, 15]. The sum of these three constituents, S_{Σ}, is presented in the table. The value of S_{tot} was found experimentally by redox titration with a potassium bromide-bromate solution [16, 17]. The data obtained were used to calculate the formulas of the polysulfides.

It can be seen in the table that, depending on the nature of a metal atom, the number of sulfur atoms in the molecule ranges from 3 for K_2S_4 to 4.8 for $BaS_{4.8}$. The difference between the initial amounts of a metal and sulfur and those experimentally found in alkaline-earth polysulfides is observed because part of reagents in the latter are in the precipitate.

Linewidth *B* for reflections from the planes (*1*) (313), (*2*) (135), and (*3*) (026) vs. the number *n* of mechanical treatments.

To determine the fungicide activity[1], we performed industrial tests of the new preparative form of sulfur, which contained, together with calcium polysulfide, solution stabilizers (glycerol) and polyvinyl alcohol as a film-forming agent. The analysis demonstrated that spraying with the preparation enables effective distribution over the surface of plants (pine trunks and needles) of highly dispersed sulfur formed in decomposition of calcium polysulfide. It was found that hydrophobic sulfur is fixed on the surface of plants upon the subsequent drying, which makes it possible to reduce the number of treatments.

Tests were carried out in three variants, with concentrations of 10, 5, and 2.5% in terms of the preparation or 2.0, 1.0, and 0.5% in terms of pure sulfur and an application rate of 400 l of the working liquid per 1 ha. As a reference for treatment of pine yearlings served a 2% solution of colloid sulfur at the same application rate of the working liquid. The treatments were performed on a total area of 2 ha. An examination of the treated seedlings demonstrated the following.

(1) The average number of infested seedlings on treated plots was 0.67, 0.97, and 2.8% with 10, 5, and 2.5% solutions, respectively. The number of infested seedlings in the control was 3.7%. A comparison of the effect of the preparation under study, with concentrations of 10 and 2% in terms of pure sulfur, and of the reference 2% solution of colloid sulfur demonstrated that the efficiency of the form we developed is 5.5 times higher.

(2) Laboratory tests aimed to evaluate the activities of different doses of the preparative form of sulfur as an aqueous solution were performed on pure cultures of the most harmful and widely occurring agents causing diseases in conifer seedlings. The colloid sulfur conventionally used as a fungicide was used as reference. The preparations were introduced into a not-yet-solidified nutritional medium and the fungus cultures *Phacidium infestans Karst* (snow blight) and *Lophodermium pinastri Chev* (pine needle cast) were applied to its already solidified surface. As controls served nutritional media with fungus cultures, but without addition of the preparations. The fungicide effect of the preparations tested was judged from the occurrence or absence of mycelium growth and from the colony diameter after 7 days of growth of the mycelium of the fungi. The results obtained demonstrated that the preparation exhibits a fungicide effect.

The preparation suppressed the growth of colonies of the agent causing show blight, whose diameters were 25, 20, and 12.5 mm after 7 days of growth in media with 4, 6, and 10% aqueous solutions of the preparation, respectively. This diameter was 47 mm with the reference preparation, and 59 mm in the control.

An even more pronounced fungicide effect was produced by the preparation on the growth of colonies of agents of pine needle cast, whose diameters were 18, 14, and 8.5 mm after 7 days of growth in media with 4, 6, and 10% aqueous solutions of calcium polysulfide, respectively. This diameter was 52 mm with the reference preparation, and 60 mm in the control. Thus, the preparation tested under industrial conditions exhibited a stronger fungicide effect for forest cultures, compared with colloid sulfur.

CONCLUSIONS

(1) It was found that elementary sulfur can be used upon its conversion to the polysulfide form, followed by isolation in the highly dispersed (submicrometer) state.

(2) The possibility of intensifying the reaction of polysulfide formation by using sulfur mechanically activated in a disintegrator was demonstrated.

(3) Tests of calcium polysulfide as a means of plant protection from fungal diseases demonstrated that the preparative form suggested is more efficient than ground, colloid sulfur, which makes it possible to recommend its use as a component of an integrated scheme for protection of cultivated plants and forest plantations.

Abstract—Effect of carbamide on sulfuric acid decomposition of phosphate raw materials in nonthickening suspensions in production of integrated fertilizers was studied. The mechanism and phase composition of the intermediate and final products of the decomposition process in the presence of carbamide were examined. The results obtained served as a theoretical basis for development of a new technological process for manufacture of integrated sulfur-containing fertilizers.

DOI: 10.1134/S1070427208020067

Processes of acid decomposition of phosphate materials in nonthickening suspensions are of fundamental importance in the technology of inorganic substances, because they are employed to obtain a number of most important chemical products and, in particular, extractive phosphoric acid (EPA) and simple and double superphosphate. At the same time, a stable tendency is conversion of shops for production of simple single-component fertilizers to manufacture of integrated NP and NPK fertilizers. For example, the fraction of simple phosphate fertilizers in Russia is only 1.6% of the total [1]. About 200 brands of phosphorus-containing integrated fertilizers are offered at present by the European market. The main way to optimize the assortment of mineral fertilizers in the Republic of Belarus is, according to the data obtained by agrochemists [2], a substantial increase in volume of manufacture and application of complete integrated fertilizers. This will diminish by 65–70% the expenditure for introduction of fertilizers and optimize the mineral feeding of plants, which is extremely difficult with simple forms and existing application techniques.

At present, a considerable researchers' and manufacturers' attention is given to production of integrated fertilizers with introduction of carbamide. The use of carbamide in synthesis of complex fertilizers based on products of acid processing of phosphates is advisable from the agrochemical standpoint. The interest in systems constituted by carbamide and superphosphate, and carbamide and ammonium phosphates is also due to the fact that reactions of adduct formation occur between the components of these systems. Fertilizers containing adducts of carbamide with calcium sulfate and hydrosulfate release nitrogen into soils at a considerably slower rate than carbamide, which enables their use in production of prolonged-action integrated fertilizers and diminishes the loss of nutritive components in soils. However, production of integrated fertilizers with introduction of carbamide is a rather difficult task. Direct mixing of carbamide and superphosphate (ammonium phosphates) is undesirable because the differences in the physical properties and, in particular, bulk density result in that the mixture is inhomogeneous in composition and separate components are nonuniformly distributed over fields. Introduction of carbamide in the industrial process of superphosphate synthesis and, in particular, that together with the recycle is not simple, either, because it involves release of water and formation of a large amount of an additional liquid phase, increase in the extent of recycling, higher energy expenditure, and stronger caking of the final product.

It seems appropriate to introduce carbamide directly into the acid, or partly ammonized suspension before the granulation stage. This will diminish the amount of the liquid phase introduced into the process together with the starting reagents and, accordingly, will make lower the expenditure for its subsequent drying because of the improvement of the rheological properties

of the suspensions upon introduction of carbamide. However, the available data on the effect of carbamide on the process of sulfuric acid decomposition of phosphate raw materials are of unsystematic nature and frequently contradictory and give no way of making an unambiguous conclusion about the optimal method and place of carbamide introduction into the technological cycle in production of integrated fertilizers.

The goal of this study was to examine specific features of the process of sulfuric acid decomposition of phosphate raw materials in nonthickening suspensions in the presence of carbamide and to determine the chemical and phase composition of the products formed. The results obtained were used to develop a new low-waste technology for manufacture of sulfur-containing integrated NPKS fertilizers.

EXPERIMENTAL

The effect of carbamide on the process of sulfuric acid decomposition of phosphate raw materials was studied under conditions corresponding to the dihydrate mode of extraction in manufacture of EPA from the apatite concentrate as the phosphate raw material. The necessary amount of sulfuric acid, calculated from the stoichiometry and corresponding to the molar ratio P : S = 3 : 5, was 89.4 mass fractions of H_2SO_4 per 100 mass fractions of apatite. The content of $CO(NH_2)_2$ was varied within the range 10–40 wt % relative to the mass of the liquid fraction. The duration of decomposition was 30 min.

The decomposition yields well-fluid suspensions; however, separation of the solid and liquid phases is difficult, and, therefore, the suspensions obtained were diluted with water and filtered for further analyses. The precipitate was washed with water to pH 5–6 and dried at 95°C to constant weight. In parallel, in order to study the additional decomposition of apatite in drying, the forming suspensions were dried at 95°C to constant weight without preliminary separation. The content of biologically available and total P_2O_5 was determined in the dried sulfur and precipitate, and that of water-soluble P_2O_5 and carbamide, in an aqueous extract from the dried sulfur and in the filtrate. The chemical analysis was performed by the standard procedures [3].

The results of these analyses were used to find the basic technological parameters of the process. The decomposition coefficients were calculated both from the amount of P_2O_5 soluble in water and citric acid, i.e., biologically available P_2O_5 (K_1), and from the difference between the total P_2O_5 and that soluble in citric acid, i.e., from the amount of biologically unavailable P_2O_5 (K_2). After the dilution with water, filtration, and washing and drying of the precipitate

$$K_{1f} = (P_2O_{5\,aq} + P_2O_{5\,b.a}^{pr})/P_2O_{5\,init}, \quad (1)$$

$$K_{2f} = 1 - (P_2O_{5\,tot}^{pr} - P_2O_{5\,b.a}^{pr})/P_2O_{5\,init}; \quad (2)$$

and after drying of the suspension

$$K_{1s} = P_2O_{5\,b.a}/P_2O_{5\,init}, \quad (3)$$

$$K_{2s} = 1 - (P_2O_{5\,tot} - P_2O_{5b.a})/P_2O_{5\,init}, \quad (4)$$

with the following designations for the content of phosphorus(V) oxide: $P_2O_{5\,init}$, in a weighed portion of apatite; $P_2O_{5\,aq}$, water-soluble; $P_2O_{5b.a}^{pr}$ and $P_2O_{5tot}^{pr}$, biologically available and total in dried precipitate; and $P_2O_{5\,b.a}$ and $P_2O_{5\,tot}$, biologically available and total in dried suspension; the contents of all forms of phosphorus(V) oxide can be expressed in any identical units.

Data on the loss of mass in drying and the results obtained in analysis of dried suspensions for the content of carbamide were used to estimate the mass of water remaining in the suspension (H_2O_{res}) on the assumption that the loss of mass in drying is constituted by loss of H_2O and CO_2 formed in conversion of carbamide:

$$m(H_2O_{res}) = m(H_2O_{init}) - \Delta m + m(CO_2) - m(H_2O_r), \quad (5)$$

where $m(H_2O_{init})$ is the total mass of water in the mixture of the starting substances (g); Δm, loss of the suspension mass in drying (g); $m(CO_2)$, mass of CO_2 formed in conversion of carbamide (g); and $\Delta m(H_2O_r)$, mass of water entering into the reaction of carbamide hydrolysis (g).

The resulting samples of dried suspensions and precipitates were studied by the methods of X-ray phase analysis (XPA) and IR spectroscopy. The X-ray study was performed using a Bruker D8 Advance X-ray diffractometer. The phase composition of the samples was determined using the database [4]. IR bands were assigned using the reference book [5]. The results of chemical analyses of the filtrates and precipitates and the process parameters calculated from these data are listed in Table 1.

The deviation of the total amount of P_2O_5 found in the filtrate and precipitate from the initial amount of P_2O_5 in apatite is 0.1–2.5%, the decomposition

Content of $CO(NH_2)_2$ (%) relative to the initial value		103.0	104.0	104.2	103.6	Content of $CO(NH_2)_2$ (%) relative to the initial value		97.0	95.4	97.3	97.7
K_{1f}, %	44.1	29.9	22.8	19.9	21.2	K_1, %	70.4	76.7	67.8	67.6	51.8
K_{2f}, %	43.8	32.3	25.3	18.2	20.5	K_2, %	69.4	74.7	65.6	66.5	51.9

coefficients calculated from analytical data for the filtrates (K_1) and precipitates (K_2) differ by 0.1–2.2%; the amount of carbamide in the filtrate differs from the initial value by 2.3–4.6%, which confirms the reliability of the results obtained.

Comparison of the data obtained in filtration of suspensions immediately after the end of decomposition and a week after the dilution shows that further decomposition of apatite occurs in the diluted suspension. Therefore, the process of separation of the solid and liquid phases was evaluated immediately after the decomposition was complete.

As follows from an analysis of the data in Fig. 1a, the distribution of phosphorus among various forms strongly varies with the content of carbamide. As the amount of carbamide grows, the fraction of P_2O_5 in the liquid phase decreases, and that in the solid phase, increases, which indicates that the content of water-soluble forms becomes lower. In this case, the content of biologically available phosphates in

$K_{2\,s}$, %	80.6	64.8	52.3	35.1	21.9

the precipitate is low and independent of the presence of carbamide. As can be seen from an analysis of the curves (Fig. 2) describing the variation of the extent to which raw materials decompose, the decomposition coefficient K_{1f} decreases from 44.1 to 21.2%, and K_{2f}, from 43.8 to 20.5%, i.e., by more than a factor of 2, as the content of carbamide increases to 40%. This suggests that the decomposition is impaired in the presence of carbamide.

It is known that a strong change in the phase composition and basic process parameters is observed in the stage of drying of phosphoric acid suspensions in flow production of phosphorus-containing fertilizers: in particular, in an apparatus with a drum granulator-drier. Therefore, analysis of how carbamide affects the composition and basic technological parameters of dried phosphoric acid suspensions is of scientific and practical interest. Dried carbamide-containing suspensions are tarry products, which is natural in view of their high acidity. The results of the analysis and the process parameters calculated from these data are listed in Table 2.

It was found that the loss of carbamide increases as its initial content in the system becomes higher and this dependence is nonlinear, which indicates that hydrolysis partly proceeds by the scheme

$$CO(NH_2)_2 + 2H_2O \rightarrow (NH_4)_2CO_3.$$

The data obtained confirm that additional decomposition of phosphate raw material occurs in drying of phosphoric acid suspensions, which is indicated by the increase in the decomposition coefficient. However, the tendency toward a decrease in the degree of its decomposition and in the content of water-soluble forms of phosphorus in the presence of carbamide is preserved (Table 2, Figs. 1b and 2), and, at a carbamide content of 40 wt %, the additional decomposition of the raw material in the course of drying virtually ends.

It is known that a decrease in the solubility of calcium phosphates is promoted by all cations neutraliz-

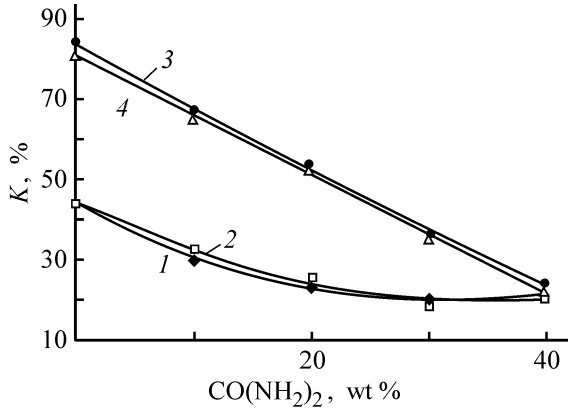

Fig. 2. Effect of the content of carbamide on the process of sulfuric acid decomposition of natural phosphates (*K*) Decomposition coefficient. Calculation of *K* from the amount of P_2O_5: (*1*) biologically available immediately after decomposition (K_{1f}), (*2*) biologically unavailable immediately after decompositions (K_{2f}), (*3*) biologically available in dried suspensions (K_{1s}), and (*4*) biologically unavailable in dried suspensions (K_{2s}).

ing the acid, which leads to an increase in pH and decrease in the activity of hydrogen ions, a_{H^+} [6]. According to [7], the rate of apatite dissolution is directly proportional to a_{H^+}. Because carbamide is a weak base, the solution pH increases in its presence, which leads to a decrease in the rate and degree of decomposition. Additional neutralization of the acid in the course of the process is possible as a result of partial hydrolysis of carbamide to give ammonium ions in the stage of drying of the phosphoric acid suspension.

It is known that carbamide can form salt-like compounds with acids and complex compounds with salts. Carbamide can react with components present in the system in decomposition of apatite with sulfuric acid to give the following compounds: $H_2SO_4 \cdot CO(NH_2)_2$, $H_2SO_4 \cdot 2CO(NH_2)_2$ [8]; $H_3PO_4 \cdot CO(NH_2)_2$ [9]; $H_2SiF_6 \cdot 2CO(NH_2)_2$, $H_2SiF_6 \cdot 4CO(NH_2)_2$ [10]; $CaSO_4 \cdot 4CO(NH_2)_2$ [11]; $MgSO_4 \cdot CO(NH_2)_2 \cdot 2H_2O$, $MgSO_4 \cdot 4CO(NH_2)_2 \cdot H_2O$ [12]; $Al_2(SO_4)_3 \cdot CO(NH_2)_2 \cdot 2H_2O$ [13]. In the opinion of the authors of [8], when carbamide sulfates are formed, the strong inorganic acid neutralizes the weak base via protonation or direct addition to its molecule. If the formation of the above compounds in the system under study is confirmed, this phenomenon is the main reason why the degree of sulfuric acid decomposition of phosphate raw material decreases in the presence of carbamide. However, not all of these compounds will equally affect the process of acid decomposition of natural phosphates. In particular, carbamide phosphate dissolves in water incongruently [8], and, therefore, the formation of the compound $H_3PO_4 \cdot CO(NH_2)_2$ probably has no direct negative effect on the process

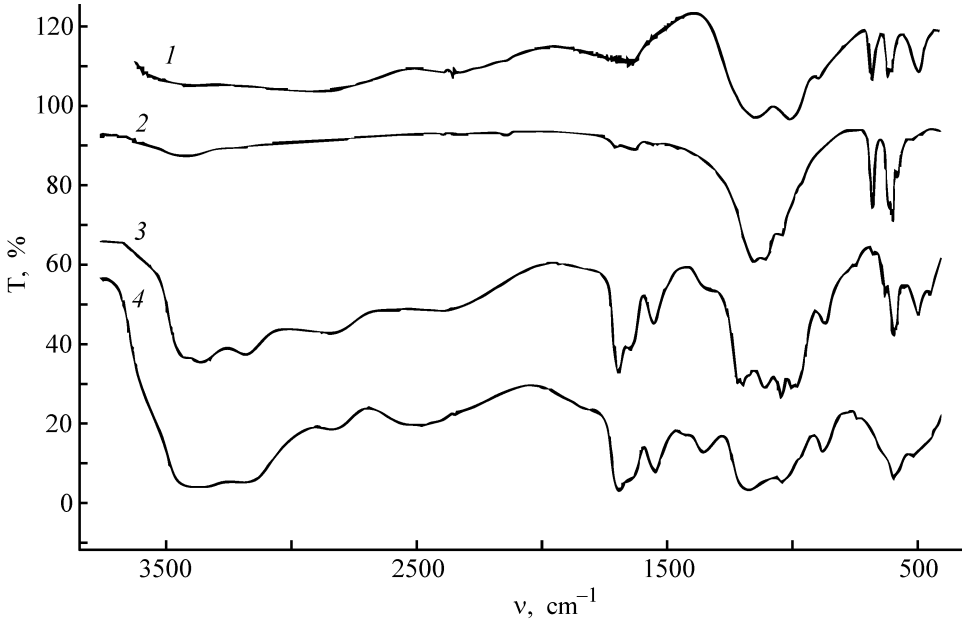

Fig. 4. IR spectra of products formed in apatite decomposition with sulfuric acid (dried suspensions) with introduction of carbamide. (T) Transmission and (ν) wave number; the same for Fig. 5. Amount of carbamide introduced in the decomposition stage (wt %): (*1*) 0, (*2*) 10, (*3*) 20, and (*4*) 40.

of apatite decomposition. An admixture of H_2SiF_6 makes larger the decomposition coefficient [14]. In the system H_2SiF_6–$CO(NH_2)_2$–H_2O, two congruently soluble compounds, $H_2SiF_6 \cdot 2CO(NH_2)_2$ and $H_2SiF_6 \cdot 4CO(NH_2)_2$, are formed [10], with the result that the positive effect of H_2SiF_6 on the decomposition process can be weakened. The process of sulfuric acid decomposition of apatite is strongly affected by the size and shape of the forming crystals of calcium sulfate and its solubility. Of particular interest in this context is the compound $CaSO_4 \cdot 4CO(NH_2)_2$ [11], whose formation can change the equilibrium conditions and the suspension properties. With other sulfates, carbamide forms adducts of different compositions; in particular, carbamide can react with impurities present in the system to give the compounds $MgSO_4 \cdot CO(NH_2)_2 \cdot 2H_2O$, $MgSO_4 \cdot 4CO(NH_2)_2 \cdot H_2O$ [12], and $Al_2(SO_4)_3 \cdot CO(NH_2)_2 \cdot 2H_2O$ [13]. The compounds of magnesium and aluminum mostly affect the size and shape of calcium sulfate crystals [15], and, therefore, formation of these adducts can change these parameters; however, their effect on the decomposition process will be insignificant.

To understand the observed specific features of the acid decomposition of natural phosphates in the presence of carbamide, samples of precipitates and suspensions obtained in the decomposition stage were subjected to an X-ray phase analysis and studied by IR spectroscopy. According to the XPA data, the main crystalline phase present in washed and dried precipitates after dilution and filtration of suspensions formed in apatite decomposition with sulfuric acid is $CaSO_4$, which seems to be natural. In addition, the precipitates contain the starting apatite, whose relative amount increases with the content of carbamide because of the decrease in the degree of decomposition of the raw material. No carbamide or its compounds were found in the precipitates, which confirms its presence in the suspensions under study in the liquid phase.

The X-ray diffraction patterns of samples of dried sulfuric acid suspensions with an initial carbamide content of up to 20 wt % contain $CaSO_4$ reflections (Fig. 3). The reflections related to apatite have an exceedingly low intensity. In the X-ray diffraction pattern of a sample containing 40% carbamide, the presence of apatite is manifested to a greater extent and, in addition, there are reflections associated with $CaSO_4 \cdot 0.5H_2O$. As the content of carbamide grows, the background peaked at around $2\theta = 23°$ becomes more pronounced as a result of the increase in the amount of the amorphous phase.

Similar changes are also observed in analysis of the IR spectra of these suspensions. The application of IR spectroscopy made it possible to reveal changes occurring in the course of sulfuric acid decomposition in the presence of carbamide and to explain why the degree of decomposition of phosphate raw materials decreases (Figs. 4 and 5).

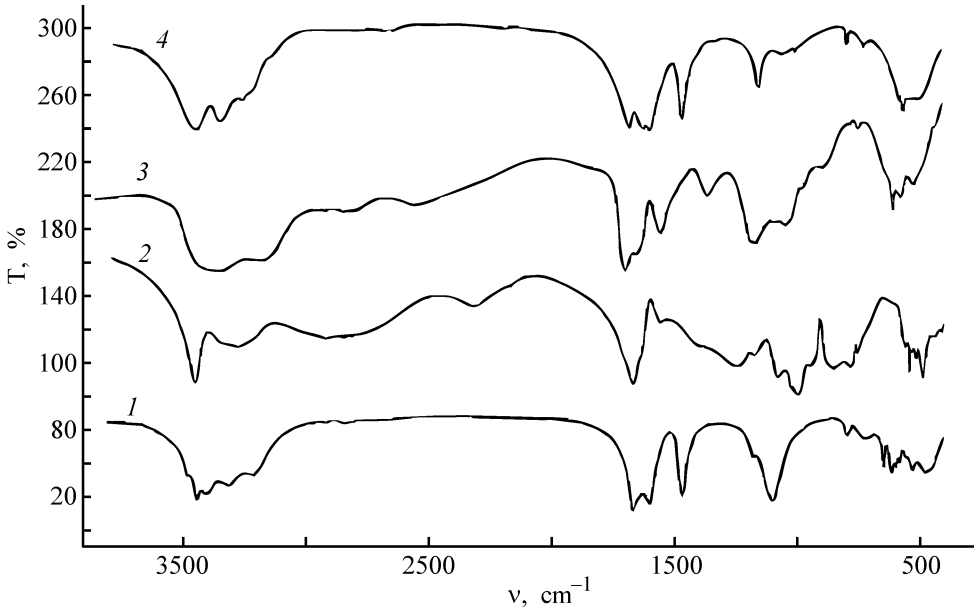

Fig. 5. IR spectra of carbamide adducts. (*1*) $4CO(NH_2)_2 \cdot CaSO_4$, (*2*) $CO(NH_2)_2 \cdot H_3PO_4$, (*3*) $2CO(NH_2)_2 \cdot H_2SO_4$, and (*4*) $CO(NH_2)_2$.

The frequency range best suitable for analysis is 1700–1400 cm^{-1}. In this range, carbamide shows absorption at 1680, 1625, 1598, and 1467 cm^{-1}. The IR spectra of a carbamide-free sample and that with 10% $CO(NH_2)_2$ contain bands characteristic of $CaSO_4$ (1153, 674, 615, 595 cm^{-1}) [5]. The IR spectra of samples with a higher content of carbamide show, in addition to the bands characteristic of calcium sulfate and apatite, also bands in the frequency range of vibrations of the N–H, C=O, and C–N bonds (3500–3200 and 1700–1400 cm^{-1}) and, in particular, bands at 1699, 1650–1655, 1557 cm^{-1} (Fig. 4), which differ from the bands characteristic of carbamide and its adducts with calcium sulfate and phosphoric acid. For interpretation of these data, model compounds of carbamide with H_2SO_4, H_3PO_4, and $CaSO_4$ were synthesized and their IR spectra were recorded (Fig. 5). A comparison of the IR spectra of these compounds led to a conclusion that dried suspensions contain carbamide sulfate (3358, 3185, 1700, 1655, and 1558 cm^{-1}), whose formation is the main reason why the degree of apatite decomposition with sulfuric acid decreases in the presence of carbamide.

CONCLUSIONS

(1) The rate and degree of sulfuric acid decomposition of natural phosphates in nonthickening suspensions decrease if carbamide is introduced together with the acid in the initial stage of the process.

(2) The main reason for the decrease in the degree of decomposition is that an adduct of carbamide sulfate is formed.

(3) When organizing a technological process for production of sulfur-containing integrated fertilizers, it is recommended to introduce carbamide after the stage of acid decomposition into acid or partly ammonized suspensions.

(4) Introduction of carbamide strongly affects changes in the phase composition of the forming products and the content and distribution of various forms of phosphorus. The process of adduct formation leads to deceleration of nitrogen dissolution from the fertilizers obtained, which allows their classification with prolonged-action fertilizers.

Abstract—Sorption of molybdenum(VI), tungsten(VI), and vanadium(V) on amino silica gels in the presence of an anionic dye, bromopyrogallol red, and cationic surfactants fixed on the sorbent surface or present in solution was studied.

DOI: 10.1134/S1070427208020079

Basic principles of interactions in a system constituted by a metal, an organic dye, and a surfactant in solution have been described in the literature [1–6]. They primarily consist in that the hydrate shell of a metal (M) ion is loosened, i.e., the interaction between water molecules becomes stronger, and the binding between water and the metal, weaker. This leads to an increase in the number of coordinated ligands, and addition of a larger number of ions of the cationic surfactant to the organic dye bound into a complex with the metal ion. These factors cause an increase in the absorption intensity and, as a rule, lead to a bathochromic shift of the absorption spectra of the solutions and to a shift of the complexation pH into a more acid region.

It would be expected that these factors will be also manifested in a system constituted by M, organic dye, and surfactant in the case when complexation processes occur at the surface of dispersed silicas. At the same time, limitations on the degrees of freedom of fixed molecules of a surfactant and(or) an organic dye may result in that interactions in the heterogeneous system under consideration will differ from those in a homogeneous system.

The aims of this study were as follows: (1) to find the optimal conditions of sorption of molybdenum(VI), tungsten(VI), and vanadium(V) on silica gels with aminopropyl (NH_2-C) or ethylenediamine (en-C) groups covalently bound to the surface, with bromopyrogallol red (BPR) dye fixed on the surface or present in solution together with the metal being sorbed and a cationic surfactant, dodecylpyridinium chloride (DPC); and (2) to determine the optimal conditions of sorption of molybdenum(VI), tungsten(VI), and vanadium(V) on a silica gel with a polymeric cationic surfactant, polyhexamethyleneguanidinium chloride (PHMGC), deposited on its surface, in the presence of BPR fixed on the surface or present in solution together with the metal being sorbed.

The choice of PHMGC is due to its high sorption capacity on the silica gel surface and to the combination of properties of a surfactant and an anion exchanger.

Thus, the following systems were studied in order to optimize complexation-related sorption of metals: systems with amino silica gels (Am-C): Am-C (surface) and M^{n+} (solution), [Am-C + BPR] (surface) and M^{n+} (solution), Am-C (surface) and [BPR + M^{n+}] (solution), Am-C (surface) and [BPR + DPC + M^{n+}] (solution); and those with a silica gel modified with PHMGC (PHMGC-C): [PHMGC-C + BPR] (surface) and M^{n+} (solution), PHMGC-C surface) and [BPR + M^{n+}] (solution).

The charges and forms of existence of the metal ions are omitted for the sake of simplicity.

EXPERIMENTAL

The starting solutions of molybdenum(VI), tungsten(VI), and vanadium(V) were prepared by dissolu-

tion of precisely weighed portions of $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, $Na_2WO_4 \cdot 2H_2O$, and $Na_3VO_4 \cdot 12H_2O$ in distilled water by the procedures described in [7]. The working solutions with lower metal concentrations were obtained by dilution of the starting solutions. Aqueous solutions of BPR (1×10^{-4} M) and DPC (1×10^{-3} M) were prepared with twice-distilled water immediately before use.

Amino silica gels were synthesized by the method described in [8] from Silica Gel 60 (Merck), with a specific surface area found from low-temperature adsorption of nitrogen by the Brunauer–Emmett–Teller (BET) technique to be 260 $m^2 g^{-1}$ and average pore size of 12 nm. As modifiers served 3-aminopropyltriethoxysilane and 3-diethyldiaminopropyltroethoxysilane (Merck) without additional purification. The concentrations of grafted amino groups, found by elemental analysis for nitrogen and potentiometric titration with HCI on the surface of NH_2-C and en-C, were 0.88 and 0.70 mmol g^{-1}, respectively.

The concentration of the metals in the aqueous solution was found using a Spectroflame Modula optical atomic-emission spectrometer with inductively coupled plasma, from the lines of molybdenum (281.615 nm), tungsten (207.911 nm), and vanadium (311.071 nm).

The acidity of the solutions was monitored with an Ionometr I-130.2m.1 pH-meter with a glass electrode.

Diffuse reflection spectra of the sorbates in the spectral range 12 000–27 000 cm^{-1} were recorded with a UV-VIS Specord M40 spectrophotometer.

BPR was fixed on amino silica gels by bringing them in contact with a 0.05 M solution of BPR in H_2SO_4 under vigorous agitation for 10 min (quantitative sorption of BPR on amino silica gels occurs at pH 0.8–5.6 in 2–3 min). The samples obtained were filtered off; air-dry samples were used for further sorption of the metals from solution.

The sorption of the metals on the modified silica gels was studied under static conditions. For this purpose, precisely weighed portions of a sorbent (0.2 g) were placed in vessels with ground-in stoppers and poured-over with 25 ml of a metal salt solution of a known concentration with necessary ingredients. The resulting suspensions were agitated with a magnetic stirrer for a required time. The sorbent was separated from the solution by filtration and the equilibrium metal concentrations and solution pH values were measured in the filtrate.

The generalized experimental data on the sorption of Mo(VI), W(VI), and V(V) on NH_2-C (Figs. 1a–1c,

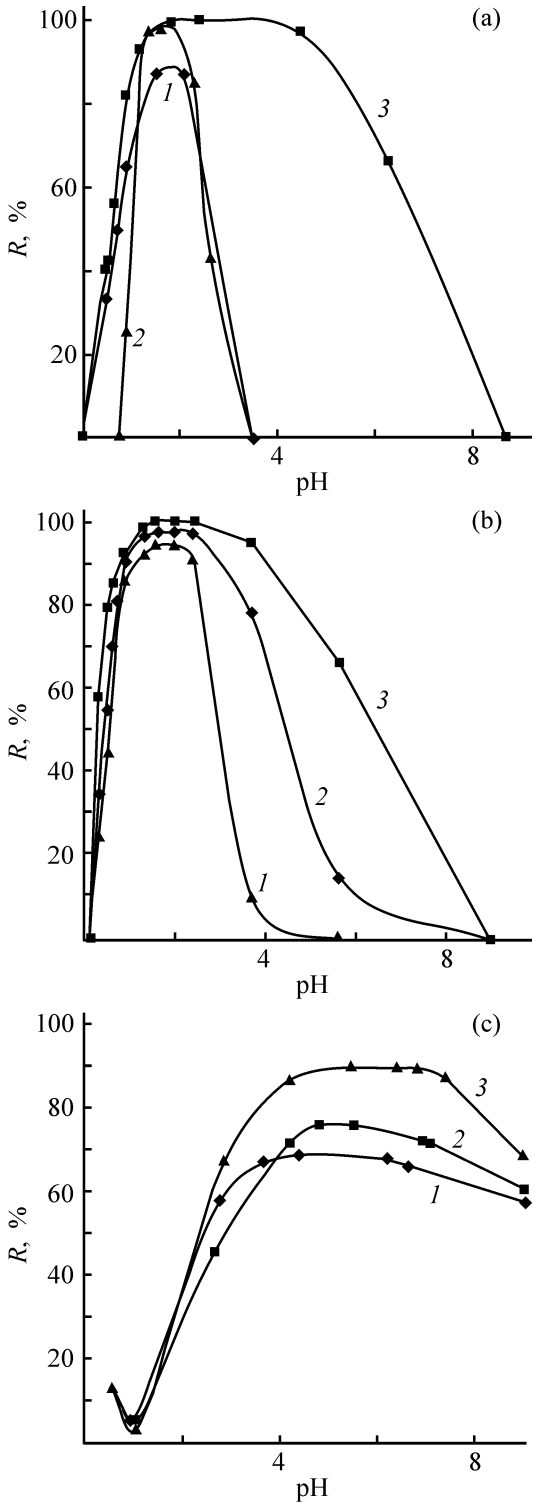

Fig. 1. Degree R of sorption of (a) Mo(VI), (b) W(VI), and (c) V(V) on NH_2-C in the presence of BPR and DPC vs. pH. $c_{Mo} = 2.0 \times 10^{-5}$ M, $c_{BPR} = 4.0 \times 10^{-5}$ M, $c_{DPC} = 4.0 \times 10^{-5}$ M, $m_{sorb} = 0.2$ g. (a) (*1*) Mo(VI), (*2*) Mo(VI)–BPR, (*3*) Mo(VI)–BPR–DPC; (b) (*1*) W(VI), (*2*) W(VI)–BPR, (*3*) W(VI)–BPR–DPC; (c) (*1*) V(V), (*2*) V(V)–BPR, (*3*) V(V)–BPR–DPC.

Sorption of Mo(VI), W(VI), and V(V) on en-C in relation to modification of the sorbent and chemical composition of the solution

Sorption conditions	Optimal-sorption pH	Degree of sorption under the optimal conditions
Mo(VI):		
solution of the metal (M) on Am-C	1.8–2.1	89
M solution on Am-C with sorbed BPR	1–3	90
M solution on DPC–Am-C with sorbed BPR	1–3	95
M solution on BPR–Am-C	0.8–3	>99
M solution on BPR and DPC–Am-C	1–5	>99
W(VI):		
solution of the metal (M) on Am-C	1.8–2.2	92
M solution on Am-C with sorbed BPR	0.5–3.5	93
M solution on DPC–Am-C with sorbed BPR	1–3	>99
M solution on BPR–Am-C	0.8–3.0	>99
M solution on BPR and DPC–Am-C	0.5–5	>99
V(V):		
solution of the metal (M) on Am-C	5–9	89
M solution on Am-C with sorbed BPR	6–9	90
M solution on DPC–Am-C with sorbed BPR	7–9	95
M solution on BPR–Am-C	6–9	96
M solution on BPR and DPC–Am-C	6–9	>99

respectively) and on en-C (see table) show that the degree of metal recovery on NH_2-C is lower, compared with NH_2-C with fixed BPR. This points to a somewhat higher stability of complex compounds of the metals with BPR, compared with aminopropyl groups grafted to the silica gel surface.

Upon introduction of DPC into solutions of metals, the sorption activity of Am-C with fixed BPR grows further. This increase is due to the possible formation, in the presence of DPC, of more stable complexes of metals with BPR on the surface of silicon dioxide for the same reasons why this occurs in solution, when a cationic surfactant has no less than 12 carbon atoms in the hydrophobic chain.

The complexes Mo(VI)–BPR and W(VI)–BPR are not sorbed on the surface of unmodified silica gel and do not color it. The strongest effect of sorption concentration is observed in sorption of Mo(VI), W(VI), and V(V) on amino silica gels from metal solutions in the presence of BPR and DPC. In all probability, this is due to the optimal conditions of metal complexation with BPR and to the specific effect of DPC on their hydrate shell, which improves the stability of the complexes being formed and, consequently, extends the pH range of complexation.

As can be seen in Fig. 1c, the degree of vanadium sorption on NH_2-C decreases as pH grows in the range 0–1 and, as the acidity decreases further, again starts to increase. The same pattern is observed in the case of V(V) sorption on en-C. This occurs because V(V) exists in strongly acidic solutions as mononuclear particles. At pH > 2, the overwhelming majority of vanadium(V) is in the form of VO_2^+, VO_3^-, and $H_2V_{10}O_{28}^{4-}$. According to [9], BPR forms under these conditions complexes with VO_2^+ and $H_2V_{10}O_{28}^{4-}$. As pH increases, coordination of BPR to vanadium(V), which also exists in the form of other polynuclear species, becomes possible. It should be noted that both in sorption of metal ions on amino silica gels with BPR fixed on their surface, which occurs by the scheme

$$\text{–}NH_3^+ \cdot {}^-O_3S\text{–BPR} + M^{n+} = \text{–}NH_3^+ \cdot {}^-O_3S\text{–BPR}\cdots M^{n+}, \quad (1)$$

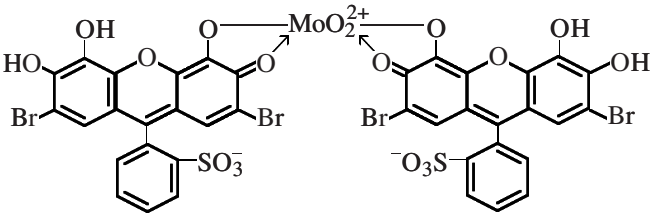
and in sorption of metal complexes with BPR

$$\text{–}NH_3^+ + {}^-O_3S\text{–BPR}\cdots M^{n+} = \text{–}NH_3^+ \cdot {}^-O_3S\text{–BPR}\cdots M^{n+}, \quad (2)$$

or

$$\text{–}NH_3^+ + {}^-O_3S\text{–BPR}\cdots M^{n+}\cdots {}^-O_3S\text{–BPR} = \text{–}NH_3^+ \cdot {}^-O_3S\text{–BPR}\cdots M^{n+}\cdots {}^-O_3S\text{–BPR}, \quad (3)$$

the time in which the sorption equilibrium is attained is 5–7 min. This enables sorption concentration of metals from the solutions under consideration in both static and dynamic conditions.



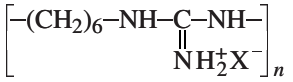
It is known [10] that, on passing from strongly acidic to strongly alkaline media, the coloration of BPR in solution successively changes from yellow, to orange, red, violet, and blue, with the peak of the absorption spectra of BPR shifted from 450 to 600 nm. The peaks of the absorption spectra of Mo(VI), W(VI), and V(V) complexes with BPR in solution virtually coincide with those of the absorption spectra of the dye itself. The diffuse-reflection spectra of the BPR sorbates on amino silica gels have a peak at 17000–18000 cm^{-1} (λ = 555–588 nm), which is shifted with pH to a lesser extent, compared with aqueous solutions. Introduction of DPC into solution leads to formation of different-ligand complexes characterized by a shift to longer wavelengths (16000 cm^{-1}, λ = 625 nm). A similar pattern is observed in diffuse-reflection spectra of complexes with tungsten(VI), which are shifted to longer wavelengths upon introduction of DPC (17000 cm^{-1}, λ = 588 nm).

The bathochromic effect is due to the influence of surfactants on the auxochromic groups of BPR, which are bound by a common system of conjugated bonds of the reagent and are not involved in the complexation with a metal [11]. The formation of associates at ionized auxochromic groups of the reagents may also be accompanied by hypsochromic effects. The reason is that the complexation occurs in the hydrophobic core of a micelle and is accompanied by a pronounced dehydration of the components in the surface layer of the sorbent. In particular, such a hypsochromic effect is observed in the case of V(V) complexation. The diffuse-reflection spectra of V(V)–BPR complexes preliminarily obtained in solution and adsorbed on the surface of amino silica gels are peaked at around 17000 cm^{-1} (λ = 588 nm). Introduction of DPC into solution gives rise to a complex that shows, in sorption on amino silica gels, an absorption peak at 21000 cm^{-1} (λ = 476 nm). This phenomenon is nontrivial and can be observed in other systems [6].

Molybdenum and tungsten exist in the form of ions MoO_2^{2+} and WO_2^{2+} in acid solutions (pH < 1) and as $MoO_2(OH)^+$ and $WO_2(OH)^+$, $MoO_2(OH)_2$ and $WO_2(OH)_2$, $HMoP_4^-$ and HWO_4^- in weakly acidic solutions (pH 1–4); at pH > 5, MoO_4^{2-} and WO_4^{2-} ions predominate [12].

The method of the equilibrium shift was used to determine the ratios between a metal and BPR in complexes with W(VI) and V(V) in the presence of DPC on the Am-C surface. For the complexes of tungsten and vanadium, M : BPR = 1 : 1 was found. Introduction of a surfactant does not change the ratio between the components of a metal and the dye. BPR interacts with Mo(VI) to give two complexes with λ_{max} = 540 and 630 nm and molar ratios of the components equal to 1 : 1 and 1 : 2, respectively. According to the data of [11], the 1 : 1 complexes are formed by MoO_2OH^+ ions, and the 1 : 2 complexes, by MoO_2^{2+} ions.

With account of the state of the reagent and molybdenum(VI), the following formula can be suggested for the complex formed in a 1 : 2 ratio:



For BPR solvated with dodecylpyridinium chloride, a second complex with absorption peak at ν = 16000 cm^{-1} (625 nm) is characteristically formed.

Thus, use of amino silica gels favors fixation on their surface of anionic dyes or complex compounds of these dyes with metals [Eq. (3)], and introduction of a cationic surfactant with a carbon radical containing no less than 12 carbon atoms into solution improves the strength of the forming mixed-ligand complexes, with their spectral characteristics changed.

It should be noted that Am-C are rather expensive sorbents. Because, in addition, molecules of organic dyes are comparatively large, there fixation on the surface will always leave "free" amino groups, which themselves possess ligand properties and can affect the properties of the resulting analytical form of the reagent. Therefore, anionic dyes are frequently fixed with a quaternary ammonium salt (QAS). Silica gel is modified with QAS under static conditions in toxic organic solvents, for the most part hexane, toluene, or a mixture of these [13], which is an important disadvantage of this sorbate. In addition, QAS are partly soluble in water, especially in acid media, which restricts their applicability area and affects the reproducibility of analytical determinations.

It was suggested to use for fixation on the silica gel surface the salt form of polyhexamethyleneguanidinium (PHMG) of general formula

where n = 30–90, and X is the anion of an inorganic or organic acid.

PHMG salts are macromolecular derivatives of a specific base of guanidine and cationic surfactants.

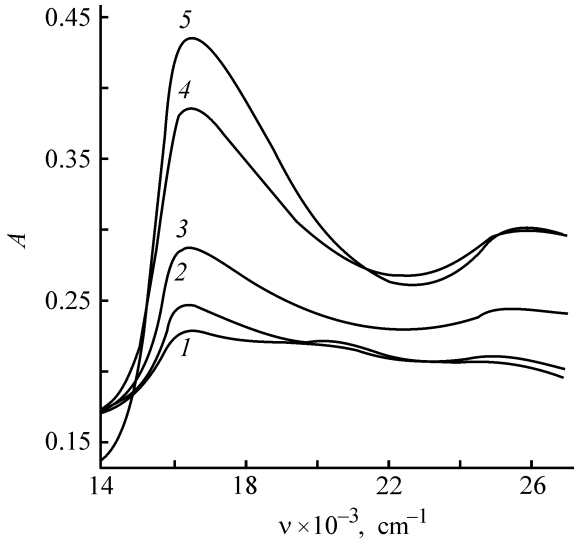


Fig. 2. Diffuse-reflection spectra $A = f(\nu)$ of Mo(VI)–BPR complexes on the surface of silica gels modified with PHMGC on the background of 0.1 N H_2SO_4. $c_{Mo} = 2.0 \times 10^{-5}$ M, $c_{BPR} = 4.0 \times 10^{-5}$ M, $m_{sil} = 0.2$ g. c_{PHMGC} (μg ml^{-1}): (*1*) 0, (*2*) 0.1, (*3*) 0.3, (*4*) 0.5, and (*5*) 0.7.

The convenient spatial arrangement of atoms in the guanidine group creates favorable conditions for formation of multicenter hydrogen bonds, and, therefore, PHMG salts containing a hydrophobic polymethylene chain can serve as good anion exchangers. In view of the aforesaid, it would be expected that PHMG sorption on the silica gel surface will be efficient in aqueous solutions and the sorbate obtained will be convenient for creating an analytical form of the reagent via fixation of anionic dyes. The PHMG sorbate fixed as a salt form on the silica surface has an important advantage over polyamine sorbates, which possess both anion-exchange and ligand properties. Because of the incomplete interaction of amino centers with organic dyes as a result of steric hindrances, silica gels of this kind have the same disadvantages as chemically modified Am-C.

Of the salt forms, it is most appropriate to use PHMGC, which is well soluble in water (50 wt % at 250°C) and is readily available and widely used bactericidal preparation, for modifying the silica gel surface. It was found that quantitative sorption of PHMGC on silica gel occurs in the pH range 0–9 as a result of a corporative interaction of charged PHMG macromolecules with active groups on the silica gel surface. The time in which the sorption equilibrium is attained does not exceed 3 min. The sorbate formed is so stable that it cannot be removed by washing with water in a Soxhlet apparatus for several days.

It is quite understandable that only part of guanidine groups of the polymer are involved in multicenter interaction with the silanol groups of the surface in modification of the silica gel surface with PHMGC (PHMGC-C). "Free" groups of guanidine on the PHMGC-C surface are involved in formation of ionic associates in interaction with anionic dyes by the scheme

$$\left[-(CH_2)_6-NH-\underset{\underset{NH_2^+X^-}{\|}}{C}-NH-\right]_n + {}^-O_3S-R$$

$$\rightarrow \left[-(CH_2)_6-NH-\underset{\underset{NH_2^+\ {}^-O_3S-R}{\|}}{C}-NH-\right]_n \qquad (4)$$

The time in which the adsorption equilibrium is attained is 3–5 min. The complexes of Mo(VI), W(VI), and V(V) with BPR are sorbed on the PHMGC-C surface at the same rate, with the sorption of these metals under the optimal conditions being quantitative.

When the complexes Mo(VI)–BPR and W(VI)–BPR are brought in contact with PHMGC-C, intensely colored ionic associates are formed. These associates are blue, with the maximum absorption at 16 000 cm^{-1} (λ = 625 nm), for molybdenum(VI) and violet, with the maximum absorption at 17 000 cm^{-1} (λ = 588 nm), for tungsten(VI). Thus, PHMGC fixed on the silica gel surface behaves as a cationic surfactant with a hydrocarbon radical containing no less than 12 atoms, despite that 6 methylene units alternate with guanidine groups in the polymeric chain of PHMGC.

As can be seen in Fig. 2, the intensity of absorption by Mo(VI)–BPR complexes increases with the PHMGC concentration sorbed on the surface. The same behavior is observed in sorption of W(VI)–BPR on PHMGC-C. The dependence was found to be linear for Mo(VI)–BPR and W(VI)–BPR complexes at PHMGC concentrations of 0–40 and 0–25 μg per 0.2 g of silica gel, respectively. This fact was used to develop a procedure for sorption-photometric determination of microscopic amounts of PHMGC in aqueous solutions, with sorption processes performed under static or dynamic conditions.

Thus, PHMGC-C is a simple and convenient form for sorption of BPR and its complexes with Mo(VI), W(VI), and V(V). The formation of ionic associates on the surface of PHMGC-C enables fixation of other anionic dyes without changes in their ligand (*o*-oxyquinone groups) centers to create new analytical forms for analysis of inorganic and organic compounds.

CONCLUSIONS

(1) In sorption of molybdenum(VI), tungsten(VI), and vanadium(V) on amino silica gels in the presence of an anionic dye BPR at pH 0.6–7.8, complexes of the metals with BPR are formed on the surface, with M : BPR = 1 : 1 [M = W(VI), V(V)] and 1 : 2 [Mo(VI)].

(2) It is advisable to use polyhexamethyleneguanidinium chloride as a cationic surfactant. This compound also acts as an ion exchanger and favors fixation of anionic dyes, including BPR. Quantitative recovery of molybdenum(VI) and tungsten(VI) on silica gels impregnated with polyhexamethyleneguanidinium chloride occurs at pH 0.5–3.5.

(3) The coloration intensity of sorbed Mo(VI) and W(VI) complexes with BPR depends both on their surface concentration and on the concentration of polyhexamethyleneguanidinium chloride itself, which can be used to develop a procedure for determining microscopic amounts of this compound in water.

Abstract—A technique for nickel recovery from spent electroless nickel-plating solutions was developed. The process yields nickel sulfate, a source for preparing an electroless nickel-plating solution, and a nickel-containing concentrate.

DOI: 10.1134/S1070427208020080

Many Russian machine-building companies use the high-temperature (90–95°C) electroless nickel-plating in weak-acid solutions. During the process, the solutions are continuously adjusted with respect to nickel sulfate and sodium hypophosphite by introducing a concentrated solution of these salts; simultaneously, the evaporation loss of water is replenished. Because the electroless nickel-plating is accompanied by acidification of the working solution, its pH is maintained by addition of ammonia. The concentration of sodium phosphite steadily increases during the apparatus operation, which makes necessary frequent (approximately once a week) discharges of spent electroless nickel-plating solutions (SENPS) to sewage-purification facilities. In wastewater purification, nickel is mixed with other toxic metals and irretrievably lost, with the presence of a large quantity of the ammonium nitrogen in SENPS making difficult high-quality purification of wastewater to remove of many metals.

The results of a four-month study[1] [1] allowed us to compose a material balance of nickel transfer in electroless nickel-plating. It was found that 58.3% of nickel coming into the process with nickel sulfate is consumed for plating of articles, and 22.5% for coating of technological pallets (grid baskets). The loss of nickel with SENPS sewage volleys is 16.1%, and that with washing water, only 3.1%. These data indicate that it is advisable to separately collect and accumulate SENPS, with composition averaging and subsequent utilization of nickel from SENPS.

[1] The study was carried out at Velkont plant (Kirovo-Chepetsk, Kirov oblast).

EXPERIMENTAL

When developing the utilization technique, we chose the reagent method which is more economical than ion exchange and electrolysis. However, the presence of ammonium nitrogen in the sewage volley demanded a preliminary calculation of ionic equilibria in the Ni^{2+}–NH_4^+–NH_3–OH^- system with account of the range of actual NH_4^+ concentrations in SENPS (0.32–1.13 M).

The accumulation of the ammonium nitrogen in solution in electroless nickel-plating results in that the ammonium nitrogen is converted to ammonia nitrogen in the subsequent neutralization of SENPS with alkaline reagents:

$$NH_4^+ + OH^- \rightarrow NH_4OH \rightarrow NH_3 + H_2O. \quad (1)$$

The ammonia nitrogen, in turn, binds nickel ions into stable complexes:

$$Ni^{2+} + nNH_3 \rightarrow Ni(NH_3)_n^{2+} \quad (n = 1–6). \quad (2)$$

This results in an appreciable increase in the total solubility of nickel as compared with SENPS, which contain no ammonium nitrogen. Disintegration of ammine complexes and precipitation of nickel requires a considerable excess of an alkali [to shift equilibrium (3) to the right]:

$$Ni(NH_3)_n^{2+} + 2OH^- \rightleftarrows Ni(OH)_2\downarrow + nNH_3. \quad (3)$$

The total activity of nickel in a solution, [Ni], has the following constituents: the activity of simple Ni^{2+}

ions, found from the solubility product (SP) of nickel hydroxide and dependent on pH; activity of nickel in the form of hydroxo complexes with stability constants K_m; and activity of nickel in the form of ammine complexes with stability constants K_n [2]:

$$[\mathrm{Ni}] = [\mathrm{Ni}^{2+}] + [\mathrm{Ni}^{2+}]\sum_{1-3}^{m} K_m [\mathrm{OH}^-]^m + [\mathrm{Ni}^{2+}]\sum_{1-6}^{m} K_n [\mathrm{NH_3}]^n$$

$$= [\mathrm{Ni}^{2+}]\left(1 + \sum_{1-3}^{m} K_m [\mathrm{OH}^-]^m + \sum_{1-6}^{m} K_n [\mathrm{NH_3}]^n\right). \quad (4)$$

To calculate the nickel solubility by Eq. (4), we took values of SP, K_m, and K_n from the handbook [3]. The value of SP for freshly precipitated $Ni(OH)_2$ was used. Because there are no published data on the activity coefficients of various forms of nickel ions and ammonia nitrogen in SENPS subjected to neutralization, we replaced in our calculations the activities of the equilibrium participants with their concentrations (except for hydroxide ions whose activities are determined by the pH values in neutralization).

In the calculations, we varied the pH values in the range 7–13.5. The initial concentration of the ammonium nitrogen was set in the range 0–1.2 M with a step of 0.2 M. At pH 3.1–5.6, which corresponds to the real SENPS (see table), virtually the whole amount of nitrogen is in the ammonium form. The total concentration of nitrogen remains constant in the conversion of the ammonium nitrogen to the ammonia nitrogen and to nitrogen bound into complexes by reactions (1) and (2). Therefore, Eq. (4) gives us the total molar concentration of nitrogen compounds (with account of the equilibrium constant of reaction (1), equal to 1.76×10^{-5} [3]). Using the method of successive approximations, we found such a value of $[NH_3]$ at which the total concentration of nitrogen compounds is equal to the initial concentration of NH_4^+ ions in SENPS, with a discrepancy not exceeding 0.0001 M. The calculations were carried out using a specially written computer program.

SENPS composition and NaOH consumption for their neutralization

SENPS no.	Concentration			pH	Consumption of solid NaOH, kg m^{-3} of SENPS for adjusting pH to 13
	Ni, g l^{-1}	NH_4^+			
		g l^{-1}	M

7	14.1	10.08	0.56	4.0	132
8	11.03	10.8	0.6	3.1	125
9	14.15	20.16	1.12	3.5	118
Average					134

The calculated data (Fig. 1) show that the pH value corresponding to the minimum solubility of nickel is determined by the NH_4^+ content of SENPS and falls within the range 11.9–13.1. In view of the fact that SENPS mainly contain about 1 M of NH_4^+ ions (see table), the precipitation of nickel hydroxide should be finished at pH 13.

The calculated nickel solubility is compared in Fig. 2 with the residual nickel concentration determined by chemical analysis during neutralization

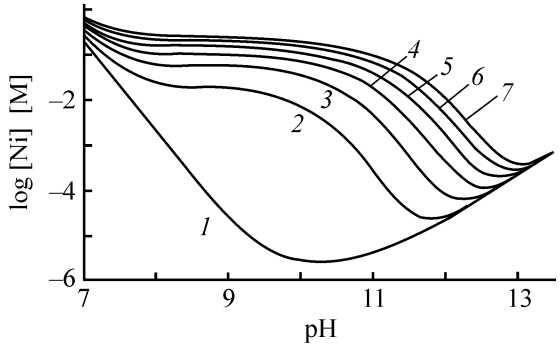

Fig. 1. Calculated curves of the effect of pH on the nickel solubility log [Ni] at various total concentrations of the ammonium nitrogen. NH_4^+ concentration (M): (*1*) 0, (*2*) 0.2, (*3*) 0.4, (*4*) 0.6, (*5*) 0.8, (*6*) 1.0, (*7*) 1.2.

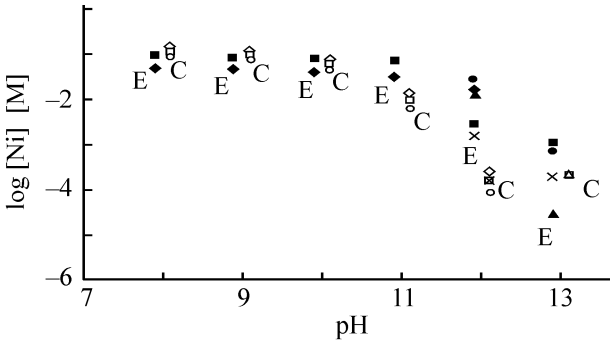

Fig. 2. Calculated (C) values of the nickel solubility and experimental (E) values of the residual nickel concentration in titration with a 10% NaOH solution to various final pH values of SENPS. [Ni] is the nickel concentration.

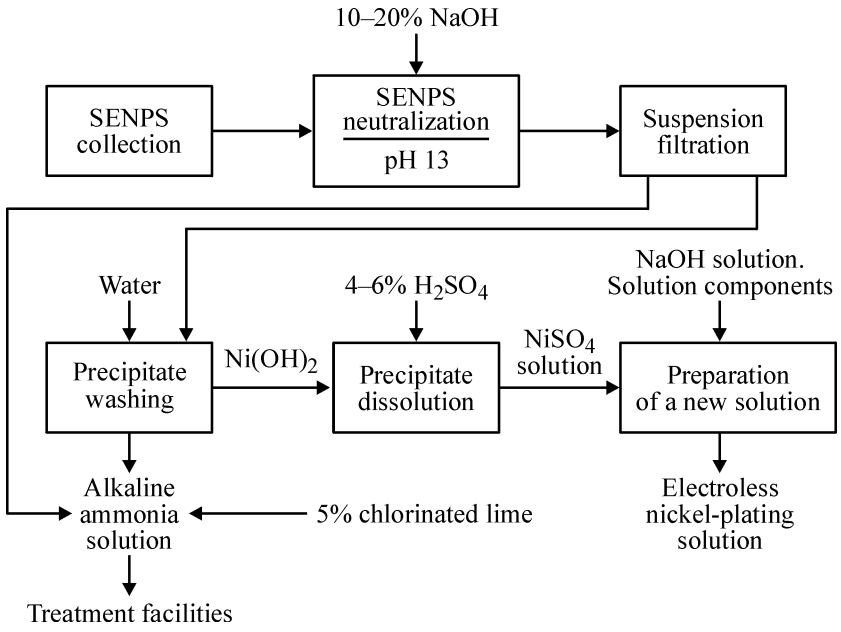
of SENPS with a NaOH solution. The nickel content was determined by trilonometry or photocolorimetry. When calculating the nickel solubility, we took into account that the solution is diluted in SENPS neutralization and the total concentration of all forms of nitrogen decreases.

The calculated data agree with the experimental values at pH 8–10 and 13, which indicates that the assumptions made in the calculations are correct. A certain excess of the experimental nickel concentrations over the values calculated for pH 11–12 may be due to formation of polynuclear hydroxo and mixed hydroxo-ammine complexes in this range. $Fe_2(OH)_2^{4+}$ and $Co(NH_3)_4(OH)_2^+$ can serve as an example of such complexes [2]. However, this discrepancy does not refute the above conclusion that pH should be brought to 13.

To determine the consumption of sodium hydroxide for the SENPS neutralization, we recorded potentiometric titration curves for several SENPS taken from two plants of Kirov oblast with a 10% NaOH solution (with pH brought to 13). The solution compositions and the NaOH consumption are listed in the table. It is necessary to note that the consumption of the alkali cannot be calculated theoretically, because the reagent neutralization of SENPS is complicated by the presence in their composition of lactic acid, phosphites formed in electroless nickel plating, and ammonium salts. This leads to a sharp increase in the total consumption of the precipitating agent because of the occurrence of the following side reactions [4]: neutralization of lactic acid, reaction of alkali with sodium phosphite, conversion of ammonium nitrogen to ammonia nitrogen, and reaction of alkali with a buffer additive. Under industrial conditions, the alkali consumption can be determined in a simpler way by preliminary recording of potentiometric titration curves after the accumulation of a SENPS mixture.



The first variant of the technique for nickel recovery [5] assumed the following technological sequence of SENPS processing: accumulation of SENPS, with averaging of their composition and addition of a stabilizer $\rightarrow$ neutralization of the SENPS mixture with a NaOH solution $\rightarrow$ thermal desorption of ammonia by heating of a $Ni(OH)_2$ suspension $\rightarrow$ filtering of the $Ni(OH)_2$ suspension and thorough washing of the precipitate with water to remove water-soluble salts $\rightarrow$ dissolution of the precipitate in a weak sulfuric acid solution for the subsequent preparation of new solutions for electroless nickel-plating (ENP). A critical consideration of this technique enabled its improvement.

The introduction of the stabilizer (sodium thiosulfate, ~2 g l^{-1}) into SENPS was aimed to prevent partial spontaneous decomposition of SENPS to give a powdered Ni–P alloy upon neutralization. However, the use of a stabilizer requires a very thorough washing of nickel hydroxide to remove water-soluble salts. The absence of the stabilizer imposes less stringent requirements on the quality of washing of the $Ni(OH)_2$ precipitate. Our experiments demonstrated that, when a 10% alkali solution is slowly introduced (within 0.5 h in small portions) under continuous stirring, nickel hydroxide can be precipitated without self-decomposition of the solution (warming-up is weak, SENPS does not decompose, and no Ni–P alloy powder is formed). Thus, the addition of the stabilizer is not obligatory.

The thermal desorption of ammonia from the alkaline suspension of $Ni(OH)_2$ was aimed to remove ammonia from wastewater after filtering the suspension. Calculations of the percentage ratio of various forms of nitrogen demonstrated that, at pH 12 and higher, the main part of nitrogen is in the ammonia form. For example, even at pH 12, the fractions of ammonia in nickel complexes and ammonium ions are as low as 0.95 and 0.17%, respectively. The ammonia nitrogen can be removed from the filtrate by heating the solution at $80 \pm 5°C$ for 3 h (or at $100 \pm 2°C$ for 1 h), which was confirmed by special experiments with three SENPS.

Washed $Ni(OH)_2$ precipitates were dissolved in 5% H_2SO_4 to form $NiSO_4$ solutions, a basis for new SCNP. High-quality nickel coatings on steel articles were obtained in these solutions.

However, an insignificant amount of a gelatinous precipitate was formed in one of the three solutions in the bottom part. An analysis of the possible reasons for the appearance of this precipitate allowed us to conclude that, during a long-term thermal desorption of ammonia, phosphites from SENPS are oxidized to phosphates, with the subsequent binding of a part of phosphate ions into nickel phosphate contaminating the $Ni(OH)_2$ precipitate. In view of this assumption, we reprocessed SENPS without ammonia desorption, by the following scheme: neutralization with a NaOH solution $\rightarrow$ filtration $\rightarrow$ washing of the precipitate $\rightarrow$ dissolution of the precipitate in 5% sulfuric acid $\rightarrow$ preparation of a new ENPS. The solution obtained using this scheme contained no gelatinous precipitate. High-quality nickel coatings were also obtained in this solution.

Technological scheme of nickel sulfate recovery from SENPS.

In view of the aforesaid, we suggested the second variant of nickel recovery (see scheme). Because this scheme does not assume thermal desorption of NH_3, an alkaline ammonia solution appears in the sewage. Its ammonia can be oxidized with chlorinated lime (as confirmed by separate experiments).

Economical calculations demonstrated that the price of recycled nickel sulfate is 2.5 times the expenditure for sodium hydroxide and sulfuric acid. Furthermore, plants can cut expenses for purification of SENPS volleys and burial of the slimes formed.

The presented techniques for nickel recovery from SENPS, with recycling of nickel sulfate are cost-effective even though they require the expensive sodium hydroxide. In this context, it is important to search for less expensive precipitating agents for SENPS neutralization. We tested spent degreasing solutions from a galvanic production line and CaO suspensions as precipitating agents of this kind.

Spent degreasing solutions contain NaOH, Na_2CO_3, and Na_3PO_4. Our experiments demonstrated that presence of soda brings no complications in the process of SENPS neutralization. However, the presence of trisodium phosphate in this process results in precipitation of nickel phosphate, which hinders deposition of a nickel coating on articles in a new solution. Therefore, use of spent degreasing solutions for SENPS neutralization is only advisable for obtaining a nickel-containing concentrate. The sequence of operations in this variant of technology is as follows: accumulation of SENPS with averaging of their composition → neutralization of the SENPS mixture with a spent degreasing solution → desorption of ammonia by heating of the suspension → filtering of the suspension of poorly soluble nickel compounds → washing of the precipitate with water to remove water-soluble salts → drying of the precipitate. This technique makes it possible not only to obtain a concentrate of nickel salts (with a nickel content of no less than 23%), but also to diminish the volume of toxic galvanic slimes formed at a plant.

Experiments on SENPS neutralization with a CaO suspension were carried out by the following scheme: neutralization of SENPS with a 5% CaO suspension → filtering and washing of the precipitate with water to remove water-soluble salts → $Ni(OH)_2$ dissolution in a weak solution of sulfuric acid with heating for 0.5–2 h → filtering of the solution to remove $CaSO_4$ → preparation of a new electroless nickel-plating solution.

The experimental results demonstrate that the 5% CaO suspension sufficiently completely transfers nickel from SENPS to $Ni(OH)_2$ on reaching a pH value close to 13 (concentrations of nickel ions in the filtrate 0.0016–0.008 g l^{-1}). The highest degrees of nickel extraction (DE_{Ni}) into a sulfate solution were reached upon dissolution of the precipitate for 2 h at 50–70°C (DE_{Ni} = 98–99%). A simplification of the technological procedure (temperature lowered to 20°C or a shorter dissolution time) results in a less

complete extraction of nickel (DE_{Ni} = 92–93%). A rather important factor determining the efficiency of the process is the time during which the $Ni(OH)_2$ precipitate is stored before dissolution in the acid. This was confirmed by an experiment in which a precipitate was dissolved at 70°C for 2 h, but a week after SENPS neutralization and filtering of the resulting suspension. During this time, crystals were coarsened and the precipitate was solidified, which resulted in a low degree of nickel extraction (about 24%). Therefore, a freshly precipitated $Ni(OH)_2$ should be dissolved in sulfuric acid.

The $NiSO_4$ solutions obtained in SENPS neutralization with a CaO suspension were used to prepare new ENPS, in which electroless nickel coatings of the required industrial quality were obtained.

An additional variant of a technique for nickel recovery from SENPS, with a CaO suspension used as a precipitating agent, was suggested on the basis of the experiments we performed. It differs from the second variant (see scheme) in that a $Ni(OH)_2$ precipitate is dissolved in a heated sulfuric acid (50°C, 0.5 h) not later than 24 h after the precipitation. Furthermore, an operation of filtration of the sulfuric acid solution to remove calcium sulfate is added after the dissolution.

An economical analysis of the process demonstrated that the price of nickel sulfate recycled in this way is, on average, three times the expenditure for lime hydrate and sulfuric acid.

CONCLUSIONS

(1) A procedure for calculation of ionic equilibria in the system Ni^{2+}–NH_4^+–NH_3–OH^- for the conditions of neutralization of spent electroless nickel-plating solutions was suggested. Systematic calculations by this procedure were carried out. This allowed substantiation of the pH values to be reached by the end of the neutralization, which were confirmed experimentally.

(2) Techniques for nickel recovery from spent electroless nickel-plating solutions with the use of an alkali solution and a CaO suspension as precipitating agents were developed. Recycling of the above-mentioned solutions gives a nickel sulfate solution that can serve as a basis for preparation of a new electroless nickel-plating solution providing high-quality coatings.

(3) It was shown that neutralization of spent electroless nickel-plating solutions with spent degreasing solutions is accompanied by precipitation of a mixture of poorly soluble nickel compounds, including nickel phosphate, which gives no way of using the precipitate for preparation of new solutions. A procedure for recovery of nickel from spent electroless nickel-plating solutions into a concentrate with a nickel content of about 23% was developed.

Abstract—Behavior of hydrosilicate nanotubes of composition $Mg_3Si_2O_5(OH)_4$ in aqueous dispersions was studied. Experiments devoted to observation of steady-state and relaxation electro-optical effects demonstrated that, irrespective of their initial concentration in water, nanotubes form stable bulk aggregates with weak anisotropy, rather than a homogeneous system of separate suspended nanosize cylinders.

DOI: 10.1134/S1070427208020092

The unique properties of substances with a nanotubular structure [1–3] have initiated systematic studies of the possibility of their use for developing new materials and technologies [4–7]. Recently, there have been numerous reports devoted to nanomaterials based on carbon nanotubes [8, 9] and heterostructural nanorolls [10] synthesized by the method suggested in [11]. At the same time, there exists, together with the above-mentioned types of nanotubes, a vast class of inorganic and, in particular, silicate nanotubes with various chemical compositions and morphologies [12–19], formed by twisting of layers of chemical compounds with layered structure [20]. The experience of application of silicate nanotubes in, e.g., the development of polymer-inorganic nanocomposites has shown that their introduction into a polymeric matrix improves the mechanical and pervaporation characteristics of materials [21–23]. A promising field of application of these nanotubes is water purification to remove impurities, including radionuclides [24].

Purposeful use of nanotubes in the above-listed and many other practical areas requires that their behavior in aqueous dispersions and dispersions based on other liquids should be understood. This is necessary because the structure of dispersions of nanotubes largely determines the efficiency of their use in composite materials and technologies involving contact of nanotubes with liquid media of various compositions.

EXPERIMENTAL

Nanotube hydrosilicates of composition $Mg_3Si_2O_5 \cdot (OH)_4$ were synthesized under hydrothermal conditions. As precursors served mixtures of magnesium and silicon oxides, as well as magnesium silicates and hydrosilicates of varied structure and composition and, in particular, $MgSiO_3$ having a chain structure and $Mg_3Si_4O_{10}(OH)_2$ with layered structure. All the mixtures were prepared in terms of the stoichiometry $MgO : SiO_2 = 3 : 2$, for which purpose magnesium oxide was added to the starting mixtures based on magnesium silicates. The starting mixtures were subjected to hydrothermal treatment with distilled water and aqueous solutions of NaOH (0.3–3 wt %) at temperatures of 200–500°C and pressures of 10–100 MPa by the method described in [25]. The products of this treatment were washed to remove alkaline components and dried. After that their chemical composition, morphological parameters, and optical and electro-optical characteristics were determined.

It was found that nanotubes of hydrosilicates with a chrysotile structure and chemical composition close to that given by the theory, $Mg_3Si_2O_5(OH)_4$, were synthesized from all the precursors under the hydrothermal conditions at temperatures of 250–450°C and pressures of 10–100 MPa. The refractive indices of the hydrosilicates synthesized, found by optical microscopy in immersion liquids, are as follows: n_g =

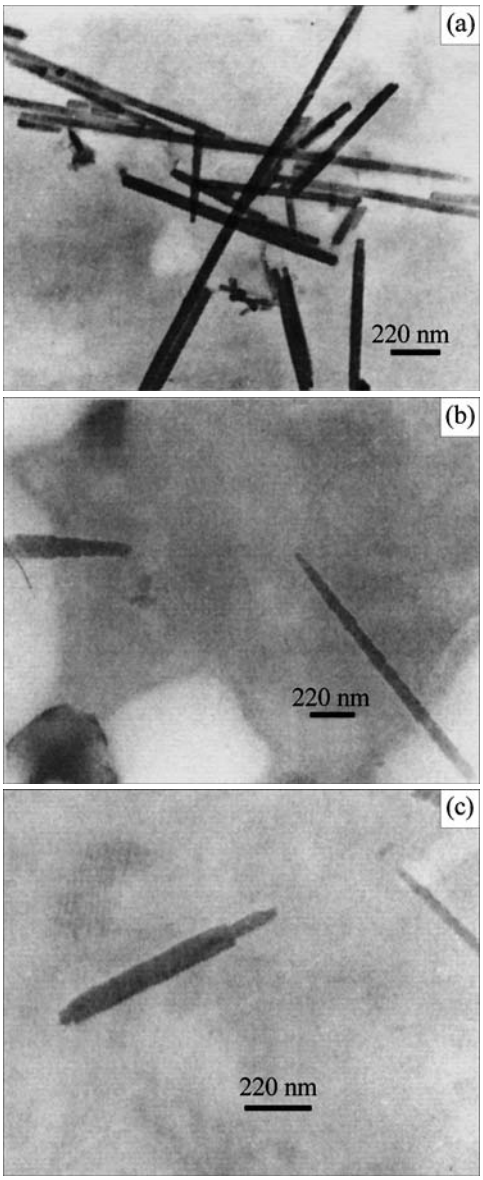

Fig. 1. Electron micrographs of nanotubes of various forms: (a) cylindrical, (b) conical, and (c) socket-like.

Fig. 2. Electron micrograph of an ensemble of nanotubes.

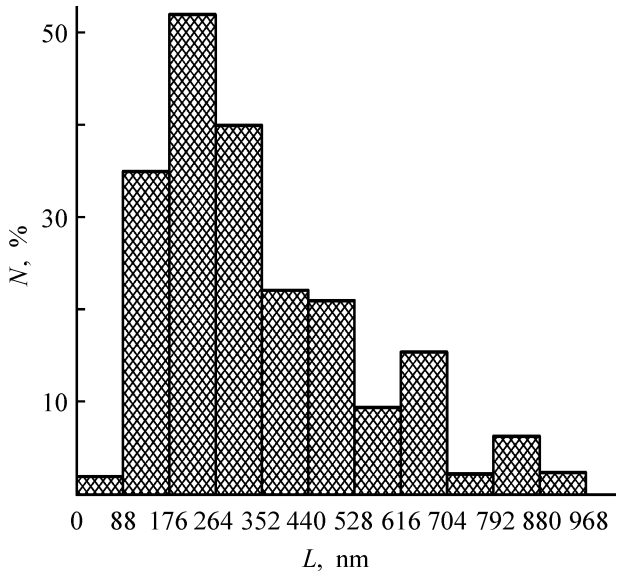

Fig. 3. Histogram of the nanotube distribution over length *L*. (*N*) Number of nanotubes.

1.545–1.551, n_p = 1.539–1.545, $n_g - n_p$ = 0.006. An electron-microscopic study revealed a wide variety of morphological forms of nanotubes: cylinders, cones, socket tubes (Fig. 1). The outer diameter varies from 20 to 70 nm for cylindrical nanotubes and from 20 to 50 nm for conical nanotubes. The inner diameter of cylindrical nanotubes is 3–5 nm. It was shown that prevalence of some morphological forms of nanotubes depends on synthesis conditions: composition of the hydrothermal solution, temperature and duration of the hydrothermal treatment of precursors.

The hydrothermal synthesis of nanotubes of composition $Mg_3Si_2O_5(OH)_4$ at temperatures of 300–350°C and pressures of 30–100 MPa for 12–24 h in a hydrothermal solution containing 0.8–1 wt % NaOH can give, with a 100% yield of the final product, exclusively cylindrical nanotubes with weakly varying inner and outer diameters of about 3 and 25 nm, respectively.

Aqueous dispersions of $Mg_3Si_2O_5(OH)_4$ nanotubes, whose electron micrograph is shown in Fig. 2, were studied. The histogram of the length distribution for such nanotubes is shown in Fig. 3. As follows from an analysis of the data presented in the form of a histogram, the length of most of nanotubes falls within the range 100–500 nm and their outer diameters vary

from 10 to 25 nm. Even a minor addition of nanotubes to water (no more than 10 μg cm^{-3}) and shaking leads to a noticeable light scattering by the dispersion. In several days, a loose white precipitate is formed at the bottom of the test tube and the aqueous solution over this precipitate becomes virtually transparent. The precipitate is easily destroyed by repeated shaking and ultrasonic treatment of suspensions of this kind. These observations of the behavior of suspensions suggest that nanotubes form aggregates in water. Then these aggregates become larger, which leads to their sedimentation.

To evaluate the geometric and electrical parameters of nanotube aggregates, electro-optical studies of their aqueous suspensions were carried out. In these studies, an external electric field induced an optical anisotropy of the dispersion and characteristics of this anisotropy were measured. The nanotubes shown in Fig. 2 have lengths comparable with the wavelength of the electromagnetic radiation in the visible spectral range. The scattering of linearly polarized light by tubes of this kind strongly depends on their orientation with respect to the propagation direction of the light wave and its polarization. The contribution made by a separate tube to the total optical anisotropy of the suspension can be defined as the difference between the energies of light propagating perpendicularly to the tube axis and polarized along or perpendicularly to this axis. This difference is proportional to the tube length and its changes with the tube orientation can be described theoretically [26].

The experimental setup for studies of this kind, described in detail in [27], comprises the electrical and optical parts. It includes a sound generator, field pulse-forming unit, power amplifier, and a transparent cuvette with electrodes, filled with a system under study. The setup enables orientation of nanoparticles suspended in the liquid between the electrodes of the cuvette along the force lines of the external field. The optical part of the setup includes the following components: white-light source; movable polarizer, which can pass light whose polarization plane is parallel or perpendicular to the electric field strength vector; and a system for recording the intensity of light that passes through the cuvette. In the experiment, relative changes in the intensity of transmitted light, $\Delta J_{\|}/J$ and $\Delta J_{\perp}/J$, polarized along and perpendicularly to the field that gives rise to the optical anisotropy of the suspension in the cuvette, were measured. It is the difference between these relative changes in the intensity of light that determines the magnitude of

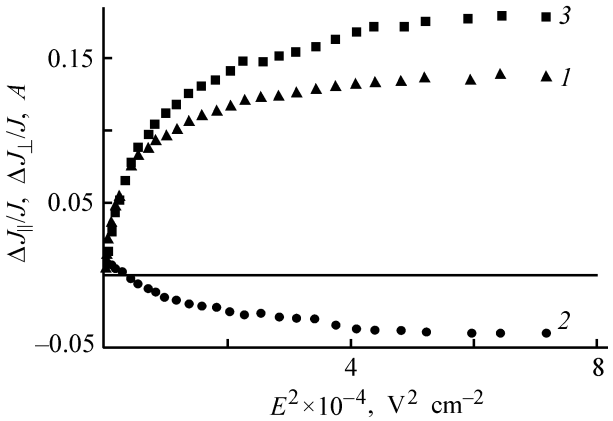

Fig. 4. Relative changes (*1*) $\Delta J_{\|}/J$ and (*2*) $\Delta J_{\perp}/J$ in the light flux and (*3*) their difference A vs. the field strength E in the cuvette. (E^2) Squared electric field strength.

the electro-optical effect, $A = \Delta J_{\|}/J - \Delta J_{\perp}/J$. Dependences of A on the strength E of a sinusoidal radio-frequency field (field dependences) make it possible to evaluate the anisotropy of polarizability of separate independent nanotubes or their aggregates, which are oriented along the field in the cuvette. The type of the time dependence of A after switching-off the field (relaxation dependences) can be used to determine the length of noninteracting nanotubes or the size of their aggregates.

In the study, the field and relaxation dependences of $\Delta J_{\|}/J$, $\Delta J_{\perp}/J$, and A were measured for a diluted suspension of $Mg_3Si_2O_5(OH)_4$ nanotubes in water, with a concentration of 100 μg cm^{-3}. The measurement results are presented in Figs. 4 and 5. As follows from these data, $\Delta J_{\|}/J$ and $\Delta J_{\perp}/J$ have different signs, with the applied field clarifying the system under study if light is oriented along the field in the cuvette and, by contrast, making it less transparent to light polarized perpendicularly to the field. It follows from the dependence of the steady-state electro-optical ef-

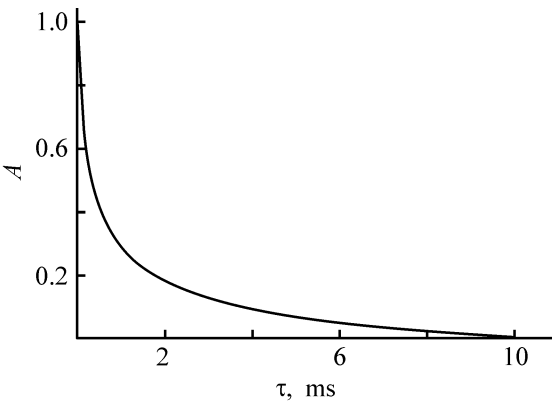

Fig. 6. Relaxation dependence of A, calculated for noninteracting nanotubes. (τ) Relaxation time.

fect on the strength of the 10-kHz sinusoidal electric field (Fig. 4) the induced optical anisotropy reaches a constant value ("saturates") at field strengths of 250–300 V cm^{-1}. It is interesting to note that nanoparticles of length 100–500 nm, which constitute the majority of dispersion particles according to the histogram, must have an unrealistically high anisotropy of polarizability, γ. Indeed, the limiting values of $\Delta J_{\parallel}/J$, $\Delta J_{\perp}/J$, and A, corresponding to the saturated orientation of particles along the field are reached at $\gamma E^2/2k_B T \approx 3$, where γ is the anisotropy of particle polarizability and $k_B T$ is the thermal energy [27]. Hence follows an estimate for the average anisotropy of polarizability, $\gamma \approx 5 \times 10^{-13}$ cm^3. At the same time, a calculation of γ for a separate nanotube of medium length, assumed to be dielectric and possessing a broadened double layer, gives $\gamma \approx 10^{-15}$ cm^3 [28]. This discrepancy between the model and experimental values of γ may be due either to an exceedingly high intrinsic anisotropy of the polarizability of nanotubes, which is unlikely, or to formation by these nanotubes of large aggregates suspended in water. As follows from the data in Fig. 4, the optical anisotropy induced by electric field remains invariable at field strengths E of 300 to 700 V cm^{-1}.

The process of free relaxation of the induced optical anisotropy is illustrated by Fig. 5. As follows from an analysis of the curves in Fig. 5, the characteristic relaxation time is close to 0.1 s. If the free relaxation of A is calculated for nanotubes as a system of independent thin cylinders [28], a value on the order of fractions of a millisecond is obtained for the characteristic time of transition of the system from the ordered-orientation state to the chaotic state. A more detailed calculation based on the histogram shown in Fig. 3 yields a relaxation dependence $A(\tau)$, with amplitude normalized to unity. This dependence is shown in Fig. 6. The experimentally observed relaxation time is found to be two orders of magnitude larger than that calculated on the assumption of rotation of the long axes of independent cylinders.

Thus, the results of the experiments in which steady-state and relaxation electro-optical effects were observed suggest that a system of $Mg_3Si_2O_5(OH)_4$ nanotubes suspended in water is aggregated in all the three directions, with the size of the aggregates exceeding the average length of the nanotubes by approximately a factor of 4–5.

In order to obtain a dispersion composed of separate nanotubes, the starting system was diluted by a factor of 10–100 and more and treated with ultrasound. However, measurements demonstrated that, in this case, the relaxation time of the electro-optical effect remains virtually unchanged and fields leading to saturation are close for diluted and undiluted systems. This points to a rather high stability of the aggregates.

In fields of strength exceeding 700 V cm^{-1}, the optical anisotropy starts to grow again, which is due to elongation of the aggregates in the field. It was found that, if separate pulses of a sinusoidal field (pulse width 0.2 s, amplitude 2 kV cm^{-1}) are applied at intervals of 10 s, the relaxation time of the electro-optical effect markedly increases. This indicates that nanotube aggregates become coarser. The action of longer pulses, with width of about 10 s, leads to nonmonotonic time dependences, both for the rise in the optical anisotropy and for its decay after switching-off the field. This may be due to a pronounced influence of strong fields on the process of formation of nanostructured dispersions.

CONCLUSIONS

(1) Aqueous dispersions of $Mg_3Si_2O_5(OH)_4$ nanotubes are composed of aggregates with a size exceeding the average nanotube length by a factor of 4–5.

(2) Aggregates of nanotubes do not change their size upon dilution of the suspension with water and its ultrasonic treatment, i.e., are rather stable formations.

(3) Under the action of an electric field, the aggregates in an aqueous medium change their shape (are elongated) and become coarser.

Abstract—X-ray phase, differential-thermal, and elemental analyses were used to study the transformation of the phase structure of an iron oxide catalyst for dehydrogenation of methyl butenes after exploitation.

DOI: 10.1134/S1070427208020109

Isoamylenes are dehydrated in a flow-through adiabatic reactor in a fixed bed of an iron oxide catalyst at a temperature of 600–640°C in the presence of steam [1]. Industrial exploitation of the catalyst under severe conditions (low dilution of raw materials with steam, high temperature) leads to its gradual deactivation [2], with the result that the basic catalytic parameters of the catalyst fall in 1–2 years. Accordingly, its reloading and utilization becomes necessary after this period of time.

It is known [3] that the main reason for the irreversible deactivation of the iron oxide catalyst is the loss of potassium promoter. However, there are no data on the distribution of potassium along the height and diameter of the catalyst bed. Issues associated with the efficiency of the regeneration performed and with the uniform operation of the whole catalyst bed remain unclear.

The goal of this study was to examine the transformation of the phase structure of the iron oxide catalyst for dehydrogenation of methyl butenes under industrial conditions to determine the efficiency of its operation in high-power adiabatic reactors.

EXPERIMENTAL

As objects of study served fresh and spent (8000 h) samples of the domestic KDO catalyst [4], taken at different places along the height and diameter of the adiabatic reactor.

An X-ray phase analysis (XPA) of all the samples was performed on a modified automatic X-ray diffractometer based on a standard DRON-2 instrument, with independent rotation of a sample and the counter and with Cu_{K_α} radiation. A graphite monochromator was used in the diffracted beam. The angles 2θ were recorded in the range 5–60° with a step of 0.5°. The X-ray diffraction patterns were recorded at 30 kV and 15 mA with an exposure time of 3 s. The average size of the coherent-scattering region (CSR) was found from the broadening of diffraction lines.

The thermal behavior and thermal transformations under nonisothermal conditions were studied on a Netzsch CTA-409 PC Luxx synchronous thermal analyzer (Germany) in air in the temperature range 25–1100°C at a heating rate of 10–40 deg min^{-1}. The accuracy of determining the loss of mass was ±0.5%.

An analysis for the content of carbon was made on a HORIBA EMIA-510 instrument with a heat-conductivity detector by the ASTM method, with a 1-g catalyst sample burnt at 1450°C in the course of 60 s.

The elemental composition of the catalyst (iron, calcium, magnesium, potassium, and cerium oxides) was determined on a Hitachi Z-6100 atomic-absorption spectrometer with an acetylene–air flame by the method of a calibration plot.

Table 1. XPA data for fresh and spent catalyst samples

Sample no.	Catalyst	CSR size at indicated *d*, Å			Area under the strongest reflections, arb. units, at indicated *d*, Å			Phases present
		2.70 (hematite)	11.90 (polyferrite)	3.12 (cerium oxide)	2.70 (hematite)	11.90 (polyferrite)	3.12 (cerium oxide)	
1	Fresh	612	396	155	21	69	84	$K_xFe_{22}O_{34}$, α-Fe_2O_3, CeO_2
	Spent:							
2	from the upper part of the bed	312	–	416	169	–	68	α-Fe_2O_3, CeO_2, Fe_3O_4
3	from the middle of the bed	136	–	375	126	–	72	α-Fe_2O_3, CeO_2, Fe_3O_4
4	from the lower part of the bed	265	–	452	36	–	57	α-Fe_2O_3, CeO_2, Fe_3O_4

It can be seen from the X-ray diffraction patterns in Fig. 1 that the phase compositions of the fresh and spent samples are markedly different.

The fresh catalyst contains phases of potassium polyferrite (*d* 11.90, 5.95, 2.98, 2.66 Å, etc.), hematite (*d* 3.66, 2.70, 2.51 Å), and cerianite (*d* 3.11 Å), and spent samples, the phases of magnetite (*d* 2.53, 2.96, 4.84 Å, etc.), cerianite, and trace amounts of hematite. The observed transformation of the phase structure is due to reduction of Fe^{3+} to Fe^{2+}, with the phase of hematite converted to magnetite and that of potassium polyferrite decomposed into hematite and potassium compounds. The crystal lattice of iron oxide changes from hexagonal to cubic. As can be seen in Table 1, hematite present in spent catalyst samples has smaller crystallites in the CSR.

A detailed analysis of samples taken from different points along the reactor height demonstrated that the hematite phase predominates in the upper layer of the catalyst bed, which is indicated by the areas under the diffraction lines (Fig. 1). This is due to partial oxidation of magnetite to hematite during preliminary regeneration of the catalyst before its being discharged.

During the operation of the catalyst, the content of potassium in the upper layer decreases as a result of decomposition of potassium polyferrite to hematite and potassium compounds, which are present in the form of a liquid film on the catalyst surface [5].

To determine the potassium distribution throughout the reactor, samples taken not only along the height of the catalyst bed, but also along its diameter were analyzed. It was shown that potassium is nonuniformly carried away along both the height and diameter of

the catalyst bed (Fig. 2), although the content of other components does not change significantly (Table 2).

It can be assumed that, in the course of exploitation, channeling of the raw material flow is observed within the catalyst bed because of the unsatisfactory operation of the distributing device.

Regeneration is performed under industrial conditions with steam at a temperature of 630–660°C in the course of 5–10 h. To test the quality of the steam regeneration and determine the conditions of burning-out of carbon deposits, spent samples were subjected to differential-thermal analysis. Figure 3 shows DSC, DTG, and TG curves for samples from the upper, middle, and lower parts of the catalyst bed after preliminary regeneration with overheated steam. The endothermic effects in the temperature range 24–200°C are due to removal of physically adsorbed water. The exothermic effects at 200–530°C are associated with oxidation of magnetite to hematite, with a gain in mass. The exothermic effects in the temperature range 530–700°C are associated with burning-out of carbon deposits to give CO_2. According to XPA data, the hematite phase is predominant in the sample from the upper layer, and, therefore, no gain in mass is observed. In the TG curves for other samples, the gain in mass is 1.18 wt % (for medium layer) and 1.11 wt % (for lower layer). Because of the superposition of the exothermic effects of magnetite oxidation and burning-out of carbon deposits, the loss of mass cannot be determined for each particular sample.

In contrast to the sample from the upper layer, the DSC curves for other samples show endothermic effects in the temperature range 650–850°C, associated with formation of potassium ferrites. This can be understood as follows: according to the results of elemental analysis, the content of potassium is virtually zero in a sample from the upper layer and considerably higher in other layers (Table 2). It follows

from the data presented that samples from the middle and upper layers contain free potassium carbonate, which again forms, in reaction with hematite, potassium ferrites, the active components of iron oxide catalysts. A distinctive feature of these samples is that, upon heating, the endothermic dip is shifted from 745°C (for the middle layer) to 791°C (for the lower layer) and the loss of mass in the temperature range 650–850°C increases from 5.07 to 6.48 wt %, respectively (Table 3). Probably, this occurs because the concentration of potassium carbonate in the lower layers is high and, consequently, a larger amount of potassium ferrites is formed. These data are confirmed by the results of titration (Table 4). The DSC curve for a sample from the lower layer (Fig. 3) shows a distinct endothermic effect at T_{min} = 882°C, which is associated with decomposition of potassium carbonate to the oxide and cannot be determined quantitatively.

The amount of carbon formed in the course of catalyst operation was determined using an analyzer for sulfur and coke; the corresponding kinetic curves are shown in Fig. 4. The kinetic curve describing the sample burning-out at the upper layer exhibits a single peak in the interval 0–30 s. According to DTA and elemental analysis data, this range is related to burning-out of carbon deposits, which is confirmed by the results of titration and quantitative determination of carbon deposits and potassium carbonate in spent catalyst samples (Table 4).

The kinetic curves of carbon burning-out (Fig. 4) show two peaks for samples from the middle and

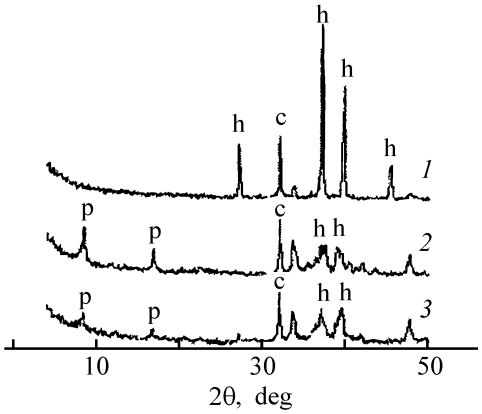
2	17.9	82.6	4	35.9	88.5

lower layers. The carbon deposits burn-out to the maximum extent in 30 s. The first peak is formed before the end of this period and belongs to burning-out of carbon deposits, and the second in the range 35–40 s, to decomposition of potassium carbonate, because K_2CO_3 decomposes at higher temperatures and, accordingly, its burning-out takes a longer time.

Thus, the concentration of potassium in the middle and lower layers is close to that in a fresh sample, with ferrites formed in repeated calcination of the samples under study. To verify the formation of potassium ferrites with certain parameters, the samples were repeatedly calcined at 750°C for 1 h and 850°C for 30 min and subjected to XPA. The X-ray diffraction patterns of the calcined samples are shown in Fig. 5.



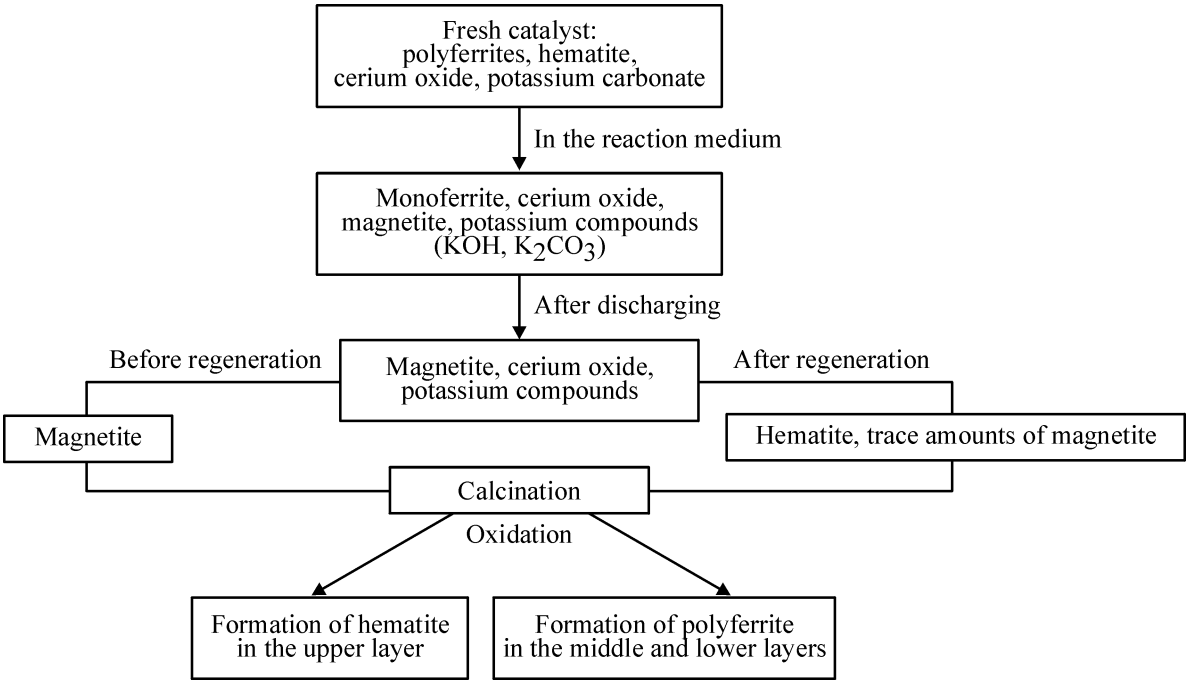


Fig. 5. X-ray diffraction patterns of calcined spent samples from (*1*) upper, (*2*) middle, and (*3*) lower layer of the catalyst bed in an adiabatic reactor.

It can be seen from the X-ray diffraction patterns in Fig. 5 that the phase composition of calcined samples differs from that of spent samples. In calcined spent samples, the following phases are observed: hematite (d = 2.70 Å), potassium polyferrite (d = 11.90 Å), cerianite (d = 3.12 Å), and magnetite (d = 2.53 Å). The calcined samples are characterized, in contrast to the spent samples, by the presence of the polyferrite phase in the middle and lower layers, because, in sample calcination, magnetite is oxidized to hematite and interacts with potassium carbonate. In this case, the quantitative content of potassium polyferrites and hematite is, respectively, lower and higher than that in the fresh sample. This is indicated by the XPA data in Tables 1 and 5.

Probably, the less intensive ferrite formation is due to healing of defects in iron oxide in the course of catalyst operation. According to XPA data, spent calcined samples from the upper, middle, and lower layers are characterized by a smaller CSR in hematite (Table 5), compared with that for the fresh catalyst (Table 1). The CSR of hematite in samples from middle and lower layers is nearly two times smaller in size than the CSR of hematite from the upper layer. Probably, this is due to the effect of potassium compounds on the crystallization of hematite.

Block diagram of transformations of the phase composition of the iron oxide catalyst in exploitation and reactivation.

Thus, the phase component of the catalyst changes both in the course of exploitation and in reactivation at different points of the reactor (see scheme).

To determine the catalytic activity of spent samples, they were tested under laboratory conditions. In the course of exploitation, the catalyst is deactivated, with its catalytic parameters under laboratory conditions impaired.

As can be seen in Table 6, the fresh catalyst has high activity *A* and selectivity *S*, in contrast to the spent sample from the upper layer, although samples from the lower and middle layers have rather high values of the catalytic parameters. Under industrial conditions, the catalyst is completely discharged from all the layers, which is not quite advisable because the capacity of the middle and lower layer is not fully exhausted. Therefore, further use of the catalyst from lower layers is possible.

CONCLUSIONS

(1) The phase composition of the catalyst changes in the course of its exploitation, with the CSR size for hematite decreasing.

(2) According to the results of a differential-thermal analysis, the steam regeneration of the catalyst under industrial conditions fails to fully remove carbon deposits and to oxidize magnetite to hematite.

(3) The distribution of the residual potassium along the height and diameter of the catalyst bed is not uniform because of the inefficient operation of the distributing device.

(4) Spent catalysts from lower layers have sufficiently high catalytic parameters. Consequently, the spent catalyst can be repeatedly used as a precatalyst or in the main bed.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Equilibrium in the Liquid–Liquid System and Critical Phenomena in the Ternary System Constituted by Water, Pyridine, and Butyric Acid in the Temperature Range 5–55°C

Abstract—Visual-polythermic method was used to study the mutual solubility of the components and critical phenomena in the system constituted by water, pyridine, and butyric acid in the temperature range 5.0–55.0°C. The temperature dependence of the composition of the critical solubility point was determined.

DOI: 10.1134/S1070427208020110

Extractive methods of extraction, separation, and concentration of substances are widely used in the technological practice. These methods have a number of disadvantages, the main of which is use of easily volatile and combustible solvents, hydrocarbons. This problem can be solved by using unconventional ternary extractive systems [1] containing no hydrocarbons. System of this kind are frequently characterized by a closed binodal curve, whose appearance was attributed by Mertslin [2] and, later, by his followers [3–5] to chemical interaction of the components of a binary boundary system. In this system, a new compound with limited solubility in water is formed. The wide diversity of stratifying systems and the simplicity and high selectivity of methods for recovery of various substances indicate that these methods are promising.

The most complete pattern of phase equilibria, necessary for optimization of extractive processes, can be obtained by constructing solubility diagrams and determining the coordinates of the critical point of the stratification region. The position of the critical point on a stratification isotherm characterizes the interaction of components in a system, and, therefore the problem of its coordinates and factors affecting its composition are rather important in a study of the mutual solubility of liquids. As temperature is raised or lowered, the closed stratification region may disappear via, respectively, the upper or lower three-component critical solubility point (UTCSP or LTCSP) [2–5]. Unfortunately, the compositions of the critical points in the solubility isotherms are unknown for the overwhelming majority of systems with a closed stratification region and the coordinates of UTCSP and LTSCP have been occasionally determined inaccurately and not for all systems.

In [4], the system constituted by water, pyridine, and butyric acid was studied by the method of isothermal titration and closed binodal curves were plotted in the concentration triangle at 12, 25, 38, and 50°C. The area of the stratification field decreased as temperature was elevated. The mutual solubility minima in the binodals demonstrated that an unstable compound was formed in the system with pyridine and butyric acid, with the component ratio of 1 : 2, respectively. The dissociation of this compound became stronger upon heating. The authors suggested that the given system has a UTCSP at 53°C and provided an approximate critical composition (wt %): C_5H_5N 19, $C_4H_8O_2$ 26, and H_2O 55. However, the compositions of the critical points in the solubility isotherms were not determined and the UTCSP coordinates were found approximately.

In the present study, the effect of temperature on the mutual solubility of the components and the composition of the critical solution for the system constituted by water, pyridine, and butyric acid in the temperature range 5.0–55.0°C was analyzed in order to reveal fundamental aspects of the topological transformation of the solubility diagrams of ternary systems with a closed stratification region.

EXPERIMENTAL

The solvents used in the study were thoroughly purified. Water was obtained using a DEM-20 MERA-POLNA redistiller. An analytically pure preparation of pyridine (content of main substance > 99%) was dried and distilled by the procedure described in [6]. A butyric acid preparation of pure grade was purified using the procedure developed in this study: it was first dried over calcined magnesium sulfate for one week, the filtrate was distilled on an installation with a herringbone dephlegmator of height 0.3 m, and the fraction boiling in the range 163.0–164.0°C was taken. The solvents were identified by the boiling points, refractive indices, and densities; their physical constants are in good agreement with reference data [7].

The polythermic study of the phase equilibria in the ternary system was performed by the visual-polythermic method, and the solution compositions corresponding to the critical solubility points were found by the method of phase volume ratio [8]. The method used to process the results of the polythermic study and to construct isothermal phase diagrams of the ternary system was described in [8]. The relative error in determining the mixture compositions corresponding to the phase transition points at the chosen temperature was ±0.5%.

The compositions of the component mixtures were varied along 11 sections of the concentration triangle of the system. The component mixtures for sections *I–V* had a variable content of pyridine and constant mass ratio between butyric acid and water: *I* 24.00 : 76.00, *II* 30.00 : 70.00, *III* 37.00 : 63.00, *IV* 44.00 : 56.00, and *V* 52.00 : 48.00. The component mixtures along sections *VI–XI* had a variable content of water and constant mass ratio between butyric acid and pyridine: *VI* 77.00 : 23.00, *VII* 68.00 : 32.00, *VIII* 61.00 : 39.00, *IX* 58.30 : 41.70, *X* 57.00 : 43.00, and *XI* 56.00 : 44.00.

It was found that the polytherms of mutual solubility of the components of the system are similar for all the sections: the parabola-shaped solubility curve separates the stratification field $l_1 + l_2$ from the field of homogeneous solutions, *l*. Of particular interest were the polytherms for sections *III* and *VI–XI*, some of whose mixtures exhibited critical phenomena between two liquid phases. In each of these sections, as well as in a number of additional sections, the mixture composition and the temperature corresponding to the critical solubility point were determined. Temperature dependences of the content of butyric acid and pyridine in critical solutions are shown in Fig. 1. At 50.7°C, these curves exhibit a temperature maximum at the point *K*' corresponding to a mixture of composition (wt %): $C_4H_8O_2$ 27.97, C_5H_5N 20.00, and H_2O 52.03.

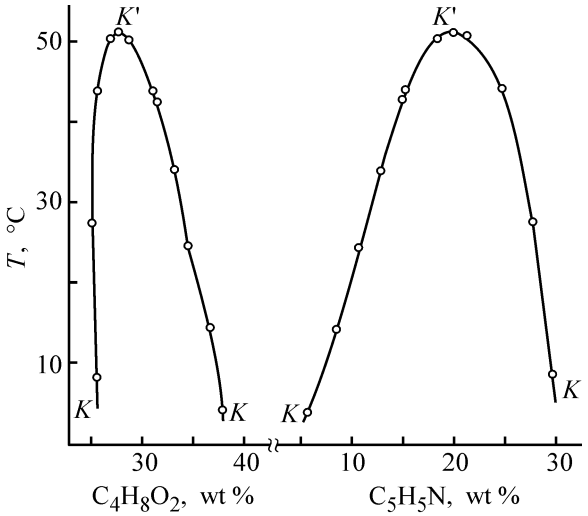

Fig. 1. Content of $C_4H_8O_2$ and C_5H_5N in the mixtures corresponding to the critical solubility points of the system H_2O–C_5H_5N–$C_4H_8O_2$ vs. temperature *T*.

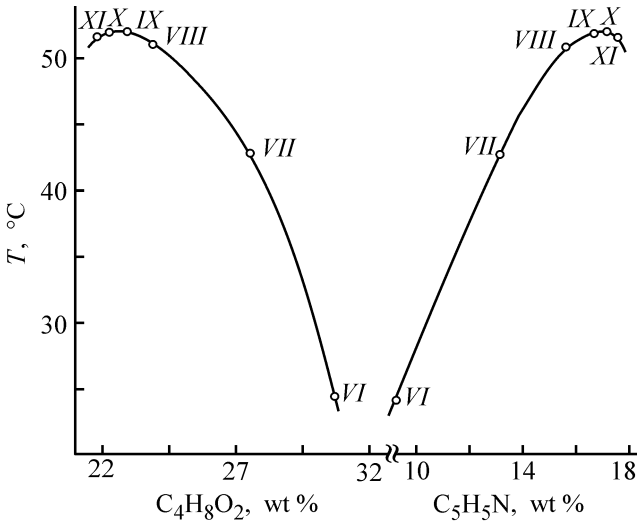

Fig. 2. Content of $C_4H_8O_2$ and C_5H_5N in the mixtures corresponding to the maximum coexistence temperatures of two liquid phases along sections *VI–XI* of the system H_2O–C_5H_5N–$C_4H_8O_2$ vs. temperature *T*.

The polytherms of mutual solubility of the components were used to construct dependences of the content of butyric acid and pyridine in mixtures corresponding to the coexistence temperatures of two liquid phases along sections *VI–XI* of the ternary system (Fig. 2). The coordinates of peaks in these curves correspond to the maximum coexistence temperature

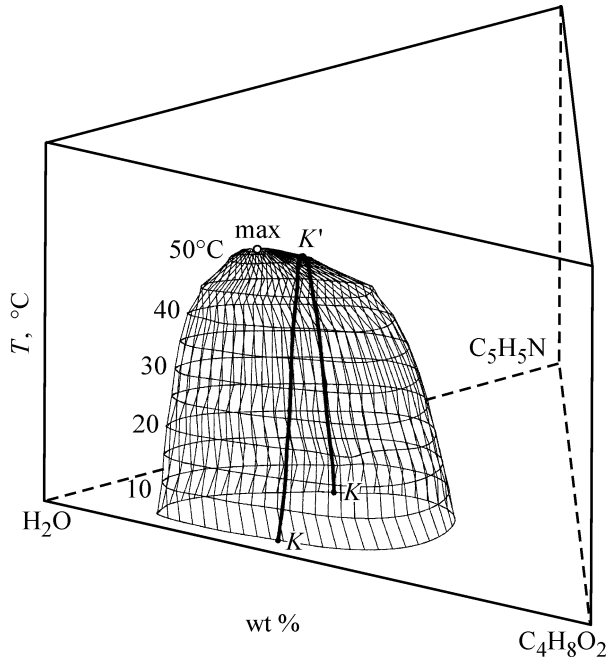

Fig. 3. Volume of two liquid phases delimited by the surface with a line of critical solubility points *KK'K* of the system H_2O–C_5H_5N–$C_4H_8O_2$ in the temperature–concentration prism. (*T*) Temperature.

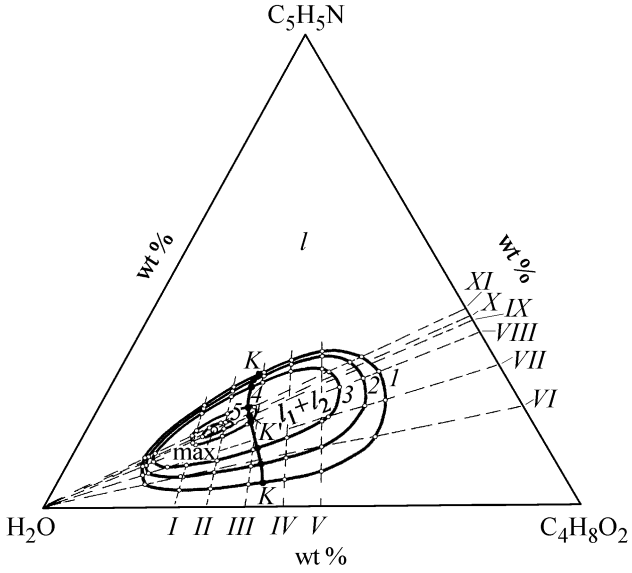

Fig. 4. Orthogonal projections of isothermal sections of the volume of two liquid phases in the system H_2O–C_5H_5N–$C_4H_8O_2$ onto the base of the temperature–concentration prism at different temperatures. Temperature (°C): (*1*) 5.0, (*2*) 20.0, (*3*) 35.0, (*4*) 50.0, and (*5*) 51.5. *KK'K* curve is the orthogonal projection of the line of critical solubility points on the binodal surface.

of two liquid phases in the given system (52.0°C) and to the composition (wt %): $C_4H_8O_2$ 22.77, C_5H_5N 17.17, and H_2O 60.06.

The method of graphical interpolation was used to determine, from the solubility polytherms and critical curves (Fig. 1), the mutual solubility of the components and the compositions of the critical points at 5.0, 10.0, 15.0, 20.0, 25.0, 30.0, 35.0, 40.0, 45.0, 50.0, and 51.5°C. The table lists data for 5.0, 20.0, 25.0, 35.0, 40.0, 50.0, and 51.5°C. To determine the fundamental aspects of the topological transformation of the volume of two liquid phases at different temperatures, the binodal surface (Fig. 3) along which passes the line of critical solubility points *KK'K* was constructed. This surface has a temperature maximum at the point *K'* at 50.7°C. There is a point (designated as max) on the binodal surface, to which corresponds a mixture with the maximum existence temperature of equilibrium between two phases in the system (52.0°C).

Figure 4 shows orthogonal projections of isothermal sections of the volume of two liquid phases of the system to the base of the temperature–concentration prism (solubility isotherms) at 5.0, 20.0, 35.0, 50.0, and 51.5°C. Each solubility isotherm is a closed binodal curve separating the field of the two-phase liquid phase, $l_1 + l_2$, from that of homogeneous solutions, *l*. The binodal curve at 5.0°C runs near the H_2O–$C_4H_8O_2$ side of the concentration triangle from the vertex corresponding to water toward the C_5H_5N–$C_4H_8O_2$ side. As temperature is elevated, the area of the field of two liquid phases decreases because of the increase in the mutual solubility of the components. At a higher temperature the stratification field lies within the stratification field for a lower temperature. In each binodal curve for 5.0, 20.0, 35.0, and 50.0°C (Fig. 4), there are two critical solubility points denoted by black circles. The critical points lie against those sides of the composition triangle which correspond to binary systems water + pyridine and water + butyric acid, which points to a weaker interaction between the components of these binary systems, compared with the chemical interaction of the components in the system constituted by pyridine and butyric acid. In the last binary system, there occurs an acid–base interaction of the components to give a molecular compound with a hydrogen bond [9]. According to Mertslin's concept [10], the boundary binary system pyridine + butyric acid is a system with a predominant interaction between the components in the ternary system under study.

The *KK'K* curve in Fig. 4 is an orthogonal projection of the line of critical points *KK'K* on the binodal surface delimiting the volume of two liquid phases that are in equilibrium (Fig. 3). The point *K'* in this curve corresponds to the composition of a mixture with the maximum critical temperature of equilibrium

* Critical solubility point.

between the two liquid phases (50.7°C) in the system (Fig. 1). Within the stratification field at 51.5°C, there is a point (designated by a large circle and an inscription max) corresponding to the composition of a mixture with the maximum coexistence temperature of two liquid phases (52.0°C) in the given system (Fig. 2). Thus, the volume of two liquid phases in the system constituted by water, pyridine, and butyric acid disappears as temperature is elevated via the noncritical point. This conclusion disagrees with the results of [4]. Such a transformation of the closed stratification region, with its disappearance via the noncritical point, is observed for the first time.

The transversal line passed from the H_2O vertex of the concentration triangle via the extremum points of the binodal points at 5.0 and 20.0°C intersects the C_5H_5N–$C_4H_8O_2$ size (Fig. 4) at the point corresponding to the composition of the rational compound between the components of this binary system, in a ratio of 2 : 3, respectively. This compound has a limited solubility in water, in contrast to pyridine and butyric acid exhibiting unlimited solubility. As temperature increases, the solubility extrema are shifted from this composition to an irrational component ratio. It can be assumed that the mutual solubility of the components of the ternary system increases, as temperature is elevated, because of the decomposition of the chemical compound formed.

CONCLUSIONS

(1) The mutual solubility of the components was determined in the range 5.0–55.0°C and the temperature dependence of the critical solution was found for the ternary system constituted by water, pyridine, and butyric acid. It was shown that the solubility of the components increases with temperature.

(2) The mixture compositions corresponding to the maximum coexistence temperature of two liquid phases in the system under study (52.0°C) and to the maximum critical temperature (50.7°C) were determined. On the basis of these data, it was found for the first time that, in systems with a closed stratification region, the volume of two liquid phases can disappear via the noncritical point as temperature is elevated.

(3) A polythermic study of the solubility diagram of the system constituted by water, pyridine, and butyric acid yielded results that can be used in extractive practice as reference data.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Solubility in the System Constituted by Acetic Acid, *n*-Propanol, Water, and *n*-Propyl Acetate

M. A. Toikka, B. I. Gorovits, and A. M. Toikka

Abstract—Experimental data on the solubility in the system constituted by acetic acid, *n*-propanol, water, and *n*-propyl acetate at 313.15 K are presented. The position of the critical curve for the liquid–liquid equilibrium, including that of the critical points on the chemical equilibrium surface, is discussed.

DOI: 10.1134/S1070427208020122

Studies of the compositions of equilibrium liquid phases in stratifying systems are highly important both for the development of the fundamental theory of phase equilibria and for practical purposes, e.g., for performing extraction processes. In recent years, a particular practical interest has aroused in combined reactive mass-exchange processes in which a chemical reaction and a phase transition occur simultaneously. An example of the related applications most widely used in chemical technology is the reactive rectification [1–5], i.e., a combined process involving a liquid–vapor phase transition. Theoretical studies are also mostly devoted to problems of equilibrium of chemically reacting liquid phases with a vapor [1–9]. A considerably smaller attention is given in the literature to extraction processes accompanied by chemical reactions. In this context, of certain importance for the development of the theory of reactive mass-exchange processes are studies of chemically reacting systems with stratifying liquid phases. In this communication, we present and discuss the results of an experimental study of the solubility of liquid phases in a system with an etherification reaction.

As object of study served the system constituted by acetic acid, *n*-propanol, water, and *n*-propyl acetate at 313.15 K. Our choice of the system was governed by the availability of detailed experimental data on the chemical equilibrium for the reaction of etherification-hydrolysis of the ester in this system [10], which enable construction of the chemical equilibrium surface in the concentration tetrahedron. Also, there are published data on the liquid–liquid equilibrium in both stratifying ternary subsystems: acetic acid + *n*-propyl acetate + water at 313.15 K [11] and *n*-propanol + *n*-propyl acetate + water under isothermal and isobaric conditions [12, 13]. Because the temperature in [12, 13] differed from 313.15 K, we experimentally studied the solubility at this temperature. In addition, data on certain compositions of the equilibrium liquid–liquid phases of the quaternary system have been obtained previously [14–16], with a gas-chromatographic analysis used.

All the reagents used in the study were thoroughly purified and their physicochemical constants (refractive index and boiling point) were in agreement with published data [17, 18]. The refractive index was determined with an IRF-454B2M refractometer at a temperature of 293.15 K, maintained by a TZh-TS-01 liquid thermostat. The boiling points were determined with a Sventoslavskii ebulliometer at several pressures close to the atmospheric pressure and then were recalculated to a pressure of 101 kPa. Also, the purity of the substances was additionally monitored by gas chromatography. The chromatographic analysis was performed with an LKhM-8MD chromatograph, model 2. Its fluoroplastic column with a length of about 2.5 m and inner diameter of 3 mm was packed with Chromaton N-Super with grain size of 0.3–0.4 mm, impregnated with 7 wt % dinonylphthalate and 1 wt % 1,2,3-tris(β-cyanoetoxy)-propane relative to the mass of the solid carrier. The working thermostating temperature was about 370 K for the columns and 390 K for the heat-conductivity detector. These conditions enable separation of the components of the system and provide sensitivity to possible impurities and primarily to products of the etherification-hydrolysis reaction [15].

The solubility (stratification limits) was determined by isothermal titration. As is known, this method can, in most cases, most accurately determine the position of the binodal [19–21]. We carried out the experiment in two ways; (a) by titration of a stratifying solution with a solvent until a homogeneous state was reached (titration to "clarification") and (b) by titration of a homogeneous solution until stratification occurred (titration to "turbidization"). The starting solutions were prepared by the gravimetrical method on an HF0-200 analytical balance with an accuracy as good as 0.001 g. The titration was performed in a thermostat (313.15 K) under continuous stirring with a magnetic stirrer. The titrating liquid was introduced into the mixture with microburettes (2 and 5 ml). The titrant volume was measured with an accuracy of 0.05 ml; when determining the amount of the liquid spent for the titration, its density was taken into account (commonly, the microburette temperature was about 298 K). As the final point of titration (both to clarification and to turbidization) and, accordingly, the solubility (stratification) limit were taken clarification or turbidization of a solution being titrated during no less than 2 min. With account of the volume of the mixture being titrated and the drop size of the titrating liquid (0.02 ml in the case of titration with twice-distilled water and 0.01 ml in titration with *n*-propanol), the accuracy with which the concentrations were determined was not worse than 0.001 mol %. With account of all the other possible factors affecting the accuracy of the results (purity of reagents, thermostating errors), the maximum error of the data obtained can be estimated as not exceeding ±0.002 mole fractions of a component.

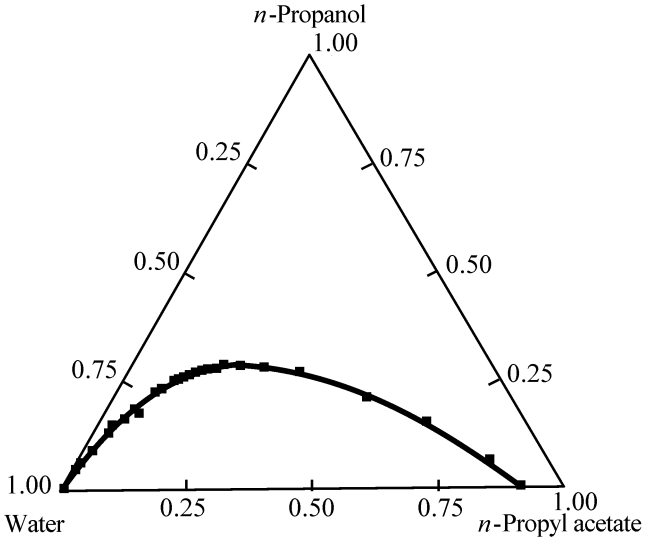

Fig. 1. Solubility curve for the three-component system constituted by *n*-propanol, water, and *n*-propyl acetate at 313.15 K.

When studying the three-component system constituted by *n*-propanol, water, and *n*-propyl acetate, we titrated binary stratifying mixtures of water and ester with *n*-propanol. The starting compositions were chosen in such a way that the points were, on the whole, uniformly distributed along the binodal; at the same time, the density of the points near the critical point was considerably higher. The data we obtained for the solubility in the ternary system constituted by *n*-propanol, water, and *n*-propyl acetate are listed in Table 1, and the solubility curve is shown in Fig. 1.

* System of water and *n*-propyl acetate.

As noted above, data on phase equilibria in this ternary system have also been obtained previously [12, 13] for temperatures other than 313.15 K. To compare these results with our experiment and to make additional correlations, we interpolated polythermic (from 309.22 to 357.5 K) data from [12, 13] to the temperature of 313.15 K. The results of this interpolation and our experimental data for 313.15 K are in good agreement: the maximum discrepancy is about 0.01 mole fraction of a component.

The solubility in the four-component system constituted by acetic acid, *n*-propanol, water, and *n*-propyl acetate were studied with account of the subsequent possibility of a sufficiently full representation of the stratification surface in the concentration tetrahedron on the basis of the experimental data. To achieve an ordered arrangement of the composition points, the set of solutions under study was prepared with a constant ratio between the concentrations of two components in the mixture. Simultaneously, this choice of the starting compositions facilitates evaluation of the accuracy of the data with respect to accidental errors. Because stratification is observed in two of the four ternary subsystems, the ternary mixtures (acid, alcohol, ester) were titrated with water at a constant ratio between the concentrations of *n*-propanol and acetic acid.

As is known, the choice of a variant of isothermal titration (to turbidization or clarification) depends on the physicochemical properties of the system, including the concentration interval. Based on the results of the experiments performed, we established for the system under consideration that the stratification limit is more distinctly determined in titration to clarification. In this case, we chose the tetrahedron-cutting planes corresponding to a constant ratio between the concentrations of the ester and acetic acid. The compositions of the ternary mixtures (water, ester, and acid) to be subjected to titration belonged to the heterogeneous region.

The results of an experimental determination of the solubility in the system constituted by (1) acetic acid, (2) *n*-propanol, (3) water, and (4) *n*-propyl acetate at 313.15 K are listed in Table 2. The triangular diagrams corresponding to the tetrahedron sections under study, with compositions x_i/x_k = const (where x_i and x_k are the mole fractions of *i*th and *k*th components) are shown in Fig. 2; the positions of the corresponding solubility curves rather fully reflect the shape of the stratification surface of the quaternary system as a whole.

Figure 3 shows the stratification surface at 313.15 K, constructed using the experimental data obtained in our study and the data reported in [16] for the cutting planes with x_1/x_2 = 0.5, 1, and 2. In addition, we

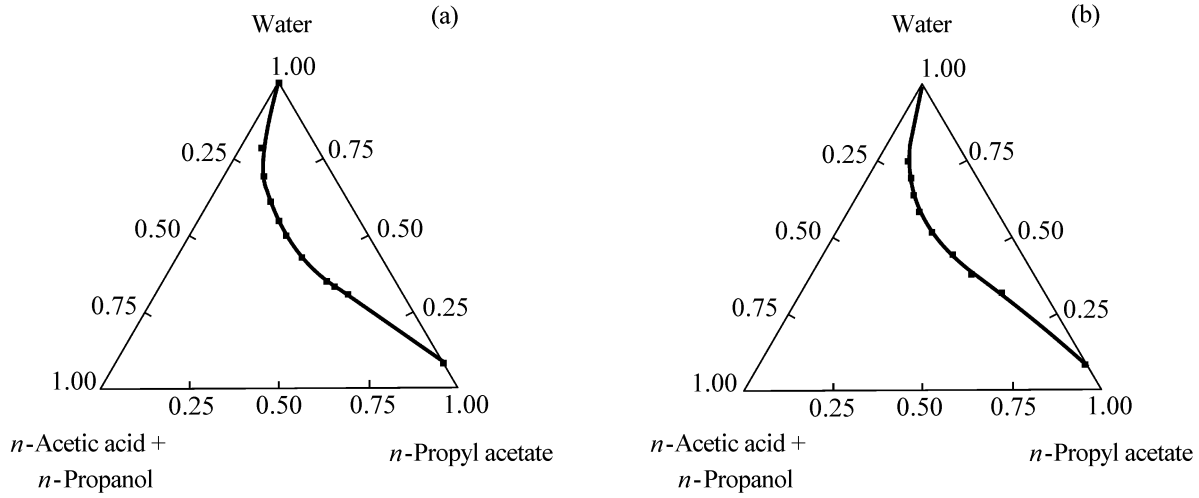

Fig. 2. Composition points belonging to the solubility surface in the system constituted by (1) acetic acid, (2) *n*-propanol, (3) water, and (4) *n*-propyl acetate at 313.15 K. Cutting planes of the concentration tetrahedron, which correspond to a constant ratio between the concentrations (mole fraction) of the components: (a) $x_1 : x_2 = 1 : 3$ (titration with water), (b) $x_1 : x_2 = 4 : 1$ (titration with water), (c) $x_1 : x_2 = 1 : 3$ (titration with water), (d) $x_1 : x_2 = 1 : 4$ (titration with water), (e) $x_1 : x_4 = 1 : 1$ (titration with alcohol), (f) $x_1 : x_4 = 1 : 2$ (titration with alcohol), and (g) $x_1 : x_4 = 2 : 1$ (titration with alcohol).

invoked, when analyzing the run of the critical curve and the position of the stratification surface, the data of [14, 15] on the liquid–liquid–vapor equilibrium (their thermodynamic consistency was preliminarily estimated using the Gibbs–Duhem equation). The stratification surface in Fig. 3 is presented in the concentration space having the form of an irregular tetrahedron.

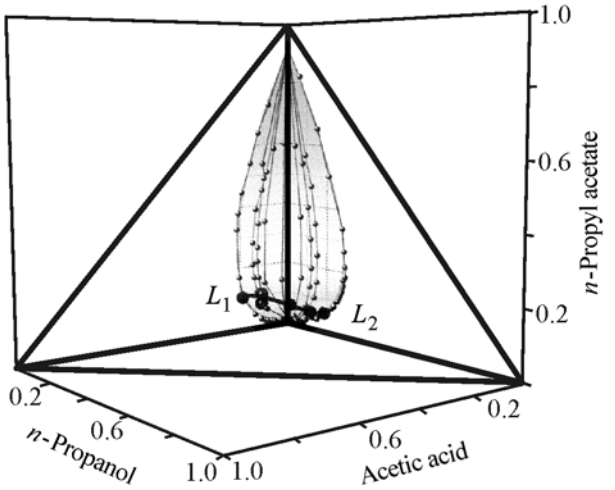

Fig. 3. Solubility surface of the system (mole fraction) constituted by acetic acid, *n*-propanol, water, and *n*-propyl acetate at 313.15 K. L_1L_2 is the critical curve for the liquid–liquid equilibrium.

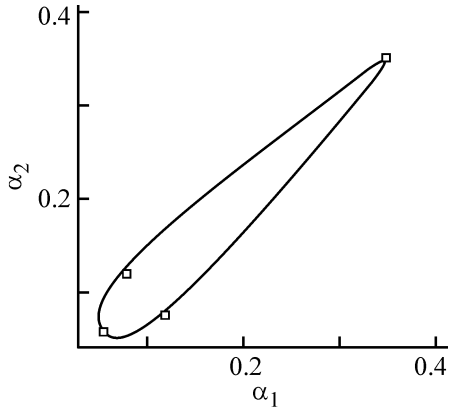

Fig. 4. Region of intersection of the solubility surface with the chemical equilibrium surface in the space of α-variables at 313.15 K. *Solid curve*, closed line; *points*, chemically equilibrium compositions belonging to the stratification surface (according to the experimental data obtained in this study).

Figure 3 also qualitatively shows the run of the liquid–liquid critical curve in the quaternary system. To analyze the run of the critical curve, we used, in addition to the results of the present study, data of [14, 15] on the liquid–liquid equilibrium in the four-component system. The compositions corresponding to the critical points and the critical curve in the quaternary system were found from data on the liquid–liquid equilibrium and monitored in the course of isothermal titration. The composition of the critical point in the ternary subsystem constituted by water, acetic acid, and *n*-propyl acetate was determined using the data of [11]. The composition of the critical point of the ternary subsystem constituted by *n*-propyl acetate, *n*-propanol, and water at 313.15 K was found experimentally (x_1 = 0.187, x_2 = 0.054, x_3 = 0.759). The composition of the same critical point was determined by processing the data of [12, 13], interpolated to 313.15 K using the geometric Coolidge method [21]. The compositions of the critical point, found by these two methods, are in good agreement. The data for constructing the critical curve in the quaternary system are listed in Table 3.

Table 3. Compositions belonging to the liquid–liquid critical curve in the system constituted by (1) acetic acid, (2) *n*-propanol, (3) water, and (4) *n*-propyl acetate at 313.15 K

Concentration, mole fraction			
x_1	x_2	x_3	x_4
0	0.187	0.759	0.054
0.190	0	0.710	0.100
0.148	0.049	0.687	0.116
0.138	0.035	0.747	0.081
0.081	0.112	0.726	0.081
0.029	0.150	0.764	0.057

The results obtained in determining the solubility and the run of the critical curve were compared with data on the chemical equilibrium of the reaction of etherification-hydrolysis of the ester at 313.15 K [10]. To the chemical equilibrium of the reactions of the type

$$R_1 + R_2 \rightleftarrows R_3 + R_4, \quad (1)$$

whose stoichiometry is similar to that of the reactions of ester synthesis, corresponds the surface in the composition tetrahedron. This surface is delimited by the ribs of the given concentration simplex, which correspond to chemically inert mixtures (acid–water, acid–ester, alcohol–water, alcohol–ester). The chemical equilibrium surface for the system constituted by acetic acid, *n*-propanol, water, and *n*-propyl acetate at 313.15 K was reported in [22]. To represent the thermodynamic properties of chemically equilibrium systems, Zharov suggested new composition variables (transformed concentration variables, or α-variables) [6, 23], which can be represented, in the case of reaction (1), as

$$\left.\begin{aligned}\alpha_1 &= x_1 + x_4,\\ \alpha_2 &= x_2 + x_4,\\ \alpha_3 &= x_3 - x_4.\end{aligned}\right\} \quad (2)$$

These variables furnish a compact and clearly understandable representation of properties for states of chemical equilibrium: the concentration space is transformed into a 2*D* complex, square of α-variables.

Based on the results of our study, we established that the chemical equilibrium surface intersects the stratification surface for the system constituted by acetic acid, *n*-propanol, water, and *n*-propyl acetate at 313.15 K in the composition tetrahedron. In other words, the states of chemical equilibrium of the given reaction include not only the region of homogeneous solutions, but also the heterogeneous region. In Fig. 4, the boundaries of this region are represented in the square of α-variables. Two points in Fig. 4 for the stratification surface and for the chemical equilibrium surface ($\alpha_1 = 0.16$, $\alpha_2 = 0.199$ and $\alpha_1 = 0.19$, $\alpha_2 = 0.14$) correspond to the critical state of the liquid–liquid equilibrium [the corresponding concentrations are as follows (mole fraction): $x_1 = 0.12$, $x_2 = 0.09$, $x_3 = 0.07$ and $x_1 = 0.07$, $x_2 = 0.12$, $x_3 = 0.07$]. These compositions can also be interpreted as points at which the critical curve intersects the chemical equilibrium surface. Thus, the results obtained in the study can be of use both for development of solubility a database for four-component liquid-phase systems and for studies of critical phenomena in chemically reacting systems. Previously, the related issues, including the topology of diagrams with reactions of another stoichiometry, were discussed only theoretically in some publications of recent years [24–28].

CONCLUSIONS

(1) Detailed experimental data on the solubility of liquid phases in the system constituted by acetic acid, *n*-propanol, water, and *n*-propyl acetate at 313.15 K were obtained. These data were used to establish that the stratification surface intersects the chemical equilibrium surface (reactions of synthesis of *n*-propyl acetate) in the composition tetrahedron. To the chemical equilibrium in the system constituted by acetic acid, *n*-propanol, water, and *n*-propyl acetate at 313.15 K corresponds not only a homogeneous region, but also a heterogeneous liquid-phase region. This region is represented in the square of transformed composition variables.

(2) It was demonstrated that the critical curve of the liquid–liquid equilibrium intersects the chemical equilibrium surface in the concentration space; accordingly, the system constituted by acetic acid, *n*-propanol, water, and *n*-propyl acetate at 313.15 K has two liquid–liquid critical points corresponding to chemically equilibrium states.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Sorption of Pt(IV) Chloride Complexes with a Chelating Resin Based on Modified Lignin

N. N. Chopabaeva and E. E. Ergozhin

Bekturov Institute of Chemical Sciences, Ministry of Education and Science of the Republic of Kazakhstan, Almaty, Kazakhstan

Received June 22, 2007

Abstract—Sorption of hexachloroplatinic(IV) acid on a new phytosorbent based on lignin modified with thioamide groups was studied. The sorption capacity of the sorbent for Pt(IV) was examined in relation to the Pt(IV) concentration in the aqueous phase, pH, temperature, and sorption time. The kinetic characteristics of sorption of Pt(IV) on the lignin sorbent were studied.

DOI: 10.1134/S1070427208020134

As compared to common ion-exchange resins, chelating sorbents are characterized by higher sorption capacity and selectivity to chemical elements with similar properties. Therefore, these sorbents find growing use for separation and preconcentration of metals. The high selectivity of chelating resins is controlled not only by the chemical composition of the polymeric matrix and sorption sites, but also by their steric arrangement. An important role in this respect is played by both the remoteness of functional groups from the matrix and the uniformity of the sorbent framework.

A wide variety of commercial chelating sorbents are available today. The techniques for preparation of chelating sorbents and physicochemical characteristics of these resins have been described in detail in numerous reviews and monographs [1–6]. These sorbents are mainly prepared by polycondensation of the initial compounds containing chelating groups or by polymeryzation of vinyl monomers containing complexing groups. Chelating sorbents can also be prepared by modification of the initial nonchelating resins with chelating agents. The latter approach is the most promising since it allows preparation of chelating sorbents not only from common macrocellular (polystyrene, polyacrylate, etc.) or fibrous (e.g., polyacrylonitrile, polyvinyl alcohol) polymers, but also from natural porous hydrophilic polyelectrolytic matrices (cellulose, chitin, tannin, and gelatin) [4, 7, 8].

In this study, we examined the sorption of Pt(IV) from aqueous hydrochloric acid solutions on a new chelating phytosorbent prepared from commercial hydrolytic lignin by its modification with thioamide functional groups.

EXPERIMENTAL

The phytosorbent was prepared from lignin of cotton peel from the Chimkent hydrolytic plant. This raw material was subjected to catalytic alkylation with ED-20 bifunctional epoxy oligomer [9], followed by modification with the thiourea α-oxide derivative [10]. The resulting resin contains the chelating thioamide groups (SEC_{HCl} 3.70 mg-equiv g^{-1}, N 6.72, and S 9.02 wt %). This sorbent is an analog of SRAFION NMRR commercial poly(styrene–divinylbenzene) complexone [4, 11] and MSPVS [4, 12–15], MTILON-T [4, 7, 8, 16–21] and TIOPAN-4 [22] complexing sorbents based on graft copolymers of polyvinyl alcohol, cellulose, and polyacrylonitrile.

The sorption of Pt(IV) on the modified lignin sorbent from aqueous and aqueous HCl solutions of hexachloroplatinic(IV) acid hexahydrate was carried out under static conditions at 20, 40, and 60°C without stirring. The weighed portion of the phytosorbent was 0.05 g. The liquid phase volume was 100 ml. A stock solution was prepared by dissolving a weighed portion of $H_2[PtCl_6] \cdot 6H_2O$ (pure grade) in water [23]. The correct concentration of platinum in this solution was determined gravimetrically with Thionalide [24–27]. The working solutions were prepared by accurate dilution of the stock solution. The content of platinum(IV) in the initial and equilibrium solutions in

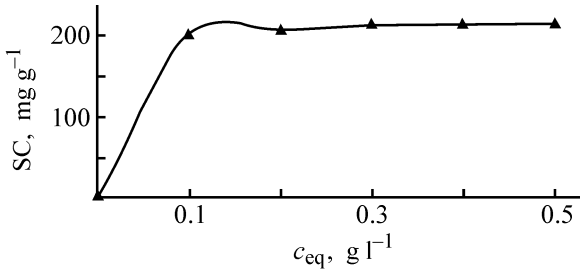

Fig. 1. Isotherm of Pt(IV) sorption from aqueous solutions with modified lignin sorbent. Contact time τ 3 days; the same for Figs. 2 and 3. (SC) Sorption capacity of modified lignin sorbent for Pt and (c_{eq}) equilibrium concentration of Pt(IV).

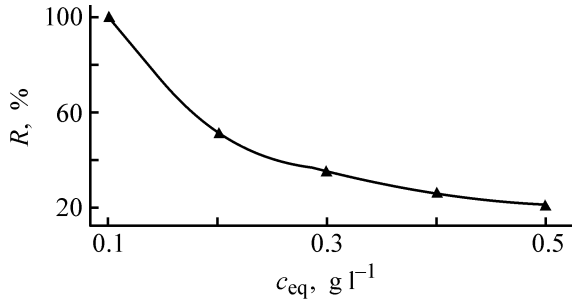

Fig. 2. Degree of Pt(IV) sorption, R, on modified lignin sorbent vs. the equilibrium concentration of Pt(IV) in the aqueous phase c_{eq}.

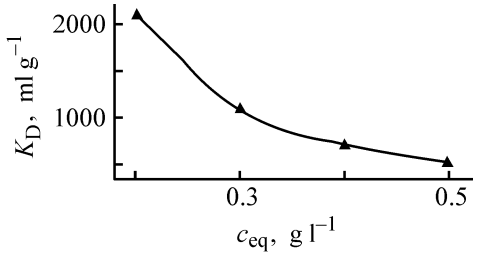

Fig. 3. Distribution ratio of Pt(IV) between modified lignin and aqueous phase K_D vs. the equilibrium concentration of Pt(IV) in the aqueous phase c_{eq}.

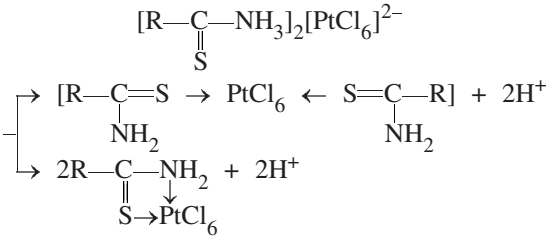
the sorption systems was determined photocolorimetrically with $SnCl_2$ on a KFK-2MP photocolorimeter (λ = 440 nm, l = 10.07 mm, V = 5 ml) [23]. The calibration curve was processed by the least-squares technique. The sorption capacity of the phytosorbent for Pt(IV) (SC) and the distribution ratio K_D were calculated by the procedure described in [28, 29]. The degree of platinum sorption, R, was determined according to [30]. The degree of sorption completion, F, was determined as the ratio of SC at a certain time to the equilibrium SC. The IR spectra of the initial sorbent and that after the sorption of Pt were recorded on a Nicolet FT-IR spectrophotometer (KBr pellets).

Effect of pH of the liquid phase on the sorption capacity of the modified lignin for platinum (c_{Pt} = 0.1 g l^{-1}, τ = 3 days)

pH	SC, mg g^{-1}	R, %	K_D, ml g^{-1}
1	145	72.5	5272
2	150	75	6000
3	160	80	8000
4	178	89	16181
5	200	100	∞
6	200	100	∞

The sorption isotherm shows (Fig. 1) that the sorption of Pt(IV) is the most efficient from dilute aqueous solutions. With increasing Pt(IV) concentration in the aqueous phase, the degree of sorption of Pt(IV) (Fig. 2) and the distribution ratio of Pt(IV) between the sorbent and aqueous phase (Fig. 3) decrease.

The table shows that modified lignin exhibits strong sorption capacity for Pt(IV) within a wide pH range. It is seen that, with increasing pH, the sorption of Pt(IV) grows. This trend is typical of complexing sorbents containing sulfamide groups, e.g., Movinex [31] and SRAFION NMRR [21] sorbents based on macroporous copolymers of styrene and divinylbenzene.



Presumably [32], sorbents containing the sulfamide groups sorb chloroplatinate anions from weakly acidic (pH > 2) and neutral solutions by the coordination mechanism to form chelate compounds. This sorption mechanism is favored by the fact that, under these conditions, the amino groups of the sorbent are present in the deprotonated state and the aquated chloroplatinate anions formed in this case undergo the ligand substitution more readily than do the initial chloroplatinate complexes [21]. It is also suggested [33] that the sorbable chelate compound can be formed by Anderson's rearrangement of onium complexes containing NH_3^+ groups protonated in the neutral pH range by protons of water molecules.

In acidic media, the amide groups are protonated, and thermodynamically stable and kinetically inert hexachloroplatinate complexes are weakly hydrolyzed [24, 25]. Under these conditions, hexachloroplatinate anions are apparently sorbed by the following heterogeneous reaction [21]:

$$2R{-}\underset{\underset{S}{\|}}{C}{-}NH_2HCl + [PtCl_6]^{2-} \leftrightarrows [R{-}\underset{\underset{S}{\|}}{C}{-}NH_3^+]_2[PtCl_6]^{2-} + 2Cl^-.$$

We found that chloroplatinate anions sorbed on modified lignin are not eluted with 1–5 N solutions

of nitric, hydrochloric, and oxalic acids. This means that chloroplatinate anions form very strong, not salt-like, complexes with the thioamide groups of the sorbent. We believe that the initially formed outer-sphere ionic associates are converted to donor–acceptor complexes between hexachloroplatinate anions and the thioureide groups of the sorbent. This rearrangement is accompanied by incorporation of the polymer ligands into the inner coordination sphere of Pt(IV). Under these conditions, the chelate thioamide complexes of the sorbent with chloroplatinate anions are formed. In these complexes, the donor atoms of sulfur or of sulfur and nitrogen simultaneously are coordinated with Pt(IV) [21]:

This complexation pattern is in agreement with published data [21, 30, 33]. In sorption of Pt(IV) from 1–6 M aqueous HCl with a sorbent containing bidentate thioamide functional groups [34], the ion-exchange mechanism of sorption is complicated by strong complexation of Pt(IV) with the sulfur donor atoms. As a result, the desorption of Pt(IV) from the resin saturated with Pt(IV) becomes impossible.

The strong covalent binding of Pt(IV) with modified lignin is confirmed by the IR spectra of the modified lignin sorbent saturated with Pt(IV) from its acidic and neutral solutions. In these spectra, the absorption band of the bending vibrations of the thioamide groups >C(NH)=S at 1606 cm^{-1} (1471–1613 cm^{-1} [35]) is shifted toward higher frequencies and is split in two peaks at 1616 and 1636 cm^{-1}. In the range of stretching vibrations of the NH groups (3500–3200 cm^{-1}), new bands at 3276 and 3178 cm^{-1} appear. The absorption band of the C–S stretching vibrations at 767 cm^{-1} is shifted toward lower frequencies and is split in two bands at 710 and 730 cm^{-1}. On the whole, these changes in the IR spectra suggest the complexation of Pt(IV) with the nitrogen and sulfur atoms of the thioamide functional groups of the modified lignin.

The limiting stage of sorption of Pt(IV) with modified lignin was elucidated by analysis of the kinetic curves of Pt(IV) sorption from solutions of $H_2[PtCl_6]$ at pH 1 (Fig. 4) and the curves plotted in the coordinates F vs. $\tau^{1/2}$ (Fig. 5a) [hypothesis that sorption of Pt(IV) is controlled by internal diffusion] and

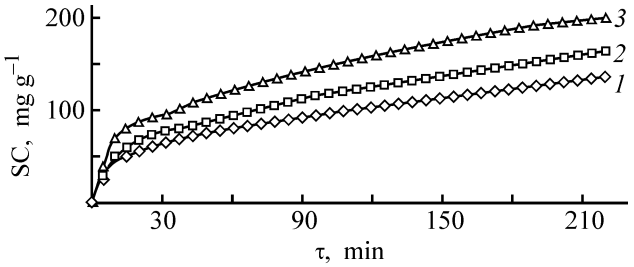


Fig. 4. Kinetic curves of sorption of Pt(IV) with modified lignin. pH 1, c_{Pt} = 0.1 g l^{-1}; the same for Fig. 5. (SC) Sorption capacity of sorbent (mg g^{-1}) and (τ) time. Temperature, °C: (*1*) 20, (*2*) 40, and (*3*) 60; the same for Fig. 5.

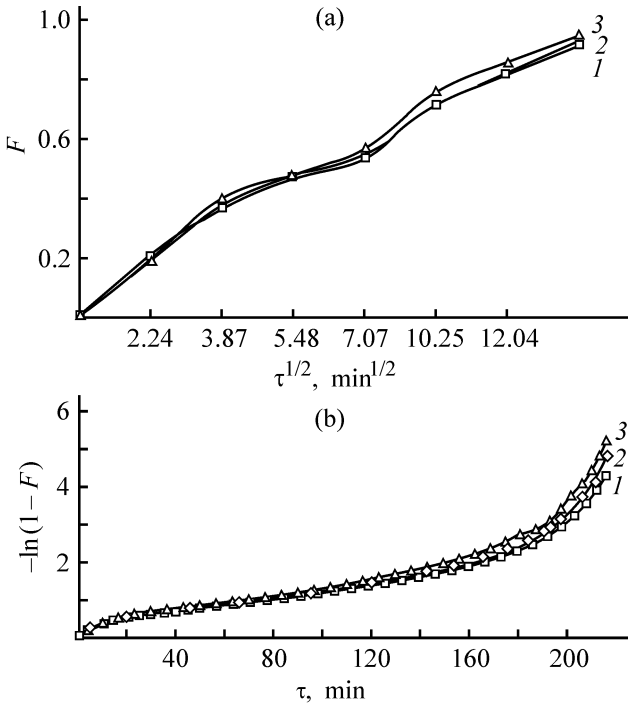

Fig. 5. Kinetic curves of sorption of Pt(IV) on modified lignin from aqueous hydrochloric acid, plotted in the coordinates (a) F vs. $\tau^{1/2}$ and (b) $-\log(1 - F)$ vs. τ. (F) Degree of sorption completeness and (τ) time.

$-\log(1 - F)$ vs. τ (Fig. 5b) [hypothesis that sorption of Pt(IV) is controlled by external diffusion] at different temperatures. The complicated shape of the curves and the lack of distinct linearity in their initial portion suggest that the sorption of Pt(IV) is characterized by mixed diffusion-controlled kinetics.

Figure 4 shows that, irrespective of temperature, the equilibrium in sorption of Pt(IV) on modified lignin is attained within 220 min. The half-sorption time is also temperature-independent. This parameter is 35, 40, and 35 min at 20, 40, and 60°C, respectively. It should be noted that the sorption kinetic

curves are also independent of temperature. Both the increase in the sorption capacity of modified lignin for Pt(IV) in acidic solutions with increasing temperature and the decelerated sorption kinetics suggest that Pt(IV) is sorbed on modified lignin by the coordination mechanism rather than by the faster anion-exchange mechanism.

CONCLUSIONS

(1) A phytosorbent containing the chelating thioamide groups was prepared by chemical modification of hydrolytic lignin with ED-20 commercial epoxy resin and thiourea. This sorbent quantitatively recovers chloroplatinate anions from weakly acidic and neutral aqueous solutions at $c_{Pt} = 0.1$ g l^{-1}.

(2) Sorption of Pt(IV) on modified lignin increases with temperature.

(3) Pt(IV) is irreversibly sorbed on modified lignin by complexation of chloroplatinate anions with the thioamide functional groups.

Abstract—Possibility of modification of polyphenyleneisophthalamide with 5 wt % nanocarbon additive (fullerene, astralene, or graphite soot) was studied. The resulting composites were used to prepare asymmetric membranes, and the effect of carbon additives on the performance of these membranes was examined. Finally, the membranes were tested using a mixture of proteins of various molecular weights.

DOI: 10.1134/S1070427208020146

Ultrafiltration membrane processes are widely used in microbiology, food industry, pharmaceutics, and other branches of industry, and also for solving environmental problems [1]. The diversity of systems to be separated requires extension of the spectrum of membrane materials. Modification of polymers commonly used as membrane materials shows promise as a way to develop novel membranes.

Among the common commercial polymers used for production of fibers and membranes, a firm place is held by aromatic polyamides and, in particular, products of condensation of isoterephthaloyl chloride with *p*- and *m*-phenylenediamine. The structure and properties of polyphenyleneisophthalamide (PA), as well as some features of supramolecular structures in its concentrated solutions, were reported in [2, 3]. The formation of polyamide-based ultrafiltration membranes was studied by Bil'dyukevich et al. [4–6].

In this study, we modified PA with nanocarbon additives: fullerene C_{60}, astralene, and graphite soot, which are essentially different in their structure and properties. Graphite soot is a chemically inert amorphous form of carbon. Fullerene C_{60}, prepared by laser ablation of graphite, has a closed-shell spheroid configuration consisting of 20 hexagons and 12 pentagons [7]. It is this configuration that is responsible for the high chemical activity and noticeable solubility of C_{60} in organic solvents [8, 9]. Astralene is a carbonaceous nanomaterial formed in synthesis of fullerene soot. This material contains 20 to 90 wt % fulleroid nanoparticles (primarily with cage structure): multi- and single-wall nanotubes, nanobarrels, nanobulbs, and nanocones [10].

There is scarce information on gas-separation and pervaporation membranes based on polymer nanocomposites with fullerene [11–13]. Preparation and characterization of ultrafilters with membranes of fullerene-containing polyphenylene oxide were reported in [14]. Despite that fullerenes are produced on a commercial scale in a number of countries, only proton-conducting Nafion 117 fuel-cell membranes with addition of C_{60} fullerene are ready for commercial introduction [15].

The goals of this study were to prepare polyamide composites with nanocarbon additives, to form asymmetric membranes on their basis, and to examine the effect of nanocarbon additives (graphite soot, C_{60}, and astralene) on the ultrafiltration performance of the membranes.

EXPERIMENTAL

Polyphenyleneisophthalamide (Fenilon®) (PA) was used as a test subject. Composites of PA with 5 wt % nanoadditive (fullerene C_{60}, astralene, or graphite soot) were prepared by mixing PA and nanocarbon in a porcelain mortar. The resulting mixture was dissolved in *N*,*N*-dimethylacetamide. A 0.12% polymer

solution was cast onto a glass plate using a draw die with a 0.30-mm passageway. Finally, the glass plate was immersed in a precipitation bath to form an asymmetric porous membrane through phase inversion.

The rigidity of the structure of the membranes was monitored when passing solvent across them in the order ethanol, water, isopropanol, hexane, i.e., in accordance with their mutual solubility. The experiments on determination of the solvent flux across the membranes and on ultrafiltration of protein solutions were carried out in stirred cells under a pressure of 0.1 MPa.

The rejection curves of the ultrafiltration membranes were obtained according to the procedure described in [16], using a 0.4 wt % aqueous solution of a model mixture of proteins of various molecular weights: vitamin B_{12} (MW 1340), cytochrome C (MW 12 500), chemotrypsinogen (MW 24 000), egg albumin (MW 44 500), bovine serum albumin (MW 67 000), and γ-globulin (MW 160 000). The selectivity of the membranes was characterized by the rejection factor φ, which was estimated as $\varphi = 1 - c_p/c_f$, where c_p and c_f are the concentrations of the permeate and feed solution, respectively.

The experiments on static sorption of proteins on the membranes were carried out in hermetically sealed weighing bottles by immersing the membranes into 4 ml of the solution of protein mixture, with intermittent stirring. The protein concentration in the solution was monitored by the optical density at 280 and 415 nm at fixed intervals. The equilibrium concentration was established in 4 h, and the total experiment time was 20 h.

The contact angles of the membrane surface with water were determined by the Wilhelmy method on a KRUSS contact-angle-measuring system with computer-controlled sample immersion rate and data processing.

To gain insight into the effect of a modifier, we performed a comparative study of the PA-based membranes containing 5 wt % of various nanocarbon additives. The membrane morphology was examined by scanning electron microscopy (SEM). The SEM results revealed that nanocarbon additives had virtually no effect on the pore structure. Figure 1 shows a cross-sectional SEM micrograph of a PA membrane modified with 5 wt % fullerene. It should be pointed out that the performance characteristics of membranes are not always manifested on the morphological level as judged from SEM data. For example, polysulfone gas-separation membranes modified with various carbonaceous additives have similar morphology, but demonstrate considerable differences in their transport characteristics [17].

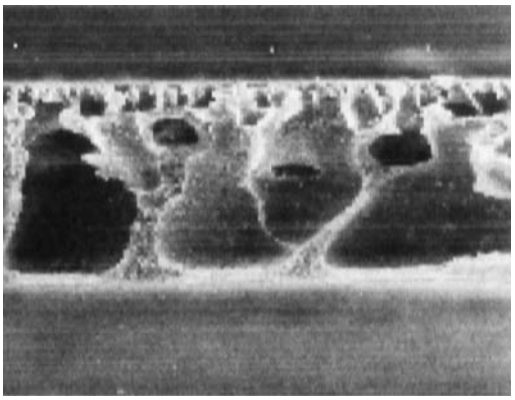

Fig. 1. Cross-sectional SEM image of a polyimide membrane modified with 5 wt % fullerene C_{60}.

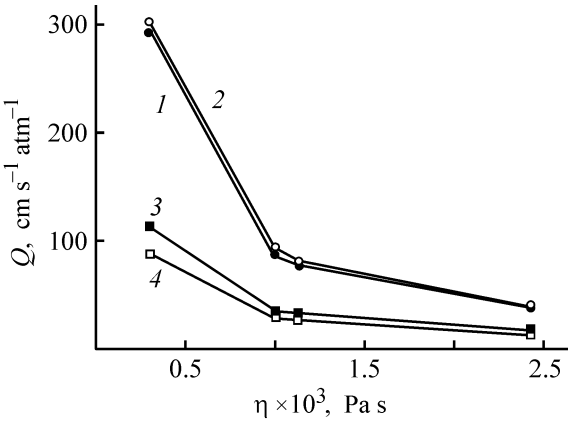

Fig. 2. Flux Q vs. the solvent viscosity η for asymmetric membranes: (*1*) PA, (*2*) PA + 5 wt % graphite soot, (*3*) PA + 5 wt % fullerene, and (*4*) PA + 5 wt % astralene; the same for Figs. 3 and 4.

The modifier nature affects the structure of the skin layer. The skin porosity can be characterized by the solvent flux across the membrane. In this study, the durability of the membranes and their resistance with respect to various media were characterized by the flux of water and several organic solvents (hexane, ethanol, and isopropanol) across the ultrafiltration membranes modified with 5 wt % nanocarbon additives. The solvents used were different in their viscosity ($\eta_{hexane} = 0.30 \times 10^{-3}$, $\eta_w = 1.0 \times 10^{-3}$, $\eta_{EtOH} = 1.13 \times 10^{-3}$, and $\eta_{i\text{-PrOH}} = 2.43 \times 10^{-3}$ Pa s) and, therefore, in their flux across the membranes.

Figure 2 shows that, in accordance with the Hagen–Poiseuille law [18], the flux decreases with increasing viscosity of the fluid for all the membranes studied. It is noteworthy that, for all the solvents studied,

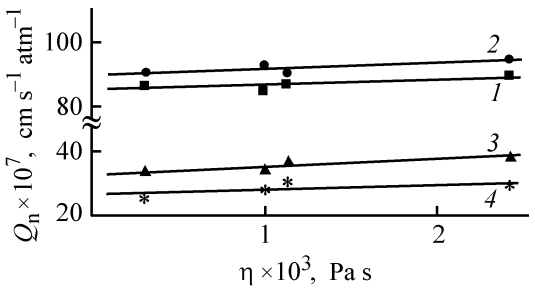

Fig. 3. Normalized flux Q_n (cm Pa atm^{-1}) vs. the fluid viscosity η (Pa s) for the asymmetric membranes.

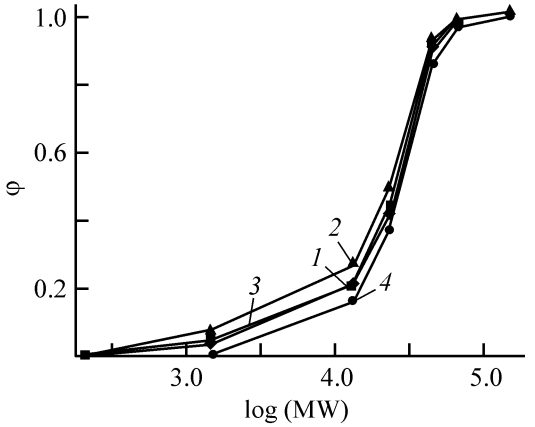

Fig. 4. Rejection factors of the membranes φ vs. the molecular weight of proteins.

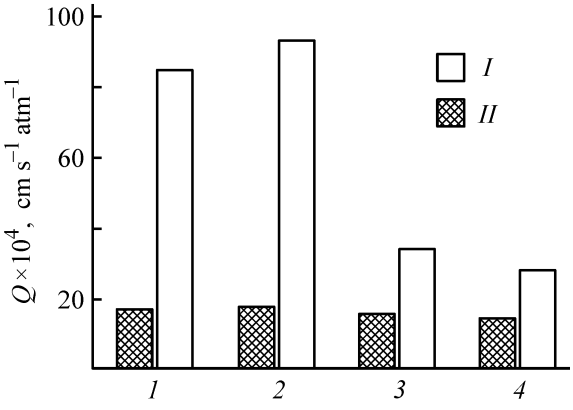

Fig. 5. Flux Q (cm s^{-1} atm^{-1}) of (*I*) water and (*II*) protein mixture across the membranes.

the flux across the PA membrane modified with 5 wt % graphite soot was slightly higher as compared to the unmodified membrane, suggesting that this chemically inert additive serves as a filler for both the casting solution and the resulting membrane. For all the solvents, the flux across the fullerene-modified membranes considerably decreased as compared to the PA membrane, which can be attributed to formation of donor–acceptor and maybe covalent bonds, thus influencing the polymer structure [19, 20]. With the astralene-modified membranes, the flux of all the solvents decreased even stronger than with the fullerene additive, which is probably due to the high reactivity of the fulleroid particles with respect to the PA matrix.

In addition to the solvent flux Q, we estimated the normalized flux Q_n written as a product $Q_n = Q\eta$, where η is the solvent viscosity. The normalized flux is intended to characterize the stability of the membranes in the media investigated. Our results show (Fig. 3) that the normalized fluxes of all the solvents are similar, suggesting an insignificant swellability of the membranes in solvents of varied chemical nature.

The modified PA membranes were tested with a solution of a protein mixture. The data obtained in the ultrafiltration experiments were then used to construct the rejection curves, which represent the dependences of the rejection factor on the molecular weight of proteins (Fig. 4). An important characteristic of the rejection curves is the molecular weight corresponding to the rejection factor of 0.9, which is known as the molecular-weight cut-off (M_L). All the membranes studied are characterized by similar values of M_L [(40–50) × 10^{3}g mol^{-1}].

As can be seen from Fig. 5, the flux of the protein solution is considerably lower than that of water. The primary factors responsible for the increase in the hydraulic resistance and the corresponding decrease in the flux are considered to be concentration polarization, formation of a deposit layer on the membrane, and adsorption. The last factor depends primarily on the chemical nature of the molecules to be filtered and on the polymer material of the membrane. It is the adsorption that essentially causes the decrease in the flux in the case of filtration of hydrophilic compounds [21], among them proteins.

The suggestion that the adsorption of proteins on the surface and in the pores of the membranes is responsible for the flux decrease was checked by comparison of the water flux restoration after the membranes were in contact with protein mixture under the ultrafiltration conditions and also under the static sorption conditions, when the membranes were held in a solution of protein mixture for 20 h. In both cases, the water flux restoration ratio (FRR) was estimated as FRR = Q_1/Q_0, where Q_0 and Q_1 are the water fluxes before and after contacting the membranes with the protein solution.

Figure 6 shows data on the water flux restoration in the ultrafiltration and static sorption modes. The membranes modified with fullerene and astralene show high FRR in the range 0.8–0.9. For PA membranes unmodified and modified with graphite soot, FRR was below 0.45. Such a low FRR suggests that these membranes strongly absorb proteins in both ultrafiltration and static sorption modes. It should be pointed out that such a behavior is typical of most of the existing polymeric membranes.

For the membranes modified with fullerene C_{60} and astralene, the sorption of proteins is considerably lower, which can be attributed to the fact that these additives block the sorption sites of PA. This suggestion is supported by data on the contact angles of the membranes with water. The contact angle increases from 81° for unmodified PA membranes to 85° for the membranes modified with 5 wt % fullerene, suggesting an increase in the hydrophobicity.

Finally, modification of PA membranes with fullerene C_{60} and astralene improves such an important performance characteristic as the water flux restoration ratio, which facilitates regeneration of the membranes and reduces the loss of the target products.

CONCLUSIONS

(1) Modification of polyphenyleneisophthalamide with nanocarbon additives has no significant effect on the initial porous sponge-like structure of the membranes. The modifier nature is manifested in a change in the surface porosity and sorption activity of the membranes.

(2) The membrane permeability depends on the modifier nature. For each of the membranes studied, the normalized fluxes of hexane, water, ethanol, and isopropanol are similar, suggesting virtually no swelling of the membranes in these solvents.

(3) The membranes modified with fullerene and astralene demonstrate good water flux restoration after being in contact with a protein mixture (FRR ≈ 0.8–0.9), in contrast to straight polyphenyleneisophthalamide membranes and those modified with carbon black (FRR < 0.45). This is due to the fact that addition of fullerene and astralene increases the hydrophobicity of the membrane matrix and decreases its sorption capacity for proteins. Modification of the polyamide with fullerene and astralene improves the ultrafiltration performance of the membranes.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Dye Molecules as Nanosize Sensors for Low-Temperature Fuel Cells

Abstract—Dye molecules were suggested as a sensitive element for an optical sensor of parameters determining the efficiency of a fuel cell with a proton-exchange membrane, in which a water–methanol mixture is used as a fuel. The sensitivity of representatives of three different types of dyes to the concentrations of protons and methanol was examined.

DOI: 10.1134/S1070427208020158

Extensive research and development activities have been aimed recently to make fuel cells (FCs) a source of power supply for various purposes, such as microelectronic devices [1], automobiles [2], industrial plants [3], etc. One of the most attractive low-power devices is a low-temperature FC with a water–methanol mixture as a fuel, a membrane with proton conductivity [4], and catalysts of electrode reactions [5].

The studies showed that, among the parameters determining the FC efficiency, the proton conductivity of a membrane and its permeability to methanol are the most important [6]. The membrane conductivity should be at a maximum, and the permeability to methanol, at a minimum. FC efficiency can be optimized in different ways. Monitoring of membrane parameters with a warning issued upon their deviation beyond the admissible range is possible. Optimization of parameters in real time through a control system capable of controlling the composition of the fuel mixture and the FC temperature is also possible. However, in both cases, a sensor that transforms the optimization parameters into a signal convenient for recording (e.g., into an optical and then electric signal) is required. For FCs of the type under consideration, the concentration of methanol that penetrated into the membrane from the fuel mixture and the proton concentration inside the membrane can be such parameters. The mechanism of the proton concentration effect on the FC efficiency is determined by the fact that protons are charge carriers and provide current transport across the membrane. Hence, the membrane conductivity should be proportional to the proton concentration. The mechanism of the methanol concentration effect can be more complex. For instance, the penetration of methanol in the molecular (not deprotonated) form can suggest an insufficient performance of the anodic catalyst. Methanol that penetrated across the membrane can also negatively affect the cathodic catalyst.

At present, main attention is focused on indirect estimation of the membrane conductivity through the methanol concentration in the fuel mixture. There have been reports of ammetric [7], ultrasonic [8], and optical [9] sensors for this purpose. The common feature of these sensors is that they do not allow measurement of the proton concentration. The measurement of the proton concentration in the membrane by traditional potentiometric sensors [10, 11] is problematic. The use of potentiometric sensors (ion-selective electrodes and field-effect transistors [12]) in FC is complicated by the fact that FC is a power electricity-generating device in which the current across the membrane can amount to amperes or even tens of amperes. Such a current may produce a parasitic drop potential across electrodes of the potentiometric sensor of hundreds of millivolts, which can chaotically change in time. Under such conditions, the error in proton concentration measured using a potentiometric sensor can amount to several orders of magnitude, which makes such type of sensors useless for this purpose.

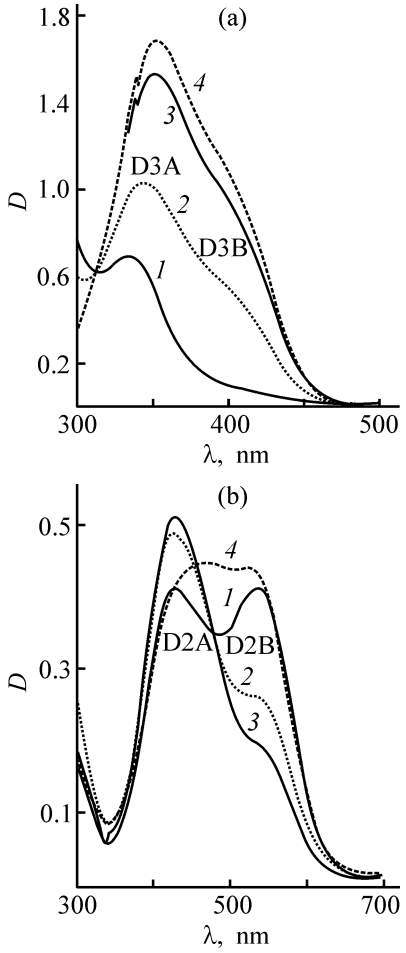

Fig. 1. Absorption spectra of (a) picric acid at various pH values and methanol concentration of 90 vol % and (b) Tropeolin OO at pH 1.1 and various methanol concentrations. (a) pH: (*1*) 0.1, (*2*) 1.1, (*3*) 2.1, and (*4*) 3.1. (b) Methanol concentration, vol %: (*1*) 90, (*2*) 85, (*3*) 80, and (*4*) 50.

Segregation of the proton-conducting membrane into hydrophilic and hydrophobic phases of microscopic size [13] gives rise to additional problems.

It follows from the aforesaid that, to measure the proton concentration inside a membrane, we should have very small sensor (micro- or even nano-size) whose response is independent of the electric current passing through the membrane. As such a sensor we suggest dye molecules whose optical spectrum depends on the proton concentration in the solution. The experimental part of this study is devoted to examination of such dyes in solutions simulating the internal medium of a proton-conducting membrane of the most widespread type. In so doing, a question arises as to how methanol affects the molecular sensor response to the proton concentration, because detailed data on the dye behavior in membrane media are lacking, and the results to be obtained can be used in further studies with real membranes.

EXPERIMENTAL

Today, membranes based on perfluorinated hydrocarbons with readily dissociating sulfonate groups are the most widespread (e.g., Nafion or its analog, MF4SK). The internal medium of such membrane contains water, an analog of sulfuric acid in the form of sulfonate groups covalently bonded to a polymeric matrix, and, probably, methanol, which can penetrate into the membrane from the fuel mixture. Correspondingly, our simulating solutions contain water, sulfuric acid, and methanol. It should be taken into consideration that the proton concentration is usually expressed as $pH = -\log[H^+]$, where $[H^+]$ is the proton concentration expressed in moles per liter. Correspondingly, we hereinafter use pH units as a measure of proton concentration in model solutions.

Chemically pure methanol and sulfuric acid and distilled water were used. Dyes Malachite Green (D1), Tropeolin OO (D2), and picric acid (D3) served as molecular sensors. Their optical absorption spectra can be used to determine pH in the strongly acidic region. The structural formulas of these dyes were reported in [14]. The dyes belong to three different groups, namely, triphenylmethane dyes, diazo dyes, and dyes based on nitro compounds, respectively. Such a choice is made for two reasons: (1) to provide the maximal conductivity of the FC membrane, the maximal proton concentration should be supported (i.e., the medium inside the membrane should be highly acidic) and (2) in a multicomponent solution, selective solvation is possible, and it can differently affect the molecules with different structures [15].

The optical spectra of the dyes were recorded on an SF-56 spectrophotometer within the 300–700 nm range. For each dye, spectra of 24 solutions with six fixed values of methanol concentrations and four fixed pH values were measured. The methanol concentrations were 0, 20, 50, 80, 85, and 90 vol %. In the region of high methanol concentrations, measurements were performed at a 5% interval because methanol at concentrations higher than 80% starts to strongly affect the pH of water–methanol mixtures [16]. The pH values of model solutions were 0.1, 1.1, 2.1, and 3.1. The acidity of a water–methanol mixture prepared in advance was brought to the required value with sulfuric acid; in so doing, pH was measured with a glass electrode with an accuracy of ±0.1 pH unit.

The spectra of D3 and D2 in water–methanol mixtures are shown in Fig. 1. As can be seen, they have two broad bands *A* and *B*, whose intensity can depend

on pH (Fig. 1a) and methanol concentration (Fig. 1b). In Fig. 1, each band is designated by a three-character index. The first two characters unambiguously refer to the dye to which the given band belongs. We will use this index hereinafter. In the spectrum of D1 (not shown because of the limited volume of this paper), there are also two readily identifiable bands whose intensity may depend on the proton and/or methanol concentration. Let us consider in detail the behavior of the dye bands behave as the pH or methanol concentration in model solutions is varied.

The dependence of the intensity of D1B band on pH and methanol concentration is shown in Fig. 2. As can be seen, the intensity of D1 bands depends on both parameters of the model solution, i.e., this dye can be regarded as a sensor of both pH and methanol concentration.

The intensity of the D1B band increases with pH. Its sensitivity to pH is different in different pH intervals and depends on the methanol concentration. As can be seen from Fig. 2a, at low methanol concentration (0–20 vol %) it is advisable to use D1 as a pH sensor within the pH range 1.1–3.1, in which the pH response is fairly strong. At higher methanol concentrations (50–90 vol %), the range of the pH response of this dye shifts toward the acid region (0.1–1.1).

It also follows from Fig. 2b that, in solutions with pH 0.1–1.1, the intensity of the D1B band monotonically increases as the methanol concentration is raised from 0 to 80 vol %. In the spectra of the solutions with pH 2.1–3.1, the intensity of the D1B band tends to a constant value at methanol concentrations exceeding 50 vol %.

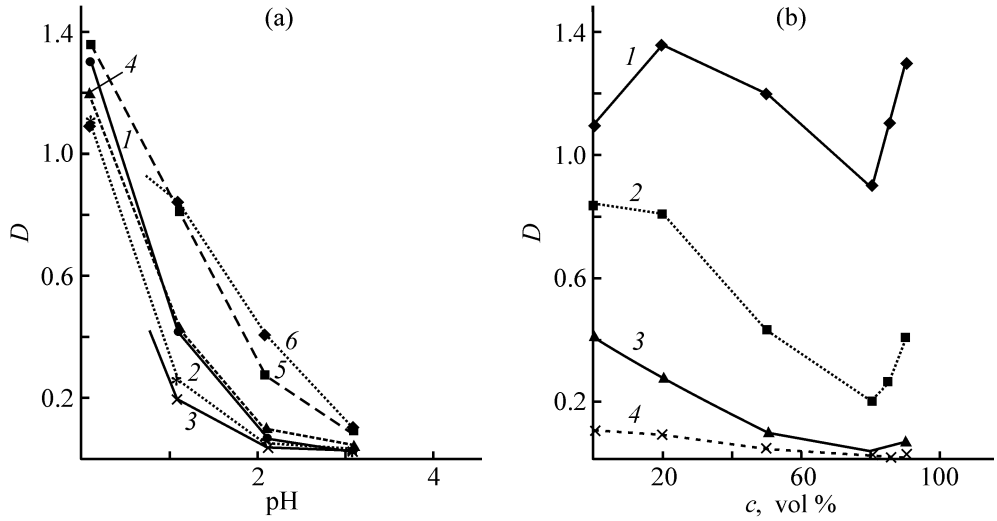

Fig. 4. Dependences of the optical density on (a) pH at various methanol concentrations and (b) methanol concentration at various pH values. Tropeolin OO (dye D2), band D2B.

The D1A band as an acidity sensor and sensor of the methanol concentration behaves similarly; however, its intensity is several times lower. Thus, both D1A and D1B bands give a combined response to both parameters of the model solution.

The pH dependences of the intensity of D2A and D2B bands are shown in Figs. 3a and 4a, and those on the methanol concentration, in Figs. 3b and 4b. As can be seen, the intensity of D2 bands depends on both parameters of the model solution, i.e., this dye is a sensor of both pH and methanol concentration. The specific feature of D2 as a pH sensor is that the D2A band intensity increases and the D2B band intensity decreases as the acidity becomes higher. The pH sensitivity of D2 bands is different in different intervals of the pH range studied and depends on the methanol concentration. Figure 3a shows that the working range of the D2A band as pH sensor covers the whole pH range studied, from 0.1 to 3.1, in the methanol concentration range 0–20 vol %. At higher methanol concentrations (50–90 vol %), the response of the D2A band within pH 1.1–3.1 is lower than the response in the more acidic region (pH 0.1–1.1). The behavior of the D2B band as a pH sensor differs from the behavior of the D2A band (Fig. 4a). An approximately uniform distribution of the pH sensitivity throughout the pH range studied, pH 0.1–3.1, is attained only at a methanol concentration of 20 vol %. For the solution without methanol, the pH response in the strongly acidic region (pH 0.1–1.1) decreases. An increase in the methanol concentration from 50 to 90 vol % strongly diminishes the pH response within the pH 2.1–3.1 range.

The responses of the D2A and D2B bands to the methanol concentration also substantially differ (Figs. 3b and 4b). The intensity of the D2A band monotonically increases as the methanol concentration is raised from 0 to 80 vol % within the entire pH range studied, pH 0.1–3.1. The dependence of the intensity of the D2B band on the methanol concentration becomes nonmonotonic in the strongly acidic region (pH 0.1–1.1). In less acid solutions (pH 2.1–3.1), the intensity of the D2B band decreases with increasing methanol concentration.

Thus, D2A and D2B bands give a combined response to pH and methanol concentration. The behavior of these bands as both pH sensors and sensors of the methanol concentration substantially differs.

The dependence of the intensity of the D3A band on pH and methanol concentration is plotted in Fig. 5. As can be seen, at a methanol concentration less than 80 vol %, D3 dye is mainly a pH sensor, and it gives only a weak response to changes in the methanol concentration. The maximal response to pH change is observed in the pH interval 0.1–1.1. Nevertheless, at fairly high accuracy of measurements, the working interval of the D3A band as pH sensor can be extended to pH 2.1, since in the interval from pH 1.1 to pH 2.1 the intensity of this band continues to monotonically increase with pH, but the trend is less pronounced.

The D3B band as a sensor of acidity and methanol concentration behaves similarly, although its intensity is lower and it overlaps with the D3A band. An appropriate mathematical processing is required for its separation from the total spectrum.

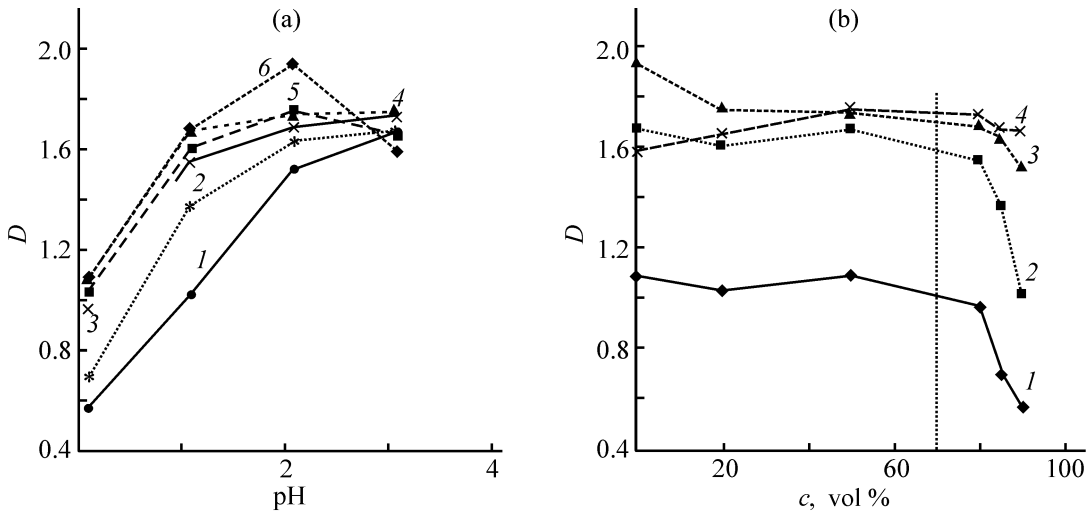

Fig. 5. Dependences of the optical density on (a) pH at various methanol concentrations and (b) methanol concentration at various pH values. Picric acid (dye D3), band D3A.

Thus, D3A and D3B bands give the response mainly to pH of the model solution when the methanol concentration does not exceed 80 vol %.

In should be noted that the reported FCs use a fuel mixture with a low methanol concentration, from 0.5 to 20 vol % [17, 18]. Fuel mixtures with a higher methanol content have also been reported, but, in any case, the methanol fraction does not exceed 70 vol % [19]. The published data allow determination of the upper boundary of the methanol content (which is of interest for FC) as 70 vol %. This boundary is designated by the dotted vertical line in Fig. 5b. As can be seen, dye D3 can be used as pH sensor within the entire range of methanol concentrations of practical interest.

It follows from the experimental data that none of the dyes studied, taken separately, can be regarded as a sensor of simultaneously two parameters of the model solution, pH and methanol concentration. However, we may suggest that the combination of D3 + D1 or D3 + D2 can be used for this purpose, provided that the dyes exert no interfering effect on each other.

To confirm this assumption, let us consider the D3 + D1 combination. The absorption bands D3A and D1B are situated so that they can be observed without additional processing to improve the spectral resolution. The D3B band overlaps with the D1A band so strongly that their use as sensors is seriously complicated. The behavior of the D3A band as a pH sensor in the solution containing the D3 + D1 combination does not substantially differ from its behavior in a model solution containing D3 only. The weak sensitivity of the D3A band to methanol concentration within the 0–80 vol % range is also preserved for the D3 + D1 combination. The response of the D1B band to the methanol concentration is preserved for the D3 + D1 combination within the same methanol concentration range.

Consideration of the D3 + D2 combination shows that the D3A and D2B bands do not require any additional processing for their resolution. The D3B band overlaps with the D2A band so strongly that their use as sensors is seriously complicated. The behavior of the D3A band as a pH sensor in the solution containing the D3 + D2 combination does not substantially differ from its behavior in a model solution containing D3 only. The weak sensitivity of the D3A band to methanol concentration within the 0–80 vol % range is also preserved for the D3 + D2 combination. The response of the D2B band to the methanol concentration is preserved for the D3 + D2 combination within the same methanol concentration range. It should be noted that the properties of the D2A and D2B bands as sensors of the methanol concentration are substantially different. The D2A band is more convenient because of its monotonic response to the methanol concentration up to 80 vol % at all pH values studied. The impossibility of using the D2A band for the D3 + D2 combination makes this combination less convenient in the combined monitoring of pH and methanol concentration as compared to the D3 + D1 combination.

The mechanism of formation of the combined or selective response of the molecular sensor to parameters of the model solution is unknown. However, we

can suggest that the primary response to pH observed for D3 and the combined response to pH and methanol concentration observed for D1 and D2 are determined by the formation of the dye molecule solvate core consisting of water or water + methanol. This assumption can be verified by quantum-chemical simulation of the absorption spectrum in the solutions with different compositions, which will be the topic of our further study. An analysis of the mechanism of the molecular sensor response to pH and methanol concentration may be useful in the development of molecular sensors whose properties are adapted to specific conditions of application.

CONCLUSIONS

(1) Examination of the optical spectra of dyes in water–methanol mixtures simulating the internal medium of Nafion type membranes for fuel cells shows that picric acid and Malachite Green can be used as optical sensors.

(2) Dyes of different type (triphenylmethane derivatives, diazo compounds, phenol nitro derivatives) can give response mainly to proton concentration or to proton and methanol concentrations simultaneously.

Abstract—Changes in the electrochemical properties and morphology of the surface of fibrous materials in the course of their modification with chitosan were studied in relation to the conditions of biopolymer deposition. The capacitances of the electrical double layer of the chitosan-carbon materials in NaCl solutions of various concentrations were determined by of cyclic voltammetry and the method of charging curves. The parameters of charging of the modified electrodes were calculated.

DOI: 10.1134/S107042720802016X

Carbon materials (CMs) with highly developed surface, thermal and electrical conductivity, and high chemical and electrochemical stability are used as sorbents and electrode materials for electrosorption processes and energy storage [1–3]. Various properties of CMs allowing their use as sorbents and electrodes are actually interrelated, The common property of CMs is their highly developed surface providing sorption of molecules and ions in the electrical double layer or its charging and discharge [2].

To enhance the properties of CMs (i.e., to raise the surface area, make the surface more accessible to electrolyte ions, and enhance the capacity and selectivity), they are modified by oxidation and deposition of metal oxides [4–7], hydrolyzed antimony compounds [8], and natural and synthetic polymers [4, 9]. Natural chitosan is one of promising modifying agents. It can form membranes and is characterized by mechanical strength and susceptibility to chemical modification owing to the presence of amino and hydroxy groups [10]. Deposition on a solid biopolymer matrix provides the highest development of its surface [11] and enables preparation of carbon materials that combine the porous structure of the matrix with the ion-exchange and complexing properties of chitosan.

Along with common procedures [12], the properties of carbon materials are often analyzed using electrochemical methods for studying carbon electrodes with a highly developed surface [1, 13, 14]. Electrochemical properties of a carbon material, including a fibrous material, brought in contact with an electrolyte solution allow evaluation of changes in the structural and surface properties of the material. One of the main characteristics of electrode is the capacitance of the electrical double layer (EDL), which is determined by the conditions of EDL formation in the pores of a carbon material. The EDL capacitance can be determined by electrochemical impedance spectroscopy, cyclic voltammetry, and the method of charging curves [1]. Data on the EDL capacitance of porous electrodes allow determination of the conditions of their charging [15], which determines the efficiency of using modified fibrous materials as electrodes in various processes occurring at electrode polarization.

In this study, we examined the correlation between the electrochemical properties of carbon fibers modified with chitosan natural biopolymer and changes in the pore structure and morphology of the chitosan-carbon materials (CCMs) as influenced by the conditions of chitosan deposition.

EXPERIMENTAL

As electrode material we used activated carbon roving fiber Aktilen B (ACB), whose specific surface

* C_1 was determined from voltammetric measurements at minimal potential sweeping rate $v = 4 \times 10^{-5}$ V s^{-1}, C_2 was determined from the galvanostatic measurements.

area (determined from nitrogen adsorption by the BET procedure), pore volume, and average pore radius were 700 m^2 g^{-1}, 0.4 cm^3 g^{-1}, and 0.4 nm, respectively. We also used the modified carbon fibers prepared by deposition of chitosan on the surface of the initial fiber without polarization [ACF-n/p] and at potentials of +900 [ACF(+900)] and –900 [ACF(–900)] mV [16]. The permeability of the chitosan films and accessibility of the surface to electrolyte ions forming the electrical double layer were studied using unmodified fiberglass and that modified with chitosan at a potential of –1200 mV.

The electrochemical measurements were carried out in a standard three-electrode cell by methods of cyclic voltammetry and charging curves. Aqueous 0.9 (physiological) and 3.5% NaCl solutions were used as electrolytes. The solutions were vigorously stirred and purged with an inert gas. The electrolyte choice was governed by the further use of ACF in electrosorption processes. Samples of carbon materials in question were placed in a gold gauze (an inert current lead). A silver chloride electrode was used as a reference electrode, and the auxiliary electrode prepared from the porous carbon material was separated from the working electrode with an MB-2 membrane.

The potentiodynamic curves in the EDL area in the ±50 mV range relative to the immersion potential of the working electrode [1] were determined with a P-5848 potentiostat. The EDL capacitance C (F g^{-1}) were calculated from Eq. (1) [1, 17]:

$$C = I/mv = (I_a + I_c)/2mv, \quad (1)$$

where I_a and I_c are the anodic and cathodic polarization currents, A; m, electrode weight, g; and v, potential sweeping rate, V s^{-1}. The degree of involvement of the electrode surface in the electrochemical process, α, was calculated from Eq. (2):

$$\alpha = C/C_{max}, \quad (2)$$

where C and C_{max} are the electrode capacitances at given and minimal potential sweeping rates, respectively, F g^{-1}. Then, the potentiodynamic data were treated by the least-squares method using Eq. (3) [18]:

$$i = Cv\left\{1 - \frac{2}{\pi^2}\sum_{n=0}^{\infty}\frac{1}{(n+1/2)^2}e^{-\pi^2(n+1/2)^2\frac{t}{\tau}}\right\}, \quad (3)$$

where i is the current density, A g^{-1}; v, potential sweeping rate, V s^{-1}; t, time, s; C, capacitance, F g^{-1}; and n, summation index. Using this equation, we calculated the specific time of EDL charging τ and the ohmic resistance of electrolyte in the pores, $R = \tau/C$ (Ω).

When the galvanostatic charging curves were recorded, the polarizing current density was chosen empirically. The current at which the position of the polarization curve became constant was considered the boundary between the equilibrium and nonequilibrium current values. In all the cases, the density of the equilibrium charging current was varied within 10^{-11}–10^{-10} A cm^{-2}. From the linear portion of the charging curve, the EDL capacitances C (F g^{-1}) were calculated using Eq. (4):

$$C = I\Delta t/m\Delta E, \quad (4)$$

where I is the polarization current, A; Δt, time of electrode charging, s; m, electrode weight, g; and ΔE, shift of the electrode potential, V.

The calculated electrochemical characteristics are listed in the table.

The morphology of the fiber surface was studied with an EVO-50XVP scanning electron microscope (Germany) in the mode of recording secondary electrons at an acceleration voltage of 20 to 30 keV. Before the experiments, the materials studied were fixed with a conducting silver adhesive to an aluminum support. The microscopic experiments were also performed on a atomic-force microscope (AFM) (Zelenograd, Russia) in the contact and tapping modes.

Carbon electrodes with a developed system of internal pores filled with an electrolyte improve the efficiency of an electrochemical process, depending on the working surface area of the electrode. However, due to hindered ion supply (diffusion limitations) and to changes in the potential in the pores (ohmic limitations), certain limitations can appear in polarization of porous electrodes. As a result, various regions of the internal surface are not equally accessible to the electrochemical process. Previously published data have shown [14, 19–21] that, in the course of EDL formation, the pores whose size is larger than 0.5 nm are accessible to simple hydrated ions at low concentration-dependent rates of EDL formation. In this case, the limiting pore size providing formation of EDL is 0.4 nm [19, 22]. Modification of the surface can lead, depending on the conditions of chitosan deposition, to different changes in the pore structure of the carbon matrix and, as a result, to different conditions of its charging.

To evaluate the permeability of a chitosan film and accessibility of the carbon surface to electrolyte ions forming the EDL, we first determined the capacitance of the initial and chitosan-modified fiberglass samples. Our results showed that the capacitances of these electrodes are the same and equal to 8 $\mu F\,cm^{-2}$. This value is comparable with published data on the capacitances of the fiberglass electrodes in various solutions [1, 23]. These results suggest that the chitosan film does not hinder penetration of the electrolyte ions to the carbon surface to form EDL. As shown in [10] by various methods including cyclic voltammetry, the chitosan film deposited on the fiberglass surface exhibits high permeability and promotes rapid transfer of electrolyte ions to the surface of the carbon material.

Activated carbon fibers exhibit semiconductor properties [23], which can affect the charge redistribution at EDL formation. Changes in the structural and surface properties of the carbon material during modification can also affect the EDL formation [1, 23]. In this study, the electrode capacitances were determined by the methods of cyclic voltammetry and charging curves. The agreement of the results confirms that these methods are equivalent in determining the capacitances of the porous materials (see table). Analysis of our experimental data suggests that the capacitances of the chitosan-carbon electrodes depend on the conditions of modification of the carbon matrix. This is due to the fact that chitosan being precipitated on the carbon fiber under certain conditions changes its pore structure, which affects the EDL formation and hence the parameters of charging and the capacitance of CCM.

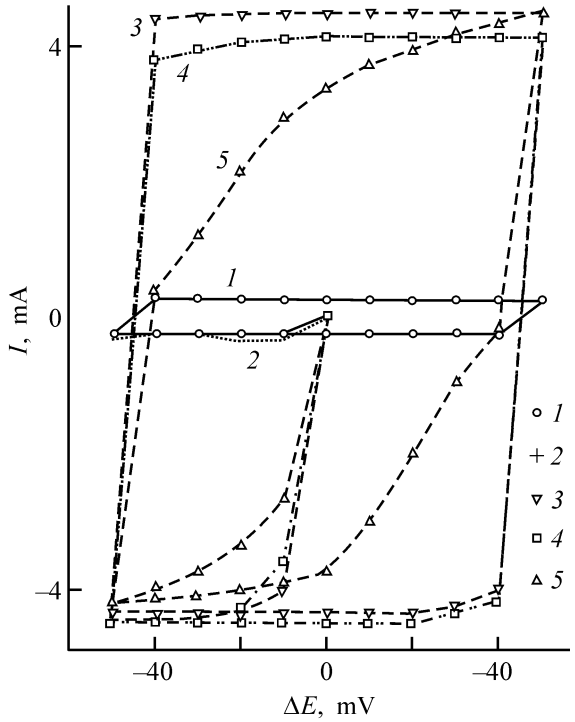

Fig. 1. Cyclic voltammograms recorded for the initial and modified fibers at different potential sweeping rates v in 0.9% NaCl solutions. (I) Current and (ΔE) potential. (*1*, *3*) ACF_{ini}, (*2*, *4*) ACF(–900), and (*5*) ACF-n/p. v, $V\,s^{-1}$: (*1*, *2*) 4×10^{-5} and (3–5) 1×10^{-4}.

The cyclic voltammograms recorded at various rates of polarization in 0.9% NaCl solution are shown as an example in Fig. 1. The shape of cyclic curves with equal areas above and below the potential axis is indicative of the absence of irreversible Faraday processes [24]. It should be noted that voltammograms recorded for the initial ACF and ACF electrochemically modified at cathodic polarization are rectangular (Fig. 1, curves *1*–*4* for ACF-n/p at $v = 4 \times 10^{-5}$ $V\,s^{-1}$ coincide with curves *1* and *2*]. This fact suggests that there is no hindrance in charging of such electrodes, in contrast to CCM prepared by chitosan deposition on the carbon surface at anodic polarization (Fig. 1, curve *5*). Hindrance of the charging processes can be due to the porous structure of the fibers, interfacial phenomena at the electrode-solution boundary, and properties of the electronic conduction band of the carbon material [25], depending on the condition of the initial fiber preparation [1, 23]. Moreover, certain changes in the inner structure and surface morphology of CCM can also occur in the course of modification. The effect of the form of precipitated chitosan and thickness of the film prepared under various deposition conditions can also affect the rate of electrolyte ion supply to the carbon matrix surface.

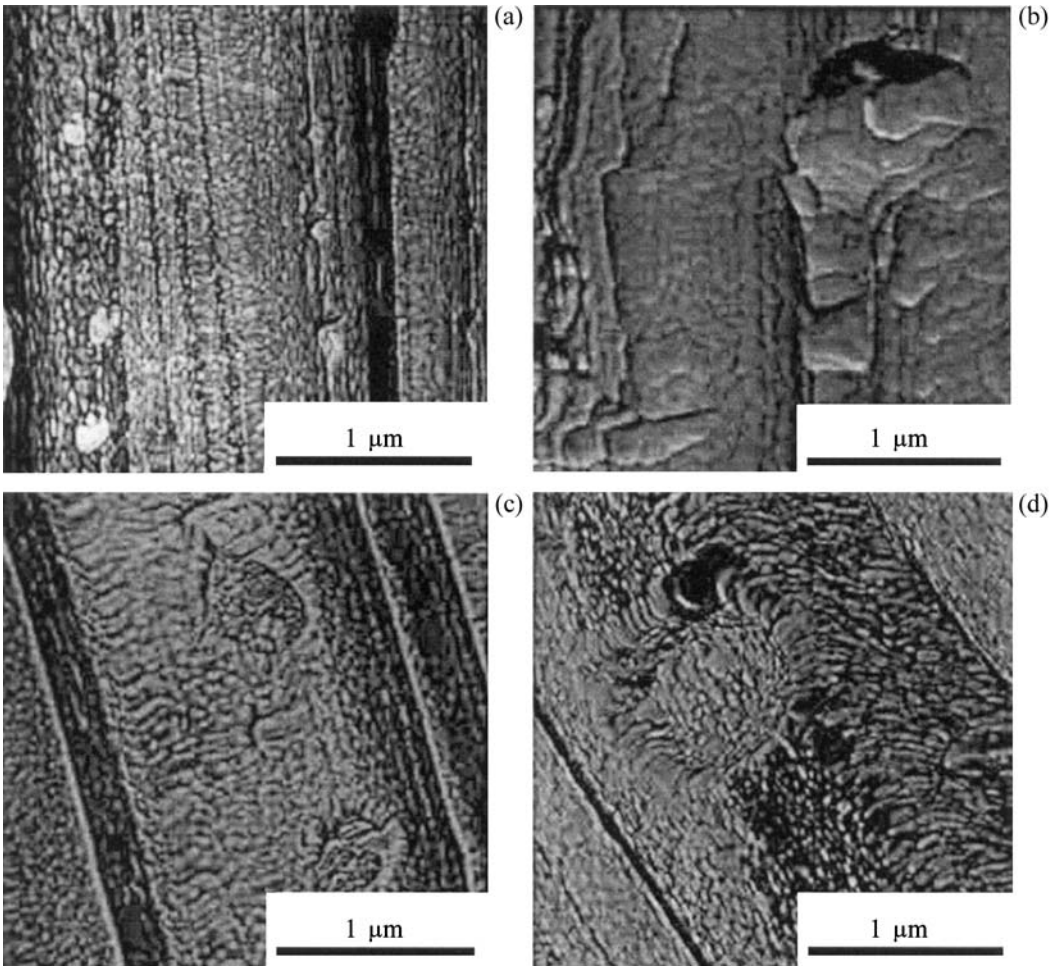

Fig. 2. AFM images of carbon fibers; 2.5 × 2.5 μm image size. (a) ACF_{ini}, (b) ACF(–900), (c) ACF(+900), and (d) ACF-n/p.

Changes in the pore structure of the fibers in the course of their modification can be evaluated using the atomic-force (AFM) and scanning electron (SEM) microscopy [26]. The AFM images of the initial and modified fibrous materials obtained are shown in Fig. 2. As seen from AFM data, the surface of the initial fiber consists of blocks (microfibrils) with cross-section diameter of about 50 nm between which micropores (~5 nm size) are distributed. Microfibrils, in turn, consist of smaller blocks (~10 nm size) between which there are supermicropores (~1 nm size). The fiber surface also has macropores (up to 1000 nm size) localized between microfibrils. Depending on the conditions of chitosan deposition on the ACF surface in the course of modification, either a film (Fig. 2b) or particle agglomerates (about 50 nm size) (Fig. 2c and 2d) are formed. Thus, by varying the conditions of the fiber modification, it is possible to prepare materials with various structural characteristics affecting the electrochemical characteristics of CCM and conditions of its charging.

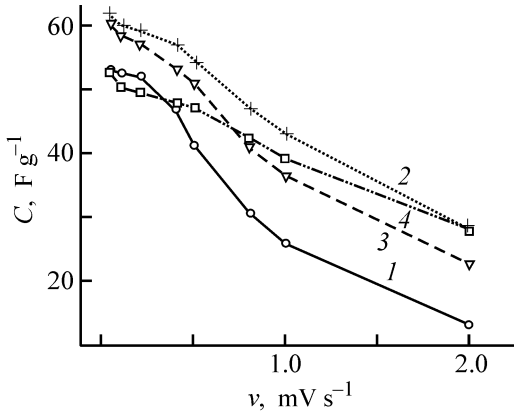

Fig. 3. Capacitance C ($F g^{-1}$) vs. the potential sweeping rate v ($mV s^{-1}$) at polarization in 0.9% NaCl solution. (*1*) ACF_{ini}, (*2*) ACF(+900), (*3*) ACF-n/p, and (*4*) ACF(–900); the same for Fig. 4.

Differences in charging and structural features of carbon materials can be judged from the dependences of the electrode capacitances in EDL areas or of

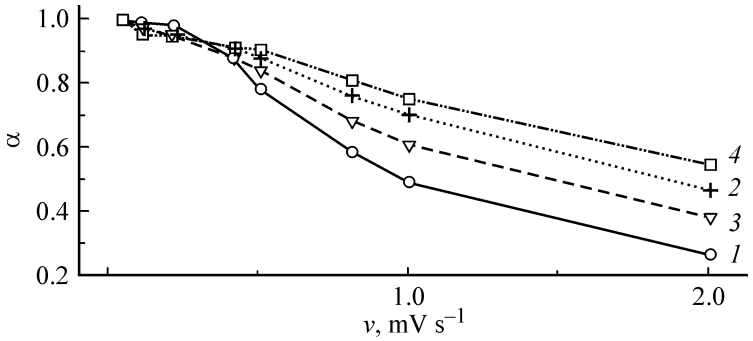

Fig. 4. Fraction α of the surface area involved in an electrochemical process vs. the potential sweeping rate v at polarization in 0.9% NaCl solution.

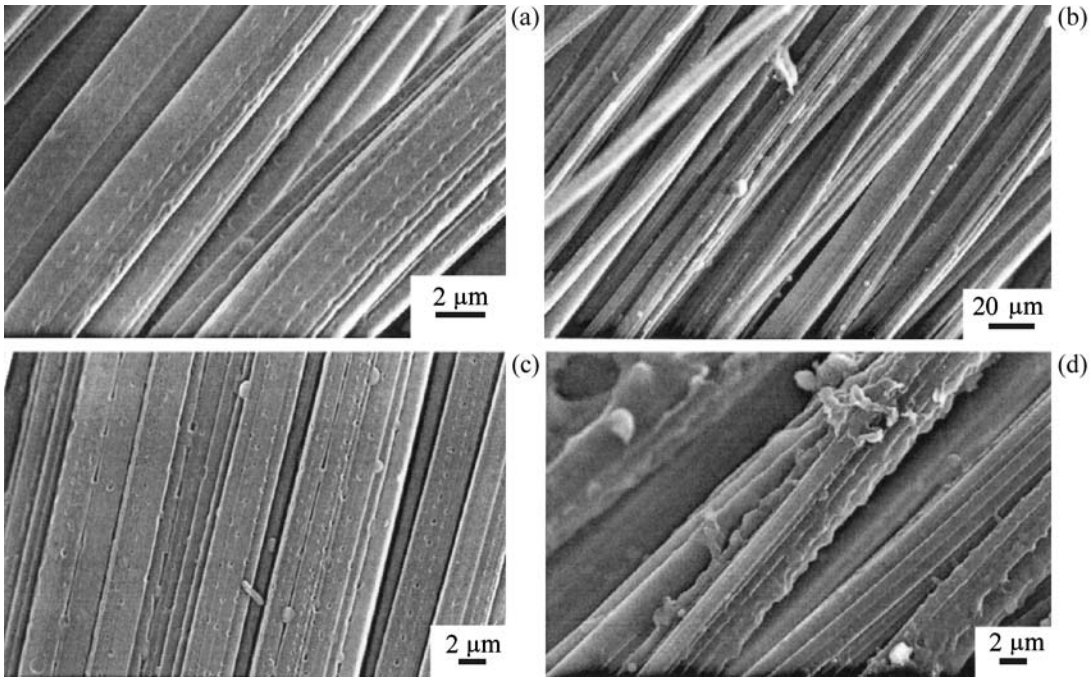

Fig. 5. SEM images of the fibers surfaces. (a) ACF_{ini}, (b) ACF-n/p, (c) ACF(+900), and (d) ACF(–900).

the degree of utilization of their surfaces on the potential sweeping rate (Figs. 3, 4). As can be seen, the electrode capacities decrease with increasing potential sweeping rate in all the cases. This is due to the fact that, at slow polarization, when the rate of applying the potential is comparable with the rate of supplying the electrolyte ions forming the EDL, the capacitance corresponds to the whole electrode surface involved in the electrochemical process. Both ohmic potential drop and diffusion limitations of the electrode process rate increase with the rate of polarization of the microporous electrode. As a result, the EDL capacitance decreases because the measured capacitance corresponds only to a certain fraction of the surface area involved in the electrochemical process.

As can be seen, a CCM prepared at anodic potentials exhibits a higher capacitance than unmodified ACF (see table). This is due to the changes in the fiber structure, in which new pores and cracks appear under the effect of anodic polarization or chitosan penetration. As a result, both the surface area and the capacitance increase. Unmodified ACF and ACF(–900) are characterized by the same capacitance. Owing to alkalization of the solution in the near-electrode layer in the course of CCM preparation under the conditions of cathodic polarization, chitosan forms an insoluble film on the fiber surface (Fig. 5d). In this case, the pore structure of the fiber remains unchanged. The chitosan film is permeable to electrolyte ions and the capacitances of ACF(–900) and the initial fiber are the same. Hence, a rather simple procedure of

cyclic voltammetry allows evaluation of differences in the pore structure of the chitosan-carbon materials, which was additionally confirmed by the AFM and SEM methods.

The SEM images of the carbon material surface are shown in Fig. 5. The surface of unmodified roving fibers is smooth and covered with a developed system of pores (Fig. 5a). It should be noted that the magnifications used in our study do not allow visualization of micropores (AFM data); however, this method provides visualization of meso- and macropores, which are probably formed on the fiber surface owing to activation in the course of its preparation [27].

Chitosan precipitated on the carbon material surface alters the morphology of the fiber surface. A SEM micrograph of the fiber modified without external polarization is shown in Fig. 5b. Chitosan occurs on the surface of carbon materials in various forms, as a film or spherical particles (500–2000 nm in diameter).

The surface image of CCM prepared by electrochemical deposition of chitosan in the range of anodic potentials is shown in Fig. 5c. With this deposition procedure, chitosan is also precipitated on the carbon material surface as a film or spherical particles localized at the macropore boundaries. In contrast to the initial material and fiberglass modified without external polarization, the CCM surface is covered with a developed system of macropores (100–600 nm size) formed under the influence of polarization. In anodic treatment of the fibers at high potentials, the pores can be formed owing to both the displacement of fibrils in the electric field and surface electrooxidation [28].

The image of the CCM surface prepared by electrochemical oxidation of chitosan in the range of cathodic potentials is shown in Fig. 5d. With this procedure of biopolymer deposition, chitosan forms an insoluble film (200–250 nm thick) or large outgrowths of irregular shape. Thus, in accordance with SEM data, the morphology of the carbon fiber strongly changes, depending on the procedure of chitosan deposition. Hence, the directed change of the surface properties of the carbon material by appropriate procedures of the fiber modification allows preparation of CCMs with various structures, which provides various conditions of charging of modified ACF.

Mathematical processing of the results of potentiodynamic charging of the porous electrode in the area of EDL potentials makes it possible to evaluate the electrolyte resistance in the pores [Eq. (3)] and the characteristic time of charging, τ (see table). Analysis of these data showed that the charging of modified electrode in 0.9% NaCl solution depends on the modification condition of carbon matrix. In contrast to the initial ACF, CCM prepared by cathodic deposition of chitosan are charged more rapidly and are characterized by lower resistance of electrolyte in the pores. This modification procedure probably yields a structure promoting formation of EDL and more uniform charging of the electrode. In contrast to initial the ACF, the composite materials prepared by anodic deposition of chitosan are charged more slowly with higher resistance of the electrolyte in the pores. These differences in the CCM charging are primarily due to changes in the pore structure and fiber morphology in the course of their modification under various conditions of chitosan deposition on the carbon material surface. It should be noted that an increase in the electrolyte concentration levels the parameters of charging of the modified materials. This effect is probably due to an increase in the number of charge carriers reducing the diffusion and ohmic limitations on the process of charging of the porous electrode.

CONCLUSIONS

(1) The conditions of biopolymer deposition on the carbon matrix affect electrochemical properties of modified fibers. As regards its electrochemical and thermal characteristics, the chitosan-carbon material prepared by electrochemical deposition of chitosan in the range of anodic potentials seems to be the most promising as an electrode material.

(2) The cyclovoltammetric data allows evaluation of changes in the pore structure of the modified fiber, which is confirmed by atomic force and scanning electron microscopy.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of Isomeric Bis(aminophenyl)pyrimidines from Nitrochalcones

Abstract—A series of isomeric bis(nitrophenyl)pyrimidines containing a phenyl substituent in the heteroring were synthesized from nitrochalcones and benzamidines. The corresponding isomeric bis(aminophenyl)-pyrimidines were prepared by reductive acetylation followed by hydrolytic elimination of the acetyl group.

DOI: 10.1134/S1070427208020171

Polyimides containing pyrimidine rings in the backbone exhibit increased heat resistance, compared to the related aromatic polyimides [1]. This is due to strong intermolecular interactions provided by pyrimidine rings in adjacent chains of polymeric molecules [2]. Polyimides exhibiting high thermomechanical characteristics have been prepared from dianhydrides of aromatic tetracarboxylic acids and such diamines as 2,5-bis(*p*-aminophenyl)pyrimidine, 2-phenyl-4,6-bis-(*p*-aminophenyl)pyrimidine, etc. [3–5]. Therefore, it has been suggested to use such diamines as starting monomers for preparing new films and fibers capable of operation at elevated temperatures [6, 7].

Here we report on the synthesis of isomeric bis-(*m*/*p*-aminophenyl)pyrimidines with an additional phenyl substituent in the pyrimidine ring, which enhances the resistance of polyimides to thermal oxidative degradation [1]. The synthesized diamines can serve as a basis for preparing other polymers, such as poly(amino imides) and poly(ester imides), and also for examining the effect of nitrogen heterocycles on the properties and structural features of the polymers [2, 8]. The most efficient route to the above-mentioned triarylpyrimidines is cyclization of substituted chalcones with arylamidines [9, 10]. The reaction is performed in a strongly alkaline solution. This procedure cannot be applied to nitro-substituted chalcones and benzamidines because of the tarring and formation of by-products (azoxy compounds) [11]. We found conditions under which the tarring of the reaction mixture is reduced to a minimum and formation of azoxy compounds is prevented. This is provided by replacing strong bases (KOH, NaOH, $NaOCH_3$, etc.) as catalysts of reactions of nitro-substituted chalcones with benzamidines with excess amidine and by performing the reaction in DMF at 120–130°C. At this temperature, the rate of dehydrogenation of the intermediate nitrophenyldihydropyrimidines [11] by atmospheric oxygen prevails over the rate of the conjugated oxidation with the nitro groups, and azoxy compounds are not formed. To attain the optimal reaction conditions, we also used zeolite as a dehydrating agent. Dry air was bubbled through the reaction mixture to ensure more efficient dehydrogenation of the dihydropyrimidine ring [11, 12]. The condensation of nitrochalcones **I**–**V** with benzamidine and with 3- and 4-nitrobenzamidines under these conditions occurs fairly smoothly and gives bis(nitrophenyl)-pyrimidines **VI**–**XII** in 50–66% yield:

An exception is the reaction of 4,4'-dinitrochalcone **II** with benzamidine, accompanied by extensive tarring (Table 1).

In the IR spectra of **VI**–**XII**, there are absorption bands of aromatic NO_2 groups in the ranges 1339–1352 and 1528–1537 cm^{-1}, and in the mass spectra there are a molecular ion peak at *m*/*z* 398 and peaks of fragment ions (*m*/*z* 352, 306) corresponding to the successive loss of two NO_2 groups.

To convert dinitro derivatives **VI**–**XII** into diamino derivatives **XX**–**XXVI**, we chose reductive acetylation with Fe powder in the presence of acetic anhydride, instead of catalytic hydrogenation. This choice is governed by the fact that the preparation of acetylamino derivatives and their subsequent hydrolysis to amino derivatives occur in high yield without formation of by-products [11]. It should be noted that catalytic hydrogenation with hydrogen, which is usually the most efficient procedure for reduction of nitro compounds, is accompanied in the case of bis(nitrophenyl)pyrimidines by formation of noticeable amounts of

* Two partly overlapping signals.

** Two partly overlapping triplet signals, forming a quartet.

*** The low-field component of the doublet is superimposed by the multiplet of the phenyl group.

difficultly removable azo compounds deteriorating the quality of the desired diamines [13]. Bis(acetylaminophenyl)pyrimidines **XIII**–**XIX** were prepared from the corresponding bis(nitrophenyl)pyrimidines **VI**–**XII** by reduction with Fe powder in a mixture of acetic acid and acetic anhydride at 130°C in 72–93% yield (Table 2). In their IR spectra, there are absorption bands at 1661–1668 and 3287–3312 cm^{-1}, characteristic of the CH_3CONH group, and in the mass spectra there are a molecular ion peak at *m*/*z* 422 and peaks of fragment ions (*m*/*z* 380, 338) corresponding to the successive loss of two CH_2CO fragments [14].

The hydrolytic deacetylation of **XIII**–**XIX** was performed by heating in a mixture of hydrochloric and acetic acids, followed by treatment of the reaction products with aqueous ammonia. The reaction occurs smoothly and gives bis(aminophenyl)pyrimidines **XX**–**XXVI** in high yield (Table 2). In their IR spectra, there are stretching vibration bands of NH_2 groups in the range 3211–3448 cm^{-1}, and in the mass spectra there is a strong peak of the molecular ion with *m*/*z* 338 (I_{rel} = 100%). The ^{1}H NMR spectra (Table 3) fully confirm the structure of these diamines. These spectra contain a singlet of the 5-H atom of the pyri-

midine ring at 8.0–8.3 ppm and show the characteristic splitting pattern of the phenylene protons. Amino group protons appear as broadened singlets whose chemical shift depends on the substitution pattern of the aminophenyl group and on its position in the heteroring. Protons of *m*-amino groups give higher-field signals (5.22–5.30 ppm) compared to *p*-amino groups (5.51–5.74 ppm), which is due to direct polar conjugation of the amino group with the electron-withdrawing pyrimidine ring in the latter case [15] and suggests a lower basicity of the *p*-aminophenyl derivatives. Approximate estimation of pK_a for diamines **XX**–**XXVI** from the $\delta(NH_2)$ values [16] gives the range pK_a 3.1–3.9, which is close to the optimum for the polycondensation of diamines with acid dianhydrides [17].

EXPERIMENTAL

The IR spectra of the compounds in KBr were recorded on a Specord M-80 spectrophotometer, and the ^1H NMR spectra, on a Bruker AM 400 spectrometer (400 MHz) in DMSO-d_6 with the residual proton signal of the solvent (2.50 ppm relative to TMS) as reference. The mass spectra were measured on a Finnigan MAT-8200 spectrometer (EI, 70 eV). The reaction progress and product purity were monitored by thinlayer chromatography (TLC) on Silufol UV-254 plates [mobile phase: benzene for nitro derivatives **VI**–**XII**, ethyl acetate for acetylamino derivatives **XIII**–**XIX**, benzene–acetone (4 : 1) for diamino derivatives **XX**–**XXVI**], with UV detection. We used 4A zeolites activated by heating for 6 h at 350°C. The starting nitroand dinitrochalcones were prepared by the procedure described in [18].

Bis(nitrophenyl)pyrimidines VI–XII were prepared by a general procedure. To a stirred suspension of 11 mmol of benzamidine hydrochloride or nitrobenzamidine hydrochloride in 40 ml of dry DMF, we added 11 mmol of sodium methylate and then, 0.5 h later, 10 mmol of appropriate chalcone **I**–**V** and 4 g of the zeolite. The mixture was heated at 120–130°C, and dry air was bubbled for 8 h. The mixture was filtered while hot and cooled to room temperature. The precipitated product was filtered off, washed with methanol, and vacuum-dried. Compound **XI** was isolated by adding 20 ml of ethanol to the hot reaction mixture; after cooling to room temperature, the precipitate was separated, washed with ethanol, and vacuum-dried. For the subsequent use, compounds **VI** and **VII** were crystallized from DMF, and compounds **VIII**–**XII** were used without additional purification. For elemental analysis, the compounds were crystallized from DMF. The yields, melting points, and analytical and IR data are listed in Table 1.

Bis(acetylaminophenyl)pyrimidines XIII–XIX. A mixture of 10 mmol of bis(nitrophenyl)pyrimidine **VI**–**XII**, 80 ml of acetic acid, 12 ml of acetic anhydride, and 7 g of Fe powder was heated with stirring for 8 h at 130°C, cooled to room temperature, and poured onto ice. The precipitate was filtered off and washed on the filter with water to remove iron salts, acetic acid, and acetic anhydride. Then the precipitate was suspended in water, the mixture was alkalized to pH 8 with a 10% NH_4OH solution, and the precipitate was filtered off, washed with water, and dried.

To purify the product of the reductive acetylation (4.22 g, 10 mmol), it was dissolved in a minimal amount of DMF at 120°C, the solution was filtered while hot through a 1–2-cm bed of Al_2O_3, and the adsorbent on the filter was washed with 2 ml of hot DMF and then with 2 ml of ethanol. The required amount of ethanol of appropriate concentration was gradually added with stirring to the combined filtrate, heated to 100–120°C. The mixture was allowed to stand at room temperature for several hours. Below are given the compound, amount of DMF (ml), and amount of aqueous ethanol (ml) and its concentration (%, in parentheses): **XIII**, 28, 140 (60%); **XIV**, 33, 70 (95%); **XV**, 12, 45 (70%); **XVI**, 10, 20 (30%); **XVII**, 36, 55 (95%); **XVIII**, 20, 6 (30%); **XIX**, 34, 76 (95%). The precipitates were filtered off, washed on the filter with two portions of ethanol of the same concentration, and dried in air at 100–120°C to constant weight. The yields, melting points, and analytical data are listed in Table 2.

Bis(aminophenyl)pyrimidines XX–XXVI. To a suspension of 4.22 g (10 mmol) of purified bis(acetylaminophenyl)pyrimidine **XIII**–**XIX** in 10 ml of acetic acid, 20 ml of concentrated HCl was added with stirring, and the resulting strongly colored solution was heated at 120°C for 1.5 h. The mixture was cooled to room temperature, the precipitate of the corresponding hydrochloride was filtered off and then suspended in 20 ml of water, and the mixture was alkalized to pH 8 with a 10% NH_4OH solution (~20 ml) with stirring. The precipitate of the diamine was filtered off, washed with water (2 × 10 ml), and dried in a vacuum over P_2O_5/KOH to constant weight.

In hydrolysis of diacetyl derivative **XV**, for more complete isolation of the dihydrochloride, 20 g of ice was added to the cooled reaction mixture, and the subsequent treatment was performed by the general procedure. The yields of the isolated compounds, their melting points, and analytical data are listed in Table 2.

CONCLUSION

A modified procedure was suggested for synthesis of triarylpyrimidines with two aminophenyl groups in even positions of the pyrimidine ring. These compounds may be of interest for preparing various polymers.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Antioxidant Activity of Alkaloid- and Amine-containing Salts of 1,3,4-Thiadiazole-2,5-disulfonic Acid

Abstract—1,3,4-Thiadiazole-2,5-disulfonic acid was synthesized by oxidation of 2,5-dimercapto-1,3,4-thiadiazole, and onium salts of this acid were prepared by its reactions with selected alkaloids and secondary amines. The antioxidant activity of the compounds synthesized was evaluated.

DOI: 10.1134/S1070427208020183

1,3,4-Thiadiazole derivatives exhibit various kinds of physiological activity [1–5]. However, data on alkaloid derivatives of symmetrical 2,5-disubstituted 1,3,4-thiadiazoles are lacking. Therefore, readily accessible 2,5-dimercapto-1,3,4-thiadiazole [6] is of interest as the starting compound that can be modified with the aim to prepare new potentially bioactive substances.

Oxidation of 2,5-dimercapto-1,3,4-thiadiazole with an aqueous solution of $KMnO_4$ involves exclusively the thiol groups, leaving the heterocyclic sulfur atom intact, and yields 1,3,4-thiadiazole-2,5-disulfonic acid **I**, which forms with alkaloids and their structural analogs the corresponding onium salts **II**–**VIII**:

The ratio of 2,5-dimercapto-1,3,4-thiadiazole and $KMnO_4$, required for complete oxidation of thiol groups to sulfo groups, was determined by acid–base titration to be 1 : 4. In the process, permanganate anions are reduced to manganese dioxide.

Compounds **I**–**VIII** are white crystalline substances with high melting points, readily soluble in water.

1,3,4-Thiadiazole-2,5-disulfonic acid **I** is formed in almost quantitative yield (about 98%). The yields of salts **II**–**VIII** range from 50 to 77%, depending on

Table 1. Yields, physicochemical constants, and elemental analyses of **I**–**VIII**

Compound	Yield, %	mp, °C	Found, %			Formula	Calculated, %		
			C	H	N		C	H	N
I	98.0	>350	9.67	0.90	11.30	$C_2H_2N_2O_6S_3$	9.76	0.81	11.38
II	76.9	>350	34.70	5.72	13.35	$C_{12}H_{24}N_4O_6S_3$	34.62	5.77	13.46
III	66.9	>350	28.50	4.68	13.25	$C_{10}H_{20}N_4O_8S_3$	28.57	4.76	13.33
IV	42.8	>350	46.39	5.20	14.84	$C_{22}H_{30}O_6S_3$	46.32	5.26	14.74
V	52.6	>350	50.81	5.38	9.81	$C_{24}H_{30}N_4O_6S_3$	50.88	5.30	9.89
VI	70.0	>350	46.00	4.70	13.51	$C_{24}H_{30}N_6O_8S_3$	46.01	4.79	13.42
VII	50.1	>350	45.89	5.50	9.82	$C_{22}H_{32}N_4O_8S_3$	45.83	5.56	9.72
VIII	56.1	>350	45.77	5.44	9.70	$C_{22}H_{32}N_4O_8S_3$	45.83	5.56	9.72

the electron-donor properties of the substituents and conformational rigidity of the rings in the molecules of the starting alkaloids and secondary amines. Salts **II** and **VI** were prepared in the highest yields, because in the respective bases (piperidine, cytisine), the nitrogen atom bears a higher negative charge owing to the electron-donor effect of the cycloalkyl substituent and is, therefore, more reactive. With morpholine, the yield of salt **III** is somewhat lower because of the electron-withdrawing effect of the oxygen atom. In *L*-ephedrine and *D*-pseudoephedrine, the effect of electron-donor methyl groups is weakened by the electron-withdrawing effect of the benzene ring, and this is accompanied by the steric shielding effect of methyl groups at the nitrogen atom. Therefore, the yields of **VII** and **VIII** are lower than those of **II**, **III**, and **VI**. The poor yield of **IV** is due to the steric shielding effect of the pyridyl substituent in the anabasine molecule. The presence of the electron-withdrawing benzene ring and the steric shielding effect of the methyl substituent in the salsoline molecule cause the relatively low yield of **V**.

The structure and composition of **I**–**VIII** were confirmed by IR, ^{1}H NMR, and ^{13}C NMR spectroscopy, and also by elemental analysis.

The IR spectra of all the onium salts synthesized contain characteristic absorption bands of the thiadiazole ring at 680, 730, 1400 ± 20, and 1500 ± 20 cm^{-1}, bands in the range 656–649 cm^{-1} assigned to $-SO_3^-$ vibrations, and absorption bands at 3501–3421 cm^{-1} characteristic of secondary ammonium salts [7].

In the ^{1}H NMR spectra of **II**–**VIII**, recorded in DMSO-d_6, protons of the ammonium group appear as an ill-resolved multiplet centered at 14.6 ppm. The chemical shifts of signals from protons of alkaloid and secondary amine fragments have typical values [8].

In the ^{13}C NMR spectrum of 1,3,4-thiadiazole-2,5-disulfonic acid **I**, the heterocyclic carbon atom appears as a singlet at 168.0 ppm. In the ^{13}C NMR spectrum of piperidinium salt of 1,3,4-thiadiazole-2,5-disulfonic acid **II**, the heterocyclic carbon atom appears as a singlet at 158.4 ppm, and carbon atoms of the piperidine fragment give signals at 23.1, 25.5, 26.0, 42.5, and 45.5 ppm [9].

The yields, physicochemical constants, and elemental analyses of **I**–**VIII** are listed in Table 1.

Common antioxidants are phenolic compounds [10]. At the same time, among nitrogen heterocycles containing piperidine, pyridine, pyrimidine, thiazole, and other fragments there are compounds exhibiting anti- or prooxidant effect [11].

The antioxidant activity[1] of 1,3,4-thiazole-2,5-disulfonic acid **I** and its onium salts **II**–**IV**, **VI**, and **VII** was evaluated with the aim to reveal the effect of the thiadiazole ring and sulfonic acid groups in the nitrogen-containing heterocycles on the antioxidant activity (AOA). As reference antioxidant we used Ionol. The results are listed in Table 2.

All the compounds tested, 1,3,4-thiadiazole-2,5-disulfonic acid **I** and its alkaloid- and amine-containing salts **II**–**IV**, **VI**, and **VII**, exhibited antioxidant properties, though to different extents. In view of the fact that anabasine and *L*-ephedrine exhibit no antioxidant properties and cytisine is a prooxidant [11], it can be suggested that just the introduction of the sulfo groups and thiadiazole fragment into the structure of alkaloids and secondary amines imparts to them antioxidant properties. Comparison of the antioxidant deactivities of 1,3,4-thiadiazole-2,5-disulfonic acid

[1] The antioxidant activity was evaluated at Kazakh State Medical Academy (Astana) under the guidance of A.Zh. Seitembetova.

Table 2. Antioxidant activity of compounds **I**–**IV**, **VI**, and **VII**

Compound	c_{MDA},* nM (30-min incubation)	Decrease in c_{MDA} relative to control, %
Control	30.01	–
2,6-Di-*tert*-butyl-4-methylphenol (Ionol)	9.32	68.94
1,3,4-Thiadiazole-2,5-disulfonic acid **I**	15.16	50.52
Piperidinium salt **II**	4.58	84.74
Morpholinium salt **III**	14.68	51.08
Anabasine salt **IV**	20.68	31.09
Cytisine salt **VI**	14.68	51.08
L-Ephedrine salt **VII**	14.05	53.18

* (c_{MDA}) Concentration of malonic dialdehyde.

rivatives showed that introduction of the piperidine fragment considerably enhances the antioxidant properties, the effect of the *L*-ephedrine fragment is considerably weaker, and introduction of the morpholine and cytisine fragments has virtually no effect on the AOA of the disulfonic acid. The presence of the anabasine fragment in the structure of the onium salt considerably decreases the AOA of salt **VI**, compared to 1,3,4-thiadiazole-2,5-disulfonic acid **I**.

The antioxidant activity of **II**–**IV**, **VI**, and **VII** can be attributed to the conjugation arising between substituents in positions 2 and 5 due to conductivity of the thiadiazole ring, comparable with that of the phenylene bridge [12], which is consistent with the published evidence about an increased AOA of substances with a π-excessive heterocyclic system, owing to which these substances readily undergo one-electron oxidation [13]. Introduction of electron-donor substituents and the presence of multiple bonds enhance the conjugation effect, which results in increased AOA and is also consistent with published data [11, 14, 15]. Morpholinium salt **III** shows lower AOA than does piperidinium salt **II**, because introduction of the more electron-withdrawing morpholine fragment decreases the conjugation effect. This fact is consistent with published data that introduction of the morpholinium fragment enhances the prooxidant properties [16].

EXPERIMENTAL

The IR spectra of the compounds were recorded on an Avatar-320 spectrometer in KBr pellets and mulls in mineral oil, and the ^1H and ^{13}C NMR spectra, on a Mercury-300 spectrometer with a working frequency of 300 MHz, solvent DMSO-d_6.

1,3,4-Thiadiazole-2,5-disulfonic acid I. A 2.5% aqueous solution of 6.32 g (0.04 mol) of $KMnO_4$ was added dropwise with stirring at room temperature over a period of 3 h to an aqueous solution of 1.5 g (0.01 mol) of 2,5-dimercapto-1,3,4-thiadiazole. The mixture was heated with stirring on a water bath until its complete decolorization. The precipitate of manganese dioxide was filtered off, the filtrate was evaporated, and the dry residue was washed with alcohol. 1,3,4-Thiadiazole-2,5-disulfonic acid **I** was recrystallized from ethanol–water, 10 : 1.

Alkaloid- and amine-containing salts of 1,3,4-thiadiazole-2,5-disulfonic acid, II–VIII. An aqueous solution of 0.02 mol of appropriate secondary amine or alkaloid was added dropwise with stirring over a period of 1 h to an aqueous solution of 2.46 g (0.01 mol) of 1,3,4-thiadiazole-2,5-disulfonic acid **I**. The mixture was stirred at room temperature for 12 h and left in a vacuum desiccator to remove the solvent. The solid residue was washed with alcohol, filtered off, and recrystallized from ethanol–water, 10 : 1.

The antioxidant acitivity of 1,3,4-thiadiazole-2,5-disulfonic acid **I** and its salts **II**–**IV**, **VI**, and **VII** was evaluated with oxidation of phosphatidylcholine liposomes as model reaction (test with thiobarbituric acid) [14]. The oxidation supression effect was evaluated by measuring the concentration of malonic dialdehyde (MDA) 10, 15, 20, and 30 min after the onset of the reaction.

CONCLUSIONS

(1) Oxidation of 2,5-dimercapto-1,3,4-thiadiazole with an aqueous solution of $KMnO_4$ yielded 1,3,4-thiadiazole-2,5-disulfonic acid. Its reactions with selected alkaloids and cyclic secondary amines gave the corresponding salts.

(2) The antioxidant activity of 1,3,4-thiadiazole-2,5-disulfonic acid and its alkaloid- and amine-containing salts was revealed.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of *N*-Alkaloidacyl Derivatives of Phenothiazine

I. V. Kulakov, A. A. Ainabaev, O. A. Nurkenov, and A. M. Gazaliev

Institute of Organic Synthesis and Coal Fuel Chemistry of the Republic of Kazakhstan, Karaganda, Kazakhstan

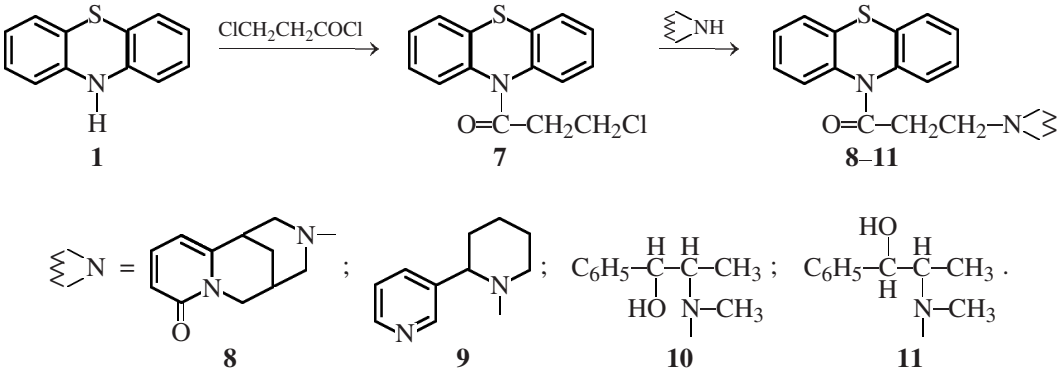
Abstract—Compounds in which cytisine, anabasine, *D*-pseudoephedrine, and *L*-ephedrine fragments are linked to the phenothiazine nitrogen atom via acyl group were synthesized. These compounds are potential drugs, and their activity was confirmed by computer prediction using PASS software.

DOI: 10.1134/S1070427208020195

Many S,N-containing heterocyclic compounds exhibit a broad spectrum of biological activity. Fused tricyclic systems occupy a particular place in this series. For example, phenothiazine **1** is very important as insecticide and helminthicide [1]. The toxicity of phenothiazine, like that of many sulfur-containing compounds, is very low.

The discovery in the 1960s of compounds with a high neuroleptic activity (aminazine, largactil) [2, 3] among 10-aminoalkyl phenothiazine derivatives stimulated their synthesis and comprehensive study. It was also found that 10-aminoacyl phenothiazine derivatives, inactive as neuroleptics, show high cholino- and adrenolytic activity and pronounced antianginal and antiarrhythmic action [4]. Among more than a thousand of new phenothiazine compounds, certain relationships were revealed between the biological activity and the structure of substituents at the N atom and in the cyclic system. 10-Aminopropionyl derivatives proved to be the most active, and lengthening or shortening of the acylalkyl chain decreased the activity [5]. However, despite a huge number of the phenothiazine derivatives synthesized, compounds combining a tricyclic phenothiazine core with certain physiologically active alkaloids as substituents have not been reported.

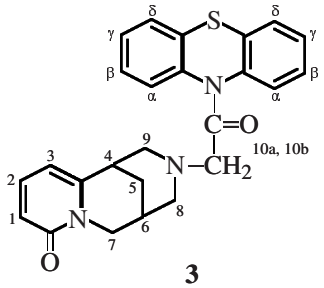


Therefore, it was interesting to prepare previously unknown phenothiazine derivatives of certain alkaloids:

The starting phenothiazine was prepared by the procedure described in [6]. The alkylation of cytisine, anabasine, *L*-ephedrine, and *D*-pseudoephedrine with 10-(2-chloroacetyl)phenothiazine was performed in refluxing toluene in the presence of triethylamine. The target products were purified by column chromatography and by conversion of the hydrochlorides into free bases that are difficultly soluble in water.

Compounds **3**–**6** are white or gray crystalline substances readily soluble in the majority of organic solvents.

To further study the structure–activity relationship, we also prepared *N*-alkaloidpropionyl phenothiazine derivatives, because specifically 10-aminopropionyl phenothiazine derivatives exhibit high cholino- and adrenolytic activity and pronounced antianginal and antiarrhythmic action:



Compounds **8**–**11** are white or gray crystalline substances melting at lower temperatures than their acetyl analogs. The compounds are soluble in the majority of organic solvents. The yield, physicochemical constants, and analytical data are listed in Table 1.

The IR spectra of all the compounds prepared contain, along with bands of the functional groups of alkaloid fragments [ν(OH) at 3320–3280 cm^{-1} for ephedrine alkaloids; ν(C=O) of the cytisine core at 1647 cm^{-1}], also a strong absorption band of the carbonyl (amide) group at 1672–1650 cm^{-1}.

The mass spectra of **3**–**6** and **8**–**11** contain a peak of the molecular ion M^+ with a relative intensity of 5 to 30% and fragment peaks. Their *m*/*z* values and relative intensities I_{rel} (%) are given below for compound **4** as an example: 175 (100%), 199 (22%), 132 (24%), and 44% (58%). These peaks were assigned to the anabasine core >N–CH_2^+, phenothiazine, and other fragmentation products.

The ^1H NMR spectra of **3**–**11** contain, along with signals of phenothiazine protons (multiplets and doublets at 7.20–7.70 ppm), also signals of protons of the alkaloid fragments, having typical chemical shifts:

In particular, in the ^{1}H NMR spectrum of 10-(2-*N*-cytisinoacetyl)phenothiazine **3**, the phenothiazine protons give groups of overlapping multiplets and doublets centered at 7.47 ppm for H^{α} and H^{β} and at 7.25 ppm for H^{γ} and H^{δ}. The next three low-field signals belong to protons of the pyridine core. The signal at 7.35 ppm corresponds to H^2 ($J_{H^2H^3}$ ~3.2 Hz). The doublet at 6.23 ppm corresponds to H^1 ($J_{H^1H^2}$ ~3.6 Hz), and the doublet at 6.05 ppm, to H^3. The next group of lines (a complex multiplet centered at 3.66 ppm) corresponds to the axial and equatorial H^7 protons. The methylene protons of the $-NC=(O)CH_2$ group are nonequivalent and give two doublets at 3.14 and 3.20 ppm with the coupling constant $J_{H^{10a}H^{10b}}$ = 4.0 Hz. The group of lines in the range 2.67–2.85 ppm originates from the H^4 and H^6 protons. The doublets from the H^8 and H^9 protons are situated at 2.42 and 2.32 ppm. The methylene protons H^5 give a pair of doublets centered at 1.68 ppm. The integral curves are consistent with the numbers of protons.

To estimate the expected biological activity of the synthesized phenothiazine derivatives, we performed a bioprediction using the PASS software (Prediction of Activity Spectra for Substances) [7]. The results are listed in Table 2 as the expected kinds of activity and coefficients of the probability of the presence (P_a) and absence (P_i) of each kind of activity, ranging from 0 to 1. In the analysis of the predicted activity spectra, we chose the condition $P_a > 70\%$.

Analysis of the predicted bioactivity of the new alkaloid-containing phenothiazine derivatives shows that their expected activity combines the physiological activity of both the starting alkaloids and aminoacyl phenothiazine derivatives. With fairly high probability, compounds **3**–**11** may exhibit antismoking, antiarrhythmic, psychotropic, spasmolytic, analeptic, and nootropic activity. They can be suggested for tests as new effective drugs.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Bruker DRX500 device operating at 500 MHz from DMSO-d_6 solutions relative to internal TMS; the IR spectra, on an Avatar-320 FTIR spectrometer from KBr pellets; and the mass spectra, on a Finnigan MAT.INCOS 50 device with direct sample inlet, at an ionizing electron energy of 70 eV. The melting points were determined with a Boëtius device. The reaction progress and product purity were monitored by thin-layer chromatography on Sorbfil plates in the system benzene–acetone, 1 : 1. The plates were developed with iodine vapor.

10-(2-Cytisinoacetyl)phenothiazine 3. To a mixture of 0.97 g (0.005 mol) of cytisine and 1.38 g (0.005 mol) of 10-(2-choloroacetyl)phenothiazine in 7 ml of toluene, we added 2.02 g (0.02 mol) of triethylamine and refluxed the mixture for 3 h. The precipitate of triethylamine hydrochloride was filtered off, the solvent was removed, and the residue was crystallized from petroleum ether and purified by passing through a column packed with a 1 : 1 blend of Al_2O_3 and SiO_2 (eluent benzene). The dilution of the solution with a threefold volume of hexane resulted in the precipitation of a white crystalline product.

10-(2-*N*-Cytisinopropionyl)phenothiazine 8 was prepared similarly to **3**.

10-(2-*N*-*D*-Pseudoephedrinoacetyl)phenothiazine 6. To a mixture of 0.66 g (0.004 mol) of *D*-pseudoephedrine and 1.11 g (0.004 mol) of 10-(2-chloroacetyl)phenothiazine in 7 ml of toluene, we added 1.21 g (0.012 mol) of triethylamine and refluxed the mixture for 5 h. The precipitate of triethylamine hydrochloride was filtered off. The toluene solution was washed with distilled water and extracted with 10% HCl. The acidic solution was diluted with water, clarified with activated carbon, and alkalized with aqueous ammonia. The precipitate was filtered off and dried in air.

10-(2-*N*-Anabasinoacetyl)phenothiazine **4**, 10-(2-*N*-*L*-ephedrinoacetyl)phenothiazine **5**, 10-(3-*N*-anabasinopropionyl)phenothiazine **9**, 10-(3-*N*-*L*-ephedrinopropionyl)phenothiazine **10**, and 10-(3-*N*-*D*-pseudoephedrinopropionyl)phenothiazine **11** were prepared similarly to **6**.

CONCLUSIONS

(1) Alkylation of physiologically active alkaloids cytisine, anabasine, *D*-pseudoephedrine, and *L*-ephedrine with 10-(2-chloroacetyl)phenothiazine and 10-(3-chloropropionyl)phenothiazine was performed.

(2) The physicochemical constants of the compounds synthesized were determined, and their compositions and structures were confirmed by ^{1}H NMR, IR, and mass spectroscopy.

(3) The bioactivity of the synthesized alkaloid-containing phenothiazine derivatives was evaluated by computer prediction using the PASS program. The results obtained show that it is appropriate to further study these compounds as new effective drugs.

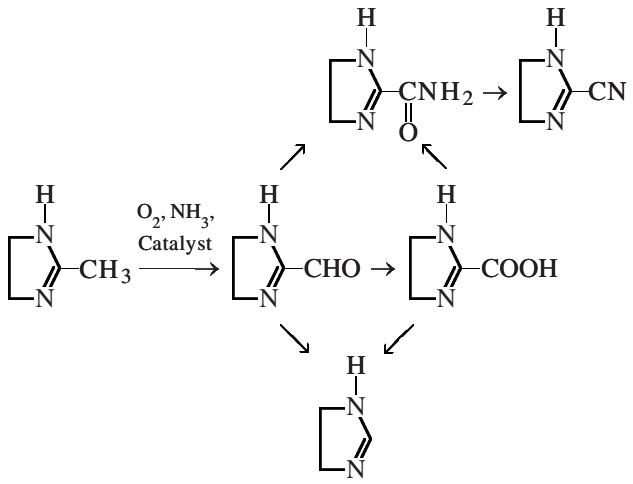
Received July 21, 2007

Abstract—Catalytic ammonolysis of 2-methylimidazoline (lysidine) in the presence of a number of ternary molybdenum–antimony–titanium oxide systems was studied.



DOI: 10.1134/S1070427208020201

Imidazoline derivatives are characterized by a fairly wide spectrum of biological activity. Some of them are effective analgesics, anesthetics for central nervous system, antidiabetic and antiischemic drugs, and medicines affecting lipidic exchange [1–3]; certain imidazoline derivatives are antagonists of α-adrenergic receptors [4]. However, the chemistry of imidazolines is poorly developed and compounds of this class are relatively few [5].

To prepare functional derivatives of the imidazoline ring, it was of particular interest to study oxidative ammonolysis of the available 2-methylimidazoline (lysidine) using tertiary molybdenum–antimony–titanium oxide systems. Previously it has been found that ammonolysis of alkylpyrazines in the presence of these catalysts yields the corresponding pyrazinecarboxamides in a fairly high yield [6].

Preliminarily experiments showed that, in the presence of these compounds, 2-imidazolinecarboxamide is also the major product of lysidine ammonolysis. In addition, small amounts of compounds (namely, aldehyde, acid, and nitrile) formed by transformation of the methyl groups in the course of oxidative ammonolysis [7] were found in catalyzates. The general pattern of the process studied was complicated by the fact that it was accompanied by partial dealkylation and dehydrogenation of the initial compound to give one more product, imidazole.

Thus, the above data suggest that transformations of 2-methylimidazoline in the course of oxidative ammonolysis involve the following reactions:

We studied four samples of oxide catalysts in which the content of titanium dioxide varied from 0.00 to 0.75 mol at a constant molar ratio MoO_3 : Sb_2O_4 = 1.0 : 0.5. The results (see table) show that the selectivity with respect to 2-imidazolinecarboxamide increases with the content of TiO_2 in the catalysts.

Among the catalysts studied, the highest yield of the amide (85–90%) was provided by the catalyst with the molar ratio MoO_3 : Sb_2O_4 : TiO_2 = 1.00 : 0.50 : 0.75. The effect of temperature on the yield of the reaction products is illustrated in Fig. 1. With the temperature increasing from 320 to 360°C at a constant ratio of the starting reagents (lysidine, ammonia, water, atmospheric oxygen) and constant contact time, the lysidine conversion increases from

Yield of imidazole-2-carboxamide at various temperatures

Catalyst $MoO_3 : Sb_2O_4 : TiO_2$ (mol)	Yield, %, at indicated temperature, °C						
	320	330	340	350	360	370	380
1.00 : 0.50 : 0.00	11	13	14	14	15	16	18
1.00 : 0.50 : 0.25	35	57	64	77	75	70	65
1.00 : 0.50 : 0.50	43	61	73	82	80	78	75
1.00 : 0.50 : 0.75	74	90	89	85	82	80	78

75 to 90%. The yield of the amide increases from 70–72 to more than 80% and passes through a maximum (90%) at 330°C. Under the given experimental conditions, the yield of imidazole also increases with temperature but does not exceed 10%.

The contact time exerts a similar effect on the lysidine conversion (Fig. 2). With this time increasing from 0.6 to 1.4 s, the conversion of the initial compound grows to become virtually quantitative at a contact time of 1.2 s. Under these conditions, the yield of the amide changes insignificantly (from 80 to 90%) and reaches a maximum at 0.8–0.9 s. As for demethylation with the formation of imidazole, its yield grows with increasing contact time and reaches 16–18%.

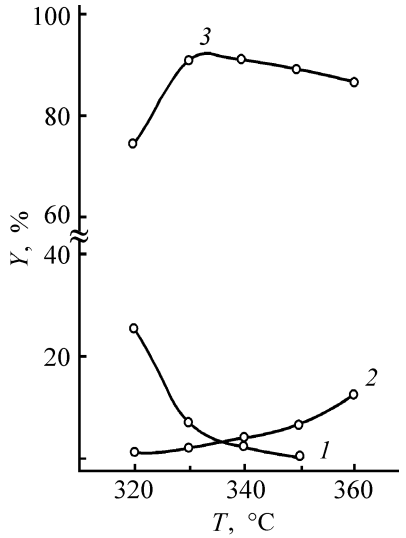


Fig. 1. Yield of the products of oxidative ammonolysis of 2-methylimidazoline vs. temperature *T*. (*Y*) Yield of the reaction products; the same for Figs. 3 and 4. Concentration of NH_3 9.1 mol/mol lysidine, τ 0.8 s. (*1*) 2-Methylimidazoline, (*2*) imidazole, and (*3*) 2-imidazolinecarboxamide; the same for Figs. 2 and 3.

Experiments in which the lysidine : NH_3 molar ratio was varied from 1 : 2.5 to 1 : 11 showed (Fig. 3) that the optimal content of ammonia to obtain the amide is 7–9 mol per mole of the initial compound. With the content of ammonia in the contact zone increasing above the optimal value, the conversion of lysidine and the yields of 2-imidazolinecarboxamide and imidazole noticeably decrease. Such an effect of ammonia on the process is probably due to the fact that, at high concentrations, it occupies the catalyst surface, hinders the adsorption of lysidine, and thus decelerates the conversion of lysidine into the amide and imidazole.

The influence of the content of titanium oxide in the catalysts studied on the conversion of the initial compound and on the yields of the main products of

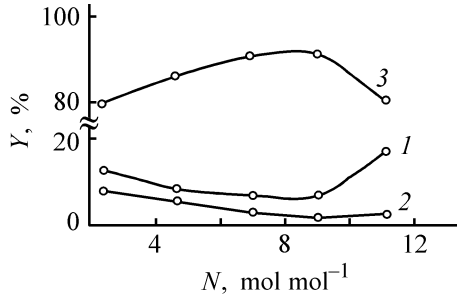

Fig. 3. Yield of the products of oxidative ammonolysis of 2-methylimidazoline vs. the NH_3/lysidine molar ratio. *T* 330°C, τ 0.8 s.

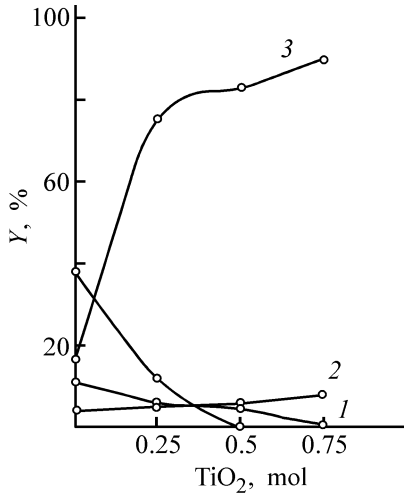

Fig. 4. Yield of the products of oxidative ammonolysis of 2-methylimidazoline vs. the content of TiO_2 in $MoO_3 : Sb_2O_4 : TiO_2$ catalysts. *T* 350°C, concentration of NH_3 9.1 mol/mol lysidine, τ 1.0 s. (*1*) 2-Methylimidazoline, (*2*) imidazole, (*3*) 2-imidazolinecarboxamide, and (*4*) 2-imidazolinecarbonitrile.

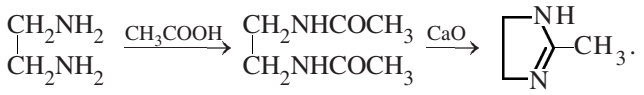

oxidative ammonolysis of lysidine is illustrated by Fig. 4. The process performed under optimal conditions determined in our previous experiments confirmed that the catalyst containing 0.75 mol of TiO_2 seems to be the most promising and provides synthesis of 2-imidazolinecarboxamide in 90% yield. However, it should be noted that the selectivity of the other two catalysts is only slightly lower.

A quite different pattern was observed with the catalysts containing no TiO_2. In this case, the main product of lysidine conversion was 2-imidazolinecarbonitrile, whose yield was a factor of 2 higher than that of the amide. These results unambiguously suggest that the formation of 2-imidazolinecarboxamide is due to a secondary process, hydrolysis of the nitrile, and the extent of this reaction is determined by the content of TiO_2 in the catalyst [8, 9].

Thus, oxidative ammonolysis of lysidine is an efficient procedure for preparing 2-imidazolinecarboxamide.

EXPERIMENTAL

2-Methylimidazoline was prepared by the procedure given in [10]:

The oxidative ammonolysis was performed in a direct-flow unit with a stainless steel tubular reactor (20 mm in diameter and 300 mm long), which was charged with a required amount (65 cm^3) of the ternary oxide catalyst with the molar ratio $MoO_3 : Sb_2O_4 : TiO_2 = 1.0 : 0.5 : (0.25 – 0.75)$, prepared by fusion of the thoroughly ground mixture of the individual oxides at 850°C.

The oxidative ammonolysis was studied under the following reaction conditions: temperature 320–370°C, ammonia concentration 0.8–11.3 mol/mol lysidine, and contact time 0.4–1.6 s.

The catalyzate was condensed in a cooled trap and the reaction products were extracted into chloroform [11]. Then, the solvent was removed on a rotary evaporator. The products were separated by column chromatography (alumina, Brockmann grade II, hexane–chloroform gradient elution).

Analysis of the reaction products was performed on a Chrom-5 gas–liquid chromatograph equipped with a flame-ionization detector. A 2.5-m glass column (0.3 cm internal diameter) was packed with Inerton AW-HMDS impregnated with 5% SE-30. Argon as carrier gas was supplied at a rate of 40 ml min^{-1}. The temperatures of the column, vaporizer, and detector were 100, 200, and 230°C, respectively. The retention times were as follows, s: imidazole 78, 2-methylimidazoline 168, 2-imidazolinecarbonitrile 230, and 2-imidazolinecarboxamide 362.

The IR spectra were recorded on a Nicolet Avatar Fourier spectrophotometer using KBr pellets. The elemental analysis was carried out on a Carlo Erba device (Italy).

Inidazole: mp 92°C; IR, ν, cm^{-1}: 3169, 3114 (NH), 1664 (C=N). Elemental analysis:

Found (%), C 53.13, H 6.01, N 41.42.
$C_3H_4N_2$.
Calculated (%): C 52.93, H 5.92, N 41.15.

2-Imidazolinecarbonitrile: mp 131–132°C; IR, ν, cm^{-1}: 3178, 3047 (NH), 2236 (C≡N), 1669 (C=N). Elemental analysis:

Found (%): C 50.89, H 5.39, N 44.52.
$C_4H_5N_3$.
Calculated (%): C 50.52, H 5.30, N 44.18.

2-Imidazolinecarboxamide: mp 148–150°C; IR, ν, cm^{-1}: 3221 ($CONH_2$), 3162, 3116 (NH), 3052 ($CONH_2$), 1650 (C=O). Elemental analysis:

Found (%): C 42.83, H 6.30, N 37.47.

$C_4H_7N_3O$.

Calculated (%): C 42.47, H 6.24, N 37.15.

The IR spectra of the catalyzates contained absorption bands at 2700–2500 and 1764 cm^{-1} corresponding to a compound with a carboxy group, i.e., to 2-imidazolinecarboxylic acid.

CONCLUSIONS

(1) 2-Methylimidazoline undergoes oxidative ammonolysis in the presence of ternary molybdenum–antimony–titanium oxide catalysts.

(2) The catalyst with the optimal composition (0.75 mol of TiO_2) provides formation of 2-imidazolecarboxamide in 85–90% yield.

(3) The formation of the amide is preceded by the stage of formation of the CN group whose hydrolysis yields the final product.

Abstract—The enthalpies of solution of imidazolidine-2-thione and potassium isopropylxanthate in ethanol and their isobaric heat capacity in the range from 173 to (T_{m-100}) K were measured by calorimetry at 298.15 K. The standard enthalpies of formation, combustion, and melting of these compounds were estimated.

DOI: 10.1134/S1070427208020213

A study of thermodynamic characteristics of biologically active substances and their derivatives is of practical and theoretical importance for their direct synthesis and establishment of relationships between their structural and energy characteristics.

EXPERIMENTAL

In this context, we performed calorimetric studies to determine the enthalpy of solution of biologically active substances, imidazolidine-2-thione $C_3H_6N_2S$ (**I**) and potassium isopropylxanthate $C_4H_7OS_2$ (**II**), in 96% ethanol, their isobaric heat capacities in the range from 173 to (T_{m-100}) K, and the thermodynamic functions ΔH^0_c, ΔH^0_m, and $\Delta_f H^0_{298.15}$.[1]

The enthalpies of solution of the above compounds in 96% ethanol were studied using a DAK-1-1A isothermal calorimeter at three dilutions [1 : 3000, 1 : 6000, and 1 : 12000 (mole of compound : mole of solvent)]. The weighed portions of **I** and **II** for calorimetric studies at the above dilutions were as follows, g: 0.0029, 0.0014, 0.0008 (**I**) and 0.0049, 0.0025, 0.0012 (**II**). The procedure used of the study was described in detail in [1–4]. At each dilution at 298.15 K, we performed five replicate measurements whose results were averaged and treated by the methods of mathematic statistics. For each averaged value of ΔH^0_{dis} we calcilated the random error using the Student test; the homogeneity of variance was estimated using the Cochran test [5]. The hypothesis of the variance homogeneity was taken with 5% significance level.

The device operation was tested by measuring the heat of solution of triply recrystallized potassium chloride at dilutions equal to 1 : 1600, 1 : 2400, and 1 : 3200 (moles of salt : moles of water). The average heat of KCl solution in water is 17640 ± 320 J mol^{-1}, which agrees well with the recommended and reference values of 17577 ± 34 [6] and 17489 ± 371 J mol^{-1} [7]. The enthalpies of solution of **I** and **II** in 96% ethanol at three dilutions are listed in Tables 1 and 2.

Table 1. Experimental enthalpies of solution of **I** (MW = 102) and **II** (MW = 174) in 96% ethanol at various dilutions

Dilution	$\Delta\bar{H}^0_{dis}$, kJ mol^{-1}, for indicated compound	
	I	**II**
1 : 3000	19.48 ± 0.48	20.37 ± 0.41
1 : 6000	23.09 ± 0.24	22.98 ± 0.20
1 : 12000	25.26 ± 0.24	25.58 ± 0.37

[1] The samples were prepared at the Institute of Organic Synthesis and Coal Chemistry (Karaganda). Their purity corresponded to the chemically pure grade.

The experimental enthalpies of solution of **I** and **II** in 96% ethanol were extrapolated to infinite dilution using the least-squares technique. Based on the well-known relationship $\Delta H^0_{dis} \sim f\sqrt{m}$ (m is molality) [8], we derived linear equations for each compound (kJ mol^{-1}):

$$\Delta H^0_{dis}\ (\mathbf{I}) = 31.59 - 161.02\sqrt{m}, \quad (1)$$

$$\Delta H^0_{dis}\ (\mathbf{II}) = 30.53 - 136.8\sqrt{m}, \quad (2)$$

from which the standard enthalpies of solution of **I** and **II** in 96% ethanol at infinite dilution were determined to be 31.6 ± 0.5 and 30.5 ± 0.4 kJ mol^{-1}, respectively.

The isobaric heat capacities of **I** and **II** were studied by the known procedure [9] on an IT-s-400 dynamic calorimeter in the temperature range from 173 to (T_{m-100}) K. Liquid nitrogen was used as a refrigerant. The rated maximum permissible error of the device is ±10%. The delay in the attainment of the required temperature was recorded with an F-136 microvoltammeter and an SETs-100 commercial stopwatch with a step of 25 K. For each temperature, we performed five replicate runs. The results were averaged and processed by the methods of mathematic statistics with subsequent evaluation of the standard deviation $\bar{\delta}$ and random error $\mathring{\Delta}$ [5, 9]. The data obtained for the specific and molar heat capacity of the samples are listed in Table 2. The dependence $C_p^0 \sim f(T)$ is plotted in Fig. 1.

The device operation was tested by determining the heat capacity of an α-Al_2O_3 sample. The resulting value, $C_p^0(298.15)$ = 76.0 J mol^{-1} K^{-1}, agrees

II	2507	41.8	545.2	587.2

within the limits of the device error with the value of 79.0 J mol^{-1} K^{-1} recommended in [11].

Equations for the temperature dependence of the heat capacity of the compounds, presented in Table 3 were derived by mathematical processing of the experimental data. As can be seen from Table 2 and Fig. 1, the curve for the heat capacity of potassium isopropylxanthate shows in the range 173–448 K (peak temperature 248 K), a λ-shaped effect, which is apparently caused by some variations in the molecular structure or by a second-order phase transition. In this context, we derived three equations for the dependence $C_p^0 \sim f(T)$ for the above compound (Table 3).

The enthalpy characteristics of **I** and **II**, ΔH_c^0 and ΔH_m^0 (Table 4), were calculated with the equations that were recommended in [11, 12] and used for evaluation of the thermochemical quantities of the similar compounds [13–15]. To calculate the heat of combustion (kcal mol^{-1}), we used the Karas method [11], which is the most suitable for the compounds under study:

$$\Delta H_c^0 = -26.050(4C + H - P) + \Sigma k_i \Delta_i, \qquad (3)$$

where 26.050 kcal mol^{-1} is the heat of dissociation of the C–C and C–H bonds and subsequent formation of CO_2 and H_2O; C, number of hydrogen atoms in the compound; P, number of partially displaced electrons in the compound molecule; k_i, number of identical substituents; and Δ_i, heat correction corresponding to a given substituent.

The ΔH_m^0 values of the compounds were estimated by the well-known Gambill equation recommended for organic compounds [12]:

$$\Delta H_m^0 / T_m = 20.72 \times 10^{0.00324M}, \qquad (4)$$

where M is the molecular weight of the compound.

Based on the Hess cycle, we calculated from the reactions

$$C_3H_6N_2S_{(l)} + 5.5O_{2(g)} = 3CO_{2(g)} + 3H_2O_{(l)} + N_{2(g)} + SO_{2(g)} - \Delta H_c^0, \qquad (5)$$

$$2C_4H_7OS_2K_{(l)} + 14O_{2(g)} = 8CO_{2(g)} + 7H_2O_{(l)} + 2SO_{2(g)} + K_2O_{(s)} - \Delta H_c^0 \qquad (6)$$

the standard enthalpies of formation of compounds in the liquid (molten) state (Table 4). The data required for calculation of $\Delta_f H_{298.15}^0$ [$CO_{2(g)}$, $H_2O_{(l)}$, $SO_{2(g)}$, $K_2O_{(s)}$] were taken from [16, 19].

Using the equation

$$\Delta_f H_{298.15(s)}^0 = \Delta_f H_{298.15(l)}^0 - \Delta H_m^0, \qquad (7)$$

we calculated the standard enthalpies of formation of **I** and **II** in the solid (crystalline) states (Table 4).

CONCLUSIONS

(1) The enthalpy characteristics ΔH_s^0 in 96% ethanol, ΔH_c^0, ΔH_m^0, and $\Delta_f H_{298.16}^0$ of important biolog-

ically active compounds, imidazolidine-2-thione and potassium isopropylxanthate, were determined experimentally and by calculation. The temperature dependences of the isobaric heat capacities of these compounds in the range from 173 to (T_{m-100}) K were studied and equations describing these dependences were derived.

(2) The results obtained are primary data for inclusion into databases and handbooks of thermodynamic constants. They are of interest for physicochemical simulation of reactions involving the compounds studied and their analogs.

Abstract—Microencapsulation of *N*-benzylmorpholine and its water-soluble derivative, *N*-benzylmorpholine hydrochloride, by simple and complex coacervation was studied, and the main steps of the processes were worked through.

DOI: 10.1134/S1070427208020225

Microencapsulation as a method for preparing disperse systems is widely used in many branches of industry, such as medicine, cosmetics, perfumery, production of dyes, etc. [1–5]. Such useful features of microencapsulated systems as the controllable and selective mass transfer across the microcapsule shell, prolonged action of the core substances, and the possibility of controlling their reactivity make the encapsulation a promising innovative technique for development of novel composite materials.

Here we present methods for microencapsulation of *N*-benzylmorpholine. The choice of this compound is caused by the wide use of morpholine derivatives in pharmaceutics. For example, derivatives of morpholine and morpholinone (3,4,5,6-tetrahydro-2*H*-1,4-oxazin-2-one) appear to be effective for treating glaucoma, prostate hyperplasia, and cardiovascular diseases (arrhythmia) [6]. One more example of the use of morpholine derivatives in pharmaceutics is the synthesis of tachykinin receptor antagonists based on *N*-substituted morpholine derivatives [7]. However, the available information on microencapsulation of such compounds is scarce. Therefore, the goal of this study was to develop methods for encapsulation of such model compounds as *N*-benzylmorpholine (BM) and its water-soluble derivative, *N*-benzylmorpholine hydrochloride (BMH).

EXPERIMENTAL

We chose a simple and a complex coacervation techniques [8] for microencapsulation of BMH and BM, respectively.

Since BM is poorly soluble in water, we chose the complex coacervation technique for its microencapsulation [1, 9]. This method is based on the interaction of two oppositely charged compounds, at least one of them being a polyelectrolyte, to give a polyelectrolyte complex. In this study, we chose for BM microencapsulation two polyelectrolytes, gelatin and chitosane succinate. A preliminary study of various polyelectrolyte pairs (gelatin–Polyquaternium-11, gum-arabic–chitosane succinate, gum-arabic–Polyquaternium-11, and gelatin–chitosane succinate) revealed that the highest efficiency of BM microencapsulation (81%) was obtained with the last pair.

The optimal polyelectrolyte weight ratio was determined spectrophotometrically. Figure 1 shows the results of titration of 0.6 wt % chitosan succinate solution with 0.6 wt % gelatin solution at pH 6.0. In this case, the solution pH is a key condition for formation of a polyelectrolyte complex, since gelatin is a polyampholyte. Chitosan succinate is a basic poly-

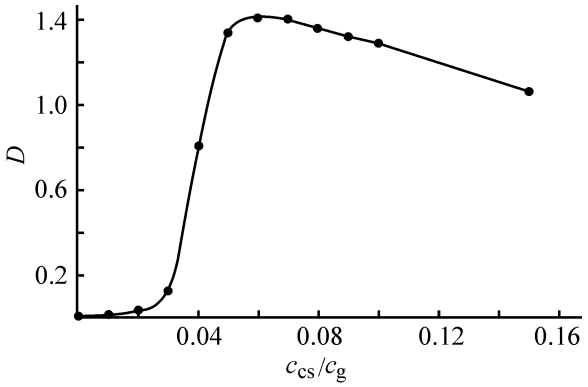

Fig. 1. Optical density D of aqueous solutions of chitosan succinate and gelatin vs. their concentration ratio c_{cs}/c_g at pH 6.0.

electrolyte, and gelatin used in our experiments demonstrates acidic properties at pH above its isoelectric point (pI 5.2). Based on the titration data, the optimal chitosan-succinate-to gelatin ratio was found to be 0.07.

The microencapsulation of BM was carried out in two stages. In the first stage, an emulsion of BM (5% of the total weight of the system) in an aqueous solution of gelatin and chitosan succinate was prepared with continuous stirring at 40°C. Aqueous solutions of the two polymers were prepared separately so that their total concentration was 0.6 wt % and the c_{cs}/c_g ratio was 0.07. The polymer solutions were heated to 40°C and then mixed just prior to preparation of the emulsion. The resulting emulsion was homogenized for 10 min by stirring at 1500 rpm, cooled to 15°C, and repeatedly homogenized for 15 min at the same stirring rate. In the second stage, the walls of the microcapsules were hardened by adding a 25 wt % aqueous solution of glutaraldehyde and aging for 3 h. A micrograph of the resulting microcapsules is shown in Fig. 2. The mean size of the BM microcapsules was 2 μm.

The most important pharmaceutical characteristics of encapsulated drug preparations are the full release time and release rate of an active component in the human body. There are different methods for studying the release of the fill of microcapsules, including in vitro methods for studying the release of an active component to a model system [10, 11]. In this study, we examined the release of BM from the microcapsules to a phosphate buffer solution (pH 6.68). The BM concentration in the aqueous phase was determined spectrophotometrically at 256 nm (UV spectrum of BM is shown in Fig. 3) using a calibration curve. The BM concentration in the phosphate buffer solution was determined at fixed intervals [dispersion of the microcapsules in the buffer solution was maintained at constant temperature (37°C) and continuous stirring throughout the sampling]. The microcapsule concentration was 1.4 wt %. The kinetic curve of BM release from the microcapsules is shown in Fig. 4.

As seen, the full release time of BM from the microcapsules was 8 h. In this case, 16.6% of BM was released in the first 0.5 h, and in the next 6 h the release rate was constant (10 wt % per hour). The initial portion of the kinetic curve is characterized by high release rate, which is possibly the case because, during encapsulation, some part of BM is adsorbed on the outer side of the polymeric coating and, therefore, is released to the solution in the first place.

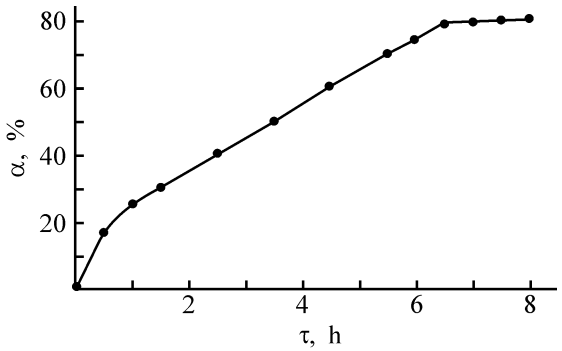

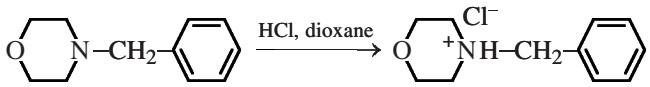

Fig. 4. Kinetic curve of BM release from the microcapsules with a shell composed of gelatin and chitosan succinate. (α) Release of BM and (τ) time; the same for Fig. 8.

In the next step of the study, we attempted to encapsulate *N*-benzylmorpholine hydrochloride, a water-soluble derivative of BM, since in some cases, it is impractical to employ oil-soluble forms of bioactive compounds. *N*-Benzylmorpholine hydrochloride was prepared by adding BM to a solution of HCl in dioxane, i.e., by the reaction

The melting point of the product twice recrystallized from an aqueous-alcoholic mixture was 239–242°C, which is well consistent with the reference data [12]. The BMH concentration in the aqueous phase was determined spectrophotometrically at 258 nm (UV spectrum of BMH is shown in Fig. 5), using a calibration curve.

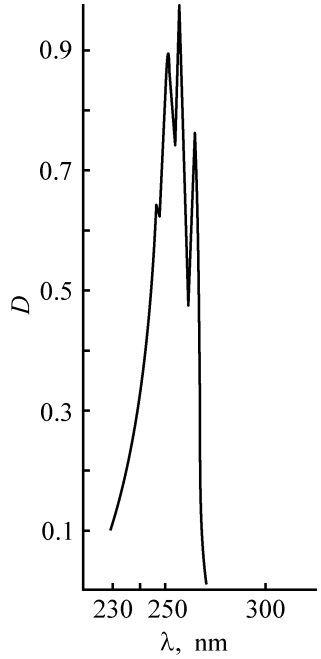

Fig. 5. UV spectrum of an aqueous solution of *N*-benzylmorpholine hydrochloride.

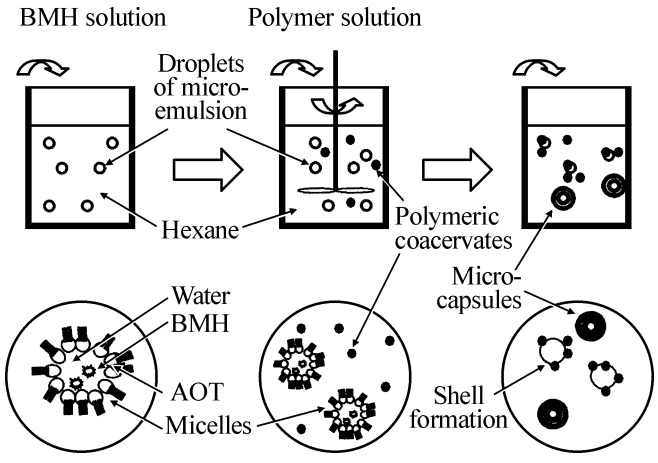

Fig. 6. Schematic of microemulsion microencapsulation of *N*-benzylmorpholine hydrochloride.

It is known that cellulose derivatives are widely used in microencapsulation of various bioactive compounds [13]. For our experiments, we chose nontoxic and biodegradable triacetyl cellulose (TAC) as a shell-forming polymer. The molecular weight of TAC was determined viscometrically, using the Kuhn–Mark–Houwink equation [14], to be 150000 g mol^{-1}.

Microencapsulation of BMH was carried out in two steps. First, an inverse microemulsion consisting of water droplets containing a certain amount of BMH in an organic solvent (hexane), stabilized with sodium di-2-ethylhexyl sulfosuccinate (AOT), was prepared. AOT was chosen as a surfactant stabilizer because of its solubility in both water and hexane, and also because it is nontoxic for human body over a wide concentration range. In the second step, a methylene chloride solution of TAC was added dropwise to the resulting microemulsion with continuous stirring. Methylene chloride was selected as a solvent because it is infinitely miscible with hexane. However, TAC is insoluble in hexane and, therefore, it precipitates in this step on the preliminarily formed droplets of the microemulsion, thus forming a shell of the microcapsules. Such microemulsion microencapsulation can be represented by the scheme shown in Fig. 6. In this case, the degree of encapsulation of water-soluble BMH approached 100%. The electronic spectra of the dispersion medium after formation of the polymeric shell revealed the absence of BMH in it. Of course, one cannot but take into account that free (nonencapsulated) BMH can be adsorbed on the outer surface of the microcapsule. However, the kinetic data on the release of BMH from the microcapsules (see below) suggests that the adsorption is insignificant.

Turning to the scheme presented in Fig. 6, let us focus on some key points of this encapsulation technique. In particular, the optimization of the AOT concentration requires data on its solubilization capacity with respect to aqueous BMH. The critical micelle concentrations (CMC) of AOT in water and hexane were determined by the solubilization of water-soluble (Thymol Blue) and oil-soluble (Sudan Yellow) dyes to be 3.7×10^{-3} and 5.0×10^{-5} M, respectively. These values are well consistent with those obtained for AOT by other methods [15].

The highest solubilization capacity of the organic (hexane) solutions of AOT for BMH was obtained at an AOT concentration of 0.05 M, which is equal to 1000 CMC. This concentration was then used for preparing microemulsions. The existence range of the microemulsion water + BMH/AOT/hexane is

shown in the phase diagram (Fig. 7). The microemulsion range *II* lies between the high-temperature T_2 (50°C) and low-temperature T_1 (5°C) solubilization phase boundaries. In outward appearance, the microemulsion is a bluish transparent opalescent fluid. The liquid–liquid interfacial tension, determined by the drop weight (volume) method, was ≤1 mN throughout range *II*, which confirms the formation of a microemulsion. The droplet size was determined by photon correlation spectroscopy to be 20–35 nm. Ranges *I* and *III* in the phase diagram correspond to binary systems. The maximal BMH concentration in the aqueous solution can amount to 0.6 wt %. Above this concentration, it becomes impossible to obtain the microemulsion at a fixed AOT concentration equal to 1000 CMC. The optimal TAC concentration in the methylene chloride solution added to the microemulsion in the second step of the process (Fig. 6) was found to be 0.25 wt %.

Finally, we experimentally optimized the microemulsion microencapsulation of BMH. At the maximal attainable 20% concentration of the microemulsion obtained in the first step of the process, the concentration of encapsulated BMH was 1.26 g l^{-1}, which is a quite reasonable concentration for practical use. The size of microcapsules in the liquid phase, i.e., before they were separated as particulate species, was determined by dynamic light scattering to be 80–150 nm.

The kinetics of BMH release from the microcapsules was also studied by the in vitro method. The microcapsules were separated from the organic medium in a vacuum using a rotary evaporator, washed three times with distilled water, filtered off, and dried to constant weight. It should be pointed out that, with such a separation method, the microcapsules could form aggregates with a size larger than 150–200 nm. To eliminate this effect, freeze drying is the best separation method. However, in this study, the kinetics of release of the active component was examined without taking into account the particle size. The electronic spectra revealed no BMH in the wash water (filtrate), suggesting that it is not adsorbed on the outer surface of the capsules, because otherwise, adsorbed BMH would have been readily washed away because of the reversibility of physisorption. Since the shell-forming material, TAC, is insoluble in water, we examined the BMH release to 0.1 N HCl at 35°C. The concentration of the filtered-off and dried microcapsules in the suspension was 7 wt %. The BMH content in the dispersion medium was determined spectrophotometrically at fixed intervals (dispersion of the microcapsules in the hydrochloric acid solution was maintained under continuous stirring throughout the sampling). It was demonstrated in the preliminary experiments that HCl has no effect on the position of the absorption maxima of BMH.

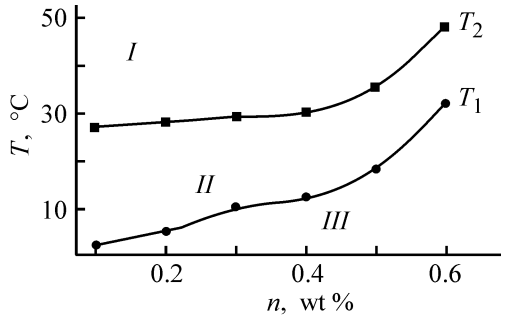

Fig. 7. Phase diagram of the system water + *N*-benzylmorpholine hydrochloride/AOT/hexane. (*T*) Temperature and (*n*) salt concentration in the solution.

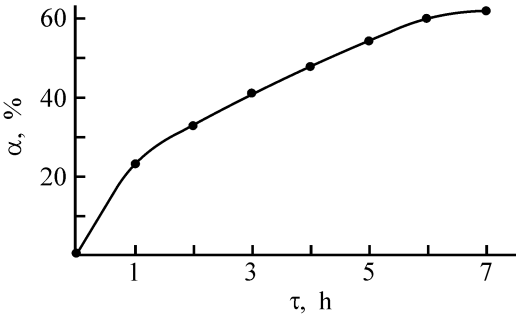

Fig. 8. Kinetic curve of *N*-benzylmorpholine hydrochloride release from the microcapsules with triacetyl cellulose shells.

Figure 8 shows the kinetics *N*-benzylmorpholine hydrochloride release from the microcapsules with triacetyl cellulose shells. As seen, about 70% of encapsulated BMH was released in 7 h, and then the kinetic curve leveled off. A virtually 100% release of BMH in the same time could be attained by raising the HCl concentration by a factor of 1.2. These data are well consistent with those presented in Fig. 4. Here, we also observe a high initial release rate of BMH, which is probably due to nonuniformity of the polymeric shell.

CONCLUSIONS

(1) A procedure for microencapsulation of *N*-benzylmorpholine by complex coacervation was developed, and the microencapsulation conditions were optimized. The best microencapsulation results were obtained with gelatin and chitosan succinate as shell-forming materials. In this case, the degree of *N*-benzylmorpholine encapsulation was 81%, and the mean size of microcapsules, 2 μm.

(2) A procedure for microemulsion microencapsulation of *N*-benzylmorpholine hydrochloride by simple coacervation was developed. The existence range of the microemulsion in the phase diagram was characterized. The droplet size of the microemulsion was found to be 20–35 nm, and the interfacial tension at the liquid/liquid interface did not exceed 1 mN m^{-1}. The method provides a virtually 100% degree of encapsulation of *N*-benzylmorpholine hydrochloride into microcapsules with triacetylcellulose shell.

(3) The release of the active compound from the microcapsules prepared by microemulsion microencapsulation was 70% in 7 h to 0.1 N HCl and 80% in 8 h to the phosphate buffer solution (pH 6.68) from the microcapsules prepared by complex coacervation.

Abstract—The method of impedance measurements was tested in a study of curing of ED-20 epoxy resin with 1,2,3,6-tetrahydro-3-methylphthalic anhydride (CAS 5333-84-6) in a thin layer between capacitor plates. A new equivalent electric circuit was suggested to describe the dielectric properties of the resin without using empirical equations.

DOI: 10.1134/S1070427208020237

Thermally curable adhesive and sealing compounds based on epoxy resins cured by amines and anhydrides are used to glue together and hermetically seal narrow (up to 0.5 mm) gaps between two metal surfaces. Classical optical and calorimetric methods are unsuitable for direct study of the properties of the resin, as well as the properties and formation kinetics of the resulting polymer under such conditions. It was of interest to test for this purpose the method of dielectric spectroscopy, modified by us, with the system constituted by ED-20 epoxy resin, 1,2,3,6-tetrahydro-3-methylphthalic anhydride (CAS 5333-84-6), and a catalyst as an example.

The starting epoxy resin ED-20 and the polymers formed during its curing contain hydroxy, carboxy, carbonyl, and epoxy functional groups possessing their own dipole moments. Such a structure suggests that the dipole-group, segmental, and total mobility of the molecules in a liquid oligomeric compound and in the resulting polymer vary with temperature and external electric field intensity [1, 2]. This makes the dielectric spectroscopy a suitable method for studying the properties of the oligomeric composition and the resulting polymer and the curing kinetics [3, 4]. The mobility of the dipole groups in an external alternating electric field is quantitatively characterized by the complex dielectric permittivity and dielectric loss tangent [1–4]:

$$\varepsilon^* = \varepsilon' - i\varepsilon'', \quad (1)$$

$$\tan\delta = \varepsilon''/\varepsilon'. \quad (2)$$

Variation of ε with frequency is described by the empirical equation [2]

$$[\varepsilon^*(\omega) - \varepsilon_\infty]/(\varepsilon_0 - \varepsilon_\infty) = [1 + (i\omega\tau_0)^{1-\alpha}]^{-\beta}, \quad (3)$$

where ε_0 is the static dielectric permittivity; ε_∞, high-frequency dielectric permittivity; τ, relaxation time; ω, angular frequency; α, width of the dispersion area; and β, parameter of the asymmetry of the dispersion curve.

Thus, analysis of the patterns of variation with the ac frequency for the components of the complex dielectric permittivity and dielectric loss tangent $\tan\delta$ provides information about the properties of the polymer, and analysis of the time dependences of the same parameters (at a fixed frequency), about the polymerization kinetics (kinetics of the liquid-solid phase transition of the oligomer).

EXPERIMENTAL

The impedance measurements were performed on setup consisting of a control computer with an analog-digital converter, ac generator, and a matching amplifying and measuring unit. At each preset ac frequency we recorded the active (Re) and reactive (Im) components of the impedance of the circuit consisting of two metal plates, each with an area of

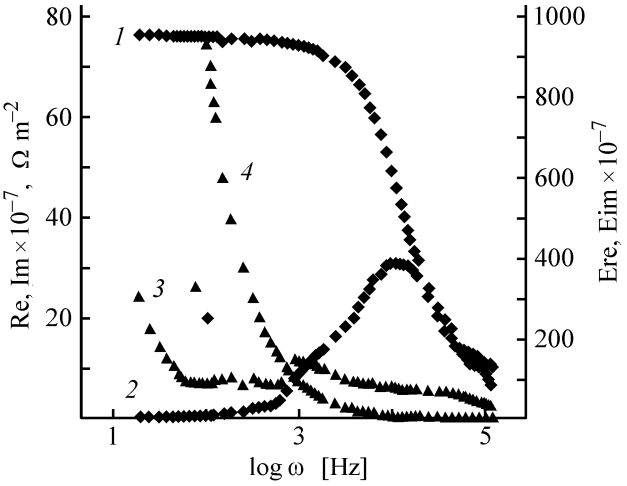

Fig. 1. Semilog plot of the components of the complex dielectric permittivity ε' and ε'' and of the impedance Re, Im of ED-20 resin vs. ω: (*1*) Re, (*2*) Im, (*3*) Eim (ε''), and (*4*) Ere (ε').

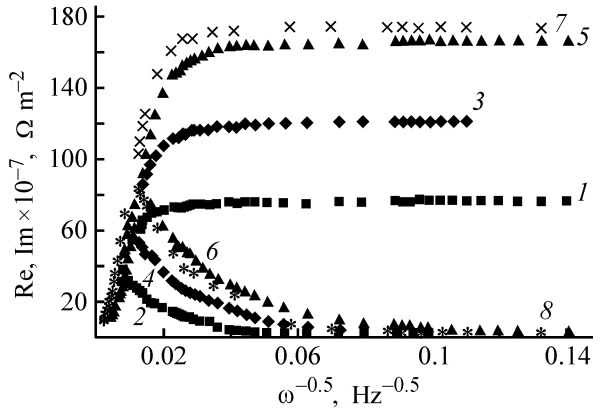

Fig. 2. Plots of the impedance components Re, Im of the ED-20 resin and the polymer vs. $\omega^{-0.5}$: (*1*) Re, 120°C; (*2*) Im, 120°C; (*3*) Re, 80°C; (*4*) Im, 80°C; (*5*) Re, 40°C; (*6*) Im, 40°C; (*7*) Re, polymer; and (*8*) Im, polymer.

4 cm^2, separated by a layer of ED-20 resin (1 mm) or, upon curing, of the polymer (a parallel-plate capacitor filled with the resin or polymer). To preclude any influence of the alternating current on the object examined, the amplitude of the signal fed into the circuit did not exceed 5–10 mV [5]. The measurements were carried out at frequencies ranging from 1 Hz to 20 kHz. The active ε' and reactive ε'' components of the complex dielectric permittivity were calculated by the formulas for a parallel-plate capacitor:

$$\varepsilon' = 1/\omega C_0 \mathrm{Re}(1 + \tan^2\delta), \quad (4)$$

$$\varepsilon'' = \tan^2\delta/\omega C_0 \mathrm{Im}(1 + \tan^2\delta), \quad (5)$$

where $C_0 = \varepsilon_0 S/d$; $\tan\delta$ = Im/Re; $\omega = 2\pi f$, $\varepsilon_0 = 8.854 \times 10^{-12}$ F m^{-1}; d is the thickness of the compound or the polymer layer, m; Re, active component of the impedance, Ω; Im, reactive component of the impedance, Ω; f, ac frequency, Hz; and S, area of the compound or polymer layer, m^2.

The formula $\tan\delta = \varepsilon''/\varepsilon'$ = Im/Re, i.e., ε'' = Im Const and ε'' = Re Const, suggests identical shapes of the frequency dependences for ε'' and Im, as well as for ε' and Re. However, actually these dependences qualitatively differ, since the impedance of the geometric vacuum capacitor relative to which the dielectric permittivity is calculated depends on frequency [i.e., Const = $f(\omega)$].

On passing from high to low frequencies, the ε'' = $f(\log\omega)$ [or ε'' = $f(\omega^{-1/2})$] plot (Fig. 1) exhibits a plateau associated with α relaxation, an extremum associated with the normal relaxation mode, and a dielectric permittivity growth area associated with the conductivity of the polymer. The active component of the dielectric permittivity increases nonlinearly as ac frequency decreases. Such a pattern of ε'' and ε' variation with frequency is also observed for other monomers and polymers [6].

The Re, Im = $f(\log\omega)$ [or Re, Im = $f(\omega^{-1/2})$] plots represent these processes in a different way (Fig. 1). With decreasing frequency, two extrema appear, which correspond to α relaxation processes and the normal relaxation mode, respectively, and a plateau is observed in the conductivity area of the polymer. The active component of the impedance initially increases with decreasing ac frequency and then levels off. An increase in the temperature of the resin (Fig. 2) causes the impedance components to decrease throughout the frequency range examined. The position of the maximum in the plot of the reactive component of the impedance is shifted to higher frequencies. A measurement of the impedance of the epoxy polymer at room temperature showed that the curing temperature (80–140°C) does not affects the impedance components but strongly affected the impedance speed. At the same time, the intensity of the bands in the IR spectra of the epoxy resins are known to be affected by the temperature changes, as revealed by Khozin [7] who attributed this phenomenon to the conformation transformations of the epoxy oligomer molecules.

An analysis of the run of the Im = f(Re) and Y_{Im} = $f(Y_{Re})$ plots for the active and reactive impedance components (by the technique from [8]) showed that the equivalent electric circuit of the system examined cannot be adequately described by an electric circuit

consisting of a limited number of interconnected resistors and capacitors. At the same time, this circuit is adequately described by the $-G_1-G_2-$ scheme, where G_1 is the frequency-sensitive Gerisher element [5] associated with α relaxation, and G_2, frequency-sensitive Gerisher element associated with the normal relaxation mode.

These frequency-sensitive elements of the equivalent electric circuit are evidently associated with transitions of the polymer macromolecules from one state to another and can be described by the corresponding chemical reactions:

$$A \rightleftarrows B^{\delta\pm} \rightleftarrows C, \qquad (6)$$

where A is the initial conformer; $B^{\delta\pm}$, intermediate conformer or a complex bearing an increased charge (governs the conductivity of the substance as a whole); and C, a new conformer.

The equilibrium volume concentration of the intermediate conformer involved in α relaxation, as calculated from the Re, Im = $f(\omega^{-1/2})$ dependence by the technique from [5] (for the degree of ionization equal to unity and diffusion coefficient of 10^{-6} m^2 s^{-1}), is temperature-dependent (Fig. 3); specifically, it increases with temperature.

Combined analysis of this dependence and the concentration of this phase in the polymer suggests that an appreciable curing of the system under consideration starts at temperatures not lower than 70°C.

We analyzed the patterns of variation of the parameters $|Z|$, $|\varepsilon^*|$, and tan δ of the epoxy resin–curing agent system in the gap between the metal plates during curing at different temperatures and found that they vary synchronously with the phase transformations and describe the curing kinetics. The range of variation of these parameters strongly depends on the ac frequency and attains a maximum in measurements of the impedance and tan δ at a frequency of 1 kHz, and in measurements of the dielectric permittivity, at a frequency of 50 Hz (in the range of the corresponding extrema in these dependences). It should be noted that, in the course of curing, the impedance increased by more than a factor of 100, and tan δ, by a factor of 10 upon the liquid-solid transition of the epoxy resin–curing agent system (Fig. 4). The dielectric loss tangent tan δ = Im/Re exhibits a more complex pattern of variation (Fig. 4).

When the system is placed in a thermostat, tan δ initially tends to increase (within the first 10 min); which is due to warming-up and conformation transformations, which cause the viscosity to change. This

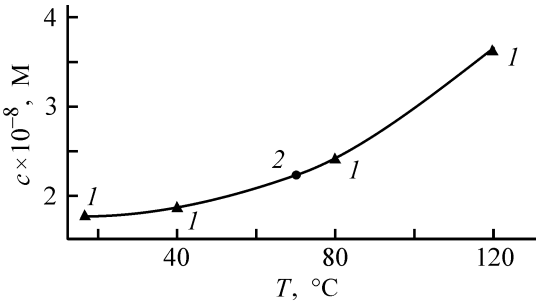

Fig. 3. Temperature dependene of the equilibrium concentration of the intermediate conformer c for (*1*) ED-20 resin and (*2*) polymer.

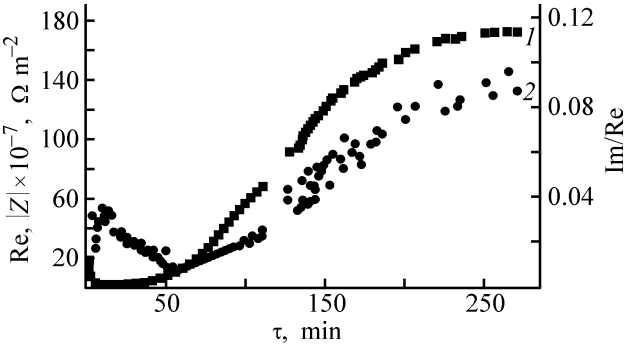

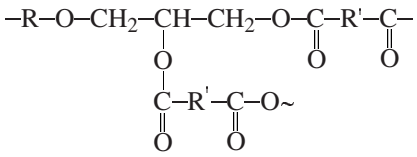

Fig. 4. Plots of (*1*) impedance $|Z|$ and (*2*) dielectric loss tangent tan δ = Im/Re vs. polymerization time τ, at a frequency of 50 Hz at 80°C.

is followed by a decrease in tan δ during 50 min, owing to the formation of the fragments of 3*D* chemical network by the condensation mechanism to the point of gelation.

In the third stage, tan δ tends to increase to a limiting value owing to the formation of a network structure of the epoxy polymer at the molecular and topological levels.

As is known, there are all the prerequisites for strong intermolecular interaction in epoxy polymers; it is of key importance for the properties of glassy polymers, as shown by numerous studies. This concerns, above all, the deformation-strength properties whose variation at temperatures below the glass transition point is determined primarily by the topological structure. Most likely, the scatter of the measured data for tan δ in the third stage is associated with this phenomenon.

We compared the kinetic data on curing of the epoxy composition, derived by the method of impedance measurements, with the corresponding DSC data. To this end, we used a DSC-111 calorimeter (SETARAM, France); the compound (weighed portion 55 ± 5 mg) was heated from room temperature to 500°C at a rate of 5 deg min^{-1}. The curing conditions were as follows: onset temperature 70°C; end temperature 144°C; activation energy of curing $E_{app} = 91.1$ kJ mol^{-1}; and reaction rate $V = 815.3 \times 10^8$ s^{-1}.

In constructing the plot of the conversion α of the liquid oligomeric fractions vs. the curing time τ we took into account the fact that, initially, the compound is a liquid ($\alpha = 0$ %), and upon curing completion, it is a solid polymer ($\alpha = 100\%$). This allows the dependence of the impedance $|Z|$ on the curing time (Fig. 4) to be easily recalculated to the $\alpha = f(\tau)$ dependence. Thus, the method of impedance measurements is suitable for studying the properties and formation kinetics of epoxy polymers in a thin layer.

CONCLUSIONS

(1) The method of impedance measurements is suitable for studying the polymerization kinetics of ED-20 epoxy resin and the physicomechanical and electrical properties of the resulting polymer.

(2) Polymerization can be adequately simulated by a homogeneous reaction of the conformation transition of the macromolecules from the stationary to a topological structure with increased energy characteristics.

Abstract—The possibility of preparing copolymers by radical copolymerization of 1-vinyl-1,2,4-triazole with divinyl sulfide and divinyl diethylene glycol ether in the bulk was examined. The sorption characteristics of the new cross-linked copolymers with respect to mercury(II) ions under static conditions in acid solutions were studied.

DOI: 10.1134/S1070427208020249

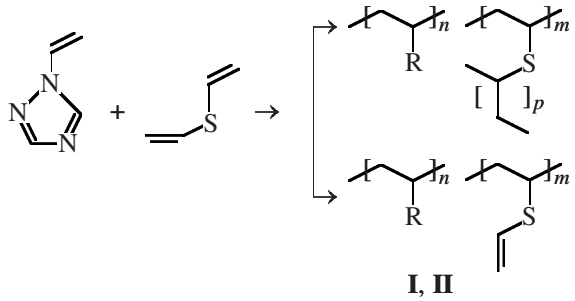
Mercury is one of the most significant contaminants in the world system of environmental monitoring. The high stability of mercury compounds and their toxicity, and also the lack of efficient sorption procedures for their recovery result in that even an insignificant content of mercury in the environment presents hazard to human health and all living creatures on the Earth due to the cumulative effect [1–3]. For preconcentration and recovery of various mercury species, a large number of complexing sorbents based on various polymer matrices have been suggested [4–9]. The most efficient sorbents for preconcentration and separation of mercury are complexing copolymers with sulfur- and nitrogen-containing functional groups [10–12]. The sorption preconcentration and separation of elements, among them mercury ions, from process solutions require using sorbents resistant to corrosive media. Copolymers containing sulfur and nitrogen atoms in macromolecules are of particular interest as sorbents of mercury. Along with functional groups containing donor atoms, the performance of the sorbents is also affected by cross-linking agents, which provide a definite structure of macromolecules and their high chemical and thermal stability.

This study was aimed to prepare new cross-linked complexing copolymers with network structure by radical copolymerization of 1-vinyl-1,2,4-triazole (VT) with divinyl sulfide (DVS) and divinyl diethylene glycol ether (DVDEGE) and to examine their sorption power with respect to mercury(II) ions in acid solutions.

EXPERIMENTAL

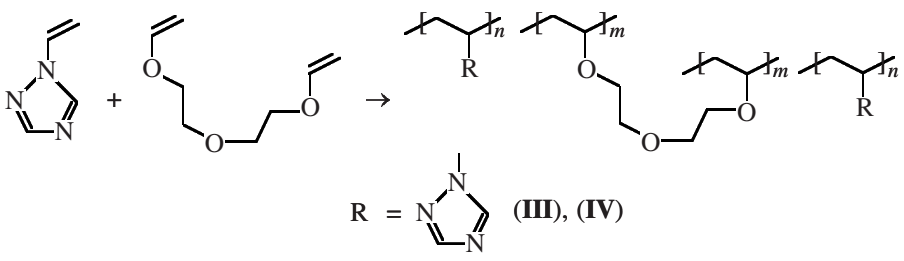
1-Vinyl-1,2,4-triazole was synthesized by the procedure described in [13]. Before use, monomer was distilled in a vacuum: bp 48°C/3 mm Hg, n_D^{20} 1.5075, d_4^{20} 1.0857. The unique characteristics of VT such as hydrophilicity, complexing ability, chemical and thermal stability, adhesion, and nontoxicity allow preparation of copolymers with valuable characteristics for wide application in engineering, medicine, and biology [14]. Divinyl sulfide was synthesized by the procedure described in [15]; bp 86°C, n_D^{20} 1.5060. Divinyl diethylene glycol ether (synthesis procedure was described in [16]) was additionally washed with water, dried with potassium hydroxide, and distilled in a vacuum; bp 85°C/14 mm Hg, n_D^{20} 1.4430. Copolymerization of VT with DVS and VT with DVDEGE was performed in the bulk in the presence of azobis(isobutyronitrile) (AIBN, 2 wt %) at 60°C. After synthesis, the copolymers were washed with ethanol in a Soxhlet apparatus and dried in a vacuum to constant weight. The compositions of the copolymers were evaluated from the content of nitrogen and sulfur (data of elemental analysis). The degree of swelling of the copolymers, α (%), was determined gravimetrically by the formula $\alpha = (P_s - P_d/P_s) \times 100\%$, where P_s is the weight of a swollen sample and P_d is that of a sample. The softening point of the copolymers was determined on a Boëtius table. The IR spectra were recorded on a Bruker IFS-25 spectrometer from KBr pellets.

Table 1. Characteristics of copolymers of VT with DVS (**I**, **II**) and DVDEGE (**III**, **IV**) (AIBN concentration 2 wt %, 60°C)



Co-polymer	Composition of starting mixture, mol %			Yield, %	Elemental analysis, wt %			Copolymer composition, mol %		
	VT	DVS	DVDEGE		N	S	O	VT	DVS	DVDEGE
I	97	3	–	71	35.83	2.72	–	80	20	–
II	70	30	–	64	25.01	10.97	–	54	46	–
III	97	–	3	30	40.01	–	3.84	99	–	1
IV	70	–	30	50	34.02	–	10.74	84	–	16

The sorption characteristics of the copolymers synthesized were studied under static conditions. A 0.01-g weighed portion of the sorbent was brought in contact for a definite time with 20 ml of a solution with a definite acidity, containing a known amount of mercury. The solid phase was separated by filtration. The mercury content of the solutions was determined by the extraction-photometric method with Dithizone [17]. The reproducibility of measurements of sorption and extraction-photometric determination of mercury is characterized by the standard deviation of 5.2%.



The radical copolymerization of VT with DVS and DVDEGE was performed at various molar ratios of the starting monomers: 0.97 : 0.03 and 0.70 : 0.30 (Table 1). The synthesis time depends on the nature of cross-linking agent and is 3–4 h for the system VT–DVS and 0.16–0.25 h for VT–DVDEGE. The new cross-linked copolymers, obtained in a yield of 30–71%, are colorless or light yellow glassy powders. They are insoluble in water, acids, and organic solvents and have high wettability. We found a higher reactivity of DVS in copolymerization with VT, in comparison with DVDEGE: the content of DVS in the copolymer is 20 and 46, and that of DVDEGE, 1 and 16% (Table 1). Elemental analysis shows that the copolymers are enriched in VT units whose swelling capacity is 77–100% in water and 80–120% in acid media. The compounds synthesized are thermally stable: the softening point T_{soft} is 290–330°C.

In the IR spectra of VT–DVS copolymers (**I**, **II**), there are no stretching vibration bands of the vinyl group of the VT triazole ring at 960 and 1640 cm^{-1}, but the stretching vibration bands of the triazole ring (1110, 1420, and 1500 cm^{-1}) are preserved, and an absorption band at 660 cm^{-1} assigned to stretching vibrations of the C–S bond appears. In the IR spectrum of copolymer **II**, there is a band at 1584 cm^{-1} corresponding to residual double bonds CH_2=CHS. In the IR spectra of copolymers VT–DVDEGE (**III**, **IV**), there are no absorption bands at 960 and 1650 cm^{-1} [ν(CH=CH_2)]; there are absorption bands of stretching modes of triazole heteroring at 1500 [ν(–C=N–)] and 3120 cm^{-1} [ν(CH)] and also DVDEGE units at 1100 [ν(C–O–C) of ether groups] and 1620 cm^{-1} [ν(C=C) bonds of vinyloxy groups].

The resulting swollen copolymers presumably have the following network structures:

I, **II**

R = **(III)**, **(IV)**

where n = 54–80 mol %; $m + l$ = 20–46 mol % (**I**, **II**); n = 84–99 mol %; m = 1–16 mol % (**III**, **IV**).

The synthesized copolymers have several reaction centers: pyridine nitrogen atom of VT, sulfide sulfur atoms of DVS, and oxygen atoms of ether groups of DVDEGE.

Experiments on sorption of mercury ions with new copolymers from solutions of nitric, sulfuric, and hydrochloric acids in the concentration range 1–7 M showed that mercury is recovered efficiently. As can be seen from Figs. 1a and 1b, sorption with copolymers **I**–**IV** does not noticeably depend on the anion and the concentration of nitric and sulfuric acids. The dependence appears in hydrochloric acid solutions: for sorbent **I** and **II** containing DVS units in the macromolecule, the degree of mercury recovery from hydrochloric acid solutions decreases with increasing acid concentration to a greater extent than that for sorbents **III** and **IV** containing DVDEGE fragments in the macromolecule. For sorbent **IV** at an HCl concentration of 1–3 M, the degree of mercury recovery decreases. This trend can be accounted for by the fact that the sorption from nitric and sulfuric acid solutions is due to the donor-acceptor interaction of cationic mercury species with active nitrogen and sulfur atoms in the copolymer structure. In chloride solutions, mercury is present in the form of a poorly dissociated molecular compound $HgCl_2$ and also in the form of fairly stable complexes $HgCl_3^-$ and $HgCl_4^{2-}$. The sorption is possible by the ion-exchange mechanism involving interaction of anionic mercury species with protonated nitrogen atoms, with a stronger or weaker competing effect of chloride ions. However, the ion coordination interaction of acido complexes through nitrogen and sulfur atoms is not ruled out. A larger degree of recovery is observed for cationic mercury species, in comparison with the anionic complex species $HgCl_3^-$ and $HgCl_4^{2-}$ prevailing in chloride solutions. However, an increase in the acid concentration decreases the contribution of ion-exchange interaction.

To elucidate the mechanism of interaction of mercury ions with electron-donor atoms of the sorbent, such as sulfur and oxygen, we studied the IR spectra of copolymers treated with acid and their concentrates. For copolymer **I** containing, along with vinyltriazole units, divinyl sulfide fragments, noticeable changes are observed. The absorption band of stretching vibrations of the triazole ring at 1120 cm^{-1} for the concentrate is shifted to higher frequencies by 10 cm^{-1}. There are significant changes in the range 1350–1500 cm^{-1}. This fact supports the donor-acceptor mechanism involving interaction of cationic mercury

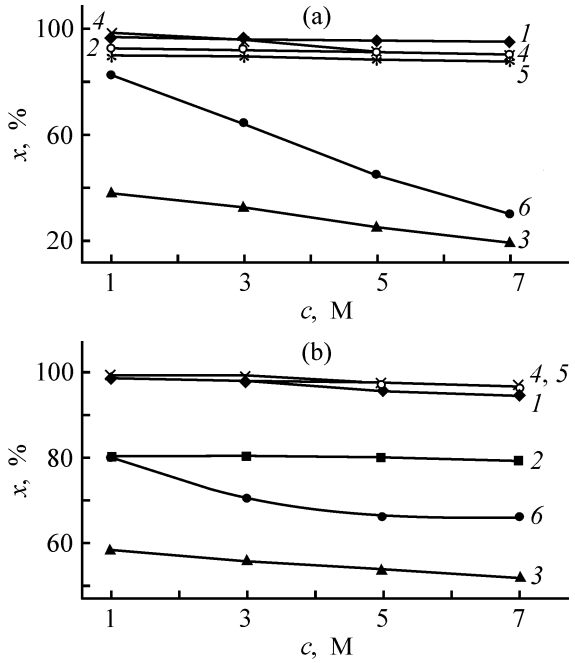


Fig. 1. Degree x of recovery of mercury(II) ions from solutions vs. concentration c of acids of varied nature. m_{sorb} = 10 mg; sorption duration 2 h. (a) Sorbents **I** and **II**: (*1*, *4*) H_2SO_4, $m(Hg^{2+})$ = 3.0 mg; (*2*, *5*) HNO_3, $m(Hg^{2+})$ = 3.0 mg; (*3*, *6*) HCl, $m(Hg^{2+})$ = 0.5 mg; (b) sorbents **III** and **IV**: (*1*, *4*) H_2SO_4, $m(Hg^{2+})$ = 4.0 mg; (*2*, *5*) HNO_3, $m(Hg^{2+})$ = 4.0 mg; (*3*, *6*) HCl, $m(Hg^{2+})$ = 1.0 mg.

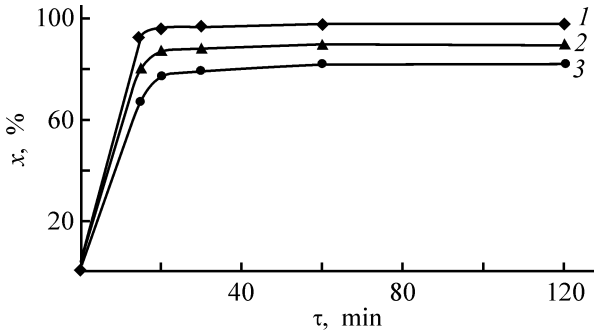

Fig. 2. Degree x of mercury(II) recovery from solutions with sorbent **II** vs. contact time τ of phases. (*1*, *2*) H_2SO_4, HNO_3, m_{sorb} = 10 mg, $m(Hg^{2+})$ = 3.0 mg; (*3*) HCl, $m(Hg^{2+})$ = 0.5 mg.

species with the nitrogen atom in position 4 of the triazole ring to form vinyltriazole-divinyl sulfide copolymer complexes of mercury(II). For copolymer of VT with DVDEGE, no significant changes in the IR spectra were observed, but a small long-wavelength shift of the band at 1490 cm^{-1} was observed in the spectrum of the concentrate.

Both cationic and anionic mercury species are recovered at a high rate. As can be seen from Fig. 2, in

sorption from 1 M acid solutions the equilibrium is established within 20–30 min; in this case, the half-sorption time is 5–10 min and the nature of cross-linking agent in copolymers does not noticeably affect the recovery kinetics.

From the equilibrium distribution curves obtained when studying the distribution of mercury ions between phases in sorption with increasing mercury concentration in 1 M acid solutions (Fig. 3), we evaluated the sorption capacity (SC) of the copolymers and the distribution coefficients *D* (Table 2).

As can be seen from the results obtained, mercury is efficiently recovered with the synthesized sorbents. The sorption capacity in 1 M sulfuric acid is approximately 2 times that in nitric acid. The decrease in sorption is apparently caused by the higher stability of mercury nitrate complexes in the solutions. In hydrochloric acid medium, sorbent **I** of the system VT–DVS with the highest content of nitrogen atoms shows a lower SC, and sorbent **II** with the lowest content of nitrogen, a higher SC. In sulfuric and nitric acid solutions, the SCs of sorbents **I** and **II** are close despite that the difference in the content of donor atoms is approximately 10%. These facts confirm

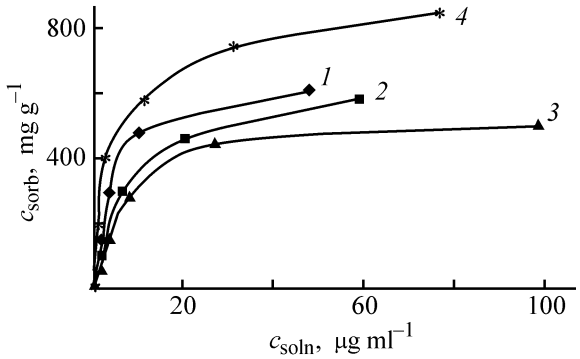

Fig. 3. Equilibrium distribution of mercury(II) for sorbents **I**–**IV** (*1*–*4*, respectively) in 1 M H_2SO_4. (c_{sorb}, c_{soln}) Concentration.

the suggestion that the coordination is affected not only by the content of active atoms, but also by the steric structure of the copolymer and packing density of its functional groups. Sorbent IV of the system VT–DVDEGE has the highest SC, which is apparently caused by more porous structure, in comparison with the other copolymers synthesized. The higher SC values of sorbents **II** and **IV** in hydrochloric acid medium, in comparison with those of sorbents **I** and **II**, are apparently caused by decease in the steric hindrance to diffusion of anionic mercury species in a sorbent particle. Apparently, the steric configuration makes nitrogen atoms of the heteroring more accessible to interaction with anionic mercury species.

The high distribution coefficients of mercury (Table 2) and the shapes of the equilibrium distribution curves (in particular, their slopes, Fig. 3) suggest the efficient operation of the sorbents at low concentrations and the possibility of mercury recovery from dilute corrosive solutions.

With the aim to recover mercury from multicomponent solutions, we studied the sorption power of sorbents **II** and **III** with respect to heavy metal ions, such as Fe^{3+}, Ni^{2+}, Co^{2+}, and Cu^{2+}. The sorption was performed from 1 M nitric acid solutions for 2 h. The sorbent weight was 10 mg, and the total solution volume, 20 ml. The solution contained solutions of 1 mg ml^{-1} Fe^{3+}, Co^{2+}, and Cu^{2+} ions, 1 ml each. The residual concentration of metals in the solution after sorption was determined by the atomic absorption method. The results showed that the polymers did not noticeably recover iron, cobalt, and nickel ions, but up to 30% of copper ions was recovered. The experimental data show that mercury can be desorbed from the sorbent phase with an ammonia solution (1 : 1), and a large elution percentage is reached with the concentrates prepared using the copolymers containing DVS units.

CONCLUSIONS

(1) New network copolymers of 1-vinyl-1,2,4-triazole with divinyl sulfide and divinyl diethyle glycol ether, containing nitrogen-, sulfur-, and oxygen-containing units, were synthesized by radical copolymerization.

(2) The effect of the nature and concentration of acids on the recovery of mercury ions was elucidated. A high sorption power of the complexing sorbents with respect to mercury ions in sulfuric and nitric acid solutions under static conditions was established. The influence of the steric structure of the polymer on its sorption capacity was shown. The sorbent containing 84 mol % 1-vinyl-1,2,4-triazole and 16 mol % divinyl diethylene glycol ether has the highest sorption capacity. The high distribution coefficients ($n \times 10^5$) suggest the possibility of mercury recovery from dilute and corrosive solutions.

(3) Along with mercury, copper ions are also recovered with the sorbents from multicomponent salt solutions.

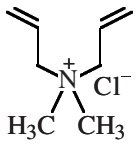
Abstract—Possibility of preparing optically active polymers from *N*,*N*-diallyl-*N*,*N*-dimethylammonium chloride-sulfur dioxide copolymer and optically active acids was studied by the ion-exchange method.



DOI: 10.1134/S1070427208020250

Optically active polymers are widely used both in studies of the mechanism of stereospecific catalysis [1–3] and in practice, e.g., as adsorbents and ion exchangers in separation of racemic mixtures, as asymmetric catalysts and modifiers in heterogeneous catalytic systems in asymmetric organic synthesis, and for preparing glass and films rotating the polarization plane of transmitted light [3–7]. In some cases, the stereoselectivity of optically active catalytic systems is higher than that of their low-molecular-weight analogs [3]. Preparation of optically active polymeric salts of amino acids with *N*,*N*-diallyl-*N*,*N*-dimethylammonium chloride (AMAC)–sulfur dioxide copolymer is of interest. This copolymer is an effective catalyst of some organic reactions [8, 9] and exhibits high physiological activity [10]. Presumably, not only chlorides, but also other polysulfonylpyrrolidinium salts may exhibit high physiological activity. In this context, preparation of polysulfonylpyrrolidinium salts of biologically active amino acids is a topical problem.

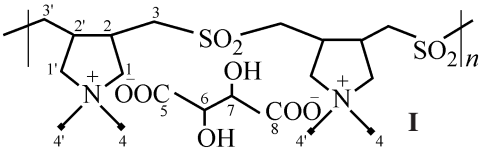
In this study, we prepared optically active salts of AMAC–SO_2 copolymer with some amino acids and tartaric acid by ion-exchange method and determined their structure.

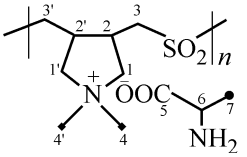
EXPERIMENTAL

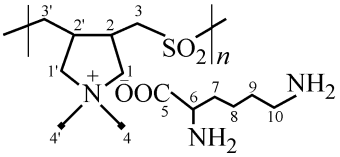
N,*N*-Diallyl-*N*,*N*-dimethylammonium chloride

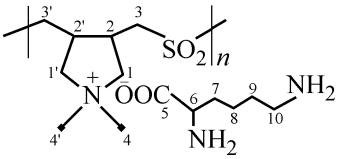
was prepared from dimethylamine and allyl chloride by the procedure described in [11]. The number of AMAC units was estimated from the double bond content determined by elemental analysis and by ^{13}C NMR spectroscopy:

Found, %: C 59.38, H 10.42, N 8.48, Cl 21.51, C=C 29.61.









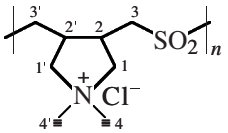
Calculated, %: C 59.44, H 9.91, N 8.67, Cl 21.98, C=C 29.72.

^{13}C NMR spectrum, ppm: C^1 68.39 t, C^2 126.62 d, C^3 131.38 t, C^4 51.75 q. No other signals were observed.

Sulfur dioxide was dried by passing through concentrated sulfuric acid and freshly calcined calcium chloride. Potassium persulfate (PP) (analytically pure grade) was doubly recrystallized from ethanol and dried in a vacuum at room temperature to constant weight.

Optically active acids (OAAs): *D*-tartaric (ultrapure grade), α-aminopropionic (*L*-α-alanine, pure grade),

Table 1. Optically active polymeric salts (OAPSs) formed by polysulfonylpyrrolidinium hydroxide and optically active acids



Structure of OAPS	OAA	Found, % / Calculated, %				Characteristic IR bands, cm^{-1}	$[\alpha]_D^{20}$
		C	H	N	S		
 **I**	*D*-Tartaric acid	43.82 / 45.45	6.62 / 6.82	4.22 / 5.30	10.86 / 12.12	1132, 1300 (SO_2); 1612 (COO); 964, 3536, 3400, 3160 (OH)	+8.8
 **II**	*L*-α-Alanine	45.71 / 47.48	7.18 / 7.91	9.03 / 10.07	10.62 / 11.51	1130, 1300 (SO_2); 1620 (NH_2); 1580 (COO)	+2.3
 **III**	*L*-Lysine	48.76 / 50.15	8.38 / 8.66	11.62 / 12.54	8.61 / 9.55	1132, 1300 (SO_2); 1580 (COO); 1620 (NH_2)	+4.9
 **IV**	*L*-Proline	50.12 / 51.32	7.71 / 7.89	8.98 / 9.21	9.75 / 10.53	1132, 1300 (SO_2); 1584 (COO); 1540 (NH)	–35.7

2,6-diaminocaproic (*L*-lysine, pure grade), and 2-pyrrolidinecarboxylic (*L*-proline, analytically pure grade), and also acetone (analytically pure grade) taken as a precipitant, were used without additional purification. The properties of all the chemicals used in this study were in agreement with published data.

The IR spectra of the polymers were recorded on a Specord M-80 spectrophotometer in the range 3600–600 cm^{-1}. The ^{13}C NMR spectra were recorded on a Bruker AM-300 spectrometer operating at 75.5 MHz with broad-band proton decoupling and in the JMOD mode. The spectra were recorded in D_2O and DMSO-d_6. 2,2-Dimethyl-2-silapentane-5-sulfonic acid and tetramethylsilane, respectively, were used as internal references.

The optical rotary powers $[\alpha]_D^{20}$ of the OAAs and optically active polymers were measured on a Perkin–Elmer 241 MC polarimeter (589 nm) in 20% aqueous solutions. The optical rotary powers $[\alpha]_D^{20}$ of *D*-tartaric acid, *L*-α-alanine, *L*-lysine, and *L*-proline were +12.0, +2.9, +2.9, and –86.0, respectively.

N,*N*-Diallyl-*N*,*N*-dimethylammonium chloride-sulfur dioxide copolymer, polysulfonylpyrrolidinium chloride (PSPC)

was prepared by the known procedure [12]. The purity of PSPC was determined by elemental analysis and ^{13}C NMR spectroscopy.

Found, %: C 42.28, H 7.32, N 6.12, Cl 15.51, S 14.32.
Calculated, %: C 42.57, H 7.10, N 6.21, Cl 15.74, S 14.19.

^{13}C NMR spectrum of PSPC, ppm: C^1 70.48 t, C^2 34.25 d, C^3 53.88 t, C^4 56.35 q, $C^{4'}$ 54.79 q. No signals of the initial AMAC were observed.

An attent to substitute the chloride ion in PSPC with optically active amino acid failed. Therefore, subsequent experiments on preparation of OAPSs were

Table 2. ^{13}C NMR spectra of optically active salts of polysulfonylpyrrolidinium hydroxide

Structure	Chemical shift (ppm) and multiplicity										
	C^1	C^2	C^3	C^4	$C^{4'}$	C^5	C^6	C^7	C^8	C^9	C^{10}
I	65.50 t	32.00 d	54.00 t	52.80 q	52.00 q	176.40 s	72.94 d	72.94 d	176.40 s		
II	68.34 t	32.02 d	54.30 t	52.67 q	52.50 q	177.34 s	50.66 d	17.03 q			
III	68.41 t	32.11 d	54.39 t	51.75 q	52.64 q	177.02 s	54.90 d	31.09 t	21.62 t	26.62 t	39.21 t
IV	68.38 t	32.08 d	55.24 t	53.50 q	53.03 q	176.90 s	63.36 d	34.00 t	25.02 t	47.13 t	

performed via formation of a polysulfonylpyrrolidinium hydroxide intermediate.

Polysulfonylpyrrolidinium hydroxide (PSPH) was prepared from PSPC by ion exchange on AV-17-8 strongly basic anion exchanger by the following procedure. The anion exchanger was successively washed with water and 4, 7, and 15% aqueous alkali solution until no chloride ions were detected with $AgNO_3$ in the wash water. Then the anion exchanger was washed with water to neutral reaction. An aqueous solution of PSPH was prepared by passing a 20% aqueous solution of PSPC through the anion exchanger. PSPH was precipitated from aqueous solution into acetone, reprecipitated from aqueous solution into acetone, washed with three portions of acetone, and dried in a vacuum at 50°C to constant weight. The purity of PSPH was determined by elemental analysis and ^{13}C NMR spectroscopy.

Found, %: C 46.21, H 8.52, N 6.62, S 15.34, Cl 0.24.
Calculated, %: C 46.38, H 8.21, N 6.76, S 15.46, Cl 0.

^{13}C NMR spectrum of PSPH, ppm: C^1 70.87 t, C^2 34.50 d, C^3 54.00 t, C^4 56.82 q, $C^{4'}$ 55.18 q. No other signals were observed.

OAPSs were prepared by the reaction of PSPH with optically active amino acids. To a 40% aqueous solution of PSPH, a 30% aqueous solution of OAA was added dropwise at room temperature (except for reaction with L-α-alanine). The PSPH:OAA ratio was 1.0 : 1.1. The reaction mixture was kept at the required temperature for 1 h. Since the solubility of *L*-α-alanine in water is relatively low (no more than 17.4%), the reaction with *L*-α-alanine was performed at 50°C. The reaction products were precipitated from aqueous solutions with acetone, washed with three portions of acetone, and dried in a vacuum at 50°C to constant weight. The yield was 85-87% based on the initial amount of the reactants. The elemental composition of these products is close to the calculated data (Table 1).

The IR spectra of the reaction products contain strong bands of the COO group in the range 1580–1612 cm^{-1} (depending on the acid) and the bands of NH_2 and NH groups at 1620 and 1540 cm^{-1}, respectively (Table 1). The IR spectrum of the tartaric acid salt obtained at PSPH : OAA ratio of 1.0 : 1.1 contains the band at 1705 cm^{-1} along with the band at 1612 cm^{-1}. These bands are absent in the spectrum of the product prepared at the PSPH : OAA ratio of 2 : 1 (Table 1).

All the reaction products of PSPH with OAAs are optically active. Their $[\alpha]_D^{20}$ values are listed in Table 1. The absence of the signals of the initial PSPH and other impurities in the ^{13}C NMR spectrum of OAPSs suggests complete substitution of the OH anion by OAA anions (Table 2).

CONCLUSIONS

(1) Polysulfonylpyrrolidinium hydroxide was prepared by ion exchange of chloride ions in polysulfonylpyrrolidinium chloride.

(2) It was found that polysulfonylpyrrolidinium salts with anions of *L*-α-amino acids and Dtartaric acid are optically active.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Photosensitive Materials Based on Copolymers of Vinyl Cyclopropyl Ether with Maleic Anhydride

R. Z. Shakhnazarli, A. A. Alieva, Kh. G. Nazaraliev, and A. M. Guliev

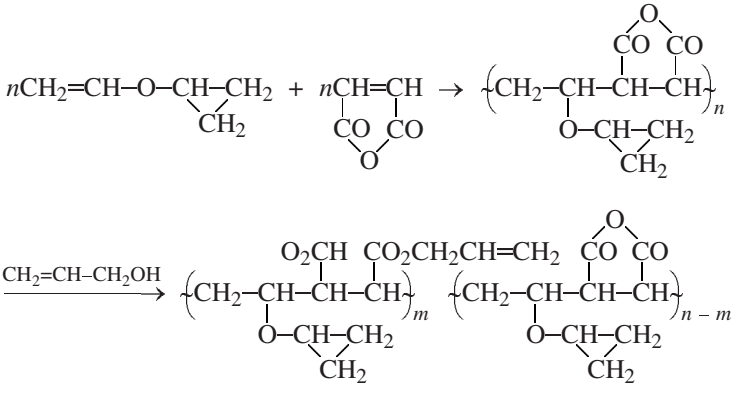
Received October 16, 2007



Abstract—Copolymers prepared from vinyl cyclopropyl ether and maleic anhydride were modified with allyl alcohol, and the products obtained were thermally cross-linked with styrene. Photoresists were prepared from these copolymers, and their photolithographic parameters were determined.

DOI: 10.1134/S1070427208020262

It is known that introduction of a reactive functional group into a macromolecule by chemical modification alters the structure and properties of the polymer. Films composed of such modified polymers change, after an appropriate irradiation, their physical and chemical properties. This is due to the fact that the energy of the penetrating electrons or rays considerably exceeds the energy of chemical bonds. As a result, bonds are ruptured, which is followed by cross-linking and/or degradation. This property allows such materials to be used in various photo- and electron-beam resists for microelectronics [1].

Various classes of polymers and, in particular, poly(meth)acrylates, styrene copolymers, and aliphatic polysulfones, are used today as functional polymers for preparation of photo- and electron-beam resists [2–4]. Of much interest are also copolymers of maleic anhydride (MA), which enter into various chemical reactions with opening of the anhydride ring [5]. The ease of such transformation makes these copolymers convenient as starting products for synthesis of new materials [6, 7]. At the same time, it is known that polymers whose macromolecules contain unsaturated groups in side chains readily transform into 3*D* network structures upon heat or radiation treatment. A similar pattern can also be observed in their homopolymerization of copolymerization with various vinyl monomers in the presence of both ionic catalysts and radical initiators. Such polymer-analogous transformations yield valuable products. In particular, it was suggested to use polymers containing in side chains chemically active groups, such as vinyl, epoxy, or allyl groups for fabrication of negative photo- and electron-beam resists [8, 9].

In this study, we performed esterification of previously synthesized [10] copolymers of cyclopropyl vinyl ether with MA. As a modifier we chose allyl alcohol (AA). The esterification yielded copolymers modified to different extents, depending on the reaction conditions:

The experimental results show that the copolymers are readily esterified with AA at 70–90°C without a catalyst, with a fairly high conversion of the anhydride units. With excess AA, the conversion of the anhydride units in the macromolecular chain reaches 85% in 3 h.

As the esterification is performed without catalyst and the carboxy groups formed by the anhydride ring opening appear in sterically hindered positions, their reaction with AA (in the initial steps and at a small excess of AA) becomes improbable. Hence, determination of the amount of free carboxy groups will allow estimation of the conversion of the anhydride units in the course of esterification. Since the degree of conversion of anhydride groups chiefly depends on the reaction conditions, we first examined the influence exerted by the molar ratio of the copolymer and AA and by the reaction temperature and time on the amount of carboxy groups formed by opening of the anhydride rings. The results of esterification of the copolymers with AA are listed in the table. It can be seen that, the reaction time being the same, the content of the free carboxy groups increases with the molar ratio of AA to the copolymer. For example, at a 2 : 1 ratio of AA to the copolymer, the content of carboxy groups formed in 180 min (longer reaction leads to an only insignificant increase in the content of carboxy groups) is 5.9%, whereas at a fivefold excess of AA, the content of carboxy groups at the same reaction time increases to 10.6%. The conversion of anhydride units also increases with temperature. At the reactant ratio and reaction time indicated above, the content of free carboxy groups increases from 7.8 to 12.4% as the temperature is elevated from 70 to 90°C. In other words, at 90°C the same conversion is reached in a shorter time than at 70°C.

The table shows that the copolymer synthesized is fairly readily esterified with AA without a catalyst, to a relatively high conversion of the anhydride units. Under the optimal conditions (AA : copolymer ratio 4 : 1, 80°C, 180 min), the conversion of anhydride units in the macromolecular chain of the copolymer reaches 80–87%. The modified copolymers obtained by the esterification are readily soluble in ketones and esters and insoluble in alcohols, aromatic hydrocarbons, and alkanes. The modified copolymers can be recovered from their solutions in methyl ethyl ketone by precipitation with a 3–4-fold volume of petroleum ether, followed by drying of the precipitated powders in a vacuum oven at 30–40°C.

The presence of the allyl groups in the macromolecular chains of the modified copolymers was confirmed by the IR data and by decolorization of bromine water.

Content of carboxy groups in relation to the molar ratio of the reactants and temperature

T, °C	τ, min	Content of carboxy groups at indicated allyl alcohol : copolymer ratio		
		2 : 1	4 : 1	5 : 1
70	30	1.0	1.1	1.4
	60	2.0	2.9	4.3
	90	3.1	4.5	6.7
	120	4.0	6.0	8.2
	150	4.9	7.2	9.7
	180	5.9	8.2	10.6

	120	4.7	6.3	9.3
	150	5.7	7.5	10.7
	180	6.8	8.7	11.6
90	30	1.1	1.3	2.2
	60	2.7	3.3	7.0
	90	4.3	5.4	9.4
	120	5.6	7.2	10.9
	150	6.7	8.6	11.8
	180	7.8	9.8	12.4

The IR spectra of the allylated copolymers contain absorption bands characteristic of the double bond (1645, 990, 915, 900 cm^{-1}). The bands at 1150–1300 and 1700–1745 cm^{-1} are indicative of the presence of ether and carbonyl groups in the macromolecular chain. Hence, the reaction of AA with the anhydride ring yields the fragments $CO_2CH_2CH{=}CH_2$. A broad absorption band centered at 3000 cm^{-1} can be assigned to out-of-plane bending vibrations of the associated OH group in the carboxyl moiety [11]. The carbonyl stretching vibration band of the carboxyl moiety is obscured by strong vibration bands of the carbonyl group in the ester moiety at 1745 cm^{-1}.

The IR and ^1H NMR data show that UV irradiation induces cross-linking of the modified copolymers, with opening of the double bond of the allyl group. Other groups and bonds are not invilved in the process. As a result of irradiation, a 3*D* cross-linked structure is formed, and the modified copolymers become insoluble.

The allylated copolymers were also converted into insoluble cross-linked products by radical copolymer-

ization with styrene in the presence of benzoyl peroxide. The reaction was performed at 70°C. The extent of gelation was the greater, and the time required for complete cross-linking the shorter, the higher the molar ratio of styrene to the copolymer.

As expected, an raising the temperature to 90°C leads to an increase in the yield of the crosslinked product and, accordingly, in the gelation rate. In particular, it was found that the yield of the cross-linked product in 40 min was 27.0% at 70°C, and 45.5% at 90°C.

Photochemical cross-linking of functional polymers is of interest in the context of their application to photo- and electron-beam lithographic processes and, in particular, to preparation of photoresists. The practice of using these resists in photolithography revealed their essential drawbacks, in particular, relatively low photosensitivity. Modified analogs of these polymers, exhibiting enhanced photosensitivity, are used today.

To assess the prospects for using the modified copolymers that we obtained, we prepared their acetone solutions with and without addition of a sensitizer (benzophenone) in an amount of about 10 wt % (relative to the dry polymer). Films of photoresists of both the straight copolymer and its modified analogs were prepared under identical conditions. After definite irradiation times, the optical density of the films was determined by UV spectroscopy and compared with that of the unirradiated films. Changes in the irradiated copolymer films were evaluated gravimetrically, by determining the amount of the soluble fraction (extraction with acetone).

Irradiation of the modified cyclopropane-containing anhydride copolymers with monochromatic light (λ = 365 nm) altered the intensity of the absorption band of the double bond at 1645 cm^{-1}. Taking as an internal reference the band of the cyclopropane group at 1045 cm^{-1}, we estimated the photosensitivity of the films of the modified copolymer to be 70–80 mJ cm^{-2}. This irradiation dose required for the exposure allows formation in the modified copolymer film of topological structures in which the component size is the minimum possible for this system. Upon irradiation of the film to a dose of 80 mJ cm^{-2}, the conversion of side double bonds is 40–45%. Irradiation to doses exceeding 120 mJ cm^{-2} raises the conversion of allyl groups to 80%. However, such an exposure is accompanied by side effects: postradiation transformations deteriorating the resolving power of the resist.

The properties of the resists obtained are consistent with the microheterogeneous model of radical polymerization of polyfunctional acrylic compounds [12]. In accordance with this model, thickly cross-linked polymeric particles (microgel) formed in the initial step of the polymerization transformation shield the yet unchanged allyl groups and thereby considerably decrease their activity. Furthermore, the 3*D* cross-linked structure hinders relaxation processes (translation and segmental motion of particles). Therefore, the hindered motion of side groups makes less probable the involvement of the allyl fragments in the photochemical cross-linking.

The photoresist we developed shows not only a high sensitivity (70–80 mJ cm^{-2}), but also increased resolving power (a structure with a component size of 1.0–1.2 μm is formed in a 1.0-μm-thick resist film).

EXPERIMENTAL

The IR spectra were recorded on a Specord M 80 spectrophotometer, and the ^1H NMR spectra, on a BS-487B spectrometer (Tesla, 80 MHz) against HMDS. The copolymers were prepared by the procedure described in [10], under the conditions of radical initiation. The esterification of the copolymers with allyl alcohol was performed in solution. The required amount of allyl alcohol was added from a dropping funnel to 0.003 mol of the copolymer in 100 ml of methyl ethyl ketone at 70°C. After a definite period, the mixture was sampled to determine the content of carboxy groups. For this purpose, the esterified copolymer was precipitated from the solution with petroleum ether, repeatedly washed, dried, and analyzed to determine the content of carboxy groups by the procedure described in [13].

The reaction of the modified copolymers with styrene was performed in sealed ampules in a dry nitrogen atmosphere. After the reaction completion, the ampules were opened and toluene (or benzene) was added. The mixture was allowed to stand for several hours to extract the forming styrene homopolymer. The insoluble fraction, cross-linked copolymer, was washed several times with toluene or benzene and dried in a vacuum oven. The process was performed at various molar ratios of the modified copolymer and styrene.

The polymeric films were irradiated under the following conditions: PRK-2 lamp as radiation source; exposure time 30–120 s (depending on the degree of esterification of the copolymers). As developer we used cyclohexanone. The development time was up

to 15 s. The photoresist layers were dried at 120°C for 30 min.

CONCLUSIONS

(1) Chemical modification of the copolymer of vinyl cyclopropyl ether and maleic anhydride with allyl alcohol was performed, and esterified copolymers with side allyloxycarbonyl and carboxy groups were prepared. The degree of esterification depends on the ratio of the reactants (copolymer and allyl alcohol) and on the reaction temperature and time.

(2) Modified copolymers readily undergo photochemical and thermal cross-linking. Introduction of allyl groups into the pendant chains of the copolymers imparts to them the capability to form 3*D* cross-linked structures under UV irradiation or in the reaction with styrene.

Abstract—Influence of the filler (chalk) on migration of the plasticizer into air and water from poly(vinyl chloride) films plasticized with EDOS was studied by gravimetry, thermal analysis, and IR spectroscopy.

DOI: 10.1134/S1070427208020274

Low-toxic and relatively inexpensive EDOS plasticizer prepared from high-boiling by-products of isoprene production is suggested for use instead of, or along with conventional phthalate plasticizers in production of polymers, including poly(vinyl chloride) [1–3]. EDOS is a mixture of dioxane alcohols and their high-boiling ethers [4]. However, the high volatility of EDOX can result in a significant loss of the plasticizer in production and application of PVC materials [2, 3], which deteriorates the physicomechanical properties of the composites and makes them less environmentally safe. Polymeric materials can be modified by introduction of fillers, which makes these materials less expensive. Previously we have shown [3] that introduction of chalk into PVC films plasticized with EDOS at PVC : EDOS : chalk weight ratio of 100 : 64 : 245 decreases the loss of the plasticizer. We suggested [5] that the nonmonotonic dependence of the diffusion coefficient of EDOS plasticizer in the polymer film on the filler content is caused, unlike the systems with phthalate plasticizers, by interaction of chalk with EDOS in PVC composites. The aim of this study was to examine the influence of the chalk content on the migration of EDOS from PVC films into air and water, since PVC materials can contact not only with air, but also with water. The heat resistance and physicomechanical properties of PVC films were estimated in relation to the chalk content.

EXPERIMENTAL

We studied PVC films plasticized with EDOS and filled with chalk in different amounts. The composites were prepared from the following commercial components: suspension PVC S-70 with the molecular weight determined by viscometry $M = 8.5 \times 10^4$; EDOS plasticizer; and MTD-2 chalk as the filler. All the composites were stabilized with calcium stearate and urea. The samples had the following composition (weight proportion): PVC 100, EDOS 64, chalk 0-245, Ca stearate 0.9, and urea 0.45. The samples were prepared in the form of 1-mm films by rolling on bench rollers at 140°C for 10 min. We studied samples aged for 1 month.

The weight loss Δm of the samples in air under atmospheric pressure at room temperature and 90°C was determined gravimetrically. The relative determination error of Δm at room temperature and 90°C did not exceed 10 and 5%, respectively.

The weight loss of the samples upon gradual heating from room temperature to 400°C was determined by a thermal gravimetric analysis on a TA-4000 derivatograph. The heating rate was 10 deg min^{-1}.

The qualitative composition of the substances released into air from the films and the kinetics of their liberation at 90°C in a dynamic vacuum (residual pressure ~30 Pa) were studied by the IR spectrometric procedure developed in our laboratory, with a thermal vacuum chamber (TVC) [5, 6].

The migration of low-molecular-weight compounds from PVC films into water was evaluated by their weight loss in the course of time at room temperature and by analysis of the liquid phase being in the contact with the samples [6]. The weight loss of the sam-

ples kept in water was determined gravimetrically and was calculated from the equation $\Delta m = [(m - m_0)/m_0] \times 100$ (%), where m_0 is the initial weight of the sample and m is the sample weight in a time τ. The relative weight of substances that diffused from the film into water within the experimental time was calculated by the equation $\Delta m_w = [(m_d - m_0)/m_0] \times 100$ (%), where m_0 is the initial weight of the sample and m_d is the weight of the samples kept in water for the required time and dried to constant weight at 50°C under atmospheric pressure. The swelling of the sample after the experiment completion, α, was calculated from Δm and Δm_w by the equation $\alpha = \Delta m + |\Delta m_w|$ (%).

The qualitative composition of substances that diffused from the films into water was determined as follows. The aqueous phase was evaporated to dryness at 50°C under atmospheric pressure. Tetrahydrofuran (THF) was added to the dry residue. The THF extract was applied to a KBr window. The IR spectrum of the sample was recorded after evaporation of the solvent. The absence of residual THF in the sample was determined by IR spectroscopy.

The strain curves were measured on a PT-250M2 tensile-testing machine. The stretching rate was 25 mm min^{-1}. The samples were cut in the form of trowels whose working part was 6.5 mm wide. The result was the average of two replicate experiments. The stress in the samples was calculated by the equation

$$\sigma = P/S, \quad (1)$$

where σ is the stress (MPa); P, force (kN); and S, cross section of the working part of the sample (m^2).

The tensile stress of the samples σ_t was measured. The nominal elastic modulus at elongation E, characterizing the rigidity of the material, was calculated by the equation

$$E = \sigma/\varepsilon, \quad (2)$$

where σ is the stress and ε is the strain in the initial deformation steps.

The time dependences of the relative weight loss of the samples under atmospheric pressure are shown in Fig. 1. The weight loss of all the samples at room temperature did not exceed 1.5%. The weight loss of unfilled PVC at 90°C during the experimental time was 17% (Fig. 1b). The amount of compounds released from the samples decreased with increasing filler content. The weight loss of the composite

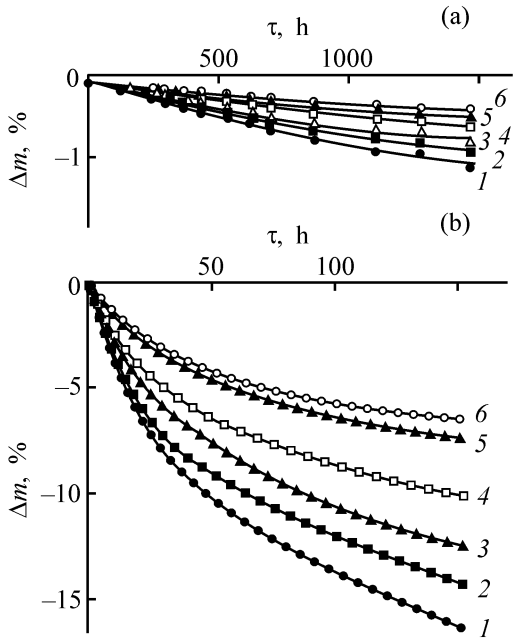

Fig. 1. Weight loss Δm of PVC films containing (*1*) 0, (*2*) 5.5, (*3*) 45, (*4*) 91, (*5*) 164, and (*6*) 245 parts by weight of chalk per 100 parts by weight of PVC (the same for Figs. 4 and 6) at (a) room temperature and (b) 90°C, vs. time τ.

containing 245 wt % chalk (relative to PVC) was approximately 6.5%. As determined by IR spectroscopy, EDOS plasticizer is released from all PVC films.

We also studied the migration of the plasticizer from the samples at 90°C. In these experiments, the released plasticizer was removed from the sample in TVC in a dynamic vacuum. The release of EDOS from the samples was monitored by IR spectroscopy. The kinetics of plasticizer liberation from the samples in the form of $A_\tau/A_\infty = f(\tau^{1/2})$ dependences was also determined by IR spectroscopy, where A_τ is the optical density of the EDOS band at ~1030 cm^{-1} in the IR spectra of the compounds liberated from the sample in time τ, and A_∞ is the optical density of this band corresponding to the initial content of the plasticizer in the sample [5]. The band at ~1030 cm^{-1} is common to all the compounds present in the plasticizer. This band can be assigned to δ_{C-OH} bending vibrations of the OH groups of primary alcohols and ν_{C-O} stretching vibrations of the C–O groups of primary alcohols and ethers [7, 8]. The kinetic curves measured in the initial desorption steps after attainment of the required temperature in TVC were linear. This fact suggests that migration of the EDOS plasticizer from PVC composites is controlled by diffusion in the polymer matrix and allows calculation of the apparent diffusion coefficient of the plasticizer D [5].

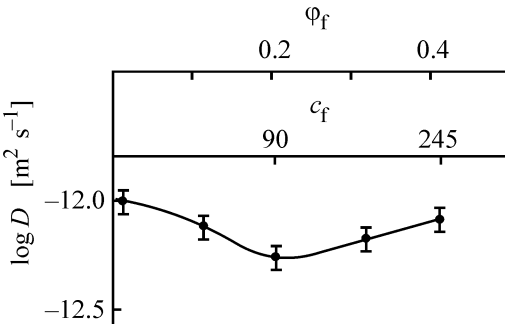

Fig. 2. Diffusion coefficient of plasticizer, D, vs. the chalk content c_f of PVC films. (φ_f) volume fraction of chalk.

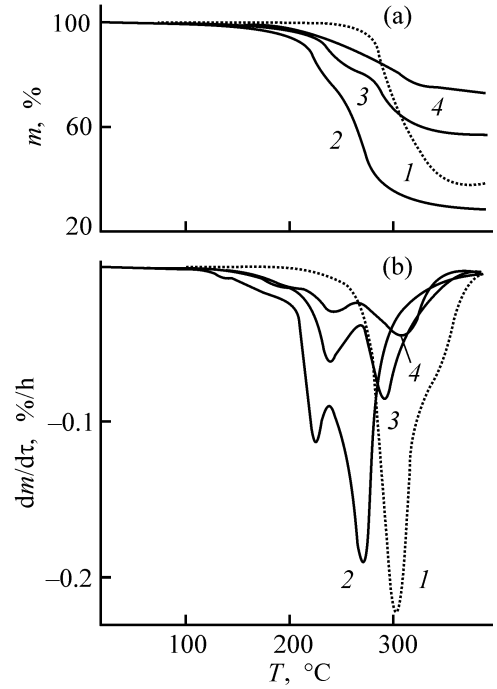

Fig. 3. (a) TG and (b) DTG curves for (*1*) nonplasiticized and (*2*–*4*) plasticized PVC films containing (*1*, *2*) 0, (*3*) 91, and (*4*) 245 parts by weight of chalk. (*m*) Weight and (*T*) temperature.

The dependence of D_{EDOS} on the chalk content of the samples is shown in Fig. 2. It can be seen that the dependence passes through a minimum. This fact confirmed our previous assumption [3] that the dependence of D of the plasticizer in the system examined can be nonmonotonic. A complex dependence of D of low-molecular-weight compounds on the filler content has been observed previously [5, 9] for some filled polymer systems. For example, the dependence of D of di-*n*-butyl-*o*-phthalate (DBP) in PVC composites on the kaolin content was nonmonotonic. The spectroscopic and thermodynamic data show that kaolin reacts with the polymer. By contrast, the dependence of D_{DBP} on the content of chalk, which does not react with PVC, is monotonic [5]. The nonmonotonic dependence of D_{EDOS} on the chalk content of the systems examined can be due to competing interaction of the components. We have shown previously [3] that PVC interacts with EDOS to form H bonds between the C–O groups of the plasticizer and CHCl groups of the polymer (C–O···CHCl) and does not interact with chalk. Under these conditions, chalk can interact with OH groups of the hydroxyl-containing component of EDOS [4], unlike phthalate plasticizers [the heats of wetting of chalk with di-(2-ethylhexyl) *o*-phthalate (DOP) and DBP are close to zero]. The decrease in the diffusion coefficient with the chalk content increasing to 90 parts by weight in PVC composite plasticized with EDOS can be due to formation of additional bonds between the plasticizer and the filler. The rize in the diffusion coefficient of EDOS with a further increase in the chalk content of the samples can be probably caused by structural features of polymer composites with a high filler content [10]. At a high chalk content, the polymer matrix can become looser, with discontinuities appearing [11, 12], which can increase the diffusion coefficient of the plasticizer into air.

The weight loss of the samples under gradual heating from room temperature to 400°C is shown in Fig. 3a. It is seen that the weight loss decreases with increasing filler content. These data are consistent with the weight loss determined under isothermal heating at 90°C (Fig. 1b). The DTG curves (first derivative of the change in the sample weight), which characterizes the thermolysis rate of the samples and removal of volatile products, is shown in Fig. 3b. The TG and DTG curves (curves *1*) for stabilized nonplasticized PVC film free of the filler are also shown in Fig. 3. The peak at ~302°C in the DTG curve of this sample is assigned to dechlorinatiion of PVC (liberation of HCl) [13]. The shoulder in the range 240–270°C in the thermal analysis curve of the plasticized samples, unlike the curve for the nonplasticized sample, is probably due to the release of the plasticizer from the PVC composite [14]. The DTG curve of the unfilled samples plasticized with EDOS (curve *2*) contains two peaks at ~270 and ~226°C and two shoulders at ~250 and ~180°C.

The thermal effect at ~270°C is probably due to dehydrochlorination of PVC. Its rate is maximal at temperatures lower (270°C) than that for the nonplasticized sample (302°C) (curve *1*). This is consistent with the data of Glazyrin et al. [2] who showed that, unlike DOP, EDOS catalyzes PVC degradation. The thermal effects observed at lower temperatures (curve *2*) can be probably assigned to liberation of dif-

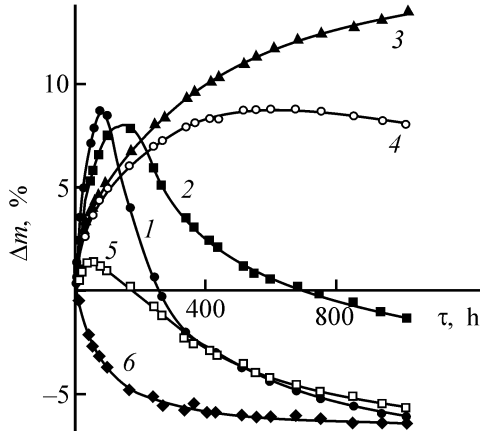

Fig. 4. Variation in the weight of PVC films, Δm, in water at room temperature with time τ.

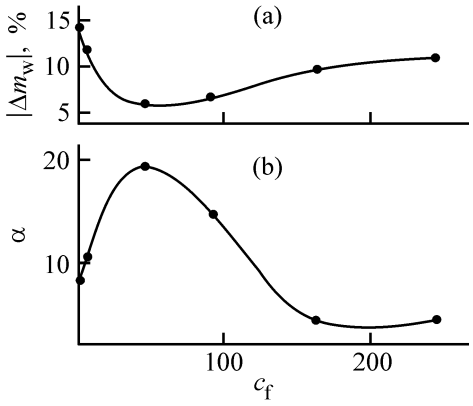

Fig. 5. (a) Wash-out of the components Δm_w and (b) swelling α of PVC films vs. the chalk content c_f (parts by weight).

ferent components of EDOS plasticizer [4]. The temperature corresponding to the maximal degradation rate increases from ~292 to ~307°C as the chalk content of the sample is raised from 91 to 245 parts by weight, respectively (Fig. 3b, curves *3* and *4*), which agrees with the rise in the heat resistance of PVC in the presence of chalk [15].

The time dependence of the weight change of PVC films in water at room temperature is shown in Fig. 4. The weight change of the samples can be due to swelling of the polymer films in the liquid and wash-out of their components. It is seen that that the unfilled samples and the samples containing 5.5 and 164 parts by weight of chalk swell first and then their components are washed out. The samples containing 45 and 91 parts by weight of chalk swell mainly in the course of the entire examined period. The main process observed throughout the experiment for the samples with the maximal filler content (245 parts by weight) is wash-out of its components.

The contributions of swelling of the films in water and wash-out of their components in the final experimental point (Fig. 4, 10^3 h) are listed in Table 1.

As can be seen from Table 1, the wash-out of the components and swelling of the samples are significant. As determined by IR spectroscopy, the EDOS plasticizer and urea are the main components washed out into water from all samples. The release of EDOS makes the major contribution to the total wash-out, since the urea concentration in the samples is 0.1–0.3%. The dependence of Δm_w and α on the chalk content of the samples is shown in Fig. 5.

The wash-out from the unfilled film is the maximal. The wash-out of EDOS can be due to its high hydrophilicity [16], in contrast to the phthalate plasticizers, and formation of solvates by interaction of polar OH and C–O groups of EDOS with water. The wash-out decreases as the chalk content increases to 90 parts by weight, which can be due to additional binding of the plasticizer via its interaction with the filler [3]. The increase in the wash-out from the samples containing 164 and 245 parts by weight of chalk can be due to loosening of the polymer matrix. The dependence of wash-out of the components (Fig. 5a) on the filler content of the PVC films correlates with the change in the apparent diffusion coefficient D_{EDOS} into air with increasing the chalk content of the composite (Fig. 2). As can be seen from Fig. 5b, the dependences of the degree of swelling of PVC films and Δm_w on the filler content pass through extrema. The wash-out of EDOS plasticizer makes lower the hydrophilicity of the polymer composite, which, in turn, changes the degree of swelling of the sample in water.

Table 1. Weight change in water at room temperature in 10^3 h of PVC films plasticized with EDOS and the contributions from swelling in water and wash-out of the components from the samples

Chalk content, parts by weight	Δm	Δm_w	α
	%		
0	–5.9	–14.1	8.2
5.5	–1.1	–11.6	10.5
45	13.5	–5.9	19.4
91	8.2	–6.5	14.7
164	–5.4	–9.6	4.2
245	–6.5	–10.9	4.3

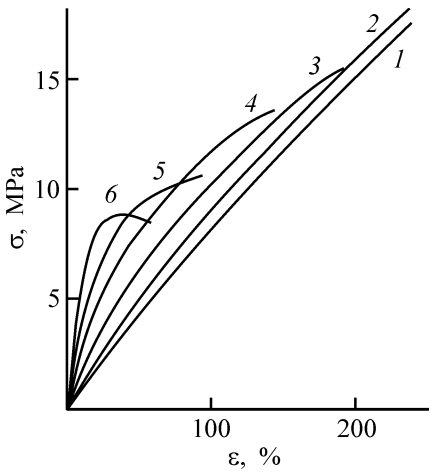

Fig. 6. Strain–stress curves of PVC films. (σ) Stress and (ε) strain.

The strain–stress curves of PVC films are shown in Fig. 6. The shape of these curves is typical of the glassy state of polymers: strong strain is observed under high stresses [17]. According to the strain–stress curves, composites containing 245 parts of chalk per 100 parts of PVC by weight are deformed with the formation of a "neck." In this case, the elongation of the sample is insignificant because of its failure. This is probably caused by structural features of highly filled polymer systems [10]. Weakly bonded structures formed by interaction of filler particles with each other also degrade during deformation of these systems. The ultimate tensile stress σ_t and elastic modulus E of PVC films are listted in Table 2.

The tensile strength of PVC films plasticized with EDOS decreases and the elastic modulus increases as the filler content becomes higher, which is consistent with changes in these parameters when powdered fillers not interacting with the polymer matrix are used [18].

Table 2. Deformation and strength properties of PVC films

Chalk content, parts by weight	σ_u	E
	MPa	
0	15.4	11.2
5.5	18.1	12.2
45	15.5	17.8
91	13.5	28.1
164	10.7	40.0
245	8.6	57.3

CONCLUSIONS

(1) The dependence of the diffusion coefficient of plasticizer into air from PVC composites plasticized with EDOS on the chalk content in the composite passes through a minimum. This can be due to competing intermolecular interaction of the components and the structural features of the polymer composites with high filler content.

(2) Large amounts of EDOS plasticizer are washed out in water. The dependence of the wash-out of the plasticizer on the filler content of the film passes through a minimum. The dependence of the swelling of the sample on the chalk content passes through a maximum. The swelling in water of poly(vinyl chloride) films plasticized with EDOS and the wash-out of the plasticizer are caused by the high hydrophilicity of EDOS.

(3) EDOS plasticizer should not be used for preparing waterproofing poly(vinyl chloride) materials since it does not provide the required stability of their performance in water.

Abstract—The possibility, in principle, of using tertiary phosphine oxides with different structures as fire retardants for polyvinyl chloride plastisols was examined, and their ability to reduce the flammability of these materials was analyzed.

DOI: 10.1134/S1070427208020286

The use of polymeric materials in civil engineering provides significant economic and technical benefits by increasing the use of prefabrication technologies in construction, considerably decreasing the weight of buildings and structures, enhancing the quality of construction works and finishing, improving the exterior, and reducing the transportation volumes and labor spent for erection works. At the same time, virtually all polymeric materials suffer from an essential drawback, increased fire hazard.

The very nature of polymeric materials prevents them from being absolutely fireproof. However, their combustibility and combustion-sustaining power can be decreased. Among the state-of-the-art techniques for decreasing the combustibility of polymeric materials and, in particular, those based on polyvinyl chloride (PVC), are introduction of filling agents, application of fireproofing coatings, and use of halogenated plasticizers. However, these techniques typically impair the mechanical properties, heat resistance, and appearance of the polymeric materials [2].

Also, the combustibility of polymeric materials prepared from base polymers and, in particular, PVC can be decreased by chemical or physical modification. This typically implies the use of combustion-limiting additives, such as mineral fillers, low-combustibility plasticizers, and fire retardants. At present, significant deceleration of combustion is achieved mainly through application of fire retardants. Among them, the best performance characteristics are exhibited by phosphorus-containing fire retardants.

Most researchers believe that phosphorus compounds decrease the combustibility of polymers when added in a concentration of no less than 5% (for the base element). They attribute the decrease in combustibility to decomposition of the phosphoric acids formed, which yields P_2O_5 in the gas phase or a continuous glassy film of polyphosphoric acid on the surface [3, 4].

Wide application in preparation of polymeric materials with decreased combustibility is found by such plasticizers as esters of phosphorus acids, which replace, partially or completely, the combustible plasticizer (dioctyl phthalate) used for imparting the plasticity to PVC. Up to 80–90% of all the commercial phosphorus-containing plasticizers are triaryl phosphates. However, their commercial application is restricted by the lack of simple and efficient methods for synthesis of organophosphorus compounds (OPCs). These compounds are commonly prepared from fire- and explosion-hazardous alkali metals and highly toxic phosphorus halides, and commercial phosphorus-containing compounds are expensive.

The phosphine oxides tested in this study as fire retardants were synthesized by the Trofimov–Gusa-

rova reaction based on a new method for activation of elemental phosphorus (primarily, of its least active, though most environmentally safe red modification) in heterogeneous strongly basic media, composed of an alkali metal hydroxide and a polar aprotic solvent (DMSO, HMPA) or aqueous solution of alkali metal hydroxide, organic solvent, and a phase-transfer catalyst [5–7]. In this case, organophosphorus compounds are synthesized in a single step, and the preparation technology is very simple. This opens real prospects for commercial implementation of the synthesis procedure and wide application of these compounds, which have been previously prepared by a complex multistep procedure.

EXPERIMENTAL

We examined polyvinyl chloride based plastisols that differ from other PVC-based materials by the maximal content of the plasticizer and have the highest combustibility. The formulations were prepared from PVKh E 6250-Zh emulsion polyvinyl chloride [GOST (State Standard) 14039–78]. This is a white combustible powder consisting of 97.3 wt % main substance and 2.7 wt % monoalkyl sulfonate (an emulsifier used for preparation of PVC). Polyvinyl chloride has the following characteristics: mp 82°C, density 1430 kg m^{-3}, particle size under 0.6 μm, ignition point 335°C, and self-ignition point 530°C.

Dioctyl phthalate $C_6H_4(COOC_8H_{17})_2$ (DOP) served as plasticizer. As fire retardants we tested tertiary phosphine oxides synthesized from elemental phosphorus and alkyl bromides [8–10], benzyl chloride [11], allyl halides [12, 13], vinylpyridines [14], and phenylacetylene [5, 15, 16], as well as tris(hydroxymethyl)phosphine oxide synthesized from phosphine and formaldehyde in the presence of catalytic amounts of $PdCl_2$ [6]. Barium and cadmium stearates [TU (Technical Specifications) 6-09-17-319–96] served as stabilizers.

The necessary amounts of the components were thoroughly mixed using an electric drill with attachments until a homogeneous mass free from embedded impurities and lumps was obtained. The resulting PVC-based formulation was poured into a 30 × 20-cm metallic mold. After settling of the formulation for 2 h (to let out air bubbles), the mold containing the PVC-based formulation was placed in a desiccator for 10 min and heat-treated at 150°C.

Next, OPC, DOP, and stabilizer were introduced into the formulations in amount of 0.1–2.0, 65, and 2 parts per 100 parts of PVC by weight, respectively.

The inflammability, ignition delay time, ignition point, and self-ignition point were determined according to GOST 12.1.044–89. The ^{31}P NMR spectra were taken on a Bruker DPX 400 spectrometer with 85% H_3PO_4 as external reference and $CDCl_3$ as solvent. The flame temperature was estimated with a Promin' pyrometer, and the sample surface temperature, with a TK-505 contact thermometer.

To determine one of the major ignitability parameters, the ignition delay time, we prepared 15 samples, each shaped as a square with a side of 165 × 5 mm.

The conditioned sample to be tested was wrapped in an aluminum foil sheet (nominal thickness 0.2 mm) with a hole (140 mm in diameter) cut out in the middle. The center of the hole in the foil had to coincide with that of the exposed surface of the sample. The flame was brought in contact with the sample, and the time was noted. The time elapsed from the onset of the flame exposure till the occurrence of self-sustained combustion of the sample was taken as the ignition delay time.

To determine the flash point and the inflammation temperature we used PVC plastisol samples that were not heat-treated in an oven. The mixture examined was charged into a clean dry crucible. The latter was mounted onto the heating plate of a device for determination of the flash point and ignition point in an open crucible; a thermometer was immersed into the mixture in the crucible to the middle point between the crucible center and the wall at a distance of 6 mm from the bottom. Next, a gas burner was lit. As the flash point in the open crucible we took the temperature indicated by the thermometer at the instant of time when a flame appeared above a part of, or entire mixture surface. The flash point was measured accurately to within 1°C.

Immediately after the flash point was determined, the ignition point was measured; to this end, the crucible was further heated and exposed to an ignition source. After self-sustained combustion of the sample was established, the readings of the thermometer were taken during a period of 5 s. Specifically this temperature was taken as the ignition point of the sample.

We found that the inflammation dynamics is affected by the aliphatic phosphine oxides introduced

Table 1. Flame temperature T_{flame}, sample surface temperature T_{sur}, and self-ignition point T_{self} of plastisols with aliphatic phosphine oxide additives

into the PVC-based plastisols (Table 1). The flame temperature appreciably decreases, which suggests deceleration of the oxidation reaction the occurs in the flame zone. At the same time, the ignition and self-ignition points of the samples containing these OPCs exceed those of the PVC-based plastisols free from the additives. These effects become more prominent as the length of the alkyl radical of the phosphine oxides increases, although this is paralleled by a decrease in the phosphorus content in them and, accordingly, in the formulation.

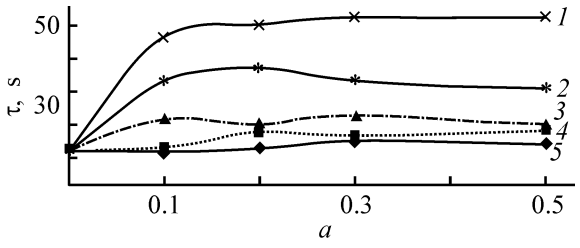

Fig. 1. Plot of the ignition delay time τ vs. the content of the phosphine oxides *a*, parts per 100 parts of PVC by weight: (*1*) tris(hydroxymethyl)phosphine oxide, (*2*) trioctylphosphine oxide, (*3*) a mixture of tripropenylphosphine oxides, (*4*) tripropylphosphine oxide, and (5) triethyphosphine oxide.

Introduction of even small amounts of trialkylphosphine oxides significantly increases the ignition delay time relative to that for the plastisols free from additives (Fig. 1).

The ignition and self-ignition points for the plastisol free from OPC additives and for DOP taken separately are very close: T_{self} was estimated at 400 and 394°C, and T_{ign}, at 205 and 200°C, respectively. Most likely, the inflammability and combustibility of the plastisols are governed by the plasticizer. Therefore, decelerated combustion of the plastisols with phosphine oxide additives is associated with the limited delivery of DOP (and its decomposition products) to the flame zone.

The high fire-retarding power of tris(hydroxymethyl)phosphine oxide can be attributed both to a high phosphorus content of its molecule and the possibility of interaction of this polyfunctional phosphine oxide with the plasticizer. For example, in the ^{31}P NMR spectrum (Fig. 2), the signal at 48 ppm characteristic of tris(hydroxymethyl)phosphine oxide disappears upon its heating with DOP, i.e., new organophosphorus compounds are formed.

The reason for the good performance characteristics of trioctylphosphine oxide as fire retardant can be

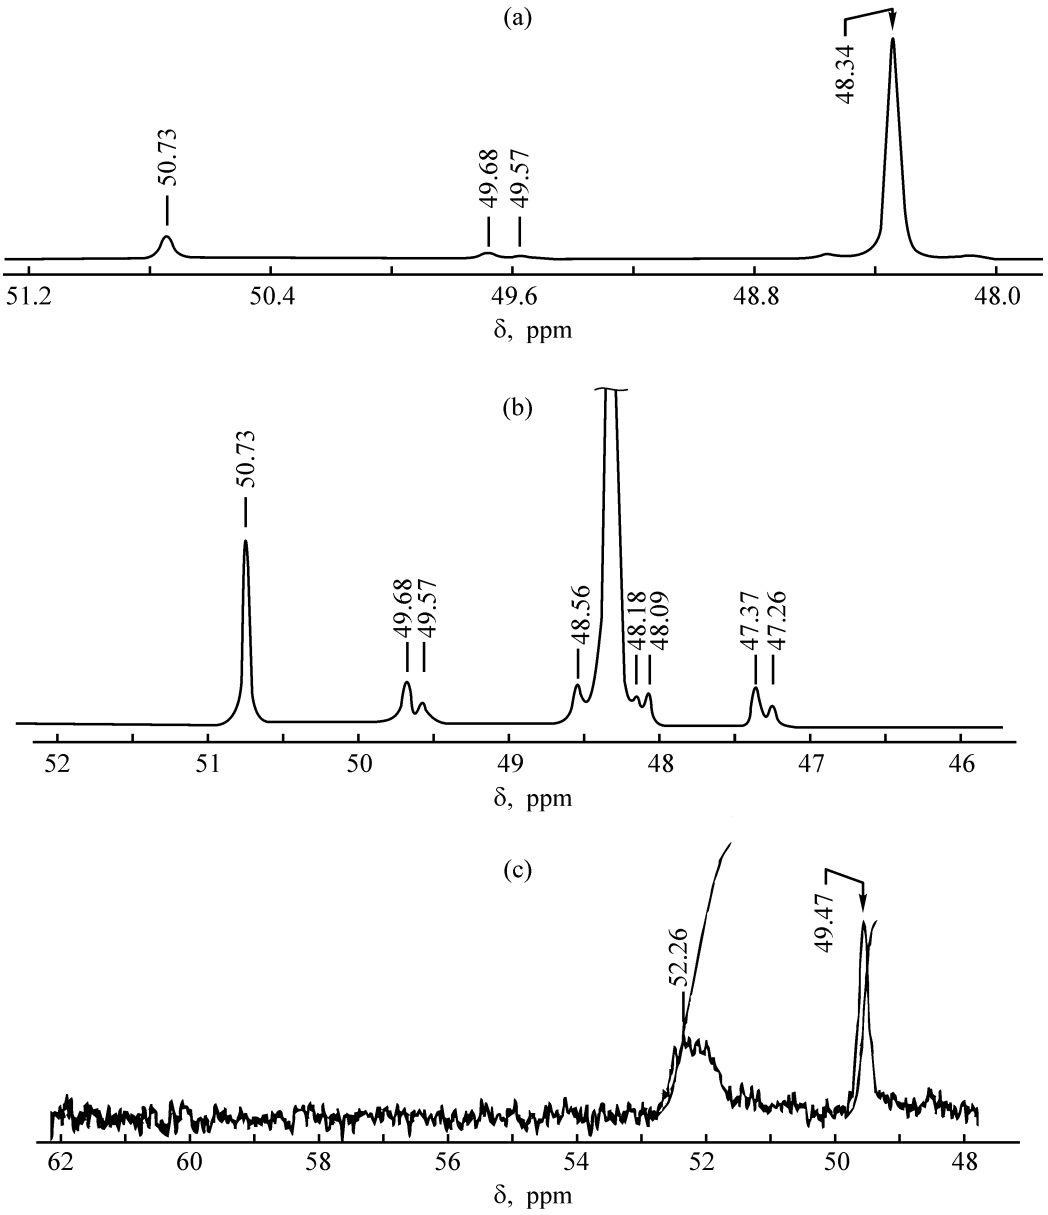

Fig. 2. ^{31}P NMR spectra of the tris(hydroxymethyl)phosphine oxide–DOP system after mixing at (a) 20, (b) 65, and (c) 80°C. (δ) Chemical shift, ppm.

found in its high complexing activity with respect to metal salts and capability to react with barium and cadmium stearates present in the plastisol formulations examined [17]. These reactions yield organometallic compounds probably incorporating DOP molecules. These compounds can catalyze the processes responsible for the formation on the burning material surface of a layer precluding both the delivery of the combustible decomposition products to the flame zone and oxygen diffusion to the surface of the burning material, as well as the heat transfer from the flame to the polymer [18].

Another factor that can be responsible for good fire-retarding characteristics of trioctylphosphine oxide is its high thermal stability: The decomposition temperature of trioctylphosphine oxide (240°C) exceeds the inflammation temperature of the PVC-based plastisol (230°C) containing a trioctylphosphine oxide addition.

The enhanced volatility of triethyl- and tripropylphosphine oxides is responsible for their faster (compared to trioctylphosphine oxide) removal from the material in the initial stage of combustion and, hence, for their enhanced inflammability.

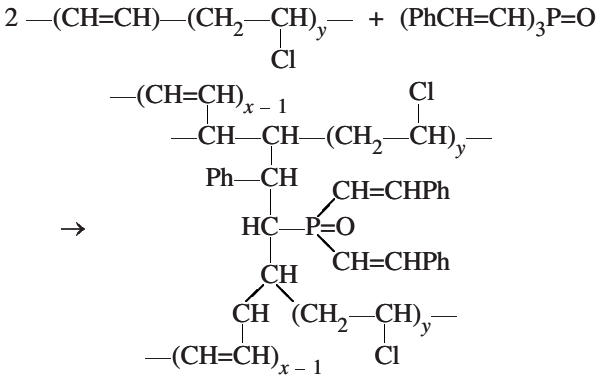

Table 2. Temperature characteristics of combustion processes for plastisols containing OPC additives with aryl(hetaryl)alkyl and styryl fragments

Phosphine oxide	OPC content, parts per 100 parts by weight of PVC	T_{flame}	T_{sur}	T_{self}
		°C		
None	0	1270	610	400
Tribenzylphosphineoxide	0.1	1105	600	500
	0.5	1095	590	500
	1.0	1020	580	510
Tris[2-(2-pyridyl)ethyl]phosphineoxide	0.1	1005	500	560
	0.5	990	485	575
	1.0	990	475	580
Tristyrylphosphineoxide	0.1	1000	545	560
	0.5	985	535	565
	1.0	980	539	570

The samples of plastisols with OPC additives comprising aromatic and heteroaromatic groups are distinguished from materials fireproofed with aliphatic phosphine oxides by higher self-ignition points (Table 2).

The self-ignition points of the samples containing tris[2-(2-pyridyl)ethyl] phosphine oxide and tristyrylphosphine oxide appreciably exceed the surface temperature of these materials. This enables self-extinguishing of fire in them, i.e., termination of combustion of a sample removed from the flame. This fact is supported by a decrease in the time of self-sustained combustion of the above-mentioned materials. The best fire-retarding characteristics were exhibited by tristyrylphosphine oxide, with which the self-sustained combustion time decreased by a factor of 6.5 relative to that for the plastisols free from additives.

A considerable fireproofing effect exerted by tristyrylphosphine oxide on the PVC-based plastisol can be associated with the possibility of interaction between this unsaturated fire retardand and the polyene blocks of decomposed PVC, in particular, by the cross-linking mechanism:

Even minor changes in the formulation of the PVC-based plastics can affect various characteristics of these materials. Hence, we must be certain that mitigation of the fire hazard posed by PVC-based plastisols does not entail deterioration of other properties. We checked this by estimating the operation and technical characteristics of PVC-based plastisols in relation to phosphorus-containing fire retardants, taking advantage of the tensile strength data from [19]. The modulus of elasticity of these formulations increases by 10–20% upon introduction of OPC additions.

Our data suggest that all the tertiary phosphine oxides we tested exert a fire-retarding effect on the plastisols examined by changing the nature of the processes occurring in the condensed phase of the combusting material. Probably, the specific influence of the phosphoryl group on this process consists in binding of HCl evolved in thermal decomposition of PVC, since phosphine oxides are known to form stable adducts with hydrogen halides [17].

At the same time, the fire-retarding effect exhibited by the examined phosphine oxides decreases in the order trioctylphosphine oxide > tris(hydroxymethyl)phosphine oxide ≈ tristyrylphosphine oxide > propenylphosphine oxides ≈ tris[2-(2-pyridyl)ethyl]phosphine oxide > tribenzylphosphine oxide ≥ tripropylphosphine oxide ≈ triethylphosphine oxide. This suggests that the fire-retarding properties of phosphine oxides are more strongly dependent on the structure of the organic radical than on the phosphorus content of their molecule.

CONCLUSIONS

(1) Tertiary phosphine oxides with different structures, containing alkyl, arylalkyl, hetarylalkyl, hy-

droxyalkyl, propenyl, and styryl substitutents are, in principle, suitable as fire retardants for polyvinyl chloride based plastisols.

(2) The fire-retarding properties of the phosphine oxides examined are more strongly dependent on their structure than on the phosphorus content of their molecule.

Abstract—Structural and rheological properties of polycomplex gels of sodium carboxymethyl cellulose (Na-CMC) with urea-formaldehyde oligomers were studied at various component ratios at 298–343 K. The polycomplexes were examined by IR spectroscopy. Mechanical characteristics of solutions of Na-CMC and its complexes with urea-formaldehyde oligomers and the size of structural units of these solutions were determined.

DOI: 10.1134/S1070427208020298

Studies of polymer complexation, including evaluation of the capacity of various water-soluble natural and synthetic polymers to form stable products of cooperative reactions between different polymers and between macromolecules and low-molecular-weight compounds, are of great theoretical and practical interest. Products formed in reactions between polymers and oligomers, known as polycomplexes (PCs) or polycomplex gels (PCGs), form a separate significant group. These products often demonstrate all signs of individual compounds, being characterized by a number of unique properties different from those of the starting components [1]. The topicality of a study of the polymer complexation yielding PCGs is caused by the high importance of such reactions for many natural and industrial processes, including those involving biopolymers, directed polymer modification, and technical use of polycomplexes [1].

Examination of molecular complexes of polymers allows understanding of the contribution of intermolecular interactions to special structure and properties of the complexes. In this relation, polymer–oligomer systems in which self-organization of macromolecules in the course of formation of polycomplexes leads to the formation of nanostructures are of great interest. Furthermore, polymers can be used as matrix carriers for nanoparticles, ready for synthesis of macromolecules on their surface [2, 3].

Study of the mechanism of such a matrix polymerization is important in view of directed synthesis of polymers. In this relation, intermolecular complexes based on Na-CMC and ureaformaldehyde oligomers (UFOs) show promise as models for examination of specific features of the cooperative interaction between various chemically and structurally complementary macromolecules. Such structural features of Na-CMC as the presence of reactive polar functional groups and the high degree of orientation make this rigid-chain polymer suitable for use as a matrix carrier in complexation with UFOs.

Polycomplexes and polycomplex gels find use in the following fields: as flocculants and reagents in the environmental protection practice [4]; as materials for manufacture of separating membranes and biocompatible polymers for medical use [5, 6]; as highly efficient structure-forming agents for dispersed systems and, in particular, soils in agriculture [3]; as hydrogels, for water saving in irrigation [7]; etc. In recent years, PCs and PCGs are more and more widely used in pharmacy, as base materials in preparation of ointments and other gentle drug formulations [8, 9].

Therefore, it is of interest to examine those properties of PCs and PCGs which are caused by specific interactions in the macromolecular matrices, such as mechanical properties of concentrated solutions of

Na-CMC–UFO polycomplexes and polycomplex gels, the behavior of PCs and PCGs under conditions of high shear stress, and the effect of PC and PCG composition on the viscous-flow behavior. Optimal consistency and mechanical characteristics of the matrix should provide good bioavailability of drugs and easy and painless spreading of an ointment on the skin, mucous coats, etc. [10]. Constituents of the polycomplexes and polycomplex gels should be inexpensive commercial polymers of local origin.

In this study, we examined the rheological behavior of concentrated aqueous solutions of Na-CMC–UFO-based PCs and PCGs at various component ratios. Also we monitored the variation of the size of PC and PCG nanoparticles on changing the solution composition and in the course of degradation of the concentrated solutions that form a base of ointments and other gentle drug formulations.

EXPERIMENTAL

In the study, we used purified Na-CMC produced at the Namangan Chemical Plant (degree of substitution 70; degree of polymerization 450). The second component of the polycomplex is a nitrogen-containing polymer formed in a solution of urea and formaldehyde (solution concentration 60–70%). The polycomplexes and polycomplex gels were prepared by mixing 0.1–0.4 aqueous solutions at 1 : 1 or 4 : 1 Na-CMC : UFO ratio [10].

The IR spectra over the range 400–4000 cm^{-1} were recorded on Specord-75IR and UR-20 instruments (Germany). The samples were prepared as KBr pellets, films on KRS-5 windows (prepared by removing water at 22–24°C), and 8–12-μm films.

The rheological properties of concentrated aqueous solutions of the polycomplex gels were examined on a Reotest-2 rotary viscometer with a system of coaxial cylinders. The measurements were carried out at various temperatures over the ranges of shear stress and shear rate of 2–380 Pa and 1.5–130 s^{-1}, respectively. From the rheological data, the viscous volume V^*, or the average size of kinetic units, was determined. This parameter characterizes the flexibility of structural units and their size [11]:

$$V^* = \{2K[E_a R - (\log\eta - \log A_\tau)T]\}/\tau,$$

where K is the Boltzmann constant; R, gas constant; τ, shear stress; T, absolute temperature; A_τ, preexponential factor; and E_a, apparent activation energy (determined from the slope of the $\log\eta = f(T)$ plot).

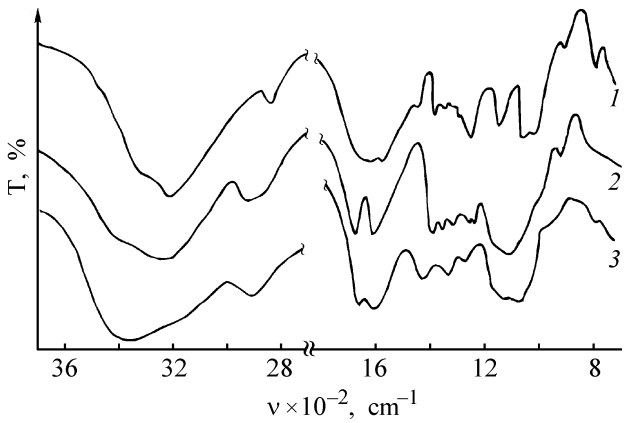

Fig. 1. IR spectra of (*1*) UFO, (*2*) Na-CMC, and (*3*) Na-CMC–UFO polycomplex gel. (T) Transmission and (ν) wavenumber.

The preexponential factor A_τ is insignificant and can be neglected.

Polymer–polymer complexes are, in fact, new polymeric materials, even though they are obtained mostly from common polymers by simply mixing solutions of components in a common solvent, i.e., by the method that can be regarded as polymer modification [12]. It is obvious that the polymer complexation alters the rheological characteristics of the resulting polymer solutions, since it is the rheological behavior that is frequently the most sensitive to changes in the polymer structure.

A detailed examination of the rheological characteristics of the concentrated systems is required to understand the interplay between the structure and properties of polycomplexes. As is known, Na-CMC is a derivative of the natural polysaccharide, cellulose. Its properties are controlled by the features of the structure of cellulose macromolecules, which are highly lyophilic rigid polymer chains. Key factors controlling the viscosity characteristics of Na-CMC are the degree of polymerization, solution concentration, temperature, solvent, and solution pH.

Note that Na-CMC is an anionic cellulose derivative. When mixed with an UFO solution, it forms polycomplex gels by virtue of electrostatic interaction, as demonstrated by the IR spectra reported in [3, 13, 14] (Fig. 1). The IR spectrum of UFO shows the bands of NH^+ and NH_2^+ at 1290 and 1580–1600 cm^{-1}, and that of Na-CMC, the COO^- at 1590–1620 and 1410 cm^{-1}. Therefore, these compounds are polyelectrolytes. Mixing of aqueous solutions of Na-CMC and UFO yields polycomplex gels stabilized by the ionic bonds between the carboxy groups of Na-CMC and amino groups of UFO (Fig. 1, spectrum *3*) [3].

Table 1. Physicochemical characteristics of Na-CMC–UFO polycomplex gels

Composition	Appearance	pH (1 : 10) (normally 6.5–7.6)	Thermal resistance		Film formation time, min	Shelf life, years
			heating (40 ± 0.2°C)	cooling (–10 ± 0.2°C)		
Na-CMC	Yellowish mass with a characteristic odor	7.2	Unstable	Unstable	8–10	0.5
Na-CMC–UFO	Yellow-white mass with a characteristic odor	6.8	Stable	Stable	5–8	2.25
Na-CMC–UFO–glycerol	The same	7.6	″	″	6–8	2.5

Physicochemical and performance characteristics of the polycomplex gels are summarized in Table 1.

Experimental results show (Table 1) that the Na-CMC–UFO polycomplex gels remain homogeneous and stable in prolonged storage. Such characteristics as the color, odor, appearance, pH, and aggregative stability at elevated and lower temperatures meet the requirements of State Pharmacopoeia XI [15].

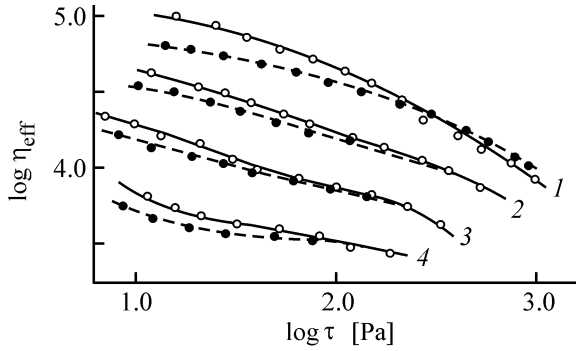

Fig. 2. Flow curves of aqueous Na-CMC solutions at various temperatures. (η_{eff}) Effective viscosity and (τ) shear stress (Pa); the same for Fig. 4. *T*, K: (*1*) 298, (*2*) 313, (*3*) 328, and (*4*) 343; the same for Fig. 4. *Dotted lines* show the viscosity hysteresis; the same for Fig. 4.

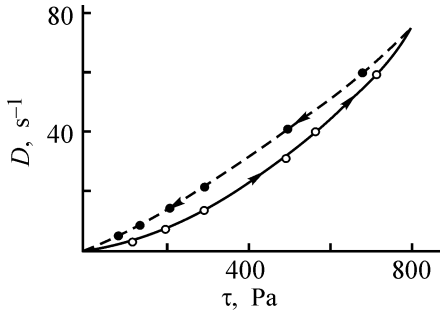

Fig. 3. Rheogram of a concentrated Na-CMC solution. (*D*) Shear rate and (τ) shear stress.

In this study, we examined the rheological behavior of polymer solutions. Experimental data were plotted as log η vs. log τ, where η is the shear viscosity and τ, shear stress. The flow curves were obtained at various temperatures ranging from 298 to 343 K and shear stresses of up to 380 Pa for aqueous solutions of Na-CMC and its polycomplex gels with urea-formaldehyde oligomers at 4 : 1 and 1 : 1 component ratios.

The mechanical properties of Na-CMC solutions were examined on a rotary viscometer initially with increasing and then with decreasing rotary speed. The resulting rheograms are shown in Figs. 2 and 3. The NaCMC solutions are thixotropic, as demonstrated by the clearly pronounced non-Newtonian type of viscous flow. It follows from the modern concepts of solutions of cellulose derivatives in various solvents that these substances form true solutions, in which the macromolecules are kinetically free. However, if cellulose ethers are inhomogeneous with respect to the degree of substitution, particular fractions of Na-CMC can be poorly soluble. The reason is that the initial cellulose consists of both amorphous and crystalline domains. The internal highly crystalline domains are less reactive in the course of preparation of alkali cellulose and its subsequent etherification [16]. As a result, the distribution of substituents along the macrochains appears to be nonuniform. Therefore, the solution contains a certain amount of dispersed Na-CMC, i.e., of aggregates of the macromolecules associated in the same manner as in the crystalline domains of the initial cellulose. As is known [16], such crystallites behave as gelation centers, i.e., they attract a relatively large amount of dissolved Na-CMC and form a 3*D* lattice stabilized by electrostatic and van der Waals interactions.

It is well known that the thixotropy of Na-CMC solutions is a result of formation of the gelation cen-

ters [17]. THe shear stress initiates partial disintegration of the gelation centers and their aggregates with the macromolecules. The effective viscosity decreases in the course of time at a constant shear stress. In this case, the structural degradation of the thixotropic solution takes a finite time. After the removal of shear stress, the thixotropic structure is formed again. When the solution is allowed to stand, the gelation centers aggregate, and the apparent viscosity of the system increases. It was demonstrated in [16] that, depending on the structure of a system in hand, the reversion time can vary from several seconds to several days. Since the thixotropic effect appeared to be time-dependent, all the experimental conditions were standardized. The rheograms presented in Figs. 2 and 3 show a clearly pronounced hysteresis, also suggesting a thixotropy. Concentrated Na-CMC solutions, like those of many other macromolecular compounds, are non-Newtonian fluids.

Complexation of the Na-CMC macromolecules with urea-formaldehyde oligomers strongly alters the structure of the polymer matrix, affecting the rheological behavior of the aqueous solutions (Figs. 4a, 4b). On passing to the equiconcentrated PCG solutions, the viscosity and critical shear stress considerably decrease, the effect being more pronounced at 1 : 1 Na-CMC/UFO ratio, compared to the 4 : 1 ratio. These systems behave essentially like ordinary pseudoplastics. The investigated interpolymer complexes were obtained by mixing the interacting components in a common solvent (water).

Mixing of Na-CMC (a rigid-chain polymer) with the oligomer yields highly oriented polymer complexes, in which the macromolecular matrix is responsible for the organization of the associating systems and their complementarity. An important characteristic of the matrix–oligomer systems is their self-organization ability [18, 19], which is manifested in a nonuniform distribution of the oligomer chains between the matrices and also in the tendency of the short chains to be arranged along the long macromolecular chain of the matrix so that to provide a maximally dense packing. As a result, some parts of the matrices will be completely filled in the limiting case. Most likely, this effect is responsible for the difference in rheological behavior between the 1 : 1 and 4 : 1 systems. Thus, in the 4 : 1 systems, the excessive content of Na-CMC causes a partial (very weak) preservation of the thixotropic effect and a slight increase in the viscosity as compared to the 1 : 1 systems. Our results show that polycomplex gels have acquired some extra properties relative to the constituent polymers (Figs. 4a, 4b).

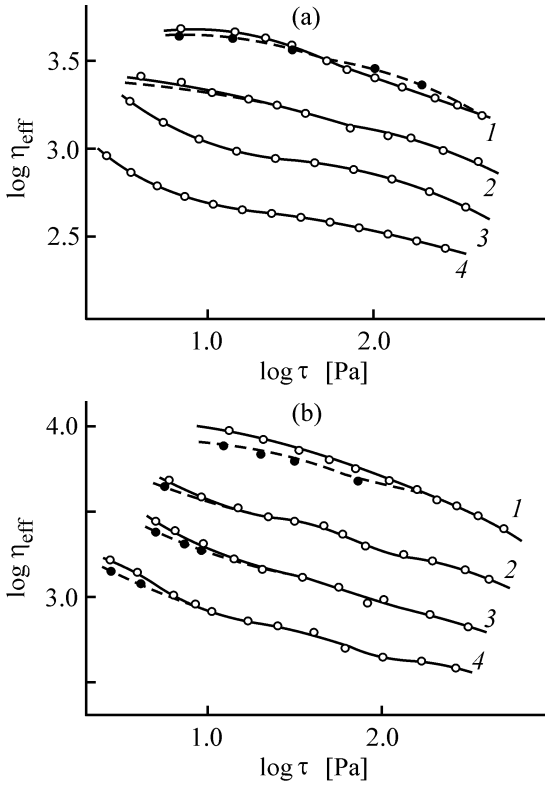

Fig. 4. Flow curves of concentrated Na-CMC–UFO polycomplex gels at various temperatures. Na-CMC : UFO ratio: (a) 1 : 1 and (b) 4 : 1.

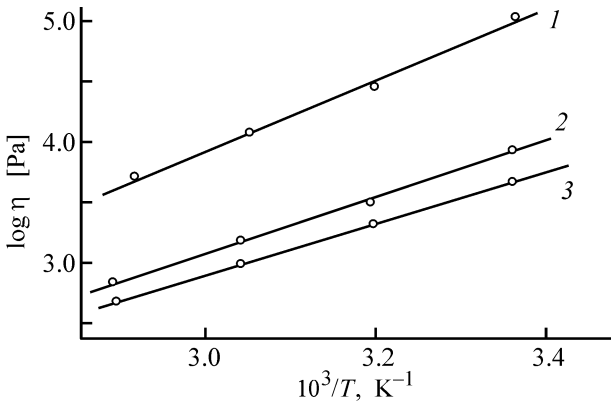

Fig. 5. log η vs. 1/*T* plot for concentrated solutions of (*1*) Na-CMC and (*2*) 4 : 1 Na-CMC–UFO and (*3*) 1 : 1 Na-CMC–UFO polycomplex gels. (η) Viscosity and (*T*) temperature.

Thus, in the PCGs studied, the thixotropic properties are virtually degenerated with a simultaneous decrease in the viscosity characteristics. The Arrhenius–Frenkel plot of the viscosity in the range 298–343 K, $\eta = Ae^{\Delta E_a/R}$, is shown in Fig. 5 for Na-CMC and PCG solutions. The Na-CMC solutions are more structured, and demonstrate higher viscosity char-

acteristics and critical shear stress. In these solutions, the activation energy of viscous flow, characterizing the intermolecular interaction between macromolecules and, indirectly, the strength of the polymer structure in solution, was estimated to be ΔE_a = 55.7 kJ mol^{-1}. For the 1 : 1 and 4 : 1 PCGs, the activation energies are 43.13 and 45.96 kJ mol^{-1}. Complexation of Na-CMC containing the carboxy, hydroxy, and other functional groups with UFO yields interpolymer associating systems, in which the intensity of intermolecular interaction is considerably lower than in the straight Na-CMC solutions. As a result, the structural strength and viscosity characteristics decrease. The polycomplex structure, directly related to the chemical nature of the polymer constituents, is responsible for the degeneration of the thixotropic properties in PCGs (Na-CMC macromolecules and molecular associates are shielded on the matrix surface by the UFO arrangements).

The interaction between chemically and structurally complementary macromolecules is cooperative in its nature. In this case, a linear (unidimensional) sequence of similar interchain bonds is formed, which is typical of the simplest cooperative systems. Evidently, a cooperative system can be built through formation of two or more types of bonds, e.g., ionic and hydrogen bonds. Because of the cooperative nature of bonding between different polymer chains in the complex, the formation and cleavage of the bonds occur under a definite external impact, e.g., under deformation stress. This is due to the fact that decomposition or formation of an interpolymer complex requires a simultaneous cleavage or formation of a great number of bonds, even though weak. In polymer–polymer and polymer–oligomer interactions, there typically occur equilibria of two kinds at both macromolecular and intracomplex levels, which causes a time-dependent character of the formation of polycomplexes and slow rearrangement of the intra- and supramolecular structures [20]. A high shear stress initiates fundamental changes in the initial PCG structure. To each stress corresponds a definite initial structure of the material, and the elementary event of flow consists in a chain segment hopping from a new initial state to an activated state. It is seen from the flow curves (Figs. 2–4) that the high stress significantly alters the structure and viscous properties of the polycomplex systems. From the rheological data, we estimated the viscous volume V^* [11] for Na-CMC and Na-CMC–UFO solutions (Table 2).

In the Na-CMC solutions, V^* (measure of the size and flexibility of structural units) and the lateral size of structural units D are slightly smaller than those in the PCG solutions, which gives additional evidence in favor of the complexation of the anionic derivative of cellulose with cationic MFOs. Table 2 shows that V^* increases with temperature in both Na-CMC and PCG solutions, which is due to disentangling of the macromolecules. This facilitates intermolecular interaction, resulting in an increase in the size of PCG associates.

As the shear stress increases, supramolecular structures and, therefore, PCG associates disintegrate. At a low shear stress (<10 Pa), the size of PCG associates exceeds that of Na-CMC associates, and the reverse is observed at a higher shear stress of up to 158.8 Pa, which suggest that, under high shear stress, not only PCG associates, but also the polycomplexes themselves disintegrate.

Finally, complexation of Na-CMC with synthetic oligomers allows control over the size and properties

of polymeric associates. This opens up new ways to rational use of Na-CMC, and the complexation itself can be regarded as modification and size control methods for this common polymer. Examination of molecular complexes of natural polymers allows understanding of the contribution of intermolecular interactions to the specific structure and properties of the complexes.

CONCLUSIONS

(1) Aqueous solutions of sodium carboxymethyl cellulose are thixotropic systems. Introduction of urea-formaldehyde oligomers into Na-CMC solutions results in the degeneration of the thixotropic effect.

(2) Aqueous solutions of polycomplex gels demonstrate a considerably lower structural stability as compared to Na-CMC solutions, which is due to the weaker intermolecular interactions in the polymer–oligomer complex.

(3) The structural units in the polycomplex gels are considerably larger than those in NaCMC solutions. At a high shear stress, simultaneous degradation of the polycomplex and polycomplex gel takes place through breakdown of the intermolecular associates.

Abstract—Rheological method was used to study structural-mechanical properties of a solution of starch gelatinized in a two-stage rotary-pulsatory apparatus with a combined operation principle.

DOI: 10.1134/S1070427208020304

Starch is a natural annually replenishable low-cost biopolymer whose physicochemical properties can be easily modified to satisfy requirements of particular industries. Recently, it has been finding steadily increasing use in techniques for synthesis of new biodegradable materials, hybrid nanobiocomposites, and "smart" biopolymeric systems, e.g., electrorheological fluids. Synthesis of liquid-phase materials based on natural starch necessarily involves a prolonged and energy-intensive process of gelatinization of biopolymer grains. The physical treatments conventionally used for starch gelatinization (heating and pressurization) fail to provide the prescribed degree of disintegration of the crystal structure formed by amylopectin and amylose in a starch grain. Therefore, chemical compounds, environmentally hazardous splitters, are frequently additionally used when transferring starch polysaccharides into solution.

In this communication, a new alternative ecologically safe energy- and resource-saving way to obtain jellies and colloid starch solutions is suggested. The method consists in that starch suspensions are treated in a two-stage rotary-pulsatory apparatus (RPA) with a combined operation principle [1]. In the first RPA stage, the fluid flow moving along radial channels of the stator is interrupted by the rotating actuators of the rotor. This gives rise to flow pulsations at a frequency of 5 Hz. In the second stage, the fluid flow us subjected to the action of periodically changing shear deformation, whose rate gradient varies within the range $(0.5–5) \times 10^4$ s^{-1}. In the operation of the installation, quite a number of physical phenomena provoking release of a large amount of heat occur in the medium being treated. The combination of the mechanical and thermal treatments of starch dispersions in RPA provides a high degree of gelatinization of biopolymer grains.

At the same time, it is necessary to take into account that mechanical deformations of polymeric, including polysaccharide, solutions can initiate destruction and synthesis of macromolecules, and association and disintegration of structural formations [2, 4]. As a result, the structure and properties of polymer solutions are strongly changed, which is reflected in the structural-mechanical characteristics of these systems.

The aim of this study was to examine rheological properties of colloid solutions of starch, produced by mechanical-thermal treatment of its aqueous dispersions in RPA.

EXPERIMENTAL

As object of study served cornstarch [GOST (State Standard) 7697–82)] with a characteristic viscosity in water of 1.03 dl g^{-1}. To obtain colloid solutions of starch, its aqueous suspensions were heated to 90°C in two ways: on a water bath and in an RPA of original design at a rotor rotation rate of 4000 rpm [rate gradient of shear deformations $(4–4.5) \times 10^4$ s^{-1}]. The content of starch in the systems studied was varied from 3 to 6%.

The rheological studies were carried out on a Reotest-2 rotary viscometer with a set of coaxial cylinders. The shear rate was varied from 1.5 to 1312 s^{-1}. The temperature at which the viscosity was measured was in the range 30–70°C. The measure-

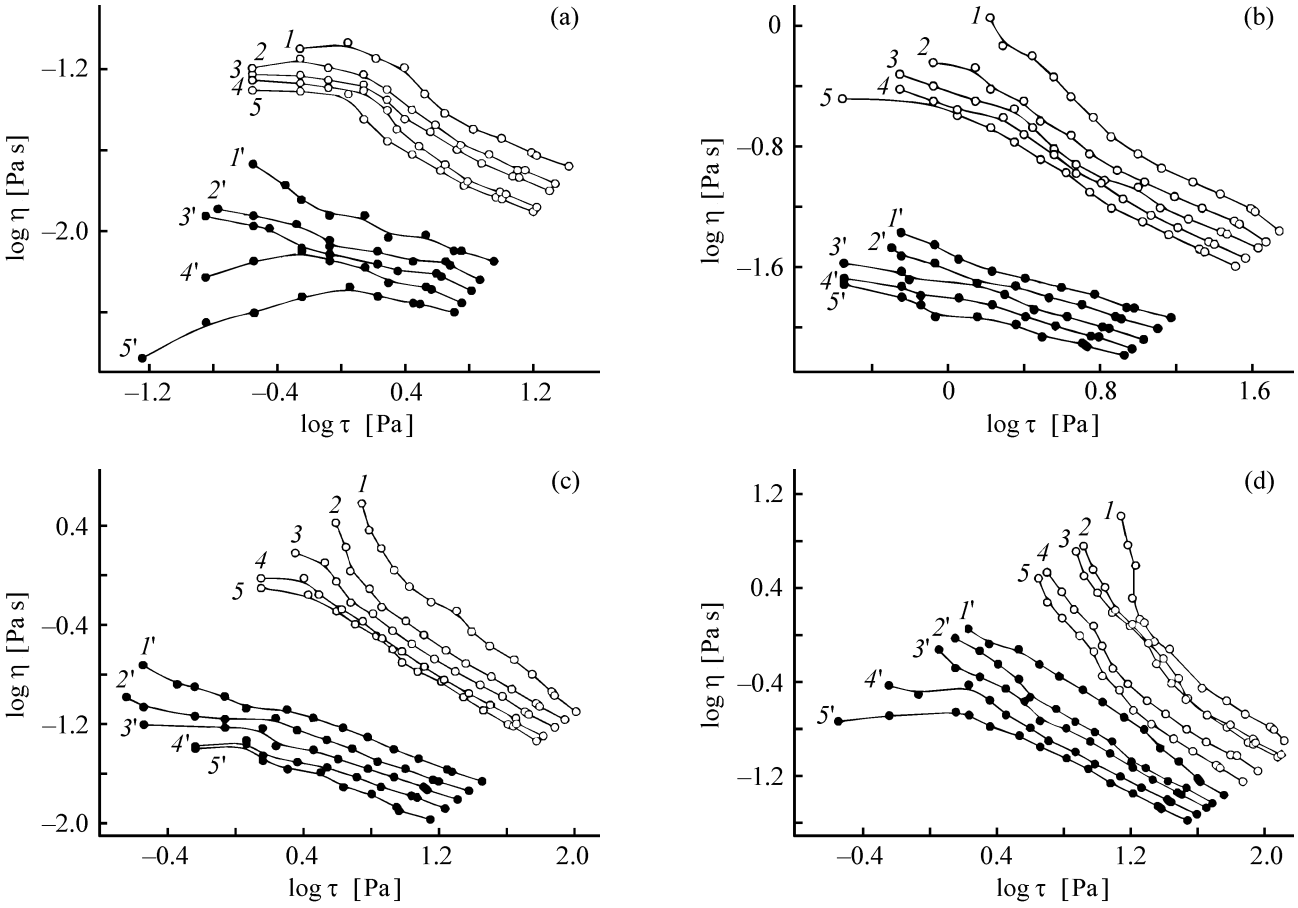

Fig. 1. Viscosity η plotted against the shear stress τ in log–log coordinates for colloid starch solutions produced by (*1*–*5*) thermal and (*1*'–*5*') mechanothermal methods. Temperature of viscosity measurements (°C): (*1*, *1*') 30, (*2*, *2*') 40, (*3*, *3*') 50, (*4*, *4*') 60, and (*5*, *5*') 70. Starch content of a solution (wt %): (a) 3, (b) 4, (c) 5, and (d) 6.

ment accuracy was ±3% according to the ratings of the viscometer.

The relative viscosity was measured at 293 K with a VPZh-2 capillary Ostwald viscometer with a capillary diameter of 1.2 mm. The rms viscosity measurement error was ±0.3%. Gelatinized starch systems were examined with a Biolam microscope.

The resulting values of the shear stress and viscosity were used to plot flow curves of gelatinized starch systems (Fig. 1). The rheograms of samples prepared by the conventional method confirm the known fact of a non-Newtonian flow of colloid starch solutions. A similar behavior in deformation is also characteristic of solutions of the biopolymer gelatinized in RPA. For both sets of the samples studied, the viscosity increases with the concentration of starch in the system.

A distinctive feature of the rheological properties of starch solutions obtained in RPA is that the shear stress and effective viscosity are low. In addition, these solutions with a starch content of 3% behave at high temperatures as dilatant fluids for which the viscosity characteristically increases with the shear stress.

The dilatant properties of colloid systems are attributed to presence in their structure of aggregates with weak interparticle interactions [5]. Aggregates of this kind can easily disintegrate to separate particles, which become closer as the shear rate increases, with the number of contacts between these particles growing to give a network of bonds that is stronger than the initial network. Such an enhancement of interparticle interactions in a colloid solution or jelly occurs to a certain limit, above which there already are no conditions for structural rearrangements. Therefore, the viscosity of colloid systems starts to decrease as the shear deformation rate increases further. It should be noted that the structural rearrangement in a colloid solution or jelly occurs markedly easier at a high temperature of rheological measurements.

Rheological parameters of the starch solutions studied (viscosity measurement temperature 30°C)

Starch content, wt %	Gelatinization method	Viscosity, Pa s		Dynamic yield point P_{k2}, Pa
		$\eta_{1.5}$	η_{1312}	
3	Thermal	–	0.020	1.1
	Mechanothermal	–	0.007	0.3
4	Thermal	1.14	0.040	19.2
	Mechanothermal	–	0.010	0.7
5	Thermal	3.79	0.070	35.8
	Mechanothermal	0.19	0.020	3.6
6	Thermal	10.24	0.100	52.0
	Mechanothermal	1.13	0.040	16.4

The conventional heating of starch suspensions to 90°C leads to formation of highly structured colloid systems in which the dispersed phase is a mixture of swollen grains, fragments of disintegrated grains, and retrograded starch [6]. A combined mechanical and thermal treatment presumably makes higher the degree of disintegration of polysaccharide aggregates of gelatinized starch. The resulting colloid solution of starch is a highly dispersed system with weak interparticle interactions. Under the conditions providing easy structural rearrangements (high temperatures and low biopolymer concentrations), a system of this kind behaves as a dilatant fluid.

The degree of structuring and strength of interparticle interactions in the samples under study can be evaluated using the rheological parameters listed in the table. It is believed that a colloid solution or jelly is the stronger, the larger the difference between the viscosity of an intact structure (η_0) and that of the structure disintegrated to the maximum extent (η_m) and the higher the dynamic yield point P_{k2} corresponding to overcoming of the elasticity of the structure and to the onset of its plastic flow [7, 8]. Because the method for evaluating the rheological properties on the Reotest-2 instrument made it possible to obtain only a limited part of the flow curve of the samples studied, the table lists the effective viscosities at the minimum and maximum shear rates $\eta_{1.5}$ and η_{1312} possible for the viscometer.

It can be seen that, as the concentration of starch in the systems under study increases, the values of the parameters listed in the table steadily grow. On

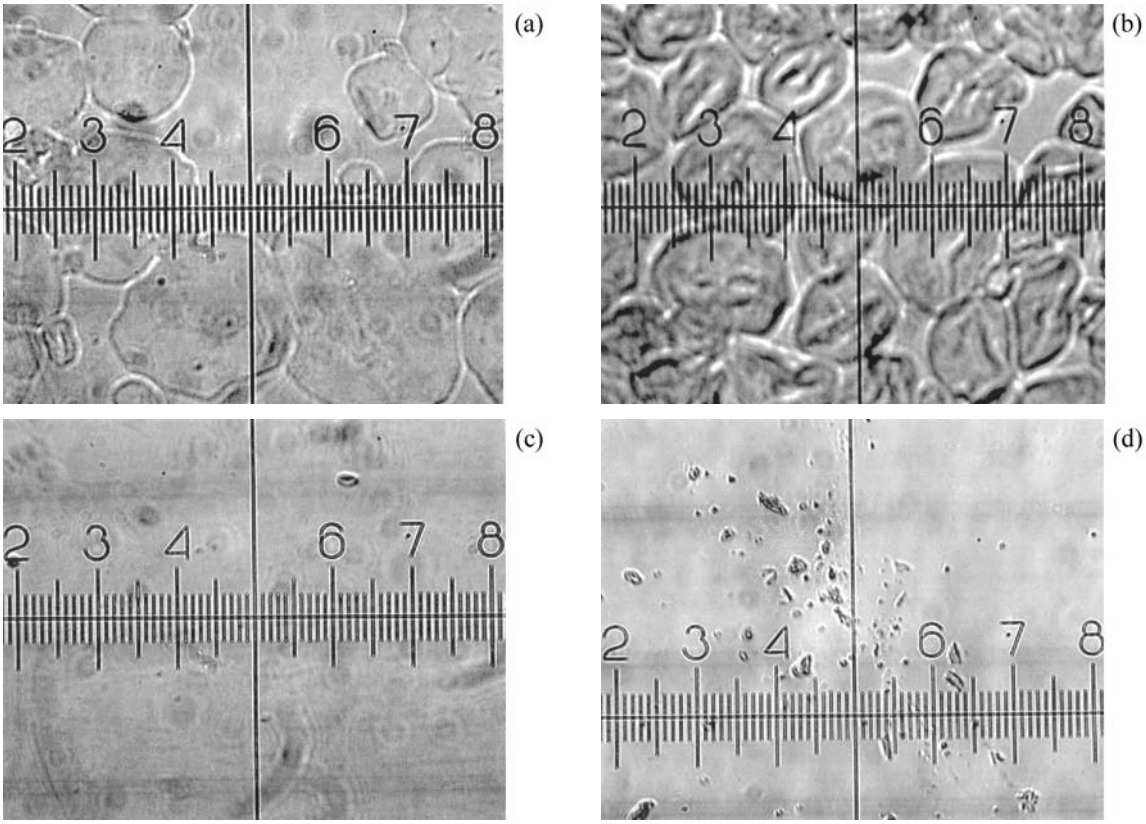

Fig. 2. Micrographs of colloid starch solutions produced by (a, b) thermal and (c, d) mechanothermal methods. Microscope scale division value 2.8 μm. Starch content of the solution (wt %): (a, c) 3 and (b, d) 6.

the whole, analysis of these data confirms the conclusion about the poor strength of the network of bonds formed by particles of starch gelatinized by the mechanothermal method. The absence of values of $\eta_{1.5}$ for 3 and 4% colloid starch solutions obtained in the RPA is an additional evidence in favor of the low degree of their structuring.

A possible reason why the structure of gelatinized starch systems becomes weaker on passing from the conventional to mechanothermal method of their synthesis is destruction of the polysaccharides of the biopolymer. Analysis of this process assumes that the degree of polymerization of macromolecules of starch subjected to gelatinization by the methods mentioned should be recorded. As is known, this is an extremely difficult experimental task. However, it has been confirmed in a number of scientific publications that determining the degree of starch destruction from changes in the viscosity of solutions containing no more than 0.5 wt % biopolymer is justified [9, 10]. This approach is based on the fact that the probability of interaction between polymer macromolecules in dilute solutions is low and, therefore, there are no supramolecular formations. Consequently, the viscosity of such systems is determined by the molecular mass of the polymer and is independent of the solution structure.

It was found that the relative viscosity of the 0.5 wt % starch solution produced by the conventional thermal method is 22, and that of a solution obtained in RPA is 17.3. These results can be regarded as evidence that, with RPA, heating of a biopolymer suspension to 90°C is accompanied by its mechanically initiated destruction, which results in that associates of macromolecules, forming the supramolecular structure of the colloid starch solution, decrease in size.

The conclusion that particles of starch gelatinized in RPA are highly dispersed is also confirmed by micrographs of colloid solutions containing 3 and 6 wt % biopolymer (Fig. 2). Swollen starch grains are clearly seen in the structure of systems obtained by heating starch suspensions on a water bath. Gelatinization of biopolymer grains by mechanochemical treatment leads to another situation, specifically, to a substantial decrease in the average size of particles of the dispersed phase. Grains of starch disintegrate upon its gelatinization in RPA in such a way that the texture of a colloid solution, observed in the light field of the microscope, virtually completely disappears. To conclude, it is important to note that the weak structuring and considerable dispersity of colloid starch solutions are necessary for obtaining functional composites with high adhesive and film-forming capacity.

CONCLUSIONS

(1) It is advisable to obtain colloid starch solutions in a rotary cavitation generator without additional supply of heat.

(2) Integrated action of mechanical deformations and heat, created in the rotary cavitation generator, provides deep disintegration of starch grains. This leads to formation of colloid biopolymer solutions with low degree of structuring.

Abstract—The behavior of 2-methylquinoxaline in the course of oxidative ammonolysis on V–Ti oxide catalyst in a wide range of conditions was studied, and this reaction was examined as a route to 2-quinoxalinecarbonitrile.

DOI: 10.1134/S1070427208020316

Quinoxalines, or benzopyrazines, form an important group of heterocycles. They exhibit a broad spectrum of biological activity, including antibacterial, antitumor, fungicidal, and antiviral activity [1–3].

Interest in oxidative transformations of quinoxalines is due to the fact that the oxidation products can be used as starting compounds for preparing various drugs by more efficient procedures than multistep methods of classical organic chemistry.

As investigation object we chose readily accessible 2-methylquinoxaline synthesized by condensation of *o*-phenylenediamine with α-isonitrosoacetone [4]:

The majority of studies devoted to oxidation of quinoxalines are concerned with transformations of substituents at both benzene and pyrazine rings. Some papers deal with various procedures for preparing quinoxaline *N*-oxides showing pronounced biological activity. There are also papers reporting on oxidation of quinoxalines with the aim to obtain pyrazine derivatives, in particular, pyrazinecarboxylic acid [3, 4].

It seemed interesting to perform oxidative ammonolysis of 2-methylquinoxaline as a possible route to 2-quinoxalinecarbonitrile, a synthetic precursor of new compounds of the quinoxaline series. As catalyst we used the system $V_2O_5 : TiO_2 = 1 : 8$ [5]. The starting compound was fed as a solution in aqueous ammonia.

The process parameters were as follows: temperature 320–460°C; amounts of ammonia and water 2.5–12.5 and 35–48 mol per mole of 2-methylquinoxaline, respectively; contact time 0.3–2.0 s.

The reaction products were trapped in an airlift absorber filled with chloroform. The products were separated by column chromatography on silica gel, eluent hexane–chloroform, 6 : 1.

Gas-chromatographic and spectral studies showed that the catalyzates from oxidative ammonolysis of 2-methylquinoxaline contained unchanged starting compound, 2-quinoxalinocarbonitrile, quinoxaline,

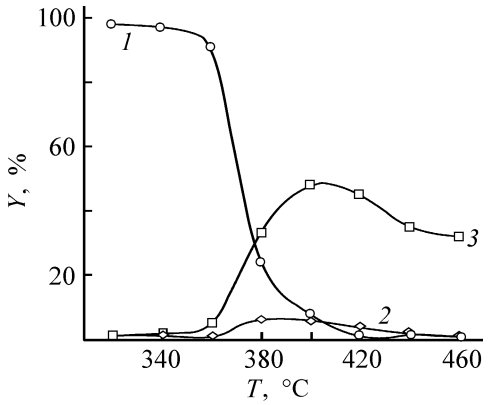

Fig. 1. Yield *Y* of products of oxidative ammonolysis of 2-methylquinoxaline in the presence of the catalyst $V_2O_5 : TiO_2$ vs. temperature *T*. Amounts of NH_3 and H_2O 12.5 and 35 mol per mole of 2-methylquinoxaline, respectively; contact time 0.7 s. (*1*) 2-Methylquinoxaline, (*2*) quinoxaline, and (*3*) 2-quinoxalinecarbonitrile; the same for Figs. 2 and 3.

and C_1 products (carbon oxides, ammonium cyanide). It should be noted that, in contrast to oxidative ammonolysis of 2-methylpyrazine [6], the reaction was not accompanied by hydrolysis of the 2-cyano derivative to the corresponding amide.

The ratio of the catalyzate components and the degree of conversion of the starting compound largely depend on the process parameters. As the reaction temperature is raised from 320 to 460°C at a constant ratio of the reactants (2-methylquinoxaline, ammonia, water) and constant contact time, the conversion of the starting compound steadily increases, becoming virtually quantitative at 420°C (Fig. 1). The yield of the major reaction product, 2-quinoxalinecarbonitrile, first considerably grows, reaching 50% at 400°C, but at higher temperatures it decreases because of the increased contribution of degradation processes yielding quinoxaline and products of deep oxidation: carbon oxides and ammonium cyanide.

As the contact time is made longer than 0.7 s, the contribution of the undesirable reactions grows, and quinoxaline becomes the major product: Its yield increases from 5 to 60% (Fig. 2).

The above specific features of the behavior of 2-methylquinoxaline in the course of oxidative ammonolysis well correlate with the data previously obtained for 2-methylpyridine [7, 8] and 2-methyl-5-ethylpyridine under similar conditions: The presence of water vapor in the contact zone favors removal of the methyl substituent in the *o*-position relative to heterocyclic nitrogen [9].

This conclusion is confirmed by experiments with a varied concentration of the aqueous ammonia solution fed to the reaction zone (Fig. 3). The lower the ammonia concentration (i.e., the larger the amount of water),

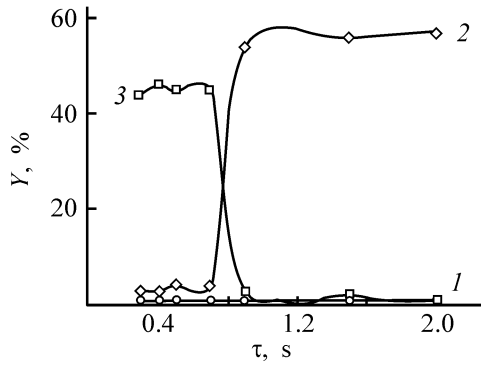

Fig. 2. Yield *Y* of products of oxidative ammonolysis of 2-methylquinoxaline in the presence of the catalyst $V_2O_5 : TiO_2$ vs. contact time τ. *T* = 420°C, amounts of NH_3 and H_2O 12.5 and 35 mol per mole of 2-methylquinoxaline, respectively.

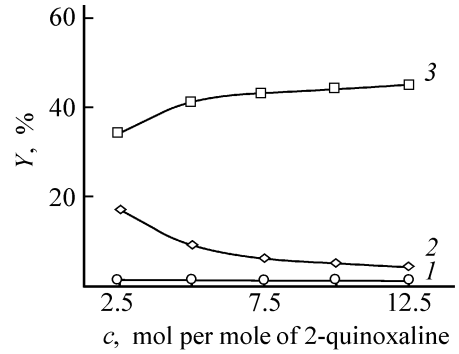

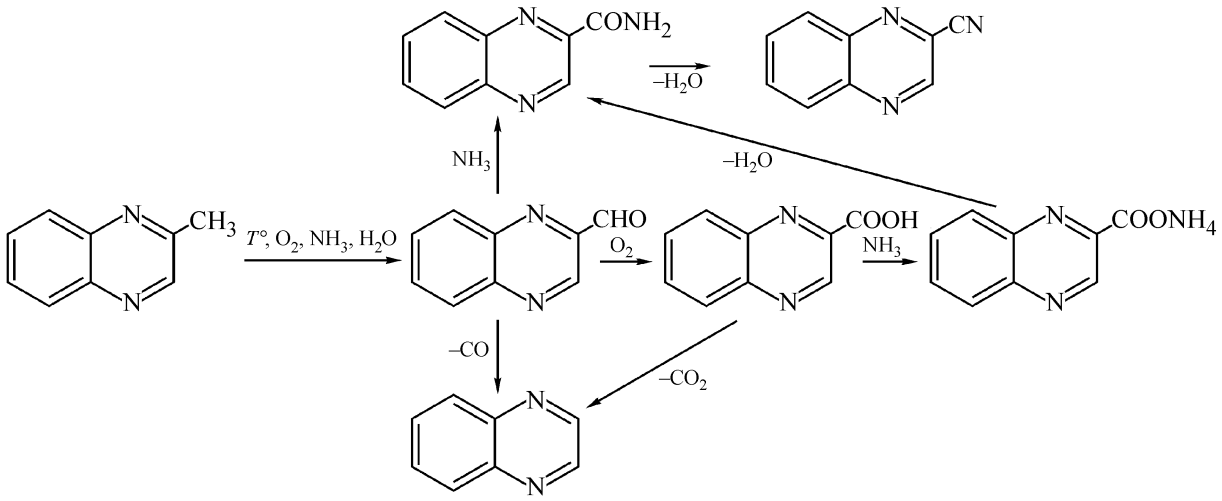

Fig. 3. Yield *Y* of products of oxidative ammonolysis of 2-methylquinoxaline in the presence of the catalyst $V_2O_5 : TiO_2$ vs. ammonia amount *c*. *T* = 420°C, τ = 0.7 s.

Scheme of transformations of 2-methylquinoxaline in the course of oxidative ammonolysis.

the higher the yield of quinoxaline. This trend is due to an increased contribution of the reaction pathways yielding aldehydes and acids, which have no time to react with ammonia under the reaction conditions and undergo decarbonylation and decarboxylation.

Based on the results obtained and conclusions made in the above-cited papers, we suggest a scheme of 2-methylquinoxaline transformations under the conditions of oxidative ammonolysis (see Scheme).

Thus, oxidative ammonolysis of 2-methylquinoxaline shows promise as a route to 2-quinoxalinecarbonitrile, taking into account the accessibility of 2-methylquinoxaline and the simplicity of the process, compared to the known procedures for preparing nitriles of the quinoxaline series, which are, as a rule, multistep and require difficultly available chemicals [3, 10].

CONCLUSION

A procedure for one-step preparation of 2-quinoxalinecarbonitrile in ~50% yield was suggested.

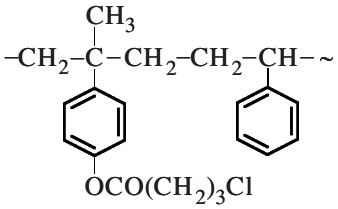
Received June 20, 2007

Abstract—Free-radical cooligomerization of a new polyfunctional monomer, *p*-isopropenylphenyl γ-chlorobutyrate, with styrene was studied.

DOI: 10.1134/S1070427208020328



Functionalization of oligomers of α-methylstyrene and its analogs and derivatives is a promising line of the modern petrochemistry and polymer chemistry, expands possible applications of oligomers.

In view of the relative simplicity of the process for preparing *p*-isopropenylphenol and its esters and because of the lack of data on their chemical modification, it becomes topical to develop new procedures for functionalization of oligomers by copolymerization or copolycondensation with various monomers.

In this study, we examined free-radical cooligomerization of a new polyfunctional monomer, *p*-isopropenylphenyl γ-chlorobutyrate (IPCB), with styrene. We found that IPCB does not undergo homopolymerization or any other transformations when heated at 80–140°C for 30 h. In this respect, it behaves similarly to α-methylstyrene and its derivatives substituted in the aromatic ring.

The IR spectra of the cooligomers contain a strong band at 1740 cm^{-1} belonging to the carbonyl group of IPCB. The band at 1490 cm^{-1} is characteristic of a skeleton vibration of the benzene ring in the styrene unit. The bands at 1630 and 890 cm^{-1}, characteristic of the double bond, are lacking.

Comparison of the optical densities of the bands at 1250 and 1510 cm^{-1} in the spectra of the monomer and cooligomer shows that the cooligomerization occurs exclusively at the ethylene bond and the structure of the cooligomers prepared can be presented as follows:

The cooligomer is a white powder soluble in aromatic hydrocarbons, chloroform, and CCl_4, but insoluble in alcohol and hexane. All the samples of the cooligomers have amorphous structure.

With the aim to find the optimal conditions providing virtually complete conversion of the monomers, we examined the effect of temperature, amount of the initiator, cooligomerization time, and monomer ratio on the yield and properties of the cooligomers.

We found that an increase in the cooligomerization temperature to 140°C leads to acceleration of the process and favors formation of the cooligomers of lower viscosity (Fig. 1a). The accumulation rate and yield of the cooligomers are also strongly affected by the amount of the initiator, *tert*-butyl peroxide (TBP). At its concentration in the mixture equal to 0.2%, the conversion of the monomers at 120°C reaches 97% in 15 h (Fig. 1b). The influence of the monomer ratio on the cooligomerization was studied at 120°C. The ester : styrene molar ratio was varied from 1 : 2 to 1 : 10. We found that an increase in the styrene concentration in the monomer mixture accelerated the reaction, and a 97–99% conversion was reached in 15 h (Fig. 1c).

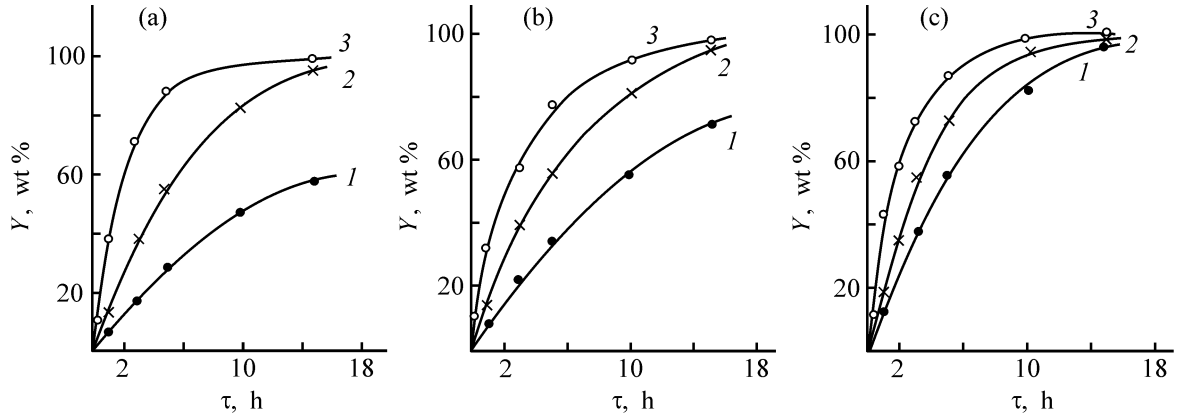


Fig. 1. Yield Y of cooligomers vs. time τ: (a) IPCB : styrene molar ratio 1 : 2, initiator (TBP) concentration 0.2 wt %; T, °C: (*1*) 100, (*2*) 120, and (*3*) 140. (b) IPCB : styrene molar ratio 1 : 2, T = 120°C; initiator (TBP) concentration, wt %: (*1*) 0.5, (*2*) 0.2, and (*3*) 0.1. (c) Initiator (TBP) concentration 0.1 wt %, T = 120°C; IPCB : styrene molar ratio: (*1*) 1 : 2, (*2*) 1 : 5, and (*3*) 1 : 10.

Experiments on fractionation and cross-linking of the cooligomers showed that the homopolymers were not formed. To determine the cooligomerization constants of IPCB (M_2) with styrene (M_1), we performed the reaction for the time providing low (~5%) conversion of the monomers. The composition of the cooligomers (Table 1) was determined from the optical densities of the absorption bands of the monosubstituted benzene ring (1490 cm^{-1}) and carbonyl group of IPCB (1740 cm^{-1}), using the previously obtained calibration curve of the ratio of the optical densities D_{1490}/D_{1740} vs. the ratio of styrene and IPCB units in the cooligomers prepared at complete conversion of the monomers. We found the following copolymerization constants: $r_1 = 2.4 \pm 0.76$, $r_2 = 0.00$ (Table 1).

The characteristics of the cooligomers with various contents of IPCB units are listed in Table 2. The characteristics of polystyrene prepared under identical conditions are given for comparison. It can be seen that, as the IPCB content of the cooligomer increases, the softening (T_s) and dropping (T_d) points and the reduced viscosity (η_r) decrease. The dielectric strength also decreases and the melt flow index increases, showing that IPCB units in the cooligomer chain exert a plasticizing effect. The strength of adhe-

sion of the cooligomers to steel reaches a maximum, 32 kg cm^{-2}, at 1 : 2 molar ratio of IPCB to styrene. The dielectric strength of the cooligomers approaches that of polystyrene.

EXPERIMENTAL

p-Isopropenylphenol (IPP) was prepared by homogeneous-catalytic cracking of bisphenol [1]; IPCB was synthesized by the reaction of IPP with γ-chlorobutyric acid, following the protocol from [2]. The monomers were purified by the standard procedure and had the following constants: IPCB, bp 150°C/1 mm Hg, n_D^{20} = 1.5368, d_4^{20} = 1.0987 g cm^{-3}; styrene, bp 26.5°C/5 mm Hg, n_D^{20} = 1.5462, d_4^{20} = 0.9060 g cm^{-3}. The monomers were 99.95% pure.

The cooligomerization of IPCB with styrene was performed in sealed ampules under argon in the presence of TBP at 120 and 140°C. The monomers and initiator were placed in ampules and degassed by triple freezing–pumping–thawing, the system was purged with purified argon, and the ampules were sealed and placed in an ultrathermostat.

The products were separated from the unchanged monomers by precipitation from a benzene solution into hexane. The precipitated cooligomer was dried in a vacuum at 120°C for 2–3 h to constant weight.

The IR spectra of the cooligomers were taken from thin films on a KRS-5 plate with a UR-10 spectrophotometer in the range 4000 – 650 cm^{-1}.

The reduced viscosity of the synthesized cooligomers was measured in benzene (0.5% solutions). Also, we determined the softening and dropping points, Brinell hardness, adhesion (shear test), dielectric strength of the coating on metal, and melt flow index (at 200°C and a load of 5 kg). The samples were heated at a rate of 4 deg min^{-1}. The cooligomer compositions were determined by IR spectroscopy. The cooligomerization constants were calculated by the Fineman–Ross method.

CONCLUSIONS

(1) New cooligomers of *p*-isopropenylphenyl γ-chlorobutyrate with styrene were prepared and characterized.

(2) The optimal conditions providing complete conversion of the monomers were determined.

Received December 25, 2007

Abstract—1,1,5-Trihydrooctafluoropentyl dehydroabietate was prepared by esterification of dehydroabietic acid with 1,1,5-trihydrooctafluoropentanol.

DOI: 10.1134/S107042720802033X

Rosin esters are widely used in the production of varnishes, paints, and adhesive composites, thanks to diversity of their properties dependent on the kind of a raw material and alcohol [1]. The use of straight rosin for this purpose is restricted by its acidity, low melting point, poor moisture resistance, and tendency toward polymerization [2].

To impart water- and oil-repellent properties to fibers and paper, these materials are treated with compounds containing long-chain fluoroalkyl groups in their molecule. This treatment is efficiently used in industry. Furthermore, fibrous materials treated with fluorinated compounds almost fully preserve their gas permeability, softness, color, strength, and other characteristics [3].

Therefore, the development of new fluorinated compounds based on esters of rosin and polyfluorinated telomeric alcohols for treatment of fibrous materials is a promising line of organic synthesis.

Various procedures for preparing esters from resin acids of rosin and various alcohols have been reported [4–7], but these do not include esterification with polyfluorinated telomeric alcohols.

The goal of this study was to synthesize of 1,1,5-trihydrooctafluoropentyl dehydroabietate, a potentially effective hydrooleophobizing agent for fibrous materials. As synthesis procedure we chose esterification of dehydroabietic acid with 1,1,5-trihydrooctafluoropentanol in the presence of catalytic amounts of concentrated sulfuric acid.

The promising source of dehydroabietic acid is tall rosin, a by-product from kraft pulp production. The ester is a noncrystallizing red-brown resinous substance.

EXPERIMENTAL

The ^{1}H and ^{19}F NMR spectra of the dehydroabietic acid ester were recorded on a Bruker WH-400 spectrometer (400.13 MHz) from 5% solutions in $CDCl_3$. The chemical shifts were determined relative to internal reference, tetramethylsilane (^{1}H) and trifluoroacetic acid (^{19}F).

The purity of the starting dehydroabietic acid and the reaction progress were monitored by TLC on Silufol UV 254 plates (eluent hexane–methylene chloride–acetone, 1 : 1 : 0.5).

Dehydroabietic acid was recovered from tall rosin (Segezha Pulp and Paper Combine, Karelia, Russia) by the procedure described in [9].

Synthesis of 1,1,5-trihydrooctafluoropentyl dehydroabietate. To a solution of 3 g (9.9×10^{-3} mol) of dehydroabietic acid in 50 ml of hexane, we added 1.6 ml (11.5×10^{-3} mol) of 1,1,5-trihydrooctafluoropentanol and a catalytic amount of concentrated sulfuric acid. The reaction mixture was stirred for 10 h at 70°C and then cooled to room temperature. The solvent was distilled off at reduced pressure (5 mm Hg), the reaction mixture was extracted with ether, and the extract was washed with water to neutral reaction and dried over $MgSO_4$. The solvent was removed on a rotary evaporator, and the product was dried in a vacuum. Yield of the ether 80–85%.

^{1}H NMR spectrum, δ, ppm: 7.2 d, 7.0 d ($-C_{ar}H=C_{ar}H-$, $^3J_{HH}$ 21 Hz); 6.89 s ($=C_{ar}H-$); 5.9 t (HCF_3-, $^2J_{HF}$ 52 Hz); 4.5 m ($-OCH_2CF_2-$, $^3J_{HF}$ 14 Hz). ^{19}F NMR spectrum, δ_F, ppm: –124.3 s, –127.2 s, –132 s ($-C^{2-4}F_2-$); –139.5 d (F_2CH-, $^2J_{HF}$ 50 Hz).

CONCLUSION

A procedure was suggested for preparing 1,1,5-trihydrooctafluoropentyl dehydroabietate by direct esterification in the presence of concentrated sulfuric acid.

Received May 16, 2007

Abstract—Corrosion-electrochemical behavior of aluminum and a samarium-alloyed aluminum–manganese alloy of eutectic composition in a neutral aqueous medium was studied.

DOI: 10.1134/S1070427208020341

Owing to the positive effect on a number of most important properties of industrial alloys, rare-earth metals (REM) find use in a number of industries: metallurgy of nonferrous and ferrous metals, electronics, and nuclear power engineering. Addition of REM in an amount of 0.5% improves the strength and hardness of aluminum alloys and simultaneously raises the relative elongation by a factor of 1.5–2; at higher REM contents, aluminum alloys acquire heat-resistant properties [1]. Therefore, a study of corrosion-electrochemical properties of aluminum (and its alloys) with addition of REM is of particular scientific and practical interest.

The available published data on the corrosion resistance of aluminum and its alloys alloyed with rare-earth metals are scarce. As a rule, cerium and yttrium are used most frequently, and other REM, considerably more rarely [2–5]. That is why samarium was chosen as object of study.

It is known that light REM, from lanthanum to samarium, have a more complicated hexagonal structure, whereas heavy REM crystallize in an ordinary hexagonal close-packed lattice. Samarium is markedly distinctive in this regard: it crystallizes in a rhombohedral lattice [6].

It is known that REM (R) interact with aluminum to give a number of intermetallic compounds, of which phases of composition RAl_4 are in equilibrium with an aluminum solid solution. It has been found that no compound of the type RAl_4 exists in the system Sm–Al, in contrast to the systems Al–La, Al–Pr, Al–Ce, and Al–Nd [6]. Similarly to diagrams of most of REM, the phase diagram of Al–Sm shows formation of a eutectic $l \rightarrow Al + SmAl_3$ on the aluminum side at a temperature of 633°C and samarium content of 15%. The solubility of samarium in solid aluminum is low (< 0.10 wt %) [7].

REM-containing aluminum alloys are difficult to synthesize because the components introduced into aluminum have a high chemical activity, and the melting points of numerous binary and ternary alloys substantially exceed those of the pure components. It is known that alloying of aluminum with manganese diminishes the adverse effect of impurities, because of the formation of intermetallic compounds with a sufficiently negative electrode potential, and thereby improve the protective properties of the oxide film.

The aim of this study was to synthesize and examine the effect of samarium on the corrosion-electrochemical properties of aluminum and aluminum–manganese eutectic Al–Mn (1.9%) in a neutral aqueous medium.

EXPERIMENTAL

With account of the diagrams of state of Al–REM [7], alloys for study were obtained so as to cover the regions of solid solutions of REM in aluminum and pre-eutectic alloys whose structure is constituted by primary precipitates of the aluminum solid solution and a eutectic of composition α-Al + $SmAl_3$. The chemical-structural homogeneity, dependent on the solubility and distribution coefficient of the alloying elements (manganese and samarium) in the base metal (aluminum), predetermines the uniformity and stability of its electrochemical properties. homogeneity, alloys (10% aluminum–manganese and 15% Al–Sm based on A995 aluminum) were obtained in corundum crucibles at temperatures of 900–1000°C. Cylindrical rods (8 mm in diameter and 100 mm long) were cast in a heated graphite mold. Before being submerged in the electrochemical cell, the rods were ground, polished to mirror shine, washed with distilled water, and degreased with ethanol.

The corrosion-electrochemical studies were carried out using a PI 50-1 potentiostat with a preset program by the procedure described in [8] at a potential sweep rate of 2 mV s^{-1}. A prepared sample of an aluminum alloy was placed in the 3% NaCl solution under study. In the electrochemical cell, a silver chloride electrode served as reference, and platinum as auxiliary electrode. The potentials are given relative to the silver chloride electrode. The solution temperature of 20°C was maintained with a thermostat. The following electrochemical parameters were determined using the polarization curves obtained: free corrosion potential E_{fc} and the pitting potential and current, E_{pit} and i_{pit}, from the forward-run anodic polarization curve; repassivation potential E_{rp}, graphically from the reverse-run anodic curve; corrosion potential and current, E_{cor} and i_{cor}, corresponding to the potential at which the cathodic branch appears; passivation onset potential E_{po}; pitting potential in the absence of a natural oxide film on the surface, E'_{pit}, and the corresponding dissolution current in the repassivation region, $i_{d.rp}$, from the repeated anodic polarization curve. Then, the passivation interval ΔE_{pas} was calculated as the difference of the full passivation potential and E'_{pit}. The basic indicator of the corrosion stability, corrosion rate K (g m^{-2} h^{-1}), was calculated from the corrosion current found from the cathodic polarization curve (with a Tafel slope b_c = 0.12 V), using the formula

$$K = i_{cor}\, k,$$

where k is the electrochemical equivalent whose numerical value for aluminum is 0.335 g A^{-1} h^{-1} [9].

The results of the study are listed in the table.

The figure shows how the corrosion rate K (g m^{-2} h^{-1}) of the aluminum alloy (curve *1*) and alu-

Effect of the samarium content c on the corrosion rate K of (*1*) aluminum and (*2*) aluminum–manganese alloy of eutectic composition in 3% NaCl solution.

minum–manganese alloy of eutectic composition (curve *2*) depend on the samarium content *c* (wt %). It can be seen that the main changes in the corrosion rate are observed at samarium contents lower than 0.2%; further increase in the content of samarium has virtually no effect on the corrosion rate.

As can be seen from the figure, the runs of both the curves are identical. For example, the corrosion rate is at a minimum at a samarium content of 0.05%. However, the corrosion rate in the presence of manganese is 1.5 times lower. Further increase in the content of samarium leads only to a slight increase in the corrosion rate, with the rise beginning at 0.1% Sm for binary alloys and 0.2% Sm for alloys of the ternary system.

The facilitation of passivation processes and the improvement of the corrosion resistance of an alloy under study via amorphization may be due to a change in its microstructure. For example, a decrease in the grain size because of the modification with samarium improves the corrosion resistance of aluminum and its alloy, because the passivation process becomes more efficient.

The process of aluminum oxidation is decelerated as the potential is shifted to more negative values. The activation of the alloy is enhanced as the content of REM (samarium) in the alloy increases. Thus, the following can be noted when characterizing the effect of samarium on the corrosion-electrochemical behavior of aluminum.

(1) The free-corrosion potentials of the alloys under study (binary and ternary systems) are in the passivation region.

(2) The potentials of free corrosion, pitting, and corrosion are shifted to more positive values as a result of alloying with samarium. A similar shift occurs for the eutectic alloy Al + 1.9% Mn, with only a slight shift of the corrosion potential to more negative values.

(3) Alloying of aluminum with samarium makes lower the pitting and dissolution currents in a transition from the passive state. For the aluminum–manganese alloy, these parameters decrease by virtually a factor of 2.

(4) Introduction of samarium extends the passivation interval of the alloys and improves their corrosion resistance.

CONCLUSIONS

(1) It was shown that, similarly to other REM (Ce, Y, Pr, Nd), samarium is an effective modifier for aluminum and an aluminum–manganese alloy of eutectic composition.

(2) The optimal compositions of corrosion-resistant binary and ternary alloys of the systems Al + 0.05% Sm and Al + 1.9% Mn + 0.05% Sm in a neutral chloride-containing medium were determined

Abstract—Postpolymerization of the epoxy–acrylic oligomer derived from an aliphatic epoxy resin was studied.

DOI: 10.1134/S1070427208020353

The first report on a posteffect is apparently dated 1938 [1]; the effect was observed in photopolymerization of methyl methacrylate. By now postpolymerization effects have been reported for all vinyl monomers and oligomers. In all the cases, the point is that long-lived radicals with a lifetime of several minutes to tens of hours are formed [2–4].

Epoxy–acrylic oligomers are characterized by high photopolymerization rates, which complicates studying their curing kinetics. Therefore, examination of posteffects in photoinitiated polymerization of epoxy–acrylic oligomers makes it possible to relatively readily derive information valuable for describing the process as a whole.

EXPERIMENTAL

In our study we used epoxy–acrylic oligomer formed by esterification of an aliphatic diepoxide [DEG-1, TU (Technical Specification) 6-05-1747–76] with acrylic acid (AA). The structure of the oligoether acrylate [α,ω-bis(1-acryloyloxy-2-hydroxyprop-3-yl)-oligooxyethylene] CH_2=CHCOOCH$_2$CH(OH)–CH$_2$–[–O–CH$_2$CH$_2$OCH$_2$CH$_2$–O–CH(OH)–CH$_2$–]$_n$–OOC–CH=CH$_2$ was determined by elemental analysis and by IR and NMR spectroscopy. The polymerization initiators were benzophenone and uranyl sulfoxide complex [5]. The IR radiation source was a DRT-400 medium-pressure mercury lamp. The distance from a substrate being irradiated to the UV source was 0.14 m. The dynamic viscosity was measured with a Reotest 2.1 device. The hydrogen bonds in the oligomer were revealed by ^{1}H NMR spectroscopy. The NMR spectra were recorded on a Bruker AM-300 spectrometer with a working frequency of 300 MHz; the solvent was $CDCl_3$, and the internal reference was TMS. Analysis of the spectra and assignment of the signals were performed by 2*D* NMR correlation spectroscopy (COSY H–H, C–H).

Previously, we have described a posteffect in photosensitized (benzophenone, uranyl sulfoxide complex)

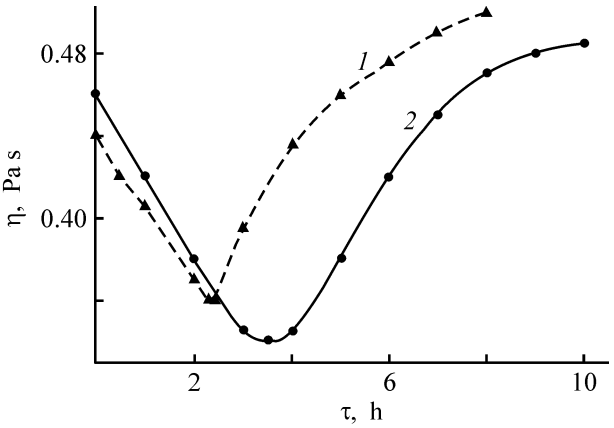

Fig. 1. Variation of the dynamic viscosity η of the epoxy–acrylic oligomer based on DEG-1 aliphatic epoxy resin after UV irradiation for 15 s. (τ) Time. Photoinitiator, M: (*1*) benzophenone, 1.0×10^{-2}; (*2*) $UO_2Cl_2 \cdot 2$DHSO (DHSO is dihexyl sulfoxide), 1.2×10^{-3}.

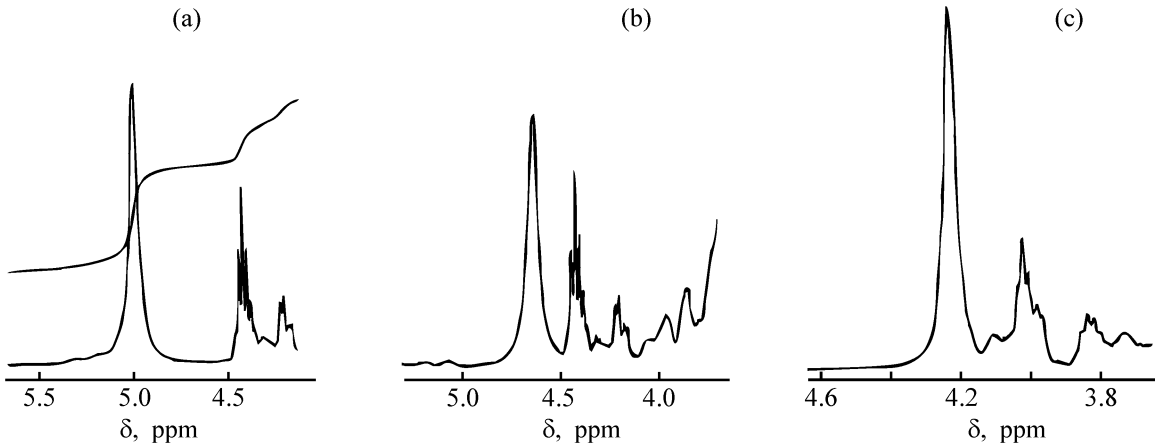

Fig. 2. ^{1}H NMR spectra of the epoxy–acrylic oligomer derived from the aliphatic epoxy resin after UV irradiation for 15 s. (δ) Chemical shift. Oligomer: (a) starting, (b) UV-irradiated, and (c) diluted by a factor of 3.

polymerization of epoxy–acrylic oligomers based on cycloaliphatic and epoxy–4,4'-isopropylidenediphenol resins. The effect consisted in a gradual increase in the dynamic viscosity of the system after a short-term UV irradiation, observed during a long period [5]. This effect was indicative of prolonged postpolymerization owing to the presence of long-lived free radicals in the viscous polymer matrix.

A different pattern is observed under similar conditions with the epoxy–acrylic oligomer, α,ω-bis(1-acryloyloxy-2-hydroxyprop-3-yl)oligooxyethylene synthesized by the reaction of diethylene glycol diglycidyl ether (DEG-1 aliphatic epoxy resin, hydroxy group content 4–5 wt %) with acrylic acid. After a short-term irradiation (15 s), the dynamic viscosity of the oligomer decreases by a factor of 1.2–1.3 over a period of 2.5–3.5 h and only later starts to increase (Fig. 1).

The viscosity increases during a long period (10 h and more), reaching the level exceeding the viscosity of the starting oligomer. In the ^{1}H NMR spectrum of the starting epoxy–acrylic oligomers, the signals of hydroxyl protons are noticeably shifted, suggesting the involvement of these protons in reversible association via hydrogen bonds (downfield shift by 4 ppm and more of hydroxyl proton signals). After UV irradiation or a therefold dilution, the signals are shifted upfield in 2.5–3.5 h, apparently owing to breakdown of the hydrogen-bonded associates of the initial oligomer molecules (Figs. 2a–2c). In the process, the major contribution to variation of the chemical shift of the hydroxyl proton signal is made by variation of the polarity of the O–H bond [6].

Thus, the absorbed of energy UV light is primarily consumed in our case for the breakdown of the supramolecular structure of the oligomer matrix and for the formation of free radicals inducing the postpolymerization. This fact indicates that intermolecular hydrogen bonds should be taken into account in studies of the postpolymerization of certain monomers and oligomers.

CONCLUSION

The postpolymerization of an epoxy–acrylic oligomer formed by the reaction of diethylene glycol diglycidyl ether with acrylic acid is accompanied by a decrease in the dynamic viscosity, due to cleavage of intermolecular hydrogen bonds.

BRIEF COMMUNICATIONS

Effect of *p*-Hydroxydiphenylamine and Boron-Containing Pentaerythritol Esters on Properties of an Ester Oil

Z. V. Mamarasulova and V. V. Gromova

St. Petersburg State Institute of Technology (Technical University), St. Petersburg, Russia

Received June 19, 2007

Abstract—The influence of the amount of incorporated boron on the physicochemical and service properties of a pentaerythritol ester used as a base of aviation oil was examined. The effect of an antioxidant additive, *p*-hydroxydiphenylamine, on the temperature dependence of the oil viscosity was evaluated.

DOI: 10.1134/S1070427208020365

Esters of neopentanepolyols, primarily pentaerythritol, with synthetic fatty acids C_5–C_9 are widely used as synthetic lubricating oils for aviation gas turbine engines, helicopter reduction gears, and other devices with working temperatures of oil equal to up to 200°C. The most important requirements to oils of this kind are high resistance to thermal oxidation, good lubricating, anticorrosive, and protective properties, slightly sloping temperature dependence of the viscosity, and some other standardized parameters [1].

Previously published data indicate that the resistance of pentaerythritol esters to thermal oxidation is mainly determined by the presence of readily oxidizable impurities in the raw material and by the degree of pentaerythritol esterification [2, 3]. The presence of incomplete esters considerably impairs the oil stability. At the same time, it is known that incomplete pentaerythritol esters considerably surpass their complete analogs in the lubricating properties [4].

One of possible ways to enhance simultaneously the resistance of pentaerythritol esters to thermal oxidation, their lubricating properties, and other characteristics is afteresterification of incomplete esters with boric acid. Published data show that boric acid esters exhibit high antifriction, antiwear, and anticorrosive properties, as well as high resistance to thermal oxidation [5]. At the same time, boration of the incomplete esters may alter the physicochemical properties of the oil owing to an increase in the molecular weight of the product or appearance of nonesterified OH groups of boric acid. A certain influence on the physicochemical properties of oil should also be exerted by functional groups of the commonly used antioxidant, *p*-hydroxydiphenylamine (PHDA).

Therefore, our goal was to determine the optimal concentration of boron in pentaerythritol esters and to evaluate the effect of PHDA on the physicochemical characteristics of oil.

EXPERIMENTAL

Boron was introduced into the ester molecule by esterification of free hydroxy groups of incomplete pentaerythritol esters with boric acid. The reaction was performed without a catalyst on a laboratory installation with vacuum separation of water released in the reaction. Reaction conditions: 140°C, 1 h, residual pressure 40 kPa.

The reaction products were characterized by standard methods accepted for testing Efir-2 basic oil with pentaerythritol esters as major components [6] and B-3V commercial aviation oil [1]. The viscosity of the oils was determined in accordance with GOST (State Standard) 33–2000 with a VPZh-4 Pinkevich viscometer with an accuracy of 0.2%. The tribological properties of the samples were estimated with a four-ball friction machine according to GOST 9490–75. The error in determining the wear scar diameter was ±0.1 mm. The resistance to thermal oxidation was tested according to technical specification for B-3V synthetic oil at 200°C for 10 h, at an air flow rate of 50 ml min^{-1} [1]. The oil stability was evaluated by variation of the kinematic viscosity ν at 100 and –40°C, increase in the acid number (AN), and formation of a precipitate insoluble in isooctane.

As starting materials we used pentaerythritol esters (PEEs) of individual monocarboxylic acids and their fractions: caprylic acid ester (PEE C_8), ester of C_5–

C_{10} fatty acid fraction [PEE C_5–C_{10} (lab.)], and ester of the C_5–C_9 fatty acid fraction [PEE C_5–C_9 (imp.)]. The esters PEE C_8 and PEE C_5–C_{10} (lab.) were prepared in laboratory. Their hydroxyl number was 35 (mg KOH) g^{-1}, which is close to the hydroxyl number of Efir-2 basic synthetic oil produced in Russia. The ester PEE C_5–C_9 (imp.) was a sample of imported oil similar to Efir-2, with the hydroxyl number of 5 (mg KOH) g^{-1}.

p-Hydroxyphenylenediamine was added to the cooled product after the synthesis and was dissolved at 60–80°C.

When choosing the PEE : boric acid ratio, we considered the possibility of the reaction of boric acid with one or two molecules of the incomplete pentaerythritol ester:

$$(RCOOCH_2)_3CCH_2OH + H_3BO_3 = (RCOOCH_2)_3CCH_2OB(OH)_2 + H_2O, \quad (1)$$

$$2(RCOOCH_2)_3CCH_2OH + H_3BO_3 = [(RCOOCH_2)_3CCH_2O]_2BOH + 2H_2O. \quad (2)$$

Into PEE with the incomplete ester content corresponding to a hydroxyl number of 35 (mg KOH) g^{-1}, it is possible to introduce up to 1.5 wt % boron by reaction (1) and up to 0.75 wt % boron by reaction (2). At a hydroxyl number of 5 (mg KOH) g^{-1}, up to 0.1 wt % boron can be introduced into the ester.

According to [7], introduction of 0.45 wt % boron into PEE with a hydroxyl number of 40 (mg KOH) g^{-1} decreased the hydroxyl number to 10 (mg KOH) g^{-1}. However, the viscosity of the oil at –40°C increased in this case by more than a factor of 1.5: from 10950 to 16249 $mm^2 s^{-1}$ (the limit prescribed by the standard is 10600 $mm^2 s^{-1}$).

In this study we prepared PEE C_8 with 0.2 wt % boron. The characteristics of the modified ester are compared in Table 1 with those of the initial ester.

The results obtained indicate that introduction of 0.2 wt % boron into PEE also makes the viscosity too high and deteriorates the low-temperature properties of the product.

Published data on the use of oils with boron-containing additives show that the boron content does not exceed hundredths of a percent relative to oil [8]. The effect of boron in a concentration of 0.02–0.04 wt % on the physicochemical parameters of imported PEE C_5–C_9 with a hydroxyl number of 5 (mg KOH) g^{-1} is illustrated by Table 2. Also given are data on the effect of PHDA additive taken separately or in combination with boron.

Table 1. Kinematic viscosity ν and congelation point T_c of the modified ester

Boron content, wt %	ν, $mm^2 s^{-1}$, at indicated temperature, °C		T_c, °C
	–40	100	
–	34.00	5.98	–22
0.2	39.50	7.12	–14

Table 2. Physicochemical characteristics of PEE as influenced by the boron content and addition of PHDA to the ready product

Content, wt %		ν, $mm^2 s^{-1}$, at indicated temperature, °C			Viscosity index
boron	PHDA	40	100	–40	
Sample of PEE C_5–C_9 (imp.)					
–	–	22.86	4.94	7560	146
0.02	–	23.56	5.04	7610	147
0.04	–	24.07	5.07	7650	144
–	0.5	23.68	4.92	8060	136
0.03	0.5	24.29	5.05	8030	139
Sample of PEE C_5–C_{10} (lab.)					
–	–	23.08	4.87	8610	138
0.03	–	23.61	4.98	8710	138
–	0.5	25.23	4,92	10990	120
0.03	0.5	25.03	5.00	10340	128

Table 2 shows that introduction of 0.02–0.04 wt % boron into molecules of pentaerythritol esters affects the physicochemical characteristics of the product insignificantly. The congelation point of all the samples (not given in Table 2) is virtually constant, 60 ± 2°C. Addition of PHDA in a concentration accepted for ester oils (about 0.5 wt %) considerably increases the viscosity of the oil at low temperatures and decreases the viscosity index. The observed negative effect of PHDA on the physicochemical properties of the oil is apparently due to the formation at low temperatures of hydrogen bonds between the hydroxy and amino groups of PHDA and the carbonyl oxygen atom of ester groups of the oil. At 100°C, these bonds are ruptured, and the viscosity varies insignificantly.

Table 3. Resistance of PEE to thermal oxidation, as influenced by the boron content and presence of PHDA*

Content, wt %		Increase relative to unoxidized oil			Residue insoluble in isooctane, %
boron	PHDA	AN, (mg KOH) g^{-1}	ν, %		
			100°C	–40°C

0.03	0.5	0.04	0.0	–	–

* The rate of air supply was increased relative to the standard procedure by a factor of 1.5.

The effect of boron and PHDA on PEE C_5–C_{10} (lab.) with a hydroxyl number of 35 (mg KOH) g^{-1} is qualitatively identical to the effect of these additives on imported PEE C_5–C_9 whose hydroxyl number is 5 (mg KOH) g^{-1}, but is accompanied by a somewhat stronger increase in the viscosity of the products at low temperatures (Table 2).

Table 3 shows the results of testing the resistance to thermal oxidation of products whose physicochemical characteristics are listed in Table 2.

It can be seen that modification with small amounts of boron enhances the resistance of the esters to thermal oxidation. Boron incorporated in the PEE structure affects to the greatest extent the viscosity of the oxidates at both 100 and –40°C and the formation of the precipitate insoluble in isooctane. The efficiency of modification with boron of a laboratory PEE sample containing the largest amount of unstable incomplete esters is higher, compared to the modification of the imported sample with a low content of free hydroxy groups. As expected, *p*-hydroxydiphenylamine acts as an effective antioxidant. Modification of PEE with boron, followed by addition of PHDA, further enhances the oxidation resistance of the oil.

Introduction of boron also positively affects the lubricating power of PEE. Below are the tribological characteristics of PEE C_5–C_9 (imp.), initial and modified with boron (both samples contain 0.5 wt % PHDA):

Boron content, wt %	Critical load, N	Wear scar diameter, m
–	581	0.70
0.03	697	0.67

The effect of boron is manifested to the greatest extent in the increase in the critical load.

Our results show that it is possible to enhance simultaneously the resistance of PEEs to thermal oxidation and their lubricating properties, with the low-temperature viscosity and the temperature dependence of the viscosity kept on the acceptable level, by esterification of a part of free hydroxy groups with boric acid. Modification with small amounts of boron of PEE with a low degree of esterification is the most efficient.

CONCLUSIONS

(1) Introduction of 0.02–0.04 wt % boron into the structure of incomplete pentaerythritol esters by esterification of free hydroxy groups with boric acid affects the low-temperature viscosity and the temperature dependence of the viscosity insignificantly, but noticeably enhances their resistance to thermal oxidation and improves to a certain extent the lubricating properties. Modification with boron of pentaerythritol esters with a low degree of esterification is the most efficient.

(2) *p*-Hydroxydiphenylamine, an antioxidant widely used in ester oils, appreciably increases the viscosity of pentaerythritol esters at low temperatures and makes steeper the temperature dependence of the viscosity.

BOOK REVIEWS

Popova, A.A., *Anodnoe Povedenie Perekhodnykh Metallov v Vodnykh i Organicheskikh Sredakh* (Anodic Behavior of Transition Metals in Aqueous and Organic Media), Rostov-on-Don: Izd. SKNTs VSh, 2006, 184 pp.

DOI: 10.1134/S1070427208020377

The monograph by A.A. Popova summarizes and analyzes the results of numerous studies of the anodic behavior of a large group of metals, mostly in aqueous–organic and organic media. Special attention in the presentation of the material is given to the influence of complexation in solutions on the anodic behavior of metals and formation of anodic films. The book comprises an introduction, four chapters, conclusion, and a bibliographic list for the monograph as a whole.

The brief introduction (pp. 5, 6) substantiates the topicality of the issues considered in the monograph and notes the importance of the influence exerted by the type and properties of an electrolyte on anodic processes and on the formation and nature of the films formed. The first chapter (pp. 7–34) considers the fundamental aspects of the anodic behavior of metals passivated in aqueous-organic and organic media. The thermodynamic characteristics of the occurring processes, role of water in anodic reactions, and effect of anions on the anodic behavior of transition metals are discussed.

The second chapter (pp. 35–69) is devoted to the effect of complexation in solutions on the processes occurring in anodic polarization of metals. A section of the chapter contains evidence about application of chromatographic methods to determine transition metal ions in organic and mixed media. The third chapter (pp. 70–121) discusses a whole group of issues related to the nature of processes that occur on the surface of passivable metals, structure of the double layer, and formation of the metal–electrolyte interface.

The fourth chapter (pp. 122–154) includes material about the passive state of transition metals and the structure of oxide films on these metals. Also, some data obtained in studies of the semiconducting properties of anodic films are presented. In the conclusion (p. 155), the authors express hope that the monograph offered to readers' attention and based on a vast body of processed information sources will make up for the deficiency of review information about the problem discussed. The bibliographic list (pp. 156–183) is, indeed, rather spacious, with 503 references included. Unfortunately, the article titles are not presented, which somewhat reduces the information value of the list.

There is no escape from mentioning the shortcomings of the book, which are, in our opinion, due to two main reasons, lack of author's standpoint concerning the problems discussed and attempt to cover a too wide variety of issues. In fact, the monograph is a review of published information within rather uncertain limits. There are no sufficient interrelations between the chapters and between sections within the chapters. Separate publications are taken and an attempt is made to present their essence in an as brief manner as possible. What is the relationship between the phenomena of anodic dissolution, passivity, and entropy of the double layer. This is difficult to understand from the text in pp. 103–109.

There are numerous minor defects of presentation, which hinder the understanding of the material, both in the text and in the figure design. There is no such notion as "activity coefficient of the medium" (p. 7). The term "free energy" was many years ago replaced in the world literature with the term "Gibbs energy." What is the terminological difference between the heat (ΔH) of the sorption process (Figs. 2.4, 2.5) and heat of adsorption (Q) (Figs. 2.6, 2.7). In Table 2.2, the symbol ΔH already designates the "differential molar energy of sorption." The least attention is given by the book to electrochemical processes: anodic dissolution and transition to the passive state. Anodic polarization curves are shown only in a single figure (Fig. 1.3).

The author should have taken as an example of a book devoted to a similar problem the monograph by B.N. Kabakov *Elektrokhimiya metallov i adsorbtsiya* (Electrochemistry of Metals and Adsorption, Moscow: Nauka, 1966, 222 pp.). Published 40 years ago, this book still retains its scientific value.

Abstract—Methods for determining the distribution ratios of volatile substances between liquid and gas phases, based on gas–liquid chromatography or gas extraction in systems with constant or variable volume under static or dynamic conditions, are classified and described, and their application fields are indicated.

DOI: 10.1134/S1070427208030014

INTRODUCTION

The distribution ratio K, i.e., the ratio of the equilibrium concentrations of a substance in the liquid (c_L) and gas (c_G) phases

$$K = c_L/c_G, \quad (1)$$

is the most important characteristic of a heterogeneous liquid–gas system. The quantity K is dimensionless, but can be different for a given system depending on the concentration scale chosen. In analytical measurements, c_L and c_G are commonly expressed in mass concentrations (mass in volume), because these units considerably simplify the calculations, as data on the molecular masses and densities of the gas and liquid are not required. Furthermore, the distribution ratios in the mass and molar concentration scales coincide. Knowledge of the distribution ratios is necessary for the development and optimization of many industrial and laboratory chemical processes.

Formula (1) expresses the Nernst distribution law. The quantity K is constant for ideal systems and strongly diluted nonelectrolyte solutions to which the Henry law is applicable. The distribution ratio generally depends on the solution composition. The area in which the Henry law is obeyed (and K is constant) depends on particular system. For example [1], for solutions of lower alcohols in nonpolar solvents, the upper limit of this area is on the level of 0.1 mol %. Solutions of low-boiling hydrocarbons (*n*-pentane, *n*-hexane) in high-boiling hydrocarbons (squalane) obey the Henry law up to a concentration of ~1.5, and systems of polar components (water–methanol), up to a concentration of ~0.5 mol %.

In the case of dilute solutions, the distribution ratio and its temperature dependence allow calculation of the limiting activity coefficients of solutes γ^∞, which are useful for the calculation of the thermodynamic properties of dilute solutions, determination of the parameters of molecular-statistics models for simulating phase equilibria in a wide range of conditions [1], estimation of the energy of solvation of solutes [2], and evaluation of intermolecular interactions in solutions.

For solutions of limit dilution, the distribution ratio can be calculated from physicochemcial constants of the solvent and *i*th solute by the formula [1]

$$K_i = RTd_L/(\gamma_i^\infty p_i^0 M_L), \quad (2)$$

if the following quantities are known or can be measured: saturated vapor pressure p_i^0 and limiting activity coefficient γ_i^∞ (symmetrical normalization) of the solute, and the molecular weight M_L and density d_L of the solvent. In formula (2), R is the universal gas constant and T is temperature (K).

A powerful tool for determining the content of volatiles in liquid and gaseous objects is gas-chromatographic head-space analysis (HSA) [3–5]. This method is based on the principles of gas extraction [6], i.e., on the distribution of a substance in the liquid–gas system. Therefore, the key parameter determining the reliability of measurements of the content of volatiles in liquid and gas media is the distribution ratio K.

There are two ways of determining K by chromatographic and head-space analysis. The first way is gas–liquid chromatography (dynamic GLC) in which volatile substances are distributed between the mobile gas phase and stationary condensed phase. The second way is based on the gas extraction. It also involves chromatography, but the substance to be determined is distributed between the gas and liquid phases in a vessel arranged beyond the chromatographic system. In this case, the absolute or relative concentrations of a substance in one or both phases of the equilibrium system are determined by gas chromatography.

These principles underlie different procedures for gas-chromatographic determination of K, each of which has certain advantages, specific features, and limitations. For the majority of methods, such information is lacking.

In this paper, we systematize gas-chromatographic methods for measuring the distribution ratios of volatile substances between the liquid and gas phases, describe the principles and implementation of the majority of these methdos, and assess their potentialities (range of measurable values of K and attainable accuracy). In addition, we consider methods that are not yet used in experiments but deserve attention.

DETERMINATION OF DISTRIBUTION RATIOS BY GLC FROM RETENTION PARAMETERS

The distribution ratios of volatile compounds between the condensed and gas phases affect the retention of components in a chromatographic system. Measurement of K by GLC is based on the dependence of the retention volume V_R on the distribution ratio [1, 7]:

$$V_R = V_M + KV_L. \quad (3)$$

Therefore, K can be calculated from the retention parameters:

$$K = (V_R - V_M)/V_L = V'_R/V_L, \quad (4)$$

where V_M is the so-called dead volume, i.e., the volume of the gas phase of the chromatoghaphic system; V'_R, corrected retention volume; and V_L, volume of the stationary phase in the chromatographic system.

Under actual conditions of the chromatographic analysis, the gas phase of the system is under excess pressure. Because of the gradient of the carrier gas pressure, arising along the column (P_i is the inlet pressure and P_0, outlet pressure), an additional empirical parameter j, compressibility of an ideal carrier gas [8]

$$j = \frac{3(P_i/P_0)^2 - 1}{2(P_i/P_0)^3 - 1}$$

or a real carrier gas [9]

$$j = \frac{3(P_i/P_0)^4 - 1}{2(P_i/P_0)^3 - 1}$$

is introduced into Eq. (3):

$$V_R j = V_M j + KV_L,$$

whence follows

$$K = V'_R j/V_L, \quad (5)$$

This approach to the determination of the distribution ratios was developed in detail more than 50 years ago [10–12], at the outset of the development of gas–liquid distribution chromatography. Papers [10–12] are still topical. The modern viewpoint on the potentialities, limitations, and application prospects of the chromatographic method for measuring the distribution ratios is reflected in Castells' review [13].

Experimental implementation of the method is fairly simple and mainly requires only the standard chromatographic equipment. Therefore, determination of K of volatile substances from the parameters of their retention by the stationary phase is very popular and is widely used not only for analytical purposes, but also in studies of thermodynamic properties of dilute solutions. As much as 95% of data on the limiting activity coefficients of volatile substances in solutions were obtained by this dynamic method [1]. Although in most cases high-boiling liquids are used as stationary phases, there are examples of using relatively volatile liquids such as water and blood [14].

Despite simplicity of the method, to obtain accurate and reliable results it is necessary to solve certain problems. The main of them are to evaluate accurately the gas volume in the column V_G and dead volume V_M, corrected for the vaporizer and detector volumes, and to take into account an increase in the gas volume of the system upon vaporization of the sample. Furthermore, problems may arise with the accurate evaluation of C_L, which is usually calculated from the mass and density of the liquid phase. In rigorous consideration of the correlation between the retention volume and distribution ratio, it is necessary to take into

account the nonideality of the vapor phase and the solubility of the carrier gas in the stationary liquid phase [1, 7].

The sorption effects on the phase boundary in a chromatographic column can also give rise to serious problems in measurements of K from the retention parameters, because the procedure for calculating K is based on the assumption that V'_R is governed only by the dissolution of substances being chromatographed in the stationary phase in accordance with (3) or (5). At the same time, as early as the 1960s it was shown [15–21] that Eq. (5) is a particular case of the general equation

$$V_R j = KV_L + K_{G/L}S_L + K_{L/S}S_S, \quad (6)$$

taking into account not only the absorption of a substance by the liquid phase (first term), but also its adsorption on the liquid–gas phase boundary (surface area S_L, adsorption coefficient $K_{G/L}$, second term) and on the solid support surface under the layer of the liquid phase (surface area S_S, adsorption coefficient $K_{L/S}$, third term).

The contribution of adsorption on the liquid phase surface to the retention of a substance by the column packing, examined by Martin [15], may be very significant. For example, in chromatographic analysis of nonpolar substances (hydrocarbons) on polar phases, the effects of dissolution in the liquid phase and adsorption on its surface make comparable contributions. In other cases, the contrubution of the second term of Eq. (6) depends on the active surface area of the solid support and amount of the liquid phase on it.

The effect exerted on V'_R by adsorption on the solid–liquid phase boundary, revealed for the first time in [17–21], becomes considerably more pronounced with a decrease in the thickness of the liquid layer on the solid support and with an increase in the surface area of the support. Therefore, the amount of the stationary liquid phase in the column packing should be no less than 10–15%. The general case of simultaneous occurrence of the absorption and two kinds of adsorption was considered in [18, 21, 22]. Quantitative evaluation of additional adsorption interactions in the course of gas-chromatographic analysis of substances of different classes, with 1,2,3-tris(2-cyanoethoxy)propane (TCEP) as stationary phase and Chromosorb W or fire-brick as support, showed that the adsorption contribution to the retention volume of certain organic substances ranges from 40 to 70%.

The results of studying adsorption effects in chromatographic analysis of polar and nonpolar substances on a column with a polar stationary phase (TCEP), plotted in Fig. 1 [21], show that the specific retention volume V_g^0[1] of such polar substances as benzene, vinyl acetate, cyclohexene, and acetone linearly increases with the amount of the liquid phase at its content exceeding 4–8%. At a lower amount of the stationary phase, V_g^0 dramatically increases. Nonpolar hydrocarbons show anomalous behavior on this sorbent. With a decrease in the liquid phase content on the solid support (INZ-600 fire-brick), V_g^0 increases. This fact is paradoxical for gas–liquid distribution chromatography. The main cause of such behavior of nonpolar substances is their sorption on the surface of the polar phase, which makes the major contribution to the retention of substances by the column packing. Some curves in Fig. 1 intersect. This effect corresponds to the inversion of the order in which the components of the same mixture are eluted, depending on the content of the liquid phase on the solid support.

Significant and difficult-to-reveal systematic errors in measurements of the distribution ratios can be eliminated by taking into account the adsorption contribution to V'_R or by performing measurements under the conditions when this contribution is negligible. The contribution from adsorption on the solid support can be reduced by modification of the support surface with high-boiling polar substances reacting with the active surface of the support, or with substances forming protective polymeric films on the solid surface (dimethyldichlorosilane, dimethyldisilazane, etc.).

According to the existing extimates [1, 23], the error of measuring K and γ^∞ varies within 1–4% if corrections for the nonideality of the vapor phase are not required and there are no additional adsorption interactions. However, if the vapor phase is essentially nonideal and if the adsorption effects noticeably contribute to the chromatographic retention parameters, the error in measuring the distribution ratios or activity coefficients can reach tens of percents [24].

METHODS FOR MEASURING DISTRIBUTION RATIOS BY GAS EXTRACTION

Direct determination of K by measuring the absolute concentrations of a substance in the liquid and gas phases, with the calculation by Eq. (1) [25–27], is used seldom. The main reason is the necessity of calibration of the chromatograph for liquid and gas mixtures, which considerably complicates the analysis and decreases its accuracy.

[1] V_g^0 is calculated by dividing V'_R by the mass of the column packing.

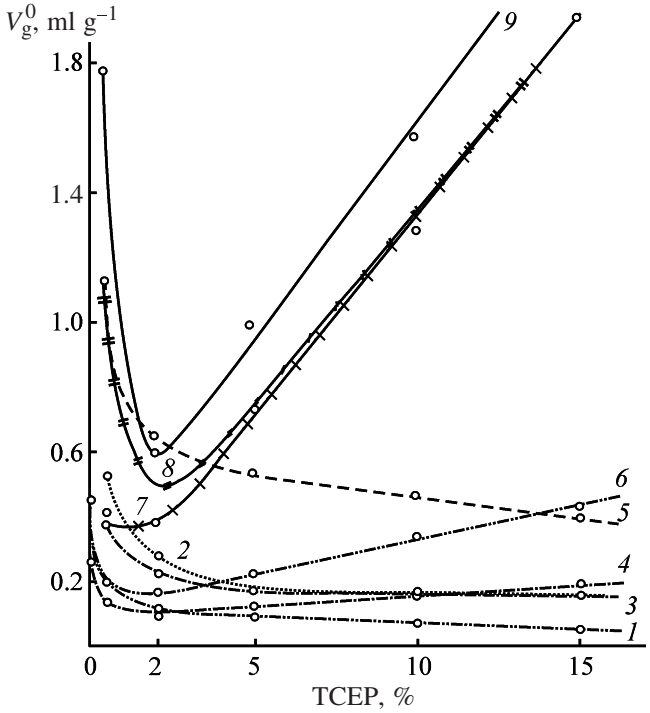

Fig. 1. Specific retention volume V_g^0 as a function of the content of TCEP liquid phase on INZ-600 solid support: (*1*) *n*-hexane, (*2*) 2,2,4-trimethylpentane, (*3*) *n*-heptane, (*4*) cyclohexane, (*5*) *n*-octane, (*6*) cyclohexene, (*7*) benzene, (*8*) vinyl acetate, and (*9*) acetone. Conditions of gas-chromatographic analysis: PAI chromatograph, model 12001, argon ionization detector; glass column 1.25 mm long, 4 mm i.d.; particle size of the solid support 0.17–0.25 mm; column temperature 50°C; carrier gas argon, flow rate 25 ml min^{-1}.

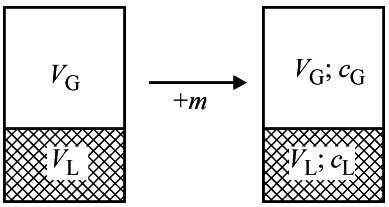

Fig. 2. Scheme of head-space determination of the distribution ratio by absolute calibration of the gas phase (Rohrschneider's method). For comments, see text.

Rohrschneider [28] suggested a procedure involving absolute calibration for the gas phase only. In that study, an automatic apparatus for head-space analysis was used for the first time, and ample data were obtained on the distribution ratios of selected reference substances (octane, toluene, ethanol, methyl ethyl ketone, dioxane, nitromethane) in 81 solvents differing in the polarity. These data are still of interest.

Rohrschneider's method consists in injecting a portion of a target substance of accurately measured volume or mass with a microsyringe into a glass vessel stoppered with an elastic plug, containing a solvent of volume V_L and a gas phase of volume V_G (Fig. 2). After the phase equilibrium is attained, the absolute concentration c_G in the gas phase is determined from the chromatographic peak height using the preliminarily obtained calibration plot. The distribution ratio is calculated in accordance with the given volume ratio of the gas and liquid phases $r = V_G/V_L$ by the formula

$$K = mV_L r/c_G. \quad (7)$$

The accuracy of the distribution ratios thus determined was not reported; according to our estimates, the error is no less than 5–10%.

A kind of absolute calibration is used for studying the thermodynamic characteristics of dilute solutions. Measurement of the limiting activity coefficients is based on relating the partial pressure of a volatile substance p_i over a solution with the known molar concentration of this substance $x_{i,L}$ to the saturated vapor pressure of the pure substance p_i^0. The equilibrium gas phase is subjected to gas-chromatographic analysis, p_i and p_i^0 are determined from the peak areas in the chromatogram (A_i^0 and A_i^0) at ultimate dilutions and in the range of the linear detector response, and γ_i^∞ is calculated by the formula [1, 29]

$$\gamma_i^\infty = \frac{p_i/p_i^0}{x_{i,L}} = \frac{A_i/A_i^0}{x_{i,L}}. \quad (8)$$

From γ_i^∞, it is possible to calculate the distribution ratio by formula (2). In contrast to Rohrschneider's method, in this case the absolute calibration is performed for solutions with the given molar concentrations of the solute $x_{i,L}$. However, this method is applicable only to systems with relatively high distribution ratios, considerably exceeding the volume ratio of the equilibrium phases in the vessel. In such cases, a change in the preset value of $x_{i,L}$ due to transfer of a part of the substance into the gas phase in the course of attainment of the phase equilibrium can be neglected. In the overwhelming majority of papers, the method is implemented under static conditions on automatic head-space analyzers [3–5, 24, 29], but a circulation pattern of head-space dosage has also been reported [30].

The progress of head-space chromatographic analysis and the development of its new versions led to the development of indirect methods for measuring *K*,

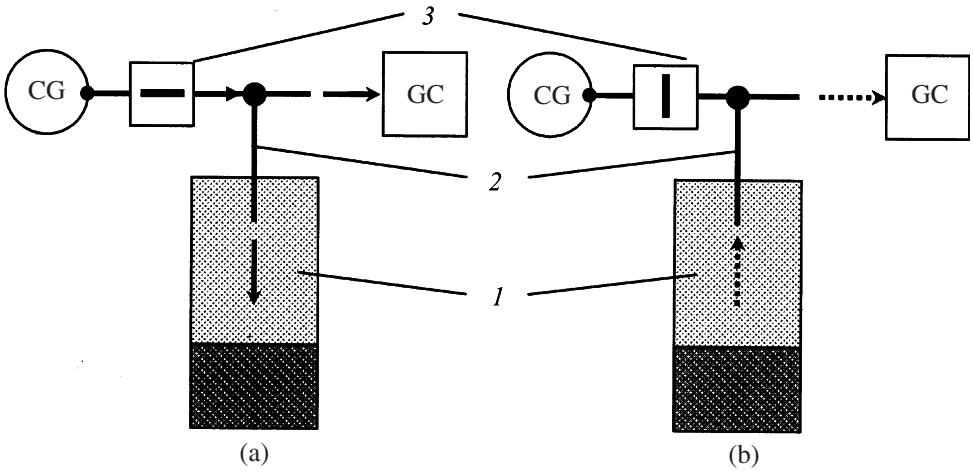

Fig. 3. Scheme of pneumatic head-space injection of equilibrium gas into a chromatograph from constant-volume vessels by providing a pressure differential at the moment of dosing (used in automatic head-space analyzers produced by Perkin–Elmer): (a) making excess pressure in the vessel with the sample and (b) dosing the equilibrium gas into a chromatograph. (CG) Source of stabilized carrier gas flow and (GC) gas chromatograph. (*1*) Vial with a sample of a solution to be analyzed, (*2*) heated needle of head-space dosing unit, and (*3*) automatically controlled electromagnetic valve.

consisting in evaluation of the change in the substance concentration in one of the phases after bringing it into a thermodynamic equilibrium with the other phase or after changing the system parameters. The main advantage of the methods developed is that K can be calculated solely from a relative change in the detector signal (peak area in the chromatogram). This procedure eliminates systematic inaccuracies associated with the determination of the absolute concentrations of a substance in the equilibrium phases and makes the results considerably more reliable. This principle was implemented in various procedures for determining K, based on single, multiple, and continuous gas extraction (CGE).

The devices used in HSA for gas extraction and subsequent dosing of the equilibrium gas into a chromatograph can be subdivided into two groups. Vessels of the first group have a constant volume, and doses[2] are taken at varied pressure. Vessels of the second group have variable volume of the gas phase, and doses are taken at a constant pressure. The constant-pressure mode is also realized in all dynamic versions of HSA. Each of these groups of devices has certain specific features which should be taken into account in choosing a procedure for sample preparation, a version of quantitative analysis, and a method for dosing gas samples into a chromatograph.

[2] By the dose is inderstood the volume of the gas phase taken from the equilibration vessel and injected into a chromatograph, and by the sample is understood the volume or mass of the solution to be analyzed (condensed phase) injected into the equilibration vessel.

Constant-volume vessels are used fairly frequently. In the standard HSA apparatus, such vessels are glass vials of the volume ranging from 10 to 25 ml. The equilibrium gas from these vials is dosed into a chromatographic column by several methods [3–5], most frequently by the pneumatic method used in automatic head-space analyzers. Pneumatic dosing is based on making a pressure differential between the vaporizer of the chromatograph and the vessel with the sample to be analyzed. This principle was implemented for the first time in the most perfect apparatus for head-space analysis, developed by Perkin–Elmer (Fig. 3). Vial *1* with a solution sample is connected via a special heated needle *2* to the carrier gas line. In the process, valve *3* of the dosing unit is open, and excess pressure equal to the gas pressure in the chromatograph vaporizer is made in the vial. The required pressure differential in this unit (Fig. 3a) is provided at the moment of dosing by automatically cutting off the carrier gas flow by valve *3*, which is followed by a decrease in the pressure in the chromatograph vaporizer (Fig. 3b).

An ingenious device for HSA with pneumatic dosing was developed in the Laboratory of Gas Chromatography of the St. Petersburg State University [31]. This device differs from the Perkin–Elmer dosing unit in that the pressure differential in it is provided in advance with an additional carrier gas line (CG_2), by setting in a vessel with a sample the pressure p' that is higher than the pressure p in the chromatograph vaporizer (Fig. 4a) [32]. The subsequent connection of the gas space of vessel *1* with the chromatograph vapor-

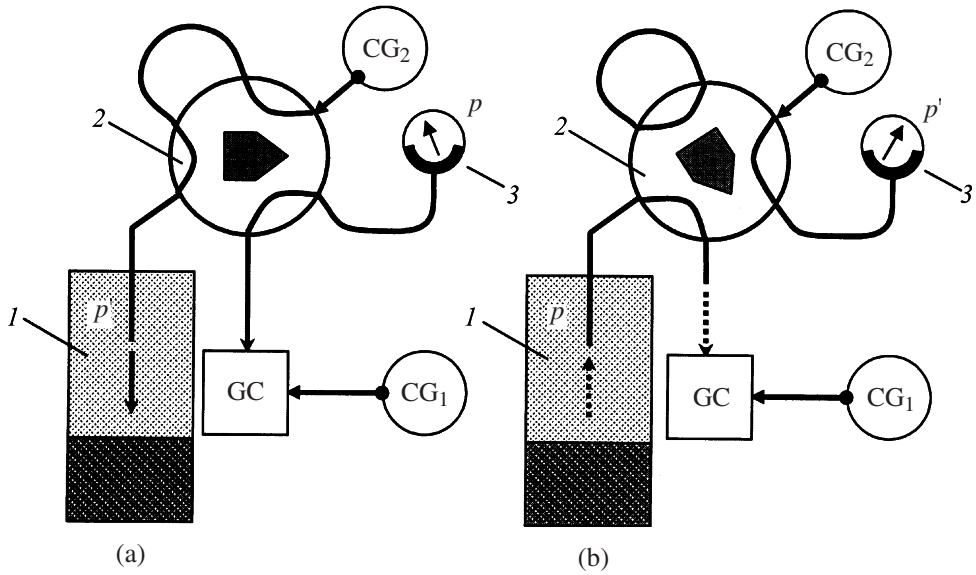

Fig. 4. Scheme of pneumatic head-space dosing of equilibrium gas into a chromatograph from constant-volume vessels with preset pressure differential: (a) making excess pressure in the vessel with the sample and (b) dosing the equilibrium gas into the chromatograph. (CG_1) Source of stabilized carrier gas flow fed to a chromatographic column, (CG_2) source of carrier gas providing the preset pressure in the vessel with the sample, and (GC) gas chromatograph. (*1*) Vial with a sample of a solution to be analyzed, (*2*) two-position gas stopcock, and (*3*) manometer.

izer via stopcock *2* provides rapid injection of the dose whose volume at atmospheric pressure v_g is determined not only by the difference between the pressures in the equilibration vessel (p') and the gas circuit of the chromatograph (p), but also by the volume of the gas phase of the heterogeneous system V_G:

$$v_g = V_G(p' - p)/p'. \quad (9)$$

This version of the pneumatic method allows accurate measurement and setting of the pressure differential and thus calculation and control of the volume of the equilibrium gas taken from the vessel.

The main advantage of the pneumatic head-space dosing is pulsed injection of the equilibrium gas directly from a vessel with a sample into a chromatographic column, without injection into intermediate units, which decreases the sorption loss and the "memory" of the dosing unit. Maintenance of a stable pressure differential provides high reproducibility of dosing of the equilibrium gas (on the level of tenth fractions of percent), and short and well heated gas tubes connecting the vial with the chromatographic column cardinally reduce the substance loss. Furthermore, pneumatic dosing can be automated more readily than other methods of injecting the equilibrium gas into a chromatograph.

"Pseudopneumatic" head-space dosing is widely used in standard gas-chromatographic apparatus produced by many companies. In this method, the equilibrium gas is injected into a chromatograph with a temperature-controlled gas stopcock whose dosing volume is filled with the gas phase from the vial by the pneumatic method (Fig. 5). To this end, excess pressure p in a vessel with a sample is provided by connecting it to an additional carrier gas line (CG_2) (Fig. 5a). The subsequent connection of vessel *1* with gas stopcock *2* occurring in the position indicated in the scheme by solid lines fills dosing loop *3* with the equilibrium gas (Fig. 3b). By turning stopcock *2* to the position indicated in the scheme by dashed lines, the equilibrium gas is dosed into a chromatograph.

A specific feature of the pseudopneumatic injection of the equilibrium gas into a chromatograph is that the concentration of the target substance in the dosing volume (loop) of the stopcock (at atmospheric pressure), as compared to its concentration in the gas phase of the vessel with the sample, decreases with an increase in the preliminarily created pressure p. As a result, the sensitivity of the analysis somewhat decreases. Furthermore, repeated pneumatic dosing of the equilibrium gas into a chromatograph from the same vial leads to a considerably greater decrease in the concentration of the target substance in the dose, which is the more pronounced, the lower the distribution ratio.

Dosing of the equilibrium gas from constant-vol-

ume vessels leads to a change in the initially set concentration of the substance in solution and in the gas phase over it. In many cases this is a drawback, because the possibility of repeated dosing of the equilibrium gas is limited by the parameters of the system being analyzed (values of K and r), volume of the dose taken, and required reproducibility of detector readings at successive injection of a gas with a constant substance concentration into a chromatograph.

With variable-volume vessels (namely, glass syringes of the volume ranging from 10 to 200 ml), the limitations of pneumatic dosing are eliminated, and doses of the equilibrium gas can be repeatedly taken from a vessel with a sample without changes in the substance concentration in the contacting phases [33]. This is due to the preservation of the initially set pressure in the system. A decrease in the pressure in the vessel after removing a certain volume of the gas is compensated by a decrease in the total volume of the system.

The equilibrium gas is dosed into a chromatographic column with a gas stopcock in accordance with the scheme shown in Fig. 6. The equilibrium gas displaced from vessel *1* fills dosing loop *3* of the gas stopcock set in the position indicated in the scheme by solid lines. By turning stopcock *2* into the position indicated by dashed lines, the dose is injected into the gas chromatograph (GC).

The major advantage of using variable-volume vessels for HSA is the possibility of taking liquid or gaseous doses from a liquid–gas heterogeneous system without disturbing the previously attained phase equilibrium. Therefore, the number of repeated measurements of the substance concentration in the gas phase is limited only by the gas phase volume.

Head-space injection of doses in this mode ensures the reproducibility of measuring the substance concentration in the gas phase on the level of no less than 1% and allows implementation of static versions of HSA, based on complete or partial replacement of the equilibrium gas by a pure extractant gas, and also of other versions involving a change in the volume of the system.

The drawback of systems with variable volume of the gas space, along with difficulty of HSA automation, consists in the necessity of using gas stopcocks for dosing the equilibrium gas into a chromatographic column. This may give rise to sorption loss and to the effect of "memory" of the dosing units in analysis of microimpurities, especially of those of polar substances.

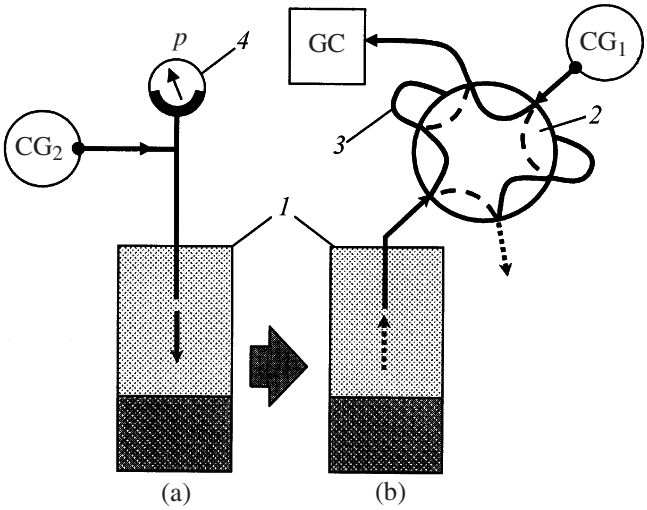

Fig. 5. Scheme of "pseudopneumatic" head-space dosing of the equilibrium gas into a chromatograph: (a) making excess pressure in a vessel with a sample; (b) filling the dosing loop with the equilibrium gas and dosing it into a chromatograph. (CG_1) Source of stabilized carrier gas flow fed to a chromatographic column, (CG_2) carier gas source providing the preset pressure in the vessel with the sample, and (GC) gas chromatograph. (*1*) Vial with a sample of a solution to be analyzed, (*2*) two-position gas stopcock, (*3*) dosing loop, and (*4*) manometer.

In dynamic systems (CGA), substances to be determined are usually injected directly into a chromatographic column with a gas stopcock kept at an elevated temperature, whose dosing volume (loop) is

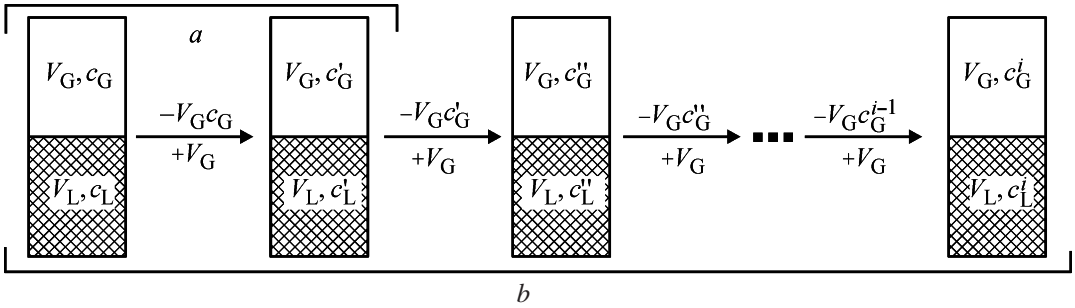

Fig. 7. Scheme of (*a*) repeated and (*b*) multiple gas extraction with complete replacement of the equilibrium gas by the pure gas. For comments, see text.

continuously flushed with a flow of a gas that has been passed through a solution being analyzed or over it.

Gas Extraction with Complete Replacement of the Equilibrium Gas by the Pure Gas

Complete replacement of the equilibrium gas by the pure gas can be realized only in variable-volume vessels, e.g., in glass syringes of the volume 10–100 ml [34, 35]. As early as the 1970s, two versions of this method, based on repeated [34–36] and multiple [37, 38] gas extraction under static conditions, were developed. These versions are still used for analytical and physicochemical measurements.

Repeated extraction. In an equilibrium liquid–gas system (Fig. 7, block *a*) with the volatile substance concentrations c_L in the liquid phase of volume V_L and c_G in the gas phase of volume V_G, after replacement of the whole volume of the equilibrium gas by the pure gas of the same volume and attainment of the phase equilibrium, new concentrations of the substance in the liquid (c'_L) and gas (c'_G) phases will be attained. According to the material balance equation

$$V_L c_L = V_L c'_L + V_G c'_G,$$

in the region of limit dilution the quantity K can be calculated by the formula

$$K = c'_G r/(c_G - c'_G).$$

In the range of linear detector response, at constant conditions of gas-chromatographic analysis, when $c_G/c'_G = A_G/A'_G$, this expression takes the form

$$K = A'_G r/(A_G - A'_G). \quad (10)$$

where A_G and A'_G are the peak areas in the chromatograms of the gas phases with the substance concentrations c_G and c'_G, respectively.

The numerical value of the distribution ratio, as well as the volume ratio of the phases in the vessel in which the equilibrium is attained and the relative error of measuring the peak areas in the chromatograms can significantly affect the accuracy of determining K. If K is large and r is small, the peak areas A_G and A'_G will differ insignificantly. As a result, the relative error of K will be large. This is well illustrated by the equation

$$\Delta K/K = [(\Delta A_G/A_G + \Delta A'_G/A'_G)A'_G]/(A_G - A'_G)$$
$$= [(\Delta A_G/A_G + \Delta A'_G/A'_G)(K + r)]/r, \quad (11)$$

obtained from Eq. (10) assuming that the error of measuring the phase volumes is negligible compared to the error of measuring the peak areas in the chromatograms. It follows from Eq. (11) that, at $r \gg K$, the relative error of measuring the distribution ratio is close to the total error of measuring the peak areas in the chromatograms. With the existing HSA technique, the gas phase volume in variable-volume vessels can exceed the liquid phas volume by a factor of no more than 100, and the accuracy of measuring the peak areas in the chromatogram reaches tenth fractions of percent. Therefore, complete replacement of the equilibrium gas by the pure gas allows measurement of K with a 10% error if $K \le 100$, but only the K values not exceeding 10 can be measured with an accuracy no worse than 1%.

Multiple extraction. This mode involves no less than two complete replacements of the equilibrium gas by a pure gas, i.e., no less than three extractions (Fig. 7, block *b*). The substance concentration in the gas phase after nth replacement or $(n + 1)$ extraction, c^i_G, is related to c_G by the equation [5]

$$c^i_G = c_G[K/(K + r)]^n, \quad (12)$$

from which it follows that, in the range of the linear distribution isotherm under the conditions of equilib-

rium distribution of a substance between two phases, the logarithm of the relative concentration of a substance in the gas phase, $\ln(c_G/c_G^i) = \ln(A_G/A_G^i)$, in the course of multiple gas extraction linearly increases with the number of replacements. The slope of this dependence, $\varphi = \ln[(K + r)/K]$ allows calculation of the distribution ratio provided that the volume ratio of the phases r is known.

The shape of the dependence $\ln(A_G/A_G^i) = f(n)$ is determined by the ratio of K and r. At $K \gg r$, the slope $\varphi \to 0$, and the peak area in the chromatogram A_G^i corresponding to the concentration c_G^i decreases insignificantly even after a large number of extraction runs. For example, at $K = 10^3$ and $r = 10$, after 11 extraction runs the concentration in the gas phase C_G^i differs from c_G by only 1.4%. In this case, it is impossible to calculate the distribution ratio with acceptable accuracy. At $K \ll r$, the concentration c_G^i drastically decreases after each extraction run. In this case, it is also difficult to calculate the distribution ratio, because the extent to which c_G^i decreases in each subsequent extraction is mainly determined by the ratio of the phase volumes in the system. The optimal conditions for measuring the distribution ratios by this method are when the values of K and r are close or comparable.

From the results of measuring A_G and A_G^i by multiple gas extraction, K can also be calculated by the formula

$$K = [(A_G/A_G^i)^{1/n}]^{-1} r. \quad (13)$$

By differentiating (13), we obtain a relationship for the relative error of measuring the distribution ratios by this method:

$$\Delta K/K = [(\Delta A_G/A_G + \Delta A'_G/A'_G)(A_G/A_G^i)^{1/n}] \times \{n[(A_G/A_G^i)^{1/n} - 1]\}^{-1}, \quad (14)$$

whence follows that an increase in the number of extraction runs decreases the relative error of measuring the distribution ratio and thus increases the upper limit of the K values accessible to determination. However, in such cases the analysis becomes more time-consuming. Therefore, it is appropriate to use multiple gas extraction with complete replacement of the equilibrium gas by the pure gas for determining large values of K (exceeding several hundreds), when single replacement of the equilibrium gas by the pure gas, even with r as large as possible, leads to only minor differences between A_G and A_G^i.

Gas Extraction with Partial Replacement of the Equilibrium Gas by the Pure Gas

This mode is used for measuring the distribution ratios of volatile substances with low K or in cases when complete replacement of the equilibrium gas by the pure gas is impossible. Partial replacement of the equilibrium gas phase by the pure gas can be performed in variable- and constant-volume vessels. However, only multiple extraction with partial replacement of the gas phase in constant-volume vessels has been realized in practice [39]; this procedure was termed multiple head-space extraction (MHE). The method is based on an exponential decrease in the concentration of a volatile substance in the gas phase of a vessel with a liquid sample in the course of successive sampling of the same fraction of the gas volume β:

$$\beta = v_g/V_G,$$

where v_g is the volume of the gas phase replaced by the pure gas.

The gas dosing and incomplete replacement of the equilibrium gas by the pure gas are performed by the pneumatic method under the conditions of excess pressure in the system, by relieving a part of the gas from the vessel (Fig. 8). In this case, excess pressure in the system first decreases from p' to p, after which the initial pressure is restored by introducing the volume of the pure gas equal to the volume of the equilibrium gas taken for the analysis.

The advantages of this version of head-space extraction are easy automation and the possibility of attaining high reproducibility of β, which at pneumatic dosing is calculated from the preset pressure differnetial by the formula

$$\beta = 1 - p/p'. \quad (15)$$

According to the equation [5, 39]

$$A_G^i = A_G e^{-q(i-1)}$$

or

$$\ln A_G^i = -q(i-1) + \ln A_G, \quad (16)$$

the slope of the dependence of $\ln c_G^i$ on $(i - 1)$, i.e., on the number of partial replacements of the equilibrium gas by the pure gas, allows calculation of the factor Q given by the relationship

$$Q = A'_G/A_G = A''_G/A'_G = ... = A_G^i/A_G^{i-1} = e^{-q},$$

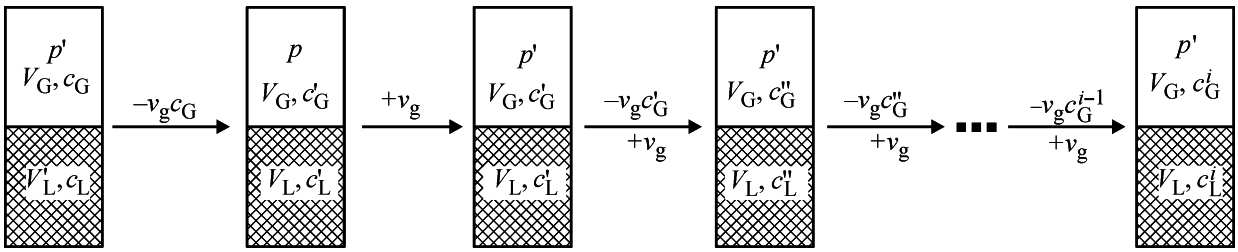

Fig. 8. Scheme of multiple head-space extraction (MHE) with partial replacement of the equilibrium gas by the pure gas in constant-volume vessels. For explanations, see text.

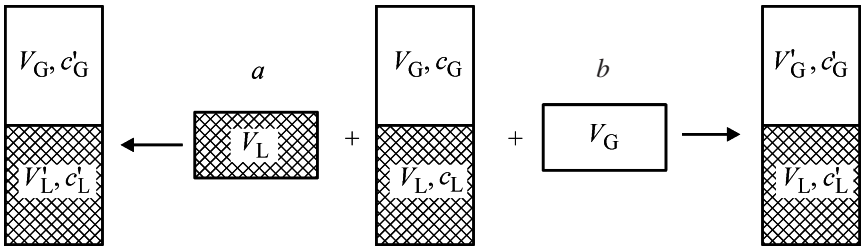

Fig. 9. Scheme of measuring the distribution ratio by the method involving variation of the phase volume ratio in variable-volume vessels by adding an additional amount of the (*a*) liquid solvent or (*b*) extractant gas.

where A_G and A_G^i are the peak areas in the chromatograms coresponding to the substance concentrations in the gas phase in the first (c_G) and *i*th (c_G^i) extraction runs; q is a constant; and i is the number of extraction runs.

The quantity Q is related to K, r, and fraction of the equilibrium gas taken for analysis β by the equation [38]

$$Q = \frac{K/r + 1 - \beta}{K/r + 1}, \quad (17)$$

whence follows

$$K = [(Q + \beta - 1)(1 - Q)]r. \quad (18)$$

Thus, the slope of dependence (16) in combination with the phase volume ratio r and the pressure differential p/p' set in the experiment allows calculation of K. The maximal values of K that can be measured by this method reach several tens.

Method of Varying the Phase Volume Ratio

The method is based on the dependence of the concentration of a volatile substance in the gas phase of a liquid–gas system, c_G, on the initial concentration of the substance in solution, c_G^0, and phase volume ratio r. This dependence is illustrated by the main relationship of quantitative head-space analysis [3, 4, 6]

$$c_G = c_L^0/(K + r), \quad (19)$$

The method can be impemented with variable- and constant-volume vessels. The principal difference between these versions is that, in variable-volume systems, the mass of the substance distributed between the liquid and gas phases is the same, whereas in constant-volume systems different portions of the same amount of the target substance are distributed. This difference changes essentially the technique and procedure of the experiment and the methods for calculating K.

Variable-volume systems. Measurements are usually performed in glass syringes of the volume larger than 50 ml and involve addition of a known amount of the pure gas or liquid (free of the substance being determined), to an equilibrium liquid–gas system containing the substance being distributed in an amount of $V_L c_L + V_G c_G$. For the case of adding the gas (Fig. 9, block *b*), the material balance equation takes the form

$$V_L c_L + V_G c_G = V'_L c'_L + V'_G c'_G. \quad (20)$$

If V'_G exceeds V_G by a factor of n_G, the distribution ratio can be calculated from the results of gas-chromatographic measurements of the concentrations c_G and c'_G (in the form of peak areas A_G and A'_G) in accordance with Eq. (20) by the formula

$$K = (n_G A'_G - A_G)r/(A_G - A'_G). \quad (21)$$

As in the previous cases, the accuracy of determin-

ing K by this method strongly depend on the experimental conditions (r and n). According to (21),

$$\Delta K/K = (\Delta A_G/A_G + \Delta A'_G/A'_G)[A_G/(A_G - A'_G)]$$
$$\times [A'_G(n - 1)]/(nA'_G - A_G)$$
$$= (\Delta A_G/A_G + \Delta A'_G/A'_G)\{[(K + rn)(K + r)]/[Kr(n - 1)]\}. \quad (22)$$

It follows from Eq. (22) that the error of determining the distribution ratio decreases with increasing n, and the quantity r should not be much greater than K. At maximal values of n and r not exceeding 20, K values as large as several hundreds can be calculated accurately to within 10%.

When a liquid solvent is added to an equilibrium liquid–gas system to a volume V'_L exceeding V_L by a factor of n_L (Fig. 9, block *a*), the distribution ratio is calculated by the formula

$$K = r(A_G - A'_G)/(n_L A'_G - A_G), \quad (23)$$

similar to (21). The experimental conditions and the maximal measurable values of K only slightly differ from those given for the case when the volume of the gas phase is increased.

Constant-volume systems. The version suggested in [7, 40] for constant-volume vessels was termed the phase ratio variation (PRV) method. If different volumes of a solution with a constant concentration of a volatile substance are introduced into several vessels of the same capacity V (Fig. 10), then, after the attainment of the phase equilibrium under isothermal conditions, different values of c_G and r will be attained in these vessels, whereas the quantity K will remain constant in the range of limit dilutions. The main relationship (19) for single extraction under static conditions can be presented in the form

$$1/c_G = r/c^0_L + K/c^0_L. \quad (24)$$

Equation (24) can be presented in the form of a linear dependence of the type $y = ax + b$, where $y = 1/c_G$, $x = r$. The experimental measurement of the concentrations c^i_G in the form of chromatographic peak areas A^i_G at different r values allows determination of the slope $a = 1/c^0_L$ and initial ordinate $b = K/c^0_L$ of this dependence. The distribution ratio is calculated from these two quantities:

$$K = b/a. \quad (25)$$

According to [5, 7, 40], it is appropriate to use the PRV method at $K \le 100$. Its main advantage is the use

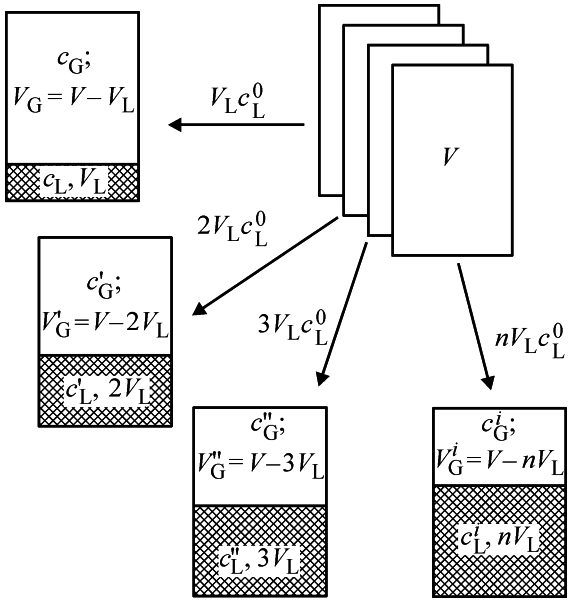

Fig. 10. Scheme of measuring the distribution ratio by varying the phase volume ratio (PRV) in constant-volume vessels. For explanations, see text.

of automatic apparatus for gas-chromatographic head-space determination of c_G. Among drawbacks are possible problems with sampling of the same dose of the gas phase from different vessels in pneumatic head-space dosing of samples into a chromatographic column.

Chai and Zhu [41] described a similar but less labor-consuming method, phase ratio calibration (PRC), which can also be implemented in constant-volume systems. It differs from the PRV method in that only two vessels of the same volume V are used. Different volumes V_L and V'_L of the same solution containing a volatile substance which is distributed between the phases are added into these vessels. After the attainment of the phase equilibrium and gas-chromatographic determination of the substance concentration in the gas phase in each vessel, c_G and c'_G, in the form of peak areas A_G and A'_G, the distribution ratio is calculated by the formula

$$K = [A_G(V - V_L) - n_L A'_G(V - V'_L)]V_L(A'_G - A_G), \quad (26)$$

where $n_L = V_L/V'_L$.

A sort of the PRV and PRC methods is the EPICS (equilibrium partitioning in closed systems) method [42] in which equal amounts of a gas mixture are introduced into two vessels hermetically stoppered with elastic rubber plugs. The vessels are of equal capacity but contain different volumes of the liquid

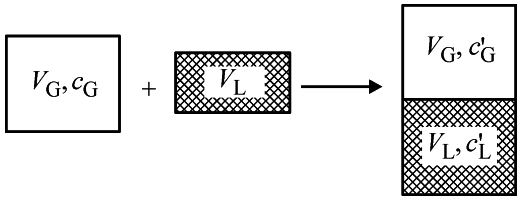

Fig. 11. Scheme of measuring the distribution ratio by introducing a liquid solvent into a gas mixture.

phase, V_L and V'_L, with concentrations c_L and c'_L, and hence different gas volumes V_G and V'_G with concentrations c_G and c'_G. Since equal amounts of a substance distributed between the phases are introduced into the vessels, the mass balance has the form similar to Eq. (20):

$$V_L c_L + V_G c_G = V'_L c'_L + V'_G c'_G.$$

and the distribution ratio, provided that $c_G/c'_G = A_G/A'_G$, is calculated by the formula

$$K = (V'_G A'_G - V_G A_G)/V_L A_G - V'_L A'_G). \quad (27)$$

The potentialities of the PRV, PRC, and EPICS methods are comparable as regards the range of measurable values of K and the accuracy actually attained (2–10%). It should be noted, however, that Eqs. (26) and (27), like (21) and (22), contain in the numerator and denominator the differences between the measured quantities A_G and A'_G. If these quantities are close, the error of determining K drastically increases [similarly, e.g., to the case of variation of the phase volume ratio in variable-volume vessels, Eq. (22)]. Therefore, to attain the best (and sometimes acceptable) accuracy in choosing the experimental conditions, it is necessary to provide the difference between the solution volumes V_L and V'_L as large as possible, and this difference should be the greater, the larger the distribution ratio. According to [41], the maximum measurable values of K can reach several hundreds; in this case, the volumes of the liquid phases in the vessels should differ by a factor (n_L) of no less than several tens.

Introduction of a Liquid into a Gas Mixture [31]

The method is based on liquid extraction, i.e., on extraction of volatile substances from a gas volume with a liquid solvent (Fig. 11). It is implemented with variable-volume vessels allowing sampling of the equilibrium gas without affecting the concentration c_G or c'_G in the gas phase. Introduction of a liquid into a gas mixture whose volume remains unchanged provides reliable information on the distribution of volatile substances between the liquid and gas phases in the range of distribution ratios from tenth fractions to several thousands. According to the material balance

$$V_G c_G = V_L c'_L + V_G c'_G.$$

the distribution ratio is calculated by the formula

$$K = r(A_G - A'_G)/A'_G. \quad (28)$$

The relative error of K

$$\Delta K/K = (\Delta A_G/A_G + \Delta A'_G/A'_G)[A_G/(A_G - A'_G)]$$

$$= (\Delta A_G/A_G + \Delta A'_G/A'_G)[(K + r)/K], \quad (29)$$

as in the methods considered above, depends on the extraction conditions. To improve the measurement accuracy, the conditions should be chosen so as to ensure significant difference between A'_G and A_G. According to Eq. (29), this condition, in contrast to repeated head-space extraction, is attained at $K > r$. Therefore, the pattern with the accuracy of measuring K is opposite to that in repeated head-space extraction: The main restrictions concern the lower, rather than higher, limit of K. At accurate measurement of the peak areas in the chromatograms (accuracy no less than 1%) and $r \approx 0.1$, introduction of a liquid into a gas mixture allows measurement of K values no lower than 1 with an error not exceeding 10%.

The uppoer limit is determined by the possibility of measuring the concentration c'_G with acceptable accuracy, i.e., by the admissible decrease in A'_G relative to A_G. According to (28), $A_G/A'_G = (K + r)/r$. If introduction of a liquid into a gas mixture provides $A_G/A'_G \leq 100$, at r close to 100 the maximum measurable values of K reach 10^4.

The vapor phase calibration (VPC) method [5, 7] is essentially similar to the method of introducing a liquid into a gas mixture, but is implemented in constant-volume vessels. Strictly equal masses m (or volumes) of a volatile substance are introduced into two different vessels of volume V, one of which is filled with a neutral gas (air) only, and the other contains a certain volume V_L of a solvent (Fig. 12). After attainment of the phase equilibrium and gas-chromatographic measurement of the substance concentrations in the head space, c_G and c'_G, in the form of chromatographic peak areas A_G and A'_G, the distribution ratio is calculated in accordance with the material balance

$Vc_G = V_G c'_G + V_L c'_L$ by the formula

$$K = [VA_G - (V - V_L)A'_G]/V_L A'_G = A_G(1 + r)/A'_G - r.$$

Although the VPC method is classed with direct methods [43], as follows from its name, it is actually an indirect method, because the absolute concentrations of a substance in the gas phase are not measured and only the peak areas in the chromatogram, along with the phase volumes, appear in the formula for calculating K.

The MHE, PRV, PRC, VPC, and EPICS methods implemented with constant-volume vessels on special chromatographic equipment for HSA are most frequently used in the analytical practice for determining the distribution ratios of volatile compounds in liquid–gas systems. Such automatic head-space analyzers considerably simplify and accelerate the experiments, providing the measurement accuracy acceptable for analytical purposes. However, specific features of pneumatic head-space dosing of the equilibrium gas in some cases may lead to significant systematic inaccuracies. In particular, the dose taken from the equilibration vessel may depend on the volume of the gas phase in it. At the same time, the above methods implemented with pneumatic dosing from constant-volume vessels are based on the compulsory condition that the dose of the equilibrium gas taken from different vessels with different volumes of the gas phase should be the same.

In cases of preliminary setting of the pressure differential (Fig. 4), the dose volume v_g is determined by Eq. (9), i.e., it varies in proportion with V_G, but in this case the fraction of the target compound taken from the gas phase, $v_g/V_G = (p' - p)/p'$, remains constant, as it depends only on the pressure differential.

When the pressure differential is created at the moment of dosing (Perkin–Elmer apparatus, Fig. 3), in Kolb and Etter's opinion [5], the volume of the equilibrium gas injected into a chromatographic column is determined only by the flow rate of the carrier gas at the inlet of the chromatographic column and by the dosing time, but is independent of the pressure. This approach is apparently suitable for rough estimation of the dose, but is absolutely unacceptable for accurate calculations. More rigorous consideration of this version of pneumatic head-space dosing showed that the volume of the equilibrium gas injected into a chromatographic column depends also on the dosing unit temperature, viscosity of the carrier gas, gas-dynamic resistance of the chromatographic column, and other factors, including V_G.

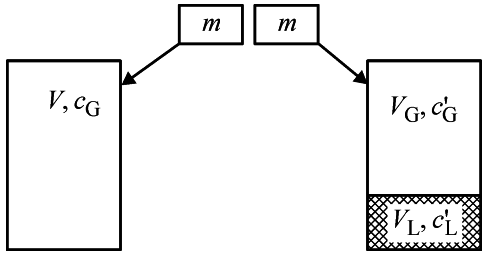

Fig. 12. Scheme of measuring the distribution ratio by vapor phase calibration (VPC) in constant-volume vessels.

The influence exerted by the volume of the gas phase in a vessel with a liquid sample on the amount of a substances pneumatically dosed into a chromatographic column was checked experimentally by the example of head-space analysis of constant-volume vessels containing different amounts of pure *n*-propyl alcohol. A neat volatile compound was chosen as the liquid phase because the saturated vapor pressure, i.e., the concentration of 1-propanol in the gas phase, under isothermal conditions is constant and independent of the volume ratio of the phases in the equilibration vessel. Therefore, if the volume V_G does not affect the dose, the peak areas in the chromatograms of the equilibrium gas taken successively from vessels with different volumes of the gas phase should be equal. If the peak areas will be different, the difference will characterize the extent to which V_G affects the dose volume.

Measurements were performed on a Perkin–Elmer chromatograph, model F-45, with pneumatic dosing of the equilibrium gas into packed and capillary columns. The results (Table 1) show that the volume V_G of the vessel with the liquid sample does affect the amount of the equilibrium gas injected into a chromatographic column.

In our case, e.g., for a packed column, with a decrease in the gas phase volume by 3 ml (from 13.5 to 10.5 mol), the amount of the introduced substance and hence the dose volume decrease by only 2.1%. However, if V_G is decreased by the same 3 ml but from 7.5 to 4.5 ml, the dose decreases by 18%. Larger changes in the volume of the vessel with the sample (very desirable in PRV, PRC, VPC, and EPICS methods) can lead to still larger changes in the dose and hence in significant errors in the determination of K.

Procedures for determining K implemented with variable-volume vessels are used more seldom, because they involve the use of special attachments and devices for HSA, which are not yet produced on the commercial scale. However, these procedures ensure

Table 1. Influence of the gas phase volume in a vessel with a liquid sample of neat 1-propanol on the amount of the substance (chromatographic peak area) injected into a chromatographic column. Analysis conditions: steel packed column 2 m long, 3 mm i.d., liquid phase 10% PEG-4000 on Chromaton N AW, carrier gas helium, 25 ml min^{-1}, dosing time 3 s; or aluminum-coated quartz capillary column 20 m long, 0.53 mm i.d., liquid phase SE-30, layer thickness 3 μm, carrier gas flow rate through the column 5 ml min^{-1}, flow splitting ratio 1 : 2, dosing time 2 s; column temperature 100°C; flame ionization detector, 150°C; injector needle temperature 100°C; column inlet pressure 1 atm

higher accuracy and wider range of measurable values of K. Furthermore, with variable-volume vessels, as in the pseudopneumatic method, the equilibrium gas is injected into a chromatographic column with a gas stopcock ensuring a constant dose volume. Therefore, in such cases the volume V_G of a vessel with a sample does not affect the dose of the equilibrium gas injected into a chromatographic column.

Comparative evaluation of different methods for determining low values of K was made using 11 gaseous substances (hydrogen, oxygen, nitrogen, methane, carbon monoxide, carbon dioxide, acetylene, ethylene, ethane, propene, propane) and the system transformer oil–air [43]. The choice of this system and of the set of gases was governed by the relevance to an efficient method for monitoring the state of high-voltage electrical equipment, used throughout the world. Studies performed in the 1970s showed that flaws of high-power transformers, arising in the course of their operation, can be reliably revealed and diagnosed by the presence of traces of the above gases in the oil. The static HSA technique allows the development of a simple and reliable procedure for gas analysis in transformer oil [44], meeting the existing requirements and widely used in Russia and other countries [45]. Calculations of the initial content of the dissolved gases in the oil sample are based on Eq. (19). Therefore, the distribution ratios K of the characteristic gases in trasnformer oil at various temperatures still attract considerable researchers's attention in various countries.

Jalbert et al. [43] compared the distribution ratios K of characteristic gases in transformer oil, measured at 70°C by various methods implemented with constant-volume vessels with pneumatic dosing of the equilibrium gas into a chromatograph. The results of that study, given in Table 2, show that, in most cases, the measurement error for each method does not exceed 10%, being 2–4% on the average. The highest accuracy was attained with EPICS method, and the lowest accuracy, with MHE method. The deviations of the mean values for each component, calculated from the data of various methods, also do not exceed 10%. The exceptions are hydrogen, propene, and propane. Along with the data obtained with constant-volume vessels, the distribution ratios K measured at 25°C by other methods {repeated head-space extraction in variable-volume vessels [46], determination from gas-chromatographic (GC) retention parameters [47]} are also given in Table 2. These values are well consistent with each other and with data of the International Electrotechnical Commission (IEC) [48], but disagree with the results obtained at 70°C. The strongest inconsistency is observed with hydrogen, because at 70°C the distribution ratio is three times higher than that at 25°C, whereas actually the former value should be lower than, or at least equal to the latter value. According to [46], the distribution ratio K of hydrogen remains constant in the range 15–40°C. For the other components, with an increase in K, the extent of the inconsistency decreases. For example, the distribution ratio of propane decreases by a factor of more than 2 in going from 25 to 70°C, in agreement with the expectations. The significant differences in the results of measuring small (≤2) distribution ratios K should be attributed to systematic inaccuracies of

measurements at 70°C with constant-volume vessels, whereas at 25°C well consistent distribution ratios were obtained by methods based on different principles.

The potentialities of methods using variable-volume vessels are illustrated by Table 3 in which the distribution ratios of a number of gaseous and low-boiling substances at 37°C in the water–air system are given [49]. Many of these substances exhibit anesthetic and pronounced toxic action. Therefore, such data can be of interest for physicians and toxicologists, as the K values for water and whole blood or blood plasma differ insignificantly (within 10%). The error in measuring K, similarly to the above-considered gas–oil systems, in most cases does not exceed 10%, being about 6% on the average. On the whole, data of Table 3 (especially K and S_r for acetaldehyde and acetone) confirm the conclusion that the K values accessible to measurements by repeated head-space extraction do not exceed 100 units, but the upper limit can be increased by using multiple head-space extraction.

Continuous Gas Extraction

Dynamic HSA decreases the sorption effects in the gas circuit of a CGE installation and chromatograph,

which significantly distort the analysis results. This method is used for determining the distribution ratios in a wide range, from several units to values exceeding 10^4. An important advantage is the possibility of performing the extraction in the absence of even traces of oxygen [55], which is particularly important for readily oxidizable and unstable substances, e.g., for hydrogen sulfide and mercaptans. Continuous gas extraction as a method for measuring the distribution ratios was suggested for the first time in 1963 by Burnett [56] and was tested in studying the distribution of ketones and alcohols between aqueous and gas phases in the range of limit dilutions. Considerably later, in 1977, Leroi et al. [57] used this method for determining the limiting activity coefficients of solutes in volatile and nonvolatile solvents.

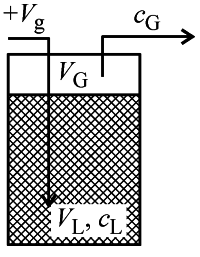

Fig. 13. Scheme of continuous gas extraction of volatile components from a solution in a nonvolatile solvent. For comments, see text.

The dynamic HSA is underlain by the equilibrium theory of continuous gas extraction, which was formulated for the first time by Vitenberg and Ioffe [58, 59] under the assumptions that the gas phase is ideal, the distribution isotherms are linear, and the solvent vapor over the pure liquid does not differ from that over the solution containing impurities of volatile substances. These assumptions are valid at limit dilutions and allow not only analytical but also physicochemical measurements [3–5].

The CGE is realized by passing a flow of a neutral extractant gas of the volume V_g through a solution of a volatile component with the initial concentration c_L^0 (Fig. 13). In the course of CGE from a nonvolatile solvent, the running concentration of the target component in solution c_L corresponding to the volume of the passed extractant gas V_g is related to the initial concentration c_L^0 by the equation [60]

$$c_L = c_L^0 \exp[-V_g/(KV_L + V_G)]. \quad (30)$$

From the results of gas-chromatographic determination of the solute concentration in the gas flow passing through a solution being analyzed, in accordance with (1) and within the range of linear detector response, the distribution ratio is calculated by the formula

$$K = \frac{V_g/V_L}{\ln(A_G^0/A_G)} - r, \quad (31)$$

where A_G^0 and A_G are the peak areas in the chromatogram corresponding to c_G^0 (initial concentration of the solute vapor in the volume V_G at $V_g = 0$) and c_G (solute concentration in the gas flow at the vessel outlet after passing the gas volume V_g), respectively.

The accuracy of the results obtained strongly depends on the volume ratio of the solution and extractant gas passed through it or, in other words, on the fraction of the target component extracted from the solution, δ_g:

$$\delta_g = 1 - \exp[-V_g/(KV_L + V_G)] = 1 - A_G/A_G^0. \quad (32)$$

The error of measuring the volumes V_G and V_L is negligible compared to the error of measuring the concentrations c_G and c_G^0 in the form of the peak areas in the chromatogram, A_G and A_G^0. In such cases, the relative error of determining the distribution ratio is related to the CGE conditions and fraction of the substance extracted from the solution by the formula

$$\Delta K/K = (\Delta A_G^0/A_G^0 + \Delta A_G/A_G)\{\ln[1/(1 - \delta_g)]\}^{-1}$$

$$= (\Delta A_G^0/A_G^0 + \Delta A_G/A_G)[\ln(\Delta A_G^0/A_G)]^{-1}$$

following from Eq. (31). It is quite evident that the relative error of measuring K by CGE decreases with an increase in the volume of the passed extractant gas, V_g, and will not exceed the total error of measuring the peak areas in the chromatogram if the fraction of the substance extracted to the gas phase will be no less than 63% and the A_G^0/A_G ratio will be no less than e (base of natural logarithm).

As an example of using dynamic HSA for determining low values of K, let us consider the results of studying the distribution of sulfur compounds (hydrogen sulfide, methyl mercaptan, ethyl mercaptan) between aqueous solutions and the gas phase [55]. The data obtained in that paper are fairly well consistent with the published values of K [61] determined by the static method. As seen from Fig. 14, in both cases the temperature dependence of the distribution ratios

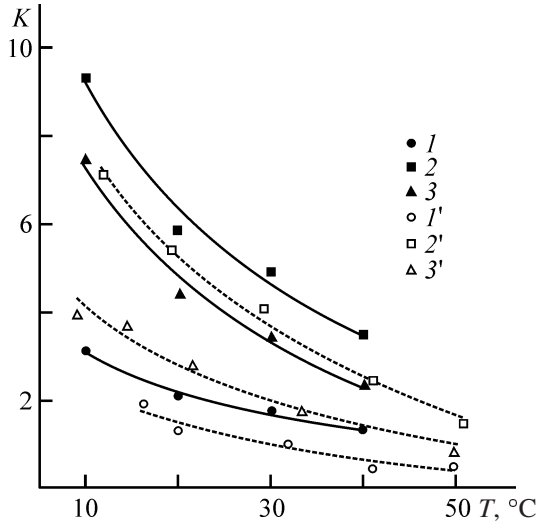

Fig. 14. Comparison of the (*1*–*3*) measured and (*1*'–*3*') published [61] distribution ratios K. (T) Temperature. (*1*) Hydrogen sulfide, (*2*) methyl mercaptan, and (*3*) ethyl mercaptan.

shows similar trend. The discrepancies are systematic, are within 10–50% for different components, and are apparently associated with the chemical composition of aqueous soltuions containing different amounts of mineral substances.

The acidity of aqueous solutions can significantly affect the fraction of the molecular form of components dissociating in the liquid phase. As the partial vapor pressure of such substances over the solution and hence their concentration in the gas phase are proportional to the fraction of the nondissociated species, the distribution ratios of hydrogen sulfide and mercaptans strongly depend on the degree of their dissociation in solution. The dissociation equilibrium is virtually totally shifted to the left at pH ≤ pK_a – 2 [3, 4, 6]. The pK_a values for hydrogen sulfide, methyl mercaptan, and ethyl mercaptan at 25°C are 7.2, 10.33, and 10.6, respectively [62]. Thus, the solution acidity should not affect the distribution ratio of hydrogen sulfide at pH ≤ 5 and those of mercaptans at pH ≤ 8. Therefore, in experiments for measuring the distribution ratios (Fig. 14), a buffer solution with pH 4.8 was chosen as the aqeuous phase. In going to a neutral solution, the distribution ratio of hydrogen sulfide becomes several times higher, whereas those of mercaptants increase insignificantly. In distilled water (Table 4), a significant fraction of hydrogen sulfide molecules occurs in the hydrated, bound form, which considerably decreases the fraction of molecular species. For mercaptans, the neutral medium is still sufficiently acidic, so that its effect on the distribution

*** Our measurements.

ratios is insignificant. Certain differences in the distribution ratios of mercaptans between distilled water and buffer solutions are apparently due to the salt background.

The potentialities of continuous gas extraction for the determination of large ($>10^3$) distribution ratios are illustrated by Table 5 in which the results of measuring K of lower alcohols between aqueous and gas phases by CGE are compared with the data of traditional static methods: vapor pressure measurements, tensimetric and chromatographic analysis of equilibrium vapor (AEV), and very popular dynamic GLC method (from chromatographic retention parameters). As distribution ratios obtained by CGE we took the data from [56, 63] and the values that we measured by the procedure described in [55]. The K values given for the other methods were calculated from data on the limiting activity coefficients γ^{∞} by formula (2).

It follows from Table 5 that the best agreement of data obtained by different authors is observed in the case of static AEV: The standard deviation does not exceed 6.5%. Somewhat worse agreement (≤10%) is

observed in the case of CGE. The differences between the average values obtained by these methods do not exceed 10%. The largest scatter of K is observed in the case of GLC, which may be due to problems that arise when water is used as a stationary phase in gas chromatography.

The dynamic versions of HSA, compared to static methods, required more sophisticated equipment, and more stringent limitations are imposed on the experimental conditions. For example, to attain the equilibrium distribution, it is necessary to restrict the gas flow rate and ensure small size of gas bubbles in the liquid. Therefore, SHE should be used in cases when static measurements are inconvenient or impossible. This concerns, in particular, determination of distribution ratios of substances unstable in air or of the ratios exceeding 100.

CONCLUSION

The suggested classification of chromatographic methods for determining distribution ratios of volatile compounds in the liquid–gas system involves the use of two principally different approaches. The first approach, based on a gas-chromatographic process, involves measurement of retention parameters of substances being chromatographed. The second approach is based on gas extraction and involves gas-chromatographic measurement of the absolute or relative concentrations of substances distributed between the condensed and gas phases.

The method for determining the distribution ratios of volatile substances from their retention parameters in a chromatographic column, suggested as early as the mid-1950s, still remains very popular, as being simple and prompt [23]. However, the sorption effects at the phase boundary in a chromatographic column can lead to significant errors in measuring K, which are systematic and reach tens of percents and more.

Methods involving the use of procedures and apparatus of gas extraction are based on various versions of static and dynamic HSA. Methods involving relative measurements of chromatographic peak areas, proportional to the concentration of the target substance on one of the phases of a heterogeneous system, are the most widely used for determining K for physicochemical and analytical purposes. In such cases, the accuracy of determining K considerably increases, because errors associated with the calibration of the chromatograph and measurement of absolute concentrations of substances are eliminated.

REVIEWS

Thin-Layer Size-Exclusion Chromatography of Polymers

E. A. Gurkovskaya

Moscow State University of Technology and Management, Moscow, Russia

Received May 15, 2007

Abstract—Modern concepts of thin-layer chromatography of macromolecular compounds are reviewed, including the features and potentialities of thin-layer size-exclusion chromatography.

DOI: 10.1134/S1070427208030026

INTRODUCTION

The use of thin-layer chromatography (TLC) for analysis of polymers was a sign of a big success of this method. The first TLC studies of random polymers were reported in 1968 [1, 2]. Since that the primary research direction in the field of TLC of polymers was associated with the use of this method for characterization of the polydispersity of polymers (compositional and molecular heterogeneity) and identification of polymers of various classes [3, 5]. The use of TLC allowed separation of random copolymers; identification of random, block, and alternating copolymers; identification and separation of di- and triblock copolymers; separation of block and graft copolymers from homopolymers; identification and separation of stereoregular poly(methyl methacrylates) (PMMAs) and polystyrenes (PSs) of various microtacticities; separation of geometric isomers of polybutadiene (PBD) and polyisoprene (PI); and identification of linear and branched PSs as well as PSs with different terminal groups and their separation from bi- and multifunctional PSs. In polymer separations, combined TLC methods are often used, e.g., polymer separation at the origin by selective desorption, followed by fractionation using adsorption or precipitation TLC. Adsorption TLC (ATLC) was first suggested for separation of copolymers [1, 3, 6, 7] and employed for MWD analysis in homopolymers [8]. To fractionate polymers by the molecular weight, Inagaki et al. [9, 10] proposed precipitation TLC (PTLC).

All the versions of TLC of polymers can be subdivided into two groups. The first group covers the methods based on adsorption. The second group includes the methods based on phase distribution of polymer solutions: precipitation and extraction TLC. Extraction TLC (ETLC) of polymers is based on selective dissolution of polymer solution at the origin. It has been used for separation of isotactic and atactic PMMA [11] and PS [12].

THIN-LAYER SIZE-EXCLUSION CHROMATOGRAPHY

Thin-layer size-exclusion chromatography (TLSEC) of polymers is based on the molecular-sieve effect. In this technique, adsorption of polymers is suppressed, and the pore space of the sorbent is presaturated with a solvent either by virtue of capillary condensation in exposing the plate to solvent vapor [3, 8] or by using so-called preelution [13] (passing a solvent through the chromatographic layer prior to applying a sample to be analyzed). The process is schematically shown in Fig. 1.

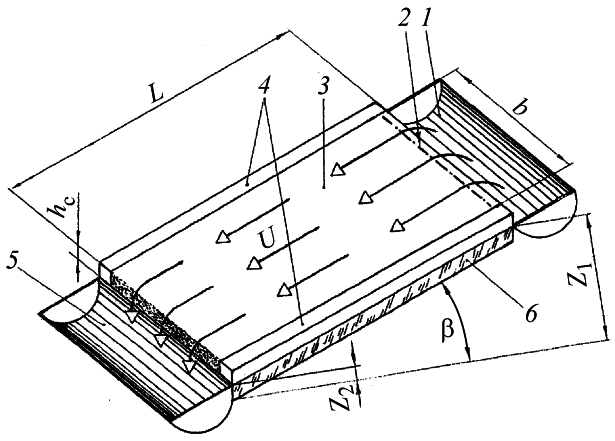

Fig. 1. Schematic of thin-layer size-exclusion chromatography. (*L*) Plate length and (*b*) plate width; (β) plate angle; (Z_1, Z_2) geometric head; and (*U*) mobile phase flow rate. (*1, 5*) Development tanks, (*2*) start line, (*3*) sorbent layer, (*4*) layer thickness control, and (*6*) glass support.

It was demonstrated that passing from size-exclusion chromatography to adsorption chromatography of polymers may be considered as a first-order phase transition. One always can accentuate one mechanism over the others by carefully controlling the chromatographic conditions. Furthermore, the molecular weight and chemical composition distributions could be analyzed separately using so-called critical chromatography. These methods were successfully used for separating oligomers, polymers, and biopolymers [14–17], and also for characterizing the compositional homogeneity of copolymers and functionality of oligomers.

The efficiency of TLSEC strongly depends on the characteristics of the adsorbent layer, particularly, its thickness [11, 17–19]. The thickness of 0.5–1 mm proved to be optimal. With decreasing adsorbent layer thickness, on the one hand, the band tailing decreases, and on the other hand, the ratio between the pore and interparticle spaces changes (interparticle space increases) as a result of decrease in the packing density of the adsorbent layer.

The effect of the packing density is particularly pronounced when comparing K_f vs. M relationships for the thin-layer mode of SEC and column gel chromatography, where the packing can be very dense (K_f is defined as the ratio of the path lengths of an analyte and a polymer completely displaced from the sorbent pores, and M is the molecular weight).

Principles of Thin-Layer Size-Exclusion Chromatography

Thin-layer size-exclusion chromatography was founded at the time when chromatographic separations on porous gels have become a routine laboratory technique of column HPLC [17–19]. Combining both techniques opened the door for the use of TLSEC for separation of macromolecular compounds, primarily proteins, as demonstrated by the experiments with various Sephadexes. In fact, a layer of a swollen Sephadex represents an "open" bed of a gel, which differs from the support in the column in only that it is amenable to manipulations, e.g., for applying samples and band development. Generally, in TLC, dry-bed plates are used [20, 21]. A solvent is moved by capillary forces after immersing the plate (most often vertically) in an eluent [22]. Johansson and Rymo [23, 24] were first who described an "open" gel bed.

As mentioned above, the use of thin-layer gel chromatography was bound to separations of proteins in aqueous buffer solutions, except a few experiments with peptides [24, 25], mucopolysaccharides [26], and ribonucleotides [27]. However, there are all reasons to believe that thin-layer gel chromatography will be widely used as a micromethod in these areas as well. The method operates with small samples, and its hardware implementation is rather simple. It allows performing a great number of determinations in a relatively short time. Therefore, thin-layer gel chromatography is particularly efficient in determination of the molecular weight of proteins. A slightly lower accuracy of this method (relative to the column mode) could be compensated by more extended statistics [14, 17, 18, 28]. Since many enzymes can be detected directly on a plate or paper strip using specific tests [28, 29], their molecular weights can be evaluated by analyzing even not very pure preparations. Moreover, this technique allows quick optimization of conditions for their further purification.

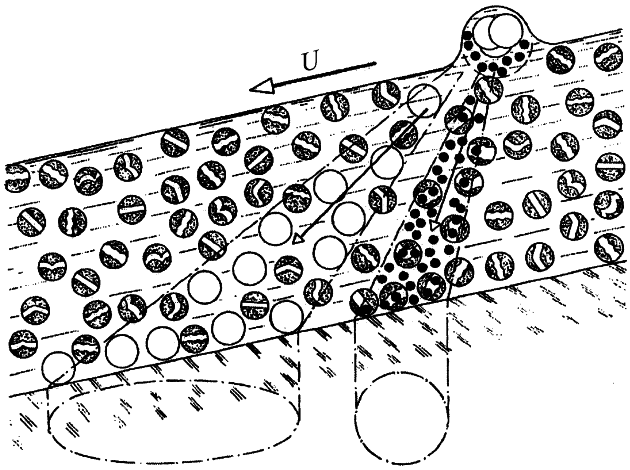

Fig. 2. Schematic of molecular-weight distribution of biopolymers and formation of chromatographic zones in TLSEC.

Thin-layer SEC can satisfactorily fractionate both macromolecular compounds (nucleic acids, polypeptides, proteins, and polysaccharides) and many oligomers such as relatively low-molecular-weight tannins and complexes. Compared to the column mode, TLSEC is simpler, more cost-efficient, much more express, and often more sensitive and precise [14, 17, 18, 30]. A schematic of molecular-weight distribution (MWD) of biopolymers in TLSEC is shown in Fig. 2.

However, the TLSEC technique is not identical to ordinary TLC. Thin-layer SEC resembles the classical TLC in that a thin layer of a sorbent is deposited onto a glass plate, a sample is spotted, and a mobile

phase is moved along the layer. The differences are as follows:

(1) In TLC, a sorbent is dried prior to sample spotting, and in TLSEC, a sample is spotted on a wet gel bed with compensation using a proper solvent.

(2) TLC is realized in the ascending mode, while TLSEC, in the descending mode; the flow rate is controlled by the plate angle; like that in TLC, the run is finished before the target compound passed into the lower tank. However, in TLSEC, continuous flow of a fluid is realized, i.e., unlike ordinary TLC, there is no solvent front here. Therefore, in TLSEC, R_f is not measured, but the position of the spots relative to appropriate references is determined.

(3) The separation efficiency should not depend on the solution concentration. The limit to which the initial solution concentration could be increased is controlled by its viscosity. High viscosity negatively affects the diffusion of the analyte, thus deteriorating the quality of separation.

The problems are in formation of a stable uniform thin layer of an adsorbent, data processing, precise determination of the molecular-weight distribution, and optimization of the development procedure.

Process and Instrumentation

Selection of sorbent. The major factor controlling the sorbent efficiency is the structure of its pore system, primarily the pore size. Following the Dubinin classification [31], the pores can be subdivided in their size into macropores ($r \sim 10^{-7}$ m), mesopores [$r = (15–1000) \times 10^{-10}$ m], and micropores ($r < 15 \times 10^{-10}$ m, specific surface area up to 10^5 $m^2\,kg^{-1}$).

Thin-layer SEC combines the experimental technique of TLC and separation mechanisms realized in gel chromatography. The same gels that are used in the column mode could be employed in TLSEC. However, in the thin-layer mode, there is a limitation in the particle size of the gel-forming material [18, 19].

The key point in gel permeation chromatography is the decision on the gel. In TLSEC, the key factor is the ability of the gel to form a stable adhesion layer on the support surface. This ability depends on the grain size, porosity, and solvation properties of the gel particles. As for widely used dextran-based Sephadex gels, superfine grades (10–40 μm) are best suited for the thin-layer mode, as providing the highest resolution [19, 28].

Dextran gels for gel-permeation chromatography are manufactured by Pharmacia Fine Chemicals AB (Uppsala, Sweden). Dextran is a polysaccharide build by glucose residues. It is obtained by fermentation of sucrose with *Leuconostoc mesenteroides*. In dextran, glucose residues are linked via α-1,6-glycoside bonds. The initial dextran is characterized by a broad molecular-weight distribution from 10^7 to 3×10^8. Purification, partial hydrolysis, and fractionation by precipitation with ethanol yield starting material for preparation of Sephadex. Alkaline solution of dextran (emulsion) is treated with epichlorohydrin to cross-link dextran chains with glyceryl bridges. As a result, an insoluble strongly hydrophilic 3D structure is formed, whose swellability depends on the degree of cross-linking.

Table 1 summarize characteristics of eight grades of Sephadex.

G-grade Sephadexes swell in DMSO, formamide, and glycol; and G-10 and G-15 gels, also in DMF. However, their swellability in organic solvents differs from that in water. These gels are stable in water, salt solutions, organic solvents, and alkaline and weakly acidic media. In strongly acidic solutions, the gels undergo hydrolysis, especially at elevated temperature. Sephadex is stable for 1–2 h in 0.1 N HCl, and for up to 6 months in 0.02 HCl.

Characteristics of Sephadex G-25 remain unchanged after keeping in 0.25 N NaOH at 60°C for 2 months. Sephadex wetted with a neutral solution is stable at 110°C, and, therefore, it can be sterilized in an autoclave. Dry Sephadex is stable up to 120°C; at higher temperature, it undergoes caramelization.

It is not allowed to expose Sephadex to long action of oxidants, since they destroy the gel matrix with the formation of free carboxy groups. The numbers marking eight grades of Sephadex gels from G-10 to G-200 correspond to their water regain W_R from 1 to 20.

Reliable MW fractionation range of Sephadex gels starts from 1500 for globular molecules and from 5000 to 10^8 for linear molecules. The grain structure of dry gels controls their water-regaining value, which, in turn, controls the possibility of formation of a stable stationary phase layer in TLSEC. Characteristics of Sephadex gels are presented in Table 2.

To apply a sorbent layer to a plate, a suspension of a swollen gel in a buffer solution is prepared first. The swelling time depends on the sorbent grade, ranging from several hours to 1 day and more. After applying a sorbent layer, a plate is arranged inside

Table 1. Characteristics of commercial dextran-based gels (according to manufacturer's data)

Gel	Dry grain size*, μm	Water regain, ml g^{-1}	Specific volume, ml g^{-1}	MW of peptides and globular proteins separated	MW of dextran fraction
G-10	4–120	1.0 ± 0.1	2–3	Up to 700	Up to 700
G-15	4–120	1.5 ± 0.1	2.5–3.5	Up to 1500	Up to 1500

* Gel of each grade is also produced as ultrafine fraction (grain size 10–40 μm).

a close chamber and connected to two tanks with buffer solutions via filter-paper bridges. The working chamber is arranged at an angle of 10°–20° to the horizon so that the mobile phase from the upper tank was supplied though the filter paper to the sorbent layer and passed through this layer down under gravity [18, 21, 30, 32, 33].

The plate angle, along with the sorbent type, is a key factor controlling the separation efficiency in TLSEC [18]. By changing the plate angle one can optimize the eluent flow (generally within the range from about 1 to 6 cm h^{-1}). The eluent flow depends on the sorbent type, plate angle, and molecular weight of an analyte. The eluent flow increases with increasing plate angle. The chromatographic layer should be equilibrated with the mobile phase for several hours prior to separation.

Therefore, the following conditions should be met in conducting chromatography in a thin layer of a gel: (1) the gel layer should not be dried up during several hours, (2) the plate angle and, therefore, the eluent flow should be kept constant throughout the experiment, and (3) supply and removal of the buffer solution should be continuous.

A significant advantage of TLSEC is that several samples may be spotted on a single plate, and their run could be directly compared with references. Changing the layer thickness, plate angle, and gel porosity allows optimization of the process simply by the common trial-and-error method [18, 19, 28, 33, 34].

It is not allowed to perform TLSEC separation with a dry gel layer, since a solvent from a sample, moving along the plate, causes swelling of the gel, making partitioning of a dissolved analyte impossible. The problem is eliminated in using a swollen gel in the descending flow mode [27, 35, 36].

It follows from the aforementioned that the key difference between the ordinary TLC and thin-layer gel chromatography is in that the latter is accomplished in a swollen layer of a gel suspension, and that the mobile phase is continuously moving through the gel bed.

The consistence of the gel suspension used for preparation of the chromatographic layer is the crucial

Table 2. Characteristics of Sephadex G gels

Gel	Water regain, ml g^{-1}	MW fractionation range	
		globular proteins	polysaccharides

G-100, G-150, G-200	72	5

factor controlling the quality of the sorbent bed (Table 3). Complete swelling of gels with high W_R takes a long time. There are two methods to prepare a swollen gel. In the first method, a dry gel is soaked in an estimated volume of the buffer solution to obtain the desired consistence. In the second method, the gel is soaked in an excess of the buffer solution, and, after settling, excess solvent is removed by decantation. Occasionally, centrifugation is used to separate strongly swelling gels. Table 4 shows the complete swelling times of Sephadex gels.

The optimal layer thickness depends to a certain extent on the gel type and gel coating procedure [14, 18, 19]. The simplest tool for gel coating is a stainless steel rod or glass cylinder with a diameter no larger than 10 mm, and a length slightly above the plate width. At its edges the rod is equipped with bushings or clamps of the same thickness as the layer that is planned to apply.

An excess of the slurry is put onto the plate and drawn along it with uniform motions back and forth to obtain a layer with a thickness not above 0.5–1 mm (with layers with a thickness above 1 mm, separations were demonstrated to be unsatisfactory). The adhesion of the slurry is sufficient to eliminate the need in some additional fixing tool [17, 18, 36, 37]. After applying the layer, the plate is placed in a chamber and connected via filter bridges to reservoirs filled with the eluent, and the chamber is arranged at an angle required for the experiment. In this position, the plate is left for 3–5 h for uniform distribution of the liquid in the sorbent layer, to obtain a constant-rate flow in the course of the experiments. In applying samples, the plate (chamber) should be arranged horizontally. Otherwise, the spots appear to be expanded, resulting in distortion of the chromatogram [30, 38, 39].

After plate development, the molecular weight of an analyte is estimated from the run using a calibration curve obtained with reference compounds.

In [40–43] we reported analytical applications based on TLSEC, including those for studying biopolymers. We have optimized conditions for analysis of low- and high-molecular-weight proteins, including such factors as pH of the mobile phase [44] and protein structure [41, 44]. The features of formation of chromatographic zones in TLSEC have been considered with an example of poly(ethylene glycols) (PEGs) [45]. For total and fractionated proteins, the mechanism of formation of chromatographic zones was analyzed using data on the aspect ratio and diffusion–sorption kinetics of the process. The mechanism of conformational transformations and their effect on the globule–coil phase transitions in protein molecules in the course of TLSEC were studied [40, 46, 47].

The mass transfer and factors controlling physicochemical processes occurring in analysis of proteins by TLSEC were studied in [48]. It was demonstrated that the plate angle is the key parameter in optimization of flow modes in TLSEC as a hydraulic system.

It was demonstrated experimentally that the resolution, which can be attained in TLSEC, is well comparable with that realized in combined methods such as column gel chromatography, low voltage electrophoresis, and gel electrophoresis [49].

Features and Potentialities

The TLC features are determined by the development mechanism during elution across the open adsorbent layer. This is a simple, rapid, and relatively low-cost technique.

The adsorbent layer plays a triple role: it is a chromatographic separation substrate, a point of generation and application of capillary forces driving the eluent across the plate, and a platform for detection (visualization) of chromatographic zones (spots) formed in the chromatogram after the development. All these provide simple realization of adsorption chromatography, which is an efficient tool for analysis

of weakly polar compounds. The open adsorbent bed used in TLC allows easy application of a sample, visualization of chromatograms by spraying with some common or specific visualizing agent, or, if needed, successive treatment with several reagents, and simultaneous analysis of a great number of samples, thus providing simple visualization and preservation of thin-layer chromatograms. There are broad possibilities in selective development of chromatograms and detection of any components, including radioactive isotopes. It is also possible to detect strongly adsorbable components. These features allow easy realization of secondary (two-dimensional and multiple) chromatography, employment of gradient development techniques, programming of the activity and pH gradient for the adsorbent layer, and realization of polyzonal and multiple TLC, etc.

Advantages of TLC are simplicity, rapidity, high separation efficiency and sharpness, and clearness of results. Despite up-to-date rather complex hardware implementation of TLC, this method now, as before, remains the simplest and most available version of liquid chromatography, combining such advantages as versatility, ultrahigh sensitivity, high resolution, rapidity, and applicability to analysis of wide spectrum of compounds. In TLC, separation conditions can be varied over a wide range by changing the elution system, adsorbent nature, and development procedure (two-dimensional, gradient, isocratic, etc.). The method is best suited for analysis of low- and medium-polarity compounds. It can be used for micropreparative fractionation, preconcentration, and trace analysis. In this case, a TLC plate may be used directly for sample enrichment by compressing a chromatographic zone (spot). Multiple TLC is the most efficient technique for enrichment of strongly adsorbable compounds. In this method, a trace component migrates in the least mobile zone of the eluent. It is advisable to begin selective enrichment of a sample for TLC analysis from solid-state extraction (SSE).

Visualization. A significant advantage of TLC is the possibility of broad variation of visualizing reagents for detection of colorless compounds on the chromatogram. In TLC, detection can be performed as follows: (1) without using reagents, by registration of UV absorption or natural fluorescence and (2) with suitable detection reagents (universal and selective) to form colored, fluorescent, or UV-absorbing compounds.

The first method is realized either by UV photograph of the chromatograph, or by the use of fluorescence quenching. In the latter case, a fluorescent indicator (luminophore) is introduced into the adsorbent layer. When excited with UV light at a wavelength corresponding to the absorption of the analyte, absorbing compounds quench the uniform layer luminescence and are detected as dark spots on a bright background. In the second method, concentrated acids, primarily sulfuric acid, are used as universal reagents. After spraying with sulfuric acid, some of compounds are detected in the cold, while most compounds, after heat treatment. To detect chemically resistant compounds, some oxidants such as 5% nitric acid, $KMnO_4$, and $K_2Cr_2O_7$ are added to sulfuric acid. As universal reagents for detecting organic compounds, phosphoric, perchloric, and other acids are used, and also iodine vapor, chlorine, and sulfur dioxide. One of the most sensitive and selective detection methods is registration of the natural fluorescence of analytes or of selective fluorescent indicators added.

Selective reagents form colored or fluorescent compounds on a group- or substance-specific basis. It is possible to use several reagents successively, to detect compounds of various classes or compounds with various functional groups.

In TLC, detection may be preceded by prechromatographic derivatization. In addition to the aid of detection, derivatization could be directed to increase the separation efficiency, e.g., by virtue of changing chromatographic behavior of compounds similar in their chemical structure or chromatographic properties. Derivatization can also increase the stability of analytes against oxidation or decomposition and regulate their adsorption activity, solubility, and other characteristics. An advantage of postchromatographic derivatization is the possibility of simultaneous conversion of all components, which allows identification of compounds with close R_f values on the basis of differences in the derivatization kinetics.

Identification. The detected TLC zones are primarily identified by comparison of the characteristic R_f values of the samples and references chromatographed on the same plate. The identity of zones is confirmed further by chemical or physicochemical analysis of compounds extracted from the sorbent layer or their analysis directly on the layer.

Quantitative Analysis

Quantitative TLC analysis was developed just in very early stages of the method. The first attempts to quantify the chromatograms, based on spot size measurements, were performed in 1948 [50]. In 1962, Gagliardi and Pokorny [51] have developed a quan-

tification procedure based on an empirical relationship between the spot area and the amount of a compound contained in it. In further progress of quantitative TLC, extraction of the spot with subsequent measurement by spectroscopic or other techniques was used. Starting from 1967, passing from such elution methods to quantitative analysis in situ, i.e., to determination directly by scanning the spots on the layer, was outlined. In this case, registration by the light absorption, fluorescence, radioactivity, or some other quantities, e.g., conductivity, can be used [32, 50].

Thus, there are three approaches to quantitative TLC: (1) extraction of the material from the spot with subsequent measurement using some proper analytical method (photometry, spectrophotometry, mass spectrometry, fluorometry, gravimetry, etc.); (2) measurement of the spot area; and (3) assessment of the distribution of the compound in the spot directly on the layer (in situ) (scanning).

The scanning methods cover optical methods (reflectivity, transmission, fluorometry, and fluorescence quenching); nuclear-physical methods (autoradiography, scintillation, and ionization); electrochemical methods (polarography and conductometry); methods employing gas-chromatographic detectors (flame ionization, thermal conductivity, and electron capture detectors); and enzymatic methods (bioautography).

In ordinary TLC, semiquantitative methods are widely used. They are based on measuring parameters characterizing the geometry of the chromatographic zone. The methods employ empirical linear relationship

$$S^{1/2} = n \log q + p,$$

where S is the spot area; q, weight of the compound; and n and p are empirical constants determined from the calibration curves.

However, this relationship does not always give satisfactory results because of imperfect detection of the spot boundaries, and quantitative determination can be performed directly by comparison with a series of references spotted on the plate along with the samples.

By now, many stages of the chromatographic process are standardized, improving the reproducibility and precision of the method. This has been favored by the introduction of specially designed devices for quantitative TLC.

Optical scanning methods are based on registration of the light absorption, reflection, and their combination. Also fluorescence and fluorescence quenching can be detected. The use of glass supports limits the spectral range to >325 nm, since glass and the adsorbent layer absorb UV radiation. Detection by measuring the reflection can be used over the entire spectral range from 196 to 2500 nm, including the UV range.

A significant drawback of the quantitative methods based on light transmission is associated with the nonlinear dependence of the signal of an optical detector on the amount of a compound in the spot. This nonlinearity is caused by nonuniform thickness of the adsorbent layer and by specific features of passing light through a scattering medium (described by the Kubelka–Munk equation). The use of the two-wavelength detection technique, with the first wavelength λ_1 corresponding to the absorption by both the analyte and adsorbent and the second wavelength λ_2, to the absorption by the adsorbent only, allows determination of the analyte by the difference signal. As a result of these improvements, the accuracy of up-to-date quantitative high-performance TLC approaches 1%.

The use of two-axis scanning for elliptical spots (two-dimensional TLC) and of multistep scanning of spots of imperfect shape (TLSEC) using a densitometer with a spotlight probe improved the accuracy to about 1%.

The detection based on measuring both the reflection and fluorescence quenching is used in TLC of compounds absorbing UV radiation. The most efficient method is measurement of the fluorescence of compounds in the sorbent layer. This is a highly selective and highly sensitive technique (more so with the use of laser fluorescence detectors). Its results are independent of the spot shape. The method is characterized by a wide range of linearity of the amount vs. fluorescence intensity plot.

Many companies manufacture devices for optical scanning of TLC chromatograms, e.g., Opton universal scanning system (Zeiss, Germany–the United States). Shimadzu (Japan) produces scanning systems (c-910, 920, 930, 9000) with two-wavelength scanning over the range 200–800 nm. The systems employ single-beam scheme with variable wavelength or fixed wavelength, double-beam scheme, and fluorometer. The double-beam version allows quantitative determination of one more compound in the chromatographic

spot [52]. Camag (Switzerland) produces scanners operating in the reflectance mode for measuring the light absorption, fluorescence, and fluorescence quenching. They are used for detection in circular and anticircular TLC with macro- and microslits.

For standardization of quantitative determinations, Russian manufacturers produce automated densitometers-fluorometers Den-Skan (Lenkhrom Science and Technology Center, St. Petersburg, Russia), based on a diode matrix. Densitoscopes of two types are also produced: Sorbfil (Sorbpolimer, Krasnodar, Russia) for quantitative assessments in TLC and Sorbfil-D for quantification of chromatograms using illumination with visible light (image is registered using a flatbed scanner).

Several conditions should be met in performing analyses by elution TLC: (1) complete extraction of the sorbent material with the analyte, (2) quantitative extraction of the analyte from the sorbent, and (3) precise analysis of the resulting solutions.

In quantitative elution TLC, it is recommended to use special measures to stabilize the compounds to be separated, e.g., to perform TLC in the dark or under diminished illumination, to remove traces of heavy metals from the sorbent, etc. [21, 51].

For quantitative elution TLC, like for other quantitative TLC techniques, the sample application procedure is of great significance. Generally, a sample is applied as a continuous band or a number of spots at the start line. For quantitative elution TLC, both methods are equivalent.

The reproducibility in quantitative elution TLC is so high that, in analysis of a 50-μg sample, the method gives a standard deviation of 2.5–4% (at $N = 10$). However, it should be pointed out that such a high accuracy is attained only at optimal experimental conditions. With decreasing sample to 10 μg, the error increases to 15% [53, 54]. Therefore, the elution techniques are not employed for quantitative analysis of microgram samples.

CONCLUSION

The major trends in TLC, and TLC of polymers in particular, are instrumentalization, passing to quantitative analysis, theoretical substantiation of ways to improve the efficiency of the method, and further extension of the applications to analysis of a broad spectrum of macromolecular compounds.

Important advantages of TLC of polymers are as follows: possibility of analyzing simultaneously a large number of samples (mass screening); easy detection of any compounds by developing the plate surface; complete analysis of all components of the sample spotted on a TLC plate; analysis of samples containing insoluble particles; and possibility of analyzing compounds requiring additional exposure to visualization reagents after chromatography.

Size-exclusion TLC of biopolymers demonstrates a number of useful characteristics such as pH and temperature independence and preservation of the native composition and structure of the analyte.

Thin-layer chromatography is realized in one of two versions: (1) qualitative (semiquantitative) and (2) quantitative. It allows operation with nano- and microgram samples, providing (under optimal conditions) the detection limit at a level of 10^{-8}–10^{-7} g, i.e., at a level characteristic of such physical methods as atomic absorption, mass spectrometry, X-ray fluorescence, etc., differing advantageously from them in simplicity of hardware implementation, analysis time, sensitivity, and cost.

Abstract—Results of thermodynamic calculations and kinetic studies of the reaction of zinc ferrite $ZnFe_2O_4$ and of a mixture of oxides, ZnO and Fe_2O_3, with chlorine and SO_2 are presented.

DOI: 10.1134/S1070427208030038

Chloride sublimation processes are widely used to produce anhydrous chlorides and oxychlorides in inorganic synthesis, recover rare and nonferrous metals from complex polymetallic raw materials in metallurgy, purify compounds to remove impurities, and separate metals [1–3]. In all these cases, the reacting systems are multicomponent.

Introduction of a new reagent into a heterogeneous system is, as a rule, accompanied by a change not only in the equilibrium composition of the products formed, but also in the rates of particular reactions occurring in the system [4]. It has been shown previously that results obtained in chlorination of individual metal oxides cannot be used to make definite conclusions about the chlorination kinetics of their mixtures [5, 6]. A noticeable influence on the rate of chloride sublimation is exerted by the composition of the gas phase. For example, addition of sulfur dioxide to chlorine accelerates the process even in those cases when the sulfur oxide does not react with a metal oxide in the absence of chlorine [7]. It has been found that the recovery of tungsten dioxydichloride from scheelite–wolframite concentrates into the sublimate increases in the presence of sulfur dioxide [8].

To find the optimal conditions of selective recovery of metals in the form of chlorides, it is highly important to study the reaction of double oxides or their mixtures with chlorine and the effect of the composition of the gas phase on this process.

However, published data on the behavior of double oxides in the atmosphere of chlorine are scarce. It was found in [9–11] that, in the reaction of cobalt and nickel ferrites with chlorine, the degree of chlorination of the elements contained in these compounds differs from that observed in chlorination of their individual oxides, but this fact was not explained.

Most kinds of zinc raw materials contain a large amount of iron. The basic form of zinc compounds in oxidized materials is ferrite. It has been found in a study of the reaction of ZnO with mixtures of chlorine and sulfur dioxide that formation of a stable zinc sulfate markedly diminishes the rate at which zinc chloride is formed [12]. By contrast, formation of iron sulfate in the reaction of Fe_2O_3 with chlorine in the presence of SO_2 leads to an increase in the degree of chloride sublimation of iron [13].

Here we report the results of thermodynamic calculations and kinetic studies of chlorination of zinc ferrite $ZnFe_2O_4$ and of an equimolar mixture of ZnO and Fe_2O_3 in the presence of SO_2.

EXPERIMENTAL

The equilibrium compositions of the gas and condensed phases of the system under study were calculated by the method of free energy minimization by ASTRA software [14] in the temperature range 300–800°C. The chlorination kinetics was studied at 500–700°C by the gravimetric method under isothermal conditions on an installation that automatically recorded the variation of mass with time. The sensitivity of the installation was 0.001 g per 1 mm of the scale. The weighed portion of a sample was 0.180–0.200 g. Under the experimental conditions, the $Cl_2 : SO_2$ ratio was 1 : 1. The total gas flow rate was 200 ml min^{-1} at a linear flow velocity of 0.05 m s^{-1}. Such a rate of gas supply to the surface did not impose any limitations on the chlorination process.

The reaction products formed were identified by X-ray phase analysis (XPA) on an ADP-2-01 diffractometer and by chemical analysis using standard procedures.

An equimolar mixture of oxides was produced by mechanical mixing of ZnO and α-Fe_2O_3 of ultrapure grade, and zinc ferrite, by joint decomposition of zinc and iron carbonates at 800°C [15]. According to the results of chemical and X-ray phase analyses, the sample produced by decomposition of the carbonates was composed of a single phase, $ZnFe_2O_4$, stable in air below 1590°C [16].

The specific surface area was found by the BET method from the low-temperature adsorption of krypton. The specific surface areas of ZnO, Fe_2O_3, and $ZnFe_2O_4$ were 3.4, 10.0, and 40.0 $m^2\ g^{-1}$, respectively.

The equilibrium compositions of the condensed and gas phases of the system ZnO–Fe_2O_3–Cl_2–SO_2 are shown in Figs. 1 and 2. In contrast to the system with individual zinc oxide, there is no $ZnSO_4$ in the condensed phase at 300–500°C (Fig. 1). Zinc is represented by the chloride. Iron is in the form of $Fe_2(SO_4)_3$ and Fe_2O_3. Noticeable amounts of $ZnSO_4$ appear above 550°C, when the content of $Fe_2(SO_4)_3$ and $ZnCl_2$ substantially decreases.

The main components of the gas phase (Fig. 2) are zinc and iron chlorides, SO_2, SO_3, O_2, and Cl_2. Even at 300–550°C, when the main part of $ZnCl_2$ is in the condensed phase, the partial pressure of zinc dichloride exceeds the partial pressures of iron chlorides by two orders of magnitude. At higher temperatures, the difference between the equilibrium pressures of zinc and iron becomes as large as four orders of magnitude. The partial pressures of $ZnCl_2$, SO_2, and SO_3 steadily increase with temperature, the maximum content of iron chlorides is reached at 550–600°C, when zinc is partly present in the form of a sulfate. The overall process at 300–550°C can be described by the equation

$$3ZnO + Fe_2O_3 + 3Cl_2 + 3SO_2 = 3ZnCl_2 + Fe_2(SO_4)_3.$$

At 550–650°C, part of chlorine is consumed for chlorination of Fe_2O_3 because of the parallel formation of zinc dichloride and zinc sulfate. At 650–800°C, the main part of iron is in the condensed phase in the form of an oxide. The gas phase contains considerable amounts of sulfur oxides, i.e., processes of parallel formation of $ZnCl_2$ and SO_3 may occur in the system.

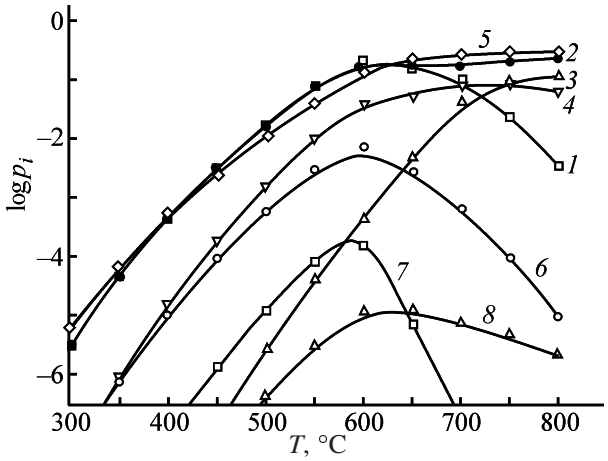

Fig. 2. Equilibrium composition of the gas phase of the system ZnO–Fe_2O_3–Cl_2–SO_2 vs. temperature T. (p_i) Partial pressure. (*1*) Cl_2, (*2*) SO_2, (*3*) O_2, (*4*) SO_3, (*5*) $ZnCl_2$, (*6*) $FeCl_3$, (*7*) Fe_2Cl_6, and (*8*) $FeCl_2$.

An increase in the content of chlorine in the starting system leads to a substantial rise in the content of iron chlorides in the gas phase and, accordingly, to a decrease in the selectivity of the process.

The pronounced difference between the partial pressures of zinc and iron chlorides in the system ZnO–Fe_2O_3–Cl_2 led the authors of [6] to conclude that selective transfer of $ZnCl_2$ to the gas phase is possible in joint chlorination of ZnO and Fe_2O_3. The thermodynamic calculations performed demonstrated that addition of SO_2 to the system under consideration must lead to a decrease in the selectivity of the process because of the increase in the concentration of iron chlorides in the gas phase.

The chlorination kinetics in the reaction of both

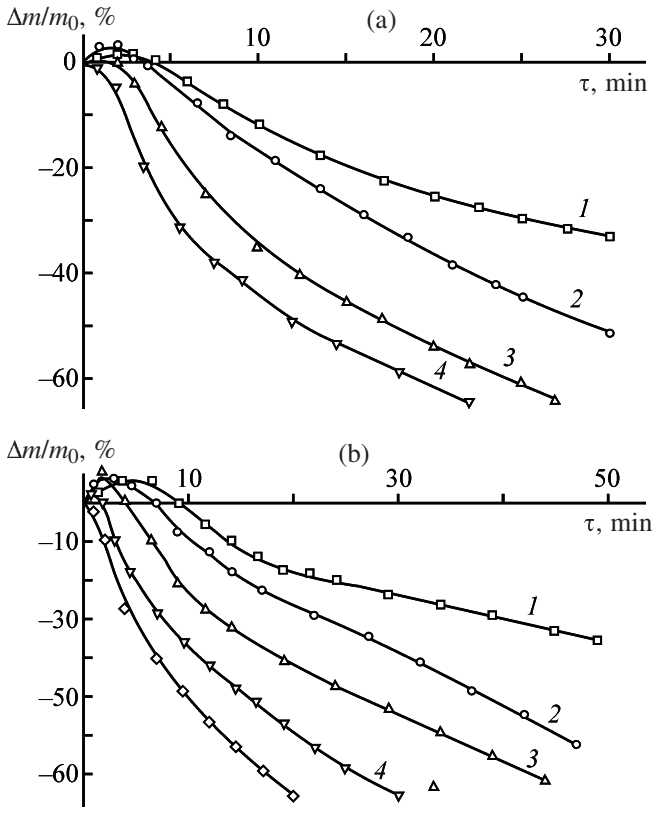

Fig. 3. Isotherms of interaction of (a) mixture of ZnO and Fe_2O_3 and (b) $ZnFe_2O_4$ with an equimolar mixture of Cl_2 and SO_2 at different temperatures. T, °C: (*1*) 500, (*2*) 550, (*3*) 600, (*4*) 650, and (*5*) 700. ($\Delta m/m_0$) Relative change in mass and (τ) time.

the equimolar mixture ZnO + Fe_2O_3 and $ZnFe_2O_4$ with chlorine in the presence of SO_2 was studied in the temperature range 500–650°C. Isotherms of chlorination of a mixture of ZnO with Fe_2O_3 are shown in Fig. 3a. At 500–600°C, the isotherms show a slight initial increase in the sample mass, which is due, according to chemical analysis data, to the formation of $Fe_2(SO_4)_3$. Making the experiment longer results in that the mass decreases because of the transfer of $ZnCl_2$ and $FeCl_3$ to the gas phase. At 500°C, the process rate markedly decreases in the course of time.

The activation energy of the process was estimated for a 15% decrease in mass. A value of 62.8 kJ mol^{-1} was obtained, which coincides with that calculated for chlorination of Fe_2O_3 in the presence of SO_2 at temperatures of 600–750°C [13].

For a more detailed examination of the composition of the chlorination products and solid-phase residue, a number of special-purpose experiments were carried out with an increased sample weight (0.600–1.000 g). The solid-phase residue was analyzed for the content of zinc, iron, and Cl^- and SO_4^{2-} ions. The distribution of zinc and iron in the chlorination products is presented in Table 1. The results obtained demonstrated that nearly the whole amount of zinc is in the form of chloride in the entire temperature range studied (400–600°C). At 400°C, $ZnCl_2$ is contained in the solid phase. As temperature is raised, the chloride sublimes. The formation of minor amounts of

$ZnSO_4$ is observed only in the initial stage of chlorination at comparatively low temperatures. In contrast to $ZnSO_4$, the presence of a considerable amount of $Fe_2(SO_4)_3$ is recorded in the entire temperature range studied. As the experimental temperature increases, the content of $Fe_2(SO_4)_3$ in the solid phase grows, so that the fraction of iron in the form of sulfate approaches 50% at 500–600°C. In parallel with the accumulation of $Fe_2(SO_4)_3$, $FeCl_3$ is formed. Iron trichloride virtually completely passes into the gas phase. At 550–600°C, more than 30% of iron is in the form of $FeCl_3$.

Table 2 compares the rates at which zinc and iron chlorides pass into the gas phase under kinetic conditions in the atmosphere of chlorine or a mixture of Cl_2 with SO_2. The results obtained demonstrate that the rate at which the mass of the mixture of ZnO and Fe_2O_3 changes in the presence of SO_2 exceeds that in the atmosphere of chlorine. This is particularly noticeable at temperatures higher than 500°C. The chlorination rate of zinc is virtually unaffected by SO_2, whereas chlorination of iron occurs at a higher rate. In the atmosphere of chlorine, the appearance of iron chlorides in the gas phase was observed only upon complete chemical sublimation of zinc, whereas in the presence of SO_2, iron and zinc chlorides pass into the gas phase virtually simultaneously. As also in the atmosphere of chlorine, the rate of chemical sublimation of zinc dichloride exceeds that of iron chlorides, but the difference between the rates is not so significant.

Figure 3b shows isotherms of interaction of zinc ferrite $ZnFe_2O_4$ with an equimolar mixture of Cl_2 and SO_2. They virtually coincide with the isotherms of chlorination of a mixture of oxides. The stage of the initial increase in mass, caused by the formation of $Fe_2(SO_4)_3$, is followed by that in which the sample mass decreases because of the sublimation of both $ZnCl_2$ and $FeCl_3$. The rates of chemical sublimation of the chlorides are close for $ZnFe_2O_4$ and a mixture of oxides. As in the case of the mixture of oxides, the rate at which $FeCl_3$ passes into the gas phase from the ferrite in the presence of SO_2 exceeds that in the atmosphere of individual chlorine.

An X-ray phase analysis made after chemical sublimation of zinc chloride from the ferrite demonstrated that the solid-phase residue contains exclusively α-Fe_2O_3. The data obtained and the fact that the processes of chemical sublimation of the chlorides from the ferrite and the mixture of oxides are virtually completely identical suggest that, in the course of chlorination, the ferrite stable in air in the temperature range under consideration decomposes into ZnO and α-Fe_2O_3. The specific structural features of $ZnFe_2O_4$, which is a normal spinel, suggest that $ZnFe_2O_4$ will decompose to χ-Fe_2O_3. However, no χ-phase was found in the temperature range studied. Thus, the chlorination of $ZnFe_2O_4$ occurs simultaneously with its decomposition to ZnO and α-Fe_2O_3. The same conclusion was made by the authors of [9–11], who considered the chlorination of cobalt and nickel ferrites.

The fundamental aspects of the chemical sublimation of iron from a mixture of ZnO and Fe_2O_3 in the presence of SO_2 are similar to those observed in the chlorination of Fe_2O_3 [13]: at comparatively low temperatures (300–500°C) it predominantly occurs via the reaction of simultaneous formation of $Fe_2(SO_4)_3$ and $FeCl_3$. The accumulation of $Fe_2(SO_4)_3$, stable in the atmosphere of chlorine, in the solid phase decelerates the process. At 600–750°C, the chemical sublimation of iron is due to the parallel formation of $FeCl_3$ and SO_3.

The kinetics of the chemical sublimation of zinc from the mixture of oxides in the presence of SO_2 strongly differs from that observed in chlorination of ZnO under the same conditions [12], when $ZnCl_2$ is formed as a result of successive occurrence of the reactions of formation and chlorination of $ZnSO_4$, whose considerable amounts were recorded in a wide temperature range.

In the reaction of a mixture of oxides with Cl_2 and SO_2, the amount of $ZnSO_4$ in the solid phase is extremely low. This cannot be due to the thermal instability of the sulfate, because $ZnSO_4$ decomposes at temperatures higher than 700°C [12]. In the system under consideration, $ZnCl_2$ is formed by direct chlorination of ZnO. SO_2 is bound because of the occurrence of the most thermodynamically favorable processes of formation of $Fe_2(SO_4)_3$, which is more stable in the atmosphere of chlorine than $ZnSO_4$, and also via the reaction of simultaneous formation of $FeCl_3$ and SO_3. As a result, the rate of transfer to the gas phase changes for only a single component, iron. The rate of the chemical sublimation of $ZnCl_2$ is independent of whether SO_2 is present in the gas phase.

This process is affected by Fe_2O_3 to a considerably greater extent. As shown previously [6], the rate of the chemical sublimation of $ZnCl_2$ both from a mixture of oxides and from zinc ferrite in the atmosphere of chlorine increases nearly 10-fold in the presence of Fe_2O_3. This is due to specific features of the interaction of chlorine with the inhomogeneous surface of Fe_2O_3. Although the chlorination rate of Fe_2O_3 is lower than that of ZnO, microscopic amounts of $FeCl_3$ are formed on the most active areas of the Fe_2O_3 surface even at 350°C. The multiple involvement of $FeCl_3$ in events of reaction with ZnO results in that the concentration of chlorine near the surface of the substance being chlorinated increases and the chemical sublimation of zinc is intensified. The chemical sublimation of iron occurs only after $ZnCl_2$ completely passes into the sublimate. The presence of SO_2 in the gas phase markedly facilitates the formation of $FeCl_3$ and thereby impairs the selectivity of the chemical sublimation.

CONCLUSIONS

(1) The fundamental aspects of chlorination in the presence of SO_2 are the same for zinc ferrite $ZnFe_2O_4$ and an equimolar mixture of ZnO and Fe_2O_3, just as in the case of chlorination in the atmosphere of pure chlorine.

(2) Making the system $ZnO–Fe_2O_2–Cl_2$ more complex by introduction of an additional component, SO_2, into the gas phase does not change fundamentally the pathway of the process.

(3) Presence in the reaction mixture of a solid component, Fe_2O_3, whose reaction with chlorine changes the composition of the gas phase, affects the fundamental aspects of chlorination to a considerably greater extent.

Abstract—Interaction of $Mg_3Si_2O_5(OH)_4$ nanotubes with aqueous solutions of potassium hydroxide in various temperature–time treatment modes was studied.

DOI: 10.1134/S107042720803004X

The discovery of carbon nanotubes [1], which possess a unique set of electronic, mechanical, and chemical properties and, therefore, are of particular practical interest, stimulated studies devoted to synthesis of nanotubes of various chemical compositions and analysis of their properties. It has been found that nanotubes can be formed from numerous chemical compounds [2–4]. It was shown in [5, 6] that compounds with layered structure can roll into nanotubes. By now, a large number of compounds with nanotubular structure have been synthesized, e.g., those based on boron nitride, dichalcogenides of transition metals, and oxides and hydroxides of vanadium, titanium, aluminum, silicon, etc. [2–4, 7–10]. However, the properties of such compounds are still poorly understood.

A topical issue is analysis of the mechanisms of mass transfer and chemical interaction of substances localized within inorganic nanotubes or on their surface. Studies of the behavior of fluids localized within nanotubes are primarily important because they lead to solution of a number of fundamental problems related to the structure of fluids on the nanometer scale and to the possible mutual influence of this structure on the transport of the fluid within nanochannels [11, 12] and on chemical transformations in nanoreactors [13, 14].

The applied interest in studies of the state of a substance in nanotubes is due to the potential possibility of filling the nanotubes with various substances. This makes it possible to affect their physicochemical properties [15, 18], creates conditions for immobilization and storage of substances [19], and furnishes an opportunity to improve the selectivity of separation and raise the rate of mass-transfer across membranes by using nanotubes in membrane materials [20, 21]. The large specific surface area of contact between the fluid and nanotube walls and the effect of the field of chemical interaction forces created by a nanotube on most part of the liquid medium it contains make topical an integrated study of mass transfer and chemical interaction of the fluid with nanotube walls.

Of particular interest are nanotubes based on hydrosilicates with a chrysotile structure, formed from double layers [22] via their rolling into nanorolls under the action of internal stresses in the double layer [5]. In [10, 23–26], the mechanism of nanotube formation was studied and nanotubes of chrysotile structure with varied chemical composition and morphology were obtained. The outer surface of nanotubes of this kind is mainly composed of magnesium, iron, cobalt, and nickel hydroxides, and the inner surface, of silicon dioxide.

The possibility of occurrence of chemical reactions between silicon dioxide and alkali metal hydroxides to give the corresponding salts of silicic acid makes promising an integrated study of mass-transfer processes in $Mg_3Si_2O_5(OH)_4$ nanotubes and of the chemical interaction between alkali solutions and the inner wall of a nanotube.

This study is concerned with mass-transfer processes in $Mg_3Si_2O_5(OH)_4$ nanotubes and their chemical interaction with aqueous solutions of KOH.

EXPERIMENTAL

Magnesium hydrosilicates $Mg_3Si_2O_5(OH)_4$ with a nanotubular structure were synthesized under hydrothermal conditions. As starting components served

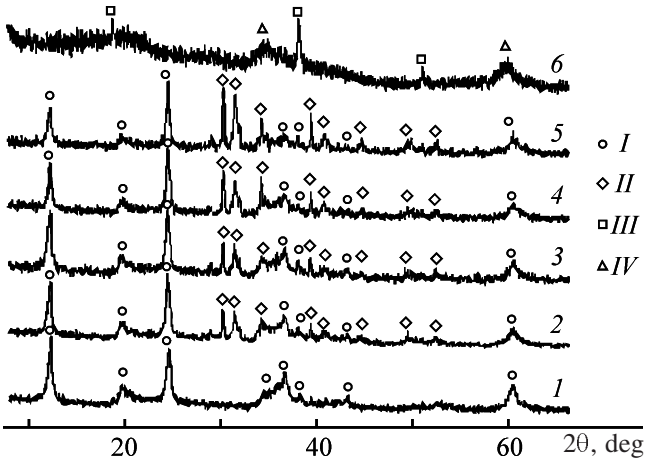

Fig. 1. X-ray diffraction patterns of (*1*) starting and (*2*–*6*) treated $Mg_3Si_2O_5(OH)_4$ nanotubes. (2θ) Bragg angle. Treatment duration, h: (*2*) 2, (*3*) 4, (*4*) 6, (*5*) 8, and (*6*) 10. (*I*) $Mg_3Si_2O_5(OH)_4$, (*II*) K_2SiO_3, (*III*) $Mg(OH)_2$, and (*IV*) $SiO_2 \cdot nH_2O$.

mixtures of magnesium oxide (analytically pure grade) and silicon oxide [KSMG silica gel, GOST (State Standard) 3956–76] with $MgO : SiO_2 = 3 : 2$. $Mg_3Si_2O_5(OH)_4$ nanotubes were synthesized, in accordance with the results of [26], at a temperature of 350°C and pressure of 70 MPa, with the starting mixture treated with a 1 wt % aqueous NaOH solution (NaOH of analytically pure grade) for 24 h. This yielded a morphologically homogeneous product, nanotubes with a chrysotile structure (Fig. 1), based on magnesium hydrosilicate. In these hydrothermal treatment modes, cylindrical nanotubes (Fig. 2) with narrowly varying inner (~4 nm) and outer (~25 nm) diameters were obtained. The products of the hydrothermal treatment were washed with distilled water to remove the alkaline components, dried, and subjected to an integrated physicochemical study.

The X-ray phase analysis of the nanotubes was performed on a DRON-3 diffractometer (CuK_α radiation). The shape and size of the nanotubes were determined by transmission electron microscopy (TEM) on an EM-125 electron microscope with an accelerating voltage of 75 kV.

The elemental composition of the samples was found by energy-dispersion X-ray fluorescence microanalysis with an Oxford Link microprobe attachment to a scanning electron microscope. The error in determining the content of elements was, on average, 0.3 wt % [27].

To study processes of filling of $Mg_3Si_2O_5(OH)_4$ nanotubes with a KOH solution and their chemical

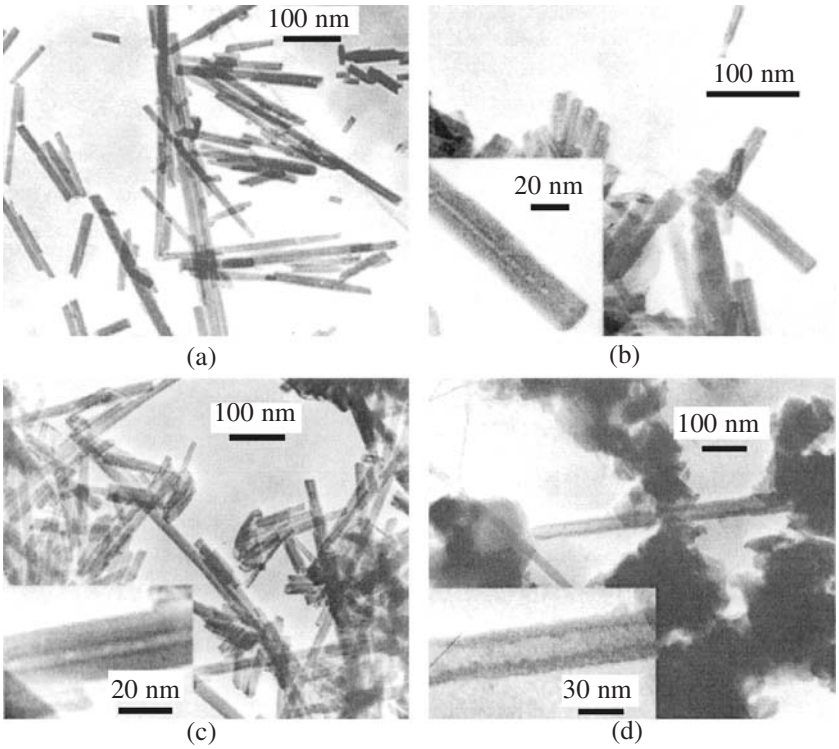

Fig. 2. TEM micrographs of (a) starting and (b–d) treated $Mg_3Si_2O_5(OH)_4$ nanotubes. Treatment duration, h: (b) 4, (c) 8, and (d) 10.

interaction at certain temperatures, weighed portions of nanotubes were placed in glass vessels with caps and poured over with a 0.5 M solution of KOH (KOH of chemically pure grade). The vessels were heated and kept in a thermostat at temperatures of 50 and 80°C for 2, 4, 6, 8, and 10 h. The thus treated nanotubes were washed with distilled water at room temperature, dried in air, and studied by the methods described above.

It was found that, in treatment of $Mg_3Si_2O_5(OH)_4$ nanotubes at 80°C for 2 and 4 h, the nanotubes are filled with the KOH solution (Fig. 3) and their inner layer, composed of SiO_2, reacts with potassium hydroxide, which is confirmed by the appearance of lines associated with K_2SiO_3 in the X-ray diffraction patterns of the samples (Fig. 1). However, the morphology and size of the nanotubes remain unchanged in this temperature–time mode of nanotube treatment with the KOH solution (Fig. 2b). If the duration of nanotube treatment with the KOH solution was extended to 6 h, and especially to 8 h, a substantial increase in the inner diameter of the nanotubes was observed (Fig. 2c).

The X-ray diffraction patterns of nanotubes treated with the KOH solution at 80°C for 8 h contain, in addition to the lines characteristic of magnesium hydrosilicate with a chrysotile structure, lines associated with K_2SiO_3, whose intensity is approximately equal to that of the $Mg_3Si_2O_5(OH)_4$ lines. A longer treatment (up to 10 h) of nanotubes with the KOH solution leads to their virtually complete disintegration (Figs. 1 and 2d). The micrograph of such a sample shows only single nanotubes with a substantially increased inner diameter (Fig. 3) and thin walls. The sample is mostly constituted by aggregates of lamellar particles, presumably composed of crystalline $Mg(OH)_2$ (Fig. 1). Thus, the chemical interaction is virtually complete after a 10-h treatment of $Mg_3Si_2O_5(OH)_4$ nanotubes with a 0.5 M KOH solution at 80°C.

In treatment of nanotubes with the KOH solution at 50°C, the chemical interaction of $Mg_3Si_2O_5(OH)_4$ nanotubes with potassium hydroxide is, presumably, considerably slower than that at 80°C, because no destruction of nanotubes was observed upon treatment of the nanotubes with the KOH solution during the whole time of the experiment, i.e., up to 10 h.

The study demonstrated that the interaction of $Mg_3Si_2O_5(OH)_4$ with an aqueous solution of KOH at 80°C can be represented as occurring in several stages at different rates. First, the nanotubes are filled with the KOH solution. KOH reacts within a nanotube

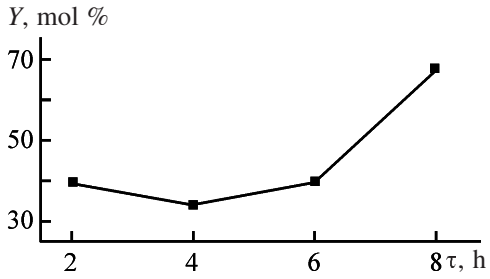

Fig. 3. Amount Y of potassium localized in a $Mg_3Si_2O_5(OH)_4$ nanotube vs. the treatment duration τ.

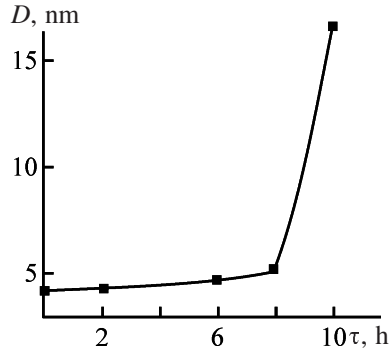

Fig. 4. Nanotube diameter D vs. the duration τ of treatment with the KOH solution. The largest of the diameters observed are presented.

with its inner silicon dioxide layer to give K_2SiO_3 and H_2O (Fig. 1). Because the potassium silicate solution has a higher viscosity, compared to water and the KOH solution [28], further supply of the reagent (KOH) and removal of the reaction product (K_2SiO_3) from the chemical interaction zone are hindered. However, the inner diameter of the nanotube increases in the course of the reaction of SiO_2 with KOH (Figs. 2 and 4), and, consequently, the transport of the components in the nanotube is facilitated, with the result that the rate of the chemical reaction increases. Thus, the chemical interaction occurs with self-acceleration after the stage in which the nanotube is filled with the KOH solution, which is manifested in the accelerating rise in the amount of the reaction product because of the increase in the inner diameter of the nanotube.

After the inner diameter of the nanotube reaches a certain critical value and the interlayer spaces increase because of the intercalation of potassium ions therein, the nanotube unrolls and the layers are split [5]. Because, as a result, the contact of the SiO_2 layer with the KOH solution becomes virtually unhindered by the transport of reagents to the surface, this stage will occur at a very high rate. This behavior of the process is confirmed both by data indicating that the reaction rate substantially increases after 8 h

of interaction and by the morphology of one of the reaction products, agglomerates of $Mg(OH)_2$ platelets (Fig. 2).

Thus, after the stage of filling of $Mg_3Si_2O_5(OH)_4$ nanotubes with a KOH solution, their interaction proceeds in two self-accelerating stages. The self-acceleration occurs because the transport of the reagent, KOH solution, into the reaction zone and the removal of the reaction products, and primarily K_2SiO_3, markedly raising the viscosity of aqueous solutions [28], from the reaction zone in the course of the chemical reaction itself are facilitated.

CONCLUSIONS

(1) Treatment of hydrosilicate nanotubes with a KOH solution at 50°C for up to 10 h does not lead to their degradation.

(2) On filling of the nanotubes with a KOH solution at 80°C, the nanotubes chemically interact with potassium hydroxide, which results in a structural-morphological transformation of nanotubes.

(3) The chemical interaction of KOH with $Mg_3Si_2O_5(OH)_4$ nanotubes and their structure mutually affect each other. As a result, the chemical interaction of KOH with nanotubes proceeds in two self-accelerating stages. The self-acceleration of the chemical reaction in the first stage occurs because the transport of components in the solution localized within the nanotube is facilitated by an increase in the nanotube diameter in the course of the chemical reaction. The self-acceleration in the second stage is due to unrolling of the nanotube.

Abstract—Stability of sodium borohydride in the form of concentrated solutions and suspensions and solids corresponding to a crystal hydrate in composition was studied. The effects of temperature, concentrations of sodium borohydride and alkali, and nature of alkali metal cation on the rate of sodium borohydride hydrolysis were studied.

DOI: 10.1134/S1070427208030051

Hydrogen storage is an urgent problem of hydrogen power engineering. None of existing methods of hydrogen storage (under a high pressure, in the liquid state, and in the cryoadsorbed state) meet the technical and service requirements to the hydrogen content (5 wt % and 45 kg m^{-3}), working pressure, temperature, and kinetics of hydrogen absorption and liberation [1, 2]. At present, the storage of hydrogen in a bound state using hydride-forming materials with high specific surface areas, hydrides, and borohydrides is considered promising. It is expected that such approach will provide fairly compact and safety hydrogen storage.

Preparation of hydrogen by reactions of alkali metal borohydrides with water is actively studied with the aim of developing hydrogen generators for fuel cells. Sodium borohydride is the most promising in relation to hydrogen content and safety of storage [3, 4].

Sodium borohydride is known to be a hygroscopic substance actively absorbing moisture. In the literature there are some data on the stability of borohydrides of alkali metals in water and in aqueous-alkaline solutions [5–8]. However, these studies were carried out either with very dilute solutions of borohydrides or with buffer solutions.

Here we report on an experimental study of various formulations of sodium borohydride, water, and alkali with the aim of determining hydrogen loss on storage of the formulations at various temperatures.

EXPERIMENTAL

We used a sodium borohydride powder containing 98% $NaBH_4$ as the starting substance. Experiments on the stability of aqueous-alkaline solutions of sodium borohydride were carried out in sealed vessels using the following technique. A solution of an alkali of a given concentration was prepared in a beaker. A dry sodium borohydride powder was added to the cooled (to prevent $NaBH_4$ decomposition before starting the experiment) alkali solution, and the beaker was placed in an ultrasonic stirrer up to complete visual mixing and formation of a uniform formulation. Then the beaker was placed in a stainless steel reactor. The reactor was hermetically sealed and placed in a thermostat kept at a preset temperature. The increase in the hydrogen pressure in the reactor was recorded by pressure gages (PA-21SR/80520.3 Keller manometers). A signal from the manometer was recorded and processed on a computer.

Such technique records the amount of hydrogen liberated during the hydrolysis of sodium borohydride. The amount of decomposed $NaBH_4$ was calculated by Eq. (1) using the following relationships.

$$NaBH_4 + 2H_2O = NaBO_2 + 4H_2 \quad (1)$$

$$m_{H_2} = \rho_{H_2} V_{H_2} = M_{H_2} P V_{H_2}/RT,$$

$$\Delta m_{NaBH_4} = -m_{H_2} M_{NaBH_4}/4M_{H_2} = -M_{NaBH_4} P V_{H_2}/4RT,$$

where m_{H_2} is the weight of liberated hydrogen (kg); V_{H_2}; free volume of the reactor (m^3); ρ_{H_2}, hydrogen

density (kg m^{-3}); T, temperature in a reactor (K); P, hydrogen pressure in a reactor (Pa); Δm_{NaBH_4}, weight of decomposed $NaBH_4$; M, molecular weight of a component; and R, universal gas constant (J mol^{-1} K^{-1}).

The weights of the consumed water and formed sodium metaborate $NaBO_2$ were calculated similarly:

$$\Delta m_{H_2O} = -M_{H_2O} P V_{H_2}/2RT,$$

$$\Delta m_{NaBO_2} = -M_{NaBO_2} P V_{H_2}/4RT,$$

The degree of sodium borohydride decomposition (%) as a result of its hydrolysis was calculated by the relationship

$$\xi = (\Delta m_{NaBH_4}/m_{NaBH_4}) \times 100,$$

where m_{NaBH_4} is the weight of $NaBH_4$ in the starting solution (kg).

This calculation procedure assumes that the amount of intermediates in the reaction mixture is insignificant. If the amount of intermediate compounds will be noticeable, it will lead to deviations from the calculated values. This remark concerns the commonly accepted presentation of the results of hydrolysis as the degree of $NaBH_4$ decomposition, based on measuring the concentration of the BH_4^- ion by iodometric titration. From the applied point of view, it is more natural to determine the degree of hydrolysis by hydrogen liberation. In this case, the amount of liberated hydrogen is related to its amount corresponding to the complete hydrolysis. We used this approach in our study.

The experiments on the determination of the stability of concentrated sodium borohydride solutions with a content of alkali $c \geq 3$ wt % by the above-described technique take much time. Such ternary formulations are viscous solutions with a low hydrolysis rate.

In the experiments on the determination of the stability of aqueous-alkaline solutions with the molar ratio $NaBH_4 : H_2O = 1 : 5$ at room temperature (22°C) at all NaOH concentrations, kinetic curves of $NaBH_4$ hydrolysis were linear (Fig. 1). At 22°C, the average rate of $NaBH_4$ hydrolysis v (% of $NaBH_4$/h) within 50 days for $NaBH_4$–$5H_2O$ with 3, 5, and 10% NaOH was, respectively, 0.004, 0.002, and 0.0005% $NaBH_4$/h.

In the experiments, we measured either the volume of liberated hydrogen or the pressure in a sealed vessel where the hydrolysis took place. Both procedures involve difficulties associated with prolonged

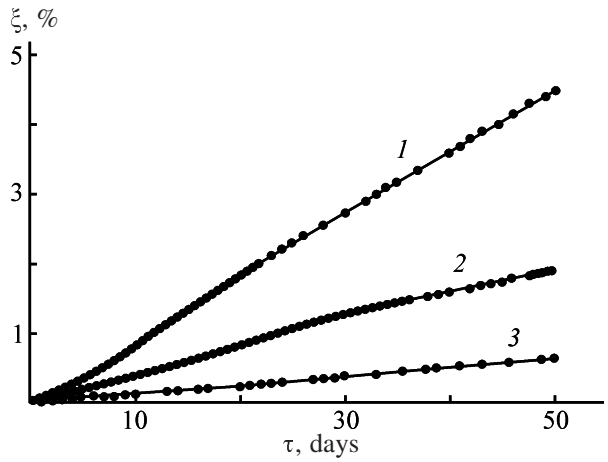

Fig. 1. Dependence of the degree of $NaBH_4$ decomposition ξ on time τ at 22°C. Molar ratio $NaBH_4 : H_2O = 1 : 5$. NaOH concentration, wt %: (*1*) 3, (*2*) 5, and (*3*) 10.

(lasting many days) measurements. When measuring volumes, it is necessary to use an instrument that provides the required accuracy both in the initial stage of the experiment (fast hydrogen liberation) and in the final stage of the hydrolysis. In measuring pressure, problems arise from high hydrogen fluidity and its leakage through joints.

To increase the accuracy of measurements at low hydrolysis rates, it is possible to use large volumes of solutions for increasing hydrogen liberation. Another step is the replacement of measurements of a time dependence of hydrogen liberation during the whole hydrolysis process from the initial state to the complete decomposition (integral procedure) by measurements of hydrolysis rates for various intermediate compositions (differential procedure).

The differential procedure requires that intermediates are absent (or present in small amounts) during the hydrolysis. Then, knowing the composition of the starting solution, it is possible to describe all the intermediate compositions of the system $NaBH_4$–$NaBO_2$–NaOH–H_2O during the hydrolysis using Eq. (1). Any composition can be prepared from $NaBH_4$, $NaBO_2$, water, and NaOH (if the alkali is added to a solution to enhance its stability). After preparing such solution of an intermediate composition, it is possible to measure the rate of its hydrolysis during a relatively short time. After carrying out measurements of hydrolysis rate for several characteristic compositions, it is possible to plot an integral time dependence of the degree of decomposition of sodium borohydride.

With such approach, several short-term experiments are carried out instead of one long-term ex-

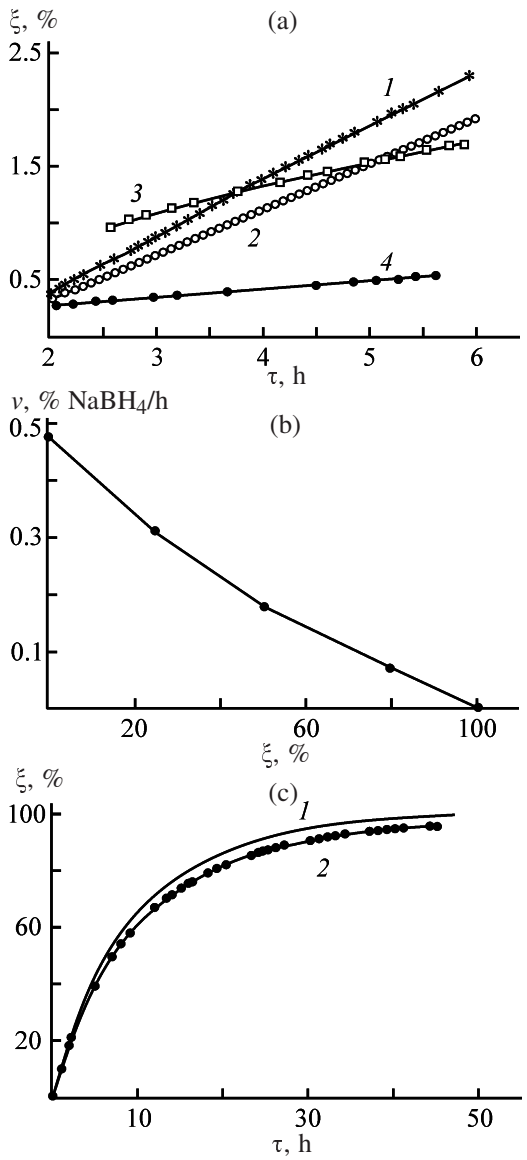

Fig. 2. Dependences of the (a) degree of $NaBH_4$ decomposition ξ on time τ for solutions of intermediate compositions, (b) rate of $NaBH_4$ hydrolysis on the degree of its decomposition ξ, and (c) degree of $NaBH_4$ decomposition ξ on time τ. (a) Degree of $NaBH_4$ decomposition, %: (*1*) 0, (*2*) 25, (*3*) 50, (*4*) 80. (c) Procedure: (*1*) differential and (*2*) integral.

periment. For slow processes, the gain in time can be appreciable, especially if it is required to obtain information on high degrees of decomposition. Advantages of such procedure consist in the possibility of carrying out simultaneous experiments with several intermediate solutions and of controlling the accuracy by varying the volumes of reactors and solutions in accordance with the hydrolysis rate.

To test the differential procedure, we used the data on the hydrolysis occurring for 45 days at 50°C up to the degree of $NaBH_4$ decomposition close to 100% (solution composition: 6.9% $NaBH_4$–90.1% H_2O–3% NaOH). The data of four experiments for the compositions corresponding to 0, 25, 50, and 80% decomposition of $NaBH_4$ are given in Fig. 2a. Points corresponding to the initial warming-up of the reactor and to attainment of the steady-stated mode are omitted from the plot. The curve of the rate of the $NaBH_4$ hydrolysis and the curve of the degree of the $NaBH_4$ decomposition obtained by integrating the former, together with the experimental data obtained by the integral procedure (a continuous experiment), are given in Figs. 2b and 2c. The maximal discrepancy between the data of the two procedures does not exceed 5% (Fig. 2c).

Stability of solutions of sodium borohydride in the system $NaBH_4$–$5H_2O$ was studied at 30 and 50°C and at concentrations of added alkali within the range 1–10% NaOH. The hydrolysis rate in the system $NaBH_4 : H_2O = 1 : 5$ was determined by a differential procedure with the following set of intermediate compositions: at 30°C, ξ_{NaBH_4} 0, 10, 20, 30, and 40%, 1% NaOH; ξ_{NaBH_4} 0, 25, and 50%, 3% NaOH; ξ_{NaBH_4} 0, 10, 30, and 40%, 5% NaOH; at 50°C, ξ_{NaBH_4} 0, 10, 20, 30, and 40%, 5% NaOH; ξ_{NaBH_4} 0, 25, and 50%, 10% NaOH.

The dependence of the rate of sodium borohydride hydrolysis and the integral dependences of the degree of its decomposition on time are given in Figs. 3 and 4. The average hydrolysis rate in the system $NaBH_4$–$5H_2O$ in a 50-day period at 30°C with 1, 3, and 5% NaOH was 0.02, 0.01, and 0.006% $NaBH_4$/h, respectively; at 50°C with 5 and 10% NaOH, 0.03 and 0.02% $NaBH_4$/h, respectively.

In going from room temperature (Fig. 1) to 50°C (Fig. 4b), the stability of sodium borohydride aqueous-alkaline solutions becomes tens times lower, and the loss of sodium borohydride becomes appreciable. At the same time, at temperatures of up to 30°C the solutions studied are sufficiently stable from the practical point of view.

The addition of alkali to a solution accelerates the aging of catalysts, which occurs the faster, the higher the alkali concentration. Weight indices of hydrogen storage also go down as the alkali concentration in the working formulation increases. The presence of alkali in the final product (sodium metaborate solution) will also make the recycling $NaBO_2 \rightarrow NaBH_4$ more difficult. We note that the experiments preformed in a thermostat allow us to estimate the kinetics and the lower boundary for the storage. Real

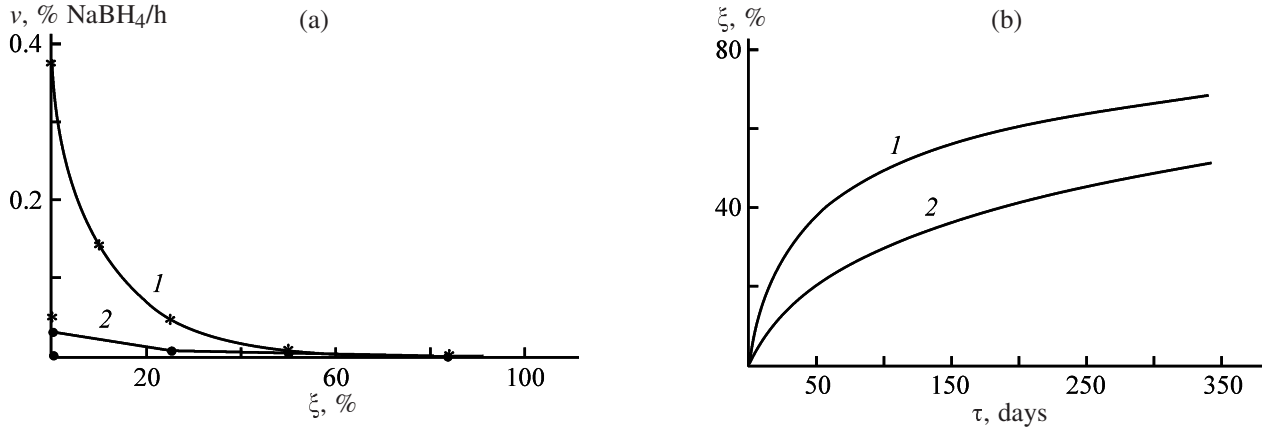

Fig. 4. Dependences of the (a) rate of $NaBH_4$ hydrolysis v on the degree of its decomposition ξ and (b) degree of $NaBH_4$ decomposition ξ on time τ at 50°C for the system $NaBH_4$–$5H_2O$. NaOH concentration, wt %: (*1*) 5 and (*2*) 10.

storage of appreciable volumes of such solutions will become complicated because of their self-heating.

The effect of the nature of alkali metal cations on the rate of hydrolysis of concentrated solutions was determined at the molar ratio $NaBH_4 : H_2O = 1 : 5$ both at equal weight concentrations of alkalis and at their equal mole fractions (see table).

The stability of $NaBH_4$–$5H_2O$ solutions at 50°C was determined by a differential procedure with the following set of intermediate compositions: 0, 10, and 20% $NaBH_4$ decomposition with 5% KOH; 0, 10, 20, 30, and 40% $NaBH_4$ decomposition with 6.85% KOH and with 5% NaOH. Curves of the rate of sodium borohydride hydrolysis and integral curves of the time dependence of the degree of its decomposition are given in Fig. 5.

At equal pH of solutions, i.e., at equal water/alkali molar ratios, the rate of the hydrolysis of BH_4^- ions is independent of the nature of alkali metal cations (Na^+ or K^+, Fig. 5, curves *1* and *2*).

The data obtained show that the hydrolysis of sodium borohydride in solutions cannot be completely suppressed by adding alkali. The addition of alkali to a solution decelerates the hydrolysis, but it is insufficiently effective at elevated temperatures. To stabilize the solutions so as to make possible their storage at temperatures above 30°C, the concentration of the added alkali should be no less than 5%.

Along with sodium borohydride solutions, we studied their suspension with a small amount of water

and solid samples with a low concentration of added alkali as a stabilizer.

Anhydrous $NaBH_4$ is a fine white hygroscopic powder with a bulk weight of 0.57 g cm^{-3}. As it absorbs water in open air at room temperature, the powder transforms into a wet foaming mass (hydrogen is liberated) and then into a vitreous mass.

It follows from the solubility polytherm of the binary system $NaBH_4$–H_2O that anhydrous $NaBH_4$ crystallizes from the aqueous solution at temperatures higher than 36.4°C, and the dihydrate $NaBH_4 \cdot 2H_2O$ crystallizes at lower temperatures. On heating, water is released from the crystal hydrate $NaBH_4 \cdot 2H_2O$, and a part of $NaBH_4$ dissolves in it, with the hydrolysis starting immediately. At $NaBH_4$ concentrations higher than 51.2 wt % and temperatures below 36.4°C, this system will be in the solid state in the form of a mixture of $NaBH_4 \cdot 2H_2O$ and $NaBH_4$. At lower concentrations, there will be mixtures of a solution and undissolved $NaBH_4 \cdot 2H_2O$. No other solid phases except for those mentioned above were found in equilibrium with a saturated aqueous solution.

It is known that alkali dehydrates sodium borohydride crystal hydrate. The concentration of alkali necessary for the dehydration is the higher, the lower the temperature. To assess the possibility of using solid formulations, we prepared pellets of dry sodium borohydride (I), sodium borohydride crystal hydrate $NaBH_4 \cdot 2H_2O$ (II), and $NaBH_4 \cdot 2H_2O$ with 0.1% NaOH (III) and studied their stability as a function of temperature. At room temperature, formulation II is in the solid state, and formulation III at the moment of its preparation looks like a dense suspension which rapidly hardens. In a closed vessel, all pellets preserve their properties and are stable up to 36.4°C for unlimited time. When stored in ~70% humid air, they "melt" within several days. Pellets of formulations II and III preserve their shape for a longer time, as they already contain water in the crystal hydrate form and absorb it more slowly than do $NaBH_4$ pellets. When stored in 30–40% humid air for 3 months, all the three types of pellets underwent no significant changes.

At temperatures exceeding 36.4°C, water of hydration is released from pellets of formulations II and III, and hydrolysis starts. The data of two experiments with pellets of formulations II and III at 40°C are presented in Fig. 6 (curves *1* and *2*). The curves practically coincide, i.e., the presence of alkali with such concentration (0.1% NaOH) under the conditions of water deficiency does not influence the hydrolysis, which occurs at a rate of approximately 0.045% $NaBH_4$/h for these formulations.

The indications [9] that sodium borohydride undergoes virtually no hydrolysis (0.01% $NaBH_4$/h) in

the course of storage in the form of a suspension in the system 44% $NaBH_4$–55.9% H_2O–0.1% NaOH at 40°C seem doubtful. The concentration of alkali suggested in [9] for the stabilization of sodium borohydride is very low, whereas water is contained in a larger amount than it is necessary for the formation of the crystal hydrate $NaBH_4 \cdot 2H_2O$ (molar composition of the suspension $NaBH_4$–$2.67H_2O$–0.002NaOH).

The experiments with this formulation (Fig. 6, curve *3*) have shown that the hydrolysis rate is approximately 20 times higher than that specified in the patent [9] and 4 times higher than the rate of the hydrolysis of sodium borohydride crystal hydrate (Fig. 6, curve *1*).

The storage in the form of suspension is an intermediate mode between the storage of solutions and solid formulations. The suspension is slightly more stable than solutions and, apparently, is more suitable for dosing than solid forms. However, it has also drawbacks inherent in both forms: like solutions, suspensions require special precautions against temperature rise; like solid forms of sodium borohydride, they are difficult to dose and require dilution with water before use.

Separate storage of water and anhydrous sodium borohydride completely eliminates stability problems. The main inconvenience of the separate storage is the necessity to prepare a working solution before its use in a reactor. Making a reliable block for feeding granules would be a natural engineering solution for a hydrogen source based on hydrolysis of sodium borohydride.

CONCLUSIONS

(1) The rate of hydrolysis in systems containing sodium borohydride, alkali, and water does not exceed 0.02% $NaBH_4$/h at temperatures of up to 30°C. An increase in temperature accelerates the hydrolysis, and even at 50°C it is impossible to store such formulations for a long time.

(2) To stabilize solutions for making possible their storage at temperatures above 30°C, it is necessary to add alkali in a concentration higher than 5 wt %.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Preparation of Double Nickel(II) Cobalt(II) Phosphates with Controlled Cationic Composition

N. N. Prokopchuk, V. A. Kopilevich, and L. V. Voitenko

Abstract—The possibility of the heterogeneous synthesis of crystalline nickel(II) cobalt(II) aqua ammine orthophosphates with a specified ratio of cations was studied. The substances were studied by IR spectroscopy, X-ray phase analysis, and thermal analysis. Owing to a wide color spectrum, they show promise as pigments for ceramic industry.

DOI: 10.1134/S1070427208030063

Orthophosphates of the type $M_3(PO_4)_2$ are widely used in various industries. Their representatives are selective catalysts, pigments, fertilizers, active substances of corrosion-protecting materials, components of medicinal formulations, and matrices for phosphors [1–3]. Both individual phosphates and their solid solutions are of considerable practical importance. The variation of solid solution compositions allows (within the limits of the homogeneity region) adjustment of certain properties, e.g., of the color of pigments, temperature of color change for temperature-sensitive pigments, etc. [4, 5]. Therefore, the search for solid solutions based on such phosphates is promising for obtaining new materials with valuable properties. Solid neutral aqua ammine orthophosphates of certain transition metals [cobalt(II), nickel(II), copper(II), and zinc(II)] [6, 7] have been described in the literature.

The aim of this study was to prepare crystalline heterometallic nickel(II) cobalt(II) aqua ammine orthophosphates with a specified ratio of cationic contents and to examine the synthesized substances by chemical analysis, IR spectroscopy, X-ray phase analysis, and thermal analysis.

Nickel(II) cobalt(II) aqua ammine orthophosphates were prepared by heterogeneous synthesis. As starting reagents we used orthophosphates of the compositions $Ni_3(PO_4)_2 \cdot 8H_2O$ and $Co_3(PO_4)_2 \cdot 8H_2O$ synthesized by the procedure described in [8]. A mechanical mixture consisting of thoroughly ground and intermixed weighed portions of hydrated nickel(II) and cobalt(II) orthophosphates with a specified molar ratio of the metal cations was kept in a hermetically sealed chamber in the atmosphere of gaseous ammonia at room temperature up to its complete deliquescence, i.e., transformation into a transparent oily mass of bright blue color. After that, the samples were withdrawn from the chamber and left to crystallize in air at 20–25°C to constant weight. The chemical composition of the synthesized compounds is given in Table 1.

The nickel content of the samples was determined gravimetrically with dimethylglyoxime [9]; the cobalt content, photometrically with nitroso-R salt [10]; the phosphorus content, gravimetrically by the quinoline–molybdenum method [11]; the ammonia content, by distillation in a vacuum on Seren'ev's apparatus [11]; and total water and ammonia content, from the weight loss on heating to 750°C in the course of 2 h. The IR spectra were taken on a Specord 75-IR spectrophotometer. Samples of compounds to be analyzed were prepared in the form of KBr pellets in which the concentration of a substance under study was 0.2–0.3 wt %. The X-ray phase analysis was carried out on a DRON-UM1 diffractometer (CuK_α radiation). A single crystal of graphite placed in a diffracted beam was used as a monochromator. The diffraction patterns were taken by the method of step scanning in the range of angles $2\theta = 4°$–$80°$. The scanning step was 0.05°, and the exposure time in a point, 3–9 s. The measured diffraction maxima were approximated by the pseudo-Voight function, with the K_{α_1} component being separated out. Unit cell parameters were calculated by the known procedure [12].

Thermal transformations of the substances were

studied on a Q-1500D derivatograph. Samples were heated in air up to termination of weight loss in the range 16–850°C. The experiment with the dynamic heating mode was carried out using cylindrical platinum crucibles with lids; the weighed portion of the compound was 0.450 g. The final and all intermediate decomposition products were obtained at a heating rate of the samples of 5 deg min^{-1}. Qualitative and quantitative anionic compositions of all the intermediate products and of the final heating product were determined by paper chromatography [13].

The absorption band corresponding to stretching vibrations of the N–H bonds is observed in the IR spectra of all the synthesized samples in the range 3420–3435 cm^{-1}. The bending vibrations of water and ammonia are recorded in the range 1600–1540 cm^{-1}. In the range 1470–1310 cm^{-1}, there is an absorption band corresponding to bending vibrations of metal-coordinated ammonia molecules, which form stable hydrogen bonds with the anion [14]. It should be noted that in the range 1285–1205 cm^{-1} there are only the absorption maxima corresponding to the symmetric bending vibrations of ammonia [15]. Antisymmetric and symmetric stretching vibrations of the PO_4^{3-} group are observed in the range 1050–710 cm^{-1}. Absorption bands at 680–535 cm^{-1} correspond to the vibrations of the P–O–P and O–P–O groups.

In the IR spectra of the synthesized nickel(II) cobalt(II) aqua ammine orthophosphates, there are absorption bands characteristic of coordinated ammonia molecules, which coincides with the results of chemical analysis of the substances, including the molar ratio $(NiO + CoO) : P_2O_5 = 3 : 1$ found for them.

It was found by X-ray phase analysis that all the synthesized nickel(II) cobalt(II) aqua ammine orthophosphates are crystalline and isostuctural to each other and also to hydrated cobalt orthophosphate $Co_3(PO_4)_2 \cdot 8H_2O$ [16]. The unit cell parameters of the compounds are given in Table 2.

For a detailed thermal analysis we chose nickel(II) cobalt(II) aqua ammine orthophosphate of the composition $Ni_{1.5}Co_{1.5}(PO_4)_2 \cdot 3.5NH_3 \cdot 7.9H_2O$. According to the data obtained (Fig. 1), thermolysis of the compound occurs in the range 20–830°C and is accompanied by three endothermic effects in the DTA curve with minima at 109, 174, and 208°C. At 450 and 615°C, we found two maxima of exothermic effects, which superimpose on endothermic effects and are accompanied by steps of the sample weight loss in the DTG and TG curves.

Products of thermolysis in the range 2–180°C are crystalline and isostuctural to each other and also to the starting $Co_3(PO_4)_2 \cdot 8H_2O$ [16]. On further heating, the substance becomes amorphous. The sample obtained at 505°C crystallizes again to become isostuctural to anhydrous cobalt(II) orthophosphate $Co_3(PO_4)_2$ [17]. It should be noted that, after com-

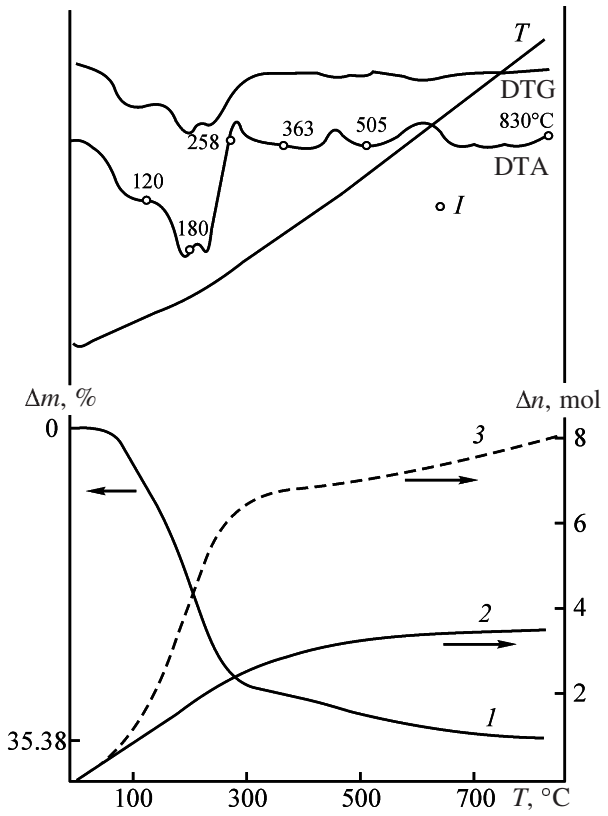

Fig. 1. DTA and TG curves of $Ni_{1.5}Co_{1.5}(PO_4)_2 \cdot 3.5NH_3 \cdot 7.9H_2O$. ($\Delta m$) Weight change, ($\Delta n$) change of the substance amount, and (T) temperature. (I) points of taking samples for analysis; (*1*) total weight loss of a sample under dynamic heating at a rate of 2.5 deg min^{-1}, (*2*) NH_3 loss, and (*3*) H_2O loss.

plete removal of water and ammonia from the starting compound, it decays to give two crystal phases, one of which is isostuctural to anhydrous cobalt orthophosphate [17] and the other, to nickel orthophosphate [18].

Absorption bands in the range 3430–1210 cm^{-1}, characteristic of vibrations of water and ammonia molecules, are observed in the IR spectra of both the initial phosphate and products of its heating to 505°C. They are absent only in the spectrum of the final sample obtained at 830°C (Table 3) from which, according to the data of chemical analysis (Table 4), H_2O and NH_3 have been completely removed. In the range 1070–730 cm^{-1}, absorption bands corresponding to asymmetric and symmetric stretching vibrations of PO_4^{3-} groups and absorption bands at 690–560 cm^{-1} corresponding to vibrations of the P–O–P and O–P–O groups are observed. Absorption maxima corresponding to bending vibrations of the phosphate tetrahedron and to vibrations of M–O bonds, which are most clearly pronounced in the spectrum of a sample taken at 830°C, are observed below 560 cm^{-1}.

The sample weight loss in the TG curve (Fig. 1) is observed in the range 60–750°C. The chemical analysis of the products of heating the compound of the composition $Ni_{1.5}Co_{1.5}(PO_4)_2 \cdot 3.5NH_3 \cdot 7.9H_2O$ (Table 4) indicates that, at 120°C, 1 mol of the sample loses 1.16 mol of ammonia and the same number of water moles, with the crystal structure remaining unchanged:

$$[Ni_{1.5}Co_{1.5}(NH_3)_{3.5}(H_2O)_{7.9}(PO_4)_2] \xrightarrow{120^\circ C} 1.16NH_3$$

$$+ 1.16H_2O + [Ni_{1.5}Co_{1.5}(NH_3)_{2.33}(H_2O)_{6.76}(PO_4)_2].$$

Upon further heating, the ammonia and water losses reach about a half of their total amount. This is accompanied by a strong endothermic effect with a minimum at 174°C:

$$[Ni_{1.5}Co_{1.5}(NH_3)_{2.33}(H_2O)_{6.76}(PO_4)_2] \xrightarrow{180^\circ C} 0.57NH_3$$

$$+ 3.25H_2O + [Ni_{1.5}Co_{1.5}(NH_3)_{1.76}(H_2O)_{3.51}(PO_4)_2].$$

In the range 180–258°C, the ammonia loss reaches approximately 70%, and the water loss, 80% of the initial content. The product of heating becomes amorphous, and, according to the data of qualitative paper chromatography, a negligible part of monophosphate anions PO_4^{3-} (less than 5 wt % of the total P_2O_5 content) transforms into the corresponding amount of the diphosphate $P_2O_7^{4-}$. This step of transformations can be described by a combination of the reactions of orthophosphate anion hydrolysis and hydrophosphate condensation to diphosphate, according to the following generalized schemes.

$$[Ni_{1.5}Co_{1.5}(NH_3)_{1.76}(H_2O)_{3.51}(PO_4)_2] \xrightarrow{258^\circ C} 0.71NH_3$$

$$+ 2.03H_2O + [Ni_{1.5}Co_{1.5}(NH_3)_{1.05}(H_2O)_{1.48}(PO_4)_2],$$

$$[M{\leftarrow}OH_2\cdots(PO_4)] \xrightarrow{180\text{–}258^\circ C} MOH^+ + HPO_4^{2-},$$

$$HPO_4^{2-} \longrightarrow P_2O_7^{4-} + H_2O.$$

Upon further heating to 363°C, the compound under study is still X-ray amorphous and contains trace amounts of diphosphate ions:

$$[Ni_{1.5}Co_{1.5}(NH_3)_{1.05}(H_2O)_{1.48}(PO_4)_2] \xrightarrow{363^\circ C} 0.45NH_3$$

$$+ 0.38H_2O + [Ni_{1.5}Co_{1.5}(NH_3)_{0.60}(H_2O)_{1.10}(PO_4)_2].$$

830	Mixture of two components	100	–	3.49	7.92

In the range 363–505°C, a new crystal phase, isostructural to cobalt orthophosphate [17], is formed, which is accompanied by an exothermic effect and removal of almost whole amount of ammonia and 88% of the initial amount of water:

$$[Ni_{1.5}Co_{1.5}(NH_3)_{0.60}(H_2O)_{1.10}(PO_4)_2] \xrightarrow{550°C} 0.50NH_3 + 0.16H_2O + [Ni_{1.5}Co_{1.5}(NH_3)_{0.10}(H_2O)_{0.94}(PO_4)_2].$$

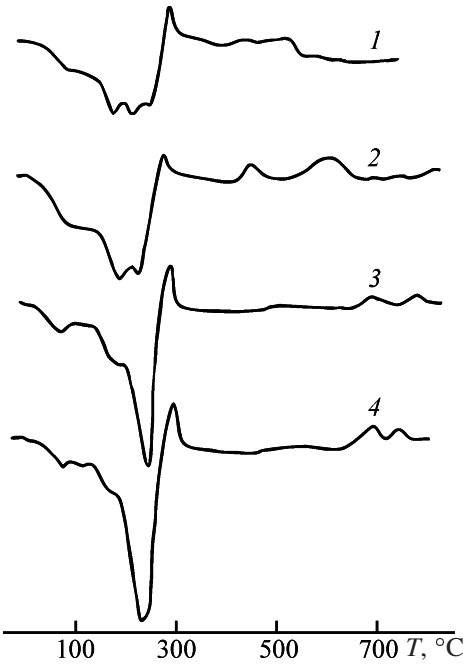

Fig. 2. DTA curves of (*1*) $Ni_{0.5}Co_{2.5}(PO_4)_2 \cdot 6.2NH_3 \cdot 8.7H_2O$, (*2*) $Ni_{1.5}Co_{1.5}(PO_4)_2 \cdot 3.5NH_3 \cdot 7.9H_2O$, (*3*) $Ni_{2.0} \cdot Co_{1.0}(PO_4)_2 \cdot 31NH_3 \cdot 7.6H_2O$, and (*4*) $Ni_{2.5}Co_{0.5}(PO_4)_2 \cdot 3.5NH_3 \cdot 7.5H_2O$. (*T*) Temperature.

With a further increase in temperature, residues of ammonia and water are removed to form two crystalline phases. This process is accompanied by a powerful exothermic effect with a maximum at 615°C:

$$[Ni_{1.5}Co_{1.5}(NH_3)_{0.10}(H_2O)_{0.94}(PO_4)_2] \xrightarrow{830°C} 0.10NH_3 + 0.94H_2O + Ni_{3.0}(PO_4)_2 + Co_{3.0}(PO_4)_2.$$

Thermal transformations of the synthesized nickel(II) cobalt(II) ammine phosphates with other ratios of cations occur similarly, as follows from the similarity of the shapes of the DTA curves shown in Fig. 2.

The X-ray analysis of final products of heating the aqua ammine phosphates $Ni_{0.5}Co_{2.5}(PO_4)_2 \cdot 6.2NH_3 \cdot 8.7H_2O$, $Ni_{2.0}Co_{1.0}(PO_4)_2 \cdot 3.1NH_3 \cdot 7.6H_2O$, and $Ni_{2.5}Co_{0.5}(PO_4)_2 \cdot 3.5NH_3 \cdot 7.5H_2O$ has shown that all of them are crystalline and are presented by a single phase, in contrast to the product of the thermolysis of the above-described sample of the composition $Ni_{1.5}Co_{1.5}(PO_4)_2 \cdot 3.5NH_3 \cdot 7.9H_2O$. It is interesting that, at the $Ni^{2+} : Co^{2+}$ molar ratio in the starting aqua ammine orthophosphate equal to 0.5 : 2.5, the final product of its thermal decomposition after complete removal of water and ammonia is isostructural to cobalt(II) orthophosphate [17]. On the contrary, in samples in which the mole fraction of Ni^{2+} is higher than 2.0 and that of Co^{2+} is lower than 1.0, the final thermolysis products are isostructural to nickel(II) orthophosphate [18].

Thus, we have determined the structure and properties of the synthesized compounds, nickel(II) cobalt(II) aqua ammine orthophosphates differing from each other in the $Ni^{2+} : Co^{2+}$ ratio.

To conclude, the synthesized substances and products of their thermolysis have various tints of lilac-violet color, which, in combination with their chemical composition, makes them promising as pigments for ceramic industry.

CONCLUSIONS

(1) Crystalline nickel(II) cobalt(II) aqua ammine orthophosphates with a specified ratio of cations have been prepared by heterogeneous synthesis.

(2) Nickel(II) cobalt(II) aqua ammine orthophosphates with the ratio NiO : CoO = 1.5 : 1.5 decompose on heating into two phases: the first phase is isostructural to nickel(II) orthophosphate, and the second, to cobalt(II) orthophosphate.

(3) At essential prevalence of one of the metals, the final thermolysis product is isostructural to the anhydrous orthophosphate of the corresponding metal.

Abstract—The conditions of synthesis of potassium oxotriperoxovanadate(V) $K_3[VO(O–O)_3]$ were developed, and the compound was isolated pure. Its physicochemical characteristics, including X-ray diffraction pattern, thermogravimetric data, and IR spectrum, are presented.

DOI: 10.1134/S1070427208030075

The composition and structure of various (cationic, anionic, and neutral) forms of peroxovanadates(V), determined by cryoscopic, potentiometric, spectrophotometric, X-ray structural, and NMR methods, have been reported [1–3]. In anionic forms, various ligands (chloride, fluoride, and oxalate anions, ammonia, pyridine, etc.) can also be present along with O–O groups. Among anionic forms of peroxovanadates(V), compounds containing only O–O groups are of the greatest interest. According to the ^{51}V and ^{17}O NMR data, anions of the following composition exist: $[VO_3(O–O)]^{3–}$, $[VO_2(O–O)_2]^{3–}$, $[VO(O–O)_3]^{3–}$, $[V(O–O)_4]^{3–}$, and $[\{VO_2(O–O)\}_2O]^{4–}$ [4, 5]. Peroxovanadates with the above anions are rich in oxygen in its common (oxo) and available (peroxo) form. The properties of individual salts of the above anions are poorly studied. As known, Li^+, Na^+, NH_4^+ salts of fully substituted peroxovanadates(V) do not dissolve in the reaction mixtures (V_2O_5–MOH–H_2O_2) in which they are formed, whereas the potassium salt dissolves and can be precipitated by adding ethyl alcohol [1]. Data on the compound stability are known only for several fully substituted peroxovanadates(V). These data are rather controversial. According to [6], under polythermal conditions Na_3VO_8 and K_3VO_8 decompose at 150°C. According to other data [1], K_3VO_8 is stable in storage only at 0°C and its aqueous solutions are also unstable.

In this study we developed the methods of synthesis of trisubstituted peroxovanadate(V) $K_3[VO(O–O)_3]$ (O_{av} = 17.2%), which is promising owing to high content of available oxygen. Presumably, owing to smaller size of the vanadium(V) coordination sphere, peroxovanadate of this composition is more stable than fully substituted $K_3[V(O–O)_4]$. The $[VO(O–O)_3]^{3–}$ anion in alkaline solution is stable [7]. Potassium oxotriperoxovanadate was isolated pure, and its properties were studied in the context of the problem of subsequent conversion of available oxygen into the form suitable for application in disinfection technology.

EXPERIMENTAL

To develop the synthesis of peroxovanadate(V) $K_3[VO(O–O)_3]$, we studied how the composition of the forming compounds varies with the ratio of the starting reactants (KOH, V_2O_5, and H_2O_2) and with synthesis temperature. We used the following method in the study. To a concentrated aqueous solution of KOH, dry V_2O_5 was added to complete dissolution. Then, a 30% H_2O_2 solution was added slowly. After the whole amount of hydrogen peroxide was added, a yellow-green mixture of a solid substance and a solution was formed, and then a yellow-green product was rapidly precipitated on adding ethanol. The precipitate was filtered onto a polymer filter, dried in a desiccator over sulfuric acid, and analyzed for the content of O_{av} and potassium. The potassium content was determined gravimetrically, and the O_{av} content,

* $K_3[VO(O–O)_3]$. Calculated, %: O_{av} 17.14, K 41.79.

permanganatometrically. Since peroxovanadates are analyzed for the content of available oxygen mainly by the pyrometric method [1], the permanganatometric and pyrometric methods were compared.

In the pyrometric method, a weighed portion of the substance in a porcelain crucible was placed into a muffle furnace, heated slowly from room temperature to 300°C, cooled, and then weighed again. The permanganatometric titration was performed by the standard procedure. In the course of the titration, the initially yellowish peroxovanadate solution became light brown and then, by the end of titration, transparent and colorless. The equivalence point was determined clearly. The products prepared in various syntheses contained the following amounts of O_{av}:

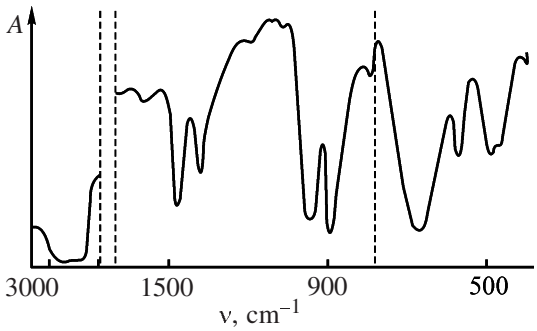
Method	Content, wt %			
Permanganatometric	15.91	15.52	16.17	15.51
Pyrometric	16.01	15.70	16.17	15.50

The samples with the O_{av} and potassium concentrations close to the calculated values were studied by X-ray phase and thermogravimetric analyses and by IR spectroscopy. Their stability in storage was also determined. X-ray diffraction patterns were recorded on an ADP-2-0.1 diffractometer (CuK_α radiation, Ni filter) and processed with a program developed for DRON diffractometers. The thermograms were recorded on a Q 1500 D derivatograph connected to a Pt–Pt/Rh thermocouple. Al_2O_3 was reference. The heating rate was 5 deg min^{-1}. The IR spectra of the compounds prepared (mulls in mineral oil between KBr plates) were recorded on a UR-20 spectrometer.

Table 1 shows how the composition of the peroxovanadates prepared varies with the reactant ratio and temperature.

As can be seen, peroxovanadate of the composition close to $K_3[VO(O–O)_3]$ is synthesized either at KOH excess ($KOH : V_2O_5$ = 6.2–6.4) or at a stoichiometric ratio of 6 : 1, upon cooling to 0°C. The resulting peroxovanadate $K_3[VO(O–O)_3]$ is a greenish-yellow finely crystalline substance difficultly soluble in water. It exhibits stability during storage in dry atmosphere. In storage for 50 days, peroxovanadate decomposes at an average rate of 2.6×10^{-2} (wt %) day^{-1}, whereas in storage for 85 days, at a rate of 4.6×10^{-3} (wt %) day^{-1}, i.e., in the late storage periods the decomposition rate decreases, which is characteristic of other substances containing available oxygen, for example, of peroxosolvates of salts of inorganic acids [8].

The results of X-ray phase analysis of $K_3[VO(O–O)_3]$ are given in Table 2. The X-ray characteristics of $K_3[V(O–O)_4]$ from [9] are listed for comparison.



It may be suggested that, in the course of the synthesis, the asymmetric anion $[VO(O–O)_3]^{3–}$ disproportionates with the formation of more symmetric anions, $[VO_2(O–O)_2]^{3–}$ and $[V(O–O)_4]^{3–}$. The diffraction pattern of the product prepared contains no bands of fully substituted peroxovanadate. To our knowledge, no X-ray data are available from the literature on other incompletely substituted peroxovanadates, including $K_3[VO_2(O–O)_2]$. We believe that the compound synthesized is pure potassium oxotriperoxovanadate $K_3[VO(O–O)_3]$.

Thermogravimetric analysis shows that the synthesized peroxovanadate $K_3[VO(O–O)_3]$ is reasonably stable. It decomposes with the exothermic effect at 195–200°C. The mass loss in the process is 16%, which is in satisfactory agreement with the value of 16.7% found for the O_{av} content by permanganatometric titration. For all the peroxovanadates formed,

we recorded the IR spectra (Table 1). The absorption bands of water were found in none of the spectra (see figure). Evidently, under the chosen conditions of the synthesis, peroxovanadates are isolated in the anhydrous state. The observed bands (cm^{-1}) can be assigned as follows: 875 s ν(O–O), 550 s ν_{as}[V<(O–O)], 615 s ν_s[V<(O–O)], 960 vs ν(V=O). The IR spectra of potassium tetraperoxovanadate contain bands of ν(O–O) and ν[V<(O–O)] (cm^{-1}) at 850 s, 560 s, and

IR spectrum of $K_3[VO(O–O)_3]$. (*T*) Transmission and (ν) wavenumber.

605 m [10]. The absorption band ν(V=O) at 970 cm^{-1} is present in the spectra of $K_2[VO(O–O)_2Cl]$ [7] and $K_4[V_4O_4(O–O)_6F_4]$ [11]. In addition to the above bands, the spectrum contains a band at 490 cm^{-1}, which is difficult to assign in our case. In this region, the band of halooxoperoxovanadates ν(V–Hal), where Hal is F or Cl, is present [7, 12].

Evidently, application of oxoperoxovanadate $K_4[VO(O–O)_3]$ in disinfection technology will require catalysts or solvents facilitating rupture of the O–O bond and formation of ions and radicals similar to those generated in decomposition of hydrogen peroxide: H_3O^+, HO_2^-, $OH^\bullet$, and $OH_2^\bullet$. Such ions and radicals, as hydrogen peroxide itself, directly participate in suppression and killing of pathogenic microorganisms.

CONCLUSION

The conditions of synthesis of individual pure oxotriperoxovanadate $K_3[VO(O–O)_3]$ were developed. The peroxovanadate is stable: it decomposes at 150°C, the rate of loss of O_{av} in storage for 85 days is 4.6×10^{-3} (wt %) day^{-1}.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Nanofiltration Treatment of Aqueous Solutions to Remove Triazine Herbicides

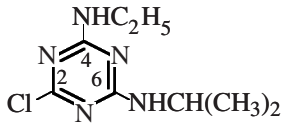
V. V. Siyanitsa, V. M. Kochkodan, and V. V. Goncharuk

Dumanskii Institute of Colloid and Water Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received July 9, 2007

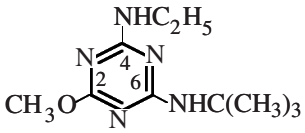
Abstract—Nanofiltration treatment of aqueous solutions to remove triazine herbicides (terbumetone, desmetrine, atrazine) with an OPMN-P membrane was studied. The effect of the molecular mass of herbicides, working pressure, and extent of permeate removal on the retention of solutes was analyzed.

DOI: 10.1134/S1070427208030087



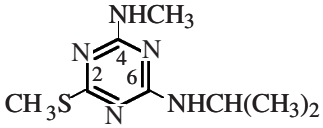
Treatment of natural water to remove herbicides is a serious environmental problem. When finding way into drainage and ground water, the herbicides used in agriculture exert a carcinogenic, mutagenic, and allergic effect on humans. Under the natural conditions, triazine herbicides are metabolized during a long time, including formation of more toxic forms [1].

Herbicides are removed from water by various physicochemical methods: ozonation, biodegradation, adsorption on activated carbons and ion-exchange resins, and coagulation [1]. However, these methods cannot always provide the necessary degree of toxicant removal from aqueous solutions, and, therefore, the problem of water treatment to remove herbicides remains topical.



Recently, considerable attention has been given to nanofiltration treatment of underground, natural, and waste water to remove herbicides [2–4]. In this case, water is treated in a single stage, which is the most important advantage of nanofiltration over coagulation and flocculation. Moreover, this technique can replace the adsorption treatment and reagent disinfection. Other advantages of nanofiltration include no need for reagents, simple apparatus, low materials consumption, and ease of automation [5]. At the same time, the nanofiltration treatment of water to remove herbicides of various classes has been insufficiently studied.

EXPERIMENTAL



This study is concerned with the nanofiltration treatment of water to remove widely used herbicides of the triazine series: atrazine, desmetrine, and terbumetone (manufactured by Dr. Riedel de Haën, Germany):

Atrazine

Terbumetone

Desmetrine

The principal physicochemical parameters of the compounds are listed in the table. The concentration of the pesticides in solution was 10 mg dm^{-3}.

An OPMN-P nanofiltration composite membrane (manufactured by Vladipor, Russia), which is a polyamide polymeric film on a porous polypropylene substrate, was used in the study.

The nanofiltration treatment of aqueous solutions to remove herbicides was performed in the dead-end filtration mode. For this purpose, a 0.4 dm^3 stainless steel experimental membrane (membrane area 50.2 cm^2) cell equipped with a stirrer was used. The stirrer rotation rate was 300 rpm. The working pressure in the cell was created with compressed nitrogen. The solution pH was adjusted with 0.1 N NaOH or HCl. The measurements were made with an LPU-01 pH-meter.

The concentration of herbicides in the solutions

Principal physicochemical parameters of pesticides

Parameter	Atrazine	Desmetrine	Terbumetone
Molecular formula	$C_8H_{14}ClN_5$	$C_8H_{15}N_5S$	$C_{10}H_{19}N_5O$
Molecular mass	215.69	213.13	225.29
Dissociation constant pK [6]	1.68–1.85	3.1–3.93	4.2
log P*	2.61	1.82	2.09

* log P is the coefficient of substance distribution between the organic phase and water (hydrophobicity coefficient) according to [6, 7].

was determined spectrophotometrically with a Specord UV-VIS instrument (Germany) at a wavelength of 200 nm. The retention coefficient R (%) of herbicides by the membrane was calculated by the formula

$$R = 100 \times (c_0 - c_p)/c_0,$$

where c_0 and c_p are the herbicide concentrations in the starting solution and the permeate, respectively.

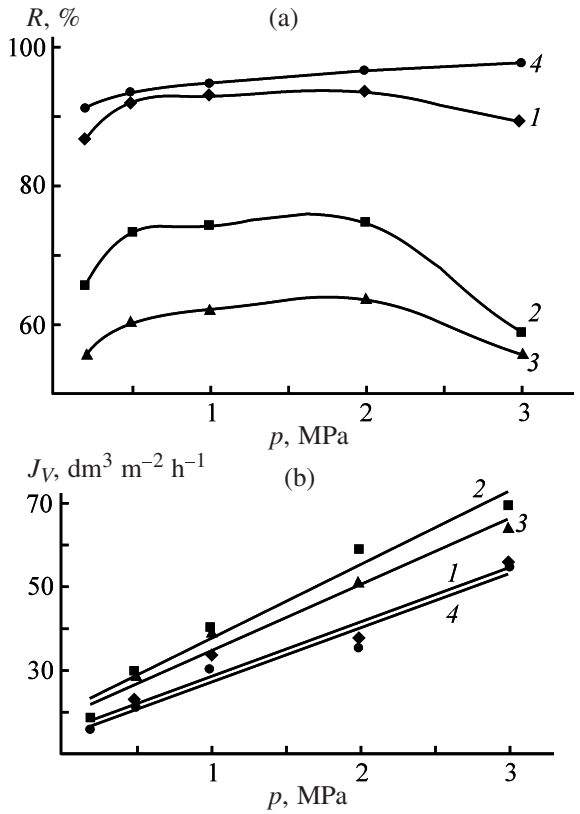


Fig. 1. (a) Retention coefficient R of herbicides and (b) membrane throughput J_V vs. the working pressure p. Herbicide concentration, mg dm^{-3}: (*1–3*) 10 and (*4*) 1; pH 6.2; extent of permeate removal 10%. (*1, 4*) Terbumetone, (*2*) desmetrine, and (*3*) atrazine.

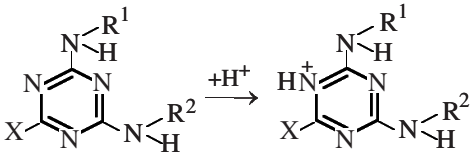
The transmembrane flux (throughput) J_V was calculated by the equation [18]

$$J_V = \Delta V/S\Delta\tau,$$

where ΔV is the permeate volume (dm^3) that passed across a membrane of area S (m^2) in a time $\Delta\tau$ (h).

The ζ potential of the membrane was determined with an Anton Paar electrokinetic analyzer (Austria) by measuring the streaming potential along the membrane surface for a flow of a 0.001 M KCl solution. The software of the analyzer enables automatic calculation of the ζ potential by the Helmholtz–Smoluchowski equation with account of the surface conductivity of the membrane.



The dependences of the retention coefficient and throughput of the OPMN-P membrane on the working pressure in filtration of aqueous solutions of the herbicides under study are shown in Fig. 1. It can be seen that, as the working pressure is raised to 1.0 MPa, the retention of the herbicides becomes larger (Fig. 1a, curves *1–3*). The retention of the herbicides increases with the working pressure, as also does salt retention in reverse-osmosis water treatment, because the flux of water across the membrane is directly proportional to the working pressure, whereas the flux of the solute is virtually independent of this parameter [9]. Thus, the membrane becomes more selective as the working pressure increases. At the same time, as the working pressure is raised to above 1.0 MPa, the retention of the herbicides by the membrane somewhat decreases, which is presumably due to enhancement of the concentration polarization under these conditions [8, 9].

As can be seen in Fig. 1a, the retention of the herbicides decreases in the order terbumetone > desmetrine > atrazine, which well correlates with the decrease in their molecular mass (see table). The maximum retention of terbumetone at working pressures of 0.5–2.0 MPa is 92–94%. It should be noted that, as the herbicide concentration in the starting aqueous solution decreases to 1 mg dm^{-3}, the degree of purification with the membrane increases to 98% (Fig. 1, curve *4*), in agreement with the known data on nanofiltration of low-molecular-weight organic substances [10].

The throughput of the membrane treatment increases virtually linearly with the working pressure (Fig. 1b), which indicates that there is no shrinking of the porous structure of the membrane under the experimental conditions.

Figure 2 shows that the retention of the herbicides by the membrane strongly depends on pH of the solu-

tion being filtered. The strongest retention of the substances studied is observed in acid and alkaline media, whereas in a neutral medium it decreases. It should be noted that, at pH 3.4, the efficiency of treatment of aqueous solutions to remove terbumetone and desmetrine exceeds that for atrazine. This difference is presumably due to an electrostatic interaction of the membrane with the solutes. In an acid medium (pH < 3.4), terbumetone (pK 4.2) and desmetrine (pK 3.0) are protonated and, as a result, their molecules take on a positive charge

At the same time, at low pH values, the surface of the OPMN-P membrane is also charged positively (Fig. 3) because of the dissociation of amino groups of the selective polymeric layer [2]. Because of the appearance of electrostatic repulsion forces between the likely charged molecules of the solutes and the membrane surface, the retention of terbumetone and desmetrine exceeds that of atrazine, whose molecules are virtually not protonated under the given conditions (pK 1.7) and, consequently, cannot electrostatically interact with the membrane.

As the solution pH increases (pH ~6), the degree of protonation of terbumetone and desmetrine decreases, and so does the positive charge of the membrane (Fig. 3), which leads to weakening of the repulsion forces between the herbicide molecules and the membrane and, as a result, makes lower the retention of the solutes (Fig. 2).

It is interesting that, as pH increases further (pH > 7), the retention of the herbicides somewhat increases (Fig. 2), despite that, under these conditions, undissociated molecules of the herbicides virtually do not interact electrostatically with the membrane surface, whose negative charge is presumably due to dissociation of carboxy groups present in the aromatic polyamide layer [2, 11]. Consequently, the pH dependence of the efficiency of the nanofiltration treatment to remove herbicides with an OPMN-P membrane is governed not only by the electrostatic interaction of the membrane with the solutes, but, apparently, also by other factors.

In this context, the separating characteristics of the membrane were additionally studied at different degrees of permeate removal in filtration of an atrazine solution, which virtually does not dissociate in

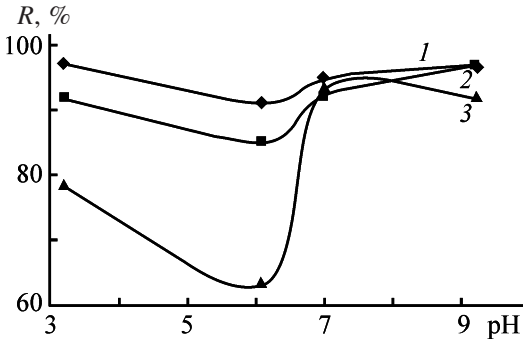


Fig. 2. Retention coefficient R of (*1*) terbumetone, (*2*) desmetrine, and (*3*) atrazine vs. pH at a working pressure of 0.5 MPa. Herbicide concentration 10 mg dm^{-3}.

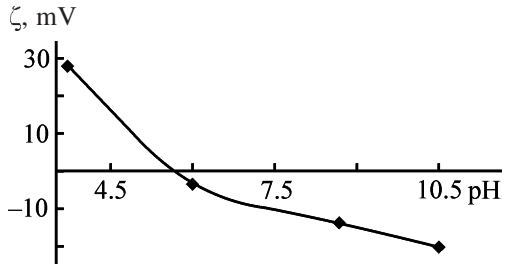

Fig. 3. ζ Potential of the OPMN-P membrane vs. pH of solution.

the pH range under study. Figure 4a shows that the retention of atrazine in acid and alkaline media markedly exceeds that at pH ~6. At the same time, the fluxes across the membrane at low and high pH are substantially lower than the throughput of the membrane at pH ~6 (Fig. 4b). It can be assumed that the effects observed are due to changes in the porous structure of the membrane upon changes in pH. For example, carboxy groups present in the active layer are completely dissociated in the alkaline region and the membrane surface acquires a negative charge [3]. Because of the mutual repulsion, negatively charged macromolecules take a more unfolded conformation, with the result that the "effective" pore size in the active layer of the membrane somewhat decreases. Similar changes apparently also occur in the active layer at low pH, when amino groups of the polymer macromolecules become positively charged [2]. Conformational transitions in the polymer macromolecules in the active layer of the membrane lead to a decrease in the flux across the membrane at low and high pH values (Fig. 4b). At the same time, it follows from Fig. 3 that the isoelectric point (IEP) of the membrane surface corresponds to pH ~6. Presumably, at this point, polymer macromolecules are more closely packed in the active layer of the membrane, so that

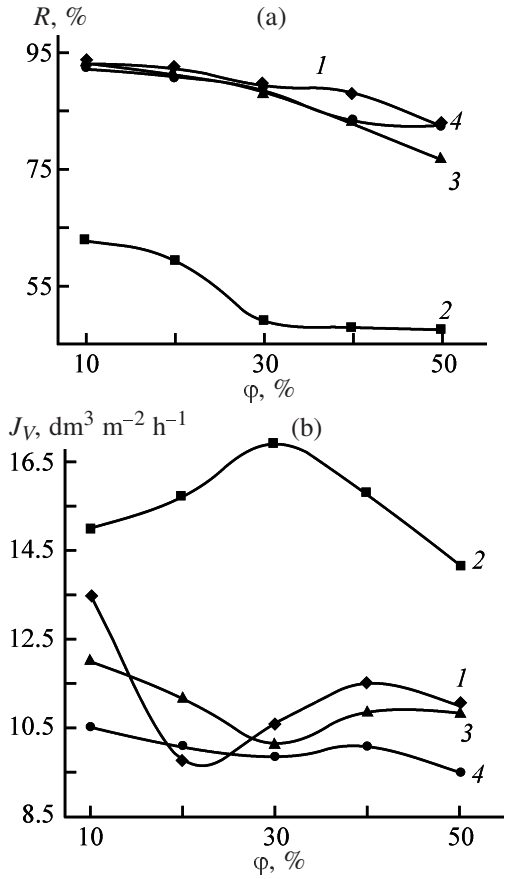

Fig. 4. (a) Retention coefficient R of atrazine and (b) membrane throughput J_V vs. the degree φ of permeate removal at different pH values. pH: (*1*) 3.2, (*2*) 6.1, (*3*) 7.0, and (*4*) 9.2.

its effective pore size somewhat increases. This assumption is confirmed both by a sharp decrease in the retention of atrazine and by an increase in the transmembrane flux in filtration of a solution with pH corresponding to the IEP of the membrane (Fig. 4).

Thus, when interpreting the dependences of the herbicide retention on pH of the medium, it is necessary to take into account the possibility of conformation transitions of charged polymer chains in the active layer of the OPMN-P membrane. Previously, similar effects associated with conformational transformations of macromolecules upon a change in pH of the solution being filtered were reported for nanofiltration separation of salts and glucose [11] and for composite membranes modified with polyelectrolytes [12].

CONCLUSIONS

(1) Nanofiltration treatment of aqueous solutions with an OPMN-P membrane can provide a high degree of removal of triazine herbicides (97–98%).

(2) The efficiency of removal of herbicides from aqueous solutions is affected by their molecular mass, working pressure, and concentration and pH of the solution being filtered.

(3) Electrostatic interactions are important in the mechanism of nanofiltration treatment of water to remove triazine herbicides with an OPMN-P membrane.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Sorption Properties of Nitrogen-Containing Ion Exchangers

Abstract—Sorption capacity of ion exchangers based on glycidyl derivatives of aromatic compounds and polyamines was studied in relation to pH of solution. The mechanism of sorption of polyvalent metal ions was examined.

DOI: 10.1134/S1070427208030099

High-performance ion exchangers are of particular importance in integrated processing of mineral raw materials, preservation of the environment, and development of wasteless processes. The ion-exchange processes used for treatment of potable and waste waters are environmentally safe. These processes can also be used in hydrometallurgy because modern precipitation and extraction procedures of recovery and separation of metal ions do not provide the required purification [1, 2].

EXPERIMENTAL

The ion exchangers were prepared by polycondensation of polyethylenepolyamine (PEPA), polyethylenimine (PEI), and poly-2-methyl-5-vinylpyridine (PMVP) with diglycidyl compounds, namely, diglycidylaniline (DGA) and diglycidyl phenol–aniline–formaldehyde (DGPAF) and diglycidyl toluene–phenol–formaldehyde (DGTPF) oligomers [3, 4]. The static exchange capacity (SEC) of the resulting anion exchangers for metal ions was determined using solutions of ammonium metavanadate (6 g l^{-1} V_2O_5, 3 g l^{-1} V), sodium molybdate (3 g l^{-1} Mo), sodium tungstate (3 g l^{-1} W), ammonium perrhenate (1 g l^{-1} Re), and also 0.05 M solutions of copper nitrate (1.6 g l^{-1} Cu) and nickel nitrate (1.5 g l^{-1} Ni), prepared from chemically pure grade salts. The concentrations of metal ions in solutions were determined by atomic absorption spectroscopy.

Along with chemical and thermal stability [3], the anion exchangers prepared exhibit high sorption capacity for transition metal ions (Table 1). The sorption capacity of these materials for polyvalent *d*-metal ions is higher than that of commercial AN-31 and EDE-10P resins by a factor of 2–3.

The dependence of the sorption capacity of the ion exchanger based on DGPAF and PEPA on the time of its contact with solution (Table 2) shows that the equilibrium is attained in 5 days, with 70–79% of the initial amount of polyvalent metal ions being recovered in the first 12 h, i.e., these anion exchangers exhibit high kinetic properties.

Owing to high sorption capacity for polyvalent metal ions (Table 1), the resulting anion exchangers can be used in hydrometallurgy of vanadium, molybdenum, tungsten, and rhenium, which are mainly used in various branches of industry such as metallurgy, mechanical engineering, chemistry, and electrical and radio engineering. More than 75% of molybdenum is used in alloying of cast iron and steels for aircraft and motor-car building. Heat-resistant (for jet engines) and acid-resistant (for chemical industry installations) molybdenum alloys show much promise. Vanadium, which is one of the most important alloying elements, improves such properties of steel as strength, lightness, flexibility, and heat resistance. Since vanadium compounds are highly toxic [5], its content in the environment and industrial wastes should be thoroughly controlled. It should be noted that the ion exchange is the most efficient procedure providing recovery of metal ions from aqueous solutions.

Polyvalent *d* metals occurring in solutions in the form of complex anions are sorbed on anion exchangers through anion exchange and complexation with coordination-active groups of the sorbent [6].

In the case of protonated ion exchangers, anionic

Table 2. Effect of sorption time on SEC_M on the ion exchanger based on DGPAF–PEPA

Recovered component	SEC_M, mg g^{-1} (%), at indicated sorption time				
	6 h	12 h	3 days	5 days	10 days
V_2O_5	335.2 (40)	583.0 (70)	791.0 (95)	832.9 (100)	832.9
Mo	525.2 (55)	754.4 (79)	927.0 (97)	955.0 (100)	955.0
W	212.6 (30)	510.8 (72)	652.1 (92)	708.8 (100)	708.8

complexes are first adsorbed by the mechanism of anion exchange:

$$(n-e)\left(\begin{matrix}\diagup\\ \diagdown\end{matrix}\!\!>\!\mathrm{NH}^+\ \mathrm{An}^-\right) + [\mathrm{MAn}_n]^{-n+e}$$
$$\rightleftarrows \left(\begin{matrix}\diagup\\ \diagdown\end{matrix}\!\!>\!\mathrm{NH}^+\right)_{n-e}[\mathrm{MAn}_n] + (n-e)\mathrm{An}^-,$$

Then, the ligands in the first coordination sphere of the metal are substituted by amino groups of the ion exchanger. On a nonprotonated ion exchanger, the sorption proceeds only by substitution of a ligand in the metal complex by ligand groups of the sorbent:

$$m\left(\begin{matrix}\diagup\\ \diagdown\end{matrix}\!\!>\!\mathrm{N}:\right) + [\mathrm{MAn}_n]^{e-n}$$
$$\rightleftarrows \left[\mathrm{M}\left(\begin{matrix}\diagup\\ \diagdown\end{matrix}\!\!>\!\mathrm{N}\right)_m \mathrm{An}_{n-m}\right]^{-n+m+e} + m\mathrm{An}^-.$$

Since the stability of complexes and their composition depends on the degree of protonation of the ionic groups in the anion exchanger [7, 8], we studied the dependence of the sorption capacity of the ion exchangers on the concentration of hydrogen ions (Fig. 1). As can be seen, the optimal pH range for sorption of vanadium is 1.9–2.2 (733–1200 mg g^{-1}); for molybdenum, 1.8–2.5 (501–1190 mg g^{-1}); for tungsten, 1.6–2.8 (502–1030 mg g^{-1}); and for rhenium, 3.0 (519–713 mg g^{-1}).

The concentration of the coordination-active (nonprotonated) ionic groups and their basicity increase with increasing solution acidity; in the process, the swelling of the ion exchangers studied also increases.

The observed increase in the sorption capacity for polyvalent metal ions with decreasing pH is probably due to the fact that the protonation enhances the hydrophilicity and, thus, the swelling of the ion exchangers, weakens the intermolecular bonds, and increases the mobility of the polymer units with ligand groups fixed on them. However, further protonation of the nitrogen atoms decreases the number of the coordination-active centers in the solid phase, increases the positive charge of the matrix and acidity inside the grain, and decreases sorption capacity of the ion exchanger [9]. As a result, with decreasing pH the sorption capacity of the ion exchangers increases to a certain limit (Fig. 1), after which the coordination activity decreases, because the concentration of the coordination-active centers and their basicity become the decisive factors.

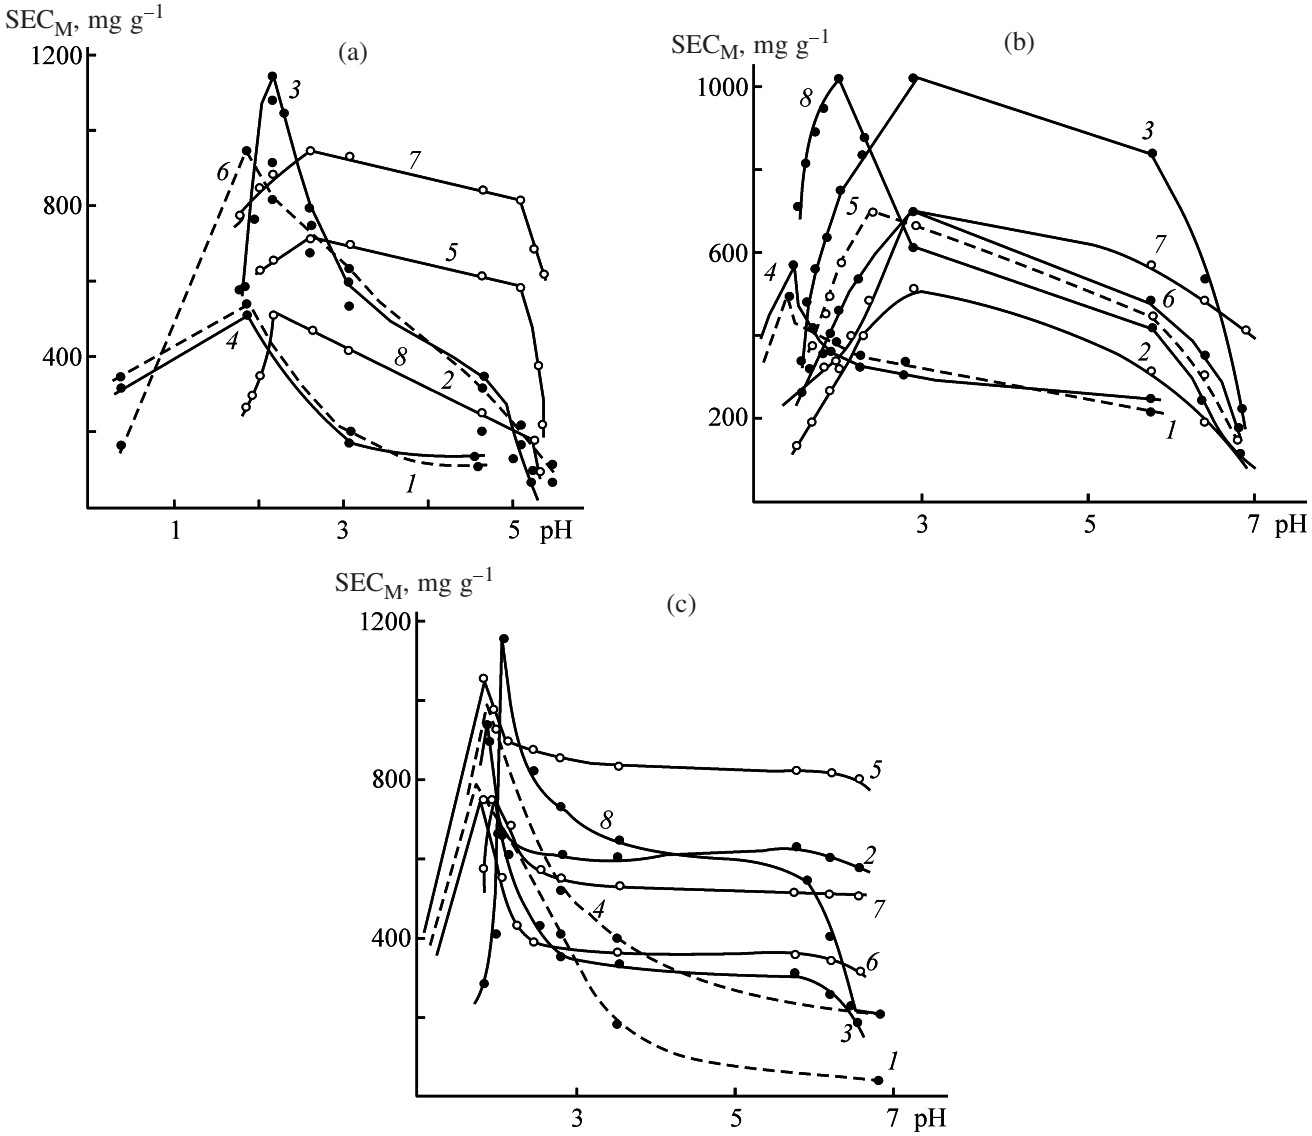

Fig. 1. Sorption of (a) Mo, (b) W, and (c) V as a function of solution pH. Ion exchangers: (*1*) DGA–PMVP, (*2*) DGA–PEI, (*3*) DGA–PEPA, (*4*) DGPAF–PMVP, (*5*) DGPAF–PEI, (*6*) DGPAF–PEPA, (*7*) DGTPF–PEI, (*8*) and DGTPF–PEPA. (SEC_M) Static exchange capacity.

The dependence of the sorption capacity of the ion exchangers on pH of the solution is also due to the ionic state of the metal. With increasing concentration of H^+ ions, MoO_4^{2-} undergoes polymerization and protonation yielding molybdenum species with various specific charges. In a weakly acidic solution, the most stable species are paramolybdate $Mo_7O_{24}^{6-}$ (pH 5–7) and tetramolybdate ions $Mo_4O_{13}^{2-}$ or $HMo_4O_{13}^{-}$ (pH 5–1.5) [10, 11].

The IR spectra of the ion exchangers after their saturation with molybdenum from solutions with optimal pH (1.8–2.5) exhibit the vibration bands of tetramolybdate ions (895–900, 906, 942 cm^{-1}). Hence, at pH 1.8–2.5 the ion exchangers studied recover molybdenum as tetramolybdate ions whose low specific charge probably also leads to an increase in the sorption capacity in the given pH range. In its physical, mechanical, and chemical properties, molybdenum is close to tungsten, which is due to similarity of their ionic radii (0.065 nm) [1]. Similarly to MoO_4^{2-}, WO_4^{2-} undergoes polymerization to form paratungstate $W_7O_{24}^{6-}$ or $W_{12}O_{41}^{10-}$ and tetratungstate ions $W_4O_{13}^{2-}$, whose small specific charge leads to an increase in the sorption capacity of the ion exchangers in the pH range 1.6–2.8.

The ionic state of vanadium also changes depending on pH of solution [13]. Sorption of decavanadate ion $V_{10}O_{28}^{6-}$ with a small specific charge on the ion

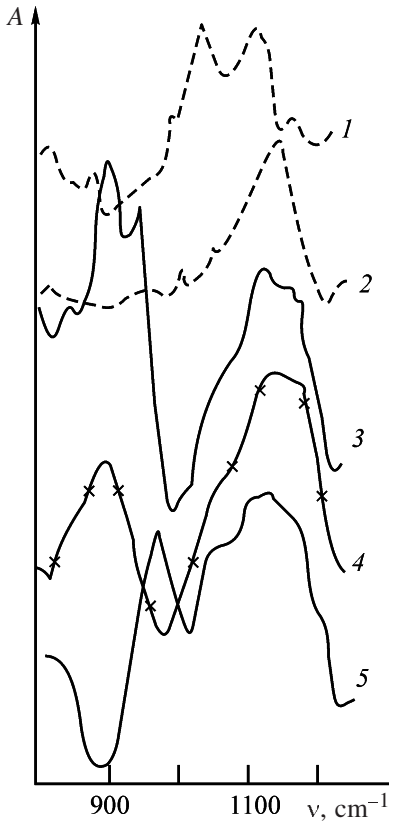

Fig. 2. IR spectra of the ion exchangers based on (*1*) DGPAF–PEPA and (*2*) DGPAF–PEI and of their complexes with (*3, 4*) molybdenum and (*5*) vanadium (DGPAF–PEPA). (*A*) Absorption and (ν) wavenumber.

exchangers studied at optimal pH 1.9–2.2 is confirmed by appearance of the absorption band at 960 cm^{-1} (Fig. 2).

CONCLUSIONS

(1) The sorption capacity of the ion exchangers studied depends on the content of coordination-active (nonprotonated) ionic groups, degree of swelling of the oligomer, and ionic state of metal in solution.

(2) The pH ranges optimal for sorption of transition metal ions were determined.

Abstract—Effect of a number of factors (time of contact and mass ratio of phases, acidity and temperature of the medium, concentrations of macrocomponents of geothermal water) on the sorption recovery of iodide ions with 3-(octadecyldimethylammonio)propylsilica and 3-(trimethylammonio)propylsilica from aqueous solutions was studied. Sorption isotherms were discussed. The possibility of using 3-(octadecyldimethylammonio)-propylsilica for recovery of iodide ions from highly mineralized geothermal water was analyzed.

DOI: 10.1134/S1070427208030105

The main raw material for industrial manufacture of iodine is natural mineral water accompanying oil and gas in oil-and-gas fields. The content of iodine in this kind of water is 10–120 mg l^{-1}, with more than 90–95% of this amount present in the form of iodide ions [1]. I^- is recovered from water without changes in the degree of oxidation in the form of poorly soluble copper, silver, and mercury iodides or with the use of ion-exchange resins, e.g., AV-17 [2, 4]. The sorption technology of I^- recovery from underground water and brine of salt lakes occupies the leading place among the industrial techniques for manufacture of iodine.

At present, organomineral composite materials find wide use in sorption, chromatography, and catalysis [5]. Ion exchangers of this group frequently combine advantages of synthetic organic polymers with ionic functional groups and inorganic substances (silica, aluminum oxide, zeolites). The mechanical and mass-exchange properties of organomineral mass exchangers are determined by the rigid wide-porous mineral skeleton of the inorganic support, and the ion-exchange properties, by the nature of fixed functional groups.

An advantage of modified silica sorbents is the rather high rate of attainment of the sorption equilibrium, which is particularly important in the case of recovery of ions from large volumes of dilute solutions. Also important is that the quantitative desorption of ions from their surface can be provided in most cases by small volumes of eluents. As a result, the concentration coefficient in a single sorption–desorption cycle reaches 10^3–10^4, which markedly exceeds the parameters of organopolymeric analogs [6].

In this study we examined the possibility of recovering iodine in the form of iodide ions from highly mineralized geothermal water with silica gels with grafted alkylammonium groups.

EXPERIMENTAL

As object of study served anion exchangers, 3-(trimethylammonio)propylsilica (**I**) and 3-(octadecyldimethylammonio)propylsilica (**II**), which contain strongly basic quaternary ammonium groups. These functional groups were chosen for modification of the silica gel because the stability of ionic associates of tetraalkylammonium increases as the ionic radius of the counterion becomes larger. This property can favor an increased selectivity of the materials under study with respect to iodide ions, compared with other halides. In this study, we used anion exchangers with a bromide or chloride salt of a strong base, covalently fixed on the surface of the silica matrix:

$$(SiO_2)\equiv Si–C_3H_6–N^+(CH_3)_3Br^- \quad (\mathbf{I});$$

$$(SiO_2)\equiv Si–C_3H_6–N^+(CH_3)_2(C_{18}H_{37})Cl^- \quad (\mathbf{II}).$$

The procedure used to obtain samples **I** and **II** included preliminary purification and activation of silica (Merck, S_s = 500 m^2 g^{-1}, d = 60 Å) with hot (120°C) concentrated nitric acid, washing with distilled water

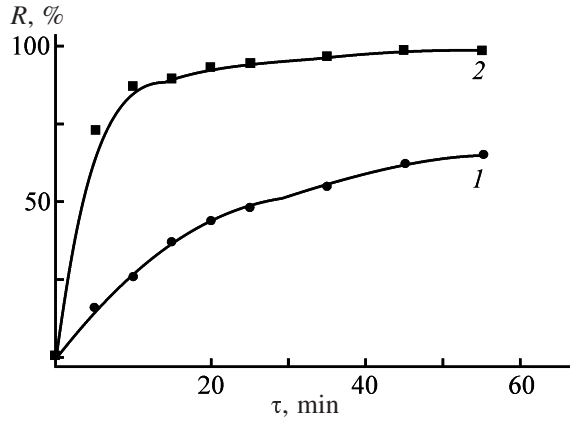

Fig. 1. Degree R of sorption of iodide ions vs. the time τ of contact between the phases. $m_{\mathbf{I,II}}$ = 0.02 g, $c_{I^-} = 8.42 \times 10^{-6}$ M, V_{aq} = 15 ml. Sorbent: (*1*) 3-(trimethylammonio)propylsilica and (*2*) 3-(octadecyldimethylammonio)-propylsilica; the same for Fig. 2.

to neutral pH, and subsequent modification of its surface with the corresponding silane in an organic solvent [5]. The concentration of grafted groups on the surface of the materials obtained was 520 ± 10 and 440 ± 10 μmol g^{-1} for **I** and **II**, respectively, as indicated by conductometric back-titration of aqueous suspensions for Cl^- and Br^- ions. The stock solutions, 1.0 M potassium chloride and 0.2 M potassium iodide, bromide, sulfate, and hydrocarbonate, were prepared by dissolving the corresponding weighed portions in distilled water. Working solutions were prepared by diluting the stock solutions.

For sorption studies, we placed a weighed portion of a sorbent in a beaker and added a solution prepared. The sorption was studied under static conditions and agitation with a magnetic stirrer at a certain temperature. The concentration of iodide ions in solutions was determined a certain time after these solutions were brought in contact with the sorbents.

The distribution of iodide ions between phases was monitored spectrophotometrically by the iodine–starch reaction [7]. For this purpose, the iodide was oxidized with bromine water to the iodate and excess bromine was removed by heating the solution and then adding phenol. After that, an excess amount of potassium iodide was added and the solution was acidified. As a result, elemental iodine was released in an amount proportional to the content of the iodate, i.e., to the initial content of I^-. When necessary, the residual concentration of microscopic amounts of iodide ions was found using the kinetic cerium(IV)–arsenite reaction [8], which is catalyzed by I^-. The light absorption of the solutions was measured with an SF-26 spectrophotometer, and their pH was monitored with an EV-74 ion meter. The electrical conductivity of the solutions was measured with an R-5058 ac bridge with a working frequency of 1 kHz.

The degree of sorption R (%) and the amount of sorbed iodide a (mol g^{-1}) were calculated by the formulas

$$R = c \times 100/c_0, \qquad a = (c_0 - c)V/m,$$

where c_0 and c are the initial and running concentrations of iodide ions in solution (M); V, solution volume (l); and m, sorbent mass (g).

The data obtained were used to plot curves describing how the amount of I^- sorption on sorbents **I** and **II** depends on various parameters of the medium and to construct the sorption isotherms.

The sorption equilibrium in the system constituted by iodide ions and a sorbent is attained in 50 min for compound **I** and 20 min for **II**, with the degree of sorption reaching 60 and 98%, respectively (Fig. 1). The difference in the behavior of the sorbents with respect to iodide ions can be attributed, first, to an increase in the stability of ionic associates of tetraalkylammonium with the molecular mass of substituents and, second, to a lower degree of dissociation of the bromide ionic associate on the surface of **I**, compared with that of the chloride associate on the surface of **II**.

The effect of the phase mass ratio $m_{aq}/m_{\mathbf{I,II}}$ on the degree of recovery of iodide ions was studied at their constant amount. A quantitative recovery of the analyte was observed at $m_{aq}/m_{\mathbf{I,II}} \leq 1300$. In this case, the concentration coefficient reaches 1.3×10^3. If the phase mass ratio increases further, the degree of recovery of iodide ions steeply falls because of the poorer contact between the sorbent and sorbate.

As the temperature of aqueous solutions increases, the degree of recovery of iodide ions steadily decreases, from 98% at 20°C to 85% at 60°C for sorbent **II** because of the rise in the entropy factor. Lowering the temperature of the solutions to 5°C has no significant effect on the degree of recovery.

In the pH range 2–8, the acidity of a solution has virtually no effect on the degree of sorption. However, raising the pH to more than 8 makes the degree of sorption of iodide ions lower, possibly because of partial disintegration of the matrix of sorbents and a decrease in the amount of ionic groups on its surface.

The sorption isotherms of iodide ions are of the Langmuir type (Fig. 2). The limiting sorption a_l (μmol g^{-1}) and sorption constant K (M^{-1}), calculated

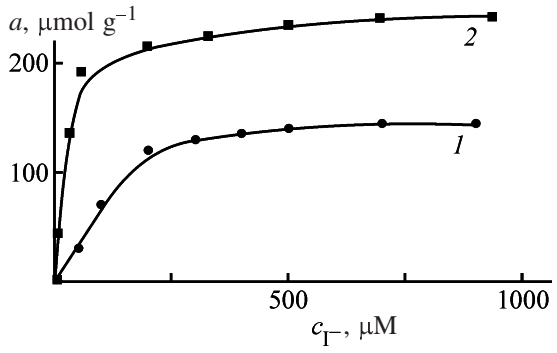

Fig. 2. Sorption isotherms of iodide ions (T = 293 ± 1 K). (*a*) Amount of sorbed iodide and (c_{I^-}) equilibrium concentration of iodide ions.

using the linear form of the Langmuir equation [9], are, respectively, 145 and $(0.21 \pm 0.08) \times 10^{-7}$ for compound **I**, and 242 and $(0.47 \pm 0.10) \times 10^{-7}$ for compound **II** at concentrations of grafted groups equal to 520 and 440 μmol g^{-1}, respectively. Thus, up to 30 and 60% of grafted groups of **I** and **II** are involved in the ion-exchange process. The sorption constant of **II** exceeds that of **I**.

Taking into account the rate at which the sorption equilibrium is attained and the capacity of the sorbents for iodide ions, we performed further experiments with compound **II**.

Geothermal water is highly mineralized and contains, mg l^{-1} (M): chlorides up to 20000 (0.56), bromides up to 100 (1.25×10^{-3}), sulfates up to 600 (6.25×10^{-3}), and hydrocarbonates up to 400 (6.55×10^{-3}) [1]. Taking into account this circumstance, we studied the effect of the concentration of these anions on the sorption of iodide ions from model solutions. As the concentration of chloride ions increases to 0.2 M, the degree of sorption of iodide ions sharply falls because of the competing effect of this anion (Fig. 3). As the concentration of chloride ions increases further, the degree of I^- sorption increases, which is possibly due to salting-out, and reaches a value of 71.3% at a Cl^- concentration of 0.6 M. In amounts commonly present in geothermal water, sulfate, hydrocarbonate, and bromide ions diminish the degree of I^- sorption at a constant sorbent mass to 56, 60, and 95%, respectively (Fig. 4).

A study of the I^- sorption by 3-(octadecyldimethylammonio)propylsilica from natural geothermal water demonstrated that the degree of sorption of iodide ions from real geothermal water is lower than that for model solutions, possibly as a result of the cooperative action of the anions present. Table 1 shows how

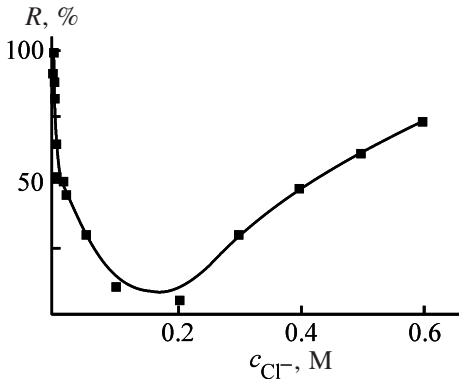

Fig. 3. Degree R of sorption of iodide ions by 3-(octadecyldimethylammonio)propylsilica vs. the concentration c_{Cl} of chloride ions. m_{II} = 0.02 g, $c_{I^-} = 8.42 \times 10^{-6}$ M, V_{aq} = 15 ml; the same for Fig. 4.

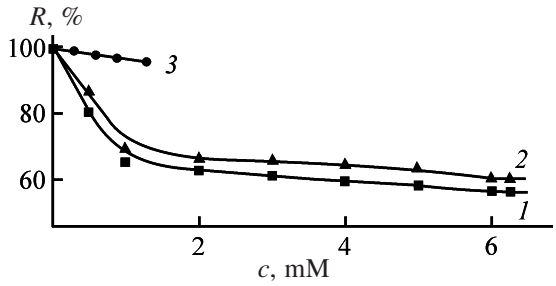

Fig. 4. Degree R of sorption of iodide ions by 3-(octadecyldimethylammonio)propylsilica vs. the concentration c of anions. Anion: (*1*) SO_4^{2-}, (*2*) HCO_3^{2-}, and (*3*) Br^-.

the degree of sorption of iodide ions from geothermal water varies with its gradual dilution, made to decrease the salt background. It can be seen that, upon a twofold dilution of a sample of geothermal water, the degree of I^- recovery exceeds 56%. An increase

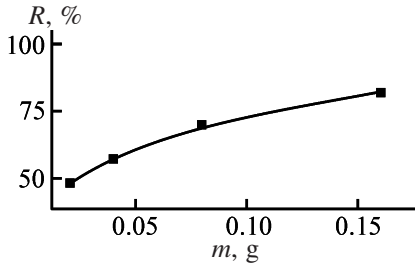

Fig. 5. Degree R of recovery of iodide ions from geothermal water vs. mass m of 3-(octadecyldimethylammonio)propylsilica. $c_{I^-} = 8.42 \times 10^{-6}$ M, V_{aq} = 15 ml. Concentration of anions (mg l^{-1}): Cl^- 15000, Br^- 85, SO_4^{2-} 400, HCO_3^{2-} 380.

in the sorbent mass from 0.02 to 0.15 g substantially improves the sorption recovery of iodide ions from geothermal water (Fig. 5). This is possible because of the increase in the number of sorption sites on the surface of the sorbent under study and the resulting decrease in the competing effect of the concomitant components. At a phase mass ratio $m_{aq}/m_{\mathbf{II}} = 100$, about 80% of iodide ions is sorbed from real geothermal water (Table 2).

CONCLUSIONS

(1) The efficiency of iodide recovery from aqueous solutions on 3-(octadecyldimethylammonio)propylsilica markedly exceeds that on 3-(trimethylammonio)-propylsilica because the stability of ionic associates of tetraalkylammonium and iodide ions increases with the molecular mass of substituents.

(2) Quantitative recovery of iodide ions on 3-(octadecyldimethylammonio)propylsilica is observed in 20 min at room temperature in the pH range 2–8, with the concentration coefficient reaching 1.3×10^3.

(3) The sorption isotherms of iodide ions are of the Langmuir type. The sorption constant of **II** exceeds that of **I**.

(4) Use of 3-(octadecyldimethylammonio)propylsilica enables recovery of about 80% of iodide ions from real geothermal water under the optimal conditions.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Influence of Eluent Composition on the Retention Factor of Azoles in Reversed-Phase High-Performance Liquid Chromatography

S. V. Kurbatova and O. V. Kharitonova

Samara State University, Samara, Russia

Received April 18, 2007

Abstract—The linear dependence of the retention factor of indole, imidazole, triazole, and tetrazole derivatives on the acetonitrile content of the mobile phase was studied.

DOI: 10.1134/S1070427208030117

Chemistry of five-membered heterocycles and their derivatives attracts researchers' attention mainly due to their high physiological activity and their use as models in solving some problems of theoretical organic chemistry [1, 2]. It is known that many derivatives of diazoles and triazoles exhibit adrenoblocking, antimicrobial, and others kinds of pharmacological activity. In addition, many important natural compounds such as histamine, histidine, allantoin, etc. contain the imidazole group.

Azoles of various structures are relatively widely used as models in theoretical determination of the quantitative structure–property relationships (QSPR) and quantitative structure–activity relationships (QSAR) [4]. These compounds show promise in determination of the quantitative structure–retention factor relationships described in detail in [5, 6]. It should be noted that the dependence between the structure and retention factor of nitrogen-containing heterocycles was studied mainly for gas chromatography. At the same time, high-performance liquid chromatography (HPLC) is a convenient and promising tool not only for determination of structures and many physicochemical properties of compounds, but also in simulation of biochromatographic processes occurring after introduction of physiologically active compounds into a living body. In many cases, the sorption mechanism of the physiological action of a pharmaceutical or biologically active substance is suggested. Therefore, determination of sorption properties of these compounds by chromatographic methods is of interest. HPLC allows variation of the chromatographic conditions, in particular, of the type and composition of the eluent, in a wide range [7].

In this study we examined the influence of the eluent composition on the retention factor of derivatives of nitrogen-containing five-membered heterocycles under conditions of reversed-phase HPLC.

EXPERIMENTAL

The experiments were performed on a Biotronik Chromatographic system with a BT 8100 HPLC Pump and an ultraviolet detector. A 4×150 mm Separon SGX-C_{18} column was used. Elution was performed in the isocratic mode using an acetonitrile–water mixture (1 : 1, 5 : 3, and 3 : 1, v/v) as the eluent.

Prior to analysis the eluent was degassed with a UZDN-2T device and filtered. The flow rate of the eluent was 0.3 ml min^{-1}. Substrate solutions were prepared by dissolution of dry pure heterocyclic compounds in appropriate solvents. The volume of the injected sample was 20 μl. Sodium nitrite was used as nonsorbable compound.

The UV detector operated at 254 nm. The analysis was performed at 20°C.

The retention factor k was calculated by the following equation:

$$k = t'_R/t_M = (t_R - t_M)/t_M,$$

where t_R is the retention time of the examined compound and t_M is the retention time of the unsorbable compound (min) [8].

Five replicate runs were performed for each point.

It is known that chromatographic retention depends on many factors. Among them the main factors are

the type of the chromatographic system (mobile and stationary phases between which the adsorbent molecules are distributed), chromatographic conditions, and the molecular structure of the sorbate [7]. Therefore, in chromatographic studies, correlation between sorption of samples and their structure or chromatographic conditions is usually considered. In both cases the main approach is semiempirical mathematical simulaiton based on the general concept of the sorption mechanism in systems of different types.

Retention in reversed-phase HPLC is due to competing interactions of sorbate molecules with nonpolar hydrophobic surface of the sorbent and specific interactions with the polar eluent. Since, unlike gas chromatography, the mobile phase in HPLC (especially in reversed-phase HPLC) interacts with substances to be separated, its composition and properties will significantly affect the distribution of these substances in a chromatographic column, and hence will affect the retention parameters.

Correlation between the retention parameters and quantitative composition of the mobile phase was extensively studied [9, 10]. It was described by different models [7, 11] and is most frequently approximated by the following equations [7]:

$$\log k = a - bc, \quad (1)$$

$$\log k = a_1 - b_1 \log c, \quad (2)$$

$$\log k = a_2 - b_2 c + pc^2, \quad (3)$$

where k is the retention factor, c is the concentration of the organic component, and a, b, p are coefficients.

As shown in numerous studies, Eqs. (1)–(3) describe well the retention of substrates of different chemical nature. However, the use of each particular equation is determined, as a rule, by hydrophobicity of eluted compounds and the retention model. Shatts and Sakhartova [7] noted that Eq. (3) was relatively rarely used to describe and predict retention, since the influence of the pc^2 term was appreciable only in a wide concentration range of the organic component in the mobile phase.

Equation (2) is used, as a rule, in the framework of the Horvath solvophobic theory, with coefficient b_1 equal to the number of organic solvent molecules displaced from the sorbent surface by one sorbate molecule.

In this study we used acetonitrile as a modifier of the mobile phase, since it has a high affinity for the examined compounds. In general, the retention of the derivatives of five-membered nitrogen-containing heterocycles decreases with increasing acetonitrile concentration owing to strengthening of the specific interactions with the organic component of the mobile phase. Similar results were obtained for imidazole derivatives [12, 13]. The retention of all sorbates is maximal at 50% acetonitrile content.

The dependence of the retention factor of most of the examined azole derivatives on the acetonitrile content c (M) in the mobile phase is linear and can be described by equations like (1) and (2). The correlation coefficients for these equations are presented in the table. As seen from the table, Eq. (2) fits the dependence of the retention factor on the composition of the mobile phase with a higher correlation coefficient r. Coefficient a in Eq. (1) is equal to the retention factor in the absence of the organic solvent in the mobile phase. The physical meaning of term a_1 in Eq. (2) differs. This coefficient is equal to the logarithm of the retention factor at 1 M concentration of the organic modifier [7].

It is known [7] that a phenomenon similar to the compensation of the entropy and enthalpy is revealed in consideration of the dependence of the retention parameters of structurally similar compounds on the concentration of an organic modifier. If this effect takes place, extrapolated dependences of the retention factors on the concentration of the organic component should intersect in one region of the coordinate plane. As seen from the table, this is the case with some azole derivatives, i.e., the curves described by Eqs. (1) and (2) tend to an isoparametric point. It is known that the intersection point of straight lines $y = a + bx$ is described by the equation $a_1/(1 - b_1) = a_2/(1 - b_2) = K$ = constant, where a and b are equation coefficients [14]. According to the Horvath solvophobic theory, the physical meaning of a isoparametric point is determined by parameters of a chromatographic system such as molar volume, dipole moment, and polarizability. In our case, K of the sorbate in question depends on the above parameters and is in the range 0.14–1.99 and 0.34–1.04 for coefficients of Eqs. (1) and (2), respectively.

The compensation effect suggests the similar retention mechanism of the compounds in question. This fact is confirmed by the correlation between the retention factors of the examined compounds at different water : acetonitrile ratios in the eluent (Fig. 1). Usually these dependences are used to compare the retention on two sorbents [15]. For this purpose, the equation $\log k_A = a + b \log k_B$ (where k_A and k_B are the retention factors on sorbents A and B, respectively) is

used. Coefficient b reflects the thermodynamic similarity of the processes in these systems.

To estimate the overall effect of all interaction types in an HPLC chromatographic system, different properties of the solvents were suggested. In particular, the eluting power of the mobile phase can be characterized by the adsorption power of the solvent ε^0 which, in turn, characterizes the relative interaction energy of mobile phase molecules with the adsorbent surface [11]. Contrary to the eluting power, Snyder developed a comparison system based on different properties of the solvents. According to this approach, each solvent is characterized by the power S depending on its chromatographic properties [7]. The solubility parameter δ introduced by Hildebrand and Scott [15] is also used along with ε^0 and S to describe the mobile phase.

The solvent polarity calculated as a sum of logarithms of distribution coefficients of reference compounds between the vapor phase and the examined solvent was also introduced by Snyder [16]. The polarity of a mixture of solvents A and B can be calculated as $P'_{mixt} = V_A P'_A + V_B P'_B$, where V_A and V_B are the volume fraction of solvents A and B, and P'_A

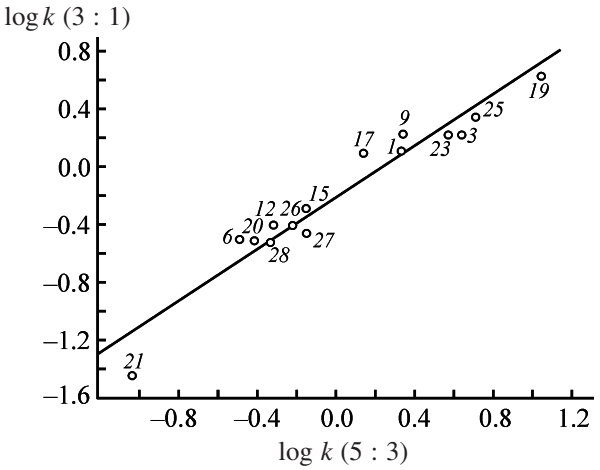

Fig. 1. Correlation between the logarithms of the retention factors of the examined compounds at acetonitrile : water ratios in the mobile phase of 3 : 1 and 5 : 3. Figures at points are compound nos. in the table; the same for Figs. 2 and 3. Regression equation: $\log k\ (3:1) = -0.229 + 0.939 \times \log k\ (5:3)$.

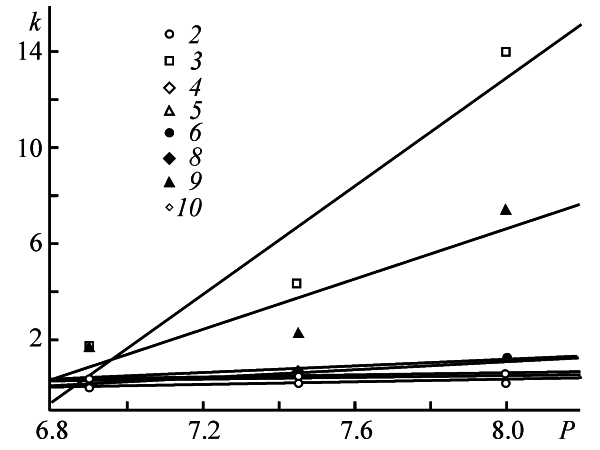

Fig. 2. Retention factor k of imidazole derivatives as a function of the eluent polarity P.

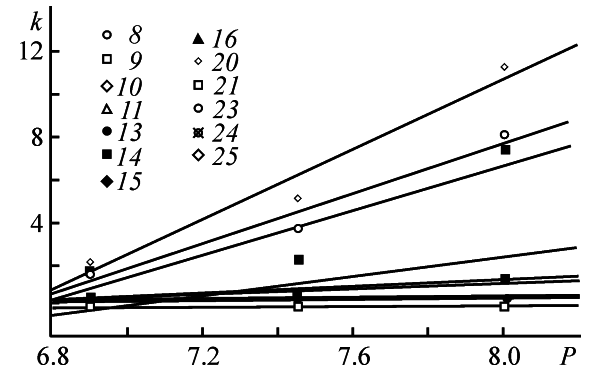

Fig. 3. Retention factor k of sulfonic acid azolides as a function of the eluent polarity P.

and P'_B are the polarities of solvents A and B, respectively. The eluting power in reversed-phase HPLC decreases and the retention on a stationary phase increases with increasing polarity. The dependence of the retention factors of the compounds in question on the eluent polarity is shown in Figs. 2 and 3. As seen from these figures, these dependences are linear. The dependence of the retention factors on the acetonitrile concentration is inverse. This is the case for all the examined compounds and eluent compositions.

Thus, the retention of azole derivatives under conditions of reversed-phase HPLC is determined by both structural features of the adsorbate and the type and composition of the eluent.

CONCLUSIONS

(1) The dependence of the retention factors of indole, imidazole, triazole, and tetrazole derivatives on the mobile phase composition is linear and can be described by Eqs. (1) and (2).

(2) The dependence of the retention parameters of the examined azoles on the concentration of the organic modifier is characterized by a phenomenon similar to the compensation effect of the entropy and enthalpy. The coordinates of the isoparametric point can be determined from the coefficients of equations of the corresponding dependences.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Difference in Transfer of Magnesium and Sodium Ions through Electrodialytic Membranes Modified with Chitosan

V. P. Greben' and I. G. Rodzik

Institute of Chemistry, Far-Eastern Branch, Russian Academy of Sciences, Vladivostok, Russia

Received April 4, 2007

Abstract—The difference in transfer of magnesium and sodium ions through electrodialytic cation-exchange membranes modified with chitosan was studied. The membranes were modified by electrodeposition of chitosan from solution on the membrane surface in the course of electrodialysis, preliminary sorption of chitosan on the membrane surface from aqueous chitosan hydrochloride, or application of a chitosan film to the dry membrane surface. The Mg^{2+}/Na^{+} selectivity of transfer through modified electrodialytic membranes was examined in relation to the current density.

DOI: 10.1134/S1070427208030129

It is known [1] that single-, double- and triple-charged cations can be separated by electrodialysis. The separation can be improved by surface modification with appropriate reagents of the electrodialytic cation-exchange membrane from the side contacting with the diluate. For example, in [2] we used poly(4-vinyl-*N*-propylpyridinium) bromide as modifier.

Chitosan, polysaccharide amino-2-deoxy-β-*D*-glucan, is prepared by deacetylation of chitin extracted from arthropoda shell. Chitosan macromolecules contain the NH_2 and OH functional groups. This compound is widely used in food and pharmaceutical industries and in medicine. Chitosan has ionic conductivity, in particular, with respect to chloride anions [4], i.e., it exhibits the properties of an anion-exchange membrane. Cross-linked strongly basic electrodialytic anion-exchange membranes for food industry can be prepared from alkylated chitosan [5].

Membranes based on chitosan have different permeability with respect to particular metal ions. It was reported in [6] that the diffusion permeability of metal ions through gel-like chitosan increases in the order $Cu^{2+} < Ni^{2+} < Zn^{2+} < Mn^{2+} < Pb^{2+} < Co^{2+} < Cd^{2+} < Ag^{+}$ [6]. For membranes based on combination of silk fibroin and chitosan, the order was as follows [7]: $Ni^{2+} < Cu^{2+} < Pb^{2+} < Cd^{2+} < Ca^{2+} < K^{+}$. Chitosan membranes can be used for treatment of aqueous solutions to remove Cr(III) [8] and Cr(VI) [9].

Presumably, in electrodialysis through a cation-exchange membrane coated with an anion-exchange chitosan layer from the diluate side, this layer as a positively charged electrostatic barrier will hinder the transmembrane transfer of single-charged cations to a lesser extent than that of double-charged cations.

In this study we examined the effect of modification of sulfonic cation-exchange heterogeneous membranes with chitosan on the selectivity of transmembrane electrodialytic transfer of Mg^{2+} relative to Na^{+}. The effect of the current density on the electrodialysis selectivity was also studied.

EXPERIMENTAL

Water-soluble chitosan hydrochloride was produced by Dal'khitosorb Limited Liability Company by treatment of chitosan with hydrochloric acid taken in an amount equivalent to the content of primary amino groups in chitosan. Chitosan was prepared by deacetylation of chitin (degree of deacetylation 85%) recovered from king crab shells. The chitosan molecular weight was 150 kDa.

The electrodialytic cell and procedures for electrodialysis and determination of chloride and magnesium ions in the diluate were identical to those reported in [10]. The separation of Mg^{2+} and Na^{+} in electrodialysis was characterized by the transference selectivity factor of Mg^{2+} relative to Na^{+} $P_{Na^+}^{Mg^{2+}}$:

$$P_{Na^+}^{Mg^{2+}} = \bar{t}^{Mg^{2+}} c_{Na^+}/(\bar{t}^{Na^+} c_{Mg^{2+}}), \quad (1)$$

where $\bar{t}^{Mg^{2+}}$ and $\bar{t}^{Na^+}$ are the transmembrane transference numbers of Mg^{2+} and Na^{+}, respectively; $c_{Mg^{2+}}$ and c_{Na^+}, magnesium and sodium concentration in the diluate.

The selectivity of transmembrane electrodialytic transfer of Mg^{2+} and Na^{+} was studied in a solution containing NaCl (0.25 N) and $MgCl_2$ (0.25 N). The

membranes tested were modified by (1) electrodeposition of chitosan from solution at the membrane surface, (2) sorption of chitosan from aqueous chitosan hydrochloride, and (3) application of chitosan film to dry cation-exchange membrane surface.

In method 1, chitosan hydrochloride was preliminarily added to the solution containing magnesium and sodium cations and then this solution was subjected to electrodialysis. Under these conditions, chitosan macromolecules are not transferred through the cation-exchange membrane and are deposited on its surface to form a film. In reference experiments, $P_{Na^+}^{Mg^{2+}}$ was determined in solutions containing no chitosan hydrochloride.

In method 2, cation-exchange membrane was kept for a certain time in aqueous chitosan hydrochloride of prescribed concentration. After this treatment, the membrane was washed with a small volume of distilled water and arranged in an electrodialytic cell, and elecrodialysis was carried out without addition of chitosan to the solution.

In method 3, a certain volume of aqueous chitosan hydrochloride (2.5%) was applied to the cation-exchange membrane surface, and the membrane was dried in air for 3–5 min and then finally dried at 50°C for 3 h. Then this membrane was kept in 1 N aqueous NaOH for 1.5 h to convert water-soluble chitosan hydrochloride into the form insoluble in alkaline and neutral media. After such treatment, the membrane was washed with distilled water to neutral reaction and arranged in an electrodialytic cell so that its modified surface contacted with the diluate.

In electrodialysis of an aqueous solution containing NaCl (0.25 N) and $MgCl_2$ (0.25 N) without chitosan, $P_{Na^+}^{Mg^{2+}}$ of sulfonic cation-exchange membrane was 1.19 at a current density of 1 A dm^{-2}. Figure 1 shows that, within the range of aqueous chitosan hydrochloride concentrations of 0–0.02 g l^{-1}, $P_{Na^+}^{Mg^{2+}}$ relatively steeply decreases with increasing chitosan hydrochloride concentration, but then the dependence becomes approximately linear. We believe that a decrease in $P_{Na^+}^{Mg^{2+}}$ and in $\bar{t}^{Mg^{2+}}$ with a simultaneous increase in $\bar{t}^{Na^+}$ with increasing chitosan hydrochloride concentration is caused by thickening of the chitosan film on the membrane surface with increasing chitosan hydrochloride concentration in the solution (Fig. 1).

Figure 2 shows that, in electrodialysis of solutions containing NaCl–$MgCl_2$ mixture and chitosan hydrochloride, an increase in the current density is accompanied by an increase in $\bar{t}^{Na^+}$ and a decrease in $\bar{t}^{Mg^{2+}}$.

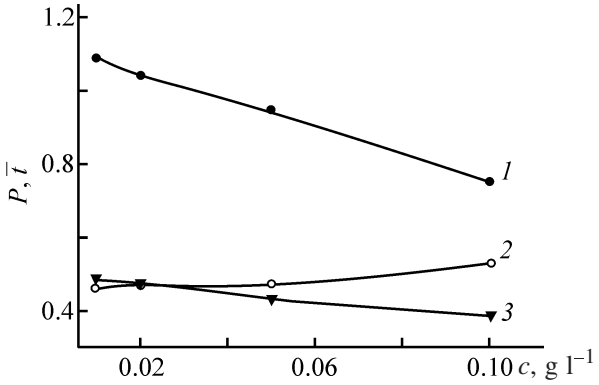

Fig. 1. Dependences of the (*1*) transference selectivity factor $P_{Na^+}^{Mg^{2+}}$ of Mg^{2+} relative to Na^+ in electrodialysis through cation-exchange membrane, (*2*) Na^+ transference number $\bar{t}^{Na^+}$, and (*3*) Mg^{2+} transference number $\bar{t}^{Mg^{2+}}$ on the chitosan hydrochloride concentration c in the diluate at a current density of 1 A dm^{-2}.

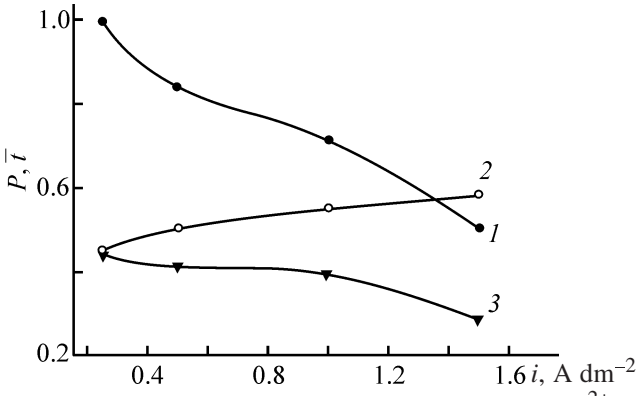

Fig. 2. Influence of the current density i on (*1*) $P_{Na^+}^{Mg^{2+}}$, (*2*) $\bar{t}^{Na^+}$, and (*3*) $\bar{t}^{Mg^{2+}}$ in electrodialysis of a solution containing NaCl (0.25 N), $MgCl_2$ (0.25 N), and chitosan hydrochloride (0.1 g l^{-1}) through cation-exchange membrane.

As a result, with increasing current density, $P_{Na^+}^{Mg^{2+}}$ decreases. We believe that these effects are caused by an increase in the chitosan flow toward the membrane surface and, therefore, by formation of thicker and denser chitosan films with an increase in the current density. Under these conditions, the separation of Mg^{2+} from Na^+ increases, whereas $P_{Na^+}^{Mg^{2+}}$ decreases.

As seen from Fig. 3, for cation-exchange membranes modified by their keeping in solution of chitosan hydrochloride the Na^+ and Mg^{2+} transference numbers change and $P_{Na^+}^{Mg^{2+}}$ decreases. These experiments show that the sorption of chitosan on the cation-exchange membrane surface is slow. For example, in keeping cation-exchange membranes in aqueous solution of chitosan hydrochloride (15 g l^{-1}) for 48 and 144 h, $P_{Na^+}^{Mg^{2+}}$ decreases from 1.19 to approximately

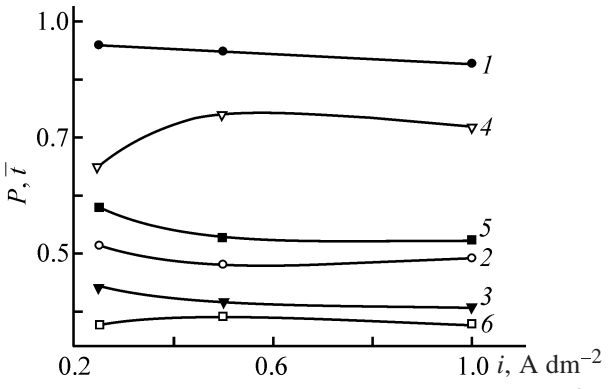

Fig. 3. Influence of the current density i on (*1, 4*) $P_{Na^+}^{Mg^{2+}}$, (*2, 5*) $\bar{t}^{Na^+}$, and (*3, 6*) $\bar{t}^{Mg^{2+}}$ in electrodialysis through a cation-exchange membrane preliminarily kept in solution of chitosan hydrochloride (15 g l^{-1}) for (*1–3*) 48 and (*4–6*) 144 h.

0.85 and 0.7, respectively (Fig. 3). As opposed to membranes modified with chitosan added to the diluate directly in the course of electrodialysis, for membranes preliminarily modified by sorption of chitosan from its solutions, $P_{Na^+}^{Mg^{2+}}$ depending on sorption time either slightly decreases (Fig. 3, curve *1*) or increases (Fig. 3, curve *4*) with increasing current density. These results are consistent with the above hypothesis that, in introduction of chitosan hydrochloride directly into the solution in the course of electrodyalysis, an increase in the current density leads to an increase in the chitosan flow toward the membrane surface; as a result, thicker and denser chitosan films are formed on the membrane surface. This factor improves the Mg^{2+}/Na^+ separation with the membrane.

For a cation-exchange membrane modified by the third method (chitosan hydrochloride film applied to membrane surface), with increasing membrane thickness, $\bar{t}^{Na^+}$ increases, whereas $\bar{t}^{Mg^{2+}}$ decreases and, as a result, $P_{Na^+}^{Mg^{2+}}$ decreases. In these experiments, the dependence of $P_{Na^+}^{Mg^{2+}}$, $\bar{t}^{Mg^{2+}}$, and $\bar{t}^{Na^+}$ on the film thickness (5–20 μm) was virtually identical to that shown in Fig. 1 for the chitosan concentration ranging from 0.01 to 0.1 g l^{-1}. These results are consistent with our hypothesis that, in electrodeposition of chitosan on the membrane surface, the chitosan film thickness increases with increasing chitosan concentration in the solution.

It should be noted in conclusion that, in analysis of the selectivity of Na^+ and Mg^{2+} transfer through membranes modified with chitosan, not only the electrostatic barrier effect of the chitosan film, but also the difference in hydration of these cations [10] should be taking into account.

CONCLUSIONS

(1) The Mg^{2+}/Na^+ selectivity factor $P_{Na^+}^{Mg^{2+}}$ of transfer through cation-exchange membranes in electrodialysis can be decreased by modification of the membrane with chitosan hydrochloride by the following techniques: electrodeposition of chitosan on the membrane surface, sorption of chitosan on the membrane surface from aqueous solution, and application of a chitosan film to the membrane surface.

(2) Increase in both the chitosan hydrochloride concentration in the diluate and the current density lead to a decrease in $P_{Na^+}^{Mg^{2+}}$ due to an increase in the chitosan film thickness. After prolonged keeping of the cation-exchange membrane in a solution of chitosan hydrochloride, $P_{Na^+}^{Mg^{2+}}$ increases with increasing current density. With a cation-exchange membrane modified by application of chitosan film to the dry membrane surface, $P_{Na^+}^{Mg^{2+}}$ decreases with increasing film thickness.

ACKNOWLEDGMENTS

The authors are grateful to D.V. Chervonetskii for submitting chitosan hydrochloride sample (flocculant Khitoflok-4).

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Sorption of Copper(II) Ions with Soybean Crush Modified with Sodium Monochloroacetate

T. E. Nikiforova and V. A. Kozlov

Ivanovo State University of Chemical Technology, Ivanovo, Russia

Received April 9, 2007

Abstract—The effect of chemical modification on sorption properties of soybean crush with respect to copper(II) ions was examined. The optimal parameters of soybean crush treatment with sodium monochloroacetate to ensure the maximal sorption capacity of the sorbent were determined.

DOI: 10.1134/S1070427208030130

Various vegetable products can be promising sorbents for recovery of heavy metal ions from aqueous solutions, since they are cheap and renewable raw materials [1, 2]. The main drawback of such sorbents is their comparatively low sorption capacity. Therefore, modification of unconventional materials containing protein and cellulose components to increase their sorption capacity is an important step in preparation of new sorbents. Various methods of modifying cellulose-containing polymers (including mechanical, physical, chemical, mechanochemical, and physicochemical methods) were suggested [3–9]. The main goal of such modification is to increase the internal adsorption surface area and accessibility of the active groups, and also to form new sorption-active groups on the sorbent surface.

The chemical modification of secondary products from treatment of oil-bearing crop seeds (sunflower, flax, mustard, soybean, rape), formed in a large amount (>40%) in the course of vegetable oil making, shows much promise.

In spite of available data on using soybean crush [10–14], the possible presence in it of certain substances dangerous for human and animal health excludes its use as food and fodder without additional treatment. Therefore, utilization of secondary products from oil crop treatment is of interest in view of the development of resource-saving processes. One of possible directions of soybean crush and mill cake use is the sorption treatment of aqueous solutions to remove heavy metal ions. An important requirement to such sorbents is that they should not be the source of secondary pollution for media to be purified.

The goal of this study is to prepare a new efficient sorbent based on chemically modified soybean crush containing chelating sorption centers for recovery of copper(II) ions from aqueous solutions.

EXPERIMENTAL

We used soybean crush of the following composition (wt %): crude protein 43.8, moisture 11.5, ashes 6.1, crude cellulose 5.6, fat 1.6, phosphorus 0.75, calcium 0.24, total acidity 8.8, no toxicity [14], and the following chemicals: $CH_2ClCOONa$, NaOH or Na_2CO_3, HCl or H_2SO_4, and $CuSO_4 \cdot 5H_2O$ (all chemically pure grade).

Initially soybean crush was ground and bolted through sieves with mesh diameters of 1.0 mm to separate coarse particles and 0.8 mm to separate fine particles. Thus, the size of sorbent particles used in the experiment was 0.8–1.0 mm. Samples were air-dry; their moisture content did not exceed 14%.

Sorption of copper(II) ions was studied under static conditions from aqueous solutions of copper sulfate with stirring and thermostating at 293 K. The sorption kinetics was investigated by the method of limited solution volume. To obtain the kinetic curves of sorption, samples (m = 0.1 g) of the sorbent were introduced into test tubes, V = 10 ml of copper sulfate solution was added into each, and the mixtures were stored for a period from 30 min to 24 h. The initial copper ion concentration c_0 was 1.5×10^{-4} M. After definite periods of time, the solution was separated from the precipitate by filtration and the current copper concentration c_τ in it was determined by atomic absorption spectroscopy on a Saturn spectrometer.

Determination of optimal parameters of sorbent modification

Sample no.	Solvent/sorbent ratio	T, °C	τ, min	pH_{in}	pH_{fin}	Concentration, % of sorbent weight		α, %
						$ClCH_2COONa$	Na_2CO_3	
1	1	100	60	8	9	1.0	0.5	77
2	5	100	60	10	8	1.0	1.0	80
3	5	100	60	8.5	8	10	5	87

8	5	100	90	8.5	5.5	20	10	98
9	Unmodified soybean crush							75

The sorption capacity A_τ of the sorbent at instant of time τ was calculated by the formula

$$A_\tau = (c_0 - c_\tau)V/m.$$

When the equilibrium was attained, the metal ion concentration c_{eq} was determined and the equilibrium sorption capacity A_{eq} of the sorbent was calculated by the formula

$$A_{eq} = (c_0 - c_{eq})V/m.$$

The degree of metal ion recovery was determined as follows:

$$\alpha_{eq} = (c_0 - c_{eq}) \times 100/c_0.$$

To obtain sorption isotherms, 0.1-g portions of soybean crush were introduced into test tubes, and 10 ml of copper sulfate solutions with diffferent initial concentrations (10, 50, 100, 200, 250, and 500 mg l^{-1}) were added. The resulting mixtures were kept to attain the equilibrium. Then, the solution was separated by filtration, and the residual metal ion concentration in solution was determined.

The IR reflection spectra of the initial and modified soybean crush samples were recorded on an Avatar 360 FT-IR E.S.P. IR Fourier spectrometer within the 400–4000 cm^{-1} range. The error of determination of the sorption capacity did not exceed 10%.

Modification of soybean crush was performed in aqueous solution of sodium monochloroacetate. The following parameters were varied: time and temperature of treatment, solution/sorbent ratio, initial and final pH of the modifying solution, and concentration of the modifying agent.

As a result, eight samples of modified soybean crush were prepared. These samples were tested for sorption ability (characterized by sorption capacity and degree of recovery). The results are listed in the table. The varied parameters affect the modification of soybean crush differently. The most important factors are concentration of sodium monochloroacetate and pH. The influence of the concentration of the modifying agent is probably associated with the amount of modified sorption-active groups or polydentate sorption centers. The sorption ability of the sorbent increases with an increase in the number of such centers. The effect of pH of the resulting solution after modification is associated with the isoelectric point (IEP) of the protein component of soybean crush. It is known that the solubility of protein is minimal in IEP. Hence, the final pH value of the modifying solution should be taken so as to ensure as low amount of protein in the solution before filtration as possible. Usually pH in IEP is within the range 4–6.5 [15]. Proteins are readily precipitated at pH in IEP, because the total charge of the protein molecule is equal to zero and there is no electrostatic repulsion between the neighboring molecules.

Analysis of the experimental data shows that samples 6–8 have the best sorption properties.

Thus, modification of soybean crush was optimal when it was treated with an aqueous solution containing $CH_2ClCOONa$ (10–20% of sorbent weight) at pH 8–10, solution/sorbent ratio of 5–50 for 30–60 min on a boiling water bath. Then the acid was added to pH 5.5–6.5. The time of contact of the modified sorbent with the solution was 0.5–1.5 h at solution/sorbent ratio of 50–200.

In contrast to unprocessed soybean crush, the

modified crush does not impair the quality of the purified (to remove heavy metal ions) water. Upon modification, filtration of purified water to remove the sorbent is accelerated, and water remains transparent and preserves the initial color.

The main characteristics of the sorbent are the sorption capacity and time of attainment of the sorption equilibrium. To find the time of equilibrium attainment with aqueous solution of copper(II) sulfate, we measured the kinetic curves of sorption for the initial and modified soybean crush samples.

As seen from Fig. 1, the equilibrium is attained slowly, in 20–22 h, and the half-sorption time is 5 h irrespective of the sorbent. The equilibrium sorption capacities of the initial and modified soybean crush samples with respect to copper(II) amount to 1.8 and 15.4×10^{-3} mol kg^{-1}, respectively (degree of recovery 78 and 98%). Thus, substantial (by 23%) increase in copper(II) recovery by modified soybean crush is observed.

To determine the parameters of the sorption capacity of the initial and modified soybean crush samples, we measured isotherms of copper(II) sorption from $CuSO_4$ solutions (Fig. 2).

The data obtained can be described by Langmuir equation of absorption isotherm

$$A = A_\infty K_0 c_{eq}/(Kc_{eq} + 1),$$

where K is the concentration constant of the sorption equilibrium, which characterizes the intensity of the sorption process (l mol^{-1}).

Linearization of the sorption isotherm by the equation

$$1/A = 1/A_\infty + 1/A_\infty Kc_{eq}$$

allows graphic determination of the limiting sorption A_∞ for both the initial and modified soybean crush samples, which amounts to 0.7 and 0.8 mol kg^{-1}, respectively.

Increase in the sorption capacity of the modified sorbent as compared to the initial sorbent can be accounted for by the fact that, in the course of treatment of soybean crush with sodium monochloroacetate, polydentate sorption centers involving protein amino acids and acetate groups of the modifying agent are formed. Among amino acids composing soybean crush (valine, leucine, isoleucine, serine, threonine, cysteine, methionine, lysine, arginine, aspartic acid, glutamic acid, phenylalanine, tyrosine, histidine, proline, alanine), arginine (3%), lysine (2.5%), and cysteine (0.6%) should be noted. In addition to α-amino groups participating in formation of peptide (amide) bonds in the course of assembling peptide molecules, they contain additional functional groups:

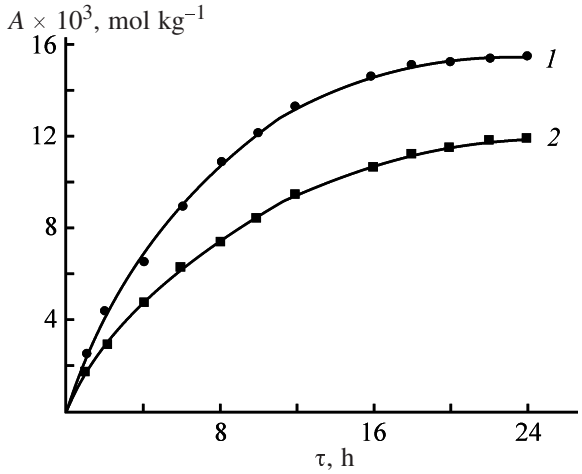

Fig. 1. Kinetic curves of sorption of copper(II) ions from $CuSO_4$ aqueous solutions with (*1*) modified and (*2*) unmodified soybean cake. (*A*) Sorption capacity and (τ) time of sorption.

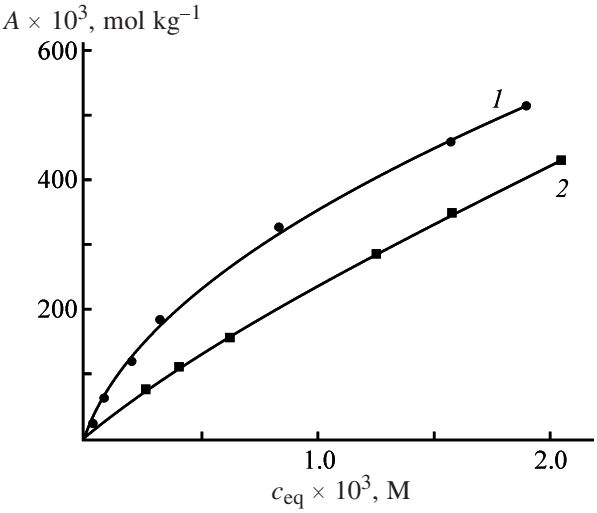

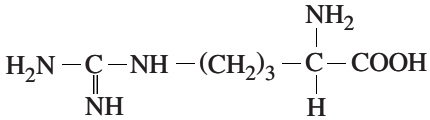

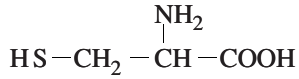

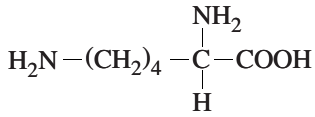

Fig. 2. Isotherms of sorption of copper(II) ions from $CuSO_4$ aqueous solutions with (*1*) modified and (*2*) unmodified soybean crush. (*A*) Sorption capacity and (c_{eq}) equilibrium copper(II) concentration.

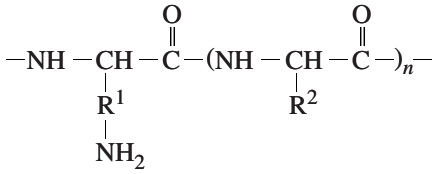
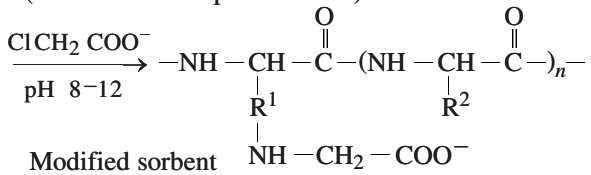
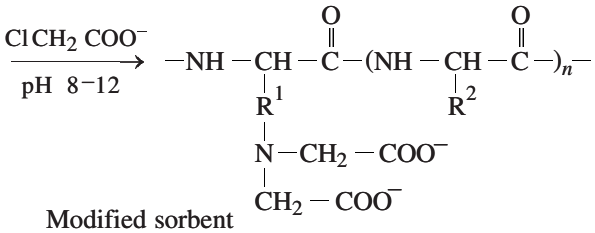
Arginine



Cysteine

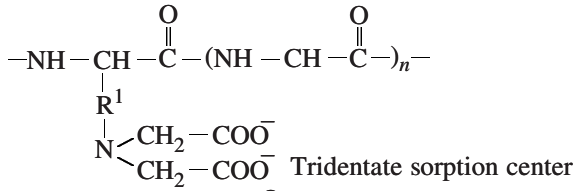


Lysine

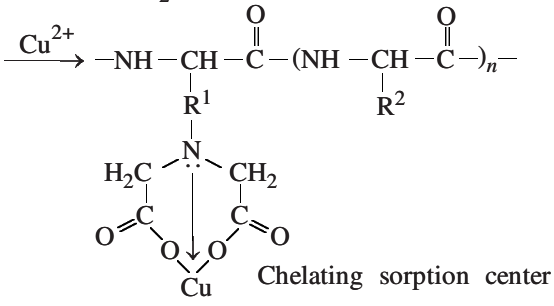


Probably, just the free functional groups of arginine, lysine, and cysteine are the first to be subjected to modification with sodium monochloroacetate. In the process, monodentate sorption centers transform into polydentate chelating centers of sorption, e.g., –NH–CH_2–COOH and –N–(CH_2–COOH)$_2$:

Initial (unmodified) sorbent
(monodentate sorption centers)



Modified sorbent
(bidentate sorption centers)



Modified sorbent
(tridentate sorption centers)

Sorption results in formation of very stable five-membered chelate rings capable to strongly retain copper(II) ions in the sorbent phase, e.g.:

Tridentate sorption center

Chelating sorption center

The strength of copper(II) binding in the complex increases with increasing number of polydentate centers in the ligand [16].

To confirm the above suggestion, we recorded the IR spectra of the initial and modified soybean crush samples (Fig. 3).

Soybean crush is a mixture of polymers (mainly proteins and cellulose) containing various functional donor groups (carboxy, hydroxy, amide, and amino groups). In the IR spectrum of unmodified soybean crush, strong absorption bands belonging to stretching vibrations of the N–H, C–N, C=O, and O–H bonds are observed. In the range 3600–3300 cm^{-1}, there are strong bands of stretching vibrations of O–H groups and N–H bonds of amino and amide groups. Bands at 3500 and 3400 cm^{-1} belong to antisymmetric and symmetric stretching vibrations of N–H group in amines, respectively. Weak bands at 3350–3310 cm^{-1} are due to N–H stretching vibrations in amides. Absorption at 1650 cm^{-1} belongs to stretching vibrations of carbonyl C=O groups in peptide bonds of proteins (amide I band). In the spectrum of modified soybean crush, splitting of this band becomes less pronounced. Bands at 1640–1560 cm^{-1} belong to bending vibrations of N–H bonds in amides. In this region, the initial soybean crush has a weak doublet, which disappears in the spectrum of the modified soybean crush. In the range 1580–1490 cm^{-1}, there are weak bands of bending vibrations of N–H groups in amides (amide II band). Splitting of the band at 1538–1539 cm^{-1} in the spectrum of the modified sorbent is less weaker than that in the spectrum of the initial cake. In the range 1300–1030 cm^{-1}, there are bending vibrations of O–H groups, bending and stretching vibrations of C–O groups in acids, and stretching vibrations of C–N groups in amines and amides (amide III band) appear. This region is characterized by bands at 1245 and 1055 cm^{-1} in the spectrum of the initial soybean crush. In the spectrum of the modified crush, these bands are shifted to 1241 and 1065 cm^{-1}, respectively. In the range 900–650 cm^{-1}, bending vibrations of N–H groups in amides appear [17]. In this range, a broad band is observed in the spectra of both initial and modified soybean crush samples. The changes observed are associated with the change of the substrate structure due to interaction of free amino groups or probably amide groups of protein molecules of soybean crush with modifying agent, sodium monochloroacetate, and formation of new functional groups that are polydentate sorption centers.

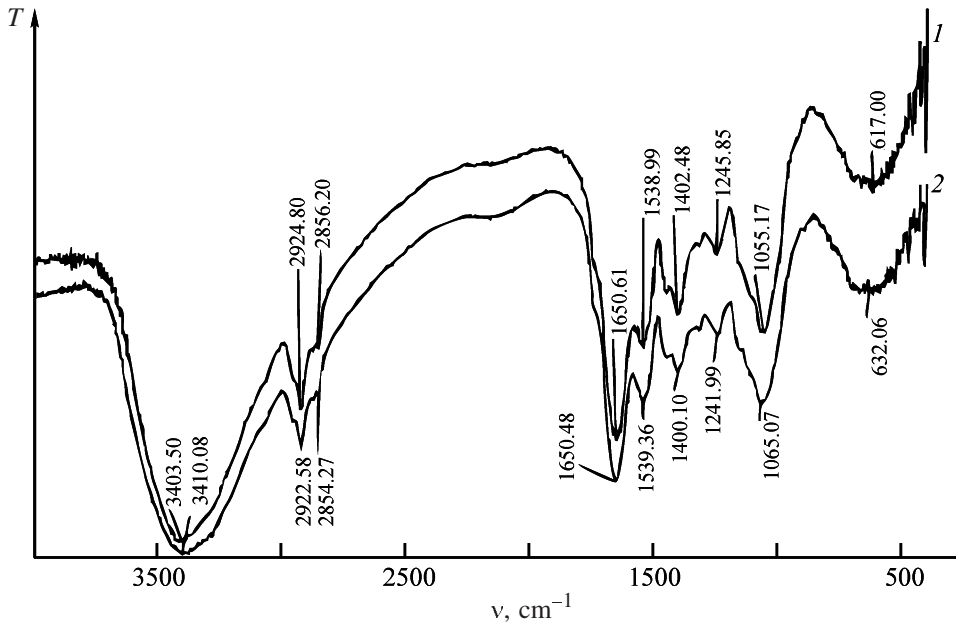


Fig. 3. IR spectra of (*1*) unmodified and (*2*) modified soybean crush. (*T*) Transmittance and (ν) wavenumber.

CONCLUSIONS

(1) Soybean crush was subjected to chemical modification by treatment with aqueous solution of sodium monochloroacetate to obtain a new efficient sorbent which recovers copper(II) from aqueous solutions through chelating sorption centers formed. The optimal parameters of modification were determined.

(2) Sorption properties of the initial and modified soybean crush with respect to copper(II) ions were studied. The treatment of soybean crush with sodium monochloroacetate increases the recovery of copper(II) ions by 23%, and the degree of recovery reaches 98%.

(3) IR spectra show that the substrate structure undergoes changes upon chemical modification, with the formation of new bonds and functional groups acting as polydentate sorption centers.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Determination of Zinc in Aqueous Solutions by a Combined No-Standard Electrochemical Method with Preliminary Electrolytic Separation of Copper

S. S. Ermakov, A. A. Sheremet, and L. N. Moskvin

St. Petersburg State University, St. Petersburg, Russia

Received September 20, 2007

Abstract—A combined method for no-standard determination of zinc in aqueous solutions (calibration of the device against standard solutions or use of standard additions is not required) is suggested. The method is based on principles of stripping voltammetry and potentiostatic coulometry.

DOI: 10.1134/S1070427208030142

Stripping voltammetry (SVA) is a commonly used method for determination of copper, cadmium, lead, and zinc in various aqueous media and food products. One of drawbacks of the method is the necessity of calibration against reference samples, i.e., it requires time-consuming construction of calibration plots.

Several versions of no-standard electrochemical methods without references, allowing determination of metals in aqueous solution, have been suggested [1–5]. Companys et al. [1, 2] used the potentiometric analytical procedure: they deposited on the surface of an electrode by pre-electrolysis an amalgam with a known concentration of a metal being determined and then used the quasi-equilibrium potential of the $M(Hg)/M_e^{n+}$ system to calculate the concentration of a substance being analyzed in solution. A stripping chronopotentiometric version of the no-standard electrochemical method has been suggested [3]. This method is based on multiple-cycle dissolution of a metal from an amalgam obtained in the pre-electrolysis stage and subsequent finding of a charge Q_∞ corresponding to complete deposition of the substance from solution. A technique termed dynamic coulometry was suggested in [4, 5]. This method is based on multiple-cycle scanning of the potential. A combined electrochemical method based on principles of SVA and potentiostatic coulometry was developed in [6–8]. The possibility of using it for the determination of lead ions [6], of copper and cadmium ions in the absence and in the presence of lead ions [7], and of mercury ions [8] was demonstrated previously. One of the main drawbacks of SVA in the case of simultaneous presence of ions of several metals is manifestation of the effects associated with formation of intermetallic compounds (IMC) in the amalgam of the working electrode. This phenomenon results in the shift of the peaks of the analyzed substances or leads to the appearance of new peaks [8].

This study is concerned with the development of a combined no-standard electrochemical method for zinc determination in the presence of copper, which includes preliminary electrolytic separation of copper to prevent formation of IMCs.

The stripping-voltammetric measurements were performed on a PU-1 polarograph (ZIP, Gomel, Belarus) with an AKV-07 sensor (Akvilon NPKF, Moscow) and on an AKV-07MK voltammetric analyzer (Akvilon) with Polar-4.1 software in the dc and ac modes. Solutions with various concentrations of zinc and copper ions were prepared from solutions of 1 g l^{-1} state reference samples (GSO 6742 and GSO 7255, respectively) using chemicals of chemically pure or analytically pure grade and double-distilled water. The measurements were carried out on a mercury–graphite film electrode rotating at a speed of 1000 rpm in the accumulation stage. A solution of composition (M) 1×10^{-4} $Hg(NO_3)_2$ + 5×10^{-2} HCl + 1×10^{-4} HNO_3 was used as supporting electrolyte. The pre-electrolysis in SVA measurements was performed at a potential of about –1.3 V, with a silver chloride reference electrode. The design of the electrochemical cell and electrodes has been described previously [6, 7]. To satisfy the conditions of complete dissolution of the metal from the amalgam, slow (2–5 mV s^{-1}) potential sweep rates were used [6].

Results of determination of zinc ions by a combined no-standard electrochemical method

Measurement no.	Introduced, M	Q_∞, μC		Found, M
		calculated	experimental	
1	1.0×10^{-7}	38.6	37.6/38.4*	$9.74 \times 10^{-8}/9.95 \times 10^{-8}$
2			39.0/36.8	$1.01 \times 10^{-7}/9.53 \times 10^{-8}$
3			41.3/36.4	$1.07 \times 10^{-7}/9.43 \times 10^{-8}$
Average			$39.9 \pm 8.0/37.2 \pm 2.3$	$(1.0 \pm 0.1) \times 10^{-7}/(9.6 \pm 0.4) \times 10^{-8}$

* After preliminary electrolytic separation of copper.

The rate at which zinc concentration varies with the electrolysis time was studied by the method used previously for lead [6] and for copper and cadmium [7]. The results of the measurements are plotted in Fig. 1. It can be seen that the $\log(c/c^0)$ vs. t plot is linear, which agrees well with the equation $\log(c/c^0) = -kt$, where c/c^0 is the ratio of current to initial concentration and k, coulometric constant. The dependence of the normalized zinc concentration on the solution volume at a constant accumulation time was determined similarly. As seen from Fig. 2, the plot in the coordinates $\log(c/c^0)$–$(-1/V)$ is linear. This agrees with the known dependence of the coulometric constant k on the solution volume V [9]:

$$k = DS/V\delta,$$

where D is the diffusion coefficient; S, electrode area; and δ, thickness of the diffusion layer.

The data obtained show that the processes occurring in an electrochemical cell in the course of successive electrolysis agree with the relationships of potentiostatic coulometry and, correspondingly, indicate that the methodic principles of the combined no-standard method can be applied to zinc determination in solution. The results of its determination at accumulation times t_1, t_2, and t_3 (240, 360, and 480 s, respectively) are presented in Table 1.

The possibility of zinc determination with preliminary electrolytic separation of copper was studied in a solution containing copper and zinc at a potential of –0.35 V (solution volume 5 ml). Under these conditions, copper is deposited at the electrode, whereas zinc remains in the solution. Then, the cathodic copper deposit was dissolved in another cell to clean the electrode.

As known, 99% of a substance is deposited within 12.5 min of electrolysis at intense agitation [9], with 70% being deposited within 8 min. Thus, simple calculation shows that, if copper is in a threefold excess with respect to zinc, then after 8 min of electrolysis a concentration ratio of less than 1 : 1 is obtained. At this ratio, IMCs practically are not formed [10]. At the same time, in natural water zinc is always present in larger amounts than copper, and the time of copper deposition can be made shorter [10].

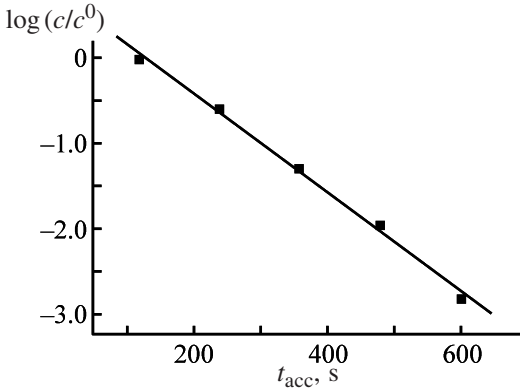

Fig. 1. Dependence of the logarithm of the normalized concentration of zinc ions, $\log(c/c^0)$, on the electrolysis duration t_{acc}.

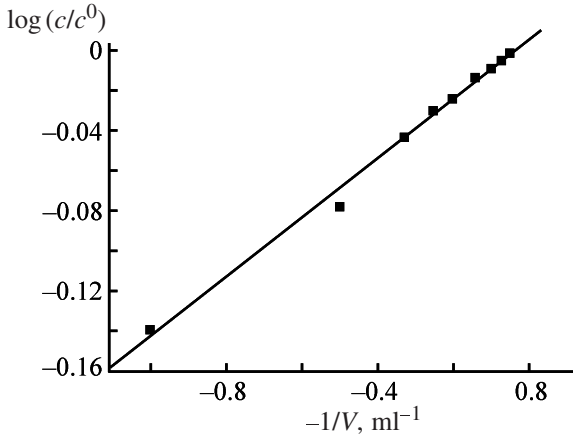

Fig. 2. Dependence of the logarithm of the normalized concentration of zinc ions, $\log(c/c^0)$, on the volume of a solution being analyzed V. Accumulation time t_{acc} = 5 min, $c^0_{Zn} = 5 \times 10^{-8}$ M.

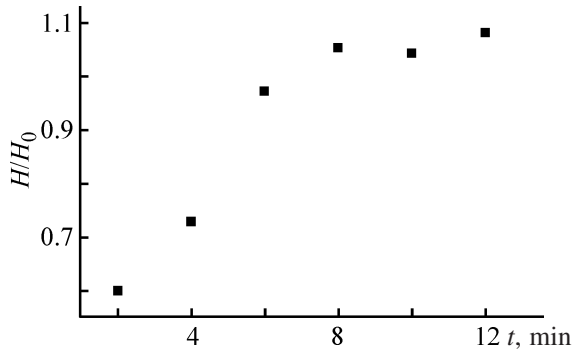

Fig. 3. Relative height of the zinc ionization peaks, H/H_0, vs. the time of electrolytical copper recovery t. Solution volume V = 5 ml, $c^0_{Cu} = c^0_{Zn} = 5 \times 10^{-8}$ M. H and H_0 the heights of the zinc ionization peaks with and without copper ions, respectively.

The effect of copper on the zinc analytical signal was studied by measuring the height of the zinc peak at various times of the electrolytic copper recovery (Fig. 3) in the solutions with equal initial concentrations of copper(II) and zinc(II). The data of Fig. 3 show that, after 8 min of electrolysis, the height of the zinc peak is a constant value equal to the analytical signal in a solution free of copper ions.

To examine the possibility of determining zinc and copper in the case of their simultaneous presence in solution by the no-standard electrochemical method, we measured solutions containing 1×10^{-7} M zinc and copper ions. The volume of the electrochemical cell was 2 ml, and the accumulation potential, –1.3 V. The total amount of electricity was calculated by the Mates formula. The electrolytic deposition of copper was performed for 8 min with subsequent dissolution in another cell (20 ml). Then, the voltammograms were recorded and the amount of electricity and the concentrations were calculated in accordance with the principles of a combined no-standard electrochemical method. The results are presented in the table. As can be seen, after electrolytic deposition of copper, the combined no-standard electrochemical method of zinc determination gives satisfactory results.

CONCLUSIONS

(1) A combined no-standard method for determination of zinc is convenient for automated analysis of process solutions and wastewater from electroplating and hydrometallurgical shops.

(2) For zinc determination in the presence of copper, it was suggested to electrolytically separate copper ions prior to analysis, to prevent formation of intermetallic compounds.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrochemical Reduction of Oxygen in Gas-Diffusion Electrodes Based on Expanded Natural Graphite

G. A. Kolyagin and V. L. Kornienko

Institute of Chemistry and Chemical Technology, Siberian Branch, Russian Academy of Sciences, Krasnoyarsk, Russia

Received May 17, 2007

Abstract—Electroreduction of oxygen in gas-diffusion hydrophobized porous electrodes containing 8–10 wt % fluoroplastic, made of expanded natural graphite and acetylene black, in acidic (pH 0.6) and alkaline electrolytes was studied.

DOI: 10.1134/S1070427208030154

Expanded natural graphite (ENG) has been extensively studied, in particular, with the aim of applying it to various electrochemical systems [1]. Application of ENG to manufacturing bipolar plates of fuel cells has been studied in [2, 3]. Such plates are used to supply starting components and remove reaction products from electrodes, ensure good electrical contact with the catalyst, and provide sealing of the electrochemical system. For the same purpose, composites of ENG with polymers, i.e., with aromatic polysulfides are considered in [4], and those based on ENG and high-density polyethylene, in [3, 5]. As cathode material of alkaline batteries, mixture of ENG with natural graphite was studied in [6]. Physicochemical and electrochemical properties of expanded graphite oxide and ENG are being examined [7, 8]. In [9], the electrochemical methods were used to study the structural characteristics of ENG articles; ENG electrodes are applied to determination of uric acid [10] and ethanol [11].

Since in electrochemical systems ENG can be in contact with oxygen, it is important to know the parameters of electrochemical reduction of oxygen on ENG. Because of water release in fuel cells, it is necessary to make lower the wettability of materials being used. This can be done, e.g., by introducing polytetrafluoroethylene into a composite material. Electrolytic reduction of oxygen on ENG was not studied previously; therefore, the study of electrochemical reduction of oxygen on ENG is of interest in both applied and theoretical aspects.

This study is concerned with the electrochemical reduction of oxygen in gas-diffusion hydrophobized electrodes made of ENG in aqueous alkaline and acidic solutions at atmospheric pressure. The activity of electrodes was determined, the slope of the polarization curves plotted in the Tafel coordinates was estimated, and fractions of current consumed for formation of H_2O_2 and water were determined. These studies have been started previously and reported in [1, 12]. A-437E acetylene black (AB) electrodes with a specific surface area of 100 $m^2\ g^{-1}$ were also studied for the comparison of ENG with other electrode materials.

EXPERIMENTAL

Gas-diffusion hydrophobized electrodes were made of ENG powders. To obtain them, intercalation compounds of natural graphite with inorganic acids, synthesized by electrochemical method, were heated after washing in water and drying (see table). To fabricate electrodes, a hydrophobized electrode mass constituting an aqueous suspension of F-4D fluoroplastic (analog of Teflon) as water repellant was pressed in a mold to obtain discs (thickness 0.5 mm, weight about 0.3 g, porosity 60 vol %, F-4D concentration 10 wt %), which were heated in air at 360°C for 5 min. Carbon black electrodes (thickness 1 mm, porosity 69 vol %) were fabricated from a mass containing 8 wt % F-4D. To increase their strength and electrical conductivity, a 0.1-mm-thick nickel gauze was placed inside the carbon black electrodes. Preparation of intercalation compounds, the scheme of the electrolyzer, and preparation and study of gas-diffusion ENG electrodes have been described in detail in [1, 13].

Properties of graphites used for fabricating electrodes and values of Tafel slopes

Electrode no.	Graphite brand	Concentration of intercalated acid, wt %	Amount of passed electricity in electrosynthesis of intercalation compounds, A h g^{-1}	Tafel slope, mV, for indicated electrolyte, M	
				0.2 K_2SO_4 + 0.3 H_2SO_4 (pH 0.6)	3 KOH
1	Carbon black A437E	–	–	95	40
2	GAK-3	92 H_2SO_4	0.15	130	80
3	GT-1	70 HNO_3	0.15	130	60
4	GAK-3	70 HNO_3	0.17	300	60

The electrochemical measurements were carried out in a three-chamber glass cell [13] at 20°C and atmospheric pressure. The electrolytes were 3 M KOH and 0.2 M K_2SO_4 + 0.3 M H_2SO_4 (pH 0.6). The cathodic and anodic chambers were separated with an MF-4SK-100 cation-exchange membrane. The catholyte volume was 0.023 l. As anolyte was used 1 M H_2SO_4. Oxygen was flown at atmospheric pressure through a gas chamber to enter the real side of the electrode. Polarization curves were recorded at a potential sweep rate of 1–80 mV s^{-1}. The geometric current density was calculated per unit visible frontal electrode surface (5 cm^2). The electrode potential was measured relative to a silver chloride reference electrode. The volume of the pores wetted with the electrolyte was determined by hydrostatic weighing of the electrodes in 3 M KOH after the experiments and was calculated by the formula

$$E = [1 - (P - P_s)/d_s V] \times 100,$$

where E is the electrode porosity (vol %); P, mass of dry electrode in air; P_s, mass of the wetted electrode in the solution; d_s, solution density; and V, electrode volume.

The electrolyte porosity of the samples studied was within 4–15 vol %.

According to the published data [13–15], O_2 on graphitic carbon materials is mainly reduced to H_2O_2 and then it can be reduced to H_2O. Fractions of current consumed for either reaction are determined by electrolysis conditions and by the material and structure of the electrode [16]. Therefore, we measured the fraction of current γ consumed for oxygen reduction to hydrogen peroxide or water on the electrodes studied. The time necessary for the uptake of a certain amount of oxygen was determined by the gasometric method. The quantity γ was calculated by the Faraday law

$$\gamma = Q_t/Q - 1 = (2FV_0)/(V_m I\tau) - 1,$$

where Q_t is the theoretical amount of electricity; Q, experimentally determined amount of electricity; F, Faraday constant ($2F$ is the amount of electricity required for obtaining 1 mol of H_2O_2 from O_2, 1 mol of H_2O from H_2O_2, or 1 mol of H_2 from H_2O); V_m, volume of 1 mol of oxygen (molar volume); I, current strength; τ, time of reduction of a certain volume of oxygen; V_0, volume of oxygen taken up, converted to standard conditions.

The γ value is affected by the further reduction of hydrogen peroxide to water and by repeated reduction of oxygen, which appears upon hydrogen peroxide decomposition. Naturally, γ is 1 if all oxygen is reduced to H_2O_2, or zero if all oxygen is reduced to water or to hydroxide ions. In the case when the hydrogen evolution starts simultaneously with O_2 reduction, γ becomes less than zero. If all the amount of electricity is consumed for hydrogen evolution, then $\tau = \infty$ and $\gamma = -1$. The effect exerted by the current density on γ for carbon black electrode and electrode no. 4 is shown in Fig. 1 as example (see table). In this case, it should be noted that, with increasing current density, the potential of a carbon black electrode varied from –0.25 to –0.48 V in 3 M KOH and from –0.2 to –0.55 V in an acidic solution. The potential of the ENG electrode varied from –0.64 to –1.86 V in 3 M KOH and from –0.56 to –1.24 V in an acidic solution.

As the current density increases, γ on carbon black remains virtually constant in alkaline electrolyte, whereas in acidic electrolyte it sharply increases from virtually zero to constant value, i.e., most of the obtained hydrogen peroxide is not further reduced and

is accumulated in the electrolyte. Changes in γ on gas-diffusion carbon black electrodes in acidic medium are due to the diffusion limitations with respect to hydrogen ions, which appear at higher current densities, and, consequently, due to deceleration of further reduction of H_2O_2 to H_2O [16].

In electrolysis proceeding on electrodes made of expanded natural graphite, the amount of H_2O_2 is insignificant and γ does not rise above zero. This fact indicates that virtually all H_2O_2 is reduced to water, since, evidently, owing to diffusion limitations on removal of the reaction products and high polarization, H_2O_2 has no time to leave the electrode and is reduced to water. In alkaline solution, γ starts to sharply decrease on reaching the hydrogen evolution potential (about –1.5 V), i.e., the hydrogen evolution occurs on the frontal surface of the electrode and in the region close to it, whereas, in the depth of the electrode, O_2 reduction associated with ohmic loss also occurs. In an acidic solution, hydrogen evolution starts even at small current densities and γ sharply decreases with increasing current. All these facts indicate that the boundaries of a three-phase contact are undeveloped and delivery of O_2 toward the reaction area and removal of H_2O_2 are significantly limited. Also, in acidic solution, the dissociation and reduction of O_2 to water due to strong adsorption on edge atoms of ENG cannot be ruled out. The effect of the current density on γ showed that, the lower the electrode activity in O_2 reduction, the faster the decrease in γ with increasing current density.

The Tafel slopes of the polarization curve make it possible to suggest the mechanism of O_2 reduction. Therefore, we estimated the above slopes on ENG electrodes, taking into account that, at small geometric current densities and at large inner surface area of the electrodes, the true current density will be low and the diffusion and ohmic components will be insignificant. For comparison, we determined the slopes obtained with carbon black electrode. The results are presented in Fig. 2 and Table 1. At low current densities, the values we obtained, to within probable errors associated with the effect of porous electrode structure, are mainly in qualitative agreement with the slopes of $2.3RT/2F$, $2.3RT/F$, and $2 \times 2.3RT/F$, i.e., are about 30, 60, and 120 mV, respectively. At larger polarizations, the slopes sharply increase, which, according to published data, can be caused by strong hydrogen adsorption [17, 18] or by diffusion hindrance [19]. This refers, in particular, to a slope of 300 mV obtained on electrode no. 4 in an acidic solution. Note that this value, obtained on expanded graphite, can be due to strong adsorption on edge carbon atoms whose number is considerably larger in expanded graphite than in compact graphitic carbon materials. A slope of $2.3RT/2F$ in alkaline solutions at small current densities is due to by concentration polarization with respect to removal of H_2O_2 (HO_2^-) [20], which is especially important for the porous electrode. The slopes of $2.3RT/F$ and $2 \times 2.3RT/F$ show that the stage

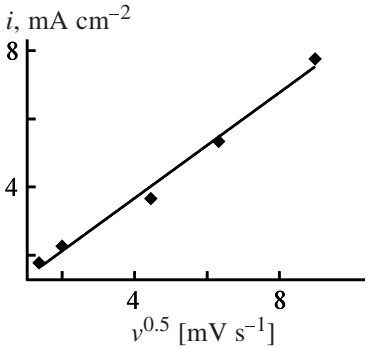

Fig. 4. Current density of the O_2 reduction vs. the square root of the potential sweep rate *v* obtained on electrode no. 4 at a potential of –0.4 V in a solution containing 0.2 M K_2SO_4 + 0.3 M H_2SO_4.

of the first electron transfer at different fillings of the surface is decelerated [17]. The slopes of the polarization curves obtained on AC electrodes qualitatively coincide with those presented in the literature: 60 mV in 2–4 M KOH on carbon black of unknown brand [15], 130 mV on AD-100 carbon black in 0.5 M H_2SO_4 [21], 35 mV in 1 M KOH, more than 120 mV in 0.5 M H_2SO_4 on acetylene black [17], and 120 mV on acetylene black in a phosphate buffer solution [19]. The slope obtained on graphite electrodes is approximately two times larger than on carbon black electrodes. Qualitatively, the slopes obtained on ENG coincided with the values obtained on pyrographite in [22]: 80 mV in 0.1 M KOH and 160 mV at pH 0.6. This fact suggests that the mechanism of O_2 electroreduction on expanded graphite is similar to that on pyrographite [14, 22]. The oxygen molecule is reduced to hydrogen peroxide without the bond cleavage, which is confirmed by the presence of H_2O_2 in an electrolyte and by its further reduction to water. The initial slope on ENG, as on other carbon materials, is larger in acidic medium than in alkaline medium. No regular trends related to the influence of the fabrication conditions of ENG on their electrochemical characteristics were found. The curves taken on electrode nos. 2 and 3 were identical. At the same time, the activity of the electrodes was lower than that of electrode no. 4, though they were made of ENG powders obtained from different graphite brands and under the different conditions.

The rate of oxygen electroreduction on ENG electrodes, as on carbon black and other graphitic carbon materials, increases as the rate of potential sweep increases [18, 23]. This dependence is presented in Fig. 3 as example. The electrode activity in alkaline electrolyte is higher than in acid electrolyte (Fig. 3, curves *3, 6*). The current peak of O_2 reduction at potential sweeping was not recorded because of gradual replacement of oxygen reduction by hydrogen evolution. Based on the voltammetry principles and owing to the fact that the experimental dependence of the current on the square root of the potential sweep rate is a straight line (Fig. 4), we may suggest that the electrode operates in the diffusion mode. On the polarization curve obtained in O_2 reduction in alkaline electrolyte, the peak or the limiting current is absent also, though active evolution of hydrogen starts only at –1.6 V. This is accounted for by the fact that the inner surface of a porous electrode is larger than that of a smooth electrode and, consequently, the true current density is low, i.e., it does not reach the limiting value in the examined range of the geometric current densities.

The replacement of oxygen by air decreases the activity of all the electrodes by a factor of approximately 2 (Fig. 3, curves *2, 3*), which indicates that the surfaces of the electrodes wetted with the electrolyte are not equally accessible. Similar results were observed on hydrophobized electrodes made of acetylene black [19]. At the same time, in [15], on an industrial gas-diffusion electrode used for H_2O_2 preparation, a five-fold decrease in the activity was observed, as in the case of equally accessible inner surface area of the electrode.

CONCLUSIONS

(1) Porous composite materials based on expanded natural graphite and F-4D fluoroplastic have low elec-

trochemical activity in oxygen reduction. In alkaline medium, the activity is higher than in acid medium.

(2) On electrodes made of expanded natural graphite, in contrast to carbon black electrodes, the main mass of oxygen is reduced to water without accumulation of H_2O_2 in the electrolyte.

(3) The obtained values of the Tafel slopes and the presence of H_2O_2 in solutions show that the O_2 electroreduction on expanded graphite electrode, as on the majority of graphitic carbon materials, occurs via formation of H_2O_2 and is limited by attachment of the first electron.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Concentration Conditions of Formation of Electrically Conducting Coatings from Colloid-Graphite Dispersions

V. N. Gorshenev, S. B. Bibikov, and A. M. Kuznetsov

Institute of Biochemical Physics, Russian Academy of Sciences, Moscow, Russia

Received September 17, 2007

Abstract—Concentration conditions under which electrically conducting graphite coatings can be formed on cardboard and polymeric dielectric substrates by deposition of graphite particles from colloid graphite dispersions were studied. It was found how the surface resistance of the samples varies, in the dc mode and in the microwave range, with the concentration and time conditions of formation of electrically conducting coatings. The transmittance and reflectance to microwave electromagnetic radiation were measured for samples coated with particles of colloid graphite from suspensions with various particle sizes.

DOI: 10.1134/S1070427208030166

Deposition of electrically conducting composites is a topical task of materials science, aimed to solve problems of science and technology, provide efficient operation of various kinds of radio equipment under the action of electromagnetic radiation, etc. There exist electrically conducting materials with a broad spectrum of physicochemical and physicomechanical properties, composed of polymers volume-filled with various conducting fillers [1–4].

Use of electrically conducting composite materials volume-filled with electrically conducting particles is not always justified as regards weight, electrical, and economical requirements. At present, there is increasing interest in studies of physicochemical properties of colloid structures of varied nature and particle size: metallic, graphite, and organosilicon [5, 6]. This specifically refers to nanostructures (<100 nm), for which it is necessary to develop technologies of production and compaction of nanoparticles, e.g., on dielectric substrates in order to form electrically conducting layers. In particular, colloid-graphite suspensions deposited onto dielectric substrates of varied nature are used to obtain electrically conducting materials [7]. Both in the case of composites with volume filling with electrically conducting particles and in treatment of dielectric materials with colloid-graphite preparation, it is necessary to determine what concentrations of graphite fillers provide a percolation transition.

In this study, we examined the concentration conditions under which dielectric materials become electrically conducting upon treatment with solutions of colloid graphites and evaluated the achievable radiophysical parameters of materials treated with colloid graphite.

EXPERIMENTAL

To obtain colloid-graphite dispersions, we used the chemical activation method [8]. Colloid graphite (CG) was produced from the thermally deashed graphite from the Taiginskoe deposit (ash content 0.2%), ground in an M-10 vibration mill. As the time of the vibration grinding was raised from 3 to 6 h, the specific surface area of graphite powders, determined by BET, increased from 250 to 450 $m^2 g^{-1}$.

To impart hydrophilic properties to graphite particles, they were oxidized with a 3 : 1 mixture of concentrated sulfuric and nitric acids. It is known [7, 8] that the redox reaction of graphite modification occurs with release of heat and nitrogen(IV) oxide to give a product close in composition to graphite disulfate. The activating agents (acids) were first removed by decantation to a density of the solution being decanted equal to 1.01–1.005 $g\ cm^{-3}$ and then by vacuum filtration to complete removal of SO_4^{2-} ions, as indicated by treating the filtrate with an aqueous solution of barium chloride in the presence of hydrochloric acid. The graphite deposit formed on the filter was mixed, depending on further use, with distilled water or isopropyl alcohol (IPA) to obtain a stable ultradisperse suspension of activated graphite. The acid modifica-

tion of graphite particles subjected to vibration grinding for 3 and 6 h yielded colloid-graphite preparations TO-3 and TO-6 with a specific surface area no less than 1300 and 1500 $m^2 g^{-1}$ for TO-3 and TO-6, respectively.

To determine the diffusion coefficients of colloid particles, we measured the average motion velocity of graphite particles in aqueous and alcoholic solutions on a photon-correlation spectrometer.

As dielectric substrates served cardboard with a density of 400 g m^{-2} and Lavsan (analog of Mylar) of thickness 52 μm. The samples were impregnated in solutions of certain concentrations during a prescribed time. The consumption of a colloid graphite solution for impregnation of dielectric materials was determined in relation to the concentration and time by the gravimetric method. The samples were dried at room temperature (20°C), with the cardboard and Lavsan samples subsequently heated to 200 and 60°C, respectively.

The conductivity of graphite coatings on dielectric materials was measured using the standard four-probe technique [4]. The volume electrical resistivity ρ_V was found using the well-known expression for the plane-parallel configuration of the samples being measured, $\rho_V = R_{av}SL^{-1}$, where R_{av} is the average measured electrical resistance of a sample; S, sample area; and L, spacing between the potential electrodes. In the case when the electrically conducting coating is homogeneous, its volume electrical resistivity ρ_V is equal (in the absence of a frequency dispersion) to the product of the surface resistance of the coating, ρ_S, by its thickness h.

The electrical parameters of the materials were also evaluated by contactless measurements of the transmittance to electromagnetic radiation with a frequency of 8–12.4 GHz. For this purpose, we used an installation based on an R2-61 panoramic scalar meter. A planar sample with a conducting surface was placed in the waveguide perpendicularly to the incident radiation (H_{01} mode) so that it completely blocked the waveguide cross section. The transmittance corresponding to the magnitude of the shielding effect of a material (by the electric field and in the far-field zone) was found as the logarithm of the power ratio between the wave incident onto, and transmitted through the sample (in decibels). The experimentally measured transmittance and reflectance to radio frequency radiation were used to calculate the surface resistance.

* After drying at 20°C for four days.

A distinctive feature of oxidized graphite after washing is its ability to form colloid systems exhibiting kinetic and aggregative stability. Graphite particles are stabilized by oxygen-containing functional groups of the type –OH, –COOH, and =C=O, formed on the surface of graphite particles [9]. The suspension can be stabilized via formation of hydrogen bonds between active surface groups and molecules of a polar solvent. The size of graphite particles in the suspension is less than 2 μm, depending on the conditions of preparation and vibration grinding of the starting graphite material [10].

The following processes may occur in the course of further technological use of graphite solutions in interaction of a dielectric material with a colloid-graphite dispersion: precipitation of graphite particles on the surface, aggregation of these particles, and desorption. In this case, the mass of a sample steadily increases, with the quantitative parameters of this trend strongly dependent on the properties of the surface and on the ability of CG to be accumulated on the surface of the dielectric material.

Table 1 lists experimental data obtained in treatment of cardboard samples (with area S = 0.1 m^2) with an aqueous solution of TO-3, with the content of colloid-graphite particles equal to 15 and 30 g l^{-1}, in relation to the treatment time. The samples were dried at room temperature for 4 days.

To eliminate the errors in electrical conductivity measurements that are related to the contact resistance exhibiting a wide scatter for cardboard, the surface resistance was measured by the contactless method.

The increase in the mass of the solution absorbed by the cardboard sample and, accordingly, that in

the mass of graphite particles (Table 1, in the range 0.1–1.0 g) forming the electrically conducting coating naturally lead to a decrease in the surface resistance ρ_S. Presumably, the process of deposition of graphite particles on the surface of a dielectric material can be represented as a diffusion process, with the mass of graphite particles necessary for a conductivity to appear on the dielectric substrate determined using the Einstein–Smoluchowski diffusion equation [11]. Assuming that a graphite particle has the shape of a thin disk of diameter d and thickness h, we can apply the following expression for the average value of the diffusion coefficient D [12]:

$$D = kT/6\eta d, \quad (1)$$

where k is the Boltzmann constant; T, absolute temperature; and η, solvent viscosity.

The average value of the diffusion coefficient D is given by $D = 1/3(2D_{\|} + D_{\perp})$, where $D_{\|}$ and $D_{\perp}$ are the diffusion coefficients for a thin disk along (d) and across (h) its plane. To estimate the diffusion coefficients, we used the relations $D_{\|} = 3kT/16\eta d$ and $D_{\perp} = kT/8\eta d$, reported in [12]. Let colloid graphite particles diffuse from a solution with initial concentration n_0 onto a plane at $x = 0$. The particle concentration n at instant of time t is described by the known unidimensional diffusion equation. If the probability of particle adherence to the substrate is unity, the solution to the unidimensional diffusion equation [11] for the number N of particles on unit substrate surface area at instant of time t has the form

$$N(t) = n_0(4Dt/\pi)^{1/2}. \quad (2)$$

Expression (2) has a simple meaning: in a time t, a diffusing colloid particle moves to a distance equal to the diffusion length $L_d \approx (Dt)^{1/2}$ and, consequently, all the particles that are at distances shorter than L_d from the substrate will be on the substrate surface at instant of time t. Accordingly, the mass of deposited particles per unit area will be given by

$$m(t) = \gamma_g d^2 h n_0(\pi/4Dt)^{1/2}, \quad (3)$$

where γ_g is the density of graphite.

Measurements of the average motion velocity of graphite particles in aqueous and alcoholic solutions with the photon-correlation spectrometer made it possible to find the diffusion coefficients of colloid particles. The diffusion coefficients for the aqueous and alcoholic solutions of TO-3 graphite are 1.2×10^{-8} and 5.3×10^{-9} $cm^2\ s^{-1}$. Numerical estimates of the average value of the diffusion coefficient $D = 1/3(2D_{\|} + D_{\perp})$, made on the assumption that the graphite particle has the shape of a disk with a diameter $d = 5 \times 10^{-5}$ cm and thickness $h = 5 \times 10^{-6}$ cm, yielded for the aqueous and alcoholic solutions 1.35×10^{-8} and 5.6×10^{-9} $cm^2\ s^{-1}$, respectively.

Estimation by formula (3) of the mass of graphite particles deposited in 600 s from a solution of TO-3 CG with a concentration of 3 g l^{-1} onto the surface of the samples under study gives $m \approx 3 \times 10^{-3}$ g. This value is an order of magnitude smaller than that observed experimentally, which is presumably due to the strongly developed surface of cardboard and to differences in the size of colloid particles and in other factors.

The results obtained in treatment of cardboard samples with 15, 30, and 60 g l^{-1} aqueous solutions of colloid-graphite dispersions at treatment durations of 1 to 120 s demonstrated that, as the solution concentration and treatment time increase, the surface resistance of the samples decreases by two orders of magnitude, from 2.2×10^3 to 20 Ω. At a short impregnation time (up to 20 s), a wide scatter of ρ_S (by up to 20%) was observed along the surface of the samples, whereas for samples treated with concentrated solutions during a time longer than 30 s, the similar value did not exceed 10%. This may be due to a stronger influence of the solution draining from a sample during drying at lower solution concentrations.

As the concentration of the aqueous solution of TO-3 was lowered, a percolation transition was observed. The results obtained when measuring the resistance of the samples studied are listed in Table 2.

An analysis of SEM micrographs demonstrated that paper fibers of size 4–7 μm not covered with graphite

particles are seen on cardboard samples impregnated with a CG solution of concentration 3 g l^{-1}. On cardboard samples treated with TO-3 CG solutions of concentrations 3 and 5 g l^{-1}, separate graphite particles with planar structure are observed at a magnification of 10 000 (Figs. 1a–1c). The particles can be seen because of the low degree of interparticle cohesion. Because of the low degree of cohesion, scale edges differ from the lower-lying layers of the carbon coating. In this case, the electron work function decreases and a region of high intensity of secondary electrons (white fringe) appears on the electron receiver. Analysis of the electron-microscopic data shows that the average particle size is approximately 0.5–1 μm. The planar structure of the carbon coating based on TO-3 is better pronounced than that of a graphite coating based on TO-6, on which particles that are not strictly oriented in the coating plane can be seen (Figs. 1b, 1c). The increase in the mass of the cardboard sample (with a total working area of 156 cm^2) upon impregnation with a 3 g l^{-1} aqueous solution of TO-3 for 10 s and drying did not exceed 0.04 g.

The average distance L_{av} between deposited particles on the substrate surface is equal in order of magnitude to $L_{av} = N^{-1/2}$, where N is the number of particles per unit area. If we assume that percolation (a through current flow) via graphite particles occurs when $L_{av} \approx d$, where d is the characteristic size (diameter) of particles, then we obtain the following percolation condition:

$$N_{per} \sim 1/d^2. \quad (4)$$

In this case, particles cover approximately a half of the substrate surface. Consequently, the smaller the particle diameter, the greater number of particles is necessary for the percolation transition to occur.

The impregnation of cardboard samples presumably includes several stages: penetration of H_2O with graphite particles, sorption of graphite particles on the substrate surface, and formation of solid particle aggregations into a coating. A more detailed analysis shows that the number of graphite particles necessary for an electrically conducting layer to be formed depends on the structure of the substrate material, concentration of the impregnating solution, and duration of the impregnation process. It is also possible that functional groups on the surface of the dielectric material and functional groups on the surface of modified graphites may be important.

Upon impregnation of cardboard samples with a 3 g l^{-1} alcoholic solution of TO-3 for 10 to 600 s, and with a 5 g l^{-1} solution for 1 to 600 s, the surface resistance of the samples was higher than 10^7 Ω. On raising the concentration of the alcoholic solution of TO-3 to 10 g l^{-1}, an electrically conducting coating was formed on the cardboard sample surface. As the interaction time was raised from 10 to 720 s, the surface resistance of the samples changed only slightly and was in the range 5.1×10^5–4.5×10^4 Ω.

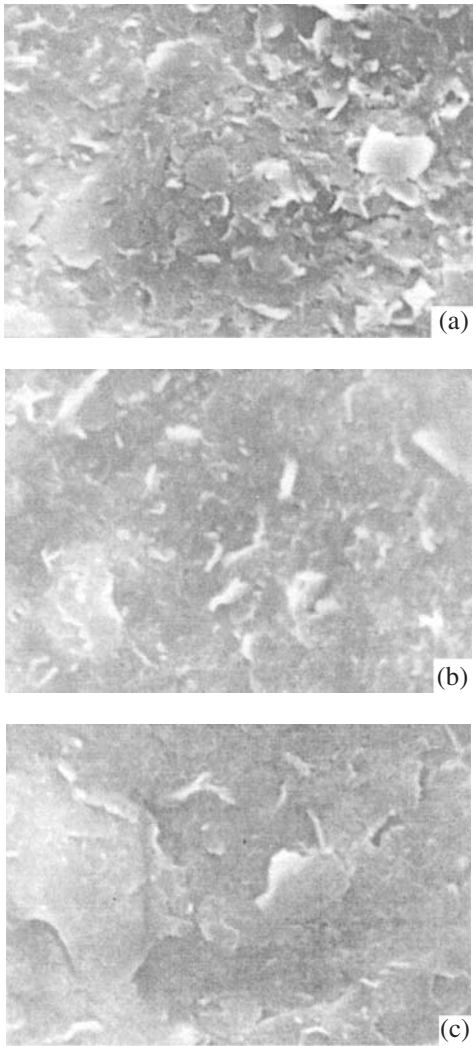

Fig. 1. SEM micrographs of the surface of carbon coatings formed on cardboard in (a, b) alcoholic and (c) aqueous CG suspensions of different concentrations. Concentration, g l^{-1}: (a) 5 (TO-3) and (b, c) 60 (TO-6).

The higher alcoholic solution concentrations necessary for overcoming the percolation transition, compared with the aqueous solutions, can be attributed to lower diffusion coefficients of colloid particles in the alcoholic solution and also, possibly, to another

Table 3. Changes in the surface resistance ρ_S of Lavsan films upon treatment in TO-3 and TO-6 (C_3H_8O) solutions of different concentrations

t, s	ρ_S, Ω, at indicated solution concentration, g l^{-1}

type of distribution of colloid particles on the surface of the material in their aggregation.

It is rather difficult to accurately determine the mass of graphite particles on a cardboard sample because of the difficulties in determining the amount of water in the sample. On drying a sample at 200°C, the increase in the sample mass in air at room temperature is determined by graphite particles. For a cardboard sample with a graphite coating, the surface resistance R equal to 1.4 kΩ decreased to 0.7 kΩ after drying at 160°C for 30 min. A treatment of cardboard plates with a working surface area of 2456 cm^2 with a 5 g l^{-1} aqueous solution of TO-3 for 0.5, 1.0, 2.0, 4.0, and 6.0 min led to a change in the mass of the graphite coating equal to 11, 27, 55, 88, and 120 mg, respectively. It was found that the change in the coating mass is proportional to the square root of the time of interaction between the CG solution and a dielectric cardboard sample, which corresponds to the diffusion model of formation of the graphite coating.

In contrast to cardboard samples, Lavsan films treated with a low-concentration alcoholic solution of CG were electrically conducting. In treatment of 113 cm^2 Lavsan films with a 5 g l^{-1} alcoholic colloid solution of TO-6, the mass of CG particles adsorbed on the surface was about 0.7–0.8 g; upon drying, the films were electrically conducting. In the case of exposure of Lavsan films for 5 to 180 s, their resistance decreased from 300 to 115 kΩ.

The zero current in cardboard samples upon a similar treatment can be presumably attributed to the porous, more branched surface structure of this material. The rough fibrous surface structure of cardboard requires that a larger amount of colloid graphite particles should be deposited for an electrically conducting graphite layer to be formed.

To evaluate the amount of graphite particles deposited onto the Lavsan surface, we fabricated 12.5 × 12.5 cm samples. The samples were treated with solutions of colloid graphite TO-3 and TO-6 in isopropyl alcohol, with concentrations of 60 and 30 g l^{-1}.

The results obtained in dc surface conductivity measurements are listed in Table 3. It can be seen that, as the concentration of the CG suspension is raised from 30 to 60 g l^{-1}, the conductivity of the graphite coating on Lavsan films increases, which is due to the larger number of CG particles involved in the coating formation. At the same time, the data in Table 3 show that treatment of Lavsan films with a TO-6 solution gives higher resistances, compared with the treatment with a TO-3 solution. This occurs because a decrease in the size of colloid particles makes the electrical conductivity of the coating lower under the same treatment conditions, in accordance with formula (4).

A study of electrically conducting coatings on Lavsan films demonstrated that the increase in the coating mass with the time of surface treatment with the alcoholic solution of CG is not proportional to the square root of time, in contrast to the case of treatment with aqueous solutions of CG. This may be due to absence of diffusion accumulation of CG particles on the surface of Lavsan films. Having a free affinity, the surface of the dielectric film and, specifically, the surface layer of atoms, molecules, or macromolecules interacts with CG particles upon their contact with the surface. We can assume, based on electron-microscopic data, that the adsorption layer formed on the surface of the Lavsan film and retained by attraction forces upon drying is a film composed of lamellar agglomerates of carbon particles. It was found that, as the concentration of the alcoholic suspension of TO-3 is raised from 30 to 60 g l^{-1}, the conductivity of the graphite coating grows, which is due to the larger number of CG particles involved in the formation of the coating. The dc surface resistance of the coating, measured on a sample whose width was equal to the distance between the potential electrodes, was 112 and 11 Ω at coating thicknesses of 1 and 2 μm, respectively, for two TO-3 concentrations. The shielding coefficients of the samples at a frequency of 10 GHz were 10.8 and 21.2 dB, respectively. The shielding coefficients K_{SC} are in satisfactory agreement with the values calculated by the relation derived in terms of the model of normal transmis-

Table 4. Transmittance K_{tr} and reflectance K_r of cardboard samples treated with aqueous (TO-3) and alcoholic (TO-6) colloid graphite solutions of various concentrations c. Treatment duration 10 s

sion of an electromagnetic wave of THE or H_{01} mode across a thin ($d \ll \lambda$) sample:

$$K_{SC} = 20\log(1 + z_0/2\rho_S), \quad (5)$$

where ρ_S is the surface resistance of the coating and z_0 is the wave impedance of free space.

The materials with graphite coatings, obtained in this study, can be used to accomplish a number of tasks requiring materials with a prescribed surface resistance. These are, in particular, materials for shielding and absorption of electromagnetic radiation. Table 4 lists the results of measurements of the transmittance and reflectance to 10 GHz electromagnetic radiation for paper samples treated with CG solutions. At equal treatment times of the cardboard surface (~10 s), the coating conductivity increases with the concentration of the colloid-graphite dispersion. Simultaneously, the transmittance K_{tr} steadily decreases, and the reflectance K_r, increases as the concentration of the colloid-graphite dispersion becomes higher. As in the case of dc measurements, the higher transmittance for samples treated with an alcoholic solution of TO-6 is accounted for by the smaller particle size, compared to the TO-3 dispersion.

The paper- and cardboard-based electrically conducting materials obtained in this study can be successfully used in development of radio-absorbing and radio-scattering materials and structures.

CONCLUSIONS

(1) The concentration and time conditions under which electrically conducting graphite coatings can be formed on dielectric materials, cardboard and Lavsan, using aqueous and alcoholic colloid-graphite solutions were determined.

(2) A difference was revealed between the deposition conditions of colloid graphite particles from aqueous and alcoholic solutions. At the same impregnation time, conductivity appears on the surface at a concentration of 3 g l^{-1} in treatment with an aqueous solution of TO-3 and at 7.5 g l^{-1} for an alcoholic solution of TO-3. For polymeric films treated with a solution of TO-3, the conductivity of the coatings obtained exceeds that of coatings deposited from a TO-6 solution because of the larger size of colloid graphite particles in the TO-3 solution.

(3) The transmittance and reflectance to microwave electromagnetic radiation were measured for samples coated with colloid graphite particles from TO-3 and TO-6 solutions. It was shown that, in different modes of cardboard treatment with colloid graphite solutions, materials with a wide range of radiophysical properties can be obtained and, in particular, a shielding coefficient exceeding 35 dB can be provided for a planar sheet.

ACKNOWLEDGMENTS

The study was supported by the Russian Foundation for Basic Research (project no. 06-08-01590-a).

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Deposition of Electrically Conducting Polymeric Coatings Using Copper-Plated Silica

L. E. Shpilevskaya and A. M. Safonova

Institute of General and Inorganic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

Received June 18, 2007

Abstract—Silica was metallized by chemical copper plating, and the possibility of using this kind of silica as an electrically conducting filler by itself and with addition of carbon or metal–carbon fibers for preparing polymeric and paint-and-varnish electrically conducting coatings was studied.

DOI: 10.1134/S1070427208030178

Of particular interest with the development of technology (micro- and radio electronics) is a new type of polymeric and paint-and-varnish coatings, electrically conducting coatings. Preserving all the qualities of polymeric coatings, namely, low density, high strength and elasticity of films, good adhesion and anticorrosion properties, and a number of other valuable physicochemical and mechanical parameters, electrically conducting coatings, in addition, acquire one of the most important properties of a metal, ability to conduct electric current. This enables their use instead of metallic coatings in some cases.

The electrically conducting coatings are composite coatings that contain conducting fillers in a polymeric binder. As conducting fillers are used substances with high conductivity: carbon black, graphite, technical-grade carbon, carbon fibers, and powdered metals and metal alloys. The choice of a component for preparing electrically conducting coatings is governed by the set of requirements to a coating as regards its electrical, physical, chemical, and mechanical properties. The electrical conductivity of composite coatings depends on the type of a conducting filler (ability to conduct electric current), size and shape of its particles, filler concentration, chemical nature of the polymeric binder, conditions of film formation, mode of its curing and exploitation, and deposition technology [1].

The electrical conductivity is the highest for composite coatings containing a metallic filler. However, a disadvantage of such a filler is the high rate of its sedimentation in the composite, which causes segregation of the material and leads to inhomogeneity of the coatings obtained. In addition, a good conductivity of coatings can be only achieved at a high metal content (wt %) of the composite [2]. This impairs physicomechanical parameters of the coatings obtained and makes higher their density.

At present, the so-called core-pigments, combined particles with a metal-plated surface, find steadily increasing use as fillers [3, 4]. Core-pigments make it possible to diminish the density of a conducting polymeric coating and its cost, without making lower its electrical conductivity. Of particular interest are core-pigments produced by metallization of inorganic materials and, in particular, mica, glass spheres, and silica. Polymeric composites containing pigments of this kind show high spreading capacity and slower filler settling, and coatings produced on their basis have low electrical resistance and good heat-insulating properties [5]. In addition, metallized silica particles can be used as a starting stock for the subsequent sintering of ceramics, by analogy with the processes described in [6].

The electroless method for deposition of metallic coatings onto nonmetallic surfaces is well understood [7, 8], and, therefore, its application to metal plating of various insulators poses no difficulties. However, the deposition conditions should be adjusted to each particular kind of a substrate.

The aim of this study was to obtain copper-plated silica and analyze the possibility of its use as an electrically conducting filler in deposition of polymeric and paint-and-varnish coatings.

EXPERIMENTAL

Sieved silica of the OVS-15 brand from the Novoselkovskoe deposit (Ukraine) was used in the study.

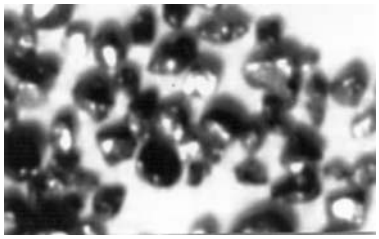

Fig. 1. Micrograph of metallized silica particles. Magnification 25.

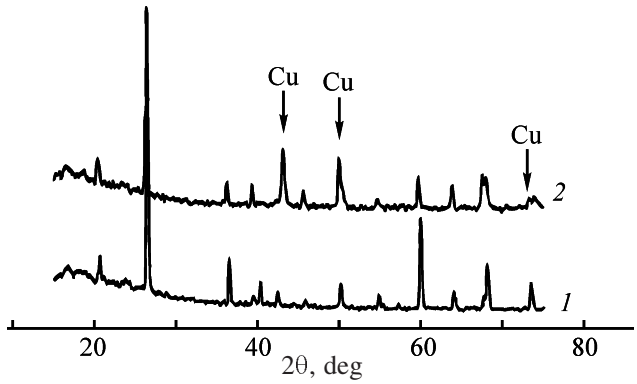

Fig. 2. X-ray diffraction pattern of (*1*) starting and (*2*) copper-plated silica. (2θ) Bragg angle.

The silica had a bulk density of 1.83 g cm^{-3} and particles with an average size of 150 μm, which enabled use of this filler without preliminary grinding. Prior to copper plating, silica was preliminarily sensitized in a 0.005 g l^{-1} palladium chloride solution. To perform metal plating, two compositions of copper-plating solutions with different component concentrations were tested. It was found that, in a solution containing an increased amount of a copper salt (35 g l^{-1} instead of 6 g l^{-1}) and, accordingly, of the other components, copper plating occurs at a substantially higher rate, so that a thicker copper layer can be obtained. That is why the copper plating was performed in all the subsequent experiments in a solution of the following composition (g l^{-1}): $CuSO_4 \cdot 5H_2O$ 35, K–Na tartrate 170, and NaOH 50; a 40% formaldehyde solution (Formalin) was added to the developer immediately before the copper plating in 1 : 10 ratio. The time of copper plating was 25 min at 20°C. Each stage was performed under permanent agitation with a magnetic stirrer. After each stage, silica was washed with water.

Table 1. Electrical resistivity ρ_v of composite films based on BS latex and zapon lacquer in relation to the content of metal-plated silica in the films

Binder	Content of components, wt %		ρ_v, Ω m
	binder	Cu-quartz	
BS latex	80	20	1.0×10^{6}
	70	30	1.0×10^{6}
	60	40	2.5×10^{1}
	50	50	7.0×10^{-1}
	40	60	7.0×10^{-2}
Zapon lacquer	80	20	1.0×10^{6}
	70	30	1.0×10^{6}
	60	40	1.0×10^{-1}
	50	50	1.0×10^{-2}
	40	60	6.0×10^{-3}

The gain in the silica mass upon the copper plating was 0.07 g g^{-1} sand, and the thickness of the copper coating was 1 μm. The silica particles obtained have a characteristic color and bright shine. The optical micrograph taken at a 25× magnification (Fig. 1) shows copper-plated silica particles. The results of an X-ray phase analysis indicate that the plated coating is composed of a single phase, metallic copper (Fig. 2).

The copper-plated silica was used as an electrically conducting filler in deposition of composite polymeric films and coatings based on a butadiene–styrene latex BS-65 of A brand and zapon lacquer [TU (Technical Specification) 2313-041-32811438–2001]. In addition, a binary filler was produced using, together with copper-plated silica, carbon fibers (CF) manufactured by Khimvolokno Production Association, Republican Unitary Enterprise (Svetlogorsk, Belarus) and Ni-containing carbon fibers (Ni-CF).[1] Ni-CF were synthesized by carbonization at 900°C of viscose rayon impregnated with an aqueous solution of nickel chloride [9]. The average length of the fibers used was 0.5 mm. Formulations of prescribed composition were deposited onto glass substrates and dried at room temperature. The coating thickness was 250–400 μm, depending on the degree of filling.

The electrical resistance of 2 × 1-cm composite coatings was measured with a V7-16A general-purpose voltmeter and related to the film thickness to find the volume electrical resistivity ρ_v. The results obtained are listed in Table 1. It can be seen that the resistivity of the coatings under study falls if the polymer contains 40 wt % metal-plated quartz or more. At the same time, it has been reported [2] that, with an ultradispersed copper powder used for polymer filling, the electrical resistance substantially decreases only at degrees of filling equal to 60–70 wt %.

[1] Method developed at the Institute of General and Inorganic Chemistry, National Academy of Sciences of Belarus.

Table 2. Resistivity ρ_v of composite films based on BS latex and containing a combined filler (metal-plated silica + carbon fibers) at various relative contents of the components

Content of components, wt %				ρ_v, Ω m
binder	Cu-quartz	CF	Ni-CF	
70	30	–	–	1.0×10^6
70	27	3	–	2.0×10^1
70	24	6	–	8.0×10^0
80	20	–	–	1.0×10^6
80	18	2	–	1.0×10^2
80	16	4	–	3.0×10^1
80	19.6	–	0.4	1.0×10^1
80	18	–	2	1.0×10^0
80	16	–	4	6.0×10^1

Thus, use of metal-plated silica makes it possible to obtain electrically conducting coatings at considerably smaller degrees of filling, which improves the physicomechanical properties of the coatings obtained.

As the degree of filling increases from 40 to 60 wt %, the resistivity of the coatings based on BS latex decreases from 2.5×10^1 to 7.0×10^{-2} Ω m. Coatings based on zapon lacquer have a lower resistivity than the composite films of the BS latex (1.0×10^{-1} and 6.0×10^{-3} Ω m at filler content of 40 and 60 wt %, respectively). To decrease the film resistance at degrees of filling with metal-plated silica equal to 20 and 30 wt %, a minor amount of carbon or Ni-carbon fibers was introduced into the formulations because these fibers (having an anisotropic shape and good electrical conductivity) combined with the main filler favor the formation of an electrically conducting cluster at smaller degrees of filling [1].

It was found that replacement of 2 and 4 wt % quartz with CF in a formulation based on BS latex and containing metal-plated quartz at a degree of filling equal to 20 wt % reduces the film resistivity by four and five orders of magnitude, respectively (Table 2). If Ni-FC is used for this purpose, ρ_v decreases by five orders of magnitude when 0.4 wt % metallized quartz sand is replaced with Ni-FC, and by six orders of magnitude (to 1.0×10^0 Ω m) upon replacement of 2 wt % metal-plated quartz with Ni-FC. Thus, addition of a minor amount of carbon fibers to metal-plated silica diminishes the threshold silica content at which the composite coating becomes electrically conducting from 40 to 18 wt %.

CONCLUSIONS

(1) Metal-plated silica can be used to obtain low-cost electrically conducting composite coatings with resistivities in the range 2.5×10^1–6.0×10^{-3} Ω m, depending on the degree of filling and type of a binder.

(2) At equal degrees of filling, coatings based on zapon lacquer have an order of magnitude lower electrical resistance than coatings based on butadiene–styrene latex.

(3) Use of a combined filler containing, together with metallized silica, a minor amount (2 wt %) of carbon or Ni-carbon fibers makes it possible to diminish the threshold content of metallized silica at which coatings become electrically conducting from 40 to 18 wt %. The decrease is more pronounced upon addition of a Ni-containing carbon fiber, compared with that upon addition of the same amount of a carbon fiber.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Photostabilizing Properties of Hexachlorobicyclo[2.2.1]hept-5-enylmethyl Esters of Substituted Benzoic Acids

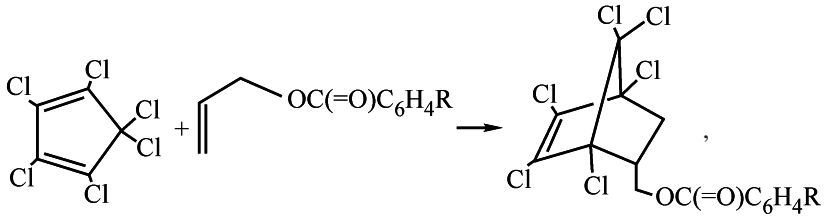
Abstract—Polychlorinated bicyclic esters of *p*-substituted benzoic acids were prepared by the Diels–Alder reaction of hexachlorocyclopentadiene with allyl esters of *p*-substitutted benzoic acids. Some of the adducts synthesized were tested as photostabilizers for polyethylene-based polymer formulations.

DOI: 10.1134/S107042720803018X



Hexachlorocyclopentadiene (HCCPD, **I**) and related compounds are among unusual objects of the modern organic chemistry. Thanks to HCCPD, the theory of X-philic reactions was developed, and the theory of pericyclic reactions was supplemented by the reversed Diels–Alder reaction. The *syn–anti* isomerism of diene condensation adducts was substantiated using data for HCCPD derivatives [1]. Simple synthesis of dihomocubane compounds from polyhalogenated cyclopentadienes attracts attention. Hexachlorocyclopentadiene and related compounds, along with practical significance, are of interest for elucidating the mechanism of the Diels–Alder reaction [2].

Halogen-containing bicyclic esters with other unique fragments are widely used for imparting flame resistance to polymeric materials, and also as modifiers and curing agents for epoxy resins and biologically active substances [3].

Synthesis of various polyhalogenated bicyclic esters from unsaturated esters of substituted benzoic acids attracts researchers' attention [4, 5].

Proceeding with studies in the field of synthesis of polyhalogenated bicyclic esters [6–9], we prepared, identified, and examined polyhalonorbornenylmethyl esters of *p*-substituted benzoic acids. First, we prepared by a common esterification procedure allyl esters of *p*-substituted benzoic acids **II**–**VIII**. Their physicochemical properties are given in Table 1.

Target products **IX**–**XV** were prepared by diene condensation of HCCPD **I** with allyl esters of *p*-substituted benzoic acids **II**–**VIII**. The reaction follows the scheme

I **II–VIII** **IX–XV**

where R = H (**II**, **IX**), CH_3 (**III**, **X**), HO (**IV**, **XI**), MeO (**V**, **XII**), Cl (**VI**, **XIII**), Br (**VII**, **XIV**), NO_2 (**VIII**, **XV**).

The reaction was performed in the temperature range 100–160°C for 4–12 h; the diene : dienophile molar ratio was from 1 : 1 to 4 : 1. The physicochemi-

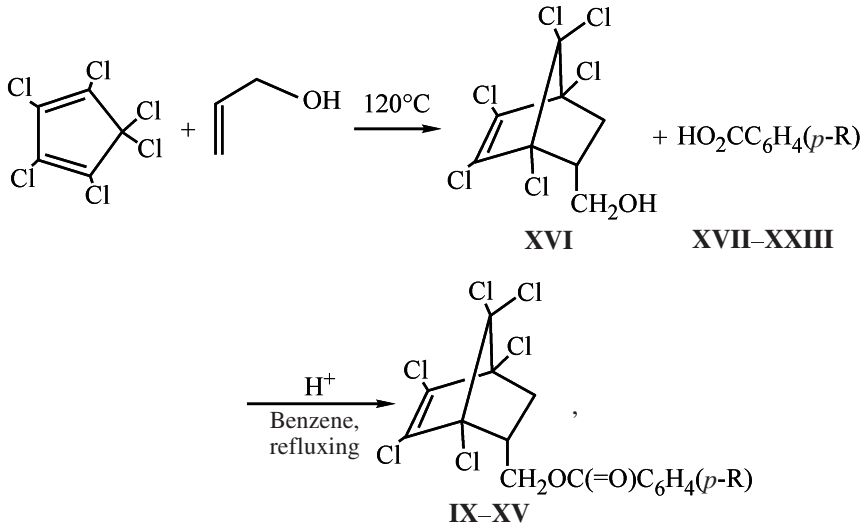
cal properties of **IX**–**XV** are given in Table 2.

We examined the effect of reaction conditions (temperature, time, reactant ratio) on the yield of the adducts (Table 3).



As can be seen, with an increase in the temperature from 100 to 150°C the yield of adduct **IX** increases from 58.2 to 82.4%. Further increase in the temperature (160°C) only slightly affects the yield of **IX**. The data obtained also show that the optimal conditions of adduct formation (with the reaction **I** + **II** → **IX** as example) are as follows: 150°C, 12 h, diene : dienophile ratio 2 : 1.

Under similar optimal conditions (150°C, 12 h, diene : dienophile molar ratio 2 : 1), we performed the condensation of HCCPD with allyl esters of other *p*-substituted benzoic acids **III**–**VIII**. The yields of adducts **X**–**XII** vary within 65.4–90.7%, with the lowest yield observed with allyl halobenzoates **VI** and **VII** (78.8 and 65.4%, respectively). On introducing *p*-hydroxy, *p*-methoxy, and *p*-nitro groups into the aromatic ring, the yield of the adducts increases (90.7, 88.6, and 82.7%, respectively).

The compositions and structures of **IX**–**XV** were proved by independent synthesis: preparation of 2-*endo*-hydroxymethyl-1,4,5,6,7,7-hexachlorobicyclo-[2.2.1]hept-5-ene **XVI** by the reaction of **I** with allyl alcohol according to [10], followed by esterification of alcohol **XVI** with *p*-substituted benzoic acids **XVII**–**XXIII** to obtain the corresponding bicyclic esters **IX**–**XV**:

Table 3. Influence of reaction conditions on the yield of adducts **IX**–**XV**

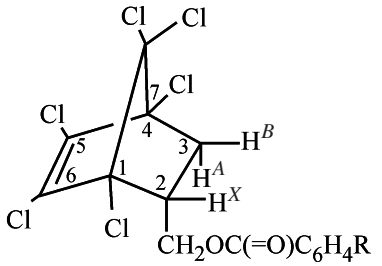
where R = H, CH_3, HO, MeO, Cl, Br, NO_2.

All the physicochemical characteristics of compounds **IX**–**XV** prepared by both procedures are identical.

The compositions and structures of **IX**–**XV** are confirmed by IR and ^{1}H NMR spectra. The purity was checked by TLC. In the IR spectra of **IX**–**XV**, there are characteristic bands of the C=O bond at 1720–1740, ester C–O bond at 1000–1200, and C–Cl bonds at 750 cm^{-1}. The C=C vibrations have somewhat decreased frequency, 1575–1685 cm^{-1}, because of the presence of chlorine atoms at the double bond. The ^{1}H NMR data for **IX**–**XV** are given in Table 4.

The ^{1}H NMR spectra of polychlorinated norbornenylmethyl derivatives show an *ABX* pattern. The lowest-field signal was assigned to the proton adjacent to the electronegative substituent, H^X. As indicated in [11], the coupling constants of H^X with protons H^A and H^B differ by a factor of approximately 2. The *endo* orientation of the substituent at C^2 is confirmed by the ^{1}H NMR spectra (Table 4) whose parameters are similar to those of the spectra of the known chlorinated analogs [12], hexabromonorbornenes [13], and 1,4,5,6-tetrabromo-7,7-dimethoxynorbornenes [14]. The *endo* orientation of the CN substituent at the C^2 atom of the hexabromonorbornene core is confirmed by comparison of the experimental and calculated dipole moments [13]. In addition, it is known that, in the case of *exo* orientation of the CN substituent at the C^2 atom of pentachloronorbornene, the parameters of the ^{1}H NMR spectrum are essentially different [15].

The *endo* configuration of 2*S*-(–)-menthyl hexachloronorborn-5-ene-2-carboxylate was confirmed by single crystal X-ray diffraction [16].



The synthesized compounds **IX**–**XV** were tested as photostabilizers for polymer formulations based on high-density polyethylene (HDPE). These compounds were added in amounts of 0.2, 0.5, and 0.8%. Compounds **IX** and **XIV** appeared to be the most active. On adding stabilizer **IX** to HDPE, the relative breaking elongation ε of the irradiated samples increased by a factor of almost 2 compared to the pure polymer, which is due to good compatibility of the stabilizer with HDPE. The results of the tests are given in Table 5.

After UV irradiation for 200 h, the stabilized formulations exhibited considerably better properties than straight high-density polyethylene. The breaking tensile stress (σ_B) of the initial polymer decreased upon irradiation by 70%, and that of the stabilized polymer, by only 10–13%. The dielectric loss tangent ($\tan\delta$) of the stabilized samples also varied significantly. The lack of degradation of the stabilized HDPE after UV irradiation is confirmed by the results of UV studies. The suggested photostabilizers are light yellow, and their performance meets the requirements of the modern standards.

EXPERIMENTAL

The IR spectra were recorded on a UR-20 spectrophotometer in the range 4000–400 cm^{-1}, and the ^{1}H NMR spectra, on a Tesla BS-48 spectrometer (80 MHz) in CCl_4, internal reference hexamethyldisiloxane. The TLC analysis was performed by the

XIV	0.8	230	14	0.46	10.9	19

procedure described in [17]. Alumina (Brockmann grade II) was used as sorbent, and heptane–acetone, as eluent. The spots were visualized by irradiation with a mercury lamp equipped with a light filter.

Hexachlorocyclopentadiene I was prepared by the procedure described in [18], bp 104°C/9 mm Hg; n_D^{20} = 1.5652, d_4^{20} = 1.719.

Allyl esters of *p*-substituted benzoic acids **II**–**VIII** were prepared by the standard procedure, esterification in benzene in the presence of an acid catalyst (sulfuric acid, 5 wt % relative to the reaction mixture). The mixture was washed with a $NaHCO_3$ solution and water, dried over $MgSO_4$, and distilled. The physicochemical parameters of the esters are given in Table 1.

Hexachloronorbornenylmethyl esters of *p*-substituted benzoic acids **IX**–**XV** were prepared by diene synthesis from HCCPD and the corresponding dienophiles **II**–**VIII**.

1,4,5,6,7,7-Hexachlorobicyclo[2.2.1]hept-2-enylmethyl benzoate IX. A mixture of 1.6 g (0.01 mol) of **II** and 5.46 g (0.02 mol) of HCCPD was heated at 150°C for 12 h. Adduct **IX** was obtained; yield 3.58 g (83%). Adducts **X**–**XV** were prepared similarly. The conditions and results are given in Tables 2 and 3.

***endo*-2-Hydroxymethyl-1,4,5,6,7,7-hexachlorobicyclo[2.2.1]hept-5-ene XVI** was prepared according to [19]. Independent synthesis of **IX**–**XV** was performed by esterification of alcohol **XVI** with the corresponding benzoic acids **XVII**–**XXIII** in the presence of an acid catalyst (5% H_2SO_4) in refluxing benzene

with azeotropic distillation of water. All the physicochemical parameters of compounds **IX**–**XV** prepared by independent synthesis are identical to those of the respective compounds prepared by the condensation of HCCPD with allyl esters **II**–**VIII**.

CONCLUSIONS

(1) The Diels–Alder reaction of allyl esters of *p*-substituted benzoic acids with hexachlorocyclopentadiene, performed at 150°C for 12 h at the diene : dienophile ratio of 2 : 1, gave in good yields (65–90%) the corresponding adducts, exclusively in the form of *endo* isomers.

(2) It was demonstrated by the example of high-density polyethylene that polychlorobicyclic esters of *p*-substituted benzoic acids are effective photostabilizers.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Products of Reaction of the Piperylene Fraction with Elemental Sulfur as Additives to Lubricating Oils

R. Z. Biglova, R. F. Talipov, and A. U. Galimzyanova

Bashkir State University, Ufa, Bashkortostan, Russia

Received June 20, 2007

Abstract—A method for quantitative introduction of sulfur into piperylene fraction was developed. The structure of the product was examined, and the effect it exerts on the washing power of bis(oligoisobutenylsuccinimide) in model oil compositions was elucidated. The antiwear and antiscuff properties of the product were tested under pilot conditions.

DOI: 10.1134/S1070427208030191

The performance characteristics of lubricants are efficiently improved by introducing various additives. Up to now, a considerable number of compounds whose influence on the quality of lubricating oils is determined by their structure and the nature of functional groups in their molecules were synthesized and tested [1]. Among organic, above all low-molecular-weight substances, a particular place is occupied by sulfur-containing compounds which are the subject of numerous studies [2–4]. The presence of sulfur in the molecules of additives can be responsible for both antioxidant and antiwear properties they exhibit. The lubricating action of sulfur-containing substances is strongly dependent on their structural properties and character of sulfur bonding [5].

Reactions of unsaturated hydrocarbons with sulfur-containing compounds still remain to be examined more adequately. It should be noted that application of many sulfurizing agents is environmentally unsafe, which makes extremely promising the use of elemental sulfur yielded in huge amounts by hydrodesulfurization of oil products at oil refineries. However, reactions involving elemental sulfur, which is a seemingly simple object, are studied insufficiently. This is due to a complex structure of sulfur proper and to its ability to follow several reaction pathways simultaneously, as well as to possible side reactions at unsaturated bonds of piperylene. In this connection, we synthesized here sulfur-containing additives based on piperylene fraction and elemental sulfur, examined their structure and the lubrication properties of these products when introduced into various compositions, and elucidated how they affect the washing power of an alkenylsuccinimide additive.

EXPERIMENTAL

Our study was concerned with inexpensive and readily available piperylene fraction, a large-capacity by-product of isoprene dehydrogenation in isoprene rubber manufacture at synthetic rubber plants. As known [6], the performance characteristics of sulfur-containing organic compounds when used as additives to improve the lubricating properties of oils are determined by the sulfur content. The process was optimized over a wide temperature and time ranges so that the maximal possible amount of covalently bound sulfur was introduced into the final product.

The reaction of the piperylene fraction with sulfur in a temperature-controlled autoclave without stirring in the presence of cobalt phthalocyanine as catalyst [(>C=C<) : S molar ratio 1 : 4, 130°C, nonpolar solvent] gave a product containing 54.95% sulfur in 10.0% yield. When the reaction was run in a continuously rotating autoclave at the same synthesis parameters, but in a toluene medium, the content of sulfur in the product increased to 70.35%, and the yield of the product was 49.5%. The resulting samples contained a certain amount of ash because of the presence of cobalt phthalocyanine. Sulfurization of piperylene fraction was further optimized in the absence of catalyst (Table 1). The tabulated data suggest that, upon changing from toluene to kerosene, a solvent more readily available commercially, both the yield of the product and its sulfur content decreased insignificantly. At the (>C=C<) : S molar ratio of 1 : 2 in a *p*-xylene medium, sulfur reacts quantitatively. The scatter in the sulfur content of the final compound

Table 1. Reaction of the piperylene fraction with elemental sulfur in an autoclave (130°C, 3 h)

(>C=C<) : S molar ratio	Solvent	Product yield, %	Sulfur content of the product, %
1 : 2	Toluene	48.0	69.86
1 : 1	Toluene	24.9	48.23
1 : 2	Kerosene	43.0	66.11
1 : 1	Kerosene	19.5	47.01
1 : 2	*p*-Xylene	100.0	68.24
1 : 1	*p*-Xylene	78.6	50.71

is due, probably, to varying composition of the initial diene fraction.

To identify the resulting compound, we isolated *trans*-piperylene from the piperylene fraction and brought it into the reaction with sulfur. The product yield was 70%, and the mass fraction of sulfur, 64.8%. The molecular weight of the substance was estimated cryoscopically (in CCl_4) at 386 [7]. The ^1H NMR spectrum of the product exhibits signals at 6.50–7.50 ppm, characteristic of olefin protons. A signal at 1.10–1.50 ppm belongs to methyl protons, and a strong multiplet at 2.10–2.50 ppm, to methine protons. The relative integral intensities of the signals from methylene and methyl protons suggest the presence of two double bonds in the molecule of the product. The presence of double bonds is also supported by characteristic bands in the IR spectra at 1600–1660 cm^{-1}. In the ^{13}C NMR spectrum, there are signals at 38.0–39.0 ppm associated with CH_2–S groups and those at 45.0–47.0 ppm associated with –CH–S groups. Absorption at 600–450 cm^{-1} in the IR spectrum can be attributed to –S–S– vibrations.

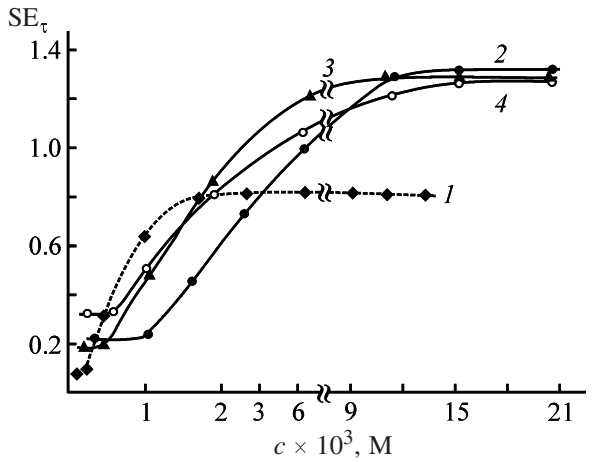

Fig. 1. Solubilizing power vs. concentration c of the additives in isooctane. (SE_τ) Solubilization effect in time τ = 15 min. Additive: (*1*) SI, (*2*) bis(piperylene tetrasulfide), (*3*) bis(piperylene tetrasulfide)–SI (0.5 wt %), and (*4*) bis(piperylene tetrasulfide)–SI (1.0 wt %).

Taken together, the results of the physicochemical analysis suggest that the reaction of *trans*-piperylene with sulfur yields bis(piperylene tetrasulfide):

$$2CH_2{=}CH{-}CH{=}CH{-}CH_3 + S_8 \longrightarrow CH_2{-}CH{=}CH{-}CH(S_4){-}CH_3$$
$$CH_2{-}CH{=}CH{-}CH(S_4){-}CH_3.$$

This scheme is in agreement with the data [2] obtained for the reaction of low-molecular-weight dienes with sulfur. The developed method of quantitative introduction of sulfur into piperylene fraction in a *p*-xylene medium was used for accumulation of an experimental batch (~2 kg) of the substance for industrial tests.

The performance characteristics of lubricating oils are typically improved by introducing formulations (packages) of several additives. Individual compounds from the packages exhibit the desired performance characteristics to a different extent; the overall result is achieved through correctly choosing, both qualitatively and quantitatively, the components, taking into account their possible interaction. In [8, 9], we elucidated the mutual influence of antioxidizing and washing and dispersing additives. Here, we attempted to optimize the composition of the additive package, to which end we elucidated how the reaction products of piperylene fraction and elemental sulfur affect the performance characteristics of a washing and dispersing additive, bis(oligoisobutenylsuccinimide) (SI).

Since the washing effect of surfactants is determined by their solubilizing power, we determined the critical micelle concentration (CMC) of bis(piperylene tetrasulfide) and SI by the dye solubilization method. The solubilizing action of the additives was examined in an isooctane medium by the technique we described in [8]. A solubilizing effect with respect to a dye in a hydrocarbon medium is observed at the surfactant content in the system lying within the CMC range. The solubilization effect (SE) is determined as the difference in the optical densities of the corresponding systems before and after introduction of the dye. The plots of the SE vs. concentration of the ingredients exhibit an exponential run up to certain ratios at which they flatten out (Fig. 1). The plots of SE vs. concentration of the additives and

Table 2 suggest that the solubilizing power of SI with respect to dyes increases when SI is combined with sulfur-containing products. This is manifested in a shift of the CMC range to low concentration and an increase in the dD/dc parameter. This effect allows not only decreased dosages of the components in an oil composition, but also significant improvement of their performance characteristics.

The antiwear and antiscuff properties of the synthesized sulfur-containing compounds based on piperylene fraction were examined on an experimental setup by known techniques [10]. These properties were characterized by the wear rate of steel rods a_m and friction coefficient K_{fr}. The antiwear properties of the composition based on cylinder oil no. 52 upon introduction of bis(piperylene tetrasulfide) were estimated on an Ekspress friction machine under stepwise increase of the specific load in the presence of 3 wt % additives (Fig. 2). We found that bis(piperylene tetrasulfide) causes the wear resistance of the rods to increase relative to a commercial analog, zinc *O,O'*-bis(octylphenyl) phosphorodithioate (VNII NP-354 additive). A sharp difference in the wear rates of rods in the presence of commercial and experimental additives, observed upon increasing the specific load, is due probably to the specific structural features of sulfur-containing moieties of the additives. The energy required for breaking the P–S bonds in the phosphorodithioate exceeds that for the S–S bond in polysulfide (260 against 218 kJ mol^{-}) [11]. A smaller energy consumed in breaking the polysulfide bonds favors more intensive tribochemical processes occurring on the metal surface, which increases the wear resistance of the surfaces under exploitation.

Comparison of the plots of the steel wear vs. the specific load at different bis(piperylene tetrasulfide) concentrations in KS-19 oil (Fig. 3) with the concentration dependence of the solubilizing power of this additive (Fig. 1) suggests the following. The antiwear properties of the oil (curves *1, 2*) are appreciably improved specifically in the CMC area [for bis(piperylene tetrasulfide), 0.05–0.45 wt %, Fig. 1]. Beyond this range, the steel wear decreases to a considerably smaller extent (curves *3, 4*). The observed effect allows the antiwear performance to be correlated with micellization. The wear resistance sharply increases at the additive concentrations approaching the micellization onset concentration. Our results agree with the data reported by Loznetsova et al. [12] and Tyul'pakov et al. [13], who examined the antiwear performance as influenced by the concentration of the fluorine- and sulfur-containing alkyl phosphates.

Table 2. Critical micelle concentration and dD/dc parameters of the additives in isooctane for the case of rhodamine solubilization

Surfactant	$c \times 10^3$, M	dD/d$c \times 10^{-3}$
SI	0.26–1.38	1.82
Bis(piperylene bistetrasulfide)	0.86–7.80	0.37
Bis(piperylene bistetrasulfide)–SI, wt %:		
0.5	0.35–8.69	0.54
1.0	0.17–8.69	0.64

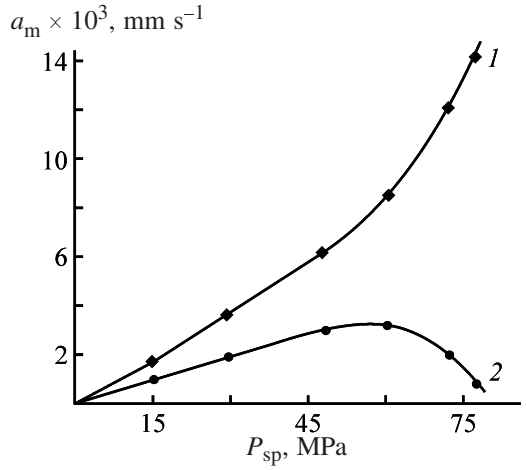

Fig. 2. Steel wear rate a_m vs. specific load P_{sp} in the presence of compositions of cylinder oil no. 52 containing various additives. Additive: (*1*) zinc *O,O'*-bis(octylphenyl) phosphorodithioate (VNII NP-354) and (*2*) bis(piperylene tetrasulfide).

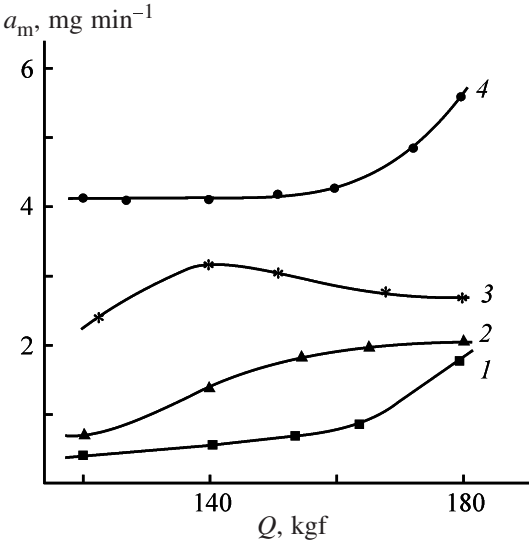

Fig. 3. Steel wear rate a_m vs. specific load Q in KS-19 oil in the presence of various concentrations of bis(piperylene bistetrasulfide). Bis(piperylene tetrasulfide) concentration, wt %: (*1*) 0.10, (*2*) 0.50, (*3*) 1.00, and (*4*) 2.00.

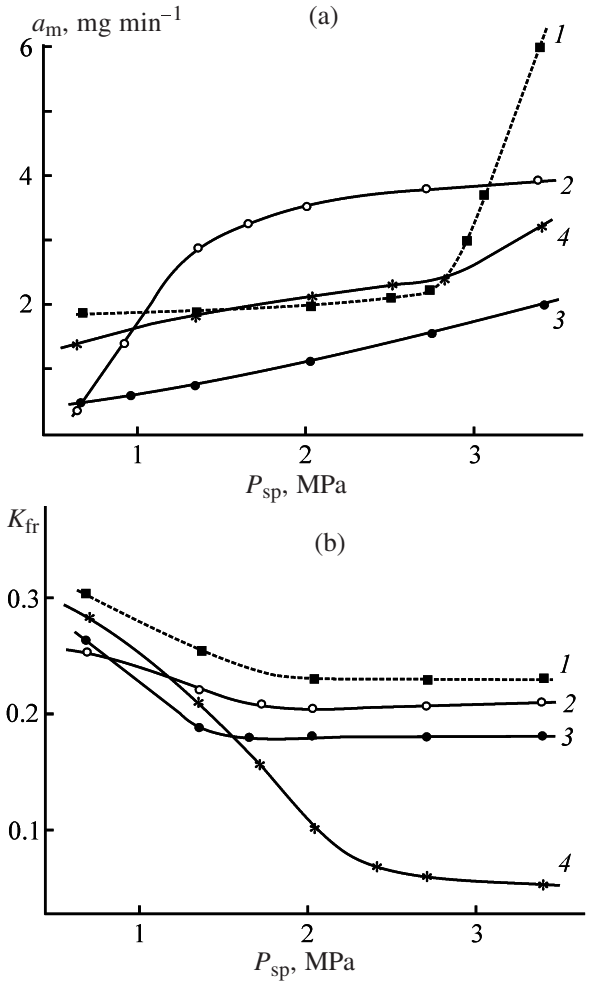

Fig. 4. (a) Steel wear rate a_m and (b) friction coefficient K_{fr} of the steel–steel couple in drilling muds containing various additives vs. the specific load P_{sp}. Additive: (*1*) none, (*2*) SDBUR (1%), (*3*) SDBUR (1%) + bis(piperylene tetrasulfide) (0.1%), and (*4*) SDBUR (1%) + bis-(piperylene tetrasulfide) (0.1%) in xylene.

We also examined here the antiwear and antifriction properties of drilling muds in the presence of minor (up to 1 wt %) amounts of bis(piperylene tetrasulfide) and up to 3 wt of SDBUR lubricant additive, a water-soluble surfactant. It was found that, in the examined range of specific loads, all the additives tend to decrease the friction coefficient of the steel–steel couple in drilling muds. The most pronounced effect was observed in the case of the SDBUR additive combined with bis(piperylene tetrasulfide) (Fig. 4b, curves *3, 4*). The same composition of the additives provides a minimal wear rate for steel (Fig. 4a, curve *3*).

Table 3. Average performance characteristics of III-215.9 MS3GV bits

Hole	Performance characteristics of base/experimental bits			
	n, number	H, m	t_d, h	V_m, m h^{-1}
3728	23/8	107/142	12.3/15.9	8.7/8.9
411	14/7	87/102	7.3/9.35	11.7/10.9
1963	19/5	114/153	9.3/12.9	12.3/11.8

We found that the performance characteristics of the compositions examined are also affected by the ingredient mixing order: The best results were obtained for SDBUR water-soluble additive preliminarily mixed with the sulfurization product of piperylene fraction.

The product of the reaction between piperylene fraction and elemental sulfur, accumulated at plants,[1] was tested under commercial conditions. Table 3 presents the results of testing a sulfur-containing additive (1%) introduced into SDP-3M lubricating grease for unsealed supports of rotary bits used in hole drilling. Table 3 shows that the headway per drill bit increased by 25.3% on the average, and the strength of the drill bit supports, by 28.6% at virtually unchanged mechanical drilling speed V_M.

Thus, the tests showed that the substances we obtained are suitable as high-performance antiwear additives to lubricants used in drilling technology.

CONCLUSIONS

(1) A method of quantitative introduction of up to 70% elemental sulfur into piperylene fraction was developed. The reaction of *trans*-piperylene with sulfur yields bis(piperylene tetrasulfide).

(2) Bis(piperylene tetrasulfide) causes the solubilizing power of succinimide additives to increase.

(3) Bis(piperylene tetrasulfide) exhibits the best antiwear performance characteristics when its concentration in oil lies within the critical micelle concentration range.

(4) Commercial tests showed that introduction of 1% sulfur-containing piperylene fraction improves the antiwear and antiscuff performance of lubricant compositions on drilling plants by 25%, on the average.

[1] The tests were carried out in Neftekamsk, Surgut, and Kogalym, as well as in Gubkino settlement (Komsomol'skoe oil and gas deposit).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

A New Electrochemical Procedure for Preparing 2,4,6-Triphenylselenopyran from 1,5-Diketones under Conditions of Acid Catalysis

Abstract—A new electrochemical procedure was developed for preparing 2,4,6-triphenylselenopyran from 1,5-diketones under conditions of acid catalysis at oxidative electrochemical activation of hydrogen selenide in the presence of a one-electron oxidizing agent in a nonaqueous solution. The electrolysis products were analyzed by gas chromatography with a mass-selective detector.

DOI: 10.1134/S1070427208030208

Selenium-containing heterocyclic compounds are widely used for preparing pharmaceuticals, odorants in perfumery, photomaterials, photosensitizers, dyes, and polymer fibers [1, 2]. High biological activity of low-toxic 4H-selenopyrans was revealed recently. Therefore, development of new convenient methods for preparing these compounds becomes an urgent problem [1]. Reaction of 1,5-diketones with hydrogen sulfide in the presence of acids yields thiopyrans or their disproportionation products, thiopyrylium salts, thiacyclohexanes, or dihydrothiopyrans [3]. Selenopyrans and selenopyrylium salts can be prepared similarly by acid-catalyzed reaction with hydrogen selenide [4].

Most of methods for preparing arylaliphactic 4H-selenopyrans are based on reactions of gaseous hydrogen selenide with appropriate 1,5-diketones or reactions of selenopyrylium salts with metal hydrides [4]. The most convenient reactions of arylaliphatic 1,5-diketones with hydrogen selenide can be performed only with polysubstituted diketones. The main products of these reactions were mixtures of selenopyrylium salts and selenacyclohexanes.

Electrochemical synthesis of some organoselenium compounds and electrochemical behavior of some selenium-containing heterocyclic compounds is a relatively new field of selenium electrochemistry. Therefore, development of new procedures for preparing selenium-containing heterocyclic compounds and study of their redox properties are urgent problems.

As chemical synthesis of selenopyrans has already been developed [1], the aim of this study was to develop an electrochemical synthesis of selenopyrans and selenopyrylium salts. In this study we developed a new procedure for preparing 4H-selenopyrans and examined some features of their reactions. For this purpose, we studied reaction of 1,5-diketones with electrolytically generated hydrogen selenide under conditions of acid catalysis and oxidative activation of the reagent. Hydrogen selenide formed by electrolysis on a selenium electrode reacts with a 1,5-diketone in ethanol to give 4H-selenopyran as one of the products.

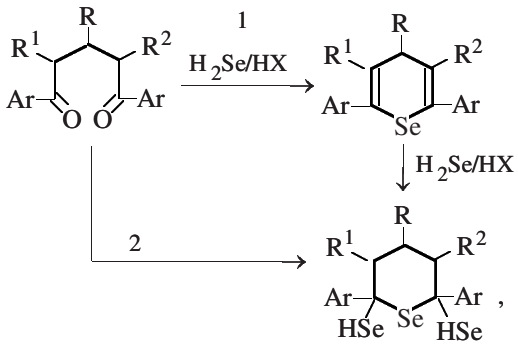
EXPERIMENTAL

Electrochemical synthesis was performed in a glass three-electrode electrochemical cell with nonseparated anode and cathode compartments in a nonaqueous solution at a fixed temperature with stirring. A platinum wire 0.25 mm in diameter was used as an auxiliary electrode (anode). Electrodes prepared by application of selenium to the surface of different metals or selenium electrodes prepared by different methods were used as working electrodes (cathodes). The first step was the development of the electrode design. Selenium was applied to nickel, copper, and platinum electrodes of different configurations. The nickel electrode was a 5 cm^2 plate cut from Ni foil; the copper electrode was a copper wire 1.5 and 2.5 mm in diameter and 5 cm long; the platinum electrode was platinum wire 0.25 mm in diameter and 10 mm long,

which was sealed in a glass tube. Selenium was applied as follows. Selenium powder in a ceramic crucible was placed in a muffle furnace and was melted at 273°C. An appropriate metallic electrode was immersed in the melt and kept there for 5 s. The electrode was taken out from the melt and cooled in air until the selenium completely solidified.

The electrolyte was prepared as follows: PCl_3 (3.1 ml) was added from a dropping funnel to ethanol (22 ml) placed in a conical flask. The flask was cooled on an ice bath, and its contents were stirred with a magnetic stirrer. Then a weighed portion of 1,3,5-triphenylpentane-1,5-dione was dissolved in the flask. The reaction course and the purity of the reaction products were monitored by thin-layer chromatography (TLC) using a hexane–ether–chloroform mixture (3 : 1 : 1) as an eluent (the chromatogram was developed with iodine vapor) and gas chromatography with mass-selective detector (GC–MSD).

The selenium electrode potential controlled with the aid of a P-5848 potentiostat was –0.4 V. The organoselenium salt was electrochemically identified by measuring its voltametric properties with a stationary platinum electrode with a surface area of 3.48 mm^2 as the working electrode and a saturated silver chloride electrode with a waterproof diaphragm as the reference electrode. A 70 mm^2 platinum plate was used as an auxiliary electrode. The supporting electrolyte was 0.20 M NBu_4ClO_4. The electrochemically prepared salt was identified on the background of 2,4,6-triphenylselenopyrylium perchlorate prepared by the chemical procedure described in [1]. Exhaustive microelectrolysis of 2,4,6-triphenylselenopyran was performed at a constant potential E_a = 1.0 V. Microelectrolysis of 2,4,6-triphenylselenopyrylium perchlorate was performed at a cathode potential E_c = –0.8 V for 3 h.



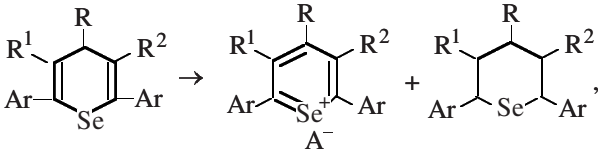
It is known [5, 6] that electrochemical preparation of different organoselenium compounds involves formation of organoelement compounds in the course of both anodic and cathodic processes. However, the electrochemical method, based on these reactions, for preparing compounds with carbon–element bonds is poorly understood.

Usually an organic compound present in an electrolyte can be reduced at the cathode during electrolysis of this solution. However, in some case another cathodic process involving dissolution of the cathode is observed. This reaction is mainly typical for electroreduction of aldehydes, ketones, some unsaturated compounds, and alkyl halides. The formation mechanism of organoelement compounds by cathodic reactions is an open question. Cathodic dissolution of an element is a paradoxical fact itself.

The majority of researchers believe [5, 6] that organoelement compounds are formed by the radical mechanism by the reaction of a radical formed at the cathode with the electrode material. However, not all the cathodic reactions of formation of organoelement compounds can be described within the framework of this concept. These facts suggest that radicals formed in the course of electrolysis are present in the form of an intermediate complex with the cathode material, rather than in the form of kinetically independent species. Under favorable conditions, this complex abstracts an atom from the crystal lattice of the cathode to form an organoelement compound. In some cases, an organoelement compound is formed by a pathway other than a direct electrochemical reaction.

Tomilov et al. [6] showed that the formation mechanism of organoelement compounds by cathodic reactions strongly depends on the type of the organic compound and cathode and should be considered separately in each particular case. The electrochemical behavior of the most widely known organoselenium compounds was examined in [7, 8]. Not only HCl but also HBr, CH_3COOH, and Lewis acids ($ZnCl_2$ and $ZnBr_2$) can be used to produce an acid media. It should be noted that chemical and electrochemical one-electron irreversible oxidation of hydrogen selenide in nonaqueous solutions yields a highly reactive radical cation which exhibits strong acid properties and can be fragmented in nonaqueous solution with proton elimination.

Electrolysis of 1,5-diketones in 4 N HCl solution in ethanol gives the following most probable products:

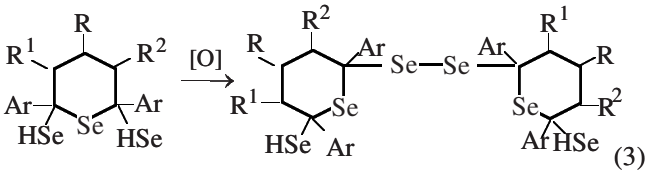


(1)

where Ar, R = Ph; R^1, R^2 = H; X = Cl, Br.

4H-Selenopyran formed at an excess of hydrogen selenide can add the HSe group to the double bonds of the selenopyran ring to form hydroselenium derivatives. The hydroselenium derivatives can be formed directly from 1,5-diketone by scheme (1.2).

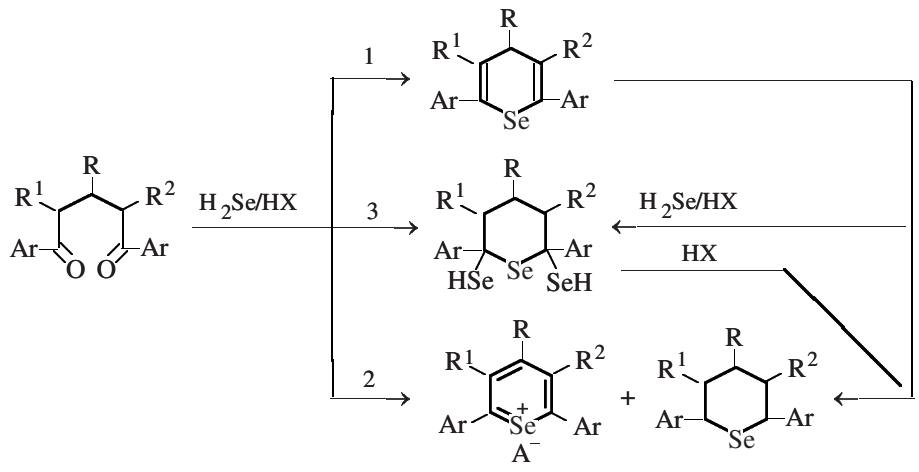
The GC–MSD analysis of the electrolysis products shows that 2,4,6-triphenylselenopyran is formed even at a low current (6 mA) after electrolysis for 1 h. The amount of 2,4,6-triphenylselenopyran significantly increases and the amount of the initial 1,3,5-triphenylpentane-1,5-dione decreases after electrolysis for 1.5 h at this current. Further analysis performed at 2-h intervals showed formation and gradual accumulation of 2,4,6-triphenylselenopyran in the solution and a decrease in the amount of the initial 1,5-diketone up to its complete disappearance in 8 h after the reaction start. A flaky precipitate of 2,4,6-triphenylselenopyran was obtained after completion of the electrolysis in 4 N HCl in C_2H_5OH. However, in this case formation of selenopyrylium salts and the corresponding selenacyclohexanes by disproportionation of 4H-selenopyran is also possible:



(2)

where A is anion; Ar, R = Ph; R^1, R^2 = H; X = Cl, Br.

Taking into account that fact that selenopyrylium salts are readily soluble in alcohol, we suggest that the precipitate is 2,4,6-triphenylselenacyclohexane which is poorly soluble in this solvent.



Electrolysis on a selenium-coated nickel plate as the cathode was performed for 13 h at constant current (10 mA) and voltage. Formation of 2,4,6-triphenylselenopyran was observed in 1 h after starting the electrolysis. The reaction mixture was analyzed at 2-h intervals. Hydroselenium derivatives [2,6-(dihydroseleno)-2,4,6-triphenylselenacyclohexane] and the corresponding diselenides (hydroseleno derivatives are oxidized with atmospheric oxygen to diselenides) were detected by GC–MSD in 5 h after starting the electrolysis. The fact that only a very small amount of the initial 1,5-diketone in the reaction mixture was determined by GC suggests that the reaction goes virtually to completion.

A change in the electrolysis parameters (J = 15 mA, τ = 7 h) has no effect on the quantitative composition of the system but accelerates formation of the above compounds and increases their yields. Thus, the reaction can be described by the following scheme:

(3)

where Ar, R = Ph; R^1, R^2 = H; X = Cl, Br.

Electrochemical synthesis of heterocyclic selenium-containing compounds under conditions of acid catalysis in a nonaqueous solution yields a mixture of products and can be described by the following scheme:

(4)

where A is anion; Ar, R = Ph; R^1, R^2 = H; X = Cl, Br.

Arylaliphatic 1,5-diketones react with hydrogen selenide under conditions of acid catalysis in an inert atmosphere along three pathways which differ in the extent of transformation. Reaction (4.1) yields arylaliphatic 4*H*-selenopyrans; reaction (4.2) yields disproportionation products of 4*H*-selenopyrans; and

reaction (4.3) is characterized by addition of hydrogen selenide to the double bonds of the selenopyran ring [scheme (4)].

It should be noted that the cathode material is consumed in the course of electrolysis, which is probably due to occurrence of multistep reactions and free radical formation. Two sharp waves at –0.93 and –1.19 V (I_p = 7 μA) appear in the cathodic curve after introduction of 2×10^{-5} M 2,4,6-triphenylselenopyrylium perchlorate into the cell. These waves can be probably due to oxidation and reduction of the heteroaromatic ring rather than of the substituents.

Thus, formation of organoselenium compounds in the course of electrolysis on a selenium electrode was determined by GC–MSD. 2,4,6-Triphenylselenopyran and 2,4,6-triphenylselenopyrylium perchlorate were prepared by oxidative electrochemical activation of hydrogen selenide in the presence of one-electron oxidizing agents. Solid salts of the heterocyclic aromatic cation have a layered structure typical for graphitized carbon materials. This fact suggests that electrode materials with new properties can be prepared from mixtures of the organic salt with graphitized carbon.

CONCLUSIONS

(1) An electrochemical procedure was developed for preparing 2,4,6-triphenylselenopyran and selenopyrylium salts from 1,5-diketones under conditions of acid catalysis in a nonaqueous solution on a selenium cathode. The 2,4,6-triphenylselenopyran yield was 67%.

(2) The electrolysis products were identified by gas chromatography with mass-selective detector.

(3) Procedures for preparing selenium electrodes were developed.

Abstract—A series of quaternary bisammonium salts containing the common 5-oxanonane-2,7-diyne-1,9-diyl fragment and different alkoxycarbonylmethyl groups was synthesized. The surfactant properties and antimicrobial activity of these compounds were studied.

DOI: 10.1134/S107042720803021X

Many practically important properties of surface-active quaternary bisammonium salts depend on the structure of the common group binding the terminal alkylammonium groups. Among these compounds, functionally substituted derivatives of mono- and bisammonium salts containing unsaturated bonds are of particular interest [1–3].

Taking into account that ammonium salts with the allyl and propargyl groups exhibit distinct antimicrobial activity, in this study we synthesized bisammonium salts containing, along with the alkoxycarbonylmethyl radicals ensuring surface activity, the common 5-oxononane-2,7-diyne-1,9-diyl group (see table).

These salts were prepared in high yields by the following reactions:

$$HC{\equiv}CCH_2Br + HOCH_2C{\equiv}CH \xrightarrow{NaOH} HC{\equiv}CCH_2OCH_2C{\equiv}CH$$

$$HC{\equiv}CCH_2OCH_2C{\equiv}CH \xrightarrow[(CH_3)_2NH,\ CH_2O]{FeCl_3,\ \text{dioxane}} (CH_3)_2NCH_2C{\equiv}CCH_2OCH_2C{\equiv}CCH_2N(CH_3)_2$$

$$(CH_3)_2NCH_2C{\equiv}CCH_2OCH_2C{\equiv}CCH_2N(CH_3)_2 \xrightarrow[ROCOCH_2Cl]{\text{Ethanol}} (CH_3)_2\overset{+}{N}(Cl^-)CH_2C{\equiv}CCH_2OCH_2C{\equiv}CCH_2\overset{+}{N}(Cl^-)(CH_3)_2,$$

* (CMC) Critical micelle concentration; (γ_{CMC}) surface tension at CMC, mN m^{-1}; (h) froth stability; (G) surface activity, N m^2 kmol^{-1}; (t_{death}) time of death of microorganisms, where (M_1) *Escherichia coli* (strain 1257), (M_2) *Staphylococcus aureus* (strain 906).

We found that variation of G values in the series of QASs under considerations deviates from the Duclot–Traube rule, which is typical of colloidal surfactants [5].

One of practically important characteristics of surfactants is their froth stability [5]. The froth-forming ability of aqueous QASs was determined as the ratio of the initial froth column height to that after settling for 5 min [6]. We found that the froth stability increases with increasing length of radicals R. All QASs under consideration were found to be efficient froth-forming aqents.

The antimicrobial activity of QASs **I–IV** was determined by a technique based on disinfection of cambric test-objects sown with standard strains of *Staphylococcus aureus* (strain 906) and *Escherichia coli* (strain 1257) containing 2×10^9 microbial cells in 1 ml at an exposure time of 5–30 min and solution temperature of 20°C [7].

Our results show that 0.025–1% aqueous solutions of the synthesized QASs exhibit bactericidal effect with respect to the above-noted strains, and this effect is dependent on the length of hydrophobic radical R. The maximal bactericidal effect was shown by QAS **III** (R = $C_{10}H_{21}$) whose 0.05% aqueous solution eliminates *Escherichia coli* and *Staphylococcus aureus* within 5 min.

EXPERIMENTAL

The IR spectra of QASs were recorded on a Specord IR-75 spectrometer (mulls in mineral oil). The QAS purity was tested by thin-layer chromatography with Silufol UV-254 plates using *n*-butanol–ethanol–water–acidic acid mixture (10 : 7 : 6 : 4) as solvent and iodine vapor as developer.

Quaternary ammonium salts I–IV. A mixture of 1,9-dimethylamino-5-oxanonane-2,7-diyne (0.01 mol) and appropriate alkyl monochloroacetate in absolute ethanol (5 ml) was kept at room temperature for 5 days. The resulting salt was washed with absolute diethyl ether and dried in a desiccator over $CaCl_2$. The IR spectrum of the final compound contains the following absorption bands, ν, cm^{-1}: 1075, 1230, 1725 (COO), 2240 (–C≡C–).

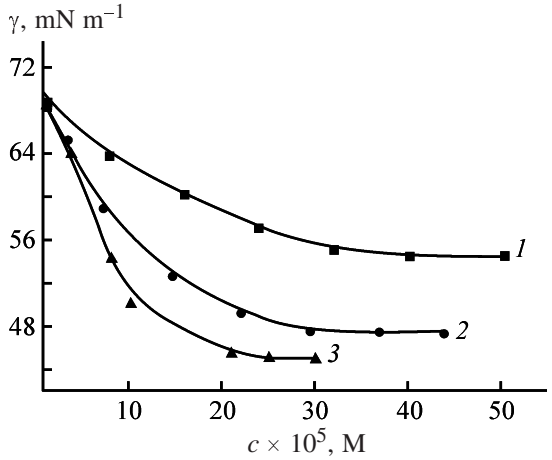

Fig. 1. Surface tension γ in the systems QAS–H_2O at T = 303 K. (c) QAS concentration. (*1*) C_8, (*2*) C_{10} and (*3*) C_{12}.

CONCLUSIONS

(1) Quaternary ammonium salts containing the common 5-oxanonane-2,7-diyne-1,9-diyl fragment and different alkoxycarbonylmethyl groups ehhibit bactericidal effect. Their antimicrobial activity depends on the length of the hydrophobic radical.

(2) With an increase in the length of the alkyl radicals in QAS molecules, both the critical micelle concentration and the surface tension decrease, whereas the surface activity increases. The strongest bactericidal effect is exhibited by *N,N*'-(5-oxanonane-2,7-diyne-1,9-diyl)bis[(decyloxycarbonylmethyl)dimethylammonium] chloride.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

A New Synthetic Route to 1,3,5-Undecatrienes and Fucoserratene

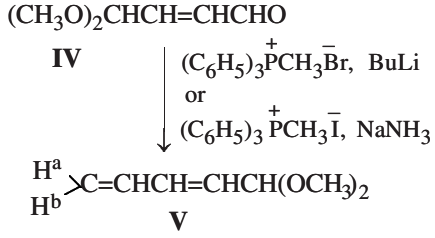
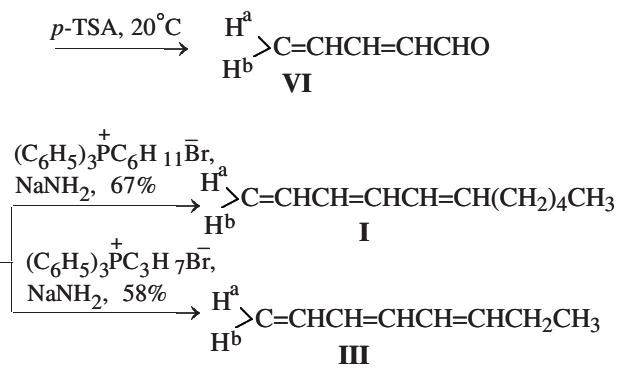
Received May 15, 2007



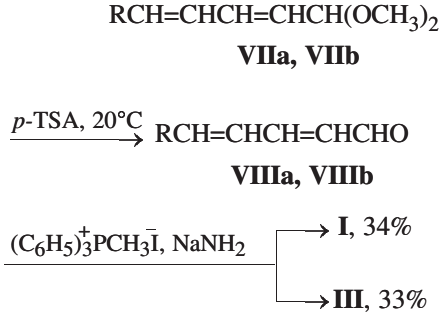
Abstract—A new procedure for preparing natural alkatrienes, fucoserratene and 1,3,5-undecatrienes, was developed. The key step of both syntheses is stereoselective formation of double bonds by the Wittig reaction starting from (*E*)-4,4-dimethoxy-2-butenal.



DOI: 10.1134/S1070427208030221

Conjugated trienes containing terminal vinyl group widely occur in the nature. *trans,cis*- and *trans,trans*-1,3,5-undecatrienes **I** and **II** were isolated from essential oils of *Galbanum* gum of various origins [1]. They were also found in essential oils of various algae [2, 3] and are components of various perfume compounds. In addition, triene **I** is one of the components of the odor of parsley, mandarins, apples, and pears [4]; it acts as sex pheromone on gametes of Australian kelps [5]. (3*E*,5*Z*)-1,3,5-Octatriene **III** (fucoserratene) is a pheromone isolated from fertilized ovums of some insect species [6]. These compounds are a subject of numerous studies. They are synthesized by heterolytic fragmentation of unsaturated 1,5-diols [6], stereo- and regioselective palladium-catalyzed synthesis [7], alkylation of terminal acetylene compounds [8], Wittig reation [9, 10], and also using α-haloalkylsulfonyl bromides [11], pentadienyl dithiocarbamates [12], and pyridazine *N*-oxides [13].

Here we suggest two alternative routes to the target products, (3*E*,5*Z*)-1,3,5-undecatriene **I** and fucoserratene **III**, starting from (*E*)-4,4-dimethoxy-2-butenal **IV**. The first route is the sequence of two Wittig reactions: first with triphenylmethylidenephosphorane and then with triphenylpropylidenephosphorane or triphenylhexylidenephosphorane (Scheme 1).



Scheme 1.

In the second route, the same reactions are performed in the reverse order (Scheme 2).

Scheme 2.

where R = Et (**VIIa**, **VIIIa**), Am (**VIIb**, **VIIIb**).

Olefination with triphenylmethylidenephosphorane (Scheme 1) was performed at 0°C in tetrahydrofuran (THF) in the presence of butyllithium. Since the yield of (3*E*)-5,5-dimethoxy-1,1-pentadiene **V** did not exceed 30%, butyllithium was replaced by sodium amide. By so doing, the yield of acetal **V** was in-

creased to 62%. After deprotection of the carbonyl group (20°C, acetone–water, 2 : 1) in the presence of catalytic amounts of *p*-toluenesulfonic acid (*p*-TSA), (2*E*)-penta-2,4-dienal **VI** was prepared in 93% yield. The second Wittig reaction with dienal **VI** was also performed in THF at 0°C. The phosphonium salts were deprotonated with sodium amide. Mixtures of stereoisomers of 1,3,5-undecatriene **I** and fucoserratene **III** were obtained in 67 and 58% yields, respectively. The content of the (3*E*,5*Z*) isomers in the isomeric mixtures exceeded 80%.

The isomer ratio was determined by ^{1}H NMR spectroscopy from the chemical shift of the H^6 atom. In the (*E*,*Z*) isomer, the H^6 signal is shifted upfield (5.50 ppm) relative to the (*E*,*E*) isomer (5.75 ppm) [8]. In the case of undecatriene **I**, the isomer ratio was also determined by GLC on a capillary column coated with SE-30.

By Wittig olefination of butenal **IV** with triphenylpropylidenephosphorane and triphenylhexylidenephosphorane, we previously prepared mixtures of isomers of acetals **VIIa** and **VIIb**, respectively, with more than 95% content of (2*E*,4*Z*) isomers. The acetal protection was removed at 0°C in acetone–water (2 : 1) in the presence of catalytic amount of *p*-toluenesulfonic acid to obtain the corresponding dienals **VIIIa** and **VIIIb**, with the configuration of (4*Z*) double bond being almost fully retained [14]. Then, by the Wittig reaction, we prepared the desired trienes: (3*E*,5*Z*)-1,3,5-undecatriene **I** and fucoserratene **III** (Scheme 2).

By choosing appropriate deprotection conditions, from acetal **VIIb** we prepared (*E*,*Z*)- and (*E*,*E*)-decadienals **IX** with the prevalence of the (*E*,*E*) isomer. For example, at 20°C in the presence of catalytic amounts of *p*-toluenesulfonic acid and equimolar amounts of water in acetone, we prepared decadienal **IX** with 81% content of the (*E*,*E*) isomer [14], which was converted by the Wittig reaction into (3*E*,5*E*)-1,3,5-undecatriene **II** with 34% yield:

$$\underset{\textbf{IX}}{CH_3(CH_2)_4CH{=}CHCH{=}CHCHO} \xrightarrow{(C_6H_5)_3^+PCH_3\bar{I},\ NaNH_2} \underset{\textbf{II}}{CH_3(CH_2)_4CH{=}CHCH{=}CHCH{=}C\begin{matrix}H^a\\H^b\end{matrix}}$$

Undecatriene **II** was also synthesized by the Schlosser reaction. (2*E*,4*E*)-1,1-Dimethoxy-2,4-decadiene **V** was prepared in 57% yield form butenal **IV** and hexyltriphenylphosphonium bromide; the product contained 90% (*E*,*E*) isomer [14]. Deacetalization of **V** followed by the Wittig reaction yielded undecatriene **II** containing 87% (*E*,*E*) isomer.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Varian VXR-300 spectrometer (300 MHz) in $(CD_3)_2CO$ or $CDCl_3$. The chemical shifts (δ, ppm) are given relative to TMS. The IR spectra were recorded on a UR-20 spectrophotometer from thin films. GLC analysis was performed with a Chrom-5 chromatograph (flame ionization detector, 25 m × 0.25 mm glass capillary column, liquid phase SE-30, carrier gas nitrogen, flow rate 3 ml min^{-1}). Column chromatography was performed on silica gel L 40/100. Thin-layer chromatography was performed on Silufol UV-254 plates; the chromatograms were developed by treatment with iodine vapor or $KMnO_4$ solution. Compound **IV** was prepared as described in [15], and phosphonium salts, as described in [16].

(3*E*)-5,5-Dimethoxy-1,3-pentadiene V. *a.* A 1.45 N solution of butyllithium (16.8 ml) was added dropwise at room temperature to 8.9 g of methyltriphenylphosphonium bromide in 35 ml of THF. Then the mixture was cooled to a temperature from 0 to –5°C, and a solution of 3.0 g of butenal **IV** in 5 ml of THF was added dropwise. The mixture was allowed to stand for 1 h, after which it was poured onto ice and extracted with ether. The extract was dried over sodium sulfate. The solvent was distilled off, and the residue was distilled in a vacuum to obtain 1.3 g (30%) of (3*E*)-5,5-dimethoxy-1,3-pentadiene **V**, bp 72–73°C (12 mm Hg). IR spectrum, ν, cm^{-1}: 1116 (CH_3O–C–OCH_3), 1600 (C=C). ^{1}H NMR spectrum [$(CD_3)_2CO$], δ, ppm (*J*, Hz): 3.2 s (6H, OCH_3), 4.8 d (1H, H^5, $J_{5,4}$ 5.0), 5.12 d (1H, H^{1a}, $J_{1a,2}$ 10.5), 5.28 d (1H, H^{1b}, $J_{1b,2}$ 16.0), 5.61 d.d (1H, H^4, $J_{4,3}$ 15.5, $J_{4,5}$ 5.0), 6.07 d.d.d (1H, H^2, $J_{2,1a}$ 10.5, $J_{2,1b}$ 16.0, $J_{2,3}$ 11.2), 6.67 d.d (1H, H^3, $J_{3,2}$ 11.2, $J_{3,4}$ 15.5).

Found, %: C 65.56, H 9.41.

$C_7H_{12}O_2$. Calculated, %: C 65.60, H 9.44.

b. Methyltriphenylphosphonium iodide (28.7 g) was added to 3.6 g of sodium amide in 40 ml of THF under nitrogen. The mixture was refluxed for 1 h, after which it was cooled to a temperature from 0 to –10°C, and a solution of 9.2 g of aldehyde **IV** in 10 ml of THF was added dropwise. The mixture was allowed to stand dor 1 h, after which 50 ml of water was added, and the mixture was extracted with ether. The extract was dried over sodium sulfate, the solv-

ents were removed, and the residue was distilled in a vacuum. Dimethoxy diene **V** was obtained, bp 72–73°C (12 mm Hg); yield 5.6 g (62%).

(2*E*)-2,4-Pentadienal VI. *p*-Toluenesulfonic acid (36 mg) was added to a mixture of 0.9 g of dimethoxy diene **V** in 10 ml of acetone and 5 ml of water. The mixture was stirred for 10 min at 20°C and neutralized with Na_2CO_3, after which acetone was removed and the residue was extracted with ether. The extract was dried over sodium sulfate, and the crude mixture after removing the solvent was purified on a column (silica gel, hexane : ether = 10 : 1). (2*E*)-2,4-Pentadienal **VI** was isolated; yield 534 mg (93%). IR spectrum, ν, cm^{-1}: 1620 (C=C), 1675, 2720 (C=O). ^1H NMR spectrum [$(CD_3)_2CO$], δ, ppm (*J*, Hz): 5.64 d (1H, H^{5a}, $J_{5a,4}$ 10.5), 5.81 d (1H, H^{5b}, $J_{5b,4}$ 16.0), 6.05 d.d (1H, H^2, $J_{2,1}$ 8.5, $J_{2,3}$ 15.3), 6.40 m (1H, H^4), 7.12 d.d (1H, H^3, $J_{3,2}$ 15.3, $J_{3,4}$ 10.3), 9.55 d (1H, H^1, $J_{1,2}$ 8.5) [17].

(3*E*,5*Z*)-1,3,5-Undecatriene I. *a.* Hexyltriphenylphosphonium bromide (1.6 g) was added to 0.185 g of sodium amide in 2 ml of THF. The mixture was refluxed for 1 h and cooled to a temperature from 0 to –10°C, and a solution of 0.3 g of dienal **VI** in 1 ml of THF was added dropwise. After keeping for 1 h, 3 ml of water was added, and the mixture was extracted with ether and dried over sodium sulfate. After removing the solvents, the crude mixture was purified on a column (silica gel, hexane : ether from 19 : 1 to 10 : 1) to obtain 0.37 g (67%) of (3*E*,5*Z*)-1,3,5-undecatriene **I** [relative content of the (3*E*,5*Z*) isomer 86%]. IR spectrum, ν, cm^{-1}: 840 (C=C), 935 [(*E*)-C=C], 1560 (C=C), 3100 (CH_2=CH). ^1H NMR spectrum ($CDCl_3$), δ, ppm (*J*, Hz): 0.91 t (3H, H^{11}, $J_{11,10}$ 7.0) 1.28–1.46 m (6H, H^8, H^9, H^{10}), 2.20 q (2H, H^7, $J_{7,6} = J_{7,8}$ = 7.2), 5.08 d.d (1H, H^{1a}, $J_{1a,1b}$ 1.2, $J_{1a,2}$ 10.0), 5.22 d.d (1H, H^{1b}, $J_{1b,1a}$ 1.2, $J_{1b,2}$ 16.0), 5.50 d.t (1H, H^6, $J_{6,5}$ 10.0, $J_{6,7}$ 7.0), 5.98–6.56 m (4H, H^2, H^3, H^4, H^5). Signals belonging to (3*E*,5*E*)-1,3,5-undecatriene **II** were also present: 2.14 q (2H, H^7, $J_{7,6} = J_{7,8}$ = 7.4), 5.05 d.d (1H, H^{1a}, $J_{1a,1b}$ 1.2, $J_{1a,2}$ 10.0), 5.19 d.d (1H, H^{1b}, $J_{1b,1a}$ 1.2, $J_{1b,2}$ 16.0), 5.74 d.t (1H, H^6, $J_{6,5}$ 15.0, $J_{6,7}$ 7.0) [9].

b. Methyltriphenylphosphonium iodide (0.94 g) was added to 0.13 g of sodium amide in 4 ml of THF, and the mixture was refluxed for 1 h. After cooling to a temperature from 0 to –10°C, a solution of 0.4 g of aldehyde **VIII** in 1 ml of THF was added. One hour later, 3 ml of water was added, the mixture was extracted with ether, and the extract was dried over sodium sulfate. After removing the solvent, the crude mixture was purified on a column (silica gel, hexane : ether from 19 : 1 to 10 : 1) to obtain 0.13 g (34%) of undecatriene **I** with 84% content of the (3*E*,5*Z*) isomer.

(3*E*,5*Z*)-1,3,5-Octatriene III. *a.* Propyltriphenylphosphonium bromide (1.4 g) was added to 0.185 g of sodium amide in 2 ml of THF. The mixture was refluxed for 1 h, after which it was cooled to a temperature from 0 to –10°C, and a solution of 0.3 g of aldehyde **VI** in 1 ml of THF was added dropwise. One hour later, 3 ml of water was added, and the mixture was extracted with ether. The extract was dried over sodium sulfate. After distilling off the solvents, the crude mixture was purified on a column (silica gel, hexane : ether from 19 : 1 to 10 : 1) to obtain 0.23 g (58%) of octatriene **III** with 85% content of the (3*E*, 5*Z*) isomer. IR spectrum, ν, cm^{-1}: 840 [(*Z*)-C=C], 935 [(*E*)-C=C], 1560 (C=C), 3100 (CH_2=CH). ^1H NMR spectrum ($CDCl_3$), δ, ppm (*J*, Hz): 0.9 t (3H, H^8, $J_{8,7}$ 7.0), 2.16 m (2H, H^7), 5.10 d.d (1H, H^{1a}, $J_{1a,1b}$ 1.2, $J_{1a,2}$ 10.0), 5.22 d.d (1H, H^{1b}, $J_{1b,1a}$ 1.2, $J_{1b,2}$ 16.0), 5.48 d.t (1H, H^6, $J_{6,5}$ 10.0, $J_{6,7}$ 7.0), 5.96–6.56 m (4H, H^2, H^3, H^4, H^5). Along with these signals, we found a signal at 5.78 d.t (1H, $J_{6,5}$ 15.0, $J_{6,7}$ 7.0), belonging to the H^6 atom of (3*E*,5*E*)-1,3,5-octatriene **III**.

b. Methyltriphenylphosphonium iodide (6.2 g) was added to 0.85 g of sodium amide in 6 ml of THF, and the mixture was refluxed for 1 h. After cooling to a temperature from 0 to –10°C, a solution of 1.7 g of (2*E*,4*Z*)-2,4-heptadienal **VIII** was added dropwise. The mixture was allowed to stand for 1 h, treated with water, and extracted with ether. The extract was dried over sodium sulfate. The residue after removing the solvents was chromatographed on a column (silica gel, hexane : ether = 20 : 1) to obtain 0.55 g (33%) of octatriene **III** with 89% content of the (3*E*,5*Z*) isomer.

(3*E*,5*E*)-1,3,5-Undecatriene II. Methyltriphenylphosphonium iodide was added to 0.13 g of sodium amide in 2 ml of THF. The mixture was refluxed for 1 h. After cooling to a temperature from 0 to –10°C, a solution of 0.4 g of dienal **IX** in 1 ml of THF was added dropwise. One hour later, 3 ml of water was added, and the mixture was extracted with ether. The extract was dried over sodium sulfate. The residue after removing the solvents was chromatographed on a column (silica gel, hexane : ether = 20 : 1) to obtain 0.13 g (34%) of undecatriene **II** with 87% content of the (3*E*,5*E*) isomer. IR spectrum, ν, cm^{-1}: 965 [(*E*)-C=C], 1585 (C=C), 3080 (C=C). ^1H NMR spectrum [$(CD_3)_2CO$], δ, ppm (*J*, Hz): 0.91 t (3H, H^{11}, $J_{11,10}$

7.0), 1.23–1.46 m (6H, H^8, H^9, H^{10}), 2.14 q (2H, H^7, $J_{7,8}$ 7.2), 5.05 d.d (1H, H^{1a}, $J_{1a,1b}$ 1.3, $J_{1a,2}$ 10.0), 5.19 d.d (1H, H^{1b}, $J_{1a,1b}$ 1.3, $J_{1b,2}$ 6.0), 5.74 d.t (1H, H^6, $J_{6,5}$ 14.5, $J_{6,7}$ 7.2), 5.98–6.58 m (4H, H^2, H^3, H^4, H^5).

CONCLUSION

A stereoselective procedure for preparing conjugated alkatrienes by the Wittig reaction with (*E*)-4,4-dimethoxy-2-butenal was developed.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Development of a Procedure for Preparing 2-Nitro-4-thiocyanoaniline

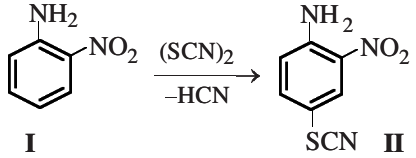
Received April 9, 2007



Abstract—A procedure was developed for preparing 2-nitro-4-thiocyanoaniline by thiocyanation of 2-nitroaniline with ammonium thiocyanate in acetic acid in the presence of bromine as oxidant.

DOI: 10.1134/S1070427208030233

Thiocyanation of organic compounds is most frequently performed with nascent thiocyanogen. To this end, a thiocyanic acid salt is dissolved in appropriate solvent (methanol, acetic acid, etc.), the solution is mixed with a substrate to be thiocyanated, and an oxidant (halogen or another substance capable of displacing thiocyanogen from thiocyanates) is added dropwise [1].

In thiocyanation of aromatic amines, the thiocyanato group is introduced in the *p*-position, and if this position is occupied, in the *o*-position to the amino group. In thiocyanation of chloro- and nitroanilines, the orienting effect of the amino group is preserved.

Thiocyanation of 2-nitroaniline **I** can be performed via intermediate diazo compound with the formation of 2-nitrothiocyanobenzene [1], or by the reaction with ammonium or potassium thiocyanate and bromine in acetic acid with the formation of 2-nitro-4-thiocyanoaniline **II** [2, 3]:

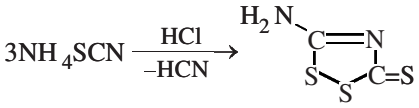
I **II**

Treatment of anilines or naphthylamines with ammonium thiocyanate and halogen or *N*-halo amide ($CH_3CONHBr$, $C_6H_5CONHBr$, *N*-bromosuccinimide, *N*-bromophthalimide, etc.) yields the corresponding 4-thiocyanates. The reaction is performed at 10–20°C in methanol or acetone in the presence of Chloramine T [4].

A procedure for preparing aromatic thiocyanates by treatment of the corresponding anilines with a mineral acid and alkali metal or ammonium thiocyanate is described in a patent [4]. A mixture of aniline and ammonium thiocyanate is dissolved in DMSO, concentrated sulfuric acid is added to the solution at 40–50°C, and the mixture is allowed to stand for 16 h at 20°C and poured into a 5% solution of sodium carbonate. 4-Thiocyanoaniline is thus obtained in 80% yield.

One of possible procedures for preparing organic thiocyanates (including chloro-, nitro-, and acetyl-substituted benzenes) is cleavage of organic disulfides with sodium cyanate and bromine or iodine in methanol or acetonitrile at approximately –5°C; the product yield varies from 50 to 95% [6, 7].

Under the synthesis conditions, both thiocyanogen itself and the released thiocyanic acid are unstable and can enter into side reactions. For example, thiocyanogen can partially polymerize to polythiocyanogen and react with bromine to give polybromothiocyanogen [4]:



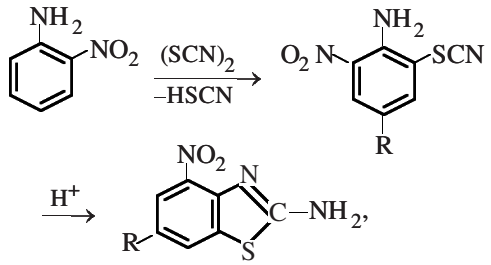
$$x(SCN)_2 \longrightarrow (SCN)_{2x}$$

$$x(SCN)_2 + Br_2 \longrightarrow 2x\text{BrSCN} \longrightarrow [\text{–S–N=C(Br)–}]_{2x}$$

It was found that, when 2-nitroaniline **I** in acetic acid is thiocyanated with ammonium (or potassium) thiocyanate using bromine as oxidant, the desired product **II** contains, along with 4-bromo-2-nitroaniline

III and minor amounts of 6-bromo-2-nitroaniline **IV** and 4,6-dibromo-2-nitroaniline **V**, also an unidentified water-insoluble organic impurity whose amount can reach 30% depending on the synthesis conditions.

Published data show that this impurity may be 1,3,5-trimercapto-*sym*-triazine or isoperthiocyanic acid **VI** (5-amino-1,2,4-dithiazole-3-thione, xanthane hydride). Acid **VI** is formed in ~25% yield by adding concentrated hydrochloric acid to an aqueous solution of ammonium thiocyanate and keeping the reaction mixture at 20–25°C for 16 h [7]:

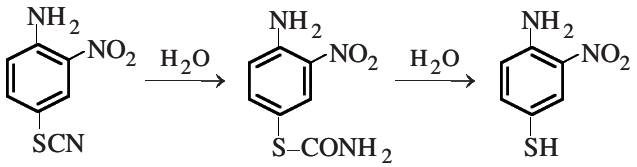


VI

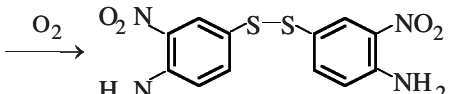
Acid **VI** can also be formed directly from ammonium thiocyanate under the action of hydrogen bromide formed in the course of synthesis of thiocyanoaniline **II** [7, 8].

All these facts lead to the formation of organosulfur products insoluble in water and acetic acid. Under the conditions of preparing **II**, these substances are precipitated together with the desired products.

To prepare thiocyanoaniline **II**, we tested a procedure for direct thiocyanation of 2-nitroaniline in methanol or acetic acid. Thiocyanogen generated from potassium or ammonium thiocyanate by adding a solution of bromine reacted with aniline occurring in the same solution to give thiocyanoaniline **II**. In the process, 4-bromo-2-nitroaniline **III** (up to 1.0%) and trace amounts of 6-bromoaniline **IV** and 4,6-dibromoaniline **V** are formed as by-products.



From 2-nitroaniline, 2-amino-4-nitro-1,3-benzothiazole **VII**, 2-amino-4-nitro-6-thiocyano-1,3-benzothiazole **VIII**, and 2-amino-6-bromo-4-nitro-1,3-benzothiazole **IX** can also be formed via the corresponding intermediates:



where R = H (**VII**), SCN (**VIII**), Br (**IX**).

It is known [7, 9, 10] that organic thiocyanates under the action of moisture in the presence of strong acids undergo hydrolysis with the formation of thiocarbamates, and further steps of the process yield thio compounds, disulfides, and other products.

Thiocyanation of **I** is accompanied by accumulation of hydrogen thiocyanate and hydrogen bromide in the reaction mixture, and moisture can be introduced together with the reactants and solvents. Therefore, in our case the above-mentioned processes seem to be possible. Their expected products are 4-amino-3-nitrophenyl thiocarbamate **X**, 4-amino-3-nitrothiophenol **XI**, bis(4-amino-3-nitrophenyl) disulfide **XII**, and other compounds:

X **XI**

XII

These factors were taken into account in the development of a technologically acceptable procedure for preparing 2-nitro-4-thiocyanoaniline **II** for the subsequent synthesis of anthelmintic agents based on it [11, 12].

Attempted synthesis of **II** in methanol gave unsatisfactory results: The reproducibility was poor, the main substance content of the crude product varied from 75 to 93%, and the amount of 4-bromoaniline **III** in some samples reached 4–5%. High-performance liquid chromatography of the reaction products revealed the presence of a significant amount (25–30%) of unidentified impurities. With an increase in the reaction time, the yield and quality of product **II** drastically decreased, and by-products rapidly accumulated in the reaction mixture. The use of acetic acid as solvent proved to be more efficient.

When bromine was replaced by other oxidants [Cu(II) salts, Chloramine B), thiocyanation of 2-nitroaniline proceeded more difficultly. Although copper salts were taken in excess, the reaction mixture contained a large amount of the unchanged starting compound, and other impurities were accumulated. With Chloramine B as oxidant, the desired aniline **II** was not detected in the reaction products at all. Therefore, all further studies were aimed to optimize a procedure for preparing aniline **II** in acetic acid using bromine as oxidant.

Table 1. Influence of the rate of bromine addition on the quality of crude 2-nitro-4-thiocyanoaniline. Reaction temperature 20°C; component dosage: 500 ml of acetic acid, 110.4 g (0.8 mol) of 2-nitroaniline, 250 g (2.5 mol) of potassium thiocyanate, and 176 g (1.09 mol) of bromine dissolved in 200 ml of acetic acid

240	98.11	Traces	0.21	1.65

Thiocyanation of aromatic amines with nascent thiocyanogen is usually performed at 0–5°C and only seldom at room temperature. Our studies showed that aniline **II** prepared at 18–20°C does not differ in the quality and yield from the product obtained at a lower temperature. Therefore, all the subsequent experiments on the development of the synthesis procedure were performed at room temperature.

It was found that removal of the residual amounts of the starting 2-nitroaniline and of by-products, bromonitroanilines, from the target products was difficult. On the one hand, to ensure more complete conversion of **I**, bromine was added in excess. At the molar ratio of **I** to bromine of 1.0 : (1.30–1.5), the resulting crude aniline **II** contained no more than 0.1% **I**.

On the other hand, to prevent formation of bromonitroanilines, thiocyanate was taken in excess. Experiments showed that the amount of ammonium or potassium thiocyanate should be 2.5–3.6 mol per mole of aniline **I**. In this case, an impurity of bromonitroanilines in the target product will be minimal. However, in the case of quick addition of bromine into the reaction mixture, the amount of thiocyanate dissolved in acetic acid can decrease considerably because of insufficient rate of its dissolution. In this case also significant amounts of bromoanilines can appear in the reaction mixture (Table 1).

We attempted to eliminate the formation of bromoanilines by preparing a solution of thiocyanogen in acetic acid in advance and adding it to the reaction mixture. For this purpose, a calculated amount of bromine was added dropwise to a suspension of potassium thiocyanate in acetic acid. The precipitate consisting of excess potassium thiocyanate and potassium bromide formed in the reaction was filtered off, and a solution of thiocyanoghen in acetic acid was used for the subsequent thiocyanation of aniline **I**. However, the resulting solution of thiocyanogen appeared to be unstable. In the course of storage and in the thiocyanation step, thiocyanogen partially polymerized with the precipitation of polymeric products.

Experiments showed that an increase in the time of bromine addition from 1 to 2–3 h led to a decrease in the content of by-product **III** in crude aniline **II** from 1.0 to 0.4%, with the content of other impurities also somewhat decreasing. Therefore, in the subsequent experiments the time of bromine addition was 3 h. An increase in the excess of potassium thiocyanate from 15 to 40% did not lead to a decrease in the amount of 4-bromoaniline **III** in the product obtained. Replacement of potassium thiocyanate by ammonium thiocyanate did not affect the yield and quality of **II**.

Becuase 4-thiocyanoaniline **II** is prone to hydrolysis under the action of moisture with the formation of the thiocarbamate and other degradation products, we examined its stability in concentrated hydrochloric and acetic acids, and also in the presence of moisture.

The stability of aniline **II** in hydrochloric acid was studied at room temperature in the course of 4 and 10 days (samples A and B, respectively). For comparison, we also obtained data on the system consisting of aniline **II** and 85% acetic acid, with the addition of the same amount of hydrochloric acid as in experiments A and B (experiment C). In this experiment, the storage time was 30 days. We found that acid hydrolysis results in accumulation in the starting compound

of an unidentified product whose content under the experimental conditions reached 4–5%. It should also be noted that the rate of accumulation of this impurity in weakly hydrated (99.5%) acetic acid was approximately two times lower than in concentrated hydrochloric acid.

Experiments performed to examine the effect of water on the product quality in the course of preparation of aniline **II** show that the use of even 95% acetic acid noticeably decreases its yield and also decreases the content of the desired compound in the crude product by 3–5%, which is mainly caused by accumulation of one of unidentified impurities whose amount in some experiments reached 8–9%. According to high-performance liquid chromatography, this impurity is identical to the product accumulating in the course of hydrolysis of thiocyanoaniline **II** in concentrated hydrochloric and 85% acetic acids.

In the course of optimization of the process for preparing aniline **II**, we examined the possibility of reusing the acetic acid filtrate for the synthesis of the crude product without preliminary regeneration of acetic acid. We found that, when acetic acid was replaced by the mother liquor from the previous experiment, the content of the desired substance in the crude product decreased from 95.8 to 78.4%, and the next reuse of this mother liquor led to a further decrease in the desired substance content to 68%, mainly owing to a sharp increase in the content of the same unidentified impurity: to 18 and 25%, respectively. Appreciable amounts (up to 2.8%) of 4-bromo-2-nitroaniline also accumulated in the crude product. The content of the other components did not change appreciably.

In the course of the studies, we tested two procedures for separating insoluble by-products in the course of the synthesis of thiocyanoaniline **II**. In the first procedure, after the reaction completion, the mixture was heated to 80°C, the insoluble precipitate was filtered off, and the filtrate was poured into a fourfold volume of cold water. The target product was isolated in 95.5% yield; it was 93.5% pure. In the second procedure, acetic acid was taken in a 2.5 times larger amount. In this case, it was unnecessary to increase the temperature. The precipitate after the reaction completion was filtered off, and thiocyanoaniline **II** containing up to 99% main substance was isolated from the filtrate in up to 60% yield with cold water.

The above-described methods for preparing pure 4-thiocyanoaniline **II** complicate the commercial process, decrease the product output from unit equipment, and make the regeneration of acetic acid more difficult. Attempts to stabilize thiocyanogen and hydrogen thiocyanate under the reaction conditions and thus to prevent formation of organosulfur by-products failed.

However, as shown previously [11, 12], the above-indicated by-products under the conditions of the synthesis of 4-amino-3,4'-dinitrodiphenyl sulfide (target product synthesized from **II**; the procedure for preparing **II** was developed with the aim of its synthesis) are either well soluble in the aqueous-alkaline reaction mixture or decompose to form water-soluble salts. Therefore, these by-products could be readily separated from 4-amino-3,4'-dinitrodiphenyl sulfide by washing.

The results of the synthesis of thiocyanoaniline **II** (Table 2) were checked on a semicommercial installation with a 160-l reactor. The data obtained (Table 3) show that the results of laboratory experiments are reproduced.

Thus, to prepare 2-nitro-4-thiocyanoaniline **II**, the water content of acetic acid used as solvent should not exceed 0.5%. Crude 2-nitroaniline whose water content may reach 25 wt % should be dried before use to a residual moisture content not exceeding 1–2%. The best results were obtained with bromine as oxidant. It was preliminarily dissolved in acetic acid on cooling. It is appropriate to perform the synthesis with slight cooling, so as to maintain the reaction temperature within 16–20°C. The molar ratio of 2-nitroaniline, bromine, and ammonium or potassium thiocyanate should be 1.0 : (1.33–1.43) : (3.4–3.6).

EXPERIMENTAL

2-Nitro-4-thiocyanoaniline **II** was prepared in a 2.0-l glass reactor equipped with a heat-exchange jacket, a thermometer, a dropping funnel, and a reflux condenser. The cooling agent cooled to the required temperature was fed to the reactor jacket from a thermostat, which allowed the preset temperature to be reliably maintained throughout the synthesis.

The thiocyanation progress was monitored by thin-layer chromatography on Silufol UV-254 plates.

The product quality was determined by high-performance liquid chromatography with a column packed with Bondapac C_{18} reversed phase. The compounds were detected with a UV detector at a wavelength of 254 nm. An Altex liquid chromatograph equipped with 25 cm × 4.6 mm stainless steel columns was used. The chromatograms were treated by the methods of internal area normalization.

Table 2. Results of the synthesis of 2-nitro-4-thiocyanoaniline on a laboratory installation.* Reaction temperature 20°C; dosage of components: 110.4 g (0.8 mol) of 2-nitroaniline, 250 g (2.5 mol) of potassium thiocyanate, and 160 g (1.0 mol) of bromine in 200 ml of acetic acid; time of adding the bromine solution 3 h

* The crude product was isolated by pouring the reaction mixture into 4000 ml of water.
** Instead of potassium thiocyanate, ammonium thiocyanate was used in an amount of (a) 2.6 and (b) 3.0 mol.

Table 3. Results of the synthesis of 2-nitro-4-thiocyanoaniline on a semicommercial installation. Dosage of components: acetic acid 50 l, 2-nitroaniline 15.5 kg, ammonium thiocyanate 25.5 kg, bromine 20.3 kg in 30 l of acetic acid; reaction temperature 18–20°C

Time, min		Product composition, wt %			Yield of crude **II**, %
of bromine addition	of additional stirring	2-nitro-4-thiocyano-aniline **II**	2-nitroaniline **I**	4-bromo-2-nitro-aniline **III**	
180	360	93.55	Traces	1.10	88.8
200	360	93.74	Traces	0.91	90.2
205	360	94.75	0.16	Traces	92.4
205	300	94.39	0.09	1.23	89.7
220	360	94.02	0.07	0.87	90.2
225	300	94.40	Traces	0.97	90.2
240	360	95.60	0.04	0.52	96.9
255	360	95.89	Traces	0.62	92.3

2-Nitro-4-thiocyanoaniline **II** was prepared as follows: To a solution of 110.4 g (0.8 mol) of 2-nitroaniline in 500 ml of acetic acid at 20°C, 250 g (2.5 mol) of potassium thiocyanate was added, after which a solution of 176 g (1.09 mol) of bromine in 200 ml of acetic acid was added with stirring from a dropping funnel over a period of 3 h. After adding the whole amount of bromine, the mixture was stirred at 20°C for an additional 3–4 h.

Thiocyanation was performed until 2-nitroaniline was detected in the reaction mixture in trace amounts. Therefore, if necessary, an additional amount of bromine was added in the course of stirring after introduction of the prescribed amount. After the residual 2-nitroaniline content decreased to the prescribed level (≤0.1%), the reaction mixture was heated to 80°C, the precipitated impurities were filtered off, and the filtrate was poured into a fourfold volume (4 l) of cold water. The precipitate formed in the process was filtered off and washed on the filter with water until the content of bromide ions in the wash water decreased to the trace level.

Semicommercial synthesis of 2-nitro-4-thiocyanoaniline **II** was performed in a 160-ml enameled react-

or equipped with a heat-exchange jacket, a bottom discharge pipe, a stirrer, a reflux condenser, and a thermocouple. The reactor with the operating stirrer was charged successively with 50 l of acetic acid, 15.5 kg of preliminarily dried 2-nitroaniline, and 25.5 g of ammonium thiocyanate. The temperature inside the reactor was maintained at 18–20°C by feeding cold water into the jacket. The mixture was stirred at this temperature for 30 min. After that, a solution of 20.3 kg of bromine in 30 l of acetic acid was added to the reactor from a dosing unit over a period of 3–4 h. In the process, the temperature in the reactor was maintained at 16–20°C. After adding the whole amount of bromine, the mixture was stirred at the same temperature for an additional 5–6 h. In the course of adding the bromine solution and subsequent stirring, the thiocyanation progress was monitored by thin-layer chromatography.

After the thiocyanation completion, the reactor contents were heated to 80°C, the precipitated impurities were filtered off, and the filtrate was diluted with cold water by a factor of 4 in a mixer. After stirring, the suspension was poured onto a nutsch filter, squeezed, and washed with water until the content of bromide ions in the wash water decreased to the trace level. The washed and well squeezed product was dried at a temperature not exceeding 60°C.

CONCLUSIONS

(1) Thiocyanation of 2-nitroaniline with ammonium or potassium thiocyanate in acetic acid in the presence of bromine as oxidant was studied as a preparative route to 2-nitro-4-thiocyanoaniline. The parameters of the thiocyanation process were optimized.

(2) The developed procedure for preparing 2-nitro-4-thiocyanoaniline was tested on a semicommercial installation.

Abstract—Kinetics of polyvinylidene fluoride etching with a permanganate alkaline solution used in manufacture of track membranes from hydrogen-containing fluoropolymers, and also products formed in the process, were studied in relation to temperature and relative content of mixture components.

DOI: 10.1134/S1070427208030245

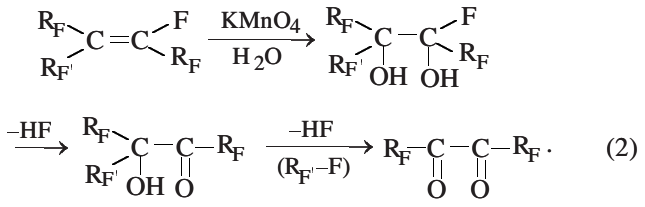
A particular place among the wide variety of polymeric membranes used in modern technology is occupied by track membranes (TMs). They are distinguished by narrow pore size distribution, precisely preset pore radius, and possibility of wide variation of their porosity, pore shape, and other structural parameters [1, 2]. The manufacture of TM from polycarbonate (PC) and polyethylene terephthalate (PET) films was commenced on the industrial scale in the 1970s–1980s. The membranes are produced by chemical etching with alkaline solutions of a polymeric film irradiated with accelerated ions. The PET and PC track membranes have found use in biotechnology, medicine industry, water treatment, etc. At the same time, there are promising areas in which PET and PC track membranes cannot be effectively used because of their insufficient chemical stability. By contrast, the unique chemical stability of TMs based on fluoropolymers enables their use in corrosive media, with multiple regeneration possible.

Among the industrially manufactured fluoropolymeric films, the most suitable material for fabrication of TMs is polyvinylidene fluoride (PVDF) [3].

Hydrogen-containing fluoropolymeric films irradiated with heavy ions are commonly etched with a hot alkaline solution of potassium permanganate. The etching conditions were first suggested in [4]; however, the chemical processes by which tracks are etched have not been studied in detail, primarily because of the complexity of processes occurring in this redox system. The etching of tracks in PVDF with a concentrated caustic alkali solution has also been described in the literature [5]. Under these conditions, i.e., in the absence of a strong oxidizing agent, the etching is substantially slower. The mechanism of interaction between the polymer and the alkali and the composition of the products obtained have not been determined, either.

So far, fluoropolymeric TMs have been produced only in laboratory. Development of a technology for manufacture of fluoropolymeric TM requires that the chemical processes occurring in their etching should be studied. It is necessary to know the main products formed in oxidative etching of fluoropolymers in order to, first, have at least a rough notion of the stoichiometry of the chemical reaction and, second, obtain input data for the development of appropriate procedure for waste utilization.

In the early development of the chemistry of fluoro compounds as far back as the 1950s, a number of studies concerned with oxidation of fluorinated hydrocarbons were carried out [6–11]. In the absence of modern analytical methods, the authors of these studies used procedures of preparative organic chemistry and, while working with gram amounts of substances, could identify a number of oxidation products of partly fluorinated hydrocarbons. These studies furnished valuable data on the conditions and mechanism of the dehydrofluorination occurring under the action of concentrated alkalis and on oxidation of double bonds formed in dehydrofluorination. A characteristic feature of the oxidation reactions studied is their non-



stoichiometric nature. In addition to the main product frequently formed in 70–80% yield, other products are also obtained in various proportions. This means that there occur several parallel reactions with comparable probabilities. The degree of conversion commonly depends on the time during which the reaction is carried out. The yield of the main product may markedly vary as temperature is changed by 10°C [12].

Studies carried out with low-molecular-weight organic compounds of fluorine revealed the following fundamental aspects of their reaction with NaOH and $KMnO_4$.

It was found that, if the fluorocarbon chain contains at least a single hydrogen atom, the dehydrofluorination reaction occurs in the liquid phase rather easily even at a moderate concentration of hydroxide ions [13]:

$$-CF_2-CF_2-CHF-CF_2- + OH^- \rightarrow -CF_2-CF=CF-CF_2- + F^- + H_2O. \quad (1)$$

When oxidized by potassium permanganate, fluoroolefins are converted into carbonyl compounds (α-hydroxy ketones or diketones, depending on substituents at the C=C bond) via intermediate geminal fluorocarbinols by the following scheme [14]:

(2)

Under homogeneous conditions (mixture of water and acetone as a solvent), this reaction occurs at room temperature. At high temperature, the action of potassium permanganate leads to a deeper oxidation with rupture of the C=C bond [10]. Prolonged action of $KMnO_4$ on fluoroolefins at approximately 100°C oxidizes in high yield both carbon atoms of the C=C bond to carboxy groups. For example, octafluorocyclohexa-1,4-diene oxidized with concentrated $KMnO_4$ at 95°C for 17 h gives difluoromalonic acid [15].

In [15], etching of tracks produced by heavy ions in PVDF was described and an attempt was made to determine the predominant chemical changes in the polymer under the action of a permanganate–alkaline etchant. A comparison of the IR spectra of the PVDF film, measured before and after the treatment, demonstrated that the alkali treatment leads to dehydrofluorination of PVDF and accumulation of double bonds, including conjugated bonds. Presumably, concentrated alkali can rupture the backbone of PVDF, which is identified by the appearance of terminal fluorovinyl groups $-CH=CF_2$. Acid –OH groups (contained in the carboxy group) are clearly identified. Under the action of the permanganate anion, double bonds within the chain are ruptured. The strong absorption at 1754 cm^{-1}, presumably associated with carboxylic acids of the structure $\sim CF_2-CH_2-COOH$ or $\sim CH_2-CF_2-COOH$, is preserved.

Studies by ESCA, Raman spectroscopy, and secondary-ion mass spectrometry have shown that conjugated double bonds are accumulated in PVDF under the action of an alkali [16, 17]. Because, as already noted, each double bond must be oxidized with backbone rupture, it is natural to assume that PVDF decomposes in hot alkaline permanganate solutions to complete mineralization. Complete PVDF oxidation in an alkaline permanganate solution can be represented by the equation

$$3(-CH_2CF_2-) + 8MnO_4^- + 10OH^- \longrightarrow CO_3^{2-} + 8MnO_2 + 8H_2O + 6F^-. \quad (3)$$

According to published data [6], the manganate ion MnO_4^{2-} is formed in a concentrated alkali in the presence of an excess amount of MnO_4^-:

$$4MnO_4^- + 4OH^- \longrightarrow 4MnO_4^{2-} + 2H_2O + O_2. \quad (4)$$

If reaction (4) occurs under the conditions of the experiment, the corresponding equation of the oxidation of polyvinylidene fluoride by manganate takes the form

$$(-CH_2CF_2-) + 4MnO_4^{2-} \longrightarrow 2CO_3^{2-} + 4MnO_2 + 2F^- + 2OH^-. \quad (5)$$

It can be assumed that the main part of PVDF is decomposed to complete mineralization, possibly in accordance with these equations. Presumably, other oxidation products can only be present as impurities.

Because there is no common standpoint concerning the mechanism of PVDF etching in an alkaline permanganate solution, the aim of this study was to identify the main inorganic products of PVDF oxidation and measure the stoichiometric coefficients of the presumed reaction.

EXPERIMENTAL

The study was performed with a polyvinylidene fluoride film of thickness 9 μm, manufactured by Kurecha Chemical Industries Co., Ltd. (Japan). Under the real conditions of TM production, the weight amount of the polymer per unit volume of the etching solution is commonly too small for further analysis. Therefore, the PVDF etching was studied at very high polymer concentrations in the solutions: 0.5, 1.0, and 1.5 g per 50 ml of the solution. Weighed portions (10.00 g) of $KMnO_4$ were placed in Teflon vessels, 50 ml of a 3.3 M solution of NaOH was added, and PVDF was introduced in the form of a finely cut film. The vessels were hermetically closed and placed in a thermostat heated to 115°C. The process was performed to complete dissolution of the PVDF film, which took no less than 24 h. To preclude the possible mechanical degradation of the polymer, the reaction mixture was not agitated. Because potassium permanganate decomposes at high temperatures in an alkaline medium, a blank experiment was performed under the same conditions, with the same $KMnO_4$ + NaOH solution heated without PVDF. After the dissolution process was complete, the vessels with the reaction mixture were removed from the thermostat, cooled to room temperature, and opened. The contents of the vessel were transferred to 250-ml volumetric flasks and diluted with distilled water to the mark. In the resulting solution, the expenditure of potassium permanganate and hydroxide ions and the amounts of the forming manganese dioxide and carbonate ions were determined.

The amount of the permanganate remaining in solution after the etching reaction was complete was determined by titration with oxalic acid in an acid medium. A 0.05 M solution of the titrant was prepared by dissolving a precisely weighed portion (6.303 g) of reagent-grade $H_2C_2O_4 \cdot 2H_2O$, preliminarily dried at 105–110°C, in a 1-l volumetric flask in the course of 2 h. In titration, 1 ml of the titrant solution is equivalent to a content of 0.1 mg-equiv of $KMnO_4$, or 3.161 mg, in the solution being titrated. To determine the amount of the permanganate, an aliquot of the solution (1–2 ml) was placed in a beaker flask, 10 ml of 1 M sulfuric acid was added, and the mixture was heated to 70–80°C and titrated with an oxalic acid solution. The reaction completion was judged from the disappearance of the coloration of the solution being titrated [18].

The amount of manganese dioxide in the reaction mixture was determined by weighing on an analytical balance the precipitate filtered off and dried at 165°C to constant weight. Because there was doubt concerning the possibility of determining the content of manganese dioxide gravimetrically, the precipitate formed upon etching and MnO_2 obtained by reaction of potassium permanganate with oxalic acid in a neutral medium were subjected to a differential-thermal analysis.

The precipitates were thoroughly washed to remove the solution and dried in air for several days. The analysis was made on an STA-449 Netzsch instrument in the atmosphere of argon, with heating to a temperature of 1000°C at a rate of 5 deg min^{-1}.

The heating curve of the precipitate comprises three and two portions of fast and slow loss of mass, respectively. Approximately in the range from 75 to 163°C, there occurs loss of water, which is accompanied by a rather pronounced endothermic peak. Upon further heating, two additional minor endothermic peaks, accompanied by the weight loss, appear in the curve at 544 and 772°C. The first of these presumably corresponds to decomposition of MnO_2 to Mn_2O_3 (which occurs at 506–735°C), and the second, to the onset of Mn_2O_3 decomposition to Mn_3O_4 (at 796–932°C). The thermogram of manganese dioxide, measured for comparison, was virtually identical to that of the precipitate under study, which confirms that $KMnO_4$ is reduced to manganese dioxide, stable under the given conditions, in the course of PVDF etching. These results validate the assumption that the MnO_2 precipitate is unsuitable for precise gravimetric determinations. The rather large amount of water retained by this compound and its thermolysis hinder obtaining this compound in a weighable form. However, prolonged drying of the precipitate at 165°C to constant weight and its subsequent rapid weighing on analytical balance make it possible to consider the precipitate mass reliable.

The amount of hydroxide ions remaining in solution after the etching reaction is complete was determined by titration with 0.1 M nitric acid prepared using the reference sample. The titration was performed potentiometrically with a SCHOTT-Geräte Titroline-96 instrument, with a combined glass electrode. This method also enabled differential titration of OH^- and CO_3^{2-} ions in solution.

In titration with a standard acid solution of a solution of simultaneously present alkali and carbonate, the reaction occurs in two stages:

$$OH^- + CO_3^{2-} + 2H^+ = HCO_3^- + H_2O \text{ (stage I)},$$

$$HCO_3^- + H^+ = CO_2\uparrow + H_2O \text{ (stage II)}.$$

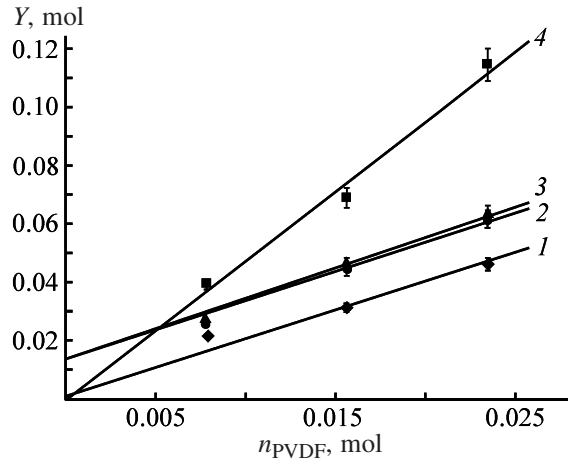


Fig. 1. Variation of the amount of the starting reactants and reaction products, *Y*, with the amount of dissolved PVDF: (*1*) accumulation of CO_3^{2-} groups, (*2*) consumption of $KMnO_4$, (*3*) accumulation of MnO_2, and (*4*) consumption of NaOH.

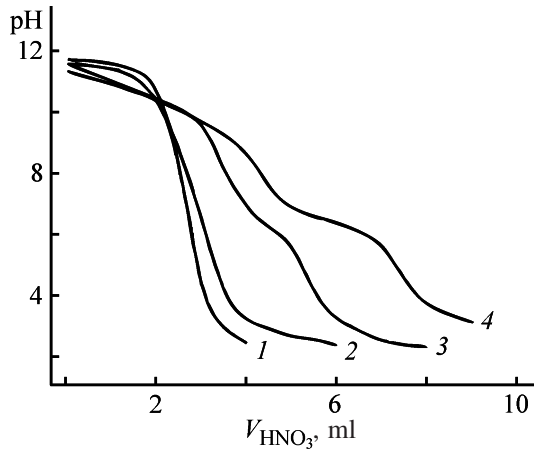

Fig. 2. Potentiometric titration curves of model solutions of a mixture of NaOH and K_2CO_3. NaOH : K_2CO_3 molar ratio: (*1*) 1 : 0, (*2*) 5 : 1, (*3*) 1 : 1, and (*4*) 0.5 : 1. (V_{HNO_3}) Volume of 0.1 M HNO_3; the same for Fig. 3.

By the end of the first stage, pH is 8.3, and by the end of the second, pH is 3.8. Potentiometric titration makes it possible to find from the titration curve, after it is differentiated and the first derivative is determined, the points of the steepest drop in the pH value, the first of which corresponds to the concentration sum $[OH^-] + [CO_3^{2-}]$, and the difference between the first and second, to the concentration of CO_3^{2-} ions [19].

The dependence of the loss of potassium permanganate on the amount of dissolved polymer is shown in Fig. 1 (curve *3*). A mathematical processing of the results obtained in three sets of experiments demonstrated that the molar expenditure *Y* of permanganate ions for PVDF dissolution can be expressed by a linear dependence of the amount *x* of the polymer (also expressed in moles):

$$Y = A + Bx,$$

where *A*, found to be 0.013 ± 0.003, is the average amount of $KMnO_4$ decomposed in a blank run (without contact with PVDF); the slope ratio $B = 2.0 \pm 0.2$ is the average amount of $KMnO_4$ spent for dissolution of a mole of PVDF.

The amount of the MnO_2 precipitate extracted from the reaction mass after the dissolution of the polymer is shown in Fig. 1 (curve *2*). It can be seen that the accumulation of manganese dioxide can also be approximated with a linear dependence on the amount of degraded PVDF. The slope of 2.0 ± 0.2 corresponds to the average amount of MnO_2 formed from potassium permanganate in etching of a mole of PVDF, and the quantity *A*, corresponding to precipitate formation in a blank experiment, is 0.013 ± 0.003 mol.

Thus, the amount of the permanganate spent in the course of etching exactly corresponds to the amount of the manganese dioxide precipitate formed from it. Such a coincidence can serve as additional evidence that the permanganate is completely reduced in the course of etching to MnO_2, which is stable under the given conditions.

The amounts of hydroxide ions spent in the course of etching and of the carbonate ions formed were calculated by differentiation of pH variation curves obtained in potentiometric titration of aliquot portions of the reaction mixtures. To analyze the capabilities of this method, we preliminarily titrated model solutions containing a mixture of a hydroxide and carbonate in various proportions (Fig. 2). It was found that, at a low content of CO_3^{2-} ions on the background of OH^-, this method fails to reveal the second step of a steep drop in pH in the titration curve. However, at comparable amounts of OH^- and CO_3^-, the run of the titration curves becomes quite suitable for processing and calculation of the amounts of these ions in the solutions being titrated.

Figure 3 shows typical potentiometric titration curves of aliquot portions of the NaOH solution used to prepare the working solution, blank NaOH + $KMnO_4$ solution warming-up under the experimental conditions, and reaction mixtures formed upon etching of various amounts of PVDF.

The amount of the acid, consumed for separate titration of CO_3^{2-} and OH^- ions, found from these

plots, made it possible to calculate their concentrations as functions of the amount of dissolved PVDF and to plot the corresponding curves (Fig. 1, curves *1* and *4*). It can be seen that, in both cases, the molar expenditure of the alkali for PVDF dissolution and the amount of carbonate ions formed in the reaction linearly depend on the amount of the polymer (also given in moles).

The formation of carbonate ions is described by a straight line with a slope of 1.9 ± 0.3, which emerges from the origin of coordinates, in good agreement with the assumption of complete oxidation of carbon contained in the polymer chain of PVDF.

The expenditure of the hydroxide for PVDF etching is described by a linear dependence with [NaOH] : [PVDF] = 4.8 ± 0.6.

To take into account the influence exerted by the reaction conditions on the decomposition of the etching solution, not associated with the dissolution of the polymer, we carried out a set of blank runs with a solution containing no PVDF film, which was heated to 115°C for various intervals of time, comparable with the etching time. The permanganate decomposition in the course of time is described by a linear dependence (Fig. 4). Even though the amount of the decomposed permanganate is small compared with its expenditure for PVDF etching, it reaches 20% upon prolonged heating for 50 h. Thus, under the TM manufacture conditions, when the mass of the polymer in the etching bath is substantially smaller than that of the solution, the loss of the oxidizing agent may be largely due to its spontaneous decomposition.

Potentiometric titration of the same solutions to determine the amount of NaOH demonstrated virtually full coincidence of the titration curves, irrespective of the heating duration. This indicates that the reaction of potassium permanganate decomposition does not involve under the given conditions the hydroxide. Also noteworthy is that the curves show total lack of the second titration step pointing to presence of carbonate ions in these solutions. This indicates that, under the experimental conditions, there was no noticeable absorption of carbon dioxide from air by the working solution.

Mass-spectrometric analyses of extracts from the reaction mixture after complete dissolution of PVDF did not reveal any fluorinated organic compounds in concentrations measurable by this technique. This confirms the assumption that PVDF decomposes in concentrated solutions of $KMnO_4$ + NaOH to complete mineralization.

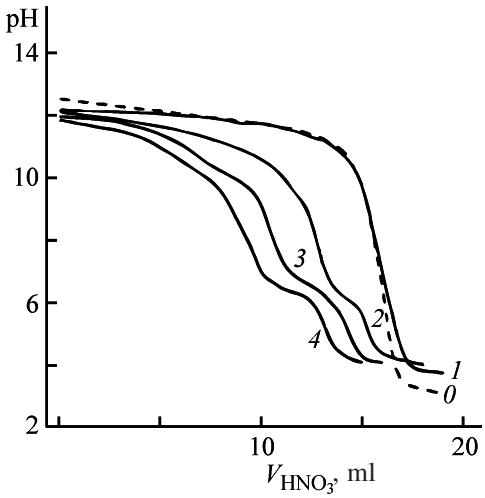

Fig. 3. Potentiometric titration curves of the starting solutions and reaction mixtures after PVDF dissolution. Solution composition, PVDF mass (g): (*0*) starting 3.3 M solution of NaOH, (*1*) blank solution, (*2*) 1.0, (*3*) 1.5, and (*4*) 2.0.

The table lists the experimentally found ratios between the consumption of the polymer and consumption/accumulation of the etching solution components in comparison with the ratios predicted by

Consumption of the etching solution components and accumulation of reaction products (moles per mole of consumed monomeric unit of the polymer) in comparison with those corresponding to reaction equations (3) and (5)

Data	$-KMnO_4$	–NaOH	$+MnO_2$	$+CO_3^{2-}$
Experiment	2.0 ± 0.2	4.8 ± 0.6	2.0 ± 0.2	1.9 ± 0.3
Calculation by equation:				
(3)	2.7	3.3	2.7	2.0
(5)	4.0	2.0*	4.0	2.0

* The consumption of the hydroxide for the formation of manganate in accordance with Eq. (4).

reactions (3) and (5). Noteworthy is the similarity between the experimentally found ratios and the coefficients of reaction (3). Nevertheless, the expenditure of sodium hydroxide markedly exceeds the value of 3.3 corresponding to Eq. (3). On the one hand, this difference may be due to the rather large experimental errors. On the other hand, a possible reason is occurrence of other reactions leading to degradation of PVDF. For example, it was shown in [17, 18] that PVDF is partly oxidized in concentrated hydroxide solutions (even without introduction of strong oxidizing agents), which results in that hydroxy and carbonyl groups appear in the polymer chain. It was found in [5] that treatment with concentrated alkali solutions at high temperatures enables slow etching of PVDF, i.e., provides rupture of the polymer backbone. Thus, it is not improbable that, under the experimental conditions, part of the hydroxide is expended for degradation of PVDF by a reaction other than reaction (3).

CONCLUSIONS

(1) It was found that, in alkaline solutions, polyvinylidene fluoride undergoes complete oxidation to carbonate ions.

(2) The coefficients characterizing the loss of components of the working solution and accumulation of manganese oxide and carbonate ions in manufacture of track membranes from polyvinylidene fluoride films were determined.

Received November 27, 2007

Abstract—Agglomeration of SKS-30 ARK latex particles using dispersions of butadiene–methyl methacrylate–methacrylic acid copolymer with various contents of methacrylic acid (up to 25 wt %) was studied.

DOI: 10.1134/S1070427208030257

Synthetic latexes with elevated content of the polymer (up to 60–65 wt %) are used in such branches of industry as production of foam rubber, some types of adhesives, etc. In turn, so high latex concentrations can be only attained at a rather large size of latex particles (~200–250 nm), because, at concentrating (e.g., by evaporation) highly dispersed latexes (50–100 nm particle size) commonly formed by emulsion polymerization, the system becomes paste-like and loses fluidity even at a polymer concentration of 40–45 wt %. Although modern procedures of emulsion polymerization allow preparation of latexes with relatively large particles, this is possible only at a very low polymerization rate, which is economically unfeasible. Preparation of latexes with common dispersion and their further agglomeration up to required particle size seem more promising.

Various methods of agglomeration are known, which in all the cases are related to controlled destabilization of latex particles with their subsequent coalescence and adhesion and stabilization to prevent irreversible coagulation yielding polymer macrophase [1]. Such procedures as agglomeration under pressure (mechanical agglomeration) and frosting–defrosting method are used in industry. However, these procedures, being rather complex, not only increase particle size but also broaden the particle size distribution. Chemical agglomeration caused by small (sensitizing) additives of water-soluble polymers {e.g., poly(vinyl methyl ether) [2], polyethylenepolyamine [3], etc.} is simpler in implementation. However, this procedure has not found wide application because of a significant drawback, prolonged aftereffect (i.e., continued agglomeration up to coagulation in storage of latex after its concentration).

A peculiar procedure based on latex agglomeration using a carboxyl-containing polymer was suggested in [4]. This procedure is simple and allows elimination of the aftereffect; the particles of such latex, being agglomeration nuclei, should lose the agglomeration activity upon formation of a layer of the main latex particles on their surface. However, despite principal possibility and advantages, this procedure has not been implemented on the industrial scale.

To develop scientific principles for industrial application of chemical agglomeration, it was advisable to perform a systematic study of the relationships and mechanisms of agglomeration using carboxylated latexes and to reveal various factors affecting this process.

Previously [5, 6] we demonstrated high agglomeration performance of BMK latex, which is a copolymer of butadiene, methyl methacrylate (MMA), and methacrylic acid (MAA) containing 10 wt % MAA, in agglomeration of adsorption-unsaturated latexes with various polymer phases (butadiene–styrene, –nitrile, vinylidene chloride, polybutadiene). The average particle size of the resulting latexes was 200–250 nm (in some cases up to 300 nm); they were characterized by low surface tension and retained fluidity upon evaporation up to a polymer concentration exceeding 60 wt %.

Table 1. Characteristics of latexes

Latex brand	Copolymer composition, wt %	Weight fraction of dry compound, %	Emulsifier	σ, mN m^{-1}	pH	Average particle size, nm
SKS-30 ARK	Styrene 30, Butadiene 70	23.0	K paraffinate and resinate	67.0	10.1	78
BMK-5	Butadiene 42, MMA 53, MAA 5	34.2	Sodium alkylbenzenesulfonate (Sulfonol)	56.5	4.3	91
BMK-7	Butadiene 41, MMA 51.5, MAA 7	33.0	Sodium alkylbenzenesulfonate (Sulfonol)	54.2	4.4	110
BMK-10	Butadiene 40, MMA 50, MAA 10	36.0	Sodium alkylbenzenesulfonate (Sulfonol)	55.0	3.3	105
BMK-15	Butadiene 38, MMA 48, MAA 15	34.4	Sodium alkylbenzenesulfonate (Sulfonol)	55.3	3.7	98
BMK-20	Butadiene 36, MMA 44, MAA 20	34.0	Sodium alkylbenzenesulfonate (Sulfonol)	53.0	3.8	102
BMK-25	Butadiene 33, MMA 41.5, MAA 25	33.5	Sodium alkylbenzenesulfonate (Sulfonol)	52.6	3.6	99

In this study we examined the dependence of agglomeration using BMK latex in relation to the degree of its carboxylation.

EXPERIMENTAL

We prepared samples of BMK latex with various contents of MAA in copolymer α_m (5–25 wt % MAA recalculated to the weight of the butadiene : MMA monomer mixture at their constant ratio of 2 : 8). The synthesis was performed with increased amounts of *tert*-dodecyl mercaptan (chain-terminating agent) to obtain short copolymer chains with high mobility of the molecules. Agglomeration was studied using SKS-30 ARK commercial butadiene–styrene latex. The characteristics of latexes are listed in Table 1. The surface tension σ of latexes was measured by the anchor–ring method on a Du Nouy apparatus, and the average particle size was determined by turbidimetry from the dependences of the optical density D on the wavelength [6]. The D values were measured on an FEK-56 M photoelectrocolorimeter. The solution pH was determined with an EV-74 pH-meter.

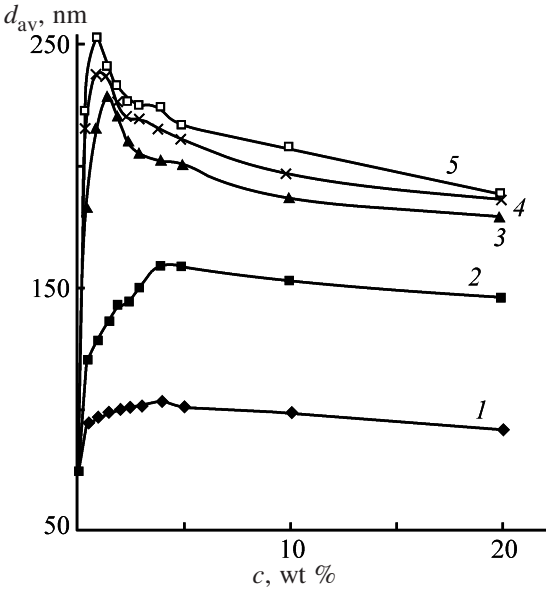

Fig. 1. Average particle size d_{av} as a function of the amount of BMK polymer c added into SKS-30 ARK latex. Degree of carboxylation n: (*1*) 5, (*2*) 7, (*3*) 10, (*4*) 15, (*5*) 20, and (*6*) 25.

A required volume of BMK latex (0.5–25.0 wt % copolymer relative to rubber) was added with stirring to a sample of SKS-30 ARK latex. After agglomeration completion (3–4 days), the optical density was measured and the average particle size d_{av} was calculated. The resulting dependences of d_{av} on the concentration of BMK are shown in Fig. 1. As can be seen, at a content of MAA in the copolymer α_m = 5 wt %, the agglomeration is inefficient and the average particle size increases insignificantly (from 80 to 105 nm). At α_m of 10, 15, 20, and 25 wt %, the dependences pass through a maximum at a concentration of agglomeration agent of 1–2 wt %, and the average particle size increases to 225–250 nm. The agglomeration performance of BMK-7 latex is intermediate between those of BMK-5 and BMK-10, and the average particle size increases to 160 nm upon addition of

4 wt % agglomeration agent. In general, the dependences shown in Fig. 1 illustrate a monotonic increase in the agglomeration effect of BMK latex with increasing degree of carboxylation (at MAA concentration of up to 25 wt %). At the same time, it should be noted that the concentration of BMK providing the maximal agglomeration effect is essentially independent of the degree of carboxylation and comprised 1–2 wt % relative to the rubber.

It was of particular importance to study the kinetics of agglomeration in relation to the degree of carboxylation of agglomeration agent. For this purpose, samples of SRS-30 ARK latex were mixed with the calculated amounts of BMK polymer with various degrees of carboxylation in amounts of 1 wt % per latex. Then samples of the reaction mixture taken in equal periods were stabilized with 1% solution of Sulfonol to prevent further particle growth, and the optical density was measured. The time dependences of the optical density are shown in Fig. 2. As seen, at MAA content of the copolymer of 5–7 wt % the optical density and, thus, the average particle size increase with time very slowly. At a higher content of MAA (10 wt % and more), D sharply increases within the first several tenths of seconds and then slowly increases up to a certain constant value in 3–4 days. The D values measured after storage for 10 days showed the absence of further increase in the optical density, i.e., the agglomeration aftereffect typical for water-soluble polymers was not observed at agglomeration of the latex dispersions using carboxylated polymers.

Sharp deceleration and subsequent termination of the particle growth suggest certain similarity of agglomeration with the first stage of coagulation of adsorption-unsaturated latexes under the action of electrolytes [7]. In both cases the absorption saturation of agglomerates increases, which is confirmed by a decrease in the surface tension of the systems observed both at coagulation [7] and agglomeration [6]. In the first case, coarsening of the particles is terminated owing to formation of a compact saturated adsorption-hydrated shell of surfactant-emulsifier on the surface of primary agglomerates and appearance of nonelectrostatic protection factor in addition to electrostatic repulsion [7]. Similar compaction of the adsorption layer should be observed in the second case. At the same time, the other mechanism of formation of the additional protection shell should be taken into account in the case of agglomeration using dispersions of the carboxylated polymer.

We assumed that, upon addition of agglomeration agent, the BMK globules become agglomeration centers at which the particles of the main latex are fixed. Further coalescence of these particles yields coarse agglomerates formed from the main and agglomerating polymers. Owing to significant molecular affinity to aqueous solutions and high molecular mobility of short polymer chains of the highly carboxylated reagent (BMK), these chains undergo spontaneous redistribution in the agglomerate bulk and become concentrated at the surface boundary. As a result, a thin layer of macromolecules of the highly carboxylated polymer is formed at the particle boundary, making the surface hydrophilic and imparting to it an additional electrical charge owing to fixed carboxylate anions. Both factors provide additional stabilization of the dispersions with coarsened particles and cause deceleration and termination of the agglomeration [5].

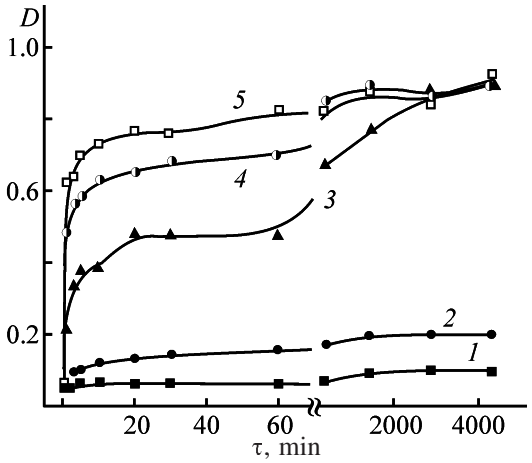

Fig. 2. Optical density D as a function of time τ in agglomeration of SKS-30 ARK latex using BMK polymer added in an amount of 1 wt % relative to rubber. Degree of carboxylation n: (*1*) 5, (*2*) 7, (*3*) 10, (*4*) 15, and (*5*) 20.

Using the data on the average particle size and composition of the initial and agglomerated latexes, we calculated their characteristics considering latexes as monodisperse systems. The degree of agglomeration was calculated as the ratio of the number of particles in the initial and agglomerated samples. The thickness of the film of highly carboxylated polymer on the agglomerate surface was calculated assuming that the BMK polymer is uniformly distributed over the particles of the agglomerated latex and is fully concentrated on their surface owing to diffusion. The results are listed in Table 2. It should be noted that the shell thicknesses given are the effective quantities which at incomplete saturation of the surface do not correspond to the actual size of macromolecules.

Our experimental data show that the highest degree

of agglomeration is attained when the amount of carboxylated latex added provides formation of a monomolecular layer (0.4–0.6 nm thick) of the highly carboxylated polymer on the surface of latex particles.

CONCLUSIONS

(1) Dispersions of highly carboxylated butadiene–methyl methacrylate copolymer provide effective agglomeration of butadiene–styrene latex without agglomeration aftereffect.

(2) The average particle size of agglomerates and the rate of agglomeration increase with increasing degree of carboxylation in the range of methacrylic acid content of the copolymer from 5 to 25 wt %.

Received January 16, 2007

Abstract—Condensation of vinyl- and vinylmethyl-1,1-dichlorocyclopropanes with formaldehyde in organic solvents of various polarities was studied.

DOI: 10.1134/S1070427208030269

Reaction of olefins with formaldehyde in the presence of acid catalysts (Prins reaction) is the main route to substituted 1,3-dioxanes [1–4]. This process is widely used in commercial synthesis of 4,4-dimethyl-1,3-dioxane whose cleavage yields isoprene [3]. The condensation is performed most frequently in an aqueous solution, but in this case it is accompanied by formation of hydroxyl-containing by-products: unsaturated alcohols, diols, hydroxyfurans, etc. [4].

To prepare dioxanes containing a *gem*-dichlorocyclopropane fragment, which can be of interest as biologically active compounds and intermediates for organic synthesis, we used the reaction of vinyl-*gem*-dichlorocyclopropanes **Ia** and **Ib** with formaldehyde in organic solvents (1,2-dichloroethane, chlorobenzene, 1,4-dioxane, diisopropyl ether) in the presence of catalytic amounds of H_2SO_4. The starting vinyl-*gem*-dichlorocyclopropanes are formed in virtually quantitative yield by the addition of dichlorocarbene to the corresponding dienes in a two-phase system [5].

We found that the reaction of **Ia** and **Ib** with formaldehyde yielded the coresponding 1,3-dioxanes (**IIa**, **IIb**) and 1,3-dioxolanes (**IIIa**, **IIIb**) in comparable amounts. Apparently, the highly reactive intermediate unsaturated alcohol reacts with formaldehyde to form a hemiacetal whose hydroxy group undergoes intramolecular adition to the double bond to form heterocycles **IIa**, **IIb**, **IIIa**, and **IIIb**:

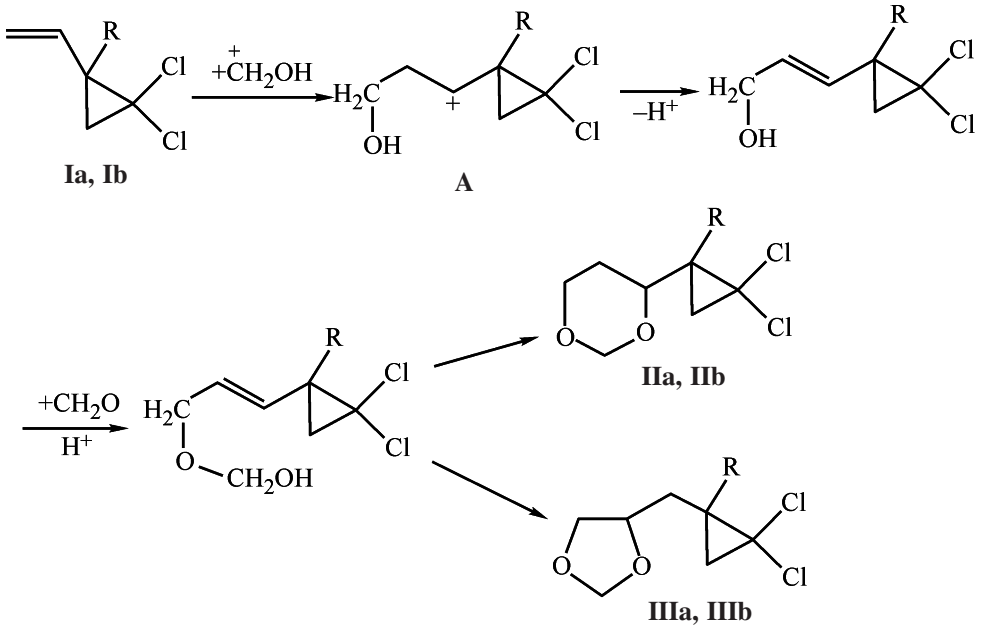

Table 1. Reaction of vinyl-*gem*-dichlorocyclopropanes **Ia** and **Ib** with formaldehyde. Molar ratio of **Ia** or **Ib** to CH_2O and H_2SO_4 1 : 2.5 : 0.5, 55°C, 3 h

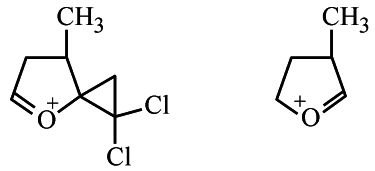
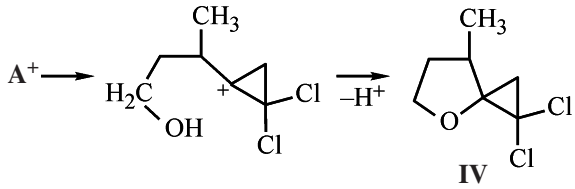


Solvent	Conversion, %		Selectivity, %			
	Ia	**Ib**	**Ia**	**Ib**	**Ia**	**Ib**
1,2-Dichloroethane	95	85*	40	50	35	35
Chlorobenzene	65	60	45	45	45	40
1,4-Dioxane	50	40**	70	50	40	20
Diisopropyl ether	95	90	75	60	35	20

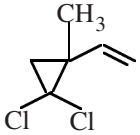
* More than 20% high-boiling unidentified products.
** About 5% low-boiling components.

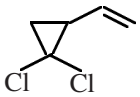


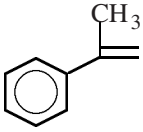
where R = H (**a**), CH_3 (**b**).

It is interesting that, in polar solvents (1,4-dioxane, diisopropyl ether), the selectivity with respect to 1,3-dioxanes **IIa** and **IIb** is somewhat higher than in chlorinated hydrocarbons (Table 1). Apparently, the ratio of the six- (**IIa**, **IIb**) and five-membered (**IIIa**, **IIIb**) products is determined by the rate of proton addition to carbon atoms of the double bond of the intermediate hemiacetal. In the isoprene derivative, the methyl group facilitates the formation of carbocations in which the positive charge is conjugated with the quasiaromatic orbitals of the three-membered carbocycle, which may be responsible for the observed prevalence the reaction pathway leading to the six-membered heterocycle.

The reaction with **Ia** in 1,2-dichloroethane yields more than 20% high-boiling unidentified products, which may be due to hindered cyclization of oligoformals and formation of noticeable amounts of polyformals. The condensation with **Ia** in 1,4-dioxane yields an impurity of low-boiling substances. The mass spectrum of one of them contains peaks of ions **B** and **C** with *m*/*z* 179 and 85, respectively. We believe that this minor component (1–1.5%) is spirocyclic compound **IV** formed by 1,2-migration of the methyl group and closure of the pyran ring in intermediate carbocation **A**:







B, *m*/*z* = 179 **C**, *m*/*z* = 85

IV

Sigmatropic shifts in the course of the Prins reaction were observed previously [6].

Table 2. Relative activity of olefins in the Prins reaction. Olefin : CH_2O : H_2SO_4 molar ratio 1 : 2.5 : 0.5, 55°C, 30 min, solvent $(i\text{-Pr})_2O$

Compound	Relative activity
	1
	2.5
	0.5
	15

The activity of olefins **Ia** and **Ib** was compared with that of 1-heptene and styrene in competitive reactions. The relative activity of these unsaturated compounds was judged from the rates of formation of 1,3-dioxacyclanes **IIa**, **IIb**, **IIIa**, and **IIIb** and of 4-amyl- and 4-methyl-4-phenyl-1,3-dioxanes which are selectively formed from 1-heptene and α-methylstyrene, respectively [1]. The activity of the aromatic olefin exceeds that of **Ia** by more than an order of magnitude, and compound **IIa**, in turn, is two times more active than the terminal linear unsaturated hydrocarbon (Table 2).

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Bruker AM-300 spectrometer (300 MHz) in acetone-d_6, $CDCl_3$, or C_6D_6 + CCl_4. GLC analyses were performed on a Tsvet-500M device (flame ionization detector, 5 × 1000-mm metal column, stationary phase 5% SE-30 on Chromaton N-AW, programmed heating from 50 to 220°C at a rate of 6 deg min^{-1}, carrier gas helium).

Vinyl-*gem*-dichlorocyclopropanes **Ia** and **Ib** were prepared by the published procedure [5]. The unsaturated compounds used in the study were no less than 99% pure.

Acid-catalyzed reaction of olefins with formaldehyde (general procedure). A solution of 0.1 mol of appropriate olefin in 10 ml of appropriate solvent was added with vigorous stirring to a mixture of 7.7 g (0.26 mol) of paraform, 3.1 ml of concentrated H_2SO_4, and 5 ml of the solvent. The mixture was heated to 50–60°C, with the stirring continued, until the paraform dissolved completely. After cooling, the mixture was neutralized with aqueous ammonia, the organic layer was separated and dried over $CaCl_2$, and the solvent was evaporated. The products were isolated by column chromatography on silica gel (eluent hexane–ethyl acetate, 6 : 1).

Some characteristics of the synthesized compounds are given in Table 3.

CONCLUSION

Condensation of vinyl- and vinylmethyl-*gem*-dichlorocyclopropanes with formaldehyde in organic solvents of various polarities was performed. The reaction occurs along two parallel pathways, yielding the corresponding 4-*gem*-dichlorocyclopropyl-1,3-dioxolanes and -1,3-dioxanes via the intermediate unsaturated alcohol.

Abstract—A procedure of suspension polymerization and copolymerization in a medium of thermally reversible gels was developed.

DOI: 10.1134/S1070427208030270

Three-dimensional radical bulk copolymerization of divinylbenzene with a series of vinyl monomers was studied previously [1]. To prepare spherical particles based on these copolymers, a new procedure of polymerization in a gel medium was suggested [2, 3].

This work was aimed to prepare spherical particles of copolymers of *p*-divinylbenzene (DVB) with styrene (St) and diethyl fumarate (DEF) by suspension copolymerization in a gel medium. Since the matrices of these polymers should serve in future to produce sorbents, in the reaction we used diluents favorable for the formation of the porous structure of the copolymers (CPs).

EXPERIMENTAL

The solvents [octanol (OC), toluene (T)], monomers (St, DVB, DEF), and initiators [benzoyl peroxide (BP), azobis(isobutyronitrile) (AIBN)] were purified by the procedures described previously [1]. The linear copolymer St–DEF used as polymeric diluent for creation of the porous structure was synthesized by bulk polymerization (Table 1, run no. 1).

Copolymerization in a gel was performed as follows. To dissolve methyl cellulose (MC), it was poured over with hot distilled water; after swelling for 20 min, cold water was added and MC was dissolved with stirring over a period of 5 h at 292 K. Copolymerization of the monomer mixture in a gel was performed by dispersion of the monomer mixture in an aqueous solution of MC at 292–298 K with subsequent heating at a temperature above the gelatinization point up to the polymerization point (333–363 K). The monomer mixture was added dropwise through an extrusion nozzle into a flask filled with an aqueous solution of MC, with continuous stirring on a laboratory shaker at 293 K. A stable system of drops uniform in size is formed in the MC solution. This system does not separate into layers during a period of more than 30–60 min. Within 10 min, the MC gel is formed. The reaction vessels with the dispersion of drops were purged with argon and placed into a thermostat at 333–363 K. The gelatinization time of the MC solution was 10–15 min. Then, the polymerization proceeded in drops immobilized in the MC gel. After the reaction completion, within a certain time, the reaction mixture was cooled to 293 K; in so doing, the gel melted and granules were separated from the dispersion medium (DM) by decantation. The polymerization was carried out in an inert medium. Finer particles (from 0.1 to 1 μm) were separated by repeated decantation. The polymer was washed with cold water to remove MC, with acetone, and with diethyl ether to remove the unchanged monomer, solvent, and sol fraction. Then, the polymer was dried to constant weight. The yield of spherical particles was determined gravimetrically.

The true density of CPs was determined by the pycnometric method in hexane. The coefficient of volume swelling K_s is

$$K_s = V_s/V_0,$$

where V_s is the volume of the swollen polymer and V_0 is the polymer volume before swelling.

The molecular weight of segments between crosslinks M_c was determined by the equilibrium swelling method. The sol–gel analysis of CPs was performed

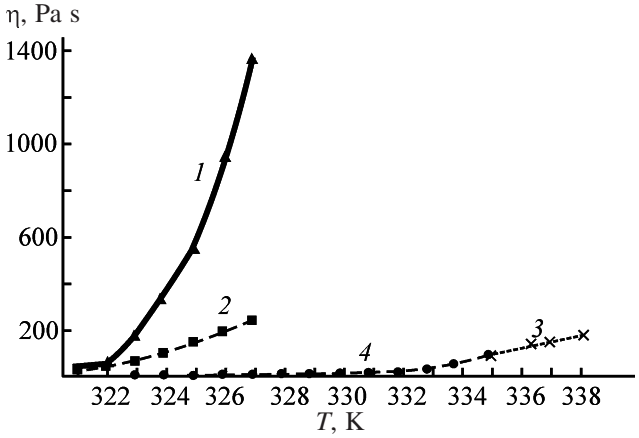
by extraction with acetone in a Soxhlet apparatus. The samples obtained in run nos. 4–6 were examined by elemental analysis and IR spectroscopy (Specord 75-IR, KBr pellets).



The concentration of aqueous MC solution was varied from 1 to 6 wt %. At a higher MC concentration, the solution viscosity exceeds 600 cP, which hampers the dispersion. At lower MC concentrations, the gel does not hold the drops of the monomer mixture.

The procedure of polymerization in a gel medium does not require stirring of the polymerizate during the process. In so doing, thermally reversible gels such as methyl cellulose, carboxymethyl cellulose, agar-agar, etc., are used. We performed the reaction in the methyl cellulose gel; the range of its gelatinization is shown in the figure. In the presence of sodium chloride, the gel is formed at lower temperatures. With increasing concentration of methyl cellulose, the gelatinization temperature decreases.

When the classical variant of suspension polymerization is realized below and in the gelatinization point, the dispersion system is unstable, which results in formation of coarse particles and irregular-shaped clots [4]. In the initial stage, a fairly narrow drop size distribution is reached, but coalescence results in particle consolidation and the particle size distribution becomes broad.

Polymerization in a gel implies that the dispersion of drops before polymerization and the polymerization proper are separated in time. The monomer drops having the required size are subsequently immobilized in the gel, and each drop is separated by the gel medium. During and after the gel formation, the dispersion system should not be stirred, so that the gel will not be destroyed under mechanical stress.

As a gel medium we used an aqueous solution of MC, which undergoes gelatinization under heating in the range from 308 to 329 K to form a turbid heterogeneous moderately dense gel holding drops of the monomer mixture. With decreasing temperature to 298–219 K, the gel is destroyed. The polymer structure is formed even in the stage when monomer drops dispersed in the gel are formed. There is no coales-

cence of particles in the stage of polymerization. The yields of spherical polymeric particles in linear (Table 1, run no. 1) and three-dimensional (run no. 2) copolymerization in diluent are practically the same. As reaction time is increased, the yield of the polymer increases (runs nos. 2, 3).

As already mentioned, the aim of this study was to synthesize copolymers in the form of spherical particles; therefore, we first considered the influence of the reaction conditions in the gel on the yield of copolymers (Table 1, run nos. 4, 5). The experiments were performed with BP and AIBN (run nos. 4, 5, 7–9). After spherical particles of the copolymers with the size of 50 μm were obtained under conditions of traditional suspension polymerization (Table 1, run no. 6), we performed experiments on polymerization in a gel to obtain the same particle size with BP (runs nos. 10, 11). It was found that BP decreases the yield of copolymers; therefore, further experiments were performed with AIBN. Increase in the process temperature and time favors an increase in the yield. In 2 h (Table 2, run nos. 9, 12) we obtained copolymers having spherical particles in a yield of up to 70%. To form copolymers with porous structure, we performed polymerization in the MC gel medium in the presence of polymeric (Table 1, run nos. 8, 9) and low-molecular-weight (Table 1, run no. 13) diluents. The yield of spherical particles of the copolymers is from 66 to 80%. In the ternary system of monomers (Table 1, run no. 13), the yield of CPs is 80% (diluent OC).

During polymerization in a gel, the forced convection mass transfer is excluded. According to data of optical spectroscopy, the drops of the monomer mixture have a size exceeding 30 μm. The phase boundary in the system is limited in area, and the diffusion process alone cannot affect significantly the AIBN concentration in drops of the monomer mixture in 2 h. With decreasing concentration of the initiator, the yield of CPs decreases and its swellability increases.

In polymerization in gel for a longer time, the yield of spherical uniform particles with a size from 46 to 123 μm was up to 80% (Table 1, run no. 13). The yield of the gel fraction of the polymers obtained in the solution was 66 wt % (run no. 2).

Polymerization in gel a proceeds in monomer drops by the mechanism of radical polymerization in the bulk. The relative activity of DVB is 0.43, and that of St, 0.5. The relative activity of monomers in the system DVB–DEF is as follows: DVB 0.15 and DEF 0.001 [1].

Polymers obtained by polymerization in a gel have narrow particle size distribution (Table 2), whereas suspension polymerization (Table 1, run no. 6) is characterized by broad particle size distribution despite the additional stabilization of the dispersion system with gelatin.

As mentioned above, in this study polymerization in a gel was performed with the aim to obtain porous matrices. It was important to exclude mechanical action on the polymerizate at the onset of porous structure formation. In so doing, we used the copolymer of styrene with DEF as a diluent (Table 1, runs nos. 8, 9). The developed porosity can be obtained at a low concentration of the polymeric diluent. The use of various polymers of vinyl monomers as diluents is well known [5]. However, we found no studies in which polymeric and low-molecular-weight diluents were present simultaneously. Run no. 12 was performed under the same conditions in the absence of polymeric diluent. According to Table 2, the yields of CPs are governed to a greater extent by the reaction temperature and time.

The presence of a band at 990 cm^{-1} in the IR spectrum of CPs confirms the presence of DVB units in CPs. The band at 1510 cm^{-1} confirms the presence of St units. From the ratio of intensities of the absorption bands at 840 (double bonds) and 990 cm^{-1} (aromatic ring of DVB), we determined the ratio between pendant (free) double bonds (unchanged vinyl groups in DVB units) in CPs and *para*-substituted aromatic rings of DVB units. It was found that 30–40% of double bonds in DVB units were unchanged.

In the presence of a diluent, copolymers are formed in the form of white opaque particles, which is caused by their porous structure. Without blowing agent, transparent solid spherical glass-like particles were obtained. The samples obtained in a gel and in OC

Table 3. Characteristics of three-dimensional CPs synthesized in a gel

Run no.	Bulk density, g cm^{-3}	K_s (in toluene)	M_c,* g mol^{-1}
4	0.43	3.9	2242
5	0.18	2.7	473
6	0.27	1.9	342
7	0.28	2.6	858
9	0.16	2.6	694
10	0.26	2.7	774
13	0.62	1.8	1080

* Molecular weight of chain segments between cross-links.

diluent (Table 2, run no. 2) show somewhat better swelling (Table 3) than CPs synthesized by copolymerization in suspension. Under conditions of suspension copolymerization in a gel, cross-linking proceeds efficiently. In suspension polymerization in a gel, the forced convection is excluded and atmospheric oxygen does not penetrate into the gel. The samples obtained by suspension copolymerization in an argon medium (run no. 8) and in the course of copolymerization in a gel have close swelling ability with respect to M_c value (Table 3). There are ten styrene units between cross-links; the network is dense.

The diluent (a mixture of OC and T) forms pores, since under the conditions of precipitation polymerization the polymer separates out from the reaction mixture and has a dull white color. The polymer obtained in the diluent dissolving only the monomer (run no. 2) is brighter. The polymeric porophore (linear CP of styrene with DEF in an amount of 5 wt %) should favor formation of the porous structure since it promotes syneresis in the earlier stages of the copolymerization and increases the viscosity of the reaction mixture. In addition of the polymeric diluent, the swellability of CPs increased insignificantly. The regularly shaped spherical granules were formed. The particle size of CPs is governed by the reaction conditions (Table 2) and varies from 60 to 130 μm.

The density of porous copolymers St–DVB is 1.12 ± 0.19 g cm^{-3} and corresponds to fairly dense packing. The bulk density of porous samples of CPs varies from 0.11 to 0.43 g cm^{-3} and characterizes these samples as porous polymers. The pore volume is from 1.25 to 3.2 cm^3 g^{-1}, which corresponds to the developed porous structure. Under the conditions of polymerization in a gel, the densely cross-linked ternary porous copolymer DEF-St-DVB (run no. 14) was obtained.

The above data show that the molecular weight of segments of the CP chains between cross-links is the lowest in the sample prepared at the higher temperature; it is cross-linked most densely (Table 1, run no. 6). We believe that the influence of temperature is the most significant since it governs the mobility of DVB units in the structure of CP. On the whole, all CPs have densely cross-linked molecular network structure, are porous, and consist of spherical particles with a narrow size distribution. Copolymerization in a gel, due to exclusion of coalescence of polymer–monomer particles, extends the possibilities of synthesis of polymeric spherical particles from various monomers.

CONCLUSIONS

(1) Spherical particles of copolymers of *p*-divinylbenzene with styrene and diethyl fumarate were prepared by copolymerization in a medium of thermally reversible gel of methyl cellulose.

(2) The gel readily holding the drops of the monomer and reaction mixture is obtained at the concentration of methyl cellulose in water equal to 6 wt %.

(3) The polymer matrices with developed porous structure were synthesized in the presence of polymeric diluent presenting a linear analog of the cross-linked copolymer.

Abstract—Preparation and modification of low-viscous polymeric composites in rotary-pulsatory apparatus operating in the self-oscillating mode are described. These are synthesis of antioxidant dispersions, preparation of artificial latexes from an isoprene rubber, modification of epoxy resins with low-molecular-weight carboxyl-containing rubbers, modification of *cis*-1,4-polyisoprene with a salt of *n*-nitrosodiphenylamine. The possibility of substantial intensification of these processes is analyzed.

DOI: 10.1134/S1070427208030282

Preparation and modification of polymeric composites in the course of mixing is one of the main ways to develop new materials. In recent years, new phenomenological concepts of activating mixing as a process for obtaining polymeric composite materials were put forward. According to these concepts, the energy imparted to the components not only causes homogenization and dispersion, but also either initiates chemical reactions between the components that do not occur in other conditions or accelerates the chemical transformations that otherwise are slow. These concepts have proved to be the most fruitful in the development of processes for preparation and modification of composites based on low-molecular-weight polymers [1–3].

At the same time, the already developed technologies need modification in order to raise the output capacity of the process and improve the quality of the composites obtained. One of the most effective ways to implement the activating mixing of low-viscous polymers is treatment of the mixture components in rotary-pulsatory apparatus (RPA) operating in both the laminar and turbulent modes. Under certain conditions, these apparatus can also operate in a specific self-oscillation mode, in which the power consumed is substantially lowered and the pulsating dynamic load on materials is raised. This opens up new opportunities for intensification of the processes performed in these apparatus [4].

EXPERIMENTAL

To develop a technology for synthesis and modification of formulations of various compositions in RPA under self-oscillation conditions, we used the following four groups of materials.

(A) Materials for preparing dispersions of antioxidants. We used an aqueous solution of a biodegradable and nontoxic nonionic (an oxyethylated alcohol) or anionic (a carboxylic or sulfonic acid) surfactant. The concentration of the antioxidant suspension was 1–20 wt %. As antioxidants served those commonly used for stabilization of rubbers: Neozone-D (phenyl-β-naphthylamine), DPPD (diphenyl-*p*-phenylenediamine), and Ionol (4-methyl-2,6-di-*tert*-butylphenol). Other antioxidants were also studied.

(B) Materials for preparing artificial latexes. As objects of study served aqueous emulsions of SKI-3 rubber with a concentration of 10–14 wt %.

(C) Materials for preparing composites based on epoxy resins with low-molecular-weight carboxyl-containing rubbers: composites based on an epoxy oligomer (oligoether epoxide) and liquid rubbers with terminal carboxy groups (butadiene–nitrile and butadiene); epoxy oligomer and liquid butadiene–nitrile rubber with terminal carboxy groups, diluted with furfuryl glycidyl ether.

(D) Materials for rubber modification: solutions of *cis*-1,4-polyisoprene in hexane, with various

concentrations; solutions of the sodium salt of *p*-nitrosodiphenylamine (PNDPA) in hexane, with various concentrations; and phosphoric acid of A and B grades.

The rheological characteristics of the polymers were determined on a Rheotest-2 rotational viscometer.

The physical and chemical transformations in the polymers were studied and the composites obtained were analyzed by the following methods.

The quality of the composites obtained was evaluated by the optical method, with the dynamics of antioxidant (Neozone) settling from a suspension and the number and size of particles in the microscopic field recorded, and by the oxidation rate of rubber samples with introduced antioxidant (by the decrease in the intrinsic viscosity in 1 min).

The quality of the latexes was evaluated by the optical method, with the size of rubber particles and their number in the microscopic field determined.

The structure of uncured mixtures of oligomers was studied by optical microscopy, and that of cured composites, by scanning electron microscopy (REM-100, BS-500). The chemical and physical transformations of the components were analyzed as follows: existence of chemical bonds between the functional groups of a rubber and an epoxy oligomer, by IR spectroscopy; consumption of the functional groups of the epoxy oligomer, by acid–base back-titration; and the kinetics of curing of the composites, by determining the temperature effect of curing.

The physicochemical transformations in polyisoprene in the course of its modification with PNDPA were studied with a UV spectrophotometer.

The physicomechanical and performance properties of the composites were determined in conformity with the existing GOSTs (State Standards) 270–75, 14760–91, 10722–89, 19338–90, 27109–86, etc.

The most important issue is to determine the design parameters and process operation modes of an apparatus under which there appear conditions for occurrence of a controllable oscillatory process. Self-oscillations in RPA are nonsteady hydromechanical processes and belong to complex physical phenomena that can be only described with a set of nonlinear partial differential equations. The boundary conditions necessary for solution of these equations are most frequently represented also by differential equations. For practical purposes, it is advisable to develop simple models of motion of the media being processed, which would reflect the most important features of the physical pattern of the process (criterial approach).

The main similarity criteria in fluid dynamics to which the given process belongs are Reynolds (Re), Froude, Strouhal (St), and Mach numbers. When determining the process and design parameters of RPA, required for maintaining self-oscillations in a material being processed, it is necessary to take into account at least two numbers, Re and St.

The characteristic linear size for the number Re ($\mathrm{Re} = Ul/\nu$, where U is the characteristic velocity of the fluid; l, characteristic linear size; and ν, kinematic viscosity of the fluid) will be the rotor diameter D_r, and the characteristic velocity, the average motion velocity of the fluid in the gap between the teeth of the rotor and stator. With the assumptions made, we take $U = 0.5\pi D_r n_r$. Then $\mathrm{Re} = 0.5\pi D_r^2 n_r(\rho/\mu)$. The expression obtained gives the so-called centrifugal Reynolds number.

The number St ($\mathrm{St} = VT/L$, where V is the characteristic velocity; T, characteristic interval of time, e.g., T is the period for periodic motion; and L, characteristic size) has other characteristic parameters. For the free-turbulence conditions, $V = (V_{max} - V_{min})$ and $l \approx b$, where $V_{max} - V_{min}$ is the maximum difference of averaged velocities in the cross section under consideration, and b is the agitation zone width. We take $(V_{max} - V_{min}) = 1/2\omega R$ and b equal to the width h of the gap between the rotor and stator.

Pulsations of the dynamic pressure appear when the slits in the stator are periodically closed by the teeth of the rotor. The basic frequency of these pulsations will be $F = Z_r n$, where n is the rotation rate of the rotor (rpm), and Z_r is the number of the rotor teeth.

The vortex formation is due to sharp changes in the velocity and, accordingly, in the pressure of the fluid after it leaves the gap between the teeth of the rotor and stator into the slits. In this case, there occurs separation of the boundary layer with the simultaneous formation of vortexes, which gives rise to a pressure pulse. The frequency of this process is directly proportional to the average flow velocity in the gap between the cylinders and inversely proportional to the characteristic linear size, width h of the gap between the rotor and stator.

The period of vortex formation is found from the dependence $1/T_v = f_v = æStV/h$ (æ = 1 is the harmonic number). Let us take as the characteristic period the time of vortex formation, $1/T_v = f = 1/Z_k n_r$. Then

the number St can be written, with account of $\omega = \pi n/30$, as

$$St = \pi D_r/120hZ_k.$$

Let us introduce a new parameter, ratio of the numbers Re and St, BT = Re/St, which can be written as

$$BT = [0.5\pi D_r^2 n_r(\rho/\mu)]/[\pi D_r/120hZ_k].$$

After some transformations, we obtain a dimensionless parameter, $BT = 60D_r/n_r hZ_k$.

Let us analyze the parameter obtained. It includes the following: the product of the number of revolutions, n_r, by the number of slits, Z_k, equal to the frequency f of vortex formation (or to the quantity inverse to the characteristic interval of time, $1/T$); product of the rotor diameter D_r by the width h of the minimum gap between the rotor and stator (characteristic size H); and ratio between the density ρ and viscosity μ of the fluid (quantity inverse to the kinematic viscosity ν). Thus, $BT = 60(1/T)H(1/\nu)$.

This parameter characterizes the conditions in which a self-oscillating process can occur in a viscous fluid processed in RPA. Knowing the condition in which the given process occurs in an ideal fluid, we can make a correction for the viscosity of the real medium and calculate all the necessary process and design parameters of RPA operation.

The processes occurring in the composites studied in their treatment in RPA in the self-oscillation mode can be divided into two groups: those accompanied by physical and chemical transformations.

PROCESSES FOR SYNTHESIS OF COMPOSITES WITH PHYSICAL TRANSFORMATIONS

Preparation of antioxidant dispersions. Antioxidant dispersions are used to stabilize synthetic rubbers for various purposes. Previously, RPA has been used as a mixer-disperser to improve the stability of antioxidant dispersions in the course of their preparation. It was found that the process of dispersing of antioxidant agglomerates in an aqueous solution in RPA occurs with a considerably higher efficiency when the apparatus operates in the self-oscillating mode (Table 1).

In all the cases, the power consumption decreased by 20–30%.

Preparation of artificial latexes. Let us consider a process for synthesis of the artificial latex SKI-3. This latex is widely used to replace natural latex in manufacture of foamed rubber and other articles. The most critical stage predetermining the possibility of obtaining high-quality SKI-3 latex is emulsification of the polymerizate of the SKI-3 rubber in an aqueous medium. Because the viscosity of the polymer solution is low (the content of rubber in the aqueous solution of the emulsifier is 10–14%), it is very difficult to create the required shear stresses in the system with ordinary equipment. Previously, this problem has been solved by using RPA.

Under real industrial conditions, the action of high shear stresses in the initial stages of emulsification leads to mechanical degradation of the rubber. Therefore, the process is performed in two stages: at low shear rates $\gamma = 10^4$ s^{-1} (apparatus with a stirrer, jet mixer, comb mixer), and at high shear rates $\gamma = 5 \times 10^4$ s^{-1}. The use of an RPA including a static mixture enabled a significant simplification of the process scheme and improvement of the product quality. As regards the homogenizing capacity, the static mixer with screw elements can replace the stirrer and the jet and comb mixers. At the same time, the shear stresses being developed in the material will be exceedingly low.

Processing of a material in a static mixture yields emulsions with a drop size of 20–50 μm (in the case of the conventional scheme, the drop size is 20–100 μm).

Finer emulsification occurs in the rotor part of RPA. In the conventional scheme, the required emulsification quality could only be achieved upon 5–6-fold recycling of the flow being processed.

Treatment of the material in the self-oscillating mode cannot completely exclude the recycling procedure, either. However, the number of recyclings can be reduced to two.

PROCESSES OF SYNTHESIS AND MODIFICATION OF COMPOSITES WITH PHYSICOCHEMICAL TRANSFORMATIONS

Modification of epoxy resins with low-molecular-weight carboxyl-containing rubbers. In the first stage, we examined the possibility of obtaining stable epoxy–rubber systems in RPA in the self-oscillating mode. The most stable systems were, naturally, obtained from mixtures with equal amounts of components. In a triple processing of a 1 : 1 mixture of SKN-10KTR and ED-20 in laminar and transition modes, a system that remained unsegregated for

Table 1. Advantages of the self-oscillation method over the ordinary treatment in RPA in preparation of antioxidant dispersions

Material	Advantages of self-oscillation method	Method for assessing quality of materials obtained
Dispersion of Neozone-D in 5% aqueous solution of alkylnaphthalenesulfonate (Neozone-D concentration 15%), with subsequent introduction of SKS-30 rubber into latex	Finer grinding and distribution in polymer (by 15% on average); 30% increase in output capacity of the process	By concentration of Neozone-D (shorter time of its settling from latex)
Dispersion of Ionol (1%) in 3.5% solution of sodium salt of synthetic fatty acids of C_8–C_{14} fraction, with subsequent introduction of SKS-30 ARK polymer into latex	25–30% increase in homogeneity the mixture	By concentration of Ionol in rubber
Dispersion of mixture of Neozone-D and DPPD in 5% solution of potassium stearate (DPPD : Neozone-D = 3 : 5), with subsequent introduction into SKI-3	20% increase in homogeneity of antioxidant distribution in rubber	By oxidation rate of rubber samples (by decrease in intrinsic viscosity in 1 min)
Dispersion of Neozone-D (2 wt %) in 5% solution of OS-40 surfactant (oxyethylated alcohol of C_{10} fraction)	Fivefold increase in stratification time of the mixture	Optical method
Dispersion of DPPD (20 wt %) in 8% aqueous solution of sodium oleate	Threefold increase in stratification time of the mixture	Optical method
Dispersion of Neozone-D in 5% aqueous solution of alkylnaphthalenesulfonate (Neozone-D concentration 15%), with subsequent stabilization of SKI-3 rubber obtained in solution	30% increase in homogeneity of antioxidant distribution in rubber	By concentration of Neozone-D
Dispersion of Neozone-D in 3% aqueous solution of a mixture of fractions of alkylarenesulfonates and alkanesulfonates	Twofold increase in stratification time of the mixture	Optical method

Table 2. Physicomechanical and performance parameters of composites produced by different methods

Parameter	Simple mixture (apparatus with stirrer)	Product formed upon treatment in RPA	
		six passings	with a static mixer in the self-oscillating mode
Tensile strength σ_t, MPa	4.3	14.0	16.0
Relative elongation ε, %	10.2	66.1	66.6
Adhesion strength σ_{ad}, MPa	4.0	12.2	14.8

14 days was obtained, whereas in treatment in an RPA in self-oscillation conditions, a composite that did not settle for 20 days was obtained upon single passing through the processing zone.

In the second stage of the study of the effect exerted by the mechanical treatment of epoxy–rubber composites, we identified changes introduced by the self-oscillating process into the chemical reaction between the functional groups of the oligomers being mixed. In the first stage of the study, a homogeneous system stable in the course of time was obtained and, consequently, the most favorable conditions for interaction between the groups were created. At the same time, on making the agitation conditions more "severe," the chemical interaction of the components could be achieved in a shorter time. In the case of processing in an ordinary RPA in the turbulent mode, the chemical interaction occurred only on passing the reaction mixture six times through the working zone of the mixer, whereas in the self-oscillating mode, such an interaction occurred already after the first passing. Table 2 lists the physicomechanical and performance parameters of the mixtures.

Such an improvement of the properties of the composites can be explained as follows. The processes occurring in the self-oscillating mode in an RPA with a static mixture are the same as those in an ordinary apparatus. At the same time, the dispersity of one component in the medium of the other and the homogeneity of the mixture obtained is substantially higher owing to the preliminary mixing of the components in the static mixture and to performing the process in the self-oscillating mode. This leads to narrower scatter of the physicomechanical and performance parameters being analyzed and, in the end, to their improvement upon statistical processing of the data obtained. In addition, we observed a drop in the power consumed by the mixer, compared with the conventional process in an RPA, by, on the average, 20–25%.

Modification of rubbers in solution. The self-oscillating process in RPA may be of particular importance in processes of chemical modification of rubbers in the stage of preparation of the polymer. As an example of a system of this kind can serve a solution of the SKI-3 isoprene rubber in hexane, mixed with the sodium salt of *p*-nitrosodiphenylamine. The modification process performed previously in apparatus with stirrers was distinguished by a longer duration. The use of an RPA operating in the conventional mode made it possible to reduce the process duration by a factor of 3–5.

In an experimental study, we determined the percentage content of free and bound PNDPA in solutions treated in an RPA in the conventional mode and in the mode of self-oscillations (after 1, 3, and 5 h of solution treatment in the reactor). The results obtained suggest that treatment of a system in the self-oscillating mode intensifies the chemical modification process by 25–30% on the average, which makes it possible to reduce the process duration at the same extent of the reaction.

CONCLUSIONS

(1) The processes occurring in a rotary-pulsatory apparatus can be quantitatively described using the generalizing parameter of an external energy effect, which is a combination of Reynolds and Strouhal numbers and characterizes the conditions in which a self-oscillating process may arise in a viscous fluid. This enables calculation of the operation modes and design parameters of the rotary-pulsatory apparatus.

(2) The improved technologies for synthesis and modification of composites in a rotary-pulsatory apparatus in which the mixtures undergo physical transformations yield antioxidant dispersions with a finer comminution and distribution of the antioxidant in the polymer, with the settling time of the mixture increasing, on the average, by a factor of 2–5. The preparation technology of SKI-3 artificial latexes provides finer emulsification of the polymer and reduction of the cycle duration by a factor of 2–3.

(3) The improved technologies for synthesis and modification of composites in which the mixtures undergo chemical transformations provide modification of epoxy resins with low-molecular-weight carboxyl-containing rubbers and make it possible to raise the homogeneity of the mixtures and their performance parameters by, on the average, 15%. The technology of modification of *cis*-1,4-polyisoprene with a salt of *p*-nitrosodiphenylamine reduces the process duration by, on average, 25–30% at the same extent of the reaction.

Abstract—Possibility of obtaining rigid foamed polyurethanes filled with aluminosilicate microspheres was analyzed. The physicomechanical and rheological properties of these composites were studied.

DOI: 10.1134/S1070427208030294

Foamed polyurethanes (FPU) are widely used in building, transportation, and many other fields of natural economy because of their unique heat- and sound-insulating properties and simplicity of preparation and use. Numerous plants in our country and abroad manufacture on a large scale both FPU systems and finished articles for various purposes.

At the same time, purely FPU systems have exhausted their potentialities, because it is impossible to control physicomechanical and other parameters, e.g., combustibility and softening point, by only varying the FPU composition, and, therefore, use of various organic and inorganic fillers, plasticizers, and fire retardants opens up wide opportunities of modification of their properties [1].

The post promising in this context is modification of properties of FPU systems with ash aluminosilicate microspheres (AASM), which are formed as a waste, the so-called ash carryover, at thermal power plants.

The unique properties of AASM, such as the microspherical shape with diameters of 20 to 400 μm, low bulk density (0.32–0.68 g cm^{-3}), low heat conductivity, high strength, and inertness toward organic solvents, acids, and alkalis predetermined the wide applicability of this product. The low density of AASM is the most important property, which enables their use as a filler for polymeric materials and provides a low materials consumption without impairing the heat- and sound-insulating properties.

EXPERIMENTAL

As a filler were used AASM [TU (Technical Specification) 14.2-25 595 170-001–2003]. Composite FPUs were obtained by a single-stage method consisting in simultaneous mixing of all the components (A and B). Because single-stage systems are mixed at room temperature, it is necessary that all the components should be in the liquid phase and have a satisfactory degree of compatibility [2, 3]. When preparing FPU, microspheres were preliminarily mixed with component A to obtain a homogeneous mass. The samples obtained were kept at 20°C for no less than 24 h from the instant of material preparation to its study.

The kinetic parameters of foam formation (times of foaming onset, gelation, and foam rise) were monitored using a stopwatch. The apparent density was determined in conformity with GOST (State Standard) 409–77 with a determination error of ±0.5 kg m^{-3}.

The breaking compression stress was determined on an METEFEM-khr01 machine at room temperature. The dimensions of the samples for tests were 50 × 50 × 50 mm, and the compression rate was 60 mm min^{-1}. It should be particularly noted that the samples being tested are only compressed, without crumbling or brittle fracture. The measurement error was ±5%.

The heat conductivity λ (W m^{-1} K^{-1}) was determined by measuring the steady heat flux in a monotonic heating mode on an ITP-MG4 instrument in conformity with its working manual [4].

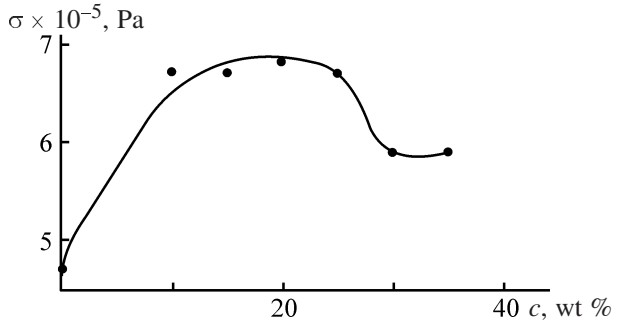

Fig. 1. Breaking compression stress σ vs. the filler content *c*.

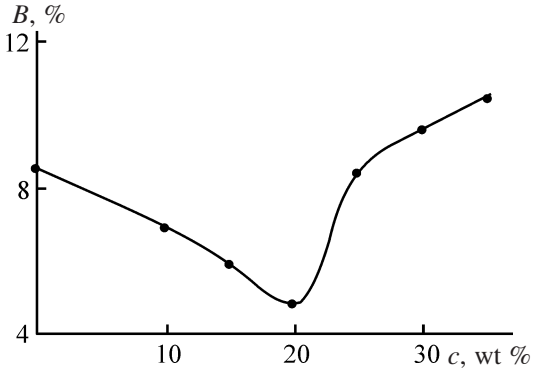

Fig. 2. Water-absorption capacity *W* vs. the filler content *c*.

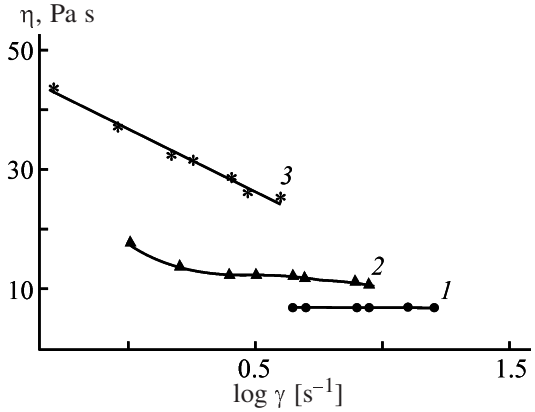

Fig. 3. Viscosity η vs. the shear rate γ in semilog coordinates. Polyol + AASM, wt %: (*1*) 34.8, (*2*) 40, and (*3*) 44.5.

The moisture-absorption capacity was measured as follows: weighed samples (d = 4.5 cm, h = 5 cm) were placed on the grid of a desiccator filled with water to a certain level and kept there for 24 h. Then the samples were again weighed and the moisture-absorption capacity W (%) was calculated by the formula

$$W = \frac{m(\tau) - m(0)}{m(0)} \times 100,$$

where $m(0)$ is the average mass of a sample before tests (g), and $m(\tau)$, that in 24 h (g).

The rheological properties were studied on a Rheotest-2 rotary viscometer in a wide range of stresses (120–3×10^3 Pa) and shear rates (0.5–437.3 s^{-1}). The operation principle of the device is based on the shear of a solution (composite) being measured in the gap between the coaxial cylinders. The device can measure the viscosity in the range 10^{-2}–10^4 Pa s. In the calculation, tabulated data on the shear rate γ (s^{-1}) were taken and the shear stress τ (Pa) and the viscosity η (Pa s) were calculated using the expressions

$$\tau = z\alpha,$$

$$\eta = (\tau/\gamma) \times 100,$$

where z is the cylinder constant (Pa) and α is the reading of the measuring instrument in scale divisions.

Different cylinders S–S_2 with constants z and z_2 were used in measurements. The rheological parameters were determined at 20°C.

It can be seen in Fig. 1 that introduction of a filler into a rigid FPU leads to an increase in the breaking compression stress σ. Introduction of ash microspheres in amounts of up to 20 wt % raises the compression strength by a factor of 1.5 because of the loss of mobility by the polymer matrix. Further increase in the content of the filler (>20 wt %) causes a decrease in σ as a result of the disruption of the integrity of the FPU matrix because of the presence of a large amount of microspheres and of the "gas phase."

Noteworthy is the fact that the catalyst concentration was chosen so that all the samples had the same apparent density (70 ± 3 kg m^{-3}), irrespective of the filler content. It should also be noted that the heat conductivity of samples with various amounts of AASM is virtually independent of the AASM content because the heat conductivity is determined by the fraction of voids in a material, the total fraction in FPU and AASM. The heat conductivity of the starting formulation is 0.028 W m^{-1} K^{-1}, and that of a composite with 25 wt % AASM, 0.029 W m^{-1} K^{-1}.

It was found that, upon introduction of 10, 15, and 25 wt % AASM into the FPU system, the water absorption somewhat decreases, compared with the starting formulation (Fig. 2), whereas introduction of a larger amount of AASM impairs the integrity of the FPU matrix via formation of contacts between ash microspheres whose surface is wetted by water.

It can be seen in Fig. 3 that both the starting systems and those containing up to 40 vol % AASM are

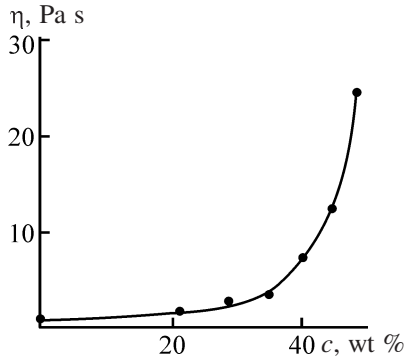

Fig. 4. Shear viscosity η vs. the AASM content c at $\log\gamma$ = 0.6.

Newtonian fluids (straight line *1*). Upon introduction of 40% AASM, the Newtonian system becomes anomalously viscous (curves *2, 3*). In this case, introduction of AASM leads to an increase in the viscosity of filled composites because of the rise in the fraction of the nonfluid component.

Introduction of a filler leads to an increase in the viscosity of the filled composite, with the most pronounced changes in viscosity observed beginning with an AASM content of about 30 wt % (Fig. 4).

Thus, FPU systems can be modified with aluminosilicate microspheres, which enables development of filled FPU composites with good physicomechanical and service properties and preserved heat-insulating characteristics and fluidity [5]. The rheological properties of filled polyol (component A) make it possible to recommend the conditions of processing of filled composites on high- and medium-pressure filling machines, which could provide a high quality of component mixing.

CONCLUSIONS

(1) Rigid foamed polyurethane systems filled with aluminosilicate microspheres were obtained.

(2) These composites enable use of standard filling machines to obtain rigid filled foamed polyurethane articles.

Abstract—A method for reclaiming of vulcanized rubbers, combining the treatment with a chemical degrading agent and exposure to electromagnetic field, was described. This method considerably extends the technological potentialities of reclaiming, allowing utilization of waste based on virtually any kind of rubber, in particular, nonpolar, in the form of coarse crumb.

DOI: 10.1134/S1070427208030300

The existing methods of vulcanized rubber reclaiming are underlain by breaking the cross-links. Degrading agents (typically, chemical compounds) are selected to fit the nature of the cross-links and break them via chemical reactions. The penetration of the agent into vulcanized rubber is facilitated by its dissolution in a product that acts as rubber plasticizer and transports the degrading agent. Simultaneously, vulcanization agents are introduced into the system; they take effect at elevated temperatures and form a new vulcanization network in the reclaimed rubber.

By now, a large number of degrading formulations were developed, but their application is complicated by certain factors. First, all these formulations are selective, i.e., applicable to a certain rubber type (depending on the nature of the plasticizer solvent), which requires additional sorting of the raw material. Second, the action of the degrading and cross-linking agents is difficult to balance in time and temperature, for which reason the corresponding processes go on at room temperature, thereby affecting the properties of the reclaim. At the present time, increased interest is displayed in methods of rubber degradation under exposure to fields of different nature. They should break down the three-dimensional vulcanization network of the exposed material in such a way that the structure of the raw material used in rubber manufacture is affected to the least possible extent. The efficiency of the controlled mechanocracking can be considerably increased through exposure of the material to a combination of external fields of different nature.

We elucidated here the suitability of chemical treatment combined with electromagnetic field exposure for vulcanized rubber reclaiming. There were earlier attempts to develop reclaiming methods combining exposures to fields of different nature. In one of such methods, rubber waste was crushed and mixed with 1–15 parts by weight of the reclaiming activator comprising hydroxy and/or carboxy groups and/or quinone (in particular, organic and inorganic compounds), which was followed by 3–5-min exposure (at least once) of the resulting mixture to high-frequency currents (HFCs) with the frequency in the range 915–15 000 MHz [1].

This reclaiming process requires high temperatures and long time; otherwise, permanent irradiation for over 5 min results in overheating and degradation of the vulcanized rubber being treated. Also, analysis showed that the neat reclaim is unfit for use and can only be introduced into a new stock as addition. Satisfactorily running of this reclaiming process requires preliminary crushing of the rubber waste to a particle size under 1 mm (0.3 mm preferably); of all rubber wastes only those based on natural and styrene rubbers are suitable for utilization.

We sought here to decrease the temperature and time of the process, as well as to extend the process potentialities of reclaiming. To this end, we used the previously developed reclaiming method [2]. Essential for implementation of this method are three interconnected factors: the activator composition and

the application mode and frequency range of a high-frequency electromagnetic field.

As the reclaimimng activator served the composition including 2-mercaptobenzothiazole (Captax), hexamethylenetetramine, iron stearate, and glycol in the molar ratio of 1 : (0.2–1.0) : (0.0017– 0.017) : (0.37–0.61), respectively. This formulation was introduced in amount of 3–12 per 100 parts by weight of the waste, followed by single 1–3-min exposure of the product to a high-frequency electromagnetic field in the meter frequency range.

Thus, reclaiming of vulcanized elastomer waste consisted in the following. Vulcanized rubber waste was crushed (the method is of no significance) into crumb (with particles up to 5 mm in size) and mixed on a standard mixing equipment with a pasty reclaiming activator having the above-described composition [3]. This was followed by a single 1–3-min exposure of the resulting mixture to a high-frequency electromagnetic field in the meter frequency range, e.g., at the frequencies of 13.56, 27, or 50 MHz.

The resulting product (neat regenerate) is suitable for manufacture of various, e.g., roll articles, and also can be used as addition to new rubber stocks.

Table 1 summarizes the qualitative and quantitative compositions of the reclaims based on different wastes, as well as the properties of the reclaims and rubbers containing these reclaims. For comparison, we also presented the data for the materials obtained according to [1], which is one of the best foreign analogs.

Table 1 contains the strength characteristics of the reclaim obtained upon exposure of crumb rubber to HFCs and treatment with the reclaiming activator, both separately and in combination. Also tabulated are the properties of the rubbers containing untreated crumb and reclaims prepared by the method known from the world practice and the method we developed. The crumb rubber is comprised of wastes from various rubbers: natural (NR), styrene–butadiene (SKS), isoprene (SKI-3), and butadiene (SKD) rubber.

Also, Table 1 contains the coefficient characterizing the change of the strength properties of the rubbers, %:

$$K_0 = [(\sigma_1 - \sigma_2)/\sigma_1] \times 100,$$

where σ_1 and σ_2 are the tensile strengths of the rubbers containing untreated crumb and reclaim (crumb treated by the method we suggested), respectively.

The coefficient K_0 characterizes the extent to which the treatment method affects the quality (strength properties) of the reclaim.

Table 1 suggests that, in rubber waste reclaiming, only combined action of electromagnetic field and activator of the developed composition provides the desired properties of the reclaim.

Table 2 presents the compositions of the rubber stocks containing the reclaim obtained by the known and developed methods. For stock A, only basic components are listed. Stock B is characterized by the composition according to GOST (State Standard) 11138–89; it contains 10 parts by weight of the reclaim obtained by the procedure we suggested.

Thus, the procedure we proposed considerably extends the potentialities of the reclaiming process through creating prerequisites for continuous production of articles from "neat" reclaim (such as, e.g., roll, roofing, and waterproofing materials); utilization of rubber wastes of various compositions (based on virtually any kind of rubber); utilization of wastes comprising coarse crumb; and utilization of rubber wastes based on nonpolar rubbers and filling agents that do not contain polar groups (carbon black), since in this case the electrical conductivity of the mixtures

Table 2. Stock compositions

Diphenylguanidine	–	0.3
Zinc white	–	5.0
Sulfur	–	2.0
Reclaim	10.0	10.0

is preserved owing to the presence of a reclaiming activator of the above-mentioned composition and its ability to create an electrically conducting film on the crumb surface. Also, it is possible to control the reclaiming owing to the self-regulation ability of the system: The waste exposure to a high-frequency electromagnetic field solely causes combustion and decomposition of the crumb; efficient reclaiming is possible only in the presence of the reclaiming activator we suggested, i.e., under combined action of the two factors. The reason is that the activator film formed on the crumb surface prevents its contact with atmospheric oxygen, thereby decelerating the thermal oxidative degradation and preventing local overheating of the waste, responsible for its ignition.

CONCLUSIONS

(1) Combined action of a chemical agent and electromagnetic field extends the potentialities of rubber reclaiming to include continuous production of roll, roofing, and waterproofing articles from neat reclaim.

(2) Reclaim can be obtained from waste based on any kind of rubber, as well as from such waste as coarse crumb.

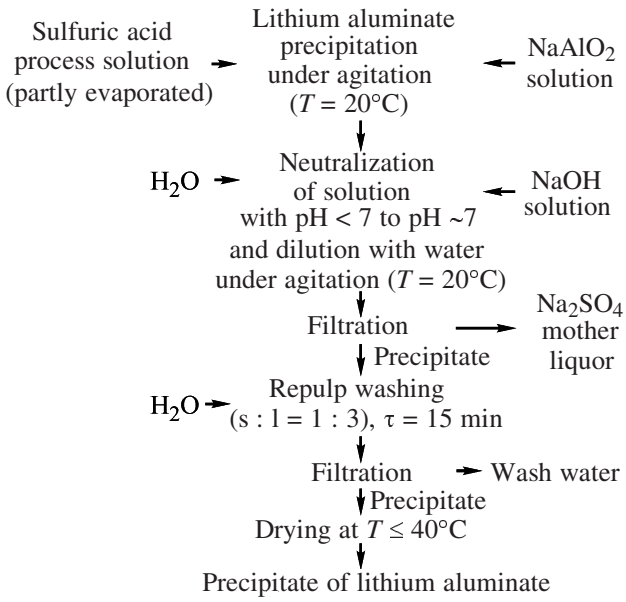
Abstract—Integrated processing of spodumene in hydrometallurgy in order to recover lithium, aluminum, and silica was studied.

DOI: 10.1134/S1070427208030312



A method for alkaline decomposition of spodumene, based on its fusion with sodium carbonate and subsequent aqueous granulation of the fusion cake, is known [1, 2]. Sulfuric acid leaching of the granulate yields a sulfuric acid solution (containing about 6 g l^{-1} of lithium and aluminum, sodium, and sulfuric acid in amounts of 20–25 g l^{-1} each) and a cake (with a silica content of up to 95 wt % and more). For full use of the granulate, it can be processed to give a liquid glass by the classical technology for manufacture of glass from natural silica [2, 3]. For integrated processing of the sulfate solution produced in the granulate leaching stage, the possibility of precipitating the poorly soluble lithium aluminate was considered. In view of the fact that the technology of alkaline decomposition of spodumene [1] assumes that the obtained solution of lithium and aluminum sulfates has pH lower than the values at which $Al(OH)_3$ precipitates, it seemed appropriate to analyze the possibility of precipitating a mixture of lithium hydroxodialuminate (LHODA, $Li_2O \cdot Al_2O_3 \cdot 11H_2O$) and aluminum hydroxide by neutralization of the starting acid solution with a sodium aluminate solution (at a final pH value of mixture precipitation of about 7). For simultaneous recovery of lithium and aluminum from the sulfate solution under consideration, the scheme presented below was tested. The results obtained in a laboratory experiment are listed in the table and shown in the figure.

The results obtained (see table) show that lithium is precipitated fairly completely (83.55–99.65 wt %) at a Li : Al mass ratio in the lithium aluminate sludge equal to 1 : (11.3–16.8). In this case, 86–98 wt % of Al is recovered into the precipitate.

Thus, the method we suggest ensures simultaneously recovery of Li and Al into the precipitate from dilute solutions.

Because aluminum hydroxide decomposes at 1000°C [4], the gravimetric curve in the figure shows only a change that is characteristic of $Li_2O \cdot 2Al_2O_3 \cdot 11H_2O$ and points to dehydration of the product.

* The initial solution was prepared by fusion of spodumene with Na_2CO_3, aqueous granulation of fusion cake, and sulfuric acid leaching of granulate. Lithium aluminate and $Al(OH)_3$ were precipitated with an alkaline solution of $NaAlO_2$ (c_{Al} = 219–250 g l^{-1}) and NaOH solution (concentration 640 g l^{-1}). For the fullest precipitation of Li and Al, the sludge obtained upon precipitation was kept at 20°C without agitation for 20 h and then filtered.

A comparative X-ray diffraction analysis of the precipitates obtained and $Li_2O \cdot 2Al_2O_3 \cdot 11H_2O$ demonstrated that these substances contain all the phases of LHODA precipitated from neutral solutions. However, the phases that were earlier characterized by weak intensity of peaks now have the maximum intensity, and, vice versa, the phases earlier exhibiting the highest intensity now show peaks with comparatively low intensity. This suggests that the mass fraction of aluminum in the LHODA precipitates obtained in this precipitation mode (pH_{con} ~7) is higher. In this case, the $Li_2O \cdot 2Al_2O_3 \cdot 11H_2O$ phase is contaminated with sodium to a greater extent than that obtained from neutral solutions. With account of the low content of lithium in the aluminate precipitates (see table), they can be recommended as starting concentrates for the classical sulfuric acid processing to give aluminum alum and, further, lithium carbonate [2].

As for the utilization of sodium discharged from the suggested process with the mother liquor from the stage of precipitation of a mixture of LHODA and aluminum hydroxide, evaporation of this mother liquor can give crystalline sodium sulfate whose

Thermogram of a lithium aluminate precipitate (see table, run no. 3). (*T*) Temperature and (Δ*m*) change in mass.

reductive smelting with breeze coke yields sodium sulfide, which is in short supply [2].

CONCLUSIONS

The technology suggested for spodumene processing enables simultaneous recovery of lithium, aluminum, and silica from this mineral and provides utilization of sodium from the dump solution.

Joint Extraction of Vanadium(V) and Vanadium(IV) with Di(2-ethylhexyl) Hydrogen Phosphate

L. D. Kurbatova and D. I. Kurbatov

Institute of Solid State Chemistry, Ural Branch, Russian Academy of Sciences, Yekaterinburg, Russia

Received November 27, 2007

Abstract—The organic extracts formed in joint extraction of vanadium(V) and vanadium(IV) with di(2-ethylhexyl) hydrogen phosphate from weakly acidic aqueous solutions were characterized by IR and electronic spectroscopy and chemical analysis.

DOI: 10.1134/S1070427208030324

It is known that vanadium(IV) is extracted with di(2-ethylhexyl) hydrogen phosphate (HDEHP) [1]. As opposed to vanadium(IV), vanadium(V) dioxocations VO_2^+ are poorly extracted with this extractant [2]. At the same time, it was reported previously that vanadium(V) is efficiently extracted with HDEHP from weakly acidic solutions [3]. Taking into account that HDEHP is bifunctional, it was of interest to study joint extraction of vanadium(V) and vanadium(IV) with this extractant. No data have been reported previously on this matter.

EXPERIMENTAL

Vanadium(V) and vanadium(IV) were extracted with neat HDEHP at 25.0±5.0°C at the organic to aqueous phase ratio of 1 : 1 ($V_o : V_{aq} = 1 : 1$). Di(2-ethylhexyl) hydrogen phosphate was preliminarily treated to remove mono(2-ethylhexyl) dihydrogen phosphate (H_2MEHP). The working solutions were prepared from sodium metavanadate, oxovanadium(IV) sulfate, and sulfuric acid (chemically pure grade). The vanadium concentration in the aqueous and organic phases was determined by atomic-absorption and titrimetric methods [4]. The hydrogen ion concentration was determined with a pH-262 potentiometer with a glass electrode. The electronic absorption spectra of vanadium–HDEHP extracts were recorded on a Specord UV VIS spectrometer in the visible range (quartz cells, l = 0.999 and 0.199 cm). The IR spectra of these extracts were recorded on a Specord IR spectrometer in the 400–4000 cm^{-1} range (thin films of extracts between KRS-6 plates).

First the optimal conditions for extraction of vanadium(V) in the system V(V)–V(IV)–H_2SO_4–HDEHP were found at various V(V) : V(IV) ratios. The V(V) and V(IV) concentrations ranged from 5×10^{-2} to 2.5×10^{-1} M. We found that the V(V) distribution ratio increases in the presence of V(IV).

The mechanisms of joint extraction of vanadium(V) and vanadium(IV) were studied using IR and electronic spectroscopy, method of saturation of the extractant with extractable compounds, and chemical analysis. The extraction isotherms of vanadium(V) and vanadium(IV) from weakly acidic solutions were also obtained. These isotherms show that 1 mol of HDEHP extracts 10 mol of vanadium(V). Since under the extraction conditions vanadium(V) is present in the form of decavanadate anions [3], this means that in the extractable complex one decavanadate anion is bound with one HDEHP molecule. In extraction of vanadium(IV), 1 mol of HDEHP extracts 0.5 mol of vanadium. This ratio is consistent with the stoichiometry of the extraction reaction of vanadium(IV) with HDEHP reported in [1]:

$$VO^{2+} + H_2A_2 = VOA_2 + 2H^+. \quad (1)$$

We found that, in joint extraction of vanadium (V) and vanadium(IV), 1 mol of HDEHP extracts more than 10 mol of vanadium(V) and approximately 0.5 mol of vanadium(IV). Thus, the extraction of vanadium(V) sharply increases in the presence of vanadium(IV).

The IR spectra of vanadium(V, IV)–HDEHP extracts contain absorption bands at 1650, 1715, 2140, and 3410 cm^{-1} typical of the dioxonium ion [5] (Fig. 1). In accordance with [5], these absorption bands can be assigned, respectively, to the following

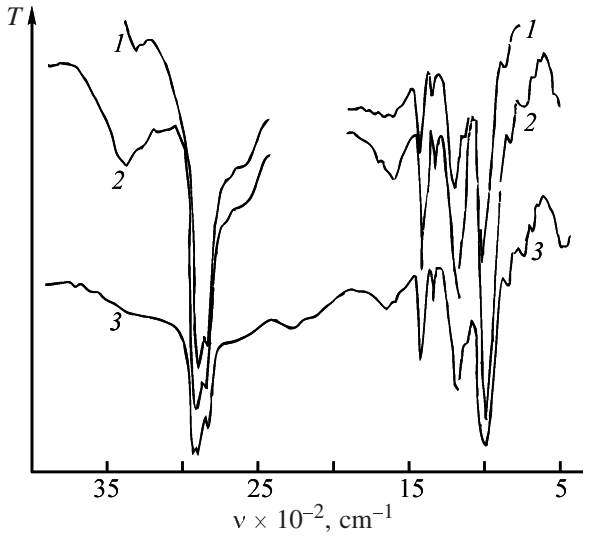

Fig. 1. IR spectra of straight HDEHP and of V(V, IV)–HDEHP and V(IV)–HDEHP extracts. (*T*) Transmission and (ν) wavenumber. (*1*) HDEHP, (*2*) V(V, IV)–HDEHP extract (C_V^{init} = 0.15 M), (*3*) V(IV)–HDEHP extract (C_V^{init} = 0.15 M).

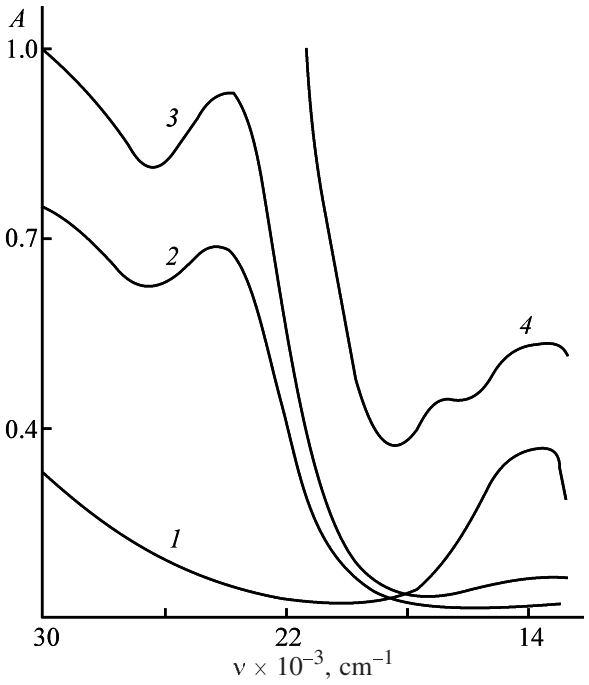

Fig. 2. Electronic absorption spectra of (*1*) vanadium(IV)–HDEPH extract, (*2*) vanadium(V)–HDEHP extract, (*3*) vanadium(V, IV)–HDEHP extract (l = 0.2 cm), and (*4*) vanadium(V, IV)–HDEHP extract (l = 1 cm). (*A*) Optical density and (ν) wavenumber.

vibrations of H_2O molecules in the organic extract (cm^{-1}): (1) bending vibrations (H_2O bound to $H_5O_2^+$), (2) bending vibrations (OH_2 groups contained in the $H_5O_2^+$ cation), (3) bending and libration vibrations (H_2O bound to $H_5O_2^+$), and (4) stretching vibrations (H_2O bound to $H_5O_2^+$). Other absorption bands belonging to $H_5O_2^+$ (1170, 1370, and 2900 cm^{-1}) partly overlapped with the stronger absorption bands of HDEHP. The IR spectra of the vanadium(IV,V)–HDEHP and vanadium(IV)–HDEHP extracts contain also the absorption bands of the P=O groups ($\nu_{P=O}^{as}$) at 1210 and 1200 cm^{-1}, respectively. In the IR spectrum of neat HDEHP, the absorption band of the phosphoryl groups occurs at 1225 cm^{-1}. Both the low-frequency shift of the absorption band of the P=O groups and the presence in the IR spectra of the absorption bands typical of dioxonium cation suggest that the hydrogen bonds are formed between the dioxonium cations and the phosphoryl group P=O. This means that, in joint extraction of vanadium(IV) and vanadium(V), vanadium(V) is extracted with HDEHP by a hydrate–solvate mechanism [3]. Along with the above-considered spectroscopic effects, the IR spectra of vanadium(IV, V)–HDEHP extracts contain no components of ν(OH) absorption bands present in the IR spectrum of the straight extractant (2660, 2260, and 1700 cm^{-1}). The disappearance of these bands shows that, in joint extraction of vanadium(V) and vanadium(IV), vanadium(IV) is extracted by the cation-exchange mechanism [6].

Thus, IR-spectra of vanadium(V)–HDEHP and vanadium(IV)–HDEHP extracts show that vanadium(V) and vanadium(IV) are bound with HDEHP molecule in the extractable complex by two different mechanisms. Whereas vanadium(V) forms hydrate–solvate complexes, vanadium(IV) is coordinated by the cation-exchange mechanism. In going from mixed vanadium(V, IV)–HDEHP extracts to vanadium(IV)–HDEHP extract, the low-frequency shift of the absorption bands of the phosphoryl group $\nu_{P=O}^{as}$ decreases. This means that, in the presence of vanadiun(V), the coordination of the phosphoryl oxygen of HDEHP with vanadium(IV) becomes weaker. It is also possible that, under these conditions, one of di(2-ethylhexyl) phosphate ligands in the inner coordination surrounding of V(V) is substituted by decavanadate anions. It should be noted that the similar low-frequency shift of the absorption band $\nu_{P=O}^{as}$ was observed in the IR spectrum of the extract of potassium chloride with copper di(2-ethylhexyl) phosphate. This shift was attributed to coordination of copper with chloride anions [7].

The formation of mixed V(V)–V(IV)–HDEHP extractable complexes was confirmed by the electronic spectra of organic extracts of vanadium(V), vanadium(IV), and their mixtures (Fig. 2).

Figure 2 shows that the electronic absorption spectrum of vanadium(IV)–HDEHP extract contains a broad asymmetric absorption band. This band can be resolved into two Gaussian components with the maxima at 13 500 and 14 500 cm^{-1}, which were assigned to *d–d* electronic transitions [8]. The electronic spectra of vanadium(V)–HDEHP extract contains a single band at 24 000 cm^{-1}. In accordance with [8], this absorption band is caused by charge transfer from occupied 2*p* orbitals of oxygen to 3*d* orbitals of vanadium(V). The electronic spectra of the vanadium(V, IV)–HDEHP extract contains four absorption bands at 24 000, 17 000, 14 500, and 13 500 cm^{-1}.

The complex electronic spectra of vanadium(V, IV)–HDEHP extracts reflect the complicated mechanism of joint extraction of vanadium(V) and vanadium(IV). The absorption band at 24 000 cm^{-1} present in the electronic spectra of the vanadium(V)–HDEHP extract and the absorption bands at 14 500 and 13 500 cm^{-1} present in the electronic spectra of the vanadium(IV)–HDEHP extract remain in the electronic spectra of the vanadium(V, IV)–HDEHP extract. This fact confirms the conclusion we made previously that, in joint extraction of vanadium(IV) and vanadium(V) with HDEHP, vanadium(V) and vanadium(IV) are extracted by hydrate–solvate and cation-exchange mechanisms, respectively. The band at 17 000 cm^{-1} is absent in the electronic spectra of the vanadium(V)–HDEHP and vanadium(IV)–HDEHP extracts but appears in the electronic spectrum of the vanadium(V, IV)–HDEHP extract. We believe that this absorption band is caused by the electronic transitions from occupied to vacant *d* orbitals and is broadened due to vanadium(V)–vanadium(IV) interactions [8].

It was reported in [9] that vanadium(V) aqua dioxo cation forms a cation–cation complex $V_2O_3^{3+}$ with vanadium(IV) aqua oxo cation. Mixed vanadium(V, IV) complexes with organic reagents were studied in [10]. The formation of mixed vanadium(V, IV) polyvanadates was also described elsewhere [10]. For example, Ostrowetsky [11] studied aqueous solutions of vanadium(V) and vanadium(IV) in the pH range 4.0–6.5 and found six polyvanadate anions with the V(IV) : V(V) ratio from 2 : 8 to 7 : 8, in particular, $[V_3^{IV}V_7O_{28}H]^{4-}$.

Thus, our results show that the vanadium(V)–vanadium(IV) mixture is extracted with HDEHP by the mixed cation-exchange and hydrate–solvate mechanisms in the form of mixed-ligand extractable complexes of vanadium(IV) with di(2-ethylhexyl) phosphate and decavanadate anions.

CONCLUSION

Infrared and electronic absorption spectra suggest that vanadium(V)–vanadium(IV) mixture is extracted with HDEHP by the mixed cation-exchange and hydrate-solvate mechanisms in the form of mixed-ligand extractable complexes of vanadium(IV) with di-(2-ethylhexyl) phosphate and decavanadate anions.

Received June 29, 2007

Abstract—Combined three-stage installation with swirling flows for drying and grinding of shungite was designed. Experimental data on drying and grinding of this mineral in the third stage of the installation are presented.

DOI: 10.1134/S1070427208030336

The advisability of using combined drying methods and apparatus has been confirmed by numerous scientific studies and by practical use [1, 2]. The development of drying apparatus has taken the way of designing apparatus that would not only provide high performance parameters, but also could satisfy high consumers' requirements, such as particle size, uniformity of the granulometric composition, and bulk density. Apparently, these requirements have also affected the design of combined dryers, in which apparatus with various hydrodynamic modes are used together with additional built-in devices for mechanical and thermal treatment of dispersed materials.

The design, improvement, and application of combined drying installations is one of the most promising areas of development of modern drying technology. These apparatus enable a considerably more rational organization of the process of thermal treatment of a material by subjecting it to fundamentally different thermal treatments with drying in various hydrodynamic modes and can combine, e.g., drying with granulation, grinding, dehydration, and cooling.

A combined whirl dryer has been suggested for drying of shungite [3, 4]. This dryer comprises three stages: cyclone, whirling chamber, and finish-dryer–grinder.

Figure 1 schematically shows a combined whirl dryer whose operation principle is as follows. A humid material is delivered into the dryer via the loading bunker *1*, after which it is preliminarily ground in the first stage of cyclone *2* with a dismembering unit *3*. The heat-transfer agent is delivered by ventilator *4* into inner chamber *2* of the cyclone via whirler *5*. In the first stage of the dryer, the material is heated and preliminarily dried in a flow of the heat-transfer agent spent in whirling chamber *6* (second stage) and finishing dryer *7* (third stage). Because of the contact of dust-like carryover particles with the product charged, the flowability of the material being processed is improved and, simultaneously, the discharged air is cleaned. The use of the heat of the dis-

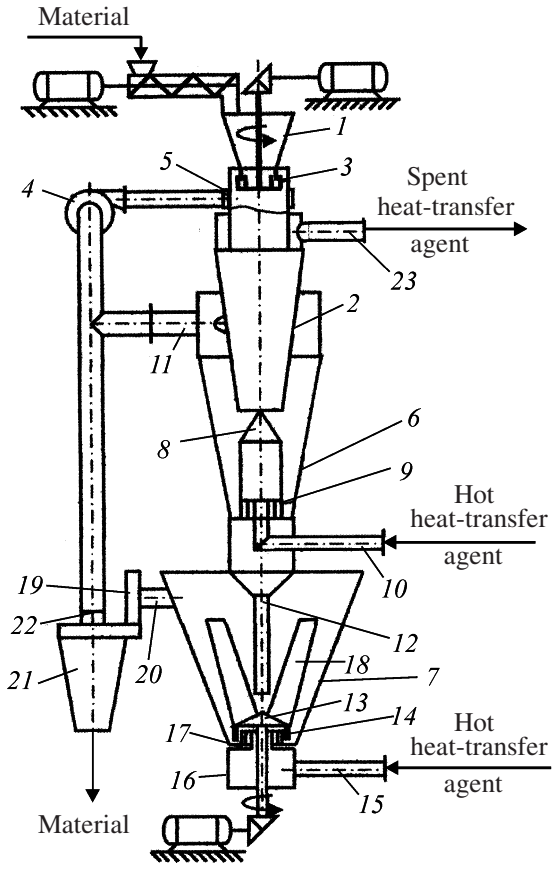

Fig. 1. Schematic of a combined whirl dryer. (*I*) Material, (*II*) spent heat-transfer agent, and (*III*) hot heat-transfer agent. For comments, see text.

charge drying agent to heat the material and subject it to preliminary drying in the cyclone makes it possible to utilize the energy of the heat-transfer agent to a fuller extent and thereby to improve the engineering and economic performance of the dryer.

The second stage of the installation is the whirling chamber intended to remove free moisture from the product being processed. Dispersed particles, delivered into the chamber from cyclone *2*, pass divider *8* and, while moving opposite to the ascending whirled flow of air heated to a high temperature, emerging from whirler *9*, form a whirled suspended bed of the product, whose mass depends on the working conditions of the dryer.

The hot heat-transfer agent is delivered into the second stage via pipe *10* and discharged via pipe *11* tangentially attached to the outer shell of the apparatus.

After the whirling chamber *6*, the material is delivered via overflow pipe *12* into the third stage *7* to grinding section *13*, where the material is subjected to finishing grinding by beaters *14*. In finishing dryer *7*, internal bound moisture is removed from the material in the ascending whirling flow.

The hot heat-transfer agent is delivered into the third stage of the apparatus via pipe *15*, arrives at gas-feeding box *16*, passes the bottom of diffuser *17*, and comes in the form of a whirling flow into bottom whirling chamber *7*. In the third stage *7*, a gas-dispersed whirling flow with a stable hydrodynamic mode is formed and maintained by blades *18*. Then, the gas-dispersed whirling flow is directed by ventilator *19* via pipe *20* into cyclone *21*, where the material is discharged. The spent heat-transfer agent is removed from the cyclone via pipe *23*.

EXPERIMENTAL

As the experimental material served shungite, a formation of unique composition, structure, and properties. This compound is a natural composite of unusual structure, a uniform distribution of highly dispersed crystalline silicate particles in an amorphous silicate matrix. The average size of the silicate particles is about 1 μm. The average composition of rocks from the deposit is 30% carbon + 70% silicates. The rock has high strength, density, chemical resistance, and electrical conductivity. The shungite carbon exhibits high activity in redox reactions. Thanks to this circumstance, the shungite rock is a valuable raw material for manufacture of foundry iron, ferrous alloys, silicon carbide and as a filler of building mixtures and paint-and-varnish coatings absorbing electromagnetic radiation.

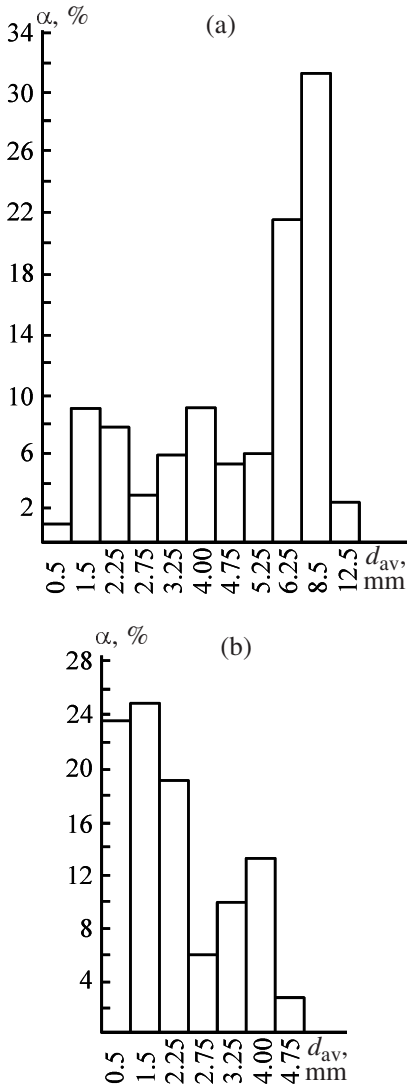

Fig. 2. Histograms of (a) starting product and (b) shungite after grinding and drying. (α) Share of fraction and (d_{av}) particle diameter.

Figures 2a and 2b show histograms of the starting and final products. It can be seen that coarse fractions (4 to 15 mm) constitute more than 70% in a shungite sample under study, and the amount of the 0.5–2.25-mm fraction in the final product at the outlet of the finishing-dryer–grinder is up to 70%, which favorably affects its subsequent grinding in a ball mill.

To determine the amount of free and bound moisture in the material, the kinetics of drying of the starting shungite at temperatures of 105 and 20°C were studied. Analysis of the curves in Fig. 3 shows that

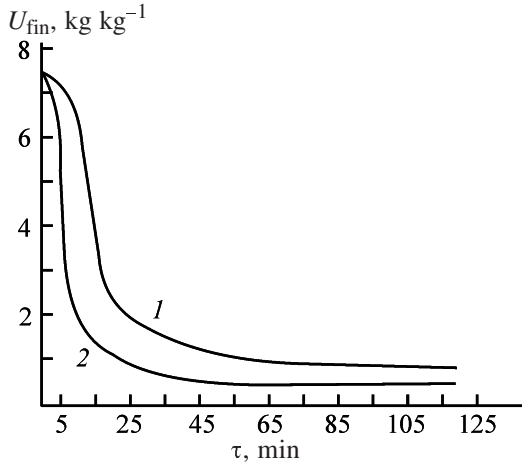

Fig. 3. Kinetics of shungite drying at (*1*) 105 and (*2*) 200°C. (U_{fin}) Final moisture content and (τ) drying duration.

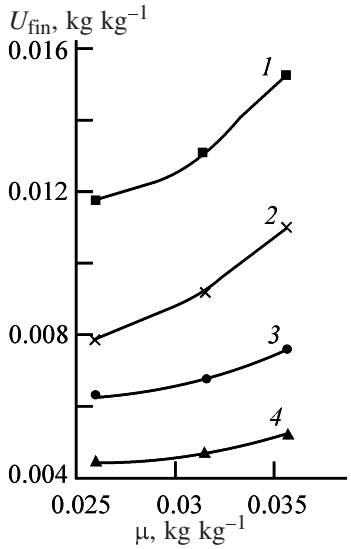

Fig. 4. Final moisture content U_{fin} vs. the consumed solid phase concentration. Drying temperature, °C: (*1*) 100, (*2*) 150, (*3*) 200, and (*4*) 250.

a considerable part of moisture is in the free state. The critical absolute moisture content is 2.3%. The prescribed final moisture content U_{fin} = 0.5% is reached in 37 min at 105°C and in 17 min at 200°C.

Figure 4 shows how the final moisture content of shungite depends on the consumed concentration of the solid phase. Analysis of the corresponding curves shows that the final moisture content of the product decreases as the temperature of the heat-transfer agent is raised and increases as the feeding rate of the solid phase becomes higher. This is accounted for by an insufficient supply of heat and too short residence time in the whirling chamber.

It should be noted, when analyzing the experimental data obtained, that the following parameters can be recommended for drying and grinding in the finish-dryer–grinder: heat-transfer agent temperature 200–250°C, consumed solid phase concentration 0.036–0.026 kg kg^{-1}.

CONCLUSIONS

(1) A combined dryer comprising a cyclone, whirling chamber, and finish-dryer–grinder was developed.

(2) The drying kinetics of the shungite mineral was studied under steady-state conditions. It was found that most part of moisture is in the free state and an effective technical and economic solution for obtaining a product with a final moisture content of 0.5% is to introduce a third stage into the installation. This can diminish the energy expenditure in subsequent grinding of the material in the ball mill.

Abstract—A new efficient procedure of synthesis of 3,4-dinitrotoluene from 3-nitro-4-aminotoluene was developed. Oxidation of 3,4-dinitrotoluene with an ozone–oxygen mixture to 3,4-dinitrobenzoic acid in the presence of cobalt(II) acetate was studied.

DOI: 10.1134/S1070427208030348

Along with other isomeric dinitrobenzoic acids, 3,4-dinitrobenzoic acid (DNBA) is widely used as intermediate in synthesis of photosensitive materials for electrophotography [1, 2], X-ray contrast agents [3, 4], and modifying and vulcanizing agents for polyurethane plastics [5].

In common practice, DNBA is synthesized by oxidation of 3,4-dinitrotoluene (DNT) with Cr(VI) compounds or potassium permanganate. Oxidation with mineral oxidants proceeds under mild conditions; however, it is characterized by low selectivity and formation of large amounts of toxic wastes. Additional and important problem in synthesis of DNBA is the fact that the dinitrotoluenes are obtained as an isomeric mixture from which the desired 3,4 isomer (DNT) should be isolated.

With the aim to develop a new procedure of synthesis of DNBA, we studied the synthesis of DNT from 3-nitro-4-aminotoluene (NAT) and the liquid-phase oxidation of DNT with ozone–oxygen mixture in glacial acetic acid.

For the synthesis of DNT we developed a procedure based on the known procedure of synthesis of 2-dinitrobenzene from 2-nitroaniline [6]. This procedure involves diazotization of NAT with subsequent substitution of nitro group for diazo group. The yield of DNT is 92%.

Considering drawbacks of mineral oxidants, oxidation of DNT with ozone is of practical interest. At 30°C and atmospheric pressure, ozone reacts with DNT by two competing pathways, at double bonds of the aromatic ring and at the methyl group:

$$ArCH_3 + O_3 \rightarrow \begin{cases} \rightarrow Ar\dot{C}H_2 + HO^{\bullet}, & (1) \\ \rightarrow ArCH_2OH + O_2, & (2) \\ \rightarrow \text{ozonides}, & (3) \end{cases}$$

where Ar is $C_6H_3(NO_2)_2$.

Among the aromatic products, we identified 3,4-dinitrobenzaldehyde (DNBAld) and traces of 3,4-dinitrobenzyl alcohol (DNBAlc) in the initial period of the reaction and DNBA in deeper stages (Fig. 1). The yield of products formed by oxidation of the methyl group in DNT is 38%.

The selectivity of oxidation at the methyl group increases on adding variable-valence metal salts [7, 8].

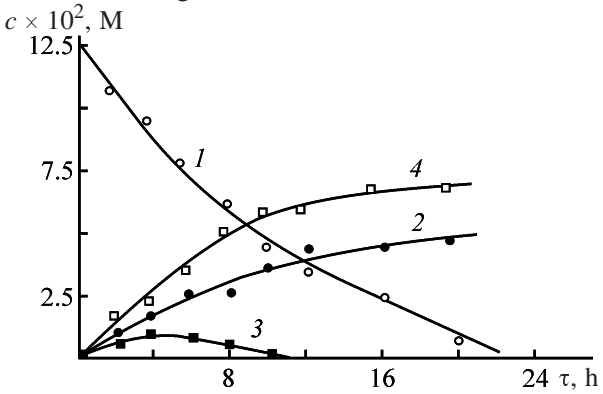

Fig. 1. Content of components of the reaction mixture as a function of time in oxidation of DNT with ozone–oxygen mixture. $W_{O_2} = 8.3 \times 10^{-3}$ l s^{-1}; $[ArCH_3]_0 = 0.125$, $[O_3]_0 = 9.5 \times 10^{-4}$ M; T = 30°C. (*c*) Concentration and (τ) time; the same for Fig. 2. (*1*) DNT, (*2*) DNBA, (*3*) DNBAld, and (*4*) peroxides.

Effect of catalyst on the selectivity of oxidation of methylbenzenes at 100°C. $[ArCH_3]_0$ = 0.50, $[M(OAc)_2]_0$ = 0.14, $[O_3]_0 = 4.0 \times 10^{-4}$ M

Catalyst	E_p^{298} M^n/M^{n+1}, V [11]	Maximum yield of acid, %		
		benzoic [12]	4-nitrobenzoic [13]	3,4-dinitrobenzoic
$Co(OAc)_2$	1.810	72.2	95.6	97.6
$Mn(OAc)_2$	1.510	31.8	36.4	62.8
$Pd(OAc)_2$	0.987	22.4	31.2	52.4
$Cr(OAc)_3$	0.740	18.6	27.9	48.2

According to published data, the selective oxidation of methylbenzenes depends on the redox potential of the catalyst [9, 10]. As seem from the table, cobalt and manganese compounds have the highest potential and these compounds are the most efficient catalysts of ozonation of methylbenzenes in acetic acid solutions.

The kinetic data for oxidation of DNT with ozone–oxygen mixture in the presence of cobalt(II) acetate at 100°C are presented in Fig. 2. The main product of oxidation at the methyl group is DNBA with a yield of 97%. DNBAld and traces of DNBAlc were also found as intermediates. In the system, the equilibrium between the oxidized and reduced cobalt species, in which cobalt occurs predominantly in the form of Co^{3+} throughout the process, is reached in the first 10–20 min.

It follows from the above facts that, in the presence of cobalt(II) acetate, DNT is oxidized in two stages: ozone predominantly reacts with Co^{2+} to form Co^{3+}:

$$Co^{2+} + O_3 + H^+ \rightarrow Co^{3+} + HO^\bullet + O_2, \qquad (4)$$

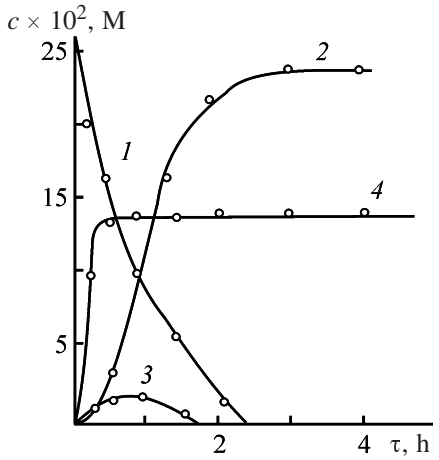

Fig. 2. Oxidation of DNT with ozone in the presence of cobalt(II) acetate in acetic acid solution. $W_{O_2} = 8.3 \times 10^{-3}$ l s^{-1}; $[ArCH_3]_0$ = 0.25, $[O_3]_0 = 6.70 \times 10^{-4}$, $[Co(AcO)_2]_0$ = 0.14 M; T = 100°C. (*1*) DNT, (*2*) DNBA, (*3*) DNBAld, and (*4*) Co^{3+}.

which further participates in initiation of selective oxidation of the substrate at the methyl group:

$$ArCH_3 + Co^{3+} \rightarrow Ar\dot{C}H_2 + Co^{2+} + H^+. \qquad (5)$$

Thus, we developed a new efficient procedure for preparing DNT from 3-nitro-4-aminotoluene. Oxidation of DNT with ozone in the presence of cobalt(II) acetate gives DNBA with an overall yield of 89%.

EXPERIMENTAL

3,4-Dinitrotoluene. 3-Nitro-4-aminotoluene of chemically pure grade (5 g) was dissolved in 30 ml of 60% sulfuric acid with heating. A 100-ml three-necked round-bottomed flask was charged with 20 ml of water and 10 g of ice, and a sulfuric acid solution of NAT was added with vigorous stirring. To the resulting mixture, 4 g of $NaNO_2$ in 15 ml of water was quickly added with vigorous stirring, and the mixture was stirred for 20 min.

The resulting solution of diazonium salt was placed into an ice bath. Then, a solution of 50 g of $NaNO_2$, 20 g of $NaHCO_3$, and 3 g of $CuNO_2$ in 500 ml of water was prepared in a 1-l three-necked round-bottomed flask. To the resulting solution, a solution of diazonium salt was added with vigorous stirring in portions through a glass tube touching the flask bottom. The solution temperature was maintained within 10–20°C. Addition of the diazonium salt was accompanied by active foaming. Ten minutes after adding the whole amount of the mixture, the precipitate was filtered off, washed with water, and dried in air.

Oxidation of DNT was performed in a reactor presenting a glass column with a finely porous membrane for dispersion of the gas mixture. The reactor was charged with 15 ml of glacial acetic acid and calculated amount of DNT; then, the reactor was thermostated and ozone–oxygen mixture was fed at a flow

rate of 8.3×10^{-1} l s^{-1}. The amount of the initial DNT and oxidation intermediates in the mixture was determined by gas–liquid chromatography on an LKhM-80 chromatograph equipped with a flame-ionization detector on a 2 m × 3 mm column packed with Chromaton N-AW support with the applied PNFS-6 stationary phase. The concentration of DNBA formed was determined by titration with 0.01 N NaOH solution on an EV-74 pH meter.

CONCLUSIONS

(1) 3,4-Dinitrotoluene was synthesized in 92% yield by diazotization of 3-amino-4-nitrotoluene with subsequent substitution of the nitro group for diazo group.

(2) In ozonation of 3,4-dinitrotoluene in acetic acid at 30°C, the yield of 3,4-dinitrobenzoic acid does not exceed 38%; the use of cobalt(II) acetate as a catalyst increases the yield of 3,4-dinitrobenzoic acid to 97%.

Abstract—Procedures for esterification of biologically active mono- and bispiperidols by reactions with benzoyl and terephthaloyl chlorides were developed.

DOI: 10.1134/S107042720803035X

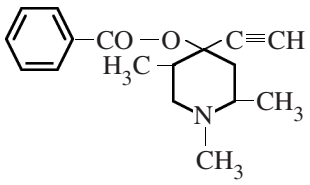
The development of highly effective chemical agents increasing the output of agricultural production is one of priority problems of chemical science and industry. Regulators of plant growth and development occupy an important place among such chemical agents. Numerous low-molecular-weight compounds, both natural (auxins, gibberellins, kinins, abscisic acid) and synthetic, exerting growth-regulating, stimulating, and herbicidal effect are known. At the same time, active studies aimed to develop new plant growth regulators and their derivatives are continued.

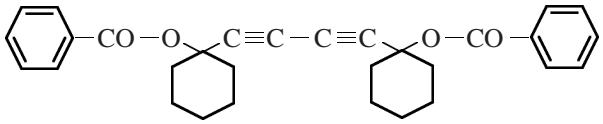
Numerous studies showed that the performance of biologically active substances (BASs) can be considerably enhanced by their chemical modification, mainly with various polymers [1, 2].

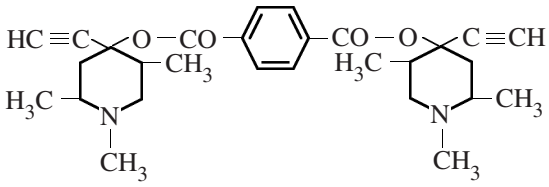
For a long period we perform comprehensive studies dealing with immobilization of low-molecular-weight BASs on a polymeric matrix with the aim to enhance and prolong their action and to ensure controlled release of the growth-regulating agent. We developed and implemented polymer-analogous transformations of copolymers of maleic anhydride with derivatives of acetylenic nitrogen- and phosphorus-containing carbo- and heterocyclic systems [3–7]. As a result, we obtained a new generation of polymeric water-soluble agents controlling the growth and development of plants and exhibiting durable action. We developed new polymeric preparations surpassing in the performance the known plant growth regulators. The laboratory, field, and commercial trials show that the polymeric preparations Zhiger, PAG, and PASA increase the productivity of crops (potatoes, sugar-beet) by 20–30% on the average, and the saccharinity of sugar-beet, by 1.5%. Polymeric plant growth regulators increase the germination energy of seeds (lucerne, goose-foot, licorice) by 12–18%, and the germinating power, by 60–80% on the average.[1]

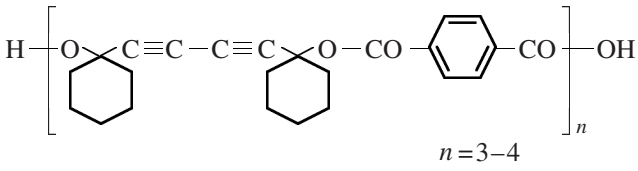
Here we report on a new route to modified BASs. As modification substrates we chose a series of mono- and bispiperidols and their analogs: 1,2,5-trimethyl-4-(butoxypropyn-1-yl)piperid-4-ol, di(1-hydroxycyclohexyl)buta-1,3-diyne, and 1,4-bis(1,2,5-trimethyl-4-hydroxypiperid-4-yl)buta-1,3-diyne. These agents increase the productivity and improve the quality of crops such as potatoes, sugar-beet, corn, etc.

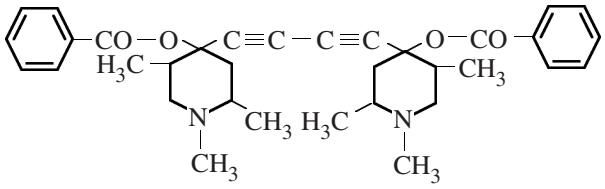
EXPERIMENTAL

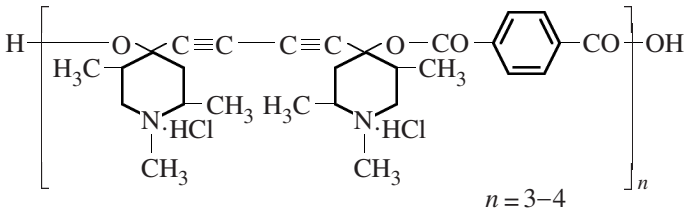












The starting compounds and solvents were purified by standard procedures. The IR spectra were measured on an IR-25 spectrophotometer (KBr pellets).

As the BASs under consideration contain hydroxy groups, one of the ways of their modification is condensation with acid chlorides. In our study we used benzoyl and terephthaloyl chlorides.

The products were identified by IR spectroscopy and elemental analysis. The main characteristics of the compounds are given in the table.

VI		73	132–134	67.41 64.95	7.02 7.60	N 5.61 5.61 Cl 7.12 8.08

First we prepared monoesters of the above-mentioned BASs with benzoyl chloride. Monoesters **I**, **II**, and **V** (see table) were prepared at 60°C in a benzene solution in excess benzoyl chloride in the presence of triethylamine. The reaction progress was monitored by thin-layer chromatography. The synthesis was performed for 7–8 h. After removing benzene and excess benzoyl chloride, an only product was obtained, which crystallized on trituration in petroleum ether. In the IR spectrum of the products, there is an absorp-

tion band at about 1730 cm^{-1}, corresponding to vibrations of the ester group.

Diester **III** (see table) derived from 1,2,5-trimethyl-4-(3-butoxypropyn-1-yl)piperid-4-ol and terephthaloyl chloride was synthesized by the procedure for preparing activated diesters at 60°C in dioxane in the presence of pyridine. The synthesis was performed for 10 h, after which the mixture was evaporated to dryness, thoroughly washed with cold water, dried, and recrystallized from ethanol–petroleum ether. The product was identified by elemental analysis and IR spectroscopy.

Terephthalic acid esters of di(1-hydroxycyclohexyl)buta-1,3-diyne and 1,4-bis(1,2,5-trimethyl-4-hydroxypiperid-4-yl)buta-1,3-diyne (compounds **IV** and **V**, see table) were prepared by reaction of these alcohols with terephthaloyl chloride in a three-necked flask equipped with a bubbler, a stirrer, and an outlet pipe equipped with a calcium chloride tube. The reaction was performed in dichloroethane at 60–80°C in the presence of triethylamine. The synthesis time was 12 h. After the reaction completion, the product was precipitated with acetone, washed on the filter alternately with methanol and cold distilled water, and dried in a vacuum oven. The esters are readily soluble in amide solvents.

Tests performed with dicotyledonous cereals showed that the mono-, di-, and oligoesters we prepared, taken in low concentrations, exhibit a growth-stimulating effect. At the same time, esters derived from di(1-hydroxycyclohexyl)buta-1,3-diyne (see table, products **II** and **IV**) exhibit a herbicidal effect.

CONCLUSIONS

(1) New esters derived from benzoyl and terephthaloyl chlorides and biologically active mono- and bispiperidols and their analogs [1,2,5-trimethyl-4-(butoxypropyn-1-yl)piperid-4-ol, di(1-hydroxycyclohexyl)buta-1,3-diyne, and 1,4-bis(1,2,5-trimethyl-4-hydroxypiperid-4-yl)buta-1,3-diyne] were prepared and identified by IR spectroscopy and elemental analysis.

(2) The synthesized mono-, di-, and oligoesters taken in low concentrations exhibit a growth-stimulating effect.

Abstract—Dihydric phenols and their monomethyl ethers were converted into diadamantyl derivatives by the reaction with 1-adamantanol in trifluoroacetic acid.

DOI: 10.1134/S1070427208030361

It is known that adamantyl derivatives of phenols, in particular, of 3,5-di(1-adamantyl)pyrocatechol, are effective antioxidants in the model reaction of cumene oxidation [1]. In addition, the antioxidant activity of 2,6-di(1-adamantyl)-4-methylphenol toward SKI-3 isoprene rubber was studied recently [3]. In this connection, it is interesting to perform diadamantylation of pyrocatechol, hydroquinone, and their monomethyl ethers.

The existing methods of diadamantylation of pyrocatechol and hydroquinone either led to poor yields of the target products [3] or required harsh reaction conditions [4]. It is known that adamantylation of *o*-methoxyphenol with 1-bromoadamantane is accompanied by elimination of the methoxy group and formation of *p*-(1-adamantyl)phenol [5]. Adamantylation of aromatic compounds with 1-adamantanol in trifluoroacetic acid was performed recently [6, 7].

Here we report on diadamantylation of pyrocatechol, hydroquinone, and their monomethyl ethers with 1-adamantanol in trifluoroacetic acid. The reaction occurs readily and with a high yield at 18–20°C:

Ia–Id **IIa–IId**

where $R^1 = OCH_3$, $R^2 = H$ (**Ia**); $R^1 = H$, $R^2 = OCH_3$ (**Ib**); $R^1 = OH$, $R^2 = H$ (**Ic**); $R^1 = H$, $R^2 = OH$ (**Id**); $R^1 = OCH_3$, $R^2 = R^4 = Ad$, $R^3 = H$ (**IIa**); $R^1 = R^3 = Ad$, $R^2 = OCH_3$, $R^4 = H$ (**IIb**); $R^1 = OH$, $R^2 = R^4 = Ad$, $R^3 = H$ (**IIc**); $R^1 = R^3 = Ad$, $R^2 = OH$, $R^4 = H$ (**IId**).

EXPERIMENTAL

The IR spectra were recorded on a Vektor-22 Fourier spectrometer in KBr, and the ^1H NMR spectra, on a Bruker-Avance DPX-200 spectrometer.

Diadamantyl derivatives IIa–IId. To a mixture of 1 mmol of **Ia–Id** and 2 mmol of 1-adamantanol, 2 ml of trifluoroacetic acid was added. The mixture was stirred and allowed to stand at 18–20°C for 16 h. The precipitate was filtered off, washed with water to neutral reaction of wash waters, and dried. The products were recrystallized from heptane–benzene, 10 : 1.

4,6-Di(1-adamantyl)-2-methoxyphenol IIa. Yield 76%, mp 201–203°C.

Found, %: C 82.96; H 9.62.

TECHNOLOGY OF ORGANIC AND INORGANIC CHEMISTRY

Synthesis of α-Bromoisovaleric Acid in the Poliphosphoric Acid Medium

S. A. Malin, A. S. Malin, and B. M. Laskin

Russian Scientific Center "Applied Chemistry," St. Petersburg, Russia

Received March 19, 2007

Abstract—Bromination of isovaleric acid with bromine in the polyphosphoric acid mediumis was studied, regularities of the process including influence of the polyphosphoric acid composition were revealed, the process was shown technologically attractive for the organization of industrial manufacturing of α-bromoisovaleric acid.

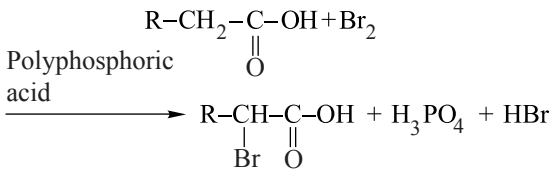
DOI: 10.1134/S1070427208030373

As is known, α-bromoisovaleric acid is commonly obtained by the method of Gell–Folgard Zelinskii by which consists of bromination of isovaleric acid with elemental bromine in the presence of various catalysts such as red phosphorus or phosphorus halides, acyl halides, in part, isovaleroyl halides, thionyl chloride and mineral acids [1–5]. These methods are disadvantageous because of high consuming of bromine and catalyst, high temperature of the process and due to formation of isovaleric acid chlorine derivatives as side products.

An attractive method is bromination of isovaleric acid with bromine in the medium of polyphosphoric acid. This method has been considered in [6, 7], but the process features have not been published. Preparation of α-bromoisovaleric acid by his method in our opinion seems acceptable in respect of technology.

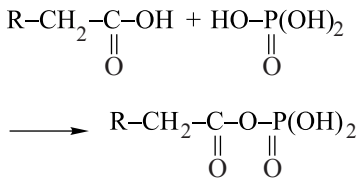
We explored bromination of isovaleric acid in the medium of polyphosphoric acid in details. We studied effects of reagents ratio, their total concentration in polyphosphoric acid, thermal and timing parameters. We found that bromination proceeds smoothly in 30–60% solutions of the reagents in polyphosphoric acid and affords α-bromoisovaleric acid in the yield up to 92–94%. For example, at the reagents content in polyphosphoric acid in the range 25–45% and isovaleric acid–bromine ratio 1 : 1.09 the bromination proceeds at 40–70°C in 4–5 h with 90–94% yield. Therewith, duration of the reaction completing increases owing probably to diffusion character of the process. The results obtained are listed in Table 1.

Yield of bromoisovaleric acid is high enough and achieves 92–94%.



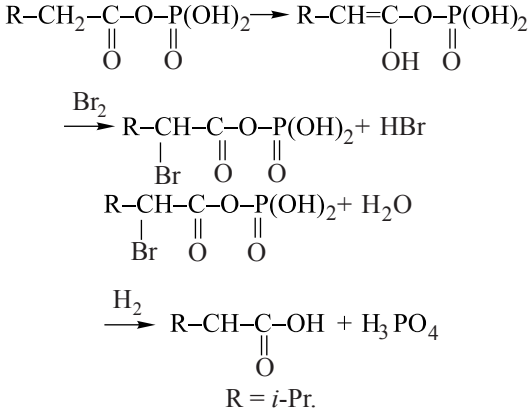
Study of isovaleric acid bromination in polyphosphoric acid of different compositions showed that at the phosphoric anhydride content in polyphosphoric acid from 20 to 40 wt% the bromination proceeds smoothly resulting in up to 92% yield of α-bromoisovaleric acid. Further increase in phosphoric anhydride content to 55% affects negatively the bromination process because the system becomes

Table 1. Bromination of isovaleric acid in the medium of polyphosphoric acid



No.	Amount of polyphosphoric acid		Amount of isovalericacid		Amount of bromine		Phosphoric anhydride concentration in polyphosphoric acid		Concentration of reagents in polyphosphoric acid	Temperature of the process	Process duration	Yield
	ml	g	g	mol	g	mol	g	%	%	°C	h	%
	1	2	3	4	5	6	7	8	9	10	11	12
1	25	50	6	0.05	10.8	0.0 6	12.5	25	25	75–80	6	92–94
2	12.5	25					7.5	30	40	80	5	93–95
3	10	20					7.8	39	46	95–100	8	90–93
4	11	22					12.1	55	43	100–110	12–14	85

extremely viscous. Noteworthy that the formed α-bromoisovaleric acid is practically insoluble in polyphosphoric acid, forms a separate layer and can be isolated by separation or extraction with methylene chloride. The used polyphosphoric acid after bromination, as we established, can be further applied in bromination operations several times by refreshing with new portions of phosphoric anhydride for binding water formed in the process.



Bromination in the medium of polyphosphoric acid obviously proceeds alongside the scheme:

Probably initially isovaleroyl phosphate is formed:

The phosphate then exerts enolization and reacts with bromine to form α-bromoisovaleroyl phosphate which by controlled hydrolysis is converted into α-bromoisovaleric acid and phosphoric acid, providing high (up to 92–95%) yield of α-bromoisovaleric acid.

The studied method of α-bromoisovaleric acid formation is acceptable from the viewpoint of technology. It is advantageous because avoids application of toxic and dangerous catalysts such as phosphorus halides, thionyl chloride and others.

EXPERIMENTAL

Synthesis of α-bromoisovaleric acid. To a three-necks flask equipped with jacket, reflux condenser, dropping funnel, thermometer and magnet stirrer was loaded 20 g of polyphosphoric acid prepared alongside the procedure in [7]. For enhancing its rheological properties the acid was heated to 40–45°C, and then 6 g (0.05 mol) of isovaleric acid was added, stirring was switched on and 18.8 g (0.06 mol) of bromine was added dropwise. The mixture was heated to the temperature 95–100°C and kept at this temperature for 6–8 h. Then α-bromoisovaleric acid formed was extracted with methylene chloride, organic phase was washed and dried over magnesium sulfate. Solvent was distilled off and 9.6 g (90%) of α-bromoisovaleric acid was isolated, mp 44°C, bp 230°C.

TECHNOLOGY OF ORGANIC AND INORGANIC CHEMISTRY

Synthesis of New Substituted Thiazoles Containing Aminooxadiazole Ring

O. V. Platonova, S. B. Volkova, S. A. Malin, E. A. Veretennikov, B. M. Laskin, and A. S. Malin

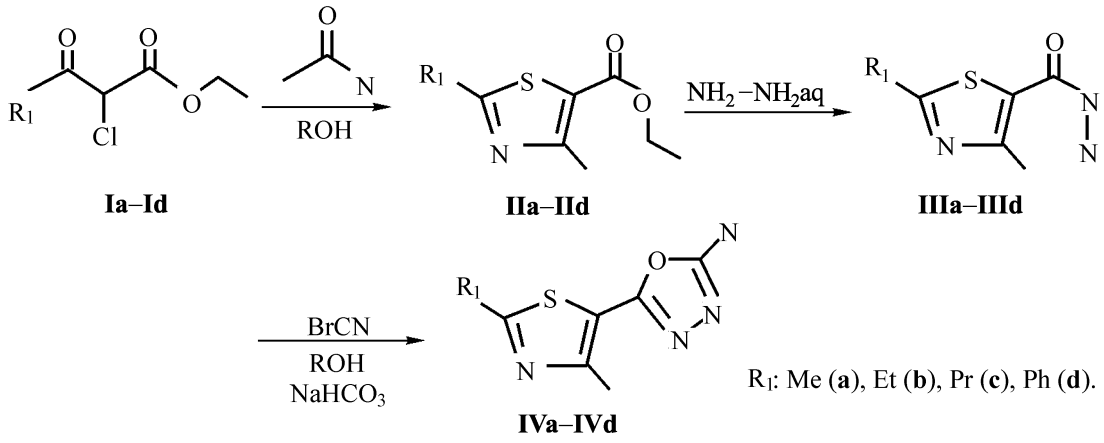
Russian Scientific Center "Applied Chemistry," St. Petersburg, Russia

Received February 12, 2007

Abstract—Synthesis of biheterocyclic thiazole–amonooxadiazoles, the potential biologically active compounds is developed. Regularities of transformations and physico-chemical characteristics of intermediates and final compounds are revealed.

DOI: 10.1134/S1070427208030385

The heterocycles of thiazole series are known to possess biological activity; some representatives of this class compounds are well-known medicine preparations [1, 2]. Compounds containing simultaneously thiazole and aminooxadiazole fragments merit special mentioning. Synthesis of these potentially biologically active compounds practically has not been described. We developed a few-step procedure for the synthesis of thiazole–aminooxadiazoles and studied conditions of the process and its technological parameters.



Substituted thiazoles **IIa**–**IId** were prepared by reaction of chloroacetoacetic esters prepared in correspondence with the procedure in [3] with thioacetamide in alcohol medium (like Hanch reaction [4, 5]) at 80–90°C, duration period 7–12 h, yield up to 75–80%.

Compounds **IIa**–**IId** are crystalline substances melting in the temperature range from 56 to 65°C.

Note that at the synthesis of compounds **IIa**–**IIc** the process duration increases for the series of substituents a to c, probably in connection with steric properties of these substituents. The process duration for compound **IId** increases probably due to strong electromeric effect of conjugated system that includes phenyl group. Introduction of triethylamine to the reaction zone allows accelerate the process considerably and increase yield of compound **IId** to 75%.

The process conditions for the synthesis of the thiazoles and some of their characteristics are listed in Table 1.

Synthesis of corresponding hydrazines **IIIa**–**IIId** has been poorly illuminated in literature. We prepared hydra-

IVd	10	40	68 2	30

zides **IIIa–IIId** by reaction of thiazoles **IIa–IId** with 3–5-fold excess of 64% hydrazine hydrate in absolute ethnol at 90–100°C, reaction duration was 10 to 20 h, yield is as high as 95%. The compounds obtained are characterized by high melting point; they are well crystallizing from water–alcohol solutions. Results of the synthesis of compounds **IIIa–IIId** are shown in Table 2.

Aminooxadiazole derivatives **IVa–IVd** were obtained in 65–80% yield by cyclization of the prepared hydrazides [6, 7] with bromocyane in the presence of anhydrous potassium carbonate at equimolar ratio of reagents in ethanol medium at 20–40°C for 6–10h. IR spectra of the obtained compound do not contain adsorption bands of carbonyl and hydrazide groups while adsorption of aminooxadiazole NH_2 group appears in the spectra.

Structure, purity and nature of compounds **IVa–IVd** were revealed using 1H NMR spectroscopy. The NMR data obtained showed that amine fragment in compounds **IVa–IVd** is considerably less basic as compared with related unsubstituted aminooxazoles. The most probably this is defined by the presence of conjugated system thiazole–aminooxadiazole, in the case of **IVd** in particular, due to presence of phenyl group expanding conjugation. Spectral characteristics of the synthesized compounds are listed in Table 4.

CONCLUSIONS

A series of new potentially biologically active biheterocyclic compounds containing thiazole and aminooxazole rings is synthesized, optimal conditions of the synthesis are studied and revealed.

Structure of the obtained compounds is proved and they are characterized by means of ^{1}H NMR spectroscopy.

EXPERIMENTAL

The ^{1}H NMR spectra are recorded on a e Bruker AM 500 spectrometer, internal reference TMS, solvent DMSO-d_6. Melting points are measured on a PTP unit.

Synthesis of R-substituted ethyl esters of thiazolecarboxylic acids IIa–IId. Mixture of preliminary prepared R-substituted chloroacetoacetic ester **Ia–Id** (0.236 mol) and thioacetamide (0.236 mol) in 100 ml of ethanol or isopropyl alcohol was refluxed on water bath with stirring for 7–12 h. After cooling the reaction mixture was diluted with 200 ml of dichloromethane. Precipitate formed was removed by filtration and filtrate was washed with 20% solution of sodium hydrocarbonate (100 ml) to neutral reaction and then by solution (100 ml) of sodium chloride. The layers were separated, and from organic layer dicloromethane was distilled off after drying over magnesium sulfate, and then compounds **IIa–IId** were isolated in 85–90% yield.

Spectral characteristics of compounds **IIa–IId** obtained are listed in Table 4.

Synthesis of hydrazides of R-substituted thiazolecarboxylic acids IIIa–IIId. To a solution of the obtained by above procedure R-substituted ethyl ester of thiazolecarboxylic acid **IIa–IId** (0.5 mol) in 125 ml of ethanol or isopropyl alcohol was dozed at 20–30°C 100 ml of 64% hydrazine hydrate (0.236 mol) and the raction mixture obtained was refluxed with stirring for 10–20 h. Then reaction mixture was concentrated in a vacuum to 60–75%. The crystals dropped are soluble in water. They were recryctallized from ethanol, and compounds **IIIa–IIId** were obtained in 85–93% yield.

Table 4. 1H NMR spectral data of compounds **II–IV** (solutions in DMSO–*d*6)

Received March 19, 2007

Abstract—A catalyst obtained by impregnation of a mesoporous carbon carrier *sibunit* with orthophosphoric acid is examined under conditions of pilot plant manufacturing for producing α-methylstyrene dimer. The produced *catalyzate* (the product obtained with catalysis, 300 ton) containing ca. 70% of targeted 2,4-diphenyl-4-methyl-1-penetene at 95% conversion was after filtration used for control of molecular mass at producing polystyrene of different sorts. Consumption of the catalyst under optimal conditions of exploitation of the installation was ca. 1.5 kg per 1 ton of dimer at temperature ca. 50°C and volume rate ~ 0.5 h^{-1}. Content of 2,4-diphenyl-4-methyl-1-pentene in the dimer can be elevated to 80% by significant decreasing conversion (~50%) and by application of solvents.

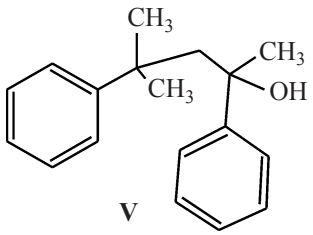
DOI: 10.1134/S1070427208030397

α-Methylstyrene dimer consisting mainly of 2,4-diphenyl-4-metyl-1-pentene (α-isomer **I**) is used for control over molecular mass at producing polystyrene and its co-polymers. After complete hydrogenation of the dimer the product obtained is the best base for high-power lubricant oil [1].

World market proposes a dimer containing up to 94% of α-isomer at the total content of linear dimers above 98%. The α-isomer serves as substance for the molecular mass control, in distinct to unwanted admixtures of 2,4-diphenyl-4-methyl-2-pentene (β-isomer **II**) and 1,1,3-trimethyl-3-phenylindane (cyclic isomer **III**). The dimer produced in Russia in correspondence with technical requirements [2] commonly contains less than 75% of α-isomer [2].

Information on the technology of α-methylstyrene oligomerization and catalysts used can be found in patent publications mainly [3]. As catalysts were applied liquid or solid acids (the latter are more useful in technology): clays, ceolites, sulfocationites, various phosphate systems, e.g., industrial catalysts used at hydrogenation of ethylene, often in the presence of a solvent. With some ceolites without a solvent was achieved high selectivity at producing α-dimer (90%) [4–6]. However, duration of application of such catalyst before regeneration has not been reported.

There is US patent on obtaining individual α-isomer in the presence of cobalt complexes as radical initiators [7]. Possibility of practical application of such process in view that domestic technologies are commonly below the high-tech range is doubtful.



The main purpose of the present work is search of catalyst for α-methylstyrene oligomerization to provide styrene producing in Omsk with simplest technology for the synthesis of molecular mass controlling substance free of by-products, satisfactory from the viewpoint of domestic requirements, at minimal investment and producing cost.

The catalyst "phosphoric acid on sibunit" is obtained at primary screening on catalytic activity and contact selectivity of the catalysts obtained by impregnation with orthophosphoric acid of carbon material sibunit with medium diameter of mesopores of the carrier at varied acid content and regime of thermal treatment. The catalyst with appropriate catalytic activity, selectivity and life time for pilot plant manufacturing was obtained with the sibunit with average pore diameter 40 nm, phosphate

content recalculated on P_2O_5 10–15% and maximal temperature at roasting the catalyst below 250°C.

After examination of the catalyst on a laboratory installation (Fig. 1) the catalyst was tested for industrial application. Various batches of the catalyst produced in Sorbents and catalysts pilot plant department of Omsk plant were for three years used for producing dimer in low tonnage industrial circulation installation of plastic fabric of join stock company "Zavod Plastmass" on pipe type reactor for 100 kg of the catalyst constructed on the basis of ordinary heat exchanging unity which allowed maintaining the optimal reaction temperature ca. 50°C by water circulating in jacket. With fresh catalyst effective cooling was needed, at further work it should be heated to the operating temperature. The table shows data on the catalyzate content obtained under industrial conditions at two-times circulation. At exploitation of the installation was produced over 300 ton of such dimer using various batches of the catalyst. It was found that long enough (up to 30 days) pauses do not lead to significant loss in the catalyst activity. Consumption of the catalyst at optimal winter conditions of exploitation was about 1.5 kg of the catalyst per one ton of dimer. In the period from May to September the catalyst resource is affected considerably due to its hygroscopicity, therefore additional means should be applied to protect the system against moisture. Without such protection in summer time the catalyst may loss activity in a few days.

The catalyzate obtained was not purified additionally but filtered for removing catalyst particles, and used as agent for chain transfer at producing polystyrene in "Zavod Plastmass" plant. It was noted that the dimer displays inhibiting effect and decreases stability of styrene–water dispersions, like has been noted for the case of similar molecular mass controlling substance obtained with aqueous benzenesulfonic acid as catalyst [7]. The dimer obtained under optimal conditions with "phosphoric acid on sibunit" as catalyst in distinct to the dimer obtained with aqueous benzenesulfonic acid is not contaminated with 2,4-diphenyl-4-methyl-2-hydroxypentane (**V**) which suggested inherent in the mentioned negative effect on the exploitation properties of the dimeric substance [8].

III

IV

T, °C	Volume rate, h^{-1} (two passes)	Catalyzate composition, %				
		α -methylstyrene	α-dimer **I**	β-dimer **II**	trimers (basically **IV**)	cyclic dimer **III**
50	1					
Composition of catalyzate		3	71	10	8	8

As the laboratory and industrial tests showed, the proposed catalyst does not allow achieving content of targeted isomer above 90% at high conversion (above 95%) on raw material.

We succeeded in approaching high results on the content of α-isomer like in the substance from foreign producers using "phosphoric acid on sibunit" as catalyst, without a solvent, taking a flask with stirrer as a reactor, with raw material and the catalyst in 5:1 ratio, maintaining temperature 45°C, and carrying out the process to low conversion of α-methylstyrene a (~20%). Unreacted raw material and then fraction of dimers were distilled off under reduced pressure. About 10–15% of raw material was lost therewith due to formation of trimers collected in bottom residue. Under these conditions by direct distillation was isolated dimer with content of α-isomer ca. 92%.

Use of appropriate solvent should lead to decrease in content of trimers in the catalyzate. Really, when raw material was diluted 4 – 5-fold with methylene chloride or carbon tetrachloride, we succeeded in laboratory installation (Fig. 1) at 40–50°C to increase selectivity on the targeted substance to 80% at 50% conversion.

According to published data, as the solvent can be taken also e.g., toluene or cumene and selectivity can be achieved with $HCOOH + C_6H_5OH$ system where phenol is solvent [3]. Besides, principally the selectivity can be increased at application of solvents by choosing a carrier with less size pores [6, 8], in part, with sibunit containing pores of less width. Thus, there are quite real pathways of increasing selectivity of the proposed catalyst, however, necessarily with considerable complication of technology.

EXPERIMENTAL

The catalyst "phosphoric acid on sibunit" is prepared by impregnation of spherical granules of mesoporous carbon carrier sibunit (dimeter of the granules 1.6–2.0 mm for industrial and 0.3–0.5 mm for laboratory testing) with orthophosphoric acid (10% as recalculated to P_2O_5) followed by thermal treatment at the temperature not higher than 250°C.

The catalyst samples were examined in an installation shown in Fig. 1. In some experiments the catalyzate obtained was separated in commonly used laboratory equipment by distillation at reduced pressure. α-Methylstyrene passes at ~70°C and a fraction of dimers at ~200°C, which corresponds to pressure ~30 mm Hg.

Analysis of the catalyzate was conducted on a chromato-mass spectrometer of Agilent Technologies firm (GS-MS 6890N-5973) with capillary column HP-5MS.

CONCLUSIONS

Industrial examination during three years showed that the proposed catalyst for α-methylstyrene oligomerization "phosphoric acid on sibumit" and free of by-product technology allow successfully solve the problem

of providing polystyrene production in Omsk with low tonnage molecular mass controlling substance containing targeted 2,4-diphenyl-4-methyl-1-pentene (α-isomer) approx. 70% at 95% conversion of raw material.

ACKNOWLEDGMENT

The authors grateful to Volodchenko Ludmila Ivanovna, the Principal Technologist of join stock company "Zavod Plastmass" for organization of the line for producing dimeric α-methylstyrene and testing this substance at polystyrene manufacturing.

St. Petersburg State Technological Institute, St. Petersburg, Russia

Abstract—Heat exchangers of circulating type are used extensively in the heat exchange processes. Circulation of liquid in these devices is ensured by mechanical mixing devices, and heat exchange is enhanced by the increase of the heat exchange surface. The application of the upright heat exchange elements like double pipes providing a cross-flow regime in the device is the most effective. Calculation of the apparatus with the vertical heat-exchange elements for determination of constructive and regime parameters at maximum output of the device was presented.

DOI: 10.1134/S1070427208030403

Heat exchangers with the upright heat-exchange elements possess sufficiently high intensity of heat exchange even at the mixing of non-Newtonian fluids [1]. Rational combination of the construction of inside units and the agitator ensures intensive circulation of working media at sufficiently uniform velocity field.

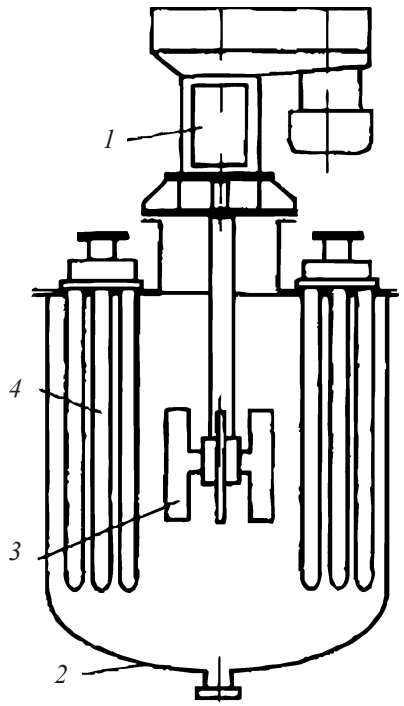

Fig. 1. Batch reactor. (*1*) Drive, (*2*) reactor body, (*3*) agitator, (*4*) upright heat exchange elements.

On the stage of calculation and development of the apparatus with upright heat-exchange elements two problems should be solved. First one is to determine constructive and regime parameters which provide maximum output of the device within conditions of the given constructions. Second problem consists in providing the given output at the minimum of costs at designing and operation of the device. A calculation and optimization of the following parameters: pipe diameter (d_t), number of pipes in the bundle (n_{tb}), number of bundles (n_b), and bundle diameter(d_b), total heat exchange surface (F), agitator diameter (d_m), drive power, characteristics of heat pump [pressure (ΔP), and cooling agent flow (V_r)] are necessary to solve the first and the second problems. The cited parameters define values of heat radiation coefficients α_1 and α_2, heat transfer coefficient (K), and heat flow through surface of heat-exchangers.

Volume of device (V_d) and heat efficiency of the processes per mass unit of heat carrier (q_u) are initial parameters to calculate maximum possible output. Required volume of the device is calculated according to equation (1):

$$V = G\tau / \rho, \quad (1)$$

where G is heat-carrier flow, kg/s; ρ is heat carrier density, kg/m^3, average duration of residence of heat carrier, s.

If the value of the volume is preset the heat carrier flow is calculated by equation (1). In such a way the found output of the apparatus G is not final. It can be limited by the possibility of heat removal. Maximum heat loads have to be provided at the non-stationary process.

$$Q \geq K_Q q_u G,$$

where Q is the required value of heat flow, Wt; K_Q is coefficients of reserve.

The optimal correlations of geometrical and technological parameters must be provided to determine heat characteristics. Some optimum relations of geometric sizes which set the most uniform hydrodynamic processes were determined earlier [2]. According to experimental data the height of cylindrical section of the apparatus body is $H_c = (0.8–1.0)D$; agitator height is $h_m = (1 + 1.2)$ d_m. The values V_d, q_u, G according to the given limits permit the calculation and optimization of the necessary designing parameters. The most compactness of heat exchangers is reached using the pipes of smaller diameter. At these conditions resistance to vibration should be provided:

$$f_t \leq 0.6 f_d \quad (2)$$

$$f_t \leq 0.6 f_v, \quad (3)$$

where f_t is the intrinsic oscillation frequency of pipes, s^{-1}; f_v is the frequency of vortex shedding in trace at rear of pipes, s^{-1}; f_d is vibration frequency caused by hydrodynamic forces originating from the flow pressure pulsation which can result from the agitator blade passing close to the pipe.

$$f_d = nz_a, \quad (4)$$

where n is agitator speed, z_a is number of the agitator blades.

The periodicity of vortex shedding is determined by dimensionless Strouhal number: relation of the frequency of vortex shedding, the characteristic size of body (d_b), and the velocity of the fluid (v) is described as:

$$\mathrm{Sh} = f_v, d_b/v.$$

According to the experimental data the maximum speed of flow is observed in the region of radial stream close to the agitator. Assuming that $w_r = w_t$ and taking into account that $w_r = 0.6\, w_{rm} / 2$ it can be written

$$w = \sqrt{w_t^2 + w_r^2} = \sqrt{2 \cdot 0.6 \omega^2 r_{rm}^2} = 0.85\, \omega r_{rm}.$$

Maximum allowable linear speed of agitator rotation $w = w_{max}$ may be used as a value of agitator diameter since the latter is not defined. If longitudinal and cross space between tubes is equal to Strouhal number for first row of staggered bundle may be obtained from the equation [2]

$$\mathrm{Sh} = 0.2 + \exp\,[-0.44\,(S_t / d_t)^{1.8}],$$

where S_t is the space between the pipes.

The intrinsic oscillation frequency of pipes is defined by equation

$$f_{tr} = \frac{\beta}{2\pi h_t} \sqrt{\frac{EI}{m}},$$

where E is the elasticity of pipe material, N/m^2, I is pipe flexural rigidity, m^4, β is the coefficient depending on the mode of pipe fixation; h_t is the pipe length, m; m is mass of the pipe and of the liquid within the pipe, kg

$$I = \frac{\pi}{64} (d_t^4 - d_{t1}^4),$$

$$m = \rho_{liq} \frac{\pi d_{t1}^2}{4} h_t + \rho_t \frac{\pi (d_{t1}^2 - d_{t1}^2) h_t}{4}, \quad (5)$$

where d_t is the inside pipe diameter, m.

Setting pipe diameter we can find values f_t, f_d, and f_v by equations (4) and (11).

When the conditions (2) and (3) are not met the diameter of pipes must be increased. The calculation is continued until the condition of resistance to vibration is met. Diameter of bundles is related to the diameters of apparatus and agitator by an equation.

$$d_B = \frac{D - d_M}{2} - \delta_{\Phi 1} - \delta_{\Phi 2}, \quad (6)$$

where $\delta_{\Phi 1}$ is the size of flange for drive installation drive, m, and $\delta_{\Phi 2}$ is the size of flange for fastening the bundles to the cover, m.

Equation defining the number of bundles is

$$n_B = \frac{2\pi}{\gamma}, \quad (7)$$

where γ (see Fig. 1) is

$$\gamma = 2\arcsin \left[\frac{\left(\frac{d_B}{2} - \delta_\Phi \right)}{\left(\frac{d_M}{2} + \frac{d_B}{2} + \delta + \delta_{\Phi 2} \right)} \right]. \quad (8)$$

With an increase of the agitator diameter the number of bundles is increased and their diameter is decreased. So an optimum value d_m/D exists corresponding to the overall maximum number of installed pipes.

Number of pipes in the bundle may change depending on a manner of their mounting. At the mounting of pipes on sides of regular triangles their number under the same conditions is greater or equal to the number of pipes placed on the sides of squares and on concentric circles with a center coinciding with the bundle center. Thus later on we use only the mounting the pipes on the sides of squares and on concentric circles with the center coinciding with the bundle center. To calculate number of pipes in a bundle the following algorithm is used. Equations of straight-lines parallel to axis x

$$(y_1 = \pm \frac{\sqrt{3}}{2} S_T i)$$

and lines inclined to the axis x at an angle of 60°

$$y_2 = x\sqrt{3} \pm iS_T \sqrt{3})$$

(Fig. 2) are solved jointly in rectangular coordinates x–y. Coordinates of points like $y_1 = y_2$ are found. Number of horizontal and inclined straight lines is chosen as the nearest to the integer number found by division

$$d_B / S_T \frac{\sqrt{3}}{2}$$

at a rounding off to the greater value. Amounts of pipes in a bundle will be equal to the number of points of crossings of straight lines for which the condition is satisfied

$$\sqrt{x^2 - y^2} \le R = \left(\frac{d_B}{2} - \frac{d_T}{2} - \delta_{\Phi 2} - \delta_n \right),$$

where δ_n – width of a gasket for installation of the bundle.

The search for the version providing the maximum output of the device is carried out by a net method which consists in calculating the criterion function for all points of the area of its existence with a certain step for arguments [2]. As target function the value of heat flow Q occurring in the apparatus is used. The area in which Q is calculated and the parameters of design are defined is set in the form of the equations

$$\alpha_1 = \alpha_{1\,max}, S_T \ge S_{T\,min}, d_T \ge d_{T\,min},$$

$$\Delta T_D \le \Delta T_{D\,max}, \quad (9)$$

$$w_b \le w_{b\,max}. \quad (10)$$

Since with increase in the agitator diameter the size of bundles decreases and their number increases the size of a heat exchange surface at the change in d_m should have an extremum. The algorithm of the search consists in the following. At increase with small step of value d_m/D in some range $d_m/D = 0.2$–0.7 the number of bundle n_B and bundle diameter d_B are calculated by equations (6)–(8). The designs are chosen where bundle are placed without a gap, and then the number of pipes in the bundle n_t is

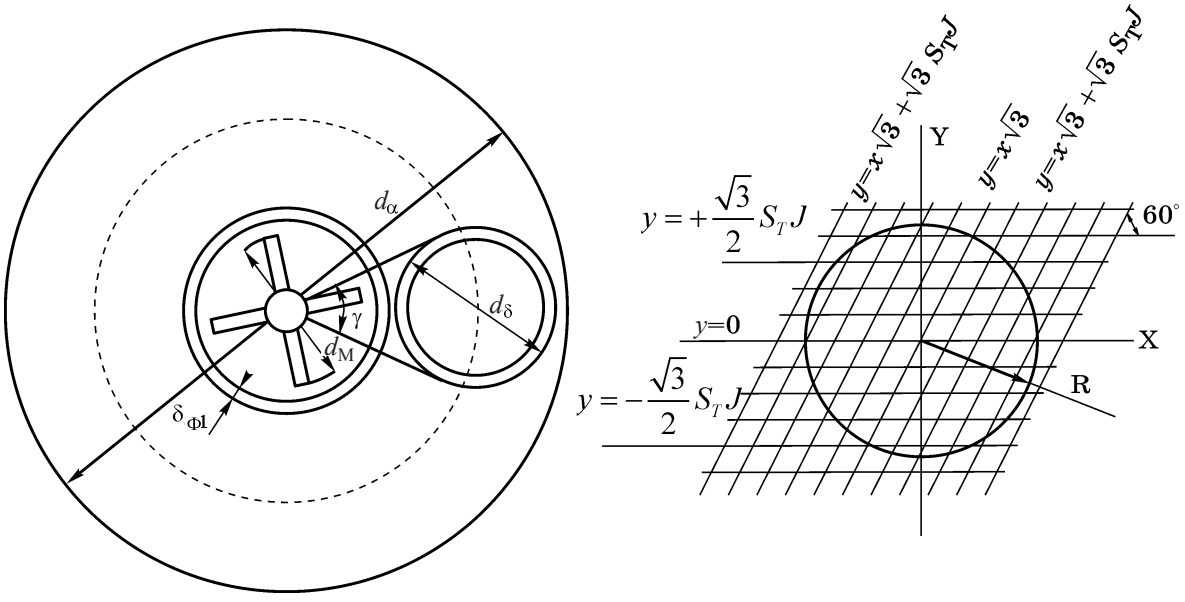

Fig. 2. Figures pertaining to the calculation of heat exchange devices.

calculated at a constriction and total number of pipes ($n_t = n_{tB}\ n_B$) is calculated. The heat exchange surface will begin as

$$F = \pi\, d_t h_t n_t$$

The constriction (10) defines for each value d_m/D the specific power which can be entered into the agitated volume

$$N_{max} = K_{N\rho}\, n^3_{max}\, d^5_m \qquad (11)$$

where n_{max} is maximum allowable frequency of rotation of an agitator, s^{-1}.

Definition for each version of size F and N_{max} allows the calculation of the heat flow.

$$Q = K_{max} F \Delta T_{Dmax},$$

$$K_{max} = \frac{1}{\frac{1}{\alpha_1} + \frac{\delta_{ST}}{\lambda_{ST}} + \frac{1}{\alpha_{2\,max}}}.$$

The equation (9) in which w_τ and w_r are estimated by an example with the greatest possible number of pipes is used. to define heat radiation coefficient α_2. Comparing Q obtained at various value d_m/D the alternative providing the maximum value of heat flow is found. Output of the apparatus is obtained from the equation

$$G_{max} = \frac{Q_{max}}{K_Q\ \ q_{ED}}.$$

If value of heat flow Q_{max} more than demanded under the conditions of the process, establishing optimum relations between α_1, α_2, F at which the minimum for designing and operation of the device is necessary. The calculations show, that the maximum heat release from the unit volume of the studied device can reach to 105 kWt/m^3.

Abstract—On a fragment of a bubble-cap reactive plate in the water–air system by methods of pulse and step disturbance the features of liquid phase hydrodynamics of a reactive plate at a wide range of the liquid and gas flows were investigated. Modes of the feed input in the reaction zone and of cooling of the feed to suppress side reactions at the initial stage of ethylene oxide hydration are developed. Effect of processing modes on the chemistry of ethylene oxide hydration is considered.

DOI: 10.1134/S1070427208030415

Last years attention has grown to a development of reactive fractionating devices [1] combining executing of a chemical process with separation of reaction products that allows essential simplifying of the technological scheme of process and reduction of capital costs for design, and also optimization of process as a whole [2–8]. In [9–14] by simulation we studied in detail the features of chemical and fraction stages of the process proceeding in the reactive fractionating column for ethylene glycol manufacturing.

The most commonly used method of the ethylene glycol production is a direct hydration of ethylene oxide. Simultaneously with the target reaction side processes occur between glycols and ethylene oxide with formation of di-, tri-, and tetraethylene glycol. It was shown using simulation that for suppression of side reactions in the synthesis of ethylene glycol it should be executed at essential water excess in the reaction zone with water–ethylene oxide mole ratio of 60–90 : 1. Thus practically complete conversion of initial ethylene oxide in the reaction zone of the column where the phlegm from an overlying plate that represents practically pure water with insignificant content of organic contaminants (concentration of water in the phlegm is more than 0.9999 mol%) should mix up with the feed.

Calculating the column for the output of ethylene glycol 6.2 t/h in a wide range of the phlegm–ethylene oxide ratio and the column pressure (Table 1) it was shown that residence time of the reaction mixture on the real plate does not depend on phlegm–ethylene oxide ratio and drops with the column pressure rise owing to the decrease in the column diameter. Values of the column diameter in the field of the high pressures required for increase of temperature and acceleration of chemical process range from 2 to 4 m and that is quite feasible especially regarding the high reflux ratio ranging from 30 to 90. At temperatures 475-493 K for carrying out the reaction it is enough to have 1–3 real plates therefore the process is practically completely realized on single theoretical plate of the column.

One of the difficulties in the fractionating column operation is to set the nearby ideal mix condition for mixing the feed entered on the reactive plate with the downflowing phlegm. A good mixing of these flows should be provided otherwise on the reactive plate local streams of the feed with low water–ethylene oxide ratio will form thereby enhancing the side reactions within these streams with yield of side poly(ethylene) glycols that will move to a residuum without separation and decrease ethylene glycol concentration in the residuum. As a result the typical local feed on the plate is unsuitable.

Table 1. The phlegm : ethylene oxide ratio and pressure effects on the diameter of the reactive fractionating column

Column pressure	Specific vapor flow, kg/(m^2 h)	Column diameter (m) at the phlegm : ethylene oxide ratio				
		10:1	30:1	50:1	70:1	90:1
0.1	4345	2.30	3.98	5.13	6.07	6.89
0.5	8899	1.60	2.78	3.59	4.25	4.81
1.0	11925	1.38	2.40	3.10	3.67	4.16
1.5	14218	1.27	2.20	2.78	3.36	3.81
2.0	15962	1.20	2.07	2.68	3.17	3.59

The mixing of the feed with the phlegm should be performed stepwise putting in the feed to zones of intensive mix, e.g., in a downcomer or in an overflow section of the reaction plate (Fig. 1a, 1b), and also directly to the first row caps (Fig. 1b, 1c). In the first case the feed under the pressure may be sprayed over the surface of the phlegm downflowing through an overflow baffle (Fig. 1a) or put in through a perforated dispatch device to pressure layer of the phlegm in overflow section (Fig. 1b), also for better mixing swirlers on the dispatch devices may be used. At entering the feed directly to the plate this operation may be performed under pressure through a perforated collector over the plate width (Fig. 1c) or local feed may be provided to each cap of the first row in the zone of the vapor and liquid mixing (Fig. 1c).

Analysis of the mixing efficiency was done in the course of investigation of the process hydrodynamics on a laboratory setup simulating the first row caps operation of reactive plates in the water–air system. Ethylene glycol used as tracer has been entered either with pulse or stepped feed. Water flow was varied in the range of 0.06–0.18 m^3/h, and airflow, 0–2.4 m^3/h. In a bottom of the cap of 100 mm diameter there are openings in the form of equilateral triangle with side 10mm for uniform air bubbling. Air streams passing through the openings with equivalent diameter 5.6 mm in the liquid flow were broken to bubbles of various size which contacting with water could break further or flow together. Calculations by Todes method show that gas bubbles of diameter ranging 1–15 mm float to the water surface with speed 0.13–0.66 m/s. Time of bubble contact with water ranges from 0.34 to 0.06 s that is considerably higher than airflow speed under conditions of free skip (bypassing) across annular space around the cap of air consumption 0.42–2.4 m^3/h and airflow rate 0.021–0.093 m/s respectively. Thus on the laboratory setup air bubbling through the water is well-run without channeling effect.

The tracer was entered in the overflow device as well as in the air bubbling zone near the cap. Concentration of the tracer in the liquid flow at the outlet of bubbling zone defined with refractometry allows the displaying the functions of response of the system on the entered disturbance (tracer feeding). The obtained functions are qualitatively close to hydrodynamical model of ideal mixing (Fig. 3) and in the coordinates ln $C(\tau)$–(τ) the experimental points of these functions at presence of the bubbling well fit to a straight line, and the absence of air feeding on a plate there is a tracer delay leading to a deviation from the linearity revealing the diffusive character of the hydrodynamics (Fig. 3).

With approximation of the response functions obtained at the various regimes of operation by the method of static moments [16] we can calculate first and second static moments of the response function, its dispersion, number of cells of the ideal mixing appropriate for the examined construction, coefficient of longitudinal stirring in the liquid flow in the absence of the bubbling. The calculations showed (Table 3), that even at air flow about 1 m^3/h the liquid mixing near the cap corresponds to the cell of the ideal mixing, and at air flow 2.4 m^3/h this correspondence ranges 1.3–1.4 of the cells of the ideal mixing.

Important parameter for simulation of an industrial apparatus is water-air mole ratio in the cap examined experimentally in a wide range from tenth to hundreds (Table 3). It should be taken into account that if the number of caps in a front row of the plate is N_F, along the plate length is N_L (along the liquid flow), the vapor feed is G, mol/h, and the liquid flow is L, mol/h, then a

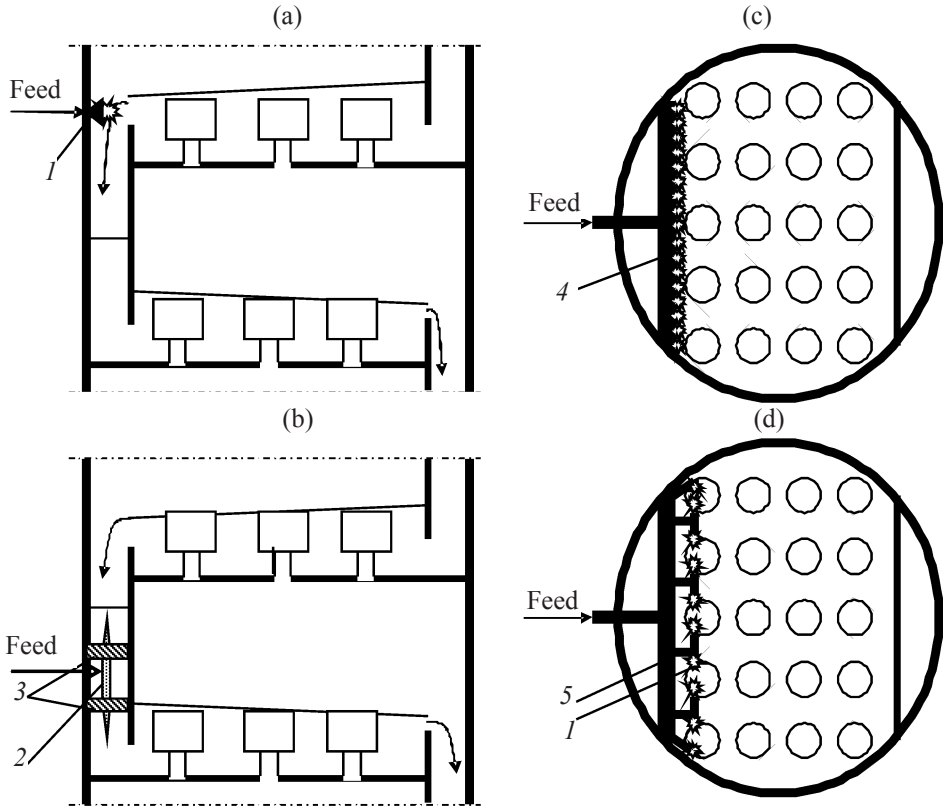

Fig. 1. Modes of the feeding on the reactive plate. (a) input of the feed over the phlegm surface; (b) input of the feed in the phlegm volume; (c) input of the feed through a perforated collector over the plate width; (d) local input of the feed directly to the caps. (*1*) Sprayer, (*2*) a distributing perforated device, (*3*) a swirler, (*4*) a pressure perforated collector, (*5*) a pressure collector.

load per a cap by vapor is $G/(N_F N_L)$, and by liquid, L/N_F. In the reactive fractionating column in the course of ethylene glycol production the vapor–liquid mole ratio is close to unity over the column section. Then the vapor–liquid mole ratio for the real plate (assuming that the caps are placed on the plate at inscribed rectangle) for a first row of the caps in a first approximation will be $(L N_L)/G$ close to N_L. Let us assume the cap diameter at 90 mm and inter-axis distance at 110 mm then for the above given data according to the column computation with output about 6.2 t/h (Table 1) we obtain, that the results of laboratory setup examined where the vapor–liquid mole ratio was in the range from 23.3 to 535.5 can be used also for estimating of the operation of

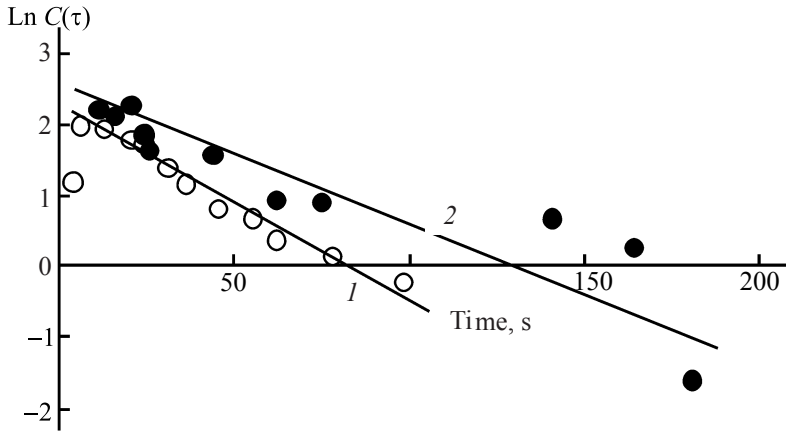

Fig. 3. The response function in the coordinates ln $C(\tau)$–(τ) in response to the impulse disturbance put in the plate at the air flow (*1*) 0 m³/h, and (*2*) 2.4 m³/h and at the water flow 0.06 m³/h.

contact device in industrial reactive fractionating column with the vapor–liquid mole ratio from 15 (columns of high pressure with low water–ethylene oxide ratio) to 90 (columns of low pressure with high water–ethylene oxide ratio) (Fig. 4). Note that the lower vapor–liquid mole ratio the higher mixing efficiency of raw material feed and the phlegm in the first row caps.

Calculation of the first static moment of the response functions of the system on an impulse disturbance appropriate for the average residence time of the tracer and respectively of the local streams in the liquid flow shows (Table 3) that the average residence time of the liquid in the mixing zone at the water flow 0.18 m³/h and the variable air flow is on average about a minute,

* The flow length from the input point of the tracer to the point of the sampling is 160 mm.
** The flow length from the input point of the tracer in the overflow device to the point of the sampling is 280 mm.

therewith main portion of the liquid passes the mixing zone in 10–15 s (Fig. 1). Testing the laboratory setup by the impulse disturbance (water flow was 0.18 m^3/h, air flow was 2.4 m^3/h) with input of the ethylene glycol tracer at 65 cm^3/min we took simultaneously 20 samples before cap of the water flow from four levels along the water flow height in five probe points of each level. The sampling was executed after 10 minutes of the tracer input to provide a steady state system. Computed mean tracer concentration in the flow at the outlet of the mixing zone should be 2.17 vol%. The experiment shows that actually at the outlet of the mixing zone averaging of concentrations does not occur (Fig. 5). Ethylene glycol concentration in water surface layer varied in the range 2.4–2.6 vol% and decreased across the water layer of the column, being 1.5–1.9 vol% near the bottom; therewith mean ethylene glycol concentration over 20 samples was 2.14 vol% and was close to the computed.

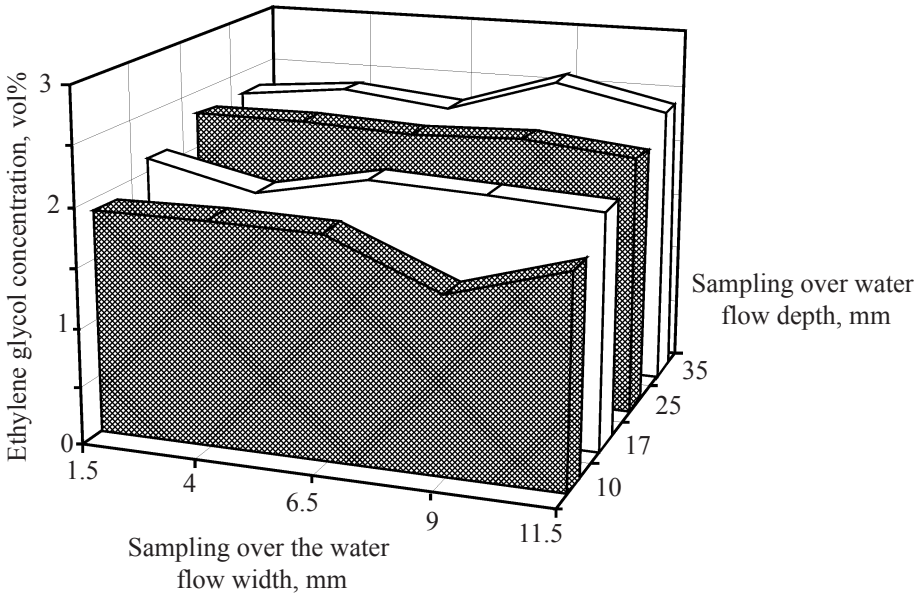

Fig. 5. Distribution of the tracer concentration over the normal section of the water flow on the laboratory setup.

With experimental data obtained we calculated kinetics of the ethylene oxide hydration taking into account the mixing of the raw material with the phlegm on the reactive plate. In the calculation we assumed that the conventional unit time of the mixing was the time of the mixing of two local streams of the equal volume therewith one of the streams contained, in part, raw components, and the second stream was phlegm. On the first unit time raw material fed as local stream of water and ethylene oxide in 1:1 ratio, at the last unit time we obtained a mixture of water and ethylene oxide in 66.5:1 ratio. For achieving such mixing of water and ethylene oxide six unit times of mixing are required. If the experimental average residence time of the flow in the mixing zone of the cap is 60 s then we set unit time of mixing equal to 10 s.

Mathematic modeling of kinetics of the hydration reaction of ethylene oxide regarding dynamics of real mixing of the feed with the phlegm shows that in initial stage ethylene oxide concentration considerably increases in comparison with the ideal mixing resulting

Table 4. (Contd.)

Feed content in the reaction start, mole fraction	Theoretic plate	Plate with the mixing of the local streams	Plate with the mixing of the local streams and with cool feeding
Ethylene glycol	0.015	0.5	0.5
Water	0.985	0.5	0.5
Feed temperature, K	470.7	470.7	300
Time for reaching the maximum output of ethylene glycol, min	1.95	1.98	2.55
Ethylene oxide concentration at the moment of the reaching maximum outout of ethylene glycol, mole fraction	1.2910"^{6}	1.49.10"^{6}	1.2610"^{6}
Time of practical reaction canceling, min	1.0	1.6	2.2
Ethylene glycol – higher glycols in the moment of reaching maximum output of ethylene glycol	80.43	6.29	50.74
Potential ethylene glycol content in the column residuum, mole fraction	0.9877	0.8629	0.9806

in a decrease in ethylene glycol output because of enhanced side reaction with giving diethylene glycol (Table 4, Fig. 6a), and adversely affects the column operation. The potential content of ethylene glycol in the residuum of reactive fractionating column falls to 0.826 mole fraction as compared with 0.9877 mole fraction expected at ideal mixing of the raw material and phlegm on the reactive plate.

For suppression of the side reaction it may be recommend feeding the raw material at low temperature (300–310 K, water–ethylene oxide mixture in 1:1 ratio) because at such temperatures ethylene oxide hydration does not occur. At mixing of the feed with the hot phlegm the feed temperature will raise with mixing and to the moment of the reaction start the water–ethylene oxide ratio will be sufficiently large to suppress the side reactions (Table 4, Fig. 6b).

One of the features of the chemistry of ethylene oxide hydration with significant water excess is maintenance of maximum concentration of ethylene glycol in the reaction mixture downflowing through the plate of the reactive fractionating column because in a point of achieving the maximum the ethylene oxide concentration is about 0.0001 of ethylene glycol concentration, and the side reactions do not practically proceed.

CONCLUSIONS

1. Structure of the flows on the laboratory fragment of the reactive plates by pulse and step disturbance was studied. The character and parameters of hydrodynamic models of the liquid phase flow were established.
2. It was shown that the regime of ideal mixing is provided in the operation zone of the first row caps.
3. The methods of feeding on the reactive plate to avoid the effects of side reactions on chemical nature of process were suggested.
4. Cold feeding on the reactive plate to suppress the ethylene oxide hydration in the local streams at the mixing the feed with phlegm on the initial stage of reactive plate operation was confirmed.

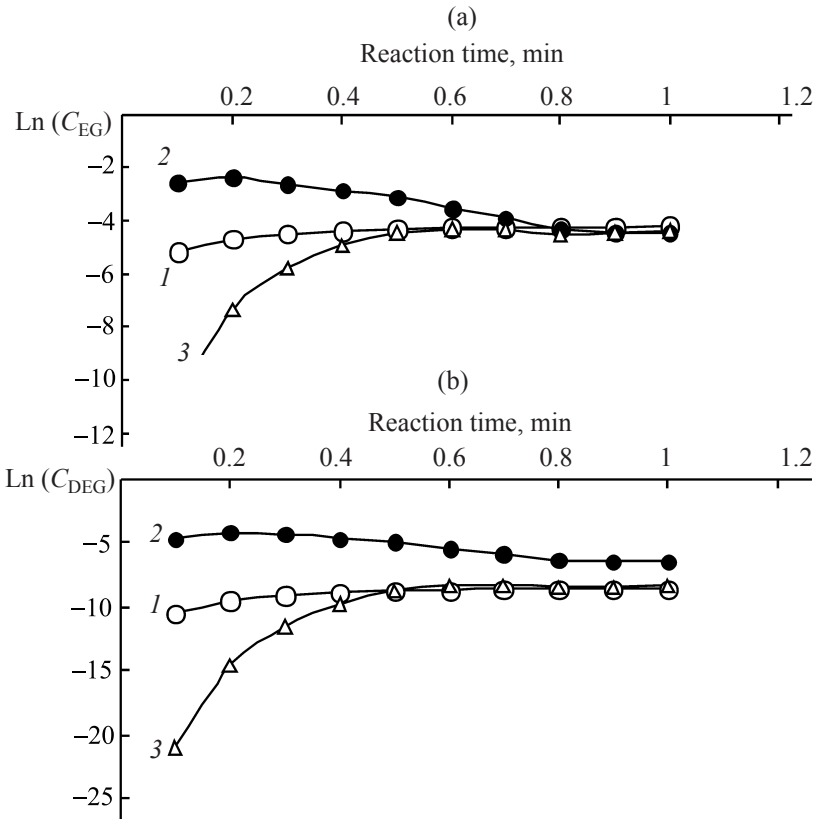

Fig. 6. Dependence of logarithm of the ethylene glycol (a) and diethylene glycol (b) concentration in the reactive mixture on the reaction time with the various flow structure of the liquid phase on the reactive plate. (*1*) The ideal mixing of the feed with the phlegm near the plate entrance at the temperature 470 K; (*2*) the real mixing of the feed with the phlegm on the plate at the feed and phlegm temperature 470 K; (*3*) the real mixing of the feed with the phlegm on the plate at the temperature of the feed near the plate entrance 300 K and of the phlegm 470.7 K.

MODELING AND CALCULATION OF TECHNOLOGICAL PROCESSES

Heat Exchange in Apparatus with a Blade Agitator

N. A. Gazizulin

Kazan State Technological University, Kazan, Russia

Received June 2, 2007

Abstract—Three-dimensional model of a convective heat exchange in the apparatus with two blade agitators equipped with an outside heating device was formulated using the equations of laminar motion of viscous fluid and of energy. The Arrhenius–Frenkel–Eyring equation was used to account for the temperature dependence on the fluid viscosity. A numerical computations of the fields of velocity, pressure, and temperature were performed with algorithm Simple. The results were presented as isotherms in the meridional, and in the horizontal sections of apparatus.

DOI: 10.1134/S1070427208030427

Study of heat exchange in apparatus with an agitator is of interest both for finding theoretical dependencies describing the change of a temperature field over the volume of the apparatus and in connection with wide range of the technological application of heat exchanger. In the present work attempts on numerical computation of convective heat exchange in the apparatus with the two blade agitators under the condition of laminar motion of viscous fluid were done.

STATEMENT OF A PROBLEM

In regard to the fixed frame of reference the equations of continuity dynamics in terms of stress, energy, and continuity will read (in vector form) [1]

$$\rho \frac{\partial \bar{v}}{\partial t} + \rho(\bar{v} \quad \nabla)\bar{v} = \nabla P, \tag{1}$$

$$\frac{\partial T}{\partial t} + \bar{v} \quad \nabla T = a\nabla^2 T, \tag{2}$$

$$\nabla \bar{v} \quad = 0. \tag{3}$$

For viscous fluid taking into account general Newton's law $P = -pE + 2\mu D$ and according to rules of the actions with operator ∇ [2] equation (1) is reduced to:

$$\rho \frac{\partial \bar{v}}{\partial t} + \rho(\bar{v} \quad \nabla)\bar{v} = -\nabla p + \mu\nabla^2 \bar{v} + \quad 2D \quad \nabla\eta\,. \tag{4}$$

Assuming constant viscosity the last item in right side of the equation (4) is eliminated, and equation (4) simplifies to Navier–Stokes equation. The numerical computation by the equation (4) is connected with the feature of the viscosity change over the fluid volume. The fluid viscosity variation versus temperature is taken into account. To describe temperature dependence on the coefficient of the fluid dynamic viscosity the Arrhenius–Frenkel–Eyring equation is used [3].

$$\mu(T) = \mu(T_0)\exp\left[\frac{E_a}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right)\right].$$

Introducing the cylindrical system of coordinates r, φ, z the projects of the velocity vector within the system are *u, v, w,* respectively. The fluid free surface is regarded as the surface of rotation. The basis in a space connected with a current point on the free surface and consisting of a vector of a normal is

$$\bar{n} = \left\{-\frac{dh}{dr}; 0; 1\right\}$$

and of tangents to this surface of vectors is also regarded

$$\bar{\tau}_1 = \left\{1; 0; \frac{\mathrm{d}h}{\mathrm{d}r}\right\}, \quad \bar{\tau}_2 = \{0; 1; 0\}.$$

Boundary conditions for the velocity on solid walls are reduced to the conditions of zero convective flow

and of attaching the fluid. Thus, at the bottom and at the sidewall

$$u = 0,\ v = 0,\ w = 0, \tag{5}$$

and at the surface of shaft, and of agitator, respectively

$$u = 0,\ v = wr,\ w = 0. \tag{6}$$

Boundary conditions on the free fluid surface include kinematic and dynamic conditions. The kinematic condition represents an equality to zero of a projection of a velocity vector onto a normal to the surface:

$$u\,\frac{\mathrm{d}h}{\mathrm{d}r} - w = 0 \tag{7}$$

Dynamic condition corresponds to the balance of stress tensors applied to both sides of the surface. Since curvature radius of the free surface is sufficiently large evidently the surface tension force is neglected. Therefore dynamic condition is [4]:

$$\overline{n}\quad P = -p_0\,\overline{n}\quad \mathrm{E}. \tag{8}$$

Projections of the vector equation (8) onto directions of the basis vectors represent three dynamic conditions in the coordinate form

$$(p_{zz} - p_{rr})\frac{dh}{dr} + \left[1 - \left(\frac{dh}{dr}\right)^2\right]p_{zr} = 0, \tag{9}$$

$$p_{z\varphi} - p_{\varphi r}\,\frac{dh}{dr} = 0, \tag{10}$$

$$(p_{rr} + p_0)\left(\frac{dh}{dr}\right)^2 - 2p_{zr}\,\frac{dh}{dr} + p_{zz} + p_0 = 0. \tag{11}$$

Examining the boundary condition for temperature we assume that the heat exchange in the device is steady. Let the cylindrical wall and the bottom of the apparatus are equipped with outside heating elements which maintain constant temperature T_1. Then on the cylindrical sidewall and on the bottom there boundary condition of the first type will be valid.

$$T = T_1 \tag{12}$$

Simultaneous heating and cooling of the fluid in the apparatus is not necessary to maintain the steady-state process. The fluid cooling may occur through the agitator, the shaft, and also through the fluid free surface. Boundary condition of the third type is determined by the law of heat exchange between a free surface and surroundings [5]:

$$\alpha(T - T_0) = -\lambda\,\frac{\partial T_{\mathrm{liq}}}{\partial n}, \tag{13}$$

According to this law amount of heat removed from fluid surface in the surroundings originating from the heat radiation has to be equal to the amount of heat input to the surface from the fluid by heat conductivity.

Let the boundary condition on boundary of the shaft and of the surroundings is $T = T_{\mathrm{Q}}$, and on the surface of the agitator and that of shaft there are so-called conditions of interface

$$T_{\mathrm{as}} = T_{\mathrm{liq}},\quad -\lambda_{\mathrm{as}}\,\frac{\partial T_{\mathrm{as}}}{\partial n} = -\lambda_{\mathrm{liq}}\,\frac{\partial T_{\mathrm{liq}}}{\partial n}, \tag{14}$$

that meet to physical requirements of continuity of the temperature and of the heat flow on the solid body–fluid interface (here n is a normal to a solid surface). An interface problem of two media heat exchange is solved basing on the allowed conditions. Evidently distribution of temperature inside the shaft and the agitator is described by the heat conductivity equation.

$$\nabla^2 T = 0. \tag{15}$$

If it is assumed that the rotation axis of the shaft and the agitator coincide with the rotation axis of the flow then on the rotation axis the following conditions are valid:

$$u = 0,\ v = 0,\ \frac{\partial w}{\partial z} = 0,\ \frac{\partial T}{\partial z} = 0. \tag{16}$$

BASIC RELATIONSHIPS

Since position of the free fluid surface is not known and demands definition during the solution of the problem the representation of the physical area (area of current) on the computing area with the known boundary is useful. For that overall physical area divided into bottom and top zones by a plane lying on the top of the agitator surface. Dimensionless coordinates and functions are introduced

$$t^* = \frac{Ut}{L},\quad r^* = \frac{r}{L},\quad \varphi^* = \varphi,$$

$$z^* = \begin{cases} \dfrac{z}{L}, z \le H_{\mathrm{a}} + h_{\mathrm{a}} \\ \dfrac{z - H_{\mathrm{a}} - h_{\mathrm{a}}}{h},\ z > H_{\mathrm{a}} + h_{\mathrm{a}} \end{cases},$$

$$\bar{v}^* = \frac{\bar{v}}{U}, \quad \bar{p}^* = \frac{p - p_0}{\rho U^2}, \quad \theta = \frac{T - T_0}{T_1 - T_0}. \qquad (17)$$

An agitator diameter and the agitator speed at the rim are chosen as characteristic length (L) and characteristic velocity of flow (U), respectively. A transformation (17) allows the displaying of the fluid surface in the physical area on a horizontal plane in the computing area.

As a result of transformation of coordinates the equations (2)–(4) are reduced to a dimensionless form in each of the zones of the computing area. However the continuity equation keeps the same form $\nabla\bar{V} = 0$. according to which projection U, V, W of the velocity vector in the computing area are defined in the bottom zone as follows:

$$U = u^*, \; V = v^*, \; W = w^*,$$

and in the top zone as

$$U = h^* u^*, \quad V = h^* v^*,$$
$$W = -u^* z^* \frac{dh^*}{dr^*} + w^*.$$

Here $h^* = h/L$, and u^*, v, w^* are components of the velocity vector in dimensionless physical area which is expressed by the following transformation

Three equations in the coordinate form according to the equation of motion (4) in the computing area are written as a common transport equation.

$$\frac{\partial \Phi}{\partial t^*} + \frac{1}{\gamma r^*}\frac{\partial}{\partial r^*}\left(r^* U\Phi\right) + \frac{1}{\gamma r^*}\frac{\partial}{\partial \varphi^*}(V\Phi)$$
$$+ \frac{1}{\gamma}\frac{\partial}{\partial z^*}(W\Phi) - \frac{1}{r^*}\frac{\partial}{\partial r^*}\left(\Gamma r^* \frac{\partial \Phi}{\partial r^*}\right)$$
$$- \frac{1}{r^*}\frac{\partial}{\partial \varphi^*}\left(\Gamma \frac{1}{r^*}\frac{\partial \Phi}{\partial \varphi^*}\right) - \frac{1}{\gamma^2}\frac{\partial}{\partial z^*}\left(\Gamma \frac{\partial \Phi}{\partial z^*}\right) = S_\Phi \qquad (18)$$

where $\Gamma = (\mu/(\pi\mu_0 \mathrm{Re}_c)$, $\gamma = 1$ for the bottom zone and $\gamma = h^*$ for the top zones, S_Φ is the term like source which is appropriate for the target function Φ.

The heat energy equation (2) in the dimensionless form is also reduced to Eq. (18), where $\Gamma = 1/(\pi \mathrm{Re}_c \mathrm{Pr})$.

In the bottom zone of the computed area the source items of Eq. (8) are defined by the following relations

$$S_{u^*} = -\frac{\partial p^*}{\partial r^*} + \frac{v^{*2}}{r^*} - \Gamma\frac{2}{r^{*2}}\frac{\partial v^*}{\partial \varphi^*} - \mathrm{X}_{u^*}$$
$$+ (2D \;\; \nabla\Gamma)_{r^*},$$
$$S_{r^* v^*} = -\frac{\partial p^*}{\partial \varphi^*} + \Gamma\frac{2}{r^*}\frac{\partial u^*}{\partial \varphi^*}$$
$$- \Gamma\frac{2}{r^*}\frac{\partial}{\partial r^*}\left(r^* v^*\right) - \mathrm{X}_{r^* v^*} + (2D \;\; \nabla\Gamma)_{\varphi^*},$$
$$S_{w^*} = -\frac{\partial p^*}{\partial z^*} - \mathrm{X}_{w^*} + (2D \;\; \nabla\Gamma)_{z^*}, \quad S_\theta = 0,$$

and in the top zone

$$S_{u^*} = -\frac{\partial p^*}{\partial r^*} + \frac{z^*}{h^*}\frac{dh^*}{dr^*}\frac{\partial p^*}{\partial z^*} + \frac{v^{*2}}{r^*} + \Gamma\left(\frac{1}{\mathrm{h}^*}\frac{\mathrm{dh}^*}{\mathrm{dr}^*}\right)^2 \mathrm{z}^*\frac{\partial}{\partial \mathrm{z}^*}\left(\mathrm{z}^*\frac{\partial \mathrm{u}^*}{\partial \mathrm{z}^*}\right)$$
$$- \frac{\Gamma}{r^{*2}}\left(u^* + 2\frac{\partial v^*}{\partial \varphi^*}\right) - \frac{\Gamma z^*}{r^*}\frac{\partial}{\partial r^*}\left(\frac{r^*}{h^*}\frac{dh^*}{dr^*}\frac{\partial u^*}{\partial z^*}\right) - \frac{\Gamma z^*}{h^*}\frac{dh^*}{dr^*}\frac{\partial^2 u^*}{\partial r^* \partial z^*} - -\mathrm{X}_{u^*} + (2\;D\;\nabla\Gamma)_{r^*},$$
$$S_{r^* v^*} = -\frac{\partial p^*}{\partial \varphi^*} + \frac{2\Gamma}{r^*}\frac{\partial \mathrm{u}^*}{\partial \varphi^*} + \Gamma z^*\left(\frac{1}{h^*}\frac{dh^*}{dr^*}\right)^2 \frac{\partial}{\partial z^*}\left[z^*\frac{\partial}{\partial z^*}\left(r^* v^*\right)\right]$$
$$+ \frac{2\Gamma z^*}{h^* r^*}\frac{dh^*}{dr^*}\frac{\partial}{\partial \mathrm{z}^*}\left(r^* v^*\right) - \frac{\Gamma z^*}{r^*}\frac{\partial}{\partial r^*}\left[\frac{r^*}{h^*}\frac{dh^*}{dr^*}\frac{\partial}{\partial z^*}\left(r^* v^*\right)\right]$$
$$- \frac{\Gamma z^*}{h^*}\frac{dh^*}{dr^*}\frac{\partial^2}{\partial r^* \partial z^*}\left(r^* v^*\right) - \frac{2\Gamma}{r^*}\frac{\partial}{\partial r^*}\left(r^* v^*\right) - \mathrm{X}_{r^* v^*} + (2D\;\nabla\Gamma)_{\varphi^*},$$
$$S_{w^*} = -\frac{1}{h^*}\frac{\partial p^*}{\partial z^*} + \Gamma z^*\left(\frac{1}{h^*}\frac{dh^*}{dr^*}\right)^2 \frac{\partial}{\partial z^*}\left(\mathrm{z}^*\frac{\partial w^*}{\partial z^*}\right) - \frac{\Gamma z^*}{h^*}\frac{dh^*}{dr^*}\frac{\partial^2 w^*}{\partial r^* \partial z^*}$$

$$-\frac{\Gamma z^*}{r^*}\frac{\partial}{\partial r^*}\left(\frac{r^*}{h^*}\frac{dh^*}{dr^*}\frac{\partial w^*}{\partial r^*}\right)-\mathrm{X}_{w^*}+(2D\cdot\nabla\Gamma)_{z^*},$$

$$S_\theta=\Gamma\frac{z^*}{h^{*2}}\left(\frac{dh^*}{dr^*}\right)^2\frac{\partial}{\partial z^*}\left(z^*\frac{\partial\theta}{\partial z^*}\right)-\Gamma\frac{z^*}{r^*}\frac{\partial}{\partial r^*}\left(\frac{r^*}{h^*}\frac{dh^*}{dr^*}\frac{\partial\theta}{\partial z^*}\right)-\Gamma\frac{z^*}{h^*}\frac{dh^*}{dr^*}\frac{\partial^2\theta}{\partial r^*\partial z^*},$$

where X_Φ is appropriate for the target function Φ and is described as

$$\mathrm{X}_\Phi=\frac{\partial\Phi}{\partial r^*}\frac{\partial\Gamma}{\partial r^*}+\frac{1}{r^{*2}}\frac{\partial\Phi}{\partial\varphi^*}\frac{\partial\Gamma}{\partial\varphi^*}+\frac{1}{\gamma^2}\frac{\partial\Phi}{\partial z^*}\frac{\partial\Gamma}{\partial z^*},$$

and the last items represent components of the vector 2D $\nabla\Gamma$.

The heat conductivity equation (15) in the dimensionless form is written as

$$\frac{1}{r^*}\frac{\partial}{\partial r^*}\left(r^*\frac{\partial\theta}{\partial r^*}\right)+\frac{1}{r^{*2}}\frac{\partial^2\theta}{\partial\varphi^{*2}}+\frac{1}{h_{as}^{*2}}\frac{\partial^2\theta}{\partial z^{*2}}=0, \quad (19)$$

where $h_{as}^* = h^*(r_{as}^*)$.

In the computing area the form of the boundary conditions (5), (6), and (16) is kept but the second of the conditions (6) acquires following appearance. $v^* = 2r^*$, and the boundary conditions (7), (9) – (11) respectively are reduces to

$$u^*\frac{dh^*}{dr^*}-w^*=0, \quad (20)$$

$$\frac{1}{h^*}\left[1+\left(\frac{dh^*}{dr^*}\right)^2\right]\left(\frac{\partial u^*}{\partial z^*}+\frac{dh^*}{dr^*}\frac{\partial w^*}{\partial z^*}\right)+\left[1-\left(\frac{dh^*}{dr^*}\right)^2\right]\frac{\partial w^*}{\partial r^*}-2\frac{dh^*}{dr^*}\frac{\partial u^*}{\partial r^*}=0, \quad (21)$$

$$\left[1+\left(\frac{dh^*}{dr^*}\right)^2\right]\frac{1}{h^*}\frac{\partial v^*}{\partial z^*}+\left(\frac{v^*}{r^*}-\frac{\partial v^*}{\partial r^*}-\frac{1}{r^*}\frac{\partial u^*}{\partial\varphi^*}\right)\frac{dh^*}{dr^*}+\frac{1}{r^*}\frac{\partial w^*}{\partial\varphi^*}=0, \quad (22)$$

$$\left[1+\left(\frac{dh^*}{dr^*}\right)^2\right]\left[p^*\,Re_c+\frac{2}{h^*}\left(\frac{dh^*}{dr^*}\frac{\partial u^*}{\partial z^*}+\frac{\partial w^*}{\partial z^*}\right)\right]-2\frac{dh^*}{dr^*}\left(\frac{dh^*}{dr^*}\frac{\partial u^*}{\partial r^*}-\frac{\partial w^*}{\partial r^*}\right)=0. \quad (23)$$

As regards the boundary conditions for temperature (12)–(14) in the computing area,

$$\theta=1, \quad (24)$$

$$\left(z^*\frac{dh^*}{dr^*}\cos\beta_1-\cos\beta_2\right)\frac{1}{h^*}\frac{\partial\theta}{\partial z^*}-\cos\beta_1\frac{\partial\theta}{\partial r^*}=\theta Nu, \quad (25)$$

$$\theta_{as}=\theta_{liq},\quad \lambda_{liq}\frac{\partial\theta_{as}}{\partial n}=\lambda_{liq}\frac{\partial\theta_{liq}}{\partial n}, \quad (26)$$

where $\cos\beta_1$ and $\cos\beta_2$ are directional cosines of the vector of the normal to the fluid free surface.

The theory of the central vortex formation in apparatus with an agitator according to which the vortex surface equilibrium condition expressed as [6]

$$\frac{dh}{dr}=\frac{v^2}{gr},$$

and in the dimensionless physical area looking like

$$\frac{dh^*}{dr^*}=\pi^2 Fr_c\frac{v^{*2}}{r^*}. \quad (27)$$

is used for calculation of the form of the fluid free surface.

An algorithm for solving the equation (27) is accurately described in [7] and yields

$$h^*\left(r^*\right) = \pi^2 Fr_c \int_{r_s^* + \Delta r^*}^{r^*} \frac{v^{*2}}{r} dr + h^*\left(r_a^* + \Delta r^*\right),$$

$$h^*\left(r_s^* + \Delta r^*\right) = \frac{1}{\left(r_{app}^* - \Delta r^*\right)^2 - \Delta r^{*2}} \quad (28)$$

$$\times \left[\left(h_0^* \; r_{app}^{*2} - r_a^{*2}\right) - \left(2\, r_{app}^* - \Delta r^*\right)\Delta r^* h^* \left(r_{app}^*\right)\right.$$

$$\left. -2\pi^2 \, Fr_c \int_{r_s^* + \Delta r^*}^{r_{app}^* - \Delta r^*} r^* dr^* \int_{r_s^* + \Delta r^*}^{r^*} \frac{v^{*2}}{r} dr \right]. \quad (29)$$

ALGORITHM OF CALCULATION

Numerical modeling of the flow and the heat exchange in the computing area was made by a method of control volume [8, 9] based on representation of the considered equation in integrated form. The conservatism of this method is one of its most important advantages, in other words it provides exact integrated performance of the conservation principles for overall computing area.

Let the planes divide the computing area into the control volumes (spatial meshes) and on each of the planes only one of coordinates with the constant value occurs. Let node points are placed so that each of them is in the separate mesh and the mesh sides are in the middle of the adjacent node meshes. Such arrangement of the mesh sides provides sufficiently high accuracy of the heat flow calculation through the side [9].

Placement of all node functions in the same node points leads to additional computing difficulties, namely, it results in appearance of the oscillation in a solution in particular for the pressure. Therefore the moved or so-called chess grid is chosen [10] where the node points of the velocity component are displaced on a half step in proper directions towards the main points in which the pressure and the temperature are defined. As a result the node points for velocity components are on the appropriate sides of the main control volumes for the temperature and for the pressure. Thus there are four sets of control volumes for all node functions.

Calculation of the flow and the heat exchange is done on basis of algorithm SIMPLE [9] in which the equation digitization according to the control volume method on the moved grids is used. Realization of algorithm SIMPLE originally intended just for the solution of the Navier–Stokes equation seems more effective in pseudo-non-stationary statement [11]. Hence we shall integrate the common equation (18) over the control volume ΔQ and over the time interval Δt^*. Then we shall obtain the conservation principles for Φ in the integrated form

$$\iiint_{\Delta\Omega} \int_{t^*}^{t^* + \Delta t^*} \left[\frac{\partial \Phi}{\partial t^*} + \frac{1}{\gamma r^*}\frac{\partial}{\partial r^*}\left(r^* U\Phi\right)\right.$$

$$+ \frac{1}{\gamma r^*}\frac{\partial}{\partial \varphi^*}\left(V\Phi\right) + \frac{1}{\gamma}\frac{\partial}{\partial z^*}\left(W\Phi\right)$$

$$- \frac{\Gamma}{r^*}\frac{\partial}{\partial r^*}\left(r^* \frac{\partial \Phi}{\partial r^*}\right) - \frac{\Gamma}{r^*}\frac{\partial}{\partial \varphi^*}\left(\frac{1}{r^*}\frac{\partial \Phi}{\partial \varphi^*}\right)$$

$$\left. - \frac{\Gamma}{\gamma^2}\frac{\partial}{\partial z^*}\left(\frac{\partial \Phi}{\partial z^*}\right) - S_\Phi\right] dt^* dV = 0. \quad (30)$$

Thus solution is obtained by advance over the time from some given initial distribution of the target function Φ. Since the problem is stationary the time plays role of the relaxation parameter under these conditions. An implicit scheme is used for approximation of the convective and diffusive items in the equation (30) according to which the node function Φ within the limits of the overall time step Δt^* is characterized by new value Φ^1 which is appropriate to the following time $\Delta t + \Delta t^*$. Then discrete differential analog of the equation (30) is written as

$$\frac{\Delta V}{\Delta t^*}\Phi_P^1 + \Delta\varphi^* \Delta z^* \left[r^* \left(\frac{U\Phi^1}{\gamma_P} - \Gamma\frac{\partial \Phi^1}{\partial r^*}\right)\right]_w^e$$

$$+ \Delta r^* \Delta z^* \left(\frac{V\Phi^1}{\gamma_P} - \frac{\Gamma}{r^*}\frac{\partial \Phi^1}{\partial \varphi^*}\right)_s^n$$

$$+ \frac{r_P^* \Delta r^* \Delta \varphi^*}{\gamma_P}\left(W\Phi^1 - \frac{\Gamma}{\gamma_P}\frac{\partial \Phi^1}{\partial z^*}\right)_l^u$$

$$= \Delta V\left(S_P + \frac{\Phi_P^0}{\Delta t^*}\right), \quad (31)$$

where ΔV is the mesh volume, S_p is a node value of the source item, and Φ^0 is the value of Φ at the time t^*.

The way of calculation of the target function Φ on the sides *w, e, s, n, I, u* of the cells in the equation (31) is defined by the difference scheme according to which difference approximation of the convective items of this equation occurs. The combined scheme representing a combination of the midmost difference and countercurrent schemes is used [9]. This results in the following equation

$$a_P \Phi_P^1 = a_W \Phi_W^1 + a_E \Phi_E^1 + a_S \Phi_S^1 + a_N \Phi_N^1 + a_L \Phi_L^1 + a_U \Phi_U^1 + \Delta V \left(S_P + \frac{\Phi_P^0}{\Delta t^*} \right), \quad (32)$$

connecting value of the target function in the node point *P* with its values in centers *W, E, S, N, L, U* of the next meshes.

Algorithm SIMPLE represents cyclic sequence of operations of type "guess–correction". Hence the values of the velocity components on each point of iteration are defined in two stages. At the first stage on the basis of a guess field of pressure p^{**} as a result of the solution of the equations (32) the initial guess of values u^{**}, v^{**}, w^{**} unsatisfying to the continuity equation is done. As concerns the approached solution for the velocity a correction to the pressure p^c was found from the equation (33)

$$a_P p_P^c = a_W p_W^c + a_E p_E^c + a_S p_S^c + a_N p_N^c + a_L p_L^c + a_U p_U^c + b, \quad (33)$$

which is a discrete analogue of the continuity equation. Therefore the continuity equation is fulfilled in each step of the time at the pressure field calculation

On the second stage taking into account values p^c corrected values of the velocity components satisfying to equation (33) are found by formulas

$$u_e^* = u_e^{**} + \frac{r_e^* \Delta\varphi^* \Delta z^*}{a_e} \left(p_P^c - p_E^c \right), \quad (34)$$

$$v_n^* = v_n^{**} + \frac{\Delta r^* \Delta z^*}{a_n} \left(p_P^c - p_N^c \right), \quad (35)$$

$$w_u^* = w_u^{**} + \frac{r_u^* \Delta\varphi^* \Delta r^*}{a_u} \left(p_P^c - p_U^c \right) \quad (36)$$

and the pressure

$$p^* = p^{**} + \alpha_p p^c, \quad (37)$$

where α_p is relaxation. It is assumed in the calculations that $\alpha_p = 0.8$.

Solving Eq. (32) for u^{**}, v^{**}, w^{**} on the free surface the boundary conditions (21), (22), and 23) respectively are used. Boundary values of p^c according to relationship (34) –(36) are supposed to be zero because the boundary velocity values do not require correction. Since the pressure according to Eq. (37) is defined by the correction p^c the boundary condition involving the pressure is not applied.

After calculation of fields of the velocity and of the pressure the calculation of a temperature field and refining the viscosity values $\mu(T)$ were done. The temperature was defined solving Eq. (32) in combination with the heat conductivity equation (19) whose discrete analog has the structure like Eq. (33). The boundary conditions (24) –(26) were used, and the equation (19) was solved on each step of the time.

The form of the free fluid surface according to computed flow field was defined with Eqs. (28)–(29) at the end of each iteration. A value corresponding to unperturbed surface position was considered as an initial value h^*.

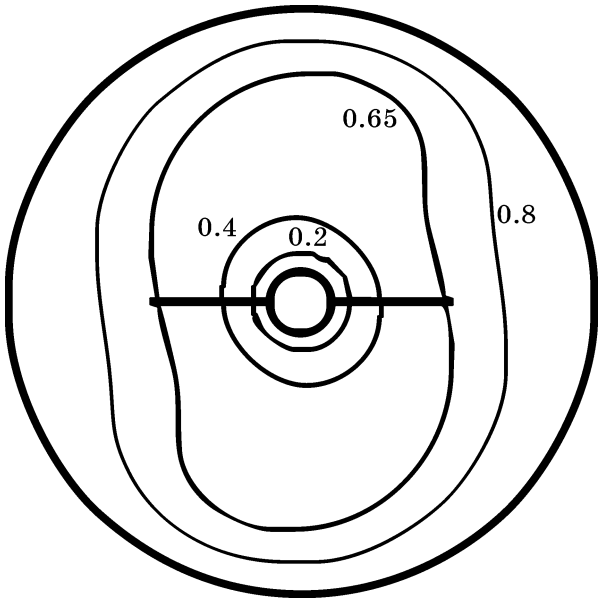

Fig. 1. The isotherm, depicted in the horisontal section of the apparatus above the agitator at $Re_c = 20$, $Fr_c = 0.1$, $Nu = 3$.

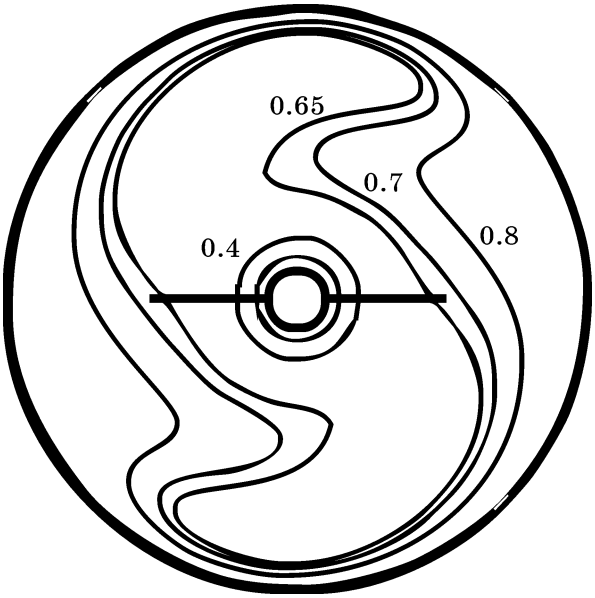

Fig. 2. The isotherm, depicted in the horisontal section of the apparatus above the agitator at $Re_c = 50$, $Fr_c = 0.1$, Nu = 3.

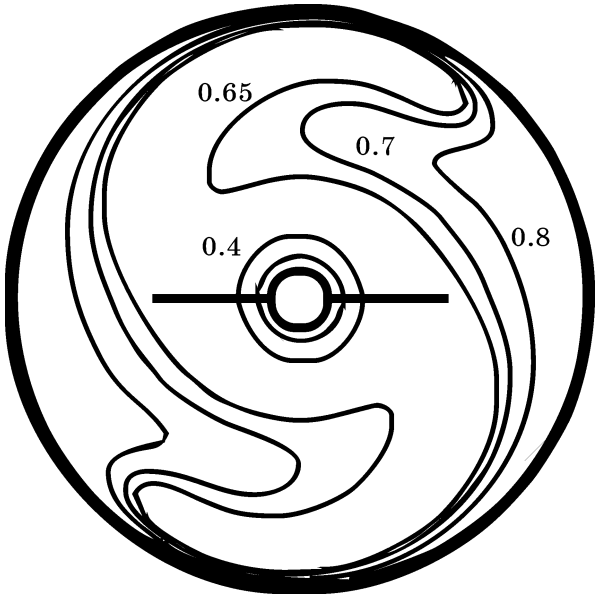

Fig. 3. The isotherm, depicted in the horisontal section of the apparatus above the agitator at $Re_c = 100$, $Fr_c = 0.1$, Nu = 3.

The Eqs. (32) and (33) were solved by the sweep method along radial direction. Ratio of sum of modules of divergences according to the continuity equation for the each mesh to the overall volume of the fluid in the computing area is considered as convergence criterion. The computation was performed according to this criterion to within 0.01%.

RESULTS OF CALCULATIONS

The calculations were executed in the grid with regular distribution of the nodes. It was assumed that $Ho = D_{app}$, $d = r_{app}$, $h_a/d = 0.2$, $H_a/H_0 = 0.3$, $\lambda_{as}/\lambda_s = 17$, Pr=2, $E_a = 22$ kJ/mol. Isotherms in horizontal and meridional sections of the apparatus present the results of calculations. The isotherms $\theta = const$ in the horizontal section located above the agitator on the distance of $0.15H_0$ are shown on the Figs. 1–3 At the small values of Reynolds number the heat convection from the heated sidewall to center of apparatus is insignificant and the formation of thermal field is mainly determined by heat conductivity (Fig. 1).

The increase of Reynolds number denotes the increase of the velocity gradients and accordingly an enhancement of the radially tangential streams. The convective component of the heat transfer increases. The tendency to increase in convective component especially appears in a tangential direction. However, close to a wall the convective heat exchange does not play an appreciable role and the heat transfer occurs due to molecular heat conductivity as a result of contact of the fluid with a heated wall (Fig. 2).

The further enhancement of tangential streams causes more evident heat transfer in the tangential direction. Quickly moving streams entrain heated liquid that results in mixing and gradual temperature smoothing (Fig. 3).

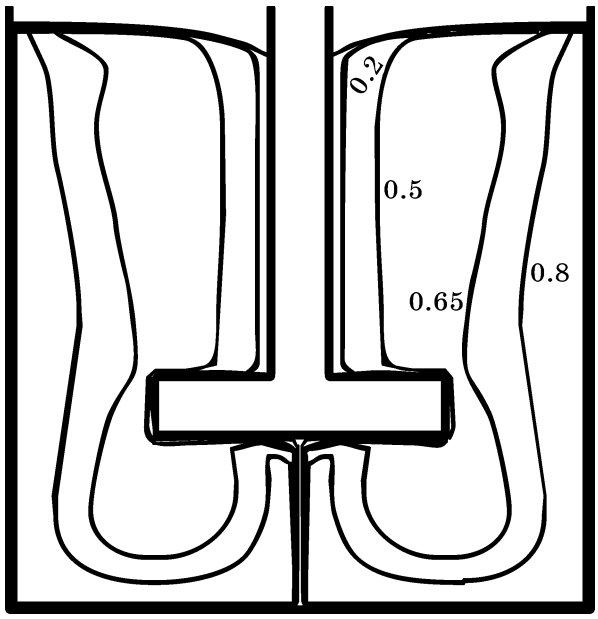

Fig. 4. Distribution of the isotherms depicted in the meridional section of the apparatus at $Re_c = 150$, $Fr_c = 0.3$, Nu = 3.

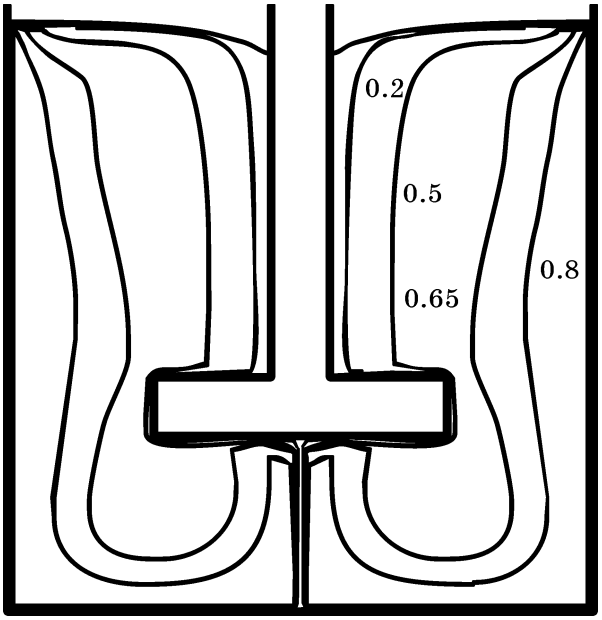

Fig. 5. Distribution of the isotherms depicted in the meridional section of the apparatus at $Re_c = 150$, $Fr_c = 0.3$, $Nu = 9$.

The further analysis of the results may be done on the basis of the isotherm in meridional section that leads through the agitator blade. Distribution of the isotherm depending on Nusselt number is presented on Figs 4, 5. At relatively small values of Nusselt number the isotherms are fairly flat near the free fluid surface and they almost closely come near the top border of the flow (Fig. 4). With increase of Nusselt number the distribution of these curves becomes more abrupt close to the free surface, namely, the heating of the top layers of a liquid decreases that quite speaks more appreciable outflow of heat in surroundings (Fig. 5).

The author expresses gratitude to Prof. Garifullin F. for the attention to this work and valuable remarks.

LEGEND

ρ is liquid density, kg/ m^3;

p is pressure, N/ m^2;

Po is atmosphere pressure, N/m^2;

p_{rr}, $p_{\varphi\varphi}$, p_{zz}, $p_{r\varphi}$, $p_{\varphi z}$, p_{zr} are components of stress tenzor, N/m^2;

g is acceleration of gravity, m/s^2;

μ is dynamic viscosity, kg/(m^2 s^2), t is time, s; T is temperature, K;

T_{env} is environment temperature, K; λ, is heat conductivity coefficient, W/(m K);

a is coefficient of thermal diffusivity, m^2/s;

α is coefficient of heat radiation, W/(m^2 K);

E_a is activation energy of viscous flow, J/mol;

R is universal gas constant, J/(mol K);

n is number of rotation of an agitator, s^{-1};

ω is agitator speed, rad/s;

d is agitator diameter, m;

h_a is height of blade, m;

h is height of free fluid surface above the agitator, m;

h_0 is height of unperturbed free fluid surface above the agitator, m;

h_Q is height of unperturbed free fluid surface above the bottom of apparatus, m;

H_a is height of location of the agitator over the bottom of apparatus, m;

P is stress tensor;

D is deformation velocity tensor;

E is unit tensor;

$Re_c = \rho n d^2/ \mu_0$ is centrifugal Reynolds number;

$Fr_c = n^2 d/g$ is centrifugal Froude number;

$Pr = \mu/(\rho a)$ is Prandtl number;

$Nu = \alpha d/\lambda$ is Nusselt number.

SUBSCRIPT INDEXES

liq is the fluid, s is the shaft, as is the agitator or the shaft of the apparatus.

INTRODUCTION

Consideration of published data shows that most investigations concerning aerodynamics of graduating coolers denoted to tower graduators. These coolers are widely applied, e.g., in the atomic power engineering which exerted renewing in the recent years. Much less publications concern single- and poly-sectional ventilator coolers despite the fact that they cover larger part of world productivity and widely used, e.g., in chemical and petroleum processing industry.

Whole, proceeding from the published data [1–6] we resume that further development of packing* for the process of evaporation cooling is directed to their quantitative efficiency, application of novel materials and modern technology. Meanwhile, improving of aerodynamics of evaporating coolers can be ever more effective for significant increasing their performance. This publication is denoted just to development of this direction of investigations.

1. ANALYSIS OF AERODYNAMIC SITUATION IN THE INDUSTRIAL EVAPORATING COOLERS

In the recent time appeared communications on extension of reconstruction of evaporating coolers in chemical industry and other branches, including replacement of unsuitable packing blocks, eliminating sections* and sprayers* [1–6]. At the projecting reconstruction of ventilator coolers it is significant taking into account of real aerodynamic situation in the unit.

Performance of the process of evaporating cooling of circulating water in an evaporating cooler is known to depend on the uniformity of distribution of counterflow contacting gas (atmospheric air) and liquid (water) phases [1].

In a general case the aerodynamic situation in an evaporating cooler is affected by the following factors:

- Wind power;
- Size and orientation of inlet windows;
- Presence of flow separators in sectional cooler;
- Presence of flow-guiding blades in the inlet windows;
- Type of sprinkler (packing): film or drop, its construction and height;
- Uniformity of distribution of spraying density over the cooler cross-section and the whole cooler volume.

Exploitation in winter period can introduce additional negative effect on the aerodynamic situation due to partial icing of inlet windows and neighboring packing blocks.

Cooling power of counterflow tower and ventilator cooler depends significantly on the value of air flow passing through the cooler. Noteworthy that higher rate of air flow characteristic of ventilator cooler leads to more significant influence of aerodynamic situation on the process of evaporating cooling in these coolers as compared with the tower cooler with much lower flow rate.

In the recent time many experimental and theoretical investigations were denoted to the study of the features

* Concerning terminology: *Packing* is a device for increase contact surface of reacting phases in the processes of heat and mass transfer; this definition is assumed in the literature on the processes and apparatuses of chemical technology. In the literature on evaporating coolers is used term *sprinkler*. English language literature uses term *filler*. We prefer two first definitions.

Eliminator is a device, commonly of jalousie type, for trapping the drops carried away by ascending air flow. This term is used in English literature and can be defined as drop entrainment trap.

of aerodynamic situation in evaporating coolers that take above said into account [7–14].

The schemes of most used in industry coolers of the types of multisection ventilator, single section ventilator, and tower without ventilator with natural air flow are shown in Figs. 1–3, respectively.

Distribution of the air flow vector at the inlet in the bottom region of tower cooler according to the data of [7] is shown in Fig.4. In that publication Hoffmann and Kroeger) proposed approximate solution for the air flow parameters at the inlet of the tower based on the theory of the flow potential energy. The coefficients obtained depend on the drop size, the tower size and the ratio of water and air flows.

Serous investigation by Zuciga–Gonzalez [8] is denoted to modeling the heat and mass transfer processes

in tower coolers at the natural convection. Fig. 5 shows the field of rates in tower cooler obtained in [8] on the ground of developed by the author model of turbulent diffusion.

Note that in some publications, e.g. in [13], is suggested debatable assumption about uniform rate profile in the tower coolers. However, the most other authors disprove this viewpoint. Even in their early work, Bulanina, Morozov and Sukhov [14] by the investigation on the model of tower cooler with sprinkled area F = 6500 m^2 scaled to 1 : 65 showed that specific volume of air flow along the tower radius varies from 0 to 1.2 near the wall. This result was confirmed in more recent study carried out in Vedeneev Halurgy Research Institute.

Experimental data obtained in the Vadeneev Halurgy Research Institute [9] are shown in Fig. 6. The experimental research of the field of the air flow rates was carried out at the tower cooler with cross section F_{sprink} = 1520 m^2, the film sprinkler was preliminary demounted. From the plots obtained is clearly seen non-uniformity of the rate field in the tower leading, as noted by the authors [9], to non-uniform air heating from the center to periphery and to sharp, by 30–40%, decrease in efficiency as compared with typical tower coolers with film type sprinkler.

Fundamental investigation of rate field in the industrial ventilator cooler of SK-400 type operating at many fabrics of chemical industry, e.g. at the carbamide manufacturing in ACHEMA Stock Company of Achema Group Concern (Ionava, Lithuania Republic) were carried out by Gladkov, Aref'ev and Ponomarenko [10]. The results obtained are discussed in details and used by us below in the Section 3 of this article at the development of our own two-zone structural model of evaporating cooler aerodynamics. From the shown in [10] graphic representation of rates follows that maximum rate at the cooler inlet is located, like in the tower coolers, near inlet windows.

Thus, even this preliminary consideration of the published results of experimental study and theoretical investigation on the aerodynamics of industrial evaporating coolers leads to conclusion that the rate field over the cooler cross section is characterized by significant non-uniformity whose scale is comparable with the cooler size.

Whole, we can notify that a significant aerodynamic non-uniformity induced, beside others, by obvious construction features of the cooler body and in a certain extent by distribution of sprinkling density over the cross section are inherent in both tower and ventilator type coolers, the latter both of multi-section and single-section types. The construction features of the cooler body are considered as location of inlet windows in the bottom part of the body which induce sharp turning, by 90°, of air flow and its rearranging before passing to the bottom part of sprinkled volume of the cooler filled by packing.

2. INFLUENCE OF THE AIR FLOW RATE ON THE PROCESS OF EVAPORATING COOLING

The integral characteristics describing the process of evaporating cooling of circulating water in the cooler sprinkler is evaporation number K_{vap}:

$$K_{vap} = \beta_{P\sigma v} \; H / Q_L$$

Here $\beta_{P\sigma v}$ is volume coefficient of mass release assigned to the difference in partial pressure divided by barometric pressure, kg/(m^3 s).

Dependence of evaporation number K_{vap} on the relative air consumtion λ is expressed as:

$$K_{vap} = A \; \lambda^m$$

where A^m are coefficients, $\lambda = Q_G / Q_L$, Q_G =

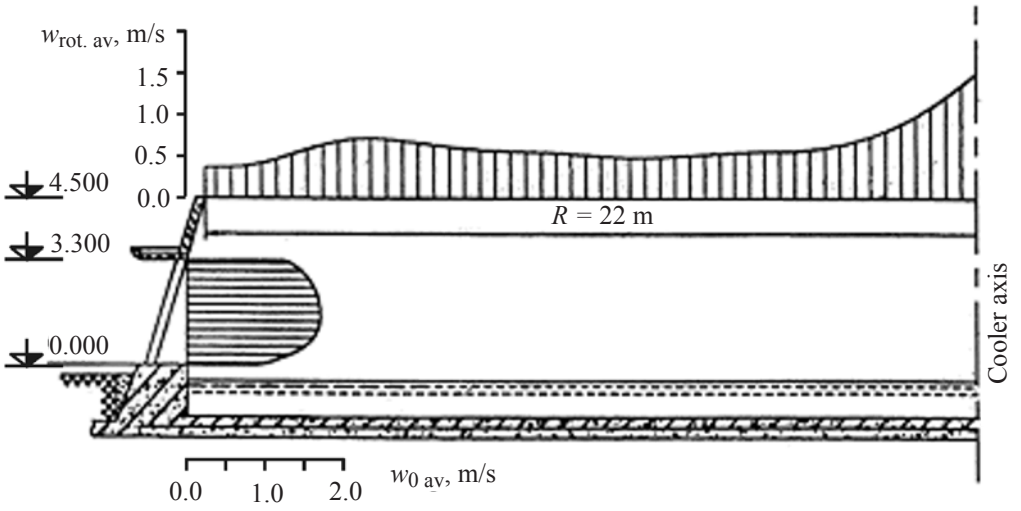

Fig. 6. Experimental investigations of the rate field of air flow in a cooler with preliminary demounted film sprinkler by the data of Vedeneev Halurgy Research Institute [9].

ρ_G (θ_1,φ_1) W_1 [kg/(m² s)], Q_G is specific mass air consuming; ρ_G is gas density; θ_1 is gas temperature; φ_1 is gas humidity; W is gas flow rate. $Q_L = \rho_L q_L/3600$ [kg/(m² s)], Q_L is specific mass water consuming; ρ_L is water density; q_L is spraying density, m³/(m² h).

In English literature is used Merkel number, the analogue of evaporation number:

$$Me = D\,\beta_{xv} H/Q_L ,$$

where β_{xv} is mass release coefficient, H is packing height, D is coefficient.

Linear dependence of Merkel number on the relative air consuming for film sprinkler in tower cooler according to the data of [8] is illustrated by the plot in Fig. 7 in logarithmic coordinates. As seen from this plot, increase in the relative air consuming λ from 1 to 2 results in growing the Merkel number from 2 to 5. Dependence of evaporation number K_{vap} on the λ parameter by the data of Gelfand [15] is given in Fig. 8.

Influencing the mass release coefficient β_{xv} by the air flow rate W_o in the cooler for net type packing of different height by the data of [16] is shown in Fig. 9. From the curves 2 and 3 follows that increase in the flow rate of gas phase leads to increase in mass release coefficient. This effect is seen better at higher packing layer.

It is clear that increase in the rate of air flow in the cooler leads to increase in pressure loss. This is well seen

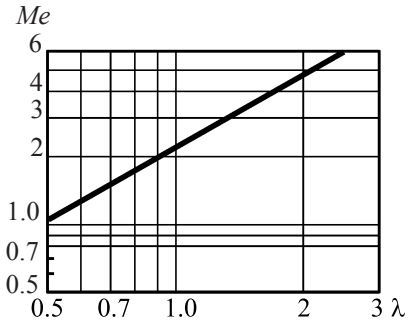

Fig. 7. Dependence of M*e* number on the ratio of the flovs gas/liquid λ by the data of [8].

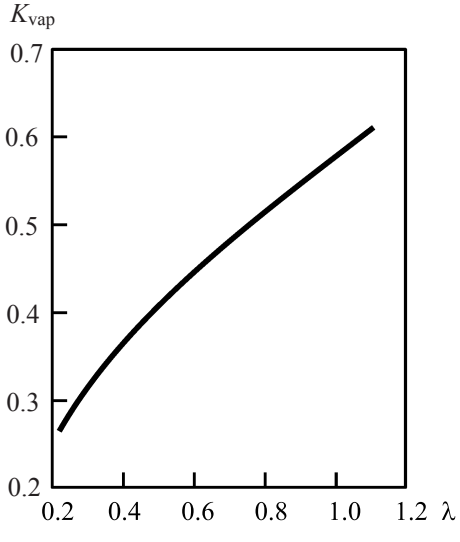

Fig. 8. Dependence of evaporation number K_{vap} on the relative air consuming λ by the data of Gelfand [15] for tower cooler with film type sprinkler.

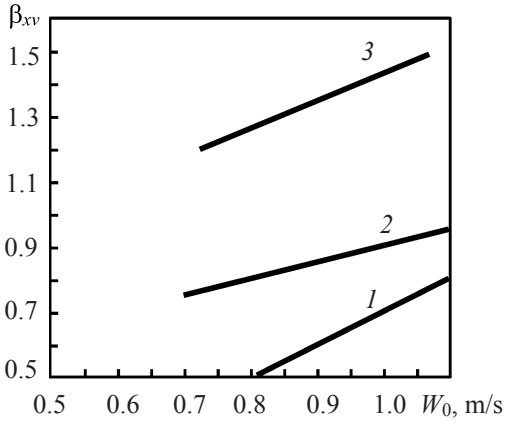

Fig. 9. Influence of air flow rate W_o on the mass release coefficient β_{xv} for the net type packing by the data of Vishnyakova [16]. (*1*) no packing; (*2*) packing layer height is 10 packing elements; (*3*) packing layer height is 18 packing elements.

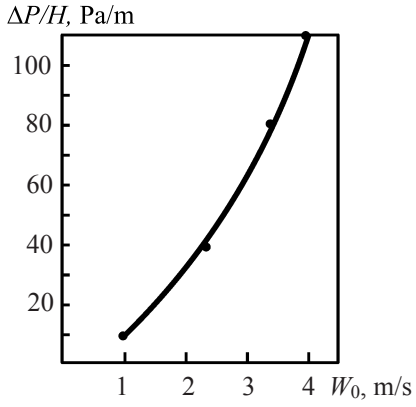

Fig. 10. Influence of air flow rate W_0 on the hydraulic resistance $\Delta P/H$ of dry regular packing from SULZER by the data of Dmitrieva [17].

from the dependence $\Delta P = f(W_0)$ for dry regular structured packing of SULZER firm (Switzerland) by the data of experiments in [17] represented as plot in Fig. 10.

Effects of height of regular film-drop type paking H of PN-2D type from TsNTU RINVO (Russia) on the value of hydraulic resistance coefficient ξ by the data of our own experiments at different productivity on liquid are shown in Fig. 11. Effect of air flow rate W_0 on the degree of cooling the water Δt in the packing layer of PN-2D type at different density of sprinkling q_L is shown in Fig. 12.

Thus, as follows from the consideration of experimental data, the value of rate of air flow in cooler affect directly orv indirectly the characteristics of the process of evaporating cooling in the graduator.

3. GENERALIZED STATISTICALLY REPRESENTATIVE PROFILE OF AIR FLOW RATE IN VENTILATOR COOLER

Analysis of published data [10] on experimental measurements of rate field in a widely distributed industrial cooler SK-400 showed a possibility of their generalization using numerical equation describing average statistical rate profile in such type coolers.

We carried out statistical treatment of experimental observations [10] using methodology of Naumov and co-authors [18–21]. This procedure has been used earlier for description of gas flow rate fields in the apparatuses of chemical technology with grain type layer. The averaging procedure was realized with the basic array of experimental data [10] on the rate fields in cooler at the air flow inlet to and outlet from the sprinkler. Normalization of current rate W_i was found convenient to carry out relatively to the rate maximum W_{max} as a dimensionless ratio W_i/W_{max}. The current coordinate is represented as dimensionless ratio Y/B, where Y is a distance from external wall of cooler [m] and B is width of the sprinkling block of cooler [m].

Initial basic array of experimental data [10], the results of its statistical treatment and of normalization on the value of maximal rate W_{max} are listed in Tables 1 and 2.

The next step is averaging rate profiles at the inlet and outlet of sprinkler followed by calculation of the value $U^* = W_{av}/W_{max}$. Final data on generalized statistically average rate profile are shown in Table 3.

Our analysis of the scope of all published [10] fragmentally represented data on the rate fields in the industrial working coolers SK-400 allowed us to describe them by one characteristic curve obeying the following equation:

$$U^* = \frac{Y/B}{a + b\left(\frac{Y}{B}\right) + c\left(\frac{Y}{B}\right)^2 + d\left(\frac{Y}{B}\right)^3 + e\left(\frac{Y}{B}\right)^4 + f\left(\frac{Y}{B}\right)^5}. \quad (1)$$

In the eq. 1 the constant coefficients are of the following values: $a = 0.053$; $b = 1.14$; $c = -0.8$; $d = 0.84$; $e = -0.22$; $f = 0.0177$. At $Y/B \geq 3$ eq. 1 looks as: $U^* \approx \approx 0.65$.

Graphically generalized statistically representative rate profile is shown in Fig. 13.

Table 1. Procedure of normalization of the experimental measurements [10] on the rate fields at the inlet into sprinkler

Y/B	1	2	3	4	5	6	7
W'_i, μ/C	1.55	1.32	1.05	0.71	0.68	0.54	0.46
W'_i/W_{max}	1.55/1.55	1.32/1.55	1.05/1.55	0.71/1.55	0.68/1.55	0.54/1.55	0.46/1.55

W''_i/W_{max}	0.928	0.736	0.768	0.808	0.848	0.976	1

Table 3. Averaging of experimental data over sprinkler volume in SK-400 evaporating cooler

Y/B	1	2	3	4	5	6	7
$(W'_i+W''_i)/2$, m/s	(1.16+1.55)/2	(0.92+1.32)/2	(0.96+1.05)/2	(1.01+0.71)/2	(1.06+0.68)/2	(1.22+0.54)/2	(1.25+0.46)/2
W_{Cp}, m/s	1.356	1.12	1.005	0.86	0.87	0.88	0.885
$U_*=W_{av}/W_{max}$	1.356/1.356	1.12/1.356	1.005/1.356	0.86/1.356	0.87/1.356	0.88/1.356	0.885/1.356
U_*	1.0	0.826	0.741	0.634	0.642	0.649	0.630

As seen from the $U^*=f(Y/B)$ plot in Fig. 13, this cooler contains two characteristic aerodynamic zones: peripheral near outlet windows with enhanced air consumption, and central, where specific air consumption is less deviates form the average value. The frontier between these zones is at $Y/B = 3$.

Graphical integration of generalized statistically representative rate profile in the cooler shown in Figs. 14 and 15 gives V^* value in the central zone equal to 0.66, in peripheral zone 0.88.

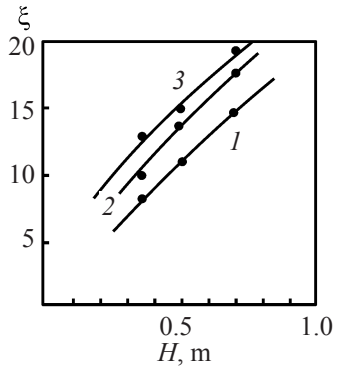

Fig. 11. Influence of packing of PN-2D type height (*H*) on the value of ξ coefficient at different efficiency by liquid (q_L = var) at $W = 2.0$ m/s (const): (1) $q_L = 0$ m³/(m² h); (2) $q_L = 7$ m³/(m² h); (3) $q_L = 11.0$ m³/(m² h).

Thus, the ratio of specific air consumptions in the two zones of the cooler is:

$$\frac{U_p^*}{U_c^*} = \frac{0.88}{0.66} = 1.333. \quad (2)$$

The numerical data on the specific air consumption thus obtained are typical for the SK-400 cooler that in the period of experimental measurements [10] contained sprinkler with the construction characterized by certain values of porosity (ε), live section (*f*) and specific surface (*s*). It can be suggested that specific consumptions in other coolers with another construction of sprinkler blocks differ by geometric characteristics can slightly differ from the U^* values in eq. (2). For example, in [22] has been shown in part that change in porosity ratio in neighboring zones by 1% only leads to change in specific consumption ratio in the same zones by 5%. However, absolute values of porosity of the layer of granules in [22] was equal or less than $\varepsilon = 0.4$, while in regular packing $\varepsilon \sim 0.8$–0.95. Therefore the qualitative regularities revealed here will

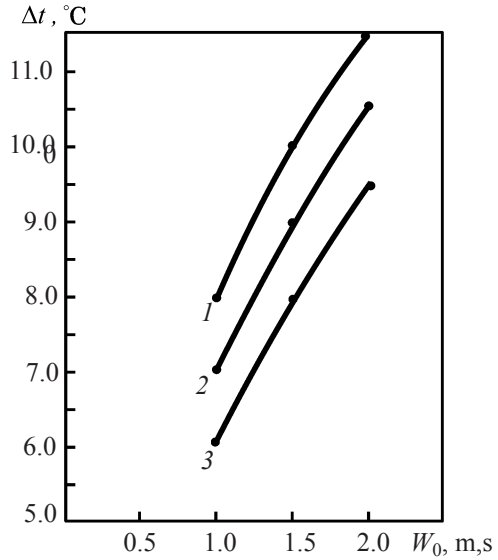

Fig. 12. Influence of air flow rate W_0 on the value of water cooling Δt in the packing layer of PN-2D type at various density of spraying: (*1*) q_L = 0 m³/(m² h); (*2*) q_L = 7 m³/(m² h); (*3*) q_L = 11.0 m³/(m² h).

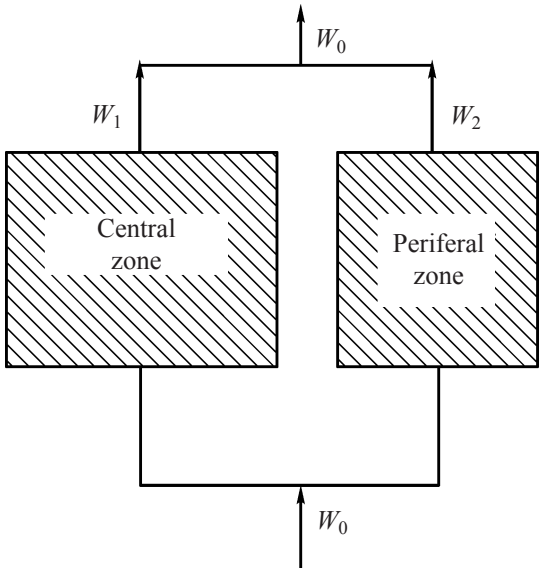

Fig. 16. Two-zone structural model of cooler aerodynamics.

be appropriate for other coolers with similar aerodynamic scheme and type of packing.

The SK-400 ventilator cooler geometry is close to cylinder. The fraction of sprinkling zone of the cooler related to peripheral region can be estimated by the following calculation. Let

$$f_2 = 1 - \left(1 - 2\frac{B}{D}\,Z\right)^2 \qquad (3)$$

where f_2 is fraction of peripheral region of cooler, D is diameter of the whole cooler.

Above in the description of generalized statistically representative rate profile was defined the frontier between peripheral and central zones of cooler Z = 3. Taking this into account we obtain:

$$f_2 = 1 - \left(1 - \frac{6}{D/B}\right)^2. \quad (4)$$

From geometry, the fraction of central zone is:

$$f_1 = 1 - f_2. \quad (5)$$

4. TWO-ZONE STRUCTURAL MODEL OF COOLER AERODYNAMICS. GEOMETRIC CHARACTERISTICS OF PACKING

The obtained statistically representative rate profile allows us to prove two-zone structural model of cooler aerodynamics. The scheme of flows in the cooler according to such model is shown in Fig. 16 where W_0 is average input-output linear rate over full section of empty cooler, W_1 and W_2 are average flow rates in central and peripheral regions of cooler, respectively.

In earlier publications by Riman [28] and Idelchik [29] has been shown principal possibility of equalization the rate field of gas flow in technological apparatuses by means of lattices. The smoothing action of lattice on the initially non-uniform gas steram in the apparatus is illustrated by plots in Fig. 17. More recently by experimental study [30] the soothing action of packing layers of different heights on the rate profile was revealed. Also, were have described [15] constructions of non-uniform sprinkler in a counterflow cooler with productivity on water 100000 m^3/h. In central region of the cooler were located the blocks with extended gape between the sprinkler sheets, that led to the difference in the coefficients of heat and mass transfer in peripheral and central regions of the cooler sprinkled zone. Constructions of coolers differ by packing type at different height are also known [16].

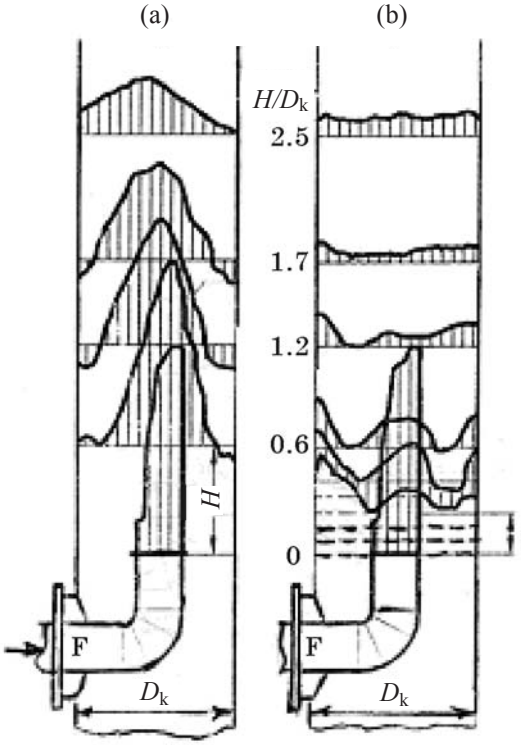

Fig. 17. Redistribution of air flow by lattice by the data of [31] (a) empty apparatus, (b) apparatus with gas redistributing lattice. D_k is diameter of the apparatus.

Meanwhile, there are no reliable methodology and recommendations in literature on the choice and calculation of aerodynamics in such complicated constructions. In earlier publication [33] has been noted than the main disadvantage of the known calculation procedure at projecting of evaporating coolers is not precise enough description of the input-output characteristics of the cooling air flow passing through the sprinkling zone of cooler.

Our two-zone structural model of cooler aerodynamics accounting for the data of investigations [28–30, 16, 18] allows programming of theoretically any possible rate profile (see Fig. 18) by placing packing blocks differ by hydraulic resistance in certain characteristic regions of the cooler sprinkling space. For this purpose we focused on the following geometric characteristics of regular packing: porosity ε [m^3/m^3], specific surface S [m^2/m^3] and equivalent diameter d [μ].

The most important integral geometric characteristics of regular and irregular packing differ by configuration and linear size is porosity. In this work, as well as in the education course “Processes and apparatuses of chemical technology” the term *porosity* is considered as empty

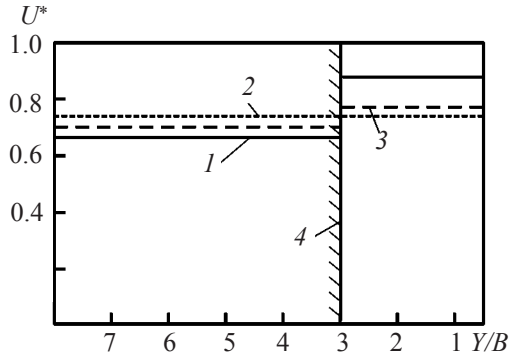

Fig. 18. Th plot $U^* = f(Y/B)$ for two-zone model. (*1*) the profile calculated with the equation; (*2*) theoretically predictable uniform rate profile in cooler; (*3*) calculated rate profile in the cooler obtained by the method of application of sprinkler blocks differ by porosity.

volume (fraction of macro cavities) in the volume unity minus the volume occupied by the packing solid phase.

For example, porosity value in a cylinder apparatus can be estimated using equation [20]:

$$\varepsilon = \left[\int_0^H \int_0^{2\pi} \varepsilon \, d\theta \, dz \right] / 2\pi H \quad [\text{m}^3/\text{m}^3], \qquad (6)$$

where θ is angular coordinate, z is axial coordinate, H is height of packing layer.

By definition, the packing porosity value depends on the geometry, size and mutual location of elements in the regular packing block. Taking this into account, we used this parameter for estimation of distribution of air flow in the cooler.

The effect of geometric characteristics of packing layer on the gas flow distribution is very significant, ever for the layer in an apparatus filled with balls. In [23] have been studied two different tetrahedral packing of balls characterized by the same value of the solid phase volume concentration $\tau = 0.74$. The difference in packing consisted only in the following: in one case there were canals through the balls layer, in the second case the packing was not "transparent" for the flow. The hydraulic resistance τ of the layer in the first case was found by 15–20% lower. The τ value is connected with the porosity value ε by the obvious relation:

$$\varepsilon = 1 - \tau. \qquad (7)$$

In [24] has been determined character of influence of the packing layer porosity on the hydraulic resistance and has been shown that this influence is different at the different values of Reynolds number. In the region of high values of Reynolds number:

$$\Delta P \approx (1 - \varepsilon)/\varepsilon^3,$$

while at small Reynolds numbers:

$$\Delta P \approx \varepsilon^3.$$

Hence, changing porosity of the blocks according to certain law allows to control distribution of rate field in cooler in a specific case of apparatus with packing.

Free volume of regular packing numerically coincides with free section and can be expressed via equivalent diameter d_{equiv}:

$$d_{\text{equiv}} = \frac{4\varepsilon}{S}, \text{ [m]} \qquad (8)$$

where S is specific surface of the packing [m²/m³].

5. PROGNOSIS OF SPECIFIC AIR CONSUMPTION IN CHARACTERISTIC ZONES OF COOLER AT DIFFERENT GEOMETRIC CHARACTERISTICS OF PACKING BLOCKS

The proposed methodology for prognosis of specific consumptions of air flows in two characteristic regions of cooler can be applied to projecting construction of new or reconstruction of currently exploited evaporating coolers for the choice optimal scheme of location and sprinkler blocks type to provide the best uniformity of the rate field. We propose to take into account not only the sprinkler type but also its principal geometric characteristic, the porosity. This is actual because industry produces now rather a wide spectrum of evaporating cooler packing differ by geometric characteristics [1, 2, 33].

Below we derive theoretical relations for calculation specific consumption of air flow based on the proposed two-zone structural model of cooler aerodynamics.

Equations for the numerical estimation of the ratio of specific consumption of air flow in characteristic regions of cooler we will deduce basing on the known equations describing hydraulic resistance of packing layer taking into account that these equations can be applied to both irregular and regular packings [27, 35]. For better statistical representation and reliability we derived relations for estimation of specific consumption of air flow in the characteristic regions of cooler using one methodology, but two different basic equations for estimation of pressure loss in grain layer, namely, Gelperin – Kagan equation [26] and widely known Ergun equation [25]. While derived the targeted relations we used the ideas developed in publications by Naumov and co-authors [18, 22] for the apparatuses of chemical technology with fixed granulated layer.

We accept the following presumptions:

– As model system (packing) we got balls with proper shape;

– Contribution of liquid phase (counter-flow) is omitted.

5.1. Deriving Expressions for Calculation of Specific Consumption of Air Flow in Two Zones of Cooler Differ by Porosity, Based on Gelperin–Kagan [26] Equation

The initial equation has form:

$$Eu_m = \frac{100}{\text{Re}_{\text{eq}}} + 0.9 \qquad (9)$$

where $Eu_m = \frac{\Delta p}{H}\frac{\varepsilon^2}{\rho\, w^2 S}$ is modified Euler criterion; $\mathrm{Re}_e = \frac{w\, d_e}{\upsilon\, \varepsilon}$ is Reynolds criterion referred to equivalent diameter of canal for granulated packing $d_{\mathrm{equiv}} = 4\varepsilon/S$; ρ is gas density, kg s^2/m^4; $S = \varphi\,(1-\varepsilon)$ is specific surface of packing, m^2/ m^3; υ is cinematic gas viscosity, m^2/s.

Let us assume that the rate field discontinuity in the two zones of cooler results from the difference in the values of packing porosity only, as shown in [22]. Therewith, the packing height in both the zones is the same. The calculation scheme is shown in Fig. 19.

After substitutions and transformations we obtain:

$$\frac{\Delta P}{H} = 100\ \frac{\rho\nu W S^2}{4\ \varepsilon^2} + 0.9\ \frac{\rho W^2 S}{\varepsilon^2}\ .$$

Finally:

$$\frac{\Delta P}{H} = 100\,\frac{\nu\ \rho\ \varphi^2\ (1-\varepsilon)^2}{4\ \varepsilon^2}\ W\left[1 + 0.036\frac{W}{\nu\ \varphi\ (1-\varepsilon)}\right]. \quad (10)$$

For a sphere:

$$\varphi = \frac{S_{1sphere}}{V_{1sphere}} = \frac{4\ \pi\ r^2}{\frac{4}{3}\ \pi\ r^3} = \frac{3}{r} = \frac{6}{d}\ .$$

In correspondence with the equation of flow continuity we accept that for both the taken zones, peripheral and central, is true:

$$\Delta P_1 = \Delta P_2 = \Delta P\ ,$$

where ΔP_1 and ΔP_2 are pressure loss in the central and peripheral zones respectively.

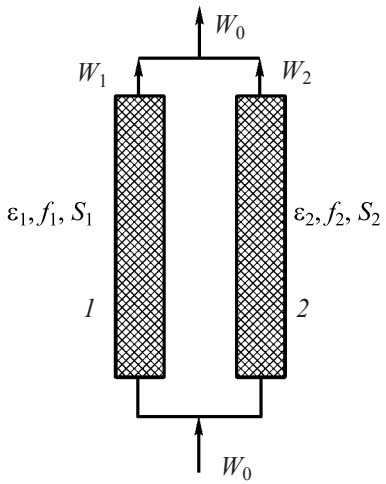

Fig. 19. Calculated scheme of cooler. (*1*) Central zone; (*2*) peripheral zone.

Then:

$$\frac{W_2}{W_1} = \left[\frac{(1-\varepsilon_1)\ \varepsilon_2}{(1-\varepsilon_2)\ \varepsilon_1}\right]^2\ \frac{1+0.006\ \frac{W_1\ d}{\nu(1-\varepsilon_1)}}{1+0.006\ \frac{W_2\ d}{\nu(1-\varepsilon_2)}},$$

And accounting for the expression for Reynolds number $\mathrm{Re}_0 = \frac{W_0\ d}{\nu}$, we obtain:

$$\frac{W_2}{W_1} = \left[\frac{(1-\varepsilon_1)\ \varepsilon_2}{(1-\varepsilon_2)\ \varepsilon_1}\right]^2\ \frac{1+0.006\ \mathrm{Re}_0\frac{1}{1-\varepsilon_1}\ \frac{W_1}{W_0}}{1+0.006\ \mathrm{Re}_0\frac{1}{1-\varepsilon_2}\ \frac{W_2}{W_0}}. \quad (11)$$

From the consumption balance in two-zone model follows:

$$\frac{W_1}{W_0} = \frac{1-\frac{W_2}{W_0}f_2}{1-f_2}\ W_1 = \frac{W_0 - W_2 f_2}{1-f_2}\ \frac{W_1}{W_2} = \frac{(W_0/W_2) - f_2}{1-f_2}$$

Or

$$\frac{W_2}{W_1} = \frac{1-f_1}{\frac{W_0}{W_2}-f_2} = \frac{\frac{W_2}{W_0}(1-f_2)}{1-f_2\ \frac{W_2}{W_0}}\ .$$

As far as $f_2 < 1$, from the last expression follows that $f_2\left(\frac{W_2}{W_0}\right) < 1$ or $\left(\frac{W_2}{W_0}\right) < \left(\frac{1}{f_2}\right)$.

In the framework of the considering model we can write:

$$\varepsilon_1 = \frac{\varepsilon_0 - \varepsilon_2\ f_2}{1-f_2},$$

$$1-\varepsilon_1 = 1 - \frac{\varepsilon_0 - \varepsilon_2\ f_2}{1-f_2} = \frac{(1-\varepsilon_0) - (1-\varepsilon_2)\ f_2}{1-f_2}\ ,$$

$$\mathrm{E} = \left[\frac{1-\varepsilon_0 - (1-\varepsilon_2)\ f_2}{\varepsilon_2 - \varepsilon_2\ f_2}\ \frac{\varepsilon_2}{1-\varepsilon_2}\right]^2 = \left[\frac{\frac{1-\varepsilon_0}{1-\varepsilon_2} - f_2}{\frac{\varepsilon_0}{\varepsilon_2} - f_2}\right]. \quad (12)$$

After algebraic transformations of expression (11) taking (12) into account we obtain:

$$\frac{\frac{W_2}{W_0}\ (1-f_2)}{1-\frac{W_2}{W_0}\ f_2} = \mathrm{E}\ \frac{1+\frac{0.006\ \mathrm{Re}_0}{1-\varepsilon_2}\ \frac{1-\frac{W_2}{W_0}\ f_2}{[(1-\varepsilon_0)/(1-\varepsilon_2)]-f_2}}{1+\frac{0.006}{1-\varepsilon_2}\ \frac{W_2}{W_0}}$$

Let us designate:

$$\frac{0.006\,\mathrm{Re}_0}{1-\varepsilon_2} = C.$$

Then:

$$\frac{\frac{W_2}{W_0}(1-f_2)}{1-\frac{W_2}{W_0}f_2} = \mathrm{E}\,\frac{\left\{1+\frac{C}{[(1-\varepsilon_0)/(1-\varepsilon_2)]-f_2}\right\}-\left\{\frac{C\,f_2}{[(1-\varepsilon_0)/(1-\varepsilon_2)]-f_2}\right\}\frac{W_2}{W_0}}{1+C\,\frac{W_2}{W_0}}.$$

After transformations from the last expression we obtain the following equation:

$$\mathrm{A}\left(\frac{W_2}{W_0}\right)^2 - \mathrm{B}\left(\frac{W_2}{W_0}\right) + Q = 0, \qquad (13)$$

where:

$$\mathrm{A} = C\left[\frac{\mathrm{E}\,f_2}{\frac{1-\varepsilon_0}{1-\varepsilon_2}-f_2}-(1-f_2)\right];$$

$$\mathrm{B} = \mathrm{E}\,f_2\left(1+\frac{C}{\frac{1-\varepsilon_0}{1-\varepsilon_2}-f_2}\right)+C\,\frac{\mathrm{E}\,f_2}{\frac{1-\varepsilon_0}{1-\varepsilon_2}-f_2}+(1-f_2);$$

$$Q = \mathrm{E}\left(1+\frac{C}{\frac{1-\varepsilon_0}{1-\varepsilon_2}-f_2}\right).$$

Following solution of eq. (13) has physical sense:

$$\mathrm{A}\left(\frac{W_2}{W_0}\right)^2 - \mathrm{B}\left(\frac{W_2}{W_0}\right) + Q = 0. \qquad (14)$$

Analysis of eq. (14) for two extreme cases gives:

for $\mathrm{Re}_0 \to 0$: $\dfrac{W_2}{W_0} = \dfrac{\mathrm{E}}{\mathrm{E}f_2 + (1-f_2)}$;

for $\mathrm{Re}_0 \to \infty$: $\dfrac{W_2}{W_0} = \dfrac{(1+\mathrm{E}\,f_2)-\hat{\mathrm{E}}}{2}$.

Here:

$$\hat{\mathrm{E}} = \sqrt{(1+f_2)^2 - 4\left[\mathrm{E}\,f_2^2 - (1-f_2)\left(\frac{1-\varepsilon_0}{1-\varepsilon_2}-f_2\right)\right]}$$

Expression for calculation W_1/W_0 value can be obtained from the consumption balance:

$$\frac{W_1}{W_0} = \frac{1-\frac{W_2}{W_0}f_2}{1-f_2}. \qquad (15)$$

Expressions (14) and (15) obviously reflect satisfactorily the process physics, because they are obtained on the basis of empirical equation [26] which in turn corresponds well to the results of ΔP calculation for, e.g., balls alongside the Sergeev's theoretical equation [36].

5.2. Deriving Expressions for Calculation of Specific Consumption of Air Flow in Two Cooler Zones Differ by Porosity, on the Basis of Ergun's Equation [25]

Initial Ergun's equation for calculation of hydraulic resistance of packing layer has the form [25]:

$$\frac{\Delta P}{H} = \mathrm{A}\,\frac{(1-\varepsilon)^2}{\varepsilon^3}\,\frac{\mu W}{d^2} + \mathrm{B}\,\frac{1-\varepsilon^2}{\varepsilon^3}\,\frac{\rho W}{d}, \qquad (16)$$

where A and B are constant coefficients. By the data [25] A = 150, B = 1.75.

Assuming that equation $\Delta P_1 = \Delta P_2 = \Delta P$ is true for both centar and peripheral zones of sprinkled region of cooler, we can writhe the Ergun's equation for the each zone:

$$\frac{\Delta P}{H} = \mathrm{A}\,\frac{(1-\varepsilon_2)^2}{\varepsilon_2^3}\,\frac{\mu W_2}{d^2} + \mathrm{B}\,\frac{1-\varepsilon^2}{\varepsilon_2^3}\,\frac{\rho W_2^2}{d}, \qquad (17)$$

$$\frac{\Delta P}{H} = \mathrm{A}\,\frac{(1-\varepsilon_1)^2}{\varepsilon_1^3}\,\frac{\mu W_1}{d^2} + \mathrm{B}\,\frac{1-\varepsilon_1}{\varepsilon_1^3}\,\frac{\rho W_1^2}{d}. \qquad (18)$$

Multiplying first and second terms in the right part of eq. (17) by (W_2/W_0) and $(W_2/W_0)^2$, respectively, we obtain:

$$\frac{\Delta P}{H} = \mathrm{A}\,\frac{(1-\varepsilon_2)^2}{\varepsilon_2^3}\,\frac{\mu W_0}{d^2}\,\frac{W_2}{W_0} + \mathrm{B}\,\frac{1-\varepsilon_2}{\varepsilon_2^3}\,\frac{\mu W_0}{d^2}\,\frac{W_0\,\rho\,d}{\mu}\left(\frac{W_2}{W_0}\right)^2. \qquad (19)$$

Index 0 in (19) and in following expressions points to the whole volume of cooler assuming that its section is empty.

As far as $\dfrac{W_0\,\rho\,d}{\mu} = \mathrm{Re}_d$, eq. (19) can be rewritten as:

$$\frac{\Delta P}{H} = \mathrm{A}\,\frac{(1-\varepsilon_2)^2}{\varepsilon_2^3}\,\frac{\mu W_0}{d^2}\,\frac{W_2}{W_0} + \mathrm{B}\,\frac{1-\varepsilon_2}{\varepsilon_2^3}\,\frac{\mu W_0}{d^2}\,\mathrm{Re}_d\left(\frac{W_2}{W_0}\right)^2.$$

After algebraic transformations of the last equation we obtain:

$$\frac{\Delta P}{H} = \mathrm{A}\ \frac{(1-\varepsilon_2)^2}{\varepsilon_2^3}\ \frac{\mu\ W_0}{d^2}\ \frac{W_2}{W_0}\left[1+\frac{\mathrm{B}}{\mathrm{A}}\ \frac{\mathrm{Re}d}{1-\varepsilon_2}\left(\frac{W_2}{W_0}\right)\right]. \quad (20)$$

Similarly, from eq. (18) we obtain expression for the cooler central zone:

$$\frac{\Delta P}{H} = \mathrm{A}\ \frac{(1-\varepsilon_1)^2}{\varepsilon_1^3}\ \frac{\mu\ W_0}{d^2}\ \frac{W_1}{W_0}\left[1+\frac{\mathrm{B}}{\mathrm{A}}\ \frac{\mathrm{Re}_d}{1-\varepsilon_1}\left(\frac{W_1}{W_0}\right)\right]. \quad (21)$$

As far as left parts of (20) and (21) are the same, we can write:

$$\frac{W_2}{W_1} = \frac{1+\frac{\mathrm{B}}{\mathrm{A}}\ \frac{\mathrm{Re}_d}{1-\varepsilon_1}\ \frac{W_1}{W_0}}{1+\frac{\mathrm{B}}{\mathrm{A}}\ \frac{\mathrm{Re}d}{1-\varepsilon_2}\ \frac{W_2}{W_0}}\left(\frac{1-\varepsilon_1}{1-\varepsilon_2}\right)^2\left(\frac{\varepsilon_2}{\varepsilon_1}\right)^3. \quad (22)$$

Expression for the balance of consumption in cooler in the framework of two-zone structural model has the form:

$$W_0 = W_2\ f_2 + W_1\ (1-f_2). \quad (23)$$

Deviding eq. (23) by W_2 we obtain:

$$\frac{W_0}{W_2} = f_2 + \frac{W_1}{W_2}\ (1-f_2), \text{ hence:}$$

$$\frac{W_2}{W_0} = \frac{\frac{W_2}{W_1}}{1-f_2+f_2\ \frac{W_2}{W_1}}. \quad (24)$$

Deviding eq. (23) by W_1 we obtain:

$$\frac{W_0}{W_1} = \left(\frac{W_2}{W_1}\right)\ f_2 + (1-f_2), \text{ hence:}$$

$$\frac{W_1}{W_0} = \frac{1}{1-f_2+f_2\left(\frac{W_2}{W_1}\right)}. \quad (25)$$

Let in (22):

$$\frac{\mathrm{B}}{\mathrm{A}}\ \frac{\mathrm{Re}_d}{1-\varepsilon_1} = Z;\ \ \frac{1-\varepsilon_1}{1-\varepsilon_2} = M;\ \ \left(\frac{1-\varepsilon_1}{1-\varepsilon_2}\right)^2\left(\frac{\varepsilon_2}{\varepsilon_1}\right)^3 = K;\ \ \frac{W_2}{W_1} = U.$$

With these assignments, eqs. (24) and (25) can be rewritten as:

$$\frac{W_2}{W_0} = \frac{U}{1-f_2+f_2\ U} \quad (26)$$

and

$$\frac{W_1}{W_0} = \frac{1}{1-f_2+f_2\ U}. \quad (27)$$

From (26) and (27) accounting for the accepted assignments, eq. (22) after simple algebraic transformations becomes:

$$(f_2 + ZM)U^2 + (1 - f_2 - K f_2)\,U - K(1-f_2+Z) = 0.$$

Only one solution of the last equation has physical sense:

$$U = \frac{-(1-f_2-Kf)}{2(f_2+ZM)} + \frac{\sqrt{(1-f_2-Kf_2)^2+4(f_2+ZM)(1-f_2+Z)K}}{2(f_2+ZM)}. \quad (28)$$

Analysis of eq. (28) for two extreme cases gives:

for $\mathrm{Re_d} \to 0$: $\frac{W_2}{W_1} = \left(\frac{1-\varepsilon_1}{1-\varepsilon_2}\right)^2\left(\frac{\varepsilon_2}{\varepsilon_1}\right)^3$;

for $\mathrm{Re_d} \to \infty$: $\frac{W_2}{W_1} = \sqrt{\frac{1-\varepsilon_1}{1-\varepsilon_2}\left(\frac{\varepsilon_2}{\varepsilon_1}\right)^3}$.

Expression for calculation of flow rate in the cooler peripheral zone becomes:

$$\frac{W_2}{W_0} = \frac{-L+\sqrt{L^2+\ 4\ F\ (1+Q\ W_0)\ W_0}}{2\ F\ W_0}, \quad (29)$$

where *L, Q, F* are defined as:

$$L = \frac{\mu_2}{\mu_0}\left(\frac{1-\varepsilon_2}{1-\varepsilon}\right)^2\left(\frac{\varepsilon}{\varepsilon_2}\right)^3; \quad (30)$$

$$Q = 1.167\cdot 10^{-2}\ \frac{\rho_0\ d}{(1-\varepsilon)\ \mu_0}; \quad (31)$$

$$F = Q\ \frac{\rho_2}{\rho_0}\left(\frac{\varepsilon}{\varepsilon_2}\right)^3\frac{1-\varepsilon_2}{1-\varepsilon}. \quad (32)$$

Expression for calculation of flow rate in the cooler central zone becomes :

$$\frac{W_1}{W_0} = \frac{-\mathrm{E}+\sqrt{\mathrm{E}^2+4\ \mathrm{X}\ (1+Q\ W_0)\ W_0}}{2\ \mathrm{X}\ W_0}, \quad (33)$$

where the constants E and X are defined as:

$$\mathrm{E} = \frac{\mu_1}{\mu_0}\left(\frac{1-\varepsilon_1}{1-\varepsilon}\right)^2\left(\frac{\varepsilon}{\varepsilon_1}\right)^3; \quad (34)$$

$$X = Q\,\frac{\rho_1}{\rho_0}\left(\frac{\varepsilon}{\varepsilon_1}\right)^3\frac{1-\varepsilon_1}{1-\varepsilon}\,. \qquad (35)$$

The set of equations (29)–(35) allows calculation of specific consuming of gas flow in the cooler peripheral and central zones in the framework of the proposed two-zone structural model of aerodynamics.

5.3. Comparing Results of Calculation by Means of the Obtained Expressions of Air Flow Specific Consumption in the Cooler Two Zones

The results of calculations of W_2/W_0 and W_1/W_0 using relations (14), (15) and (29)–(35), respectively are found differ by 5% or less at W_0 = 0.1 m/sec for the model system with ball packing d = 5 mm in the apparatus with D = 50 mm. Calculation with formulas (14), (15) leads to underestimation of W_2/W_0 values.

For practical purposes cam be recommended both relations (14), (15) and (29)–(35), the latter are obtained on the basis of Ergun's equation [25], which gas been tested within wider range of Reynolds numbers and packing types, forms and sizes as compared with Gelperin–Kagan equation [26].

6. PRACTICAL METHODS FOR AVERAGING RATE PROFILE IN THE COOLER SPRINKLING SPACE

The following method can be used for the control over distribution of specific consumption of air flow in the section of the cooler sprinkling space:

– Varying sprinkler blocks height;

– Varying the sprinkler dinsity;

– Varying the sprinkler living section.

In contrast to the method proposed in [18] based on the varying the height of the sprinkler blocks, we suggest optimal to apply the blocks with the same height but differ by living section. The advantage of the technical solution proposed by us is the absence of reasons for appearance unwanted aerodynamic non-uniformity in the upper zone of cooler near the water trapping devices.

According to the proposed methodology the problem of programming uniform rate field for the air flow in ventilator cooler is solved by means of installation in peripheral zones of sprinkling space of the packing blocks with constant height but differ by hydraulic resistance. Equalizing the flow is achieved due to the difference in living section (porosity) of packing blocks in the corresponding zones. For equalization of non-uniform initial rate profile, in the region within the cooler section characterized by lower calculated air flow rate (se Figs. 15, 18) should be installed the packing blocks with lower value of the coefficient of hydraulic resistance or, respectively, with higher living section (porosity).

Characteristics of some industrial packing made of polymer material are shown in Table 4. By the data of [2] the values of hydraulic resistance coefficient for the sprinkler packing blocks of different construction fall to the range from ξ = 7.5 to ξ = 35.4. Unfortunately, the constructions listed in the Table 4 differ by height (from 0.92 m to 2.38 m) and this retards their practical application for programmed uniform rate profile in cooler.

The optimal construction for solving the problem of programmed rate profile in the cross section of cooler is

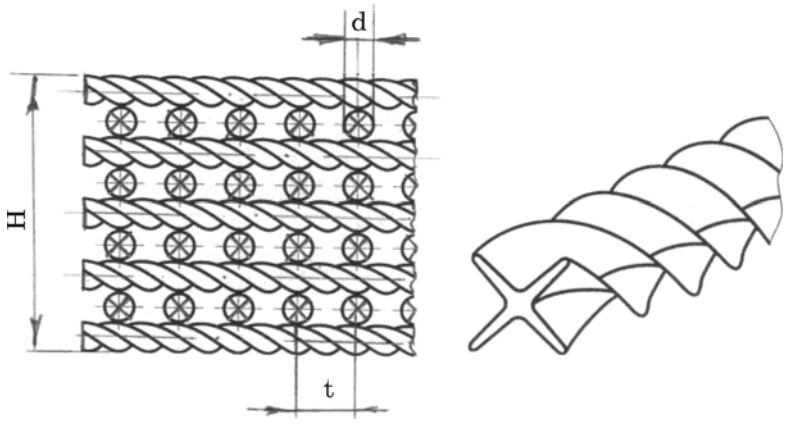

Fig. 20. General view of sprinkler block of PN-2D type and separate packing element: H is the block height; t is pitch between the central axes of neighboring helicoids in one row; d is helicoids external diameter.

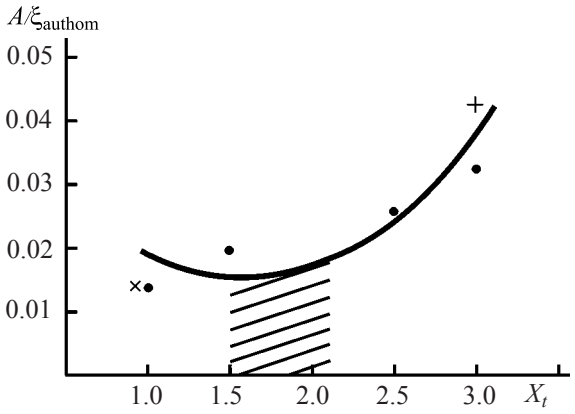

Fig. 21. Dependence of A/ξ_{authom} on geometry patameter X_t obtained in experiments with sprinkler block of PN-2D type.

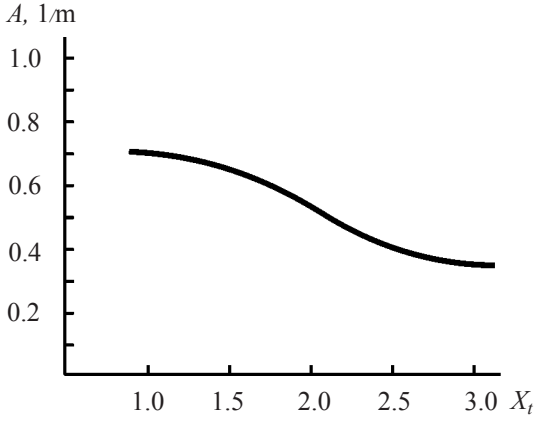

Fig. 22. Effect of geometry parameters of PN-2D packing on the value of A coefficient from the data of the experiments carried out by the authors.

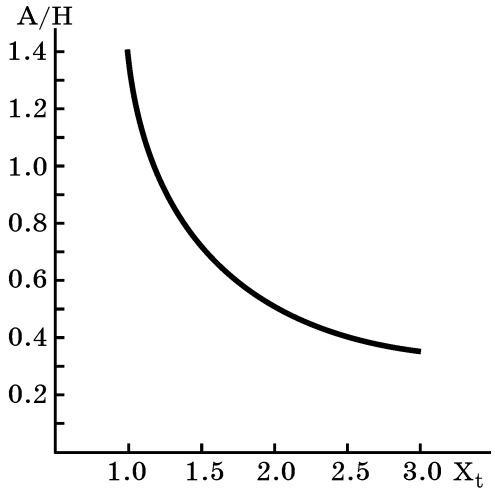

Fig. 23. Dependence of A/*H* simplex on the geometry parameter X_t from our experiments with PN-2D sprinkler block.

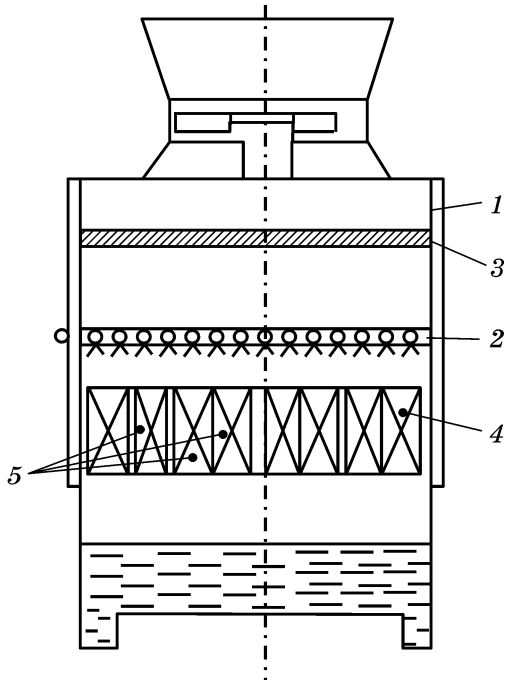

Fig. 24. Scheme of packaging sprinkler blocks in the zones of sectional ventilator cooler: (*1*) body; (*2*) water distributing system; (*3*) water trapping lattices; (*4*) sprinkler block with smaller live section in the cooler peripheral zone; (*5*) sprinkler block with larger live section in the cooler peripheral zone.

represented by the developed for this purpose a family of packing with helicoid structure and varied geometry of packing of separate helicoids in the packing block. The general view of such packing block is shown by Fig. 20. The distance between the neighboring helicoids X_t is variable value:

$$X_t = t/d,$$

where d is external diameter of a helicoid.

The dependence of A/ξ_{authom} on the geometric parameter X_t obtained in our experiments with a sprinkler block of PN-2D type is shown in Fig. 21. As seen, the optimal from the viewpoint of efficiency – energy consumption ratio are the X_t values in the range from 1.5 to 2.1.

Effect of geometry parameter X_t of packing block on the value of coefficient A charactreizing, efficiency of the process of evaporating cooling on an example of the packing of PN-2D type is shown in Fig. 22. From the plot is seen that PN-2D packing allows varying the X_t value from 1.0 to 3.0, which leads to change in A coefficient from 0.3 to 0.7. In a dimensionless form, the $A/H = f(X_t)$ dependence is shown in Fig. 23. The whole characteristics of helicoids structural packing with varied packing geometry are listed completely in [34].

To minimize losses due to hydraulic resistance, the ξ_π coefficient should be chosen according to the well known Idelchik's formula [29]:

$$\xi_\pi = \xi_{opt.i} = 2\ [1-(W_{0i})_{\min}/W_{0i}], \quad (36)$$

where:

$$\xi_\pi = \frac{2\ \Delta P_i}{\rho\ W_\pi^2}\ , \quad (37)$$

ξ_π is hydraulic resistance coefficient for *i*-th region of the flow assigned to the rate W_π ; W_π is average rate in the *i*-th region of air flow at the inlet into the sprinkler block, m/sec; W_{0i} is averaged over the section of *i*-th regionrate of air flow before the inlet into sprinkler block, m/sec.

From eq. (37) follows: $\Delta P_i = 0.5\ \xi_\pi\ \rho\ W_\pi^2$ is pressure loss in the *i*-th region of air flow, Pa.

Practically, the problem of providing uniform distribution of air flow rate profile after the sprinkler blocks in cooler is solved by selection of constructions with $\xi_p = \xi_{opt}$, that is, by solving the following equations:

$$\xi_p = \xi_{opt} = \frac{W_{01}^2 - W_{02}^2}{W_{p1}^2 - W_{p2}^2} \quad (38)$$

$$W_{p1} = \frac{W_{01}\ (W_{01}+W_{02})}{2\ W_{01}+\ W_{02}-1} \quad (39)$$

$$W_{p2} = \frac{W_{02}\ (W_{01}+\ W_{02})\ (W_{02}+1)}{2\ W_{02}^2+W_{01}\ W_{02}+W_{01}+W_{02}-1} \quad (40)$$

The scheme of packaging the sprinler blocks in certain zones of sectional ventilator cooler is shown in Fig. 24. It is seen that the proposed technical solution can be easily achieved practically at the cooler reconstruction.

In some cases when there is no data on the packing porosity but there are data on the pressure loss ΔP, for selection of two sprinklers in the framework of two-zone model can be used approximate formula:

$$\frac{W_2}{W_1} = \sqrt{\frac{\Delta P_1}{\Delta P_2}} \quad (41)$$

For example, if a cooler under project (or reconstruction) of SK-400 has: $W_2/W_1 = 1.333$.

Then from eq. (41) we have:

$$\Delta P_1 = \Delta P_2\ \ (1.333)^2 = \Delta P_2\ \ 1.7769$$

Let us assume that according to the data of producer the packing blocks $\Delta P_2 = 4$ mm water column, then:

$\Delta P_1 = 4 \cdot 1.7769 = 7.1$ mm water column.

If the packing with such hydraulic resistance is absent in the market, the nearest can be chosen and verifying calculation should be made.

CONCLUSIONS

1. An equation is proposed for the calculation the generalized statistically representative rate profile in ventilator cooler.

2. Two-zone structural model of cooler aerodynamics is proved.

3. Theoretical relations for the calculation of specific consumption of air flow in the two characteristic zones of cooler differ by live section of packing blocks is proposed.

4. A method for increasing uniformity of rate profile over the cross section of the cooler sprinkler space is proposed by means of application of helicoids-structural packing blocks with varieg packaging geometry in the blocks.

Abstract—General structure of informatization of the control over the process of separation of solid and gas phases is described for a class of such processes characterized by similarity of technological scheme. The informatization is realized by means of organization of observability the characteristics of energetic balance of the process. A special application is the process of vacuum separation of titanium sponge.

DOI: 10.1134/S1070427208030440

1. INTRODUCTION. DEFINITION OF A CLASS OF PROCESSES

There is a series of the processes of substances isolation by separation of phases (solid and gas) of periodical type: vacuum separation, evaporation, drying, etc., characterized by the features: (a) electric heating, (b) temperature in the technological unit is stabilized by application of controlling contour while temperature is measured by electronic gage inside the unit, (c) vacuum evacuation of internal space of the technological unit (uniformly during the process). Examples of such processes are the process of vacuum separation of titanium sponge [9], the process of crystallization [7], drying [6].

The process of vacuum separation of titanium sponge consists in distilling magnesium and magnesium chloride off from the titanium sponge block at high temperature under vacuum, practically to their complete removing. The process of crystallization consists in distilling under vacuum water off from saturated solution of a substance practically to complete crystallization. The process of drying consists in distilling off water under partial vacuuming practically to it complete removing water from wet material.

2. FORMULATING CRITERION OF PROCESS COMPLETING

For optimal control over such processes in respect of quality separation of substances of the parent non-uniform mixture at minimization of energy consuming, it is necessary in real time determine precisely enough the moment of the process ending, accounting for non-predictable process duration due to variations in the state of initial material, for, on the one hand, minimization the process duration (lower limit) and, on the other hand, maximizing the fraction of quality product, that is, minimizing contribution of the processes with insufficient separation (evaporation, drying) and determining for each process coefficient of average elongation relatively to individual for each process lower duration edge. Thermodynamic formulation of the criterion for ending such a process which has been initially made for the process of vacuum separation of titanium sponge [10] now is extended over whole class of above mentioned processes.

"As is known from the second law of thermodynamics

$$ds \geq dQ / T \quad (1)$$

where Q is heat, $dQ = E$, where E – energy flow into the system, then

$$ds \geq E/T \quad (1')$$

When the process is under equilibrium, then

$$ds = E/T \quad (1'')$$

In the system of separating furnance E and T are measured (observable) values (by means automatic means for control over technological process, AMCTP), therewith $T = const$ (is stabilized automatically). Thus, in the end of the process of separation (complete evaporation of Mg and $MgCl_2$) the system achieves equilibrium state: $ds = const$ (minimum), hence, from (1") follows that $E = const$ (energy flow is defined by energy loss only) and to the end of the process definitely observed constancy in energy flow into the system." Besides necessity, in [10] was shown also sufficiency of fulfilling this condition, which is even more important for determination of the moment of the process ending. Existence of such fundamental criterion that has not been described earlier (in [3,4,15]) allows us to formulate further practical mathematic methods for its calculation.

On the other hand, according to Aleskovskii theorem (2002) [1] on the connection between anisotropy and information, $s + I = 1$, $dI = -ds$, change in information equals to change in the entropy, correct to a sign. Informatively the end of separation process at the achieving entropy minimum ($dI = 0$) corresponds exactly to zeroing the entropy differential of the process of contaminants distilling off ($ds = 0$, heat loss omitted). When relatively constant heat loss is taken into account the process entropy becomes a sum of two terms: entropy of the process of phase transfer (evaporation) and entropy of heat flow of heat loss, $s = s_f + s_m$, thus $ds = ds_f + ds_m$, and the process end corresponds to the zeroing $ds_f = 0$, that is, informatively the process is completed when change in entropy mecomes constant, $ds_m = 0$. Further is describe a method for calculating this information criterion.

A necessary and sufficient condition of completing the process of separation at the separation of solid and gas phases (defined by difference in melting point, decomposition of first component and boiling point of second component (separated material) at not necessary vacuuming theoretically, according to the Second law of thermodynamics, is stabilization of energy flow into the system, E = *const*, but actually determination of this theoretically detectable moment consists [11], [10] in the following: "when process is completed, $E = const$, $E = 0$, and for determination the process end it is sufficient to test fulfilling the hypothesis on the equality to 0 of mathematical expectation of the value E", the first derivative of measurable, directly or indirectly, of energy flow into boilers (indirectly, at pulse type control, via calculated by computer routine using known power of heaters and results of current measurements with automatic system of control over technological process, on-off time ratio of the pulses of control over heaters)

3. DESCRIPTION OF MATHEMATIC AND ALGORITHMIC PROCEDURES FOR CALCULATION

The hypothesis about the process completing can be verified using a statistical criterion [11] [5, p. 633]: "using statistical t-criterion

$$y = \frac{\overline{E}_{(t_c)n} - 0}{S(E'(t))_{(t_c)n}/\sqrt{n}} \quad . \qquad (2)$$

Let us determine <practically> the moment of theoretical process ending ", where

$$\overline{E}_{(t_c)} = \frac{1}{t_c}\int_{t-t_c}^{t} E'(t)\,dt \qquad (3),$$

the average value of $E'(t)$ reflects change in energy flow in the interval of duration t_c from the current moment t to $t - t_c$. The expected value $E'(t)$ is known, $M(E'(t)) = 0$. Standard deviation $S(E(t))$ can be calculated within $[t - t_c, t]$ interval relatively to 0:

$$S(E'(t))_{(t_c)} = \sqrt{\frac{1}{t_c}\int_{t-t_c}^{t} (E'(t) - 0)^2\,dt}\,. \qquad (4)$$

We introduce renormalization of expressions (3), (4) relatively to E_{max}, the nominal value of heater power:

$$\overline{E}(t_c)n = \frac{1}{t_c}\int_{t-t_c}^{t} \frac{E'(t)}{E_{\max}}\,dt\,, \qquad (5)$$

$$S(E'(t))_{(t_c)n} = \sqrt{\frac{1}{t - t_c}\int_{t-t_c}^{t} \frac{(E'(t) - 0)^2}{E_{\max}}\,dt}\,. \qquad (6)$$

By means of the described statistical procedures, verifying of the hypothesis about equality of first derivative of energy flow into the unit to zero can be algorithmed. The algorithmed procedure of determination completing a given class of the process of chemical technology is general for various processes of this class and at informatization of the corresponding process can be built into information system (technology operator automatized work place).

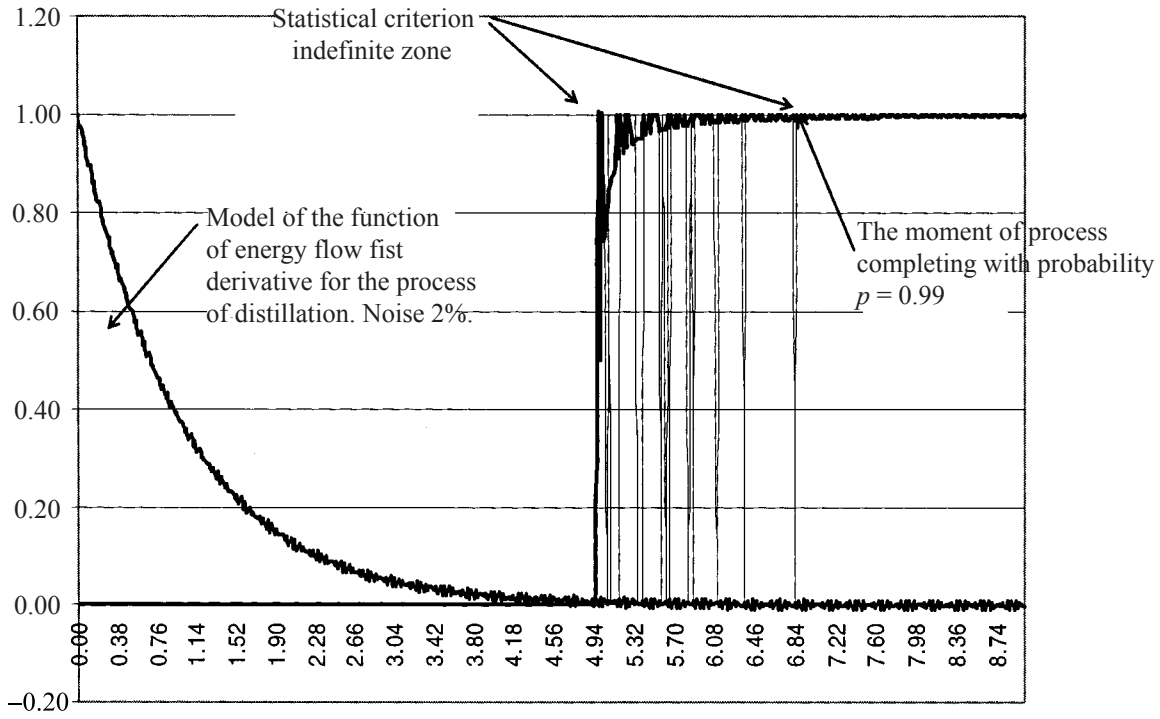

Fig. 1. The results of working of the algorithm for determination the process completing ising data of model.

These algorithms were tested on a model describing such processes. At a high noise level that corresponds to fluctuations in the function of energy flow derivative (not precise measurements) practical model determination of the process completing is enough unambiguous (see Figs. 1, 4, 5 and [14]). A system with the algorithms of less performance with quit another formulation of the criterion of process completing has been used in "Avisma" company plant since 1981 [3]. Application of statistical methods gives solution that is simoler in respect of calculations than the attempted direct analytical modeling of the system by means of integral-differential equations described in [15].

4. GENERAL TECHNOLOGICALINFORMATIONAL SCHEME OF PROCESS CONTROL

Thus, at the possibility of informational determination of completing the given class of processes using theoretical thermodynamically proven criterion of process completing, the technological and informational scheme of building this class of processes can be generalized as follows:

(1) A system of heating with measuring energy flow (system of vacuum evacuation), (2) A system of temperature stabilization inside the unit, (3) Informational measuring system (with saving data in a computer) creating data base of the process characteristics, (4) pseudoparallel in time determining the moments of processes completing (when numerous of parallel technological units are in work), (5) probability based accounting for the second sort product measure for determination on the level 4 of optimal elongation of the processes relatively to algorithmically determined moment of processes completing.

Building of the system of process control with several levels corresponds commonly used 6-level structure of Automatic system for control over technological processes (levels 1 – 3 are automatized, levels 4 – 6 are informational ones): (1) measuring (probes), 2) control over local contours (controllers), (3) data acquisition and saving (computer data base), (4) procedures of optimization in real time under monitoring by operation specialist, (5) accounting for material flows and labor consuming, solutions for supporting the process schedule, (6) prognosis and planning of commercial profit.

For example, the technological scheme of earlier studied process of crystallization (vacuum evaporation) [7] at the above considered methodology of building

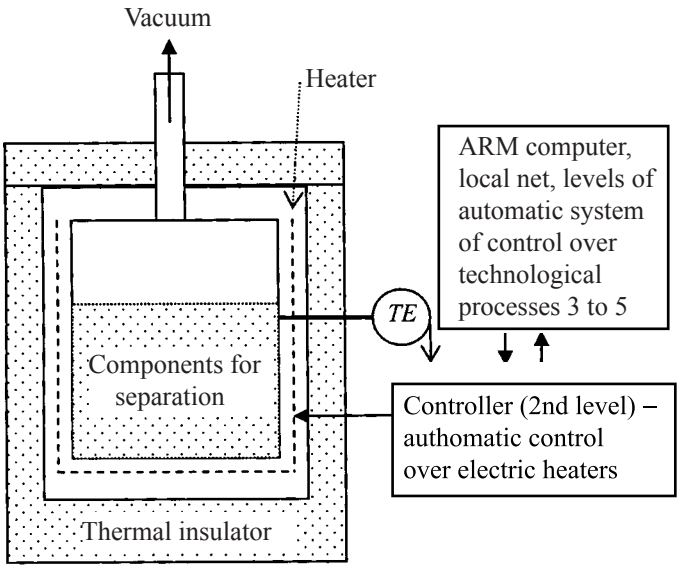

Fig. 2. The apparatuses based scheme of the process.

informational technological system for periodical process coincides (except difference in temperature regime) with the technological scheme for separation (Fig. 2).

When certain high quality of substances separation is required (minimizing the fraction of non-qualitative final product) with minimization of cost, then appears necessity of solving the problems of above mentioned real time optimization of process control which is similar for various processes owing to similarity in technological schemes. Solving the problem of optimization assumes treatment a flow of not only technological data, but also of economy data.

5. PERSPECTIVES OF OPTIMIZATION OF THE PROCESS OF DISTILLING OFF

Let us assume a number of spaces corresponding to the number of separate processes, and in each the space is defined the measuring unit of the process completing according to algorithmed criterion and can be observed actual time of the process completing and a characteristic of quality of separation substances (logarithmic, v_0 is maximum allowed concentration, v is current concentration), and let us projecting these spaces on the common coordinate system (Fig. 3). However it is impossible to determine optimal extension coefficient by a simple statistical method (like the solution of 4-th level problem of determination of the process duration). Then is remained to use knowledge on the cost and averaging over the spaces for certain preceding period to determine two functions: S_1 , the cost of the product not obtained (low quality) and S_2, the cost of extra expenditures on the process (energy consuming). The minimum of total extra expenditures, $min(S_1 + S_2)$, corresponds to optimal duration extension $k_{optim.}$, which can be recommended to the technology operator for the process control.

While optimization is possible, generally, on the characteristics of (a) material balance, (b) kinetic balance (productivity) and (c) energy balance, in this particular case the latter, energy balance, is considered for the optimization: the optimal process elongation measure relatively to the duration determined using criterion of maximal duration at the fulfilled conditions of equality

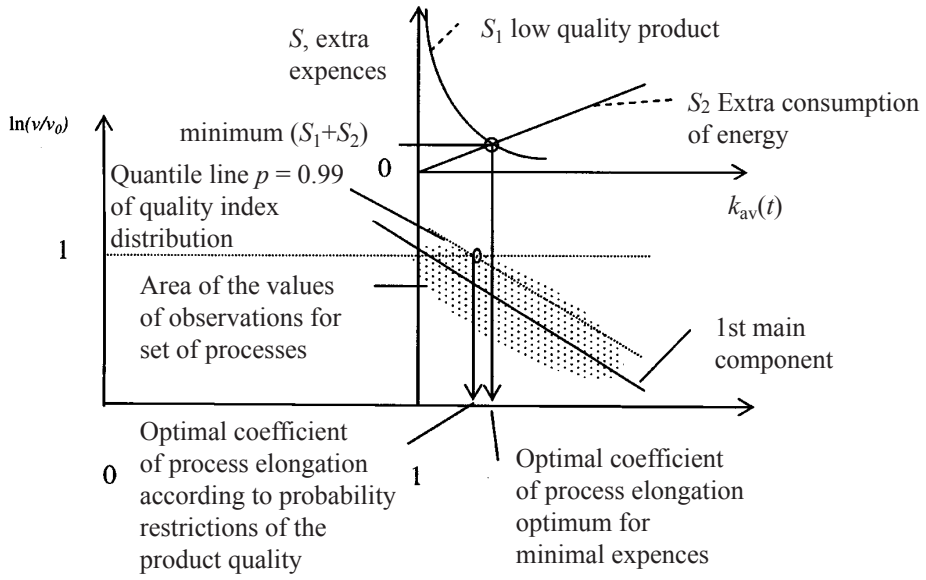

Fig. 3. Control optimization statistical diagram.

the maximum of extra expenses on electric energy to the minimum of extra expenses on electric energy due to partial formation of low quality product. A short description of the procedures is as follows: Let in first approximation that the measure of process elongation is revealed, e.g., k = 1.2, and allowed probability of obtaining quality product is defined, p = 0.995 (at the definition of the measure of quality, that means the measure of allowed fraction of not separtated product). If statistics is acquired, at the given process elongation, on the probability of obtaining quality product in a certain period (e.g., week, month, dot set 100–200), then from the revealed actual probability p_{fact} should be refined the measure of elongation k, taking into account financial estimations. If the cost of not obtained quality product S_1 (non=quality product due to non-separated substances) is higher than the cost of extra consumed energy S_2, then the measure of the process elongation k should ne increased. On the contrary, at low fraction of non-quality product and large elongation (low cost of not obtained product S_1) and substantial extra energy consuming S_2 the elongation coefficient should be decreased. Obviously, the iteration process is converged, at corrections introduced by technology operator, to equalization of the cost for the extra energy consuming and the cost of not obtained quality product, that is, to the equation minimizing total financial expenses:

$$S_1 = S_2, \; S_1 + S_2 \to min, \tag{7}$$

$$S_1 = S_0 (1 - p_{\text{observ}}), \tag{8}$$

where S_0, [Rubls] is the cost of all product (for a given period n processes), p_{observ} Is probability measure of the fraction of quality product (for the given period);

$$S_2 = C_{en} \sum_{i=1}^{n} \left(\int_{t_{init.i}}^{t_{fact.i}} \mathrm{E}_i(t)\, dt - \int_{t_{crit.i}}^{t_{fact.i}} \mathrm{E}_i(t)\, dt \right), \tag{9}$$

where C_{en} is the cost of energy (rubles per kWt/h), $t_{init.i}$, $t_{crit.i}$, $t_{fact.i}$ are the moments of beginning, ending according to criterion, and actual ending an i-th process, respectively, $\mathrm{E}_i(t)$ is the function of measure of energy flow into the system in the i-th process.

The average coefficient of the process elongation:

$$\overline{k} = \frac{1}{n} \sum_{i=1}^{n} k_i, \text{ where } k_i = \frac{t_{crit.i} - t_{init.i}}{t_{fact.i} - t_{init.i}}, \tag{10}$$

is actual and should be corrected at issuing recommendations for the cost minimization (7).

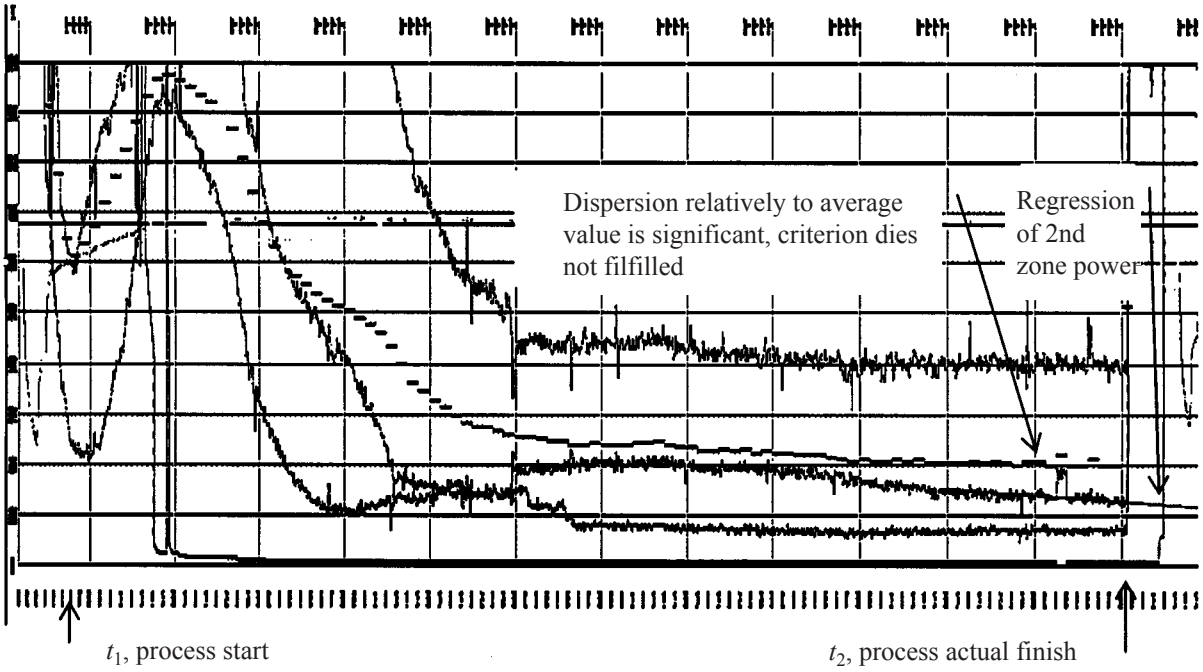

Fig. 5. Plots of the process parameters with non-quality product.

6. CONCLUSION

Information levels in the system of control over different processes of a given class of processes are fulfilled similarly, and this simplifies creation of program product capable of transfer from one information system to another. Detailed description of information system is given in [11]. At the informatization of the processes of chemical technology the methods of building technological information schemes of control over process and the methods of optimization by minimization expenses with restriction by the parameters of product quality are very similar (e.g., see [12], [13]).

INDUSTRUAL ECOLOGY

Toxicology Problems at Sulfuric Acid Technology of Processing Natural Phosphates at Producing Mineral Fertilizers and Salts for Technological Application

B. A. Dmitrevskii, M. A. Shapkin, N. N. Terushchenko, and E. B. Yarosh

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received August 1, 2007

Abstract—The article contains data on the content of trace contaminant of cadmium compounds in phosphate ores of volcanic and sedimentary origin. On the basis of the data of laboratory and industrial studies with participation of the authors analyzed distribution of cadmium compounds at the processing apatite concentrate of Kolskii peninsula and Maroc phosphorites. It is shown that the toxic contaminants are mostly extracted with phosphoric acid and contaminates its and products of its further processing. The most advantageous from the toxicology viewpoint is appatite concentrate of Kolskii peninsula that contaminated minimally as compared with the phosphates originated at other birthplaces.

DOI: 10.1134/S1070427208030452

The problem of contamination of mineral fertilizers with cadmium compounds harmful for human health is actual, in particular at their manufacturing from imported phosphate raw material. Ever at producing salts of food and feed quality from Kolskii peninsula apatite concentrate that contain cadmium by the order of magnitude less than foreign analogs, additional technique should be applied to provide decrease in heavy metal concentration to the allowed limit.

About 43% of world birthplaces of natural phosphates are known to afford phosphates containing 10 to 19 ppm of cadmium. 20% of resources contain 20 to 40 ppm of Cd, and in 10% of birthplaces the cadmium content is above 50 ppm. Phosphate row material of volcanic sources (apatite) contain average up to 2.5 ppm of Cd (maximal value is 5 ppm), while mass fraction of this element in phosphate ore of sedimentary origin achieves 150 ppm (Central Africa and USA) [1].

Resources of the most pure on cadmium (0.5–3 ppm) sedimentary raw material are localized in Australia (deposit Duchess), Burkina Faso (deposit Kodjari) and Iordania (deposit El Hasa). Average world content of cadmium in phosphate ore being now 21 ppm can increase in future [2].

Table 1 shows obtained by us data on the cadmium trace content in four samples of phosphate raw material: volcanic (magma) origin (Kolskii apatite flotation concentrate, Russia) and sediment origin (grinded phosphorites of birthplaces in Iordania, Maroc and Tunis).

Cadmium content was measured by the method of atomic absorption spectroscopy on inductively coupled plasma spectrophotometers "Liberty – 200" (Australia) [10] and "Unicam 939" (England) [6, 9]. For measuring mass fraction of P_2O_5 was applied chemical (photocolorimetric) method of analysis [3], which gave bone phosphate of lime (BPL) value for the natural phosphate. The data obtained are in conformity enough precisely with the data of van Kauwenburgh [1]. The cadmium trace contaminant content falls to the range from 1.5 to 51 ppm. The purest phosphate raw material in respect of the level of cadmium is apatite flotation concentrate of Kolskii birthplace related to natural phosphates of volcanic origin. Good enough material in respect of the trace contaminant content is Iordanian phosphorite. On the contrary, phosphates from North Africa and phosphorites mined in Maroc and particularly in Tunis are highly contaminated with cadmium.

The most widespread method for manufacturing extractive phosphoric acid [4–6] is dihydrate process. By this technology is produced over 80% of phosphorus-containing solutions which are processed to produce

Table 1. Content of cadmium trace contaminant in the samples of natural phosphates of volcanic (1) and sediment (2–4)

No.	Country and region of birthplace of natural phosphate	Type of natural phosphate	P_2O_5 wt. Fraction in enriched or grinded phosphate,%	BPL*	Cd concentration in phosphate, ppm
1	Rissia, Kolskii peninsula	Apatite fltation concentrate from the plant in Kirovsk town, Murmansk region	39.45	86 1	.51
2	Iordania G	rinded phosphorite 2	9.82 6	5	4.80
3	Maroc	Grinded phosphorite 3	1.60 6	9	16.2
4	Tunis	Grinded phosphorite 2	9.31 6	4	51.0
