J_2 Effect and Elliptic Inclined Periodic Orbits in the Collision Restricted Three-Body Problem*

E. Barrabés†, J. M. Cors‡, C. Pinyol§, and J. Soler†

Abstract. The existence of a new class of inclined periodic orbits of the collision restricted three-body problem is shown. The symmetric periodic solutions found are perturbations of elliptic Kepler orbits, and they exist only for special values of the inclination and are related to the motion of a satellite around an oblate planet.

Key words. collision restricted three-body problem, periodic orbits, symmetric orbits, critical inclination, continuation method

1. Introduction.

The launch of Sputnik in October 1957 opened the space age. The use of circular, elliptic, and synchronous orbits, combined with dynamical effects due to the Earth's equatorial bulge, gives rise to an array of orbits with specific properties to support various mission constraints. One example is the Molniya orbit, a highly elliptic 12-hour-period orbit the former USSR originally designed to observe the northern hemisphere. The orbital plane makes an angle of about 63 degrees with the equatorial plane of the Earth, and this is the only value that prevents the orbit itself from rotating slowly within its plane and around the focus.

In what follows we will introduce briefly a few common notions of orbital dynamics, together with the current terminology (sometimes a few centuries old), and state the aim of the paper.

The position of a body on a Keplerian elliptic orbit can be completely characterized by six parameters. One such set of parameters are the classical orbital elements. As the orbital plane is fixed in any inertial frame and passes through the origin, one should first give the position of this plane. In a Cartesian frame with axes xyz, this is given by the inclination i with respect to the xy-plane and the angle Ω from the positive x-axis to the intersection of the orbital plane with the xy-plane. In the classical terminology of astronomy this line is

known as the *line of nodes* (the nodes of the orbit being the two points of intersection with the xy-plane, and the ascending node that in which the body crosses from $z < 0$ to $z > 0$), and Ω is called the *longitude of the ascending node*.

Then we need the position of the ellipse on its plane. One focus is at the origin, and the line joining the pericenter and the apocenter (classically the *line of apsides*) forms an angle ω with the line of nodes which gives the position of the ellipse. Usually the half-line from the origin to the pericenter and the half-line from the origin to the ascending node are taken, and then we say that ω is the *longitude of the pericenter*.

The size and shape of the ellipse are given by the semimajor axis a (directly related to the energy) and the eccentricity e (related to the energy and the angular momentum).

Finally, the position of the body along the orbit is given either by the angle f (true anomaly) pericenter–origin–body, or by some other related angles such as E (eccentric anomaly) or M (mean anomaly). The three anomalies (a name already used in Greek astronomy) are related among themselves by the geometry and the dynamics of Keplerian motion. The position is actually a function of time, and the origin of time is called the *epoch* (see, for example, [2]).

Of course, Ω, ω, and f are not well defined for circular or zero-inclination orbits, a problem that can be solved in a variety of ways which go back to Laplace in the case of the classical elements and to Poincaré for the Hamiltonian formulation.

Thus the position and velocity of a point in space are completely characterized by the six orbital elements, which are constant (except f, or whichever anomaly is used) for a Keplerian orbit. This rather strange system of coordinates in phase space is useful because in most cases the non-Keplerian motion of a body subject to perturbations can be seen as a fast motion along a Keplerian orbit with slowly varying elements.

A set of variables closely related to the orbital elements are the *Delaunay elements*, which could be considered as the canonical (in the sense of Hamiltonian) version of the classical elements and will be defined in section 2.

Any small perturbation of the Keplerian motion has two kinds of effects on the motion: periodic and secular. An element subject to periodic perturbations simply oscillates around its central unperturbed value, while a secular perturbation is a steady, linear increase or decrease of its value. Of course, this is true only in a first order approximation, and it is a qualitative description, because a first order approximation is valid only on a finite interval of time, and the very concept of periodicity does not make sense. As for the secular effects we must remember that one of the major problems of the classical dynamical astronomy of the nineteenth century was the distinction between true secular effects and linearization of periodic effects of very long period, and that the whole matter has been settled only by the KAM theory.

In this sense, it is a result of classical astronomy that a, e, and i are subject to only periodic effects, while Ω, ω, and M display periodic and secular effects. In short, a perturbed Keplerian conic can be thought of, roughly speaking, as a conic which rotates slowly on its plane while the plane itself rotates around the z-axis.

The most common perturbations of the potential in celestial mechanics are due either to the presence of a third body or to lack of sphericity of the bodies. The latter can be dealt with by expanding the potential in spherical harmonics, so that if the body has axial symmetry,

the potential can be seen as that of an inverse square distance central force plus other terms:

$$V(r,\phi) = -Gm\frac{r_{eq}}{r}\left(1 - \sum_{k=2}^{\infty} J_k \left(\frac{r_{eq}}{r}\right)^k P_k(\cos\phi)\right),$$

where G is the gravitational constant, m is the mass of the body, r_{eq} is its equatorial radius, (r,θ,ϕ) are spherical coordinates (θ does not appear because of the axial symmetry), P_k is the kth Legendre polynomial, and J_k are the coefficients defining the expansion (see, for example, [10]).

The third body perturbation is quite a different matter because the equations of motion must be supplemented with those of the new body. In the restricted three-body problem, it is assumed that one of the bodies is so small that it does not affect the motion of the other two (the *primaries*), and then we usually have a Keplerian motion plus a nonautonomous perturbation. If, however, we consider the potential in a region far away from the primaries and normalize this distance to unity, the velocities of the primaries are very high and heuristically we can somehow average their mass along their whole orbits, so that dynamically we are again in the case of a nonspherical potential.

For Earth-orbit design, the main perturbation is that of the J_2 term in the expansion of the potential of an oblate ellipsoid. This term perturbs the orbit in the sense explained above, resulting in a precession both of the line of nodes and of the pericenter. It is apparent (see, for example, pages 503–504 of [2]) that there exists a critical inclination angle, $i \simeq 63^\circ$, such that the perigee is fixed in the first approximation because its secular terms are of opposite sign for inclinations above or under the critical value, irrespective of the eccentricity. The case of a prolate ellipsoid, though apparently not frequent in astronomy, could be treated in the same way, the only difference being that the J_2 term has the opposite sign, so that all the precessions are in the opposite direction.

The existence of a class of inclined periodic solutions of the circular three-body problem was shown by Jefferys in [5]. He showed the existence of families of elliptic orbits with inclination close to critical for any value of the eccentricity. His proof rests on a mirror theorem: in the rotating coordinate system of the restricted three-body problem any trajectory that hits twice perpendicularly a certain plane is a periodic solution. For an elliptic orbit, perpendicular crossing means that the body is at either the pericenter or the apocenter and the line of apsides lies on the mirror plane; for this situation to happen twice in time it is sufficient that the line of apsides does not have a secular motion, so the inclination must be near critical. Of course a precession of the line of nodes does exist, but it is hidden, as it were, in the rotating frame. It must be borne in mind that in celestial mechanics periodic usually means periodic in some rotating frame, and thus periodic or quasi-periodic in the inertial frame depending on whether the angle advanced by the rotating frame in a period is a rational multiple of π or not. The method used is the continuation method developed by Poincaré (see [8]), which is one of the most frequently used methods for proving the existence of periodic orbits.

The case dealt with in this paper is different from Jefferys's because the primaries move on an elliptic collision orbit along the z-axis. Heuristically speaking, however, it can be expected that far away from the primaries the potential will be similar to that of a very eccentric prolate

ellipsoid, so that a J_2 effect, with its critical inclination, will exist. We show the existence of periodic solutions of Jefferys type: large semiaxis compared to the that of the primaries, arbitrary eccentricity, and inclination close to critical.

The problem can be seen as a perturbed Kepler problem, where the small parameter is the semimajor axis of the primaries' orbit after rescaling. The perturbed problem is degenerate due to the fast motion of the primaries, and the equations are no longer analytic when the parameter equals zero, which precludes the use of a standard implicit function theorem. We overcome the difficulty by using Arenstorf's theorem, where weaker assumptions of differentiability are needed (see [1]). A planar configuration of this problem is studied in [6].

In our case, the problem has a rotational symmetry around the z-axis (which contains the colliding primaries). This symmetry would be lost if we considered elliptic noncollision orbits for the primaries. See [3] and [4], where the elliptic restricted three-body problem is considered. In those papers, the periodic orbits are perturbations of the circular solutions of the Kepler problem having large radii on a plane perpendicular to that of the primaries. Periodic orbits in the spatial elliptic restricted three-body problem are also studied using double averaging in [7].

The paper is organized as follows. Section 2 describes the general setting of the collision restricted three-body problem. Section 3 shows how its solutions can be approximated through successive corrections to Keplerian motion. Section 4 deals with the continuation problem. The main result is the existence of quasi-elliptic orbits for discrete values of the semimajor axis of the primaries, with arbitrary eccentricity and inclination close to critical. A number of technical computations are presented in section 5.

Figure 1 shows one of the orbits predicted by the main theorem, numerically computed with initial values $r_0 = 0.621114405$, $\phi_0 = 1.116457610$, $\theta_0 = 0$, $p_r = 0$, $p_\phi = 0$, $p_\theta = 0.4098780306$, and $\mu = 30^{-2/3}$. The equations of motion and the first variational equations were numerically integrated with a Runge–Kutta 7-8 routine, and the equations defining the initial conditions were solved with a Newton method starting with the Keplerian orbit with $a = 1$, $e = 0.4$, and $\cos i = 1/\sqrt{5}$ (critical inclination).

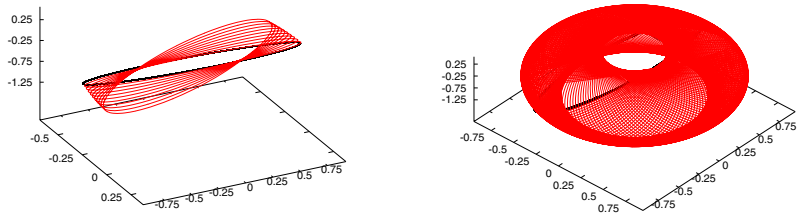

Figure 1. *Example of a quasi-periodic orbit in a Cartesian frame. The orbit is followed during* 6 *(plot on the left) and* 150 *(plot on the right) times the period of the primaries. The Keplerian orbit for* $\mu = 0$ *is plotted (black line). The primaries move along the vertical line passing through the origin.*

2. The collision restricted three-body problem.

The collision restricted three-body problem describes the motion of a massless particle under the attraction of two primaries with equal

masses, $m_1 = m_2 = 1/2$, moving on a collision elliptic orbit. In order to avoid a triple collision, we consider that the third body is far from the primaries compared to the distance between them. This fact can be introduced in the equations of motion by making the primaries very close to each other and looking for solutions of the massless particle at distance of order unity to the primaries.

Let μ be a small parameter. The distance between both primaries is given by

$$\rho = \mu(1 - \cos E_p(t)), \tag{2.1}$$

where $E_p = E_p(t)$ is the eccentric anomaly of m_1 and it is related to its mean anomaly ℓ_p through Kepler's equation

$$E_p - \sin E_p = \ell_p, \tag{2.2}$$

where $\ell_p = \mu^{-3/2}t$. The period of the motion of the primaries is $T_p = 2\pi\mu^{3/2}$, so that $E_p = k\pi$ when $t = \pi k\mu^{3/2}$.

Equation (2.2) is a particular case (for $e = 1$) of Kepler's equation $\ell = E - e\sin E$, where e is the eccentricity, ℓ is the mean anomaly (real time measured in such units that the period is 2π), and E is the eccentric anomaly, which is related to the angular position f of the body on the orbit (from the pericenter) through $\tan f/2 = \sqrt{(1+e)/(1-e)}\tan E/2$. The latter equation results from the geometry of elliptic orbits, and Kepler's equation is just the mathematical expression of the law of areas, i.e., the conservation of the angular momentum (see [10]).

We consider a fixed coordinate system (q_1, q_2, q_3) (see Figure 2) with origin at the center of mass of m_1 and m_2 in such a way that the primaries move along the q_3-axis. Their positions are given by $\mathbf{r}_1 = (0, 0, \frac{\mu}{2}(1 - \cos E_p))$ and $\mathbf{r}_2 = -\mathbf{r}_1$. Let $\mathbf{q} = (q_1, q_2, q_3)$ and $\mathbf{p} = (p_1, p_2, p_3) = (\dot q_1, \dot q_2, \dot q_3)$ be the position and momentum of the infinitesimal body m_3. The problem of describing its motion is known as the *three-dimensional collision restricted three-body problem*.

The equations of motion for the infinitesimal body can be written as a nonautonomous Hamiltonian system depending on the parameter μ as

$$\dot q_i = \frac{\partial \mathcal{H}}{\partial p_i}, \qquad \dot p_i = -\frac{\partial \mathcal{H}}{\partial q_i}, \qquad i = 1, 2, 3,$$

where

$$\mathcal{H} = \frac{1}{2}(p_1^2 + p_2^2 + p_3^3)^2 - \frac{1}{2}\left(\frac{1}{R_1} + \frac{1}{R_2}\right), \tag{2.3}$$

and R_1 and R_2 are given by

$$\begin{aligned} R_1^2 &= q_1^2 + q_2^2 + \left(q_3 - \tfrac{\mu}{2}(1 - \cos E_p)\right)^2, \\ R_2^2 &= q_1^2 + q_2^2 + \left(q_3 + \tfrac{\mu}{2}(1 - \cos E_p)\right)^2. \end{aligned}$$

Let us introduce spherical coordinates (r, ϕ, θ), and (p_r, p_ϕ, p_θ) by means of the canonical change

$$\begin{aligned} q_1 &= r\cos\phi\cos\theta, & p_1 &= p_r\cos\phi\cos\theta - \tfrac{p_\phi}{r}\sin\phi\cos\theta - \tfrac{p_\theta}{r\cos\phi}\sin\theta, \\ q_2 &= r\cos\phi\sin\theta, & p_2 &= p_r\cos\phi\sin\theta - \tfrac{p_\phi}{r}\sin\phi\sin\theta + \tfrac{p_\theta}{r\cos\phi}\cos\theta, \\ q_3 &= r\sin\phi, & p_3 &= p_r\sin\phi + \tfrac{p_\phi}{r}\cos\phi. \end{aligned}$$

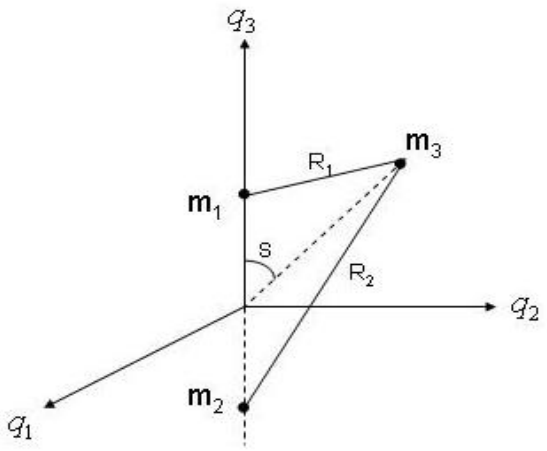

Figure 2. *Collision restricted three-body problem.*

In the new variables, the Hamiltonian (2.3) becomes

$$H = \frac{1}{2}\left(p_r^2 + \frac{p_\phi^2}{r^2} + \frac{p_\theta^2}{r^2\cos^2\phi}\right) - \frac{1}{2}\left(\frac{1}{R_1} + \frac{1}{R_2}\right), \tag{2.4}$$

with R_1 and R_2 given by

$$\begin{aligned} R_1^2 &= r^2 + \left(\tfrac{\mu}{2}\right)^2 (1-\cos E_p)^2 - r\mu(1-\cos E_p)\sin\phi, \\ R_2^2 &= r^2 + \left(\tfrac{\mu}{2}\right)^2 (1-\cos E_p)^2 + r\mu(1-\cos E_p)\sin\phi. \end{aligned} \tag{2.5}$$

Notice that E_p as given by (2.2) is a function of time t and μ, which is not defined for $\mu = 0$. So, neither the Hamiltonian (2.3) nor (2.4) is defined.

The equations of motion for the infinitesimal mass in spherical coordinates are

$$\begin{aligned} \dot r &= p_r, & \dot p_r &= -\tfrac{\partial \mathcal{H}}{\partial r}, \\ \dot\theta &= \tfrac{p_\theta}{r^2\cos^2\phi}, & \dot p_\theta &= 0, \\ \dot\phi &= \tfrac{p_\phi}{r^2}, & \dot p_\phi &= -\tfrac{\partial \mathcal{H}}{\partial \phi}. \end{aligned} \tag{2.6}$$

Since R_1 and R_2 do not depend on θ, $\dot p_\theta = 0$ and the angular momentum $p_\theta = \Theta$ is constant. Thus, it can be calculated from the initial conditions, and the equation for θ can be decoupled from the other equations. In this way, we can consider the system of equations

$$\begin{aligned} \dot r &= p_r, & \dot p_r &= -\tfrac{\partial \mathcal{H}}{\partial r}, \\ \dot\phi &= \tfrac{p_\phi}{r^2}, & \dot p_\phi &= -\tfrac{\partial \mathcal{H}}{\partial \phi}. \end{aligned} \tag{2.7}$$

Once r and ϕ are obtained, we will get θ from its equation in (2.6).

From now on, *reduced problem* means the problem given by (2.7), and *complete problem* means the whole set of equations (2.6). Our aim is to find periodic solutions of the reduced problem that will be periodic or quasi-periodic solutions of the complete problem.

It is easy to see that the equations of the reduced problem are invariant by the symmetry

$$S : (t, r, \phi, p_r, p_\phi, E_p) \quad \longrightarrow \quad (-t, r, \phi, -p_r, -p_\phi, -E_p),$$

so that, if

$$\gamma(t) = (r(t), \phi(t), p_r(t), p_\phi(t), E_p(t))$$

is a particular solution of (2.7), then so is

$$(r(-t), \phi(-t), -p_r(-t), -p_\phi(-t), -E_p(-t)),$$

and we have the following well-known result.

Proposition 2.1. *Let $\gamma(t) = (r(t), \phi(t), p_r(t), p_\phi(t), E_p(t))$ be a solution of the reduced problem given by (2.7). If $\gamma(t)$ satisfies $(p_r(0), p_\phi(0)) = (0, 0)$, $(p_r(T/2), p_\phi(T/2)) = (0, 0)$, and $E_p(T/2) = k\pi$, then $\gamma(t)$ is a periodic solution of period T.*

In order to find elliptic orbits we will introduce Delaunay variables (l, g, h) and (L, G, H), where

$$L = \sqrt{a}, \qquad H = G\cos i, \qquad G = \sqrt{a(1-e^2)},$$

a is the semimajor axis of the infinitesimal mass, G its angular momentum, i the inclination of its orbital plane with respect to the q_1q_2 reference plane, l the mean anomaly, g the argument of the pericenter measured from the ascending node, and h the longitude of the ascending node (see, for example, [9]).

We will use the symmetry conditions stated in Proposition 2.1 to obtain periodic solutions of the reduced problem. These conditions can be expressed in Delaunay variables as

$$l(t) = 0 \mod \pi, \qquad g(t) = \pi/2 \mod \pi \tag{2.8}$$

for epochs $t = 0$ and $t = T/2$, where $T = 2k\pi\mu^{3/2}$ in order to satisfy $E_p(T/2) = k\pi$.

3. Approximate solutions.

In this section we will show how those solutions of the three-dimensional collision elliptic restricted three-body problem in which the infinitesimal body keeps moving far away from the primaries can be approximated through successive corrections to the Keplerian motion. In section 4, we will use these approximations to continue some elliptic solutions of the Kepler problem to the case $\mu \neq 0$.

As the Hamiltonian (2.3) is not defined when $\mu = 0$, instead of expansions in power series (which are no longer available) we use asymptotic series. Using expressions (2.5) and (2.1), we can write

$$R_1 = r\sqrt{1 + \frac{\rho^2}{4r^2} - \frac{\rho}{r}\cos\mathcal{S}},$$

where $\mathcal{S} = \frac{\pi}{2} - \phi$ is the angle between the position vectors of m_1 and m_3 (see Figure 2). We assume that the distance from the origin to the primaries $(\mu/2)$ is small compared to the

distance from the origin to the infinitesimal body, so that $\rho \ll r$ and we can expand R_1^{-1} as a power series in $\frac{\rho}{2r}$ by using Legendre polynomials. Then

$$\frac{1}{R_1} = \frac{1}{r}\sum_{j=0}^{\infty} P_j(\cos\mathcal{S})\left(\frac{\rho}{2r}\right)^j = \frac{1}{r}\left[1 + \sum_{j=1}^{\infty} \mu^j P_j(\cos\mathcal{S})\left(\frac{1-\cos E_p}{2r}\right)^j\right],$$

where $P_j(\cos\mathcal{S})$ is the jth Legendre polynomial. Expanding R_2^{-1} in a similar way, the Hamiltonian (2.4) becomes

$$\mathcal{H}(\mathbf{q},\mathbf{p},t,\mu) = \mathcal{H}_0(\mathbf{q},\mathbf{p}) + \mu^2\mathcal{H}_1(\mathbf{q},\mathbf{p},t,\mu) + \mu^4\mathcal{H}_R(\mathbf{q},\mathbf{p},t,\mu), \tag{3.1}$$

where

$$\mathcal{H}_0(\mathbf{q},\mathbf{p}) = \frac{1}{2}\left(p_r^2 + \frac{p_\phi^2}{r^2} + \frac{p_\theta^2}{r^2\cos^2\phi}\right) - \frac{1}{r},$$

$$\mathcal{H}_1(\mathbf{q},\mathbf{p},t,\mu) = \frac{-1}{r}P_2(\cos S)\left(\frac{1-\cos E_p}{2r}\right)^2 = \frac{(1-\cos E_p)^2}{8r^3}\left(1-3\cos^2\mathcal{S}\right),$$

and

$$\mathcal{H}_R(\mathbf{q},\mathbf{p},t,\mu) = \frac{-1}{r}\sum_{k=2}^{\infty}\mu^{2(k-2)}P_{2k}(\cos\mathcal{S})\left(\frac{1-\cos E_p}{2r}\right)^{2k}.$$

The dependence on (t,μ) comes from the eccentric anomaly $E_p = E_p(t,\mu)$ given by (2.2). Notice that if $r \geq \delta$ for some fixed $\delta > 0$, then $\mathcal{H}_1(\mathbf{q},\mathbf{p},t,\mu)$ and $\mathcal{H}_R(\mathbf{q},\mathbf{p},t,\mu)$ are bounded. Thus, $\mu^2\mathcal{H}_1$ and $\mu^4\mathcal{H}_R$ are continuous at $\mu = 0$, although $\mathcal{H}_1$ and $\mathcal{H}_R$ are not so. This is the reason why expansions as power series in μ cannot be used.

Let us denote $\mathbf{z} = (l,g,h,L,G,H)$. Applying the corresponding symplectic change of variables, Hamiltonian (3.1) becomes

$$\mathcal{H}(\mathbf{z},t,\mu) = \mathcal{H}_0(\mathbf{z}) + \mu^2\mathcal{H}_1(\mathbf{z},t,\mu) + \mu^4\mathcal{H}_R(\mathbf{z},t,\mu), \tag{3.2}$$

where

$$\mathcal{H}_0(\mathbf{z}) = -\frac{1}{2L^2}, \tag{3.3}$$

$$\mathcal{H}_1(\mathbf{z},t,\mu) = \frac{(1-\cos E_p)^2}{8r^3}\left[1 - 3\left(1-\frac{H^2}{G^2}\right)\sin^2(g+f)\right]. \tag{3.4}$$

In (3.4) we have used the true anomaly f of the motion of the infinitesimal mass in order to write $q_3 = r\sin i\sin(f+g)$ and

$$\cos^2(\mathcal{S}) = \frac{q_3^2}{r^2} = \sin^2 i\sin^2(f+g) = \left(1-\frac{H^2}{G^2}\right)\sin^2(g+f).$$

Observe that $\mathcal{H}_0$ is the Hamiltonian of the Kepler problem and that, despite that Hamiltonian (3.2) is not defined for $\mu = 0$, the limit when $\mu \to 0$ exists and

$$\lim_{\mu\to 0}\mathcal{H}(\mathbf{z},t,\mu) = \mathcal{H}_0(\mathbf{z}).$$

Therefore, the equations of motion can be written as

$$\dot{\mathbf{z}} = \mathcal{F}(\mathbf{z}, t, \mu), \tag{3.5}$$

where $\mathcal{F} = J \cdot \nabla \mathcal{H}$, $J = \left(\begin{smallmatrix} 0 & I \\ -I & 0 \end{smallmatrix}\right)$, and I is the identity matrix of dimension 3×3. Using (3.2), the vector field $\mathcal{F}$ is given by

$$\mathcal{F}(\mathbf{z}, t, \mu) = \mathcal{F}_0(\mathbf{z}) + \mu^2 \mathcal{F}_1(\mathbf{z}, t, \mu) + \mu^4 \mathcal{F}_R(\mathbf{z}, t, \mu),$$

where

$$\begin{aligned} \mathcal{F}_0(\mathbf{z}) &= (L^{-3}, 0, 0, 0, 0, 0)^t, \\ \mathcal{F}_1(\mathbf{z}, t, \mu) &= J \cdot \nabla \mathcal{H}_1, \\ \mathcal{F}_R(\mathbf{z}, t, \mu) &= J \cdot \nabla \mathcal{H}_R, \end{aligned}$$

and $\mathcal{H}_1$ and $\mathcal{H}_R$ are the terms in (3.2).

The next lemma shows that the solutions of (3.5) can be written as the solutions of the Kepler problem plus terms of order μ^2, and the same is true of its partial derivatives with respect to the initial conditions.

Lemma 3.1. *Let $\mathbf{z}_0$ be an initial condition and $\mathbf{z}^{(0)}(t, \mathbf{z}_0)$ a solution of*

$$\dot{\mathbf{z}} = \mathcal{F}_0(\mathbf{z})$$

with $\mathbf{z}^{(0)}(0, \mathbf{z}_0) = \mathbf{z}_0$ such that it remains bounded and bounded away from the singularities of $\mathcal{F}(\mathbf{z}, t, \mu)$. Let $\mathbf{z}(t, \mathbf{z}_0, \mu)$ be a solution of (3.5) with the same initial condition $\mathbf{z}_0$. Then we can write

$$\mathbf{z}(t, \mathbf{z}_0, \mu) = \mathbf{z}^{(0)}(t, \mathbf{z}_0) + \mu^2 \mathbf{z}^{(1)}(t, \mathbf{z}_0, \mu) + \mathbf{z}_R(t, \mathbf{z}_0, \mu),$$

where $\mathbf{z}^{(1)}(t, \mathbf{z}_0, \mu)$ is the solution of

$$\dot{\mathbf{z}} = \mathcal{F}_1(\mathbf{z}^{(0)}(t, \mathbf{z}_0), t, \mu) + D\mathcal{F}_0(\mathbf{z}^{(0)}(t, \mathbf{z}_0))\, \mathbf{z}$$

with initial condition $\mathbf{z}^{(1)}(0, \mathbf{z}_0, \mu) = 0$, and $D\mathcal{F}$ is the matrix whose entries are the partial derivatives of $\mathcal{F}$ with respect to the $\mathbf{z}$ variables. Furthermore, $\mathbf{z}_R(t, \mathbf{z}_0, \mu)$ and $D_{\mathbf{z}_0}\mathbf{z}_R(t, \mathbf{z}_0, \mu)$ are $\mathcal{O}(\mu^4)$ in a finite interval of time.

These results can be obtained by using Taylor's expansions and Gronwall's inequality (see [4]). They are also valid for any initial conditions in a compact neighborhood of $\mathbf{z}_0$ satisfying the hypothesis of the lemma.

4. Continuation of symmetric periodic solutions. In this section we use the results of section 3 to show the existence of symmetric periodic solutions of the reduced problem.

Let us start by considering the Kepler problem given by Hamiltonian (3.3), whose solution with initial condition $\mathbf{z}_0$ is

$$\mathbf{z}^{(0)}(t, \mathbf{z}_0) = (l_0 + L_0^{-3} t, g_0, h_0, L_0, G_0, H_0).$$

Clearly, the orbit with initial conditions $\mathbf{z}_0^* = (0, \pi/2, h_0^*, 1, G_0^*, H_0^*)$ is symmetric and periodic of period $T = 2\pi$. We want to find periodic symmetric solutions close to $\mathbf{z}^{(0)}(t, \mathbf{z}_0^*)$.

From Lemma 3.1, any solution of the reduced problem can be written as the solution of the Kepler problem plus a perturbation, provided that $\mathbf{z}^{(0)}(t, \mathbf{z}_0^*)$ remains bounded and bounded away from the singularities. To ensure that $\mathbf{z}_0^*$ satisfies these conditions, it is sufficient that $G_0^* > 0$; that is, the eccentricity is less than 1. Also, notice that we are dealing with elliptic orbits, so $G_0^* < 1$.

Thus, we will look for initial conditions $\mathbf{z}_0 = (0, \pi/2, h_0, L_0, G_0, H_0)$ in a neighborhood of a fixed $\mathbf{z}_0^*$ with $0 < G_0^* < 1$, in such a way that the solution $\mathbf{z}(t, \mathbf{z}_0, \mu)$ of (3.5), with $\mu \neq 0$ small enough, is a symmetric periodic orbit of the reduced problem.

For a fixed $\mathbf{z}_0^*$, let $\mathcal{D}$ be a compact neighborhood of $\mathbf{z}_0^*$ where the conditions of Lemma 3.1 hold and $0 < G_0 < 1$.

Then, given $\mathbf{z}_0 \in \mathcal{D}$, we know that

$$\mathbf{z}(t, \mathbf{z}_0, \mu) = \mathbf{z}^{(0)}(t, \mathbf{z}_0) + \mu^2 \mathbf{z}^{(1)}(t, \mathbf{z}_0, \mu) + \mathcal{O}(\mu^4), \tag{4.1}$$

where

$$\mathbf{z}^{(0)}(t, \mathbf{z}_0) = (L_0^{-3} t, \pi/2, h_0, L_0, G_0, H_0), \tag{4.2}$$

$$\mathbf{z}^{(1)}(t, \mathbf{z}_0, \mu) = \mathcal{Z}(t, \mathbf{z}_0) \int_0^t \mathcal{Z}^{-1}(s, \mathbf{z}_0) \mathcal{F}_1(\mathbf{z}^{(0)}(s, \mathbf{z}_0), s, \mu)\, ds, \tag{4.3}$$

and

$$\mathcal{Z}(t, \mathbf{z}_0) = \left. \frac{\partial \mathbf{z}^{(0)}(t, \xi)}{\partial \xi} \right|_{\xi = \mathbf{z}_0}.$$

From (4.1),

$$\begin{aligned} l(t, \mathbf{z}_0, \mu) &= L_0^{-3} t + \mu^2 l^{(1)}(t, \mathbf{z}_0, \mu) + \mathcal{O}(\mu^4), \\ g(t, \mathbf{z}_0, \mu) &= \pi/2 + \mu^2 g^{(1)}(t, \mathbf{z}_0, \mu) + \mathcal{O}(\mu^4), \end{aligned}$$

where $l^{(1)}$ and $g^{(1)}$ are the first and second coordinates of $\mathbf{z}^{(1)}$, given by (4.3), respectively.

Obviously, the symmetry conditions given by (2.8) are fulfilled at $t = 0$. They also must be satisfied at $t = T/2 = k\pi\mu^{3/2}$ in order to have $E_p(T/2) = k\pi$. We consider k a natural number and $\mu > 0$ such that $\mu = k^{-2/3}$. Then, $T/2 = \pi$ and we have to find initial conditions $\mathbf{z}_0 \in \mathcal{D}$ satisfying

$$\begin{aligned} L_0^{-3}\pi - \pi + \mu^2 l^{(1)}(\pi, \mathbf{z}_0, \mu) + \mathcal{O}(\mu^4) &= 0, \\ g^{(1)}(\pi, \mathbf{z}_0, \mu) + \mathcal{O}(\mu^2) &= 0. \end{aligned} \tag{4.4}$$

A natural way to solve (4.4) is to find a solution for the case $\mu = 0$ and then to apply an implicit function theorem. The first handicap is that neither $l^{(1)}(\pi, \mathbf{z}_0, \mu)$ nor $g^{(1)}(\pi, \mathbf{z}_0, \mu)$ is defined for $\mu = 0$, and neither is the Hamiltonian $\mathcal{H}_1$. Moreover, they do not satisfy the differentiability conditions of the standard implicit function theorem. In order to overcome these difficulties, we will see first that both equations can be extended to the case $\mu = 0$. Second, we will use Arenstorf's theorem, which requires weaker conditions (see [1]).

Let us start by extending (4.4) to the case $\mu = 0$. Observe that, from (4.3), $l^{(1)}$ and $g^{(1)}$ are bounded. This fact will be sufficient to define the first equation in (4.4) for $\mu = 0$. As for the second one, we show that $g^{(1)}(\pi, \mathbf{z}_0, \mu)$ can be written in terms of L_0, H_0, and G_0 plus a term of order $\mu^{3/2}$. In order to prove this we need the following technical lemma.

Lemma 4.1. *Given $\mathbf{z}_0^*$, let $\mathbf{z}_0 = (0, \pi/2, h_0, L_0, G_0, H_0) \in \mathcal{D}$. Let be $\varphi(t, \mathbf{z}_0)$ be a function bounded in $\mathcal{D}$, such that $\frac{d\varphi}{dt}(t, \mathbf{z}_0)$ is also bounded in $\mathcal{D}$. Then,*

$$\int_0^\pi (1 - \cos E_p)^2 \varphi(t, \mathbf{z}_0)\, dt = \frac{5}{2} \int_0^\pi \varphi(t, \mathbf{z}_0)\, dt + \mathcal{R}(\mathbf{z}_0, \mu),$$

where $|\mathcal{R}(\mathbf{z}_0, \mu)| \leq K\mu^{3/2}$ for a certain constant K.

Proof. From (2.2), the function $(1 - \cos E_p)^2$ is even and 2π-periodic with respect to the variable ℓ_p. Its Fourier series is given by

$$(1 - \cos E_p)^2 = \frac{a_0}{2} + \sum_{k=1}^{\infty} a_k \cos(k\ell_p),$$

where

$$a_k = \frac{2}{\pi} \int_0^\pi (1 - \cos E_p)^2 \cos(k\ell_p)\, d\ell_p.$$

From the fact that $(1 - \cos E_p)\, dE_p = d\ell_p$, the zero coefficient is

$$a_0 = \frac{2}{\pi} \int_0^\pi (1 - \cos E_p)^3\, dE_p = 5.$$

Then, using that $\ell_p = \mu^{-3/2} t$,

$$\int_0^\pi (1 - \cos E_p)^2 \varphi(t, \mathbf{z}_0)\, dt = \frac{5}{2} \int_0^\pi \varphi(t, \mathbf{z}_0)\, dt + \underbrace{\sum_{k=1}^{\infty} a_k \int_0^\pi \varphi(t, \mathbf{z}_0) \cos(k\mu^{-3/2} t)\, dt}_{\mathcal{R}(\mathbf{z}_0, \mu)}.$$

Integrating by parts,

$$\int_0^\pi \varphi(t, \mathbf{z}_0) \cos(k\mu^{-3/2} t)\, dt = \frac{\mu^{3/2}}{k} \left(\varphi(\pi, \mathbf{z}_0) \sin(k\mu^{-3/2}\pi) - \int_0^\pi \frac{d\varphi}{dt}(t, \mathbf{z}_0) \sin(k\mu^{-3/2} t)\, dt \right).$$

Since $\varphi(t, \mathbf{z}_0)$, $\frac{d\varphi}{dt}(t, \mathbf{z}_0)$ are bounded for all $(t, \mathbf{z}_0)$ with $\mathbf{z}_0 \in \mathcal{D}$ (say, $|\varphi(t, \mathbf{z}_0)| \leq k_1$ and $|\frac{d\varphi}{dt}(t, \mathbf{z}_0)| \leq k_2$), we have that for a certain constant C

$$\left| \int_0^\pi \varphi(t, \mathbf{z}_0) \cos(k\mu^{-3/2} t)\, dt \right| \leq \frac{\mu^{3/2}}{k} \left(k_1 + 2k_2 \frac{\mu^{3/2}}{k} \right) = \frac{\mu^{3/2}}{k} C,$$

and

$$|\mathcal{R}(\mathbf{z}_0, \mu)| \leq \mu^{3/2} C \sum_{k=1}^{\infty} \frac{|a_k|}{k}.$$

The series on the right-hand side converges because a_k are Fourier coefficients of a regular function, and so the lemma is proved. ∎

Lemma 4.2. *Given $\mathbf{z}_0^*$, let $\mathbf{z}_0 = (0, \pi/2, h_0, L_0, G_0, H_0) \in \mathcal{D}$. Then, for $\mu > 0$ and small enough, $g^{(1)}(\pi, \mathbf{z}_0, \mu)$ is of type $\mathcal{C}^1$ in $\mathcal{D}$ and there exist functions $I_1(L_0, G_0)$ and $I_2(L_0, G_0)$ such that*

$$g^{(1)}(\pi, \mathbf{z}_0, \mu) = -\frac{15}{16}(I_1(L_0, G_0) - H_0^2 I_2(L_0, G_0)) + \mathcal{O}(\mu^{3/2}).$$

Furthermore, if $L_0 = 1$, then

$$g^{(1)}(\pi, \mathbf{z}_0, \mu) = -\frac{15\pi}{32 G_0^4}\left(5\frac{H_0^2}{G_0^2} - 1\right) + \mathcal{O}(\mu^{3/2}).$$

Proof. From (4.3), we have that

$$g^{(1)}(t, \mathbf{z}_0, \mu) = \int_0^t \left.\frac{\partial \mathcal{H}_1}{\partial G}\right|_{\mathbf{z}^{(0)}(s, \mathbf{z}_0)} ds,$$

where $\mathbf{z}^{(0)}(s, \mathbf{z}_0)$ is the function defined in (4.2). Then, using (3.4) we obtain that

$$g^{(1)}(\pi, \mathbf{z}_0, \mu) = \frac{-3}{8}\int_0^\pi (1 - \cos E_p)^2 \varphi(t, \mathbf{z}_0)\, dt,$$

where

$$\varphi(t, \mathbf{z}_0) = \frac{\partial}{\partial G}\left(\frac{1}{r^3}\left(\cos^2 f - \frac{1}{3}\right) - \frac{H^2 \cos^2 f}{r^3 G^2}\right)\Bigg|_{\mathbf{z}^{(0)}(t, \mathbf{z}_0)}. \tag{4.5}$$

Since $\mathbf{z}_0 \in \mathcal{D}$, it is clear that $g^{(1)}(\pi, \mathbf{z}_0, \mu)$ is of type $\mathcal{C}^1$ in $\mathcal{D}$.

From Lemma 4.1 and (4.5), we have that

$$\begin{aligned} g^{(1)}(\pi, \mathbf{z}_0, \mu) &= \frac{-15}{16}\int_0^\pi \varphi(t, \mathbf{z}_0)\, dt + \mathcal{O}(\mu^{3/2}) \\ &= \frac{-15}{16}\left(\int_0^\pi \frac{\partial}{\partial G}\left(\frac{1}{r^3}\left(\cos^2 f - \frac{1}{3}\right)\right)\Bigg|_{\mathbf{z}^{(0)}(t, \mathbf{z}_0)} dt \right. \\ &\qquad \left. - H_0^2 \int_0^\pi \frac{\partial}{\partial G}\left(\frac{\cos^2 f}{G^2 r^3}\right)\Bigg|_{\mathbf{z}^{(0)}(t, \mathbf{z}_0)} dt\right) + \mathcal{O}(\mu^{3/2}) \\ &= -\frac{15}{16}(I_1(L_0, G_0) - H_0^2 I_2(L_0, G_0)) + \mathcal{O}(\mu^{3/2}), \end{aligned}$$

where

$$I_1(L_0, G_0) = \frac{G_0}{e_0 L_0^5}\int_0^{E(e_0, L_0)} (e_0 - \cos E)\frac{5e_0^2 - 5 - 2e_0\cos E + (7 - 3e_0^2)\cos^2 E - 2e_0\cos^3 E}{(1 - e_0\cos E)^6}\, dE,$$

$$\begin{aligned} I_2(L_0, G_0) = \frac{1}{G_0 e_0 L_0^5}\left(\int_0^{E(e_0, L_0)} \frac{-2e_0}{1 - e_0^2}\frac{(\cos E - e_0)^2}{(1 - e_0\cos E)^4}\, dE \right. \\ \left. + \int_0^{E(e_0, L_0)} (\cos E - e_0)\frac{4 - 5e_0^2 + 4e_0\cos E + (2e_0^2 - 7)\cos^2 E + 2e_0\cos^3 E}{(1 - e_0\cos E)^6}\, dE\right), \end{aligned}$$

and $E(e_0, L_0)$ is the solution of the equation $\pi = L_0^3(E - e_0 \sin E)$ (see section 5 for the details). In particular, when $L_0 = 1$, both integrals can be calculated explicitly and

$$I_1(1, G_0) = \frac{-\pi}{2G_0^4}, \qquad I_2(1, G_0) = \frac{-5\pi}{2G_0^6},$$

which ensures the last statement of the lemma. ∎

The next lemma shows that derivatives of $g^{(1)}$ satisfy conditions similar to those in Lemma 4.2; i.e., they can be written in terms of L_0, H_0, and G_0 plus terms of order $\mu^{3/2}$.

Lemma 4.3. *Under the same hypothesis as in Lemma 4.2,*

$$\frac{\partial g^{(1)}}{\partial L_0}(\pi, \mathbf{z}_0, \mu) = -\frac{15}{16}\left(\frac{\partial I_1}{\partial L_0}(L_0, G_0) - H_0^2 \frac{\partial I_2}{\partial L_0}(L_0, G_0)\right) + \mathcal{O}(\mu^{3/2}),$$
$$\frac{\partial g^{(1)}}{\partial H_0}(\pi, \mathbf{z}_0, \mu) = \frac{15}{8} H_0 I_2(L_0, G_0) + \mathcal{O}(\mu^{3/2}).$$

Proof. The result is straightforward using arguments similar to those of Lemma 4.2. ∎

In order to extend the symmetry equation to $\mu = 0$, let

$$\Omega = \{(L_0, H_0);\, \mathbf{z}_0 = (0, \pi/2, h_0, L_0, G_0, H_0) \in \mathcal{D}\}.$$

We define the function

$$\Phi(\xi, \mu) = (\Phi_1(\xi, \mu), \Phi_2(\xi, \mu))$$

for $\xi = (L_0, H_0) \in \Omega$ and $\mu \geq 0$ as

$$\Phi_1(\xi, \mu) = \begin{cases} L_0^{-3}\pi - \pi + \mu^2 l^{(1)}(\pi, \mathbf{z}_0, \mu) + \mathcal{O}(\mu^4) & \text{if } \mu \neq 0, \\ L_0^{-3}\pi - \pi & \text{if } \mu = 0, \end{cases} \tag{4.6}$$

and

$$\Phi_2(\xi, \mu) = \begin{cases} g^{(1)}(\pi, \mathbf{z}_0, \mu) + \mathcal{O}(\mu^2) & \text{if } \mu \neq 0, \\ -\frac{15}{16}(I_1(L_0, G_0) - H_0^2 I_2(L_0, G_0)) & \text{if } \mu = 0, \end{cases} \tag{4.7}$$

where $I_1(L_0, G_0)$ and $I_2(L_0, G_0)$ are the functions stated in the proof of Lemma 4.2. Then, (4.4) can be written as

$$\Phi(\xi, \mu) = (0, 0)$$

for $\mu \geq 0$, and for $\mu = 0$, $L_0 = 1$, satisfies

$$\Phi_1(\xi, 0) = 0, \qquad \Phi_2(\xi, 0) = -\frac{15\pi}{32G_0^4}\left(5\frac{H_0^2}{G_0^2} - 1\right).$$

Thus, for each fixed value of G_0, $\Phi(\xi_0, 0) = (0, 0)$ if $\xi_0 = (1, G_0/\sqrt{5})$. Observe that $H_0^2/G_0^2 = \cos^2 i$, and so the solution for $\mu = 0$ corresponds to an inclination i with $\cos i = 1/\sqrt{5}$, which is the critical inclination angle obtained in the case of the problem of an Earth-centered orbit when the effects of J_2 are considered.

In order to show that there exist symmetric periodic solutions of the reduced problem for $\mu \neq 0$, we need to show that there exist solutions of $\Phi(\xi, \mu) = (0, 0)$. In this case, we will use the next proposition, proved in [4], which is a sufficient condition for Arenstorf's theorem.

Proposition 4.4. *Let U be an open domain in R^n, $I \subset R$ an open neighborhood of the origin, $f : U \times I \to R^n$ with $f(0, 0) = 0$, differentiable with respect to $x \in U$, and $D_x f(0, 0)$ nonsingular. Assume that there exist $c > 0$, $k > 0$ such that for $x \in U$, $\epsilon \in I$,*

1. $\|D_x f(x, \epsilon) - D_x f(0, 0)\| \leq c(\|x\| + \epsilon)$,
2. $\|f(0, \epsilon)\| \leq k\epsilon$.

Then there exists a function $x(\epsilon) \in U$, defined for $\epsilon \in I' \subset I$, such that $f(x(\epsilon), \epsilon) = 0$ and $x(0) = 0$.

In order to apply Proposition 4.4 we need to prove that the function Φ satisfies some properties.

Proposition 4.5. *Let G_0 be fixed and $\xi_0 = (1, G_0/\sqrt{5})$. For μ small enough, there exists η such that the function $\Phi(\xi, \mu)$ is differentiable with respect to ξ in $\mathcal{B} = \{\xi \in \Omega;\ \|\xi - \xi_0\| \leq \eta\}$ and satisfies the three properties*

(i) $\|\Phi(\xi_0, \mu)\| \leq C_0 \mu^{3/2}$,
(ii) $\|(D_\xi \Phi)^{-1}(\xi_0, 0)\| \leq M$,
(iii) $\|D_\xi \Phi(\xi, \mu) - D_\xi \Phi(\xi_0, 0)\| \leq C_1(\|\xi - \xi_0\| + \mu^{3/2})$,

where M, C_0, and C_1 are constants independent of μ and $D_\xi \Phi(\xi, \mu)$ denotes the Jacobi matrix of Φ with respect to the variables ξ.

Proof. Statement (i) is a direct consequence of the definition of Φ (see (4.6) and (4.7)), the fact that $l^{(1)}$ is a bounded function, and Lemma 4.2.

Using that the derivatives of $l^{(1)}$ are also bounded and Lemma 4.3, we have that

$$
\begin{aligned}
D_\xi \Phi(\xi, \mu) &= \begin{pmatrix} \frac{-3\pi}{L_0^4} + \mathcal{O}(\mu^2) & \mathcal{O}(\mu^2) \\ \mathcal{J}(L_0, G_0) + \mathcal{O}(\mu^{3/2}) & \frac{15}{8} H_0 I_2(L_0, G_0) + \mathcal{O}(\mu^{3/2}) \end{pmatrix}, \\
D_\xi \Phi(\xi, 0) &= \begin{pmatrix} \frac{-3\pi}{L_0^4} & 0 \\ \mathcal{J}(L_0, G_0) & \frac{15}{8} H_0 I_2(L_0, G_0) \end{pmatrix},
\end{aligned}
\tag{4.8}
$$

where $\mathcal{J}(L_0, G_0) = \frac{-15}{16} \frac{\partial (I_1 - H_0^2 I_2)}{\partial L_0}$. Then, as $I_2(1, G_0) = -5\pi/(2G_0^6) \neq 0$, $D_\xi \Phi(\xi_0, 0)$ can be inverted, and item (ii) is proved.

Let us prove (iii). First, we have that

$$
\|D_\xi \Phi(\xi, \mu) - D_\xi \Phi(\xi_0, 0)\| \leq \|D_\xi \Phi(\xi, \mu) - D_\xi \Phi(\xi, 0)\| + \|D_\xi \Phi(\xi, 0) - D_\xi \Phi(\xi_0, 0)\|. \tag{4.9}
$$

On one hand, as the components of $\Phi(\xi, 0)$ are of type $\mathcal{C}^1$ with respect to ξ, we get that

$$
\|D_\xi \Phi(\xi, 0) - D_\xi \Phi(\xi_0, 0)\| \leq c_0 \|\xi - \xi_0\|. \tag{4.10}
$$

On the other hand,

$$
\|D_\xi \Phi(\xi, \mu) - D_\xi \Phi(\xi, 0)\| \leq \sum_{i=1}^{2} \|D_\xi \Phi_i(\xi, \mu) - D_\xi \Phi_i(\xi, 0)\| \leq c_1 \mu^2 + c_2 \mu^{3/2} \tag{4.11}
$$

by expressions (4.8). Substituting (4.10) and (4.11) into (4.9), we prove item (iii). ■

Notice that, given h_0, G_0, and $\mathbf{z}_0^* = (0, \pi/2, h_0, 1, G_0, G_0/\sqrt{5})$, the solution $\mathbf{z}^{(0)}(t, \mathbf{z}_0^*)$ is a solution of the Kepler problem lying on a plane of the critical inclination i with $\cos i = 1/\sqrt{5}$. Finally, let us prove that there exist periodic symmetric solutions of the perturbed reduced problem close to $\mathbf{z}^{(0)}(t, \mathbf{z}_0^*)$.

Theorem 4.6. *Consider the three-dimensional collision restricted three-body problem with masses $m_1 = m_2 = 1/2$, and primaries' semimajor axis $\mu/2$. If $\mu = k^{-2/3}$, where k is a positive integer large enough, there exist initial conditions such that the infinitesimal body moves in a symmetric periodic orbit of the* reduced problem*, of period 2π, near a Keplerian elliptic orbit. The inclination of the orbit is close to the "critical value"* $\cos i = 1/\sqrt{5}$.

Proof. Let us consider initial values h_0, G_0, and $\xi_0 = (1, G_0/\sqrt{5})$. It is clear that $\Phi(\xi_0, 0) = (0, 0)$. Given $\xi \in \Omega$, we define $f(x, \mu) = \Phi(x + \xi_0, \mu)$, where $x = \xi - \xi_0$. From Proposition 4.5 we can easily prove that $f(x, \mu)$ is under the hypothesis of Proposition 4.4. Then there exists a function $x(\mu)$ such that $f(x(\mu), \mu) = (0, 0)$ and $x(0) = 0$.

This yields a continuum of solutions of system $\Phi(\xi, \mu) = (0, 0)$. These conditions must be satisfied simultaneously with $E_p(T/2) = k\pi$, which is equivalent to $T = 2k\pi\mu^{3/2}$. Thus, for each $\mu = k^{-2/3}$, k a large positive integer, a periodic solution of the reduced problem exists. ■

Remark. All the orbits found are on an integral resonance with the motion of the primaries; i.e., the primaries undergo k complete orbits in one orbit of the infinitesimal body. If $k = p/q$ is an irreducible rational, then similar arguments show that in q complete orbits of the infinitesimal the primaries undergo p complete orbits.

5. Appendix. Here we develop the calculations needed in the proof of Lemma 4.2. We want to compute

$$\begin{aligned}\int_0^\pi \varphi(t, \mathbf{z}_0)dt &= \int_0^\pi \left.\frac{\partial \Delta_1}{\partial G}\right|_{\mathbf{z}^{(0)}(t,\mathbf{z}_0)} dt - H_0^2 \int_0^\pi \left.\frac{\partial \Delta_2}{\partial G}\right|_{\mathbf{z}^{(0)}(t,\mathbf{z}_0)} dt \\ &= I_1(L_0, G_0) - H_0^2 I_2(L_0, G_0),\end{aligned}$$

where $\Delta_1 = \frac{\cos^2 f - 1/3}{r^3}$ and $\Delta_2 = \frac{\cos^2 f}{G^2 r^3}$.

We will introduce the change of variables given by $t = L_0^3(E - e_0 \sin E)$, where L_0^2 and e_0 correspond to the semimajor axis and the eccentricity of the Keplerian orbit $\mathbf{z}^{(0)}(t, \mathbf{z}_0)$, respectively. As the new variable to integrate will be E, we use the rule

$$\frac{\partial \Delta_i}{\partial G} = \frac{\partial \Delta_i}{\partial E}\frac{dE}{de}\frac{de}{dE} \tag{5.1}$$

for $i = 1, 2$. On one hand, from Kepler's equation $t = a^{3/2}(E - e \sin E)$, we have that

$$0 = a^{3/2}\left(\frac{dE}{de} - \sin E - e\cos E \frac{dE}{de}\right) \quad \text{and} \quad \frac{dE}{de} = \frac{\sin E}{1 - e\cos e}.$$

On the other hand, as $G^2 = a(1 - e^2)$, we have that $\frac{de}{dG} = \frac{-G}{ae}$. Substituting into (5.1), we have that

$$\frac{\partial \Delta_i}{\partial G} = \frac{-G \sin E}{ae(1 - e\cos E)}\frac{\partial \Delta_i}{\partial E}. \tag{5.2}$$

Next, as $r = a(1 - e\cos E) = \frac{a(1-e^2)}{1+e\cos f}$, we have that $\cos f = \frac{\cos E - e}{1 - e\cos E}$, and deriving both expressions we obtain

$$\frac{\partial r}{\partial E} = a\,\frac{e - \cos E}{\sin E}, \qquad -\sin f\,\frac{df}{dE} = \frac{\sin E(e^2 - 2 + e\cos E)}{(1 - e\cos E)^2}. \tag{5.3}$$

Thus, using the expressions (5.2) and (5.3), we have that

$$\begin{aligned}
\frac{\partial \Delta_1}{\partial G} &= \frac{G(e - \cos E)(5e^2 - 5 - 2\,e\cos E + (7 - 3\,e^2)\cos^2 E - 2\,e\cos^3 E)}{ea^4(1 - e\cos E)^7},\\
\frac{\partial \Delta_2}{\partial G} &= \frac{-2(\cos E - e)^2}{G^3a^3(1 - e\cos E)^5}\\
&\quad + \frac{(\cos E - e)}{Gea^4}\,\frac{4 - 5e^2 + 4e\cos E + (2e^2 - 7)\cos^2 E + 2e\cos^3 E}{(1 - e\cos E)^7}.
\end{aligned}$$

Finally, evaluating both expressions on the solution $\mathbf{z}^{(0)}(t, \mathbf{z}_0)$ of the Kepler problem, we obtain the expressions for the functions I_1 and I_2 as

$$\begin{aligned}
\int_0^\pi \left.\frac{\partial \Delta_1}{\partial G}\right|_{\mathbf{z}^{(0)}(t,\mathbf{z}_0)} dt &= \frac{G_0}{e_0L_0^5}\int_0^{E(e_0,L_0)} f_1(e_0, E)\,dE = I_1(L_0, G_0),\\
\int_0^\pi \left.\frac{\partial \Delta_2}{\partial G}\right|_{\mathbf{z}^{(0)}(t,\mathbf{z}_0)} dt &= \frac{1}{G_0e_0L_0^5}\int_0^{E(e_0,L_0)} f_2(e_0, E)\,dE = I_2(L_0, G_0),
\end{aligned}$$

where $E(e_0, L_0)$ is the solution of the equation $\pi = L_0^3(E - e_0\sin E)$ and

$$\begin{aligned}
f_1(e_0, E) &= (e_0 - \cos E)\frac{5e_0^2 - 5 - 2e_0\cos E + (7 - 3e_0^2)\cos^2 E - 2e_0\cos^3 E}{(1 - e_0\cos E)^6},\\
f_2(e_0, E) &= \frac{-2e_0}{1 - e_0^2}\,\frac{(\cos E - e_0)^2}{(1 - e_0\cos E)^4}\\
&\quad + (\cos E - e_0)\,\frac{4 - 5e_0^2 + 4e_0\cos E + (2e_0^2 - 7)\cos^2 E + 2e_0\cos^3 E}{(1 - e_0\cos E)^6}.
\end{aligned}$$

Furthermore, it is clear that for a fixed value of $e_0 < 1$ the functions f_1 and f_2 are continuous and differentiable with respect to E and e_0, and so $I_1(L_0, G_0)$ and $I_2(L_0, G_0)$ are functions of type $\mathcal{C}^1$ with respect to e_0. In particular, when $L_0 = 1$, $E(e_0, L_0) = \pi$, and both integrals can be calculated explicitly:

$$I_1(1, G_0) = \frac{-\pi}{2G_0^4}, \qquad I_2(1, G_0) = \frac{-5\pi}{2G_0^6}.$$

Corner-Impact Bifurcations: A Novel Class of Discontinuity-Induced Bifurcations in Cam-Follower Systems*

Gustavo Osorio†, Mario di Bernardo‡, and Stefania Santini‡

Abstract. This paper is concerned with the analysis of a class of impacting systems of relevance in applications: cam-follower systems. We show that these systems, which can be modeled as discontinuously forced impact oscillators, can exhibit complex behavior due to the detachment at high rotational speeds between the follower and the cam. We propose that the observed phenomena can be explained in terms of a novel type of discontinuity-induced bifurcation, termed as corner-impact. We present a complete analysis of this bifurcation in the case of a nonautonomous impact oscillator and explain the transition to chaos observed in a representative cam-follower example. The theoretical findings are validated numerically.

Key words. discontinuity-induced bifurcation, piecewise-smooth systems, impact oscillator, cam-follower system

1. Introduction.

Recently, much research effort has been spent to analyze the dynamics of piecewise-smooth dynamical systems with impacts [5, 41]. These systems arise in many areas of engineering and applied science. A typical example is that of mechanical systems characterized by structural components with displacement constraints. Examples include bouncing or hopping robots, systems with backlash or friction, gears, and vibro-impacting mechanical devices [5].

Cam-follower systems are a particularly important class of mechanical systems with displacement constraints widely used for the operation of various machines and mechanical devices [30]. Usually, their purpose is to actuate valves or other mechanisms through the movement of a follower forced by a rotating cam. For example, all types of automated production machines, including screw machines, spring winders, and assembly machines, rely heavily on this kind of system for their operation. One of the most common application is to the valve train of internal combustion engines (ICEs) [18], where the effectiveness of the ICE is based

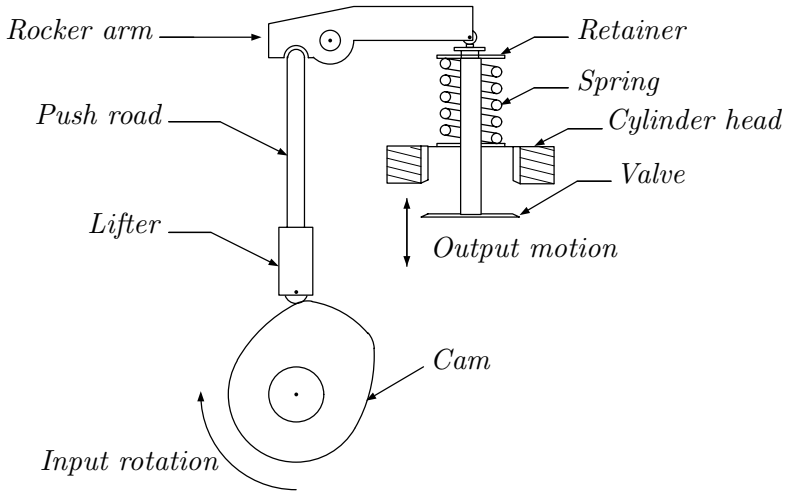

Figure 1. *Valve train configuration.*

on the proper working of a cam-follower system. A schematic of a single valve for a typical pushrod-type engine is presented in Figure 1. Here, the cam rotation results in a linear motion imparted to the valve. The valve spring in the system provides the restoring force necessary to maintain contact between the components.

To guarantee that the follower moves as required, it is important in applications to carefully design the cam profile. Different cam geometries are used in practice ranging from circular cams to highly complex cam profiles. In general, there is now a large variety of alternative methods to select the cam profile. For example, by using the constrained optimization algorithm, it is possible to use splines to obtain the cam geometry from the desired motion that the cam is required to impart on the follower (for examples see [9] and [16]). This often means that while the cam has a continuous displacement profile, it might have discontinuities in its acceleration [31].

It has been observed that, as the cam rotational speed increases, the follower can detach from the cam. This causes the onset of undesired behavior associated to impacts taking place between the follower and the cam. For example, in automotive engines this phenomenon can seriously deteriorate the engine performance as the valves can close with abnormally high velocity and even bounce off the seat (valve floating and bouncing) [21, 37, 10]. To avoid this phenomenon, a large spring force and preload are applied to the follower [34]. This often causes an increase in the contact force, which induces higher stresses possibly leading to early surface failure of the parts. The resulting high friction valve train reduces the efficiency of the engine system [39].

In general, cam-follower systems can be thought of as impact oscillators with moving boundaries [20, 30, 15, 40]. While the dynamics of impact oscillators with continuous forcing has been the subject of many papers in the existing literature (see, for example, [32, 17, 6, 7]), the possible intricate bifurcation behavior of impact oscillators with discontinuous forcing was discussed only recently, as, for example, in [8]. It was proposed that discontinuously forced oscillators can show a novel bifurcation phenomenon unique to their nature which was termed

as corner-impact bifurcation. Namely, in [8] the dynamics of an impact oscillator forced by a discontinuous sinusoidal forcing of the form $f(t) = A|\sin(\omega t)|$ are studied. It was shown that, under variation of the system parameters, abrupt changes of the system's qualitative behavior are observed when an impact occurs at a point where the forcing velocity is discontinuous (a corner-impact bifurcation point).

The observed behavior was explained in terms of appropriate local maps. In particular, by using the technique of discontinuity mappings recently proposed in [17] and [12], it was suggested that a corner-impact bifurcation of the oscillator corresponds to a border-collision of a fixed point of the associated Poincaré map. An important difference was highlighted between corner-impact bifurcations and other types of discontinuity-induced bifurcations [4] in impacting systems such as grazing of limit cycles [28, 38, 22, 26, 33, 24]. While the normal form map of a grazing bifurcation is typically characterized by a square root singularity [28], the local normal form map associated to a corner-impact bifurcation was shown to be a piecewise-linear map with a gap such as those studied in [19]. Hence, as explained in [8], an appropriate classification method needs to be used to investigate this novel class of bifurcations.

In [14], it was conjectured for the first time that corner-impact bifurcations are fundamental in organizing the complex behavior observed in cam-follower systems. It was shown that, as the cam rotational speed increases, these systems can exhibit sudden transitions from periodic solutions to chaos. Such transitions were conjectured to be due to corner-impact bifurcations.

In this paper, we present a careful analysis of corner-impact bifurcations in cam-follower systems. We analytically derive the normal form map associated to such a bifurcation in a representative example of interest where the cam profile is characterized by a discontinuous acceleration. In particular, we investigate the bifurcation behavior exhibited by this system under variations of the cam rotational speed. We find that following the detachment of the follower from the cam, the system can exhibit complex nonlinear phenomena involving chattering, period adding cascades, and the sudden transition from periodic attractors to chaos. We explain the sudden transition to chaos observed in the system in terms of a corner-impact bifurcation. Namely, we show that dramatic changes in the system's behavior are observed when, under parameter variation, one of the impacts characterizing the system's trajectory crosses one of the manifolds in phase space where the cam acceleration is discontinuous.

We prove that the normal form map of the corner-impact bifurcation in these systems is a piecewise-linear continuous map rather than discontinuous because of the higher degree of discontinuity of the forcing signal provided by the cam with respect to that of the forcing considered in [8]. We wish to emphasize that such a finding is generic for the wide class of impacting systems characterized by forcing terms with discontinuous acceleration.

As shown in the paper, the derivation of the mapping has an immediate practical relevance. In fact, the derivation of a piecewise-linear normal form map implies that the strategy to classify border-collisions in piecewise-linear continuous maps due to Feigin [13] can be used, under some circumstances, to classify corner-impact bifurcations in continuous-time impacting flows.

The rest of the paper is outlined as follows. In section 2, we present the modeling of the cam-follower system of our concern, where the cam profile has been assumed to be characterized by a discontinuous acceleration. Then in section 3 the numerical bifurcation analysis is

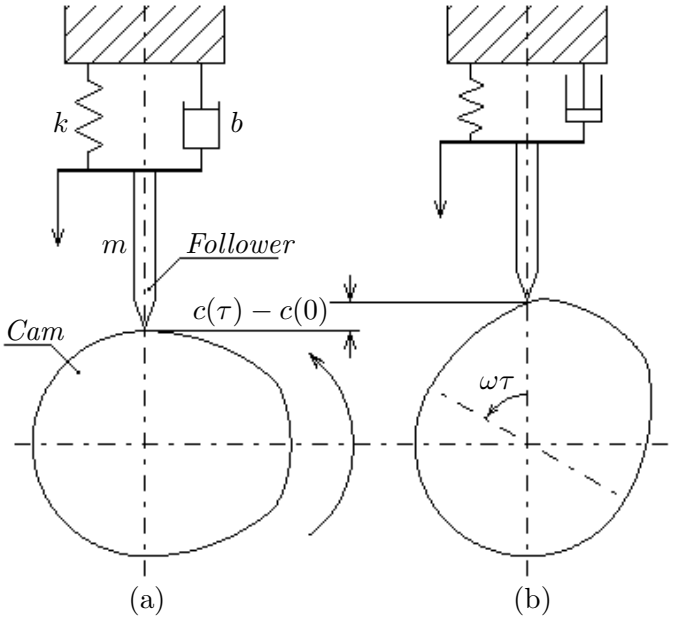

Figure 2. *Cam-follower schematics.* (a) $t = 0$. (b) $t = \tau$.

presented under variation of the cam rotational speed. In section 4 we present the analysis of the corner-impact bifurcation phenomenon detected in the system, and we classify the ensuing dynamics by using an appropriately derived local mapping. Finally, conclusions are drawn in section 5.

2. Modeling. The formulation of an appropriate model for a cam-follower system can be a challenging task for most applications. Various models with different degrees of complexity have been proposed and extensively studied. They range from simple models with one degree-of-freedom (DOF) such as that described in [20] to complex models characterized by many DOFs, as, for example, the 21 DOF model studied in [36], where additional effects of camshaft torsion and bending, backlashing, and squeezing of lubricant in bearings are included. Nevertheless, there is general agreement in the literature, confirmed by experiments, that a lumped parameter single DOF model is adequate to represent the main qualitative features of the dynamic behavior of the system of interest [3, 20, 1, 15].

The schematic diagram of the cam-follower system under investigation is shown in Figure 2. We consider the following second order equation to model the free body dynamics of the follower away from the cam:

$$\begin{aligned} mq''(t) + bq'(t) + kq(t) &= -mg \\ \text{if } q(t) &> c(t), \end{aligned} \tag{2.1}$$

where m, b, k, and g are constant positive parameters representing the follower mass, viscous damping, spring stiffness, and gravitational constant, respectively. The state of the follower is given by the position $q(t)$ and the velocity $q'(t)$. The cam position is given by $c(t)$, and we assume that the follower motion is constrained to the phase-space region where $q(t) > c(t)$.

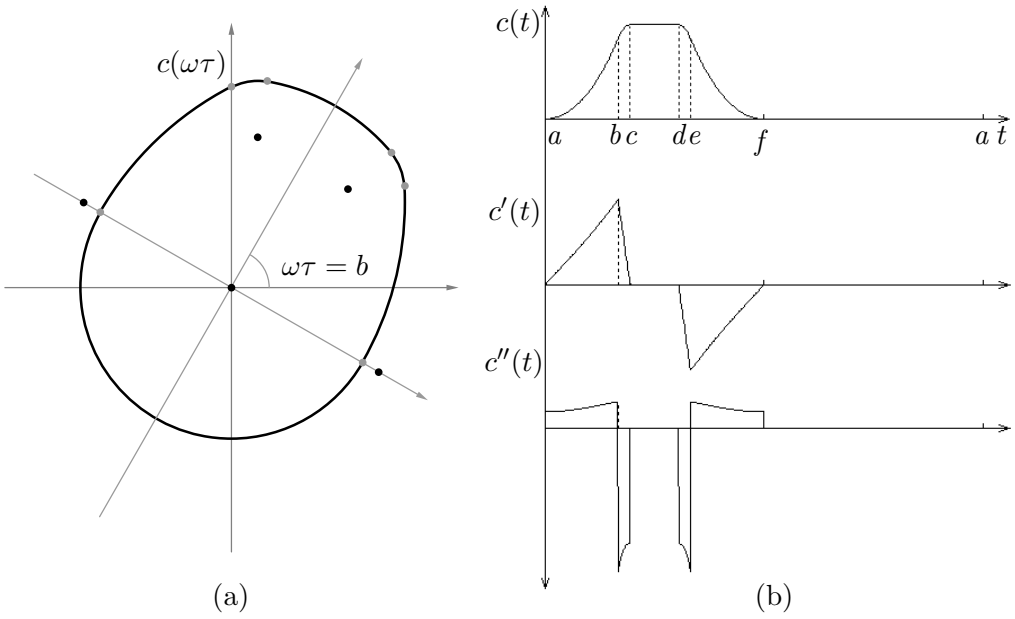

Figure 3. (a) *Cam profile.* (b) *Constraint position $c(t)$, velocity $c'(t)$, and acceleration $c''(t)$.*

The dynamic behavior when impact occurs (i.e., $q(t) = c(t)$) is modeled via a Newton restitution law as [5, 23, 29]

$$q'(t^+) = (1+r)c'(t) - rq'(t^-) \quad \text{if } q(t) = c(t), \tag{2.2}$$

where $q'(t^+)$ and $q'(t^-)$ are the post- and preimpact velocities, respectively, $c'(t)$ is the projection of the cam velocity vector at the contact point along the direction of the free movement of the follower, and $r \in [0, 1]$ is the coefficient of restitution used to model from plastic to elastic impacts.

An essential ingredient of the model is the choice of the cam profile, $c(t)$. The cam is assumed to be rotating at a constant angular velocity ω and can be interpreted as the "control action" acting on the follower state, as suggested in [30]. Therefore, $c(t)$ is carefully selected in applications as a trade-off between several optimality criteria dependent upon the specific device being considered and the unavoidable physical constraints on the system.

Typically, this results in a design process where the cam profile is selected by using splines and can contain several degrees of discontinuity. For example, the cam for a single overhead camshaft valve train is designed by using quadratic splines, and, as a consequence, discontinuities are present in its acceleration. In general, it is not uncommon in applications to find cam geometries characterized by continuous cam positions and velocities but a discontinuous second derivative [30].

In what follows, we assume the cam profile to be characterized by a discontinuous second derivative as shown in Figure 3. For the sake of brevity, the analytical expressions of the cam profile and its derivatives are reported in Appendix A. The case of a smooth cam profile with

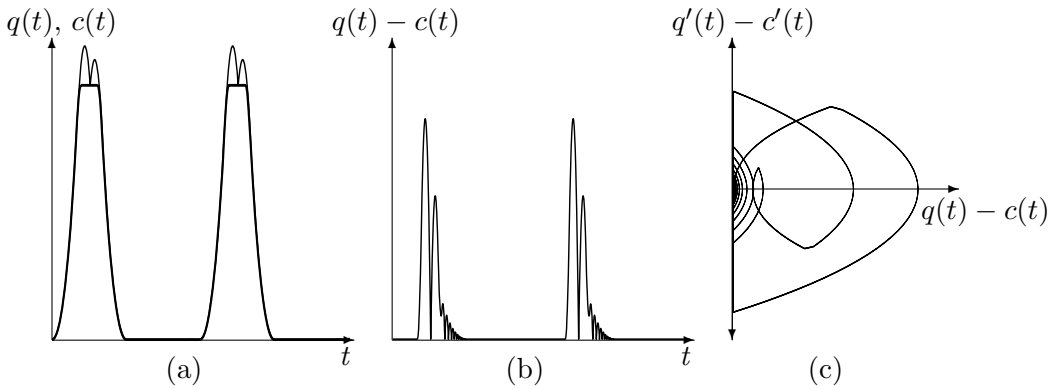

Figure 4. *Time simulation at $\omega = 183$ rpm.* (a) *Follower position, $q(t)$ (light); Cam position, $c(t)$ (dark).* (b) *Relative position, $q(t) - c(t)$.* (c) *Phase space, $q(t) - c(t)$ versus $q'(t) - c'(t)$.*

continuous first and second order derivatives is also of interest in applications and was studied experimentally in [2].

3. Numerical bifurcation analysis. The model represented by (2.1) and (2.2) was found to exhibit an intricate bifurcation behavior including the sudden transition to chaos under variation of the cam rotational speed, ω [14]. The presence of bifurcations and chaos was also confirmed by experiments, as described in [2].

Here we briefly summarize some of the most striking behavior exhibited by the system focusing on the abrupt transition from a one-periodic impacting solution to chaos observed when $\omega \approx 673.234445$ rpm.

In general, starting from low values of ω, the system exhibits solutions characterized by permanent contact between the cam and the follower. As ω increases, the follower is observed to detach from the cam during its evolution and then to impact with it. A typical periodic evolution with impacts is shown in Figure 4(a) when $\omega = 183$ rpm. We observe that the follower and the cam are in contact with zero relative velocity for part of the orbit (*sticking*) and then detach, giving rise to impacting behavior. As shown in Figure 4(b)–(c) a careful look at the follower evolution shows that a *chattering sequence* is present, where theoretically an infinite number of impacts accumulates in finite time. (Note that in practice chattering is associated to a large but finite number of impacts.)

Chattering can be associated to an intricate bifurcation structure. In Figure 5(a), the location of the impacts in the cam surface is depicted for each value of ω, characterizing the follower asymptotic solution. We see that following detachment at about 114 rpm, the follower immediately exhibits multi-impacting behavior and chattering (characterized by the accumulation of the impact lines in the diagram onto the darker areas corresponding to the chattering accumulation points). An interesting phenomenon is the appearance of resonant peaks associated to impact lines crossing the boundaries where the cam acceleration profile is discontinuous (represented by dotted lines in the figure). A detailed analysis of this bifurcation scenario is presented in [27].

This phenomenon can be classified as due to a *corner-impact bifurcation*, a type of discontinuity-induced bifurcation recently described in [8]. Namely, at certain values of ω, one of

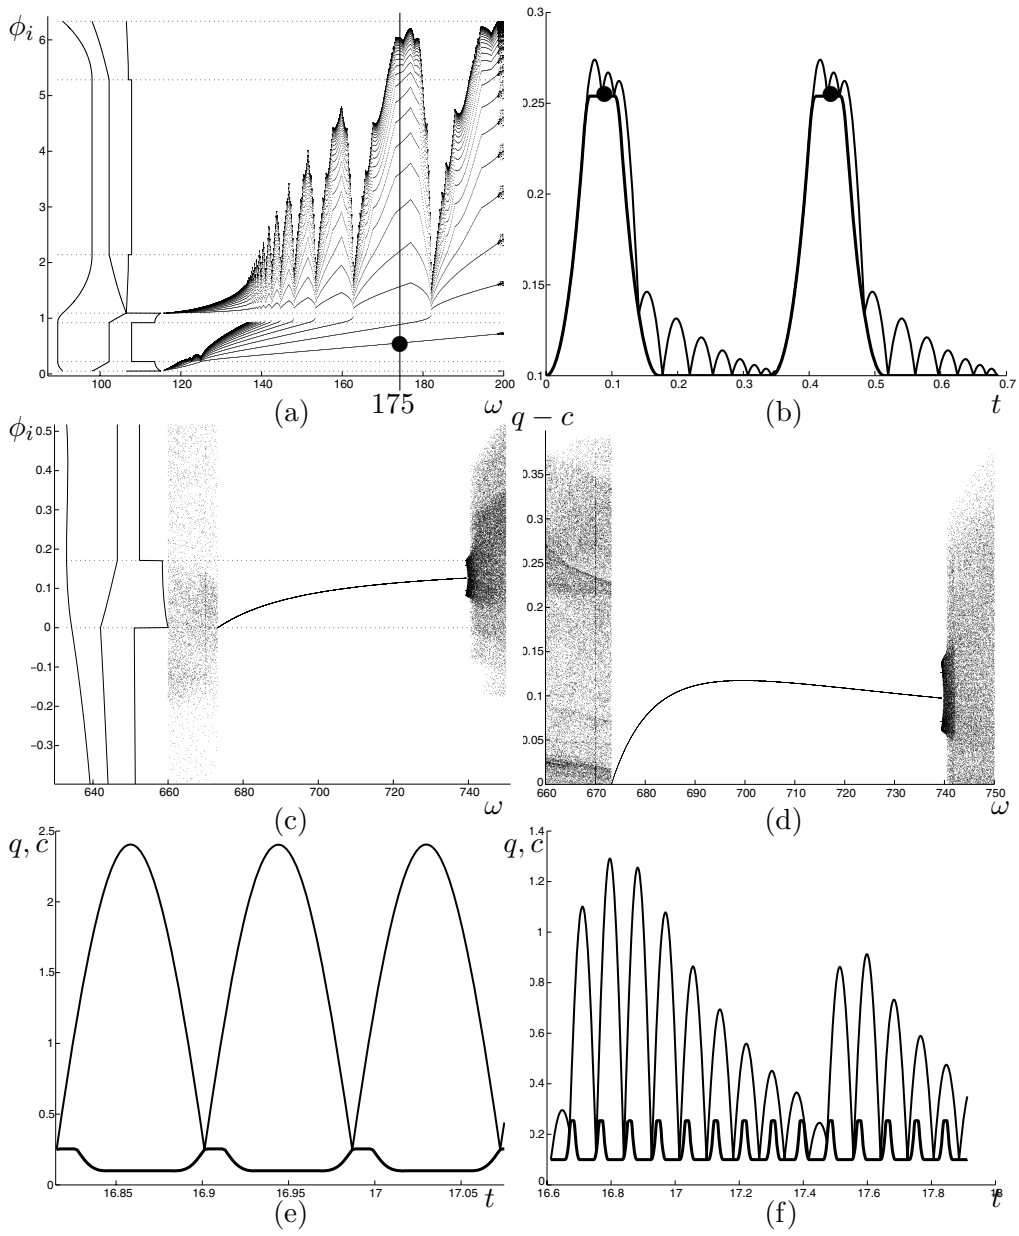

Figure 5. (a) *Impact bifurcation diagram for* $[115, 200]$ *rpm. The phase of an impact* ϕ_i *(rad) is plotted against* ω. the impacts characterizing the follower motion occurs at a point on the cam profile where the acceleration is discontinuous. We shall seek to analytically investigate this phenomenon and classify the behavior following the corner-impact event in the cam-follower system of interest. For the sake of simplicity, we focus on a different region of the system bifurcation diagram depicted in Figure 5(c). Here a one-periodic solution characterized by one impact per period exhibits sudden transitions to chaos as ω is decreased below 673.234445 rpm. A close look at the impact bifurcation diagram in Figure 5(c) and in the stroboscopic bifurcation diagram in Figure 5(d) shows that such transitions occur precisely when the impact characterizing the solution crosses the cam discontinuity boundaries (the dotted lines in Figure 5(c)). Specifically, the sudden transition to chaos is due to the corner-impact bifurcation of the periodic solution depicted in Figure 5(e). Past the corner-impact bifurcation point, the system exhibits chaotic behavior (see, for example, the trajectory reported in Figure 5(f) for $\omega \approx 670$ rpm). The rest of this paper is devoted to the analysis of this bifurcation scenario.

4. Corner-impact bifurcation analysis. The numerical observations reported above indicate that a corner-impact bifurcation is causing the transition to chaos observed in the cam-follower system. Specifically, we are interested in analyzing the occurrence of the corner-impact bifurcation depicted in Figure 5(c) when $\omega \approx 673.234445$ rpm. Numerically, we detected that the bifurcating orbit, shown in Figure 5(e), is a one-periodic orbit characterized by one impact per period. As the rotational speed of the cam is decreased, at the bifurcation point, the impact is observed to cross the point on the cam surface where the cam acceleration is discontinuous. To investigate this novel type of discontinuity-induced bifurcation we will analytically construct the Poincaré map of the system close to the bifurcation point. We will then study the bifurcations of the fixed point corresponding to the periodic solution of interest. A crucial point in the analysis is to assess whether the resulting map is piecewise-linear continuous or not. Indeed, only if this is the case, the theory of border-collision bifurcations (see [35, 13]) can be used to classify the possible solutions branching from the corner-impact bifurcation point [25].

We use the concept of discontinuity mapping (or normal form mapping) recently introduced in [17, 12] to analytically construct the Poincaré map associated to the bifurcating orbit of interest. We use the cam-follower system described in section 2 as a representative example to carry out the analytical derivations.

4.1. Poincaré map derivation. We are interested in the analysis of the period one orbit at the corner-impact bifurcation point. Such an orbit is sketched in Figure 6. Then, close to such a periodic orbit we define the stroboscopic map P as the mapping from the follower state $x_1 \in \Pi_1$ at a stroboscopic time instant t_1 to the next stroboscopic point $x_2 \in \Pi_2$. Without loss of generality, we assume that $t_n = -\frac{T}{2} + (n-1)T$ for $n = 1, 2, 3, \ldots$, where T is the period of the cam forcing cycle (note that $T = 2\pi/\omega$). Namely, we have

$$x_2 = P(x_1). \tag{4.1}$$

To construct P we would need to flow forward using the system evolution from x_1 to x_2 for time T taking into account the possible occurrence of impacts and therefore applying Newton's restitution law as required. Alternatively, as shown in [17], it is possible to construct P as the composition of three submappings: (i) an affine transformation $P_{1,T/2}$ from the stroboscopic

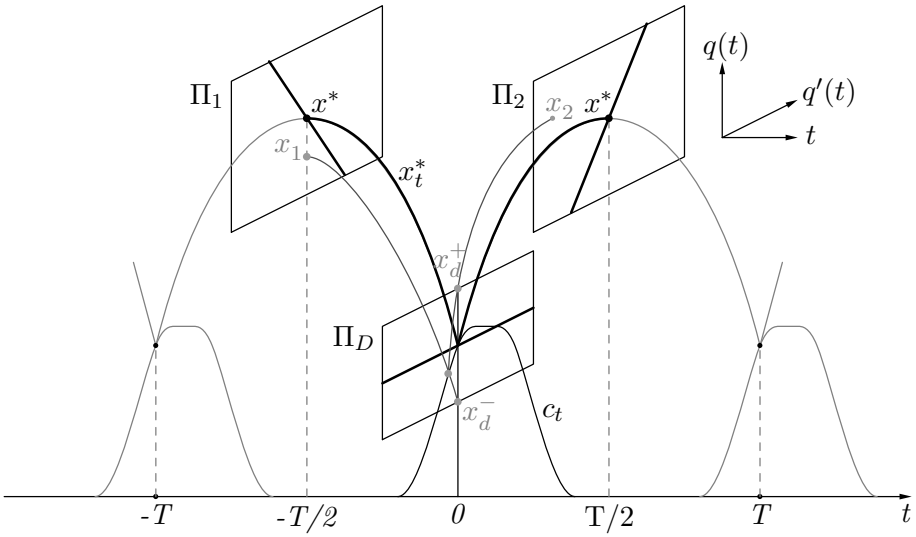

Figure 6. *Global map composition.*

plane Π_1 at $t_1 = -\frac{T}{2}$ to the plane Π_D going through the corner-impact point at $t = 0$; (ii) an appropriate zero-time discontinuity mapping (ZDM) P_D on Π_D accounting for the presence of the discontinuity; and again (iii) an affine transformation $P_{2,T/2}$ from the plane Π_D at $t = 0$ back to the stroboscopic plane Π_2 at $t_2 = \frac{T}{2}$. Specifically, while $P_{1,T/2}$ and $P_{2,T/2}$ are fixed time maps that account for the follower evolution away from the cam as if no impact had occurred, the ZDM represents the correction that needs to be made to the system trajectories because of the presence of impacts. Figure 6 represents the global map composition. This means that we can write

$$P = P_{2,T/2} \circ P_D \circ P_{1,T/2}, \tag{4.2}$$

where $P_{1,T/2} : \Pi_1 \mapsto \Pi_D$ will map the state from the initial condition x_1 on the stroboscopic plane Π_1 to a point x_d^- on the discontinuity plane Π_D as if no impacts had occurred. $P_D : \Pi_D \mapsto \Pi_D$ will then map x_d^- to the point x_d^+ appropriately correcting the evolution for the presence of impacts (see Figure 7). Finally, $P_{2,T/2} : \Pi_D \mapsto \Pi_2$ will map x_d^+ to a point x_2 back onto the stroboscopic plane Π_2. In so doing, as discussed in [17, 12], the effect of the system discontinuities due to impacts is taken into account by the ZDM, P_D, which is therefore often termed as the local normal form map in the context of the theory of discontinuity-induced bifurcations [26].

4.1.1. Derivation of $P_{1,T/2}$ and $P_{2,T/2}$. As explained above, the maps $P_{1,T/2}$ and $P_{2,T/2}$ are defined only in terms of the free body dynamics of the follower and the cam rotating period T (depending upon the cam rotational speed ω). Therefore, we can solve (2.1) to get an analytical expression of the flows generating the mappings of interest.

Specifically, we define

$$x_t = \begin{bmatrix} q(t) + \frac{g}{\omega_0^2} \\ q'(t) \end{bmatrix}, \qquad y_t = \begin{bmatrix} c(t) \\ c'(t) \end{bmatrix}$$

as the state vectors for the follower and the cam, respectively.

Then the generalized solution of (2.1) is

$$x_t = e^{-\zeta t}\left(I\cos(\omega_s t) + A\sin(\omega_s t)\right)x_0 = \phi_t x_0, \tag{4.3}$$

where $\zeta = \frac{b}{2m}$, $\omega_0 = \sqrt{\frac{k}{m}}$, $\omega_s = \sqrt{\omega_0^2 - \zeta^2}$, I is the identity matrix, $\phi_t x_0$ represents the system flow for time t starting from the initial condition x_0, and

$$A = \begin{bmatrix} \frac{\zeta}{\omega_s} & \frac{1}{\omega_s} \\ -\frac{\omega_0^2}{\omega_s} & -\frac{\zeta}{\omega_s} \end{bmatrix}.$$

Note that, in general, the system flow operator can be expressed as

$$\phi_t = \frac{e^{-\zeta t}}{\omega_s}\begin{bmatrix} \omega_s\cos(\omega_s t) + \zeta\sin(\omega_s t) & \sin(\omega_s t) \\ -\omega_0^2\sin(\omega_s t) & \omega_s\cos(\omega_s t) - \zeta\sin(\omega_s t) \end{bmatrix}. \tag{4.4}$$

The submapping $P_{i,T/2}$ can then be easily obtained using (4.3) as

$$\begin{aligned} P_{i,T/2}(x) &= e^{-\zeta T/2}\left(I\cos(\omega_s T/2) + A\sin(\omega_s T/2)\right)x \\ &:= \phi_{\frac{T}{2}}x. \end{aligned} \tag{4.5}$$

4.1.2. Derivation of P_D. As explained in [12], the ZDM can be obtained by an appropriate composition of backward and forward flows so that the overall time spent following backward and forward is zero. As explained earlier, the ZDM is the correction that maps the point $x_d^- \in \Pi_D$ onto the point $x_d^+ \in \Pi_D$, taking into account the presence of impacts in the trajectory of interest. In what follows we assume that only one impact occurs over one cycle of the periodic orbit of interest as we suppose to be sufficiently close to the bifurcating orbit x_t^* shown in Figure 6. Figure 7 shows a schematic diagram that describes the construction of the ZDM, close to the corner-impact bifurcations. Without loss of generality we assume that the origin is placed at the Poincaré section Π_D. To analytically derive the mapping $x_d^+ = P_D(x_d^-)$ we need to perform the following steps:

1. Starting from x_d^-, we find the time t_i at which the impact occurs. Namely, t_i is obtained by looking at the difference, $(q(t) - c(t))$, between the follower position and the cam position close to $t = 0$. Given a vector z, we indicate by $[z]_1$ its first component. Then $q(t) = [x_t]_1 - \frac{g}{\omega_0^2}$, and therefore, close to x_d^-, t_i can be obtained as the nearest solution of the equation

$$H(x_{-t_i}^-, t_i) := \left[x_{-t_i}^- - y_{-t_i}\right]_1 = h\cdot\left[\phi_{-t_i}x_d^- - y_{-t_i}\right] = 0, \tag{4.6}$$

where $h = [\ 1 \quad 0\ ]$.
Hence, t_i is implicitly defined by the equation $H(x_{-t_i}^-, t_i) = 0$. Once t_i is found, the preimpact state of the system, $x_{-t_i}^-$, can also be obtained as

$$x_{-t_i}^- = \phi_{-t_i}x_d^-. \tag{4.7}$$

Note that t_i can be either negative or positive according to whether the impact occurs to the left or to the right of $t = 0$.

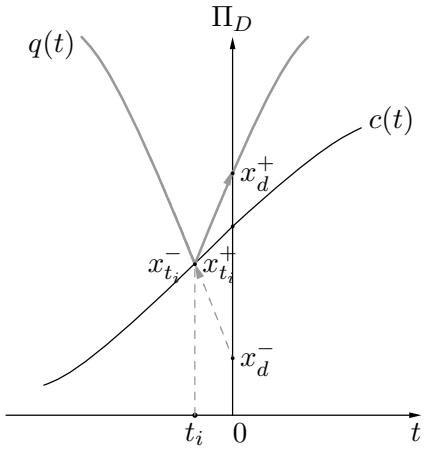

Figure 7. *ZDM construction.*

2. Using the restitution law (2.2), we can then write the postimpact state of the follower $x^+_{-t_i}$ as

$$x^+_{-t_i} = x^-_{-t_i} + R(x^-_{-t_i} - y_{-t_i}) = \rho(x^-_{-t_i}, y_{-t_i}), \tag{4.8}$$

where

$$R = \begin{bmatrix} 0 & 0 \\ 0 & -(1+r) \end{bmatrix}.$$

3. Finally, to obtain x_d^+, we flow forward for time t_i starting from the postimpact state $x^+_{-t_i}$ found at the previous step. In so doing, the state of the follower $x_d^+ \in \Pi_D$ can be computed as

$$x_d^+ = \phi_{t_i} x^+_{-t_i}. \tag{4.9}$$

Using (4.7), (4.8), and (4.9), we can then explicitly write the ZDM as

$$x_d^+ = P_D(x_d^-) = (\mathbf{I} + \phi_{t_i} R \phi_{-t_i})\, x_d^- - \phi_{t_i} R y_{-t_i}, \tag{4.10}$$

with t_i defined implicitly by (4.6).

4.1.3. Constructing the stroboscopic map. Composing the submappings $P_{1,T/2}$, $P_{2,T/2}$, and P_D given by (4.5) and (4.10), we can then construct the stroboscopic Poincaré map, P, of the system close to the corner-impact bifurcation point from a generic $x_n \in \Pi_n$ to $x_{n+1} \in \Pi_{n+1}$ as

$$\begin{aligned} x_{n+1} = P(x_n, T) &= P_{2,T/2}(P_D(P_{1,T/2}(x_n))) \\ &= \phi_{\frac{T}{2}} \left((\mathbf{I} + \phi_{t_i} R \phi_{-t_i})\, \phi_{\frac{T}{2}} x_n - \phi_{t_i} R y_{-t_i} \right), \end{aligned} \tag{4.11}$$

where t_i is implicitly defined by the equation $H(x_n, t_i) = h \cdot (\phi_{\frac{T}{2} - t_i} x_n - y_{-t_i}) = 0$.

Note that the fixed point (x^* associated to the periodic solution existing for a fixed value of the cam period $T = T^*$) can be obtained by solving (4.11) for $x_{n+1} = x_n = x^*$, i.e.,

$$x^* = -\left[\mathbf{I} - \phi_{T^*} + \phi_{\frac{T^*}{2}} R \phi_{\frac{T^*}{2}}\right]^{-1} \phi_{\frac{T}{2}} R y_0, \tag{4.12}$$

with $t_i^* = 0$.

In what follows we are interested in studying such a mapping locally to the corner-impact bifurcation point detected when $\omega = \omega^* = 673.234445$ rpm, corresponding to a period $T^* = 0.08912199969159$ s. The fixed point associated to the bifurcating orbit is $x^* = \begin{bmatrix} 5.09700788184250 & 0 \end{bmatrix}'$. These values were detected first numerically and then obtained analytically by solving (4.12) through an algebraic manipulation software. (For the sake of brevity we leave out the computer algebra here.)

4.2. A locally piecewise-linear continuous map. Let δx_n and δT be sufficiently small variations of the state and parameter from the bifurcation point x^*, T^*. We can then linearize the map $x_{n+1} = P(x_n, T)$ in (4.11) about this point as

$$\delta x_{n+1} = \frac{\partial P(x^*, T^*)}{\partial x_n} \delta x_n + \frac{\partial P(x^*, T^*)}{\partial T} \delta T. \tag{4.13}$$

For the computation of $\frac{\partial P}{\partial x_n}$ it is essential to take into account the implicit dependence of t_i on x_n and T. Hence, using implicit differentiation, we have

$$\frac{\partial P(x_n, T)}{\partial x_n} = \frac{\partial P(x_n)}{\partial x_n} + \frac{\partial P(t_i)}{\partial t_i} \frac{\partial t_i(x_n)}{\partial x_n}. \tag{4.14}$$

Using (4.11), we can then write

$$\frac{\partial P(x_n)}{\partial x_n} = \phi_{\frac{T}{2}} (I + \phi_{-t_i} R \phi_{t_i}) \phi_{\frac{T}{2}}, \tag{4.15}$$

$$\frac{\partial P(t_i)}{\partial t_i} = \phi_{\frac{T}{2}} \left(\phi'_{t_i} R \phi_{-t_i} - \left(\phi_{t_i} R \phi'_{-t_i} \right) \phi_{\frac{T}{2}} x_n - \phi'_{t_i} R y_{-t_i} + \phi_{t_i} R y'_{-t_i} \right). \tag{4.16}$$

Moreover, using the implicit differentiation theorem, from (4.6) we have

$$\frac{\partial H(x_n, t_i(x_n))}{\partial x_n} = \frac{\partial H(x_n)}{\partial x_n} + \frac{\partial H(t_i)}{\partial t_i} \frac{\partial t_i(x_n)}{\partial x_n} = 0.$$

The above expression can be used to compute the remaining term in (4.14) as

$$\frac{\partial t_i(x_n)}{\partial x_n} = -\left(\frac{\partial H(t_i)}{\partial t_i} \right)^{-1} \frac{\partial H(x_n)}{\partial x_n}, \tag{4.17}$$

where

$$\frac{\partial H(t_i)}{\partial t_i} = -h \cdot \left(\phi'_{\frac{T}{2} - t_i} x_n - y'_{-t_i} \right),$$
$$\frac{\partial H(x_n)}{\partial x_n} = h \cdot \phi_{\frac{T}{2} - t_i},$$

and $h = \begin{bmatrix} 1 & 0 \end{bmatrix}$.

After substituting (4.15), (4.16), and (4.17) into (4.14) we obtain

$$\begin{aligned} (4.18)\quad & \left.\frac{\partial P(x_n,T)}{\partial x_n}\right|_{\substack{x_n=x^* \\ T=T^*}} \\ & = \phi_{\frac{T}{2}^*} \left((I+R) + \frac{\left(R\phi_0' - \phi_0' R\right)\phi_{\frac{T}{2}^*} x^* + \phi_0' R y_0 - R y_0'}{h \cdot \left(\phi'_{\frac{T}{2}^*} x^* - y_0'\right)} \right) \phi_{\frac{T}{2}^*}. \end{aligned}$$

In an analogous way, for the computation of $\frac{\partial P}{\partial T}$, it is essential to take into account the implicit dependence of t_i on x_n and T. Hence, by using implicit differentiation, we have

$$(4.19)\quad \frac{\partial P(x_n,T)}{\partial T} = \frac{\partial P(T)}{\partial T} + \frac{\partial P(t_i)}{\partial t_i}\frac{\partial t_i(T)}{\partial T}.$$

Using (4.11), we can then write

$$\begin{aligned} (4.20)\quad & \frac{\partial P(T)}{\partial T} \\ & = \left(\phi_T' + \frac{1}{2}\phi'_{\frac{T}{2}+t_i} R \phi_{\frac{T}{2}-t_i} + \frac{1}{2}\phi_{\frac{T}{2}+t_i} R \phi'_{\frac{T}{2}-t_i}\right) x_n - \frac{1}{2}\phi'_{\frac{T}{2}+t_i} R y_{-t_i} - \phi_{\frac{T}{2}+t_i} R \frac{\partial y_{-t_i,T}}{\partial T}. \end{aligned}$$

Again, from (4.6) we have

$$\frac{\partial H(x_n, t_i(x_n))}{\partial T} = \frac{\partial H(T)}{\partial T} + \frac{\partial H(t_i)}{\partial t_i}\frac{\partial t_i(T)}{\partial T} = 0,$$

which can be used to compute the remaining term in (4.19). Namely, we obtain

$$(4.21)\quad \frac{\partial t_i(T)}{\partial T} = -\left(\frac{\partial H(t_i)}{\partial t_i}\right)^{-1} \frac{\partial H(T)}{\partial T},$$

where

$$\begin{aligned} \frac{\partial H(t_i)}{\partial t_i} &= -h \cdot \left(\phi'_{\frac{T}{2}-t_i} x_n - y'_{-t_i}\right), \\ \frac{\partial H(T)}{\partial T} &= h \cdot \left(\frac{1}{2}\phi'_{\frac{T}{2}-t_i} x_n - \frac{\partial y_{-t_i,T}}{\partial T}\right), \end{aligned}$$

and

$$\frac{\partial y_{t,T}}{\partial T} = \begin{bmatrix} -\frac{t}{T}c'(t) \\ -\frac{1}{T}c'(t) - \frac{t}{T}c''(t) \end{bmatrix}.$$

Finally, substituting (4.16), (4.20), and (4.21) into (4.19) yields

$$\begin{aligned}(4.22)\quad \left.\frac{\partial P(x_n,T)}{\partial T}\right|_{\substack{x_n=x^*\\T=T^*}} &= \left(\phi'_{T^*}+\frac{1}{2}\phi'_{\frac{T}{2}^*}R\phi_{\frac{T}{2}^*}+\frac{1}{2}\phi_{\frac{T}{2}^*}R\phi'_{\frac{T}{2}^*}\right)x^*-\frac{1}{2}\phi'_{\frac{T}{2}^*}Ry_0-\phi_{\frac{T^*}{2}}R\frac{\partial y_{0,T^*}}{\partial T}\\ &\quad+\phi_{\frac{T}{2}^*}\left(\left(R\phi'_0-\phi'_0R\right)\phi_{\frac{T}{2}^*}x^*+\phi'_0Ry_0-Ry'_0\right)\cdot\frac{h\cdot\left(\frac{1}{2}\phi'_{\frac{T}{2}^*}x^*-\frac{\partial y_{0,T^*}}{\partial T}\right)}{h\cdot\left(\phi'_{\frac{T}{2}^*}x^*-y'_0\right)}.\end{aligned}$$

We can then explicitly compute these quantities for the cam-follower system of interest. In particular, after some algebraic manipulation, we have

$$(4.23)\qquad A:=\frac{\partial P}{\partial x_n}(x^*,T^*)=\phi_{\frac{T}{2}^*}\begin{bmatrix}-r & 0\\ -\frac{(1+r)(2\zeta c'_0+c''_0+\omega_0^2q_d^*)}{q_d'^*-c'_0} & -r\end{bmatrix}\phi_{\frac{T}{2}^*}$$

and

$$\begin{aligned}(4.24)\quad B:=\frac{\partial P}{\partial T}(x^*,T^*)&=\frac{1}{2}\phi_{\frac{T}{2}^*}\begin{bmatrix}q_d^*\\ -rq_d'^*+(1+r)c'_0\end{bmatrix}+\frac{1}{2}\phi'_{\frac{T}{2}^*}\begin{bmatrix}q_d^*\\ -rq_d'^*-\frac{2(1+r)}{T^*}c'_0\end{bmatrix}\\ &\quad+\frac{1}{2}\phi_{\frac{T}{2}^*}\frac{(1+r)q_d'^*}{q_d'^*-c'_0}\begin{bmatrix}q_d'^*-c'_0\\ 2\zeta c'_0+c''_0+\omega_0^2q_d^*\end{bmatrix}.\end{aligned}$$

Note that both the matrices A and B as defined by (4.23)–(4.24) depend on the value of the second derivative of the cam acceleration c''_0 at the impact point. Therefore, the map is actually piecewise-linear locally to the bifurcation point where the cam acceleration is discontinuous; i.e.,

$$c''^-_0:=\lim_{t\to0^-}c''(t)\neq\lim_{t\to0^-}c''(t):=c''^+_0.$$

Then, the local map can be expressed as

$$(4.25)\qquad \delta x_{n+1}=\begin{cases}A^-\delta x_n+B^-\delta T & \text{if } C\cdot\delta x_n+D\cdot\delta T<0,\\ A^+\delta x_n+B^+\delta T & \text{if } C\cdot\delta x_n+D\cdot\delta T>0,\end{cases}$$

where

$$A^\pm=\frac{\partial P^\pm}{\partial x},\quad B^\pm=\frac{\partial P^\pm}{\partial T},$$

with the index $\pm$ indicating whether the matrices are evaluated with $c''_0=c''^-_0$ or $c''_0=c''^+_0$.

We have established that close to the corner-impact bifurcation point, the dynamics of the follower can be studied by means of the local mapping (4.25).

Now, from (4.11), the global Poincaré map is known to be a continuous function of the cam position and velocity through the term y_{-t_i}. Moreover, the map is independent from the

cam acceleration. It follows that the map is continuous at the bifurcation point; i.e., we must have that

$$A^-\delta x_n + B^-\delta T = A^+\delta x_n + B^+\delta T$$

when

$$C\delta x_n + D\delta T = 0.$$

Therefore, we have

$$C = h\cdot(A^+ - A^-) \quad \text{and} \quad D = h\cdot(B^+ - B^-).$$

Substituting the numerical values of the map parameters for the cam-follower system of interest, we obtain the following analytical estimates of the map matrices:

$$A^- = \begin{bmatrix} 0.82093496821478 & 0.01346530915655 \\ 2.52012201452530 & 0.82093496821478 \end{bmatrix},\ B^- = \begin{bmatrix} -51.62757990297 \\ -5455.79455977621 \end{bmatrix},$$

$$A^+ = \begin{bmatrix} 0.68571072072040 & -0.07351052377964 \\ 2.30988433707948 & 0.68571072072040 \end{bmatrix},\ B^+ = \begin{bmatrix} 208.11740649865 \\ -5051.96030903248 \end{bmatrix},$$

and

$$C = [-0.13522424749438\ \ -0.08697583293619],\ D = 259.7449864016200.$$

4.2.1. Numerical validation. We will now validate our numerical findings by comparing the map (4.25), which was derived analytically, with the numerical estimates of the mapping obtained by means of simulation and an optimized fitting algorithm close to the bifurcation point.

To derive such an estimate, we use an accurate event-driven numerical algorithm to simulate the cam dynamics over one period starting from a set of M different initial conditions and parameter values—namely, say, $\delta\bar{x}_n$, the vector of M possible perturbations of x^*, and $\delta\bar{T}$, the vector of M possible perturbations of T. We then simulate the cam dynamics from each of the perturbed initial conditions and parameter values to obtain the vector $\delta\bar{x}_{n+1} = x^* - x_{n+1}$ after one period. We repeat the set of simulations twice, once with the cam acceleration set to $c_0''^+$ and once with the acceleration set to $c_0''^-$. In so doing, we numerically obtain the vectors

$$\delta\bar{x}^{\pm}_{n+1} = \begin{bmatrix} \delta\bar{x}^1_{n+1} & \dots & \delta\bar{x}^m_{n+1} & \dots & \delta\bar{x}^M_{n+1} \end{bmatrix}.$$

We then use a least-squares fitting algorithm to estimate the matrices $\hat{A}^{\pm}$ and $\hat{B}^{\pm}$ that minimize the error

$$e = \left\| \delta\bar{x}^{\pm}_{n+1} - \begin{bmatrix} \hat{A}^{\pm} & | & \hat{B}^{\pm} \end{bmatrix} \begin{bmatrix} \delta\bar{x}_n \\ \delta\bar{T} \end{bmatrix} \right\|^2.$$

The estimated map matrices found using this numerical strategy are

$$\hat{A}^- = \begin{bmatrix} 0.82093497830369 & 0.01346530945739 \\ 2.52012201542191 & 0.82093496286678 \end{bmatrix}, \hat{B}^- = \begin{bmatrix} -51.62757113994 \\ -5455.79411324739 \end{bmatrix},$$

$$\hat{A}^+ = \begin{bmatrix} 0.68571065978423 & -0.07351053029558 \\ 2.30988432418263 & 0.68571073479454 \end{bmatrix}, \hat{B}^+ = \begin{bmatrix} 208.11731732063 \\ -5051.95951604729 \end{bmatrix}.$$

We notice that these numerical estimates are almost identical (up to at least five decimal places) to those obtained analytically earlier in the paper. This validates our analysis and shows the reliability of the analytical derivation used to get a leading order estimate of the Poincaré map close to the bifurcation point under investigation.

4.3. Classification of the nonsmooth bifurcation scenario. We can now use the locally derived map (analytical or numerical) to classify and explain the bifurcation scenario due to the corner-impact bifurcation detected in the cam-follower system of interest. In particular, the map derived above is a piecewise-linear continuous map. As the cam rotational speed is increased, the period T of the forcing provided by the cam varies. Correspondingly, at the corner-impact bifurcation point ($\delta T = 0$), the map fixed point undergoes a border-collision. The Feigin strategy for border-collision bifurcations can then be used to classify the corner-impact bifurcation scenario [13].

The idea is to start by recasting the map (4.25) into a canonical form following the procedure presented in [4]. Specifically, we do the following.

1. We eliminate the term depending on δT by considering an appropriate change of coordinates. In particular, if we say that c_1 and c_2 are the coefficients of C, we choose
$$\delta\tilde{x}_n^1 = \delta x_n^1 + D\frac{\mu}{c_1},$$
$$\delta\tilde{x}_n^2 = \delta x_n^2,$$
so that the map becomes
$$\delta\tilde{x}_{n+1} = \begin{cases} A^-\delta\tilde{x}_n + \tilde{B}\delta T & \text{if } C\cdot\delta\tilde{x}_n < 0, \\ \\ A^+\delta\tilde{x}_n + \tilde{B}\delta T & \text{if } C\cdot\delta\tilde{x}_n > 0, \end{cases}$$
where
$$\tilde{B} = \begin{bmatrix} b_1^- - \frac{a_{11}^-}{c_1}d \\ b_2^- - \frac{a_{21}^-}{c_1}d \end{bmatrix} = \begin{bmatrix} b_1^+ - \frac{a_{11}^+}{c_1}d \\ b_2^+ - \frac{a_{21}^+}{c_1}d \end{bmatrix} = \begin{bmatrix} 1525.26226128059 \\ -615.02768162765 \end{bmatrix},$$
with $a_{ij}^{\pm}$ being the coefficients of $A^{\pm}$.
2. Then, using the strategy presented in [4, 11], we consider the change of coordinates $x = W^{-1}\tilde{x}$, where the matrix W is obtained as $W = T^-O^-$ with
$$O^- = \begin{bmatrix} C \\ CA^- \end{bmatrix}, \; T^- = \begin{bmatrix} 1 & 0 \\ d_1^- & 1 \end{bmatrix},$$
where d_1^- is the linear coefficient of the characteristic polynomial of A^- given by $p^-(\lambda) = \lambda^2 + d_1^-\lambda + d_2^-$. Applying such a similarity transformation, the map matrices become
$$\bar{A}^- = \begin{bmatrix} 1.64186993642956 & 1 \\ -0.64 & 0 \end{bmatrix}, \; \bar{A}^+ = \begin{bmatrix} 1.37142144144080 & 1 \\ -0.64 & 0 \end{bmatrix},$$
and
$$\bar{B} = \begin{bmatrix} 152.75990 \\ 207,79599 \end{bmatrix}, \qquad \bar{C} = \begin{bmatrix} 1 & 0 \end{bmatrix}.$$

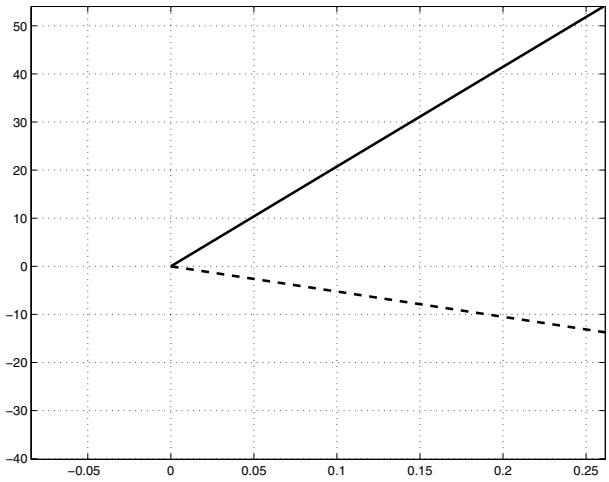

Figure 8. *Numerical bifurcation diagram of the local map* (4.25) *with the analytically estimated matrices. The border-collision when* $\delta T = 0$ *corresponds to the corner-impact bifurcation point at* $\omega \approx 673.2$ *rpm. Note that as predicted a nonsmooth fold scenario is observed with no fixed point existing for* $\delta T < 0$ *and two coexisting fixed points, one stable and the other unstable for* $\delta T > 0$.

As explained in [13, 4], we can now classify the type of bifurcation scenario observed at the bifurcation point under investigation by computing the map eigenvalues on both sides of the boundary. For the case under investigation, we have that (i) the eigenvalues of A^- are $\lambda_1^- = 1.0052$ and $\lambda_2^- = 0.6367$; (ii) the eigenvalues of A^+ are $\lambda_{1,2}^+ = 0.6857 \pm \mathbf{j}0.4120$. Hence, according to Feigin's classification strategy, since the total number of real eigenvalues greater than unity on both sides of the boundary is odd, the bifurcating fixed point will undergo a nonsmooth saddle node bifurcation and will cease to exist [13]. This is in perfect agreement with what is observed numerically in the local bifurcation scenario in the map in Figure 8.

Therefore, we can explain the sudden transition to chaos observed in the cam-follower system under investigation as due to the occurrence of a corner-impact bifurcation. Namely, the corner-impact is associated to a nonsmooth-fold scenario causing the disappearance of the stable impacting solution undergoing the bifurcation. This causes trajectories to leave the local neighborhood where they are confined before the bifurcation and converge toward the stable coexisting chaotic attractor when ω is decreased below the corner-impact bifurcation point.

Hence, we can conclude that corner-impact bifurcations in cam-follower systems can indeed lead to dramatic changes of the system qualitative behavior including sudden transitions from periodic solutions to chaos.

5. Conclusions.

We have studied a novel type of discontinuity-induced bifurcation in a class of mechanical devices widely used in applications: cam-follower systems. Using a representative second order model of the follower, we have shown that its dynamics can undergo several bifurcations including sudden transitions to chaos as the cam rotational speed is varied. We analyzed in detail the corner-impact bifurcation of a one-periodic solution characterized by one impact per period. In particular, we observed that the system's behavior undergoes dra-

matic changes when the impact occurs at a point where the cam profile is discontinuous. Using the concept of discontinuity mappings, we analytically derived the Poincaré map associated to the bifurcating orbit in the case where the cam profile has a discontinuous acceleration. Then, using the classification strategy for border-collision bifurcations, we proved that the corner-impact causes the fixed point associated to the bifurcating orbit to undergo a nonsmooth saddle node bifurcation. Namely, the fixed point ceases to exist, with the trajectories being attracted toward a chaotic invariant set.

We wish to emphasize the following.

- The analysis presented above applies with minor changes to the case of impact oscillators forced by signals with discontinuous second derivative. As shown above, this leads to maps which are locally piecewise-linear continuous close to a corner-impact bifurcation point. This extends the analysis presented in [8] for the case of an impact oscillator forced by a function with discontinuous first derivative. We conjecture that the properties of the local mapping depend on the degree of discontinuity of the forcing signal. This is the subject of ongoing work.
- As shown in [12], discontinuity-induced bifurcations in flows are usually associated to maps which are not piecewise-linear. Grazing bifurcations of limit cycles are known to be associated to maps with square-root singularities in impacting systems and Filippov systems [26] or maps with higher order nonlinear terms in the case of piecewise-smooth continuous (PWSC) flows. The only cases in the literature where the map was indeed found to be piecewise-linear continuous were corner-collisions in PWSC systems and grazing sliding bifurcations in Filippov systems. So far, no evidence was given of a bifurcation event in impacting systems associated to locally piecewise-linear continuous maps. The corner-impact bifurcation scenario presented in this paper fills this gap in the literature.
- We believe cam-follower systems are a particularly useful set-up to show generically the behavior of impacting systems with discontinuous forcing.

Finally, the results presented here can pave the way to future work toward a better understanding of the complex dynamics of cam-follower systems. This can lead to less conservative solutions to detachment avoidance, hopefully without resorting to highly stiff closing springs, and maybe active control strategies.

Appendix A. Cam profile. We report below the analytical description of the representative cam profile considered in this paper. As shown in Figure 9, in this case the cam profile is the result of a geometrically based design.

The lift profile $c(\theta)$ can be defined from the construction as a piecewise-smooth function of the angle θ as

$$c(\theta) = \begin{cases} c_0(\theta) & \text{if } 0 < \theta \le \frac{\pi}{2} - \theta_1, \\ c_1(\theta) & \text{if } \frac{\pi}{2} - \theta_1 < \theta \le \frac{\pi}{2} - \theta_2, \\ c_2(\theta) & \text{if } \frac{\pi}{2} - \theta_2 < \theta \le \frac{\pi}{2} - \theta_3, \\ c_3(\theta) & \text{if } \frac{\pi}{2} - \theta_3 < \theta \le \pi, \end{cases} \tag{A.1}$$

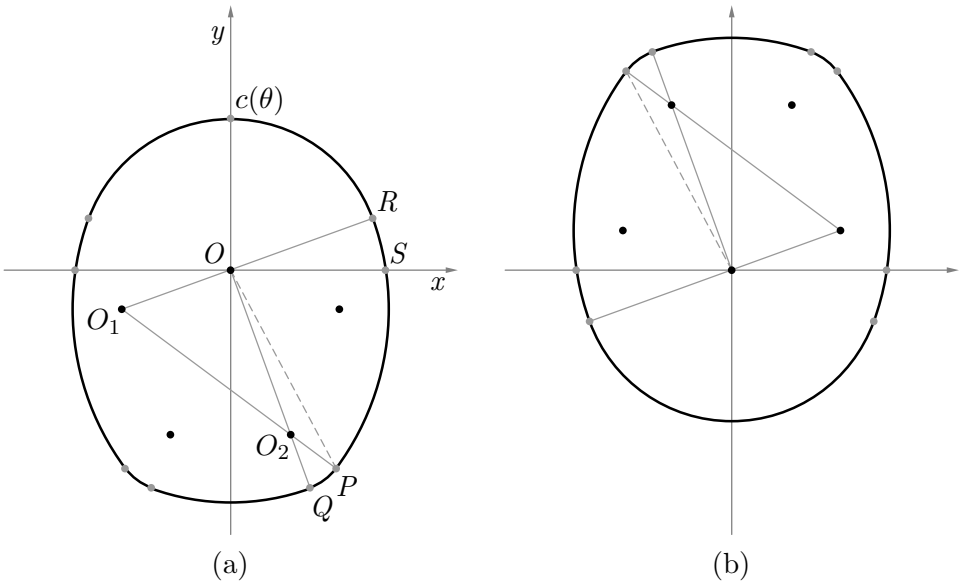

Figure 9. *Cam profile definition.* (a) $\theta = 0$. (b) $\theta = \pi$.

$$
\begin{aligned}
c_0(\theta) &= \rho_0,\\
c_1(\theta) &= -\kappa_1 \sin(\theta + \theta_1) + (\rho_1^2 - \kappa_1^2 \cos(\theta + \theta_1)^2)^{\frac{1}{2}},\\
c_2(\theta) &= \kappa_2 \sin(\theta + \theta_3) + (\rho_2^2 - \kappa_2^2 \cos(\theta + \theta_3)^2)^{\frac{1}{2}},\\
c_3(\theta) &= \rho_3,
\end{aligned}
$$

where $\theta_1 = \angle SOR$, $\theta_2 = \angle SOP$, and $\theta_3 = \angle SOQ$. Additionally, κ_i and ρ_i are constant parameters given by our particular geometrical construction of the cam as (see Figure 9)

$$
\begin{aligned}
\kappa_1 &= \|\overline{OO_1}\|, \quad \rho_0 = \|\overline{OR}\|, \quad \rho_2 = \|\overline{O_2P}\|,\\
\kappa_2 &= \|\overline{OO_2}\|, \quad \rho_1 = \|\overline{O_1R}\|, \quad \rho_3 = \|\overline{OQ}\|.
\end{aligned} \tag{A.2}
$$

Quantitative Characteristic of Rotating Stall and Surge for Moore–Greitzer PDE Model of an Axial Flow Compressor*

MingQing Xiao†

Abstract. A commonly used mathematical model for axial flow compressors that captures the flow behavior of a compression system, known as the Moore–Greitzer model, consists of a PDE and two ODEs. The PDE describes the dynamical behavior of disturbances in the inlet region of the compression system, and the two ODEs describe the coupling of the disturbances with the mean flow. In this paper, we obtain a quantitative characteristic Δ, depending on the compressor geometry, to identify the type of oscillations of the system. More specifically, the sign of Δ indicates the physical oscillations predominated by rotating stall or by surge. In mathematical terminology, these three types of oscillations are distinctive Hopf bifurcations occurring in the system as the throttle coefficient decreases, and they present quite different dynamical behaviors in axial engine compressors. Estimations of oscillation frequencies corresponding to surge and rotating stall, respectively, are also given in the paper. Numerical simulations are provided to demonstrate different types of flow oscillation of the system.

Key words. Moore–Greitzer PDE model, axial flow compressors, rotating stall and surge, Hopf bifurcations

1. Introduction.

The problem of compressor instability has been studied for many years because engine efficiency could be reduced significantly by rotating stall and surge (e.g., [14], [12], [9], and references therein). Rotating stall, which corresponds to a traveling wave of gas around the annulus of the compressor, occurs when a nonaxisymmetric flow disturbance develops (around the annulus of the rotor) and causes a drastic reduction in the performance of the compressor. On the other hand, surge is an axisymmetric oscillation across the compression system. It is a low-frequency, large-amplitude oscillation of the mean flow rate in the compressor which induces a high blade, causing stress levels and possibly reversed flow which affects flow conditions throughout the entire compression system. Such instability phenomena can damage engine components during operations.

Moore and Greitzer [14] developed a relatively simple model that captures the dynamical behavior of a compression system. This model consists of a PDE, which describes the behavior of disturbances in the inlet region of compression systems, and two ODEs, which describe the coupling of the disturbances with the mean flow. Considerable research has been carried out on the analysis and control of the stall and the surge, using simplified models obtained by a Galerkin projection of the PDE describing the stall dynamics onto its *first* or *first several Fourier models* (for example, see [12], [10], [2], [11], [19], and references therein), but relatively

little research has been conducted heretofore on the analysis of the full PDE model. Although the single harmonic Galerkin method is a useful approximation for general transients and provides a correct picture of the nonlinear effect of rotating stall on performances, it cannot accurately represent a wave of the relaxation type of transition which arises in fully developed rotating stall. Experimental observations of the behavior of disturbance velocity potential in compression systems indicate that its shape is often far from being sinusoidal [14]. Recently studies on the analysis (and control) of the full PDE model of Moore and Greitzer, mainly focusing on low-speed compressors, were conducted by Banaszuk, Hauksson, and Mezić [3], Birnir and Hauksson [4], [5], [6], Chung and Titi [1], Xiao and Başar [18], [20], and Xiao [17].

To the best of our knowledge, currently there is no quantitative criteria available in the literature for identifying which type of flow oscillations, such as rotating stall or surge, will predominate the dynamics in the analysis and control of the full Moore–Greitzer model. As Moore and Greitzer point out in [14], these two types of oscillations differ fundamentally in that the flow dominated by stall is nonaxisymmetric, while the flow dominated by surge is symmetric. Moreover, from the point of view of control, surge is linearly controllable and rotating stall is not linearly controllable (by the throttle coefficient). Thus the control strategies for these two types of oscillations need considerably different methodologies. This motivates us to look for a quantitative criterion which can identify the different types of oscillations occurring inside a compressor.

In this paper we provide a useful indicator Δ which depends on the geometric structure of a compressor and is computable from the parameters of the system for a given axial flow engine compressor. The sign of Δ predicts which type of oscillations will develop and ultimately predominate the dynamical behavior of the system. Let us first recall the stability analysis of nonlinear evolution equations in a Banach space by studying its linearized system. Consider Cauchy problems of form

$$\dot{x} = Ax + f(x), \qquad x(0) = x_0, \tag{1.1}$$

where $x(t)$ takes values in a Banach space $(X, \|\cdot\|)$, A generates a continuous semigroup on X, f is Fréchet differentiable, with Fréchet derivative df, and the mapping $x \to df_x$ is continuous from X to $\mathcal{L}(X)$ ($\mathcal{L}(X)$ is the space of linear maps of X onto itself with the usual norm-topology). Let $x_e \in X$ be an equilibrium solution; that is, x_e is a steady solution of $Ax + f(x) = 0$. x_e is said to be locally exponentially asymptotically stable if there is a neighborhood N of x_e and positive numbers c, α such that if x is a solution of (1.1) with $x(0) \in N$, then $x(t)$ exists for all $t > 0$ and

$$\|x(t) - x_e\| \le ce^{-\alpha t}\|x(0) - x_e\|, \qquad t > 0. \tag{1.2}$$

Now we consider the linearized system of (1.1) at the equilibrium x_e:

$$\dot{x} = Ax + df_{x_e}(x), \qquad x(0) = x_0. \tag{1.3}$$

It is known that if $A + df_{x_e}$ generates a compact C_0 semigroup $S(t)$ for $t > 0$, then the spectrum of $A + df_{x_e}$ consists solely of a point spectrum (e.g., see [15]). In this case x_e is asymptotically stable if and only if there exists an $\alpha < 0$ such that the eigenvalues of $A + df_{x_e}$

lie in the half-space $\operatorname{Re} z \leq \alpha$. The connection of stability between (1.1) and (1.3) in this case is given by Smoller [16] as follows: if x_e is an asymptotically stable solution of (1.3), then x_e is also a locally asymptotically stable solution of (1.1). Thus the stability of the system around x_e will be determined by the eigenvalues of $A + df_{x_e}$ provided that the real parts of all eigenvalues are nonzero. Although when some real parts of the eigenvalues become zero, $A+df_{x_e}$ is not able to provide any stability information, and other methods such as the center manifold approach or the averaging integral method must be employed to study the nonlinear effect in order to determine the stability of the system [20]; however, for the Hopf bifurcation case, $A + df_{x_e}$ still offers us the information of periods of bifurcating closed orbits, which are useful for the study of oscillations of the system.

The axial flow engine compressor PDE model, also called the Moore–Greitzer PDE model, can be put into an abstract evolution form,

$$\dot{x} = Ax + f(\mu, x), \qquad x(0) = x_0, \tag{1.4}$$

in an infinite-dimensional Hilbert space H, where μ is a real parameter varied in $(0, \infty)$. Both equilibrium solutions and the spectrum of $A + df_{x_e}(\mu)$ depend on the parameter μ. As μ decreases, the spectrum of $A + df_{x_e}(\mu)$ moves from the left half plane to the right half plane, which results in an oscillation of the system. In this paper we provide a quantitative criterion which can identify three different types of Hopf bifurcations by checking $\Delta > 0$, or $\Delta < 0$, or $\Delta = 0$. These three types of Hopf bifurcations correspond to the occurrence of three types of physical oscillations predominated by surge, or rotating stall, or a mixture of both. Estimations of oscillation frequencies corresponding to surge and rotating stall, respectively, are also provided in the paper.

2. Axial flow engine compressor model. The basic compression system is shown in Figure 1. It consists of an inlet duct, a compressor, a downstream duct, a plenum, and a throttle. The compressor operates between the inlet duct and the downstream duct. The flow enters the compressor from the inlet duct and exits into the plenum through the downstream duct. The throttle controls the flow through the system at the plenum exit in order to model the turbine. The compressor geometry is shown in Figure 2. Variable ϕ in Figure 1 represents the local, unsteady axial velocity at the compressor face, which depends on both the angle θ around the wheel and (dimensionless) time $\xi = t$. Ψ is the pressure in the plenum, which is defined as

$$\Psi := \frac{\text{exit static pressure} - \text{inlet total pressure}}{\text{density} \times \text{mean rotary speed}^2}.$$

The annulus-averaged axial flow coefficient Φ of ϕ around the wheel is defined as

$$\Phi(t) := \frac{1}{2\pi} \int_0^{2\pi} \phi(\theta, t) d\theta.$$

The model consists of three states, Φ, Ψ, and g, where $\Phi = \Phi(t)$ is the annulus-averaged axial flow coefficient, and $\Psi = \Psi(t)$ is the annulus-averaged total-to-static pressure rise coefficient. We denote $\phi(t, \theta, \eta)$ as the upstream disturbance velocity at any point (θ, η) of the compressor, where η represents the position along the axial direction of the compressor. Let

$$g = \phi_\eta|_{\eta=0},$$

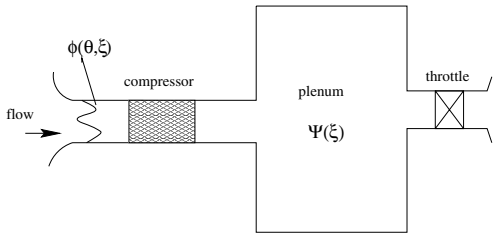

Figure 1. *An outline of a compression system.*

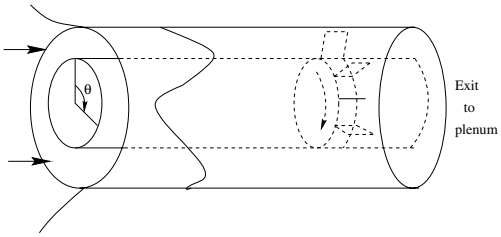

Figure 2. *Compressor geometry.*

which represents the derivative of the upstream disturbance velocity with respect to η at the duct entrance $\eta = 0$. The free variables in the system are t and θ, where t is the dimensionless time variable, and θ is the circumferential angle around the compressor annulus. Before the flow enters the duct, the upstream disturbance velocity ϕ satisfies the Laplace equation,

$$\phi_{\theta\theta} + \phi_{\eta\eta} = 0, \quad (\theta, \eta) \in [0, 2\pi] \times (-\infty, 0), \tag{2.1}$$

and $\phi \equiv 0$ at $\eta = -\infty$. At the duct entrance, we denote $\phi_\eta|_{\eta=0} = g$ and the pressure rise coefficient satisfies

$$\Psi(t) = \psi_c(\Phi + g) - l_c\tfrac{d\Phi}{dt} - \tfrac{\partial}{\partial t}(m\phi + \tfrac{1}{a}g) + \tfrac{1}{2a}g_\theta - \tfrac{\nu}{2a}g_{\theta\theta}, \tag{2.2}$$

where ψ_c is the characteristic function of the compressor, which will be given later; m is the duct parameter; a is the internal compressor lag; l_c is the length of the compressor; and ν is the viscous coefficient. By computing the circumferential mean of boundary condition (2.2), the annulus-averaged axial flow coefficient Φ has a dynamics in the form of

$$l_c\frac{d\Phi}{dt} = -\Psi + \frac{1}{2\pi}\int_0^{2\pi} \psi_c(\Phi + g)d\theta, \tag{2.3}$$

which describes the change of mass flow through the compressor. The annulus-averaged total-to-static pressure rise coefficient Ψ satisfies the pressure-balance equation

$$l_c\frac{d\Psi}{dt} = \frac{1}{4B^2}(\Phi - \mu\sqrt{\Psi}), \tag{2.4}$$

where B is the plenum/compressor volume ratio, which is called the Greitzer B-parameter, and μ is the throttle coefficient, which is used to control the mass flow through the throttle.

It accounts for dynamic pressure changes downstream of the compressor exit, in the plenum and across the throttle.

The compressor characteristic is an inherent feature of the compressor and has a cubic form in terms of Φ (see [14]), as shown in Figure 3,

$$\psi_c(\Phi) = \psi_{c_0} + H\left[1 + \frac{3}{2}\left(\frac{\Phi}{W} - 1\right) - \frac{1}{2}\left(\frac{\Phi}{W} - 1\right)^3\right], \tag{2.5}$$

where $\psi_{c_0} > 0$ is the shut-off value parameter, $H > 0$ is the semiheight parameter, and $W > 0$ is the semiwidth parameter.

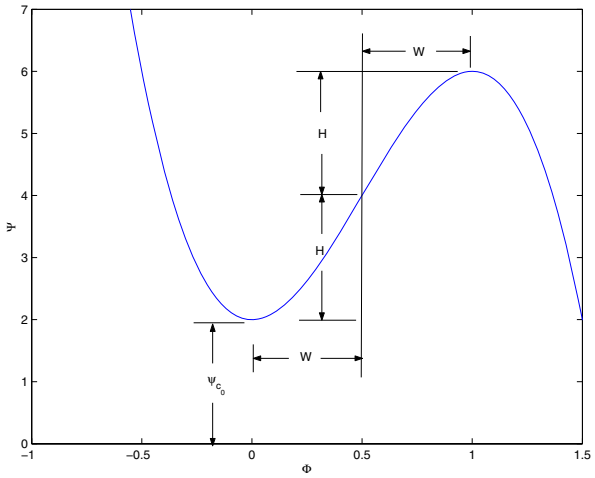

Figure 3. *Notation used in the definition of compressor characteristic with* $w = 0.5$, *and* $H = \psi_{c_0} = 2$.

The throttle characteristic is defined to be

$$\Phi = \mu\sqrt{\Psi}, \tag{2.6}$$

which characterizes the mass flow through the throttle, where $\mu > 0$ is the throttle coefficient which controls the flow through the throttle. When μ is changed from small to large, it implies that the throttle is being opened up and more flow is leaving the plenum (see Figure 1).

Let us denote the intersection of the compressor characteristic $\Psi = \psi_c(\Phi)$ and throttle characteristic $\Phi = \mu\sqrt{\Psi}$ by $(\phi_e(\mu), \psi_e(\mu))$ (see Figure 4). Then $(0, \phi_e(\mu), \psi_e(\mu))$ is called an unstalled or nominal equilibrium point of (2.2)–(2.4).

The viscous coefficient ν usually is small in axial flow engine compression systems; thus throughout this paper we assume[1]

$$\frac{\nu W}{3aH} \leq 1. \tag{2.7}$$

[1]If $\frac{\nu W}{3aH} > 1$, then the system becomes less interesting, since in this case surge will always become predominant.

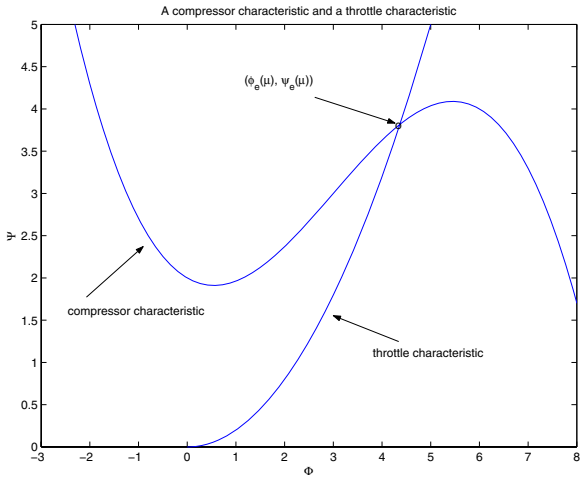

Figure 4. *Notation used in the definition of a nominal equilibrium point.*

This assumption implies that the slope of $\Psi = \psi_c(\Phi)$ at the reflection point $\Phi = W$ is not smaller than $\frac{\nu}{2a}$. This can be seen by observing

$$\frac{\nu}{2a} \leq \frac{3H}{2W} = \psi_c'(W).$$

3. Main results.

Theorem 3.1.

1. *When the throttle coefficient* $\mu \geq \frac{2W}{\sqrt{2H+\psi_{c_0}}}$, *the state* $(g(t,\theta), \Phi(t), \Psi(t))$ *governed by* (2.2)–(2.4) *is locally asymptotically stable and as* $t \to +\infty$

$$\int_0^{2\pi} |g(t,\theta)|^2 \, d\theta \to 0, \qquad \Phi(t) \to \phi_e(\mu), \qquad \Psi(t) \to \psi_e(\mu).$$

2. *Suppose* $\frac{\nu W}{3aH} \leq 1$. *Let*

$$\Delta = \frac{\psi_{c_0} + H\left[1 + \frac{3}{2}\sqrt{1-\frac{\nu W}{3aH}} - \frac{1}{2}\left(\sqrt{1-\frac{\nu W}{3aH}}\right)^3\right]}{W\left(1+\sqrt{1-\frac{\nu W}{3aH}}\right)} - \frac{a}{4B^2\nu}. \tag{3.1}$$

Then, as the throttle coefficient μ *is decreasing, oscillations inside the compressor occur. If* $\Delta > 0$, *the frequency of the flow oscillation is smaller than* $1/(4\sqrt{2}\pi B l_c)$ *(i.e., the flow oscillation is predominated by surge). While* $\Delta < 0$, *the frequency of the flow oscillation is greater than* $1/\left(4\pi\left(\frac{3aH}{\nu W} + am\right)\right)$ *(i.e., the oscillation is predominated by rotating stall). When* $\Delta = 0$ *a motion composed of the above two types of oscillations is expected.*

The above main theorem implies that the sign of

$$\Delta = \frac{\psi_{c_0} + H\left[1 + \frac{3}{2}\sqrt{1 - \frac{\nu W}{3aH}} - \frac{1}{2}\left(\sqrt{1 - \frac{\nu W}{3aH}}\right)^3\right]}{W\left(1 + \sqrt{1 - \frac{\nu W}{3aH}}\right)} - \frac{a}{4B^2\nu}$$

describes how the spectrum moves across the imaginary axis. The quantity Δ depends on the geometry structure (parameters W, H, a, ψ_{c_0}, B) of the axial flow compressor system as well as the viscous coefficient ν. An important observation for Δ is that it can also be written as

$$\Delta = \frac{\psi_e^{(\nu)}}{\phi_e^{(\nu)}} - \frac{a}{4B^2\nu},$$

where

$$\phi_e^{(\nu)} := W\left(1 + \sqrt{1 - \frac{\nu W}{3aH}}\right), \qquad \psi_e^{(\nu)} = \psi_c\left(\phi_e^{(\nu)}\right),$$

and, according to the definition of the compressor characteristic ψ_c, one can see that

$$\psi_e^{(\nu)} := \psi_c\left(\phi_e^{(\nu)}\right) = \psi_{c_0} + H\left[1 + \frac{3}{2}\sqrt{1 - \frac{\nu W}{3aH}} - \frac{1}{2}\left(\sqrt{1 - \frac{\nu W}{3aH}}\right)^3\right].$$

Thus the sign of Δ implies the relationship between two quantities: the slope of the line segment through two points $(\phi_e^{(\nu)}, \psi_e^{(\nu)})$, $(0,0)$ and the fraction $\frac{a}{4B^2\nu}$. For the high speed compressor, parameter B (the plenum/compressor volume ratio) is large, which leads to $\Delta > 0$ in most cases. In this case we shall show that a pair of eigenvalues $\gamma_{\pm 1}$ crosses the imaginary axis with nonzero speed, and a Hopf bifurcation occurs at $\mu = \hat{\mu}$ according to the Hopf bifurcation theorem (see, for example, [7], [8]). Experiments show that for a high-speed compressor there is often a low frequency with large-amplitude flow oscillation through the compressor, which is called *surge*, and it can induce vibrations in other components of the compression system, such as connected piping. On the other hand, for the low-speed compressor, B is small and usually leads to $\Delta < 0$. In this case another pair of eigenvalues $\lambda_{\pm 1}$ crosses the imaginary axis with nonzero speed, and the compressor will enter another type of high-frequency oscillation, called *rotating stall* from the experiments. Thus the sign of Δ is a quantitative criterion for identifying the dynamics predominated by surge or by rotating stall. If $\Delta = 0$, the dynamics of the system becomes even more complicated at $\mu = \mu_\nu$ since two Hopf bifurcations appear simultaneously, as two pairs of eigenvalues $\lambda_{\pm 1}$ and $\gamma_{\pm 1}$ cross the imaginary axis with nonzero speed, and in such a case a mixed type of oscillation takes place. Therefore, Δ predicts the system dynamics as the throttle of the plenum is being closed (μ is reduced). We will provide details in the following sections.

3.1. Abstract formulation. Let $\dot{L}^2(0, 2\pi)$ be the space of all square integrable 2π-periodic complex-valued functions with zero average, that is,

$$\int_0^{2\pi} \phi(\theta) d\theta = 0$$

for any $\phi \in \dot{L}^2(0,2\pi)$. Note that for any $\phi \in \dot{L}^2(0,2\pi)$, its Fourier series is given by

$$\phi(\theta) = \sum_{n\in\mathbf{Z}\setminus\{0\}} \phi_n e^{in\theta}, \quad \text{where} \quad \phi_n = \int_0^{2\pi} \phi(\theta) e^{-in\theta} d\theta,$$

where $\mathbf{Z}$ stands for the set of all integers. Boundary condition $\phi = 0$ at $\eta = -\infty$ implies that Laplace's equation (2.1) has a solution of the form

$$\phi(t,\theta,\eta) = \sum_{n\in\mathbf{Z}\setminus\{0\}} \phi_n(t) e^{|n|\eta + in\theta}.$$

We define the flow disturbance at the compressor face to be $g := \phi_\eta|_{\eta=0}$; it thus can be written as

$$g(t,\theta) = \sum_{n\in\mathbf{Z}\setminus\{0\}} |n| g_n e^{in\theta}.$$

We next introduce a linear operator $\Pi : \dot{L}^2(0,2\pi) \to \dot{L}^2(0,2\pi)$ by

$$\Pi(\phi) = \sum_{n\in\mathbf{Z}\setminus\{0\}} \left\{1 + \frac{am}{|n|}\right\} \phi_n e^{in\theta}$$

for any $\phi = \sum_{n\in\mathbf{Z}\setminus\{0\}} \phi_n e^{in\cdot} \in \dot{L}^2(0,2\pi)$. It is not difficult to see that Π is a positive definite, self-adjoint linear operator on $\dot{L}^2(0,2\pi)$. Thus

$$\langle \phi, \psi \rangle_\Pi := \langle \phi, \Pi\psi \rangle_{L^2(0,2\pi)}$$

defines an equivalent inner product on $\dot{L}^2(0,2\pi)$, and we denote by $\dot{L}^2_\Pi(0,2\pi)$ the space which consists of elements of $\dot{L}^2(0,2\pi)$ with inner product $\langle\cdot,\cdot\rangle_\Pi$. By using the operator Π, (2.2) can equivalently be written as

$$\frac{\partial g}{\partial t} = \Pi^{-1}\left(\frac{\nu}{2}\frac{\partial^2 g(t,\theta)}{\partial\theta^2} - \frac{1}{2}\frac{\partial g(t,\theta)}{\partial\theta}\right) + a\Pi^{-1}\left(\psi_c(\Phi(t)+g(t,\theta)) - \frac{1}{2\pi}\int_0^{2\pi} \psi_c(\Phi(t)+g(t,\theta))d\theta\right).$$

Let $X = L^2_\Pi(0,2\pi)\times\mathbb{R}\times\mathbb{R}$, with inner product

$$\langle x_1, x_2\rangle = a^{-1}\langle g_1, g_2\rangle_{\dot{L}^2_\Pi(0,2\pi)} + l_c\Phi_1\Phi_2 + (4l_cB^2)\Psi_1\Psi_2, \tag{3.2}$$

where $x_i = (g_i, \Phi_i, \Psi_i)^T \in X$, $i = 1,2$, and let the norm on this space be defined by $\|x\| := \sqrt{\langle x, x\rangle}$ for $x \in X$. The system defined by (2.2), (2.3), and (2.4) can thus be written as

$$\frac{\partial}{\partial t}\begin{bmatrix} g \\ \Phi \\ \Psi \end{bmatrix} = \begin{bmatrix} \Pi^{-1}\left(\frac{\nu}{2}\frac{\partial^2}{\partial\theta^2} - \frac{1}{2}\frac{\partial}{\partial\theta}\right) & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}\begin{bmatrix} g \\ \Phi \\ \Psi \end{bmatrix} + \begin{bmatrix} a\Pi^{-1}(\psi_c(\Phi+g) + \overline{\psi}_c) \\ \frac{1}{l_c}(\overline{\psi}_c - \Psi) \\ \frac{1}{4l_cB^2}(\Phi - \mu\sqrt{\Psi}) \end{bmatrix}, \tag{3.3}$$

where

$$\overline{\psi}_c = \frac{1}{2\pi}\int_0^{2\pi} \psi_c(\Phi+g)d\theta,$$

or in an evolution form of

$$\frac{dx}{dt} = Ax + f(\mu, x), \tag{3.4}$$

where $x = (g, \Phi, \Psi)^T$ and the linear operator A is defined by

$$A = \begin{bmatrix} \Pi^{-1}\left(\frac{\nu}{2}\frac{\partial^2}{\partial\theta^2} - \frac{1}{2}\frac{\partial}{\partial\theta}\right) & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \tag{3.5}$$

with

$$D(A) = \left\{ x \in X \;\middle|\; \frac{\partial g}{\partial\theta}, \frac{\partial^2 g}{\partial\theta^2} \in \dot{L}^2_\Pi(0, 2\pi), \text{ and } g(0) = g(2\pi), \text{ where } x = (g, \Phi, \Psi)^T \in X \right\},$$

and the function $f(\mu, x)$ is defined to be

$$f(\mu, x) = \begin{bmatrix} a\Pi^{-1}\left(\psi_c(\Psi - g) - \overline{\psi}_c\right) \\ \frac{1}{l_c}(\overline{\psi}_c - \Psi) \\ \frac{1}{4l_cB^2}(\Phi - \mu\sqrt{\Psi}) \end{bmatrix},$$

where $x = (g, \Phi, \Psi)^T$.

Remark. When we study (3.4), all parameters such as B, l_c, a, ν, W, H, and ψ_{c_0} are fixed except the throttle coefficient μ, which is varied in $(0, \infty)$.

We will show the main result through a sequence of lemmas.

Lemma 3.1. *The operator A defined in (3.5) is the infinitesimal generator of an analytic compact C_0 semigroup on X.*

Proof of Lemma 3.1 is provided in the appendix. We would like to point out here that Chung and Titi provide a detailed discussion of the analyticity of the solution of (3.4) by establishing Geverey regularity of the system [1]. Their main purpose is to show the existence of a global invariant manifold; thus some subtle technique has to be applied to deal with the term $\sqrt{\Psi}$ since it is not an analytic function near $\Psi = 0$. In this paper we focus on local dynamics of the systems since in reality small perturbations occur more often. Lemma 3.1 can lead to local analyticity of the solution without heavy exposition of other mathematical tools.

A direct calculation gives the following.

Lemma 3.2. *The Fréchet derivative of $f(\mu, x)$ at $x_e(\mu) = (0, \phi_e(\mu), \psi_e(\mu))$ is*

$$df_{x_e}(\mu) = \begin{bmatrix} a\Pi^{-1}\left(\psi_c'(\phi_e(\mu)) - \overline{\psi}_c{}'\right) & 0 & 0 \\ \frac{1}{l_c}\overline{\psi}_c{}' & \frac{1}{l_c}\overline{\psi}_c{}' & -\frac{1}{l_c} \\ 0 & \frac{1}{4l_cB^2} & -\frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e(\mu)}} \end{bmatrix}, \tag{3.6}$$

where ψ_c' and $\overline{\psi}_c'$ are the Fréchet derivatives of ψ_c and $\overline{\psi}_c$, respectively, at x, and for any $x = (g, \Phi, \Psi) \in X$

$$df_{x_e}(\mu)(x) = \begin{bmatrix} a\Pi^{-1}\left(\psi_c'(\phi_e(\mu))g\right) \\ \frac{1}{l_c}\left(\psi_c'(\phi_e(\mu))\Phi - \Psi\right) \\ \frac{1}{4l_cB^2}\left(\Phi - \frac{\mu\Psi}{2\sqrt{\psi_e(\mu)}}\right) \end{bmatrix}. \tag{3.7}$$

Notice that $df_{x_e}(\mu)$ is a bounded operator on X. According to Proposition 3.1.4 and Corollary 3.2.2 of [15], we have the following lemma.

Lemma 3.3. *$A+df_{x_e}(\mu)$ is the infinitesimal generator of an analytic compact C_0 semigroup on X.*

Lemma 3.4 implies that the eigenvalues of $A + df_{x_e}(\mu)$ will determine the stability of the system around the equilibrium point x_e if their real parts are not equal to zero, according to the discussion given in section 1.

Lemma 3.4. *The point spectrum of $A + df_{x_e}(\mu)$ is given by*

$$\sigma\left(A + df_{x_e}(\mu)\right) = \{\gamma_{\pm1}(\mu), \lambda_n(\mu),\ n = \pm1, \pm2, \dots\},$$

where

$$\lambda_n(\mu) = \frac{a|n|}{|n| + am}\left(\psi_c'\left(\phi_e\right) - \frac{\nu}{2a}n^2 - \frac{1}{2a}ni\right), \tag{3.8}$$

and

$$\gamma_{\pm1}(\mu) = \frac{\frac{1}{l_c}\psi_c'(\phi_e) - \frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}} \pm \sqrt{\left(\frac{1}{l_c}\psi_c'(\phi_e) - \frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}}\right)^2 + \frac{\psi_c'(\phi_e)}{l_c^2B^2}\frac{\mu}{2\sqrt{\psi_e}} - \frac{1}{l_c^2B^2}}}{2}, \tag{3.9}$$

where (ϕ_e, ψ_e) satisfies $\phi_e = \psi_c(\phi_e)$, $\phi_e = \mu\sqrt{\psi_e}$. The eigenvector corresponding to $\lambda_n(\mu)$ is given by $\vec{v}_n = (e^{in\theta}, 0, 0)$.

Proof. Recall that

$$A + df_{x_e}(\mu) = \begin{bmatrix} \Pi^{-1}\left(\frac{\nu}{2}\frac{\partial^2}{\partial\theta^2} - \frac{1}{2}\frac{\partial}{\partial\theta}\right) + a\Pi^{-1}\left(\psi_c' - \overline{\psi}_c{}'\right) & 0 & 0 \\ \frac{1}{l_c}\overline{\psi}_c{}' & \frac{1}{l_c}\overline{\psi}_c{}' & -\frac{1}{l_c} \\ 0 & \frac{1}{4l_cB^2} & -\frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}} \end{bmatrix} \tag{3.10}$$

with

$$D(A+df_{x_e}(\mu)) = \left\{x \in X \mid \frac{\partial g}{\partial\theta}, \frac{\partial^2 g}{\partial\theta^2} \in \dot{L}^2_\Pi(0, 2\pi), \text{ and } g(0) = g(2\pi), \text{ where } x = (g, \Phi, \Psi)^T \in X\right\}.$$

In order to obtain the eigenvalues and eigenvectors, we need to solve the boundary value problem

$$\Pi^{-1}\left(\frac{\nu}{2}\frac{\partial^2 v^{(1)}(\theta)}{\partial\theta^2} - \frac{1}{2}\frac{\partial v^{(1)}(\theta)}{\partial\theta}\right) + a\Pi^{-1}\psi_c' v^{(1)}(\theta) = \lambda v^{(1)}(\theta), \tag{3.11}$$

$$\frac{1}{l_c}\psi_c'(\phi_e)v^{(2)} - \frac{1}{l_c}v^{(3)} = \lambda v^{(2)}, \tag{3.12}$$

$$\frac{1}{4l_cB^2}v^{(2)} - \frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}}v^{(3)} = \lambda v^{(3)}, \tag{3.13}$$

where $v^{(1)}(0) = v^{(1)}(2\pi)$.

The solutions of (3.11)–(3.13) are given by

$$\lambda_n(\mu) = \frac{a|n|}{|n| + am}\left(\psi_c'(\phi_e(\mu)) - \frac{\nu}{2a}n^2 - \frac{1}{2a}ni\right), \quad \vec{v}_n = (e^{in\theta}, 0, 0), \quad n = \pm 1, \pm 2, \dots, \tag{3.14}$$

and

$$\gamma_{\pm 1}(\mu) = \frac{\frac{1}{l_c}\psi_c'(\phi_e) - \frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}} \pm \sqrt{\left(\frac{1}{l_c}\psi_c'(\phi_e) - \frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}}\right)^2 + \frac{\psi_c'(\phi_e)}{l_c^2B^2}\frac{\mu}{2\sqrt{\psi_e}} - \frac{1}{l_c^2B^2}}}{2}, \tag{3.15}$$

$\vec{v}_{\gamma_i} = (0, \hat{\phi}_i, \hat{\psi}_i)$, $i = \pm 1$, where $\hat{\phi}_i, \hat{\psi}_i$ satisfy

$$\frac{1}{l_c}\psi_c'(\phi_e)\hat{\phi}_i - \frac{1}{l_c}\hat{\psi}_i = \gamma_i\hat{\phi}_i, \tag{3.16}$$

$$\frac{1}{4l_cB^2}\hat{\phi}_i - \frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}}\hat{\psi}_i = \gamma_i\hat{\psi}_i. \tag{3.17}$$

We thus have obtained the spectrum of $A + df_{x_e}(\mu)$, which is

$$\sigma\left(A + df_{x_e}(\mu)\right) = \{\gamma_{\pm 1}(\mu), \lambda_n(\mu),\ n = \pm 1, \pm 2, \dots\}, \tag{3.18}$$

and the proof is complete. ■

Let X_1 = the closure of span$\{e^{in\theta};\ n = \pm 1, \pm 2, \dots\}$ and $X_2 = \mathbb{R}^2$. Clearly we have $X = X_1 \oplus X_2$.

Lemma 3.5. *Let the semigroup $T_1^\mu(t)$ and $T_2^\mu(t)$ be the restrictions of $e^{t(A+df_{x_e}(\mu))}$ to X_1 and X_2, respectively. Then X_1 is $T_1^\mu(t)$-invariant and X_2 is $T_2^\mu(t)$-invariant. Thus for any $(g_0, \Phi_0, \Psi_0) \in X$ we have*

$$e^{t(A+df_{x_e}(\mu))}\begin{pmatrix} g_0 \\ \Phi_0 \\ \Psi_0 \end{pmatrix} = \begin{pmatrix} T_1^\mu(t)g_0 \\ 0 \\ 0 \end{pmatrix} + \begin{pmatrix} 0 \\ T_2^\mu(t)\begin{pmatrix} \Phi_0 \\ \Psi_0 \end{pmatrix} \end{pmatrix}. \tag{3.19}$$

Proof. Recall that

$$A + df_{x_e}(\mu) = \begin{bmatrix} \Pi^{-1}\left(\frac{\nu}{2}\frac{\partial^2}{\partial\theta^2} - \frac{1}{2}\frac{\partial}{\partial\theta}\right) + a\Pi^{-1}\left(\psi_c' - \overline{\psi}_c'\right) & 0 & 0 \\ \frac{1}{l_c}\overline{\psi}_c' & \frac{1}{l_c}\overline{\psi}_c' & -\frac{1}{l_c} \\ 0 & \frac{1}{4l_cB^2} & -\frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}} \end{bmatrix}. \tag{3.20}$$

For any $(g, \Phi, \Psi) \in D(A)$, we have

$$(A + df_{x_e}(\mu))\begin{pmatrix} g \\ \Phi \\ \Psi \end{pmatrix} = \begin{pmatrix} \Pi^{-1}\left(\frac{\nu}{2}g_{\theta\theta} - \frac{1}{2}g_\theta\right) + a\Pi^{-1}\left(\psi_c'(\phi_e)g\right) \\ \frac{1}{l_c}\left(\psi_c'(\phi_e)\Phi - \Psi\right) \\ \frac{1}{4l_cB^2}\Phi - \frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}}\Psi \end{pmatrix}, \tag{3.21}$$

since $\overline{\psi}_c' g = 0$ according to the definition of X. Thus the restriction of $A + df_{x_e}(\mu)$ to x_1 is

$$(A + df_{x_e}(\mu))\Big|_{X_1}(g) = \Pi^{-1}\left(\frac{\nu}{2}g_{\theta\theta} - \frac{1}{2}g_\theta\right) + a\Pi^{-1}\left(\psi_c'(\phi_e)g\right) \in X_1, \tag{3.22}$$

and that to x_2 is

$$(A + df_{x_e}(\mu))\Big|_{X_2}\begin{pmatrix}\Phi\\ \Psi\end{pmatrix} = \begin{pmatrix} \frac{1}{l_c}\left(\psi_c'(\phi_e)\Phi - \Psi\right)\\ \frac{1}{4l_cB^2}\Phi - \frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}}\Psi\end{pmatrix} \in X_2, \tag{3.23}$$

which implies that the restrictions of $A + df_{x_e}(\mu)$ to X_1 and X_2 are invariant, respectively. Therefore, the restrictions of $e^{t(A+df_{x_e}(\mu))}$ to X_1 and X_2 are invariant, respectively. ■

Before we proceed in a further discussion, let us make some important comments based on Lemmas 3.1–3.6.

1. The semigroup $e^{t(A+df_{x_e}(\mu))}$ is asymptotically stable if and only if both $T_1^\mu(t)$ and $T_2^\mu(t)$ are asymptotically stable.
2. The semigroup $T_1^\mu(t)$ is determined by the evolution of the upstream disturbance velocity at the duct entrance, while the semigroup $T_2^\mu(t)$ is decided by dynamics of the flow coefficient and the pressure rise coefficient.
3. As we will see later, as μ is reduced, both $T_1^\mu(t)$ and $T_2^\mu(t)$ will lose asymptotical stability (i.e., their spectra will cross the unit disk, respectively). Resulting dynamical behaviors (rotating stall or surge) of the system depend on which one loses its asymptotic stability first.
4. We will show that the eigenvalues of $T_1^\mu(t)$ and $T_2^\mu(t)$ move across the unit circle with nonzero speeds as μ is reduced. Thus bifurcations to periodic orbits take place.
5. The center manifold theorem indicates that the periodic orbit (rotating stall) due to the spectrum of $T_1^\mu(t)$ is in a two-dimensional subspace of X_1, while the periodic orbit (surge) due to the spectrum of $T_2^\mu(t)$ is in X_2.

In the following, we will show that quantitative Δ given by (3.1) can identify two different dynamical behaviors of the system: rotating stall and surge.

Lemma 3.6. *When $\mu \geq \frac{2W}{\sqrt{2H+\psi_{c_0}}}$, all eigenvalues of $A + df_{x_e}(\mu)$ are in the left half plane.*

Proof. Notice that $\mu \geq \frac{2W}{\sqrt{\psi_{c_0}+2H}}$ implies that $\phi_e(\mu) \geq 2W$, and hence $\psi_c'(\phi_e(\mu)) \leq 0$. Now we consider $\mathrm{Re}(\lambda_n)$ and $\mathrm{Re}(\gamma_{\pm 1})$, respectively. Notice that

$$\begin{aligned}\mathrm{Re}(\lambda_n(\mu)) &= \frac{a|n|}{|n| + am}\left(\psi_c'\left(\phi_e(\mu)\right) - \frac{\nu}{2a}n^2\right) \leq \frac{a|n|}{|n| + am}\left(-\frac{\nu}{2a}n^2\right)\\ &\leq -\frac{\nu}{2(1+am)} \qquad \text{for} \quad n = \pm 1, \pm 2, \ldots.\end{aligned}$$

Next we denote $\chi(\mu)$ as

$$\chi(\mu) = \frac{1}{l_c}\psi_c'(\phi_e(\mu)) - \frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e(\mu)}}, \tag{3.24}$$

and notice that $\mu = \phi_e/\sqrt{\psi_e}$, and when $\mu \geq \frac{2W}{\sqrt{\psi_{c_0}+2H}}$ (that is, $\phi_e \geq 2W$),

$$\frac{d\chi}{d\mu}(\mu) = \frac{1}{l_c}\frac{d}{d\mu}\psi_c'(\phi_e(\mu)) - \frac{1}{4l_cB^2}\frac{d}{d\mu}\left(\frac{\phi_e(\mu)}{\psi_e(\mu)}\right) < 0, \tag{3.25}$$

since $\psi_c'(\phi_e(\mu))$ is a decreasing function of μ and $\phi_e(\mu)/\psi_e(\mu)$ is an increasing function of μ. Hence when $\mu \geq \mu_0$ one has

$$\chi(\mu) \leq \chi(\mu_0) = \frac{1}{l_c}\psi_c'(\phi_e(\mu_0)) - \frac{1}{4l_cB^2}\frac{\mu_0}{2\sqrt{\psi_e(\mu_0)}} = -\frac{1}{4l_cB^2}\frac{\mu_0}{2\sqrt{\psi_e(\mu_0)}}$$
$$= -\frac{1}{4l_cB^2}\frac{\phi_e(\mu_0)}{2\psi_e(\mu_0)} = -\frac{W}{4l_cB^2(\psi_{c_0}+2H)}$$

since $\psi_c'(\phi_e(\mu_0)) = 0$. Recall that $\gamma_{\pm 1}$ is given by

$$\gamma_{\pm 1}(\mu) = \frac{\frac{1}{l_c}\psi_c'(\phi_e) - \frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}} \pm \sqrt{\left(\frac{1}{l_c}\psi_c'(\phi_e) - \frac{1}{4l_cB^2}\frac{\mu}{2\sqrt{\psi_e}}\right)^2 + \frac{\psi_c'(\phi_e)}{l_c^2B^2}\frac{\mu}{2\sqrt{\psi_e}} - \frac{1}{l_c^2B^2}}}{2}$$
$$= \frac{\chi(\mu) \pm \sqrt{\chi^2(\mu) + \frac{\psi_c'(\phi_e)}{l_c^2B^2}\frac{\mu}{2\sqrt{\psi_e}} - \frac{1}{l_c^2B^2}}}{2}.$$

According to the definition of χ given in (3.24), $\gamma_{\pm 1}$ can be further written as

$$\gamma_{\pm 1}(\mu) = \frac{\chi(\mu) \pm \sqrt{\left(\chi(\mu) - \frac{2}{l_c}\psi_c'(\phi_e)\right)^2 - \frac{1}{l_c^2B^2}}}{2}.$$

Notice that $\psi_c'(\phi_e) \leq 0$ and $\chi(\mu) < 0$; thus $\operatorname{Re}\gamma_{\pm 1}(\mu) < 0$, and the proof is complete. ■

Now we are ready to prove part 1 of Theorem 3.1.

Lemma 3.7. *When $\mu > \frac{W}{\sqrt{\psi_{c_0}+H}} := \mu_{00}$, the real parts of eigenvalues $\lambda_n(\mu)$ and $\gamma_{\pm 1}(\mu)$ cross the imaginary axis with nonzero speeds. Specifically, if there are $\mu_1 \geq \mu_{00}$ and $\mu_2 \geq \mu_{00}$ such that $\operatorname{Re}(\lambda_n(\mu_1)) = 0$ and $\operatorname{Re}(\gamma_{\pm 1}(\mu_2)) = 0$, respectively, then*

$$\frac{d}{d\mu}\operatorname{Re}\left(\lambda_{\pm 1}(\mu)\right)\Big|_{\mu=\mu_1} < 0, \qquad \frac{d}{d\mu}\operatorname{Re}\left(\gamma_{\pm 1}(\mu)\right)\Big|_{\mu=\mu_2} < 0.$$

Proof. Recall that (ϕ_e, ψ_e) satisfies $\psi_e = \psi_c(\phi_e)$, $\phi_e = \mu\sqrt{\psi_e}$. Notice that $\mu \geq \frac{W}{\sqrt{\psi_{c_0}+H}}$ implies $\phi_e(\mu) \geq W$. Moreover, $\phi_e(\mu)$ increases as μ increases, which leads to

$$\frac{d\phi_e(\mu)}{d\mu} > 0.$$

Thus for $n = \pm 1, \pm 2, \ldots$, we have

$$\frac{d}{d\mu}\operatorname{Re}\left(\lambda_n(\mu)\right) = \frac{|n|a}{|n| + am}\frac{d^2\psi_c(\phi_e(\mu))}{d\phi_e^2}\frac{d\phi_e(\mu)}{d\mu} < 0$$

since $\Psi = \psi_c(\Phi)$ is concave downward for $\Phi > W$.

For $\operatorname{Re}(\gamma_{\pm 1})$, recall that

$$\gamma_{\pm 1}(\mu) = \frac{\chi(\mu) \pm \sqrt{\chi^2(\mu) + \frac{\psi_c'(\phi_e)}{l_c^2B^2}\frac{\mu}{2\sqrt{\psi_e}} - \frac{1}{l_c^2B^2}}}{2}. \tag{3.26}$$

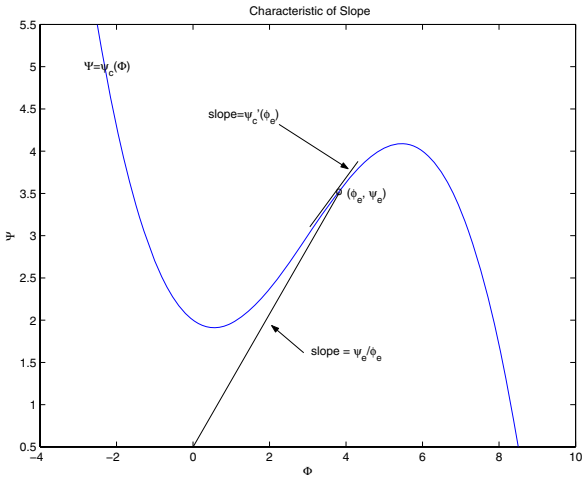

Figure 5. *Slope on the compressor characteristic at* (ϕ_e, ψ_e) *and slope for the line segment between* $(0, 0)$ *and* (ϕ_e, ψ_e).

Notice that

$$\psi_c'(\phi_e) < \frac{\psi_e}{\phi_e}$$

for $\mu > \mu_{00}$ since the slope of the tangent line of $\Psi = \psi_c(\Phi)$ is always smaller than the slope of the line segment between the origin and (ϕ_e, ψ_e), which can be seen in Figure 5. Hence it yields

$$\frac{\psi_c'(\phi_e)}{l_c^2 B^2}\frac{\mu}{2\sqrt{\psi_e}} = \frac{\psi_c'(\phi_e)}{l_c^2 B^2}\frac{\phi_e}{2\psi_e} \le \frac{1}{2l_c^2 B^2},$$

which implies

$$\frac{\psi_c'(\phi_e)}{l_c^2 B^2}\frac{\mu}{2\sqrt{\psi_e}} - \frac{1}{l_c^2 B^2} \le -\frac{1}{2l_c^2 B^2} < 0.$$

Thus according to (3.26) $\mathrm{Re}(\gamma_{\pm 1}(\mu)) = 0$ if and only if $\chi(\mu) = 0$ as μ decreases from μ_0. Now we differentiate $\gamma_{\pm 1}(\mu)$ with respect to μ:

$$\frac{d\gamma_{\pm 1}(\mu)}{d\mu} = \frac{1}{2}\left(\frac{d\chi(\mu)}{d\mu} + \frac{2\chi(\mu)\frac{d\chi(\mu)}{d\mu} + \frac{d}{d\mu}\left(\frac{\psi_c'(\phi_e)}{l_c^2 B^2}\frac{\mu}{2\sqrt{\psi_e}}\right)}{2\sqrt{\chi^2(\mu) + \frac{\psi_c'(\phi_e)}{l_c^2 B^2}\frac{\mu}{2\sqrt{\psi_e}} - \frac{1}{l_c^2 B^2}}}\right).$$

Applying $\chi(\mu_1) = 0$, we have

$$\frac{d\gamma_{\pm 1}(\mu)}{d\mu}\Big|_{\mu=\mu_1} = \frac{1}{2}\left(\frac{d\chi(\mu)}{d\mu} - i\frac{\frac{d}{d\mu}\left(\frac{\psi_c'(\phi_e)}{l_c^2 B^2}\frac{\mu}{2\sqrt{\psi_e}}\right)}{2\sqrt{-\frac{\psi_c'(\phi_e)}{l_c^2 B^2}\frac{\mu}{2\sqrt{\psi_e}} + \frac{1}{l_c^2 B^2}}}\right)_{\mu=\mu_1}.$$

Therefore,

$$\frac{d}{d\mu}\mathrm{Re}\,\gamma_{\pm 1}(\mu)\Big|_{\mu=\mu_1} = \frac{1}{2}\frac{d\chi(\mu)}{d\mu}\Big|_{\mu=\mu_1} < 0,$$

since $\psi_c'(\phi_e(\mu))$ is a decreasing function of μ and $\phi_e(\mu)/\psi_e(\mu)$ is an increasing function of μ for $\mu \geq \mu_{00}$. ■

Let

$$\phi_e^{(\nu)} := W\left(1+\sqrt{1-\frac{\nu W}{3aH}}\right), \qquad \psi_e^{(\nu)} = \psi_c\left(\phi_e^{(\nu)}\right);$$

then according to the definition of the compressor characteristic ψ_c one can see that

$$\psi_e^{(\nu)} := \psi_c\left(\phi_e^{(\nu)}\right) = \psi_{c_0} + H\left[1+\frac{3}{2}\sqrt{1-\frac{\nu W}{3aH}} - \frac{1}{2}\left(\sqrt{1-\frac{\nu W}{3aH}}\right)^3\right],$$

and $\phi_e^{(\nu)}$ satisfies the equation

$$\psi_c'(\Phi)\,|_{\Phi=\phi_e^{(\nu)}} = \frac{\nu}{2a}.$$

Let us now denote

$$\mu_\nu = \frac{W\left(1+\sqrt{1-\frac{\nu W}{3aH}}\right)}{\sqrt{\psi_{c_0} + H\left[1+\frac{3}{2}\sqrt{1-\frac{\nu W}{3aH}} - \frac{1}{2}\left(\sqrt{1-\frac{\nu W}{3aH}}\right)^3\right]}} = \frac{\phi_e^{(\nu)}}{\sqrt{\psi_e^{(\nu)}}}.$$

One can verify that $\frac{W}{\sqrt{\psi_0+H}} < \mu_\nu < \frac{2W}{\sqrt{\psi_0+2H}}$ (see Figure 3).

Lemma 3.8.

1. *If $\Delta > 0$, there exists a positive number $\hat{\mu}$ with $\mu_\nu < \hat{\mu} < \frac{2W}{\sqrt{\psi_{c_0}+2H}}$ such that when $\mu \in (\hat{\mu}, \infty)$ the spectrum of $A + df_{x_e}(\mu)$ is contained in the left half plane, and when $\mu = \hat{\mu}$, a pair of eigenvalues $\gamma_{\pm 1}$ crosses the imaginary axis with*

$$\frac{d}{d\mu}\operatorname{Re}\left(\gamma_{\pm 1}(\mu)\right)\Big|_{\mu=\hat{\mu}} < 0. \tag{3.27}$$

2. *If $\Delta < 0$, then when $\mu \in (\mu_\nu, \infty)$ the point spectrum of $A + df_{x_e}(\mu)$ is contained in the left half plane, and when $\mu = \mu_\nu$, a pair of eigenvalues $\lambda_{\pm 1} \neq \gamma_{\pm 1}$ crosses the imaginary axis with*

$$\frac{d}{d\mu}\operatorname{Re}\left(\lambda_{\pm 1}(\mu)\right)\Big|_{\mu=\mu_\nu} < 0. \tag{3.28}$$

3. *If $\Delta = 0$, then when $\mu \in (\mu_\nu, \infty)$ the point spectrum of $A + df_{x_e}(\mu)$ is contained in the left half plane, and when $\mu = \mu_\nu$, two pairs of eigenvalues $\lambda_{\pm 1}, \gamma_{\pm 1}$ cross the imaginary axis with*

$$\frac{d}{d\mu}\operatorname{Re}\left(\lambda_{\pm 1}(\mu)\right)\Big|_{\mu=\mu_\nu} < 0,$$
$$\frac{d}{d\mu}\operatorname{Re}\left(\gamma_{\pm 1}(\mu)\right)\Big|_{\mu=\mu_\nu} < 0.$$

Proof. 1. Suppose $\Delta > 0$. According to the definition of the compressor characteristic given in (2.5), one can see when $\phi_e = 2W$ we have $\psi_c'(\phi_e) = 0$. The corresponding throttle coefficient μ_0 can be obtained as

$$\mu_0 = \frac{\phi_e}{\sqrt{\psi_e}} = \frac{2W}{\sqrt{\psi_{c_0} + 2H}}.$$

At $\mu = \mu_0$ we have

$$\begin{aligned} \mathrm{Re}(\lambda_n(\mu_0)) &= \frac{a|n|}{|n| + am}\left(\psi_c'(\phi_e) - \frac{\nu}{2a}n^2\right) < 0, \\ \mathrm{Re}(\gamma_{\pm 0}(\mu_1)) &< 0. \end{aligned}$$

As μ is reduced from μ_0 to μ_ν, the eigenvalues λ_n, $n = \pm 1, \pm 2, \ldots$, become

$$\begin{aligned} \mathrm{Re}(\lambda_{\pm 1}(\mu_\nu)) &= \frac{a}{1 + am}\left(\psi_c'(\phi_e^{(\nu)}) - \frac{\nu}{2a}\right) = 0, \\ \mathrm{Re}(\lambda_n(\mu_\nu)) &= \frac{a|n|}{|n| + am}\left(\psi_c'(\phi_e^{(\nu)}) - \frac{\nu}{2a}n^2\right) < 0, \quad n = \pm 2, \pm 3, \ldots. \end{aligned}$$

Notice that

$$\begin{aligned} \chi(\mu_\nu) &= \frac{1}{l_c}\psi_c'(\phi_e^{(\nu)}) - \frac{1}{4l_cB^2}\frac{\mu_\nu}{2\sqrt{\psi_e^{(\nu)}}} = \frac{1}{l_c}\left(\frac{\nu}{2a} - \frac{1}{4l_cB^2}\frac{\phi_e^{(\nu)}}{2\psi_e^{(\nu)}}\right) \\ &= \frac{\nu\phi_e^{(\nu)}}{2al_c\psi_e^{(\nu)}}\left(\frac{\psi_e^{(\nu)}}{\phi_e^{(\nu)}} - \frac{a}{4B^2\nu}\right) = \frac{\nu\phi_e^{(\nu)}}{2al_c\psi_e^{(\nu)}}\Delta > 0, \end{aligned}$$

which indicates $\mathrm{Re}\,\gamma_1(\mu_\nu) \geq \frac{\chi(\mu_\nu)}{2} > 0$. Since $\mathrm{Re}\,\gamma_{\pm 1}(\mu)$ is a continuous function of μ, the intermediate theorem implies that there exists $\hat{\mu}$ with $\mu_\nu < \hat{\mu} < \mu_0$ such that $\mathrm{Re}\,\gamma_{\pm 1}(\hat{\mu}) = 0$ and $\mathrm{Re}\,\gamma_{\pm 1}(\mu) < 0$ when $\mu > \hat{\mu}$. Since $\hat{\mu} > \frac{W}{\sqrt{\psi_{c_0}+H}} = \mu_{00}$, applying Lemma 3.7 leads to

$$\frac{d}{d\mu}\,\mathrm{Re}\,(\gamma_{\pm 1}(\mu))\Big|_{\mu=\hat{\mu}} < 0.$$

2. Suppose $\Delta < 0$. When $\mu = \mu_\nu$ we have

$$\mathrm{Re}(\lambda_{\pm 1}(\mu_\nu)) = \frac{a}{1 + am}\left(\psi_c'\left(\phi_e^{(\nu)}\right) - \frac{\nu}{2a}\right) = 0$$

and

$$\begin{aligned} \mathrm{Re}(\lambda_n(\mu_\nu)) &= \frac{a|n|}{|n| + am}\left(\psi_c'\left(\phi_e\right) - \frac{\nu}{2a}n^2\right) < 0, \quad n = \pm 2, \pm 3, \ldots, \\ \chi(\mu_\nu) &= \frac{\nu\phi_e^{(\nu)}}{2al_c\psi_e^{(\nu)}}\Delta < 0. \end{aligned}$$

Lemma 3.7 implies that both $\mathrm{Re}(\lambda_n(\mu))$ and $\chi(\mu)$ are decreasing functions of μ when $\mu > \frac{W}{\sqrt{\psi_{c_0}+H}}$. Hence when $\mu > \mu_\nu$ we have

$$\mathrm{Re}(\lambda_n(\mu_\nu)) < 0, \quad n = \pm 2, \ldots, \quad \text{and} \quad \mathrm{Re}(\gamma_{\pm 1}(\mu)) < 0.$$

Thus in this case $\lambda_{\pm 1}$ crosses the imaginary axis and the rest of the spectrum of $A + df_{x_e}(\mu)$ is contained in the left half plane when $\mu > \mu_\nu$. Applying Lemma 3.7 again we know that

$$\frac{d}{d\mu} \mathrm{Re}\left(\lambda_{\pm 1}(\mu)\right)\Big|_{\mu=\mu_\nu} < 0.$$

3. Suppose $\Delta = 0$. Then when $\mu = \mu_\nu$ we have

$$\mathrm{Re}(\lambda_{\pm 1}(\mu_\nu)) = \frac{a}{1+am}\left(\psi_c'\left(\phi_e^{(\nu)}\right) - \frac{\nu}{2a}\right) = 0,$$
$$\chi(\mu_\nu) = \frac{\nu\phi_e^{(\nu)}}{2al_c\psi_e^{(\nu)}}\Delta = 0,$$

and

$$\mathrm{Re}(\lambda_n(\mu_\nu)) = \frac{a|n|}{|n|+am}\left(\psi_c'\left(\phi_e^{(\nu)}\right) - \frac{\nu}{2a}n^2\right) = \frac{a|n|}{|n|+am}\left(\frac{\nu}{2a} - \frac{\nu}{2a}n^2\right) < 0, \quad n = \pm 2, \pm 3 \ldots.$$

Lemma 3.7 leads to

$$\frac{d}{d\mu} \mathrm{Re}\left(\lambda_{\pm 1}(\mu)\right)\Big|_{\mu=\mu_\nu} < 0, \qquad \frac{d}{d\mu} \mathrm{Re}\left(\gamma_{\pm 1}(\mu)\right)\Big|_{\mu=\mu_\nu} < 0,$$

and the proof of the lemma is complete. ■

Lemma 3.9. *If $\Delta > 0$, the frequency of the flow oscillation is smaller than $1/(4\sqrt{2}\pi Bl_c)$ (i.e., the flow oscillation is predominated by surge). While $\Delta < 0$, the frequency of the flow oscillation is greater than $1/\left(4\pi\left(\frac{3aH}{\nu W} + am\right)\right)$ (i.e., the oscillation is predominated by rotating stall).*

Proof. When $\Delta > 0$, as μ is decreasing from μ_0, according to Lemma 3.8 $\gamma_{\pm 1}(\mu)$ crosses the imaginary axis with nonzero speed at $\mu = \hat{\mu}$. In this case the bifurcating periodic orbit lies in X_2, that is, in the $\Phi\Psi$-plane. According to the Hopf bifurcation theorem [13], the period of the closed orbit is about $\frac{2\pi}{|\gamma_{\pm 1}(\hat{\mu})|}$. In the proof of Lemma 3.7 we know that

$$\gamma_{\pm 1}(\hat{\mu}) = \frac{\pm\sqrt{\frac{\psi_c'(\phi_e)}{l_c^2B^2}\frac{\hat{\mu}}{2\sqrt{\psi_e}} - \frac{1}{l_c^2B^2}}}{2}$$

and

$$\frac{\psi_c'(\phi_e)}{l_c^2B^2}\frac{\mu}{2\sqrt{\psi_e}} - \frac{1}{l_c^2B^2} < -\frac{1}{2l_c^2B^2}.$$

Hence we have

$$\text{the period} \approx \frac{2\pi}{|\gamma_{\pm 1}(\hat{\mu})|} > \frac{2\pi}{\frac{1}{2}\sqrt{\frac{1}{2l_c^2B^2}}} = 4\sqrt{2}\pi Bl_c.$$

Therefore, the frequency of the flow oscillation is smaller than $1/(4\sqrt{2}\pi B l_c)$.

When $\Delta < 0$, as μ is decreasing from μ_0, $\lambda_{\pm 1}(\mu)$ crosses the imaginary axis with nonzero speed at $\mu = \mu_\nu$ according to Lemma 3.8 again. Now the bifurcating periodic orbit lies in a two-dimensional subspace of X_1, and $\lambda_{\pm 1}(\mu_\nu) = \pm \frac{1}{2(1+am)} i$. Thus according to the Hopf bifurcation theorem the period of the flow oscillation is about $\frac{2\pi}{\frac{1}{2(1+am)}} = 4\pi(1+am)$. Notice that $\frac{\nu W}{3aH} \leq 1$; we have

$$4\pi(1+am) \leq 4\pi \left(\frac{3aH}{\nu W} + am \right),$$

which implies that the frequency is greater than $1/\left(4\pi\left(\frac{3aH}{\nu W} + am\right)\right)$. Therefore, we finish the proof of Theorem 3.1. ■

4. Numerical simulations. Following Moore and Greitzer [14], in the simulations the parameter values for the compressor characteristic (2.5) are chosen as

$$H = 0.18, \qquad W = 0.25, \qquad \psi_{c_0} = 1.67H.$$

In this case the peak of the compressor characteristic is at $(\Phi, \Psi) = (0.5, 0.6606)$. Without loss of generality we also set operator Π, defined in section 3.1, to be the identity of X, since Π does not affect the stability of the system (see Lemma 3.4). Other parameters for system (2.2)–(2.4) are set to be

$$l_c = 8, \qquad a = 1/3.5, \qquad \nu = 0.1.$$

The initial disturbance is set to be $g(0, \theta) = 0.005 \sin\theta$, and the initial flow and initial pressure rise are set near the peak of the compressor characteristic, that is, $(\Phi(0), \Psi(0)) = (0.51, 0.66)$. The simulations for the full model (3.3) are conducted by using the *Mathematica* PDE package.

Asymptotically stable case. In this case we choose $\mu = 0.66$ which is greater than $\frac{2W}{\sqrt{2H+\psi_{c_0}}} = 0.615$. The simulation is given by Figure 6, which is consistent with the first part of the main results.

Surge case. We pick $B = 2$. Based on parameters we set, we have $\Delta = 1.19706 > 0$, $\mu_\nu = 0.589996$. We choose $\mu = 0.6$ (so that μ is the value between μ_ν and $\frac{2W}{\sqrt{2H+\psi_{c_0}}}$), and simulation is provided in Figure 7. Simulation shows that the frequency of the flow is about $1/500$, which is smaller than $1/(4\sqrt{2}\pi B l_c) \approx 1/284$. Moreover, one can see that some inverse flow appears, which is one of the features of surge behavior.

Rotating stall case. In this case we set $B = 0.5$. Then we have $\Delta = -1.48151 < 0$. We set $\mu = 0.565$, which is smaller than $\mu_\nu = 0.589996$. Simulation is presented in Figure 8. From the simulation, one can see that the frequency of the flow oscillation is about $1/50$, which is greater than $1/\left(4\pi\left(\frac{3aH}{\nu W}\right)\right) \approx 1/77$ ($m = 0$ due to $\Pi =$ identity). Moreover, the amplitudes of both Φ and Ψ are relatively smaller than those in previous (surge) case.

A mixture case. If we set $B = 0.72058$, then $\Delta = -0.000017316$. We pick $\mu = 0.572$, and simulation is given in Figure 9. The frequency of the flow oscillation is about $1/100$, which lies between the frequency of surge and the frequency of rotating stall. The amplitudes of Φ and Ψ are similar to those in the surge case. Simulation shows that the dynamics of the system evolves as a combination of rotating stall and surge.

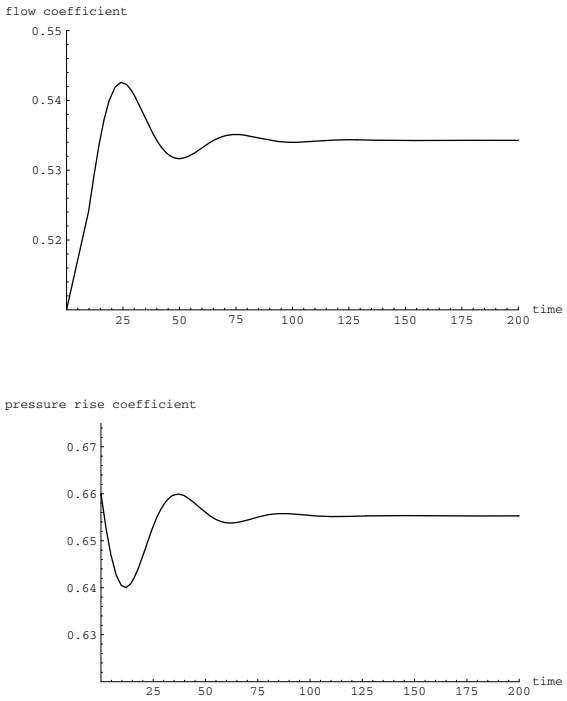

Figure 6. *Asymptotically stable case with* $B = 0.5$ *and* $\mu = 0.66 \geq 0.615 = \frac{2W}{\sqrt{2H+\psi_{c_0}}}$.

5. Concluding remarks. In this paper we provide a quantity Δ for predicting the type of oscillations of the Moore–Greitzer PDE model of an axial flow compressor. $\Delta > 0$ indicates that the dynamics will be predominated by surge, an oscillation which is induced by the flow coefficient Φ and the pressure coefficient Ψ. $\Delta < 0$ implies that the dynamics will be predominated by rotating stall g, an oscillation that results from the flow velocity disturbance at the duct entrance of a compressor. If $\Delta = 0$, then the dynamics will be governed by both. These instability phenomena can be further quantified by applying the infinite-dimensional version of the Hopf bifurcation theorem (see, e.g., [21], [7], and [8]). To avoid an overwhelming presentation in this paper, such results will be reported elsewhere.

6. Appendix.

Lemma 3.1. *The operator* A *defined in* (3.5) *is the infinitesimal generator of an analytic compact* C_0 *semigroup on* X.

Proof. We first claim that A generates an analytic C_0 semigroup on X. Notice that $D(A) = \left(H^2(0,2\pi) \cap X\right) \times \mathbb{R} \times \mathbb{R}$ is dense in X. Let $y \in X$ and $\lambda = \rho e^{i\vartheta}$ with $\rho > 0$, $-\frac{\pi}{2} < \vartheta < \frac{\pi}{2}$. Consider the eigenvalue problem

$$\lambda x - Ax = y.$$

By taking the inner product of both sides of the above identity with $e^{-i\vartheta}x$, and then taking the real part, we arrive at

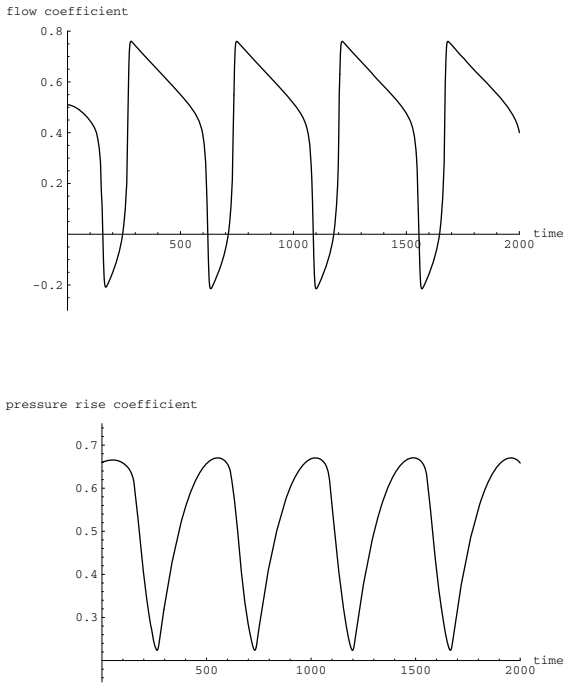

Figure 7. *Surge oscillation* $\Delta \approx 1.197 > 0$ *with* $B = 2$ *and* $\mu = 0.6$.

$$\rho \cos\vartheta \|x\|^2 - \cos\vartheta \operatorname{Re}\langle Ax, x\rangle + \sin\vartheta \operatorname{Im}\langle Ax, x\rangle = \operatorname{Re}[e^{-i\vartheta}\langle x, y\rangle], \tag{6.1}$$

where $\operatorname{Re}\langle Ax, x\rangle$ and $\operatorname{Im}\langle Ax, x\rangle$ stand for the real part and the imaginary part of $\langle Ax, x\rangle$, respectively. Next we show that there exists ϑ_0 with $0 < \vartheta_0 < \frac{\pi}{2}$ such that when $|\vartheta| < \frac{\pi}{2} + \vartheta_0$ we have

$$-\cos\vartheta \operatorname{Re}\langle Ax, x\rangle + \sin\vartheta \operatorname{Im}\langle Ax, x\rangle \geq 0 \tag{6.2}$$

for any $x \in D(A)$. Let $x = (g, \Phi, \Psi)$ with $g = g_1 + ig_2$. The conjugate function of g is denoted by $g^* = g_1 - ig_2$. A direct calculation shows that

$$\begin{aligned}
\operatorname{Re}\langle Ax, x\rangle &= \operatorname{Re}\int_0^{2\pi} \left(\frac{\nu}{2a}\frac{\partial^2 g}{\partial\theta^2} - \frac{1}{2a}\frac{\partial g}{\partial\theta}\right) g^* d\theta \\
&= \int_0^{2\pi} \left(\frac{\nu}{2a}\frac{\partial^2 g_1}{\partial\theta^2} - \frac{1}{2a}\frac{\partial g_1}{\partial\theta}\right) g_1 d\theta + \int_0^{2\pi} \left(\frac{\nu}{2a}\frac{\partial^2 g_2}{\partial\theta^2} - \frac{1}{2a}\frac{\partial g_2}{\partial\theta}\right) g_2 d\theta \\
&= -\frac{\nu}{2a}\int_0^{2\pi} \left(\left|\frac{\partial g_1}{\partial\theta}\right|^2 + \left|\frac{\partial g_2}{\partial\theta}\right|^2\right) d\theta
\end{aligned}$$

and

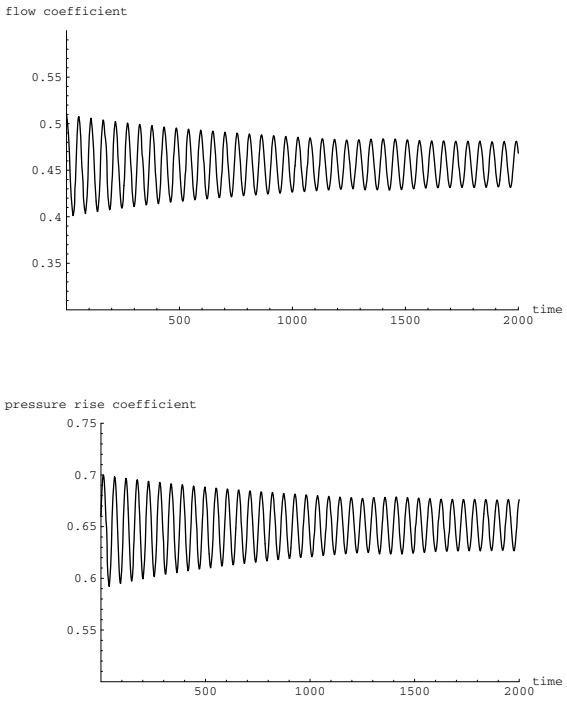

Figure 8. *Rotating stall oscillation* $\Delta \approx -1.482 < 0$ *with* $B = 0.5$ *and* $\mu = 0.572$.

$$\begin{aligned}\operatorname{Im}\langle Ax, x\rangle &= \operatorname{Im}\int_0^{2\pi}\left(\frac{\nu}{2a}\frac{\partial^2 g}{\partial\theta^2} - \frac{1}{2a}\frac{\partial g}{\partial\theta}\right) g^* d\theta \\ &= -\int_0^{2\pi}\left(\frac{\nu}{2a}\frac{\partial^2 g_1}{\partial\theta^2} - \frac{1}{2a}\frac{\partial g_1}{\partial\theta}\right) g_2 d\theta + \int_0^{2\pi}\left(\frac{\nu}{2a}\frac{\partial^2 g_2}{\partial\theta^2} - \frac{1}{2a}\frac{\partial g_2}{\partial\theta}\right) g_1 d\theta \\ &= \frac{1}{2a}\int_0^{2\pi} 2\frac{\partial g_1}{\partial\theta} g_2 d\theta.\end{aligned}$$

According to Poincaré's inequality we know that for any $g \in \dot{L}(0, 2\pi)$ we have

$$\int_0^{2\pi} |g|^2 d\theta \le 4\pi^2 \int_0^{2\pi} \left|\frac{\partial g}{\partial\theta}\right|^2 d\theta. \tag{6.3}$$

According to Cauchy's inequality and (6.3) we obtain

$$\left|\frac{\operatorname{Im}\langle Ax, x\rangle}{\operatorname{Re}\langle Ax, x\rangle}\right| = \left|\frac{\displaystyle\int_0^{2\pi} 2\left|\frac{\partial g_1}{\partial\theta} g_2\right| d\theta}{\displaystyle\nu\int_0^{2\pi}\left(\left|\frac{\partial g_1}{\partial\theta}\right|^2 + \left|\frac{\partial g_2}{\partial\theta}\right|^2\right) d\theta}\right|$$

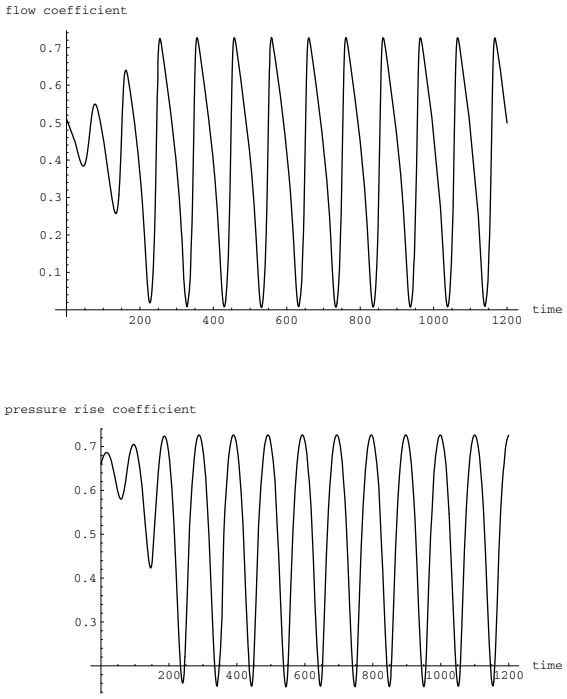

Figure 9. *A mixed oscillation* $\Delta \approx 0$ *with* $B = 0.72061$ *and* $\mu = 0.572$.

$$\leq \frac{2\left(\int_0^{2\pi}\left|\frac{\partial g_1}{\partial\theta}\right|^2 d\theta\right)^{\frac{1}{2}}\left(\int_0^{2\pi}|g_2|^2 d\theta\right)^{\frac{1}{2}}}{\nu\int_0^{2\pi}\left(\left|\frac{\partial g_1}{\partial\theta}\right|^2+\left|\frac{\partial g_2}{\partial\theta}\right|^2\right)d\theta}$$

$$\leq \frac{4\pi\left(\int_0^{2\pi}\left|\frac{\partial g_1}{\partial\theta}\right|^2 d\theta\right)^{\frac{1}{2}}\left(\int_0^{2\pi}\left|\frac{\partial g_2}{\partial\theta}\right|^2 d\theta\right)^{\frac{1}{2}}}{\nu\int_0^{2\pi}\left(\left|\frac{\partial g_1}{\partial\theta}\right|^2+\left|\frac{\partial g_2}{\partial\theta}\right|^2\right)d\theta} \leq \frac{2\pi}{\nu}.$$

On the other hand, one can see that

$$-\cos\vartheta\,\mathrm{Re}\,\langle Ax,x\rangle+\sin\vartheta\,\mathrm{Im}\,\langle Ax,x\rangle=-|\langle Ax,x\rangle|\cos(\vartheta+\varphi), \tag{6.4}$$

where

$$\tan\varphi=\frac{\mathrm{Im}\,\langle Ax,x\rangle}{\mathrm{Re}\,\langle Ax,x\rangle}. \tag{6.5}$$

Thus, if we let $\vartheta_0 := \tan^{-1}\frac{2\pi}{\nu}$, then for $|\vartheta| < \frac{\pi}{2}+\vartheta_0$ we have $\cos(\vartheta+\varphi) > 0$, and thus $-\cos\vartheta\,\mathrm{Re}\,\langle Ax,x\rangle+\sin\vartheta\,\mathrm{Im}\,\langle Ax,x\rangle \geq 0$.

From (6.1) it follows that when $|\vartheta| < \frac{\pi}{2} + \vartheta_0$ we have $\|x\| \le (\rho \cos \frac{\vartheta_0}{2})^{-1} \|y\|$, so that

$$\|(\lambda I - A)^{-1}\| \le \frac{1}{|\lambda| \cos \frac{\vartheta_0}{2}}, \qquad |\arg \lambda| < \frac{\pi}{2} + \vartheta_0,$$

and hence

$$\rho(A) \supset \Sigma(\vartheta) = \left\{ \lambda \in \mathbf{C} : \ |\arg \lambda| < \frac{\pi}{2} + \vartheta_0 \right\}.$$

Therefore, it follows that A is the infinitesimal generator of an analytic semigroup on X.

Next we claim that A also generates a compact C_0 semigroup on X. Since the semigroup $T(t)$ generated by A is analytic, it is continuous in the uniform operator topology for $t > 0$. Furthermore, the embedding $H^2_\pi(0, 2\pi) \hookrightarrow L^2_\pi(0, 2\pi)$ is compact and $R(\lambda, A)X \subseteq D(A) \subseteq H^2_\pi(0, 2\pi)$. Thus $R(\lambda, A)$ is a compact operator. Therefore, $T(t)$, $t > 0$, is a compact semigroup, and this completes the proof. ■

Acknowledgment. The author would like to thank the anonymous reviewers for their suggestions which have been very helpful in the improvement of the paper.

Pattern Formation in a Model of a Vibrated Granular Layer*

D. M. Winterbottom†, S. M. Cox†, and P. C. Matthews†

Abstract. A phenomenological model for pattern formation in a vertically vibrated granular layer is examined in order to investigate its nonlinear dynamics. The model comprises two coupled partial differential equations: one describes the evolution of the short-scale pattern, while the other enforces conservation of granular material. In a layer of moderate horizontal extent, the model predicts that a variety of exotic regular patterns may be stable, according to the system parameters. The usual cubic-order amplitude equations are unable to determine the stable solution over a significant parameter range; we compute the corresponding fifth-order terms necessary to resolve this degeneracy. When spatial modulation of the pattern is taken into account, in a sufficiently wide layer, a stability analysis of regular one-dimensional roll and two-dimensional square patterns demonstrates that each may suffer a modulational instability, which tends to localize the pattern. The corresponding modulational stability boundaries, for both rolls and squares, coincide with the transition between stable rolls and squares in the unmodulated problem. As a consequence, in a suitably large container, squares are always unstable, and corresponding numerical simulations indicate highly localized worm- or chain-like patterns. The numerical simulations and stability results are compared with appropriate experimental results.

Key words. pattern formation, phenomenological model, vibrated granular layer

DOI. 10.1137/06067540X

1. Introduction.

The near-threshold behavior of a vertically vibrated granular layer has been the subject of considerable attention in recent years. Experimentally, a diverse collection of extended cellular and localized patterns has been observed, including rolls, squares, hexagons, interfaces, and oscillons [1, 25, 26, 33, 34]. Theoretically, however, there is no widely accepted continuum description for the highly complicated rheology of granular media [2, 3, 6, 19]; granular materials are known to exhibit some of the dynamical properties of fluids and solids, as well as their own unique properties [15, 16, 19]. Aranson and Tsimring [3] have provided a comprehensive recent review of the behavior of granular media.

A thin horizontal layer of granular material on a flat plate that oscillates with vertical displacement $z = \mathcal{A}\sin(2\pi ft)$ can form a pattern, which is governed by the driving frequency f and the nondimensional acceleration amplitude $\Gamma = 4\pi^2\mathcal{A}f^2/g$, where g is the acceleration due to gravity [25, 26, 33]. Almost irrespective of the driving frequency, patterned states appear at $\Gamma \approx 2.4$, where rolls, squares, or oscillons may be found (all oscillating at half the driving frequency). At low frequencies, a hysteretic transition to a regular square pattern is observed, while above some critical frequency, rolls are selected [25]; localized structures such

†School of Mathematical Sciences, University of Nottingham, University Park, Nottingham, NG7 2RD, UK (david.winterbottom@gmail.com, stephen.cox@nottingham.ac.uk, paul.matthews@nottingham.ac.uk).

as oscillons are observed in the slightly subcritical region. At higher accelerations ($\Gamma > 3.72$), these patterns become unstable and are replaced by hexagons. Further increases in Γ lead to the appearance of interfaces (also known as kinks) and, subsequently, quarter-harmonic patterns [26].

Several theoretical approaches to this phenomenon have been developed, including simulations of molecular dynamics [6, 12, 31], hydrodynamic-type and phenomenological models [11, 14, 27], and semicontinuum models [8, 17, 18, 30, 35]. In particular, granular hydrodynamic models have had considerable success in describing granular flow in appropriate parameter regimes [3]. However, while many features of the experiments have been reproduced, no model offers a complete description of the rich variety of observed phenomena [19].

In this paper, we consider the phenomenological model proposed by Tsimring and Aranson [2, 32], which comprises a Ginzburg–Landau-type amplitude equation for an order parameter, coupled to an equation expressing the net conservation of granular material. A weakly nonlinear analysis of the emerging pattern reveals how the constraint that the granular material be conserved leads to a mechanism for localization of the pattern. The resulting weakly nonlinear equations allow the computation of the stability boundaries for regular patterns; beyond these boundaries in parameter space localized patterns are indeed found in numerical simulations. We emphasize that although the underlying model [2, 32] is purely phenomenological, the mechanism by which the localization of the pattern takes place relies essentially only on the physical constraint of mass conservation, and so we expect our results to be robust, and to extend in principle to more sophisticated models of granular media.

We also expect our results to be applicable to vibrated fluid layers where, experimentally, a wide range of patterns are observed [5, 23] but, as with granular layers, a number of theoretical models are employed [37, 38]. Indeed, the Ginzburg–Landau-type amplitude equation (2.1), with no coupling to a mean-field, has been studied previously as a model for parametric surface waves [20, 37].

The structure of the paper is as follows. In section 2 we recall the phenomenological order-parameter model of Tsimring and Aranson [2, 32] and review the corresponding linear stability results. In section 3 we develop two weakly nonlinear models: one describes a spatially regular pattern comprising modes with up to four distinct wavevectors, and the other describes the spatial modulations of the pattern that may arise in a layer of greater horizontal extent. The stability of various patterns is then determined and the results confirmed and extended through numerical simulation. Finally, in section 4 we discuss the implications of these results and present our conclusions.

2. Order-parameter model. Since there is no generally accepted continuum model, our starting point is the phenomenological model [2, 32]

$$\psi_t = \gamma\psi^* - (1 - \mathrm{i}\omega)\psi + (1 + \mathrm{i}b)\nabla^2\psi - |\psi|^2\psi - \rho\psi, \tag{2.1}$$

$$\rho_t = \beta\nabla^2\rho + \alpha\vec{\nabla}\cdot(\rho\vec{\nabla}|\psi|^2) \tag{2.2}$$

that incorporates the essential physical ingredients of a subharmonic pattern-forming instability and mass conservation. The order parameter $\psi(x, y, t)$ characterizes the complex amplitude of the subharmonic pattern, with the disturbance to the planar layer surface being

$$h = \psi \mathrm{e}^{\mathrm{i}\pi f t} + \text{c.c.}, \tag{2.3}$$

while $\rho(x, y, t)$ represents the local mass of the granular layer per unit area.

As described by Blair et al. [7], the linear terms in (2.1) follow from an expansion of the linear dispersion relation for surface perturbations in the form $h \propto \exp(\Lambda(k)t + \mathrm{i}kx)$ for small k. If we retain only the terms $\Lambda(k) = -\Lambda_0 - \Lambda_2 k^2$ in this expansion then we obtain the linearized evolution equation $h_t = -\Lambda_{0r}(1 + \mathrm{i}\Lambda_{0i}/\Lambda_{0r})h + \Lambda_{2r}(1 + \mathrm{i}\Lambda_{2i}/\Lambda_{2r})\nabla^2 h$, where subscripts r and i denote real and imaginary parts, respectively. If we now remove the factors Λ_{0r} and Λ_{2r} by rescaling time and space variables, we see that ψ satisfies

$$\psi_t + \mathrm{i}\pi f\psi = -(1 + \mathrm{i}\Lambda_{0i}/\Lambda_{0r})\psi + (1 + \mathrm{i}\Lambda_{2i}/\Lambda_{2r})\nabla^2\psi,$$

and hence we obtain the linear terms in (2.1), with $\omega = -\Lambda_{0i}/\Lambda_{0r} - \pi f$ and $b = \Lambda_{2i}/\Lambda_{2r}$. Since the subharmonic oscillation in the physical variable h is already accounted for in (2.3), the simplest subharmonic pattern is realized with ψ of the time-independent form $\psi = \Psi(x, y)$.

Equation (2.1), with no coupling to the mean-field $\rho(x, y, t)$, has been studied previously as a model for a vibrated fluid layer [20, 37] as well as for the large-Γ regime of a vibrated granular layer [4, 7], where ρ is assumed constant. The term $\gamma\psi^*$ provides the parametric driving required for standing waves to become excited, where the control parameter γ is the normalized amplitude of the parametric forcing. The coupling term $-\rho\psi$ indicates that increasing the depth of the layer makes the system more stable, as observed in experiments [25].

Equation (2.2) describes the conservation of mass in the layer; the distributive mechanisms are a diffusive flux (proportional to $-\vec{\nabla}\rho$) and a flux proportional to $-\rho\vec{\nabla}|\psi|^2$ corresponding to particles escaping from regions of large fluctuation. The mass diffusion constant β is expected to be proportional to the energy of the plate vibrations and should increase with the driving frequency f [32]. It is the rapid diffusive smoothing which allows the role of ρ to be discounted in investigations of the high-acceleration regime of a vibrated granular layer [4, 7]. Since ρ is conserved, its mean value ρ_0 is effectively another parameter in the model. Since the model comprising (2.1) and (2.2) involves pattern formation coupled to a conservation law, it is likely to exhibit localized patterns [24].

Perturbations to the uniform solution $\psi = 0$, $\rho = \rho_0$ (corresponding to a flat homogeneous layer) with wavenumber k give rise to a neutral curve of the form

$$\gamma^2 = (1 + k^2 + \rho_0)^2 + (\omega - bk^2)^2. \tag{2.4}$$

The nature of the primary bifurcation as the control parameter γ is increased then depends on the sign of $\omega b - 1 - \rho_0$. For $\omega b - 1 - \rho_0 > 0$, stability is lost at $\gamma = \gamma_c$, where

$$\gamma_c^2 = \frac{[\omega + b(1 + \rho_0)]^2}{1 + b^2}; \tag{2.5}$$

corresponding perturbations have finite critical wavenumber k_c, determined by

$$k_c^2 = \frac{\omega b - 1 - \rho_0}{1 + b^2}. \tag{2.6}$$

By contrast, for $\omega b - 1 - \rho_0 < 0$, the instability is first manifest through disturbances on the largest spatial scales (i.e., as the wavenumber $k \to 0$) with corresponding threshold

$$\gamma_c^2 = (1 + \rho_0)^2 + \omega^2. \tag{2.7}$$

We restrict our attention in this paper to the case of instability to finite-wavelength perturbations; henceforth, we assume $\omega b - 1 - \rho_0 > 0$.

3. Amplitude equations. We suppose the system to be close to the primary bifurcation of the uniform solution, near the onset of a pattern-forming instability at finite wavelength. We proceed with a weakly nonlinear framework, setting $\gamma = \gamma_c + \epsilon^2\gamma_2$ and expanding ψ and ρ about the uniform state $\psi = 0$, $\rho = \rho_0$ as series in the small parameter ϵ:

$$\psi = \epsilon\psi_1 + \epsilon^2\psi_2 + \epsilon^3\psi_3 + \cdots, \tag{3.1}$$

$$\rho = \rho_0 + \epsilon^2\rho_2 + \cdots. \tag{3.2}$$

Note that only even powers of ϵ appear in the expansion for ρ because the forcing in (2.2) is quadratic in ψ. Making the appropriate substitutions in (2.1) and (2.2), and collecting linear terms, we find

$$\partial_t\psi_1 = \gamma_c\psi_1^* - (1 - \mathrm{i}\omega)\psi_1 + (1 + \mathrm{i}b)\nabla^2\psi_1 - \rho_0\psi_1. \tag{3.3}$$

This equation inherits from (2.1) a rotational symmetry: all modes with a given wavenumber k have equal rate of growth or decay, regardless of their orientation. The modes that can be realized in practice are dictated by the container; for analytical simplicity, we assume that periodic boundary conditions are applied in x and y. Here we examine two pattern formation problems: the first involves the competition between two sets of modes, aligned at some angle to one another, and the second involves the competition between four modes.

3.1. No spatial modulation. Consider a two-mode rhombic standing wave ansatz

$$\psi_1 = (b + s + \mathrm{i})\left\{\left[\tilde{A}\mathrm{e}^{\mathrm{i}kx} + \tilde{B}\mathrm{e}^{\mathrm{i}k(x\cos\theta + y\sin\theta)}\right] + \text{c.c.}\right\}, \tag{3.4}$$

where $\tilde{A}$ and $\tilde{B}$ are complex amplitudes, evolving on the slow time scale $\tilde{T} = \epsilon^2 t$, θ parameterizes the angle between the two modes, and we have introduced

$$s = \sqrt{1 + b^2}.$$

Note that the argument of ψ_1, indicated by the factor $b + s + \mathrm{i}$, follows from (3.3).

At $O(\epsilon^2)$ we are permitted to choose $\psi_2 = 0$, while ρ_2 is found to be slaved to the quadratic self-interactions of ψ_1. Finally at $O(\epsilon^3)$, applying the appropriate solvability condition yields the evolution equations for A and B (compare with equation (4) of [2, 32]):

$$\tilde{A}_{\tilde{T}} = r\tilde{A} - 2s(s + b)(3 - \phi)|\tilde{A}|^2\tilde{A} - 4s(s + b)(3 - 2\phi)|\tilde{B}|^2\tilde{A}, \tag{3.5}$$

$$\tilde{B}_{\tilde{T}} = r\tilde{B} - 2s(s + b)(3 - \phi)|\tilde{B}|^2\tilde{B} - 4s(s + b)(3 - 2\phi)|\tilde{A}|^2\tilde{B}, \tag{3.6}$$

where

$$r = \frac{\gamma_2}{\gamma_c}\left(\frac{\omega}{b} + 1 + \rho_0\right), \qquad \phi = \frac{\alpha\rho_0}{\beta}.$$

Note that these equations are independent of the angle θ between the two modes. We assume henceforth that ϕ, which measures the strength of coupling between ψ and ρ, satisfies $0 < \phi < 3$, so that the primary bifurcation to a single mode is supercritical. The interesting dynamical

behavior of (3.5) and (3.6) then arises for $r > 0$, which we assume henceforth. To reduce (3.5) and (3.6) to a canonical form, we introduce

$$(A, B) = \sqrt{\frac{2s(s+b)(3-\phi)}{r}}(\tilde{A}, \tilde{B}), \qquad T = r\tilde{T}; \tag{3.7}$$

then the governing equations (3.5) and (3.6) become

$$A_T = A - |A|^2 A - \lambda |B|^2 A, \tag{3.8}$$

$$B_T = B - |B|^2 B - \lambda |A|^2 B, \tag{3.9}$$

where the nonlinear coupling coefficient is

$$\lambda = 2\left(\frac{3-2\phi}{3-\phi}\right). \tag{3.10}$$

The equations (3.8) and (3.9) reveal two nontrivial solutions [21]: rolls (e.g., $|A| = 1$, $B = 0$), which are stable when $\lambda > 1$, and rhombs (i.e., $|A|^2 = |B|^2 = 1/(1+\lambda)$), which are stable when $-1 < \lambda < 1$. Thus rolls are predicted to be stable for $\phi < 1$, while rhombs (which include squares as the special case $\theta = \pi/2$) are stable when $1 < \phi < 9/5$. This picture is consistent with experimental observations, since β is expected to increase (and hence ϕ is expected to decrease) with increasing f [32].

When there is no coupling between the order-parameter equation (2.1) and ρ (see [4, 7, 20, 37]), $\alpha = 0$, and so $\phi = 0$, and the nonlinear coupling coefficient is simply $\lambda = 2$. Thus, in this case the predictions of the amplitude equations are insensitive to the model parameters, and only rolls can be stable.

An extended version of the amplitude equations (3.8) and (3.9) was derived in [2, 32] including terms up to $O(\epsilon^5)$, by making the simplifying approximation that ρ is slaved to $|\psi|^2$ in (2.2). These extended equations allow a phase diagram to be constructed, illustrating the stability regions of rolls and squares in Γ-ϕ parameter space. However, the region of validity of the inherent approximations is limited to large α and β. Furthermore, we shall see below, when we describe our numerical simulations of (2.1) and (2.2), that the *global* conservation of ρ provides a mechanism for the generation of highly localized patterns, and this mechanism is lost by imposing a *local* enslavement of ρ to $|\psi|^2$.

We turn now to a lattice-periodic ansatz comprising four modes, such as may arise in a periodic square box of side $L = n\sqrt{5}\Lambda_c$ for $n \in \mathbb{N}$, where $\Lambda_c = 2\pi/k_c$ is the critical wavelength. Thus [13]

$$\begin{aligned}\psi_1 = (b+s+\mathrm{i})\Bigg\{\Bigg[&\tilde{A}\exp\left\{\frac{\mathrm{i}k}{\sqrt{5}}(2x+y)\right\} + \tilde{B}\exp\left\{\frac{\mathrm{i}k}{\sqrt{5}}(x+2y)\right\} \\ &+ \tilde{C}\exp\left\{\frac{\mathrm{i}k}{\sqrt{5}}(-x+2y)\right\} + \tilde{D}\exp\left\{\frac{\mathrm{i}k}{\sqrt{5}}(-2x+y)\right\}\Bigg] + \text{c.c.}\Bigg\}.\end{aligned} \tag{3.11}$$

Performing a weakly nonlinear expansion as for the roll–rhomb ansatz (3.4), we obtain, at

$O(\epsilon^3)$, after a rescaling as in (3.7), the amplitude equations

$$A_T = A - |A|^2 A - \lambda A\left(|B|^2 + |C|^2 + |D|^2\right), \tag{3.12}$$

$$B_T = B - |B|^2 B - \lambda B\left(|A|^2 + |C|^2 + |D|^2\right), \tag{3.13}$$

$$C_T = C - |C|^2 C - \lambda C\left(|A|^2 + |B|^2 + |D|^2\right), \tag{3.14}$$

$$D_T = D - |D|^2 D - \lambda D\left(|A|^2 + |B|^2 + |C|^2\right), \tag{3.15}$$

where the nonlinear coupling coefficient λ is just that for the rhombic case, given by (3.10). We find that the only steady solutions to these four amplitude equations that may be stable in some region of parameter space are rolls (e.g., $|A| = 1$, $B = C = D = 0$), which are stable for $\phi < 1$, and four-mode solutions with $|A|^2 = |B|^2 = |C|^2 = |D|^2 = 1/(1+3\lambda)$, which are stable when $1 < \phi < 21/13$. The amplitude equations also allow stationary solutions in the form of squares (e.g., $|A| = |C| = 1/(1+\lambda)$, $B = D = 0$) and rhombs (e.g., $|A| = |B| = 1/(1+\lambda)$, $C = D = 0$), but these solutions are always unstable.

Since (3.12)–(3.15) are invariant under phase translations ($A \mapsto Ae^{i\theta}$), higher-order terms are required to resolve the relationships between the phases of the four modes in the latter case. However, it has been shown using the equivariant branching lemma that such solutions exist in two forms—"supersquares" and "antisquares" [13], with stability being determined by the coefficients of some quintic-order terms in the amplitude equations. To determine the necessary coefficients, we write for each amplitude an evolution equation of the form $\tilde{A}_t = \epsilon^2 f_2 + \epsilon^4 f_4 + \cdots$, where, as indicated above, prior to any rescaling,

$$f_2 = r\tilde{A} - 2s(s+b)(3-\phi)|\tilde{A}|^2\tilde{A} - 4s(s+b)(3-2\phi)\tilde{A}(|\tilde{B}|^2 + |\tilde{C}|^2 + |\tilde{D}|^2).$$

The relevant terms for distinguishing between the stability of supersquares and antisquares arise in f_4, which may be written in the form

$$f_4 = \tilde{A}F_4(|\tilde{A}|^2, |\tilde{B}|^2, |\tilde{C}|^2, |\tilde{D}|^2) + b_{41}\tilde{B}^2\tilde{C}^{*2}\tilde{D} + b_{42}\tilde{A}^*\tilde{B}\tilde{C}\tilde{D}^{*2}$$

for some real-valued coefficients b_{41} and b_{42}. Fortunately, for the purpose of determining the stability of supersquares and antisquares it is not necessary to compute F_4; it proves necessary only to calculate the quantity $b_{41} + 2b_{42}$. It turns out that antisquares are stable if $1 < \phi < 21/13$ and $b_{41} + 2b_{42} < 0$; supersquares are stable if the latter inequality is reversed. We find

$$b_{41} = 12s^2(s+b)^2\left\{\frac{(453b\gamma_c - 32sk_c^2)(\phi-1)^2}{40s^3k_c^4} - \frac{\phi^2}{\rho_0}\right\}, \tag{3.16}$$

$$b_{42} = 2b_{41}. \tag{3.17}$$

Thus we conclude that (provided $1 < \phi < 21/13$) antisquares are stable when

$$\frac{\phi^2}{(\phi-1)^2} > \delta, \tag{3.18}$$

where

$$\delta = \frac{(453b\gamma_c - 32sk_c^2)\rho_0}{40s^3k_c^4}$$

(and supersquares are stable when the inequality in (3.18) is reversed). It follows that, as we increase ϕ from $\phi = 1$, antisquares are stable, at least at first. If $\delta < 441/64$, then (3.18) is satisfied for all ϕ in the range $1 < \phi < 21/13$, so supersquares are never stable. Alternatively, if $\delta > 441/64$, then antisquares are stable for $1 < \phi < \phi_1$, while supersquares are stable for $\phi_1 < \phi < 21/13$, where $\phi_1 = 2\sqrt{\delta}/(\sqrt{\delta} - 1)$.

3.1.1. Rotational degeneracy of the amplitude equation coefficients. We now briefly comment on the fact that the cross-coupling coefficients in (3.5) and (3.6) are independent of the angle θ between the two sets of modes. Because of this degeneracy, there is no selection of θ in the cubic-order amplitude equations. One might ask whether one could augment the phenomenological model for ψ and ρ to overcome this degeneracy. The obvious candidate respecting the symmetry $\psi \mapsto -\psi$ is the addition of a term $\psi_t = \cdots - p\psi|\vec{\nabla}\psi|^2$. However, it turns out that the corresponding contribution to the cross-terms (e.g., the term proportional to $A|B|^2$ in the A_T equation) then vanishes identically. Other terms, such as quadratic terms of the form $\psi_t = \cdots + p\psi^2 + q\psi^{2*}$, succeed in resolving the degeneracy, in that the cross-coupling term depends on θ, but require more substantial justification: such terms might represent, for example, an additional component of the forcing of the layer, proportional to $\sin(3\pi ft)$ or $\cos(3\pi ft)$.

3.2. Small-container numerical simulations. The analytical results of the preceding section can be used to predict interesting parameter regimes in which to numerically simulate the model equations (2.1) and (2.2) in a container of moderate horizontal extent (so that long-wavelength modulational effects are not relevant). For all our simulations, we set the parameter values

$$\beta = \rho_0 = 0.3, \quad b = 1, \quad \omega = 2.5,$$

and use the mobility coefficient α (which equals ϕ with this choice of parameters) as a control parameter. For these parameter values, we find $b_{41} + 2b_{42} = P(\alpha - \alpha_1)(\alpha - \alpha_2)$, where $P = 12425(3 + 2\sqrt{2})/4 > 0$, $\alpha_1 \approx 0.7475$, and $\alpha_2 \approx 1.5100$. Thus, since $21/13 \approx 1.6154$, antisquares are predicted to be stable for $1 < \alpha < \alpha_2$, and supersquares are predicted to be stable for $\alpha_2 < \alpha < 21/13$.

Our simulations use periodic boundary conditions, implemented with a Fourier spectral method. The initial conditions are the uniform state plus small-amplitude noise, and the time-stepping is carried out with the exponential time differencing method [9]. If we choose a square container with side $L = n\Lambda_c$, $n \in \mathbb{N}$, then the dominant modes are perpendicular to and aligned with the periodic boundaries. In this situation, the leading-order pattern is of the form (3.4) with $\theta = \pi/2$. Near-threshold simulations in such containers confirm the predictions of (3.8)–(3.9), displaying stable rolls for $\phi < 1$ and stable squares for $1 < \phi < 3/2$.

Alternatively, if we choose $L = n\sqrt{5}\Lambda_c$, $n \in \mathbb{N}$, then the dominant modes take the form of those in (3.11). Again simulations support the theory: near onset, rolls are stable for $\phi < 1$ and a four-mode solution is stable for $1 < \phi < 3/2$. Figure 1 shows simulations for $\phi = 1.1$: Figure 1(a) shows a stable four-mode solution, which takes the form of antisquares, as predicted above. An accompanying video (67540_01.mov [334KB]) shows a random initial condition leading to stable antisquares for parameters as in Figure 1(a). As far as we are aware this is the first example of a pattern-forming system exhibiting stable antisquares. However,

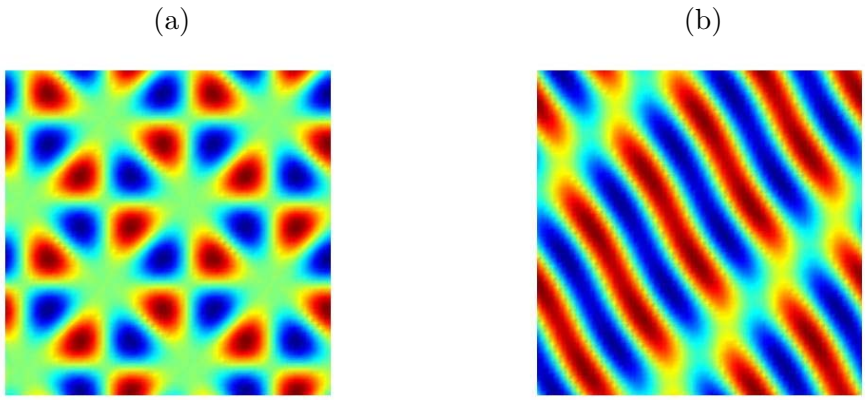

Figure 1. *Plots of $Re(\psi)$ from spectral simulations of (2.1) and (2.2) with a container size $L = 2\sqrt{5}\Lambda_c$ and periodic boundary conditions:* (a) *antisquares found at* 0.5% *above threshold;* (b) *split rolls at* 1% *above threshold. Further above threshold, roll patterns are found. The parameter values for these simulations are $\alpha = 1.1$, $\beta = \rho_0 = 0.3$, $b = 1$, $\omega = 2.5$; these values of β, ρ_0, b, and ω are used for all simulations reported here.*

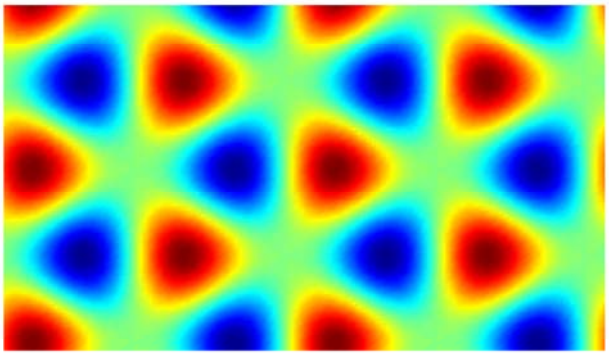

Figure 2. *Plots of $Re(\psi)$ from spectral simulations of (2.1) and (2.2) with a container size $4\Lambda_c \times 4\Lambda_c/\sqrt{3}$ and periodic boundary conditions, showing a pattern of triangles. The parameter values are as for Figure 1*(a).

the range of validity of the weakly nonlinear approximation is found to be fairly small; at 1% above threshold, antisquares are no longer realized, and instead we find rolls or roll-like patterns (Figure 1(b)).

The theoretical results predict that supersquares are stable only in a very small region of parameter space near the point at which the bifurcation becomes subcritical, but we were unable to find stable supersquares in this region in our numerical simulations. However, if we change the parameters to $\beta = \rho_0 = 2$, $b = 1$, $\omega = 4$, the theory predicts a larger region of stable supersquares, $1.0867 < \alpha < 1.6154$, and stable supersquares were found in numerical simulations in this range.

Since the model equations do not select a preferred angle between modes when $\phi > 1$, this angle is in fact determined by the imposed periodic lattice. As an illustration of this, Figure 2

shows a simulation in a periodic domain of size $4\Lambda_c \times 4\Lambda_c/\sqrt{3}$, designed to permit patterns that reside on a hexagonal lattice. In this case a stable pattern of regular triangles is found.

3.3. Spatial modulation. The weakly nonlinear analysis presented above holds when the pattern spectrum consists of discrete modes whose wavenumbers are close to the critical circle $k^2 = k_c^2$. However, in a spatially extended domain, the fact of mass conservation leads to the existence of slowly evolving modes of large wavelength (i.e., with wavenumber close to zero), representing adjustments of large-scale inhomogeneities in the thickness of the layer. These slowly varying modes, even though linearly damped through the diffusive term in the equation of mass conservation, must be included in any amplitude-equation description of the near-threshold dynamics of the pattern [10, 22, 24]. Previous theoretical work has indicated the appropriate amplitude equations for a system undergoing a stationary bifurcation to a pattern [10, 22, 24], and we sketch below how this analysis may straightforwardly be extended to the present problem of parametric forcing.

To this end, we restrict our attention to mutually perpendicular modes ($\theta = \pi/2$) and consider the planforms

$$\psi_1 = (b + s + \mathrm{i})\left(\tilde{A}(\tilde{X}, \tilde{Y}, \tilde{T}) \exp(\mathrm{i}kx) + \tilde{B}(\tilde{X}, \tilde{Y}, \tilde{T}) \exp(\mathrm{i}ky) + \text{c.c.}\right), \tag{3.19}$$

$$\rho_2 = \tilde{C}(\tilde{X}, \tilde{Y}, \tilde{T}) + \text{q.t.}, \tag{3.20}$$

where "q.t." denotes quadratic interaction terms involving $\tilde{A}$ and $\tilde{B}$ (proportional to $\mathrm{e}^{2\mathrm{i}kx}$, $\mathrm{e}^{\mathrm{i}k(x+y)}$, etc.). The amplitudes $\tilde{A}, \tilde{B}$ are complex, but $\tilde{C}$, the large-scale mode arising from mass conservation, is real.

As before, the evolution of the amplitudes takes place on the slow time scale $\tilde{T} = \epsilon^2 t$, while spatial modulations occur over the scales given by $\tilde{X} = \epsilon x$ and $\tilde{Y} = \epsilon y$. Examining the problems that arise at successive orders in ϵ, we find at $O(\epsilon^3)$, after a rescaling of amplitudes and time as in (3.7), and a spatial scaling

$$(X, Y) = \sqrt{\frac{b(\omega + b(1 + \rho_0))}{2(1 + b^2)(\omega b - 1 - \rho_0)}}\,(\tilde{X}, \tilde{Y}),$$

the amplitude equations

$$A_T = A + A_{XX} - |A|^2 A - \lambda |B|^2 A - AC, \tag{3.21}$$

$$B_T = B + B_{YY} - |B|^2 B - \lambda |A|^2 B - BC, \tag{3.22}$$

where λ is given in (3.10). In addition, at $O(\epsilon^4)$ the evolution equation for C is found to be (after the same rescaling of variables that leads to (3.21) and (3.22))

$$C_T = \sigma \nabla^2 C + \mu \nabla^2 \left(|A|^2 + |B|^2\right), \tag{3.23}$$

where

$$\sigma = \frac{\beta}{2}\left[\frac{\omega b + b^2(1 + \rho_0)}{(\omega b - 1 - \rho_0)(1 + b^2)}\right], \tag{3.24}$$

$$\mu = \frac{\alpha \rho_0}{3 - \phi}\left[\frac{\omega b + b^2(1 + \rho_0)}{(\omega b - 1 - \rho_0)(1 + b^2)}\right]. \tag{3.25}$$

The average of C over X and Y is conserved, according to (3.23), corresponding to conservation of mass in (2.2). We must set this average to zero, so that the average of ρ is ρ_0. The amplitude equations (3.21)–(3.23) are precisely those of Cox and Matthews [10] (in the special case that their parameter $\mu_- = 0$), and so we may directly apply their modulational stability results for rolls and squares.

We first consider rolls: a family of roll solutions to (3.21)–(3.23) exists in the form $A = Q\mathrm{e}^{\mathrm{i}qX}$, $B = C = 0$, where $Q^2 = 1 - q^2$, corresponding to rolls of wavenumber $k_c + \epsilon q$. Of course, we recover the results of section 3.1 regarding the stability of rolls to disturbances with exactly critical wavenumber: rolls are unstable to squares if $\lambda < 1$ (i.e., if $\phi > 1$). An analysis of the modulational stability of rolls [10] indicates that a new instability, leading to amplitude modulation, replaces the usual Eckhaus instability and, when $\mu > 0$, is more widespread than the case when there is no conserved mode. Indeed, all rolls may be modulationally unstable if $\mu > \sigma$, with the last rolls to succumb to the instability being those at band-center ($q = 0$). We thus focus on the band-center rolls. For these rolls, in terms of the original variables, the region of modulational instability corresponds to $1 < \phi < 3$, which is identical to that for instability to perturbations in a perpendicular mode. Since we expect the time-scale for the growth of perpendicular modes to be less than that for modulational modes, we do not expect to see long-wavelength instability of rolls in simulations, except under contrived circumstances, and we expect instead to see only the transition to squares. This coincidence of stability conditions is also found in the modified Swift–Hohenberg model considered in [10] and is a consequence of the fact that in these simple models the cross-coupling coefficient λ does not depend on the angle between the modes.

Squares take the form $A = Q\mathrm{e}^{\mathrm{i}qX}$, $B = Q\mathrm{e}^{\mathrm{i}qY}$, $C = 0$ with $Q^2 = (1 - q^2)/(1 + \lambda)$ and are stable to roll-type perturbations only while $|\lambda| < 1$, i.e., $1 < \phi < 9/5$. All square patterns are found to be unstable to modulational perturbations when $2\mu > (1 + \lambda)\sigma$ [10]. This implies that squares are modulationally unstable while $\phi > 1$, again matching the roll-perturbation stability boundary. This leads to the remarkable result that all square patterns are unstable, provided the container size is suitably large, and so a regular square pattern can never be seen in corresponding simulations. A more detailed analysis indicates that the initial deformation of a modulationally unstable square pattern will be primarily to its amplitude if the wavenumber $k + \epsilon q$ lies near the band-center, but to its phase otherwise [10]. Nevertheless, in a finite computational box, one would generally expect some modulation of both the amplitude and phase; in very long boxes, different modulational scalings are appropriate [28].

3.4. Large-container numerical simulations. For a numerical extension of the preceding analytical results, we simulate (2.1) and (2.2) in a large square container (so that long-wavelength modulations to the pattern can occur), again with periodic boundary conditions. Extensive simulations support the predictions regarding the modulational stability of both rolls and squares. Figure 3 illustrates the predicted long-wavelength instability of squares. We see that the initial manifestation of the instability is an amplitude modulation in the form of a large-scale square "superstructure" (a limited analysis of such a superstructure [10] is consistent with the square shape observed here). The final state reached in this example is a highly localized oscillon chain. Similar patterns have been found through a model based on the assumption of nearest-pattern interaction [17, 18], which indicates that the observed state is not merely an artifact of the present model. We find such localized states, composed of straight or

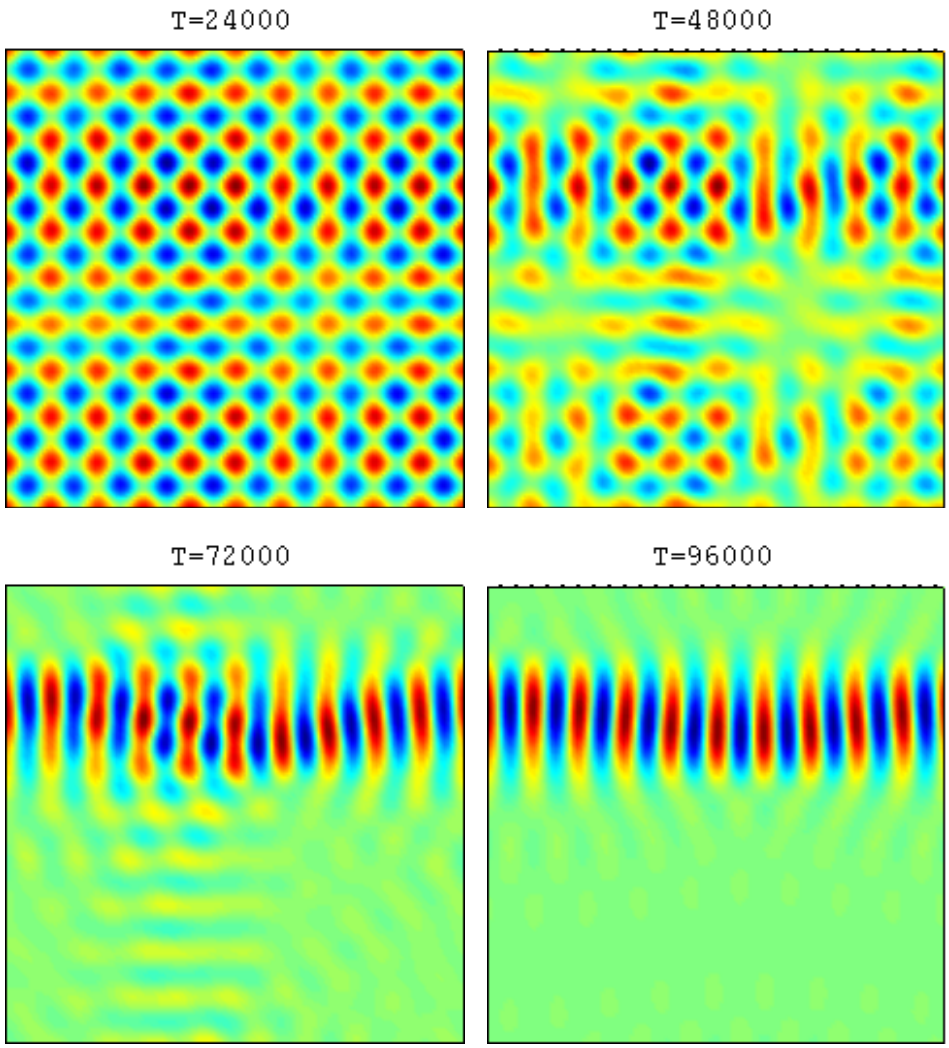

Figure 3. *Plots of $Re(\psi)$ depicting four snapshots of the long-wavelength instability of square patterns. The initial manifestation of the instability takes the form of a square modulation (cf. Figure* 5(a) *of* [10]*), while the final state is an oscillon chain (cf. Figure* 10(f) *of* [17]*), spreading across the entire width of the domain. For this simulation, parameter values are the same as for Figure* 1 *except the container size is $L = 10\Lambda_c$, γ is* 0.1% *above critical, and $\alpha = \phi = 1.1$. The initial condition is periodic squares perturbed by small amplitude noise.*

wavy oscillon chains, widely in our simulations in intermediate to large containers with $\phi > 1$ [36]. In large containers we also commonly observe worm-like patterns [29], several of which can coexist in any given simulation, in various orientations in different parts of the domain.

Although no corresponding analysis is currently available, an analogous modulational instability for antisquares can be seen in the simulations illustrated in snapshot in Figure 4. After an initial condition of small-amplitude noise, we see regular antisquares initially being selected before a long-wavelength amplitude modulation takes place in the form of a one-dimensional superstructure. Subsequently, the system evolves to a single oscillon chain.

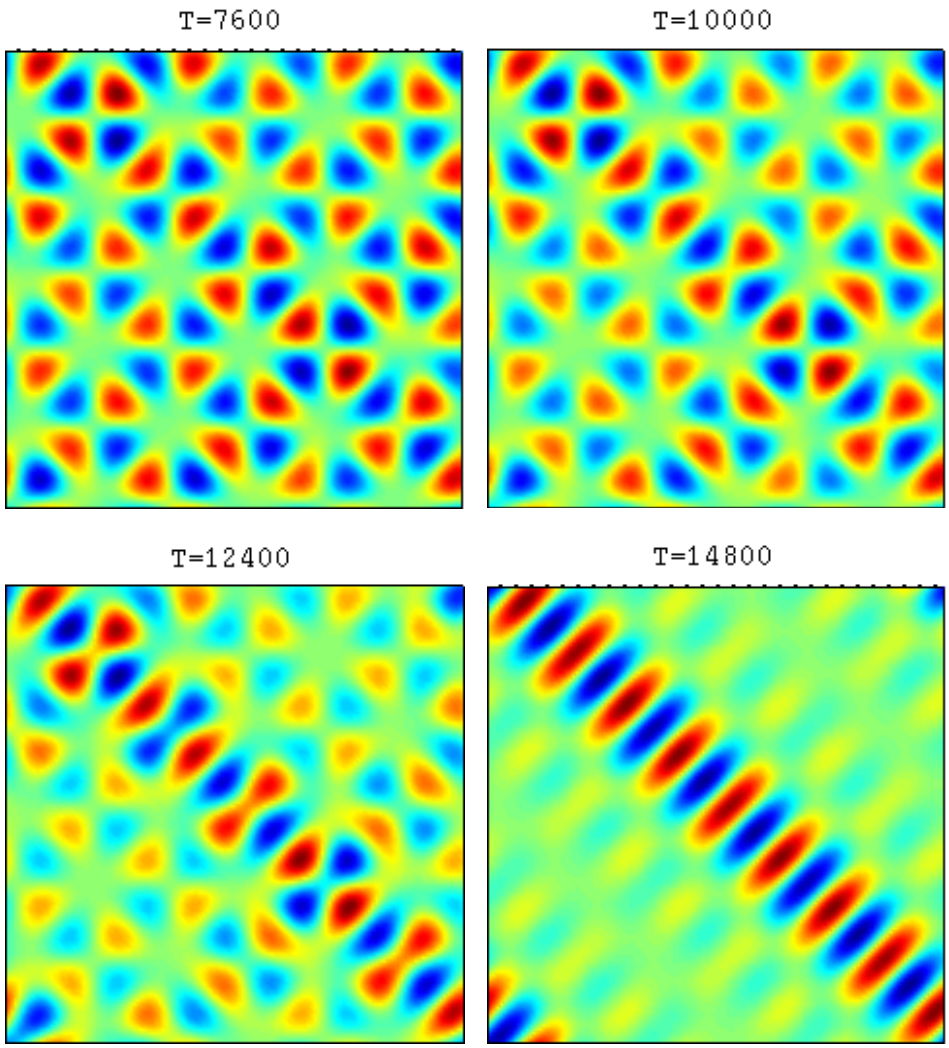

Figure 4. *Plots of $Re(\psi)$ depicting four snapshots of the long-wavelength instability of antisquare patterns. The initial manifestation of the instability takes the form of a roll modulation, while the final state is a single oscillon chain. For this simulation, the container size is $L = 3\sqrt{5}\Lambda_c$, γ is 0.1% above critical, and α is 1.25. The initial condition is small-amplitude noise.*

Simulating the model equations at increasing values of ϕ shows the degree of localization to increase as ϕ moves away from 1. This phenomenon is illustrated in Figure 5, where the final states are shown for four values of ϕ. We see roll solutions for $\phi = 0.9$, while rhombs are found at $\phi = 1.1$. Subsequently, at $\phi = 1.2$, we find a disordered cellular pattern, where a slight localization can be observed. Finally, at $\phi = 1.3$, a similar cellular pattern is apparent but with a far stronger degree of localization. Indeed, the final state can be thought of as comprising several oscillon chains. This behavior is characteristic of much of parameter space. An accompanying video (67540_02.mov [604KB]) shows a typical example of increasing localization leading to oscillon chains for $\phi = 1.2$, with γ chosen to be 0.2% above critical.

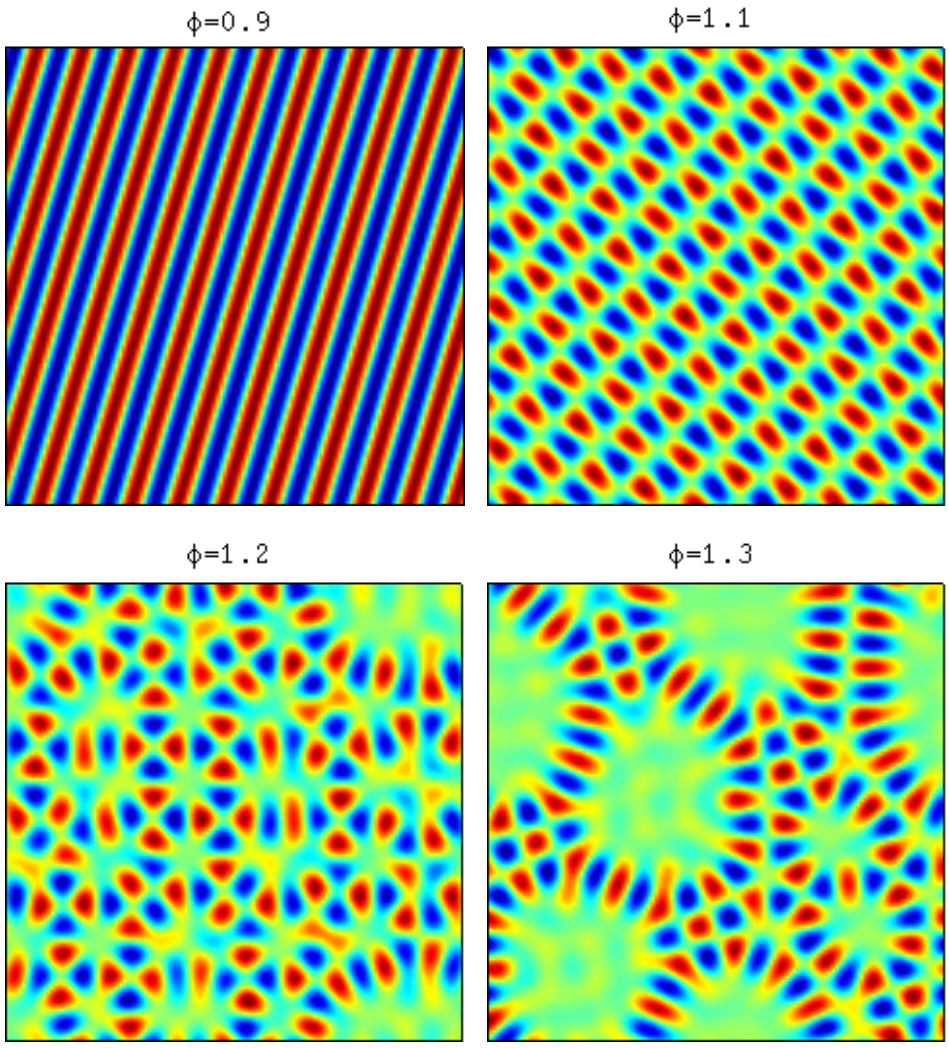

Figure 5. *Plots of $Re(\psi)$ illustrating the steady states realized as ϕ is increased. The parameter values are the same as in Figure 1, the container size is $L = 10.5\Lambda_c$, γ is 0.5% above critical, and the initial condition is noise of amplitude 10^{-3}.*

4. Discussion. The analysis presented here extends that of Tsimring and Aranson [2, 32] in providing a more complete description of the stability of patterns in their phenomenological model for pattern formation in a vertically vibrated granular layer. Extensive numerical experiments on (2.1) and (2.2) have supported all the analysis.

In small domains, a variety of unusual patterns can be stable, including antisquares and triangles. In larger domains, our results show that rolls and squares may suffer a modulational instability, which is strongly influenced by the constraint of mass conservation. It turns out that rolls are effectively immune to this modulational instability because it arises only where a regular roll pattern is already unstable to a regular pattern of squares. By contrast, squares are always susceptible; both these modulational results have been confirmed numerically. The

fact that squares are always unstable would appear to be in conflict with the experimental results, where stable square patterns are commonly observed [25]; it may thus indicate a shortcoming in the phenomenological model of (2.1) and (2.2). However, other explanations for the discrepancy are not ruled out. For example, since the modulational instability leads to long-wavelength perturbations becoming unstable first, the instability can take place only if perturbations on a sufficiently large spatial scale can be accommodated in the container. So for finite containers squares will generally be stable close to the roll–square transition, but will lose stability as the driving frequency is decreased (effectively increasing ϕ). A further possible explanation for the absence of observations of the instability of squares is that the long-wavelength nature of the instability corresponds to a very slow temporal growth of the disturbance. Thus, square patterns may be observed for a significant period of time before the long-wavelength modulation manifests itself; this has certainly been apparent in our numerical simulations. However, the exact coincidence of the roll–square transition and the modulational instability is a consequence of the simplicity of the model.

Since we have considered only a supercritical bifurcation from the uniform state, bistability arguments are not necessary in explaining the existence of strongly localized solutions. Rather, it is the influence of the conserved quantity that provides the localization mechanism: particles tend to flee regions in which ψ is large, leading to an increased flux of particles and a reduction in the local density ρ. This, in turn, decreases the damping in the ψ equation (2.1). Such mass redistribution, and corresponding localization, is observed in numerical simulations of models such as that of Eggers and Riecke [14]. The feedback loop just described enables localized structures to remain stable. In effect, a large-scale redistribution of the granular medium causes some regions to be locally "supercritical" and others locally "subcritical," while the system as a whole is supercritical. Many other models of a vertically vibrated granular layer include in them the principle of conservation of mass, and one might expect corresponding long-wavelength effects to be applicable in a wide range of models. However, few continuous order-parameter models exist; most are of a semicontinuum or stroboscopic nature and the weakly nonlinear analysis carried out here is not immediately transferable.

Our interest in (2.1) and (2.2) is not exclusively in the context of vibrated granular layers; such a phenomenological model could also account for a vibrated fluid layer. In this situation, the complex order-parameter ψ corresponds to the velocity potential at the free surface [37], while ρ represents the displacement from the undisturbed fluid height (the volume of fluid being conserved). In addition, aside from its application to granular and fluid layers, the phenomenological model (2.1) and (2.2) is an interesting and unusual model of pattern formation in its own right. It is unusual in the sense that the coupling to a mean field enables the selection of cellular patterns to be determined by the parameter values rather than being solely dependent on symmetries as in other common models such as the Swift–Hohenberg equation. What makes (2.1) and (2.2) particularly interesting is how the coupling with a large-scale mode facilitates the near-threshold exhibition of a plethora of cellular, but predominantly localized, patterns.

Near Invariance for Markov Diffusion Systems*

Fritz Colonius†, Tobias Gayer†, and Wolfgang Kliemann‡

Abstract. A concept of "near invariance" is developed starting from sets that are actually invariant under smaller perturbations. This is based on a theory for system dynamics of Markov diffusion processes illuminating the idea of "large" noise perturbations turning invariant sets for smaller noise ranges into transient sets. The controllability behavior of associated deterministic systems plays a crucial role. This setup also allows for numerical computation of nearly invariant sets, the exit times from these sets, and the exit locations under varying perturbation ranges. Three examples with additive perturbations are included: a one degree of freedom system with double well potential and the escape equation without and with periodic excitation.

Key words. almost invariance, Markov diffusions, control sets

DOI. 10.1137/040618539

1. Introduction.

Almost invariance is an often used concept for stochastic dynamical systems that intends to describe sets such that the system

- stays within a set in the state space for a "long" time,
- exits from the set only under "large" noise perturbations,
- and may return to this set at a later, much "longer" time.

Hence almost invariance tries to describe a transient phenomenon of stochastic systems, but on "large" time intervals. The interpretation of "large" time intervals and "large" perturbations usually depends on the application one has in mind.

Recently, these phenomena have found renewed interest. This includes approaches based on transfer operator theory combined with set oriented numerics (Dellnitz and Junge [11], [12], Froyland [20], [21], and Froyland and Dellnitz [22]) and graph theoretic methods (Dellnitz et al. [14]) as well as extensions of metastability in the classical Freidlin–Wentzell theory [19] in Huisinga, Meyn, and Schütte [27] and the analysis of dominant eigenvalues of transfer operators (Schütte, Huisinga, and Deuflhard [37]; Deuflhard et al. [16]). An important approach is also developed in the work of Bovier [2] and Bovier et al. [3], [4].

Applications of almost invariant sets include, e.g., the analysis of molecular dynamics, where they can symbolize conformations of a molecule that are essential for its chemical properties (Deuflhard and Schütte [15]); Mezic [34] proposes a different dynamical systems explanation of conformation dynamics based on an interplay between local and global interconnections for coupled oscillator networks. Similar problems of almost invariance occur,

e.g., in dynamical astronomy (Dellnitz et al. [13]), in the analysis of dynamic reliability when one tries to estimate rare occurrences of system failure due to large perturbations (see, e.g., Colonius, Häckl, and Kliemann [5]), and in other models in engineering and science.

The goal of this paper is to develop a theory that

- defines a plausible concept of "nearly invariant sets" based on the actual system dynamics of Markov diffusion processes,
- illuminates the idea of "large" noise perturbations turning invariant sets for smaller noise ranges into transient sets,
- explores the idea of invariance over "large" time intervals,
- and allows for numerical computation of nearly invariant sets, the exit times from these sets, and the exit locations under varying perturbation ranges.

Thus the concept of near invariance captures essential features of "almost invariance." Our approach is, roughly, as follows:

- We consider Markov diffusion models (i.e., the system does not anticipate future behavior of the noise) with perturbations entering as parameter or additive noise into the system dynamics, which are modeled as a set of ordinary differential equations

$$\dot{x} = X_0(x) + \sum_{i=1}^{m} \xi_i(t,\omega) X_i(x) \tag{1}$$

  on a finite dimensional C^∞ manifold M, where the C^∞ vector field X_0 describes the unperturbed dynamics and $\xi(t,\omega) = (\xi_i(t,\omega),\ i = 1,\dots,m)$ is the vector of random perturbation processes with C^∞ dynamics $X_1,\dots,X_m$. We model ξ as a function $\xi = f(\eta)$ of a background noise η, $f : N \to U$, where N is the state space of the background noise and $U \subset \mathbb{R}^m$ is the set of perturbation values. We assume η to be a stationary, ergodic Markov process.
- The noise range is treated as a parameter $\rho \geq 0$ of the system by introducing a family $f^\rho : N \to U^\rho$, $\rho \geq 0$, of functions such that the sets U^ρ of perturbation values increase with ρ. Setting $U^0 = \{0\}$, we recover the unperturbed dynamics of the system (1).
- We identify the invariant sets of the stochastic system (1), depending on the noise range. Under mild conditions, the invariant control sets of an associated control system are the supports of the invariant measures of (1) and they form the cores of the invariant sets for the system.
- Analyzing the change of the invariant sets as the noise range $\rho \geq 0$ increases leads to the study of the loss of invariance, specifically to the analysis of bifurcation points ρ_0 where an invariant set loses its invariance and becomes transient or "nearly invariant."
- Finally, we study the exit time distributions from invariant sets as they become transient under the influence of larger perturbations.

This approach develops a concept for near invariance starting from sets that are actually invariant under smaller perturbations. In other approaches the term "almost invariance" is used to describe the behavior in certain regions, usually in relation to an invariant probability measure with support on the whole state space; see, e.g., Huisinga, Meyn, and Schütte in [27]. In the approach outlined above, such a reference measure need not exist, and we suggest the term "near invariance" for the concept developed here.

Though our analytical approach applies to systems in arbitrary finite dimension, numerical evaluations appear possible for low dimensional systems only thus restricting the range of applicability.

It is worth noting that recently, in the context of random diffeomorphisms, problems similar to near invariance have been analyzed by Zmarrou and Homburg [41]. They analyze average escape times from sets as functions of a bifurcation parameter.

In section 2 we describe the setup used in this paper and recall some background material on Markov diffusion systems and their qualitative behavior, based on the analysis of associated control systems with varying control range. Section 3 presents the definition of near invariance together with the main result on the existence of nearly invariant sets. Theorem 3.3 and Corollary 3.4 describe the bifurcation points where an invariant and a variant set merge to generate a nearly invariant set. The rest of this section is devoted to the study of the exit sets from variant sets. Section 4 discusses the numerical computation of exit times for nearly invariants sets and the corresponding exit locations. Section 5 analyzes three examples in some detail: a one degree of freedom system with double well potential and additive perturbation and two perturbed versions of the escape equation, without and with an extra periodic excitation; see, e.g., [40], [35], [17], [26], and the references therein. The latter example is three dimensional and at the present limit of our computational possibilities. The appendix, section 6, contains some background information on parameter dependent deterministic control systems that is used throughout the paper.

2. Markov diffusion systems and associated control systems. In this section we recall some facts about Markov diffusion systems, their relations to associated control systems, and the support theorem of Stroock and Varadhan. We start from the system

$$\dot{x} = X_0(x) + \sum_{i=1}^{m} f_i(\eta_t) X_i(x) \tag{2}$$

on a finite dimensional, C^∞ manifold M with C^∞ vector fields $X_0, \dots, X_m$ as in section 1. First we specify our assumptions on the background noise η. Let N be a compact connected finite dimensional C^∞ manifold on which the stochastic differential equation

$$d\eta = Y_0(\eta)dt + \sum_{j=1}^{l} Y_j(\eta) \circ dW_j \tag{3}$$

is defined. Here $W = (W_j)$ is an l dimensional Wiener process, $Y_0, \dots, Y_l$ are C^∞ vector fields on N, and "$\circ$" denotes the Stratonovich stochastic differential. The compactness of the noise space N rules out excitation processes with Gaussian statistics, and thus (3) can be regarded as a realistic model of physical systems with bounded noise. We assume that (3) admits at least one stationary Markov solution. Imposing the Lie algebra rank condition

$$\dim \mathcal{LA}\{Y_1, \dots, Y_l\}(q) = \dim N \text{ for all } q \in N \tag{4}$$

as a nondegeneracy condition on N guarantees that this stationary solution is unique (see Kunita [31]) and can be extended to a stationary Markov solution η_t^*, $t \in \mathbb{R}$.

The noise process $\xi_t := f_i(\eta_t)$ in (2) is defined in the following way: Let $U \subset \mathbb{R}^m$ be a compact convex set with $0 \in \operatorname{int} U$ and $U = \operatorname{cl} \operatorname{int} U$. Let

$$f : N \to U$$

be a continuous surjective function such that there exists a closed connected subset $L \subset N$. $f|_L$ is C^1 and $Df(\eta)$ has full rank for all $\eta \in L$ with $f(\eta) \in U$; see [7]. Then $\xi_t := f(\eta_t^*)$ is a stationary process with values in U.

We model variations in the size of the noise by introducing a parameter $\rho \geq 0$ and the noise ranges U^ρ, satisfying the same assumption as U above. We consider the process η_t^* as a background noise, which for every ρ is mapped into the stochastic perturbation space $\mathcal{U}^\rho = \{u : \mathbb{R} \to U^\rho, \textit{measurable}\}$ by a continuous surjective function

$$f^\rho : N \to U^\rho,$$

which satisfies the assumptions on f above. Combining this perturbation model with system (1), we arrive at the Markov diffusion system

$$\begin{aligned} d\eta &= Y_0(\eta)dt + \textstyle\sum_{j=1}^{\ell} Y_i(\eta) \circ dW_j, \quad \eta_0 = \eta_0^*, \\ \dot{x} &= X_0(x) + \textstyle\sum_{i=1}^{m} f_i^\rho(\eta_t) X_i(x) \end{aligned} \tag{5}$$

on the state space $M \times N$, for which we assume the existence and uniqueness of a strong solution for all $t \geq 0$. This system is degenerate since the Wiener process acts only on the second component. Note that, in general, the component $x(t)$ by itself is not Markovian. The pair process $(x(t), \eta_t)$ is, however, a Markov diffusion process for all ρ, if the initial random variable x_0 in M is independent of the increments of the Wiener process. Compare, in particular, especially [29] for results on degenerate diffusions along these lines, and [7] and [8] for more details on our setting in general.

The system (5) can be analyzed using control theory via the support theorem presented by Stroock and Varadhan in [38]. To make this more precise, we set up the control system associated with (5) to be

$$\begin{aligned} \dot{\eta} &= Y_0(\eta) + \textstyle\sum_{j=1}^{\ell} w_j(t) Y_i(\eta), \\ \dot{x} &= X_0(x) + \textstyle\sum_{i=1}^{m} f_i^\rho(\eta_t) X_i(x), \end{aligned} \tag{6}$$

where $w \in \mathcal{W} := \{w : [0, \infty) \to \mathbb{R}^l, \text{piecewise constant}\}$, and we assume the Lie algebra rank condition (4) for the η-component. Furthermore, we want the pair system (5) to be regular; i.e., we want the topological support of its transition probabilities from each point $(x, p) \in M \times N$ to have nonvoid interior in $M \times N$. This is guaranteed by

$$\dim \mathcal{LA} \left\{ \begin{pmatrix} X_0 + \sum \eta_i X_i(x) \\ Y_0 + \sum w_j Y_j \end{pmatrix}, w \in \mathbb{R}^l \right\} \begin{pmatrix} x \\ \eta \end{pmatrix} = \dim M + \dim N \tag{7}$$

for all $(x, \eta) \in M \times N$ (see Meyn and Tweedie [33] for a relaxation of this condition). Instead of (6) it will be sufficient to consider the system

$$\dot{x}(t) = X_0(x(t)) + \sum_{i=1}^{m} u_i(t)\, X_i(x(t)), \quad u \in \mathcal{U}^\rho; \tag{8}$$

see the appendix, section 6, for definitions and notation of control systems. Note that the condition (7) implies local accessibility for the x-component (8).

We fix $\rho \geq 0$ for the remainder of this section and drop it in the notation. For all $(x, \eta) \in M \times N$ the orbits $\mathcal{O}^+(x, \eta)$ of system (6) are of the form $\operatorname{cl} \mathcal{O}^+(x, \eta) = \operatorname{cl} \mathcal{O}^+(x) \times N$, where $\mathcal{O}^+(x)$ is the forward orbit of the system (8) from $x \in M$. In particular, the invariant control sets $\hat{C} \subset M \times N$ of (6) correspond one-to-one to the invariant control sets $C \subset M$ of (8) via $\hat{C} = C \times N$. This follows from Lemma 3.17 in [7]. (We remark that in the statement of that lemma one has to add the surjectivity assumption for f which is used in the proof.) Therefore, the global control structure of the x-component (8) determines the control structure of the pair process (6).

The natural probability space to work in is $\hat{\Omega} := \mathcal{C}(\mathbb{R}_0^+, M \times N) = \{\omega : R_0^+ \to M \times N, \textit{continuous}\}$ and for fixed initial conditions $(x, q) \in M \times N$ the pair process (5) induces a probability measure $\hat{P}_{(x,q)}$ on $\hat{\Omega}$. By $\hat{P}_{(x,\eta^*)}$ we denote the measure corresponding to the stationary Markov solution $\{\eta_t^*, t \geq 0\}$ in the η-component. Its marginal distribution on $\Omega := \mathcal{C}(\mathbb{R}_0^+, M)$ will be denoted by P_x, $x \in M$. The trajectories of the pair process are $(\varphi(t, (x, q), \omega), \eta(t, q, \omega))$ for $(x, q) \in M \times N$, and we will write the x-component under $\{\eta_t^*, t \geq 0\}$ as $\varphi(t, x, \omega)$, $x \in M$. Then the "transition probability" from $x \in M$ to a set $A \subset M$ in time $t \geq 0$ is

$$P(t, x, A) = P_x(\varphi(t, x, \omega) \in A). \tag{9}$$

Using the tube method introduced by Arnold and Kliemann in [1], it follows (compare with [28]) from the support theorem that

$$\operatorname{supp} P(t, x, \cdot) = \operatorname{cl} \left\{ \begin{matrix} y \in M \mid \text{there is a piecewise continuous} \\ u \in \mathcal{U} \text{ such that } \varphi(t, x, u) = y \end{matrix} \right\}. \tag{10}$$

It now follows from [29] and [7] that the invariant Markov probability measures μ of (5) have support given by $\operatorname{supp} \mu = C \times N$, where C is an invariant control set of (8), and these measures are unique on each set of this form. We call *ergodic sets* those invariant control sets C of (8) such that $C \times N$ is the support of some invariant Markov measure, which includes, in particular, all bounded invariant control sets. All points in $M \times N$ outside of invariant control sets are transient.

To describe the consequences of the support theorem for the relationship between the Markov diffusion process (5) and the control system (8) in more detail, we define the *first entrance time* of (5) to a set $A \subset M$ from a point $x \in M$ as the random variable

$$\tau_x(A) := \inf\{t \geq 0, \varphi(t, x, \omega) \in A\},$$

and the *first exit time* of (5) from a set $A \subset M$ starting at a point $x \in M$ as the random variable

$$\sigma_x(A) := \inf\{t \geq 0, \varphi(t, x, \omega) \notin A\}.$$

The corresponding *exit location* is given as

$$h_x(A)(\omega) := \begin{cases} y \in M, \ y = \varphi(\sigma_x(A), x, \omega) & \text{for } \sigma_x(A)(\omega) < \infty, \\ \emptyset & \text{for } \sigma_x(A)(\omega) = \infty. \end{cases}$$

Due to Theorem 3.19 in [7], for invariant control sets $C \subset M$ of system (8) the equation $P_x(\sigma_x(C) < \infty) = 0$ holds for all $x \in C$. For bounded variant control sets $D \subset M$, on the other hand, it holds that $P_x(\sigma_x(D) < \infty) = 1$ for all $x \in D$. Under the measure P_x we even have that the expectation of the sojourn time $E_x[\sigma_x(D)]$ is finite (see [5, Theorem 11]).

3. Near invariance and mergers of control sets. If a bounded invariant control set C^ρ for $\rho \leq \rho_0$ becomes variant for $\rho > \rho_0$, then the corresponding ergodic set of the Markov process disappears and becomes transient. Nevertheless, although the disappearance of an ergodic set changes the global behavior of a stochastic system considerably, we expect the system to experience large exit times from the resulting variant control set as long as ρ is close to ρ_0 (see [25] for an example that can serve as a prototype of this phenomenon). This behavior is captured more generally in the following definition.

Definition 3.1. *Consider the family of Markov diffusion systems* $(5)^\rho$. *A closed set* $A \subset M$ *with* $\operatorname{int} A \neq \emptyset$ *is* nearly invariant *in* $x_0 \in \operatorname{int} A$ *for* $\rho > \rho_0$ *if*

(i) $\sigma^\rho_{x_0}(A) < \infty$ *with positive probability for* $\rho > \rho_0$, *and*

(ii) *for all* $x \in A$ *one has* $\sigma^\rho_x(A) \nearrow \infty$ *almost surely for* $\rho \searrow \rho_0$ *and* $\sigma^{\rho_0}_x(A) = \infty$ *almost surely.*

If A *is nearly invariant in every* $x_0 \in \operatorname{int} A$, *the set* A *is called* nearly invariant.

The following theorem reduces the search for nearly invariant sets to the search for closed sets A which are invariant for the control range U^{ρ_0} and lose their invariance under increased control ranges.

Theorem 3.2. *Suppose the Markov diffusion systems* $(5)^\rho$ *satisfy the Lie algebra rank conditions* (7) *and* (4) *and that* U^ρ *increases upper semicontinuously with respect to* $\rho \in (\rho_*, \rho^*)$. *Let* $x_0 \in \operatorname{int} A$ *for some closed set* $A \subset M$, $\operatorname{int} A \neq \varnothing$, *and consider* $\rho_0 \in (\rho_*, \rho^*)$. *Then the set* A *is nearly invariant in* x_0 *if and only if the set* A *is positively invariant for* ρ_0, *and for each* $\rho > \rho_0$

$$\operatorname{int}(\mathcal{O}^{\rho,+}(x_0) \setminus A) \neq \emptyset. \tag{11}$$

Proof. First we show that from positive invariance of A and upper semicontinuity of U^ρ at $\rho = \rho_0$ property (ii) of Definition 3.1 follows. By Lemma 6.1, $\operatorname{int} A$ is also positively invariant and hence $\sigma^{\rho_0}_x(A) = \infty$ almost surely. Now assume, contrary to the other assertion, that there are $x \in A$, a positive time $T > 0$, and $\rho_n \searrow \rho_0$ such that $P_x(\sigma^{\rho_n}_x(A) < T) > 0$. Then from (10) it follows that for all ρ_n there is a control $u_n \in \mathcal{U}^{\rho_n}$ with $\varphi(T, x, u_n) \notin A$, and, due to continuity, there are positive times $t_n < T$ such that $\varphi(t_n, x, u_n) \in \partial A$. Since U^ρ is increasing, we can look upon the sequence u_n as a sequence in the compact set $\mathcal{U}^{\rho_1}$ endowed with the weak*-topology. Then there are subsequences, called (t_n) and (u_n) again, such that $t_n \to t_*$ and $u_n \to u_*$. By (20) it follows that $\varphi(t_n, x, u_n) \to \varphi(t_*, x, u_*)$. Now observe that on a bounded interval weak*-convergence in L_∞ implies weak convergence in L_2; and here a subsequence of a weakly convergent sequence converges pointwise. Hence upper semicontinuity of the closed sets U^ρ implies that $u_* \in \mathcal{U}^{\rho_0}$, because if $u_*(t)$ was not in U^{ρ_0} for some t, this would contradict $u_n(t) \in U^{\rho_n}$ for all n. Then by continuity it follows that $\varphi(t_*, x, u_*) \in \partial A$, contradicting the positive invariance of $\operatorname{int} A$.

Next we prove that assumption (11) implies property (i) of near invariance by showing that $P_{x_0}(\sigma^\rho_{x_0}(A) < \infty) > 0$ for all $\rho > \rho_0$. Pick $\rho > \rho_0$; then there are some open set

$V \subset \operatorname{int}(\mathcal{O}^{\rho,+}(x_0) \setminus A)$, a positive time $t_0 < \infty$, and a piecewise constant control $u_0 \in \mathcal{U}^\rho$ such that $\varphi(t_0, x_0, u_0) \in V$. By continuous dependence of the solutions of $(8)^\rho$ on u, there is an open neighborhood $\mathcal{V}(u_0) \subset \mathcal{U}^\rho$ such that $\varphi(t_0, x_0, u) \in V$ for all $u \in \mathcal{V}(u_0)$. The support theorem implies that $P(\eta \in \mathcal{C}(\mathbb{R}_0^+, N),\ f^\rho(\eta) \in \mathcal{V}(u_0)) > 0$. Since the trajectories of (5) are continuous, we obtain

$$\begin{aligned} P_{x_0}(\sigma^\rho_{x_0}(A) < \infty) &\geq P_{x_0}(\sigma^\rho_{x_0}(A) < t_0) \\ &\geq P(\eta \in \mathcal{C}(\mathbb{R}_0^+, N),\ f^\rho(\eta) \in \mathcal{V}(u_0)) > 0. \end{aligned} \tag{12}$$

For the converse implication assume that A is nearly invariant in $x_0 \in \operatorname{int} A$ for $\rho > \rho_0$. Then $\sigma^\rho_{x_0}(A) < \infty$ with positive probability for $\rho > \rho_0$. Thus for every $\rho > \rho_0$ there is a realization of η and a time T such that with $u^\rho := f^\rho(\eta) \in \mathcal{U}^\rho$

$$\varphi(T, x_0, u^\rho) \notin A.$$

Thus $\varphi(T, x_0, u^\rho) \in \mathcal{O}^{\rho,+}(x_0) \setminus A$. Local accessibility of (8) implies that

$$\mathcal{O}^{\rho,+}(x_0) \subset \operatorname{cl} \operatorname{int} \mathcal{O}^{\rho,+}(x_0).$$

Since A is closed, we see that for every $\rho > \rho_0$ condition (11) holds.

It remains to show that the set A is positively invariant for ρ_0. This follows from $\sigma^{\rho_0}_x(A) = \infty$ almost surely. In fact, if A is not positively invariant, we obtain a contradiction using the same reasoning as above in the proof that (11) implies property (i) of near invariance. ■

This result shows that we have to look for closed sets which are positively invariant for ρ_0 and lose their invariance for $\rho > \rho_0$. Naturally, the sets A that are nearly invariant for all $x_0 \in \operatorname{int} A$ are of particular interest. These sets are specified in the following theorem. Recall from section 6 that $\mathbf{A}^{inv}(I)$ denotes the largest invariant set in the domain of attraction of a set I.

Theorem 3.3. (i) *Let the assumptions of Theorem 3.2 be satisfied and let C^{ρ_0} be a compact invariant control set for ρ_0. For each $\rho > \rho_0$ denote by C^ρ the unique control set of $(8)^\rho$ for which $C^{\rho_0} \subset C^\rho$. Suppose that there is $x \in \operatorname{int} C^{\rho_0}$ with*

$$\operatorname{int}(\mathcal{O}^{\rho,+}(x) \setminus C^{\rho_0}) \neq \emptyset \text{ for all } \rho > \rho_0. \tag{13}$$

Then the invariant control set C^{ρ_0} is nearly invariant for $\rho > \rho_0$.

(ii) *For every compact set $K \subset M$ the intersection $\mathbf{A}^{inv}(C^{\rho_0}) \cap K$ is nearly invariant for ρ_0 if the intersection is positively invariant for ρ_0.*

(iii) *If the invariant control set C^{ρ_0} is nearly invariant for $\rho > \rho_0$ and bounded, then $P_{x_o}\{\sigma^\rho_{x_0}(C^{\rho_0}) < \infty\} = 1$ for all $x_0 \in C^{\rho_0}$ and all $\rho > \rho_0$.*

(iv) *Condition (13) is satisfied, in particular, if C^{ρ_0} merges with a variant control set D^{ρ_0} with nonvoid interior, i.e., $D^{\rho_0} \subset C^\rho$ for all $\rho > \rho_0$, or if all $(u, x) \in \mathcal{U}^{\rho_0} \times C^{\rho_0}$ are inner pairs of system $(8)^\rho$ for every $\rho > \rho_0$; compare with the appendix, section 6.*

Proof. (i) We show that C^{ρ_0} is nearly invariant for $\rho > \rho_0$. Since $\operatorname{int}(C^\rho \setminus C^{\rho_0}) \neq \emptyset$ and C^ρ is a control set, there are $y \in \operatorname{int}(C^\rho \setminus C^{\rho_0})$ and $x \in \operatorname{int} C^{\rho_0}$ such that $y \in \mathcal{O}^{\rho,+}(x)$. Due

to continuity, it follows that there is an open neighborhood $V(y) \subset \operatorname{int}(C^\rho \setminus C^{\rho_0})$ of y such that $V(y) \subset \mathcal{O}^{\rho,+}(C^{\rho_0})$, and therefore condition (11) holds.

(ii) Condition (13) implies that (11) is satisfied for every $x_0 \in A := \mathbf{A}^{inv}(C^{\rho_0})$, since

$$\mathcal{O}^{\rho,+}(x) \subset \mathcal{O}^{\rho,+}(x_0) \text{ for all } x_0 \in \mathbf{A}^{inv}(C^{\rho_0}).$$

(iii) According to [29], all points $x \in M$ are either recurrent or transient, and points in variant control sets are transient. Furthermore, the first exit time from bounded sets of transient points is almost surely finite.

(iv) If C^{ρ_0} merges with a variant control set D^{ρ_0} with nonvoid interior, one has $D^{\rho_0} \cap C^{\rho_0} = \emptyset$ and $D^{\rho_0} \subset C^\rho$ for $\rho > \rho_0$, and therefore condition (13) is satisfied. Finally, from the assumption that all $(u,x) \in \mathcal{U}^{\rho_0} \times C^{\rho_0}$ are inner pairs of system $(8)^\rho$ for $\rho > \rho_0$, it ensues that $C^{\rho_0} \subset \operatorname{int} C^\rho$ according to Theorem 6.4. Therefore there is some open set $V \subset C^\rho \setminus C^{\rho_0}$, and condition (13) holds. ■

This theorem shows that control sets C^{ρ_0} that are invariant for the perturbation range ρ_0, but variant for $\rho > \rho_0$, are the key nearly invariant sets of a stochastic system. They are contained in the variant control sets $D^\rho \supset C^{\rho_0}$ as "nearly invariant" sets. If these nearly invariant sets are also bounded, then property (i) of Definition 3.1 holds with probability 1. In this situation, we also have the following consequence.

Corollary 3.4. *Let the assumptions of Theorem 3.2 be satisfied and let C^{ρ_0} be a compact invariant control set for ρ_0. For each $\rho > \rho_0$ denote by C^ρ the unique control set of $(8)^\rho$ for which $C^{\rho_0} \subset C^\rho$. Assume that C^{ρ_0} merges with a variant control set D^{ρ_0} with nonvoid interior, i.e., $D^{\rho_0} \subset C^\rho$ for all $\rho > \rho_0$. If C^ρ is bounded, then $P_x\{\sigma_x^\rho(C^\rho) < \infty\} = 1$ for all $x \in C^\rho$, $\rho > \rho_0$, and $\sigma_x(C^\rho)$ has finite expectation. This holds, in particular, for $x \in C^{\rho_0}$.*

The proof of this lemma is a direct consequence of Theorem 11 in [5].

We now analyze how the stochastic system can exit from variant control sets. The following propositions show how the continuity results for exit boundaries of control sets (see section 6) can be translated to the stochastic situation.

Proposition 3.5. *Suppose the family of Markov diffusion systems $(5)^\rho$ fulfills the Lie algebra rank conditions (4) and (7) for all $\rho \in [\rho_*, \rho^*]$.*

Let $D^\rho \subset M$ be a bounded variant control set of $(8)^\rho$ with nonvoid interior such that $D^{\rho_*} \subset D^\rho$, and let $x \in D^\rho$. For each ρ we define a probability measure on M via

$$Q_x(D^\rho)(A) := P_x(\omega \in \Omega,\, h_x(D^\rho)(\omega) \in A) \quad \textit{for all Borel sets } A \subset M,$$

with support $\operatorname{cl} \partial_{ex} D^\rho$. If the mapping $\rho \to \operatorname{cl} D^\rho$ is continuous in the Hausdorff distance at ρ_0 and if the perturbation range U^ρ increases lower semicontinuously at ρ_0, then the support of $Q_x(D^\rho)$ changes continuously.

Proof. Recall that $P_x(\sigma_x(D) < \infty) = 1$ for a bounded variant control set D with $x \in D$, and since all trajectories $\varphi(t,x,\omega)$ are continuous, $Q_x(D^\rho)$ is a probability measure. Equation (10) implies that $\operatorname{supp} Q_x(D^\rho) = \operatorname{cl} \partial_{ex} D^\rho$ by definition of $\partial_{ex} D^\rho$. The desired continuity follows from the deterministic situation in Theorem 6.5. ■

Finally, we study the exit locations when an invariant control set merges with a variant control set. The deterministic situation is described in Theorem 6.5.

Proposition 3.6. *Suppose the family of Markov diffusion systems* (5)$^\rho$ *fulfills the Lie algebra rank conditions* (4) *and* (7) *for all* $\rho \in [\rho_*, \rho^*]$. *For* $\rho_o \in (\rho_*, \rho^*)$ *let* C^{ρ_0} *and* D^{ρ_0} *be an invariant and a variant control set, respectively, satisfying the conditions of Theorem* 6.6.

Then for the stochastic system (5)$^{\rho_0}$ *we have for the first entrance time* $\tau_x(C^{\rho_0})$ *to the set* C^{ρ_0} *that the probability* $p_x := P_x(\tau_x(C^{\rho_0}) < \infty) < 1$ *for* $x \in D^{\rho_0}$. *By*

$$Q_{x \not\to C^{\rho_0}}(D^\rho)(A) := \tfrac{1}{1-p_x} P_x\big(\omega \in \Omega, \quad h_x(D^\rho) \in A \text{ and } \tau_x(C^{\rho_0}) = \infty\big) \\ \text{for all Borel sets } A \subset M$$

a probability measure is defined on M *with support* $\operatorname{cl} \partial^{ex \not\to C^{\rho_0}} D^\rho$. *Furthermore, for the variant control set* $F^\rho \supset C^{\rho_0} \cup D^{\rho_0}$ *we have that*

$$\operatorname{supp} Q_x(F^\rho) \to \operatorname{supp} Q_{x \not\to C^{\rho_0}}(D^{\rho_0}) \text{ for } \rho \searrow \rho_0$$

in the Hausdorff metric.

Proof. We first show that $p_x < 1$ for $x \in D^{\rho_0}$. Since it is assumed that the exit boundary of D^{ρ_0} can be nontrivially decomposed into $\partial^{ex \to C^{\rho_0}} D^{\rho_0}$ and $\partial^{ex \not\to C^{\rho_0}} D^{\rho_0}$, it follows that $\operatorname{cl} \partial^{ex \not\to C^{\rho_0}} D^{\rho_0} \neq \emptyset$. Then (10) implies $p_x < 1$.

Thus $Q_{x \not\to C^{\rho_0}}(D^{\rho_0})$ is well defined and $Q_{x \not\to C^{\rho_0}}(D^{\rho_0})(M) = 1$. As before, due to (10) and the continuity of the trajectories, $\operatorname{supp} Q_{x \not\to C^{\rho_0}}(D^{\rho_0}) = \operatorname{cl} \partial^{ex \not\to C^{\rho_0}} D^{\rho_0}$. Now the asserted right continuity follows from Theorem 6.6. ∎

4. Computation of exit times and exit locations for nearly invariant sets. In this section we present an algorithm to compute exit times of stochastic systems from sets, based on set oriented methods as they were developed for dynamical systems by Dellnitz, Hohmann, and Junge (see [10], [11]) and for control systems by Szolnoki (cf. [39]). We start from the setup in Theorem 3.3 and Corollary 3.4: For the parameter interval $[\rho_*, \rho^*]$ we assume that there is a "bifurcation point" ρ_0 such that C^{ρ_0} is an invariant control set that is contained in a variant control set C^ρ for $\rho > \rho_0$. According to Theorem 3.3, points x in the set C^{ρ_0} and in $\mathbf{A}^{inv}(C^{\rho_0}) \cap K$ of the stochastic system (5)$^{\rho_0}$ can be expected to be identified in the analysis of system (5)$^\rho$ for $\rho > \rho_0$, with $\rho - \rho_0$ small, by significantly large first exit times. However, it is impossible to analytically compute $\sigma_x(C^\rho)$ in general. We know, however, that for bounded variant C^ρ we have $P_x(\sigma_x(C^\rho) < \infty) = 1$ for all $x \in C^\rho$. For more detailed information on exit time distributions, one has to use numerical methods.

The following algorithm produces a numerical approximation to the distribution of exit times from sets in the state space. We will concentrate here on the distribution $P_x\{\sigma_x(C^\rho) \leq t\}$, $t \geq 0$, for bounded variant control sets C^ρ of the system (5)$^\rho$.

Algorithm.

Step 1. Compute the bounded variant control set $C^\rho \subset M$ of the control system (8)$^\rho$.

Step 2. Choose a compact set $K \subset M$ with $\operatorname{cl} C^\rho \subset \operatorname{int} K$ and define a partition $\mathcal{P}$ of K into finitely many boxes B_i. Define the collection $\mathcal{C} = \{B_1, B_2, \ldots, B_N\}$ of all boxes in $\mathcal{P}$ that have nonvoid intersection with C^ρ, and denote by B_{N+1} the "sink box" which symbolizes the area outside of $\bigcup_{i=1}^N B_i$. Since $C^\rho \subset \bigcup_{i=1}^N B_i$, and we are interested in the first exit time, one box suffices to cover the area of "no return."

Step 3. Choose a discretization time $T > 0$, and compute the "transition probabilities" $p_{ij} := \frac{1}{m(B_i)} \int_{B_i} P(T, y, B_j)\, dy$ for the ensuing discretized system, with $P(T, y, B_j)$ as defined in (9) for $i = 1, \ldots, N$. Here $m(\cdot)$ denotes the Lebesgue measure. We set $p_{N+1,j} = 1$ for $j = 1, \ldots, N+1$. The resulting matrix $P := (p_{ij}) \in \mathbb{R}^{(N+1)\times(N+1)}$ is row stochastic and hence the transition matrix of a certain Markov chain on the box space.

Step 4. Compute the cumulative distribution function (cdf) of the first exit time $\sigma_x(C^\rho)$ for $x \in B_i$: $P\{\sigma_x(C^\rho) \le nT\}$ is approximated by the ith entry in the last column $(p^{(n)}_{i,N+1})$ of P^n. Specifically, for a given time T_{exit} we find n_e with $(n_e - 1)T \le T_{exit} \le n_e T$, and the last column of P^{n_e} approximates the probability to exit C^ρ from B_i until time T_{exit}.

For the approximation of the control sets, numerical methods have been developed in [39] relying on subdivision techniques for the numerical analysis of dynamical systems from [10], [11]. These references also describe the generation of a partition $\mathcal{P}$ and of the boxes.

For the approximation of the dynamics of $(5)^\rho$ we have created a Markov chain on a finite box partition. After choosing a discretization time T in Step 3, the transition probabilities between the states are computed by Monte Carlo simulation. This idea is rather old and goes back to Metropolis, Ulam, and von Neumann (see [32]). Although in the meantime many sophisticated variants for different disciplines have been developed, there are no general error estimates available; hence one can never be sure that the Monte Carlo simulation recognizes all relevant behavior of the stochastic system. This is especially problematic if one wants to compute stationary measures or long time simulations of stochastic processes that visit certain areas of the state space only infrequently. There have been some developments to overcome these problems for specific systems. For instance, for systems with purely additive noise, the deterministic part and the noise influence can be decoupled, as has been done by Fischer in [17] and Fischer and Kreuzer in [18] following some work by Froyland [20]. Subsequent application of the so-called exhaustion algorithm produces some error bounds for such systems. In the algorithm described above we start from a given partition $\mathcal{P}$, a fixed discretization time T, and several starting points within each box B_i. Hence this algorithm does not follow a simulated trajectory of one initial point over a long time period, and it has proven to be quite reliable.

To approximate the dynamics of $(5)^\rho$, in Step 3 we first simulate a large number of trajectories $\hat{\eta}^l$, $l = 1, \ldots, s_1$, of the background noise process η. For this we choose initial values in the compact space N according to the stationary solution η^* (provided this is known) and approximate solutions of the stochastic differential equation (3) until time T. Strong schemes are the methods of choice for the approximation because information about the whole solution path of $(3)^\rho$ is needed for solving the x-component of $(5)^\rho$ (see Kloeden and Platen [30] for an introduction to numerical methods for stochastic differential equations).

Subsequently, s_2 starting points x^k are picked in each box B_i. From each starting point, the solution of the x-component of $(5)^\rho$ is approximated for all samples $\hat{\eta}^l$ generating $s_1 s_2$ target points, denoted by $\hat{\varphi}(T, x^k, \hat{\eta}^l)$. The transition probability from box B_i to B_j is then approximated by

$$p_{ij} = \frac{1}{m(B_i)} \int_{B_i} P(T, x, B_j)\, dx \approx \frac{1}{s_1 s_2} \sum_{k=1}^{s_2} \sum_{l=1}^{s_1} \chi_{B_j}\left(\hat{\varphi}(T, x^k, \hat{\eta}^l)\right),$$

where χ_{B_j} denotes the characteristic function of the set B_j. The question as to how many

boxes, starting points, and sample paths of the background process should be used depends on the properties of the system, the time length T, and the box size—and, of course, on the availability of computing resources. While the number of boxes $N+1$ is mainly limited by available memory (note that it is necessary to multiply full matrices with $(N+1)^2$ entries in Step 4), we have observed that the algorithm is more sensitive to a change of the noise realization than to a change of the initial values within a box. It seems that the solution trajectories $\eta_\cdot^*(\omega)$ of (3) are less smooth than the solutions of the system (2). Therefore, it is reasonable to increase the number of realizations of the background noise at the expense of initial values in each box when computing resources become an issue.

Repeated multiplication of the matrix P with itself in Step 4 may pose a problem for fine partitions, particularly in higher dimensions. When computing the cdf of the first exit time, this problem cannot be avoided. If one is interested mainly in the probability of exit until some large time T_{exit}, one can save certain iterations: Instead of performing $n_e = \frac{T_{exit}}{T}$ multiplications with P, we find $\widehat{n} = \max\{n \in N,\, 2^{\widehat{n}} \le n_e\}$ and compute $P^{2^{\widehat{n}}}$ in $\widehat{n}$ steps. If $2^{\widehat{n}} < n_e$, we continue the same process with $n_e - 2^{\widehat{n}}$, etc., until P^{n_e} is computed. (Of course, bases other than 2 can be used and sometimes lead to fewer factors in the decomposition of n_e.) For $T_{exit} = 10^4$ and $T = 10^{-2}$, this process results in 25 matrix multiplications instead of 10^6. If the cdf of the first exit time is not required in a resolution corresponding to n_e time intervals, one can proceed similarly by expressing the size of the desired resolution in powers of a prime, e.g., of 2. In our example, choosing a resolution of $10^3 T$, we compute P^{1000} with 14 multiplications, and then P^{1000k}, $k = 2, \dots, 1000$, resulting in 1013 steps.

Recall that for bounded variant control sets C^ρ the expected exit time from a point $x \in C^\rho$ is finite and given by

$$E[\sigma_x(C^\rho)] = \int_0^\infty t \, dP_\sigma,$$

where P_σ is the distribution of σ_x. This expected value can be approximated by

$$\hat{E}[\sigma_x(C^\rho)] = T \sum_{n=1}^{\infty} n \, (p_{i,N+1}^{(n)} - p_{i,N+1}^{(n-1)}) \qquad \text{for } x \in B_i.$$

For the actual computation, naturally an upper limit n_{max} on n has to be chosen, which results in an approximation of the expected exit time before $n_{max}T$.

To compute the exit locations for the system (2), we again approximate its dynamics by the Markov chain defined in Step 3. For an initial value $x \in C^\rho$ we identify the box B_i with $x \in B_i$. As before, $p_{i,j}^{(n)}$ is the probability to reach the state B_j from B_i in n steps. If $B_j \neq B_{N+1}$, and if $p_{j,N+1}^{(n+1)} > 0$, then the Markov chain exits from $\mathcal{C}$ in step $n+1$. In this case the state B_j is an exit state for the chain, starting from B_i. Let h_i denote the corresponding random exit location. We then have

$$P\{h_i = B_j\} = \sum_{n=0}^{\infty} p_{ij}^{(n)} p(j, N+1),$$

and this distribution approximates that of $h_x(C^\rho)$ as defined in section 2. In practice, again one will have to choose a maximal time $T_{exit} \in \mathbb{N}$, and the finite sum with $T_{exit}+1$ terms is computed.

5. Examples.

5.1. A perturbed escape equation. As a first example we will present some results for the perturbed escape equation. It describes the movement of a particle with unit mass in the potential $V(x) = \frac{1}{2}x^2 - \frac{1}{3}x^3$ with inertia and linear viscous damping under the influence of some perturbation. This equation has attracted great interest and has been analyzed thoroughly (see, e.g., [40], [35], or [17] and the references therein). We consider the perturbed escape equation

$$\ddot{x} + \gamma\dot{x} + x - x^2 = \rho \sin \eta_t$$

with a background noise process η_t on the one dimensional sphere $\mathbb{S}^1$. The Wiener process on this sphere is considered as the one dimensional Wiener process on $\mathbb{R}$ modulo 2π. For $t \geq 0$ and $\bar{x}, \bar{y} \in \mathbb{S}^1$ and $x, y \in \mathbb{R}$ such that $\bar{x} \equiv x \bmod 2\pi$ and $\bar{y} \equiv y \bmod 2\pi$, the transition densities of this process, resulting from the corresponding normally distributed process on $\mathbb{R}$, are given by

$$p(t, \bar{x}, \bar{y}) = \frac{1}{\sqrt{2\pi t}} \sum_{n=-\infty}^{\infty} \exp\left(-\frac{(y - x + 2n\pi)^2}{2t}\right).$$

The sum on the right-hand side converges uniformly and absolutely. Then, for an integrable nonnegative function $f : \mathbb{S}^1 \to \mathbb{R}$, it holds that

$$\begin{aligned} U_t f(\bar{x}) &:= \textstyle\int_{S^1} p(t, \bar{x}, \bar{y})\, f(\bar{y})\, d\bar{y} \\ &= \tfrac{1}{\sqrt{2\pi t}} \textstyle\int_0^{2\pi} \left(\sum_{n=-\infty}^{\infty} \exp\left(-\frac{(y-x+2n\pi)^2}{2t}\right)\right) f(y)\, dy \\ &= \tfrac{1}{\sqrt{2\pi t}} \textstyle\int_{-\infty}^{\infty} \exp\left(-\frac{(y-x)^2}{2t}\right) f(y \bmod 2\pi)\, dy. \end{aligned}$$

The function $f(\bar{x}) \equiv \frac{1}{2\pi}$ fulfills $U_t f(\bar{x}) = f(\bar{x})$. Thus $f(\bar{x})$ is the unique stationary density of the noise process because (4) obviously holds.

The perturbed escape equation driven by this background process is given by

$$\begin{aligned} \dot{x}(t) &= y(t), \\ \dot{y}(t) &= -\gamma\, y(t) - x(t) + x(t)^2 + \rho \sin(\eta_t), \\ d\eta_t &= dW_t \bmod 2\pi. \end{aligned} \tag{14}$$

As we saw, the stationary process η_t^* has the uniform distribution on $\mathbb{S}^1$ as its one dimensional distribution.

The associated controlled version of this equation on $\mathbb{R}^2$ reads

$$\begin{pmatrix} \dot{x}(t) \\ \dot{y}(t) \end{pmatrix} = \begin{pmatrix} y(t) \\ -\gamma\, y(t) - x(t) + x(t)^2 \end{pmatrix} + \begin{pmatrix} 0 \\ u(t) \end{pmatrix}, \tag{15}$$

where $u(t) \in U^\rho := [-\rho, \rho]$. For our computations we set the damping coefficient γ to 0.1. Computation of the control sets using the method described in section 4 yields for $\rho = 0.04$ the existence of one invariant control set $C^{0.04}$ that contains the stable fixed point $(0, 0)$ of the uncontrolled equation and one variant control set $D^{0.04}$ containing the hyperbolic fixed point $(1, 0)$ of the uncontrolled equation (cf. Figure 1). Increasing the control range, one finds that

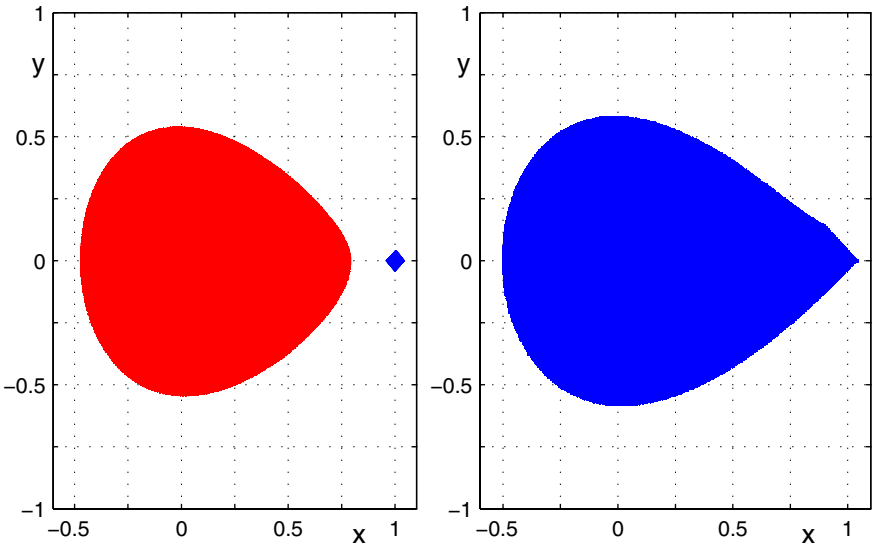

Figure 1. *Control sets for the controlled escape equation for $\rho = 0.04$ (left) and $\rho = 0.045$ (right).*

the two control sets merge for some ρ_0 close to 0.0411 (see [23]) to form one variant control set. The assumptions of Theorem 6.6 are satisfied for this example.

For the computation of the exit times from the merged control set we set $\rho = 0.15$ and distinguish two different scenarios. The first one explores the exit time distribution for a very short time, i.e., $T_{exit} \leq 1.0$. In this case we choose a fine partition of the compact set K containing $D^{0.15}$. The second one aims at long times, and we choose a coarser partition to accelerate the computation time. In both cases we pick only the center of each box as the initial value because the system (14) proves to be more sensitive to a variation in the noise sample than to a small change of the initial value.

In order to approximate the background noise process in the short time case ($T_{exit} \leq 1.0$), we choose $\hat{\eta}_0^l = l \cdot 2\pi/100$ for $l = \{0, 1, \ldots, 99\}$ as initial values to represent the uniform distribution of η_t^*. Then the background noise part of (14) is solved for each of these initial values with step size 0.1 until time 1.0, generating 100 sample paths $\hat{\eta}^l$ of the Wiener process on $\mathbb{S}^1$. For this integration, a simple Euler scheme can be used efficiently because drift and diffusion coefficients are both constant. The exit probability from a box B_i is then approximated directly by solving the (x, y)-component for each sample $\hat{\eta}^l$ starting at the center of B_i. This way, the upper left graph in Figure 2 was produced, where different colors represent different exit probabilities until time $T_{exit} = 1.0$. The other three graphs in Figure 2 follow the same procedure for $T_{exit} = 5$, 30, and 220.

To compute the distribution of the exit times $\sigma_x(D^{0.15})$, which requires large time intervals, we follow the same scheme to integrate the Wiener process, but compute more samples by starting from $\hat{\eta}_0^l = l \cdot 2\pi/10000$ for $l = \{0, 1, \ldots, 9999\}$ to compensate for the increased box sizes. Once again, the approximation of the (x, y)-component for each sample $\hat{\eta}^l$ starts at the center of B_i. Here the limiting factor for the number of boxes is the multiples of the transition matrix P that are to be computed. Multiples P^n of P are computed for $n = 2, \ldots, 1500$. The

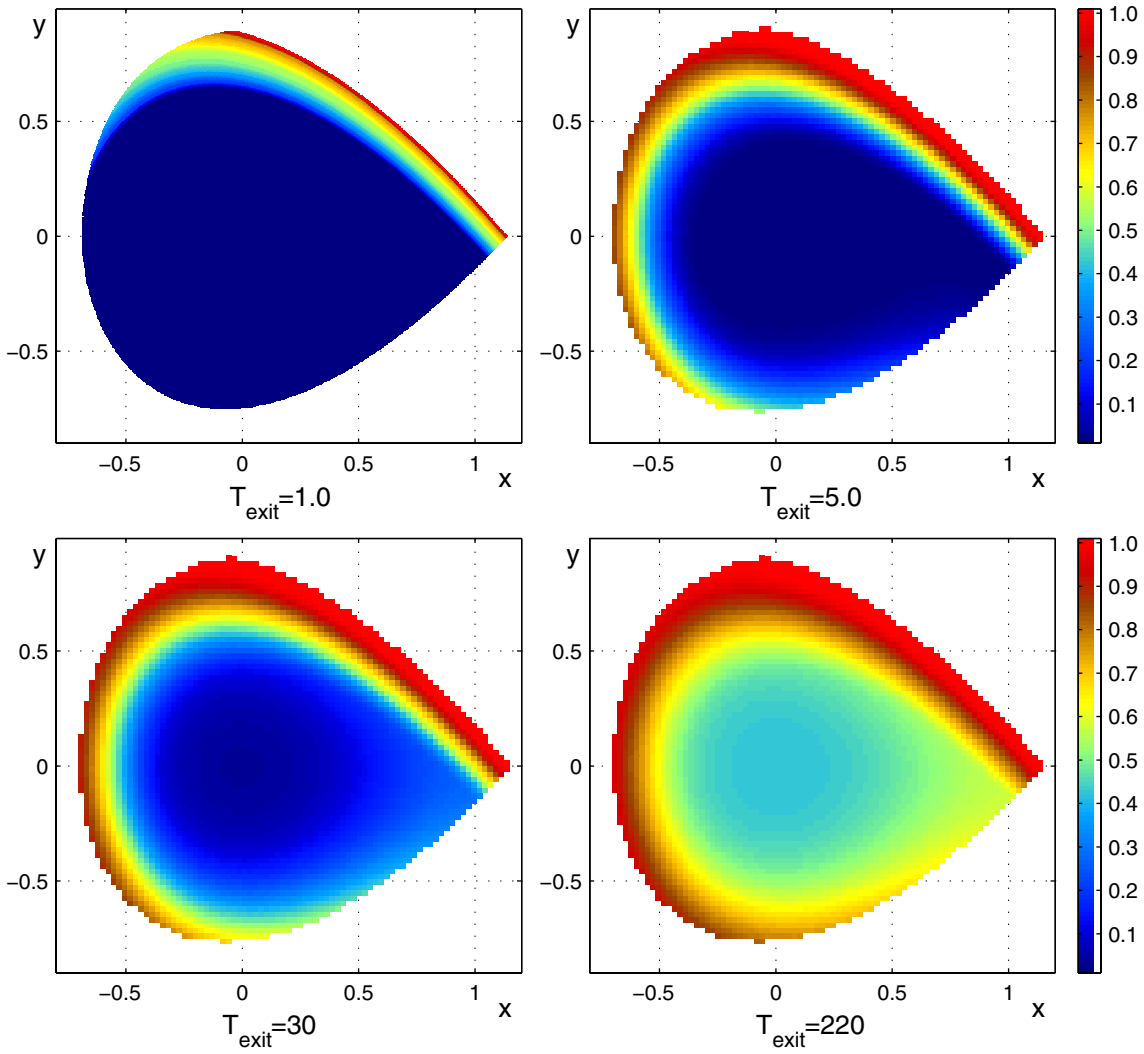

Figure 2. *Exit probabilities from* $D^{0.15}$ *for* $\rho = 0.15$ *until* T_{exit}.

minimum over all boxes of the exit probabilities $\min_i p_{i,N+1}^{(1500)}$ until $T_{exit} = 1500$ is then 0.98, and the computation is terminated. The left-hand graph in Figure 3 shows the distribution of the exit probability until time $n = 1500$ for the initial value $(0, 0)$, and Figure 4 shows the distribution for the initial values $(0.0, -0.5)$ and $(0.9, -0.1)$, now on a logarithmic scale. Both graphs show an exponential tail for the exit time distribution. Indeed, these numerically computed distributions (after some oscillations during the initial settling-in period) closely resemble a three-parameter Weibull distribution, which is the standard model for lifetime distributions in reliability theory. The oscillations stem from the deterministic dynamics of system (14). Computing an unperturbed solution that starts not too far away from $(0, 0)$ on the positive x-axis, one obtains a time of roughly 6.5 before the trajectory intersects the positive x-axis again. This is exactly the average distance between two maxima in the

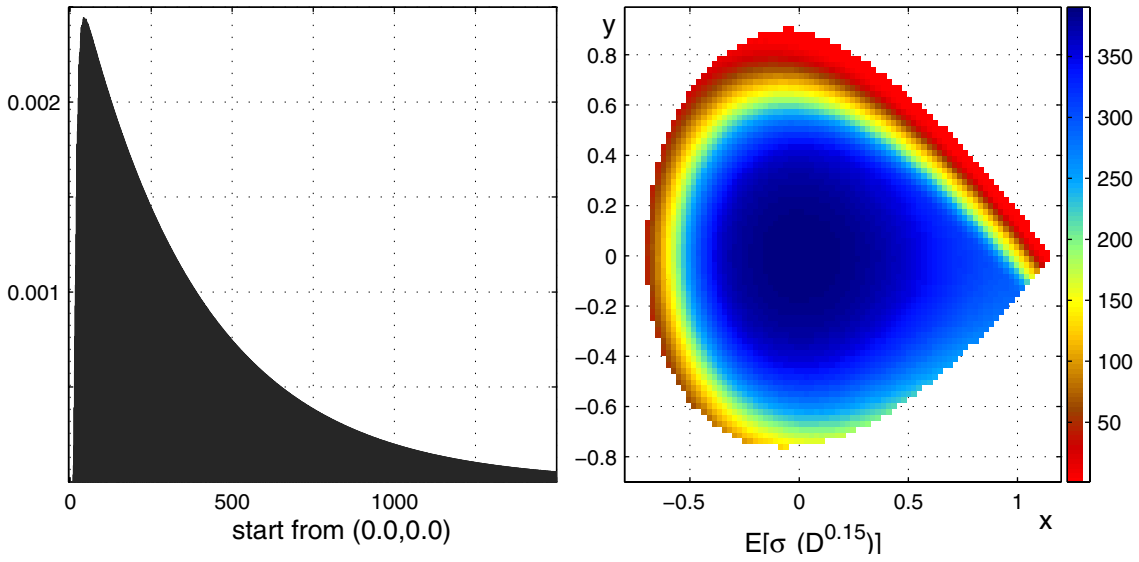

Figure 3. *Exit time distribution and expected exit times until time* 1500.

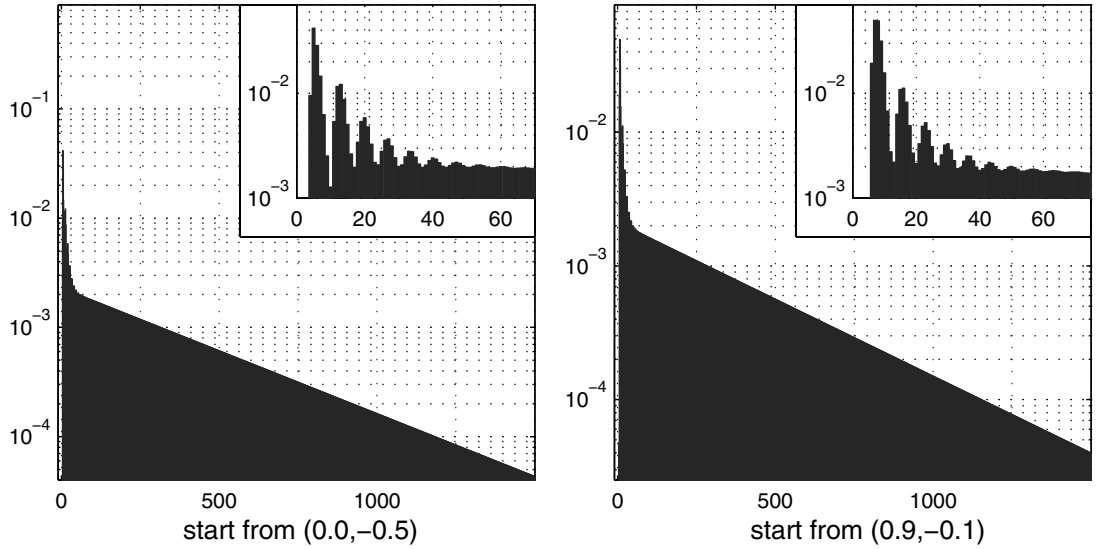

Figure 4. *Exit time distribution starting from* $(0.0, -0.5)$ *and* $(0.9, -0.1)$.

histograms of the distributions. The right-hand graph in Figure 3 shows the expected value of the exit time from all boxes in $D^{0.15}$. These expected times reflect the separation between long sojourn times in the formerly invariant region and short ones outside this area; compare with Figure 1.

5.2. A system with perturbed double well potential. Next we investigate a particle in a two-well potential and consider the following equation:

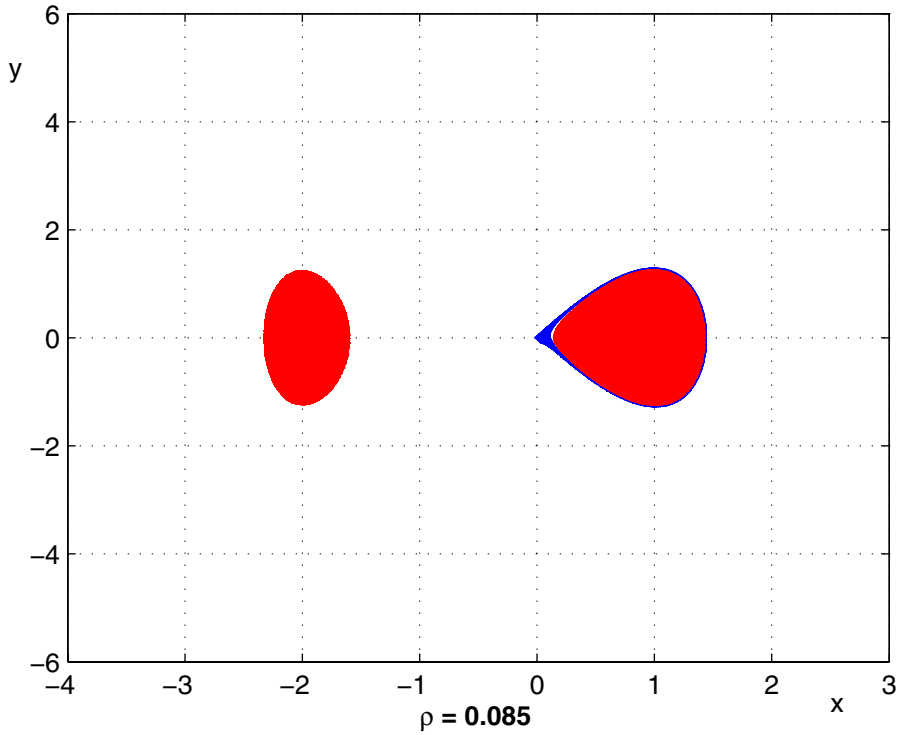

Figure 5. *Control sets for the double well potential at* $\rho = 0.085$.

$$
\begin{aligned}
\dot{x}(t) &= y(t),\\
\dot{y}(t) &= -\gamma\, y(t) - x(t)\,(2x^2(t) + 2\,x(t) - 4) + \rho \sin(\eta_t),\\
d\eta_t &= dW_t \bmod 2\pi,
\end{aligned}
\tag{16}
$$

with associated control system

$$
\begin{pmatrix} \dot{x}(t) \\ \dot{y}(t) \end{pmatrix} = \begin{pmatrix} y(t) \\ -\gamma\, y(t) - x(t)\,(2x^2(t) + 2\,x(t) - 4) \end{pmatrix} + \begin{pmatrix} 0 \\ u(t) \end{pmatrix}, \tag{17}
$$

where again $u(t) \in U^\rho := [-\rho, \rho]$ and the damping coefficient γ is set to 0.1. For $\rho = 0.07$ there are two invariant control sets $C_1^{0.07}$ and $C_2^{0.07}$ that contain the stable fixed points $(1, 0)$ and $(-2, 0)$, respectively, of the uncontrolled equation and one variant control set $D^{0.07}$ containing the hyperbolic fixed point $(0, 0)$ of the uncontrolled equation. Increasing the control range, one finds that the control sets $C_1^{\rho_0}$ and D^{ρ_0} merge for some ρ_0 close to 0.085 and form one variant control set (see Figure 5). Note that before the merger of the control sets, the variant control set increases discontinuously and forms a ring around the invariant control set.

At some ρ_1 close to $\rho = 0.2$ the remaining control sets $C_2^{\rho_1}$ and D^{ρ_1} merge in a similar way (see Figures 6, 7, and 8).

Thus the corresponding stochastic system (16) possesses one nearly invariant region $C_1^{\rho_0}$ and one nearly invariant region $C_2^{\rho_1}$. Figure 9 shows the exit probabilities until the given exit

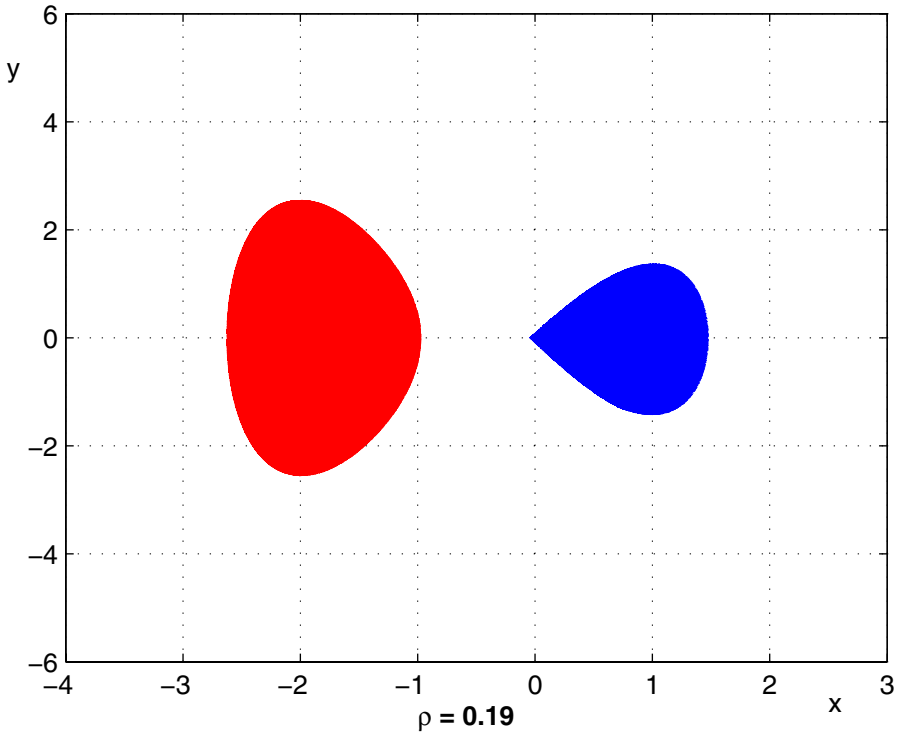

Figure 6. *Control sets for the double well potential at* $\rho = 0.19$.

times from the colored subsets for $\rho = 0.4$. Again, a comparison of the regions of large exit time in Figure 9 with the invariant control sets $C_1^{\rho_0}$ in Figure 5 and $C_2^{\rho_1}$ in Figure 7 show remarkable agreement. Also the invariant domains of attraction of the control sets become visible in Figure 9 as regions, whose exit times are rather large.

5.3. The escape equation with periodic excitation. Our third example is a perturbed escape equation with a periodic excitation and the same noise process as above. The standard way of removing the periodic time dependence leads to a three dimensional system which we analyze via its Poincaré sections. Specifically, we consider

$$\begin{aligned}
\dot{x}(t) &= y(t),\\
\dot{y}(t) &= -\gamma y(t) - x(t) - x(t)^2 + F\sin z(t) + \rho\sin\eta_t,\\
\dot{z}(t) &= \omega \bmod 2\pi,\\
d\eta_t &= dW_t \bmod 2\pi
\end{aligned}$$

with parameters

$$F = 0.06,\ \omega = 0.85,\ \gamma = 0.1, \text{ and } \rho = 0.02. \tag{18}$$

The somewhat involved control set structure of the associated control system has been studied in detail in [26]. For $\rho = 0.0$ there are two orbitally stable periodic solutions and two hyperbolic

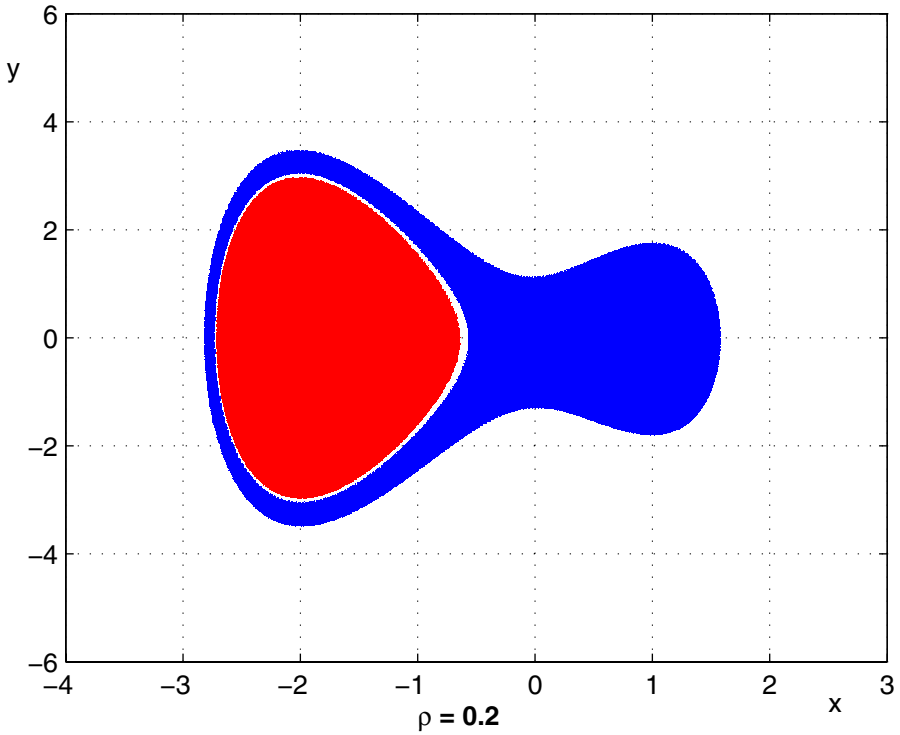

Figure 7. *Control sets for the double well potential at* $\rho = 0.2$.

periodic solutions. For small amplitude, e.g., for $\rho = 0.005$, they are included in the interior of control sets $D_1^{0.005}, D_2^{0.005}, D_3^{0.005}, D_4^{0.005}$. Figure 10 shows a slice at the phase π/ω; the potential hill top is to the right. Here $D_1^{0.005}$ and $D_3^{0.005}$ (in red) are invariant control sets, while $D_2^{0.005}$ (in the potential well) and $D_4^{0.005}$ (on the potential hill top) are variant control sets. The white regions around $D_1^{0.005}$ and $D_3^{0.005}$ show their domains of attraction $\mathbf{A}(D_1^{0.005})$ and $\mathbf{A}(D_3^{0.005})$, respectively.

For $\rho = 0.0085$, the two control sets $D_1^{0.005}$ and $D_2^{0.005}$ have merged into a variant control set $D_{12}^{0.0085}$, while $D_3^{0.0085}$ and $D_4^{0.0085}$ remain distinct. For $\rho = 0.01$ also, the control sets $D_{12}^{0.0085}$ and the invariant control set $D_3^{0.0085}$ have merged into an invariant control set $D_{123}^{0.01}$, and, finally, for $\rho \geq 0.013$ also, the control set $D_4^{0.01}$ has merged with $D_{123}^{0.01}$ forming a variant control set D_{1234}^{ρ}. In this latter situation, no invariance properties prevail.

We remark that the results presented in [26] have to be slightly modified: For the periodic control $u(t) = 0.0064 \sin \omega t, t \in \mathbb{R}$, there is a hill top periodic solution which, for $\rho > 0.0064$, is contained in the interior of D_4^{ρ}. Numerical results show that its stable and unstable manifolds have transversal intersections. Hence, for these ρ-values, there exists a homoclinic orbit which is also contained in the control set D_4^{ρ} (compare with [9]).

Figures 11–13 show, for Poincaré sections at the phase π/ω, the exit probabilities from initial points in the control set $D_{1234}^{0.2}$ for different exit times (note that the color coding differs). One sees, as expected, that exit is highly probable from a first area above the hill top. It is also probable from an area below the hill top. Here, in fact, an intersection point of the

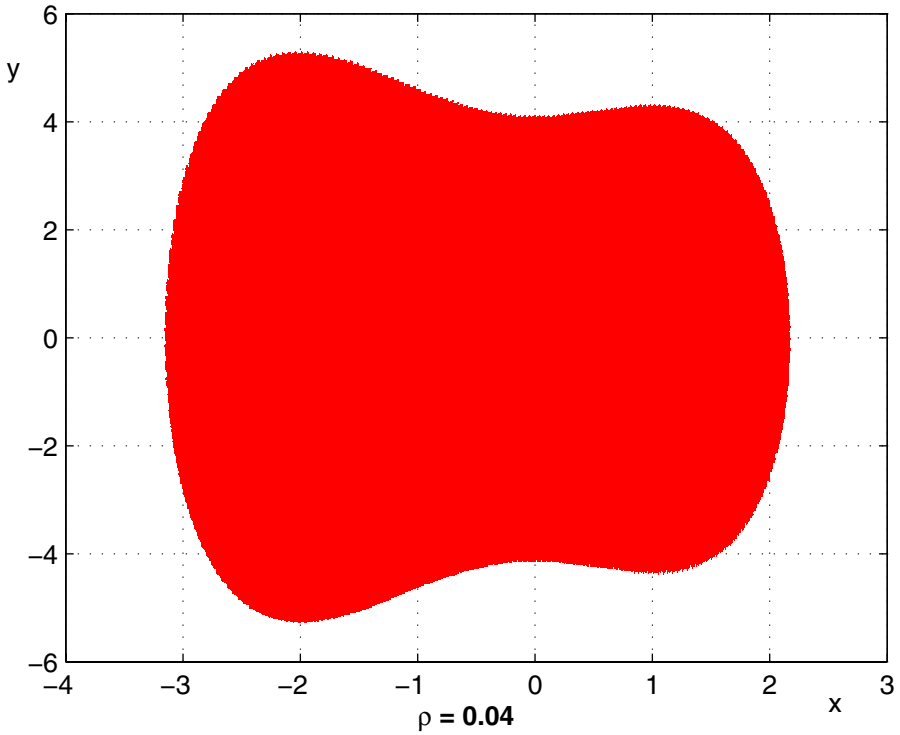

Figure 8. *Control sets for the double well potential at* $\rho = 0.4$.

stable and the unstable manifolds of the hill top periodic solution lies, and one iteration of the Poincaré map leads into the first area.

One also notes remarkable differences of exit probabilities from other areas of the control set. This is explored in more detail in Figures 14–16, which show slices through the domain of attraction $\mathbf{A}(D_{1234}^{0.2})$ for different exit times.

In Figure 16 one can discern two areas color coded by blue and brown. A comparison to Figure 10 reveals that they correspond to the domains of attraction of the two invariant control sets D_1^ρ and D_3^ρ (before their merging). They are separated by an area which corresponds to the (variant) control set D_2^ρ in the potential well. These results illustrate that the near invariance property is still present for control range $\rho = 0.02$, which is well above the control ranges where the two invariant control sets D_1^ρ and D_3^ρ lose their invariance.

We remark that, particularly due to memory requirements as discussed above, a direct numerical analysis of the three dimensional problem would be much harder. Furthermore, Poincaré sections are convenient for visualization of the results.

6. Appendix: Some background on nonlinear control systems.

In this appendix, we recall some facts on nonlinear control systems. See, for example, [6] for more information.

6.1. Accessibility and control sets.

Consider the control-affine system (8) given by

$$\dot{x}(t) = X_0(x(t)) + \sum_{i=1}^{m} u_i(t)\, X_i(x(t)) \tag{19}$$

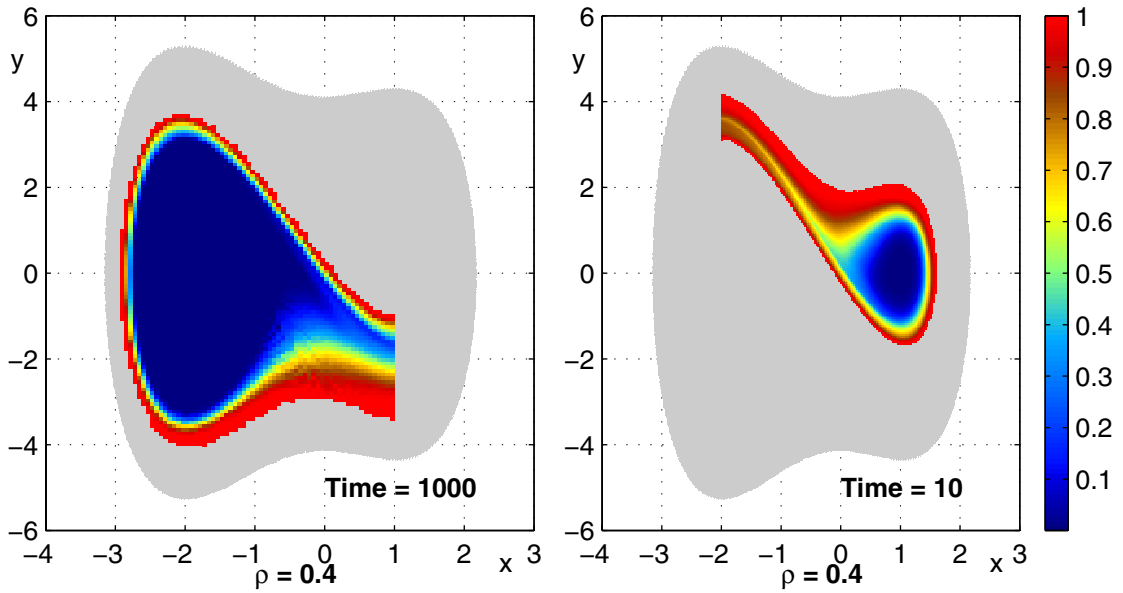

Figure 9. *Exit probabilities from the colored region around $C_1^{\rho_0}$ until time $T = 10$ (right) and from the colored region around $C_2^{\rho_0}$ until time $T = 1000$ (left) for $\rho = 0.4$. Parts of the invariant domains of attraction $A^{inv}(C_1^{\rho_0})$ and $A^{inv}(C_2^{\rho_0})$ become visible.*

with C^∞ vector fields $X_0, \dots, X_m$ on a C^∞ manifold M of dimension $d < \infty$. We obtain a family of systems by specifying an increasing family of compact convex control ranges $0 \in \operatorname{int} U^\rho \subset \mathbb{R}^m$ with $U^\rho = \operatorname{cl} \operatorname{int} U^\rho$ for all $\rho \in [\rho_*, \rho^*]$ and define corresponding sets of control functions $\mathcal{U}^\rho = \{u : \mathbb{R} \to U^\rho, \text{ measurable}\}$. Setting $u \equiv 0$ models the uncontrolled system. We assume that there exists a unique solution $\varphi(t, x, u)$ of (19) for each ρ, for every $u \in \mathcal{U}^\rho$, for every initial state $x \in M$, and for all $t \in (-\infty, \infty)$. If the dependence on ρ is not important, we will simply omit the notation of ρ in the following.

The positive and negative orbits at time $t > 0$ are

$$\mathcal{O}_t^+(x) = \{\varphi(t, x, u),\, u \in \mathcal{U}\}, \qquad \mathcal{O}_t^-(x) = \{\varphi(-t, x, u),\, u \in \mathcal{U}\},$$

and we set

$$\mathcal{O}_{\le T}^+(x) = \bigcup_{t \in [0,T]} \mathcal{O}_t^+(x), \qquad \mathcal{O}_{\le T}^-(x) = \bigcup_{t \in [0,T]} \mathcal{O}_t^-(x),$$

$$\mathcal{O}^+(x) = \bigcup_{t \in [0,\infty)} \mathcal{O}_t^+(x), \qquad \mathcal{O}^-(x) = \bigcup_{t \in [0,\infty)} \mathcal{O}_t^-(x),$$

respectively. A set $D \subset M$ with nonvoid interior is a control set if it is a maximal set with the property $D \subset \operatorname{cl} \mathcal{O}^+(x)$ for every $x \in D$. A control set C with $C = \operatorname{cl} \mathcal{O}^+(x)$ for every $x \in C$ is an invariant control set; the others are called variant. Throughout we assume that system (8) is locally accessible, i.e.,

$$\operatorname{int} \mathcal{O}_{\le T}^+(x) \neq \varnothing \text{ and } \operatorname{int} \mathcal{O}_{\le T}^-(x) \neq \varnothing \text{ for all } T > 0.$$

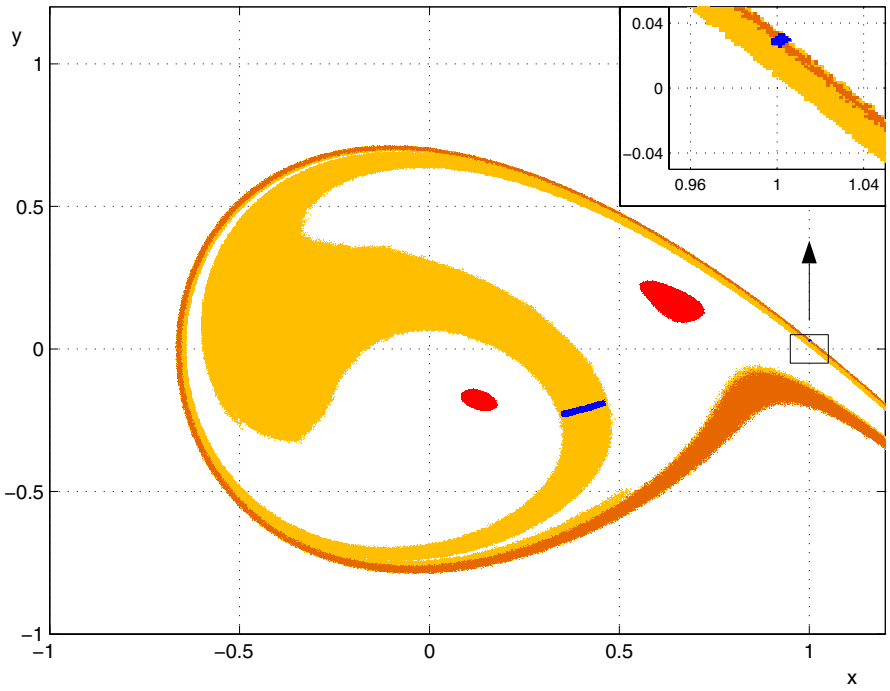

Figure 10. *Control sets and domains of attraction for* $\rho = 0.005$.

This is guaranteed by the Lie algebra rank condition $\dim \mathcal{LA}\{X_0, \ldots, X_m\}(x) = d$ for all $x \in M$. We endow the set of control functions $\mathcal{U} \subset L_\infty(\mathbb{R}, \mathbb{R}^m)$ with the weak*- (or L_1-) topology, which makes $\mathcal{U}$ a compact metric space. Then for $t_n \to t$, $x_n \to x$, and $u_n \to u$ in $\mathcal{U}$, it follows that

$$\varphi(t_n, x_n, u_n) \to \varphi(t, x, u). \tag{20}$$

We note the following lemma which states that the interior of a positively invariant set is positively invariant.

Lemma 6.1. *Suppose that* $I \subset M$ *is closed and satisfies* $\varphi(t, x, u) \in I$ *for all* $t \geq 0$, $x \in I$, *and* $u \in \mathcal{U}$. *Then* $\varphi(t, x, u) \in \operatorname{int} I$ *for all* $x \in \operatorname{int} I$, $u \in \mathcal{U}$, *and* $t \geq 0$.

Proof. Suppose that there are $x \in \operatorname{int} I$, $t > 0$, and $u \in \mathcal{U}$ with $\varphi(t, x, u) \notin \operatorname{int} I$. Then $\tau := \sup\{s \in (0, t],\, \varphi(t, x, u) \in \operatorname{int} I\}$ satisfies $\varphi(\tau, x, u) \in \partial I$. Hence there is a neighborhood V of $\varphi(\tau, x, u)$ with $V \cap (M \setminus I) \neq \varnothing$. Continuous dependence on initial conditions implies that there are $y \in \operatorname{int} I$ with $\varphi(\tau, y, u) \notin I$ contradicting the positive invariance of I. ∎

Invariant control sets and hence their interiors are positively invariant. For a set $I \subset M$ with nonvoid interior the domain of attraction is

$$\mathbf{A}(I) = \left\{x \in M,\, \operatorname{cl} \mathcal{O}^+(x) \cap \operatorname{int} I \neq \varnothing\right\}.$$

Domains of attraction are open, since by local accessibility $\operatorname{cl} \mathcal{O}^+(x) = \operatorname{cl} \operatorname{int} \mathcal{O}^+(x)$. We define the invariant domain of attraction as the largest invariant set contained in $\mathbf{A}(I)$ (sometimes called its invariance kernel).

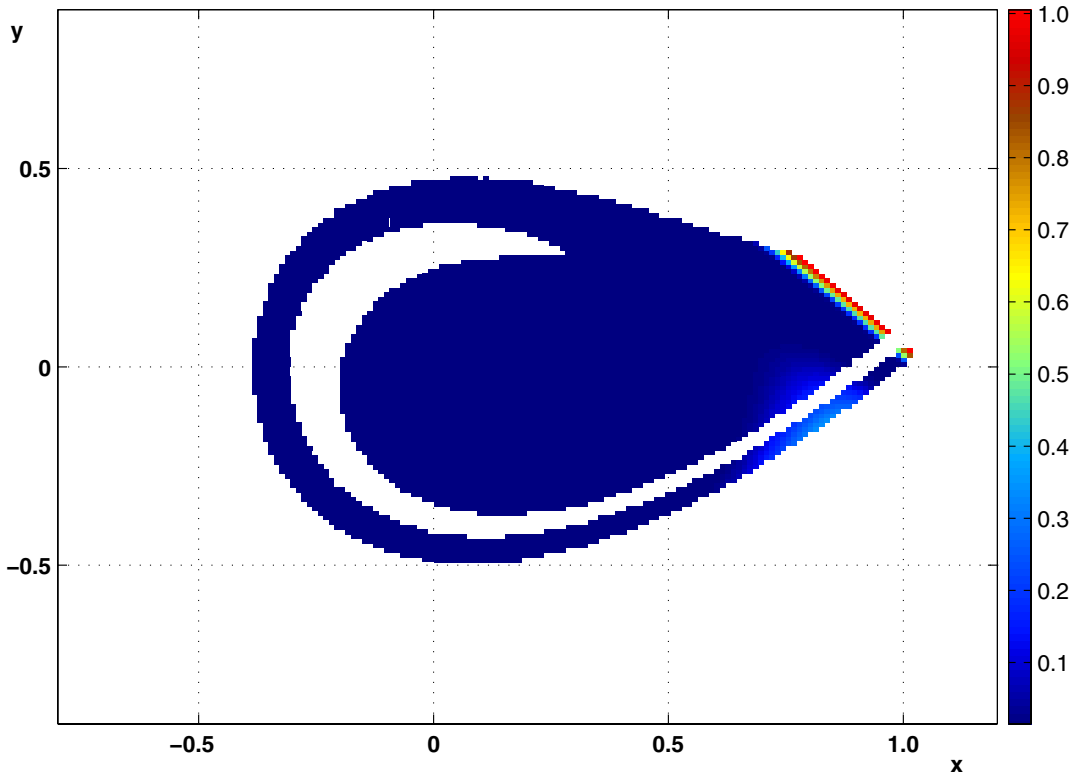

Figure 11. *Exit probabilities from the control set $D_{1234}^{0.2}$ until time $T_{exit} = 2\pi/\omega$.*

Definition 6.2. *For $I \subset M$ the invariant domain of attraction is*

$$\mathbf{A}^{inv}(I) = \{x \in \mathbf{A}(I),\, \varphi(t,x,u) \in \mathbf{A}(I) \text{ for all } u \in \mathcal{U} \text{ and } t \in \mathbb{R}_+\}.$$

This set is related to invariant control sets by the following observation.

Proposition 6.3. *Assume that $\mathbf{A}(I) \cap K$ is positively invariant for a compact set K. Then*

$$\mathbf{A}^{inv}(I) \cap K = \left\{ x \in \mathbf{A}(I) \cap K, \begin{array}{c} \text{if } C \subset \operatorname{cl} \mathcal{O}^+(x) \text{ is an invariant} \\ \text{control set, then } C \cap \operatorname{int} I \neq \varnothing \end{array} \right\}, \tag{21}$$

and this set is compact. Furthermore, $\operatorname{int}[\mathbf{A}^{inv}(I) \cap K]$ *is positively invariant.*

Proof. Let $x \in \mathbf{A}^{inv}(I) \cap K$ and suppose that $C \subset \operatorname{cl} \mathcal{O}^+(x)$ is an invariant control set. Then $\operatorname{int} C \subset \mathcal{O}^+(x)$. If $C \cap \operatorname{int} I = \varnothing$, invariance of $\operatorname{int} C$ implies that we can find $y \in C \cap \mathcal{O}^+(x)$, which is not in $\mathbf{A}(I)$, contradicting $x \in \mathbf{A}^{inv}(I)$. For the converse, let $x \in \mathbf{A}(I) \cap K$ be in the set on the right-hand side of (21). Consider $\varphi(t,x,u)$ with $u \in \mathcal{U}$ and $t \in \mathbb{R}_+$. Then by [6, Theorem 3.2.8] there is an invariant control set $C \subset \operatorname{cl} \mathcal{O}^+(x) \cap K$. Then $C \cap \operatorname{int} I \neq \varnothing$ and it follows that $\varphi(t,x,u) \in \mathbf{A}(I)$, and hence $x \in \mathbf{A}^{inv}(I) \cap K$. This proves the other inclusion. In order to see closedness, let $x_n \in \mathbf{A}^{inv}(I) \cap K$ with $x_n \to x$. Then $x \in K$ and, again by [6, Theorem 3.2.8], there is an invariant control set $C \subset \operatorname{cl} \mathcal{O}^+(x) \cap K$. We find $T > 0$ and

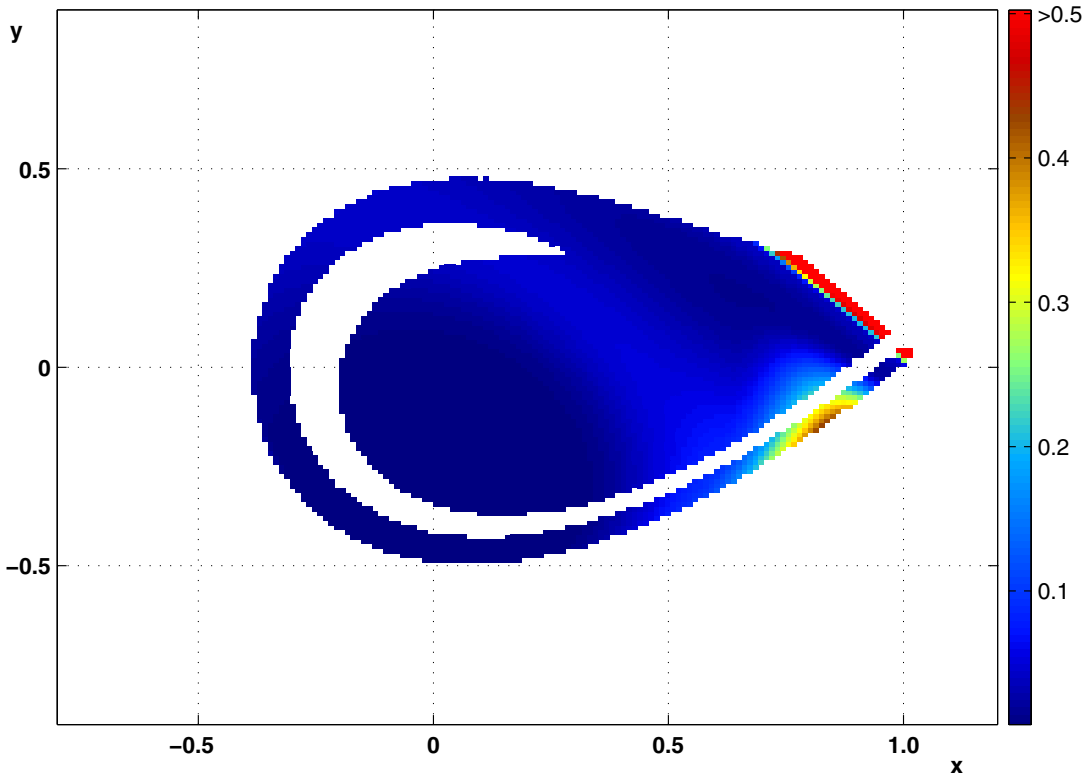

Figure 12. *Exit probabilities from the control set* $D^{0.2}_{1234}$ *until time* $T_{exit} = 10 * 2\pi/\omega$.

$u \in \mathcal{U}$ with $\varphi(T, x, u) \in \operatorname{int} C$. Then for n large enough, also $\varphi(T, x_n, u) \in \operatorname{int} C$ and hence $C \subset \operatorname{cl} \mathcal{O}^+(x_n)$. Now (21) implies $C \cap \operatorname{int} I \neq \varnothing$ and $x \in \mathbf{A}^{inv}(I) \cap K$ follows. Invariance of the interior follows by Lemma 6.1. ■

Note also that every invariant control set C satisfies $C \subset \mathbf{A}^{inv}(C)$, but not necessarily $C \subset \operatorname{int} \mathbf{A}^{inv}(C)$.

6.2. Parameter dependent control systems. In this section we describe the behavior of control sets under perturbations of the control range. Here, in addition to control sets, also chain control sets are needed. A nonvoid set $E \subset M$ is a chain control set for (19) if it is a maximal set such that for all $x \in E$ there is a control $u \in \mathcal{U}$ with $\varphi(t, x, u) \in E$ for all $t \in \mathbb{R}$, and for every $\varepsilon > 0, T > 0$ any two points $x, y \in E$ can be connected by controlled (ε, T)-chains; i.e., there are

$$n \in \mathbb{N},\ x_0 = x, \ldots, x_n = y,\ u_0, \ldots, u_{n-1} \in \mathcal{U}, \text{ and } T_0, \ldots, T_{n-1} > T$$

with

$$\mathrm{d}(\varphi(T_i, x_i, u_i), x_{i+1}) < \varepsilon \text{ for all } i = 0, \ldots, n-1.$$

For a given interval $[\rho_*, \rho^*]$ of parameters, we denote by $(19)^\rho$ the corresponding control system with control range U^ρ, $\rho \in [\rho_*, \rho^*]$. For every control set D^{ρ_*} and every chain control set E^{ρ_*}

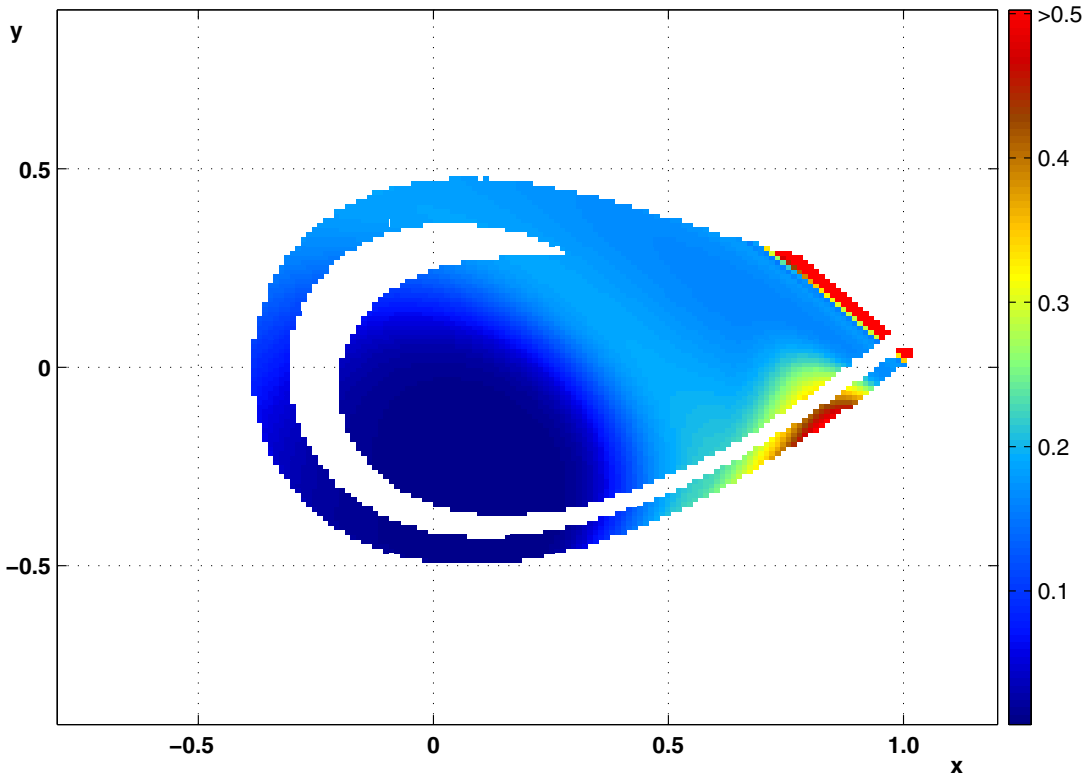

Figure 13. *Exit probabilities from the control set* $D_{1234}^{0.2}$ *until time* $T_{exit} = 100 * 2\pi/\omega$.

of the system $(19)^{\rho_*}$ there are unique control sets D^ρ and unique chain control sets E^ρ for each $\rho \in [\rho_*, \rho^*]$ such that $D^{\rho_*} \subset D^\rho$ and $E^{\rho_*} \subset E^\rho$. If all involved sets are bounded, it is well known that the increasing compact-valued mappings $\rho \mapsto \operatorname{cl} D^\rho$ and $\rho \mapsto \operatorname{cl} E^\rho$ are continuous with respect to the Hausdorff metric at all but countably many ρ-values (Scherbina's lemma [36]).

In order to obtain stronger results on the behavior of control sets and chain control sets, the following inner-pair condition is needed. A pair $(x, u) \in M \times \mathcal{U}$ is called an *inner pair* of the control system (19) if there exists $T > 0$ such that $\phi(T, x, u) \in \operatorname{int} \mathcal{O}^+(x)$. The family of systems $(19)^\rho$ is said to satisfy the *inner-pair condition* if for all $\rho_1 < \rho_2$ each pair $(x, u) \in M \times \mathcal{U}^{\rho_1}$ is an inner pair of the ρ_2-system $(19)^{\rho_2}$. We say that a set $K \subset M$ fulfills the *no-return condition* if $x \in \mathcal{O}^+(K) \cap K^c$ implies that $\mathcal{O}^+(x) \cap K = \emptyset$, where K^c denotes the complement of K in M.

The following theorem (see [6, Lemma 4.7.3, Lemma 4.7.4, and Theorem 4.7.5]) describes the close relation between control sets and chain control sets if the inner-pair condition holds.

Theorem 6.4. *Consider the family of control-affine systems* $(19)^\rho$ *for* $\rho \in [\rho_*, \rho^*]$, *where* $\rho \mapsto U^\rho$ *is continuous with respect to the Hausdorff metric. Let* D^{ρ_*} *be a control set and* E^{ρ_*} *be a chain control set of* $(19)^{\rho_*}$ *such that* $D^{\rho_*} \subset E^{\rho_*}$. *Then for all* ρ *it holds that* $D^\rho \subset E^\rho$, *where the sets* D^ρ *and* E^ρ *are defined as above. Suppose* $E^{\rho^*} \subset K$ *for a compact set* $K \subset M$

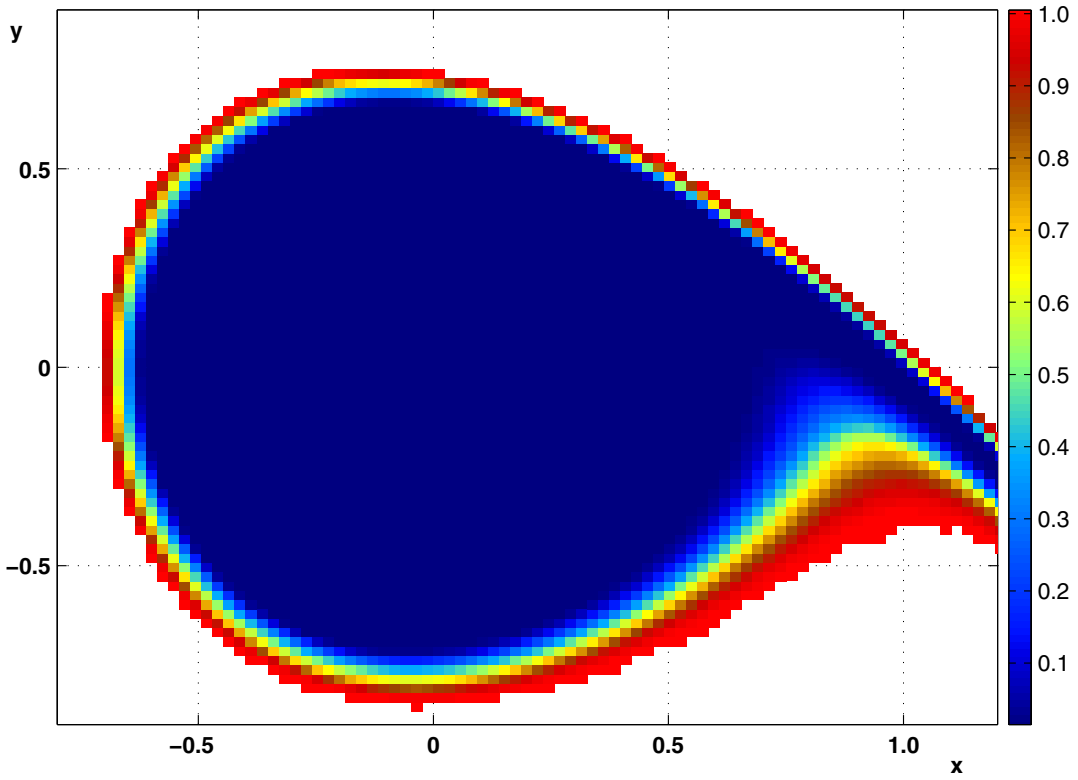

Figure 14. *Exit probabilities from the domain of attraction* $\mathbf{A}(D_{1234}^{0.2})$ *until time* $T_{exit} = 2\pi/\omega$.

that fulfills the no-return condition for the ρ^**-system, and assume that the family* (19)$^\rho$ *satisfies the inner-pair condition in* $[\rho_*, \rho^*]$.

Then for $\rho_1 < \rho_2$ *in* $(\rho_*, \rho^*]$ *it holds that* $\operatorname{cl} D^{\rho_1} \subset E^{\rho_1} \subset \operatorname{int} D^{\rho_2}$, *and for all up to at most countably many* ρ*-values, the equation* $\operatorname{cl} D^\rho = E^\rho$ *is satisfied. The map* $(\rho_*, \rho^*) \to \mathcal{C}(K) : \rho \mapsto \operatorname{cl} D^\rho$ *is continuous at* ρ *if and only if* $\operatorname{cl} D^\rho = E^\rho$*; the same is true for the map* $\rho \mapsto E^\rho$. *Here* $\mathcal{C}(K)$ *denotes the space of compact subsets of* K.

In [24] it is shown that the inner-pair condition holds for an important class of systems that includes, in particular, the escape equation (15) and the double well equation (17).

We also need some results on the boundaries of control sets D. Define the entrance and exit boundaries by

$$\begin{aligned} \partial^{ex} D &:= \{x \in \partial D \mid \text{there is } y \in \operatorname{int} D \text{ such that } x \in \mathcal{O}^+(y)\}, \\ \partial^{en} D &:= \{x \in \partial D \mid \text{there is } y \in \operatorname{int} D \text{ such that } y \in \mathcal{O}^+(x)\}, \end{aligned} \tag{22}$$

and the tangential boundary $\partial^{tg} D := \partial D \setminus (\partial^{ex} D \cup \partial^{en} D)$. The sets $\partial^{ex} D$ and $\partial^{en} D$ are disjoint and open in ∂D, and $\partial^{tg} D$ is closed in ∂D. Furthermore, $\partial^{tg} D = \operatorname{cl} \partial^{ex} D \cap \operatorname{cl} \partial^{en} D$ and $\operatorname{int}_{\partial D} \partial^{tg} D = \emptyset$. The following theorem from [24] shows that exit and entrance boundaries change continuously if the control range U^ρ increases lower semicontinuously and if the control

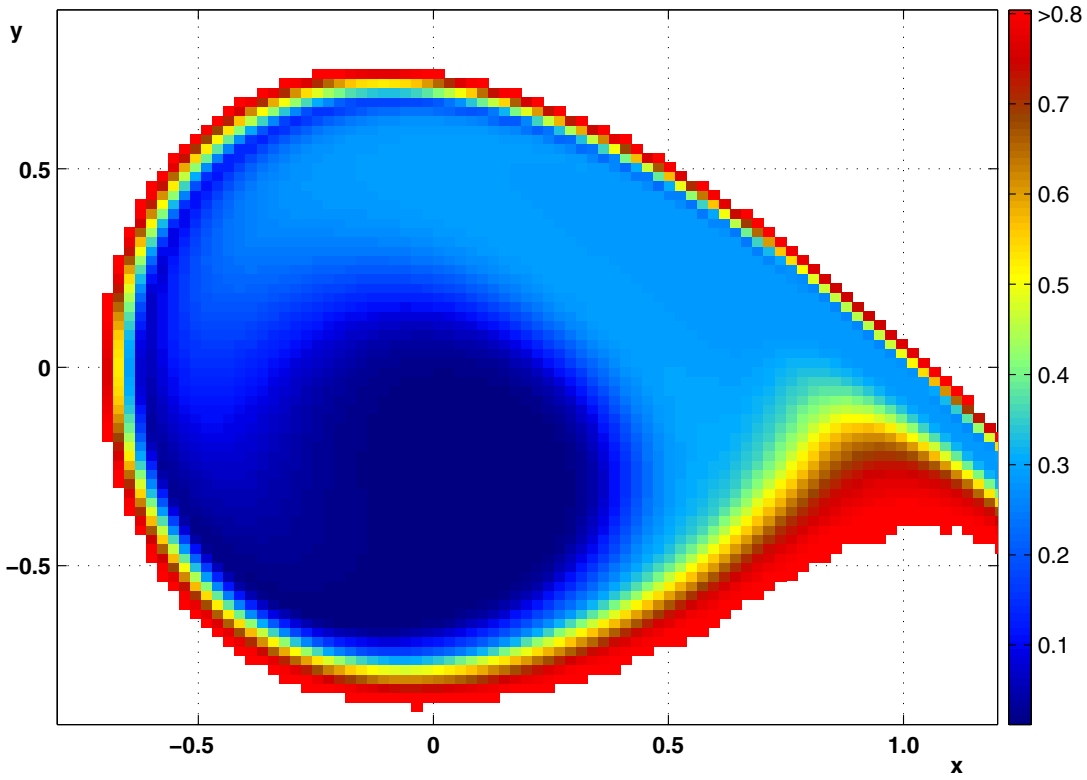

Figure 15. *Exit probabilities from the domain of attraction* $\mathbf{A}(D_{1234}^{0.2})$ *until time* $T_{exit} = 254 * 2\pi/\omega$.

sets themselves change continuously.

Theorem 6.5. *Consider the set-valued mapping* $[\rho_*, \rho^*] \to \mathcal{C}(M)$, $\rho \mapsto \operatorname{cl} D^\rho$, *as in the previous theorem, where now* D^{ρ_*} *is a control set of* $(19)^{\rho_*}$ *and* D^ρ *denotes the unique control set of* $(19)^\rho$ *with* $D^{\rho_*} \subset D^\rho$. *If this map is continuous in the Hausdorff distance at* $\rho_0 \in (\rho_*, \rho^*)$, D^{ρ^*} *is bounded, and if the control range* U^ρ *increases lower semicontinuously at* ρ_0, *then the mappings* $\rho \mapsto \partial D^\rho$, $\rho \mapsto \operatorname{cl} \partial^{ex} D^\rho$, *and* $\rho \mapsto \operatorname{cl} \partial^{en} D^\rho$ *are continuous in the Hausdorff distance at* ρ_0.

Next we will examine more closely how an invariant control set C loses its invariance when merging with a variant control set D while the control range U^ρ is increased. For this we introduce two further specifications of exit boundaries: the part from where under all admissible controls exactly one invariant control set C can be reached, and the part from where C cannot be reached at all. We denote the first set by

$$\partial^{ex \to C} D := \left\{ \begin{array}{c} x \in \partial^{ex} D \mid \mathcal{O}^+(x) \text{ bounded, and if for some invariant} \\ \text{control set } C' \subset M \text{ we have } C' \cap \mathcal{O}^+(x) \neq \emptyset, \text{ then } C = C' \end{array} \right\}$$

and the second one by

$$\partial^{ex \not\to C} D := \{x \in \partial^{ex} D \mid \mathcal{O}^+(x) \cap C = \emptyset\}.$$

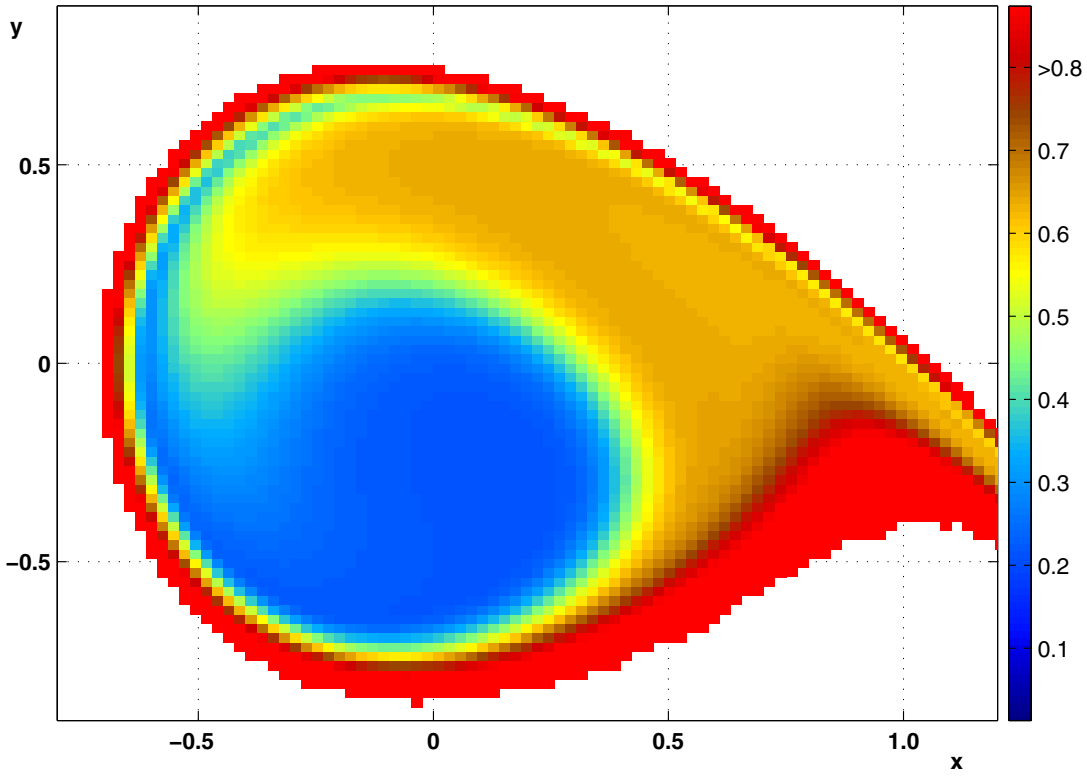

Figure 16. *Exit probabilities from the domain of attraction* $\mathbf{A}(D_{1234}^{0.2})$ *until time* $T_{exit} = 1000 * 2\pi/\omega$.

Note that from [6, Theorem 3.2.8] it follows that $\mathcal{O}^+(x) \subset \mathcal{O}^-(C) \cap \mathcal{O}^+(D)$ for all $x \in \partial^{ex \to C} D$.

If the exit boundary of D^{ρ_0} can be decomposed into $\partial^{ex \to C^{\rho_0}} D^{\rho_0}$ and $\partial^{ex \not\to C^{\rho_0}} D^{\rho_0}$, then the exit boundary of the merged set is continuous in the following sense [24].

Theorem 6.6. *Let* $K \subset M$ *be a compact set such that all control sets of the control systems* $(19)^\rho$ *have void intersection with the boundary of* K. *Assume that system* $(19)^{\rho_0}$ *has precisely one invariant control set* $C^{\rho_0} \subset K$ *and one variant control set* $D^{\rho_0} \subset K$ *such that* $C^{\rho_0} \cap \operatorname{cl} D^{\rho_0} \neq \emptyset$. *For each* $\rho > \rho_0$ *let there be precisely one variant control set* $F^\rho \subset K$ *of* $(19)^\rho$ *and* $C^{\rho_0} \cup D^{\rho_0} \subset F^\rho$. *Suppose that* $\operatorname{cl} F^\rho$ *are chain control sets of* $(19)^\rho$ *for each* $\rho > \rho_0$ *and* $\operatorname{cl}(\mathcal{O}^{\rho_0,-}(C^{\rho_0}) \cap \mathcal{O}^{\rho,+}(D^{\rho_0}))$ *is a chain control set of* $(19)^{\rho_0}$. *Finally, assume that* U^ρ *depends continuously on* ρ *with respect to the Hausdorff metric at* ρ_0 *and let* $\delta^{ex \to C^{\rho_0}} D^{\rho_0}$ *and* $\delta^{ex \not\to C^{\rho_0}} D^{\rho_0}$ *be a nontrivial decomposition of* $\delta^{ex} D^{\rho_0}$.

Then $\operatorname{cl} \partial^{ex} F^\rho \to \operatorname{cl} \partial^{ex \not\to C^{\rho_0}} D^{\rho_0}$ *in the Hausdorff metric for* $\rho \searrow \rho_0$.

Acknowledgments. The algorithms used have been implemented into the MATLAB version of the program package GAIO by Junge. Thus the box handling algorithms from Junge could be used. The control sets are found using methods based on Szolnoki [39]. The necessary solvers for stochastic differential equations and the routines for the computation of the transition matrix were added into the GAIO structure.

Global Synchronization of Linearly Hybrid Coupled Networks with Time-Varying Delay*

Wenwu Yu†, Jinde Cao‡, and Jinhu Lü§

Abstract. Many real-world large-scale complex networks demonstrate a surprising degree of synchronization. To unravel the underlying mechanics of synchronization in these complex networks, a generally linearly hybrid coupled network with time-varying delay is proposed, and its global synchronization is then further investigated. Several effective sufficient conditions of global synchronization are attained based on the Lyapunov function and a linear matrix inequality (LMI). Both delay-independent and delay-dependent conditions are deduced. In particular, the coupling matrix may be nonsymmetric or nondiagonal. Moreover, the derivative of the time-varying delay is extended to any given value. Finally, a small-world network, a regular network, and scale-free networks with network size are constructed to show the effectiveness of the proposed synchronous criteria.

Key words. Lyapunov function, linear matrix inequality (LMI), global synchronization, time-varying delay, complex networks

1. Introduction.

Over the last few years, complex networks have received increasing attention from all fields of sciences and humanities [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40]. Networks are everywhere in the real world, such as food-webs, ecosystems, metabolic pathways, the Internet, the World Wide Web, social networks, and global economic markets [1, 2]. The ubiquity of networks in the biological, physical, engineering, and social sciences leads naturally to two important common problems: How does network structure affect network function? How do individual dynamics affect global dynamics?

Despite advances in understanding network structure and dynamical behaviors in idealized cases, relatively little is known about large-scale, real-world complex networks and their

dynamical characteristics, especially for the evolving networks [3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 20, 21, 22, 23, 24, 25, 26, 27, 28, 30, 31, 32, 33, 34]. Historically, many models were proposed to describe various complex networks, including regular graph, random graph, small-world network, scale-free network, evolving networks, etc. [1, 2]. Undoubtedly, these models well describe many real networks in nature, such as social, biological, and engineering networks.

On the other hand, one can also extend the existing network models by introducing dynamical elements into the network nodes [3, 4, 14, 32, 33, 34]. Over the last few years, nonlinear dynamics of complex networks have been intensively investigated. Synchronization is a kind of typical collective behavior and a basic motion in nature [14]. Our intuition is that loosely coupled dynamical systems tend to synchronize with respect to periodic behavior [18]. This synchronization is essentially a form of self-organization. Moreover, it has been demonstrated that many real-world problems have a close relationship with network synchronization. For example, theoretical and experimental results reveal that a mammalian brain not only displays its storage of associative memories but also modulates oscillatory neuronal synchronization by selective perceived attention [6].

Recently, network synchronization has been intensively investigated in various different fields [3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 20, 21, 22, 23, 24, 25, 26, 27, 28, 30, 31, 32, 33, 34]. For example, some researchers studied the synchronization of coupled connected neural networks [6, 8, 9, 10]; Yu, Cao, and their colleagues explored the synchronization of an array of linearly coupled networks with time-delay [7, 16]; Lü and his colleagues introduced several synchronization criteria for the time-varying complex dynamical networks [16, 32, 33, 34]; and Li and Chen studied the robust adaptive synchronization of some uncertain dynamical networks [15].

In this paper, we introduce a linearly hybrid coupled network with time-varying delay. Based on this network model, several simply sufficient conditions of global network synchronization are then deduced by using the Lyapunov function and a linear matrix inequality (LMI). Both delay-independent and delay-dependent sufficient conditions are also attained. It should be especially emphasized that we do not assume that the coupling matrix is symmetric or diagonal. However, most of the former works on network synchronization are based on this assumption. Furthermore, we extend the derivative of the time-varying delay to any given value. Last but not least, one constructs a small-world network, a regular network, and scale-free networks with network size to verify the effectiveness of the proposed synchronous criteria.

The remainder of this paper is organized as follows: In section 2, the main background of complex networks is briefly outlined, and a generally linearly hybrid coupled network with time-varying delay is proposed. The main theorems and corollaries for global network synchronization are then given in section 3. In section 4, a small-world network, a regular network, and scale-free networks with network size are constructed to show the effectiveness of the proposed global network synchronous criteria. The conclusions are finally drawn in section 5.

2. Preliminaries. Consider a complex dynamical network consisting of N identical nodes with linearly diffusive couplings [3, 4, 5, 14, 32, 33, 34], which is described by

$$\dot{x}_i(t) = f(x_i(t)) + c\sum_{j=1, j\neq i}^{N} G_{ij}\Gamma(x_j(t) - x_i(t)), \quad i = 1, 2, \ldots, N, \tag{1}$$

where $i = 1, 2, \ldots, N$, $x_i(t) = (x_{i1}(t), x_{i2}(t), \ldots, x_{in}(t))^T \in R^n$ is the state vector of the ith node, $f : R^n \longrightarrow R^n$ is continuously differentiable, c is the coupling strength, $\Gamma = \mathrm{diag}(\gamma_1, \gamma_2, \ldots, \gamma_n) \in R^{n\times n}$ is a 0-1 diagonal matrix with specific $\gamma_i = 1$ and 0 for others, and $G = (G_{ij})_{N\times N}$ is a coupling configuration matrix representing the topological structure of the network, where G_{ij} is defined as follows: if there exists a connection from node i to another node j, then the coupling strength $G_{ij} = G_{ji} = 1$; otherwise, $G_{ij} = G_{ji} = 0$ $(j \neq i)$, and the diagonal elements of matrix G are defined by

$$G_{ii} = -\sum_{j=1, j\neq i}^{N} G_{ij} = -\sum_{j=1, j\neq i}^{N} G_{ji}. \tag{2}$$

Thus network (1) can be rewritten as follows:

$$\dot{x}_i(t) = f(x_i(t)) + c\sum_{j=1}^{N} G_{ij}\Gamma x_j(t), \quad i = 1, 2, \ldots, N. \tag{3}$$

Hereafter, suppose network (3) is connected in the sense that there are no isolate clusters. That is, the coupling configuration matrix G is an irreducible matrix.

However, most real-world complex networks are time-varying. To characterize the real-world evolving networks, Lü and Chen introduced a time-varying network [14, 32, 33, 34] which represents many real biological and engineering networks. Also, there inevitably exists time-delay in many practical complex networks because of the finite information exchanging speed. Considering the time-delay, we propose a simple complex network model as follows [13]. Recently, a linearly coupled complex network was presented and further studied [6, 7, 8]. Considering the time delay, Cao and his colleagues further introduced the following constant delayed complex dynamical network [16].

In this paper, we will consider the following linearly hybrid coupled network with time-varying delay:

$$\dot{x}_i(t) = -Cx_i(t) + Af(x_i(t)) + Bf(x_i(t-\tau)) + I(t) + \sum_{j=1}^{N} G_{ij}Dx_j(t) + \sum_{j=1}^{N} G_{ij}D_\tau x_j(t-\tau(t)), \tag{4}$$

where $i = 1, 2, \ldots, N$, $C = \mathrm{diag}(c_1, c_2, \ldots, c_n) \in R^{n\times n}$ is a diagonal matrix with positive diagonal entries $c_i > 0$, $i = 1, 2, \ldots, n$, $A = (a_{ij})_{n\times n}$ and $B = (b_{ij})_{n\times n}$ are weight and delayed weight matrices, respectively, $I(t) = (I_1(t), I_2(t), \ldots, I_n(t))^T \in R^n$ is an external input vector, $D = (d_{ij}) \in R^{n\times n}$ and $D_\tau = (d_{\tau ij}) \in R^{n\times n}$ are constant and delayed inner coupling matrices of complex networks, respectively, $f(x_i(t)) = (f_1(x_{i1}(t)), f_2(x_{i2}(t)), \ldots, f_n(x_{in}(t)))^T \in R^n$

corresponds to the activation functions of neurons, and $G = (G_{ij})_{N\times N}$ satisfies the diffusive condition (2). In particular, one does not assume that the constant and delayed inner coupling matrices $D = (d_{ij}) \in R^{n\times n}$ and $D_\tau = (d_{\tau ij}) \in R^{n\times n}$ are diagonal matrices.

Denote $x_i(t) = \phi_i(t) \in \mathcal{C}([-r, 0], R)$ $(i = 1, 2, \ldots, N)$, where $r = \sup_{t\in R}\{\tau(t)\}$ and $\mathcal{C}([-r, 0], R)$ is the set of continuous functions from $[-r, 0]$ to R. To simplify, one has the following fundamental assumptions.

A_1: $f_i(x_i)$ $(i = 1, 2, \ldots, n)$ are monotonically nondecreasing on R.

A_2: $f_i(x_i)$ $(i = 1, 2, \ldots, n)$ are Lipschitz continuous; i.e., there exist constants $F_i > 0$ such that

$$|f_i(\alpha_1) - f_i(\alpha_2)| \le F_i|\alpha_1 - \alpha_2| \quad \forall \alpha_1, \alpha_2 \in R. \tag{5}$$

A_3: $\tau(t)$ is a bounded differential function of time t satisfying

$$0 \le \dot{\tau}(t) \le h < 1,$$

where h is a positive real constant.

A_4: The coupling matrix G satisfies the conditions

$$G_{ij} \ge 0, \quad i \ne j, \qquad G_{ii} = -\sum_{j=1,\, j\ne i}^{N} G_{ij}, \quad i = 1, 2, \ldots, N. \tag{6}$$

Before stating the main results, some similar definitions and lemmas are given [6, 7, 8, 9, 10].

Definition 1. *Let* $r = \max_{t\in R}\{\tau(t)\}$. *Set* $\mathbf{S} = \{x = (x_1(s), x_2(s), \ldots, x_N(s)) : x_i(s) \in \mathcal{C}([-r, 0], R),\ x_i(s) = x_j(s),\ i, j = 1, 2, \ldots, N\}$, *which is called the synchronization manifold of network* (4).

Definition 2. *Let* $\widehat{R}$ *be a ring and* $T(\widehat{R}, K) = \{$*the set of matrices with entries* $\widehat{R}$ *such that the sum of the entries in each row is equal to* K *for some* $K \in \widehat{R}\}$.

Definition 3. *The set of* $M_1^N(1)$: $M_1^N(1)$ *is composed of matrices with* N *columns; each row (such as the* i*th row) of* $\widetilde{M} \in M_1^N(1)$ *has exactly one entry* α_i *and one entry* $-\alpha_i$, *where* $\alpha_i \ne 0$, *and all other entries are zeros.*

Definition 4. *The set of* $M_1^N(n)$: $M_1^N(n) = \{\mathbf{M} = M \otimes I_n : M \in M_1^N(1)$, I_n *is the* n*-dimensional identity matrix*$\}$, *where* $\otimes$ *is Kronecker product.*

Definition 5. $M_2^N(n) \subset M_1^N(n)$: *If* $M \in M_2^N(n)$, *for any pair of indices* i *and* j, *there exist indices* $j_1, j_2, \ldots, j_l$ *and* $p_1, p_2, \ldots, p_{l-1}$ *such that* $M_{p_q,i_q} \ne 0$ *and* $M_{p_q,i_{q+1}} \ne 0$ *for all* $1 \le q < l$, *where* $j_1 = i$ *and* $j_l = j$.

Definition 6. *Synchronization manifold* $\mathbf{S}$ *is said to be globally exponentially stable (or network* (4) *is globally exponentially synchronized) if there exist* $\epsilon > 0$, $T > t_0$, *and* $M > 0$ *such that*

$$\|x_i(t) - x_j(t)\| \le Me^{-\epsilon t}, \tag{7}$$

where $\phi_i \in \mathcal{C}([-r, 0], R)$, $t > T$, $i, j = 1, 2, \ldots, N$.

Definition 7. *Synchronization manifold* $\mathbf{S}$ *is said to be globally asymptotically stable (or network* (4) *is globally asymptotically synchronized) if for any* $\varepsilon > 0$, *there exists* $T > t_0$ *such that*

$$\|x_i(t) - x_j(t)\| \le \varepsilon, \tag{8}$$

where $\phi_i, \phi_j \in \mathcal{C}([-r, 0], R)$, $t > T$, $i, j = 1, 2, \ldots, N$.

Lemma 1 (see [9]). *Let* G *be an* $N \times N$ *matrix in the set* $T(\widehat{R}, K)$. *Then the* $(N-1)\times(N-1)$ *matrix* H *satisfies* $MG = HM$, *where* $H = MGJ$,

(9)

$$M = \begin{pmatrix} \mathbf{1} & \mathbf{-1} & & & \\ & \mathbf{1} & \mathbf{-1} & & \\ & & & \ddots & \\ & & & \mathbf{1} & \mathbf{-1} \end{pmatrix}_{((N-1)\times N)}, \quad J = \begin{pmatrix} \mathbf{1} & \mathbf{1} & \mathbf{1} & \cdots & \mathbf{1} \\ \mathbf{0} & \mathbf{1} & \mathbf{1} & \cdots & \mathbf{1} \\ & & \ddots & & \mathbf{1} \\ & & \cdots & \mathbf{1} & \mathbf{1} \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{0} & \mathbf{1} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \cdots & \mathbf{0} \end{pmatrix}_{(N\times(N-1))},$$

in which $\mathbf{1}$ *is the multiplicative identity of* $\widehat{R}$. *Moreover, the matrix* H *can be rewritten explicitly as follows:* $H_{(i,j)} = \sum_{k=1}^{j} G_{(i,k)} - G_{(i+1,k)}$ *for* $i, j \in \{1, 2, \ldots, N-1\}$.

Lemma 2 (Schur complement [17]). *The LMI*

$$\begin{pmatrix} \widetilde{Q}(x) & \widetilde{S}(x) \\ \widetilde{S}(x)^T & \widetilde{R}(x) \end{pmatrix} > 0$$

is equivalent to one of the following conditions:

(i) $\widetilde{Q}(x) > 0$, $\widetilde{R}(x) - \widetilde{S}(x)^T \widetilde{Q}(x)^{-1} \widetilde{S}(x) > 0$,

(ii) $\widetilde{R}(x) > 0$, $\widetilde{Q}(x) - \widetilde{S}(x) \widetilde{R}(x)^{-1} \widetilde{S}(x)^T > 0$,

where $\widetilde{Q}(x) = \widetilde{Q}(x)^T$, $\widetilde{R}(x) = \widetilde{R}(x)^T$.

Lemma 3 (see [9]). *If matrix* G *is symmetric and also satisfies condition* A_4, *then* G *is irreducible iff there exists a* $p \times N$ *matrix* $M \in M_2^N(1)$, *such that* $G = -M^T M$.

Lemma 4 (see [9]). *Let* $x = (x_1, x_2, \ldots, x_N)^T$, *where* $x_i \in R^n$, $i = 1, 2, \ldots, N$. *Then* $x \in \mathbf{S}$ *iff there exists* $\mathbf{M} \in M_2^N(n)$ *satisfying* $\|\mathbf{M}x\| = 0$.

Denote

$$d(x) = \|\mathbf{M}x\|^2 = x^T \mathbf{M}^T \mathbf{M} x, \quad \mathbf{M} \in M_2^N(n). \tag{10}$$

Then $d(x)$ *is a nonnegative distance function. From the assumptions of* $\mathbf{M}$, *one has* $d(x) \longrightarrow 0$ *iff* $\|x_i(t) - x_j(t)\| \longrightarrow 0$ *for all* $i, j = 1, 2, \ldots, N$.

Lemma 5 (see [19]). *The Kronecker product has the following properties:*

(1) $(\alpha A) \otimes B = A \otimes (\alpha B)$;

(2) $(A + B) \otimes C = A \otimes C + B \otimes C$;

(3) $(A \otimes B)(C \otimes D) = (AC) \otimes (BD)$.

Lemma 6 (Jensen inequality [29]). *Assume that the vector function* $\omega : [0, r] \in R^{m\times m}$ *is well defined for the following integrations. For any symmetric matrix* $W \in R^{m\times m}$ *and scalar*

$r > 0$, one has

$$r\int_0^r \omega(s)W\omega(s)\,ds \geq \left(\int_0^r \omega(s)\,ds\right)^T W\left(\int_0^r \omega(s)\,ds\right).$$

3. Main results. In this section, several novel criteria are proposed for the global synchronization of complex network (4) based on the Lyapunov function and an LMI.

To simplify the presentation, some notation is given in the following. Let T be a symmetric and irreducible matrix satisfying assumption A_4. From Lemma 3, there exists a $p \times N$ matrix $\widetilde{M} \in M_2^N(1)$ such that $T = -\widetilde{M}^T\widetilde{M}$. Denote $\mathbf{M} = \widetilde{M} \otimes I_n \in M_2^N(n)$, and let $\mathbf{M}_i = (M_{i1}, M_{i2}, \ldots, M_{iN})$ be the ith row of $\mathbf{M}$, where $M_{ii_1} = \alpha_i I_n$, $M_{ii_2} = -\alpha_i I_n$, and $M_{ij} = 0$ for $j \neq i_1, i_2$. Let $A \otimes B$ be the Kroneker product of matrices A and B.

$$\mathbf{C} = I_N \otimes C, \quad \mathbf{C^1} = I_p \otimes C, \quad \mathbf{A} = I_N \otimes A, \quad \mathbf{A^1} = I_p \otimes A,$$

$$\mathbf{B} = I_N \otimes B, \quad \mathbf{B^1} = I_p \otimes B, \quad \mathbf{G} = G \otimes D, \quad \mathbf{G}_\tau = G \otimes D_\tau,$$

$$x_i(t) = (x_{i1}(t), x_{i2}(t), \ldots, x_{in}(t))^T \ (\forall i = 1, 2, \ldots, N), \quad x(t) = (x_1^T(t), x_2^T(t), \ldots, x_N^T(t))^T,$$

$$\mathbf{f}(x(t)) = (f^T(x_1(t)), f^T(x_2(t)), \ldots, f^T(x_N(t)))^T, \quad \mathbf{I}(t) = (I^T(t), I^T(t), \ldots, I^T(t))^T, \tag{11}$$

where I_N is the N dimensional identity matrix.

Then the complex network (4) can be recast as follows:

$$\dot{x}(t) = -\mathbf{C}x(t) + \mathbf{A}\mathbf{f}(x(t)) + \mathbf{B}\mathbf{f}(x(t-\tau(t))) + \mathbf{I}(t) + \mathbf{G}x(t) + \mathbf{G}_\tau x(t-\tau(t)), \quad i = 1, 2, \ldots, N. \tag{12}$$

Theorem 1. *Suppose A_2–A_4 hold. Network (12) is globally exponentially synchronized if there exist positive definite matrices $P = (p_{ij})_{n\times n} \in R^{n\times n}$, $Q = (q_{ij})_{n\times n} \in R^{n\times n}$, and $\Omega = (\Omega_{ij})_{n\times n} \in R^{n\times n}$, a positive definite diagonal matrix $\Sigma = \mathrm{diag}(\Sigma_1, \Sigma_2, \ldots, \Sigma_n) \in R^{n\times n}$, a symmetric matrix $\Delta = (\Delta_{ij})_{n\times n} \in R^{n\times n}$, and an irreducible symmetric matrix $T = (t_{ij}) \in R^{N\times N}$ satisfying A_4, such that*

$$\Lambda_0 = \begin{pmatrix} -2PC - \Delta + F\Sigma F & PA & PB \\ A^TP & -\Sigma + Q & 0 \\ B^TP & 0 & -(1-h)Q \end{pmatrix} < 0, \tag{13}$$

where $F = \mathrm{diag}(F_1, F_2, \ldots, F_n) \in R^{n\times n}$ and one of the following conditions holds:

$$\text{(i) } \Lambda_{ij} = \begin{pmatrix} \sum_{k=1}^N T_{ik}G_{kj}(PD + D^TP) + T_{ij}(\Omega + \Delta) & \sum_{k=1}^N T_{ik}G_{kj}PD_\tau \\ \sum_{k=1}^N T_{ik}G_{kj}D_\tau^TP & -(1-h)T_{ij}\Omega \end{pmatrix} < 0 \tag{14}$$

$$\forall 1 \leq i < j \leq N.$$

$$\text{(ii) } \widetilde{\Lambda}_{ij} = \begin{pmatrix} 2\sum_{k=1}^n p_{ik}d_{kj}TG + (\Omega_{ij} + \Delta_{ij})T & \sum_{k=1}^n p_{ik}d_{\tau kj}TG \\ \sum_{k=1}^n p_{ik}d_{\tau kj}G^TT & -(1-h)\Omega_{ij}T \end{pmatrix} > 0 \tag{15}$$

$$\forall 1 \leq i, j \leq n.$$

Proof. See Appendix A.

Instead of using inequality (A.4), from assumption A_1, one has

$$\begin{aligned}\mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{\Sigma}\mathbf{M}\mathbf{f}(x(t)) &= \sum_{j=1}^{p}\alpha_j^2[f(x_{j_1}(t))-f(x_{j_2}(t))]^T\Sigma[f(x_{j_1}(t))-f(x_{j_2}(t))]\\ &\le \sum_{j=1}^{p} y_j^T(t)F\Sigma[f(x_{j_1}(t))-f(x_{j_2}(t))].\end{aligned} \tag{16}$$

Similarly, following the same steps in part (i) of Theorem 1, one can easily attain the following corollary.

Corollary 1. *Suppose that assumptions A_1–A_4 hold. Then network (12) is globally exponentially synchronized if there exist positive definite matrices $P=(p_{ij})_{n\times n}\in R^{n\times n}$, $Q=(q_{ij})_{n\times n}\in R^{n\times n}$, and $\Omega=(\Omega_{ij})_{n\times n}\in R^{n\times n}$, a positive definite diagonal matrix $\Sigma=\operatorname{diag}(\Sigma_1,\Sigma_2,\ldots,\Sigma_n)\in R^{n\times n}$, a symmetric matrix $\Delta=(\Delta_{ij})_{n\times n}\in R^{n\times n}$, and an irreducible symmetric matrix $T=(t_{ij})\in R^{N\times N}$ satisfying A_4, such that*

$$\begin{pmatrix} -2PC-\Delta & PA+F\Sigma & PB\\ A^TP+\Sigma F & -2\Sigma+Q & 0\\ B^TP & 0 & -(1-h)Q\end{pmatrix}<0, \tag{17}$$

where $F=\operatorname{diag}(F_1,F_2,\ldots,F_n)\in R^{n\times n}$ and

$$\begin{pmatrix} \sum_{k=1}^{N}T_{ik}G_{kj}(PD+D^TP)+T_{ij}(\Omega+\Delta) & \sum_{k=1}^{N}T_{ik}G_{kj}PD_\tau\\ \sum_{k=1}^{N}T_{ik}G_{kj}D_\tau^TP & -(1-h)T_{ij}\Omega\end{pmatrix}<0 \quad \forall 1\le i<j\le N. \tag{18}$$

Denote $e=(1,1,\ldots,1)^T\in R^N$, $J=ee^T$, $U=NI_N-J$. Let $T=-U=J-NI_N$; then $T_{ij}=1$ $(i\ne j)$, $T_{ij}=-(N-1)$ $(i=j)$, $i,j=1,2,\ldots,N$. It is easy to verify that T satisfies assumption A_4. According to Lemma 3, there exists a $p\times N$ matrix $M\in M_2^N(1)$, such that $T=-M^TM$. Since G satisfies assumption A_4, then one has

$$\begin{aligned}\sum_{k=1}^{N}T_{ik}G_{kj} &= (T_{ii}-1)G_{ij}+\sum_{k=1,\,k\ne i}^{N}T_{ik}G_{kj}+G_{ij}\\ &= -NG_{ij}+\sum_{k=1}^{N}G_{kj}=-NG_{ij}.\end{aligned} \tag{19}$$

Therefore, from Theorem 1, one gets the following corollary.

Corollary 2. *Suppose assumptions A_2–A_4 hold. Then network (12) is globally exponentially synchronized if there exist positive definite matrices $P=(p_{ij})_{n\times n}\in R^{n\times n}$, $Q=(q_{ij})_{n\times n}\in R^{n\times n}$, and $\Omega=(\Omega_{ij})_{n\times n}\in R^{n\times n}$, a positive definite diagonal matrix $\Sigma=\operatorname{diag}(\Sigma_1,\Sigma_2,\ldots,\Sigma_n)\in R^{n\times n}$, and a symmetric matrix $\Delta=(\Delta_{ij})_{n\times n}\in R^{n\times n}$, such that*

$$\begin{pmatrix} -2PC-\Delta+F\Sigma F & PA & PB\\ A^TP & -\Sigma+Q & 0\\ B^TP & 0 & -(1-h)Q\end{pmatrix}<0, \tag{20}$$

where $F=\operatorname{diag}(F_1,F_2,\ldots,F_n)\in R^{n\times n}$ and

$$\begin{pmatrix} -NG_{ij}(PD+D^TP)+(\Omega+\Delta) & -NG_{ij}PD_\tau\\ -NG_{ij}D_\tau^TP & -(1-h)\Omega\end{pmatrix}<0 \quad \forall 1\le i<j\le N. \tag{21}$$

Remark 1. In [16], Cao and his colleagues investigated the global synchronization of a coupled complex network with constant time-delay. The main theorem in [16] is Corollary 2 with $h = 0$, where the time-delay is a constant. Therefore, the main result in [16] is a special case of Theorem 1.

Let $G_\tau = 0$; i.e., there is no linearly delayed coupling in network (12) as that in [6, 7, 8]. Let $\Omega = \zeta I_n$, where ζ is a sufficient small positive number. Then one has the following corollary.

Corollary 3. *Suppose assumptions A_2–A_4 hold. Network (12) with $D_\tau = 0$ is globally exponentially synchronized if there exist positive definite matrices $P = (p_{ij})_{n\times n} \in R^{n\times n}$ and $Q = (q_{ij})_{n\times n} \in R^{n\times n}$, a positive definite diagonal matrix $\Sigma = \operatorname{diag}(\Sigma_1, \Sigma_2, \ldots, \Sigma_n) \in R^{n\times n}$, a symmetric matrix $\Delta = (\Delta_{ij})_{n\times n} \in R^{n\times n}$, and an irreducible symmetric matrix $T = (t_{ij}) \in R^{N\times N}$ satisfying A_4, such that*

$$\begin{pmatrix} -2PC - \Delta + F\Sigma F & PA & PB \\ A^T P & -\Sigma + Q & 0 \\ B^T P & 0 & -(1-h)Q \end{pmatrix} < 0, \tag{22}$$

where $F = \operatorname{diag}(F_1, F_2, \ldots, F_n) \in R^{n\times n}$ and

$$\left(2\sum_{k=1}^{n} p_{ik} d_{kj} TG + \Delta_{ij} T\right) > 0 \quad \forall 1 \le i, j \le n. \tag{23}$$

It should be especially emphasized that the inner coupling matrix D is not necessarily a diagonal matrix in Theorem 1. If D is a diagonal matrix, then one gets the following corollary.

Corollary 4. *Suppose that assumptions A_2–A_4 hold. Assume also that $D_\tau = 0$ and D is diagonal. Network (12) is globally exponentially synchronized if there exist a positive definite matrix $Q = (q_{ij})_{n\times n} \in R^{n\times n}$, positive definite diagonal matrices $P = \operatorname{diag}(p_1, p_2, \ldots, p_n) \in R^{n\times n}$ and $\Sigma = \operatorname{diag}(\Sigma_1, \Sigma_2, \ldots, \Sigma_n) \in R^{n\times n}$, a symmetric matrix $\Delta = \operatorname{diag}(\delta_1, \delta_2, \ldots, \delta_n) \in R^{n\times n}$, and an irreducible symmetric matrix $T = (t_{ij}) \in R^{N\times N}$ satisfying A_4, such that*

$$\begin{pmatrix} -2PC - \Delta + F\Sigma F & PA & PB \\ A^T P & -\Sigma + Q & 0 \\ B^T P & 0 & -(1-h)Q \end{pmatrix} < 0, \tag{24}$$

where $F = \operatorname{diag}(F_1, F_2, \ldots, F_n) \in R^{n\times n}$ and

$$T\left(2p_i d_i G + \delta_i\right) > 0, \quad i = 1, 2, \ldots, n. \tag{25}$$

Let P, Ω, and Δ be diagonal matrices. According to part (ii) of Theorem 1, one has the following corollary.

Corollary 5. *Suppose assumptions A_2–A_4 hold. Suppose also that D and D_τ are diagonal matrices. Then network (12) is globally exponentially synchronized if there exist a positive definite matrix $Q = (q_{ij})_{n\times n} \in R^{n\times n}$, positive definite diagonal matrices $P = \operatorname{diag}(p_1, p_2, \ldots, p_n) \in R^{n\times n}$, $\Sigma = \operatorname{diag}(\Sigma_1, \Sigma_2, \ldots, \Sigma_n) \in R^{n\times n}$, and $\Sigma = \operatorname{diag}(\Omega_1, \Omega_2, \ldots, \Omega_n) \in R^{n\times n}$, a*

symmetric matrix $\Delta = \operatorname{diag}(\delta_1, \delta_2, \ldots, \delta_n) \in R^{n\times n}$, *and an irreducible symmetric matrix* $T = (t_{ij}) \in R^{N\times N}$ *satisfying* A_4, *such that*

$$\begin{pmatrix} -2PC - \Delta + F\Sigma F & PA & PB \\ A^T P & -\Sigma + Q & 0 \\ B^T P & 0 & -(1-h)Q \end{pmatrix} < 0, \tag{26}$$

where $F = \operatorname{diag}(F_1, F_2, \ldots, F_n) \in R^{n\times n}$ *and*

$$\begin{pmatrix} 2p_i d_i TG + \Omega_i + \delta_i T & p_i d_{\tau i} TG \\ p_i d_{\tau i} G^T T & -(1-h)\Omega_i T \end{pmatrix} > 0, \quad i = 1, 2, \ldots, n. \tag{27}$$

Remark 2. In [6], Lu and Chen further investigated the synchronization of a coupled connected neural network with constant time-delay. Theorem 3 in [6] is Corollary 4 with $h = 0$. Therefore, the main result in [6] is a special case of Theorem 1. Moreover, in [6], the inner coupling matrix D and the inner delayed coupling matrix D_τ are both diagonal matrices. However, one removes these limit conditions in this paper.

Remark 3. To minimize the number of LMIs in the conditions of Theorem 1, one can apply the following rule: if $N < n$, one can use condition (i) of Theorem 1; otherwise, one can use condition (ii) of Theorem 1.

Since the conditions of Theorem 1 are relatively complex, one will simplify these LMIs by introducing some special $M \in M_2^N(1)$.

Theorem 2. *Suppose that assumptions* A_2–A_4 *hold. Network* (12) *is globally asymptotically synchronized if there exist positive definite matrices* $\mathbf{P} = (p_{ij})_{(N-1)n\times(N-1)n} \in R^{(N-1)n\times(N-1)n}$, $\mathbf{Q} = (q_{ij})_{(N-1)n\times(N-1)n} \in R^{(N-1)n\times(N-1)n}$, *and* $\mathbf{R} = (r_{ij})_{(N-1)n\times(N-1)n} \in R^{(N-1)n\times(N-1)n}$ *and a positive definite diagonal matrix* $\mathbf{\Sigma} = \operatorname{diag}(\Sigma_1, \Sigma_2, \ldots, \Sigma_{(N-1)n}) \in R^{(N-1)n\times(N-1)n}$, *such that*

$$\mathbf{\Omega} = \begin{pmatrix} -2\mathbf{PC^1} + \mathbf{PH} + \mathbf{H}^T\mathbf{P} + \mathbf{F\Sigma F} + \mathbf{R} & \mathbf{PH}_\tau & \mathbf{PA^1} & \mathbf{PB^1} \\ \mathbf{H}_\tau^T\mathbf{P} & -(1-h)\mathbf{R} & 0 & 0 \\ \mathbf{A^1}^T\mathbf{P} & 0 & -\mathbf{\Sigma} + \mathbf{Q} & 0 \\ \mathbf{B^1}^T\mathbf{P} & 0 & 0 & -(1-h)\mathbf{Q} \end{pmatrix} < 0, \tag{28}$$

where $F = \operatorname{diag}(F_1, F_2, \ldots, F_n) \in R^{n\times n}$, $\mathbf{F} = I_{N-1} \otimes F$, $H = MGJ$, $\mathbf{H} = (MGJ) \otimes D$, $\mathbf{H}_\tau = (MGJ) \otimes D_\tau$, *and* M *and* J *are defined in* (9).

Proof. See Appendix B.

Instead of using inequality (B.4), from assumption A_1, one has

$$\begin{aligned} \mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{\Sigma}\mathbf{M}\mathbf{f}(x(t)) &= \textstyle\sum_{j=1}^{N-1} [f(x_j(t)) - f(x_{j+1}(t))]^T \mathbf{\Sigma}_j [f(x_j(t)) - f(x_{j+1}(t))] \\ &\le \textstyle\sum_{j=1}^{N-1} [x_j(t) - x_{j+1}(t)]^T F \mathbf{\Sigma}_j [x_j(t) - x_{j+1}(t)] \\ &= x^T(t)\mathbf{M}^T\mathbf{F\Sigma M}x(t), \end{aligned} \tag{29}$$

where $\mathbf{\Sigma}_j = \operatorname{diag}(\Sigma_{(j-1)n+1}, \ldots, \Sigma_{jn})$. Following the same steps in Theorem 2, other conditions can be similarly verified. Then the following corollary is obtained.

Corollary 6. *Suppose assumptions A_1–A_4 hold. Network (12) is globally asymptotically synchronized if there exist positive definite matrices $\mathbf{P} = (p_{ij})_{(N-1)n\times(N-1)n} \in R^{(N-1)n\times(N-1)n}$, $\mathbf{Q} = (q_{ij})_{(N-1)n\times(N-1)n} \in R^{(N-1)n\times(N-1)n}$, and $\mathbf{R} = (r_{ij})_{(N-1)n\times(N-1)n} \in R^{(N-1)n\times(N-1)n}$ and a positive definite diagonal matrix $\mathbf{\Sigma} = \mathrm{diag}(\Sigma_1, \Sigma_2, \ldots, \Sigma_{(N-1)n}) \in R^{(N-1)n\times(N-1)n}$, such that*

$$\begin{pmatrix} -2\mathbf{PC^1} + \mathbf{PH} + \mathbf{H}^T\mathbf{P} + \mathbf{R} & \mathbf{PH}_\tau & \mathbf{PA^1} + \mathbf{F\Sigma} & \mathbf{PB^1} \\ \mathbf{H}_\tau^T\mathbf{P} & -(1-h)\mathbf{R} & 0 & 0 \\ \mathbf{A^1}^T\mathbf{P} + \mathbf{\Sigma F} & 0 & -2\mathbf{\Sigma} + \mathbf{Q} & 0 \\ \mathbf{B^1}^T\mathbf{P} & 0 & 0 & -(1-h)\mathbf{Q} \end{pmatrix} < 0, \tag{30}$$

where $F = \mathrm{diag}(F_1, F_2, \ldots, F_n) \in R^{n\times n}$, $\mathbf{F} = I_{N-1} \otimes F$, $H = MGJ$, $\mathbf{H} = (MGJ) \otimes D$, $\mathbf{H}_\tau = (MGJ) \otimes D_\tau$, and M and J are defined in (9).

Corollary 7. *Suppose that assumptions A_2–A_4 hold. Network (12) is globally asymptotically synchronized if there exist positive definite matrices $P = (p_{ij})_{n\times n} \in R^{n\times n}$, $Q = (q_{ij})_{n\times n} \in R^{n\times n}$, and $R = (r_{ij})_{n\times n} \in R^{n\times n}$, a positive definite diagonal matrix $\Sigma = \mathrm{diag}(\Sigma_1, \Sigma_2, \ldots, \Sigma_n) \in R^{n\times n}$, and a symmetric matrix $\Delta = (\Delta_{ij})_{n\times n} \in R^{n\times n}$, such that*

$$\Lambda_0 = \begin{pmatrix} -2PC - \Delta + F\Sigma F & PA & PB \\ A^TP & -\Sigma + Q & 0 \\ B^TP & 0 & -(1-h)Q \end{pmatrix} < 0 \tag{31}$$

and

$$\Xi = \begin{pmatrix} \mathbf{PH} + \mathbf{H}^T\mathbf{P} + \mathbf{R} + \mathbf{\Delta} & \mathbf{PH}_\tau \\ \mathbf{H}_\tau^T\mathbf{P} & -(1-h)\mathbf{R} \end{pmatrix} < 0, \tag{32}$$

where $F = \mathrm{diag}(F_1, F_2, \ldots, F_n) \in R^{n\times n}$, $\mathbf{P} = I_{N-1} \otimes P$, $\mathbf{R} = I_{N-1} \otimes R$, $\mathbf{\Delta} = I_{N-1} \otimes \Delta$, $\mathbf{H} = H \otimes D$, $\mathbf{H}_\tau = H \otimes D_\tau$, $H = MGJ$, and M and J are defined in (9).

Proof. See Appendix C.

When $D_\tau = 0$, there is no linearly delayed coupling in network (12). Let $R = \zeta I_n$ in Corollary 7, where ζ is a sufficiently small positive number. Then Corollary 7 can be simplified as follows.

Corollary 8. *Suppose that assumptions A_2–A_4 hold. Network (12) with $D_\tau = 0$ is globally exponentially synchronized if there exist positive definite matrices $P = (p_{ij})_{n\times n} \in R^{n\times n}$ and $Q = (q_{ij})_{n\times n} \in R^{n\times n}$, a positive definite diagonal matrix $\Sigma = \mathrm{diag}(\Sigma_1, \Sigma_2, \ldots, \Sigma_n) \in R^{n\times n}$, and a symmetric matrix $\Delta = (\Delta_{ij})_{n\times n} \in R^{n\times n}$, such that*

$$\Lambda_0 = \begin{pmatrix} -2PC - \Delta + F\Sigma F & PA & PB \\ A^TP & -\Sigma + Q & 0 \\ B^TP & 0 & -(1-h)Q \end{pmatrix} < 0$$

and

$$\mathbf{PH} + \mathbf{H}^T\mathbf{P} + \mathbf{\Delta} < 0,$$

where $F = \mathrm{diag}(F_1, F_2, \ldots, F_n) \in R^{n\times n}$, $\mathbf{P} = I_{N-1} \otimes P$, $\mathbf{\Delta} = I_{N-1} \otimes \Delta$, $\mathbf{H} = H \otimes D$, $H = MGJ$, and M and J are defined in (9).

Remark 4. In [7], Wang and Cao further studied the synchronization of an array of linearly coupled networks with time-varying delay. The main theorem, Theorem 2, in [7] is Corollary 8. Therefore, the main result in [7] is a special case of Theorem 2. Moreover, the inner coupling matrix D and inner delayed coupling matrix D_τ are both diagonal matrices in [7]. However, one removes these limit conditions. Furthermore, one also introduces the time-delay in the linear coupling in this paper.

If assumption A_3 is not satisfied, i.e., $\dot{\tau}(t) \geq 1$ for some t, one attains the following synchronous theorem.

Theorem 3. *Suppose assumptions A_2 and A_4 hold. Then network (12) is globally asymptotically synchronized if there exist positive definite matrices $\mathbf{P} = (p_{ij})_{(N-1)n\times(N-1)n} \in R^{(N-1)n\times(N-1)n}$, $\mathbf{Q} = (q_{ij})_{(N-1)n\times(N-1)n} \in R^{(N-1)n\times(N-1)n}$, $\mathbf{R} = (r_{ij})_{(N-1)n\times(N-1)n} \in R^{(N-1)n\times(N-1)n}$, and $\mathbf{T} = (t_{ij})_{(N-1)n\times(N-1)n} \in R^{(N-1)n\times(N-1)n}$, positive definite diagonal matrices $\mathbf{\Sigma} = \mathrm{diag}(\Sigma_1, \Sigma_2, \ldots, \Sigma_{(N-1)n}) \in R^{(N-1)n\times(N-1)n}$ and $\mathbf{\Lambda} = \mathrm{diag}(\Lambda_1, \Lambda_2, \ldots, \Lambda_{(N-1)n}) \in R^{(N-1)n\times(N-1)n}$, and a matrix $\mathbf{U} = (u_{ij})_{(N-1)n\times(N-1)n} \in R^{(N-1)n\times(N-1)n}$, such that*

(33)
$$\mathbf{\Omega_1} = \begin{pmatrix} \Psi & \mathbf{PH}_\tau + \mathbf{U}^T & \mathbf{PA^1} & \mathbf{PB^1} & 0 & (-\mathbf{C^1} + \mathbf{H})^T\mathbf{T} \\ \mathbf{H}_\tau^T\mathbf{P} + \mathbf{U} & \Psi_1 & 0 & 0 & -\mathbf{U} & \mathbf{H}_\tau^T\mathbf{T} \\ \mathbf{A^1}^T\mathbf{P} & 0 & -\mathbf{\Sigma} + \mathbf{Q} & 0 & 0 & \mathbf{A^1}^T\mathbf{T} \\ \mathbf{B^1}^T\mathbf{P} & 0 & 0 & -(1-h)\mathbf{Q} - \mathbf{\Lambda} & 0 & \mathbf{B^1}^T\mathbf{T} \\ 0 & -\mathbf{U}^T & 0 & 0 & -\frac{1}{r}\mathbf{T} & 0 \\ \mathbf{T}(-\mathbf{C^1} + \mathbf{H}) & \mathbf{TH}_\tau & \mathbf{TA^1} & \mathbf{TB^1} & 0 & -\frac{1}{r}\mathbf{T} \end{pmatrix} < 0,$$

where $\Psi = -2\mathbf{PC^1} + \mathbf{PH} + \mathbf{H}^T\mathbf{P} + \mathbf{R} + \mathbf{F\Sigma F}$, $\Psi_1 = -(1-h)\mathbf{R} - 2\mathbf{U} + \mathbf{F\Lambda F}$, $F = \mathrm{diag}(F_1, F_2, \ldots, F_n) \in R^{n\times n}$, $\mathbf{F} = I_{N-1} \otimes F$, $H = MGJ$, $\mathbf{H} = (MGJ) \otimes D$, $\mathbf{H}_\tau = (MGJ) \otimes D_\tau$, and M and J are defined in (9).

Proof. See Appendix D.

Remark 5. Although Theorems 1–3 and Corollaries 1–8 give some rigorously theoretical conditions for the synchronization of network (12), it is also difficult to fix the suitable parameters of matrixes in these conditions. However, in real-world control systems, one can easily use MATLAB LMI Toolbox to numerically solve these system parameters. For example, in Theorem 1, fixing matrix T as in Corollary 2, one can use MATLAB LMI Toolbox to solve (20) and (21); in Theorems 2–3, one can use MATLAB LMI Toolbox to solve (28) and (33), respectively.

In this paper, the delay-independent and delay-dependent conditions are both further investigated. It is well known that the delay-independent conditions tend to be conservative for small time-delay. In addition, for the coupled networks with time-varying delay, the state estimation criteria proposed in [7] are not applicable to the case in which the derivative of the time-varying delay is larger than 1. In this case, assumption A_3 is not satisfied. In this paper, one overcomes this difficulty in Theorem 3. Moreover, in [6, 7, 8], the coupling matrix G is a diagonal matrix. However, we do not need this assumption in all theorems.

4. Numerical simulations.

To verify the effectiveness of the proposed theorems and corollaries, three simple examples are given in the following.

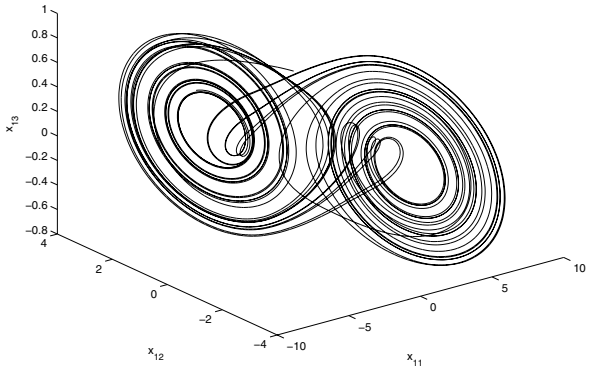

Figure 1. *Phase portrait of a single node.*

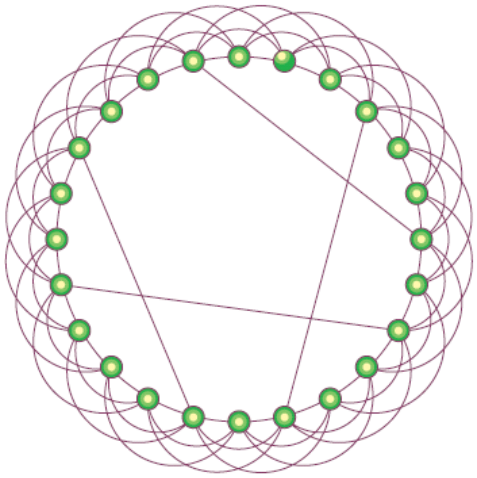

Figure 2. *Small-world network.*

4.1. Synchronization of small-world network. Consider the following Chua circuit described by [37]:

$$\begin{cases} \dot{x}_1 = \theta(-x_1 + x_2 - l(x_1)), \\ \dot{x}_2 = x_1 - x_2 + x_3, \\ \dot{x}_3 = -\beta x_2, \end{cases} \tag{34}$$

where $l(x_1) = bx_1 + 0.5(a-b)(|x_1+1| - |x_1-1|)$. The system (34) is chaotic as shown in Figure 1 when $\theta = 10$, $\beta = 18$, $a = -4/3$, and $b = -3/4$.

Now one considers network (4) with small-world connection as shown in Figure 2 [1], where the single node is given as above, and

$$D = \begin{pmatrix} 4 & 0.4 & 0.4 \\ 0.8 & 4 & 1.2 \\ -0.4 & -0.8 & 4 \end{pmatrix}.$$

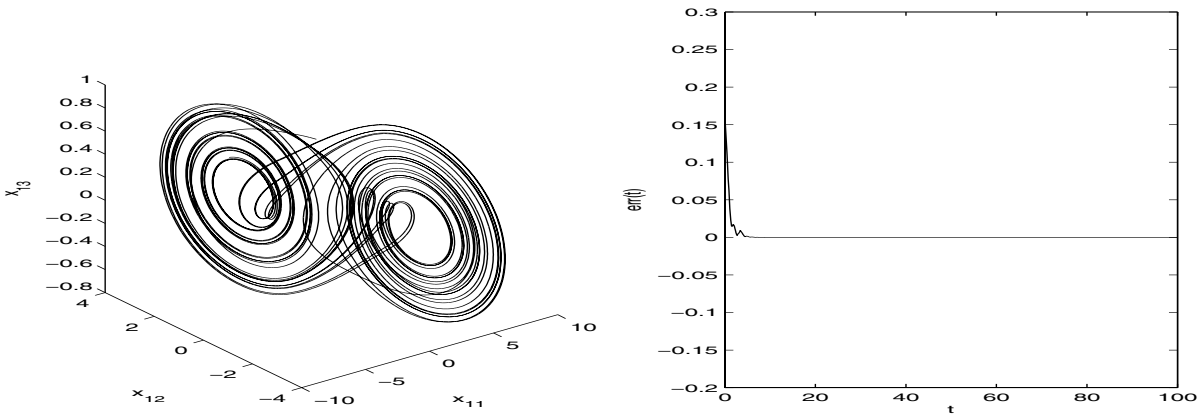

Figure 3. *Phase portrait of single node in network* (4) *and total synchronous error of the small-world network* (4).

According to Theorem 2 and MATLAB LMI Toolbox, one can easily attain the feasible solutions. Then network (4) is globally asymptotically synchronized. The total synchronous error of the small-world network is defined as follows:

$$err(t) = \frac{1}{25}\sum_{i=1}^{2}\sqrt{\sum_{j=1}^{25}[x_{1i}(t) - x_{ji}(t)]^2}.$$

Figure 3 shows the phase portrait of single node in network (4) and the total synchronous error of the small-world network (4). Similarly, one can verify the synchronization of network (4) with other topological structures, such as random graph and scale-free distribution.

4.2. Synchronization of a regular network. Consider the following 2-dimensional delayed system as a node, which is described by

$$\dot{x}(t) = -Cx(t) + Af(x(t)) + Bf(x(t-\tau(t))) + I(t), \tag{35}$$

where $x(t) = (x_1(t), x_2(t))^T$, $f(x(t)) = (\tanh(x_1(t)), \tanh(x_2(t)))^T$, $I(t) = (0,0)^T$,

$$C = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad A = \begin{pmatrix} 2.0 & -0.1 \\ -5.0 & 3.0 \end{pmatrix}, \quad B = \begin{pmatrix} -1.5 & -0.1 \\ -0.2 & -2.5 \end{pmatrix},$$

and $\tau(t) = 0.03[1 + \sin(40t)]$.

It is easy to verify that assumptions A_1 and A_2 hold for $F = I_2$ and assumption A_3 does not hold for $h = 1.2$, $r = 0.06$. The initial values are given as follows:

$$x_1(s) = 0.4, \quad x_2(s) = 0.6 \qquad \forall s \in [-1, 0].$$

Then system (35) has a chaotic attractor as shown in Figure 4.

Consider a regular network (4), where $A, B, C, I(t), f, \tau(t)$ are given above, and

$$G = \begin{pmatrix} -3 & 1 & 2 \\ 1 & -2 & 1 \\ 2 & 1 & -3 \end{pmatrix}, \quad D = \begin{pmatrix} 4 & 0.4 \\ 0.8 & 4 \end{pmatrix}, \quad D_\tau = \begin{pmatrix} 1 & 0.2 \\ 0.1 & 1 \end{pmatrix}.$$

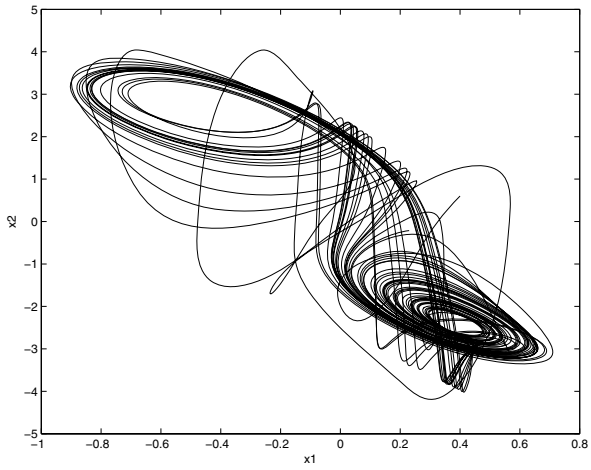

Figure 4. *Phase portrait of a single node.*

From Theorem 3, one gets the feasible solutions as follows:

$$\mathbf{P} = \begin{pmatrix} 9.4243 & -0.9377 & -1.6670 & 0.2372 \\ -0.9377 & 7.7092 & 0.2372 & -1.2747 \\ -1.6670 & 0.2372 & 9.4243 & -0.9377 \\ 0.2372 & -1.2747 & -0.9377 & 7.7092 \end{pmatrix},$$

$$\mathbf{Q} = \begin{pmatrix} 31.5252 & 8.0596 & 2.1015 & -0.8115 \\ 8.0596 & 21.9258 & -0.8115 & 0.8043 \\ 2.1015 & -0.8115 & 31.5252 & 8.0596 \\ -0.8115 & 0.8043 & 8.0596 & 21.9258 \end{pmatrix},$$

$$\mathbf{R} = \begin{pmatrix} 38.3723 & 2.7562 & -3.4028 & -3.1834 \\ 2.7562 & 20.8588 & -3.1834 & 1.0167 \\ -3.4028 & -3.1834 & 38.3723 & 2.7562 \\ -3.1834 & 1.0167 & 2.7562 & 20.8588 \end{pmatrix},$$

$$\mathbf{T} = \begin{pmatrix} 4.5225 & 0.1097 & -0.4335 & -0.1062 \\ 0.1097 & 3.1546 & -0.1062 & -0.0711 \\ -0.4335 & -0.1062 & 4.5225 & 0.1097 \\ -0.1062 & -0.0711 & 0.1097 & 3.1546 \end{pmatrix},$$

$$\mathbf{U} = \begin{pmatrix} 52.2980 & 3.7695 & 4.8829 & 1.0437 \\ 3.7695 & 44.0932 & 1.0437 & 5.5130 \\ 4.8829 & 1.0437 & 52.2980 & 3.7695 \\ 1.0437 & 5.5130 & 3.7695 & 44.0932 \end{pmatrix},$$

$$\mathbf{\Sigma} = \begin{pmatrix} 118.7802 & 0 & 0 & 0 \\ 0 & 66.5769 & 0 & 0 \\ 0 & 0 & 118.7802 & 0 \\ 0 & 0 & 0 & 66.5769 \end{pmatrix},$$

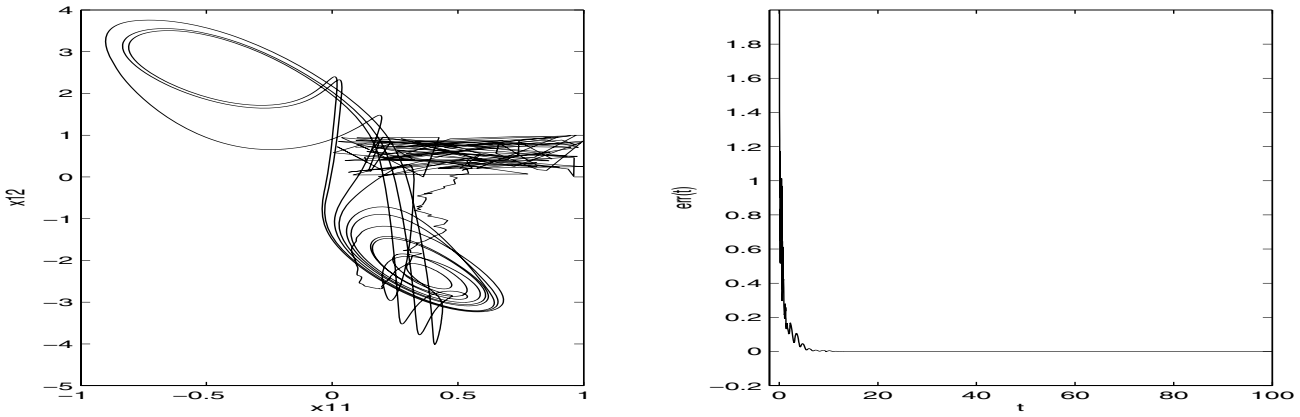

Figure 5. *Total synchronous error of network* (4) *with a regular structure.*

$$\mathbf{\Lambda} = \begin{pmatrix} 35.4724 & 0 & 0 & 0 \\ 0 & 30.6460 & 0 & 0 \\ 0 & 0 & 35.4724 & 0 \\ 0 & 0 & 0 & 30.6460 \end{pmatrix}.$$

According to Theorem 3, network (4) is globally asymptotically synchronized. The total error of network (4) is defined by

$$err(t) = \frac{1}{3}\sum_{i=1}^{2}\sqrt{[x_{1i}(t) - x_{2i}(t)]^2 + [x_{1i}(t) - x_{3i}(t)]^2}.$$

Figure 5 shows the total synchronous error of network (5), where the initial values are given by

$$x_1(s) = \begin{pmatrix} 0.1 \\ -0.3 \end{pmatrix}, \quad x_2(s) = \begin{pmatrix} 0.5 \\ -1 \end{pmatrix}, \quad x_3(s) = \begin{pmatrix} 1 \\ -0.5 \end{pmatrix}.$$

4.3. Synchronization of scale-free networks with network size. The scale-free network model was proposed by Barabási and Albert [40]; they generated the network as follows:

(1) *Growth*: Starting with a small number (m_0) of nodes, at every time step a new node is introduced and connected to m ($\leq m_0$) existing nodes by undirected links.

(2) *Preferential attachment*: The probability that the new node is connected to node i is based on the degree k_i of node i:

$$p_i = \frac{k_i}{\sum_{j=1}^{N} k_j}.$$

After t time steps, this complex network has $N = t+m_0$ nodes and mt links. In the simulation, we take $m_0 = m = 5$, with each node being the same system as (35) except $\tau(t) = \frac{e^t}{1+e^t}$. It is obvious that $0 < \tau(t) < 1$, $\dot{\tau}(t) = \frac{e^t}{(1+e^t)^2} \leq \frac{1}{2} < 1$. G is connected in the scale-free network sense: if there exists a connection from node i to another node j in the scale-free

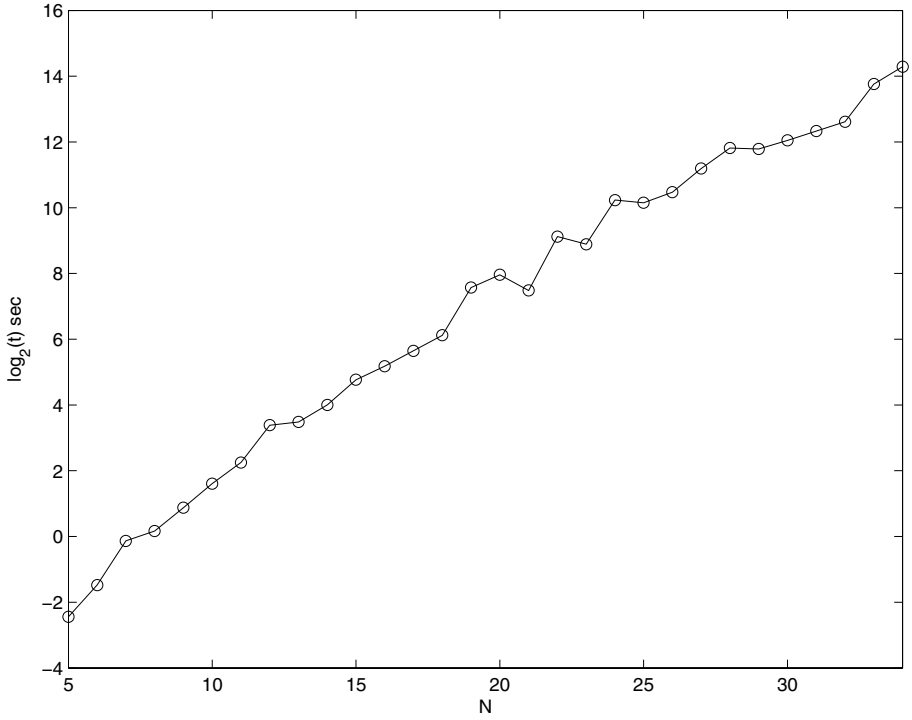

Figure 6. *The time for solving the LMI with network size in scale-free networks.*

network, then the coupling strength $G_{ij} = G_{ji} = 1$; otherwise, $G_{ij} = G_{ji} = 0$ $(j \neq i)$, and $G_{ii} = -\sum_{j=1, j\neq i}^{N} G_{ij}$.

$$D = \begin{pmatrix} 10 & 1 \\ 2 & 10 \end{pmatrix}, \quad D_\tau = \begin{pmatrix} 1 & 0.2 \\ 0.1 & 1 \end{pmatrix}.$$

Theorem 1 is available only when the scale-free network size $N = 5$ or $N = 6$. Therefore, the previous works [6, 7, 16] cannot be used to solve the network with size $N > 6$. However, Theorem 2 in this paper can be used to solve this problem. The sufficient condition in Theorem 2 is satisfied with more larger network size N. The time for solving the LMI in MATLAB Toolbox by using a normal computer and the corresponding network size are given in Figure 6.

Though the size of matrices $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{\Sigma}$ in Theorem 2 are of order $N \times N$, it can provide general and good results which is applicable for ensuring the synchronization of coupled networks with large size N. If the network size N is very large, the computation of LMI conditions is very difficult as in Figure 6 which should be further considered in the near future.

5. Conclusions. We have developed a generally linearly hybrid coupled network with time-varying delay and also further investigated its global synchronization. Based on this model, several effective sufficient conditions of global network synchronization are then deduced by using the Lyapunov function and an LMI. Both delay-independent and delay-

dependent sufficient conditions are attained. It should be especially pointed out that we do not assume that the coupling matrix is symmetric or diagonal. However, most of the former works on network synchronization are based on this assumption. Moreover, we also generalize the derivative of the time-varying delay to any given value in this paper, although most of the former results are based on assumption A_3. To verify the effectiveness of the proposed synchronous criteria, a small-world network, a regular network, and scale-free networks with increasing network size are finally constructed to show the global network synchronization.

The proposed network model builds a platform for the study of network synchronization and other network dynamical behaviors. These network synchronous criteria also provide some new insight for the underlying mechanics of network synchronization. Furthermore, there are some abundant dynamical behaviors in the network which deserve to be also further investigated in the near future, such as the relation between network structure and function, the individual and global dynamics, etc. We will also explore the possible applications for these criteria in the real-world biological and engineering networks.

Appendix A. Proof of Theorem 1.

Let

$$\mathbf{\Sigma} = I_N \otimes \Sigma, \quad \mathbf{\Sigma^1} = I_p \otimes \Sigma, \quad \mathbf{\Delta} = I_p \otimes \Delta, \quad \mathbf{P} = I_p \otimes P,$$

$$\mathbf{Q} = I_p \otimes Q, \quad \mathbf{\Omega} = I_p \otimes \Omega, \quad \mathbf{I_n} = I_N \otimes I_n, \quad \mathbf{I_n^1} = I_p \otimes I_n.$$

Let $y(t) = \mathbf{M}x(t) = (y_1^T(t), y_2^T(t), \ldots, y_p^T(t))^T$, $y_i(t) = (y_{i1}(t), y_{i2}(t), \ldots, y_{in}(t))^T$, $i = 1, 2, \ldots, p$.

According to (13), there exists a sufficiently small $\varepsilon > 0$, such that

$$\widetilde{\Lambda_0} = \begin{pmatrix} -2P(C - \varepsilon I_n) - \Delta + F\Sigma F & PA & PB \\ A^T P & -\Sigma + Q & 0 \\ B^T P & 0 & -(1-h)Q \end{pmatrix} < 0.$$

(i) Consider the Lyapunov candidate

$$\begin{aligned} V(t) = {} & e^{2\varepsilon t} x^T(t) \mathbf{M}^T \mathbf{P} \mathbf{M} x(t) + \int_{t-\tau(t)}^{t} e^{2\varepsilon s} \mathbf{f}^T(x(s)) \mathbf{M}^T \mathbf{Q} \mathbf{M} \mathbf{f}(x(s))\, ds \\ & + \int_{t-\tau(t)}^{t} e^{2\varepsilon s} x^T(s) \mathbf{M}^T \mathbf{\Omega} \mathbf{M} x(s)\, ds. \end{aligned} \tag{A.1}$$

Differentiating $V(t)$ along the trajectories of (12) yields

(A.2)
$$\begin{aligned}\dot{V}(t)|_{(12)} &= 2\varepsilon e^{2\varepsilon t}x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}x(t) + 2e^{2\varepsilon t}x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}\dot{x}(t) + e^{2\varepsilon t}\mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t))\\ &\quad - (1-\dot{\tau}(t))e^{2\varepsilon(t-\tau(t))}\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t-\tau(t)))\\ &\quad + e^{2\varepsilon t}x^T(t)\mathbf{M}^T\mathbf{\Omega}\mathbf{M}x(t)\\ &\quad - (1-\dot{\tau}(t))e^{2\varepsilon(t-\tau(t))}x^T(t-\tau(t))\mathbf{M}^T\mathbf{\Omega}\mathbf{M}x(t-\tau(t))\\ &\le 2e^{2\varepsilon t}x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}[-(\mathbf{C}-\varepsilon\mathbf{I_n})x(t) + \mathbf{A}\mathbf{f}(x(t)) + \mathbf{B}\mathbf{f}(x(t-\tau(t))) + \mathbf{I}(t)\\ &\quad + \mathbf{G}x(t) + \mathbf{G}_\tau x(t-\tau(t))] + e^{2\varepsilon t}\mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t))\\ &\quad - (1-h)e^{2\varepsilon t}\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t-\tau(t)))\\ &\quad + e^{2\varepsilon t}x^T(t)\mathbf{M}^T(\mathbf{\Omega}+\mathbf{\Delta}-\mathbf{\Delta})\mathbf{M}x(t)\\ &\quad - (1-h)e^{2\varepsilon t}x^T(t-\tau(t))\mathbf{M}^T\mathbf{\Omega}\mathbf{M}x(t-\tau(t)).\end{aligned}$$

From the definition of $\mathbf{M}$, one gets

$$\mathbf{MC} = \mathbf{C^1M}, \quad \mathbf{MA} = \mathbf{A^1M}, \quad \mathbf{MB} = \mathbf{B^1M}, \quad \mathbf{MI_n} = \mathbf{I_n^1M}, \quad \mathbf{MI}(t) = 0.$$

Therefore, one has

(A.3)
$$\begin{aligned}\dot{V}(t)|_{(12)} &\le 2e^{2\varepsilon t}x^T(t)\mathbf{M}^T\mathbf{P}[-(\mathbf{C^1}-\varepsilon\mathbf{I_n^1})\mathbf{M}x(t) + \mathbf{A^1}\mathbf{M}\mathbf{f}(x(t)) + \mathbf{B^1}\mathbf{M}\mathbf{f}(x(t-\tau(t)))\\ &\quad + \mathbf{M}\mathbf{G}x(t) + \mathbf{M}\mathbf{G}_\tau x(t-\tau(t))] + e^{2\varepsilon t}\mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t))\\ &\quad - (1-h)e^{2\varepsilon t}\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t-\tau(t)))\\ &\quad + e^{2\varepsilon t}x^T(t)\mathbf{M}^T(\mathbf{\Omega}+\mathbf{\Delta}-\mathbf{\Delta})\mathbf{M}x(t)\\ &\quad - (1-h)e^{2\varepsilon t}x^T(t-\tau(t))\mathbf{M}^T\mathbf{\Omega}\mathbf{M}x(t-\tau(t)).\end{aligned}$$

According to assumption A_2, one gets

(A.4)
$$\begin{aligned}\mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{\Sigma}\mathbf{M}\mathbf{f}(x(t)) &= \textstyle\sum_{j=1}^p \alpha_j^2[f(x_{j_1}(t)) - f(x_{j_2}(t))]^T\Sigma[f(x_{j_1}(t)) - f(x_{j_2}(t))]\\ &\le \textstyle\sum_{j=1}^p y_j^T(t)F\Sigma F y_j(t).\end{aligned}$$

Let

$$\xi_j = \begin{pmatrix} y_j^T(t) & \alpha_j(f(x_{j_1}(t)) - f(x_{j_2}(t)))^T & \alpha_j(f(x_{j_1}(t-\tau(t))) - f(x_{j_2}(t-\tau(t))))^T \end{pmatrix}^T.$$

It follows from (A.3)–(A.4) that

(A.5)
$$\begin{aligned}
\dot{V}(t)|_{(12)} &\le e^{2\varepsilon t}\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda}_0\xi_j + 2e^{2\varepsilon t}x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}[\mathbf{G}x(t)+\mathbf{G}_\tau x(t-\tau(t))] + e^{2\varepsilon t}x^T(t)\mathbf{M}^T\\
&\quad\times(\mathbf{\Omega}+\mathbf{\Delta})\mathbf{M}x(t) - (1-h)e^{2\varepsilon t}x^T(t-\tau(t))\mathbf{M}^T\mathbf{\Omega}\mathbf{M}x(t-\tau(t))\\
&= e^{2\varepsilon t}\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda}_0\xi_j + 2e^{2\varepsilon t}x^T(t)(\widetilde{M}^T\otimes I_n)(I_p\otimes P)(\widetilde{M}\otimes I_n)(G\otimes D)x(t)\\
&\quad + 2e^{2\varepsilon t}x^T(t)(\widetilde{M}^T\otimes I_n)(I_p\otimes P)(\widetilde{M}\otimes I_n)(G\otimes D_\tau)x(t-\tau(t))\\
&\quad + e^{2\varepsilon t}x^T(t)(\widetilde{M}^T\otimes I_n)(I_p\otimes(\Omega+\Delta))(\widetilde{M}\otimes I_n)x(t)\\
&\quad - (1-h)e^{2\varepsilon t}x^T(t-\tau(t))(\widetilde{M}^T\otimes I_n)(I_p\otimes\Omega)(\widetilde{M}\otimes I_n)x(t-\tau(t))\\
&= e^{2\varepsilon t}\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda}_0\xi_j + 2e^{2\varepsilon t}x^T(t)(\widetilde{M}^T\widetilde{M}G\otimes PD)x(t) + 2e^{2\varepsilon t}x^T(t)(\widetilde{M}^T\widetilde{M}G\otimes PD_\tau)\\
&\quad\times x(t-\tau(t)) + e^{2\varepsilon t}x^T(t)(\widetilde{M}^T\widetilde{M}\otimes(\Omega+\Delta))x(t) - (1-h)e^{2\varepsilon t}x^T(t-\tau(t))\\
&\quad\times(\widetilde{M}^T\widetilde{M}\otimes\Omega)x(t-\tau(t))\\
&= e^{2\varepsilon t}\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda}_0\xi_j - 2e^{2\varepsilon t}x^T(t)(TG\otimes PD)x(t) - 2e^{2\varepsilon t}x^T(t)(TG\otimes PD_\tau)x(t-\tau(t))\\
&\quad - e^{2\varepsilon t}x^T(t)(T\otimes(\Omega+\Delta))x(t) + (1-h)e^{2\varepsilon t}x^T(t-\tau(t))(T\otimes\Omega)x(t-\tau(t))\\
&= e^{2\varepsilon t}\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda}_0\xi_j - 2e^{2\varepsilon t}\sum_{i=1}^{N}\sum_{j=1}^{N}x_i^T(t)(\sum_{k=1}^{N}T_{ik}G_{kj}PD)x_j(t)\\
&\quad - 2e^{2\varepsilon t}\sum_{i=1}^{N}\sum_{j=1}^{N}x_i^T(t)(\sum_{k=1}^{N}T_{ik}G_{kj}PD_\tau)x_j(t-\tau(t)) - e^{2\varepsilon t}\sum_{i=1}^{N}\sum_{j=1}^{N}x_i^T(t)T_{ij}\\
&\quad\times(\Omega+\Delta)x_j(t) + (1-h)e^{2\varepsilon t}\sum_{i=1}^{N}\sum_{j=1}^{N}x_i^T(t-\tau(t))T_{ij}\Omega x_j(t-\tau(t)).
\end{aligned}$$

Denote $L_{ij}=\sum_{k=1}^{N}T_{ik}G_{kj}$. Then one obtains

(A.6)
$$\begin{aligned}
\sum_{j=1}^{N}L_{ij} &= \sum_{j=1,\,j\neq i}^{N}L_{ij} + L_{ii}\\
&= \sum_{j=1,\,j\neq i}^{N}\sum_{k=1}^{N}T_{ik}G_{kj} + \sum_{k=1}^{N}T_{ik}G_{ki}\\
&= \sum_{k=1}^{N}(\sum_{j=1,\,j\neq i}^{N}T_{ik}G_{kj} + T_{ik}G_{ki})\\
&= \sum_{k=1}^{N}T_{ik}(\sum_{j=1}G_{kj}) = 0.
\end{aligned}$$

Thus one has

(A.7)
$$L_{ii} = -\sum_{j=1,\,j\neq i}^{N}L_{ij},\quad i=1,2,\ldots,N.$$

Let $\eta_{ij} = (x_i^T(t) - x_j^T(t),\, x_i^T(t-\tau(t)) - x_j^T(t-\tau(t)))^T$. From (A.5), one gets

(A.8)
$$\begin{aligned}
\dot{V}(t)|_{(12)} \le{}& e^{2\varepsilon t}\textstyle\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda_0}\xi_j - 2e^{2\varepsilon t}\sum_{i=1}^{N}\sum_{j=1}^{N}x_i^T(t)(L_{ij}PD)x_j(t)\\
&- 2e^{2\varepsilon t}\textstyle\sum_{i=1}^{N}\sum_{j=1}^{N}x_i^T(t)(L_{ij}PD_\tau)x_j(t-\tau(t))\\
&- e^{2\varepsilon t}\textstyle\sum_{i=1}^{N}\sum_{j=1}^{N}x_i^T(t)T_{ij}(\Omega+\Delta)x_j(t)\\
&+ (1-h)e^{2\varepsilon t}\textstyle\sum_{i=1}^{N}\sum_{j=1}^{N}x_i^T(t-\tau(t))T_{ij}\Omega x_j(t-\tau(t))\\
={}& e^{2\varepsilon t}\textstyle\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda_0}\xi_j - 2e^{2\varepsilon t}\sum_{i=1}^{N}\Big(\sum_{j=1,\,j\neq i}^{N}x_i^T(t)(L_{ij}PD)x_j(t) + x_i^T(t)L_{ii}PDx_i(t)\Big)\\
&- 2e^{2\varepsilon t}\textstyle\sum_{i=1}^{N}\Big(\sum_{j=1,\,j\neq i}^{N}x_i^T(t)(L_{ij}PD_\tau)x_j(t-\tau(t)) + x_i^T(t)L_{ii}PD_\tau x_i(t-\tau(t))\Big)\\
&- e^{2\varepsilon t}\textstyle\sum_{i=1}^{N}\Big(\sum_{j=1,\,j\neq i}^{N}x_i^T(t)T_{ij}(\Omega+\Delta)x_j(t) + x_i^T(t)T_{ii}(\Omega+\Delta)x_i(t)\Big) + (1-h)\\
&\times e^{2\varepsilon t}\textstyle\sum_{i=1}^{N}\Big(\sum_{j=1,\,j\neq i}^{N}x_i^T(t-\tau(t))T_{ij}\Omega x_j(t-\tau(t)) + x_i^T(t-\tau(t))T_{ii}\Omega x_i(t-\tau(t))\Big)\\
={}& e^{2\varepsilon t}\textstyle\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda_0}\xi_j + 2e^{2\varepsilon t}\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}(x_i(t)-x_j(t))^T(L_{ij}PD)(x_i(t)-x_j(t))\\
&+ 2e^{2\varepsilon t}\textstyle\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}(x_i(t)-x_j(t))^T(L_{ij}PD_\tau)(x_i(t-\tau(t))-x_j(t-\tau(t)))\\
&+ e^{2\varepsilon t}\textstyle\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}(x_i(t)-x_j(t))^T T_{ij}(\Omega+\Delta)(x_i(t)-x_j(t)) - (1-h)\\
&\times e^{2\varepsilon t}\textstyle\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}(x_i(t-\tau(t))-x_j(t-\tau(t)))^T T_{ij}\Omega(x_i(t-\tau(t))-x_j(t-\tau(t)))\\
={}& e^{2\varepsilon t}\textstyle\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda_0}\xi_j + e^{2\varepsilon t}\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}\eta_{ij}^T\Lambda_{ij}\eta_{ij}.
\end{aligned}$$

According to Lemma 4 and (A.8), under conditions (13)–(14), $\dot{V}(y(t)) \le 0$ and $V(t) \le V(0)$. That is, $V(t)$ is a bounded function and $\|y(t)\| = O(e^{-\varepsilon t})$. This completes the proof of part (i).

(ii) Let $y(t) = \mathbf{M}x(t) = (y_1^T(t), y_2^T(t), \ldots, y_p^T(t))^T$, $y_i(t) = (y_{i1}(t), y_{i2}(t), \ldots, y_{in}(t))^T$, $i = 1, 2, \ldots, p$, $\widetilde{x}_j(t) = (x_{1j}(t), x_{2j}(t), \ldots, x_{Nj}(t))^T$, and $\widetilde{y}_j(t) = (y_{1j}(t), y_{2j}(t), \ldots, y_{pj}(t))^T$. Then $\widetilde{y}_j(t) = \widetilde{M}\widetilde{x}_j(t)$ for $j = 1, 2, \ldots, n$.

Following the same method in part (i), from (A.5), one has

(A.9)
$$\begin{aligned}
\dot{V}(t)|_{(12)} \le{}& e^{2\varepsilon t}\textstyle\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda_0}\xi_j - 2e^{2\varepsilon t}x^T(t)(TG\otimes PD)x(t) - 2e^{2\varepsilon t}x^T(t)(TG\otimes PD_\tau)x(t-\tau(t))\\
&- e^{2\varepsilon t}x^T(t)(T\otimes(\Omega+\Delta))x(t) + (1-h)e^{2\varepsilon t}x^T(t-\tau(t))(T\otimes\Omega)x(t-\tau(t))\\
={}& e^{2\varepsilon t}\textstyle\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda_0}\xi_j - 2e^{2\varepsilon t}\sum_{i=1}^{n}\sum_{j=1}^{n}\widetilde{x}_i^T(t)(\sum_{k=1}^{n}p_{ik}d_{kj}TG)\widetilde{x}_j(t)\\
&- 2e^{2\varepsilon t}\textstyle\sum_{i=1}^{n}\sum_{j=1}^{n}\widetilde{x}_i^T(t)(\sum_{k=1}^{n}p_{ik}d_{\tau kj}TG)\widetilde{x}_j(t-\tau(t)) - e^{2\varepsilon t}\sum_{i=1}^{n}\sum_{j=1}^{n}\widetilde{x}_i^T(t)\\
&\times(\Omega_{ij}+\Delta_{ij})T\widetilde{x}_j(t) + (1-h)e^{2\varepsilon t}\textstyle\sum_{i=1}^{n}\sum_{j=1}^{n}\widetilde{x}_i^T(t-\tau(t))\Omega_{ij}T\widetilde{x}_j(t-\tau(t)).
\end{aligned}$$

Let $\widetilde{\eta}_{ij} = (\widetilde{x}_i^T(t) - \widetilde{x}_j^T(t),\, \widetilde{x}_i^T(t-\tau(t)) - \widetilde{x}_j^T(t-\tau(t)))^T$. According to (A.9), one obtains

$$\dot{V}(t)|_{(12)} \le e^{2\varepsilon t}\sum_{j=1}^{p}\xi_j^T\widetilde{\Lambda_0}\xi_j + e^{2\varepsilon t}\sum_{i=1}^{n}\sum_{j=1}^{n}\widetilde{\eta}_{ij}^T\widetilde{\Lambda}_{ij}\widetilde{\eta}_{ij}. \tag{A.10}$$

From Lemma 4 and (A.10), under conditions (13) and (15), $\dot{V}(y(t)) \le 0$ and $V(t) \le V(0)$. That is, $V(t)$ is a bounded function and $\|y(t)\| = O(e^{-\varepsilon t})$. This completes the proof of part (ii).

Appendix B. Proof of Theorem 2. Consider the following Lyapunov candidate:

(B.1)
$$V(t) = x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}x(t) + \int_{t-\tau(t)}^{t} \mathbf{f}^T(x(s))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(s))\,ds + \int_{t-\tau(t)}^{t} x^T(s)\mathbf{M}^T\mathbf{R}\mathbf{M}x(s)\,ds.$$

Differentiating $V(t)$ along the trajectories of (12) yields

(B.2)
$$\begin{aligned}\dot{V}(t)|_{(12)} &= 2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}\dot{x}(t) + \mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t)) - (1-\dot{\tau}(t))\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T\\ &\quad\times \mathbf{Q}\mathbf{M}\mathbf{f}(x(t-\tau(t))) + x^T(t)\mathbf{M}^T\mathbf{R}\mathbf{M}x(t)\\ &\quad - (1-\dot{\tau}(t))x^T(t-\tau(t))\mathbf{M}^T\mathbf{R}\mathbf{M}x(t-\tau(t))\\ &\le 2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}[-\mathbf{C}x(t) + \mathbf{A}\mathbf{f}(x(t)) + \mathbf{B}\mathbf{f}(x(t-\tau(t))) + \mathbf{I}(t) + \mathbf{G}x(t)\\ &\qquad + \mathbf{G}_\tau x(t-\tau(t))]\\ &\quad + \mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t)) - (1-h)\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t-\tau(t)))\\ &\quad + x^T(t)\mathbf{M}^T\mathbf{R}\mathbf{M}x(t) - (1-\dot{\tau}(t))x^T(t-\tau(t))\mathbf{M}^T\mathbf{R}\mathbf{M}x(t-\tau(t)).\end{aligned}$$

From the definition of $\mathbf{M}$, one has

$$\mathbf{M}\mathbf{C} = \mathbf{C}^{\mathbf{1}}\mathbf{M}, \quad \mathbf{M}\mathbf{A} = \mathbf{A}^{\mathbf{1}}\mathbf{M}, \quad \mathbf{M}\mathbf{B} = \mathbf{B}^{\mathbf{1}}\mathbf{M}, \quad \mathbf{M}\mathbf{I}(t) = 0.$$

Therefore, one obtains

(B.3)
$$\begin{aligned}\dot{V}(t)|_{(12)} &\le 2x^T(t)\mathbf{M}^T\mathbf{P}[-\mathbf{C}^{\mathbf{1}}\mathbf{M}x(t) + \mathbf{A}^{\mathbf{1}}\mathbf{M}\mathbf{f}(x(t)) + \mathbf{B}^{\mathbf{1}}\mathbf{M}\mathbf{f}(x(t-\tau(t))) + \mathbf{M}\mathbf{G}x(t)\\ &\qquad + \mathbf{G}_\tau x(t-\tau(t))]\\ &\quad + \mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t)) - (1-h)\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t-\tau(t)))\\ &\quad + x^T(t)\mathbf{M}^T\mathbf{R}\mathbf{M}x(t) - (1-h)x^T(t-\tau(t))\mathbf{M}^T\mathbf{R}\mathbf{M}x(t-\tau(t)).\end{aligned}$$

According to assumption A_2, one gets

(B.4)
$$\begin{aligned}\mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{\Sigma}\mathbf{M}\mathbf{f}(x(t)) &= \textstyle\sum_{j=1}^{N-1}[f(x_j(t)) - f(x_{j+1}(t))]^T\mathbf{\Sigma}_j[f(x_j(t)) - f(x_{j+1}(t))]\\ &\le \textstyle\sum_{j=1}^{N-1}[x_j(t) - x_{j+1}(t)]^T F\mathbf{\Sigma}_j F[x_j(t) - x_{j+1}(t)]\\ &= x^T(t)\mathbf{M}^T\mathbf{F}\mathbf{\Sigma}\mathbf{F}\mathbf{M}x(t),\end{aligned}$$

where $\mathbf{\Sigma}_j = \operatorname{diag}(\Sigma_{(j-1)n+1}, \ldots, \Sigma_{jn})$. From Lemmas 1 and 5, one has

(B.5)
$$\begin{aligned}2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}\mathbf{G}x(t) &= 2x^T(t)\mathbf{M}^T\mathbf{P}[(M\otimes I_n)(G\otimes D)]x(t)\\ &= 2x^T(t)\mathbf{M}^T\mathbf{P}[MG\otimes D]x(t)\\ &= 2x^T(t)\mathbf{M}^T\mathbf{P}[HM\otimes D]x(t)\\ &= 2x^T(t)\mathbf{M}^T\mathbf{P}[(H\otimes D)(M\otimes I_n)]x(t)\\ &= 2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{H}\mathbf{M}x(t)\end{aligned}$$

and

$$
\begin{aligned}
2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}\mathbf{G}_\tau x(t-\tau(t)) &= 2x^T(t)\mathbf{M}^T\mathbf{P}[(M\otimes I_n)(G\otimes D_\tau)]x(t-\tau(t)) \\
&= 2x^T(t)\mathbf{M}^T\mathbf{P}[MG\otimes D_\tau]x(t-\tau(t)) \\
&= 2x^T(t)\mathbf{M}^T\mathbf{P}[HM\otimes D_\tau]x(t-\tau(t)) \\
&= 2x^T(t)\mathbf{M}^T\mathbf{P}[(H\otimes D_\tau)(M\otimes I_n)]x(t-\tau(t)) \\
&= 2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{H}_\tau\mathbf{M}x(t-\tau(t)),
\end{aligned} \tag{B.6}
$$

where $H = MGJ$, $\mathbf{H} = (MGJ)\otimes D$, $\mathbf{H}_\tau = (MGJ)\otimes D_\tau$, and M and J are defined in (9).

According to (B.3)–(B.6), one obtains

$$
\begin{aligned}
\dot{V}(t)|_{(12)} \le\ & -2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{C}^{\mathbf{1}}\mathbf{M}x(t) + 2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{A}^{\mathbf{1}}\mathbf{M}\mathbf{f}(x(t)) \\
& + 2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{B}^{\mathbf{1}}\mathbf{M}\mathbf{f}(x(t-\tau(t))) \\
& + 2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{H}\mathbf{M}x(t) + 2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{H}_\tau\mathbf{M}x(t-\tau(t)) + x^T(t)\mathbf{M}^T\mathbf{F}\mathbf{\Sigma}\mathbf{F}\mathbf{M}x(t) \\
& - \mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{\Sigma}\mathbf{M}\mathbf{f}(x(t)) + \mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t)) - (1-h)\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T \\
& \times \mathbf{Q}\mathbf{M}\mathbf{f}(x(t-\tau(t))) + x^T(t)\mathbf{M}^T\mathbf{R}\mathbf{M}x(t) - (1-h)x^T(t-\tau(t))\mathbf{M}^T\mathbf{R}\mathbf{M}x(t-\tau(t)) \\
=\ & \eta^T(t)\mathbf{\Omega}\eta(t),
\end{aligned} \tag{B.7}
$$

where

$$
\eta(t) = \begin{pmatrix} x^T(t)\mathbf{M}^T & x^T(t-\tau(t))\mathbf{M}^T & \mathbf{f}^T(x(t))\mathbf{M}^T & \mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T \end{pmatrix}^T.
$$

From Lemma 4 and (B.7), under the condition (28), $\dot{V}(t) \le 0$ and $V(t) \le V(0)$. That is, $V(t)$ is a bounded function and $\|\mathbf{M}x(t)\| \longrightarrow 0$. This proof is thus completed.

Appendix C. Proof of Corollary 7. Select the Lyapunov candidate (B.1), where M and J are also defined in (9), $\mathbf{P} = I_{N-1}\otimes P$, $\mathbf{Q} = I_{N-1}\otimes Q$, $\mathbf{R} = I_{N-1}\otimes R$, and $\mathbf{\Sigma} = I_{N-1}\otimes\Sigma$.

From (B.7), one obtains

$$
\begin{aligned}
\dot{V}(t)|_{(12)} &\le \eta^T(t)\mathbf{\Omega}\eta(t) \\
&= \textstyle\sum_{j=1}^{N-1}\xi_j^T\Lambda_0\xi_j + \left(x^T(t)\mathbf{M}^T, x^T(t-\tau(t))\mathbf{M}^T\right)\Xi\left(\mathbf{M}x^T(t), \mathbf{M}x^T(t-\tau(t))\right)^T,
\end{aligned} \tag{C.1}
$$

where

$$
\xi_j = \begin{pmatrix} (x_j(t)-x_{j+1}(t))^T & (f(x_j(t))-f(x_{j+1}(t)))^T & (f(x_j(t-\tau(t)))-f(x_{j+1}(t-\tau(t))))^T \end{pmatrix}^T
$$

and $\mathbf{\Omega}$ is defined in (28). According to Lemma 4 and (C.1), under the conditions (31)–(32), $\dot{V}(t) \le 0$ and $V(t) \le V(0)$. That is, $V(t)$ is a bounded function, and $\|\mathbf{M}x(t)\| \longrightarrow 0$. This

completes the proof.

Appendix D. Proof of Theorem 3. Construct the Lyapunov function as follows:

(D.1)
$$V(t) = x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}x(t) + \int_{t-\tau(t)}^{t} \mathbf{f}^T(x(s))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(s))\,ds + \int_{t-\tau(t)}^{t} x^T(s)\mathbf{M}^T\mathbf{R}\mathbf{M}x(s)\,ds + \int_{-r}^{0} d\theta \int_{t+\theta}^{t} \dot{x}^T(s)\mathbf{M}^T\mathbf{T}\mathbf{M}\dot{x}(s)\,ds.$$

From Lemma 6, differentiating $V(t)$ along the trajectories of (12) results in

(D.2)
$$\begin{aligned}\dot{V}(t)|_{(12)} &= 2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}\dot{x}(t) + \mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t)) - (1-\dot{\tau}(t))\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T \\ &\quad \times \mathbf{Q}\mathbf{M}\mathbf{f}(x(t-\tau(t))) + x^T(t)\mathbf{M}^T\mathbf{R}\mathbf{M}x(t) \\ &\quad - (1-\dot{\tau}(t))x^T(t-\tau(t))\mathbf{M}^T\mathbf{R}\mathbf{M}x(t-\tau(t)) \\ &\quad + r\dot{x}^T(t)\mathbf{M}^T\mathbf{T}\mathbf{M}\dot{x}(t) - \int_{t-r}^{t} \dot{x}^T(\theta)\mathbf{M}^T\mathbf{T}\mathbf{M}\dot{x}(\theta)\,d\theta \\ &\le 2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{M}[-\mathbf{C}x(t) + \mathbf{A}\mathbf{f}(x(t)) + \mathbf{B}\mathbf{f}(x(t-\tau(t))) + \mathbf{I}(t) + \mathbf{G}x(t) \\ &\qquad + \mathbf{G}_\tau x(t-\tau(t))] \\ &\quad + \mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t)) - (1-h)\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t-\tau(t))) \\ &\quad + x^T(t)\mathbf{M}^T\mathbf{R}\mathbf{M}x(t) - (1-h)x^T(t-\tau(t))\mathbf{M}^T\mathbf{R}\mathbf{M}x(t-\tau(t)) + r\dot{x}^T(t)\mathbf{M}^T\mathbf{T}\mathbf{M}\dot{x}(t) \\ &\quad - \frac{1}{r}\left(\int_{t-\tau(t)}^{t} \mathbf{M}\dot{x}(\theta)\,d\theta\right)^T \mathbf{T}\left(\int_{t-\tau(t)}^{t} \mathbf{M}\dot{x}(\theta)\,d\theta\right).\end{aligned}$$

From the definition of $\mathbf{M}$, one has

$$\mathbf{M}\mathbf{C} = \mathbf{C}^{\mathbf{1}}\mathbf{M}, \quad \mathbf{M}\mathbf{A} = \mathbf{A}^{\mathbf{1}}\mathbf{M}, \quad \mathbf{M}\mathbf{B} = \mathbf{B}^{\mathbf{1}}\mathbf{M}, \quad \mathbf{M}\mathbf{I}(t) = 0.$$

According to (D.2), one obtains

(D.3)
$$\begin{aligned}\dot{V}(t)|_{(12)} &\le 2x^T(t)\mathbf{M}^T\mathbf{P}[-\mathbf{C}^{\mathbf{1}}\mathbf{M}x(t) + \mathbf{A}^{\mathbf{1}}\mathbf{M}\mathbf{f}(x(t)) + \mathbf{B}^{\mathbf{1}}\mathbf{M}\mathbf{f}(x(t-\tau(t))) + \mathbf{H}\mathbf{M}x(t) \\ &\qquad + \mathbf{H}_\tau\mathbf{M}x(t-\tau(t))] \\ &\quad + \mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t)) - (1-h)\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t-\tau(t))) \\ &\quad + x^T(t)\mathbf{M}^T\mathbf{R}\mathbf{M}x(t) - (1-h)x^T(t-\tau(t))\mathbf{M}^T\mathbf{R}\mathbf{M}x(t-\tau(t)) + r\dot{x}^T(t)\mathbf{M}^T\mathbf{T}\mathbf{M}\dot{x}(t) \\ &\quad - \frac{1}{r}\left(\int_{t-\tau(t)}^{t} \mathbf{M}\dot{x}(\theta)\,d\theta\right)^T \mathbf{T}\left(\int_{t-\tau(t)}^{t} \mathbf{M}\dot{x}(\theta)\,d\theta\right).\end{aligned}$$

Similar to (B.4), one has

$$\mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{\Sigma}\mathbf{M}\mathbf{f}(x(t)) \le x^T(t)\mathbf{M}^T\mathbf{F}\mathbf{\Sigma}\mathbf{F}\mathbf{M}x(t) \tag{D.4}$$

and

$$\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T\mathbf{\Lambda}\mathbf{M}\mathbf{f}(x(t-\tau(t))) \le x^T(t-\tau(t))\mathbf{M}^T\mathbf{F}\mathbf{\Lambda}\mathbf{F}\mathbf{M}x(t-\tau(t)). \tag{D.5}$$

From the Leibniz–Newton formula, for any matrix $\mathbf{U}$ with appropriate dimensions, one gets

$$x^T(t-\tau(t))\mathbf{M}^T\mathbf{U}\mathbf{M}\left(x(t)-x(t-\tau(t))-\int_{t-\tau(t)}^{t}\dot{x}(s)\,ds\right)=0. \tag{D.6}$$

Let

$$\xi(t)=\begin{pmatrix} x^T(t)\mathbf{M}^T & x^T(t-\tau(t))\mathbf{M}^T & \mathbf{f}^T(x(t))\mathbf{M}^T & \mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T & \int_{t-\tau(t)}^{t}\dot{x}^T(s)\,ds\,\mathbf{M}^T \end{pmatrix}^T,$$
$$\Pi=\begin{pmatrix} -\mathbf{C^1}+\mathbf{H} & \mathbf{H}_\tau & \mathbf{A^1} & \mathbf{B^1} & 0 \end{pmatrix};$$

then one has

$$\dot{x}^T(t)\mathbf{M}^T\mathbf{T}\mathbf{M}\dot{x}(t)=\xi^T(t)\Pi^T\mathbf{T}\Pi\xi(t). \tag{D.7}$$

Combining this with (D.3)–(D.7), one obtains

(D.8)
$$\begin{aligned}\dot{V}(t)|_{(12)} \le{}& -2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{C^1}\mathbf{M}x(t)+2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{A^1}\mathbf{M}\mathbf{f}(x(t))+2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{B^1}\mathbf{M}\mathbf{f}(x(t-\tau(t)))\\
&+2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{H}\mathbf{M}x(t)+2x^T(t)\mathbf{M}^T\mathbf{P}\mathbf{H}_\tau\mathbf{M}x(t-\tau(t))+x^T(t)\mathbf{M}^T\mathbf{F}\mathbf{\Sigma}\mathbf{F}\mathbf{M}x(t)\\
&-\mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{\Sigma}\mathbf{M}\mathbf{f}(x(t))+x^T(t-\tau(t))\mathbf{M}^T\mathbf{F}\mathbf{\Lambda}\mathbf{F}\mathbf{M}x(t-\tau(t))-\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T\\
&\times\mathbf{\Lambda}\mathbf{M}\mathbf{f}(x(t-\tau(t)))+\mathbf{f}^T(x(t))\mathbf{M}^T\mathbf{Q}\mathbf{M}\mathbf{f}(x(t))-(1-h)\mathbf{f}^T(x(t-\tau(t)))\mathbf{M}^T\mathbf{Q}\mathbf{M}\\
&\times\mathbf{f}(x(t-\tau(t)))+x^T(t)\mathbf{M}^T\mathbf{R}\mathbf{M}x(t)-(1-h)x^T(t-\tau(t))\mathbf{M}^T\mathbf{R}\mathbf{M}x(t-\tau(t))\\
&+r\xi^T(t)\Pi^T\mathbf{T}\Pi\xi(t)-\frac{1}{r}\left(\int_{t-\tau(t)}^{t}\mathbf{M}\dot{x}(\theta)\,d\theta\right)^T\mathbf{T}\left(\int_{t-\tau(t)}^{t}\mathbf{M}\dot{x}(\theta)\,d\theta\right)\\
&+2x^T(t-\tau(t))\mathbf{M}^T\mathbf{U}\mathbf{M}\left(x(t)-x(t-\tau(t))-\int_{t-\tau(t)}^{t}\dot{x}(s)\,ds\right)\\
={}&\xi^T(t)(\mathbf{\Xi}+r\Pi^T\mathbf{T}\Pi)\xi(t),\end{aligned}$$

where

$$\mathbf{\Xi}=\begin{pmatrix} \Psi & \mathbf{P}\mathbf{H}_\tau+\mathbf{U}^T & \mathbf{P}\mathbf{A^1} & \mathbf{P}\mathbf{B^1} & 0\\ \mathbf{H}_\tau^T\mathbf{P}+\mathbf{U} & -(1-h)\mathbf{R}-2\mathbf{U}+\mathbf{F}\mathbf{\Lambda}\mathbf{F} & 0 & 0 & -\mathbf{U}\\ \mathbf{A^1}^T\mathbf{P} & 0 & -\mathbf{\Sigma}+\mathbf{Q} & 0 & 0\\ \mathbf{B^1}^T\mathbf{P} & 0 & 0 & -(1-h)\mathbf{Q}-\mathbf{\Lambda} & 0\\ 0 & -\mathbf{U}^T & 0 & 0 & -\frac{1}{r}\mathbf{T} \end{pmatrix}$$

and $\Psi=-2\mathbf{P}\mathbf{C^1}+\mathbf{P}\mathbf{H}+\mathbf{H}^T\mathbf{P}+\mathbf{R}+\mathbf{F}\mathbf{\Sigma}\mathbf{F}$.

According to Schur complement Lemma 2, $\mathbf{\Xi}+r\Pi^T\mathbf{T}\Pi<0$ is equivalent to $\mathbf{\Omega_1}<0$. From Lemma 4 and (D.8), under the condition (33), $\dot{V}(t)\le 0$ and $V(t)\le V(0)$. That is, $V(t)$ is a bounded function, and $\|\mathbf{M}x(t)\|\longrightarrow 0$. Thus the proof is completed.

Global Phase-Locking in Finite Populations of Phase-Coupled Oscillators*

Mark Verwoerd† and Oliver Mason†

Abstract. We present new necessary and sufficient conditions for the existence of fixed points in a finite system of coupled phase oscillators on a complete graph. We use these conditions to derive bounds on the critical coupling.

Key words. synchronization, coupled oscillators, fixed points

1. Introduction.

The phenomenon of synchronization arises in a wide variety of application areas across neuroscience, biology, engineering, and physics [6, 17, 2, 16, 5]. As such, the identification and study of structures and mechanisms that support the onset of synchronized behavior is a key issue in the theory of interconnected dynamical systems. In particular, there has been a great deal of interest across the mathematics, physics, and engineering communities in the development and analysis of simple mathematical models of synchronization [9, 19, 20, 3, 21, 22].

To date, one of the most widely studied frameworks for the analysis of synchronization is the so-called *Kuramoto model* of phase-coupled oscillators [10, 23]. In fact, this model has been used in numerous applications in the chemical and biological sciences, and its basic properties have been analyzed using a combination of numerical and analytical techniques [11, 23, 24, 1]. The basic Kuramoto model is comprised of a system of coupled oscillators, which may have different natural frequencies, where the coupling between two oscillators is given by a weighted sinusoidal function of the difference of their phases. The weights used in the model are typically taken to be the same for all pairs of oscillators and are given by the ratio of a fixed parameter, the coupling strength, to the network size.

The aspect of the Kuramoto model that has attracted the most attention to date is the manner in which the onset of synchronization depends on the strength of coupling between the oscillators. For instance, at very low values of the coupling strength, little or no synchronization is observed. As the coupling strength is increased, some partial synchronization appears in the network up to a threshold value of the coupling strength, referred to here as the critical coupling, at which fully synchronized behavior emerges [9, 3]. The mechanism of (de)synchronization in finite populations of oscillators has been described in considerable

detail [13, 12]. In particular, when the coupling strength drops below its critical value and as it continues to decrease, the system undergoes a series of so-called *frequency-splitting bifurcations*. At each such bifurcation, the ensemble of oscillators subdivides into smaller and smaller groups of oscillators with identical average frequency, until eventually all oscillators oscillate at their own intrinsic frequency. A detailed analysis of this behavior for a system with three oscillators was given in [13]. While the aforementioned contributions focus on the behavior of the system in the *sub*critical coupling regime, the present paper studies globally phase-locked solutions, which by definition exist only in the *super*critical coupling regime.

Another aspect of the Kuramoto model that has attracted attention recently is the emergence of phase chaos [14, 18] in systems of dimension four and higher. A generic feature of coupled oscillator systems, phase chaos in the Kuramoto model is most prominent in systems with relatively low dimension (comprising between ten and fifteen oscillators) [14]. Again, this phenomenon can exist only in the subcritical coupling regime, and we shall not further consider it here.

In the original Kuramoto model, it is assumed that all pairs of oscillators in the network are connected with the same coupling strength [10]. This type of coupling is referred to as "all-to-all" coupling and corresponds to a network in which the underlying graph is complete [4]. Extensions of the Kuramoto model to lattices [8] and rings [20] have also been considered, and more recently the dynamics of coupled oscillators on networks with small-world [27, 7] and scale-free [15] topologies have started to attract a lot of interest. More generally, there are many fundamental questions relating to the interplay between a network's topology and dynamical processes taking place on it which are still unanswered. The work described in [6], which proposes an extension of group-based symmetry, using so-called groupoid formalism, as a means of classifying possible behaviors for networked dynamical systems is particularly noteworthy in this context.

Many of the recent results concerned with the dynamics and synchronization of coupled oscillators have either been based on numerical simulations or else have been derived for the limiting case of networks of infinite size. In contrast, relatively few rigorous results are available for finite-size networks [23, 9]. In this paper, we shall be concerned with synchronization in finite systems of coupled oscillators. Specifically, we shall establish (new) necessary and sufficient conditions for the existence of fixed points in a finite system of coupled oscillators (see also [25, 26]), compute bounds on the critical coupling strength for such systems, and provide insight into the number of fixed points possible under strong coupling. Our analysis is in the spirit of the work presented in [9, 3] and places particular emphasis on the *existence* of fixed points. Of course, the stability of such fixed points is also a topic of great interest and has been considered in [9, 19, 20, 3]. However, we shall not explicitly address the question of stability in the current paper.

The outline of the paper is as follows. In section 2, we introduce the Kuramoto model and review some of its basic properties. Here, we also give a formal definition of critical coupling, which is essentially the lowest value of the coupling strength for which fixed points exist. In section 3, we show that fixed points will always exist for sufficiently strong coupling (essentially proving that the critical coupling is a finite number), and then, in section 4 we provide lower bounds on the critical coupling. Section 5 contains necessary and sufficient conditions for the existence of fixed points, which are then used in section 6 to describe an

algorithm for computing the critical coupling. Section 7 contains a numerical example to illustrate the results of the paper, and finally, in section 8 we present our concluding remarks.

2. Mathematical preliminaries and the Kuramoto model.

2.1. Basic notation.

Throughout the paper, $\mathbb{R}$ ($\mathbb{C}$) denotes the field of real (complex) numbers, $\mathbb{R}^N$ ($\mathbb{C}^N$) denotes the vector space of all N-tuples of real (complex) numbers, and $\mathbb{R}^{N\times N}$ ($\mathbb{C}^{N\times N}$) denotes the space of $N\times N$ matrices with entries in $\mathbb{R}$ ($\mathbb{C}$). i is used to denote the complex number satisfying $i^2=-1$. For a vector $x\in\mathbb{R}^N$, x_i denotes the ith entry of x. Also, $\mathbf{1}_N$ denotes the vector in $\mathbb{R}^N$, all of whose entries are equal to one.

We shall use V to denote the projection matrix in $\mathbb{R}^{N\times N}$ given by

$$[V_{ij}] := \begin{cases} \frac{N-1}{N}, & j=i, \\ -\frac{1}{N}, & j\neq i, \end{cases} \qquad i,j=1,\dots,N, \tag{1}$$

and $V\mathbb{R}^N$ shall denote the image of $\mathbb{R}^N$ under V. Formally,

$$V\mathbb{R}^N := \left\{ x\in\mathbb{R}^N : \sum_{j=1}^N x_j = 0 \right\}.$$

2.2. The basic Kuramoto model.

The basic Kuramoto model of phase-coupled oscillators under the assumption of all-to-all coupling is given by

$$\dot{\theta}_i = \omega_i + \frac{k}{N}\sum_{j=1}^N \sin(\theta_j-\theta_i), \quad i=1,\dots,N. \tag{2}$$

Here, $\theta_i(\cdot)\in\mathbb{R}$ (S^1) and $\omega_i\in\mathbb{R}$ respectively denote the phase and intrinsic (or natural) frequency of oscillator i, and the constant $k\in\mathbb{R}_+$ is a global coupling coefficient.

This model can be described more compactly in vector notation as

$$\dot{\theta} = \omega + kf(\theta), \tag{3}$$

where $\theta(t) := (\theta_1(t),\dots,\theta_N(t))$, $\omega := (\omega_1,\dots,\omega_N)$, and the mapping $f:\mathbb{R}^N\mapsto\mathbb{R}^N$ is given by

$$\begin{aligned} f(\xi) &= (f_1(\xi),\dots,f_N(\xi)), \\ f_i(\xi) &:= \frac{1}{N}\sum_{j=1}^N \sin(\xi_j-\xi_i), \quad 1\le i\le N. \end{aligned} \tag{4}$$

The assumption of all-to-all coupling is naturally very restrictive and ought to be relaxed in order for this work to be more directly applicable to the modeling of biological systems, or most engineering systems for that matter. Work toward this end is underway, and we hope to be able to present some results in the near future. Meanwhile, in this paper, we shall focus exclusively on configurations with all-to-all coupling. First, we recall some fundamental notions in the theory of synchronized oscillators.

2.3. The order parameter. Let $\mathbb{D}$ denote the complex unit disc $\{z \in \mathbb{C} : |z| \leq 1\}$. Then define $r : \mathbb{R}^N \mapsto \mathbb{D}$ by

$$r(\xi) := \frac{1}{N}\sum_{j=1}^{N} e^{i\xi_j}. \tag{5}$$

Let $r^{-1}(z) := \{\xi \in \mathbb{R}^N : r(\xi) = z\}$ denote the preimage of r, and note that the preimage is nonempty for all $z \in \mathbb{D}$ provided $N \geq 2$. We introduce the notation $\mathcal{R}_0 := r^{-1}(0)$. Then, for $\xi \in \mathbb{R}^N$, we may express $r(\xi)$ in polar coordinates:

$$r(\xi) = \begin{cases} R(\xi)e^{i\psi(\xi)}, & \xi \in \mathbb{R}^N \backslash \mathcal{R}_0, \\ 0, & \xi \in \mathcal{R}_0. \end{cases} \tag{6}$$

Here, $R : \mathbb{R}^N \mapsto [0, 1]$ and $\psi : \mathbb{R}^N \backslash \mathcal{R}_0 \mapsto [0, 2\pi)$ are respectively defined as

$$R(\xi) := \sqrt{\left(\frac{1}{N}\sum_{j=1}^{N} \sin(\xi_j)\right)^2 + \left(\frac{1}{N}\sum_{j=1}^{N} \cos(\xi_j)\right)^2} \tag{7}$$

and

$$\psi(\xi) := \arctan\left(\frac{\frac{1}{N}\sum_{j=1}^{N} \sin(\xi_j)}{\frac{1}{N}\sum_{j=1}^{N} \cos(\xi_j)}\right). \tag{8}$$

The following properties of the maps $R(\cdot)$ and $\psi(\cdot)$ follow immediately from (5):

$$R(\xi + c\mathbf{1}_N) := \left|\frac{1}{N}\sum_{j=1}^{N} e^{i(\xi_j + c)}\right| = |e^{ic}|R(\xi) = R(\xi) \quad \forall \xi \in \mathbb{R}^N; \tag{9}$$

$$\psi(\xi + c\mathbf{1}_N) = \psi(\xi) + c \mod 2\pi \quad \forall \xi \in \mathbb{R}^N \backslash \mathcal{R}_0. \tag{10}$$

In the physics literature, $r(\cdot)$ is known as the *order parameter* and is used to characterize the amount of order or synchronization in the system (2). The idea is to think of the phase θ_j of oscillator j as a unit vector $e^{i\theta_j}$ in $\mathbb{C}$; the order parameter then corresponds to the geometric centroid of the set of vectors $\{e^{i\theta_j} : j = 1, \ldots, N\}$, as illustrated in Figure 1. The magnitude of the order parameter, given by $R(\theta)$, serves as a measure of the order in the system in the sense that the closer the vectors are to being perfectly aligned, the closer $R(\theta)$ is to its maximal value 1, while vectors that are far from alignment will give rise to values of $R(\theta)$ significantly smaller than 1.

It follows from (6) that for $\xi \in \mathbb{R}^N \backslash \mathcal{R}_0$,

$$R(\xi) = e^{-i\psi(\xi)} r(\xi) \tag{11}$$

$$= \frac{1}{N}\sum_{j=1}^{N} e^{i(\xi_j - \psi(\xi))}. \tag{12}$$

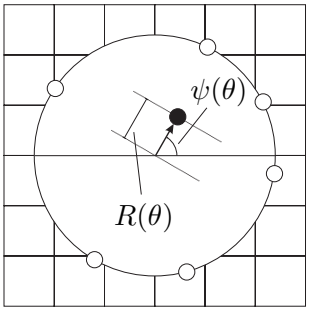

Figure 1. *The order parameter $r(\theta) := R(\theta)e^{i\psi(\theta)}$ is defined as the centroid (closed circle) of the set of unit vectors (open circles) associated with the phases of the oscillators.*

Equating real and imaginary parts in (11), we immediately see that for $\xi \in \mathbb{R}^N \backslash \mathcal{R}_0$,

$$R(\xi) = \frac{1}{N}\sum_{j=1}^{N} \cos(\psi(\xi) - \xi_j); \tag{13}$$

$$\sum_{j=1}^{N} \sin(\psi(\xi) - \xi_j) = 0. \tag{14}$$

Both of these identities shall prove useful throughout the paper.

Before proceeding, note that the function $f : \mathbb{R}^N \mapsto \mathbb{R}^N$ given by (4) can be written in terms of the functions $R(\cdot)$ and $\psi(\cdot)$ as

$$f_i(\xi) := \begin{cases} R(\xi)\sin(\psi(\xi) - \xi_i), & \xi \in \mathbb{R}^N \backslash \mathcal{R}_0, \\ 0, & \xi \in \mathcal{R}_0, \end{cases} \tag{15}$$

for $1 \leq i \leq N$.

2.4. Fixed points and global phase-locking. Let $\langle \omega \rangle$ denote the sample mean of the natural frequencies, $\langle \omega \rangle := \frac{1}{N}\sum_{j=1}^{N} \omega_j$. Similarly, let $\langle \theta(t) \rangle$ denote the mean phase of a solution of (2) at time t. In general, $\langle \omega \rangle$ and $\langle \theta(t) \rangle$ will be nonzero. However, we shall now show that for the study of phase-locked solutions of (2), we may assume without loss of generality that $\langle \omega \rangle = 0$, $\langle \theta(t) \rangle = 0$ for $t \geq t_0$. This helps to simplify the analysis of phase-locked solutions of (2), as it allows us to transform the problem into a question of fixed point existence for a lower-dimensional system.

Consider the new coordinates

$$x_i(t) := \theta_i(t) - \langle \theta(t) \rangle, \quad i = 1, \ldots, N. \tag{16}$$

Then $x(t) := V\theta(t)$. Similarly, define $\Omega := V\omega$. In the new coordinates, the system dynamics are given by

$$\dot{x} = \Omega + kf(x), \quad x(t) \in V\mathbb{R}^N, \tag{17}$$

where $f(\cdot)$ is defined in (4).

The key point here is that as $\langle\Omega\rangle = 0$, $V\mathbb{R}^N$ is invariant under (17). To avoid confusion, we shall use $x(t)$ to denote solutions to the system (17) on $V\mathbb{R}^N$, while $\theta(t)$ shall be used to denote solutions to the original Kuramoto system (2) on $\mathbb{R}^N$. Our main concern for the remainder of the paper is to find conditions on k and Ω under which the system (17) has one or more fixed points in the sense of the following definition.

Definition 1 (fixed point). *Given $\omega \in \mathbb{R}^N$, let $\Omega := V\omega$. We say that $x \in V\mathbb{R}^N$ is a* fixed point *(of the system (17)) if*

$$kf(x) = -\Omega. \tag{18}$$

There is a natural correspondence between fixed points of (17) and phase-locked solutions of (2). In fact, for every fixed point $x^* \in V\mathbb{R}^N$ there is a 1-dimensional manifold $\mathcal{M} := \{\theta \in \mathbb{R}^N : \theta = x^* + \langle\omega\rangle t,\ t \in \mathbb{R}\}$ that is invariant under the original system dynamics (2). More precisely, let x^* be a fixed point and let $\theta^0 \in \mathbb{R}^N$ be such that $V\theta^0 = x^*$. Then the solution $\theta(t)$ of the system (2) with initial condition $\theta(t_0) = \theta^0$ satisfies

$$\theta_i(t) - \theta_j(t) = \theta_i^0 - \theta_j^0 \tag{19}$$

for all $t \geq t_0$ and all (i, j). In other words, a fixed point in the sense of Definition 1 corresponds to a situation in which each oscillator is phase-locked to every other and moves at constant speed $\dot{\theta}_i = \langle\omega\rangle$. We shall refer to this phenomenon as global phase-locking. In the literature, it is also known as full (or complete) synchronization. See also [9].

2.5. Critical coupling. We next define the notion of *critical coupling*, which is central to the work of the rest of the paper. Essentially, the critical coupling is the smallest k for which the system (17) has at least one fixed point. Formally, we have the following definition.

Definition 2. *Given $\omega \in \mathbb{R}^N$, let $\Omega := V\omega$. We define the* critical coupling*, k_c, as follows:*

$$k_c := \inf_k \left\{k \in \mathbb{R}_+ : \exists x \in V\mathbb{R}^N \text{ s.t. } kf(x) = -\Omega\right\}. \tag{20}$$

Note that this definition of the critical coupling, which is equivalent to that of K_L in [9], does not coincide with the traditional notion used in the physics literature. Indeed, the traditional notion of critical coupling is defined in terms of the lowest value of k for which there exists at least one solution $x(t)$, $t \geq t_0$, and a constant $c \in (0, 1]$ such that $R(x(t)) = c$ for all $t \geq t_0$ (so-called stationary or steady solutions [23]). Note that these solutions are not necessarily fixed points, although, in finite dimensions, the probability of finding stationary solutions that are not fixed points is vanishingly small. In his original analysis, Kuramoto showed that in the limiting case when N tends to infinity, stationary solutions always exist for large enough k, provided the distribution of natural frequencies is symmetric. Our definition, although more restrictive in a sense, does not impose any restriction on the shape of the distribution of natural frequencies other than that it should have compact support. In fact, it follows from the result of Lemma 4 below that, if the distribution of natural frequencies does not have compact support, then the critical coupling will exceed any finite number with probability tending to 1 as N tends to infinity. In this paper we shall therefore focus on distributions with compact support.

3. Existence of fixed points under strong coupling. In this section we shall show that, provided the distribution of intrinsic frequencies has compact support, the critical coupling given in Definition 2 is always finite. Following from this, in the next section, we shall derive a number of lower bounds for the value of the critical coupling. There are two steps in the derivation given here: first, we characterize the fixed points of the homogeneous system

$$\dot{x} = kf(x). \tag{21}$$

Then, in the second step, we use a perturbation argument to show that for every fixed point of the homogeneous system, we can find an open set containing it, such that, under strong enough coupling, the original system (17) has a unique fixed point on this set. As a first step, the following lemma characterizes the fixed points of the homogeneous system.

Lemma 1. *Let $f(\cdot)$ be given by (4) and $\xi \in \mathbb{R}^N$. We have that $f(\xi) = 0$ if and only if one or both of the following conditions are satisfied:*

(a) $R(\xi) = 0$;

(b) $\sin(\xi_i - \xi_j) = 0$ *for all* (i, j).

Proof. Sufficiency of conditions (a) and (b) follows from (15) and (4), respectively. To prove necessity, suppose $f(\xi) = 0$ and $R(\xi) \neq 0$ (if $R(\xi) = 0$, we are done). It follows that $\sin(\psi(\xi) - \xi_i) = 0$ for all i. This implies that there exist integers $k_i \in \mathbb{Z}$, $i = 1, 2, \ldots, N$, such that $\psi(\xi) - \xi_i = k_i\pi$ for all i, and we have that $\xi_i - \xi_j = (k_j - k_i)\pi$. We conclude that $\sin(\xi_i - \xi_j) = 0$ for all (i, j). ∎

Remark 1. *It is not hard to see that conditions* (a) *and* (b) *in Lemma 1 are mutually exclusive if and only if the dimension N is odd. We shall prove necessity. Suppose conditions* (a) *and* (b) *both hold and suppose furthermore that N is odd. Then for all (i, j) we have that either $\cos(\xi_i - \xi_j) = 1$ or $\cos(\xi_i - \xi_j) = -1$. We write $R^2(\xi) = \frac{1}{N^2}\sum_{i,j}\cos(\xi_i - \xi_j) = \frac{1}{N^2}\left(N + 2\sum_{i,j>i}\cos(\xi_i - \xi_j)\right)$. Since $R(\xi) = 0$ by assumption, it follows that $2\sum_{i,j>i}\cos(\xi_i - \xi_j) = -N$. The left-hand side evaluates to an even integer. By assumption, the number on the right-hand side is odd. We arrive at a contradiction and conclude that if N is odd, conditions* (a) *and* (b) *cannot both hold.*

Next we shall prove that the fixed points of our N-dimensional system (17) can be found by solving a system of $N - 1$ equations in as many variables. We have the following result.

Lemma 2. *Let $p \in \{1, \ldots, N\}$ and let $x^* \in V\mathbb{R}^N$. Then x^* is a fixed point of (17) if and only if $kf_i(x^*) = -\Omega_i$ for $i \neq p$.*

Proof. The proof of necessity is trivial. To prove sufficiency, recall that

$$\sum_{j=1}^{N}(\Omega_j + kf_j(x)) = 0 \quad \forall x \in \mathbb{R}^N. \tag{22}$$

Now suppose $kf_i(x) = -\Omega_i$ for all $i \neq p$. Then it follows from (22) that $\Omega_p + kf_p(x) = 0$. In other words, it follows that $kf_i(x) = -\Omega_i$ for *all* i. We conclude that x is a fixed point. ∎

Let $x^* \in V\mathbb{R}^N$ be a fixed point of the homogeneous system (21) such that $R(x^*) \neq 0$. We shall now show that *locally*, in a neighborhood of x^*, the system of equations

$$\begin{cases} -\Omega_1 &= kf_1(x_1, \ldots, x_{N-1}, -\sum_{j=1}^{N-1} x_j) \\ \vdots & \vdots \\ -\Omega_{N-1} &= kf_{N-1}(x_1, \ldots, x_{N-1}, -\sum_{j=1}^{N-1} x_j) \end{cases} \tag{23}$$

has a unique solution, provided k is large enough. It follows directly from Lemma 2 that every solution of (23) defines a fixed point and, conversely, that every fixed point satisfies (23). We proceed as follows. Let $x^* \in V\mathbb{R}^N$. We define the Jacobian $J(x^*)$ as follows:

$$[J_{ij}(x^*)] := \left.\frac{\partial f_i(x_1, \ldots, -\sum_{j=1}^{N-1} x_j)}{\partial x_j}\right|_{x=x^*}, \tag{24}$$

where $i, j = 1, \ldots, N-1$. We have the following result.

Lemma 3. *Let $f(\cdot)$ be given by (4) and suppose that $x^* \in V\mathbb{R}^N$ satisfies $f(x) = 0$ and $R(x) \neq 0$. Then* $\det(J(x^*)) \neq 0$.

Proof. Let x^* be a fixed point of the homogeneous system and suppose $R(x^*) \neq 0$. Then by Lemma 1, we have that $\sin(x_j^* - x_i^*) = 0$ for all (i, j), and it follows that

$$\begin{aligned} \cos(x_j^* - x_i^*) &= \cos((x_j^* - x_s^*) - (x_i^* - x_s^*)) \\ &= \cos(x_j^* - x_s^*)\cos(x_i^* - x_s^*) \end{aligned} \tag{25}$$

for all s and all (i, j). The claim is that $J(x^*)$ is nonsingular. To prove this, we proceed as follows. From the definition, we have that

$$J_{ij}(x^*) = \begin{cases} -\sum_{m=1,\, m\neq i}^{N-1} \cos(x_m^* - x_i^*) - 2\cos(x_N^* - x_i^*), & i = j, \\ \cos(x_j^* - x_i^*) - \cos(x_N^* - x_i^*), & i \neq j. \end{cases} \tag{26}$$

Using the aforementioned identity, setting $s = N$, we rewrite (26) as follows:

$$J_{ij}(x^*) = \begin{cases} -\left(\sum_{m=1,\, m\neq i}^{N-1} \cos(x_m^* - x_N^*) + 2\right)\cos(x_i^* - x_N^*), & i = j, \\ \left(\cos(x_j^* - x_N^*) - 1\right)\cos(x_i^* - x_N^*), & i \neq j. \end{cases} \tag{27}$$

Inspection shows that the rank of $J(x^*)$ is invariant under permutations of the components of x^*. Hence we can assume, without loss of generality, that there exists $\rho \in \{0, \ldots, N-1\}$, such that

$$\cos(x_j^* - x_N^*) = \begin{cases} -1, & 1 \leq i \leq \rho, \\ +1, & \rho + 1 \leq i \leq N. \end{cases} \tag{28}$$

Under this assumption $J(x^*)$ takes the form

$$J(x^*) = \begin{pmatrix} A & 0 \\ C & B \end{pmatrix}, \tag{29}$$

where A and B are square matrices of dimension $\rho \times \rho$ and $(N-1-\rho)\times(N-1-\rho)$, respectively. It follows that $J(x^*)$ is nonsingular if and only if A and B are nonsingular. Inspection shows that $A = (N-2\rho)I + 2\mathbf{1}\mathbf{1}^T$ and $B = (2\rho - N)I$. It follows that A or B is singular if and only if $N = 2\rho$. In case N is odd, this condition is never satisfied. In case N is even, this condition, combined with (25) and the fact that $R^2(x) = \frac{1}{N^2}\sum_{i,j}\cos(x_i - x_j)$, implies that $R(x^*) = 0$,

which contradicts our starting assumption. We conclude that, under the hypotheses of the lemma, J is nonsingular. This concludes the proof. ■

Let $\Pi : \mathbb{R}^{N-1} \mapsto V\mathbb{R}^N$ be given as

$$(\Pi(y))_i := \begin{cases} y_i & \text{for } i = 1, 2, \dots N-1; \\ -\sum_{j=1}^{N-1} y_j & \text{for } i = N, \end{cases} \tag{30}$$

and note that Π has an inverse Π^{-1} that is defined everywhere in $V\mathbb{R}^N$. We are now ready to state the main result.

Theorem 1. *Let $f(\cdot)$ be given by (4) and $x^* \in V\mathbb{R}^N$ be such that $f(x^*) = 0$ and $R(x^*) \neq 0$. Also, let $\Omega \in V\mathbb{R}^N$. Then there exist $K \in \mathbb{R}$ and an open set $U \in \mathbb{R}^{N-1}$ such that* (a) *$\Pi^{-1}(x^*)$ is an interior point of U; and* (b) *for all $k > K$, the system of equations (23) has a unique solution on U.*

Proof. Define $y^* := \Pi^{-1}(x^*)$, and let $g : \mathbb{R}^{N-1} \mapsto \mathbb{R}^{N-1}$ be given as $g_i(y) := f_i(y_1, \dots, y_{N-1}, -\sum_{j=1}^{N-1} y_j)$, $i = 1, \dots, N-1$. Note that $g(y^*) = 0$. Also, by Lemma 3, we have that $\det(\frac{\partial g}{\partial y}(y^*))| \neq 0$. Under these conditions, the inverse function theorem says that there exists an open set $U \subset \mathbb{R}^{N-1}$ containing y^* such that $g|_U : U \mapsto g(U)$ is a diffeomorphism. By continuity (and bijectivity) of g^{-1} there exists $\delta > 0$ such that for all $z \in \mathbb{R}^{N-1}$ satisfying $\|z\| < \delta$, the equation $g(y) = z$ has a unique solution on U. Now let z be given as $z_i := -\Omega_i/k$. Since, by assumption, $\max_i |\Omega_i| < \infty$, it follows that, provided k is large enough, the system of equations $\{kg_i(y) = -\Omega : i = 1, \dots, N-1\}$ has a unique solution on U. This concludes the proof. ■

As alluded to earlier, there is a unique correspondence between solutions of (23) and the fixed points of the system (17). Indeed, by Lemma 2 we have that if y is a solution of (23), then $\Pi^{-1}(y)$ is a fixed point, and conversely, if y is a fixed point, then $\Pi(y)$ is a solution of (23). Thus, an immediate consequence of Theorem 1 is that for large enough k, the system (23) will have at least one fixed point. In other words, Theorem 1 tells us that the critical coupling, k_c, is always finite.

Note furthermore that the proof of Theorem 1 does not require detailed knowledge of the coupling function g and that, as such, its applicability is not restricted to networks with all-to-all coupling. To illustrate this, consider the case of a 4-cycle, where g is given as

$$\begin{aligned} g_1(y) &= \frac{1}{4}\sin(y_2 - y_1) + \frac{1}{4}\sin(-2y_1 - y_2 - y_3), \\ g_2(y) &= \frac{1}{4}\sin(y_3 - y_2) + \frac{1}{4}\sin(y_1 - y_2), \\ g_3(y) &= \frac{1}{4}\sin(-2y_3 - y_1 - y_2) + \frac{1}{4}\sin(y_2 - y_3). \end{aligned} \tag{31}$$

We have that $g(0) = 0$ and $\det(\frac{\partial g}{\partial y}(0)) = -\frac{1}{4} \neq 0$. This implies that for k large enough, the system of equations $\{kg_i(y) = -\Omega_i : i = 1, 2, 3\}$ has a unique solution on some open set containing the origin.

Last, note that continuity of g^{-1} implies that the fixed points of the original system (17) will converge to the fixed points of the homogeneous system (21) as k tends to infinity.

4. Lower bounds on the critical coupling. In the previous section we showed that the critical coupling is finite, provided the oscillator's intrinsic frequencies are finite. In the present section we shall investigate in more detail the relation between the distribution of intrinsic frequencies and the critical coupling. In particular, we shall derive various lower bounds and discuss some of these bounds' implications for the system's dynamic behavior.

First, let us observe that k_c (Definition 2) is lower bounded by the l^∞ norm of Ω:

$$k_c \geq \|\Omega\|_\infty := \max_i |\omega_i - \langle\omega\rangle|. \tag{32}$$

This follows trivially from inspection of (17). In order to derive another lower bound, we shall need the following result.

Lemma 4. *Let $f(\cdot)$ be given by (4). Then the following hold:*

1. *For all $x \in \mathbb{R}^N$,*

$$\|f(x)\|_2 \leq \sqrt{NR^2(x)\,(1-R^2(x))}. \tag{33}$$

2. *If N is even, then for every $c \in [0,1]$ there exists $x \in V\mathbb{R}^N$ such that $R(x) = c$ and $\|f(x)\|_2 = \sqrt{NR^2(x)\,(1-R^2(x))}$.*
3. *If N is odd, then inequality (33) is strict for all $x \in \mathbb{R}^N$ such that $0 < R(x) < 1$.*

Proof. Part 1. Observe that inequality (33) is trivially satisfied when $x \in \mathcal{R}_0$. Suppose therefore that $x \in \mathbb{R}^N \backslash \mathcal{R}_0$. Then by definition

$$\begin{aligned} \|f(x)\|_2^2 &:= \sum_{j=1}^N (f_j(x))^2 \\ &= R^2(x) \sum_{j=1}^N \sin^2(\psi(x) - x_j), \end{aligned} \tag{34}$$

where $\psi(x)$ and $R(x)$ are the phase and magnitude of the order parameter, previously defined in (8) and (7), respectively. Introducing the shorthand notation $z_i(x) := \cos(\psi(x) - x_i)$ and using (13), we now rewrite (34) as follows:

$$\|f(x)\|_2^2 = \left(\frac{1}{N}\sum_{j=1}^N z_j(x)\right)^2 \sum_{j=1}^N \left(1 - z_j(x)^2\right). \tag{35}$$

To derive the desired inequality we pick a $c \in [0,1]$ and maximize $\|f(x)\|_2$ over the set $\{x \in \mathbb{R}^N : R(x) = c\}$. We shall not solve this optimization problem directly but shall take an indirect route by considering another, easier optimization problem, whose solution will then give us an upper bound on the solution to the first problem. Then we shall show that, under certain conditions, the two solutions coincide.

To this end, let $c \in (0,1]$ and consider the constrained optimization problem

OPT 1:

maximize	$\sum_{j=1}^N \left(1 - z_j(x)^2\right)$
subject to	$\frac{1}{N}\sum_{j=1}^N z_j(x) = c, \quad x \in \mathbb{R}^N \backslash \mathcal{R}_0$

Note that the constraint is feasible for all values of c in the specified interval. We shall denote the solution to OPT 1 as $s_1(c)$. Next consider a second optimization problem

$$\text{OPT 2:} \quad \boxed{\begin{array}{ll} \text{maximize} & \sum_{j=1}^{N} \left(1 - y_j^2\right) \\ \text{subject to} & \frac{1}{N}\sum_{j=1}^{N} y_j = c, \quad y \in \mathbb{R}^N \end{array}}$$

and let the solution to this problem be denoted as $s_2(c)$. We then have that $s_2(c) \geq s_1(c)$ for all $c \in (0, 1]$. In other words, the solution to OPT 1 is upper bounded by the solution to OPT 2. The solution to OPT 2 can be found by means of standard Lagrange multiplier techniques. The optimum $s_2(c) = N\left(1 - c^2\right)$ is attained when $y_i = c$ for all i. We conclude that

$$\max_{\{x \in \mathbb{R}^N : R(x) = c\}} \|f(x)\|_2^2 \leq Nc^2\left(1 - c^2\right), \tag{36}$$

and hence

$$\|f(x)\|_2 \leq \sqrt{N} R(x) \sqrt{1 - R^2(x)} \tag{37}$$

for all $x \in \mathbb{R}^N$.

Part 2. To prove the second part of the theorem, let $c \in (0, 1]$ and note that $s_1(c) = s_2(c)$ if and only there exists $x \in \mathbb{R}^N \backslash \mathcal{R}_0$ such that

$$\cos(\psi(x) - x_i) = c \tag{38}$$

for all i. Suppose N is even and let x be given as

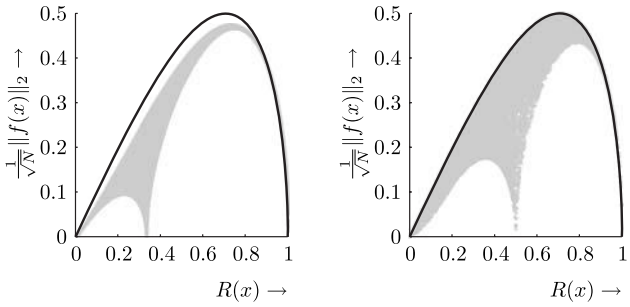
$$x_i := \begin{cases} \arccos(c), & i = 1, \ldots, \frac{N}{2}, \\ -\arccos(c), & i = \frac{N}{2}, \ldots, N. \end{cases} \tag{39}$$

Then $\sum_{j=1}^{N} x_j = 0$, and, by definition, $x \in V\mathbb{R}^N$. Moreover, $\psi(x) = 0$, and $\cos(\psi(x) - x_i) = c$ for all i. This completes the second part.

Part 3. To prove the third part, let N be odd and suppose there exists $x \in \mathbb{R}^N$ such that condition (38) is satisfied. Then it follows from the identity $\sin^2(\psi(x) - x_i) + \cos^2(\psi(x) - x_i) = 1$ that there must exist $a \in \{-1, 1\}^N$ such that $\sin(\psi(x) - x_i) = a_i\sqrt{1 - c^2}$ for all i. By identity (14), we have that $\sum_j \sin(\psi(x) - x_j) = 0$, which, assuming $c \neq 1$, implies that $\sum_{j=1}^{N} a_j = 0$. But this cannot be true unless N is even. Thus we arrive at a contradiction and we conclude that if N is odd then $s_2(c) > s_1(c)$ for all c such that $0 < c < 1$. This concludes the proof. ■

Figure 2 illustrates the result of Lemma 4. When $N = 4$ (even), the lower bound is attained at every value of $R(x)$, which shows that the given bound is the tightest possible. However, as illustrated in the left panel, when $N = 3$, the bound is never attained except on the set $\{x \in \mathbb{R}^N : R(x) \in \{0, 1\}\}$. It can be shown, however, that in the limit of large N the given bound is arbitrarily tight, even for odd N, in the sense that for every $c \in [0, 1]$,

$$\min_{\{x \in \mathbb{R}^{2m+1} : R(x) = c\}} \frac{1}{\sqrt{2m+1}} \left| \|f(x)\|_2 - \sqrt{(2m+1)c^2\left(1 - c^2\right)} \right|$$



(a) $N = 3$ (b) $N = 4$

Figure 2. *Scatter plot of* $\frac{1}{\sqrt{N}}\|f(x)\|_2$ *for* $N = 3$ *(left panel) and* $N = 4$ *(right panel). The phases* x *were drawn from a uniform distribution. The solid black line in both panels is the upper bound* $R(x)\sqrt{1 - R^2(x)}$.

tends to zero as m tends to infinity.

Lemma 4 has some interesting implications. For instance, it can provide insight into the rate at which solutions of a homogeneous system of Kuramoto oscillators ((2) with $\omega_i = 0$ for $1 \leq i \leq N$) on $\mathbb{R}^N$ converge to fixed points. To see this, consider the homogeneous system

$$\begin{cases} \dot{\theta}(t) &= kf(\theta(t)), \\ \theta(t_0) &= \theta_0, \end{cases} \tag{40}$$

where $\theta_0 \in \mathbb{R}^N$. We shall compute the time-derivative of the magnitude squared of the order parameter, $L(\cdot) := R^2(\cdot)$, and show that this derivative is (i) nonnegative along solutions of (40) and (ii) bounded from above by a certain function $D(t)$ for every t. We proceed as follows [9]. By definition,

$$\frac{\mathrm{d}L(\theta(t))}{\mathrm{d}t} := \frac{L(\theta)}{\partial\theta}\dot{\theta}(t) = \frac{L(\theta)}{\partial\theta}kf(\theta(t)).$$

Using the identity

$$\frac{\partial L(\theta)}{\partial\theta} = \frac{2}{N}\left[f(\theta)\right]^T,$$

it follows that

$$\frac{\mathrm{d}L(\theta(t))}{\mathrm{d}t} = \frac{2k}{N}\|f(\theta(t))\|_2^2, \tag{41}$$

which shows that the time-derivative is positive everywhere, except at the equilibria, where it is zero. It follows that the magnitude of the order parameter is a nondecreasing function of time. Based on the observation that the time-derivative of L is positive almost everywhere (the set of equilibria having measure zero), we formulate the following conjecture [3, 9].

Conjecture 1. *For almost all initial conditions* θ_0*, the solution* $\theta(t)$ *to the homogeneous system* (40) *has the property that* $\lim_{t\to\infty} R(\theta(t)) = 1$.

In agreement with Conjecture 1, one can prove that, for the homogeneous system, the global phase-locking manifold $\mathcal{M} := \{\theta \in \mathbb{R}^N : \theta_i = \theta_j \text{ for all } i, j\}$ is (locally) asymptotically stable. However, the existence of other invariant manifolds, not contained in $\mathcal{M}$, implies

that $\mathcal{M}$ is not globally asymptotically stable. We conjecture that $\mathcal{M}$ is "almost globally asymptotically stable" in the sense that its region of attraction is the entire space minus a set of measure zero.

For our next result, we shall need the concept of a dominating function, which is defined as follows.

Definition 3. *Let $h, g : \mathbb{R} \mapsto \mathbb{R}$ and let $\mathcal{I} \subset \mathbb{R}$ be some interval. We say that h dominates g on $\mathcal{I}$ if $h(t) \geq g(t)$ for all $t \in \mathcal{I}$. In that case we call h a* dominating function *for g on $\mathcal{I}$.*

Our next result states that $L(\theta(t))$ is dominated by a certain scalar function $D(t)$ that depends only on θ_0. In order to prove this result, we need the following two lemmas.

Lemma 5. *Let $\theta(\cdot)$ be a solution of the homogeneous system (40) and suppose $\dot{L}(\theta(t')) = 2kL(\theta(t'))\,(1 - L(\theta(t')))$ for some $t' \in \mathbb{R}$. Then*

$$\dot{L}(\theta(t)) = 2kL(\theta(t))\,(1 - L(\theta(t))) \quad \forall t \geq t'.$$

Proof. Recall that $\dot{L}(\theta(t)) = \frac{2k}{N}\|f(\theta(t))\|_2^2$. It follows from the proof of Lemma 4 that $\|f(\theta(t'))\|_2^2 = NL(\theta(t'))\,(1 - L(\theta(t')))$ for some $t' \in \mathbb{R}$ if and only if one or two of the following conditions hold: (a) $L(\theta(t')) = 0$; (b) N is even and there exists a permutation $\hat{\theta}(t')$ of $\theta(t')$ such that

$$\cos(\hat{\theta}_i(t') - \hat{\theta}_1(t')) = 1, \qquad i = 1, 2, \ldots, \frac{N}{2}, \tag{42}$$

$$\cos(\hat{\theta}_i(t') - \hat{\theta}_N(t')) = 1, \qquad i = \frac{N}{2} + 1, \ldots, N. \tag{43}$$

If $L(\theta(t')) = 0$, we have that $L(\theta(t)) = 0$ for all $t \geq t'$ and the result follows trivially. Now suppose conditions (42) and (43) hold. It follows that $\dot{\hat{\theta}}_i(t') = \dot{\hat{\theta}}_j(t')$ for $i, j \leq \frac{N}{2}$ and $i, j > \frac{N}{2}$, and hence

$$\frac{\mathrm{d}}{\mathrm{d}\tau}\left(\cos(\hat{\theta}_i(\tau) - \hat{\theta}_j(\tau))\right)\Big|_{\tau=t'} = 0, \quad i, j \leq \frac{N}{2}; \quad i, j > \frac{N}{2}.$$

In other words, if $\hat{\theta}(\cdot)$ satisfies conditions (42) and (43) for some t', it satisfies (42) and (43) for all $t \geq t'$. This concludes the proof. ∎

Lemma 6. *Let $h, g : \mathbb{R} \mapsto \mathbb{R}$ be such that for every $x_0 \in \mathbb{R}$, the systems*

$$\begin{cases} \dot{x} &= h(x), \\ x(0) &= x_0, \end{cases} \qquad \begin{cases} \dot{x} &= g(x), \\ x(0) &= x_0 \end{cases}$$

have unique solutions in $C^1[0, \infty)$. Let these solution be denoted $x_h(t; x_0)$ and $x_g(t; x_0)$, respectively. Suppose there exist $a, b \in \mathbb{R}$, $a \neq b$, such that

$$h(x) > g(x) \geq 0$$

for all $x \in (a, b) \subset \mathbb{R}$. Then for every $x_0 \in (a, b)$, we have that

$$x_h(t; x_0) \geq x_g(t; x_0) \tag{44}$$

for all $t \in I$, where $I \subset \mathbb{R}$ is defined as

$$I := \begin{cases} [0, \min_t\{x_h(t; x_0) = b\}) & \text{when } \{x_h(t; x_0) = b\} \neq \emptyset; \\ [0, \infty) & \text{otherwise.} \end{cases} \tag{45}$$

Proof. Under the hypotheses of the lemma we have that $h(x_0) > g(x_0)$, and it follows that for small enough t, $x_h(t) > x_g(t)$ (omitting the argument x_0 for notational convenience). Note also that x_h and x_g are increasing whenever $x_h(t; x_0) < b$ and $x_g(t; x_0) < b$, respectively. Now suppose there exists $t_2 > 0$ such that $x_g(t_2) > x_h(t_2)$ and $x_g(t_2) < b$. Then by continuity there exists $t_1 < t_2$ such that $a < x_h(t_1) = x_g(t_1) < b$ and $h(x_h(t_1)) \leq g(x_g(t_1))$. Define $x' := x_h(t_1) = x_g(t_1)$. It follows that $g(x') \geq h(x')$, which contradicts our starting hypothesis. We conclude that $x_h(t) \geq x_g(t)$ for all $t \in I$. ∎

We have the following result.

Corollary 1. *Let $\theta(\cdot)$ be a solution to the homogeneous system (40) with initial condition $\theta(t_0) = \theta_0$. Then*

$$D(t) := \frac{1}{1 - e^{-2k(t-t_0)}\left(\frac{L(\theta_0)-1}{L(\theta_0)}\right)} \tag{46}$$

is a dominating function for $L(\theta(t))$ on $[t_0, \infty)$.

Proof. By Lemma 4 we have that $\dot{L}(\theta(t)) \leq 2kL(\theta(t))\,(1 - L(\theta(t)))$ for all t. We claim that, on $[t_0, \infty)$, $L(\theta(t))$ is dominated by the solution $y(t)$ of the ODE

$$\begin{cases} \dot{y} &= 2ky(1-y), \\ y(t_0) &= L(\theta_0), \end{cases} \tag{47}$$

which is given as

$$y(t) = \frac{1}{1 - e^{-2k(t-t_0)}\left(\frac{L(\theta_0)-1}{L(\theta_0)}\right)}, \quad t \geq t_0. \tag{48}$$

To prove this, suppose $\dot{L}(\theta(t)) = 2kL(\theta(t))\,(1 - L(\theta(t)))$ for some $t \geq t_0$ and let t' denote the smallest such t (in case $\dot{L}(\theta(t)) < 2kL(\theta(t))\,(1 - L(\theta(t)))$ for all $t \geq t_0$, the result follows immediately from Lemma 6). Then by Lemma 5, we have that $\dot{L}(\theta(t)) = 2kL(\theta(t))\,(1 - L(\theta(t)))$ for all $t \geq t'$, and it follows that

$$L(\theta(t))|_{L(\theta(t'))=a} = \frac{1}{1 - e^{-2k(t-t')}\left(\frac{a-1}{a}\right)}, \quad t \geq t'. \tag{49}$$

One can easily verify that $L(\theta(t))|_{L(\theta(t'))=a}$ is nondecreasing as a function of a for all $t \geq t'$ (and $a \in [0, 1]$). Now let l be an upper bound for $L(\theta(t'))$. It follows that $\frac{1}{1-e^{-2k(t-t')}\left(\frac{l-1}{l}\right)}$ is a dominating function for $L(\theta(t))$ on the interval $[t', \infty)$. To compute an upper bound for $L(\theta(t')$, we proceed as follows. By definition of t', we have that $\dot{L}(\theta(t)) < 2kL(\theta(t))\,(1 - L(\theta(t)))$ for all $t < t'$. It follows from Lemma 6 that

$$L(\theta(t)) \leq \frac{1}{1 - e^{-2k(t-t_0)}\left(\frac{L(\theta_0)-1}{L(\theta_0)}\right)}, \quad t_0 \leq t < t'. \tag{50}$$

By continuity, we have that

$$L(\theta(t')) \leq \frac{1}{1 - e^{-2k(t'-t_0)}\left(\frac{L(\theta_0)-1}{L(\theta_0)}\right)}.$$

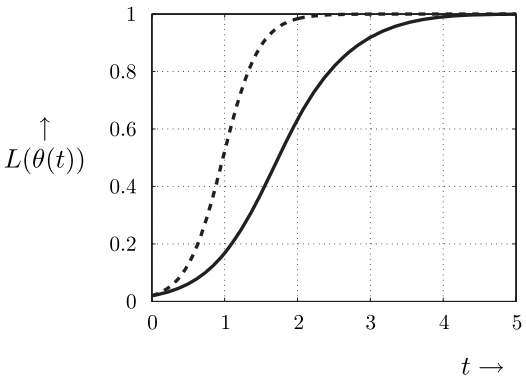


Figure 3. *Numerical simulation of the homogeneous system (40) with $N = 100$ oscillators and coupling coefficient $k = 2$: Time evolution of $L(\theta(t)) := R^2(\theta(t))$ (solid line) and the dominating function $D(t)$—(46) (dashed line).*

Using the upper bound $\frac{1}{1-e^{-2k(t'-t_0)}\left(\frac{L(\theta_0)-1}{L(\theta_0)}\right)}$ for $L(\theta(t'))$, it follows from (49) that

$$L(\theta(t)) \leq \frac{1}{1-e^{-2k(t-t_0)}\left(\frac{L(\theta_0)-1}{L(\theta_0)}\right)}, \quad t \geq t'. \tag{51}$$

Combining (50) and (51), we arrive at the desired result. This concludes the proof. ∎

Figure 3 shows the graph of $L(\theta(t))$ and that of the dominating function $D(t)$—(46) for a particular realization of the initial condition θ_0. In this example, $N = 100$ and $k = 2$. We observe that, in agreement with Conjecture 1, the solution converges to a globally phase-locked state, that is, $L(\theta(t)) \to 1$. Note that convergence can be very slow depending on the choice of initial condition. Indeed, for any $T \in \mathbb{R}$ and any $\epsilon > 0$, we can find $\delta > 0$ such that if $L(\theta_0) < \delta$ then $L(\theta(t)) < \epsilon$ for all $t \leq t_0 + T$. The upshot of this is that if the initial condition θ_0 is selected by drawing from a uniform distribution and the number of oscillators is large, then $L(\theta_0)$ is likely to be small, and as a consequence convergence to the stable equilibrium is likely to be slow. In the limit case when N tends to infinity, we have that $L(\theta_0)$ tends to zero with probability 1 and the time required for $L(\theta(t))$ to exceed some given finite threshold diverges to infinity.

Let $\sigma_\omega := \sqrt{\frac{1}{N}\sum_{j=1}^{N}(\omega_j - \langle\omega\rangle)^2}$ denote the (sample) standard deviation associated with the vector of intrinsic frequencies ω. Using Lemma 4 we derive another lower bound on the critical coupling, as follows.

Corollary 2. *The critical coupling k_c satisfies*

$$k_c \geq 2\sigma_\omega. \tag{52}$$

Proof. Let $x^* \in V\mathbb{R}^N$ be a fixed point of the system (17). Then by definition $k\|f(x^*)\|_2 = \|V\omega\|_2 = \sqrt{N}\sigma_\omega$ and by Lemma 4 we have that

$$\|f(x^*)\|_2 \leq \sqrt{N}\sqrt{R^2(x^*)\,(1 - R^2(x^*))}. \tag{53}$$

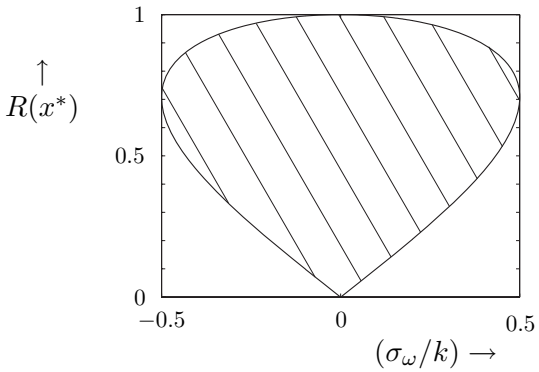

Figure 4. *Graph associated with inequality (56). For a given value of the ratio (σ_ω/k), the magnitude of the order parameter $R(\cdot)$, evaluated at a fixed point x^*, must lie within the striped region.*

It is not hard to see that the right-hand side of (53) is upper bounded by $\frac{1}{2}\sqrt{N}$. It follows that

$$k \geq \frac{\sqrt{N}\sigma_\omega}{\sqrt{N}\frac{1}{2}} = 2\sigma_\omega. \tag{54}$$

This completes the proof. ■

Note that Corollary 2 is in agreement with the intuition that greater variation in intrinsic frequencies requires stronger coupling to achieve global phase-locking.

Using Lemma 4 we can compute bounds on the value of the order parameter evaluated at the fixed points of the system, should they exist. Indeed, suppose $k > k_c$; then for any fixed point $x^* \in V\mathbb{R}^N$ we have that

$$\sqrt{R^2(x^*)\left(1 - R^2(x^*)\right)} \geq \frac{\sigma_\omega}{k}. \tag{55}$$

Solving for $R(x^*)$ gives

$$\frac{1}{2} - \frac{1}{2}\sqrt{1 - 4\left(\frac{\sigma_\omega}{k}\right)^2} \leq R^2(x^*) \leq \frac{1}{2} + \frac{1}{2}\sqrt{1 - 4\left(\frac{\sigma_\omega}{k}\right)^2}. \tag{56}$$

The graph associated with inequality (56) is shown in Figure 4.

5. Necessary and sufficient conditions. In the last section, we derived lower bounds for the critical coupling of the system (17) which provided necessary conditions for the existence of fixed points. We next derive conditions that are both necessary and sufficient for fixed points to exist, and we shall use these results to describe an algorithm for computing the critical coupling in section 6.

Throughout this section, the function $f : \mathbb{R}^N \mapsto \mathbb{R}^N$ is given by (4) and the set $\mathcal{F}(k, \Omega)$ is defined as

$$\mathcal{F}(k, \Omega) := \left\{x \in V\mathbb{R}^N : kf(x) = -\Omega\right\}, \quad k \geq 0, \quad \Omega \in V\mathbb{R}^N.$$

On $\mathcal{F}(k, \Omega)$ we introduce a notion of equivalence as follows.

Definition 4 (equivalence on $\mathcal{F}(k,\Omega)$). *Given $\Omega \in V\mathbb{R}^N$ and $k \geq 0$, let $x, x' \in F(k,\Omega)$. We say that x and x' are equivalent ($x \simeq x'$) if $R(x) = R(x')$.*

To motivate this definition consider the following fact. Let k, Ω be given, and let $s \in \mathbb{Z}^N$ be such that $\sum_{j=1}^N s_j = 0$. If x is a fixed point of the system (17), then $x' := x + 2s\pi$ is also a fixed point of the system (17) and, in addition, $R(x') = R(x)$.

The following theorem provides a necessary and sufficient condition for the system (17) to have a fixed point, given a particular coupling strength k, and a particular realization of intrinsic frequencies, Ω. Note that the first part of this theorem is essentially identical to the result of Theorem 1 in [19].

Theorem 2. *Let $k > 0$ and $\Omega \in V\mathbb{R}^N$. Then $\mathcal{F}(k,\Omega) \neq \emptyset$ if and only if there exist $\beta \in [\frac{1}{k}\|\Omega\|_\infty, 1] \subset \mathbb{R}$ and $a \in \{-1,1\}^N$ such that*

$$\beta = \frac{1}{N}\sum_{j=1}^N a_j \sqrt{1 - \left(\frac{\Omega_j}{k\beta}\right)^2}. \tag{57}$$

Moreover, suppose (a^1, β^1) and (a^2, β^2) both satisfy (57), and let $x^1, x^2 \in F(k,\Omega)$ be such that

$$\begin{cases} k\beta^i \sin(\psi(x^i) - x^i_j) &= -\Omega_j, \\ a_j \cos(\psi(x^i) - x^i_j) &\geq 0, \end{cases} \qquad i \in \{1,2\}, \quad j = 1,2,\ldots,N. \tag{58}$$

Then $x^1 \simeq x^2$ if and only if $\beta^1 = \beta^2$ and $\sum_{j=1}^N (a_i - a_j)\sqrt{1 - \left(\frac{\Omega_j}{k\beta^1}\right)^2} = 0$.

Proof. Suppose $\Omega \neq 0$ (the case $\Omega = 0$ is easy). Let $x^* \in V\mathbb{R}^N$ be a fixed point of (17). By definition, $kf(x^*) = -\Omega$, and since $\Omega \neq 0$, we have that $f(x^*) \neq 0$, and consequently $R(x^*) \neq 0$. It follows that

$$\sin(\psi(x^*) - x^*_i) = -\frac{\Omega_i}{kR(x^*)}, \qquad i = 1,2,\ldots,N. \tag{59}$$

Let $\beta := R(x^*)$. By (59) we have that $\beta \geq \frac{1}{k}\|\Omega\|_\infty$. Recall that for all $x \in \mathbb{R}^N \backslash \mathcal{R}_0$, $R(x)$ can be written as

$$R(x) = \frac{1}{N}\sum_{j=1}^N \cos(\psi(x) - x_j), \tag{60}$$

and let a_i be given as

$$a_i := \begin{cases} -1 & \text{if } \cos(\psi(x^*) - x^*_i) \leq 0; \\ +1 & \text{otherwise.} \end{cases} \tag{61}$$

Combining (59), (60), and (61), we arrive at

$$\beta = \frac{1}{N}\sum_{j=1}^N a_j \sqrt{1 - \left(\frac{\Omega_j}{k\beta}\right)^2}. \tag{62}$$

This proves necessity. To prove sufficiency, let $a \in \{-1,1\}^N$ be given, and suppose $\beta \geq \frac{1}{k}\|\Omega\|_\infty > 0$ (again, the case $\Omega = 0$ is easy). Then for every $c \in \mathbb{R}$, the system

$$\left\{ \begin{array}{rcl} k\beta \sin(-y_i - c) & = & -\Omega_i, \\ a_i \cos(-y_i - c) & \geq & 0, \end{array} \right. \qquad i = 1, 2, \ldots, N, \tag{63}$$

has a unique solution $y^* \in [-\pi, \pi)^N$. We pick c such that $\sum_{j=1}^N y_j^* = 0$. Since $\sum_{j=1}^N \sin(y_j^* + c) = 0$, it follows that

$$R(y^*) = R(y^* + c\mathbf{1}) = \left| \sum_{j=1}^N \cos(y_j^* + c) \right|. \tag{64}$$

From (63), we have that

$$\cos(y_i^* + c) = a_i \sqrt{1 - \left(\frac{\Omega_i}{k\beta}\right)^2}, \quad i = 1, \ldots, N. \tag{65}$$

Combining (64) and (65), we arrive at

$$R(y^*) = \left| \frac{1}{N} \sum_{j=1}^N a_j \sqrt{1 - \left(\frac{\Omega_j}{k\beta}\right)^2} \right|. \tag{66}$$

The second part of the theorem follows easily after noting that if x^i satisfies (58) then $R(x^i) = \beta^i$, $i = 1, 2$. ■

Theorem 2 gives us a necessary and sufficient condition for the equation $kf(x) = -\Omega$ to have at least one solution for a given value of k. It is not clear, however, that there exists a k for which this condition is satisfied. The following corollary provides an easy sufficient condition.

Corollary 3. *Let $k > 0$ and $\Omega \in V\mathbb{R}^N$. Suppose*

$$\frac{1}{k}\|\Omega\|_\infty \leq \frac{1}{N} \sum_{j=1}^N a_j \sqrt{1 - \left(\frac{\Omega_j}{\|\Omega\|_\infty}\right)^2} \tag{67}$$

for some $a \in \{-1,1\}^N$. Then $\mathcal{F}(k, \Omega) \neq \emptyset$.

Proof. Suppose $\Omega \neq 0$ (again, the case $\Omega = 0$ is easy). Let $a \in \{-1,1\}^N$. Define $m : [\frac{1}{k}\|\Omega\|_\infty, 1] \mapsto \mathbb{R}$, $m(\beta) := \beta$, and $n : [\frac{1}{k}\|\Omega\|_\infty, 1] \times \{-1,1\}^N \mapsto \mathbb{R}$,

$$n(\beta, a) := \frac{1}{N} \sum_{j=1}^N a_j \sqrt{1 - \left(\frac{\Omega_j}{k\beta}\right)^2}. \tag{68}$$

Since $\Omega \neq 0$ we have that $m(1) > n(1, a)$. Now suppose condition (67) is satisfied. Then we have that $m(\frac{1}{k}\|\Omega\|_\infty) \leq n(\frac{1}{k}\|\Omega\|_\infty, a)$, and by the intermediate value theorem there must exist $\beta^* \in [\frac{1}{k}\|\Omega\|_\infty, 1]$ such that $m(\beta^*) = n(\beta^*, a)$. It follows from Theorem 2 that the system (17) has a fixed point. ■

Corollary 4. *Let $\Omega \in V\mathbb{R}^N$. Then* (i) *the critical coupling k_c is finite, and* (ii) *for large enough coupling, the system* (17) *has at least 2^{N-1} fixed points.*

Proof. Note that the right-hand side of (67) does not depend on k. Hence, it follows that, provided

$$\frac{1}{N}\sum_{j=1}^{N} a_j \sqrt{1-\left(\frac{\Omega_j}{\|\Omega\|_\infty}\right)^2} > 0, \tag{69}$$

condition (67) is always satisfied for large enough k. Furthermore, it follows easily that if (69) is not satisfied for given a, then it is satisfied for $a' := -a$. This implies (i) that the critical coupling k_c is always finite, and (ii) that the set $A^+ := \{a \in \{-1,1\}^N : (69) \text{ is satisfied}\}$ contains precisely 2^{N-1} elements (counting multiplicity), each of which defines a unique (up to equivalence in the sense of Definition 4) fixed point. This concludes the proof. ∎

Corollary 5. *Let $k > 0$ and $\Omega \in V\mathbb{R}^N$. Then $\mathcal{F}(k,\Omega) \neq \emptyset$ if and only if there exist $\beta \in [\frac{1}{k}\|\Omega\|_\infty, 1]$ such that*

$$\beta = \frac{1}{N}\sum_{j=1}^{N} \sqrt{1-\left(\frac{\Omega_j}{k\beta}\right)^2}.$$

Proof. The proof of Corollary 3 suggests that if the fixed point equation (57) does not have a solution, then necessarily

$$\beta > \frac{1}{N}\sum_{j=1}^{N} a_j \sqrt{1-\left(\frac{\Omega_j}{k\beta}\right)^2}$$

for all $\beta \in [\frac{1}{k}\|\Omega\|_\infty, 1]$ and all $a \in \{-1,1\}^N$. Since we have that

$$\frac{1}{N}\sum_{j=1}^{N} \sqrt{1-\left(\frac{\Omega_j}{k\beta}\right)^2} \geq \frac{1}{N}\sum_{j=1}^{N} a_j \sqrt{1-\left(\frac{\Omega_j}{k\beta}\right)^2}$$

for all $a \in \{-1,1\}^N$, it follows that the given condition is necessary and sufficient for the system (17) to have at least one fixed point. This concludes the proof. ∎

The next and final corollary gives us an upper bound on the critical coupling.

Corollary 6. *The critical coupling, k_c, satisfies*

$$k_c \leq \frac{\|\Omega\|_\infty}{\frac{1}{N}\sum_{j=1}^{N} \sqrt{1-\left(\frac{\Omega_j}{\|\Omega\|_\infty}\right)^2}}. \tag{70}$$

Proof. The proof follows directly from Corollary 3. ∎

6. An algorithm for computing k_c. In this section we present a bisection algorithm that will allow us to numerically evaluate the critical coupling with arbitrary precision. Throughout, we shall assume that $\Omega \neq 0$. Define $\mathcal{I} := (\|\Omega\|_\infty, \infty)$, and let $p_i : \mathcal{I} \mapsto (0,1]$ and

$P : \mathcal{I} \mapsto (0, 1]$ be given as

$$p_i(u) := \sqrt{1 - \left(\frac{\Omega_i}{u}\right)^2}; \qquad P(u) := \frac{1}{N}\sum_{j=1}^{N} p_j(u). \tag{71}$$

Also, define $h(u; k) : \mathcal{I} \times \mathbb{R}_+ \mapsto \mathbb{R}_+$:

$$h(u; k) := \frac{1}{k}u. \tag{72}$$

From Corollary 5 it follows that the critical coupling is the smallest k for which the equation $P(u) = h(u; k)$ has at least one solution on $\mathcal{I}$. We have the following result.

Theorem 3. *For all $\Omega \in V\mathbb{R}^N$, $\Omega \neq 0$, the equation*

$$2\frac{1}{N}\sum_{j=1}^{N}\sqrt{1 - \left(\frac{\Omega_j}{u}\right)^2} = \frac{1}{N}\sum_{j=1}^{N}\frac{1}{\sqrt{1 - \left(\frac{\Omega_j}{u}\right)^2}} \tag{73}$$

has a unique solution $u^* \in \mathcal{I}$, and we have that

$$k_c = \frac{u^*}{\frac{1}{N}\sum_{j=1}^{N}\sqrt{1 - \left(\frac{\Omega_j}{u^*}\right)^2}}. \tag{74}$$

Proof. Observe that, by strict concavity of P and linearity of $h(\,\cdot\,; k)$, the equation $P(u) = h(u; k)$ can have at most two solutions on $\mathcal{I}$ for any $k > 0$. We shall now show that, when $k = k_c$, it can have no more than one solution. Since, by definition of critical coupling, $P(u) = h(u; k_c)$ must have *at least* one solution, we shall conclude that it has precisely one solution. Let $k = k_c$, and suppose there exist $u^1, u^2 \in \mathcal{I}$, $u^1 \neq u^2$, such that $P(u^1) = h(u^1; k_c)$ and $P(u^2) = h(u^2; k_c)$. By strict concavity of P we have that $P(\frac{1}{2}(u^1 + u^2)) > \frac{1}{2}\big(P(u^1) + P(u^2)\big)$. Define $u' := \frac{1}{2}(u^1 + u^2)$ and note that $u' \in \mathcal{I}$. We have that $P(u') > h(u'; k_c)$. This implies that there exists $k' < k_c$ such that $P(u') = h(u'; k')$. But by definition k_c is the smallest k for which $P(u) = h(u; k)$ has a solution. We arrive at a contradiction and conclude that $u^1 = u^2$ or, in other words, that the equation $P(u) = h(u; k_c)$ has exactly one solution on $\mathcal{I}$. Denoting this solution by u^*, it is not hard to see that, at $u = u^*$, the derivative of P with respect to u and the derivative of h with respect to u (both of which are defined on the entire interval $\mathcal{I}$) must coincide. For suppose $\frac{\partial h}{\partial u}(u^*) < \frac{\partial P}{\partial u}(u^*)$; then by continuity there exists $\delta > 0$ such that $h(u; k_c) < P(u)$ for all u such that $u - u^* < \delta$. Let u' be one such u. It follows that there exists $k' < k_c$ such that $P(u') = h(u'; k')$. This leads to a contradiction, and we conclude that $h(u; k_c) \geq P(u)$. By analogy we have that $h(u; k_c) \leq P(u)$. We conclude that $\frac{\partial h}{\partial u}(u^*) = \frac{\partial P}{\partial u}(u^*)$. That is,

$$\frac{1}{k_c} = \frac{1}{u^*}\frac{1}{N}\sum_{j=1}^{N}\frac{\left(\frac{\Omega_j}{u^*}\right)^2}{\sqrt{1 - \left(\frac{\Omega_j}{u^*}\right)^2}} \tag{75}$$

or, equivalently,

$$\begin{aligned}\frac{u^*}{k_c} &= \frac{1}{N}\sum_{j=1}^{N}\frac{\left(\frac{\Omega_j}{u^*}\right)^2}{\sqrt{1-\left(\frac{\Omega_j}{u^*}\right)^2}} \\ &= -\frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{u^*}\right)^2}+\frac{1}{N}\sum_{j=1}^{N}\frac{1}{\sqrt{1-\left(\frac{\Omega_j}{u^*}\right)^2}}. \end{aligned} \tag{76}$$

Now recall that by definition of u^*, we have that

$$\frac{u^*}{k_c} = \frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{u^*}\right)^2}. \tag{77}$$

Equating the right-hand side of (76) with the right-hand side of (77) gives

$$2\frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{u^*}\right)^2} = \frac{1}{N}\sum_{j=1}^{N}\frac{1}{\sqrt{1-\left(\frac{\Omega_j}{u^*}\right)^2}}. \tag{78}$$

This shows that u^* is a solution to (73). What remains to be shown is that u^* is the only solution. Define $v, w : \mathcal{I} \mapsto \mathbb{R}$:

$$v(u) := 2\frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{u}\right)^2}, \quad w(u) := \frac{1}{N}\sum_{j=1}^{N}\frac{1}{\sqrt{1-\left(\frac{\Omega_j}{u}\right)^2}}.$$

Note that, on their respective domains, v is strictly monotonically decreasing, while w is strictly monotonically increasing. In addition, note that there exist $a, b \in \mathcal{I}$ such that $v(a) > w(a)$ and $v(b) < w(b)$. Hence, by continuity, there must exist a point $u' \in (a, b) \subset \mathcal{I}$ such that $v(u') = w(u')$. Monotonicity of v and w implies that this point is unique. It follows that u^* is the unique solution of (73) on $\mathcal{I}$. And by (77) we have that

$$k_c = \frac{u^*}{\frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{u^*}\right)^2}}. \tag{79}$$

This concludes the proof. ■

Based on the result of Theorem 3, we define the map $K : V\mathbb{R}^N\backslash\{0\} \mapsto \mathbb{R}_+$:

$$K(\Omega) = \frac{u^*}{\frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{u^*}\right)^2}}, \tag{80}$$

where, as before, u^* denotes the unique solution of (73) on $\mathcal{I}$, given Ω. Note that, given any realization of ω such that $V\omega \neq 0$, we have that $k_c = K(V\omega)$. We have the following corollary.

Corollary 7.

1. *For all* $\Omega \in V\mathbb{R}^N$, $\Omega \neq 0$, *we have that* $\|\Omega\|_\infty \leq K(\Omega) \leq 2\|\Omega\|_\infty$;
2. *there exists* $\Omega \in V\mathbb{R}^N$ *such that* $K(\Omega) = 2\|\Omega\|_\infty$ *if and only if* N *is even;*
3. *for every* $\epsilon > 0$ *there exist a positive integer* N *and* $\Omega \in V\mathbb{R}^N$ *such that* $|K(\Omega) - \|\Omega\|_\infty| < \epsilon$.

Proof. Part 1. We show that for all $\Omega \neq 0$, the solution u^* of (73) satisfies $u^* \leq \sqrt{2}\|\Omega\|_\infty$. The result then follows easily. Let $u' := \sqrt{2}\|\Omega\|_\infty$. Then we have that

$$2\frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{u}\right)^2} > \frac{1}{N}\sum_{j=1}^{N}\frac{1}{\sqrt{1-\left(\frac{\Omega_j}{u}\right)^2}} \quad \forall u > u'.$$

It follows that

$$K(\Omega) \leq \frac{u'}{\frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{u'}\right)^2}} \leq \frac{\sqrt{2}\|\Omega\|_\infty}{\frac{1}{2}\sqrt{2}} = 2\|\Omega\|_\infty$$

for all $\Omega \in V\mathbb{R}^N$. The lower bound $K(\Omega) \geq \|\Omega\|_\infty$ was obtained earlier in section 4.

Part 2. From the above it follows that $K(\Omega) = 2\|\Omega\|_\infty$ if and only if

$$2\frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{u'}\right)^2} = \frac{1}{N}\sum_{j=1}^{N}\frac{1}{\sqrt{1-\left(\frac{\Omega_j}{u'}\right)^2}}$$

or, equivalently, $\Omega_i^2 = \Omega_j^2$ for all (i,j). It is easy to see that this latter condition is never satisfied when N is odd (keeping in mind that $\sum_j \Omega_j = 0$). Now suppose N is even and pick any $c \neq 0$. Define

$$\Omega_i := \begin{cases} c, & i = 1, 2, \ldots, \frac{N}{2}; \\ -c, & i = \frac{N}{2}+1, \ldots, N. \end{cases}$$

Then we have that $\Omega \in V\mathbb{R}^N$. Moreover, $\Omega_i^2 = \Omega_j^2 = c^2$ for all (i,j). It follows that $K(\Omega) = 2\|\Omega\|_\infty$.

Part 3. Let $\epsilon > 0$ be given and suppose N is odd. Pick $c \neq 0$ and define

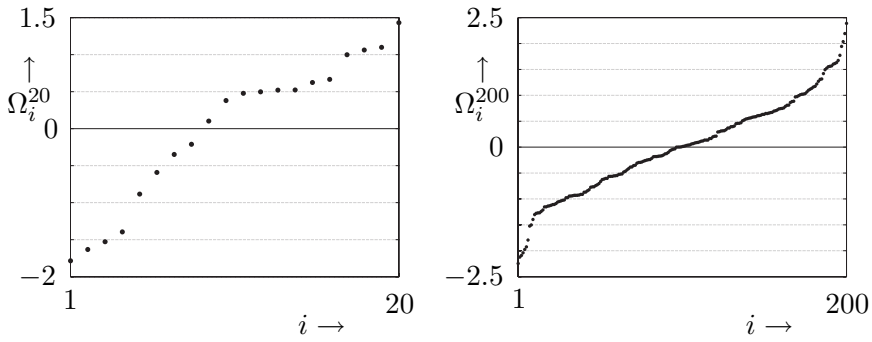
$$\Omega_i := \begin{cases} 0, & i = 1, 2, \ldots, N-1; \\ c, & i = N. \end{cases}$$

Then (73) evaluates to

$$2(N-1) + 2\sqrt{1-\left(\frac{c}{u}\right)^2} = (N-1) + \frac{1}{\sqrt{1-\left(\frac{c}{u}\right)^2}}, \tag{81}$$

and it is not hard to see that as N tends to infinity, the solution u^* of (81) tends to c. Indeed, for $N \geq 2$ we have

$$\left(\frac{c}{u^*}\right)^2 = \frac{1}{2}(N-1)\left(-\frac{1}{4}(N-1) + \frac{1}{4}\sqrt{(N-1)^2+8}\right). \tag{82}$$



(a) $N = 20$ (b) $N = 200$

Figure 5. *The vector of frequencies $\Omega_i^N := \omega_i^N - \langle \omega^N \rangle$, $N \in \{20, 200\}$, used in this example. The natural frequencies ω_i^N were sampled from a normal distribution with zero mean and unit variance and relabeled in such a way that $\omega_1^N \leq \omega_2^N \leq \cdots \leq \omega_N^N$.*

Let $\epsilon_1 > 0$, and pick N such that $\frac{1}{N} < \epsilon_1$ and $u^* < (1+\epsilon_1)c$. It follows that

$$\frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{u^*}\right)^2} < 1-\epsilon_1, \tag{83}$$

and hence

$$K(\Omega) := \frac{u^*}{\frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{u^*}\right)^2}} < c\left(\frac{1+\epsilon_1}{1-\epsilon_1}\right) = c + 2\left(\frac{\epsilon_1}{1-\epsilon_1}\right)c. \tag{84}$$

Now let ϵ_1 be given as $\epsilon_1 := \frac{\epsilon}{2c+\epsilon}$ and choose N accordingly. It follows that $K(\Omega) < \|\Omega\|_\infty + \epsilon$. This concludes the proof. ■

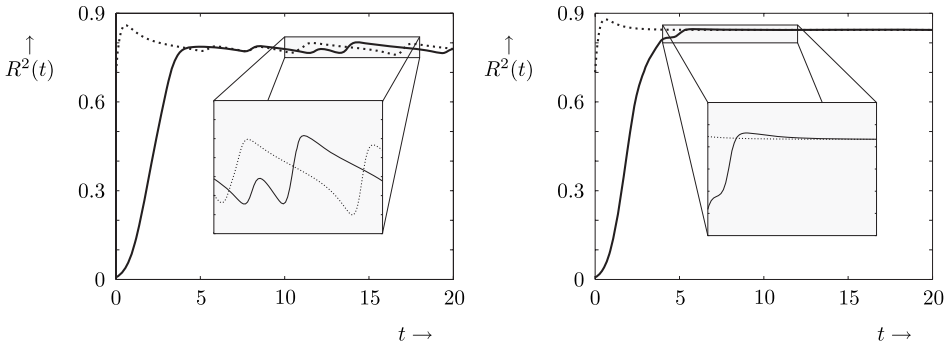
We are now ready to present our algorithm, which, given Ω, will compute u^* with user-defined precision $\epsilon > 0$ in a finite number of iterations, $n = \lceil \log_2(\frac{\|\Omega\|_\infty}{\epsilon}) \rceil + 1$.

Algorithm 1.

1. $a := \|\Omega\|_\infty$, $b := \sqrt{2}\|\Omega\|_\infty$
2. *While* $(b-a) > \epsilon$,
3. $\quad u := \frac{1}{2}(b-a)$.
4. $\quad$ *If* $\left[\sum_j \sqrt{\left(1-\frac{\Omega_j}{u}\right)^2} > \frac{1}{2}\sum_j \frac{1}{\sqrt{\left(1-\frac{\Omega_j}{u}\right)^2}}\right]$ *then* $a := u$, *else* $b := u$.
5. *End.*

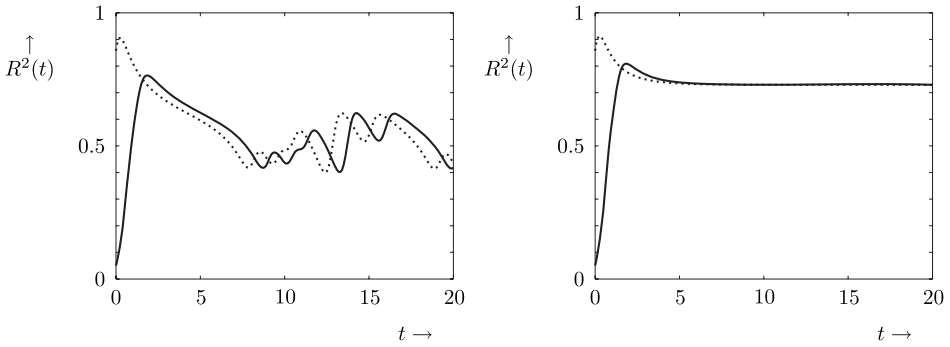
Once we have an estimate $\hat{u}$ of u^*, we can use (74), replacing u^* with $\hat{u}$, to estimate k_c.

7. Numerical example. We illustrate the results presented in this paper by means of a numerical example. We consider two systems with $N = 20$ and $N = 200$ oscillators, respectively, with frequencies $\{\Omega_i^N\}$, as depicted in Figures 5 and 6. The frequencies in this example were sampled from a normal distribution with zero mean and unit variance and relabeled such that $\omega_1^N \leq \omega_2^N \leq \cdots \leq \omega_N^N$ (note that this can be done without loss



(a) $k = 2.4$ (b) $k = 2.65$

Figure 6. *Case $N = 200$: Time evolution of the magnitude squared of the order parameter, $R^2(t)$, for two different initial conditions (indicated by a dashed and solid line, respectively) and two values of k. In the left panel, the value of k (2.4) is (well) below the known upper bound on k_c (2.6145), and the system does not converge to a fixed point; in the right panel the value of k (2.65) is slightly above the known upper bound on k_c, and the system converges to a fixed point, as expected.*



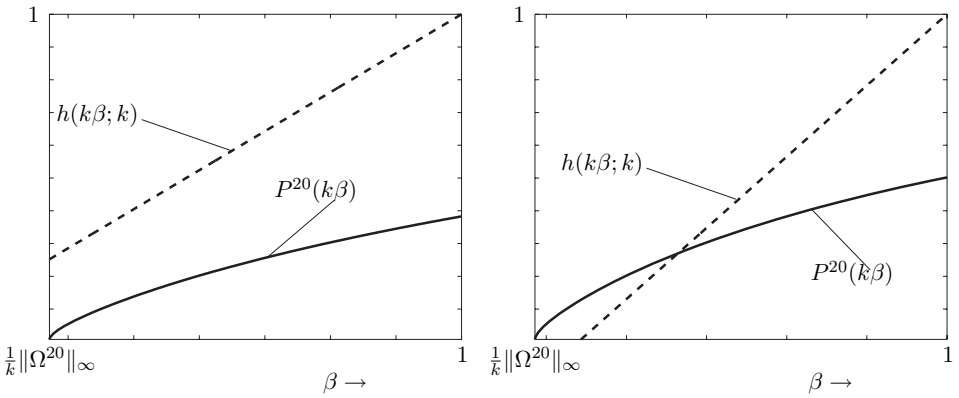
(a) $k = 2.1$ (b) $k = 2.3$

Figure 7. *Case $N = 20$: Time evolution of the magnitude squared of the order parameter, $R^2(t)$, for two different initial conditions (indicated by a dashed and solid line, respectively) and two values of k. In the left panel, the value of k (2.1) is slightly below the known upper bound on k_c (2.2281), and the system does not converge to a fixed point; in the right panel the value of k (2.3) is slightly above the known upper bound on k_c, and the system converges to a fixed point, as expected.*

of generality). For this particular realization of ω^{20} (ω^{200}), we have that $\|\Omega^{20}\|_\infty = 1.7858$ ($\|\Omega^{200}\|_\infty = 2.3893$) and

$$\frac{1}{N}\sum_{j=1}^{N}\sqrt{1-\left(\frac{\Omega_j}{\|\Omega\|_\infty}\right)^2} = 0.8015\ (0.9139).$$

It follows from Corollary 6 that $k_c \leq 2.2281$ (2.6145), and by (32), we have that $k_c \geq \|\Omega\|_\infty = 1.7858$ (2.3893). Figure 7 shows the time evolution of the magnitude squared of the order parameter, $R^2(t)$ (previously denoted as $L(t)$), for two different initial conditions and two values of the coupling coefficient, $k = 2.3$ and $k = 2.65$ ($k = 2.1$ and $k = 2.3$). We observe that when k is slightly greater than the known lower bound on k_c, the value of $R^2(t)$ converges



(a) $k = 2.1$ (b) $k = 2.3$

Figure 8. *Case $N = 20$: The graph of $P^{20}(k\beta)$ (71) versus β for $k = 2.1, 2.3$ and $\beta \in [\frac{1}{k}\|\Omega^{20}\|_\infty, 1]$. The dashed line is the graph of $h(k\beta;k) = \beta$ (72). An intersection corresponds to a solution of the fixed point equation $P(k\beta) = h(k\beta;k)$, and thus, by Theorem 2, to a fixed point of the system (17).*

to a constant and inspection shows that the solution $x(t)$ of the system (17) tends to a fixed point. On the other hand, when the coupling coefficient is slightly below the known upper bound on the critical coupling, the trajectories $x(t)$ appear not to converge. Note that in this case we do not know whether the system (17) has a fixed point or not, as the condition stated in Corollary 6 is only sufficient while at the same time the respective coupling strengths exceed their known lower bounds (1.7858 and 2.3893, respectively). To gain more insight into this situation, let us consider the case $N = 20$ in some more detail. We fix the coupling coefficient at $k = 2.1$ and numerically evaluate the function $P^{20}(k, \cdot)$,

$$P^{20}(k\beta) = \frac{1}{20}\sum_{j=1}^{20}\sqrt{1 - \left(\frac{\Omega_j^{20}}{k\beta}\right)^2}, \tag{85}$$

for several values of β in the interval $[\frac{1}{k}\|\Omega^{20}\|_\infty, 1]$. We repeat the same computation for $k = 2.3$. The result is shown in Figure 8. We observe that the equation $P^{20}(k\beta) = \beta$ does not have a solution on the interval $[\frac{1}{k}\|\Omega^{20}\|_\infty, 1]$ when $k = 2.1$ but does have a solution when $k = 2.3$.

We use Algorithm 1 to compute the "exact" value of the critical coupling to the fifth significant digit. We find that $k_c = 2.2198$ for the case $N = 20$ and $k_c = 2.6144$ for the case $N = 200$. Note that in both cases, but particularly in the latter, the upper bounds (2.2281 and 2.6145, respectively) provide good estimates of the true values of the critical coupling.

8. Conclusion. We derived necessary and sufficient conditions for the existence of fixed points in a finite system of coupled oscillators. In particular, we derived an easy sufficient condition in terms of the individual oscillator frequencies (Corollary 3), which we used to compute an upper bound on the critical coupling (Corollary 6). We showed that when no prior knowledge of the distribution of frequencies is available, we can still bound the critical coupling in terms of the infinity norm of the frequencies with their mean removed (Corollary 7).

These bounds were shown to be the tightest possible in the sense that we can find realizations of the intrinsic frequencies for which the upper bound is attained and others for which the critical coupling is arbitrarily close to the lower bound. Finally, we proposed an efficient algorithm (Algorithm 1) for computing the critical coupling to within arbitrary bounds in a finite number of steps. In future work we shall seek to extend the present analysis to complex networks of arbitrary topology and investigate more closely the impact of the shape of the distribution of intrinsic frequencies on the value of the critical coupling. We shall also consider the important question of stability and present analytical results for the limit case when the number of oscillators tends to infinity.

Acknowledgment. The authors would like to thank the anonymous reviewers for their thorough and insightful reviews which have helped to improve the paper.

Traveling Pulses and Wave Propagation Failure in Inhomogeneous Neural Media*

Zachary P. Kilpatrick†, Stefanos E. Folias‡, and Paul C. Bressloff†

Abstract. We use averaging and homogenization theory to study the propagation of traveling pulses in an inhomogeneous excitable neural network. The network is modeled in terms of a nonlocal integro-differential equation, in which the integral kernel represents the spatial distribution of synaptic weights. We show how a spatially periodic modulation of homogeneous synaptic connections leads to an effective reduction in the speed of a traveling pulse. In the case of large amplitude modulations, the traveling pulse represents the envelope of a multibump solution, in which individual bumps are nonpropagating and transient. The appearance (disappearance) of bumps at the leading (trailing) edge of the pulse generates the coherent propagation of the pulse. Wave propagation failure occurs when activity is insufficient to maintain bumps at the leading edge.

Key words. traveling waves, excitatory neural network, inhomogeneous media, homogenization, neural field theory, wave propagation failure

1. Introduction.

Traveling waves of electrical activity have been observed in vivo in a number of sensory cortical areas including the somatosensory cortex of behaving rats [30], turtle and mollusk olfactory bulbs [22, 23], turtle cortex [34], and visuomotor cortices in the cat [36]. Such waves are usually seen during periods without sensory stimulation; the subsequent presentation of a stimulus then induces a switch to synchronous oscillatory behavior [13]. Traveling waves are also a characteristic feature of certain neurological disorders in humans, including epilepsy [8] and migraines [24]. Therefore, investigating the mechanisms underlying wave propagation in neural tissue is important for understanding both normal and pathological brain states. A common experimental paradigm is to record electrical activity in vitro using thin slices of cortical tissue, in which inhibition has been suppressed by blocking $GABA_A$ receptors with an antagonist such as bicuculline [7, 15, 40, 35, 32, 18]. Synchronized discharges can then be evoked by a weak electrical stimulus from any site on the cortical slice. Following rapid vertical propagation, each discharge propagates away from the stimulus in both horizontal directions at a mean velocity of about 6–9 cm/s. Although the conditions for wave propagation may differ from the intact cortex due to the removal of some long-range connections during slice preparation, the in vitro slice is more amenable to pharmacological manipulation and to multielectrode recordings.

Mathematical analyses of cortical wave propagation typically consider reduced one-dimensional network models. Under the additional assumption that the synaptic interactions are homogeneous, it has been shown that an excitatory neural network supports the propagation of a traveling front [12, 19, 5] or, in the presence of slow adaptation, a traveling pulse [39, 1, 31, 42, 43, 10, 11, 14, 38]. However, the patchy nature of long-range horizontal connections in superficial layers of certain cortical areas suggests that the cortex is more realistically modeled as an inhomogeneous neural medium. For example, in the primary visual cortex the horizontal connections tend to link cells with similar stimulus feature preferences such as orientation and ocular dominance [28, 41, 2]. Moreover, these patchy connections tend to be anisotropic, with the direction of anisotropy correlated with the underlying orientation preference map. Hence the anisotropic pattern of connections rotates approximately periodically across the cortex resulting in a periodic inhomogeneous medium [3, 4]. Another example of inhomogeneous horizontal connections is found in the prefrontal cortex [27, 29, 17], where pyramidal cells are segregated into stripes that are mutually connected via horizontally projecting axon collaterals; neurons within the gaps between stripes do not have such projections.

In this paper we investigate how a spatially periodic modulation of long-range synaptic weights affects the propagation of traveling pulses in a one-dimensional excitatory neural network, extending previous work on traveling fronts in neural network models [3] and reaction-diffusion systems [20, 21]. We proceed by introducing a slowly varying phase into the traveling wave solution of the unperturbed homogeneous network, and then we use perturbation theory to derive a dynamical equation for the phase, from which the mean speed of the wave can be calculated. We show that a periodic modulation of the long-range connections slows down the wave, and if the amplitude and wavelength of the periodic modulation is sufficiently large, then wave propagation failure can occur. A particularly interesting result of our analysis is that in the case of large amplitude modulations, the traveling pulse is no longer superthreshold everywhere within its interior, even though it still propagates as a coherent solitary wave. We find that the pulse now corresponds to the envelope of a multibump solution, in which individual bumps are nonpropagating and transient. The appearance (disappearance) of bumps at the leading (trailing) edge of the pulse generates the propagation of activity; propagation failure occurs when activity is insufficient to create new bumps at the leading edge.

2. Inhomogeneous network model. Consider a one-dimensional neural network model of the form [31]

$$\begin{aligned} \tau_m \frac{\partial u(x,t)}{\partial t} &= -u(x,t) + \int_{-\infty}^{\infty} w(x,x') f(u(x',t)) dx' - \beta v(x,t), \\ \frac{1}{\alpha}\frac{\partial v(x,t)}{\partial t} &= -v(x,t) + u(x,t), \end{aligned} \tag{2.1}$$

where $u(x,t)$ is the population activity at position $x \in \mathbb{R}$, τ_m is a membrane time constant, $f(u)$ is the output firing rate function, $w(x,x')$ is the excitatory connection strength from neurons at x' to neurons at x, and $v(x,t)$ is a local negative feedback mechanism, with β and α determining the relative strength and rate of feedback. This type of feedback, which could be spike frequency adaptation or synaptic depression, favors traveling waves [1, 31]. The nonlinearity f is a smooth monotonic increasing function,

$$f(u) = \frac{1}{1 + e^{-\eta(u-\kappa)}}, \tag{2.2}$$

where η is a gain parameter and κ is a threshold. As $\eta \to \infty$, $f \to H$, where $H(u) = \Theta(u - \kappa)$ and

$$\Theta[u] = \begin{cases} 0, & u \le 0, \\ 1, & u > 0. \end{cases} \tag{2.3}$$

The periodic microstructure of the cortex is incorporated by taking the weight distribution to be of the form [3, 4]

$$w(x, x') = W(|x - x'|) \left[1 + \mathcal{D}'\left(\frac{x'}{\varepsilon}\right)\right], \tag{2.4}$$

where $\mathcal{D}$ is a 2π-periodic function and ε determines the microscopic length-scale. (We consider the first-order derivative of $\mathcal{D}$ so that the zeroth-order harmonic is explicitly excluded.) It is important to note that (2.4) is a one-dimensional abstraction of the detailed anatomical structure found in the two-dimensional layers of real cortex. (See [6] for a more detailed discussion of cortical models.) However, it captures both the periodic-like nature of long-range connections and possible inhomogeneities arising from the fact that this periodicity is correlated with a fixed set of cortical feature maps.

For concreteness, we take the homogeneous weight function W to be an exponential,

$$W(x) = \frac{W_0}{2d} \mathrm{e}^{-|x|/d}, \tag{2.5}$$

where d is the effective range of the excitatory weight distribution, and set

$$\mathcal{D}(x) = \rho \sin(x), \quad 0 \le \rho < 1, \tag{2.6}$$

where ρ is the amplitude of the periodic modulation. We require that $0 \le \rho < 1$ so that the weight distribution remains nonnegative everywhere. Example plots of the resulting weight function $w(x, y)$ of (2.4) are shown in Figure 1 for fixed x. This illustrates both the periodic modulation and the associated network inhomogeneity, since the shape of the weight distribution varies periodically as the location x of the postsynaptic neuron shifts. Plotting $w(x, x')$ for fixed x' simply gives an exponential distribution whose maximum depends on x'. Finally, the temporal and spatial scales of the network are fixed by setting $\tau_m = 1$, $d = 1$, and the scale of the synaptic weights is fixed by setting $W_0 = 1$. The membrane time constant is typically around 10 ms and the length-scale of synaptic connections is typically 1 mm. Thus, in dimensionless units the speed of an experimentally measured wave will be $c = \mathcal{O}(1)$.

3. Averaging theory and homogenization. Our goal in this paper is to determine how the periodic modulation of the weight function affects properties of traveling pulses in the one-dimensional system obtained by substituting (2.4) into (2.1):

$$\begin{aligned} \frac{\partial u(x,t)}{\partial t} &= -u(x,t) + \int_{-\infty}^{\infty} W(|x - x'|) \left[1 + \mathcal{D}'\left(\frac{x'}{\varepsilon}\right)\right] f(u(x',t))dx' - \beta v(x,t), \\ \frac{1}{\alpha}\frac{\partial v(x,t)}{\partial t} &= -v(x,t) + u(x,t). \end{aligned} \tag{3.1}$$

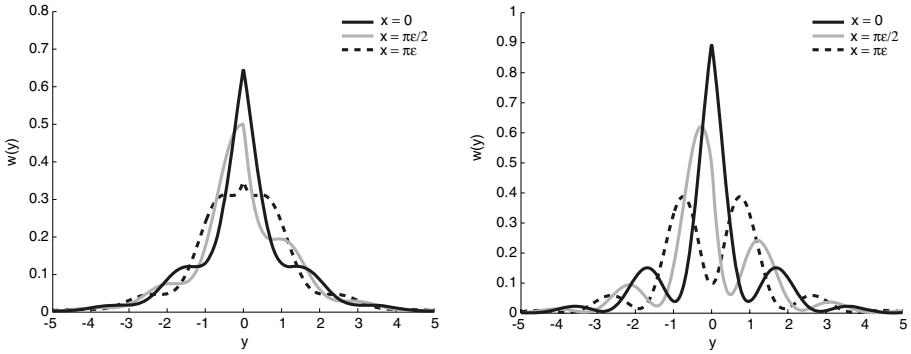

Figure 1. *Left: Weight kernel $w(y) = w(x, y)$ for a neuron centered at $x = 0, \pi\varepsilon/2, \pi\varepsilon$ when $\rho = 0.3$, and $\varepsilon = 0.3$. Right: Corresponding weight kernel when $\rho = 0.8$ and $\varepsilon = 0.3$.*

Assuming ε is a small parameter (in units of the space constant d), a zeroth-order approximation to (3.1) can be generated by performing spatial averaging with respect to the periodic weight modulation, leading to the homogeneous system given by (2.1) with weight distribution $w(x, x') = W(|x - x'|)$. Suppose that the homogeneous network supports the propagation of a traveling pulse of constant speed c. That is, $u(x, t) = U(\xi)$, $v(x, t) = V(\xi)$, where $\xi = x - ct$ is the traveling wave coordinate, and $U(\xi), V(\xi) \to 0$ as $\xi \to \pm\infty$. Substituting such a solution into (2.1) with $w(x, x') = W(|x - x'|)$ gives

$$-cU'(\xi) = -U(\xi) + \int_{-\infty}^{\infty} W(\xi - \xi')f(U(\xi'))d\xi' - \beta V(\xi),$$

$$-\frac{c}{\alpha}V'(\xi) = -V(\xi) + U(\xi). \tag{3.2}$$

Assuming the existence of a solution $(U(\xi), V(\xi))$ to (3.2), we would like to determine whether or not a traveling wave persists in the presence of the periodic weight modulation. A crucial requirement for trajectories of the averaged homogeneous system to remain sufficiently close to trajectories of the exact inhomogeneous system for sufficiently small ε is that solutions of the averaged system be structurally stable [16]. However, traveling pulses correspond to homoclinic trajectories within a dynamical systems framework and are thus not structurally stable. Therefore, one must go beyond lowest-order averaging to resolve differences between the homogeneous and inhomogeneous systems. We will proceed by carrying out a perturbation expansion in ε, extending previous work on traveling fronts in reaction-diffusion systems [20, 21] and excitable neural networks [3].

We begin by performing an integration by parts on the first equation in the system (3.1) so that

$$\frac{\partial u(x,t)}{\partial t} = -u(x,t) + \int_{-\infty}^{\infty} W(x - x')f(u(x',t))\mathrm{d}x' + \varepsilon \int_{-\infty}^{\infty} \mathcal{D}\left(\frac{x'}{\varepsilon}\right)\left[W'(x - x')f(u(x',t)) - W(x - x')\frac{\partial f(u(x',t))}{\partial x'}\right]\mathrm{d}x',$$

$$\frac{1}{\alpha}\frac{\partial v(x,t)}{\partial t} = -v(x,t) + u(x,t). \tag{3.3}$$

Although the inhomogeneous system is not translationally invariant, we can assume that perturbations about the homogeneous system will provide us with nearly translationally invariant solutions [20]. Thus, we perform the change of variables $\xi = x - \phi(t)$ and $\tau = t$ so that (3.3) becomes

$$\begin{aligned}\frac{\partial u(\xi,\tau)}{\partial \tau} &= -u(\xi,\tau) + \int_{-\infty}^{\infty} W(\xi-\xi')f(u(\xi',\tau))\mathrm{d}\xi' + \phi'\frac{\partial u(\xi,\tau)}{\partial \xi} \\ &\quad + \varepsilon\int_{-\infty}^{\infty}\mathcal{D}\left(\frac{\xi'+\phi}{\varepsilon}\right)\left[W'(\xi-\xi')f(u(\xi',\tau)) - W(\xi-\xi')\frac{\partial f(u(\xi',\tau))}{\partial \xi'}\right]\mathrm{d}\xi', \\ \frac{1}{\alpha}\frac{\partial v(\xi,\tau)}{\partial \tau} &= -v(\xi,\tau) + u(\xi,\tau) + \frac{\phi'}{\alpha}\frac{\partial v(\xi,\tau)}{\partial \xi}. \end{aligned} \tag{3.4}$$

Next perform the perturbation expansions

$$u(\xi,\tau) = U(\xi) + \varepsilon u_1(\xi,\tau) + \varepsilon^2 u_2(\xi,\tau) + \cdots, \tag{3.5}$$

$$v(\xi,\tau) = V(\xi) + \varepsilon v_1(\xi,\tau) + \varepsilon^2 v_2(\xi,\tau) + \cdots, \tag{3.6}$$

$$\phi'(\tau) = c + \varepsilon\phi_1'(\tau) + \varepsilon^2\phi_2'(\tau) + \cdots, \tag{3.7}$$

where $(U(\xi), V(\xi))^{\mathrm{T}}$ is a traveling pulse solution of the corresponding homogeneous system (see (3.2)) and c is the speed of the unperturbed pulse. The first-order terms u_1, v_1 satisfy

$$-\frac{\partial}{\partial\tau}\begin{pmatrix} u_1(\xi,\tau) \\ v_1(\xi,\tau)/\alpha \end{pmatrix} + \mathcal{L}\begin{pmatrix} u_1(\xi,\tau) \\ v_1(\xi,\tau) \end{pmatrix} = -\phi_1'(\tau)\begin{pmatrix} U'(\xi) \\ V'(\xi)/\alpha \end{pmatrix} + \begin{pmatrix} h_1(\xi,\frac{\phi}{\varepsilon}) \\ 0 \end{pmatrix}, \tag{3.8}$$

where

$$\mathcal{L}\begin{pmatrix} u \\ v \end{pmatrix} = \begin{pmatrix} c\frac{du}{d\xi} - u + \int_{-\infty}^{\infty} W(\xi-\xi')f'(U(\xi'))u(\xi')d\xi' - \beta v \\ \frac{c}{\alpha}\frac{dv}{d\xi} - v + u \end{pmatrix} \tag{3.9}$$

for $u, v \in \mathcal{C}^1(\mathbb{R},\mathbb{C})$ and

$$h_1\left(\xi,\frac{\phi}{\varepsilon}\right) = -\int_{-\infty}^{\infty}\mathcal{D}\left(\frac{\xi'+\phi}{\varepsilon}\right)\left[W'(\xi-\xi')f(U(\xi')) - W(\xi-\xi')\frac{\mathrm{d}f(U(\xi'))}{\mathrm{d}\xi'}\right]\mathrm{d}\xi'. \tag{3.10}$$

The linear operator $\mathcal{L}$ has a one-dimensional null-space spanned by $(U'(\xi), V'(\xi))^{\mathrm{T}}$. The existence of $(U'(\xi), V'(\xi))^{\mathrm{T}}$ as a null-vector follows immediately from differentiating the homogeneous equation (3.2) and is a consequence of the translation invariance of the homogeneous system. Uniqueness can be shown using properties of positive linear operators. A bounded solution to (3.9) then exists if and only if the right-hand side is orthogonal to all elements of the null-space of the adjoint operator $\mathcal{L}^*$. The latter is defined according to the inner product relation

$$\int_{-\infty}^{\infty}(a(\xi)\ \ b(\xi))\mathcal{L}\begin{pmatrix} u(\xi) \\ v(\xi) \end{pmatrix}d\xi = \int_{-\infty}^{\infty}(u(\xi)\ \ v(\xi))\mathcal{L}^*\begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix}, \tag{3.11}$$

where $u(\xi)$, $v(\xi)$, $a(\xi)$, and $b(\xi)$ are arbitrary integrable functions. It follows that

$$\mathcal{L}^*\begin{pmatrix} a \\ b \end{pmatrix} = \begin{pmatrix} -c\frac{da}{d\xi} - a + b + f'(U(\xi))\int_{-\infty}^{\infty} W(\xi-\xi')a(\xi')d\xi' \\ -\frac{c}{\alpha}\frac{db}{d\xi} - \beta a - b \end{pmatrix}. \tag{3.12}$$

The adjoint operator also has a one-dimensional null-space spanned by some vector $(A,B)^T$. (An explicit construction of this null-vector in the case of a Heaviside nonlinearity will be presented in section 4.) Therefore, for (3.9) to have a solution, it is necessary that

$$K\phi_1'(\tau) = \int_{-\infty}^{\infty} A(\xi) h_1\left(\xi, \frac{\phi}{\varepsilon}\right) d\xi, \tag{3.13}$$

where

$$K = \int_{-\infty}^{\infty} [A(\xi)U'(\xi) + \alpha^{-1}B(\xi)V'(\xi)]d\xi. \tag{3.14}$$

Substituting for h_1 using (3.10) leads to a first-order differential equation for the phase ϕ:

$$\frac{d\phi}{d\tau} = c - \varepsilon\Phi_1\left(\frac{\phi}{\varepsilon}\right), \tag{3.15}$$

where

$$\Phi_1\left(\frac{\phi}{\varepsilon}\right) = \frac{1}{K}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} A(\xi)\mathcal{D}\left(\frac{\xi'+\phi}{\varepsilon}\right) \times \left[W'(\xi-\xi')f(U(\xi')) - W(\xi-\xi')\frac{df(U(\xi'))}{d\xi'}\right] d\xi' d\xi. \tag{3.16}$$

If the right-hand side of (3.15) is strictly positive, then there exists a traveling pulse of the approximate form $U(x-\phi(t))$ and of average speed $\bar{c} = 2\pi\varepsilon/T$ with

$$T = \int_0^{2\pi\varepsilon} \frac{d\phi}{c - \varepsilon\Phi_1(\phi/\varepsilon)}. \tag{3.17}$$

However, if the right-hand side of (3.15) vanishes for some ϕ, then the first-order analysis predicts wave propagation failure.

4. Calculation of average wave speed.

In this section we use (3.17) to calculate the average wave speed $\bar{c}$ as a function of ε in the limiting case of a Heaviside nonlinearity. Note that since derivatives of f always appear inside integral terms, the high gain limit $\eta \to \infty$ is well defined. One advantage of using a Heaviside nonlinearity is that all calculations can be carried out explicitly. Moreover, as previously shown for traveling fronts [3], in the case of smooth nonlinearities it is necessary to develop the perturbation analysis to $\mathcal{O}(\varepsilon^2)$ since the $\mathcal{O}(\varepsilon)$ terms may be exponentially small; see also section 4.3.

4.1. Homogeneous network with Heaviside nonlinearity.

The existence (and stability) of single bump traveling pulse solutions in the homogeneous network obtained by setting $f = H$ and $w(x,x') = W(|x-x'|)$ in (2.1) has been studied by a number of authors [31, 33, 42, 10, 14]. A single bump solution $(U(\xi), V(\xi))$ is one for which U is above threshold over a domain of length a, corresponding to the width of the bump, and subthreshold everywhere else. In other words, the activity U crosses threshold at only two points, which by translation invariance can be taken to be $\xi = -a, 0$:

$$U(-a) = U(0) = \kappa; \qquad U(\xi) \longrightarrow 0 \ \text{ as } \ \xi \longrightarrow \pm\infty;$$
$$U(\xi) > \kappa, \ \ -a < \xi < 0; \qquad U(\xi) \ < \ \kappa \qquad \text{otherwise.}$$

It follows from (3.2) with $f = H$ that

$$-c\,U_\xi = -U - \beta V + \int_{-a}^{0} W(\xi-\eta)d\eta,$$
$$-\frac{c}{\alpha}\,V_\xi = -V \;+\; U. \tag{4.1}$$

One way to solve this pair of equations is to use variation of parameters [42, 14]. For completeness, we present the details of this calculation here, since some of the results will be used in our subsequent analysis.

Let $\mathbf{s} = (U, V)^T$ and rewrite the system as

$$\mathcal{L}\mathbf{s} \equiv \begin{pmatrix} cU'(\xi) - U(\xi) - \beta V(\xi) \\ cV'(\xi) + \alpha U(\xi) - \alpha V(\xi) \end{pmatrix} = -\begin{pmatrix} N_e(\xi) \\ 0 \end{pmatrix}, \tag{4.2}$$

where

$$N_e(\xi) = \Omega(\xi + a) - \Omega(\xi), \quad \Omega(\xi) = \int_{-\infty}^{\xi} W(\xi')d\xi'. \tag{4.3}$$

We solve (4.2) using variation of parameters. The homogeneous problem $\mathcal{L}\mathbf{s} = \mathbf{0}$ has two linearly independent solutions,

$$\mathbf{S}_+(\xi) = \begin{pmatrix} \beta \\ m_+ - 1 \end{pmatrix} \exp(\mu_+\xi), \qquad \mathbf{S}_-(\xi) = \begin{pmatrix} \beta \\ m_- - 1 \end{pmatrix} \exp(\mu_-\xi),$$

where

$$\mu_\pm = \frac{m_\pm}{c}, \qquad m_\pm = \frac{1}{2}(1 + \alpha \pm \sqrt{(1-\alpha)^2 - 4\mu\beta}). \tag{4.4}$$

We shall work in the parameter regime where $\mu_\pm$ are real, though interesting behavior can arise when $\mu_\pm$ is complex [38]. Thus, set

$$\mathbf{s}(\xi) = [\mathbf{S}_+|\mathbf{S}_-] \begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix},$$

where $a, b \in \mathcal{C}^1(\mathbb{R}, \mathbb{R})$, and $[A|B]$ denotes the matrix whose first column is A and whose second column is B. Since $\mathcal{L}\mathbf{S}_\pm = 0$, (4.2) becomes

$$[\mathbf{S}_+|\mathbf{S}_-] \frac{\partial}{\partial\xi} \begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix} = -\frac{1}{c} \begin{pmatrix} N_e(\xi) \\ 0 \end{pmatrix}. \tag{4.5}$$

Since $[\mathbf{S}_+|\mathbf{S}_-]$ is invertible, we find that

$$\frac{\partial}{\partial\xi} \begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix} = -\frac{1}{c\beta(m_+ - m_-)} [\mathbf{Z}_+|\mathbf{Z}_-]^T \begin{pmatrix} N_e(\xi) \\ 0 \end{pmatrix},$$

where

$$\mathbf{Z}_+(\xi) = \begin{pmatrix} 1 - m_- \\ \beta \end{pmatrix} \exp(-\mu_+\xi), \qquad \mathbf{Z}_-(\xi) = -\begin{pmatrix} 1 - m_+ \\ \beta \end{pmatrix} \exp(-\mu_-\xi).$$

For $c > 0$, we can integrate from ξ to ∞ and find

$$\begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix} = \begin{pmatrix} a_\infty \\ b_\infty \end{pmatrix} + \frac{1}{c\beta(m_+ - m_-)} \int_\xi^\infty [\mathbf{Z}_+|\mathbf{Z}_-]^T \begin{pmatrix} N_e(\xi') \\ 0 \end{pmatrix} d\xi',$$

where a_∞, b_∞ are the values of $a(\xi)$, $b(\xi)$ as $\xi \to \infty$. Thus

$$\mathbf{s}(\xi) = [\mathbf{S}_+|\mathbf{S}_-] \begin{pmatrix} a_\infty \\ b_\infty \end{pmatrix} + \frac{1}{c\beta(m_+ - m_-)} [\mathbf{S}_+|\mathbf{S}_-] \int_\xi^\infty [\mathbf{Z}_+|\mathbf{Z}_-]^T \begin{pmatrix} N_e(\xi') \\ 0 \end{pmatrix} d\xi'. \tag{4.6}$$

Using Hölder's inequality and that $N_e \in \mathcal{C}^0(\mathbb{R}, \mathbb{R})$, we can show that the integral in (4.6) is bounded for all $\xi \in R$. Thus, a bounded solution $\mathbf{s}$ exists if $a_\infty = b_\infty = 0$. Our general traveling pulse solution is given by

$$\mathbf{s}(\xi) = \frac{1}{c\beta(m_+ - m_-)} [\mathbf{S}_+|\mathbf{S}_-] \int_\xi^\infty [\mathbf{Z}_+|\mathbf{Z}_-]^T \begin{pmatrix} N_e(\xi') \\ 0 \end{pmatrix} d\xi'.$$

Furthermore, if we define

$$\mathcal{M}_\pm(\xi) = \frac{1}{c(m_+ - m_-)} \int_\xi^\infty \mathrm{e}^{\mu_\pm(\xi - \xi')} N_e(\xi') d\xi',$$

we can express our solution (U, V) as

$$U(\xi) = (1 - m_-)\mathcal{M}_+(\xi) - (1 - m_+)\mathcal{M}_-(\xi), \tag{4.7}$$

$$V(\xi) = \beta^{-1}(m_+ - 1)(1 - m_-)\left[\mathcal{M}_+(\xi) - \mathcal{M}_-(\xi)\right]. \tag{4.8}$$

Since $N_e(\xi)$ is dependent upon the pulse width a, the threshold conditions $U(-a) = U(0) = \kappa$ lead to the following consistency conditions for the existence of a traveling pulse:

$$\kappa = (1 - m_-)\mathcal{M}_+(-a) - (1 - m_+)\mathcal{M}_-(-a), \tag{4.9}$$

$$\kappa = (1 - m_-)\mathcal{M}_+(0) - (1 - m_+)\mathcal{M}_-(0). \tag{4.10}$$

This pair of nonlinear equations determines the pulse width a and wave speed c of a single bump traveling wave solution as a function of the various parameters of the network. For a given weight distribution $W(x)$, existence of such a solution is established if a solution for a, c can be found, and provided that U does not cross threshold at any other points besides $\xi = -a, 0$. Recently the existence (and stability) of single bump traveling waves has been examined for quite a general class of weight distributions [32] which includes both exponential and Gaussian distributions. For concreteness, we consider the exponential weight function (2.5) with $W_0 = d = 1$. Numerically solving (4.9) and (4.10) for a and c as a function of the adaptation rate α yields the existence curves shown in Figure 2. This figure illustrates the well-known result that for sufficiently slow adaptation (small α) there exists a pair of traveling pulses with the fast/wide pulse stable and the slow/narrow pulse unstable [31]. Also shown in the figure is the stability of the various solution branches, which can be determined analytically using an Evans function approach [42, 10, 14, 32].

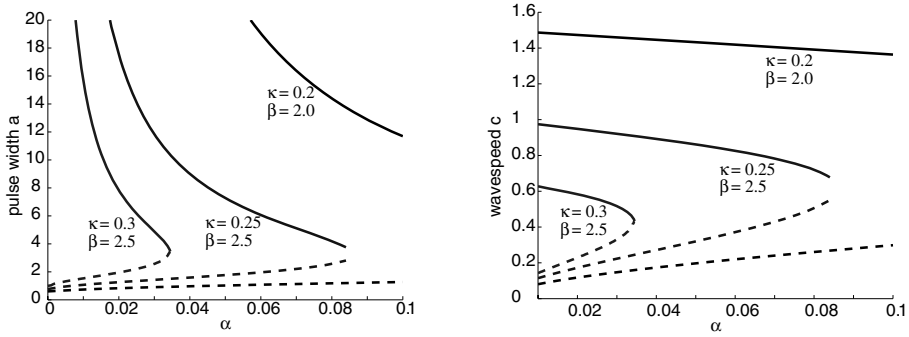

Figure 2. *Existence curves for a single bump traveling pulse solution of* (2.1) *in the case of a homogeneous network with an exponential weight distribution* $W(x) = \mathrm{e}^{-|x|/2}$. *Left: Existence curves in the* (α, a) *plane. Right: Existence curves in the* (α, c) *plane. Pulses exist only for small enough* α *(sufficiently slow adaptation). For each parameter set, there exists a stable branch (solid) of wide/fast pulses and an unstable branch (dashed) of narrow/slow pulses. In the case* $\kappa = 0.3$ *the branches annihilate at a saddle-node bifurcation at a critical value* α_c. *In the other two cases, the branches end abruptly due to the fact that the eigenvalues* $\mu_\pm$ *become complex-valued* [38].

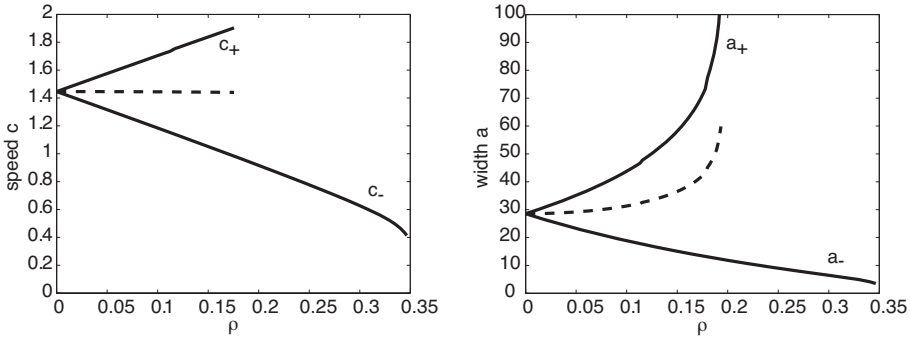

Figure 3. *Existence curves for a single bump traveling pulse solution of* (2.1) *in the case of a homogeneous network with an exponential weight distribution* $W(x) = W_\pm \mathrm{e}^{-|x|/2}$ *with* $W_\pm = 1 \pm \rho$. *Left: Plot of wave speed* $c_\pm$ *as a function of* ρ *for weight amplitudes* $W_\pm$. *The dashed curve indicates the arithmetic mean of pair* $c_\pm$. *The slower branch terminates at around* $\rho = 0.35$ *due to a saddle-node bifurcation. The faster branch terminates due to a blow-up of the pulse width. Right: Plot of pulse width* $a_\pm$ *as a function of* ρ *for weight amplitudes* $W_\pm$.

The analysis of existence in a homogeneous network also provides some insight into what happens when we include a periodic modulation of the weights according to (2.4) and (2.6). Such a modulation induces a periodic variation in the amplitude W_0 of the exponential weight distribution (2.5) between the limiting values $W_\pm = (1 \pm \rho)W_0$. This suggests that the speed of a wave in the inhomogeneous network will be bounded by the speeds $c_\pm$ of a traveling wave in the corresponding homogeneous network obtained by taking $W_0 \to W_\pm$. Note that rescaling the weight distribution in (4.9) and (4.10) is equivalent to rescaling the threshold according to $\kappa \to \kappa/(1 \pm \rho)$. In Figure 3 we plot the speeds $c_\pm$ and the corresponding pulse widths $a_\pm$ as a function of ρ. For sufficiently small ρ, the wave speed c_+ increases with ρ at approximately the same rate as c_- decreases so that their arithmetic mean remains constant. Therefore, one might expect that a periodic variation in weights would lead to a corresponding periodic

variation in wave speed such that the mean wave speed is approximately independent of ρ. However, when a pulse enters a region of enhanced synaptic weights, the resulting increase in wave speed coincides with a rapid increase in pulse width as a function of ρ. Thus, the pulse will tend to extend into neighboring regions of reduced synaptic weights and the resulting spatial averaging will counteract the speeding up of the wave. On the other hand, when a pulse enters a region of reduced synaptic weights, the reduction in wave speed coincides with a reduction in pulse width so that spatial averaging can no longer be carried out as effectively. (The effectiveness of spatial averaging will depend on the ratio of the pulse width a to the periodicity $2\pi\varepsilon$ of the weight modulation.) Hence, we expect regions where the weights are reduced to have more effect on wave propagation than regions where the weights are enhanced, suggesting that a periodic weight modulation leads to slower, narrower waves. This is indeed found to be the case, both in our perturbation analysis (section 4.2) and in our numerical simulations (section 5). Interestingly, we also find that traveling waves persist for larger values of ρ than predicted by our analysis of single bumps in homogeneous networks, although such waves tend to consist of multiple bumps (see section 5).

4.2. Inhomogeneous network with Heaviside nonlinearity. Suppose that the homogeneous network with a Heaviside nonlinearity supports a stable traveling wave solution $(U(\xi), V(\xi))^T$ of wave speed c. As shown in section 4.1, a stable/unstable pair of traveling waves exists for sufficiently slow adaptation. In order to calculate the average wave speed $\bar{c}$ for nonzero ε and ρ (see (3.17)), we first need to compute the null-vector $(A(\xi), B(\xi))^T$ of the adjoint operator $\mathcal{L}^*$ defined by (3.12). In the case of a Heaviside nonlinearity,

$$\begin{aligned} -c\frac{dA(\xi)}{d\xi} - A(\xi) + B(\xi) + \frac{\delta(\xi)}{|U'(0)|}\int_{-\infty}^{\infty} W(\xi-\xi')A(\xi')d\xi' \\ + \frac{\delta(\xi+a)}{|U'(-a)|}\int_{-\infty}^{\infty} W(\xi-\xi')A(\xi')d\xi' = 0, \\ -\frac{c}{\alpha}\frac{dB(\xi)}{d\xi} - \beta A(\xi) - B(\xi) = 0. \end{aligned} \tag{4.11}$$

For $\xi \neq 0, -a$, this has solutions of the form $(A(\xi), B(\xi)^T) = \mathbf{u}e^{-\lambda\xi}$ with associated characteristic equation $\mathbf{M}\mathbf{u} = c\lambda\mathbf{u}$ and

$$\mathbf{M} = \begin{pmatrix} 1 & -1 \\ \beta\alpha & \alpha \end{pmatrix}. \tag{4.12}$$

The eigenvalues are $\lambda = \mu_\pm = m_\pm/c$ with $m_\pm$ given by (4.4). The corresponding eigenvectors are

$$\mathbf{u}_\pm = \begin{pmatrix} 1 \\ 1 - m_\pm \end{pmatrix}. \tag{4.13}$$

The presence of the Dirac delta functions at $\xi = 0, -a$ then suggests that we take the null-solution to be of the form

$$\begin{aligned} \mathbf{V}^*(\xi) = \gamma_+\mathbf{u}_+\left[e^{-\mu_+\xi}\Theta(\xi) + \chi e^{-\mu_+(\xi+a)}\Theta(\xi+a)\right] \\ + \gamma_-\mathbf{u}_-\left[e^{-\mu_-\xi}\Theta(\xi) + \chi e^{-\mu_-(\xi+a)}\Theta(\xi+a)\right] \end{aligned} \tag{4.14}$$

with the coefficients $\gamma_\pm$ chosen such that the Dirac delta function terms that come from differentiating the null-vector appear only in the $A(\xi)$ term,

$$\gamma_+ \mathbf{u}_+ + \gamma_- \mathbf{u}_- = \begin{pmatrix} \Gamma \\ 0 \end{pmatrix}, \tag{4.15}$$

and χ is a constant yet to be determined. Taking

$$\gamma_\pm = \pm(1 - m_\mp), \tag{4.16}$$

we have $\Gamma = m_+ - m_-$.

In order to determine χ, substitute (4.14) into (4.11) to obtain the pair of equations

$$c(m_+ - m_-) = \frac{1}{|U'(0)|}(\Lambda(0) + \chi\Lambda(-a)) \tag{4.17}$$

and

$$\chi c(m_+ - m_-) = \frac{1}{|U'(-a)|}(\Lambda(a) + \chi\Lambda(0)) \tag{4.18}$$

with

$$\Lambda(\zeta) = \int_0^\infty [(1 - m_-)W(\xi + \zeta)e^{-\mu_+\xi} - (1 - m_+)W(\xi + \zeta)e^{-\mu_-\xi}]d\xi. \tag{4.19}$$

We require that (4.17) and (4.18) be consistent with the formula for $U'(\xi)$ obtained by differentiating (4.7) with respect to ξ:

$$\begin{aligned} U'(\xi) = &\frac{1 - m_-}{c(m_+ - m_-)} \int_\xi^\infty e^{\mu_+(\xi - \xi')}[W(\xi' + a) - W(\xi')]d\xi' \\ &- \frac{1 - m_+}{c(m_+ - m_-)} \int_\xi^\infty e^{\mu_-(\xi - \xi')}[W(\xi' + a) - W(\xi')]d\xi'. \end{aligned} \tag{4.20}$$

It follows that

$$|U'(0)| = -U'(0) = \frac{\Lambda(0) - \Lambda(a)}{c(m_+ - m_-)}, \quad |U'(-a)| = U'(-a) = \frac{\Lambda(0) - \Lambda(-a)}{c(m_+ - m_-)},$$

which, together with (4.17) and (4.18), imply

$$\Lambda(0) - \Lambda(a) = \Lambda(0) + \chi\Lambda(-a), \quad \chi(\Lambda(0) - \Lambda(-a)) = \Lambda(a) + \chi\Lambda(0).$$

Hence, (4.14) is a solution provided that

$$\chi = -\frac{\Lambda(a)}{\Lambda(-a)}. \tag{4.21}$$

This is also a constructive proof that the adjoint linear operator $\mathcal{L}^*$ for a Heaviside nonlinearity has a one-dimensional null-space spanned by $\mathbf{V}^*$.

Having found the null-solution (4.14), we now determine the phase function Φ_1 given by (3.16) with $f = H$. First, the constant K of (3.14) is evaluated by substituting for $(A(\xi), B(\xi))$ using (4.14) and substituting for $(U(\xi), V(\xi))$ using (4.7) and (4.8). The rather lengthy expression for K is given in the appendix. Next, we evaluate the double integral on the right-hand side of (3.16) by setting $\mathcal{D}(x) = \mathrm{e}^{ix}$ and using Fourier transforms. This gives

$$K\Phi_1\left(\frac{\phi}{\varepsilon}\right) = \frac{i}{\varepsilon}\mathrm{e}^{i\phi/\varepsilon}\int_{-\infty}^{\infty} W(x)\left[\int_{-\infty}^{\infty}\mathrm{e}^{iqx}\widetilde{A}^*(q)\widetilde{f(U)}(q+\varepsilon^{-1})\frac{\mathrm{d}q}{2\pi}\right]dx, \tag{4.22}$$

where * denotes complex conjugate and

$$\widetilde{A}(q) = \int_{-\infty}^{\infty}\mathrm{e}^{iqx}A(x)\mathrm{d}x. \tag{4.23}$$

In the case of a Heaviside nonlinearity and a pulse of width a, $f(U(\xi)) = \Theta(\xi + a) - \Theta(\xi)$, and $A(x)$ is given explicitly by the first component of the null-vector in (4.14). Taking Fourier transforms of these expressions shows that

$$\widetilde{A}(q) = -\left(1+\chi\mathrm{e}^{-iqa}\right)\left[\frac{\gamma_+}{iq-\mu_+} + \frac{\gamma_-}{iq-\mu_-}\right], \quad \widetilde{f(U)}(q) = \frac{1-\mathrm{e}^{-iqa}}{iq-0^+}. \tag{4.24}$$

If these Fourier transforms are now substituted into (4.22), we have

$$\begin{aligned} K\Phi_1\left(\frac{\phi}{\varepsilon}\right) = \frac{\mathrm{e}^{i\phi/\varepsilon}}{\varepsilon}\int_{-\infty}^{\infty} W(x)\Bigg[\int_{-\infty}^{\infty}\Bigg\{&\frac{\gamma_+(1-\mathrm{e}^{-i(q+\varepsilon^{-1})a}+\chi\mathrm{e}^{iqa}-\chi\mathrm{e}^{-ia/\varepsilon})\mathrm{e}^{iqx}}{(q+\varepsilon^{-1}+i0^+)(q-i\mu_+)} \\ &+\frac{\gamma_-(1-\mathrm{e}^{-i(q+\varepsilon^{-1})a}+\chi\mathrm{e}^{iqa}-\chi\mathrm{e}^{-ia/\varepsilon})\mathrm{e}^{iqx}}{(q+\varepsilon^{-1}+i0^+)(q-i\mu_-)}\Bigg\}\frac{\mathrm{d}q}{2\pi i}\Bigg]\mathrm{d}x. \end{aligned} \tag{4.25}$$

The resulting integral over q can be evaluated by closing the contour in the upper-half or lower-half complex q-plane depending on the sign of $x, x \pm a$. We find that there are only contributions from the poles at $q = i\mu_\pm$ with $\mu_\pm > 0$, whereas there is a removable singularity at $q = -\varepsilon^{-1} - i0^+$. Thus

$$\begin{aligned} K\Phi_1\left(\frac{\phi}{\varepsilon}\right) = &\frac{\gamma_+\mathrm{e}^{i\phi/\varepsilon}}{\varepsilon(\varepsilon^{-1}+i\mu_+)}\left[\left(1-\chi\mathrm{e}^{-ia/\varepsilon}\right)\widehat{\Omega}_+(0)+\chi\widehat{\Omega}_+(-a)-\mathrm{e}^{-ia/\varepsilon}\widehat{\Omega}_+(a)\right] \\ &+\frac{\gamma_-\mathrm{e}^{i\phi/\varepsilon}}{\varepsilon(\varepsilon^{-1}+i\mu_-)}\left[\left(1-\chi\mathrm{e}^{-ia/\varepsilon}\right)\widehat{\Omega}_-(0)+\chi\widehat{\Omega}_-(-a)-\mathrm{e}^{-ia/\varepsilon}\widehat{\Omega}_-(a)\right], \end{aligned} \tag{4.26}$$

with

$$\widehat{\Omega}_\pm(s) = \int_0^\infty W(x+s)\mathrm{e}^{-\mu_\pm x}\mathrm{d}x. \tag{4.27}$$

Taking the imaginary part of the above equation then determines the phase function $K\Phi_1$ for $\mathcal{D}(x) = \rho\sin(x)$. After a straightforward calculation, we find that

$$\begin{aligned} \frac{K}{\rho}\Phi_1\left(\frac{\phi}{\varepsilon}\right) = &(\Xi_+ + \Xi_-)\sin\left(\frac{\phi}{\varepsilon}\right) + (\Pi_+ + \Pi_-)\sin\left(\frac{\phi-a}{\varepsilon}\right) \\ &+ (\Upsilon_+ + \Upsilon_-)\cos\left(\frac{\phi}{\varepsilon}\right) + (\Psi_+ + \Psi_-)\cos\left(\frac{\phi-a}{\varepsilon}\right), \end{aligned} \tag{4.28}$$

where the explicit expressions for $\Xi_\pm, \Pi_\pm, \Upsilon_\pm, \Psi_\pm$ are given in the appendix.

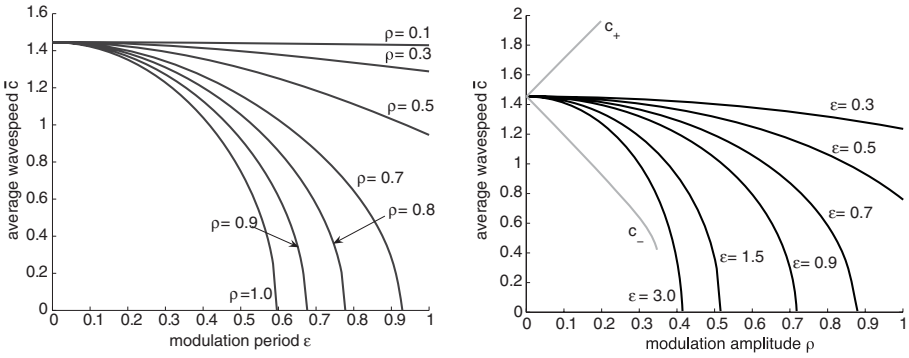

Figure 4. *Left: Average wave speed $\bar{c}$ versus ε for various values of the modulation amplitude ρ. The critical value of ε for wave propagation failure decreases as ρ increases. Right: Average wave speed $\bar{c}$ versus ρ for various values of the modulation period ε. For the sake of comparison, the speed curves previously plotted in Figure 3 for a homogeneous network are also shown (gray curves). Other parameters are $\kappa = 0.2$, $\alpha = 0.04$, and $\beta = 2.0$.*

Finally, we numerically calculate the average wave speed $\bar{c}$ by substituting (4.28) into (3.17). Note that we use the exact expression for Φ_1 that includes all higher-order terms in ε, rather than keeping only the $\mathcal{O}(1)$ term, since this gives a better estimate of the wave speed. In Figure 4 we show some example plots of $\bar{c}$ as a function of ε and ρ. It can be seen that for each choice of parameters, $\bar{c}$ is a monotonically decreasing function of ε and ρ, with $\bar{c}$ approaching the speed c of the homogeneous wave in the limits $\varepsilon \to 0$ and $\rho \to 0$. Hence, although the periodic modulation enhances the strength of connections in some regions and reduces them in others compared to the homogeneous case (see Figure 1), the net result is an effective reduction in wave speed. This is consistent with our discussion of Figure 3 in section 4.1, where we used a spatial averaging argument combined with the observation that faster waves are wider to infer that regions of reduced synaptic weights affect wave propagation more than regions of enhanced weights. Figure 4 also suggests that for sufficiently small ε there exists a traveling wave solution for all ρ, $0 \leq \rho < 1$, whereas for larger values of ε there is a critical value ρ_c beyond which propagation failure occurs. That is, $\bar{c} \to 0$ as $\rho \to \rho_c$, and this critical value decreases as the periodicity ε of the inhomogeneity increases. Similarly, for sufficiently large ρ there exists a critical period ε_c such that $\bar{c} \to 0$ as $\varepsilon \to \varepsilon_c$. Analogous results were previously obtained for traveling fronts in a scalar equation [3]. It is important to bear in mind that the calculation of $\bar{c}$ is based on the $\mathcal{O}(\varepsilon)$ perturbation analysis of section 3, although we do include higher-order terms in the calculation of Φ_1. This raises the important question as to whether or not our analysis correctly predicts wave propagation failure in the full system, given that $\bar{c}$ tends to approach zero at relatively large values of ε and ρ. Moreover, the perturbation analysis does not determine the stability of the wave so that propagation failure could occur due to destabilization of the wave for $\rho < \rho_c$ or $\varepsilon < \varepsilon_c$. This will indeed turn out to be the case as we show in section 5, where we present numerical solutions of (2.1) and provide further insight into the mechanism for propagation failure.

4.3. Smooth nonlinearities and higher-order corrections. In the case of smooth nonlinearities, the Fourier transforms $\widetilde{A}(q)$ and $\widetilde{f(U)}(q)$ appearing in (4.22) no longer have simple

poles, and in general Φ_1 will consist of exponentially small terms. It follows that Φ_1 may be less significant than the $\mathcal{O}(\varepsilon^2)$ terms ignored in the perturbation expansion of (3.4). Therefore, following the treatment of traveling fronts [3], we carry out a perturbation expansion of system (3.4) to $\mathcal{O}(\varepsilon^2)$. This yields an equation for (u_2, v_2) of the form

$$-\frac{\partial}{\partial\tau}\begin{pmatrix} u_2(\xi,\tau) \\ v_2(\xi,\tau)/\alpha \end{pmatrix} + \mathcal{L}\begin{pmatrix} u_2(\xi,\tau) \\ v_2(\xi,\tau) \end{pmatrix} = -\phi_2'(\tau)\begin{pmatrix} U'(\xi) \\ V'(\xi)/\alpha \end{pmatrix} - \phi_1'(\tau)\begin{pmatrix} u_1'(\xi) \\ v_1'(\xi)/\alpha \end{pmatrix} + \begin{pmatrix} h_2(\xi,\frac{\phi}{\varepsilon}) \\ 0 \end{pmatrix}, \tag{4.29}$$

where $\mathcal{L}$ is defined by (3.9) and

$$\begin{aligned} h_2\left(\xi,\frac{\phi}{\varepsilon}\right) &= -\frac{1}{2}\int_{-\infty}^{\infty} W(\xi-\xi')f''(U(\xi'))[u_1(\xi')]^2 \mathrm{d}\xi' \\ &\quad - \int_{-\infty}^{\infty} \mathcal{D}\left(\frac{[\xi'+\phi]}{\varepsilon}\right) W'(\xi-\xi')f'(U(\xi'))u_1(\xi')\mathrm{d}\xi' \\ &\quad + \int_{-\infty}^{\infty} \mathcal{D}\left(\frac{[\xi'+\phi]}{\varepsilon}\right) W(\xi-\xi')[f'(U(\xi'))u_1'(\xi') + f''(U(\xi'))U'(\xi')u_1(\xi)]\mathrm{d}\xi'. \end{aligned} \tag{4.30}$$

The existence of a bounded solution requires the solvability conditions (3.13) and

$$K\phi_2'(\tau) + L(\tau)\phi_1'(\tau) = \int_{-\infty}^{\infty} A(\xi)h_2\left(\xi,\frac{\phi}{\varepsilon}\right)\mathrm{d}\xi, \tag{4.31}$$

where

$$L(\tau) = \int_{-\infty}^{\infty}\left[A(\xi)\frac{\partial u_1(\xi,\tau)}{\partial\xi} + \alpha^{-1}B(\xi)\frac{\partial v_1(\xi,\tau)}{\partial\xi}\right]\mathrm{d}\xi. \tag{4.32}$$

In order to evaluate the solvability condition (4.31), we must first determine $u_1(\xi,\phi/\varepsilon)$ from (3.8). If we choose $\mathcal{D}(x)$ to be a sinusoid, then $u_1(\xi,\phi/\varepsilon)$ will include terms that are proportional to $\sin(\phi/\varepsilon)$ and $\cos(\phi/\varepsilon)$. Thus substituting $u_1(\xi/\phi/\varepsilon)$ into (4.30) will generate terms of the form $\sin^2(\phi/\varepsilon)$ and $\cos^2(\phi/\varepsilon)$ due to the quadratic term in u_1. Using the identities $2\sin^2(x) = 1-\cos(2x)$ and $2\cos^2(x) = 1+\cos(2x)$ implies that there will be an ε-independent contribution to ϕ_2'. Thus for smooth nonlinearities we find that

$$\frac{\mathrm{d}\phi}{\mathrm{d}\tau} = c + \varepsilon^2 C_2(c) + D_2\left(c,\frac{\phi}{\varepsilon}\right), \tag{4.33}$$

where C_2 is independent of ε and D_2 is exponentially small in ε. Equation (4.33) is the second-order version of the phase equation (3.15) in cases where the first-order term is exponentially small. Again, the condition for wave propagation failure is that the right-hand side of (4.33) vanishes for some ϕ.

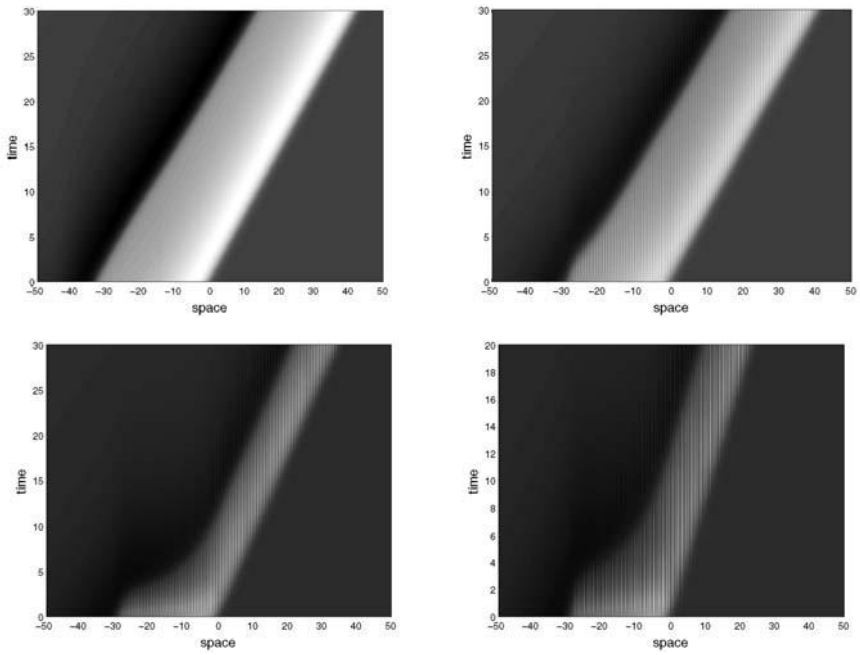

Figure 5. *Top left: Stable traveling pulse for a homogeneous network with exponential weight function (2.5) and fixed parameters $\kappa = 0.2$, $\beta = 2.0$, and $\alpha = 0.04$ (for all plots). Top right: Corresponding traveling pulse for an inhomogeneous network with weight distribution (2.4) and a sinusoidal modulation with $\varepsilon = 0.1$ and $\rho = 0.3$. We see rippling in the interior of the pulse. Bottom left: Using a more severe inhomogeneity, $\rho = 0.8$, leads to rippling in the active region of the pulse such that now the interior crosses below threshold periodically. Bottom right: For $\rho = 1$, the effect is even more severe.*

5. Numerical results. Our perturbation analysis suggests that as ρ increases, the mean speed of a traveling pulse decreases, and, at least for sufficiently large periods ε of the weight modulation, wave propagation failure can occur. However, one of the simplifying assumptions of our analysis is that the perturbed solution is still a traveling pulse; that is, at each time t there is a single bounded interval over which the solution is above threshold, which is equal to the pulse width a of the homogeneous pulse in the limit $\varepsilon \to 0$. The inclusion of a periodic modulation of a monotonically decreasing weight function suggests that the assumption of a single pulse solution may break down as ρ increases toward unity. In this section we explore this issue by numerically solving the full system of equations (2.1) in the case of a Heaviside nonlinearity ($f = H$), and we show that wave propagation can persist in the presence of multiple bumps. Numerical simulations of propagating pulses are carried out using MATLAB. Initial conditions are taken to be solutions to the homogeneous problem given by (4.7) and (4.8). We then apply backward Euler to the linear terms and forward Euler with a Riemann sum to the convolution operator. Space and time discretizations are taken to be $\Delta t = 0.01$ and $\Delta x = 0.01$. The numerical results are stable with respect to reductions in the mesh size provided that $\Delta x \ll 2\pi\varepsilon$. Finally, boundary points evolve freely, rather than by prescription, and the domain size is wide enough so that pulses are unaffected by boundaries.

In Figure 5 we show some examples of traveling pulse solutions in an inhomogeneous

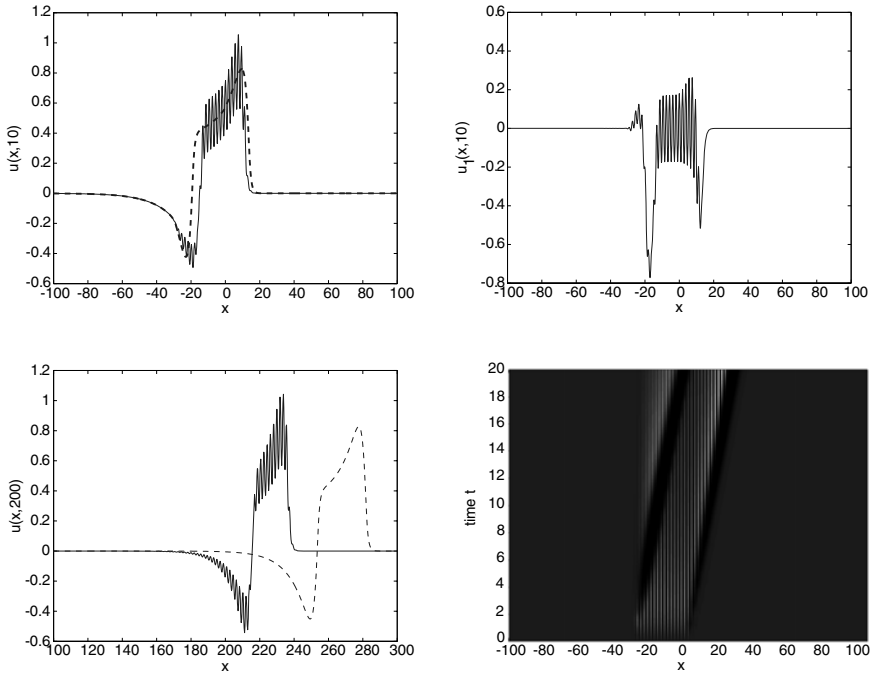

Figure 6. *Top left: Comparison of the wave profiles at time $t = 10$ for the homogeneous (dashed line) and the inhomogeneous (solid line) cases. Here, the parameters are $\kappa = 0.2$, $\beta = 2.0$, $\alpha = 0.04$, $\varepsilon = 0.3$, and $\rho = 0.3$. Including periodic modulation clearly thins the pulse as we see its profile fits within that of the homogeneous medium. Top right: Subtraction of the homogeneous solution from the inhomogeneous solution at time $t = 10$. We see here an approximation of $u_1(x,t)$, from our perturbation analysis. The dominant detail is the oscillations with period $2\pi\varepsilon$. Bottom left: Profile comparison at $t = 200$. The homogeneous solution has moved well ahead of the inhomogeneous solution due to speed difference. Bottom right: Pseudocolor plot of $u_1(x,t)$, obtained by subtracting the homogeneous solution from the inhomogeneous solution. The dark bands delineate the underlying homogeneous solution.*

network with weight distribution given by (2.4), (2.5), and (2.6). The period of the modulation is taken to be relatively small ($\varepsilon = 0.1$). We take as initial conditions the invariant profile for the corresponding homogeneous case, obtained by solving in traveling wave coordinates for the $\varepsilon = 0$ case, which gives (U, V) in (4.7) and (4.8). It can be seen from Figure 5 that as the amplitude ρ of the periodic modulation increases the wave slows down and narrows, which is consistent with our perturbation analysis. Moreover, the network activity develops a rippling within the interior of the pulse, as can be seen more clearly in Figure 6, where we directly compare the numerical solution of the homogeneous network with that of a corresponding inhomogeneous network. Superimposing the two wave profiles at an early time ($t = 10$) illustrates the thinning of the pulse and shows that the difference between the two wave profiles is an oscillatory component of approximately zero mean, which would correspond to u_1 in our perturbation analysis. Similarly, comparing the two wave profiles at a later time ($t = 200$) illustrates the slowing down of the pulse. As ρ increases, the amplitude of the ripples also increases such that, for sufficiently large ρ, activity at any given time t alternates between superthreshold and subthreshold domains. This is illustrated in Figure 7. A closer

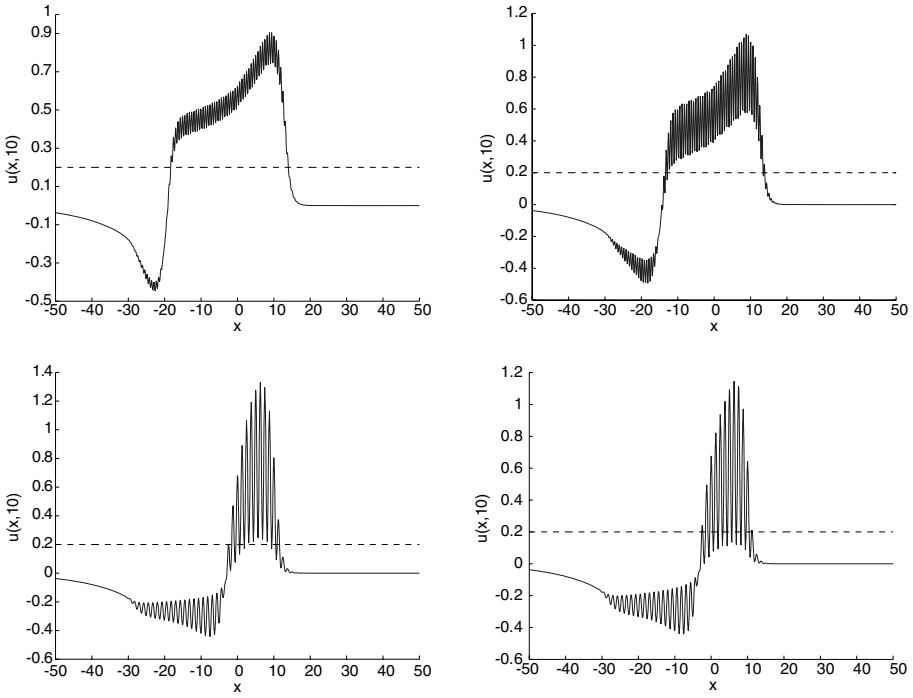

Figure 7. *A collection of traveling wave profiles taken at time $t = 10$ for various amplitudes ρ and $\varepsilon = 0.1$. Other parameters are as in Figure 5. Top left: $\rho = 0.1$. Notice that rippling of the activity does not dip below threshold within the pulse interior. Top right: $\rho = 0.3$. Rippling crosses below threshold at the edges of the pulse creating a couple of bumps. Bottom left: $\rho = 0.7$. Rippling now generates a multiple bump solution. Bottom right: $\rho = 0.8$.*

look at the time evolution of the wave profile when the rippling is above threshold within the interior of the pulse shows that individual ripples are nonpropagating and transient, with new ripples appearing at the leading edge of the wave and subsequently disappearing at the trailing edge; see Figure 8. Interestingly, such behavior persists for large ρ when the ripples cross below threshold within the interior of the pulse; see Figure 9. Now the pulse actually consists of multiple bumps, each of which is nonpropagating but only exists for a finite length of time. The sequence of events associated with the emergence and disappearance of these bumps generates a wave envelope that behaves very much like a single coherent traveling pulse. Hence, for sufficiently short wavelength oscillatory modulations of the weight distribution, the transient multiple bump solution can be homogenized and treated as a single traveling pulse. However, the wave speed of the multiple bump solution differs from that predicted using perturbation theory. This is shown in Figure 10, where we compare the $\bar{c}$ versus ε curves obtained using perturbation theory with data obtained by directly simulating the full system (2.1). In the case of small ρ, a stable (single bump) traveling pulse persists for all ε, $0 \leq \varepsilon < 1$, and $\bar{c}$ is a monotonically decreasing function of ε. Moreover, the numerically calculated value of the average wave speed agrees quite well with the first-order perturbation analysis. On the other hand, for large values of ρ, such agreement no longer holds, and we find that the traveling pulse destabilizes at a critical value of ε that is well below the value predicted from

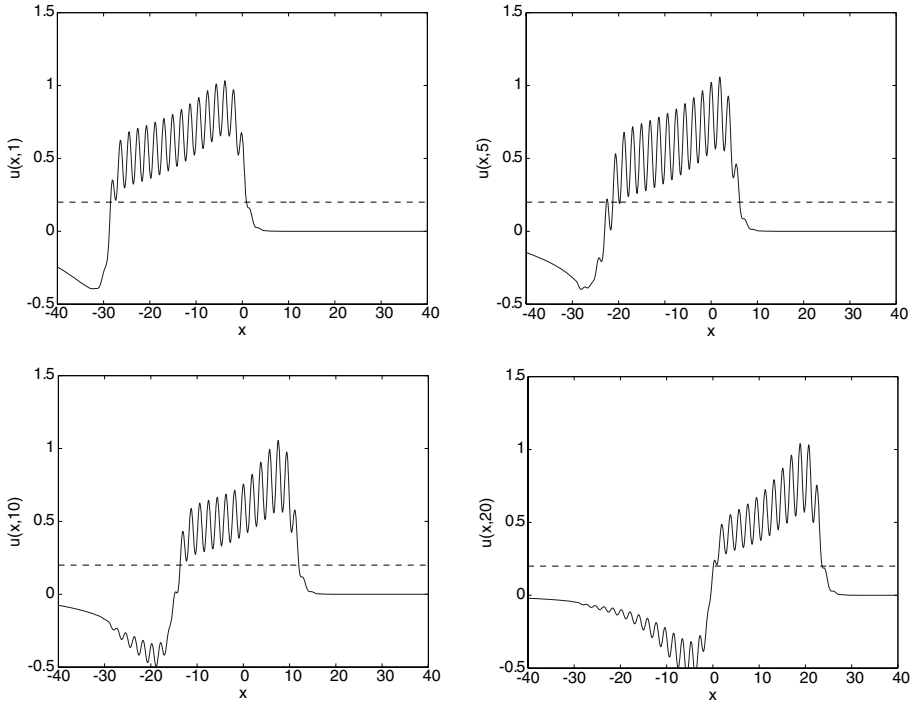

Figure 8. *A series of snapshots in time of a traveling pulse for* $\kappa = 0.2$, $\beta = 2.0$, $\alpha = 0.04$, $\rho = 0.3$, $\varepsilon = 0.3$. *The interior of the pulse consists of nonpropagating, transient ripples. The disappearance of ripples at one end and the emergence of new ripples at the other end generate the propagation of activity. Notice that the solitary wave profile is not invariant, reflecting the underlying inhomogeneity. the perturbation analysis.

In Figure 11 we compare the behavior of traveling pulses for short wavelength ($\varepsilon = 0.2$) and long wavelength ($\varepsilon = 0.9$) periodic modulation. The amplitude is taken to be relatively large, $\rho = 0.8$, so that multiple bump solutions occur. We see that for long wavelength modulation, the initial pulse transitions into a nonpropagating multiple bump solution, with successive bumps disappearing sequentially and no additional bumps being created; the failure to generate new bumps means that activity cannot propagate. We can see this more clearly when examining a series of snapshots of the pulse/bump profiles in Figure 12. In conclusion, one way to understand wave propagation failure for large ρ is to note that a large amplitude periodic weight modulation can generate a pinned multiple bump solution. However, in the absence of any inhibition, such a multiple bump solution is unstable [26, 37]. In the case of small ε, destabilization of the bumps generates new bumps at the leading edge of the bump such that activity can propagate in a coherent fashion. Increasing ε prevents the creation of new bumps and propagation failure occurs.

The effect of the periodic weight modulation on a different type of solution is illustrated in Figure 13, where, motivated by a prior numerical study of multiple bumps [25], the initial condition of the network is taken to consist of three bumps,

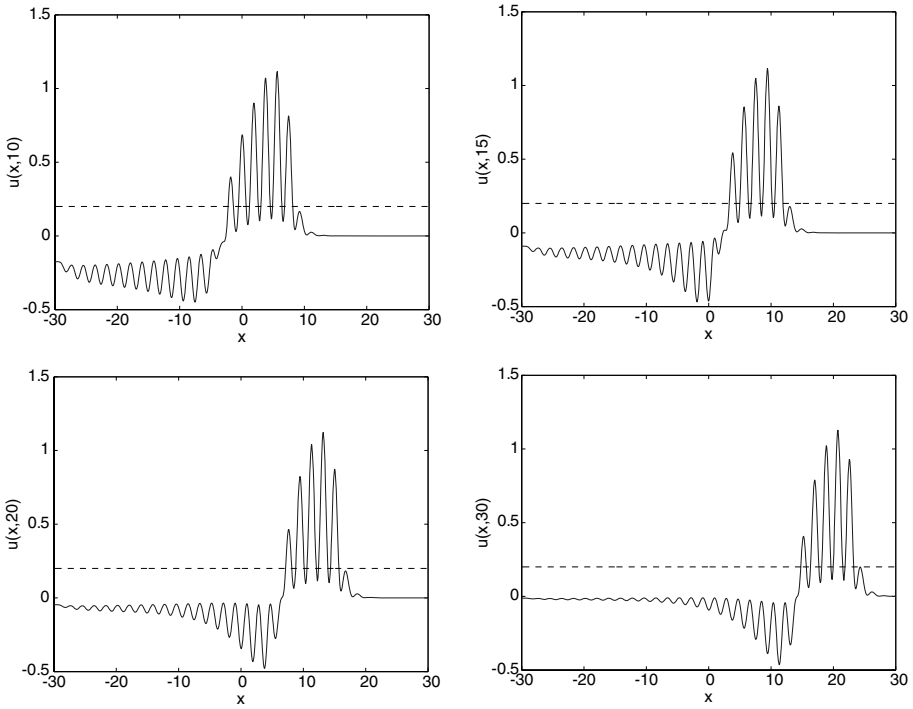

Figure 9. *A series of snapshots in time of the "pulse" profile for* $\kappa = 0.2$, $\beta = 2.0$, $\alpha = 0.04$, $\rho = 0.8$, $\varepsilon = 0.3$. *The solitary pulse corresponds to the envelope of a multiple bump solution, in which individual bumps are nonpropagating and transient. The disappearance of bumps at one end and the emergence of new bumps at the other end generate the propagation of activity. Notice that the solitary wave profile is not invariant, reflecting the underlying inhomogeneity. Top left:* $t = 10$. *Top right:* $t = 15$. *Bottom left:* $t = 20$. *Bottom right:* $t = 30$. *Clicking on the above images displays the accompanying movie* (69921_02.avi [1.9MB]).

$$u(x,0) = \sum_{j=-1}^{1} \cos\left(\frac{x}{\varepsilon}\right) \exp\left(-\left(\frac{0.1(x - j \cdot 20)}{\varepsilon}\right)^2\right). \tag{5.1}$$

Each initial bump generates a pair of left and right moving fronts. In the homogeneous case, we see that collision of left and right moving waves results in a bidirectional front. That is, the region within the interior of the boundary formed by the two outermost fronts becomes superthreshold. In the inhomogeneous case, the collision of the waves is insufficient to maintain activity across this region, and one finds a pair of counterpropagating pulses.

6. Discussion. In this paper we analyzed wave propagation in an excitatory neural network treated as a periodic excitable medium. The periodicity was introduced as an inhomogeneous periodic modulation in the long-range synaptic connections and was motivated by the existence of patchy horizontal connections in the cerebral cortex. We showed that for small amplitude, short wavelength periodic modulation the main effect of the inhomogeneity is to slow down a traveling pulse, and the mean speed of the pulse can be estimated quite well using perturbation theory. In the case of large amplitude modulation, a stable traveling pulse still exists for sufficiently small ε, but now the pulse is the envelope of a multiple bump

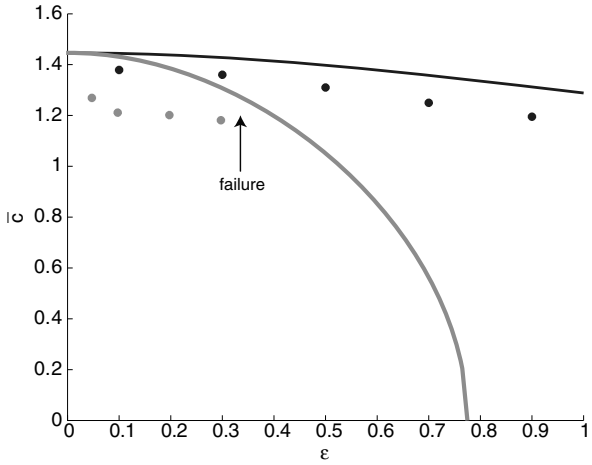

Figure 10. *Comparison of perturbation theory with direct numerical simulations. Continuous curves show average wave speed $\bar{c}$ as a function of ε obtained using perturbation theory. Data points are the corresponding wave speeds determined from numerically solving (2.1). In the case of low amplitude modulation ($\rho = 0.3$, dark curve) a stable traveling pulse persists for all ε, $\varepsilon < 1$, whereas for large amplitude modulation ($\rho = 0.8$, light curve), wave propagation failure occurs as ε increases.*

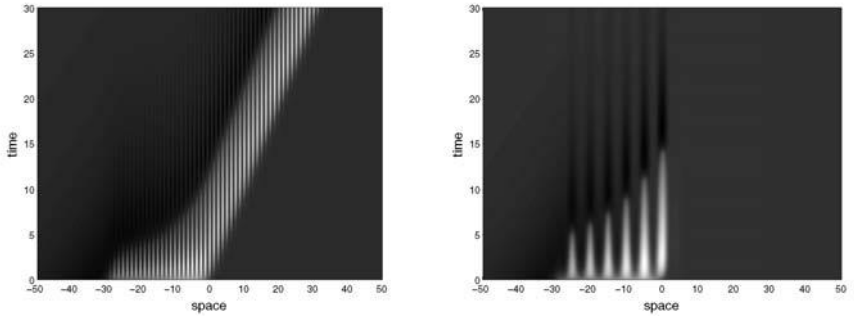

Figure 11. *Comparison of traveling pulses in the case of short and long wavelength periodic modulation with $\rho = 0.8$ and all other parameters as in Figure 5. Left: For short wavelength modulation ($\varepsilon = 0.2$) the traveling pulse shrinks and slows but does not annihilate. Right: For long wavelength modulation ($\varepsilon = 0.9$) wave propagation failure occurs. The initial pulse transitions into a collection of multiple equal width stationary bumps which are unstable.*

solution in which individual bumps are unstable and transient. Wave propagation arises via the appearance (disappearance) of bumps at the leading (trailing) edge of the pulse. As ε increases, wave propagation failure occurs due to the fact that there is insufficient activity to generate new bumps.

Although the existence of multiple bump traveling "pulses" is interesting from a dynamical systems perspective, it is less clear whether such solutions can be observed in real neural tissue. One of the biological limitations of the integrodifferential equations used in this and other studies is that, although these equations support traveling waves that have speeds consistent with neurophysiology, the pulses tend to be too wide. That is, taking the range of synaptic connections to be 1 mm, the width of a stable pulse tends to vary between 5–30

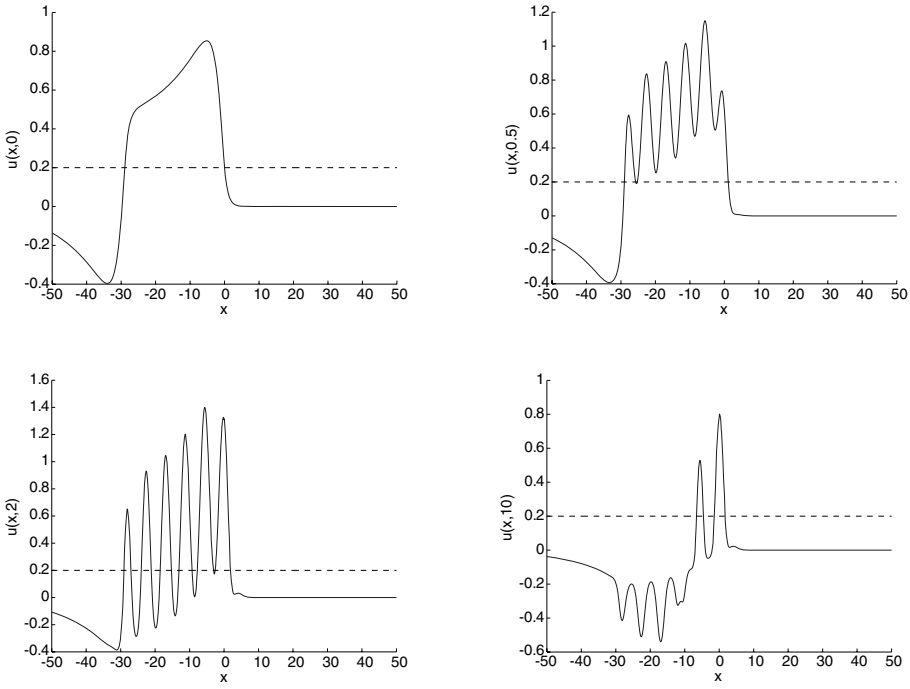

Figure 12. *A series of snapshots in time of the "pulse" profile for the inhomogeneous network with* $\kappa = 0.2$, $\beta = 2.0$, $\alpha = 0.04$, $\rho = 0.8$, $\varepsilon = 0.9$. *Top left: The initial wave profile, which is taken to be the invariant wave profile* U *of the homogeneous network. Top right: Shortly after the simulation begins* ($t = 0.5$), *the interior of the pulse develops ripples such that the active region contains a subregion for which activity is subthreshold. Bottom left: At time* $t = 2$ *a multiple bump profile has emerged. We can really see here how a multiple bump solution, as defined by multiple neighboring standing profiles, emerges from the pulse profile of* $t = 0$. *Bottom right: Collapse of the pulse interior occurs due to the disappearance of the unstable bumps. Since no new bumps emerge, there is no propagating activity. Clicking on the above images displays the accompanying movie* (69921_03.avi [1.1MB]).

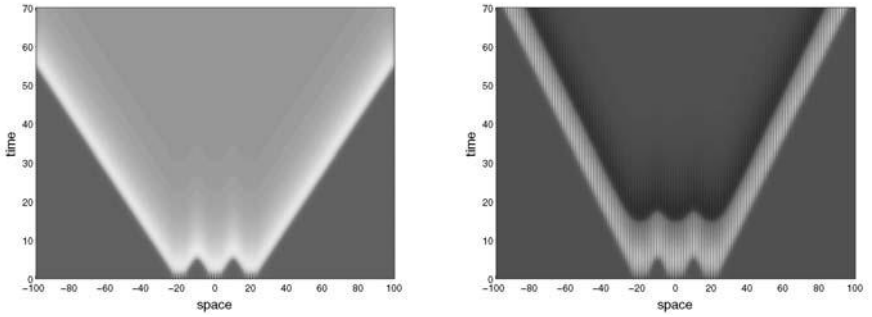

Figure 13. *Left: In the case of a homogeneous network, a three bump initial condition evolves into a bidirectional front following the collision of left and right traveling waves. The parameters are* $\kappa = 0.2$, $\beta = 2.0$, $\alpha = 0.04$. *Right: In the corresponding inhomogeneous network with* $\varepsilon = 0.2$ *and* $\rho = 0.8$, *the collision of left and right traveling waves results in a pair of counterpropagating pulses. Here the modulated synaptic interactions are insufficient to maintain activity in the region between the two pulses.*

mm (see Figure 2), whereas waves in slices tend to be only 1 mm wide [31]. More realistic widths and wave speeds could be generated by taking the effective range of synaptic connections to be a few hundred μ m, that is, by assuming that the predominant contribution to synaptic excitability is via local circuitry rather than via long-range patchy horizontal connections. However, inhomogeneities occurring at smaller spatial scales are unlikely to exhibit any periodic structure.

Irrespective of these particular issues, our analysis raises a more general point that would be interesting to pursue experimentally; namely, is it possible to detect the effects of network inhomogeneities by measuring the properties of traveling waves? Signatures of such inhomogeneities would include time-dependent rippling of the wave profile and variations in wave speed. However, such features may not be detectable given the current resolution of microelectrode recordings.

Appendix. In this appendix we present the explicit parameter-dependent expressions for the various coefficients appearing in the solution of the phase function Φ_1, (4.28). First, the constants premultiplying the periodic functions on the right-hand side of (4.28) are as follows:

$$\Xi_\pm = \frac{\gamma_\pm}{1+\mu_\pm^2\varepsilon^2}\left[\frac{1}{2(1+\mu_\pm)}+\frac{\chi}{2}\left(\frac{\mathrm{e}^{-a}-\mathrm{e}^{-\mu_\pm a}}{\mu_\pm-1}+\frac{\mathrm{e}^{-\mu_\pm a}}{\mu_\pm+1}\right)\right],$$

$$\Pi_\pm = \frac{\gamma_\pm}{1+\mu_\pm^2\varepsilon^2}\left[-\frac{\chi}{2(1+\mu_\pm)}-\frac{\mathrm{e}^{-a}}{2(\mu_\pm+1)}\right],$$

$$\Upsilon_\pm = \frac{\gamma_\pm}{1+\mu_\pm^2\varepsilon^2}\left[-\frac{\mu_\pm\varepsilon}{2(1+\mu_\pm)}-\frac{\chi\mu_\pm\varepsilon}{2}\left(\frac{\mathrm{e}^{-a}-\mathrm{e}^{-\mu_\pm a}}{\mu_\pm-1}+\frac{\mathrm{e}^{-\mu_\pm a}}{\mu_\pm+1}\right)\right],$$

$$\Psi_\pm = \frac{\gamma_\pm}{1+\mu_\pm^2\varepsilon^2}\left[\frac{\chi\mu_\pm\varepsilon}{2(1+\mu_\pm)}+\frac{\mu_\pm\varepsilon\mathrm{e}^{-a}}{2(1+\mu_\pm)}\right].$$

Second, the constant scaling factor K on the left-hand side of (4.28) is determined by substituting (4.7), (4.8), and (4.14) into (3.14). Using the fact that the null-vector is zero for $\xi<-a$, we can expand the integral in terms of definite integrals of exponential products with the $\mathcal{M}_\pm(\xi)$ functions

$$\begin{aligned}
K = {} & [\gamma_+(1-m_-)(1+\chi e^{-\mu_+ a})(1-\alpha^{-1}\beta^{-1}(1-m_+)^2)]\int_0^\infty e^{-\mu_+\xi}\mathcal{M}'_+(\xi)\mathrm{d}\xi \\
& + [\gamma_-(1-m_-)(1+\chi e^{-\mu_- a})(1+\alpha^{-1}\beta^{-1}(m_+-1)(1-m_-))]\int_0^\infty e^{-\mu_-\xi}\mathcal{M}'_+(\xi)\mathrm{d}\xi \\
& - [\gamma_+(1-m_+)(1+\chi e^{-\mu_+ a})(1+\alpha^{-1}\beta^{-1}(m_--1)(1-m_+))]\int_0^\infty e^{-\mu_+\xi}\mathcal{M}'_-(\xi)\mathrm{d}\xi \\
& - [\gamma_-(1-m_+)(1+\chi e^{-\mu_- a})(1-\alpha^{-1}\beta^{-1}(1-m_-)^2)]\int_0^\infty e^{-\mu_-\xi}\mathcal{M}'_-(\xi)\mathrm{d}\xi \\
& + \chi[\gamma_+ e^{-\mu_+ a}(1-m_-)(1-\alpha^{-1}\beta^{-1}(1-m_+)^2)]\int_{-a}^0 e^{-\mu_+\xi}\mathcal{M}'_+(\xi)\mathrm{d}\xi \\
& + \chi[\gamma_- e^{-\mu_- a}(1-m_-)(1+\alpha^{-1}\beta^{-1}(m_+-1)(1-m_-))]\int_{-a}^0 e^{-\mu_-\xi}\mathcal{M}'_+(\xi)\mathrm{d}\xi
\end{aligned}$$

$$- \chi[\gamma_+ e^{-\mu_+ a}(1-m_+)(1+\alpha^{-1}\beta^{-1}(m_- - 1)(1-m_+))] \int_{-a}^{0} e^{-\mu_+ \xi}\mathcal{M}'_-(\xi)\mathrm{d}\xi$$
$$- \chi[\gamma_- e^{-\mu_- a}(1-m_+)(1-\alpha^{-1}\beta^{-1}(1-m_-)^2)] \int_{-a}^{0} e^{-\mu_- \xi}\mathcal{M}'_-(\xi)\mathrm{d}\xi.$$

The individual integrals can be computed as follows:

$$\int_0^\infty e^{-\mu_\pm \xi}\mathcal{M}'_\pm(\xi)\mathrm{d}\xi = \frac{e^{-a}-1}{2c(m_+-m_-)(\mu_\pm+1)^2},$$
$$\int_0^\infty e^{-\mu_+ \xi}\mathcal{M}'_-(\xi)\mathrm{d}\xi = \frac{e^{-a}-1}{2c(m_+-m_-)(\mu_-+1)(\mu_++1)},$$
$$\int_0^\infty e^{-\mu_- \xi}\mathcal{M}'_+(\xi)\mathrm{d}\xi = \frac{e^{-a}-1}{2c(m_+-m_-)(\mu_++1)(\mu_-+1)},$$

and

$$\int_{-a}^{0} e^{-\mu_\pm \xi}\mathcal{M}'_\pm(\xi)\mathrm{d}\xi = \frac{1}{2c(m_+-m_-)}\left\{\frac{a}{(\mu_\pm-1)} + \frac{1-e^{(\mu_\pm-1)a}}{(\mu_\pm-1)^2} + \frac{e^{-a}(e^{(\mu_\pm+1)a}-1)}{(\mu_\pm+1)^2} - \frac{a}{2(\mu_\pm+1)}\right\},$$

$$\int_{-a}^{0} e^{-\mu_+ \xi}\mathcal{M}'_-(\xi)\mathrm{d}\xi = \frac{1}{2c(m_+-m_-)}\left\{\frac{1-e^{-(\mu_- - \mu_+)a}}{(\mu_- - \mu_+)(\mu_- - 1)} - \frac{e^{(\mu_+-1)a}-1}{(\mu_+-1)(\mu_--1)} + \frac{e^{\mu_+ a}-e^{-a}}{(\mu_++1)(\mu_-+1)} - \frac{1-e^{-(\mu_- - \mu_+)a}}{(\mu_-+1)(\mu_- - \mu_+)}\right\},$$

$$\int_{-a}^{0} e^{-\mu_- \xi}\mathcal{M}'_+(\xi)\mathrm{d}\xi = \frac{1}{2c(m_+-m_-)}\left\{\frac{1-e^{-(\mu_+ - \mu_-)a}}{(\mu_+-1)(\mu_+ - \mu_-)} - \frac{e^{(\mu_- -1)a}-1}{(\mu_+-1)(\mu_--1)} + e^{-a}\frac{e^{(\mu_-+1)a}-1}{(\mu_++1)(\mu_-+1)} - \frac{1-e^{-(\mu_+ - \mu_-)a}}{(\mu_++1)(\mu_+ - \mu_-)}\right\}.$$

Localized Pattern Formation with a Large-Scale Mode: Slanted Snaking*

J. H. P. Dawes†

Abstract. Steady states of localized activity appear naturally in uniformly driven, dissipative systems as a result of subcritical instabilities. In the usual setting of an infinite domain, branches of such localized states bifurcate at the subcritical "pattern-forming" instability and intertwine in a manner often referred to as "homoclinic snaking." In this paper we consider an extension of this paradigm where, in addition to the pattern-forming instability (with nonzero wavenumber), a large-scale neutral mode exists, having zero growth rate at zero wavenumber. Such a situation naturally arises in the presence of a conservation law; we give examples of physical systems in which this arises, in particular, thermal convection in a horizontal fluid layer with a vertical magnetic field. We introduce a novel scaling that allows the derivation of a nonlocal Ginzburg–Landau equation to describe the formation of localized states. Our results show that the existence of the large-scale mode substantially enlarges the region of parameter space where localized states exist and are stable.

Key words. homoclinic snaking, pattern formation, bifurcation

1. Introduction.

Recent decades have seen a sustained level of interest in systems whose response is spatially localized despite a spatially uniform applied forcing. One broad class of systems which display such localized states of activity is both driven and strongly dissipative, and displays "pattern-forming" (also called Turing) instabilities at which spatially homogeneous solutions become unstable and spatial structure appears [11, 19, 25]. It is widely appreciated that, while supercritical pattern-forming instabilities lead to spatially extended (and almost periodic) structures, subcritical instabilities robustly lead to localized patterns [21, 37, 8, 30, 5]. Localized steady-state pattern formation has been observed in a huge variety of experiments and models for physical, chemical, and biological systems, for example, neural dynamics [23], elastic buckling [20], and nonlinear optics [1, 35]. In other cases, for example, vertically vibrated granular media [34], the localized pattern is oscillatory in nature. In many problems the existence of the localized states can be heuristically explained by an energetic argument: at a critical parameter value, often called the "Maxwell point," the system has no energetic preference between the "ground state," corresponding to no pattern, and the patterned state. Once a localized state has been formed there is a locking between the phase of the pattern and the phase of the envelope which allows the localized state to persist over a finite range of parameter values, as first remarked on by Pomeau [26].

Mathematically, much has been done to investigate canonical model problems displaying subcritical pattern-forming instabilities and therefore localized patterns. One such model equation is the one-dimensional Swift–Hohenberg equation

$$w_t = [r - (1 + \partial_{xx}^2)^2]w + N(w) \tag{1.1}$$

(writing ∂_{xx}^2 as a convenient abbreviation for $\partial^2/\partial x^2$), which has been studied in detail in the particular cases $N(w) = sw^2 - w^3$ and $N(w) = sw^3 - w^5$, where $s > 0$ controls the subcritical nature of the pattern-forming instability. These choices for $N(w)$ are commonly referred to as the "quadratic-cubic" and "cubic-quintic" cases, respectively. Careful investigations of these localized states have been carried out by several authors including Sakaguchi and Brand [30] and Burke and Knobloch [5]. Many different localized and front-like solutions between steady states have been reported. For our present purposes, we note that the most obvious consequence of a subcritical bifurcation is the existence of stable localized states in a small subregion between the linear instability of the state $w(x, t) \equiv 0$ at $r = 0$ and the saddle-node bifurcation at $r = r_{sn} < 0$ on the primary branch of uniform amplitude pattern. The width of this region is exponentially small in the small amplitude parameter ε employed in the standard Ginzburg–Landau multiple-scales expansion near $r = 0$ [22]. Moreover, since the usual "spatial dynamics" analysis assumes an infinitely wide domain $-\infty < x < \infty$, localized states containing arbitrary numbers of pattern bumps are simultaneously stable over almost all of this region.

Concentrating on the cubic-quintic case, a final widely appreciated, and well-understood, point is that two distinct pairs of branches of localized states persist over the locking region. One pair corresponds to locking at relative phases of $\phi = 0$ and $\phi = \pi$ (these are related by the $w \to -w$ symmetry present in the cubic-quintic case) and the other pair to the relative phases $\phi = \pi/2$ and $\phi = -\pi/2$, similarly related by symmetry. The first pair corresponds to localized states that are even about the midpoint, and the second pair corresponds to states that are odd about the midpoint. This robust phase-locking is exactly the "locking" intuitively understood by Pomeau.

Intriguingly, the spatial dynamics analysis shows that these branches of localized states, that generically bifurcate from $r = 0$, exist in $r < 0$ down to saddle-node bifurcations slightly below the Maxwell point. They then undergo a sequence of repeated and intertwined saddle-node bifurcations on alternate sides of the Maxwell point; after each pair of saddle-node bifurcations the localized state gains an extra pair of bumps. In a finite domain the branches terminate in bifurcations from the uniform amplitude pattern located near $r = 0$ and near the saddle-node bifurcation at $r = r_{sn}$. In an infinite domain the process of saddle-node bifurcations and gaining extra bumps continues ad infinitum. This sequence of repeated saddle-node bifurcations in an infinite domain is known as "homoclinic snaking" since all the states approach $w = 0$ as $x \to \pm\infty$. A brief explanation of the "homoclinic snaking" phenomenon is that at some parameter value $r = r_{mx}$, $r_{sn} < r_{mx} < 0$, there exists a "Maxwell point" where there exists a stationary front between the trivial solution $w = 0$ and the uniform spatially periodic pattern. In the corresponding spatial dynamical system this heteroclinic connection becomes a heteroclinic tangle when normal form symmetry is broken. Within the heteroclinic tangle we can identify intersections of the stable and unstable manifolds of $w = 0$;

these correspond to spatial homoclinic orbits that comprise the "homoclinic snaking" and they can be shown to persist near $r = r_{mx}$, rather than existing only exactly at $r = r_{mx}$.

In a large but finite domain (with periodic boundary conditions), it appears that localized states persist and continue to exhibit intertwined wiggles around the Maxwell point [18]. In a finite domain they are not truly "localized" since the domain is bounded, but they clearly converge to the infinite domain solutions as the domain size $L \to \infty$. A detailed discussion of persistence and the evolution of the bifurcation structure with domain size will be presented elsewhere.

In this paper we consider a class of pattern-forming systems that differs from (1.1) in a fundamental way; a neutrally stable long-wavelength mode exists in addition to the pattern-forming instability at wavenumber $k = 1$. Our broad motivation comes from three physical situations: thermal convection in the presence of a vertical magnetic field [13, 10], vertically vibrated granular media [17, 34], and thin films [16]. In all three cases the large-scale mode arises due to the existence of a conserved quantity in the dynamics. In magnetoconvection this is the total flux of magnetic field through the fluid layer; in the granular and thin film cases the conserved quantity is the total mass. We remark that such a conserved quantity makes sense only for *finite* experimental domains, and our analysis takes this into account.

The treatment of the large-scale mode in magnetoconvection differs in one respect from the granular media and thin film cases; in the former problem the large-scale mode (the horizontally averaged vertical component of the magnetic field) can take either sign; the dynamics is unchanged by this, so the dynamical equations must also remain unchanged. In the latter two cases the large-scale mode quantity is a scalar, density-like, quantity and no sign-change symmetry exists. We focus in this paper on the symmetric case relevant to magnetoconvection; the density-like case is very similar and we summarize a few calculations in an appendix. As we will show, the presence of a large-scale mode stretches the snaking behavior out over a substantial region of parameter space and enables localized states to exist both below the saddle-node bifurcation on the subcritical uniform amplitude branch at $r = r_{sn}$ and far above the point of linear instability of the trivial state.

Pattern formation in the presence of a long-wavelength neutral mode of this kind was considered by Matthews and Cox [24], who carried out a weakly nonlinear analysis of a Swift–Hohenberg-type equation modified by applying ∂^2_{xx} to the right-hand side of (1.1) to produce a dispersion relation that tended to zero (i.e., indicated neutral stability) as $k \to 0$. These authors considered the pattern amplitude to be $O(\varepsilon)$ and the large-scale mode to deviate by only an $O(\varepsilon^2)$ amount from the initially homogeneous state. While asymptotically correct, these scalings are unable to capture solutions where the fluctuations in the large-scale mode are large. As a result, numerical solutions often blow up, and higher-order stabilizing terms were found to be required [10]. Similar difficulties were noted by Golovin, Davis, and Voorhees [16].

In this paper we present a modified multiple-scales analysis that uses the diffusivity of the large-scale mode as the small parameter. We show that this enables the asymptotics for small-amplitude patterns to nevertheless capture the effect of $O(1)$ fluctuations in the large-scale mode. In consequence, this asymptotic treatment avoids the singularities found by earlier authors. The layout of the paper is as follows. Section 2 proposes the extension of (1.1) which we study; details linking it directly to the governing equations for magnetoconvection are deferred to Appendix A. Appendix B summarizes the multiple-scales derivation in the very

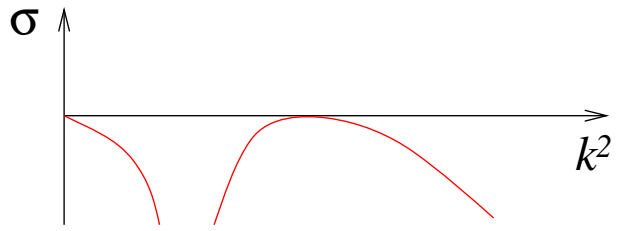

Figure 1. *Sketch of the growth rate $\sigma(k^2)$ for a reflection-symmetric pattern-forming instability at wavenumber $k = 1$, in the presence of a large-scale mode that is neutrally stable as $k \to 0$.*

similar case of a density-like large-scale mode, appropriate to the vibrated granular medium and thin film cases. In section 3 we return to the Swift–Hohenberg ansatz and compare the results of the multiple-scales approach with results from numerical continuation. Section 4 concludes the paper.

2. Ginzburg–Landau asymptotics.

In this section we propose a model equation for pattern formation coupled to a large-scale mode, appropriate for magnetoconvection. We assume that the pattern-forming domain $0 \le x \le L$ is large, but, crucially, finite, and we carry out a multiple-scales analysis to derive an amplitude equation similar to the Ginzburg–Landau equation, but containing a nonlocal term, which captures the influence of the large-scale mode. From the Ginzburg–Landau equation we deduce the existence of modulational instabilities that lead to localized states and investigate scaling laws governing the location of the bifurcation points.

2.1. Model equations.

Suppose that a one-dimensional pattern-forming system is described by the pattern amplitude $w(x,t)$ and the large-scale mode $B(x,t)$. We consider the dispersion curves of the linearized growth rate as a function of perturbation wavenumber k to take the form shown in Figure 1, with quadratic maxima at $k = 0$ and $k = 1$.

We further assume that the system is translationally invariant and reflection-symmetric (i.e., $x \to -x$). Hence a conservation law for $B(x,t)$ contains only even numbers of derivatives. In the absence of the large-scale mode we assume that the pattern-forming instability is supercritical; this is appropriate for thermal convection. An additional symmetry requirement is appropriate for magnetoconvection: that the dynamics is invariant under a change in the sign of the large-scale mode $B(x,t)$. Model equations constrained to have these properties are

$$w_t = [r - (1 + \partial_{xx}^2)^2]w - w^3 - QB^2 w, \tag{2.1}$$

$$B_t = \varepsilon B_{xx} + \frac{c}{\varepsilon}(Bw^2)_{xx}, \tag{2.2}$$

where natural (and analytically tractable) forms of the coupling terms with coefficients Q and c/ε have been taken. The factor of ε^{-1} in the second equation enables an asymptotic balance between the nonlinear and the diffusion terms to occur when the pattern amplitude $w(x,t)$ is $O(\varepsilon)$. As shown in Appendix B, this factor of ε^{-1} appears naturally in magnetoconvection.

Integrating (2.2) over the domain $0 \le x \le L$ and applying periodic boundary conditions imply that $\frac{1}{L}\int_0^L B(x,t)dx \equiv \langle B \rangle$ is constant in time; by rescaling $B(x,t)$ we may take it to be

unity. Essentially, this rescaling absorbs the original mean value $\langle B\rangle$ into the coupling parameter Q. Such a rescaling corresponds exactly to the usual nondimensionalization employed in magnetoconvection, where Q is known as the Chandrasekhar number [7, 27].

We now restrict our attention to steady solutions, setting $\partial_t \equiv 0$, and integrating (2.2) twice to obtain

$$B = \frac{P}{1+cw^2/\varepsilon^2}, \tag{2.3}$$

where P is a constant of integration that corresponds to the value of the large-scale mode away from the localized pattern. Using $\langle B\rangle = 1$ we can now compute P as an integral over the domain; P therefore becomes a nonlocal functional of the pattern amplitude $w(x)$:

$$\frac{1}{P} = \left\langle \frac{1}{1+cw^2/\varepsilon^2} \right\rangle. \tag{2.4}$$

Substituting into (2.1) and looking for steady states, we obtain the nonlocal Swift–Hohenberg equation

$$0 = [r-(1+\partial_{xx}^2)^2]w - w^3 - \frac{QP^2w}{(1+cw^2/\varepsilon^2)^2}. \tag{2.5}$$

The study of bifurcations and solution stability in nonlocal equations is an area of substantial current interest; see, for example, [4, 12] and the references therein. In this paper such difficulties are largely bypassed since, although (2.5) is nonlocal, the linear stability analysis of $w(x) \equiv 0$ remains a local problem. As a result, the usual approaches to small-amplitude solutions of the Swift–Hohenberg equation can be applied, as we now show.

We now introduce the multiple-scales ansatz

$$w(x,t) = \varepsilon A(X)\sin x + \varepsilon^2 w_2 + \varepsilon^3 w_3 + \cdots, \tag{2.6}$$

defining the long lengthscale $X = \varepsilon x$. We rescale the parameters $r = \varepsilon^2\mu$ and $Q = \varepsilon^2 q$ since we are focusing on small-amplitude patterns. The amplitude $A(X)$ can be taken to be real since the instability which generates localized states occurs in the pattern amplitude and not in its phase. At third order in the expansion an amplitude equation for $A(X)$ is obtained by multiplying by $\sin x$ and integrating over the short lengthscale, denoting the average as $\frac{1}{2\pi}\int_0^{2\pi} f(x)dx \equiv \langle f(x)\rangle_x$. We obtain

$$0 = \mu A + 4A_{XX} - 3A^3 - 2qP^2\left\langle \frac{A\sin^2 x}{(1+cA^2\sin^2 x)^2}\right\rangle_x, \tag{2.7}$$

where P now becomes

$$\begin{aligned}\frac{1}{P} &= \frac{1}{\varepsilon L}\int_0^{\varepsilon L}\frac{1}{2\pi}\int_0^{2\pi}\frac{1}{1+cA^2\sin^2 x}\,dx\,dX \\ &\equiv \left\langle \left\langle \frac{1}{1+cA^2\sin^2 x}\right\rangle_x\right\rangle_X = \left\langle \frac{1}{\sqrt{1+cA^2}}\right\rangle_X.\end{aligned} \tag{2.8}$$

Carrying out the x-integral in (2.7), we obtain

$$0 = \mu A + 4A_{XX} - 3A^3 - \frac{qP^2A}{(1+cA^2)^{3/2}}. \tag{2.9}$$

It follows that the trivial state $A(X) \equiv 0$ (for which $B = 1$) undergoes a pitchfork bifurcation at $\mu = q$. The pitchfork bifurcation is supercritical for small q but becomes subcritical for $cq > 6$, as can be checked by expanding both the nonlinear term and P for small A in (2.9).

2.2. Modulational instabilities. As is typical in subcritical bifurcations of this kind, secondary bifurcations occur close to $\mu = 0$, and close to the saddle-node point on the uniform branch, which results in localized states. Interestingly, for this problem these secondary modulational instabilities exist also for $2 < cq < 6$ where the primary bifurcation is supercritical. On the primary branch, where $A = A_0$ constant, we find $P = \sqrt{1 + cA_0^2}$, and hence from (2.9)

$$q = (\mu - 3A_0^2)\sqrt{1 + cA_0^2}, \tag{2.10}$$

which, on simplifying, yields

$$9cA_0^6 + (9 - 6c\mu)A_0^4 + (c\mu^2 - 6\mu)A_0^2 + \mu^2 - q^2 = 0.$$

To locate the bifurcation points indicating modulational instability we set $A = A_0(1 + ae^{iKX})$. Substituting this ansatz into (2.9) and linearizing in a, we obtain

$$0 = (\mu - 4K^2 - 9A_0^2)a - (\mu - 3A_0^2)\frac{1 - 2cA_0^2}{1 + cA_0^2}a,$$

where we have used (2.10) to eliminate q. Simplifying further, we find that modulational instability occurs when

$$15cA_0^4 + (6 - 3c\mu + 4cK^2)A_0^2 + 4K^2 = 0.$$

In the limit of large domains, $K = 2\pi/(\varepsilon L) \ll 1$, we therefore expect instabilities when

$$A_0^2 = \frac{4K^2}{3c\mu - 6} + O(K^4) \qquad \text{and} \qquad A_0^2 = \frac{c\mu - 2}{5c} + O(K^2). \tag{2.11}$$

Clearly, no modulational instability is possible if $c\mu < 2$. The first of the conditions in (2.11) indicates that instability occurs at small A_0, near the primary bifurcation at $\mu = q$. The second condition indicates that instability also occurs at large amplitudes.

The continuation software AUTO [14] was used to solve (2.9) as a boundary-value problem in a finite domain. Neumann boundary conditions $A_X = A_{XXX} = 0$ at $X = 0, \varepsilon L$ were imposed to avoid numerical difficulties arising from the continuous translational symmetry implied by periodic boundary conditions. Bifurcation diagrams for the supercritical and subcritical cases are shown in Figure 2. Of particular note in Figure 2(b) is that the branch of localized states both extends further into $\mu < q$ than the uniform branch, i.e., $\mu_{sn1} < \mu_{sn2} < q$, and also extends substantially into $\mu > q$ before rejoining the primary branch at large amplitudes.

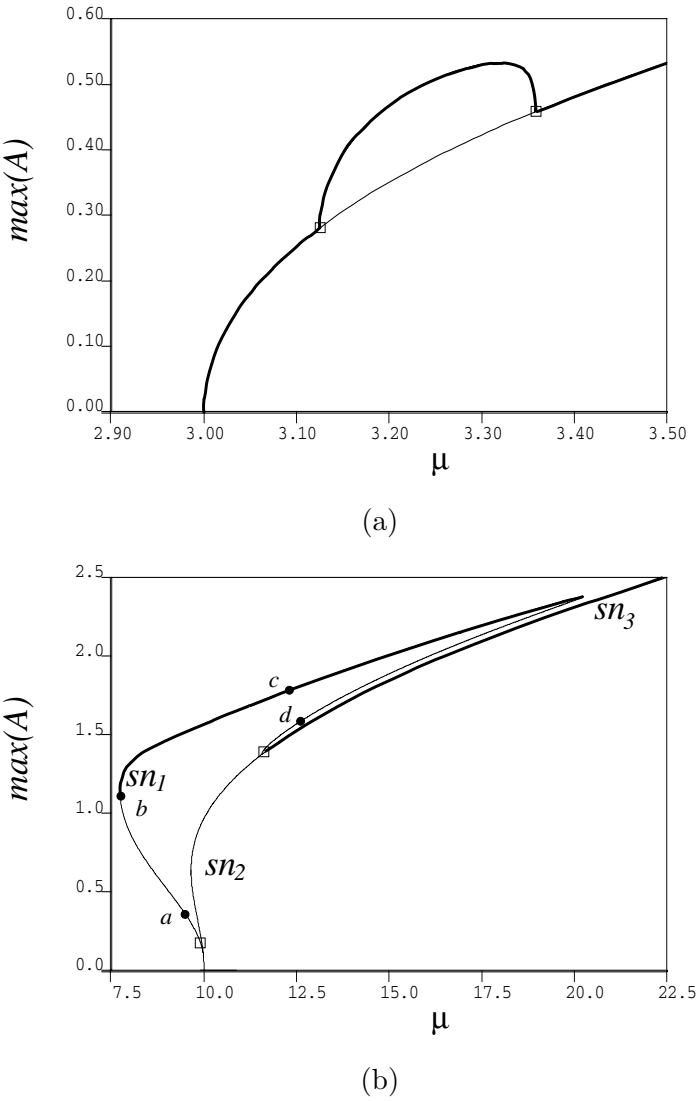

Figure 2. *Bifurcation diagrams in the* $(\mu, \max(A))$ *plane. Thick and thin lines denote stable and unstable branches, respectively. A primary branch of uniform amplitude pattern bifurcates from* $A(X) \equiv 0$ *when* $\mu = q$*. We fix* $c = 1$ *and the domain size* $\varepsilon L = 10\pi$*.* $\square$ *denotes bifurcation points from the uniform branch to the branch of modulated states.* (a) $q = 3$*, for which the primary bifurcation is supercritical.* (b) $q = 10$*, for which the primary bifurcation is subcritical. Note in both cases the existence of a secondary instability leading to a branch of spatially localized states. Labels in* (b) *correspond to the different parts of Figure 3.*

Figure 3 shows solutions to (2.9) at the four points indicated on the localized branch in Figure 2(b). Close to the ends of the branch the solution takes on the usual sech-like profile; at the center it resembles a pair of tanh-like fronts between the trivial state $A = 0$ and a nonzero constant value A_0. Stable fronts are possible when the two states have the same "energy"; in the standard description of localized states the energies are equal at a single value of the driving parameter μ, known as the "Maxwell point." In the present case we

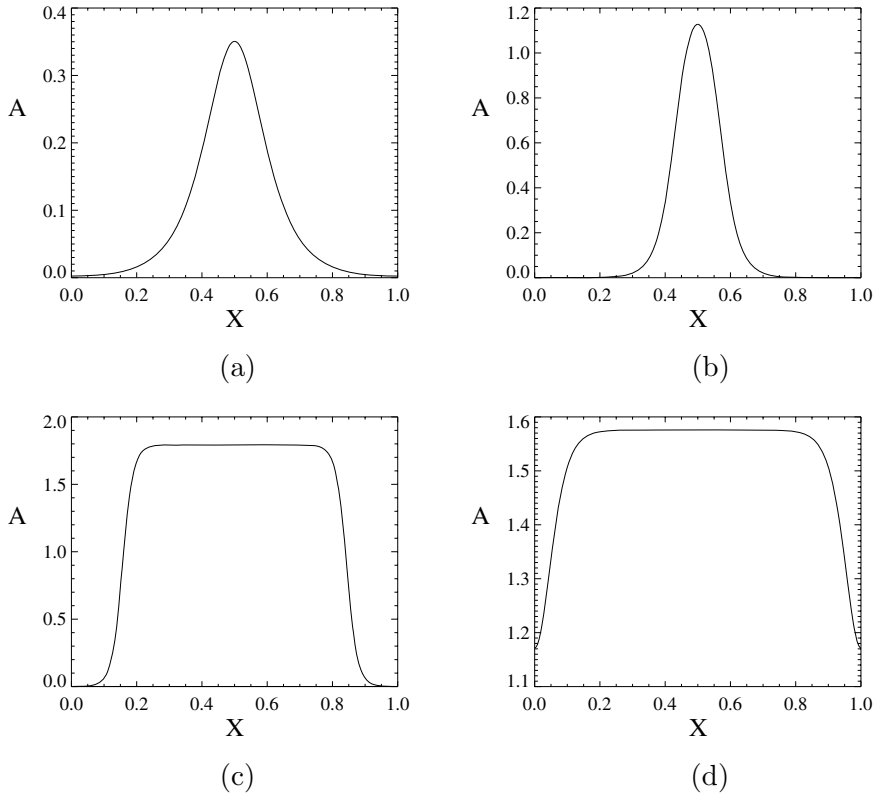

Figure 3. *Localized solutions $A(X)$ of (2.9) at the four points on the secondary branch of localized states indicated on Figure 2(b). Parameter values:* (a) $\mu = 9.523$; (b) $\mu = 7.737$; (c) $\mu = 12.373$; (d) $\mu = 12.534$. *Domain size $\varepsilon L = 10\pi$, $c = 1$, $q = 10$. Note that the horizontal axis is rescaled to $[0, 1]$ in the figures.*

expect that the value A_0 depends on the driving parameter μ but not on the domain size or the overall magnitude q of the large-scale mode. These intuitions can be demonstrated with a straightforward, but surprisingly accurate, calculation to estimate the relation between A_0 and μ, as we now show.

Equation (2.9) has a first integral, obtained by multiplying by A_X and integrating:

$$E = \frac{\mu}{2}A^2 + 2A_X^2 - \frac{3}{4}A^4 + \frac{qP^2}{c}\frac{1}{\sqrt{1+cA^2}}. \tag{2.12}$$

Assuming that the localized solution resembles Figure 3(c) and is nearly piecewise constant, we may neglect the A_X term in (2.12); this turns out not to affect the accuracy of the following calculation in any significant way, while considerably simplifying the computation. Supposing that the solution is $A = A_0 \neq 0$ over a proportion ℓ/L of the domain, and zero on the remainder, from (2.8) we obtain $P = P_\ell$, where

$$\frac{1}{P_\ell} = 1 + \frac{\ell}{L}\left(\frac{1}{\sqrt{1+cA_0^2}} - 1\right). \tag{2.13}$$

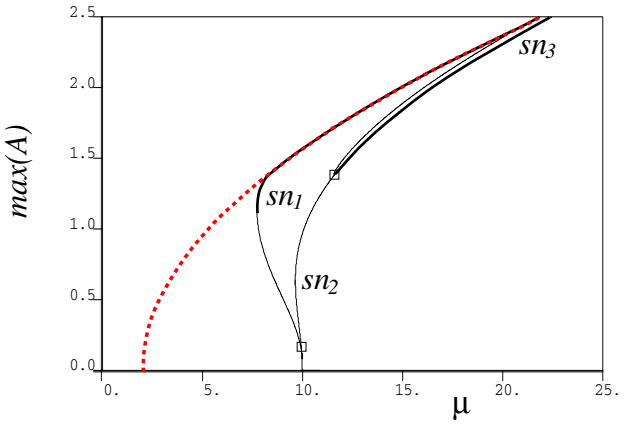

Figure 4. *Bifurcation diagram in the* $(\mu, \max(A))$ *plane for* $q = 10$, $c = 1$, $\varepsilon L = 10\pi$, *as in Figure* 2(b). *Thick and thin lines denote stable and unstable branches, respectively.* □ *denotes bifurcation points from the uniform branch to the branch of modulated states. The "Maxwell curve" given by* (2.15) *is the dashed red curve. The central part of the stable branch of localized states is indistinguishable from it.*

Comparing the values of E above and below a front connecting the trivial and nontrivial states in different parts of the domain, we obtain

$$E|_{A=0} = \frac{qP_\ell^2}{c},$$
$$E|_{A=A_0} = \frac{\mu}{2}A_0^2 - \frac{3}{4}A_0^4 + \frac{qP_\ell^2}{c}\frac{1}{\sqrt{1+cA_0^2}},$$

and from (2.9) we also have

$$qP_\ell^2 = (\mu - 3A_0^2)(1+cA_0^2)^{3/2}. \tag{2.14}$$

Equating $E|_{A=0} = E|_{A=A_0}$ and eliminating qP_ℓ^2 using (2.14), we obtain the following relation between μ and A_0:

$$cA_0^2\left(\mu - \frac{3}{2}A_0^2\right) = 2(\mu - 3A_0^2)(1+cA_0^2)\left(\sqrt{1+cA_0^2} - 1\right).$$

This can be simplified to the cubic polynomial in A_0^2:

$$144c^2A_0^6 + (207c - 96c^2\mu)A_0^4 + (72 + 16c^2\mu^2 - 108c\mu)A_0^2 + 12\mu(c\mu - 2) = 0. \tag{2.15}$$

For $\mu = 12$ we find that this analytic result predicts $A_0 = 1.7590818$, compared to the numerical value from (2.9), corresponding to Figure 3(c), of $A_0 = 1.759082$. Moreover, instead of a Maxwell point we have a "Maxwell curve" along which stable fronts, and therefore localized states, exist; see Figure 4. It is worth remarking that (2.15) relates the amplitude A_0 only to the linear driving parameter μ and does not contain the coupling parameter q or the proportion ℓ/L of the domain that contains the localized pattern. As a result, the localized pattern

amplitude depends only on μ. This is physically reasonable in the magnetoconvection case: when the magnetic field has been expelled from one part of the fluid domain, the amplitude of the thermal convection that results is due to the thermal driving alone.

Our final remark in this section is that on combining (2.13) and (2.14) we can relate q and ℓ/L, assuming that A_0 is determined from μ using (2.15):

$$q = (\mu - 3A_0^2)(1 + cA_0^2)^{3/2}\left(1 + \frac{\ell}{L}\left(\frac{1}{\sqrt{1+cA_0^2}} - 1\right)\right)^2.$$

Approximating this expression in the limit of "strong coupling and strong driving," where $q \sim \mu \gg 3A_0^2 \gg 1$, it can be written in the form

$$\frac{q}{\mu} \approx A_0^3\left(1 - \frac{\ell}{L}\right)^2,$$

which is reminiscent of (4.5) in [13] and indicates that in the strong coupling and strong driving regime it is some combination of q and μ that determines the width of the localized state. Note that the amplitude A_0 scales in some unspecified way with μ and q, and so this relation does not indicate a simple power-law scaling exponent, as we discuss further in the next section.

2.3. Scaling laws in the nonlocal Ginzburg–Landau equation. The location and shape of the primary and secondary branches evolve continuously between Figures 2(a) and 2(b) as q is increased, first by the introduction of saddle-node points on the secondary branch, and then by the subcriticality of the primary branch. Figure 5 displays the bifurcation structure in the (μ, q) plane; for $q \gg 10$ the bifurcation points appear to scale as power-laws with increasing q, and the region of existence of stable localized states increases in size rapidly. Figure 5 (in which $c = 1$) shows that the localized states exist subcritically (i.e., for $\mu - q < 0$) even for $q < 6$, where the primary bifurcation is still supercritical.

The scaling law for the saddle-node bifurcation sn_2 on the uniform amplitude branch can be located by eliminating A_0^2 between the second condition of (2.11) and (2.10). This yields the curve

$$\left(cq\frac{5\sqrt{5}}{2}\right)^2 = (3 + c\mu)^3, \tag{2.16}$$

which agrees closely with numerical calculations and is shown as the red dot-dashed curve in Figure 5(b). At large q, (2.16) agrees exactly with the numerical results in Figure 5(a).

Fitting the same functional form to the saddle-node curves sn_1 and sn_3 results in the scaling laws sn_1: $q \approx 0.0927(\mu + 3.55)^{1.987}$, sn_3: $q \approx 0.298(\mu + 27.9)^{0.986}$ to three significant figures. These exponents are intriguing, and, while they fit the data extremely well at large q, they differ significantly from ratios of small integers. It is possible that they can be deduced using the properties of solutions of (2.9) involving the snoidal and cnoidal special functions. At small q we note that there is systematic deviation from power-law scalings.

3. Numerical results for slanted snaking. Returning to the Swift–Hohenberg model (2.1)–(2.2), we find, corresponding to the Ginzburg–Landau analysis, that the modulational instability leads to branches of localized states for which the periodic pattern is locked to the modulating envelope. As for the standard snaking scenario, two distinct pairs of branches persist—one pair where the phase difference between pattern and envelope is 0 or π and one pair where it is $\pm\pi/2$. The numerical procedure, again using AUTO [14], was as follows.

Starting at the trivial solution $w(x) \equiv 0$, either "Dirichlet" $w(0) = w_{xx}(0) = w(L) = w_{xx}(L) = 0$ or "Neumann" $w_x(0) = w_{xxx}(0) = w_x(L) = w_{xxx}(L) = 0$ boundary conditions were used to avoid the neutral eigenvalue associated with the translational invariance when locating the linear instability at $r = Q$ and switch easily onto the uniform amplitude pattern branch. By continuation along the uniform amplitude branch we located the first modulational instability (indicated by the lower solid square symbol in Figure 6), and AUTO was able to switch onto the modulated branch. We now replace the Dirichlet or Neumann boundary conditions in the numerics with periodic ones, supplemented with a global integral constraint to fix the overall phase of the solution and ensure that there is no drift in the direction of the neutrally stable translation mode. The implementation of the integral constraint followed Rademacher, Sandstede, and Scheel [29]; it was found to be numerically very robust. This approach also accurately detects the "cross-link" or "ladder" branches [5, 22] of asymmetric localized states that complete the bifurcation structure. As in the standard homoclinic snaking scenario, these cross-link branches are never stable; they are omitted from Figure 6 to aid clarity.

Two continuations, one beginning with Dirichlet boundary conditions and one with Neumann boundary conditions, were carried out. The full snaking bifurcation diagram is obtained by superimposing the results. This procedure provides an additional check on the numerical accuracy. Figure 6 indicates that, as expected, these branches are intertwined (around the "Maxwell curve") and stretch both below and above the bifurcation points from the uniform amplitude branch. We call this behavior "slanted snaking." Figure 7 illustrates the evolution of the localized states along the snaking branches.

Another feature of Figure 6 not captured by the Ginzburg–Landau reduction is that the wavelength along the branch of localized states in Figure 6 decreases as r increases; in consequence the branches of localized states terminate on a different uniform amplitude primary branch, in this case one with wavelength $L/8$. This aspect of the bifurcation diagram is brought out clearly in Figure 8, where the vertical axis is $\max(w)$ rather than the L^2 norm.

Decreasing r from, say, $r = 3.5$ on the localized branch therefore results in a stepwise decrease in the number of bumps of localized pattern, as the successive saddle-node bifurcations are passed. As ε decreases the localization becomes increasingly pronounced.

Alternatively we may consider the driving parameter r to be fixed and consider the effect of increasing the strength of the coupling Q between the large-scale field and the pattern mode. For the Ginzburg–Landau system this corresponds to a vertical section through Figure 5(a); the same stepwise series of saddle-node bifurcations is seen in (2.1)–(2.2) when Q is decreased at fixed r. Figure 9 (for which $r = 1$) illustrates the location of the lowest two saddle-node bifurcations on the snaking branch as ε is decreased. Localized states are born in a modulational instability close to $Q = 1$ and exist in $Q > 1$ up to the curve sn_1 on which they undergo the first saddle-node bifurcation on the snaking curve. The branch then turns around

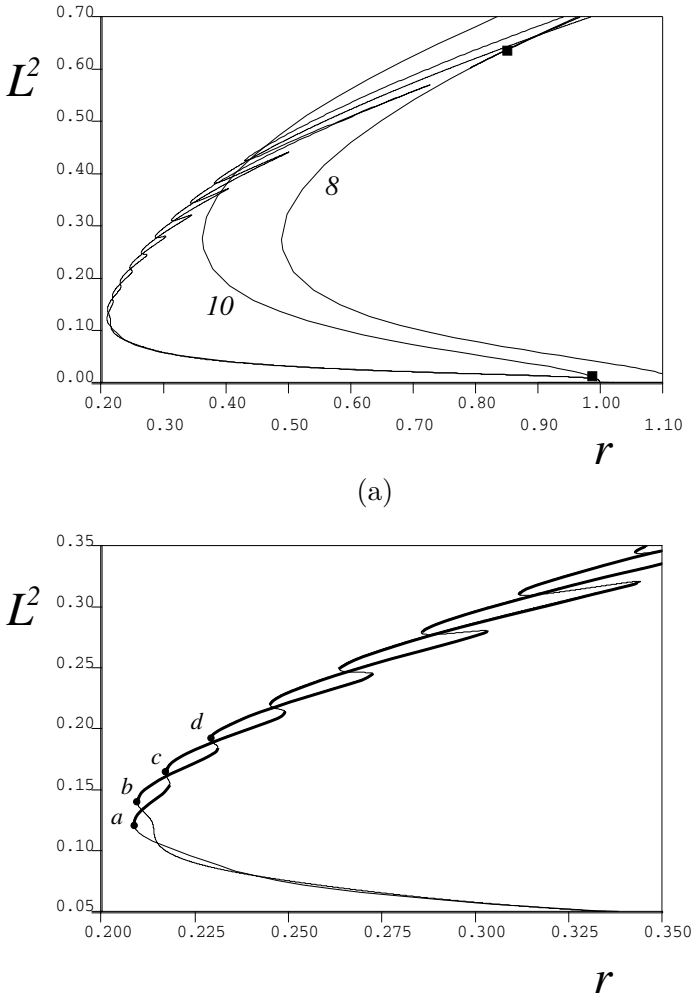

Figure 6. *Slanted snaking in* (2.1)–(2.2)*,* $c = Q = 1$*, domain size* $L = 20\pi$*.* (a) *Branches* 10 *and* 8 *denote uniform spatial patterns with wavelengths* $L/10$ *and* $L/8$*, respectively. Snaking branches bifurcate from the* 10 *branch near* $r = 1$ *(at the solid square) and extend down to* $r = 0.21$*. They then continue up to* $r \approx 3.8$ *(not shown) before returning to terminate on the* 8 *branch, indicated by a solid square.* (b) *Enlargement of* (a) *showing the characteristic intertwining of the two snaking branches. and continues as Q decreases, up to the second solid line at which the second saddle-node bifurcation on the snaking curve takes place. Subsequent pairs of saddle-node bifurcations are not shown; numerical results indicate that the next pair, and possibly others, rather curiously follows the same power-law scaling with ε as the first pair. As ε increases, the region of stable localized states shrinks until it disappears for $\varepsilon > 0.46$. For comparison, Figure 9 also shows the location of the saddle-node bifurcation of the uniform amplitude pattern sn_2. The power-law for the curve sn_2 follows that derived in (2.16) for the location of the modulational instability near the saddle-node bifurcation sn_2: the scaling $q^2 \propto \mu^3$ for large q and μ implies

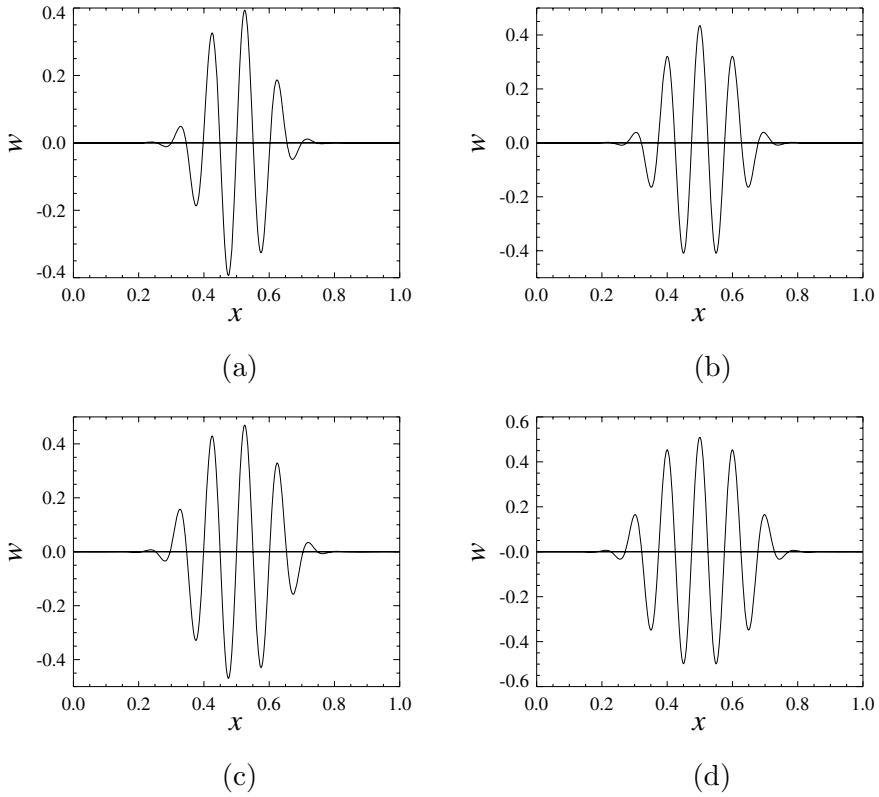

Figure 7. *Localized states at four saddle-node bifurcation points in Figure* 6(b). (a) *and* (c) *lie on the* $\phi = \pi/2$ *(odd) branch;* (b) *and* (d) *lie on the* $\phi = 0$ *(even) branch.* $c = Q = 1$*;* $L = 20\pi$*. Note that the domain has been rescaled to* $[0, 1]$.

$(Q/\varepsilon^2)^2 \propto (r/\varepsilon^2)^3$, i.e., $Q \propto \varepsilon^{-1} r^{3/2}$. This scaling agrees with Figure 9.

For sn_1 we found in the Ginzburg–Landau approximation (shown in Figure 5) that $q \propto \mu^{1.987}$ for large q, μ. This implies $Q/\varepsilon^2 \propto (r/\varepsilon^2)^{1.987}$, which yields $Q \propto \varepsilon^{-1.974}$. For comparison, Figure 9 indicates the different scaling $Q \propto \varepsilon^{-2.03}$. This difference is too large to be explained purely in terms of numerical errors. We believe that the difference is due to the "beyond-all-orders" terms that determine the width of the homoclinic snaking wiggles in Figure 6 and that are neglected in the multiple-scales analysis of section 2.

For completeness we note that the lower solid line in Figure 9 follows the power-law $Q \propto \varepsilon^{-1.31}$, which has no counterpart in the multiple-scales asymptotics of section 2; clearly the width of the snake, and therefore this power law exponent also, is influenced by the beyond-all-orders asymptotic scalings.

4. Discussion. In this paper we have examined a very simple model equation for the influence of a neutrally stable long-wavelength mode on steady-state pattern formation. Such a situation is motivated by several physical problems, and we have fixed on model equations containing symmetries appropriate to the onset of thermal convection in an imposed vertical magnetic field, a long-studied problem in the literature [7, 6, 27].

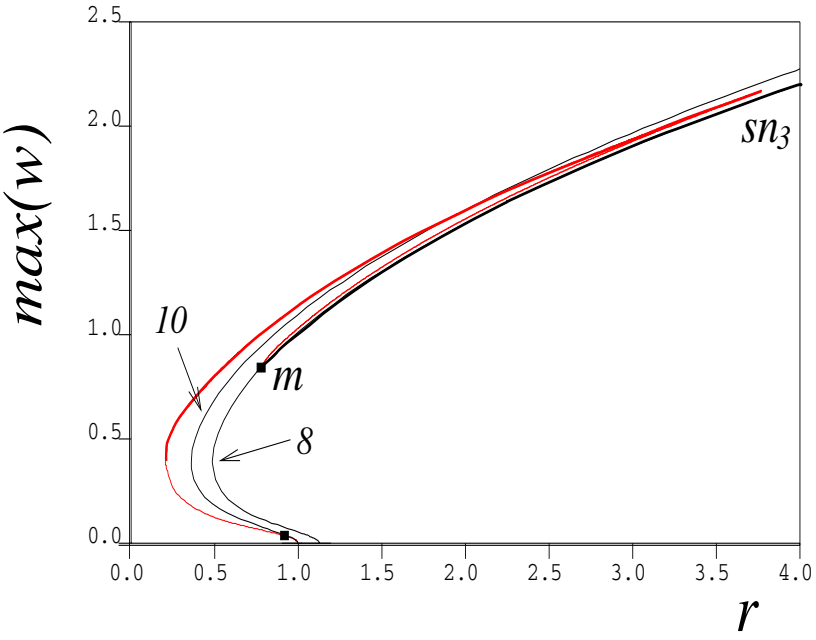

Figure 8. *Bifurcation behavior in (2.1)–(2.2) for $c = Q = 1$ and domain size $L = 20\pi$. The bifurcation curves are as for Figure 6; plotting $\max(w)$ against r shows more clearly the excursion of the secondary branch up to $r \approx 3.8$, and the termination of the snaking branches (now superimposed) on the 8 branch. Solid squares denote the bifurcations from uniform periodic patterns to localized patterns. Thick and thin lines denote stable and unstable branches, respectively. Red and black lines denote localized and spatially periodic solution branches, respectively.*

We introduce a new approach to the usual weakly nonlinear multiple-scales analysis, taking the diffusivity of the large-scale mode as the small parameter while allowing order unity fluctuations in amplitude. We then carry out the multiple-scales expansion to third order and deduce a nonlocal Ginzburg–Landau equation that describes the dynamics. It is found that the subcriticality induced by the large-scale mode distorts the usual homoclinic snaking picture and allows localized states to exist over a much larger region of parameter space than is possible in its absence. We refer to this distortion of homoclinic snaking as "slanted snaking." As a result, the existence of a large-scale mode provides a far more robust physical mechanism for the stabilization of localized solutions than the "locking" or "pinning" mechanism that explains their existence in an exponentially small wedge of parameter space in the standard picture.

In other respects the localized states qualitatively resemble standard homoclinic snaking. For example, the secondary branches of asymmetric localized states, found by Burke and Knobloch [5] (called "ladders" in that paper), which link the two snaking branches exist also in this problem, although for clarity we have omitted them from the figures. For the parameter values we investigate in detail ($\varepsilon = 0.1$, $Q = 1$), it is interesting that the lowest saddle-node point on the snake does not correspond to a single isolated period of the pattern. This indicates that our coupling terms, of a simple kind that admit analytic investigation, do

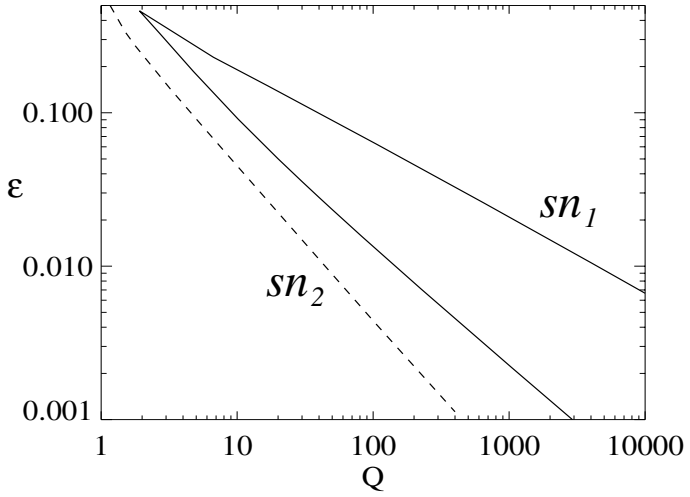

Figure 9. *Scaling of the saddle-node bifurcations on the primary and secondary branches of solutions to (2.1)–(2.2) in the (ε, Q) plane for fixed $r = c = 1$ and domain size $L = 20\pi$. The trivial solution $w(x,t) \equiv 0$ is stable for $Q > 1$. A single localized cell exists between $Q = 1$ and the saddle-node curve sn_1; it is stable between the two solid curves. Uniform amplitude states exist (subcritically) below the dashed line sn_2.*

not force the pattern to be quite as localized as convection cells appear to be in simulations of the full fluid equations [2, 13]. It is quite possible that more complicated coupled terms, involving extra derivatives of either $B(x,t)$ or $w(x,t)$, deform the snake still further, allowing only a single convection cell to persist at small r or, equivalently, large Q. Possible forms for these coupling terms are discussed further in Appendix A.

Overall, these results provide a convincing explanation of the link between homoclinic snaking and the stepwise reduction in the number of cells in the localized states with increasing Q as found first by Blanchflower [3] and reproduced in [13] (see Figure 8 therein). Various features of the full magnetoconvection problem, such as the destabilization of localized steady states by an oscillatory instability in the quiescent region, are, of course, not reproduced by this model. But steady-state features are well reproduced, for example, the evidence, from Figure 9(a) of [13], that the two curves of saddle-node bifurcations that bound the region of the existence of a single-roll localized state scale in different ways with the small parameter $\varepsilon \equiv \zeta$. This is certainly true for the solid lines in Figure 9.

The exponents of the power-law scalings that we present, in both the multiple-scales analysis and the full Swift–Hohenberg model, seem to be strongly dependent on the exact form of the nonlinear coupling terms. A detailed investigation of such dependencies and possible explanations through the properties of analytic solutions in terms of Jacobi elliptic functions are left for future work.

The corresponding calculation for systems for which the large-scale mode is a density is very similar to the analysis presented in detail here. Indeed, the only change required to the model equations is to take the coupling term to be QBw in (2.1). Brief details of the resulting calculations are contained in Appendix B. A further extension is to examine systems where it

appears that the large-scale mode promotes localized activity but the short-scale dynamics is not "pattern-forming." A clear example of this is the vertically and horizontally shaken granular layer experiments of Götzendorfer et al. [17]. In these experiments the vertical excitation of a granular layer does not result in uniform excitation of the material, but rather in a patch of highly energetic particles, while the remainder of the domain remains inactive. Götzendorfer et al. refer to this, slightly fancifully perhaps, as the "sublimation" of the "solid" phase of the material into a "gaseous" form. The general mechanism is, however, physically clear: there is a balance between the (rapid) flux of particles from the active part of the layer into the quiet part as energetic particles are propelled upward and outward, and the natural (slow) trickling of particles from the quiet part back into the active one. These two processes correspond, respectively, to the two terms on the right-hand side of (B.2). Moreover, when the layer height locally exceeds a critical value, the vertical excitation cannot excite particles directly in that part of the bed; this effect is captured by the damping term $Q\rho w$ in (B.1). Model equations capturing exactly these effects were written down by Tsimring and Aranson [32].

There are close connections between this work and that of Matthews and Cox and others [24, 9, 10, 16, 36]; these authors studied systems essentially equivalent to (2.1)–(2.2) obtained by applying ∂_{xx}^2 to the right-hand side of the standard Swift–Hohenberg equation (1.1), including both quadratic and cubic nonlinearities in $N(w)$. In these papers the weakly nonlinear analysis proceeds by looking for small distortions of the large-scale mode, i.e., a small parameter δ and a long lengthscale $X = \delta x$ are introduced, before expanding $w = \delta a(X)\sin x + O(\delta^2)$ and $B = 1 + \delta^2 b(X) + O(\delta^3)$. The resulting amplitude equations for $a(X)$ and $b(X)$ enable the detection of secondary modulational instabilities, as happens here, even in the case that the initial pattern-forming instability is supercritical, which is analogous to Figure 2(a). However, these scalings implicitly restrict our attention only to cases of small disturbances to the distribution of the large-scale mode; the present analysis can, in this sense, go further.

Other physical systems that show related phenomena, and which we intend to examine in future work, include the numerical results of Tsitverblit and Kit [33] on natural double-diffusive convection (see, for example, their Figure 1, which appears to show snaking behavior that does not have the saddle-node points aligned to only two values of the bifurcation parameter). Moreover, model equations for dielectric gas discharge (due to Purwins and collaborators [31, 28]) and for optical cavity lasers [15] have been proposed which include integral terms. These integral terms appear to play the same role in enhancing localization in these systems as the nonlinear diffusion equation for the large-scale mode does in this paper.

Appendix A. Magnetoconvection. In this appendix we briefly sketch the derivation of an evolution equation for the large-scale mode in the magnetoconvection case, starting from the governing equations. This justifies the form of our model equation (2.2).

For thermal convection in a vertical magnetic field, the appropriate governing equations for the fluid velocity $\mathbf{u}(x,y,z,t)$, the temperature perturbation $\theta(x,y,z,t)$, and the magnetic field $\mathbf{B}(x,y,z,t)$ are the momentum, temperature, and induction equations:

$$\begin{aligned}\partial_t\mathbf{u} + \mathbf{u}\cdot\nabla\mathbf{u} &= -\nabla p + \sigma R\theta\hat{\mathbf{z}} + \sigma\zeta Q\mathbf{B}\cdot\nabla\mathbf{B} + \sigma\nabla^2\mathbf{u},\\ \partial_t\theta + \mathbf{u}\cdot\nabla\theta &= w + \nabla^2\theta,\\ \partial_t\mathbf{B} &= \nabla\times(\mathbf{u}\times\mathbf{B}) + \zeta\nabla^2\mathbf{B}.\end{aligned}$$

For simplicity we restrict our attention to two-dimensional solutions, ignoring the y coordinate; the extension of these calculations to three dimensions would appear to be straightforward. The temperature variable $\theta(x,z,t)$ is the perturbation to the conduction profile $T = 1 - z$. The velocity and magnetic fields are solenoidal: $\nabla \cdot \mathbf{u} = \nabla \cdot \mathbf{B} = 0$. Note that $\mathbf{B}$ is the full magnetic field—not the perturbation to an initially vertical field of strength unity.

The dimensionless groups are the Rayleigh number R, Chandrasekhar number Q, Prandtl number $\sigma = \nu/\kappa$, and magnetic Prandtl number $\zeta = \eta/\kappa$.

We suppose that the boundaries are stress-free and are held at fixed temperatures, and we constrain the field to be vertical there. These boundary conditions allow a simple analytical treatment. The linear theory for the onset of thermal convection in a vertical field is well known [7, 27, 10, 13]. We look for small-amplitude solutions in one horizontal dimension, taking ζ as our small parameter (i.e., $\varepsilon = \zeta$). We propose the solution ansatz

$$\begin{aligned}\mathbf{u} &= (u_1 \cos \pi z, 0, w_1 \sin \pi z),\\ \theta &= \theta_1 \sin \pi z,\\ \mathbf{B} &= (B_x \sin \pi z, 0, B_z \cos \pi z + B_0),\end{aligned}$$

where u_1, w_1, B_x, B_z, and B_0 are functions of x and t only. Computing $\hat{\mathbf{z}} \cdot \nabla \times (\mathbf{u} \times \mathbf{B})$ we obtain equations for the z independent terms and, separately, those that depend on $\cos \pi z$:

$$\partial_t B_0 = \frac{1}{2}(w_1 B_x - u_1 B_z)' + \zeta B_0'', \tag{A.1}$$

$$\partial_t B_z = -(u_1 B_0)' + \zeta(B_z'' - \pi^2 B_z), \tag{A.2}$$

where primes $'$ denote ∂_x. We assume that the quantities u_1, w_1, B_x, B_z all vary on a short spatial scale with wavenumber k, so that we may, at leading order, replace $\partial_{xx}^2 \to -k^2$, where it acts on these variables. As a result the solenoidal conditions $\nabla \cdot \mathbf{u} = 0$ and $\nabla \cdot \mathbf{B} = 0$ imply $u_1 = \pi/k^2 \partial_x w_1$ and $B_x = -\pi/k^2 B_z$, which allows us to eliminate u_1 and B_x from (A.1)–(A.2). We obtain

$$\partial_t B_0 = -\frac{\pi}{2k^2}(w_1 B_z)'' + \zeta B_0'', \tag{A.3}$$

$$\partial_t B_z = -\frac{\pi}{k^2}(w_1' B_0)' + \zeta(B_z'' - \pi^2 B_z). \tag{A.4}$$

Since the linear eigenfunction for the onset of weakly nonlinear convection involves u_1, w_1, B_x, and B_z, it is clear also that B_z does not evolve independently of w_1. Looking for steady states of (A.4), we expect, therefore, that $B_z = -\pi/(k^2\beta^2\zeta)(w_1' B_0)'$ near onset, where $\beta^2 = k^2 + \pi^2$. Substituting this into (A.3) yields an evolution equation for the large-scale field $B_0(x,t)$, coupling it to the weakly nonlinear convection pattern amplitude $w_1(x,t)$:

$$\partial_t B_0 = \frac{\pi^2}{2k^4\beta^2\zeta}\left(w_1(w_1' B_0)'\right)'' + \zeta B_0''.$$

This is of the same form as (2.2), setting $c = \pi^2/(2k^4\beta^2)$, except for two extra derivatives in the first term. Since near onset w_1 involves only the single lengthscale $2\pi/k$, and $B_0 \approx 1$, it is clear that these derivatives will not qualitatively change the behavior. However, it is quite

possible that they will alter the exponents of various scaling laws, for example, those shown in Figure 9. A similar evaluation of the $\hat{\mathbf{z}}$ component of the $\mathbf{B}\cdot\nabla\mathbf{B}$ term, and subsequent use of the above approximations of B_x and B_z in terms of B_0 and w_1, yield, heuristically, the term that couples the large-scale mode back to the vertical velocity:

$$\partial_t w_1 = \cdots + \frac{\sigma Q\pi^2}{k^2\beta^2}\left(\frac{B_0'}{k^2}+B_0\right)(w_1'B_0)'.$$

Appendix B. A density-like large-scale mode. Suppose that a one-dimensional pattern-forming system is described by the pattern amplitude $w(x,t)$ and a density-like large-scale mode $\rho(x,t)$, for example, the local layer height in a granular medium or thin film. In this case the symmetry $\rho\to-\rho$ is absent, and the corresponding model equations are

$$w_t = [r-(1+\partial_{xx}^2)^2]w - w^3 - Q\rho w, \tag{B.1}$$

$$\rho_t = \varepsilon\rho_{xx} + \frac{c}{\varepsilon}(\rho w^2)_{xx}. \tag{B.2}$$

As before, we set $\frac{1}{L}\int_0^L \rho(x,t)dx \equiv \langle\rho\rangle = 1$. We restrict our attention to steady solutions, setting $\partial_t\equiv 0$, and integrate (B.2) twice to obtain

$$\rho = \frac{P}{1+cw^2/\varepsilon^2}, \qquad \text{where} \qquad \frac{1}{P}\equiv\left\langle\frac{1}{1+cw^2/\varepsilon^2}\right\rangle_x. \tag{B.3}$$

Substituting this into (B.1) and looking for steady states, we find

$$0 = [r-(1+\partial_{xx}^2)^2]w - w^3 - \frac{QPw}{1+cw^2/\varepsilon^2}.$$

We now introduce the multiple-scales ansatz $w(x,t) = \varepsilon A(X)\sin x + \varepsilon^2 w_2 + \varepsilon^3 w_3 + \cdots$, introducing the long lengthscale $X=\varepsilon x$. We rescale the parameters $r=\varepsilon^2\mu$ and $Q=\varepsilon^2 q$ in the standard way. At third order in the expansion an amplitude equation for $A(X)$ is obtained by multiplying by $\sin x$ and integrating over the short lengthscale, denoting the average $\frac{1}{2\pi}\int_0^{2\pi}\cdot\,dx \equiv \langle\,\cdot\,\rangle$. This yields

$$0 = \mu A + 4A_{XX} - 3A^3 - 2qP\left\langle\frac{A\sin^2 x}{1+cA^2\sin^2 x}\right\rangle_x, \tag{B.4}$$

where the constant P is defined as before:

$$\frac{1}{P} = \frac{1}{\varepsilon L}\int_0^{\varepsilon L}\frac{1}{2\pi}\int_0^{2\pi}\frac{1}{1+cA^2\sin^2 x}\,dx\,dX \equiv \left\langle\left\langle\frac{1}{1+cA^2\sin^2 x}\right\rangle_x\right\rangle_X = \left\langle\frac{1}{\sqrt{1+cA^2}}\right\rangle_X.$$

Carrying out the x-integral in (B.4), we obtain

$$0 = \mu A + 4A_{XX} - 3A^3 - \frac{2qP(\sqrt{1+cA^2}-1)}{cA\sqrt{1+cA^2}}. \tag{B.5}$$

Consideration of the last term in the limit $A \to 0$ indicates that there is no singularity at small A and that the trivial solution $A = 0$ is linearly unstable when $\mu > q$.

It can be seen that (B.5) has a first integral,

$$E = \frac{\mu}{2} + 2(A_X)^2 - \frac{3}{4}A^4 - \frac{2qP}{c}\left[\log A + \tanh^{-1}\left(\frac{1}{\sqrt{1+cA^2}}\right)\right],$$

in which, after some manipulation, the last term on the right-hand side can be rewritten to give

$$E = \frac{\mu}{2} + 2(A_X)^2 - \frac{3}{4}A^4 - \frac{qP}{c}\log F(A),$$

where $F(A) = A^2 + \frac{2}{c}\left[1 + \left(cA^2+1\right)^{1/2}\right]$. We may also eliminate qP to yield the expression corresponding to (2.15) that describes the amplitude of a localized state as a function of μ:

$$(\mu - 3A_0^2)\sqrt{1+cA_0^2}\left[\frac{1}{2}\log F(A_0) - \log\frac{2}{\sqrt{c}}\right] = \left(\frac{\mu}{2} - \frac{3A_0^2}{4}\right)\left(\sqrt{1+cA_0^2} - 1\right).$$

Despite the more complicated functional form, this curve is qualitatively very similar to that defined by (2.15) and provides an analytic estimate of the "Maxwell curve" in this case.

Acknowledgments. I would like to acknowledge constructive suggestions from the referees. This work has benefited from instructive and useful conversations with Alan Champneys, Steve Cox, Paul Matthews, and Mike Proctor. It was begun at the Isaac Newton Institute, Cambridge.

Numerical Experiments on Noisy Chains: From Collective Transitions to Nucleation-Diffusion*

Mario Castro† and Grant Lythe‡

Abstract. We consider chains of particles with nearest-neighbor coupling, independently subjected to noise, all initially in the same well of a symmetric double-well potential. If there are sufficiently few particles, transitions from one well to another are "collective"; i.e., all particles remain close together as they make the passage from one well to the other. In longer chains, only a fraction of the particles make an initial transition, creating a nucleated region that may grow or collapse by diffusion of its boundaries. Numerical experiments are used to explore the change of the scaling of the passage time as a function of the length of the chain, which distinguishes the two regimes. A suitable relationship between the noise amplitude, coupling, and number of particles in the chain yields convergence to the continuum ϕ^4 or Allen–Cahn stochastic partial differential equations in one space dimension. We estimate the characteristic width of newly nucleated regions and construct a numerical effective potential describing the dynamics in the nucleation-diffusion regime.

1. Introduction.

Many spatially extended systems exhibit two locally stable states that coexist in the sense that, at any one time, different parts of the system are in different states. Nucleation events are fluctuation-driven transitions of part of the system from one state to another, creating domains in which the system is in one state. The domain boundaries are coherent structures [1, 2] that subsequently move about due to fluctuations [3]. The model system we study here is homogeneous and symmetric; i.e., there is no preferred part of the system, and, in the long run, each of the two states is present in equal proportion on average. These properties also mean that there is no a priori natural lengthscale of a newly nucleated region. Behind the apparent simplicity of the energy landscape lies a challenging problem of determining the most probable nucleation pathways [4, 5, 6].

In this article, we consider the model system of a chain of overdamped particles, each coupled to its two neighbors, subject to noise and to the double-well potential with minima at $\phi = \pm 1$:

$$V(\phi) = -\frac{1}{2}\phi^2 + \frac{1}{4}\phi^4. \tag{1.1}$$

The position of the ith particle at time t is a real-valued random variable $\mathbf{\Phi}_t(i)$, and the stochastic differential equation for the ith particle is

$$\mathrm{d}\mathbf{\Phi}_t(i) = \left(\mathbf{\Phi}_t(i) - \mathbf{\Phi}_t^3(i) + k(\mathbf{\Phi}_t(i-1) + \mathbf{\Phi}_t(i+1) - 2\mathbf{\Phi}_t(i))\right)\mathrm{d}t + (2/\beta)^{1/2}\,\mathrm{d}\mathbf{B}_t(i), \tag{1.2}$$

where $\mathbb{E}(\mathrm{d}\mathbf{B}_t(i)\mathrm{d}\mathbf{B}_{t'}(j)) = \delta_{i-j}\mathrm{d}t$. The index i runs from 1 to N, and we shall always use periodic boundaries. In our numerical experiments, the whole chain is initially in the left-hand well of the potential. We record the first $t > 0$ at which the chain is in the right-hand well. As a function of N, with k and β fixed, we find that the mean of this time, which we call the complete passage time, increases exponentially until a certain value and then increases less rapidly. This change corresponds to a transition from "collective" behavior, where all the particles surmount the potential barrier together, to "nucleation-diffusion" behavior, where only a subset of the chain makes the initial transition and the domain subsequently grows by diffusion of its boundaries. A Java applet that permits interactive numerical experiments is at http://www.maths.leeds.ac.uk/Applied/stochastic/chain.htm.

Although a discrete system is an appropriate model in many situations, an important reason for interest in (1.2) is as a finite-difference approximation of a continuum stochastic partial differential equation (SPDE) in one space dimension. Let

$$k = \Delta x^{-2}, \qquad N = \frac{L}{\Delta x}, \qquad \text{and} \qquad \beta = \frac{\Delta x}{\Theta}. \tag{1.3}$$

As $\Delta x \to 0$, the limit of the set of equations (1.2) is the overdamped ϕ^4 SPDE [7, 8, 1, 9]

$$\frac{\partial}{\partial t}\boldsymbol{\phi}_t(x) = \frac{\partial^2}{\partial x^2}\boldsymbol{\phi}_t(x) + \boldsymbol{\phi}_t(x) - \boldsymbol{\phi}_t^3(x) + (2\Theta)^{1/2}\,\boldsymbol{\xi}_t(x), \tag{1.4}$$

where $\boldsymbol{\phi}_t(i\Delta x) = \mathbf{\Phi}_t(i)$ and $x \in [0, L]$. The last term in (1.4) is space-time white noise:

$$\mathbb{E}(\boldsymbol{\xi}_t(x)\boldsymbol{\xi}_{t'}(x')) = \delta(x - x')\delta(t - t'), \tag{1.5}$$

where Θ is thought of as proportional to temperature. We will often refer to (1.3) as it provides scaling relations among the parameters of the problem and it will help us to understand the nucleation process in terms of adimensional relations. If, instead of (1.3), we let $N = \Delta x^{-1}$ with β and k fixed then, as $\Delta x \to 0$, we obtain the stochastic Allen–Cahn equation:

$$\frac{\partial}{\partial t}\boldsymbol{\phi}_t(x) = \epsilon^2\frac{\partial^2}{\partial x^2}\boldsymbol{\phi}_t(x) + \boldsymbol{\phi}_t(x) - \boldsymbol{\phi}_t^3(x) + \sigma\,\boldsymbol{\xi}_t(x), \tag{1.6}$$

where $\epsilon^2 = k/N^2$, $\sigma = (2\Delta x/\beta)^{1/2}$, and $x \in [0, 1]$. In the SPDEs, a configuration is a continuous function of x, $\boldsymbol{\phi}_t(x)$, obtained by fixing t in one realization. At most values of x, $\boldsymbol{\phi}_t(x)$ is close to either -1 or $+1$. A narrow region where the configuration crosses through 0 from below is called a kink; one where it crosses from above is called an antikink. The width of a kink in the ϕ^4 SPDE is order 1; in the Allen–Cahn case it is proportional to ϵ [10, 11, 12]. We shall concentrate on the ϕ^4 SPDE below.

After a sufficiently long time, in both the continuum SPDEs and the discrete system, a statistically steady state is attained and maintained by a balance between continual nucleation of new domains and the diffusion and annihilation of existing ones [13, 14, 3]. Many steady-state quantities, such as the mean number of kinks per unit length, can be calculated from

the invariant density of the SPDE, by evaluating the partition function [15, 16, 17]. Further insight has recently been obtained by demonstrating the equivalence between the invariant density of paths of the SPDE, on the spatial domain $[0, L]$, and the density of paths of a suitable bridge process [18, 19], with time in the interval $[0, L]$.

Simple models, in which kinks and antikinks are nucleated with a fixed separation, diffuse and annihilate on collision and give insight into the dynamics that produces and maintains the stationary density [20, 21, 22, 23]. If kink-antikink dynamics in our symmetric system is described in terms of a potential as a function of separation, a nucleation event is a fluctuation-induced escape from a well to a flat region. Büttiker and Christen calculated the nucleation rate by introducing a parameter analogous to a nucleus size s [20]. The mean kink lifetime is proportional to s and the nucleation rate is inversely proportional to s, so that the steady-state kink density is independent of s. More detailed models also calculate the distribution of kink lifetimes [3, 21, 23]. The initial separation at the instant of nucleation is an input parameter in these simple models; in order to calculate the appropriate value in the SPDE dynamics, it is necessary to return the focus to the details of the nucleation process.

1.1. The energy landscape. In chains sufficiently short that transitions are collective, the complete passage time is most conveniently calculated by considering the energy function of the discretized system:

$$E(\mathbf{\Phi}_t(1), \ldots, \mathbf{\Phi}_t(N)) = \sum_{i=1}^{N} \left(V(\mathbf{\Phi}_t(i)) + \frac{1}{2} k \left(\mathbf{\Phi}_t(i) - \mathbf{\Phi}_t(i-1) \right)^2 \right). \tag{1.7}$$

The initial condition is at the energy minimum: $E(-1, \ldots, -1) = -N/4$. If the transition is collective, crossing the saddle point on the energy surface at the origin $E(0, \ldots, 0) = 0$ involves surmounting an energy barrier $\frac{1}{4}N$; the mean time for such a transition is proportional to $\exp(\frac{1}{4}\beta N)$. On the other hand, if only a part of the system makes the initial transition, the energy barrier is less than $\frac{1}{4}N$; the nucleation event produces a region with two boundaries. In the latter case, which we call the "nucleation-diffusion regime," it is convenient to calculate the nucleation rate working in the continuum limit, (1.4), where the analogue of (1.7) is the energy functional [4]

$$\mathcal{E}[\boldsymbol{\phi}_t] = \int \left(V(\boldsymbol{\phi}_t) + \frac{1}{2} \left(\frac{\partial}{\partial x} \boldsymbol{\phi}_t \right)^2 \right) \mathrm{d}x. \tag{1.8}$$

The energy of a kink is $E_k = \mathcal{E}[\psi] = \sqrt{8/9}$ [1]. A kink or antikink has energy E_0; a transition creates one of each and therefore has energy barrier $2E_0$ and characteristic time $\exp(\frac{2E_0}{\Theta})$ [24, 25, 26, 27, 15, 4]. The numerical value of the kink energy depends on the precise potential used, but the qualitative dynamics requires only a double-well potential with wells of equal depth. It is also possible to study SPDEs where $V(\phi)$ has two (or more) wells of unequal depth, so that there are stable and metastable states. Then, one can base calculations of nucleation rates on the idea of a critical nucleus or droplet [27, 28, 29, 30, 31], an extremum of (1.8), whose length diverges as the asymmetry between wells vanishes.

In an interval containing only one kink, centered at $\mathbf{X}_t$, the configuration can be written as $\boldsymbol{\phi}_t(x) = \psi(x - \mathbf{X}_t) + (\Theta/E_\mathrm{k})^{1/2} \chi(x - \mathbf{X}_t)$, where ψ is a smooth function, satisfying

$V'(\psi) + \psi''(x) = 0$, with $\psi(x) \to \pm 1$ as $x \to \pm\infty$, that gives the shape of an unperturbed kink. The fluctuating stochastic field χ then has stationary statistical properties [32, 33].

The idea that collective transitions are favored in small domains but another mechanism is at work in larger domains has also emerged from numerical and analytical studies of minimum-action transition paths [4, 34, 6, 5]. Optimal transitions consist of nucleation events followed by propagation of domain walls, with behavior depending on L and on the (periodic, Dirichlet, or Neumann) boundary conditions.

In this work we locate, by simple numerical experiments, the crossover from collective transitions to nucleation-diffusion behavior. In the latter regime, the characteristic width of newly nucleated regions is $b = 8E_0$ and the complete passage time is proportional to $\exp(2E_0/\Theta)$. This value of b, obtained from the slope of the logarithm of the complete passage time versus Θ^{-1}, is consistent with numerical observations of the critical value of L at which the crossover from collective to nucleation-diffusion behavior is found, and with the long-held hypothesis that the separation between a kink and an antikink at nucleation is several times the kink width.

Systematic computational studies of the ϕ^4 SPDE, in the limit $L \to \infty$, require low temperatures in order to unambiguously identify kinks; they are computationally costly because the steady-state density of kinks decreases exponentially with temperature (necessitating very long chains) and the equilibration time increases exponentially with temperature (necessitating very long runs). Our aim in this paper is complementary to such studies. We focus on the dynamics of small- to medium-length chains in order to distinguish the regimes of collective transitions and of nucleation-diffusion. Although a first-principles theory of nucleation is the most difficult theoretical challenge, numerical studies that focus only on the measurement of the nucleation rate have the advantage of not needing to first attain a steady state.

In section 2 we define the complete passage time, our adopted measure of the mean time for the whole chain to make the transition from one well to another. The key observation is that there is a critical number of particles in the chain, below which the complete passage time increases exponentially and above which it increases more slowly. In the course of deriving theoretical expressions for the complete passage time, we are led to consider the short-range interaction between kinks and antikinks. This is examined in a second set of numerical experiments, differing from the first in the initial conditions, which now have a kink and an antikink relatively close together. Also, in section 2, we use numerical results to make an estimate of the typical separation, b, of a kink-antikink pair at nucleation. In section 3 we report on numerical experiments where the distribution of the "center-of-mass" of the chain is measured by means of long numerical runs and displayed in terms of an "effective potential" that has the Büttiker–Christen form of two wells separated by a long flat region.

2. Complete passage time.

Our first set of numerical experiments measures the time taken for all particles to make the transition from one minimum to the other. We choose the initial condition $\mathbf{\Phi}_0(i) = -1$, $i = 1, \ldots, N$, and denote

$$\mathbf{h} = \inf\left\{ t > 0 : \sum_{i=1}^{N} \mathbf{\Phi}_t(i) = N \right\}. \tag{2.1}$$

The complete passage time, τ, is defined as the mean of $\mathbf{h}$: $\tau = \mathbb{E}(\mathbf{h})$.

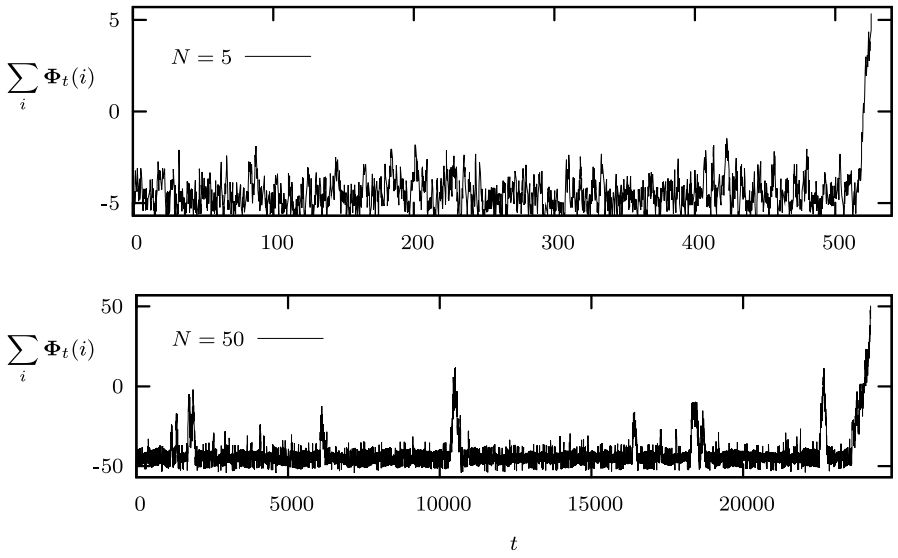

Figure 1. *Realizations of the coupled-particle system with $\beta = 6$ and $k = 1$, illustrating the two routes to a complete passage of the chain from one well to another. Upper timeseries: $N = 5$, collective regime; Lower timeseries: $N = 50$, nucleation-diffusion regime.*

In Figure 1, the sum $\sum_i \mathbf{\Phi}_t(i)$ is plotted as a function of time for two realizations. In the top part of the figure, $N = 5$, $\beta = 6$, and $k = 1$. The transition from one well to the other is collective; all particles in the chain make the transition close together. The second realization, shown in the lower part of the figure, has $N = 50$, $\beta = 6$, and $k = 1$. Several episodes are visible where the sum increases and then falls back to its starting level. These correspond to nucleation-diffusion episodes: a group of nearby particles makes the transition to the upper well, creating a region with two boundaries. The boundaries diffuse until the region either disappears or encompasses the whole chain.

Figure 2 shows τ versus N for $k = 1$ and four values of β. A data point typically corresponds to 10^3 realizations. We observe, in numerical experiments of this type, that the critical number of particles, at which the crossover from collective to nucleation-diffusion behavior is found, is independent of β if k is fixed. In Figure 3, three graphs of τ against N are displayed with different values of k; all have $\beta = 6$. The critical number of particles is seen to be an increasing function of k.

The existence of the SPDE limit implies that the passage time should approach a limit as $k \to \infty$ ($\Delta x \to 0$), with $L = N/\sqrt{k}$ fixed. In Figure 4, the mean passage time is plotted against L, using the scaled variables (1.3). Each data set has the same value of $\Theta = (\beta\sqrt{k})^{-1}$. The figure shows a much greater degree of universality than we expected: the data corresponding to large and small values of k are difficult to distinguish on the scale of the figure.

2.1. Analytical expressions. We develop our analytical approximations in the continuum limit using the scaled variables (1.3). Then the complete passage time, $\tau(\Theta, L)$, is a function of the temperature and the length of the domain.

Transitions are collective in sufficiently short chains because there is a single, well-defined, saddle point on the energy surface, with the whole chain at 0, separating two global minima,

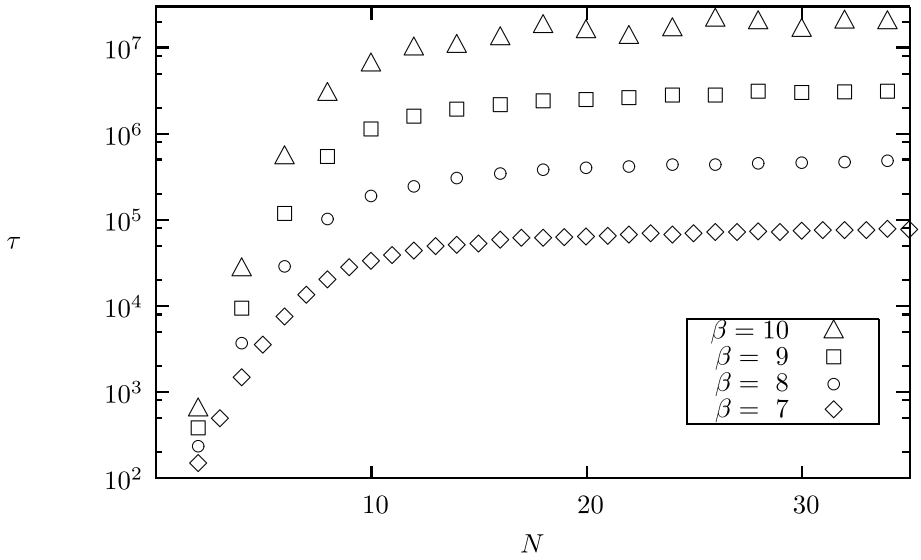

Figure 2. *Complete passage time versus number of particles for $k = 1$. The critical number of particles is independent of β. (Statistical errors are approximately the symbol sizes.)*

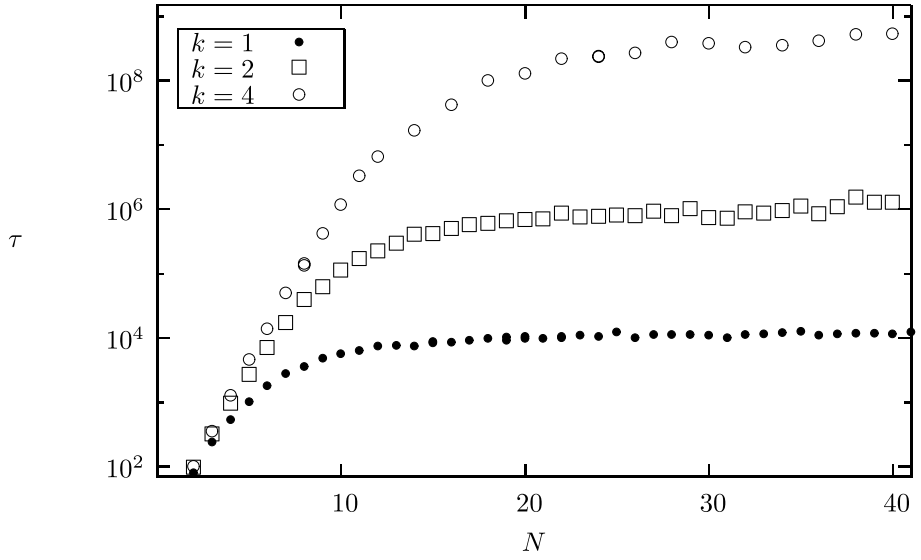

Figure 3. *Complete passage time versus number of particles for $\beta = 6$. The critical number of particles is an increasing function of k.*

with the whole chain at ± 1. The probability per unit time of a transition over the saddle point is calculated by constructing a nonequilibrium steady-state density which is the equilibrium density multiplied by a function of the distance along a line connecting the minima via the saddle [24, 25, 26]. As $\Theta \to 0$ and $L \to 0$, $\tau(\Theta, L) \to \tau_{\mathrm{c}}(\Theta, L)$, where

$$\tau_{\mathrm{c}}(\Theta, L) = \left(A_{\mathrm{c}}(L) + \mathcal{O}(\Theta^{-1})\right) \exp\left(\frac{1}{4}\frac{L}{\Theta}\right). \tag{2.2}$$

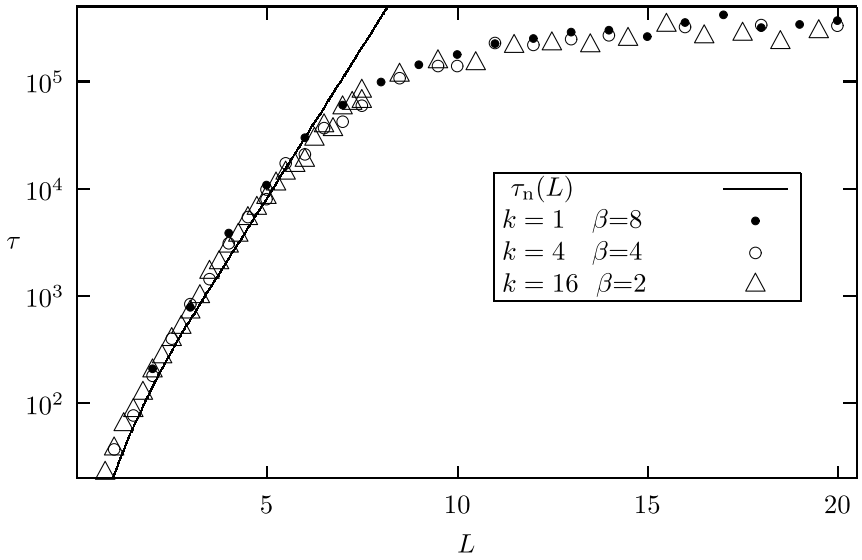

Figure 4. *Complete passage time versus L for $\Theta = \frac{1}{8}$. The values of $k = 1$, $k = 4$, and $k = 16$ correspond to $\Delta x = 1$, $\Delta x = 0.5$, and $\Delta x = 0.25$. The solid line is $4\pi \exp(-\frac{L}{\sqrt{2}}) \exp(\frac{1}{4}\frac{L}{\Theta})$, valid for collective transitions.*

The exponent in (2.2) is the difference between the energy at the saddle point and that at the minima; the prefactor $A_c(L)$ is sometimes referred to as a frequency factor. Its square is the ratio of the products of the eigenvalues corresponding to the N stable directions at a minimum and the $N-1$ stable directions at the saddle point. Interestingly, the ratio diverges at $L = 2\pi$ [34, 12, 35], corresponding to a breakdown of the collective-transition hypothesis. For our purposes, let us write

$$\tau(\Theta, L) = \left(A(L) + \mathcal{O}(\Theta^{-1})\right) \exp\left(\frac{f(L)}{4\Theta}\right), \tag{2.3}$$

with $A(L)$ and $f(L)$ to be determined, in the collective regime, the nucleation-diffusion regime, and the crossover region between the two. According to (2.2), as $L \to 0$, $f(L)/L \to 1$. We conjecture that, as L increases, $f(L) \to b$ and $A(L) \to A_\infty$ for constants b and A_∞ to be determined. This choice of functional form will be justified a posteriori by comparison with numerical data.

Next, consider the situation for $L > b$. Here, we make the hypothesis that nucleation events, equally likely to happen anywhere, always produce a region of width b. In other words, there is a constant probability per unit length and time, $\Gamma = (b\tau_n(\Theta, b))^{-1}$, of a nucleation event. Let the probability that a region of width x grows to encompass the whole domain be $q(x, L)$. Then

$$\tau(\Theta, L) = \frac{b}{L}\frac{1}{q(b, L)}\left(\tau_n(\Theta, b) + \tau_d(\Theta, b, L)\right), \quad L > b,$$

where $\tau_d(\Theta, b, L)$ is the mean time spent during a diffusion episode. It is easy to calculate an upper limit on $\tau_d(\Theta, b, L)$ by ignoring the short-range kink-antikink attraction, assuming that each diffuses with diffusivity Θ/E_0 [32, 36]:

$$\tau_{\mathrm{d}}(\Theta, b, L) < \frac{bLE_0}{4\Theta}.$$

The strict limit $L \to \infty$ requires a statistical theory of multiple kinks and antikinks and a different stopping criterion than (2.1); it is not the subject of this article. We concentrate on small- to medium-length domains that do not contain multiple kink-antikink pairs. In particular, we choose L sufficiently small that the probability of a second nucleation event during a diffusion episode is negligible, which is precisely the condition that $\tau_{\mathrm{n}}(\Theta, b) \gg \tau_{\mathrm{d}}(\Theta, b, L)$. The complete passage time then simplifies to

$$\tau(\Theta, L) \simeq \frac{b}{L} \frac{\tau_{\mathrm{n}}(\Theta, b)}{q(b, L)}, \quad b \ll L \ll L^*, \tag{2.4}$$

where $L^* = \frac{4\Theta}{bE_0} \exp(b/4\Theta)$. At the temperature ranges of interest here, L^* is many orders of magnitude greater than b.

2.2. Short-range kink-antikink interaction. To proceed in the calculation of the complete passage time, we need to consider the function $q(b, L)$. If we were to ignore the attraction between kinks and antikinks, their motion would be purely diffusive and the probability that a region of width x grows to encompass the entire domain of length L would be equal to the probability that a Brownian motion, started at $x > 0$, reaches L before 0. Thus, at first approximation, $q(x, L) \simeq q_0(x, L)$, where

$$q_0(x, L) = \frac{x}{L}. \tag{2.5}$$

In order to ascertain the effect on $q(x, L)$ of the short-term interaction between a kink and an antikink, we performed a set of numerical experiments with initial conditions corresponding to a domain of width x:

$$\mathbf{\Phi}_0(i) = \begin{cases} 1, & i \le n, \\ -1, & n < i \le N, \end{cases}$$

where $n = x/\sqrt{k}$. Realizations were stopped the first time that either $\sum_{i=1}^{N} \mathbf{\Phi}_t(i) = 0$ or $\sum_{i=1}^{N} \mathbf{\Phi}_t(i) = N$. The probability of the latter outcome is plotted as a function of L in Figure 5. Based on these numerical data, we devised the following approximation:

$$q(b, L) \simeq \frac{b - a}{L - 2a}. \tag{2.6}$$

The intuitive motivation for the form (2.6) is that two domain walls experience a strong attraction at separations less than a. The lines in Figure 5 are (2.5) and (2.6), using the least-squares best fit value of a, which yielded $a = 5.4 \pm 0.1$.

With (2.6), we have the following expression for the complete passage time in the nucleation-diffusion regime as $\Theta \to 0$:

$$\tau(\Theta, L) \to \frac{1 - 2a/L}{1 - a/b} A_\infty \exp\left(\frac{1}{4}\frac{b}{\Theta}\right). \tag{2.7}$$

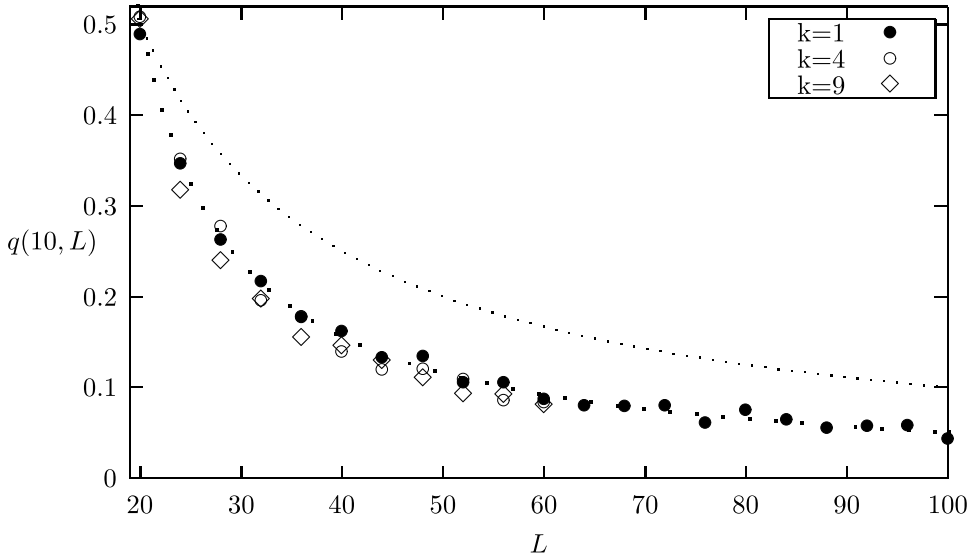

Figure 5. *The effect of the short-range kink-antikink attraction. The probability that an initial region of width $x = 10$ grows to encompass the entire domain of length L is plotted against L for $k = 1$, $k = 4$, and $k = 9$. In all cases $\Theta = 0.01$. The dotted lines are (2.5), which would hold if there were no attraction, and (2.6).*

2.3. Estimating the width *b*. By comparing the expression (2.7) with numerical data, we can estimate the value of the parameter b, the characteristic width of nucleation regions. In particular,

$$\tau(\Theta, L) \to \frac{A_\infty}{1 - a/b} \exp\left(\frac{1}{4}\frac{b}{\Theta}\right), \quad b \ll L \ll L^*. \tag{2.8}$$

That is, the logarithm of the complete passage time is a linear function of Θ^{-1}. The slope is proportional to b as L/b increases.

Figure 6 contains four plots summarizing numerical data with $L = 5$, $L = 10$, $L = 20$, and $L = 30$. The numerical runs were carried out with $k = 4$. For sufficiently small L, transitions are collective and (2.2) holds, so that the slope of a graph of $\ln \tau$ versus Θ^{-1} is proportional to L. The first set of numerical data, with $L = 5$, falls into this regime. As a function of L, the slope does not increase indefinitely but approaches a well-defined limit. A least-squares fit of the numerical data for large L gives $b = 7.4 \pm 0.1$. This value is consistent with the knee in our numerical curves of complete passage time versus L and with the following argument.

The complete passage time is proportional to $\exp(\frac{1}{4}\frac{L}{\Theta})$ for sufficiently small L and proportional to $\exp(\frac{2E_0}{\Theta})$ for long chains. With the ansatz $\tau \propto \exp(\frac{1}{4}\frac{f(L)}{\Theta})$,

- $f(L)/L \to 1$ as $L \to 0$, and
- $f(L) \to 8E_0$ when $b \ll L \ll L^*$,

thus identifying the characteristic mean width of newly nucleated regions as $b = 8E_0$. (In the Allen–Cahn scaling (1.6), the characteristic width of a newly nucleated region is $8E_0\epsilon$.)

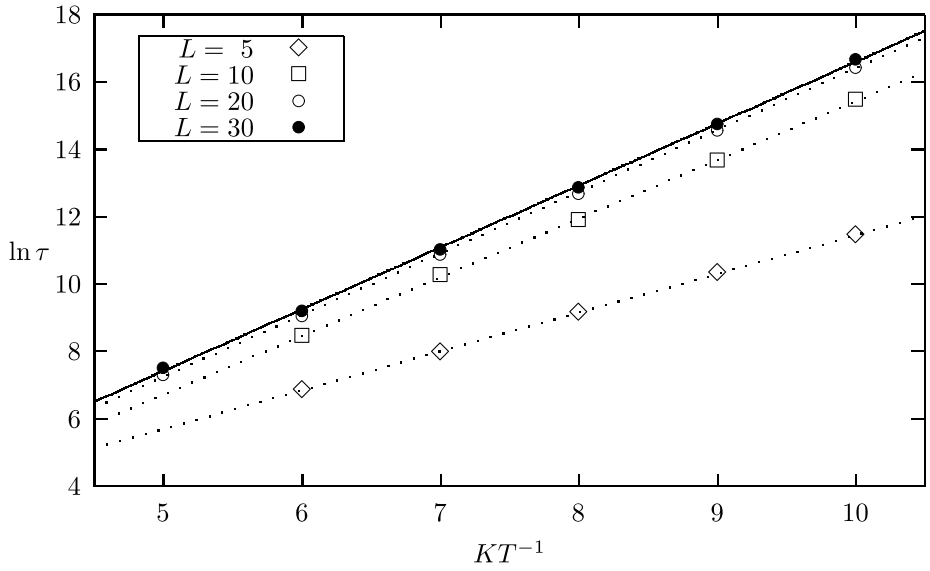

Figure 6. *Estimating the width, b, from numerical data. For sufficiently small L, the complete passage time of a domain length L is proportional to* $\exp(\frac{1}{4}\frac{L}{\Theta})$*; when* $L \gg b$*, it is proportional to* $\exp(\frac{1}{4}\frac{b}{\Theta})$*. The solid line, a least-squares fit to the* $L = 40$ *data, has slope corresponding to* $b = 7.4$*.*

3. Effective potential. Chains, whatever their length, eventually reach a stationary state where transitions are equally frequent in either direction. In the final set of numerical experiments reported here, we exploit the stationarity of the long-term dynamics by considering the "center-of-mass" process, defined as

$$\boldsymbol{\phi}_t = \frac{1}{N}\sum_{i=1}^{N} \boldsymbol{\Phi}_t(i), \tag{3.1}$$

and we construct its stationary density. In practice, the time for the system to explore all regions of state space thoroughly is several orders of magnitude greater than the complete passage time. The stationary density of the center-of-mass is denoted

$$\rho(\phi) = \lim_{t\to\infty} \frac{\mathrm{d}}{\mathrm{d}x}\mathcal{P}[\boldsymbol{\phi}_t < \phi]; \tag{3.2}$$

the effective potential, $V_{\mathrm{eff}}(\phi)$, is defined via $\rho(\phi) = \mathrm{e}^{-V_{\mathrm{eff}}(\phi)}$.

At parameter values such that transitions are collective, the effective potential is not dissimilar to $V(\phi)$. In the regime of nucleation-diffusion behavior, on the other hand, a long plateau appears in the effective potential, terminated at either end by a narrow well. See Figure 7. The wells are approximately quadratic near the minima, at $\boldsymbol{\phi} = \pm(1 - \frac{1}{2}\frac{\Theta}{E_0})$ [37, 38, 39]; the width of each well is $(\Theta/(3N))^{1/2}$ [37].

The effective potential takes a pleasingly universal form under the scaling (1.3). In Figure 8, we plot numerical results, all obtained on chains with $L = 100$ and $\Theta = \frac{1}{8}$. The three values of k correspond to $N = 100$, $N = 200$, and $N = 400$.

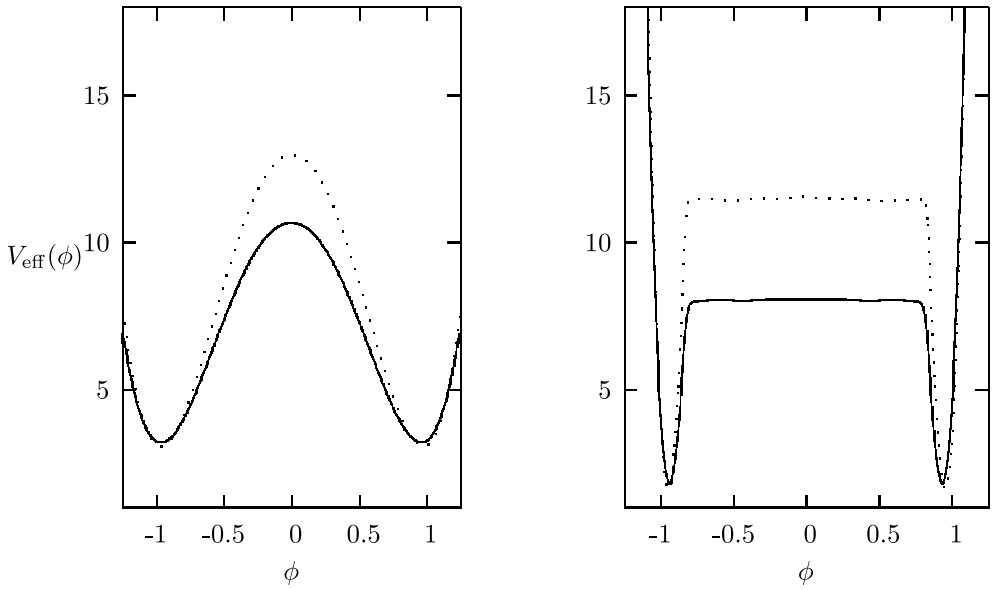

Figure 7. *Effective potential: Numerical results with $k = 1$. Solid lines: $\beta = 8$. Dotted lines: $\beta = 10$. On the left, $N = 5$ and transitions are collective. On the right, $N = 100$ and the chain exhibits nucleation-diffusion behavior.*

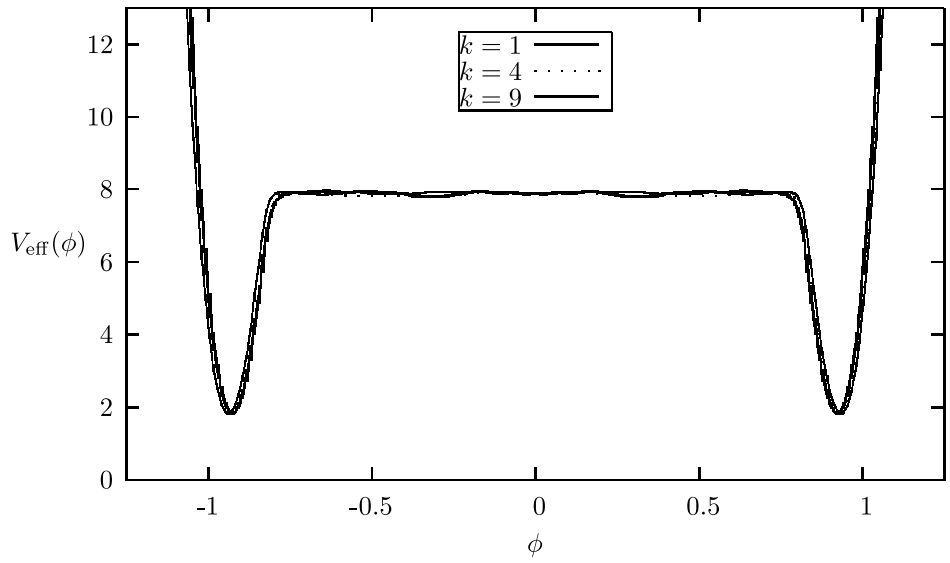

Figure 8. *The effective potential for three values of k, with $\Theta = \frac{1}{8}$ and $L = 100$. The wide central plateau corresponds to the freedom of a kink-antikink separation to wander over the majority of the length of the chain without noticeably affecting the total energy.*

The effective potentials, in Figure 8 and on the right in Figure 7, bear a striking resemblance to those of Büttiker and Christen [14, 20], introduced to provide an intuitive understanding of the dynamics of the nucleation-diffusion regime. A nucleation event is imagined as an exit from a potential well to a long flat region, which corresponds to the freedom of the

kink and antikink, once they have attained a certain separation, to wander over large parts of the chain without affecting the total energy of the configuration. The potential well at the opposite end of the flat region corresponds to the possibility that the nucleated region grows to encompass the whole domain; the kink and antikink meet again and annihilate. Our numerical experiments construct, in a systematic manner, a potential with these useful illustrative properties.

Hopf Bifurcation in Coupled Cell Networks with Interior Symmetries*

Fernando Antoneli†, Ana Paula S. Dias‡†, and Rui C. Paiva‡†

Abstract. We consider an important class of nonsymmetric networks that lies between the class of general networks and the class of symmetric networks, where group theoretic methods still apply—namely, networks admitting "interior symmetries." The main result of this paper is the full analogue of the equivariant Hopf theorem for networks with symmetries. We extend the result of Golubitsky, Pivato, and Stewart [*Dyn. Syst.*, 19 (2004), pp. 389–407] to obtain states whose linearizations on certain subsets of cells, near bifurcation, are superpositions of synchronous states with states having spatio-temporal symmetries.

Key words. interior symmetries, coupled cell networks, bifurcation theory

DOI. 10.1137/070684604

1. Introduction.

Recently, a new framework for the dynamics of networks has been proposed, with particular attention to patterns of synchrony and associated bifurcations. See Stewart, Golubitsky, and Pivato [11], Golubitsky, Pivato, and Stewart [4], Golubitsky, Nicol, and Stewart [3], and Golubitsky, Stewart, and Török [9]. Here, a network is represented by a directed graph whose nodes and edges are classified according to associated labels or "types." The nodes (or "cells") of a network $\mathcal{G}$ represent dynamical systems, and the edges ("arrows") represent couplings. Cells with the same label have "identical" internal dynamics; arrows with the same label correspond to identical couplings. The "input set" of a cell is the set of edges directed to that cell. Label-preserving bijections between input sets of cells are called "input isomorphisms," and they capture the "local" symmetries of the network. The set of all these local symmetries has the structure of a groupoid. (A groupoid is an algebraic structure similar to a group, except that products of elements may not always be defined.)

Coupled cell systems are dynamical systems compatible with the architecture or topology of a directed graph representing the network. Formally, they are defined in the following way. Each cell c is equipped with a phase space P_c, and the total phase space of the network is the Cartesian product $P = \prod_c P_c$. A vector field f is called "admissible" if its component f_c for cell c depends only on variables associated with the input set of c (domain condition) and

if its components for cells c, d that have isomorphic input sets are identical up to a suitable permutation of the relevant variables (pull-back condition).

In the study of network dynamics there is an important class of networks, namely, networks that possess a group of symmetries. In this context there is a group of permutations of the cells (and arrows) that preserves the network structure (including cell-types and arrow-types), and its action on P is by permutation of cell coordinates. Moreover, the coupled cell systems (ODEs) are of the form

$$\frac{\mathrm{d}x}{\mathrm{d}t} = f(x),$$

where the vector field f is smooth (C^∞) and satisfies

$$f(\gamma x) = \gamma f(x) \qquad \forall\, x \in P,\, \gamma \in \Gamma.$$

That is, f is "equivariant" under the action of the group Γ on phase space P.

The theory of equivariant dynamical systems (see Golubitsky and coworkers [6, 8]) can be applied to such dynamical systems. In this theory, a central role is played by the "fixed-point spaces" of subgroups $\Sigma \subseteq \Gamma$, defined by

$$\mathrm{Fix}(\Sigma) = \{x \in P : \sigma x = x \ \ \forall\, \sigma \in \Sigma\}.$$

Fixed-point spaces have the important property of flow invariance: they are invariant under *every* smooth equivariant vector field f, so that

$$f(\mathrm{Fix}(\Sigma)) \subseteq \mathrm{Fix}(\Sigma).$$

See [6, Lemma XIII 2.1] or [8, Theorem 1.17] for the simple proof and the implications for symmetry-breaking. In this context, there are two main local bifurcation theorems. The *equivariant branching lemma* (see Golubitsky, Stewart, and Schaeffer [8, Theorem XIII 3.3]) proves the existence of certain branches of symmetry-breaking steady states; the *equivariant Hopf theorem* (see [8, Theorem XVI 4.1]) proves the existence of certain branches of spatio-temporal symmetry-breaking time-periodic states.

In between the class of general networks and the class of symmetric networks lies an interesting class of nonsymmetric networks, where group theoretic methods still apply, namely, networks admitting "interior symmetries." In this case there is a group of permutations of a subset $\mathcal{S}$ of the cells (and edges directed to $\mathcal{S}$) that partially preserves the network structure (including cell-types and edge-types), and its action on P is by permutation of cell coordinates. In other words, the cells in $\mathcal{S}$ together with all the edges directed to them form a subnetwork which possesses a nontrivial group of symmetry $\Sigma_{\mathcal{S}}$. For example, network $\mathcal{G}_1$ (Figure 1 (left)) has exact $\mathbf{S}_3$-symmetry, whereas network $\mathcal{G}_2$ (Figure 1 (right)) has $\mathbf{S}_3$-interior symmetry. This notion was introduced and investigated by Golubitsky, Pivato, and Stewart [4]. The presence of interior symmetries places some restrictions on the structure of the network.

The local bifurcations from a synchronous equilibrium can be classified into two types: "synchrony-breaking" bifurcations and "synchrony-preserving" bifurcations. The synchrony-breaking bifurcations occur when a synchronous state loses stability and bifurcates to a state with less synchrony. Such bifurcations can be considered to be generalizations of symmetry-breaking bifurcations in symmetric coupled cell systems. Golubitsky, Pivato, and Stewart [4]

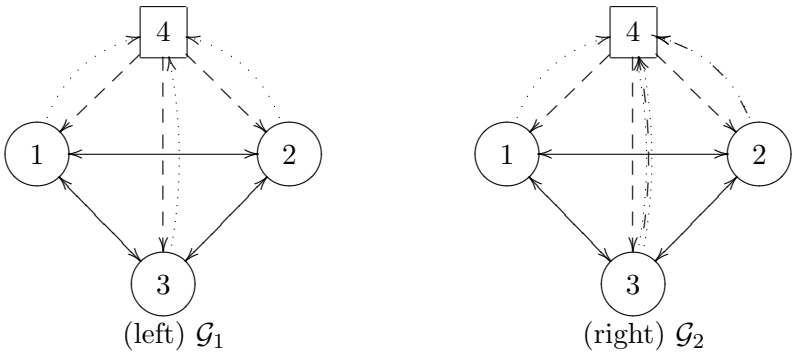

Figure 1. *(Left) Network $\mathcal{G}_1$ with exact $\mathbf{S}_3$-symmetry. (Right) Network $\mathcal{G}_2$ with $\mathbf{S}_3$-interior symmetry.*

provided analogues of the equivariant branching lemma and the equivariant Hopf theorem for coupled cell systems with interior symmetries. The analogue of the equivariant branching lemma is a natural generalization of the symmetric case, but the analogue of the equivariant Hopf theorem has novel and rather restrictive features. In particular, instead of proving the existence of states with certain spatio-temporal symmetries, they prove the existence of states whose linearizations on certain subsets of cells, near bifurcation, are superpositions of synchronous states with states having spatial symmetries.

The main result of this paper is the full analogue of the equivariant Hopf theorem for networks with symmetries (Theorem 4.8). We extend the result of Golubitsky, Pivato, and Stewart [4] to obtain states whose linearizations on certain subsets of cells, near bifurcation, are superpositions of synchronous states with states having *spatio-temporal symmetries*, that is, corresponding to "interiorly" $\mathbf{C}$-axial subgroups of $\Sigma_{\mathcal{S}} \times \mathbf{S}^1$. This new version of the Hopf theorem with interior symmetries includes the previous version as a special case and is in complete analogy with the equivariant Hopf theorem (see Theorem 4.8). Our proof uses a modification of the Lyapunov–Schmidt reduction to arrive at a situation where the proof of the standard Hopf bifurcation theorem can be applied. This completes the program of generalizing the two main results from equivariant bifurcation theory to the class of networks with interior symmetries.

Structure of the paper. Section 2 recalls the formal definition of a coupled cell network and the associated dynamical systems, and states some basic features, including the concept of a balanced equivalence relation (coloring). We also discuss the symmetry group of a network. Section 3 recalls the definition of interior symmetry given by Golubitsky, Pivato, and Stewart [4] and gives an equivalent condition, in terms of symmetries of a subnetwork, which in some cases (no multiple edges and no self-connections) amounts to finding the symmetries of the subnetwork. We also analyze the structure of these networks and discuss some features of the admissible vector fields associated with such a class of networks. Section 4 recalls the notion of synchrony-breaking bifurcation in coupled cell networks. Then we specialize to networks with interior symmetries where group theoretic concepts play a significant role, focusing on the important case of codimension-one synchrony-breaking bifurcations. The main part of this section gives the statement and proof of the interior symmetry-breaking Hopf bifurcation theorem (Theorem 4.8) for networks with interior symmetries. We illustrate all the concepts

and results by a running example of the simplest network with $\mathbf{S}_3$-interior symmetry and the closely related network with exact $\mathbf{S}_3$-symmetry (see Figure 1). Finally, we present a numerical simulation of the states provided by Theorem 4.8 in the case of our running example.

2. Network formalism. First, we recall the formal definition of a coupled cell network and the associated dynamical systems. For a survey, overview, and examples, see [7]. The initial definition of coupled cell network [11] was modified in [9] to permit multiple arrows and self-connections, which turns out to have major advantages. More recently, Stewart [10] extended the formalism introduced in [9] to include a large class of infinite networks—the so-called *networks of finite type*.

2.1. Coupled cell networks. In this paper we consider *finite networks* and so employ the "finite multiarrow" formalism for consistency with the existing literature.

Definition 2.1 (see [9]). *A* coupled cell network $\mathcal{G}$ *comprises the following:*

(a) *A finite set* $\mathcal{C}$ *of* nodes *or* cells.

(b) *An equivalence relation* $\sim_C$ *on cells in* $\mathcal{C}$*, called* cell-equivalence. *The* type *or* cell label *of cell* c *is its* $\sim_C$*-equivalence class.*

(c) *A finite set* $\mathcal{E}$ *of* edges *or* arrows.

(d) *An equivalence relation* $\sim_E$ *on edges in* $\mathcal{E}$*, called* edge-equivalence *or* arrow-equivalence. *The* type *or* coupling label *of edge* e *is its* $\sim_E$*-equivalence class.*

(e) *Two maps* $\mathcal{H} : \mathcal{E} \to \mathcal{C}$ *and* $\mathcal{T} : \mathcal{E} \to \mathcal{C}$*. For* $e \in \mathcal{E}$ *we call* $\mathcal{H}(e)$ *the* head *of* e *and* $\mathcal{T}(e)$ *the* tail *of* e*.*

We also require a consistency condition:

(f) *Equivalent arrows have equivalent tails and heads:*

$$\mathcal{H}(e_1) \sim_C \mathcal{H}(e_2), \qquad \mathcal{T}(e_1) \sim_C \mathcal{T}(e_2)$$

for all $e_1, e_2 \in \mathcal{E}$ *with* $e_1 \sim_E e_2$*.*

Example 2.2. We can represent abstract networks by labeled directed graphs. Figure 1 shows two examples. Here the node labels, drawn as the three circles and the square, indicate the cells; the symbols show that cells $1, 2, 3$ have the same type, whereas cell 4 is different, in both cases. In the network $\mathcal{G}_1$ there are three types of edge label, whereas in the network $\mathcal{G}_2$ there are five types of edge label, drawn as different styles of arrows. The tail and head of each edge is, respectively, indicated by the absence or presence of a tip on one end of the arrow. When an arrow between cells c and d is drawn with tips at both ends, then it represents two arrows of the same type with opposite orientation between cells c and d.

2.2. Input sets and the symmetry groupoid. Associated with each cell $c \in \mathcal{C}$ is a canonical set of edges, namely, those that represent couplings into cell c, as described next.

Definition 2.3 (see [9]). *If* $c \in \mathcal{C}$*, then the* input set *of* c *is the finite set of edges directed to* c*,*

$$I(c) = \{e \in \mathcal{E} : \mathcal{H}(e) = c\}. \tag{2.1}$$

Definition 2.4 (see [9]). *The relation* $\sim_I$ *of* input equivalence *on* $\mathcal{C}$ *is defined by* $c \sim_I d$ *if and only if there exists a bijection*

$$\beta : I(c) \to I(d) \tag{2.2}$$

such that for every $i \in I(c)$,

$$i \sim_E \beta(i). \tag{2.3}$$

Any such bijection β *is called an* input isomorphism *from cell* c *to cell* d. *The set* $B(c,d)$ *denotes the collection of all input isomorphisms from cell* c *to cell* d. *The union*

$$\mathcal{B}_{\mathcal{G}} = \bigcup_{c,d\in\mathcal{C}} B(c,d) \tag{2.4}$$

is the symmetry groupoid *of the network* $\mathcal{G}$. *A coupled cell network is* homogeneous *if all input sets are isomorphic.*

The groupoid operation on $\mathcal{B}_{\mathcal{G}}$ is composition of maps, and in general the composition $\beta\alpha$ is defined only when $\alpha \in B(a,b)$ and $\beta \in B(b,c)$ for cells a, b, c. This is why $\mathcal{B}_{\mathcal{G}}$ need not be a group.

Example 2.5. In our running examples, shown in Figure 1, it is easy to see that both networks have only two input isomorphism classes of cells: $\{1,2,3\}$ and $\{4\}$. The input sets of cells $1, 2, 3$ are isomorphic, since each one of them contains three edges, two of them drawn as a solid arrow with a circle in the tail and one of them drawn as a dashed arrow with a square in the tail.

2.3. Admissible vector fields. We now explain how to interpret such diagrams as Figure 1 as being representative of a class of vector fields.

For each cell in $\mathcal{C}$ choose a *cell phase space* P_c, which we assume to be a nonzero finite-dimensional real vector space. We require

$$c \sim_C d \quad \Rightarrow \quad P_c = P_d,$$

and in this case we employ the same coordinate systems on P_c and P_d. The *total phase space* is then

$$P = \prod_{c\in\mathcal{C}} P_c$$

with a cell-based coordinate system

$$x = (x_c)_{c\in\mathcal{C}}.$$

If $\mathcal{D} \subseteq \mathcal{C}$ is any finite set of cells, then we write

$$P_{\mathcal{D}} = \prod_{d\in\mathcal{D}} P_d$$

and

$$x_{\mathcal{D}} = (x_{c_1}, \ldots, x_{c_\ell}),$$

where $x_c \in P_c$.

For any $\beta \in B(c,d)$ we define the *pull-back map*

$$\beta^* : P_{\mathcal{T}(I(d))} \to P_{\mathcal{T}(I(c))}$$

by

$$(\beta^* z)_{\mathcal{T}(i)} = z_{\mathcal{T}(\beta(i))} \tag{2.5}$$

for all $i \in I(c)$ and $z \in P_{\mathcal{T}(I(d))}$.

We use pull-back maps to relate different components of a vector field associated with a given coupled cell network. Specifically, the class of vector fields that are encoded by a coupled cell network is given by the following definition.

Definition 2.6 (see [9]). *A map $f : P \to P$ is* $\mathcal{G}$-admissible *if the following hold:*

(a) Domain condition: *For all $c \in \mathcal{C}$ the component $f_c(x)$ depends only on the internal phase space variables x_c and the coupling phase space variables $x_{\mathcal{T}(I(c))}$; that is, there exists $\hat{f}_c : P_c \times P_{\mathcal{T}(I(c))} \to P_c$ such that*

$$f_c(x) = \hat{f}_c(x_c, x_{\mathcal{T}(I(c))}). \tag{2.6}$$

(b) Pull-back condition: *For all $c, d \in \mathcal{C}$ and $\beta \in B(c, d)$*

$$\hat{f}_d(x_d, x_{\mathcal{T}(I(d))}) = \hat{f}_c(x_d, \beta^* x_{\mathcal{T}(I(d))}) \tag{2.7}$$

for all $x \in P$.

Example 2.7. For the networks $\mathcal{G}_1$ and $\mathcal{G}_2$ of Figure 1 the cell phase spaces P_1, P_2, and P_3 are identical and equal to $\mathbf{R}^k$, whereas $P_4 = \mathbf{R}^l$. The general form of the admissible vector fields (ODEs) encoded by the network $\mathcal{G}_1$ is

$$\begin{aligned} \dot{x_1} &= f(x_1, \overline{x_2, x_3}, x_4), \\ \dot{x_2} &= f(x_2, \overline{x_3, x_1}, x_4), \\ \dot{x_3} &= f(x_3, \overline{x_1, x_2}, x_4), \\ \dot{x_4} &= g(x_4, \overline{x_1, x_2, x_3}), \end{aligned} \tag{2.8}$$

where $x_i \in \mathbf{R}^k$ $(i = 1, 2, 3)$, $x_4 \in \mathbf{R}^l$, $f : \mathbf{R}^{3k} \times \mathbf{R}^l \to \mathbf{R}^k$ is a smooth map invariant under permutation of the second and third arguments, and $g : \mathbf{R}^{3k} \times \mathbf{R}^l \to \mathbf{R}^l$ is a smooth map invariant under any permutation of the last three arguments. The general form of the admissible vector fields (ODEs) associated with the network $\mathcal{G}_2$ is

$$\begin{aligned} \dot{x_1} &= f(x_1, \overline{x_2, x_3}, x_4), \\ \dot{x_2} &= f(x_2, \overline{x_3, x_1}, x_4), \\ \dot{x_3} &= f(x_3, \overline{x_1, x_2}, x_4), \\ \dot{x_4} &= g(x_4, x_1, x_2, x_3), \end{aligned} \tag{2.9}$$

where $x_i \in \mathbf{R}^k$ $(i = 1, 2, 3)$, $x_4 \in \mathbf{R}^l$, $f : \mathbf{R}^{3k} \times \mathbf{R}^l \to \mathbf{R}^l$ is a smooth map invariant under permutation of the second and third arguments, and $g : \mathbf{R}^{3k} \times \mathbf{R}^l \to \mathbf{R}^l$ is a general smooth map.

2.4. Balanced equivalence relations. An equivalence relation $\bowtie$ on $\mathcal{C}$ determines a unique partition of $\mathcal{C}$ into $\bowtie$-equivalence classes, which can be interpreted as a coloring of $\mathcal{C}$ in which $\bowtie$-equivalent cells receive the same color. Conversely, any partition (coloring) determines a unique equivalence relation. The corresponding *polydiagonal* is

$$\triangle_{\bowtie} = \{x \in P : c \bowtie d \Rightarrow x_c = x_d\}. \tag{2.10}$$

A subspace V of P is called *admissibly flow-invariant* if $f(V) \subset V$ for all admissible vector fields f on P.

Definition 2.8 (see [9]). *An equivalence relation $\bowtie$ on $\mathcal{C}$ is* balanced *if for every $c, d \in \mathcal{C}$ with $c \bowtie d$ there exists $\beta \in B(c,d)$ such that $\mathcal{T}(i) \bowtie \mathcal{T}(\beta(i))$ for all $i \in I(c)$. The associated coloring is called a* balanced coloring. *In particular, $B(c,d) \neq \emptyset$ implies $c \sim_I d$. Hence, balanced equivalence relations refine input equivalence.*

A crucial property of balanced equivalence relations is that they define admissibly flow-invariant subspaces, and conversely the following holds.

Theorem 2.9 (Stewart, Golubitsky, and Pivato [11]). *Let $\bowtie$ be an equivalence relation on a coupled cell network. Then $\triangle_{\bowtie}$ is admissibly flow-invariant if and only if $\bowtie$ is balanced.*

The proof of the above result for finite networks is given in [9, 11] and for networks of finite type in [10]. The dynamical implication of such flow-invariance is that $\bowtie$ determines a *robust pattern of synchrony*: there exist trajectories $x(t)$ of the ODE such that

$$c \bowtie d \;\Rightarrow\; x_c(t) = x_d(t) \quad \forall\, t \in \mathbf{R}.$$

Such trajectories arise when initial conditions $x(0)$ lie in $\triangle_{\bowtie}$. Then the entire trajectory, for all positive and negative time, lies in $\triangle_{\bowtie}$ and is a trajectory of the restriction $f|_{\triangle_{\bowtie}}$. The associated dynamics can be steady-state, periodic, even chaotic, depending on f and its restriction to $\triangle_{\bowtie}$. An example of synchronized chaos generated by this mechanism can be found in [7].

Since there is always a canonical balanced relation $\sim_I$ on every network, let $\triangle_I$ denote the polydiagonal subspace of P associated with the input equivalence relation $\sim_I$, that is,

$$\triangle_I = \{x \in P : c \sim_I d \Rightarrow x_c = x_d\}.$$

Then $\triangle_I$ is a flow invariant subspace. Solutions of admissible vector fields contained in $\triangle_I$ represent the states of highest degree of synchrony allowed by the network.

Remark 2.10. Whenever self-connections or multiple arrows do not occur it will be convenient to revert to the formalism of [11], but now considered as a specialization of the multiarrow formalism. Since no two distinct arrows have the same head and tail, we can identify an arrow e with the pair of cells $(\mathcal{T}(e), \mathcal{H}(e))$. Now the set $\mathcal{E}$ of arrows identifies with a subset of $\mathcal{C} \times \mathcal{C} \setminus \{(c,c) : c \in \mathcal{C}\}$. Similarly the input set $I(c)$ can be identified with the set of all tail cells of arrows e that have c as a head cell.

Example 2.11. We continue with our running examples, the networks $\mathcal{G}_1$ and $\mathcal{G}_2$ of Figure 1. There is an equivalence relation $\bowtie$ for which $1 \bowtie 2$; its equivalence classes are $\{1,2\}$, $\{3\}$, and $\{4\}$. The corresponding polydiagonal is

$$\triangle_{\bowtie} = \{x \in P : x_1 = x_2\} = \{(x,x,y,z)\}.$$

On this subspace the differential equations become

$$\begin{aligned} \dot{x} &= f(x, \overline{x, y}, z), \\ \dot{x} &= f(x, \overline{y, x}, z), \\ \dot{y} &= f(y, \overline{x, x}, z), \\ \dot{z} &= g(z, x, x, y). \end{aligned} \tag{2.11}$$

Since the first two equations are identical (recall that the bar over x, y means that they can be interchanged), $\triangle_{\bowtie}$ is invariant under all admissible vector fields. The relation $\bowtie$ is balanced. The only condition to verify is that cells 1 and 2, which are $\bowtie$-equivalent but distinct, have input sets that are isomorphic by an isomorphism that preserves $\bowtie$-equivalence classes for both networks. In both networks the input sets are

$$I(1) = \{(2,1),(3,1),(4,1)\} \qquad \text{and} \qquad I(2) = \{(1,2),(3,2),(4,2)\},$$

where (c,d) denotes an arrow with tail c and head d (see Remark 2.10). The bijection $\beta : I(1) \to I(2)$ with $\beta((2,1)) = (1,2)$, $\beta((3,1)) = (3,2)$, and $\beta((4,1)) = (4,2)$ is an input isomorphism that preserves $\bowtie$-equivalence classes since $1 \bowtie 2$, $3 \bowtie 3$, and $4 \bowtie 4$. That is, $\bowtie$ is a balanced relation as claimed. There are two other balanced equivalence relations (different from $\sim_I$) on the networks $\mathcal{G}_1$ and $\mathcal{G}_2$. In one of them the equivalence classes are $\{2,3\}$, $\{1\}$, and $\{4\}$. In the other the equivalence classes are $\{1,3\}$, $\{2\}$, and $\{4\}$.

2.5. Symmetry groups of networks. We now consider symmetries of networks in the group theoretic ("global") sense.

Definition 2.12 (see [1]). *Let $\mathcal{G}$ be a network. A* symmetry *of $\mathcal{G}$ consists of a pair of bijections $\gamma_C : \mathcal{C} \to \mathcal{C}$ and $\gamma_E : \mathcal{E} \to \mathcal{E}$, where γ_C preserves input equivalence and γ_E preserves edge equivalence; that is, for all $c \in \mathcal{C}$ and $e \in \mathcal{E}$,*

$$\gamma_C(c) \sim_I c \qquad \text{and} \qquad \gamma_E(e) \sim_E e. \tag{2.12}$$

In addition, the two bijections must satisfy the consistency conditions

$$\gamma_C(\mathcal{H}(e)) = \mathcal{H}(\gamma_E(e)) \qquad \text{and} \qquad \gamma_C(\mathcal{T}(e)) = \mathcal{T}(\gamma_E(e)) \tag{2.13}$$

for all $e \in \mathcal{E}$. The set of all $\gamma = (\gamma_C, \gamma_E)$ forms a finite group $\mathrm{Aut}(\mathcal{G})$ *called the* symmetry group *of the network of $\mathcal{G}$.*

Observe that a symmetry γ preserves input sets in a natural sense. Because of the way input sets are defined in the multiarrow formalism, the precise relation is

$$\gamma_E(I(c)) = I(\gamma_C(c)),$$

where $\gamma = (\gamma_C, \gamma_E) \in \mathrm{Aut}(\mathcal{G})$.

Remark 2.13. When the network $\mathcal{G}$ has no self-connections and multiarrows there is a simplification of the notion of symmetry due to the following observation. Given a vertex permutation γ_C, there is a unique edge permutation γ_E satisfying the consistency condition (2.13); that is, γ_E is implicitly defined by γ_C since, by Remark 2.10, each arrow e can be identified with a pair of cells $(\mathcal{T}(e), \mathcal{H}(e))$. Thus a *symmetry* of $\mathcal{G}$ is given by a permutation γ of $\mathcal{C}$ such that

(a) $\gamma(c) \sim_I c$ for all $c \in \mathcal{C}$.
(b) $(\gamma(a), \gamma(b)) \in \mathcal{E} \Leftrightarrow (a, b) \in \mathcal{E}$.
(c) $(\gamma(a), \gamma(b)) \sim_E (a, b)\ \forall\ (a, b) \in \mathcal{E}$.

In this case, the group $\mathrm{Aut}(\mathcal{G})$ of symmetries of the network $\mathcal{G}$ is a subgroup of the group $\mathrm{Sym}(\mathcal{C})$ of permutations on the set of cells of the network. We shall adopt this convention throughout the remainder of the paper whenever the network under consideration has no self-connections and multiarrows.

Example 2.14. Since the networks $\mathcal{G}_1$ and $\mathcal{G}_2$ of our running example of Figure 1 do not have multiple arrows and self-connections, Remark 2.13 applies. The group $\mathbf{S}_3 \subset \mathbf{S}_4$ consisting of the transpositions $(1\,2)$, $(1\,3)$, $(2\,3)$, the 3-cycle permutations $(1\,2\,3)$, $(1\,3\,2)$, and the identity is the symmetry group of the network $\mathcal{G}_1$. Observe that cell 4 is fixed by the symmetry group. On the other hand, the network $\mathcal{G}_2$ has only the identity permutation as a symmetry because the arrows $(1, 4)$, $(2, 4)$, and $(3, 4)$ are all different amongst each other.

This last example shows that the definition of symmetry of a network is very rigid. In the next section we will generalize the definition of symmetry of a network by introducing the notion of *interior symmetry*. In this new context the network $\mathcal{G}_2$ of our example admits an action of the permutation group $\mathbf{S}_3$ as a group of interior symmetries. This corresponds to the symmetry group of the subnetwork of $\mathcal{G}_2$ obtained by ignoring the arrows $(1, 4)$, $(2, 4)$, and $(3, 4)$ of $\mathcal{G}_2$.

3. Interior symmetry.

We present the notion of interior symmetry following [4] and give an alternative characterization in terms of the symmetries of a subnetwork.

3.1. Interior symmetry groups of networks.

Definition 3.1 (see [4]). *Let $\mathcal{G}$ be a coupled cell network. Let $\mathcal{S} \subseteq \mathcal{C}$ be a subset of cells, and let $I(\mathcal{S}) = \{e \in \mathcal{E} : \mathcal{H}(e) \in \mathcal{S}\}$. A pair of bijections $\sigma_C : \mathcal{C} \to \mathcal{C}$ and $\sigma_E : \mathcal{E} \to \mathcal{E}$ is an* interior symmetry *of $\mathcal{G}$ (on the subset $\mathcal{S}$) if the following hold:*

(a) *$\sigma_C : \mathcal{C} \to \mathcal{C}$ is an input equivalence-preserving permutation which is the identity map on the complement $\mathcal{C} \setminus \mathcal{S}$ of $\mathcal{S}$ in $\mathcal{C}$,*
(b) *$\sigma_E : \mathcal{E} \to \mathcal{E}$ is an edge equivalence-preserving permutation which is the identity map on the complement $\mathcal{E} \setminus I(\mathcal{S})$ of $I(\mathcal{S})$ in $\mathcal{E}$,*
(c) *the consistency condition*

$$\sigma_C(\mathcal{H}(e)) = \mathcal{H}(\sigma_E(e)) \qquad \text{and} \qquad \sigma_C(\mathcal{T}(e)) = \mathcal{T}(\sigma_E(e)) \tag{3.1}$$

is satisfied for every $e \in I(\mathcal{S})$.

The set of all interior symmetries of $\mathcal{G}$ (on the subset $\mathcal{S}$) forms a finite group $\Sigma_{\mathcal{S}}$ called the group of interior symmetries *of $\mathcal{G}$ (on the subset $\mathcal{S}$).*

Note that in Definition 3.1 if $\mathcal{S} = \mathcal{C}$, then $\Sigma_{\mathcal{S}} = \mathrm{Aut}(\mathcal{G})$. Hence, the definition of interior symmetry of a network is a generalization of a symmetry of a network. That is why we refer to the elements of $\mathrm{Aut}(\mathcal{G})$ as *global symmetries* of $\mathcal{G}$. The most interesting case is when $\mathrm{Aut}(\mathcal{G})$ is trivial but $\Sigma_{\mathcal{S}}$ is nontrivial for some $\mathcal{S}$.

Example 3.2. We continue with our running example, the two networks $\mathcal{G}_1$ and $\mathcal{G}_2$ of Figure 1. We have seen that the network $\mathcal{G}_1$ is $\mathbf{S}_3$-symmetric and the network $\mathcal{G}_2$ has only the trivial symmetry. However, the group of permutations

$$\mathbf{S}_3 = \{\mathrm{id}, (1\,2), (1\,3), (2\,3), (1\,2\,3), (1\,3\,2)\}$$

is the group of interior symmetries of the network $\mathcal{G}_2$ on the subset $\mathcal{S} = \{1, 2, 3\}$. Observe that all elements of $\mathbf{S}_3$ fix cell 4 and

$$I(\mathcal{S}) = \{(1,2),(2,1),(1,3),(3,1),(2,3),(3,2),(4,1),(4,2),(4,3)\}.$$

If we assume that the permutations in $\mathbf{S}_3$ act as identity on the set of arrows

$$\mathcal{E} \setminus I(\mathcal{S}) = \{(1,4),(2,4),(3,4)\},$$

then $\mathbf{S}_3$ is the group of interior symmetries of the network $\mathcal{G}_2$ on the subset $\mathcal{S} = \{1, 2, 3\}$.

There is an alternative characterization of interior symmetries using the notion of symmetry of a network. The main idea is the following: by "ignoring" some arrows we find a subnetwork whose symmetry group is the group of interior symmetries of the original network.

Let us be more precise. Given a coupled cell network $\mathcal{G}$ and a subset $\mathcal{S} \subset \mathcal{C}$ of cells, define $\mathcal{G}_\mathcal{S} = (\mathcal{C}, I(\mathcal{S}), \sim_C, \sim_E)$ to be the subnetwork of $\mathcal{G}$ whose set of cells is $\mathcal{C}$ (together with its cell-equivalence $\sim_C$) and whose set of arrows is $I(\mathcal{S})$. The edge-equivalence on $I(\mathcal{S})$ is obtained by the restriction of the edge-equivalence $\sim_E$ on $\mathcal{E}$.

Proposition 3.3. *Let $\mathcal{G}$ be a coupled cell network and $\mathcal{S} \subset \mathcal{C}$ be a subset of cells of the set of cells of $\mathcal{G}$. Consider the network $\mathcal{G}_\mathcal{S}$ as defined above. Then the group of interior symmetries of the network $\mathcal{G}$ (on the subset $\mathcal{S}$) can be canonically identified with the group of symmetries of the network $\mathcal{G}_\mathcal{S}$:*

$$\Sigma_\mathcal{S} \cong \mathrm{Aut}(\mathcal{G}_\mathcal{S}).$$

Proof. We start by proving that $\Sigma_\mathcal{S}$ can be canonically identified with a subset of $\mathrm{Aut}(\mathcal{G}_\mathcal{S})$. Let $\sigma = (\sigma_C, \sigma_E) \in \Sigma_\mathcal{S}$ be an interior symmetry of $\mathcal{G}$ (on the subset S), as in Definition 3.1. Then, because σ_C and σ_E are the identity maps on $\mathcal{C} \setminus \mathcal{S}$ and $\mathcal{E} \setminus I(S)$, respectively, it follows that σ is a symmetry of $\mathcal{G}_\mathcal{S}$, according to Definition 2.12. Now we show that the above identification is surjective. Let $\gamma = (\gamma_C, \gamma_E) \in \mathrm{Aut}(\mathcal{G}_\mathcal{S})$ be a symmetry of $\mathcal{G}_\mathcal{S}$ (in the sense of Definition 2.12); that is, γ_E is a permutation on the set $I(\mathcal{S})$. Now we can extend γ_E to a permutation σ_E on $\mathcal{E}$ which acts as identity on $\mathcal{E} \setminus I(\mathcal{S})$. The pair $\sigma = (\sigma_C, \sigma_E)$, where $\sigma_C = \gamma_C$ is an interior symmetry of $\mathcal{G}$ (on the subset $\mathcal{S}$) according to Definition 3.1. ∎

The characterization of interior symmetry provided by Proposition 3.3 is particularly useful when the network does not have multiple arrows and/or self-connections, since by Remark 2.13, a symmetry is simply a permutation on the set vertices of the underlying graph.

Example 3.4. Consider the two networks $\mathcal{G}_1$ and $\mathcal{G}_2$ of Figure 1. Let $\mathcal{S} = \{1, 2, 3\}$. Note that the network $\mathcal{G}_\mathcal{S}$ obtained from $\mathcal{G}_1$ is the same as the one obtained from $\mathcal{G}_2$. In Figure 2 we show these three networks. Observe that for the three networks the sets of arrows coming from the set $\mathcal{S} = \{1, 2, 3\}$ and directed to the complement $\mathcal{C} \setminus \mathcal{S} = \{4\}$ are different.

Let $\mathcal{G}$ be a network, and fix a phase space P. Suppose that $\mathcal{G}$ admits nontrivial interior symmetries $\Sigma_\mathcal{S}$ on a subset of cells $\mathcal{S}$. Then we can decompose the phase space P as a Cartesian product $P = P_\mathcal{S} \times P_{\mathcal{C}\setminus\mathcal{S}}$, where

$$P_\mathcal{S} = \prod_{s\in\mathcal{S}} P_s \qquad \text{and} \qquad P_{\mathcal{C}\setminus\mathcal{S}} = \prod_{c\in\mathcal{C}\setminus\mathcal{S}} P_c.$$

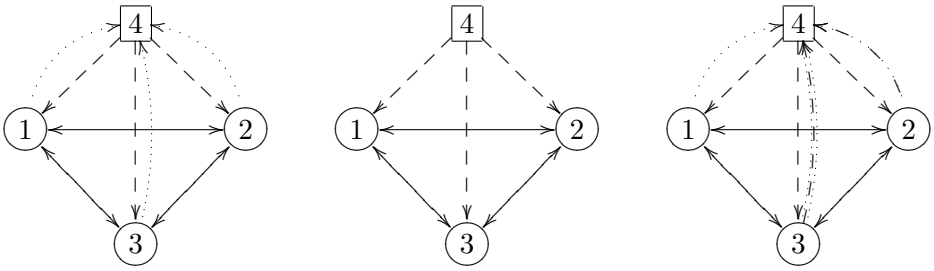

Figure 2. *(Left) Network $\mathcal{G}_1$. (Center) Network $\mathcal{G}_\mathcal{S}$, where $\mathcal{S} = \{1, 2, 3\}$. (Right) Network $\mathcal{G}_2$.*

For any $x \in P$ we write $x = (x_\mathcal{S}, x_{\mathcal{C}\setminus\mathcal{S}})$, where $x_\mathcal{S} \in P_\mathcal{S}$ and $x_{\mathcal{C}\setminus\mathcal{S}} \in P_{\mathcal{C}\setminus\mathcal{S}}$. If $\sigma = (\sigma_C, \sigma_E) \in \Sigma_\mathcal{S}$, then σ_C permutes the cells of $\mathcal{S}$ and induces an action of $\Sigma_\mathcal{S}$ on P by permuting the cell coordinates

$$\sigma(x_c)_{c\in\mathcal{C}} = (x_{\sigma_C^{-1}(c)})_{c\in\mathcal{C}}.$$

Since $\Sigma_\mathcal{S}$ fixes all cells in $\mathcal{C} \setminus \mathcal{S}$ we can write

$$\sigma(x_\mathcal{S}, x_{\mathcal{C}\setminus\mathcal{S}}) = (\sigma x_\mathcal{S}, x_{\mathcal{C}\setminus\mathcal{S}}). \tag{3.2}$$

As in the case of symmetric networks, we can construct (some) balanced equivalence relations on a network $\mathcal{G}$ from subgroups of the interior symmetry group. Suppose that $K \subseteq \Sigma_\mathcal{S}$ is a subgroup. Then

$$\mathrm{Fix}_P(K) = \{(x_\mathcal{S}, x_{\mathcal{C}\setminus\mathcal{S}}) : \sigma x_\mathcal{S} = x_\mathcal{S} \ \ \forall\, \sigma \in K\}.$$

Define the relation $\bowtie_K$ on the cells in $\mathcal{C}$ by

$$c \bowtie_K d \quad \Leftrightarrow \quad \exists\, \sigma = (\sigma_C, \sigma_E) \in K : \sigma_C(c) = d.$$

Then the $\bowtie_K$-classes are the K-orbits on the cells in $\mathcal{S}$, and the corresponding polydiagonal is

$$\triangle_K = \triangle_{\bowtie_K} = \mathrm{Fix}_P(K).$$

The following proposition from [4, Proposition 1, p. 397] is fundamental in the study of coupled cell networks with interior symmetries.

Proposition 3.5 (Golubitsky, Pivato, and Stewart [4]). *Let $\mathcal{G}$ be a network admitting a non-trivial interior symmetry group $\Sigma_\mathcal{S}$ and fix a phase space P. Let K be any subgroup of $\Sigma_\mathcal{S}$. Then $\bowtie_K$ is a balanced relation on $\mathcal{G}$. In particular, $\mathrm{Fix}_P(K)$ is a flow invariant subspace for all $\mathcal{G}$-admissible vector fields.*

Proof. Let s_1 and s_2 be two cells on the same K-orbit. Then there exists an element $\sigma = (\sigma_C, \sigma_E)$ of K such that $\sigma_C(s_1) = s_2$, and by the consistency condition (3.1) it follows that the restriction

$$\sigma_E|_{I(s_1)} : I(s_1) \to I(s_2)$$

is an input isomorphism. Since the $\bowtie_K$-equivalence classes are exactly the K-orbits on $\mathcal{C}$ it follows that the input isomorphism $\sigma_E|_{I(s_1)}$ preserves the $\bowtie_K$ equivalence relation. Hence, by

Theorem 2.9, it follows that $\triangle_H = \mathrm{Fix}_P(K)$ is a flow invariant subspace for all $\mathcal{G}$-admissible vector fields. ■

Example 3.6. Consider the networks $\mathcal{G}_1$ and $\mathcal{G}_2$ of Figure 1 and fix a phase space P for both networks. There are two nontrivial conjugacy classes of subgroups of $\mathbf{S}_3$. The first conjugacy class is represented, for example, by the subgroup generated by a 3-cycle,

$$\mathbf{Z}_3 = \langle (1\,2\,3) \rangle.$$

The associated balanced relation has two equivalence classes $\{1,2,3\}$ and $\{4\}$ given by the three orbits of $\mathbf{Z}_3$ on the set of cells $\mathcal{C}$. The fixed-point subspace of $\mathbf{Z}_3$ is

$$\mathrm{Fix}_P(\mathbf{Z}_3) = \{(x,x,x,y) : x \in P_{\mathcal{S}},\, y \in P_{\mathcal{C}\setminus\mathcal{S}}\} = \mathrm{Fix}_P(\mathbf{S}_3).$$

The second conjugacy class of subgroups is represented, for example, by the subgroup generated by a transposition

$$\mathbf{Z}_2 = \langle (1\,2) \rangle.$$

The associated balanced relation has three equivalence classes $\{1,2\}$, $\{3\}$, and $\{4\}$ given by the three orbits of $\mathbf{Z}_2$ on the set of cells $\mathcal{C}$. The fixed-point subspace of $\mathbf{Z}_2$ is

$$\mathrm{Fix}_P(\mathbf{Z}_2) = \{(x,x,y,z) : x,y \in P_{\mathcal{S}},\, z \in P_{\mathcal{C}\setminus\mathcal{S}}\}.$$

The other two subgroups in the conjugacy class of $\langle (1\,2) \rangle$ are the ones generated by $(1\,3)$ and $(2\,3)$. Observe that these three balanced equivalence relations given by orbits of subgroups are exactly the same balanced equivalence relations previously found by direct methods (Example 2.11). Therefore, in our running example all flow-invariant subspaces can be given as fixed-point subspaces of subgroups.

Remark 3.7. It is not true, even for symmetric networks, that all balanced equivalence relations are given by orbits of subgroups of the symmetry group of the network. Balanced equivalence relations that are not of this type are called *exotic*. For examples of exotic balanced relations, see Antoneli and Stewart [1, 2].

3.2. Admissible vector fields with interior symmetry. Let $\mathcal{G}$ be a network with a nontrivial interior symmetry group $\Sigma_{\mathcal{S}}$ on a subset of cells $\mathcal{S}$, and fix a phase space P. We have a natural decomposition

$$P = P_{\mathcal{S}} \oplus P_{\mathcal{C}\setminus\mathcal{S}} \tag{3.3}$$

with coordinates $(x_{\mathcal{S}}, x_{\mathcal{C}\setminus\mathcal{S}})$. If $f : P \to P$ is a $\mathcal{G}$-admissible vector field, then we can write $f = (f_{\mathcal{S}}, f_{\mathcal{C}\setminus\mathcal{S}})$, where $f_{\mathcal{S}} : P \to P_{\mathcal{S}}$ and $f_{\mathcal{C}\setminus\mathcal{S}} : P \to P_{\mathcal{C}\setminus\mathcal{S}}$. Groupoid-equivariance of the coupled cell system implies that

$$\sigma f_{\mathcal{S}}(x_{\mathcal{S}}, x_{\mathcal{C}\setminus\mathcal{S}}) = f_{\mathcal{S}}(\sigma x_{\mathcal{S}}, x_{\mathcal{C}\setminus\mathcal{S}}) \tag{3.4}$$

for all $\sigma \in \Sigma_{\mathcal{S}}$.

A $\mathcal{G}$-admissible vector field f can be written as

$$f(x_{\mathcal{S}}, x_{\mathcal{C}\setminus\mathcal{S}}) = \begin{bmatrix} f_{\mathcal{S}}(x_{\mathcal{S}}, x_{\mathcal{C}\setminus\mathcal{S}}) \\ \tilde{f}_{\mathcal{C}\setminus\mathcal{S}}(x_{\mathcal{S}}, x_{\mathcal{C}\setminus\mathcal{S}}) \end{bmatrix} + \begin{bmatrix} 0 \\ h(x_{\mathcal{S}}, x_{\mathcal{C}\setminus\mathcal{S}}) \end{bmatrix}, \tag{3.5}$$

where $\tilde{f}_{\mathcal{C}\setminus\mathcal{S}}, h : P \to P_{\mathcal{C}\setminus\mathcal{S}}$ and $f_{\mathcal{C}\setminus\mathcal{S}} = \tilde{f}_{\mathcal{C}\setminus\mathcal{S}} + h$. The vector field $\tilde{f} = (f_{\mathcal{S}}, \tilde{f}_{\mathcal{C}\setminus\mathcal{S}})$ is the $\Sigma_{\mathcal{S}}$-*equivariant part* of f; that is, for all $\sigma \in \Sigma_{\mathcal{S}}$,

$$\sigma\tilde{f}(x) = \tilde{f}(\sigma x),$$

or more explicitly,

$$\begin{bmatrix} \sigma f_{\mathcal{S}}(x_{\mathcal{S}}, x_{\mathcal{C}\setminus\mathcal{S}}) \\ \tilde{f}_{\mathcal{C}\setminus\mathcal{S}}(x_{\mathcal{S}}, x_{\mathcal{C}\setminus\mathcal{S}}) \end{bmatrix} = \begin{bmatrix} f_{\mathcal{S}}(\sigma x_{\mathcal{S}}, x_{\mathcal{C}\setminus\mathcal{S}}) \\ \tilde{f}_{\mathcal{C}\setminus\mathcal{S}}(\sigma x_{\mathcal{S}}, x_{\mathcal{C}\setminus\mathcal{S}}) \end{bmatrix}, \tag{3.6}$$

since $\Sigma_{\mathcal{S}}$ acts trivially on $P_{\mathcal{C}\setminus\mathcal{S}}$. Equation (3.5) can be seen as a decomposition of the vector field f as the sum of a $\Sigma_{\mathcal{S}}$-equivariant vector field and a nonequivariant "perturbation" with null components in $\mathcal{S}$.

Example 3.8. Consider the network $\mathcal{G}_2$ of Figure 1. Recall from Example 2.7 the general form of the ODEs associated with the network $\mathcal{G}_2$. Using the decomposition (3.3), we have $x_{\mathcal{S}} = (x_1, x_2, x_3)$ and $x_{\mathcal{C}\setminus\mathcal{S}} = (x_4)$, where $x_i \in \mathbf{R}^k$ $(i = 1, 2, 3)$, $x_4 \in \mathbf{R}^l$. Then by (3.5) we can write a general ODE for the network $\mathcal{G}_2$ as

$$\begin{aligned} \dot{x_1} &= f(x_1, \overline{x_2, x_3}, x_4), \\ \dot{x_2} &= f(x_2, \overline{x_3, x_1}, x_4), \\ \dot{x_3} &= f(x_3, \overline{x_1, x_2}, x_4), \\ \dot{x_4} &= g(x_4, \overline{x_1, x_2, x_3}) + h(x_4, x_1, x_2, x_3), \end{aligned}$$

where $f : \mathbf{R}^{3k} \times \mathbf{R}^l \to \mathbf{R}^k$ is a smooth map invariant under permutation of the second and third argument, $g : \mathbf{R}^l \times \mathbf{R}^{3k} \to \mathbf{R}^l$ is $\mathbf{S}_3$-invariant with respect to (x_1, x_2, x_3), and $h : \mathbf{R}^l \times \mathbf{R}^{3k} \to \mathbf{R}^l$ is a general smooth map.

Now we introduce another set of coordinates on P, adapted to the action of the interior symmetry group. By Proposition 3.5 the subspace $\mathrm{Fix}_P(\Sigma_{\mathcal{S}})$ is flow invariant. Since $\mathrm{Fix}_P(\Sigma_{\mathcal{S}})$ is $\Sigma_{\mathcal{S}}$-invariant and $\Sigma_{\mathcal{S}}$ acts trivially on the cells in $\mathcal{C} \setminus \mathcal{S}$ we have that $P_{\mathcal{C}\setminus\mathcal{S}} \subset \mathrm{Fix}_P(\Sigma_{\mathcal{S}})$. Let

$$U = \mathrm{Fix}_P(\Sigma_{\mathcal{S}}). \tag{3.7}$$

The action of the group $\Sigma_{\mathcal{S}}$ decomposes the set $\mathcal{S}$ as

$$\mathcal{S} = \mathcal{S}_1 \cup \cdots \cup \mathcal{S}_k,$$

where the sets $\mathcal{S}_i$ $(i = 1, \ldots, k)$ are the orbits of the $\Sigma_{\mathcal{S}}$-action. Let

$$W = \left\{ x \in P \ : \ x_c = 0 \ \ \forall\, c \in \mathcal{C} \setminus \mathcal{S} \ \text{ and } \ \sum_{s \in \mathcal{S}_i} x_s = 0 \ \text{ for } 1 \leqslant i \leqslant k \right\}. \tag{3.8}$$

Since W is a $\Sigma_{\mathcal{S}}$-invariant subspace of $P_{\mathcal{S}}$ and $W \cap U = \{0\}$ we can decompose the phase space P as a direct sum of $\Sigma_{\mathcal{S}}$-invariant subspaces,

$$P = W \oplus U. \tag{3.9}$$

In particular, (3.8) implies that vectors in W, when written in coupled cell coordinates, have zero components on all cells in $\mathcal{C} \setminus \mathcal{S}$.

We can choose coordinates (w, u) with $w \in W$ and $u \in U$ adapted to the decomposition (3.9) and write any admissible vector field f as

$$f(w,u) = \begin{bmatrix} f_W(w,u) \\ f_U(w,u) \end{bmatrix} + \begin{bmatrix} 0 \\ h(w,u) \end{bmatrix}, \tag{3.10}$$

where $f_U, h : P \to U$ and $f_W : P \to W$ satisfies

$$\sigma f_W(w,u) = f_W(\sigma w, u) \qquad \forall\, \sigma \in \Sigma_{\mathcal{S}}.$$

With respect to the decomposition (3.9), the equivariant part of f is written as $\tilde{f}(w,u) = (f_W(w,u), f_U(w,u))$, and for all $\sigma \in \Sigma_{\mathcal{S}}$ we have

$$\begin{bmatrix} \sigma f_W(w,u) \\ f_U(w,u) \end{bmatrix} = \begin{bmatrix} f_W(\sigma w, u) \\ f_U(\sigma w, u) \end{bmatrix}, \tag{3.11}$$

since $\Sigma_{\mathcal{S}}$ acts trivially on $U = \mathrm{Fix}_P(\Sigma_{\mathcal{S}})$.

Example 3.9. Consider the network $\mathcal{G}_2$ of Figure 1. With respect to the decomposition (3.3) adapted to the network structure, the total phase space P has coordinates $x_{\mathcal{S}} = (x_1, x_2, x_3)$ and $x_{\mathcal{C}\setminus\mathcal{S}} = (x_4)$, where $x_i \in \mathbf{R}^k$ $(i = 1, 2, 3)$, $x_4 \in \mathbf{R}^l$. Now with respect to the decomposition (3.9) adapted to the $\mathbf{S}_3$-action on P we have that

$$W = \{(w_1, w_2, -w_1 - w_2, 0) : w_1, w_2 \in \mathbf{R}^k\}$$

and

$$U = \mathrm{Fix}_P(\mathbf{S}_3) = \{(u_1, u_1, u_1, u_2) : u_1 \in \mathbf{R}^k,\ u_2 \in \mathbf{R}^l\}.$$

In the linear case, we may choose a basis of P adapted to the decomposition (3.9), and then a $\mathcal{G}$-admissible linear vector field L can be written as

$$L = \begin{bmatrix} A & 0 \\ C & B \end{bmatrix}, \tag{3.12}$$

where $B = L|_U : U \to U$, $C : W \to U$, and $A : W \to W$ satisfies (by (3.11))

$$A\,\sigma = \sigma A \qquad \forall\, \sigma \in \Sigma_{\mathcal{S}}.$$

The spectral properties of L in (3.12) are given by Golubitsky, Pivato, and Stewart [4, Lemma 1, p. 399]. Since we will use these results several times we reproduce them here.

Lemma 3.10 (see [4]). *Let $\mathcal{G}$ be a network admitting a nontrivial group of interior symmetries $\Sigma_{\mathcal{S}}$, and fix a total phase space P. Let $L : P \to P$ be a $\mathcal{G}$-admissible linear vector field, and consider the decomposition of L given by (3.12). Then the following hold:*

(i) *The eigenvalues of L are the eigenvalues of A together with the eigenvalues of B.*

(ii) *A vector $u \in U = \mathrm{Fix}_P(\Sigma_{\mathcal{S}})$ is an eigenvector of B with eigenvalue ν if and only if u is an eigenvector of L with eigenvalue ν.*

(iii) *If $w \in W$ is an eigenvector of A with eigenvalue μ, then there exists an eigenvector v of L with eigenvalue μ of the form*

$$v = w + u,$$

where $u \in U = \mathrm{Fix}_P(\Sigma_{\mathcal{S}})$.

(iv) *All eigenspaces of A are $\Sigma_{\mathcal{S}}$-invariant.*

Proof. Parts (i), (ii), and (iii) are consequences of the block form (3.12) of L. Part (iv) follows from the $\Sigma_{\mathcal{S}}$-equivariance of A. ∎

Example 3.11. We continue our running example, the networks $\mathcal{G}_1$ and $\mathcal{G}_2$ of Figure 1. The general form of the admissible linear mappings associated with the networks $\mathcal{G}_1$ and $\mathcal{G}_2$ of Figure 1 are (in cell coordinates)

$$L_1 = \begin{pmatrix} a & b & b & d \\ b & a & b & d \\ b & b & a & d \\ e & e & e & c \end{pmatrix} \quad \text{and} \quad L_2 = \begin{pmatrix} a & b & b & d \\ b & a & b & d \\ b & b & a & d \\ e_1 & e_2 & e_3 & c \end{pmatrix},$$

where a, b are $k \times k$ matrices, c is an $l \times l$ matrix, d is a $k \times l$ matrix, and e, e_1, e_2, e_3 are $l \times k$ matrices. Choosing adequate bases for W and U, the linear mappings L_1 and L_2 can be written as

$$L_1 = \begin{pmatrix} a-b & 0 & 0 & 0 \\ 0 & a-b & 0 & 0 \\ 0 & 0 & a+2b & d \\ 0 & 0 & 3e & c \end{pmatrix}$$

and

$$L_2 = \begin{pmatrix} a-b & 0 & 0 & 0 \\ 0 & a-b & 0 & 0 \\ 0 & 0 & a+2b & d \\ e_1-e_3 & e_2-e_3 & e_1+e_2+e_3 & c \end{pmatrix}.$$

4. Synchrony-breaking bifurcations. Now we study local bifurcations in coupled cell networks with nontrivial interior symmetries. We are interested in codimension-one synchrony-breaking bifurcations. Steady-state and Hopf bifurcations in coupled cell networks with interior symmetries were studied by Golubitsky, Pivato, and Stewart [4].

4.1. Local bifurcations in coupled cell systems. Let $\mathcal{G}$ be a coupled cell network, and fix a phase space P. Let $f : P \times \mathbf{R}^k \to P$ be a smooth k-parameter family of $\mathcal{G}$-admissible vector fields in P, and assume that the ODE

$$\frac{\mathrm{d}x}{\mathrm{d}t} = f(x, \lambda) \tag{4.1}$$

has a synchronous equilibrium x_0 in $\triangle_I$ (the polydiagonal subspace of P associated with the input equivalence relation $\sim_I$). In the present context we may assume that

$$f(x_0, \lambda) \equiv 0$$

and that a bifurcation occurs at $\lambda = 0$. Let $L = (\mathrm{d}f)_{(x_0,0)}$ be the linearization of f at $(x_0, 0)$, and denote by E^c the center subspace of L.

Local bifurcations in coupled cell networks can be divided into two types according to whether or not E^c is contained in the flow-invariant subspace $\triangle_I$.

Definition 4.1. *We say that a coupled cell system* (4.1) *undergoes a* synchrony-preserving *bifurcation at a synchronous equilibrium in* $\triangle_I$ *if* $E^c \subset \triangle_I$ *and that* (4.1) *undergoes a* synchrony-breaking *bifurcation if* $E^c \not\subset \triangle_I$.

Now we specialize to codimension-one bifurcations; that is, $f : P \times \mathbf{R} \to P$ is a smooth 1-parameter family of $\mathcal{G}$-admissible vector fields in P. These bifurcations fall into two classes: *steady-state* bifurcations ($L|_{E^c}$ has a zero eigenvalue) and *Hopf* bifurcations ($L|_{E^c}$ has a pair of purely imaginary eigenvalues). The new steady states and periodic solutions that emanate from the synchrony-preserving bifurcations are themselves synchronous solutions. For the remainder of this paper we will focus on codimension-one synchrony-breaking bifurcations from a synchronous equilibrium.

4.2. Local bifurcations with interior symmetry. Interior symmetries introduce genuine restrictions on the form of the linearization, and this structure can be used to study certain kinds of synchrony-breaking bifurcations, namely, the bifurcations that break the interior symmetry.

Let $\mathcal{G}$ be a network admitting a nontrivial group of interior symmetries $\Sigma_{\mathcal{S}}$ on $\mathcal{S}$, and fix a phase space P. First, note that the polydiagonal subspace $\triangle_I$ associated with the input equivalence relation $\sim_I$ satisfies

$$\triangle_I \subseteq \mathrm{Fix}_P(\Sigma_{\mathcal{S}}).$$

Since we are interested in synchrony-breaking bifurcations that also break the interior symmetry we may assume that $x_0 \in \mathrm{Fix}_P(\Sigma_{\mathcal{S}})$ and that the center subspace $E^c(L)$ associated with the critical eigenvalues satisfies

$$E^c(L) \not\subset \mathrm{Fix}_P(\Sigma_{\mathcal{S}}). \tag{4.2}$$

However, this is not enough to exclude the possibility of having critical eigenvectors in $\mathrm{Fix}_P(\Sigma_{\mathcal{S}})$ in a synchrony-breaking bifurcation. That is, we could have a situation where some critical eigenvectors belong to $\mathrm{Fix}_P(\Sigma_{\mathcal{S}})$ and the others are outside $\mathrm{Fix}_P(\Sigma_{\mathcal{S}})$. Indeed, it is well known [3] that (nonsymmetric) coupled cell systems generically can exhibit mode interaction in codimension-one bifurcations. In this paper we make a stronger assumption. We assume

$$E^c(L) \cap \mathrm{Fix}_P(\Sigma_{\mathcal{S}}) = \{0\}, \tag{4.3}$$

and so we exclude the possibility of having eigenvectors in $\mathrm{Fix}_P(\Sigma_{\mathcal{S}})$. This situation corresponds to a synchrony-breaking bifurcation that "breaks *only* the interior symmetry."

Definition 4.2. *Let* $f : P \to P$ *be a* $\mathcal{G}$*-admissible vector field, and let* $L = (\mathrm{d}f)_{(x_0)}$ *be the linearization of* f *at* x_0. *Consider the decomposition* (3.9) *of* P *adapted to the* $\Sigma_{\mathcal{S}}$*-action, and write* L *in block form as*

$$L = \begin{bmatrix} A & 0 \\ C & B \end{bmatrix}.$$

Then the matrix A is called the $\Sigma_{\mathcal{S}}$-equivariant subblock *of L.*

If we write f using coordinates (w,u) adapted to the decomposition $P = W \oplus U$ as

$$f(w,u) = \begin{bmatrix} f_W(w,u) \\ f_U(w,u) \end{bmatrix} + \begin{bmatrix} 0 \\ h(w,u) \end{bmatrix},$$

then

$$A = \big(\mathrm{d}_{(1)} f_W\big)_{(w_0)},$$

where $x_0 = (w_0, u_0)$ and

$$\big(\mathrm{d}_{(1)} f_W\big)_{(w_0)} \cdot w = \big(\mathrm{d} f_W\big)_{(w_0,u_0)} \cdot (w,0)$$

for all $w \in W$.

Remark 4.3. It can be shown that the following three conditions are equivalent:

(a) $E^c(L) \cap \mathrm{Fix}_P(\Sigma_{\mathcal{S}}) = \{0\}$.

(b) $\dim E^c(L) = \dim E^c(A)$.

(c) All the critical eigenvalues of L come from the $\Sigma_{\mathcal{S}}$-equivariant subblock A of L.

It is obvious that (a) implies both (b) and (c). On the other hand, to prove that (b) implies (a), we observe that by Lemma 3.10(iii), we always have $\dim E^c(A) \leqslant \dim E^c(L)$. Finally, to prove that (c) implies (a), we observe that the block form of L guarantees that no generalized eigenvector associated with an eigenvalue coming from subblock A belongs to $\mathrm{Fix}_P(\Sigma_{\mathcal{S}})$.

In general f is not $\Sigma_{\mathcal{S}}$-equivariant and L does not commute with $\Sigma_{\mathcal{S}}$. In particular, $E^c(L) \not\subset W$. However, the block matrix A does commute with $\Sigma_{\mathcal{S}}$, and thus $E^c(A) \subset W$ is $\Sigma_{\mathcal{S}}$-invariant. Moreover, if A has purely imaginary eigenvalues, there is a natural action of $\Sigma_{\mathcal{S}} \times \mathbf{S}^1$ on $E^c(A)$, where $\mathbf{S}^1$ acts by $\exp(sA^{\mathrm{t}})$.

Definition 4.4. *Consider a* 1*-parameter family of coupled cell systems* (4.1) *with interior symmetry group $\Sigma_{\mathcal{S}}$ on $\mathcal{S}$ undergoing a codimension-one synchrony-breaking bifurcation at a synchronous equilibrium x_0 when $\lambda = 0$. We say that f undergoes a* codimension-one interior symmetry-breaking bifurcation *if the following conditions hold:*

(a) *All the critical eigenvalues μ of L come from the $\Sigma_{\mathcal{S}}$-equivariant subblock A of L.*

(b) *The critical eigenvalues μ extend uniquely and smoothly to eigenvalues $\mu(\lambda)$ of $(\mathrm{d}f)_{(x_0,\lambda)}$ for λ near 0.*

(c) *The* eigenvalue crossing condition:

$$\frac{\mathrm{d}}{\mathrm{d}\lambda} \mathrm{Re}(\mu(\lambda))\Big|_{\lambda=0} \neq 0. \tag{4.4}$$

More specifically, the bifurcation problem (4.1) *is called*

- *a* codimension-one interior symmetry-breaking steady-state bifurcation *if, in addition to the conditions* (a), (b), (c) *above, the matrix A has a zero eigenvalue and the associated center subspace is given by*

$$E_0(A) = \ker(A); \tag{4.5}$$

- *a* codimension-one interior symmetry-breaking Hopf bifurcation *if, in addition to the conditions* (a), (b), (c) *above, the matrix A is nonsingular, all the critical eigenvalues (after rescaling time if necessary) have the form $\pm i$, and the associated center subspace is given by*

$$E_i(A) = \{x \in W : (A^2 + 1)x = 0\}. \tag{4.6}$$

Example 4.5. Consider the networks $\mathcal{G}_1$ and $\mathcal{G}_2$ of Figure 1. Suppose that for all cells c we choose the internal phase space to be $P_c = \mathbf{C}$, and so the total phase space is $P = \mathbf{C}^4$. Consider the decomposition of $P = W \oplus U$ adapted to the $\mathbf{S}_3$-action. Then

$$W = \{(w_1, w_2, -w_1 - w_2, 0) : w_1, w_2 \in \mathbf{C}\}$$

and

$$U = \mathrm{Fix}_P(\mathbf{S}_3) = \{(u_1, u_1, u_1, u_2) : u_1, u_2 \in \mathbf{C}\},$$

and W is an $\mathbf{S}_3$-simple representation ($W = W_1 \oplus W_2$, where W_1, W_2 are two isomorphic $\mathbf{S}_3$-absolutely irreducible spaces). Now consider a 1-parameter family $f : P \times \mathbf{R} \to P$ of $\mathcal{G}$-admissible vector fields on P undergoing a codimension-one interior symmetry-breaking Hopf bifurcation at an equilibrium point x_0 when $\lambda = 0$. Since W is an $\mathbf{S}_3$-simple representation, one necessarily has that $E^c(A) = W$. Moreover, the action of the circle group $\mathbf{S}^1$ defined by $\exp(sA^{\mathrm{t}})$ is equivalent to the standard action of $\mathbf{S}^1$ on $\mathbf{C}^2$, that is,

$$\theta \cdot (z_1, z_2) = (\mathrm{e}^{i\theta} z_1, \mathrm{e}^{i\theta} z_2)$$

for all $\theta \in \mathbf{S}^1$ and $z_1, z_2 \in \mathbf{C}$.

4.3. Interior symmetry-breaking Hopf theorem. The Hopf bifurcation theorem concerns periodic solutions to differential equations near a point where the linearization has purely imaginary eigenvalues.

Let $\mathcal{G}$ be a coupled cell network admitting a nontrivial group of interior symmetries $\Sigma_{\mathcal{S}}$ on a subset $\mathcal{S}$ of cells, and choose a total phase space P. Consider a smooth 1-parameter family $f : P \times \mathbf{R} \to P$ of $\mathcal{G}$-admissible vector fields on P, and assume that

$$\frac{\mathrm{d}x}{\mathrm{d}t} = f(x, \lambda) \tag{4.7}$$

has an equilibrium x_0 such that for $\lambda = 0$ the linearization $L = (\mathrm{d}f)_{(x_0,0)}$ of f at $(x_0, 0)$ is nonsingular but has purely imaginary eigenvalues.

Before stating the next theorem let us introduce an important concept which generalizes the notion of a $\mathbf{C}$-axial subgroup from equivariant bifurcation theory.

Definition 4.6. *Let $\mathcal{G}$ be a coupled cell network admitting a nontrivial group of interior symmetries $\Sigma_{\mathcal{S}}$ on a subset $\mathcal{S}$. Let P denote the total phase space, and consider the decomposition* (3.9) *of P adapted to the $\Sigma_{\mathcal{S}}$-action. Suppose that there is an action of circle group $\mathbf{S}^1$ on W which commutes with the action of $\Sigma_{\mathcal{S}}$. Let $E \subset W$ be a $\Sigma_{\mathcal{S}} \times \mathbf{S}^1$-invariant subspace. An isotropy subgroup $\Delta \subseteq \Sigma_{\mathcal{S}} \times \mathbf{S}^1$ is called* interiorly $\mathbf{C}$-axial (on E) *if*

$$\dim_{\mathbf{R}} \mathrm{Fix}_E(\Delta) = 2.$$

Now suppose that the family (4.7) undergoes a codimension-one interior symmetry-breaking Hopf bifurcation at the equilibrium x_0 when $\lambda = 0$. Then the center subspace $E^c(A)$ of the $\Sigma_{\mathcal{S}}$-equivariant subblock of the linearization $L = (\mathrm{d}f)_{(x_0,0)}$ of f at $(x_0, 0)$ is a $\Sigma_{\mathcal{S}}$-invariant subspace of W. Therefore, the action of the circle group $\mathbf{S}^1$ defined by $\exp(sA^{\mathrm{t}})$ commutes with the action of $\Sigma_{\mathcal{S}}$, and so there is a well-defined action of $\Sigma_{\mathcal{S}} \times \mathbf{S}^1$ on W and $E^c(A)$ is a $\Sigma_{\mathcal{S}} \times \mathbf{S}^1$-invariant subspace.

Example 4.7. Consider the networks $\mathcal{G}_1$ and $\mathcal{G}_2$ of Figure 1. Suppose that for all cells c we choose the internal phase space to be $P_c = \mathbf{C}$, and so the total phase space is $P = \mathbf{C}^4$. Suppose that a smooth 1-parameter family $f : P \times \mathbf{R} \to P$ of $\mathcal{G}$-admissible vector fields on P undergoes a codimension-one interior symmetry-breaking Hopf bifurcation at the equilibrium $x_0 = 0$ when $\lambda = 0$. Then $E_i(A) = W$, where A is the $\Sigma_{\mathcal{S}}$-equivariant subblock of the linearization $L = (\mathrm{d}f)_{(0,0)}$ of f at $(0, 0)$. In Example 4.5 we observed that the action of $\mathbf{S}^1$ on W, given by $\exp(sA^{\mathrm{t}})$, can be identified with the standard action of $\mathbf{S}^1$ on $\mathbf{C}^2$. There are three nontrivial conjugacy classes of isotropy subgroups of $\mathbf{S}_3 \times \mathbf{S}^1$ acting on W. The first conjugacy class of subgroups is represented, for example, by the subgroup

$$\mathbf{Z}_2 = \big\langle ((1\,2), \mathbf{1}) \big\rangle.$$

The fixed-point subspace of $\mathbf{Z}_2$ is

$$\mathrm{Fix}_W(\mathbf{Z}_2) = \{(-w, -w, 2w, 0) : w \in \mathbf{C}\}.$$

The second conjugacy class of subgroups is represented, for example, by the subgroup

$$\tilde{\mathbf{Z}}_2 = \big\langle ((1\,2), \pi) \big\rangle.$$

The fixed-point subspace of $\tilde{\mathbf{Z}}_2$ is

$$\mathrm{Fix}_W(\tilde{\mathbf{Z}}_2) = \{(w, -w, 0, 0) : w \in \mathbf{C}\}.$$

The third conjugacy class of subgroups is represented, for example, by the subgroup

$$\tilde{\mathbf{Z}}_3 = \big\langle ((1\,2\,3), \tfrac{2\pi}{3}) \big\rangle.$$

The fixed-point subspace of $\tilde{\mathbf{Z}}_3$ is

$$\mathrm{Fix}_W(\tilde{\mathbf{Z}}_3) = \{(w, \mathrm{e}^{i\frac{2\pi}{3}} w, \mathrm{e}^{i\frac{4\pi}{3}} w, 0) : w \in \mathbf{C}\}.$$

The main result of this paper is the interior symmetry-breaking Hopf bifurcation theorem.

Theorem 4.8. *Let $\mathcal{G}$ be a coupled cell network admitting a nontrivial group of interior symmetries $\Sigma_{\mathcal{S}}$ relative to a subset $\mathcal{S}$ of cells, and fix a phase space P. Consider (4.7), where $f : P \times \mathbf{R} \to P$ is a smooth 1-parameter family of $\mathcal{G}$-admissible vector fields on P. Suppose that a codimension-one interior symmetry-breaking Hopf bifurcation (see Definition 4.4) occurs at an equilibrium point $x_0 \in \mathrm{Fix}_P(\Sigma_{\mathcal{S}})$ when $\lambda = 0$. Let $\Delta \subset \Sigma_{\mathcal{S}} \times \mathbf{S}^1$ be an interiorly $\mathbf{C}$-axial subgroup (on $E^c(A)$). Then generically there exists a family of small amplitude periodic*

solutions of (4.7) *bifurcating from* $(x_0, 0)$ *and having period near* 2π. *Moreover, to lowest order in the bifurcation parameter* λ, *the solution* $x(t)$ *is of the form*

$$x(t) \approx w(t) + u(t), \tag{4.8}$$

where $w(t) = \exp(tL)w_0$ *(*$w_0 \in \mathrm{Fix}_W(\Delta)$*) has exact spatio-temporal symmetry* Δ *on the cells in* $\mathcal{S}$ *and* $u(t) = \exp(tL)u_0$ *(*$u_0 \in \mathrm{Fix}_P(\Sigma_{\mathcal{S}})$*) is synchronous on the* $\Sigma_{\mathcal{S}}$*-orbits of cells in* $\mathcal{S}$.

We call such a state a *synchronously modulated* Δ*-symmetric wave* on $\mathcal{S}$.

Remarks 4.9.

(a) The above theorem asserts no restriction on $u_j(t)$ when $j \in \mathcal{C} \setminus \mathcal{S}$.

(b) Theorem 4.8 generalizes the interior symmetry Hopf theorem of Golubitsky, Pivato, and Stewart [4, Theorem 3]. Given a subgroup $\Delta \subseteq \Sigma_{\mathcal{S}} \times \mathbf{S}^1$, we define the *spatial subgroup* of Δ to be $K = \Delta \cap \Sigma_{\mathcal{S}}$. A subgroup Δ is called *spatially* $\mathbf{C}$*-axial* if

$$\dim_{\mathbf{R}} \mathrm{Fix}_{E_i(A)}(\Delta) = \dim_{\mathbf{R}} \mathrm{Fix}_{E_i(A)}(K) = 2,$$

where K is the spatial subgroup of Δ. Obviously every spatially $\mathbf{C}$-axial subgroup is interiorly $\mathbf{C}$-axial. Since the Hopf theorem of [4] is proved for all spatially $\mathbf{C}$-axial subgroups, it is a special case of Theorem 4.8.

(c) Theorem 4.8 holds if the assumption (4.6) is generalized to: the matrix A is nonsingular and semisimple, and (after rescaling time if necessary) all the critical eigenvalues have the form $k_l i$ $(k_l \in \mathbf{Z})$.

The proof of Theorem 4.8 follows from a couple of lemmas that we state and prove below. We start by setting up the framework.

Let $C^0_{2\pi}(P)$ be the space consisting of all continuous 2π-periodic mappings from $\mathbf{R}$ to P endowed with the C^0 norm, and let $C^1_{2\pi}(P)$ be the space consisting of all continuous differentiable 2π-periodic mappings from $\mathbf{R}$ to P endowed with the C^1 norm.

By introducing a perturbed period parameter τ we can rescale time again, from t to $s(1+\tau)t$, and consider the operator $\mathcal{F} : C^1_{2\pi}(P) \times \mathbf{R} \times \mathbf{R} \to C^0_{2\pi}(P)$ given by

$$\mathcal{F}(x, \lambda, \tau) = (1+\tau)\frac{\mathrm{d}x}{\mathrm{d}s}(s) - f(x(s), \lambda). \tag{4.9}$$

The 2π-periodic solutions of the equation $\mathcal{F}(x, \lambda, \tau) = 0$ near $(0, 0, 0)$ correspond bijectively to the small amplitude periodic solutions of (4.7) near x_0 and with period near 2π. As is well known, the operator $\mathcal{F}$ is $\mathbf{S}^1$-equivariant with respect to the *phase shift action* of $\mathbf{S}^1$ on the spaces $C^1_{2\pi}(P)$ and $C^0_{2\pi}(P)$; that is, if $x \in C^0_{2\pi}(P)$ and $\theta \in \mathbf{S}^1$, then

$$\big(\theta \cdot x\big)(s) = x(s + \theta)$$

and thus

$$\theta \cdot \mathcal{F}(x, \tau, \lambda) = \mathcal{F}(\theta \cdot x, \tau, \lambda).$$

The linearization of $\mathcal{F}$ about the origin is

$$\mathcal{L}(x) = \frac{\mathrm{d}x}{\mathrm{d}s}(s) - L\,x(s), \tag{4.10}$$

and $\ker(\mathcal{L})$ consists of all functions $\mathrm{Re}(e^{is}v)$, where v is an eigenvector of L associated with the eigenvalue i.

In the standard Hopf bifurcation theorem [5, Theorem VIII 3.1] $\ker(\mathcal{L})$ is two-dimensional, and Lyapunov–Schmidt reduction in the presence of symmetry leads to a reduced equation that can be solved for a unique branch of 2π-periodic solutions as long as the eigenvalues crossing condition is valid. In the equivariant context, $\ker(\mathcal{L})$ may be higher-dimensional—generically $\ker(\mathcal{L})$ is a Γ-simple representation. The proof of the equivariant Hopf bifurcation theorem [8, Theorem XVI 4.1] proceeds by restricting the Lyapunov–Schmidt reduced equation to the fixed-point subspace $\mathrm{Fix}_{E_i(L)}(\Delta)$ of a $\mathbf{C}$-axial subgroup Δ, which is two-dimensional. Then the proof is completed as in the standard Hopf bifurcation theorem.

That approach does not work in the context of interior symmetries since in general there is no action of $\Sigma_{\mathcal{S}} \times \mathbf{S}^1$ on $E_i(L)$, because the original vector field f (and its linearization L) is not $\Sigma_{\mathcal{S}}$-equivariant. Nevertheless, we shall introduce a "modified Lyapunov–Schmidt procedure" that does work in the context of interior symmetries.

The decomposition in (3.9) induces the decompositions

$$C^0_{2\pi}(P) = C^0_{2\pi}(W) \oplus C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))$$

and

$$C^1_{2\pi}(P) = C^1_{2\pi}(W) \oplus C^1_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}})).$$

In our modification of the standard Lyapunov–Schmidt procedure we consider the following action of the group $\Sigma_{\mathcal{S}} \times \mathbf{S}^1$ on the spaces $C^0_{2\pi}(P)$ and $C^1_{2\pi}(P)$. Let us write $x \in C^0_{2\pi}(P)$ as $x(s) = (w(s), u(s))$, where $w \in C^0_{2\pi}(W)$ and $u \in C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))$. Then

$$(\delta, \theta) \cdot x(s) = (\delta, \theta) \cdot (w(s), u(s)) = \big(\delta w(s+\theta), u(s)\big). \tag{4.11}$$

The difference from the usual action on the loop space (see, for example, [8]) is that in (4.11) the group $\Sigma_{\mathcal{S}} \times \mathbf{S}^1$ acts trivially on $C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))$ and $C^1_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))$, respectively. A straightforward consequence of the above definition is stated in the next lemma for convenience.

Lemma 4.10. *For any subgroup Δ of $\Sigma_{\mathcal{S}} \times \mathbf{S}^1$ we have the decompositions*

$$\mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta) = C^0_{2\pi}(\mathrm{Fix}_W(\Delta)) \oplus C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))$$

and

$$\mathrm{Fix}_{C^1_{2\pi}(P)}(\Delta) = C^1_{2\pi}(\mathrm{Fix}_W(\Delta)) \oplus C^1_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}})).$$

Proof. Let $x \in C^0_{2\pi}(P)$ be written as $x(s) = (w(s), u(s))$, where $w \in C^0_{2\pi}(W)$ and $u \in C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))$. Then (4.11) implies that

$$C^0_{2\pi}(\mathrm{Fix}_W(\Delta)) \oplus C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}})) \subseteq \mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta).$$

Now let $(\delta, \theta) \in \Delta$ and suppose that $x \in \mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta)$. Then

$$(\delta, \theta) \cdot x(s) = x(s).$$

The decomposition $x(s) = (w(s), u(s))$ yields

$$\big((\delta w)(s+\theta), u(s)\big) = (w(s), u(s));$$

that is, $w(s) \in \mathrm{Fix}_W(\Delta)$ and $u(s) \in \mathrm{Fix}_P(\Sigma_{\mathcal{S}})$ for all $s \in \mathbf{R}$. Hence

$$\mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta) \subseteq C^0_{2\pi}(\mathrm{Fix}_W(\Delta)) \oplus C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}})).$$

Therefore,

$$\mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta) = C^0_{2\pi}(\mathrm{Fix}_W(\Delta)) \oplus C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}})).$$

The same argument with $C^1_{2\pi}$ instead of $C^0_{2\pi}$ gives the other equality. ■

Lemma 4.11. *Let $L : P \to P$ be a $\mathcal{G}$-admissible linear mapping. Let $\mathcal{L} : C^1_{2\pi}(P) \times \mathbf{R} \times \mathbf{R} \to C^0_{2\pi}(P)$ be the linear operator given by (4.10) and $\Delta \subset \Sigma_{\mathcal{S}} \times \mathbf{S}^1$ be a subgroup. Then we have that*

$$\begin{aligned}
\mathcal{L}\big(C^1_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))\big) &\subseteq C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}})),\\
\mathcal{L}\big(C^1_{2\pi}(\mathrm{Fix}_W(\Delta))\big) &\subseteq \big(C^0_{2\pi}(\mathrm{Fix}_W(\Delta)) \oplus C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))\big)
\end{aligned}$$

and

$$\mathcal{L}\big(\mathrm{Fix}_{C^1_{2\pi}(P)}(\Delta)\big) \subseteq \mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta). \tag{4.12}$$

In particular, we can define a linear operator

$$\mathcal{L}_\Delta : \mathrm{Fix}_{C^1_{2\pi}(P)}(\Delta) \longrightarrow \mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta) \tag{4.13}$$

by restriction.

Proof. Note that since the circle group $\mathbf{S}^1$ acts on the domain of the mappings, all the decompositions above are $\mathbf{S}^1$-invariant.

First suppose $x(s) = (0, u(s))$ with $u(s) \in C^1_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))$. Then

$$\mathcal{L}(x) = \frac{\mathrm{d}u}{\mathrm{d}s}(s) - L(0, u(s)).$$

If $\sigma \in \Sigma_{\mathcal{S}}$, then

$$\begin{aligned}
\sigma\mathcal{L}(x) &= \sigma\frac{\mathrm{d}u}{\mathrm{d}s}(s) - \sigma L\,(0, u(s))\\
&= \frac{\mathrm{d}\sigma u}{\mathrm{d}s}(s) - L\,(0, u(s))\\
&= \frac{\mathrm{d}u}{\mathrm{d}s}(s) - L\,(0, u(s))\\
&= \mathcal{L}(x).
\end{aligned}$$

The second equality above follows from the fact that

$$\sigma\big(L\,(0, u)\big) = L\,(0, u)$$

for all $\sigma \in \Sigma_{\mathcal{S}}$. Therefore, we have $\mathcal{L}(x(s)) \in C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))$.

Next suppose that $x(s) = (w(s), 0)$ with $w(s) \in C^1_{2\pi}(\mathrm{Fix}_W(\Delta))$. Since $w(s) \in W$ for all $s \in \mathbf{R}$, we have that

$$(\delta, \theta) \cdot w(s) = \delta w(s + \theta) = w(s)$$

for all $(\delta, \theta) \in \Delta$, $s \in \mathbf{R}$. Write

$$\mathcal{L}(x) = \big([\mathcal{L}(x)]_1(s), [\mathcal{L}(x)]_2(s)\big)$$

with

$$[\mathcal{L}(x)]_1(s) \in W \quad \forall\, s \in \mathbf{R}$$

and

$$[\mathcal{L}(x)]_2(s) \in \mathrm{Fix}_P(\Sigma_{\mathcal{S}}) \quad \forall\, s \in \mathbf{R}.$$

Then

$$[\mathcal{L}(x)]_1(s) = \frac{\mathrm{d}w}{\mathrm{d}s}(s) - A\, w(s)$$

and

$$[\mathcal{L}(x)]_2(s) = -[C\, w(s) + B\, 0] = -Cw(s).$$

Clearly, $[\mathcal{L}(x)]_2(s) \in \mathrm{Fix}_P(\Sigma_{\mathcal{S}})$. Let $(\delta, \theta) \in \Delta$; then

$$\begin{aligned}
(\delta, \theta) \cdot [\mathcal{L}(x)]_1(s) &= (\delta, \theta) \cdot \frac{\mathrm{d}w}{\mathrm{d}s}(s) - (\delta, \theta) \cdot A\, w(s) \\
&= \delta\, \frac{\mathrm{d}w}{\mathrm{d}s}(s + \theta) - \delta A\, w(s + \theta) \\
&= \frac{\mathrm{d}\delta w}{\mathrm{d}s}(s + \theta) - A\delta\, w(s + \theta) \\
&= \frac{\mathrm{d}w}{\mathrm{d}s}(s) - A\, w(s) \\
&= [\mathcal{L}(x)]_1(s)
\end{aligned}$$

and thus $[\mathcal{L}(x)]_1(s) \in \mathrm{Fix}_W(\Delta)$. Therefore

$$\mathcal{L}(x) \in C^0_{2\pi}(\mathrm{Fix}_W(\Delta)) \oplus C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}})).$$

Thus by linearity of $\mathcal{L}$ and Lemma 4.10 we have

$$\mathcal{L}\big(\mathrm{Fix}_{C^1_{2\pi}(P)}(\Delta)\big) \subseteq \mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta). \qquad \blacksquare$$

Consider now a 1-parameter family of $\mathcal{G}$-admissible vector fields $f(x, \lambda)$ such that $L = (\mathrm{d}f)_{(x_0,0)}$ satisfies the conditions of the definition of interior symmetry-breaking Hopf bifurcation (Definition 4.4), where A is the $\Sigma_{\mathcal{S}}$-equivariant subblock of L.

Lemma 4.12. *Let $\Delta \subset \Sigma_{\mathcal{S}} \times \mathbf{S}^1$ be a subgroup. Let $\mathcal{L}_\Delta : \mathrm{Fix}_{C^1_{2\pi}(P)}(\Delta) \to \mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta)$ be the operator given by (4.13) with $L = (\mathrm{d}f)_{(x_0,0)}$. Then*

$$\dim_{\mathbf{R}} \ker(\mathcal{L}_\Delta) = \dim_{\mathbf{R}} \mathrm{Fix}_{E_i(A)}(\Delta).$$

Proof. By Lemma 3.10 and assumption (4.6), $\ker(\mathcal{L}_\Delta)$ consists of all functions $\mathrm{Re}(\mathrm{e}^{is}v_0)$, where v_0 is an eigenvector of L associated with the eigenvalue i which can be decomposed as

$$v_0 = w_0 + u_0,$$

where $u_0 \in \mathrm{Fix}_P(\Sigma_\mathcal{S})$ is uniquely determined by an eigenvector $w_0 \in \mathrm{Fix}_W(\Delta)$ of A with purely imaginary eigenvalue and

$$(\delta,\theta)\cdot \mathrm{Re}(\mathrm{e}^{is}w_0) = \mathrm{Re}(\mathrm{e}^{i(s+\theta)}\,\delta w_0) = \mathrm{Re}(\mathrm{e}^{is}w_0)$$

for all $(\delta,\theta)\in\Delta$. Hence

$$w_0 \in \mathrm{Fix}_W(\Delta)\cap E_i(A) = \mathrm{Fix}_{E_i(A)}(\Delta).$$

By uniqueness of the decomposition $v_0 = w_0 + u_0$ and the dimension condition (b) of Remark 4.3 we have

$$\dim_{\mathbf{R}}\ker(\mathcal{L}_\Delta) = \dim_{\mathbf{R}}\mathrm{Fix}_{E_i(A)}(\Delta). \qquad \blacksquare$$

Lemma 4.13. *Let us write the 1-parameter family of admissible vector fields $f(x,\lambda)$ in the form*

$$f(x,\lambda) = \begin{bmatrix} f_\mathcal{S}(x,\lambda) \\ \tilde{f}_{\mathcal{C}\setminus\mathcal{S}}(x,\lambda)\end{bmatrix} + \begin{bmatrix} 0 \\ h(x,\lambda)\end{bmatrix}, \tag{4.14}$$

where

$$\tilde{f}(x,\lambda) = \begin{bmatrix} f_\mathcal{S}(x,\lambda) \\ \tilde{f}_{\mathcal{C}\setminus\mathcal{S}}(x,\lambda)\end{bmatrix}$$

is the $\Sigma_\mathcal{S}$-equivariant part of f. Let $\mathcal{F}$, $\tilde{\mathcal{F}}$ be operators on $C^1_{2\pi}(P)\times\mathbf{R}\times\mathbf{R}\to C^0_{2\pi}(P)$ defined by formula (4.9) using f and $\tilde{f}$, respectively. Define

$$\mathcal{H}(x,\tau,\lambda) = h(x(s),\lambda),$$

so that

$$\mathcal{F}(x,\tau,\lambda) = \tilde{\mathcal{F}}(x,\tau,\lambda) - \mathcal{H}(x,\tau,\lambda).$$

Then

$$\mathcal{F}\big(\mathrm{Fix}_{C^1_{2\pi}(P)}(\Delta)\times\mathbf{R}\times\mathbf{R}\big)\subseteq \mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta).$$

In particular, we may define the operator

$$\mathcal{F}_\Delta : \mathrm{Fix}_{C^1_{2\pi}(P)}(\Delta)\times\mathbf{R}\times\mathbf{R} \longrightarrow \mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta) \tag{4.15}$$

by restriction, and the linearization of $\mathcal{F}_\Delta$ about the origin is the linear operator $\mathcal{L}_\Delta$ given by the formula (4.13), where $L = (\mathrm{d}f)_{(x_0,0)}$.

Proof. The $\Sigma_\mathcal{S}$-equivariance of $\tilde{f}$ implies that $\tilde{\mathcal{F}}$ is $\Sigma_\mathcal{S}\times\mathbf{S}^1$-equivariant (see [8, Lemma XVI 3.2]). It follows then that

$$\tilde{\mathcal{F}}\big(\mathrm{Fix}_{C^1_{2\pi}(P)}(\Delta)\times\mathbf{R}\times\mathbf{R}\big)\subseteq \mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta).$$

Then it is enough to show that

$$\mathcal{H}\big(\mathrm{Fix}_{C^1_{2\pi}(P)}(\Delta)\times\mathbf{R}\times\mathbf{R}\big)\subseteq \mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta).$$

Now let $x(s)\in \mathrm{Fix}_{C^1_{2\pi}(P)}(\Delta)$. Recall that $h: P\to P_{\mathcal{C}\setminus\mathcal{S}}$ and $P_{\mathcal{C}\setminus\mathcal{S}}\subset \mathrm{Fix}_P(\Sigma_{\mathcal{S}})$. Therefore,

$$\mathcal{H}(x,\tau,\lambda)(s)=h(x(s),\lambda)\in \mathrm{Fix}_P(\Sigma_{\mathcal{S}})\quad (s\in\mathbf{R})$$

for all $\lambda,\tau\in\mathbf{R}$. By Lemma 4.10 we have that

$$C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))\subset C^0_{2\pi}(\mathrm{Fix}_W(\Delta))\oplus C^0_{2\pi}(\mathrm{Fix}_P(\Sigma_{\mathcal{S}}))=\mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta),$$

and the result follows. ■

Remark 4.14. Equation (4.12) of Lemma 4.11 can derived directly from the above lemma.

Proof of Theorem 4.8. Consider the operator

$$\mathcal{F}_\Delta : \mathrm{Fix}_{C^1_{2\pi}(P)}(\Delta)\times\mathbf{R}\times\mathbf{R}\longrightarrow \mathrm{Fix}_{C^0_{2\pi}(P)}(\Delta).$$

The linearization of $\mathcal{F}_\Delta$ about the origin is the linear operator $\mathcal{L}_\Delta$. Now we invoke the assumption that Δ is $\mathbf{C}$-axial for the natural $\Sigma_{\mathcal{S}}\times\mathbf{S}^1$-action on $E_i(A)$, which together with Lemma 4.12 implies that

$$\dim_{\mathbf{R}}\ker(\mathcal{L}_\Delta)=2.$$

Now we may proceed as in the proof of the standard Hopf bifurcation theorem. If we identify $\ker(\mathcal{L}_\Delta)\cong\mathbf{C}$, then the action of $\mathbf{S}^1$ on $\ker(\mathcal{L}_\Delta)$ is equivalent to the standard the action of $\mathbf{S}^1$ on $\mathbf{C}$. The Lyapunov–Schmidt reduction applied to $\mathcal{F}_\Delta$ yields a $\mathbf{S}^1$-equivariant bifurcation equation,

$$\phi:\mathbf{C}\times\mathbf{R}\times\mathbf{R}\to\mathbf{C}.$$

Moreover, the assumptions of the definition of codimension-one interior symmetry-breaking bifurcation are exactly the conditions necessary to carry out the proof. ■

Table 1

Branches of synchronously modulated Δ-symmetric waves supported by the network $\mathcal{G}_2$ and the associated subgroup. The hat over a variable indicates that $\hat{w}$ has twice the frequency.

Subgroup	Form of solution to lowest order in λ
$\mathbf{Z}_2$	$(w_1(t)+u(t), w_1(t)+u(t), w_2(t)+u(t), v(t))$
$\tilde{\mathbf{Z}}_2$	$(w_1(t)+u(t), w_1(t+\frac{1}{2})+u(t), \hat{w}(t)+u(t), v(t))$
$\tilde{\mathbf{Z}}_3$	$(w_1(t)+u(t), w_1(t+\frac{1}{3})+u(t), w_1(t+\frac{2}{3})+u(t), v(t))$

Example 4.15. Consider the network $\mathcal{G}_2$ of Figure 1. Suppose that for all cells c we choose the internal phase space to be $P_c=\mathbf{C}$. Then the total phase space is $P=\mathbf{C}^4$. Suppose that a smooth 1-parameter family $f: P\times\mathbf{R}\to P$ of $\mathcal{G}$-admissible vector fields on P undergoes a codimension-one interior symmetry-breaking Hopf bifurcation at the equilibrium $x_0=0$ when $\lambda=0$. Then $E_i(A)=W$, where A is the $\Sigma_{\mathcal{S}}$-equivariant subblock of the linearization $L=(\mathrm{d}f)_{(0,0)}$ of f at $(0,0)$. By Theorem 4.8 there are three branches of synchronously modulated Δ-symmetric waves associated with the three conjugacy classes of interiorly $\mathbf{C}$-axial subgroups of $\Sigma_{\mathcal{S}}\times\mathbf{S}^1$ (see Table 1). Observe that the first periodic state of Table 1 is associated with a spatially $\mathbf{C}$-axial subgroup, as is predicted by [4, Theorem 3]. The third periodic state of Table 1 is an approximate rotating wave.

4.4. Numerical simulation. In this last section we illustrate the conclusions of Example 4.15 with a numerical simulation. In order to write down an explicit coupled cell system associated with network $\mathcal{G}_2$ we choose the internal phase space of all four cells to be $P_c = \mathbf{C} \cong \mathbf{R}^2$.

Consider the coupled cell system

$$\begin{aligned} \dot{x_1} &= g(x_1, x_2, x_3) + 2x_4, \\ \dot{x_2} &= g(x_2, x_3, x_1) + 2x_4, \\ \dot{x_3} &= g(x_3, x_1, x_2) + 2x_4, \\ \dot{x_4} &= -x_4 + e_1 x_1 + e_2 x_2 + e_3 x_3, \end{aligned} \tag{4.16}$$

where $g : (\mathbf{R}^2)^3 \to \mathbf{R}^2$ is given by

$$\begin{aligned} g(x, y, z) = -x + (a - 2b_2)\, x\|x\|^2 + b_1\,(y + z) + b_2\,(y\|y\|^2 + z\|z\|^2) \\ + a\,(x\|y\|^2 + x\|z\|^2) + b_3\,(y\|y\|^4 + z\|z\|^4) \end{aligned}$$

and $a, b_1(\lambda), b_2, b_3, e_1, e_2, e_3$ are 2×2 matrices with b_1 depending smoothly on a parameter λ. Let f be the vector field defined by (4.16). Observe that the origin is an equilibrium point for all λ,

$$f(0, \lambda) \equiv 0.$$

The linearization of f at $(0, \lambda)$ is given by (as 2×2 block matrix)

$$L(\lambda) = \begin{pmatrix} -1 & b_1 & b_1 & 2 \\ b_1 & -1 & b_1 & 2 \\ b_1 & b_1 & -1 & 2 \\ e_1 & e_2 & e_3 & -1 \end{pmatrix},$$

where $\pm c$ represents $\pm\left(\begin{smallmatrix} c & 0 \\ 0 & c \end{smallmatrix}\right)$.

We need to choose the coefficients b_1 and e_1, e_2, e_3 in order to have purely imaginary eigenvalues for some λ coming from the subblock A when L is written in the form (3.12). The following values will do the job:

$$b_1(\lambda) = \begin{pmatrix} -1 - \lambda & -1.5 \\ 1.5 & -1 \end{pmatrix}$$

and any values between -1 and 1 for the entries of the matrices e_1, e_2, e_3.

The spectrum of the matrix $L(\lambda)$ has the following properties:

(1) For $\lambda < 0$ all eigenvalues of $L(\lambda)$ have negative real parts.
(2) For $\lambda = 0$ the matrix $L = L(0)$ has two pairs of eigenvalues $\pm i$, and the remaining eigenvalues have negative real parts. Moreover, the eigenvectors associated with the purely imaginary eigenvalues are not in $\mathrm{Fix}(\mathbf{S}_3)$.
(3) For $\lambda > 0$ all eigenvalues of $L(\lambda)$ whose associated eigenvectors are in $\mathrm{Fix}(\mathbf{S}_3)$ have negative real parts, and the remaining eigenvalues have positive real parts.

Thus (4.16) undergoes an interior symmetry-breaking Hopf bifurcation when $\lambda = 0$, giving rise to one branch of periodic solutions for each one of the three interiorly $\mathbf{C}$-axial subgroups of $\mathbf{S}_3 \times \mathbf{S}^1$, as in Table 1, when $\lambda > 0$. However, depending on the choice of the coefficients a, b_2, and b_3 of g, one can make at least one of these periodic solutions be stable. In our simulations we have chosen the following coefficients:

$$a = \begin{pmatrix} -0.5 & 0 \\ 0 & -0.5 \end{pmatrix},$$

(1) for a solution with (interior) symmetry $\tilde{\mathbf{Z}}_3$:

$$b_2 = \begin{pmatrix} 0.6 & 2 \\ 2 & 0.6 \end{pmatrix}, \qquad b_3 = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}.$$

(2) for a solution with (interior) symmetry $\tilde{\mathbf{Z}}_2$:

$$b_2 = \begin{pmatrix} -0.6 & 1 \\ 1 & -0.6 \end{pmatrix}, \qquad b_3 = \begin{pmatrix} 0.2 & -0.7 \\ -0.7 & 0.2 \end{pmatrix}.$$

(3) for a solution with (interior) symmetry $\mathbf{Z}_2$:

$$b_2 = \begin{pmatrix} -0.6 & 0 \\ 0 & -0.6 \end{pmatrix}, \qquad b_3 = \begin{pmatrix} 0 & 0.7 \\ 0.7 & 0 \end{pmatrix}.$$

The coefficients e_1, e_2, and e_3 represent the coupling that breaks the $\mathbf{S}_3$-symmetry. If $e_1 = e_2 = e_3$, then the coupled cell system (4.16) is admissible for the network $\mathcal{G}_1$ of Figure 1, and so it is $\mathbf{S}_3$-symmetric. On the other hand, if $e_1 \neq e_2 \neq e_3$, then the coupled cell system (4.16) is admissible for the network $\mathcal{G}_2$ of Figure 1 and has genuine $\mathbf{S}_3$-interior symmetry.

In the following we present the results of numerical simulations obtaining the three types of periodic solutions mentioned above, for both of the networks $\mathcal{G}_1$ and $\mathcal{G}_2$ of our running example. In Figures 3, 4, and 5 we superimpose the time series of all four cells, which are identified by colors:

$$1 = \text{blue}, \qquad 2 = \text{red}, \qquad 3 = \text{green}, \qquad 4 = \text{black}.$$

The upper panels show the first components, and the lower panels show the second components. The left panels refer to network $\mathcal{G}_1$ with exact $\mathbf{S}_3$-symmetry, and the panels on the right refer to network $\mathcal{G}_1$ with $\mathbf{S}_3$-interior symmetry. Finally, in Figure 6 we present the solution with interior symmetry $\tilde{\mathbf{Z}}_3$ of network $\mathcal{G}_2$, i.e., the approximate rotating wave from Figure 3 (right), viewed in difference coordinates:

$$x_1 - x_2 = \text{blue}, \qquad x_2 - x_3 = \text{green}, \qquad x_3 - x_1 = \text{red}.$$

Acknowledgment. We thank Marty Golubitsky for useful discussions.

Surface Gap Solitons at a Nonlinearity Interface*

Tomáš Dohnal† and Dmitry Pelinovsky‡

Abstract. We demonstrate existence of waves localized at the interface of two nonlinear periodic media with different coefficients of the cubic nonlinearity via the one-dimensional Gross–Pitaevsky equation. We call these waves the surface gap solitons (SGSs). In the case of smooth symmetric periodic potentials, we study analytically bifurcations of SGSs from standard gap solitons and determine numerically the maximal jump of the nonlinearity coefficient allowing for SGS existence. We show that the maximal jump vanishes near the thresholds of bifurcations of gap solitons. In the case of continuous potentials with a jump in the first derivative at the interface, we develop a homotopy method of continuation of SGS families from the solution obtained via gluing of parts of the standard gap solitons and study existence of SGSs in the photonic band gaps. We explain the termination of the SGS families in the interior points of the band gaps from the bifurcation of linear bound states in continuous nonsmooth potentials.

Key words. surface gap solitons, Gross–Pitaevsky equation, nonlinear Schrödinger equation, nonlinearity interface

1. Introduction.

We are concerned with localized waves at the interface of two periodic nonlinear media called surface gap solitons (SGSs). One of the first publications on optical solitons propagating along material interfaces is [17], where the interface of a linear and a focusing Kerr nonlinear medium is studied. In the last two years relevant publications in the context of nonlinear optics have dealt, for instance, with discrete surface solitons in nonlinear waveguide arrays [4, 10, 16], SGSs at the interface of a uniform and a periodic medium with the defocusing cubic nonlinearity [7], and surface vortex solitons at the interface of two periodic media with different mean values of the refractive index and with saturable nonlinearity [5, 6]. One of the typical models employed in the theory of gap solitons is the one-dimensional nonlinear Schrödinger (NLS) equation with cubic nonlinearity and periodic potential called the Gross–Pitaevsky equation.

We investigate here the existence of surface waves at the interface of two media with identical periodic linear parts of the refractive index and with different cubic nonlinearities. It is known that for most photonic materials a variation in the nonlinear part of the refractive index n_2 is necessarily accompanied by a larger change in the linear part n_0. Nevertheless,

certain materials exhibit large variations in n_2 accompanied by small variations in n_0; see [1, 15]. Localized states have been studied theoretically in media with constant n_0 and spatially periodic n_2 in [3].

Each of the two periodic nonlinear media supports at least two families of standard gap solitons in every bounded nonempty frequency gap. One family is always unstable, while the other can be stable depending on the locations of spectral bands and bifurcations of eigenvalues from the band edges [13]. The potentially stable family looks like a single-humped envelope soliton with exponential decay and oscillations near the central peak. Multihumped envelope solitons may also exist in such periodic nonlinear media, but we shall focus herein on existence of a single-humped solution localized near the interface between the two periodic nonlinear media.

The paper is organized as follows. Section 2 reviews Floquet theory for the governing Gross–Pitaevsky equation and summarizes the results on existence of gap solitons. In section 3 we study the existence of SGSs for a smooth symmetric periodic potential function and find the maximal allowed jump in the nonlinearity coefficient between the two media for existence of SGSs. Section 4 discusses bifurcations and existence of SGSs for a continuous potential function with a derivative jump at the nonlinearity interface. Section 5 concludes the paper with conjectures on the stability of SGSs.

2. Background: Floquet theory and gap soliton existence. We consider the one-dimensional periodic cubic Schrödinger equation in the form

$$iu_t = -u_{xx} + V(x)u - \Gamma(x)|u|^2 u, \quad x \in \mathbb{R}, \quad t \geq 0, \tag{2.1}$$

where x and t are the spatial and temporal variables, respectively, $V(x)$ is a real, continuous, and d-periodic potential, and $\Gamma(x) = \Gamma_\pm$ for $\pm x > 0$ is a real nonlinearity coefficient with constants Γ_+ and Γ_-. The positive values of $\Gamma(x)$ correspond to the focusing nonlinearity and the negative values of $\Gamma(x)$ to the defocusing nonlinearity.

We are interested in the existence of stationary solutions of (2.1) localized near the interface at $x = 0$ and having the form

$$u(x,t) = e^{-i\omega t}\phi(x) \quad \text{s.t.} \quad \phi : \mathbb{R} \to \mathbb{R}, \quad \phi \to 0 \ \text{ as } \ |x| \to \infty. \tag{2.2}$$

The function $\phi(x)$ has to satisfy the second-order nonautonomous ODE

$$-\phi'' - \omega\phi + V(x)\phi - \Gamma(x)\phi^3 = 0, \tag{2.3}$$

which can be cast in the Hamiltonian form with the Hamiltonian function

$$H[\phi] = \frac{1}{2}\left[(\phi')^2 + \omega\phi^2 - V(x)\phi^2\right] + \frac{1}{4}\Gamma(x)\phi^4. \tag{2.4}$$

Since $\Gamma(x)$ is discontinuous at $x = 0$, $\phi(x)$ is a weak solution of the ODE (2.3) in $\phi \in C^2(\mathbb{R}_+ \cup \mathbb{R}_-)$, such that the second derivative $\phi''(x)$ may have a jump at $x = 0$. The continuously differentiable solution $\phi \in C^1(\mathbb{R})$ is a critical point of the energy functional

$$E_\omega[\phi] = \frac{1}{2}\int_{\mathbb{R}} \left[|\phi'|^2 + \omega|\phi|^2 - V(x)|\phi|^2\right] dx + \frac{1}{4}\int_{\mathbb{R}} \Gamma(x)|\phi|^4 dx,$$

such that the first variation $E'_\omega[\phi]$ recovers the ODE (2.3).

Replacing t by z in (2.1) and (2.2), the x-localized solution $u(x,z)$ can be viewed as a spatial soliton propagating along the direction z and localized in the transverse direction x. The parameter ω plays the role of the propagation constant. Other applications of the ODE (2.3) occur in the theory of stationary solutions of the nonlinear Maxwell and Klein–Gordon equations in one dimension.

As we show below, the localized solutions of the ODE (2.3) decay exponentially as $|x| \to \infty$ only if ω belongs to the frequency gaps in the continuous spectra of the operator $L := -\partial_{xx} + V(x)$ called the photonic band gaps. To do so, we recall the basic Floquet theory (see [2, 9]) for the Hill equation

$$L\psi(x) = -\psi''(x) + V(x)\psi(x) = \omega\psi(x), \qquad x \in \mathbb{R}. \tag{2.5}$$

The bounded solutions $\psi(x)$ of the Hill equation (2.5) are usually called Bloch functions. Given a real, continuous, and d-periodic potential $V(x)$, bounded solutions $\psi(x)$ exist for ω in a union of (possibly disjoint) spectral bands

$$\Sigma := [\omega_0, \omega_1] \cup [\omega_2, \omega_3] \cup [\omega_4, \omega_5] \cup \dots,$$

where $\omega_{2n-2} < \omega_{2n-1} \leq \omega_{2n}$, $n \in \mathbb{N}$, and $\omega_n \to \infty$ as $n \to \infty$. The set Σ represents the complete (purely continuous) spectrum of the operator L [2]. We shall *assume* for simplicity that all spectral bands are disjoint with $\omega_{2n-1} < \omega_{2n}$, $n \in \mathbb{N}$, such that all finite frequency gaps are nonempty.

For a fixed ω in the interior point of Σ, both fundamental solutions of the second-order ODE (2.5) are quasi-periodic in x and have the representation $\psi = p_\pm(x)e^{\pm ikx}$, where $p_\pm(x) = p_\pm(x+d)$ and $k \in \left[0, \frac{\pi}{d}\right]$. The parameter k parameterizes the frequency parameter ω, such that we shall use the notation $\omega = \omega_{2n,2n+1}(k)$ for the spectral band in $\omega \in [\omega_{2n}, \omega_{2n+1}]$. If the nth band is separated from the $(n+1)$th band (i.e., $\omega_{2n-1} < \omega_{2n}$ and $\omega_{2n+1} < \omega_{2n+2}$), then $\omega'_{2n,2n+1}(k) = 0$ and $\omega''_{2n,2n+1}(k) \neq 0$ at the endpoints $k = 0$ and $k = \frac{\pi}{d}$ [8].

When $\omega = \omega_n$, one of the solutions $\psi = \psi_n(x)$ is either d-periodic (corresponding to $k = 0$) or d-antiperiodic (corresponding to $k = \frac{\pi}{d}$), and the other fundamental solution $\psi(x)$ grows linearly in x. For a fixed $\omega \in \mathbb{R} \setminus \Sigma$ the two fundamental solutions of (2.5) grow exponentially in either x or $-x$ and have the representation $\psi = u_\pm(x)e^{\pm\kappa x}$, where $u_\pm(x)$ is either periodic or antiperiodic and $\kappa = \kappa(\omega) \in \mathbb{R}_+$. The functions $u_\pm(x)$ are periodic (antiperiodic) if the bounded solutions $\psi_n(x)$ are periodic (antiperiodic) at the band edges ω_{2n-1} and ω_{2n}, which surround the band gap.

Suppose that $\phi(x)$ is a localized solution of the ODE (2.3). It is then obvious from the linearized analysis that the solution $\phi(x)$ decays exponentially as $|x| \to \infty$ only if $\omega \in \mathbb{R} \setminus \Sigma$. It was shown under fairly general assumptions (see [13] and references therein) that the families of gap solitons of the ODE (2.3) with constant coefficient $\Gamma(x) = \Gamma_0$ undertake a local bifurcation from all points $\omega = \omega_{2m}$, $m \geq 0$, to the left if $\Gamma_0 > 0$ and from all points $\omega = \omega_{2m+1}$, $m \geq 0$, to the right if $\Gamma_0 < 0$ (the term *local bifurcation* means that $\|\phi\|_{L^\infty} \to 0$ as $\omega \to \omega_n$). This conjecture was rigorously proved in [11], where existence of exponentially decaying gap solitons in $H^1(\mathbb{R})$ was confirmed in every finite frequency gap $\omega \in (\omega_{2m-1}, \omega_{2m})$, $m \in \mathbb{N}$, and in the semi-infinite frequency gap $\omega < \omega_0$ for $\Gamma_0 > 0$. We use this result but

simplify our consideration by working with the class of symmetric potentials $V = V_0(x)$, where $V_0(-x) = V_0(x)$ on $x \in \mathbb{R}$. In particular, we shall perform numerical computations with

$$V_0(x) = \sin^2\left(\frac{\pi x}{d}\right), \quad d = 10, \tag{2.6}$$

which has a minimum at $x = 0$, i.e., at our interface location. The spectral bands and gaps of $V_0(x)$ are approximated numerically from the Hill equation (2.5). For instance, the first five band edges of the potential (2.6) are located as follows:

$$\omega_0 \approx 0.283, \quad \omega_1 \approx 0.291, \quad \omega_2 \approx 0.747, \quad \omega_3 \approx 0.843, \quad \omega_4 \approx 1.057.$$

As seen in Figure 1 of [13], the Bloch functions $\psi = \psi_n(x)$ at the band edges $\omega = \omega_n$, $n \geq 0$, have the following symmetry properties:

$$\begin{aligned} &\psi_n(-x) = \psi_n(x), \ n \in \{0, 1, 4, 5, 8, 9, \ldots\}, \\ &\psi_n(-x) = -\psi_n(x), \ n \in \{2, 3, 6, 7, \ldots\}. \end{aligned} \tag{2.7}$$

Symmetry properties (2.7) can be proved for any even potential $V_0(-x) = V_0(x)$. Indeed, since the Hill equation (2.5) is symmetric with respect to reflection $x \mapsto -x$ and admits only one linearly independent bounded eigenfunction $\psi = \psi_n(x)$ at $\omega = \omega_n$, the function $\psi_n(x)$ must be either even or odd in x. By the trace of the monodromy matrix [2], the periodic functions $\psi_n(x)$ correspond to the set $n \in S_+$ with $S_+ = \{0, 3, 4, 7, 8, \ldots\}$, and the antiperiodic functions $\psi_n(x)$ correspond to the set $n \in S_-$ with $S_- = \{1, 2, 5, 6, \ldots\}$. By Sturm's theorem [2], the periodic functions $\psi_n(x)$ with $n \in S_+$ have exactly $\text{ind}_{S_+}(n) - 1$ nodes on $x \in \left(-\frac{d}{2}, \frac{d}{2}\right)$, where $\text{ind}_{S_+}(n)$ is the order number of n in the set S_+. For instance, $\psi_0(x)$ has no nodes (positive definite), $\psi_3(x)$ has one node, $\psi_4(x)$ has two nodes, etc. Combining the symmetry with respect to reflections and the number of nodes, we conclude that the set of eigenfunctions $\{\psi_n(x)\}_{n \in S_+}$ alternates the symmetry in x, such that $\psi_0(x)$ is even, $\psi_3(x)$ is odd, $\psi_4(x)$ is even, etc. Similarly, the antiperiodic functions $\psi_n(x)$ with $n \in S_-$ have exactly $\text{ind}_{S_-}(n) - 1$ nodes on $x \in \left(-\frac{d}{2}, \frac{d}{2}\right)$. For instance, $\psi_1(x)$ has no nodes, $\psi_2(x)$ has one node, etc. We conclude again that the set of eigenfunctions $\{\psi_n(x)\}_{n \in S_-}$ alternates the symmetry in x, such that $\psi_1(x)$ is even, $\psi_2(x)$ is odd, etc.

Altogether, this set of facts is summarized in Table 1.

Table 1

Properties of the Bloch functions $\psi_n(x)$ and gap soliton bifurcations at the first eight band edges of an even potential $V_0(-x) = V_0(x)$.

n	0	1	2	3	4	5	6	7
symmetry	even	even	odd	odd	even	even	odd	odd
periodicity	S_+	S_-	S_-	S_+	S_+	S_-	S_-	S_+
# nodes on $\left(-\frac{d}{2}, \frac{d}{2}\right)$	0	0	1	1	2	2	3	3
sign of Γ_0 for local bifurcation	1	-1	1	-1	1	-1	1	-1

Let $\phi_0(x)$ be a single-humped solution of the ODE (2.3) with $\Gamma(x) = \Gamma_0$ and $V(x) = V_0(x)$ which bifurcates from the band edge $\omega = \omega_n$. By the local bifurcation theory [13], it inherits the symmetry properties (2.7) of the Bloch function $\psi_n(x)$. Therefore, $\phi_0(-x) = \phi_0(x)$ for branches of gap solitons to the left of ω_n with $n = \{0, 4, 8, \ldots\}$ (for $\Gamma_0 > 0$) and to the right

of ω_n with $n = \{1, 5, 9, \ldots\}$ (for $\Gamma_0 < 0$), while $\phi_0(-x) = -\phi_0(x)$ for branches of gap solitons to the left of ω_n with $n = \{2, 6, \ldots\}$ (for $\Gamma_0 > 0$) and to the right of ω_n with $n = \{3, 7, \ldots\}$ (for $\Gamma_0 < 0$). See Figures 2–3 in [13] for gap solitons $\phi_0(x)$ in the potential (2.6).

In this paper, we shall consider the existence of SGSs in the ODE (2.3) with piecewise constant coefficient $\Gamma(x) = \Gamma_\pm$ for $\pm x > 0$ and potential $V(x)$ of the following two classes:

$$\text{(2.8)} \qquad \text{(i) } V = V_0(x), \qquad \text{(ii) } V = V_0(x-\delta)\chi_{(-\infty,0)} + V_0(x+\delta)\chi_{[0,\infty)},$$

where $\chi_{[a,b]} = 1$ on $x \in [a, b]$ and zero otherwise, while $0 < \delta < d$. Here $V_0(x)$ is a smooth, even, d-periodic function on $x \in \mathbb{R}$. We note that $V(x)$ in (ii) is continuous and even on $x \in \mathbb{R}$ but smooth and periodic only on each $\pm x > 0$.

One can develop a general shooting method for numerical approximations of SGSs from the condition that a localized solution $\phi(x)$ of the second-order ODE (2.3) with $\omega \in (\omega_{2m-1}, \omega_{2m})$, $m \in \mathbb{N}$, decays to zero at infinity according to two fundamental solutions $p_\pm(x)e^{\mp\kappa x}$ as $x \to \pm\infty$, where $\kappa = \kappa(\omega)$ is a positive number. Solving the ODE (2.3) with $\Gamma(x) = \Gamma_+$ for a general initial value $\phi(0)$ and $\phi'(0)$ to $x > 0$ and the same ODE with $\Gamma(x) = \Gamma_-$ to $x < 0$, one can construct a continuously differentiable solution $\phi(x)$ on $x \in \mathbb{R}$ which decays to zero as $x \to \pm\infty$ if and only if the projections to the growing fundamental solutions $p_\pm(x)e^{\pm\kappa x}$ are zero at infinity. The system of two constraints for two initial values constitutes a well-posed problem of numerical analysis. This numerical approach was adopted in recent work [18]. Practical implementations of this algorithm are unclear as the shooting method may depend sensitively on starting approximations of the initial value and may require long computational time to search through all appropriate initial values. In addition, the ODE solvers of the shooting method may develop numerical instabilities in approximations of growing solutions.

Due to these reasons, we shall develop an alternative view on numerical approximations of SGSs, starting with local bifurcation analysis and using the homotopy continuation method to trace the solution families along parameters ω, $\Gamma_\pm$, and δ. Using these analytical and numerical results, we have obtained the following main results.

(1) We prove analytically that any gap soliton for $\Gamma_+ = \Gamma_-$ can be continued to the SGS for sufficiently small $|\Gamma_+ - \Gamma_-|$ under a nondegeneracy assumption.
(2) We prove analytically that the maximal difference $|\Gamma_+ - \Gamma_-|$ leading to SGS existence converges to 0 when ω approaches the band edge which features the local bifurcation of a gap soliton.
(3) SGSs are computed numerically when the potential $V(x)$ is given by (2.8)(i), and the maximal $|\Gamma_+ - \Gamma_-|$ allowing their existence is found. Our numerical results confirm the analytical results (1)–(2) above.
(4) Existence of SGSs for $V(x)$ in (2.8)(ii) with $\Gamma_+ > 0$ and $\Gamma_- < 0$ is studied. We numerically show that local bifurcations may occur from a countable set of points in the parameter domain $(\omega, \delta) \in (\omega_{2m-1}, \omega_{2m}) \times (0, d)$, $m \in \mathbb{N}$.
(5) We numerically compute the points of local bifurcation of SGSs for the potential (2.8)(ii) and use the homotopy continuation of the bifurcating solution. As a result, we show that the family of SGSs exists typically in a subset of the plane (ω, δ).
(6) We analytically show that the termination of families of SGSs for the potential (2.8)(ii) is related to existence of linear bound states for the nonsmooth potential.

Results (1)–(3) are reported in section 3, and results (4)–(6) are described in section 4.

3. Bifurcations of SGSs for smooth potentials. In this section we study continuation of SGSs from gap solitons existing for $\Gamma_+ = \Gamma_-$ in the case of a smooth potential function $V(x)$. A prototypical example of such potential is the symmetric function $V_0(x)$ in (2.8)(i).

3.1. Existence of bifurcations from gap solitons. Let $\gamma = (\Gamma_+ + \Gamma_-)/2$ and $\nu = (\Gamma_+ - \Gamma_-)/2$. Then, the ODE (2.3) can be rewritten in the form

$$F(\phi, \nu) = -\phi'' - \omega\phi + V(x)\phi - \gamma\phi^3 - \nu\,\mathrm{sign}(x)\phi^3 = 0, \tag{3.1}$$

where $F(\phi, \nu) : H^1(\mathbb{R}) \times \mathbb{R} \mapsto H^{-1}(\mathbb{R})$ is a nonlinear operator acting on a function $\phi(x)$ in space $H^1(\mathbb{R})$ and parameter $\nu \in \mathbb{R}$.

We assume that there exists a solution $\phi_0(x) \in H^1(\mathbb{R})$ for $\omega \in \mathbb{R} \setminus \Sigma$ and some γ and $V(x)$, such that $F(\phi_0, 0) = 0$. The Jacobian $D_\phi F(\phi_0, 0)$ is given by the Schrödinger operator $\mathcal{L} : H^2(\mathbb{R}) \mapsto L^2(\mathbb{R})$, where

$$\mathcal{L} = -\partial_x^2 - \omega + V(x) - 3\gamma\phi_0^2(x). \tag{3.2}$$

Since $\omega \in \mathbb{R}\setminus\Sigma$, we have $\phi_0^2(x) \to 0$ exponentially fast as $|x| \to \infty$, such that the term $-3\gamma\phi_0^2(x)$ is a relatively compact perturbation to the unbounded operator $L - \omega$, where $L = -\partial_x^2 + V(x)$. By a standard argument (see Corollary 2 in section XIII.4 in [14]), the essential spectrum of $\mathcal{L}$ and $(L - \omega)$ coincide. Since $\omega \in \mathbb{R} \setminus \Sigma$, the zero point is isolated from the essential spectrum of $\mathcal{L}$. If we further assume that $\mathcal{L}$ has the trivial kernel in $H^1(\mathbb{R})$, then $\mathcal{L}$ is invertible on $L^2(\mathbb{R})$. Since the translational invariance is broken if $V(x) \neq 0$, $\mathcal{L}$ generally has the trivial kernel, unless a bifurcation of branches of gap solitons occur. By the standard analysis based on the implicit function theorem, there exists a unique smooth continuation of $\phi_\nu(x)$ from $\phi_0(x)$ in $H^1(\mathbb{R})$ for sufficiently small ν, such that $F(\phi_\nu, \nu) = 0$ and $\phi_\nu(x) \to \phi_0(x)$ in $H^1(\mathbb{R})$ as $\nu \to 0$.

In other words, we have proved above that if a gap soliton exists for $\Gamma_+ = \Gamma_-$ and $\omega \in \mathbb{R} \setminus \Sigma$ and the linearized operator $\mathcal{L}$ is nondegenerate, then the gap soliton is uniquely continued into the SGS for small nonzero $|\Gamma_+ - \Gamma_-|$. We confirm this prediction via numerical analysis of the ODE (2.3) with $V(x)$ in (2.8)(i) for ω taken in the semi-infinite band gap and the first two finite gaps. Numerical approximations of $\phi_0(x)$ for $\Gamma_+ = \Gamma_-$ are obtained from the Newton–Raphson iterations and the homotopy continuation method. The initial guess for the Newton iteration is taken from an asymptotic expansion leading to the NLS approximation [13] when ω is close to the local bifurcation threshold ω_n. After a successful convergence for one such ω we use a standard homotopy continuation and generate a family of gap solitons $\phi_0(x)$ parameterized by ω. The discretization of the ODE (2.3) is based on a fourth-order central difference approximation of ∂_{xx} on a truncated domain with zero Dirichlet boundary conditions.

3.2. Numerical computations of SGSs. We now proceed to construct SGSs, i.e., solutions $\phi(x)$ of the second-order ODE (2.3) with $\Gamma_+ \neq \Gamma_-$. When $\phi_0(x)$ is obtained for a given value of ω, we can apply the numerical homotopy continuation of the solution by deviating Γ_- from Γ_+. At each step, the SGS $\phi(x)$ is thus found via Newton's iterations. The final value of Γ_-, up to which the iteration converges, is denoted by Γ_*.

Figure 1 shows the values of Γ_* for $\Gamma_+ = +1$ (a) and $\Gamma_+ = -1$ (b). The computational tolerance in Γ_* is 0.006 inside the band gaps and 0.002 near the band edges. In the case

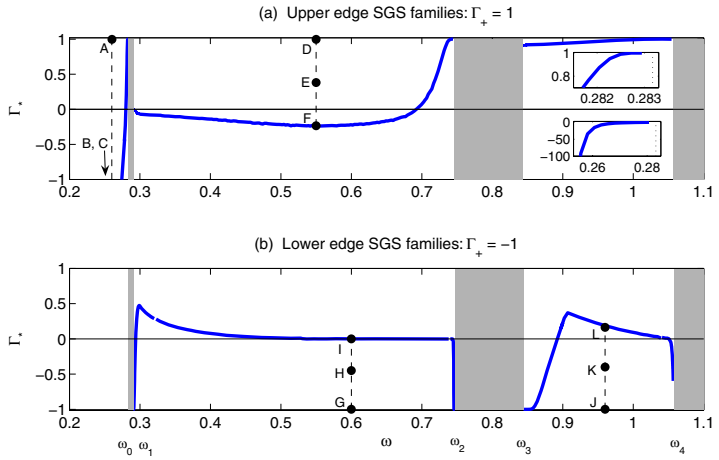

Figure 1. *The values of* Γ_* *for SGSs originating from symmetric GS families of the first three frequency gaps of* $V(x) = \sin^2(\pi x/10)$. *In* (a) *the upper inset zooms in and the lower inset zooms out on the graph in the semi-infinite gap. The points A–L are referenced in Figure 2.*

$\Gamma_+ = 1$, local bifurcations of small-amplitude gap solitons occur from the lower band edges. Figure 1(a) shows that the SGSs exist in the semi-infinite gap, as well as in the first two frequency gaps. In the case $\Gamma_+ = -1$, local bifurcations of gap solitons occur from the upper band edges. Figure 1(b) shows that the SGSs exist in the first and second frequency gaps. The two insets of Figure 1(a) show that Γ_* decreases quickly as ω moves away from the edge of the first band and that the convergence $\Gamma_* \uparrow 1$ as $\omega \uparrow \omega_0$ is smooth. We further see from Figure 1 that the interval of existence shrinks as ω approaches the value ω_n for any band edge, where gap solitons undertake a local bifurcation. In addition, the interval of existence is extremely large in the semi-infinite gap $(-\infty, \omega_0)$, but it becomes narrow in the finite gaps $(\omega_{2m-1}, \omega_{2m})$ for $m \geq 1$.

For comparison, the family of SGSs in the gap (ω_1, ω_2) exists for $-0.24 < \Gamma_* < 1$ in the case $\Gamma_+ = +1$ and $-1 < \Gamma_* < 0.47$ in the case $\Gamma_+ = -1$. The family of SGSs in the gap (ω_3, ω_4) exists in a very narrow region of $0.92 < \Gamma_* < 1$ in the case $\Gamma_+ = +1$ and in a bigger interval $-1 < \Gamma_* < 0.37$ in the case $\Gamma_+ = -1$ (similarly to that in the first gap).

Figure 2 shows profiles of SGSs which correspond to the twelve points labeled A–L in Figure 1. The solid lines correspond to the gap solitons from which the homotopy in Γ_- is started (i.e., points A, D, G, and J). Clearly, the total power and maximum amplitude of the SGSs increase as $|\Gamma_+ - \Gamma_-|$ increases. Also notice that the profiles become more concentrated on the half $x > 0$ in the case $\Gamma_+ = +1$ (see Figure 2 (a–b)) and on the half $x < 0$ in the case $\Gamma_+ = -1$ (see Figure 2 (c–d)) as $|\Gamma_+ - \Gamma_-|$ increases. This is in accord with the law of refraction: when $\Gamma_+ = +1$ and Γ_- decreases from 1, the half $x > 0$ becomes relatively more focusing and therefore attracts more energy of the soliton, while when $\Gamma_+ = -1$ and Γ_- increases from -1, the situation is the opposite.

3.3. Asymptotic analysis near gap soliton bifurcation points. Now we shall explain why the existence interval shrinks to zero when ω approaches the value ω_n where a local bifurcation

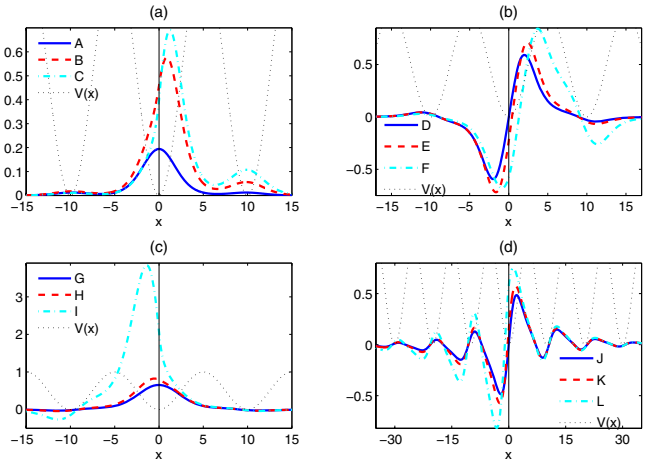

Figure 2. *The profiles of SGSs corresponding to the points A–L in Figure 1. Values of ω are A–C:* 0.26, *D–F:* 0.55, *G–I:* 0.6, *J–L:* 0.96. *Values of Γ_- are A:* 1, *B:* -3.9, *C:* -15.3, *D:* 1, *E:* 0.38, *F:* -0.235, *G:* -1, *H:* -0.45, *I:* 0.002, *J:* -1, *K:* -0.4, *L:* 0.164.

of gap solitons occurs. As $\omega \to \omega_n$, we have $\|\phi_0\|_{L^\infty} \to 0$ and $\mathcal{L} \to (L-\omega_n)$. Since the operator $(L-\omega_n)$ is not invertible, the implicit function theorem cannot be used and the solution $\phi_0(x)$ cannot be continued beyond $\nu = 0$. In order to give a more precise explanation of this phenomenon, we adopt the NLS approximation for local bifurcation of gap solitons from [13] (see also the review in [12]). In particular, we consider an asymptotic solution to the ODE (2.3),

$$\begin{aligned} &\omega = \omega_n + \varepsilon^2\,\Omega + \mathcal{O}(\varepsilon^4), \\ &\phi(x) = \varepsilon\,A(X)\psi_n(x) + \varepsilon^2\,A'(X)\tilde{\psi}_n(x) + \varepsilon^3\,\phi^{(3)}(x,X) + \mathcal{O}(\varepsilon^4), \end{aligned} \tag{3.3}$$

where $X = \varepsilon\,x$, $\varepsilon << 1$, the function $A(X)$ and parameter Ω are defined below, and ψ_n and $\tilde{\psi}_n$ are the d-periodic (or d-antiperiodic) Bloch functions and generalized Bloch functions, respectively, of the Hill equation (2.5) for $\omega = \omega_n$, such that

$$(L-\omega_n)\psi_n = 0, \qquad (L-\omega_n)\tilde{\psi}_n = 2\psi_n'. \tag{3.4}$$

The correction term $\phi^{(3)}(x,X)$ at $\mathcal{O}(\varepsilon^3)$ solves the nonhomogeneous problem

$$(L-\omega_n)\phi^{(3)} = \Omega A\psi_n + A''\psi_n + 2A''\tilde{\psi}_n' + \Gamma(X)A^3\psi_n^3. \tag{3.5}$$

To ensure boundedness of $\phi^{(3)}(x,X)$ with respect to the variable x, and, hence, legitimacy of the expansion (3.3), one has to apply the Fredholm alternative which imposes the orthogonality condition of the right-hand side of (3.5) with respect to $\psi_n(x)$ on $x \in [0,d]$. The orthogonality condition is written as

$$\Omega A + \mu A'' + \rho\Gamma(X)A^3 = 0, \tag{3.6}$$

where

$$\mu = 1 + 2\frac{(\tilde{\psi}_n', \psi_n)}{(\psi_n, \psi_n)}, \qquad \rho = \frac{(\psi_n^2, \psi_n^2)}{(\psi_n, \psi_n)},$$

and we have used the standard L^2 inner product $(\cdot, \cdot)$ over one period $x \in [0, d]$. It is shown in [13] that $\mu = \frac{1}{2}\omega''_{2n,2n+1}(k)$ with either $k = 0$ or $k = \frac{\pi}{d}$ at the point $\omega = \omega_n$, where $\omega_{2n,2n+1}(k)$ is the dispersion relation between $\omega \in [\omega_{2n}, \omega_{2n+1}]$ and $k \in [0, \frac{\pi}{d}]$.

Due to the nature of the nonlinearity interface, the function $\Gamma(X)$ is the same as $\Gamma(x)$, i.e., $\Gamma(X) = \Gamma_\pm$ for $\pm X > 0$. We shall prove that no localized solution of the ODE (3.6) exists under the condition $\Gamma_- \neq \Gamma_+$. Indeed, consider the Hamiltonian of the ODE (3.6):

$$H[A] = \frac{1}{2}\left[\mu (A')^2 + \Omega A^2\right] + \frac{1}{4}\rho\Gamma(X)A^4. \tag{3.7}$$

If $A(X)$ solves the ODE (3.6), then

$$\frac{d}{dX}H[A(X)] = \frac{1}{4}\rho\Gamma'(X)A^4(X) = \frac{1}{4}\rho(\Gamma_+ - \Gamma_-)\delta(X)A^4(X),$$

where $\delta(X)$ is the Dirac delta-function. If $A(X)$ is a localized solution on $X \in \mathbb{R}$, then the integration on $X \in \mathbb{R}$ gives the constraint

$$0 = \lim_{x\to+\infty} H[A(X)] - \lim_{x\to-\infty} H[A(X)] = \frac{1}{4}\rho(\Gamma_+ - \Gamma_-)A^4(0),$$

since $H[A(X)] \to 0$ if $A(X), A'(X) \to 0$ as $|X| \to \infty$. Therefore, $A(0) = 0$ if $\Gamma_+ \neq \Gamma_-$. Consider now $H[A(X)]$ on $X > 0$. It is clear from the decaying conditions as $X \to \infty$ that $H[A(X)] = \text{const} = 0$, which together with the fact that $A(0) = 0$ leads to $0 = \lim_{X\downarrow 0} H[A(X)] = \frac{1}{2}\mu|A'(0)|^2$, such that $A'(0) = 0$. The only solution of the ODE (3.6) with $A(0) = A'(0) = 0$ is the zero solution $A(X) \equiv 0$.

If $\Gamma_+ = \Gamma_- = \Gamma_0$ and $\text{sign}(\mu) = \text{sign}(\rho\Gamma_0) = -\text{sign}(\Omega)$, the ODE (3.6) has the standard sech-soliton decaying as $|X| \to \infty$. However, the result above shows that the sech-soliton with $\Gamma_+ = \Gamma_-$ cannot be homotopically continued to a decaying solution of (3.6) for $\Gamma_+ \neq \Gamma_-$. This proves that $\Gamma_* \to \Gamma_+$ as $\omega \to \omega_n$, where ω_n is a local bifurcation value.

4. Bifurcations of SGSs for nonsmooth potentials.

In this section, we study local bifurcations of solutions of the ODE (2.3) when $V(x)$ is a continuous function with the jump in the first derivative at the nonlinearity interface. The prototypical example of such potentials is given by (2.8)(ii), where $V_0(x)$ is an even potential (in our numerical computations we use V_0 from (2.6)). We shall consider the existence of SGSs under the normalization $\Gamma_+ = -\Gamma_- = +1$.

4.1. SGS numerical construction via gluing.

The point (δ_*, ω_*) in the parameter domain $\delta \in (0, d)$ and $\omega \in (\omega_{2m-1}, \omega_{2m})$, $m \in \mathbb{N}$, is defined to be a point of a local bifurcation of SGSs according to the following two-step algorithm.

(i) *Construction of continuous solutions.* Let $\phi_\pm(x; \omega)$ denote the family of single-humped gap solitons parameterized by $\omega \in (\omega_{2m-1}, \omega_{2m})$ and centered at $x = 0$ corresponding to (2.3) with $\Gamma(x) \equiv \Gamma_\pm$, respectively. These families bifurcate from the points $\omega = \omega_{2m}$ for $\Gamma_+ > 0$

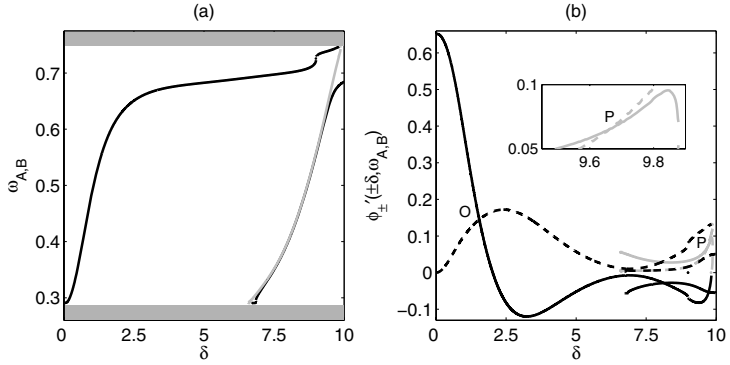

Figure 3. *Two-step search for (ω_*, δ_*) in the gap (ω_1, ω_2). (a) Result of step* (i)*—parametrization of the families of continuous solutions* (4.1)*: black line $\omega_A(\delta)$, gray line $\omega_B(\delta)$. (b) Step* (ii)*—search for δ_*: solid black $\phi_+'(\delta;\omega_A)$, dashed black $\phi_-'(-\delta;\omega_A)$, solid gray $-\phi_+'(\delta;\omega_B)$, and dashed gray $\phi_-'(-\delta;\omega_B)$. Labeled points correspond to SGSs.*

and $\omega = \omega_{2m-1}$ for $\Gamma_- < 0$. In order to find continuous solutions, we now study for each fixed $\delta \in (0, d)$ the two functions

$$f_A(\omega) = \phi_-(-\delta;\omega) - \phi_+(\delta;\omega), \quad f_B(\omega) = \phi_-(-\delta;\omega) + \phi_+(\delta;\omega)$$

and find their zeros denoted by $\omega_{A,B} = \omega_{A,B}(\delta)$, respectively. For each δ existence of zeros of either $f_A(\omega)$ or $f_B(\omega)$ is guaranteed by continuity of $\phi_\pm$ as functions of ω and by the fact that $\phi_-(-\delta;\omega_{2m-1}) = \phi_+(\delta;\omega_{2m}) = 0$ and $\phi_-(-\delta;\omega_{2m}) \neq 0$, $\phi_+(\delta;\omega_{2m-1}) \neq 0$. Moreover, several zeros of these functions may occur for the same δ.

When a zero $\omega_A(\delta)$ or $\omega_B(\delta)$ is found, a δ-parameterized family of continuous solutions $\phi_A(x;\delta)$ or $\phi_B(x;\delta)$, respectively, is constructed by gluing two individual gap solitons:

$$\begin{aligned} \phi_A(x;\delta) &= \phi_-(x-\delta;\omega_A)\chi_{(-\infty,0)} + \phi_+(x+\delta;\omega_A)\chi_{[0,\infty)}, \\ \phi_B(x;\delta) &= \phi_-(x-\delta;\omega_B)\chi_{(-\infty,0)} - \phi_+(x+\delta;\omega_B)\chi_{[0,\infty)}. \end{aligned} \tag{4.1}$$

The functions $\phi_{A,B}(x;\delta)$ decay as $|x| \to \infty$ and are smooth in x everywhere except at the nonlinearity interface $x = 0$, where they generally have a jump in the first derivative.

Note that it is important to consider both ϕ_A and ϕ_B due to the sign invariance of the ODE (2.3). Each sign produces a branch of continuous solutions of the ODE (2.3).

Figures 3 (a) and 4 (a) present the numerically computed $\omega_{A,B}(\delta)$ for $\delta \in (0, d)$ in the gaps (ω_1, ω_2) and (ω_3, ω_4), respectively. The lack of smoothness in the curves in these figures is due to an insufficient resolution in the search algorithm and can be corrected with a finer resolution. Note that when $\omega_{A,B}(\delta)$ is multiple-valued, as seen in Figures 3 (a) and 4 (a), we may have several decaying solutions $\phi_A(x)$ and/or $\phi_B(x)$ for the same δ.

(ii) *Construction of SGSs.* Next, we search for continuously differentiable solutions within the above family $\phi_{A,B}(x;\delta)$. To ensure the continuity of the first derivative of $\phi(x;\delta)$ at $x = 0$, we search for zeros of the two functions

$$g_A(\delta) = \phi_-'(-\delta;\omega_A) - \phi_+'(\delta;\omega_A), \quad g_B(\delta) = \phi_-'(-\delta;\omega_B) + \phi_+'(\delta;\omega_B).$$

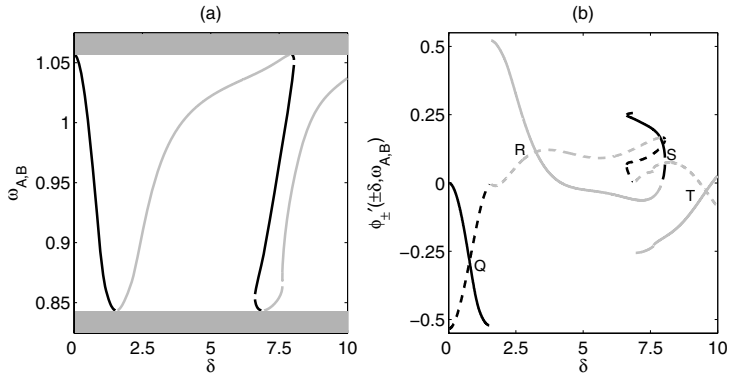

Figure 4. *Analogous to Figure 3 but for the gap* (ω_3, ω_4).

If a zero of either $g_A(\delta)$ or $g_B(\delta)$, denoted by δ_*, exists, then the function $\phi_A(x;\delta_*)$ or $\phi_B(x;\delta_*)$, respectively, in (4.1) has a continuous first derivative across the point $x = 0$. Figures 3 (b) and 4 (b) present the numerical results on computing δ_*. The labeled intersection points O, P, Q, R, S, and T correspond to zeros of $g_{A,B}(\delta)$. They are found as intersection points of solid and dashed curves of the same color. The solid black line shows the plot of $\phi'_+(\delta;\omega_A)$, and the dashed black line shows $\phi'_-(-\delta;\omega_A)$. Similarly, the solid gray line plots $-\phi'_+(\delta;\omega_B)$, and the dashed gray line plots $\phi'_-(-\delta;\omega_B)$. Therefore, an intersection of a solid black and a dashed black line (points O, Q, S) gives zeros δ_* of $g_A(\delta)$ and, thus, a solution $\phi_A(x;\delta_*)$. Similarly, an intersection of a solid gray and a dashed gray line (points P, R, T) gives zeros δ_* of $g_B(\delta)$ and, thus, a solution $\phi_B(x;\delta_*)$.

Table 2 shows the approximate computed values of δ_* and corresponding $\omega_* = \omega_{A,B}(\delta_*)$ at the points O–T for branches A, B of solutions given by (4.1). Note that additional points (δ_*, ω_*) can be obtained by generalizing the above functions $f_{A,B}$ and $g_{A,B}$ to

$$f_{j_A}(\omega) = \phi_-(-(jd+\delta);\omega) - \phi_+(jd+\delta;\omega), \quad f_{j_B}(\omega) = \phi_-(-(jd+\delta);\omega) + \phi_+(jd+\delta;\omega)$$

and

$$g_{j_A}(\delta) = \phi'_-(-(jd+\delta);\omega_A) - \phi'_+(jd+\delta;\omega_A), \quad g_{j_B}(\delta) = \phi'_-(-(jd+\delta);\omega_B) + \phi'_+(jd+\delta;\omega_B)$$

for $j \in \{1, 2, \ldots\}$ with V still defined as in (2.8)(ii). Nontrivial points (ω_*, δ_*) may exist for any such j. For example, we have found one such point for $j = 1$. The computed value is $(\omega_*, \delta_*) \approx (0.73, 7.33)$, and the resulting SGS corresponds to the point Z in Figure 5(a). Such additional solutions are SGSs of smaller amplitude compared to those for $j = 0$.

Table 2

Bifurcation points for SGSs in the domain $\omega \in (\omega_1, \omega_2) \cup (\omega_3, \omega_4)$ *and* $\delta \in (0, d)$.

4.2. Numerical homotopy continuation of SGSs. Assuming the existence of a point (ω_*, δ_*), we have constructed the SGS of the ODE (2.3), where the potential function $V(x)$ is given by (2.8)(ii) and $(\omega, \delta) = (\omega_*, \delta_*)$. The SGS denoted as $\phi_*(x)$ is represented by one of the functions in (4.1) with $(\omega, \delta) = (\omega_*, \delta_*)$. Each of these solutions can be used as a starting point for a numerical homotopy continuation to generate a family of SGSs parameterized by $\omega \subset (\omega_{2m-1}, \omega_{2m})$ for a given value of $\delta = \delta_*$. Similarly, for a fixed $\omega = \omega_*$ a family parameterized by $\delta \subset (0, d)$ can be constructed. Under the same assumption that the operator $\mathcal{L} = -\partial_x^2 - \omega_* + V(x) - 3\Gamma(x)\phi_*^2(x)$ is invertible, the implicit function theorem implies that there exists a unique smooth continuation of the particular solution $\phi_*(x)$ to the family of solutions along parameters ω and δ.

We restrict our numerical studies to the continuation in ω. Numerical results of such continuation from the SGSs at points O–T are shown in Figures 5 (a) and 6 (a). The curves

plot the total soliton power $\|\phi\|^2_{L^2(\mathbb{R})}$ as a function of frequency ω for fixed $\delta = \delta_*$. Note that each curve corresponds to a different value of δ_* and hence a different potential $V(x)$. The values of δ_* can be read in Table 2. Termination of a continuation curve is defined when the total power of the soliton becomes zero or when Newton iteration convergence fails. As the figures show, the latter case is always accompanied by the slope of the continuation curve becoming infinite, suggesting a violation of the implicit function theorem assumptions. The former termination case is studied in the following subsection.

4.3. Analysis of termination points of SGSs. We shall now consider the termination points of the solution families plotted in Figures 5 (a) and 6 (a), where the soliton power becomes zero. The points are labeled O_L–T_L, and their corresponding values of δ and ω are given in Table 3.

Table 3
Termination points for the six SGS families in Figures 5 (a) and 6 (a).

Point	O_L	P_L	Q_L	R_L	S_L	T_L
δ	1.54	9.66	0.78	3.24	7.97	9.57
ω	0.65	0.70	0.98	1.02	1.03	1.03

The termination points are expected to be related to the existence of nontrivial bound states in the (point) spectrum of the Schrödinger operator for the same potential $V(x)$, i.e., with exponentially decaying solutions of the linear ODE

$$-\psi'' - \omega\psi + V(x)\psi = 0, \qquad \psi : \mathbb{R} \mapsto \mathbb{R}, \tag{4.2}$$

for $V(x)$ in (2.8)(ii) and $\omega \in \mathbb{R}\backslash\Sigma$. The point spectrum is nonempty due to the singularity of $V(x)$ at $x = 0$.

4.3.1. Numerical results. Results of numerical computations of the point spectrum contained in the first two finite gaps (ω_1, ω_2) and (ω_3, ω_4) are shown in Figures 5 (b) and 6 (b) for all values $\delta \in [0, d]$. The eigenfunctions ψ are either even (solid lines) or odd (dashed lines). For the six values of δ corresponding to the SGS families in Figures 5 (a) and 6 (a) the eigenvalues are marked by black dots and are in perfect agreement with the values of ω at the termination points O_L–T_L. The symmetry (even/odd) of the bound states at O_L–T_L also matches that of the eigenfunctions at the marked points in the point spectrum. The eigenvalue curve originating as well as ending at ω_2 in Figure 5 (b) corresponds to the termination point Z_L of the SGS family for $j = 1$ in Figure 5 (a). The termination point Z_L for the same value of δ is shown by a triangle.

4.3.2. Bifurcation analysis for $|\delta|$ small. In this subsection we consider bifurcations of point spectrum of the Schrödinger operator from the band edges for small values of $|\delta|$ (or, due to the d periodicity of V, equivalently for δ near 0 from above and near d from below). This analysis will prove the existence of the spectral curves near $\delta = 0$ and $\delta = 10$ in Figures 5 (b) and 6 (b), i.e., the existence of curves with points O_L and Q_L locally to $\delta = 0$ and the curves with points P_L and T_L locally to $\delta = 10$.

In order to construct solutions of the spectral problem (4.2), we first consider exponentially decaying solutions of the ODE on the half-line

$$-\psi_+'' - \omega\psi_+ + V_0(x+\delta)\psi_+ = 0, \qquad \psi_+ : \mathbb{R}_+ \mapsto \mathbb{R}.$$

By using the fundamental solution of the Hill equation (2.5), we can express $\psi_+(x)$ in the form $\psi_+ = e^{-\kappa x}u_-(x+\delta)$, where $u_-(x)$ are periodic or antiperiodic bounded solutions of the Hill equation (2.5) with $V(x) = V_0(x)$.

As $V(x)$ is even, the function $\psi_+(x)$ admits a symmetric (even) reflection about $x = 0$ if $\psi_+'(0) = 0$, which is equivalent to the condition

$$G_1(\delta,\kappa) = u_-'(\delta) - \kappa u_-(\delta) = 0,$$

and it admits an antisymmetric (odd) reflection about $x = 0$ if $\psi_+(0) = 0$, which is equivalent to the condition

$$G_2(\delta,\kappa) = u_-(\delta) = 0.$$

Since eigenvalues of the spectral problem (4.2) are simple and the eigenfunctions are either even or odd, all eigenvalues of the spectral problem (4.2) in the band gaps $\omega \in \mathbb{R}\backslash\Sigma$ are defined by zeros of the functions $G_1(\delta,\kappa)$ and $G_2(\delta,\kappa)$ in κ for a given value of δ, where $\kappa \geq 0$ and the values of κ are related to the values of ω in the band gaps. Both functions $G_{1,2}$ are analytic in $\delta \in \mathbb{R}$ and periodic with period d. Both functions admit analytic continuation in the parameter $\kappa \in \mathbb{R}_+$ [8].

If $\delta = 0$, the only zeros of $G_1(\delta,\kappa)$ and $G_2(\delta,\kappa)$ occur at $\kappa = 0$, i.e., at the band edges $\omega = \omega_n$. Indeed, if $G_1(0,\kappa) = 0$, then $\psi_+'(0) = 0$, such that $\psi_+(x) = \psi_n(x)$ is an even function on $x \in \mathbb{R}$. However, $\psi_+(x)$ decays exponentially as $x \to \infty$ and grows exponentially as $x \to -\infty$ if $\kappa > 0$. Therefore, $G_1(0,\kappa) = 0$ is equivalent to $\kappa = 0$. A similar argument works for $G_2(0,\kappa) = 0$.

(i) *Bifurcation of even eigenfunctions.* Let us first consider the zeros of $G_1(\delta,\kappa)$. Computing the derivatives of $G_1(\delta,\kappa)$ in δ and κ at $(\delta,\kappa) = (0,0)$, we obtain

$$\begin{aligned}
\partial_\delta G_1(0,0) &= u_-''(0) = \psi_n''(0) = (V_0(0) - \omega_n)\psi_n(0),\\
\partial_\kappa G_1(0,0) &= -\tilde\psi_n'(0) - \psi_n(0),
\end{aligned}$$

where $\tilde\psi_n$ is the generalized Bloch function; see (3.4). The fact that $\tilde\psi_n = -\frac{\partial u_-}{\partial\kappa}\big|_{\kappa=0}$ is clear from differentiation of (2.5) with respect to κ.

It is found in [12] that

$$D(x) = \psi_n(x)\tilde\psi_n'(x) - \psi_n'(x)\tilde\psi_n(x) + \psi_n^2(x)$$

is constant in x, i.e., $D(x) = D(0)$, and that

$$D(0) = \frac{1}{2}\omega_{2n-1,2n}''(k)(\psi_n,\psi_n), \tag{4.3}$$

where either $k = 0$ or $k = \frac{\pi}{d}$ at the bifurcation point $\omega = \omega_n$. Since $\psi_n'(0) = 0$, $D(0) = \psi_n(0)(\tilde\psi_n'(0)+\psi_n(0))$, and the leading-order approximation for the root of $G_1(\delta,\kappa)$ near $(\delta,\kappa) =$

$(0,0)$ is given by

$$\delta = \frac{\tilde{\psi}_n'(0) + \psi_n(0)}{\psi_n(0)(V_0(0) - \omega_n)}\kappa + \mathcal{O}(\kappa^2) = \frac{D(0)}{\psi_n^2(0)(V_0(0) - \omega_n)}\kappa + \mathcal{O}(\kappa^2),$$

where $\psi_n(0) \neq 0$ (which is met since $\psi_n'(0) = 0$). Using (4.3) and the facts that $\omega_n > 0$ and $V_0(0) = 0$ for the numerical example (2.6), we get

$$\delta = -\frac{\omega_{2n-1,2n}''(k)(\psi_n, \psi_n)}{2\psi_n^2(0)\omega_n}\kappa + \mathcal{O}(\kappa^2).$$

Therefore, the bifurcation occurs for $\delta > 0$ if $\omega_{2n-1,2n}''(k) < 0$ (e.g., for ω to the right of ω_1) and for $\delta < 0$ if $\omega_{2n-1,2n}''(k) > 0$ (e.g., for ω to the left of ω_0 and ω_4); see Table 1. Note that the negative values of δ correspond to the values of δ below the level $\delta = d$ due to periodicity of the function $G_1(\delta, \kappa)$ in δ. The above local existence analysis for even bound states is confirmed by the solid lines near $\delta = 0$ in Figure 5 (b) and near $\delta = d = 10$ in Figure 6 (b).

(ii) *Bifurcation of odd eigenfunctions.* Similarly to (i), we study the zeros of $G_2(\delta, \kappa)$. We compute the derivatives of $G_2(\delta, \kappa)$ in δ and κ at $(\delta, \kappa) = (0, 0)$,

$$\partial_\delta G_2(0,0) = u_-'(0) = \psi_n'(0),$$
$$\partial_\kappa G_2(0,0) = -\tilde{\psi}_n(0),$$

such that the leading-order approximation for the root of $G_2(\delta, \kappa)$ near $(\delta, \kappa) = (0, 0)$ is given by

$$\delta = \frac{\tilde{\psi}_n(0)}{\psi_n'(0)}\kappa + \mathcal{O}(\kappa^2) = -\frac{\omega_{2n-1,2n}''(k)(\psi_n, \psi_n)}{2(\psi_n'(0))^2}\kappa + \mathcal{O}(\kappa^2),$$

where $\psi_n'(0) \neq 0$ (which is met since $\psi_n(0) = 0$). From the expansion, we conclude that the bifurcation occurs for $\delta > 0$ if $\omega_{2n-1,2n}''(k) < 0$ (e.g., for ω to the right of ω_3) and for $\delta < 0$ if $\omega_{2n-1,2n}''(k) > 0$ (e.g., for ω to the left of ω_2). The dashed lines near $\delta = 0$ in Figure 6 (b) and near $\delta = d = 10$ in Figure 5 (b) confirm this analysis.

Note that there are curves in Figures 5 (b) and 6 (b) which do not bifurcate from $\delta = 0$ and $\delta = d = 10$ but still bifurcate from the band edge $\omega = \omega_n$. Bifurcations of these curves cannot be confirmed from the analytical theory above, unless the values of $G_{1,2}(\delta; 0)$ for $0 < \delta < d$ are approximated numerically.

5. Conclusion.

We have employed methods of bifurcation theory for the existence problem of SGSs supported by the nonlinearity interface and the periodic potential. Two bifurcation problems are considered numerically. The first bifurcation takes place from the standard gap solitons existing at the zero jump of the nonlinearity coefficient. The second bifurcation takes place from the bound state consisting of parts of two standard gap solitons glued together in a continuously differentiable SGS. Three asymptotic results are described in the article. We show that the standard gap solitons can be continued generally for small jumps in the nonlinearity coefficient. On the contrary, no SGSs for nonzero jump of the nonlinearity coefficient exist in the NLS approximation which is valid near the band edges. In addition, we analytically study bifurcations of eigenvalues of the Schrödinger operator with a nonsmooth potential from band edges of the Hill equation.

One can argue that the SGSs bifurcating from a standard gap soliton or a gluing combination of two gap solitons inherit stability properties of gap solitons in the neighborhood of the local bifurcation points. Stability of standard gap solitons was considered analytically and numerically in [13]. The stability properties can change far from the bifurcation points. Detailed computations of stability of the SGSs will be the subject of a forthcoming work.

Bounded Solutions of Nonlocal Complex Ginzburg–Landau Equations for a Subcritical Bifurcation*

V. A. Volpert†, A. A. Nepomnyashchy‡, L. G. Stanton†, and A. A. Golovin†

Abstract. Stable periodic solutions of a system of two nonlocal coupled complex Ginzburg–Landau (CGL) equations describing the dynamics of a subcritical Hopf bifurcation in a spatially extended system are found analytically in the limit of large dispersion coefficients. The domains in the parameter space where these solutions exist and are stable are determined. It is shown that the existence and stability depend on the sign of the coupling parameter and on the ratio of the dispersion coefficients. Numerical simulations of the system of nonlocal coupled CGL equations confirm the analytical results and exhibit other bounded dynamic regimes, such as standing waves and spatio-temporal chaos.

1. Introduction.

A Ginzburg–Landau equation,

$$A_t = \mu A + (\alpha_1 + i\alpha_2)A_{xx} + (\beta_1 + i\beta_2)A|A|^2, \tag{1.1}$$

for the amplitude of an unstable mode $A(x,t)$ as a function of slow temporal and spatial variables describes the behavior of a system near a Hopf bifurcation point. This has been a subject of continuing attention over the last three decades [1]. Most works address various types of solutions in the case of a supercritical bifurcation ($\mu = 1$, $\beta_1 < 0$). However, in applications, subcritical bifurcations ($\beta_1 > 0$) occur as often as supercritical ones. Indeed, subcritical Hopf bifurcations are found in convection in binary fluids [7, 13, 14, 15, 20, 24], in nonlinear optics and lasers [16, 19, 22], in directional solidification [5], in combustion [2, 17], and in many other applications including lesser known examples of explosive crystallization fronts [25] and frontal polymerization [4].

One might expect that unless higher order nonlinear saturation terms are accounted for in the equations, all the solutions for $\mu = 1$ in case of a subcritical bifurcation will blow up in a finite time. In this case, the amplitude equations would be of little use as a means to describe the behavior of the original system. However, this is not necessarily the case. Beginning with the work by Hocking and Stewartson [8], bounded solutions were found for

the supercritical parameter value $\mu = 1$ in the case of a subcritical bifurcation $\beta_1 > 0$ under certain conditions on the magnitude of the coefficients of the equation. These results were apparently forgotten [1] and then rediscovered and extended by Bretherton and Spiegel [3] and Schöpf and Kramer [23]. Further extensions of these results can be found in [10, 11, 16, 21, 22].

The works cited above were performed for a single complex Ginzburg–Landau (CGL) equation (1.1). However, for a large class of systems with reflection symmetry, a more complete description of a Hopf bifurcation problem in the case of a short-wave instability involves a system of two *nonlocal coupled* Ginzburg–Landau equations for the amplitudes of two counterpropagating waves, $A^{\pm}(x,t)$ [12, 18]:

$$A_t^+ = \mu A^+ + (\alpha_1 + i\alpha_2)A_{xx}^+ + (\beta_1 + i\beta_2)A^+|A^+|^2 + (p_1 + ip_2)A^+\langle|A^-|^2\rangle, \tag{1.2a}$$

$$A_t^- = \mu A^- + (\alpha_1 + i\alpha_2)A_{xx}^- + (\beta_1 + i\beta_2)A^-|A^-|^2 + (p_1 + ip_2)A^-\langle|A^+|^2\rangle. \tag{1.2b}$$

Here the coupling term involves the averaged quantities defined as

$$\langle f\rangle = \lim_{L\to\infty}\frac{1}{2L}\int_{-L}^{L} f(x)dx,$$

where x is the spatial variable. The averaging procedure is defined for any positive, locally integrable function that is bounded for $-\infty < x < \infty$. For a periodic function $f(x)$, the average coincides with the average over a period. The averaged terms appear in the equations due to the fact that the effect of one wave on the other, traveling with a group velocity in the opposite direction on the intermediate time scale, enters only through its average on the slowest time scale.

We emphasize that it is these equations rather than equations with local cubic coupling that generically arise in the case of Hopf bifurcation in systems with right-left symmetries. Ginzburg–Landau equations with local coupling in the nonlinear terms cannot be derived from the original equations except in the nongeneric case of an asymptotically small group velocity of waves. Thus, in order to understand the dynamics of systems undergoing subcritical Hopf bifurcations, nonlocal coupled CGL equations must be considered, as is done in this paper.

As noted in [23], in the limit $\alpha_2 \to \infty$, $\beta_2 \to \infty$, (1.1) reduces to the nonlinear Schrödinger (NLS) equation, which has a continuum of soliton solutions that reduces to a discrete set when the equation is perturbed. The method used in [23] allows one to find not only soliton solutions but also spatially periodic solutions of (1.1) in the case of large α_2 and β_2. In this paper, we extend the analysis done in [23] to the system of equations (1.2) and show that the system (1.2) may have stable, bounded solutions for the supercritical parameter value $\mu = 1$ in the case of a subcritical bifurcation $\beta_1 > 0$ under the assumption that α_2 and β_2 are sufficiently large. We also perform numerical simulations that confirm our analytical results.

2. Periodic solutions.

Equations (1.2) can be rescaled as

$$A_t^+ = A^+ + (1 + i\alpha)A_{xx}^+ + (1 + i\beta)A^+|A^+|^2 + (p + ip_i)A^+\langle|A^-|^2\rangle, \tag{2.1a}$$

$$A_t^- = A^- + (1 + i\alpha)A_{xx}^- + (1 + i\beta)A^-|A^-|^2 + (p + ip_i)A^-\langle|A^+|^2\rangle \tag{2.1b}$$

(we retain the same notation for the amplitudes $A^{\pm}$). It is convenient to write these equations in the real form by substituting

$$A^{\pm}(x,t) = R^{\pm}(x,t)\exp\left(i\Theta^{\pm}(x,t)\right)$$

into (2.1) and separating real and imaginary parts to obtain

$$R_t^{\pm} = R^{\pm} + R_{xx}^{\pm} - R^{\pm}(\Theta_x^{\pm})^2 - \alpha(2R_x^{\pm}\Theta_x^{\pm} + R^{\pm}\Theta_{xx}^{\pm}) + (R^{\pm})^3 + pR^{\pm}\langle(R^{\mp})^2\rangle, \tag{2.2a}$$

$$R^{\pm}\Theta_t^{\pm} = R^{\pm}\Theta_{xx}^{\pm} + 2R_x^{\pm}\Theta_x^{\pm} + \alpha(R_{xx}^{\pm} - R^{\pm}(\Theta_x^{\pm})^2) + \beta(R^{\pm})^3 + p_i R^{\pm}\langle(R^{\mp})^2\rangle. \tag{2.2b}$$

The superscript $\pm$ means that each of the equations (2.2) includes two equations, one with the upper superscript and the other with the lower superscript. Note that the terms $\langle(R^{\mp})^2\rangle$ do not depend on x. Thus, the change of variables

$$\tilde{\Theta}^{\pm} = \Theta^{\pm} - p_i \int \langle(R^{\mp})^2\rangle\, dt$$

allows us to eliminate the term proportional to p_i in (2.2b). We retain the same notation, $\Theta^{\pm}$, for the phase but set $p_i = 0$ in (2.2b).

We consider the case when the coefficients α and β in the equations are large and set

$$\alpha = \frac{1}{\varepsilon}, \quad \beta = \frac{F}{\varepsilon}, \quad |\varepsilon| \ll 1, \quad F = O(1).$$

The equations then take the form

$$R_t^{\pm} = R^{\pm} + R_{xx}^{\pm} - R^{\pm}(\Theta_x^{\pm})^2 - \frac{1}{\varepsilon}\left(2R_x^{\pm}\Theta_x^{\pm} + R^{\pm}\Theta_{xx}^{\pm}\right) + (R^{\pm})^3 + pR^{\pm}\langle(R^{\mp})^2\rangle, \tag{2.3a}$$

$$R^{\pm}\Theta_t^{\pm} = R^{\pm}\Theta_{xx}^{\pm} + 2R_x^{\pm}\Theta_x^{\pm} + \frac{1}{\varepsilon}\left(R_{xx}^{\pm} - R^{\pm}(\Theta_x^{\pm})^2\right) + \frac{F}{\varepsilon}(R^{\pm})^3. \tag{2.3b}$$

Multiplying (2.3a) by ε^2 and (2.3b) by ε and taking the sum of the resulting equations yield

$$\varepsilon^2 R_t^{\pm} + \varepsilon R^{\pm}\Theta_t^{\pm} = \varepsilon^2 R^{\pm} + (1+\varepsilon^2)[R_{xx}^{\pm} - R^{\pm}(\Theta_x^{\pm})^2] + (F+\varepsilon^2)(R^{\pm})^3 + \varepsilon^2 pR^{\pm}\langle(R^{\mp})^2\rangle. \tag{2.4a}$$

Multiplying (2.3a) by ε and (2.3b) by ε^2 and taking the difference of the resulting equations yield

$$-\varepsilon R_t^{\pm} + \varepsilon^2 R^{\pm}\Theta_t^{\pm} = -\varepsilon R^{\pm} + (1+\varepsilon^2)[R^{\pm}\Theta_{xx}^{\pm} + 2R_x^{\pm}\Theta_x^{\pm}] + \varepsilon(F-1)(R^{\pm})^3 - \varepsilon pR^{\pm}\langle(R^{\mp})^2\rangle. \tag{2.4b}$$

We seek the solution of (2.4) as an expansion in powers of ε,

$$R^{\pm} = R_0^{\pm} + \varepsilon^2 R_2^{\pm} + \ldots, \quad \Theta^{\pm} = \frac{1}{\varepsilon}\Theta_{-1}^{\pm} + \varepsilon\Theta_1^{\pm} + \ldots.$$

Substituting the expansions into (2.4) and collecting like powers of ε, we obtain

$$O(\varepsilon^{-2}): \qquad R_0^{\pm}(\Theta_{-1}^{\pm})_x^2 = 0, \tag{2.5a}$$

$$O(\varepsilon^{-1}): \qquad R_0^{\pm}(\Theta_{-1}^{\pm})_{xx} + 2(R_0^{\pm})_x(\Theta_{-1}^{\pm})_x = 0, \tag{2.5b}$$

$$O(\varepsilon^{0}): \qquad R_0^{\pm}(\Theta_{-1}^{\pm})_t = (R_0^{\pm})_{xx} + F(R_0^{\pm})^3, \tag{2.5c}$$

$$O(\varepsilon): \qquad -(R_0^{\pm})_t + R_0^{\pm}(\Theta_{-1}^{\pm})_t = -R_0^{\pm} + R_0^{\pm}(\Theta_1^{\pm})_{xx} + 2(R_0^{\pm})_x(\Theta_1^{\pm})_x + (F-1)(R_0^{\pm})^3 - pR_0^{\pm}\langle(R_0^{\mp})^2\rangle. \tag{2.5d}$$

Equations (2.5a) and (2.5b) imply that $\Theta_{-1}^{\pm}$ does not depend on x and is a function of t only, $\Theta_{-1}^{\pm} = \Theta_{-1}^{\pm}(t)$. We assume that $F > 0$ and $\gamma_{\pm}(t) \equiv (\Theta_{-1}^{\pm})_t > 0$, in which case (2.5c) has a family of solutions

$$R_0^{\pm}(x,t) = \left[\frac{2\gamma_{\pm}(t)}{[2-m_{\pm}(t)]F}\right]^{1/2} \mathrm{dn}\left(\left[\frac{\gamma_{\pm}(t)}{[2-m_{\pm}(t)]}\right]^{1/2} x|m_{\pm}(t)\right). \tag{2.6}$$

Here $0 < m_{\pm} < 1$ is any function of t, and $\mathrm{dn}(u|m)$ is the Jacobi elliptic function that varies between $(1-m)^{1/2}$ and 1 with the period $2K(m)$, where $K(m)$ is the complete elliptic integral of the first kind. Thus, (2.6) represents a spatially periodic solution with the period

$$\lambda_{\pm} = 2K(m_{\pm}(t))\left[\frac{2-m_{\pm}(t)}{\gamma_{\pm}(t)}\right]^{1/2}. \tag{2.7}$$

In what follows we assume that the period $\lambda_{\pm}$ of the solution is constant, i.e., that there is a relation (2.7) between the time-dependent functions $m_{\pm}(t)$ and $\gamma_{\pm}(t)$. We remark that $m_{\pm} \to 1$ implies $K(m_{\pm}) \to \infty$ and the solution (2.6) degenerates into the pulse $(2\gamma_{\pm}/F)^{1/2}\,\mathrm{sech}(\gamma_{\pm}^{1/2}x)$, whereas $m_{\pm} \to 0$ corresponds to small harmonic oscillations.

Next we multiply (2.5d) by $R_0^{\pm}$ to rewrite it as

$$[(R_0^{\pm})^2(\Theta_1^{\pm})_x]_x = -\frac{1}{2}[(R_0^{\pm})^2]_t + (1+\gamma_{\pm})(R_0^{\pm})^2 - (F-1)(R_0^{\pm})^4 + p(R_0^{\pm})^2\langle(R_0^{\mp})^2\rangle. \tag{2.8}$$

The local wavenumber $(\Theta_1^{\pm})_x$ must be a bounded function, from which, taking into account that $R_0^{\pm}$ is periodic, we can draw a number of important conclusions. First, the integral of the right-hand side of (2.8) over this period must vanish. Indeed, suppose this is not the case and the integral over a period is equal to $a \neq 0$. Then integrating (2.8) over N periods of $R_0^{\pm}$, from x to $x + N\lambda_{\pm}$, yields

$$(R_0^{\pm})^2(\Theta_1^{\pm})_x\,\big|_{x+N\lambda_{\pm}} - (R_0^{\pm})^2(\Theta_1^{\pm})_x\big|_x = aN. \tag{2.9}$$

Since

$$(R_0^{\pm})^2\,\big|_{x+N\lambda_{\pm}} = (R_0^{\pm})^2\big|_x$$

due to periodicity of $R_0^{\pm}$, we obtain

$$(\Theta_1^{\pm})_x\,\big|_{x+N\lambda_{\pm}} = (\Theta_1^{\pm})_x\big|_x + \frac{aN}{(R_0^{\pm})^2|_x}. \tag{2.10}$$

That N can be arbitrarily large implies that $(\Theta_1^{\pm})_x$ is unbounded, contrary to our assumption about the local wavenumber. Thus, $a = 0$, and using (2.10) with $N = 1$ we arrive at another important conclusion that $(\Theta_1^{\pm})_x$ is periodic with period $\lambda_{\pm}$. Moreover, since $R_0^{\pm}$ is an even function, $(\Theta_1^{\pm})_x$ defined by (2.5d) is an odd one, and hence the phase $\Theta_1^{\pm}$ is even and periodic with the same period as $R_0^{\pm}$.

Upon some calculations using

$$\int_0^{K(m)} \mathrm{dn}^2\,u\,du = E(m), \quad \int_0^{K(m)} \mathrm{dn}^4\,u\,du = \frac{2}{3}(2-m)E(m) - \frac{1}{3}(1-m)K(m),$$

the condition that the integral of the right-hand side of (2.8) over the period vanishes yields

$$\frac{d}{dt}\left[\frac{K_\pm E_\pm}{\lambda_\pm^2 F}\right] = (1+\gamma_\pm)\frac{2K_\pm E_\pm}{\lambda_\pm^2 F} - \frac{16(K_\pm)^4(F-1)}{3\lambda_\pm^4 F^2}\left[2(2-m_\pm)\frac{E_\pm}{K_\pm} - (1-m_\pm)\right] + 16p\frac{K_\pm E_\pm}{\lambda_\pm^2 F}\frac{K_\mp E_\mp}{\lambda_\mp^2 F}. \tag{2.11}$$

Here $K_\pm = K(m_\pm)$, $E_\pm = E(m_\pm)$, and $E(m)$ is the complete elliptic integral of the second kind. Using (2.7) to eliminate $\lambda_\pm$, the above equation can be written as

$$D_\pm \frac{1}{\gamma_\pm}\frac{d\gamma_\pm}{dt} = 1 - B_\pm\gamma_\pm + pC_\mp\gamma_\mp, \tag{2.12}$$

where

$$D_\pm = D(m_\pm), \quad D(m) = \frac{1}{4E(m)}\frac{E^2(m) - (1-m)K^2(m)}{E(m) - 2(1-m)K(m)/(2-m)} > 0,$$

$$B_\pm = B(m_\pm), \quad B(m) = \frac{1}{3F}\left[F - 4 - 2(F-1)\frac{(1-m)K(m)}{(2-m)E(m)}\right],$$

$$C_\pm = C(m_\pm), \quad C(m) = \frac{2}{F}\frac{E(m)}{(2-m)K(m)} > 0.$$

The critical points $\gamma_\pm^s$ of (2.12), i.e., the solutions of

$$-B_+\gamma_+^s + pC_-\gamma_-^s = -1, \tag{2.13a}$$

$$-B_-\gamma_-^s + pC_+\gamma_+^s = -1, \tag{2.13b}$$

are given by

$$\gamma_+^s = \frac{1}{C_+}\frac{\Gamma_- + p}{\Gamma_-\Gamma_+ - p^2}, \qquad \gamma_-^s = \frac{1}{C_-}\frac{\Gamma_+ + p}{\Gamma_-\Gamma_+ - p^2}, \tag{2.14}$$

where

$$\Gamma_\pm = \Gamma(m_\pm), \quad \Gamma(m) = B(m)/C(m). \tag{2.15}$$

These critical points $\gamma_\pm^s$ are time-independent, as the corresponding $m_\pm$ are (see (2.7)). The behavior of the function $\Gamma(m)$ is important for subsequent calculations and is shown in Figure 1. One can show that $\Gamma(0) = -1$ and

$$\Gamma \sim (4\ln 2 - \ln(1-m))(F-4)/12 \quad \text{as } m \to 1.$$

For $F > 4$, $\Gamma(m)$ is a monotonically increasing function that has one zero at $m = m_0$, which depends on F. The function $m_0(F)$ is shown in Figure 2. It monotonically decreases from $m_0 = 1$ at $F = 4$ to zero as $F \to \infty$. For $F < 4$, $\Gamma(m) < 0$ for all $0 < m < 1$. It has a single maximum if $2 < F < 4$ and is a monotonically decreasing function if $0 < F < 2$. Thus

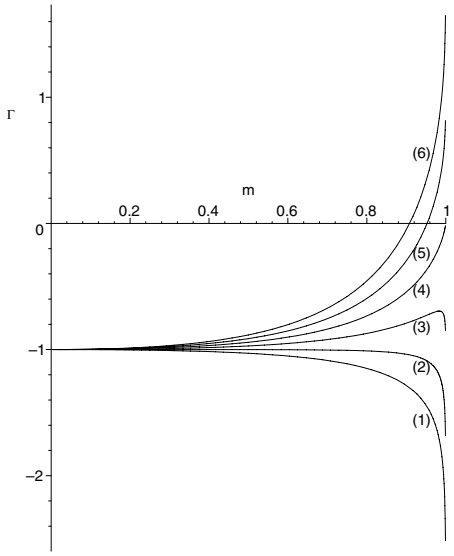

Figure 1. *The graph of the function* $\Gamma(m)$ *defined by* (2.15) *for various values of* F. *The curves are plotted for* $F = 1$ *(curve* (1)*),* $F = 2$ *(curve* (2)*),* $F = 3$ *(curve* (3)*),* $F = 4$ *(curve* (4)*),* $F = 5$ *(curve* (5)*), and* $F = 6$ *(curve* (6)*).*

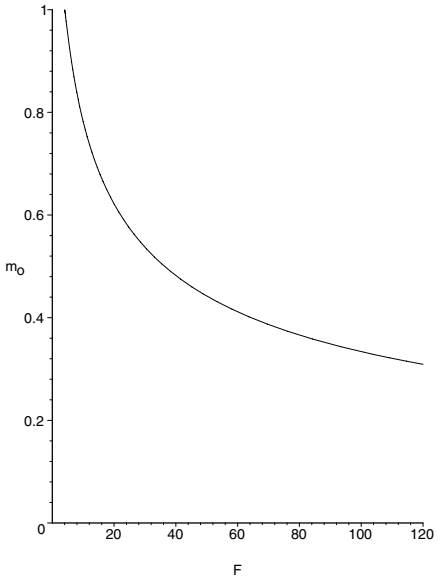

Figure 2. *The graph of the functions* $m_0(F)$.

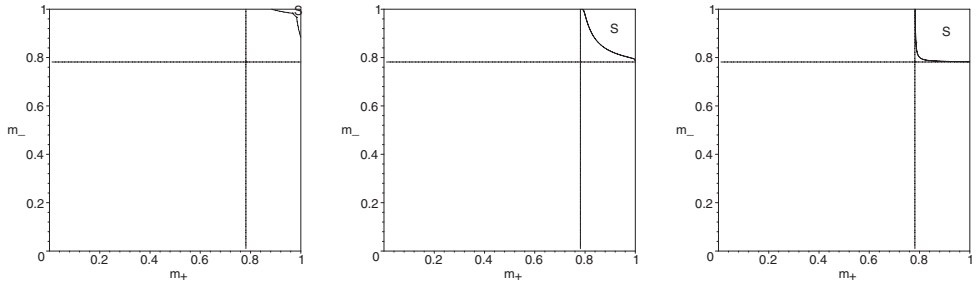
we obtain a two-parameter (m_+, m_-) family of solutions (2.14) that determine the amplitude (2.6). The corresponding wavelengths are given by (2.7). Since $\gamma_\pm^s$ are required to be positive, there are certain conditions on the choice of the parameters m_+ and m_-. To describe these conditions, we consider the cases $p > 0$ and $p < 0$ separately. Consider first $p > 0$. Then,



(a) $p = 2.5$ (b) $p = 0.5$ (c) $p = 0.1$

Figure 3. *Existence regions for $F = 10$ and three different values of $p > 0$. See text.*

since $C_\pm > 0$, the stationary equations (2.13) imply that $m_\pm$ must be such that

$$\Gamma_\pm > 0, \quad p^2 < p_e^2(m_+, m_-) \equiv \Gamma_+ \Gamma_-, \tag{2.16}$$

which, in turn, requires $F > 4$ (otherwise, $\Gamma(m) < 0$ for $0 < m < 1$) and $m_\pm > m_0$. Thus, for $p > 0$, positive critical points $\gamma_\pm$ exist only if $F > 4$ and for parameter values $m_\pm$ that lie in the square $m_0 < m_+ < 1$, $m_0 < m_- < 1$ subject to the condition $p < p_e$. This result is illustrated by Figure 3, where the existence regions are shown in the (m_+, m_-)-plane for $F = 10$ and three different values of $p > 0$. The existence regions are marked by S, since all the existing solutions are stable, as shown in the next section. The existence region is bounded by the curve $p_e(m_+, m_-) = p$ and the line segments $m_+ = 1$, $m_0 < m_- < 1$ and $m_- = 1$, $m_0 < m_+ < 1$. Note that the ends of the curve $p_e(m_+, m_-) = p$ are the points $(m_0, 1)$, $(1, m_0)$, which is not necessarily seen on the scale of the figure. To better understand the form of the solution $R_0^\pm$, we consider a point (m_+, m_-) close to one of the existence boundaries. As (m_+, m_-) approaches the existence boundary $p_e(m_+, m_-) = p$, $\gamma_\pm^s \to \infty$. As a result, $\lambda_\pm \to 0$, and $R_0^\pm$ in (2.6) goes to infinity so that the solution (2.6) has the form of an array of closely spaced spikes. As (m_+, m_-) approaches other existence boundaries, the form of the solution is different. Consider the case $m_+ \to 1$, $m_0 < m_- < 1$ (the case $m_- \to 1$, $m_0 < m_+ < 1$ is similar). Then both γ_+^s and γ_-^s have finite limits. As a result, $\lambda_+ \to \infty$, and, as mentioned earlier, R_0^+ degenerates into a pulse

$$R_0^+ = \sqrt{\frac{2\gamma_+}{F}}\,\mathrm{sech}(x\sqrt{\gamma_+}).$$

Different types of solutions corresponding to different values of $m_\pm$ are shown in Figure 4. Figure 3 also shows that decreasing p increases the existence region. In the limit $p \to 0$, the existence region occupies the entire square $m_0 < m_\pm < 1$. The evolution of the existence region for other values of $F > 4$ as p varies is similar to that for $F = 10$. The main difference is the size of the square $m_0 < m_\pm < 1$, since m_0 depends on F (see Figure 2).

Next, consider the case $p < 0$. We distinguish between two subcases, $F > 4$ and $F < 4$. As discussed earlier, an important difference between them is in the behavior of the function $\Gamma(m)$. Consider first $F > 4$, so that Γ is a monotonically increasing function of m. Suppose m_1 is such that $\Gamma(m_1) = -p$. Then the critical points $\gamma_\pm^s$ are positive if either $m_1 < m_\pm < 1$

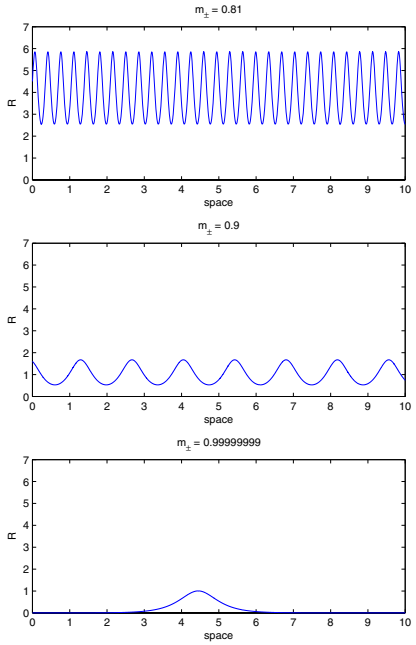


Figure 4. *Different types of solutions* (2.6), (2.14) *for* $F = 10$, $p = 0.1$.

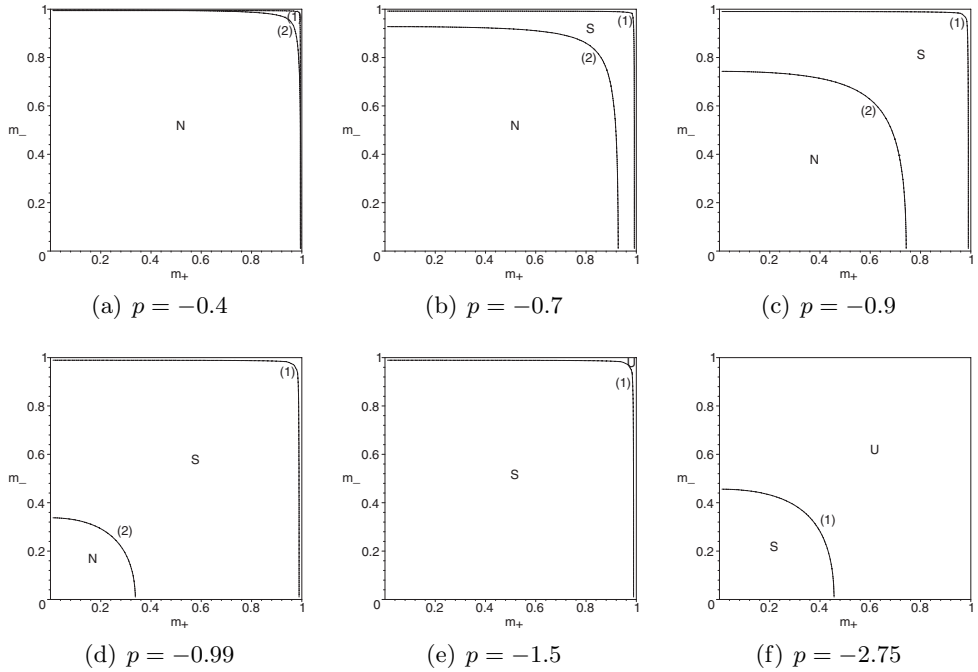
(in which case both the numerators and denominators in (2.14) are positive) or $0 < m_\pm < m_1$ and $p_e^2(m_+, m_-) < p^2$ (in which case both the numerators and denominators in (2.14) are negative). Note that the condition $p_e^2 < p^2$ gives a restriction on the range of $m_\pm$ only if $-1 < p < 0$. Otherwise, it is satisfied for all $0 < m_\pm < m_1$. Figure 5 illustrates these results for $F = 10$ and three different values of p. Here the vertical and horizontal lines inside the unit square are $m_+ = m_1$ and $m_- = m_1$, respectively. Curves (1) and (2) represent the boundaries $p_e^2(m_+, m_-) = p^2$. Existence regions are marked by S as, for these parameter values, all the existing solutions are stable. For other parameter values, the solutions may be unstable, as discussed in the next section. We observe that increasing $|p|$ results in the broadening of the existence region inside the $0 < m_\pm < m_1$ square. At $|p| = 1$, curve (2) disappears so that, for



(a) $p = -0.4$ (b) $p = -0.7$ (c) $p = -0.9$

(d) $p = -0.99$ (e) $p = -1.5$ (f) $p = -2.75$

Figure 6. *Existence and stability regions for $F = 3.9$ and six different values of $p < 0$. Here (1) is the stability boundary $p_s^2 = p^2$; (2) is the existence boundary $p_e^2 = p^2$. $|p| > 1$, the existence regions are the two squares, $0 < m_\pm < m_1$ and $m_1 < m_\pm < 1$.

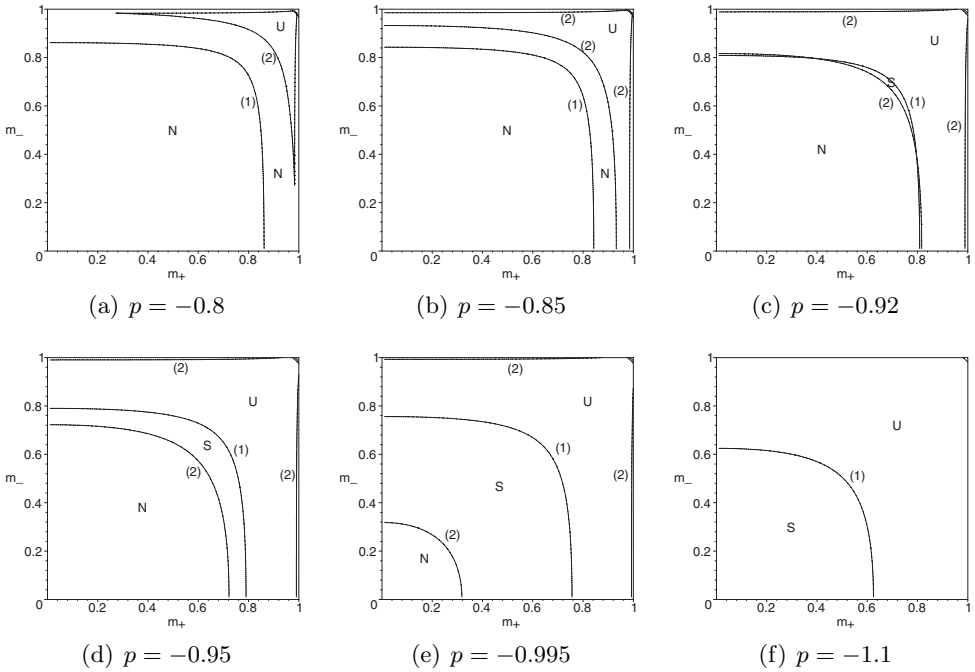
For $F < 4$, $\Gamma(m) < 0$, so that the numerators in (2.14) are negative, and for $\gamma_\pm^s > 0$, the denominator must be negative as well, i.e., $p_e^2(m_+, m_-) < p^2$. This condition implies that $|p| > \max_{0<m<1} \Gamma(m)$. It is convenient to consult the graph of $\Gamma(m)$ (see Figure 1) to understand the evolution of the existence regions as p varies. For $2 < F < 4$, $\Gamma(m)$ has a local maximum. Thus, if $|p|$ is less than this maximum value, there are no solutions. If $|p|$ slightly exceeds the maximum, an existence island appears. It broadens as $|p|$ increases. As p reaches $\Gamma(0) = -1$, the existence region occupies the entire unit square with the exception of a little region of sufficiently large $m_\pm$. These results are illustrated in Figures 6 and 7, where the evolution of the existence region as p varies is shown for $F = 3.9$ and $F = 3.1$, respectively. Here curve (2) is the existence boundary $p_e^2 = p^2$. The nonexistence region is marked by N. The existence region is marked by either S or U, depending on whether the solution is stable or unstable (stability is discussed in the next section). Note that the little region of nonexistence that occurs for sufficiently large $m_\pm$ is not seen on the scale of Figures 6 and 7.

Finally, as shown in the next section, for $0 < F < 2$ all the solutions are unstable, and therefore we do not discuss this case here.

We remark that the existence of bounded solutions and their stability (see section 3) are analyzed based on the first several terms of the expansions in powers of ϵ. We expect that



(a) $p = -0.8$ (b) $p = -0.85$ (c) $p = -0.92$

(d) $p = -0.95$ (e) $p = -0.995$ (f) $p = -1.1$

Figure 7. *Existence and stability regions for $F = 3.1$ and six different values of $p < 0$. Here (1) is the stability boundary $p_s^2 = p^2$; (2) is the existence boundary $p_e^2 = p^2$. the higher-order terms will not significantly change the existence and stability properties. Though we do not have a rigorous proof of this statement, we believe that, unlike solitary waves, which are described by nongeneric homoclinic/heteroclinic solutions in the x-space and therefore their very existence is sensitive to the equation perturbations (see, e.g., [9]), the cnoidal waves correspond to periodic solutions which are generic in systems with the $x \to -x$ symmetry, and thus we expect that the influence of the higher-order terms will not lead to drastic changes. Our expectation that the higher-order terms will not significantly change the existence and stability properties is somewhat backed up by our direct numerical simulations of the system (2.1) presented below. Though exhaustive numerical studies that would cover the entire parameter space have not been performed, the computations for selected parameter values agree with the analytical results that do not account for higher-order terms.

3. Stability.

In this section, we study stability of the critical points $\gamma_\pm^s$ of the system (2.12). Thus, we analyze the stability of the solutions (2.6) with respect to a specific class of perturbations. Specifically, we restrict our stability analysis to the perturbations that are periodic with constant periods $\lambda_\pm$ and keep the shape of the cnoidal wave (2.6). Therefore, the results of the stability analysis presented in this section give the necessary conditions for stability of solutions (2.6) rather than the sufficient conditions. In general, one could impose perturbations of an incommensurate period and get a modulational instability of the periodic wave. This is beyond the scope of the present paper.

Instabilities in the CGL equations in the NLS limit can be thought of as being of two kinds. One is the instability inherited from the NLS equation. The other is the instability due to the presence of nonconservative terms in the CGL equations. As a solution of the NLS equation, the cnoidal wave (2.6) is stable within the class of solutions with the same period (and the same Floquet exponent; see [6] and the references therein). Thus, all the instabilities that we obtain in this section for solutions of the CGL equations, with respect to the disturbances with the same period, have nothing to do with the NLS equation; they are specifically due to the presence of nonconservative terms in the equations.

In the case of general perturbations that do not have to be of the same period as the solution, the cnoidal solutions of the NLS equation are unstable in the focusing case $F > 0$ that is considered in this paper (again, see [6] and the references therein). This instability is inherited by the Ginzburg–Landau equations. We observe it in our numerical computations that are described below. However, we do not perform any stability analyses in this paper to discover these instabilities.

It is convenient to rewrite (2.11) as an equation for $m_\pm$. Using (2.7) to eliminate $\gamma_\pm$, we reduce (2.11) to

$$\widehat{D}_\pm \frac{dm_\pm}{dt} = 1 - \frac{8a_\pm}{\lambda_\pm^2 F} + \frac{8pb_\mp}{\lambda_\mp^2 F}, \tag{3.1}$$

where

$$\widehat{D}_\pm = \widehat{D}(m_\pm), \quad a_\pm = a(m_\pm), \quad b_\pm = b(m_\pm),$$

$$\widehat{D}(m) = \frac{E^2(m) - (1-m)K^2(m)}{4m(1-m)K(m)E(m)}, \quad a(m) = E(m)K(m)\Gamma(m), \quad b(m) = E(m)K(m).$$

We linearize (3.1) about its critical point $m_\pm^s$,

$$m_\pm = m_\pm^s + e^{\sigma t}\widetilde{m}_\pm,$$

and assume that the periods $\lambda_\pm$ are fixed and time-independent to obtain the dispersion relation

$$\sigma^2 \widehat{D}_+\widehat{D}_- + \sigma\left[\widehat{D}_- \frac{8}{F\lambda_+^2}\frac{da_+}{dm_+} + \widehat{D}_+ \frac{8}{F\lambda_-^2}\frac{da_-}{dm_-}\right] + \frac{64}{(F\lambda_+\lambda_-)^2}\left[\frac{da_+}{dm_+}\frac{da_-}{dm_-} - p^2\frac{db_+}{dm_+}\frac{db_-}{dm_-}\right] = 0. \tag{3.2}$$

We remark that $\widehat{D} > 0$, and for $F > 4$, the function $a(m)$ is an increasing function of m, $0 < m < 1$. Thus, the coefficient of σ to the first power in the quadratic equation (3.2) is positive provided $F > 4$. The stability boundary in this case is determined by

$$p^2 = \frac{da_+}{dm_+}\frac{da_-}{dm_-}\left[\frac{db_+}{dm_+}\frac{db_-}{dm_-}\right]^{-1} \equiv p_s^2, \quad p_s > 0. \tag{3.3}$$

Finally, if $F > 4$, the critical point is stable if $|p| < p_s$ and unstable otherwise.

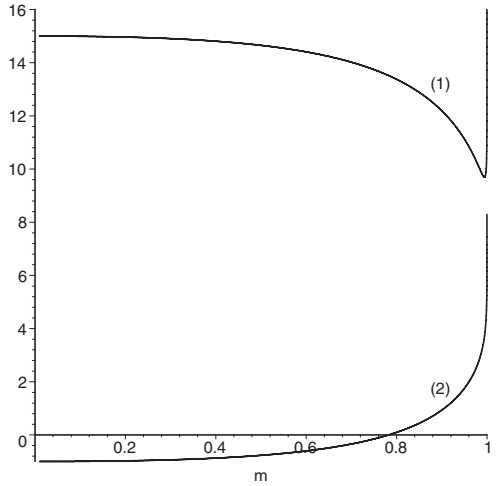

Figure 8. *The graphs of the functions $f(m)$ (curve (1)) and $\Gamma(m)$ (curve (2)). Here $F = 10$.*

In order to determine how the stability of the critical point depends on parameter values, we turn to various cases considered in the previous section. Let us first consider the case $p > 0$. Then, as discussed in the previous section, $F > 4$ in order for the critical points to be positive. Thus, the stability condition is $|p| < p_s$. It is easy to see that

$$f(m) \equiv \frac{da(m)}{dm} \Big/ \frac{db(m)}{dm} = \Gamma + \frac{d\Gamma}{dm} b(m) \left[\frac{db(m)}{dm}\right]^{-1} > \Gamma.$$

Thus, $p_e < p_s$ so that all the existing solutions in the case $p > 0$ are stable.

Consider next the case $p < 0$ and $F > 4$. All the solutions $m_\pm$ such that $m_0 < m_\pm < 1$ are stable. Indeed,

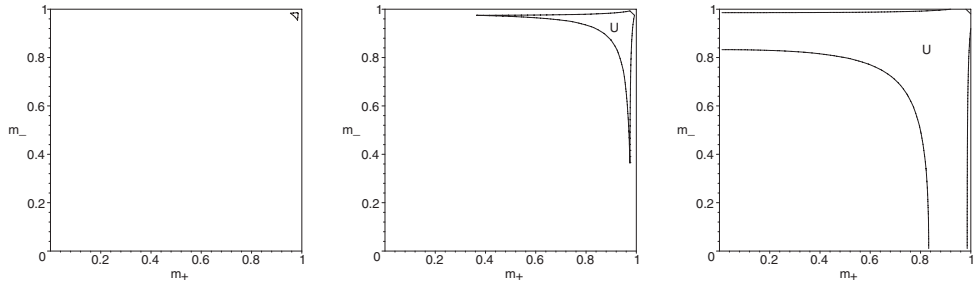
$$p_s^2 = f(m_+) f(m_-) > \Gamma_+ \Gamma_- > \Gamma^2(m_1) = p^2.$$

Stability of solutions in the other existence region, $0 < m_\pm < m_1$, $p_e^2 < p^2$, depends on the parameter values. It is convenient to analyze the stability by comparing the graphs of $f(m)$ and $\Gamma(m)$ (Figure 8). We remark that the function $f(m)$ is positive for $0 < m < 1$, has one minimum, and goes to infinity as m approaches 1:

$$f(m) \sim (4 \ln 2 - \ln(1 - m))(F - 4)/6, \quad m \to 1.$$

If $|p|$ is less than the minimum of the function $f(m)$, then any existing solution is stable, because $p^2 < f(m_-) f(m_+) = p_s^2$ in this case. The onset of instability occurs at $|p| = \min f(m)$. For $|p|$ slightly above this value, there is a little island of unstable solutions, which, as $|p|$ increases, gradually occupies the entire existence region $0 < m_\pm < m_1$. For $|p| > f(0) = 2F - 6$, only a small corner near the point $m_\pm = m_1$ is stable. The minimum of the function $f(m)$ can be accurately approximated as

$$\min_{0<m<1} f(m) \approx \frac{3}{2}(F - 4).$$



(a) $p = -10.5$ (b) $p = -12.4$ (c) $p = -14$

Figure 9. *Evolution of the instability region (marked by U) for $F > 4$ as p varies. Here $F = 10$. See text for a detailed discussion.*

For $F = 10$, the approximation yields the value of 9, while the numerical value (see Figure 8) is 9.6. This explains why the solutions depicted in Figure 5 are all stable: the values of $|p|$ there are less than the minimum of f. The stability results are illustrated in Figure 9 for $F = 10$ and larger values of $|p|$. As follows from the above discussion, the instability first occurs at $|p| \approx 9.6$, and for $|p| = 10.5$ the unstable solutions occupy a noticeable region in the upper right corner of the $0 < m_\pm < m_1$ square; see Figure 9(a). As $|p|$ increases, the instability region expands. Note that in this figure, we do not see the $m_1 < m_\pm < 1$ square that was shown in Figure 5. Indeed, for $|p|$ large, the value of m_1 is so close to 1 that this square is not seen on the scale of the figure (one can use the asymptotic expression in (2.16) to see that for $|p| = 10$, m_1 differs from 1 by less than 10^{-7}).

Next, consider the case $p < 0$ and $0 < F < 5/2$. In this case $da/dm < 0$. Indeed, the condition $da/dm < 0$ can be written as $F < F_*(m)$, where $F_*(m)$ can be explicitly found. The function $F_*(m)$ is a monotonically increasing function of m, $0 < m < 1$, which varies from $F_*(0) = 5/2$ to $F_*(1) = 4$, so that $da/dm < 0$ for $0 < F < 5/2$. Since $da/dm < 0$, the coefficient of the linear term in σ in the quadratic equation (3.2) is negative, so that there is a positive solution σ of (3.2), and all the existing solutions $m_\pm$ are unstable.

It turns out that all the solutions in the case $p < 0$ and $5/2 \le F < 3$ are also unstable. This follows from the fact that in this case $p_s^2 < p_e^2$. To better understand it, consider again Figure 7. Here we see that in order for the solutions to become stable, the relative positions of curves (1) and (2) have to change. The above inequality, $p_s^2 < p_e^2$, means that the curves will never change their relative positions. This inequality is equivalent to

$$\frac{f(m_+)}{\Gamma(m_+)}\frac{f(m_-)}{\Gamma(m_-)} < 1,$$

which is true if

$$\frac{f(m)}{|\Gamma(m)|} < 1,$$

i.e., if

$$\hat{f} \equiv f(m) + \Gamma(m) < 0.$$

One can see that $\hat{f}$ is a monotonically decreasing function of m with $\hat{f}(0) = 2F - 6$. Thus, $\hat{f} < 0$ for all $0 < m < 1$ if $F \le 3$.

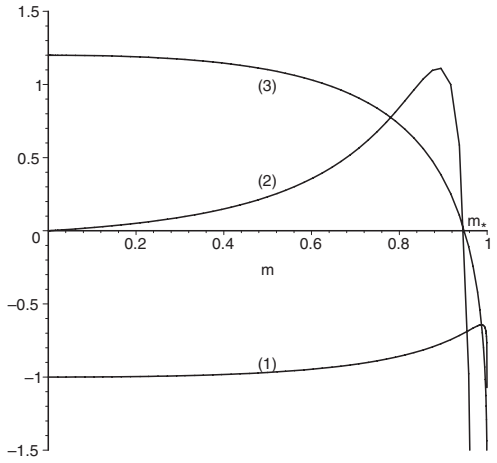


Figure 10. *The graphs of the functions* $\Gamma(m)$ *(curve* (1)*),* da/dm *(curve* (2)*), and* $f(m)$ *(curve* (3)*). Here* $F = 3.1$*. Note that* da/dm *and* $f(m)$ *become equal to zero at the same point* $m = m_*$*.*

Finally, consider the case $p < 0$ and $3 < F < 4$. In order for the solution (m_+, m_-) to be stable, we need

$$f(m_+)f(m_-) > p^2 \tag{3.4}$$

and the coefficient of the linear in σ term in (3.2) to be positive, i.e.,

$$\frac{\widehat{D}_+}{\lambda_-^2}\frac{da_-}{dm_-} + \frac{\widehat{D}_-}{\lambda_+^2}\frac{da_+}{dm_+} > 0. \tag{3.5}$$

Figure 10 illustrates the following result: the solution (m_+, m_-) is stable if $m_\pm < m_*$ and (3.4) is satisfied; otherwise, it is unstable. Indeed, if $m_\pm > m_*$, then $da_\pm/dm_\pm < 0$, and condition (3.5) is not satisfied; if one of the numbers m_+, m_- is greater than m_* and the other one is less than m_*, then $f(m_+)$ and $f(m_-)$ have different signs, and condition (3.4) is not satisfied. If $m_\pm < m_*$, then $da_\pm/dm_\pm > 0$, so that (3.5) is satisfied, which proves the above statement.

The main conclusion that follows from this stability analysis is that increasing $|p|$ decreases the stability region. At $|p| = f(0) = 2F - 6$ the stability region shrinks to zero. No stable solutions exist for $|p| > 2F - 6$.

The evolution of the stability boundary as p varies is shown in Figures 6 and 7 for $F = 3.9$ and $F = 3.1$, respectively.

4. Numerical simulations. In this section, we verify the stability and existence of our analytical solution through numerical simulations. We have used a pseudospectral code with periodic boundary conditions. A semi-implicit scheme has been used with a Crank–Nicolson method to handle the linear terms and with an Adams–Bashforth method for the nonlinear terms.

We first examine the case $F > 4$. Using (2.6) perturbed with small-amplitude noise as an initial condition, the solutions were observed to be stable for chosen values of $m_\pm$ in the stable

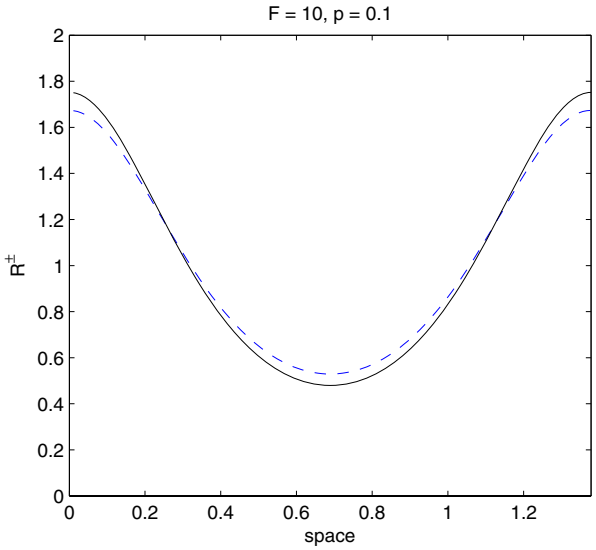

Figure 11. *Plots of the analytic solution (dashed) and the stable numerical solution (solid); here* $\epsilon = 0.1$ *and* $m_{\pm} = 0.9$.

regions shown in Figures 3, 5, and 9. A plot of the stable solution together with the analytical solution is shown in Figure 11. If the initial condition is taken to be small-amplitude noise, the system eventually evolves to a standing wave regime whose period is equal to the domain length (see Figure 12). The standing wave regime manifests itself as a periodic alternation of relatively long time intervals of nearly homogeneous spatial distributions of variables and short intervals of strongly inhomogeneous distributions characterized by the formation of wavenumber kinks and by phase-slip events. The oscillations in both waves, A^+ and A^-, are synchronized in time but not in space, due to the nonlocal nature of the coupling. For $p < -\min f(m)$, there exists a region of unstable solutions, as seen in Figure 9. In this region, the solution destabilizes to the standing waves similar to those shown in Figure 12. One can see that the spatial structure of this standing wave contains a wavenumber kink corresponding to a phase slip. We note that the formation of the standing waves shown in Figure 12 is the finite-domain effect: with the increase of the computational domain length L the solution never stabilizes to the standing waves but stays chaotic, as shown in Figure 13. This chaotic behavior consists of wiggling localized pulses accompanied by phase slips.

We next examine the case $F < 4$. In this case, solutions do not exist for $p > 0$, and numerical simulations using small-amplitude noise as an initial condition blow up in finite time. For $p < 0$, the solutions (2.6) were observed to be stable for values of $m_{\pm}$ in the stable regions seen in Figures 6 and 7. For values of $m_{\pm}$ in the unstable regions, the solutions blow up in finite time. This is also the case for all solutions with $F < 3$.

It should be noted that in all cases, the solutions destabilize as $m_{\pm}$ approaches existence boundaries. As $m_{\pm} \to 1$, the solution (2.6) becomes an array of pulse-like peaks with $\lambda_{\pm} \to \infty$. The tails of these peaks then approach 0 and destabilize, since the trivial solution ($A^{\pm} = 0$) is unstable. Eventually the solution evolves to standing waves. Conversely, as $m_{\pm}$ approaches

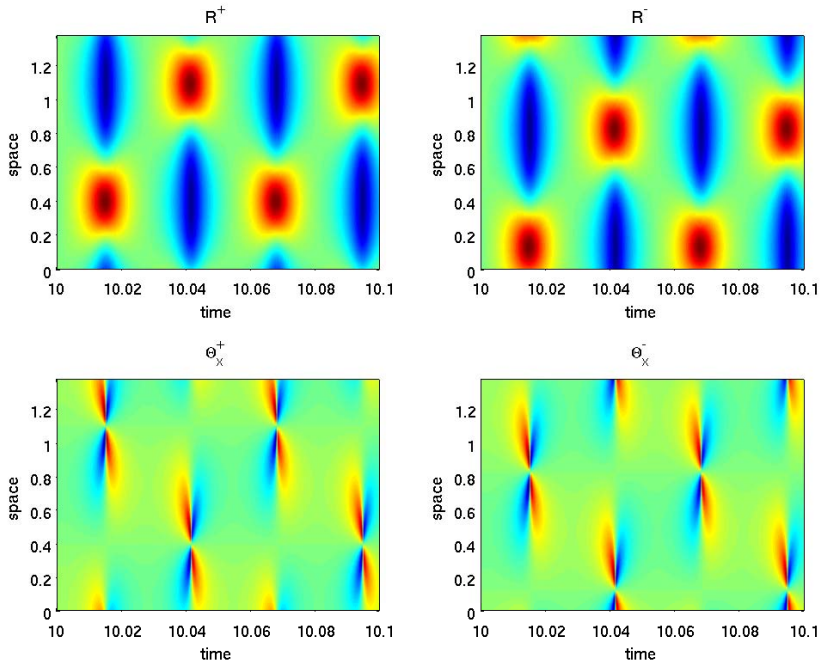

Figure 12. *Spatio-temporal plots of* $R^{\pm}$ *and* $\Theta_x^{\pm}$ *for* $F = 10$, $p = 0.1$, $m_{\pm} = 0.9$, $L = \lambda_{\pm} = 1.3779$ *showing alternating standing waves.*

the other existence boundary, $\lambda_{\pm} \to 0$, and the solution amplitude tends to infinity. Since the amplitude was assumed to be an $O(1)$ quantity, our analysis is no longer valid in this case. In the corresponding numerical simulations the solution blows up in finite time. It should also be noted that stable solutions were observed only for initial conditions with one period in the domain. In the case of starting with multiple periods, the solution then evolves to standing waves in a small domain or to chaotic behavior in large domains.

5. Conclusions. We have investigated the spatio-temporal dynamics of a system with subcritical Hopf bifurcation with reflection symmetry described near the instability threshold by a system of two nonlocally coupled CGL equations (2.1). We have shown that in the limit of large dispersion coefficients α and β, the system (2.1) may have bounded solutions corresponding to periodically modulated waves in the original physical system. These solutions are generalizations of the solutions of a single subcritical CGL equation found in [23]. In the parameter space, corresponding to the periods of the modulation waves and the coupling coefficient, we have found the regions where these solutions exist. We have shown that the existence of the solutions essentially depends on the sign of the coupling parameter and the ratio of the dispersion coefficients. We have performed a linear stability analysis and have found the necessary conditions for the stability of these solutions. We have also performed numerical simulations of the system (2.1). We have shown that for the parameters corresponding to the stability domain and the initial conditions close enough to the analytical solution (2.6), the

system indeed evolves toward this solution. However, for different initial conditions, as well as for the parameter values for which (2.6) is unstable, we have found that the system evolves toward standing waves, spatio-temporal chaos, or a finite-time blow-up, depending on the size of the computational domain.

We would also like to discuss two possible extensions of this work that were suggested by one of the anonymous referees of the paper. These extensions are beyond the scope of the present paper and may be a subject of a separate study.

The first extension addresses a supercritical Hopf bifurcation; i.e., we consider $\mu = -1$ instead of $\mu = 1$ in (1.2). In this case, solutions of the same type as (2.6) are expected to exist. Indeed, their characteristics and stability are governed by the same equation (2.11) with the only difference being that the factor $(F - 1)$ in the second term of the right-hand side of the equation is replaced by $(F + 1)$. Of course, the existence and stability conditions for the supercritical solutions will be different from those for subcritical solutions. However, if F is large, the relative difference between the factors $(F + 1)$ and $(F - 1)$ is small, and all the characteristics of the sub- and supercritical solutions will be very similar. This brings up an interesting question of why the criticality, which is typically a determining parameter in Hopf bifurcations, is not as crucial in the NLS limit. We believe that the reason for this is that the cnoidal waves we study are actually not created just by the Hopf bifurcation. They are basically the solutions of the NLS equation and, in fact, form a family of neutrally stable solutions. The Ginzburg–Landau nonconservative terms do not create these solutions,

as usually the Hopf bifurcation does, but rather create a slow dynamics inside this already existing family. Since what we study is exactly this dynamics, all the nonconservative terms are as important as the criticality, and the final results depend equally strongly on both the criticality and such parameters as F and p rather than the criticality itself.

The other extension addresses (2.1) in the case when the coefficients α and β have different signs, i.e., the parameter $F = \beta/\alpha < 0$. This case can be called defocusing by analogy with the terminology for the NLS equation, while the case $F > 0$ that has been considered in this paper is the focusing case. In the defocusing case, solutions of the dn type (see (2.6)) do not exist. However, one can find bounded solutions of the sn type in this case, both for sub- and supercritical bifurcations. All the characteristics and stability of these solutions can be studied similarly to how the dn-type solutions are studied in this paper.

Acknowledgment. The authors would like to thank an anonymous referee for useful comments that are reflected in this version of the paper.

Asynchronous and Synchronous Dispersals in Spatially Discrete Population Models*

Abdul-Aziz Yakubu†

Abstract. This study is on the role of synchronous and asynchronous dispersals in a discrete-time single-species population model with dispersal between two patches, where predispersal dynamics are compensatory or overcompensatory and dispersal is synchronous or asynchronous or mixed synchronous and asynchronous. It is known that single-species dispersal-linked population models behave as single-species single-patch models whenever all predispersal local dynamics are compensatory and dispersal is synchronous. However, the dynamics of the corresponding model connected by asynchronous and mixed synchronous-asynchronous dispersals depend on the dispersal rates, intrinsic growth rates, and the parameter that models the possible modes of dispersal. The species becomes extinct on at least one patch when the asynchronous dispersal rates are high, while it persists when the rates are low. In mixed synchronous-asynchronous systems, depending on the model parameters, the pioneer species either becomes extinct on all patches or persists on all patches. Overcompensatory predispersal dynamics with synchronous dispersal can lead to multiple attractors with fractal basin boundaries. However, the associated models with either asynchronous or mixed synchronous and asynchronous dispersals exhibit multiple attractors with fewer numbers of distinct attractors. That is, the long-term dynamics of synchronous dispersal-linked systems can be more sensitive to initial population sizes than that of the corresponding asynchronous and mixed synchronous-asynchronous systems. Also, synchronous, asynchronous, and mixed synchronous-asynchronous dispersals can "stabilize" the local patch dynamics from overcompensatory to compensatory dynamics. In our mixed synchronous-asynchronous model, the dominant mode of dispersal usually drives the dynamics of the full system.

Key words. asynchronous dispersal, compensatory dynamics, mixed synchronous-asynchronous dispersals, multiple attractors, overcompensatory dynamics, synchronous dispersal

1. Introduction.

In host-parasite systems, the timing of density effects and parasitism can have a profound impact on the population dynamics [35]. Doebeli made a similar observation in a two-patch, single-species, dispersal-linked model of coupled Smith–Slatkin difference equations. He showed that differences in the timing of reproduction and dispersal enhance the stabilizing effect of dispersal [7]. Hastings [22], Gyllenberg, Söderbacka, and Ericsson [17], Doebeli [7, 8], Gonzalez-Andújar and Perry [15], and Castillo-Chavez and Yakubu [5, 44] have studied single-species discrete-time dispersal-linked models that implicitly assume no difference in the timing of reproduction and dispersal *(dispersal synchrony)*. Their work showed that

the interaction between local dynamics and symmetric synchronous dispersal can lead to the replacement of chaotic local dynamics by periodic dynamics for some initial population sizes.

In this paper, we introduce a single-species two-patch dispersal-linked model where predispersal dynamics are *compensatory* (equilibrium dynamics) or *overcompensatory* (oscillatory dynamics) and dispersal is synchronous or asynchronous or mixed synchronous and asynchronous [2, 3, 39, 44, 45]. The novelty of our model is in the embedding of synchronous and asynchronous models into a single framework. Depending on a single continuous parameter, the model is capable of exhibiting synchronous dispersal, asynchronous dispersal, and *mixed* synchronous and asynchronous dispersals. Under dispersal synchrony (that is, where there is no asynchronous dispersal), our model reduces to that of Hastings [22, 23], Gyllenberg, Söderbacka, and Ericsson [17], Doebeli [7, 8], and Castillo-Chavez and Yakubu [5, 44], whereas it reduces to a model of Doebeli when dispersal is asynchronous (that is, where there is no synchronous dispersal) [7, 8].

A large number of researchers have carried out extensive studies on the interplay between local dynamics and dispersal in dispersal-linked models. Early work on this was done by Cohen and Levin [6], Gadgil [14], Hastings [23], Levin [27, 28], Levin and Paine [29], and Levins [30, 31], and later work was done by Allen [1], Doebeli [7], Doebeli and Ruxton [8], Earn, Levin, and Rohani [9], Gonzalez-Andújar and Perry [15], Gyllenberg, Söderbacka, and Ericsson [17], Hanski [18], Hanski and Gilpin [19], Hastings [22], and Castillo-Chavez and Yakubu [4, 5, 44]. In this paper, we focus on the impact of synchronous and asynchronous modes of dispersals on local populations with discrete nonoverlapping generations [7, 8, 9, 15, 17, 22, 44]. In particular, we extend Doebeli's idea that the detailed timing of dispersal can affect the global dynamics of dispersal-linked systems [7, 8].

We review, in section 2, the impact of compensatory and overcompensatory dynamics on "unstructured" single-species, single-patch discrete-time models. The Beverton–Holt [2, 3, 4, 5, 11, 12, 13, 20, 21, 38], bobwhite quail "hump-with-tail" [10, 44], Ricker [4, 7, 8, 22, 24, 25, 32, 33, 34, 35, 36, 37, 40, 44, 45], and Smith–Slatkin [20, 36, 41, 45] models are used to describe either compensatory or overcompensatory dynamics. Only *pioneer* species are considered (pioneer species are species that persist at very small population sizes when left in isolation with no outside interference) [11, 12, 13].

In section 3, three basic single-species dispersal-linked models consisting of two subpopulations (with nonoverlapping generations) connected by one of the three modes of dispersals (synchronous, asynchronous, and mixed synchronous-asynchronous dispersals) are introduced. To understand the behavior of the mixed synchronous-asynchronous model, in section 4, we review prior work on the model with dispersal synchrony. Single-species dispersal-linked population models under the *same* qualitative local compensatory dynamics are known to behave as single-patch systems whenever dispersal is synchronous [5, 44]. When predispersal local dynamics are overcompensatory, dispersal synchrony can fracture the basins of attraction through its support of multiple attractors. We highlight, in section 4, the possible structures of the coexisting attractors where local populations (in the absence of dispersal) live on either a preselected *n-cycle* attractor or a chaotic attractor (overcompensatory dynamics). Hastings and others have observed similar multiple attractors in synchronous models [4, 5, 22, 44].

The model under dispersal asynchrony is studied in sections 5 and 6. We show, in section 5, that the dynamics of the full system depend on the asynchronous dispersal rates. The species

becomes extinct on at least one patch when asynchronous dispersal rates are high, while it persists when the rates are low. In sharp contrast to dispersal synchrony, dispersal asynchrony impacts compensatory local dynamics [7, 23, 28, 29].

The difference in the timing of reproduction and dispersal enlarges the asynchrony of interactions, and Doebeli predicted the "likelihood" of simple system dynamics due to asynchronous dispersal [7]. In general, dispersal can give rise to multiple attractors with interesting basin structures, whenever the local patch dynamics are overcompensatory [4, 5, 7, 9, 16, 19, 22, 26, 44]. In section 6, several examples are introduced to show that dispersal-linked models with "unstructured" overcompensatory predispersal patch dynamics connected by asynchronous symmetric or asymmetric dispersal support multiple attractors with a smaller number of distinct attractors than the corresponding model under dispersal synchrony. We use MATLAB and the Dynamics software of Nusse and Yorke to study the differences among the structures of the attractors and the differences between the synchronous and asynchronous cases [39]. Our results show that asynchronous dispersal can stabilize or shift the predispersal local dynamics from an attracting period four to a period two or to a fixed point or to a limit cycle attractor. That is, both synchronous and asynchronous dispersals can generate period-doubling reversals in dispersal-linked models under overcompensatory dynamics.

Models under mixed synchronous-asynchronous dispersals are studied in sections 7, 8, and 9. As in synchronous models, in mixed models, the pioneer species either persists on all patches or becomes extinct on all patches. In section 7, we derive conditions for the extinction (respectively, persistence) of the species on all patches. Mixed synchronous-asynchronous systems under compensatory and overcompensatory local dynamics are studied in sections 8 and 9, respectively. When the local dynamics are overcompensatory, mixed models exhibit multiple attractors with a smaller number of distinct attractors than the corresponding model under dispersal asynchrony. Section 10 discusses some possible implications of the results of this paper, and relevant mathematical details of all technical terms are collected in the appendix.

2. Predispersal local patch dynamics. In this section, we review single-species discrete-time population models without dispersal. As in [7, 22, 44], the equation for the local dynamics in each Patch $i \in \{1, 2\}$ at generation t *after* reproduction but *before* dispersal is modeled by

$$x_i(t+1) = x_i(t)g_i(x_i(t)) \qquad (i = 1, 2), \tag{1}$$

where $x_i(t)$ denotes the population size and the per capita growth functions, $g_i : [0, \infty) \to (0, \infty)$ are assumed to be strictly decreasing, positive, and twice differentiable (C^2 on $[0, \infty)$), where $g_i(0) > 1$ and $\lim_{x_i \to \infty} g_i(x_i) < 1$. System (1) is a discrete-time, single-species, population model with two (uncoupled) patches. It describes the population dynamics of pioneer species [4, 5, 11, 12, 13, 44].

Predispersal Patch i local reproduction function $f_i(x_i) = x_i g_i(x_i)$ describes the local dynamics of the species, where x_i is the measure of the size of the population in the patch. Each f_i has a unique positive fixed point denoted by X_i. Since g_i is a strictly decreasing continuous function, $f_i(x_i) > x_i$ whenever $0 < x_i < X_i$ and $f_i(x_i) < x_i$ whenever $x_i > X_i$. Consequently, $I_i \equiv f_i([0, X_i])$ is a global attractor. That is, every initial population eventually reaches a limit in I_i.

We focus on two types of local dynamics—*compensatory* and *overcompensatory* dynamics.

Definition 1. *Patch i predispersal local dynamics are compensatory whenever all positive population sizes approach the positive equilibrium at X_i monotonically under f_i iterations* [4, 38, 44].

Definition 2. *Patch i predispersal local dynamics are overcompensatory whenever some positive population sizes "overshoot" the positive equilibrium at X_i under f_i iterations (that is, $f_i'(X_i) < 0$)* [4, 38, 44].

If f_i increases monotonically from zero with the rate of increase slowing down as x_i gets large, then all population sizes "undershoot" the globally attracting positive equilibrium, and by Definition 1 Patch i local dynamics are compensatory. The Beverton–Holt stock recruitment model, $f_i(x_i) = \frac{a_i x_i}{1+b_i x_i}$, portrays compensatory dynamics in Patch i whenever $a_i > 1$ and $b_i > 0$ [4, 44, 45]. If f_i is an orientation-reversing one-hump map with a stable positive fixed point (respectively, an unstable positive fixed point), then the return to the stable fixed point takes the form of damped oscillations (respectively, the local behavior near the unstable fixed point takes the form of divergent oscillations), and by Definition 2 Patch i dynamics are overcompensatory. Whenever $r_i > 1$ and f_i is Ricker's model, $f_i(x_i) = x_i \exp(r_i - x_i)$, then the dynamics in Patch i are overcompensatory [2, 3, 4, 5, 7, 8, 9, 10, 11, 12, 13, 20, 21, 22, 32, 33, 34, 35, 36, 37, 38, 39, 40, 44, 45]. In general, f_i supports either an *n-cycle* (nonchaotic) attractor with $n > 1$ or a chaotic (interval) attractor whenever Patch i dynamics are overcompensatory and the positive fixed point is unstable.

A detailed description of functions under compensatory or overcompensatory dynamics requires the introduction of the concept of an *α-monotone concave map*.

Definition 3. *f_i is an α-monotone concave map if $f_i'(x_i) > 0$ and $f_i''(x_i) < 0$ for each $x_i \in [0, \alpha)$* [4, 38, 44].

Patch i population is under compensatory dynamics at population sizes in the interval $[0, \alpha)$ whenever f_i is an *α-monotone concave map* with a unique positive fixed point in the open interval $(0, \alpha)$ (see [44, Definition 3]). The bobwhite quail "hump-with-tail" model $f_i(x_i) = x_i(k_i + \frac{K_i}{1+x_i^{n_i}})$, the Ricker model $f_i(x_i) = x_i \exp(r_i - x_i)$, and the Smith–Slatkin model $f_i(x_i) = \frac{a_i x_i}{1+(b_i x_i)^{l_i}}$ describe overcompensatory and compensatory dynamics (depending on parameter values). If $l_i = 1$ and $a_i > 1$, the Smith–Slatkin model reduces to the Beverton–Holt model, an *∞-monotone concave map* (compensatory dynamics [2, 36, 42, 44]).

3. Synchronous and asynchronous dispersal-linked two-patch model. Hastings [22], Gyllenberg, Söderbacka, and Ericsson [17], Doebeli [7, 8], Yakubu and Castillo-Chavez [44], and others have studied discrete-time single-species dispersal-linked population models that implicitly assume that the timing of reproduction and dispersal *do not* differ from patch to patch. A two-patch version of these models with *dispersal synchrony* is given by the following system of coupled nonlinear difference equations:

$$\left.\begin{aligned} x_1(t+1) &= (1-d_1)f_1(x_1(t)) + d_2 f_2(x_2(t)), \\ x_2(t+1) &= d_1 f_1(x_1(t)) + (1-d_2)f_2(x_2(t)). \end{aligned}\right\} \tag{2}$$

In system (2), reproduction occurs prior to dispersal within each generation and in each patch. After reproduction, the constant fraction $d_1 \in (0,1)$ of the population disperses from Patch 1 to Patch 2 while the constant fraction $d_2 \in (0,1)$ disperses from Patch 2 to Patch 1.

Doebeli, in 1995, studied a simple two-patch discrete-time model of coupled Smith–Slatkin single-species ecological models where the timing of reproduction and dispersal *differs* from patch to patch. In Doebeli's two-patch model, in each generation reproduction occurs in Patch 1 first, followed by the dispersal, from Patch 1 to Patch 2, of the fraction d_1 of the population. As a result, Patch 2 population experiences the effects of its own density as well as that of the newly dispersed individuals from Patch 1 to Patch 2. In Patch 2, the fraction d_2 of the population disperses from Patch 2 to Patch 1 after reproduction [7]. The dynamics of the two-patch system under *asynchronous* dispersal are then described by the following system of coupled nonlinear difference equations:

$$\left.\begin{array}{rcl} x_1(t+1) &=& (1-d_1)f_1(x_1(t)) + d_2x_2(t)g_2(x_2(t)+d_1f_1(x_1(t))), \\ x_2(t+1) &=& (1-d_2)x_2(t)g_2(x_2(t)+d_1f_1(x_1(t))), \end{array}\right\} \tag{3}$$

where $0 < d_1, d_2 < 1$ and $f_1(x_1) = x_1g_1(x_1)$.

In Doebeli's simple model with dispersal asynchrony, at the next generation, the population size in Patch 1 is increased by the dispersal from Patch 2. However, unlike the Patch 1 population size, the population size in Patch 2 at the next generation is *not* increased by the dispersal from Patch 1. By their own nature, such simple models do not incorporate many of the important biological factors. However, they often provide useful insights to help our understanding of complex processes.

To embed synchronous and asynchronous dispersals into a single framework, we let the constant parameter $\gamma \in [0,1]$ span the range of possible modes of dispersal, where $\gamma = 0$ implies synchronous dispersal, $\gamma = 1$ implies asynchronous dispersal, and $\gamma \in (0,1)$ implies *mixed* synchronous and asynchronous dispersal. This leads to the following equations describing the dispersal phase:

$$\left.\begin{array}{rcccl} x_1(t+1) &=& F_1(x_1(t),x_2(t)) &=& (1-d_1)f_1(x_1(t)) + d_2x_2(t)g_2(\overline{x}(t)), \\ x_2(t+1) &=& F_2(x_1(t),x_2(t)) &=& (1-\gamma)d_1f_1(x_1(t)) + (1-d_2)x_2(t)g_2(\overline{x}(t)), \end{array}\right\} \tag{4}$$

where

$$\overline{x}(t) = x_2(t) + \gamma d_1 f_1(x_1(t)).$$

Unlike Doebeli's model, in models (2) and (4), at the next generation the population size in Patch 1 is increased by the dispersal from Patch 2, while that of Patch 2 is increased by the dispersal from Patch 1. In each generation, reproductions in Patch 2 of models (3) and (4) experience crowding from the dispersal from Patch 1.

The vector of population densities $x(t) = (x_1(t), x_2(t))$ is written as $x = (x_1, x_2)$ so that the *dispersal-linked* function is

$$F : \mathbb{R}^2_+ \to \mathbb{R}^2_+,$$

where

$$F(x_1, x_2) = (F_1(x_1, x_2), F_2(x_1, x_2)).$$

Then F^t is the dispersal-linked function composed with itself t times. $F^t_i(x)$ is the ith component of F^t evaluated at the point x in $\mathbb{R}^2_+$. In system (4), F^t gives the population densities in generation t.

When $\gamma = 0$ (respectively, $\gamma = 1$), dispersal is synchronous (respectively, asynchronous), and system (4) reduces to system (2) (respectively, system (3)). Dispersal is *symmetric* when $d_1 = d_2$, while it is *asymmetric* when $d_1 \neq d_2$. When there are no dispersals, $d_1 = d_2 = 0$ and system (4) reduces to the uncoupled system (1). The predispersal basic demographic reproductive number in each patch ($d_1 = d_2 = 0$) is

$$\Re_d^i = g_i(0).$$

$\Re_d^i > 1$ guarantees the successful invasion and survival of the discretely reproducing population in Patch i, while $\Re_d^i < 1$ guarantees the extinction of the initial population in the patch (no dispersal). We assume throughout that the species is a pioneer in each Patch $i \in \{1, 2\}$. That is, $\Re_d^i > 1$.

In system (4), there is no population explosion.

Lemma 1. *In system (4), the positive cone is positively invariant and no point has an unbounded orbit.*

4. Dispersal synchrony in two-patch models. In this section, we consider system (4) with *only* dispersal synchrony (that is, system (2) or system (4) with $\gamma = 0$). Others have studied synchronous dispersal models, and in this section we review some of these prior works. When all local dynamics are compensatory, Yakubu and Castillo-Chavez proved that system (2) supports a positive equilibrium that attracts all positive initial population sizes [44]. That is, when all local dynamics are compensatory, the qualitative dynamics of system (2) with symmetric or asymmetric synchronous dispersal between patches is qualitatively equivalent to those of each of the local single patches before dispersal. With synchronous symmetric dispersal and symmetric initial population sizes, system (2) behaves as a single patch system whenever the local reproduction functions are identical ($f_1 = f_2$) and the predispersal local dynamics are either compensatory or overcompensatory.

In 1993, Hastings [22] and Gyllenberg, Söderbacka, and Ericsson [17] used two identical logistic difference equations in system (2) with parameters in the chaotic regime to illustrate that synchronous dispersal-linked population models are capable of supporting multiple attractors with complicated attraction-basin boundaries. In a recent paper, Yakubu and Castillo-Chavez studied the role of synchronous dispersal in generating multiple attractors where local dynamics are overcompensatory [44]. They focused on situations where the local populations (in the absence of dispersal) live on either a preselected *n-cycle* attractor or a chaotic attractor. Yakubu and Castillo-Chavez supported the results of Hastings and obtained that synchronous dispersal can force the preselected (chaotic or nonchaotic) attractor to coexist with one or more "new" attractors (multiple attractors). Example 1 illustrates multiple attractors in system (2) with synchronous symmetric dispersal, where the local dynamics are governed by the Ricker model. In Example 1, we choose the values of the parameters so that the predispersal local dynamics and the full system dynamics under synchronous symmetric dispersal are as listed in Table 1.

Example 1. *Consider system (2) with the Ricker model*

$$f_i(x_i) = x_i \exp(r_i - x_i)$$

for each $i \in \{1, 2\}$. Set the following parameter values:

$$r = r_1 = r_2 \in (2, 2.52) \quad \textit{and} \quad d_1 = d_2 = 0.03.$$

Table 1

Predispersal local dynamics versus postdispersal synchronous dynamics.

r values	Predispersal attractors	Synchronous attractors
1. $(2, 2.53)$	2-cycle	two 2-cycles (see Fig. 1)
2. $(2.53, 2.59)$	4-cycle	4- and 2-cycles
3. $(2.66, 2.68)$	8-cycle	8-, 4-, and 2-cycles
4. $(2.69, 2.6901)$	16-cycle	16-, 8-, 4-, and 2-cycles
5. $(2.695, 2.701)$	chaotic attractor	four attractors (see Fig. 2)

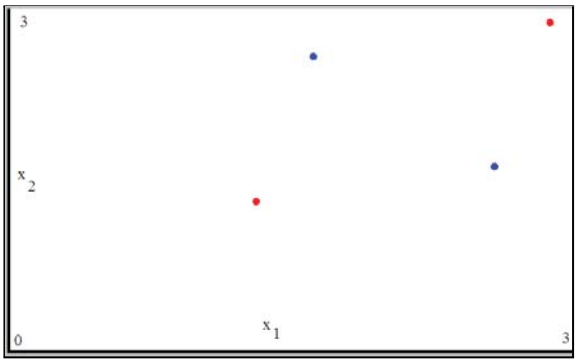

Figure 1. *Two coexisting attractors: Symmetric* 2*-cycle (red dots) and an asymmetric* 2*-cycle (blue dots) in the* (x_1, x_2)*-plane, where* $r_1 = r_2 = 2.1$ *and* $d_1 = d_2 = 0.03$*. Figure* 1 *is plotted over* 3000 *time steps.*

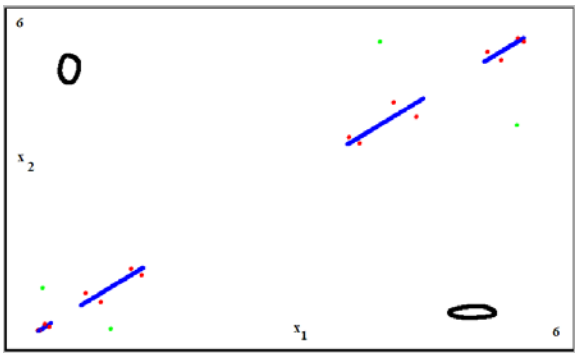

Figure 2. *Four attractors: Symmetric* 4*-piece chaotic attractor (blue region), asymmetric* 4*-cycle (green dots), asymmetric* 16*-cycle (red dots), and a period-*2 *limit cycle (black region), where* $r_1 = r_2 = 2.7$ *and* $d_1 = d_2 = 0.03$*. Figure* 2 *is plotted over* 5000 *time steps.*

The predispersal local dynamics in Example 1, $f_i(x_i) = x_i \exp(r_i - x_i)$, have a stable positive fixed point at $X_i = r_i$ whenever $0 < r_i < 2$ [44]. As r_i is increased past 2, the fixed point X_i undergoes a period-doubling bifurcation route to chaos [33, 34, 35, 39]. In Example 1, the predispersal identical local patches are on a 2-cycle attractor (overcompensatory dynamics), and the full system with symmetric dispersal supports multiple attractors—a symmetric 2-cycle attractor coexisting with an asymmetric 2-cycle attractor (see Figure 1 and Table 1). To study the impact of increasing the identical intrinsic growth rates, $r = r_1 = r_2$, the symmetric dispersal rates are kept fixed at $d_1 = d_2 = 0.03$ while r is increased past 2.52.

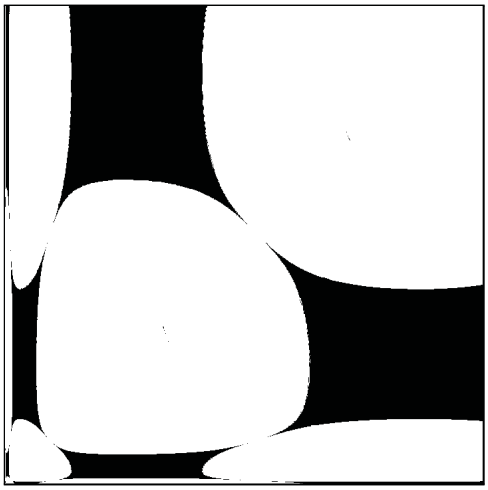

Figure 3. *Basins of attraction of two coexisting* 2*-cycle attractors, where the parameters are exactly as in Figure* 1*. The white region is the basin of attraction of the black "specks" (*2*-cycle) in the figure, and the black region is the basin of attraction of the other coexisting attractor. On the horizontal axis* $0 \leq x_1 \leq 4$*, and on the vertical axis* $0 \leq x_2 \leq 4$*. Figure* 3 *is plotted over* 5000 *time steps.*

When $r \in (2.53, 2.59)$, the predispersal identical local patches are on a 4-cycle attractor, and the full system with symmetric dispersal supports two coexisting attractors consisting of a symmetric 4-cycle attractor and an asymmetric 2-cycle attractor (see Table 1). At $r \in (2.6, 2.65)$, the predispersal identical local patches are on a 4-cycle attractor, while the full system with symmetric dispersal supports three coexisting attractors consisting of a symmetric 4-cycle attractor, an asymmetric 4-cycle attractor, and an asymmetric 2-cycle attractor (see Table 1). For values of $r \in (2.66, 2.68)$, the predispersal identical local patches are on an 8-cycle attractor, and the full system with symmetric dispersal supports three coexisting attractors consisting of a symmetric 8-cycle attractor, an asymmetric 4-cycle attractor, and an asymmetric 2-cycle attractor (see Table 1). At $r \in (2.69, 2.6901)$, the predispersal identical local patches are on a 16-cycle attractor, while the full system with symmetric dispersal supports four coexisting attractors consisting of a symmetric 16-cycle attractor, an asymmetric 8-cycle attractor, an asymmetric 4-cycle attractor, and an asymmetric 2-cycle attractor (see Table 1). When $r \in (2.695, 2.701)$, the predispersal identical local patches are on a chaotic attractor, and the full system with symmetric dispersal supports four coexisting attractors consisting of a symmetric chaotic attractor, a period-2 limit cycle attractor, an asymmetric 4-cycle attractor, and an asymmetric 16-cycle attractor (see Figure 2 and Table 1).

The qualitative structure and number of the attractors in dispersal-linked population models are the result of a complex interaction between the dispersal rate and predispersal local patch dynamics. The *basins of attraction*, the set of all population sizes that eventually settle into an attractor under iteration, may provide critical information on a variety of issues including the final attractor observed. In Example 1, the *Dynamics* software of Nusse and Yorke is used to study the nature of the basins of attraction of the multiple attractors in Figures 1 and 2 [39]. As in [44], Figures 3 and 4 highlight that the basins of attraction

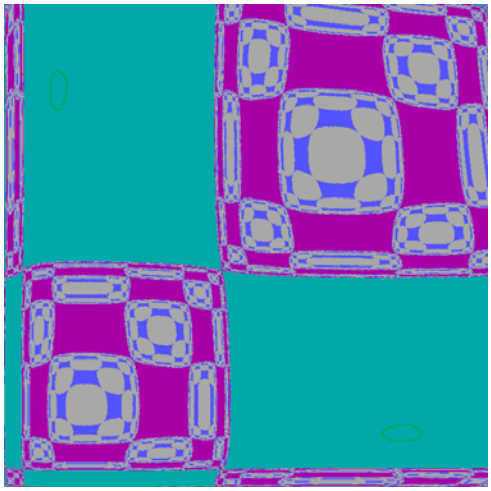

Figure 4. *Basins of attraction of the* 4 *attractors, where the parameters are exactly as in Figure* 2*. On the horizontal axis* $0 \leq x_1 \leq 6$*, and on the vertical axis* $0 \leq x_2 \leq 6$*. Figure* 4 *is plotted over* 5000 *time steps.*

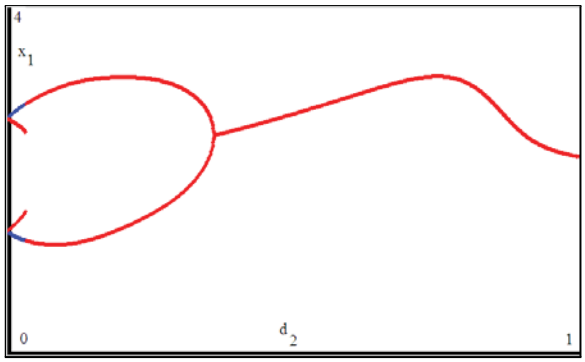

Figure 5. *The full system shifts from two* 2*-cycle attractors (red* 2*-cycle and blue* 2*-cycle) to a single (red)* 2*-cycle attractor or to a single (red) fixed point attractor with synchronous asymmetric dispersal, where* $r_1 = r_2 = 2.1$ *and* $d_1 = 0.03$ *while* d_2 *is varied continuously between* 0.03 *and* 1*.*

become thinner and their boundaries exhibit increasing fractal structures as the number of attractors increases or as the period of the attractors increases.

4.1. Asymmetric dispersal synchrony. In Figures 1, 2, 3, and 4, only synchronous *symmetric* dispersal is assumed. To illustrate the impact of synchronous *asymmetric* dispersal on Figure 1, we keep the parameters fixed at $r = 2.1$ and $d_1 = 0.03$, while d_2 is varied continuously between 0 and 1 (see Figure 5). The full system stabilizes or shifts from the two coexisting 2-cycle attractors to a single 2-cycle attractor (saddle-node bifurcation reversal) or to a single fixed point attractor (period-doubling reversal). Similarly, when the predispersal local dynamics are chaotic, asymmetric dispersal synchrony can change the number and nature of the coexisting attractors. For example, when $r = 2.7$, $d_1 = 0.03$, and $d_2 = 0.7$, the full system appears to support a single attractor, an attracting fixed point at $(4.308, 1.513)$ where the predispersal local dynamics are chaotic (see Figure 6).

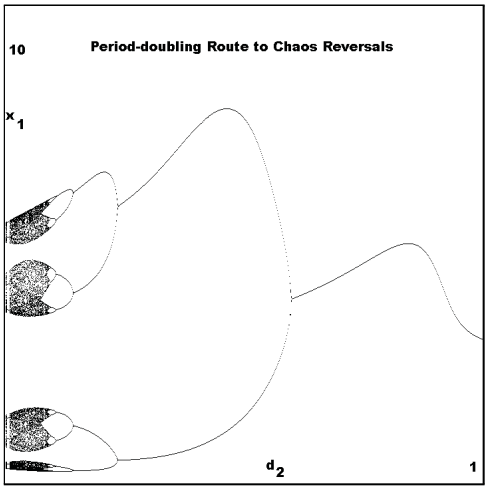

Figure 6. *The full system shifts from four coexisting attractors to a single fixed point attractor with synchronous asymmetric dispersal, where* $r_1 = r_2 = 2.7$ *and* $d_1 = 0.03$ *while* d_2 *is varied continuously between* 0.03 *and* 1.

As in [44], Figures 5 and 6 highlight that for most values of asymmetric dispersal rates ($d_1 \neq d_2$) simple dynamics are supported in the full system, in sharp contrast to Figures 1, 2, 3, and 4, where dispersal is symmetric and multiple attractors with complicated basins of attraction are supported. That is, asymmetry enhances the stabilizing effect of dispersal in system (2), where dispersal is completely synchronous.

5. Dispersal asynchrony in two-patch models. The work of Doebeli shows the dependence of the dynamics of dispersal-linked models on asynchronous dispersal rates where the predispersal local dynamics are chaotic (overcompensatory dynamics) and are governed by the Smith–Slatkin model [7]. In this section, we consider system (4) with *only* dispersal asynchrony (that is, system (3) or system (4) with $\gamma = 1$), where the predispersal dynamics are noncyclic (compensatory), cyclic, and chaotic (overcompensatory). Next, we show that the species becomes extinct (respectively, persists) on at least one patch when the asynchronous dispersal rates are high (respectively, low). We collect these in the following result.

Theorem 1. *In system* (3)*, we have the following:*

(i) $(1-d_2)\Re_d^2 < 1$ *implies that the* ω*-limit set of every positive population vector is a subset of* $[0,\infty)\times\{0\}$*. Hence, the species becomes extinct in Patch* 2*.*

(ii) $(1-d_1)\Re_d^1 > 1$ *and* $(1-d_2)\Re_d^2 > 1$ *imply that* $(0,0)$ *is unstable and there is no catastrophic extinction of the species in both Patches* 1 *and* 2*.*

(iii) $\Re_d = \max\{(1-d_1)\Re_d^1, (1-d_2)\Re_d^2\} < 1$ *implies that* $(0,0)$ *is globally asymptotically stable. Hence, the species becomes extinct in both Patches* 1 *and* 2*.*

(iv) $(1-d_1)\Re_d^1 > 1$ *and* $(1-d_2)\Re_d^2 < 1$ *imply that* $(g_1^{-1}(\frac{1}{1-d_1}), 0)$ *is a globally stable fixed point in* $(0,\infty)\times[0,\infty)$ *whenever the Patch* 1 *dynamics are compensatory. Hence, the species persists in Patch* 1*, while it becomes extinct in Patch* 2*.*

The proof of Theorem 1 is in the appendix.

The four cases in Theorem 1 are not exhaustive. For example, conditions for the persistence of the species in both Patches 1 and 2 via a stable positive equilibrium population

vector can be obtained if one assumes the persistence of the species in Patch 2 where the asynchronous dispersal rates are low and the local dynamics are compensatory. To illustrate this in the simplest setting, we assume that the predispersal Patch 1 local population has reached the positive equilibrium X_1, and we let $f_1(x_1) \equiv X_1$ [43, 46]. Then system (3) reduces to the system

$$\left.\begin{array}{rcl} x_1(t+1) &=& (1-d_1)X_1 + d_2 x_2(t) g_2(x_2(t)+d_1X_1), \\ x_2(t+1) &=& (1-d_2)x_2(t)g_2(x_2(t)+d_1X_1). \end{array}\right\} \tag{5}$$

If the dispersal rate from Patch 2 to Patch 1 is low, then system (5) supports a globally stable positive equilibrium whenever the predispersal local patch dynamics are compensatory and the Patch 1 carrying capacity is small. That is, dispersal asynchrony like dispersal synchrony is capable of supporting the persistence of the pioneer species in all patches. We summarize these in the following result.

Theorem 2. *In system (5), let each local patch dynamics be modeled by f_i, an α-monotone concave map, with the positive fixed point $X_i \in (0,\alpha)$. If $(1-d_2)\Re_d^2 > 1$, then the positive equilibrium population vector,*

$$\left((1-d_1)X_1 + \frac{d_2}{1-d_2}\left(g_2^{-1}\left(\frac{1}{1-d_2}\right) - d_1X_1\right),\ g_2^{-1}\left(\frac{1}{1-d_2}\right) - d_1X_1\right),$$

is globally attracting whenever $X_1 < \frac{g_2^{-1}(\frac{1}{1-d_2})}{d_1}$. That is, the dispersal-linked system supports a globally stable positive fixed point whenever the predispersal local patch dynamics are compensatory.

The proof of Theorem 2 is in the appendix.

In Example 2, we use compensatory local dynamics via the Beverton–Holt model to illustrate the dependence of the dynamics of system (3) on the asynchronous dispersal rates.

Example 2. *Consider system (3) with*

$$f_i(x_i) = \frac{a_i x_i}{1+b_i x_i}$$

for each $i \in \{1,2\}$. Set the following parameter values:

$$a_1 = 2,\ a_2 = 2.1,\ b_1 = b_2 = 1,\ \text{and}\ d_1 = d_2 = 0.01.$$

In Example 2, the local dynamics in both patches are compensatory, where $g_1(0) = a_1$, $g_2(0) = a_2$, $X_1 = 0.01$, $X_2 = 0.1$, $(1-d_2)\Re_d^2 > 1$, and $X_1 < \frac{g_2^{-1}(\frac{1}{1-d_2})}{d_1}$. Consequently, the resulting system with symmetric dispersal asynchrony supports a globally stable positive equilibrium population vector at $(1.002, 1.069)$ (Theorem 2). We study the impact of increasing the dispersal parameters on Example 2. In Figures 7, 8, and 9 the parameters a_1, a_2, b_1, and b_2 are kept fixed at their current values.

In Figure 7, symmetric dispersal is assumed and $d_1 = d_2$ is varied continuously between 0 and 1. The population in each patch decreases to zero monotonically with increasing symmetric dispersal rates (see Figure 7). That is, when the symmetric dispersal rate is high and

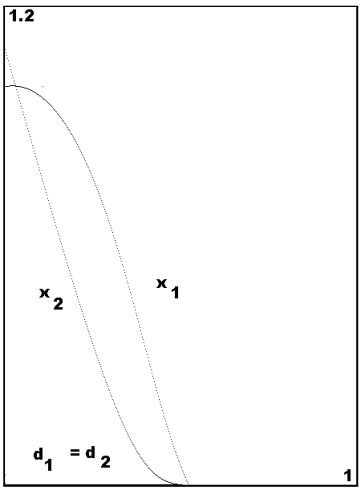

Figure 7. *When the symmetric dispersal rate $d_1 = d_2$ is low the species persists in both Patches* 1 *and* 2. *However, when $d_1 = d_2 > 0.53$ it becomes extinct in both Patches* 1 *and* 2.

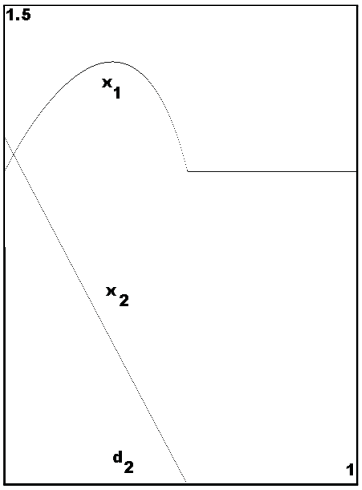

Figure 8. *Persistence in both Patches* 1 *and* 2 *with asymmetric dispersal asynchrony.*

$\Re_d < 1$, the species becomes extinct in both Patches 1 and 2 (Theorem 1), and when the symmetric dispersal rate is low and $\Re_d > 1$, the species persists in both Patches 1 and 2.

Asymmetric dispersal is assumed in Figures 8 and 9. In Figure 8, d_1 is fixed at $d_1 = 0.01$ while d_2 is varied continuously between 0 and 1. As the values of d_2 increase, the Patch 2 population decreases monotonically to zero while the Patch 1 population first increases to a maximum value before decreasing monotonically to the carrying capacity in Patch 1. As in Figure 7, the species persists in both Patches 1 and 2 when the asymmetric dispersal rate is low. In contrast to Figure 7, when the dispersal rate from Patch 2 to Patch 1 is high and $(1 - d_1)\Re_d^1 > 1$, the species persists in Patch 1, while it is extinct in Patch 2 (Theorem 1 and Figure 8). In Figure 8, this explains the sudden leveling of the graphs of x_1 and x_2 at high levels of d_2. In Figure 9, d_2 is fixed at $d_2 = 0.01$ while d_1 is varied continuously between

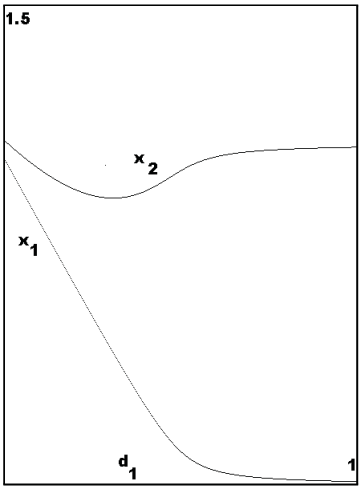

Figure 9. *Persistence in both Patches* 1 *and* 2 *with asymmetric dispersal asynchrony.*

0 and 1. As the values of d_1 increase, the population in Patch 1 decreases monotonically to a very small positive value, while the Patch 2 population first decreases to a positive minimum value before increasing monotonically to a value close to the carrying capacity in Patch 2 (see Figure 9). In Figure 9, for all values of the asymmetric dispersal rates, the species persists in both Patch 1 and Patch 2.

Figures 7, 8, and 9 show that dispersal asynchrony is capable of shifting the local dynamics from persistence of the pioneer species to its extinction on at least one patch. Thus, dispersal asynchrony impacts local patch dynamics. Clearly, these new results have highlighted only a few possibilities with the selected examples.

6. Multiple attractors: Asynchronous versus synchronous symmetric dispersal. Population models with "unstructured" overcompensatory predispersal local patch dynamics connected by either asynchronous or synchronous dispersals are capable of supporting multiple attractors. However, asynchronous symmetric dispersal-linked models are more likely to support multiple attractors with smaller numbers of distinct attractors than the corresponding models under dispersal synchrony. In this section, we use examples to highlight the differences among the attractors and the differences between the asynchronous and synchronous cases.

6.1. Symmetric dispersal asynchrony. In this section, we consider the asynchronous dispersal model, system (3), with symmetric dispersal (that is, $d_1 = d_2 = d$), where the per capita growth rates are identical (that is, $g_1 = g_2 = g$). Doebeli, in 1994, used two identical Smith–Slatkin difference equations with parameters in a chaotic regime to describe the predispersal local dynamics, where the asynchronous dispersal is symmetric [7].

In section 3, we generated multiple attractors in synchronous systems under symmetric dispersal ($d_1 = d_2$), where the identical predispersal local reproduction function is the Ricker model [10, 37, 44]. To study the corresponding asynchronous symmetric dispersal case, we repeat those results using system (3) and the identical Ricker model as the predispersal local dynamics, where asynchronous dispersal is symmetric. As in Example 1, in Example 3 we choose the values of the parameters so that the predispersal local dynamics and full system

Table 2

Predispersal local dynamics versus postdispersal asynchronous dynamics.

under asynchronous symmetric dispersal are as listed in Table 2.

Example 3. *Consider system* (3) *with the Ricker predispersal identical local dynamics*

$$g(x_i) = \exp(r - x_i).$$

Set the following parameter values:

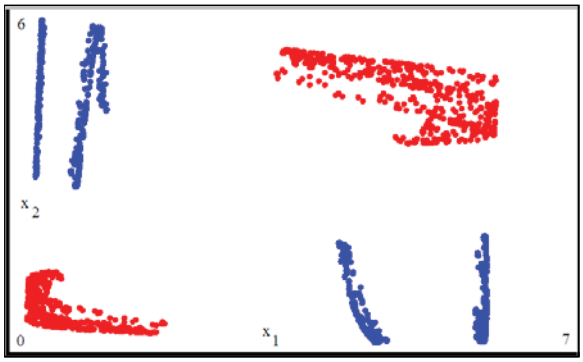

Figure 12. *Multiple chaotic attractors in system* (3)*, with* $g(x_i) = \exp(r - x_i)$ *and symmetric asynchronous dispersal. A* 2*-piece chaotic attractor along the diagonal (red region) coexisting with a* 4*-piece chaotic attractor off the diagonal (blue region), where* $r = 2.8$ *and* $d = 0.03$ *in Example* 3*. Figure* 12 *is plotted over* 5000 *time steps.*

$$r \in (2, 2.52) \text{ and } d = d_1 = d_2 = 0.03.$$

For values of the parameter $r \in (2, 2.52)$, the predispersal identical local patches are on a 2-cycle attractor, and the full system with symmetric dispersal synchrony supports two 2-cycle attractors (see Table 1). However, the dynamics of the corresponding system under symmetric dispersal asynchrony depends on the value of r. It supports a single fixed point attractor when $r \in (2, 2.06)$, a single limit cycle attractor when $r \in (2.07, 2.09)$, a single 2-cycle attractor when $r \in (2.098, 2.2)$ (no multiple attractors; see Figure 10), and two 2-cycle attractors when $r \in (2.3, 2.5)$. At $r \in (2.6, 2.65)$, the predispersal identical local patches are on a 4-cycle attractor, and the full system with symmetric dispersal asynchrony supports two 4-cycle attractors, where the corresponding synchronous model supports a 4-cycle attractor coexisting with a 2-cycle attractor. When $r \in (2.66, 2.68)$, the predispersal identical local patches are on an 8-cycle attractor, and the full system with symmetric dispersal synchrony supports three 4-cycle attractors, where the corresponding asynchronous model supports two 4-cycle attractors. For values of $r \in (2.69, 2.6901)$, the predispersal identical local patches are on a 16-cycle attractor, and the full system with symmetric dispersal synchrony supports four attractors, where the corresponding asynchronous model supports an 8-cycle attractor coexisting with a 4-cycle attractor. At $r \in (2.695, 2.701)$, the predispersal identical local patches are on a chaotic attractor, and the full system with symmetric dispersal synchrony supports four attractors, where the corresponding asynchronous model supports an 8-cycle attractor coexisting with a 4-cycle attractor (see Table 2 and Figure 11). Figure 12 demonstrates that population models under dispersal asynchrony are capable of supporting coexisting chaotic attractors.

As in Figures 3 and 4, the *Dynamics* software of Nusse and Yorke is used to study the nature of the basins of attraction of the multiple attractors in Figure 11 (see Figure 13) [39].

Figures 1, 2, 3, 4, 10, 11, 12, and 13 together with Tables 1 and 2 illustrate that asynchronous symmetric dispersal-linked models support multiple attractors with simpler basins of attraction than the corresponding synchronous symmetric ones. However, in both dispersal-linked models, our results show that the boundary between the initial population sizes leading

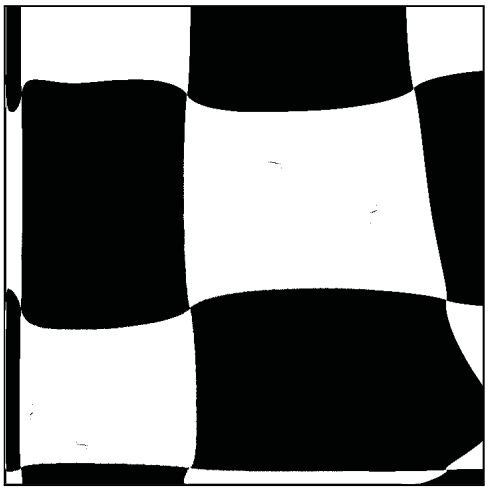

Figure 13. *Basins of attraction of the two coexisting* 4*-cycle and* 8*-cycle attractors in Figure* 11*, where the parameters are exactly as in Figure* 2*. The black region is the basin of attraction of the* 4*-cycle (four black "specks" in the white region) and the white region is that of the* 8*-cycle. On the horizontal axis* $0 \le x_1 \le 4$*, and on the vertical axis* $0 \le x_2 \le 4$*. Figure* 13 *is plotted over* 5000 *time steps.*

to each of the coexisting attractors is a fractal that fills up the entire set of initial population sizes. Consequently, both deterministic dispersal-linked models exhibit sensitive dependence of the long-term dynamical behavior on initial population sizes. Fractal basin boundaries have been studied in synchronous dispersal-linked models [5, 22, 44], epidemic models [4], as well as in physics [16, 26, 39].

6.2. Asymmetric dispersal asynchrony. In Example 3, asynchronous *symmetric* dispersal is assumed. To illustrate the impact of asynchronous *asymmetric* dispersal we now assume asymmetric dispersal in system (3), where the per capita growth rates are identical (that is, $g_1 = g_2 = g$ and $d_1 \neq d_2$).

As in Examples 1 and 3, we use the Ricker model as predispersal local population dynamics. To study the impact of asynchronous *asymmetric* dispersal on Figure 10, we keep the parameters in Example 3 fixed at $r = 2.1$ and $d_1 = 0.03$ while d_2 is varied continuously between 0 and 1 (see Figures 14 and 15). The full system stabilizes or shifts from the single 2-cycle attractor to a single limit cycle attractor (discrete Hopf bifurcation) or to a single fixed point attractor.

Similarly, when the predispersal local dynamics are chaotic, asymmetric dispersal asynchrony can change the number and nature of the coexisting attractors (see Figure 16). Figures 14, 15, and 16 highlight that the stabilizing effect of dispersal is much larger with asymmetry. Thus, asynchronous or synchronous asymmetric dispersals can stabilize or shift the local dynamics from a stable cycle or to a stable fixed point or to a stable limit cycle. However, high asynchronous dispersal rates can lead to the extinction of the species on at least one patch (Theorem 1).

7. Mixed synchronous-asynchronous dispersals in two-patch models. In this section and the next two sections, we consider system (4) with *mixed* synchronous and asynchronous

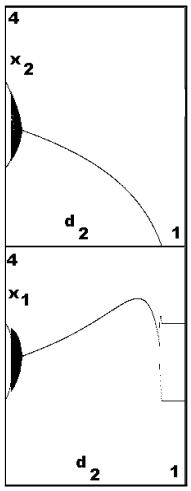

Figure 14. *After period-doubling reversals and Hopf bifurcation, Patch* 2 *population decreases monotonically to zero, while Patch* 1 *population increases monotonically to a maximum value before decreasing to the Patch* 1 *predispersal* 2*-cycle dynamics, where* $r_1 = 2.1$*,* $d_1 = 0.03$*, and* d_2 *is varied continuously between* 0 *and* 1*.*

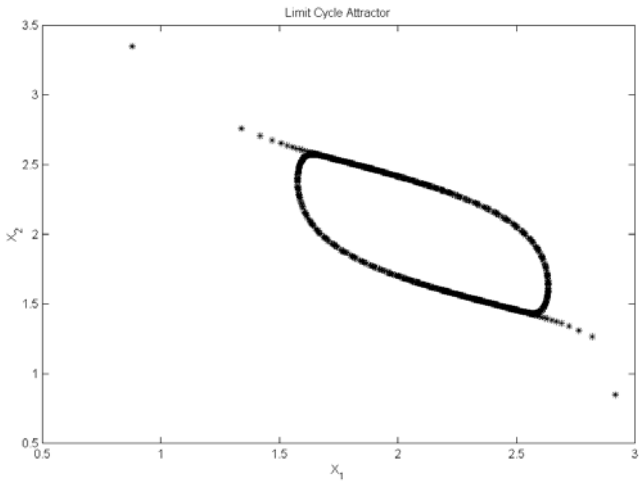

Figure 15. *A limit cycle attractor with asymmetric dispersal asynchrony, where* $r_1 = 2.1$*,* $d_1 = 0.03$*, and* $d_2 = 0.032$*.*

dispersals (that is, system (4) with $0 < \gamma < 1$). Recall that there is no population explosion in system (4). Consequently, by regular perturbation analysis at the endpoints $\gamma = 0$ and $\gamma = 1$, one obtains that when γ is sufficiently small (respectively, large) the qualitative dynamics of the dispersal-linked system under mixed synchronous and asynchronous dispersals are similar to that of the corresponding system under only synchronous (respectively, asynchronous) dispersal.

If $\gamma = 0$ and dispersal is synchronous ($0 < d_1, d_2 < 1$), it is known that the species always persists in both patches, where $g_1(0), g_2(0) > 1$ [44]. However, if $\gamma = 1$ and dispersal is asynchronous, then the species does not always persist in both patches (Theorem 3). If $\gamma \neq 1$ in

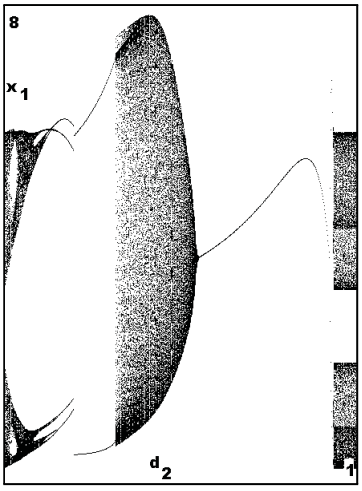

Figure 16. *Period-doubling reversals and Hopf bifurcation, where $r_1 = 2.8$, $d_1 = 0.03$, and d_2 is varied continuously between 0 and 1 (predispersal local dynamics is chaotic; see Figure 12).*

system (4), then $x_1 > 0$ or $x_2 > 0$ implies that $F_1(x) > 0$ and $F_2(x) > 0$. Consequently, in the mixed synchronous-asynchronous dispersal model with $\gamma \neq 1$, the single species either persists in both patches or becomes extinct in both patches. As in the model with asynchronous dispersal, in this section we obtain conditions that guarantee the extinction of the species in both Patches 1 and 2 of the mixed synchronous-asynchronous dispersal model.

Theorem 3. *In system (4), if $\gamma \in (0,1)$, then*

$$(1-\gamma)d_1d_2\Re_d^1\Re_d^2 < \left(1-(1-d_1)\,\Re_d^1\right)\left(1-(1-d_2)\Re_d^2\right)$$

implies that $(0,0)$ is globally asymptotically stable, where $(1-d_i)\,\Re_d^i < 1$ for each $i \in \{1,2\}$. Hence, the species becomes extinct in both Patches 1 and 2.

The proof of Theorem 3 is in the appendix.

By Theorem 3, when the product of the dispersal rates (d_1 and d_2), the intrinsic growth rates ($\Re_d^1$ and $\Re_d^2$), and $(1-\gamma)$ is smaller than the product of $\left(1-(1-d_1)\Re_d^1\right)$ and $\left(1-(1-d_2)\Re_d^2\right)$, then the species becomes extinct in all patches. In the next section, we use the Beverton–Holt model to provide examples of species extinction and persistence in mixed synchronous-asynchronous models.

8. Mixed synchronous-asynchronous dispersal models and compensatory dynamics. Mixed synchronous-asynchronous systems can exhibit species persistence in both Patches 1 and 2. To illustrate this with a simple example, we proceed as in system (3) and assume that the predispersal Patch 1 local population has reached the positive equilibrium X_1, and we let $f_1(x_1) \equiv X_1$ [43, 46]. Then the mixed model, system (4), reduces to

$$\left.\begin{aligned} x_1(t+1) &= (1-d_1)X_1 + d_2x_2(t)g_2(x_2(t)+\gamma d_1X_1), \\ x_2(t+1) &= (1-\gamma)d_1X_1 + (1-d_2)x_2(t)g_2(x_2(t)+\gamma d_1X_1). \end{aligned}\right\} \tag{6}$$

System (6) supports a globally stable positive equilibrium whenever the predispersal local patch dynamics are compensatory. We summarize these in the following result.

Theorem 4. *In system (6), let each local patch dynamics be modeled by f_i, an α-monotone concave map, with the positive fixed point $X_i \in (0, \alpha)$. Then the positive equilibrium population vector,*

$$\left((1-d_1)X_1 + \frac{d_2}{1-d_2}(\widehat{X}_2 - (1-\gamma)d_1X_1),\ \widehat{X}_2\right),$$

is globally attracting, where $\widehat{X}_2$ is the unique positive solution of the equation

$$(1-\gamma)d_1X_1 + (1-d_2)x_2g_2(x_2 + \gamma d_1X_1) = x_2.$$

That is, the dispersal-linked mixed system supports a globally stable positive fixed point whenever the predispersal local patch dynamics are compensatory.

The proof of Theorem 4 is similar to that of Theorem 2 and is omitted.

In Example 4, we use compensatory local dynamics and the Beverton–Holt model to study the dependence of the dynamics of system (4) on the mixed synchronous-asynchronous dispersal rates.

Example 4. *Consider system (4) with*

$$f_i(x_i) = \frac{a_ix_i}{1+b_ix_i}$$

for each $i \in \{1, 2\}$. Set the following parameter values:

$$a_1 = 2,\ a_2 = 2.1,\ b_1 = b_2 = 1,\ \gamma = 0.95,\ \text{and}\ d_1 = d_2 = 0.01.$$

As in Example 2, in Example 4 the local dynamics in both patches are compensatory and the system exhibits a globally stable positive equilibrium population vector at $(1.002, 1.070)$ (Theorem 4). When symmetric dispersal is assumed and $d_1 = d_2$ is varied continuously between 0 and 1, as in the asynchronous dispersal model the population in each patch decreases to zero monotonically with increasing values of the symmetric dispersal coefficients (see Figure 7). In particular, when $d_1 = d_2 > 0.7$,

$$(1-\gamma)d_1d_2\Re_d^1\Re_d^2 < \left(1-(1-d_1)\,\Re_d^1\right)\left(1-(1-d_2)\Re_d^2\right)$$

and the species becomes extinct in both patches (Theorem 3).

When $\gamma = 1$, $d_1 = d_2 > 0.53$, and all the other parameters remain at their current values in Example 4, dispersal is asynchronous and the species becomes extinct in both patches (Figure 7 and Theorem 1). To illustrate species persistence in mixed synchronous-asynchronous dispersal models, where the species is extinct in the associated asynchronous dispersal model, we keep all parameters fixed at their current values and let $\gamma = 0.75$ in Example 4. With this choice of parameters, the species persists for all values of the symmetric dispersal coefficients $d_1 = d_2 \in (0, 1)$ (see Figure 17).

As in asynchronous dispersal models, our numerical explorations show that asymmetric mixed synchronous-asynchronous dispersals are capable of shifting the population dynamics from persistence to extinction in both patches. Furthermore, our results show that in mixed systems the parameter that spans the range of possible modes of dispersal is also capable of forcing a similar shift from extinction to persistence of the species in all patches.

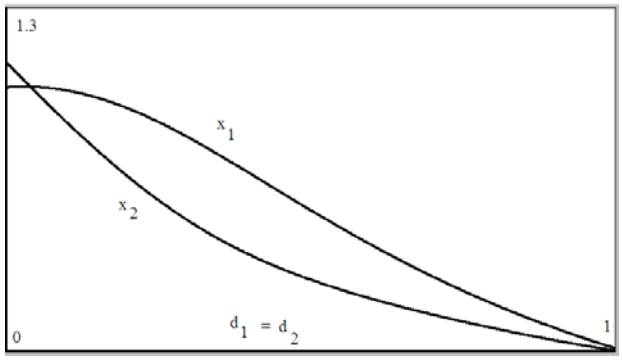

Figure 17. *Persistence in both Patches* 1 *and* 2 *with symmetric mixed synchronous-asynchronous dispersal, where* $\gamma = 0.75$, $d_1 = d_2 \in (0, 1)$, *and all other parameters remain fixed at their current values in Example* 4.

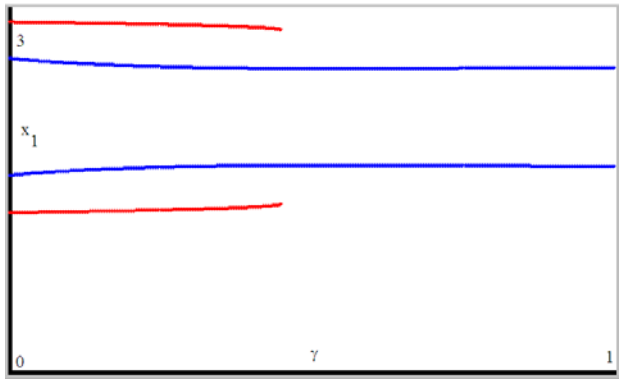

Figure 18. *Example* 5 *has two coexisting* 2*-cycle attractors for values of* $\gamma \in [0.0.45)$ *and only a single* 2*-cycle attractor for values of* $\gamma \in (0.45, 1)$.

9. Mixed synchronous-asynchronous dispersal models and overcompensatory dynamics. The qualitative dynamics of mixed synchronous-asynchronous dispersal systems are similar to those of the associated synchronous (respectively, asynchronous) dispersal systems when γ, the parameter that spans the range of possible modes of dispersal, is close to 0 (respectively, close to 1). In this section, we highlight the possible behaviors of mixed synchronous-asynchronous systems, where the local dynamics are overcompensatory and are governed by the Ricker model.

Example 5. *Consider system* (4) *with the Ricker model*

$$f_i(x_i) = x_i \exp(r_i - x_i)$$

for each $i \in \{1, 2\}$. *Set the following parameter values:*

$$r = r_1 = r_2 = 2.1, \ \gamma \in [0, 1], \ \text{and} \ d = d_1 = d_2 = 0.03.$$

With our choice of parameters, Example 4 exhibits two coexisting 2-cycle attractors (see Example 1 and Figures 1 and 18) when $\gamma \in [0, 0.45)$. That is, for these values of the parameters, the qualitative dynamics of the system with mixed synchronous-asynchronous dispersals

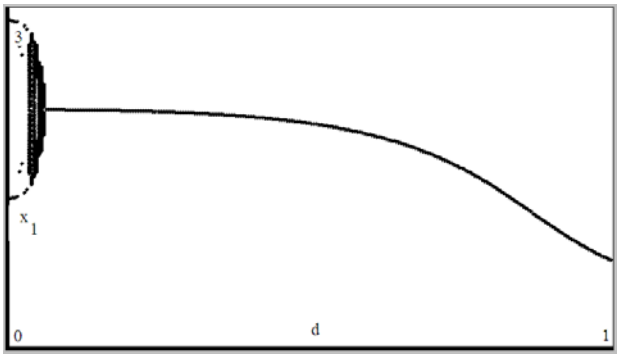

Figure 19. *The full mixed system shifts from a* 2*-cycle attractor to a limit cycle attractor, and then to a fixed point attractor, where* $r_1 = r_2 = 2.1$ *and* $\gamma = 0.4$ *while* $d_1 = d_2$ *is varied continuously between* 0 *and* 1*.*

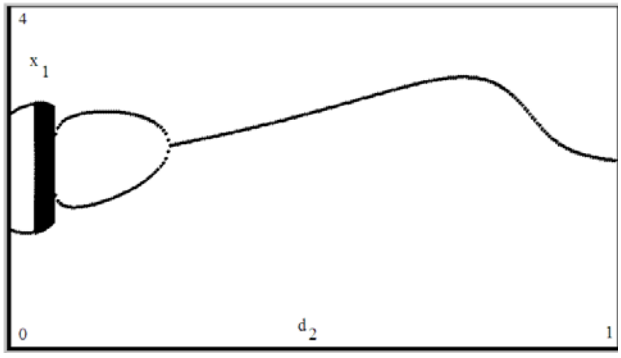

Figure 20. *The full mixed system shifts from a* 2*-cycle attractor to a limit cycle attractor back to a* 2*-cycle attractor, and then to a fixed point attractor, where* $r_1 = r_2 = 2.1$*,* $\gamma = 0.4$*, and* $d_1 = 0.03$ *while* d_2 *is varied continuously between* 0 *and* 1*.*

are the same as those of the corresponding system with only dispersal synchrony. Furthermore, our simulations show that the full system shifts from the two (multiple) 2-cycle attractors to a single 2-cycle attractor (see Example 3 and Figures 10 and 18) when $\gamma \in [0.45, 1]$. In this case, the qualitative dynamics of the mixed synchronous-asynchronous dispersal model are the same as those of the corresponding system with only asynchronous dispersal.

To study the impact of symmetric mixed synchronous-asynchronous dispersals on Example 5, we let $\gamma = 0.4$ and vary d continuously between 0 and 1 while r is kept fixed at 2.1. Figure 19 shows that with increasing values of d, the mixed system shifts from a 2-cycle attractor to a limit cycle attractor and then to a fixed point attractor.

Mixed models under asymmetric dispersals can exhibit qualitative dynamics that are different from those of the associated mixed models under symmetric dispersal. To demonstrate this difference, we let $r_1 = r_2 = 2.1$, $\gamma = 0.4$, and $d_1 = 0.03$, and we vary d_2 continuously between 0 and 1 (see Figures 19 and 20). Unlike Figure 19, Figure 20 shows that with increasing values of the asymmetric dispersal coefficient d_2, the mixed system shifts from a 2-cycle attractor to a limit cycle attractor and then returns to a 2-cycle attractor. This return to a 2-cycle attractor after a limit cycle attractor is different from the bifurcations in Figure 19

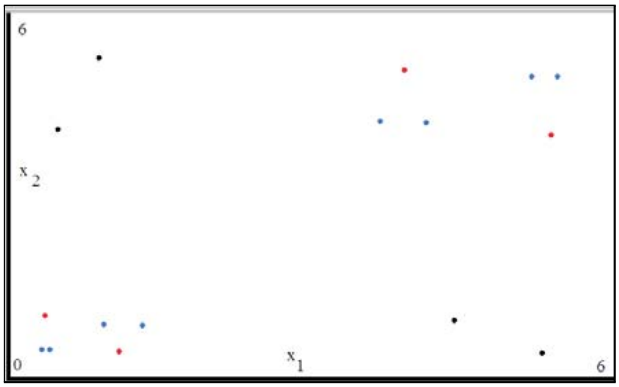

Figure 21. *Three coexisting attractors in Example 6: Two 4-cycle (red and black dots) attractors coexisting with an 8-cycle (blue dots) attractor. Figure 21 is plotted over 3000 time steps.*

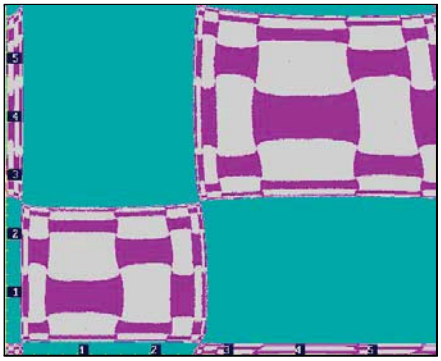

Figure 22. *Basins of attraction of the three coexisting attractors in Figure 21. Figure 22 is plotted over 5000 time steps.*

with the symmetric mixed dispersal. However, with increasing values of the asymmetric dispersal coefficient, as in Figure 19, the 2-cycle attractor undergoes a period-doubling reversal bifurcation (see Figure 20).

Recall that Figures 1, 2, 3, 4, 10, 11, 12, and 13 and Tables 1 and 2 demonstrate that synchronous dispersal-linked systems can be more sensitive to initial population sizes than the corresponding asynchronous ones. Next, we use an example with an intermediate value of the parameter γ to illustrate that mixed dispersal-linked systems can be more (respectively, less) sensitive to initial population sizes than the corresponding asynchronous (respectively, synchronous) systems.

Example 6. *In Example 5, set the following parameter values:*

$$r_1 = r_2 = 2.7,\ \gamma = 0.5,\ \textit{and}\ d_1 = d_2 = 0.03.$$

Figure 21 exhibits the three coexisting attractors (two 4-cycle attractors and an 8-cycle attractor) of Example 6, and Figure 22 shows their basins of attraction. However, the associated synchronous model of Example 6 ($\gamma = 0$) has four coexisting attractors (see Figures 2 and 4), while the associated asynchronous model ($\gamma = 1$) has two coexisting attractors (see

Figures 11 and 13). These examples illustrate that when predispersal dynamics are cyclic, then synchronous-asynchronous dispersal-linked mixed systems become more sensitive to initial population sizes as the values of γ decrease.

10. Conclusions. In this paper, we generalize the classical single species, discrete-time, two-patch synchronous dispersal linked-model to a mixed synchronous-asynchronous dispersal model which includes a model of Doebeli for asynchronous dispersal. We extend an idea of Doebeli and show how the detailed timing of dispersal can affect the global dynamics of dispersal-linked systems [7, 8]. The dynamics of discrete-time population models connected by either asynchronous or mixed synchronous-asynchronous dispersals depend on the dispersal rates and the predispersal local patch dynamics. In asynchronous models, the species becomes extinct on at least one patch when the dispersal rates are high, while it persists when the dispersal rates are low. However, in mixed synchronous-asynchronous systems, depending on the dispersal rates, the range of possible modes of dispersals, and the intrinsic growth rates in the two patches, the pioneer species either persists in all patches or becomes extinct in all patches.

The results of Hastings and Levin on continuous-time metapopulation models and those of Yakubu and Castillo-Chavez on discrete-time models connected by synchronous dispersal predict that an equilibrium population is stable only if it corresponds to a stable equilibrium within each patch [22, 29, 44]. Our results support this prediction for two-patch discrete-time models under asynchronous dispersal rates as long as the dispersal rate from Patch 2 to Patch 1 is low and the predispersal local patch dynamics are compensatory.

Local unstructured populations under compensatory or overcompensatory dynamics tend to support single attractors; that is, the population has a single outcome. However, in dispersal-linked population models with overcompensatory local dynamics, both synchronous and asynchronous dispersals can fracture the basins of attraction through their support of multiple attractors. Hastings [22] and Yakubu and Castillo-Chavez [44] showed that both symmetric and asymmetric synchronous dispersals are capable of generating multiple attractors where the predispersal local patch dynamics are overcompensatory. Our results show that asynchronous dispersal-linked systems support multiple attractors with a smaller number of distinct attractors than the corresponding synchronous systems. The interactions via dispersal of various forms of intraspecific competition has not only led to the generation of a dynamical landscape capable of supporting multiple attractors but also has aided our understanding of the role that initial population sizes play in the ultimate fate (life-history) of dispersal-linked systems. As the complexity of the local dynamics increases, dispersal-linked deterministic systems exhibit sensitive dependence of the long-term behavior on the initial population sizes. The smaller number of distinct attractors makes synchronous dispersal-linked systems more sensitive to initial population sizes than the corresponding asynchronous systems [5, 16, 22, 26, 44]. Complex overcompensatory local dynamics give rise to sensitive dependence of mixed dispersal-linked dynamics on initial population sizes when the dominant dispersal mode is synchronous. However, our results show that mixed dynamics are less sensitive to initial population sizes when the dominant dispersal mode is asynchronous.

Asymmetric dispersal is capable of stabilizing or shifting the predispersal local dynamics from overcompensatory to compensatory dynamics. Thus, asymmetry enhances the stabilizing role of dispersal in synchronous, asynchronous, and mixed synchronous-asynchronous models.

Our results show that it is possible for the long-term qualitative dynamics of models with mixed synchronous-asynchronous dispersals to be identical to that of the corresponding model with either only dispersal synchrony or only dispersal asynchrony. That is, in mixed synchronous-asynchronous models, the dominant mode of dispersal is capable of driving the population dynamics of the dispersal-linked systems.

Appendix.

Proof of Lemma 1. Recall that $F_1(x) = (1-d_1)f_1(x_1) + d_2x_2g_2(x_2+\gamma d_1f_1(x_1))$ and $F_2(x) = (1-\gamma)d_1f_1(x_1) + (1-d_2)x_2g_2(x_2+\gamma d_1f_1(x_1))$, where $x=(x_1,x_2)\in\mathbb{R}^2_+$. Since each $g_i>0$, $0\le\gamma\le 1$, and $0<d_i<1$, we have $F_1(x)>0$ and $F_2(x)>0$ whenever $x_1,x_2>0$. That is, the positive cone is positively invariant.

Next, we show that for each $i\in\{1,2\}$ the sequence $\{F_i^t(x)\}_{t\ge0}$ is bounded. By the monotonicity condition on g_2 and the fact that $0<d_1,d_2<1$, we obtain that

$$F_1(x)+F_2(x)\le f_1(x_1)+f_2(x_2).$$

If $x_i\le\max I_i$, then $f_i(x_i)=x_ig_i(x_i)\le\max I_i$, but if $x_i>\max I_i$, then $f_i(x_i)=x_ig_i(x_i)<x_i$, where $I_i\equiv f_i([0,X_i])$. As a result,

$$F_1(x)+F_2(x)\le\begin{cases}\max I_1+\max I_2 & \text{if } x_1\le\max I_1 \text{ and } x_2\le\max I_2,\\ x_1+\max I_2 & \text{if } x_1>\max I_1 \text{ and } x_2\le\max I_2,\\ \max I_1+x_2 & \text{if } x_1\le\max I_1 \text{ and } x_2>\max I_2,\\ x_1+x_2 & \text{if } x_1>\max I_1 \text{ and } x_2>\max I_2.\end{cases}$$

Hence, each sequence $\{F_i^t(x)\}_{t\ge0}$ is bounded. Consequently, no point in system (4) has an unbounded orbit.

Proof of Theorem 1. By Lemma 1, the ω-limit set of every point in $[0,\infty)\times[0,\infty)$ is nonempty. As a result, we consider an arbitrary point $y=(y_1,y_2)\in[0,\infty)\times[0,\infty)$. Let $x=(x_1,x_2)\in\omega(y)$. By definition, there exists $n_i\to+\infty$ such that $F^{n_i}(y)\to x$ as $n_i\to+\infty$.

To prove (i), we need to show that $F_2^{n_i}(y)\to0$ as $n_i\to+\infty$. Define the function $V:\mathbb{R}^2_+\to\mathbb{R}_+$ by $V(y_1,y_2)=y_2$. Next, we show that V is a Lyapunov function for system (3). Hence, it decreases to a limit point with second coordinate zero.

If $y_2>0$, then $V(F(y))<(1-d_2)\Re_d^2y_2$ and $V(F(y))<V(y)$ whenever $(1-d_2)\Re_d^2<1$. Therefore, for all points $y=(y_1,y_2)$ satisfying $y_2>0$ we know that $V(F(y))<V(y)$. If $x_2>0$, then $V(F(x))<V(x)$. However, this is impossible for an ω-limit point. This proves (i).

To prove (ii), notice that the eigenvalues of the Jacobian matrix $DF(0,0)$ are $(1-d_1)\Re_d^1$ and $(1-d_2)\Re_d^2$. Consequently, $(0,0)$ is unstable whenever $(1-d_1)\Re_d^1>1$ and $(1-d_2)\Re_d^2>1$. Furthermore, $F_1(x)\ge(1-d_1)f_1(x_1)$ and $(1-d_1)\Re_d^1>1$ imply that $\{0\}$ is an unstable fixed point of the one-dimensional map $\widehat{f}_1(x_1)=(1-d_1)f_1(x_1)$. Also, $(1-d_1)\Re_d^1>1$ implies that $\widehat{f}_1$ has a unique positive fixed point, denoted by $\widehat{X}_1$. Moreover, $\widehat{f}_1(x_1)>x_1$ whenever $0<x_1<\widehat{X}_1$ and $\widehat{f}_1(x_1)<x_1$ whenever $x_1>\widehat{X}_1$. Consequently, $\widehat{I}_1\equiv\widehat{f}_1([0,\widehat{X}_1])$ is a global attractor; that is, every initial population eventually reaches a limit in $\widehat{I}_1$. Let $\widehat{J}_1\equiv\widehat{f}_1\left([\widehat{X}_1,\max\widehat{I}_1]\right)$, where $\max\widehat{I}_1$ is the largest endpoint of $\widehat{I}_1$. Notice that the smallest endpoint of $\widehat{J}_1$, $\min\widehat{J}_1$, is positive. That is, $\min\widehat{J}_1>0$. Furthermore, $\lim_{t\to\infty}F_1^t(x)\ge\lim_{t\to\infty}\widehat{f}_1^t(x_1)\ge\min\widehat{J}_1$ for any $x_1>0$. Hence, the species persists in Patch 1.

To prove (iii) and (iv), notice that when Patch 2 is empty (that is, when $(1-d_2)\Re_d^2 < 1$), the Patch 1 population is governed by the "limiting equation" $F_1(x) = (1-d_1)f_1(x_1)$. That Patch 1 dynamics are compensatory implies that $(0,0)$ is globally stable when $\Re_d < 1$, while $(0,0)$ is unstable and $(g_1^{-1}(\frac{1}{1-d_1}),0)$ is globally stable when $(1-d_1)\Re_d^1 > 1$ and $(1-d_2)\Re_d^2 < 1$. This completes the proof.

The following result is useful in the proof of Theorem 2.

Lemma 2. *Let $\widehat{f}_2(x_2) = (1-d_2)x_2 g_2(x_2 + d_1X_1)$. If Patch 2 dynamics are compensatory and $(1-d_2)\Re_d^2 > 1$, then $\widehat{f}_2$ is orientation-preserving and all positive densities approach the positive equilibrium at $\widehat{X}_2 = g_2^{-1}(\frac{1}{1-d_2}) - d_1X_1$ monotonically under $\widehat{f}_2$ iterations.*

Proof of Lemma 2. First, notice that $(1-d_2)\Re_d^2 > 1$ implies that $\widehat{f}_2$ has a unique positive fixed point at $\widehat{X}_2$. To prove the result, we need to show that $\widehat{X}_2$ is globally stable in $(0,\infty)$. If we know that $\widehat{f}_2$ cannot support 2-*cycles*, then Sharkovskii's theorem implies that $\widehat{f}_2$ cannot have cycles except for a fixed point. Using the monotonicity condition on g_2 and the fact that $\widehat{X}_2 > 0$, we obtain that zero and infinity are repellors under $\widehat{f}_2$ iterations. Since no point overshoots X_2, we obtain that the unique positive fixed point of $\widehat{f}_2$, $\widehat{X}_2$ is globally stable in $(0,\infty)$ and no point overshoots it under $\widehat{f}_2$ iterations.

Now, we prove that $\widehat{f}_2$ cannot support 2-*cycles*. Suppose that $\widehat{f}_2$ has a 2-*cycle*. Since Patch 2 predispersal local dynamics are compensatory and $(1-d_2)\Re_d^2 > 1$, we have that the fixed point $\widehat{X}_2$ must be unstable and $(\widehat{f}_2)'(\widehat{X}_2) < -1$. That is, $(\widehat{f}_2)'(\widehat{X}_2) = (1-d_1)(g_2(X_2) + \widehat{X}_2 g_2'(X_2)) < -1$. Since $g_i(X_i) = 1$ and $\widehat{X}_2 = X_2 - d_1X_1$, we have

$$\begin{aligned}(1-d_1)f_2'(X_2) &= (1-d_1)(1 + X_2 g_2'(X_2))\\ \leq (1-d_1)(1 + (\widehat{X}_2 + d_1X_1)g_2'(X_2)) &< -1 + (1-d_1)d_1X_1 g_2'(X_2) < 0.\end{aligned}$$

This contradicts the fact that $(1-d_1)f_2'(X_2) > 0$ (compensatory dynamics). As a result, $\widehat{f}_2$ cannot support 2-*cycles*. This establishes Lemma 2.

Proof of Theorem 2. Notice that system (4) is essentially a one-dimensional system. By Lemma 2, $\lim_{t\to\infty} F_2^t(x) = (g_2^{-1}(\frac{1}{1-d_2}) - d_1X_1)$ for each point $x = (x_1, x_2) \in (0,\infty)\times(0,\infty)$. Consequently, $\lim_{t\to\infty} F_1^t(x) = (1-d_1)X_1 + \frac{d_2}{1-d_2}(g_2^{-1}(\frac{1}{1-d_2}) - d_1X_1)$, and the positive fixed point is globally asymptotically stable in $(0,\infty)\times(0,\infty)$.

Proof of Theorem 3. To prove Theorem 3, we proceed as in the proof of Theorem 1 and define the function $V : \mathbb{R}_+^2 \to \mathbb{R}_+$ by

$$V(y_1, y_2) = y_1 + by_2,$$

where

$$0 < \frac{d_2\Re_d^2}{1-(1-d_2)\Re_d^2} < b < \frac{1-(1-d_1)\,\Re_d^1}{(1-\gamma)d_1\Re_d^1}.$$

Next, we show that V is a Lyapunov function for system (4), where $\gamma \neq 0, 1$. Hence, it decreases to a limit point with both coordinates equal to zero.

$V(F(y)) = ((1-d_1) + (1-\gamma)bd_1)\, f_1(y_1) + (d_2 + b(1-d_2))y_2 g_2(y_2 + \gamma d_1 f_1(y_1))$. If $y = (y_1, y_2) \neq (0,0)$, then

$$V(F(y)) < ((1-d_1) + (1-\gamma)bd_1)\,\Re_d^1 y_1 + (d_2 + b(1-d_2))\Re_d^2 y_2.$$

With our choice of the positive constant b, we have

$$((1-d_1)+(1-\gamma)bd_1)\,\Re_d^1 < 1$$

and

$$(d_2+b(1-d_2))\Re_d^2 < b.$$

Hence $V(F(y)) < V(y)$ whenever $0 < \frac{d_2\Re_d^2}{1-(1-d_2)\Re_d^2} < \frac{1-(1-d_1)\Re_d^1}{(1-\gamma)d_1\Re_d^1}$. Therefore, for all points $y=(y_1,y_2)\neq(0,0)$ we know that $V(F(y)) < V(y)$. Now, proceed exactly as in the proof of Theorem 1 to complete the proof.

Periodic Solutions in Hamiltonian Systems, Averaging, and the Lunar Problem*

Patricia Yanguas†, Jesús F. Palacián†, Kenneth R. Meyer‡, and H. Scott Dumas‡

Abstract. We investigate the existence, characteristic multipliers, and stability of periodic solutions to a Hamiltonian vector field which is a small perturbation of a vector field tangent to the fibers of a circle bundle. Our primary examples are the planar lunar and spatial lunar problems of celestial mechanics, i.e., the restricted three-body problem where the infinitesimal is close to one of the primaries. By averaging the perturbation over the fibers of the circle bundle one obtains a Hamiltonian system on the reduced (orbit) space of the circle bundle. Our goal in the first part of the paper is to state and prove results which have hypotheses on the reduced system and have conclusions about the full system. Starting with the classical work of Reeb, we give a summary of lemmas, corollaries, and theorems about the existence, characteristic multipliers, and stability of periodic solutions to Hamiltonian systems which are perturbations of circle bundle flows. By reformulating the classical results in modern language and giving alternative proofs in place of the original proofs, we are able to infer new consequences of these classical results. The second part of the paper is devoted to applications of the general results. We apply these general results to the planar and spatial lunar problem. After scaling, the lunar problem is a perturbation of the Kepler problem, which after regularization is a circle bundle flow. We find the classical near-circular periodic solutions and the near-rectilinear periodic solutions. Then we compute their approximate multipliers and show that there is a "twist." However, the twist is too degenerate to apply the classical KAM theorem on invariant tori. We also find symmetric periodic solutions which are continuations of elliptic solutions of the Kepler problem.

1. Introduction.

For us the lunar problem is the circular restricted three-body problem where the infinitesimal is close to one of the primaries. After scaling the restricted problem, the lunar problem is a perturbation of the Kepler problem, and Moser [39] has shown that the Kepler problem after regularization is a circle bundle flow. Thus, the lunar problem is a prototype for Hamiltonian systems that arise as perturbations of circle bundle flows.

By averaging the perturbation over the fibers of the circle bundle, Reeb [43] and Moser [39] obtained a Hamiltonian vector field on the base (or reduced) space; see also [32, 33]. They were able to give sufficient conditions for the existence of periodic solutions by looking at the system on the base alone.

Since then a number of papers have appeared which analyze systems by looking at the reduced system only; see [7, 16, 21, 27, 28, 29, 41] and the many references therein. One starts with a small parameter which is a measure of the perturbation of an integrable system where all solutions are periodic. Then one normalizes (or averages) the perturbation term-by-term in the small parameter. After a finite number of terms have been normalized, the higher-order perturbations are truncated, giving an approximation of the full system. This approximation is well defined on the lower-dimensional reduced space. Being lower-dimensional, sometimes just two-dimensional, the system on the reduced space is easier to understand. But not all the features of the full system are accurately reflected by the reduced system; it typically does not display the breakdown of invariant tori, ergodic regions, solenoids, etc.

Our goal in the first part of the paper is to state, prove, and apply results which have hypotheses on the reduced system and have conclusions about the full system. Starting with the work of Reeb, we give in section 2 a summary of lemmas, corollaries, and theorems about the existence, characteristic multipliers, and parametric stability of periodic solutions for Hamiltonian systems which are perturbations of circle bundle flows. Some of the results are old, some are just extensions, and a few are new. Lemma 2.1 is the key to an original direct proof of Reeb's theorems using symplectic geometry arguments. Corollary 2.3 constitutes a new application of Krein–Gel'fand theory [47] about the stability of linear Hamiltonian vector fields with periodic coefficients. Theorem 2.5 connects, through Lemma 2.1, the theory of reduction in Hamiltonian systems with the existence of KAM tori in a simple way. Theorem 2.6, about the existence of symmetric periodic solutions, is also new.

The second part of the paper is devoted to applying these general results to the lunar problem. In section 3 we apply these general results to the planar lunar problem and in section 4 to the spatial lunar problem. In the planar problem we find Hill's classical near-circular periodic solutions, compute their approximate multipliers, and then show that there is a "twist" term. The twist is of too high an order in the perturbation parameter to apply the classical KAM theorem. We also find symmetric periodic solutions which are continuations of elliptic solutions of the Kepler problem.

For the spatial problem we again find the classical Hill periodic solutions, but also the near-rectilinear periodic solutions, and we compute their approximate multipliers. These solutions are shown to be parametrically stable and elliptic. Again we compute a twist term for all these periodic solutions. We pay particular attention to the near-rectilinear periodic solutions and show that they are not collision orbits.

2. Averaging theorems.

Here we summarize some general results from the classic paper by Reeb [43] on averaging Hamiltonian systems on manifolds, along with some obvious corollaries. We also extend these results to systems with discrete symmetries.

Let (M, Ω) be a symplectic manifold of dimension $2n$, $\mathcal{H}_0 : M \to \mathbb{R}$ a smooth Hamiltonian which defines a Hamiltonian vector field $Y_0 = (d\mathcal{H}_0)^{\#}$ with symplectic flow ϕ_0^t (see [1]). Let $\mathbb{I} \subset \mathbb{R}$ be an interval such that each $h \in \mathbb{I}$ is a regular value of $\mathcal{H}_0$ and $\mathcal{N}_0(h) = \mathcal{H}_0^{-1}(h)$ is a compact connected circle bundle over a base space $B(h)$ with projection $\pi : \mathcal{N}_0(h) \to B(h)$. Assume the vector field Y_0 is everywhere tangent to the fibers of $\mathcal{N}_0(h)$; i.e., assume that all the solutions of Y_0 in $\mathcal{N}_0(h)$ are periodic. There is no loss of generality [22] in assuming that all these periodic solutions have periods smoothly depending only on the value of the

Hamiltonian; i.e., the period is a smooth function $T = T(h)$ (sometimes the dependence on h will be omitted in the notation).

For example, consider a pair of harmonic oscillators

$$\ddot{x} + x = 0, \qquad \ddot{y} + y = 0,$$

which may be written as the Hamiltonian system

$$\dot{x} = \frac{\partial H}{\partial u} = u, \qquad \dot{u} = -\frac{\partial H}{\partial x} = -x, \qquad \dot{y} = \frac{\partial H}{\partial v} = v, \qquad \dot{v} = -\frac{\partial H}{\partial y} = -y,$$

with Hamiltonian

$$H = \frac{1}{2}(x^2 + u^2) + \frac{1}{2}(y^2 + v^2).$$

In polar coordinates

$$r^2 = x^2 + u^2, \qquad \theta = \tan^{-1} u/x, \qquad \rho^2 = y^2 + v^2, \qquad \phi = \tan^{-1} v/y,$$

the equations become

$$\dot{r} = 0, \qquad \dot{\theta} = -1, \qquad \dot{\rho} = 0, \qquad \dot{\phi} = -1,$$

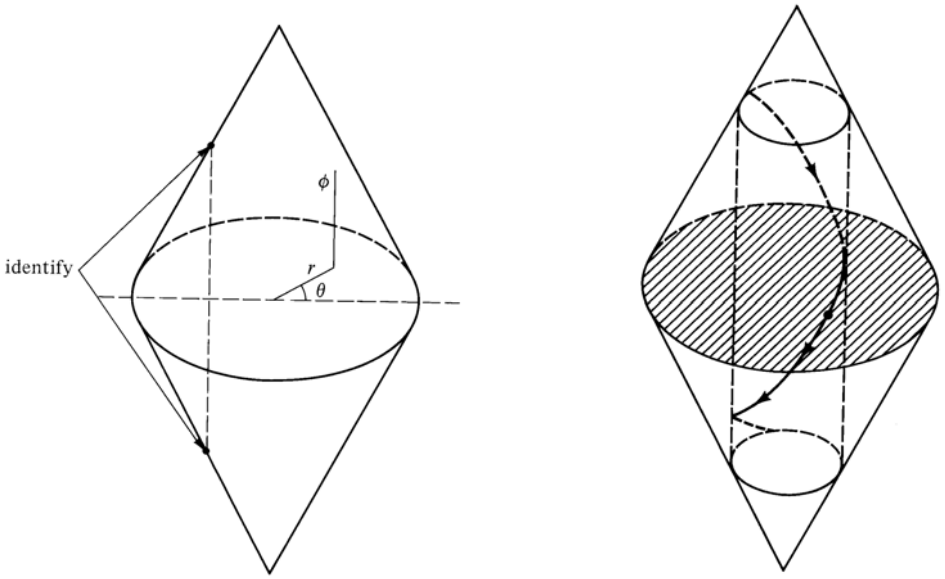
and they admit the two integrals r and ρ.

The energy level $E = H^{-1}(\frac{1}{2})$ is a 3-sphere and is invariant under the flow. All the solutions are 2π-periodic, and so the orbits are circles. Thus the 3-sphere is a union of circles. We can use polar coordinates to coordinatize the sphere provided we are careful to observe the proper conventions.

Starting with the polar coordinates r, θ, ρ, ϕ for $\mathbb{R}^4$, we note that on the 3-sphere, $E = r^2 + \rho^2 = 1$; so we may discard ρ and take $0 \le r \le 1$. We will use r, θ, ϕ as coordinates on S^3. Now r, θ with $0 \le r \le 1$ are just polar coordinates for the closed unit disk. For each point of the open disk, there is a circle with coordinate ϕ (defined mod 2π), but when $r = 1$, $\rho = 0$; so the circle collapses to a point over the boundary of the disk. The geometric model of S^3 is two solid cones with points on the boundary cones identified, as shown in Figure 1a. Through each point in the open unit disk with coordinates r, θ there is a line segment (the dashed line) perpendicular to the disk. The angular coordinate ϕ is measured on this segment, $\phi = 0$ is the disk, $\phi = \pi$ is the upper boundary cone, and $\phi = -\pi$ is the lower boundary cone. Each point on the upper boundary cone with coordinates r, θ, $\phi = \pi$ is identified with the point on the lower boundary cone with coordinates r, θ, $\phi = -\pi$.

In this model there are two special orbits where $r = 0$ and $\rho = 0$. Other than these two special circles, on each orbit, as θ increases by 2π, so does ϕ. Thus, each such orbit meets the open disk where $\phi = 0$ (the shaded disk in Figure 1b) in one point. We can identify each such orbit with the unique point where it intersects the disk. One special orbit meets the disk at the center, and so we can identify it with the center. The other is the outer boundary circle, which is a single orbit. When we identify this circle with a point, the closed disk with its outer circle identified with a point becomes a 2-sphere.

Thus, the 3-sphere S^3 is the union of circles. The quotient space obtained by identifying a circle with a point is a 2-sphere (the Hopf fibration of S^3).



(a) A model of S^3 (b) An orbit on S^3

Figure 1. *S^3 as a circle bundle over S^2.*

Let D be the open disk $\phi = 0$ (the shaded disk in Figure 1b). The union of all the orbits which meet D is a product of a circle and a 2-disk, so each point not on the special circle $r = 1$ lies in an open set that is the product of a 2-disk and a circle. By reversing r and ρ in the discussion above, the circle where $r = 1$ has a similar neighborhood. So locally the 3-sphere is the product of a disk and a circle, but the sphere is not the product of a 2-manifold and a circle (the sphere has a trivial fundamental group, but such a product would not).

In higher dimensions, consider n harmonic oscillators all with frequency 1; i.e., let $M = \mathbb{R}^{2n}$, $\mathcal{H}_0 = \frac{1}{2}\sum_1^n (x_i^2 + y_i^2)$, and $\mathcal{N} = \mathcal{H}_0^{-1}(h) = S^{2n-1}$ (the sphere of radius $\sqrt{2h}$). Then all solutions are 2π-periodic and B is the complex projective $(n-1)$-space, $\mathbb{CP}^{n-1}$. $\mathbb{CP}^1$ is homeomorphic to the 2-sphere, so when $n = 2$ the reduced space is $B = S^2$ as illustrated above.

Another example is the geodesic flow on the n-sphere S^n; i.e., $M = TS^n$ (the tangent bundle of the sphere), $\mathcal{H}_0 : M \to \mathbb{R} : v_p \mapsto |v_p|$ ($\mathcal{H}_0(v_p)$ is the length of the vector $v_p \in T_pM$), $\mathcal{N} = \{v_p \in TS^n : |v_p| = h\}$ (the h-sphere bundle), and B is $G_{2,n+1}$, the Grassmannian manifold of oriented 2-planes in $\mathbb{R}^{n+1}$ (see, for instance, [38]). If $n = 2$, then B is S^2, whereas it is $S^2 \times S^2$ when $n = 3$.

2.1. Reeb's theorems. Here we state and prove two of Reeb's theorems in more modern terminology. Our proof gives more of the Hamiltonian structure and therefore leads to further applications.

Theorem 2.1. *The base space B inherits a symplectic structure ω from (M, Ω); i.e., (B, ω) is a symplectic manifold.*

This is the original reduction theorem. Now let us look at a perturbation of this situation.

Let ε be a small parameter, $\mathcal{H}_1 : M \to \mathbb{R}$ be smooth, $\mathcal{H}_\varepsilon = \mathcal{H}_0 + \varepsilon\mathcal{H}_1$, $Y_\varepsilon = Y_0 + \varepsilon Y_1 = d\mathcal{H}_\varepsilon^{\#}$, $\mathcal{N}_\varepsilon(h) = \mathcal{H}_\varepsilon^{-1}(h)$, and ϕ_ε^t be the flow defined by Y_ε.

Let the average of $\mathcal{H}_1$ be

$$\bar{\mathcal{H}} = \frac{1}{T}\int_0^T \mathcal{H}_1(\phi_0^t)dt,$$

which is a smooth function on $B(h)$, and let $\bar{\phi}^t$ be the flow on $B(h)$ defined by $\bar{Y} = d\bar{\mathcal{H}}^{\#}$.

A critical point of $\bar{\mathcal{H}}$ is *nondegenerate* if the Hessian at the critical point is nonsingular, and the function $\bar{\mathcal{H}}$ is a *Morse function* if all its critical points are nondegenerate. The *index* of a nondegenerate critical point p of $\bar{\mathcal{H}}$ is the dimension of the maximal linear subspace where the Hessian of $\bar{\mathcal{H}}$ at p is negative definite.

Theorem 2.2. *If $\bar{\mathcal{H}}$ has a nondegenerate critical point at $\pi(p) = \bar{p} \in B$ with $p \in \mathcal{N}_0$, then there are smooth functions $p(\varepsilon)$ and $T(\varepsilon)$ for ε small with $p(0) = p$, $T(0) = T$, and $p(\varepsilon) \in \mathcal{N}_\varepsilon$, and the solution of Y_ε through $p(\varepsilon)$ is $T(\varepsilon)$-periodic.*

If $\bar{\mathcal{H}}$ is a Morse function, then Y_ε has at least $\chi(B)$ periodic solutions, where $\chi(B)$ is the Euler–Poincaré characteristic of B.

The proof of Theorem 2.2 yields additional corollaries. The essence of the proof of the local part of Theorem 2.2 is the existence of symplectic coordinates for a tubular neighborhood of the orbit through p. Here we give the proof of the existence of these coordinates.

Lemma 2.1. *Let $p \in \mathcal{N}_0(h)$, with $h \in \mathbb{I}$ fixed. Then there are symplectic coordinates (I, θ, y), valid in a tubular neighborhood of the periodic solution $\phi_0^t(p)$ of $Y_0(h)$, where (I, θ) are action-angle coordinates and $y \in \mathbb{N}$, where $\mathbb{N}$ is an open neighborhood of the origin in $\mathbb{R}^{2n-2}$. The point p corresponds to $(I, \theta, y) = (0, 0, 0)$.*

In these coordinates $\mathcal{H}_0$ is a function of I only; i.e., $\mathcal{H}_0 = \mathcal{H}_0(I)$. A local cross section is $\theta = \alpha$, and a local cross section in an energy level is $\theta = \alpha, I = \beta$, where α, β are constants. In addition, $y \in \mathbb{N}$ are coordinates in the cross section in the energy level.

The Hamiltonian is

$$\mathcal{H}_\varepsilon(I, \theta, y) = \mathcal{H}_0(I) + \varepsilon\mathcal{H}_1(I, \theta, y) = \mathcal{H}_0(I) + \varepsilon\bar{\mathcal{H}}(I, y) + O(\varepsilon^2). \tag{1}$$

Proof. By the Hamiltonian flow box theorem [36, 40] there are local symplectic coordinates $u = (u_1, \dots, u_{2n})$ for M in a neighborhood W of p such that p corresponds to $u_j = 0$, $j = 1, \dots, 2n$ (note that we locate p at the origin). The Hamiltonian is $\mathcal{H}_0 = u_{n+1}$ (so we take $h = 0$), and Y_0 is the differential equation

$$\dot{u}_1 = \partial\mathcal{H}_0/\partial u_{n+1} = 1, \qquad \dot{u}_j = 0, \quad j = 2, \dots, 2n.$$

A local cross section to the flow of Y_0 is $\Sigma = \{u : u_1 = 0\} \cap W$, and a local cross section in an energy level $\mathcal{H}^{-1}(0)$ is $\sigma = \{u : u_1 = u_{n+1} = 0\} \cap W$.

The validity of these coordinates can be extended to a tubular neighborhood $U = \{\phi_0^t(q) : q \in \Sigma, t \in \mathbb{R}\}$ of the Y_0-orbit through p. Let $Z = \Sigma \times \mathbb{R}$, and let $\eta : Z \to U : (q, t) \to \phi_0^t(q)$ be a symplectic map. The vector field Y_0 on U lifts to $\dot{u}_1 = 1$, $\dot{u}_j = 0$, $j = 2, \dots, 2n$, on Z.

Recall that we assume that the period T depends smoothly on the value of $\mathcal{H}_0$, which in these coordinates means that the period depends smoothly on u_{n+1}, i.e., that $T(u_{n+1})$ is

smooth. Let $F(w)$ satisfy $dF/dw = -2\pi/T(w)$, and let $f = F^{-1}$. Change variables on Z from $\{u_1, u_{n+1}\}$ to $\{I, \theta\}$ by

$$I = f(u_{n+1}), \qquad \theta = -\frac{u_1}{f'(u_{n+1})}.$$

One checks that $dI \wedge d\theta = du_1 \wedge du_{n+1}$, so this is a symplectic change of variables. Since $I = f(u_{n+1})$, we have $\mathcal{H}_0 = u_{n+1} = F(I)$ and $\dot\theta = -F'(I) = 2\pi/T(I)$. Thus, when t increases by $T(I)$, the variable θ increases by 2π and so can be considered as an angular variable. Therefore, $(I, u_2, \dots, u_n, \theta, u_{n+2}, \dots, u_{2n})$ is a full set of symplectic coordinates for Z and, via η, a full set of symplectic coordinates for U. Let $v = (u_2, \dots, u_n, u_{n+2}, \dots, u_{2n})$. So the Hamiltonian is

$$\mathcal{H}_\varepsilon(I, \theta, v) = \mathcal{H}_0(I) + \varepsilon \mathcal{H}_1(I, \theta, v). \tag{2}$$

We use the method of Lie transforms to effect the average. Let $W_1(I, \theta, v)$ be the solution of

$$\mathcal{H}_1 + \{\mathcal{H}_0, W_1\} = \mathcal{H}_1 + \frac{\partial \mathcal{H}_0}{\partial I}\frac{\partial W_1}{\partial \phi} = \bar{\mathcal{H}},$$

that is,

$$W_1 = \int^\theta \frac{\partial \mathcal{H}_0}{\partial I}^{-1} \{\mathcal{H}_1 - \bar{\mathcal{H}}\} d\theta.$$

Since $\bar{\mathcal{H}}$ is the mean value of $\mathcal{H}_1$, the function W_1 is 2π-periodic in θ. Let us change variables by $v = V(I, \theta, y, \varepsilon)$, where $V(I, \theta, y, \varepsilon)$ is the solution of

$$\frac{dv}{d\varepsilon} = J\nabla_y W_1(I, \theta, y), \qquad v(0) = y,$$

where J denotes the skew-symmetric matrix

$$J = \begin{bmatrix} 0 & E \\ -E & 0 \end{bmatrix}$$

and E stands for the identity matrix. Since V is the solution of a Hamiltonian equation, the change of variables is symplectic, and since W_1 is 2π-periodic in θ, so is V. The resulting Hamiltonian becomes

$$\mathcal{H}_\varepsilon(I, \theta, y) = \mathcal{H}_0(I) + \varepsilon \bar{\mathcal{H}}(I, y) + O(\varepsilon^2)$$

by the theory of Lie transforms (cf. [36, p. 168ff]). ■

The proofs of Theorems 2.1 and 2.2 follow from this lemma.

Proof of Reeb's theorems. First, each orbit of $\mathcal{H}_0$ in the level set $\mathcal{H}_0^{-1}(0)$ intersects σ once, so σ can be considered a coordinate patch on the base space B, and y provides symplectic coordinates for σ. Thus, B has an atlas of symplectic charts, and therefore B is a symplectic manifold. This proves Theorem 2.1.

Up to terms of order ε the equations are

$$\dot I = O(\varepsilon^2), \quad \dot\theta = 2\pi/T(I) + O(\varepsilon^2), \quad \dot y = \varepsilon J \nabla_y \bar{\mathcal{H}}(I, y) + O(\varepsilon^2).$$

The return time for θ to increase from 0 to 2π is $T+O(\varepsilon^2)$, and the section map in an energy level ($I=0$) is $P:\sigma\to\sigma: y\mapsto P(y)$, where $P(y)=y+\varepsilon TJ\nabla_y\bar{\mathcal{H}}(0,y)+O(\varepsilon^2)$. A fixed point of P gives rise to a periodic solution, and so we must solve $P(y)=y$ or, equivalently, $TJ\nabla_y\bar{\mathcal{H}}(0,y)+O(\varepsilon)=0$. By hypothesis $y=0$ is a nondegenerate critical point of $\bar{\mathcal{H}}$ when $I=0$ or $\nabla_y\bar{\mathcal{H}}(0,0)=0$ and $\partial^2\bar{\mathcal{H}}/\partial y^2(0,0)$ is nonsingular. Thus by the implicit function theorem there is a function $\bar{y}(\varepsilon)=O(\varepsilon)$ such that $P(\bar{y}(\varepsilon))=\bar{y}(\varepsilon)$. This fixed point of P is the initial condition for the periodic solution asserted in Theorem 2.2. ■

2.2. Corollaries. Only the last sentence in Theorem 2.2 gives a truly global result. Those conversant with Morse theory [13] will see that there is a sharper global result.

Corollary 2.1. *Let $\bar{\mathcal{H}}$ be a Morse function, let β_j be the jth Betti number of B, and let C_j be the number of critical points of index j. Then $C_j\geq\beta_j$ or, better yet,*

$$
\begin{aligned}
C_0 &\geq \beta_0,\\
C_1-C_0 &\geq \beta_1-\beta_0,\\
C_2-C_1+C_0 &\geq \beta_2-\beta_1+\beta_0,\\
&\cdots\\
C_k-C_{k-1}+C_{k+2}-\cdots\pm C_0 &\geq \beta_k-\beta_{k-1}+\beta_{k+2}-\cdots\pm\beta_0 \qquad (k<2n-2),\\
C_{2n-2}-C_{2n-3}+C_{2n-4}-\cdots+C_0 &= \beta_{2n-2}-\beta_{2n-3}+\beta_{2n-4}-\cdots+\beta_0=\chi(B).
\end{aligned}
\tag{3}
$$

For these better inequalities on a Morse function, see [37]. The lower estimate on the number of periodic solutions in Theorem 2.2 is $\chi(B)$, the alternating sum of the Betti numbers which could be 0 or negative, whereas the Morse inequalities $C_j\geq\beta_j$ give a lower estimate which is the sum of the Betti numbers. Moreover, the estimates give some information on the number of critical points of various indices. For example, Milnor [37] remarks that if $C_{j+1}=C_{j-1}=0$, then $C_j=\beta_j$.

The nontrivial characteristic multipliers of the periodic solution given in Theorem 2.2 are the eigenvalues of

$$\mathcal{P}=\frac{\partial P}{\partial y}(\bar{y}(\varepsilon))=E+\varepsilon TJ\frac{\partial^2\bar{\mathcal{H}}}{\partial y^2}(0,0)+O(\varepsilon^2),$$

where E is the identity matrix. The eigenvalues of the Hamiltonian matrix

$$A=J\frac{\partial^2\bar{\mathcal{H}}}{\partial y^2}(0,0) \tag{4}$$

are the characteristic exponents of the critical point of $\bar{Y}$ at $\bar{p}$ on B. Thus, the lemma also yields the following corollary.

Corollary 2.2. *Let p be as in Theorem 2.2 and let the characteristic exponents of $\bar{Y}(\bar{p})$ be $\lambda_1,\lambda_2,\ldots,\lambda_{2n-2}$. Then the characteristic multipliers of the periodic solution through $p(\varepsilon)$ are*

$$1,\ 1,\ 1+\varepsilon\lambda_1T+O(\varepsilon^2),\ 1+\varepsilon\lambda_2T+O(\varepsilon^2),\ldots,1+\varepsilon\lambda_{2n-2}T+O(\varepsilon^2).$$

This result was used in [33]. We shall say that a periodic solution is *elliptic* or *linearly stable* if the monodromy matrix is diagonalizable and all its eigenvalues have unit modulus.

One must be careful in applying this corollary, because it gives only an approximation of the characteristic multipliers. Consider the case $2\bar{\mathcal{H}}=(u_1^2+v_1^2)-(u_2^2+v_2^2)$, where $y=$

(u_1, u_2, v_1, v_2), so the eigenvalues are $i, i, -i, -i$. When $T = 1$, Corollary 2.2 says that the multipliers are 1, 1, $1+\varepsilon i+O(\varepsilon^2)$, $1+\varepsilon i+O(\varepsilon^2)$, $1-\varepsilon i+O(\varepsilon^2)$, and $1-\varepsilon i+O(\varepsilon^2)$, which looks like an elliptic periodic solution. But higher-order terms can change the stability. Consider now a perturbation of this example, namely, $2\bar{\mathcal{H}} = (u_1^2 + v_1^2) - (u_2^2 + v_2^2) + 2\varepsilon v_1 v_2$. Now the estimates of the multipliers would be 1, 1, $1 + \varepsilon i + \frac{1}{2}\varepsilon^2 + O(\varepsilon^3)$, $1 + \varepsilon i - \frac{1}{2}\varepsilon^2 + O(\varepsilon^3)$, $1 - \varepsilon i + \frac{1}{2}\varepsilon^2 + O(\varepsilon^3)$, and $1 - \varepsilon i - \frac{1}{2}\varepsilon^2 + O(\varepsilon^3)$, which gives an unstable periodic solution. The solution of this problem lies in the Krein–Gel'fand concept of parametric stability [47], which we briefly summarize below.

For the moment consider the linear constant coefficient Hamiltonian system

$$\dot{y} = Cy = J\nabla H(y), \qquad H = \frac{1}{2} y^T S y, \tag{5}$$

where S is a symmetric matrix and $C = JS$ is a Hamiltonian matrix. System (5) (or the Hamiltonian matrix C) is *stable* if all its solutions are bounded for all t, and it is said to be *parametrically stable* or *strongly stable* if it and all sufficiently small linear constant coefficient Hamiltonian perturbations of it are stable. If system (5) is parametrically stable, then it is stable, and it is stable if and only if C is diagonalizable and has only purely imaginary eigenvalues.

Let $\pm\alpha_1 i, \pm\alpha_2 i, \ldots, \pm\alpha_s i$ be the eigenvalues of the stable matrix C, and V_j, $j = 1, \ldots, s$, be the maximal real linear subspace where C has eigenvalues $\pm\alpha_j i$. So V_j is a C-invariant symplectic subspace, C restricted to V_j has eigenvalues $\pm\alpha_j i$, and $\mathbb{R}^{2n} = V_1 \oplus V_2 \oplus \cdots \oplus V_s$. Let H_j be the restriction of H to V_j.

Theorem 2.3 (see [47]). *System* (5) *is parametrically stable if and only if*

- *all the eigenvalues of C are purely imaginary,*
- *C is nonsingular,*
- *C is diagonalizable over the complex numbers, and*
- *the Hamiltonian H_j is positive or negative definite for each j.*

Thus, $2H = (u_1^2+v_1^2)+(u_2^2+v_2^2)$ is parametrically stable, as the corresponding eigenvalues are $\pm i$ (double); hence $H_1 = H$ is positive definite. The Hamiltonian $2H = (u_1^2+v_1^2)-4(u_2^2+v_2^2)$ has eigenvalues $\pm i$ and $\pm 2i$, so $2H_1 = u_1^2 + v_1^2$ is positive definite and $2H_2 = -4(u_2^2 + v_2^2)$ is negative definite; therefore, H is parametrically stable. However, $2H = (u_1^2 + v_1^2) - (u_2^2 + v_2^2)$ has eigenvalues $\pm i$ (double), and, as $H_1 = H$ is not positive or negative definite, it cannot be parametrically stable.

Now consider the linear T-periodic Hamiltonian system

$$\dot{y} = D(t)y = J\nabla H(y), \qquad H = \frac{1}{2} y^T R(t) y, \tag{6}$$

where $R(t) = R(t+T)$ is symmetric and $D(t) = JR(t)$ is Hamiltonian. The periodic system (6) is *stable* if all its solutions are bounded for all t, and it is said to be *parametrically stable* or *strongly stable* if it and all sufficiently small linear T-periodic Hamiltonian perturbations of it are stable. The monodromy matrix is $M = Z(T)$, where $Z(t)$ is a fundamental matrix solution of (6). If the system is parametrically stable, then it is stable, and (6) is stable if and only if its monodromy matrix is diagonalizable and has only eigenvalues (multipliers) of unit modulus.

Let $\beta_1^{\pm 1}, \beta_2^{\pm 1}, \ldots, \beta_s^{\pm 1}$ be the eigenvalues of M and V_j, $j = 1, \ldots, s$, be the maximal real linear subspace where M has eigenvalues $\beta_j^{\pm 1}$. So V_j is an M-invariant symplectic subspace, M restricted to V_j (denoted by M_j) is symplectic and has eigenvalues $\beta_j^{\pm 1}$, and $\mathbb{R}^{2n} = V_1 \oplus V_2 \oplus \cdots \oplus V_s$.

For periodic systems we need to define the analogue of the quadratic form H_j. There are at least three ways to do this: (1) define a bilinear form on the eigenvectors corresponding to $\beta_j^{\pm 1}$ [47], (2) use Floquet theory and take logs of M, or (3) use a Cayley transformation. All three ways yield the same result, and we choose the latter because of its simplicity. The particular Möbius transformation

$$\Psi : z \mapsto w = (z-1)(z+1)^{-1}, \qquad \Psi^{-1} : w \mapsto z = (1+w)(1-w)^{-1}$$

is known as the *Cayley transformation*. One checks that $\Psi(1) = 0$, $\Psi(i) = i$, and $\Psi(-1) = \infty$, and so Ψ takes the unit circle in the z-plane to the imaginary axis in the w-plane, the interior of the unit circle in the z-plane to the left half w-plane, etc. Ψ can be applied to any matrix B which does not have -1 as an eigenvalue, and if λ is an eigenvalue of B, then $\Psi(\lambda)$ is an eigenvalue of $\Psi(B)$.

Lemma 2.2. *If M is a symplectic matrix which does not have eigenvalue -1, then $C = \Psi(M)$ is a Hamiltonian matrix. Moreover, if M has only eigenvalues of unit modulus and is diagonalizable, then $C = \Psi(M)$ has only purely imaginary eigenvalues and is diagonalizable.*

Proof. Simply check. ∎

M_j is the restriction of M to V_j and is a symplectic matrix, so $C_j = \Psi(M_j)$ is a Hamiltonian matrix and $S_j = JC_j$ is a symmetric matrix.

Theorem 2.4 (see [47]). *System (6) is parametrically stable if and only if*

- *all the eigenvalues of M have unit modulus,*
- *M does not have eigenvalue $+1$ or -1,*
- *M is diagonalizable over the complex numbers, and*
- *the symmetric matrix S_j is positive or negative definite for each j.*

Corollary 2.3. *If one or more of the λ_j of Corollary 2.2 is real or has nonzero real part, then the periodic solution through $p(\varepsilon)$ is unstable.*

If the matrix A in (4) is the coefficient matrix of a parametrically stable system, then the periodic solution through $p(\varepsilon)$ is elliptic. In particular, if $\bar{p}$ is a nondegenerate maximum or minimum of $\bar{\mathcal{H}}$, then the periodic solution through $p(\varepsilon)$ is elliptic. If $\bar{\mathcal{H}}$ is a Morse function, then there are at least two elliptic periodic solutions, since $\bar{\mathcal{H}}$ must have a nondegenerate maximum and minimum.

The authors believe this application of Krein–Gel'fand theory to be new.

Proof. The first sentence is obvious. Recall that the nontrivial multipliers are the eigenvalues of the symplectic matrix $\mathcal{P} = E + \varepsilon TA + O(\varepsilon^2)$. Applying Cayley's transformation to $\mathcal{P}$ yields the Hamiltonian matrix

$$\mathcal{A} = \Psi(\mathcal{P}) = \Psi(E + \varepsilon TA + O(\varepsilon^2)) = \frac{1}{2}\varepsilon TA + O(\varepsilon^2) = \frac{1}{2}\varepsilon T(A + O(\varepsilon)).$$

If A is the matrix of a parametrically stable system, the matrix $A + O(\varepsilon)$ is stable for all small ε, and hence so is $\mathcal{A}$. Thus all eigenvalues of $\mathcal{P} = \Psi^{-1}(\mathcal{A})$ have unit modulus. ∎

2.3. KAM tori. One can also detect invariant tori using KAM theory.

Theorem 2.5. *Let p be as in Theorem 2.2 and suppose there are symplectic action-angle variables $(I_1,\dots,I_{n-1},\theta_1,\dots\theta_{n-1})$ at $\bar{p}$ in B such that*

$$\bar{\mathcal{H}} = \sum_{k=1}^{n-1} \omega_k I_k + \frac{1}{2}\sum_{k=1}^{n-1}\sum_{j=1}^{n-1} C_{kj} I_k I_j + \mathcal{H}^{\#}, \tag{7}$$

where the ω_k are nonzero, $C_{kj} = C_{jk}$, and $\mathcal{H}^{\#}(I_1,\dots,I_{n-1},\theta_1,\dots\theta_{n-1})$ is at least cubic in $I_1,\dots,I_{n-1}$.

Assume that $\det C_{kj} \neq 0$. *That is, assume the system has been put into Birkhoff normal form and the "twist" condition is satisfied. Furthermore, assume $dT/dh \neq 0$; i.e., assume the period varies with $\mathcal{H}_0$ in a nontrivial way.*

Then near the periodic solutions given in Theorem 2.2 there are invariant KAM tori of dimension n. In particular, when $n = 2$, the periodic solution of Theorem 2.2 is orbitally stable.

Proof. In the tubular neighborhood constructed in Lemma 2.1, a full set of symplectic coordinates is $(I, I_1,\dots,I_{n-1},\theta,\theta_1,\dots\theta_{n-1})$ and the Hamiltonian is

$$\mathcal{H} = \mathcal{H}_0(I) + \varepsilon\left\{\sum_{k=1}^{n-1}\omega_k I_k + \frac{1}{2}\sum_{k=1}^{n-1}\sum_{j=1}^{n-1} C_{kj} I_k I_j\right\} + \cdots,$$

and the theorem follows by Theorem 14 on page 185 of [5]. ∎

This is just one of many KAM theorems. We place it here because of its simplicity. We will return to KAM-type results in subsequent papers.

2.4. Symmetric periodic solutions. In some cases the problem admits a discrete symmetry. Let $R : M \to M$ be an antisymplectic involution; i.e., $R^*\Omega = -\Omega$ and R^2 is the identity map of M. Then $F = \{p \in M : R(p) = p\}$ is a Lagrangian submanifold of M. The system defined by $\mathcal{H}_0$ (or $\mathcal{H}_\varepsilon$) is *reversible* or *admits R as a symmetry* if $\mathcal{H}_0 \circ R = \mathcal{H}_0$ (or $\mathcal{H}_\varepsilon \circ R = \mathcal{H}_\varepsilon$).

Now R maps an orbit of Y_0 into itself and so is well defined on B. Let $\bar{R}$ be R on B, so $\bar{R} : B \to B$, $\bar{R}^*\omega = -\omega$, $\bar{R}^2$ is the identity map on B, and $\bar{\mathcal{H}} \circ \bar{R} = \bar{\mathcal{H}}$. Let $\bar{F} = \{p \in B : \bar{R}(p) = p\}$.

A classical result [8] is the following lemma.

Lemma 2.3. *If a solution of Y_0 (or Y_ε) starts on F at time $t = 0$ and returns to F after time $t = T$, then the solution is $2T$-periodic, and its orbit is mapped onto itself by R.*

Similarly, if a solution of $\bar{Y}$ starts on $\bar{F}$ at time $t = 0$ and returns to $\bar{F}$ after time $t = T$, then the solution is $2T$-periodic and its orbit is mapped onto itself by $\bar{R}$.

These statements follow from the general identities

$$\phi_\varepsilon^t \circ R = R \circ \phi_\varepsilon^{-t}, \qquad \bar{\phi}^t \circ \bar{R} = \bar{R} \circ \bar{\phi}^{-t}. \tag{8}$$

Such periodic solutions are called *symmetric periodic solutions*. Let $\bar{\phi}^t(\bar{p})$ be a symmetric 2τ-periodic solution of $\bar{Y}$ and $\bar{q} = \bar{\phi}^\tau(\bar{p})$; then there are symplectic coordinate systems (ξ,ζ)

and (X, Z) for $\bar{B}$ at $\bar{p}$ and $\bar{q}$ with $(\xi(\bar{p}), \zeta(\bar{p})) = (0,0)$ and $(X(\bar{q}), Z(\bar{q})) = (0,0)$ such that

$$\bar{R}(\xi, \zeta) = (\xi, -\zeta) \qquad \text{and} \qquad \bar{R}(X, Z) = (X, -Z)$$

(see [34]). Locally $\bar{F}$ is given by $\zeta = 0$ near $\bar{p}$ and by $Z = 0$ near $\bar{q}$. Let $\bar{\phi}^t(\xi, \zeta) = (X(t, \xi, \zeta), Z(t, \xi, \zeta))$. In these coordinates the solution is a symmetric periodic solution if $Z(\tau, 0, 0) = 0$. Such a periodic solution is called a *nondegenerate symmetric periodic solution* if

$$\det \frac{\partial Z}{\partial \xi}(\tau, 0, 0) \neq 0.$$

In general, a nondegenerate symmetric periodic solution persists under small symmetric perturbations. However, in our case the problem is somewhat degenerate, requiring the use of the method and implicit function theorem of Arenstorf [2, 3, 4]. But first we present another lemma. For simplicity let $n = 2$.

Lemma 2.4. *Let $\mathcal{H}_0$ admit R as a symmetry, and let p and (I, θ, y) be as in Lemma 2.1. If $p \in F$, then $R(I, \theta, y) = (I, -\theta, \bar{R}(y))$ and $R(I, \pi + \theta, y) = (I, \pi - \theta, \bar{R}(y))$.*

Let $n = 2$ and $\bar{\phi}^t(\bar{p})$ be a nondegenerate symmetric 2τ-periodic solution of $\bar{Y}$. There exists a set of symplectic action-angle variables (I_1, θ_1) for $\bar{B}$, valid in a neighborhood of $\{\bar{\phi}^t(\bar{p}) : 0 \leq t \leq \tau\}$, such that $\bar{\mathcal{H}}$ is independent of θ_1. Thus $\bar{\mathcal{H}} = \bar{\mathcal{H}}(I, I_1)$, and in these coordinates $\bar{R}(I_1, \theta_1) = (I_1, -\theta_1)$ and $\bar{R}(I_1, \pi + \theta_1) = (I_1, \pi - \theta_1)$, so $\bar{F} = \{(I_1, \theta_1) : \theta_1 \equiv 0 \mod \pi\}$.

If the periodic solution corresponds to $I = I_1 = 0$, then the solution is nondegenerate if

$$\frac{\partial^2 \bar{\mathcal{H}}}{\partial I_1^2}(0,0) \neq 0.$$

Since the reduced space B depends on $\mathcal{H}$ or I, we have coordinates such that

$$\mathcal{H}_\varepsilon = \mathcal{H}_0(I) + \varepsilon \bar{\mathcal{H}}(I, I_1) + O(\varepsilon^2). \tag{9}$$

Proof. By Lemma 2.3 we have $\phi_0^t(p) = R\phi_0^{-t}(p)$ since $R(p) = p$. By construction, θ is t measured from p, so $R : \theta \mapsto -\theta$. Also, $R(I, \pi + \theta, y) = (I, -\pi - \theta + 2\pi, \bar{R}(y)) = (I, \pi - \theta, \bar{R}(y))$.

The proof of the existence of the action-angle variables (I_1, θ_1) for B follows the proof of Lemma 2.1 and the paragraph above. ∎

Theorem 2.6. *Let $\partial \mathcal{H}_0 / \partial I$ be nonzero, let $n = 2$, and let $\bar{p} \in \bar{B}$ with $\bar{R}(\bar{p}) = \bar{p}$ be an initial point for a nondegenerate τ-periodic solution of $\bar{Y}$. Let $p \in M$ with $R(p) = p$ be a point on the orbit which projects to $\bar{p}$. Let α, β be positive integers with α fixed, β large, and ε small.*

Then near the initial condition p, the flow of Y_ε has a symmetric periodic solution where $T(\varepsilon) = \alpha\tau + O(\varepsilon) = \beta T + O(\varepsilon)$.

Arenstorf's method of establishing the existence of symmetric periodic solutions has been around for a long time and has been applied to several problems [3, 4, 14, 25]. The authors believe that the above theorem is new at this level of generality.

Proof. Choose coordinates $(I, I_1, \theta, \theta_1)$ by Lemma 2.4 so that

$$\mathcal{H}_\varepsilon = \mathcal{H}_0(I) + \varepsilon \bar{\mathcal{H}}(I, I_1) + O(\varepsilon^2),$$

and the equations of motion are

$$\dot{I} = O(\varepsilon^2), \qquad \dot{\theta} = -\frac{\partial \mathcal{H}_0}{\partial I}(I) + O(\varepsilon),$$
$$\dot{I}_1 = O(\varepsilon^2), \qquad \dot{\theta}_1 = -\varepsilon \frac{\partial \bar{\mathcal{H}}}{\partial I_1}(I, I_1) + O(\varepsilon^2).$$

Since these equations are autonomous, we may take the fast angle θ as the independent variable so that the equations become

$$\frac{\partial I}{\partial \theta} = 0, \qquad \frac{\partial I_1}{\partial \theta} = 0, \qquad \frac{\partial \theta_1}{\partial \theta} = \varepsilon G(I, I_1) = \varepsilon \left\{ \frac{\partial \mathcal{H}_0}{\partial I}(I) \right\}^{-1} \frac{\partial \bar{\mathcal{H}}}{\partial I_1}(I, I_1), \tag{10}$$

plus $O(\varepsilon^2)$ terms. For the moment, ignore the $O(\varepsilon^2)$ terms and seek a symmetric periodic solution of the approximate equations. Let α and β be relatively prime integers, $\nu = G(0,0)^{-1}$, and set $\varepsilon = \nu\alpha/\beta$. Start with initial conditions $I = I_1 = \theta_1 = 0$ and integrate the approximate equations on θ from 0 to $\beta\pi$ to obtain the approximate solution

$$I = 0, \qquad I_1 = 0, \qquad \theta_1 = \alpha\pi.$$

This approximate solution satisfies the symmetry conditions and so to this level of approximation is a symmetric periodic solution.

Fixing α and taking β large, the parameter ε becomes small, and so we might expect that this approximate solution could be continued into the full problem. However, the problem is complicated by the fact that taking β large corresponds to integrating the equations over a large variation of θ. As Arenstorf has observed, the usual implicit function theorem cannot be applied since one cannot set $\varepsilon = 0$ to find an approximate solution. Thus, we must follow Arenstorf and make careful estimates.

First, we fix the integer α and the initial condition $I = 0$ once and for all. Let the superscript f denote the full solution of (10) including $O(\varepsilon^2)$ terms, the superscript a the approximate solution, and the superscript e the error term. Integrate the full equations with initial condition $I_1 = K$, and integrate from $\theta = 0$ to $\theta = \beta\pi$ to obtain

$$\theta_1^f(\beta\pi, \varepsilon, K) = \theta_1^a(\beta\pi, \varepsilon, K) + \theta_1^e(\beta\pi, \varepsilon, K), \tag{11}$$

where $\theta_1^a(\beta\pi, \varepsilon, K) = \varepsilon\beta\pi\, G(0, K)$.

The error term θ_1^e is due to the $O(\varepsilon^2)$ terms appended to (10). Bounding these $O(\varepsilon^2)$ terms by $C\varepsilon^2$, and taking the $O(\varepsilon)$-Lipschitz constant of the θ_1-flow to be $L\varepsilon$, we apply to θ_1^e a standard Gronwall estimate of the form $\{u(0) = 0 \text{ and } d|u|/d\theta \le L\varepsilon|u| + C\varepsilon^2\} \Rightarrow |u(\theta)| \le \varepsilon C(e^{\varepsilon L\theta} - 1)/L$ (see, e.g., Hartman [23]) to conclude that

$$|\theta_1^e| \le \varepsilon C(e^{\varepsilon L\beta\pi} - 1)/L. \tag{12}$$

A similar estimate holds for the first partial derivatives of θ_1^e.

The approximate equation has solution $\theta_1^a(\beta\pi, \varepsilon, K) = \alpha\pi$ by taking $\varepsilon = \nu\alpha/\beta$ and $K = 0$. Also by assumption $\partial\theta_1^a/\partial K$ is nonzero. From the estimate (12) the error term can be made arbitrarily small by taking β large with $\varepsilon = \nu\alpha/\beta$, since in this case the estimate (12) reads

$|\theta_1^e| \le C\nu\alpha(e^{L\nu\alpha\pi} - 1)/(L\beta)$. Similarly, the derivatives of θ_1^e can be made small by taking β large. These estimates ensure that we remain in a compact neighborhood of the approximate solution. Thus, the implicit function theorem of Arenstorf [2, 3, 4] applies, and there exists β_0 such that if $\beta > \beta_0$, then there is a solution $K_s(\beta)$ such that

$$\theta_1^f(\beta\pi, \nu\alpha/\beta, K_s(\beta)) = \alpha\pi.$$

This gives the initial conditions for a symmetric periodic solution. ■

2.5. Weinstein's theorem. For completeness we add this much deeper global result on the existence of periodic solutions which is not a corollary of Reeb's theorems. Let X be a topological space; then the category of X in the sense of Lusternik–Schnirelmann, $\mathrm{cat}(X)$, is the smallest number of open sets that are contractible in X and that cover X [26, 31]. One of the main uses of this concept is in the theorem that says that every smooth function on a compact manifold M has at least $\mathrm{cat}(M)$ critical points. Weinstein extended the connection between critical points of functions and periodic solutions of Hamiltonian systems to prove the following theorem.

Theorem 2.7. *Assume B is compact and simply connected in the sense that $H^1(B, \mathbb{R}) = 0$, where $H^1(B, \mathbb{R})$ is the one-dimensional cohomology group of B over the real numbers, and let $\ell = cat(B)$ be the Lusternik–Schnirelmann category of B. Then for small ε the flow of Y_ε has at least ℓ periodic solutions with periods near T (there is no nondegeneracy assumption)* [45, 46].

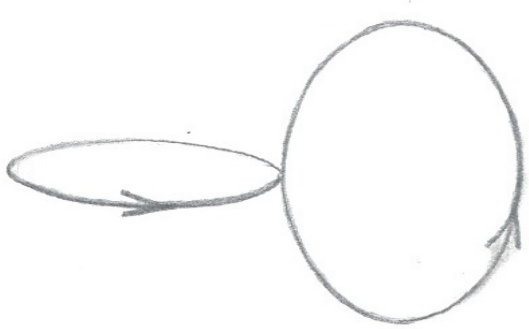
The n-sphere S^n has category 2 and all other compact manifolds have category greater than 2. For $X = S^n \times S^n$, we produce three contractible open sets that cover X, so $\mathrm{cat}(S^n \times S^n) = 3$. (We illustrate this in Figure 2 for the case $n = 1$.)

It is helpful to think of X as a cellular complex. Starting with two n-cells, identify one point in one cell with one point in the other cell to form the wedge product (or wedge sum) of two spheres $S^n \vee S^n$. (The wedge product of two circles is thus a figure eight, as in Figure 2a; for a precise definition of $S^n \vee S^n$, see [24, p. 10].) Now attach a $2n$-cell to $S^n \vee S^n$ to form X (Figure 2b). Take the $2n$-cell to be the first contractible set. For the second set, delete one point from each of the two spheres in $S^n \vee S^n$. This set is $D^n \vee D^n$ and can easily be "fattened up" to an open set in $S^n \times S^n$. These two sets cover all but the two points deleted from $S^n \times S^n$. For the third set, choose any contractible open set in X that covers these two points. (Figure 2c shows sets that could be fattened up to form the second and third contractible open sets for $n = 1$.)

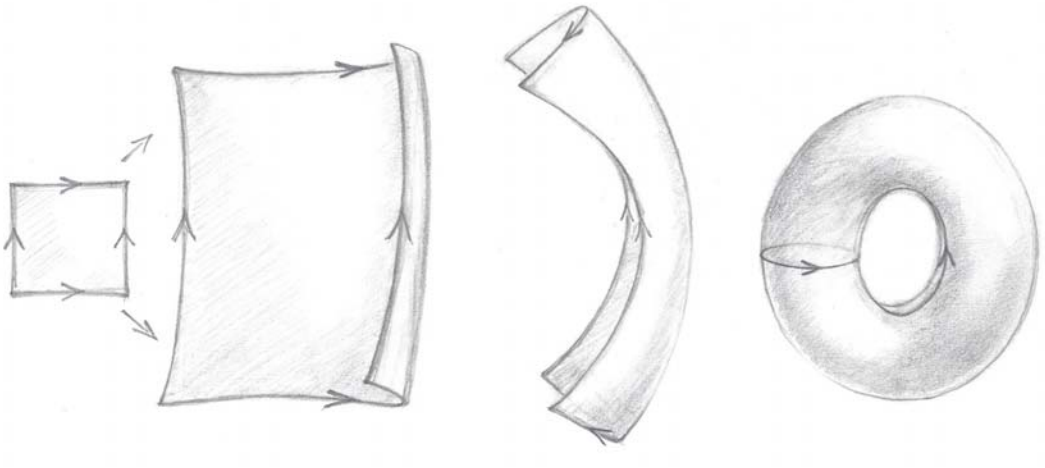
3. The planar lunar problem.

3.1. The Hamiltonians. For us the lunar problem is the restricted three-body problem where the infinitesimal particle is close to one of the primaries [35, 36]. Note that, in this context, the terminology "lunar problem" means that the zero mass point can move about either primary, which is more general than the way it is historically defined, where the infinitesimal mass point moves only about the smaller primary (or secondary).

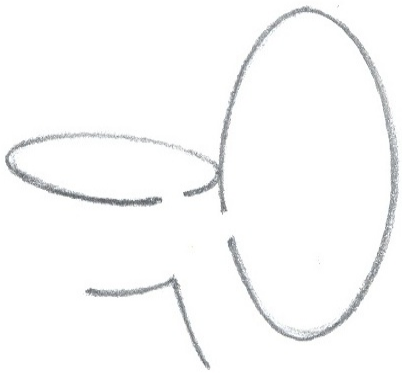
Here we summarize the normalization and reduction as given in [42] and then apply the general theorems from section 2. Figure 3 is a sketch of the planar lunar problem in the rotating frame—the projection on the $x_1\,x_2$-plane. The primary bodies are point particles



(a) $S^1 \vee S^1$



(b) Attaching the 2-cell to $S^1 \vee S^1$ to form $S^1 \times S^1$



(c) The second and third contractible sets (before "fattening")

Figure 2. *The Lusternik–Schnirelmann category of* $S^1 \times S^1$.

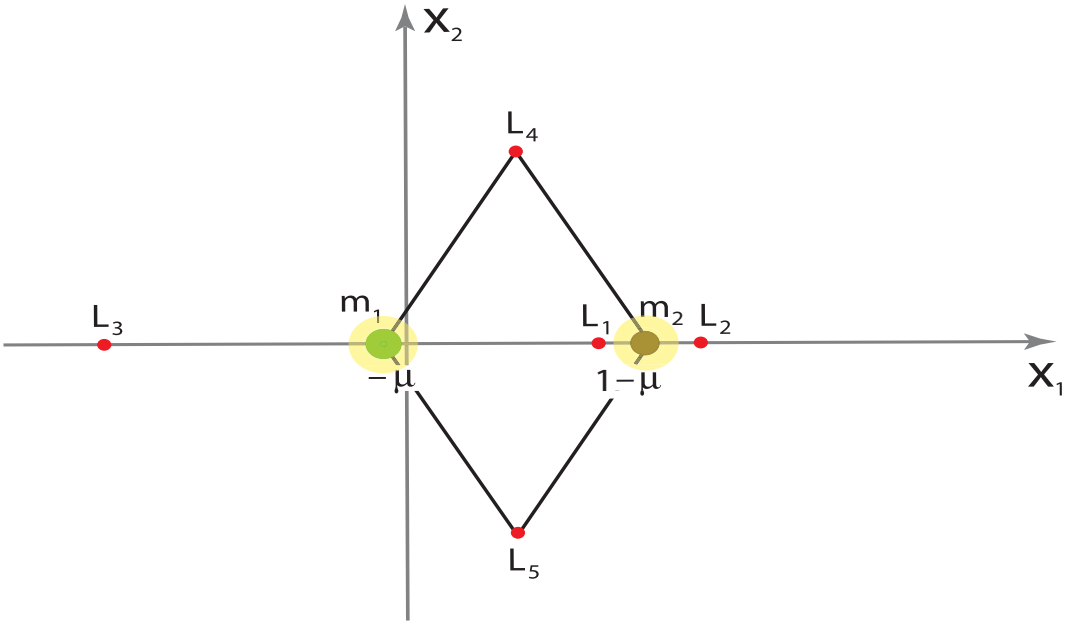


Figure 3. *The lunar problem.*

with masses m_1 and m_2 and are located at the points $(-\mu, 0)$ and $(1-\mu, 0)$, respectively. Parameter $\mu = m_1/(m_1+m_2)$ (it is assumed that $m_1 \geq m_2$). The motion of the infinitesimal particle is confined to either one of the yellow regions around the primaries. The points $L_1, \ldots, L_5$ are the equilibria of the restricted three-body problem in the rotating frame. The infinitesimal particle touches neither L_1 nor L_2.

We start with the Hamiltonian of the planar circular restricted three-body problem in rotating coordinates given by

$$\mathcal{H} = \frac{1}{2}(y_1^2 + y_2^2) - (x_1 y_2 - x_2 y_1) - \frac{\mu}{\sqrt{(x_1 - 1 + \mu)^2 + x_2^2}} - \frac{1-\mu}{\sqrt{(x_1 + \mu)^2 + x_2^2}}. \tag{13}$$

We now change coordinates in order to bring $\mathcal{H}$ into suitable form. First we perform the linear change from y_2 and x_1 to $y_2 - \mu$ and $x_1 - \mu$, respectively, to bring one primary to the origin. Then, we introduce a small parameter ε by replacing $y = (y_1, y_2)$ by $\varepsilon^{-1}(1-\mu)^{1/3} y$ and $x = (x_1, x_2)$ by $\varepsilon^2 (1-\mu)^{1/3} x$. By doing so we restrict $\mathcal{H}$ to a particular case where the infinitesimal particle is moving around one of the primaries. This change is symplectic with multiplier $\varepsilon^{-1}(1-\mu)^{-2/3}$; thus $\mathcal{H}$ must be replaced by $\varepsilon^{-1}(1-\mu)^{-2/3}\mathcal{H}$.

In the next step, we scale time by dividing t by ε^3 and multiplying $\mathcal{H}$ by ε^3. Then we expand the resulting Hamiltonian in powers of ε to get

$$\mathcal{H}_\varepsilon = \frac{1}{2}(y_1^2 + y_2^2) - \frac{1}{\sqrt{x_1^2 + x_2^2}} - \varepsilon^3 (x_1 y_2 - x_2 y_1) + \frac{1}{2}\varepsilon^6 \mu(-2x_1^2 + x_2^2) + \cdots. \tag{14}$$

The zeroth-order term is the Hamiltonian of the Kepler problem and the $O(\varepsilon^3)$ term is due to the rotating coordinates. It is not until $O(\varepsilon^6)$ that the second primary influences the motion.

Moser has shown [39] that the n-dimensional Kepler problem can be regularized and the regularized flow is equivalent to the geodesic flow on S^n. Let us be more specific for our case. Let $\mathcal{K} = \mathcal{H}_0$ be the Hamiltonian of the planar Kepler problem defined on $(\mathbb{R}^2 \setminus \{0\}) \times \mathbb{R}^2$, $K_0 = \{(x, y) \in (\mathbb{R}^2 \setminus \{0\}) \times \mathbb{R}^2 : \mathcal{K}(x, y) = -\frac{1}{2}\}$. Let S^2 be the unit sphere, $\hat{S}^2$ the unit sphere punctured at the north pole, TS^2 ($T\hat{S}^2$) the tangent bundle of the (punctured) 2-sphere, and $T_0S^2 = \{v \in TS^2 : \|v\| = 1\}$ ($T_0\hat{S}^2 = \{v \in T\hat{S}^2 : \|v\| = 1\}$) the unit (punctured) sphere bundle.

The elliptic domain $\mathcal{E}$ is the set of points in K_0 which gives rise to elliptic orbits. All the solutions of the Kepler problem in $\mathcal{E}$ are periodic with the same period. Thus $\mathcal{E}$ is a circle bundle but is not compact. The base is two punctured disks, as we show below.

Moser constructs a symplectic diffeomorphism from $(\mathbb{R}^2 \setminus \{0\}) \times \mathbb{R}^2$ onto $T\hat{S}^2$ which, when restricted to K_0, maps onto $T_0\hat{S}^2$. After changing the time variable for the Kepler problem, the diffeomorphism takes Kepler flow on K_0 to the geodesic flow on $T_0\hat{S}^2$. The geodesic flow on $T_0\hat{S}^2$ obviously extends to all of T_0S^2 and is considered the regularized Kepler problem.

All the geodesics on T_0S^2 are periodic, so T_0S^2 is a circle bundle with base S^2. Moser shows that a small perturbation of the Kepler problem can be carried over as a small perturbation of the geodesic problem. He then shows that the average of the perturbation over the geodesic flow defines a smooth flow on the base. We next proceed to construct this flow on the base.

Now express (14) in mixed polar and Delaunay coordinates (see, for instance, [9, 18]) so that the Hamiltonian becomes

$$\mathcal{H}_\varepsilon = -\frac{1}{2\,L^2} - \varepsilon^3 G - \frac{1}{4}\varepsilon^6 \mu r^2 \big(1 + 3\cos(2\vartheta)\big) + \cdots .$$

Here, (ℓ, g, L, G) are the usual Delaunay variables, ℓ the mean anomaly, g the argument of the pericenter, and L the square of the semimajor axis. G is the third component of the angular momentum vector $\mathbf{G} = (0, 0, G)$; thus $0 \le |G| \le L$ and G can be positive, negative, or zero. This is a coordinate system on $\mathcal{E}$. Finally, (r, ϑ) are the usual polar coordinates.

We eliminate the mean anomaly ℓ to a certain order by means of a special Lie transformation well suited for perturbed Kepler problems, the so-called normalization of Delaunay [18, 19]. We arrive at

$$\mathcal{H}_\varepsilon = -\frac{1}{2\,L^2} - \varepsilon^3 G + \frac{1}{8}\varepsilon^6\,\mu\,L^2\left(3\,G^2 - 5\,L^2 + 15\,(G^2 - L^2)\cos(2g)\right) + \cdots . \tag{15}$$

Here only finitely many terms have been put into normal form. This normalization is effectively the average of the perturbations over the periodic orbits of the Kepler problem in $\mathcal{E}$.

The base space (or reduced space or orbit space) for the regularized Kepler problem is a 2-sphere S^2 [39]. Figure 4 may be helpful in visualizing this base space. The flow is given by the circles around the poles on the sphere. A coordinate system for the reduced space is $\mathbf{a} = \mathbf{G} + LA$, where A is the Laplace–Runge–Lenz vector. One has $A = e\,(\cos g, \sin g, 0)$ and then $a_1 = e\cos g$, $a_2 = e\sin g$, and $a_3 = G$ on $\mathcal{E}$, where $e = \sqrt{1 - G^2/L^2}$ is the eccentricity. One can check that $|\mathbf{a}| = L$ and the vector $\mathbf{a}$ uniquely determines an orbit of the Kepler problem on the energy level $h = -1/(2L^2)$. Each point on the sphere $a_1^2 + a_2^2 + a_3^2 = L^2$ corresponds to a bounded orbit of the Kepler problem. Points $(0, 0, \pm L)$ correspond to the circular orbits, the circle $a_3 = 0$ (the equator, or the green circle in Figure 4) corresponds to collision orbits, and the other points on the sphere correspond to elliptic orbits. The

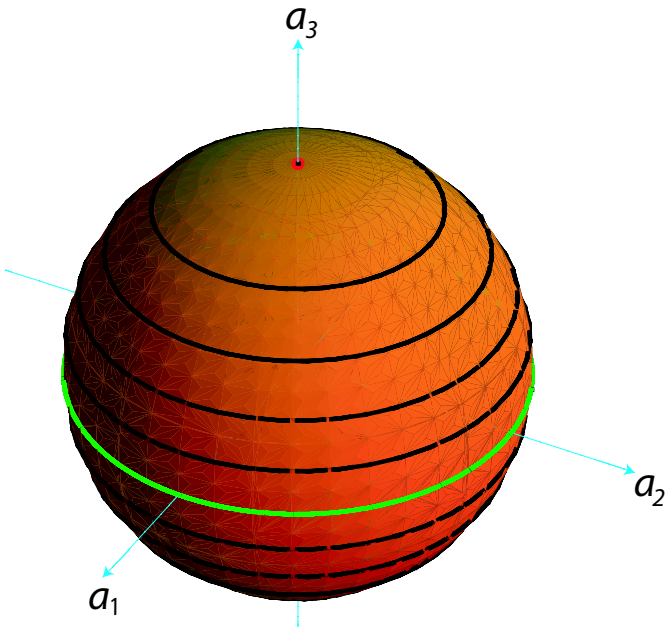

Figure 4. *The base space for the regularized Kepler problem.*

complement of $(0, 0, \pm L) \cup \{a_3 = 0\}$ is the reduced space of the elliptic domain $\mathcal{E}$.

Now compute from (15) the Hamiltonian on the reduced space of $\mathcal{E}$. Use $\cos(2g) = (a_1^2 - a_2^2)/(L^2 - G^2)$, so

$$\mathcal{H}_\varepsilon = -\frac{1}{2L^2} - \varepsilon^3 a_3 + \frac{1}{8}\varepsilon^6 \mu L^2 \left(3a_3^2 - 5L^2 - 15(a_1^2 - a_2^2)\right) + \cdots .$$

We first drop the higher-order nonnormalized terms and then use $a_3^2 = L^2 - a_1^2 - a_2^2$, dropping additive constants and dividing by ε^3 to get the Hamiltonian

$$\bar{\mathcal{H}} = -a_3 - \frac{3}{4}\varepsilon^3 \mu L^2 \left(3a_1^2 - 2a_2^2\right) + \cdots . \tag{16}$$

We note that this Hamiltonian is well defined and smooth on the exceptional set $(0, 0, \pm L) \cup \{a_3 = 0\}$. Since Moser proved that the averaged (normalized) Hamiltonian of the perturbation is defined and smooth on all of S^2, (16) is the Hamiltonian on the full reduced space S^2.

To obtain the equations of motion, note that $\{a_1, a_2\} = a_3$, $\{a_2, a_3\} = a_1$, $\{a_3, a_1\} = a_2$, and $\dot{a}_j = \sum_l \{a_j, a_l\} \partial \bar{\mathcal{H}} / \partial a_l$. So the equations of motion become

$$\begin{aligned} \dot{a}_1 &= a_2 + 3\varepsilon^3 \mu L^2 a_2 a_3 + \cdots , \\ \dot{a}_2 &= -a_1 + \tfrac{9}{2} \varepsilon^3 \mu L^2 a_3 a_1 + \cdots , \\ \dot{a}_3 &= -\tfrac{15}{2} \varepsilon^3 \mu L^2 a_1 a_2 + \cdots . \end{aligned} \tag{17}$$

3.2. Analysis of equilibria. We now apply the results of section 2 to the Hamiltonians for the planar lunar problem. Just from the facts that $B = S^2 = \{a_1^2 + a_2^2 + a_3^2 = L^2\}$, $H^1(S^2) = 0$,

and the Lusternik–Schnirelmann category of S^2 is 2, by Weinstein's theorem, Theorem 2.7, we conclude that there are at least two periodic solutions of the corresponding flow defined by Y_ε with period near $T = 2\pi L^3$. This applies to any (small) perturbation of the planar Kepler problem.

Looking at the Hamiltonian on B yields more information about these periodic solutions. The Hamiltonian (16) has two nondegenerate critical points, a maximum at $\mathbf{a} = (0, 0, -L)$ and a minimum at $\mathbf{a} = (0, 0, L)$, which by Reeb's theorem, Theorem 2.2, and Corollaries 2.2 and 2.3 correspond to elliptic periodic solutions of the planar restricted three-body problem of period $T(\varepsilon) = T + O(\varepsilon^3)$. (Note that $(0, 0, -L)$ and $(0, 0, L)$ are parametrically stable points according to Corollary 2.3, as they are respectively a minimum and a maximum.) These are the classical Hill's orbits of the restricted problem, which are the continuation of the circular solutions of the Kepler problem (see [12, 36] and the references therein). The maximum gives the prograde orbit, which is located at the north pole of the sphere in Figure 4 (it is represented by a red point), and the minimum provides the retrograde orbit (the south pole in Figure 4). The index of $(0, 0, -L)$ is 2, whereas the index of $(0, 0, L)$ is 0. Hence $C_0 = C_2 = 1$ and $C_j = 0$ for $j \notin \{0, 2\}$. The Betti numbers of S^2 are $\beta_0 = \beta_2 = 1$, and the others are zero. Moreover, the Euler–Poincaré characteristic of S^2 is 2, which is consistent with the Betti and C_j numbers. Thus, for all j, $C_j = \beta_j$, and the Morse inequalities (given in Corollary 2.1) become equalities. Note that in this case the Lusternik–Schnirelmann category and the Euler–Poincaré characteristic of S^2 yield the same estimate, which coincides with the number of critical points of the Hamiltonian $\bar{\mathcal{H}}$.

Since $\bar{\mathcal{H}} = -a_3 + \cdots$ the linearized equations about $(0, 0, \pm L)$ are

$$\dot{a}_1 = a_2, \qquad \dot{a}_2 = -a_1,$$

and so the characteristic exponents at these critical points are $\pm i$ (see Figure 4).

Thus, these near-circular periodic solutions are elliptic with characteristic multipliers 1, 1, $1 + \varepsilon^3 T i + O(\varepsilon^6)$, *and* $1 - \varepsilon^3 T i + O(\varepsilon^6)$.

As a last step, we have to undo the initial scalings and the shift to return to the Hamiltonian $\mathcal{H}$. Taking into account that the periodic solutions are near-circular, they have approximate radii $|x| \approx L^2$ and periods near $2\pi L^3$. Hence, because of the scalings, we conclude that the periodic solutions of $\mathcal{H}$ have radii $|x| \approx \varepsilon^2 L^2$ and periods $T(\varepsilon) \approx 2\pi\varepsilon^3 L^3$.

3.3. A twist condition. To see if Theorem 2.5 applies at $(0, 0, \pm L)$ we need several changes of variables. We start by moving the equilibria $(0, 0, \pm L)$ to the origin of a coordinate system. Therefore, we define

$$\bar{a}_1 = a_1, \quad \bar{a}_2 = a_2, \quad \bar{a}_3 = a_3 \mp L,$$

and then we introduce (local) symplectic coordinates Q and P as

$$Q = \sqrt{2}\frac{L\,\bar{a}_1}{\sqrt{2\,L \pm \bar{a}_3}} = \sqrt{2}\sqrt{L \mp G}\cos g,$$
$$P = \pm\sqrt{2}\frac{L\,\bar{a}_2}{\sqrt{2\,L \pm \bar{a}_3}} = \pm\sqrt{2}\sqrt{L \mp G}\sin g.$$

By recalling that (ℓ, g, L, G) are symplectic variables, it is almost straightforward to check that $\{Q, P\} = 1$; thus Q has the role of a coordinate, whereas P corresponds to its conjugate

momentum. These coordinates are valid in the hemispheres $\pm a_3 > 0$ (i.e., $\pm G < L$).

Now, to write $\bar{\mathcal{H}}$ in these coordinates, first note that

$$\frac{1}{2}(Q^2 + P^2) = L \mp G = L \mp a_3,$$

and also

$$a_1^2 = \frac{Q^2}{2L^2}(L \pm a_3), \qquad a_2^2 = \frac{P^2}{2L^2}(L \pm a_3).$$

Making this change of variables and dropping additive constants gives

$$\bar{\mathcal{H}} = \pm\frac{1}{2}(Q^2 + P^2) - \frac{3}{16}\varepsilon^3\mu(2P^2 - 3Q^2)(P^2 + Q^2 - 4L) + \cdots.$$

Change to action-angle variables by

$$Q = \sqrt{2I_1}\cos\theta_1, \qquad P = \sqrt{2I_1}\sin\theta_1$$

(note that $dQ \wedge dP = dI_1 \wedge d\theta_1$) to get

$$\bar{\mathcal{H}} = \pm I_1 - \frac{3}{4}\varepsilon^3\mu\, I_1\,(2L - I_1)\,(-2 + 5\cos^2\theta_1) + \cdots,$$

and then average over θ_1 to get

$$\bar{\mathcal{H}} = \pm I_1 - \frac{3}{8}\varepsilon^3\mu\, I_1\,(2L - I_1) + \cdots.$$

Note that the second derivative of $\bar{\mathcal{H}}$ with respect to I_1 is

$$\frac{\partial^2\bar{\mathcal{H}}}{\partial I_1^2} = \frac{3}{4}\varepsilon^3\,\mu, \tag{18}$$

and it does not vanish. Thus there is a twist term, but the hypothesis of Theorem 2.5 does not hold, as there is an additional ε^3 in front of the twist term.

This suggests, but does not prove, that these near-circular periodic solutions are stable and enclosed by invariant KAM tori.

We push the normalization up to order ε^8 in order to prove that the periodic solutions associated with the equilibria $(0, 0, \pm L)$ are not circular but have a small eccentricity. The terms factorized by ε^8 are

$$\tfrac{5}{32}\varepsilon^8\,\mu\,(1-\mu)^{1/3}\,e\,L^4\cos g\left(13\,G^2 - 7\,L^2 - 35\,(G^2 - L^2)\cos(2\,g)\right). \tag{19}$$

Now, after incorporating these terms into the Hamiltonian $\mathcal{H}_\varepsilon$ given by (15), the equilibria $(0, 0, \pm L)$ are transformed to

$$\left(\mp\frac{15}{16}\,\varepsilon^5\,\mu\,(1-\mu)^{1/3}\,L^6,\quad 0,\quad \pm\frac{\sqrt{256L^2 - 225\varepsilon^{10}\mu^2(1-\mu)^{2/3}L^{12}}}{16}\right).$$

Now the above equilibria do not correspond to circular solutions because their eccentricity is given by $e = \frac{15}{16}\varepsilon^5\,\mu\,(1-\mu)^{1/3}\,L^5+\cdots$. The magnitude of their angular momentum vector is $G = \pm L \mp \frac{225}{512}\varepsilon^{10}\,\mu^2\,(1-\mu)^{2/3}\,L^{11}+\cdots$. This implies that the periodic solutions associated with $(0,0,\pm L)$ are indeed elliptic periodic solutions whose projections onto configuration space yield elliptic orbits with eccentricity close to zero. The inclination is zero for the periodic solution related to $(0,0,L)$, while it is π for the periodic solution related to $(0,0,-L)$. This proves that up to terms of order ε^8 the periodic solutions are near-circular periodic solutions.

Thus, these equilibria correspond to near-circular elliptic periodic orbits.

3.4. Continuation of elliptic orbits. The planar restricted three-body problem is symmetric in the line of syzygy; i.e., $R : (x_1, x_2, y_1, y_2) \to (x_1, -x_2, -y_1, y_2)$ is an antisymplectic involution that leaves the Hamiltonian (13) invariant. The Lagrangian subspace $F = \{(x_1, 0, 0, y_2)\}$ corresponds to orthogonal crossings of the line of syzygy. In Delaunay variables $R : (\ell, g, L, G) \to (-\ell, -g, L, G)$ and $F = \{(0, 0, L, G)\}$.

On the reduced space $\bar{R} : (a_1, a_2, a_3) \to (a_1, -a_2, a_3)$ or $\bar{R} : (Q, P) \to (Q, -P)$. The Lagrangian subspace $\bar{F}$ is the meridian circle $\{(a_1, 0, a_3)\}$ or $\{(Q, 0)\}$. A point on $\bar{F}$ corresponds to a symmetric elliptic orbit of the Kepler problem and the periodic solution on $\bar{\mathcal{H}} =$ constant corresponds to a family of precessing Keplerian ellipses which start and end at a symmetric ellipse.

By Theorem 2.6 the existence of symmetric periodic solutions which are the continuation of this family of precessing Keplerian ellipses is ensured because, according to (18), the condition $\frac{\partial^2 \bar{\mathcal{H}}}{\partial I_1^2} \neq 0$ holds. These are the periodic solutions obtained by Arenstorf in [3].

4. The spatial lunar problem.

4.1. The Hamiltonians. The Hamiltonian of the spatial problem is given in the rotating frame by

$$\mathcal{H} = \frac{1}{2}(y_1^2 + y_2^2 + y_3^2) - (x_1 y_2 - x_2 y_1) - \frac{\mu}{\sqrt{(x_1 - 1 + \mu)^2 + x_2^2 + x_3^2}} - \frac{1-\mu}{\sqrt{(x_1 + \mu)^2 + x_2^2 + x_3^2}}.$$

We change variables, scale time, and scale the Hamiltonian in the same way as in the planar case in order to arrive to the lunar case of the spatial restricted circular three-body problem (see [25]). After expanding in powers of the small parameter, we end up with the system

$$\mathcal{H}_\varepsilon = \frac{1}{2}(y_1^2 + y_2^2 + y_3^2) - \frac{1}{\sqrt{x_1^2 + x_2^2 + x_3^2}} - \varepsilon^3\,(x_1 y_2 - x_2 y_1) + \frac{1}{2}\,\varepsilon^6\,\mu\,(-2x_1^2 + x_2^2 + x_3^2) + \cdots.$$

Now we have a perturbation of the spatial Kepler problem. Moser has shown that the three-dimensional Kepler problem can be regularized and the regularized flow is equivalent to the geodesic flow on S^3. We proceed just as in the planar problem to find and analyze the averaged equations on the reduced space.

The following step consists in expressing $\mathcal{H}_\varepsilon$ in such a way that we can perform Lie transformations conveniently (see [17]). We use polar-nodal coordinates $(r, \vartheta, \nu, R, G, N)$ and Delaunay coordinates (ℓ, g, ν, L, G, N). The angle ϑ is the argument of the latitude, and ν is the argument of the node. The coordinate R is the momentum conjugate to the radial

variable r, $G = |\mathbf{G}|$ is the magnitude of angular momentum, and N is the third component of the angular momentum $\mathbf{G}$, so $0 \le |N| \le G \le L$. Expressing $\mathcal{H}_\varepsilon$ in these variables, we get

$$\mathcal{H}_\varepsilon = -\frac{1}{2\,L^2} - \varepsilon^3\,N + \frac{1}{8}\,\varepsilon^6\,\mu\,r^2\,\Big(1 - 3\,c^2 - 3\,(1-c^2)\cos(2\,\vartheta) \\ - 3\,\big(1 - c^2 + (1+c^2)\cos(2\,\vartheta)\big)\cos(2\,\nu) + 6\,c\sin(2\,\nu)\sin(2\,\vartheta)\Big) + \cdots,$$

where $c = N/G$. After performing the normalization of Delaunay to a fixed finite order, we arrive at the Hamiltonian

$$\mathcal{H}_\varepsilon = -\frac{1}{2\,L^2} - \varepsilon^3 N + \frac{1}{16}\varepsilon^6\,\mu\,L^4\,\Big((2+3\,e^2)\,\big(1 - 3\,c^2 - 3\,(1-c^2)\cos(2\,\nu)\big) \\ - 15\,e^2\cos(2\,g)\big(1 - c^2 + (1+c^2)\cos(2\,\nu)\big) + 30\,c\,e^2\sin(2\,g)\sin(2\,\nu)\Big) + \cdots, \tag{20}$$

where $e = \sqrt{1 - G^2/L^2}$. This normal form Hamiltonian was calculated previously in [42]. The transformed Hamiltonian, after truncating higher-order terms, depends on the two angles g and ν and their associated momenta G and N, respectively, whereas L is an integral of motion. Applying reduction theory, once higher-order terms have been dropped, $\mathcal{H}_\varepsilon$ is defined on the orbit space, or base space, which is the four-dimensional space $S^2 \times S^2$ [39].

We can use the set of variables given by $\mathbf{a} = (a_1, a_2, a_3)$ and $\mathbf{b} = (b_1, b_2, b_3)$ with the constraints $a_1^2 + a_2^2 + a_3^2 = L^2$ and $b_1^2 + b_2^2 + b_3^2 = L^2$ to parameterize $S^2 \times S^2$, where $\mathbf{a} = \mathbf{G} + LA$ and $\mathbf{b} = \mathbf{G} - LA$. We recall that $\mathbf{G}$ is the angular momentum vector and A is the Laplace–Runge–Lenz vector; moreover, $|\mathbf{a}| = |\mathbf{b}| = L$. Notice that the a_i and b_i belong to the interval $[-L, L]$. The explicit expressions for $\mathbf{a}$ and $\mathbf{b}$ in terms of Delaunay variables are found in Coffey, Deprit, and Miller [11] and in Cushman [15].

In particular, $2G = ((a_1 + b_1)^2 + (a_2 + b_2)^2 + (a_3 + b_3)^2)^{1/2}$, so $G = 0$ in $S^2 \times S^2$ if and only if $a_1 + b_1 = a_2 + b_2 = a_3 + b_3 \equiv 0$, $a_1^2 + a_2^2 + a_3^2 = L^2$, and $b_1^2 + b_2^2 + b_3^2 = L^2$. Thus, the subset of $S^2 \times S^2$ given by $\mathcal{R} = \{(\mathbf{a}, -\mathbf{a}) \in \mathbb{R}^6 \mid a_1^2 + a_2^2 + a_3^2 = L^2\}$ is a two-dimensional set homeomorphic to S^2 consisting of the rectilinear trajectories. In Delaunay elements the circular orbits satisfy the condition $G = L$, and in terms of $\mathbf{a}$ and $\mathbf{b}$ this implies that $a_1 = b_1$, $a_2 = b_2$, and $a_3 = b_3$. So the circular orbits define the two-dimensional set homeomorphic to S^2 given by $\mathcal{C} = \{(\mathbf{a}, \mathbf{a}) \in \mathbb{R}^6 \mid a_1^2 + a_2^2 + a_3^2 = L^2\}$. Similarly, equatorial trajectories satisfy $G = |N|$ and are given by the two-dimensional set $\mathcal{E} = \{(\mathbf{a}, \mathbf{b}) \in \mathbb{R}^6 \mid a_1^2 + a_2^2 + a_3^2 = L^2$, $b_1 = -a_1$, $b_2 = -a_2$, $b_3 = a_3\}$, which is again homeomorphic to S^2. Just as in the planar case, the introduction of these invariants extends the use of the Delaunay variables, as we can include equatorial, circular, and rectilinear solutions [41]. The other points on $S^2 \times S^2$ correspond to elliptic orbits of the Kepler problem.

After several simplifications and manipulations over $\mathcal{H}_\varepsilon$, including the dropping of the constant term $-1/(2L^2)$ and division by ε^3, we arrive at

$$\bar{\mathcal{H}} = -\frac{1}{2}\,(a_3 + b_3) - \frac{1}{8}\,\varepsilon^3\,\mu\,L^2\,\big(3\,a_1^2 - 3\,a_2^2 - 3\,a_3^2 - 12\,a_1\,b_1 + 3\,b_1^2 \\ + 6\,a_2\,b_2 - 3\,b_2^2 + 6\,a_3\,b_3 - 3\,b_3^2\big) + \cdots. \tag{21}$$

The Poisson structure on $S^2 \times S^2$ in these coordinates is

$$\{a_1, a_2\} = 2\,a_3, \qquad \{a_2, a_3\} = 2\,a_1, \qquad \{a_3, a_1\} = 2\,a_2,$$
$$\{b_1, b_2\} = 2\,b_3, \qquad \{b_2, b_3\} = 2\,b_1, \qquad \{b_3, b_1\} = 2\,b_2, \qquad \{a_i, b_j\} = 0.$$

The corresponding equations of motion are

$$\begin{aligned}
\dot{a_1} &= a_2 - \tfrac{3}{2}\,\varepsilon^3\,\mu\,L^2\,(a_3\,b_2 - a_2\,b_3) + \cdots,\\
\dot{a_2} &= -a_1 + \tfrac{3}{2}\,\varepsilon^3\,\mu\,L^2\,(2a_1\,a_3 - 2\,a_3\,b_1 - a_1\,b_3) + \cdots,\\
\dot{a_3} &= -\tfrac{3}{2}\,\varepsilon^3\,\mu\,L^2\,(2\,a_1\,a_2 - 2\,a_2\,b_1 - a_1\,b_2) + \cdots,\\
\dot{b_1} &= b_2 + \tfrac{3}{2}\,\varepsilon^3\,\mu\,L^2\,(a_3\,b_2 - a_2\,b_3) + \cdots,\\
\dot{b_2} &= -b_1 - \tfrac{3}{2}\,\varepsilon^3\,\mu\,L^2\,(a_3\,b_1 + 2\,a_1\,b_3 - 2\,b_1\,b_3) + \cdots,\\
\dot{b_3} &= \tfrac{3}{2}\,\varepsilon^3\,\mu\,L^2\,(a_2\,b_1 + 2\,a_1\,b_2 - 2\,b_1\,b_2) + \cdots.
\end{aligned} \tag{22}$$

We stress that the equations of motion are global in the whole base space B. Including terms of order ε^3 is enough to determine the relative equilibria of $\bar{\mathcal{H}}$.

4.2. Analysis of equilibria. Let us now turn to the application of the results of section 2 to the spatial lunar problem. Just from the facts that $B = S^2 \times S^2 = \{a_1^2 + a_2^2 + a_3^2 = L^2, b_1^2 + b_2^2 + b_3^2 = L^2\}$, $H^1(S^2 \times S^2) = 0$, and the Lusternik–Schnirelmann category of $S^2 \times S^2$ is 3, by Weinstein's theorem, Theorem 2.7, we can conclude that there are at least three periodic solutions of the corresponding flow defined by Y_ε with period near $T = 2\pi L^3$. This holds for any perturbation of the spatial Kepler problem.

Looking at the Hamiltonian on B yields more information about these periodic solutions. The Hamiltonian (21) starts as $\bar{\mathcal{H}} = -\frac{1}{2}(a_3 + b_3) + \cdots$, so it has a nondegenerate maximum at $(\mathbf{a}, \mathbf{b}) = (0, 0, -L, 0, 0, -L)$ and a nondegenerate minimum at $(\mathbf{a}, \mathbf{b}) = (0, 0, L, 0, 0, L)$, which by Reeb's theorem, Theorem 2.2, and Corollary 2.2 correspond to elliptic periodic solutions of the spatial restricted three-body problem of period $T(\varepsilon) = T + O(\varepsilon^3)$. These are the circular equatorial motions already encountered in the planar case. It also has two nondegenerate critical points of index 2 at $(\mathbf{a}, \mathbf{b}) = (0, 0, \pm L, 0, 0, \mp L)$ which correspond to rectilinear motions whose projection in the coordinate space leads to periodic orbits in the vertical axis x_3. They correspond to the rectilinear trajectories found by Belbruno [6] for small μ.

The Betti numbers of $S^2 \times S^2$ are $\beta_0 = \beta_4 = 1$, $\beta_2 = 2$, and all the others are zero. As we have seen, $\bar{\mathcal{H}}$ is a Morse function and has the minimum number of critical points consistent with the Morse inequalities found in Corollary 2.1.

Near the critical points we can use (a_1, a_2, b_1, b_2) as coordinates on $B = S^2 \times S^2$. From the equations (22) one sees that the characteristic exponents of all four critical points of Y_ε at the four equilibria are $\pm i$ (double). Thus, by Corollary 2.2, the characteristic multipliers of the corresponding periodic solutions are 1, 1, $1 + \varepsilon^3\,T\,i$, $1 + \varepsilon^3\,T\,i$, $1 - \varepsilon^3\,T\,i$, and $1 - \varepsilon^3\,T\,i$ plus terms of order ε^6. As we have said, the maxima and minima at $(0, 0, \pm L, 0, 0, \pm L)$ give rise to elliptic periodic solutions, but since the minimax critical points at $(0, 0, \pm L, 0, 0, \mp L)$ have not been shown to be parametrically stable, we cannot conclude at this point that they give rise to elliptic periodic solutions. The deeper analysis of the next subsection is needed to decide the stability of those periodic solutions arising from the minimax critical points.

4.3. Linear stability and the twist condition. The aim of this section is the analysis of the linear stability of the families of periodic solutions established before, using the methods given in section 2. We also check that the twist condition needed for the possible existence of invariant tori is too degenerate. Finally, we also deal with the nonlinear stability of the four critical points of $S^2 \times S^2$. We start with the points related to the periodic near-rectilinear solutions.

4.3.1. Points $(0, 0, \pm L, 0, 0, \mp L)$. After moving the origin to the point of interest through

$$a_1 = \bar{a}_1, \quad a_2 = \bar{a}_2, \quad a_3 = \bar{a}_3 \pm L, \quad b_1 = \bar{b}_1, \quad b_2 = \bar{b}_2, \quad b_3 = \bar{b}_3 \mp L,$$

we introduce the local transformation

$$Q_1 = \frac{\bar{a}_2}{\sqrt{\pm\bar{a}_3 + 2L}}, \qquad Q_2 = \frac{\bar{b}_2}{\sqrt{\mp\bar{b}_3 + 2L}},$$
$$P_1 = \mp\frac{\bar{a}_1}{\sqrt{\pm\bar{a}_3 + 2L}}, \qquad P_2 = \pm\frac{\bar{b}_1}{\sqrt{\mp\bar{b}_3 + 2L}},$$

with inverse

$$\bar{a}_1 = \mp P_1\sqrt{2L - P_1^2 - Q_1^2}, \qquad \bar{a}_2 = Q_1\sqrt{2L - P_1^2 - Q_1^2}, \qquad \bar{a}_3 = \mp(P_1^2 + Q_1^2),$$
$$\bar{b}_1 = \pm P_2\sqrt{2L - P_2^2 - Q_2^2}, \qquad \bar{b}_2 = Q_2\sqrt{2L - P_2^2 - Q_2^2}, \qquad \bar{b}_3 = \pm(P_2^2 + Q_2^2).$$

The variables (Q_1, Q_2, P_1, P_2) are a canonical set for which Q_1, Q_2 can be interpreted as coordinates, whereas P_1 and P_2 represent their associated momenta, respectively.

The resulting Hamiltonian is obtained after putting $\bar{\mathcal{H}}$ in terms of Q_i and P_i and dropping constant terms. We get

$$\begin{aligned}\bar{\mathcal{H}} \;=\;& \pm\tfrac{1}{2}(P_1^2 + Q_1^2) \mp \tfrac{1}{2}(P_2^2 + Q_2^2) - \tfrac{3}{4}\varepsilon^3\,\mu\,L^2\left(3L\,(P_1^2 + P_2^2) + L\,(Q_1^2 + Q_2^2)\right.\\ &+ (2P_1\,P_2 + Q_1\,Q_2)\,\sqrt{2\,L - P_1^2 - Q_1^2}\,\sqrt{2\,L - P_2^2 - Q_2^2}\\ &\left.- (P_2^2 + Q_1^2)\,(P_2^2 + Q_2^2) - P_1^2\,(P_1^2 + P_2^2 + Q_1^2 + Q_2^2)\right) + \cdots.\end{aligned}$$

The Hamiltonian $\bar{\mathcal{H}}$ is valid in a neighborhood of the points $(0, 0, \pm L, 0, 0, \mp L)$.

Next we scale variables through the change $\bar{Q}_j = \varepsilon^{-3/2}\,Q_j$ and $\bar{P}_j = \varepsilon^{-3/2}\,P_j$ for $j \in \{1, 2\}$. To make the change canonical we must divide $\bar{\mathcal{H}}$ by ε^3. Expanding this Hamiltonian in powers of ε (and keeping the same name for it), we arrive at the Hamiltonian

$$\begin{aligned}\bar{\mathcal{H}} \;=\;& \pm\tfrac{1}{2}(\bar{P}_1^2 + \bar{Q}_1^2) \mp \tfrac{1}{2}(\bar{P}_2^2 + \bar{Q}_2^2) - \tfrac{3}{4}\varepsilon^3\,\mu\,L^3\left(3(\bar{P}_1^2 + \bar{P}_2^2) + 4\bar{P}_1\,\bar{P}_2 + \bar{Q}_1^2 + \bar{Q}_2^2 + 2\bar{Q}_1\,\bar{Q}_2\right)\\ &+ \tfrac{3}{8}\varepsilon^6\,\mu\,L^2\left(2(\bar{P}_1^4 + \bar{P}_1^3\,\bar{P}_2 + \bar{P}_1^2\,\bar{P}_2^2 + \bar{P}_1\,\bar{P}_2^3 + \bar{P}_2^4) + 2\bar{P}_2\,(\bar{P}_1 + \bar{P}_2)\,\bar{Q}_1^2\right.\\ &\left.+ (\bar{P}_1^2 + \bar{P}_2^2)\,\bar{Q}_1\,\bar{Q}_2 + 2(\bar{P}_1^2 + \bar{P}_1\,\bar{P}_2 + \bar{P}_2^2)\,\bar{Q}_2^2 + \bar{Q}_1\,\bar{Q}_2\,(\bar{Q}_1 + \bar{Q}_2)^2\right) + \cdots.\end{aligned}$$

The eigenvalues associated with the linear differential equation given through the quadratic part of $\bar{\mathcal{H}}$ are the expressions

$$(23)\quad \pm\sqrt{1 + 20\bar{\varepsilon}^2 + 2\sqrt{5}\bar{\varepsilon}\sqrt{3 + 20\bar{\varepsilon}^2}}\,i = \pm\omega_1\,i, \quad \pm\sqrt{1 + 20\bar{\varepsilon}^2 - 2\sqrt{5}\bar{\varepsilon}\sqrt{3 + 20\bar{\varepsilon}^2}}\,i = \pm\omega_2\,i,$$

where $\bar{\varepsilon}$ stands for $\frac{3}{4}\varepsilon^3\,\mu\,L^3$ and $\omega_1 > 1 > \omega_2 > 0$. Note that $\omega_1 = \omega_2 = 1$ when $\varepsilon = 0$, and the quadratic part of $\bar{\mathcal{H}}$ is in 1-1 resonance. However, we now see that when $\varepsilon \neq 0$ the eigenvalues are distinct.

These equilibria are parametrically stable and correspond to elliptic periodic solutions.

We keep ε small but positive so that we may perform further normalization. By doing so, both ω_1 and ω_2 remain close to 1 but different from it. As the corresponding set of eigenvectors forms a basis of $\mathbb{R}^4$, the quadratic part of $\bar{\mathcal{H}}$ may be brought into normal form through a canonical change of variables. This linear change has to be applied to $\bar{\mathcal{H}}$. The columns of the transformation matrix are the eigenvectors related to $\pm\omega_1 i$ and $\pm\omega_2 i$ multiplied by scale constants chosen to make the change symplectic. We do not give the explicit expression for this change because it is lengthy and the procedure is standard; see, for instance, [10, 30]. Defining the new variables by (q_1, q_2, p_1, p_2) and using the same name for the Hamiltonian, its quadratic part becomes

$$\pm\omega_1\, i\, q_1\, p_1 \mp \omega_2\, i\, q_2\, p_2.$$

Next we introduce action-angle variables $(I_1, I_2, \varphi_1, \varphi_2)$ by means of

$$\begin{aligned} q_1 &= \sqrt{I_1/\omega_1}\,(\cos\varphi_1 - i\sin\varphi_1), & q_2 &= \sqrt{I_2/\omega_2}\,(\cos\varphi_2 - i\sin\varphi_2),\\ p_1 &= \sqrt{\omega_1\, I_1}\,(\sin\varphi_1 - i\cos\varphi_1), & p_2 &= \sqrt{\omega_2\, I_2}\,(\sin\varphi_2 - i\cos\varphi_2). \end{aligned}$$

It is easy to check that $dq_1 \wedge dp_1 + dq_2 \wedge dp_2 = dI_1 \wedge d\varphi_1 + dI_2 \wedge d\varphi_2$. This transformation brings the quadratic terms of $\bar{\mathcal{H}}$ to $\pm\omega_1\, I_1 \mp \omega_2\, I_2$, while its quartic terms are converted into a finite Fourier series in φ_1 and φ_2 whose coefficients are homogeneous quadratic polynomials in I_1 and I_2. We do not give the Hamiltonian because it is enormous.

Now we average $\bar{\mathcal{H}}$ over φ_1 and φ_2, arriving in both cases at

$$\begin{aligned} \bar{\mathcal{H}} \;=\; & \pm\omega_1\, I_1 \mp \omega_2\, I_2 + \frac{(7\omega_1^6 + 13\omega_1^4 + 13\omega_1^2 + 3)(\omega_1^2 - 1)^2}{30\mu\, L^4\, \omega_1^2\, (\omega_1^2 + 2)^2\, (2\omega_1^2 + 1)}\, I_1^2 \\ & + \frac{2(\omega_1^2 - 1)^2\, (\omega_1^4 - 14\omega_1^2 - 5)\, (2\omega_2^2 + 1)}{135\mu\, L^4\, \omega_1\, (\omega_1^2 + 2)^2\, \omega_2}\, I_1\, I_2 \\ & + \frac{(7\omega_2^6 + 13\omega_2^4 + 13\omega_2^2 + 3)(\omega_2^2 - 1)^2}{30\mu\, L^4\, \omega_2^2\, (\omega_2^2 + 2)^2\, (2\omega_2^2 + 1)}\, I_2^2 + \cdots . \end{aligned}$$

The coefficients of I_1^2, I_2^2 and I_1, I_2 may be expressed in terms of $\bar{\varepsilon}$, and, after expanding them in powers of $\bar{\varepsilon}$ about 0, one obtains a formula starting in $\bar{\varepsilon}^2$. The generating function responsible for this averaging step is too big to be reproduced here, but it is a finite Fourier series in the angles φ_1 and φ_2.

Now we can compute the determinant of the Hessian associated with $\bar{\mathcal{H}}$. Using the constraint which relates ω_1 and ω_2 through (23) given by

$$\omega_2 = \sqrt{\frac{4 - \omega_1^2}{2\omega_1^2 + 1}},$$

we get

$$\det\begin{bmatrix} \dfrac{\partial^2\bar{\mathcal{H}}}{\partial I_1^2} & \dfrac{\partial^2\bar{\mathcal{H}}}{\partial I_1\partial I_2} \\ \dfrac{\partial^2\bar{\mathcal{H}}}{\partial I_2\partial I_1} & \dfrac{\partial^2\bar{\mathcal{H}}}{\partial I_2^2} \end{bmatrix} = \frac{(\omega_1^2-1)^6\,(7\omega_1^8-28\omega_1^6-534\omega_1^4-604\omega_1^2-137)}{225\mu^2\,L^8\,\omega_1^2\,(\omega_1^2-4)\,(\omega_1^2+2)^4\,(2\omega_1^2+1)^2}+\cdots,$$

which does not vanish since the (positive) real roots of the determinant occur for $\omega_1 = 1$ or $\omega_1 = 3.37369\ldots$, but as ε does not vanish, ω_1 remains greater than 1. Unfortunately, Theorem 2.5 does not apply since the twist condition is at a higher order in ε.

This suggests, but does not prove, that there are families of invariant 3*-tori around these periodic solutions.*

We leave the question of the existence of invariant KAM tori about these periodic solutions to a future paper. However, we can say something about the stability of the equilibria $(0,0,\pm L,0,0,\mp L)$ of the reduced system on the base space.

For the analysis of the stability of these equilibria we use Arnold's theorem [44]. We fix ε small and positive for this analysis. We need to find $\bar{\mathcal{H}}_4$, i.e., the quartic terms of $\bar{\mathcal{H}}$, and then compute

$$\begin{aligned}\bar{\mathcal{H}}_4(-\omega_2,\omega_1) &= \det\begin{bmatrix} \dfrac{\partial^2\bar{\mathcal{H}}_4}{\partial I_1^2} & \dfrac{\partial^2\bar{\mathcal{H}}_4}{\partial I_1\partial I_2} & \omega_1 \\ \dfrac{\partial^2\bar{\mathcal{H}}_4}{\partial I_2\partial I_1} & \dfrac{\partial^2\bar{\mathcal{H}}_4}{\partial I_2^2} & \omega_2 \\ \omega_1 & \omega_2 & 0 \end{bmatrix} \\ &= \frac{(\omega_1^2-1)^2\,(\omega_1^{12}-16\,\omega_1^{10}+66\,\omega_1^8-268\,\omega_1^6-275\,\omega_1^4-132\,\omega_1^2-24)}{15\,\mu\,L^4\,\omega_1^2\,(\omega_1^2-4)\,(2\,\omega_1^4+5\,\omega_1^2+2)^2}.\end{aligned}$$

Since this term does not vanish for ω_1 close to (but larger than) 1, Arnold's theorem applies, and so the following statement holds.

The equilibrium points $(0,0,\pm L,0,0,\mp L)$ *are stable on the reduced space* $S^2\times S^2$.

Now, if higher-order terms are included in the Hamiltonian (20), we see that the equilibria $(0,0,\pm L,0,0,\mp L)$ are distorted a bit. Specifically, the terms factorized by ε^8 are

$$\begin{aligned}&\tfrac{5}{64}\,\varepsilon^8\,\mu\,(1-\mu)^{1/3}\,e^2\,L^6\,(\cos g\cos h - c\sin g\sin h)\\ &\quad\times\Big(-18-31\,e^2+5\,c^2\,(6+e^2)+5\,(1-c^2)\,(6+e^2)\cos(2\,h)\\ &\qquad+35\,e^2\cos(2\,g)\,(1-c^2+(1+c^2)\cos(2\,h))-70\,c\,e^2\sin(2\,g)\sin(2\,h)\Big).\end{aligned}\tag{24}$$

Thus, after incorporating terms of order ε^8, the equilibria are transformed to

$$\begin{aligned}&\Big(\pm\tfrac{105}{16}\,\varepsilon^5\,\mu\,(1-\mu)^{1/3}\,L^6,\quad 0,\quad \pm\tfrac{\sqrt{256\,L^2-11025\,\varepsilon^{10}\,\mu^2\,(1-\mu)^{2/3}\,L^{12}}}{16},\\ &\ \pm\tfrac{105}{16}\,\varepsilon^5\,\mu\,(1-\mu)^{1/3}\,L^6,\quad 0,\quad \mp\tfrac{\sqrt{256\,L^2-11025\,\varepsilon^{10}\,\mu^2\,(1-\mu)^{2/3}\,L^{12}}}{16}\Big).\end{aligned}$$

Hence, it is not difficult to deduce that these equilibria correspond to near-rectilinear solutions whose eccentricity is given by $e = 1-\frac{11025}{512}\,\varepsilon^{10}\,\mu^2\,(1-\mu)^{2/3}\,L^{10}+\cdots$. The magnitude of their

angular momentum vector is $G = \frac{105}{16}\,\varepsilon^5\,\mu\,(1-\mu)^{1/3}\,L^6 + \cdots$, and its third component is $N = -\frac{33075}{512}\,\varepsilon^{13}\,\mu^3\,(1-\mu)^{2/3}\,L^{14} + \cdots$. This implies that the periodic solutions associated with $(0,0,\pm L,0,0,\mp L)$ are indeed elliptic periodic solutions such that their projections in configuration space yield elliptic orbits with eccentricity close to 1 and inclination angles given by $\pm\cos^{-1}(-\frac{315}{32}\,\varepsilon^8\,\mu^2\,(1-\mu)^{1/3}\,L^8 + \cdots)$.

Thus, these equilibria correspond to elliptic periodic orbits close to rectilinear orbits.

Moreover, it can be proved that the projection of the periodic orbits onto configuration space lies in the plane defined by x_2 and x_3. More precisely, in (the averaged) Cartesian variables $x_1, x_2, x_3, y_1, y_2, y_3$, the coordinates of these periodic orbits up to terms of order ε^{10} are

$$\left(0, \pm\frac{105}{8y_3}\,\varepsilon^5\,\mu\,(1-\mu)^{1/3}\,L^6, \mp\frac{2}{y_3^2} \pm \frac{33075}{512}\,\varepsilon^{10}\,\mu^2\,(1-\mu)^{2/3}\,L^{12}, 0, -\frac{105}{32}\,\varepsilon^5\,\mu\,(1-\mu)^{1/3}\,L^6\,y_3^2, y_3\right).$$

We remark that y_3 acts as the parameter of the periodic solution.

Next, the points related to the periodic near-circular equatorial solutions are analyzed.

4.3.2. Points $(0,0,\pm L,0,0,\pm L)$. We first move the Hamiltonian to the origin by

$$a_1 = \bar{a}_1, \quad a_2 = \bar{a}_2, \quad a_3 = \bar{a}_3 \pm L, \quad b_1 = \bar{b}_1, \quad b_2 = \bar{b}_2, \quad b_3 = \bar{b}_3 \pm L;$$

then we change variables by

$$Q_1 = \frac{\bar{a}_2}{\sqrt{\pm\bar{a}_3 + 2L}}, \qquad Q_2 = \frac{\bar{b}_2}{\sqrt{\pm\bar{b}_3 + 2L}},$$
$$P_1 = \mp\frac{\bar{a}_1}{\sqrt{\pm\bar{a}_3 + 2L}}, \qquad P_2 = \mp\frac{\bar{b}_1}{\sqrt{\pm\bar{b}_3 + 2L}},$$

with inverse

$$\bar{a}_1 = \mp P_1\sqrt{2L - P_1^2 - Q_1^2}, \qquad \bar{a}_2 = Q_1\sqrt{2L - P_1^2 - Q_1^2}, \qquad \bar{a}_3 = \mp(P_1^2 + Q_1^2),$$
$$\bar{b}_1 = \mp P_2\sqrt{2L - P_2^2 - Q_2^2}, \qquad \bar{b}_2 = Q_2\sqrt{2L - P_2^2 - Q_2^2}, \qquad \bar{b}_3 = \mp(P_2^2 + Q_2^2).$$

The change of variables is canonical, with Q_1 and Q_2 as coordinates and P_1 and P_2 as their associated momenta.

The resulting Hamiltonian is obtained after writing $\bar{\mathcal{H}}$ in terms of Q_i and P_i and dropping constant terms, so

$$\begin{aligned}\bar{\mathcal{H}} \;=\;& \pm\tfrac{1}{2}(P_1^2 + Q_1^2) \pm \tfrac{1}{2}(P_2^2 + Q_2^2) - \tfrac{3}{4}\varepsilon^3\,\mu\,L^2\,\big(L\,(P_1^2 + P_2^2) - L(Q_1^2 + Q_2^2)\\ &- (2P_1\,P_2 - Q_1\,Q_2)\,\sqrt{2\,L - P_1^2 - Q_1^2}\,\sqrt{2\,L - P_2^2 - Q_2^2}\\ &- (P_2^2 - Q_1^2)\,(P_2^2 + Q_2^2) - P_1^2\,(P_1^2 - P_2^2 + Q_1^2 - Q_2^2)\big) + \cdots.\end{aligned}$$

The Hamiltonian $\bar{\mathcal{H}}$ is valid in a neighborhood of $(0,0,\pm L,0,0,\mp L)$.

Now we scale by $\bar{Q}_j = \varepsilon^{-3/2}\, Q_j$ and $\bar{P}_j = \varepsilon^{-3/2}\, P_j$ for $j \in \{1,2\}$. The canonical structure is preserved by dividing $\bar{\mathcal{H}}$ by ε^3. After expansion of this Hamiltonian in powers of ε we obtain

$$\begin{aligned}\bar{\mathcal{H}} \;=\;& \pm\tfrac{1}{2}(\bar{P}_1^2+\bar{Q}_1^2) \pm \tfrac{1}{2}(\bar{P}_2^2+\bar{Q}_2^2) - \tfrac{3}{4}\varepsilon^3\,\mu\,L^3\left(\bar{P}_1^2+\bar{P}_2^2-4\bar{P}_1\,\bar{P}_2-\bar{Q}_1^2-\bar{Q}_2^2+2\bar{Q}_1\,\bar{Q}_2\right)\\ &+\tfrac{3}{8}\varepsilon^6\,\mu\,L^2\left(2(\bar{P}_1^4-\bar{P}_1^3\,\bar{P}_2-\bar{P}_1^2\,\bar{P}_2^2-\bar{P}_1\,\bar{P}_2^3+\bar{P}_2^4)+(\bar{P}_1^2+\bar{P}_2^2)\,\bar{Q}_1\,\bar{Q}_2\right.\\ &\left.+\,2(\bar{P}_1^2-\bar{P}_1\,\bar{P}_2+\bar{P}_2^2)\,(\bar{Q}_1^2-\bar{Q}_2^2)+\bar{Q}_1\,\bar{Q}_2\,(\bar{Q}_1-\bar{Q}_2)^2\right)+\cdots.\end{aligned}$$

For $(0,0,L,0,0,L)$ the eigenvalues associated with the linear differential equation given through the quadratic part of $\bar{\mathcal{H}}$ are

$$\pm\sqrt{1+2\bar{\varepsilon}}\,i = \pm\omega_1\,i, \quad \pm\sqrt{1-2\bar{\varepsilon}-24\bar{\varepsilon}^2}\,i = \pm\omega_2\,i \tag{25}$$

with $\bar{\varepsilon} = \frac{3}{4}\varepsilon^3\,\mu\,L^3$ and $\omega_1 > 1 > \omega_2 > 0$. For the point $(0,0,-L,0,0,-L)$ the eigenvalues are

$$\pm\sqrt{1-2\bar{\varepsilon}}\,i = \pm\omega_1\,i, \quad \pm\sqrt{1+2\bar{\varepsilon}-24\bar{\varepsilon}^2}\,i = \pm\omega_2\,i. \tag{26}$$

In this case $\omega_2 > 1 > \omega_1 > 0$. We remark that if $\varepsilon = 0$, then $\omega_1 = \omega_2 = 1$; thus the quadratic part of $\bar{\mathcal{H}}$ is in 1-1 resonance. So we keep ε small but positive so that we can apply KAM theory. As a consequence, ω_1 and ω_2 are close to 1 but different from it.

The eigenvectors related to ω_1 and ω_2 form a basis of $\mathbb{R}^4$; thus the quadratic part of $\bar{\mathcal{H}}$ is brought into normal form through a canonical change of variables. This linear change must be applied to $\bar{\mathcal{H}}$. The columns of the matrix are the eigenvectors scaled so that the matrix is symplectic. After defining the new variables by (q_1,q_2,p_1,p_2), the quadratic part of $\bar{\mathcal{H}}$ becomes

$$\pm\omega_1\,i\,q_1\,p_1 \pm \omega_2\,i\,q_2\,p_2.$$

The values of the frequencies ω_1 and ω_2 are given in (25) if the quadratic part is $\omega_1\,i\,q_1\,p_1 + \omega_2\,i\,q_2\,p_2$, whereas if the quadratic part is $-\omega_1\,i\,q_1\,p_1 - \omega_2\,i\,q_2\,p_2$, we take the frequencies from (26). From now on when we refer to $(0,0,L,0,0,L)$ we assume that ω_1 and ω_2 are as in (25), and when we study the point $(0,0,-L,0,0,-L)$ we take the frequencies from (26).

We have

$$\begin{aligned} q_1 &= \sqrt{I_1/\omega_1}\,(\cos\varphi_1 - i\sin\varphi_1), & q_2 &= \sqrt{I_2/\omega_2}\,(\cos\varphi_2 - i\sin\varphi_2),\\ p_1 &= \sqrt{\omega_1\,I_1}\,(\sin\varphi_1 - i\cos\varphi_1), & p_2 &= \sqrt{\omega_2\,I_2}\,(\sin\varphi_2 - i\cos\varphi_2),\end{aligned}$$

and the change satisfies $dq_1\wedge dp_1 + dq_2\wedge dp_2 = dI_1\wedge d\varphi_1 + dI_2\wedge d\varphi_2$. This transforms the quadratic terms of $\bar{\mathcal{H}}$ into $\pm\omega_1\,I_1 \pm \omega_2\,I_2$, while the quartic terms are converted into a finite Fourier series in φ_1 and φ_2 whose coefficients are homogeneous quadratic polynomials in I_1 and I_2.

Now we average $\bar{\mathcal{H}}$ over φ_1 and φ_2. For the two equilibria we obtain

$$\begin{aligned}\bar{\mathcal{H}} \;=\;& \omega_1\,I_1 + \omega_2\,I_2 - \frac{(\omega_1^2-1)^2\,(\omega_1^2+3)}{24\mu\,L^4\,\omega_1^2}\,I_1^2 - \frac{(\omega_1^2-1)^2\,(21\omega_1^2-13)}{6\mu\,L^4\,\omega_1\,\omega_2}\,I_1\,I_2\\ &- \frac{(6\omega_1^2-5)^2\,(48\omega_1^4+62\omega_1^2-93)}{1728\mu\,L^4\,\omega_2^2}\,I_2^2+\cdots.\end{aligned}$$

In both cases the coefficients of I_1^2, I_2^2 and I_1, I_2 may be expressed in terms of $\bar{\varepsilon}$, and expanding them in powers of $\bar{\varepsilon}$ around 0 yields expressions starting in $\bar{\varepsilon}^2$. The generating functions computed in the averaging process in the two cases are enormous, but they are finite Fourier series in the angles φ_1 and φ_2.

At this point we can compute the determinants of the Hessian associated with $\bar{\mathcal{H}}$. First we calculate the constraint relating ω_1 to ω_2 through $\bar{\varepsilon}$ using (25) or (26), obtaining in both situations

$$\omega_2 = \sqrt{(2\omega_1^2 - 1)\,(-3\omega_1^2 + 4)}.$$

We end up with the same expression for the points $(0,0,L,0,0,L)$ and $(0,0,-L,0,0,-L)$, which is

$$\det \begin{bmatrix} \dfrac{\partial^2 \bar{\mathcal{H}}}{\partial I_1^2} & \dfrac{\partial^2 \bar{\mathcal{H}}}{\partial I_1 \partial I_2} \\ \dfrac{\partial^2 \bar{\mathcal{H}}}{\partial I_2 \partial I_1} & \dfrac{\partial^2 \bar{\mathcal{H}}}{\partial I_2^2} \end{bmatrix} = \frac{(\omega_1^2 - 1)^4\,(24\omega_1^6 - 1811\omega_1^4 + 1918\omega_1^2 - 403)}{144\mu^2\,L^8\,\omega_1^2\,\omega_2^2} + \cdots.$$

The determinant vanishes when $\omega_1 \in \{0.536925\ldots, 0.88488\ldots, 1, 8.62479\ldots\}$. However, ω_1 is near 1 (either above or below, but it never reaches this value as ε cannot be zero). Again Theorem 2.5 does not apply since the twist occurs at too high an order in ε.

This suggests, but does not prove, that there are families of invariant 3*-tori around these periodic solutions.*

Again, we leave the question of the existence of invariant KAM tori about these periodic solutions to a future paper. However, we can easily say something about the stability of the equilibria $(0,0,\pm L,0,0,\pm L)$ of the reduced system on the base space. Since the Hamiltonian $\bar{\mathcal{H}}$ is positive or negative definite at these points, the classical theorem already known to Dirichlet [20, 36] applies.

The equilibrium points $(0,0,\pm L,0,0,\pm L)$ *are stable on the reduced space* $S^2 \times S^2$.

Finally, we prove that the near-circular equatorial periodic solutions are indeed equatorial but not circular periodic solutions. We start by taking into account the terms of the averaged Hamiltonian given through (24). Hence, the equilibria $(0,0,\pm L,0,0,\pm L)$ are refined, yielding

$$\Big(\mp\tfrac{15}{16}\varepsilon^5\,\mu\,(1-\mu)^{1/3}\,L^6,\quad 0,\quad \pm\tfrac{\sqrt{256\,L^2 - 225\,\varepsilon^{10}\,\mu^2\,(1-\mu)^{2/3}\,L^{12}}}{16},$$
$$\pm\tfrac{15}{16}\,\varepsilon^5\,\mu\,(1-\mu)^{1/3}\,L^6,\quad 0,\quad \pm\tfrac{\sqrt{256\,L^2 - 225\,\varepsilon^{10}\,\mu^2\,(1-\mu)^{2/3}\,L^{12}}}{16}\Big).$$

As a consequence of the above, the given equilibria no longer correspond to circular solutions, because their eccentricity is $e = \frac{15}{16}\varepsilon^5\,\mu\,(1-\mu)^{1/3}\,L^5 + \cdots$. The magnitude of their angular momentum vector is $G = L - \frac{225}{512}\varepsilon^{10}\,\mu^2\,(1-\mu)^{2/3}\,L^{11} + \cdots$, and the third component of angular momentum is $N = \pm L \mp \frac{225}{512}\varepsilon^{10}\,\mu^2\,(1-\mu)^{2/3}\,L^{11} + \cdots$. This means that the periodic solutions associated with $(0,0,\pm L,0,0,\pm L)$ are indeed elliptic periodic solutions whose projections in configuration space yield elliptic orbits with eccentricity close to zero; the inclination for the solution related to $(0,0,L,0,0,L)$ is zero, whereas it is π for the periodic solution related to $(0,0,-L,0,0,-L)$. This proves that up to terms of order ε^8 the periodic solutions are near-circular periodic solutions of equatorial type.

Thus, these equilibria correspond to elliptic periodic orbits remaining in the same plane as the two primaries.

Acknowledgments. We thank Professor Chris McCord (Northern Illinois University) for his remarks about the Lusternik–Schnirelmann category. We also thank Professor Sebastián Ferrer (Universidad de Murcia) for his fruitful comments on the relative equilibria in $S^2 \times S^2$.

Basis Markov Partitions and Transition Matrices for Stochastic Systems*

Erik Bollt†, Paweł Góra‡, Andrzej Ostruszka§, and Karol Życzkowski¶

Abstract. We analyze discrete-time dynamical systems subjected to an additive noise and their deterministic limit. In this work, we will introduce a notion by which a discrete-time stochastic system has something like a Markov partition for deterministic systems. For a chosen class of noise profiles, the Frobenius–Perron (FP) operator associated to the noisy system is exactly represented by a stochastic transition matrix of a finite size K. This feature allows us to introduce for these stochastic systems a basis Markov partition, defined herein, irrespectively of whether the deterministic system possesses a Markov partition or not. We show that in the deterministic limit, corresponding to $K \to \infty$, the sequence of invariant measures of the noisy systems tends, in the weak sense, to the invariant measure of the deterministic system. Thus, by introducing a small additive noise one may approximate transition matrices and invariant measures of deterministic dynamical systems.

Key words. stochastic dynamics, Markov partition, Frobenius–Perron operator, transition matrix

1. Introduction.

Markov partitions for deterministic dynamical systems serve a central role for determining their symbolic dynamics [3, 4, 5] whose grammar is described by a finite sized transition matrix that generates a so-called sofic shift [6, 14]. The conditions for such a projection were defined by Bowen for Anosov hyperbolic systems [3, 4] and stated succinctly for interval maps as a partition whose elements are each a homeomorphism onto a finite union of its elements [3, 5]. We remark here that a defining property in both cases is that the set of characteristic functions defined over the elements of the Markov partition project the transfer operator exactly onto an operator of finite type; that is, a matrix results, whereas an infinite matrix would be expected for a non-Markov system. We argue here that this should be the defining property of any generalization of Markov partitions, that is, a set of basis functions which project the Frobenius–Perron (FP) operator exactly onto a finite-rank matrix with no

residual. We present results here explicitly for random dynamical systems of the interval $[0,1]$ and generalizations to the L-torus $[0,1]^L$.

In physical literature on dynamical systems one often distinguishes a "natural" invariant measure of a hyperbolic system, which is stable with respect to an external noise [2, 7]. In mathematics this measure is known as the Sinai–Ruelle–Bowen (SRB) measure, and under certain assumptions one may rigorously prove its uniqueness [10]. Although the overall idea that adding the noise improves the convergence to the SRB measure is well known in the physics community, this work attempts to provide a more solid mathematical framework for this statement. In particular, for a certain class of the noise profiles, we are in position to characterize this convergence quantitatively.

First we recall the FP operator for a deterministic transformation. Associated with a discrete dynamical system acting on initial conditions, $\mathbf{x} \in M$ (say, a manifold $M \subset \Re^n$),

$$\begin{aligned} \tau &: M \to M, \\ x &\mapsto \tau(x), \end{aligned} \tag{1}$$

is another dynamical system over $L^1(M)$, the space of densities of ensembles of initial conditions

$$\begin{aligned} P_\tau &: L^1(M) \to L^1(M), \\ \rho(x) &\mapsto [P_\tau \rho](x). \end{aligned} \tag{2}$$

This FP operator (P_τ) is defined through a continuity equation [16],

$$\int_{\tau^{-1}(B)} \rho(x)dx = \int_B [P_\tau \rho](x)dx, \tag{3}$$

where B is a measurable subset of M, while PDF $\rho(x)$ belongs to $L^1(M)$. Equation (3) may be formally rewritten using the Dirac delta function:

$$[P_\tau \rho](x) = \int_M \delta(x - \tau(y))\rho(y)dy. \tag{4}$$

This heuristic form is particularly suitable for further investigation of dynamical systems with additive noise; see (6).

Now consider the stochastically perturbed dynamical system

$$\begin{aligned} \tau_\nu &: M \to M, \\ x &\mapsto \tau(x) + \xi, \end{aligned} \tag{5}$$

where ξ is a random variable with PDF ν, which is applied once per each iteration. We assume that the realizations ξ_n of ξ added to subsequent iterations form an identical independently distributed (i.i.d.) sequence. The random part ξ is assumed to be independent of state x which we tacitly assume to be relatively small, so that the deterministic part τ has primary influence. The "stochastic FP operator" has a form similar to that of the deterministic case [16],

$$[P_{\tau_\nu} \rho](x) = \int_M \nu(x - \tau(y))\rho(y)dy, \tag{6}$$

where the deterministic kernel, the delta function in (2), now becomes a stochastic kernel describing the PDF of the noise perturbation. We will denote the stochastic FP operator as $P_{\mathcal{P}}$ below. In the case that the random map (5) arises from the usual continuous Langevin process, the infinitesimal generator of the FP operator for normal ν corresponds to a general solution of a Fokker–Planck equation [16]. The FP operator formalism is particularly convenient in that it allows for an arbitrary noise distribution ν to be incorporated in a direct and simple way. Within the formalism, we can also study multiplicative noise ($x \to \eta\tau(x)$, modeling parametric noise). The kernel-type integral transfer operator is $\mathcal{K}(x,y) = \nu(x/\tau(y))/\tau(y)$ for $x \in \Re^+$, which can then also be finitely approximated as described in the next section and usefully reordered to a canonical block reduced form. In more generality, the theory of random dynamical systems [1] clearly classifies those random systems which give rise to explicit transfer operators with corresponding infinitesimal generators, and there are well-defined connections between the theories of random dynamical systems and of stochastic differential equations.

The main aim of this work is to investigate a class of stochastically perturbed dynamical systems for which the FP operator is represented by a finite stochastic transition matrix of size N. Such dynamical systems will be called *basis Markov* in analogy to deterministic dynamical systems possessing a Markov partition [15, 25], for which the associated FP operator is finite. The deterministic limit of the stochastic system corresponds to the divergence of the matrix size. In this limit, $N \to \infty$, the sequence of invariant measures of the stochastic systems acting in the N-dimensional Hilbert space converges, in the weak sense, to the invariant measure of the corresponding deterministic system.

The paper is organized as follows. The Ulam–Galerkin method of approximating the infinite dimensional FP operator and the concept of the Markov partition for a deterministic system are reviewed in sections 2 and 3, respectively. In section 4 we introduce the notion of basis Markov stochastic systems, while in section 5 we analyze a particular example of random systems perturbed by an additive noise with cosine profile. In section 6 we construct a fairly general example of the transition densities satisfying our assumptions (20). The key result on convergence of the invariant measures for stochastic and deterministic systems is proved in section 7. A discussion of isospectral matrices used to describe the FP operator is relegated to the appendix.

2. Ulam–Galerkin's method: Approximating the infinite dimensional operator. A Galerkin method may be used to approximate the FP operator by a Markov operator of finite rank. Formally, projection of the infinite dimensional linear space $L^1(M)$ results from discretely indexed basis functions $\{\phi_i(x)\}_{i=1}^{\infty} \subset L^1(M)$ onto a finite dimensional linear subspace generated by a subset of the basis functions,

$$\Delta_N = \mathrm{Span}(\{\phi_i(x)\}_{i=1}^{N}). \tag{7}$$

This projection,

$$p : L^1(M) \to \Delta_N, \tag{8}$$

is realized optimally by the Galerkin method in terms of the inner product, which we choose to be integration:

$$(f,g) \equiv \int_M f(x)g(x)dx \quad \forall f,g \in L^2(M). \tag{9}$$

Specifically, the infinite dimensional "matrix" is approximated by the $N \times N$ matrix,

$$A_{i,j} = ([P_\tau \phi_i], \phi_j) = \int_M [P_\tau \phi_i](x)\phi_j(x)dx, \quad 1 \le i,j \le N. \tag{10}$$

One approximates $\rho(x)$ through a finite linear combination of basis functions:

$$\rho(x) \simeq \sum_{i=1}^{N} d_i \phi_i(x). \tag{11}$$

The historically famous Ulam method [17, 27] for deterministic dynamical systems is equivalent to the interpretation for finding the fraction of the box B_i which maps by τ to B_j; the Ulam matrix is equivalent to the Galerkin matrix by using (10) and choosing the basis functions to be the family of characteristic functions

$$\phi_i(x) = \mathbf{1}_{B_i}(x) = \begin{cases} 1 & \text{if } x \in B_i, \\ 0 & \text{else.} \end{cases} \tag{12}$$

Specifically, we choose the ordered set of basis functions to be in terms of a nested refinement of boxes $\{B_i\}$ covering M. Though Galerkin's and Ulam's methods are formally equivalent in the deterministic case, we are of the opinion that the Galerkin description is a more natural description in the stochastic setting.

3. Markov partitions of deterministic systems, and exact projection. In this section, we discuss that a Markov partition is special for the FP operator of a deterministic dynamical system in that characteristic functions supported over those partition elements lead to an exact projection of the FP operator onto an operator of finite rank, a matrix.

For a one-dimensional transformation of the interval, the definition of a Markov partition [24] (see also [15, 25]) can be found in more recent references [3, 10, 18].

Definition. *A map of the interval $\tau : [a,b] \to [a,b]$ is* Markov *if there is a finite partition $\{I_j\}_{j=1}^N$ such that*

1. $\cup_{j=1}^N I_j = [a,b]$ *(covering property),*
2. $\mathrm{int}(I_j) \cap \mathrm{int}(I_k) = \emptyset$ *if $j \neq k$ (no overlap property),*
3. $\tau(I_j) = \cup_{i=1}^{q(j)} I_{k_i^{(j)}}$ *for some $k_i^{(j)} \in \{1,2,\ldots,N\}$, $i = 1,2,\ldots,q(j)$ (a grid interval maps completely across a union of intervals without "dangling ends" property).*

It is not hard to show that the set of characteristic functions forms a finite basis set of functions

$$\{\phi_j(x)\} = \{\mathbf{1}_{I_j}(x)\}_{j=1}^N, \tag{13}$$

such that Galerkin projection (10) is exactly onto an operator of finite rank or a matrix $A_{i,j}$. That is, (10) simplifies to

$$\begin{aligned} A_{i,j} = ([P_\tau \phi_i], \phi_j) &= \int_M [P_\tau \phi_i](x)\phi_j(x)dx, \\ &= \int_M \int_M \delta(x - \tau(y))\phi_i(y)\phi_j(x)dydx \\ &= \int_{I_j} \int_{I_i} \delta(x - \tau(y))dydx, \quad 1 \le i,j \le N. \end{aligned} \tag{14}$$

If the map τ is in addition piecewise linear on its Markov partition, then $P_\tau[\phi_i(x)]$ is a linear combination of $\phi_j(x)$.

Similarly, there is a well-defined notion of an Anosov diffeomorphism with a Markov partition [3, 4, 9, 23], and so for such systems, it can be shown that characteristic functions supported over the corresponding Markov partition create a basis set such that (10) results in an operator of finite rank.

We take these observations as motivation for the following definition, which is meant to generalize the notion of a Markov partition to stochastic systems.

Definition. *Let $\{M, \mathcal{B}, \mu\}$ be a measure space and a transformation $\tau : M \to M$ be measurable. Then the transformation τ is* "basis Markov" *if there exists a finite set of basis functions $\{\phi_i(x)\}_{i=1}^N : M \to [0,1] \in L^1(M)$ such that the FP operator is operationally closed within Δ_N, where $\Delta_N = \mathrm{Span}(\{\phi_i(x)\}_{i=1}^N)$. That is, for any density $\rho \in \Delta_N$, its image $[P_\tau \rho](x)$ belongs to Δ_N.*

Remark 1. If a transformation τ is basis Markov, then, if we perform Galerkin's method, $A_{i,j} = (P_\tau[\phi_i], \phi_j)_{N\times N}$, with that basis set, it allows that, for any initial density which can be written as a linear combination of these basis functions,

$$\rho_0(x) = \sum_{i=1}^{N} c_i \phi_i(x), \tag{15}$$

or stated simply,

$$\rho_0(x) \in \Delta_N. \tag{16}$$

The action of the FP operator on such initial densities, $\rho_1(x) = P_\tau[\rho_0(x)]$, has the matrix presentation,

$$\mathbf{c}' = A \cdot \mathbf{c}, \text{ where } \rho_1(x) = \sum_{i=1}^{N} c_i' \phi_i(x), \tag{17}$$

and is well known as a linear operator from an N-dimensional vector space into itself. This emphasizes that the FP operator projects exactly to an operator of finite rank—a matrix.

Note that for a general finite set of functions, if we take a general linear combination of those functions and then apply the FP operator, we do not expect that the resulting density can be written as a (finite) linear combination of basis functions.

The following is a direct consequence of our definition of basis Markov in relationship to the usual definition of a Markov map, stating the sense in which basis Markov is a generalization.

Remark 2. Equation (14) implies that any piecewise linear Markov map, together with the characteristic functions supported over the partition elements, is basis Markov.

4. Basis Markov stochastic systems: A general case due to separable noise. We analyze a dynamical system τ defined on an interval $M = [0,1]$ with both ends identified and subjected to a specific form of the additive noise,

$$x' = \tau(x) + \xi. \tag{18}$$

To specify the special case of the stochastic dynamical system written in (5), the stochastic perturbation will be characterized by the transition density $\mathcal{P}(x,y)$ of a transition from point x to y induced by noise. Describing the dynamics in terms of a probability density $\rho(x)$ its one-step evolution is governed by the stochastic FP operator,

$$\rho'(x) = [P_{\mathcal{P}}\rho](x) \;=\; \int_M \mathcal{P}\big(\tau(y),x\big)\,\rho(y)dy. \tag{19}$$

We will denote this stochastic FP operator by the symbol $P_{\mathcal{P}}$, referring to (6) in all that follows. The operator $P_{\mathcal{P}}$ acts on every probability density defined on M, and, in general, it cannot be represented by a finite matrix. However, in what follows we shall analyze a certain class of noise profiles for which such a representation is possible.

Definition. *The stochastic system of equations* (19) *is called* basis Markov *if there exists a finite set of basis functions* $\{\phi_i(x)\}_{i=1}^N : M \to [0,1] \in L^1(M)$ *such that the FP operator* $P_{\mathcal{P}}$ *is operationally closed within* Δ_N*, where* $\Delta_N = \mathrm{Span}(\{\phi_i(x)\}_{i=1}^N)$.

We assume that the transition probability, $\mathcal{P}(x,y) \geq 0$, satisfies the following properties [21, 22]:

$$\begin{aligned} &\text{(a)} \quad \mathcal{P}(x,y) \equiv \mathcal{P}(x-y) = \mathcal{P}(\xi),\\ &\text{(b)} \quad \mathcal{P}(x,y) \equiv \mathcal{P}(x \bmod 1, y \bmod 1),\\ &\text{(c)} \quad \mathcal{P}(x,y) = \sum_{m,n=0}^{N} A_{mn}\,u_n(x)\,v_m(y) \end{aligned} \tag{20}$$

for $x,y \in \mathbb{R}$ and some finite N. Property (a) ensures that the distribution of the random variable ξ does not depend on the position x, while the periodicity condition is provided in (b). A noise profile fulfilling property (c) is called *separable* (decomposable), and it allows us to represent the dynamics of an arbitrary system with such a noise in a finite dimensional Hilbert space. Here $A = (A_{mn})_{m,n=0,\ldots,N}$ is a yet undetermined real matrix of expansion coefficients. Note that A characterizes the noise and does not depend on the deterministic dynamics τ. We assume that the functions u_n, $n = 0,\ldots,N$, and v_m, $m = 0,\ldots,N$, are continuous in $M = [0,1)$ and linearly independent, and we can express $f \equiv 1$ as their linear combinations. Both sets of functions span bases in an $N+1$ Hilbert space. Their orthogonality is not required.

This term *separable noise* is concocted in analogy to *separable states* in quantum mechanics and *separable* probability distributions, since such a property was called $N+1$-separability by Tucci [26]. Making use of this crucial feature of the noise profile we may expand the kernel of the FP operator (19):

$$\rho'(y) = [P_{\mathcal{P}}\rho](y) = \int_0^1 \sum_{m,n=0}^{N} A_{mn}u_n(\tau(x))v_m(y)\rho(x)dx \tag{21}$$

$$\begin{aligned} &= \sum_{m,n=0}^{N} A_{mn}\left[\int_0^1 u_n(\tau(x))\rho(x)dx\right] v_m(y)\\ &= \sum_{n=0}^{N}\left[\int_0^1 u_n(\tau(x))\rho(x)dx\right]\tilde{v}_n(y) \end{aligned} \tag{22}$$

for $y \in M$, where

$$\tilde{v}_n = \sum_{m=0}^{N} A_{mn} v_m. \tag{23}$$

Thus, any initial density is projected by the FP operator $P_{\mathcal{P}}$ into the vector space spanned by the functions $\tilde{v}_m$, $m = 0, \ldots, N$.

Assuming that a given density $\rho(x)$ belongs to this space, we can expand it in this basis,

$$\rho(x) = \sum_{m=0}^{N} q_m \, \tilde{v}_m(x). \tag{24}$$

Expanding ρ' in an analogous way, we will describe it by the vector $\vec{q}' = \{q'_0, \ldots, q'_N\}$.

Let B denote a matrix of integrals,

$$B_{nm} = \int_0^1 u_n(\tau(x)) v_m(x) dx, \tag{25}$$

where $n, m = 0, \ldots, N$. Observe that B depends directly on the system τ and on the noise via the basis functions u and v. Making use of this matrix, the one-step dynamics (23) may be rewritten in a matrix form

$$q'_n = \sum_{m=0}^{N} D_{nm} \, q_m, \quad \text{where } D = BA \tag{26}$$

and A is implied by (20). In this way we have arrived at a representation of the FP operator $P_{\mathcal{P}}$ by a matrix D of size $(N+1) \times (N+1)$, the elements of which read

$$D_{nm} = \int_0^1 u_n(\tau(x)) \tilde{v}_m(x) dx, \quad n, m = 0, \ldots, N. \tag{27}$$

With (26), we now see that random dynamical systems with noise satisfying condition (20) allow a finite dimensional subspace which is preserved.

Although the probability is conserved under the action of $P_{\mathcal{P}}$, the matrix D need not be stochastic. This is due to the fact that the functions $\{\tilde{v}_m(x)\}$ forming the expansion basis in (24) were not normalized. We shall then compute their norms,

$$s_m = \int_0^1 \tilde{v}_m(y) dy = \sum_{n=0}^{N} A_{mn} b_n, \tag{28}$$

where

$$b_n = \int_0^1 v_n(y) dy. \tag{29}$$

Let $K \leq N+1$ denote the number of nonzero components of the vector $\vec{s}$, and let $k = 1, \ldots, K$ runs over all indexes $n \in 0, \ldots, N+1$, for which $s_k \neq 0$. Then the rescaled vectors,

$$V_k(y) := \tilde{v}_k(y)/s_k, \tag{30}$$

are normalized:

$$\int_0^1 V_k(y)dy = 1. \tag{31}$$

The normalization condition $\int_0^1 \rho(x)dx = 1$ implies

$$\int_0^1 \sum_{m=0}^{N} q_l \tilde{v}_m(x)dx = \sum_{m=0}^{N} q_m s_m = \sum_{k=1}^{K} q_k s_k = 1. \tag{32}$$

The same is true for the transformed density,

$$\sum_k q'_k s_k = 1. \tag{33}$$

Hence this scalar product is preserved during the time evolution. Making use of the rescaled coefficients

$$c_k := q_k s_k, \tag{34}$$

the dynamics (26) reads

$$c'_k = q'_k s_k = \sum_j D_{kj}\, q_j s_k = \sum_j D_{kj}\, \frac{s_k}{s_j}\, q_j s_j =: \sum_j T_{kj}\, c_j. \tag{35}$$

By construction the coefficients c_k sum to unity. Since some of them can in general be negative, the transition matrix

$$T_{kj} \;\equiv\; D_{kj}\, \frac{s_k}{s_j} = \sum_{ii'} D_{kj}\, \frac{A_{ki} s_i}{A_{ji'} s_{i'}} \tag{36}$$

need not be stochastic. In the above equation, all indices run from 1 to K and the coefficients s_k are nonzero by construction.

It is interesting to distinguish a special class of noises for which all functions corresponding to nonzero values of the components s_k are nonnegative: $\tilde{v}_k(x) \geq 0$ for $x \in [0,1]$ and $k = 1, \ldots, K$. This implies that for any probability density ρ its expansion coefficients q_k in (24) are not negative. Furthermore, the normalization constants of $\tilde{v}_k$ are nonnegative, $s_k > 0$, $k = 1, \ldots K$, and so are the coefficients c_k and c'_k given in (34), (35). Hence vectors c and c' form normalized K-point probability distributions, and so in this case the transition matrix T of size K is stochastic. The dimensionality $K \leq N + 1$ is determined by the parameter N and the choice of the basis functions $\{v_l(x)\}$ entering (20).

5. A special case: Cosine noise. We will now discuss a particularly simple case of the separable noise described above and introduced in [21]. Let

$$\mathcal{P}_N(\xi) = \mathrm{C_N} \cos^N(\pi\xi), \tag{37}$$

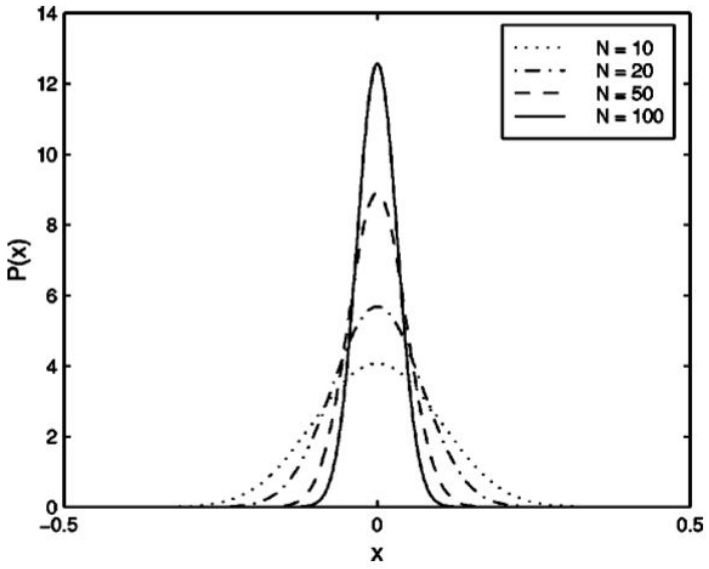

Figure 1. *The cosine noise of (37) closely resembles a normal noise profile, but with finite support. Several values of N are shown, with decreasing standard deviation with increasing N.*

where N is even ($N = 0, 2, \ldots$), and with the normalization constant

$$\mathrm{C_N} = \sqrt{\pi}\,\frac{\Gamma[N/2+1]}{\Gamma[(N+1)/2]}. \tag{38}$$

See Figure 1, in which we can see the decreasing standard deviation with respect to increasing N. This type of noise reminds us of a normal distribution, but of compact support.

The parameter N controls the strength of the noise measured by its variance

$$\sigma^2 = \frac{1}{2\pi^2}\Psi'\left(\frac{N}{2}+1\right) = \frac{1}{12} - \frac{1}{2\pi^2}\sum_{m=1}^{N/1}\frac{1}{m^2}, \tag{39}$$

where Ψ' stands for the derivative of the digamma function.

For the expansion (20) we use basis functions

$$\begin{aligned} u_m(x) &= \cos^m(\pi x)\sin^{N-m}(\pi x),\\ v_n(y) &= \cos^n(\pi y)\sin^{N-n}(\pi y), \end{aligned} \tag{40}$$

where $x \in M$ and $m, n = 0, \ldots, N$. Expanding the cosine as a sum to the Nth power in (37), we find that the $(N+1)\times(N+1)$ matrix A defined by (20) is diagonal:

$$A_{mn} = a_m\delta_{mn}, \text{ with } a_m = \mathrm{C_N}\binom{N}{m}. \tag{41}$$

Integrating trigonometric functions, we find the coefficients

$$b_m = \int_0^1 \cos^m(\pi x)\sin^{N-m}(\pi x)dx = \frac{2}{\pi N}\frac{\Gamma[(m+1)/2]\,\Gamma[(N-m+1)/2]}{\Gamma(N/2)} \tag{42}$$

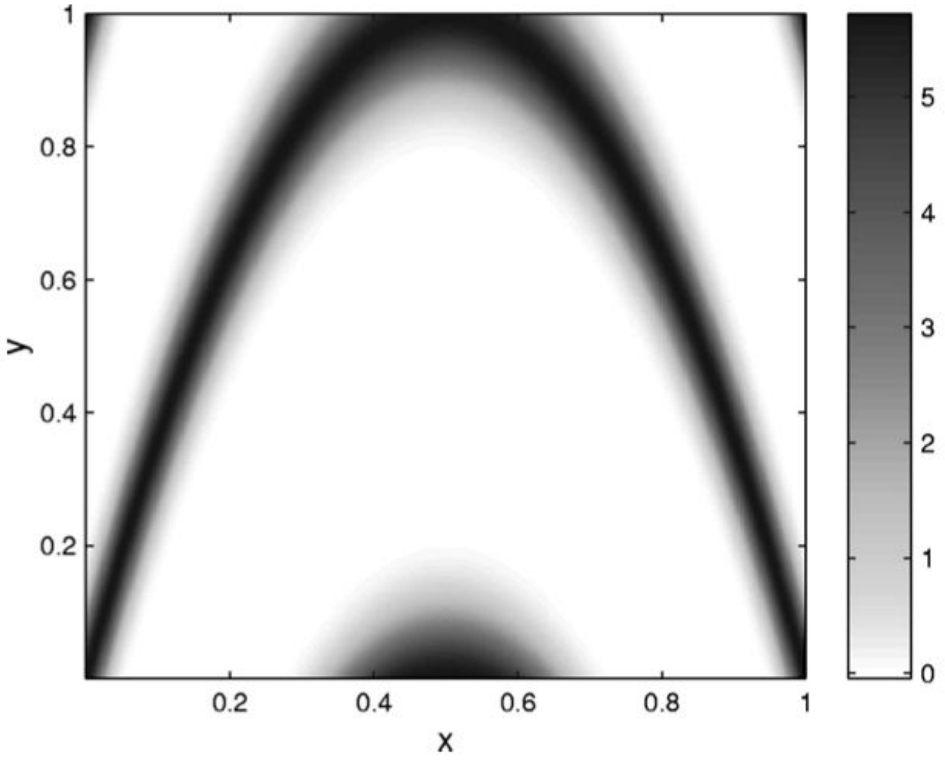

Figure 2. *The transition kernel $\mathcal{P}_N(f(x), y)$ for the logistic map $\tau(x) = 4x(1-x)$, with $N = 20$ and with cosine noise due to $N = 20$; compare to Figure 1. Note the periodicity of x of period 1.*

and

$$s_m = a_m b_m, \tag{43}$$

which are nonzero only for even values of m. Hence the size $K \times K$ of the transition matrix reads

$$K = N/2 + 1, \tag{44}$$

and the expression (36) takes the form

$$T_{kj} = D_{mn} \frac{a_m b_m}{a_n b_n}, \quad \text{where } k, j = 1, \ldots, K,\ m = 2(k-1),\ n = 2(j-1). \tag{45}$$

For the noise (37) discussed here all functions $\tilde{v}_m$ for even m, which contribute to the matrix T, are nonnegative; hence, as discussed in the previous section, the transition matrix T is stochastic. We find in this case that the transition kernel reminds us of a fuzzy but periodically repeated version of the map. See Figure 2. However, the FP operator embeds to a transition matrix T, which "appears" roughly as a different form of the original map; see Figure 3.

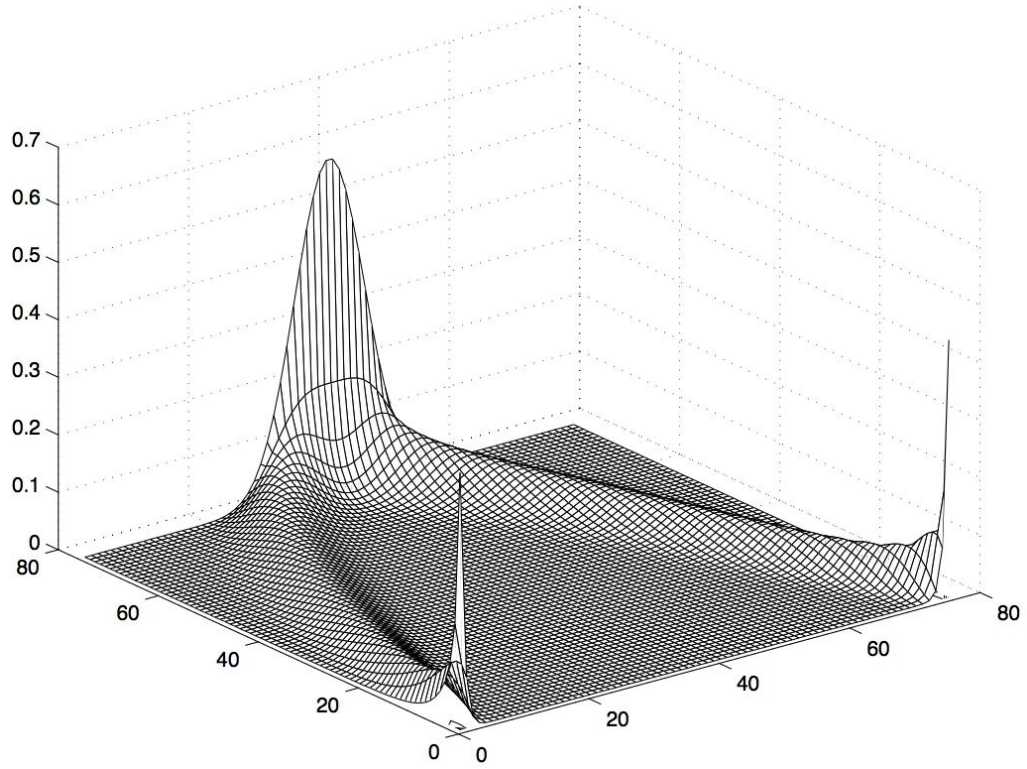

Figure 3. *The stochastic matrix T_{150} shown, from (36), exactly represents the stochastic FP operator of the stochastic tent map (47) with trig noise (37) and basis set (40) using $N = 150$. Note that $T^{(150)}$ is a matrix of size $N/2 + 1 = 150/2 + 1 = 76$ square. Compare to the matrices in (48) of smaller N.*

There is an interesting correspondence between the spectra of eigenvalues of the two matrices D and T. Since T is stochastic, its largest eigenvalue is equal to unity. Moreover, it is the only eigenvalue with modulus one, which follows from the fact that the kernel $\mathcal{P}(x, y)$ vanishes only for $x - y = 1/2 \pmod 1$, and the two-step probability function is everywhere positive:

$$\int_M \mathcal{P}(x, z)\mathcal{P}(z, y)dz > 0 \text{ for } x, y \in M \tag{46}$$

(see [16, Th. 5.7.4]). A particularly useful consequence and simplification is that the eigenstate corresponding to the largest eigenvalue of the matrix represents the invariant density of the system, $\rho_* = P_f(\rho_*)$; this can be easily found numerically by diagonalizing T.

All of the other eigenvalues are included inside the unit circle and their moduli $|\lambda_i|$ characterize the decay rates. It is worth emphasizing that the spectra of both matrix representations of the FP operator, by matrices D of size $(N + 1) \times (N + 1)$ used in [20, 21, 22] and the stochastic T matrices of size $(N/2+1) \times (N/2+1)$ developed here, coincide up to the additional $N/2$ eigenvalues which are equal to zero; see the appendix for details.

For concreteness let us discuss an exemplary one-dimensional dynamical system, a tent map:

$$\tau(x) := \begin{cases} 2x & \text{if} \quad 0 \le x \le 1/2, \\ 2(1-x) & \text{if} \quad 1/2 \le x \le 1. \end{cases} \tag{47}$$

Simple integration allows us to obtain the analytic form of the transition matrix $T^{(N)}$ for the tent map (47) perturbed by additive noise characterized by small values of N,

(48)

$$T^{(2)} = \frac{1}{2}\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}, \quad T^{(4)} = \frac{1}{24}\begin{bmatrix} 11 & 3 & 11 \\ 6 & 6 & 6 \\ 7 & 15 & 7 \end{bmatrix}, \quad T^{(6)} = \frac{1}{320}\begin{bmatrix} 145 & 25 & 25 & 145 \\ 69 & 45 & 45 & 69 \\ 51 & 75 & 75 & 51 \\ 55 & 175 & 175 & 55 \end{bmatrix}.$$

In the simplest case $N = 2$ the transition matrix is bistochastic, but it is not so for larger N. However, for this system, the matrix $T^{(N)}$ is of rank one for arbitrary value of the noise parameter N. The spectrum of T contains one eigenvalue equal to unity and all others equal to zero. This implies that every initial density is projected onto an invariant density already after the first iteration of the map. This is not the case for other dynamical systems τ, including the logistic map $\tau_r(x) = rx(1-x)$, for which the spectrum contains several resonances—eigenvalues of moduli smaller than one—which describe the decaying modes of the system [21].

In this way we have established a relation between a sequence of noisy systems τ_N and the deterministic dynamical system τ. A stochastic system (18) with the noise profile (37) for a fixed noise parameter N is described by a stochastic matrix $T^{(N)}$ of size $K = N/2 + 1$ and acts in the Hilbert space $\mathcal{H}_K$.

We have shown that the sequence of transition matrices $T^{(N)}$ *corresponds* to the dynamical system τ in the sense that the sequence μ_N of the invariant measures of $T^{(N)}$ converges weakly to the τ-invariant measure μ in the deterministic limit $N \to \infty$. Furthermore, for any initial density ρ the sequence of vectors ρ'_N transformed by $P_{\mathcal{P}_N}$ converges weakly to the density transformed by the FP operator associated with τ. Observe that the above property holds not only for one-dimensional systems but also for dynamical system τ in higher dimensional measure spaces.

6. General example. In this section we construct a fairly rich family of transition densities satisfying the assumptions (20). Let $\{g_N\}_{N\ge1}$ be a sequence of C^2 (this condition can be weakened) nonnegative functions with support in $[-1/2, 1/2]$ such that $g_N(-1/2) = g_N(1/2)$ for all $N \ge 1$ and which converges to Dirac's delta δ_0 as $N \to \infty$.

Each g_N, which can be also seen as a 1-periodic function on the whole real line, can be approximated by its partial Fourier sum arbitrarily close in the supremum norm. Let

$$h_N(\xi) = c_{S(N)} + a_{0,N} + 2\sum_{s=1}^{S(N)} \left(a_{s,N}\cos(2s\pi\xi) + b_{s,N}\sin(2s\pi\xi)\right) \tag{49}$$

be an approximation obtained from Fourier approximation by shifting it up by a small constant $c_{S(N)}$ to ensure $h_N \ge 0$ on $[-1/2, 1/2]$. We have $c_{S(N)} \to 0$ as $S(N) \to \infty$. We can make the

functions h_N also converge to Dirac's delta δ_0 as $N \to \infty$. Using the functions h_N we define a family of densities:

$$\mathcal{P}_N(\xi) = h_N(\xi) / \int_{-1/2}^{1/2} h_N(t)dt, \quad N = 1, 2, 3, \ldots, \tag{50}$$

and then a family of transition densities

$$\mathcal{P}_N(x, y) = \mathcal{P}_N(x - y), \quad N = 1, 2, 3, \ldots.$$

Since

$$\begin{aligned}\cos(2s\pi(x-y)) &= \cos(2s\pi x)\cos(2s\pi y) + \sin(2s\pi x)\sin(2s\pi y),\\ \sin(2s\pi(x-y)) &= \sin(2s\pi x)\cos(2s\pi y) - \cos(2s\pi x)\sin(2s\pi y),\end{aligned}$$

it is clear that the assumptions (20)(c) are satisfied with $u_n(x)$ equal to $\cos(2s\pi x)$ or $\sin(2s\pi x)$ and $v_m(y)$ equal to $\cos(2s\pi y)$ or $\sin(2s\pi y)$ for $0 \le s \le S(N)$. It is also clear that for each $x \in [0, 1]$, $\mathcal{P}_N(x, \cdot)$ converges to Dirac's delta δ_x as $N \to \infty$. To have the condition (3) of the next section satisfied it is enough to start with even functions g_N.

Example. Let $g(\xi) = (0.2 + x^2)\exp(-x^2)$ and $g_N(\xi) = Ng(N\xi)$, restricted to $[-1/2, 1/2]$ and extended periodically to the whole real line, $N \ge 1$. Then, the g_N's are positive and converge to Dirac's δ_0 as $N \to \infty$. In particular, let us consider g_6. Its Fourier approximation, with $S(6) = 5$, is

$$\begin{aligned}1.24032 + 1.14838\cos(2\pi\xi) - 0.470309\cos(4\pi\xi) - 0.530699\cos(6\pi\xi)\\ - 0.163161\cos(8\pi\xi) - 0.0225748\cos(10\pi\xi).\end{aligned}$$

We have used such a poor approximation to make the example simpler. We can choose constant $c_{S(6)} = 0$ and after normalization we obtain

$$\begin{aligned}\mathcal{P}_6(\xi) = 1 + 0.92587\cos(2\pi\xi) - 0.37918\cos(4\pi\xi) - 0.42787\cos(6\pi\xi)\\ - 0.131547\cos(8\pi\xi) - 0.01820\cos(10\pi\xi).\end{aligned}$$

See the transition density in Figure 4.

We have

$$\begin{aligned}\mathcal{P}_6(x-y) = 1 &+ 0.92587\cos(2\pi x)\cos(2\pi y) + 0.92587\sin(2\pi x)\sin(2\pi y)\\ &- 0.37918\cos(4\pi x)\cos(4\pi y) - 0.37918\sin(4\pi x)\sin(4\pi y)\\ &- 0.42787\cos(6\pi x)\cos(6\pi y) - 0.42787\sin(6\pi x)\sin(6\pi y)\\ &- 0.131547\cos(8\pi x)\cos(8\pi y) - 0.131547\sin(8\pi x)\sin(8\pi y)\\ &- 0.01820\cos(10\pi x)\cos(10\pi y) - 0.01820\sin(10\pi x)\sin(10\pi y).\end{aligned}$$

See the transition kernel in Figure 5.

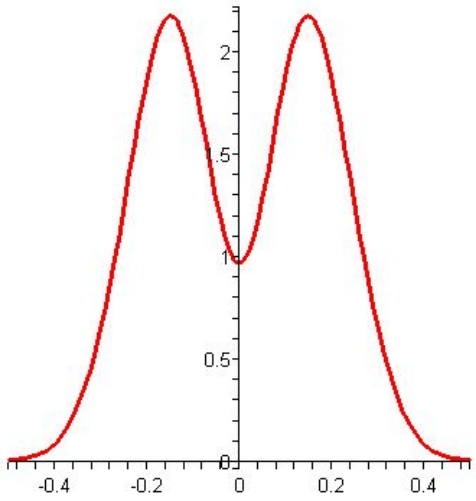

Figure 4. *The transition density* $P_6(\xi)$.

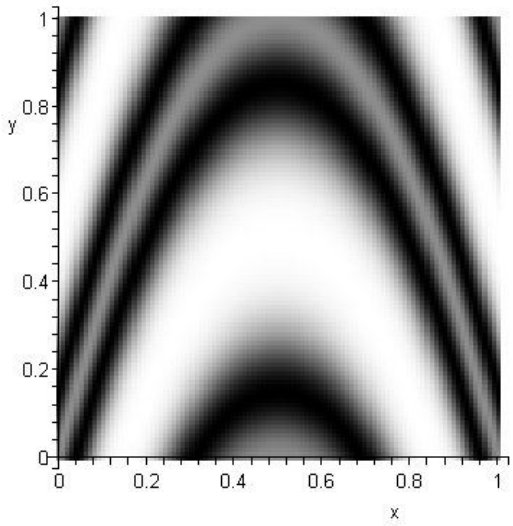

Figure 5. *The transition kernel* $\mathcal{P}_6(\tau(x), y)$ *for the logistic map* $\tau(x) = 4x(1-x)$, *with* $S(6) = 5$.

In the notation of section 4 let us define

$$\begin{aligned}
u_0(x) &= 1, \\
u_{2s+1}(x) &= \cos(2(s+1)s\pi x), \quad s = 0, 1, 2, 3, 4, \\
u_{2s}(x) &= \sin(2s\pi x), \quad s = 1, 2, 3, 4, 5, \\
v_0(y) &= 1, \\
v_{2s+1}(y) &= \cos(2(s+1)\pi y), \quad s = 0, 1, 2, 3, 4, \\
v_{2s}(y) &= \sin(2s\pi y), \quad s = 1, 2, 3, 4, 5.
\end{aligned}$$

Then, matrix $A = (A_{mn})_{0\le m,n\le 10}$ is the diagonal matrix with the diagonal

$$[1, 0.92587, 0.92587, -0.37918, -0.37918, -0.42787, -0.42787, -0.131547, -0.131547, -0.01820, -0.01820],$$

and we have

$$\tilde{v}_m = A_{mm} v_m, \quad m = 0, 1, \dots, 10.$$

Let us consider the dynamics given by the logistic map $\tau : x \mapsto 4x(1-x)$. Matrix D defined in (27) and representing FP operator $P_{\mathcal{P}_6}$ is

(51)
$$D = \begin{bmatrix}
1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0.2441 & -0.3096 & 0 & -0.08859 & 0 & -0.1209 & 0 & -0.01639 & 0 & -0.0007850 & 0 \\
-0.1717 & 0.2016 & 0 & -0.1313 & 0 & 0.00547 & 0 & 0.01382 & 0 & 0.001494 & 0 \\
0.1752 & -0.1940 & 0 & -0.09397 & 0 & 0.06079 & 0 & 0.02395 & 0 & -0.002347 & 0 \\
-0.1372 & 0.1658 & 0 & -0.0159 & 0 & 0.06947 & 0 & -0.02997 & 0 & -0.004869 & 0 \\
0.1436 & -0.1506 & 0 & -0.07445 & 0 & 0.08111 & 0 & -0.006781 & 0 & -0.002915 & 0 \\
-0.1178 & 0.1397 & 0 & 0.00971 & 0 & 0.02136 & 0 & -0.02983 & 0 & 0.001684 & 0 \\
0.1246 & -0.1268 & 0 & -0.06176 & 0 & 0.07547 & 0 & -0.01636 & 0 & -0.0003029 & 0 \\
-0.1051 & 0.1223 & 0 & 0.01799 & 0 & -0.00139 & 0 & -0.01922 & 0 & 0.002802 & 0 \\
0.1116 & -0.1116 & 0 & -0.05331 & 0 & 0.06756 & 0 & -0.01849 & 0 & 0.001108 & 0 \\
-0.09589 & 0.1098 & 0 & 0.02112 & 0 & -0.01226 & 0 & -0.01162 & 0 & 0.002350 & 0
\end{bmatrix}.$$

The eigenvalues of D are

$$1, -.4086428809, 0.0800412, -0.0117582, 0.00331119, -0.000739709, 0, 0, 0, 0, 0.$$

Although in this case all eigenvalues of D are real, in general they are complex. Since matrix D is real, the eigenvalues are placed symmetrically with respect to the real axis. The eigenvector for eigenvalue 1 is

$$w = [1, 0.164834, -0.154604, 0.139482, -0.107445, 0.116956, -0.0938748, 0.102202, -0.0843296, 0.0918404, -0.0772548],$$

and it provides a rough approximation $\sum_{m=0}^{10} w[m]\tilde{v}_m(\xi)$ to the τ-invariant density. A much better approximation shown in Figure 6 is obtained by taking the same noise profile for $N = 40$ and $S = 30$, which results in matrix D of size $2S + 1 = 61$.

For a comparison we performed Ulam's approximation of the invariant density of τ using an $N \times N$ matrix with $N = 61$. For $\phi_m = N \cdot \mathbf{1}_{[(m-1)/N, m/N]}$, Ulam's probabilistic matrix $U = \{U_{ij}\}$ can be obtained by putting

$$U_{ij} = (1/N) \int_0^1 \phi_i(t)\phi_j(\tau(t))dt, \quad 1 \le i, j \le N.$$

We found the 1-eigenvector w of U, and the function $f_N = \sum_{m=1}^{N} w[m]\phi_m$ is Ulam's approximation to τ-invariant density. It is shown in Figure 7.

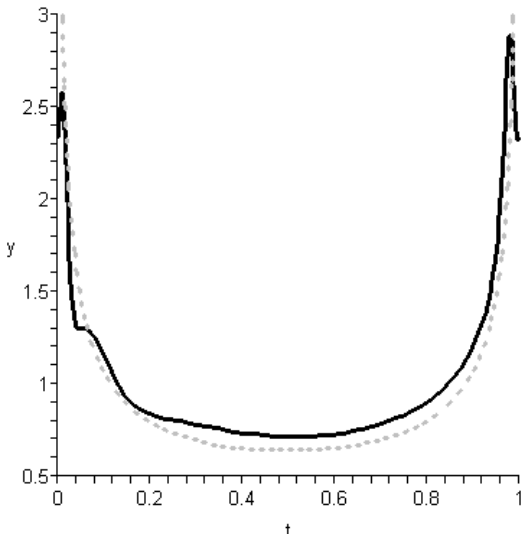

Figure 6. *An approximation to the invariant density of the logistic map (dashed line) obtained as an invariant density of transition matrix D of size 61×61 (solid line).*

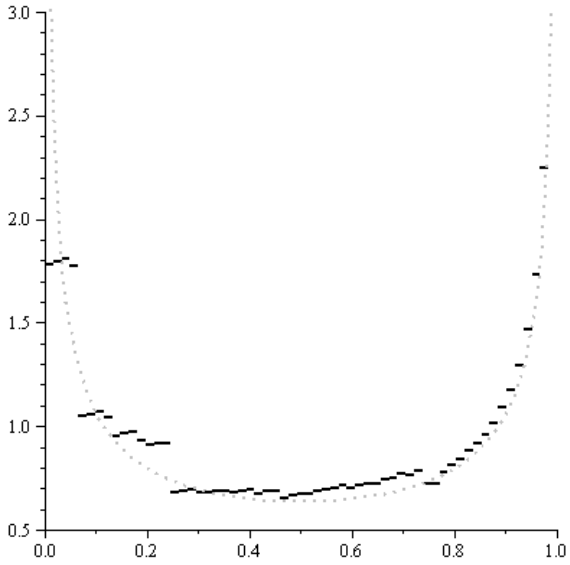

Figure 7. *An approximation to the invariant density of the logistic map (dashed line) obtained by Ulam's method with 61×61 matrix (solid line).*

The L^1 errors of approximation were comparable: 0.17 for Ulam's method and 0.20 for our method. Our method produces a smooth approximating function which is nicer for a smooth invariant density. Our method is also more general in the sense that it can be used to approximate not only the invariant density itself but also the invariant density of a random

perturbation of a map by a possibly very strange perturbing distribution. This was shown in the example above. On the other hand, Ulam's method is definitely simpler and its theoretical properties are well studied.

7. Approximation by basis Markov maps. While not all maps and noise profiles allow for the map to be basis Markov, in this section we will show that a non–basis Markov map may be weakly well approximated by basis Markov maps. In this sense, the finite approximations offered by basis Markov maps can be thought of as a good description of the general behavior, since the invariant measures of the finite approximations due to the basis Markov maps have weak-* limits to the invariant measures of the general maps.

Let us consider a family of the transition probabilities $\mathcal{P}_N(\cdot,\cdot)$ such that, for each $x \in M$, $\mathcal{P}_N(x,\cdot)$ converges to Dirac's delta δ_x as $N \to \infty$.

We require the following assumptions about the transition probabilities $\mathcal{P}_N(\cdot,\cdot)$:

1. $\mathcal{P}_N(\cdot,\cdot)$ is measurable as a function of two variables.
2. For every x we have $\int_M \mathcal{P}_N(x,y)dy = 1$.
3. For every $y \in M$ we have
$$\int_M \mathcal{P}_N(x,y)dx = 1.$$
4. Let $B(x,r) = \{y : |x-y| < r\}$ and
$$p_N(x,r) = \int_{M\setminus B(x,r)} \mathcal{P}_N(x,y)dy. \tag{52}$$
Then, for any $r > 0$,
$$p_N(r) = \sup_{x\in M} p_N(x,r) \to 0 \quad \text{as} \quad N \to +\infty.$$

Assumptions 1–3 are typical for probability measures, while assumption 4 is also rather mild, and it is easy to check that all four assumptions are satisfied by the cosine noise (37).

Under these assumptions, the following can be easily proved.

Proposition. *Let $M = [0,1]$. For any $\rho \in L^1(M)$ we have*
$$\int_M \rho(x)\mathcal{P}_N(x,y)dx \to \rho(y) \text{ as } N \to \infty \tag{53}$$
in $L^1(M)$.

In Theorem 1 below we assume that the transformation $\tau : [0,1] \to [0,1]$ is continuous. This assumption can be weakened (say, to piecewise continuous) if we impose additional restrictions on the transition probabilities $\mathcal{P}_N$ (say, such that all measures μ_N and their weak limits are continuous measures; see, for example, [8]).

Theorem 1. *Let the transformation τ be continuous. Under the assumptions 1, 2, and 4, it follows that if μ_N is an invariant measure of the stochastic perturbation of transformation f defined by the transition probability $\mathcal{P}_N$, then every weak-$*$ limit point of the set $\{\mu_N : N \geq 1\}$ is an f-invariant measure.*

This theorem can be proved following the ideas of Khasminskii [12].

A more precise result can be proved under more restrictive assumptions on the transformation τ.

Theorem 2. *Let the transformation τ be piecewise C^2 and piecewise expanding, i.e., $|\tau'| > 2$, where it exists. Then, under the assumptions 1–4, every weak-$*$ limit point of the set $\{\mu_N : N \geq 1\}$ is a τ-invariant absolutely continuous measure.*

This result was proved in Theorem I.B. of [8]. The perturbations we consider are of "convolution type" and since we treat an interval as a circle an extra factor of 2 does not occur. The example of the famous W-map [11] shows that the condition $|\tau'| > 2$ cannot be weakened.

8. Concluding remarks. In this work we have introduced the concept of basis Markov stochastic systems, for which the associated FP operator is finite. This property resembles the class of deterministic systems with a Markov partition. However, the Markov partition is characteristic to a very special class of deterministic systems, while the basis Markov property is related to the kind of stochastic perturbation. It holds for any deterministic system τ, subjected to an additive noise with a profile satisfying the separability condition (20). In this way such a random dynamical system can be described by a stochastic transition matrix of a finite size K, which diverges in the deterministic limit.

We have shown an intimate relationship between the sequence of stochastic matrices which act in the space of K-point probability distributions and the FP operator P_τ of the deterministic system, which acts in the infinite dimensional space: In the deterministic limit $K \to \infty$ the invariant densities of stochastic matrices converge in a weak sense to the invariant measure of the deterministic system τ. Thus, constructing the transition matrices T and decreasing the noise strength (and increasing the dimensionality K), one may construct arbitrary approximations of the FP operator P_τ.

Some discussion regarding generality is in order. While it is not clear at this stage how many families of examples exist that satisfy the properties in (20), we presented a concrete example in section 5, the cosine noise example, (37), with corresponding basis functions (40). We find this example instructive due to its general appearance as similar to the familiar Gaussian distribution and the fact that it provides a finite representation of the FP operator P_τ by a stochastic transition matrix T. Furthermore, in section 6 we presented a general technique of designing one-dimensional noise profiles which satisfy the separability conditions (20).

Note that the described method is not restricted to one-dimensional systems. On the contrary, the entire construction can be directly applied to a general case of multidimensional dynamical systems. In particular, the definition (20)(c) of separable noise profiles works for the case of an L-dimensional system, provided the variables x and y represent vectors with L components each.

If the dynamical system acts on the L-torus, for example, $M = [0,1]^L$, one can take the Cartesian product of the cosine noise (37) setting

$$\mathcal{P}_N(\xi_1, \ldots, \xi_L) = C_N^L \cos^N(\pi\xi_1) \cos^N(\pi\xi_2) \cdots \cos^N(\pi\xi_L), \tag{54}$$

where $\xi_k = x_k - y_k$ and $k = 1, \ldots, L$. This form of the additive noise was used in [20] to analyze a two-dimensional system (a variant of the baker map) and to compare the spectral properties of the FP operator associated with the classical stochastic system with properties

of the propagator of the corresponding quantum evolution. In such a case the deterministic limit of the classical noisy system, $K \to \infty$, is related to the classical limit, $\hbar \to 0$, of the corresponding quantum dynamics.

Note that for basis Markov stochastic systems, the transition matrices T *exactly* describe the action of the dynamical system with additive noise on densities. Thus our construction differs from an approach applied in [13, 19, 28], where a finite dimensional description of the density dynamics of a deterministic system was achieved by truncation of an infinite transition operator P_τ to the finite dimension K. The effect of such a truncation may also be regarded as a kind of noise depending on the matrix size K and the base, in which P_τ is represented. On the other hand, in our case a suitable choice of the noise profile added to the deterministic system distinguishes a relevant basis, in which the FP operator of the perturbed system is finite.

Appendix. Isospectral matrices. In this appendix we show that the matrix D defined by (27) and used in [20, 21, 22] to represent the FP operator and the stochastic transition matrix T share the same nonzero part of the spectrum. We make use of the following algebraic result.

Lemma. *Let A be a square matrix of size $N \times N$ and $\vec{s}$ a vector of length N containing only nonzero entries. Then the matrix*

$$B_{jk} \equiv A_{jk} \frac{s_j}{s_k} \tag{55}$$

has the same spectrum as A.

(There is no summation over repeating indices.)

Proof. To study equation $\det(B - \lambda \mathbb{1}) = 0$ we start analyzing an exemplary term P^B of the determinant. It consists of a product of N elements $B_{i,\sigma(j)}$, where $\sigma(i)$ stands for a certain permutation of the indices. The product of N factors of the type $s_i/s_{\sigma(i)}$ is equal to unity so that

$$P^B_\sigma = \prod_i B_{i,\sigma(i)} = \prod_i B_{i,\sigma(i)} \frac{s_1 s_2 \cdots s_N}{s_1 s_2 \cdots s_N} = \prod_i A_{i,\sigma(i)}. \tag{56}$$

Thus every term contributing to the free coefficient of the characteristic equation will be the same, $P^B_\sigma = P^A_\sigma$; hence these coefficients for both matrices A and B are equal. Since the diagonal elements of both matrices coincide, $B_{jj} = A_{jj}$, all terms forming the coefficients standing by an arbitrary power of λ are the same for both matrices. Therefore, characteristic equations for both matrices are equal and so are their spectra. ■

Treating all nonzero elements of the vector s_k, $k = 1, \ldots, K$, as vector $\vec{s}$, we may apply the lemma to (36) and obtain equivalence of the spectrum of T and the nonzero part of the spectrum of D. Since integrals (25) vanish for odd values of m, every second column of D is equal to zero, and the remaining $N/2$ eigenvalues of D are equal to zero.

Acknowledgment. We would like to thank W. Słomczyński for several fruitful discussions.

Mixed-Mode Oscillations in Three Time-Scale Systems: A Prototypical Example*

Martin Krupa†, Nikola Popović‡, and Nancy Kopell§

Abstract. Mixed-mode dynamics is a complex type of dynamical behavior that is characterized by a combination of small-amplitude oscillations and large-amplitude excursions. Mixed-mode oscillations (MMOs) have been observed both experimentally and numerically in various prototypical systems in the natural sciences. In the present article, we propose a mathematical model problem which, though analytically simple, exhibits a wide variety of MMO patterns upon variation of a control parameter. One characteristic feature of our model is the presence of three distinct time-scales, provided a singular perturbation parameter is sufficiently small. Using geometric singular perturbation theory and geometric desingularization, we show that the emergence of MMOs in this context is caused by an underlying canard phenomenon. We derive asymptotic formulae for the return map induced by the corresponding flow, which allows us to obtain precise results on the bifurcation (Farey) sequences of the resulting MMO periodic orbits. We prove that the structure of these sequences is determined by the presence of secondary canards. Finally, we perform numerical simulations that show good quantitative agreement with the asymptotics in the relevant parameter regime.

Key words. mixed-mode oscillations, canard mechanism, singular perturbations, three time-scales, geometric desingularization

1. Introduction.

Mixed-mode dynamics is a complex type of dynamical behavior that is characterized by a combination of small-amplitude oscillations and large-amplitude excursions of relaxation type. *Mixed-mode oscillations* (MMOs) are frequently encountered in multiscale dynamical systems, i.e., in systems of differential equations in which the relevant variables evolve over several distinct scales. Consequently, typical MMO patterns in such systems consist of oscillatory sequences in which amplitudes of different orders of magnitude alternate. Historically, MMOs were first observed in experiments on the well-known Belousov–Zhabotinsky reaction [38]. They have since been found both experimentally and numerically in numerous other contexts in the natural sciences. Examples include prototypical systems from chemical kinetics, electrocardiac dynamics, neuronal modeling, and laser dynamics, as

well as from various other disciplines; see, e.g., [10, 16, 23, 27, 29, 30, 32, 31] for details and references.

Among the various mechanisms which have been proposed to explain the occurrence of MMOs are the break-up of an invariant torus [21] and the loss of stability of a Shilnikov homoclinic orbit [16]. MMOs have also been linked to slow passage through a delayed Hopf bifurcation (cf., e.g., [22]) as well as to the subcritical Hopf-homoclinic bifurcation [12, 13]. In the present article, we consider another explanation for the emergence of MMOs, namely, the so-called *canard mechanism*. To the best of our knowledge, this idea was first brought forward by Milik et al. [27]. More recently, in [2], it was extended to accommodate more general classes of systems that exhibit canard dynamics.

The classical canard phenomenon [1, 5, 8, 9] was first described in the framework of two-dimensional fast-slow systems, i.e., of systems with one fast and one slow variable; a prototypical example is the system of equations given by

$$v' = -z + f_2 v^2 + f_3 v^3, \tag{1.1a}$$

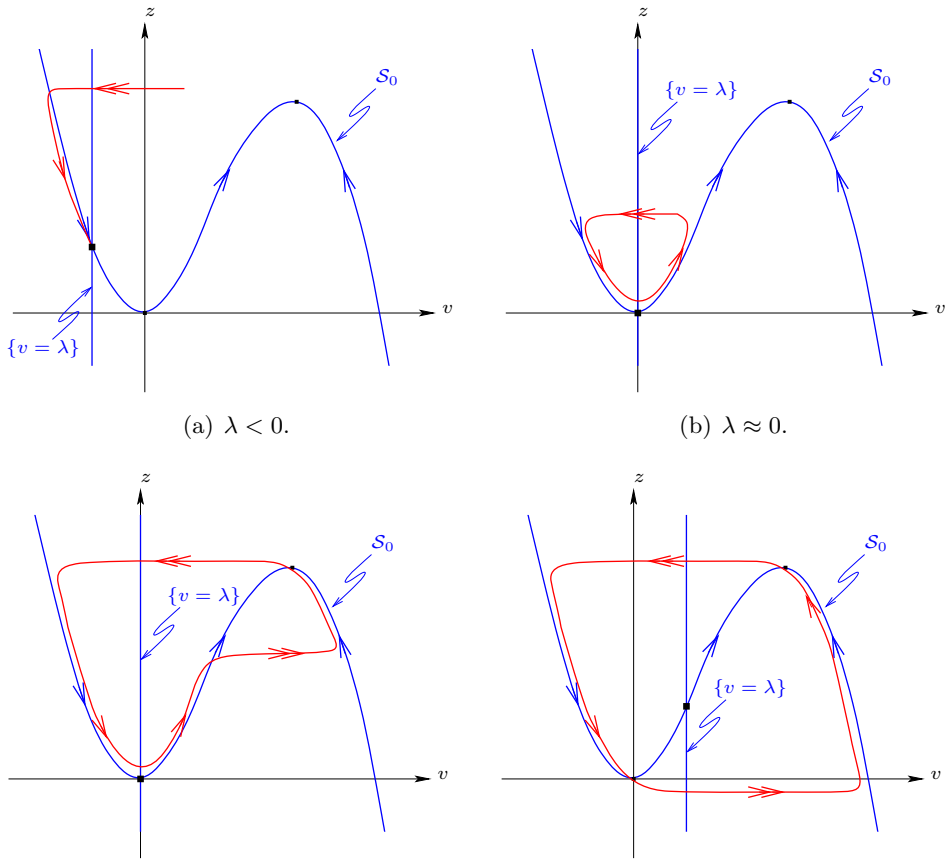
$$z' = \varepsilon(v - \lambda). \tag{1.1b}$$

(Here, $f_2 > 0$ and $f_3 < 0$ are real constants, $0 < \varepsilon \ll 1$ and λ are small parameters, and the prime denotes differentiation with respect to time t.)

The term *canard explosion* [20] is customarily used to denote a transition in (1.1) from a stable equilibrium through a family of small-amplitude cycles and subsequently to a large-amplitude relaxation oscillation. Notably, this transition occurs within an exponentially small range (in ε) of the relevant control parameter, λ. The basic mechanism of a canard explosion can be described as follows: under the above assumptions, the "fast nullcline" $\mathcal{S}_0$ for (1.1), which is given by $z = f(v) := f_2 v^2 + f_3 v^3$, is an S-shaped curve. Moreover, $\mathcal{S}_0$ is a curve of equilibria for the *layer problem* obtained for $\varepsilon = 0$ in (1.1) and is (normally) hyperbolic away from the two *fold points* where $f'(v) = 0$; in particular, the origin is one such point. Rewriting (1.1) in terms of the slow time $\tau = \varepsilon t$, one finds that the corresponding "slow nullcline" is given by $v = \lambda$. As λ passes through 0, this slow nullcline moves through the lower fold point of $\mathcal{S}_0$ at the origin, which triggers the onset of the canard explosion; see Figure 1. Finally, for $\lambda > 0$ sufficiently "large," the dynamics of (1.1) enters the relaxation regime.

One important notion that arises in the study of a canard explosion in (1.1) (as well as in other, related systems) is that of a *maximal canard*. In general, a canard is a solution of (1.1) which originates in the attracting portion of the fast nullcline $\mathcal{S}_0$ and which then crosses over to the repelling one; cf. again Figure 1. Maximal canards are canard trajectories that remain $\mathcal{O}(\varepsilon)$-close to the unstable part of $\mathcal{S}_0$ until they reach the upper fold; they mark the transition from small-amplitude (nonrelaxation) oscillations to large-amplitude oscillations of relaxation type during a canard explosion.

One of the main goals in this article is to show how systems that exhibit mixed-mode-type behavior can be constructed from systems that undergo a canard explosion by replacing the parameter moving the slow nullcline with a dynamical variable. In other words, we will argue that the emergence of MMOs in such systems is triggered by a "slow passage through a canard explosion." More specifically, consider a system of the form



(a) $\lambda < 0$. (b) $\lambda \approx 0$.

(c) $\lambda \approx 0$. (d) $\lambda > 0$.

Figure 1. *Nullcline movement leading to a canard explosion: As the slow nullcline passes through the origin, one observes a transition from* (a) *a stable equilibrium via a family of canard solutions (*(b) *"headless canard,"* (c) *"canard with head") to* (d) *a full-scale relaxation oscillation.*

$$v' = -z + f_2 v^2 + f_3 v^3, \tag{1.2a}$$

$$z' = \varepsilon(v - w), \tag{1.2b}$$

$$w' = \varepsilon\big(\mu + \phi(v, z, w)\big), \tag{1.2c}$$

where $\mu > 0$ and $\phi = \mathcal{O}(v, z, w)$ is a smooth function that will be specified in the following, and note that the new slow variable w in (1.2) assumes the role of λ in (1.1). Let $\mathcal{S}_0$ denote the (two-dimensional) *critical manifold* for (1.2), which is defined by the constraint $z = f(v)$. Finally, let $\ell^- = \{(0, 0, w)\}$ and $\ell^+ = \{(-\frac{2f_2}{3f_3}, 0, w)\}$ denote the lower and upper fold lines for (1.2), respectively, and note that $\ell^\pm$ are determined by imposing $f'(v) = 0$, in addition to $z = f(v)$. Away from these fold lines, $\mathcal{S}_0$ is normally hyperbolic; it consists of the two attracting sheets

$$\mathcal{S}_0^{a-} = \big\{(v, z, w) \,\big|\, v < 0,\, z < 0\big\} \quad \text{and} \quad \mathcal{S}_0^{a+} = \big\{(v, z, w) \,\big|\, v > -\tfrac{2f_2}{3f_3},\, z > \tfrac{4f_2^3}{27f_3^2}\big\}, \tag{1.3}$$

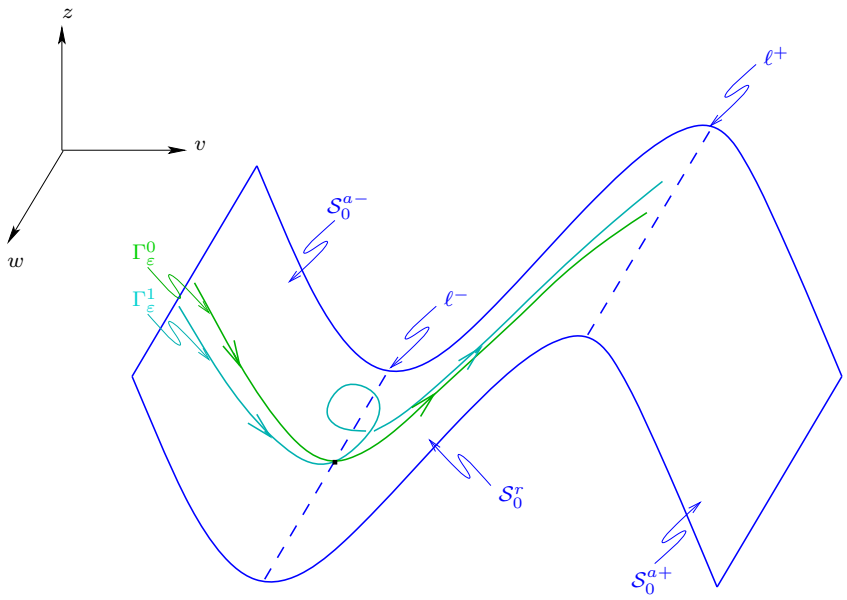


Figure 2. *The geometry of system (1.2): Critical manifold $\mathcal{S}_0$ with sheets $\mathcal{S}_0^{a\pm}$ and $\mathcal{S}_0^r$, fold lines $\ell^\pm$, and canard trajectories Γ_ε^0 and Γ_ε^1.*

as well as of a repelling sheet which is given by

$$\mathcal{S}_0^r = \left\{(v,z,w) \;\middle|\; 0 < v < -\tfrac{2f_2}{3f_3},\ 0 < z < \tfrac{4f_2^3}{27f_3^2}\right\}; \tag{1.4}$$

see Figure 2 for an illustration. (Note that, due to $f_2 > 0$ and $f_3 < 0$, there holds $-\frac{2f_2}{3f_3} > 0$ in (1.3) and (1.4).) The *singular limit* of $\varepsilon = 0$ in (1.2) is described by the dynamics of the *reduced problem* on the critical manifold $\mathcal{S}_0$.

By standard Fenichel theory [11], for $\varepsilon > 0$ sufficiently small and (v,z,w) in some bounded subset of $\mathbb{R}^3$, the critical manifold will perturb to a slow manifold $\mathcal{S}_\varepsilon$ away from $\ell^\pm$. We will denote the sheets of $\mathcal{S}_\varepsilon$ corresponding to $\mathcal{S}_0^{a-}$, $\mathcal{S}_0^{a+}$, and $\mathcal{S}_0^r$ by $\mathcal{S}_\varepsilon^{a-}$, $\mathcal{S}_\varepsilon^{a+}$, and $\mathcal{S}_\varepsilon^r$, respectively.

In analogy to the maximal canard encountered in (1.1), we define the so-called *strong canard* Γ_ε^0 for (1.2) as follows: once the two sheets $\mathcal{S}_\varepsilon^{a-}$ and $\mathcal{S}_\varepsilon^r$ are chosen, they are unique up to exponentially small terms in ε [11]. Then, Γ_ε^0 can be defined, for $\varepsilon > 0$ small, as the intersection of the continuation of these two sheets into the fold region. Moreover, as we will show in section 2, this intersection is transverse, which implies that Γ_ε^0 is well defined. It was postulated in [27] that the strong canard forms the boundary between two regions of very different dynamical behavior, in that it separates small-amplitude oscillations from large oscillations of relaxation type. We will confirm this postulate in the context of (1.2); in that sense, Γ_ε^0 can be interpreted as the "organizing center" for the emergence of MMOs in (1.2).

The detailed structure of the MMO trajectories that will be observed in (1.2) depends strongly on certain features of the specific equations under consideration. One important aspect concerns the properties of the global return mechanism, defined by the interplay of μ and ϕ in (1.2c), and in particular how far back the value of w is reset by that return.

If, during the return phase, w becomes $\mathcal{O}(1)$ and negative (i.e., if $\mu+\phi$ is not close to zero), the dynamics of (1.2) in the initial phase of the passage near the lower fold is of "node type," which means that there is strong contraction without any oscillatory behavior. That initial contractive phase is followed by oscillatory dynamics which can give rise to MMOs; however, most of the resulting oscillations are of very small amplitude. The class of these so-called *canards of folded-node type* is rather well understood and was analyzed in detail in [36].

By contrast, we will discuss a case where the global return mechanism is relatively weak in the sense that $\mu+\phi$ is $\mathcal{O}(1)$. Note that this case differs from that of the so-called *folded saddle-node* [31, 6] in that not only is μ assumed to be small, but ϕ is, too, and that the weakness of the return mechanism introduces an additional, "superslow" time-scale into the problem. In that sense, the folded saddle-node can be regarded as an intermediate case between the folded node and the situation in (1.2). (Note, however, that (1.2) could alternatively be classified as a "folded saddle-node of type II with weak global return" [35].)

The basic dynamics of (1.2) can be characterized as follows: given (v, z, w) small, the system will pass through the small-amplitude phase, where the variable w can grow slightly and become positive. Then, during the subsequent relaxation phase, w is reset to a small (negative or positive) value, and the cycle can start anew. Hence, the fact that w is always close to zero implies that there is no nonoscillatory contraction, contrary to the case of a folded node. Moreover, due to the three time-scale structure of (1.2), no slow passage through a Hopf bifurcation is observed, contrary to the case of a folded saddle-node. This distinction will be made more precise in the following; see also the discussion in section 4 below.

As we will show in this article, it is the interplay between the two main ingredients of the dynamics, the local flow close to the strong canard and the global return, that underlies the basic canard mechanism for the emergence of MMOs in (1.2). This mechanism can be generalized to other classes of systems; see, e.g., [17, 2] for details. In the following, we will refer to a combination of local, dynamical passage through a canard point and a suitably defined global return as the *generalized canard mechanism*. In other words, (1.2) represents only one specific realization of that very general mechanism. Moreover, as will follow from our analysis, (1.2) is a normal form for this class of three time-scale systems, in the sense that the addition of higher-order terms in (1.2) will not fundamentally influence the resulting dynamics.

Another aspect of the mixed-mode dynamics in (1.2), in addition to the return mechanism, is the family of so-called *secondary canards*. In the context of (1.2), we define the kth secondary canard Γ_ε^k as a trajectory that undergoes k small (nonrelaxation) rotations, or "loops," during its passage "near" the lower fold ℓ^- and that then remains $\mathcal{O}(\varepsilon)$-close to the critical manifold $\mathcal{S}_0$ until it reaches the $\mathcal{O}(\varepsilon^{\frac{1}{3}})$-vicinity of the upper fold ℓ^+ [34]. Note that the strong canard Γ_ε^0 passes through the vicinity of ℓ^- without undergoing any rotation at all, which corresponds to $k = 0$. As we will show, the existence of secondary canards in (1.2) is guaranteed by the fact that they can be defined as trajectories lying in the intersection of $\mathcal{S}_\varepsilon^r$ with subsequent iterates of $\mathcal{S}_\varepsilon^{a-}$ under the return map Π induced by the flow of (1.2); cf. section 3 below. This will allow us to give a precise asymptotic description of these canards; to the best of our knowledge, comparable results have so far been obtained only in the folded-node case [36], via a combination of asymptotics and numerics. For a qualitative illustration of the canard trajectories Γ_ε^0 and Γ_ε^1 in (1.2), cf. again Figure 2.

The notion of secondary canards leads to another important concept in this context, namely, that of the corresponding *sectors of rotation*, which are defined as (two-dimensional) portions of $\mathcal{S}_\varepsilon^{a-}$ in the fold region that are bounded by the secondary canards. These sectors, which we denote by RS^k, have the following property: trajectories starting in the kth sector undergo k small rotations near ℓ^-. Given that all MMO trajectories pass exponentially close to $\mathcal{S}_\varepsilon^{a-}$ in their relaxation phase, they must enter one of the sectors upon their return to the fold region. This fact can be exploited to reduce the corresponding (two-dimensional) return map Π for (1.2), which is a priori defined on an appropriate section for the corresponding flow, to a one-dimensional map Φ. Moreover, as we will show, the width of RS^k is $\mathcal{O}(\varepsilon^{\frac{3}{2}}\sqrt{-\ln\varepsilon})$, independent of k to leading order; see section 3. Hence, the canard phenomenon occurs rather "robustly" in the context of (1.2) in the sense that the relevant parameter intervals are not exponentially small in ε, as in the classical two-dimensional case [20].

Finally, with each MMO trajectory one can associate a sequence $L_0^{k_0}L_1^{k_1}\ldots$, called the *Farey sequence* [4], which describes the succession of large relaxation excursions and small (nonrelaxation) oscillations (loops): the segment $L_j^{k_j}$ corresponds to L_j relaxation oscillations followed by k_j small loops. (In the following, we will focus primarily on the case when $L_j = 1$.) As we will show, the Farey sequence of each trajectory is completely determined by the succession of the sectors of rotation visited by the trajectory. A natural question that arises in this context is which Farey sequences are admissible in a system of the form (1.2) and which μ-intervals they correspond to. This question is intimately related to the size of the sectors RS^k themselves, to the distance from the return point on $\mathcal{S}_\varepsilon^{a-}$ to the strong canard Γ_ε^0 after relaxation, and to the contractive (or expansive) properties of the flow induced by Π. These and similar issues will be discussed in detail in sections 3 and 4.

For the sake of definiteness, we will restrict ourselves to the more specific class of systems of the form

$$v' = -z + f_2v^2 + f_3v^3, \tag{1.5a}$$

$$z' = \varepsilon(v - w), \tag{1.5b}$$

$$w' = \varepsilon^2(\mu - g_1z) \tag{1.5c}$$

in the following, with $g_1 > 0$ constant. Note that (1.5) can be understood as a special case of (1.2), with μ rescaled by ε and $\phi(v, z, w) \equiv \phi(z) = \varepsilon g_1 z$. (Other choices of ϕ can be treated in a similar manner; see, e.g., [18].) This specific scaling of μ implies that the dynamics of (1.5) evolves on three distinct time-scales, a fast scale, a slow scale, and a "superslow" scale. Given that the flow of (1.5c) is governed by that slowest scale, w cannot vary too much, implying that trajectories cannot be reset very far back (in w) during the global return. Consequently, they will return close to the strong canard Γ_ε^0 of (1.5) after relaxation; equivalently, recalling the analogy between w and the parameter λ in (1.1), one could say that the return is close to the maximal canard of the (v, z)-subsystem in (1.5).

As we will show in section 3, it is the "lowest" sectors of rotation that will be immediately adjacent to the strong canard. Hence, only a few successive small oscillations will be observed in a typical time series of (1.5); moreover, these oscillations are relatively large in amplitude. Since the relevant parameter intervals will turn out to be relatively small, the corresponding dynamics is very sensitive to variations of μ. Also, since the stability intervals of "regular,"

L^k-type orbits (i.e., of MMO trajectories with Farey sequence $\{L^k\}$) are smaller still, the time series can be quite irregular; furthermore, there can be many relaxation cycles occurring in succession before the system returns to the small-oscillation phase. (By contrast, in the folded-node case, regular 1^k-type orbits are predicted to be stable for most μ-values; cf. [36].)

Moreover, as μ is varied in (1.5), one observes a passage through neighboring sectors of rotation: for increasing μ, the dynamics of (1.5) will be restricted to lower and lower sectors, admitting fewer and fewer small-amplitude oscillations, until eventually only relaxation cycles are seen. In other words, one observes the unfolding of a family of MMOs, including trajectories that pass through all sectors of rotation, on a fairly small parameter set. (In a folded-node system, on the other hand, such an unfolding can be expected over a μ-interval whose length is bounded below by a constant [36].) Also, numerical evidence suggests that only the Farey sequences predicted in section 3 will "generically" occur in a three time-scale system of the type of (1.5). Therefore, we conjecture that (1.5) can be interpreted as a "canonical form" for this particular class of three-dimensional systems. However, a rigorous, analytical justification of this claim is beyond the scope of this work.

In the remainder of this article, we analyze the "canonical" system (1.5) in detail, using a wide range of techniques. One of our aims is to derive asymptotic formulae for the return map induced by the flow of (1.5). To that end, we combine various methods from dynamical systems theory and, in particular, from geometric singular perturbation theory. To approximate the flow away from the fold lines $\ell^{\pm}$, we employ standard results due to Fenichel [11]. Upon entry into the neighborhood of $\ell^{\pm}$, normal hyperbolicity breaks down, and Fenichel's results are no longer applicable, which necessitates a detailed analysis of the dynamics there. We are especially interested in the lower fold ℓ^{-}, since it is there that the canard phenomenon occurs. To describe the dynamics close to ℓ^{-}, we make use of the near-integrable structure of the equations in (1.5). To access that structure, we introduce a rescaling that is akin to the blow-up transformation customarily used in this context; see, e.g., [7, 19] for details. While each of the parts of our analysis taken by itself is rather standard, the combination of the different approaches in the present context is new. In particular, by combining the leading-order global dynamics with detailed local asymptotics, we are able to obtain a closed-form description of the return map Π for (1.5) and, hence, to describe the resulting mixed-mode dynamics in detail.

This article is organized as follows. In section 2, we prove that the return map Π is well defined under an appropriate choice of sections for the flow of (1.5), and we derive precise asymptotic estimates for Π by desingularizing the dynamics of (1.5) in the fold region and by making use of the near-integrability of the resulting equations. Section 3 contains the centerpiece of our analysis in that we show how the "full," two-dimensional map Π can be reduced to a simpler, one-dimensional map Φ. This reduction is accurate with at most an exponentially small error (in ε) and is carried out in two steps: in a first step, Π is restricted from a two-dimensional section to the union of appropriately defined, one-dimensional curves, which allows us to describe the family of secondary canards, as well as the corresponding sectors of rotation, for (1.5). Then, in a second step, the map Π is further reduced and is restricted to a map Φ that is defined on a single curve. The dynamics of this map is analyzed in detail to make quantitative predictions on the relevant parameter regimes and the associated bifurcation (Farey) sequences in (1.5). In section 4, we summarize our results, and we relate

them to other mechanisms that have been proposed to explain MMOs. Moreover, we illustrate various properties of the "reduced" flow under Φ, and we compare them numerically to the "full" dynamics of (1.5). In sum, we thus obtain a fairly complete picture of the mixed-mode dynamics of (1.5), both qualitatively and quantitatively. Moreover, in doing so, we provide a framework for an even more detailed analysis of systems of the type of (1.5): once the dynamics of such a system is accurately reduced to that of a one-dimensional map, the well-developed theory of unimodal maps [25] can be applied. Our results on Φ are a first step in this direction in that there is potential for a more rigorous investigation along the lines of section 3.

Finally, we note that our analysis of (1.5) was inspired by a more specific problem, a model for the dynamics of the dopaminergic neuron that was proposed by Wilson and Callaway [37]. This model, which consists of a system of N strongly electrically coupled oscillators, was analyzed in [24] as well as in [23] (in a slightly different form) via a combination of asymptotic analysis and numerical techniques. One salient feature of the Wilson–Callaway model is precisely the unfolding of a family of MMO periodic orbits upon variation of one control parameter. In an upcoming companion paper [18], we will show how the Wilson–Callaway model can be fitted into the framework of (1.5) and how the results obtained here can be applied to study its dynamics.

2. The canonical system (1.5).

In this section, we discuss the system of equations (1.5) or, equivalently, the system obtained by rewriting (1.5) in terms of the slow time $\tau = \varepsilon t$,

$$\varepsilon \dot{v} = -z + f_2 v^2 + f_3 v^3, \tag{2.1a}$$

$$\dot{z} = v - w, \tag{2.1b}$$

$$\dot{w} = \varepsilon(\mu - g_1 z). \tag{2.1c}$$

Here, the overdot denotes differentiation with respect to τ, $f_2 > 0$, $f_3 < 0$, and $g_1 > 0$ are $\mathcal{O}(1)$ coefficients, $0 < \varepsilon \ll 1$ is small, and μ is the "free" (bifurcation) parameter; note the presence of three time-scales in (2.1).

Let $\mathcal{S}_0$ denote the critical manifold for (2.1), as before, and recall that $\mathcal{S}_0$ is given by $z = f(v) = f_2 v^2 + f_3 v^3$; cf. section 1. Moreover, recall the definition of $\mathcal{S}_0^{a\pm}$ and $\mathcal{S}_0^r$ in (1.3) and (1.4), respectively, and let $\mathcal{S}_\varepsilon^{a\pm}$ and $\mathcal{S}_\varepsilon^r$ denote the corresponding sheets of the slow manifold for $\varepsilon > 0$ sufficiently small. Finally, the upper and lower fold lines in (2.1) are again denoted by $\ell^\pm$.

2.1. Sections for the flow of (1.5).

To derive asymptotic formulae for the return of trajectories under the flow of (1.5), we will define the corresponding return map on suitable sections for the flow, which we introduce below. In the course of our analysis, we will show that the small-amplitude oscillations observed in (1.5) are due to the fact that, in the parameter regime under consideration, the system passes slowly through a canard explosion about the origin in (v, z, w)-space. The large-amplitude components of the mixed-mode time series are generated by the global return mechanism, which takes trajectories back to the fold line ℓ^- after the passage past the origin has been completed. Combining these two aspects of the dynamics will allow us to describe in detail how MMOs can arise in (1.5).

The dynamics of (1.5) can be broken down into the following four components:

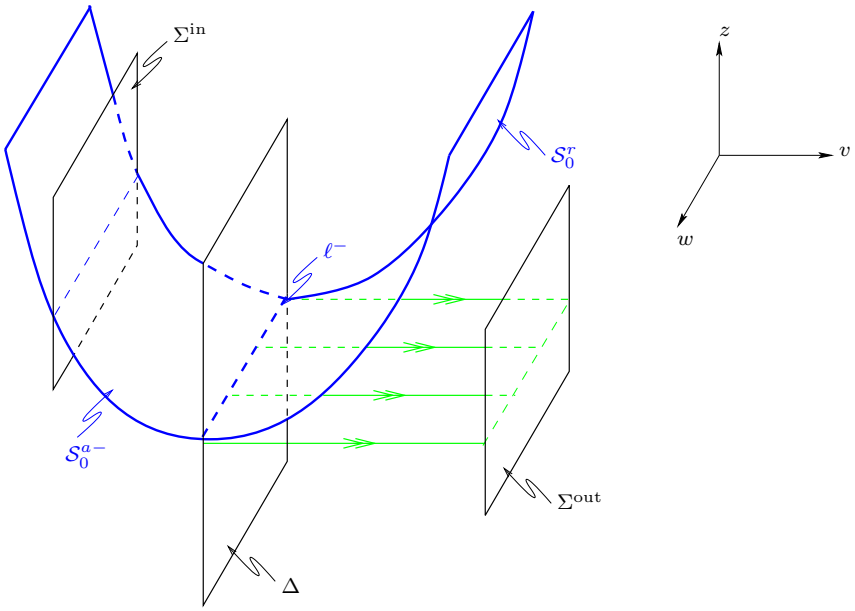

Figure 3. *The sections* Σ^{in}, Δ, *and* Σ^{out} *for the flow of* (1.5).

(i) the flow in a neighborhood of the fold line ℓ^- (section 2.2);
(ii) the entry into the fold region (section 2.3);
(iii) the exit from the fold region (section 2.4); and, finally,
(iv) the global return mechanism (section 2.5).

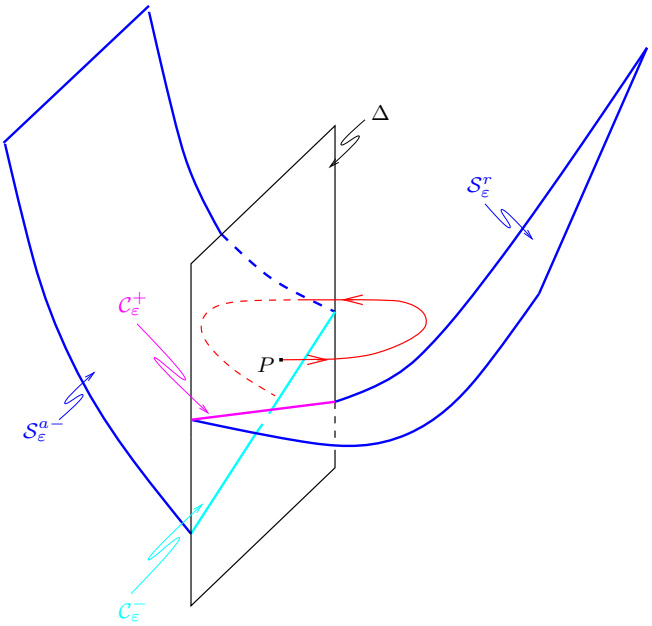
We will construct transition maps for each of the above components of the flow. The desired global return map, which we denote by Π, will then be obtained via the composition of these individual maps.

We begin by introducing *sections* for the flow of (1.5): we will require

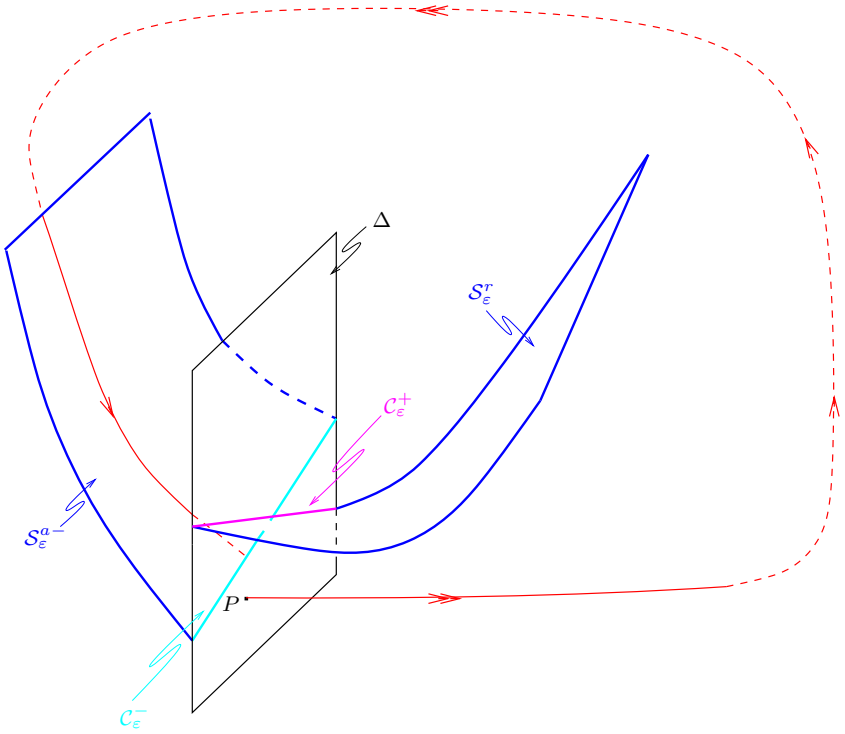
(i) a section Σ^{in} across the attracting branch $\mathcal{S}_0^{a-}$ of the critical manifold $\mathcal{S}_0$, which is given by $v = -\rho$, with $|z|$ and $|w|$ bounded;
(ii) a section Δ, which is defined by $v = 0$, with $|z|$ and $|w|$ bounded, implying that Δ lies in the (z, w)-plane and that it bisects the critical manifold $\mathcal{S}_0$ along ℓ^- (the w-axis); and
(iii) a section Σ^{out} across the fast foliation of $\mathcal{S}_0$, with $v = \delta$ and $|z|$ and $|w|$ bounded.

Here, $\rho, \delta > 0$ are small but fixed (ε-independent) constants; see Figure 3 for an illustration. The section Δ will turn out to be especially important in the following, since the global return map Π will be defined on Δ. (Note that this particular choice of Poincaré section has previously been made by Dumortier and Roussarie in their analysis of canard cycles; see, e.g., [8].)

Next, we introduce two subsets of Δ that will play a crucial role in the description of Π. We first define $\mathcal{C}_\varepsilon^-$ as follows: a point $P \in \Delta$ is an element of $\mathcal{C}_\varepsilon^-$ if P is the endpoint of a segment of trajectory that originates in $\mathcal{S}_\varepsilon^{a-}$. The set $\mathcal{C}_\varepsilon^+$ is defined analogously, with $\mathcal{S}_\varepsilon^{a-}$ replaced by $\mathcal{S}_\varepsilon^r$ and the time reversed; see Figure 4. The sets $\mathcal{C}_\varepsilon^-$ and $\mathcal{C}_\varepsilon^+$ have the following properties:



(a) Trajectory of $P \in \Delta$ above $\mathcal{C}_\varepsilon^+$.



(b) Trajectory of $P \in \Delta$ below $\mathcal{C}_\varepsilon^+$.

Figure 4. *The sets $\mathcal{C}_\varepsilon^-$ and $\mathcal{C}_\varepsilon^+$.*

(i) If $P \in \Delta$ is above $\mathcal{C}_\varepsilon^+$, the trajectory of P is blocked by $\mathcal{S}_\varepsilon^r$ from entering relaxation. Depending on the position of P, the initial motion may be toward $\mathcal{S}_\varepsilon^r$, but the trajectory must eventually turn toward $\mathcal{S}_\varepsilon^{a-}$ (under the fast flow) and return to Δ, having undergone a small-amplitude oscillation (or loop); see Figure 4(a).

(ii) If $P \in \Delta$ is below $\mathcal{C}_\varepsilon^+$, the trajectory of P must leave the vicinity of the fold in the direction of the fast flow and may re-enter only through a global return mechanism, since no trajectories can pass through $\mathcal{S}_\varepsilon^r$; see Figure 4(b).

(iii) Any trajectory that is attracted to $\mathcal{S}_\varepsilon^{a-}$ will be exponentially close to $\mathcal{C}_\varepsilon^-$ when it hits Δ.

Remark 1. Since $\mathcal{S}_\varepsilon^{a-}$ and $\mathcal{S}_\varepsilon^r$ are unique only up to exponentially small terms in ε, the sets $\mathcal{C}_\varepsilon^\pm$ are, strictly speaking, "strips" rather than curves. However, since our construction of Π will rely on leading-order ε-asymptotics throughout, this nonuniqueness will not influence our results.

A proof of these claims will be given in section 3 below. We now proceed with the derivation of the four components of the return map, as outlined above. The description of the dynamics in the fold region is the centerpiece of our analysis and will be discussed first.

2.2. Dynamics in the fold region. Our goal in this subsection is to analyze the flow in the region of the phase space of (1.5) where small-amplitude oscillations (loops) can occur. To describe these loops, we have to study the equations in (1.5) in an $\mathcal{O}(\sqrt{\varepsilon})$-vicinity of the fold line ℓ^- and, specifically, of the origin in (u, v, w)-space. Recall that under our assumptions on (1.5), ℓ^- is given by the w-axis.

To investigate the dynamics of (1.5) close to ℓ^-, we define the rescaling

$$v = \sqrt{\varepsilon}\bar{v}, \quad z = \varepsilon\bar{z}, \quad w = \sqrt{\varepsilon}\bar{w}, \quad \text{and} \quad t = \frac{\bar{t}}{\sqrt{\varepsilon}}. \tag{2.2}$$

In terms of the new "barred" variables in (2.2), (1.5) becomes

$$\bar{v}' = -\bar{z} + f_2\bar{v}^2 + \sqrt{\varepsilon} f_3 \bar{v}^3, \tag{2.3a}$$

$$\bar{z}' = \bar{v} - \bar{w}, \tag{2.3b}$$

$$\bar{w}' = \varepsilon(\mu - g_1\varepsilon\bar{z}), \tag{2.3c}$$

where the prime now denotes differentiation with regard to the new rescaled time $\bar{t}$. Note that (2.3) is a fast-slow system, with two fast variables $\bar{v}$ and $\bar{z}$ and one slow variable $\bar{w}$. In other words, the scale separation between v and z has vanished after the rescaling, whereas $\bar{w}$ is still slow and constant to leading order. Hence, we can interpret $\bar{w}$ as a slowly varying parameter.

For $\varepsilon = 0$, the equations in (2.3) reduce to

$$\bar{v}' = -\bar{z} + f_2\bar{v}^2, \tag{2.4a}$$

$$\bar{z}' = \bar{v} - \bar{w}, \tag{2.4b}$$

$$\bar{w}' = 0. \tag{2.4c}$$

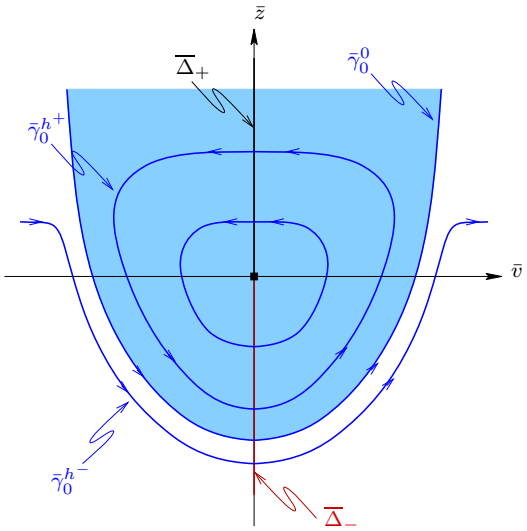


Figure 5. *Typical integral curves of H, with $h^- < 0 < h^+$. (The region where $h > 0$ is shaded.)*

Note that, up to various rescalings, (2.4) is of the form

$$x' = -y + x^2,$$
$$y' = x - \lambda,$$

which is a prototypical system for the occurrence of a canard explosion (at $\lambda = 0$) [20]; see also (1.1). In the following, we will describe how the equations in (2.3) fit into the framework of [20], where the classical two-dimensional scenario is analyzed using geometric singular perturbation theory. The role of the bifurcation parameter λ is taken by $\bar{w}$ in our case. For $\bar{w} = 0$, (2.4) is an integrable system, with constant of motion given by

$$H(\bar{v}, \bar{z}) = \frac{1}{2} \mathrm{e}^{-2f_2\bar{z}} \Big(-\bar{v}^2 + \frac{\bar{z}}{f_2} + \frac{1}{2f_2^2} \Big). \tag{2.5}$$

The equations in (2.4) have a continuous family of periodic orbits which are most conveniently described via the level curves of H; these are defined by $H(\bar{v}, \bar{z}) = h$ for h constant. The corresponding (time-parametrized) solution curves will be denoted by $\bar{\gamma}_0^h(t) = (\bar{v}_0^h, \bar{z}_0^h)(t)$ in the following.

We first note that $(\bar{v}, \bar{z}) = (0, 0)$ lies on the curve defined by $H(\bar{v}, \bar{z}) = h_0 := (4f_2^2)^{-1}$. For $h > h_0$, there exist no real solutions to $H(\bar{v}, \bar{z}) = h$. Hence, without loss of generality, we consider $h \le h_0$ now, and we note that $h_0 > 0$. For $h = 0$ in (2.5), we obtain the special solution $\bar{\gamma}_0^0$ of (2.4), with

$$\bar{\gamma}_0^0(t) = (\bar{v}_0^0, \bar{z}_0^0)(t) = \Big(\frac{1}{2f_2} t, \frac{1}{4f_2} t^2 - \frac{1}{2f_2} \Big). \tag{2.6}$$

Note that (2.6) defines an invariant parabola that separates the closed level curves of H, which are obtained for $h > 0$, from the open ones, with $h < 0$; see Figure 5 for an illustration. Since

the two branches of this parabola correspond to $\mathcal{S}_0^{a-}$ and $\mathcal{S}_0^r$ for $\bar{w}=0$, after the rescaling in (2.2), $\bar{\gamma}_0^0$ is a "singular canard solution," i.e., a solution of (2.3) that connects $\mathcal{S}_\varepsilon^{a-}$ and $\mathcal{S}_\varepsilon^r$ in the singular limit as $\varepsilon \to 0$. (In fact, as we will see in (2.16) below, the orbit determined by $\bar{\gamma}_0^0$ is precisely the strong canard Γ_ε^0 in this singular limit.)

Let $\overline{\Delta}$ denote the section that corresponds to Δ in the "barred" variables; i.e., let $\overline{\Delta} = \{\bar{v}=0\}$, with $|\bar{z}|$ and $|\bar{w}|$ bounded. For h fixed, let $\bar{z}^h$ be the corresponding value of $\bar{z}$ in $\overline{\Delta}$, with $H(0,\bar{z}^h)=h$. (In particular, by (2.6), there holds $\bar{z}^0=-(2f_2)^{-1}$.) Our first result is a direct consequence of the above discussion; see [20] for details.

Proposition 2.1. *To any $h \le h_0$, with $h_0=(4f_2^2)^{-1}>0$, there corresponds precisely one value $\bar{z}^h \le 0$ of $\bar{z}$ in $\overline{\Delta}$. Moreover, $\bar{z}^h$ is an increasing function of h.*

Since the limiting equations obtained for $\bar{w}=0=\varepsilon$ in (2.3) are integrable, we will refer to the original, "perturbed" dynamics as "near-integrable." (A related treatment of a more general family of near-integrable systems can be found in [15].) The near-integrability of (2.3) will allow us to analyze the dynamics of the equations using a perturbation analysis, and to approximate the return map from $\overline{\Delta}$ to itself, which we refer to as $\overline{\Pi}$, to leading order. Naturally, the closed level curves of H will turn out to be the singular "templates" for the small-amplitude component of the mixed-mode dynamics observed in (2.1). Moreover, as we will show, it is the bifurcation structure of $\overline{\Pi}$ that is responsible for the emergence of secondary canards in (2.3); these canards, in turn, determine the qualitative structure of the resulting MMO patterns. In that sense, the rescaling in (2.2) will enable us to access the near-integrable structure of (1.5) close to ℓ^-.

We will define the return map $\overline{\Pi}$ on $\overline{\Delta}_- \subset \overline{\Delta}$, which is the portion of $\overline{\Delta}$ where $\bar{z}<0$. Although $\overline{\Pi}$ is a priori a function of $(\bar{z},\bar{w})$, it is more convenient to parametrize $\bar{z}$ by h and to describe the asymptotics of $\overline{\Pi}$ in terms of h and $\bar{w}$ in the following. For $h \le h_0$, with h_0 as above, let $\bar{z}^h$ again denote the corresponding unique value of $\bar{z} \in \overline{\Delta}_-$, and note that we will sometimes identify $\bar{z}^h$ with its associated h-value. Moreover, let $\bar{\gamma}_\varepsilon^h(t)$ be the solution to (2.3) emanating from $(0,\bar{z}^h,\bar{w})$, where the time parametrization is chosen so that $\bar{\gamma}_\varepsilon^h(0)$ is contained in $\overline{\Delta}_+ := \overline{\Delta}\backslash\overline{\Delta}_-$. Then, we define $T_-^h(\bar{w})<0$ and $T_+^h(\bar{w})>0$ by requiring that $\bar{\gamma}_\varepsilon^h(T_\pm^h(\bar{w})) \in \overline{\Delta}_-$. Moreover, we assume that $T_\pm^h(\bar{w})$ are the times of the first such intersection. Let $T^h : \overline{\Delta}_- \to \overline{\Delta}_-$ denote the return time of solutions under the flow of (2.3), and note that, by definition, $T^h(\bar{w}) = T_+^h(\bar{w}) - T_-^h(\bar{w})$. Let $\hat{h}$ be defined by the requirement that $\bar{z}^{\hat{h}}$ is the $\bar{z}$-coordinate of $\bar{\gamma}_\varepsilon^h(T^h(\bar{w})) \in \overline{\Delta}_-$; an illustration of these definitions is given in Figure 6. Finally, for $\bar{w}=0$, we write $T^h := T_+^h(0)$, which, together with $T_-^h(0)=-T_+^h(0)$, implies

$$T^h(0) = T_+^h(0) - T_-^h(0) = 2T^h. \tag{2.7}$$

We now make the following assumption on $\bar{w}$, which will be verified a posteriori for the parameter regime we are interested in.

Assumption 1. For fixed, real $f_2>0$, $f_3<0$, $\mu>0$, and $g_1>0$ and $0<\varepsilon\ll 1$ sufficiently small in (2.3), $\bar{w}=\mathcal{O}(\sqrt{\varepsilon})$ uniformly in $\bar{t}$.

It will follow from our analysis that Assumption 1 defines an invariant region for the return map Π which roughly corresponds to the regime where $\bar{w}=\mathcal{O}(\sqrt{\varepsilon})$. More precisely, if an initial condition for (2.3) satisfies the assumption, it will be satisfied along the entire corresponding trajectory of (2.3). Finally, since $w=\sqrt{\varepsilon}\bar{w}$, Assumption 1 implies that $w=\mathcal{O}(\varepsilon)$ must hold in (2.1), uniformly in τ.

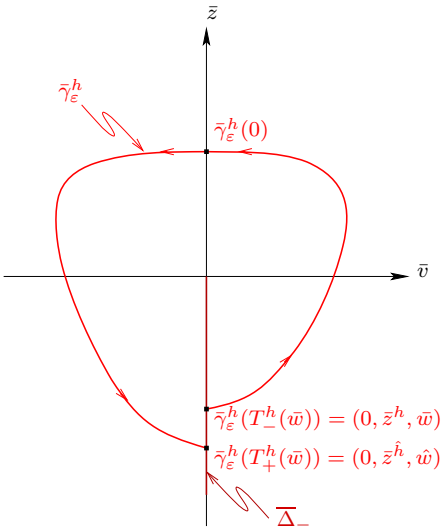

Figure 6. *The geometry of system* (2.3).

We state our next result in a slightly more general context than that of (2.3). The reason for this generalization is that we will modify (2.3) later to simplify our estimates of the return time $T^h(\bar{w})$. Thus, instead of (2.3), we now consider the following generalized system of equations:

$$\bar{v}' = -\bar{z} + f_2\bar{v}^2 + \sqrt{\varepsilon} f_3 \bar{v}^3 + \sqrt{\varepsilon} F(\bar{w}, \sqrt{\varepsilon}) + \bar{w} G(\bar{w}, \sqrt{\varepsilon}), \tag{2.8a}$$

$$\bar{z}' = \bar{v} - \bar{w} + \mathcal{O}(\varepsilon), \tag{2.8b}$$

$$\bar{w}' = \varepsilon\big(\mu - g_1 \varepsilon \bar{z} + \mathcal{O}(\varepsilon)\big), \tag{2.8c}$$

where F and G are assumed to be $\mathcal{C}^n$-smooth for $n \geq 1$ sufficiently large in both $\bar{w}$ and $\sqrt{\varepsilon}$. Note that all the definitions and notation introduced in the context of (2.3) extend without modification to (2.8).

Proposition 2.2. *Let $\overline{\Pi} : \overline{\Delta}_- \to \overline{\Delta}_-$ and $\bar{\gamma}_\varepsilon^h$ be defined as above, and let $(h, \bar{w}) \in \overline{\Delta}_-$. Suppose that $h > 0$, with $h = \mathcal{O}(\varepsilon^M)$ for some $M > 0$ and $\varepsilon > 0$ sufficiently small, and that the trajectory starting at $(h, \bar{w})$ undergoes a small oscillation ("loop") before returning to $\overline{\Delta}_-$. Then,*

$$(\hat{h}, \hat{w}) := \overline{\Pi}(h, \bar{w}) = \big(h + \sqrt{\varepsilon} d^h_{\sqrt{\varepsilon}} + \bar{w} d^h_{\bar{w}} + \mathcal{O}\big((\sqrt{\varepsilon} + \bar{w})^2\big),\ \bar{w} + \varepsilon\mu T^h(\bar{w}) + \mathcal{O}(\varepsilon^2)\big), \tag{2.9}$$

where the coefficients $d^h_{\sqrt{\varepsilon}}$ and $d^h_{\bar{w}}$ are defined as

$$d^h_{\sqrt{\varepsilon}} = \int_{-T^h}^{T^h} \nabla H(\bar{\gamma}_0^h(t)) \cdot \big(f_3 \bar{v}_0^h(t)^3, 0\big)^T \, dt \tag{2.10}$$

and

$$d^h_{\bar{w}} = \int_{-T^h}^{T^h} \nabla H(\bar{\gamma}_0^h(t)) \cdot (0, -1)^T \, dt, \tag{2.11}$$

respectively, and $\bar{\gamma}_0^h(t) = (\bar{v}_0^h, \bar{z}_0^h)(t)$ *denotes the solution to* (2.4) *with* $H(\bar{v}_0^h, \bar{z}_0^h) = h$.

Remark 2. Given Assumption 1, as well as the fact that $T^h(\bar{w}) \sim \sqrt{-2\ln h}$ by Lemma A.2, $h = \mathcal{O}(\varepsilon^M)$ implies $\varepsilon T^h(\bar{w}) = \mathcal{O}(\varepsilon\sqrt{-\ln\varepsilon})$ in (2.9) for any $M > 0$. Moreover, the expansion for $\hat{h}$ remains valid even if $M > \frac{1}{2}$, i.e., when the leading-order term in ε is given by $\sqrt{\varepsilon}d^h_{\sqrt{\varepsilon}}$. Hence, it follows that (2.9) describes the map $\overline{\Pi}$ up to an $\mathcal{O}(\varepsilon)$-error.

Proof. We only sketch the proof here and refer the reader to [19] for details.

To derive the expression for $\hat{w}$, one makes use of the near-integrability of (2.8) as well as of regular perturbation theory.

To prove the assertion for $\hat{h}$, we first note that

$$\hat{h} - h := H(0, \hat{z}^{\hat{h}}) - H(0, \bar{z}^h) = \int_{T^h_-(w)}^{T^h_+(w)} \frac{d}{dt} H(\bar{\gamma}^h_\varepsilon(t))\, dt. \tag{2.12}$$

Since, to lowest order,

$$\frac{d}{dt} H(\bar{\gamma}^h_\varepsilon(t)) = \nabla H(\bar{\gamma}^h_\varepsilon(t)) \cdot (\bar{v}', \bar{z}')^T\big|_{\bar{\gamma}^h_\varepsilon} = \nabla H(\bar{\gamma}^h_0(t)) \cdot (\bar{v}', \bar{z}')^T\big|_{\bar{\gamma}^h_0},$$

and since H is a constant of motion, it follows with (2.8a) and (2.8b) that

$$\begin{aligned}\hat{h} - h = &\int_{-T^h}^{T^h} \nabla H(\bar{\gamma}^h_0(t)) \cdot \big(f_3 \bar{v}^h_0(t)^3 + F(0,0), 0\big)^T\, dt\, \sqrt{\varepsilon} \\ &+ \int_{-T^h}^{T^h} \nabla H(\bar{\gamma}^h_0(t)) \cdot (G(0,0), -1)^T\, dt\, \bar{w} + \mathcal{O}(2);\end{aligned} \tag{2.13}$$

see also [20]. (Here, $\mathcal{O}(2)$ denotes terms of at least second order in $\sqrt{\varepsilon}$ and $\bar{w}$.) Since, however, $(\bar{v}^h_0, \bar{z}^h_0)(-t) = (-\bar{v}^h_0, \bar{z}^h_0)(t)$ on $\bar{\gamma}^h_0$ by symmetry, a change of variables via $t \mapsto -t$ in combination with (2.5) shows

$$\begin{aligned}\int_{-T^h}^{T^h} \frac{\partial H}{\partial \bar{v}}(\bar{\gamma}^h_0(t))\, dt &= -\int_{-T^h}^{T^h} \bar{v}^h_0(t) \mathrm{e}^{-2f_2 \bar{z}^h_0(t)}\, dt = -\int_{T^h}^{-T^h} \bar{v}^h_0(-t) \mathrm{e}^{-2f_2 \bar{z}^h_0(-t)}\, d(-t) \\ &= -\int_{-T^h}^{T^h} \frac{\partial H}{\partial \bar{v}}(\bar{\gamma}^h_0(t))\, dt.\end{aligned}$$

Therefore, the latter integral must be zero, which implies

$$\int_{-T^h}^{T^h} \frac{\partial H}{\partial \bar{v}}(\bar{\gamma}^h_0(t))\, F(0,0)\, dt = 0 \quad \text{and} \quad \int_{-T^h}^{T^h} \frac{\partial H}{\partial \bar{v}}(\bar{\gamma}^h_0(t))\, G(0,0)\, dt = 0.$$

It follows that (2.13) reduces to

$$\hat{h} - h = d^h_{\sqrt{\varepsilon}} \sqrt{\varepsilon} + d^h_{\bar{w}} \bar{w} + \mathcal{O}(2),$$

with the coefficients $d^h_{\sqrt{\varepsilon}}$ and $d^h_{\bar{w}}$ as defined in (2.10) and (2.11). This completes the proof. ∎

Remark 3. Note that the functions $T^h_\pm(\bar{w})$ and $T^h(\bar{w})$ depend very sensitively on h, $\bar{w}$, and $\sqrt{\varepsilon}$; in fact, since $\lim_{(h,\bar{w},\varepsilon)\to(0,0,0)} T^h(\bar{w}) = \infty$, $T^h(\bar{w})$ has a singularity at the origin. For

this reason, it is not immediately obvious that $T^h_+(\bar{w})$ and $T^h_-(\bar{w})$ can be replaced by T^h and $-T^h$, respectively, in (2.12). However, the arguments in [19] can easily be extended to justify this point.

Given Proposition 2.2, we make the following observations:

(i) Observe that, for $\mu = 0$, the equations in (2.3) have an equilibrium point at the origin. The linearization of (2.3) about this equilibrium has a pair of purely imaginary eigenvalues, as well as a simple eigenvalue 0. The corresponding steady-state Hopf-type interactions mark the onset of small-amplitude oscillations in (2.3); see also [20, Theorem 3.1]. (Note that the presence of the zero eigenvalue, which is due to the absence of a linear $\bar{w}$-term in (2.3c), introduces a degeneracy at the origin in (2.3).)

(ii) In order to obtain periodic orbits in (2.3), we have to require $h = \hat{h}$ and $\bar{w} = \hat{w}$; see the definition of $\overline{\Pi}$ in (2.9). Hence, to leading order, we must impose the condition

$$d^h_{\sqrt{\varepsilon}}\sqrt{\varepsilon} + d^h_{\bar{w}}\bar{w} = 0 \tag{2.14}$$

on $(h, \bar{w})$. To show that (2.14) can be solved for h and $\bar{w}$, we have to find the next-order correction to $\hat{w}$ in (2.9): integrating (2.3c), we obtain

$$\hat{w} = \bar{w} + 2\varepsilon\mu T^h - g_1\varepsilon^2 \int_{-T^h}^{T^h} \bar{z}(t)\,dt,$$

to leading order. Using (2.3a) to express $\bar{z}$ in terms of $\bar{v}$, we find

$$\hat{w} \sim \bar{w} + \varepsilon\left(2\mu T^h - g_1\varepsilon \int_{-T^h}^{T^h} \left(-\bar{v}'(t) + f_2\bar{v}(t)^2\right) dt\right).$$

(Here and in the following, the tilde indicates a leading-order asymptotic approximation.) Since, moreover, $\bar{v}(-T^h) = 0 = \bar{v}(T^h)$ by definition, and since (2.3b) implies $\frac{d\bar{z}}{dt} \sim \bar{v}$ by Assumption 1, it follows that

$$\hat{w} \sim \bar{w} + 2\varepsilon\left(\mu T^h - f_2 g_1 \varepsilon \int_{\xi^h}^{\zeta^h} \bar{v}(\bar{z})\,d\bar{z}\right).$$

Here, $\xi^h = \bar{z}(-T^h)$ and $\zeta^h = \bar{z}(0)$ denote the $\bar{z}$-values in $\overline{\Delta}$ corresponding to $\bar{\gamma}^h_\varepsilon(-T^h)$ and $\bar{\gamma}^h_\varepsilon(0)$, respectively. In sum, the requirement that $\bar{w} = \hat{w}$ gives

$$\mu T^h - f_2 g_1 \varepsilon \int_{\xi^h}^{\zeta^h} \bar{v}(\bar{z})\,d\bar{z} = 0 \tag{2.15}$$

to lowest order. Since $\frac{1}{T^h}\int_{\xi^h}^{\zeta^h} \bar{v}(\bar{z})\,d\bar{z}$ increases monotonically in h as $h \to 0$ (see [19]), it follows that, for ε and μ small and fixed, one can find h such that (2.15) holds. Given that h-value, one can use (2.14) to determine the associated value of $\bar{w}$.

(iii) For μ and ε sufficiently small in (2.1), there exists a canard trajectory lying in the intersection of the manifolds $\mathcal{S}^{a-}_\varepsilon$ and $\mathcal{S}^r_\varepsilon$; this trajectory is the strong canard Γ^0_ε. Since $\mathcal{S}^{a-}_\varepsilon$ and $\mathcal{S}^r_\varepsilon$ intersect transversely, as we will show in section 2.3 below, Γ^0_ε is

well defined; moreover, it is unique once specific sheets of $\mathcal{S}_\varepsilon$ have been chosen. The associated *canard critical value* $\bar{w}^{\mathrm{c}}$, i.e., the value of $\bar{w}$ in the rescaled system (2.3) that corresponds to Γ_ε^0, is given by

$$\bar{w}^{\mathrm{c}} = -\frac{d^0_{\sqrt{\varepsilon}}}{d^0_{\bar{w}}}\sqrt{\varepsilon} + \mathcal{O}(\varepsilon), \tag{2.16}$$

where $d^0_{\sqrt{\varepsilon}}$ and $d^0_{\bar{w}}$ are obtained from (2.10) and (2.11) in the limit as $h \to 0$ [19]. In particular, since $\bar{w}^{\mathrm{c}} \to 0$ for $\varepsilon \to 0$, (2.16) yields precisely the singular canard solution $\bar{\gamma}_0^0$ in this limit; cf. (2.6). Hence, as $h \to 0$, (2.3) undergoes a classical (two-dimensional) canard explosion at $\bar{w} = 0 = \varepsilon$ [20].
To evaluate (2.16), note that (2.5) implies

$$\frac{\partial H}{\partial \bar{v}} = -\bar{v}\mathrm{e}^{-2f_2\bar{z}} \quad \text{and} \quad \frac{\partial H}{\partial \bar{z}} = (f_2\bar{v}^2 - \bar{z})\mathrm{e}^{-2f_2\bar{z}}. \tag{2.17}$$

Using the parametrization of $\bar{\gamma}_0^0$ in (2.6) and taking into account that $T^0 = \infty$, one finds as in [19] that

$$d^0_{\sqrt{\varepsilon}} = -\frac{3f_3}{16f_2^4}\sqrt{2\pi}\mathrm{e} \quad \text{and} \quad d^0_{\bar{w}} = -\frac{1}{2f_2}\sqrt{2\pi}\mathrm{e}; \tag{2.18}$$

see Appendix A for details. Therefore, for given μ, the corresponding value of $\bar{w}^{\mathrm{c}}$ can be obtained from

$$\bar{w}^{\mathrm{c}} = -\frac{3f_3}{8f_2^3}\sqrt{\varepsilon} + \mathcal{O}(\varepsilon); \tag{2.19}$$

note that $\bar{w}^{\mathrm{c}} > 0$ due to $f_2 > 0$ and $f_3 < 0$.
These observations combined suggest the following: for $\varepsilon > 0$ fixed, system (2.3) undergoes a Hopf bifurcation at the origin for $\mu = 0$ by (i); this bifurcation gives rise to small-amplitude limit cycles in (2.3). These cycles will persist as long as both (2.14) and (2.15) can be satisfied, as shown in (ii). In that case, $\mu = \mathcal{O}(\varepsilon)$ must hold, since $T^h = \mathcal{O}(\sqrt{-\ln\varepsilon})$, $\zeta^h = \mathcal{O}(\sqrt{-\ln\varepsilon})$, and $\xi^h = \mathcal{O}(1)$ by Appendix A, while $\bar{v}$, f_2, and g_1 are $\mathcal{O}(1)$ by assumption. Hence, for μ sufficiently small, the dynamics of (2.3) will be dominated by 0^k-type orbits, i.e., by MMO trajectories with Farey sequence $\{0^k\}$. As μ is increased, the evolution of $\bar{w}$ in (2.3c) is governed by the positive, μ-dependent drift, with $\bar{w}' \sim \varepsilon\mu$. Since $\bar{z}$ decreases with increasing $\bar{w}$ (see (2.3b)), it follows that h must also decrease by Proposition 2.1. In other words, $h \to 0$ with increasing μ, and the system moves closer and closer toward a canard explosion, as discussed in (iii). Finally, for $\mu = \mu^{\mathrm{c}}$ large enough, the $\bar{w}$-drift is sufficiently strong for the dynamics of (2.3) to bypass the fold region and enter the relaxation regime. (The corresponding "critical" μ-value μ^{c} will be discussed in detail in section 2.5 below.)

In our analysis, we will focus primarily on the regime where μ is sufficiently large for 0^k-type orbits not to dominate the dynamics of (2.3) anymore. Since these orbits can occur only when (2.3) is close to Hopf bifurcation (i.e., as long as $\mu = \mathcal{O}(\varepsilon)$ and, hence, $\bar{w}' \sim 0$), the degeneracy of the equations at the Hopf point will not be of relevance to us. On the other

hand, we will assume that $\mu < \mu^c$, i.e., that μ is not large enough for (2.3) to have entered the relaxation regime, which is characterized by L^0-type orbits (trajectories with Farey sequence $\{L^0\}$).

As we will show, this "intermediate" regime corresponds precisely to the nontrivial mixed-mode dynamics of (1.5), with orbits of the type $\{L_j^{k_j}\}$ for $L_j, k_j \geq 1$. Correspondingly, h will have to be small in the sense that $|h| = \mathcal{O}(\varepsilon^M)$ for some $M > 0$ "large"; however, h cannot be exponentially small in ε, since trajectories must stay away from the strong canard Γ_ε^0. The statement of Proposition 2.2 pertains exactly to that intermediate case.

Finally, we remark that we will restrict ourselves to a leading-order description of the return map Π in the following, as we did in the proof of Proposition 2.2. The resulting approximation will remain consistent as long as $h = \mathcal{O}(\varepsilon^M)$ is not "too large," i.e., if $\varepsilon > 0$ is sufficiently small or if $M > 0$ is large enough: due to $T^h(\bar{w}) \sim \sqrt{-2\ln h} \sim \sqrt{-2M\ln\varepsilon}$, the $\varepsilon T^h(\bar{w})$-term in (2.9) will dominate the neglected terms of order $\mathcal{O}(\varepsilon)$ in that case. These considerations will be made more explicit in Proposition 3.4 below.

2.3. The transition from Σ^{in} to $\overline{\Delta}_-$. Let Π^{in} denote the transition map from Σ^{in} to $\overline{\Delta}_-$; see sections 2.1 and 2.2 for the definitions of Σ^{in} and $\overline{\Delta}_-$. Moreover, let us introduce an intermediate section $\overline{\Delta}^{\text{in}}$ for the rescaled equations in (2.3), with $\overline{\Delta}^{\text{in}} = \{(\bar{v}, \bar{z}, \bar{w}) \mid \bar{v} = -\alpha\}$, and let Δ^{in} denote the corresponding section in (v, z, w)-space. (Here, $0 < \alpha < \rho$ is some arbitrary constant.) Then, we have the following result on the transition from Σ^{in} to $\overline{\Delta}_-$.

Proposition 2.3. *Let $(z^{\text{in}}, w^{\text{in}}) \in \Sigma^{\text{in}}$. Then, for $\varepsilon > 0$ sufficiently small,*

$$(h^-, \bar{w}^-) := \Pi^{\text{in}}(z^{\text{in}}, w^{\text{in}}) = \Big(\sqrt{\varepsilon} d^-_{\sqrt{\varepsilon}} + \frac{w^{\text{in}}}{\sqrt{\varepsilon}} d^-_{\bar{w}} + \mathcal{O}\big((\sqrt{\varepsilon} + w^{\text{in}})^2\big),\ \frac{w^{\text{in}}}{\sqrt{\varepsilon}} + w^{\text{in}} f_2 \mu \sqrt{\varepsilon}\ln\varepsilon + \mathcal{O}(\sqrt{\varepsilon})\Big), \tag{2.20}$$

where $d^-_{\sqrt{\varepsilon}}$ and $d^-_{\bar{w}}$ are defined by

$$d^-_{\sqrt{\varepsilon}} = \int_{-\infty}^0 \nabla H(\bar{\gamma}_0^0(t)) \cdot \big(f_3 \bar{v}_0^0(t)^3, 0\big)^T\, dt \tag{2.21}$$

and

$$d^-_{\bar{w}} = \int_{-\infty}^0 \nabla H(\bar{\gamma}_0^0(t)) \cdot (0, -1)^T\, dt, \tag{2.22}$$

respectively (see (2.10) and (2.11)), and $\bar{\gamma}_0^0(t) = (\bar{v}_0^0, \bar{z}_0^0)(t)$, as in (2.6).

Remark 4. Since $w^{\text{in}} = \mathcal{O}(\varepsilon)$ by Assumption 1, it follows that $\frac{w^{\text{in}}}{\sqrt{\varepsilon}}$ in (2.20) remains bounded as $\varepsilon \to 0$.

Proof. We first analyze the transition from Σ^{in} to Δ^{in}. To that end, we desingularize the reduced problem associated with (1.5) following the ideas in [2]; see also the derivation of (2.44) in section 2.4. First, we approximate z by $f(v)$; i.e., we restrict ourselves to the critical manifold $\mathcal{S}_0^{a-}$ to leading order. The resulting "reduced" problem for (2.1) has the form

$$f'(v)\dot{v} = v - w, \tag{2.23a}$$

$$\dot{w} = \varepsilon\big(\mu - g_1 f(v)\big). \tag{2.23b}$$

(Note that this approximation is reasonable due to the form of (2.23b): since ε multiplies the entire right-hand side in (2.23b), the $\mathcal{O}(\varepsilon)$-correction to $z = f(v)$ will be $\mathcal{O}(\varepsilon^2)$ for the dynamics.) The desingularized version of (2.23) is obtained by multiplying the right-hand sides by $-f'(v) = -(2f_2v + 3f_3v^2)$:

$$\dot{v} = -(v - w), \tag{2.24a}$$

$$\dot{w} = -\varepsilon\big(\mu - g_1 f(v)\big) f'(v). \tag{2.24b}$$

We now introduce a new variable

$$W = \frac{w}{v}$$

in (2.24). (The introduction of W corresponds to a projectivization of the vector field in (2.24) that desingularizes the dynamics close to the origin.) After the transformation to the variables (v, W), system (2.24) becomes

$$\dot{v} = -v(1 - W), \tag{2.25a}$$

$$\dot{W} = W(1 - W) - \varepsilon\big(\mu - g_1(f_2v^2 + f_3v^3)\big)(2f_2 + 3f_3v). \tag{2.25b}$$

Since we are not interested in the (time-parametrized) solutions of (2.25) but only in the corresponding orbits, we can rescale time by dividing out a factor of $1 - W$ from both right-hand sides in (2.25). Moreover, since we consider $v \in [-\rho, -\alpha\sqrt{\varepsilon}]$ (by the definition of Σ^{in} and Δ^{in}) and $w = \mathcal{O}(\varepsilon)$ (see Assumption 1), W is small. Hence, we can expand $(1 - W)^{-1} = 1 + W + \mathcal{O}(W^2)$ and neglect terms of second order and upward in (v, W) in (2.25b), approximating the resulting equations by

$$\frac{dv}{d\tilde{t}} = -v, \tag{2.26a}$$

$$\frac{dW}{d\tilde{t}} = (1 - 2f_2\mu\varepsilon)W - 2f_2\mu\varepsilon - 3f_3\mu\varepsilon v. \tag{2.26b}$$

(Here, $\tilde{t}$ denotes the new rescaled time.)

Let $\widetilde{T}$ be the transition time from Σ^{in} to Δ^{in} under the flow of (2.26), and recall that $v = -\rho$ in Σ^{in} and $v = -\alpha\sqrt{\varepsilon}$ in Δ^{in}, respectively. Then, a simple computation using (2.26a) shows that $\widetilde{T}$ satisfies the identity

$$\mathrm{e}^{\widetilde{T}} = \frac{\rho}{\alpha}\frac{1}{\sqrt{\varepsilon}}. \tag{2.27}$$

(In particular, (2.27) implies that $\widetilde{T}$ depends only on α, ρ, and ε but not on the specific choice of trajectory in (2.26).) By a direct integration of (2.26b), it follows with $\varepsilon v(\widetilde{T}) = -\varepsilon\rho\mathrm{e}^{-\widetilde{T}} = \mathcal{O}(\varepsilon\sqrt{\varepsilon})$ that

$$W(\widetilde{T}) = (W^{\text{in}} - 2f_2\mu\varepsilon)\mathrm{e}^{(1-2f_2\mu\varepsilon)\widetilde{T}} + 2f_2\mu\varepsilon + \mathcal{O}(\varepsilon\sqrt{\varepsilon}), \tag{2.28}$$

where $W^{\text{in}} = -\frac{w^{\text{in}}}{\rho}$ is the value of W in Σ^{in}. The geometry of (2.26) is illustrated in Figure 7.

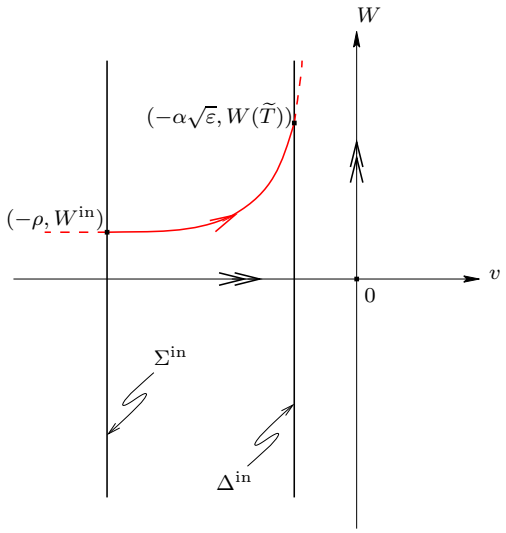

Figure 7. *The geometry of system* (2.26).

Now, note that $w = -\alpha\sqrt{\varepsilon}W(\widetilde{T})$ holds in Δ^{in} for the w-value corresponding to $W(\widetilde{T})$. Hence, expanding the exponential in (2.28), we obtain

$$w(T) = w^{\text{in}} + w^{\text{in}} f_2 \mu\varepsilon \ln\varepsilon + \mathcal{O}(\varepsilon), \tag{2.29}$$

where T denotes the transition time from Σ^{in} to Δ^{in} in the original system (2.24).

To complete the proof, we have to describe the second part of the transition, from Δ^{in} to $\overline{\Delta}_-$. To that end, we slightly modify the ideas of section 2.2. Recall the rescaled equations in (2.3), as well as the singular version obtained for $\varepsilon = 0$ (cf. (2.4)) and the parametrization of the $\bar{z}$-coordinate therein by h. (For $\bar{z}$ fixed, the corresponding (unique) value of h is determined from $H(0, \bar{z}) = h$; cf. (2.5).) Also recall that, for $h = 0$, there exists a parabolic level curve for H which corresponds to the special (singular canard) solution $\bar{\gamma}_0^0$ to (2.4) and which acts as a separatrix between the closed level curves (where $h > 0$) and the open ones (with $h < 0$).

Let $\overline{\Pi}^{\text{in}}$ denote the transition map from $\overline{\Delta}^{\text{in}}$ to $\overline{\Delta}_-$, and let $(\bar{z}, \bar{w}) \in \overline{\Delta}^{\text{in}}$. Since we are interested in describing the dynamics close to $\mathcal{S}_0^{a-}$, we may assume that $(-\alpha, \bar{z}, \bar{w})$ is the endpoint of a trajectory originating in $\mathcal{S}_\varepsilon^{a-}$. We claim that

$$(h^-, \bar{w}^-) = \overline{\Pi}^{\text{in}}(\bar{z}, \bar{w}) = \big(\sqrt{\varepsilon} d^-_{\sqrt{\varepsilon}} + \bar{w} d^-_{\bar{w}} + \mathcal{O}(2),\ \bar{w} + 2\alpha f_2 \mu\varepsilon + \mathcal{O}(\varepsilon^2)\big), \tag{2.30}$$

where $d^-_{\sqrt{\varepsilon}}$ and $d^-_{\bar{w}}$ are defined as in (2.21) and (2.22), respectively, and $\mathcal{O}(2) = \mathcal{O}((\sqrt{\varepsilon} + \bar{w})^2)$, as before.

To derive the expression for $\bar{w}^-$ in (2.30), we simply integrate the $\bar{w}$-equation in (2.3) to obtain $\bar{w}^- = \bar{w} + \varepsilon\mu\overline{T}^{\text{in}} + \mathcal{O}(\varepsilon^2)$, where $\overline{T}^{\text{in}}$ denotes the transition time from $\overline{\Delta}^{\text{in}}$ to $\overline{\Delta}$ in (2.4). Then, by integrating (2.4) directly from $\bar{v} = -\alpha$ to $\bar{v} = 0$ along $\bar{\gamma}_0^0$, we find $\overline{T}^{\text{in}} = 2\alpha f_2$.

The expression for h^- is obtained from the near-integrability of (2.3) and from the analysis in [20]; see also the proof of Proposition 2.2. More specifically, the condition for $(\bar{v}, \bar{z}, \bar{w})$ to

be on a trajectory originating in $\mathcal{S}_\varepsilon^{a-}$ is

$$h^- = \sqrt{\varepsilon} d^-_{\sqrt{\varepsilon}} + \bar{w} d^-_{\bar{w}} + \mathcal{O}(2), \tag{2.31}$$

which proves (2.30). (Here, the limits of integration in the definition of $d^-_{\sqrt{\varepsilon}}$ and $d^-_{\bar{w}}$ follow from the fact that $T^h_+(0) \to \infty$ as $h \to 0$.)

Finally, the assertion of the proposition follows by combining (2.29) and (2.30), taking into account that $\bar{w} = \frac{w}{\sqrt{\varepsilon}}$. ■

Remark 5. Note that to the order considered here, the definition of the intermediate section $\overline{\Delta}^{\text{in}}$ does not influence the asymptotics of $\overline{\Pi}^{\text{in}}$, as expected.

Proposition 2.3 has the following important implication: recall the set $\mathcal{C}_\varepsilon^- \subset \overline{\Delta}_-$ consisting of the endpoints of trajectories starting in $\mathcal{S}_\varepsilon^{a-}$. Then, it follows from (2.31) that $\mathcal{C}_\varepsilon^-$ can be represented as the graph of a function $h^-(\bar{w}, \sqrt{\varepsilon})$ satisfying

$$h^-(\bar{w}, \sqrt{\varepsilon}) = \sqrt{\varepsilon} d^-_{\sqrt{\varepsilon}} + \bar{w} d^-_{\bar{w}} + \mathcal{O}(2). \tag{2.32}$$

In analogy to (2.21) and (2.22), one can define the coefficients

$$d^+_{\sqrt{\varepsilon}} = -\int_0^\infty \nabla H(\bar{\gamma}_0^0(t)) \cdot \left(f_3 \bar{v}_0^0(t)^3, 0\right)^T dt \tag{2.33}$$

and

$$d^+_{\bar{w}} = -\int_0^\infty \nabla H(\bar{\gamma}_0^0(t)) \cdot (0, -1)^T dt \tag{2.34}$$

to describe the leading-order dynamics on $\mathcal{S}_\varepsilon^r$. Hence, it follows that the set $\mathcal{C}_\varepsilon^+$ can also be represented as the graph of a function $h^+(\bar{w}, \sqrt{\varepsilon})$ satisfying

$$h^+(\bar{w}, \sqrt{\varepsilon}) = \sqrt{\varepsilon} d^+_{\sqrt{\varepsilon}} + \bar{w} d^+_{\bar{w}} + \mathcal{O}(2). \tag{2.35}$$

Note that $d^\pm_{\sqrt{\varepsilon}} = \mp\frac{1}{2} d^0_{\sqrt{\varepsilon}}$ and, similarly, $d^\pm_{\bar{w}} = \mp\frac{1}{2} d^0_{\bar{w}}$ by symmetry, where $d^0_{\sqrt{\varepsilon}}$ and $d^0_{\bar{w}}$ are defined in (2.18).

Given the above representation of $\mathcal{C}_\varepsilon^\mp$, we make the following observations:

(i) Due to $d^-_{\bar{w}} < 0$ and $d^+_{\bar{w}} > 0$, (2.32) and (2.35) imply that $\mathcal{C}_\varepsilon^-$ and $\mathcal{C}_\varepsilon^+$ intersect transversely for $\bar{w} = \bar{w}^{\text{c}}$, with $\bar{w}^{\text{c}}$ as in (2.19). Hence, the strong canard Γ_ε^0 is indeed well defined; recall the discussion in section 1. In particular, the resulting geometry justifies the heuristic picture sketched in Figure 4; cf. Figure 8.

(ii) Similarly, the representations in (2.32) and (2.35) will be used in the definition of secondary canards Γ_ε^j for $j \geq 1$ as the transverse intersection of subsequent iterates of $\mathcal{C}_\varepsilon^-$ under $\overline{\Pi}$ with $\mathcal{C}_\varepsilon^+$; see section 3.3 for details.

2.4. The transition from $\overline{\Delta}_-$ to Σ^{out}. We now discuss the behavior of trajectories that exit the fold region in the direction of positive v and that then undergo relaxation. We begin by making a change of coordinates which transforms $\mathcal{C}_\varepsilon^+$ to the plane $\bar{z} = \bar{z}^0$, where $\bar{z}^0$ denotes the $\bar{z}$-value corresponding to $h = 0$ in (2.3). To that end, we define

$$\Delta\bar{z}(\bar{w}, \sqrt{\varepsilon}) = \bar{z}^0 - \bar{z}^{h^+(\bar{w}, \sqrt{\varepsilon})}, \tag{2.36}$$

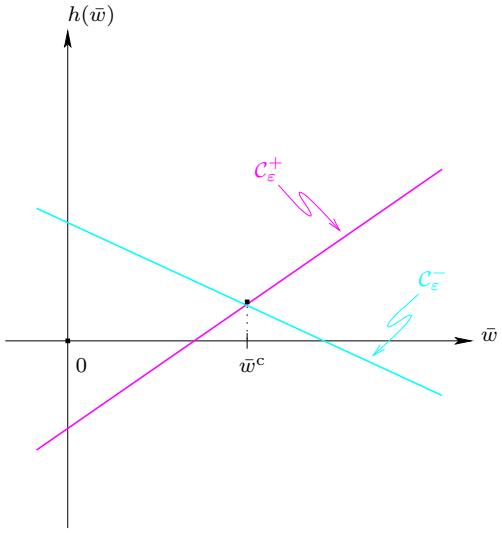

Figure 8. *The curves $\mathcal{C}_\varepsilon^-$ and $\mathcal{C}_\varepsilon^+$.*

where h^+ is as in (2.35), and we let

$$\tilde{z} = \bar{z} + \Delta\bar{z}(\bar{w}, \sqrt{\varepsilon}). \tag{2.37}$$

The transformation in (2.37) is introduced to "flatten" the repelling sheet $\mathcal{S}_\varepsilon^r$ of $\mathcal{S}_\varepsilon$ in Δ for $\varepsilon > 0$ sufficiently small: by (2.36), the $\bar{z}$-value corresponding to h^+, $\bar{z}^{h^+}$, is transformed into $\bar{z}^{h^+} + \bar{z}^0 - \bar{z}^{h^+} = \bar{z}^0$; hence, $\mathcal{C}_\varepsilon^+$ is represented as the graph of the zero function after the transformation:

$$\mathcal{C}_\varepsilon^+ = \big\{(0, \bar{w}) \,\big|\, \bar{w} = \mathcal{O}(\sqrt{\varepsilon})\big\}. \tag{2.38}$$

Recall that in the singular limit of $\varepsilon = 0 = \bar{w}$, $h = 0$ separates the small-oscillation regime in (2.3), where $h > 0$, from the relaxation regime (with $h < 0$); see Proposition 2.1. By introducing $\tilde{z}$, as defined in (2.37), we extend this characterization to the case where ε (and, hence, also $\bar{w}$) is positive but small: given (2.38), trajectories with $h < 0$ will end up "below" $\mathcal{S}_\varepsilon^r$ in Δ^-, implying that they will leave the fold region and undergo relaxation; trajectories with $h > 0$, on the other hand, will remain trapped "above" $\mathcal{S}_\varepsilon^r$ and will therefore stay in the small-oscillation regime close to ℓ^-. (This fact will simplify the following analysis and, in particular, the study of secondary canards in section 3.3, since it will facilitate the evaluation of the conditions that define these canard trajectories.)

In analogy to h^+, the function h^- in (2.32) is mapped to

$$\begin{aligned} h^0(\bar{w}) \equiv h^0(\bar{w}, \sqrt{\varepsilon}) &= h^-(\bar{w}, \sqrt{\varepsilon}) - h^+(\bar{w}, \sqrt{\varepsilon}) \\ &= \sqrt{\varepsilon}\big(d^-_{\sqrt{\varepsilon}} - d^+_{\sqrt{\varepsilon}}\big) + \bar{w}(d^-_{\bar{w}} - d^+_{\bar{w}}) + \mathcal{O}(2) \\ &= \sqrt{\varepsilon} d^0_{\sqrt{\varepsilon}} + \bar{w} d^0_{\bar{w}} + \mathcal{O}(2) \end{aligned} \tag{2.39}$$

by (2.37), where we suppress the $\sqrt{\varepsilon}$-dependence of h^0 for brevity. Hence, after performing

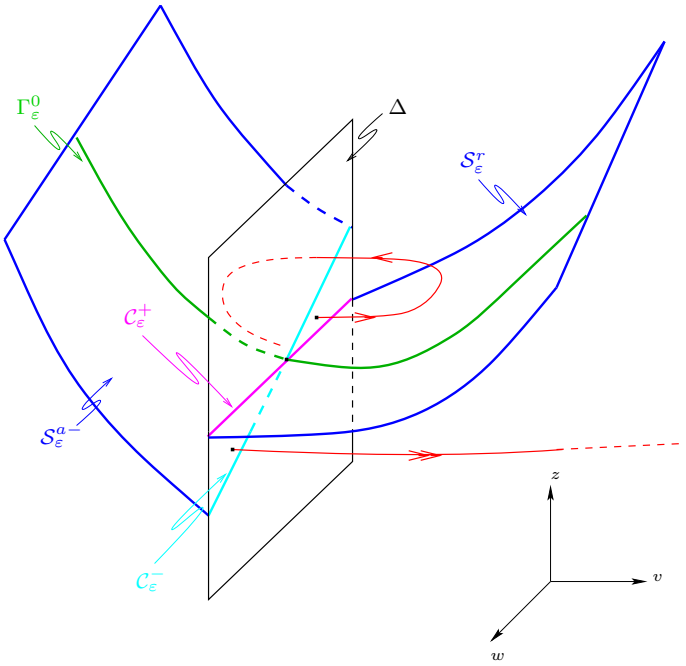

Figure 9. *The curves $\mathcal{C}_\varepsilon^-$ and $\mathcal{C}_\varepsilon^+$ after the transformation in (2.35).*

the coordinate transformation in (2.37), we find that $\mathcal{C}_\varepsilon^-$ is given by

$$\mathcal{C}_\varepsilon^- = \left\{(h^0(\bar{w}), \bar{w}) \;\middle|\; \bar{w} = \mathcal{O}(\sqrt{\varepsilon})\right\}. \tag{2.40}$$

The situation is illustrated in Figure 9; note the change from Figure 4 in that $\mathcal{C}_\varepsilon^+$ is now parallel to the w-axis, with $\mathcal{C}_\varepsilon^-$ "tilted" accordingly.

Next, we note that the higher-order terms that are introduced into (2.3) by the transformation in (2.37) are precisely of the form $\mathcal{O}(\bar{w}, \sqrt{\varepsilon})$. Hence, the resulting, transformed system is of the form (2.8), and the results of Proposition 2.2 can be applied directly to it.

Finally, in analogy to the transition times $T^h(\bar{w})$ defined for $h > 0$ above, we now define

$$T^{h,\mathrm{out}}(\bar{w}) = -T_-^{-h}(\bar{w}) \tag{2.41}$$

for $h < 0$. We have the following result on the transition from $\overline{\Delta}_-$ to Σ^{out}.

Proposition 2.4. *Let $(h, \bar{w}) \in \overline{\Delta}_-$ with $h < 0$ and $h = \mathcal{O}(\varepsilon^M)$ for some $M > 0$ and $\varepsilon > 0$ sufficiently small. Then,*

$$(z^{\mathrm{out}}, w^{\mathrm{out}}) := \Pi^{\mathrm{out}}(h, \bar{w}) = \left(\varepsilon \tilde{z}^{\mathrm{out}} + \mathcal{O}(\varepsilon \ln \varepsilon),\ \sqrt{\varepsilon}\bar{w} + \varepsilon\sqrt{\varepsilon} T^{h,\mathrm{out}}(\bar{w})\mu + \mathcal{O}(\varepsilon\sqrt{\varepsilon})\right), \tag{2.42}$$

where $\tilde{z}^{\mathrm{out}}$ is the $\tilde{z}$-value corresponding to $h^{\mathrm{out}} = h + \sqrt{\varepsilon} d_{\sqrt{\varepsilon}}^{\mathrm{out}} + \bar{w} d_{\bar{w}}^{\mathrm{out}}$, with $d_{\sqrt{\varepsilon}}^{\mathrm{out}}$ and $d_{\bar{w}}^{\mathrm{out}}$ defined by

$$d_{\sqrt{\varepsilon}}^{\mathrm{out}} = -\int_0^{T^{h,\mathrm{out}}(\bar{w})} \nabla H(\bar{\gamma}_0^h(t)) \cdot \left(f_3 \bar{v}_0^h(t)^3, 0\right)^T dt$$

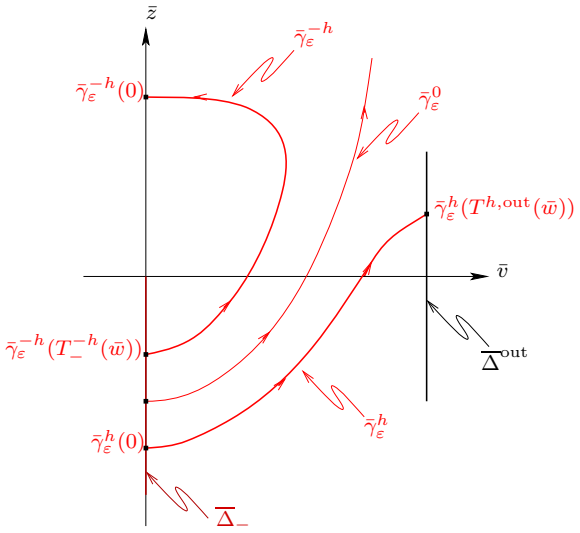

Figure 10. *The definition of $T^{h,\mathrm{out}}(\bar{w})$ for $h < 0$.*

and

$$d_{\bar{w}}^{\mathrm{out}} = -\int_0^{T^{h,\mathrm{out}}(\bar{w})} \nabla H(\bar{\gamma}_0^h(t)) \cdot (0,-1)^T \, dt,$$

respectively (see (2.10) and (2.11)).

Proof. For $(h,\bar{w}) \in \overline{\Delta}_-$ with $h < 0$ and $h = \mathcal{O}(\varepsilon^M)$, let $\overline{\Pi}^{\mathrm{out}}$ denote the time-$T^{h,\mathrm{out}}(\bar{w})$ transition map for (2.8), i.e., for the system obtained from (2.3) after the transformation to $\tilde{z}$. Moreover, let $\overline{\Delta}^{\mathrm{out}} := \overline{\Pi}^{\mathrm{out}}(\overline{\Delta}_-)$, which implies that the definition of the intermediate section $\overline{\Delta}^{\mathrm{out}}$ is now "implicit" ($\bar{w}$-dependent); cf. Figure 10. Then, it follows as in the proof of Proposition 2.2 that

$$(h^{\mathrm{out}}, \bar{w}^{\mathrm{out}}) := \overline{\Pi}^{\mathrm{out}}(h,\bar{w}) = \big(h + \sqrt{\varepsilon} d_{\sqrt{\varepsilon}}^{\mathrm{out}} + \bar{w} d_{\bar{w}}^{\mathrm{out}} + \mathcal{O}(2),\ \bar{w} + \varepsilon T^{h,\mathrm{out}}(\bar{w})\mu + \mathcal{O}(\varepsilon\sqrt{\varepsilon})\big), \tag{2.43}$$

where again $\mathcal{O}(2) = \mathcal{O}((\sqrt{\varepsilon}+\bar{w})^2)$, $T^{h,\mathrm{out}}(\bar{w})$ is, by the definition of $\overline{\Delta}^{\mathrm{out}}$, the transition time from $\overline{\Delta}$ to $\overline{\Delta}^{\mathrm{out}}$ in (2.8), and $d_{\sqrt{\varepsilon}}^{\mathrm{out}}$ and $d_{\bar{w}}^{\mathrm{out}}$ are defined as above.

To study the second part of the transition, from $\overline{\Delta}^{\mathrm{out}}$ to Σ^{out}, we introduce a new variable Z in the original (unmodified) system (1.5), where Z is defined by $z = v^2 Z$. This transformation serves to desingularize (1.5) close to the origin for v positive and small: in terms of (v,Z,w), (1.5) becomes

$$v' = v^2(-Z + f_2 + f_3 v), \tag{2.44a}$$

$$Z' = -2Zv(-Z + f_2 + f_3 v) + \frac{\varepsilon}{v}\Big(1 - \frac{w}{v}\Big), \tag{2.44b}$$

$$w' = \varepsilon^2(\mu - g_1 v^2 Z). \tag{2.44c}$$

Now, let $\Psi(v,Z) = v^2(-Z + f_2 + f_3 v)$; then, dividing the right-hand sides of (2.44) by $\Psi(v,Z)$,

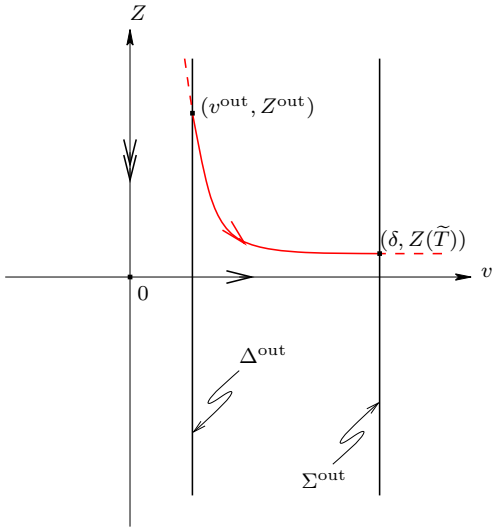

Figure 11. *The geometry of system* (2.46).

we find

$$\frac{dv}{d\hat{t}} = 1, \tag{2.45a}$$

$$\frac{dZ}{d\hat{t}} = -\frac{2}{v}Z + \frac{\varepsilon}{v\Psi(v,Z)}\Big(1 - \frac{w}{v}\Big), \tag{2.45b}$$

$$\frac{dw}{d\hat{t}} = \frac{\varepsilon^2}{\Psi(v,Z)}(\mu - g_1 v^2 Z); \tag{2.45c}$$

here, $\hat{t}$ denotes the new, rescaled time.

We first investigate the dynamics of Z in the transition. Let Δ^{out} denote the section in (v, Z, w)-space corresponding to $\overline{\Delta}^{\text{out}}$. Given an initial v-value v^{out} for (1.5) in Δ^{out}, it then follows that $v^{\text{out}} = \mathcal{O}(\sqrt{\varepsilon}T^{h,\text{out}}(\bar{w})) = \mathcal{O}(\sqrt{-\varepsilon \ln \varepsilon})$ must hold, which, together with (2.45a) and $w = \mathcal{O}(\varepsilon)$ (see Assumption 1), implies that $\frac{w}{v}$ is small throughout. Since, moreover, $\frac{dw}{d\hat{t}} = \mathcal{O}(\varepsilon(\ln \varepsilon)^{-1})$ by (2.45c), w remains almost constant, and we can neglect its evolution.

Hence, expanding Ψ in (2.45b) and truncating the resulting equation, we find that to leading order,

$$\begin{aligned} \frac{dv}{d\hat{t}} &= 1, \\ \frac{dZ}{d\hat{t}} &= -\frac{2}{v}Z + \frac{\varepsilon}{f_2 v^3}\big(1 + \mathcal{O}(v,Z)\big). \end{aligned} \tag{2.46}$$

The transition from Δ^{out} to Σ^{out} under the flow of (2.46) is illustrated in Figure 11. Now, for $(v^{\text{out}}, Z^{\text{out}}) \in \Delta^{\text{out}}$, we can solve (2.46) explicitly to leading order by variation of constants, which gives

$$Z(v) = \frac{(v^{\text{out}})^2 Z^{\text{out}}}{v^2} + \frac{\varepsilon}{f_2 v^2} \ln \frac{v}{v^{\text{out}}} + \mathcal{O}(\varepsilon). \tag{2.47}$$

Here, we have neglected the effect of the inhomogeneous $\mathcal{O}(v, Z)$-terms in (2.46), since it can be shown that these contribute only terms of order $\mathcal{O}(\varepsilon)$ in (2.47). Now, the corresponding expression in the original variable z is given by

$$z(v) = \varepsilon \tilde{z}^{\text{out}} + \frac{\varepsilon}{f_2} \ln \frac{v}{v^{\text{out}}} + \mathcal{O}(\varepsilon)$$

for $\tilde{z}^{\text{out}}$ in $\overline{\Delta}^{\text{out}}$, where we have used $v^2 Z = z = \varepsilon \tilde{z}$. Recalling that $v^{\text{out}} = \mathcal{O}(\sqrt{-\varepsilon \ln \varepsilon})$ as well as that $v = \delta$ in Σ^{out}, we find

$$z(T) = \varepsilon \tilde{z}^{\text{out}} + \mathcal{O}(\varepsilon \ln \varepsilon); \tag{2.48}$$

here, T denotes the transition time from Δ^{out} to Σ^{out}.

We now use the estimate for $z(T)$ in (2.48) to derive an estimate for $w(T)$. Since $dv = \Psi(v, Z)\, dt$ (see (2.44a)) and since, moreover, $Z = \mathcal{O}(1)$, there certainly holds $\frac{1}{2}\Psi(v, 0) \leq \Psi(v, Z)$. Hence, it follows that T satisfies the inequality

$$T \leq 2 \int_{v^{\text{out}}}^{\delta} \frac{dv}{\Psi(v, 0)}, \tag{2.49}$$

to leading order. The integral on the right-hand side of (2.49) can be evaluated explicitly, giving

$$T \leq \frac{2}{f_2 v^{\text{out}}} - \frac{f_3}{f_2^2} \ln \varepsilon + \mathcal{O}(1).$$

Integrating the w-equation (2.44c) directly and taking into account (2.43) as well as $v^{\text{out}} = \mathcal{O}(\sqrt{-\varepsilon \ln \varepsilon})$ and $w = \sqrt{\varepsilon}\bar{w}$, we obtain

$$\begin{aligned} w(T) &= \sqrt{\varepsilon}\bar{w}^{\text{out}} + \varepsilon^2 \left(\mu T - g_1 \int_{v^{\text{out}}}^{\delta} \frac{z(v)}{\Psi(v, 0)}\, dv \right) + \mathcal{O}(\varepsilon^3) \\ &= \sqrt{\varepsilon}\bar{w} + \varepsilon\sqrt{\varepsilon} T^{h,\text{out}}(\bar{w})\mu + \mathcal{O}(\varepsilon\sqrt{\varepsilon}). \end{aligned} \tag{2.50}$$

To complete the proof, it remains to collect the above estimates: with $\tilde{z}^{\text{out}}$ the $\tilde{z}$-value corresponding to h^{out} (see (2.43)), we find the desired expression for z^{out} in (2.42) from (2.48). The estimate for the w^{out}-component of Π^{out} follows directly from (2.50). ■

2.5. The global return mechanism. In this subsection, we describe the global mechanism that determines the return of trajectories of (1.5) from Σ^{out} back to Σ^{in}. The corresponding return map will be denoted by Π^{ret}. Since the necessary analysis is largely based on standard geometric singular perturbation (Fenichel) theory [11], we do not discuss it in full detail here; moreover, for the sake of exposition, we will make a number of additional, simplifying assumptions throughout this subsection. As it turns out, the resulting leading-order asymptotics of Π^{ret} will still give an approximation for the composite return map Π that is consistent to the order considered here; cf. section 4 below.

In a first approximation, we may assume that $z = f(v)$ is satisfied; i.e., for $\varepsilon > 0$ sufficiently small, we may restrict ourselves to the singular dynamics of (1.5) on $\mathcal{S}_0$. We recall the

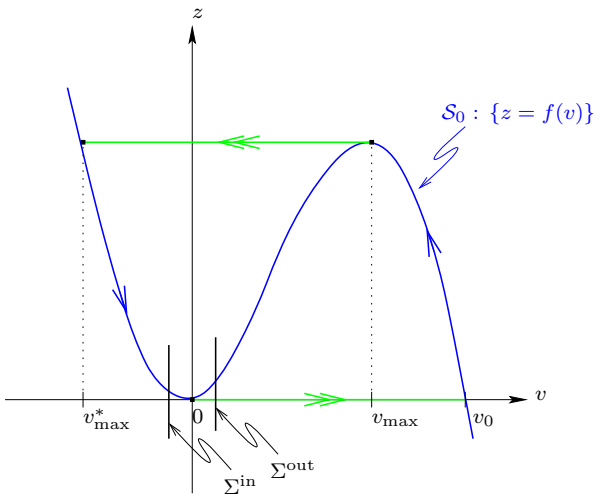

Figure 12. *The geometry of the global return mechanism.*

definition of the corresponding reduced system from (2.24):

$$\dot{v} = -(v - w), \tag{2.51a}$$

$$\dot{w} = -\varepsilon\big(\mu - g_1 f(v)\big) f'(v). \tag{2.51b}$$

Moreover, we can safely neglect the w-term on the right-hand side of (2.51a), since this term is assumed to be small throughout; see Assumption 1. Then, we rewrite (2.51) with v as the independent variable; i.e., we divide (2.51b) by (2.51a), which gives

$$\frac{dw}{dv} = \varepsilon\big(\mu - g_1 f(v)\big)\frac{f'(v)}{v}. \tag{2.52}$$

Given an initial v-value v^* on $\mathcal{S}_0$, (2.52) can be integrated explicitly as follows:

$$w(v) - w(v^*) = \varepsilon \mathcal{G}(v^*, v, \mu) := \varepsilon \int_{v^*}^{v} \big(\mu - g_1 f(\sigma)\big)\frac{f'(\sigma)}{\sigma}\, d\sigma. \tag{2.53}$$

To describe the return of trajectories from Σ^{out} to Σ^{in} under the flow of (2.52) on $\mathcal{S}_0$, we need to consider two separate parts of the transition, namely, the parts where v evolves along $\mathcal{S}_0^{a+}$ and $\mathcal{S}_0^{a-}$, respectively. (Note that by restricting ourselves to the slow flow on $\mathcal{S}_0$, we are implicitly neglecting the transition from ℓ^- to $\mathcal{S}_0^{a+}$ and from ℓ^+ to $\mathcal{S}_0^{a-}$, respectively, under the fast flow of (1.5), since, by standard Fenichel theory [11], the corresponding contributions to Π^{ret} are of higher order; cf. Figure 12.) The relevant integrals in (2.53) are given by

$$\mathcal{G}(v_0, v_{\max}, \mu) = \int_{v_0}^{v_{\max}} \big(\mu - g_1 f(\sigma)\big)\frac{f'(\sigma)}{\sigma}\, d\sigma$$

and

$$\mathcal{G}(v^*_{\max}, -\rho, \mu) = \int_{v^*_{\max}}^{-\rho} \big(\mu - g_1 f(\sigma)\big)\frac{f'(\sigma)}{\sigma}\, d\sigma,$$

respectively. Here, $v_{\max}$ is the value of v for which f attains its local maximum, $v^*_{\max} < 0$ is defined by the requirement that $f(v^*_{\max}) = f(v_{\max})$, and $v_0 > 0$ is the second (nontrivial) zero of f, with $f(v_0) = 0$; see again Figure 12. To facilitate further the evaluation of these integrals, we will approximate $\mathcal{G}(v^*_{\max}, -\rho, \mu)$ by $\mathcal{G}(v^*_{\max}, 0, \mu)$; i.e., we will evaluate the integral over $\mathcal{S}_0^{a-}$ down to and including ℓ^-. (In fact, a straightforward though lengthy computation shows that this approximation will offset precisely the part of the $\mathcal{O}(\sqrt{\varepsilon})$-error term in Π^{in} that is independent of w^{in}; cf. Proposition 2.3.)

Hence, in sum, it follows that the w-component $\hat{w}$ of $\Pi^{\text{ret}} : \Sigma^{\text{out}} \to \Sigma^{\text{in}}$ is given by

$$\hat{w} = w + \varepsilon\big(\mathcal{G}(v_0, v_{\max}, \mu) + \mathcal{G}(v^*_{\max}, 0, \mu)\big), \tag{2.54}$$

to lowest order. In particular, note that (2.54) determines the global "amount of return" of w after one relaxation cycle, expressed as a function of the parameter μ. (This fact will prove especially useful in section 3 below.) Let

$$D_\mu = \frac{d}{d\mu}\big(\mathcal{G}(v_0, v_{\max}, \mu) + \mathcal{G}(v^*_{\max}, 0, \mu)\big),$$

and observe that the rate of change of the return point with respect to μ is given by $D_\mu\varepsilon$. From the above, it follows that D_μ can easily be approximated to lowest order in terms of the function $\mathcal{G}$: by the definition of $\mathcal{G}$ and making use of the fact that

$$v_{\max} = -\frac{2f_2}{3f_3}, \quad v^*_{\max} = \frac{f_2}{3f_3}, \quad \text{and} \quad v_0 = -\frac{f_2}{f_3},$$

we obtain

$$\mathcal{G}(v_0, v_{\max}, \mu) + \mathcal{G}(v^*_{\max}, 0, \mu) = \frac{g_1}{18}\frac{f_2^5}{f_3^3} - \mu\frac{f_2^2}{f_3}. \tag{2.55}$$

Differentiating (2.55) with respect to μ, we find $D_\mu = -\frac{f_2^2}{f_3}$.

Similarly, the critical value μ^{c} of μ for which MMOs cease to exist in (1.5) is to leading order determined by requiring $\hat{w} = w$ in (2.54) or, alternatively, by finding μ such that (2.55) equals zero; again, a simple computation shows

$$\mu^{\text{c}} = \frac{g_1}{18}\frac{f_2^3}{f_3^2}. \tag{2.56}$$

For $\mu > \mu^{\text{c}}$, the dynamics of (1.5) is in the pure relaxation regime in the sense that the only admissible periodic trajectories are those with Farey sequence $\{L^0\}$.

Remark 6. Note that the fold line ℓ^+ will in general contribute logarithmic terms (in ε) to (2.56); see, e.g., [34]. In our case, however, these terms can be shown to be of higher order and are hence negligible.

2.6. Summary: The return map $\Pi : \overline{\Delta}_- \to \overline{\Delta}_-$. Given the analysis of the previous subsections, we can now define the composite return map $\Pi : \overline{\Delta}_- \to \overline{\Delta}_-$. We note that the definition of Π will depend on the sign of h: if $h > 0$, the corresponding trajectory of (1.5) will

remain in the fold region, i.e., in the small-oscillation regime, and undergo another "loop." Hence, the return to $\overline{\Delta}_-$ is described by $\overline{\Pi}$ in that case; cf. Proposition 2.2. If, on the other hand, $h < 0$, the trajectory will exit the fold region and undergo relaxation; i.e., it will leave $\overline{\Delta}_-$ in the direction of the fast flow of (1.5), move "up" the slow manifold $\mathcal{S}_\varepsilon^{a+}$ under the slow flow until it reaches ℓ^+, "jump" to $\mathcal{S}_\varepsilon^{a-}$, and move "down" that manifold until it re-enters a neighborhood of ℓ^-; cf., e.g., Figure 12. Therefore, the return to $\overline{\Delta}_-$ is described by the composition of Π^{out}, Π^{ret}, and Π^{in} in that case; see Propositions 2.3 and 2.4 as well as the discussion in section 2.5. Hence, in sum, the desired expression for Π is given as follows:

$$\Pi(h,\bar{w}) = \begin{cases} \overline{\Pi}(h,\bar{w}) & \text{if } h > 0, \\ \Pi^{\text{in}} \circ \Pi^{\text{ret}} \circ \Pi^{\text{out}}(h,\bar{w}) & \text{if } h < 0. \end{cases} \tag{2.57}$$

3. Partial dimension reduction for the map Π. In this section, we show how the two-dimensional return map Π formulated in section 2.6 can be accurately approximated by an appropriately defined one-dimensional map, which we denote by Φ. More precisely, we will prove that the resulting approximation error will be exponentially small in ε. The reduction itself is carried out in two steps: first, the map Π is restricted from the two-dimensional section $\overline{\Delta}_-$ to a union of one-dimensional curves $\cup\mathcal{C}_\varepsilon^j$, to be specified in section 3.1. In the second step, this restricted map is reduced further, in section 3.4, to a map Φ that is defined on the single curve $\mathcal{C}_\varepsilon^-$. For a detailed study of the dynamics of Φ, we require some preparatory analysis: in section 3.2, we approximate the derivative $\frac{d\Pi}{d\bar{w}}$, which, in turn, allows us to derive estimates for $\frac{d\Phi}{d\bar{w}}$ in section 3.5. The latter are needed for analyzing the contractive (or expansive) properties of the reduced flow under Φ. In section 3.3, we characterize the secondary canards introduced in section 1 above: we derive the defining conditions for these trajectories, and we use those conditions to describe the family of the associated sectors of rotation. Finally, in section 3.6, we study the dynamics of Φ on these sectors by combining the results of sections 3.3 and 3.5, and we derive precise asymptotic estimates for the bifurcation structure of the resulting mixed-mode dynamics in (1.5).

3.1. The curves $\mathcal{C}_\varepsilon^j$. In this subsection, we perform the first step in our exponentially accurate reduction of Π to a one-dimensional map Φ. More precisely, we show how Π can be restricted from $\overline{\Delta}_-$ to a union of one-dimensional curves $\cup\mathcal{C}_\varepsilon^j$ that will be defined below.

Recall the definition of the curves $\mathcal{C}_\varepsilon^-$ and $\mathcal{C}_\varepsilon^+$ from section 2.1, as well as the fact that $\mathcal{C}_\varepsilon^-$ can be represented as the graph of the function $h^0(\bar{w})$ defined in (2.39); see (2.40). For $j \geq 1$, we now make the inductive definition

$$\mathcal{C}_\varepsilon^j = \overline{\Pi}\big(\{(h,\bar{w}) \in \mathcal{C}_\varepsilon^{j-1} \mid h > 0\}\big),$$

where we define $\mathcal{C}_\varepsilon^0 \equiv \mathcal{C}_\varepsilon^-$ for the zeroth iterate of $\mathcal{C}_\varepsilon^-$ under $\overline{\Pi}$. Next, we show that for $j \geq 1$, each set $\mathcal{C}_\varepsilon^j$ can be written as the graph of a function $h^j(\bar{w})$, in analogy to the representation of $\mathcal{C}_\varepsilon^-$ given in (2.40). We first consider the case when $j = 1$. Note that by Proposition 2.2,

$$(h^1,\bar{w}^1) = \overline{\Pi}(h^0(\bar{w}),\bar{w}) = \big(h^0(\bar{w}) + \sqrt{\varepsilon}d_{\sqrt{\varepsilon}}^{h^0(\bar{w})} + \bar{w}d_{\bar{w}}^{h^0(\bar{w})} + \mathcal{O}(2),\ \bar{w} + \varepsilon\mu T^{h^0(\bar{w})} + \mathcal{O}(\varepsilon^2)\big),$$

where $\mathcal{O}(2) = \mathcal{O}((\sqrt{\varepsilon}+\bar{w})^2)$, as before. Since $h^0 = \sqrt{\varepsilon}d_{\sqrt{\varepsilon}}^0 + \bar{w}d_{\bar{w}}^0 + \mathcal{O}(2)$ by (2.39) and since

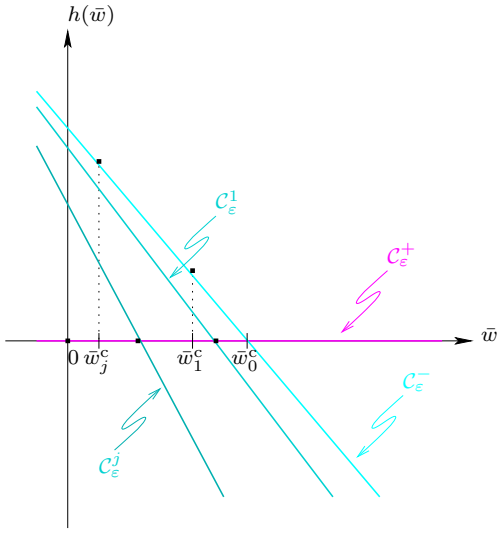

Figure 13. *The curves $\mathcal{C}_\varepsilon^j$ for $j \geq 0$, where $\mathcal{C}_\varepsilon^- \equiv \mathcal{C}_\varepsilon^0$.*

$d^{h^0}_{\sqrt{\varepsilon}} \sim d^0_{\sqrt{\varepsilon}}$ and $d^{h^0}_{\bar{w}} \sim d^0_{\bar{w}}$, respectively, it follows that

$$h^1(\bar{w}) = 2\sqrt{\varepsilon} d^0_{\sqrt{\varepsilon}} + 2\bar{w} d^0_{\bar{w}} + \mathcal{O}(2). \tag{3.1}$$

Similarly, for higher iterates of $\overline{\Pi}$, there holds

$$\begin{aligned}(h^j, \bar{w}^j) &= \overline{\Pi}^j(h^0(\bar{w}), \bar{w}) \\ &= \left(h^0(\bar{w}) + \sqrt{\varepsilon} \sum_{i=0}^{j} d^{h^i(\bar{w})}_{\sqrt{\varepsilon}} + \bar{w} \sum_{i=0}^{j} d^{h^i(\bar{w})}_{\bar{w}} + \mathcal{O}(\varepsilon),\ \bar{w} + 2\varepsilon\mu \sum_{i=0}^{j} T^{h^i(\bar{w})} + \mathcal{O}(\varepsilon^2) \right)\end{aligned} \tag{3.2}$$

and, therefore,

$$h^j(\bar{w}) = (j+1)\sqrt{\varepsilon} d^0_{\sqrt{\varepsilon}} + (j+1)\bar{w} d^0_{\bar{w}} + \mathcal{O}(2). \tag{3.3}$$

This gives the desired representation of $\mathcal{C}_\varepsilon^j$ as the graph of the function $h^j(\bar{w})$ in (3.3), with

$$\mathcal{C}_\varepsilon^j = \left\{ (h^j(\bar{w}), \bar{w}) \;\middle|\; \bar{w} = \mathcal{O}(\sqrt{\varepsilon}) \right\} \tag{3.4}$$

for $j \geq 1$; cf. Figure 13.

Finally, we prove that the map Π can be restricted from $\overline{\Delta}_-$ to the union of the set of curves $\mathcal{C}_\varepsilon^j$ with an only exponentially small error; here, Π^j denotes the jth iterate of the map Π defined in (2.57).

Proposition 3.1. *Let $(h, \bar{w}) \in \overline{\Delta}_-$, and fix $\varepsilon > 0$ sufficiently small. Then, there exists $k > 0$ such that, for $1 \leq j \leq k$, $\Pi^j(h, \bar{w})$ is exponentially close (in ε) to $\cup_{j=1}^k \mathcal{C}_\varepsilon^j$.*

Proof. First, observe that all trajectories must become exponentially close to $\mathcal{S}_\varepsilon^{a-}$ after relaxation; consequently, they must return to $\overline{\Delta}_-$ exponentially close to $\mathcal{C}_\varepsilon^-$. This is equivalent to saying that, for any $(h, \bar{w})$ with $h < 0$, $\Pi(h, \bar{w})$ is exponentially close to $\mathcal{C}_\varepsilon^-$.

We now prove that $\Pi^2(h,\bar{w})$ must be exponentially close to $\mathcal{C}_\varepsilon^- \cup \mathcal{C}_\varepsilon^1$. Let $(h^1,\bar{w}^1) = \Pi(h,\bar{w})$, and note that if $h^1 < 0$, the forward trajectory of $(h^1,\bar{w}^1)$ must undergo relaxation. Hence, by the above argument, $\Pi(h^1,\bar{w}^1) = \Pi^2(h,\bar{w})$ is exponentially close to $\mathcal{C}_\varepsilon^-$ in that case. Let us suppose that $h^1 \geq 0$ now and consider $h^1 = \mathcal{O}(\varepsilon)$ first, which is in the domain of $\overline{\Pi}$. Since the map $\overline{\Pi}$ is induced by the flow of (2.8) and since $T^{h^1}(\bar{w}^1) = \mathcal{O}(\sqrt{-\ln\varepsilon})$ for the return time to $\overline{\Delta}$ (cf. Appendix A), the expansion that can be incurred during that return is of at most algebraic order in ε. Consequently, $\Pi(h^1,\bar{w}^1)$ must be exponentially close to $\mathcal{C}_\varepsilon^1$. If, on the other hand, h^1 is exponentially small, i.e., if $\mathcal{O}(\mathrm{e}^{-\frac{\kappa}{\varepsilon}})$ for some $\kappa > 0$, the argument from the first part of the proof can be applied to show that $\Pi(h^1,\bar{w}^1)$ is again exponentially close to $\mathcal{C}_\varepsilon^-$.

The transitional regime between $h^1 = \mathcal{O}(\varepsilon)$ and exponentially small h^1 is more difficult to describe. This issue is addressed in detail in [20], where it is shown, roughly speaking, that the contraction and expansion in the z-direction cancel each other out to leading order near the fold. An analogous property can be proven to hold in our case, which allows us to conclude that $\Pi(h^1,\bar{w}^1)$ is exponentially close to $\mathcal{C}_\varepsilon^1$ even in that transitional regime. Finally, by an iteration of the above argument, it follows that $\Pi^3(h,\bar{w})$ must be exponentially close to $\mathcal{C}_\varepsilon^- \cup \mathcal{C}_\varepsilon^1 \cup \mathcal{C}_\varepsilon^2$, and so on.

To conclude the proof, we note that there exists a finite number k such that for any point $(h,\bar{w})$ with $h > 0$, there is $1 \leq j \leq k$ such that the h-coordinate of $\Pi^j(h,\bar{w})$ is negative, so that $\Pi^{j+1}(h,\bar{w})$ must again be close to $\mathcal{C}_\varepsilon^-$. (Note that k gives the maximum possible number of small oscillations a trajectory can undergo.) It follows that for any $(h,\bar{w}) \in \overline{\Delta}_-$, the trajectory of $(h,\bar{w})$ under Π must be exponentially close to the union of the sets $\mathcal{C}_\varepsilon^j$, $j = 1,\dots,k$. ∎

In the following, we will assume that the points on a trajectory of Π are on $\mathcal{C}_\varepsilon^-$ or on one of the curves $\mathcal{C}_\varepsilon^j$. By Proposition 3.1, this assumption incurs at most an exponentially small error. To find the restriction of Π to $\mathcal{C}_\varepsilon^j$, we recall that $\mathcal{C}_\varepsilon^j$ can be represented as the graph of a function $h^j(\bar{w})$; see (3.4). In analogy to the definition of Π in (2.42), we again have to distinguish between $h^j > 0$ and $h^j < 0$ here. In the former case, Π reduces to $\overline{\Pi}$, whereas in the latter case, we have to take the composition of Π^{out}, Π^{ret}, and Π^{in} to describe the return to $\cup\mathcal{C}_\varepsilon^j$; see the discussion in section 2.6 for details. Moreover, since $\mathcal{C}_\varepsilon^j$ is parametrized by $\bar{w}$ (cf. (3.4)), it is natural to consider Π as a function of $\bar{w}$. Hence, combining the definition of Π in (2.42) with (2.9) for $h^j > 0$ and with the estimates in (2.20), (2.42), and (2.54) for $h^j < 0$, respectively, we finally obtain

(3.5)
$$\Pi(\bar{w}) \equiv \Pi(h^j(\bar{w}),\bar{w}) = \begin{cases} \bar{w} + \varepsilon\mu T^{h^j(\bar{w})}(\bar{w}) + \mathcal{O}(\varepsilon^2) & \text{if } h^j(\bar{w}) > 0, \\ \bar{w} + \varepsilon\mu T^{h^j(\bar{w}),\mathrm{out}}(\bar{w}) + \bar{w} f_2 \mu\varepsilon \ln\varepsilon & \\ \quad + \sqrt{\varepsilon}\big(\mathcal{G}(0,v_{\max},\mu) + \mathcal{G}(v^*_{\max},v_0,\mu)\big) + \mathcal{O}(\varepsilon) & \text{if } h^j(\bar{w}) < 0. \end{cases}$$

3.2. The derivative of Π. To estimate the contractive (or expansive) properties of the flow induced by Π on $\cup\mathcal{C}_\varepsilon^j$, we need to estimate the derivative $\frac{d\Pi}{d\bar{w}}$ of Π. Given (3.5), it follows

that the following approximation holds to leading order, i.e., up to an $\mathcal{O}(\varepsilon)$-error:

$$\frac{d\Pi}{d\bar{w}} \sim \begin{cases} 1+\varepsilon\mu\dfrac{dT^{h^j(\bar{w})}(\bar{w})}{d\bar{w}} & \text{if } h^j(\bar{w})>0, \\ 1+\varepsilon\mu\dfrac{dT^{h^j(\bar{w}),\mathrm{out}}(\bar{w})}{d\bar{w}}+f_2\mu\varepsilon\ln\varepsilon & \text{if } h^j(\bar{w})<0. \end{cases} \tag{3.6}$$

(Here, we have used the fact that the function $\mathcal{G}$ is independent of $\bar{w}$; see (2.53).) Now, recall that $T^h(0)=2T^h$ by (2.7), and note that, for $(h,\bar{w})$ small, $T^h(\bar{w})$ depends much more sensitively on h than on $\bar{w}$. Therefore, to evaluate (3.6), we can in a first approximation neglect the $\bar{w}$-dependence of $T^h(\bar{w})$ and write

$$\frac{dT^{h^j(\bar{w})}(\bar{w})}{d\bar{w}} \sim 2\frac{dT^{h^j(\bar{w})}}{d\bar{w}}.$$

Due to $T^h\sim(-2\ln h)^{\frac{1}{2}}$ (see Appendix A), it follows that

$$\frac{dT^{h^j(\bar{w})}(\bar{w})}{d\bar{w}} \sim -\frac{2}{h^j(\bar{w})}\frac{1}{\sqrt{-2\ln h^j(\bar{w})}}(h^j)'(\bar{w}); \tag{3.7}$$

similarly, we can use the definition of $T^{h,\mathrm{out}}(\bar{w})$ in (2.41) to conclude

$$\frac{dT^{h^j(\bar{w}),\mathrm{out}}(\bar{w})}{d\bar{w}} \sim -\frac{1}{h^j(\bar{w})}\frac{1}{\sqrt{-2\ln h^j(\bar{w})}}(h^j)'(\bar{w}). \tag{3.8}$$

To complete the computation of the derivative of Π, we require approximate formulae for the derivatives of h^j with respect to $\bar{w}$: by (3.3), it follows that

$$(h^j)'(\bar{w}) = (j+1)d_{\bar{w}}^0+\mathcal{O}(\sqrt{\varepsilon},\bar{w}). \tag{3.9}$$

Combining (3.7) and (3.9), we finally obtain

$$\frac{dT^{h^j(\bar{w})}(\bar{w})}{d\bar{w}} \sim -\frac{2}{h^j(\bar{w})}\frac{1}{\sqrt{-2\ln h^j(\bar{w})}}(j+1)d_{\bar{w}}^0 \tag{3.10}$$

as well as

$$\frac{dT^{h^j(\bar{w}),\mathrm{out}}(\bar{w})}{d\bar{w}} \sim -\frac{1}{h^j(\bar{w})}\frac{1}{\sqrt{-2\ln h^j(\bar{w})}}(j+1)d_{\bar{w}}^0, \tag{3.11}$$

which can be substituted into (3.6) to obtain a more explicit expression for $\frac{d\Pi}{d\bar{w}}$.

3.3. Secondary canards and sectors of rotation. Recall the definition of the jth secondary canard Γ_ε^j as a trajectory of (1.2) that undergoes j small oscillations (loops) during its passage through the fold region. In this subsection, we derive the conditions on the rescaled equations (2.8) by which these trajectories are defined. The corresponding analysis will require us to refine the results of Proposition 2.2; see Proposition 3.2 below. Given the family

of secondary canards $\{\Gamma_\varepsilon^j\}$ for $j = 0, \dots, k$, we will define the corresponding family of sectors of rotation, $\{RS^j\}$. We will then analyze the geometry of these sectors; in particular, we will estimate the sector width (Proposition 3.3), and we will show that it is independent of j to lowest order. Here, we note that the family $\{RS^j\}$ will be crucial for the reduction of the (two-dimensional) map Π to the (one-dimensional) map Φ in section 3.4 below. Finally, in Proposition 3.4, we discuss the uniform validity of our asymptotic estimates.

Let $(h^0(\bar{w}), \bar{w}) \in \mathcal{C}_\varepsilon^-$, as before, and recall the definition of the transition map $\overline{\Pi}$ for (2.8); see Proposition 2.2. Moreover, let P_h and $P_{\bar{w}}$ denote the projections onto the h-coordinate and the $\bar{w}$-coordinate, respectively. Then, the defining condition for the jth secondary canard is given by

$$P_h \overline{\Pi}^j (h^0(\bar{w}), \bar{w}) = 0; \tag{3.12}$$

i.e., the h-coordinate of the jth iterate of $(h^0(\bar{w}), \bar{w})$ under $\overline{\Pi}$ has to be zero. In other words, we are interested in finding the points of intersection of subsequent iterates of $\mathcal{C}_\varepsilon^-$ under $\overline{\Pi}$ (i.e., of $\mathcal{C}_\varepsilon^j$) with $\mathcal{C}_\varepsilon^+$. For $j \geq 1$ fixed, let $\bar{w}_j^{\mathrm{c}}$ denote the corresponding solution of (3.12). Then, $\bar{w}_j^{\mathrm{c}}$ fixes a point in $\mathcal{C}_\varepsilon^-$ that will determine the location of the jth secondary canard Γ_ε^j; see Figure 13 for an illustration. In particular, for the first secondary canard, we have the requirement that

$$P_h \overline{\Pi}(h^0(\bar{w}_1^{\mathrm{c}}), \bar{w}_1^{\mathrm{c}}) = 0.$$

Remark 7. Recall that $\mathcal{C}_\varepsilon^-$ corresponds to the intersection of the locally invariant slow manifold $\mathcal{S}_\varepsilon^{a-}$ in (1.5) with Δ, before the rescaling. Since the critical manifold $\mathcal{S}_0$ for (1.5) is normally hyperbolic away from $\ell^\pm$, it follows that the slow manifold $\mathcal{S}_\varepsilon$ is unique up to exponentially small terms [11, 14]. Once the corresponding sheets of $\mathcal{S}_\varepsilon^{a-}$ and $\mathcal{S}_\varepsilon^r$ are chosen, the strong canard Γ_ε^0 is uniquely determined. Similarly, since the jth secondary canard Γ_ε^j, with $j \geq 1$, is defined as the trajectory lying in the intersection of the jth iterate of $\mathcal{S}_\varepsilon^{a-}$ under Π with $\mathcal{S}_\varepsilon^r$, all secondary canards will originate in the same sheet of $\mathcal{S}_\varepsilon^{a-}$. Thus, we can restrict ourselves to $\mathcal{C}_\varepsilon^-$ when studying secondary canards.

Given the asymptotics of the return map $\overline{\Pi} : \overline{\Delta}_- \to \overline{\Delta}_-$, as derived in Proposition 2.2 (cf. (2.9)), we can write

$$\overline{\Pi}(h, \bar{w}) = \overline{\Pi}_0(h, \bar{w}) + \mathcal{O}(\varepsilon), \tag{3.13}$$

where $\overline{\Pi}_0(h, \bar{w})$ denotes the return map for the system

$$\begin{aligned} \bar{v}' &= -\bar{z} + f_2 \bar{v}^2 + \sqrt{\varepsilon} f_3 \bar{v}^3 + \sqrt{\varepsilon} F(0,0) + \bar{w} G(0,0), \\ \bar{z}' &= \bar{v} - \bar{w}, \\ \bar{w}' &= 0. \end{aligned} \tag{3.14}$$

We begin by showing that the leading-order approximation $\overline{\Pi}_0$, which is obtained by omitting the $\mathcal{O}(\varepsilon)$-terms in (3.13), is not sufficiently accurate to give nontrivial solutions of (3.12), i.e., solutions that are not exponentially close (in ε) to the canard critical value $\bar{w}^{\mathrm{c}}$ for (3.14). (Recall that $\bar{w}^{\mathrm{c}}$ is the $\bar{w}$-value corresponding to the strong canard Γ_ε^0, after the rescaling in (2.2), with

$$\bar{w}^{\mathrm{c}} = \frac{d^0_{\sqrt{\varepsilon}}}{d^0_{\bar{w}}} \sqrt{\varepsilon} + \mathcal{O}(\varepsilon)$$

by (2.16).) Since Γ_ε^0 itself is only unique up to exponentially small terms, we conclude that the map $\overline{\Pi}_0$ will admit no secondary canards.

The argument goes as follows: to determine the $\bar{w}$-value corresponding to the first secondary canard Γ_ε^1 from $\overline{\Pi}_0$, one would have to solve $P_h\overline{\Pi}_0(h^0(\bar{w}),\bar{w}) = 0$. Solutions of this equation are obtained by applying the implicit function theorem about $(0,\bar{w}^{\mathrm{c}})$. (Here, we have taken into account that $h^0(\bar{w}^{\mathrm{c}}) = 0$ by the definition of $\bar{w}^{\mathrm{c}}$; cf. again (2.16).) However, since $\bar{w}^{\mathrm{c}}$ corresponds precisely to the critical value of the canard parameter $\bar{w}$ in the classical (two-dimensional) scenario, it can be shown [20] that $P_h\overline{\Pi}_0(0,\bar{w}_0^{\mathrm{c}})$ is exponentially small. By the implicit function theorem, it follows that any solution $\bar{w}^*$ of the equation $P_h\overline{\Pi}_0(h^0(\bar{w}),\bar{w}) = 0$ close to $\bar{w}^{\mathrm{c}}$ must be such that $|\bar{w}^* - \bar{w}^{\mathrm{c}}|$ is exponentially small. (Note that this is exactly the situation encountered in a two-dimensional canard explosion; see again [20].)

Hence, in order to find secondary canards, we must refine our analysis and include additional terms in the description of the "local" return map $\overline{\Pi}$. In the following, we will use the partially decoupled truncated system

$$\bar{v}' = -\bar{z} + f_2\bar{v}^2 + \sqrt{\varepsilon}f_3\bar{v}^3 + \sqrt{\varepsilon}F(0,0) + \bar{w}G(0,0), \tag{3.15a}$$

$$\bar{z}' = \bar{v} - \bar{w}, \tag{3.15b}$$

$$\bar{w}' = \varepsilon\mu \tag{3.15c}$$

as the basis for our computation. As it turns out, this refinement will suffice to solve (3.12) for $\bar{w}$, in a nontrivial fashion, to leading order. Note that the only difference between (3.14) and (3.15) lies in the $\bar{w}$-equation: instead of keeping $\bar{w}$ constant to lowest order, we let it evolve in (3.15c), according to the leading-order approximation obtained for $\bar{w}'$ from (2.8c), $\bar{w}' = \varepsilon(\mu - g_1\varepsilon\bar{z} + \mathcal{O}(\varepsilon)) \sim \varepsilon\mu$.

The relevant result on the refined asymptotics of $\overline{\Pi}$ is obtained as follows.

Proposition 3.2. *Let $\overline{\Pi} : \overline{\Delta}^- \to \overline{\Delta}_-$ denote the return map for (3.15), and fix $\varepsilon > 0$ sufficiently small. Then,*

$$\overline{\Pi}(h,\bar{w}) = \begin{pmatrix} P_h\overline{\Pi}_0(h,\bar{w}) + \varepsilon\mu\mathcal{K}(h) + \mathcal{O}(\varepsilon^2) \\ \bar{w} + 2\varepsilon\mu T^h + \mathcal{O}(\varepsilon^2) \end{pmatrix}, \tag{3.16}$$

where $\overline{\Pi}_0$ denotes the return map for (3.14) and $\mathcal{K}$ is defined via

$$\mathcal{K}(h) = \int_{-T^h}^{T^h} \nabla H(\bar{\gamma}_0^h(t)) \cdot (G(0,0),-1)^T(t+T^h)\,dt.$$

Proof. Let $\bar{w}_0^{\mathrm{c}}$ denote the critical $\bar{w}$-value for the "refined" system (3.15). We begin by showing that, to leading order, $\bar{w}_0^{\mathrm{c}}$ equals $\bar{w}^{\mathrm{c}}$, which is again the corresponding $\bar{w}$-value determined from $\overline{\Pi}_0$; cf. (2.16). Suppose that $\bar{w}$ is given and that we wish to find h^- such that $(h^-,\bar{w}) \in \mathcal{C}_\varepsilon^-$ holds. Solving (3.15c), we obtain $\bar{w}(t) = \bar{w} + \varepsilon\mu t$, which we then substitute into (3.15a) and (3.15b):

$$\begin{aligned} \bar{v}' &= -\bar{z} + f_2\bar{v}^2 + \sqrt{\varepsilon}f_3\bar{v}^3 + \sqrt{\varepsilon}F(0,0) + (\bar{w} + \varepsilon\mu t)G(0,0), \\ \bar{z}' &= \bar{v} - \bar{w} - \varepsilon\mu t. \end{aligned} \tag{3.17}$$

Fix $\bar{w}$, and suppose that h_0^- is the h-value obtained from (3.14) such that $(h_0^-, \bar{w}) \in \mathcal{C}_\varepsilon^-$; see the proof of Proposition 2.2. Then, it follows that

$$h^- = h_0^- - \varepsilon\mu \int_{-\infty}^{0} \frac{\partial H}{\partial \bar{z}}(\bar{\gamma}_0^0(t))G(0,0)t\,dt, \tag{3.18}$$

again by the proof of Proposition 2.2. A similar computation shows that

$$h^+ = h_0^+ + \varepsilon\mu \int_{0}^{\infty} \frac{\partial H}{\partial \bar{z}}(\bar{\gamma}_0^0(t))G(0,0)t\,dt, \tag{3.19}$$

where h^+ and h_0^+ are defined by the requirement that $(h^+, \bar{w}) \in \mathcal{C}_\varepsilon^+$ and $(h_0^+, \bar{w}) \in \mathcal{C}_\varepsilon^+$ in (3.15) and (3.14), respectively. By symmetry, we find that

$$\int_{-\infty}^{0} -\frac{\partial H}{\partial z}(\bar{\gamma}_0^0(t))t\,dt = \int_{0}^{\infty} \frac{\partial H}{\partial z}(\bar{\gamma}_0^0(t))t\,dt. \tag{3.20}$$

It follows that the defining condition for the strong canard in (3.15), which, for (2.8), is given by $h^- = h^+$, reduces to $h_0^- = h_0^+ + \mathcal{O}(\varepsilon^2)$ and, hence, that the corresponding critical values of $\bar{w}$ are indeed the same to leading order.

Finally, the approximation for $\overline{\Pi}$ in (3.16) is derived as in the proof of Proposition 2.2, where we note that the additional $\mathcal{K}$-term is due to the fact that $h \mapsto h^+ - h^- = h^0 + \varepsilon\mu\mathcal{K}(h)$, by (3.18), (3.19), and (3.20). ■

Remark 8. It can be shown that the inclusion of additional (higher-order) terms in (3.15) will not alter the result of Proposition 3.2, since these terms will either drop out by symmetry, as in the proof of Proposition 2.2, or contribute only terms of higher order in (3.16).

The asymptotics of $\mathcal{K}$ are studied in Appendix A, where we show that $\mathcal{K}(h) = 2d_{\bar{w}}^0 T^h + \mathcal{O}(1)$; see Lemma A.5. Therefore, the defining condition for the first secondary canard, $P_h\overline{\Pi}(h^0(\bar{w}), \bar{w}) = 0$, can be written as

$$P_h\overline{\Pi}_0(h^0(\bar{w}), \bar{w}) = -\varepsilon\mu\mathcal{K}(h^0(\bar{w})) + \mathcal{O}(\varepsilon^2), \tag{3.21}$$

to leading order. Moreover, recalling that $\bar{w}_1^c$ denotes the value of $\bar{w}$ that solves (3.21), we write $\bar{w}_1^c = \bar{w}_0^c + \Delta\bar{w}$. Then, we have the following estimate for the width $\Delta\bar{w}$ of the first sector of rotation.

Proposition 3.3. *With $\Delta\bar{w}$ defined as above, there holds*

$$\Delta\bar{w} = -2\varepsilon\mu\sqrt{-2\ln\varepsilon} + \mathcal{O}(\varepsilon) \tag{3.22}$$

for $\varepsilon > 0$ sufficiently small.

Proof. Making use of the definition of Π_0 (see Proposition 2.2), we first rewrite $P_h\overline{\Pi}_0(h^0(\bar{w}), \bar{w})$ as

$$\begin{aligned}
P_h\overline{\Pi}_0(h^0(\bar{w}), \bar{w}) &= P_h\overline{\Pi}_0(0, \bar{w}_0^c) + P_h\overline{\Pi}_0(h^0(\bar{w}), \bar{w}) - P_h\overline{\Pi}_0(0, \bar{w}_0^c) \\
&= P_h\overline{\Pi}_0(0, \bar{w}_0^c) + d_{\bar{w}}^{h^0(\bar{w})}\bar{w} - d_{\bar{w}}^0\bar{w}_0^c + \sqrt{\varepsilon}\big(d_{\sqrt{\varepsilon}}^{h^0(\bar{w})} - d_{\sqrt{\varepsilon}}^0\big) + \mathcal{O}(\varepsilon, \sqrt{\varepsilon}\Delta\bar{w}, \Delta\bar{w}^2) \\
&= P_h\overline{\Pi}_0(0, \bar{w}_0^c) + \big(d_{\bar{w}}^{h^0(\bar{w})} - d_{\bar{w}}^0\big)\bar{w} + d_{\bar{w}}^0\Delta\bar{w} + \sqrt{\varepsilon}\big(d_{\sqrt{\varepsilon}}^{h^0(\bar{w})} - d_{\sqrt{\varepsilon}}^0\big) \\
&\qquad + \mathcal{O}(\varepsilon, \sqrt{\varepsilon}\Delta\bar{w}, \Delta\bar{w}^2);
\end{aligned}$$

see the discussion in section 3.1 as well as (2.39). Now, recall that $\bar{w} = \mathcal{O}(\sqrt{\varepsilon})$ by Assumption 1, and note that one can estimate $d_{\bar{w}}^{h^0(\bar{w})} - d_{\bar{w}}^0 = \mathcal{O}(h^0(\bar{w})\ln(-h^0(\bar{w}))^{\frac{3}{2}})$; cf. (A.9). Also, since $h^0(\bar{w}_0^{\mathrm{c}}) = 0$ by (2.16) and (2.39), a Taylor expansion shows

$$h^0(\bar{w}) = d_{\bar{w}}^0 \Delta\bar{w} + \mathcal{O}(\Delta\bar{w}^2), \tag{3.23}$$

which implies in sum

$$P_h\overline{\Pi}_0(h^0(\bar{w}),\bar{w}) = P_h\overline{\Pi}_0(0,\bar{w}_0^{\mathrm{c}}) + d_{\bar{w}}^0\Delta\bar{w} + \sqrt{\varepsilon}\big(d_{\sqrt{\varepsilon}}^{h^0(\bar{w})} - d_{\sqrt{\varepsilon}}^0\big) + \mathcal{O}\big(\varepsilon, \sqrt{\varepsilon}(-\ln\varepsilon)^{\frac{3}{2}}\Delta\bar{w}, \Delta\bar{w}^2\big).$$

Using the fact that $P_h\overline{\Pi}_0(0,\bar{w}_0^{\mathrm{c}}) = \mathcal{O}(\mathrm{e}^{-\frac{\kappa}{\varepsilon}})$ for some $\kappa > 0$ as well as the estimates from (A.9) and Lemma A.5, we conclude that the $\bar{w}$-value corresponding to the first secondary canard, $\bar{w}_1^{\mathrm{c}}$, is determined from $d_{\bar{w}}^0\Delta\bar{w} = -2\varepsilon\mu d_{\bar{w}}^0 T^{h^0(\bar{w})} + \mathcal{O}((\sqrt{\varepsilon} + \Delta\bar{w})^2)$. Hence, we obtain

$$\bar{w}_1^{\mathrm{c}} = \bar{w}_0^{\mathrm{c}} - 2\varepsilon\mu T^{h^0(\bar{w}_1^{\mathrm{c}})} + \mathcal{O}(\varepsilon), \tag{3.24}$$

which implies in particular $|\bar{w}_1^{\mathrm{c}} - \bar{w}_0^{\mathrm{c}}| \gtrsim \varepsilon$, i.e., $|\bar{w}_1^{\mathrm{c}} - \bar{w}_0^{\mathrm{c}}| > \varepsilon$ as well as $|\bar{w}_1^{\mathrm{c}} - \bar{w}_0^{\mathrm{c}}| \sim \varepsilon$. Due to $h^0(\bar{w}_0^{\mathrm{c}}) = 0$ and $\frac{dh^0}{d\bar{w}} \sim d_{\bar{w}}^0$, it follows from the intermediate value theorem that $h^0(\bar{w}_1^{\mathrm{c}}) \gtrsim \varepsilon$, which, together with Lemma A.2, shows that the desired estimate for the size of the first sector of rotation is given by

$$\bar{w}_1^{\mathrm{c}} - \bar{w}_0^{\mathrm{c}} = \Delta\bar{w} = -2\varepsilon\mu\sqrt{-2\ln\varepsilon} + \mathcal{O}(\varepsilon). \tag{3.25}$$

This completes the proof. ∎

Let $k > 1$, and consider $j = 0,\dots,k$. We now set out to find an analogue of condition (3.21) for the kth secondary canard Γ_ε^k. Let $\bar{w}_k^{\mathrm{c}}$ again denote the corresponding $\bar{w}$-value, consider an initial condition $(h^0(\bar{w}),\bar{w}) \in \mathcal{C}_\varepsilon^-$, and let

$$\bar{w}^j = P_{\bar{w}}\overline{\Pi}^j(h^0(\bar{w}),\bar{w}),$$

as before. Note that $\bar{w}_k^{\mathrm{c}}$ must be a solution of the equation

$$P_h\overline{\Pi}(h^{k-1}(\bar{w}^{k-1}),\bar{w}^{k-1}) = 0$$

or, equivalently, of

$$P_h\overline{\Pi}_0(h^{k-1}(\bar{w}^{k-1}),\bar{w}^{k-1}) = -\varepsilon\mu\mathcal{K}(h^{k-1}(\bar{w}^{k-1})) + \mathcal{O}(\varepsilon^2). \tag{3.26}$$

Observe that the condition in (3.26) is analogous to (3.21), with h^0 replaced by h^{k-1}; hence, the structure of (3.21) is replicated at higher orders. Note also that it follows from (3.24) that $\bar{w}_1^{\mathrm{c},1} = \bar{w}_0^{\mathrm{c}} + \mathcal{O}(\varepsilon)$, where $\bar{w}_1^{\mathrm{c},1}$ is the first iterate of $\bar{w}_1^{\mathrm{c}}$ under $\overline{\Pi}$. This estimate, in turn, implies that $h^1(\bar{w}_0^{\mathrm{c}}) = \mathcal{O}(\varepsilon)$; see (3.1). An argument analogous to the derivation of (3.24) now leads to the estimate

$$\bar{w}_2^{\mathrm{c},1} = \bar{w}_0^{\mathrm{c}} - 2\varepsilon\mu T^{h(\bar{w}_2^{\mathrm{c},1})} + \mathcal{O}(\varepsilon)$$

or, equivalently, to

$$\bar{w}_2^{\mathrm{c}} = \bar{w}_0^{\mathrm{c}} - 2\varepsilon\mu\big(T^{h(\bar{w}_2^{\mathrm{c}})} + T^{h(\bar{w}_2^{\mathrm{c},1})}\big) + \mathcal{O}(\varepsilon). \tag{3.27}$$

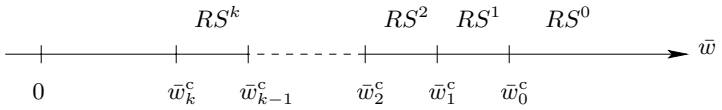

Figure 14. *The sectors of rotation, RS^j.*

Proceeding inductively, we obtain $h^{k-1}(\bar{w}_0^c) = \mathcal{O}(\varepsilon)$ and

$$\bar{w}_k^c = \bar{w}_0^c - 2\varepsilon\mu\left(\sum_{j=0}^{k-1} T^{h(\bar{w}_k^{c,j})}\right) + \mathcal{O}(\varepsilon), \tag{3.28}$$

where we define $\bar{w}_k^{c,0} \equiv \bar{w}_k^c$. Finally, using Lemma A.2 to again approximate $T^{h(\bar{w}_k^{c,j})}$ by $\sqrt{-2\ln\varepsilon} + \mathcal{O}(1)$ (nonuniformly in k), we obtain in analogy to (3.25) that

$$\bar{w}_k^c = \bar{w}_{k-1}^c - 2\varepsilon\mu\sqrt{-2\ln\varepsilon} + \mathcal{O}(\varepsilon), \tag{3.29}$$

which, in conjunction with (2.19), verifies Assumption 1 above.

One question that naturally arises in this context is whether $k > 1$ can be chosen arbitrarily large. Here, we show that our analysis, and, in particular, the estimate in (3.28), does not hold uniformly in k with respect to ε; rather, (3.28) is valid for k fixed and ε sufficiently small. This is due to the fact that the contributions coming from $T^{h(\bar{w}_k^{c,j})}$ become increasingly smaller with k: since $\bar{w}_k^c$ decreases with k and since $h(\bar{w}) \sim \sqrt{\varepsilon}d^0_{\sqrt{\varepsilon}} + \bar{w}d^0_{\bar{w}}$ with $d^0_{\bar{w}} < 0$ (see (2.18)), it follows that h increases with k. Therefore, $T^h \sim \sqrt{-2\ln h}$ decreases, and the $\mathcal{O}(\varepsilon)$-terms can come to dominate the $2\varepsilon\mu(\cdots)$-terms in (3.28) if k is sufficiently large. However, in our analysis, we had to assume that these terms are uniformly of lower order than ε, starting with the leading-order approximation for $\overline{\Pi}$ in Proposition 2.2. In summary, for k "large," ε thus has to be chosen small enough to ensure that the estimate in (3.28) remains consistent.

Proposition 3.4. *Fix any integer $K > 0$. Then, there exists an $\varepsilon > 0$ sufficiently small such that the estimate in (3.28) holds for $k \leq K$.*

For $j = 1, \ldots, k$, we now define the jth sector of rotation RS^j as follows:

$$RS^j = \left\{(h^0(\bar{w}), \bar{w}) \in \mathcal{C}_\varepsilon^- \;\middle|\; \bar{w}_j^c \leq \bar{w} < \bar{w}_{j-1}^c\right\}.$$

This definition provides a connection between the family of secondary canards $\{\Gamma_\varepsilon^j\}$ and the corresponding sectors of rotation: the jth sector, RS^j, is bounded by the secondary canards Γ_ε^{j-1} and Γ_ε^j in that the corresponding points $\bar{w}_{j-1}^c$ and $\bar{w}_j^c$ on $\mathcal{C}_\varepsilon^-$ define the boundaries of RS^j.

For notational purposes, we also introduce the zeroth sector RS^0 via

$$RS^0 = \left\{(h, \bar{w}) \in \mathcal{C}_\varepsilon^- \;\middle|\; \bar{w}_0^c \leq \bar{w}\right\},$$

and we note that this definition is equivalent to requiring that $h < 0$; see (2.37). An illustration of these sectors of rotation is given in Figure 14. In particular, since $\bar{w}_j^c < \bar{w}_{j-1}^c$ for any $j \geq 1$, the sector RS^j lies further "to the left" of RS^0 with increasing j.

It follows from the preceding analysis that all of the sectors RS^j are of equal size to leading order; cf. (3.29). (However, we conjecture that due to higher-order corrections, the sector size actually decreases as j increases.) Moreover, for ε and μ fixed, the number of sectors of rotation RS^j, and, hence, also the number of corresponding secondary canards Γ_ε^j, has to be finite: note that the frequency of the small-oscillation component in any mixed-mode time series in (1.5) is globally bounded, with the bound given approximately by the frequency determined by the Hopf bifurcation around the origin in (1.5). Additionally, the speed of the drift in $\bar{w}$ in (2.3c) is always positive for nonzero ε and μ, which implies that $\bar{w} > \bar{w}_0^c$ in finite time. Hence, trajectories of (1.5) can undergo only a finite number of small-amplitude oscillations before entering the relaxation regime, which implies that there can be only a finite number of sectors of rotation lying in $(0, \bar{w}_0^c)$; see again Figure 14.

Remark 9. It follows from Proposition 3.4 that both the number of secondary canards and that of the corresponding sectors of rotation must go to infinity as $\varepsilon \to 0$. However, it is important to note that Proposition 3.4 gives no bound on the total number of secondary canards for $\varepsilon > 0$. Rather, the integer K can be chosen arbitrarily large provided ε is small enough, implying that our analysis is then valid for all $k \leq K$.

Finally, we observe that the definition of RS^j can be extended to a small neighborhood of $\mathcal{C}_\varepsilon^-$ by the flow of (2.8) and, hence, that the sectors of rotation can be interpreted as two-dimensional subsets of $\mathcal{S}_\varepsilon^{a-}$.

3.4. The return map Φ to $\mathcal{C}_\varepsilon^-$. To show how the "full" map Π (which a priori has to be interpreted as a map that is defined on $\bigcup \mathcal{C}_\varepsilon^j$) can be approximated accurately by a "simplified" map, we introduce $\Phi : \mathcal{C}_\varepsilon^- \to \mathcal{C}_\varepsilon^-$ as follows. Let $k \geq 0$, and recall the definition of the kth sector of rotation, RS^k, from the previous subsection. Then, we define Φ via

$$\Phi(\bar{w}) = P_{\bar{w}}\big(\Pi^{\text{in}} \circ \Pi^{\text{ret}} \circ \Pi^{\text{out}} \circ \overline{\Pi}^k(h^0(\bar{w}), \bar{w})\big) \qquad \text{if } (h^0(\bar{w}), \bar{w}) \in RS^k. \tag{3.30}$$

Note that Φ is a reinterpretation of Π in that it is a composition of the same components that were used in the definition of Π in (3.5). However, it is defined on a different domain: the definition in (3.30) reduces the analysis of the flow induced by (1.5) to that of a one-dimensional map that is defined on the single curve $\mathcal{C}_\varepsilon^-$, which will allow us to study the recurrent dynamics on RS^k in considerable detail. Moreover, we note that Φ is still an exponentially accurate approximation for the full, two-dimensional return map Π, which is again due to the fact that all trajectories must return exponentially close to $\mathcal{C}_\varepsilon^-$ after relaxation, i.e., after application of Π^{ret}; cf. the proof of Proposition 3.1. One drawback of this simplification, however, lies in the fact that the defining formula (3.30) for Φ is k-dependent; in other words, the definition of Φ changes with the sector of rotation under consideration. This k-dependence will have to be taken into account throughout the subsequent analysis.

Finally, we remark that the map Φ is smooth on each of the sectors RS^k but that it has discontinuities at the points $\bar{w}_k^c$ and $\bar{w}_{k-1}^c$. We will not study the nature of these discontinuities in detail, since we are not attempting to analyze the dynamics of Φ "very close" to the secondary canards. Rather, we will restrict ourselves to describing Φ on the interior of the individual sectors RS^k.

3.5. The derivative of Φ. In this subsection, we derive estimates for the derivative $\Phi'(\bar{w}) := \frac{d\Phi}{d\bar{w}}$ of Φ on the kth sector of rotation, RS^k. We then investigate some of the

properties of Φ'. The resulting estimates are needed for the analysis of the dynamics of Φ in section 3.6 below and will allow us to characterize the admissible Farey sequences in (1.5) as well as to describe the corresponding parameter intervals.

Let $\bar{w}$ be such that $(h^0(\bar{w}), \bar{w}) \in RS^k$, and let $\bar{w}^j = P_{\bar{w}}\overline{\Pi}^j(h^0(\bar{w}^0), \bar{w}^0)$, where we set $\bar{w}^0 \equiv \bar{w}$. Given the definition of Φ in (3.30), we have the following result.

Lemma 3.5. *To leading order, there holds*

(3.31)
$$\frac{d\Phi(\bar{w})}{d\bar{w}} = 1 - \varepsilon\mu d^0_{\bar{w}}\left(\sum_{j=0}^{k-1} 2(j+1)\frac{1}{h^j(\bar{w}^j)}\frac{1}{\sqrt{-2\ln h^j(\bar{w}^j)}} + (k+1)\frac{1}{h^k(\bar{w}^k)}\frac{1}{\sqrt{-2\ln h^k(\bar{w}^k)}}\right) + \mathcal{O}(\varepsilon\ln\varepsilon)$$

for the derivative of Φ on RS^k.

Proof. By the chain rule and taking into account the definitions of $\overline{\Pi}$, Π^{in}, and Π^{out}, as well as of Π^{ret} in Propositions 2.2, 2.3, and 2.4 as well as in (2.54), respectively, we have

$$\begin{aligned}\frac{d\Phi(\bar{w})}{d\bar{w}} &= \prod_{j=0}^{k-1}\left(1 + 2\varepsilon\mu\frac{dT^{h^j(\bar{w})}}{d\bar{w}}\right)\left(1 + \varepsilon\mu\frac{dT^{h^k(\bar{w}),\text{out}}}{d\bar{w}}\right) + \mathcal{O}(\varepsilon\ln\varepsilon)\\ &= 1 + \varepsilon\mu\sum_{j=0}^{k-1} 2\frac{dT^{h^j(\bar{w})}}{d\bar{w}} + \varepsilon\mu\frac{dT^{h^k(\bar{w}),\text{out}}}{d\bar{w}} + \mathcal{O}(\varepsilon\ln\varepsilon)\\ &= 1 - \varepsilon\mu d^0_{\bar{w}}\left(\sum_{j=0}^{k-1} 2(j+1)\frac{1}{h^j(\bar{w}^j)}\frac{1}{\sqrt{-2\ln h^j(\bar{w}^j)}} + (k+1)\frac{1}{h^k(\bar{w}^k)}\frac{1}{\sqrt{-2\ln h^k(\bar{w}^k)}}\right)\\ &\quad + \mathcal{O}(\varepsilon\ln\varepsilon),\end{aligned}$$

where the last step follows from (3.10) and (3.11). ∎

Since we assume that $h^j(\bar{w}^j) = \mathcal{O}(\varepsilon\sqrt{-\ln\varepsilon})$ (see the proof of Proposition 3.3 above), we can write

$$\frac{1}{\sqrt{-2\ln h^j(\bar{w}^j)}} = \frac{1}{\sqrt{-2\ln\varepsilon}}\big(1 + o(1)\big).$$

This gives a somewhat less accurate but more concise estimate for the derivative of Φ:

$$\frac{d\Phi(\bar{w})}{d\bar{w}} \sim 1 - \varepsilon\mu d^0_{\bar{w}}\frac{1}{\sqrt{-2\ln\varepsilon}}\left(\sum_{j=0}^{k-1}\frac{2(j+1)}{h^j(\bar{w}^j)} + \frac{k+1}{h^k(\bar{w}^k)}\right). \tag{3.32}$$

(Note that again due to $h^j(\bar{w}^j) = \mathcal{O}(\varepsilon\sqrt{-\ln\varepsilon})$, the $\mathcal{O}(\varepsilon)$-correction in (3.32) will actually be of the order $(\ln\varepsilon)^{-1}$ and that we can therefore neglect the $\mathcal{O}(\varepsilon\ln\varepsilon)$-terms in (3.31).)

To simplify this estimate further, we have to distinguish between different k-values in (3.32). We first focus on the case where $k > 0$; the case when $k = 0$ will be discussed separately.

Given $k > 0$, fix an initial condition $\bar{w}^0 \in RS^k$, and let $\bar{w}^1, \bar{w}^2, \ldots, \bar{w}^k$ be defined as in section 3.4 above; i.e., let $\bar{w}^j$ be the jth iterate of $\bar{w}^0$ under $\overline{\Pi}$. Then, it follows directly from

(3.32) that $\Phi' < 1$ if $\bar{w}^0 \approx \bar{w}^{\mathrm{c}}_k$, respectively, that $\Phi' > 1$ if $\bar{w}^0 \approx \bar{w}^{\mathrm{c}}_{k-1}$. We are interested in approximating more precisely the size of the $\bar{w}$-intervals where Φ' is less than 1 and greater than 1, respectively.

To that end, let $\Delta\bar{w}^j = \bar{w}^{\mathrm{c}}_{j-1} - \bar{w}^{\mathrm{c}}_j$ be the width of the jth sector of rotation RS^j, and recall that we have the estimate

$$\Delta\bar{w}^j \sim 2\varepsilon\mu\sqrt{-2\ln\varepsilon},$$

independent of j to leading order. Given any $\bar{w}^0 \in RS^k$, we can write $\bar{w}^0 = \bar{w}^{\mathrm{c}}_k + \nu\Delta\bar{w}^k$ for some $\nu \in [0,1]$; i.e., the sector RS^k will be parametrized by the variable ν in the following. Moreover, for any $j \geq 0$, we have the following estimates:

$$\begin{aligned}
\bar{w}^{\mathrm{c}}_j &\sim \bar{w}^{\mathrm{c}}_0 - 2j\varepsilon\mu\sqrt{-2\ln\varepsilon},\\
\bar{w}^j &\sim \bar{w}^{\mathrm{c}}_0 - 2\big((k-j)-\nu\big)\varepsilon\mu\sqrt{-2\ln\varepsilon},\\
h^j(\bar{w}^j) &\sim -2d^0_{\bar{w}}(j+1)\big((k-j)-\nu\big)\varepsilon\mu\sqrt{-2\ln\varepsilon},
\end{aligned}$$

where the last expression is a consequence of (3.3). Using (3.32), we obtain

$$\frac{d\Phi(\bar{w})}{d\bar{w}} \sim 1 - \frac{\omega_k(\nu)}{4\ln\varepsilon}, \tag{3.33}$$

where the function ω_k is defined via

$$\omega_k(\nu) = \sum_{j=0}^{k-1} \frac{1}{(k-j)-\nu} - \frac{1}{2\nu}. \tag{3.34}$$

Finally, we consider the case where $k = 0$. For any initial condition $\bar{w}^0 \in RS^0$, we can write $\bar{w}^0 = \bar{w}^0_c + 2\nu\varepsilon\mu\sqrt{-2\ln\varepsilon}$, where ν is now some positive number. Then,

$$\frac{d\Phi(\bar{w})}{d\bar{w}} \sim 1 - \frac{\omega_0(\nu)}{4\ln\varepsilon}, \tag{3.35}$$

with $\omega_0(\nu) = -\frac{1}{2\nu}$. Observe that, clearly, $\Phi'(\bar{w}) < 1$ for any $\bar{w} \in RS^0$.

Remark 10. Note that for $k \geq 0$, the function $\omega_k(\nu)$ defined in (3.34) is increasing on $[0,1]$ and that ω_k changes sign exactly once if $k > 0$; see Figure 15.

The zeros of $\omega_k(\nu)$, $k > 0$, give the approximate sizes of the subintervals of RS^k where Φ' is greater than 1 and less than 1, respectively. More precisely, we have proven the following result.

Proposition 3.6. *For $k > 0$ and $\varepsilon > 0$ sufficiently small, the subinterval of RS^k on which $\Phi'(\bar{w}) < 1$ is approximately given by $(\bar{w}^{\mathrm{c}}_k, \bar{w}^{\mathrm{c}}_k + 2\nu^k_0\mu\varepsilon\sqrt{-2\ln\varepsilon})$, where ν^k_0 denotes the unique zero of ω_k on RS^k.*

3.6. The dynamics of Φ. In this subsection, we analyze the dynamics of the reduced map Φ in more detail, combining the results obtained so far in section 3. The aim of our analysis is to relate the properties of Φ to the resulting mixed-mode dynamics in (1.5) and to estimate the relevant parameter (μ-)range corresponding to this dynamics. Our first result

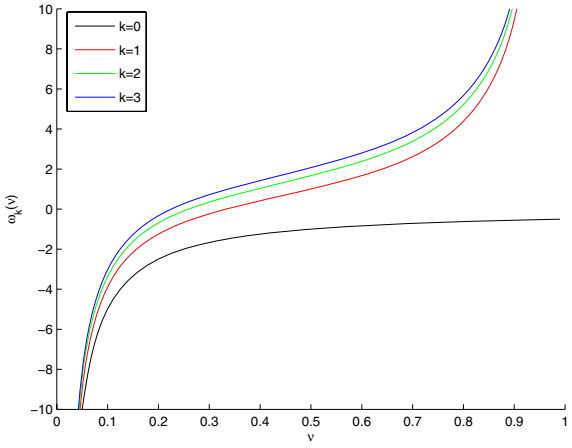

Figure 15. *The function* ω_k *on* $[0,1]$ *for* $k = 0, \dots, 3$.

(Theorem 3.7) concerns the existence and stability of 1^k-type orbits, i.e., of periodic orbits with symbolic (Farey) sequence $\{1^k\}$; these orbits correspond to the recurrent dynamics of (1.5) on the kth sector of rotation, RS^k. Then, in Theorem 3.9, we derive conditions for when a given orbit will pass through RS^k. In Theorem 3.10, Proposition 3.11, and Corollary 3.12, we apply these conditions to classify the periodic orbits of the more general type $\{L_j^{k_j}\}$, with $L_j, k_j \geq 1$, that can "typically" occur in (1.5).

We start by summarizing some of the features of Φ which follow directly from the results of sections 3.3 and 3.5; see Figure 16 for a qualitative illustration.

(i) Φ must be decreasing close to the left boundary of RS^k and increasing on most of RS^k, with $\bar{w}_k^{\mathrm{c}} + \nu_0^k \Delta\bar{w}^k$ giving an estimate of the point where Φ' becomes greater than 1; cf. Proposition 3.6.

(ii) The derivative Φ' must change sign near $\bar{w}_{\min}^k := \bar{w}_k^{\mathrm{c}} + \nu_{\min}^k \Delta\bar{w}^k$, with $\nu_{\min}^k$ determined by the condition that $\omega_k(\nu_{\min}^k) = 4\ln\varepsilon$. This implies in particular that $\nu_{\min}^k = \mathcal{O}((\ln\varepsilon)^{-1})$ and, hence, that $\bar{w}_{\min}^k \approx \bar{w}_k^{\mathrm{c}}$. (Note that our analysis does not prove the uniqueness of this minimum, though.)

(iii) A simple computation along the lines of section 3.5 shows that $\Phi(\bar{w}_{\min}^k) = \Phi_{\min} + \mathcal{O}(\varepsilon)$ is independent of k to lowest order, where

$$\Phi_{\min} := \bar{w}_0^{\mathrm{c}} + \sqrt{\varepsilon}\big(\mathcal{G}(v_0, v_{\max}, \mu) + \mathcal{G}(v_{\max}^*, 0, \mu)\big) + \varepsilon\mu\sqrt{-2\ln\varepsilon}; \tag{3.36}$$

cf. (2.54). Indeed, given the formula for Π in (3.5), as well as $P_{\bar{w}}\Pi^k(\bar{w}_{\min}^k) \sim \bar{w}_{\min}^0$, it follows with (3.30) that

$$\begin{aligned}\Phi(\bar{w}_{\min}^k) &\sim \Phi \circ P_{\bar{w}}\Pi^k(\bar{w}_{\min}^k)\\ &\sim \bar{w}_{\min}^0 + \varepsilon\mu T^{h(\bar{w}_{\min}^0),\mathrm{out}} + \bar{w}_{\min}^0 f_2 \mu\varepsilon\ln\varepsilon + \sqrt{\varepsilon}\big(\mathcal{G}(v_0, v_{\max}, \mu) + \mathcal{G}(v_{\max}^*, 0, \mu)\big).\end{aligned}$$

Since $\nu_{\min}^0 \gtrsim (\ln\varepsilon)^{-1}$ implies $\bar{w}_{\min}^k \sim \bar{w}_0^{\mathrm{c}}$ and since $T^{h(\bar{w}_{\min}^0),\mathrm{out}} \sim \sqrt{-2\ln\varepsilon}$, one obtains (3.36).

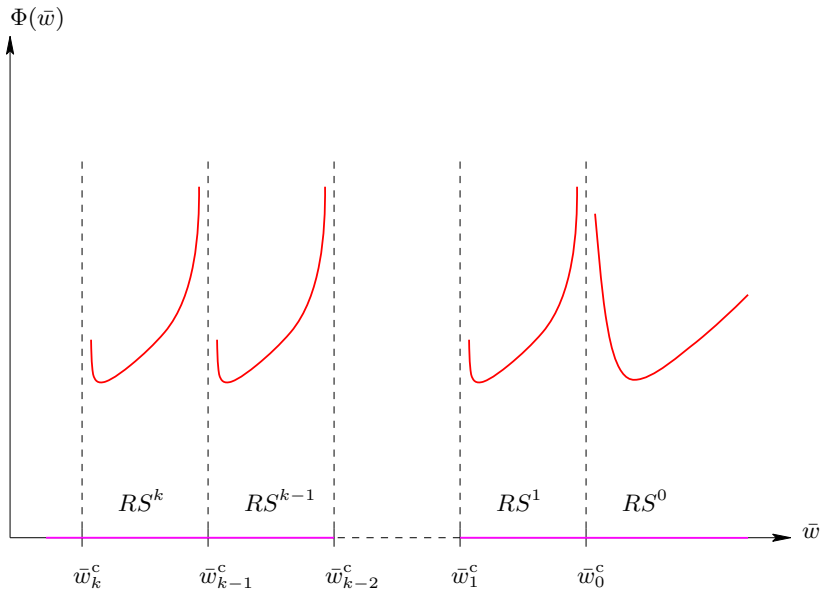

Figure 16. *A qualitative illustration of the map* Φ.

By definition, fixed points of Φ on RS^k correspond to periodic 1^k-type orbits in (2.1). We are interested in estimating the parameter range (i.e., the μ-interval) in which such orbits can be observed.

Theorem 3.7. *For* $\varepsilon > 0$ *sufficiently small, the periodic orbit of type* 1^k, $k \geq 1$, *exists and is stable on a* μ*-interval of the form* $(\underline{\mu}^k, \overline{\mu}^k)$, *with*

$$\Delta\mu^k := \overline{\mu}^k - \underline{\mu}^k = -\frac{\underline{\mu}^k}{\sqrt{2}D_\mu}\frac{\sqrt{\varepsilon}}{\sqrt{-\ln\varepsilon}}\int_{\nu_{-2}^k}^{\nu_0^k}\omega_k(\nu)\,d\nu + \mathcal{O}\big(\sqrt{\varepsilon}(-\ln\varepsilon)^{-1}\big); \tag{3.37}$$

here, ν_{-2}^k *denotes the* ν*-value that solves* $\omega_k(\nu) = 8\ln\varepsilon$.

Proof. Note that MMO orbits with Farey sequence $\{1^k\}$ correspond to solutions of the equation

$$\Phi(\bar{w}, \bar{\mu}) = \bar{w} \tag{3.38}$$

with $\bar{w} \in RS^k$, where we have now included explicitly the μ-dependence of Φ. We are interested in determining μ in (3.38) so that the corresponding fixed point of Φ will be stable. To that end, let ν_{-2}^k be defined as in the statement of the theorem, and note that for $\bar{w} \in RS^k$, the leading term of $\Phi'(\bar{w}, \mu)$ satisfies $|\Phi'(\bar{w}, \mu)| < 1$ if and only if $\bar{w} = \bar{w}_k^c + \nu\Delta\bar{w}^k$ with $\nu \in (\nu_{-2}^k, \nu_0^k)$; cf. (3.33).

Now, if (3.38) is interpreted as defining implicitly a function $\mu = \mu(\bar{w})$, we can set $\underline{\mu}^k = \mu(\bar{w}_k^c + \nu_{-2}^k\Delta\bar{w}^k)$ and $\overline{\mu}^k = \mu(\bar{w}_k^c + \nu_0^k\Delta\bar{w}^k)$. We will use the fundamental theorem of calculus to estimate $\Delta\mu^k = \overline{\mu}^k - \underline{\mu}^k$. Applying implicit differentiation to (3.38), we obtain

$$\frac{d\mu}{d\bar{w}} = -\frac{\frac{\partial}{\partial\bar{w}}\Phi(\bar{w}, \mu) - 1}{\frac{\partial}{\partial\mu}\Phi(\bar{w}, \mu)}.$$

Since

$$\frac{\partial}{\partial \mu}\Phi(\bar{w},\mu) \sim D_\mu \sqrt{\varepsilon}$$

(recall the discussion in section 2.5), it follows that

$$\frac{d\mu}{d\bar{w}} \sim \frac{1}{4D_\mu \sqrt{\varepsilon}\ln\varepsilon}\omega_k(\nu)$$

for $\bar{w} = \bar{w}_k^c + \nu\Delta\bar{w}^k$ with $\nu \in (\nu_{-2}^k, \nu_0^k)$; see (3.33). Therefore, using $\frac{d\bar{w}}{d\nu} \sim \Delta\bar{w}^k$, we find

$$\Delta\mu^k = \overline{\mu}^k - \underline{\mu}^k = \int_{\bar{w}(\underline{\mu}^k)}^{\bar{w}(\overline{\mu}^k)} \frac{d\mu}{d\bar{w}}\, d\bar{w} \sim \frac{1}{4D_\mu\sqrt{\varepsilon}\ln\varepsilon}\Delta\bar{w}^k \int_{\nu_{-2}^k}^{\nu_0^k} \omega_k(\nu)\, d\nu. \tag{3.39}$$

Given that $\Delta\bar{w}^k = 2\varepsilon\mu\sqrt{-2\ln\varepsilon} + \mathcal{O}(\varepsilon)$, the result follows. ∎

Observe that by the definition of ν_0^k, $\overline{\mu}^k$ marks the value of μ for which the orbit of type 1^k disappears in a saddle-node bifurcation of Φ, since $\Phi' = 1$ there. In the following, we summarize a few additional observations which follow from Theorem 3.7:

(i) Note that

$$\int \omega_k(\nu)\, d\nu = \ln|\Gamma(-k+\nu)| - \ln|\Gamma(1+\nu)| - \frac{1}{2}\ln\nu = -\frac{1}{2}\ln\nu + \mathcal{O}(1),$$

where Γ denotes the standard Gamma function. Since the leading-order contribution to the corresponding definite integral in (3.39) comes from $\nu_{-2}^k = \mathcal{O}((\ln\varepsilon)^{-1})$, one can show that, for ε sufficiently small,

$$\Delta\mu^k = \frac{\underline{\mu}^k}{\sqrt{2}D_\mu}\frac{\sqrt{\varepsilon}\ln(\sqrt{-\ln\varepsilon})}{\sqrt{-\ln\varepsilon}} + \mathcal{O}\big(\sqrt{\varepsilon}(-\ln\varepsilon)^{-\frac{1}{2}}\big).$$

Given that the double logarithmic term is "almost constant" (at least if ε does not vary over too many orders of magnitude), it follows that $\Delta\mu^k$ is roughly of the order $\sqrt{\varepsilon}(-\ln\varepsilon)^{-\frac{1}{2}}$ as $\varepsilon \to 0$.

(ii) The estimate in (3.37) implies that, for ε fixed, the ratio of the widths of the stability intervals of "adjacent" periodic orbits (i.e., of orbits of the types 1^{k+1} and 1^k) is approximately given by the ratio of the corresponding integrals of ω_{k+1} and ω_k. Since $\{\nu_0^k\}$ decays faster with k than $\{\nu_{-2}^k\}$ (see Figure 15), it follows that $\int_{\nu_{-2}^k}^{\nu_0^k}\omega_k(\nu)\,d\nu$ decreases. Hence, the sequence $\{\Delta\mu^k\}$ is decreasing with k.

(iii) The well-developed theory of unimodal maps [25] implies that the μ-interval for which there is an attractor for Φ in RS^k is also of size $(\underline{\mu}^k, \overline{\mu}^k)$, to lowest order. Hence, for μ in any interval given approximately by $(\overline{\mu}^k, \underline{\mu}^{k+1})$, the dynamics of Φ must involve at least two different sectors.

Next, we derive a set of conditions under which a given periodic orbit will have to pass through the kth sector of rotation RS^k. For the remainder of this subsection, we will consider only points $\bar{w} \in RS^k$, $k \geq 1$, for which $\bar{w} = \bar{w}_k^c + \nu\Delta\bar{w}^k$, with

$$\nu \in \left(\frac{1}{(-\ln\varepsilon)^p}, 1 - \frac{1}{(-\ln\varepsilon)^p}\right) \tag{3.40}$$

for some fixed integer $p > 1$. Note that the condition in (3.40) is "generic" in that it covers "most of" RS^k; to put it differently, only $\bar{w}$-values that are "very close" to the boundary points $\bar{w}_k^c$ and $\bar{w}_{k-1}^c$ are excluded by (3.40).

We begin by proving a simple preparatory result.

Lemma 3.8. *Consider $\bar{w} = \bar{w}_j^c + \nu\Delta\bar{w}^j \in RS^j$ for some $j \geq 1$, and assume that (3.40) holds. Then, if $\bar{w} \leq \bar{w}_{\min}^j$,*

$$|\Phi(\bar{w}) - \Phi_{\min}| = \mathcal{O}\Big(\frac{\ln(-\ln\varepsilon)}{-\ln\varepsilon}\Big)\Delta\bar{w}^j, \tag{3.41}$$

whereas if $\bar{w} > \bar{w}_{\min}^j$,

$$|\Phi(\bar{w}) - \Phi_{\min}| \lesssim \left(1 + \mathcal{O}\Big(\frac{\ln(-\ln\varepsilon)}{-\ln\varepsilon}\Big)\right)\Delta\bar{w}^j. \tag{3.42}$$

Proof. Let $\nu_{\min}^j$ be the ν-value corresponding to $\bar{w}_{\min}^j$. By the fundamental theorem of calculus, we have

$$\Phi(\bar{w}) - \Phi_{\min} = \Delta\bar{w}^j \int_{\nu_{\min}^j}^{\nu} \Big(1 - \frac{\omega_j(\eta)}{4\ln\varepsilon}\Big)\, d\eta = \Delta\bar{w}^j \left(\nu - \nu_{\min}^j - \frac{1}{4\ln\varepsilon}\int_{\nu_{\min}^j}^{\nu} \omega_j(\eta)\, d\eta\right).$$

Since ν is constrained by condition (3.40), we find

$$\int_{\nu_{\min}^j}^{\nu} \omega_k(\eta)\, d\eta = \mathcal{O}(\ln\nu) + \mathcal{O}(\ln\nu_{\min}^j) = \mathcal{O}\big(\ln(-\ln\varepsilon)\big);$$

see also the proof of Theorem 3.7. Now, if $\nu \leq \nu_{\min}^j$, then $\nu_{\min}^j - \nu = \mathcal{O}((-\ln\varepsilon)^{-1})$, and the estimate in (3.41) follows. If, on the other hand, $\nu > \nu_{\min}^j$, then $\nu - \nu_{\min}^j < 1$, which implies (3.42). ∎

Next, we show that orbits satisfying the generic condition in (3.40) will typically pass through the kth sector of rotation if, additionally, $\Phi_{\min} \in RS^k$ holds.

Theorem 3.9. *Assume that $\Phi_{\min} \in RS^k$ and that, for some q satisfying $0 < q < \frac{1}{2}$,*

$$\bar{w}_{k-1}^c - \Phi_{\min} \lesssim \frac{1}{(-\ln\varepsilon)^q}\Delta\bar{w}^k \quad \text{and} \quad \Phi_{\min} - \bar{w}_k^c \lesssim \frac{1}{(-\ln\varepsilon)^q}\Delta\bar{w}^k. \tag{3.43}$$

Consider a periodic orbit $\{\bar{w}^0, \dots, \bar{w}^j\}$, with $\Phi(\bar{w}^\ell) = \bar{w}^{\ell+1}$ for $\ell = 0, \dots, j-1$, and let $\{\nu^0, \dots, \nu^j\}$ be the corresponding values of ν. Assume that (3.40) holds. Then, the orbit in question must pass through RS^k provided $\varepsilon > 0$ is sufficiently small.

Proof. We will assume that $k \geq 2$ in the following and will omit the remaining cases for the sake of brevity.

First, note that Lemma 3.8 and the assumption in (3.43) imply that, for any $\bar{w} \in \mathcal{C}_\varepsilon^-$, $\Phi(\bar{w}) \in RS^k \cup RS^{k-1} \cup RS^{k-2}$. This follows from the estimates below, which are a straightforward consequence of (3.41), (3.42), and (3.43): we begin by assuming that $\bar{w} \in RS^k$;

then,

$$\begin{aligned}\Phi(\bar{w}) - \bar{w}^{\mathrm{c}}_{k-1} &= \Phi(\bar{w}) - \Phi_{\min} + \Phi_{\min} - \bar{w}^{\mathrm{c}}_{k-1} \\ &\lesssim \Phi_{\min} - \bar{w}^{\mathrm{c}}_{k-1} + \Delta\bar{w}^{k}\Big(1 + \mathcal{O}\Big(\frac{\ln(-\ln\varepsilon)}{-\ln\varepsilon}\Big)\Big) \\ &\lesssim \Delta\bar{w}^{k}\big(1 + \mathcal{O}\big((-\ln\varepsilon)^{-q}\big)\big),\end{aligned}$$

which implies that $\Phi(\bar{w})$ can be no higher than RS^{k-2} in that case.

Similarly, for $\bar{w} \in RS^{k-1} \cup RS^{k-2}$, we have the estimate

$$\begin{aligned}\Phi(\bar{w}) - \bar{w}^{\mathrm{c}}_{k-2} &= \Phi(\bar{w}) - \Phi_{\min} + \Phi_{\min} - \bar{w}^{\mathrm{c}}_{k-2} \\ &\lesssim \Phi_{\min} - \bar{w}^{\mathrm{c}}_{k-2} + \Delta\bar{w}^{k-1}\Big(1 + \mathcal{O}\Big(\frac{\ln(-\ln\varepsilon)}{-\ln\varepsilon}\Big)\Big) \\ &\lesssim \mathcal{O}\big((-\ln\varepsilon)^{-q}\big)\Delta\bar{w}^{k-1};\end{aligned}$$

see (3.41) as well as (3.43). It follows that for $\bar{w} \in RS^{k-1} \cup RS^{k-2}$, $\Phi(\bar{w})$ can be no higher than RS^{k-2}.

Finally, for any point $\bar{w} \in RS^{k-2}$ which is contained in the image of Φ, there holds

$$\bar{w} - \bar{w}^{\mathrm{c}}_{k-2} \lesssim \mathcal{O}\big((-\ln\varepsilon)^{-q}\big)\Delta\bar{w}^{k-1}$$

and, consequently,

$$\Phi(\bar{w}) \lesssim \bar{w}^{\mathrm{c}}_{k-1} + \mathcal{O}\big((-\ln\varepsilon)^{-q}\big)\Delta\bar{w}^{k-2} \tag{3.44}$$

by (3.41). It follows that any recurrent set, including the periodic orbit $\{\bar{w}^0, \dots, \bar{w}^j\}$, is contained in $RS^k \cup RS^{k-1} \cup RS^{k-2}$.

Now, suppose that such a periodic orbit is given, and note that there is an unstable fixed point $\bar{w}^*$ of Φ in RS^{k-1} close to $\bar{w}^{\mathrm{c}}_{k-2}$. Assume that $\bar{w}^0 > \bar{w}^*$. Then, the trajectory of $\bar{w}^0$ under Φ must eventually enter RS^{k-2}; moreover, by (3.44), it must terminate at a point $\bar{w}^j$ with $\bar{w}^j < \bar{w}^*$.

Looking at the forward trajectory of $\bar{w}^j$, we see that it is decreasing until it falls below $\bar{w}^{k-1}_{\min}$. In other words, there exists $\ell \geq 0$ such that $\bar{w}^j, \bar{w}^{j+1}, \dots, \bar{w}^{j+\ell-1}$ are greater than or equal to $\bar{w}^{k-1}_{\min}$ and $\bar{w}^{j+\ell}$ is less than or equal to $\bar{w}^{k-1}_{\min}$. Hence, we conclude that either $\bar{w}^{j+\ell} \in RS^k$ or, by combining (3.41) and (3.43), $\bar{w}^{j+\ell+1} \in RS^k$. ∎

It remains to comment briefly on the assumption put forward in (3.43): given that $\Phi(\bar{w}^k_{\min}) \sim \Phi_{\min}$ (cf. (3.36)) as well as that necessarily $\bar{w}^{\mathrm{c}}_k \lesssim \Phi_{\min} \lesssim \bar{w}^{\mathrm{c}}_{k-1}$ by (3.43), one can show that, to lowest order,

$$(2k-1)\frac{\mu^{\mathrm{c}}}{D_\mu}\sqrt{\varepsilon}\sqrt{-2\ln\varepsilon} \leq \mu^{\mathrm{c}} - \mu \leq (2k+1)\frac{\mu^{\mathrm{c}}}{D_\mu}\sqrt{\varepsilon}\sqrt{-2\ln\varepsilon}$$

must hold for (3.43) to be true, with μ^{c} defined as in (2.56). This condition is consistent with the estimate for $\Delta\mu^k$, e.g., given after the proof of Theorem 3.7, and will typically be satisfied if q is not "too large."

Remark 11. The restriction to $q < \frac{1}{2}$ in (3.43) is made to ensure that $\Phi_{\min} \in RS^k$ will imply $\Phi(\bar{w}^j_{\min}) \in RS^k$ for $0 \le j \le k-1$, since we can a priori conclude only $\Phi_{\min} - \Phi(\bar{w}^j_{\min}) = \mathcal{O}(\varepsilon)$ from (3.36).

One important consequence of Theorem 3.9 is that it allows us to give a precise qualitative description of the segments that the symbolic sequence of a given periodic orbit can contain. For any such orbit, let $k \ge 1$ be the largest integer such that the segment 1^k is contained in the corresponding Farey sequence. With this convention, $k = 1$ implies that the sequence can contain only the segments 1^1 and 1^0; restrictions on the sequences that can occur when $k \ge 2$ are given in the following theorem.

Theorem 3.10. *Assume that $k \ge 2$. Then, a periodic orbit can occur if its sequence consists of segments of the form 1^k (some number of times in succession), 1^{k-1} (some number of times in succession), and 1^{k-2} (preceded by 1^k and followed by 1^{k-1} or 1^k).*

Proof. First, let us assume that (3.43) is satisfied. Then, the result already follows from the proof of Theorem 3.9.

Now, suppose that (3.43) does not hold as well as that $\Phi_{\min} \sim \bar{w}^c_{k-1}$. Then, the steps given in the proof of Theorem 3.9 can be retraced until almost the very end, namely, up to the statement that $\bar{w}^{j+\ell}$ will be less than or equal to $\bar{w}^{k-1}_{\min}$ for some $\ell \ge 0$. Instead, if $\bar{w}^{j+\ell} \in RS^{k-1}$, we can now conclude only that $\bar{w}^{j+\ell+1} \in RS^k \cup RS^{k-1}$. The orbit can then either remain in RS^{k-1} or enter RS^k and subsequently jump back to either RS^{k-1} or RS^{k-2}. If, on the other hand, $\Phi_{\min} \sim \bar{w}^c_k$, the same kind of sequences can occur, with k shifted upward by 1. This completes the proof. ∎

Given the result of Theorem 3.10, a natural question that arises is how many times in succession a given segment can occur.

Proposition 3.11. *Let $k \ge 2$. If a periodic orbit involves all of the segments 1^{k-2}, 1^{k-1}, and 1^k, then both 1^{k-2} and 1^k can occur at most once in succession.*

Proof. First, note that an orbit can contain all of the segments 1^{k-2}, 1^{k-1}, and 1^k only if $\Phi_{\min} \sim \bar{w}^c_{k-1}$; see the proofs of Theorems 3.9 and 3.10. It follows that any point on the orbit that lies in RS^{k-2} must lie close to $\bar{w}^{k-1}_{\min}$ and, hence, that it must be mapped to $RS^{k-1} \cup RS^k$ under Φ. Similarly, any point on the orbit in RS^k must be close to $\bar{w}^c_{k-1}$ and therefore must be mapped to $RS^{k-2} \cup RS^{k-1}$. ∎

Finally, Theorem 3.10 allows us to make a precise statement on the periodic orbits of the type $\{L_j^{k_j}\}$ that can be observed for $L_j \ge 2$.

Corollary 3.12. *For $k \ge 2$, $L \ge 2$, and $L+k \ge 5$, there are no periodic orbits which contain the segment L^k and which pass through the part of RS^k defined by (3.40).*

Proof. Since the segment L^k corresponds to k small loops followed by L large relaxation excursions, this segment can also be written in the form $1^k(1^0)^{L-1}$. If $k = 0$ or $k = 1$, Theorem 3.10 places no restrictions on the existence of such segments. Furthermore, Theorem 3.10 implies that the only remaining admissible k-value is 2 and that $L - 1 = 1$ must hold in that case, implying $L = 2$. ∎

To put it differently, one will not "generically" observe Farey sequences of the form $\{L_j^{k_j}\}$ if $L_j \ge 3$; if $L_j = 2$, only segments of the form 2^1 or 2^2 will occur. The segment L_j^1, however, is admissible for any $L_j \ge 1$; this is due to "leakage" from RS^0 in the sense that $\Phi(\bar{w}) \lesssim \bar{w}$ for $\bar{w} \approx \bar{w}^c_0$, implying that trajectories can "drift" back into RS^1.

Finally, we note that we make no assumptions about the stability of the periodic orbits under consideration, neither in Theorem 3.10 nor in Corollary 3.12; indeed, our results apply to any orbit for which the condition in (3.40) is satisfied.

4. Conclusions and discussion. In the present article, we have studied mixed-mode oscillations (MMOs) in a three-dimensional model system of ordinary differential equations with three distinct time-scales; see (1.5). Here, the "superslow" variable w has been playing the role of a "dynamical parameter" which makes the (v, z)-subsystem of (1.5) move slowly through a canard explosion. One major advantage of our modeling ansatz is the fact that the resulting system dynamics is "almost" two-dimensional in the sense that the integrable structure close to a canard explosion can be exploited to derive the return map Π for the induced flow.

We are aware of two specific examples of three time-scale systems which exhibit mixed-mode dynamics akin to that studied here. One is a compartmental model for the dopaminergic neuron, first derived by Wilson and Callaway [37] and subsequently analyzed in [23] and [24], which in fact served as our motivation for formulating the simplified model system considered in this article. The other example is a model for a chemical reaction, discussed by Moehlis [28]. Although these two systems are not exactly analogous to the one studied here, they do share many of the underlying features and can be analyzed in a similar manner; see also the upcoming article [18].

The three time-scale model studied in this article is one realization of a more general canard mechanism that has been put forward to explain the mixed-mode dynamics often observed in multiscale dynamical systems [36, 2]. This generalized canard mechanism is defined as a combination of dynamical (local) passage through a canard point and a (global) return that resets the system dynamics after the passage has been completed; cf. also section 1. Other mechanisms that do not explicitly involve canards have been proposed to explain MMOs; examples include break-up of an invariant torus [21], loss of stability of a Shilnikov orbit [16], slow passage through Hopf bifurcation [22], and subcritical Hopf-homoclinic bifurcation [12, 13]. While these other mechanisms are consistent with some of the characteristic features of MMOs, they cannot typically explain all of them; see [2]. On the other hand, the generalized canard mechanism is consistent with most examples known to us of systems exhibiting mixed-mode-type behavior [2, 17]. In particular, we note that both the Shilnikov and the delayed Hopf mechanisms can be realized as an aspect of it. These and similar questions are the topic of ongoing research; see, e.g., the forthcoming article [3].

An explanation of mixed-mode dynamics based on the Shilnikov mechanism has been suggested by a number of authors (cf. [16] and the references therein) and is based on the similarities between the respective bifurcation sequences as well as on the presence of Shilnikov-type equilibria in systems that exhibit mixed-mode-type behavior. Roughly speaking, the Shilnikov phenomenon is the unfolding of a homoclinic orbit to an equilibrium of saddle type with a one-dimensional stable manifold and a two-dimensional unstable manifold of spiral focus type. Since Shilnikov-type equilibria are present in canard-based systems that involve a so-called *folded saddle-node (of type* II*)*, we propose that the latter systems do realize a "suitably modified" Shilnikov mechanism; cf. [3]. Similarly, a case of slow passage through Hopf bifurcation is seen in the dynamics near a folded saddle-node (of type II) and plays an important role there. This observation was made already in [26] and will also be fully

elucidated in [3].

Finally, it is important to note that the equations in (1.2) are neither of Shilnikov type nor of slow-passage-through-Hopf-bifurcation type, though they clearly realize the generalized canard mechanism. Moreover, due to our assumption that $\mu + \phi = \mathcal{O}(1)$ in (1.2), the mixed-mode dynamics analyzed in this article is neither of folded-node type nor of folded saddle-node type; cf. section 1. More precisely, in a folded-node system, i.e., for $\mu+\phi = \mathcal{O}(1)$ and negative in (1.2), the dynamics in the fold region would be strongly contractive and not oscillatory. Furthermore, this dynamics would be transient, since μ would cause w to increase until the relaxation regime in (1.1) is reached. The MMO patterns observed in this case would be regular and robust; irregular time series with two or more successive relaxation cycles would rarely occur upon variation of μ only. In a folded saddle-node system with μ small but ϕ large, on the other hand, one would typically observe slow passage through a Hopf bifurcation; moreover, the resulting mixed-mode dynamics would again be fairly regular in the sense that trajectories would generically consist of one relaxation excursion followed by a large number of "loops"; the amplitudes of these loops would be relatively small. This distinction is clearly reflected in the dynamics of (1.5), as predicted analytically in section 3 and verified numerically below.

Some of our findings on the mixed-mode dynamics of (1.5) are summarized and discussed in detail in the subsequent paragraphs.

A principal result of our analysis is the accurate reduction of the global return map Π (which is defined as a two-dimensional map on the Poincaré section $\overline{\Delta}_-$) to a one-dimensional map Φ which can be studied in a standard, straightforward way.

The first step of this reduction entails the restriction of Π from $\overline{\Delta}_-$ to the union of a set of (one-dimensional) intersecting curves. (These curves, which we have denoted by $\mathcal{C}_\varepsilon^j$, are defined recursively, with $\mathcal{C}_\varepsilon^0 \equiv \mathcal{C}_\varepsilon^-$ the flow image of the attracting slow manifold $\mathcal{S}_\varepsilon^{a-}$ in $\overline{\Delta}$ and $\mathcal{C}_\varepsilon^j = \Pi(\mathcal{C}_\varepsilon^{j-1})$, $j \geq 1$.) Most importantly, by Proposition 3.1, this reduction incurs an only exponentially small error; i.e., the sequence $\{\mathcal{C}_\varepsilon^j\}$ very accurately approximates the attractor of Π.

Then, in a second step, another reduction is performed, which yields a one-dimensional map Φ that is defined on the curve $\mathcal{C}_\varepsilon^-$. This map again gives an exponentially accurate approximation, this time for the $(k+1)$th iterate of Π on the kth sector of rotation, RS^k. (In other words, Φ restricted to RS^k describes the recurrent dynamics on RS^k with an exponentially small error.) Even though the map Φ is multimodal and possibly discontinuous at the boundaries of RS^k, it is one-dimensional and thus can be analyzed using techniques from one-dimensional discrete dynamics. It is interesting to note that, conceptually, the reduction to Φ is valid for any finite k, since the return of trajectories under Π will always eventually be to $\mathcal{C}_\varepsilon^-$. However, given the nonuniformity of our results in k (Proposition 3.4), one might have to consider higher-order terms (in ε) or, alternatively, take ε "very small" to describe the asymptotics accurately for "very large" k.

Some authors [23, 27] postulate a reduction to the dynamics of an *interval* map that would capture the properties of MMOs in systems of the type of (1.2). The fact that all MMO trajectories must pass extremely close to $\mathcal{S}_\varepsilon^{a-}$ is a strong indication that the system dynamics of (1.2) is almost two-dimensional in nature. Similarly, one might expect that the corresponding return map Π is almost one-dimensional. However, our results imply that a straightforward reduction of Π to a one-dimensional map defined on a single interval is not possible, whereas

the one-dimensional map Φ, which is defined on a *set of intervals* corresponding to the sectors of rotation, approximates Π with an only exponentially small error. By contrast, in [23], the return is approximated by a piecewise linear map, with a jump discontinuity corresponding to the strong canard, that admits a large variety of potential Farey sequences. Our analysis, on the other hand, resolves precisely the rich bifurcation structure of Φ close to the strong canard of (1.2), allowing us to characterize exactly which Farey sequences will actually be observed in (1.2), as well as to give accurate estimates of the relevant parameter intervals. (It is important to note, though, that the analysis in [23] does not focus primarily on resolving the canard structure in detail; rather, it is concerned with the system dynamics close to Hopf bifurcation which we do not analyze in detail here.)

The properties of Φ on RS^k directly determine those of the corresponding MMO trajectories of type 1^k, i.e., of periodic orbits for (1.5) which pass through the kth sector of rotation. Hence, a large part of our analysis is devoted to establishing the qualitative and quantitative asymptotics of the reduced return map Φ. More specifically, our results on the bifurcation structure of Φ as well as on the Farey sequences $L_0^{k_0} L_1^{k_1} \dots$ of the corresponding MMO trajectories include a proof of the existence and stability of 1^k-type orbits (Theorem 3.7), a precise description of the ordering of the Farey sequences that will "generically" occur for $L_j \equiv 1$ (Theorem 3.10 and Proposition 3.11), as well as a statement on the "improbability" of observing orbits with symbolic sequence $\{L_j^{k_j}\}$ when $L_j \geq 3$ (Corollary 3.12). It is important to note that these restrictions on the dynamics of Φ are by no means exhaustive; rather, they provide a sample of the types of results that can be proved using the techniques of section 3. A more comprehensive analysis, however, is beyond the scope of this work.

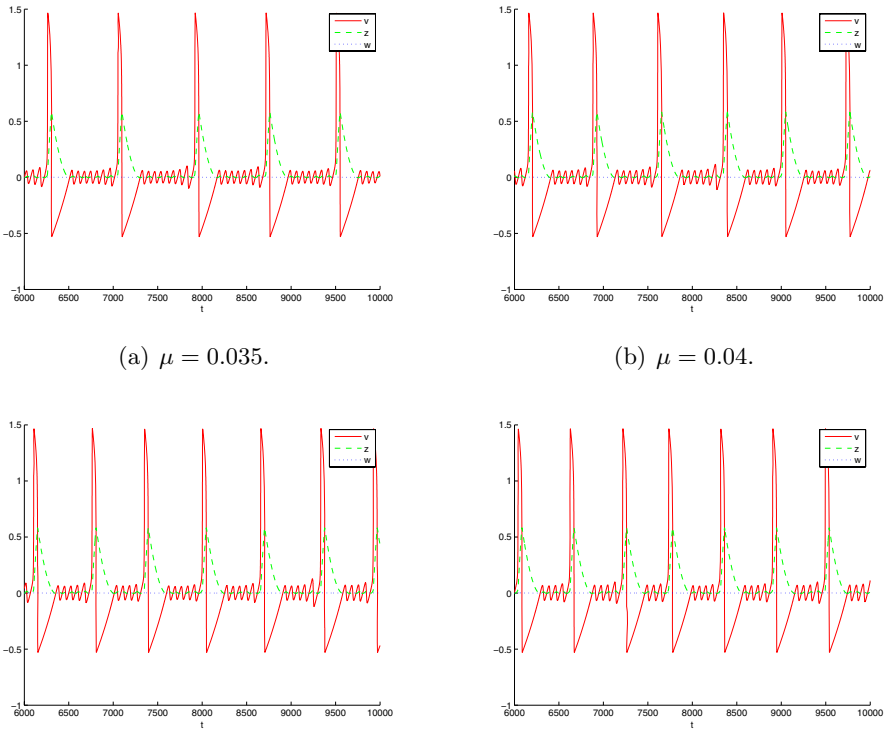
Another important aspect of the generalized canard mechanism is the asymptotic structure of secondary canards, as well as of the corresponding sectors of rotation. To date, rigorous results in this direction have only been obtained by Wechselberger [36] for systems of general folded-node type, via a bifurcation analysis of resonances. To the best of our knowledge, no comparable analysis has been available so far for other realizations of the generalized canard mechanism. The three time-scale structure of our problem in combination with the resulting near-integrability, however, allows us to obtain rather specific results; in particular, it enables us to derive a more or less explicit asymptotic estimate for the sector size: given the definition of the critical canard value $\bar{w}_0^{\mathrm{c}}$, as well as of the $\bar{w}$-value $\bar{w}_k^{\mathrm{c}}$ corresponding to the kth secondary canard Γ_ε^k, it follows with $w = \sqrt{\varepsilon}\bar{w}$ that $w^{\mathrm{c}} = \mathcal{O}(\varepsilon)$ after "blow-down," as well as that

$$\Delta w^k := \sqrt{\varepsilon}\Delta\bar{w}^k \sim 2\mu\varepsilon^{\frac{3}{2}}\sqrt{-2\ln\varepsilon}$$

is the width of $RS^k \subset \mathcal{C}_\varepsilon^-$, independent of k to leading order. This estimate confirms the well-known fact [33, 36] that the canard phenomenon is fairly "robust" in three dimensions in the sense that the relevant parameter intervals are relatively large, whereas in two dimensions, they are only exponentially small [20]: in our case, the width of the relevant w-interval will roughly be $\mathcal{O}(\varepsilon)$.

Finally, given the above discussion, our partly rigorous and partly heuristic conclusions on the bifurcation (Farey) structure of the mixed-mode dynamics which will typically be observed in (1.5) can be summed up as follows:

(i) Symbolic sequences of the form $\{1^k\}$ and $\{1^k 1^{k-1}\}$ dominate the stable dynamics; such



(a) $\mu = 0.035$. (b) $\mu = 0.04$.

(c) $\mu = 0.045$. (d) $\mu = 0.05$.

Figure 17. *The time series of v, z, and w in (1.5) for $f_2 = 1.5$, $f_3 = -1$, $g_1 = 0.5$, and $\varepsilon = 0.01$. As μ increases from* (a) 0.035 *via* (b) 0.04 *and* (c) 0.045 *to* (d) 0.05*, one observes a transition from $1^7 1^6$ via $1^6 1^5$ and $1^5 1^4$ to $1^4 1^3$ in the resulting Farey sequences.*

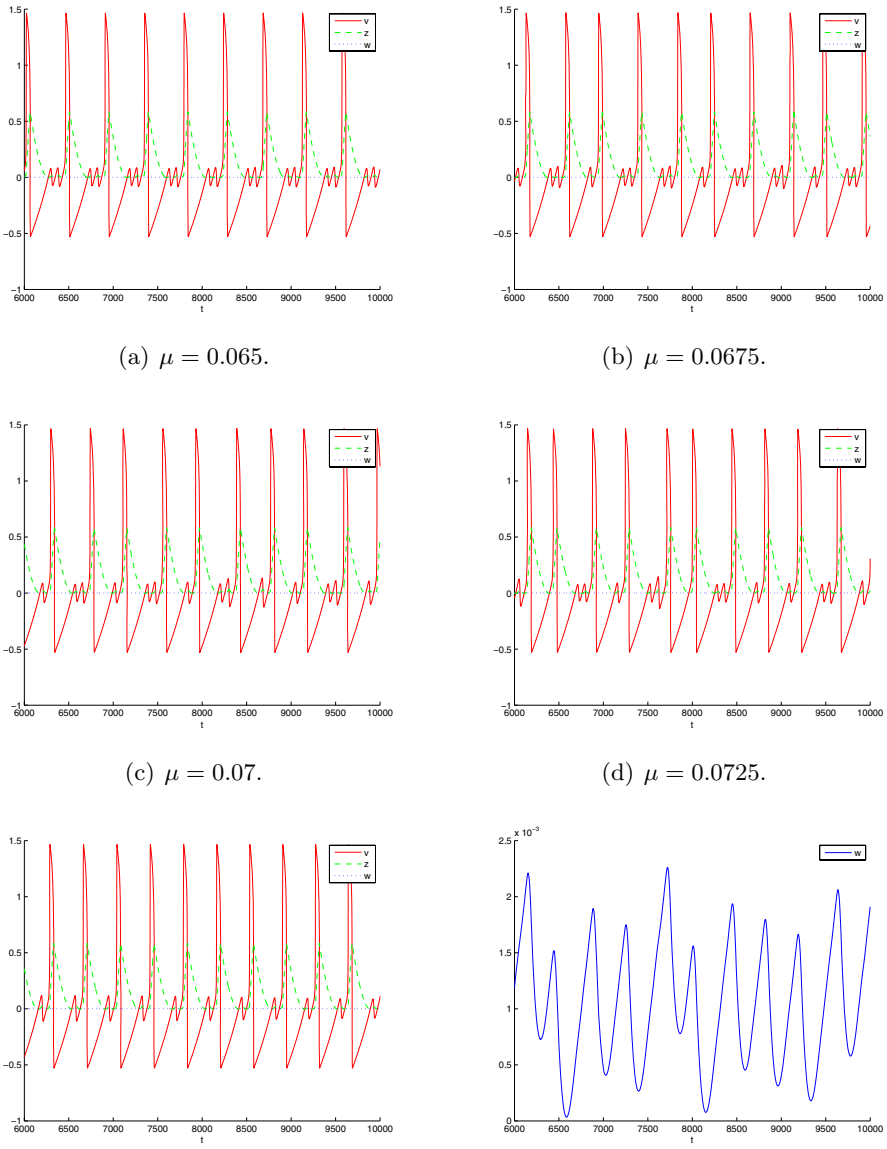
sequences correspond to MMO trajectories that visit only one sector of rotation and two adjacent sectors, respectively; see Figure 17.

(ii) Stable 1^k-type orbits are observed in a relatively small parameter range. Consequently, non-1^k orbits (i.e., orbits that are not periodic with Farey sequence $\{1^k\}$) dominate a significant portion of the parameter space. Moreover, they occur more frequently with increasing k, since the 1^k-stability intervals decrease in size as k increases; cf. Figures 17 and 18.

(iii) For $L_j \geq 2$, segments of the form $L_j^{k_j}$ are not generically observed when $k_j \geq 2$, except for the segment 2^2. The segment L_j^1, on the other hand, is possible for any $L_j \geq 1$; see Figure 19.

(iv) As μ increases, the Farey sequences observed in the transition are roughly of the form $\ldots \to 1^k \to 1^k 1^{k-1} \to 1^{k-1} \to \ldots$; in particular, all sectors of rotation are "swept through" until $\mu > \mu^c$, when the dynamics finally enters the relaxation regime (cf. Figures 18 and 20).

(v) The local dynamics depends quite sensitively on the curvature of $f(v)$, i.e., on the coefficient f_2; in particular, 1^k-type orbits become increasingly harder to observe with



(a) $\mu = 0.065$.

(b) $\mu = 0.0675$.

(c) $\mu = 0.07$.

(d) $\mu = 0.0725$.

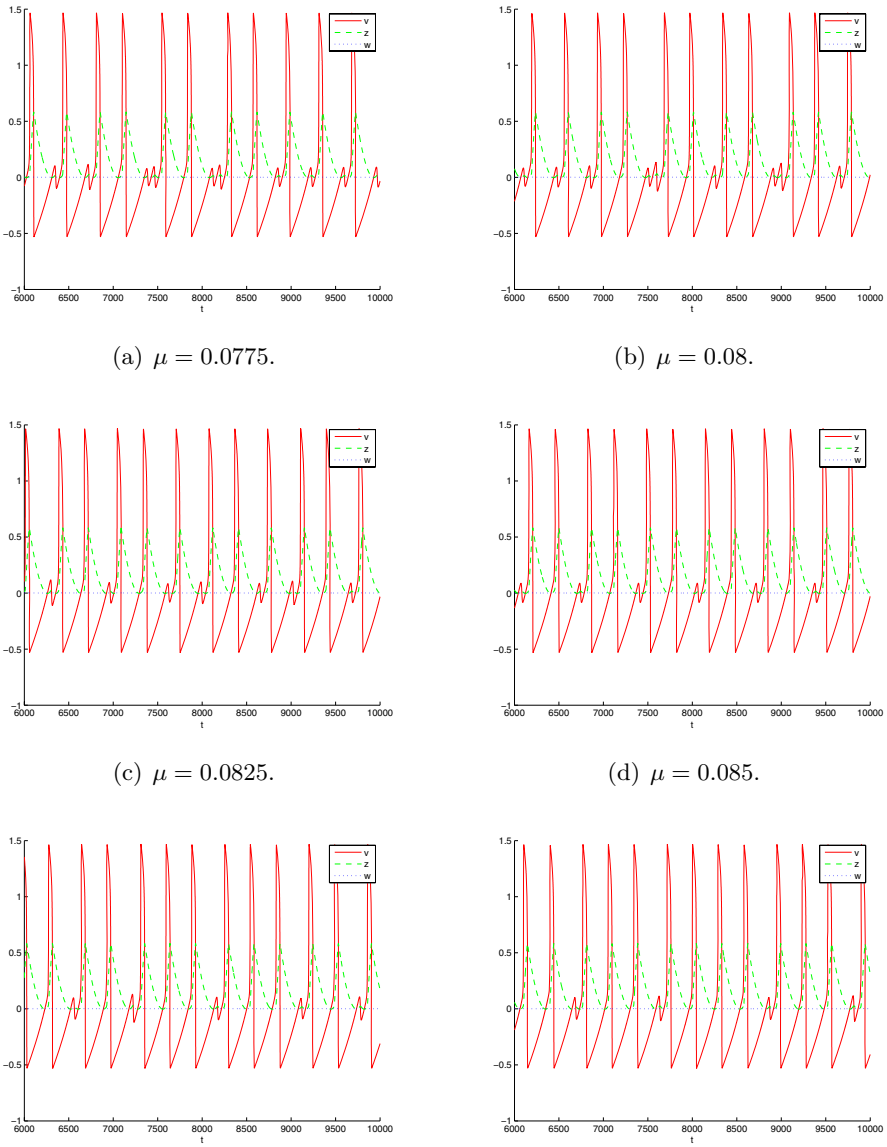
(e) $\mu = 0.075$.

(f) $\mu = 0.0725$.

Figure 18. *The time series of v, z, and w in (1.5) for $f_2 = 1.5$, $f_3 = -1$, $g_1 = 0.5$, and $\varepsilon = 0.01$. As μ increases from* (a) 0.065 *via* (b) 0.0675, (c) 0.07, *and* (d) 0.0725 *to* (e) 0.075, *one observes a transition from 1^2 to 1^1 in the resulting Farey sequences, with transitory sequences which contain mixed segments of the form $1^2 1^1$ as well as $2^2 1^2 1^1$. Panel* (f) *shows a zoom on the time series of w for $\mu = 0.0725$; clearly, $w = \mathcal{O}(\varepsilon)$, in accordance with Assumption 1 (cf. also section 3.3).*

growing f_2; see Figure 21(a).

(vi) The number of sectors visited is also influenced by the strength of the global dynamics, i.e., by how far "back" w is reset after relaxation: the smaller the parameter g_1 is, the



(a) $\mu = 0.0775$. (b) $\mu = 0.08$.

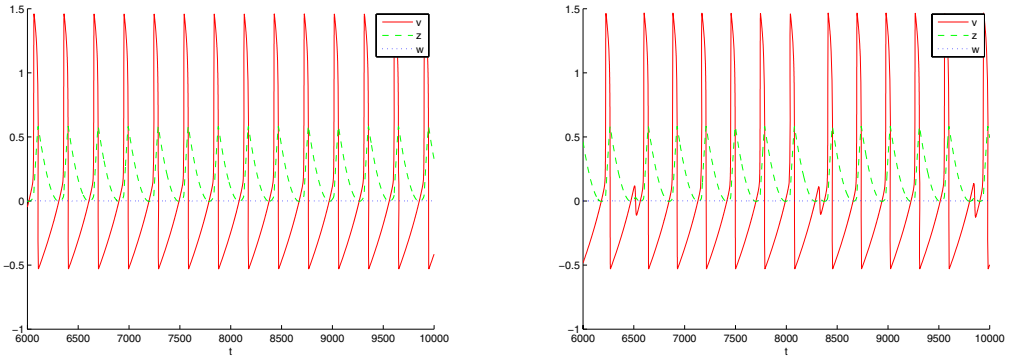
(c) $\mu = 0.0825$. (d) $\mu = 0.085$.

(e) $\mu = 0.0875$. (f) $\mu = 0.09$.

Figure 19. *The time series of v, z, and w in (1.5) for $f_2 = 1.5$, $f_3 = -1$, $g_1 = 0.5$, and $\varepsilon = 0.01$. As μ increases from* (a) 0.0775 *via* (b) 0.08 *to* (c) 0.0825, *one observes a variety of complex Farey sequences, with segments containing 1^1, 2^2, and 2^1 as well as repetitions thereof. As μ is increased further to* 0.09, *one observes a transition from* (c) $1^1 2^1$ *via* (d) 2^1 *and* (e) $2^1 3^1$ *to* (f) $3^1 4^1$, *as predicted analytically in section 3.5.*

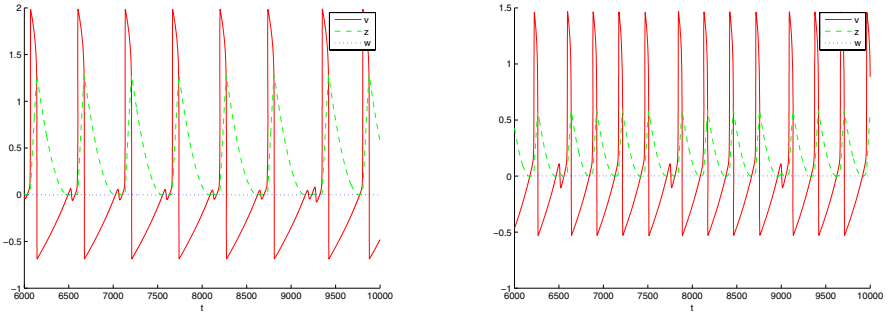
closer to the strong canard trajectories will return after relaxation, and the smaller the relevant μ-interval will be; cf. Figure 21(b).

(vii) Since $w = \mathcal{O}(\varepsilon)$ throughout (see Figure 18(f)), the global return point will be $\mathcal{O}(\varepsilon)$-close (in w) to the strong canard. This implies that only the "lower" sectors will



(a) $\mu = 0.095$. (b) $\mu = 0.0925$.

Figure 20. *The time series of v, z, and w for $\mu = 0.095$ and $\mu = 0.0925$. Clearly, the system is in the pure relaxation regime in* (a)*, whereas in* (b)*, one observes already mixed-mode dynamics, in agreement with the theoretical prediction that the critical μ-value should be $\mu^c \approx 0.0938$, up to an $\mathcal{O}(\varepsilon)$-error.*



(a) $\mu = 0.019$, $f_2 = 2$, $g_1 = 0.5$. (b) $\mu = 0.045$, $f_2 = 1.5$, $g_1 = 0.25$.

Figure 21. *The effects of a change of* (a) f_2 *and* (b) g_1 *on the dynamics of* (1.5)*. As f_2 is increased from* 1.5 *to* 2*, the stability interval of 1^1-type orbits decreases, since $D_\mu = 2.25$ is replaced by $D_\mu = 4$ and since $\Delta\mu^1 \propto D_\mu^{-1}$; see Theorem* 3.7*. As g_1 is decreased from* 0.5 *to* 0.25*, the dynamics recurs to lower sectors of rotation; cf. Figure* 17(c)*.*

typically be involved in the dynamics, resulting in MMO trajectories with a submaximum number of small oscillations.

(viii) As k increases or, alternatively, as μ decreases, the sectors of rotation decrease in size. Overall, however, the dynamics seems to become less expanding with higher k, making it less likely for sequences containing segments of the form $1^k1^{k-\ell}$, $\ell > 1$, to occur.

With the exception of the conjecture in (viii), these observations are reflected by our numerical findings; see Figures 17 to 21 as referred to in the individual items. Figure 17 shows a sample of regular 1^k1^{k-1}-type orbits for $k = 4, \ldots, 7$, while Figure 18 illustrates the transition from 1^2 to 1^1 via mixed transitory segments of the form $2^21^21^1$; Figure 19 indicates how Farey sequences with mixed segments containing 1^1, 2^2, and 2^1, as well as L_j^1-type sequences with

$L_j \geq 1$, can arise; Figure 20 illustrates the transition from mixed-mode dynamics to the pure relaxation regime at $\mu = \mu^c$ in (1.5); finally, in Figure 21, (a) and (b) exemplify the effects of a change in f_2 and g_1, respectively, on the dynamics of (1.5). In each case, the relevant parameter regimes are specified in detail in the corresponding captions. All numerical simulations were performed in MATLAB using the predefined routine `ode23tb` with absolute and relative accuracies 10^{-10} and 10^{-8}, respectively. For clarity, the results are illustrated starting at $t = 6000$, after initial transients have subsided.

Appendix A. Some asymptotic results. In this appendix, we summarize a few results on the asymptotics of the rescaled system (2.3), as well as of its generalization in (2.8). Recall that the equations in (2.3) are given by

$$\bar{v}' = -\bar{z} + f_2\bar{v}^2 + \sqrt{\varepsilon} f_3 \bar{v}^3, \tag{A.1a}$$

$$\bar{z}' = \bar{v} - \bar{w}, \tag{A.1b}$$

$$\bar{w}' = \varepsilon(\mu - g_1\varepsilon\bar{z}) \tag{A.1c}$$

as well as that they reduce, for $\varepsilon = 0$, to

$$\bar{v}' = -\bar{z} + f_2\bar{v}^2, \tag{A.2a}$$

$$\bar{z}' = \bar{v} - \bar{w}, \tag{A.2b}$$

$$\bar{w}' = 0; \tag{A.2c}$$

cf. (2.4). For $\bar{w} = 0$, the system in (A.2) is integrable. Moreover, given the constant of motion

$$H(\bar{v}, \bar{z}) = \frac{1}{2}\mathrm{e}^{-2f_2\bar{z}}\Big(-\bar{v}^2 + \frac{\bar{z}}{f_2} + \frac{1}{2f_2^2}\Big) \tag{A.3}$$

as defined in (2.5), the orbits of (A.2) correspond in a unique fashion to the level curves of H with $H = h$ constant; cf. section 2. More precisely, to any $h < h_0 = (4f_2^2)^{-1}$, we can assign a unique $\bar{z}$-value $\bar{z}^h$ in $\overline{\Delta}_-$. For any such point $(0, \bar{z}^h, \bar{w}) \in \overline{\Delta}_-$, we denote the corresponding solution to (A.1) by $\bar{\gamma}_\varepsilon^h$. Here, we assume the parametrization to be such that $\bar{\gamma}_\varepsilon^h(-T^h(\bar{w})) = (0, \bar{z}^h, \bar{w})$ holds and that $\bar{\gamma}_\varepsilon^h(T^h(\bar{w}))$ is the point of first return to $\overline{\Delta}_-$; recall Figure 6.

In the particular case when $\bar{w} = 0$, we write $T^h = T^h(0)$. Let $h > 0$ be fixed, and let $\bar{\gamma}_0^h$ denote the corresponding (periodic) solution of (A.2). For convenience, we denote the $\bar{z}$-coordinates of the two points of intersection of $\bar{\gamma}_0^h$ with $\overline{\Delta}$ by ξ^h and ζ^h, respectively; see Figure 22.

Lemma A.1. *There holds* $\zeta^h = \frac{1}{2f_2}(-\ln h) + \mathcal{O}(1)$ *and* $\xi^h = -\frac{1}{2f_2} + \mathcal{O}(h)$.

Proof. The assertion follows from (A.3): note that $\bar{v} = 0$ in $\overline{\Delta}_-$, and expand $\frac{\bar{z}}{f_2} + \frac{1}{2f_2^2} = h\frac{1}{2}\mathrm{e}^{2f_2\bar{z}}$ for $\bar{z}$ large, respectively, for $\bar{z}$ (asymptotically) constant, to obtain the expansions for ζ^h and ξ^h, respectively. ∎

Given Lemma A.1, we have the following result on the asymptotics of T^h.

Lemma A.2. *There holds* $T^h = \sqrt{2}(-\ln h)^{\frac{1}{2}} + \mathcal{O}(1)$.

Proof. Given (A.3), we first express $\bar{v}$ via

$$\bar{v} = \sqrt{\frac{\bar{z}}{f_2} + \frac{1}{2f_2^2} - 2h\mathrm{e}^{2f_2\bar{z}}} = \sqrt{\frac{\bar{z}}{f_2}}\sqrt{1 + \frac{1}{2f_2\bar{z}} - 2f_2 h\frac{\mathrm{e}^{2f_2\bar{z}}}{\bar{z}}} \tag{A.4}$$

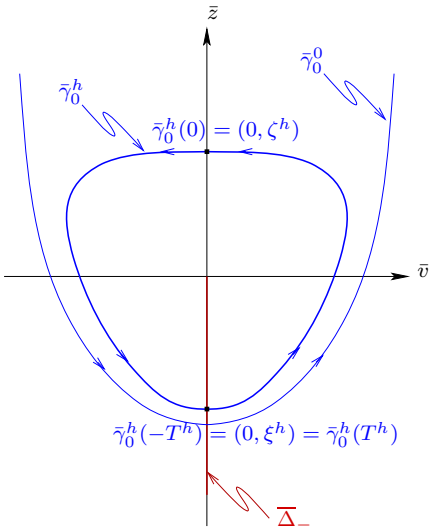


Figure 22. *A typical solution of* (A.2).

and then make use of $\bar{v} = \bar{z}' = \frac{d\bar{z}}{dt}$ for $\bar{w} = 0$ (see (A.4)) to obtain

$$\int_{\xi^h}^{\zeta^h} \frac{d\bar{z}}{\sqrt{\frac{\bar{z}}{f_2}}\sqrt{1 + \frac{1}{2f_2\bar{z}} - 2f_2 h \frac{\mathrm{e}^{2f_2\bar{z}}}{\bar{z}}}} = \int_{-T^h}^{0} dt.$$

Integrating the left-hand side by parts, we find that

$$\text{(A.5)}\quad T^h = 2\sqrt{f_2\bar{z}}\Big(1 + \frac{1}{2f_2\bar{z}} - 2f_2 h\frac{\mathrm{e}^{2f_2\bar{z}}}{\bar{z}}\Big)^{-\frac{1}{2}}\Big|_{\xi^h}^{\zeta^h} + \int_{\xi^h}^{\zeta^h} \sqrt{f_2\bar{z}}\Big(1 + \frac{1}{2f_2\bar{z}} - 2f_2 h\frac{\mathrm{e}^{2f_2\bar{z}}}{\bar{z}}\Big)^{-\frac{3}{2}}\Big(-\frac{1}{2f_2\bar{z}^2} - 2f_2 h\frac{\mathrm{e}^{2f_2\bar{z}}}{\bar{z}^2}(2f_2\bar{z} - 1)\Big)\, d\bar{z}.$$

From Lemma A.1, it follows that the leading-order contribution in the first term on the right-hand side of (A.5) comes from the evaluation at the upper limit ζ^h. Moreover, by expanding the integrand in the second term, one can check that the corresponding integral will contribute only terms of $\mathcal{O}(1)$. Hence, again by Lemma A.1, $T^h \sim 2\sqrt{f_2\zeta^h} \sim \sqrt{2}(-\ln h)^{\frac{1}{2}}$. This concludes the proof. ■

Recall the definitions of $d^h_{\sqrt{\varepsilon}}$ and $d^h_{\bar{w}}$ in (2.10) and (2.11), respectively:

$$\text{(A.6a)}\qquad d^h_{\sqrt{\varepsilon}} = \int_{-T^h}^{T^h} \nabla H(\bar{\gamma}_0^h(t)) \cdot \big(f_3\bar{v}_0^h(t)^3, 0\big)^T\, dt,$$

$$\text{(A.6b)}\qquad d^h_{\bar{w}} = \int_{-T^h}^{T^h} \nabla H(\bar{\gamma}_0^h(t)) \cdot (0, -1)^T\, dt.$$

For a numerical evaluation of the transition map $\overline{\Pi} : \overline{\Delta}_- \to \overline{\Delta}_-$ (as defined in section 2.2), it is convenient to express $d^h_{\sqrt{\varepsilon}}$ and $d^h_{\bar{w}}$ as follows.

Lemma A.3. *Let the integrals $\mathcal{I}_1$ and $\mathcal{I}_2$ be defined by*

$$\mathcal{I}_1(h) := 2\int_{\xi^h}^{\zeta^h} \mathrm{e}^{-2f_2\bar{z}}\bar{v}_0^h(\bar{z})\,d\bar{z} \quad \textit{and} \quad \mathcal{I}_2(h) := 2\int_{\xi^h}^{\zeta^h} \mathrm{e}^{-2f_2\bar{z}}\bar{v}_0^h(\bar{z})^3\,d\bar{z},$$

respectively, with ξ^h and ζ^h as above. Then, there holds

$$d_{\bar{w}}^h = -2f_2\mathcal{I}_1(h) \quad \textit{and} \quad d_{\sqrt{\varepsilon}}^h = -f_3\mathcal{I}_2(h). \tag{A.7}$$

Proof. We will verify the assertion for $d_{\sqrt{\varepsilon}}^h$ first: since

$$\frac{\partial H}{\partial \bar{v}} = -\bar{v}\mathrm{e}^{-2f_2\bar{z}} \quad \text{and} \quad \frac{\partial H}{\partial \bar{z}} = (f_2\bar{v}^2 - \bar{z})\mathrm{e}^{-2f_2\bar{z}},$$

it follows that $\nabla H \cdot (f_3\bar{v}^3, 0)^T = -f_3\bar{v}^4\mathrm{e}^{-2f_2\bar{z}}$. To replace the t-integration in (A.6a) by an integration with respect to $\bar{z}$, we make use of the fact that $\frac{d\bar{z}}{dt} = \bar{z}' = \bar{v}$ for $\bar{w} = 0$. Then,

$$d_{\sqrt{\varepsilon}}^h = -2f_3\int_{\xi^h}^{\zeta^h} \mathrm{e}^{-2f_2\bar{z}}\bar{v}_0^h(\bar{z})^3\,d\bar{z},$$

since $(\bar{v}_0^h, \bar{z}_0^h)(-t) = (-\bar{v}_0^h, \bar{z}_0^h)(t)$ on $\bar{\gamma}_0^h$. To evaluate $d_{\bar{w}}^h$, note that the corresponding integrand in (A.6b) is given by $-f_2\bar{v}^2 + \bar{z}$. Also, it follows from (A.4) that $\bar{v}$ and $\bar{z}$ are related via $\bar{z} = -\bar{v}' + f_2\bar{v}^2$. The result then follows from an integration by parts, since $\bar{v}_0^h(\xi^h) = 0 = \bar{v}_0^h(\zeta^h)$ by definition. ∎

In general, for $h \neq 0$, the integrals $\mathcal{I}_1$ and $\mathcal{I}_2$ cannot be computed analytically but have to be approximated numerically. However, for $h = 0$, one can evaluate $\mathcal{I}_1$ and $\mathcal{I}_2$ exactly by integrating by parts repeatedly. Recalling the definition of $\bar{\gamma}_0^0$ in (2.6), one finds, for instance,

$$\mathcal{I}_1(0) = \frac{\mathrm{e}}{4f_2^2}\int_{-\infty}^{\infty} t^2\mathrm{e}^{-\frac{t^2}{2}}\,dt = \frac{\mathrm{e}}{4f_2^2}\left(-t\mathrm{e}^{-\frac{t^2}{2}}\Big|_{-\infty}^{\infty} + \int_{-\infty}^{\infty} t^2\mathrm{e}^{-\frac{t^2}{2}}\,dt\right) = \frac{\mathrm{e}\sqrt{2\pi}}{4f_2^2}.$$

Similarly, one can show $\mathcal{I}_2(0) = \frac{3\mathrm{e}\sqrt{2\pi}}{16f_2^4}$; see also [19, 20]. In particular, this implies

$$d_{\bar{w}}^0 = -\frac{1}{2f_2}\sqrt{2\pi}\mathrm{e} < 0 \quad \text{and} \quad d_{\sqrt{\varepsilon}}^0 = -\frac{3f_3}{16f_2^4}\sqrt{2\pi}\mathrm{e} > 0.$$

We require the following result on the asymptotics of $\mathcal{I}_2(h)$ for h small.

Lemma A.4. *There holds $\mathcal{I}_2(h) = \mathcal{I}_2(0) - \frac{\sqrt{2}}{f_2^2}h(-\ln h)^{\frac{3}{2}} + \mathcal{O}(h(-\ln h)^{\frac{1}{2}})$.*

Proof. We will prove the assertion by first determining the leading-order behavior of $\frac{d\mathcal{I}_2}{dh}$: given $\bar{v}^2 = \frac{\bar{z}}{f_2} + \frac{1}{2f_2^2} - h\mathrm{e}^{2f_2\bar{z}}$, we obtain by implicit differentiation that $\frac{\partial\bar{v}}{\partial h} = -\bar{v}^{-1}\mathrm{e}^{2f_2\bar{z}}$ and, hence, that

$$\frac{d\mathcal{I}_2(h)}{dh} \sim -6\int_{\xi^h}^{\zeta^h} \bar{v}_0^h(\bar{z})\,d\bar{z}.$$

As in the proof of Lemma A.1, we now make use of (A.4) and then perform an integration by parts to find

$$\frac{d\mathcal{I}_2(h)}{dh} = -\frac{4}{\sqrt{f_2}}(\zeta^h)^{\frac{3}{2}} + \mathcal{O}\big((\zeta^h)^{\frac{1}{2}}\big) = -\frac{\sqrt{2}}{f_2^2}(-\ln h)^{\frac{3}{2}} + \mathcal{O}\big((-\ln h)^{\frac{1}{2}}\big). \tag{A.8}$$

The assertion follows by integrating (A.8) with respect to h, to leading order. ∎

Given Lemma A.4, one can write

$$d^h_{\sqrt{\varepsilon}} = d^0_{\sqrt{\varepsilon}} + \mathcal{R}(h) = d^0_{\sqrt{\varepsilon}} + h\widetilde{\mathcal{R}}(h), \tag{A.9}$$

where $\mathcal{R}(h)$ denotes the corresponding remainder term and $\widetilde{\mathcal{R}}(h) = -f_3\frac{d\mathcal{I}_2}{dh}$ is the first-order coefficient in the Taylor expansion of $d^h_{\sqrt{\varepsilon}}$ about $h = 0$. Note that the leading-order asymptotics of $d^h_{\bar{w}}$ can be obtained in a similar manner.

Finally, recall the generalized system of equations from (2.8), as well as the definition of the corresponding return map in (3.16),

$$\overline{\Pi}(h,\bar{w}) = \begin{pmatrix} P_h\overline{\Pi}_0(h,\bar{w}) + \varepsilon\mu\mathcal{K}(h) + \mathcal{O}(\varepsilon^2) \\ \bar{w} + 2\varepsilon\mu T^h + \mathcal{O}(\varepsilon^2) \end{pmatrix},$$

where $\overline{\Pi}_0$ denotes the return map for (3.14) and $\mathcal{K}$ is defined via

$$\mathcal{K}(h) = \int_{-T^h}^{T^h} \nabla H(\bar{\gamma}_0^h(t)) \cdot (G(0,0),-1)^T(t+T^h)\,dt.$$

An estimate for $\mathcal{K}$ is derived as follows.

Lemma A.5. *There holds*

$$\mathcal{K}(h) = 2d^0_{\bar{w}}T^h + \mathcal{O}(1). \tag{A.10}$$

Proof. Recall that, by definition, we have

$$\int_{-T^h}^{T^h} \nabla H(\bar{\gamma}_0^h(t)) \cdot (G(0,0),-1)^T\,dt = \int_{-T^h}^{T^h} \nabla H(\bar{\gamma}_0^h(t)) \cdot (0,-1)^T\,dt = d^h_{\bar{w}};$$

see (A.6b) and the proof of Proposition 2.2. It follows that

$$\mathcal{K}(h) = d^h_{\bar{w}}T^h + \int_{-T^h}^{T^h} \nabla H(\bar{\gamma}_0^h(t)) \cdot (G(0,0),-1)^T t\,dt.$$

To estimate the above integral, note that

$$\begin{aligned}\int_{-T^h}^{T^h} \nabla H(\bar{\gamma}_0^h(t)) \cdot (G(0,0),-1)^T t\,dt &= -G(0,0)\int_{-T^h}^{T^h} \bar{v}_0^h(t)\mathrm{e}^{-2f_2\bar{z}_0^h(t)}t\,dt \\ &\quad - \int_{-T^h}^{T^h} \big(f_2\bar{v}_0^h(t)^2 - \bar{z}_0^h(t)\big)\mathrm{e}^{-2f_2\bar{z}_0^h(t)}t\,dt.\end{aligned} \tag{A.11}$$

Since the integrand in the second integral on the right-hand side of (A.11) is odd in t, that integral vanishes. Hence, it remains to estimate the first integral: using integration by parts, we obtain

$$\int_{-T^h}^{T^h} \bar{v}_0^h(t)\mathrm{e}^{-2f_2\bar{z}_0^h(t)}t\,dt = T^h\int_{-T^h}^{T^h} \bar{v}_0^h(t)\mathrm{e}^{-2f_2\bar{z}_0^h(t)}\,dt - \int_{-T^h}^{T^h}\int_{-T^h}^{t} \bar{v}_0^h(s)\mathrm{e}^{-2f_2\bar{z}_0^h(s)}\,ds\,dt. \tag{A.12}$$

The first integral on the right-hand side of (A.12) is again zero, since the corresponding integrand is odd in t. Next, we recall that $(\bar{v}_0^h, \bar{z}_0^h)(t)$ is a solution of (A.2) for $\bar{w} = 0$ and, hence, that

$$\bar{v}_0^h(s)\mathrm{e}^{-2f_2\bar{z}_0^h(s)} = -\frac{1}{2f_2}\frac{d}{ds}\big(\mathrm{e}^{-2f_2\bar{z}_0^h(s)}\big).$$

Consequently,

$$\int_{-T^h}^{t} \bar{v}_0^h(s)\mathrm{e}^{-2f_2\bar{z}_0^h(s)}\,ds = -\frac{1}{2f_2}\big(\mathrm{e}^{-2f_2\bar{z}_0^h(t)} - \mathrm{e}^{-2f_2\xi^h}\big),$$

where $\xi^h = \bar{z}_0^h(\pm T^h)$, as before. Now, since

$$\int_{-T^h}^{T^h} \mathrm{e}^{-2f_2\bar{z}_0^h(t)}\,dt$$

is bounded, i.e., $\mathcal{O}(1)$, we conclude that

$$\int_{-T^h}^{T^h} \bar{v}_0^h(t)\mathrm{e}^{-2f_2\bar{z}_0^h(t)}t\,dt \sim \frac{1}{f_2}T^h\mathrm{e}^{-2f_2\xi^h},$$

and it remains only to estimate $G(0,0)$: indeed, by (2.36) and (2.37), there holds

$$G(0,0) = -\frac{d\bar{z}^{h^+(\bar{w},\varepsilon)}}{d\bar{w}}(0,0).$$

Recalling that the relationship between $\bar{z}^h$ and h is given implicitly by

$$\frac{1}{2f_2}\mathrm{e}^{-2f_2\bar{z}^h}\left(\bar{z}^h + \frac{1}{2}\right) = h$$

(cf. (A.3)), we find from an implicit differentiation that

$$\frac{d\bar{z}^h}{dh} = 2f_2\mathrm{e}^{2f_2\bar{z}^h} + \mathcal{O}(h).$$

Since $\xi^h = \bar{z}^h$, (2.35) shows that

$$\frac{dh^+(\bar{w},\sqrt{\varepsilon})}{d\bar{w}}(0,0) = d_{\bar{w}}^+ = -\frac{1}{2}d_{\bar{w}}^0$$

and, hence, that $G(0,0) = d_{\bar{w}}^0 f_2\mathrm{e}^{2f_2\xi^h}$. The result follows. ∎

Acknowledgments. The authors are grateful to Horacio Rotstein for his involvement during the early stages of this work, as well as to Alexey Kuznetsov, Georgi Medvedev, and Martin Wechselberger for valuable discussions and comments, and to Heidi Lyons and Paola Malerba for their careful reading of (parts of) the original manuscript.

Chaotic n-Dimensional Euclidean and Hyperbolic Open Billiards and Chaotic Spinning Planar Billiards*

Ali Deniz†, Judy Kennedy‡, Şahin Koçak†, Andrei V. Ratiu§, Cevat Üstün¶, and James A. Yorke¶

Abstract. We propose a new method to handle the n-dimensional billiard problem in the exterior of a finite mutually disjoint union of convex (but not necessarily strictly convex) smooth obstacles without eclipse in the Euclidean or hyperbolic n-space, and we prove that there exist trajectories visiting the obstacles in any given doubly infinite prescribed order (with the obvious restriction of no consecutive repetition). As an interesting variant of planar billiards, we consider spinning obstacles and particles and prove that any forward sequence of obstacles has a trajectory that follows it.

Key words. chaos, billiards, dissipative, friction

1. Introduction.

The billiard problems of various types have not only physical significance but also mathematical beauty. The long history of billiards is full of mathematical gems [10]. A less investigated class of dispersing billiards is the so-called open-billiards problem, where the reflections on the boundaries of some sorts of obstacles in an infinite affine space are producing the billiard map. An interesting theorem was proven by Morita [8] in the following set-up.

Let $O_1, O_2, \dots O_K$ $(K \geq 3)$ be a finite number of mutually disjoint, closed, bounded, convex subsets of $\mathbb{R}^2$ (the so-called *obstacles*) with boundaries ∂O_j, which are simple smooth closed curves. Consider a particle in $\mathbb{R}^2$ outside $\bigcup_{j=1}^{K} O_j$ which moves along a straight line with unit speed and reflects at the boundary $\bigcup_{j=1}^{K} \partial O_j$ obeying the law of reflection; i.e., the angle of reflection coincides with the angle of incidence. Assume additionally the following two conditions.

Condition 1 (strict convexity). *The boundary curves all have nonvanishing curvature.*

Condition 2 (no eclipse). *For any triple (j_1, j_2, j_3) of distinct indices,*

$$\operatorname{conv}[O_{j_1} \cup O_{j_2}] \cap O_{j_3} = \emptyset,$$

where $\mathrm{conv}[A]$ *denotes the convex hull of the set* A.

Then the following theorem holds (in $\mathbb{R}^2$).

Theorem 1 (Morita [8]). *Given an itinerary* $(O_n)_{n\in\mathbb{Z}}$ *of obstacles without consecutive repetition, there exists a unique trajectory following this itinerary.*

The setting and two assumptions of Morita go back to Ikawa [6], who proved the existence and uniqueness of arbitrary periodic trajectories in the 3-dimensional case with strictly convex obstacles without eclipse. The n-dimensional version of this problem is considered in Stoyanov [9], where important and intricate estimates for the separation of nearby trajectories are given, and very recently the problem was solved by Blokh, Misiurewicz, and Simanyi for strictly convex obstacles without eclipse in $\mathbb{R}^n$ (Theorem 2.2 in [1]), the trajectories being unique by Chernov [2].

We propose another method to solve the problem, which can be applied to other similar billiard problems, and we exemplify this for the hyperbolic case. At the same time we weaken the strict convexity assumption for obstacles and allow their boundaries to have flat parts, as suggested by one of the referees. Throughout the literature it is assumed that the obstacles are strictly convex, so we hope this generalization will be of some value. Polyhedral obstacles smoothed along a narrow region of the edges might give interesting examples. This generalization works, however, at the price of uniqueness of trajectories with a fixed itinerary. It remains to be understood to what extent uniqueness is lost.

After proving the theorem for $\mathbb{R}^n$ (see Theorem 2), we replace $\mathbb{R}^n$ by $\mathbb{H}^n$ (the n-dimensional hyperbolic space) using the conformal unit disk model $\mathbb{B}^n \subset \mathbb{R}^n$ for $\mathbb{H}^n$. The rays along which the particle moves are no longer straight lines but the geodesics of $\mathbb{H}^n$, i.e., circle arcs orthogonal to the unit sphere S^{n-1} or Euclidean straight lines going through the origin of $\mathbb{B}^n$. Theorem 3 shows that the basic result (Theorem 2) also holds in this case, taking as obstacles hyperbolically convex smooth subsets which are diffeomorphic with balls inside $\mathbb{B}^n$.

Finally, we consider another generalization of Theorem 1 on the plane, where we assume the obstacles to be (geometric) disks but allow them to spin around their fixed centers. We also allow the moving particles to spin and collide with the spinning obstacles according to the laws of physics. Under some plausible assumptions, we show that there exists a trajectory following any given (forward) sequence of obstacles.

2. n-dimensional (Euclidean) open-billiards. We define an obstacle in $\mathbb{R}^n$ to be a convex (not necessarily strictly convex) subset O (with boundary ∂O), which is diffeomorphic to the standard disk $\mathbb{D}^n$. Now, let us consider a finite number of mutually disjoint obstacles $O_1, O_2, \dots O_K$ $(K \geq 3)$ for which Condition 2 holds.

Condition 2 (no eclipse). *For any triple* (j_1, j_2, j_3) *of distinct indices,*

$$\mathrm{conv}[O_{j_1} \cup O_{j_2}] \cap O_{j_3} = \emptyset.$$

To define the billiard map, we consider the space $\mathcal{L}$ of oriented lines in $\mathbb{R}^n$ (which can be identified with the total space of the tangent bundle of the unit sphere $S^{n-1} \subset \mathbb{R}^n$; see [10]). We denote the unit orientation vector of $L \in \mathcal{L}$ by $v(L)$ and the line going through a point p and having orientation vector v by $L_p v$. We denote the ray $\{x \in L_p v \mid x = p + tv \text{ with } t \geq 0\}$ by $L_p^+ v$.

The subspace $Q \subset \mathcal{L}$ of the oriented lines intersecting at least one obstacle is compact.

We define for $i = 1, 2, \ldots, K$ the set $S_i \subset Q$ as the set of all oriented lines, which, in the direction of orientation, first hit the obstacle O_i and then, for some $j \neq i$, hit another obstacle O_j. (Thus by Condition 2, a line in S_i hits only these two obstacles O_i and O_j.) Note that the sets S_i are mutually disjoint.

Let $Q_0 = \bigcup_{i=1}^{K} S_i \subset Q$.

An oriented line L intersecting an obstacle O_i "enters" the obstacle at a point $p' \in \partial O_i$ with $\langle n_{p'}, v(L)\rangle \leq 0$ ($n_{p'}$ being the outward unit normal vector at p') and "leaves" the obstacle at a point $p \in \partial O_i$ with $\langle n_p, v(L)\rangle \geq 0$. Generically $L \cap \partial O_i$ consists of two points, but it can also be a singleton or the interval $[p', p]$.

Now we define the billiard map $f : Q_0 \to Q$.

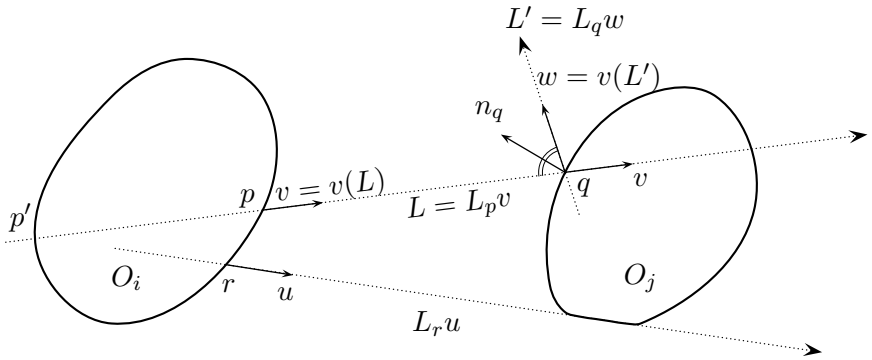

Figure 1. *The billiard map sends $L_p v$ to $L_q w$ with $w = v - 2\langle n_q, v\rangle n_q$. As a special case, $L_r u$ is sent to itself.*

Let $L \in S_i$, $L \cap O_j \neq \emptyset$, with $j \neq i$ and q the first-hit point of L on ∂O_j. We set $f(L) = L'$, where L' is the oriented line through q with the orientation vector $v(L') = v(L) - 2\langle n_q, v(L)\rangle n_q$ (see Figure 1).

We will prove the following.

Theorem 2. *Given an itinerary $(S_{i_n})_{n\in\mathbb{Z}}$ with $i_n \in \{1, 2, \ldots, K\}$ and $i_n \neq i_{n+1}$, there exists a trajectory $(L_n)_{n\in\mathbb{Z}}$ following this itinerary; i.e., $f(L_n) = L_{n+1}$ and $L_n \in S_{i_n}$.*

This means obviously that given any sequence of obstacles in $\mathbb{R}^n$, there is a billiard trajectory in the usual sense hitting every obstacle in the given order.

To prove this theorem, we will use the following special case of the result in [7].

Theorem (the chaos lemma). *Let Q be a compact metric space, $Q_0 \subset Q$ a compact subset, $f : Q_0 \to Q$ a continuous map, and $S_i \subset Q_0$ $(i = 1, 2, \ldots, K)$ pairwise disjoint compact subsets of Q_0 with $\bigcup_{i=1}^{K} S_i = Q_0$. Assume there exists a collection $\{\mathcal{E}_i\}_{i=1}^{K}$, where each $\mathcal{E}_i$ is a nonempty family of nonempty compact subsets of Q, with the following property.*

Property 1. *If $E \in \mathcal{E}_i$ and $j \neq i$, there exists a set $E_j \subset E \cap S_i$ such that $f(E_j) \in \mathcal{E}_j$.*

Then, given any bi-infinite sequence $(S_{i_n})_{n\in\mathbb{Z}}$ of the sets $\{S_1, S_2, \ldots, S_K\}$ with $i_n \in \{1, 2, \ldots, K\}$ and $i_n \neq i_{n+1}$, there exists a sequence $(x_n)_{n\in\mathbb{Z}}$ such that $x_n \in S_{i_n}$ and $f(x_n) = x_{n+1}$.

The sets S_i are called *symbol sets*, the sets $E \in \mathcal{E}_i$ are called *expanders*, and the sets $E_j \subset E \cap S_i$ with $f(E_j) \in \mathcal{E}_j$ are called *pre-expanders*.

3. Proof of Theorem 2. We shall apply the chaos lemma to the billiards setting with the notation fixed above. To make the chaos lemma work, we have to define the expander sets $\mathcal{E}_i$. For this purpose we define the notion of a dispersive vector field on a nonempty, compact subset $D \subset \partial O_i$.

Let $\sigma : D \to S^{n-1}$ be a continuous outward unit vector field; i.e., $\langle \sigma(p), n_p \rangle \geq 0$ for all $p \in D$. We call σ *dispersive* if the condition

$$\langle \sigma(p_1) - \sigma(p_2), p_1 - p_2 \rangle \geq 0 \text{ for all } p_1, p_2 \in D$$

is satisfied. See Figure 4.

Lemma 1. *For a dispersive vector field σ, either the rays $L^+_{p_1}\sigma(p_1)$ and $L^+_{p_2}\sigma(p_2)$ are disjoint or one is contained in the other.*

We omit the proof.

We call a dispersive vector field $\sigma : D \to S^{n-1}$ *exhaustive* (or call σ an exhaustively dispersive vector field) if there exists a continuous extension $\sigma^* : \partial O_i \to S^{n-1}$ of σ such that

$$\langle n_p, \sigma^*(p) \rangle \geq 0 \text{ for all } p \in \partial O_i, \text{ and}$$
$$L^+_p \sigma^*(p) \cap \partial O_j = \emptyset \text{ for all } p \in \partial O_i \backslash D,\ j \neq i.$$

(That is, σ can be extended to an outward unit vector field on ∂O_i in such a way that the rays along the new vectors outside D do not hit any of the obstacles.)

We can associate to every vector field $\sigma : D_\sigma \subset \partial O_i \to S^{n-1}$ the set $E(\sigma)$ of oriented lines defined as $E(\sigma) = \{L_p\sigma(p) \mid p \in D_\sigma\} \subset Q$.

Now we define our expanders (recall that expanders are sets of sets):

$$\mathcal{E}_i = \{E \subset Q \mid \text{there exists an exhaustively dispersive vector field}$$
$$\sigma : D_\sigma \subset \partial O_i \to S^{n-1} \text{ such that } E = E(\sigma)\}.$$

$\mathcal{E}_i$ is nonempty because the outward unit normal vector field $\mathcal{N}$ is exhaustively dispersive, and thus $E(\mathcal{N}) \in \mathcal{E}_i$.

To obtain Theorem 2 from the chaos lemma, we have to verify Property 1: For any $E \in \mathcal{E}_i$ ($E = E(\sigma)$ for some $\sigma : D_\sigma \to S^{n-1}$) and for all $j \neq i$, there exists a subset $E_j \subset E \cap S_i$ such that $f(E_j) \in \mathcal{E}_j$.

We define as a pre-expander

$$E_j = \{L_p\sigma(p) \mid p \in D_\sigma \text{ and } L^+_p\sigma(p) \cap \partial O_j \neq \emptyset\}$$

and are going to show that $f(E_j) \in \mathcal{E}_j$. To this end we first note some well-known facts.

$\sigma^* : \partial O_i \to S^{n-1}$ has degree 1 (because it is homotopic to the normal vector field) and thus it is onto. In other words, given any unit vector in $\mathbb{R}^n$, there is a point in ∂O_i at which this vector is attached. Moreover, we can state the following lemma.

Lemma 2. *Given any point $q \in \mathbb{R}^n \backslash O_i$, there exists a point $p \in \partial O_i$ such that $q \in L^+_p\sigma^*(p)$.*

Proof. Let $q \in \mathbb{R}^n \backslash O_i$. Define the map

$$\omega_q : \partial O_i \to S^{n-1},$$
$$\omega_q(p) = \frac{q-p}{\|q-p\|},$$

which assigns a unit vector in direction q for each $p \in \partial O_i$. ω_q has degree 0 because it is not onto.

Now, suppose that $\sigma^*(p) \neq \omega_q(p)$ for all $p \in \partial O_i$. Then the map

$$\begin{aligned} H : \partial O_i \times [0,1] &\to S^{n-1}, \\ H(p,t) &= \frac{t\sigma^*(p) - (1-t)\omega_q(p)}{\|t\sigma^*(p) - (1-t)\omega_q(p)\|} \end{aligned}$$

is a homotopy between $-\omega_q(p) = H(p,0)$ and $\sigma^*(p) = H(p,1)$. To see this, it is enough to show that $\|t\sigma^*(p) - (1-t)\omega_q(p)\| \neq 0$ for all $p \in \partial O_i$ and $t \in [0,1]$. If we had $\|t\sigma^*(p) - (1-t)\omega_q(p)\| = 0$ for some t, this would give $t\sigma^*(p) = (1-t)\omega_q(p)$ and thus $t = \frac{1}{2}$ (by $\|\sigma^*(p)\| = \|\omega_q(p)\| = 1$), contradicting $\sigma^*(p) \neq \omega_q(p)$.

This homotopy implies that $\mathit{degree}(\sigma^*(p)) = \mathit{degree}(-\omega_q(p))$, which is impossible, because $\mathit{degree}(-\omega_q(p)) = 0$ but $\mathit{degree}(\sigma^*(p)) = 1$. ■

As a consequence, we have $\partial O_j \subset \bigcup_{L \in E_j} L_p^+ \sigma(p)$ for any $j \neq i$.

Let $\varphi : \partial O_j \to S^{n-1}$ be defined as follows: Given $q \in \partial O_j$ there exists $p \in D_\sigma$ with $q \in L_p^+ \sigma(p)$. A point with this property might not be uniquely defined, but $\sigma(p)$ is well defined by dispersivity. So we set $\varphi(q) = \sigma(p)$. φ can be seen to be continuous.

We can now express $f(E_j)$ as $E(\tau)$ for the function

$$\begin{aligned} \tau : D_\tau &\to S^{n-1}, \\ \tau(q) &= \varphi(q) - 2\langle n_q, \varphi(q)\rangle n_q, \end{aligned}$$

where $D_\tau = \{q \in \partial O_j \mid \langle n_q, \varphi(q)\rangle \leq 0\} \subset \partial O_j$ (see Figure 2).

Lemma 3. *τ, as defined above, is exhaustively dispersive.*

Proof (τ is dispersive). We must show $\langle \tau(q_1) - \tau(q_2),\ q_1 - q_2\rangle \geq 0$ for all $q_1, q_2 \in D_\tau$. Let $q_1 = p_1 + t_1\sigma(p_1)$, $q_2 = p_2 + t_2\sigma(p_2)$ and assume $t_1 \geq t_2 > 0$. We thus have, inserting $\tau(q_\alpha) = \sigma(p_\alpha) - 2\langle \sigma(p_\alpha), n_{q_\alpha}\rangle n_{q_\alpha}$ for $\alpha = 1, 2$,

$$\begin{aligned} \langle \tau(q_1) - \tau(q_2), q_1 - q_2\rangle &= \langle \sigma(p_1) - \sigma(p_2), q_1 - q_2\rangle \\ &\quad + 2\langle [\langle \sigma(p_2), n_{q_2}\rangle n_{q_2} - \langle \sigma(p_1), n_{q_1}\rangle n_{q_1}], q_1 - q_2\rangle. \end{aligned} \tag{1}$$

We will show that both terms on the right-hand side of (1) are nonnegative. The first term satisfies

$$\begin{aligned} \langle \sigma(p_1) - \sigma(p_2), q_1 - q_2\rangle &= \langle \sigma(p_1) - \sigma(p_2), p_1 - p_2\rangle + t_2\|\sigma(p_1) - \sigma(p_2)\|^2 \\ &\quad + (t_1 - t_2)\langle \sigma(p_1) - \sigma(p_2), \sigma(p_1)\rangle. \end{aligned} \tag{2}$$

The first term on the right-hand side of (2) is nonnegative, because σ is dispersive. The other two terms are nonnegative for obvious reasons.

The second term of the right-hand side of (1),

$$\langle \sigma(p_2), n_{q_2}\rangle \langle n_{q_2}, q_1 - q_2\rangle - \langle \sigma(p_1), n_{q_1}\rangle \langle n_{q_1}, q_1 - q_2\rangle,$$

is also nonnegative because

$$\langle n_{q_2}, q_1 - q_2\rangle \leq 0 \text{ and } \langle n_{q_1}, q_1 - q_2\rangle \geq 0$$

by convexity of O_j. (The other two factors are ≤ 0 by construction.) ■

Proof (τ is exhaustive). To define the extension

$$\tau^* : \partial O_j \to S^{n-1},$$

we first note that $D_\tau = \{q \in \partial O_j \mid \langle n_q, \varphi(q)\rangle \leq 0\}$ and $D'_\tau = \{q \in \partial O_j \mid \langle n_q, \varphi(q)\rangle \geq 0\}$ are both closed.

Let

$$\tau^*(q) = \begin{cases} \varphi(q) - 2\langle \varphi(q), n_q\rangle n_q & \text{for} \quad q \in D_\tau \\ \varphi(q) & \text{for} \quad q \in D'_\tau \end{cases}$$

(see Figure 2).

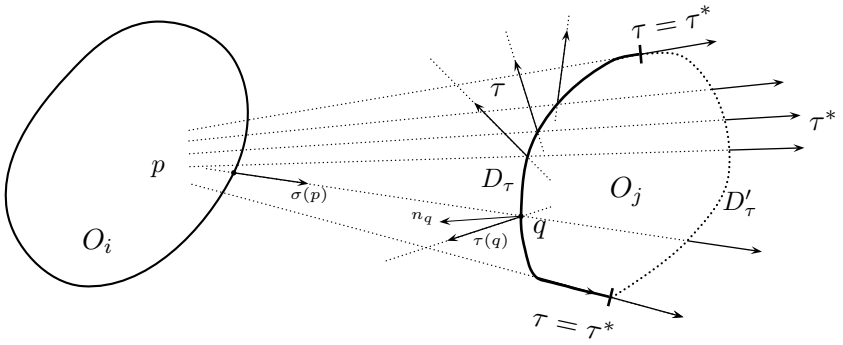

Figure 2. *The extension of* τ.

τ^* is well defined on $D_\tau \cup D'_\tau = \partial O_j$ since $\langle \varphi(q), n_q\rangle = 0$ for $q \in D_\tau \cap D'_\tau$, and consequently τ^* is continuous. τ^* is outward on D'_τ ($\langle n_q, \tau^*(q)\rangle \geq 0$ for $q \in D'_\tau$), and $L_q^+\tau^*(q) \cap \partial O_k = \emptyset$ for $k \neq j$ by Condition 2. Thus τ is exhaustive. ■

The chaos lemma now verifies Theorem 2.

4. Open billiards in hyperbolic n-space. We consider the open-billiards problem in the n-dimensional hyperbolic space $\mathbb{H}^n$ using the conformal unit-disk model $\mathbb{B}^n = \{x \in \mathbb{R}^n \mid \|x\|_{\mathbb{E}} < 1\}$ with the Riemannian metric

$$g_p(u_p, v_p) = \langle u_p, v_p\rangle_{\mathbb{H}} = \frac{4}{(1 - \|p\|^2)^2}\langle u_p, v_p\rangle_{\mathbb{E}},$$

where u_p, v_p are vectors at the point $p \in \mathbb{B}^n$ and the subscripts $\mathbb{E}$ and $\mathbb{H}$ denote the Euclidean and hyperbolic metrics, respectively. In this section we will assume the hyperbolic metric applies when the subscript is dropped. The angles between (hyperbolic) vectors are the same as in the Euclidean case; only the lengths are affected.

Given any point $p \in \mathbb{B}^n$ and any unit vector v_p at p, the geodesic going through p in the direction of v_p is a Euclidean circle-arc perpendicular to the unit sphere $S^{n-1} \subset \mathbb{R}^n$. (In the case when it goes through the origin of $\mathbb{R}^n$, it is a straight line segment.) We denote the oriented geodesic through p in the direction of v_p by $L_p v_p$, and we call the geodesic part starting at p in the direction of v_p a hyperbolic ray and denote it by $L_p^+ v_p$. As obstacles we

consider hyperbolically convex (the geodesic segment connecting any two points is contained in the obstacle) smooth subsets of $\mathbb{B}^n$ which are diffeomorphic to the standard closed disk $\mathbb{D}^n = \{x \in \mathbb{R}^n \mid \|x\|_{\mathbb{E}} \leq 1\}$.

Let $\mathcal{L}$ denote the space of oriented geodesics, and let $Q \subset \mathcal{L}$ be the compact subspace of oriented geodesics intersecting at least one obstacle. As before, let S_i be the set of all oriented geodesics which in the direction of orientation first hit the obstacle O_i and then, for some $j \neq i$, another obstacle O_j. We set $Q_0 = \bigcup_{i=1}^{K} S_i \subset Q$.

For an oriented geodesic L intersecting an obstacle O_i, there is a first-hit point $p' \in \partial O_i$ with $\langle n_{p'}, v_{p'} \rangle \leq 0$ (note that the hyperbolic normal vector is in the direction of the Euclidean normal vector, but possibly of different length) and a last-hit point $p \in \partial O_i$ with $\langle n_p, v_p \rangle \geq 0$.

The billiard map $f : Q_0 \to Q$ can be defined as before: For $L \in S_i$, $L \cap O_j \neq \emptyset$ with $j \neq i$, p the last-hit point of L on ∂O_i, q the first-hit point of L on ∂O_j, we set $f(L) = L'$, where L' is the oriented geodesic through q with the vector $w_q = P_p^q v_p - 2\langle n_q, P_p^q v_p \rangle n_q$, P_p^q denoting the parallel transportation of a vector at p, along the geodesic, to a vector at q (see Figure 3).

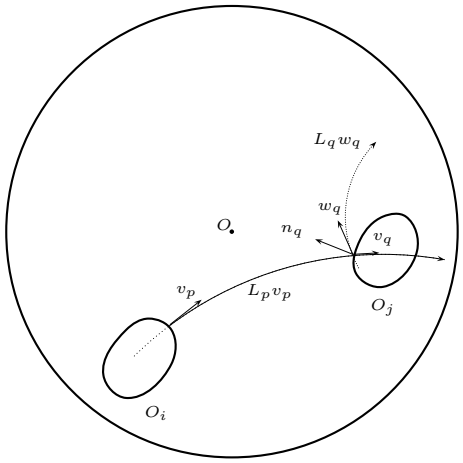

Figure 3. *The billiard map sends $L_p v_p$ to the geodesic $L_q w_q$ with $w_q = v_q - 2\langle n_q, v_q \rangle n_q$, where $v_q = P_p^q v_p$.*

Now let us consider a finite number of mutually disjoint obstacles $O_1, O_2, \ldots, O_K$ ($K \geq 3$). We again assume Condition 2.

Condition 2 (no eclipse). *For any triple (j_1, j_2, j_3) of distinct indices,*

$$\operatorname{conv}[O_{j_1} \cup O_{j_2}] \cap O_{j_3} = \emptyset.$$

Theorem 3. *Given an itinerary $(S_{i_n})_{n \in \mathbb{Z}}$ with $i_n \in \{1, 2, \ldots, K\}$ and $i_n \neq i_{n+1}$, there exists a trajectory $(L_n)_{n \in \mathbb{Z}}$ following this itinerary; i.e., $f(L_n) = L_{n+1}$ and $L_n \in S_{i_n}$.*

For proof, we again apply the chaos lemma. We will outline those points where there are slight modifications in comparison to the Euclidean case.

We denote the restriction of the hyperbolic unit tangent bundle $T_1(\mathbb{B}^n)$ to ∂O_i by Σ_i. Let $D \subset \partial O_i$ be a nonempty, compact subset of ∂O_i and $\sigma : D \to \Sigma_i$ a continuous outward vector field, i.e., $\sigma(p) = (p, \sigma_2(p))$ with $\langle n_p, \sigma_2(p) \rangle \geq 0$ for $p \in D$. Let $p_1, p_2 \in D$ and α_i denote the angle between $\sigma_2(p_i)$ and the hyperbolic segment $[p_1 p_2]$ for $i = 1, 2$. We call σ a dispersive

vector field if $\alpha_1 + \alpha_2 \geq \pi$ for all $p_1, p_2 \in D$. (This condition is equivalent to the one we used in the Euclidean case, but this formulation is more convenient for the hyperbolic setting, especially for checking the dispersiveness of reflected rays.)

Lemma 4. *For a dispersive vector field σ, either the hyperbolic rays $L^+_{p_1}\sigma_2(p_1)$ and $L^+_{p_2}\sigma_2(p_2)$ are disjoint or one is contained in the other.*

We omit the proof.

The definition of exhaustiveness remains the same. As for expanders, we take again sets of oriented geodesics determined by exhaustively dispersive vector fields. If $\sigma : D_\sigma \to \Sigma_i$, $D_\sigma \subset \partial O_i$, we set $E(\sigma) = \{L_p\sigma_2(p) \mid p \in D_\sigma\} \subset Q$ and define

$$\mathcal{E}_i = \{E(\sigma) \mid \sigma \text{ is an exhaustively dispersive vector field on } D_\sigma \subset \partial O_i\}.$$

$\mathcal{E}_i$ is nonempty because by hyperbolic convexity the segment $[p_1p_2]$ lies inside O_i for $p_1, p_2 \in \partial O_i$, making the angle with the normals n_{p_1} and n_{p_2} greater than (or equal to) $\frac{\pi}{2}$. This shows that the normal outward vector field on ∂O_i is exhaustively dispersive.

We define the pre-expanders as before: given $E \in \mathcal{E}_i$, we set

$$E_j = \{L_p\sigma_2(p) \mid p \in D_\sigma \text{ and } L^+_p\sigma_2(p) \cap \partial O_j \neq \emptyset\}.$$

We have to show that $f(E_j) \in \mathcal{E}_j$. In the Euclidean case, we used degree theory to see this. In the hyperbolic setting, degree theory can still be used with suitable modifications.

Given any section $\sigma : \partial O_i \to \Sigma_i$, for any $p \in \partial O_i$ we can parallel-transport the vector $\sigma_2(p)$ to the origin along the geodesic between p and the origin (which is a Euclidean straight line segment). We thus obtain a map $\tilde{\sigma} : \partial O_i \to S^{n-1}_{\mathbb{H}}$ (the hyperbolic unit sphere is also a Euclidean sphere) and define *degree*(σ) to be *degree*$(\tilde{\sigma})$.

If $\sigma : D_\sigma \to \Sigma_i$ is any exhaustively dispersive vector field, then we get as before *degree*$(\sigma^*) = 1$. As a consequence, given any point $q \in \mathbb{B}^n \backslash O_i$, there exists a point $p \in \partial O_i$ with $q \in L^+_p\sigma^*_2(p)$. Then we get $\partial O_j \subset \bigcup_{L \in E_j} L^+_p\sigma_2(p)$. We define as before $\varphi : \partial O_j \to \Sigma_j$ $\varphi(q) = P^q_p\sigma_2(p)$ for $q \in L^+_p\sigma_2(p)$ and $\tau : D_\tau \to \Sigma_j$ with $D_\tau = \{q \in \partial O_j \mid \langle n_q, \varphi(q)\rangle \leq 0\} \subset \partial O_j$ and

$$\tau(q) = (q, \varphi(q) - 2\langle n_q, \varphi(q)\rangle n_q).$$

With this τ it holds that $f(E_j) = E(\tau)$, and to show $f(E_j) \in \mathcal{E}_j$ we must prove that τ is continuous, dispersive, and exhaustive. Continuity and exhaustiveness go almost verbatim as in the Euclidean case, but dispersiveness requires a separate argument. We have to show that for $q_1, q_2 \in D_\tau$, the angle β_1 between $\tau_2(q_1)$ and the hyperbolic segment $[q_1q_2]$ and the angle β_2 between $\tau_2(q_2)$ and $[q_1q_2]$ satisfy the inequality $\beta_1 + \beta_2 \geq \pi$.

We first show that the angles θ_1, θ_2 between $P^{q_1}_{p_1}\sigma_2(p_1), P^{q_2}_{p_2}\sigma_2(p_2)$ and the hyperbolic segment $[q_1q_2]$ satisfy $\theta_1 + \theta_2 \geq \pi$. Then we will show $\beta_1 \geq \theta_1$ and $\beta_2 \geq \theta_2$. Now let $\measuredangle p_1p_2q_1 = \alpha'_2$, $\measuredangle q_1p_2q_2 = \alpha''_2$, $\measuredangle q_2q_1p_2 = \gamma'$, and γ be the angle between $P^{q_1}_{p_1}\sigma_2(p_1)$ and $[p_2q_1]$. By the triangle inequality for angles, we have

$$\alpha_2 \leq \alpha'_2 + \alpha''_2 \text{ and } \gamma \leq \gamma' + \theta_1.$$

On the other hand, for the hyperbolic triangle $p_1p_2q_1$, $\gamma > \alpha_1 + \alpha'_2$ (because the sum of the inner angles of a hyperbolic triangle is less than π). We thus get

$$\gamma + \alpha'_2 + \alpha''_2 \geq \alpha_1 + \alpha'_2 + \alpha_2,$$
$$\gamma + \alpha''_2 \geq \alpha_1 + \alpha_2 \geq \pi.$$

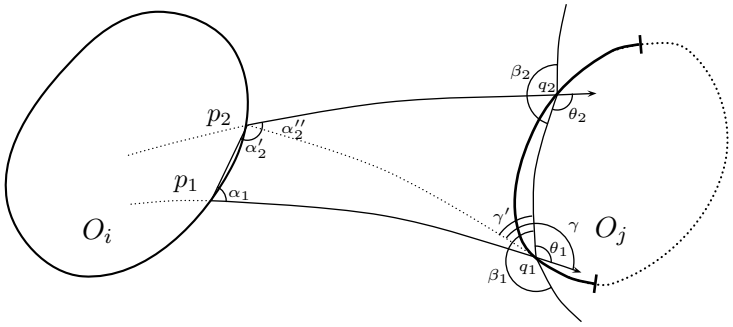

Figure 4. *τ is a dispersive vector field.*

From the hyperbolic triangle $p_2q_1q_2$ we have $\theta_2 > \gamma' + \alpha_2''$. Hence, $\theta_1 + \theta_2 \geq \theta_1 + \gamma' + \alpha_2'' \geq \gamma + \alpha_2'' \geq \alpha_1 + \alpha_2 \geq \pi$.

We now show $\beta_1 \geq \theta_1$:

$$\tau_2(q_1) = P_{p_1}^{q_1}\sigma_2(p_1) - 2\langle n_{q_1}, P_{p_1}^{q_1}\sigma_2(p_1)\rangle n_{q_1} \text{ by definition of } \tau.$$

As the scalar product on the right-hand side is negative, we have

$$\tau_2(q_1) = P_{p_1}^{q_1}\sigma_2(p_1) + \lambda n_{q_1} \text{ with } \lambda \geq 0.$$

Denote the unit vector at q_1 in the direction of q_1q_2 by u, and multiply the above equation by u:

$$\begin{aligned}\langle \tau_2(q_1), u\rangle &= \langle P_{p_1}^{q_1}\sigma_2(p_1), u\rangle + \lambda\langle n_{q_1}, u\rangle,\\ \cos\beta_1 &= \cos\theta_1 + \lambda\langle n_{q_1}, u\rangle.\end{aligned}$$

As $\langle n_{q_1}, u\rangle \leq 0$ we get $\cos\beta_1 \leq \cos\theta_1$, and thus $\beta_1 \geq \theta_1$. Similarly, $\beta_2 \geq \theta_2$, giving the dispersiveness and completing the proof.

5. Spinning planar billiards.

5.1. Introduction. Billiard dynamics has been a standard dynamics model for many years, but the model is far from a complete description of reality. Real billiard balls have spin, which is utilized by billiards players. Here we extend the model to permit the billiard to spin. See [3, 4, 5] for a discussion of the physics. We call the particle a "puck"; it is analogous to a hockey puck that can spin on the plane. In contrast, a billiard ball on a table spins in three dimensions, a case we do not consider here.

We find the new mathematics that result intriguing. The state space describing a puck is larger since it must include speed and spin rate as well as position and direction—we can no longer assume the puck's speed is constant. Our puck is assumed to have no friction between collisions, but there is friction in the collision. Friction in the collision introduces an interaction among the spin of the obstacle, the spin of the puck, and the incoming velocity of the puck. Most people have observed that a thrown rubber ball has a bounce that is affected

by the spin of the ball. A rapidly spinning ball can gain speed in the collision, translating spin energy into velocity. So-called *super balls* are resilient (i.e., they retain most of their energy in a bounce) and have a high friction coefficient. Their bounces are especially influenced by spin.

In the appendix, we discuss the equations for a collision between the puck and an obstacle, using the most commonly used rules of friction, namely, stick-slip friction. A block sliding on a surface slows down, and its deceleration is independent of its velocity, provided that the velocity is positive. The block therefore reaches 0 speed in finite time. We must compress this phenomenon into an instantaneous bounce. A key factor is the relative speeds of the points on the puck and obstacle that are in contact during the collision. For the incoming trajectory, they are unlikely to be equal, but for the outgoing trajectory, equality is quite likely if the incoming difference is small.

The stick-slip dynamics of a collision with a fixed obstacle (described in the appendix) have some easily derived properties that can be useful in modeling, though they are not necessary for the results in this section. Let Δs denote the absolute value of the difference between the incoming spin rate of a puck (just before a collision) and its spin immediately after. Similarly, let Δv denote the norm of the difference in the incoming and outgoing velocities. Let w be the norm of the normal component of the incoming velocity. Then there are constants $C_1 > 0$ and $C_2 > 0$ (that depend only on the coefficient of friction and moment of inertia of the puck) such that

$$\Delta s \le C_1 w \quad \text{and} \quad C_2 w \le \Delta v \le C_1 w.$$

In particular, in a tangential collision, $w = 0$, so the change in velocity and spin are 0.

We also note that the outgoing velocity and spin are continuous functions of initial position, velocity, and spin. Additionally, the change in the normal component of velocity depends only on w, and the outgoing velocity must be nonzero.

5.2. Spinning billiards. In our result we assume the following properties, which are much less specific than would be required by the stick-slip friction model.

Condition 2 (no eclipse). *For any triple (j_1, j_2, j_3) of distinct indices,*

$$\operatorname{conv}[O_{j_1} \cup O_{j_2}] \cap O_{j_3} = \emptyset.$$

Condition 3 (physical properties). *The obstacles are fixed disks with fixed spin rates, all having the same fixed coefficients of friction. The puck is a disk and has a fixed coefficient of restitution $e > 0$, so its outgoing speed is always positive (the puck cannot stop at a collision). The velocity and spin rate of the puck are constant between collisions.*

Condition 4 (continutity). *For each obstacle, following a collision, the puck's outward velocity and rate of spin are continuous functions of the inward velocity, rate of spin, direction of motion, and point of contact with the obstacle. Furthermore, if the puck hits an obstacle tangentially, then its velocity and rate of spin do not change.*

The ambient phase space of the dynamics (at instants of collisions) will be

$$Q = \bigcup_{i=1}^{K} (S_i^1 \times S^1 \times (0, \infty) \times \mathbb{R}),$$

where the first factor S^1_i is the boundary of the disk O_i, the second factor S^1 codes the direction of the puck, the third factor $(0,\infty)$ codes its linear speed, and the last factor $\mathbb{R}$ codes its angular velocity at the moment of leaving O_i.

The symbol sets will be

$$S_i = \{(p, v, s, r) \mid p \in S^1_i,\ \langle n_p, v\rangle \geq 0, \text{ and } \exists j \text{ such that } L^+_p v \cap S^1_j \neq \emptyset\} \subset Q,$$

where n_p and $L^+_p v$ denote as usual the outward unit normal at p and the (Euclidean) ray starting at p in direction v. Let

$$Q_0 = \bigcup_{i=1}^{K} S_i.$$

The billiard map $f : Q_0 \to Q$ is continuous by Condition 4. See Figure 5.

Theorem 4. *Assume Conditions 2, 3, and 4. Given a forward itinerary $(S_{i_n})_{n\in\mathbb{N}}$ with $i_n \in \{1, 2, \ldots, K\}$ and $i_n \neq i_{n+1}$, there exists a trajectory $(L_n)_{n\in\mathbb{N}}$ following this itinerary; i.e., $f(L_n) = L_{n+1}$ and $L_n \in S_{i_n}$.*

Since this theorem discusses only forward itineraries, the corresponding trajectories are not unique. Even if the forward and backward trajectories were specified, there is no guarantee that they would correspond to a *unique* trajectory. The approach we use is general enough that it can be applied to situations where uniqueness of trajectories does not hold.

To define the expanders in the present case, we first consider continuous maps

$$g : J \to S^1_i \times S^1 \times (0,\infty) \times \mathbb{R},$$
$$t \mapsto (p(t), v(t), s(t), r(t)),$$

where J is a compact interval in $\mathbb{R}$ or $J \subset S^1_i$ for some i and the second coordinate $v(t)$ is an outward direction at the point $p(t)$. We call such a map g *exhaustive* if it can be extended to a map g^* on a circle such that, on the complementary closed arc J', the following conditions hold:

1. For $t \in J'$, $v(t)$ is an outward direction at $p(t)$, and the ray $L^+_{p(t)}v(t)$ does not hit any disk O_j for $j \neq i$.
2. The degree of the map given by the first coordinate of g^* is ± 1. (That is, $p(t)$ winds around S^1_i once.)

The expanders are

$$\mathcal{E}_i = \{\text{Image}(g) \mid g : J \to S^1_i \times S^1 \times (0,\infty) \times \mathbb{R} \text{ is an exhaustive map}\}.$$

Each $E \in \mathcal{E}_i$ is a subset of $S^1_i \times S^1 \times (0,\infty) \times \mathbb{R} \subset Q$.

We must prove the existence of pre-expanders: Given $E = \text{Image}(g) \in \mathcal{E}_i$ and $j \neq i$, there must exist some $E_j \subset E \cap S_i$ such that $f(E_j) \in \mathcal{E}_j$.

As t traverses the interval $J = [a, b]$ from a to b, we start with the ray $L^+_{p(a)}v(a)$ which does not hit O_j. There will be t with $L^+_{p(t)}v(t)$ hitting O_j by the degree condition, and so there will be tangencies. Finally, the last ray $L^+_{p(b)}v(b)$ does not hit O_j again. This implies the existence of a subinterval $[a_j, b_j] \subset [a, b]$ sweeping O_j: $L^+_{p(a_j)}v(a_j)$ and $L^+_{p(b_j)}v(b_j)$ are tangent to O_j, $L^+_{p(t)}v(t)$ hits O_j for $t \in [a_j, b_j]$, and $O_j \subset \bigcup_{t\in[a_j,b_j]} L^+_{p(t)}v(t)$.

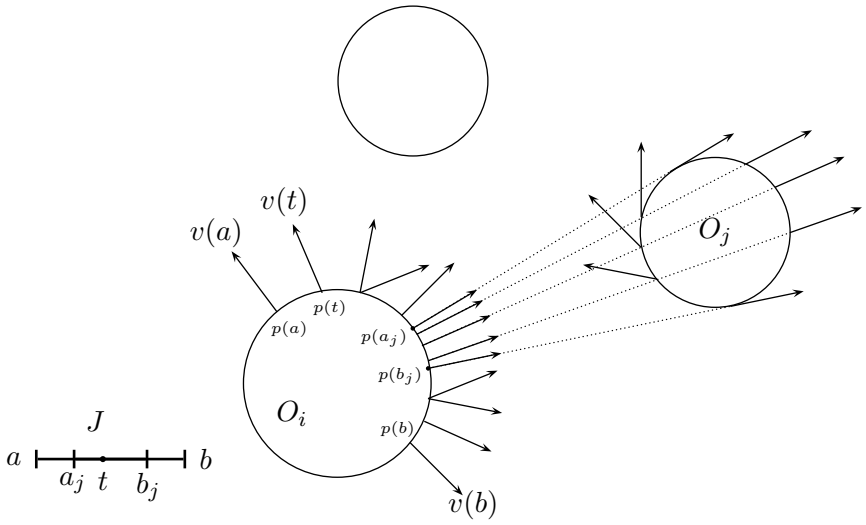

Figure 5. *Spinning billiards. Three obstacles are shown, with trajectories leaving obstacle O_i. If O_j has a strong clockwise spin, the puck's outward trajectories might be as shown. Independent of the spin of the obstacles, trajectories like $p(a_j)$ and $p(b_j)$ hit O_j tangentially and continue without deviating.*

If we set $E_j = \text{Image}\left(g|_{[a_j,b_j]}\right)$, then $E_j \subset E \cap S_i$. It can be seen by the same reasoning as at the end of the proof of Theorem 2 that $f(E_j)$ is an expander again, completing the proof that in spinning billiards in the Euclidean plane, any nonrepeating but otherwise arbitrary infinite sequence of obstacles has a trajectory that follows it.

Appendix. In this section, we develop a model for the scattering of a circular puck from an immovable circular obstacle, where the interaction between the two bodies involves friction. The obstacles' centers do not move, and each spins at a constant rate unaffected by collision with the puck.

Consider the situation shown in Figure 6. At time $t = 0$, a puck starts out at initial position $\mathbf{x_i}$ and with initial velocity $\mathbf{v}$ directed toward an obstacle situated at $\mathbf{x_o}$. The initial angular velocity of the puck is $\boldsymbol{\omega_p}$, and the obstacle is given to be always rotating with an angular velocity of $\boldsymbol{\omega_o}$. The goal is to find the final state given by $\mathbf{v}'$ and $\boldsymbol{\omega_p'}$ immediately after the collision at $\mathbf{x_c}$, the point of impact. With the exception of the angular velocities $\boldsymbol{\omega_p}$ and $\boldsymbol{\omega_o}$ which are strictly in the z direction, all vectorial quantities in this discussion are (and hence all motion is) confined to the $x - y$ plane. The dynamics are independent of the puck's mass m, which we can set to 1.

The first step is to determine if and when a collision occurs. For times t before the collision, the position vector of the puck is given by $\mathbf{x} = \mathbf{x_i} + \mathbf{v}\,t$. The collision takes place at some time t_c, when the puck is at $\mathbf{x_c}$:

$$\mathbf{x_c} = \mathbf{x_i} + \mathbf{v}\,t_c. \tag{3}$$

We assume that the collision deforms neither the puck nor the obstacle. This means that at

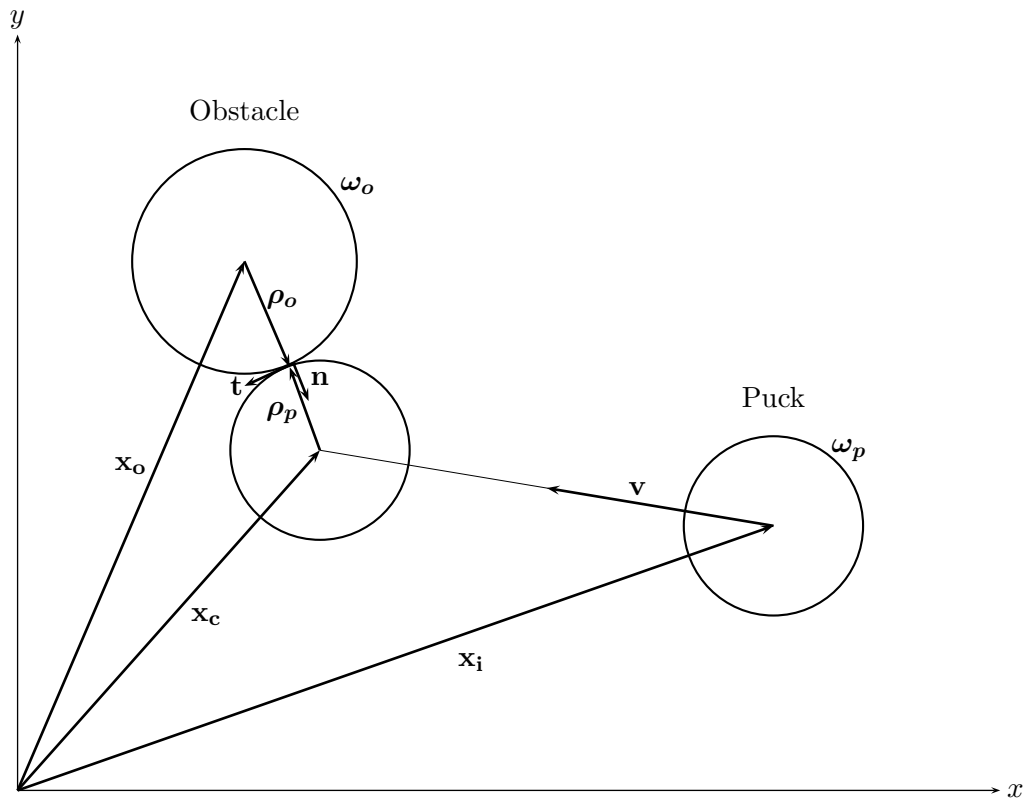

Figure 6. *A puck (smaller disk) starts at* $\mathbf{x_i}$ *and travels to* $\mathbf{x_c}$*, where it collides with an obstacle situated at* $\mathbf{x_o}$*.*

impact time,

$$|\mathbf{x_c} - \mathbf{x_o}| = R_p + R_o \tag{4}$$

will hold, where R_p and R_o are the radii of the puck and obstacle, respectively. Substituting (3) into (4) and defining $\mathbf{z} = \mathbf{x_i} - \mathbf{x_o}$ leads to

$$|\mathbf{z} + \mathbf{v}\, t_c| = R_p + R_o.$$

After squaring both sides, we get a quadratic equation for the collision time t_c of the form $a\, t_c^2 + b\, t_c + c\, t_c = 0$, where $a = v^2$, $b = 2\, \mathbf{z} \cdot \mathbf{v}$, and $c = z^2 - (R_p + R_o)^2$.

The discriminant $\Delta = b^2 - 4ac$ leads to several regimes of qualitatively different physical behavior: $\Delta < 0$ implies that the puck will miss the obstacle entirely, whereas $\Delta = 0$ means that the puck will pass tangentially to the obstacle. No interaction is assumed between the two bodies in either case. A value of $\Delta > 0$, on the other hand, means that there will be two values of t, t_+ and t_-, for which (4) is satisfied (one for each side of the obstacle). If these are positive, we pick the smaller of the two values. Of course $t_+, t_- < 0$ correspond to meaningless collisions for negative times. In short,

$$t_c = \min\{t_+, t_-\} \quad (t_\pm > 0), \tag{5}$$

and substituting this back into (3) yields the collision coordinate $\mathbf{x_c}$. For the remainder of this discussion assume that a given set of initial conditions will lead to a collision satisfying (5) above.

The second and final step is to determine what happens in a collision. Define unit vectors in the normal and tangential directions at the point of contact as

$$\mathbf{n} = (\mathbf{x_c} - \mathbf{x_o})/|\mathbf{x_c} - \mathbf{x_o}|,$$
$$\mathbf{t} = \mathbf{n} \times \mathbf{k},$$

where $\mathbf{k}$ is the unit vector in the z direction (we assume a right-handed coordinate system) and where a "$\times$" denotes the usual vector cross product. We have defined $\mathbf{n}$ to be pointing away from the obstacle. Position vectors from the centers of the puck and obstacle that extend to the point of contact are then given by $\boldsymbol{\rho_p} = -R_p\,\mathbf{n}$ and $\boldsymbol{\rho_o} = R_o\,\mathbf{n}$. These in turn allow us to write the tangential velocities of the rims of the puck and obstacle at the point of contact:

$$\mathbf{V_p} = (\mathbf{v}\cdot\mathbf{t})\,\mathbf{t} + \boldsymbol{\omega_p}\times\boldsymbol{\rho_p}, \tag{6}$$

$$\mathbf{V_o} = \boldsymbol{\omega_o}\times\boldsymbol{\rho_o}. \tag{7}$$

We now turn our attention from kinematics to dynamics. The collision is instantaneous but can be considered as the limit of a more physically realistic, very brief collision. All these approximations have the same impulse J. Throughout the collision, the obstacle will exert a normal force $N(t)$, where t lies in the small interval during which the collision takes place. The time integral of this over that small interval is the impulse $J \equiv \int N(t)dt$, which acts in the direction $\mathbf{n}$. We do not calculate $N(t)$ itself; instead, we work with J not only for motion in the normal direction but also for the tangential and rotational degrees of freedom. To begin, recall from mechanics that if $\mathbf{p} = \mathbf{v}$ is the initial momentum of the puck having mass $m = 1$ and $\mathbf{p_n} = (\mathbf{p}\cdot\mathbf{n})\mathbf{n}$ is the component of this momentum in the normal direction, then the new value of $\mathbf{p_n}$ is given by $\mathbf{p'_n} = \mathbf{p_n} + J\,\mathbf{n}$. On the other hand, the coefficient of restitution [3, 4, 5], $e \in (0, 1]$, satisfies $\mathbf{p'_n} = -e\,\mathbf{p_n}$. Therefore,

$$J = -(1+e)\mathbf{v}\cdot\mathbf{n}, \tag{8}$$

which is always positive since $\mathbf{v}\cdot\mathbf{n}$ is negative.

The impulse imparted to the puck in the tangential direction involves the force of friction, $F(t)$. If the puck and obstacle are sliding with respect to each other during the entire duration of the impact (the "sliding" regime), this force will be assumed to have the form $F(t) = \mu_s N(t)$, where μ_s is the coefficient of sliding friction. The impulse generated by $F(t)$ will then be $\mu_s J$. If, on the other hand, at some point during the collision the tangential velocities $\mathbf{V_p}$ and $\mathbf{V_o}$ are equalized due to friction, $F(t)$ has to be set to zero for the remainder of the impact (we neglect rolling friction here), and the impulse in this direction will then be correspondingly less than $\mu_s J$. Physically, this corresponds to the puck and obstacle rolling about each other (the "rolling" regime, even though the puck may have been initially sliding).

Before we discuss the details of the two regimes, we note that (6) and (7) allow us to define a unit vector in the direction of friction as $\mathbf{f} = -(\mathbf{V_p} - \mathbf{V_o})/|\mathbf{V_p} - \mathbf{V_o}|$. This simply

states that friction acts to oppose the motion of the puck relative to the obstacle at the point of contact. The force of friction is then written as $\mathbf{F}(t) = F(t)\mathbf{f}$. Since $\mathbf{f}$ and $\mathbf{t}$ have the same sense, $\mathbf{f} \cdot \mathbf{t} = \pm 1$.

The sliding regime. The velocity of the puck's center of mass after the collision is

$$\mathbf{v}' = \mathbf{v} + J\,\mathbf{n} + \mu_s J\,\mathbf{f}. \tag{9}$$

In addition to this, the presence of friction will create a torque $\boldsymbol{\rho_p} \times \mathbf{F}(t)$ on the puck, which will cause a change in its angular momentum $\mathbf{L} = I\boldsymbol{\omega_p}$, where I is the moment of inertia of the puck. The final angular velocity $\boldsymbol{\omega_p'}$ is then found to be

$$\boldsymbol{\omega_p'} = \boldsymbol{\omega_p} + (1/I)(\boldsymbol{\rho_p} \times \mathbf{f})\,\mu_s J. \tag{10}$$

Together with (8), equations (9) and (10) express the final state of the puck in the sliding regime.

The rolling regime. This case differs from the sliding friction case in that the changes in the angular and tangent velocities are smaller than those predicted by (9) and (10). As mentioned above, if rolling takes hold during a collision, the force due to friction will drop discontinuously to zero. As a result, the values of J for the puck in the tangential and rotational directions in (9) and (10) will take a new value J^L, where the superscript denotes the "locking" of the bodies. To calculate J^L we recall that the onset of rolling happens when $\mathbf{V_p'} = \mathbf{V_o}$. More explicitly, using (6) and (7),

$$(\mathbf{v}' \cdot \mathbf{t})\,\mathbf{t} + \boldsymbol{\omega_p'} \times \boldsymbol{\rho_p} = \boldsymbol{\omega_o} \times \boldsymbol{\rho_o}.$$

Substituting the previous solutions (9) and (10) into this and using the identity

$$\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = \mathbf{b}\,(\mathbf{a} \cdot \mathbf{c}) - \mathbf{c}\,(\mathbf{a} \cdot \mathbf{b}),$$

we can solve for J^L,

$$J^L = \frac{m}{\mu_s}\frac{\alpha}{1+\alpha}|\mathbf{V_p} - \mathbf{V_o}|,$$

which is also positive and where $\alpha = I/(mR_p^2)$ ($\alpha = \frac{1}{2}$ for a solid disk). The final state for the case of rolling is then

$$\mathbf{v}' = \mathbf{v} + (1/m)J\,\mathbf{n} + (1/m)\mu_s J^L\,\mathbf{f}, \tag{11}$$

$$\boldsymbol{\omega_p'} = \boldsymbol{\omega_p} + (1/I)(\boldsymbol{\rho_p} \times \mathbf{f})\,\mu_s J^L, \tag{12}$$

where J is still given by (8).

Deciding between the regimes. The question of whether a set of initial conditions leads to sliding or rolling is easily addressed by considering the relative velocities $\mathbf{V_p} - \mathbf{V_o}$ (at collision) and $\mathbf{V_p'} - \mathbf{V_o}$ (after the collision, assuming the sliding case). If the relative motion of the puck at the rim has changed direction, i.e., if $(\mathbf{V_p} - \mathbf{V_o}) \cdot (\mathbf{V_p'} - \mathbf{V_o}) < 0$, then rolling must take place, and we use (11) and (12) instead of (9) and (10) for the final state of the puck. It is also possible that $\mathbf{V_p} - \mathbf{V_o} = 0$; in this case, the bodies start rolling immediately after impact, and we take the rolling case equations and set $J^L = 0$.

Acknowledgment. As we find is often the case, the referees' comments have allowed us to significantly improve the paper. In particular, one referee suggested that we not require strict convexity of the billiards.

Asymptotics of Null Lie Quadratics in E^3*

Lyle Noakes†

Abstract. *Lie quadratics* are curves in Lie algebras, arising from studies in the mid-1980s of motion planning for rigid bodies. Attention has focused on Lie quadratics in Euclidean 3-space E^3 (with cross-product as Lie bracket), especially the codimension-3 subclass of *null* Lie quadratics in E^3. The present paper substantially improves known asymptotic results for this subclass, to an extent that the new results apply to asymptotic dynamics of spherically symmetric rigid balls in classical mechanics.

Key words. Lie group, Lie quadratic, asymptotic estimate, rigid body

AMS subject classifications. Primary, 70E99, 34E05; Secondary, 70E17, 70E18, 49S05, 49N99

DOI. 10.1137/070686755

1. Introduction.

Let $so(3)$ be the real Lie algebra of skew-symmetric 3×3 real matrices with respect to the Lie bracket $[A, B] := AB - BA$. For nonzero $B_0, B_1 \in so(3)$, the linear differential equation

$$\dot{z}(t) = (B_0 + tB_1)z(t) \tag{1}$$

for $z : \mathbb{R} \to E^3$ is significant for the mechanics of spherically symmetric rigid bodies.

Example 1. *Relative to some reference frame fixed at some point in a moving rigid body, let $(z_1(t), z_2(t), z_3(t))$ be the representation at time t of a fixed positively oriented orthonormal inertial frame in E^3. Let $z(t) \in SO(3)$ be the matrix whose columns are $z_1(t), z_2(t), z_3(t)$, and set $B(t) := -\dot{z}(t)z(t)^{\mathbf{T}}$, where $^{\mathbf{T}}$ means transpose. It is easily verified that $B(t) \in so(3)$. Define a linear isomorphism $\hat{} : E^3 \to so(3)$ by*

$$\hat{v}(w) := v \times w, \tag{2}$$

where $v, w \in E^3$ and $\times$ is the cross-product. Then $B(t) = \hat{\Omega}(t)$, where $\Omega : \mathbb{R} \to E^3$ is the angular velocity in body coordinates *of the rigid body. Alternatively,*

$$\dot{z}(t) = -\hat{\Omega}(t)z(t) \iff \dot{z}_i(t) = -\Omega(t) \times z_i(t) \iff \dot{z}_i(t) = -\hat{\Omega}(t)z_i(t).$$

When Ω is an affine function of t the vectors z_i satisfy a form of (1). More detail is given in section 7 (especially section 7.1). In section 7.2 the differential equation (1) arises in another situation in mechanics.

Now E^3 is also a Lie algebra, with respect to $\times$, and $\hat{}$ is a Lie isomorphism onto $so(3)$. An inner product $\langle\ ,\ \rangle$ on $so(3)$ is defined by requiring $\hat{}$ to be an isometry.

Since $B_1 \neq \mathbf{0}$ in (1) we can set

$$t_0 := -\frac{\langle B_0, B_1\rangle}{\langle B_1, B_1\rangle}.$$

Then (1) is equivalent to $\dot{z}(t) = ((B_0 + tB_1) + (t - t_0)B_1)z(t)$. So after translation of t by $-t_0$ we can take $\langle B_0, B_1\rangle = 0$ in (1). Similarly, after dilation of t by $\|B_1\|$ we can suppose that B_1 has unit length. Then, applying an orthogonal change of coordinates to $z(t)$, we can suppose without loss of generality that

$$B_0 = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & -\sqrt{c} \\ 0 & \sqrt{c} & 0 \end{bmatrix} \quad \text{and} \quad B_1 = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{bmatrix},$$

where $c > 0$. In other words, it suffices to study the *canonical form* of (1):

$$\dot{z}(t) = B_S(t)z(t), \quad \text{where} \quad B_S(t) := \begin{bmatrix} 0 & 0 & t \\ 0 & 0 & -\sqrt{c} \\ -t & \sqrt{c} & 0 \end{bmatrix}. \tag{3}$$

From skew-symmetry of $B_S(t)$ we see that $\langle z_i(t), z_j(t)\rangle$ is conserved, for solutions z_i, z_j of (3). Let $z_1, z_2, z_3 : \mathbb{R} \to E^3$ be the solutions of (3) satisfying $z_1(0) = (1, 0, 0)$, $z_2(0) = (0, 1, 0)$, $z_3(0) = (0, 0, 1)$. Then the z_i's map into the unit 2-sphere $S^2 \subset E^3$ and are pairwise orthogonal.

Example 2. *For $c = 3$, solutions $z_i : [-10, 10] \to E^3$ are plotted in Figures 1–3, respectively. The $z_i(t)$ appear to be asymptotic to circles in S^2 as $t \to \pm\infty$. This turns out to be true, but the asymptotic circles are not those that are apparent in Figures 1–3. In section 6 these illustrations are shown to be misleading: much longer simulations are needed to display the correct asymptotics.*

Proposition 1. *The general solution of (3) is*

$$z(t) = \frac{1}{\sqrt{c}}\begin{bmatrix} y(t) - t\dot{y}(t) & \sqrt{c}\dot{y}(t) & -\ddot{y}(t) \end{bmatrix}^{\mathbf{T}},$$

where $y : \mathbb{R} \to \mathbb{R}$ is the general solution of

$$y^{(3)}(t) = ty(t) - (t^2 + c)\dot{y}(t). \tag{4}$$

Proof. Differentiate z as given, and verify (3). ∎

Although we have superposition of solutions of linear ODEs (and not for nonlinear), a very interesting feature of (1) and (4) is that these *linear* ODEs can be effectively studied (and asymptotic solutions found) using *quadratic* ODEs (5) and (6). This is done as follows.

- In section 2, elements y_i of a basis of solutions of (4) are shown to satisfy a second order quadratic ODE (5). This nonlinear ODE is then used to prove local properties of the y_i, such as $\dot{y}_i(t) \neq 0$ for $|y_i(t)|$ large (Lemma 2).

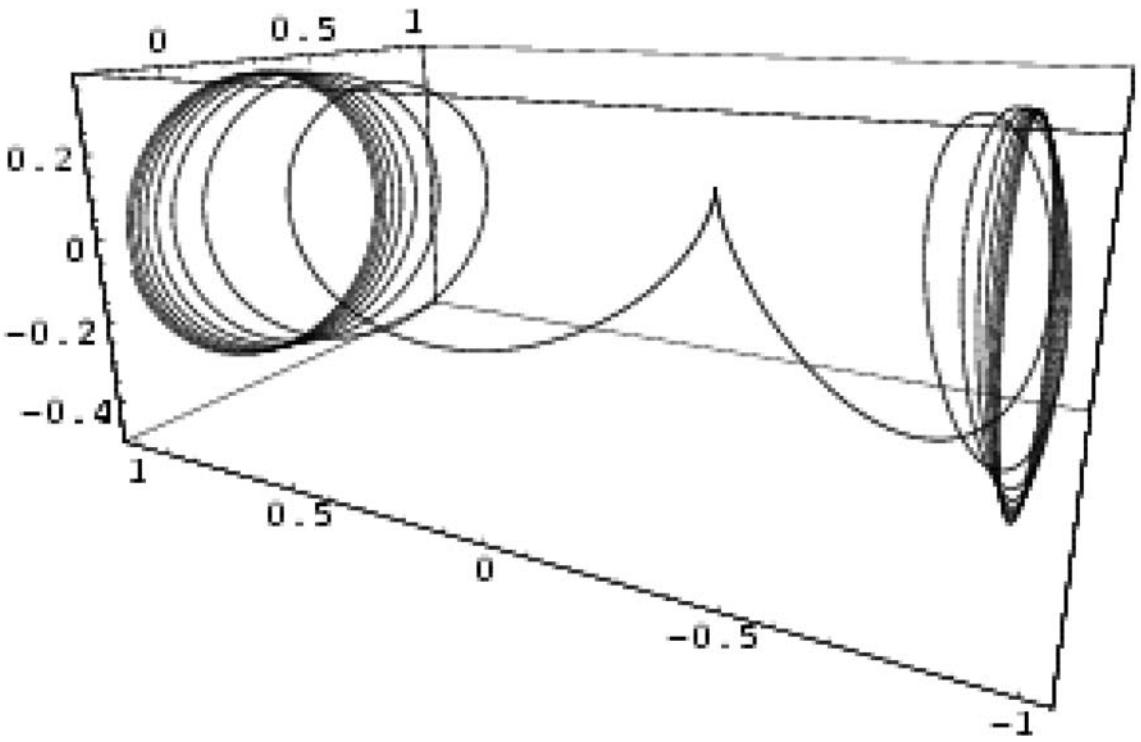

Figure 1. $z_1 : [-10, 10] \to E^3$ *with* $z_1(0) = (1, 0, 0)$ *in Example* 2.

- In section 3 background is given for the theory of Lie quadratics. Lemma 6 shows that the y_i are components of a solution (a *canonical null Lie quadratic* in E^3) of the quadratic ODE (6). All other solutions of (6) can be found from the canonical null Lie quadratic. Section 4 reviews and sharpens results of [12] on asymptotics of null Lie quadratics V in E^3. In particular, $V(t), \dot{V}(t), \ddot{V}(t)$ are estimated with errors $O(t^{-2}), O(t^{-1}), O(1)$ for $|t|$ large, corresponding (by Proposition 2) to $O(1)$ errors in estimates of solutions z_i of (3).
- We seek improved estimates of the $z_i(t)$, with only $O(t^{-1})$ errors. The improvements are significant because (3) describes dynamics of homogeneous rigid balls in simple situations (sections 7.1, 7.2), and a matrix with columns z_i is a *canonical null Riemannian cubic* in $SO(3)$ (section 7.3). Riemannian cubics are examples of higher order geodesics, used for interpolation in Riemannian manifolds. To improve the estimates of the z_i, we first find $O(t^{-3}), O(t^{-2}), O(t^{-1})$-accurate asymptotics for $V(t), \dot{V}(t), \ddot{V}(t)$ (Theorems 3, 2, 1, respectively, of section 5). New asymptotic axes $\beta_\pm$ appear in Theorem 1, after manipulations of inequalities and identities from section 4. Theorem 1 is then used to prove Theorems 2 and 3, using similar methods. This substantially improves our understanding of $V, \dot{V}, \ddot{V}$ for moderate values of t, as illustrated in Example 5.
- In section 6, the improved estimates for canonical null Lie quadratics are reexamined and applied to give $O(t^{-1})$-accurate asymptotic estimates (Theorem 4) for solutions z

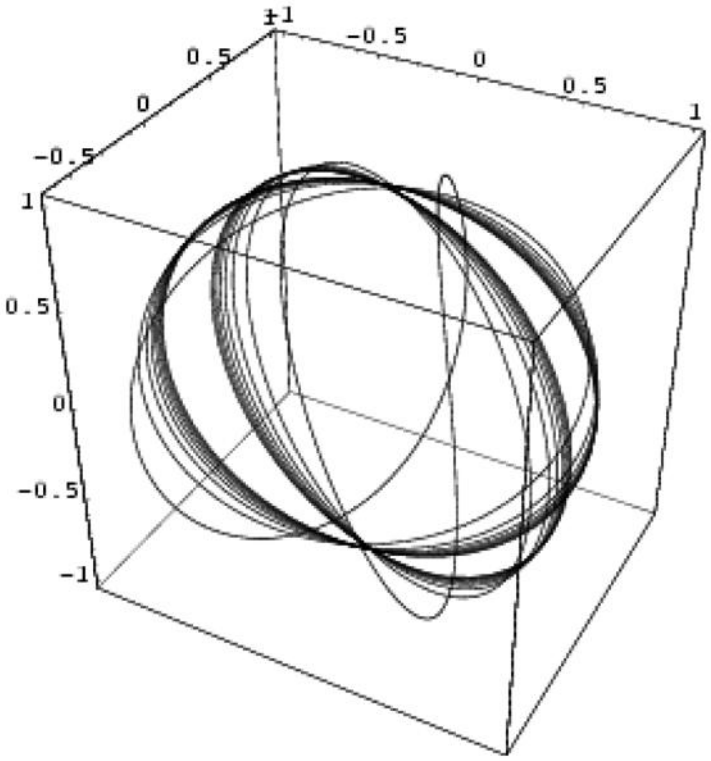

Figure 2. $z_2 : [-10, 10] \to E^3$ *with* $z_2(0) = (0, 1, 0)$ *in Example* 2.

of (3) (canonical null Riemannian cubics).

- The z_i are shown to be asymptotic to parallel pairs of circles for $i = 1, 3$, and to a single circle for $i = 2$ (Corollary 8), contradicting the apparent appearance of asymptotes in Figures 1–3 of Example 2. Simulations of $z_i(t)$ for much larger values of t confirm that the medium-term behavior is characterized by gradual shifting of apparent circular asymptotes into configurations conforming to Corollary 8.
- Section 7 discusses applications to path-planning for spherically symmetric balls.

2. The ODE (4). For $i = 1, 2, 3$ let $y_i : \mathbb{R} \to \mathbb{R}$ be the solutions of (4) corresponding by Proposition 1 to the z_i. Then

$$\begin{aligned} y_1(0) &= \sqrt{c}, \quad \dot{y}_1(0) = 0, \quad \ddot{y}_1(0) = 0, \\ y_2(0) &= 0, \quad \dot{y}_2(0) = 1, \quad \ddot{y}_2(0) = 0, \\ y_3(0) &= 0, \quad \dot{y}_3(0) = 0, \quad \ddot{y}_3(0) = -\sqrt{c}. \end{aligned}$$

From (4), y_1 and y_3 are even functions, and y_2 is odd.

Example 3. *For $c = 3$, we plot y_1, y_2, y_3 in Figures 4, 5, 6, respectively. Figure 4 resembles a parabola with a flattened base, but y_1 is not so bland as might be thought: Figure 7 shows that $\dot{y}_1$ is very convoluted. In Figure 5, y_2 also appears oscillatory with dampening as $|t|$ increases (owing to numerical error, y_2 is shown not (quite) odd). Except that it is an even function, y_3 in Figure 6 has something of the appearance of y_2.*

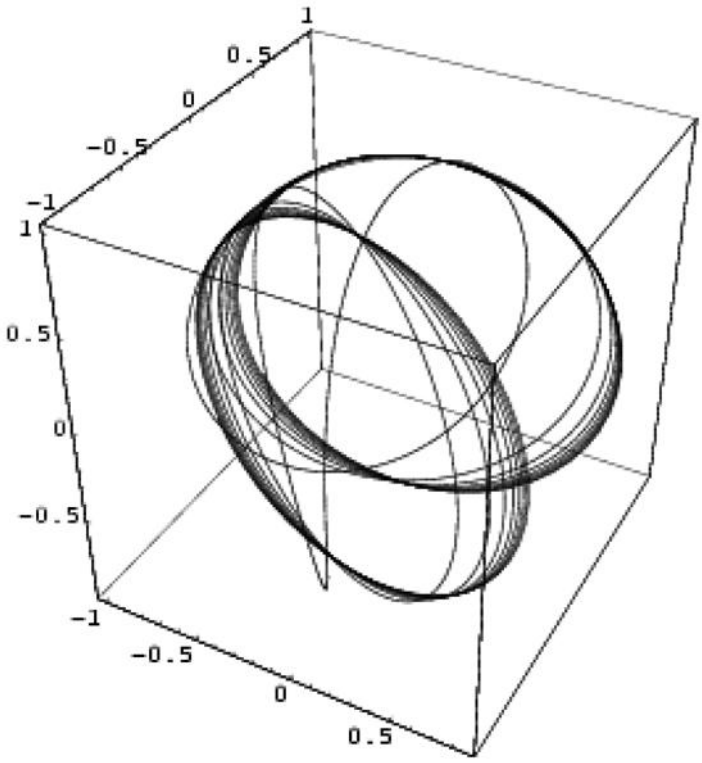

Figure 3. $z_3 : [-10, 10] \to E^3$ *with* $z_3(0) = (0, 0, 1)$ *in Example 2.*

Because $\langle z_i(t), z_j(t)\rangle$ is conserved, Proposition 1 gives the following result.

Lemma 1. *For* $i, j = 1, 2, 3$,

$$\ddot{y}_i\ddot{y}_j + c\dot{y}_i\dot{y}_j + (y_i - t\dot{y}_i)(y_j - t\dot{y}_j) = c\delta_{ij},$$

where δ_{ij} *is Kronecker's delta.*

In particular, any y_i satisfies

$$\ddot{y}^2 + c\dot{y}^2 + (y - t\dot{y})^2 = c. \tag{5}$$

For any solution y of (5) and all $t \in \mathbb{R}$

$$\begin{aligned}(t^2 + c)\dot{y}^2 - 2t\dot{y}y + y^2 &\le c,\\ c\dot{y}^2 + \ddot{y}^2 &\le c,\\ cy^2 + (t^2 + c)\ddot{y}^2 &\le c(t^2 + c),\end{aligned}$$

where the last inequality says that the discriminant of (5) as a quadratic in $\dot{y}$ is nonnegative. Also from (5), we have the following result.

Lemma 2. *For any solution* y *of* (5) *and any* $t \in \mathbb{R}$, *if* $\dot{y}(t) = 0$, *then* $y(t)^2 + \ddot{y}(t)^2 = c$.

Notice that $y(t) = \sqrt{c}$ satisfies (5), with $y(0) = \sqrt{c}$, $\dot{y}(0) = 0$. Also $y(t) = t$ satisfies (5), with $y(0) = 0$, $\dot{y}(0) = 1$. However, (5) has other solutions satisfying these initial conditions.

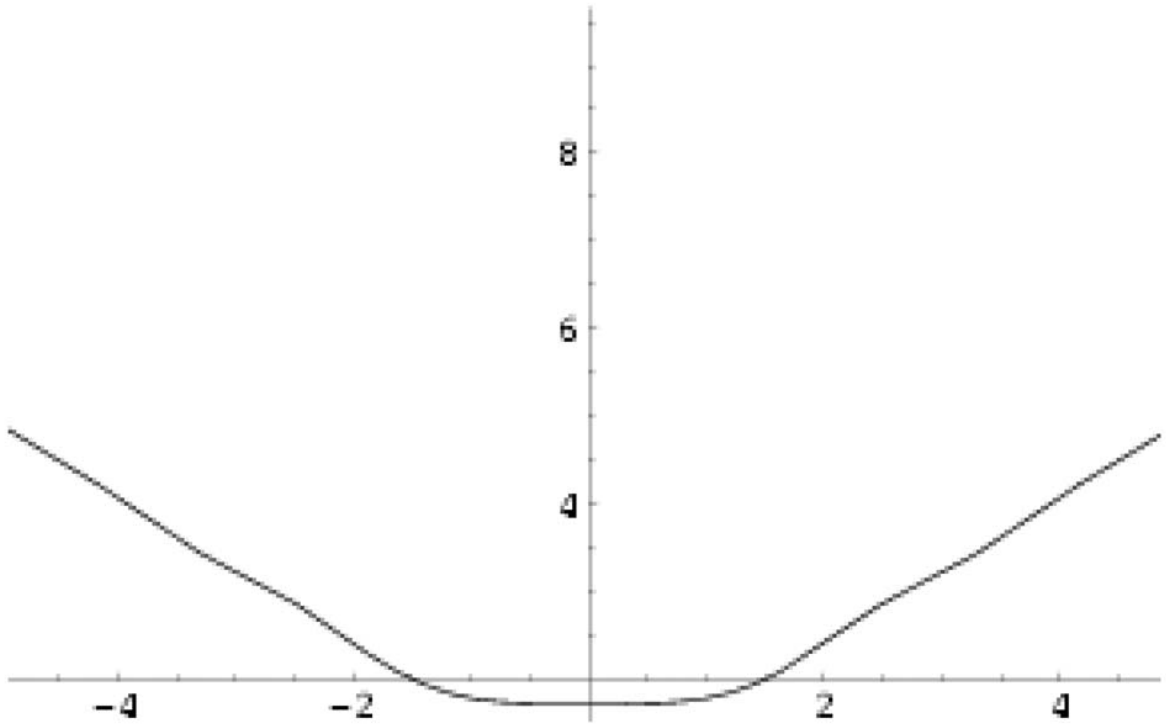

Figure 4. $y_1(0) = \sqrt{3}$, $\dot{y}_1(0) = 0$, $\ddot{y}_1(0) = 0$ *in Example* 3.

Lemma 3. $\dot{y}_1(t) > 0$ *for* $t > 0$.

Proof. We have $y_1^{(3)}(0) = 0$ and $y_1^{(4)}(0) = \sqrt{c} > 0$. So by Taylor's theorem, $\dot{y}_1(t) > 0$ for small $t > 0$. If the lemma does not hold, let t_0 be the supremum of the nonempty bounded

$$T := \{t_1 \in \mathbb{R} : \dot{y}_1(t) > 0 \ \text{ for all } t \in (0, t_1)\}.$$

Then $\dot{y}_1(t_0) = 0$ by continuity of $\dot{y}_1$. By Lemma 2, $\ddot{y}_1(t_0)^2 + y_1(t_0)^2 = c$. Now $t_0 > 0$ and therefore $y_1(t_0) > \sqrt{c}$, since y_1 is strictly increasing on $(0, t_0)$. So

$$c < y_1(t_0)^2 \leq \ddot{y}_1(t_0)^2 + y_1(t_0)^2 = c,$$

and the contradiction completes the proof. ■

From Lemma 3 the following result follows.

Proposition 2. y_1 *is an even function, strictly decreasing on* $(-\infty, 0)$, *strictly increasing on* $(0, \infty)$, *with a single point of global minimum at* $t = 0$ *and no other critical points.*

Lemma 4. *Any solution* y *of* (4) *satisfies*

$$\frac{d}{dt}\left(\ddot{y}y - \frac{1}{2}\dot{y}^2 + \frac{1}{2}(t^2 + c)y^2\right) = 2ty^2.$$

Proof. The left-hand side expands as

$$y^{(3)}y + ty^2 + (t^2 + c)\dot{y}y = y(y^{(3)} - ty + (t^2 + c)\dot{y}) + 2ty^2 = 2ty^2 \qquad \text{by (4)}. \quad ■$$

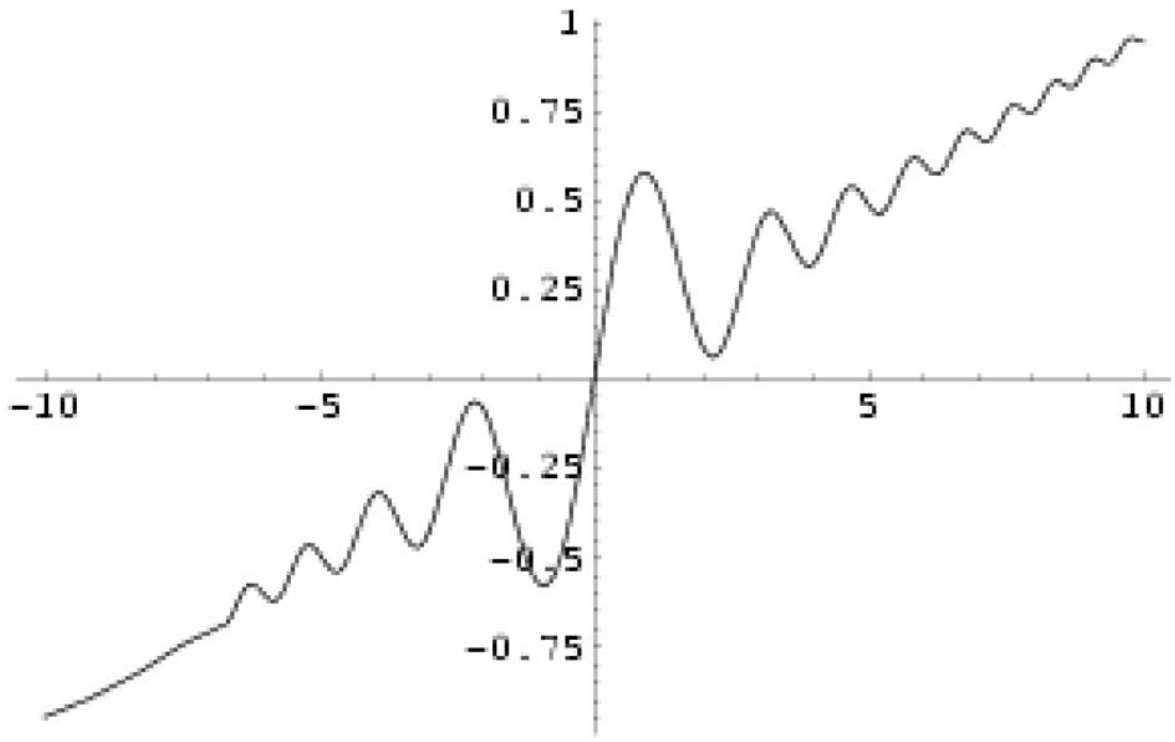

Figure 5. $y_2(0) = 0$, $\dot{y}_2(0) = 1$, $\ddot{y}_2(0) = 0$ *in Example* 3.

Proposition 3. *y_3 is an even function, strictly increasing on $(-\delta, 0)$ for some $\delta > 0$ and strictly decreasing on $(0, \delta)$. Also $y_3(0) = \dot{y}_3(0) = 0$, and $y_3(t) < 0$ for all $t \neq 0$.*

Proof. Because $c > 0$ and by Taylor's theorem, $\dot{y}_3(t) < 0$ for small $t > 0$. Assuming $y_3(t) \geq 0$ for some $t > 0$, let t_0 be the supremum of the nonempty bounded set

$$T := \{t_1 \in \mathbb{R} : y_3(t) < 0 \ \text{ for all } t \in (0, t_1)\}.$$

By continuity, $y_3(t_0) = 0$. By Lemma 4,

$$f(t) := \ddot{y}_3 y_3 - \frac{1}{2}\dot{y}_3^2 + \frac{1}{2}(t^2 + c)y_3^2$$

is strictly increasing on $(0, t_0)$, since y_3 is nowhere-zero on $(0, t_0)$. So

$$0 = f(0) < f(t_0) = -\frac{1}{2}\dot{y}_3(t_0)^2 \leq 0,$$

and the contradiction proves $y_3(t) < 0$ for $t > 0$. Because y_3 is even, this holds for all $t \neq 0$. ∎

Proposition 4. *Solutions of (4), (5) satisfy $\frac{d}{dt}(\ddot{y}\dot{y} - \frac{3t}{2}y^2 - ct) = -2(t^2 + c)\dot{y}^2 - \frac{5}{2}y^2$.*

Proof. Expanding the left-hand side gives $y^{(3)}\dot{y} + \ddot{y}^2 - 3t\dot{y}y - \frac{3}{2}y^2 - c$. Substituting for $\ddot{y}^2$ using (5), then for $y^{(3)}$ using (4), we obtain

$$\dot{y}(y^{(3)} - ty + (t^2 + c)\dot{y}) - 2(t^2 + c)\dot{y}^2 - \frac{5}{2}y^2 = -2(t^2 + c)\dot{y}^2 - \frac{5}{2}y^2. \qquad \blacksquare$$

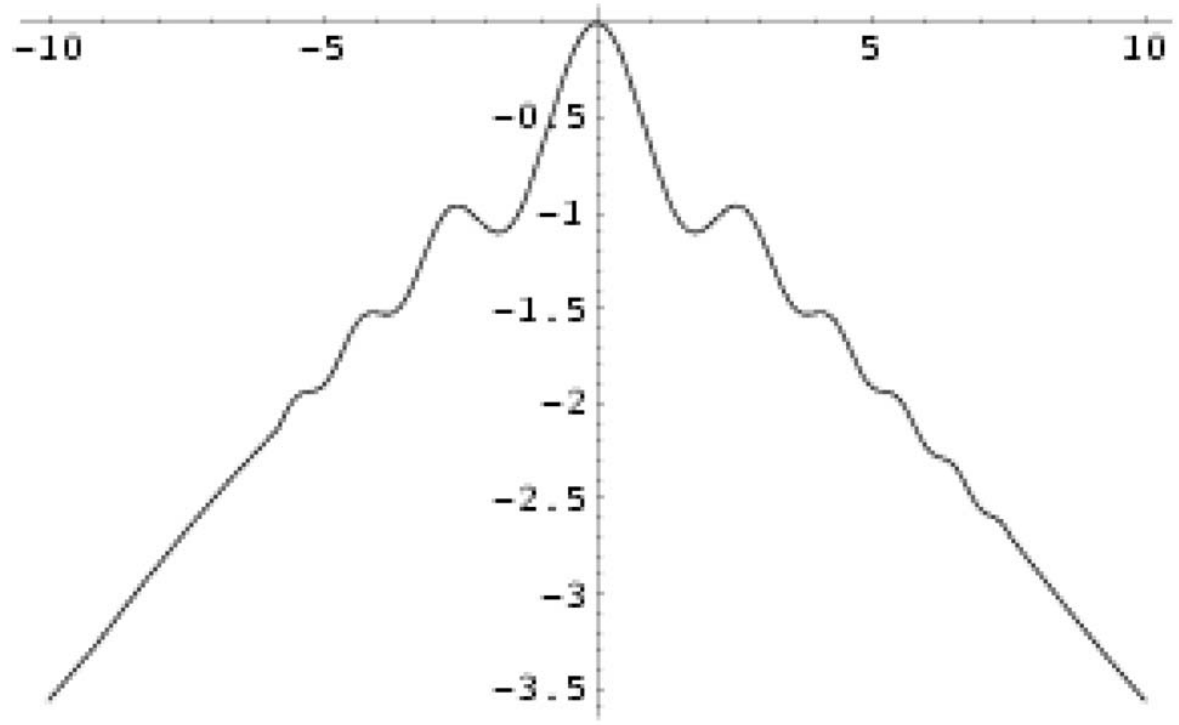

Figure 6. $y_3(0) = 0$, $\dot{y}_1(0) = 0$, $\ddot{y}_1(0) = -\sqrt{3}$ *in Example* 3.

3. Null Lie quadratics. The matrix valued function

$$x(t) := \begin{bmatrix} z_1(t) & z_2(t) & z_3(t) \end{bmatrix} \in SO(3)$$

also satisfies (3), and $x(0)$ is the identity matrix $\mathbf{1}$. Building on Definition 2, define $V : \mathbb{R} \to E^3$ by

$$\hat{V}(t) := x(t)^{-1}\dot{x}(t).$$

Lemma 5.

$$\ddot{V}(t) = \dot{V}(t) \times V(t). \tag{6}$$

Proof. By direct calculation, $\ddot{\hat{V}} = [\dot{\hat{V}}, \hat{V}]$. Also $\hat{}$ is a Lie isomorphism. ■

Curves V satisfying equations like (6) in other Lie algebras, and related curves x in Lie groups other than $SO(3)$, have been studied elsewhere.

Definition 1.

- *A smooth curve $V : \mathbb{R} \to \mathcal{G}$ in a real Lie algebra $\mathcal{G}$ is a* Lie quadratic *when*

$$\ddot{V}(t) = [\dot{V}(t), V(t)] + C$$

for some $C \in \mathcal{G}$. When $C = \mathbf{0}$ the Lie quadratic V is said to be null.

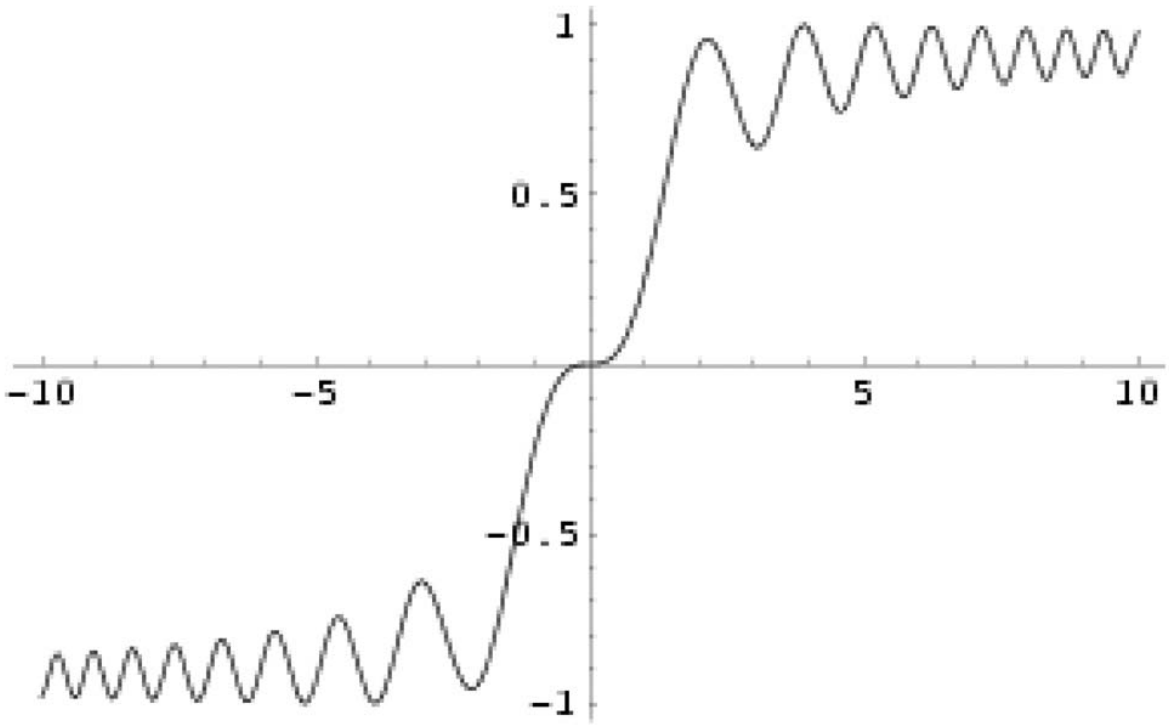

Figure 7. $\dot{y}_1$ *in Example* 3.

- *A* Riemannian cubic[1] *in a Lie group* G *is a smooth curve* $x : \mathbb{R} \to G$ *satisfying*

$$\dot{x}(t) = dL(x(t))_e V(t), \tag{7}$$

where $L(x(t))$ *is left-multiplication by* $x(t)$, $e \in G$ *is the identity, and* V *is a Lie quadratic in the Lie algebra* $\mathcal{G}$ *of* G. *The Riemannian cubic* x *is said to be* null *when* V *is a null Lie quadratic.*

By Lemma 5, our V is a null Lie quadratic in Euclidean 3-space E^3. Then, since $\hat{}$ is a Lie isomorphism, and from the definition of $V : \mathbb{R} \to E^3$, our x is a *null Riemannian cubic* in $SO(3)$. In [12] the study of null Lie quadratics is reduced to null Lie quadratics that are *canonical* in the following[2] sense.

Definition 2. *A null Lie quadratic* V *is said to be* canonical *when, for some* $c \geq 0$, $V(0) = (\sqrt{c}, 0, 0)^{\mathbf{T}}$ *and* $\dot{V}(0) = (0, 1, 0)^{\mathbf{T}}$.

Thus our V is also *canonical*. The formula for x in terms of V, given by Proposition 1, can also be obtained from [14, Theorem 5] or [15, Corollary 3.2]. An introduction to Riemannian cubics and Lie quadratics can be found in [12], where Proposition 3 says that any nonconstant

[1] In section 7.3, Riemannian cubics are defined differently, as curves in Riemannian (or even semi-Riemannian) manifolds M. The definitions are equivalent when M is a Lie group with bi-invariant Riemannian metric.

[2] Definition 2 is more restrictive than Definition 1 in [12], where it is required only that $\|V(0)\| = \sqrt{c}$ and $\|\dot{V}(0)\| = 1$.

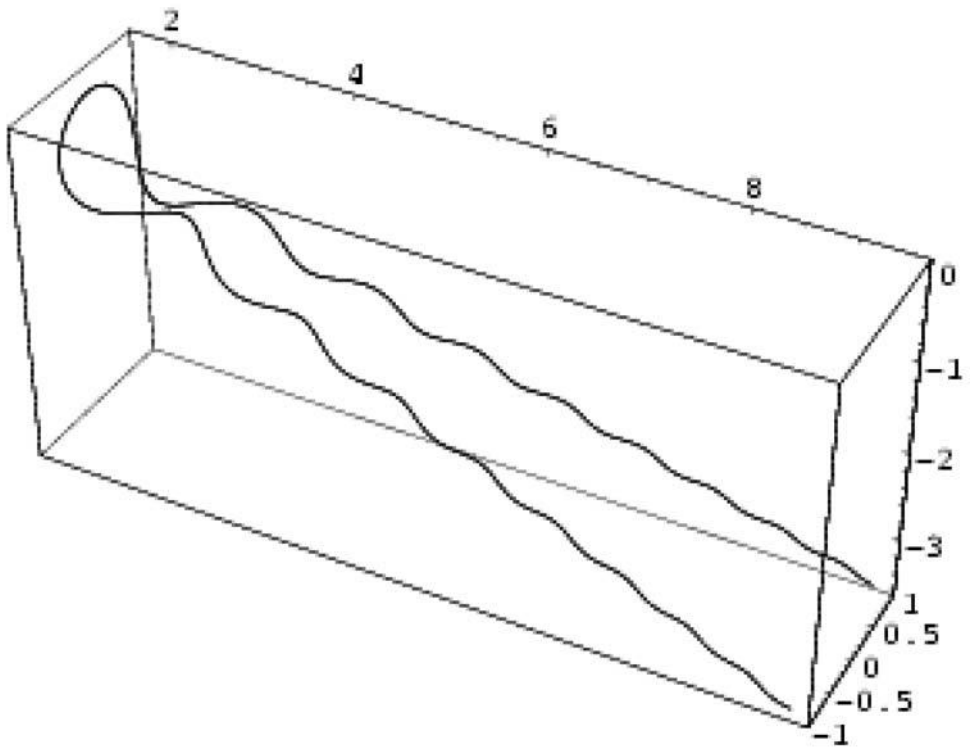

Figure 8. *The canonical null Lie quadratic V in E^3 with $c = 3$.*

null Lie quadratic can be written in terms of a canonical null Lie quadratic in the sense of [12]. The same symmetry argument proves the stronger statement where "canonical" has the meaning of Definition 2. Also in [12], canonical null Lie quadratics V in E^3 are shown to have

- constant curvature $\kappa(t) = \sqrt{c}$, and
- linear torsion $\tau(t) = -t$.

Example 4. *Figure 8 shows the canonical null Lie quadratic V with $c = 3$. The illustration certainly does not suggest constant curvature, and the illusion is accounted for by linearly varying torsion. Non-null Lie quadratics, mentioned briefly in section 7.3 (but nowhere else in the present paper), have much richer geometry [13].*

In [12] a canonical null Lie quadratic V is shown to satisfy

$$\langle V(t), V(t)\rangle = f(t)^2, \tag{8}$$

$$\langle \dot{V}(t), \dot{V}(t)\rangle = 1, \tag{9}$$

$$\langle \ddot{V}(t), \ddot{V}(t)\rangle = c, \tag{10}$$

where $f(t) := \sqrt{t^2 + c}$.

Lemma 6. $V(t) = \begin{bmatrix} y_1(t) & y_2(t) & y_3(t) \end{bmatrix}^{\mathbf{T}}$.

Proof. Differentiating the ODE in Lemma 5,

$$V^{(3)} = \ddot{V} \times V = (\dot{V} \times V) \times V = \langle \dot{V}, V\rangle V - \langle V, V\rangle \dot{V},$$

where we use the identity

$$(u \times v) \times w = \langle u, w\rangle v - \langle v, w\rangle u \quad \text{for} \quad u, v, w \in E^3. \tag{11}$$

Differentiating (8), we find $\langle \dot{V}(t), V(t)\rangle = t$. Then from (8), the components of V satisfy (4), as do the y_i. Because $V(0) = (\sqrt{c}, 0, 0)^{\mathbf{T}}$, $\dot{V}(0) = (0, 1, 0)^{\mathbf{T}}$, we have $\ddot{V}(0) = (0, 0, -\sqrt{c})^{\mathbf{T}}$. So the components of V also satisfy the initial conditions for the y_i. ■

From (8), (9), Lemma 6, and Proposition 2 we obtain the following results.

Corollary 1. *For all $t \neq 0$, $y_2(t)^2 + y_3(t)^2 < t^2$ and $\dot{y}_2(t)^2 + \dot{y}_3(t)^2 < 1$.*

Corollary 2.[3] *Let $I \subseteq \mathbb{R}$ be a nonempty open interval. Any $V : I \to E^3$ satisfying $\ddot{V} = \dot{V} \times V$ extends to a unique null Lie quadratic in E^3 defined over the whole of $\mathbb{R}$.*

Proof. As in the proof of Lemma 6, the components y_i of V are solutions of the linear ODE (4) and therefore uniquely extendible. ■

The next section reviews and sharpens some results of [12] on asymptotic properties of canonical null Lie quadratics in E^3.

4. Primary asymptotics of canonical null Lie quadratics in E^3. Notice $f\dot{f} = t$ and $\dot{f}^2 + f\ddot{f} = 1$. Thus $\ddot{f} = c/f^3$. Define $U(t) := V(t)/f(t) \in S^2$. First we have the existence of asymptotes, as follows.

Proposition 5 (see [12]). *Let V be a canonical null Lie quadratic in E^3 with $c > 0$. There exist limits*

$$\alpha_+ := \lim_{t\to\infty} U(t) \quad \textit{and} \quad \alpha_- := \lim_{t\to-\infty} U(t).$$

Unfortunately no simple formula is known giving $\alpha_\pm \in S^2$ in terms of c. However, a number of inequalities for asymptotes can be proved. Let $\rho : E^3 \to E^3$ be reflection in the hyperplane orthogonal to the second coordinate axis. Then it is known from [12] that $\alpha_- = \rho(\alpha_+)$. From Lemma 6 and Proposition 2 we find the following.

Corollary 3. $\langle \alpha_\pm, V(0)\rangle \geq 0$.

From Lemma 6 and Proposition 3 we have the next three corollaries.

Corollary 4. $\langle \alpha_\pm, \ddot{V}(0)\rangle \geq 0$.

Corollary 5. *For all $t \neq 0$, $y_1(t)^2 + y_2(t)^2 < t^2 + c$.*

Corollary 6. *For all $t \neq 0$, $-|t| < y_3(t) < 0$. If $\dot{y}_3(t) = 0$, then $y_3(t) \geq -\sqrt{c}$.*

Proof of Corollary 6. Suppose $t \neq 0$. By Corollary 1, $y_3(t)^2 < t^2$. By Proposition 3, $y_3(t) < 0$. Lemma 2 completes the proof. ■

Set $\tilde{V}(t) := V(t) + \frac{1}{f(t)^2}\ddot{V}(t)$ and $\tilde{U}(t) := \frac{f(t)^2}{\sqrt{f(t)^6+c}}\tilde{V}(t) \in S^2$. In [12] the identity

$$\frac{d}{dt}\left(U(t) + \frac{\ddot{V}(t)}{f(t)^3}\right) = -\frac{3t\ddot{V}(t)}{f(t)^5} \tag{12}$$

is used to prove the next proposition.

Proposition 6 (see [12]). *For $t \geq 0$ and $t \leq 0$, respectively,*

$$\|\tilde{V}(t) - f(t)\,\alpha_\pm\| \leq \frac{\sqrt{c}}{f(t)^2}.$$

[3] Similar results are proved in [13] for non-null Lie quadratics.

In particular, by (10), $\|V(t) - f(t)\,\alpha_\pm\| \le \frac{2\sqrt{c}}{f(t)^2}$.

Corollary 7.

$$\|\alpha_\pm - \tilde{U}(0)\| \le \frac{\sqrt{2}}{\sqrt{\sqrt{c^2+1}(\sqrt{c^2+1}+c)}} < \frac{1}{c}.$$

Proof. Squaring both sides of $\|V(0) + \frac{1}{c}\ddot{V}(0) - \sqrt{c}\alpha_\pm\| \le \frac{1}{\sqrt{c}}$ and expanding the left,

$$c + \frac{1}{c} + c - 2\sqrt{c}\langle\alpha_\pm, V(0)\rangle - \frac{2}{\sqrt{c}}\langle\alpha_\pm, \ddot{V}(0)\rangle \le \frac{1}{c},$$

namely, $\langle\alpha_\pm, \tilde{V}(0)\rangle \ge \sqrt{c}$. Since $\|\tilde{V}(0)\| = \frac{\sqrt{c^2+1}}{\sqrt{c}}$, $\langle\alpha_\pm, \tilde{U}(0)\rangle \ge \frac{c}{\sqrt{c^2+1}}$. So

$$\|\alpha_\pm - \tilde{U}(0)\|^2 = 2 - 2\langle\alpha_\pm, \tilde{U}(0)\rangle \le 2\frac{\sqrt{c^2+1}-c}{\sqrt{c^2+1}} = \frac{2}{\sqrt{c^2+1}(\sqrt{c^2+1}+c)}. \qquad \blacksquare$$

In effect, Proposition 6 calculates $V(t)$ as $f(t)\alpha_\pm + O(\frac{1}{f(t)^2})$ as $t \to \pm\infty$. This asymptotic estimate is significantly improved in section 5 below. In section 6, the improved accuracy translates into useful asymptotics for solutions z of (3).

5. Secondary asymptotics. Before estimating $V, \dot{V}, \ddot{V}$ we try to relate these as closely as possible to the asymptotes $\alpha_\pm$.

Lemma 7. *For $t \ge 0$ and $t \le 0$, respectively,* $|\langle\alpha_\pm, \ddot{V}(t)\rangle| \le \frac{2c}{f(t)^3}$.

Proof. By Proposition 6, $\|\frac{\tilde{V}(t)}{f(t)} - \alpha_\pm\| \le \frac{\sqrt{c}}{f(t)^3}$. So by the Cauchy–Schwarz inequality and (10),

$$\left|\langle\ddot{V}, \alpha_\pm\rangle - \frac{\langle\ddot{V}, \tilde{V}\rangle}{f}\right| \le \frac{c}{f^3}.$$

But by (10) and Lemma 5, $\langle\ddot{V}, \tilde{V}\rangle = \frac{c}{f^2}$. $\blacksquare$

Lemma 8. *For $t \ge 0$ and $t \le 0$, respectively,*

$$-\frac{3c}{f(t)^5} \le \langle\alpha_\pm, V(t)\rangle - f(t) \le 0.$$

Proof. Taking inner products of (12) with α_+ and integrating both sides from $s > 0$ to ∞,

$$1 - \langle U(s), \alpha_+\rangle - \frac{\langle\ddot{V}(s), \alpha_+\rangle}{f(s)^3} = -\int_s^\infty \frac{3t\langle\ddot{V}(t), \alpha_+\rangle}{(t^2+c)^{5/2}}dt.$$

So by Lemma 7, $1 - \langle U(s), \alpha_+\rangle \le \frac{2c}{f(s)^6} + \int_s^\infty \frac{6ct}{(t^2+c)^4}dt = \frac{3c}{f(s)^6}$. Replacing s by t and multiplying through by $f(t)$, the left-hand inequality holds for $t \ge 0$ and α_+. The other inequality follows from the Cauchy–Schwarz inequality. The proof for $t \le 0$ and α_- is similar. $\blacksquare$

Lemma 9. *For $t \ge 0$ and $t \le 0$, respectively,* $|\langle\alpha_\pm, \ddot{V}(t) \times V(t)\rangle| \le \frac{2c}{f(t)^2}$.

Proof. $\langle\alpha_\pm, \ddot{V}(t) \times V(t)\rangle = -\langle\alpha_\pm \times V(t), \ddot{V}(t)\rangle$. So the lemma follows from Proposition 6, the Cauchy–Schwarz inequality, and (10). $\blacksquare$

The restrictions $\hat{\alpha}'_\pm$ of $\hat{\alpha}_\pm$ to

$$H_\pm := \alpha_\pm^\perp := \{v \in E^3 : \langle v, \alpha_\pm\rangle = 0\}$$

are orthogonal endomorphisms. By (11), $\hat{\alpha}'_\pm$ is skew-adjoint, and $(\hat{\alpha}'_\pm)^2$ is multiplication by -1. Thus $\hat{\alpha}'_\pm$ defines a complex structure on $H_\pm$. As before, let $\rho : E^3 \to E^3$ be reflection in the hyperplane orthogonal to $\dot{V}(0) = (0,1,0)^{\mathbf{T}}$.

Lemma 10. *$\rho(H_+) = H_-$ and $\rho \circ \hat{\alpha}'_+ = -\hat{\alpha}'_- \circ \rho$.*

Proof. Because ρ is orthogonal and $\rho(\alpha_+) = \alpha_-$, we have for $v \in H_+$

$$0 = \langle v, \alpha_+\rangle = \langle \rho(v), \rho(\alpha_+)\rangle = \langle \rho(v), \alpha_-\rangle,$$

namely $\rho(v) \in H_-$. Because ρ is a reflection,

$$\rho \circ \hat{\alpha}'_+(v) = \rho(\alpha_+ \times v) = -(\rho(\alpha_+) \times \rho(v)) = -\alpha_- \times \rho(v). \qquad \blacksquare$$

The following function is needed to describe the asymptotics of $V, \dot{V}, \ddot{V}$.

Definition 3. $g(t) := \frac{1}{2}(|t|f(t) + c\ln(|t| + f(t)) - (c/2)\ln c)$.

Now Lemmas 7–9 are used to give an asymptotic estimate for $\ddot{V}$.

Theorem 1. *For $t \geq 0$ and $t \leq 0$, respectively, and some unit vector $\beta_\pm \in H_\pm$,*

$$\ddot{V}(t) = \sqrt{c}\exp(\mp g(t)\hat{\alpha}'_\pm)\beta_\pm + O\left(\frac{1}{f(t)}\right),$$

where $\beta_- = \rho(\beta_+)$.

Proof. By Lemma 7, $Z_\pm(t) := \ddot{V}(t) - \langle \ddot{V}(t), \alpha_\pm\rangle\alpha_\pm = \ddot{V}(t) + O(\frac{1}{f(t)^3})\alpha_\pm$ and

$$\langle Z_\pm(t), Z_\pm(t)\rangle = c - \langle \ddot{V}, \alpha_\pm\rangle^2 = c + O\left(\frac{1}{f(t)^6}\right). \tag{13}$$

Differentiating the equation in Lemma 5, $V^{(3)} = \ddot{V} \times V$, and so

$$\dot{Z}_\pm(t) = \ddot{V} \times V - \langle \ddot{V} \times V, \alpha_\pm\rangle\alpha_\pm.$$

So by Lemmas 5 and 9,

$$\begin{aligned}\langle \dot{Z}_\pm(t), \dot{Z}_\pm(t)\rangle &= \|\ddot{V} \times V\|^2 - \langle \ddot{V} \times V, \alpha_\pm\rangle^2 = cf(t)^2 - \langle \ddot{V}, \alpha_\pm \times V\rangle^2 \\ &= cf(t)^2 + O\left(\frac{1}{f(t)^4}\right). \end{aligned} \tag{14}$$

Notice that $Z_\pm(t) \in H_\pm$. By Lemmas 5 and 8,

$$\begin{aligned}\langle \dot{Z}_\pm(t), \hat{\alpha}'_\pm \circ Z_\pm(t)\rangle &= \langle \ddot{V} \times V, \alpha_\pm \times \ddot{V}\rangle = -\langle V, \alpha_\pm\rangle\langle \ddot{V}, \ddot{V}\rangle \\ &= -cf(t) + O\left(\frac{1}{f(t)^5}\right). \end{aligned} \tag{15}$$

Setting $W_\pm(t) := \dot{Z}_\pm(t) + f(t)\hat{\alpha}'_\pm \circ Z_\pm(t)$,

$$\langle W_\pm, W_\pm\rangle = \langle \dot{Z}_\pm, \dot{Z}_\pm\rangle + f^2\langle Z_\pm, Z_\pm\rangle + 2f\langle \dot{Z}_\pm, \hat{\alpha}'_\pm \circ Z_\pm\rangle = O\left(\frac{1}{f^4}\right)$$

by (13), (14), (15). So $\dot{Z}_\pm(t) + f(t)\hat{\alpha}'_\pm \circ Z_\pm(t) = W_\pm(t) = O(\frac{1}{f(t)^2})$. Since $\dot{g}(t) = f(t)$ for $t > 0$ we have, for $0 < r < s$,

$$\text{(16)}\quad \exp(g(s)\hat{\alpha}'_+)Z_+(s) - \exp(g(r)\hat{\alpha}'_+)Z_+(r) = \int_r^s \exp(g(t)\hat{\alpha}'_+)W_+(t)dt = O\left(\frac{1}{f(r)} - \frac{1}{f(s)}\right).$$

Let $\beta_+ \in H_+$ be the limit of a convergent subsequence $\{\beta_{i_j} : j \geq 1\}$ of the bounded

$$\left\{\frac{\exp(g(i)\hat{\alpha}'_+)Z_+(i)}{\sqrt{c}} : i \geq 1\right\}.$$

By (16), $\exp(g(r)\hat{\alpha}'_+)Z_+(r) = \sqrt{c}\beta_{i_j} + O(\frac{1}{f(r)})$. Taking limits as $j \to \infty$,

$$\ddot{V}(r) = Z_+(r) + O\left(\frac{1}{f(r)^3}\right)\alpha_+ = \sqrt{c}\exp(-g(r)\hat{\alpha}'_+)\beta_+ + O\left(\frac{1}{f(r)}\right),$$

proving the result for $t \geq 0$ and β_+. A symmetry argument completes the proof. ■

Now, using the asymptotic estimate for $\ddot{V}$, we are able to estimate $\dot{V}$ and V.

Theorem 2. *For $t \geq 0$ and $t \leq 0$, respectively, we have*

$$\dot{V}(t) = \frac{t}{f}\alpha_\pm + \frac{\sqrt{c}}{f}\hat{\alpha}'_\pm \exp(\mp g(t)\hat{\alpha}'_\pm)\beta_\pm + O\left(\frac{1}{f^2}\right).$$

Proof. By symmetry it suffices to consider $t \geq 0$ and β_+. By Lemma 5 and (11),

$$\ddot{V} \times V = (\dot{V} \times V) \times V = \langle \dot{V}, V\rangle V - \langle V, V\rangle \dot{V} = tV - f^2\dot{V},$$

namely $\dot{V}(t) = \frac{tV(t) - \ddot{V}(t)\times V(t)}{f(t)^2}$. So by Proposition 6, for $t \geq 0$,

$$\dot{V}(t) = \frac{tf(t)\alpha_+ - f\ddot{V}(t) \times \alpha_+}{f^2} + O\left(\frac{1}{f^3}\right)$$
$$= \frac{t}{f}\alpha_+ + \frac{1}{f}\hat{\alpha}'_+(\ddot{V}(t)) + O\left(\frac{1}{f^3}\right) = \frac{t}{f}\alpha_+ + \frac{\sqrt{c}}{f}\hat{\alpha}'_+ \exp(-g(t)\hat{\alpha}'_+)\beta_+ + O\left(\frac{1}{f^2}\right)$$

by Theorem 1. ■

Theorem 3. *For $t \geq 0$ and $t \leq 0$, respectively,*

$$V(t) = f(t)\alpha_\pm - \frac{\sqrt{c}}{f(t)^2}\exp(\mp g(t)\hat{\alpha}'_\pm)\beta_\pm + O\left(\frac{1}{f(t)^3}\right).$$

Proof. By (12) and Theorem 1, for $0 < r < s$,

$$U(s) + \frac{\ddot{V}(s)}{f(s)^3} - U(r) - \frac{\ddot{V}(r)}{f(r)^3} = -\int_r^s \frac{3\sqrt{c}t\exp(-g(t)\hat{\alpha}'_+)\beta_+}{f(t)^5}dt + O\left(\frac{1}{f(r)^4}\right)$$
$$= 3\sqrt{c}\hat{\alpha}'_+\int_r^s f(t)\hat{\alpha}'_+\exp(-g(t)\hat{\alpha}'_+)\beta_+\left(\frac{t}{f(t)^6}\right)dt + O\left(\frac{1}{f(r)^4}\right)$$
$$= 3\sqrt{c}\hat{\alpha}'_+\left(-\exp(-g(s)\hat{\alpha}'_+)\beta_+\left(\frac{s}{f(s)^6}\right) + \exp(-g(r)\hat{\alpha}'_+)\beta_+\left(\frac{r}{f(r)^6}\right)\right)$$
$$+ 3\sqrt{c}\hat{\alpha}'_+\int_r^s \exp(-g(t)\hat{\alpha}'_+)\beta_+\left(\frac{c-5t^2}{f(t)^8}\right)dt + O\left(\frac{1}{f(r)^4}\right)$$

after integration by parts using $\dot{g} = f$. Since all except the last term on the right-hand side are $O(\frac{1}{f(r)^5})$,

$$U(s) + \frac{\ddot{V}(s)}{f(s)^3} = U(r) + \frac{\ddot{V}(r)}{f(r)^3} + O\left(\frac{1}{f(r)^4}\right),$$

and, as $s \to \infty$, this gives

$$U(r) = \alpha_+ - \frac{\ddot{V}(r)}{f(r)^3} + O\left(\frac{1}{f(r)^4}\right) = \alpha_+ - \frac{\sqrt{c}}{f(r)^3}\exp(-g(r)\hat{\alpha}'_+)\beta_+ + O\left(\frac{1}{f(r)^4}\right),$$

by Theorem 1. This proves Theorem 3 for $t \geq 0$. The result follows by symmetry for $t \leq 0$. ∎

The asymptotic estimates of Theorems 1–3 can be surprisingly sharp, even for moderate values of t.

Example 5. *Figures 9 and 10 show $y_1(t)$, $\dot{y}_1(t)$, and their asymptotic estimates for $0 < t < 3$. Figure 11 does the same for $\ddot{y}_1(t)$ for $0 < t < 10$. For $|t| > 4$ the estimates are more or less indistinguishable from $y_1(t)$, $\dot{y}_1(t)$, $\ddot{y}_1(t)$ obtained by numerically solving (4). Taylor approximation about $t = 0$ suffices for $|t| \leq 4$.*

By comparison,

- *the previous best asymptotic estimates for $y_1(t)$ are linear in $|t|$ as $t \to \pm\infty$;*
- *the previous best estimate of $\dot{y}_1(t)$ is that $\lim_{t\to\pm\infty}\dot{y}_1(t)$ exist, saying nothing about the finer structure observed in Figure 10;*
- *the only asymptotic statement previously available for $\ddot{y}_1(t)$ was that it is bounded, saying nothing about the behavior (oscillations with constant amplitude and linearly increasing frequency) observed in Figure 11.*

Similar comments can be made for y_2, y_3.

6. Back to the ODE (3). For the canonical null Lie quadratic V in E^3 given by $c > 0$ Theorems 3, 2, 1 say that there are orthogonal unit vectors $\alpha, \beta \in S^2$ such that, for $t > 0$,

$$V = f\alpha - \frac{\sqrt{c}}{f^2}\exp(-gJ)\beta \quad + O\left(\frac{1}{f^3}\right), \tag{17}$$

$$\dot{V} = \frac{t}{f}\alpha + \frac{\sqrt{c}}{f}J\exp(-gJ)\beta \quad + O\left(\frac{1}{f^2}\right), \tag{18}$$

$$\ddot{V} = \sqrt{c}\exp(-gJ)\beta \quad + O\left(\frac{1}{f}\right), \tag{19}$$

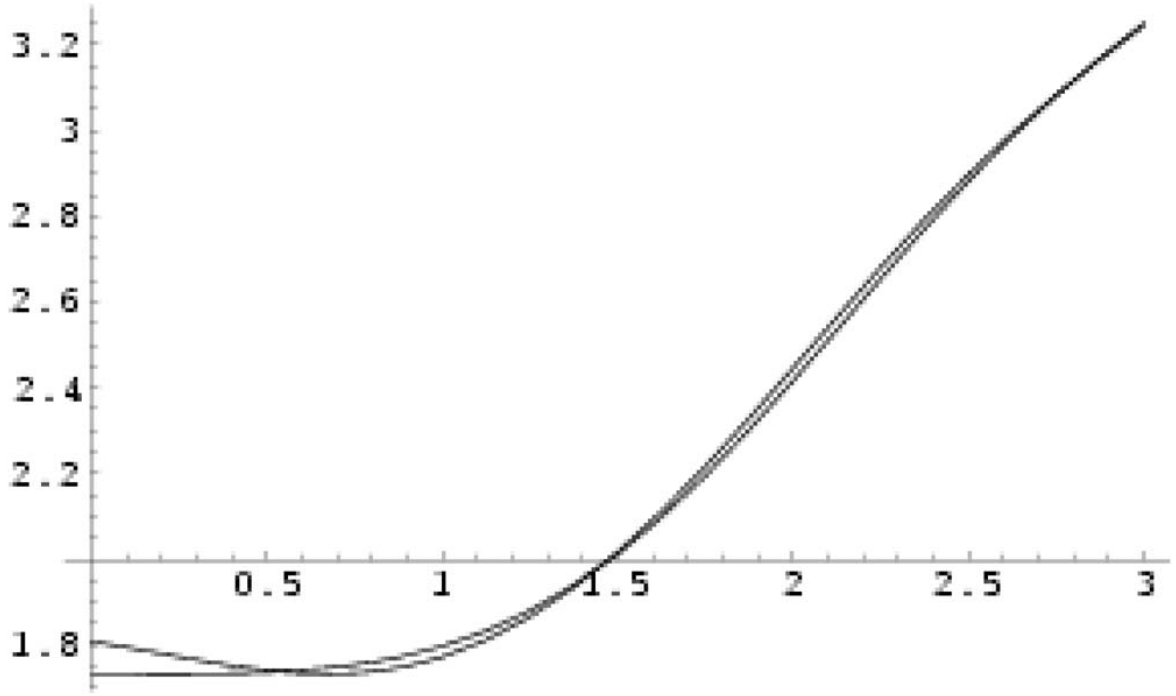

Figure 9. *$y_1(t)$ and its estimate (higher near $t = 0$) for $0 < t < 3$, with $c = 3$.*

with $\alpha = \alpha_+$, $\beta = \beta_\pm$, and J the restriction $\hat{\alpha}'$ of $\hat{\alpha}$ to $\alpha^\perp$. Defining

$$a := \langle V, \alpha\rangle, \quad b := \langle V, \exp(-gJ)\beta\rangle, \quad d := \langle V, J\exp(-gJ)\beta\rangle,$$

we have

$$\begin{bmatrix} V \\ \dot{V} \\ \ddot{V} \end{bmatrix} = \begin{bmatrix} a & b & d \\ \dot{a} & \dot{b} + df & \dot{d} - bf \\ \ddot{a} & \ddot{b} + 2\dot{d}f + d\dot{f} - bf^2 & \ddot{d} - 2\dot{b}f - b\dot{f} - df^2 \end{bmatrix} \begin{bmatrix} \alpha \\ \exp(-gJ)\beta \\ J\exp(-gJ)\beta \end{bmatrix},$$

and consequently, by (17), (18), (19),

$$\begin{bmatrix} a \\ b \\ d \end{bmatrix} = \begin{bmatrix} f \\ -\sqrt{c}f^{-2} \\ 0 \end{bmatrix} + O\left(\frac{1}{f^3}\right), \qquad \begin{bmatrix} \dot{a} \\ \dot{b} \\ \dot{d} \end{bmatrix} = \begin{bmatrix} \dot{f} \\ 0 \\ 0 \end{bmatrix} + O\left(\frac{1}{f^2}\right), \qquad \begin{bmatrix} \ddot{a} \\ \ddot{b} \\ \ddot{d} \end{bmatrix} = O\left(\frac{1}{f}\right).$$

By Lemmas 7, 8, 9, and then (24) below for $\dot{a}$,

$$a = f + O\left(\frac{1}{f^5}\right), \quad \dot{a} = \dot{f} + O\left(\frac{1}{f^4}\right), \quad \ddot{a} = O\left(\frac{1}{f^3}\right), \quad a^{(3)} = O\left(\frac{1}{f^2}\right).$$

These lemmas also give more detailed estimates which can be useful for moderate values of t.

Example 6. *By Lemma 8, $a(t) = \sqrt{t^2 + c} - \delta(t)$, where*

$$0 \le \delta(t) \le \frac{3c}{f(t)^5}.$$

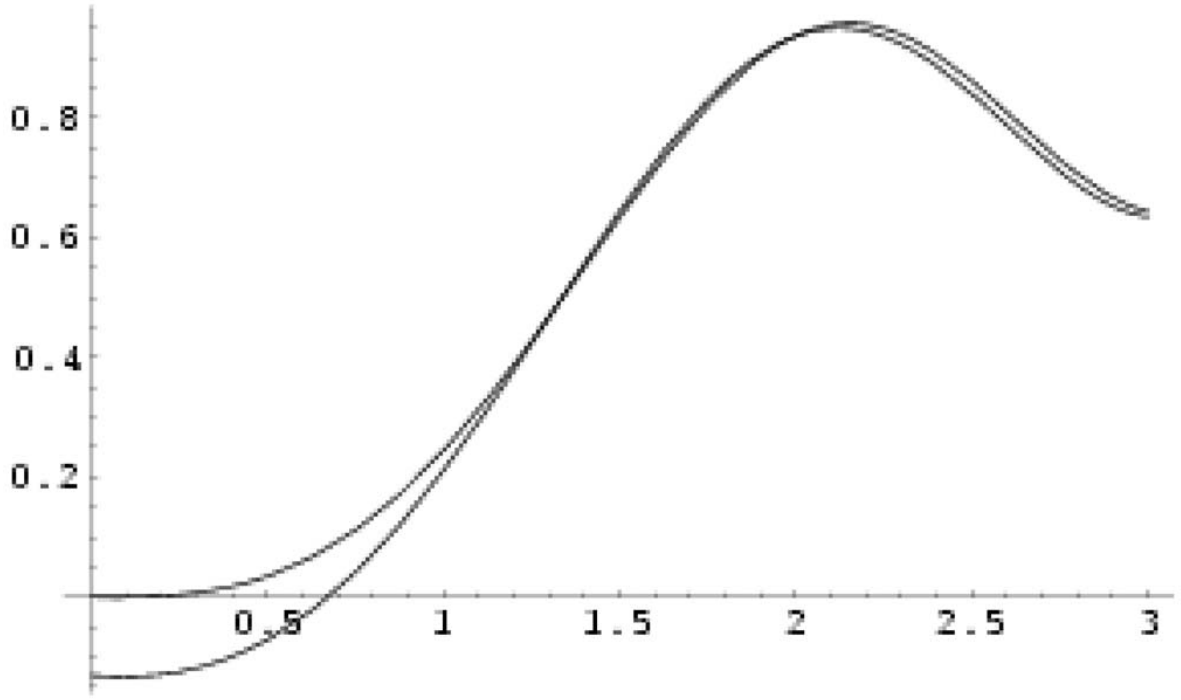

Figure 10. *$\dot{y}_1(t)$ and its estimate (lower near $t = 0$) for $0 < t < 3$, with $c = 3$.*

With $c = 3$ and $t > 2$, the bound on the right-hand side is smaller than $9/7^{5/2} \approx 0.069$. For $t > 4$ we obtain instead $9/19^{5/2} \approx 0.0057$.

Substituting for $V, \dot{V}, \ddot{V}$ in Lemma 5,

$$\ddot{V} = \ddot{a}\alpha + (\ddot{b} + 2\dot{d}f + d\dot{f} - bf^2)\exp(-gJ)\beta + (\ddot{d} - 2\dot{b}f - b\dot{f} - df^2)J\exp(-gJ)\beta$$
$$= (\dot{a}\alpha + (\dot{b} + df)\exp(-gJ)\beta + (\dot{d} - bf)J\exp(-gJ)\beta) \times (a\alpha + b\exp(-gJ)\beta + dJ\exp(-gJ)\beta)$$
$$= (-b\dot{d} + d\dot{b} + b^2 f + d^2 f)\alpha + (a\dot{d} - \dot{a}d - abf)\exp(-gJ)\beta + (\dot{a}b - a\dot{b} - adf)J\exp(-gJ)\beta,$$

and then

$$\ddot{a} = -b\dot{d} + d\dot{b} + b^2 f + d^2 f, \tag{20}$$
$$\ddot{b} = -2\dot{d}f - d\dot{f} + bf^2 + a\dot{d} - \dot{a}d - abf, \tag{21}$$
$$\ddot{d} = \quad 2\dot{b}f + b\dot{f} + df^2 + \dot{a}b - a\dot{b} - adf. \tag{22}$$

Notice also

$$a^2 + b^2 + d^2 - f^2 = 0, \tag{23}$$
$$a^{(3)} - ta + f^2\dot{a} = 0. \tag{24}$$

Similar statements hold for $t < 0$ but with different α, β, and J.

Substituting from (17), (18), (19) into Proposition 1, we obtain the following theorem.

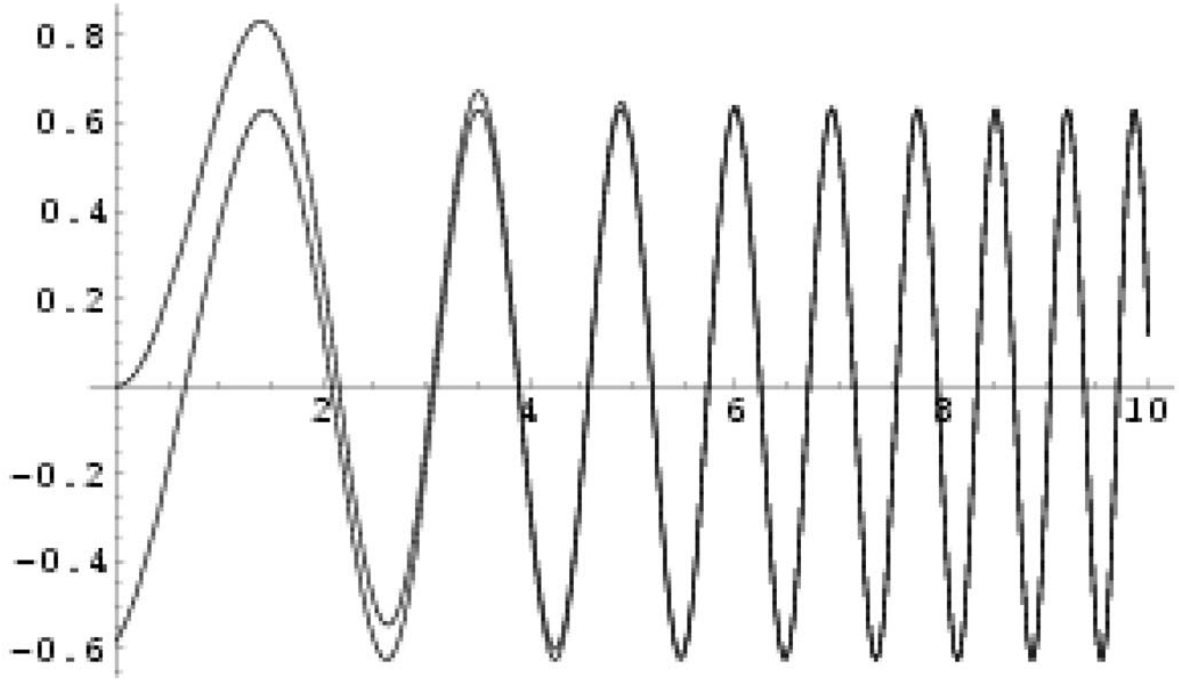

Figure 11. *$\ddot{y}_1(t)$ and its estimate (lower near $t = 0$) for $0 < t < 10$, with $c = 3$.*

Theorem 4. *As $t \to \pm\infty$, $z_1(t), z_2(t), z_3(t) \in E^3$ are the* rows *of the 3×3 matrix*

$$\left[\begin{array}{ccc} \frac{\sqrt{c}}{f}\alpha_\pm - \frac{t}{f}\hat{\alpha}'_\pm \exp(\mp g\hat{\alpha}'_\pm)\beta_\pm & \frac{t}{f}\alpha_\pm & -\exp(\mp g\hat{\alpha}'_\pm)\beta_\pm \end{array} \right] + O\left(\frac{1}{f}\right).$$

Corollary 8. *Write $\alpha_+ = \alpha = (\alpha_1, \alpha_2, \alpha_3)$. Then for $i = 1, 3$, the z_i are asymptotic to the limiting circles*

$$\{w \in E^3 : \|w\| = 1 \text{ and } w_2 = \pm\alpha_i\}$$

according as $t \to \pm\infty$, and z_2 is asymptotic to the single circle

$$\{w \in E^3 : \|w\| = 1 \text{ and } w_2 = \alpha_2\}$$

whether $t \to \pm\infty$.

In Example 2 the circles apparent in Figures 2 and 3 (especially) are not orthogonal to $(0, 1, 0)$, nor even parallel to each other, and the circles in Figure 2 appear distinct. So these cannot be the limiting circles of Corollary 8. Indeed the numerically generated $z_i : [-10, 10] \to E^3$ do not reveal the long-term asymptotics, and plots of $z_i : [-100, 100] \to E^3$ confirm Corollary 8.

As we see next, the ODE (1) is fundamental for studying

- motion of a ball under torque that is constant in body coordinates,
- rolling of a ball on an inclined plane,
- variational motion planning for a ball,

where $(z_1(t), z_2(t), z_3(t))$ is a positively oriented orthonormal frame in E^3, fixed relative to the moving ball (the configuration of the ball relative to the center of mass $c(t) \in E^3$ at time t).

7. Applications to spherically symmetric rigid bodies. Consider a rigid body $\mathbf{B}$ of mass $\mu > 0$ subject to external forces totalling $f(t)$ with total moment $n(t)$ measured in an absolute (inertial) frame. A point $Q \in \mathbf{B}$ in body coordinates with origin at the center of mass $\bar{q}(t)$ has absolute position

$$q(t) = \bar{q}(t) + x(t)Q, \quad \text{where } x(t) \in SO(3).$$

Define the *absolute angular velocity* $\omega(t) \in E^3$ by $\hat{\omega}(t) := \dot{x}(t)x(t)^{-1}$. The *body angular velocity* is $\Omega(t) := x(t)^{-1}\omega(t)$, namely $\hat{\Omega}(t) = x(t)^{-1}\dot{x}(t)$. The *body angular momentum* is $M(t) := K\Omega(t)$, where K is the inertia matrix. The *absolute angular momentum* is $m(t) := x(t)M(t)$. From Newton's second law,

$$\mu\ddot{\bar{q}}(t) = f(t), \tag{25}$$

$$\dot{m}(t) = n(t). \tag{26}$$

Substituting for $m(t)$ in (26), $\dot{x}(t)M(t)+x(t)K\dot{\Omega}(t) = n(t)$, namely $x(t)^{-1}\dot{x}(t)M(t)+K\dot{\Omega}(t) = N(t)$, where $x(t)N(t) = n(t)$. Equivalently,

$$\mu\ddot{\bar{q}}(t) = x(t)^{-1}F(t), \tag{27}$$

$$K\dot{\Omega}(t) = (K\Omega(t)) \times \Omega(t) + N(t), \tag{28}$$

where $x(t)F(t) = f(t)$.

Suppose that the mass distribution of $\mathbf{B}$ is spherically symmetric. Then (28) reads

$$\nu\dot{\Omega}(t) = N(t), \tag{29}$$

where $\nu > 0$. For a homogeneous ball $\mathbf{B}$ of radius $b > 0$ and density ρ,

$$\mu = \frac{4\pi\rho}{3}b^3 \quad \text{and} \quad \nu = \frac{8\pi\rho}{15}b^5.$$

We review some special cases.

7.1. Turning a ball in space. Let $\mathbf{B}$ be a homogeneous ball subject only to a constant torque N (turning) in body coordinates. (A ball in space might be controlled by momentum wheels with linearly increasing angular momenta.) By (29) for any given $t_0 \in \mathbb{R}$,

$$\Omega(t) = \Omega(t_0) + \frac{N}{\nu}(t - t_0)$$

so that $\Omega : \mathbb{R} \to E^3$ is affine, $x : \mathbb{R} \to SO(3)$ is given by

$$\dot{x}(t) = x(t)\hat{\Omega}(t), \tag{30}$$

and $\bar{q} : \mathbb{R} \to E^3$ is found from (27). Since $x(t)x(t)^{\mathbf{T}}$ is 3×3 the identity matrix, we obtain on differentiation

$$\dot{x}(t)x(t)^{\mathbf{T}} + x(t)\dot{x}(t)^{\mathbf{T}} = \mathbf{0} \iff x(t)^{-1}\dot{x}(t) = -\dot{z}(t)z(t)^{-1},$$

where $z(t) := x(t)^{\mathbf{T}} = x(t)^{-1}$. Thus (30) is equivalent to (1) with

$$B_0 = -\hat{\Omega}(0) = -\hat{\Omega}(t_0) + \frac{\hat{N}}{\nu}t_0 \quad \text{and} \quad B_1 = -\dot{\hat{\Omega}}(0) = -\frac{\hat{N}}{\nu}.$$

Suppose $N \neq \mathbf{0}$. As in section 1, translate and rescale t, and choose a reference frame for body coordinates, so that z satisfies the canonical form (3) of (1). Then

$$\Omega(t) = -\begin{bmatrix} \sqrt{c} & t & 0 \end{bmatrix}^{\mathbf{T}},$$

where $c \geq 0$ depends on i. Choose the inertial reference frame so that $z(0)$ is the identity matrix $\mathbf{1}$. Then $z_i(t)$ is the ith vector of the inertial frame measured in body coordinates at time t. Replacing $x(t)$ in section 3 by the present $x(t)^{-1}$, $V(t)$ becomes the negative of the absolute angular momentum $\omega(t)$ of $\mathbf{B}$. By Lemma 5, x^{-1} is a null Riemannian cubic in $SO(3)$ with associated (canonical) null Lie quadratic $-\omega$ in $E^3 \cong so(3)$. By Lemma 6, the components ω_i of ω satisfy the ODE (4) with

$$\omega(0) = -\begin{bmatrix} \sqrt{c} \\ 0 \\ 0 \end{bmatrix}, \quad \dot{\omega}(0) = -\begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}, \quad \ddot{\omega}(0) = \begin{bmatrix} 0 \\ 0 \\ \sqrt{c} \end{bmatrix}.$$

Remark 1. *These conclusions hold even when $c = 0$, although previously $c > 0$ throughout. For $c = 0$,*

$$z(t) = \begin{bmatrix} \cos(\frac{t^2}{2}) & 0 & \sin(\frac{t^2}{2}) \\ 0 & 1 & 0 \\ -\sin(\frac{t^2}{2}) & 0 & \cos(\frac{t^2}{2}) \end{bmatrix}.$$

Thus $\omega(t) = \begin{bmatrix} 0 & -t & 0 \end{bmatrix}^{\mathbf{T}}$ and, as viewed from $\mathbf{B}$, the inertial frame rotates with linearly increasing angular velocity in the plane orthogonal to the second axis. So, in body coordinates, the vectors z_i of the inertial frame move on great circles.

From now on suppose $c > 0$. Then we have the following:

- There are unit vectors $\alpha_\pm, \beta_\pm \in S^2$ with $\langle \alpha_\pm, \beta_\pm \rangle = 0$ such that (Theorem 4)

$$x(t) = \begin{bmatrix} \frac{\sqrt{c}}{f}\alpha_\pm - \frac{t}{f}\hat{\alpha}'_\pm \exp(\mp g\hat{\alpha}'_\pm)\beta_\pm & \frac{t}{f}\alpha_\pm & -\exp(\mp g\hat{\alpha}'_\pm)\beta_\pm \end{bmatrix} + O(t^{-1})$$

  as $t \to \pm\infty$. Here $f(t) := \sqrt{t^2 + c}$ and $g(t)$ is given in Definition 3 of section 5.
- The vectors $z_i(t)$ of the inertial frame viewed from $\mathbf{B}$ are asymptotic to (usually not great) circles as $t \to \pm\infty$ (Corollary 8).
- Because $\omega(t) = -V(t)$, the components ω_i of absolute angular momentum satisfy
  - if any $|\omega_i(t)| > \sqrt{c}$, then $\dot{\omega}_i(t) \neq 0$ (Lemma 2);
  - we have $\omega_1(t)$ an even function of t, with $\dot{\omega}_1(t) < 0$ for $t > 0$ (Lemma 3);
  - we have $\omega_2(t)$ an odd function of t;
  - we have $\omega_3(t)$ an even function of t, with $0 < \omega_3(t) < |t|$ for $t \neq 0$ (Corollary 6).

- Formulae (17), (18), (19) give

$$\begin{aligned}\omega(t) &= -f\alpha_\pm + \frac{\sqrt{c}}{f^2}\exp(-g\hat{\alpha}'_\pm)\beta_\pm \qquad + O(t^{-3}),\\ \dot{\omega}(t) &= -\frac{t}{f}\alpha_\pm - \frac{\sqrt{c}}{f}\hat{\alpha}'_\pm\exp(-g\hat{\alpha}'_\pm)\beta_\pm \quad + O(t^{-2}),\\ \ddot{\omega}(t) &= -\sqrt{c}\exp(-g\hat{\alpha}'_\pm)\beta_\pm \qquad + O(t^{-1})\end{aligned}$$

as $t \to \pm\infty$.

7.2. Ball rolling on a tilted plane. Consider next a nonholonomic circumstance in classical mechanics [2]: a ball $\mathbf{B}$ of radius $b > 0$ is subject to a constant force $\mu\gamma \in E^3$ and rolls without slipping on a fixed plane parallel to

$$w^\perp := \{v \in E^3 : \langle v, w\rangle = 0\},$$

where $w \in S^2 \subset E^3$ (measuring tilting). Rolling means $\dot{\bar{q}}(t) - b\omega(t) \times w = \mathbf{0}$. Taking moments about $\bar{q}(t)$,

$$\nu\dot{\omega}(t) = -bw \times \phi(t),$$

where the frictional force $\phi(t)$ at $p(t) := \bar{q}(t) - bw$ is

$$\mu\ddot{\bar{q}}(t) - \mu\gamma + \mu\langle\gamma, w\rangle w = \mu b\dot{\omega}(t) \times w - \mu\gamma + \mu\langle\gamma, w\rangle w.$$

Substituting for $\phi(t)$ and expanding cross-products,

$$(\nu + \mu b^2)\dot{\omega} = \mu b^2\langle\dot{\omega}, w\rangle w + \mu b w \times \gamma.$$

Taking inner products with w, $\langle\dot{\omega}, w\rangle = 0$ since $\nu > 0$. Then

$$\dot{\omega} = \frac{\mu b}{\nu + \mu b^2} w \times \gamma = -\frac{\mu b}{\nu + \mu b^2}\hat{\gamma}(w).$$

Given $t_0 \in \mathbb{R}$, we have

$$\omega(t) = \omega(t_0) - \frac{\mu b}{\nu + \mu b^2}\hat{\gamma}(w)(t - t_0)$$

so that $\omega : \mathbb{R} \to E^3$ is affine, $x : \mathbb{R} \to SO(3)$ is given by

$$\dot{x}(t) = \hat{\omega}(t)x(t), \tag{31}$$

and $\bar{q} : \mathbb{R} \to E^3$ is found from the rolling condition. Then (31) is equivalent to (1) with $z(t) := x(t)$,

$$B_0 := \hat{\omega}(t_0) + \frac{\mu b}{\nu + \mu b^2} t_0\,\widehat{(\gamma \times w)} \quad \text{and} \quad B_1 := -\frac{\mu b}{\nu + \mu b^2}\,\widehat{(\gamma \times w)}.$$

Suppose $B_1 \neq \mathbf{0}$. As in section 1, translate and rescale t, and choose a reference frame for inertial coordinates so that $z(t)$ satisfies the canonical form (3) of (1). Choose a reference frame for body coordinates so that $z(0) = \mathbf{1}$, and exclude the easy case where $B_0 = \mathbf{0}$.

Then $V(t) := \Omega(t)$ is a canonical null Lie quadratic in $E^3 \cong so(3)$, associated with the null Riemannian cubic $z = x$ in $SO(3)$. Thus the following hold:

- There are unit vectors $\alpha_\pm, \beta_\pm \in S^2$ with $\langle \alpha_\pm, \beta_\pm \rangle = 0$ such that (Theorem 4)

$$x(t) = \begin{bmatrix} \frac{\sqrt{c}}{f}\alpha_\pm - \frac{t}{f}\hat{\alpha}'_\pm \exp(\mp g\hat{\alpha}'_\pm)\beta_\pm & \frac{t}{f}\alpha_\pm & -\exp(\mp g\hat{\alpha}'_\pm)\beta_\pm \end{bmatrix}^{\mathbf{T}} + O(t^{-1})$$

  as $t \to \pm\infty$.
- The vectors $x_i(t)$ of the body reference frame are asymptotic to circles, as in Corollary 8.
- The components $\Omega_i(t)$ of body angular acceleration satisfy the results found in section 2 for the $y_i(t)$.
- Equations (17), (18), (19) give

$$\begin{aligned} \Omega(t) &= f\alpha_\pm - \frac{\sqrt{c}}{f^2}\exp(-g\hat{\alpha}'_\pm)\beta_\pm &&+ O(t^{-3}), \\ \dot{\Omega}(t) &= \frac{t}{f}\alpha_\pm + \frac{\sqrt{c}}{f}\hat{\alpha}'_\pm \exp(-g\hat{\alpha}'_\pm)\beta_\pm &&+ O(t^{-2}), \\ \ddot{\Omega}(t) &= \sqrt{c}\exp(-g\hat{\alpha}'_\pm)\beta_\pm &&+ O(t^{-1}) \end{aligned}$$

  as $t \to \pm\infty$.

7.3. Variational motion planning. For a Riemannian manifold M, given $t_0 < t_1 \in \mathbb{R}$ and $x_0, x_1 \in M$ with $v_0 \in TM_{x_0}$ and $v_1 \in TM_{x_1}$, let $X = X(t_0, t_1, x_0, x_1, v_0, v_1)$ be the space of C^1 curves $x : [t_0, t_1] \to M$ satisfying

$$x(t_0) = x_0, \quad \dot{x}(t_0) = v_0, \quad x(t_1) = x_1, \quad \dot{x}(t_1) = v_1. \tag{32}$$

For $x \in X$ set

$$J_2(x) := \int_{t_0}^{t_1} \|\nabla_{d/dt}\dot{x}(t)\|^2 dt,$$

where $\| \ \|$ denotes the Riemannian norm and ∇ is the Levi–Civita covariant derivative defined by the Riemannian metric. Then (see [8], [11]) a critical point x of J_2 is a *Riemannian cubic* in the sense that

$$\nabla^3_{d/dt}\dot{x} + R(\nabla_{d/dt}\dot{x}, \dot{x})\dot{x} = \mathbf{0}, \tag{33}$$

where R denotes Riemannian curvature. The derivation of (33) can be described much more simply than (say) in [11], as follows.

Consider smooth variations $x_{(h)} \in X$ of x with $h \in \mathbb{R}$ and $x_{(0)} = x$. Regarding $J_2(x_{(h)})$ as a function of h, the derivative at $h = 0$ is

$$2\int_{t_0}^{t_1} \langle \nabla_{d/dh}\nabla_{d/t}\dot{x}_{(h)}, \nabla_{d/dt}\dot{x}_{(h)} \rangle dt,$$

where, using the definition of Riemannian curvature, the integrand may be written as

$$\langle \nabla_{d/dt}\nabla_{d/dh}\dot{x}(h), \nabla_{d/dt}\dot{x}_{(h)} \rangle + \langle R(W, \dot{x})\dot{x}, \nabla_{d/dt}\dot{x} \rangle$$

with $W := W(x(t))$ the partial derivative with respect to h of $x_{(h)}$ evaluated at $h = 0$. Because ∇ is torsion-free we can write instead

$$\langle \nabla^2_{d/dt} W, \nabla_{d/dt}\dot{x}\rangle + \langle R(W,\dot{x})\dot{x}, \nabla_{d/dt}\dot{x}\rangle = \langle \nabla^2_{d/dt} W, \nabla_{d/dt}\dot{x}\rangle + \langle R(\nabla_{d/dt}\dot{x},\dot{x})\dot{x}, W\rangle$$

using standard symmetries of R [10, Lemma 9.3] for the Levi–Civita covariant derivative. Integrating twice by parts and taking account of boundary conditions,

$$\int_{t_0}^{t_1} \langle \nabla^3_{d/dt}\dot{x} + R(\nabla_{d/dt}\dot{x},\dot{x})\dot{x}, W\rangle dt = 0$$

for all W arising from variations $x_{(h)}$, and (33) follows.

In the special case where M is a Lie group G with bi-invariant Riemannian metric, it was first shown in [11] that the present definitions of Riemannian cubic and Lie quadratic agree with those of section 3. A more readable account is given in section 2 of [12].

Taking $G = SO(3)$, with x describing the trajectory of a spherically symmetric rigid body $\mathbf{B}$, the integrand in J_2 is proportional to the squared norm of the applied torque N in body coordinates. With few exceptions, non-null Lie quadratics in $so(3) \cong E^3$ and Riemannian cubics in $SO(3)$ are more complicated than the null objects [13], but there are significant remaining questions for the null case.

The present paper provides new asymptotic formulae (17), (18), (19) for canonical null Lie quadratics V in E^3. Moreover, for canonical null Riemannian cubics x in $SO(3)$, Theorem 4 gives

$$x(t) = \begin{bmatrix} \frac{\sqrt{c}}{f}\alpha_\pm - \frac{t}{f}\hat{\alpha}'_\pm \exp(\mp g\hat{\alpha}'_\pm)\beta_\pm & \frac{t}{f}\alpha_\pm & -\exp(\mp g\hat{\alpha}'_\pm)\beta_\pm \end{bmatrix}^{\mathbf{T}} + O(t^{-1})$$

as $t \to \pm\infty$, improving on previous results by an order of magnitude.

More background on dynamics of Riemannian cubics and integrability can be found in [12], [13], [14], [15]. For related research (including alternative methods for motion planning) see [3], [4], [5], [6], [7], [9], [16], [17], [18], [19]. Current work with Marin Kobilarov and Jerrold Marsden, building on the approach in [1], includes a practical implementation of Riemannian cubics for engineering.

8. Conclusion. The present paper builds on the theory of a class of curves $t \mapsto V(t)$ (canonical null Lie quadratics) in Euclidean 3-space E^3, to study a class of *first order linear* ODEs (1) in E^3 with coefficients *affine* in t. As shown in section 7, solutions of (1) have a simple interpretation in elementary problems in classical mechanics, and connections with approximation theory in Riemannian geometry (null Riemannian cubics). Known geometric properties of *nonlinear* ODEs are strengthened and used to prove asymptotic results for the *linear* system (1), as follows:

- We focus on a canonical form of (1), where the right-hand side depends on a single scalar parameter $c > 0$. (The case where $c = 0$ is standard.)
- (1) is shown to be solvable in terms of the general solution of a *third order linear* ODE (4) with *quadratic* coefficients. Local properties of solutions of (4) are found from a *second order quadratic* ODE (5).
- The strategy is to find global properties via a relationship (Lemma 6) between solutions of (4) and a particular solution V (a canonical null Lie quadratic) of a *second order quadratic* ODE (6) in E^3. All solutions of (6) can be given in terms of the canonical null Lie quadratic.

- Quite a lot is already known about canonical null Lie quadratics in E^3. They have constant curvature, linear torsion, and *asymptotes*. The present paper strengthens these results, giving asymptotic formulae for V and the derivatives $\dot{V}, \ddot{V}$.
- These formulae lead in turn to asymptotic expressions for *null Riemannian cubics* (a class of curves in $SO(3)$ satisfying a second order variational principle, of interest for interpolation problems in engineering).

Acknowledgments. I am grateful to Professor Jerrold Marsden for some valuable and illuminating conversations, including advice to explore links between Lie quadratics and classical mechanics. I also thank Professor Tasso Kaper, and an anonymous reviewer, for careful and constructive readings, resulting in a greatly improved and more readable paper.

Normal Vectors on Critical Manifolds for Robust Design of Transient Processes in the Presence of Fast Disturbances*

Johannes Gerhard†, Wolfgang Marquardt†, and Martin Mönnigmann‡

Abstract. Information on steady-state bifurcations, most notably stability boundaries, is frequently used for the analysis and design of nonlinear systems. The bifurcation points separate regions with different dynamic behavior and thus give valuable information about nonlinear systems. They cannot, however, reflect the impact of fast disturbances on the transient behavior of nonlinear systems. The influence of fast disturbances can be addressed by bifurcation points that are defined as critical points during the transient behavior of a dynamic system in the presence of fast disturbances. Specifically, we consider two types of points—grazing points and end-points. At a grazing point the trajectory of a nonlinear system tangentially touches a hypersurface spanned by a state or output constraint. At an end-point the trajectory crosses the hypersurface at a specified final time. These critical points unfold to manifolds in the parameter space of the nonlinear system separating parts of the parameter space that admit trajectories that do not violate the constraint from those where the constraint is violated. The parametric distance between a candidate design of a nonlinear system and the critical manifold is used as a robustness measure. As the closest connection between the design and the critical manifold is along the normal direction of the critical manifold, normal vectors are used to formulate minimal-distance constraints for a nonlinear program. Thus it is possible to robustly take into account state and output constraints in the presence of fast disturbances for the design of a nonlinear system. Application of the approach to closed-loop systems allows for an integration of operating point and control design. Several case studies from chemical engineering are presented to illustrate the proposed method.

Key words. grazing bifurcation, end-point constraint, normal vector, robust optimization, disturbances

1. Introduction.

We consider systems of nonlinear differential algebraic equations (DAEs) of the form

$$\begin{aligned} x_t &= f(x(t), y(t), p, d(\alpha, t), t), \quad x(t_0) = x_0, \\ 0 &= g(x(t), y(t), p, d(\alpha, t), t), \end{aligned} \tag{1.1}$$

with dynamic state variables $x \in \mathbb{R}^{n_x}$, corresponding time derivatives x_t, initial conditions x_0, algebraic variables $y \in \mathbb{R}^{n_y}$, system parameters $p \in \mathbb{R}^{n_p}$, disturbances $d \in \mathbb{R}^{n_d}$ parameterized by a set of parameters $\alpha \in \mathbb{R}^{n_\alpha}$, and time $t \in \mathbb{R}$. The functions f and g are assumed to be

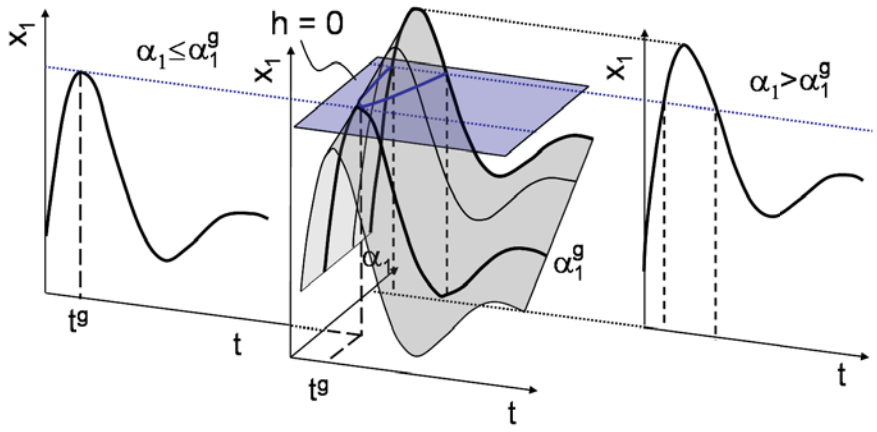

Figure 1. *Trajectories of state x_1 for different values of a step disturbance triggered at $t = 0$ and parameterized by α_1. A parabola-like curve connects the points where the trajectories cross the hypersurface spanned by constraint $h := x_{1\max} - x_1 = 0$. The grazing trajectory touches the hypersurface tangentially at $t = t^g$ for $\alpha = \alpha_1^g$.*

sufficiently smooth with respect to x, y, p, α, and t for $t > t_0$. f and g map from some open subset $U \subset \mathbb{R}^{n_x} \times \mathbb{R}^{n_y} \times \mathbb{R}^{n_p} \times \mathbb{R}^{n_\alpha} \times \mathbb{R}$ into $\mathbb{R}^{n_x}$ and $\mathbb{R}^{n_y}$, respectively. We assume the Jacobian g_y of g with respect to y to have full rank n_y; i.e., the DAE system (1.1) has a differential index of at most one [50]. This implies that consistent initial conditions of the algebraic states y_0 can be computed with the algebraic equations and specified initial conditions of the dynamic states x_0. Note that (1.1) can represent both open-loop and closed-loop systems including a controller with fixed structure. For closed-loop systems, the parameter vector p refers to both system design parameters and control parameters.

In what follows we assume that there is a set of inequality constraints,

$$0 \leq h(x(t), y(t), p, d(\alpha, t), t), \tag{1.2}$$

with h sufficiently smooth mapping from $U \subset \mathbb{R}^{n_x} \times \mathbb{R}^{n_y} \times \mathbb{R}^{n_p} \times \mathbb{R}^{n_\alpha} \times \mathbb{R}$ into $\mathbb{R}^{n_h}$. Constraints (1.2) may represent safety constraints for a physical system, such as an upper temperature limit in a chemical reactor, or constraints that are established due to economic reasons, such as a quality constraint on a product. For safe and economical operation of system (1.1) it is therefore important to ensure that bounds (1.2) hold despite disturbances $d(\alpha, t)$. Figure 1 displays an illustrative example of the transient behavior of state x_1 of a dynamic system after a step disturbance triggered at $t = 0$. The magnitude of the disturbance is parameterized by the parameter α_1. A simple upper bound for x_1, $h := x_{1\max} - x_1$ defines a plane in the space (α_1, x_1) which must not be crossed from below by the trajectories after the disturbance. As shown in Figure 1, the trajectories always violate the bound for some time for $\alpha_1 > \alpha_1^g$, whereas the trajectories do not cross the bounding plane for $\alpha_1 < \alpha_1^g$. Obviously, there is a critical value of $\alpha_1 = \alpha_1^g$ for which the trajectory only touches the bounding plane tangentially but does not cross it.

The point where the transient touches the bounding plane tangentially is a so-called grazing point [42]. The grazing point is of special interest as it separates those trajectories

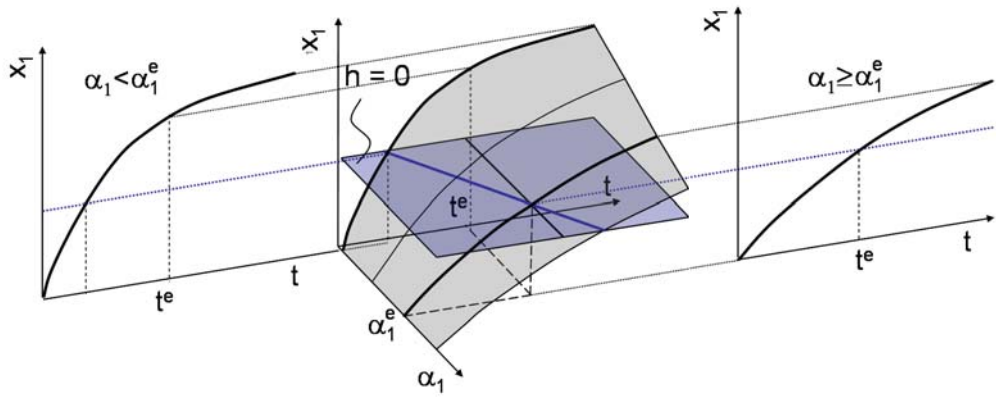

Figure 2. *End-point constraint: Trajectories of state x_1 for different values of a step disturbance triggered at $t = 0$ and parameterized by α_1. Curve on the plane $0 = h$ connects points of trajectories at which the hypersurface of the end-point constraint $h := x_{1\max} - x_1 = 0$ is crossed. The end-point constraint trajectory crosses the bound at the specified final time $t = t^e$ for $\alpha = \alpha_1^e$.*

where the disturbance does not cause a violation of the bound from those trajectories that cross the bounding plane at some point. Note that the term *grazing bifurcation* usually refers to nonsmooth dynamic systems where a bounding surface triggers a discrete event, such as a periodically forced oscillator hitting a wall [42]. Grazing bifurcations have been actively investigated in recent years for nonsmooth mechanical systems such as impact oscillators [8, 11, 42], stick slip oscillations in systems with friction [10], and rub-impact rotor systems [9], but also for switching power systems [12, 15, 16]. In this paper, we will focus on smooth systems with constraints (1.2) that must not be crossed, such as safety boundaries or product quality constraints.

Besides the grazing point we will also consider end-point constraints, referring to the trajectory which crosses a bound (1.2) at a specified final time $t = t^e$ as shown in Figure 2. This point separates those trajectories which do not cross the bound before the specified final time from those which violate the bound before the final time is reached. End-point constraints are useful, for example, to bound monotonously increasing states or outputs until a specified final time is reached. An example of a monotonously increasing output is the integrated squared error in closed-loop systems.

In this work the grazing point and the end-point constraint will be used for the robust design and optimization of dynamic systems (1.1) in the presence of parametric uncertainty according to the optimization-based approach recently presented by Mönnigmann and Marquardt [36, 37, 38, 39]. This approach uses the parametric distance between the nearest critical point and the border of a compact region of parametric uncertainty as a measure of robustness for a candidate operating point. The nearest critical point, here a grazing point or an end-point, occurs in the direction normal to the manifold of critical points, which we will refer to as a *critical manifold*. In general, the concept of critical manifolds applies to all boundaries in the parameter space at which the system behavior changes qualitatively. A parametric distance greater than zero ensures that all values the parameters may attain within the region of uncertainty are located on the side of the manifold where the system

exhibits the desired properties.

A drawback of the approach so far was the restriction to steady states and critical points of steady states. Steady states allow neither considering bounds that must hold during transient behavior of the dynamic system (1.1) nor including disturbances with dynamics that are as fast or faster than the system dynamics [37]. To overcome these limitations, we extend the existing approach to consider bounds on trajectories of nonlinear dynamic systems and the corresponding critical points. This involves the calculation of the normal direction for manifolds of grazing points and end-point constraints. The normal direction is used for the formulation of additional constraints in a nonlinear program to ensure that, at the optimal solution, no points within the region of uncertainty violate the constraints (1.2).

Independently from the work presented in this paper, the normal direction on the manifold of grazing bifurcations has also been used in a recent publication [16] to find the closest grazing bifurcation from an operating point for nonsmooth systems, specifically for switching power systems. The most important conceptual difference is that in [16] normal vectors are used for the *analysis of a fixed operating point* while the scope of this work is to use normal vectors for the *robust design of an operating point*. The point of operation is not fixed but is allowed to vary in the space of the design parameters p to minimize an objective function within an optimization problem. The normal vector direction is therefore used not only to locate the closest critical point to a fixed operating point but also to track the closest point, which will change its location with the operating point being modified by the optimizer to obtain the economically optimal point. Technical differences between the calculations presented in this paper and the derivations in [16] are briefly discussed in section 3 and in Appendix B.

As (1.1) may represent both open- and closed-loop dynamic systems, the sketched approach can be used for the simultaneous operating point and control system design of nonlinear systems to guarantee that constraints (1.2) hold despite fast disturbances. Integrated design and control is attractive as it allows incorporating operability issues directly in the system design instead of the usual consecutive approach of separated system and control design. A family of approaches addressing simultaneous design and control with output constraints is based on the robust design framework of Halemane and Grossmann [24] for steady-state design. An extension to dynamic systems to consider robustness of constraints despite disturbances was formulated by Mohideen, Perkins, and Pistikopoulos [34] using mixed-integer dynamic optimization (MIDO) programs. In this approach, first a weighted multiperiod MIDO design problem is solved for a set of fixed uncertainty realizations. A feasibility test checks for further worst-case points which are added to the design problem. Several solution strategies for the involved MIDO problems have been derived in a series of follow-up papers summarized in [46]. A similar approach is used in [2] to solve the integrated control and design problem. In all these approaches the dynamic optimization problem is solved either by complete discretization of the dynamic system by collocation, leading to a large NLP, or by bounds (1.2) being transformed to end-point constraints [46], which may cause numerical difficulties [19]. In our approach we consider special points of critical trajectories. A discretization or conversion into end-point constraints is therefore not required. Another advantage is the seamless integration of rigorous stability constraints by using the results for steady-state design with guaranteed stability derived in our previous work [36, 37]. Our approach does not rely on matrix measures [27, 35] to guarantee stability, which are known to be conservative.

Input and output constraints can also be handled by model predictive control (MPC) [33], where at each point in time a constrained optimal control problem on a finite time horizon is solved. Uncertainties and disturbances are addressed by min-max robust MPC approaches [6], where the performance is optimized for the worst possible case. To reduce the conservatism of min-max MPC approaches a family of control sequences instead of a single control input profile can be considered both for linear systems [29, 48, 53] as well as for nonlinear systems [32]. Evaluation of the control policies, though, is computationally very demanding apart from very simple problems. Linear or higher approximations of the worst-case performance can help to reduce the computational burden of nonlinear min-max robust MPC [13, 41]. The introduced approximation error might, however, lead to poor results for strongly nonlinear models and larger uncertainties [14]. Alternatively to min-max approaches robustness in MPC is addressed by methods that adapt online a nominal optimal profile in the presence of uncertainties. Examples are the use of neighboring extremals [22] or tracking of the necessary conditions of optimality [26]. There are, however, only a few approaches that use MPC or even robust MPC approaches for simultaneous system and control design. One of the early works using MPC for the integration of design and control is [5]. The complexity of the design task to find an optimal operating point is greatly increased since MPC requires the solution of an additional and computationally intensive online dynamic optimization problem. MPC for simple linear models is an exception. In this special case, the resulting optimal control laws can be written in an explicit form. In [45] control laws are evaluated offline via parametric programming. This approach, however, is not suitable for problems with many states and constraints as the number of linear control laws grows exponentially with the number of constraints. Unconstrained MPC for linear models is used in [7, 31]. This does not, however, make use of the ability of MPC to consider constraints explicitly. Additional conditions have to be introduced in [7, 31] to ensure that specified constraints hold.

Input and output constraints under uncertainty are also addressed by Lyapunov-based control design methods using invariant sets [4]. In [17, 18] an explicit Lyapunov-based control law is derived that guarantees stability and performance in the presence of input constraints and disturbances within a stability region around the operating point. A lower bound of the stability region can be estimated by computing an invariant subset of the stability region. There are, however, some drawbacks for Lyapunov-based approaches. Typically, certain assumptions, so-called matching conditions, have to hold for the uncertainties and disturbances. For the approach presented in this paper no matching conditions have to be introduced. Furthermore, we do not have to restrict nonlinear system (1.1) to be affine with respect to disturbances or control inputs. The estimation of the stability region around a nominal operating point is beyond the scope of this paper and will not be investigated.

The paper is organized as follows. In section 2 the defining equations for the grazing and end-points are presented including a short discussion on the types of disturbances which can be considered. In section 3 the corresponding normal directions of the critical manifolds are derived. In section 4 the optimization approach including the normal vector constraints is presented. Finally, illustrative case studies are shown in section 5. The notation used is summarized in Appendix A.

2. Critical manifolds due to bounds on trajectories. No matter how accurately the governing physical laws are taken into account in the mathematical modeling of a real physical system, there will always exist a mismatch between the behavior of a nominal model and the real system. Using only a nominal model for the design of an operating point will generally lead to a too optimistic design for which robustness of the design specifications cannot be guaranteed. We identify two sources for the prediction error of a nominal model:

(i) uncertainties in the model parameters that can only be determined up to a certain accuracy, and

(ii) input disturbances with dynamics that are at least as fast as the system dynamics or faster.

Uncertainty in the model parameters has been considered in previous work [36, 37, 38, 39] using critical points of steady states such as Hopf or saddle-node bifurcations. It has been shown in [37] that uncertain model parameters can also be used to model disturbances if the dynamics of the disturbances are much slower than the dynamics of the system. A slow disturbance occurs if its dominant time scale is much larger than that related to the slowest eigenvalue of the dynamic system.

Here, however, we consider fast disturbances leading to potentially hazardous transient behavior. In this case, transient behavior of the nonlinear systems cannot be neglected. In the framework of the robust design approach we are following in this work, the disturbances d have to be explicitly parameterized by parameters α. Variation of α in a compact set is introduced to bound disturbances d and to represent a rich family of disturbances. These uncertain parameters should not be confused with uncertain model parameters. In this work, parametric uncertainty always refers to the parameterization of the fast disturbances. More precisely, we assume that the parameters α are restricted to a smooth compact subset $\mathcal{A} \subset \mathbb{R}^{n_\alpha}$ and $\forall \alpha \in \mathcal{A}$, $\forall t > t_0 : d(\alpha, t) \in \mathcal{D}$, with compact subset $\mathcal{D} \subset \mathbb{R}^{n_d}$. Throughout the paper, $\mathcal{A}$ has the form

$$\mathcal{A} = \left\{ (\tilde{x}, p, \alpha) \in \tilde{U} : 0 = \hat{g}(\tilde{x}, p, \alpha),\ 0 \leq \tilde{g}(\tilde{x}, p, \alpha) \right\}, \tag{2.1}$$

with auxiliary variables $\tilde{x}$ and expressions $\hat{g}$ and $\tilde{g}$ mapping from some open subset $\tilde{U} \subset \mathbb{R}^{n_{\tilde{x}}} \times \mathbb{R}^{n_p} \times \mathbb{R}^{n_\alpha}$ into $\mathbb{R}^{n_{\tilde{x}}}$, $\mathbb{R}$, respectively. This definition includes, for example, the confidence ellipsoid for Gaussian random variables with expectation value $\overline{\alpha}$, covariance matrix Σ, and the desired confidence level $\gamma > 0$,

$$\mathcal{A} = \left\{ \alpha \in \tilde{U} : 0 \leq \gamma - (\alpha - \overline{\alpha})^T \Sigma^{-1} (\alpha - \overline{\alpha}) \right\}. \tag{2.2}$$

Frequently, parametric uncertainty is described by upper and lower bounds

$$\alpha \in [\overline{\alpha} - \Delta\alpha,\ \overline{\alpha} + \Delta\alpha], \tag{2.3}$$

where $\Delta\alpha \in \mathbb{R}^{n_\alpha}$. In our robust design approach the rectangular uncertainty region has to be approximated by a smooth hull, e.g., by an ellipse (2.2) with $\Sigma = \mathrm{diag}(\Delta\alpha^2)$ and $\gamma = n_\alpha$.

A simple example of a parameterized disturbance $d(\alpha, t)$ is a step disturbance triggered at t_0,

$$d(\alpha, t) = \begin{cases} 0, & t \leq t_0, \\ \alpha, & t > t_0, \end{cases} \tag{2.4}$$

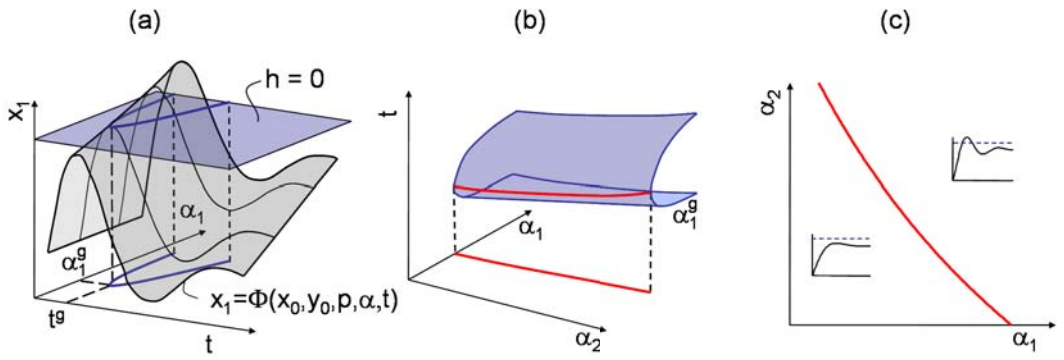

Figure 3. (a) *Trajectories of x_1 after step disturbance parameterized by α_1; a parabola-like curve connects those points where trajectories cross the constraint $h = 0$. The grazing point is located at the extremum of the curve.* (b) *The parabola unfolds into a surface of points in case of two parameters α_1 and α_2.* (c) *Projection of the manifold of grazing points separates the parameter plane (α_1, α_2). Trajectory sketches show on which side the bound h is not violated.*

with α parameterizing the magnitude of the disturbance. More general types of disturbances can be defined by a parameterized time-dependent function or by an additional set of parameterized differential equations. In the following we will replace disturbances $d(\alpha, t)$ by their parameterization α.

The flow of the nonlinear system (1.1) [44], including the dynamic and algebraic states, is denoted by Φ, i.e.,

$$\begin{aligned}[x(x_0, t_0, p, \alpha, t)^T, y(x_0, t_0, p, \alpha, t)^T]^T &= \Phi(x_0, t_0, p, \alpha, t), \\ [x_0^T, y_0^T]^T &= \Phi(x_0, t_0, p, \alpha, t_0).\end{aligned} \tag{2.5}$$

For nonlinear systems, the flow Φ is generally not available in an analytical form but has to be evaluated by numerical integration. In the following sections, we abbreviate the list of arguments of $x(x_0, t_0, p, \alpha, t)$ and $y(x_0, t_0, p, \alpha, t)$ for ease of notation and write $x(t)$, $y(t)$. Likewise, we assume for simplicity that there is only a single constraint (1.2), i.e., $n_h = 1$. This assumption will be dropped in section 4.

2.1. Critical manifold of grazing points. A manifold of grazing points is characterized by the set of trajectories that tangentially touch the hypersurface spanned by an active constraint $h = 0$. Before introducing the mathematical definitions for a grazing point, we want to show qualitatively the relevance of a grazing point for the transient behavior of a dynamic system (1.1) with constraints (1.2). Figure 3a shows several trajectories of the state x_1 after a step disturbance with its magnitude parameterized by α_1. The plane denoted by $h := x_{1\max} - x_1 = 0$ in Figure 3a is an upper bound on x_1 that must not be violated despite disturbances. The grazing trajectory for $\alpha_1 = \alpha_1^g$ touches the bound tangentially at the grazing time $t = t^g$. For values of $\alpha_1 > \alpha_1^g$ the trajectories cross the bounding plane and violate the upper bound for some time. The set of points where the trajectories cross the bound form a parabola-like curve with its extremum located at the grazing bifurcation t^g, α_1^g. For values of $\alpha_1 < \alpha_1^g$ trajectories of x_1 never cross the upper bound $x_{1\max}$. In the presence of a second disturbance parameter α_2 the parabola-like curve of the crossing points unfolds into a surface and the grazing point

into a curve in the (α_1, α_2, t)-space as depicted in Figure 3b. The projection of this curve onto the parameter plane (α_1, α_2) shown in Figure 3c separates the region where the constraint is not violated from the region where disturbances lead to trajectories that cross the bound. Figure 3c stresses the importance of the grazing bifurcation for the design of a dynamic system that has to be restricted to the region, where the constraint is not violated.

In what follows, we derive necessary conditions for a grazing bifurcation that can be used to describe boundaries of the type shown in Figure 3c. The necessary conditions for a grazing point can be derived by taking into account that the grazing trajectory

(i) must fulfill the constraint (1.2) at the grazing point

$$\begin{aligned} [x(t^g)^T, y(t^g)^T]^T &= \Phi(x_0, t_0, p, \alpha^g, t^g), \\ h(x(t^g), y(t^g), p, \alpha^g, t^g) &= 0, \end{aligned} \tag{2.6}$$

(ii) and must have a common tangent space with the hypersurface spanned by constraint (1.2) at the grazing point in the space $(x(t), y(t), t)$.

Let the tangent space of the hypersurface defined by the constraint (1.2) in the space $(x(t), y(t), t)$ be spanned by vectors $[v_d^T, v_a^T, \tilde{v}]^T$ with $v_d \in \mathbb{R}^{n_x}$, $v_a \in \mathbb{R}^{n_y}$, and $\tilde{v} \in \mathbb{R}$. The tangent space must be orthogonal to the normal space of the hypersurface. The normal space is spanned by the gradient of the constraint h with respect to the dynamic and algebraic state variables and time $[h_x, h_y, h_t]^T$ [20]. We can therefore write

$$\begin{aligned} [h_x, h_y, h_t] \begin{bmatrix} v_d \\ v_a \\ \tilde{v} \end{bmatrix} &= 0, \\ v_d^T v_d + v_a^T v_a + \tilde{v}^2 &\neq 0. \end{aligned} \tag{2.7}$$

A tangential vector of a trajectory is spanned by the derivative of the flow (2.5) with respect to time, $[\Phi_t(x_0, t_0, p, \alpha^g, t^g)^T, 1]^T$ with $\Phi_t = [x_t^T, y_t^T]^T \in \mathbb{R}^{n_x + n_y}$. The time derivative x_t is the right-hand side of (1.1) for the dynamic variables $x_t = f$. The time derivative y_t is implicitly defined by the time derivative of the algebraic equations:

$$0 = g_y y_t + g_x f + g_t. \tag{2.8}$$

Since g_y has full rank, by assumption the time derivative y_t can be calculated by solving the linear system (2.8) for y_t. Note, however, that y_t is usually provided by the numerical integrator solving the nonlinear dynamic system (1.1). At the grazing point $(x(t^g), y(t^g), t^g)$ the tangential vector of the corresponding trajectory must belong to the tangent space of the hypersurface defined by the active constraint (1.2); hence the vector $[f^T, y_t^T, 1]^T$ is a valid choice for $[v_d^T, v_a^T, \tilde{v}]^T$ such that (2.7) is satisfied. The augmented system $M^{(g)}$ for a grazing point can then be written as

$$M^{(g)} = \begin{pmatrix} h(x(t), y(t), p, \alpha, t) \\ h_x f(x(t), y(t), p, \alpha, t) + h_y y_t + h_t \end{pmatrix} = 0, \tag{2.9}$$

with the flow $\Phi = [x(t)^T, y(t)^T]^T$ as defined in (2.5). These two equations determine the time t^g and one parameter α_1^g at which the grazing point occurs. Note that the defining equations

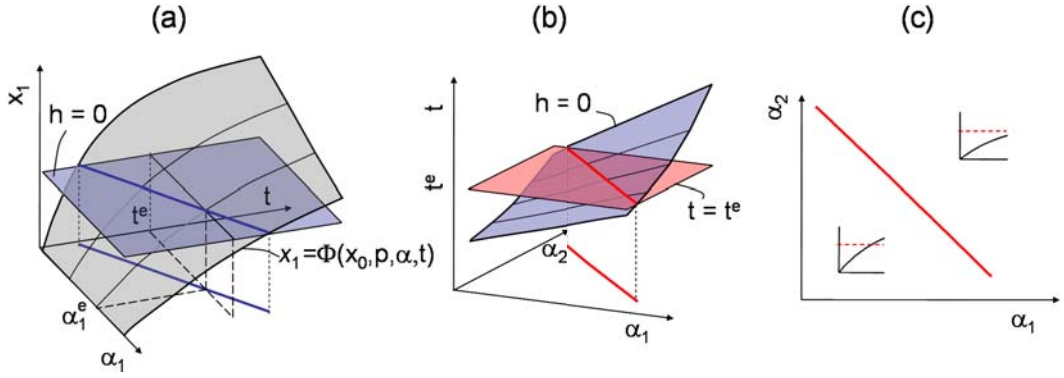

Figure 4. (a) *Trajectories for different values of disturbance parameter* α_1 *and curve connecting points where trajectories cross the boundary* $h = 0$ *with critical point at* t^e, α_1^e. (b) *Critical point unfolds to a curve of points which fulfill constraint* $h = 0$ *at* t^e *in a two-dimensional parameter space spanned by* α_1 *and* α_2. (c) *Projection of the curve splits the parameter plane* (α_1, α_2) *into a region where constraint* h *is violated by corresponding trajectories before* t^e *is reached and a region where the constraint is not crossed for* $t < t^e$.

(2.9) are also valid for those trajectories that have an inflection point at the hypersurface spanned by the active constraint (1.2). These trajectories cross the constraint directly after touching it tangentially. Such inflection points can be excluded by requiring the second order derivative of h with respect to time to be strictly positive,

$$\frac{\partial(h_x f + h_y y_t + h_t)}{\partial t} > 0,$$

as the grazing bifurcation always corresponds to a minimum of h.

In general, more than one critical manifold may exist for a constraint (1.2) if the trajectory touches or crosses the boundary several times.

2.2. Critical manifold for end-point constraints. A second type of critical manifold can be defined for a constraint (1.2), by specifying a final time t^e at which the constraint must be fulfilled exactly. The critical manifold for end-point constraints is defined by the set of parameter values for which the corresponding trajectories reach the constraint $h = 0$ at a specified final time t^e. Before stating the augmented system for the critical manifold we want to discuss the relevance of end-point constraints with the sketches in Figure 4. Several trajectories of a state x_1 after step disturbances triggered at $t = 0$ and parameterized by α_1 are shown in Figure 4a. All the trajectories are monotonically increasing and cross the upper bound $h := x_{1\max} - x_1 = 0$ at some point. For the critical parameter value α^e the upper bound is crossed exactly at the specified final time t^e. For parameter values $\alpha > \alpha^e$ the constraint is crossed for times $t > t^e$ whereas for $\alpha < \alpha^e$ the constraint is violated before t^e is reached. By taking into account a second disturbance parameter α_2, the critical point α^e, t^e unfolds into a curve in the space (t, α_1, α_2) as shown in Figure 4b. The projection of this curve on the parameter plane (α_1, α_2), as shown in Figure 4c, separates a region where the corresponding trajectories do not touch or cross the boundary until the specified time t^e is reached from a region where the constraint is always violated by the trajectories for $t < t^e$.

This type of critical manifold is particularly useful for bounds on monotonically increasing states or outputs for which grazing points cannot occur. End-point constraints can be formulated, e.g., to define an upper bound on the integrated squared error of an output with respect to its specified set-point for a closed-loop control system, as demonstrated in the case study in section 5.2.

The augmented system defining the manifold of end-point constraints is determined by the trajectory that crosses the bound (1.2) at the specified final time t^e. The augmented system is therefore given by

$$M^{(e)} = \begin{pmatrix} h(x(t), y(t), p, \alpha, t) \\ t - t^e \end{pmatrix} = 0. \tag{2.10}$$

These two equations determine the time t^e and one parameter α_1^e.

3. Derivation of the normal vector direction. The normal vector of critical manifolds can be calculated from the defining augmented systems (2.9) and (2.10) following the scheme of derivation developed by Mönnigmann and Marquardt [36]. We assume that initial conditions x_0 and design parameters p are fixed and known. Uncertain initial conditions for state x_i, $i \in \{1, \dots, n_x\}$, can easily be included by introducing a new state variable $\tilde{x}_i$ with initial conditions $\tilde{x}_{i0} = 0$ and time derivative given by $\tilde{x}_{it} = f_i(x, y, p, \alpha)$. Then $x_i = \tilde{x}_i + x_{i0}$, where x_{i0} can be treated as a parameter α. The normal space of the hypersurface defined by an augmented system $M^{(c)}$, $c \in \{g, e\}$, in the (t, α)-space is spanned by the columns of the Jacobian matrix of the partial derivatives $\nabla M^{(c)}$ [20]. In order to simplify the following derivations we collect the variables $x(t)$ and $y(t)$ in the state variable vector

$$z(t) = [x(t)^T, y(t)^T]^T, \quad z \in \mathbb{R}^{n_z}, \quad n_z = n_x + n_y,$$

and the functions f and g of (1.1) in

$$F = [f^T, g^T]^T.$$

Furthermore, we introduce the matrix $A \in \mathbb{R}^{n_z} \times \mathbb{R}^{n_z}$,

$$A = \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix},$$

with identity matrix $I \in \mathbb{R}^{n_x} \times \mathbb{R}^{n_x}$. The dynamic system (1.1) can then be rewritten as

$$Az_t = F(z, p, \alpha, t). \tag{3.1}$$

The normal space of the augmented systems (2.9) and (2.10) is an $(n_\alpha + 1) \times (n_\alpha + 1)$ matrix

$$B = \begin{bmatrix} \nabla_t M_1^{(c)} & \nabla_t M_2^{(c)} \\ \nabla_\alpha M_1^{(c)} & \nabla_\alpha M_2^{(c)} \end{bmatrix}, \quad c \in \{g, e\}. \tag{3.2}$$

For the augmented system of the grazing point (2.9), the entries of B result in

$$\begin{aligned} \nabla_t M_1^{(g)} &= h_z z_t + h_t, \\ \nabla_t M_2^{(g)} &= h_{zz} z_t z_t + h_z z_{tt} + 2h_{zt} z_t + h_{tt}, \\ \nabla_\alpha M_1^{(g)} &= (h_z \Phi_\alpha + h_\alpha)^T, \\ \nabla_\alpha M_2^{(g)} &= (h_{zz} z_t \Phi_\alpha + h_{z\alpha} z_t + h_z \Phi_{t\alpha} + h_{tz} \Phi_\alpha + h_{t\alpha})^T. \end{aligned} \tag{3.3}$$

The entries of B for the end-point system (2.10) are

$$\begin{aligned} \nabla_t M_1^{(e)} &= h_z z_t + h_t, \\ \nabla_t M_2^{(e)} &= 1, \\ \nabla_\alpha M_1^{(e)} &= (h_z \Phi_\alpha + h_\alpha)^T, \\ \nabla_\alpha M_2^{(e)} &= 0. \end{aligned} \tag{3.4}$$

The gradients include sensitivities Φ_α of the flow with respect to the uncertain parameters α. The differential and algebraic equations that define the dynamics of the sensitivities are obtained by differentiating the DAE system (1.1) with respect to the parameters α:

$$A\Phi_{\alpha t} = F_z \Phi_\alpha + F_\alpha. \tag{3.5}$$

The sensitivity system (3.5) consists of one DAE system for each parameter α_i, $i = 1, \ldots, n_\alpha$. These systems are independent of each other but all depend on the solution $z(t)$ of the state system. The sensitivities can be calculated by integrating the sensitivity equations (3.5) together with the state system (3.1). A number of numerical integrators supports efficient evaluation of the sensitivity equations by exploiting their special properties (e.g., [47]).

The parametrically closest point of a critical manifold to a given point is in the direction of the particular vector in the normal space (3.2) that has no contribution along the variable t. According to [36] this vector $r \in \mathbb{R}^{n_\alpha}$ is obtained by choosing $\kappa \in \mathbb{R}^2$ such that

$$B\kappa = \begin{bmatrix} 0 \\ r \end{bmatrix} \in \mathbb{R}^{n_\alpha + 1}, \tag{3.6}$$

where $0 \in \mathbb{R}$. Together with the regularization condition $\kappa^T \zeta - 1 = 0$ with $\zeta \in \mathbb{R}^2$ not orthogonal to κ [36], the two entries of κ are defined by the equations

$$\begin{aligned} \begin{bmatrix} \nabla_t M_1^{(c)} & \nabla_t M_2^{(c)} \end{bmatrix} \kappa = 0, \quad c \in \{g, e\}, \\ \kappa^T \zeta - 1 = 0. \end{aligned} \tag{3.7}$$

For the grazing point $c = g$, this system of equations can be solved by choosing $\kappa = [1, 0]^T$ and $\zeta = \kappa$. The trailing n_α elements of (3.6) then give the n_α equations defining the normal vector r. Substituting this choice of κ into (3.7) and using (3.2) and (3.3), the following system of equations results for the normal vector on grazing point manifolds:

$$G^{(g)} := \begin{pmatrix} z(t) - \Phi(z_0, t_0, p, \alpha, t) \\ h(z(t), p, \alpha, t) \\ h_z z_t + h_t \\ (h_z \Phi_\alpha + h_\alpha)^T - r \end{pmatrix} = 0. \tag{3.8}$$

For the end-point constraint, the system of equations (3.7) is solved by choosing $\kappa = [1, -(h_z z_t + h_t)]$ and $\zeta = [1, 0]$. The augmented system defining the normal direction for the

end-point constraint (2.10) then reads as

$$G^{(e)} := \begin{pmatrix} z(t) - \Phi(z_0, t_0, p, \alpha, t) \\ h(z(t), p, \alpha, t) \\ t - t^e \\ (h_z \Phi_\alpha + h_\alpha)^T - r \end{pmatrix} = 0. \tag{3.9}$$

Note that the required time derivatives $z_t = [x_t^T, y_t^T]$ as well as the sensitivities Φ_α can be provided by numerical simulators that allow for an efficient integration of the sensitivity equations (3.5), such as DDASPK [30], an extended version of LIMEX [47], or DAEPACK [49]. For large nonlinear systems with a Jacobian that has a sparse unordered structure the latter two should be preferred as they use sparse linear algebra packages.

The normal direction of a grazing point manifold is also calculated in a recent work of Donde and Hiskens [16]. The derivation in [16] differs from the calculations presented in this section in that Donde and Hiskens do not make use of the values calculated by the numerical integration for the algebraic states $y(t)$ and their derivatives with respect to time and parameters y_t, y_α. Instead they use the algebraic equations $0 = g$ for the calculation of y and (2.8) for the calculation of y_t. This leads to a more complex normal vector system that includes second order derivatives of the algebraic equations and $2n_x + 4n_y + n_\alpha + 4$ equations instead of $n_x + n_y + n_\alpha + 2$ equations in (3.8). For further illustration the B-matrix and the normal vector system according to [16] are given in Appendix B.

4. Optimization with normal vector constraints.

In this section we adopt the approach for the robust design of nonlinear systems first presented by Mönnigmann and Marquardt [36] that utilizes the normal vector direction of critical manifolds for the robust design of nonlinear systems. In this approach, the normal vector direction r is used to formulate constraints for a nonlinear program (NLP) to ensure that constraints (1.2) hold for the optimal design of nonlinear system (1.1) despite disturbances parameterized by uncertain parameters α. Note that in the following sections we consider again the general case of $n_h \geq 1$ constraints (1.2).

4.1. Normal vector constraints.

The approach enforces a lower bound on the parametric distance between the critical manifold and the boundary of the uncertainty region $\mathcal{A}$ (2.1). We denote the boundary as *robustness manifold* $M^{(\mathrm{rob})}$ defined by

$$M^{(\mathrm{rob})} = \begin{pmatrix} \hat{g}(\tilde{x}^{(\mathrm{rob})}, p, \alpha^{(\mathrm{rob})}) \\ \tilde{g}(\tilde{x}^{(\mathrm{rob})}, p, \alpha^{(\mathrm{rob})}) \end{pmatrix} = 0. \tag{4.1}$$

The normal vector constraint defining the lower bound then reads

$$\begin{aligned} \alpha^{(\mathrm{rob})} &= \alpha^{(c)} + lr, \\ l &\geq 0, \end{aligned} \tag{4.2}$$

with l as the measure for parametric distance and r representing the common normal direction of the critical manifold and the robustness manifold. As shown by Mönnigmann and Marquardt [37] the system of equations defining the normal direction of the robustness manifold

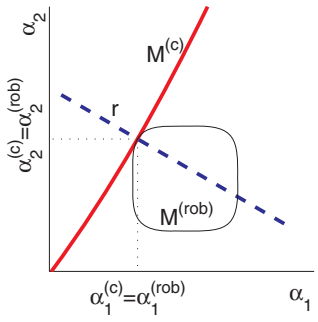

Figure 5. *Normal vector constraint: Uncertainty region is bounded by the robustness manifold $M^{(\mathrm{rob})}$. Distance is measured along common normal direction r of critical and robustness manifold.*

$r^{(\mathrm{rob})}$ can be derived following the scheme described in section 3, resulting in another normal vector system of the form

$$G^{(\mathrm{rob})}\left(\tilde{x}^{(\mathrm{rob})}, p, \alpha^{(\mathrm{rob})}, r^{(\mathrm{rob})}\right) = 0. \tag{4.3}$$

The lower bound on the parametric distance ensures that the complete range of uncertain parameters is at a safe distance from the critical boundary. This is further illustrated with Figure 5.

We are interested in finding a system design that minimizes an objective ϕ for a nominal operating point and, at the same time, satisfies the constraints (1.2). In the presence of fast disturbances parameterized by α bounded within the robustness manifold (4.1) the design problem is addressed by solving the following constrained NLP:[1]

$$\min \phi(z^{(0)}, p, t^{(0)}) \tag{4.4a}$$

$$\begin{aligned} \text{s. t. } z^{(0)} &= \Phi(z_0^{(0)}, t_0^{(0)}, p, t^{(0)}), \\ 0 &\le h_i(z^{(0)}, p, t^{(0)}) \quad \forall i \in \mathcal{I}, \end{aligned} \tag{4.4b}$$

$$0 = G^{(c,i,j)}\left(z^{(c,i,j)}, p, \alpha^{(c,i,j)}, t^{(c,i,j)}, r^{(i,j)}\right) \quad \forall i \in \mathcal{I},\ \forall j \in J_i, \tag{4.4c}$$

$$0 = G^{(\mathrm{rob},i,j)}\left(\tilde{x}^{(\mathrm{rob},i,j)}, p, \alpha^{(\mathrm{rob},i,j)}, \nu^{(i,j)} \cdot r^{(i,j)}\right) \quad \forall i \in \mathcal{I},\ \forall j \in J_i, \tag{4.4d}$$

$$\begin{aligned} 0 &= \alpha^{(c,i,j)} - \alpha^{(\mathrm{rob},i,j)} + l r^{(i,j)} \quad \forall i \in \mathcal{I},\ \forall j \in J_i, \\ 0 &\le l^{(i,j)} \quad \forall i \in \mathcal{I},\ \forall j \in J_i, \end{aligned} \tag{4.4e}$$

$$\begin{aligned} 0 &\le \tilde{h}(z^{(0)}, p, t^{(0)}, \tilde{x}_1), \\ 0 &= \hat{h}(z^{(0)}, p, t^{(0)}, \tilde{x}_2). \end{aligned} \tag{4.4f}$$

Equations (4.4b) define the states $z^{(0)}$ of the nominal system without disturbances. The set $\mathcal{I} = \{1, \ldots, n_h\}$ enumerates the constraints. Equation (4.4c) constitutes the normal vector

[1]For ease of notation, the time argument (t) for states z is omitted in the following sections.

system of the critical points. For each constraint $i \in \mathcal{I}$ several critical points $j \in J_i$ may exist in general. More than one closest point may exist due to nonconvexity of the critical manifolds [37] or in the case that there are several critical manifolds of grazing points for a single constraint. The superscript $c \in \{g, e\}$ denotes the type of critical manifold (grazing point or end-point).

The normal vector of the robustness manifold is defined by (4.4d). The scalar multiplier $\nu^{(i,j)}$ is introduced as the normal vectors of the critical manifold and the robustness manifold are not normalized in their defining equations (3.8), (3.9), and (4.3) and might furthermore point in opposite directions. Equations (4.4e) enforce the minimal distance between a point located on the robustness manifold $\alpha^{(\mathrm{rob},i,j)}$ and the nearest critical point $\alpha^{(c,i,j)}$.

Additional equality and inequality constraints (4.4f) with auxiliary variables $\tilde{x}_1 \in \mathbb{R}^{n_{\tilde{x}_1}}$ and $\tilde{x}_2 \in \mathbb{R}^{n_{\tilde{x}_2}}$ map into $\mathbb{R}^{n_{\tilde{h}}}$ or $\mathbb{R}^{n_{\tilde{h}}}$, respectively. These constraints are included in the formulation to allow for further specifications of the nominal solution that do not have to be robustly enforced. Typically, these are constraints which are not affected by the disturbances, e.g., simple box constraints on the parameters p. The degrees of freedom of the NLP (4.4) are p, $z_0^{(0)}$, $t^{(0)}$, $\tilde{x}_1$, $\tilde{x}_2$, $t^{(c,i,j)}$, $\alpha^{(c,i,j)}$, $\alpha^{(\mathrm{rob},i,j)}$, $\tilde{x}^{(\mathrm{rob},i,j)}$, $r^{(i,j)}$, $\nu^{(i,j)}$, and $l^{(i,j)}$.

4.2. Solution strategy. A number of difficulties has to be tackled to solve the NLP (4.4). Generally, the location of the critical manifolds is not known beforehand. Therefore, an algorithmic solution strategy for critical manifolds of steady states [38] has to be adapted to the new types of critical manifolds.

The algorithm builds up the sets of critical points and corresponding normal vector constraints J_i as the optimization proceeds. Newly detected critical points that violate bounds h_i will in general not satisfy the normal vector constraints (4.2). Therefore, an additional set of points $\mathcal{J}$ is introduced that comprises the newly detected critical points. An initialization step is necessary to move points from $\mathcal{J}$ to the sets of points J_i used for the normal vector constraints. The algorithm also allows for removal of normal vector constraints (i, j) if the parametric distance $l^{(i,j)}$ is larger than a specified threshold $l_{\max}$. The algorithm involves the following four steps, of which the last three may have to be carried out repeatedly:

(i) *Initialization*: Choose an initial nominal operating point for which all constraints h_i are satisfied. If points that violate h_i are known beforehand, put them into the set $\mathcal{J}$.

(ii) *Update of J_i*: Find the points on the critical manifolds $\alpha \in M^{(c,i)}$ that satisfy the normal vector constraints using the points in set $\mathcal{J}$ as initialization. The obtained critical points are moved from set $\mathcal{J}$ to the sets J_i. The last step in the update of J_i is the removal of those critical points (i, j) from the set J_i for which $l^{(i,j)} > l_{\max}$.

(iii) *Optimization*: Solve NLP (4.4) with normal vector constraints to the critical points contained in J_i.

(iv) *Search within the robustness region for constraint violations*: Check if the constraints hold within the region of parametric uncertainty. If critical points are found, update index $\mathcal{J}$ and return to step (ii).

If the test in step (iv) reveals no further critical points, an optimal operating point has been found that is robust with respect to the constraints in the presence of parametric uncertainty. The algorithm is therefore terminated.

In contrast to critical points of steady states, there are no adequate test functions to detect

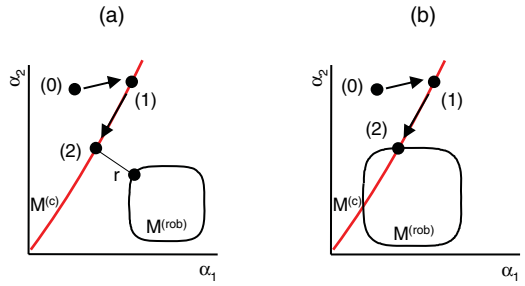

Figure 6. (a) *Initialization steps for points in $\mathcal{J}$ located outside the robustness region.* (b) *Initialization fails if critical manifold crosses the robustness manifold.*

points that directly satisfy all conditions that must hold for a point located on the critical manifold. In the following we therefore elaborate further on the detection of critical points in step (iv) and initialization of normal vector constraints in step (ii), which have to be modified in comparison to [38].

4.2.1. Detection of critical points. Detection of unknown critical points in step (iv) is realized by numerical integration of system (1.1). Since the numerical integration can only be carried out for a finite span of time, the detection is limited to a finite time horizon. The horizon length must be a compromise between computational costs on the one hand and the risk of missing constraint violations on the other hand. The check for constraint violations can be stopped at a finite time if a steady state or a stable limit cycle is reached. The search within the robustness region is carried out in this work on a grid of points of the robustness region, e.g., on the corner or center points of the faces of the hypercube (2.3).

4.2.2. Initialization of normal vector constraints. In general, critical points detected in step (iv) do not satisfy the augmented system (2.9) or (2.10). They will also not be the nearest critical point to the robustness manifold. The solver used to solve NLP (4.4), however, requires a feasible point as initialization. In step (ii), therefore, a strategy has to be employed to obtain a critical point satisfying the normal vector constraints (4.4e). For points in $\mathcal{J}$ located outside the uncertainty region, i.e., $0 \geq \tilde{g}(z, \tilde{x}, p, \alpha, t)$, the two step strategy illustrated by Figure 6a is used:

(i) *Find a point located on the critical manifold*: Here we assume that the second condition holds for the points in $\mathcal{J}$, i.e., the tangential condition for a grazing bifurcation $0 = h_z z_t + h_t$ or the time condition $0 = t - t^e$ for an end-point constraint. Bound (1.2), however, is assumed to be violated, $0 > h$. To obtain a point on the critical manifold the following optimization problem is solved:

$$
\begin{aligned}
&\max_{\alpha,t} \quad h(z,p,\alpha,t) \\
&\text{s. t. } z = \Phi(z_0^{(0)}, t_0^{(0)}, p, \alpha, t), \\
&\qquad 0 \geq h(z,p,\alpha,t), \\
&\qquad 0 = \begin{cases} h_z z_t + h_t & \text{if } c = g, \\ t - t^e & \text{if } c = e. \end{cases}
\end{aligned} \tag{4.5}
$$

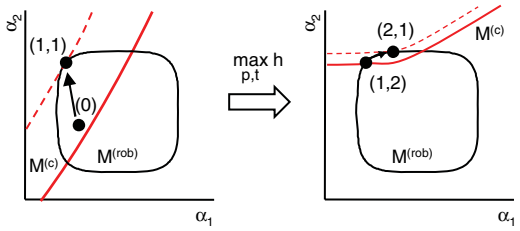

Figure 7. *Two iterations of the initialization steps for points in $\mathcal{J}$ located within the robustness region. Minimization (4.7) ($(0) \to (1,1)$ and $(1,2) \to (2,1)$) and maximization (4.8) ($(1,1) \to (1,2)$). The dashed curve is the level set $h = \text{const} < 0$, which touches the robustness region tangentially.*

This gives a point on the critical manifold if $h = 0$ at the optimum. Note that an equivalent formulation can be used in case that the first condition $h = 0$ of the augmented systems holds at the detected point by using the second condition as objective in (4.5). In Figure 6a transition of point (0) to point (1) illustrates this step.

(ii) *Find the closest critical point*: Points satisfying normal vector constraint (4.4e) are found by minimizing the parametric distance between the critical manifold and the robustness manifold over all $\alpha \in M^{(c,i)}$ and $\alpha^{(\text{rob})} \in M^{(\text{rob})}$ for a fixed nominal point

$$\begin{aligned} \min_{\alpha,t,\alpha^{(\text{rob})},\tilde{x}^{(\text{rob})}} \ & \frac{1}{2}(\alpha - \alpha^{(\text{rob})})^T(\alpha - \alpha^{(\text{rob})}) \\ \text{s. t. } & z = \Phi(z_0^{(0)}, t_0^{(0)}, p, \alpha, t), \\ & 0 = M^{(c,i)}(z, p, \alpha, t), \quad i \in \mathcal{I}, \\ & 0 = M^{(\text{rob})}(\tilde{x}^{(\text{rob})}, p, \alpha^{(\text{rob})}). \end{aligned} \tag{4.6}$$

As pointed out in [37] the Lagrange multipliers required for the definition of the Karush–Kuhn–Tucker conditions of optimality can be used to initialize the normal vector r, the distance variable l, and ν. In Figure 6a solving (4.6) corresponds to the transition from point (1) to point (2). In case $\alpha = \alpha^{(\text{rob})}$ it has to be checked if the critical manifold intersects the robustness region (cf. Figure 6b). In this case the initialization routine fails and the strategy for critical points located within the robustness region has to be pursued.

If a point in $\mathcal{J}$ is located within the uncertainty region, then the critical manifold intersects the robustness region and has to be pushed outside before NLP (4.4) can be solved. This is achieved by the following two iterative steps illustrated by Figure 7:

(i) *Find a worst-case point on the robustness manifold*: The worst-case point with respect to the constraint h on the robustness manifold is found by solving

$$\begin{aligned} \min_{\alpha,t} \quad & h(z, p, \alpha, t) \\ \text{s. t. } & z = \Phi(z_0^{(0)}, t_0^{(0)}, p, \alpha, t), \\ & 0 = \begin{cases} h_z z_t + h_t & \text{if } c = g, \\ t - t^e & \text{if } c = e, \end{cases} \\ & 0 = M^{(\text{rob})}(\tilde{x}, p, \alpha). \end{aligned} \tag{4.7}$$

In Figure 7 this is the transition from point (0) to $(1,1)$ and from point $(1,2)$ to $(2,1)$.

(ii) *Push the critical manifold to the robustness manifold*: By maximizing the constraint for fixed uncertain parameters,

$$
\begin{aligned}
\max_{p,t} \quad & h(z,p,\alpha,t) \\
\text{s. t. } & z = \Phi(z_0^{(0)}, t_0^{(0)}, p, \alpha, t), \\
& 0 \geq h(z,p,\alpha,t), \\
& 0 = \begin{cases} h_z z_t + h_t & \text{if } c = g, \\ t - t^e & \text{if } c = e, \end{cases} \\
& z = \Phi(z_0^{(0)}, t_0^{(0)}, p, t), \\
& 0 \leq h_i(z^{(0)}, p, t^{(0)}) \quad \forall i \in \mathcal{I}, \\
& 0 \leq \tilde{h}(z^{(0)}, p, t^{(0)}, \tilde{x}_1), \\
& 0 = \hat{h}(z^{(0)}, p, t^{(0)}, \tilde{x}_2),
\end{aligned}
\tag{4.8}
$$

the critical manifold crosses the robustness manifold at the former worst-case point ($(1,2)$ in Figure 7) if $h = 0$ (and if the equations defining the critical manifold do not depend on p) at the solution of (4.8).

The two steps have to be repeated iteratively until the constraint violation after step (i) is smaller than a specified threshold. Again, the Lagrangian multipliers of the optimality conditions for (4.7) can be used to initialize the normal vector r and ν of NLP (4.4).

The described initialization steps may fail due to an unsuitable control structure or too tight restrictions (1.2) for the modeled disturbances. In this case the control structure needs to be modified or the requirements have to be relaxed.

4.3. Implementational details. For the solution of the NLP the SQP-solver NPSOL [21] is used. This gradient-based solver requires the derivatives of the constraints of NLP (4.4) with respect to the degrees of freedom of the optimization problem. As the system of equations defining the normal vectors for the critical manifold of grazing points (3.8) and end-point constraints (3.9) involve sensitivities Φ_α of the state variables, the corresponding derivatives of the normal vector equations contain second order sensitivities $\Phi_{\alpha\alpha}$ (and $\Phi_{\alpha p}, \Phi_{\alpha z_0}$). The dynamics of the second order sensitivities are defined by the DAE system that is obtained by differentiating the DAE system for the first order sensitivities (3.5) with respect to α, p, and initial conditions z_0. The DAE system for the second order sensitivities with respect to the uncertain parameters α can be written as

$$
M\Phi_{\alpha\alpha t} = F_{zz}\Phi_\alpha\Phi_\alpha + 2F_{z\alpha}\Phi_\alpha + F_z\Phi_{\alpha\alpha} + F_{\alpha\alpha}. \tag{4.9}
$$

The DAE systems for the mixed second order sensitivities are defined accordingly. Numerical integration of the nonlinear system (1.1) and sensitivity equations (3.5), (4.9) is carried out either by DDASPK [30] or by an extended version of LIMEX [47]. As pointed out in [52] the structure of the equations of the second order sensitivities (4.9) is similar to the structure of the first order sensitivities. They can therefore be integrated in the same efficient fashion as the

first order sensitivities. Furthermore, the symmetry of the second order sensitivities $\Phi_{\alpha_i\alpha_j} = \Phi_{\alpha_j\alpha_i}$ can be easily exploited. For a larger number of parameters a promising alternative based on adjoints has been suggested recently [25] to further reduce the computational effort.

Finally, second order derivatives of the state variables with respect to time $z_{tt} = [x_{tt}^T, y_{tt}^T]^T$ are required to state the derivatives of the grazing bifurcation augmented system (2.9). These derivatives are usually not provided by the numerical integrator and have to be calculated by evaluating the time derivatives of the differential equations defining x_t (1.1) and the equations for y_t (2.8), respectively. x_{tt} is easily calculated by the following expression:

$$x_{tt} = f_x f + f_y y_t + f_t.$$

For y_{tt} the following system of linear equations has to be solved:

$$g_y y_{tt} = -(g_x x_{tt} + g_{xx} f f + 2 g_{xy} f y_t + g_{yy} y_t y_t + g_{tx} f + g_{ty} y_t + g_{tt}).$$

The partial derivatives of the functions f, g, and h that are needed for the constraints and gradients of the NLP (4.4) are evaluated with symbolic differentiation with Maple [40] and automatic differentiation with ADIFOR [3].

5. Illustrative case studies.

In section 5.1 we present two applications of the normal vector constraints to ensure a minimal distance to a manifold of grazing points. In section 5.2 we show an application of the approach to guarantee robustness with respect to a critical manifold for end-point constraints.

5.1. Robustness with respect to grazing points.

We investigate a bioreactor model which has already been robustly optimized with respect to steady-state stability boundaries by Mönnigmann and Marquardt [36]. Here we consider an upper bound on the substrate concentration, which should robustly hold despite fast disturbances. The second case study involves a closed-loop chemical reactor with state feedback control to illustrate the possibility of simultaneous operating point and control design with the presented approach.

5.1.1. Bioreactor.

Consider the continuous bioreactor model with two nonlinear ordinary differential equations [1]:

$$\begin{aligned} x_{1\tau} &= -x_1 + \Lambda(x_2) Da\, x_1 := f_1, \\ x_{2\tau} &= -x_2 + \Sigma(x_2) Da\, x_1 := f_2. \end{aligned} \tag{5.1}$$

Here x_1 denotes the dimensionless biomass concentration, x_2 the dimensionless substrate concentration, and τ is the dimensionless time. The uncertain parameters are the Damköhler number Da and the feed substrate concentration S_q in $\mathrm{kmol\,m^{-3}}$. Λ and Σ are known state functions describing the bioreaction [1, 36]. The bioreactor is optimized with respect to the economic profit function [36]

$$\phi = -\frac{c_\phi \mu(S_q) V}{Da}(c_1(a + bS_q)S_q x_1 - c_2(S_q)), \tag{5.2}$$

with reactor volume V, cost coefficients $c_1, c_2(S_q)$, and kinetic parameters a and b. The substrate feed concentration is limited to values between

$$S_d \le S_q \le S_c, \quad S_d = 0.3\,\mathrm{kmol\,m^{-3}},\ S_c = 1.0\,\mathrm{kmol\,m^{-3}}.$$

Parameter values are taken from [5] and [36].

The optimal operating point is unstable [5] if no additional constraints ensure the stability of the optimal solution. As shown in Figure 8, the bioreactor model exhibits two stability boundaries in the parameter plane (Da, S_q): a manifold of Hopf bifurcations and a manifold of saddle-node bifurcations. These manifolds separate the region with stable stationary points from the region with unstable steady states. In [36] the bioreactor model has been optimized with respect to the profit function (5.2) guaranteeing robust stability by normal vector constraints to the two stability boundaries. In this work we look for an optimal steady-state operating point $(x^{(0)}, p)$ for which we can guarantee that a maximal substrate concentration

$$0 < S_{\max} - S := h, \quad S_{\max} = 0.07\,\mathrm{kmol\,m^{-3}}, \tag{5.3}$$

is not violated at the outflow of the reactor after step disturbances of both the Damköhler number Da and the feed substrate concentration S_q. The disturbances are parameterized by the parameters dDa and dS_q,

$$Da = \begin{cases} \overline{Da}, & t \le t_0, \\ \overline{Da} + dDa, & t > t_0, \end{cases} \tag{5.4a}$$

$$S_q = \begin{cases} \overline{S_q}, & t \le t_0, \\ \overline{S_q} + dS_q, & t > t_0, \end{cases} \tag{5.4b}$$

which are bounded by

$$\begin{aligned} dDa &\in [-\Delta Da, \Delta Da], \quad \Delta Da = 0.05, \\ dS_q &\in [-\Delta S_q, \Delta S_q], \quad \Delta S_q = 0.03\,\mathrm{kmol\,m^{-3}}. \end{aligned}$$

Hence, we are looking for a steady state, defined by $0 = f(x_1^{(0)}, x_2^{(0)}, \overline{Da}, \overline{S_q})$, such that the upper bound on the substrate concentration in the reactor (5.3) is not violated by any of the trajectories $\Phi(x_{10}, x_{20}, t_0, Da, S_q, t)$ with initial conditions $x_{10} = x_1^{(0)}$, $x_{20} = x_2^{(0)}$ and uncertain disturbances defined by (5.4). With regard to the NLP (4.4) we have $\mathcal{I} = \{1\}$, $c = g$, $z = \{x_1, x_2\}$, $p = \{\overline{Da}, \overline{S_q}\}$, and $\alpha = \{dDa, dS_q\}$. We consider the approximation of the uncertainty box by an ellipse $\sum_i (\alpha_i/\Delta\alpha_i)^2 = n_\alpha$.

Optimization starts without robustness constraints. Unknown critical manifolds are detected by numerical integration and repeated optimization steps. Each detected critical point adds normal vector constraints with new variables $t^{(i,j)}$, $l^{(i,j)}$, $\nu^{(i,j)}$, $dDa^{(i,j)}$, $dS_q^{(i,j)}$, $dDa^{(\mathrm{rob},i,j)}$, $dS_q^{(\mathrm{rob},i,j)}$ to the NLP. In this example there is only one constraint $\mathcal{I} = \{1\}$ and one critical point $J_1 = \{1\}$. NLP (4.4) was solved in less than 0.1 seconds on a PC with 2 GHz and 1 GB RAM. The result of the optimization is shown in Figure 8 in the (Da, S_q)-plane. Figure 8 illustrates that the normal vector constraint ensuring the minimal distance between the nominal operating point and the manifold of grazing points $S^{(g)} = S_{\max}$ is active at the optimum. The profit function has a value of $\phi = 0.17$ at $Da^{(0)} = 0.99, S_q^{(0)} = 0.3\,\mathrm{kmol\,m^{-3}}$ compared to $\phi = 1$ at the unstable optimal operating point. The nearest point on the manifold of steady states satisfying the bound (5.3), denoted as $S^{(\mathrm{st})} = S_{\max}$, is located at a greater distance from the nominal point than the manifold of grazing points $S^{(g)}$. This shows that it

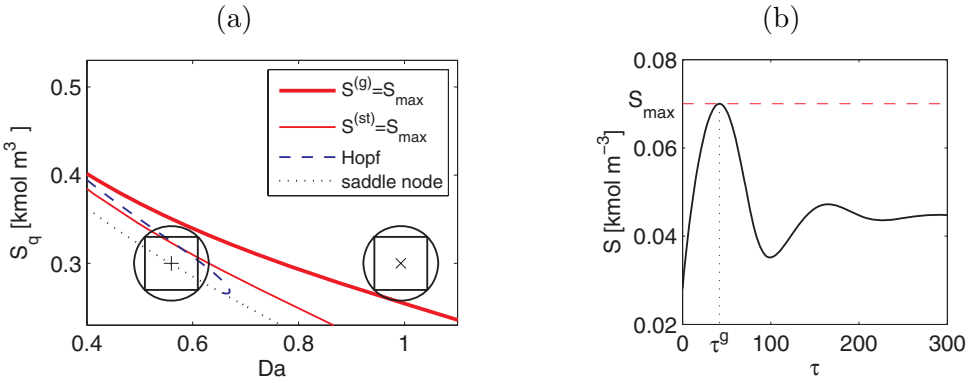

Figure 8. *Optimization of the bioreactor model* (5.1). (a) *The optimal solution without normal vector constraints* (+) *is unstable. Table 1

Optimal operating point of the fermenter obtained with optimization without normal vector constraints (unstable) (a)*, and with an ellipsoidal robustness region* (b).

	(a)	(b)
$\overline{Da}$	0.56	0.99
$\overline{S_q}\,(\mathrm{kmol\,m^{-3}})$	0.3	0.3
$x_1^{(0)}$	0.275	0.169
$x_2^{(0)}$	0.566	0.891
ϕ	1.0	0.17

is not sufficient to consider robustness with respect to steady-state constraints in the presence of fast disturbances. In this case study the stability boundaries are also located at a greater distance from the nominal point than the manifold of grazing points and do not have to be considered by additional normal vector constraints. In other cases, however, it might be necessary to take into account simultaneously normal vector constraints with respect to critical manifolds of grazing points and end-points, *and* normal vector constraints with respect to steady-state stability boundaries.

The result of the robust optimization is summarized in Table 1 together with the (unstable) optimal operating point obtained by the optimization of the objective (5.2) without normal vector constraints.

5.1.2. Continuous stirred tank reactor with state feedback control. As a second example for the robust optimization with respect to grazing points we consider a continuous stirred tank reactor (CSTR) with the exothermic consecutive reactions $A \to B \to C$ with B being the desired product. The CSTR model consists of nonlinear state equations for material balances of species A and B and energy balances for the reactor and cooling jacket assuming perfect level control [43]

$$c_{At} = \frac{q}{V}(c_{\mathrm{Aq}} - c_A) - r_1, \tag{5.5}$$

$$
\begin{aligned}
c_{Bt} &= \frac{q}{V} - c_B + r_1 - r_2, \\
T_t &= \frac{q}{V}(T_q - T) - \frac{\Delta H_1}{\rho C_p} r_1 - \frac{\Delta H_2}{\rho C_p} r_2 + \frac{UA}{V \rho C_p}(T_c - T), \\
T_{ct} &= \frac{q_c}{V_c}(T_{q_c} - T_c) - \frac{UA}{V_c \rho_c C_{pc}}(T_c - T),
\end{aligned}
$$

with reaction rates r_1 and r_2 defined by

$$
r_1 = k_{10} \exp\left(-\frac{E_1}{RT}\right) c_A^2, \quad r_2 = k_{20} \exp\left(-\frac{E_2}{RT}\right) c_B.
$$

The feed rates of the reactant q and coolant q_c are the manipulated variables; all parameter values are taken from [43]. A PI controller is considered,

$$
u(t) = u_0 + K(x(t) - x_{\mathrm{sp}}) + K_i \int_0^t (x(\tau) - x_{\mathrm{sp}}) d\tau,
$$

with $u = [q, q_c]^T$, $x = [c_A, c_B, T, T_c]^T$, and u_0, x_{sp}, K, and K_i as tunable control parameters. Integral action is used for concentration control of the desired product B and for the reactor temperature T only, i.e.,

$$
K_i = \begin{pmatrix} 0 & K_{i12} & 0 & 0 \\ 0 & 0 & K_{i23} & 0 \end{pmatrix}.
$$

In total there are 10 control parameters $K_{11}, K_{12}, K_{13}, K_{14}, K_{21}, K_{22}, K_{23}, K_{24}, K_{i12}, K_{i23}$. For simplicity, we assume that measurements for all states are available, such that a state estimator is not required. Disturbances are modeled by sinusoidal variations of the feed concentration c_{Aq} and feed temperature T_q:

$$
T_q(t) = \begin{cases} \overline{T_q}, & t \le t_0, \\ \overline{T_q} + dT_q \sin \omega_{T_q}(t - t_0), & t > t_0, \end{cases} \tag{5.6a}
$$

$$
c_{Aq} = \begin{cases} \overline{c_{Aq}}, & t \le t_0, \\ \overline{c_{Aq}} + dc_{Aq} \sin \omega_{c_{Aq}}(t - t_0), & t > t_0. \end{cases} \tag{5.6b}
$$

Disturbances and uncertainties in the feed stream can arise, e.g., if the reactor is part of a larger process plant and the reactant stream is the product of a pretreatment step. If this pretreatment process is not operated at steady state, the resulting feed temperature and concentration may also vary. The disturbance of the feed temperature is parameterized by the amplitude dT_q and frequency ω_{T_q} that are bounded by

$$
\begin{aligned}
dT_q &\in [-\Delta dT_q, \Delta dT_q], \\
\omega_{T_q} &\in [\overline{\omega_{T_q}} - \Delta\omega_{T_q}, \overline{\omega_{T_q}} + \Delta\omega_{T_q}],
\end{aligned} \tag{5.7}
$$

with

$$
\Delta dT_q = 10\,\mathrm{K}, \quad \Delta\omega_{T_q} = 2\,\mathrm{rad\,h^{-1}}, \quad \overline{\omega_{T_q}} = 3\,\mathrm{rad\,h^{-1}}.
$$

Likewise, the disturbance of the feed concentration is parameterized by the amplitude dC_{Aq} and frequency $\omega_{c_{Aq}}$ bounded by

$$\begin{aligned} dc_{Aq} &\in [-\Delta dc_{Aq}, \Delta dc_{Aq}], \\ \omega_{c_{Aq}} &\in [\overline{\omega_{c_{Aq}}} - \Delta\omega_{c_{Aq}}, \overline{\omega_{c_{Aq}}} + \Delta\omega_{c_{Aq}}], \end{aligned} \tag{5.8}$$

with

$$\Delta dc_{Aq} = 0.1\,\mathrm{kmol\,m^{-3}}, \quad \Delta\omega_{c_{Aq}} = 5\,\mathrm{rad\,h^{-1}}, \quad \overline{\omega_{c_{Aq}}} = 8\,\mathrm{rad\,h^{-1}}.$$

Here, we have a four-dimensional uncertainty box with $\alpha = [dT_q, \omega_{T_q}, dc_{Aq}, \omega_{c_{Aq}}]$. A tight approximation of the uncertainty box is important as any overestimation will generally lead to more conservative results or even prevent finding a feasible solution of (4.4). For an increasing number of uncertain parameters n_α the overestimation of the box by the ellipsoidal approximation used in the first example grows exponentially. For $n_\alpha = 2$ the volume ratio between a hypersphere with radius $\sqrt{n_\alpha}$ and a hypercube with side length 2 is approximately 1.6, whereas for $n_\alpha = 10$ the ratio is almost 250. Tighter approximations of the uncertainty box can be realized, e.g., by using higher norms for the approximation

$$\tilde{g} := \sum_{i=1}^{n_\alpha} (\alpha_i - \overline{\alpha_i})^{2j} - n_\alpha \tag{5.9}$$

with $j \in \mathbb{Z}^+$. Alternatively, one can use the approximation introduced by Kreisselmeier and Steinhauser [28]

$$\tilde{g} := \frac{1}{\rho} \ln\left(\frac{1}{2n_\alpha} \sum_{i=1}^{n_\alpha} \exp(\rho(\alpha_i - \overline{\alpha_i} - 1)) + \exp(\rho(-(\alpha_i - \overline{\alpha_i}) - 1)) \right).$$

The approximation of the uncertainty box gets closer for larger values of the parameter ρ. Here we use the less complicated formulation (5.9) with $j = 4$.

We now want to find a controller tuning and process design that guarantee that the outlet concentration of product B stays within specified bounds around the nominal value $c_B^{(0)}$ despite the presence of disturbances, i.e.,

$$0 \le -c_B + c_B^{(0)} + 0.15\,\mathrm{kmol\,m^{-1}} := h_1, \tag{5.10a}$$

$$0 \le c_B - c_B^{(0)} + 0.15\,\mathrm{kmol\,m^{-1}} := h_2. \tag{5.10b}$$

For the nominal operating point (0) steady-state constraints $0 = f^{(0)}$ are employed. Additional constraints $0 = x_{\mathrm{sp}} - x^{(0)}$ ensure that the controller is not active at the nominal point. The initial values for the critical points (i, j) with $\mathcal{I} = \{1, 2\}$, $c = g$ are set to the steady-state values of the nominal system $x_0^{(i,j)} = x^{(0)}$. Normal-vector constraints on critical manifolds of grazing points defined by the upper (5.10a) and lower concentration limit (5.10b) are used to guarantee that the outlet concentration of the product c_B stays within the bounds despite disturbances (5.6). We solve NLP (4.4) with respect to the objective function

$$\phi = q_0(\kappa_A \overline{c_A} - \kappa_B c_B^{(0)}) + q_c\kappa_c$$

with κ_A, κ_B, and κ_c as cost coefficients of reactant A, product B, and coolant c, respectively, where $\kappa_c = 0.05\kappa_A$, $\kappa_B = 2\kappa_A$ are chosen for this case study. Degrees of freedom for the NLP (4.4) are the 10 control parameters K and K_i, the nominal feed rates q_0, q_{c0}, limited to values between 60 and $100\,\mathrm{m^3\,h^{-1}}$, the nominal feed concentration $\overline{c_{Aq}}$ bounded within 2 and $12\,\mathrm{kmol\,m^{-3}}$, the nominal steady state $c_A^{(0)}, c_B^{(0)}, T^{(0)}, T_c^{(0)}$, and corresponding set points of the controller. Each normal vector constraint involves a set of disturbance parameters on the critical manifold and on the robustness manifold as well as the critical time at which the grazing point occurs.

At the optimal solution there is one active normal vector constraint corresponding to the critical manifold of the upper concentration bound (5.10a). Figures 9a and 9b show the critical manifold corresponding to $h_1 = 0$ and the robustness manifold. The shape of the critical manifold shows that all disturbance parameters have a strong influence on system (5.5). The approach is able to automatically identify the worst-case combination of the disturbances and find an economical optimal design ensuring that the concentration bound holds. The trajectory of the reactor concentration corresponding to the nearest grazing point of the upper bound (5.10a) is shown in Figure 9c. The concentration trajectory touches the upper bound at $t^{(1)} = 1.16\,\mathrm{h}$. The aggregated computational time for the solution of NLP (4.4) and the optimization problems of the initialization routine described in section 4.2 is 18 seconds on a PC with 2 GHz and 1 GB of RAM. The values of parameters p and disturbance parameters α at the optimal operating point are summarized in Table 2.

5.2. Robustness with respect to end-point constraints. Finally we show an application of the normal vector constraints for manifolds of end-point constraints.[2] We consider a cooled continuous stirred tank reactor (CSTR) with an exothermic first order reaction $A \rightarrow B$ with temperature control assuming perfect level control [23]. The CSTR model consists of nonlinear state equations for material and energy balances including reaction kinetics and heat transfer [51]:

$$\begin{aligned} c_{At} &= \frac{q}{V}(c_{\mathrm{Aq}} - c_A) - k_0 \exp\left(-\frac{E}{RT}\right) c_A, \\ T_t &= \frac{q}{V}(T_q - T) - \frac{\Delta H k_0}{\rho C_p} \exp\left(-\frac{E}{RT}\right) c_A + \frac{UA}{V\rho C_p}(T_c - T). \end{aligned} \tag{5.11}$$

The temperature of the cooling fluid T_c is the manipulated variable, the reactor temperature T is the measured and controlled variable, and c_A is the concentration of species A in the reactor. The values of the process parameters are taken from [23]. Control is realized by means of a linearizing feedback including integral action. The control law reads as [23]

$$\begin{aligned} T_c = &\frac{-\frac{q}{V}(T_q - T) + \frac{\Delta H}{\rho C_p} k_0 \exp(-\frac{E}{RT})\tilde{c}_A + \frac{UA}{V\rho C_p} T}{\frac{UA}{V\rho C_p}} \\ &+ \frac{\frac{2}{\varepsilon}(T_{\mathrm{sp}} - T) + \frac{1}{\varepsilon^2}\int_0^t (T_{\mathrm{sp}} - T) d\tau}{\frac{UA}{V\rho C_p}}. \end{aligned} \tag{5.12}$$

The control law comprises one tuning parameter ε, which corresponds to the time constant of the closed-loop dynamics; i.e., the smaller ε is, the faster the dynamics of the closed-loop system are. If the model used for the controller design and the real plant exactly match, the controller stabilizes the process for all possible set-point temperatures T_{sp}. In such a case, ε can be tuned to arbitrary small values resulting in very fast system dynamics. In real applications, however, there will always exist a mismatch between the plant and the model because of disturbances and uncertain parameters. In this case study the measured concentration $\tilde{c}_A$ used in the control law may differ from the true concentration c_A. We investigate a set-point change in the reactor temperature from $T_{\mathrm{sp0}} = 370\,\mathrm{K}$ to $T_{\mathrm{sp}} = 400\,\mathrm{K}$ at $t_0 = 0$. The initial conditions of the nominal case correspond to the steady state at $T_{\mathrm{sp0}} = 370\,\mathrm{K}$, $\overline{T_0} = 370\,\mathrm{K}$, and $\overline{c_{A0}} = 0.206\,\mathrm{mol\,l^{-1}}$. We assume a step disturbance of the feed temperature

$$T_q(t) = \begin{cases} \overline{T_q}, & t \le t_0, \\ \overline{T_q} + dT_q, & t > t_0, \end{cases} \tag{5.13}$$

with $dT_q\,(\mathrm{K}) \in [-15, 15]$. Further, the initial conditions of the reactor temperature and reactor concentration are not known exactly and may vary around the nominal values:

$$\begin{aligned} T_0 &\in [\overline{T_0} - \Delta T_0,\, \overline{T_0} + \Delta T_0],\ \Delta T_0 = 10\,\mathrm{K}, \\ c_{A0} &\in [\overline{c_{A0}} - \Delta c_{A0},\, \overline{c_{A0}} + \Delta c_{A0}],\ \Delta c_{A0} = 0.1\,\mathrm{mol\,l^{-1}}. \end{aligned}$$

[2] In [14] an alternative robust optimization method based on a bilevel formulation is applied to a dynamic optimization problem with an end-point constraint. The close relationship between the bilevel formulation and the normal vector approach is discussed in this paper, too.

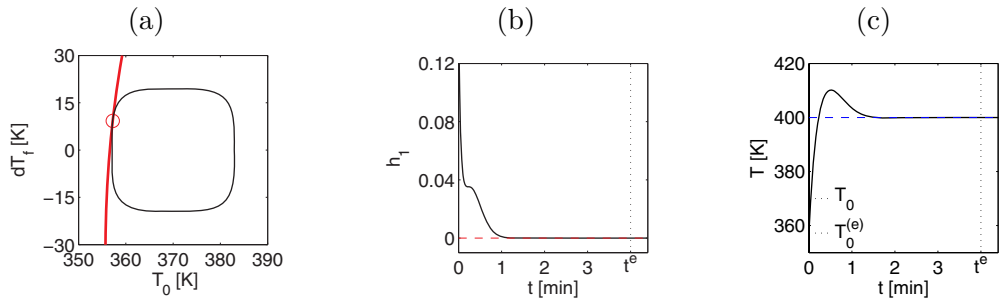

Figure 10. (a) *Robustness and critical manifold for end-point constraint* (5.14) *in the plane of the uncertain initial condition* T_0 *and disturbance parameter* dT_q. *The normal vector constraint for the closest point* ($\circ$) *on the manifold for end-point constraint* (5.14) *is active.* (b) *Trajectory of the value of* h_1 *at the critical point reaches* 0 *after approximately* 2.5 min. (c) *Temperature trajectory of the critical point with initial condition* $T_0^{(e)} = 357.2\,\mathrm{K}$ *and set-point temperature* $T_{\mathrm{sp}} = 400\,\mathrm{K}$.

Finally, the measured concentration $\tilde{c}_A$ used for the control law (5.12) is assumed to be biased from the true concentration $\tilde{c}_A = c_A + dC_A$ with

$$dC_A \in [-\Delta C_A, \Delta C_A], \quad \Delta dC_A = 0.005\,\mathrm{mol\,l^{-1}}.$$

We consider again the tighter approximation (5.9) with $j = 4$. One end-point constraint is imposed that must hold at final time t^e despite the disturbance in T_q, the uncertain initial conditions, and the uncertain measurement:

$$0 < ISE_{\max} - \sqrt{\frac{\int_0^{t_e} (T - T_{\mathrm{sp}})^2 dt}{t_e (T_{\mathrm{sp}} - T_{\mathrm{sp0}})^2}} := h_1. \tag{5.14}$$

Constraint (5.14) sets an upper bound $ISE_{\max} = 0.2$ for the integrated square error (ISE) between the set-point temperature T_{sp} and the reactor temperature T. This constraint can be interpreted as a specification for a desired performance of the closed-loop system that must be achieved despite disturbances and uncertain initial conditions. The final time is set to $t_e = 4\,\mathrm{min}$ for the end-point constraint. The objective is to minimize the control effort required to drive the system to the desired temperature $T_{\mathrm{sp}} = 400\,K$, here represented by the integral

$$\phi = \frac{V}{q(T_{\mathrm{sp}} - T_{\mathrm{sp0}})^2} \int_0^{t_e} (T_c(t) - T_c(T_{\mathrm{sp}}))^2 dt.$$

The cooling water temperature corresponding to the steady state at the new set-point temperature is $T_c(T_{\mathrm{sp}}) = 328.1\,K$.

The results of the optimization are displayed in Figure 10. The projection of the critical manifold on the (dT_q, T_0)-plane in Figure 10a shows that the normal-vector constraint to the end-point constraint h_1 is active. The uncertainty of the initial concentration has no influence on the integral (5.14) as the temperature dependence on the concentration is eliminated by the linearizing feedback control (5.12). The uncertainty of the concentration measurement has a large influence as it directly enters the control law (5.12). The transient behavior of

the value of h_1 at the critical point in Figure 10b shows that $h_1 = 0$ is attained before t_e is reached. The value stays at $h_1 = 0$ for $t > 2.5\,\text{min}$, as the reactor temperature has reached the new set-point temperature $T_{\text{sp}} = 400\,\text{K}$, (cf. Figure 10c). The value of the control parameter at the optimal solution is $\varepsilon = 0.262\,\text{min}$ and the value of the objective function is $\phi = 0.332$. The computational time was less than 0.1 seconds for this case study.

6. Conclusions. In the presence of fast disturbances critical points of trajectories of nonlinear systems can be defined. Specifically, we have investigated critical manifolds in the space of disturbance parameters α corresponding to trajectories with grazing points or trajectories which exactly fulfill an end-point constraint. These critical manifolds separate the parameter space into regions with qualitatively different transient system behavior. A manifold of grazing bifurcations separates those trajectories which do not violate an inequality constraint from those which violate the constraint for some time. A manifold defined for trajectories satisfying end-point constraints separates those trajectories which do not violate the constraint until a specified final time is reached from those that cross the constraint before the final time is reached.

These critical manifolds are used in a constructive manner for the robust design of nonlinear systems by extending a recently presented method for robust optimization. The method is based on the parametric distance between the uncertainty region of the disturbance parameters and the nearest point on the critical manifold. Normal-vector constraints guarantee that specifications for nonlinear systems are not violated in the presence of disturbances. Previous work considered critical points of steady states, e.g., Hopf and saddle-node bifurcations. We have extended this approach from steady-state specifications to state and output constraints on trajectories of nonlinear systems. Application of the approach to closed-loop systems allows for the integrated treatment of system and control design. The methodology has been successfully applied to several illustrative case studies from the area of chemical engineering.

Appendix A. Notation. The subscript μ enumerates the first dimension (rows of matrices), ν enumerates the second dimension (columns of matrices), and ρ enumerates the third dimension of three-dimensional arrays. When an index appears twice in a term it indicates summation over the index. In particular, we use

$$(f_x)_{\mu\nu} = \frac{\partial f_\mu}{\partial x_\nu} \in \mathbb{R}^{n_x \times n_x}, \qquad (f_y)_{\mu\nu} = \frac{\partial f_\mu}{\partial y_\nu} \in \mathbb{R}^{n_x \times n_y},$$

$$(f_x f)_\mu = \frac{\partial f_\mu}{\partial x_\nu} f_\nu \in \mathbb{R}^{n_x}, \qquad (f_y y_t)_\mu = \frac{\partial f_\mu}{\partial y_\nu} \frac{\partial y_\nu}{\partial t} \in \mathbb{R}^{n_y},$$

$$(g_x)_{\mu\nu} = \frac{\partial g_\mu}{\partial x_\nu} \in \mathbb{R}^{n_y \times n_x}, \qquad (g_y)_{\mu\nu} = \frac{\partial g_\mu}{\partial y_\nu} \in \mathbb{R}^{n_y \times n_y},$$

$$(g_x x_{tt})_\mu = \frac{\partial g_\mu}{\partial x_\nu} \frac{\partial^2 x_\nu}{\partial t^2} \in \mathbb{R}^{n_y}, \qquad (g_{xx} f f)_\mu = \frac{\partial^2 g_\mu}{\partial x_\nu \partial x_\rho} f_\nu f_\rho \in \mathbb{R}^{n_y},$$

$$(g_{xy} f y_t)_\mu = \frac{\partial^2 g_\mu}{\partial x_\nu \partial y_\rho} f_\nu \frac{\partial y_\rho}{\partial t} \in \mathbb{R}^{n_y}, \qquad (g_{yy} y_t y_t)_\mu = \frac{\partial^2 g_\mu}{\partial y_\nu \partial y_\rho} \frac{\partial y_\nu}{\partial t} \frac{\partial y_\rho}{\partial t} \in \mathbb{R}^{n_y},$$

$$(h_x)_\mu = \frac{\partial h}{\partial x_\mu} \in \mathbb{R}^{n_x}, \qquad (h_y)_\mu = \frac{\partial h}{\partial y_\mu} \in \mathbb{R}^{n_y},$$

$$(h_z z_t) = \frac{\partial h}{\partial z_\mu}\frac{\partial z_\mu}{\partial t} \in \mathbb{R}, \qquad (h_{zz} z_t z_t) = \frac{\partial^2 h}{\partial z_\mu \partial z_\nu}\frac{\partial z_\mu}{\partial t}\frac{\partial z_\nu}{\partial t} \in \mathbb{R},$$

$$(h_z z_{tt}) = \frac{\partial h}{\partial z_\mu}\frac{\partial^2 z_\mu}{\partial t^2} \in \mathbb{R}, \qquad (h_{zz} z_t z_t) = \frac{\partial^2 h}{\partial z_\mu \partial z_\nu}\frac{\partial z_\mu}{\partial t}\frac{\partial z_\nu}{\partial t} \in \mathbb{R},$$

$$(h_z \Phi_\alpha)_\mu = \frac{\partial h}{\partial z_\nu}\frac{\partial \Phi_\nu}{\partial \alpha_\mu} \in \mathbb{R}^{n_\alpha}, \qquad (h_{zz} z_t \Phi_\alpha)_\mu = \frac{\partial^2 h}{\partial z_\nu \partial z_\rho}\frac{\partial z_\nu}{\partial t}\frac{\partial \Phi_\rho}{\partial \alpha_\mu} \in \mathbb{R}^{n_\alpha},$$

$$(F_z \Phi_\alpha)_{\mu\nu} = \frac{\partial F_\mu}{\partial z_\rho}\frac{\partial \Phi_\rho}{\partial \alpha_\nu} \in \mathbb{R}^{n_z \times n_\alpha}, \qquad (F_{zz} \Phi_\alpha \Phi_\alpha)_{\mu\nu\rho} = \frac{\partial^2 F_\mu}{\partial z_\sigma \partial z_\tau}\frac{\partial \Phi_\sigma}{\partial \alpha_\nu}\frac{\partial \Phi_\tau}{\partial \alpha_\rho} \in \mathbb{R}^{n_z \times n_\alpha \times n_\alpha},$$

$$(F_{z\alpha} \Phi_\alpha)_{\mu\nu\rho} = \frac{\partial^2 F_\mu}{\partial z_\sigma \partial \alpha_\rho}\frac{\partial \Phi_\sigma}{\partial \alpha_\nu} \in \mathbb{R}^{n_z \times n_\alpha \times n_\alpha}, \qquad (F_z \Phi_{\alpha\alpha})_{\mu\nu\rho} = \frac{\partial F_\mu}{\partial z_\sigma}\frac{\partial^2 \Phi_\sigma}{\partial \alpha_\nu \partial \alpha_\rho} \in \mathbb{R}^{n_z \times n_\alpha \times n_\alpha}.$$

Appendix B. Augmented and normal vector system with state variables as independent variables. In this section we present the augmented and normal vector system of the grazing bifurcation if dynamic and algebraic state variables x and y are considered as independent variables as described in [16]. In comparison to (2.9) the flow equation $0 = x - \Phi(x_0, t, p, \alpha)$ is included in the augmented system to define the dynamic variables x, and the algebraic equations $0 = g$ are included to define the algebraic states y. The complete augmented system is then given by

$$M^{(g)} = \begin{pmatrix} x - \Phi(x_0, t, p, \alpha) \\ g(x, y, p, \alpha, t) \\ h(x, y, p, \alpha, t) \\ g_x f + g_y v + g_t \\ h_x f + h_y v + h_t \end{pmatrix} = 0, \tag{B.1}$$

with the time derivative of the algebraic equations denoted by v. The $n_x + 2n_y + 2$ equations define the $n_x + 2n_y + 2$ variables x, y, v, t, α_1. The gradient matrix B of the augemented system with respect to the variables x, y, v, t, α is

$$B = \begin{bmatrix} I & g_x^T & h_x^T & [g_{xx} f + g_x f_x + g_{yx} v + g_{tx}]^T & [h_{xx} f + h_x f_x + h_{yx} v + h_{tx}]^T \\ 0 & g_y^T & h_y^T & [g_{xy} f + g_x f_y + g_{yy} v + g_{ty}]^T & [h_{xy} f + h_x f_y + h_{yy} v + h_{ty}]^T \\ 0 & 0 & 0 & g_y^T & h_y^T \\ -f^T & g_t^T & h_t^T & [g_{xt} f + g_x f_t + g_{yt} v + g_{tt}]^T & [h_{xt} f + h_x f_t + h_{yt} v + h_{tt}]^T \\ -\Phi_\alpha^T & g_\alpha^T & h_\alpha^T & [g_{x\alpha} f + g_x f_\alpha + g_{y\alpha} v + g_{t\alpha}]^T & [h_{x\alpha} f + h_x f_\alpha + h_{y\alpha} v + h_{t\alpha}]^T \end{bmatrix}.$$

According to the scheme presented in section 3 for the derivation of the normal vector system, we are looking for a vector $\kappa \in \mathbb{R}^{n_x+2n_y+2}$ which spans the kernel of the first $n_x + 2n_y + 1$ rows of the matrix B

$$B\kappa = \begin{bmatrix} 0 \\ r \end{bmatrix} \in \mathbb{R}^{n_x+2n_y+1+n_\alpha},$$

with $0 \in \mathbb{R}^{n_x+2n_y+1}$ and $\kappa^T z - 1 = 0$ for some $z \in \mathbb{R}^{n_x+2n_y+2}$ not orthogonal to κ. For the matrix B in (3.3) in section 3 the choice $\kappa = [1, 0]^T$ was obvious and resulted in a drastic simplification of the normal vector system. Here, however, there is no κ such that the second order derivatives disappear in the normal vector system. Instead all entries of κ are also

unknown variables and have to be included in the normal vector system. The normal vector system for augmented system (B.1) with $z = \kappa$ is

$$G^{(g)} = \begin{pmatrix} x - \Phi(x_0, t, p, \alpha) \\ g(x, y, p, \alpha, t) \\ h(x, y, p, \alpha, t) \\ g_x f + g_y v + g_t \\ h_x f + h_y v + h_t \\ B^* \kappa \\ \kappa^T \kappa - 1 \\ \left[-\Phi_\alpha^T \;\; g_\alpha^T \;\; h_\alpha^T \;\; [g_{x\alpha} f + g_x f_\alpha + g_{y\alpha} v + g_{t\alpha}]^T \right. \\ \left. [h_{x\alpha} f + h_x f_\alpha + h_{y\alpha} v + h_{t\alpha}]^T \right] \kappa - r \end{pmatrix} = 0,$$

where $B^* \in \mathbb{R}^{n_x+2n_y+1} \times \mathbb{R}^{n_x+2n_y+2}$ is the submatrix of B with the first n_x+2n_y+1 rows of B. The $2n_x + 4n_y + n_\alpha + 4$ equations define the $2n_x + 4n_y + n_\alpha + 4$ variables $x, y, v, t, \kappa, \alpha_1, r$. In comparison, the normal vector system (3.8) has only $n_x+n_y+n_\alpha+2$ equations without second order derivatives of g. As we use normal vector systems for the formulation of constraints within a nonlinear program, gradient-based solvers would require third order derivatives of the algebraic equations if formulation (B.1) were used as the augmented system for a grazing point.

Wave Formation through the Interactions between Clustered States and Local Coupling in Arrays of Neural Oscillators*

Fatma Gürel Kazanci† and Bard Ermentrout‡

Abstract. We study a system of coupled oscillators with global inhibition and local gap junction coupling. The coupling functions are derived from a biological system in the limit of weak coupling. With global inhibition, the system evolves to a clustered state, while with local gap junctions, waves and synchrony are the only attractors. Increasing gap junction strength from zero destroys the clustered state leaving a complex pattern. Decreasing gap junction strength from a high value results in the loss of stability of waves to a Hopf bifurcation and results in periodically modulated waves. We present analytical results along with numerical simulations.

1. Introduction.

Globally coupled oscillators have been studied extensively [1, 3, 13, 14, 15]. Such systems arise in natural and physical environments such as groups of flashing fireflies, chirping crickets, coupled multimode lasers, and networks of oscillatory neurons. The behavior of generally coupled limit cycles is a daunting task; thus, simplifications are usually necessary. Reducing each oscillator to a single variable, the phase, is the simplest way to produce an analytically tractable model for systems of coupled oscillators. Through the method of averaging, when the oscillators are nearly identical and the coupling between them is sufficiently small, we can reduce a general system to an equation of the form

$$\theta_j' = \omega_j + H_j(\theta_1 - \theta_j, \ldots, \theta_N - \theta_j), \quad j = 1, \ldots, N. \tag{1.1}$$

This is the most common form for the study of patterns of coupled oscillators. Among the commonly studied classes of patterns are synchrony, in which $\theta_j = \theta_k$ for all k, j, and clustering, in which the oscillators are divided into m groups; within each group, all oscillators are synchronous, but there is no synchrony between groups. In structured networks, waves and many other patterns are possible.

While the analysis for globally coupled identical systems is simpler than that of more structured networks, there are still many complex behaviors which arise. For example, as the parameters characterizing the oscillators change, it is possible to go from synchrony to clustered states and to asynchrony [2, 7, 8, 12].

In a recent paper, we studied a spatially structured network of coupled neural oscillators in which there was local synchronizing coupling (mediated by electrical or gap junction coupling) and long range "desynchronizing" coupling mediated by synaptic inhibition [9]. The motive for this work is the appearance of traveling waves and synchronous oscillations in the olfactory lobe of the garden slug [6]. The neurons which generate these patterns are coupled with both gap junctions and synaptic inhibition. Starting with a synchronous locally coupled network, we showed that the addition of global inhibitory coupling leads to a symmetry-breaking bifurcation and ultimately to traveling waves.

In this paper, we consider the same system (local synchronization and long-range desynchronization) from a different perspective. Starting with a globally coupled network of oscillators, we introduce local synchronizing coupling and ask what kinds of behaviors arise. Our work for the inhibition only case is motivated by Hansel, Mato, and Meunier [8]. In their paper, they show a heteroclinic connection between unstable two-cluster states. The coupling functions they consider are different from the ones we used in our model. We derive the coupling functions via an approximation using the biophysical model. We alter the long range coupling function by changing the sign of one of the Fourier coefficients. This allows the globally coupled network to have stable clustered states. We then add nearest neighbor synchronizing coupling and study the resulting dynamics. Since our main interest lies in pattern formation, we thought it would be a good idea to investigate these stable patterns for the full model. Local coupling (as opposed to all-to-all) requires that we specify a geometry of the network; here we consider the simplest case, a one-dimensional ring of oscillators.

In section 2, we describe the model with only all-to-all coupling and provide a stability analysis for the two-cluster state for our choice of coupling function. In section 3, we add local gap junctions and arrange the oscillators on a ring. We show that for sufficiently strong gap junctions, there are stable traveling waves and that as the gap junction coupling decreases, there is a loss of stability of the traveling waves. In section 4, we start with the clustered states and numerically analyze the bifurcations of the clustered states. In particular, for a structured network, the ordering of the oscillators matters and there are many arrangements for a clustered state. We show that these have different stability behavior when local synchronizing coupling is added and that many new patterns bifurcate. There is a great deal of multistability in such networks.

2. Model and theory of clustering. Our goal in this paper is to study the behavior of a network of neural oscillators which are coupled with long-range inhibition (desynchronizing) and short-range gap junctions (synchronizing). The motive for our work comes from a detailed biophysical model for wave generation in the olfactory lobe of the garden slug [6]. In [9] we used the theory of averaging to reduce the biophysical model to a phase model of the form (1.1). As there are two different types of coupling, it is convenient to write (1.1) as

$$\frac{d\theta_j}{dt} = \omega + g_{syn} \sum_{k=1}^{N} c_{jk} H_{syn}(\theta_k - \theta_j) + g_{gap} \sum_{k=1}^{N} d_{jk} H_{gap}(\theta_k - \theta_j), \tag{2.1}$$

where g_{syn}, g_{gap} are the overall coupling strengths of synaptic inhibition and the gap junction coupling, c_{jk}, d_{jk} are the connectivity matrices, and $H_{syn}(\theta)$, $H_{gap}(\theta)$ are the coupling functions obtained by averaging the dynamics of the biophysical model. As these are computed

numerically, we approximate them by the first few terms of their Fourier series:

$$H_{syn}(x) = 35 + 200\cos(x) + 32\cos(2x) - 95\sin(x) + 5\sin(2x),$$

$$H_{gap}(x) = 87 - 50\cos(x) - 37\cos(2x) + 295\sin(x) - 65\sin(2x).$$

In [9] the actual coefficient of $\sin 2x$ in $H_{syn}(x)$ is -5. The theory in the next subsection requires that at least one sine coefficient of H_{syn} be positive. The small change in $\sin 2x$ results in a new H_{syn} which is nearly indistinguishable from the original but which has a much richer repertoire in its dynamics. As we will need them in subsequent sections, we observe that $H'_{syn}(0) = -85$, $H'_{syn}(\pi) = 105$, $H'_{gap}(0) = 165$, and $H'_{gap}(\pi) = -425$.

Before continuing, it is useful to clarify what we mean by synchronizing and desynchronizing coupling by considering a pair of identical mutually coupled oscillators:

$$\frac{d\theta_1}{dt} = \omega + H(\theta_2 - \theta_1),$$
$$\frac{d\theta_2}{dt} = \omega + H(\theta_1 - \theta_2).$$

Letting $\phi = \theta_2 - \theta_1$, we see that

$$\frac{d\phi}{dt} = H(-\phi) - H(\phi)$$

so that $\phi = 0, \pi$ are always solutions. The synchronous solution is stable if and only if $H'(0) > 0$, while the antiphase solution, π, is stable if $H'(\pi) > 0$. For our choice of models, synchrony is stable and antiphase is unstable for gap junctions, while the opposite is true for the synaptic coupling case. Thus, we say that gap junctions are synchronizing and synaptic inhibition is desynchronizing.

Clustered solutions are generally found with all-to-all coupling so that in this paper we assume that $c_{jk} = 1/N$ and thus synaptic inhibition is global. This is the same assumption made in the previous paper. For gap junction coupling, there are many possible topologies that we could use. However, our motivation comes from a one-dimensional phenomenon, so we will arrange the oscillators in a line. To avoid boundary effects, most of the work is done in a one-dimensional ring of oscillators with nearest neighbor gap junction coupling. Thus, $d_{jk} = 1$ if $k = j \pm 1$ or $j = 1$, $k = N$ or $j = N$, $k = 1$ and $d_{jk} = 0$ otherwise. In the last section, we show that our results do not depend crucially on the periodicity of the boundary condition. However, the analysis in section 2.1 is much easier in this case.

To begin with, we need to study the all-to-all synaptically coupled clustered state. Thus, we now consider the case when $g_{gap} = 0$.

2.1. General theory. We start our analysis by revisiting the work in [8]. Consider a globally coupled network of identical phase oscillators given by the equation

$$\frac{d\theta_j}{dt} = \omega + \frac{g_{syn}}{N}\sum_{k=1}^{N} H_{syn}(\theta_k - \theta_j) \quad \text{for} \quad j = 1, \ldots, N. \tag{2.2}$$

Here, as in the rest of the paper, the frequency of individual oscillators is identical. The case where the oscillators have different intrinsic frequencies has also been studied, but we will not consider it now.

We are interested in clustered solutions to (2.2). We look at the case where m of the oscillators have phase $\theta_A = \Omega t$ and the remaining $N - m$ have phase $\theta_B = \Omega t + \phi$ with $\phi \in [0, 2\pi]$. By letting $p = \frac{m}{N}$, we can rewrite (2.2) as

$$\theta_A' = \omega + g_{syn}(pH_{syn}(0) + (1-p)H_{syn}(\theta_B - \theta_A)),$$
$$\theta_B' = \omega + g_{syn}(pH_{syn}(\theta_A - \theta_B) + (1-p)H_{syn}(0)),$$

which then becomes

$$\Omega = \omega + g_{syn}(pH_{syn}(0) + (1-p)H_{syn}(\phi)),$$
$$\Omega = \omega + g_{syn}((1-p)H_{syn}(0) + pH_{syn}(-\phi)).$$

Subtracting the first equation from the second, we get

$$0 = g_{syn}((1-p)H_{syn}(0) + pH_{syn}(-\phi) - pH_{syn}(0) - (1-p)H_{syn}(\phi)). \tag{2.3}$$

Now, we can solve for p:

$$p = \frac{H_{syn}(0) - H_{syn}(\phi)}{2H_{syn}(0) - H_{syn}(-\phi) - H_{syn}(\phi)} \equiv F(\phi). \tag{2.4}$$

Note that $F(\pi) = 1/2$. Given H_{syn} and ϕ, we can determine the size of the clusters according to (2.4).

So far, we have established the existence of two-cluster states. One could also look at other n-cluster states. Thus, we remark that stable clustered states with more than two clusters will not arise with our particular choice of H_{syn} due to the lack of higher order Fourier terms. We limit the present analysis to two-cluster states and study their stability. To do this, we look at the linearized system for the two-cluster solution. Letting $\theta_j = \Omega t + y_j$, where the y_j's are small perturbations, we get

$$\frac{dy_j}{dt} = \frac{g_{syn}}{N}\sum_{k=1}^{N} H_{syn}'(\theta_k - \theta_j)(y_k - y_j) \quad \text{for} \quad j = 1, \ldots, N, \tag{2.5}$$

which can be written as two separate equations:

$$y_j' = \frac{g_{syn}}{N}\sum_{k=1}^{m} H_{syn}'(0)(y_k - y_j) + \frac{g_{syn}}{N}\sum_{k=m+1}^{N} H'(\phi)(y_k - y_j) \quad \text{for} \quad j = 1, \ldots, m,$$
$$y_j' = \frac{g_{syn}}{N}\sum_{k=1}^{m} H'(-\phi)(y_k - y_j) + \frac{1}{N}\sum_{k=m+1}^{N} H'(0)(y_k - y_j) \quad \text{for} \quad j = m+1, \ldots, N.$$

Letting $\alpha = H'_{syn}(0)$, $\beta = H'_{syn}(\phi)$, $\gamma = H'_{syn}(-\phi)$, $\xi = -(m-1)\alpha - (N-m)\beta$, and $\nu = -m\gamma - (N-m-1)\alpha$, we write

$$A = \begin{bmatrix} \xi & \alpha & \cdots & \alpha \\ \alpha & \xi & \cdots & \alpha \\ \vdots & \vdots & \ddots & \vdots \\ \alpha & \cdots & \alpha & \xi \end{bmatrix},$$

$$B = \beta \mathbf{1}_{m\times(N-m)},$$

$$C = \gamma \mathbf{1}_{(N-m)\times m}, \quad \text{and}$$

$$D = \begin{bmatrix} \eta & \alpha & \cdots & \alpha \\ \alpha & \eta & \cdots & \alpha \\ \vdots & \vdots & \ddots & \vdots \\ \alpha & \cdots & \alpha & \eta \end{bmatrix}.$$

We can write (2.5) as

$$\mathbf{y}' = g_{syn}\mathbf{M}\mathbf{y}, \tag{2.6}$$

where $\mathbf{y} = \begin{bmatrix} y_1 & y_2 & \cdots & y_N \end{bmatrix}^T$ and $M = \frac{1}{N}\begin{bmatrix} A & B \\ C & D \end{bmatrix}$.

In order to determine the stability of the two-cluster state, we need to find the eigenvalues of the matrix M. A similar analysis was done in [8]. We state the following theorem.

Theorem 2.1. *Let $\alpha = H'_{syn}(0)$, $\beta = H'_{syn}(\phi)$, and $\gamma = H'_{syn}(-\phi)$. The eigenvalues of the matrix M in (2.6) are*

$$\begin{aligned} \lambda_1 &= -p\alpha - (1-p)\beta, \\ \lambda_2 &= -p\gamma - (1-p)\alpha, \\ \lambda_3 &= -p\gamma - (1-p)\beta, \\ \lambda_4 &= 0, \end{aligned}$$

where $p = \frac{m}{N}$. The algebraic multiplicities of λ_1, λ_2, λ_3, and λ_4 are $m-1$, $N-m-1$, 1, and 1, respectively.

Proof. The zero eigenvalue, λ_4, is the eigenvalue corresponding to translation invariance along the limit cycle. The corresponding eigenvector is found as

$$v_4 = \begin{bmatrix} 1 & 1 & \cdots & 1 \end{bmatrix}^T.$$

λ_1, λ_2 correspond to fluctuations within a cluster, whereas λ_3 corresponds to fluctuations between two clusters. The associated eigenvector for λ_3 has the form

$$v_3 = \begin{bmatrix} 1 & \cdots & 1 & x & \cdots & x \end{bmatrix}^T,$$

where $x \neq 1$. We need to satisfy $Mv_3 = \lambda_3 v_3$,

$$Mv_3 = \begin{bmatrix} (x-1)(1-p)\beta x \\ \vdots \\ (x-1)(1-p)\beta x \\ -(x-1)p\gamma \\ \vdots \\ -(x-1)p\gamma \end{bmatrix} = \lambda_3 \begin{bmatrix} 1 \\ \vdots \\ 1 \\ x \\ \vdots \\ x \end{bmatrix},$$

which implies $(x-1)(1-p)\beta x = \lambda_3$ and $-(x-1)p\gamma = \lambda_3 x$. We solve for x to get $x = \frac{-p\gamma}{(1-p)\beta}$ and $\lambda_3 = -p\gamma - (1-p)\beta$.

We next claim that the eigenvector v_1 associated with λ_1 has the form $[\nu_1, \mathbf{0}]^T$, where ν_1 is in the null-space of C and $A\nu_1 = \lambda_1\nu_1$. We write A as

$$A = \begin{bmatrix} \xi & \alpha & \cdots & \alpha \\ \alpha & \xi & \cdots & \alpha \\ \vdots & \vdots & \ddots & \vdots \\ \alpha & \cdots & \alpha & \xi \end{bmatrix} = \begin{bmatrix} \xi-\alpha & 0 & \cdots & 0 \\ 0 & \xi-\alpha & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & \xi-\alpha \end{bmatrix} + \underbrace{\begin{bmatrix} \alpha & \cdots & \alpha \\ \vdots & \ddots & \vdots \\ \alpha & \cdots & \alpha \end{bmatrix}}_{\hat{A}}.$$

If $\hat{\lambda} \in \sigma(\hat{A})$, then $\hat{\lambda} + \xi - \alpha \in \sigma(A)$. 0 is an $m-1$-fold eigenvalue for the matrix $\hat{A}$, which implies that the eigenvalues of A are $\xi - \alpha$ with corresponding eigenvector ν_1. Substituting ξ we get $\lambda_1 = -p\alpha - (1-p)\beta$. λ_2 can be found similarly. ■

An immediate corollary of Theorem 2.1 implies that the eigenvalues for the system given in (2.6) are 0, $g_{syn}\lambda_1$, $g_{syn}\lambda_2$, $g_{syn}\lambda_3$. For stability of the two-cluster solution, the real parts of the eigenvalues have to be negative. This translates into the following conditions for stability:

- $p\alpha + (1-p)\beta > 0$,
- $p\gamma + (1-p)\alpha > 0$,
- $p\gamma + (1-p)\beta > 0$.

2.2. Application. We apply the general results of the previous section to our particular choice of H_{syn}. Figure 1 shows the dependence of p on the phase difference for H_{syn}. Since this is a monotonic function, this implies that for each choice of $p \in [0,1]$ there is a unique phase, ϕ.

Next we examine the stability of clusters of different sizes by computing the eigenvalues using Theorem 2.1. Figure 2 shows the nontrivial eigenvalues as a function of ϕ, the phase difference between the two clusters. From the monotonic relationship in Figure 1, we get a unique value of p for each ϕ so that this figure translates into the amount of asymmetry tolerated in the cluster sizes. There is a very narrow window of stable phases centered around π, which means that the cluster size is very close to 1/2; that is, there are equal numbers of oscillators in each cluster. From now on, we restrict our attention to equal size clusters, so $p = 1/2$. For cluster sizes which deviate slightly from equality, we expect the remaining results to be similar.

Using Theorem 2.1, we can simplify the conditions for the stability of the two-cluster state when the clusters are equal since $\phi = \pi$, and so $\beta = \gamma$ and $p = 1/2$. The stability conditions we need to satisfy are

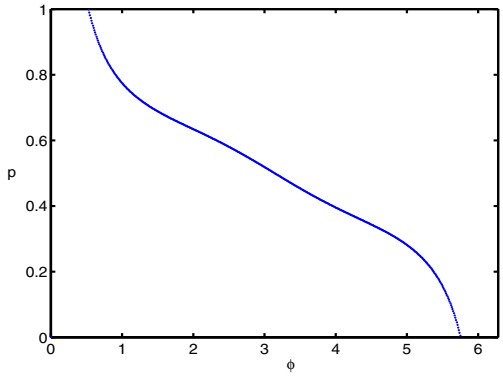

Figure 1. *Possible values for p are graphed as the phase difference, ϕ, varies from 0 to 2π.*

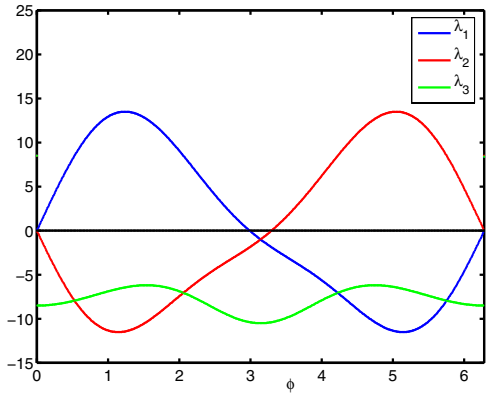

Figure 2. *Eigenvalues for the system in (2.6) are computed for all possible values of (p, ϕ).*

1. $H'_{syn}(0) + H'_{syn}(\pi) > 0$,
2. $H'_{syn}(\pi) > 0$, and
3. $H'_{syn}(0) < 0$.

Note that if the first and third conditions hold, then the second follows automatically. Recall that H_{syn} is supposed to be desynchronizing, which means that $H'_{syn}(0) < 0$ and $H'_{syn}(\pi) > 0$. Thus, desynchronizing long-range coupling is necessary for the formation of stable clusters. Before turning to our specific function H_{syn}, we interpret the stability conditions in terms of the Fourier coefficients of the function H_{syn}. Since the conditions are evaluated at the derivatives of the function at $0, \pi$, only the odd Fourier components come into play. Suppose that the odd components are a_n, $n = 1, 2, \ldots$. Then stability requires

$$\sum_{n>0} n a_n < 0,$$

$$\sum_{n>0} 2n a_{2n} > 0.$$

In particular, there must be at least one positive even Fourier sine coefficient. For our choice of $H_{syn}(\theta)$, $H'_{syn}(0) = -85$ and $H'_{syn}(\pi) = 105$, so that the three conditions hold and the two-cluster state is stable. We remark that the small change in the Fourier coefficient from the one derived from the biophysical model is thus absolutely necessary for the existence of clustered states.

3. Traveling waves in the presence of gap junctions. We now introduce local gap junction coupling and put our oscillators in a one-dimensional ring:

$$\frac{d\theta_j}{dt} = \omega + \frac{g_{syn}}{N}\sum_{k=1}^{N} H_{syn}(\theta_k - \theta_j) + g_{gap}[H_{gap}(\theta_{j+1} - \theta_j) + H_{gap}(\theta_{j-1} - \theta_j)], \tag{3.1}$$

where H_{gap} is the coupling function for the gap junction coupling between nearest neighbors with coupling strength g_{gap}.

In [9], we looked at a network of coupled oscillators with global inhibitory coupling and local (not necessarily nearest neighbor) gap junction coupling. We showed that a traveling wave was a stable solution for all the values of the parameters. In this section, we look at a similar network where the scope of the gap junction coupling extends only to nearest neighbors and the inhibitory coupling function is modified as noted in section 2. The coupling function H_{syn} is approximated from its original form by using the most dominant Fourier components. In order to get stable two-cluster solutions for the all-to-all network, we adjusted one of the coefficients in H_{syn}. Thus, in this section, we examine whether the small change in the coupling function affects the stability of waves and, if so, what kinds of bifurcations occur. A single traveling wave solution, $\theta_j = \Omega t + \frac{2\pi j}{N}$, satisfies (3.1) when

$$\Omega = \omega + \frac{g_{syn}}{N}\sum_{l=1}^{N} H_{syn}(\delta l) + g_{gap}(H_{gap}(\delta) + H_{gap}(-\delta)),$$

where $\delta = \frac{2\pi}{N}$. Given N, H_{syn}, H_{gap}, g_{syn}, and g_{gap}, we can determine Ω uniquely. If there are no cosine components in H_{syn} or H_{gap}, then $\Omega = \omega$. To determine stability, we linearize around the traveling wave. The linearized system is

$$\frac{dy_j}{dt} = \frac{g_{syn}}{N}\sum_{l=1}^{N} H'_{syn}(\delta l)(y_{j+l} - y_j) + g_{gap}[H'_{gap}(\delta)(y_{j+1} - y_j) + H'_{gap}(-\delta)(y_{j-1} - y_j)]. \tag{3.2}$$

The solutions for (3.2) are of the form $y_j = e^{\lambda_m t}e^{i\delta m j}$, where $j = 1, \ldots, N$, $m = 0, \ldots, N-1$. Solving for λ_m gives us

$$\lambda_m = \frac{g_{syn}}{N}\sum_{l=1}^{N} H'_{syn}(\delta l)(e^{i\delta m l} - 1) + g_{gap}[H'_{gap}(\delta)(e^{i\delta m} - 1) + H'_{gap}(-\delta)(e^{-i\delta m} - 1)]. \tag{3.3}$$

To determine the stability, we look at the real parts of λ_m. For $m = 0$, we have $\lambda_0 = 0$, which corresponds to translation invariance. For $m \neq 0$, we need to use the Fourier series expansions of H'_{syn} and H'_{gap}. For δ small, we can get a reasonably good estimate for λ_m when m is small as well. The local coupling contributes a term which is approximately

$$-g_{gap}H'_{gap}(0)\delta^2 m^2,$$

which is negative since $H'_{gap}(0) > 0$ by assumption. Writing

$$H'_{syn}(x) = \sum_n na_n \cos nx - b_n n \sin nx$$

for fixed m, we have to evaluate

$$S_m = \frac{1}{N}\sum_{l=1}^{N}\sum_n [na_n \cos(n\delta l) - nb_n \sin(n\delta l)][(\cos \delta ml - 1) + i \sin \delta ml].$$

The outer sum vanishes except when $n = m$ so that

$$S_m = \frac{1}{2}m(a_m - ib_m).$$

Thus we obtain an approximation for λ_m:

$$\lambda_m \approx \frac{g_{syn}}{2}n(a_m - ib_m) - g_{gap}H'_{gap}(0)\frac{4\pi^2 m^2}{N^2}. \tag{3.4}$$

Once again, the crucial players in the stability of waves are the sine coefficients, a_m. Recalling that stable clusters require that $a_{2n} > 0$ for some n, we see that it is always possible to destabilize traveling waves. We remark that traveling waves with higher wave numbers, $k > 1$, are the same as traveling waves with a wave number $k = 1$ for a ring of size N/k. For our choice of H_{syn}, $a_2 > 0$ so that the mode $m = 2$ destroys stability when either g_{syn} is large enough or g_{gap} is sufficiently small. The critical gap junction strength below which the wave is unstable is approximately

$$g_{gap}^{TW} \approx \frac{a_m}{8\pi^2 m H'_{gap}(0)}N^2 g_{syn}. \tag{3.5}$$

Since b_m is generally nonzero, the loss of stability generically occurs at a pair of imaginary eigenvalues implying a Hopf bifurcation should occur as the gap junction coupling decreases below the critical value. For our model $m = 2$, $a_2 = 5$, $H'_{gap}(0) = 165$, so for $N = 20$, $g_{gap}^{TW} \approx 0.0768 g_{syn}$, which compares well with the exact value $0.0746 g_{syn}$ obtained from (3.3). Large networks are less able to support traveling waves when there are clustering instabilities. Figure 3 shows the critical strength of g_{gap} above which the traveling wave is stable as a function of the length of the ring of oscillators. For this graph, $g_{syn} = 0.1$, so that our approximation is $g_{gap}^{TW} \approx 1.91 \times 10^{-5} N^2$.

In addition to traveling waves, an obvious solution is perfect synchrony, in which $\theta_j = \Omega t$ with

$$\Omega = \omega + g_{syn}H_{syn}(0).$$

(Note that for gap junction coupling, $H_{gap}(0) = 0$.) Stability is determined by linearizing about the synchronous solution; the methods used for traveling waves lead to the following expression for the eigenvalues:

$$\nu_m = \frac{g_{syn}H'_{syn}(0)}{N}\sum_{l=1}^{N}(e^{i\delta ml} - 1) + 2g_{gap}H'_{gap}(0)[\cos(m\delta) - 1],$$

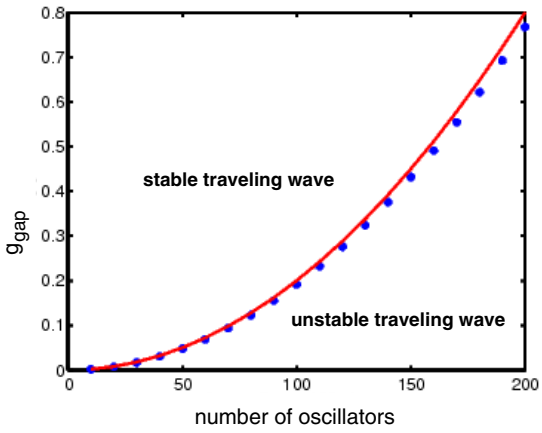

Figure 3. *Relation between g_{gap} and N is shown by the blue dots. The red line is the curve that fits the data with $y = cN^2$ and $c = 1.91 \times 10^{-5}$. g_{syn} is fixed at 0.1 throughout the computation. A Hopf bifurcation is observed at the marked g_{gap} values as $N =$ "number of oscillators" changes. The emerging traveling wave is stable in the region above the curve and unstable below it.*

which leads to $\nu_0 = 0$ and

$$\nu_m = -g_{syn}H'_{syn}(0) + 2g_{gap}H'_{gap}(0)[\cos(2\pi m/N) - 1].$$

Recall that $H'_{syn}(0) < 0$ and $H'_{gap}(0) > 0$. Thus, the first term is always positive. The second term is always negative and is least negative when $m = 1$, so this determines the minimal value of g_{gap} for stable synchrony:

$$g^S_{gap} = \frac{-H'_{syn}(0)}{H'_{gap}(0)} \frac{g_{syn}}{2[1 - \cos(2\pi/N)]}.$$

For N large, we can rewrite this expression as

$$g^S_{gap} \approx \frac{-H'_{syn}(0)}{H'_{gap}(0)} \frac{g_{syn}}{4\pi^2} N^2 \tag{3.6}$$

so that, like the traveling wave, the critical coupling strength grows as N^2. Unlike the traveling wave, however, instability of synchrony does not depend on the details of the Fourier coefficients of $H_{syn}(x)$; in particular, the ability to form clusters is irrelevant. For our model, with $g_{syn} = 0.1$, we find $g^S_{gap} \approx 1.31 \times 10^{-3}N^2$. Note that the eigenvalues are real so that as g_{gap} falls below the critical value a zero eigenvalue is crossed. By symmetry, a pitchfork bifurcation will occur. In [9], we computed this branch of solutions by calculating the normal form. We remark that the traveling wave is "more stable" than synchrony in the sense that it is able to tolerate smaller gap junction coupling than synchrony is.

4. Numerical results. In section 2, we showed that there were stable two-cluster solutions for $g_{gap} = 0$. Since they are asymptotically stable, we expect the two-cluster states to stably persist for sufficiently small values of g_{gap} by the implicit function theorem. In section 3, we

Table 1

Table of all possible two-cluster configurations for a network of 10 oscillators in a ring. The values g_{gap}^C indicate the numerical value of the bifurcation parameter g_{gap}. Two-cluster solution becomes unstable for $g_{gap} > g_{gap}^C$.

Case number	Configuration	$g_{gap}^C \times 10^3$
Case 1	0000011111	2.759
Case 2	0000101111	1.172
Case 3	0000110111	1.099
Case 4	0000111011	1.099
Case 5	0001011101	0.7612
Case 6	0001011011	0.6654
Case 7	0001101101	0.6656
Case 8	0001101011	0.6300
Case 9	0001110101	0.7551
Case 10	0001110011	1.358
Case 11	0011001011	0.7279
Case 12	0011001101	0.7266
Case 13	0011011001	0.7729
Case 14	0011010101	0.4997
Case 15	0010101101	0.5197
Case 16	0101010101	0.6535

demonstrated that there were stable traveling waves for sufficiently large values of g_{gap} and that synchrony was also stable with strong enough gap junction coupling. Thus, our goal here is to use numerical methods to fill in the details as to how the clustered state changes as g_{gap} increases and how traveling waves and synchrony evolve as g_{gap} decreases.

4.1. Bifurcations from clustered states. Traveling waves and synchrony in a one-dimensional ring are unambiguously defined. That is, we can assign phases to each of the N-oscillators in only one way, up to translation around the ring. However, the arrangement of a clustered solution on a ring is much more complicated. Suppose that there are $2m$ oscillators with m at phase 0 and m at phase π. Then, we can ask how many different (up to rotations, reflections, and translations) configurations there are. This question is equivalent to asking how many $2m$ black and white bead necklaces with m black beads there are, the answer to which can be found in The Online Encyclopedia of Integer Sequences (http://www.research.att.com/~njas/sequences/A005648). For $m = 1, \ldots, 10$, the number of such sequences is 1, 2, 3, 8, 16, 50, 133, 440, 1387, and 4752, respectively. Thus, for a twenty oscillator ring, there are 4752 ways to have a two-clustered solution with equal numbers in each cluster. For ten oscillators, it is a more reasonable number of 16. Thus, to analyze the evolution of clustered states as g_{gap} increases, it is necessary to compute the bifurcation for every possible configuration. Table 1 shows the critical values of the gap junction coupling for each of the 16 configurations in a ring of 10 oscillators when $g_{syn} = 0.1$. We use AUTO to compute the bifurcation diagram starting at a given configuration [4]. For example, starting with the configuration 0000011111 (Case 1) corresponding to the first 5 oscillators at zero phase and the next at π, we find that the pattern stably exists for $g_{gap} < 2.759 \times 10^{-3}$. Similarly, the pattern 0000110111 (Case 3) exists up to $g_{gap} = 1.099 \times 10^{-3}$. Figure 4 shows the two

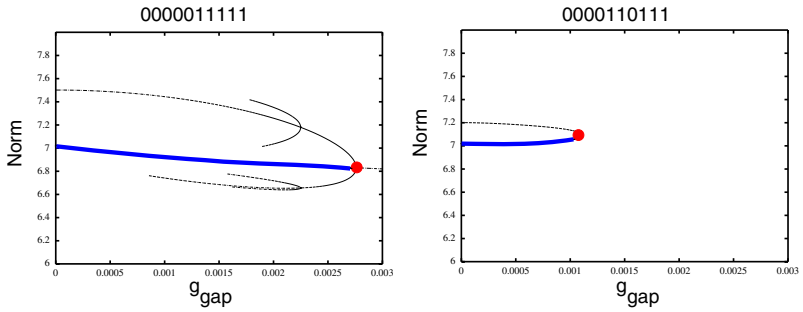

Figure 4. *Bifurcation diagram of two different clustered states as g_{gap} increases with $g_{syn} = 0.1$. Cluster* 0000011111 *loses stability at a subcritical pitchfork (red circle on left) while cluster* 0000110111 *loses stability at a saddle node (red circle on right). Stable clustered states are in blue.*

bifurcation diagrams as g_{gap} increases (stable clustered states are shown in blue). These patterns have quite different local bifurcation diagrams. The pattern in Case 1 undergoes a subcritical pitchfork bifurcation which spawns additional unstable branches. The pattern in Case 3 undergoes a saddle-node bifurcation. Thus, while the local bifurcations are different and while they happen at different values of g_{gap}, in all cases the clusters are disrupted by a small (but not infinitesimally small) amount of gap junction coupling. As can be seen in these two examples, the new branches that arise at the bifurcations do not result in any new stable solutions, so we have to look elsewhere to find out the behavior beyond the critical gap junction strength. One trend that we note is that there is a rough correlation between the minimal strength for disrupting clusters and the number of switches between the 0 and π phases. This is not a strict rule, as, for example, Case 16, which has the maximal number of 10 switches, is more resistant to disruption than is Case 14, which has 8 switches.

In the analysis of waves and synchrony, the critical coupling strength for stability depended strongly on N (cf. Figure 3). We can ask the same question for clustered states. The number of possible cases for clusters is of course rather large, and the possible clustered patterns vary tremendously. However, one pattern which appears for all even N is the pattern of m oscillators at 0 followed by m oscillators at π. For this pattern, we have computed the critical gap junction coupling for $N = 10$, 20, 40 to be, respectively, 0.002759, 0.003490, 0.003771. While there are slight differences, there are not the order of magnitude differences that are observed in the traveling wave case. Another simple pattern common to all networks with size $2m$ is the alternating one, where every other oscillator has phase 0 and the remainder have phase π. For this case, we find that the critical gap junction coupling for $N = 10$, 20, 40 is, respectively, 6.535, 6.064, 5.975×10^{-4}. Thus, there is virtually no difference. Using an eigenvalue perturbation argument, it may be possible to estimate the strength of gap junctions needed to destabilize the clustered state, but due to the multiplicity of the eigenvalues (see section 2), we could at best hope to reduce the stability issue to an $(N/2 - 1)$-dimensional system. However, we can determine the stability of the clustered state in the presence of gap junctions when both gap and synaptic coupling are all-to-all:

$$\theta_j' = \omega + \frac{1}{N}\sum_{k=1}^{N} \left(g_{syn} H_{syn}(\theta_k - \theta_j) + g_{gap} H_{gap}(\theta_k - \theta_j)\right).$$

We can replace H_{syn} in Theorem 2.1 with the combined H:

$$H(x) = g_{syn}H_{syn}(x) + g_{gap}H_{gap}(x).$$

This leads to

$$g_{gap}^{C} = -g_{syn} \min\left\{ \frac{H'_{syn}(0)}{H'_{gap}(0)}, \frac{H'_{syn}(\pi)}{H'_{gap}(\pi)}, \frac{H'_{syn}(0)+H'_{syn}(\pi)}{H'_{gap}(0)+H'_{gap}(\pi)} \right\}. \tag{4.1}$$

For our model, $g_{gap}^{C} = 0.07692\, g_{syn}$. This overestimates the values in the table, but it is at least in the right ballpark and does not depend on N as do waves and synchrony.

4.2. Bifurcations from traveling wave states. As we showed in section 3, as g_{gap} decreases, the traveling wave solution loses stability at a Hopf bifurcation, so that we expect to see oscillations below a critical gap junction strength. Our estimates in this and the previous sections show that the critical gap junction strength for the break-up of clusters is largely independent of N but that the loss of stability of the wave depends strongly on N. Thus, we expect to see qualitative changes in the nature of the bifurcations as N changes. We start with our smallest example, $N = 10$. In this and subsequent figures, we plot the solutions relative to oscillator 1. Thus, clusters, synchrony, and traveling waves are all fixed points; any periodic solutions to the relative phases represent quasi-periodic solutions to the full equations. Figure 5A superimposes the bifurcation diagram for cluster #1 in Table 1 along with the diagram for the traveling wave. As predicted by the analysis in the previous section, the traveling wave (green) loses stability at a Hopf bifurcation (red dot). For this particular model, the bifurcation is supercritical and leads to a branch of periodic solutions (red). Figure 5B shows that along these branches (labeled B) the waves are periodically modulated. As g_{gap} decreases, the modulation becomes deeper and the period longer. At a critical value of g_{gap}, the primary branch of periodic solutions undergoes a pitchfork and two new periodic solutions arise (magenta). Time series from oscillators 5, 10 (Figure 5C) show that there are slight differences in the two periodic orbits. As $g_{gap} \to 0^+$, these solutions appear to terminate on an unstable fixed point. Starting with initial data very close to this fixed point, solutions evolve to cluster #1 in our table. The final state is shown in panel E. The cluster state (shown in blue in Figure 5A) is bistable with the pure traveling wave as well as the periodically modulated traveling wave.

Figure 6 shows the bifurcation diagram for $N = 20$. Like the $N = 10$ case, the clustered state (blue) loses stability at roughly the same value of g_{gap}, while the wave (green) loses stability for a much larger value of g_{gap} as predicted by the theory. Thus, bistability is restricted to the cluster and the modulated waves (red), in contrast to $N = 10$, where there is bistability with respect to the traveling wave as well as to the modulated wave. For $N = 20$ and, likewise, for $N = 40$, the branch of modulated waves appears to terminate at a finite value of g_{gap} on a homoclinic. Initial conditions, near the modulated wave below the critical gap junction strength seem to be attracted to the cluster solution corresponding to the analogue of case #1 for $N = 10$, the "simplest" arrangement of clusters.

We close this section by remarking that, in addition to a single traveling wave, there are waves which go through multiple cycles. For example, when $N = 20$, there is a stable double wave, $\theta_j = \Omega t + 4\pi j/20$, and these waves go through similar sequences of bifurcations as the single wave with $N = 10$.

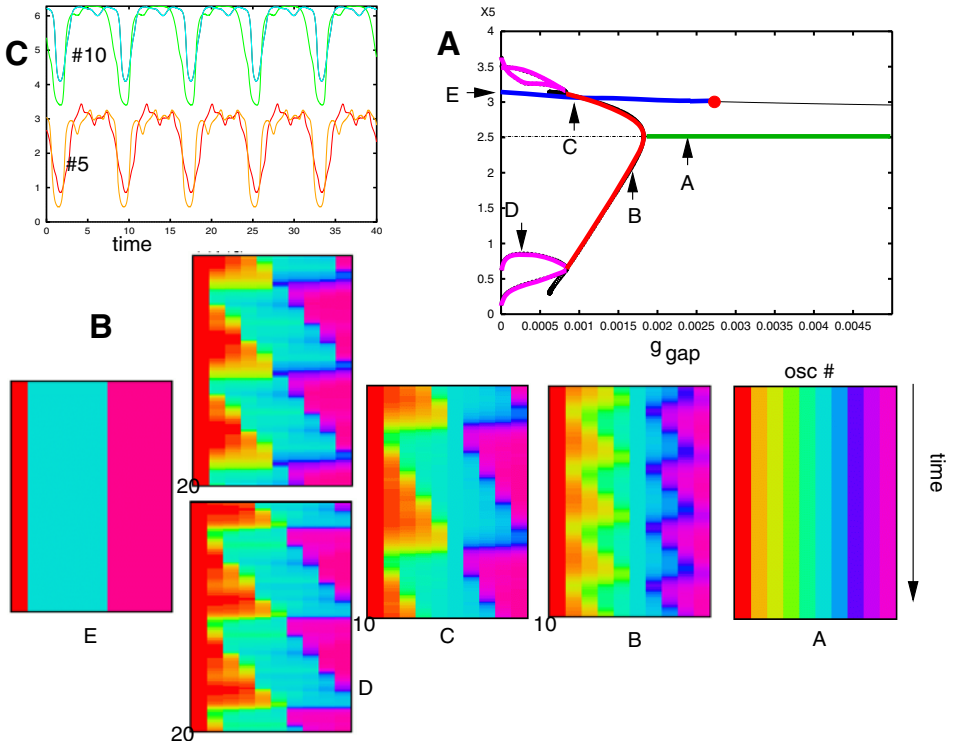

Figure 5. (A) *Bifurcation diagram for $N = 10$ oscillators as g_{gap} decreases. Line starting at E (in blue) is the curve of solutions starting at cluster #1. The green curve through A is the branch of traveling wave solutions. This loses stability at a Hopf bifurcation leading to a branch of periodic solutions (red). This undergoes a pitchfork bifurcation spawning a pair of limit cycles (magenta) which extend to g_{gap} close to 0.* (B) *Sample solutions along the diagram. Oscillators are arranged across and time increases downward.* (C) *Trajectories of $\theta_{5,10}(t)$ on the two different branches of periodic solutions. Green and orange represent one solution and red and blue the other.*

4.3. Bifurcations from synchrony. In our previous paper [9] we showed that as the ratio between the synaptic and gap junction coupling increased, the synchronous state underwent a bifurcation to a patterned state which with further increases disappeared resulting in traveling waves. Here, because of a small change in the synaptic coupling function (needed to stabilize the clustered state), the bifurcations are more complicated. As we showed above, synchrony is stable for g_{gap} sufficiently large. Due to the symmetry of the ring, it is difficult to use numerical continuation to follow bifurcations from the synchronous state. However, we can pick one of the patterned states as a starting point and follow this. Figure 7 shows the result of such a calculation. Rather than draw the full bifurcation diagram as determined via numerical continuation, we divide the behavior into two parts. Figure 7A shows our starting point, a patterned state with $g_{gap} = 0.001$. Figure 7C shows the behavior of this state as g_{gap} is decreased. The patterned state (in blue) loses stability at a Hopf bifurcation (HB) and results in a supercritical branch of periodic solutions (red). These lose stability at a pitchfork bifurcation. Unlike Figure 5, the pitchfork is subcritical and the new solutions are unstable.

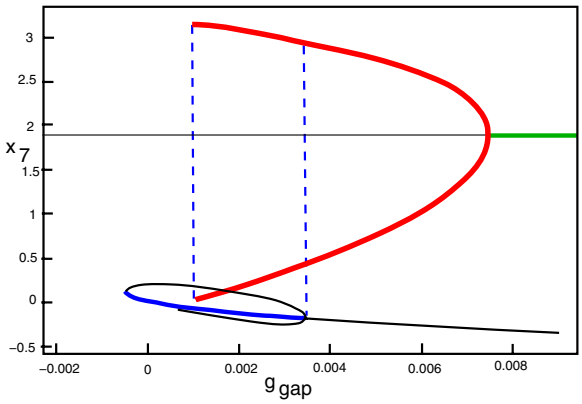

Figure 6. *Bifurcation diagram as g_{gap} varies for a system with 20 oscillators. The two-cluster state (solid blue curve) becomes unstable at $g_{gap}^{C} = 0.003491$ at a subcritical pitchfork (thin black lines). Traveling waves (solid green curve) become unstable through a Hopf bifurcation at $g_{gap}^{TW} = 0.007463$. The periodic orbits (solid red curves) are stable and do not appear to persist to $g_{gap} = 0$. There is a region where both the two-cluster state and periodic orbits are stable.*

Thus, we start near this bifurcating branch and decrease g_{gap} below the point of instability. The new solutions settle on a different branch of periodic solutions (magenta), one of which is shown in Figure 7B. The magenta branch terminates at an infinite period bifurcation (IP) as g_{gap} decreases and at a torus bifurcation (TR) as g_{gap} increases. There is a small region between TR and HB where there is bistability between periodic modulated solutions and the steady patterned solution. That is, patterns like those in Figure 7A, B can stably coexist. An attempt to track the branch of solutions starting at Figure 7A for increasing g_{gap} led to extremely complex branching diagrams that were difficult to understand. Thus, for increasing g_{gap} we took a different tack. We fix g_{gap} and integrate the equations until a steady state is reached, then we increment g_{gap} again, and so on. The result of this is plotted in Figure 7D; the phase of each oscillator is shown as g_{gap} ranges from 0.001 to 0.201 in two hundred steps. The phases all merge to the synchronous solution at $g_{gap} \approx 0.14$. Every solution on this branch looks qualitatively like Figure 7A. A similar picture is obtained with $N = 20$.

4.4. Pattern selection. Suppose that the gap junctions are sufficiently strong to support traveling waves and synchrony. A natural question is which of these patterns are selected. Given that synchrony requires stronger gap junction coupling than traveling waves, we expect traveling waves are more likely. There are many types of traveling waves: waves can travel in both the positive and negative directions or there can be higher wave number traveling waves, e.g., two cycles per ring. In order to get some idea of the basin of attraction, we have set $g_{syn} = 0.1$ and $g_{gap} = 0.6$ for a ring of 20 oscillators. (Note that synchrony is stable for g_{gap} larger than about 0.54.) For these values, synchrony and several types of traveling waves are all stable. We repeated 300 simulations with random initial data and found that 109 of the simulations or roughly one third of these initial conditions led to synchrony. The remainder of steady solutions were traveling waves of one type or another. Thus, it appears that waves are favored over the synchronous solutions but that synchrony still has a reasonably robust basin of attraction.

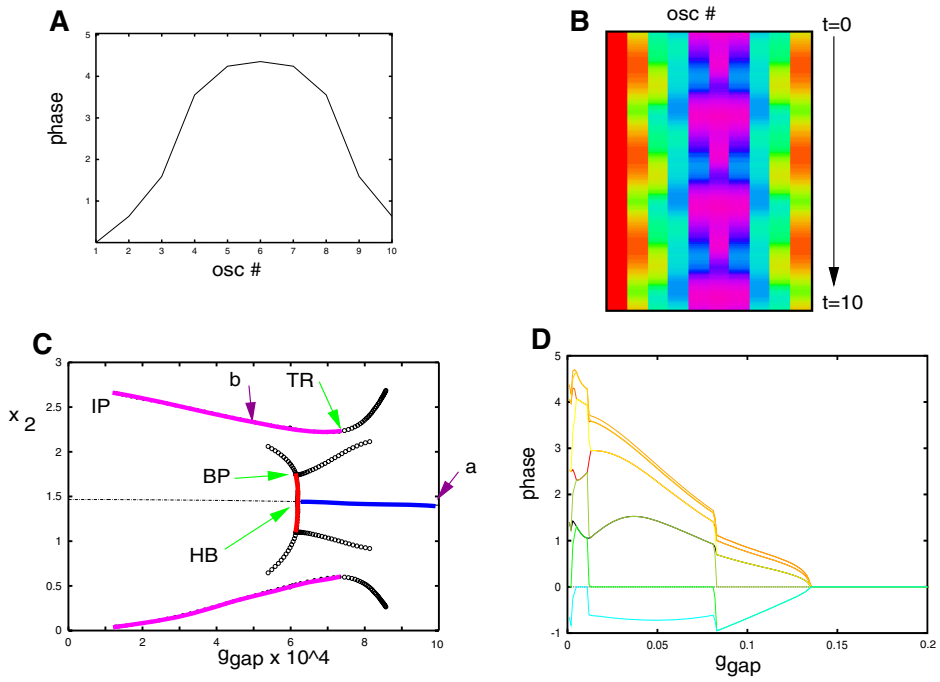

Figure 7. *Behavior of the patterned states as g_{gap} varies.* (A) *Patterned state with $g_{gap} = 0.001$.* (B) *Oscillatory state with $g_{gap} = 0.0005$.* (C) *Starting with the patterned state (blue) shown in* (A), *g_{gap} is decreased leading to a Hopf bifurcation (HB) and a branch of periodic solutions (red) which loses stability at a pitchfork (BP). In addition, there is another branch of periodic solutions (upper and lower magenta curves) that disappears for low values of g_{gap} at an infinite period bifurcation (IP) and at a torus bifurcation (TR) as g_{gap} increases. Points labeled a, b correspond to solutions in panes A, B, respectively.* (D) *Increasing g_{gap} beyond* 0.001 *leads to a cascade of steady states (all oscillator phases are plotted), terminating with the synchronous solution at $g^S_{gap} \approx 0.14$.*

4.5. Nonperiodic domains. The reader might rightfully ask how much of the behavior shown in this section is a consequence of the ring structure. To answer this, we can numerically analyze the bifurcations in a line of cells without periodic boundary conditions. That is, we replace the condition $\theta_0 = \theta_N$ with the condition $\theta_0 = \theta_2$ and the condition $\theta_{N+1} = \theta_1$ with $\theta_{N+1} = \theta_{N-1}$. Biologically, the array configuration is more realistic than the periodic domain considered earlier. Also, in this geometry, the dynamics is remarkably simple; cf. Figure 8. The synchronous solution is lost when $g_{gap} \approx 1.89$ (larger than the value on a periodic domain) via a pitchfork bifurcation. Two stable branches emerge leading to patterned states. Both of the states emerging result in monotonic (as a function of oscillator) relative phases—partial traveling waves. Examples are shown in Figure 8B. As g_{gap} decreases, these come to resemble traveling waves on the ring and nearly cover the entire range between 0 and 2π. Note that the two branches correspond to rightward and leftward waves. At roughly the same value of g_{gap}, the two branches lose stability via a Hopf bifurcation resulting in patterns similar to those in Figure 5, shown here in Figure 8C. These periodic patterns persist down to $g_{gap} \approx 0.0009$, beyond which we could no longer follow them. The period gets quite large and much time is spent near clustered solutions. For smaller g_{gap}, only clustered solutions remain.

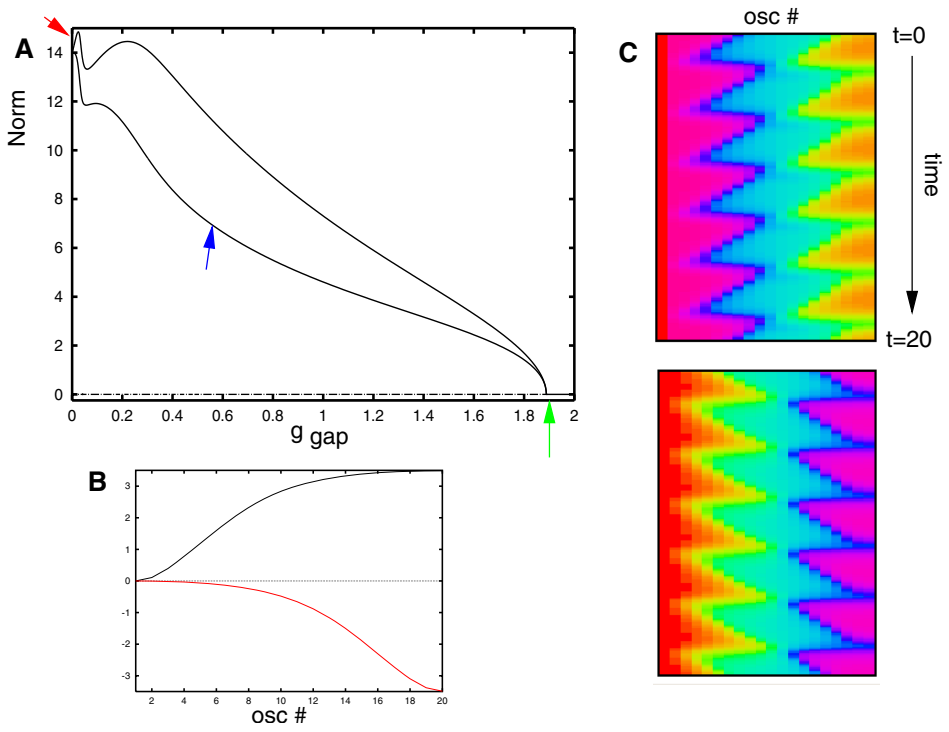

Figure 8. (A) *Bifurcation for* 20 *oscillators arranged in a line as* g_{gap} *decreases. A pair of solutions bifurcates from synchrony (green arrow) at* $g_{gap} \approx 1.89$*, persists until* $g_{gap} \approx 0.008$*, where it loses stability to a Hopf bifurcation. The periodic orbits disappear at* $g_{gap} \approx 0.0009$ *leaving clustered states.* (B) *Relative phases when* $g_{gap} = 0.5$ *(blue arrow).* (C) *Periodic solution* $g_{gap} = 0.006$ *(red arrow).*

If one returns to the diagram in Figure 7, we can see that the patterned states bifurcating from the ring resemble a pair of leftward and rightward moving waves glued together in the middle. Furthermore, the triangle-like periodic patterns are analogous to patterns formed by "gluing" together the pair of periodic patterns shown in Figure 8C.

5. Discussion. This paper continues the analysis of networks of oscillators coupled via a combination of gap junctions and synaptic inhibition. Here, our choice of coupling functions was motivated by a reduction using averaging of a biophysically based model for oscillations in the slug brain. We altered one parameter in the synaptic coupling such that a purely synaptically coupled network was able to produce clustered (rather than asynchronous) solutions. Thus, the present work addresses an interesting mathematical as well as biologically relevant problem: how do clustered states interact with local synchronizing coupling? Surprisingly, the behavior is considerably more complex than if the long-range synaptic coupling is only desynchronizing (as shown in [9]). Lewis and Rinzel have studied the interactions between gap junctions and synaptic inhibition in the case where both types of coupling encourage synchrony [11]. Similarly, Kopell and Ermentrout showed that gap junctions could prevent the suppression of oscillators which were coupled by inhibition which also synchronized [10]. Since synchronizing inhibition precludes the existence of clusters (Theorem 2.1 requires that

$H'_{syn}(0) < 0$, which implies synchrony is unstable), the results of these earlier studies cannot be applied to our model. Inhibition can be synchronizing or desynchronizing depending on the details of the model and the time course of the synapses; thus, this work could apply to systems more general than the slug brain. For example, we have computed the interaction functions for a recent biophysical model of cortical inhibitory neurons when the synaptic time course is short (2.5 msec) and the neuron is firing at 40 Hz [5]. Under reasonable physiological conditions, we compute synaptic interaction functions such that the symmetric two-cluster state is stable.

Interactions between local synchrony and clustered states are complex. We attempt to summarize our findings. For large enough gap junctions, synchrony and traveling waves are always stable, while for sufficiently small gap junctions, clustered states are stable. As gap junctions decrease, the synchronous solution bifurcates to a stationary patterned state, which then bifurcates to a modulated state. This quasiperiodic behavior disappears at sufficiently low gap junction coupling leaving only the clustered state. Conversely, starting with a patterned state, as the gap junctions increase, different patterned states emerge which are neither waves nor synchrony and result ultimately in synchrony. Traveling waves lose stability as gap junction coupling decreases, proceeding first to modulated waves and then to clusters. Thus, there are many regimes of multistability, and the waves and synchronous branches are largely independent.

We have restricted our attention to two-cluster states which have equal numbers of oscillators in each cluster and to networks on a line. It would be interesting to study other topologies with less symmetric arrays of clustering. Bifurcations starting from g_{gap} large (e.g., from synchrony or waves) are independent of the size of clusters and from our observations tend to terminate on simple symmetric clusters in which the oscillators are mainly segregated into a small number of groups. Thus, asymmetry would be expected only for very small gap junctions. Other networks, such as two-dimensional arrays, remain to be studied; these would be more relevant in cortical networks as opposed to the slug brain, which is effectively a one-dimensional network. One other possible extension of our work is to consider more complex coupling functions. This will introduce n-cluster solutions with $n \geq 2$. This study might be motivated by experimental and theoretical explanations of clustered solutions and their possible function.

A Tracking Algorithm for Car Paths on Road Networks*

Gabriella Bretti† and Benedetto Piccoli†

Abstract. In this paper we introduce a computation algorithm to trace car paths on road networks, whose load evolution is modeled by conservation laws. This algorithm is composed of two parts: computation of solutions to conservation equations on each road and localization of car position resulting by interactions with waves produced on roads. Some applications and examples to describe the behavior of a driver traveling in a road network are shown. Moreover, a convergence result for wave front tracking approximate solutions, with BV initial data on a single road, is established.

Key words. conservation laws, discontinuous ordinary differential equations, finite difference schemes, fluid-dynamic models, traffic flow

1. Introduction.

Consider the Lighthill–Whitham and Richards traffic flow model [18, 19]:

$$\begin{cases} \partial_t \rho + \partial_x f(\rho) = 0, \\ \rho(0,x) = \bar{\rho}(x), \end{cases} \tag{1.1}$$

where $\rho = \rho(t,x)$ is the car density, with $\rho \in [0, \rho_{max}]$, $(t,x) \in \mathbb{R}^+ \times \mathbb{R}$, and $\bar{\rho}$ a suitable initial datum. The flux $f(\rho)$, assumed to be strictly concave, can be written as $f(\rho) = \rho v$, where the average velocity of cars v is assumed to be a smooth strictly decreasing function of the density ρ.

Suppose that a driver travels along a road, whose load is modeled by (1.1), being influenced by traffic along the road but without influencing it significantly. Then, the driver's position $x = x(t)$ can be obtained by solving the following Cauchy problem:

$$\begin{cases} \dot{x} = v(\rho(t,x)), \\ x(\bar{t}) = \bar{x}, \end{cases} \tag{1.2}$$

with $\bar{x}$ the position at initial time $\bar{t} > 0$. Notice that ρ is, in general, a discontinuous function. We look for numerical methods to find solutions to the problem (1.1)–(1.2), which was recently studied from a theoretical point of view by Colombo and Marson in [6, 7]. Note that the speed of the driver v in (1.2) need not be identical to the overall mean traffic speed in the flow in (1.1). Therefore, the assumptions could be significantly relaxed and generalized as in [6].

Fluid-dynamic models can describe macroscopic phenomena as shock formation and propagation. Since they can develop discontinuities in finite time even starting from smooth

initial data, the study of the analytical and numerical aspects is fundamental. In the papers [4, 5, 8, 13, 14], some models for flows on networks based on the conservation law formulation (1.1) were proposed, and existence of solutions to Cauchy problems was proved. In particular, in [5] some rules to uniquely solve Riemann problems at junctions, where interactions between roads in the network occur, were introduced. In [3] some numerical approximations of the traffic models described in [4, 5] were provided. Moreover, a simulation algorithm using the Godunov scheme with boundary conditions at junctions was implemented and tested.

Here we present a simulation algorithm to trace the trajectory of a car traveling in a road network. The approximation procedure is composed of the following two parts:

- the solutions to (1.1) on each road of the network are computed by Wave Front Tracking (WFT) [1, 15] or by the Godunov scheme [10, 17];
- the problem (1.2) is solved by tracing car position through a procedure which takes into consideration interactions between the car trajectory and the (shock or rarefaction) waves on each road.

Focusing on bounded variation data, we establish a convergence result for the approximate solution on a single road, obtained by WFT technique, toward the solution of (1.1)–(1.2). While theoretical approaches do not provide a convergence rate (see, for instance, [6]), we are able to give an explicit linear convergence rate expressed in terms of total variation of initial datum of density, namely, $TV(\bar{\rho})$; see Theorem 4.4, formula (4.15).

Then we apply the algorithm to measure the efficiency of a traffic circle. Simulations are run to test how the total travel time of a driver is influenced by the right of way parameters. It is shown, as intuition may suggest, that the best choice corresponds to traffic inside the circle having priority with respect to incoming traffic. In the opposite situation, the circle may even come to a complete stop.

The case of car accidents on highways is also considered. We can give accurate estimates of the traveling times, assuming that we know the accident removal time. Such information is particularly interesting since static estimates are of low quality.

The paper is organized as follows. Section 2 is devoted to the description of the problem. The approximation algorithm is described in section 3, and in section 4 theoretical results of convergence for WFT are presented. In section 5 we propose an application of the approximation algorithm to determine the trajectory of a car moving into a portion of urban network represented by a traffic circle and into a single road when a car accident occurs. Related animations are reported on the web page [2].

2. Background.

To construct solutions to Cauchy problems like (1.1) it is important to solve Riemann problems, which are Cauchy problems with initial data of Heaviside type. If f is convex or concave, then there exist centered solutions (i.e., constant along rays $\frac{x}{t}$) consisting of a single wave, either a shock or a rarefaction. For instance, if f is concave and the initial datum is

$$\bar{\rho}(x) = \begin{cases} \rho_l, & x < 0, \\ \rho_r, & x > 0, \end{cases} \tag{2.1}$$

with ρ_l and ρ_r fixed constants, then the solution is a shock (if $\rho_l \leq \rho_r$),

$$\rho(t,x) = \begin{cases} \rho_l & \text{if } x \le \frac{f(\rho_r)-f(\rho_l)}{\rho_r-\rho_l} t, \\ \rho_r & \text{if } x > \frac{f(\rho_r)-f(\rho_l)}{\rho_r-\rho_l} t, \end{cases} \tag{2.2}$$

or a rarefaction (if $\rho_l > \rho_r$),

$$\rho(t,x) = \begin{cases} \rho_l & \text{if } x \le f'(\rho_l)t, \\ (f')^{-1}\left(\frac{x}{t}\right), & f'(\rho_l)t \le x \le f'(\rho_r)t, \\ \rho_r & \text{if } x > f'(\rho_r)t. \end{cases} \tag{2.3}$$

For (1.1), the velocity and the flux function are required to satisfy the following assumptions:

(H) $v'(\rho) < 0$ and f is smooth and strictly concave.

A road network is given by a finite number of roads modeled by intervals $[a_i, b_i]$, $i = 1, \dots, N$, that meet at some junctions. We call the Riemann problem for a road network a Cauchy problem with constant initial datum on each road. For road endpoints not linked to any junction, boundary data are required and the corresponding boundary problem is solved.

In treating networks, the main difficulty is the fact that the system at a junction is underdetermined, even imposing the conservation of cars. The latter can be expressed by the Rankine–Hugoniot condition at the junction

$$\sum_{i=1}^{n} f(\rho_i(t, b_i)) = \sum_{j=n+1}^{n+m} f(\rho_j(t, a_j)),$$

where ρ_i, $i = 1, \dots, n$, and ρ_j, $j = n+1, \dots, n+m$, are the car densities, respectively, on incoming and outgoing roads. To uniquely solve Riemann problems at junctions, as in [5], we make the following assumptions:

(A) there are some fixed coefficients, which depend on drivers preferences, expressing the distribution of traffic from incoming to outgoing roads;

(B) respecting (A), drivers behave in order to maximize the flow through junctions.

To deal with rule (A) we fix a matrix, called the *traffic distribution* matrix,

$$A = \{\alpha_{ji}\}_{j=n+1,\dots,n+m,\, i=1,\dots,n} \in \mathbb{R}^{m\times n}, \text{ with } 0 < \alpha_{ji} < 1, \quad \sum_{j=n+1}^{n+m} \alpha_{ji} = 1,$$

for $i = 1, \dots, n$ and $j = n+1, \dots, n+m$, where α_{ji} represents the percentage of drivers arriving from the ith incoming road who take the jth outgoing road. In [14] an approach based only on the maximization of a function, e.g., flux, was proposed.

In [5] the existence of solutions to Cauchy problems respecting rules (A) and (B) was proved. In the case $m < n$ it is necessary to introduce a further rule; see [4]. If, for example, $m = 1$, $n = 2$, we fix a *right of way* parameter $q \in]0, 1[$ and assume the following rule:

(C) Assume that not all cars can enter the outgoing road and C is the quantity that can do so. Then qC cars come from first incoming road and $(1-q)C$ cars from the second.

The rule (C) allows us to uniquely solve Riemann problems.

Let us now briefly describe how solutions to Riemann problems are computed; for the details the reader is referred to [5]. We look for solutions to problem (1.1) with a single

wave on each road. Rules (A)–(B) give rise to a linear programming problem. In particular, rule (B) consists in the maximization of a linear functional on a convex region determined by rule (A). More precisely, initial data of roads linked on the right (incoming roads) or on the left (outgoing roads) and constraints on the sign of wave speed determine the region where incoming fluxes are maximized.

Fix constant initial data $\rho_{i,0}$ on each incoming road and $\rho_{j,0}$ on each outgoing road. The densities of cars on the incoming roads are indicated by $\rho_i(t,x) : \mathbb{R}^+ \times I_i \to [0,1]$, $i \in \{1,\dots,n\}$, and on the outgoing roads by $\rho_j(t,x) : \mathbb{R}^+ \times I_j \to [0,1]$, $j \in \{1,\dots,m\}$. Let $\tau : [0,1] \mapsto [0,1]$ be the continuous map such that

$$f(\tau(\rho)) = f(\rho),$$

and $\tau(\rho) \neq \rho$ for each $\rho \neq \sigma$. We define the densities $\hat\rho_i, \hat\rho_j$ (and the corresponding fluxes $f(\hat\rho_i) = \hat\gamma_i$, $f(\hat\rho_j) = \hat\gamma_j$) as the new states at the junction. The unique admissible weak solution at a junction is given by the solution to the Riemann problem with data $(\rho_{i,0}, \hat\rho_i)$ for incoming roads and $(\hat\rho_j, \rho_{j,0})$ for outgoing roads. For instance, for incoming roads with $\rho_{i,0} \le \hat\rho_i$, the solution (centered in b_i) is a shock, and, for a sufficiently small time, can be expressed as

$$\rho_i(t,x) = \begin{cases} \rho_{i,0} & \text{if } x \le b_i + \frac{f(\hat\rho_i) - f(\rho_{i,0})}{\hat\rho_i - \rho_{i,0}} t, \\ \hat\rho_i & \text{otherwise,} \end{cases} \tag{2.4}$$

and the velocity is given by $\lambda = \frac{f(\hat\rho_i) - f(\rho_{i,0})}{\hat\rho_i - \rho_{i,0}}$ (namely, the Rankine–Hugoniot relation), or, if $\rho_{i,0} > \hat\rho_i$, a rarefaction that, for a sufficiently small time, reads as

$$\rho_i(t,x) = \begin{cases} \rho_{i,0} & \text{if } x \le b_i + f'(\rho_{i,0})t, \\ (f')^{-1}\left(\frac{x}{t}\right), & b_i + f'(\rho_{i,0})t < x < b_i + f'(\hat\rho_i)t, \\ \hat\rho_i & \text{if } x \ge b_i + f'(\hat\rho_i)t. \end{cases} \tag{2.5}$$

Analogously, the waves produced by the solutions to Riemann problems for the outgoing roads are centered in the left endpoint a_i.

Since we look for waves emerging out of junctions, admissible solutions are obtained by solving Riemann problems by waves of negative speed on incoming roads and by waves of positive speed on outgoing roads, as indicated by conditions (2.6)–(2.7):

$$\hat\rho_i \in \begin{cases} \{\rho_{i,0}\} \cup \,]\tau(\rho_{i,0}), 1] & \text{if } 0 \le \rho_{i,0} \le \sigma, \\ [\sigma, 1] & \text{if } \sigma \le \rho_{i,0} \le 1, \end{cases} \tag{2.6}$$

and

$$\hat\rho_j \in \begin{cases} [0, \sigma] & \text{if } 0 \le \rho_{j,0} \le \sigma, \\ \{\rho_{j,0}\} \cup [0, \tau(\rho_{j,0})[& \text{if } \sigma \le \rho_{j,0} \le 1. \end{cases} \tag{2.7}$$

The new states at junctions, namely, $\hat\rho_i$ on incoming roads and $\hat\rho_j$ on outgoing roads, are uniquely obtained by inverting the relations

$$f(\hat\rho_i) = \hat\gamma_i, \qquad f(\hat\rho_j) = \hat\gamma_j \tag{2.8}$$

on the sets given by (2.6) and (2.7).

Due to the rule (A),

$$\hat{\gamma}_j \doteq \sum_{i=1}^{n} \alpha_{ji}\hat{\gamma}_i, \qquad j = n+1, \dots, n+m,$$

it suffices to determine the incoming fluxes $\hat{\gamma}_i$, which solve the following LP problem: Define

$$\begin{aligned} \Omega_i &:= [0, \gamma_i^{max}(\rho_{i,0})], \quad i = 1, \dots, n, \\ \Omega_j &:= \left[0, \gamma_j^{max}(\rho_{j,0})\right], \quad j = n+1, \dots, n+m, \\ \Omega &:= \left\{(\gamma_1, \dots, \gamma_n) \in \Omega_1 \times \cdots \times \Omega_n \mid A \cdot (\gamma_1, \dots, \gamma_n)^T \in \Omega_{n+1} \times \cdots \times \Omega_{n+m}\right\}. \end{aligned} \tag{2.9}$$

The set Ω is compact, convex, and not empty. Then, $\hat{\gamma} \in \Omega$ is the solution to

$$\max_{\gamma \in \Omega} \gamma \cdot \mathbf{1}, \tag{2.10}$$

where $\mathbf{1} = (1, \dots, 1) \in \mathbb{R}^n$.

For definiteness, the flux function is chosen to be the Greenshields one (see [12]):

$$f(\rho) = v_{max}\, \rho \left(1 - \frac{\rho}{\rho_{max}}\right). \tag{2.11}$$

We set for simplicity $\rho_{max} = 1 = v_{max}$, so that the velocity is $v = 1 - \rho$ and the flux $f = \rho(1-\rho)$. In particular, $f(0) = 0 = f(1)$ and f has a unique maximum in $\sigma = 1/2$.

3. Approximation schemes.

In this section we describe the simulation algorithm, which is composed of the following two steps:

Step 1: The density values satisfying (1.1) are computed on each road solving Riemann problems. The numerical scheme can be indifferently WFT or Godunov scheme endowed with boundary conditions at junctions.

Step 2: The driver's position is determined solving problem (1.2) by means of an algorithm which, given the densities obtained at the previous step by WFT or the Godunov scheme, determine the car position on the network.

The choice of WFT is due to the possibility of obtaining theoretical results. On the other side, the Godunov scheme is easy to implement and gives good insight into vehicular traffic problems; see [9, 16]. Also, both schemes are based on the solution to Riemann problems, thus permitting a convenient treatment of the car trajectory approximation.

3.1. The Wave Front Tracking algorithm (WFT).

Here we recall briefly the technique of Wave Front Tracking; for a detailed description see [1, 9].

The WFT is a semidiscrete scheme which can be summarized by the following steps:

- approximate initial datum $\bar{\rho} = (\bar{\rho}_1, \dots, \bar{\rho}_N)$ by piecewise constant functions $\bar{\rho}_\nu$;
- construct solutions to Riemann problems of $\bar{\rho}_\nu$ and approximate rarefactions by a set of small shocks;
- piece approximate solutions to Riemann problems together to get a solution for t small;
- prolong waves up to first interaction time. Then one gets a new Riemann problem, solves it approximately, and goes on up to the next interaction time.

Next we detail the construction of WFT approximate solutions. Given a general initial datum $\bar\rho$, we approximate it by a sequence of piecewise constant functions $\bar\rho_\nu$ and we construct the corresponding approximate solutions. If they converge in L^1_{loc}, then the limit is a weak entropy solution on each road; see [1] for the proof.

3.1.1. Step 1: Numerical algorithm for (1.1). Let $\bar\rho = (\bar\rho_1, \dots, \bar\rho_N)$ be a map defined on the road network, $\bar\rho_i : I_i \to \mathbb{R}$, $i = 1, \dots, N$. It is possible to choose a sequence of piecewise constant functions $\bar\rho_\nu$ such that

$$Tot.Var.\{\bar\rho_\nu\} \le Tot.Var.\{\bar\rho\}, \tag{3.1}$$

$$|\bar\rho_\nu|_{L^\infty} \le |\bar\rho|_{L^\infty}, \tag{3.2}$$

$$|\bar\rho_\nu - \bar\rho|_{L^1} < \frac{1}{\nu}. \tag{3.3}$$

By (3.1), $\bar\rho_\nu$ has a finite number of discontinuities, say, $y_1^\nu < \cdots < y_K^\nu$. We approximately solve the Riemann problem generated by the jump $(\bar\rho_\nu(y_k^\nu-), \bar\rho_\nu(y_k^\nu+))$ for each $k = 1, \dots, K$ using piecewise constant functions of the type $\varphi\left(\frac{x-y_k^\nu}{t}\right)$, where $\varphi : \mathbb{R} \to \mathbb{R}$. In particular, if the solution to the Riemann problem generated by $(\bar\rho_\nu(y_k^\nu-), \bar\rho_\nu(y_k^\nu+))$ is a shock, then $\varphi\left(\frac{x-y_k^\nu}{t}\right)$ is the exact solution. On the contrary, if a rarefaction wave appears, then we split it into a centered rarefaction fan formed by a sequence of jumps of size at most $1/\nu$, traveling with the characteristic speed of the left state.

Proceeding in this way, we are able to construct an approximate solution $\rho_\nu(t, x)$ until a time t_1, where either two wave fronts interact together or a wave interacts with a junction. When a wave interacts with another one, we simply solve the new Riemann problem; instead, when a wave reaches a junction, we solve the corresponding Riemann problem at the junction.

We always split rarefaction waves, inserting the value σ (if it is in the range of the rarefaction). Moreover, we let any rarefaction shock with endpoint σ have velocity zero. In order to prove existence of a wave front tracking approximate solution for every $t \in [0, T]$, where T may be also $+\infty$, we need to estimate

1. the number of waves; and
2. the number of interactions between waves.

We call the obtained function *a wave front tracking approximate solution.*

Fix $\nu \in \mathbb{N}$ and $t > 0$. We let $K(\nu, t)$ be the time dependent set of discontinuities and for every $k \in K(\nu, t)$ we let $\rho_-^{\nu,k}(t)$, $\rho_+^{\nu,k}(t)$ be, respectively, the left and the right states of the discontinuity. In other words,

$$\rho_-^{\nu,k}(t) = \rho_\nu(t, y_k^\nu-),$$
$$\rho_+^{\nu,k}(t) = \rho_\nu(t, y_k^\nu+),$$

where y_k^ν is the position of the kth discontinuity at time t in ρ_ν. We also indicate by λ_k the velocity of the kth discontinuity. For simplicity from now on we may eventually drop the index ν.

If we get BV estimates on the WFT approximate solutions, we can pass to the limit, obtaining a weak entropy solution.

For a single conservation law on $\mathbb{R}$, the number of waves decreases; thus the number of interactions is bounded by the number of waves, and the total variation diminishes. For networks the situation is more complex. In particular, the number of waves may increase for interactions of waves at junctions. Still the necessary estimates can be carried out as described in [9].

3.1.2. Step 2: Car path. For every $\nu \in \mathbb{N}$, we call $x_\nu(t)$ the position of the car at time t if the load is given by the approximate solution ρ_ν. Then

$$\dot{x}_\nu(t) = v(\rho_\nu(t, x_\nu(t))). \tag{3.4}$$

In the following lemma we show that at interaction times with waves, the velocity of the car is greater than that of the wave in front of it.

Lemma 3.1. *If $x_\nu(t) \in (y^\nu_k, y^\nu_{k+1})$, then*

$$\dot{x}_\nu(t) = v(\rho^{\nu,k}_+(t)) > \lambda_{k+1}(t) = \frac{f(\rho^{\nu,k+1}_+(t)) - f(\rho^{\nu,k+1}_-(t))}{\rho^{\nu,k+1}_+(t) - \rho^{\nu,k+1}_-(t)}. \tag{3.5}$$

Proof. Using the Rankine–Hugoniot relation we want to prove that

$$\begin{aligned}\frac{f(\rho^{\nu,k+1}_+(t)) - f(\rho^{\nu,k+1}_-(t))}{\rho^{\nu,k+1}_+(t) - \rho^{\nu,k+1}_-(t)} &= \frac{v(\rho^{\nu,k+1}_+(t))\rho^{\nu,k+1}_+(t) - v(\rho^{\nu,k+1}_-(t))\rho^{\nu,k+1}_-(t)}{\rho^{\nu,k+1}_+(t) - \rho^{\nu,k+1}_-(t)} \\ &< v(\rho^{\nu,k+1}_-(t)).\end{aligned}$$

If $\rho^{\nu,k+1}_+(t) > \rho^{\nu,k+1}_-(t)$, then (3.5) is equivalent to

$$v(\rho^{\nu,k+1}_+(t))\rho^{\nu,k+1}_+(t) - v(\rho^{\nu,k+1}_-(t))\rho^{\nu,k+1}_-(t) < v(\rho^{\nu,k+1}_-(t))\rho^{\nu,k+1}_+(t) - v(\rho^{\nu,k+1}_-(t))\rho^{\nu,k+1}_-(t),$$

i.e., to

$$v(\rho^{\nu,k+1}_+(t)) < v(\rho^{\nu,k+1}_-(t)).$$

By the hypothesis (H), v is a strictly decreasing function; hence the last inequality is verified. On the other hand, if $\rho^{\nu,k+1}_+(t) < \rho^{\nu,k+1}_-(t)$, then we obtain the inequality $v(\rho^{\nu,k+1}_+(t)) > v(\rho^{\nu,k+1}_-(t))$, which is again verified due to the decreasing behavior of v. ∎

Therefore, $x_\nu(t)$ interacts with the waves located at y^ν_k in increasing order.

A numerical algorithm is readily obtained by setting the following:

- If $x_\nu(t) \in (y^\nu_k, y^\nu_{k+1})$, then $\dot{x}_\nu(t) = v(\rho^{\nu,k}_+(t))$. In other words, the velocity is constant as long as no interaction with waves occurs.
- If $x_\nu(t)$ interacts with the kth wave of ρ_ν, then the velocity changes from $v(\rho^{\nu,k-1}_+(t)) = v(\rho^{\nu,k}_-(t))$ to $v(\rho^{\nu,k}_+(t))$.

3.2. Godunov scheme on a road network. Now, in order to describe the Godunov scheme we need to introduce a *numerical grid* with the following notation:

- Δx is the space grid size on each road I_i;
- Δt is the time grid size on the time interval $[0, T]$;
- $(t_l, x_m) = (l\Delta t, m\Delta x)$, for $l = 0, 1, \ldots, L$ and $m = 0, 1, \ldots, M$, are the grid points, with L and M, respectively, the number of time and space nodes of the grid.

For a function v defined on the grid we write $v_m^l = v(t_l, x_m)$. Notice that for our simulations we assume to have a constant space increment since all intervals I_i are equal, but, in general, Δx may vary depending on the length of each road.

3.2.1. Step 1: Numerical algorithm for (1.1). The Godunov scheme is based on the local resolution to Riemann problems and it proceeds as follows; for further details see [11, 10].

Piecewise constant approximations of the initial data are used as the initial data of Riemann problems. Waves in two neighbor cells do not interact before time Δt under the CFL condition $\Delta t \leq \frac{1}{2v_{max}}\Delta x$, which, setting $v_{max} = 1$, reads as $\Delta t \leq \frac{1}{2}\Delta x$. It is then possible to define a unique solution in the strip $(t_l, t_{l+1}) \times \mathbb{R}$ by piecing the solutions obtained in each cell together. The exact solution is projected on a piecewise constant function $v_m^{l+1} = \frac{1}{\Delta x}\int_{x_m}^{x_{m+1}} v^{\Delta}(x, t_{l+1})dx$; then the mean is obtained by the Gauss–Green formula, and this procedure is repeated recursively. The Godunov scheme can be expressed in the conservative form as

$$v_m^{l+1} = v_m^l - \frac{\Delta t}{\Delta x}\big(g^G(v_m^l, v_{m+1}^l) - g^G(v_{m-1}^l, v_m^l)\big), \quad l = 0, 1, \ldots, L-1, \quad m = 0, 1, \ldots, M, \tag{3.6}$$

with $g^G(u, v)$ numerical flux. Boundary conditions of the scheme are imposed for any incoming road not linked on the left and for any outgoing road not linked on the right.

Conditions at a junction. For roads connected at the right endpoint, the interaction at a junction is taken into account as follows:

$$v_M^{l+1} = v_M^l - \frac{\Delta t}{\Delta x}\big(\hat{\gamma}_i - g^G(v_{M-1}^l, v_M^l)\big),$$

while for roads connected at the left endpoint we have

$$v_0^{l+1} = v_0^l - \frac{\Delta t}{\Delta x}\big(g^G(v_0^l, v_1^l) - \hat{\gamma}_j\big),$$

where $\hat{\gamma}_i$, $\hat{\gamma}_j$ are the maximized fluxes, respectively, on incoming and outgoing roads, computed solving the linear programming problem (2.10).

3.2.2. Step 2: Car path. Let us consider now a single driver moving on a road network. We develop a numerical scheme to describe car trajectory on each road composing the network. A road is parametrized as an interval and, according to the discretization previously defined, is divided into subintervals or cells of length Δx.

At each time t_l, we determine the position x^l of the driver by studying interactions between the car trajectory and the density waves within a fixed cell of the numerical grid $C_{m_l} = [(m_l - 1)\Delta x, m_j\,\Delta x[$. We distinguish the following two cases:

Case 1. $x^l \in [(m_l - 1)\Delta x, (m_l - \frac{1}{2})\Delta x[$.

Case 2. $x^l \in [(m_l - \frac{1}{2})\Delta x, m_l\,\Delta x[$.

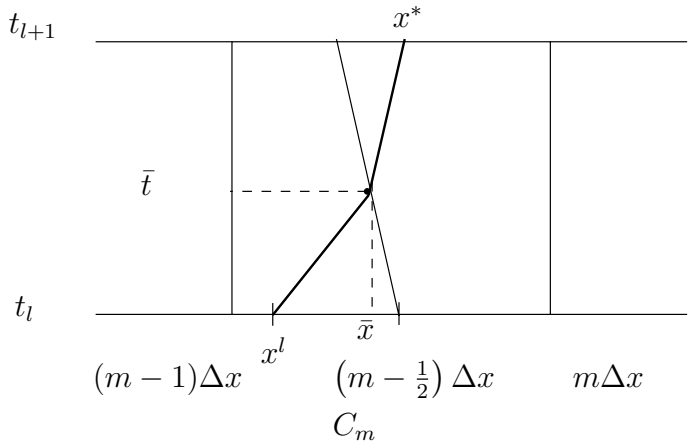

Figure 1. *Interaction with shock.*

In order to describe the car trajectory, we compute the new position x^{l+1} and possibly update the cell index m_{l+1}. The approximate value of the density on the numerical grid is denoted by $\rho_m^l = \rho(t_l, x_m)$.

Let us now detail the algorithm: for notational convenience we drop the index l from m.

3.2.3. Case 1. Two cases are distinguished:

(a) the wave starting from the space node $(m-\frac{1}{2})\Delta x$ is a shock;

(b) the wave starting from the space node $(m-\frac{1}{2})\Delta x$ is a rarefaction.

Let us first study case (a). The velocity of the wave, starting from the point $(m-\frac{1}{2})\Delta x$ at time t_l, is given by

$$\lambda_m = \frac{f(\rho_m^l) - f(\rho_{m-1}^l)}{\rho_m^l - \rho_{m-1}^l}.$$

Then the car and the wave interact at the point $(\bar{t}, \bar{x})$ given by

$$\begin{aligned} \bar{t} &= \frac{\left(m-\frac{1}{2}\right)\Delta x - x^l}{v(\rho_{m-1}^l) - \lambda_m}, \\ \bar{x} &= x^l + v(\rho_{m-1}^l)\bar{t}. \end{aligned} \tag{3.7}$$

We have to further consider the following cases:

(i) $\bar{t} \geq \Delta t$, which means no interaction on the time interval $[t_l, t_{l+1}]$. Then we have

$$x^{l+1} = x^l + v(\rho_{m-1}^l)\Delta t.$$

(ii) $\bar{t} < \Delta t$. Then, after the interaction (see Figure 1), the new position of the car is

$$x^{l+1} = \bar{x} + (\Delta t - \bar{t})v(\rho_m^l).$$

Let us now turn to case (b). Recalling that for the flux function considered we have $v(\rho(t,x)) = 1-\rho$, the driver's position is obtained by solving the ordinary differential equation

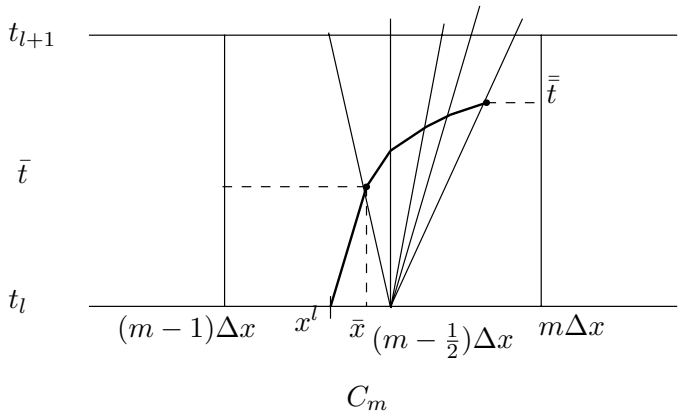

Figure 2. *Interaction with rarefaction.*

$$\dot{x} = \begin{cases} 1-\rho_m^l & \text{if } x \le (m-\frac{1}{2})\Delta x + f'(\rho_m^l)t, \\ 1-\left(\frac{1}{2} - \frac{x-(m-\frac{1}{2})\Delta x}{2\,(t-t_l)}\right) & \text{if } f'(\rho_m^l)t \le x-(m-\frac{1}{2})\Delta x \le f'(\rho_{m+1}^l)t, \\ 1-\rho_{m+1}^l & \text{if } x > (m-\frac{1}{2})\Delta x + f'(\rho_{m+1}^l)t. \end{cases} \tag{3.8}$$

The velocity of the wave, starting from the point $(m-\frac{1}{2})\Delta x$ at time t_l, is given by

$$\lambda_m = f'(\rho_m^l).$$

The first interaction point with the rarefaction wave is again expressed as in (3.7).

Then, the solution to (3.8) is

$$x(t) = \left(m-\frac{1}{2}\right)\Delta x + (t-t_l) - \sqrt{t-t_l}\left(\frac{\bar{t}-t_l+(m-\frac{1}{2})\Delta x-\bar{x}}{\sqrt{\bar{t}-t_l}}\right). \tag{3.9}$$

Now, let $\bar{\bar{t}}$ be the time coordinate of the final intersection point between the rarefaction wave and the car trajectory; see Figure 2. Then

$$\frac{x(\bar{\bar{t}}) - \left(m-\frac{1}{2}\right)\Delta x}{\bar{\bar{t}}} = f'(\rho_m^l),$$

with $x(t)$ given by (3.9).

Again we distinguish two possible cases:

Case (a) $\bar{t} \ge \Delta t$, i.e., no interaction between the car and the rarefaction wave occur. Since the car travels at constant speed, the new position is obtained by

$$x^{l+1} = x^l + v(\rho_{m-1}^l)\Delta t.$$

Case (b) $\bar{t} < \Delta t$. For case (b), we need to further distinguish the following:

Case (b1) $\bar{\bar{t}} \ge \Delta t$. Then the new position is

$$x^{l+1} = x(\Delta t),$$

with $x(t)$ given by (3.9).

Case (b2) $\bar{\bar{t}} < \Delta t$. Then

$$x^{l+1} = x(\bar{\bar{t}}) + (\Delta t - \bar{\bar{t}})v(\rho^l_m),$$

with $x(t)$ given by (3.9).

Since the trajectory remains inside the cell C_{m_l} even after interactions, in all subcases of case 1 the updated cell index is

$$m_{l+1} = m_l.$$

3.2.4. Case 2. Two cases are distinguished:

(a) The wave starting from the space node $(m + \frac{1}{2})\Delta x$ is a shock.

(b) The wave starting from the space node $(m + \frac{1}{2})\Delta x$ is a rarefaction.

We first consider case (a). The velocity of the wave, starting from the point $(m + \frac{1}{2})\Delta x$ at time t_l, is given by

$$\lambda_m = \frac{f(\rho^l_{m+1}) - f(\rho^l_m)}{\rho^l_{m+1} - \rho^l_m}.$$

The interaction point $(\bar{t}, \bar{x})$ of the wave with the car is given by

$$\begin{aligned} \bar{t} &= \frac{\left(m + \frac{1}{2}\right)\Delta x - x^l}{v(\rho^l_{m+1}) - \lambda_m}, \\ \bar{x} &= x^l + v(\rho^l_m)\bar{t}. \end{aligned} \tag{3.10}$$

As before, we have two different cases:

(i) $\bar{t} \geq \Delta t$, which means no interaction on the time interval $[t_l, t_{l+1}]$. Then we have

$$x^{l+1} = x^l + v(\rho^l_m)\Delta t.$$

(ii) $\bar{t} < \Delta t$. Then, after the interaction, the new position of the car is

$$x^{l+1} = \bar{x} + (\Delta t - \bar{t})v(\rho^l_{m+1}).$$

Let us now turn to case (b). We have the same equation as in (3.8) with $(m - \frac{1}{2})\Delta x$ replaced by $(m + \frac{1}{2})\Delta x$ and $f'(\rho^l_m)$ by $f'(\rho^l_{m+1})$. The velocity of the wave, starting from the point $(m + \frac{1}{2})\Delta x$ at time t_l, is given by

$$\lambda_m = f'(\rho^l_{m+1}).$$

The first interaction point with the rarefaction wave is again expressed as in (3.10).

Then, the car position after $\bar{t}$ and before exiting the rarefaction is given by

$$x(t) = \left(m + \frac{1}{2}\right)\Delta x + (t - t_l) - \sqrt{t - t_l}\left(\frac{\bar{t} - t_l + (m + \frac{1}{2})\Delta x - \bar{x}}{\sqrt{\bar{t} - t_l}}\right). \tag{3.11}$$

Now, the final interaction time $\bar{\bar{t}}$ of the car with the rarefaction solves

$$\frac{x(\bar{\bar{t}}) - \left(m + \frac{1}{2}\right)\Delta x}{\bar{\bar{t}}} = f'(\rho^l_{m+1}),$$

with $x(t)$ given by (3.11).

The distinction in subcases is as before:

Case (a) $\bar{t} \geq \Delta t$, i.e., no interaction between the car and the rarefaction wave occurs. Since the car travels at constant speed, the new position is obtained by

$$x^{l+1} = x^l + v(\rho_m^l)\Delta t.$$

Case (b) $\bar{t} < \Delta t$.

Case (b1) $\bar{\bar{t}} \geq \Delta t$. Then the new position is

$$x^{l+1} = x(\Delta t),$$

with $x(t)$ given by (3.11).

Case (b2) $\bar{\bar{t}} < \Delta t$. Then

$$x^{l+1} = x(\bar{\bar{t}}) + (\Delta t - \bar{\bar{t}})v(\rho_{m+1}^l),$$

with $x(t)$ given by (3.11).

Finally, the new cell index is determined as follows. If $x^{l+1} < m\Delta x$, then $m_{l+1} = m_l$; otherwise $m_{l+1} = m_l + 1$.

4. Convergence of car trajectory. This section is devoted to the analysis of the convergence of the car trajectory x_ν in case of the WFT algorithm. We consider the case of a single road $[a, b]$.

Our point of view to estimate the car position as a function of ν is the following. We think of $\rho_{\nu+1}$ as ρ_ν with shifts applied to the initial position of waves. This can be done by fixing an approximation procedure, which is simply based on sampling at points of a grid with mesh size $2^{-\nu}$. Then the position of $x_{\nu+1}$ is also thought of as the position of x_ν plus a shift. The latter changes only at interactions with waves of ρ_ν and $\rho_{\nu+1}$. Thus finally the problem reduces to estimate the increase of the shifts (both of waves and car position) at every interaction.

4.1. Wave and car shifts. Assume we have a BV initial datum $\bar{\rho}(x)$. Then we define $\bar{\rho}_\nu$ to be the sequence approximating $\bar{\rho}$ given by

$$\bar{\rho}_\nu(x) = \bar{\rho}\left(2^\nu \left[\frac{x}{2^\nu}\right]\right), \quad \nu \in \mathbb{N}. \tag{4.1}$$

Then it is easy to notice that every wave of $\rho_{\nu+1}$ corresponds to a wave of ρ_ν with a shift ξ of at most $2^{-(\nu+1)}$; see Figure 3.

Call $\rho_\nu(t, x)$ the WFT solution for initial datum $\bar{\rho}_\nu$. Then it is possible to determine the evolution of shifts of waves $\xi_k^\nu(t)$, $k \in K(\nu, t)$, using the following lemma, proved in [9].

Lemma 4.1. *Consider two waves with speeds λ_1 and λ_2, respectively, that interact together producing a wave with speed λ_3. If the first wave is shifted by ξ_1 and the second wave by ξ_2, then the shift of the resulting wave is given by*

$$\xi_3 = \frac{\lambda_3 - \lambda_2}{\lambda_1 - \lambda_2}\xi_1 + \frac{\lambda_1 - \lambda_3}{\lambda_1 - \lambda_2}\xi_2. \tag{4.2}$$

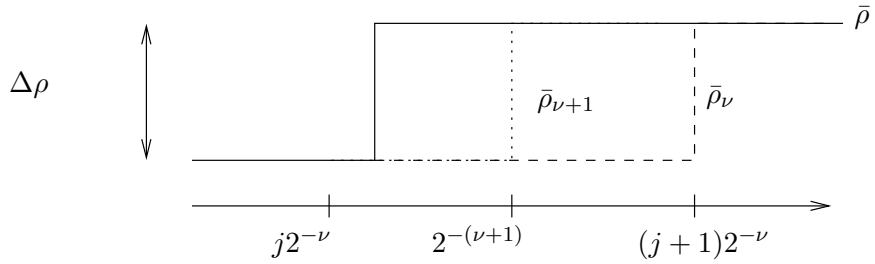

Figure 3. *Shift of discontinuities at time* 0.

Moreover, we have

$$\Delta\rho_3\xi_3 = \Delta\rho_1\xi_1 + \Delta\rho_2\xi_2, \tag{4.3}$$

where $\Delta\rho_i$ *are the signed strengths of the corresponding waves.*

Lemma 4.1 permits us to determine the evolution of shifts of waves. Moreover, even if the shift sizes are not conserved, this happens for the quantity $\xi \cdot \Delta\rho$, which represents the L^1 shift of the approximate solution. Recalling that $(\rho_-^{\nu,k}(t), \rho_+^{\nu,k}(t))$ is the value to the left and, respectively, to the right of the kth jump of $\rho_\nu(t)$, we define $\Delta\rho_k^\nu(t) = \rho_+^{\nu,k}(t) - \rho_-^{\nu,k}(t)$.

To study the convergence of car trajectories, we need to estimate the quantity

$$\|x_\nu(t) - x_{\nu+1}(t)\|. \tag{4.4}$$

As for the waves of ρ_ν, we define the shift of the car position as

$$\eta_\nu(t) = x_{\nu+1}(t) - x_\nu(t).$$

Since the initial car position does not depend on the approximate solution, we have $\eta_\nu(0) = 0$. Notice that our problem reduces to estimate $|\eta(t)|$. Such a quantity varies only at interaction times with waves of ρ_ν and $\rho_{\nu+1}$. Since the latter are obtained by shifting the formers, we can consider generic interactions of a car with waves, both presenting shifts. Thus we let η_k^ν be the value of η_ν after the interaction with the kth wave of ρ_ν and the kth wave of $\rho_{\nu+1}$. In the case of Neumann boundary conditions, and thus no wave from boundaries, the number of waves is decreasing. Hence the number of interactions is bounded by the number of waves in the initial datum, which in turn is at most $(b-a)/2^{-(\nu+1)}$. In the case of Dirichlet boundary conditions, then we approximate also the boundary data with piecewise constant functions, thus getting again a finite number of possible waves and thus of interactions.

4.2. Shifts evolution. Here we consider a generic interaction between a wave front and a car trajectory. In particular, we assume that both have an initial shift and we want to estimate the value of the car position shift after the interaction, since the wave shift does not change. Say x_0 is the initial position of the car and s_0 is the initial position of the wave front with speed $\lambda = \frac{\Delta f}{\Delta\rho}$; then the interaction point is

$$(\bar x, \bar t) = \left(x_0 + \bar t v(\rho_-), \frac{s_0 - x_0}{v(\rho_-) - \lambda}\right), \tag{4.5}$$

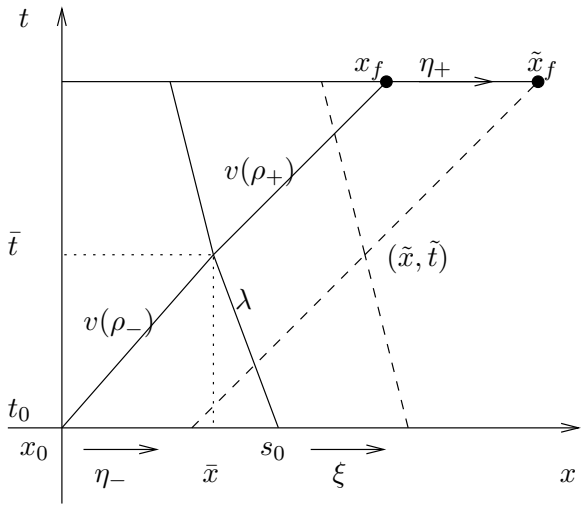

Figure 4. *The shift for the wave front, ξ, and the shifts for the car trajectory, η_-, η_+.*

and, after interaction, the (final) position x_f at time T is given by

$$x_f = \bar{x} + (T - \bar{t})v(\rho_+). \tag{4.6}$$

See Figure 4. Call $\xi \in \mathbb{R}$ the wave shift and $\eta_-, \eta_+ \in \mathbb{R}$ the shifts of the car trajectory, respectively, before and after interacting with the wave. The point of interaction for the shifted wave and car position is

$$(\tilde{x},\tilde{t}) = \left(x_0 + \eta_- + \tilde{t}v(\rho_-), \frac{(s_0+\xi) - (x_0+\eta_-)}{v(\rho_-) - \lambda}\right) \tag{4.7}$$

and the final position of the car $\tilde{x}_f$ is given by

$$\tilde{x}_f = x_f + \eta_+, \tag{4.8}$$

where η_+ is given by

$$\eta_+ = \tilde{x} + v(\rho_+)(\bar{t} - \tilde{t}) - \bar{x}. \tag{4.9}$$

Now, using (4.5)–(4.7), we can express η_+ in terms of η_-:

$$\begin{aligned}\eta_+ &= \eta_- + v(\rho_-)\frac{(s_0+\xi) - (x_0+\eta_-)}{v(\rho_-) - \lambda} + v(\rho_+)\frac{\eta_- - \xi}{v(\rho_-) - \lambda} - v(\rho_-)\frac{s_0 - x_0}{v(\rho_-) - \lambda} \\ &= \eta_-\frac{v(\rho_+) - \lambda}{v(\rho_-) - \lambda} + \xi\frac{v(\rho_-) - v(\rho_+)}{v(\rho_-) - \lambda}. \end{aligned} \tag{4.10}$$

Let us set $\beta = \frac{v(\rho_+)-\lambda}{v(\rho_-)-\lambda}$ and $\gamma = \frac{v(\rho_-)-v(\rho_+)}{v(\rho_-)-\lambda}$. Then, recalling that $\lambda = \Delta f/\Delta\rho$, it follows that

$$\begin{aligned}\beta &= \frac{v(\rho_+)(\rho_+ - \rho_-) - \rho_+ v(\rho_+) + \rho_- v(\rho_-)}{v(\rho_-)(\rho_+ - \rho_-) - \rho_+ v(\rho_+) + \rho_- v(\rho_-)} \\ &= \frac{\rho_-}{\rho_+}, \end{aligned} \tag{4.11}$$

and, similarly,

$$\gamma = \frac{(v(\rho_+) - v(\rho_-))(\rho_+ - \rho_-)}{v(\rho_-)(\rho_+ - \rho_-) - \rho_+ v(\rho_+) + \rho_- v(\rho_-)}$$
$$= \frac{\rho_+ - \rho_-}{\rho_+}. \tag{4.12}$$

Therefore, (4.10) becomes

$$\eta_+ = \eta_- \frac{\rho_-}{\rho_+} + \xi \frac{\rho_+ - \rho_-}{\rho_+}. \tag{4.13}$$

4.3. Estimates for car trajectory. The sequence of interactions between waves and with the car may happen with different orders. However, we know that the car is faster than waves (Lemma 3.1); thus the car always interacts with waves in increasing order. Moreover, the next lemma shows that the worst case, for the car shift increase, happens when the car interacts with waves before wave interactions occur.

Lemma 4.2. *Assume that $\rho_\nu(0)$ is strictly positive and presents only two waves (ρ_-^1, ρ_+^1) and (ρ_-^2, ρ_+^2). Let ξ_1 and ξ_2 be the shifts of the waves in ρ_ν, to get the position of the waves in $\rho_{\nu+1}(0)$. We define η to be the shift generated if x_ν interacts separately with the two waves and $\tilde\eta$ to be the shift if the two waves meet before interacting with x_ν. Then*

$$|\tilde\eta| \le |\eta|.$$

Proof. Using (4.13) and $\eta_0 = 0$, we get

$$\eta_1 = \frac{\rho_-^1}{\rho_+^1}\eta_0 + \frac{|\Delta\rho_1\xi_1|}{\rho_+^1} = \frac{|\Delta\rho_1\xi_1|}{\rho_+^1}, \quad \eta_2 = \frac{\rho_-^2}{\rho_+^2}\eta_1 + \frac{|\Delta\rho_2\xi_2|}{\rho_+^2};$$

then, since $\rho_+^1 = \rho_-^2$, one gets

$$\eta = \frac{1}{\rho_+^2}(|\Delta\rho_1\xi_1| + |\Delta\rho_2\xi_2|),$$

while

$$\tilde\eta = \frac{\rho_-^1}{\rho_+^1}\eta_0 + \frac{\tilde\Delta\rho\tilde\xi}{\rho_+^2} = \frac{\tilde\Delta\rho\tilde\xi}{\rho_+^2},$$

where $\tilde\Delta\rho$ and $\tilde\xi$ are, respectively, the jump and the shift coming from the interaction of the two waves. The conclusion follows by Lemma 4.1. ∎

Now we can state our first estimate for the car shift.

Lemma 4.3. *For every $N \in \mathbb{N}$, provided that $\rho_\nu(0) > 0$, the following recurrence relation holds:*

$$|\eta_N^\nu| \le \frac{1}{\rho_+^{\nu,N-1}} \sum_{k=1}^{N-1} |\Delta\rho_k^\nu(0)\xi_k^\nu(0)|. \tag{4.14}$$

Proof. By Lemmas 3.1 and 4.2 we can assume that x_ν interacts with the waves of $\rho_\nu(0)$ in increasing order before wave interactions occur. In fact, this represents the worst case for the car shift increase.

We proceed by induction. Recall that $\eta_0^\nu = \eta_\nu(0) = 0$. Supposing that (4.14) is true for N, we prove the relation for $N+1$ using (4.13):

$$\begin{aligned}
|\eta_{N+1}^\nu| &\le \frac{\rho_-^{\nu,N}}{\rho_+^{\nu,N}}|\eta_N| \;+\; \frac{|\Delta\rho_N^\nu \xi_N^\nu|}{\rho_+^{\nu,N}} \\
&\le \frac{\rho_-^{\nu,N}}{\rho_+^{\nu,N}} \frac{1}{\rho_+^{\nu,N-1}} \sum_{k=1}^{N-1} |\Delta\rho_k^\nu \xi_k^\nu| \;+\; \frac{|\Delta\rho_N^\nu \xi_N^\nu|}{\rho_+^{\nu,N}} \\
&= \frac{1}{\rho_+^{\nu,N}} \sum_{k=1}^{N} |\Delta\rho_k^\nu \xi_k^\nu| \le \frac{1}{\rho_+^{\nu,N}} \sum_{k=1}^{N} |\Delta\rho_k^\nu(0) \xi_k^\nu(0)|,
\end{aligned}$$

where the latter inequality is obtained by Lemma 4.1. ∎

We can finally state our main result.

Theorem 4.4. *Let $\bar\rho \in BV$ and assume that WFT approximate solutions are constructed taking the initial datum $\bar\rho_\nu$ as in (4.1). Assume that $\bar\rho \ge \tilde\rho > 0$; then*

$$|x_{\nu+1}(t) - x_\nu(t)| \le \frac{2^{-(\nu+1)}}{\tilde\rho} TV(\bar\rho). \tag{4.15}$$

In particular, $x_\nu(t)$ converges uniformly to some $x(t)$ solution of (1.2) when $\nu \to +\infty$. Since the grid mesh parameter is $\Delta x = 2^{-\nu}$ as shown by (4.1), the convergence speed estimate is linear in Δx.

Proof. Recall that $\eta_\nu(t) = x_{\nu+1}(t) - x_\nu(t)$. By Lemma 4.3, for every t it holds that

$$|\eta_\nu(t)| \le \frac{1}{\tilde\rho} \sum |\Delta\rho_k^\nu(0) \xi_k^\nu(0)|. \tag{4.16}$$

As noted above, the shifts at time 0 between ρ_ν and $\rho_{\nu+1}$ are bounded by $2^{-(\nu+1)}$; see Figure 3. Then, we get

$$|\eta_\nu(t)| \le \frac{2^{-(\nu+1)}}{\tilde\rho} \sum |\Delta\rho_k^\nu(0)| = \frac{2^{-(\nu+1)}}{\tilde\rho} TV(\bar\rho).$$

Thus $x_\nu(t)$ converges uniformly exponentially to some function $x(t)$. By the results of Colombo and Marson [6], x is a solution of (1.2). ∎

A possible extension of Theorem 4.4 if initial data vanish is given below.

Theorem 4.5. *Consider a single road $[a,b]$. Then, $\forall \alpha \in (0,1)$ there exist $\rho_\nu \to \rho$ and $x_{\nu+1} \to x$ such that*

$$|\rho - \rho_\nu| < 2^{-\nu\alpha}(b-a), \tag{4.17}$$

$$|x_{\nu+1} - x_\nu| \le 2^{-\nu(1-\alpha)} TV(\bar\rho). \tag{4.18}$$

Proof. It is well known that in the scalar case the following holds:

$$|\rho(t) - \rho_\nu(t)|_{L^1} \le |\rho(0) - \rho_\nu(0)|_{L^1}.$$

Let us take $\rho_\nu(0) \to \bar\rho$ such that $\rho_\nu(0) \ge 2^{-\nu\alpha}$. Then, applying Theorem 4.4, we get (4.17). ∎

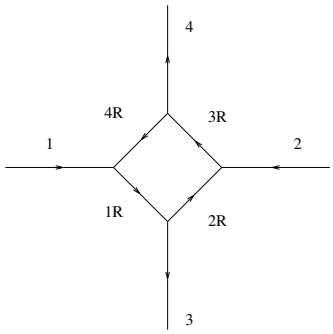

Figure 5. *Traffic circle.*

5. Numerical tests. Simulation results and animations for numerical tests presented in this section are available on the web page [2].

Here we present a study of the trajectory of a car moving into a traffic circle: the evolution of densities was already discussed in [3]. More precisely, by reproducing the evolution in time of traffic, we compute the time needed by a car for covering a fixed path within a traffic circle composed by 8 roads and 4 junctions, as depicted in Figure 5. There are two junctions with one incoming and two outgoing roads, precisely the junction $(1R, 2R, 3)$ and the junction $(3R, 4R, 4)$. Thus we need to assign the corresponding distribution coefficients, namely, $(\alpha_{1R,3}, \alpha_{1R,2R})$ and $(\alpha_{3R,4}, \alpha_{3R,4R})$. We assume all of them to be equal to $\alpha = 0.5$. For junctions with one outgoing road, namely, $(1, 4R, 1R)$ and $(2R, 2, 3R)$, we need to fix a right of way parameter between the two incoming roads in order to describe the priority to pass through the junction, as prescribed by rule (C) in section 2.

We consider the following three cases for the priorities of the roads 1 and 2 bringing traffic to the circle:

(1) $q_1 = q_1(1, 4R, 1R) = q_2 = q_2(2, 2R, 3R) = 0.25$;
(2) $q_1 = q_1(1, 4R, 1R) = q_2 = q_2(2, 2R, 3R) = 0.5$;
(3) $q_1 = q_1(1, 4R, 1R) = q_2 = q_2(2, 2R, 3R) = 0.75$.

Setting parameters as in (1), $4R$ is the through street with respect to road 1 and road $2R$ is the through street with respect to 2. This means that the traffic inside the circle has the priority with respect to the entering traffic. However, if we fix priorities as in (3), the situation is exactly opposite. Case (2), instead, represents the case of the same priority for the traffic inside the circle and that incoming.

As in [3], we consider the initial data

$$\begin{aligned} &\rho_1(0,x) = 0.25,\ \rho_2(0,x) = 0.4,\ \rho_3(0,x) = 0.5,\ \rho_4(0,x) = 0.5, \\ &\rho_{1R}(0,x) = 0.5,\ \rho_{2R}(0,x) = 0.5,\ \rho_{3R}(0,x) = 0.5,\ \rho_{4R}(0,x) = 0.5, \end{aligned} \tag{5.1}$$

and, for roads entering the circle, we impose the following boundary conditions:

$$\rho_{1,b}(t) = 0.25, \quad \rho_{2,b}(t) = 0.4. \tag{5.2}$$

Starting from the configuration given by initial data (5.1), but setting alternatively the right of way parameters according to the three mentioned cases, the behavior of traffic is different.

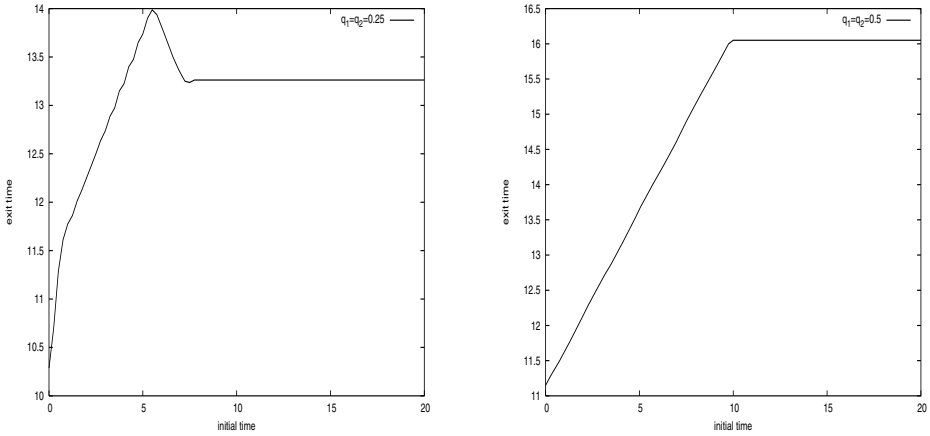

Figure 6. *On the left, exit time for $q_1 = q_2 = 0.25$; on the right, exit time for $q_1 = q_2 = 0.5$ for boundary data* (5.2).

In particular, with priorities set as in (1), shock waves causing an increase in the value of density on incoming roads 1 and 2 are rapidly produced. On the other hand, the density on roads within the circle is kept at a low level.

In case (2), the evolution of the density is similar to the previous case, except for the situation on roads $2R$ and $4R$, where a shock with zero speed is produced.

In case (3) after a short period of time, shocks propagating backward along roads $2R$ and $4R$ provoke an increase in the density inside the circle until traffic becomes completely blocked.

From the analysis of the three considered cases, we want to see how the behavior of a driver moving into the traffic circle can be influenced by the regulation of priority parameters.

Assume that the driver follows the route $(1, 1R, 2R, 3R, 4)$. This means that the car enters the circle from road 1, turns around for 3/4 of the circle, and finally exits to road 4. In the next figures we show that right of way parameters affect the time for covering the path. In particular, in Figure 6 the curve of the exit time as a function of the initial time t_0 varying in $[0, 20]$ is depicted for $q_1 = q_2 = 0.25$ and $q_1 = q_2 = 0.5$. The graph on the left underlines that, after a certain value of the initial time ($t_0 \sim 9$), the exit time becomes stable and corresponds to $T = 13.3$. Similarly, the graph on the right shows that for $t_0 \geq 12$ exit time takes asymptotically the value $T = 16.1$.

On the other hand, setting $q_1 = q_2 = 0.75$, independently by the initial time t_0, the car cannot exit the circle, since traffic within the circle is blocked.

The graph on the left side of Figure 7 represents a comparison between the cases (1) and (2) as regards the space covered by the car when starting time is $t_0 = 8$. As we can observe, taking priority parameters $q_1 = q_2 = 0.25$, the time to exit the circle is lower, even if the first part of the trip is faster for the choice (2). Starting again at time $t_0 = 8$ and setting right of way parameters according to (3), the car cannot exit by the second road of the path, namely, road $1R$, and, consequently, it stops; see the graph in Figure 7 on the right.

Then, keeping the initial data (5.1) as before, we impose at the left endpoint of roads 1

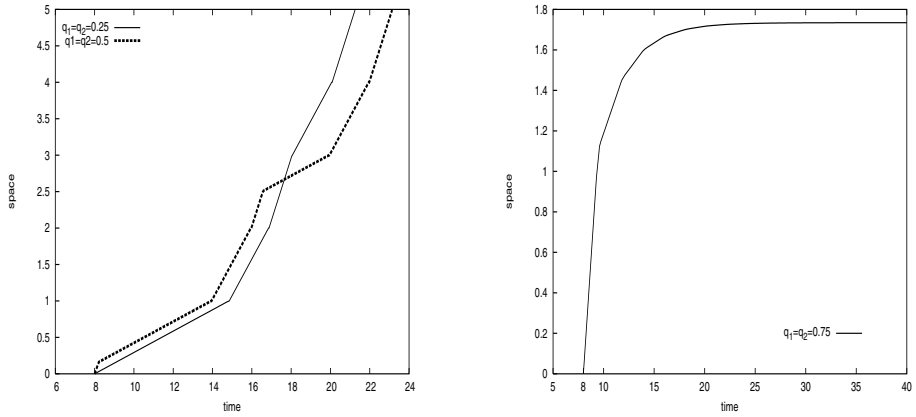

Figure 7. *Time-space diagram of the car trajectory for $t_0 = 8$. On the left, comparison between the cases* (1) *and* (2)*; on the right, priorities set as in* (3).

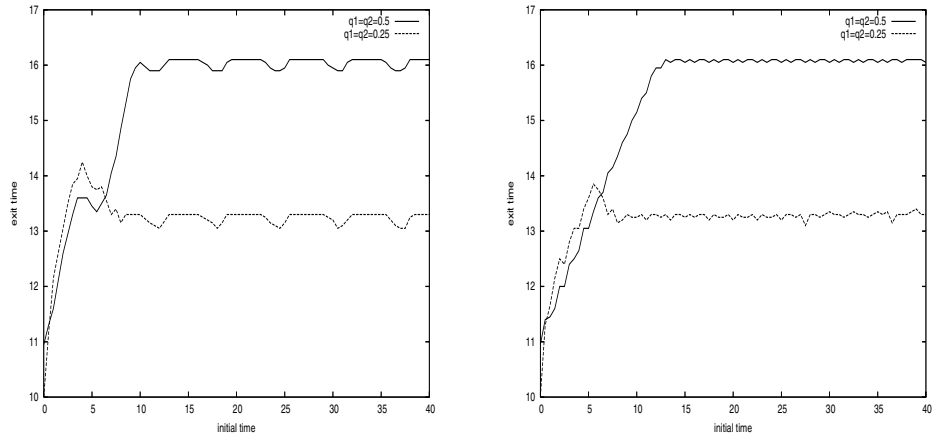

Figure 8. *Exit time for $q_1 = q_2 = 0.25$ (-) and $q_1 = q_2 = 0.5$ $(\cdots)$ when t_0 varies, with $A = 1$ (on the left) and $A = 5$ (on the right) for periodic boundary data* (5.3).

and 2 a periodic data bounded in $[0.1, 0.4]$, namely,

$$\rho_{1,b}(t) = \rho_{2,b}(t) = \frac{1}{4} + \frac{3}{20}\sin(At), \quad t \geq 0, \tag{5.3}$$

where $A > 0$. In Figure 8 the graphs of the time for covering the path for $A = 1$ (on the left) and $A = 5$ (on the right) are depicted, with the initial time t_0 varying in $[0, 40]$.

Observing Figure 8, obtained for $q_1 = q_2 = 0.25$, we can see that after a certain value of the initial time ($t_0 \sim 9$), the exit time becomes more stable, until it reaches the value $T = 13.3$, around which oscillations occur. Similarly, setting $q_1 = q_2 = 0.5$ for $t_0 \geq 12$, the time for covering the path shows oscillations around $T = 16.1$.

This last simulation shows how choice (1) is preferable with respect to choice (2) to reduce the travel time of drivers. Moreover, such convenience is stable with respect to time-varying

Table 1
CPU time and computation of $A_{\Delta x}$ at $T = 8$ for varying Δx.

$T = 8$		
Δx	CPU time	$A_{\Delta x}$
0.1	0.51 s	0.005423
0.05	1.23 s	0.002119
0.025	2.61 s	0.001588
0.0125	5.18 s	0.000635
0.00625	10.13 s	0.000319

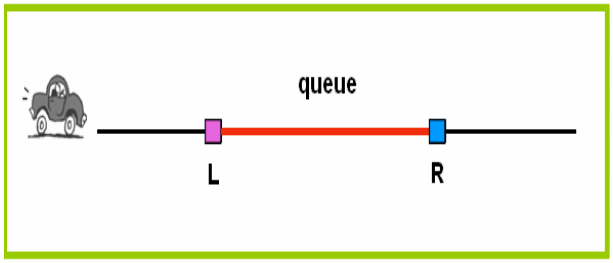

Figure 9. *Car moving on a highway segment where a car accident occurred.*

incoming traffic. In fact, even introducing oscillations with different widths, the two cases of priority parameters still produce quite different travel times.

5.0.1. Test of efficiency and of convergence of the algorithm based on the Godunov scheme. Let us consider a car traveling on a single road parametrized by the interval $[0, 2]$, where the initial and boundary data are, respectively, given by

$$\rho(0,x) = \begin{cases} 0.3 & \text{if } 0 \le x \le 0.2, \\ 0.1 & \text{if } 0.2 < x \le 0.5, \\ 0.8 & \text{if } 0.5 < x \le 2, \end{cases} \qquad \rho(t,0) = 0.3. \tag{5.4}$$

If the car starts traveling at time $t = 0$ with initial position $x^0 = 0$ the time needed to exit the road is $T = 8$. In Table 1 we present the results obtained by applying the simulation algorithm with the Godunov scheme to the proposed example. On one hand we are interested in evaluating the CPU time occupied by the algorithm and on the other hand we estimate the difference between the two positions at final time T, namely, $A_{\Delta x} = |x_{\Delta x}(T) - x_{\frac{\Delta x}{2}}(T)| = |x_\nu(T) - x_{\nu+1}(T)|$, computed numerically when the space mesh parameter $\Delta x = 2^{-\nu}$ decreases. The results in Table 1 represent numerical evidence of the convergence (with a linear rate) of the algorithm, where the evolution in time of the density is computed by the Godunov scheme, which ensures stability of solutions and thus represents a good compromise between numerical accuracy and occupation of CPU time.

All the simulations have been performed by a personal computer, processor AMD Athlon XP 2400 Mhz, RAM 512 Mb.

5.1. Application of the tracking algorithm to highway accidents. We consider the problem of exactly determining the traveling time of a car in case of an accident on a highway.

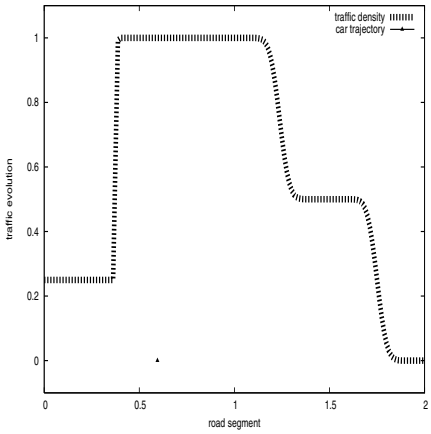

Figure 10. *Evolution of traffic density (line) and car position (point).*

More precisely, we consider a bounded highway segment and a car entering it at time $t = 0$. On the same segment an accident is present at position R and a consequent queue extending backward up to position L; see Figure 9, where (left and right) endpoints of the queue are depicted. We assume to know the inflow of the highway segment and the time t_r at which cars involved in the accident will be removed, thus permitting a free flow of traffic. The question we want to answer is: How much time is needed by the car to cross the congested road?

Using our algorithm we can compute such traveling time. The presence of the accident is simulated as a red light at point R up to time t_r, when the light turns green. If t_r is big enough, the car will reach the back of the queue at L and stop there. After time t_r, the flow will start again at R and the corresponding rarefaction wave (accelerating cars) will eventually reach L, letting the car move.

In Figure 10 a time shot of the evolution of the traffic density on the highway and of the car trajectory is given. Related animations can be found on the web page [2].

6. Conclusions. A new approximation algorithm for tracking the position of a car traveling on a road network is here developed. First the density on the network is simulated using a Godunov or a Wave Front Tracking (WFT) scheme. Then the position of the car is reconstructed determining the effects of interactions with density waves.

The theoretical framework of problem (1.2) was set up in [6].

The algorithm is tested on a portion of an urban network, i.e., a traffic circle. In particular, the time for covering the path of a single driver is measured, showing the convenience of setting the right of way parameters so as to give priority to traffic inside the circle with respect to the entering traffic. Furthermore, a possible application of the algorithm is presented.

As a theoretical result of the present work, the exponential uniform convergence of car trajectories is proved using the WFT algorithm and assuming BV initial data.

Acknowledgment. The authors would like to thank the anonymous referees for many helpful suggestions which improved the paper.

Macroscopic Dynamics of Complex Metastable Systems: Theory, Algorithms, and Application to B-DNA*

Illia Horenko†, Evelyn Dittmer†, Filip Lankas‡, John Maddocks‡, Philipp Metzner†, and Christof Schütte†

Abstract. This article is a survey of the present state of the transfer operator approach to the effective dynamics of metastable complex systems, and the variety of algorithms associated with it. We introduce new methods, and we emphasize both the conceptional foundations and the concrete application to the conformation dynamics of a biomolecular system. The algorithmic aspects are illustrated by means of several examples of various degrees of complexity, culminating in their application to a full-scale molecular dynamics simulation of a B-DNA oligomer.

Key words. metastable states, biomolecular conformations, hidden Markov model, maximum likelihood principle, free energy, stochastic differential equations, molecular dynamics, B-DNA, inter base pair parameters

1. Introduction.

With the increasing availability of ever more powerful computational resources, there is current interest in performing long numerical simulations of large nonlinear dynamical systems, for example, biomolecules, and in examining rather detailed properties of the results. For example, there is a current effort to understand the sequence-dependent physical properties of B-form DNA via the construction and analysis of a self-consistent data base of 39 compatible simulations, each of a 15 base pair fragment or oligomer, with the oligomers constructed in such a way that each of the 136 possible independent tetramer sequences is present at least twice [5]. The time series generated in this particular project comprise more than half a terabyte of data. It is accordingly evident that there is an ever increasing need to analyze such time series efficiently, with mathematical algorithms that are practical for data sets of this order of magnitude. In particular, many nonlinear dynamical systems, including biomolecules and specifically DNA, exhibit the phenomenon of *metastability*; i.e., the trajectory is localized in one subregion of phase space for comparatively long time scales, before undergoing a rapid and rare transition to another region, where it then stays for a comparatively long residency time before eventually undergoing another rapid transition, and so on. Figure 10 illustrates this phenomenon via a plot of a single, scalar-dependent variable, in this

case a certain torsional angle in one of the DNA backbones between two particular base pairs in a simulation of a poly(AT) oligomer, where A and T denote the base pair of adenine (A) and thymine (T). The time series is of length 10^5, being a sampling of a 100 nanosecond simulation at every picosecond. The time series is evidently multiwell and exhibits metastability with essentially instantaneous sharp transitions between wells that are separated by 180° or so, with rapid oscillations within each well during the long residency times.

The purpose of this article is to survey existing, and introduce new, methods for the identification of the metastable substates that are exhibited in a particular time series, and to estimate the transition probabilities between these sets. The primary messages of the article are the following. First, the notion of the number of metastable states is a hierarchical concept—the appropriate number of metastable sets to be identified in a given time series depends upon the phenomena to be modeled. Second, and nevertheless, the numbers of metastable states are not arbitrary; rather, appropriate choices of the numbers of metastable sets can be identified via various clustering techniques. For example, if the dimension of the time series is not too large, a certain transfer operator can be explicitly computed and the appropriate possible numbers of metastable states can be associated with gaps in the spectrum of the operator via a Perron cluster analysis, while the metastable sets themselves can be identified from the associated eigenfunctions. Third, the usual methods for the computation of the transfer operator suffer from the *curse of dimensionality*, which means that the methods are not practicable for large systems. However, when the dimensionality of the time series is too high, one may be able to use hidden Markov models (HMMs) or the new method of HMM stochastic differential equations (HMMSDEs) to identify metastable substates and to make good estimates of the associated transition probabilities.

The theory developed in the article is illustrated with two examples. First, there is an entirely tutorial and two-dimensional (2D) example involving the high friction or overdamped Brownian dynamics of a particle in a multiwell potential, in which all the conclusions are entirely explicit. Second, the theory is applied to the DNA simulation already mentioned above. That series is of length 10^5 and is of high dimension (for details see section 2). In this context the metastability analysis plays an important role in identifying basins within which the base pair level, structural shape, and stiffness parameters of DNA can be approximated. The DNA example lies within the class of problems that are too large for an explicit computation of the transfer operator for the full system. However, we demonstrate that the metastable sets can be captured via an HMMSDE analysis. We apply the HMMSDE analysis to a description of the system in which the coordinates are backbone angles. In these coordinates the transitions are very rapid, and the states can also be identified via a more standard, but appropriately aggregated, HMM model. However, the HMMSDE analysis additionally yields insight about nanomechanical properties of the molecule within each metastable well, e.g., local stiffness matrices that may allow us to study the changes in elastic properties between conformations.

2. Metastability.

The evolution of a single microscopic system is assumed to be given by a *homogeneous Markov process* $X_t = \{X_t\}_{t\in\mathbf{T}}$ in either continuous or discrete time with state space $\mathbf{X}$. We write $X_0 \sim \mu$ if the Markov process X_t is initially distributed according to the probability measure μ. The motion of X_t is given in terms of the *stochastic transition function*

$$p(t, x, A) \;=\; \mathbf{P}[X_{t+s} \in A \;|X_s = x] \tag{1}$$

for every $t, s \in \mathbf{T}$, $x \in \mathbf{X}$, and $A \subset \mathbf{X}$ that satisfies the well-known Chapman–Kolmogoroff equation $p(t+s, x, A) = \int_{\mathbf{X}} p(t, x, \mathrm{d}z)\, p(s, z, A)$ [15].

We say that the Markov process X_t admits an *invariant probability measure* μ, or that μ is invariant w.r.t. X_t if $\int_{\mathbf{X}} p(t, x, A)\mu(\mathrm{d}x) = \mu(A)$. In the following we always assume that the invariant measure of the process under investigation exists and is unique. A Markov process is called *reversible* w.r.t. an invariant probability measure μ if $\int_A p(t, x, B)\mu(\mathrm{d}x) = \int_B p(t, x, A)\mu(\mathrm{d}x)$ for every $t \in \mathbf{T}$ and $A, B \subset \mathbf{X}$.

2.1. Transition probabilities and transfer operators. Metastability of some subset of the state space is characterized by the property that the dynamical system is likely to remain within the subset for a long period of time, until it exits and a transition to some other region of the state space occurs. There are, in fact, several related but different definitions of metastability in literature (see, e.g., [8, 11, 41, 42]); we will focus on the so-called ensemble concept introduced in (2); for a comparison with, e.g., the exit time concept, see [40].

The objective is an identification of a *decomposition of the state space into metastable subsets* and the corresponding "flipping dynamics" between these substates. In general, a *decomposition* $\mathbf{D} = \{D_1, \ldots, D_m\}$ of the state space $\mathbf{X}$ is a collection of subsets $D_k \subset \mathbf{X}$ with the following properties: (1) positivity $\mu(D_k) > 0$ for every k, (2) disjointness up to null sets, and (3) the covering property $\cup_{k=1}^{m} \overline{D_k} = \mathbf{X}$. In particular, the appropriate number m of metastable subsets must be identified. Within a transfer operator approach this can be achieved via spectral analysis (see *key idea* below).

We define the *transition probability* $p(t, B, C)$ from $B \subset \mathbf{X}$ to $C \subset \mathbf{X}$ within the time span t as the conditional probability

$$p(t, B, C) \;=\; \mathbf{P}_\mu[X_t \in C \;|X_0 \in B] \;=\; \frac{\mathbf{P}_\mu[X_t \in C \text{ and } X_0 \in B]}{\mathbf{P}_\mu[X_0 \in B]}, \tag{2}$$

where $\mathbf{P}_\mu$ indicates that initially $X_0 \sim \mu$. Then (2) may be rewritten as

$$p(t, B, C) \;=\; \frac{1}{\mu(B)} \int_B p(t, x, C)\, \mu(\mathrm{d}x). \tag{3}$$

In other words, the transition probability quantifies the dynamical fluctuations within the stationary ensemble μ. Concomitant with our ensemble dynamics approach to metastability, we call a subset $B \subset \mathbf{X}$ *metastable* on the time scale $\tau > 0$ if

$$p(\tau, B, B^c) \approx 0 \;\text{ or, equivalently, }\; p(\tau, B, B) \;\approx\; 1,$$

where $B^c = \mathbf{X} \setminus B$ denotes the complement of B.

Transfer operator. We define the *semigroup of propagators* or forward transfer operators $P^t : L^r(\mu) \to L^r(\mu)$ with $t \in \mathbf{T}$ and $1 \le r < \infty$ as follows:

$$\int_A P^t v(y)\; \mu(\mathrm{d}y) \;=\; \int_{\mathbf{X}} v(x) p(t, x, A) \mu(\mathrm{d}x) \tag{4}$$

for $A \subset \mathbf{X}$. As a consequence of the invariance of μ, the characteristic function $\mathbf{1}_{\mathbf{X}}$ of the entire state space is an invariant density of P^t; i.e., $P^t \mathbf{1}_{\mathbf{X}} = \mathbf{1}_{\mathbf{X}}$. Furthermore, P^t is a Markov

operator; i.e., P^t conserves both norm $\|P^t v\|_1 = \|v\|_1$ and positivity $P^t v \geq 0$ if $v \geq 0$, which is a simple consequence of the definition. Due to (4), the semigroup of propagators mathematically models the evolution of subensembles in time.

The *key idea of the transfer operator approach* w.r.t. the identification of metastable decompositions can be described as follows:

> Metastable subsets can be detected via eigenvalues of the propagator P close to its maximal eigenvalue $\lambda = 1$; moreover, they can be identified by exploiting the corresponding eigenfunctions. In doing so, the number of metastable subsets is equal to the number of eigenvalues close to 1, including $\lambda = 1$ and counting multiplicity.

This strategy was first proposed by Dellnitz and Junge [12] for discrete dynamical systems with weak random perturbations and has been successfully applied to molecular dynamics in different contexts [38, 39, 40]. Its justification is given below. The key idea requires the following two *conditions on the propagator* P:

- (C1) The essential spectral radius of P is less than 1; i.e., $r_{\text{ess}}(P) < 1$.
- (C2) The eigenvalue $\lambda = 1$ of P is simple and dominant; i.e., $\eta \in \sigma(P)$ with $|\eta| = 1$ implies $\eta = 1$.

In this article, two types of Markov processes will be considered: (1) high-friction Langevin processes and (2) (Nosé–Hoover) constant temperature molecular dynamics. For both cases the dynamics is reversible, and the transfer operator is self-adjoint. For type (1) examples, conditions (C1) and (C2) are known to be satisfied under rather weak conditions on the potential [40]. For type (2) examples, it is unknown whether or not the conditions are satisfied; however, it is normally assumed in molecular dynamics that they are valid for realistically complex systems in solution.

We define the *metastability of a decomposition* $\mathbf{D}$ as the sum of the metastabilities of its subsets. That is, suppose that the time scale τ of interest is fixed. Then, for each arbitrary decomposition $\mathcal{D}_m = \{A_1, \ldots, A_m\}$ of the state space $\mathbf{X}$ into m sets, we define its metastability measure by

$$\text{meta}(\mathbf{D}_m) = \sum_{j=1}^{m} p(\tau, A_j, A_j)/m.$$

For given m the optimal metastable decomposition into m sets can then be defined as that decomposition into m sets which maximizes the functional meta.

The next result [29] justifies the above key idea.

Theorem 2.1. *Let $P^\tau : L^2(\mu) \to L^2(\mu)$ denote a reversible propagator satisfying* (C1) *and* (C2). *Then P^τ is self-adjoint with spectrum of the form*

$$\sigma(P^\tau) \subset [a, b] \cup \{\lambda_m\} \cup \cdots \cup \{\lambda_2\} \cup \{1\}$$

with $-1 < a \leq b < \lambda_m \leq \cdots \leq \lambda_1 = 1$ and λ_i isolated eigenvalues that are counted according to their finite multiplicities. Denote by $v_m, \ldots, v_1$ the corresponding eigenfunctions, normalized to $\|v_k\|_2 = 1$. Let Q be the orthogonal projection of $L^2(\mu)$ onto $\text{span}\{\mathbf{1}_{A_1}, \ldots, \mathbf{1}_{A_m}\}$. *Then the metastability of an arbitrary decomposition $\mathbf{D}_m = \{A_1, \ldots, A_m\}$ of the state space $\mathbf{X}$ can be bounded from above by*

$$p(\tau, A_1, A_1) + \cdots + p(\tau, A_m, A_m) \leq 1 + \lambda_2 + \cdots + \lambda_m,$$

while it is bounded from below according to

$$1 + \kappa_2\lambda_2 + \cdots + \kappa_m\lambda_m + c \leq p(\tau, A_1, A_1) + \cdots + p(\tau, A_m, A_m),$$

where $\kappa_j = \|Qv_j\|^2_{L^2(\mu)}$ *and* $c = a\,((1-\kappa_2) + \cdots + (1-\kappa_n))$.

Theorem 2.1 highlights the strong relation between a decomposition of the state space into metastable subsets and a *Perron cluster* of dominant eigenvalues close to 1. It states that the metastability of an arbitrary decomposition $\mathbf{D}_m$ cannot be larger than $1 + \lambda_2 + \cdots + \lambda_m$, while it is at least $1 + \kappa_2\lambda_2 + \cdots + \kappa_m\lambda_m + c$, which is close to the upper bound whenever the dominant eigenfunctions $v_2, \ldots, v_m$ are almost constant on the metastable subsets $A_1, \ldots, A_m$ implying $\kappa_j \approx 1$ and $c \approx 0$. The term c can be interpreted as a correction that is small whenever $a \approx 0$ or $\kappa_j \approx 1$. It is demonstrated in [29] that the lower and upper bounds are sharp and asymptotically exact.

2.2. Metastability analysis is hierarchical. The last theorem and the illustrations and examples below contain one main message about metastability analysis: *it has to be hierarchical*. Whenever we approximate the optimal metastable decomposition $\mathbf{D}_2$ of state space into, say, two sets, we should always be aware that there could be a decomposition $\mathbf{D}_3$ into three sets for which meta($\mathbf{D}_3$) is almost as large as meta($\mathbf{D}_2$). For example, one or both of the two subsets in $\mathbf{D}_2$ could decompose into two or several metastable subsets from which exit is comparably difficult for the system under investigation.

However, whenever there is a gap in the spectrum of the transfer operator after m dominant eigenvalues, then the results of, e.g., [28, 8], tell us that any decomposition into more than m sets will be associated with a significantly larger drop in metastability as measured by the function meta. In the context of applications to molecular dynamics, however, one should always be aware that particular aspects of interest may make it desirable to explore the hierarchy of metastable decompositions up to a certain depth that is not necessarily selected only on the values of the functional meta.

2.3. Discretization and PCCA. Let $\chi = \{\chi_1, \ldots, \chi_n\} \subset L^2(\mu)$ denote a set of *nonnegative* functions that are a partition of unity, i.e., $\sum_{k=1}^n \chi_k = \mathbf{1}_\mathbf{X}$. The *Galerkin projection* $\Pi_n : L^2(\mu) \to \mathcal{S}_n$ onto the associated finite-dimensional ansatz space $\mathcal{S}_n = \text{span}\{\chi_1, \ldots, \chi_n\}$ is defined by

$$\Pi_n v \;=\; \sum_{k=1}^{n} \frac{\langle v, \chi_k\rangle_\mu}{\langle \chi_k, \chi_k\rangle_\mu}\, \chi_k.$$

Application of the Galerkin projection to $P^\tau v = \lambda v$ yields an eigenvalue problem for the discretized propagator $\Pi_n P^\tau \Pi_n$ acting on the finite-dimensional space $\mathcal{S}_n$. The matrix representation of this finite-dimensional operator is given by the $n \times n$ *transition matrix* $\top = (\top_{kl})$, whose entries are given by

$$\top_{kl} \;=\; \frac{\langle P^\tau \chi_k, \chi_l\rangle_\mu}{\langle \chi_k, \chi_k\rangle_\mu}. \tag{5}$$

The transition matrix inherits the main properties of the transfer operator: it is a stochastic matrix with invariant measure given by the invariant measure μ of P^τ, it is reversible if P^τ

is self-adjoint, and (if the discretization is fine enough) it also exhibits a Perron cluster of eigenvalues that approximates the corresponding Perron cluster of P^τ, and with eigenvectors that approximate the dominant eigenvectors of P^τ [40]. It thus allows us to compute the metastable sets of interest by computation of the dominant eigenvectors of $\top$ and by realization of the identification strategy described in section 2.1 based on these (discrete) eigenvectors. This has led to the construction of an aggregation technique called "Perron cluster cluster analysis" (PCCA) [13, 14].

The entries of $\top$ can be computed from realizations of the underlying Markov process X_t. We have

$$\top_{kl} \;=\; \frac{1}{\langle \chi_k, \chi_k \rangle_\mu} \int_{\mathbf{X}} \chi_k(x) \mathbf{E}_x[\chi_l(X_\tau)]\, \mu(\mathrm{d}x).$$

If $x_0, \ldots, x_N$ denote a time series obtained from a realization of the Markov process with time stepping τ, then the entries of $\top$ can be approximated from the relative transition rates computed by means of this time series:

$$\top_{kl} \;\approx\; \top_{kl}^{(N)} \;=\; \frac{\sum_{j=1}^{N} \chi_k(x_j) \cdot \chi_l(x_{j+1})}{\sum_{j=1}^{N} \chi_k(x_j)^2}. \tag{6}$$

For a time series of whatever length, but with a high-dimensional configuration variable, practical evaluation of the formula (6) may become problematic. There are two main reasons for potential difficulties.

Trapping problem. The *rate of convergence* of $\top_{kl}^{(N)} \to \top_{kl}$ depends on the smoothness of the partition functions χ_k as well as on the mixing properties of the Markov process [31]. The latter property is crucial here: the convergence is geometric with a rate constant $\lambda_1 - \lambda_2 = 1 - \lambda_2$, where λ_2 denotes the second largest eigenvalue (in modulus). In the case of metastability with λ_2 being very close to $\lambda_1 = 1$, we will have dramatically slow convergence. This is of no surprise because closeness of dominant eigenvalues is typically the main difficulty in all approaches to biomolecular dynamics and statistics, and it is also a bottleneck of the transfer operator approach. Much of the literature aims to tackle this *trapping problem* [4, 17]. In our largest examples, evaluation of (6) is not practical. However, we will *not* go into the depth of the discussion on overcoming the trapping problem, because we propose alternative approaches. We will simply assume in all of the following that we have already generated or can directly generate a time series that is "long enough" in the sense that it contains statistically significant information about more than one—if not all—interesting metastable states of the system under consideration. We will discuss later whether this is the case for our poly(AT) DNA time series.

Curse of dimension. Any discretization of the transfer operator will suffer from the curse of dimension whenever it is based on a uniform partition of all of the hundreds or thousands of degrees of freedom in a typical biomolecular system. Fortunately, chemical observations reveal that—even for larger biomolecules—the curse of dimensionality can be circumvented by exploiting the hierarchical structure of the dynamical and statistical properties of biomolecular systems: only relatively few *essential degrees of freedom* are needed to describe the conformational transitions (see next section); furthermore, the canonical density has a rich spatial multiscale structure induced by the rich structure of the potential energy landscape. This

structure induces a hierarchical cluster structure of the sampling data that can be identified and used to define a multilevel discretization adapted to the structures of the statistical data (see [40] or subsequent examples).

2.4. Illustrative example. For simplicity we consider the Markov process given by the so-called high-friction Langevin equation which is the limit of high friction of the famous Langevin equation; see [36, 39]. The high-friction Langevin equation is stated in the position space only and is given by the equation

$$\dot{x} = -\nabla_x V(x) + \sigma \dot{W}_t, \tag{7}$$

with $x(t) \in \mathbf{R}^d$ being the position vector of the system, W_t denoting d-dimensional standard Brownian motion, and σ denoting the noise intensity parameter. The SDE (7) defines a continuous time Markov process X_t with invariant probability measure $\mu(\mathrm{d}x) \propto \exp(-\beta V(x))\mathrm{d}x$ with $\beta = 2/\sigma^2$ [36]. There is a long history of using it as a simple toolkit for investigation of dynamical behavior in complicated energy landscapes [10]. It is known that under weak conditions on the potential function V the Markov process is reversible [26].

The associated semigroup (P^t) of propagators admits a strong generator $\mathcal{A}$ such that the semigroup can be written as $P^t = \exp(t\mathcal{A})$. For twice continuously differentiable $u \in L^2(\mu)$ we have the identity

$$\mathcal{A}\,u \;=\; \left(\frac{\sigma^2}{2}\Delta_x - \nabla_x V(x)\cdot\nabla_x\right) u.$$

For details on $\mathcal{A}$ see the theory of Fokker–Planck equations and Kolmogoroff forward and backward equations [36, 41]. Under appropriate conditions (the Perron cluster is a discrete part of the spectrum) we can compute the dominant eigenvectors of P^t via those of $\mathcal{A}$.

For illustrative means we use the potential V illustrated in Figure 1 (thus setting $d = 2$). Figure 2 shows typical realizations of the high-friction Langevin Markov process associated with this potential (setting $\sigma = 0.131$). We observe that the vicinity of the wells in the potential energy landscape can be approximately identified with the metastable sets of the process; it is well known from large deviation theory that, in fact, for small enough noise intensity, the vicinity of the wells of the potential energy landscape are the metastable sets of high-friction Langevin processes (at least such wells that are separated from each other by significant energy barriers) [28].

Next, we discretized the transfer operator of the process (fine grid with 100×100 discretization boxes in discretization domain $[-3, 3] \times [-3, 3]$) for different values of τ, which results in the dominant eigenvalues listed in Table 1.

While the eigenvector of the largest eigenvalue is constant, the corresponding second and third eigenvectors of P^τ in $L^2(\mu)$ are shown in Figure 3 (they are identical for all values of τ because of the semigroup property).

Having computed the dominant eigenvectors, we can determine the optimal metastable decomposition by means of PCCA as introduced above. The results on the spectrum (see $\tau = 0.1$, for example) exhibit a hierarchy of metastability that is in perfect agreement with the general insight on metastability of high friction Langevin motion: we can apply PCCA to the first *two* eigenvectors of the transfer operator; this results in the metastable decomposition

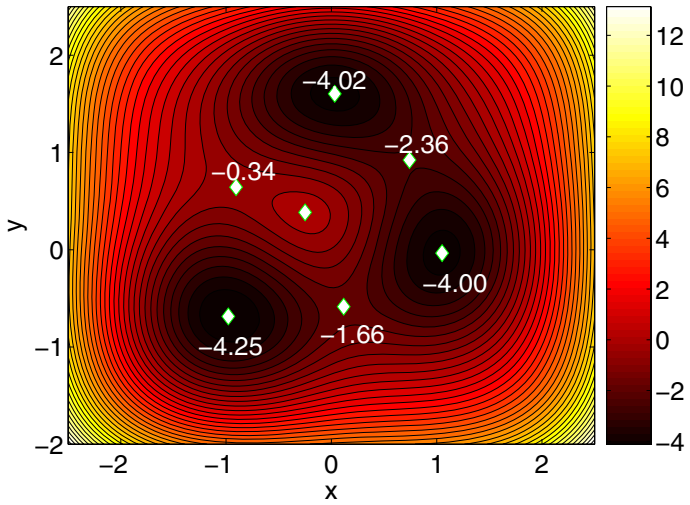

Figure 1. *Potential V used for illustrative example. We observe three wells in the potential landscape (see colorbar). The tags indicate the minima and saddle points of the potential; the numbers give the value of the potential at these points. We observe that the leftmost minimum is the deepest well separated by the most pronounced energy barrier from the other two.*

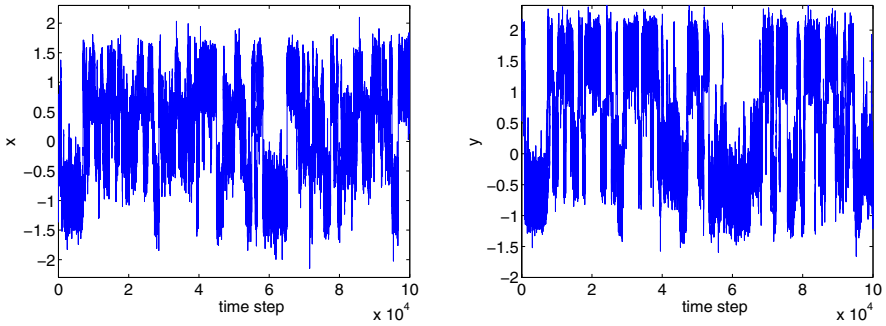

Figure 2. *Typical realization of the high-friction Langevin dynamics (both components (left/right) of the state versus time) in the potential energy landscape V shown in Figure 1 for $\sigma = 0.131$.*

Table 1

Leading four eigenvalues of transfer operator P^τ for different values of τ for high-friction Langevin motion with potential and parameters as described in the text.

$\sigma(P^\tau)$	λ_1	λ_2	λ_3	λ_4
$\tau = 0.01$	1.000	0.999	0.997	0.959
$\tau = 0.10$	1.000	0.994	0.975	0.656
$\tau = 1.00$	1.000	0.937	0.776	0.015

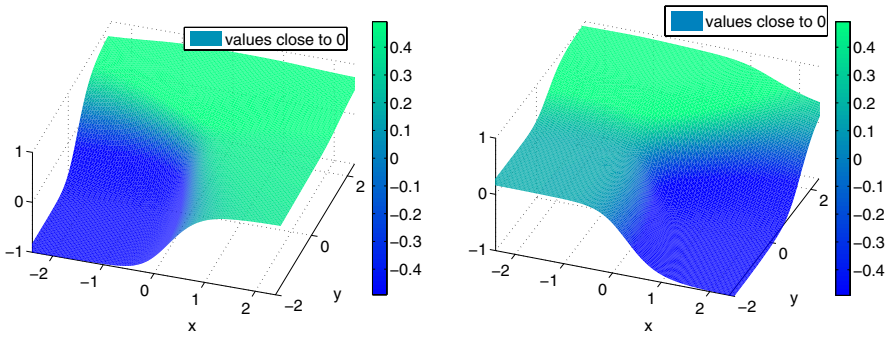

Figure 3. *Second and third eigenvectors of the transfer operator for high-friction Langevin process in potential of Figure 1 (details see text).*

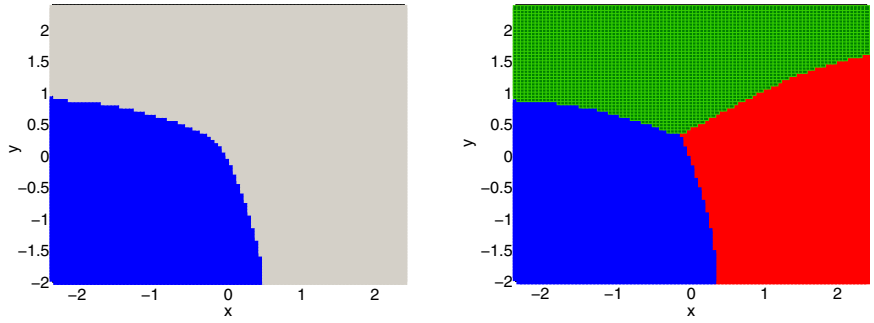

Figure 4. *Optimal metastable decomposition resulting from PCCA based on the first two (left) and first three (right) eigenvectors of the transfer operator.*

that distinguishes between the vicinity of the deepest well and the remaining state space (see Figure 4, left). When applying PCCA to the first *three* eigenvectors, however, the resulting metastable decomposition identifies the vicinities of all three wells as the metastable regions of the system (see Figure 4, right). This outcome is desirable and typical: metastable decomposition via spectral properties of the transfer operator is hierarchical in the sense that the process of including more and more leading eigenvalues uncovers finer and finer details of metastability within the system; see [40, 28].

So, what happens if we take the first four eigenvectors? This we can immediately understand by comparing the values of the functional meta for the optimal metastable decompositions $\mathbf{D}_m$ into $m = 1, 2, 3, 4$ sets ($\tau = 1$) as given in Table 2: Between $m = 3$ and $m = 4$ there is a significant drop in metastability, indicating that it makes no real sense to speak of four metastable sets for the system under consideration.

3. Algorithms. As already mentioned we assume herein that some "long enough" time series $(x_t)_{t=t_0,\ldots,t_N}$ of states (i.e., atomic positions and or momenta) of the system under consideration is already given. We are mainly interested in the case that the states x_{t_l} are from some high-dimensional state space $\mathbf{R}^d$. In this section we will often consider time series of some observables $(Z_t)_{t=t_0,\ldots,t_N}$ computed from the time series (x_t), e.g., the time series of torsion angles or inter base pair parameters; however, we could also consider the case $Z = x$.

Table 2

Metastabilities of the optimal metastable decomposition $\mathbf{D}_m$ into $m = 1, 2, 3, 4$ sets (as computed by PCCA from the dominant eigenvectors) and its theoretical upper bound as in Theorem 2.1.

m	1	2	3	4
$\mathrm{meta}(\mathbf{D}_m)$	1.000	0.967	0.899	0.613
$\frac{1}{k}\sum_{k=1}^{m}\lambda_k$	1.000	0.969	0.904	0.682

We will subsequently follow the following basic idea: from statistical analysis of the time series given we (1) construct a finite-state Markov jump process that models the hops *between* the metastable conformations, and (2) for each conformation we parameterize an appropriate stochastic model that allows us to approximate the dynamics of the systems as long as it is *within* the respective conformation. In [23, 24, 25] appropriate algorithms have been derived that combine hidden Markov models (for the construction of the unobserved jump process) and optimal, likelihood-based parameterization of the local stochastic models. We will review this framework here.

3.1. Algorithms based on hidden Markov models. Suppose the system under consideration has a metastable decomposition. Then, at any time t the system will be in exactly one of the associated metastable sets $B_q \subset \mathbf{X}$, $q = 1, \ldots, m$. Therefore, at each time t we have some "metastable state" $q(t)$ being represented by the number of the presently visited metastable set. Whenever a time series of values of observables (or "observations") $Z = (Z_t)_{t=t_0,\ldots,t_N}$ is given, we want to identify the time series of metastable states $q = (q_t)_{t=t_0,\ldots,t_N}$ associated with it. However, while the time series (Z_t) is observed, i.e., known, the series (q_t) is *hidden* within the data.

Suppose that the observed data (Z_t) is given with constant time stepping τ; i.e., $t_k = t_{k-1} + \tau$ for all $k = 1, \ldots, N$. Setting $t_0 = 0$, we have $t_k = k\tau$ and especially $T = t_N = N\tau$. For the sake of simplicity of notation we thus may simply write $t = 0, \ldots, T$.

The probability to go from one metastable/hidden state q to another, q', is given by $\top_{qq'} = p(\tau, B_q, B_{q'})$. That is, the sequence (q_t) should be seen as the realization of a Markov chain with M states with transition matrix $\top$.

The observations Z_t somehow result from the respective hidden state q_t by a priori unknown rules. For given time series of observations $Z = (Z_t)_{t=t_0,\ldots,t_N}$ one is interested in finding the most probable series of metastable/hidden states.

Models like the one coarsely described above are well known as *hidden Markov models* (HMMs). An HMM is a stochastic process with hidden and observable states; the hidden states of an HMM form a Markov chain, while the observable states are understood as output that is distributed according to a certain conditional distribution (conditioned to the hidden state).

To describe the whole system, we need to know the number M of hidden states, the transition matrix $\top$ between them, an initial distribution, and, for each state, a certain rule governing the probability distribution for the observation.

Stationary output. In standard HMMs the output distributions result from independent and identically distributed random variables; i.e., consecutive output states are statistically independent. That is, conditioned on the hidden state, the output is simply randomly chosen

from a stationary distribution. In application to the analysis of data produced in the context of molecular dynamics, this means that the system reaches the thermodynamical equilibrium distribution immediately after each transition between metastable states; this then is related to abrupt jumps of some physical observables.

The most popular choice for such stationary distributions are (multivariate) normal distributions. However, in the case of circular data (like torsion angle positions in a molecular dynamics simulation) the use of normal distributions often induces crucial problems due to periodicity, and thus they have to be replaced by von Mises distributions [32].

The problem of the statistical analysis of the time series in this case will be reduced to the identification of the Markov transition matrix and equilibrium statistical distributions (often specified in a parameterized form) [3, 34, 35]. This approach was recently successfully applied to analysis of torsion angle dynamics of a trialanine molecule [19].

SDE output. In contrast to the standard HMM approach with stationary output, molecular systems typically do not reach local equilibrium immediately after each jump of the Markov chain but relax into local equilibrium after some characteristic *relaxation time* (see Figure 11 in comparison to Figure 10). Moreover, when replacing stationary output distributions by stochastic models of the local dynamics we can hope to get more insight into the dynamical flexibilities of the molecular system within each conformation and perhaps of the mechanical processes governing this flexibility.

In order to incorporate these aspects, we couple (1) the finite-state Markov jump process that models the hops *between* the hidden states (= metastable conformations), and (2) SDE dynamics *within* the respective conformation. Putting these types of local SDEs and the jump process between conformations together, we get models of the form

$$\begin{aligned} &\dot{z}(t) = F^{(q(t))}(z - \mu^{(q(t))}) + \Sigma^{(q(t))}\,\dot{W}(t), \\ &q(t) = \text{Markov jump process with states } 1, \ldots, L, \end{aligned} \tag{8}$$

where $W(t)$ is denoting standard d'-dimensional Brownian motion (where d' is the dimension of the observations Z_t), $(\Sigma^{(1)}, \ldots, \Sigma^{(L)})$ noise intensity matrices, $(\mu^{(1)}, \ldots, \mu^{(L)})$ equilibrium positions, and $(F^{(1)}, \ldots, F^{(L)})$ appropriate stiffness matrices. The general aim of the HMMSDE extension of the HMM approach is to find the optimal model of the above form for a given time series (Z_t) (in a maximum likelihood sense).

The formal solution to the local SDE $\dot{z} = F(z - \mu) + \Sigma\dot{W}$ on the time interval $[t, t + \tau]$ is given by

$$z(t + \tau) = \mu + e^{\tau F}\,(z(t) - \mu) + \int_0^\tau e^{(\tau - s)F}\Sigma dW(s). \tag{9}$$

Thus, the probability density $\rho(Z_{k+1}|Z_k)$ of observation of Z_{k+1} at time $k + 1$ under the condition of observation of Z_k at k is proportional to

$$\exp\left[-\frac{1}{2}\xi_k^\top R^{-1}(\tau)\,\xi_k\right],$$

where

$$\xi_k = Z_{k+1} - \bar{\mu} - e^{\tau F}\,(Z_k - \bar{\mu})\,, \tag{10}$$

$$R(\tau) = \int_0^\tau e^{sF}\Sigma\Sigma^\top e^{sF^\top}\,ds. \tag{11}$$

We will now exploit this observation to construct the likelihood function of HMMSDEs.

Optimal parametrization. Both types of HMMs, whether with stationary output distribution or with SDE output, contain sets of parameters (the entries of the transition matrix $\top$, the initial output distribution v, as well as the parameters of SDEs or output distributions), herein denoted by θ. We now want to identify optimal parameters for *given* observation data $Z = (Z_t)_{t=1,\dots,T}$. We have to define the likelihood functional w.r.t. which we then will have to determine the optimal parameters θ and the sequence of hidden states $q = (q_t)_{t=1,\dots,T}$.

For given parameters θ, the likelihood $\mathcal{L}(\theta|Z_t, q_t)$ has to be the probability of output Z_t under the condition of being in metastable state q_{t_j} for given parameters θ:

$$\mathcal{L}(\theta|Z_t, q_t) = p(Z, q|\theta) = v(q_0)\rho(Z_0|q_0)\prod_{t=1}^{T}\top(q_{t-1}, q_t)\rho(Z_t|q_t, Z_{t-1}), \tag{12}$$

where $\rho(\cdot|q, Z_{t-1})$ denotes the output distribution at time t under the condition that the system is in hidden state q_t. According to our observations above we have

$$\rho(Z_t|q_t, Z_{t-1}) \propto \exp\left[-\frac{1}{2}\xi_t^\top R^{-1}(\tau)\,\xi_t\right],$$

with ξ_t and R as given by (10) and (11) with $k = t$, $F = F^{(q_t)}$, $\Sigma = \Sigma^{(q_t)}$, and $\mu = \mu^{(q_t)}$.

The next task now will be to construct algorithms that

(1) determine the optimal parameters $(\top, \mu^{(q)}, F^{(q)}, \Sigma^{(q)})_{q=1,\dots,M}$ by maximizing the likelihood $\mathcal{L}(\theta|Z, q)$ (this is a nonlinear global optimization problem),
(2) determine the optimal sequence of hidden metastable states (q_t) for given optimal parameters, and
(3) determine the number of important metastable states. Up to now we also simply assumed that the number M of hidden states is a priori given, but how can we determine the appropriate number?

To solve problem (1) we will use the *expectation-maximization* (EM) algorithm. The EM algorithm is a learning algorithm: it alternately iterates two steps, the expectation step and the maximization step. Starting with some initial parameter set θ_0, the steps iteratively refine the parameter set; i.e., in step k the present parameter set θ_k is refined to θ_{k+1}. We will work out the details of the EM algorithm for the problem under investigation by following the general framework given in [6].

The key object of the EM algorithm is the expectation

$$Q(\theta, \theta_k) \;=\; \mathbf{E}\Big(\log p(Z, q|\theta) \mid Z, \theta_k\Big) \tag{13}$$

of the complete-data likelihood $\mathcal{L}(\theta|Z, q) = p(Z, q|\theta)$ (in our case given by (12)) w.r.t. the hidden sequence q given the observation sequence and the current parameter estimate θ_k. One step of the EM algorithm then realizes the following two steps:

- Expectation step (E-step). This step evaluates the expectation value Q based on the given parameter estimate θ_k.
- Maximization step (M-step). This step determines the refined parameter set θ_{k+1} by maximizing the expectation:

$$\theta_{k+1} = \operatorname*{argmax}_{\theta} Q(\theta, \theta_k). \tag{14}$$

The maximization guarantees that $\mathcal{L}(\theta_{k+1}) \geq \mathcal{L}(\theta_k)$.

Algorithmic realizations of these two steps are standard for stationary Gaussian and von Mises output [19]; for SDEs the results of the maximization step are given below; further algorithmic details can be found in [23, 24, 25]. In both cases the necessary computational effort for one step of the EM algorithm scales linearly in the length of the observation sequence and quadratically in the number of hidden states.

Results of M-step in HMMSDE. In addition to the observation sequence $(Z_k)_{k=1,2,\ldots,}$ the E-step in each iteration yields occupation probabilities $\nu_k(q)$, $q = 1, \ldots, L$, of the hidden state q at time k (i.e., $\nu_k(q)$ denotes the probability to be in hidden state q at time k according to the present state of the EM-iteration). Then, denote the mean and covariance of the time series $(Z_1, \ldots, Z_T)$ in the state q by

$$\bar{Z}_T^{(q)} = \frac{1}{\sum_{k=1}^{T-1} \nu_{k+1}(q)} \sum_{k=1}^{T-1} \nu_{k+1}(q) Z_k,$$

$$\mathrm{Cov}_T^{(q)}(Z) = \frac{1}{\sum_{k=1}^{T-1} \nu_{k+1}(q)} \sum_{k=1}^{T-1} \nu_{k+1}(q)(Z_k - \bar{Z}_T^{(q)})(Z_k - \bar{Z}_T^{(q)})^\top.$$

Furthermore, let the one-step correlation be defined as

$$\mathrm{Cor}_T^{(q)}(Z) = \frac{1}{\sum_{k=1}^{T-1} \nu_{k+1}(q)} \sum_{k=1}^{T-1} \nu_{k+1}(q)(Z_{k+1} - \bar{Z}_T^{(q)})(Z_k - \bar{Z}_T^{(q)})^\top \cdot \mathrm{Cov}_T^{(q)}(Z)^{-1}.$$

Finally, for the sake of convenience let $\delta_T^{(q)}$ denote

$$\delta_T^{(q)} = \frac{1}{\sum_{k=1}^{T-1} \nu_{k+1}(q)} \sum_{k=1}^{T-1} \nu_{k+1}(Z_{k+1} - Z_k).$$

Then, the optimal estimators $\hat{F}^{(q)}$ and $\hat{\mu}^{(q)}$ for the parameters $F^{(q)}$ and $\mu^{(q)}$ of the local SDEs (i.e., the unique maximizers of the expectation of the likelihood) are given by the following statement.

Theorem 3.1. *Let $Cov_T^{(q)}$ be positive definite for all i. Then the optimal estimator satisfies*

$$\exp(\tau \hat{F}^{(q)}) = Cor_T^{(q)}, \tag{15}$$

$$\hat{\mu}^{(q)} = \bar{Z}_T^{(q)} + (\mathrm{Id} - Cor_T^{(q)})^{-1} \delta_T^{(q)}. \tag{16}$$

The second equation is valid whenever the typical case $\|Cor_T^{(q)}\| < 1$ *applies; we then have that the spectrum of the optimal estimator for the stiffness satisfies* $\sigma(\hat{F}^{(q)}) \subset \mathbf{C}^-$.

Furthermore, we get a linear matrix equation for the optimal noise intensity matrix estimator $\hat{\Sigma}^{(q)}\hat{\Sigma}^{(q)^\top}$:

$$e^{-\tau\hat{F}^{(q)}}W^{(q)} = \hat{\Sigma}^{(q)}\hat{\Sigma}^{(q)^\top}e^{\tau\hat{F}^{(q)^\top}} - e^{-\tau\hat{F}^{(q)}}\hat{\Sigma}^{(q)}\hat{\Sigma}^{(q)^\top}, \tag{17}$$

where

$$\begin{aligned} W^{(q)} &= \Omega^{(q)}\hat{F}^{(q)^\top} + \hat{F}^{(q)}\Omega^{(q)}, \\ \Omega^{(q)} &= \left(\frac{1}{\sum_{k=1}^{T-1}\nu_{k+1}(q)}\sum_{k=1}^{T-1}\nu_{k+1}(q)\hat{d}_k^{(q)}\hat{d}_k^{(q)^\top}\right), \\ \hat{d}_k^{(q)} &= \left(Z_{k+1} - \hat{\mu}^{(q)} - e^{\tau\hat{F}^{(q)}}\left(Z_k - \hat{\mu}^{(q)}\right)\right). \end{aligned}$$

The matrix equation (17) has a unique solution only if $\sigma(\hat{F}^{(q)}) \subset \mathbf{C}^-$ (see [25]).

This result from [25] gives us the opportunity to realize the required maximization explicitly simply by computing the autocorrelation matrices. There should be a warning: the computation of $\hat{F}^{(q)}$ from $\exp(\tau\hat{F}^{(q)})$ is far from straightforward due to the nonuniqueness of the matrix logarithm (see [25] for details and for appropriate procedures for the computation of $\hat{F}^{(q)}$).

Optimal sequence of hidden states. Based on the results of the EM algorithm, problem (2) can be solved by applying the standard Viterbi algorithm [44]. For given θ and Z this algorithm computes the most probable hidden path $q^* = (q_0^*, \ldots, q_T^*)$. This path is called the *Viterbi path*. For an efficient computation we define the highest probability along a single path, for the first t observations, ending in the hidden state S_i at time t:

$$\delta_t(q) = \max_{q_0,q_1,\ldots,q_{t-1}} P(q_0, q_1, \ldots, q_t = S_i, Z_0, Z_1, \ldots, Z_t|\theta).$$

This quantity is given by induction as

$$\delta_t(q') = \max_{1\le i\le M}[\delta_{t-1}(q)\top_{qq'}]\rho(Z_t|q_t, Z_{t-1}). \tag{18}$$

In addition, the argument q that maximizes (18) is stored in ψ in order to actually retrieve the hidden state sequence. These quantities are calculated for each t and q', and then the Viterbi path will be given by the sequence of the arguments in ψ obtained from backtracking. For more details see [19].

Number of metastable states. In the setup of all HMM techniques for a given observation sequence, one is confronted with the task of selecting *in advance* the number M of hidden states. There are no general solutions to this problem, and the best way to handle this problem often is a mixture of insight and preliminary analysis. However, since our goal is to identify metastable states we can proceed as suggested in [19]: start the EM algorithm with some sufficient number of hidden states, say M, that should be greater than the expected number of metastable states. After termination of the EM algorithm, take the resulting transition

matrix A and aggregate the M hidden states into $\mathcal{M} \leq M$ metastable states by means of PCCA. The resulting conformation states will then allow an interpretation of the results in terms of metastable states.

In all numerical experiments in the following, the initial parameter guesses are based on the same procedure: the initial $M \times M$ transition matrix is chosen to be a stochastic matrix with offdiagonal entries 0.001 and identical diagonal entries. The initial values of the model parameters were obtained by the respective re-estimation formulas of the EM algorithm based on randomized determination of the probabilities $P(Z_t|q_t, Z_{t-1})$ (they were chosen uniformly distributed on $[0, 1]$).

Combination of results from different projections (aggregated HMM). Assume that we already applied HMMSDE or some HMM-based method to several low-dimensional observation time series of the system under consideration, but to each one independently. Suppose that the different time series simply are resulting from different projections of the full time series in state space; for example, think of the different time series given by each single torsion angle of the system, or of the time series given by each single of the leading proper orthogonal decomposition (POD) modes. In this situation one may be interested in combining the hidden states from each of the single projections into "higher-dimensional" metastable states of the system. This can be done by analyzing the Viterbi paths derived from the single low-dimensional observation time series: Suppose we are concerned with J low-dimensional time series and therefore J Viterbi paths. The J Viterbi paths can be understood as a J-dimensional discrete time series. Every state of this time series lies in the discrete state space consisting of all possible combinations of the metastable states of the single low-dimensional time series. We obviously can take this time series, compute its transfer matrix by counting transitions between its discrete states, determine the dominant eigenmodes of this transfer matrix, and again apply PCCA to identify metastable decompositions of the discrete state space. The sets in such a metastable decomposition have to be interpreted as aggregates of the metastable states from the low-dimensional time series where the aggregation is done based on additional insight coming from the combination of all of the low-dimensional information. This concept leads to the following algorithm:

1. Determine model parameters and Viterbi paths for each low-dimensional observation time series.
2. Combine the Viterbi paths and compute the transfer matrix in the discrete state space of combined metastable states.
3. Determine metastable decompositions via PCCA.

3.2. Illustrative example revisited. We now assume a time series $(x(t))_{t=t_0,\ldots,t_N}$ with $t_k - t_{k-1} = \tau = 0.01$ and $N = 10^5$ being given in the test system introduced in section 2.4. For given $t = t_0, \ldots, t_N$ let $x(t) \in \mathbf{R}^2$ be the full state of the system.

For this choice of τ the transfer operator $P^\tau = \exp(\tau\mathcal{A})$ of the high-friction Langevin motion considered in section 2.4 has the following dominant eigenvalues:

$$\sigma(P^t) = \{1.000, 0.999, 0.997, 0.959, \ldots\}.$$

Let us consider the two observation time series $(Z_t^{(j)})_{t=t_0,\ldots,t_N}$, $j = 1, 2$, with $Z_t^{(j)} = x_j(t)$ (the first and second components of the state of the system).

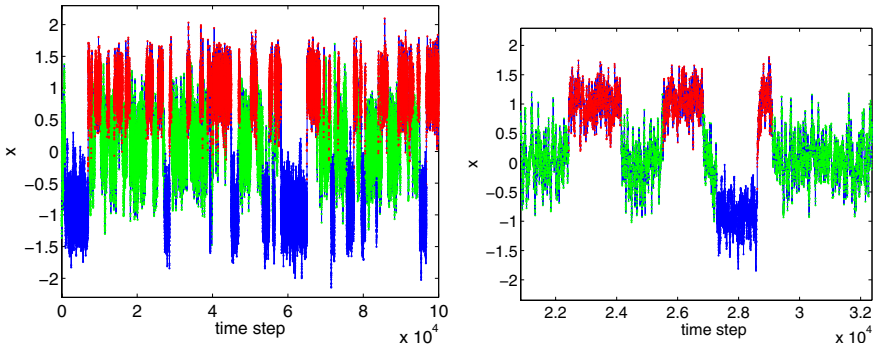

Figure 5. *Observation time series* $(Z_t^{(1)})$. *Left: entire time axis. Right: magnification clearly exhibiting metastability and overlapping. Color scale due to Viterbi path (see text below).*

We first apply HMMSDE to observation time series $(Z_t^{(1)})$ (see Figure 5 for illustration) and set $M = 3$. Eleven iterations of the EM algorithm result in the transition matrix

$$\top = \begin{pmatrix} 0.9983 & 0.0013 & 0.0004 \\ 0.0017 & 0.9983 & 0.0000 \\ 0.0008 & 0.0000 & 0.9992 \end{pmatrix}$$

that has the spectrum

$$\sigma(\top) = \{1.000, 0.999, 0.997\},$$

which agrees perfectly with the results of the transfer operator approach (that is based on the full 2D information instead of on the reduced observation time series). The HMMSDE results for the parameters of the potential and the noise intensities are given in Table 3 and are in very good agreement with the results to be expected.

Table 3
Parameters of HMMSDE *for training with* $(Z_t^{(1)})$.

Parameter	$j = 1$	$j = 2$	$j = 3$
$\mu^{(j)}$	0.0552	1.0169	-0.9584
$\sigma^{(j)^2}$	0.1325	0.1321	0.1302
$D^{(j)}$	0.5589	1.0507	0.9324

Next we apply HMMSDE to observation time series $(Z_t^{(2)})$ (see Figure 5) and set $M = 3$. Nine iterations of the EM algorithm result in the transition matrix

$$\top = \begin{pmatrix} 0.9987 & 0.0013 & 0.0000 \\ 0.0014 & 0.9981 & 0.0005 \\ 0.0000 & 0.0007 & 0.9993 \end{pmatrix}$$

with spectrum

$$\sigma(P^t) = \{1.000, 0.999, 0.997\}.$$

The HMMSDE results now are again in good agreement with the results to be expected (see Table 4).

Table 4
Parameters of HMMSDE *for training with* $(Z_t^{(2)})$.

Parameter	$j=1$	$j=2$	$j=3$
$\mu^{(j)}$	1.5526	-0.0084	-0.6693
${\sigma^{(j)}}^2$	0.1318	0.1347	0.1343
$D^{(j)}$	1.0607	0.5018	1.1037

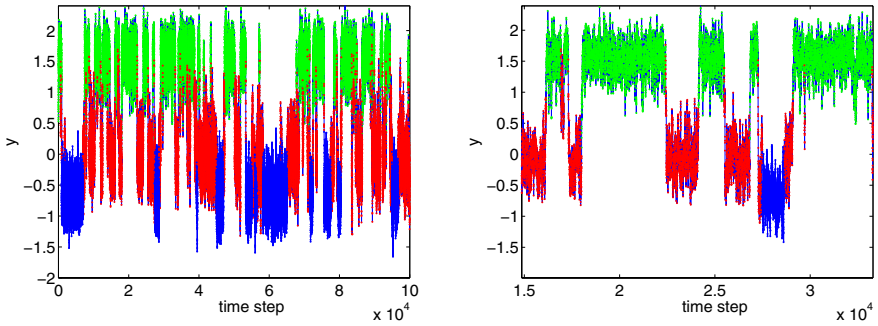

Figure 6. *Observation time series* $(Z_t^{(2)})$. *Left: entire time axis. Right: magnification clearly exhibiting metastability and overlapping. Color scale due to Viterbi path (see text below).*

Next we compute the Viterbi paths for the two HMMSDE results based on $(O_t^{(1)})$ and $(O_t^{(2)})$, respectively. This yields the assignment to metastable states as illustrated in Figures 5 and 6, and in a 2D representation in Figure 7. We observe that the agreement of the assignment with the metastable states resulting from the transfer operator approach (see Figure 3) is good. However, as can be seen from the picture, the assignment of the points in the transition regions gets ambiguous. The algorithm for combining the results of our two different projections (see *aggregated HMM algorithm* described in section 3.1) yields the results shown in Figure 8, where all points which are not clearly assigned to any of the metastable states are identified as belonging to some "transition state."

4. Application to molecular dynamics (MD) simulations of a DNA fragment.

4.1. MD and statistics. In classical MD atoms are described as mass points subject to forces that are generated by specified classical interaction potentials V. The dynamical behavior is described by a deterministic Hamiltonian system of the form

$$\dot{q} \;=\; M^{-1}\xi, \qquad \dot{\xi} \;=\; -\nabla_q V(q), \tag{19}$$

defined on the state space $\mathbf{X} = \mathbf{R}^{3N} \times \mathbf{R}^{3N}$ with M denoting the diagonal mass matrix. Equation (19) models an energetically closed system, whose total energy, given by the Hamiltonian

$$H(q,\xi) \;=\; \frac{1}{2}\,\xi^T M^{-1}\xi \;+\; V(q), \tag{20}$$

is preserved under the dynamics.

It is well known that for every smooth function $\mathcal{F} : \mathbf{R} \to \mathbf{R}$ the probability measure $\mu(\mathrm{d}x) \propto \mathcal{F}(H)(x)\mathrm{d}x$ is invariant w.r.t. the Markov process X_t given by the solution of the Hamiltonian system (19). The most frequent choice is the canonical density or *canonical ensemble*

$$f(x) \;\propto\; \exp(-\beta H(x))$$

for some constant $\beta > 0$ that can be interpreted as inverse temperature. The associated measure $\mu(\mathrm{d}x) \propto f(x)\mathrm{d}x$ is called the *canonical measure*. The canonical ensemble is often used in modeling experiments on molecular systems that are performed under the conditions of constant volume and temperature $\top = \frac{1}{k_B\beta}$, where k_B is Boltzmann's constant. Obviously, a single solution of the Hamiltonian system (19) can never be ergodic w.r.t. the canonical measure, since it conserves the internal energy H, as defined in (20). One traditional aspect of MD is the construction of (stochastic) dynamical systems that allow sampling of the canonical ensemble by means of long-term simulation. Several approaches have been discussed, most

of them reducing to the construction of a Hamiltonian system in some slightly extended state space $\hat{\mathbf{X}}$, whose projection onto the lower-dimensional state space $\mathbf{X}$ of positions and momenta generates a sampling according to (4.1). One of the most prominent examples is the Nosé–Hoover thermostat [7].

4.2. 100 ns MD time series of $GT(AT)_6C$ DNA. The time series of interest in the following was generated via an MD simulation of a 15 base pair fragment, or oligomer, using the AMBER package [9]. The detailed protocol was that of the ABC project as described in detail in [5]. That simulation provided a 100 ns time series of the oligomer with the sequence $GT(AT)_6C$ with explicit water- and counterions (see Figure 9). The MD delivers a time series of the Cartesian coordinates of all atoms (about 23000 atoms, including solvent). The MD trajectory was sampled every picosecond to obtain a series of length 10^5.

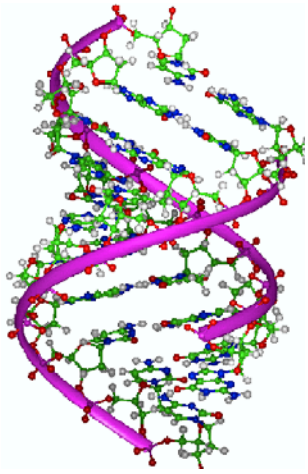

Figure 9. *Illustration of the* 15-*AT B-DNA oligonucleotide in atomic resolution. The attached violet strings indicate the backbones. The molecular dynamics simulation referred to herein includes solvent (water- and counterions), which is not shown here.*

The variables in the time series that we work with are the physically motivated projections onto two different sets of coarse-grained internal coordinates: either the torsion angle series of the backbone data [37] or the inter base pair step parameters [20]. In either case the dimension of the time series is 84, arising from the six degrees of freedom at each of the 14 junctions between 15 base pairs. At each sampling time the coarse-grain variables were extracted from the full set of Cartesian coordinates following standard conventions. Depending on the projection chosen, two basic temporal patterns of dynamics were found: abrupt, almost instantaneous change of the backbone torsion angles (see Figure 10), and slow relaxations of the inter base pair parameters with a relaxation time on the order of 1–2 ns (cf. Figure 11).

Both the backbone angle and base pair parameter descriptions of the DNA oligomer take standard, sequence-independent values on the idealized B-form Watson–Crick double helix. One of the motivations for the development of the time-series analysis developed here is to extract and understand deviations from these standard values both as a function of sequence and as a function of time.

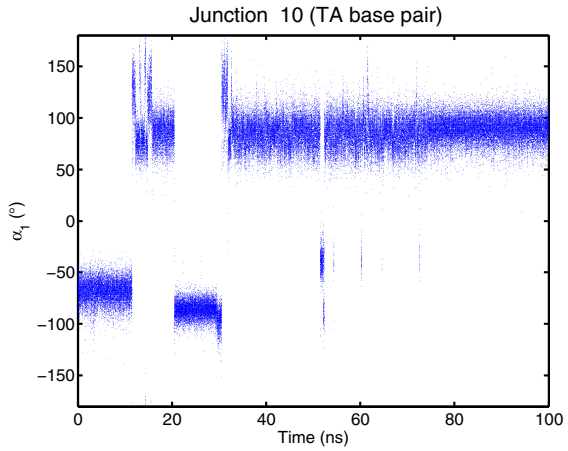

Figure 10. *Time series of the first strand α-torsion angle for the junction* 10. *The dynamics exhibits sharp transitions between the metastable sets.*

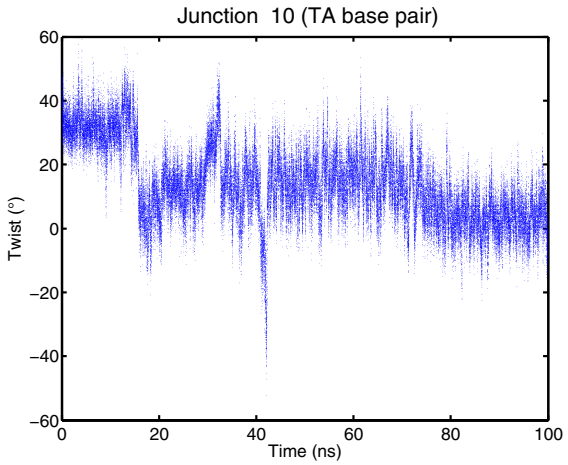

Figure 11. *Time series of the inter base pair coordinate for the junction* 10. *The dynamics exhibits slow relaxational transitions (in a nanosecond region) between the metastable sets.*

In the following we will apply the techniques of section 3 to time series of all backbone torsion angles that result from the 100 ns MD simulation described earlier in this section. This time series of the backbone angles will be denoted by $(Z_t)_{t=1,\ldots,100000}$ with $Z_t \in \mathbf{R}^{84}$ arising from the six backbone torsion angles (α, β, γ-angles at each of the strands) at each of the 14 junctions between 15 base pairs.

We will apply aggregated HMM (based on HMM with stationary van Mises output distribution for each single of the 84 torsion angle time series) and HMMSDE to the full 84-dimensional time series. After a detailed separate analysis of these two algorithms we will finally compare the outcome, especially the Viterbi paths. The section is tailored to demonstrate the application and performance of the respective algorithms; herein discussion of possible physical implications of the results is *not* the focus of our consideration.

4.3. Analysis via aggregated HMM. As can be seen from Figure 10, the torsion angles exhibit a clearly metastable behavior with sharp transitions between the metastable states. We start with the decomposition of the 84-dimensional torsion angle space into the 84 1D spaces defined by each single angle. Then, we apply our HMM analysis of the dynamics to each resulting single torsion angle time series. As a result, we get a set of 84 aggregated Viterbi paths describing the conformational change between the metastable sets in the observed 100 ns time series as identified from each single angle (for examples, see Figure 12). Of course, the aggregation depends on the strictness of the metastability criteria, i.e., on the threshold value above which eigenvalues of the associated transition matrices indicate metastability. To demonstrate that the aggregation does not destroy important dynamical information about metastability, we will in the following present two different results: one computed with a strict threshold (0.97) and another computed with a less strict threshold (0.93).

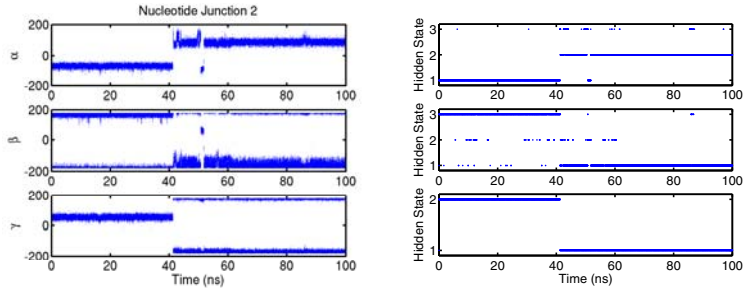

Figure 12. *Time series of the first strand α, β, γ-backbone torsion angles for junction 2 (right-hand panel). Left-hand panel: corresponding Viterbi paths as derived from the independent HMM analysis of these three torsion angle time series with an eigenvalue threshold of 0.97 (this means that all eigenvalues of the corresponding transition matrix ≥ 0.97 define the metastable sets).*

This set of 84 aggregated Viterbi paths is a coarse-grained description of the original time series and encapsulates the dynamical information about the process of the conformation change in the full 84-dimensional torsion angle space. In order to extract this information, we have to construct the transition matrix state space of the combined Viterbi path of the 84 single aggregated Viterbi paths as explained above. The resulting transition matrices have 469 combined states (for metastability threshold 0.97 for the aggregation of the single Viterbi paths) or 12567 combined states (for threshold 0.93). Figure 13 represents the dependence of the resulting eigenvalues of these transition matrices as a function of the lag time τ (lag time $\tau = l\Delta t$ means that the transition matrix counts l-step transitions between instances t and $t + l\Delta t$ along the given time series). Increasing τ means decreasing correlation between successive time steps and therefore a more informative spectrum. As can be seen in both cases, the first eigenvalue gap can always be identified after the first four dominant eigenvalues, which indicates a presence of four metastable sets in 84-dimensional space of torsion angles (for a more detailed level of description a choice of six or eight eigenvalues would be also reasonable).

In Figure 14 we compare the obtained *global* Viterbi path describing the transitions between the resulting four metastable states based on the small transition matrix (469 states) with the results based on the larger transition matrix (12567 states). As can be seen from the figure, the two global Viterbi paths are similar but not identical. The difference between

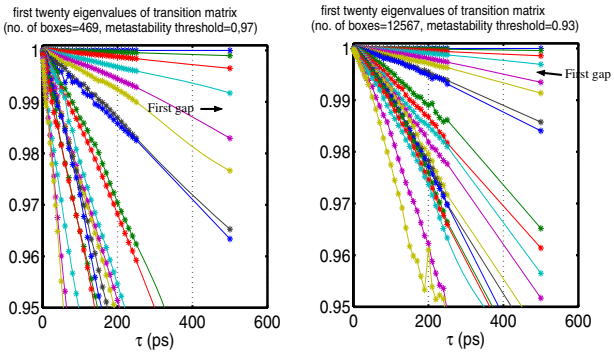

Figure 13. *Eigenvalues of the two global transition matrices as functions of the lag time τ along the respective global Viterbi path. Right-hand panel: metastability threshold* 0.97*; left-hand panel: metastability threshold* 0.93.

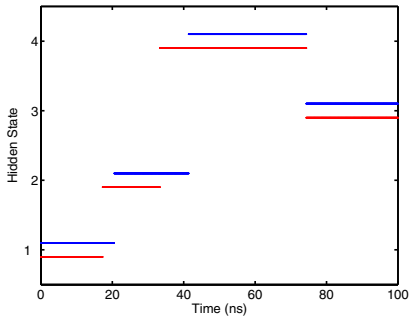

Figure 14. *Different global Viterbi paths, with each resulting from the first four eigenvalues of the global transition matrices based on two different metastability thresholds for the aggregation of the underlying* 84 *single angle Viterbi paths as described in the text. Red: threshold value* 0.93*, resulting in* 12567 *combined states; blue: threshold value of* 0.97*, resulting in* 469 *combined states.*

them can be explained by the presence of *transition states* (i.e., states that lie between the metastable states and are visited by the molecule during the transition from one metastable set to the other). Repetition of the analysis of the two transition matrices based on six dominant eigenvalues results in identification of these transition regions as additional metastable states. Then, the two global Viterbi paths (with six metastable states each) are almost identical.

Global three-dimensional (3D) structures of the DNA molecule as calculated from the mean configurations of the corresponding metastable states are presented in Figure 15.

4.4. Analysis via HMMSDE. We will now apply the HMMSDE procedure to a full 84-dimensional torsion angle time series. Before doing this, one should decide which form of local multidimensional SDE dynamics is adequate to describe the observed time series; the biophysical literature indicates that we should distinguish between Langevin diffusion (SDE in positions and momenta) and overdamped diffusion (SDE in positions only); see [25] for details. The ratio of the decay rates of position and momentum autocorrelation functions

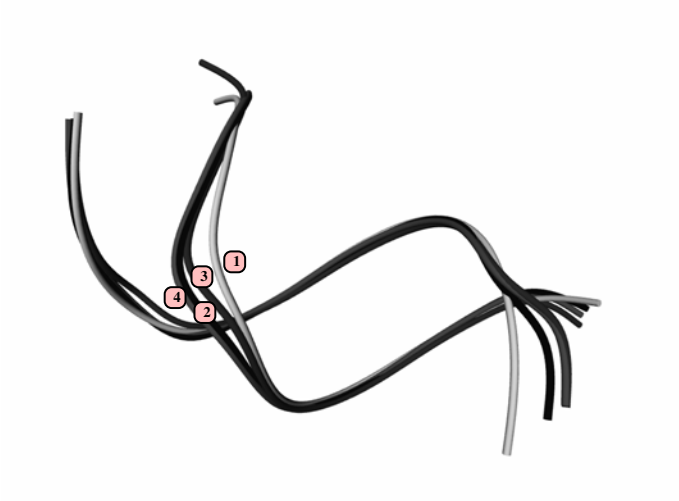

Figure 15. *Average 3D geometry of the four mean configurations defined by the four metastable states shown in Figure 14. The 3D geometry is illustrated by a string-like representation of the backbone. Numbers denote the indices of metastable states as in Figure 14. Visualization is based on AMIRA software [2].*

can indicate which of the models should be applied. This means that if the momentum autocorrelation decays much faster than the position autocorrelation function, then overdamped diffusion (also called Smolochowski dynamics) can be used to describe the observed data. Applying this criterion to the DNA data, we deduce that for a time step of 1 picosecond between observations the overdamped diffusion can be used such that we consequently use local overdamped diffusion models of the form

$$\dot{z}(t) = F^{(q(t))}(z - \mu^{(q(t))}) + \Sigma^{(q(t))}\,\dot{W}(t),$$

where z just denotes the vector of torsion angles. As has been already mentioned above, application of the EM-algorithm results in finding some *local* optimum of the log-likelihood functional. This also means that we should try to select an initial set of parameters that is "close" to the global maximum of (13): If the initial guess for the hidden probabilities $\nu_i(t)$ is not "too far off" from the real probabilities (w.r.t. the global maximum), it will take only a "few" EM-iterations to find the optimal set of parameters. Therefore we start HMMSDE with four hidden states and initialize the EM-iteration and take the hidden probabilities $\nu_i(t)$ as resulting from the Viterbi path computed via aggregated HMM (cf. Figure 14). As expected, it takes just a dozen iterations to get convergence, resulting in a 4×4 transition matrix of the hidden Markov chain; its spectrum is as shown in Figure 16.

Comparison of the resulting Viterbi path associated with the 84-dimensional HMMSDE model to the Viterbi path of the aggregated HMM procedure demonstrates the similarity of the metastable structures identified (see Figure 17).

In addition to the Viterbi path, HMMSDE also yields (optimal) estimators for the parameters of the local overdamped diffusion models (stiffness, equilibrium positions, and noise intensity matrices). Due to the fact that the Viterbi paths in Figure 17 are very similar, the mean configurations of the conformational states (denoted by μ in (8)) are also very close to

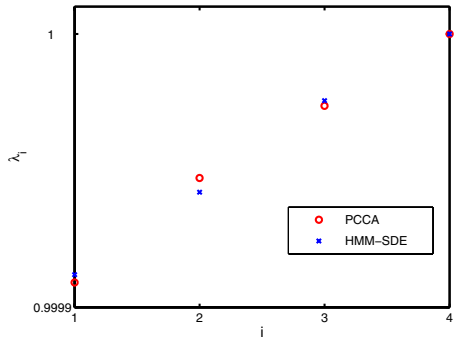

Figure 16. *Four largest eigenvalues of the transition matrix of the hidden Markov process for full-dimension HMMSDE (blue crosses) in comparison to those of aggregated HMM (metastability threshold* 0.93*, red circles).*

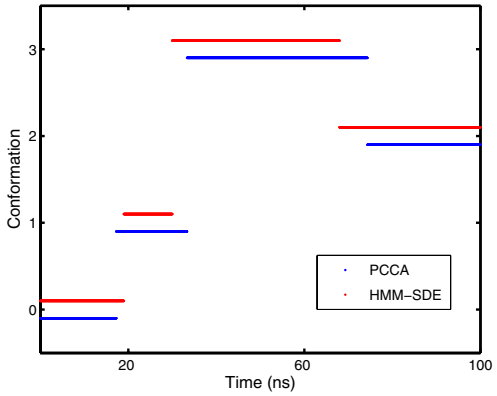

Figure 17. *Viterbi path resulting from full-dimension HMMSDE in comparison to the global Viterbi path resulting from aggregated HMM as of the previous section, with each resulting from the first four eigenvalues of the transition matrices (metastability threshold* 0.93 *for aggregated HMM). Red: full-dimension HMMSDE; blue: aggregated HMM.*

those resulting from aggregated HMM as already shown in Figure 15. Closer inspection of the resulting stiffness matrices allows us to get additional insights into physical properties of the four resulting conformations. The stiffness matrices associated with each of the conformations are shown in Figures 18–21. All four matrices are block-banded: we observe rather strong couplings between neighboring torsion angles in the same strain, weaker coupling between neighboring angles on opposed strains, and almost zero interaction between the angles not directly adjacent to each other. The stiffness matrices are also periodic along the main diagonal and the subdiagonals. This feature can be explained by the periodicity of the underlying DNA sequence. Finally, comparison among the individual stiffness matrices shows that the first conformation is the "most stiff" one, whereas the three other conformations have "loose spots" that correspond to the locations where transitions between the conformations take place.

When repeating the entire HMMSDE analysis with different initial values for the EM and

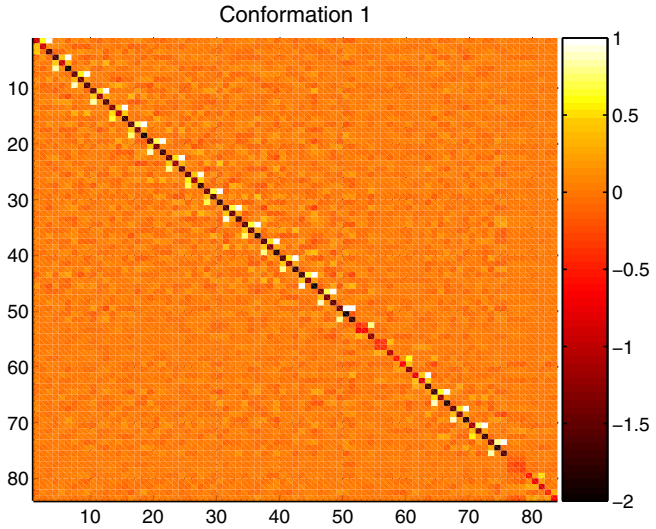

Figure 19. *Optimal estimate for the stiffness matrix F of the second conformation as resulting from full-dimension HMMSDE. For details of its computation, see text.*

Viterbi algorithms, we observe convergence to very similar results, even if the initial values are quite different from the ones taken above (however, in some cases the number of iterations increases significantly).

5. Conclusion. We have presented a variety of algorithmic concepts for the identification of metastable states in dynamical systems. Possible strategies for application to very complex metastable systems, and the performance of the resulting algorithms have been demonstrated by analyzing a full-scale MD simulation of a poly-(AT) B-DNA oligomer.

In regard to the algorithmic aspects, our conclusion is that for realistically large simulations

of biomolecules it is not practical to compute explicitly the full discretized transfer operator in Cartesian coordinates. This is due to the curse of dimensionality. In contrast, aggregated HMM and HMMSDE methods applied to a reduced time series with sharp transitions (the backbone time series in the DNA example) can identify the metastable sets.

Our results show that the backbone dynamics of B-DNA exhibit metastable behavior (visible in both base pair and torsion angles representations of the dynamics) on nano- to microsecond time scales, and that this metastability might be sequence-dependent and of importance for macroscopic modeling of B-DNA elasticity and dynamics. Most specifically the average values of AT and TA base pair parameters are quantified and confirmed to be quite distinct. In addition, the values of these averages are shown to depend upon the particular metastable set of the oligomer.

On a less positive note, it is apparent that the simulation time scale of a few hundred nanoseconds is much too short to compute transition probabilities for the backbone accurately, i.e., to analyze quantitatively the possible sequence dependence of backbone conformation transitions. Most specifically, the trajectory we have computed is demonstrably not ergodic.

On the Families of Periodic Orbits of the Sitnikov Problem*

Jaume Llibre† and Rafael Ortega‡

Abstract. The main goal of this paper is to study analytically the families of symmetric periodic orbits of the elliptic Sitnikov problem for all values of the eccentricity in the interval $[0, 1)$, providing qualitative and quantitative information on the bifurcation diagram of such families of periodic orbits. The basic tool for proving our results is the global continuation method of the zeros of a function depending on one parameter provided by Leray and Schauder and based in the Brouwer degree.

Key words. 3-body problem, Sitnikov problem, periodic orbits, global continuation

AMS subject classifications. Primary, 70F15; Secondary, 37N05

1. Introduction.

The Sitnikov problem is a special case of restricted 3-body problems where the two primaries with equal masses are moving in a circular or an elliptic orbit of the 2-body problem, and the infinitesimal mass is moving on the straight line orthogonal to the plane of motion of the primaries which passes through their center of mass.

When the orbit described by the primaries is circular the Sitnikov problem is known as the *circular Sitnikov problem*. In 1907 Pavanini [33] expressed its solutions by means of Weierstrassian elliptic functions. Four years later MacMillan [26] expressed the solutions in terms of Jacobian elliptic functions (a detailed description of this work can be found in Stumpff [38]). Some other analytical expressions for the solutions of this problem can be found, for instance, in [39], [5], [42], [17], and [20]. The precise definition of the Sitnikov problem is given in section 2.

The *elliptic Sitnikov problem* is the case when the orbit describing the primaries is elliptic. This problem became important in 1960 when Sitnikov [37] used it to show, for the first time, the possibility of the existence of oscillatory motions in the 3-body problem. The existence of this kind of motion was predicted by Chazy [8], [9], [10] in 1922–1932, when he classified the final evolutions of the 3-body problem. Later on Alekseev [2], [3], [4] in 1968–1969 proved that, in the special case of the 3-body problem studied by Sitnikov, all of the possible combinations of final motions in the sense of Chazy were realized. Moser [32] in 1973 gave alternative proofs of the results of Alekseev which are simpler than those in [2], [3], [4]. Since then many other authors have studied the circular or elliptic Sitnikov problem—for instance, Llibre and Simó [24], Perdios and Markellos [34], Liu and Sun [21], Hagel [18], Hagel and Trenkler [19],

The families of symmetric periodic orbits of the elliptic Sitnikov problem have been studied by several authors. These works assume sufficiently small values of the eccentricity and obtain the periodic solution by continuing the known periodic orbit of the circular Sitnikov problem. There are analytic studies by Corbera and Llibre [12], [13], using the analytical continuation method of Poincaré, and Cabral and Xia [7], applying the subharmonic Melnikov method. There are also numerical studies by Belbruno, Llibre, and Ollé [5] and Jiménez-Lara and Escalona-Buendía [22]. In this last paper the authors describe numerically some families of symmetric periodic orbits for almost all values of the eccentricity e in $[0, 1)$.

The main objective of this paper is to study analytically the families of symmetric periodic orbits of the elliptic Sitnikov problem for nonnecessarily small values of the eccentricity e. More precisely, we will show that some periodic orbits for $e = 0$ can be continued to all values of e in $[0, 1)$. In Theorems 3.1, 3.2, and 3.3 are the statements of our main results.

The main tool for proving our results is the global continuation of the zeros of a function depending on one parameter provided by Leray and Schauder and based in the Brouwer degree; see section 4. In section 5 we show that, with convenient formulation, the Sitnikov problem satisfies the basic assumptions of the global continuation theorem. In section 6 we study the dynamics around the unique equilibrium point of the Sitnikov problem. This equilibrium point corresponds to one of the three collinear relative equilibrium solutions of Euler for the general 3-body problem; see section 2 for more details. Finally, in section 7 we provide the last steps in the proofs of Theorems 3.1, 3.2, and 3.3.

The use of the global continuation techniques in the study of nonlinear boundary value problems is classical. We refer the reader to [36] for recent results applicable to general classes of nonlinearities. In another context we should also mention the paper [29] by Mathlouthi. He studies the Sitnikov problem with variational techniques and obtains results about the existence of periodic solutions which are global in the sense that they are valid for arbitrary eccentricity. The use of continuation methods will allow us to obtain many continuous families and to be more precise about the oscillatory properties of the solutions.

2. The Sitnikov problem.

Let $m_1 = m_2$ be two point masses (called *primaries*) describing a circular or an elliptic orbit of the 2-body problem. We consider an infinitesimal mass m_3 that moves on the straight line ρ orthogonal to the plane of motion of the primaries that passes through their center of mass. The *Sitnikov problem* will consist of describing the motion of the infinitesimal mass. In particular, if the primaries are moving in circular (respectively, elliptic) orbits, we have the circular (respectively, elliptic) Sitnikov problem.

We choose the units of mass, length, and time so that $m_1 = m_2 = 1/2$, the gravitational constant $G = 1$, and the period of the orbit described by the primaries is 2π. If z denotes the position of the particle m_3 in a coordinate system on ρ with origin at the center of mass of the primaries (see Figure 1), then the equation of motion of the Sitnikov problem becomes

$$\ddot{z} = -\frac{z}{(z^2 + r^2(t, e))^{3/2}}, \tag{2.1}$$

where $r(t, e)$ is the distance of the primaries to their center of mass and it is given by

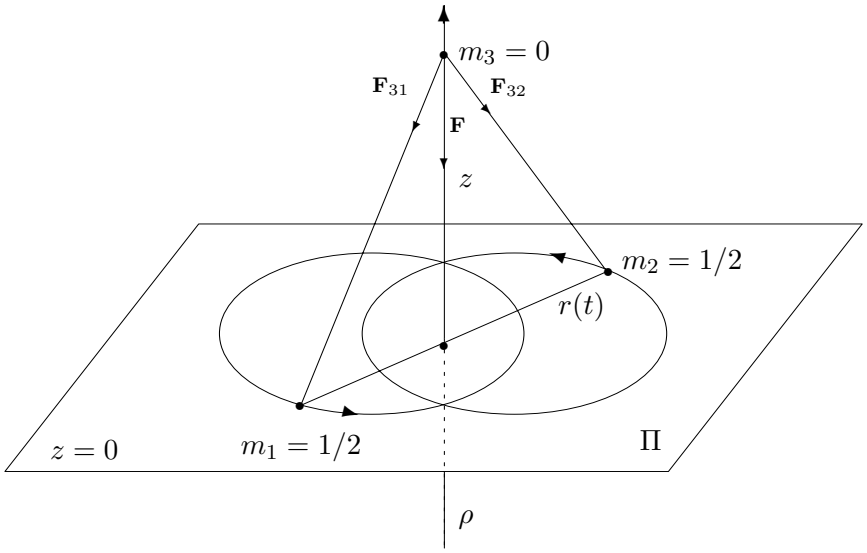

Figure 1. *The Sitnikov problem.*

$$r(t,e) = \frac{1}{2}(1 - e\cos u(t)), \tag{2.2}$$

which is a circular or an elliptic solution of the Kepler problem

$$\ddot{r} = \frac{1-e^2}{16\,r^3} - \frac{1}{8\,r^2}, \tag{2.3}$$

with eccentricity $e = 0$ or $0 < e < 1$, respectively. Here $u(t)$ is the eccentric anomaly which is a function of time via the Kepler equation

$$u - e\sin u = t - \ell, \tag{2.4}$$

with ℓ the time of pericenter passage.

Without loss of generality, when $0 < e < 1$, we usually take the origin of time in such a way that at $t = 0$ the primaries are at the pericenter of the ellipse (i.e., $\ell = 0$).

We note that system (2.1) depends on one parameter, the eccentricity $e \in [0, 1)$.

When the eccentricity e is zero (that is, the primaries move on the circular orbit $r(t) = 1/2$ of the Kepler problem (2.3)), (2.1) becomes the equation of motion

$$\ddot{z} = -\frac{z}{(z^2 + 1/4)^{3/2}} \tag{2.5}$$

for the circular Sitnikov problem. This equation defines an integrable Hamiltonian system of one degree of freedom with Hamiltonian

$$H = \frac{1}{2}v^2 - \left(z^2 + \frac{1}{4}\right)^{-1/2}, \tag{2.6}$$

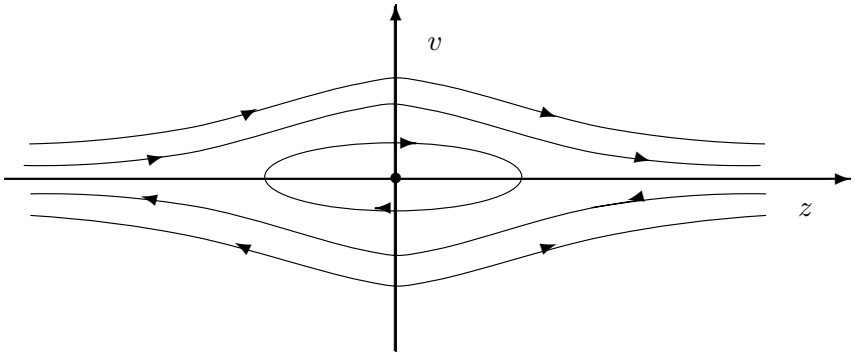

Figure 2. *The circular Sitnikov phase portrait.*

where $v = \dot{z}$.

The orbits for the circular Sitnikov problem in the energy level h are described by the curve $H = h$, where h varies in $[-2, \infty)$. Then, depending on the value of h, we have different types of orbits in the phase space (z, v) (see Figure 2):

(1) when $h < -2$ we have no orbits;
(2) when $h = -2$ we have the equilibrium point ($z = 0$, $v = 0$) or equivalently the trivial solution $z(t) \equiv 0$, which correspond to one of the well-known collinear relative equilibrium solutions of Euler for the 3-body problem (see, for instance, [1]);
(3) when $-2 < h < 0$ we have periodic orbits;
(4) when $h = 0$ we have two parabolic orbits (i.e., two orbits that leave and reach infinity with zero velocity);
(5) when $h > 0$ we have two hyperbolic orbits (i.e., two orbits that leave and reach infinity with positive velocity).

If the eccentricity $e \in (0, 1)$, then differential equation (2.1) corresponds to the elliptic Sitnikov problem. We note that this differential equation is nonautonomous; i.e., the time appears explicitly in the right-hand side of (2.1) through $r(t, e)$. Moreover, $r(t, e)$ is a periodic function in t of minimal period 2π. Consequently all periodic solutions $(z(t), \dot{z}(t))$ of (2.1) with $e \in (0, 1)$ must have period a multiple of 2π. Hence, all periodic orbits of the infinitesimal mass m_3 for the elliptic Sitnikov problem are also periodic orbits involving the three masses. Of course, in general, this was not the case for the circular Sitnikov problem.

3. Statement of the main results.

Given an integer $N \geq 1$, we define

$$\nu = \nu_N = [2\sqrt{2}N],$$

where $[\cdot]$ denotes the integer part function. Our main result is the following.

Theorem 3.1. *For each $p = 1, \ldots, \nu$ and $\varepsilon > 0$ there exists a family (or a branch) of solutions $\{(z_s(t), e_s)\}_{s\in[0,1)}$ of (2.1) satisfying the following:*

(1) *The map $(s, t) \in [0, 1) \times \mathbb{R} \to (z_s(t), \dot{z}_s(t), e_s)$ is continuous.*
(2) *The solutions $z_s(t)$ are even and $2N\pi$-periodic; i.e., for all $s \in [0, 1)$ we have*

$$z_s(-t) = z_s(t), \qquad z_s(t + 2N\pi) = z_s(t).$$

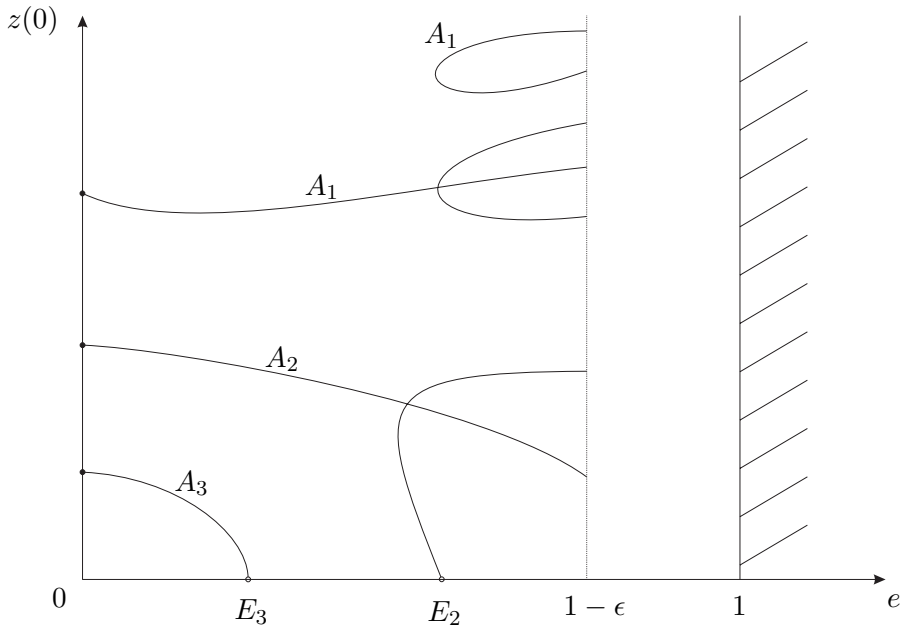

Figure 3. *Families of periodic orbits.*

(3) *For each* $s \in [0,1)$ *we have that* $z_s(0) > 0$ *(hence, the solution* $z_s(t)$ *is nontrivial; i.e.,* $z_s(t) \not\equiv 0$*), and* $z_s(t)$ *has exactly* p *zeros in the interval* $[0, N\pi]$.

(4) $e_0 = 0$, $e_s \in [0, 1-\varepsilon]$ *for each* s *and one of the following alternatives holds:*

(4.a) $e_s \to 1-\varepsilon$ *and* $z_s(0) \to \xi > 0$ *as* $s \nearrow 1$*;*

(4.b) $\lim_{s\nearrow 1} e_s = E$ *exists with* $E < 1-\varepsilon$, $z_s(t)$ *converges to* 0 *as* $s \nearrow 1$, *and the linear differential equation*

$$\ddot{y} + \frac{1}{r(t,E)^3} y = 0$$

has a nontrivial, even, $2N\pi$*-periodic solution with exactly* p *zeros in the interval* $[0, N\pi]$.

Just to illustrate the theorem we sketch a hypothetical situation in Figure 3. For a fixed $N \geq 2$ we take three numbers $1 \leq p_1 < p_2 < p_3 \leq \nu$ and draw the sets A_1, A_2, A_3 defined by

$$A_i = \{(z(0), e) : \ z(t) \text{ is an even } 2N\pi\text{-periodic solution with } p_i \text{ zeros in } [0, N\pi],\ z(0) > 0,\ e \in [0, 1-\varepsilon]\}.$$

For p_1 (respectively, p_3) one finds a family satisfying (4.a) (respectively, (4.b)). For p_2 both alternatives are possible.

The following result provides additional information about Theorem 3.1.

Theorem 3.2. *The following statements hold.*

(1) *If* $p < N$, *then statement* (4.a) *of Theorem 3.1 holds.*

(2) *If* $p \geq N$, $\rho_N < 1-\varepsilon$, *and statement* (4.b) *of Theorem 3.1 holds, then* $E > \rho_N$ *with*

$$\rho_N = \min\left\{2\left(\frac{N}{\nu}\right)^{2/3} - 1,\ 1 - 2\left(\frac{N}{\nu+1}\right)^{2/3}\right\}.$$

We note that statement (1) of Theorem 3.2 provides families which can be globally continued to the whole interval of eccentricities $[0, 1-\varepsilon]$. In the case $N/p \leq 1$, we do not know if the continued family is defined or not in the whole interval $[0, 1)$ but statement (2) of Theorem 3.2 gives us an estimation of the size of the interval of eccentricities where it can be extended. Another consequence of the previous result is the existence of even solutions with minimal period $2N\pi$, $N \geq 2$, for arbitrary eccentricity. It is sufficient to consider the global family associated to $p = 1$. A similar result was obtained in [29]. After adapting Theorem 2 and Corollary 3 of that paper to our notation, one obtains the existence of odd periodic solutions with minimal period $2N\pi$, $N \geq 2$.

Finally, we are going to compare two different families of solutions. Given positive integers M, N, p, q, $1 \leq p \leq \nu_N$, and $1 \leq q \leq \nu_M$, we denote by $\{(z_s, e_s)\}$ and $\{(z_s^*, e_s^*)\}$ the families given by Theorem 3.1 for the couples (p, N) and (q, M), respectively.

Theorem 3.3. *Using the previous notation we assume that $M/q > N/p$.*

(1) *The sets $\{(z_s(0), e_s) : s \in [0, 1)\}$ and $\{(z_s^*(0), e_s^*) : s \in [0, 1)\}$ do not intersect.*
(2) *If statement* (4.a) *of Theorem 3.1 holds for $\{(z_s, e_s)\}$, then the same is true for $\{(z_s^*, e_s^*)\}$.*
(3) *If statement* (4.b) *of Theorem 3.1 holds for $\{(z_s^*, e_s^*)\}$ with $E^* = \lim_{s \nearrow 1} e_s^*$, then the same is true for $\{(z_s, e_s)\}$ with $E = \lim_{s \nearrow 1} e_s \leq E^*$.*

4. Global continuation in the sense of Leray–Schauder. Given an open and bounded subset Ω of $\mathbb{R}^d$ and a function $f : \overline{\Omega} \to \mathbb{R}^d$ which is continuous and does not vanish on the boundary of Ω (i.e., $f(x) \neq 0$ for all $x \in \partial\Omega$), we can define the *Brouwer degree*

$$\deg(f, \Omega),$$

sometimes denoted by $\deg(f, \Omega, 0)$. As usual, $\overline{\Omega}$ denotes the closure of Ω in $\mathbb{R}^d$. There are several equivalent ways to define this degree, and we refer the reader to [25], [30] for more details. For completeness we sketch Nagumo's definition. First we assume that f is of class C^1 and has a finite number of zeros $x_1, \ldots, x_n \in \Omega$ with $\det f'(x_i) \neq 0$ for each i. Then

$$\deg(f, \Omega) = \sum_{i=1}^{n} \operatorname{sign} \det f'(x_i).$$

Now, given an arbitrary continuous function f, we approximate it by functions f_k in the previous conditions and define

$$\deg(f, \Omega) = \lim_{k \to \infty} \deg(f_k, \Omega).$$

Given $x_0 \in \Omega$ a zero of f (i.e., $f(x_0) = 0$), if it is isolated in the set of zeros, then we can define the *Brouwer index of the zero* by

$$\operatorname{ind}(f, x_0) = \deg(f, U),$$

where U is a small neighborhood of x_0. This definition is correct because x_0 is isolated and the degree has the property of excision.

An important property of the degree is its invariance by homotopy. We now state a generalized version where the domain changes with the parameter. It can be found in several papers and books on degree theory, but it is already in [25] (see Lemma 3 of that paper).

Let A be a subset of $\mathbb{R}^d \times [a,b]$. If we denote by (x,λ) the points of $\mathbb{R}^d \times [a,b]$, then we define

$$A_{\lambda_*} = \{\lambda = \lambda_*\} = \{(x,\lambda) \in A : \lambda = \lambda_*\}.$$

Lemma 4.1. *Let U be an open and bounded subset of $\mathbb{R}^d \times [a,b]$ and $f : \overline{U} \to \mathbb{R}^d$ be continuous and such that $f(x,\lambda) \neq 0$ for all $(x,\lambda) \in \partial U$. Then $\deg(f_\lambda, U_\lambda)$ is independent of λ, where $f_\lambda(x) = f(x,\lambda)$.*

We remark that U_λ can be empty for some λ in that case, by Lemma 4.1, the degree is 0.

We conclude these preliminary remarks stating some properties of continua.

Lemma 4.2. *Assume that X is a metric space, $K \subset X$ is a compact set, and $A, B \subset K$ are compact sets such that there is no subcontinuum of K connecting A and B. Then there is an open subset U of X satisfying $A \subset U$, $B \cap \overline{U} = \emptyset$, $K \cap \partial U = \emptyset$.*

Lemma 4.2 or a similar result is employed very often in papers on global bifurcation. See, for instance, [35] and [30].

The next result is stated as a remark after the *Théorème Fondamental* in [25]. Actually, the result in [25] is more general because it works in infinite dimensions for a compact map. We will review the proof of [25]. See also [35] and [30].

Theorem 4.3. *Let $F : \mathbb{R}^d \times [a,b] \to \mathbb{R}^d$ be continuous, and $Z = \{(x,\lambda) : F(x,\lambda) = 0\}$ be the set of zeros of F. Assume that*

(H1) *Z is bounded, and*

(H2) *the set Z_a is finite and there is $(x_0,a) \in Z_a$ with $ind(F_a, x_0) \neq 0$.*

Let C be the connected component of Z containing (x_0,a). Then one of the following alternatives holds:

(a) *$C \cap \{\lambda = b\} \neq \emptyset$.*

(b) *There exists $(x_1,a) \in Z_a$, $x_1 \neq x_0$, such that $(x_1,a) \in C$.*

Proof. Consider the metric space $X = \mathbb{R}^d \times [0,1]$ and the set $K = Z$. The assumption (H1) implies that K is compact. Define

$$A = \{(x_0,a)\}, \quad B = (Z_0 \setminus A) \cup \{(x,b) : |x| \leq M\},$$

where M is a large constant so that Z is included in $|x| < M$. If neither (a) nor (b) holds, then there is no subcontinuum of Z meeting A and B. We find U an open subset of X such that

$$\{(x_0,a)\} = U_a \cap Z, \quad U_b = \emptyset, \quad Z \cap \partial U = \emptyset.$$

By Lemma 4.1, the $\deg(F_\lambda, U_\lambda)$ is independent of λ. Since $U_b = \emptyset$, this degree must be zero. On the other hand, by (H2) we have

$$\deg(F_a, U_a) = \operatorname{ind}(F_a, x_a) \neq 0.$$

This contradiction shows that (a) or (b) must hold. ∎

In general, the continuum C can be rather pathological; however, there is a special case in which one can guarantee that C is arcwise connected. In this case there are arcs joining all points of C, and this corresponds to the usual idea of *continuation*.

Theorem 4.4. *Under the assumptions of Theorem 4.3 suppose that $d = 1$ and F is real and analytic. Then, there is a continuum arc $\alpha : [0,1] \to Z$, $\alpha(s) = (x(s), \lambda(s))$ with $x(0) = x_0$, $\lambda(0) = a$ such that either $\lambda(1) = b$ or $\lambda(1) = a$ and $x(1) \neq x_0$.*

Many results on the effect of analyticity on global continuation can be seen in [14] and [6]. The local structure of the set of zeros of $F(x, \lambda) = 0$ says that C is locally arcwise connected. Since C is, by definition, connected, we conclude that C is arcwise connected.

5. Periodic solutions of the Sitnikov problem. Equation (2.1) is the equation of motion for the Sitnikov problem, where $e \in [0, 1)$ is the eccentricity and $r(t, e)$ is the distance of the primaries to its center of mass. The eccentric anomaly $u(t)$ satisfies

$$u(t + 2\pi) = u(t) + 2\pi, \quad u(-t) = -u(t),$$

and so, by (2.2) and (2.4), $r(t, e)$ is an even and 2π-periodic function.

Given an integer $N \geq 1$, we shall be interested in even, $2N\pi$-periodic solutions of (2.1). They satisfy the boundary conditions

$$\dot{z}(0) = \dot{z}(N\pi) = 0. \tag{5.1}$$

Let $\varphi(t; \xi, e)$ be the solution of (2.1) satisfying

$$z(0) = \xi, \quad \dot{z}(0) = 0.$$

This is a real analytic function in the arguments $(t; \xi, e) \in \mathbb{R} \times \mathbb{R} \times [0, 1)$. Notice that these solutions are globally defined in $(-\infty, +\infty)$ because the nonlinearity in (2.1) is bounded. We define

$$F_N : \mathbb{R} \times [0, 1) \to \mathbb{R}, \qquad F_N(\xi, e) = \dot{\varphi}(N\pi; \xi, e).$$

The research of even $2N\pi$-periodic solutions of (2.1) satisfying (5.1) is equivalent to the study of the equation

$$F_N(\xi, e) = 0.$$

We want to apply Theorem 4.4 to F_N, and so we must verify its assumptions.

Toward assumption (H1). We first consider the circular Sitnikov problem

$$\ddot{z} = -\frac{z}{(z^2 + R^2)^{3/2}}$$

for some $R > 0$. Let $\psi(t; \xi)$ be its solution satisfying

$$z(0) = \xi, \quad \dot{z}(0) = 0, \quad (\xi > 0).$$

Then, $\psi(t; \xi)$ is periodic with minimal period $T(\xi) > 0$, $\lim_{\xi \to +\infty} T(\xi) = +\infty$, and

$$0 < \psi(t; \xi) < \xi, \quad \dot{\psi}(t, \xi) < 0 \text{ if } t \in \left(0, \frac{T(\xi)}{4}\right).$$

Fix $\xi_* > 0$ such that $T(\xi) > 4N\pi$ if $\xi \geq \xi_*$.

Proposition 5.1. *Assume that $r(t,e) \geq R$ for all t, and let $\varphi(t;\xi,e)$ be a solution of (2.1) satisfying (5.1). Then $|\xi| \leq \xi_*$.*

Proof. The equation of motion (2.1) is invariant under the symmetry $(z,t) \to (-z,-t)$. Therefore, we can assume that $\varphi(0;\xi,e) = \xi > 0$. Note that one can deduce from the equation that ξ is a local maximum of $\varphi(t;\xi,e)$. Also, by integrating the equation between 0 and $N\pi$, one deduces that $\varphi(t;\xi,e)$ changes sign in this interval. Let $\tau > 0$ be the first zero of $\varphi(t;\xi,e)$ in $[0,N\pi]$. We must have

$$\dot\varphi(t;\xi,e) < 0 \quad \text{for } t \in (0,\tau).$$

Otherwise, two consecutive critical points of $\varphi(t;\xi,e)$ should be maxima.

Set $\varphi = \varphi(t) = \varphi(t;\xi,e)$. For $t \in (0,\tau)$ we have

$$\frac{d}{dt}\left(\frac{1}{2}\dot\varphi^2 - \frac{1}{(\varphi^2+R^2)^{1/2}}\right) = \dot\varphi\left(-\frac{\varphi}{(\varphi^2+r^2)^{3/2}} + \frac{\varphi}{(\varphi^2+R^2)^{3/2}}\right) \leq 0,$$

and consequently

$$\frac{1}{2}\dot\varphi^2 - \frac{1}{(\varphi^2+R^2)^{1/2}} \leq -\frac{1}{(\xi^2+R^2)^{1/2}}.$$

For $t \in (0,\tau)$, φ is a solution of the differential inequality

$$\dot\varphi \geq -\sqrt{2}\left(\frac{1}{(\varphi^2+R^2)^{1/2}} - \frac{1}{(\xi^2+R^2)^{1/2}}\right)^{1/2}.$$

For $t \in \left(0, \frac{T(\xi)}{4}\right)$, $\psi(t) = \psi(t;\xi)$ satisfies the associated differential equation. In fact, $\psi(t)$ is the minimal solution of

$$\dot x = -\sqrt{2}\left(\frac{1}{(x^2+R^2)^{1/2}} - \frac{1}{(\xi^2+R^2)^{1/2}}\right)^{1/2}, \quad x(0) = \xi.$$

Therefore, the theory of differential inequalities implies that

$$\varphi(t) \geq \psi(t) \quad \text{if } 0 \leq t \leq \min\left\{\tau, \frac{T(\xi)}{4}\right\}.$$

From here we conclude that $\tau \geq T(\xi)/4$. Thus $N\pi > \tau \geq T(\xi)/4$, and so $\xi < \xi_*$. ∎

The previous proposition allows us to verify (H1) in each strip of the type $\mathbb{R}\times[0,E]$ with $E < 1$. In fact, if $e \in [0,E]$, then $r(t,e) \geq (1-E)/2$, and we can apply the previous result with $R = (1-E)/2$.

Toward assumption (H2). We want to study the zeros of $F_N(\cdot,0)$. This is equivalent to studying the solutions of

$$\ddot z = -\frac{z}{(z^2+\frac{1}{4})^{3/2}}, \quad \dot z(0) = \dot z(N\pi) = 0. \tag{5.2}$$

As we already mentioned, the solutions $\varphi(t;\xi,0)$ are periodic with minimal period $T(\xi)$, and $T(\xi)$ is an increasing function in ξ; see [5].

By the symmetry, $\varphi(t;\xi,0)$ with $\xi \neq 0$ is a solution of the boundary problem (5.2) if and only if there is an integer $p \geq 1$ such that $T(\xi)/2 = N\pi/p$.

Since $\inf T(\xi) = \pi/\sqrt{2}$ (see [5]), we have $2N\pi/p > \pi/\sqrt{2}$, and consequently $p < 2\sqrt{2}N$. Define $\nu = \nu_N = [2\sqrt{2}N]$, and let $\xi_1 > \cdots > \xi_\nu > 0$ be the solutions of $T(\xi)/2 = N\pi/p$ with $p = 1, \ldots, \nu$. Then

$$Z_0 = \{-\xi_1, \ldots, -\xi_\nu, 0, \xi_\nu, \ldots, \xi_1\}. \tag{5.3}$$

We compute the indices. Since $T = T(\xi)$ is increasing, we have that

$$\dot\varphi(N\pi;\xi,0) > 0 \quad \text{if } \xi < \xi_1 \text{ close to } \xi_1,$$
$$\dot\varphi(N\pi;\xi,0) < 0 \quad \text{if } \xi > \xi_1 \text{ close to } \xi_1.$$

From here, $\operatorname{ind}(F_N(\cdot,0),\xi_1) = -1$. In general,

$$\operatorname{ind}(F_N(\cdot,0),\xi_p) = (-1)^p. \tag{5.4}$$

The indices for $-\xi_p$ can be computed using the symmetry. We also compute the index at 0, although this information will not be employed in the rest of the paper. We do it by linearization; i.e.,

$$\operatorname{ind}(F_N(\cdot,0),0) = \operatorname{sign}\left(\frac{\partial F_N}{\partial \xi}(0;0)\right).$$

We note that $\frac{\partial F_N}{\partial \xi}(0;0) = \dot y(N\pi)$, where $y(t)$ is the solution of the variational problem

$$\ddot y + 8y = 0, \quad y(0) = 1, \quad \dot y(0) = 0.$$

So, we have

$$\operatorname{ind}(F_N(\cdot,0),0) = \operatorname{sign}\left(-\sin(2\sqrt{2}N\pi)\right) = (-1)^{\nu+1}.$$

To sum up: for $e = 0$ there exist $\nu = \nu_N = [2\sqrt{2}N]$ nontrivial, even, and $2N\pi$-periodic solutions of (5.2) with $z(0) > 0$. They can be labeled by the number of zeros of $z(t)$ in $[0, N\pi]$ for $p = 1, \ldots, \nu$ and

$$\varphi_1(0) = \xi_1 > \cdots > \varphi_\nu(0) = \xi_\nu.$$

Moreover, the index of each of these solutions, $\operatorname{ind}(F_N(\cdot,0),\xi_p)$, is ± 1.

We summarize our knowledge of the set Z. We have the trivial continuum $z = 0$, $e \in [0,1)$. Also, we have the solutions $(\xi_i, 0)$. Since the index is different from zero, there is at least a local branch emanating from them. Finally, we know that Z can only blow up as $e \uparrow 1$. We want to study the possible collisions of the branches emanating from ξ_i with the trivial continuum. To this end we linearize around $z = 0$.

6. Linearization around the equilibrium. The main objective of this section is to prove the next result.

Theorem 6.1. *Consider the boundary value problem*

$$\ddot y + \frac{1}{r(t,e)^3} y = 0, \quad \dot y(0) = \dot y(N\pi) = 0. \tag{6.1}$$

Then, there exists a sequence $\{E_{n,N}\}_{n\geq 1}$ *satisfying* $0 < E_{1,N} < \cdots < E_{n,N} < \cdots < 1$, *converging to* 1, *and such that there is a nontrivial solution of* (6.1) *if and only if* $e = E_{n,N}$. *Moreover,* $E_{1,N} > \rho_N$ *(*ρ_N *was defined in statement* (2) *of Theorem* 3.2*), and the solution* y_n *corresponding to* $E_{n,N}$ *has a number of zeros in* $[0, N\pi]$ *which becomes arbitrarily large as* $n \uparrow \infty$.

The linear differential equation (6.1) has been studied in detail in [28], and most of the statements above follow from their results. There is an alternative way of studying this equation. In fact, the change of the independent variable $u - e\sin u = t$ transforms (6.1) into

$$(1 - e\cos u)\frac{d^2y}{du^2} - e\sin u\frac{dy}{du} + 8y = 0.$$

Here we have used (2.2). This is a particular case of the so-called Ince's equation (see [27]), which has been studied by several authors. In particular, the techniques of [31] can probably be employed for the effective computation of the numbers $E_{n,N}$.

Let $y(t;e)$ be the solution of the equation appearing in (6.1) which satisfies $y(0) = 1$, $\dot{y}(0) = 0$. We study the zeros of $\dot{y}(N\pi, e) = 0$.

Proposition 6.2. *If* $e \leq \rho_N$, *then* $\dot{y}(N\pi, e) \neq 0$.

To prove Proposition 6.2 we need the following result, which is a well-known consequence of Sturm comparison theory (see [11] for more details).

Lemma 6.3. *Assume that* $a(t)$ *is continuous, is* $2N\pi$*-periodic, and for some* $n \geq 0$ *satisfies*

$$\left(\frac{n}{N}\right)^2 \leq a(t) \leq \left(\frac{n+1}{N}\right)^2 \quad \text{for all } t \in \mathbb{R},$$

and that both inequalities are strict somewhere. Then, $\ddot{y} + a(t)y = 0$ *has no* $2N\pi$*-periodic solutions (excepting* $y \equiv 0$*).*

In our case, if $e \leq \rho_N$, since $(1-e)/2 \leq r(t,e) \leq (1+e)/2$, we have

$$\left(\frac{\nu}{N}\right)^2 \leq \frac{8}{(1+e)^3} \leq \frac{1}{r(t,e)^3} \leq \frac{8}{(1-e)^3} \leq \left(\frac{\nu+1}{N}\right)^2.$$

Now, from Lemma 6.3, Proposition 6.2 follows.

Proposition 6.4. *The number of zeros of* $y(t;e)$ *in* $(0, N\pi)$ *tends to infinity as* $e \uparrow 1$.

Proof. First, we notice that $r(t,e)$ can be extended to $e = 1$. This extension is continuous in both variables and, in particular, $r(\cdot, e)$ converges uniformly to $r(\cdot, 1)$ as $e \uparrow 1$. Also, from $u - \sin u = t$ $(e = 1)$, we deduce that $u(t,1) = (6t)^{1/3}a(t)$, where a is continuous and $a(0) = 1$. Next

$$r(t,1) = \frac{1}{2}(1 - \cos u(t,1)) = \sin^2\frac{u(t,1)}{2} = \frac{6^{2/3}}{4}t^{2/3}b(t),$$

with b continuous and $b(0) = 1$. Thus,

$$\frac{1}{r(t,1)^3} = \frac{16}{9t^2b(t)^3}.$$

Let us fix a number γ in the interval $(1/4, 16/9)$. For $\Delta > 0$ small enough,

$$\frac{1}{r(t,1)^3} > \frac{\gamma}{t^2}, \quad t \in (0, \Delta].$$

Consider the Euler equation $\ddot{y}+\frac{\gamma}{t^2}y=0$. The solutions have infinitely many zeros accumulating at $t=0$ because $\gamma>1/4$. This can be checked by direct integration. Now, given an arbitrary $m\geq 1$, we can find $\delta\in(0,\Delta)$ such that the solutions of this Euler equation have at least $m+1$ zeros in the interval (δ,Δ). Since $r(\cdot,e)$ converges uniformly to $r(\cdot,1)$, it is possible to find $e_\star<1$ such that

$$\frac{1}{r(t,e)^3}>\frac{\gamma}{t^2},\quad t\in[\delta,\Delta],\ e\in[e_\star,1].$$

By Sturm comparison theory, $y(t,e)$ will have at least m zeros in $[\delta,\Delta]$. ■

Proof of Theorem 6.1. Changing (6.1) to polar coordinates $y=\rho\cos\theta$, $\dot{y}=\rho\sin\theta$, $\dot{y}(N\pi,e)=0$ becomes equivalent to $\theta(N\pi,e)\in\pi\mathbb{Z}$. The angle $\theta(t,e)$ satisfies

$$\dot{\theta}=-\frac{1}{r(t,e)^3}\cos^2\theta-\sin^2\theta.$$

Thus, $\theta(t,e)$ is decreasing in t. When e is close to 1, $\theta(t,e)\in\pi/2+\mathbb{Z}\pi$ for more and more positive t's in $[0,N\pi]$. This implies that

$$\theta(N\pi,e)=\inf_{t\in[0,N\pi]}\theta(t,e)\to-\infty$$

as $e\uparrow 1$. The function $e\in[0,1)\longmapsto\theta(N\pi,e)$ is analytic and $\lim_{e\uparrow1}\theta(N\pi,e)=-\infty$. The numbers $E_{n,N}$ are the solutions of $\theta(N\pi,e)\in\mathbb{Z}\pi$. ■

7. The conclusion. We need the following two lemmas.

Lemma 7.1. *Let $(z_n(t),e_n)$ be a sequence of solutions of* (2.1) *satisfying $\dot{z}_n(0)=\dot{z}_n(N\pi)=0$, $z_n(0)\to0$, $z_n(0)\neq0$, $e_n\to e_0<1$. Then, the number of zeros of $z_n(t)$ in $[0,N\pi]$ coincides, for large n, with the number of zeros in the same interval of the nontrivial solutions of*

$$\ddot{y}+\frac{1}{r(t,e_0)^3}y=0.$$

In particular, $e_0=E_{n,N}$ for some n.

Proof. By continuous dependence, $z_n(t)\to0$ uniformly in $[0,N\pi]$. Define $v_n(t)=z_n(t)/z_n(0)$. It satisfies

$$\ddot{v}_n+\frac{1}{(z_n(t)^2+r(t,e_n)^2)^{3/2}}v_n=0,\quad v_n(0)=1,\quad \dot{v}_n(0)=0.$$

Again, by continuous dependence $v_n(t)$ converges in $C^1[0,N\pi]$ to the solution $y(t)$ of

$$\ddot{y}+\frac{1}{r(t,e_0)^3}y=0,\quad y(0)=1,\quad \dot{y}(0)=0.$$

Since $\dot{v}_n(0)=\dot{v}_n(N\pi)=0$, we have $\dot{y}(0)=\dot{y}(N\pi)=0$. Thus, all the zeros of $y(t)$ in $[0,N\pi]$ are in its interior. Since $v_n\to y$, $\dot{v}_n\to\dot{y}$ uniformly, and all the zeros of $y(t)$ are nondegenerate (i.e., $y(\tau)=0$ and $\dot{y}(\tau)\neq0$), for large n we deduce that $v_n(t)$ and $y(t)$ have the same number of zeros. ■

Lemma 7.2. *Let $\{x_\lambda(t)\}_{\lambda\in[0,1]}$ be a family of functions in $C^1[0,T]$ satisfying the following:*

(i) $x_\lambda(0) \neq 0$, $x_\lambda(T) \neq 0$ *for all* $\lambda \in [0,1]$.
(ii) *The zeros of* x_λ *are nondegenerate (i.e.,* $x_\lambda(t)^2 + \dot{x}_\lambda(t)^2 > 0$ *everywhere).*
(iii) *The map* $(t,\lambda) \in [0,T] \times [0,1] \longmapsto (x_\lambda(t), \dot{x}_\lambda(t))$ *is continuous.*

Then, the number of zeros of x_λ *in* $[0,T]$ *is independent of* λ.

Proof. The lemma follows from the fact that the number of zeros is locally constant. This is easy because functions which are C^1 close and have nondegenerate zeros have the same number of zeros. ∎

Proof of Theorem 3.1. From the discussions of section 5 we know that searching for $z(t)$, even and $2N\pi$-periodic solution of (2.1), is equivalent to finding a root of the equation

$$F_N(z_0, e) = 0 \quad (z_0 = z(0)).$$

In this way we are lead to the framework of section 4 and we shall apply Theorem 4.4 with $F = F_N$. The parameter λ is now the eccentricity and $[a,b] = [0, 1-\epsilon]$. Let us check that (H1) and (H2) hold. The first condition follows from Proposition 5.1 and the discussion after its proof. To deal with (H2) we recall the information obtained in section 5 about the set Z_0, as given by (5.3). There is a unique $\xi_p \in Z_0 \cap (0,\infty)$ with $T(\xi_p)/2 = N\pi/p$. Here we are using $p \leq \nu$. We know from (5.4) that the index of $F_N(\cdot, 0)$ at ξ_p is different from zero and so (H2) holds for $x_0 = \xi_p$. At this moment it is important to observe that the solution of (2.5) with $z(0) = \xi_p$, $\dot{z}(0) = 0$ is even and $2N\pi$-periodic and has exactly p zeros in $[0, N\pi]$. From Theorem 4.4 we infer the existence of a continuous family $\{(\xi(s), e_s)\}_{s\in[0,1]}$ in $\mathbb{R} \times [0, 1-\epsilon]$ such that

$$F_N(\xi(s), e_s) = 0, \quad \xi(0) = \xi_p, \quad e_0 = 0,$$

and either

$$e_1 = 1 - \epsilon \tag{7.1}$$

or

$$e_1 = 0, \quad \xi(1) \neq \xi_p. \tag{7.2}$$

Let $z_s(t)$ denote the solution of (2.1) for $e = e_s$ which satisfies $z_s(0) = \xi(s)$, $\dot{z}_s(0) = 0$. The family $\{(z_s(t), e_s)\}_{s\in[0,1]}$ satisfies conditions (1) and (2) of Theorem 3.1, but there are no a priori reasons to suppose that it also satisfies (3). We distinguish two cases.

Case 1. $z_s(0) > 0$ for all $s \in [0,1]$.

Lemma 7.2 implies that $z_s(t)$ has p zeros in $[0, N\pi]$ for each $s \in [0,1]$. This proves that (3) also holds. Assuming now that the first alternative (7.1) holds, we arrive at the searched family satisfying (4.a). The second alternative (7.2) cannot occur, for otherwise $e_1 = 0$ and $\xi(1) \neq \xi_p$. Then, since $\xi(1)$ belongs to $Z_0 \cap (0,\infty)$, we deduce that $\xi(1) = \xi_q$ for some $q \neq p$. This would imply that $z_1(t)$ has q zeros in $[0, N\pi]$, a situation which would be incompatible with (3).

Case 2. $z_s(0)$ vanishes for some $s \in [0,1]$.

Let $\sigma \in (0,1]$ be the first zero of $z_s(0)$, so that

$$z_s(0) > 0 \quad \text{if } s \in [0,\sigma),\ z_\sigma(0) = 0.$$

The family $\{(\hat{z}_s, \hat{e}_s)\}_{s\in[0,1)}$, with $\hat{z}_s = z_{s\sigma}$ and $\hat{e}_s = e_{s\sigma}$, satisfies (3). Again Lemma 7.2 has been used. The definition of σ implies that $\lim_{s\to 1^-} \hat{e}_s = e_\sigma \in [0, 1-\epsilon]$ and $\hat{z}_s(t)$ converges to 0 as $s \to 1^-$. Finally, we apply Lemma 7.1 to conclude that $e_\sigma = E_{n,N}$ for some n. Moreover, nontrivial solutions of (6.1) for $e = e_\sigma$ must have p zeros in $[0, N\pi]$. In this way we have constructed a family satisfying (4.b), and the theorem is proven. ■

Proof of Theorem 3.2. Since $r(t, e_s) < 1$ everywhere, we can apply the Sturm comparison theory to the equation appearing in (6.1) and to $\ddot{y} + y = 0$, to deduce that the solutions of (6.1) must have at least N zeros in the interval $[0, N\pi]$. So, if $p < N$, statement (4.b) does not hold. Therefore, statement (1) of Theorem 3.2 is proved.

If $e \le \rho_N$, Proposition 6.2 says that (6.1) has no periodic solutions different from the trivial one. So, statement (2) of Theorem 3.2 follows. ■

Proof of Theorem 3.3. We shall prove statement (1) by contradiction. Assume the existence of $\sigma \in [0, 1)$ such that $z_\sigma(0) = z^*_\sigma(0)$ and $e_\sigma = e^*_\sigma$. Since we know that $\dot{z}_\sigma(0) = \dot{z}^*_\sigma(0) = 0$, by uniqueness, z_σ and z^*_σ are the same periodic solution. This solution has periods $2\pi M$ and $2\pi N$, having q zeros in $[0, M\pi]$ and p zeros in $[0, N\pi]$. Let $2\pi s$ be the minimal period of this solution. Then, there are integers m_1 and m_2 such that $sm_1 = M$ and $sm_2 = N$. Let r be the number of zeros of z_σ in $[0, s\pi]$. Therefore, $m_1 r = q$ and $m_2 r = p$. So, $M/q = N/p$, which is a contradiction. Consequently, statement (1) is proved.

Statements (2) and (3) follow from (1) and the fact that $z^*_0(0) > z_0(0)$. ■

In short, using the global continuation method of the zeros of a function depending on one parameter due to Leray and Schauder and based in the Brouwer degree, we have studied analytically the families of symmetric periodic orbits of the elliptic Sitnikov problem for all values of the eccentricity in the interval $[0, 1)$, providing qualitative and quantitative information on the bifurcation diagram of such families of periodic orbits. The quantitative information mainly is on the periods of the periodic orbits and on some estimations where the different families of periodic orbits can start or end. The precise statements of these results are in Theorems 3.1, 3.2, and 3.3.

Freezing Multipulses and Multifronts*

Wolf-Jürgen Beyn†, Sabrina Selle†, and Vera Thümmler†

Abstract. We consider nonlinear time dependent reaction diffusion systems in one space dimension that exhibit multiple pulses or multiple fronts. In an earlier paper two of the authors developed the freezing method that allows us to compute a moving coordinate frame in which, for example, a traveling wave becomes stationary. In this paper we extend the method to handle multifronts and multipulses traveling at different speeds. The solution of the Cauchy problem is decomposed into a finite number of single waves, each of which has its own moving coordinate system. The single solutions satisfy a system of partial differential algebraic equations coupled by nonlinear and nonlocal terms. Applications are provided to the Nagumo and the FitzHugh–Nagumo systems. We justify the method by showing that finitely many traveling waves, when patched together in an appropriate way, solve the coupled system in an asymptotic sense. The method is generalized to equivariant evolution equations and is illustrated by the complex Ginzburg–Landau equation.

Key words. multipulses, partial differential algebraic equations, unbounded domains, equivariance, Lie groups

1. Introduction.

Consider a parabolic system for a function $u(x,t) \in \mathbb{R}^m$ on the real line

$$u_t = Au_{xx} + f(u, u_x), \quad x \in \mathbb{R},\ t \geq 0, \quad u(x,0) = u_0(x), \quad x \in \mathbb{R}, \tag{1.1}$$

where $A \in \mathbb{R}^{m,m}$ is assumed to be positive definite and $f : \mathbb{R}^{2m} \to \mathbb{R}^m$ is assumed to be smooth. We are interested in systems that have more than one traveling wave solution

$$u_j(x,t) = w_j(x - c_j t), \quad j = 1, \ldots, N, \tag{1.2}$$

traveling at different speeds c_j and with limiting behavior

$$w_j^- = \lim_{\xi \to -\infty} w_j(\xi), \quad w_j^+ = \lim_{\xi \to \infty} w_j(\xi). \tag{1.3}$$

It is frequently observed that such systems exhibit special solutions that look like a superposition of several waves. In Figure 1 we illustrate the case of two pulses and two fronts that travel in opposite directions ($c_1 < 0 < c_2$) and that can be patched together (i.e., $w_1^+ = w_2^-$); see section 2 for a more precise definition of the meaning of patching. Solutions of this type are usually called multifronts or multipulses depending on whether the limits at $\pm\infty$ agree

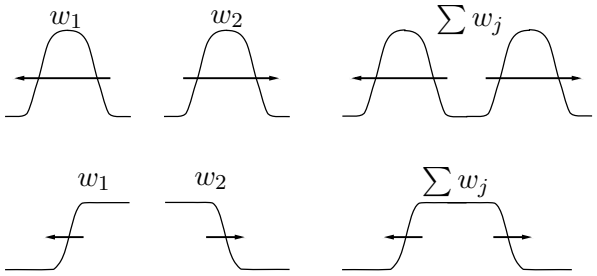

Figure 1. *Single pulses/multipulse and single fronts/multifront.*

or disagree. There is quite an extensive literature that studies existence and stability of multifronts and multipulses close to a fixed pulse configuration with the single pulses far apart and with a common speed; see [15], [13], [14], [16], [22], [7]. More recently, in [23] a center manifold is constructed that contains all types of multipulses (even infinitely many) with large spacings that travel at a slowly varying speed.

In this paper we consider a finite number of pulses, respectively, fronts, that travel at different speeds. We provide a working definition for multifront solutions in an asymptotic sense that will be sufficient for our approach. Note that in the recent paper [17] the authors construct an invariant manifold that contains and attracts such solutions up to a certain time instance prior to collision.

The main goal of this paper is to numerically construct a decomposition of the solution $u(x,t)$ of the Cauchy problem (1.1) of the form

$$u(x,t) = \sum_{j=1}^{N} v_j(x - g_j(t), t). \tag{1.4}$$

The idea is to find functions $v_j : \mathbb{R} \times [0,\infty) \to \mathbb{R}^m$, $(\xi,t) \mapsto v_j(\xi,t)$ that approximate the jth profile in the multifront and that have a rather local support when compared to the overall solution $u(x,t)$. The functions $g_j : \mathbb{R} \to \mathbb{R}$ denote the time-dependent position of the jth profile and will be determined by the numerical process as well. The N-dimensional system that determines the v_j will be set up such that the linear superposition (1.4) is an exact solution of the nonlinear system (1.1) and such that this system can be solved on a much smaller domain than the original equation. Note that, if repelling pulses or fronts appear as in Figure 1, growing spatial domains are needed to compute and represent the solution of (1.1), while our system will be solved on a domain of moderate size that stays constant for all times. Moreover, our method will produce the individual velocities automatically without any a posteriori analysis of simulation data.

We follow the freezing approach for single waves in [4], [5] (see [12] for a related approach) by setting up an appropriate phase condition for each of the single profiles v_j. In section 2 we derive the basic system of N partial differential algebraic equations (PDAEs) for the functions v_j that will be solved numerically. The nonlinearities in this system contain nonlocal terms due to the different positions of the single profiles.

For the numerical computations we truncate this system to a finite interval, use appropriate boundary conditions, and discretize by finite elements in space and BDF methods (based on

backward differentiation formulae) in time. In section 3 we show several applications of our method to multifronts that occur in the Nagumo and in the FitzHugh–Nagumo systems. It may come as a surprise that the method even works in cases for which it was not designed, namely, fronts or pulses that collide and annihilate each other.

In section 4 we give a certain theoretical justification of our method. It is shown that appropriately modified waves (1.2) satisfy the PDAE system in an asymptotic sense.

Finally, in section 5 we generalize our "decompose and freeze" approach to general evolution equations that are equivariant with respect to the action of a (not necessarily compact) Lie group. As an application we discuss the decomposition of solutions of a complex Ginzburg–Landau equation that has a two-dimensional group of equivariances.

2. Decomposition of multifronts. Let us be more precise about the process of patching single waves (1.2). Assume that the left and right limits of the waves match in the sense that

$$w_j^+ = w_{j+1}^-, \quad j = 1, \dots, N-1. \tag{2.1}$$

Then we write down the superposition

$$U(x,t) = \sum_{j=1}^{N} \hat{w}_j(x - c_j t), \quad \hat{w}_j(\xi) = \begin{cases} w_1(\xi), & j = 1, \\ w_j(\xi) - w_j^-, & j \geq 2, \end{cases} \tag{2.2}$$

where we have subtracted the left limits so that the modified profiles $\hat{w}_j$ (cf. Figure 2) fit together upon summation. In particular, this guarantees by (2.1)

$$\lim_{x \to \infty} u(x,t) = \sum_{j=1}^{N} w_j^+ - \sum_{j=2}^{N} w_j^- = w_N^+. \tag{2.3}$$

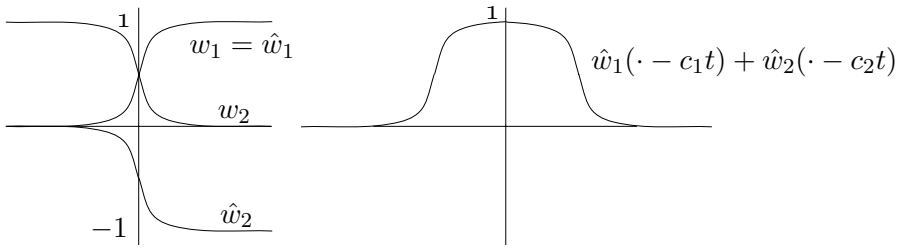

Figure 2. *The modified profiles $\hat{w}_j$, and asymptotic 2-front solution $\hat{w}_1(x - c_1 t) + \hat{w}_2(x - c_2 t)$ at $t > 0$, $c_1 < 0 < c_2$.*

In section 4 we will show that $U(x,t)$ defined by (2.2) satisfies (1.1) in an asymptotic sense, i.e.,

$$\|U_t - (AU_{xx} + f(U, U_x))\| \to 0 \quad \text{as } t \to \infty \tag{2.4}$$

for some suitable norm $\|\cdot\|$, e.g., the $\mathcal{L}_2$-norm.

Our goal is to set up a decomposition (1.4) that approaches the form (2.2) in an asympotic sense.

We use a bump function $\varphi \in C^\infty(\mathbb{R}, \mathbb{R})$ that satisfies

$$0 < \varphi(x) \le C \quad \forall x \in \mathbb{R} \tag{2.5}$$

and has its main mass located near zero. The precise form of φ is not important, but we mention that both numerical computation and the theory in section 4 work for exponential decay of type $\varphi(t) \asymp e^{-\beta|x|^k}$, $\beta > 0$, $k \ge 1$.

We look for a solution of the form (1.4) and insert this into (1.1). We suppress the arguments $(x - g_j(t), t)$ of v_j and find

$$\begin{aligned} u_t &= \sum_{j=1}^N [v_{j,t} - v_{j,\xi} g_{j,t}] \\ &= \sum_{j=1}^N A v_{j,\xi\xi} + f\left(\sum_{k=1}^N v_k, \sum_{k=1}^N v_{k,\xi}\right) \\ &= \sum_{j=1}^N \left[A v_{j,\xi\xi} + \frac{\varphi(\cdot - g_j(t))}{\sum_{k=1}^N \varphi(\cdot - g_k(t))} f\left(\sum_{k=1}^N v_k, \sum_{k=1}^N v_{k,\xi}\right)\right]. \end{aligned} \tag{2.6}$$

Note that the quotients

$$\frac{\varphi(x - g_j(t))}{\sum_{k=1}^N \varphi(x - g_k(t))} \tag{2.7}$$

form a time-dependent partition of unity and that the denominator never vanishes due to (2.5). In (2.6) we have used this partition to localize the nonlinear part of the vector field but not the solutions themselves.

A sufficient condition for (2.6) to hold is that each of the terms in brackets vanishes. Substituting $\xi = x - g_j(t)$ and $\mu_j = g_{j,t}$ leads to the following system of N coupled PDEs for $\xi \in \mathbb{R}$, $t \ge 0$,

$$\begin{aligned} v_{j,t}(\xi, t) = A v_{j,\xi\xi}(\xi, t) + v_{j,\xi}(\xi, t)\mu_j(t) + \frac{\varphi(\xi)}{\sum_{k=1}^N \varphi(\xi - g_k + g_j)} \\ \cdot f\left(\sum_{k=1}^N v_k(\xi - g_k + g_j, t), \sum_{k=1}^N v_{k,\xi}(\xi - g_k + g_j, t)\right), \quad j = 1, \dots, N, \end{aligned} \tag{2.8}$$

and the simple set of ODEs

$$g_{j,t} = \mu_j(t), \quad j = 1, \dots, N. \tag{2.9}$$

In the following it will be convenient to write $v = (v_1, \dots, v_N)$, $g = (g_1, \dots, g_N)$, and $\mu = (\mu_1, \dots, \mu_N)$ and to abbreviate terms in (2.8):

$$\begin{aligned} F_j(v, g)(\xi, t) &= Q_j^g(\xi, t) f\left(\sum_{k=1}^N v_k(\xi_{kj}^g, t), \sum_{k=1}^N v_{k,\xi}(\xi_{kj}^g, t)\right), \\ Q_j^g(\xi, t) &= \frac{\varphi(\xi)}{\sum_{k=1}^N \varphi(\xi_{kj}^g)}, \qquad \xi_{kj}^g = \xi - g_k(t) + g_j(t). \end{aligned} \tag{2.10}$$

Figure 3. *Decomposition of the initial data u_0.*

We note that the nonlinear terms $F_j(v, g)$ couple the single functions v_k, $k = 1, \dots, N$, in a nonlocal fashion. From the derivation we also see that one can allow j-dependent bump functions φ_j that take the size of the jth profile into account. The quotient in (2.7) then reads

$$\frac{\varphi_j(x - g_j(t))}{\sum_{k=1}^N \varphi_k(x - g_k(t))}. \tag{2.11}$$

The system will be completed by initial conditions for v_j, g_j and by phase conditions that compensate for the extra unknowns μ_j.

We impose initial conditions

$$v_j(\xi, 0) = v_j^0(\xi), \quad \xi \in \mathbb{R},\ j = 1, \dots, N, \tag{2.12}$$

$$g_j(0) = g_j^0, \quad j = 1, \dots, N, \tag{2.13}$$

that should satisfy

$$u_0(x) = \sum_{j=1}^N v_j^0(x - g_j^0), \quad x \in \mathbb{R}. \tag{2.14}$$

In most of our applications below we first select v_j^0, g_j^0 and then define u_0 by (2.14). If, on the other hand, u_0 is given, then one has to do some surgery to find appropriate values for v_j^0 and g_j^0. Assume, for example, that a function u_0 is given that forms plateaus near points $x_0 < x_1 < \dots, x_N$ (see Figure 3). Then one may choose $g_j^0 = \frac{1}{2}(x_{j-1} + x_j)$ for $j = 1, \dots, N$ and, similar to (2.2), define

$$v_j^0(\xi) = -u_0(x_{j-1}) + \begin{cases} u_0(x_{j-1}), & \xi + g_j^0 \le x_{j-1}, \\ u_0(\xi + g_j^0), & x_{j-1} \le \xi + g_j^0 \le x_j, \\ u_0(x_j), & x_j \le \xi + g_j^0, \end{cases} \qquad j = 2, \dots, N-1,$$

and

$$v_1^0(\xi) = \begin{cases} u_0(\xi + g_1^0), & \xi + g_1^0 \le x_1, \\ u_0(x_1), & x_1 \le \xi + g_1^0, \end{cases}$$

$$v_N^0(\xi) = \begin{cases} 0, & \xi + g_N^0 \le x_{N-1}, \\ u_0(\xi + g_N^0) - u_0(x_{N-1}), & x_{N-1} \le \xi + g_N^0. \end{cases}$$

Next we discuss the choice of phase condition that will make the solution of the system (2.8), (2.9), (2.13), (2.14) unique. For the case of freezing single waves, two possibilities were suggested in [4], [5].

First, suppose that we have template functions $\hat{v}_j$ (e.g., $\hat{v}_j = v_j^0$) to which we would like the v_j to stay as close as possible. This requires the distance $d_j(g) = \|v_j(\cdot,t) - \hat{v}_j(\cdot - g)\|_{\mathcal{L}^2}$ to achieve its minimum at $g = 0$ for all times. Differentiating with respect to g yields the necessary conditions

$$\langle v_j - \hat{v}_j, \hat{v}_{j,\xi} \rangle_{\mathcal{L}^2} = 0, \quad j = 1, \dots, N. \tag{2.15}$$

In the terminology of differential algebraic equations this constraint leads to an index 2 problem. If we differentiate (2.15) with respect to t and use (2.8), we have

$$\psi_{\mathrm{fix}}(v,\mu) = (\mu_j \langle \hat{v}_{j,\xi}, v_{j,\xi} \rangle_{\mathcal{L}^2} + \langle \hat{v}_{j,\xi}, A v_{j,\xi\xi} + F_j(v,g) \rangle_{\mathcal{L}^2})_{j=1}^N = 0. \tag{2.16}$$

If $\langle \hat{v}_{j,\xi}, v_{j,\xi} \rangle_{\mathcal{L}^2} \neq 0$, then we can determine μ_j from this equation and thus have reduced the problem to index 1.

Second, choose the values μ_j so that $v_{j,t}$ in (2.8) is minimized at each time instance. Geometrically this requires that the time derivative $v_{j,t}(\cdot,t)$ is orthogonal to the group orbit $\{v_j(\cdot - g, t) : g \in \mathbb{R}\}$ at all times. This leads to the phase condition

$$\psi_{\mathrm{orth}}(v,\mu) = (\langle v_{j,\xi}, v_{j,t} \rangle_{\mathcal{L}^2})_{j=1}^N = (\langle v_{j,\xi}, A v_{j,\xi\xi} + \mu_j v_{j,\xi} + F_j(v,g) \rangle_{\mathcal{L}^2})_{j=1}^N = 0, \tag{2.17}$$

which allows us to solve for μ_j whenever $v_{j,\xi}$ is nonconstant. Note that (2.17) can be obtained from (2.16) when replacing $\hat{v}_{j,\xi}$ by $v_{j,\xi}$. The complete system to be solved is now given by the PDAE (2.8), (2.9), (2.12), (2.13) with either (2.16) or (2.17) as phase condition.

The relative merits of both types of conditions have been discussed for the single freezing in [4], [20]. It was shown in [20], [19] that the fixed phase condition leads to a well-posed PDAE in the neighborhood of a relative equilibrium in one space dimension. Moreover, the PDAE as well as its discretization on a finite interval have the wave and its velocity as an asymptotically stable steady state in the classical Lyapunov sense. In [5] we have shown that this pertains on the continuous level to the orthogonality constraint (2.17). Locally near relative equilibria there is not much of a difference between both conditions. It is hard to make a general statement for more global situations, when the initial data are far from any equilibrium. Generally, the orthogonality condition is more flexible globally since it requires no preknowledge of the solution, whereas the fixed phase condition tends to lead to PDAEs with a better conditioning.

We conclude with some remarks concerning the numerical solution of the PDAE system. In section 3 we will discretize the PDAE as a whole by conventional methods. It is clear that the effort of solving the system grows linearly with the number of pulses or fronts present in the solution. On the other hand, in contrast to the original equation, one can solve the PDAE system on a fixed and relatively small spatial domain. So far, the interaction terms

that need values outside this domain were calculated by extrapolating with constant boundary values. One may think of reducing the spatial domain further by solving linearized equations (explicitly) in the outside domain and using this for calculating the interaction. We have not yet pursued the details of such an extension. A method of this type will be reminiscent of the vortex blob method in fluid dynamics (see [2], [8]), which follows moving vortices and then uses the Biot–Savart law for treating interactions.

3. Applications. We illustrate the method on two examples which possess traveling fronts and pulses—the Nagumo and the FitzHugh–Nagumo equations—which both model nerve conduction.

For two components the PDAE (2.8), (2.9) with the phase fixing condition (2.16) reads

$$
\begin{aligned}
v_{1,t} &= Av_{1,\xi\xi} + v_{1,\xi}\mu_1(t) + \frac{\varphi(\cdot)}{\varphi(\cdot)+\varphi(\cdot - g_2 + g_1)} f(v_1(\cdot,t) + v_2(\cdot - g_2 + g_1, t)),\\
v_{2,t} &= Av_{2,\xi\xi} + v_{2,\xi}\mu_2(t) + \frac{\varphi(\cdot)}{\varphi(\cdot)+\varphi(\cdot - g_1 + g_2)} f(v_2(\cdot,t) + v_1(\cdot - g_1 + g_2, t)),\\
0 &= \langle v_1(\cdot,t) - \hat{v}_1, \hat{v}_{1,\xi}\rangle, \qquad 0 = \langle v_2(\cdot,t) - \hat{v}_2, \hat{v}_{2,\xi}\rangle,\\
g_{1,t} &= \mu_1(t), \qquad g_{2,t} = \mu_2(t),
\end{aligned}
\tag{3.1}
$$

with initial conditions (2.12), (2.13) that will be specified below.

To solve (3.1) numerically we restrict to a finite interval $[-L, L]$ and impose Dirichlet or Neumann boundary conditions. Then we use the finite element package Comsol Multiphysics$^{\text{TM}}$ [6] with second order elements in space and a BDF method in time. As a bump function we first set $\varphi(x) = \exp(-x^2/\alpha)$ with suitable α. Later we see that the computations prove to be quite robust with respect to the choice of φ.

Whenever the nonlocal terms in the nonlinearity f have to be evaluated at arguments outside the computational domain, we extrapolate with the boundary values $v_j(\pm L)$. Inside $[-L, L]$ we use linear interpolation. As in the case of freezing single waves, we cannot expect the solutions $v_j(\cdot, t)$ to converge to $\hat{w}_j$ from (3.1) but rather to an approximation $\hat{w}_j^L$ that solves the stationary boundary value problem on $[-L, L]$.

3.1. Nagumo equation. A simple example is the scalar Nagumo equation [3]

$$
u_t = u_{xx} + u(1-u)(u-a), \quad u(x,t) \in \mathbb{R},\ x \in \mathbb{R},\ t > 0,
\tag{3.2}
$$

where $a \in (0, \frac{1}{2})$.

It has explicit traveling waves connecting the stationary points $w_1^- = w_2^+ = 0$ and $w_1^+ = w_2^- = 1$:

$$
\begin{aligned}
w_1(\xi) &= \frac{1}{1+\exp(\frac{-\xi}{\sqrt{2}})}, \quad c_1 = \sqrt{2}\,(a - \tfrac{1}{2}),\\
w_2(\xi) &= \frac{1}{1+\exp(\frac{\xi}{\sqrt{2}})}, \quad c_2 = -\sqrt{2}\,(a - \tfrac{1}{2}).
\end{aligned}
\tag{3.3}
$$

In addition, there exists a multitude of other solutions which can be computed explicitly [1].

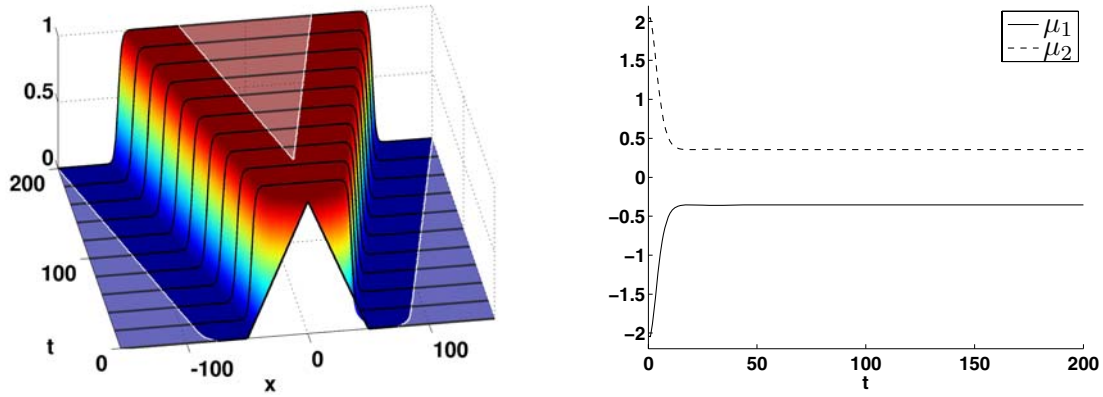

Figure 4. *Fronts moving in opposite directions in the Nagumo equation, and evolution of superposition u_c and velocities μ_1, μ_2.*

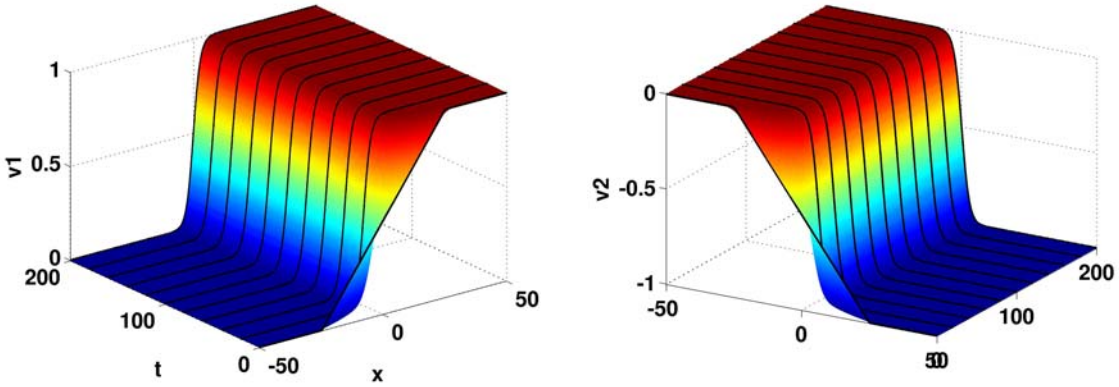

Figure 5. *Fronts moving in opposite directions in the Nagumo equation, and evolution of frozen fronts v_1, v_2.*

We use $a = \frac{1}{4}$, the spatial stepsize $\Delta x = 0.1$, and $\hat{v}_1 = v_1^0$, $\hat{v}_2 = v_2^0$ as template functions for the phase fixing condition. As bump function we take $\varphi(\xi) = \exp(x^2/\alpha)$, where the parameter $\alpha = 20$ is chosen such that the function is localized around the region of interest (see Figure 7). This setting will be used for all computations with the Nagumo equation, unless indicated otherwise.

In Figures 4 and 5 we show the result of a computation starting with initial data v_1^0, v_2^0, g_1^0, g_2^0 that add up to a hat function u^0 via the superposition (2.14). For the numerical solution on the finite interval $[-L, L]$, $L = 50$ we use Dirichlet boundary conditions

$$v_1(-L,t) = w_1^- = 0,\ v_2(-L,t) = 0,\ v_1(L,t) = w_1^+ = 1,\ v_2(L,t) = w_2^+ - w_2^- = -1.$$

Figure 4 displays the sum (1.4),

$$u_c(x,t) = v_1(x - \gamma_1(t), t) + v_2(x - \gamma_2(t), t), \tag{3.4}$$

while Figure 5 shows the components v_1 and v_2. The darker shaded regions indicate the two moving intervals $\gamma_j(t) + [-L, L]$, $j = 1, 2$, where u_c uses the computed values of v_1 or v_2, whereas the lighter shaded regions use exclusively the extrapolated boundary values of v_1 and v_2. After a short transient period the components v_1, v_2 and the velocities μ_1, μ_2 become stationary with opposite values resulting in a broadening plateau for u. The slopes of the plateau travel at speeds $\mu_1 = -\mu_2$ in opposite directions.

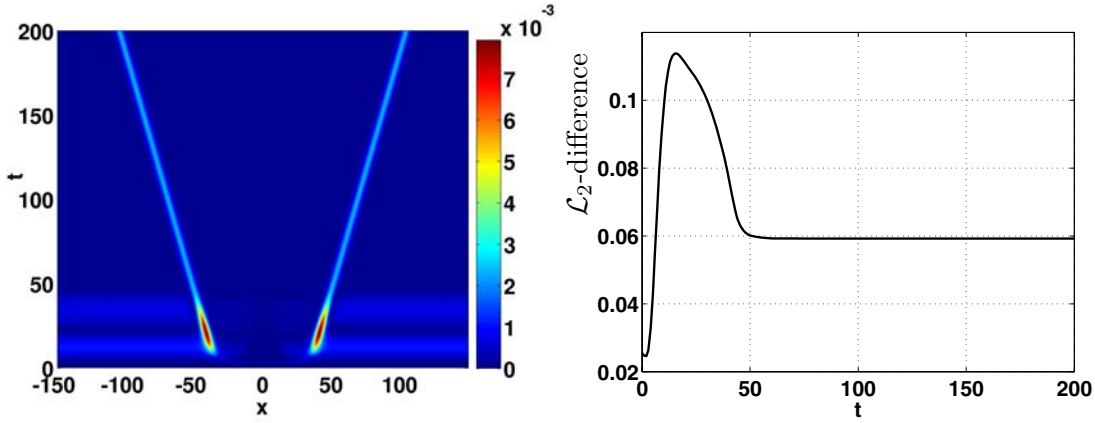

Figure 6. *Nagumo equation: Difference of traveling plateau and superposition of frozen fronts.*

For comparison, we show in Figure 6 the pointwise difference $|u_{\rm dns}(x,t) - u_c(x,t)|$ and the $\mathcal{L}_2$ difference $\|u_{\rm dns}(\cdot,t) - u_c(\cdot,t)\|_{\mathcal{L}_2}$ between the function u_c and a solution $u_{\rm dns}$ that is obtained by solving (3.2) directly on a sufficiently large interval.

There is very good agreement of the two solutions except in two thin layers close to the two fronts. Note that such errors cannot be corrected by a single phase shift, and, therefore, the $\mathcal{L}_2$- error becomes asymptotically constant; see Figure 6 (right) and (3.6) below. For the individual solutions v_j of (3.1) we expect in suitable norms

$$v_j(\cdot,t) - \hat{w}_j(\cdot - \tau_j) \to 0, \quad \mu_j(t) \to c_j \quad \text{as } t \to \infty,\ j = 1, 2. \tag{3.5}$$

Since we do not use the given profiles (3.3) for the phase condition, we can expect only convergence toward $\hat{w}_j(\cdot - \tau_j)$ for some suitable time shift τ_j. This shift is determined by the phase condition in (3.1), i.e., $\langle \hat{w}_j(\cdot - \tau_j) - \hat{v}_j, \hat{v}_{j,\xi} \rangle = 0$. From the last equation in (3.5) we then obtain

$$g_j(t) - (c_j t + g_j^0) \to \tau_j \quad \text{as } t \to \infty.$$

Therefore, our numerical calculation suggests that the exact solution $u_{\rm dns}$ of (3.2) satisfies in a suitable norm

$$u_{\rm dns}(\cdot,t) - \big(\hat{w}_1(\cdot - c_1 t - g_1^0 - \tau_1) + \hat{w}_2(\cdot - c_2 t - g_2^0 - \tau_2)\big) \to 0 \quad \text{as } t \to \infty \tag{3.6}$$

provided the difference of initial positions $g_2^0 - g_1^0$ is sufficiently large and the difference of initial values $u_{\rm dns}(\cdot,0) - \big(\hat{w}_1(\cdot - g_1^0) + \hat{w}_2(\cdot - g_2^0)\big)$ is sufficiently small. A proof of such a result is a work in progress.

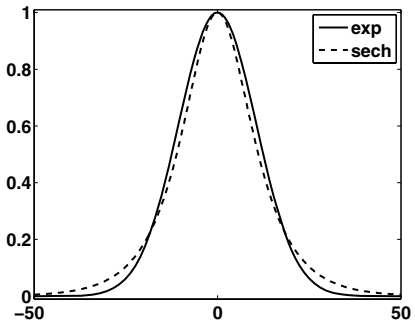

Figure 7. *Comparison of functions* $\varphi(x) = \exp(-x^2/\alpha)$ *and* $\varphi(x) = \operatorname{sech}(-x/\beta)$ *with equal integral.*

In Figure 8 we show the behavior of time derivatives $\|u_t\|$ and $\|\mu_t\|$ (left) including a comparison of $\|u_t\|$ for different bump functions (right). The second function is $\varphi(\xi) = \operatorname{sech}(x/\beta)$, where β is chosen such that the integrals of both functions over $\mathbb{R}$ coincide; see Figure 7. For a certain time interval the rate of decay is the same for both bump functions. From the numerical data one finds the slope 0.25 which coincides with the spectral gap between zero and the smallest negative eigenvalue of the linearization about the single traveling waves w_1 and w_2. This relation was verified in [20], [19] for the case of freezing a single wave. For larger times t the decay is better for the Gaussian $\varphi(x) = \exp(-x^2/\alpha)$ than for the sech-function. The effect vanishes on larger computational domains where both functions are sufficiently localized.

In the second numerical experiment we consider a situation that, in a sense, is opposite to the first case; see Figures 9 and 10. We start with a downward hat function and obtain two fronts traveling toward each other with opposite speeds. Eventually they annihilate each other resulting in a value of zero for the speeds μ_1, μ_2. In Figure 10 one can observe slight disturbances in v_1, v_2 during the strong interaction at collision. Note that after the collision the superposition (1.4) yields a constant, although the components v_1, v_2 cannot become constant due to Dirichlet boundary conditions. Rather, the asymptotic state of our system is formed by two ramp functions that are at rest and add up to a constant; see Figure 10. As before we observe a phase shift difference when comparing this with the solution of (3.2) on a large interval; see

Figure 11. But in this case the difference converges to zero as the constant solution is approached. Similar results are obtained for Neumann boundary conditions.

In Figures 12 and 13 we consider a case where a two-front turns into a single front. This is a case where the number N of components in our ansatz is larger than the number of components which constitute the final solution. This does not create any problems for our method. We use boundary conditions that do not require any a priori knowledge of the limiting stationary points for the components v_1 and v_2. Instead of prescribing $v_1^{\pm}$ and $v_2^{\pm}$ directly, we require $v_1^- + v_2^- = w^-$ and $v_1^+ + v_2^+ = w^+$ and impose Neumann boundary conditions at the remaining ends. If one insists on Dirichlet boundary conditions for every single wave, then additional boundary layers will develop.

In the current example the wave behind has a larger speed and merges with the first wave.

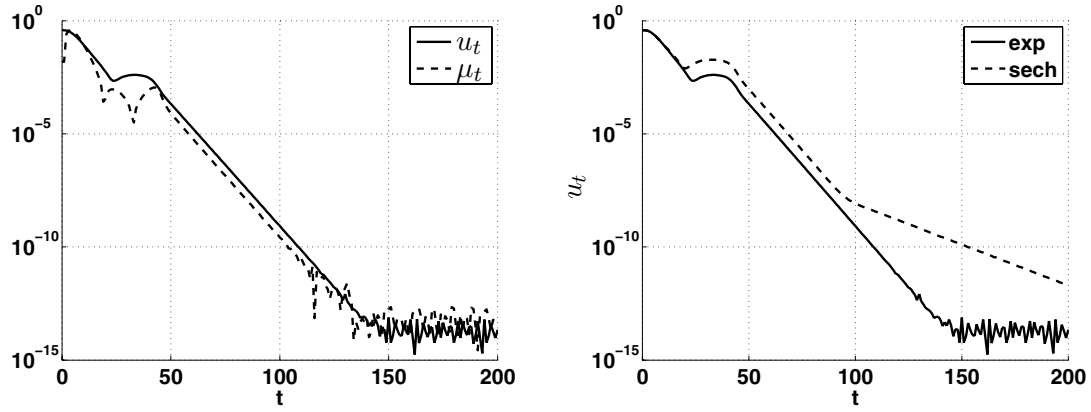

Figure 8. *Nagumo equation:* $\|u_t\|$ *and* $\|\mu_t\|$ *(on a logarithmic scale) versus time and* $\|u_t\|$ *(on a logarithmic scale) for functions* $\varphi(x) = \exp(-x^2/\alpha)$, $\alpha = 20$ *and* $\varphi(x) = \operatorname{sech}(-x/\beta)$, $\beta = 8.5$.

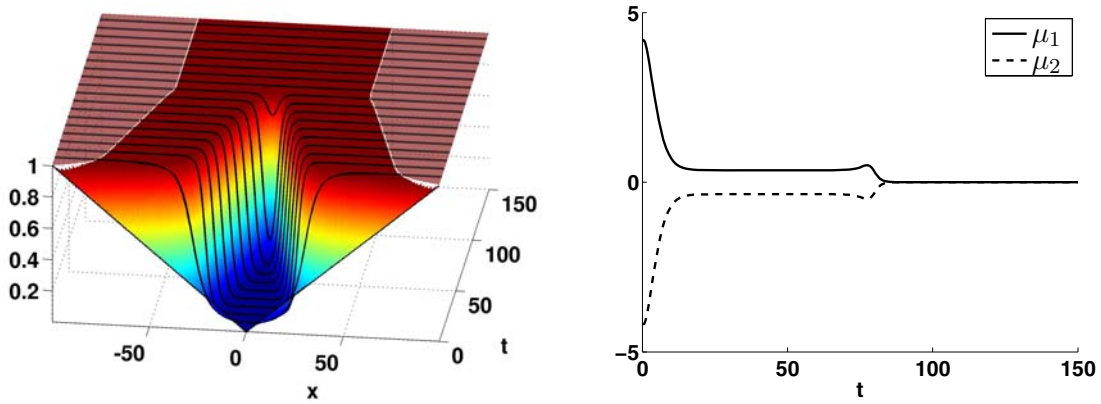

Figure 9. *Collision in the Nagumo equation, and evolution of superposition* u_c *and velocities* μ_1, μ_2.

This is correctly reproduced by our method. The speeds μ_1, μ_2 of both components converge to the same value and the superposition of the profiles v_1, v_2 forms a single front; see Figure 12.

In Figure 14 we show the difference between superposition and solution of the original equation on a large interval. After the strong interaction the rates of decay for $||u_t||_{\mathcal{L}_2}$ and $\|\mu_t\|$ (not shown) turn out to be quite similar to the previous case in Figure 8.

3.2. FitzHugh–Nagumo system.

The two component FitzHugh–Nagumo system (FHN)

$$\begin{aligned} V_t &= V_{xx} + V - \frac{1}{3}V^3 - R, \\ R_t &= \epsilon(V + a - bR) \end{aligned} \tag{3.7}$$

models nerve conduction and possesses different types of traveling wave solutions such as fronts, multifronts [11], and pulses [9], [10]. We consider the same parameters $a = 0.7$, $b = 0.8$, $\epsilon = 0.08$ as in [4] for which traveling pulses exist. Because of reflectional symmetry, with each

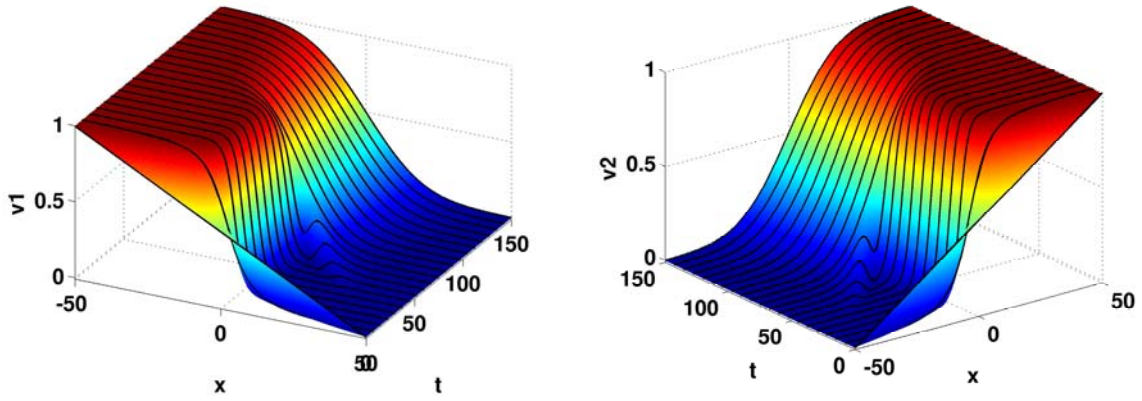

Figure 10. *Collision in the Nagumo equation, and evolution of frozen fronts* v_1, v_2.

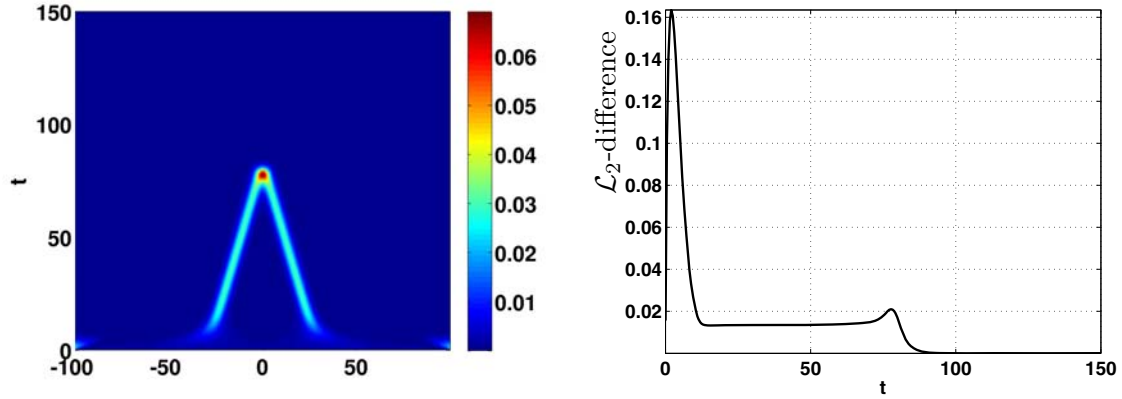

Figure 11. *Collision in the Nagumo equation, and evolution of difference* $|u_{\rm dns}(x,t) - u_{\rm c}(x,t)|$ *and of* $\mathcal{L}_2$ *difference* $\|u_{\rm dns}(\cdot,t) - u_c(\cdot,t)\|_{\mathcal{L}_2}$.

solution its mirror image is also a solution traveling at opposite speed. It is important to note that, due to the lack of diffusion in the second equation of (3.7), the PDAE system (3.1) is of mixed hyperbolic-parabolic type. In the two R-equations the convective terms that allow freezing form the principal part, and this requires some cautionary measure for the numerical solution. With the finite element code Comsol Multiphysics$^{\rm TM}$ we used streamline diffusion ($\delta_{sd} = 0.25$) in order to treat the hyperbolic part correctly. The system is solved on $[-70, 70]$ with Dirichlet boundary conditions, stepsize $\Delta x = 0.1$, and $\varphi(x) = \operatorname{sech}(x/\beta)$, $\beta = 11.3$ (results for a Gaussian φ are similar).

First we consider the formation of two pulses out of a single initial pulse. This situation was already studied in [4] with the single freezing method. There only one of the two forming pulses could be frozen depending on the choice of phase condition. Figure 15 displays the behavior of the superposition (1.4) as obtained by our method, and Figure 17 shows the difference to a solution of (3.7) obtained directly on a large interval. While the difference is small in most of the space time domain, the $\mathcal{L}_2$-difference appears to grow linearly with

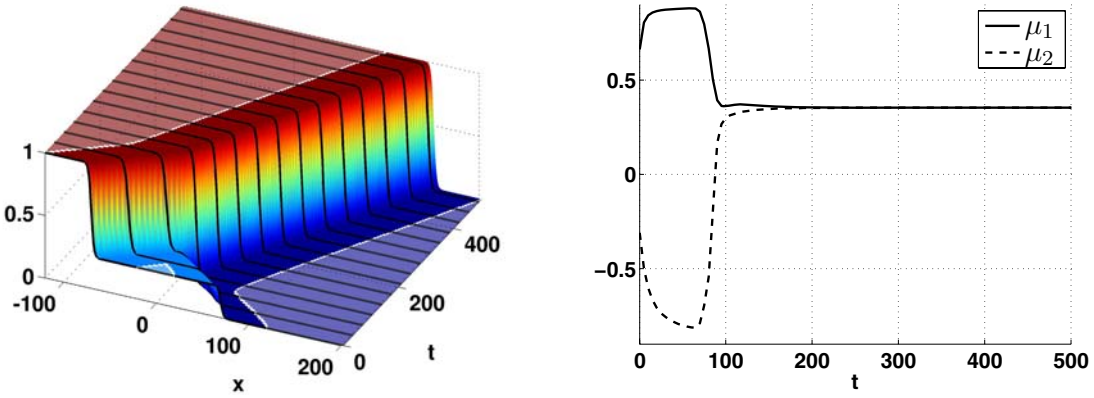

Figure 12. *Merging fronts in the Nagumo equation, and evolution of superposition u_c and velocities μ_1, μ_2.*

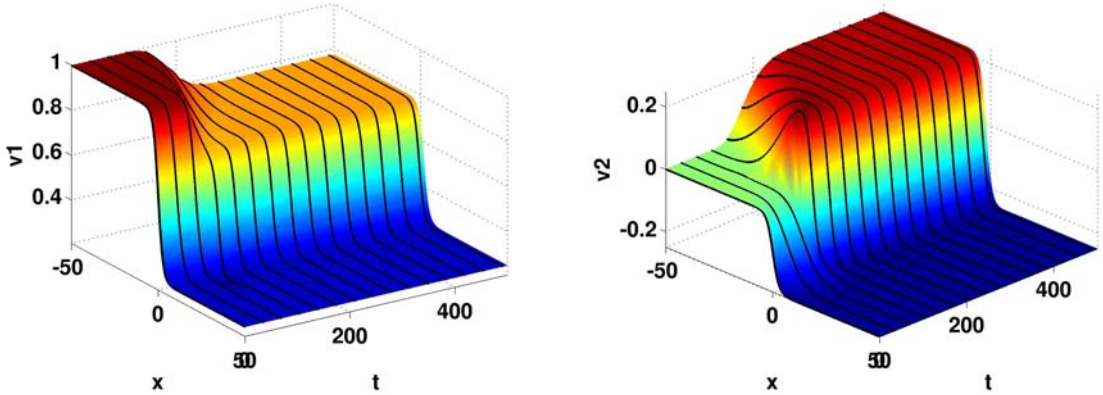

Figure 13. *Merging fronts in the Nagumo equation, and evolution of frozen fronts v_1, v_2.*

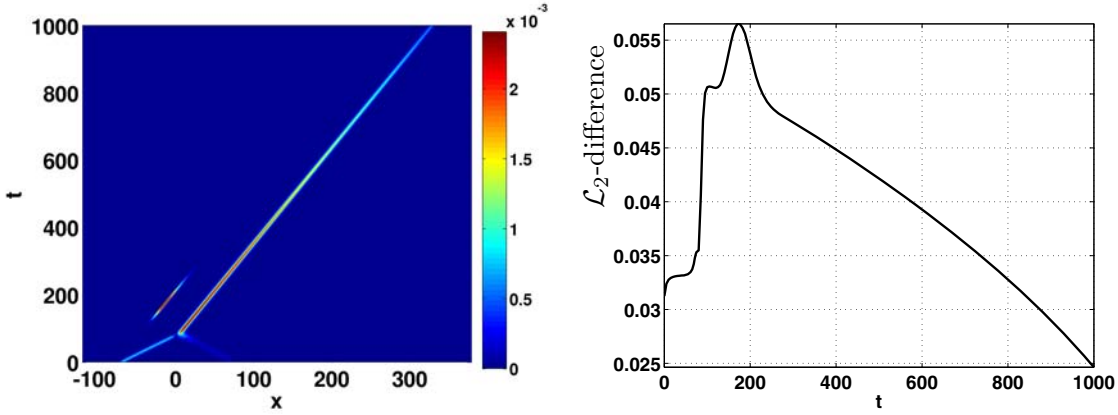

Figure 14. *Nagumo, and evolution of difference $\|u_{\mathrm{dns}}(\cdot,t) - u_c(\cdot,t)\|_{\mathcal{L}_2}$.*

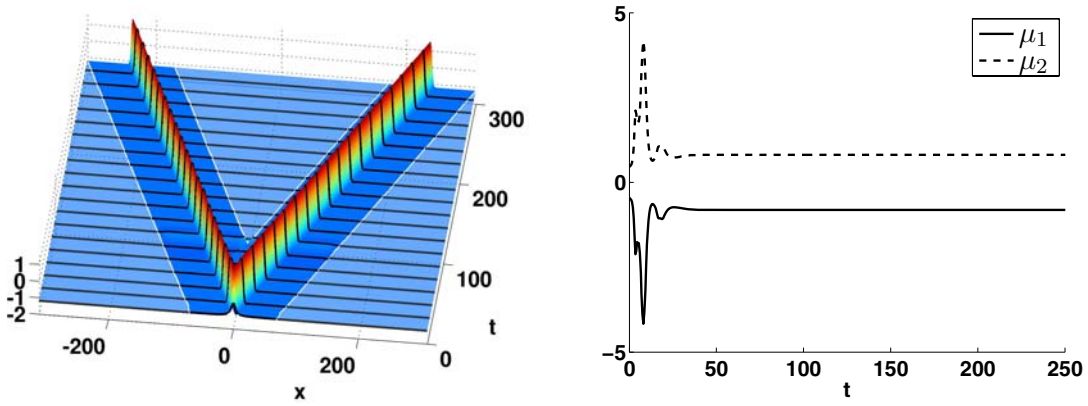

Figure 15. *Splitting of a pulse in the FHN, and evolution of superposition $V = u_c$ and of velocities μ_1, μ_2.*

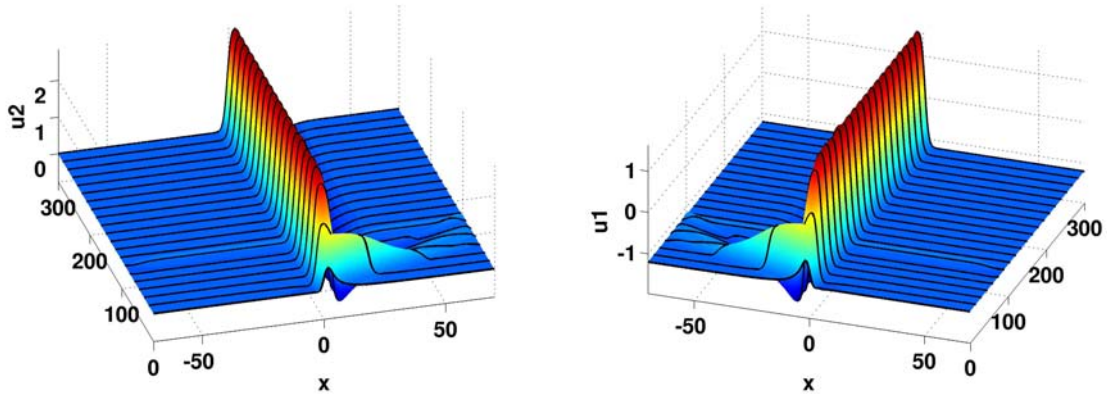

Figure 16. *Splitting of a pulse in the FHN, and evolution of pulses V_1 traveling to the left and V_2 traveling to the right.*

time. This is in contrast to the parabolic case, and we suspect that the effect is due to the hyperbolic part of the frozen equation.

In Figure 16 one observes that the components V_1 and V_2 develop tiny secondary waves that travel toward the boundary. The superposition is still correct until these reach the boundary. When they arrive a slight disturbance of the superposition in the middle of the interval develops (at about $t = 90$; see Figure 17). We expect that these boundary effects can be further reduced by using, e.g., transparent boundary conditions. After the separation phase both pulses quickly reach their asymptotic states (see Figure 16), and $||u_t||$ decays exponentially, as in the Nagumo case; see Figure 18.

Now we take the two traveling pulses which have been computed in this way and interchange their initial positions g_j^0. Then the two pulses start to move toward each other and eventually annihilate, as shown in Figure 19. The difference of the superposition and the solution of the original equation on a large domain behaves in a fashion quite similar to the Nagumo case. At the collision both wave speeds converge to zero. Figure 20 shows that both

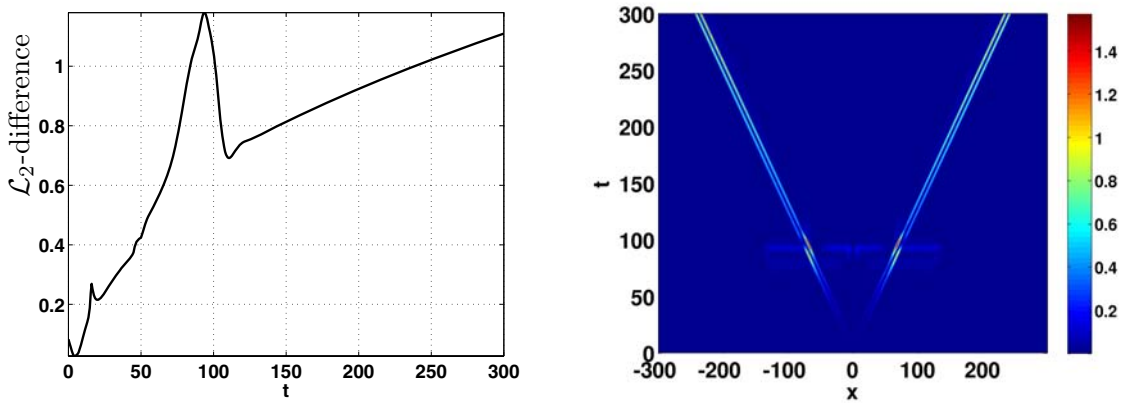

Figure 17. *Splitting of a pulse in the FHN, difference of the two-pulse computed on a large domain, and superposition of frozen single pulses* V_1, V_2.

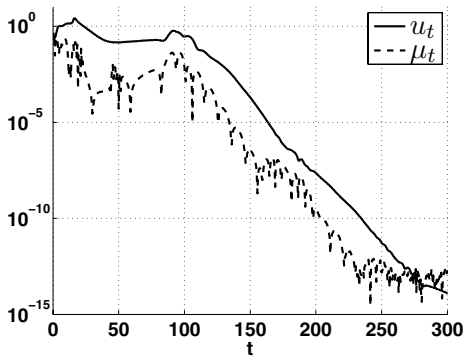

Figure 18. *Splitting of pulse in the FHN and behavior of* $\|u_t\|$, $u = (V_1, R_1, V_2, R_2)$, *and* $\|\mu_t\|$.

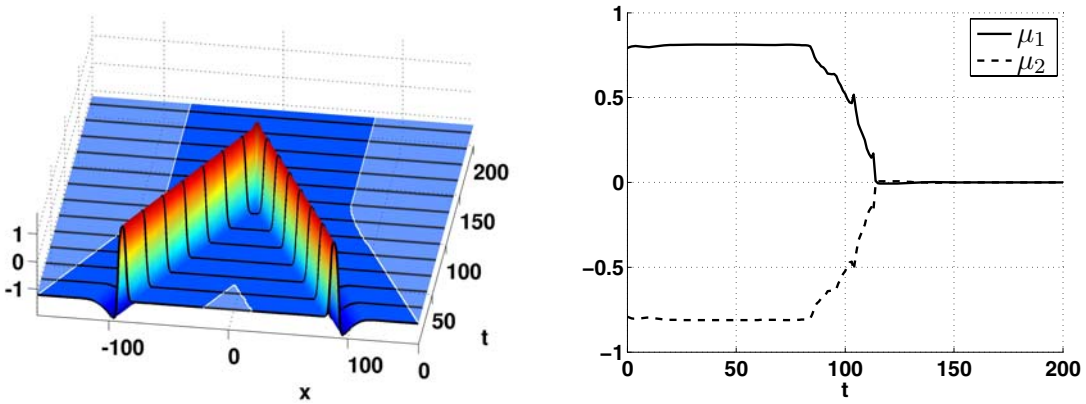

Figure 19. *Collision of pulses in the FHN, and evolution of superposition* $u_c = V$ *and velocities* μ_1, μ_2.

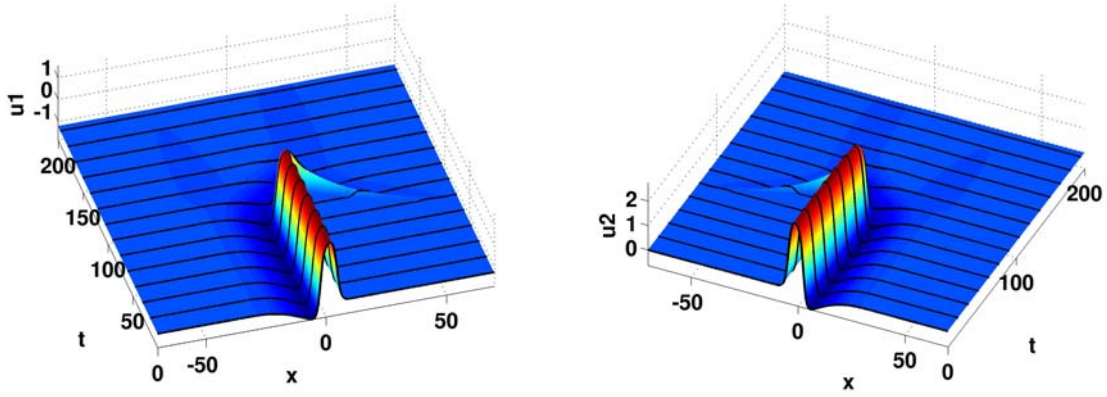

Figure 20. *Collision of pulses in the FHN, and evolution of frozen pulses* V_1, V_2.

components V_1 and V_2 converge to constants.

Contrary to the case of fronts, this can lead to numerical difficulties for large times since our phase conditions are no longer well-posed for constant functions (cf. (2.16), (2.17)). We note that after collision we have again the situation where we use a larger number N than necessary for representing the solution and where our method reproduces the behavior in a consistent manner.

4. Asymptotic properties of multifronts. In this section we show that traveling waves, when shifted as in (2.2), satisfy the PDAE system (2.8) in an asymptotic sense as $t \to \infty$. This will imply a corresponding property of the superposition (2.2) for the original system (1.1).

Definition 4.1. *A smooth function* $V : \mathbb{R}^N \to \mathbb{R}^m$ *is called an* asymptotic N-front solution *of* (1.1) *if there exist constants*

$$c_1, c_2, \ldots, c_N$$

such that

$$u(x,t) = V(x - c_1 t, \ldots, x - c_N t) \tag{4.1}$$

satisfies

$$||(u_t - Au_{xx} - f(u, u_x))(\cdot, t)||_{\mathcal{L}_2} \to 0 \quad \text{as } t \to \infty. \tag{4.2}$$

We look for asymptotic N-front solutions of the type

$$V(x_1, \ldots, x_N) = \sum_{j=1}^{N} \hat{w}_j(x_j), \tag{4.3}$$

where $\hat{w}_j$ is defined in (2.2) and $w_j(x - c_j t)$ are C^2-smooth traveling waves of (1.1). In particular, they satisfy the stationary equation

$$0 = Aw_{j,\xi\xi} + c_j w_{j,\xi} + f(w_j, w_{j,\xi}). \tag{4.4}$$

With (2.10) let us write (2.8) as

$$v_{j,t} = M_j(v,g) = Av_{j,\xi\xi} + v_{j,\xi}g_{j,t} + F_j(v,g), \quad j = 1,\dots,N. \tag{4.5}$$

For the special functions

$$v_j = \hat{w}_j,\ g_j(t) = c_j t,\ j = 1,\dots,N,\ t \in \mathbb{R}_+, \tag{4.6}$$

we show in Theorem 4.2 below that

$$||M_j(\hat{w},g)(\cdot,t)||_{\mathcal{L}_2} \to 0 \quad \text{as } t \to \infty; \tag{4.7}$$

i.e., they are asymptotic steady states of the nonautonomous system (4.5). Using the basic calculation (2.6) we obtain that

$$u(x,t) = \sum_{j=1}^{N} \hat{w}_j(x - c_j t) \tag{4.8}$$

satisfies the estimate

$$\begin{aligned} &||(u_t - Au_{xx} - f(u,u_x))(\cdot,t)||_{\mathcal{L}_2} \\ &\quad = \left|\left| \sum_{j=1}^{N} M_j(\hat{w},g)(\cdot - c_j t, t) \right|\right|_{\mathcal{L}_2} \to 0 \quad \text{as } t \to \infty. \end{aligned}$$

Therefore, the function (4.3) is an asymptotic N-front solution.

Theorem 4.2. *Let $w_j(x - c_j t)$, $j = 1,\dots,N$, be C^2-smooth traveling wave solutions of the system (1.1) that satisfy for some constants $C, \alpha > 0$*

$$c_1 < c_2 < \cdots < c_N, \tag{4.9}$$

$$\|w_j(\xi) - w_j^{\pm}\| \le Ce^{\mp\alpha\xi} \quad \textit{and} \quad \|w_{j,\xi}(\xi)\| \le Ce^{-\alpha|\xi|}, \quad j = 1,\dots,N, \tag{4.10}$$

$$w_j^{+} = w_{j+1}^{-}, \quad j = 1,\dots,N-1. \tag{4.11}$$

Moreover, let $\varphi \in C^{\infty}(\mathbb{R},\mathbb{R})$ be a function for which the exponential estimate

$$C_0 e^{-\beta_0|x|} \le \varphi(x) \le C_1 e^{-\beta_1|x|}, \quad x \in \mathbb{R}, \tag{4.12}$$

holds for some positive constants $C_0 \le C_1$ and $\beta_1 < \beta_0$.

Then the shifted waves $\hat{w}_j$ from (2.2) and $g_j(t) = c_j t$ satisfy for some constants $C, \varepsilon > 0$

$$||M_j(\hat{w},g)(\cdot,t)||_{\mathcal{L}_2} \le Ce^{-\varepsilon t} \quad \forall t \ge 0, \tag{4.13}$$

where M_j denotes the right-hand side in the PDAE system (4.5). In particular, $V(x_1,\dots,x_N) = \sum_{j=1}^{N} \hat{w}_j(x_j)$ is an asymptotic N-front solution of (1.1).

Remark 4.3. *Clearly, this result does not yet prove the behavior of the numerical solutions observed in section 3. For such a result we must show that the PDAE system (4.5) is well-posed and, moreover, that for stable traveling waves the solutions $v_j(\cdot,t)$ converge to $\hat{w}_j$ in a*

suitable way as $t \to \infty$ for sufficiently small initial perturbations. We think of Theorem 4.2 as a first step toward such a result that justifies the overall ansatz in section 2.

Remark 4.4. *The theorem remains valid for more general bump functions that satisfy*

$$C_0 e^{-\beta_0 |x|^k} \le \varphi(x) \le C_1 e^{-\beta_1 |x|^k}, \quad x \in \mathbb{R}, \quad \text{with } 0 < C_0 \le C_1,\ 0 < \beta_1 < \beta_0,\ k \ge 1.$$

The case $k = 2$ was used in some of our simulations above. The following proof will show that the only modifications occur in the estimates on the intervals marked by Q_j^g in Figure 21 and in the condition (4.17) that determines the subdivision of the real line.

Proof. Let us first note that (4.10) and (4.4) imply $\lim_{\xi \to \pm\infty} w_{j,\xi\xi}(\xi) = 0$ and hence

$$f(w_j^{\pm}, 0) = 0. \tag{4.14}$$

As noted above it suffices to prove (4.13). For ease of reading we restrict our attention to the case where f depends on u only, $f(u, u_x) = f(u)$. Using (4.14), (4.4), and (4.10) the details of the general case can be filled in easily. In the following we use C to denote a generic constant. First, the stationary equation (4.4) yields

$$\begin{aligned} ||M_j(\hat{w}, g)(\cdot, t)||_{\mathcal{L}_2}^2 &= \left|\left| Q_j^g(\cdot, t) f\left(\sum_{k=1}^N \hat{w}_k(\xi_{k,j}^g) \right) - f(w_j) \right|\right|_{\mathcal{L}_2}^2 \\ &\le C \left[\int_{\mathbb{R}} Q_j^g(\xi, t)^2 \left| f\left(\sum_{k=1}^N \hat{w}_k(\xi_{k,j}^g) \right) - f(w_j(\xi)) \right|^2 d\xi \right. \\ &\quad \left. + \int_{\mathbb{R}} (1 - Q_j^g(\xi, t))^2 |f(w_j(\xi))|^2 d\xi \right] =: I_1 + I_2. \end{aligned}$$

We estimate the integrals I_1, I_2 separately. When comparing f arguments we frequently use the following equality:

$$\sum_{k=1}^N \hat{w}_k(\xi_{kj}^g) - w_j(\xi) = \sum_{k=1}^{j-1} (w_k(\xi_{kj}^g) - w_k^+) + \sum_{k=j+1}^N (w_k(\xi_{kj}^g) - w_k^-). \tag{4.15}$$

Consider first I_1 and indices $2 \le j \le N-1$. For $q > 0$ sufficiently small we define

$$\gamma_k^{\pm} = (1 \pm q)(c_k - c_j)t, \qquad \gamma_k^0 = (c_k - c_j)t$$

and partition $\mathbb{R}$ into subintervals as follows (cf. Figure 21):

$$\begin{aligned} -\infty < \gamma_1^+ < \gamma_1^0 < \gamma_1^- < \gamma_2^+ < \cdots < \gamma_{j-1}^+ < \gamma_{j-1}^0 < \gamma_{j-1}^- < 0 = \gamma_0^{\pm} \\ < \gamma_{j+1}^- < \gamma_{j+1}^0 < \gamma_{j+1}^+ < \cdots < \gamma_N^- < \gamma_N^0 < \gamma_N^+ < \infty. \end{aligned} \tag{4.16}$$

Note that the relations $\gamma_k^- < \gamma_{k+1}^+$ for $k \le j-1$ and $\gamma_k^+ < \gamma_{k+1}^-$ for $k \ge j+1$ follow if q satisfies

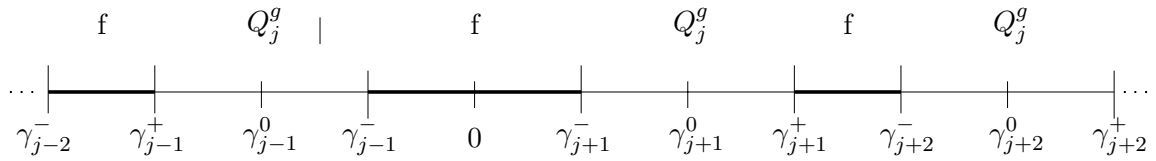

Figure 21. *Decomposition of the interval* $\mathbb{R}$.

$$q < \min\left\{ \frac{c_{k+1}-c_k}{|2c_j - c_k - c_{k+1}|} : \ 1 \le j \le N, \ 1 \le k \le N-1 \right\}.$$

Our second condition on q is

$$q < \frac{\min\big(\min\limits_{j=2,\dots,N}(c_j - c_{j-1}), 1\big)\,\beta_1}{\max\big(\max\limits_{j=2,\dots,N}(c_j - c_{j-1}), 1\big)(\beta_1+\beta_0)}. \tag{4.17}$$

For the estimate of I_1 we use $0 \le Q_j^g(\cdot,\cdot) \le 1$ and the fact that all arguments of f lie in a compact interval. On each subinterval we use the smallness of either f or Q_j^g, as indicated in Figure 21. We obtain

$$\begin{aligned}
I_1 \le C \Bigg[& \int_{-\infty}^{\gamma_1^+} \left| f\left(\sum_{k=1}^N \hat{w}_k(\xi_{k,j}^g)\right) - f(w_j(\xi)) \right|^2 d\xi + \sum_{l=1}^{j-1} \int_{\gamma_l^+}^{\gamma_l^0} Q_j^g(\xi,t)^2 d\xi \\
& + \sum_{l=1}^{j-1} \int_{\gamma_l^0}^{\gamma_l^-} Q_j^g(\xi,t)^2 d\xi + \sum_{l=1}^{j-2} \int_{\gamma_l^-}^{\gamma_{l+1}^+} \left| f\left(\sum_{k=1}^N \hat{w}_k(\xi_{k,j}^g)\right) - f(w_j(\xi)) \right|^2 d\xi \\
& + \int_{\gamma_{j-1}^-}^{\gamma_{j+1}^-} \left| f\left(\sum_{k=1}^N \hat{w}_k(\xi_{k,j}^g)\right) - f(w_j(\xi)) \right|^2 d\xi + \sum_{l=j+1}^{N} \int_{\gamma_l^-}^{\gamma_l^0} Q_j^g(\xi,t)^2 d\xi \\
& + \sum_{l=j+1}^{N} \int_{\gamma_l^0}^{\gamma_l^+} Q_j^g(\xi,t)^2 d\xi + \sum_{l=j+1}^{N-1} \int_{\gamma_l^+}^{\gamma_{l+1}^-} \left| f\left(\sum_{k=1}^N \hat{w}_k(\xi_{k,j}^g)\right) - f(w_j(\xi)) \right|^2 d\xi \\
& + \int_{\gamma_N^+}^{\infty} \left| f\left(\sum_{k=1}^N \hat{w}_k(\xi_{k,j}^g)\right) - f(w_j(\xi)) \right|^2 d\xi \Bigg] \\
=: & \ I_1^b + \sum_{l=1}^{j-1} I_{1,l}^{1-} + \sum_{l=1}^{j-1} I_{1,l}^{2-} + \sum_{l=1}^{j-2} I_{1,l}^{3-} + I_1^c \\
& + \sum_{l=j+1}^{N} I_{1,l}^{1+} + \sum_{l=j+1}^{N} I_{1,l}^{2+} + \sum_{l=j+1}^{N-1} I_{1,l}^{3+} + I_1^e.
\end{aligned}$$

For the convenience of the reader here we give only the estimate for the crucial central term I_1^c and defer the remaining laborious estimates to the appendix. With (4.9), (4.10), (4.11),

and (4.15) we obtain

$$
\begin{aligned}
I_1^c &\le C \int_{\gamma_{j-1}^-}^{\gamma_{j+1}^-} \left| \sum_{k=1}^{N} \hat{w}_k(\xi + (c_j - c_k)t) - w_j(\xi) \right|^2 d\xi \\
&\le C \int_{\gamma_{j-1}^-}^{\gamma_{j+1}^-} \left(\sum_{k=1}^{j-1} |w_k(\xi + (c_j - c_k)t) - w_k^+|^2 + \sum_{k=j+1}^{N} |w_k(\xi + (c_j - c_k)t) - w_k^-|^2 \right) d\xi \\
&\le C \left[\int_{\gamma_{j-1}^-}^{\gamma_{j+1}^-} \sum_{k=1}^{j-1} e^{-2\alpha(\xi + (c_j - c_k)t)} d\xi + \int_{\gamma_{j-1}^-}^{\gamma_{j+1}^-} \sum_{k=j+1}^{N} e^{2\alpha(\xi + (c_j - c_k)t)} d\xi \right] \\
&\le C \left[\int_{\gamma_{j-1}^-}^{\gamma_{j+1}^-} e^{-2\alpha(\xi + (c_j - c_{j-1})t)} d\xi + \int_{\gamma_{j-1}^-}^{\gamma_{j+1}^-} e^{2\alpha(\xi + (c_j - c_{j+1})t)} d\xi \right] \\
&\le C \left[e^{-2\alpha q(c_j - c_{j-1})t} + e^{-2\alpha q(c_{j+1} - c_j)t} \right]. \qquad \blacksquare
\end{aligned}
$$

5. Generalization to equivariant evolution equations. In this section we generalize the idea from section 2 to evolution equations in Banach spaces that are equivariant with respect to the action of a Lie group. The abstract setting follows the approach from [4], [5].

5.1. The abstract formulation. Consider an evolution equation

$$u_t = Au + F(u), \quad u(0) = u_0, \tag{5.1}$$

where $A, F : Y \subset X \to X$ are linear, respectively, nonlinear, operators from a dense subspace Y of some Banach space X into X. We assume equivariance of both A and F with respect to some action of the Lie group G on X,

$$a : G \to GL(X), \ g \mapsto a(g);$$

that is,

$$F(a(g)u) = a(g)F(u), \quad A(a(g)u) = a(g)Au \tag{5.2}$$

holds for all $u \in Y$, $g \in G$. In order to mimic the partition of unity construction we assume that there is a module E (i.e., a real vector space with an Abelian multiplication) acting on X via

$$\bullet : E \times X \to X, \ (\varphi, u) \mapsto \varphi \cdot u,$$

such that both distributive laws and the associative law hold.

Moreover, we assume that the group also acts on E via a possibly different action

$$\alpha : G \to GL(E), \ g \mapsto \alpha(g),$$

such that for all $g \in G$, $\varphi, \psi \in E$, $u \in X$

$$\alpha(g)(\varphi\psi) = (\alpha(g)\varphi)(\alpha(g)\psi), \tag{5.3}$$

$$a(g)(\varphi \cdot u) = (\alpha(g)\varphi) \cdot (a(g)u). \tag{5.4}$$

Furthermore, we assume that the map

$$a(\cdot)u : G \to X, \quad g \mapsto a(g)u$$

is continuous for any $u \in X$ and that it is continuously differentiable for any $u \in Y$ with derivative denoted by

$$d[a(g)u] : T_gG \to X, \quad \lambda \mapsto d[a(g)u]\lambda.$$

Example 5.1. *Consider as an example $X = \mathcal{L}^2(\mathbb{R}, \mathbb{C})$, $G = S^1 \times \mathbb{R}$ with the action given by*

$$[a(\theta, \tau)u](x) = e^{i\theta}u(x - \tau), \quad u \in X, \ (\theta, \tau) \in S^1 \times \mathbb{R}. \tag{5.5}$$

Then with $E = C^0_{unif}(\mathbb{R}, \mathbb{R})$ we find that (5.3), (5.4) hold for the setting $\alpha(\theta, \tau)\varphi(x) = \varphi(x-\tau)$ for $\varphi \in E$. Moreover, with this choice the action is continuous on E. We note, however, that this property will not be needed for the arguments to follow.

In the following we assume that we are given some $\varphi \in E$ such that $\sum_{j=1}^N \alpha(g_j)\varphi$ is invertible for any choice of $g_j \in G$. In section 2 and in Example 5.1 above this property is a consequence of (2.5). For the inverse element of some $\varphi \in E$ we use the notation $\frac{1}{\varphi} = \varphi^{-1}$.

The generalization of (1.4) is to write the solution u as

$$u(t) = \sum_{j=1}^N a(g_j(t))v_j(t), \tag{5.6}$$

with unknowns $g_j(t) \in G$, $v_j \in Y$. Inserting this into (5.1) and using equivariance (5.2) as well as (5.3), (5.4) leads to

$$\begin{aligned}
u_t &= \sum_{j=1}^N \left(a(g_j)v_{j,t} + d[a(g_j)v_j]g_{j,t}\right) \\
&= \sum_{j=1}^N A(a(g_j)v_j) + F\left(\sum_{k=1}^N a(g_k)v_k\right) \\
&= \sum_{j=1}^N a(g_j)Av_j + \sum_{j=1}^N \frac{\alpha(g_j)\varphi}{\sum_{k=1}^N \alpha(g_k)\varphi} \cdot F\left(\sum_{k=1}^N a(g_k)v_k\right) \\
&= \sum_{j=1}^N a(g_j)\left[Av_j + \frac{\varphi}{\sum_{k=1}^N \alpha(g_j^{-1}g_k)\varphi} \cdot F\left(\sum_{k=1}^N a(g_j^{-1}g_k)v_k\right)\right].
\end{aligned}$$

This equation is fulfilled if the v_j, g_j satisfy the system

$$v_{j,t} = Av_j + \frac{\varphi}{\sum_{k=1}^N \alpha(g_j^{-1}g_k)\varphi} \cdot F\left(\sum_{k=1}^N a(g_j^{-1}g_k)v_k\right) - a(g_j^{-1})d[a(g_j)v_j]g_{j,t}. \tag{5.7}$$

We simplify the last term as in [5]. Let $\mathbb{1}$ be the unit element in G; then the tangent space $T_{\mathbb{1}}G$ is the Lie algebra associated with G. By $dg(\mathbb{1}) : T_{\mathbb{1}}G \to T_gG$ we denote the derivative of

the multiplication from the left by g at $\mathbb{1}$. Differentiating the relation $a(g\circ\gamma)v = a(g)(a(\gamma)v)$ for $v \in Y$ at $\gamma = \mathbb{1}$ yields

$$a(g)d[a(\mathbb{1})v]\mu = d[a(g)v](dg(\mathbb{1})\mu) \quad \text{for } \mu \in T_{\mathbb{1}}G,\ v \in Y.$$

Therefore, defining new coordinates $\mu_j(t) \in T_{\mathbb{1}}G$ by $g_{j,t}(t) = dg_j(\mathbb{1})\mu_j(t)$ turns (5.7) into

$$\begin{aligned} v_{j,t} &= Av_j + \frac{\varphi}{\sum_{k=1}^N a(g_j^{-1}g_k)\varphi}\cdot F\left(\sum_{k=1}^N a(g_j^{-1}g_k)v_k\right) - d[a(\mathbb{1})v_j]\mu_j \\ &= Av_j + \mathcal{F}_j(v,g) - d[a(\mathbb{1})v_j]\mu_j \end{aligned} \tag{5.8}$$

and

$$g_{j,t} = dg_j(\mathbb{1})\mu_j. \tag{5.9}$$

As usual, we add initial data

$$v_j(0) = v_{j,0}, \quad g_j(0) = g_{j,0}, \quad j = 1,\dots,N, \tag{5.10}$$

which should satisfy

$$u_0 = \sum_{j=1}^N a(g_{j,0})v_{j,0}. \tag{5.11}$$

Finally, we assume that a continuous inner product $\langle\cdot,\cdot\rangle_2$ on X is available and use this to derive N phase conditions each of dimension $\dim(G)$. Suppose we have template functions $\hat v_j$ and require the distance $\operatorname{dist}(v_j, \mathcal{O}(\hat v_j)) = \inf_{g\in G}\|v_j - a(g)\hat v_j\|_2$ to the group orbit $\mathcal{O}(\hat v_j) = \{a(g)v_j : g \in G\}$ to achieve its minimum at $g = \mathbb{1}$. Then we find the necessary condition

$$\langle v_j - \hat v_j, d[a(\mathbb{1})\hat v_j]\lambda\rangle_2 = 0 \quad \forall\lambda \in T_{\mathbb{1}}G,\ j = 1,\dots,N. \tag{5.12}$$

While this generalizes (2.15), the corresponding generalization of (2.17) is

$$\langle v_{j,t}, d[a(\mathbb{1})v_j]\lambda\rangle_2 = 0 \quad \forall\lambda \in T_{\mathbb{1}}G,\ j = 1,\dots,N. \tag{5.13}$$

Note that this requires $v_{j,t}$ to be orthogonal to the group orbit $\mathcal{O}(v_j)$ at all times. When $v_{j,t}$ from (5.8) is inserted into (5.13), we obtain a linear system of dimension $\dim(G)$ for $\mu_j(t) \in T_{\mathbb{1}}G$ that has a unique solution provided $d[a(\mathbb{1})v_j] : T_{\mathbb{1}}G \to X$ is one to one.

To realize the above abstract equations in $\mathbb{R}^s$, where $s = \dim(G)$, we take a basis $\{e^1,\dots,e^s\}$, in the Lie algebra $T_{\mathbb{1}}G$ and write $\mu_j = \sum_{i=1}^s \mu_{j,i}e^i$. Then the differentiated form of (5.12) and (5.13) reads (cf. (2.16), (2.17))

$$\begin{aligned} \hat B_j\mu_j = \hat r_j,\ \text{where}\ \left((\hat B_j)_{ik}\right)_{i,k=1}^s &= \left(\langle d[a(\mathbb{1})v_j]e^k,\, d[a(\mathbb{1})\hat v_j]e^i\rangle_{\mathcal{L}_2}\right)_{i,k=1}^s \in \mathbb{R}^{s,s}, \\ \hat r_j &= \left(\langle Av_j + \mathcal{F}_j(v,g),\, d[a(\mathbb{1})\hat v_j]e^i\rangle_{\mathcal{L}_2}\right)_{i=1}^s \end{aligned} \tag{5.14}$$

and

$$\begin{aligned} B_j\mu_j = r_j,\ \text{where}\ ((B_j)_{ik})_{i,k=1}^s &= \left(\langle d[a(\mathbb{1})v_j]e^k,\, d[a(\mathbb{1})v_j]e^i\rangle_{\mathcal{L}_2}\right)_{i,k=1}^s \in \mathbb{R}^{s,s}, \\ r_j &= \left(\langle Av_j + \mathcal{F}_j(v,g),\, d[a(\mathbb{1})v_j]e^i\rangle_{\mathcal{L}_2}\right)_{i=1}^s. \end{aligned} \tag{5.15}$$

Altogether we have to solve the differential algebraic system (5.8), (5.10) with phase conditions (5.14) or (5.15).

5.2. An application to the Ginzburg–Landau equation. The cubic quintic Ginzburg–Landau equation [18], [21]

$$u_t = \alpha u_{xx} + \delta u + f(u), \quad f(u) = \beta|u|^2u + \gamma|u|^4u \\ = \alpha u_{xx} + F(u) \tag{5.16}$$

with $\delta \in \mathbb{R}$, $\alpha, \beta, \gamma \in \mathbb{C}$, $u(x,t) \in \mathbb{C}$ shows a variety of coherent structures, like pulses, fronts, sources, and sinks [21]. For certain parameter values this equation exhibits stable rotating pulses [18] as well as fronts that rotate and travel simultaneously. Equation (5.16) has the same equivariance as Example 5.1. Thus we write u as

$$u(x,t) = \sum_{j=1}^{N} e^{-i\theta_j(t)} v_j(x - \tau_j(t), t) \tag{5.17}$$

and define $\mu_j^\theta(t)$ by $\theta_{j,t}(t) = \mu_j^\theta(t)$ and $\mu_j^\tau(t)$ by $\tau_{j,t}(t) = \mu_j^\tau(t)$. The system (5.8) is of the form

$$v_{j,t}(\xi,t) = Av_j(\xi,t) + i\mu_j^\theta(t)v_j(\xi,t) + \mu_j^\tau(t)v_{j,\xi}(\xi,t) \\ + \frac{\varphi(\xi)}{\sum_{k=1}^N \varphi(\xi - \tau_k(t) + \tau_j(t))} F\left(\sum_{k=1}^{N} e^{-i(\theta_k(t)-\theta_j(t))} v_k(\xi - \tau_k(t) + \tau_j(t),\, t)\right).$$

The phase conditions are derived from the $\mathcal{L}_2$-inner product in the corresponding two dimensional real system.

$$0 = \langle \mathrm{Re}(v_j - \hat{v}_j), \mathrm{Re}(\hat{v}_{j,\xi})\rangle_{\mathcal{L}_2} + \langle \mathrm{Im}(v_j - \hat{v}_j), \mathrm{Im}(\hat{v}_{j,\xi})\rangle_{\mathcal{L}_2}, \\ 0 = \langle \mathrm{Re}(v_j - \hat{v}_j), \mathrm{Im}(\hat{v}_j)\rangle_{\mathcal{L}_2} - \langle \mathrm{Im}(v_j - \hat{v}_j), \mathrm{Re}(\hat{v}_j)\rangle_{\mathcal{L}_2}, \qquad j = 1, \ldots, N.$$

For numerical computations we used the parameters $a = 1$, $\delta = -0.1$, $\beta = 3 + i$, $\gamma = -2.75 + i$ for which the fronts and pulses mentioned above exist.

We first look at the case where the solution for the original system consists of two waves that rotate at the same speed but travel in opposite directions. As Figure 22 shows, this is reproduced correctly by our method. The values obtained from extrapolation are shown in grey shades.

The components v_1, v_2 given in Figure 23 become stationary and the parameters μ_i^τ, μ_i^θ, $i = 1, 2$, converge quickly to the correct values for the velocities of rotation and translation. Again the difference to a solution of the QCGL problem (5.16) on a large domain gives similar results as in section 3.1 (not shown), and the decay of the time derivative is exponential as before; see Figure 24 (left). Figures 25 and 26 show another result in a case where the multipulse consists of a rotating stationary pulse and a rotating traveling front with the decay rate displayed in Figure 24 (right).

6. Conclusions. We propose a numerical method for separating drifting motions of interacting pulses and fronts in a nonlinear reaction diffusion system. The method builds on an earlier approach for freezing single pulses and fronts in a comoving frame that is determined by the numerical process. The contribution of this paper is to embed the given equation into

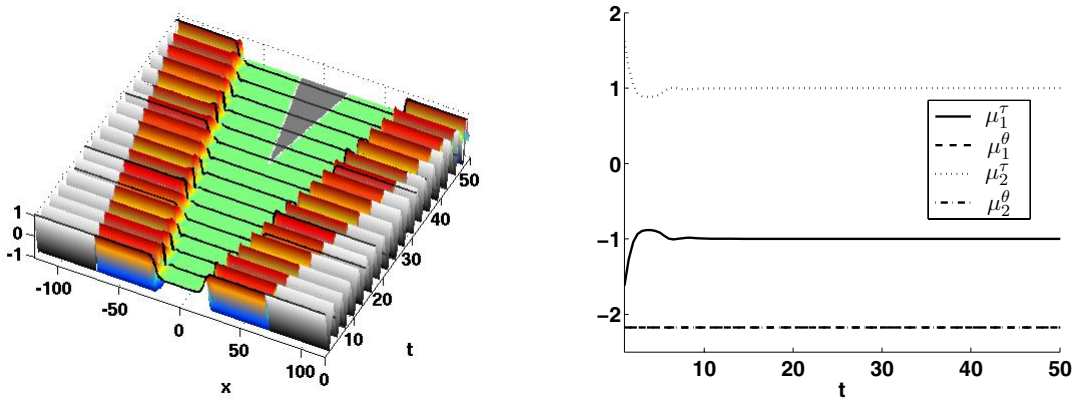

Figure 22. *Fronts moving in opposite directions in the QCGL system: Evolution of superposition* $\mathrm{Re}(u_c)$ *and velocities* $\mu_1^\tau, \mu_1^\theta, \mu_2^\tau, \mu_2^\theta$.

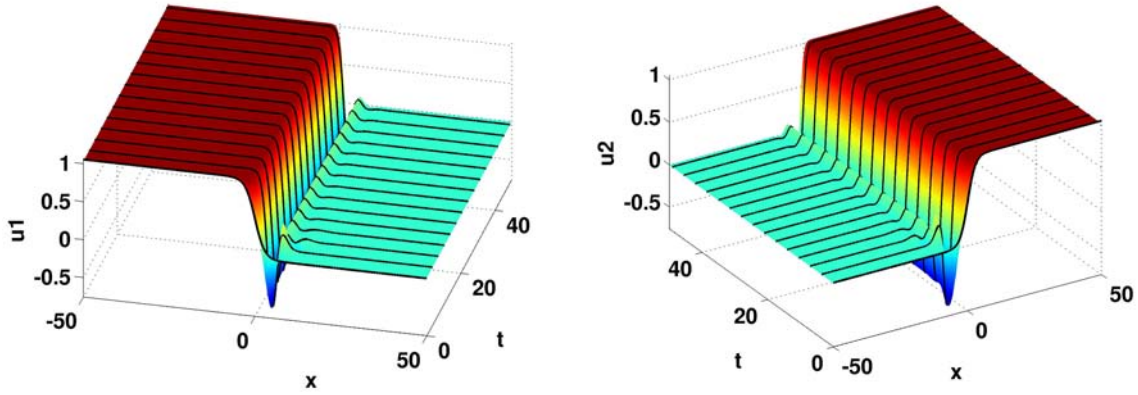

Figure 23. *Fronts moving in opposite directions in the QCGL system: Evolution of frozen fronts* $u_1 = \mathrm{Re}(v_1)$, $u_2 = \mathrm{Re}(v_2)$.

a system of N PDEs where N is at least the number of pulses, respectively, fronts, that is expected for the solution. An essential feature of the approach is to decompose the nonlinear vector field by a time-dependent partition of unity into local parts that decouple when pulses and fronts are far apart. Each subsystem is expected to describe a single front or pulse in its own moving reference frame, and the superposition of these single solutions provides an exact solution of the original system. Except for the nonlinear coupling terms, each subsystem retains a certain shift symmetry that is made use of by imposing appropriate phase conditions. Altogether, a system of partial differential algebraic equations (PDAEs) arises that is solved numerically by restricting to a finite domain and employing suitable time integrators.

There are at least two advantages of our method over solving the original equation on a (potentially very large) domain. Each subsystem can be solved on a relatively small and time-independent domain. The advantage becomes more pronounced the further apart the fronts and pulses are in the original system. Interactions in the far field are treated by extrapolating

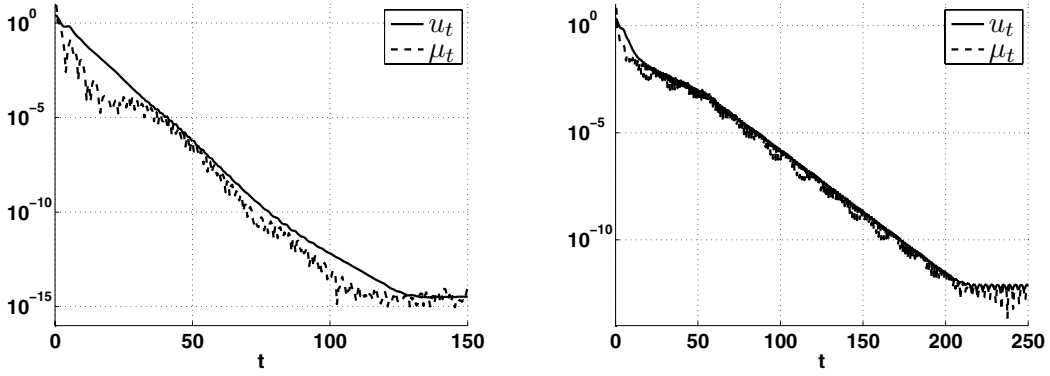

Figure 24. *Fronts moving in opposite directions in the QCGL system: Evolution of temporal change* $\|u_t\|_{\mathcal{L}_2}$ *and* $\|\mu_t\|$ *for two fronts (left) and pulse and front (right).*

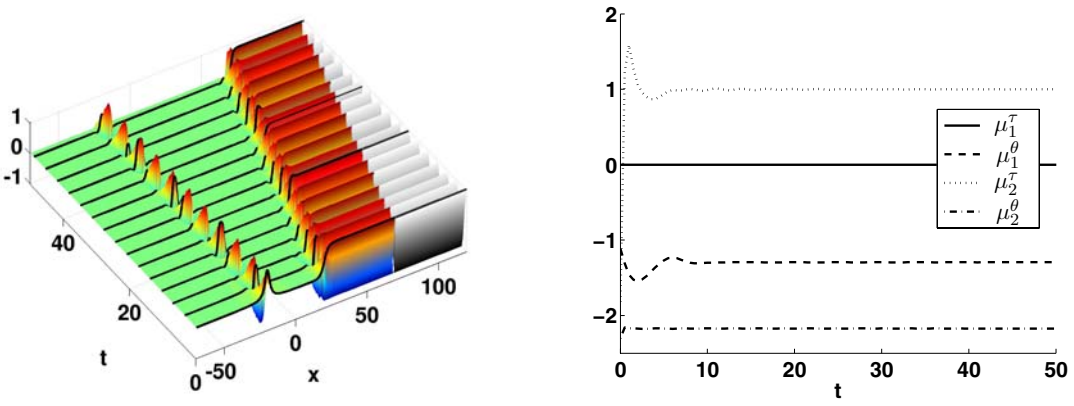

Figure 25. *Pulse and front moving in opposite directions in the QCGL system: Evolution of superposition* $\mathrm{Re}(u_c)$ *and velocities* $\mu_1^\tau, \mu_1^\theta, \mu_2^\tau, \mu_2^\theta$.

the solutions of the subsystems. Second, the approach provides direct access to the shape and velocity of the pulses and fronts present in the original solution. It avoids any a posteriori analysis of the numerical data in order to extract such information. The price to be paid for this advantage is the size of the system to be solved, which grows with the number of pulses occurring.

The method turns out to be quite robust with respect to the choice of bump function which forms the building block of the decomposition. Moreover, several numerical tests confirm that the method is able to handle strong interactions that occur during collision or merging of pulses. Typically, after such collisions the dimension of our system is larger than necessary for decomposing the solution. Then the method still works and provides single components that add up to the correct solution and travel at a common speed or do not travel at all.

The theoretical foundation of the proposed method is still in its beginning phase. We prove that single waves of the given system provide a solution of our PDAE system in an asymptotic sense. Future work will require us to show that the PDAE system is generally

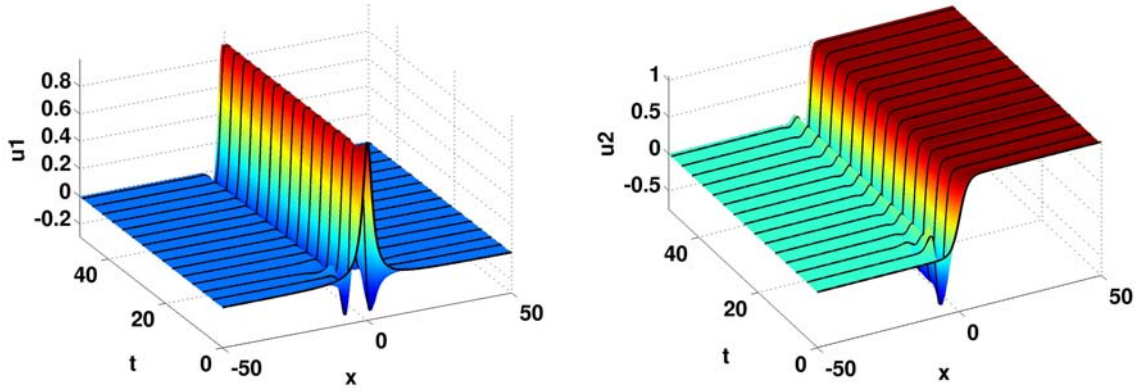

Figure 26. *Pulse and front moving in opposite directions in the QCGL system: Evolution of frozen pulse* $u_1 = \mathrm{Re}(v_1)$ *and front* $u_2 = \mathrm{Re}(v_2)$.

well-posed. Moreover, for the case of stable waves repelling each other, one expects that the set of single waves forms an asymptotically stable equilibrium for the PDAE system.

Finally, the method is formulated in the abstract framework of equivariant evolution equations, which encourages applications to much more general equations than the one-dimensional reaction diffusion systems discussed in this paper. First successful numerical tests are provided for the quintic-cubic Ginzburg–Landau equation with a two-dimensional group of equivariances.

Appendix A. Proof of Theorem 4.2 (continued). From the Lipschitz property of f and (4.12), (4.9), (4.10), (4.11), (4.14), (4.15), (4.17) we obtain the following estimates:

$$\begin{aligned} I_1^b &\le C \int_{-\infty}^{\gamma_1^+} \left| f\left(\sum_{k=1}^{N} \hat{w}_k(\xi + (c_j - c_k)t) \right) - f(w_1^-) + f(w_j^-) - f(w_j(\xi)) \right|^2 d\xi \\ &\le C \int_{-\infty}^{\gamma_1^+} \sum_{k=1}^{N} |w_k(\xi + (c_j - c_l)t) - w_k^-|^2 d\xi \\ &\le C \int_{-\infty}^{\gamma_1^+} \sum_{k=1}^{N} e^{2\alpha(\xi + (c_j - c_k)t)} d\xi \le C \int_{-\infty}^{\gamma_1^+} e^{2\alpha(\xi + (c_j - c_1)t)} d\xi \\ &\le C e^{-2\alpha q (c_j - c_1)t}; \end{aligned}$$

for $l \in \{1, \dots, j-1\}$,

$$\begin{aligned} I_{1,l}^{1-} &\le C \int_{\gamma_l^+}^{\gamma_l^0} \frac{\varphi(\xi)^2}{\varphi(\xi + (c_j - c_l)t)^2} d\xi \\ &\le C \int_{\gamma_l^+}^{\gamma_l^0} e^{2((\beta_1 - \beta_0)\xi - \beta_0(c_j - c_l)t)} d\xi \le C e^{2((\beta_0 - \beta_1)q - \beta_1)(c_j - c_l)t}; \end{aligned}$$

for $l \in \{1, \dots, j-1\}$,

$$I_{1,l}^{2-} \le C \int_{\gamma_l^0}^{\gamma_l^-} \frac{\varphi(\xi)^2}{\varphi(\xi + (c_j - c_l)t)^2} d\xi$$
$$\le C \int_{\gamma_l^0}^{\gamma_l^-} e^{2((\beta_1+\beta_0)\xi + \beta_0(c_j-c_l)t)} d\xi \le C e^{2((\beta_0+\beta_1)q-\beta_1)(c_j-c_l)t};$$

for $l \in \{1, \dots, j-2\}$,

$$I_{1,l}^{3-} \le C \int_{\gamma_l^-}^{\gamma_{l+1}^+} \left| f\left(\sum_{k=1}^{N} \hat{w}_k(\xi + (c_j - c_k)t) \right) - f(w_l^+) + f(w_j^-) - f(w_j(\xi)) \right|^2 d\xi$$
$$\le C \left[\int_{\gamma_l^-}^{\gamma_{l+1}^+} \sum_{k=1}^{l} |w_k(\xi + (c_j - c_k)t) - w_k^+|^2 d\xi \right.$$
$$\left. + \int_{\gamma_l^-}^{\gamma_{l+1}^+} \sum_{k=l+1}^{N} |w_k(\xi + (c_j - c_k)t) - w_k^-|^2 d\xi \right]$$
$$\le C \left[\int_{\gamma_l^-}^{\gamma_{l+1}^+} \sum_{k=1}^{l} e^{-2\alpha(\xi + (c_j-c_k)t)} d\xi + \int_{\gamma_l^-}^{\gamma_{l+1}^+} \sum_{k=l+1}^{N} e^{2\alpha(\xi+(c_j-c_k)t)} d\xi \right]$$
$$\le C \left[\int_{\gamma_l^-}^{\gamma_{l+1}^+} e^{-2\alpha(\xi+(c_j-c_l)t)} + e^{2\alpha(\xi+(c_j-c_{l+1})t)} d\xi \right]$$
$$\le C \left[e^{-2\alpha q(c_j-c_l)t} + e^{-2\alpha q(c_j-c_{l+1})t} \right].$$

We further obtain for $l \in \{j+1, \dots, N\}$

$$I_{1,l}^{1+} \le C \int_{\gamma_l^-}^{\gamma_l^0} \frac{\varphi(\xi)^2}{\varphi(\xi + (c_j - c_l)t)^2} d\xi$$
$$\le C \int_{\gamma_l^-}^{\gamma_l^0} e^{2((-\beta_1-\beta_0)\xi - \beta_0(c_j-c_l)t)} d\xi \le C e^{2((\beta_0+\beta_1)q-\beta_1)\gamma_l^0};$$

for $l \in \{j+1, \dots, N\}$,

$$I_{1,l}^{2+} \le C \int_{\gamma_l^0}^{\gamma_l^+} \frac{\varphi(\xi)^2}{\varphi(\xi + (c_j - c_l)t)^2} d\xi$$
$$\le C \int_{\gamma_l^0}^{\gamma_l^+} e^{2((\beta_0-\beta_1)\xi + \beta_0(c_j-c_l)t)} d\xi \le C e^{2((\beta_0-\beta_1)q-\beta_1)\gamma_l^0};$$

and for $l \in \{j+1, \dots, N-1\}$,

$$
\begin{aligned}
I_{1,l}^{3+} &\le C \int_{\gamma_l^+}^{\gamma_{l+1}^-} \left| f\left(\sum_{k=1}^{N} \hat{w}_k(\xi + (c_j - c_k)t) \right) - f(w_l^+) + f(w_j^+) - f(w_j(\xi)) \right|^2 d\xi \\
&\le C \left[\int_{\gamma_l^+}^{\gamma_{l+1}^-} \sum_{k=1}^{l} |w_k(\xi + (c_j - c_k)t) - w_k^+|^2 d\xi \right. \\
&\quad \left. + \int_{\gamma_l^+}^{\gamma_{l+1}^-} \sum_{k=l+1}^{N} |w_k(\xi + (c_j - c_k)t) - w_k^-|^2 d\xi \right] \\
&\le C \left[\int_{\gamma_l^+}^{\gamma_{l+1}^-} \sum_{k=1}^{l} e^{-2\alpha(\xi + (c_j - c_k)t)} d\xi + \int_{\gamma_l^+}^{\gamma_{l+1}^-} \sum_{k=l+1}^{N} e^{2\alpha(\xi + (c_j - c_k)t)} d\xi \right] \\
&\le C \left[\int_{\gamma_l^+}^{\gamma_{l+1}^-} \sum_{k=1}^{l} e^{-2\alpha(\xi + (c_j - c_l)t)} d\xi + \int_{\gamma_l^+}^{\gamma_{l+1}^-} \sum_{k=l+1}^{N} e^{2\alpha(\xi + (c_j - c_{l+1})t)} d\xi \right] \\
&\le C \left[e^{-2\alpha q \gamma_l^0} + e^{-2\alpha q \gamma_{l+1}^0} \right].
\end{aligned}
$$

Finally, we have

$$
\begin{aligned}
I_1^e &\le C \int_{\gamma_N^+}^{\infty} \left| f\left(\sum_{k=1}^{N} \hat{w}_k(\xi + (c_j - c_k)t) \right) - f(w_N^+) + f(w_j^+) - f(w_j(\xi)) \right|^2 d\xi \\
&\le C \sum_{k=1}^{N} |w_k(\xi + (c_j - c_k)t) - w_k^+|^2 d\xi \le C \int_{\gamma_N^+}^{\infty} \sum_{k=1}^{N} e^{-2\alpha(\xi + (c_j - c_k)t)} d\xi \\
&\le C \int_{\gamma_N^+}^{\infty} e^{-2\alpha(\xi + (c_j - c_N)t)} d\xi \le C e^{-2\alpha q (c_N - c_j)t}.
\end{aligned}
$$

For $j = 1$, the estimate of I_1 has fewer terms:

$$
\begin{aligned}
I_1 &\le C \left[\int_{-\infty}^{\gamma_2^-} \left| f\left(\sum_{k=1}^{N} \hat{w}_k(\xi_{k,1}^g) \right) - f(w_1(\xi)) \right|^2 d\xi + \sum_{k=2}^{N} \int_{\gamma_k^-}^{\gamma_k^0} Q_1^g(\xi, t)^2 d\xi \right. \\
&\quad + \sum_{k=2}^{N} \int_{\gamma_k^0}^{\gamma_k^+} Q_1^g(\xi, t)^2 d\xi + \sum_{k=2}^{N-1} \int_{\gamma_k^+}^{\gamma_{k+1}^-} \left| f\left(\sum_{k=1}^{N} \hat{w}_k(\xi_{k,1}^g) \right) - f(w_1(\xi)) \right|^2 d\xi \\
&\quad \left. + \int_{\gamma_N^+}^{\infty} \left| f\left(\sum_{k=1}^{N} \hat{w}_k(\xi_{k,1}^g) \right) - f(w_1(\xi)) \right|^2 d\xi \right] \\
&=: I_1^c + \sum_{k=2}^{N} I_{1,k}^{1+} + \sum_{k=2}^{N} I_{1,k}^{2+} + \sum_{k=2}^{N-1} I_{1,k}^{3+} + I_1^e.
\end{aligned}
$$

$I^{1+}_{1,k}, I^{2+}_{1,k}, I^{3+}_{1,k}, I^e$ are estimated as before, and for I^c_1 we have

$$\begin{aligned} I^c_1 &\le C \int_{-\infty}^{\gamma_2^-} \sum_{k=2}^{N} e^{2\alpha(\xi+(c_1-c_k)t)} d\xi \le C \int_{-\infty}^{\gamma_2^-} e^{2\alpha(\xi+(c_1-c_2)t)} d\xi \\ &\le C e^{-2\alpha q(c_2-c_1)t}. \end{aligned}$$

The estimate of I_1 for $j = N$ proceeds as follows:

$$\begin{aligned} I_1 \le C \Bigg[&\int_{-\infty}^{\gamma_1^+} \left| f\left(\sum_{k=1}^{N} \hat{w}_k(\xi^g_{k,N}) \right) - f(w_N(\xi)) \right|^2 d\xi + \sum_{k=1}^{N-1} \int_{\gamma_k^+}^{\gamma_k^0} Q^g_N(\xi,t)^2 d\xi \\ &+ \sum_{k=1}^{N-1} \int_{\gamma_k^0}^{\gamma_k^-} Q^g_N(\xi,t)^2 d\xi + \sum_{k=1}^{N-2} \int_{\gamma_k^-}^{\gamma_{k+1}^+} \left| f\left(\sum_{k=1}^{N} \hat{w}_k(\xi^g_{k,N}) \right) - f(w_N(\xi)) \right|^2 d\xi \\ &+ \int_{\gamma^-_{N-1}}^{\infty} \left| f\left(\sum_{k=1}^{N} \hat{w}_k(\xi^g_{k,N}) \right) - f(w_N(\xi)) \right|^2 d\xi \Bigg] \\ =: I^b_1 &+ \sum_{k=1}^{j-1} I^{1-}_{1,k} + \sum_{k=1}^{j-1} I^{2-}_{1,k} + \sum_{k=1}^{j-2} I^{3-}_{1,k} + I^c_1. \end{aligned}$$

The terms $I^b_1, I^{1-}_{1,k}, I^{2-}_{1,k}, I^{3-}_{1,k}$ are treated as before, and for I^c_1 we have

$$\begin{aligned} I^c_1 &\le C \int_{\gamma^-_{N-1}}^{\infty} \sum_{k=1}^{N-1} e^{-2\alpha(\xi+(c_N-c_k)t)} d\xi \\ &\le C \int_{\gamma^-_{N-1}}^{\infty} e^{-2\alpha(\xi+(c_N-c_{N-1})t)} d\xi \le C e^{-2\alpha q(c_N-c_{N-1})t}. \end{aligned}$$

Finally, we estimate I_2. For $2 \le j \le N-1$ we partition into four terms:

$$\begin{aligned} I_2 \le C \Bigg[&\int_{-\infty}^{\gamma_{j-1}} |f(w_j(\xi))|^2 d\xi + \int_{\gamma_{j-1}}^{0} (1 - Q^g_j(\xi,t))^2 d\xi \\ &+ \int_{0}^{\gamma_{j+1}} (1 - Q^g_j(\xi,t))^2 d\xi + \int_{\gamma_{j+1}}^{\infty} |f(w_j(\xi))|^2 d\xi \Bigg] \\ =: &\, I_{2,1} + I_{2,2} + I_{2,3} + I_{2,4}, \end{aligned}$$

where

$$\gamma_k = q(c_k - c_j)t.$$

Employing the same estimates as above, we find

$$
\begin{aligned}
I_{2,1} &\le C \int_{-\infty}^{\gamma_{j-1}} |f(w_j(\xi)) - f(w_j^-)|^2 d\xi \\
&\le C \int_{-\infty}^{\gamma_{j-1}} e^{2\alpha\xi} d\xi \le C e^{2\alpha\gamma_{j-1}}, \\
I_{2,2} &\le C \int_{\gamma_{j-1}}^{0} \frac{\left(\sum_{k=1}^{j-1} \varphi(\xi + (c_j - c_k)t) + \sum_{k=j+1}^{N} \varphi(\xi + (c_j - c_k)t)\right)^2}{\varphi(\xi)^2} \, d\xi \\
&\le C \left[\int_{\gamma_{j-1}}^{0} \sum_{k=1}^{j-1} e^{-2(\beta_0+\beta_1)\xi - 2\beta_1(c_j - c_k)t} + \sum_{k=j+1}^{N} e^{2(-\beta_0+\beta_1)\xi + 2\beta_1(c_j-c_k)t} d\xi \right] \\
&\le C \int_{\gamma_{j-1}}^{0} e^{-2(\beta_0+\beta_1)\xi - 2\beta_1(c_j - c_{j-1})t} + e^{2(-\beta_0+\beta_1)\xi + 2\beta_1(c_j-c_{j+1})t} d\xi \\
&\le C(e^{2((\beta_0+\beta_1)q - \beta_1)(c_j - c_{j-1})t} + e^{2(\beta_0-\beta_1)q(c_j-c_{j-1})t - 2\beta_1(c_{j+1}-c_j)t}), \\
I_{2,3} &\le C \int_{0}^{\gamma_{j+1}} \frac{\left(\sum_{k=1}^{j-1} \varphi(\xi + (c_j - c_k)t) + \sum_{k=j+1}^{N} \varphi(\xi + (c_j - c_k)t)\right)^2}{\varphi(\xi)^2} \, d\xi \\
&\le C \left[\int_{0}^{\gamma_{j+1}} \sum_{k=1}^{j-1} e^{2(\beta_0-\beta_1)\xi - 2\beta_1(c_j - c_k)t} + \sum_{k=j+1}^{N} e^{2(\beta_0+\beta_1)\xi + 2\beta_1(c_j-c_k)t} d\xi \right] \\
&\le C \int_{0}^{\gamma_{j+1}} e^{2(\beta_0-\beta_1)\xi - 2\beta_1(c_j - c_{j-1})t} + e^{2(\beta_0+\beta_1)\xi + 2\beta_1(c_j-c_{j+1})t} d\xi \\
&\le C \left[e^{2(\beta_0-\beta_1)\gamma_{j+1} - 2\beta_1(c_j - c_{j-1})t} + e^{2((\beta_0+\beta_1)q - \beta_1)(c_{j+1}-c_j)t} \right], \\
I_{2,4} &\le C \int_{\gamma_{j+1}}^{\infty} |f(w_j(\xi)) - f(w_j^+)|^2 d\xi \le C \int_{\gamma_{j+1}}^{\infty} e^{-2\alpha\xi} d\xi \le C e^{-2\alpha\gamma_{j+1}}.
\end{aligned}
$$

For $j = 1$ we estimate I_2 as follows:

$$
\begin{aligned}
I_2 &\le C \left[\int_{-\infty}^{-qt} |f(w_1(\xi))|^2 d\xi + \int_{-qt}^{0} (1 - Q_1^g(\xi, t))^2 d\xi \right. \\
&\qquad \left. + \int_{0}^{\gamma_2} (1 - Q_1^g(\xi, t))^2 d\xi + \int_{\gamma_2}^{\infty} |f(w_1(\xi))|^2 d\xi \right] \\
&=: I_{2,1} + I_{2,2} + I_{2,3} + I_{2,4}.
\end{aligned}
$$

$I_{2,3}$ and $I_{2,4}$ are estimated as before, and for $I_{2,1}$ and $I_{2,2}$ we obtain

$$
\begin{aligned}
I_{2,1} &\le C \int_{-\infty}^{-qt} |f(w_1(\xi)) - f(w_1^-)|^2 d\xi \le C \int_{-\infty}^{-qt} e^{2\alpha_1\xi} d\xi \le C e^{-2\alpha_1 qt}, \\
I_{2,2} &\le C \int_{-qt}^{0} \frac{\sum_{k=2}^{N} \varphi(\xi + (c_1 - c_k)t)}{\varphi(\xi)^2}^2 d\xi \le C \int_{-qt}^{0} \sum_{k=2}^{N} e^{2(-\beta_0+\beta_1)\xi + 2\beta_1(c_1-c_k)t} d\xi \\
&\le C \int_{-qt}^{0} e^{2(-\beta_0+\beta_1)\xi + 2\beta_1(c_1-c_2)t} d\xi \le C(e^{2(\beta_0-\beta_1)qt - 2\beta_1(c_2-c_1)t}).
\end{aligned}
$$

Similarly, we find for $j = N$

$$\begin{aligned} I_2 &\le C\left[\int_{-\infty}^{\gamma_{N-1}} |f(w_N(\xi))|^2 d\xi + \int_{\gamma_{N-1}}^{0} (1 - Q_N^g(\xi,t))^2 d\xi \right. \\ &\quad \left. + \int_0^{qt} (1 - Q_N^g(\xi,t))^2 d\xi + \int_{qt}^{\infty} |f(w_N(\xi))|^2 d\xi \right] \\ &=: I_{2,1} + I_{2,2} + I_{2,3} + I_{2,4}. \end{aligned}$$

$I_{2,1}$ and $I_{2,2}$ are as before, and $I_{2,3}$, $I_{2,4}$ satisfy

$$\begin{aligned} I_{2,3} &\le C\int_0^{qt} \frac{\sum_{k=1}^{N-1} \varphi(\xi + (c_N - c_k)t)}{\varphi(\xi)^2}^2 d\xi \le C\int_0^{qt} \sum_{k=1}^{N-1} e^{2(\beta_0-\beta_1)\xi - 2\beta_1(c_N-c_k)t} d\xi \\ &\le C\int_0^{qt} e^{2(\beta_0-\beta_1)\xi - 2\beta_1(c_N-c_{N-1})t} d\xi \le Ce^{2(\beta_0-\beta_1)qt - 2\beta_1(c_N-c_{N-1})t}, \\ I_{2,4} &\le C\int_{qt}^{\infty} |f(w_N(\xi)) - f(w_N^+)|^2 d\xi \le C\int_{qt}^{\infty} e^{-2\alpha\xi} d\xi \le Ce^{-2\alpha qt}. \end{aligned}$$

Acknowledgments. The authors thank Clarence Rowley for stimulating discussions that furthered the subject and for pointing out the relations to methods in fluid dynamics. The authors are also grateful for the constructive comments of the anonymous referees that led to improvements of the first version of the paper.

Mechanisms for Frequency Control in Neuronal Competition Models*

Rodica Curtu†, Asya Shpiro‡, Nava Rubin‡, and John Rinzel§

Abstract. We investigate analytically a firing rate model for a two-population network based on mutual inhibition and slow negative feedback in the form of spike frequency adaptation. Both neuronal populations receive external constant input whose strength determines the system's dynamical state—a steady state of identical activity levels or periodic oscillations or a winner-take-all state of bistability. We prove that oscillations appear in the system through supercritical Hopf bifurcations and that they are antiphase. The period of oscillations depends on the input strength in a nonmonotonic fashion, and we show that the increasing branch of the period versus input curve corresponds to a release mechanism and the decreasing branch to an escape mechanism. In the limiting case of infinitely slow feedback we characterize the conditions for release, escape, and occurrence of the winner-take-all behavior. Some extensions of the model are also discussed.

Key words. Hopf bifurcation, antiphase oscillations, slow negative feedback, winner-take-all, release and escape, binocular rivalry, central pattern generators

1. Introduction.

Competition models have a long tradition in ecology and population biology (see, e.g., [22]). Typically, the competition involves negative interactions in the battle for a common resource. Eventually, one of the participant populations emerges as the winner eliminating the competitors. This framework has appeared in models of neuronal development where the competition is for synapse formation such as the development of neuromuscular connections for innervated muscle fibers and for the formation of ocular dominance columns and topographic maps (as reviewed in [35]). The notion of competition has also been applied in the modeling of various neuronal computational tasks. *Winner-take-all* behavior, when one neural population remains active and the others inactive indefinitely as a result of inhibitory interactions, has been proposed in models for short term memory and attention [13] or for the selection and switching in the striatum of the basal ganglia under both normal and pathological conditions [15, 21].

The winner-take-all steady state may persist for a long time but not indefinitely if some

mechanism for slow fatigue or adaptation is at work. In this case one population may be dominant for a while, then another, and so on. Competition between, say, two neuronal populations, via reciprocal inhibition and slow adaptation underlies models for alternating rhythmic behavior in central pattern generators (CPGs) [11, 32, 6, 33] and in perceptual bistability [17, 37, 24]. CPGs consist of neural circuits that drive alternately contracting muscle groups. Perceptual bistability refers to a class of phenomena in which a deeply ambiguous stimulus gives rise to two different interpretations that alternate over time, only one being perceived at any given moment. Slow adaptation may be implemented via a cellular mechanism (fatigue in the spike generation mechanism) or a negative feedback in the coupling (depression of the synaptic transmission mechanism). In some neuronal competition models the alternations may be irregular and caused primarily by noise, with adaptation playing a secondary role [30, 10, 24].

Both for CPGs and perceptual bistability the issue of oscillations' frequency or period detection (and eventually control) seems to be important. For example, a classical example of perceptual bistability is binocular rivalry whose properties were summarized in the so-called Levelt's propositions [19]. In binocular rivalry, a subject views an ambiguous stimulus in which each eye is presented with a drastically different image. Instead of perceiving a mixture of the two images, the subject reports (over a large range of stimulus conditions) an alternation between the two competing percepts; one image is perceived for a while (a few seconds), then the other, etc. Levelt's proposition IV (LP-IV) states that *increasing the contrast of the rivaling images increases the frequency of percept switching*, or, in other words, that *dominance times of both perceived images decrease with equal increase of stimulus strength*. Since 1968, binocular rivalry has been investigated intensively in other psychophysics experiments [2, 25, 20, 1, 28, 29, 3], in experiments using fMRI techniques [34, 26, 38, 18], and also in modeling studies [17, 37, 10, 24].

In a recent modeling paper, Shpiro et al. [31] show that for a class of competition models, the LP-IV type of dynamics occurs in fact only within a limited range of stimulus strength. Outside this range four other types of behavior were observed: (i) fusion at a very high level of activity, (ii) winner-take-all behavior, (iii) a region where dominance times increase with stimulus strength (as opposed to LP-IV), and then (iv) fusion again for very low levels of activity (see Figure 3F in section 2). These differences between experimental reports and theory have important implications, either predicting new possible dynamics in binocular rivalry or, if future experiments do not confirm them, pointing to the necessity for other types of models. Meanwhile, it is important to understand the sources or mechanisms that lead to the nonmonotonic dependence of oscillation period on the stimulus strength for this class of neuronal competition models. Our paper aims to investigate this issue.

We analyze a firing rate model in which competition between populations is a result of a combination of reciprocal inhibition and a slow negative feedback process. We prove that, as the input strength changes, oscillations appear in the system through a Hopf bifurcation and that they are antiphase. Due to the two time scales involved in the system there is a regime where periodic solutions take the form of relaxation-oscillators. Their period of oscillations depends nonmonotonically on the input strength, say, I: in a range of low values for I, the period increases with I, and we show that the dynamics is due to a *release* mechanism; on the other hand, in a range of higher values for I, the period decreases with I, and *escape* is

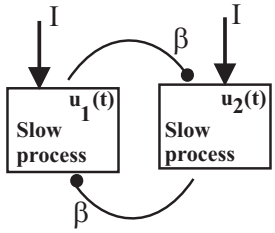

Figure 1. *Network architecture of neuronal competition model.*

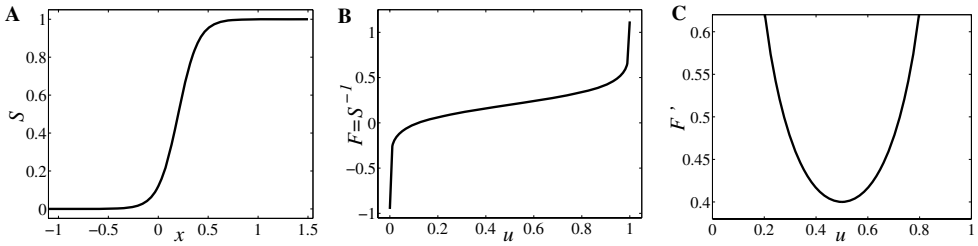

Figure 2. *Graphical representations of generic* (A) *gain function S;* (B) *its inverse F; and* (C) *first derivative F'.*

the underlying mechanism (see section 4; we define release as the case when the switch in dominance during oscillation occurs due to a significant change in the response to an input to the dominant population. On the contrary, escape corresponds to the case of a significant change in the input-output function for the suppressed population). For intermediate values of I, winner-take-all is possible and we explain how it appears. Then in section 5 we present some model modifications that allow for reducing, or even excluding, one of the escape and release regimes, thus leading to a monotonic period versus input curve.

2. The mathematical model. The model we investigate in this paper assumes a network architecture of two populations of neurons (Figure 1) that respond to two competing stimuli of equal strength:

$$\begin{aligned} \dot{u}_1 &= -u_1 + S(I - \beta u_2 - g a_1), \\ \dot{u}_2 &= -u_2 + S(I - \beta u_1 - g a_2), \\ \tau \dot{a}_1 &= -a_1 + u_1, \\ \tau \dot{a}_2 &= -a_2 + u_2. \end{aligned} \tag{2.1}$$

Variables u_j $(j = 1, 2)$ measure short-time and spatially averaged firing rates of the two populations that inhibit each other. The system is nonlinear due to the gain function S; it is the steady input-output function for the population and it has a sigmoid shape as in Figure 2A. The strength of inhibition is modeled by the positive parameter β, while I is the control parameter directly associated to the external stimulus strength (e.g., it grows with growing stimulus strength such as contrast). Each population is subject to a slow negative feedback process a_j such as spike frequency adaptation of positive strength g. Since variables a_j evolve in much slower time than u_j, the parameter τ takes large values, $\tau \gg 1$ (e.g., the

time-scale for u_j is about 10 msec, while for a_j it is about 1000 msec).

Remark 2.1. *In general, firing-rate models like (2.1) include in the equation of u_j a nonlinear term of the form $S(I + \alpha u_j - \beta u_k - g a_j)$. The product αu_j is associated with the intrapopulation recurrent excitation. It is important to note that for neuronal competition model (2.1) we have disallowed recurrent excitation (taken $\alpha = 0$) in order to preclude an isolated population ($\beta = 0$) from oscillating on its own. This is a restriction imposed by experimental observations on binocular rivalry and other perceptual bistable phenomena.*

The nonlinear gain function S that appears in the differential equations for u_j is usually defined in neuronal models by

$$S(x) = \frac{1}{1 + e^{-r(x-\theta)}} \tag{2.2}$$

with positive r and real θ.

Function S is invertible with $F = S^{-1}$ a $\mathcal{C}^\infty(0,1)$-function and $F'(u) = \frac{1}{ru(1-u)}$ (Figure 2B–C). Based on this example, we consider the following *assumptions* for the gain function S.

$S : \boldsymbol{R} \to (0,1)$ is a differentiable, monotonically increasing function with $S(\theta) = u_0 \in (0,1)$ and $\lim_{x\to-\infty} S(x) = 0$, $\lim_{x\to\infty} S(x) = 1$. Moreover, its first and second derivatives satisfy the conditions $\lim_{x\to\pm\infty} S'(x) = 0$, $S''(x) > 0$ for $x < \theta$, $S''(x) < 0$ for $x > \theta$, and $S''(\theta) = 0$, so S' has a maximum at θ.

As a consequence, S is invertible with $F = S^{-1} : (0,1) \to \boldsymbol{R}$ monotonically increasing function such that $\lim_{u\to0} F(u) = -\infty$, $\lim_{u\to1} F(u) = \infty$, $F(u_0) = \theta$, and $\lim_{u\to0} F'(u) = \lim_{u\to1} F'(u) = \infty$, $F''(u) < 0$ for $u \in (0, u_0)$, $F''(u) > 0$ for $u \in (u_0, 1)$, $F''(u_0) = 0$. Obviously, F' has a minimum value at u_0 which is $F'(u_0) = 1/S'(\theta)$.

Additionally we assume that F is a $\mathcal{C}^\infty$-function on $(0,1)$, or at least $\mathcal{C}^2$ on $(0,1)$ and $\mathcal{C}^\infty$ on $(0,1) \setminus \{u_0\}$.

The typical graphs of function S and its corresponding F and F' are drawn in Figure 2A–C. We used the example (2.2) with parameter values $r = 10$ and $\theta = 0.2$; obviously in this case $S(\theta) = u_0 = 0.5$.

All the experiments that motivated our work report oscillatory phenomena with frequencies tightly connected to the stimulus strengths. Moreover, as Levelt [19] pointed out for binocular rivalry, those experiments show large ranges for stimulus strength where the corresponding oscillation periods/frequencies behave monotonically. What kind of possible mechanism is behind this type of dynamics is the question we will focus on in this paper.

Given the neuronal competition model (2.1), the goal is to examine the effect the parameter I has on the existence of oscillations and on their period. The system is a simplified version of an entire class of competition models that, as we found [31], share important dynamical features.

To illustrate those commonalities we draw in Figure 3A–E the timecourses of activity variables $u_1(t)$ and $u_2(t)$ for different values of control parameter I. Then we summarize the result in the bifurcation diagram of the period T versus I (Figure 3F). Other parameter values are fixed to $\beta = 1.1$, $g = 0.5$, $\tau = 100$, and S as in (2.2) with $r = 10$ and $\theta = 0.2$ (here $u_0 = 1/2$). The system (2.1) exhibits five possible types of behavior: for large values of I (region I in Figure 3F) both populations are active at identically high levels (Figure 3A); the timecourses of $u_1(t)$ and $u_2(t)$ tend to a stable steady state larger than u_0. As I decreases (region II,

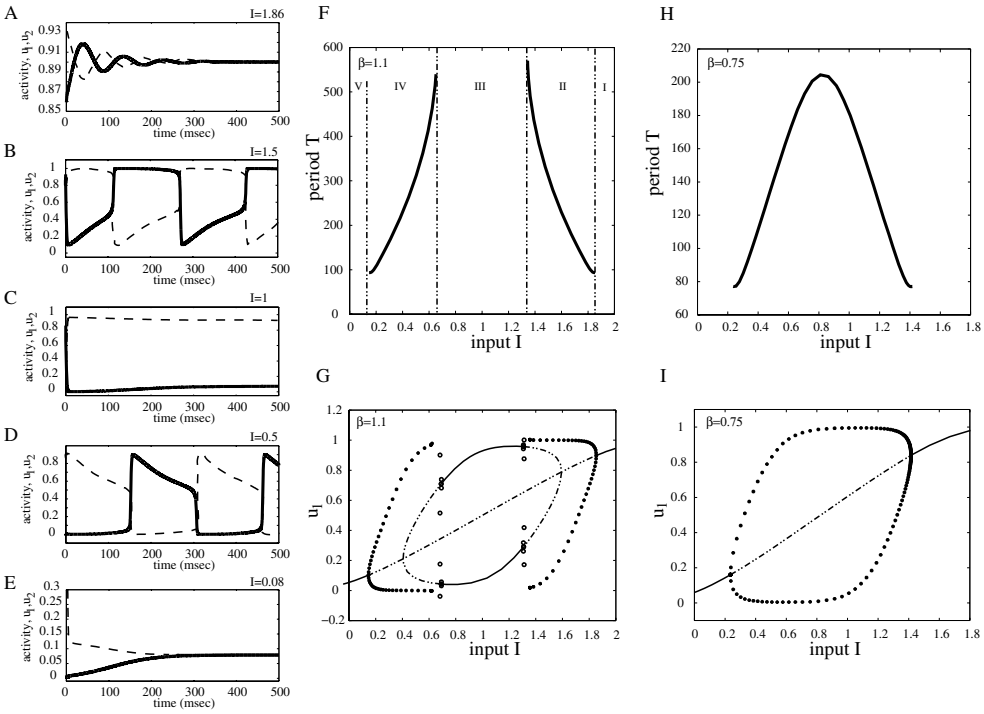

Figure 3. *Bifurcation diagrams and examples of activity timecourses for neuronal competition model* (2.1) *with parameter values* $g = 0.5$, $\tau = 100$, $r = 10$, $\theta = 0.2$, *and* $\beta = 1.1$ (A–G), *respectively,* $\beta = 0.75$ (H–I). *Timecourses of* u_1, u_2 *corresponding to panel F for different values of* I: (A) $I = 1.86$, (B) $I = 1.5$, (C) $I = 1$, (D) $I = 0.5$, *and* (E) $I = 0.08$. *Bifurcation diagrams of period* T *of the network oscillation versus input strength* I *(F and H). Bifurcation diagram of population activity* u_1 *versus* I *(G and I).*

Figure 3F) the system starts oscillating with $u_1(t)$ and $u_2(t)$ alternatively on and off (Figure 3B); in this region the period of oscillation decreases with increasing input strength. At intermediate values of I a winner-take-all kind of behavior is observed (region III, Figure 3F); depending on the choice of initial conditions, one of the two populations is active indefinitely, while the other one remains inactive (Figure 3C). Decreasing I even more (region IV, Figure 3F) the neuronal model becomes oscillatory again (Figure 3D) with u_1 and u_2 competing for the active state; however, for this range of parameter the oscillation period T increases with input value I—an opposite behavior to that observed in region II. Last, for small values of stimulus strength (region V, Figure 3F) both populations remain inactive at identically low level firing rates (Figure 3E); the timecourses of $u_1(t)$ and $u_2(t)$ tend to a stable steady state less than u_0.

To further characterize system (2.1)'s dynamics as the input value I is varied, we also construct the local bifurcation diagram of amplitude response u_1 to I (Figure 3G). For the parameter ranges I and V the trajectories are attracted to a stable fixed point satisfying the $\tilde{u}_1 = \tilde{u}_2$ condition (thick line in Figure 3G). This fixed point becomes unstable (dashed line) in regions II, III, and IV, where the attractor is replaced by either a stable limit cycle (regions II and IV: branched filled-circle curves corresponding to the maximum and minimum amplitudes during rivalry oscillations) or another stable fixed point with $\tilde{u}_1 \neq \tilde{u}_2$ (region III).

Due to the symmetry in the equations of (2.1) whenever $(\tilde{u}_1, \tilde{u}_2, \tilde{a}_1, \tilde{a}_2)$ is an equilibrium point, $(\tilde{u}_2, \tilde{u}_1, \tilde{a}_2, \tilde{a}_1)$ is as well. The local bifurcation diagram suggests the existence of some Hopf and pitchfork bifurcations in the model that we will further investigate in section 3.

There is another common feature of many neuronal competition models based on reciprocal inhibition architecture with slow negative feedback in the form of spike frequency adaptation and/or synaptic depression [31]: the absence of the winner-take-all behavior when inhibition strength β is sufficiently small. As we illustrate in Figure 3H–I for $\beta = 0.75$ (all other parameters are the same as above), the winner-take-all regime at intermediate I disappears. However, the dependency of period T on stimulus strength remains nonmonotonic.

An intriguing question is: What are the neuronal mechanisms underlying the two distinct dynamics—one of increasing period with increase of stimulus strength (for smaller values of input), and one of decreasing period (for larger values)? This issue is discussed in section 4 and then extended in section 5.

Our general goal is to understand and possibly to analytically characterize the numerical results obtained for this specific competition model (2.1). Consequently, as already pointed out, this step will help us understand the typical behavior of an entire class of neuronal competition models.

3. Oscillatory antiphase solutions and local analysis. In this section we use methods from local bifurcation theory [14, 16] to prove the existence of periodic solutions $(u_1(t), u_2(t), a_1(t), a_2(t))$ for the two-population network (2.1). We also show that the main variables u_1 and u_2 oscillate in antiphase, therefore competing for the ON/active state.

The bifurcation diagrams obtained numerically in section 2 suggest the existence of an equilibrium point satisfying $u_1 = u_2$ no matter the value of parameter I. Let us now investigate system (2.1) theoretically.

All equilibria satisfy the conditions $u_1 = S(I - \beta u_2 - g a_1)$, $u_2 = S(I - \beta u_1 - g a_2)$, $a_1 = u_1$, and $a_2 = u_2$ that are equivalent (due to the invertibility of S) to $F(u_1) = I - \beta u_2 - g a_1$, $F(u_2) = I - \beta u_1 - g a_2$, and $a_1 = u_1$, $a_2 = u_2$. Looking for a particular type of equilibrium point, that is, for points with $u_1 = u_2$, we obtain the equation $I = H(u)$ with H defined by

$$H : (0,1) \to \boldsymbol{R}, \quad H(u) \stackrel{\text{def}}{=} F(u) + (\beta + g)u. \tag{3.1}$$

Since F is monotonically increasing on $(0,1)$ with vertical asymptotes $\lim_{u\to 0} F(u) = -\infty$ and $\lim_{u\to 1} F(u) = \infty$, (3.1) has a unique solution $u_I \in (0,1)$ for any real value of the parameter I. Moreover, from the identity $I = F(u_I) + (\beta + g)u_I$ we compute

$$\frac{du_I}{dI} = \frac{1}{\beta + g + F'(u_I)}, \tag{3.2}$$

so a decrease in I leads to a decrease in u_I with $\lim_{I\to\infty} u_I = 1$ and $\lim_{I\to-\infty} u_I = 0$.

The neuronal competition model (2.1) always possesses an equilibrium of the type (u_I, u_I, u_I, u_I). Its stability properties are then defined by the linearized system $dY/dt = \mathcal{A}Y$, $Y = (u_1 - u_I, u_2 - u_I, a_1 - u_I, a_2 - u_I)^{\mathrm{T}}$, where $(\,)^{\mathrm{T}}$ stays for the transpose, and matrix

$$\mathcal{A} = \begin{pmatrix} -1 & -\beta/F'(u_I) & -g/F'(u_I) & 0 \\ -\beta/F'(u_I) & -1 & 0 & -g/F'(u_I) \\ 1/\tau & 0 & -1/\tau & 0 \\ 0 & 1/\tau & 0 & -1/\tau \end{pmatrix}.$$

This form of the matrix relies on the equality $S'(I-\beta u_2-ga_1) = S'(F(u_1)) = S'(S^{-1}(u_1)) = 1/(S^{-1})'(u_1) = 1/F'(u_1)$, which is true at the equilibrium point.

The characteristic equation of $\mathcal{A}$ takes the form

$$\left[(\lambda+1)\left(\lambda+\frac{1}{\tau}\right)+\frac{g}{\tau F'(u_I)}\right]^2-\left[\frac{\beta}{F'(u_I)}\left(\lambda+\frac{1}{\tau}\right)\right]^2=0.$$

As a difference of squares it can be decomposed into two quadratic equations: the first is $\lambda^2+\lambda\left(1+\frac{1}{\tau}+\frac{\beta}{F'(u_I)}\right)+\frac{1}{\tau}\left(1+\frac{g+\beta}{F'(u_I)}\right)=0$, so two eigenvalues of the matrix $\mathcal{A}$, say, λ_1 and λ_2, have negative real part no matter the value of parameter I. The other eigenvalues λ_3 and λ_4 satisfy the second quadratic equation $\lambda^2+\lambda\left(1+\frac{1}{\tau}-\frac{\beta}{F'(u_I)}\right)+\frac{1}{\tau}\left(1+\frac{g-\beta}{F'(u_I)}\right)=0$, and their real part can change sign when I is varied.

For $|I|$ sufficiently large, u_I is close to either zero or one, keeping $F'(u_I)$ larger than both $\beta/(1+\frac{1}{\tau})$ and $\beta-g$ (see Figure 2C); the corresponding equilibrium point (u_I,u_I,u_I,u_I) is asymptotically stable.

There are two ways this equilibrium point can lose stability: either through a pair of purely imaginary eigenvalues $\lambda_{3,4}=\pm i\omega$ at $F'(u_I)=\beta/(1+\frac{1}{\tau})$ or through a zero eigenvalue $\lambda_3=0$, $\lambda_4<0$ at $F'(u_I)=\beta-g$. Which of these two cases occurs first depends on the relationship between $\beta/(1+\frac{1}{\tau})$ and $\beta-g$: if $\beta/(1+\frac{1}{\tau})>\beta-g$, i.e., $\beta/g<\tau+1$, then the eigenvalues λ_3,λ_4 change the sign of their real part from negative to positive by crossing the imaginary axis ($\lambda_{3,4}=\pm i\omega$); if $\beta/g>\tau+1$, then the case $\lambda_3=0$, $\lambda_4<0$ is encountered first.

At this point we remind the reader of our assumption of a large time constant value τ. (The competition between the populations in the network comes from the combination of two important ingredients: reciprocal inhibition and the addition of a slow negative feedback process.) Therefore, it makes sense to situate ourselves in the case of $\beta/g\ll\tau$, which implies

$$\beta<g(\tau+1). \tag{3.3}$$

Inequality (3.3) can be interpreted as a feature of the neuronal competition model to be rather (adaptation) feedback-dominated than (inhibitory) coupling-dominated.

We will assume in the following that parameters g and τ are fixed and that β is chosen such that (3.3) is true.

Another observation is that the graph of F' has a *well-like* shape with positive minimum at $1/S'(\theta)$ as in Figure 2C. Consequently the straight horizontal line $y=\beta/(1+\frac{1}{\tau})$ intersects it twice (if $\beta/(1+\frac{1}{\tau})>1/S'(\theta)$), once (for the equality), or not at all (if $\beta/(1+\frac{1}{\tau})<1/S'(\theta)$). As observed in numerical simulations, in order for the system to oscillate, a sufficiently large inhibition strength has to be considered. Mathematically that reduces to

$$\beta>\frac{1+1/\tau}{S'(\theta)}. \tag{3.4}$$

Thus we are able to characterize the stability of the equilibrium (u_I,u_I,u_I,u_I).

Theorem 3.1. *The dynamical system (2.1) has a unique equilibrium point with $u_1=u_2$, say, $\mathbf{e}_I=(u_I,u_I,u_I,u_I)$, for any real I. The value u_I increases monotonically with I and belongs to the interval $(0,1)$.*

Let us assume that the adaptation-dominance condition (3.3) is true.

(i) *If* $\beta < \frac{1+1/\tau}{S'(\theta)}$, *then* $\mathbf{e}_I$ *is asymptotically stable for all* $I \in \boldsymbol{R}$.

(ii) *If* $\beta > \frac{1+1/\tau}{S'(\theta)}$, *then there exist exactly two values* $u^*_{hb}, u^{**}_{hb} \in (0,1)$ *such that* $u^*_{hb} < u_0 < u^{**}_{hb}$ *and*

$$F'(u^*_{hb}) = F'(u^{**}_{hb}) = \frac{\beta}{1+\frac{1}{\tau}}. \tag{3.5}$$

The equilibrium point $\mathbf{e}_I$ *is asymptotically stable for all* $I \in (-\infty, I^*_{hb}) \cup (I^{**}_{hb}, \infty)$ *and unstable for* $I \in (I^*_{hb}, I^{**}_{hb})$, *where* $I^*_{hb} = H(u^*_{hb})$, $I^{**}_{hb} = H(u^{**}_{hb})$ *defined by* (3.1). *At* I^*_{hb} *and* I^{**}_{hb} *the stability is lost through a pair of purely imaginary eigenvalues.*

Proof. (i) Since $\beta - g < \beta/(1+\frac{1}{\tau}) < 1/S'(\theta) = \min(F')$, all eigenvalues of the linearized system about $\mathbf{e}_I$ have negative real part.

(ii) The conclusion is based on the properties of F', which decreases on interval $(0, u_0)$ and increases on $(u_0, 1)$ with $F'(u_0) = \min(F')$. The sum $\lambda_3 + \lambda_4$ changes sign from negative to positive when I increases through I^*_{hb} and then back from positive to negative when passing through I^{**}_{hb}. For $I \in (I^*_{hb}, I^{**}_{hb})$ at least one real part of λ_3 and λ_4 is positive, so $\mathbf{e}_I$ is unstable. At $I = I^*_{hb}$ and $I = I^{**}_{hb}$ we have $\lambda_{3,4} = \pm i\omega$. For all other values of I we have $\lambda_3 + \lambda_4 < 0$, $\lambda_3\lambda_4 > 0$; so $\mathbf{e}_I$ is asymptotically stable. ∎

Since the equilibrium point $\mathbf{e}_I$ becomes unstable through a pair of purely imaginary eigenvalues as I crosses the values I^*_{hb} and I^{**}_{hb}, we expect to find there two Hopf bifurcation points. Indeed, in section 3.1 we prove the existence of a supercritical Hopf bifurcation at both I^*_{hb} and I^{**}_{hb} and, as a consequence, the existence of stable oscillatory solutions for system (2.1).

3.1. Normal form for the Hopf bifurcation. In the following we assume that both inequalities (3.3) and (3.4) are true; that is, we take the coupling in (2.1) to be sufficiently strong but still adaptation-dominated.

Let us use the notation I^* for any of the critical values I^*_{hb} and I^{**}_{hb} and similarly the notation u^* for $u^* \in \{u^*_{hb}, u^{**}_{hb}\}$. Then the linearization matrix $\mathcal{A}$ at u^* becomes

$$\mathcal{A}_0 = \begin{pmatrix} -1 & -(1+\frac{1}{\tau}) & -\frac{g}{\beta}(1+\frac{1}{\tau}) & 0 \\ -(1+\frac{1}{\tau}) & -1 & 0 & -\frac{g}{\beta}(1+\frac{1}{\tau}) \\ \frac{1}{\tau} & 0 & -\frac{1}{\tau} & 0 \\ 0 & \frac{1}{\tau} & 0 & -\frac{1}{\tau} \end{pmatrix},$$

and it has eigenvalues $\lambda_{1,2}$ with $\mathrm{Re}(\lambda_{1,2}) < 0$ and $\lambda_{3,4} = \pm i\omega$,

$$\omega = \frac{1}{\tau}\sqrt{\frac{g(\tau+1)}{\beta} - 1}. \tag{3.6}$$

The system (2.1) has an equilibrium $\mathbf{e}_I$ for any $I \in \boldsymbol{R}$; we translate $\mathbf{e}_I$ to the origin with the change of variables $v_j = u_j - u_I$, $b_j = a_j - u_I$ $(j = 1, 2)$ and obtain a system topologically equivalent to (2.1),

$$\begin{aligned} \dot{v}_1 &= -v_1 + S(F(u_I) - \beta v_2 - g b_1) - u_I, \\ \dot{v}_2 &= -v_2 + S(F(u_I) - \beta v_1 - g b_2) - u_I, \\ \tau \dot{b}_1 &= -b_1 + v_1, \\ \tau \dot{b}_2 &= -b_2 + v_2. \end{aligned} \tag{3.7}$$

Near u^*, $u^* \neq u_0$, we expand the nonlinear terms in (3.7) with respect to u_I and obtain for v_1 (and similarly for v_2) an equation of the form

$$\dot{v}_1 = -v_1 - S'(F(u_I)) \cdot (\beta v_2 + g b_1) + \frac{1}{2} S''(F(u_I)) \cdot (\beta v_2 + g b_1)^2 - \frac{1}{6} S'''(F(u_I)) \cdot (\beta v_2 + g b_1)^3 + h.o.t. \tag{3.8}$$

Here *h.o.t.* means the *higher order terms*. The parameter value I^* is a possible Hopf bifurcation, so we consider small perturbations about it and about the solution u^*. That is, we take

$$I - I^* = \varepsilon^2 \alpha, \qquad V(t) = \varepsilon V_0(t) + \varepsilon^2 V_1(t) + \varepsilon^3 V_2(t) + \cdots, \tag{3.9}$$

where α is the bifurcation parameter and $V = (v_1, v_2, b_1, b_2)^{\mathrm{T}}$.

The expansions of the coefficients $S^{(k)}(F(u_I))$, $k = 1, 2, 3, \ldots$, with respect to ε take the form $S'(F(u_I)) = (1 + \frac{1}{\tau})/\beta + \alpha A \varepsilon^2 + \mathcal{O}(\varepsilon^4)$, $S''(F(u_I)) = B + \mathcal{O}(\varepsilon^2)$, and $S'''(F(u_I)) = D + \mathcal{O}(\varepsilon^2)$, where A, B, and D are defined by

$$A = -\frac{F''(u^*)}{F'(u^*)^2(\beta + g + F'(u^*))}, \quad B = -\frac{F''(u^*)}{F'(u^*)^3}, \quad D = \frac{3F''(u^*)^2 - F'(u^*) \cdot F'''(u^*)}{F'(u^*)^5} \tag{3.10}$$

(see Appendix A for more details). Let us introduce the following notation: for two vectors $U = (v_1, v_2, b_1, b_2)^{\mathrm{T}}$ and $W = (w_1, w_2, c_1, c_2)^{\mathrm{T}}$ we define first the quantities $\tilde{v}_{ij} = \beta v_j + g b_i$, $\tilde{w}_{ij} = \beta w_j + g c_i$, and then, using the scalars from (3.10), we define the operators

$$L_0 U = \frac{dU}{dt} - \mathcal{A}_0 U, \quad \Lambda U = -\alpha A \, (\tilde{v}_{12}, \tilde{v}_{21}, 0, 0)^{\mathrm{T}},$$
$$\mathcal{B}(U, W) = \frac{B}{2} (\tilde{v}_{12}\tilde{w}_{12}, \, \tilde{v}_{21}\tilde{w}_{21}, \, 0, \, 0)^{\mathrm{T}}, \quad \mathcal{C}(U, U, U) = -\frac{D}{6} (\tilde{v}_{12}^3, \tilde{v}_{21}^3, 0, 0)^{\mathrm{T}}.$$

Then based on (3.8), (3.9), and (3.10), we write system (3.7) as

$$L_0 V_0 = \varepsilon [\mathcal{B}(V_0, V_0) - L_0 V_1] + \varepsilon^2 [\mathcal{C}(V_0, V_0, V_0) + 2\mathcal{B}(V_0, V_1) + \Lambda V_0 - L_0 V_2] + \mathcal{O}(\varepsilon^3).$$

The construction of the normal form relies on an algorithm that we describe in Appendix A (see also [4, 5] for a similar approach) and that involves tedious calculations; we present here only the main result.

Theorem 3.2. *Let us assume that conditions (3.3) and (3.4) are true (sufficiently strong coupling and adaptation-dominated system), and take $I^* \in \{I^*_{hb}, I^{**}_{hb}\}$, $u^* \in \{u^*_{hb}, u^{**}_{hb}\}$ as in Theorem 3.1. Then the system (2.1) has in the neighborhood of I^* the normal form*

$$\dot{z} = A\varphi (I - I^*) \, z - \mathcal{L} z^2 \bar{z}, \tag{3.11}$$

where z is a complex variable and

$$\mathcal{L} = 4\tau^2\omega^2 \frac{|\varphi|^2}{|\psi|^2} \varphi\psi \left(\frac{\beta + g}{2} + i\beta\omega\tau \right) B^2 + 2\tau^2\omega^2 |\varphi|^2 \varphi \left(\frac{2(\beta + g)}{1 + (\frac{g}{\beta} + 1)(1 + \frac{1}{\tau})} B^2 - D \right)$$

with $\varphi = \frac{\beta}{2} + i\frac{g-\beta}{2\tau\omega}$, $\psi = 2 - \frac{3g}{\beta} + \frac{1}{\tau}\left(5 - \frac{3g}{\beta}\right) - 4i\omega(\tau+1)$, *and* A, B, D *as in* (3.10).

In order to show that I^*_{hb} and I^{**}_{hb} are supercritical Hopf bifurcation points, we need to check that the coefficient of $z^2\bar{z}$ has negative real part, i.e., that $\mathrm{Re}(\mathfrak{L}) > 0$.

As we prove in the appendix, for our range of parameters β, g, and τ, the first term in $\mathfrak{L}$ has indeed positive real part (see (A.3)); on the other hand, the real part of the second term (see (A.4)) is larger than

$$\beta\tau^2\omega^2|\varphi|^2B^2F'(u^*)\left(\frac{F'(u^*)F'''(u^*)}{F''(u^*)^2} - 2\right).$$

Remark 3.1. *The inverse of function* S *defined by* (2.2) *satisfies the condition*

$$F'(u^*)F'''(u^*) > 2F''(u^*)^2. \tag{3.12}$$

Moreover, the inequality (3.12) *is true not only for* u^* *but for all* $u \in (0,1)$.

We use this observation to state our next result.

Theorem 3.3. *Let us assume the same hypotheses as in Theorem* 3.2. *Given at* $u^* \in \{u^*_{hb}, u^{**}_{hb}\}$ *the property* (3.12) *for the gain function* S, *the input value* I^* *is a supercritical Hopf bifurcation point for system* (2.1). *The stable limit cycle occurs on the left side of* I^{**}_{hb} *(that is, for sufficiently close* $I < I^{**}_{hb}$*) and on the right side of* I^*_{hb} *(*$I > I^*_{hb}$*).*

Proof. The Hopf bifurcation is supercritical since $\mathrm{Re}(\mathfrak{L}) > 0$ in the normal form; the nondegeneracy condition is $\mathrm{Re}(A\varphi) = A\beta/2 \neq 0$.

The sign of A is opposite to the sign of $F''(u^*)$, so $A > 0$ for u^*_{hb} and $A < 0$ for u^{**}_{hb}. Consequently the sign of $\mathrm{Re}(A\varphi(I - I^*))$ that shows the direction of limit cycle bifurcation is positive for $I > I^*_{hb}$ and $I < I^{**}_{hb}$. ∎

Remark 3.2. *It is possible to obtain supercritical Hopf bifurcation points for other types of gain-function than* (3.12), *as long as* $\mathrm{Re}(\mathfrak{L})$ *has positive value. When* (3.12) *is not valid, the sign of* $\mathrm{Re}(\mathfrak{L})$ *will be computed directly from the definition formula of* $\mathfrak{L}$.

3.2. Antiphase oscillations. The stable limit cycle that exists in the neighborhood of the bifurcation points I^*_{hb} (for $I > I^*_{hb}$) and I^{**}_{hb} (for $I < I^{**}_{hb}$) is a periodic solution $L_1(t) = (u_1(t), u_2(t), a_1(t), a_2(t))$ of period, say, T. Due to the symmetry of the system (2.1) with respect to the group $\Gamma = \{\mathbf{1}_4, \gamma\}$ where $\mathbf{1}_4$ is the unitary 4-by-4 matrix and

$$\gamma = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix},$$

$L_2(t) = \gamma L_1(t) = (u_2(t), u_1(t), a_2(t), a_1(t))$ is also a periodic solution for (2.1). L_2 results automatically from solution L_1 by relabeling the two network's populations. Moreover, it belongs to the same neighborhood of the equilibrium point as L_1 does.

Since the limit cycle born through the Hopf bifurcation is unique, the corresponding phase space trajectories of L_1 and L_2 coincide. Therefore, there exists a phase shift $\alpha_0 \in [0, T)$ such that $L_2(t) = L_1(t + \alpha_0)$. This implies $u_2(t) = u_1(t + \alpha_0)$ and $u_1(t) = u_2(t + \alpha_0)$, i.e., $u_1(t) = u_1(t + 2\alpha_0)$ for all real t [12]. The phase shift α_0 needs to satisfy $\alpha_0 = kT/2$ with k

an integer, so k is either $k = 0$ or $k = 1$. If $k = 0$, the two populations in the network will oscillate in synchrony. If $k = 1$, we have $u_2(t) = u_1(t + T/2)$ and $a_2(t) = a_1(t + T/2)$, which means an antiphase oscillation.

Let us assume for the moment that $k = 0$. Then $U(t) = (u_1(t), u_1(t), a_1(t), a_1(t))$ is a periodic solution of (2.1), and, as a consequence, $(u_1(t), a_1(t))$ is a periodic solution of the two-dimensional system

$$\dot{u}_1 = -u_1 + S(I - \beta u_1 - g a_1), \quad \tau \dot{a}_1 = -a_1 + u_1.$$

This contradicts Bendixon's criterion: the expression

$$\frac{\partial}{\partial u_1}(-u_1 + S(I - \beta u_1 - g a_1)) + \frac{\partial}{\partial a_1}\left(-\frac{a_1}{\tau} + \frac{u_1}{\tau}\right) = -1 - \beta S'(I - \beta u_1 - g a_1) - \frac{1}{\tau}$$

is always negative, so our initial assumption should be false.

Excluding the first case, the limit cycle has to be an antiphase solution of (2.1): the two populations compete indeed for the active state (see, for example, Figure 3B or 3D).

We state our conclusion in the following theorem.

Theorem 3.4. *Let us assume that conditions (3.3) and (3.4) are true and the coefficient $\mathcal{L}$ in the normal form (3.11) has positive real part. Then the stable limit cycle obtained at the supercritical Hopf bifurcation (as I crosses either I^*_{hb} or I^{**}_{hb}) corresponds to an antiphase oscillation: the limit cycle of period T satisfies $u_2(t) = u_1(t + T/2)$ and $a_2(t) = a_1(t + T/2)$ for any real t.*

3.3. Multiple equilibria for large enough inhibition. Our local analysis shows how stable oscillations occur in system (2.1)—through a Hopf bifurcation. The uniform equilibrium point $\mathbf{e}_I$ has four eigenvalues, λ_1 and λ_2 with negative real part independent of I ($\mathrm{Re}(\lambda_{1,2}) < 0$), and λ_3 and λ_4 that can cross the imaginary axis. Besides Hopf, another type of local bifurcation appears in (2.1) when one of the eigenvalues λ_3, λ_4 takes zero value, that is, when $F'(u_I) = \beta - g$. Because of the system's symmetry we expect it to be a pitchfork bifurcation.

Numerical simulations of system (2.1) reveal indeed the existence of additional equilibrium points. However, they exist for stronger (Figure 3G, $\beta = 1.1$) but not for weaker inhibition (Figure 3I, $\beta = 0.75$). We explain analytically how that happens.

Theorem 3.5. (i) *If $\beta - g < 1/S'(\theta)$, then the dynamical system (2.1) has a unique equilibrium point for all real I and this is $\mathbf{e}_I = (u_I, u_I, u_I, u_I)$.*

(ii) *For strong inhibition,*

$$\beta - g > 1/S'(\theta), \tag{3.13}$$

there are exactly two values, say, $u^*_{pf}, u^{**}_{pf} \in (0, 1)$, such that $u^*_{pf} < u_0 < u^{**}_{pf}$ and

$$F'(u^*_{pf}) = F'(u^{**}_{pf}) = \beta - g. \tag{3.14}$$

At $I^*_{pf} = H(u^*_{pf})$ and $I^{**}_{pf} = H(u^{**}_{pf})$ defined by (3.1), the equilibrium point $\mathbf{e}_I$ has a zero eigenvalue.

Proof. The condition that characterizes the equilibrium points of (2.1) is equivalent to $G(u_1) = G(u_2) = I - \beta(u_1 + u_2)$, where we define G by $G(u) = F(u) + (g - \beta)u$, $u \in (0, 1)$. We

have $\lim_{u\to 0} G(u) = -\infty$, $\lim_{u\to 1} G(u) = \infty$, and $G'(u) = F'(u) + g - \beta \geq F'(u_0) + g - \beta = 1/S'(\theta) + g - \beta$. Obviously, based on hypothesis (i), we have $G'(u) > 0$. Therefore, G is a monotonically increasing function; so it is injective, and the conclusion follows immediately. Statement (ii) results from the shape of F'. ■

By constructing the normal form of the system around the bifurcation point I^*_{pf} or I^{**}_{pf}, we prove the existence of a subcritical pitchfork bifurcation. Therefore, in the neighborhood of I^*_{pf} or I^{**}_{pf} the system (2.1) has multiple (three) equilibria. However, since the pitchfork is subcritical, the two newly born equilibrium points are unstable. In the four-dimensional eigenspace they actually possess two unstable modes (see Remark 3.4).

In some cases these nonuniform equilibria (having $u_1 \neq u_2$) might change their stability for I between I^*_{pf} and I^{**}_{pf}. Depending on the initial condition a trajectory will be attracted either to the fixed point with $u_1 > u_2$ or to that with $u_1 < u_2$, so one population is dominant and the other is suppressed forever. We call this type of dynamics in (2.1) *winner-take-all behavior*. The issue of the existence of the winner-take-all regime will be discussed separately in section 4.2. In this section we focus only on the mechanism that introduces additional equilibrium points to system (2.1).

Theorem 3.6. *Let us assume $\beta/(1+\frac{1}{\tau}) > \beta - g > 1/S'(\theta)$ and take $I^\circ \in \{I^*_{pf}, I^{**}_{pf}\}$, $u^\circ \in \{u^*_{pf}, u^{**}_{pf}\}$ as in (3.14), $I^\circ = F(u^\circ) + (\beta + g)u^\circ$. Then the system (2.1) has in the neighborhood of I° the normal form*

$$\dot{z} = \frac{(I - I^\circ)F''(u^\circ)}{2\beta[g(\tau+1) - \beta]}\, z + \frac{(\beta - g)^2}{6[g(\tau+1) - \beta]}\left(F'(u^\circ)F'''(u^\circ) - \frac{3}{2}F''(u^\circ)^2 + \frac{3g}{2\beta}\right) z^3. \tag{3.15}$$

Moreover, if the gain function S satisfies (3.12) at $u^\circ \in \{u^*_{pf}, u^{**}_{pf}\}$, then I° is a subcritical pitchfork bifurcation point for the system (2.1). Two additional unstable equilibrium points occur on the left side of I^{**}_{pf} ($I < I^{**}_{pf}$) and on the right side of I^*_{pf} ($I > I^*_{pf}$).

Proof. The construction of the normal form is sketched in Appendix B. Since (3.12) is true, the coefficient of z^3 in the normal form is positive and the pitchfork is subcritical. Additional equilibrium points appear for $(I - I^\circ)F''(u^\circ) < 0$ with $F''(u^\circ)$ negative at u^*_{pf} and positive at u^{**}_{pf}. ■

Remark 3.3. *In case of adaptation-dominated systems (when condition (3.3) or, equivalently, $\beta/(1+\frac{1}{\tau}) > \beta - g$ is true) we conclude the following: (1) for weak inhibition ($\beta - g < \beta/(1+\frac{1}{\tau}) < 1/S'(\theta)$), system (2.1) has a unique equilibrium point $\mathbf{e}_I$ which is asymptotically stable for all I; (2) for some intermediate value of inhibition ($\beta - g < 1/S'(\theta) < \beta/(1+\frac{1}{\tau})$), the system still has a unique equilibrium point for all I but this becomes unstable in the interval (I^*_{hb}, I^{**}_{hb}). However in order to obtain this case we need to properly adjust the maximum gain to the adaptation parameters (i.e., we need $S'(\theta) > 1/(\tau g)$); (3) for strong inhibition ($1/S'(\theta) < \beta - g < \beta/(1+\frac{1}{\tau})$), additional equilibrium points occur in system (2.1) for $I > I^*_{pf}$ and $I < I^{**}_{pf}$.*

Remark 3.4. *In case of strong inhibition and adaptation-dominated system we obtain $u^*_{hb} < u^*_{pf} < u_0 < u^{**}_{pf} < u^{**}_{hb}$ and*

$$I^*_{hb} < I^*_{pf} < I_0 < I^{**}_{pf} < I^{**}_{hb}.$$

(Note that $I_0 = H(u_0)$ is independent of β.) At each I between I^*_{hb} and I^{**}_{hb}, the equilibrium point $\mathbf{e}_I$ has at least one eigenvalue of positive real part. In fact for $I \in (I^*_{hb}, I^*_{pf}) \cup (I^{**}_{hb}, I^{**}_{pf})$,

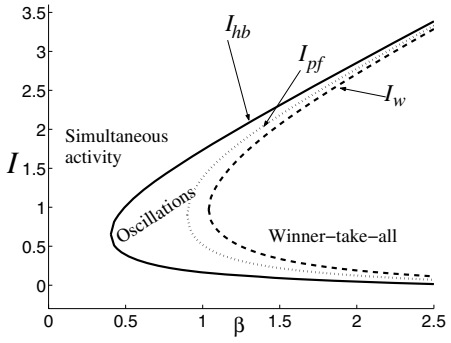

Figure 4. *Dynamical regimes in system (2.1) as inhibition strength β and stimulus strength I vary (other parameters are fixed: $g = 0.5$, $\tau = 100$, $r = 10$, $\theta = 0.2$). To the left of curve I_{hb} (solid line) the system has a unique stable equilibrium, and this satisfies $u_1 = u_2$ (simultaneous activity); in the region between curves I_{hb} and I_w (dashed line) the system oscillates; then to the right of I_w the system has a winner-take-all behavior (two stable and one unstable equilibria). The curve I_{pf} (dotted line) indicates a transition from one equilibrium to multiple equilibria in (2.1). While the attractor's type (limit cycle) does not change between I_{hb} and I_w, the number of equilibria does: we find one unstable equilibrium between I_{hb}, I_{pf} and three unstable equilibria between I_{pf}, I_w. The turning points of curves I_{hb}, I_{pf}, and I_w are obtained at $\beta = \frac{1+1/\tau}{S'(\theta)} = 0.404$, $\beta = g+1/S'(\theta) = 0.9$, and $\beta_{wta} = 1.0387$, respectively.*

it has exactly two eigenvalues with positive real part and for $I \in (I^*_{pf}, I^{**}_{pf})$ it has only one eigenvalue with positive real part. Due to the multidimensionality of the eigenspace, at I^*_{pf} and I^{**}_{pf} the equilibrium $\mathbf{e}_I$ does not actually change its stability (even if an eigenvalue takes zero value). Instead two new (nonuniform) equilibria are born (e.g., Figure 3G). The two nonuniform equilibria inherit the number of unstable modes from their "parent"–fixed point, which means they have exactly two unstable modes.

As we see, condition (3.13) is necessary but not sufficient to obtain a winner-take-all behavior in system (2.1). In section 4.2, equations (4.11) and (4.10), we will determine the minimum value of β for which winner-take-all exists (β_{wta}) and the corresponding values I^*_w, I^{**}_w where transition from oscillation to winner-take-all dynamics takes place. We summarize all these results in Figure 4 by drawing the bifurcation diagram in the parameter plane (I, β).

4. Release, escape, and winner-take-all mechanisms in neuronal competition models.

As we mentioned in section 1, some common features are observed for a large class of neuronal competition models based on mutual inhibition and slow negative feedback process. An important example is the nonmonotonic dependency of the rivalry-oscillation's period T on the stimulus strength I: in a range of small values for I the period increases with input strength; however, there exists another range for I, at larger values, where the period decreases with stimulus strength. These two dynamical regimes are usually separated by another one that is nonoscillatory; it occurs for sufficiently strong inhibition and corresponds to winner-take-all behavior (see Figures 3F and 3H).

The goal of this section is to characterize the underlying mechanisms of the above dynamical scheme. We aim to understand what causes the two opposite rivalry dynamics: as we will see, a *release* kind of mechanism is associated with the increasing branch of the T versus I curve (region IV in Figure 3F); on the other hand, for the decreasing branch of the I-T curve

(region II in Figure 3F), an *escape* mechanim is responsible.

The terms *release* and *escape* were previously introduced by [36] for inhibition-mediated rhythmic patterns in thalamic model neurons and then extended and refined by [32] for Morris–Lecar equations. Most cases include an autocatalytic process either intrinsic by voltage-gated persistent inward currents or synaptic by intrapopulation recurrent excitation. In neuronal competition model (2.1) mutual inhibition plays the role of autocatalysis: one population inhibits the network partner that inhibited it; thus the combination of these two negative factors has a positive effect on its own activity. Rhythmicity is obtained due to a fast positive feedback (disinhibition) and a slow negative feedback process. The slow negative feedback process can be either an intrinsic property of the neuronal populations (e.g., spike frequency adaptation as in (2.1)) or a property of the inhibitory connections between them (e.g., synaptic depression). A simplified model similar to (2.1) but with synaptic depression and a Heaviside step-gain function was analytically investigated in [33]. Numerical results for models with synaptic depression and smooth sigmoid gain functions were also reported in [33] and [31].

In the context of neuronal competition models we define *release* and *escape mechanisms* as follows: The two populations in the network oscillate in antiphase competing for the active state; for the dominant population of variable, say, u_1, the net input $I-\beta u_2-ga_1$ decreases as the slow negative feedback accumulates; on the contrary, for the suppressed population u_2 the feedback recovers (decays) so the net input $I-\beta u_1-ga_2$ increases. However, since the function S is highly nonlinear, equal changes in the net input $I-\beta u_j-ga_k$ of both populations can lead to drastically different changes in the corresponding effective response $S(I-\beta u_j-ga_k)$. This transformation has a direct influence on the variation of u_1 and u_2. The switch in dominance is due either to a significant, more abrupt change (decrease) in the response to an input to the dominant population, or, on the contrary, to a significant change (increase) in the response to an input to the suppressed population. In the first case the dominant population loses control, its activity drops, and it no longer suppresses its competitor, which becomes active. We call this mechanism *release*. In the latter case, when the input-output function S of the suppressed population changes faster, this population regains control, its activity rises, and it forces its competitor into the inhibited state. We call this mechanism *escape*.

Intuitively, escape occurs for higher stimulus ranges than release. Therefore, we expect that an escape (release) mechanism underlies the dynamics in region II (region IV) in Figure 3F with decreasing (increasing) I-T curve. For large values of I the gain function for the dominant population is relatively constant and close to 1 while that for the suppressed population falls in the interval where it is steeper. For example, let us consider the fast plane (u_1, u_2) and assume that u_1 is ON and u_2 is OFF; then the dominance switching point is on the shallow part of the active population nullcline $u_1 = S(I-\beta u_2-ga_1)$ and on the steeper part of the down population nullcline $u_2 = S(I-\beta u_1-ga_2)$ (see the animation 70584_01.gif [3.7MB] in Appendix C). A larger variation in u_2 than in u_1 is expected, and that corresponds to the escape mechanism. For small values of I the gain function for the dominant population is steeper (the steeper part of active population nullcline $u_1 = S(I-\beta u_2-ga_1)$), while the gain function for the suppressed population is relatively constant and close to 0 (the shallow part of the down population nullcline $u_2 = S(I-\beta u_1-ga_2)$)—see the animation 70584_02.gif [3.8MB] in Appendix C. That is what we call release.

For sufficiently large inhibition β, at intermediate I the effective response to an input to

both populations might end up being relatively constant: closer to 1 for the active population and closer to 0 for the down population. The switching does not take place anymore; instead a *winner-take-all* dynamics is obtained.

In the following we investigate analytically how the period of oscillations for system (2.1) depends on the input strength and show that the increasing (decreasing) branch of the I-T curve is associated with the release (escape) mechanism. Our analysis is done in two steps: first, in section 4.1, we consider the limiting case sigmoid function $S(x) = Heav(x-\theta)$ such that $S(x) = 0$ if $x < \theta$ and $S(x) = 1$ if $x > \theta$; the function does not obey the hypotheses in section 2, but it provides a useful example where escape, release, and winner-take-all dynamics are easily characterized. Then in section 4.2 we return to the case of smooth sigmoid function and describe the notions defined above in this more general context. We find a precise mathematical characterization for the minimum value of β and then for the corresponding input values, say, I_w^* and I_w^{**}, where the winner-take-all regime appears. In the absence of a winner-take-all regime we provide a mathematical definition for the transition between escape and release.

4.1. A relevant example: The Heaviside step function. The choice of $S(x) = Heav(x-\theta)$ allows us to solve completely for the intervals of the stimulus strength I where oscillations and winner-take-all dynamics exist. For system (2.1) with a Heaviside step function, there are only four possible equilibrium points: $(1,1,1,1)$, $(1,0,1,0)$, $(0,1,0,1)$, and $(0,0,0,0)$. Here $(1,1,1,1)$ and $(0,0,0,0)$ correspond respectively to the simultaneously high and low activity states observed in numerical simulations in regions I and V of Figure 3F. Oscillations can occur only between the states $(u_1,u_2) = (1,0)$ and $(u_1,u_2) = (0,1)$ in which one population is dominant and the other one is suppressed. Let us now determine the necessary and sufficient conditions for the oscillations to exist. The idea used in our analysis is similar to that in [17] and [33].

In the fast plane, the nullclines of u_1 and u_2 consist in two constant plateaus of zero and unit value discontinuously connected at a "threshold" point $(I-(\theta+ga_1))/\beta$ and $(I-(\theta+ga_2))/\beta$, respectively (Figure 5A). During oscillation, due to the change in slow variables a_1 and a_2 these thresholds move along the vertical and horizontal axes. For example, assuming $u_1 = 1$, $u_2 = 0$, the slow equations become $\tau\dot{a}_1 = -a_1 + 1 > 0$ and $\tau\dot{a}_2 = -a_2 < 0$; thus the u_1-nullcline moves down while the u_2-nullcline moves to the right. If these nullclines slide enough and the thresholds cross either 0 (for the u_1-nullcline) or 1 (for the u_2-nullcline), i.e., either $a_{1J} = (I-\theta)/g$ or $a_{2J} = (I-(\theta+\beta))/g$ are reached, then the equilibrium point $(u_1,u_2) = (1,0)$ disappears and the system will be attracted to $(u_1,u_2) = (0,1)$. The switch takes place and the slow equations change to $\tau\dot{a}_1 = -a_1 < 0$, $\tau\dot{a}_2 = -a_2+1 > 0$, now pushing the nullclines in opposite directions. As we explain below, depending on which of the two *jumping values* a_{1J} or a_{2J} is reached first, a *release* or an *escape* mechanism will underlie the oscillation.

We note that for an oscillatory solution, $u_1+u_2 = 1$ always, and so $\tau(\dot{a}_1+\dot{a}_2) = 1-(a_1+a_2)$. Asymptotically, the slow dynamics will occur along the diagonal $a_1+a_2 = 1$ of the unit square (Figure 5D or 5F). The positions the horizontal line $a_2 = (I-(\theta+\beta))/g$ and the vertical line $a_1 = (I-\theta)/g$ have relative to the unit square is important when the trajectory points to the lower-right corner; on the other hand, when the trajectory points to the upper-left corner, the position of vertical line $a_1 = (I-(\theta+\beta))/g$ and horizontal line $a_2 = (I-\theta)/g$ will matter.

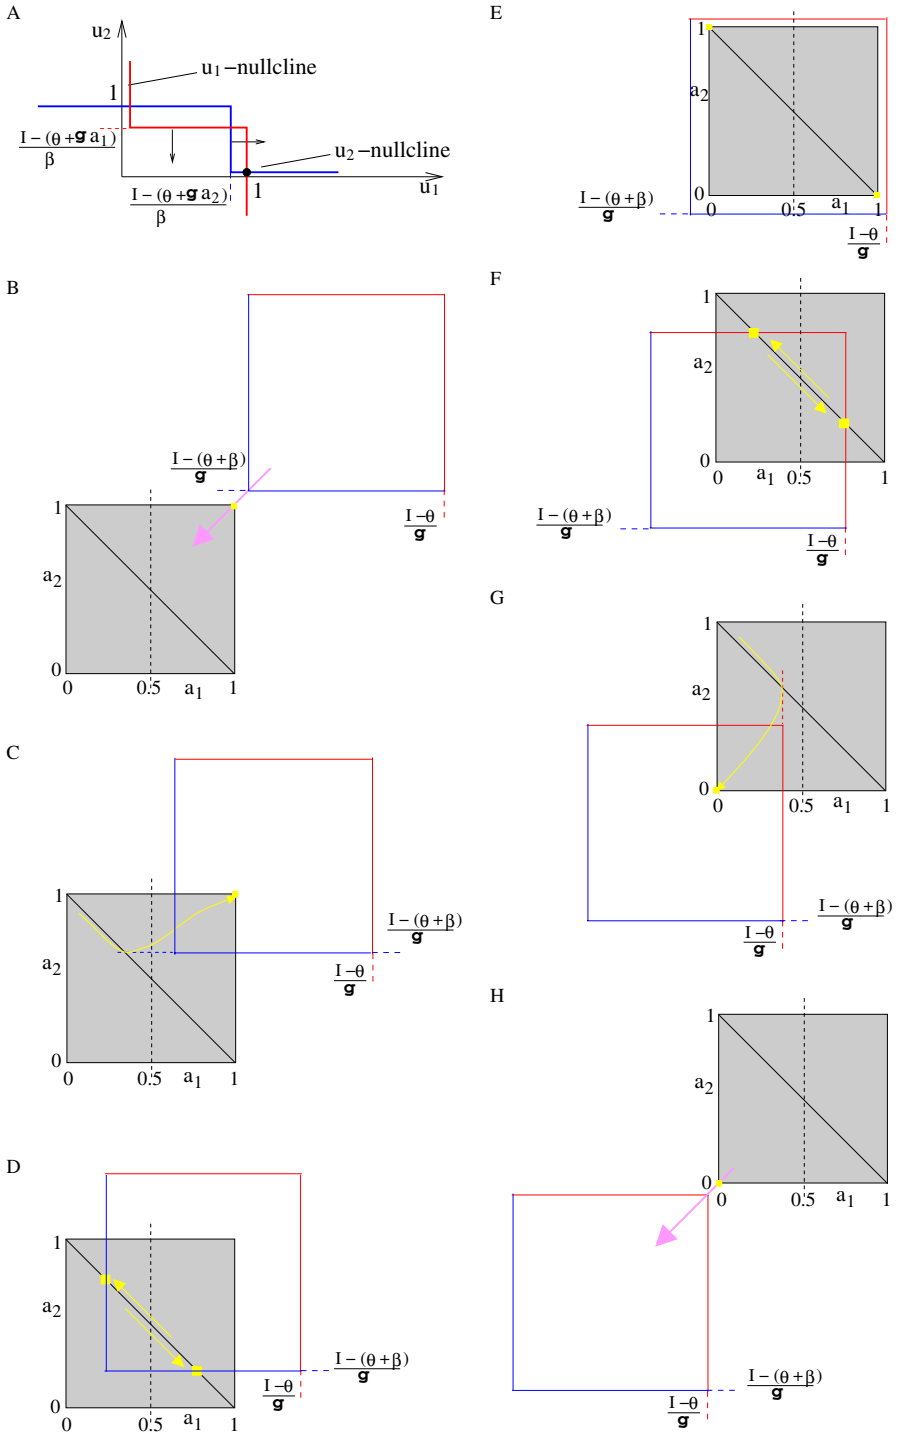

Figure 5. *System (2.1)'s dynamics for large inhibition strength ($\beta/g > 1$) and Heaviside step function.* (A) *Nullclines in the plane of fast variables (u_1, u_2);* (B–H) *System's dynamics in the slow variables plane (a_1, a_2) for:* (B) $I \geq \theta+\beta+g$; (C) $\theta+\beta+g/2 \leq I < \theta+\beta+g$; (D) $\theta+\beta < I < \theta+\beta+g/2$; (E) $\theta+g \leq I \leq \theta+\beta$; (F) $\theta + g/2 < I < \theta + g$; (G) $\theta \leq I \leq \theta + g/2$; (H) $I < \theta$.

Therefore, in the slow plane (a_1, a_2) (see Figure 5B–5H) we are interested in the intersection of the unit square (grey) with the square defined by the possible jumping values $(I-(\theta+\beta))/g$ (blue) and $(I-\theta)/g$ (red). If the red line is reached, then the active cell ($u_j = 1$) becomes suddenly inactive ($u_j = 0$), allowing its competitor to go up. That is why we call this case a release mechanism; otherwise, if the blue line is reached first, then the suppressed cell becomes suddenly active, forcing its competitor to go down. That is the escape mechanism.

As parameter I decreases, the blue-red square slides down along the first diagonal, starts to intersect the grey unit square, and then leaves it (Figure 5B–5H). The way those two squares intersect determines the system's dynamics, so we need to take into account the relative size of their sides: 1 and β/g.

Theorem 4.1 (five modes of behavior for large enough inhibition strength). *Let us assume that $\beta/g > 1$. The following five dynamical regimes exist for the neuronal competition model (2.1) with $S(x) = Heav(x-\theta)$.*

(i) *If $I \geq \theta + \beta + g/2$, then the system's attractor is the simultaneously high activity state $u_1 = u_2 = 1$.*

(ii) *If $\theta+\beta < I < \theta+\beta+g/2$, then the system oscillates between the states $(u_1, u_2) = (1, 0)$ and $(u_1, u_2) = (0, 1)$ due to an escape mechanism. The period of oscillations decreases with I and satisfies*

$$T_{escape} = 2\tau \ln\left(\frac{g}{I-(\theta+\beta)} - 1\right). \tag{4.1}$$

(iii) *If $\theta + g \leq I \leq \theta + \beta$, then the system is in a winner-take-all regime with fast variables either $(1, 0)$ or $(0, 1)$ depending on the initial condition choice.*

(iv) *If $\theta + g/2 < I < \theta + g$, then the system oscillates between the states $(u_1, u_2) = (1, 0)$ and $(u_1, u_2) = (0, 1)$ due to a release mechanism. The period of oscillations increases with I and satisfies*

$$T_{release} = 2\tau \ln\left(\frac{g}{\theta+g-I} - 1\right). \tag{4.2}$$

(v) *If $I \leq \theta + g/2$, then the system's attractor is the simultaneously low activity state $u_1 = u_2 = 0$.*

Proof. Since $\beta/g > 1$, there are exactly seven relative positions of the blue-red square to the unit square that lead to conclusions (i) to (v).

(i) For $1 \leq (I-(\theta+\beta))/g$ (Figure 5B) both a_1, a_2 are smaller than $(I-(\theta+\beta))/g$, so $I - \beta u_i - g a_k \geq I - \beta - g \geq \theta$, and we always have $u_1 = u_2 = 1$.

If $1/2 \leq (I-(\theta+\beta))/g < 1 < (I-\theta)/g$ (Figure 5C), let us assume $u_1 = 1$, $u_2 = 0$, and $a_1 + a_2 = 1$ as initial values. The slow variable a_1 increases while a_2 decreases; in this case only a_2 can cross the horizontal blue line, producing the jump of u_2 from 0 to 1. However, just after the jump, in the equation of u_1 we have $I - \beta u_2 - g a_1 = I - \beta - g(1 - a_{2J}) = 2(I-(\beta+\theta)) - g + \theta \geq \theta$, which keeps u_1 at its value 1. Therefore, the point will be attracted to the corner $(a_1, a_2) = (1, 1)$ and the oscillation dies.

(ii) For $0 < (I-(\theta+\beta))/g < 1/2 < 1 < (I-\theta)/g$ (Figure 5D), a_2 will first cross the blue line and induce a sudden change in u_2. Then in the u_1-equation we obtain $I - \beta u_2 - g a_1 =$

$I-\beta-g(1-a_{2J})=2(I-(\beta+\theta))-g+\theta<\theta$, which forces u_1 to take zero value. The fast system switches from $(1,0)$ to $(0,1)$ and the slow dynamics changes its direction of movement along the upper-left–lower-right diagonal of the unit square. The change $I-\beta u_1-ga_2=I-ga_2\geq I-g\geq\theta$ does not affect the new value $u_2=1$; oscillation exists indeed and its projection on the slow plane is the segment defined by the intersection of the unit square's secondary diagonal with the two blue lines. When I decreases, the length of this segment increases, so it will take longer to go from one endpoint to the other. We expect the period T to increase as I decreases. Indeed, at the jumping point, the slow variable for the suppressed population takes the value $a_f:=a_{2J}=(I-(\theta+\beta))/g$; however, just after the previous jump it was $a_i:=1-a_{1J}=1-(I-(\theta+\beta))/g$. Therefore, from $\tau\dot{a}_2=-a_2$ we compute the solution $a(t)=a_ie^{-t/\tau}$, $t\in(0,T/2)$. The period T of oscillation is $T=2\tau\ln(a_i/a_f)$, i.e., exactly (4.1). Moreover, $dT/dI<0$, so T decreases with I.

(iii) By choosing I such that $(I-(\theta+\beta))/g<0<1\leq(I-\theta)/g$, the unit square falls completely inside the blue-red square (Figure 5E). Starting at $u_1=1$, $u_2=0$ we have $I-\beta u_2-ga_1=I-ga_1\geq I-g\geq\theta$ and $I-\beta u_1-ga_2=I-\beta-ga_2\leq I-\beta<\theta$; the slow variables a_1 and a_2 continue to increase, respectively, decrease, approaching the lower-right corner of the unit square, and a winner-take-all state is achieved. For $u_1=0$, $u_2=1$, the point (a_1,a_2) will be attracted to the upper-left corner.

(iv) Decreasing I even more, we enter the region $(I-(\theta+\beta))/g<0<1/2<(I-\theta)/g<1$ (Figure 5F). Here the threshold is crossed at the red line and (when $u_1=1$, $u_2=0$) u_1 jumps from 1 to 0. In the u_2-equation, the expression $I-\beta u_1-ga_2$ becomes $I-g(1-a_{1J})=2(I-\theta)-g+\theta\geq\theta$, which leads to $u_2=1$. That is the release mechanism. In the slow plane (a_1,a_2) the point changes its direction of movement; the oscillation occurs along the segment defined by the intersection of the unit square's secondary diagonal with the two red lines. The length of this segment decreases as I decreases; it takes less time to go from one endpoint to the other, so we expect the period T to decrease. Indeed, for the release mechanism, $a_f:=a_{1J}=(I-\theta)/g$, with value just after the previous jump $a_i:=1-a_{2J}=1-(I-\theta)/g$. The slow differential equation is now $\tau\dot{a}_1=1-a_1$, that is, $a(t)=1-(1-a_i)e^{-t/\tau}$, $t\in(0,T/2)$. The period T of oscillation satisfies $T=2\tau\ln((1-a_i)/(1-a_f))$, or (4.2). Obviously $dT/dI>0$.

(v) Oscillations cannot exist anymore for $(I-(\theta+\beta))/g<0\leq(I-\theta)/g\leq1/2$ (Figure 5G). Say, again, that we have $u_1=1$, $u_2=0$: only a_1 can reach the threshold (red) line for u_1 to become inactive. However, just after the jump, in the u_2-equation the net input $I-\beta u_1-ga_2=I-g(1-a_{1J})=2(I-\theta)-g+\theta$ is still less than θ, and it keeps u_2 at zero. Both slow variables start to decrease approaching the corner $(a_1,a_2)=(0,0)$. The oscillation dies, and the fast system has $(0,0)$ as a single attractor. For even smaller values of input strength, $(I-(\theta+\beta))/g<(I-\theta)/g<0$ (Figure 5H), it is true that $I-\beta u_i-ga_k\leq I<\theta$ and $u_1=u_2=0$. ■

Remark 4.1. *We note that in the escape regime, $T\to0$ as $I\to\theta+\beta+g/2$ and $T\to\infty$ as $I\to\theta+\beta$. Similarly, in the release regime, $T\to0$ as $I\to\theta+g/2$ and $T\to\infty$ as $I\to\theta+g$.*

Case (iii) in Theorem 4.1 (case (E) in Figure 5) is not possible if the side of the blue-red square is smaller than the unit. Therefore, the winner-take-all dynamics is eliminated. On the other hand, the blue-red square can lie completely inside the unit square. Then we need to distinguish between two cases: the point moving along the secondary diagonal of the unit square may first reach the blue line (Figure 6A) or the red line (Figure 6B).

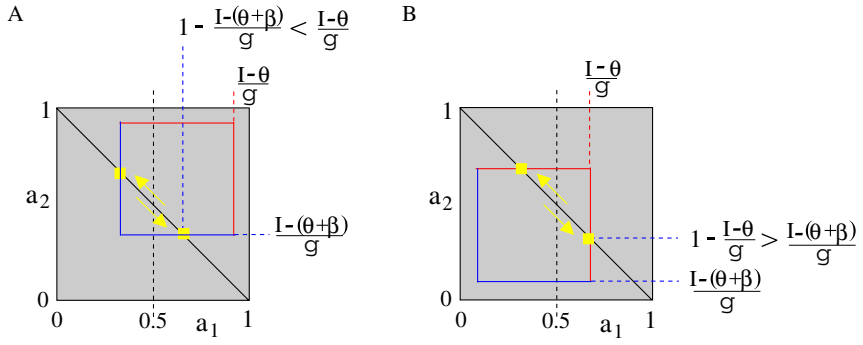

Figure 6. (A) *Escape and* (B) *release mechanisms for low inhibition strength* ($\beta/g < 1$) *in system* (2.1) *with Heaviside step function.*

Theorem 4.2 (no winner-take-all regime for low inhibition strength). *Let us assume that* $\beta/g < 1$. *Then the neuronal competition model* (2.1) *with* $S(x) = Heav(x - \theta)$ *exhibits only four dynamical regimes.*

If $I \geq \theta + \beta + g/2$, *then the system's attractor is the high activity state* $u_1 = u_2 = 1$. *Similarly, if* $I \leq \theta + g/2$, *the system's attractor is the low activity state* $u_1 = u_2 = 0$.

For intermediate values of input strength, the system oscillates between the states $(u_1, u_2) = (1, 0)$ *and* $(u_1, u_2) = (0, 1)$. *If* $\theta + (\beta + g)/2 < I < \theta + \beta + g/2$, *oscillations occur due to an escape mechanism; the period* T *decreases with* I *and satisfies* (4.1). *If* $\theta + g/2 < I < \theta + (\beta + g)/2$, *then a release mechanism underlies the oscillations and* T *increases with* I *according to* (4.2).

Moreover, at $I_{Tmax} = \theta + (\beta + g)/2$ *the system has maximum oscillation period*

$$T_{max} = 2\tau \ln\left(\frac{1 + \beta/g}{1 - \beta/g}\right).$$

Proof. Let us assume again initial conditions $u_1 = 1$, $u_2 = 0$, and $a_1 + a_2 = 1$; therefore, a_1 increases and a_2 decreases. In order to first reach the blue line (Figure 6A), the inequality $1 - (I - (\theta + \beta))/g < (I - \theta)/g$, i.e., $I > I_{Tmax}$, must be true. When the blue line is reached, the down variable u_2 switches from 0 to 1. If $(I - (\theta + \beta))/g < 1/2$, the net input for u_1 becomes $N_e := I - \beta u_2 - g a_1 = I - \beta - g(1 - a_{2J}) = 2(I - \beta - \theta) - g + \theta < \theta$, so u_1 changes to 0 and oscillation occurs due to an escape mechanism. If $(I - (\theta + \beta))/g \geq 1/2$, then $N_e \geq \theta$ and u_1 remains 1; the fast system has $(1, 1)$ as an attractor. Similar arguments are used for the release mechanism; the condition for intersection with the red line (Figure 6B) is equivalent to the inequality $1 - (I - \theta)/g > (I - (\theta + \beta))/g$, i.e., $I < I_{Tmax}$. For both (4.1) and (4.2), $T \to T_{max}$ as $I \to \theta + (\beta + g)/2$. Also, $T_{escape} \to 0$ as $I \to \theta + \beta + g/2$ and $T_{release} \to 0$ as $I \to \theta + g/2$. ■

4.2. Global features of the competition model with smooth sigmoid gain function. Numerical simulations of system (2.1) with smooth gain function S indicate that the limit cycle born through the Hopf bifurcation as in section 3 takes a relaxation-oscillator form just beyond the bifurcation (Figure 3B and 3D). That is, because of the two time-scales involved in the system, variables u_1 and u_2 evolve much faster than a_1 and a_2 ($\tau \gg 1$). We use this

observation to describe for (2.1) the relaxation-oscillator solution in the singular limit $1/\tau = 0$. In the plane (a_1, a_2) of slow variables we construct the curve of "jumping" points from the dominant to the suppressed state of each population, and back. This curve is the equivalent of the blue-red square from the case of Heaviside step function, and similarly it consists of two arcs associated with an escape and release mechanism, respectively. Then we give analytical conditions for the winner-take-all regime to exist.

4.2.1. The singular relaxation-oscillator solution. For large values of τ let us consider the slow time $s = \varepsilon t$ ($\varepsilon = 1/\tau$; $' = d/ds$) and rewrite system (2.1) as $\varepsilon u_1' = -u_1 + S(I - \beta u_2 - g a_1)$, $\varepsilon u_2' = -u_2 + S(I - \beta u_1 - g a_2)$, $a_1' = -a_1 + u_1$, $a_2' = -a_2 + u_2$.

In the singular perturbation limit $\varepsilon = 0$ any solution will belong to the slow manifold Σ defined by $-u_1 + S(I - \beta u_2 - g a_1) = 0$, $-u_2 + S(I - \beta u_1 - g a_2) = 0$ or, based on the inverse property of S ($S^{-1} = F$),

$$\Sigma = \Big\{ (u_1, u_2, a_1, a_2) \ : \ u_1, u_2 \in (0,1),\ a_1, a_2 \in \mathbf{R},\ \text{and} \\ u_2 = S(I - \beta u_1 - g a_2),\ a_1 = \frac{1}{g}[I - F(u_1) - \beta S(I - \beta u_1 - g a_2)] \Big\}. \tag{4.3}$$

The surface Σ is multivalued and can be visualized by plotting a_1 as a function of u_1 and a_2 (Figure 7).

Then the slow dynamics is according to equations $a_1' = -a_1 + \tilde{u}_1(a_1, a_2)$, $a_2' = -a_2 + \tilde{u}_2(a_1, a_2)$, where $(\tilde{u}_1, \tilde{u}_2, a_1, a_2) \in \Sigma$. The "slow" nullclines are characterized by additional conditions: $a_1 = u_1$ for a_1-nullcline ($\mathcal{N}_1$) and $a_2 = u_2$ for a_2-nullcline ($\mathcal{N}_2$); geometrically these are two curves situated on the surface Σ and defined by

$$\mathcal{N}_1(a_1' = 0) = \Big\{ (u_1, u_2, a_1, a_2) \ : \ u_1 = a_1,\ u_2 = S(I - \beta a_1 - g a_2(a_1)), \\ a_2 = \frac{1}{g}\left[I - \beta a_1 - F\left(\frac{I - g a_1 - F(a_1)}{\beta} \right) \right] \ \text{with } a_1 \in (\alpha_1, \alpha_2) \Big\} \tag{4.4}$$

and

$$\mathcal{N}_2(a_2' = 0) = \Big\{ (u_1, u_2, a_1, a_2) \ : \ u_1 = S(I - \beta a_2 - g a_1(a_2)),\ u_2 = a_2, \\ a_1 = \frac{1}{g}\left[I - \beta a_2 - F\left(\frac{I - g a_2 - F(a_2)}{\beta} \right) \right] \ \text{with } a_2 \in (\alpha_1, \alpha_2) \Big\}. \tag{4.5}$$

Here $\alpha_1, \alpha_2 \in (0,1)$ are the unique solutions of the equations $F(\alpha_1) + g\alpha_1 = I - \beta$ and $F(\alpha_2) + g\alpha_2 = I$, respectively.

The equilibrium points are at the nullclines' intersection, which means $a_1 = u_1$ and $a_2 = u_2$ simultaneously on Σ. They are characterized by the conditions

$$\mathcal{N}_1 \cap \mathcal{N}_2 : \ u_1 = a_1,\ u_2 = a_2,\ F(a_1) + g a_1 + \beta a_2 = F(a_2) + g a_2 + \beta a_1 = I. \tag{4.6}$$

We recall from section 3 that if $\beta > (1 + \frac{1}{\tau})/S'(\theta)$ (which in the limit case $\varepsilon = 0$ corresponds to $\beta > 1/S'(\theta)$), there exist two values of input parameter $I_{hb}^* < I_{hb}^{**}$ such that the system has

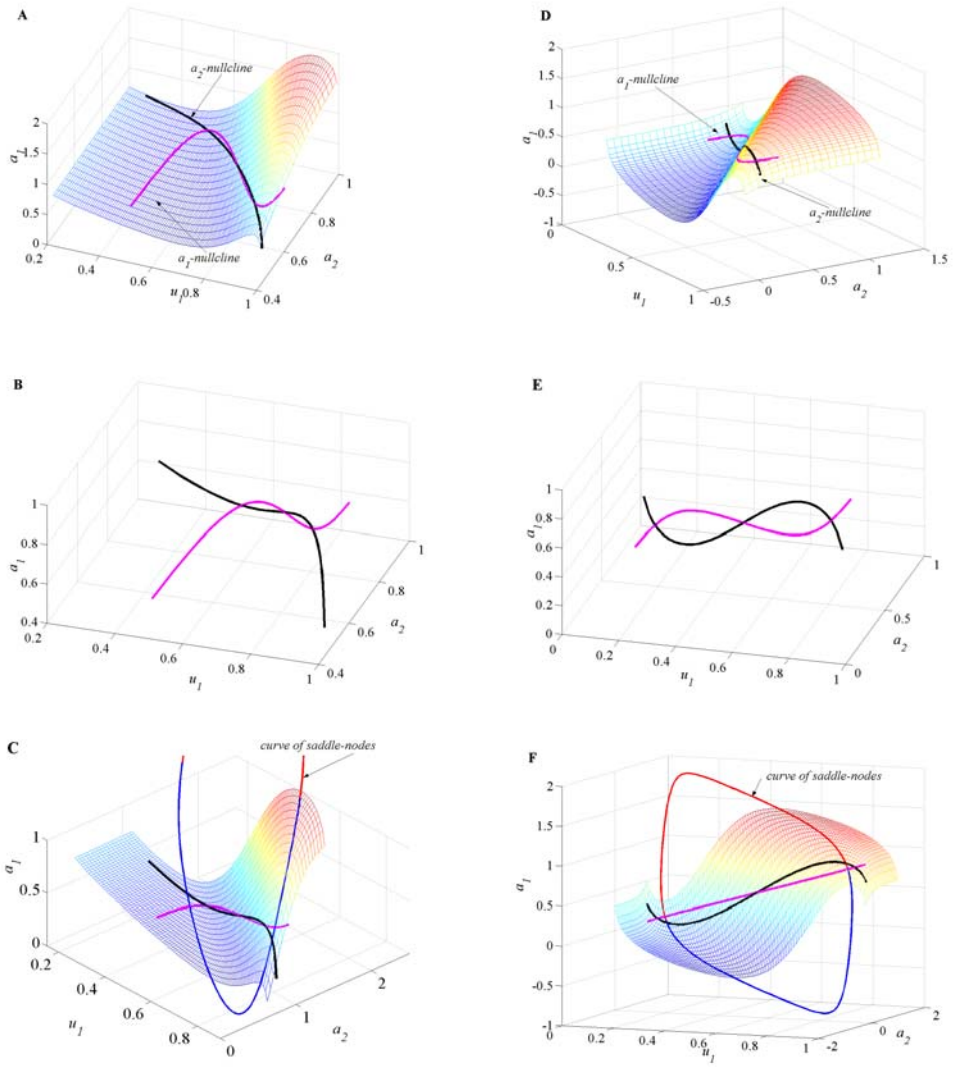

Figure 7. *Projection of the slow manifold Σ on the space (u_1, a_1, a_2). System (2.1)'s parameters are $\beta = 1.1$, $g = 0.5$, $\theta = 0.2$, $r = 10$, and $I = 1.5$ (A–C), respectively, $I = 1$ (D–F). The curve $\mathcal{SN}$ of saddle-nodes (jumping points) is represented in blue-red* (C, F). *Nullclines $\mathcal{N}_1$ (magenta) and $\mathcal{N}_2$ (black curve) intersect in three points for* (B) $I = 1.5$ *and* (E) $I = 1$. *However, either the equilibrium points can all lie on the middle branch of Σ* (A), *that is, inside the curve of saddle-nodes* (C), *or two equilibrium points can move to the lateral branches, outside of $\mathcal{SN}$* (D, F).

a unique stable equilibrium point for $I \in (-\infty, I^*_{hb}) \cup (I^{**}_{hb}, \infty)$. This equilibrium point takes the form $\mathbf{e}_I = (u_I, u_I, u_I, u_I)$ with $u_I \in (0,1)$, $F(u_I) + (\beta + g)u_I = I$, and it becomes unstable at I^*_{hb} and I^{**}_{hb}; a stable limit cycle appears for $I > I^*_{hb}$ and $I < I^{**}_{hb}$. The critical parameter values are defined by $I^*_{hb} = F(u^*_{hb}) + (\beta + g)u^*_{hb}$ and $I^{**}_{hb} = F(u^{**}_{hb}) + (\beta + g)u^{**}_{hb}$ with u^*_{hb}, u^{**}_{hb} according to (3.5). Again, in the limit case $\varepsilon = 0$, condition (3.5) becomes

$$F'(u^*_{hb}) = F'(u^{**}_{hb}) = \beta, \tag{4.7}$$

and obviously we have $F'(u_I) < \beta$ for each $I \in (I^*_{hb}, I^{**}_{hb})$.

Moreover, if $\beta - g > 1/S'(\theta)$, two additional equilibrium points occur for $I > I^*_{pf}$ and $I < I^{**}_{pf}$ through a pitchfork bifurcation. However, at least in the neighborhood of I^*_{pf} or I^{**}_{pf}, these equilibrium points are unstable. Their coordinates (u_{1p}, u_{2p}) satisfy (4.6), so either $u_{1p} < u_I < u_{2p}$ or $u_{1p} > u_I > u_{2p}$. In addition, they are close to u_I for all I sufficiently close to I^*_{pf} or I^{**}_{pf}; in conclusion, at least in a small region, $F'(u_{1p}) < \beta$ and $F'(u_{2p}) < \beta$.

In Figure 7 we plotted the projection on the three-dimensional space (u_1, a_1, a_2) of the slow manifold Σ and the nullclines $\mathcal{N}_1$ and $\mathcal{N}_2$ ($\mathcal{N}_1$ is colored in magenta and $\mathcal{N}_2$ is colored in black; because Σ is defined over the full range $-\infty$ to ∞ with respect to a_1 and a_2, we plot only part of it). All plots are done for S as in (2.2), $\beta = 1.1$, $g = 0.5$, $r = 10$, $\theta = 0.2$, and two values of input strength, $I = 1.5$ (Figure 7A–C) and $I = 1$ (Figure 7D–F). For these values of parameters we have $I^*_{pf} = 0.4064$ and $I^{**}_{pf} = 1.5936$, so at both $I = 1.5$ and $I = 1$ the system has three equilibrium points; nullclines intersect three times and the middle intersection point is exactly $\mathbf{e}_I$. We note that all equilibrium points are unstable at $I = 1.5$ while two of them become stable at $I = 1$ (see also Figure 3G).

On the surface Σ we have $\frac{\partial u_1}{\partial a_1} = g/[\beta^2 S'(I - \beta u_1 - g a_2) - F'(u_1)]$ and $\frac{\partial u_1}{\partial a_2} = -\beta g/[\beta^2 - F'(u_1)/S'(I - \beta u_1 - g a_2)]$, i.e.,

$$\frac{\partial u_1}{\partial a_1} = \frac{g F'(u_2)}{\beta^2 - F'(u_1)F'(u_2)} \quad \text{and} \quad \frac{\partial u_1}{\partial a_2} = -\frac{\beta g}{\beta^2 - F'(u_1)F'(u_2)}.$$

For an initial condition (u_1, u_2, a_1, a_2) with u_1 sufficiently large (close to 1) we have $\frac{\partial u_1}{\partial a_1} < 0$ and $\frac{\partial u_1}{\partial a_2} > 0$; therefore, a simultaneous increase in a_1 and decrease in a_2 lead to a decrease in u_1. Similarly, for a choice of u_1 sufficiently low (close to 0), $\frac{\partial u_1}{\partial a_1} < 0$, $\frac{\partial u_1}{\partial a_2} > 0$, and a simultaneous decrease in a_1 and increase in a_2 lead to an increase in u_1. On the other hand, the limit cycle exists for some $I \in (I^*_{hb}, I^{**}_{hb})$. Since here $\mathbf{e}_I \in \Sigma$ with $F'(u_I) < \beta$, we have $\frac{\partial u_1}{\partial a_1} > 0$ and $\frac{\partial u_1}{\partial a_2} < 0$ in a neighborhood of this equilibrium point; the behavior of u_1 with respect to a_1 and a_2 is opposite that previously described.

Therefore, relative to the plane (u_1, a_1) the surface Σ has a cubic-like shape: its left and right branches decrease with u_1 while the middle branch increases. The curve of lower $(u_1 < u_2)$ and upper $(u_1 > u_2)$ knees on Σ is defined by $F'(u_1)F'(u_2) = \beta^2$ (blue-red curve in Figure 7C and 7F). As we show in the following, when the trajectory on surface Σ reaches the curve of knees on its upper side, the point will jump from the right branch of Σ to its left branch. Similarly, when it reaches the lower side of the curve of knees, the point will jump from the left to the right branch of Σ. In the plane of fast variables (u_1, u_2) the curve of knees corresponds to a saddle-node bifurcation (a node approaching a saddle then merging with it and disappearing—see the animations 70584_01.gif [3.7MB] and 70584_02.gif [3.8MB] in Appendix C). For this reason we also call it the *curve of saddle-nodes* ($\mathcal{SN}$) or the *curve of jumping points*. It is defined by the equations

$$(4.8)\quad \mathcal{SN}:\ F'(u_{1J})F'(u_{2J}) = \beta^2,\ a_{1J} = \frac{1}{g}[I - F(u_{1J}) - \beta u_{2J}],\ a_{2J} = \frac{1}{g}[I - F(u_{2J}) - \beta u_{1J}].$$

We do not prove here the existence of the relaxation-oscillator singular solution. We aim only to provide the reader with the intuition for how oscillations occur in the competition

model (2.1) if a smooth sigmoid is taken as a gain function. Thus, if the oscillations exist and, for example, u_1 is dominant and u_2 is suppressed ($u_1 > u_2$), we have $-a_1 + u_1 > 0$, $-a_2 + u_2 < 0$, so a_1 increases and a_2 decreases. They push u_1 down and the point moves on the trajectory until it reaches $\mathcal{SN}$ at an upper knee U of coordinates (u_{1J}, u_{2J}); here the derivatives $\frac{\partial u_1}{\partial a_1}$ and $\frac{\partial u_1}{\partial a_2}$ become infinite, so u_1 jumps from the upper to the lower branch of Σ (Figure 8A–8B). On the lower branch ($u_1 < u_2$) we have $-a_1 + u_1 < 0$ and $-a_2 + u_2 > 0$, so u_1 increases and the point will move due to the decrease of a_1 and increase of a_2 until it touches $\mathcal{SN}$ at L. At L the point jumps up to the right branch of Σ. The projection of the limit cycle on the slow plane (a_1, a_2) is a closed curve that touches the projection of $\mathcal{SN}$ at two points (a_{1J}, a_{2J}) and (a_{2J}, a_{1J}) symmetric to the line $a_1 = a_2$ (Figures 8C and 9B).

4.2.2. Release, escape, and winner-take-all in the competition model with smooth sigmoid gain function. Analogous to our analysis in section 4.1 we consider in the following the projection of the curve of jumping points $\mathcal{SN}$ on the slow plane (a_1, a_2). As mentioned above, if the up-to-down jump takes place at (a_{1J}, a_{2J}), then the down-to-up jump is at (a_{2J}, a_{1J}); so the projection is a closed curve symmetric to the diagonal $a_1 = a_2$.

We consider in (a_1, a_2) the curve Γ_0 of equations

$$A_1 = -\frac{1}{g}[F(u_{1J}) + \beta u_{2J}], \quad A_2 = -\frac{1}{g}[F(u_{2J}) + \beta u_{1J}]$$

with $F'(u_{1J})F'(u_{2J}) = \beta^2$. Then from (4.8) we have

$$a_{1J} = A_1 + \frac{I}{g}, \quad a_{2J} = A_2 + \frac{I}{g}.$$

For a given I, the projection of $\mathcal{SN}$ on the slow plane (say, $\Gamma = \Gamma_I$) is exactly the translation of Γ_0 with quantity $(I/g, I/g)$ along the first bisector. Obviously as I decreases, the curve Γ moves down on the upper-right–lower-left direction (Figure 9B). That is similar to the movement of the blue-red square for the case of the Heaviside step function in section 4.1 (Figure 5).

Let us consider now an oscillatory solution that exists for some $I \in (I^*_{hb}, I^{**}_{hb})$. If population 1 is dominant ($u_1 > u_2$), then $-a_1 + u_1 > 0$ and $-a_2 + u_2 < 0$ imply $u_1 - u_2 > a_1 - a_2$. On the other hand, since the trajectory is on Σ, we also have $a_1 = [I - F(u_1) - \beta u_2]/g$, $a_2 = [I - F(u_2) - \beta u_1]/g$, and thus $a_1 - a_2 = [\beta(u_1 - u_2) - (F(u_1) - F(u_2))]/g$. At the jumping point a_1 reaches its maximum and a_2 its minimum, so $0 < a_{1J} - a_{2J} < u_{1J} - u_{2J}$ can be written as

$$0 < W(u_{1J}) = \frac{1}{g}\left(\beta - \frac{F(u_{1J}) - F(u_{2J})}{u_{1J} - u_{2J}}\right) < 1. \tag{4.9}$$

The point (u_{1J}, u_{2J}), $u_{1J} > u_{2J}$, satisfies $F'(u_{1J})F'(u_{2J}) = \beta^2$ and describes the part of $\mathcal{SN}$ that corresponds to the upper knees. Let $u_{m\beta}, u_{M\beta} \in (0, 1)$ be the values defined by $u_{m\beta} < u^*_{hb} < u_0 < u^{**}_{hb} < u_{M\beta}$, $F'(u_{m\beta}) = F'(u_{M\beta}) = \beta^2/F'(u_0) = \beta^2 S'(\theta)$ (see the shape of F' in Figure 2C). Then the upper branch of $\mathcal{SN}$ results by gluing together three arcs on which (1) u_{1J} increases between u^{**}_{hb} and $u_{M\beta}$ (so u_{2J} decreases from u^{**}_{hb} to u_0); (2) u_{1J} decreases

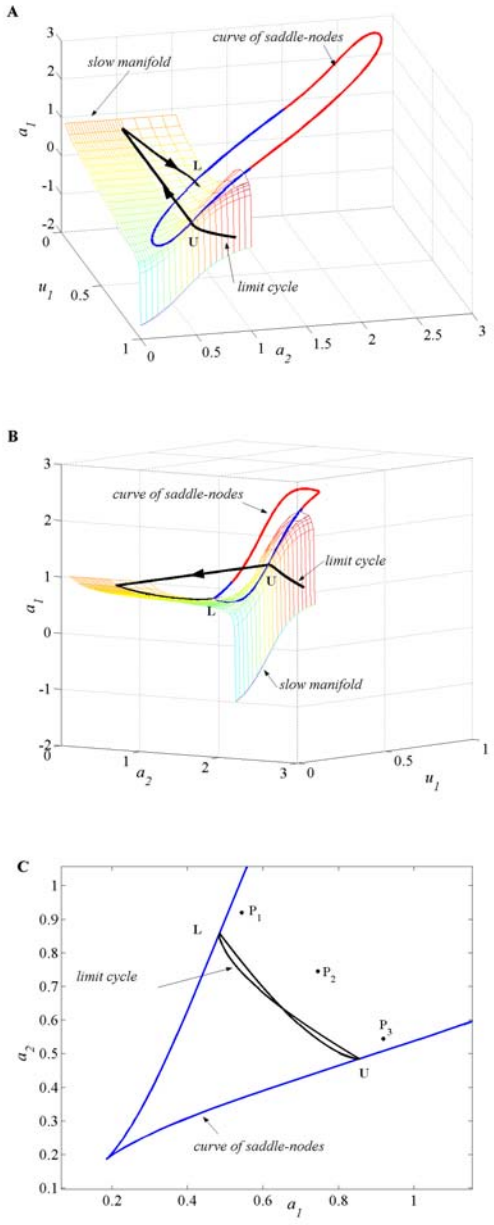

Figure 8. (A–B) *Limit cycle solution and the slow manifold* Σ *for system* (2.1) *with parameters* $I = 1.5$, $\beta = 1.1$, $g = 0.5$, $r = 10$, $\theta = 0.2$, *and* $\tau = 5000$. (C) *The projection of the limit cycle on the slow plane* (a_1, a_2); P_1, P_2, *and* P_3 *are the projections of the equilibrium points.*

from $u_{M\beta}$ to u_0 (and u_{2J} decreases from u_0 to $u_{m\beta}$); (3) u_{1J} continues to decrease from u_0 to u^*_{hb} (however, u_{2J} increases now between $u_{m\beta}$ and u^*_{hb}).

We can plot the expression $W(u_{1J})$ from (4.9) for $u_{1J} \in [u^{**}_{hb}, u_{M\beta}]$ and $u_{1J} \in [u^*_{hb}, u_{M\beta}]$ with the corresponding $u_{2J} = u_2(u_{1J})$ and check if the graph is below the horizontal line $W = 1$ (Figure 9A). If for all combinations (u_{1J}, u_{2J}) we have $W < 1$, then the winner-take-

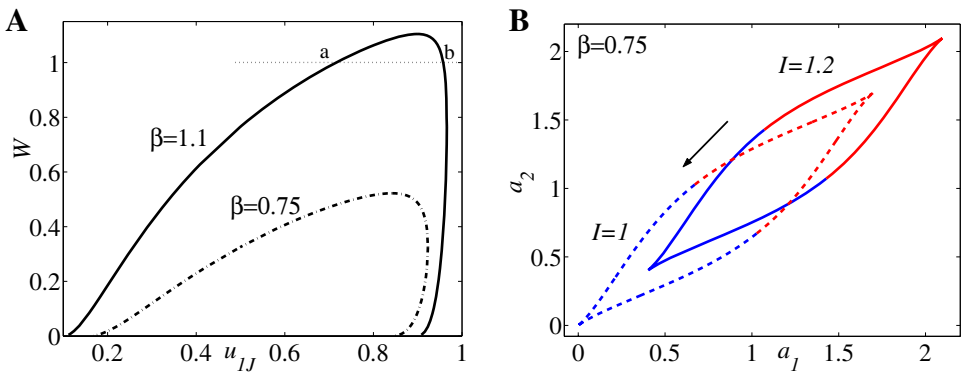

Figure 9. (A) *The graph of $W = W(u_{1J})$ for upper knees on $\mathcal{SN}$ computed for $g = 0.5$, $r = 10$, $\theta = 0.2$, and S as in (2.2). At $\beta = 0.75$ (dashed-dotted curve) the maximum value of W is less than unity: Winner-take-all regime does not exist; at $\beta = 1.1$ (thick curve) the maximum value of W is larger than unity: the values of I where winner-take-all occurs correspond to u_{1J} at points* **a** *and* **b**. (B) *Projection Γ of the curve of saddle-nodes on the slow plane (a_1, a_2) for $\beta = 0.75$, $g = 0.5$, $r = 10$, $\theta = 0.2$, S as in (2.2), and two values of input $I = 1.2$ and $I = 1$; Γ moves down on the first bisector direction as I decreases. The blue side is associated to the right branch of W in panel A, from $W = 0$ to W_{max} (an escape mechanism), and the red side is associated to the left branch of W from W_{max} to 0 (a release mechanism).*

all regime does not exist in the interval (I^*_{hb}, I^{**}_{hb}). Otherwise, for (u_{1J}, u_{2J}) where $W = 1$ we can compute the values of I where winner-take-all occurs (see below).

Remark 4.2. *Let us observe that $W(u_{1J}) = [\beta - F'(\xi)]/g$ for some intermediate ξ between u_{2J} and u_{1J}. At $u_{1J} = u_{2J} = u^{**}_{hb}$ or $u_{1J} = u_{2J} = u^*_{hb}$ (that represents exactly the equilibrium point $\mathbf{e}_I$ at $I = I^{**}_{hb}$ and I^*_{hb}, respectively) we have $F'(\xi) = \beta$; therefore, we can extend by continuity the function $W|_{[}u^{**}_{hb}, u_{M\beta}]$ at $u_{1J} = u^{**}_{hb}$ and the function $W|_{[}u^*_{hb}, u_{M\beta}]$ at $u_{1J} = u^*_{hb}$ by taking $W = 0$ at these edges.*

For gain function S as in (2.2) and different values of β we plotted the curve W; the curve W always has a maximum value W_{max} for some $u_{1J}^{Wmax} \in (u_0, u_{M\beta})$ with $u_2 = u_2(u_1) \in (u_{m\beta}, u_0)$. Here $\partial u_2/\partial u_1 = -[F'(u_2)F''(u_1)]/[F'(u_1)F''(u_2)] > 0$. W measures the relative distance between the values of slow variables against that between fast variables. Based on this observation we color $\mathcal{SN}$, and obviously Γ, in *blue* for (u_{1J}, u_{2J}) starting at $(u^{**}_{hb}, u^{**}_{hb})$ and varying until it reaches $(u_{1J}^{Wmax}, u_{2J}^{Wmax})$ and in *red* for (u_{1J}, u_{2J}) between $(u_{1J}^{Wmax}, u_{2J}^{Wmax})$ and (u^*_{hb}, u^*_{hb}) (Figures 7C, 9B). The first corresponds to the right branch of W from $W = 0$ to W_{max}, and the latter corresponds to the left branch of W from W_{max} to 0.

Well inside the interval that defines the blue part of Γ (that is, not too close to the value u_{1J}^{Wmax} that gives the maximum W) we have either $u_0 < u_{2J} < u^{**}_{hb} < u_{1J}$ or $u^*_{hb} < u_{2J} < u_0 < u^{**}_{hb} < u_{1J}$; so $F'(u_{2J}) < \beta < F'(u_{1J})$. However, we recall that $F'(u_{2J}) = 1/S'(I - \beta u_{1J} - g a_{2J})$ and $F'(u_{1J}) = 1/S'(I - \beta u_{2J} - g a_{1J})$. That means that the gain function S has at the jump a bigger slope at $I - \beta u_1 - g a_2$, the net input to the suppressed population, than at $I - \beta u_2 - g a_1$, the net input to the dominant population; in other words, the gain to the suppressed population falls in the range of steeper S. According to the definitions introduced at the beginning of section 4, this case corresponds to an *escape* type of dynamics.

On the red part of Γ there is an opposite behavior: at least away from the edge u_{1J}^{Wmax} we have either $u_{2J} < u^*_{hb} < u_0 < u_{1J} < u^{**}_{hb}$ or $u_{2J} < u^*_{hb} < u_{1J} < u_0 < u^{**}_{hb}$. That is,

$F'(u_{2J}) = 1/S'(I - \beta u_{1J} - g a_{2J}) > \beta > F'(u_{1J}) = 1/S'(I - \beta u_{2J} - g a_{1J})$. At the jump the gain $S'(I - \beta u_2 - g a_1)$ to the dominant population falls in the range of steeper S than that to the suppressed population. We called this a *release* mechanism.

In fact, the values u_{2J}^{Wmax} and u_{1J}^{Wmax} with $u_{2J}^{Wmax} < u_0 < u_{1J}^{Wmax}$ (and not u_{hb}^{*} and u_{hb}^{**}) determine what we generically call the "steeper" part of S. For the particular case of gain function symmetric to its inflection point (θ, u_0), i.e., for S such that $S(\theta + x) + S(\theta - x) = 1$ it can be shown that indeed $u_{2J}^{Wmax} = u_{hb}^{*}$ and $u_{1J}^{Wmax} = u_{hb}^{**}$ (for example, S as in (2.2); see Remark 4.3). However, in other cases that is not true anymore; then it is more difficult to interpret the terms escape and release for u_{1J} close to u_{1J}^{Wmax}, the passage point from one dynamical regime to another.

Occurrence of the winner-take-all regime. We can determine now the minimum value of β, say, β_{wta}, where the winner-take-all regime occurs in system (2.1). Moreover, for a given $\beta > \beta_{wta}$ we find the corresponding values of I that delineate this regime.

We note that if $I \in (I_{hb}^{*}, I_{pf}^{*}] \cup [I_{pf}^{**}, I_{hb}^{**})$, then system (2.1) has a unique equilibrium point and it belongs to the middle branch of Σ ($F'(u_I) < \beta$).

For $I > I_{pf}^{*}$ or $I < I_{pf}^{**}$ *sufficiently close* to the pitchfork bifurcation point, system (2.1) has three equilibria and all are situated again on the middle branch of Σ, inside $\mathcal{SN}$, the curve of lower and upper knees (Figure 7A and 7C). That is because $F'(u_{1p}) < \beta$ and $F'(u_{2p}) < \beta$, so $F'(u_{1p})F'(u_{2p}) < \beta^2$. A trajectory that starts on either the upper or the lower branch of Σ cannot approach an equilibrium point since it will first reach $\mathcal{SN}$, and so the system oscillates. However, for intermediate values of I between I_{pf}^{*} and I_{pf}^{**}, two of the equilibrium points may move on the lateral branches of Σ and become stable ($F'(u_{1p})F'(u_{2p}) > \beta^2$; see Figure 7D and 7F). That is the case where the winner-take-all regime occurs. We should point out that the equilibrium $\mathbf{e}_I = (u_I, u_I, u_I, u_I)$ always remains unstable for $I \in (I_{pf}^{*}, I_{pf}^{**}) \subset (I_{hb}^{*}, I_{hb}^{**})$. The boundary between oscillatory and winner-take-all dynamics is obtained when the equilibrium points (u_{1p}, u_{2p}) belong to $\mathcal{SN}$, that is, when on $\mathcal{SN}$ both $a_1 = u_1$ and $a_2 = u_2$ are true. We find in the following the values of I where winner-take-all appears.

The values of I, say, I_w, that delineate the winner-take-all regime are defined by

$$
\begin{aligned}
&F'(u_{1J})F'(u_{2J}) = \beta^2,\\
&\frac{1}{g}\left(\beta - \frac{F(u_{1J}) - F(u_{2J})}{u_{1J} - u_{2J}}\right) = 1,\\
&I_w = F(u_{1J}) + g u_{1J} + \beta u_{2J} \quad [\, = F(u_{2J}) + g u_{2J} + \beta u_{1J}\,].
\end{aligned}
\tag{4.10}
$$

The left-hand side of the second equation in (4.10) is in fact $W(u_{1J})$. Since the curve W always has a maximum value W_{max} for some $u_{1J}^{Wmax} \in (u_0, u_{M\beta})$, the line $W = 1$ can be either above the maximum or below it. If $W_{max} < 1$ (Figure 9A, $\beta = 0.75$), then there is no winner-take-all regime. If $W_{max} > 1$ (Figure 9A, $\beta = 1.1$), then there exist two values for u_{1J} where the curve W intersects the horizontal line $W = 1$.

The critical (minimum) value β_{wta} where the winner-take-all regime appears in system (2.1) results from the case of $W_{max} = 1$; i.e., it satisfies the conditions $W(u_{1J}) = 1$ and $W'(u_{1J}) = 0$. Thus the minimum value β_{wta} that introduces winner-take-all dynamics in system (2.1) is defined by

$$F'(u_{1J})F'(u_{2J}) = \beta^2, \qquad u_{1J} \neq u_{2J},$$
$$(F(u_{1J}) - F(u_{2J}))[F'(u_{1J})F''(u_{2J}) + F'(u_{2J})F''(u_{1J})]$$
$$= (u_{1J} - u_{2J})[F'(u_{1J})^2F''(u_{2J}) + F'(u_{2J})^2F''(u_{1J})],$$
$$\beta_{wta} = g + \frac{F(u_{1J}) - F(u_{2J})}{u_{1J} - u_{2J}}. \tag{4.11}$$

Remark 4.3. *We note that due to its particular form* (2.2)*, S is symmetric about the point (θ, u_0) with $u_0 = 0.5$. The graph of F' is symmetric to the vertical line $u = 0.5$, i.e., $F'(1-u) = F'(u)$ for all $u \in (0,1)$, and so $F''(1-u) = -F''(u)$. In this particular case we have $F'(u^*_{hb}) = F'(u^{**}_{hb}) = \beta$, so $u^*_{hb} = 1 - u^{**}_{hb}$ and $F''(u^*_{hb}) = -F''(u^{**}_{hb})$. According to* (4.11) *the maximum value W_{max} is obtained exactly at $u_{1J} = u^{**}_{hb}$, $u_{2J} = u^*_{hb}$.*

For gain function S as in (2.2) and different values of β we plotted the curve W and determined the interval $[I^*_w, I^{**}_w]$ where winner-take-all occurs. For example, choosing $r = 10$, $\theta = 0.2$, $g = 0.5$, and $\beta = 1.1$, we have $W_{max} = 1.1046$ and $I^*_w = 0.697$ (computed at $u_{1J} = 0.7158$, $u_{2J} = 0.0424$) and $I^{**}_w = 1.303$ (computed at $u_{1J} = 0.9576$, $u_{2J} = 0.2842$). The minimum value of β for the winner-take-all regime is $\beta_{wta} = 1.0387$. As expected from our analysis in section 3.3, the value of β that guarantees existence of multiple equilibria in system (2.2), i.e., $\beta_{pf} = g + 1/S'(\theta) = 0.9$, is smaller than β_{wta}.

For the same choice of parameters as above ($\beta = 1.1$, $g = 0.5$, and S as in (2.2) with $r = 10$, $\theta = 0.2$), we plot the projection of the limit cycle and the curve of saddle-nodes on the slow plane (a_1, a_2) for different values of parameter I. Figure 10A gives the bifurcation diagram of activity u_1 versus input strength I for $\tau = 100$. In the rest of the panels we choose $\tau = 5000$ to mimic the singular limit cycle solution with jumping points exactly on the curve of saddle-nodes (for smaller τ, e.g., $\tau = 100$, the jumping points do not belong to the curve of saddle-nodes but fall close to it). In this case we have

$$I^*_{hb} = 0.1434,\ I^*_{pf} = 0.4064,\ I^*_w = 0.697,\ I^{**}_w = 1.303,\ I^{**}_{pf} = 1.5936,\ I^{**}_{hb} = 1.8566.$$

At larger values of I ($I = 1.7$ and $I = 1.5$) oscillation is due to an escape mechanism (Figure 10B–C); at an intermediate value $I = 1$ the system is in the winner-take-all regime (Figure 10D); at smaller values of I ($I = 0.5$ and $I = 0.3$) oscillation is due to a release mechanism (Figure 10E–F). Besides the limit cycle other important trajectories are the equilibrium points. There are three unstable equilibria for $I = 1.5$ and $I = 0.5$ but only one equilibrium point at $I = 1.7$ and $I = 0.3$. At $I = 1$ two out of three equilibria are stable.

Remark 4.4. *Equations* (4.11) *and* (4.10)*, used to determine the critical β where the winner-take-all regime exists in system* (2.1) *and then, for $\beta > \beta_{wta}$, to estimate I^*_w and I^{**}_w, prove to be reliable. The estimations obtained by this method are in excellent agreement with the results found in system* (2.1)*'s numerical simulations for both symmetric and asymmetric gain functions. The latter case is discussed in section* 5*.*

5. Neuronal competition models that favor the escape (or release) dynamical regime.

As seen in section 4.1, the dynamical scheme of T versus I is symmetric to $I = \theta + \frac{\beta+g}{2}$ for S, the Heaviside step function. When the winner-take-all regime exists, its corresponding I-input interval is equally split around the value $\theta + \frac{\beta+g}{2}$, that is, $\theta + g \leq I \leq \theta + \beta$ as in Theorem 4.1. Moreover, an equal input range is found for both release and escape mechanisms:

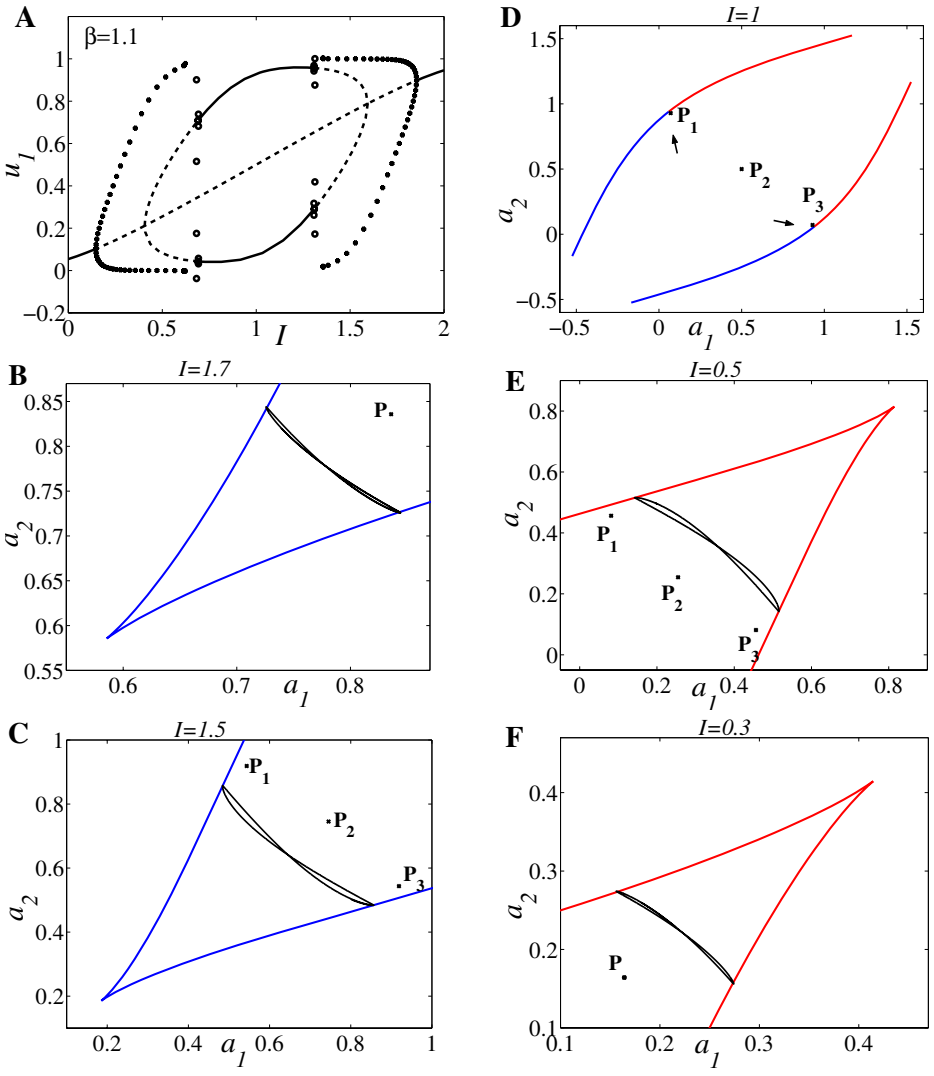

Figure 10. (A) *Bifurcation diagram of activity* u_1 *versus input* I *for* $\beta = 1.1$, $g = 0.5$, $r = 10$, $\theta = 0.2$, $\tau = 100$. (B–F) *Projection of the limit cycle and the curve of saddle-nodes on the slow plane* (a_1, a_2) *for different values of parameter* I *chosen according to the bifurcation diagram in panel A; however, in order to mimic the singular limit cycle solution we choose here* $\tau = 5000$. *Symbol* $*$ *indicates the location of equilibria. At large values of* I *oscillation is due to an escape mechanism:* (B) $I = 1.7$, (C) $I = 1.5$; (D) *at intermediate value* $I = 1$ *winner-take-all dynamics is observed; then at low values of* I *oscillation is due to a release mechanism:* (E) $I = 0.5$, (F) $I = 0.3$. *Single (panels B, F) or multiple (panels C, E) unstable equilibria can coexist with the limit cycle.*

$\theta + \frac{g}{2} < I < \theta + g$ and $\theta + \beta < I < \theta + \beta + \frac{g}{2}$ as in Theorem 4.1, or $\theta + \frac{g}{2} < I < \theta + \frac{\beta+g}{2}$ and $\theta + \frac{\beta+g}{2} < I < \theta + \beta + \frac{g}{2}$ as in Theorem 4.2. Therefore, it seems reasonable to ask to what extent the symmetry of the I-T dynamical scheme about a specific value I^* relates to the geometry of S and, more generally, to the form of the equations in (2.1). We address this question in the following and find a heuristic method to reduce one of the two ranges of

escape and release mechanisms while still maintaining the other one.

First let us note that we obtain a result similar to that in section 4.1 for any smooth sigmoid S as long as it is symmetric about its *threshold*. The threshold (say, th) is defined as the value where the gain function reaches its middle point: for S taking values between 0 and 1, it is $S(th) = 0.5$. The terminology comes from the fact that if a net input to one population is below the threshold ($x < th$), then it determines a weak effective response ($S(x) < 1/2$); at equilibrium that would correspond to an inactive state. On the other hand, a net input above the threshold ($x > th$) determines a strong effective response ($S(x) > 1/2$) which, at equilibrium, corresponds to an active state. The *symmetry condition* of S with respect to the threshold is described mathematically by the equality $S(th + x) + S(th - x) = 1$ for any real x or, equivalently, $S(x) + S(2\,th - x) = 1$. The gain function defined by (2.2) is such an example: in this case the threshold is exactly the inflection point θ ($S''(\theta) = 0$; $S(\theta) = 0.5$).

Theorem 5.1. *If the gain function S satisfies $S(\theta + x) + S(\theta - x) = 1$, then system (2.1) with input I^* is diffeomorphic equivalent to system (2.1) with input $I = 2\theta + \beta + g - I^*$.*

Proof. Due to the symmetry of S, equation $\dot{\tilde{u}}_1 = -\tilde{u}_1 + S(I^* - \beta\tilde{u}_2 - g\tilde{a}_1)$ with the change $u_1 = 1 - \tilde{u}_1$, $u_2 = 1 - \tilde{u}_2$, $a_1 = 1 - \tilde{a}_1$, $a_2 = 1 - \tilde{a}_2$ becomes $\dot{u}_1 = -u_1 + 1 - S(I^* - \beta(1 - u_2) - g(1 - a_1)) = -u_1 + S((2\theta + \beta + g - I^*) - \beta u_2 - g a_1)$; on the other hand, equation $\tau\dot{\tilde{a}}_1 = -\tilde{a}_1 + \tilde{u}_1$ becomes $\tau\dot{a}_1 = -a_1 + u_1$. Therefore, system (2.1) with input I^* is diffeomorphic equivalent to system (2.1) with input $(2\theta + \beta + g - I^*)$. ∎

Remark 5.1. *Theorem 5.1 implies that system (2.1) has the same type of solutions for any two values of input strength I_1 and I_1^* such that $\frac{1}{2}(I_1 + I_1^*) = \theta + \frac{\beta+g}{2}$. Moreover, if at I_1 and I_1^* an oscillatory solution of period T_1 and T_1^* exists, then, due to the diffeomorphism, $T_1 = T_1^*$. Obviously, if $T_1 < T_2$ for $I_1 < I_2 < \theta + \frac{\beta+g}{2}$, then $T_1^* < T_2^*$ for the corresponding values $I_1^* > I_2^* > \theta + \frac{\beta+g}{2}$. Therefore, for symmetric S to its inflection point (threshold in this case), the intervals of I for regions II and IV (see Figure 3F or H) have the same length and are symmetric to the line $I = \theta + \frac{\beta+g}{2}$.*

In order to explore the effect the asymmetry of S has on the bifurcation diagram, we consider S to be

$$S(x) = \begin{cases} 2u_0 / \left(1 + e^{-\frac{r}{2u_0}(x-\theta)}\right), & x \le \theta, \\ 1 - 2(1-u_0) / \left(1 + e^{-\frac{r}{2(1-u_0)}(\theta - x)}\right), & x > \theta, \end{cases} \tag{5.1}$$

with $u_0 \in (0, 1)$.

Therefore the inflection point θ and the threshold th satisfy $S(\theta) = u_0$ and $th > \theta$ if $u_0 < 1/2$, respectively, $th < \theta$ if $u_0 > 1/2$.

The graphs of S as in (5.1) and their corresponding F' (where $F = S^{-1}$) are drawn in Figure 11A–B with parameter values $r = 10$, $\theta = 0.2$, and $u_0 = 0.1, 0.5, 0.9$. Then the I-T bifurcation diagram for the competition model (2.1) is constructed at $\beta = 0.75$ (Figure 11C). Numerical results show that the symmetry of this bifurcation diagram is indeed a direct consequence of the symmetry of S to its threshold. Such is the case $u_0 = 0.5$. For other choices of u_0 one of the two regions that correspond to the increasing and decreasing I-T branch is favored (it is wider)—the former when $u_0 > 1/2$ and the latter when $u_0 < 1/2$.

Recall from section 4 the definition (4.8) for the curve $\mathcal{SN}$ of jumping points (with its projection Γ on the plane of slow variables (a_1, a_2)) and the definition (4.9) for W that char-

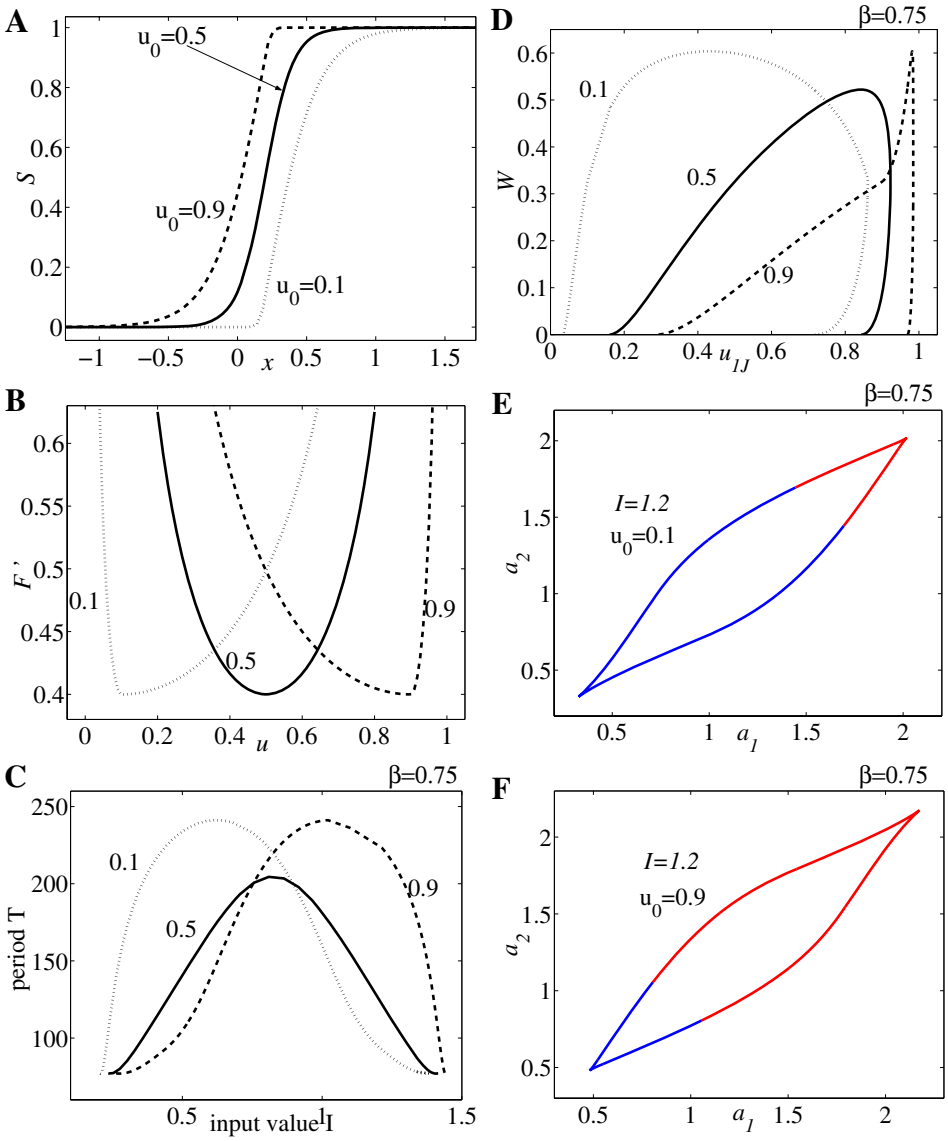

Figure 11. *Consider parameter values $r = 10$, $\theta = 0.2$, $g = 0.5$, $\tau = 100$ and gain functions S as in (5.1) with $u_0 = 0.1, 0.5, 0.9$.* (A) *Graphs of S.* (B) *Their corresponding F' where $F = S^{-1}$.* (C) *Bifurcation diagram for period T versus input I in system (2.1) as $\beta = 0.75$.* (D) *The graph of $W = W(u_{1J})$ for upper knees on $\mathcal{SN}$ computed as $\beta = 0.75$.* (E–F) *Projection Γ of the curve of saddle-nodes on the slow plane (a_1, a_2) for $\beta = 0.75$, $I = 1.2$, and $u_0 = 0.1, 0.9$. The blue side is associated to the escape mechanism and the red side to the release mechanism. The asymmetry of S to the threshold favors* (E) *escape if $u_0 < 1/2$ and* (F) *release if $u_0 > 1/2$.*

acterizes escape, release, and winner-take-all regimes. The shape of W changes dramatically with u_0 (Figure 11D, $\beta = 0.75$) but not at all with β. However, for any fixed u_0 the curve W always has a unique maximum point; this maximum moves down as β decreases.

The asymmetry of S leads to an asymmetry of the curve Γ: for $u_0 < 1/2$ we have $u_0 < u_{1J}^{Wmax} < u_{hb}^{**}$, $u_{2J}^{Wmax} < u_{hb}^{*}$, and the curves $\mathcal{SN}$ and Γ have a longer blue part than

red part; the escape mechanism is favored (Figure 11E, $u_0 = 0.1$). On the contrary, for $u_0 > 1/2$ the release mechanism is favored since the red part of Γ is longer: $u_{1J}^{Wmax} > u_{hb}^{**}$ and $u_{hb}^{*} < u_{2J}^{Wmax} < u_0$ (Figure 11F, $u_0 = 0.9$). We can understand this specific behavior by looking at the network populations' dynamics about the threshold: in case of $u_0 < 1/2$ the maximum gain to each population is reached for some net input *below* the threshold ($S'(\theta) = \max S'$ with $S(\theta) = u_0$, so $\theta < th$); then about the threshold th the gain S' has a decreasing trend. Consequently, there is a wider range for inputs where the inactive population has a significant gain compared to the active population, and so the escape mechanism is favored (the suppressed population regains control on its own, thus becoming active). On the other hand, if $u_0 > 1/2$, the maximum gain to the network's populations is reached for some net input *above* the threshold ($\theta > th$) and the gain has an increasing trend in the vicinity of th. Therefore, the release mechanism is indeed much more easily obtained.

Remark 5.2. *The function S defined by (5.1) does not entirely satisfy the hypotheses introduced in section 2. In this case $F'''(u_0)$ does not exist anymore at $u_0 \neq 1/2$ even if we still have F as $\mathcal{C}^2(0,1)$ and $\mathcal{C}^\infty((0,1) \setminus \{u_0\})$. Nevertheless this property does not affect our analytical results (e.g., the expansion we used in section 3 to prove the existence of stable oscillatory solutions still makes sense since it is done locally about some point u^* different than u_0). Consequently, all the results found for system (2.1) in previous sections remain valid.*

5.1. A competition model that favors escape. In [31] we investigated four distinct neuronal competition models: a model by Wilson [37], one by Laing and Chow (the LC-model [17]), and two other variations of the LC-model that we called depression-LC and adaptation-LC. The latter is exactly the system (2.1) with symmetric sigmoid function. Besides the models' commonalities we also noticed some differences: in some cases the bifurcation diagrams show a preference of the system to the escape mechanism (the region of I that corresponds to the decreasing I-T branch is wider; see Figures 3 and 4 in [31]). Moreover, for sufficiently low inhibition in Wilson's and the depression-LC models the increasing (release-related) branch can disappear completely. Based on the results obtained in the present paper, we can explain those numerical observations.

Let us take, for example, Wilson's model for binocular rivalry [37, 31]. Since the time-scale for inhibition is much shorter than the time-scale for the (excitatory) firing rate, we can assume that the inhibitory population tracks the excitatory population almost instantaneously. Thus Wilson's model becomes equivalent to a system of the form

$$
\begin{aligned}
\dot{u}_1 &= -u_1 + \frac{\gamma(I - \beta u_2)_+^2}{(\theta + a_1)^2 + (I - \beta u_2)_+^2}, \\
\dot{u}_2 &= -u_2 + \frac{\gamma(I - \beta u_1)_+^2}{(\theta + a_2)^2 + (I - \beta u_1)_+^2}, \\
\tau \dot{a}_1 &= -a_1 + g u_1, \\
\tau \dot{a}_2 &= -a_2 + g u_2,
\end{aligned}
\tag{5.2}
$$

where γ is a positive constant and $[x]_+$ is defined as $[x]_+ = 0$ if $x < 0$ and $[x]_+ = x$ if $x \geq 0$. As in (2.1), parameters β and g represent here the strength of the inhibition and adaptation; I is the external input strength. We see that in the differential equations for u_j the nonlinearity

is introduced through a function

$$\tilde{S}(x;\Theta) = \frac{\gamma[x]_+^2}{\Theta^2 + [x]_+^2},$$

that is, $\dot{u}_1 = -u_1 + \tilde{S}(I - \beta u_2;\, \theta + a_1)$ and $\dot{u}_2 = -u_2 + \tilde{S}(I - \beta u_1;\, \theta + a_2)$. We note that $\tilde{S}$ is asymptotic to γ as $x \to \infty$ and satisfies $\tilde{S} = 0$ for $x \le 0$ and $\tilde{S}(\Theta;\Theta) = \gamma/2$, which means Θ is the threshold. To compare system (5.2)'s dynamics with that of (2.1), we will assume without loss of generality that $\gamma = 1$.

By the change of variables $w_1 = \beta u_1 - I$, $w_2 = \beta u_2 - I$, $A_1 = \beta a_1/g - I$, $A_2 = \beta a_2/g - I$, the system (5.2) is diffeomorphic equivalent to

$$\begin{aligned} \dot{w}_1 &= -w_1 + \beta\tilde{S}(-w_2;\theta_1) - I, \\ \dot{w}_2 &= -w_2 + \beta\tilde{S}(-w_1;\theta_2) - I, \\ \tau\dot{A}_1 &= -A_1 + w_1, \\ \tau\dot{A}_2 &= -A_2 + w_2 \end{aligned} \tag{5.3}$$

with $\theta_1(t) = \theta + \frac{g}{\beta}(A_1(t) + I)$ and $\theta_2(t) = \theta + \frac{g}{\beta}(A_2(t) + I)$.

On the other hand, let us consider the system (2.1) with S as in (2.2). By a similar change of variables $w_1 = \beta u_1 - I$, $w_2 = \beta u_2 - I$, $A_1 = \beta a_1 - I$, $A_2 = \beta a_2 - I$ this system is diffeomorphic equivalent to

$$\begin{aligned} \dot{w}_1 &= -w_1 + \beta S(-w_2;\theta_1) - I, \\ \dot{w}_2 &= -w_2 + \beta S(-w_1;\theta_2) - I, \\ \tau\dot{A}_1 &= -A_1 + w_1, \\ \tau\dot{A}_2 &= -A_2 + w_2 \end{aligned} \tag{5.4}$$

with $\theta_1(t)$ and $\theta_2(t)$ as above. The threshold of S (rewritten as $S(x;\theta) = 1/(1 + e^{-r(x-\theta)})$) is θ.

As we can see, up to the specific expression of the gain function, Wilson's and the adaptation-LC models are equivalent. The reason Wilson's model shows preference to the escape mechanism instead of release (while for the adaptation-LC model the interval ranges for escape and release dynamics have equal length) resides in the asymmetric shape of $\tilde{S}$ with respect to its threshold. The threshold is Θ but the maximum gain is obtained at $\frac{\Theta}{\sqrt{3}} < \Theta$ ($\tilde{S}''_{xx}(x;\Theta) = 0$ at $x = \frac{\Theta}{\sqrt{3}}$). The resulting behavior is similar to that of S as in (5.1) with $u_0 < 1/2$ ($S''(\theta) = 0$, $S(\theta) = u_0$, and $\theta < th$). The role of θ is played by $\frac{\Theta}{\sqrt{3}}$ and the corresponding value for u_0 is $\tilde{S}(\frac{\Theta}{\sqrt{3}};\Theta) = 1/4$.

Remark 5.3. *In fact, the difference between $\tilde{S}$ and asymmetric S from (5.1) is more subtle. Take again $\gamma = 1$; the restriction of $\tilde{S}$ on $(0,\infty)$ is invertible with inverse $\tilde{F}$ defined on $(0,1)$ by $\tilde{F}(u;\Theta) = \Theta\sqrt{\frac{u}{1-u}}$. In systems (5.3) and (5.4) the graph of $\tilde{F}'_u$, $\tilde{F}'_u(u;\theta_j) = \frac{\theta_j}{2(1-u)\sqrt{u(1-u)}}$ has a well-like shape similar to that of the graph of $F'_u(u;\theta_j) = \frac{4u_0^2}{ru(2u_0-u)}$ if $u \in (0,u_0]$ and*

$\frac{4(1-u_0)^2}{r(1-u)(1-2u_0+u)}$ *if* $u \in (u_0, 1)$. *However,* $\tilde{F}'_u$ *depends on* θ_j *(that implicitly means dependence on the slow variable) while* F'_u *does not. That explains why, for* S *as in* (5.1)*, when they exist, the Hopf bifurcation points always come in pairs (and oscillations start at both points with the same frequency—see* (3.5) *and* (3.6) *in section* 3*); so release and escape oscillatory regimes (even if not equally balanced) always coexist for* (2.1)*. On the contrary, in Wilson's model* (5.2) *the dependence of* $\tilde{F}'_u$ *on the slow variable allows us to find a (reduced) parameter regime where only the escape mechanism is possible* [31].

5.2. Competition models with nonlinear slow negative feedback. The local analysis pursued in section 3 shows that the uniform equilibrium point $\mathbf{e}_I$ can lose its stability through either a Hopf bifurcation (at exactly two values I^*_{hb} and I^{**}_{hb}) or a pitchfork bifurcation (at exactly two values I^*_{pf} and I^{**}_{pf}). This result comes from the intersection of the graph of F' (which has a well-like shape) with the straight horizontal lines $y = \frac{\beta}{1+\frac{1}{\tau}}$ and $y = \beta - g$, respectively. This type of intersection restricts the possibilities to either $I^*_{hb} < I^*_{pf} < I^{**}_{pf} < I^{**}_{hb}$ or $I^*_{pf} < I^*_{hb} < I^{**}_{hb} < I^{**}_{pf}$. The first case corresponds to a feedback/adaptation-dominated neuronal competition model and ensures the existence of stable oscillations in (2.1). Moreover, these appear with the same frequency $\omega = \frac{1}{\tau}\sqrt{\frac{g(\tau+1)}{\beta} - 1}$ at both values I^*_{hb} and I^{**}_{hb}, and they are due to two different mechanisms: escape (for larger values of I) and release (for lower values of I). Thus we conclude that in system (2.1) escape and release oscillatory regimes *always coexist*. The choice of asymmetric gain function with respect to its threshold helps to reduce one or another regime but cannot eliminate it completely.

Nevertheless there is a way to modify (2.1) such that the new obtained system shows preference to either the escape or release mechanim; moreover, as for Wilson's model, in some parameter regime we can find only escape-based oscillations (or, vice versa, only release-based oscillations). In this sense we consider the neuronal competition model with nonlinear slow negative feedback

$$\begin{aligned} \dot{u}_1 &= -u_1 + S(I - \beta u_2 - g a_1), \\ \dot{u}_2 &= -u_2 + S(I - \beta u_1 - g a_2), \\ \tau \dot{a}_1 &= -a_1 + a_\infty(u_1), \\ \tau \dot{a}_2 &= -a_2 + a_\infty(u_2) \end{aligned} \tag{5.5}$$

with S as in (2.2) and

$$a_\infty(x; \theta_a) = 1/\left(1 + e^{-r_a(x-\theta_a)}\right). \tag{5.6}$$

We obtain the following result, which is similar to Theorem 5.1.

Theorem 5.2. *Consider the nonlinear term* $a_\infty(x; \theta_a)$ *defined by* (5.6)*. If the gain function* S *satisfies* $S(\theta + x) + S(\theta - x) = 1$*, then system* (5.5) *with input* I^* *and slow equation nonlinearity* $a_\infty(x; \theta_a)$ *is diffeomorphic equivalent to system* (5.5) *with input* $I = 2\theta + \beta + g - I^*$ *and slow nonlinearity* $a_\infty(x; 1 - \theta_a)$.

Proof. With the change of variables $u_1 = 1 - \tilde{u}_1$, $u_2 = 1 - \tilde{u}_2$, $a_1 = 1 - \tilde{a}_1$, $a_2 = 1 - \tilde{a}_2$, system (5.5) with input I^* and nonlinear term in the slow equation $a_\infty(x; \theta_a)$ takes the form (5.5) with input $(2\theta + \beta + g - I^*)$ and $a_\infty(x; 1 - \theta_a)$. ∎

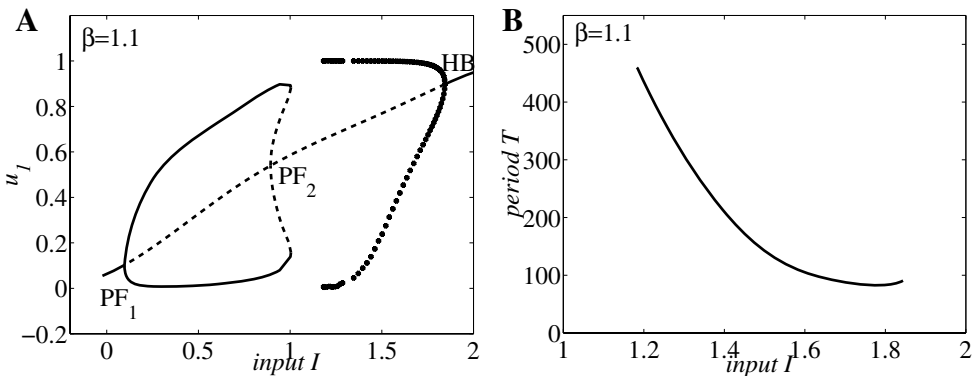

Figure 12. *Bifurcation diagrams for neuronal competition model (5.5): (A) population activity u_1 versus input strength I; (B) period T of the network oscillations versus I. Parameter values are $\beta = 1.1$, $g = 0.5$, $\tau = 100$, $\theta = 0.2$, $r = 10$, $r_a = 10$, and $\theta_a = 0.7$. Functions S and a_∞ are defined by (2.2) and (5.6).*

If $\theta_a = 1/2$, we have $a_\infty(x;\theta_a) = a_\infty(x;1-\theta_a)$, and thus the system (5.5) has the same type of solutions for any two values of input strength I_1 and I_1^* such that $\frac{1}{2}(I_1 + I_1^*) = \theta + \frac{\beta+g}{2}$. As for the case of linear adaptation (where the choice was $a_\infty(u) = u$), the intervals of I where the period of oscillations increases and decreases have the same length and are symmetric to the line $I = \theta + \frac{\beta+g}{2}$.

The symmetry of the I-T bifurcation diagram can be destroyed by choosing $\theta_a \neq 1/2$. As numerical simulations of system (5.5) show, the choice of $\theta_a > 1/2$ leads to a preference of the system for the escape mechanism (decreasing T versus I). On the contrary, for $\theta_a < 1/2$ the system shows preference to the release mechanism (increasing T versus I).

For parameters $\beta = 1.1$, $g = 0.5$, $\tau = 100$, and $\theta = 0.2$, $r = 10$ for S and $r_a = 10$ and $\theta_a = 0.7$ for a_∞, we plot in Figure 12 the bifurcation diagram of population activity u_1 versus the stimulus strength I and then the period T versus I. In Figure 12A we observe that the Hopf bifurcation point that existed for low value of I in case of linear adaptation disappears now. Instead we find a supercritical pitchfork bifurcation where stable nonuniform equilibrium points are born (they correspond to the winner-take-all case). The increasing branch of T versus I graph disappears while the decreasing branch is still present (Figure 12B). We find only four dynamical regimes (as opposed to the five described in Figure 3F and G): fusion (equal activity levels) for large and low input, winner-take-all, and oscillations with decreasing T as function of I for intermediate values of stimulus strength.

By choosing $\theta_a = 0.3$ the bifurcation diagrams in Figure 12 are virtually mirrored along the stimulus axis; in this case only the increasing I-T branch exists.

We explain these numerical results through an analytical approach. Similarly to the local analysis in section 3, we note that system (5.5) has a unique uniform equilibrium $\mathbf{e}_I = (u_I, u_I, a_\infty(u_I), a_\infty(u_I))$ for any real I. The value $u_I \in (0,1)$ is defined by equation $I = F(u_I) + \beta u_I + g a_\infty(u_I)$ and decreases with a decrease in I; moreover, $\lim_{I\to\infty} u_I = 1$ and $\lim_{I\to-\infty} u_I = 0$. The characteristic equation of the linearization matrix about $\mathbf{e}_I$ is a product of two factors: $\lambda^2 + \lambda\left(1 + \frac{1}{\tau} + \frac{\beta}{F'(u_I)}\right) + \frac{1}{\tau}\left(1 + \frac{ga'_\infty(u_I)+\beta}{F'(u_I)}\right) = 0$ and $\lambda^2 + \lambda\left(1 + \frac{1}{\tau} - \frac{\beta}{F'(u_I)}\right) + \frac{1}{\tau}\left(1 + \frac{ga'_\infty(u_I)-\beta}{F'(u_I)}\right) = 0$. Thus two of the eigenvalues always have negative real part, while the

other two show the type of stability for $\mathbf{e}_I$. Decreasing I, the stability of $\mathbf{e}_I$ is lost either through a pair of purely imaginary eigenvalues at $F'(u_I) = \beta/(1+\frac{1}{\tau})$, $F'(u_I) + ga'_\infty(u_I) > \beta$ or through a zero eigenvalue at $F'(u_I) + ga'_\infty(u_I) = \beta$ and $F'(u_I) > \beta/(1+\frac{1}{\tau})$.

Assume now that θ_a is greater than $1/2$ and close to 1. For large I the corresponding fixed point $\mathbf{e}_I$ has u_I close to 1 and in the vicinity of θ_a. Since this is the steeper (almost linear) part of a_∞, we can approximate $a_\infty(u_I) \approx ku_I$. The condition $F'(u_I) = \beta/(1+\frac{1}{\tau})$, $F'(u_I) > \beta - ga'_\infty(u_I) = \beta - gk$, can be attained (at least for adaptation-dominated systems) and stable oscillations occur. On the other hand, for small I, the fixed point $\mathbf{e}_I$ has u_I close to 0 and further away from θ_a. The function a_∞ is almost constant there, so $a'_\infty(u_I) \approx 0$. Then $F'(u_I) + ga'_\infty(u_I) \approx \beta > \beta/(1+\frac{1}{\tau})$ and the stability of $\mathbf{e}_I$ is lost through a zero eigenvalue (a pitchfork bifurcation).

Remark 5.4. *We note that the choice of $\theta_a > 1/2$ sufficiently close to 1 helps the slow variable for the suppressed population, say, a_1, to change faster than the slow variable for the dominant population, say, a_2. Since $a_\infty(u_1)$ is approximately constant to zero and $a_\infty(u_2)$ falls onto the linear part of the sigmoid, a_1 decays almost exponentially according to $\tau\dot{a}_1 \approx -a_1$, while a_2 grows more slowly according to $\tau\dot{a}_2 \approx -a_2 + ku_2$. The input-output function of the suppressed population changes faster, favoring escape. An opposite effect is obtained for $\theta_a < 1/2$.*

6. Discussion. We investigated a class of competition models that describe rhythmic (alternating) phenomena that arise in a range of neural contexts including perception of ambiguous sensory stimuli (such as binocular rivalry) and motor coordination (as in CPGs). These models rely on mutual inhibition between populations of neurons and a slow process in the form of spike frequency adaptation and/or synaptic depression, and they have the following commonalities [31].

A decrease in the strength of the input to the noise-free system leads to five possible types of dynamics: (i) at high values of input strength both competing populations are active at equal levels; (ii) by decreasing the input strength the system enters an oscillatory regime with the oscillation period increasing as input decreases; (iii) then for lower input the system is in a winner-take-all regime where only one population is dominant while the other is suppressed forever; (iv) continuing to decrease the input strength, the system oscillates again; in this region the oscillation period decreases as the input decreases; (v) at low values of input, oscillations disappear and both competing populations are inactive at an equal level. In addition, for weak inhibition the winner-take-all regime does not occur; however, the period of oscillations still depends on the input strength in a nonmonotonic fashion.

In a computational study of a model similar to (2.1), the authors of [23] also report transitions between simultaneous activity (single equilibrium), oscillations, and winner-take-all. The bifurcation diagram (Figure 4) in the parameter plane (I, β) resembles Figure 9 in [23]. However, Moldakarimov et al. were interested mostly in how the system's dynamics changes with inhibition strength (an internal parameter of the system) and not with stimulus strength. By analyzing the influence of stimulus on the oscillations' frequency/period, we provide a refined characterization of possible behaviors in this class of competition models.

The five dynamical regimes mentioned above were illustrated in Figure 3 for system (2.1), our choice as a particular example. Despite the fact that it has some limitations such as a lack of recurrent excitation, a symmetric gain function, and a nonsaturating $a_\infty(u)$, system (2.1)

has the advantage of being simple enough to allow for a thorough analytical investigation while still displaying the dynamical characteristics found in a larger class of models. Thus, for (2.1) we proved the existence of oscillations and we showed that they are antiphase as expected for a network of two competing populations. Moreover, by considering the period of oscillations T as a function of input strength I, we proved that the I-T graph is nonmonotonic. We associated the increasing I-T branch with a release mechanism and the decreasing branch with an escape mechanism. Release occurs for lower values of I. It means that during oscillation the dominant population loses control due to accumulating slow negative feedback and it becomes unable to suppress its competitor; consequently the latter becomes active and thereby takes the role of suppressor. On the contrary, escape occurs for higher values of I and it means that the suppressed population regains control on its own, starts to inhibit its competitor, and forces it into the down state. Moreover, using singular perturbation techniques, we characterized in the limiting case the conditions for occurrence of winner-take-all dynamics at intermediate values of stimulus strength.

Our presumption is that the potential for alternation of percepts depends on neuronal competition. If competition were significantly reduced or eliminated (say, effectively making β very small in the model), alternations would not occur in the presence of a stimulus. That is, we suppose that an isolated population would not oscillate. To satisfy this constraint we have disallowed recurrent excitation in (2.1): this precludes oscillations in an isolated population for any input value I. Perhaps for this goal the complete elimination of recurrent excitation is an extreme way to satisfy the constraint. Alternatively, we could consider systems with fast equations of the form $\dot{u}_j = -u_j + S(I + \alpha u_j - \beta u_k - g a_j)$ and allow for some recurrent excitation but not strong enough to let an isolated population oscillate (e.g., take $\alpha < (1 + \frac{1}{\tau})/S'(\theta)$). This modification, however, does not affect our conclusion on the nonmonotonicity of the period of oscillations versus input strength curve (not shown): both "release" and "escape" branches still appear.

Other modifications of (2.1) that favor either release or escape as responsible for oscillations were discussed in section 5. One extension of (2.1) allows the gain function to be asymmetric with respect to the threshold. This maintains one of the two oscillatory regimes while reducing the other one. A different rendition of (2.1) invokes a nonlinear slow negative feedback (a sigmoidal-shaped $a_\infty(u)$) and completely eliminates one of the two regimes. The existence of the saturating branches for a sigmoidal $a_\infty(u)$ introduces an asymmetry in the system; thus under some specific conditions either the suppressed population recovers from slow negative feedback faster than the dominant population accumulates its own negative feedback (favoring escape, see Figure 12), or the reverse occurs. Interestingly, adding noise to these specially designed models, we automatically recover the nonmonotonicity of the period versus input curve [31].

Oscillations in mutually inhibitory neuronal networks based on fast-slow dynamics [27] as well as the terms "release" and "escape" [36, 32] were previously discussed for neuronal networks in the presence of local autocatalysis. The autocatalysis was either an intrinsic process (like voltage-gated persistent inward currents) or a synaptic process (like intrapopulation recurrent excitation). Other models assumed networks of excitatory cells interacting through a global inhibitory feedback that typically produce the winner-take-all dynamics; the inhibition was dynamic with a slow time-scale and induced more complicated oscillatory patterns

with one cell being active for a while and then spontaneously turning off and allowing another one to take over [8]. Contrary to these examples, there is no autocatalysis in the neuronal competition models we investigate here. Instead the alternation is a combined result of two processes: mutual inhibition that acts effectively as a fast positive feedback (disinhibition) and a slow negative feedback (adaptation, but that could alternatively be synaptic depression).

Appendix A. Normal form for Hopf bifurcation. To construct the normal form for the Hopf bifurcation, in section 3 we use the expansion of $S^{(k)}(F(u_I))$, $k = 1, 2, 3, \ldots$, with respect to ε. That is obtained as follows: take, for example,

$$f_1(I) \stackrel{def}{=} S'(F(u_I)) = f_1(I^* + \varepsilon^2\alpha) = f_1(I^*) + f_1'(I^*)\varepsilon^2\alpha + \mathcal{O}(\varepsilon^4).$$

Here $f_1(I^*) = S'(F(u^*)) = 1/F'(u^*) = (1 + \frac{1}{\tau})/\beta$ and $f_1'(I) = S''(F(u_I)) \cdot F'(u_I) \cdot du_I/dI$.

Based on (3.2), $f_1'(I) = S''(F(u_I)) \cdot F'(u_I)/(\beta + g + F'(u_I))$. On the other hand, since $u \equiv S(F(u))$, we have $1 \equiv S'(F(u)) \cdot F'(u)$, and further $0 \equiv S''(F(u)) \cdot F'(u)^2 + S'(F(u)) \cdot F''(u)$, i.e., $S''(F(u)) = -F''(u)/F'(u)^3$. Therefore,

$$f_1(I) = \frac{1 + 1/\tau}{\beta} - \frac{F''(u^*)}{F'(u^*)^2(\beta + g + F'(u^*))}\varepsilon^2\alpha + \mathcal{O}(\varepsilon^4)\,.$$

Similarly, we compute

$$f_2(I) \stackrel{def}{=} S''(F(u_I)) = f_2(I^* + \varepsilon^2\alpha) = f_2(I^*) + \mathcal{O}(\varepsilon^2) = -\frac{F''(u^*)}{F'(u^*)^3} + \mathcal{O}(\varepsilon^2)$$

and $f_3(I) \stackrel{def}{=} S'''(F(u_I)) = f_3(I^* + \varepsilon^2\alpha) = f_3(I^*) + \mathcal{O}(\varepsilon^2) = S'''(F(u^*)) + \mathcal{O}(\varepsilon^2)$. From $S''(F(u)) = -F''(u)/F'(u)^3$ we obtain $S'''(F(u)) = [3F''(u)^2 - F'(u) \cdot F'''(u)]/F'(u^*)^5$, so

$$f_3(I) = \frac{3F''(u^*)^2 - F'(u^*) \cdot F'''(u^*)}{F'(u^*)^5} + \mathcal{O}(\varepsilon^2).$$

Normal form. Let us now present the main steps in the algorithm for the construction of the normal form starting with

$$L_0V_0 = \varepsilon[\mathcal{B}(V_0, V_0) - L_0V_1] + \varepsilon^2[\mathcal{C}(V_0, V_0, V_0) + 2\mathcal{B}(V_0, V_1) + \Lambda V_0 - L_0V_2] + \mathcal{O}(\varepsilon^3)\,. \tag{A.1}$$

In the limit $\varepsilon \to 0$, the vector V_0 is a solution of the linear system $L_0V_0 = 0$ with two eigenvalues $\lambda_{1,2}$ of negative real part and two purely imaginary eigenvalues $\lambda_{3,4} = \pm i\omega$. Thus V_0 belongs to the center manifold; i.e., for an eigenvector $\xi \in \boldsymbol{C}^4$ of $\mathcal{A}_0$ that satisfies $\mathcal{A}_0\xi = i\omega\xi$, say,

$$\xi = (-\tau\omega + i,\, \tau\omega - i,\, i,\, -i)^{\mathrm{T}}, \tag{A.2}$$

the solution V_0 takes the form

$$V_0(t) = w(t)\xi e^{i\omega t} + \bar{w}(t)\bar{\xi}e^{-i\omega t}.$$

However, since $L_0V_0 = \mathcal{O}(\varepsilon)$, $w(t)$ is ε-dependent, and it can be written in slow time $s = \varepsilon^2 t$ as $w = w(s)$. In the singular perturbation expansion, $w(s) = w(s)_{|\varepsilon=0} + \frac{dw}{ds}_{|\varepsilon=0}\varepsilon^2 t + \mathcal{O}(\varepsilon^4)$.

With notation $Z = w(s)_{|\varepsilon=0}$, $Z' = \frac{dw}{ds}_{|\varepsilon=0}$, and so on (here $'$ stands for the derivative with respect to the slow time), we have $w = Z + \varepsilon^2 t Z' + \mathcal{O}(\varepsilon^4)$ and

$$V_0 = \left(Z\xi e^{i\omega t} + \bar{Z}\bar{\xi}e^{-i\omega t}\right) + \varepsilon^2 t\left(Z'\xi e^{i\omega t} + \bar{Z}'\bar{\xi}e^{-i\omega t}\right) + \mathcal{O}(\varepsilon^4).$$

Then we compute $L_0\left(te^{i\omega t}\xi\right) = e^{i\omega t}\xi$, $L_0\left(te^{-i\omega t}\bar{\xi}\right) = e^{-i\omega t}\bar{\xi}$ and $\mathcal{B}\left(\xi e^{i\omega t}, \xi e^{i\omega t}\right) = \frac{1}{2}Bb^2\boldsymbol{p}\,e^{2i\omega t}$, $\mathcal{B}\left(\bar{\xi}e^{-i\omega t}, \bar{\xi}e^{-i\omega t}\right) = \frac{1}{2}B\bar{b}^{\,2}\boldsymbol{p}\,e^{-2i\omega t}$, $\mathcal{B}\left(\xi e^{i\omega t}, \bar{\xi}e^{-i\omega t}\right) = \frac{1}{2}B|b|^2\boldsymbol{p}$, where $b = \beta\tau\omega + i(g-\beta)$ and $\boldsymbol{p} = (1,1,0,0)^{\mathrm{T}}$. Equation (A.1) becomes

$$L_0V_1 = \frac{1}{2}Z^2Bb^2\boldsymbol{p}\,e^{2i\omega t} + \frac{1}{2}\bar{Z}^2B\bar{b}^{\,2}\boldsymbol{p}\,e^{-2i\omega t} + Z\bar{Z}B|b|^2\boldsymbol{p} + \varepsilon\left[-Z'\xi e^{i\omega t} - \bar{Z}'\bar{\xi}e^{-i\omega t} + \mathcal{C}(V_0,V_0,V_0) + 2\mathcal{B}(V_0,V_1) + \Lambda V_0 - L_0V_2\right] + \mathcal{O}(\varepsilon^2),$$

so we look for solutions V_1 of the form

$$V_1 = w^2\xi_1 e^{2i\omega t} + 2w\bar{w}\xi_2 + \bar{w}^2\xi_3 e^{-2i\omega t} = Z^2\xi_1 e^{2i\omega t} + 2Z\bar{Z}\xi_2 + \bar{Z}^2\xi_3 e^{-2i\omega t} + \mathcal{O}(\varepsilon^2).$$

From the singular perturbation expression we determine $\xi_1 = \frac{1}{2}Bb^2(2i\omega I - \mathcal{A}_0)^{-1}\boldsymbol{p}$, $\xi_2 = -\frac{1}{2}B|b|^2\mathcal{A}_0^{-1}\boldsymbol{p}$, and $\xi_3 = \bar{\xi}_1$, that is,

$$\xi_1 = \frac{Bb^2\psi}{2|\psi|^2}(1 + 2i\tau\omega, 1 + 2i\tau\omega, 1, 1)^{\mathrm{T}}, \quad \xi_2 = \frac{B|b|^2}{2\left[1 + \left(\frac{g}{\beta}+1\right)\left(1+\frac{1}{\tau}\right)\right]}(1,1,1,1)^{\mathrm{T}},$$

where $\psi = 1 - 4\omega^2\tau + \left(\frac{g}{\beta}+1\right)\left(1+\frac{1}{\tau}\right) - 4i\omega(\tau+1)$.

Then we compute $\mathcal{C}(V_0,V_0,V_0)$, $\mathcal{B}(V_0,V_1)$ and $\Lambda V_0 = -\alpha A(Zb\,e^{i\omega t} + \bar{Z}\bar{b}\,e^{-i\omega t})\boldsymbol{q} + \mathcal{O}(\varepsilon^2)$ with $\boldsymbol{q} = (1,-1,0,0)^{\mathrm{T}}$ and obtain

$$L_0V_2 = -(Z'\xi + \alpha AZb\boldsymbol{q})\,e^{i\omega t} + Z^2\bar{Z}b^2\bar{b}\boldsymbol{q}\,e^{i\omega t}\left(-\frac{D}{2} + \frac{(\beta+g)B^2}{1+\left(\frac{g}{\beta}+1\right)\left(1+\frac{1}{\tau}\right)} + \frac{B^2(\beta+g+2i\beta\omega\tau)\psi}{2|\psi|^2}\right) + e^{3i\omega t}(\ldots) + cc + \mathcal{O}(\varepsilon).$$

In order for the solution V_2 to exist, the right-hand side of the above equation should be orthogonal on the eigenvectors of the adjoint operator $L_0^* = -\frac{d}{dt} - \mathcal{A}_0^{\mathrm{T}}$ on the space of periodic solutions $V(t) = V(t + \frac{2\pi}{\omega})$ with inner product

$$\langle V, W\rangle = \frac{\omega}{2\pi}\int_0^{\frac{2\pi}{\omega}}\sum_{i=1}^{4} v_i(t)\bar{w}_i(t)\,dt, \quad V = (v_i)^{\mathrm{T}}_{i=\overline{1,4}},\ W = (w_i)^{\mathrm{T}}_{i=\overline{1,4}}.$$

That means the right-hand side should be orthogonal on $\left\{\eta e^{i\omega t}, \bar{\eta}e^{-i\omega t}\right\}$ with η solution of $\mathcal{A}_0^{\mathrm{T}}\eta = -i\omega\,\eta$ and $\xi\cdot\bar{\eta} = 1$; that is,

$$\eta = -\frac{1}{4\omega\tau}(1,\,-1,\,-1 - i\omega\tau,\,1 + i\omega\tau)^{\mathrm{T}}.$$

We obtain the normal form $Z' = \alpha A\varphi Z - \mathcal{L}Z^2\bar{Z}$ with $\mathcal{L}$ as in Theorem 3.2.

By rescaling $I - I^* = \varepsilon^2\alpha$ and $z(t) = \varepsilon Z(\varepsilon^2 t) = \varepsilon Z(s)$, we have $\dot{z} = dz/dt = \varepsilon \frac{dZ}{ds}\frac{ds}{dt} = \varepsilon^3 Z'$; the above differential equation becomes exactly (3.11).

First Lyapunov coefficient. We would like to determine sufficient conditions for the Hopf bifurcation to be supercritical, i.e., for $\mathrm{Re}(\mathcal{L}) > 0$.

We now use inequality (3.3) to show that the first term in the sum that defines $\mathcal{L}$ has positive real part:

$$\begin{aligned}\mathrm{Re}\left(\varphi\psi\left(\frac{\beta+g}{2} + i\beta\omega\tau\right)\right) &= (2\beta g)\tau + \frac{1}{4}(7g^2 + 5\beta g - 6\beta^2) + \frac{1}{4\tau}(7g^2 - 6\beta g + 3\beta^2)\\ &> 2\beta^2 - 2\beta g + \frac{1}{4}(7g^2 + 5\beta g - 6\beta^2) + \frac{1}{4\tau}(7g^2 - 6\beta g + 3\beta^2)\\ &= \frac{1}{4}(7g^2 - 3\beta g + 2\beta^2) + \frac{1}{4\tau}(7g^2 - 6\beta g + 3\beta^2) > 0\,. \end{aligned} \tag{A.3}$$

For the second term, (3.3) implies

$$l_1 = \frac{2(\beta+g)}{1 + \left(\frac{g}{\beta}+1\right)\left(1+\frac{1}{\tau}\right)} = \frac{2}{\frac{1}{\beta+g} + \frac{1}{F'(u^*)}} > \left(1 + \frac{1}{\tau+1}\right)F'(u^*) > F'(u^*).$$

Therefore, the real part of the second term satisfies

$$\beta\tau^2\omega^2|\varphi|^2B^2\left(l_1 - \frac{D}{B^2}\right) > \beta\tau^2\omega^2|\varphi|^2B^2F'(u^*)\left(\frac{F'(u^*)F'''(u^*)}{F''(u^*)^2} - 2\right). \tag{A.4}$$

Appendix B. Normal form for pitchfork bifurcation. The construction of this normal form follows similar steps to those in section 3.1 and Appendix A. Here $F'(u^\circ) = \beta - g$ with $u^\circ \in \{u^*_{pf}, u^{**}_{pf}\}$ and $I^\circ \in \{I^*_{pf}, I^{**}_{pf}\}$.

The operators $\mathcal{B}$, $\mathcal{C}$, Λ, and L_0 are defined in the same way as in section 3.1 with coefficients A, B, D as in (3.10). However, the derivatives of F at the bifurcation point u° take different values, so $S'(F(u_I)) = 1/(\beta - g) + \alpha A\varepsilon^2 + \mathcal{O}(\varepsilon^4)$, $S''(F(u_I)) = B + \mathcal{O}(\varepsilon^2)$, and $S'''(F(u_I)) = D + \mathcal{O}(\varepsilon^2)$ with A, B, and D evaluated at either u^*_{pf} or u^{**}_{pf}. The matrix of the linearized system is now

$$\mathcal{A}_0 = \begin{pmatrix} -1 & -\frac{\beta}{\beta-g} & -\frac{g}{\beta-g} & 0\\ -\frac{\beta}{\beta-g} & -1 & 0 & -\frac{g}{\beta-g}\\ \frac{1}{\tau} & 0 & -\frac{1}{\tau} & 0\\ 0 & \frac{1}{\tau} & 0 & -\frac{1}{\tau}\end{pmatrix}$$

and has a zero eigenvalue. Therefore, we find an eigenvector ξ ($\mathcal{A}_0\xi = 0$) and an eigenvector η of the adjoint matrix ($\mathcal{A}_0^{\mathrm{T}}\eta = 0$) such that $\xi \cdot \eta = 1$. They are

$$\xi = (1, -1, 1, -1)^{\mathrm{T}}, \quad \eta = \frac{1}{2(\beta - g(\tau+1))}(\beta - g, -\beta + g, -\tau g, \tau g)^{\mathrm{T}}.$$

With the perturbation $I - I^\circ = \varepsilon^2\alpha$, $V(t) = \varepsilon V_0(t) + \varepsilon^2 V_1(t) + \varepsilon^3 V_2(t) + \cdots$, we obtain that V_0 belongs to the eigenspace, that is, $V_0 = w(t)\xi$. The expansion with respect to the slow time ($s = \varepsilon^2 t$, $w = w(s)$, $Z = w(s)_{|\varepsilon=0}$, etc.) implies $V_0 = (Z + \varepsilon^2 tZ' + \mathcal{O}(\varepsilon^4))\xi$ and

$$L_0V_1 = Z^2\mathcal{B}(\xi,\xi) + \varepsilon[-Z'\xi + Z^3\mathcal{C}(\xi,\xi,\xi) + 2\mathcal{B}(V_0, V_1) + Z\Lambda\xi - L_0V_2] + \mathcal{O}(\varepsilon^2).$$

The vector V_1 is chosen to be of the form $V_1 = w^2\xi_1 = Z^2\xi_1 + \mathcal{O}(\varepsilon^2)$ with ξ_1 orthogonal on η. It results in $\xi_1 = -\mathcal{A}_0^{-1}\mathcal{B}(\xi,\xi)$, i.e., $\xi_1 = \frac{B^2(\beta-g)^3}{4\beta}(1,1,1,1)^{\mathrm{T}}$. The normal form is

$$Z' = (\Lambda\xi\cdot\eta)Z + [\mathcal{C}(\xi,\xi,\xi)\cdot\eta + 2\mathcal{B}(\xi,\xi_1)\cdot\eta]Z^3.$$

From $\Lambda\xi = \alpha A(\beta-g)\boldsymbol{q}$, $\mathcal{C}(\xi,\xi,\xi) = \frac{D}{6}(\beta-g)^3\boldsymbol{q}$, $\mathcal{B}(\xi,\xi_1) = -\frac{B^2}{8\beta}(\beta-g)^4(\beta+g)\boldsymbol{q}$ (where $\boldsymbol{q} = (1,-1,0,0)^{\mathrm{T}}$), and by rescaling $I - I^\circ = \varepsilon^2\alpha$ and $z(t) = \varepsilon Z(\varepsilon^2 t) = \varepsilon Z(s)$, we obtain exactly (3.15).

Appendix C. Additional material. To illustrate system (2.1)'s dynamics under the *escape* and *release* mechanisms we run numerical simulations in XPPAUT [7, 9] with S as in (2.2), $r = 10$, $\theta = 0.2$, and parameters $\beta = 1.1$, $g = 0.5$, $\tau = 100$ as in Figure 3F. Then in the fast plane (u_1, u_2) we obtain the trajectory of the point on the rivalry limit cycle: the point is drawn as a black thick dot; the u_1-nullcline is colored in red, and the u_2-nullcline is colored in blue.

70584_01.gif [3.7MB] illustrates the escape mechanism for $I = 1.5$.

70584_02.gif [3.8MB] illustrates the release mechanism for $I = 0.5$.

The small black square corresponds to the slow plane (a_1, a_2), where we included in green the projection of the limit cycle trajectory. This picture shows how the slow negative feedback accumulates for the dominant population and then how it recovers for the suppressed population (e.g., if u_1 is ON and u_2 is OFF, then a_1 increases and a_2 decreases). Then the cycle repeats.

Acknowledgment. We thank Sukbin Lim for helpful discussions.

Classification of Spatially Localized Oscillations in Periodically Forced Dissipative Systems*

J. Burke†, A. Yochelis‡, and E. Knobloch†

Abstract. Formation of spatially localized oscillations in parametrically driven systems is studied, focusing on the dominant 2:1 resonance tongue. Both damped and self-excited oscillatory media are considered. Near the primary subharmonic instability such systems are described by the forced complex Ginzburg–Landau equation. The technique of spatial dynamics is used to identify three basic types of coherent states described by this equation—small amplitude oscillons, large amplitude reciprocal oscillons resembling holes in an oscillating background, and fronts connecting two spatially homogeneous states oscillating out of phase. In many cases all three solution types are found in overlapping parameter regimes, and multiple solutions of each type may be simultaneously stable. The origin of this behavior can be traced to the formation of a heteroclinic cycle in space between the finite amplitude spatially homogeneous phase-locked oscillation and the zero state. The results provide an almost complete classification of the properties of spatially localized states within the one-dimensional forced complex Ginzburg–Landau equation as a function of the coefficients.

1. Introduction.

The study of parametrically driven oscillatory systems has a long history dating back to Faraday's experiments in 1831 [16]. A single periodically driven nonlinear oscillator exhibits a number of intriguing phenomena when the natural oscillation frequency and the driving frequency are close to strong resonance [2, 23]. These include frequency locking, hysteresis, and various types of chaotic oscillations [2, 19, 23]. Many of these phenomena are present in spatially extended systems as well, including charge-density waves [6], autocatalytic surface reactions [14], cardiac activity [20], the Belousov–Zhabotinsky (BZ) chemical reaction [34], and optical parametric oscillators [54]. Such systems admit, in addition, different types of spatially structured oscillations such as different types of standing waves and spirals [10, 25, 32, 39, 41, 42, 43, 46, 53, 60]. These phenomena are usually easiest to see in the vicinity of the subharmonic resonance, so called because the system responds with half the forcing frequency. In the following we refer to this resonance as the 2:1 resonance, and the resonance tongue containing homogeneous oscillations phase-locked to half the forcing frequency as the 2:1 resonance tongue. As is well known, these phase-locked states typically

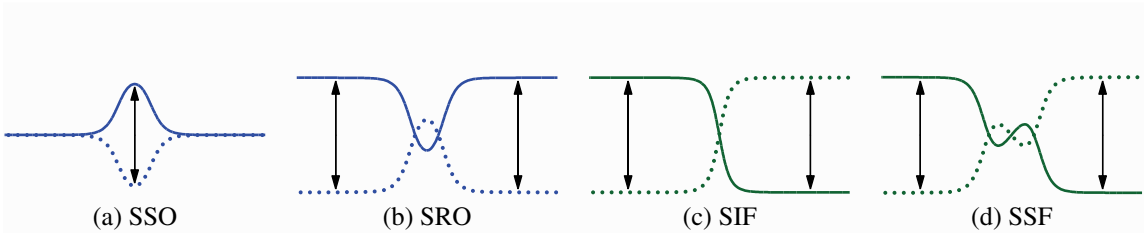

Figure 1. *Sketch of* (a) *a stable standard oscillon (SSO),* (b) *a stable reciprocal oscillon (SRO),* (c) *a stable Ising front (SIF), and* (d) *a stable structured front (SSF). The arrows indicate that after one period of forcing the profile switches from the solid profile to the dotted profile and hence returns to the original configuration only after two periods of the forcing. Although the front in* (d) *is also of Ising type, the terminology used emphasizes the difference in the front profiles. Despite their lack of reflection symmetry, the SIFs and SSFs do not drift. This is in contrast to the so-called Bloch fronts (not shown) which do drift (see text).*

coexist with the trivial state along one of the boundaries of the resonance tongue [17, 46].

Recent experiments on parametrically driven granular media have revealed, in addition, the presence of *spatially localized* oscillations that have been called *oscillons* [1, 35, 38, 52, 50]. These oscillations are embedded in a stationary background (Figure 1(a)) and also oscillate with half the forcing frequency [35, 52]. In the following we refer to states of this type as *standard* oscillons. Additional experiments have identified other types of spatially localized structures [4, 44]. These include hole-like states in a background oscillating state (Figure 1(b)) referred to here as *reciprocal oscillons* [57]. In such states both the hole and the background oscillate with half the forcing frequency, and hence both oscillate synchronously. In addition, experiments on the BZ reaction subjected to stroboscopic optical forcing and on vertically driven granular media reveal the presence of monotonic (or Ising) fronts connecting domains of spatially homogeneous oscillations, each phase-locked to half the forcing frequency but 180° out of phase. Such Ising fronts are often found in the same parameter regime as the reciprocal oscillons already mentioned, i.e., near the boundary of the 2:1 resonance tongue [40]. The Ising fronts can in turn undergo instabilities leading to traveling (Bloch) fronts [11, 18]. In two space dimensions, a transverse instability of Ising fronts may lead to the formation of standing wave labyrinths [60], while in the Bloch front case spiral turbulence was observed [39].

In this paper we show that much of this phenomenology can be captured by the forced complex Ginzburg–Landau (FCGL) equation [10, 15] valid near onset of the primary subharmonic instability. We use this equation to provide a comprehensive classification of the properties of the three types of spatially localized structures mentioned above—standard oscillons, reciprocal oscillons, and fronts—in different parameter regimes. Since the FCGL equation provides a spatial unfolding of the 2:1 strong resonance familiar from dynamical systems theory [19], it can be considered the "normal form" for this resonance in spatially extended systems. As such it arises naturally and inevitably in the applications mentioned above and will arise at small amplitude in all extended oscillatory systems driven at frequency close to twice the natural oscillation frequency. Thus the only difference between these applications lies in the values of the coefficients which are system-specific and have to be computed in terms of physical parameters via standard techniques. Examples can be found in [37, 49] for the case of optical parametric oscillators; see also [5]. In cases where the primitive field equations (or the system parameters) are not known, as frequently occurs in chemical [33, 60] and granular [4, 55]

systems, the FCGL equation is frequently used as a model equation to describe the observed behavior, particularly in two or more space dimensions.

The presence of spatially localized states in the FCGL equation should come as no surprise. As already mentioned, the parametric forcing generally leads to coexistence between a spatially homogeneous phase-locked oscillation and the trivial state along one of the boundaries of the resonance tongue. In these circumstances one can expect to find fronts connecting these two states, and by combining such fronts back-to-back one can construct spatially localized states. In the following we think of structures of this type as heteroclinic *cycles* in space and employ *spatial dynamics* [9] coupled with numerical branch following techniques to establish the presence of such cycles in appropriate parameter regimes [57]. In addition, we demonstrate, following [28], that such cycles can be responsible for the presence of multiple stable standard and reciprocal oscillons in overlapping parameter regions. We also demonstrate that different types of stable monotonic (Figure 1(c)) and structured (Figure 1(d)) fronts, i.e., different types of heteroclinic orbits, can be present in this region as well. Thus the presence of heteroclinic cycles is responsible, under appropriate conditions, for the profusion of stable homoclinic and heteroclinic structures in certain regions of parameter space. These include states we refer to as single-pulse states (discussed above), as well as a variety of so-called multipulse states that resemble bound states of the single-pulse states, and different types of fronts.

Our classification divides naturally into two parts corresponding, in the absence of parametric forcing, to damped and self-excited oscillations. In section 2 we introduce the FCGL equation describing the 2:1 resonance in one spatial dimension and review the properties of spatially homogeneous phase-locked states, i.e., the states that oscillate with half the frequency of the forcing. In section 3 we focus on the damped oscillatory regime and identify analytically bifurcations to small amplitude spatially localized states of homoclinic type, all of which are unstable. We next present the results of numerical continuation, which allows us to follow these states toward larger amplitude; these results indicate that these solutions terminate in a (spatial) heteroclinic bifurcation and show that in some parameter regimes the homoclinic states acquire stability in the vicinity of this bifurcation. We identify the resulting states with the observed standard oscillons. In addition, we find two further types of spatially localized states, corresponding to the reciprocal oscillons and front-like states. The former bifurcate from the spatially homogeneous phase-locked states at finite amplitude and are also homoclinic; in contrast, the front-like states correspond to heteroclinic connections between two phase-locked states 180° out of phase. Both types may terminate in the same heteroclinic bifurcation as the standard oscillons. We show that the reciprocal oscillons may acquire stability near this global bifurcation, while the various structured fronts may do so as well. In section 4 we present parallel results for the case of self-excited oscillations and discuss the impact of the bifurcation to Bloch fronts on the stability of both Ising and structured fronts. The paper concludes in section 5 with a discussion of the results and their significance for ongoing experiments. Details of the analytical computations are relegated to several appendices.

2. The forced complex Ginzburg–Landau equation. We consider a continuous system in one spatial dimension near a bifurcation to spatially homogeneous oscillations with natural frequency ω in the presence of spatially homogeneous forcing with frequency Ω. As is well known, interesting dynamical behavior is associated with strong resonances of the form $\Omega : \omega = n : 1$, $1 \leq n \leq 4$ [2, 23]. Of these the resonance tongue associated with the subharmonic

resonance $\Omega \approx 2\omega$ is the broadest and therefore ideally suited for experimental study [14, 18, 32, 39, 53]. Inside the resonance tongue the system responds to the forcing with oscillations at frequency $\Omega/2$, corresponding to *phase-locked* states [2, 23]. Outside of the tongue the frequency difference $|\omega - \Omega/2|$ is too large and the response frequency is no longer locked to the forcing frequency.

In the present paper we are interested in including large-scale spatial modulation in this theory. Thus we suppose that a dynamical observable w takes the form

$$w = w_0 + Ae^{i\Omega t/2} + c.c. + \cdots, \tag{2.1}$$

where w_0 represents the equilibrium state, $A(x,t)$ is a complex amplitude, and the ellipses denote higher order terms. The oscillation amplitude $A(x,t)$ obeys the FCGL equation [10, 15]

$$A_t = (\mu + i\nu)A - (1 + i\beta)|A|^2A + (1 + i\alpha)A_{xx} + \gamma\bar{A}, \tag{2.2}$$

where μ represents the distance from onset of the oscillatory instability, ν is the detuning from the unforced frequency, and α, β, and γ represent dispersion, nonlinear frequency correction, and the forcing amplitude, respectively. Here $\bar{A}$ is the complex conjugate of A. Equation (2.2) can be derived by standard asymptotic methods from the relevant governing equations provided the amplitude A remains small, i.e., provided the system is close to onset of spontaneous spatially homogeneous oscillations and the forcing amplitude is suitably small. In the absence of forcing, these oscillations grow when $\mu > 0$ but decay when $\mu < 0$.

With the exception of the trivial solution $A = 0$, stationary solutions of (2.2) are all "phase-locked" in the sense that they correspond to observables w in the original system that oscillate at exactly half the driving frequency, $\Omega/2$. We use the term *uniform* state to refer to a phase-locked state that is independent of x. States of this type take the form $A = R\exp(i\phi)$, where

$$R^2 = \left(R^{\pm}\right)^2 \equiv \frac{\beta(\nu - \nu_\beta) \pm \sqrt{\rho_\beta^2\gamma^2 - (\nu - \beta\mu)^2}}{\rho_\beta^2}, \tag{2.3}$$

and $\phi = \phi^{\pm}$ solves

$$\cos 2\phi^{\pm} = \frac{\left(R^{\pm}\right)^2 - \mu}{\gamma}, \quad \sin 2\phi^{\pm} = \frac{\nu - \beta\left(R^{\pm}\right)^2}{\gamma}. \tag{2.4}$$

The uniform phase-locked states exist provided $R^2 > 0$. Here $\rho_\beta \equiv \sqrt{1+\beta^2}$ and

$$\nu_\beta \equiv -\frac{\mu}{\beta}. \tag{2.5}$$

In the following we denote the two branches of solutions in $0 \le \phi^{\pm} < \pi$ by $A_u^{\pm}$, so $\operatorname{Im} A_u^{\pm} \ge 0$; the solutions in $\pi \le \phi^{\pm} < 2\pi$ which lie exactly out of phase with $A_u^{\pm}$ correspond to $-A_u^{\pm}$.

When $\nu > \nu_\beta$, the A_u^- states appear via a subcritical bifurcation from $A = 0$ when the forcing amplitude γ reaches $\gamma = \gamma_0$,

$$\gamma_0 \equiv \sqrt{\mu^2 + \nu^2}, \tag{2.6}$$

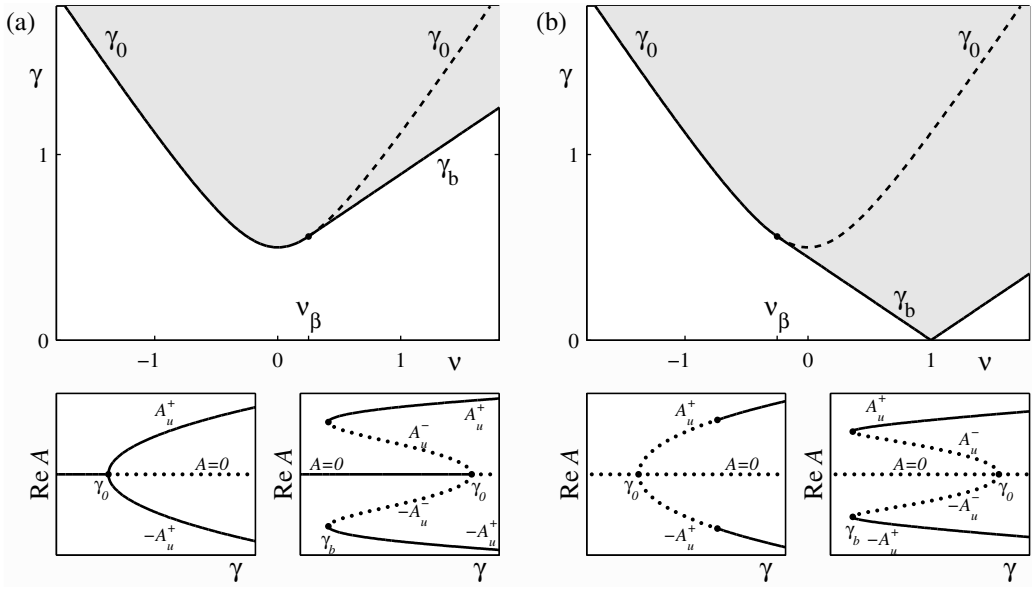

Figure 2. *The boundary of the* 2:1 *resonance tongue in the* (ν,γ) *plane when* $\alpha = 1$, $\beta = 2$, *and* (a) $\mu = -0.5$, (b) $\mu = 0.5$. *The line* $\gamma = \gamma_0$ *is plotted as solid (dashed) when the bifurcation to uniform phase-locked states is supercritical (subcritical). The shaded region indicates the existence of spatially uniform solutions* A_u^+. *The lower panels show typical bifurcation diagrams when the bifurcation at* γ_0 *is supercritical* ($\nu < \nu_\beta$) *and subcritical* ($\nu > \nu_\beta$). *In the bifurcation diagrams solid (dotted) lines represent solutions which are stable (unstable) with respect to uniform perturbations. In* (b) *the* A_u^+ *state may be stabilized either at* γ_b *or at a Hopf bifurcation.*

and are unstable. These states annihilate with the A_u^+ in a saddle-node bifurcation at $\gamma = \gamma_b$,

$$\gamma_b \equiv \frac{|\nu - \beta\mu|}{\rho_\beta}. \tag{2.7}$$

In contrast, when $\nu < \nu_\beta$, the A_u^+ states bifurcate supercritically from $A = 0$ at γ_0 and the saddle-node bifurcation is absent. The line $\gamma = \gamma_b$ is tangent to the curve $\gamma = \gamma_0$ at $\nu = \nu_\beta$, as shown in Figure 2.

The large number of parameters in (2.2) is responsible for a wide range of behavior. In section 3 we consider the case of damped oscillations, $\mu < 0$, followed by the self-excited case, $\mu > 0$, in section 4. Without loss of generality we restrict both discussions to the case $\beta > 0$ but allow α to be positive or negative. The resulting half-space splits into five regions (Figure 3), independently of μ, each characterized by distinct behavior in the (ν,γ) plane; we are free to choose $\gamma > 0$ but must allow ν to be positive or negative. Bifurcation diagrams showing branches of stationary solutions $A(x)$ as a function of the parameter γ correspond to vertical (constant ν) slices through this plane. In general, the types of solutions present in such diagrams are determined by the value of ν relative to a few critical values, such as ν_β.

3. Damped oscillatory regime. In this section we examine solutions to (2.2) in the damped case, $\mu < 0$. The resonance region containing the states $A_u^\pm$ is shown in Figure 2(a) and is characteristic of the uniform solutions found in all five regions of the (α,β) parameter

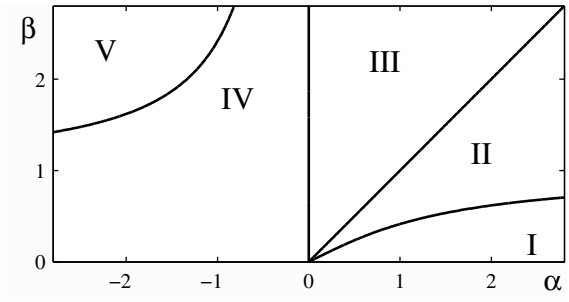

Figure 3. *The (α, β) parameter plane splits into five regions based on the behavior of the solutions. The line $\alpha = 0$ divides* III *from* IV*, while the line $\alpha = \beta$ divides* II *from* III*. The curves dividing* I *from* II *and* IV *from* V *are given by $z(\alpha, \beta) = 0$, cf. (3.18); $z < 0$ in* I *and* V *but $z > 0$ in* II–IV*. These results are independent of the sign and value of μ.*

plane introduced in Figure 3, provided that $\mu < 0$. In the following we refer to these as Regions I^-–V^-, where the superscript refers to the sign of μ. The $A = 0$ state is stable to uniform perturbations in $\gamma < \gamma_0$ and unstable in $\gamma > \gamma_0$. The A_u^+ state is present in the shaded region and is stable with respect to spatially uniform perturbations; the A_u^- state is present in $\gamma_b < \gamma < \gamma_0$ and is unstable. Thus the parametric forcing is responsible for the creation of a region of *bistability* between $A = 0$ and A_u^+, defined by $\nu > \nu_\beta$, $\gamma_b < \gamma < \gamma_0$ (Figure 2(a)). This region plays an important role in what follows.

There are two types of nonuniform solutions of (2.2)—spatially periodic and spatially localized. To study these, we rewrite (2.2) in terms of the real and imaginary parts of the amplitude A, $U \equiv \mathrm{Re}\, A$ and $V \equiv \mathrm{Im}\, A$:

$$\begin{bmatrix} U_t \\ V_t \end{bmatrix} = (\mathcal{L} + \mathcal{N}) \begin{bmatrix} U \\ V \end{bmatrix}. \tag{3.1}$$

Here $\mathcal{L}$ is the linear operator

$$\mathcal{L} = \begin{bmatrix} \mu + \gamma & -\nu \\ \nu & \mu - \gamma \end{bmatrix} + \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \partial_{xx}, \tag{3.2}$$

while $\mathcal{N}$ includes the nonlinear terms:

$$\mathcal{N} = -\left(U^2 + V^2\right) \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix}. \tag{3.3}$$

The steady states of this system satisfy a fourth order ordinary differential equation (ODE) in x that can be studied using a combination of bifurcation theory and numerical branch following techniques. It is important to recognize that (3.1) is *reversible* in the sense that it is invariant under the spatial reflection $x \to -x$. In the following we think of x as a time-like variable and classify the states of interest as either homoclinic or heteroclinic orbits depending on the behavior of $A(x)$ as $x \to \pm\infty$. In addition, we distinguish between "small" amplitude states, which bifurcate from the trivial state $A = 0$, and "large" amplitude states that are related to the finite amplitude uniform phase-locked states A_u^+. Small amplitude orbits

homoclinic to $A = 0$ correspond to standard oscillons, while large amplitude orbits homoclinic to A_u^+ correspond to reciprocal oscillons. Heteroclinic orbits between $\pm A_u^+$ correspond to the observed fronts. In either case a localized solution must leave a homogeneous state as x increases from $x = -\infty$ and must approach a homogeneous state (same or different) as $x \to \infty$. Thus we examine both the stability of the uniform states in time as well as their stability in x, i.e., their temporal *and* their spatial eigenvalues.

3.1. Small amplitude states for $\alpha > 0$. In this subsection we analyze, analytically and numerically, small amplitude states which bifurcate from the $A = 0$ state. We first consider the case $\alpha > 0$ spanning the Regions I^-–III^- of the (α, β) plane shown in Figure 3. The behavior in $\alpha < 0$, spanning Regions IV^- and V^-, is described in a subsequent section.

3.1.1. Temporal stability of $A = 0$. The (complex) growth rate s of an infinitesimal perturbation of the trivial state $A = 0$ with wavenumber k,

$$\begin{bmatrix} U \\ V \end{bmatrix} = \epsilon \begin{bmatrix} u \\ v \end{bmatrix} e^{ikx+st} + c.c., \tag{3.4}$$

where $\epsilon \ll 1$ and u, v are constants, is given by

$$s^2 + 2s(k^2 - \mu) + k^4\rho_\alpha^2 - 2k^2\alpha(\nu - \nu_\alpha) + \gamma_0^2 - \gamma^2 = 0. \tag{3.5}$$

Here $\rho_\alpha \equiv \sqrt{1 + \alpha^2}$ and

$$\nu_\alpha \equiv -\frac{\mu}{\alpha}. \tag{3.6}$$

The $A = 0$ state is stable at any value of the parameters such that $\operatorname{Re} s < 0$ for all k. Analysis of the dispersion relation reveals three bifurcations of interest. The first occurs at γ_0 and is a pitchfork bifurcation to the uniform phase-locked states $A_u^\pm$. This bifurcation is associated with the change in stability of the $k = 0$ mode. The growth rate of this mode near γ_0, for $|k| \ll 1$, is given by

$$s(k, \gamma) \approx -\frac{\alpha}{\mu}(\nu - \nu_\alpha)k^2 - \frac{\gamma_0}{\mu}(\gamma - \gamma_0) \tag{3.7}$$

and indicates that the $A = 0$ state is stable for all $\gamma < \gamma_0$ provided $\nu < \nu_\alpha$; at γ_0 this state loses stability with respect to uniform disturbances and is unstable to a range of wavenumbers in $\gamma > \gamma_0$, as shown in Figure 4(a). In contrast, when $\nu > \nu_\alpha$, the $A = 0$ state is already unstable to spatially *nonuniform* perturbations when the $k = 0$ bifurcation takes place (Figure 4(b)).

The second bifurcation associated with the dispersion relation (3.5) is a finite wavenumber (Turing) bifurcation, present when $\nu > \nu_\alpha$ (Figure 4(b)). Here the $A = 0$ state is stable for small γ and first loses stability at $\gamma = \gamma_a$,

$$\gamma_a \equiv \frac{|\nu - \mu\alpha|}{\rho_\alpha}, \tag{3.8}$$

to perturbations with wavenumber k_a,

$$k_a \equiv \frac{\sqrt{\alpha(\nu - \nu_\alpha)}}{\rho_\alpha}. \tag{3.9}$$

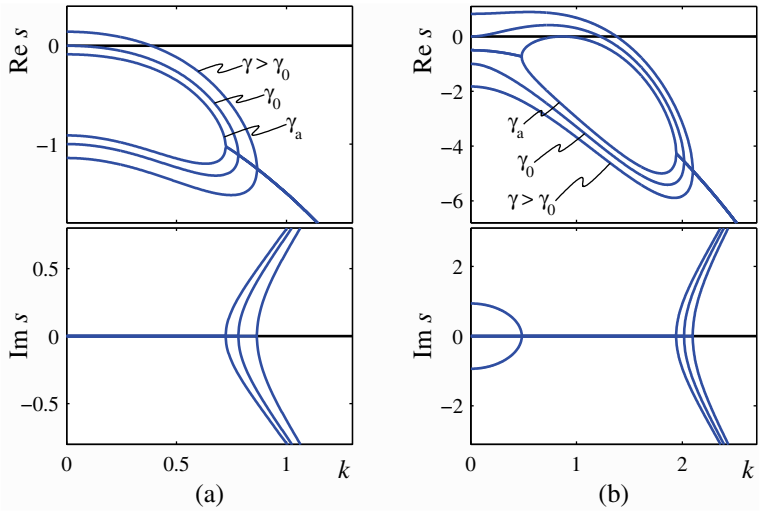

Figure 4. *Dispersion relation for the $A = 0$ state showing the growth rate* $\mathrm{Re}\, s$ *and oscillation frequency* $\mathrm{Im}\, s$ *of perturbations as a function of the wavenumber k for several values of γ. When $\alpha > 0$,* (a) *corresponds to $\nu < \nu_\alpha$ and* (b) *to $\nu > \nu_\alpha$, and vice versa when $\alpha < 0$.*

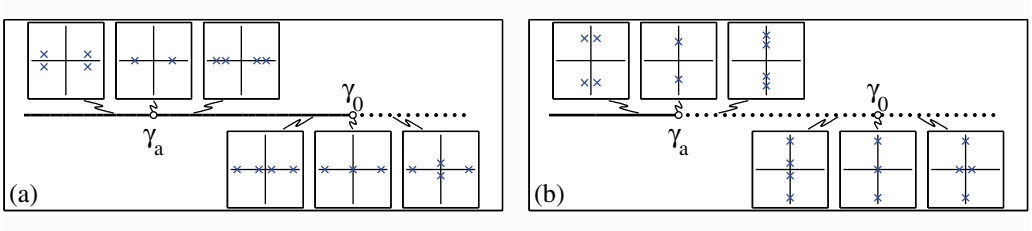

Figure 5. *Temporal stability along the $A = 0$ branch as a function of γ: solid (dotted) lines represent stable (unstable) solutions. The insets show the spatial eigenvalues λ of $A = 0$ in the complex λ plane. When $\alpha > 0$,* (a) *corresponds to $\nu < \nu_\alpha$ and* (b) *to $\nu > \nu_\alpha$, and vice versa when $\alpha < 0$.*

The resulting bifurcation produces a branch of spatially periodic states with wavenumber k_a. When $\gamma > \gamma_a$, the $A = 0$ state is unstable to a range of wavenumbers (which includes $k = 0$ once $\gamma > \gamma_0$).

The above results are summarized in Figure 5: the state $A = 0$ is stable in time (solid line) for $\gamma < \gamma_0$ when $\nu < \nu_\alpha$ and for $\gamma < \gamma_a$ when $\nu > \nu_\alpha$. The dots indicate that $A = 0$ is unstable.

The third bifurcation, mentioned briefly in the introduction, is a Hopf bifurcation corresponding to $\mathrm{Re}\, s = 0$, $\mathrm{Im}\, s \neq 0$ at $k = 0$. This bifurcation occurs at $\mu = 0$ provided $\gamma < \nu$ and produces a branch of spatially uniform oscillations. This mode and its interaction with the Turing mode have been studied in [58, 59] but are not considered in the present paper, which focuses on values of μ away from $\mu = 0$.

The line $\gamma = \gamma_a$ defined in (3.8) is tangent to the curve $\gamma = \gamma_0$ at ν_α. Figures 6 and 7 show this line in relation to γ_0 and γ_b for Regions II^- and III^- in the $\alpha > 0$ quadrant of Figure 3. A similar plot for Region I^- is omitted since the behavior resembles that found in Region II^-. In

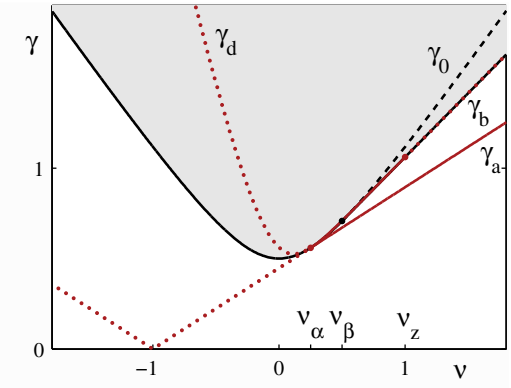

Figure 6. *The (ν,γ) plane for Region* II^-. *The curves γ_a and γ_d correspond to bifurcations in $\nu > \nu_\alpha$ and $\nu_\alpha < \nu < \nu_z$ (solid lines), and to Belyakov–Devaney points elsewhere (dotted lines). Thus γ_d forms the lower boundary of the region (shaded) of stable spatially uniform solutions A_u^+ in the interval $\nu_\alpha < \nu < \nu_z$ (barely visible). The picture for Region* I^- *is qualitatively similar except for the absence of the tangency at ν_z since $\nu_z < \nu_\beta$. Thus in* I^- *γ_d forms the lower boundary of the shaded region everywhere in $\nu > \nu_\alpha$. Other notation is the same as in Figure 2. Parameters: $\mu = -0.5$, $\alpha = 2$, $\beta = 1$.*

these figures γ_a is shown as a solid line in $\nu > \nu_\alpha$ where it corresponds to a Turing bifurcation. For later reference it is also plotted (as a dotted line) in $\nu < \nu_\alpha$. Thus the $A = 0$ state is stable up to γ_a when this is plotted as a solid line and up to γ_0 elsewhere. The value of ν_β and the location of γ_b are determined by nonlinearity and have no bearing on the linear stability of $A = 0$ discussed above, but the value of ν_α relative to ν_β will play an important role in what follows. We therefore distinguish between the case $\nu_\alpha < \nu_\beta$ (i.e., $\alpha > \beta$, spanning Regions I^- and II^-) and the case $\nu_\alpha > \nu_\beta$ (i.e., $\alpha < \beta$, Region III^-). Although γ_a must lie below γ_0, it is clear from these figures that it may lie either above or below γ_b. For future reference we include in these figures a third critical value, ν_z, as well as a curve labeled γ_d; both are related to finite amplitude effects discussed below.

For spatially nonuniform steady states $A(x)$, whether spatially extended or localized, the linearized stability problem constitutes an eigenvalue problem for the growth rate s. This problem has in general an infinite number of solutions, although only the eigenvalues with the largest growth rates are of interest. In the following we omit the details of the required computations (these are similar to those in [7]) but indicate whether a particular solution is stable or unstable. In the case of instability we indicate the number and shape of the eigenfunctions whose eigenvalues s have positive real part. For spatially localized states the two commonest instabilities are amplitude and phase instabilities. The former is characterized by an eigenfunction with the same parity (even or odd) as the steady state $A(x)$, while the latter has the opposite parity. In both instances the corresponding eigenvalues are real.

3.1.2. Spatial eigenvalues of $A = 0$. As mentioned above, a necessary condition for the presence of an exponentially localized state that approaches $A = 0$ as $x \to \pm\infty$ is that this state have at least one spatial eigenvalue with positive real part and one with negative real part. In this section we identify the regions in the (ν,γ) plane where this is the case. This amounts to examining the stability in x of the fixed point $A = 0$. The spatial eigenvalues λ

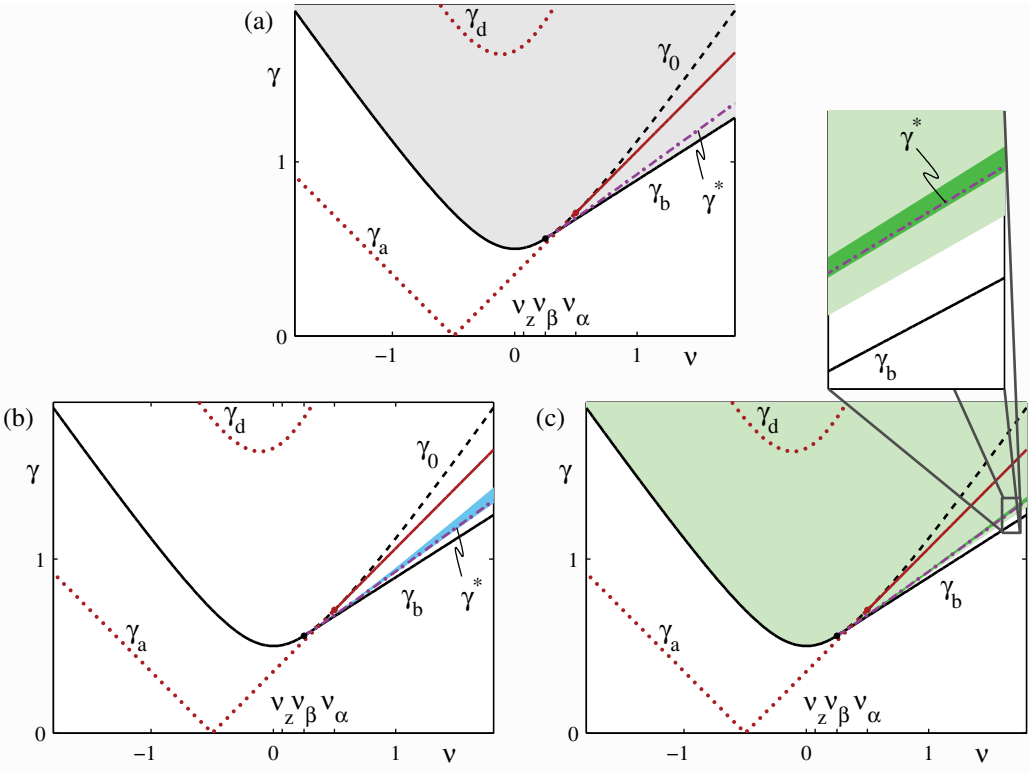

Figure 7. *The* (ν,γ) *plane for Region* III$^-$. *In* (a) *shading indicates the presence of stable uniform states* A_u^+, *while in* (b) *it indicates the existence of stable reciprocal oscillons (SROs). In* (c) *the light shading indicates existence of stable Ising fronts (SIFs), while the darker shading indicates the (very narrow) region of existence of stable structured fronts (SSFs), shown more clearly in the inset. The heteroclinic cycle forms along the dot-dashed line* γ^*. *The remaining notation is the same as in Figure* 6. *Parameters:* $\mu = -0.5$, $\alpha = 1$, $\beta = 2$.

of this fixed point are determined by linearizing (3.1) around the $A = 0$ state:

$$\begin{bmatrix} U \\ V \end{bmatrix} = \epsilon \begin{bmatrix} u \\ v \end{bmatrix} e^{\lambda x}. \tag{3.10}$$

The four eigenvalues satisfy a quadratic equation for λ^2,

$$\rho_\alpha^2 \lambda^4 + 2\alpha(\nu - \nu_\alpha)\lambda^2 + (\gamma_0^2 - \gamma^2) = 0. \tag{3.11}$$

In particular, if λ is an eigenvalue, then $\bar{\lambda}$ and $-\lambda$ are as well. Consequently there are four possibilities: (i) the spatial eigenvalues are real, (ii) there is a quartet of complex eigenvalues, (iii) the spatial eigenvalues are imaginary, and (iv) two eigenvalues are real and two are imaginary. The transition from (i) to (ii) is via a Belyakov–Devaney point [9], while the transition from (ii) to (iii) corresponds to a (spatial) Hopf bifurcation with 1:1 resonance [26].

Localized states correspond to intersections of the stable and unstable manifolds of $A = 0$. In cases (i) and (ii) this state has a two-dimensional stable and a two-dimensional unstable manifold. These manifolds are transverse to the two-dimensional fixed point subspace of the

symmetry $x \to -x$ and $A \to A$ and hence intersect in a structurally stable way [56]; i.e., we expect localized states in cases (i) and (ii) only. In contrast, in case (iv) the stable and unstable manifolds are only one-dimensional and homoclinic orbits are exceptional [30, 36].

The motion of the eigenvalues in the complex λ plane as γ varies depends critically on the value of ν relative to $\nu_\alpha > 0$. We begin by observing that for small γ the eigenvalues form a complex quartet as in case (ii). When $\nu < \nu_\alpha$ (Figure 5(a)) these eigenvalues collide on the real axis in a Belyakov–Devaney point when $\gamma = \gamma_a$. Because this collision occurs away from the imaginary λ axis, it does not correspond to a local bifurcation of the $A = 0$ state. Above γ_a the eigenvalues split but remain on the real axis, as in case (i). As γ continues to increase, two of the eigenvalues move toward the origin and collide at $\lambda = 0$ when $\gamma = \gamma_0$. This collision does correspond to a bifurcation, and in fact it is at γ_0 that the uniform phase-locked states $A_u^\pm$ bifurcate from A_0. For $\gamma > \gamma_0$ the zero eigenvalues split along the imaginary axis, resulting in eigenvalue structure (iv). In contrast, when $\nu > \nu_\alpha$ (Figure 5(b)), the complex eigenvalues that collide at γ_a do so on the imaginary axis at $\lambda = \pm i k_a$. This is the Hopf bifurcation with 1:1 resonance (in space) or equivalently the Turing bifurcation (in time) mentioned above. In the language of spatial dynamics the spatially extended states produced at this bifurcation are referred to as *spatially periodic* states with wavenumber k_a. Above γ_a the eigenvalues split but remain imaginary, as in case (iii). Two of these collide at the origin when $\gamma = \gamma_0$ and split along the real axis, resulting, as before, in eigenvalue structure of type (iv). Thus when $\nu < \nu_\alpha$, spatially localized states may exist everywhere in $\gamma < \gamma_0$, while for $\nu > \nu_\alpha$ they are expected in $\gamma < \gamma_a$ only. These regimes correspond precisely to those where the $A = 0$ state is stable in time, as indicated in Figure 5. This observation is significant since localized states in general inherit any instabilities of the background asymptotic state (but see [3, 48]).

3.1.3. Localized states bifurcating from $\gamma = \gamma_0$. The uniform phase-locked states A_u^- bifurcate from $A = 0$ at γ_0, and this bifurcation is subcritical if $\nu > \nu_\beta$. In Appendix A we show that if in addition $\nu < \nu_\alpha$ (Figure 5(a)), then at γ_0 there is in addition a subcritical bifurcation to *localized* states. Near γ_0 these take the form

$$A_{L,0}^\pm(x) = \pm(\eta_0 + i)\sqrt{\frac{\gamma_0 - \gamma}{b_0/2}}\,\operatorname{sech}\left(\sqrt{\frac{\gamma_0 - \gamma}{-a_0}}\,x\right), \tag{3.12}$$

where $\eta_0 \equiv (\gamma_0 - \mu)/\nu$, $a_0 \equiv \alpha(\nu - \nu_\alpha)/\gamma_0 < 0$, and $b_0 \equiv 2\beta(\nu - \nu_\beta)(\gamma_0 - \mu)/\nu^2 > 0$. These localized states are biasymptotic to $A = 0$ as $x \to \pm\infty$ and are present in Region III$^-$ of the (α, β) plane only, provided $\nu_\beta < \nu < \nu_\alpha$, $\gamma \le \gamma_0$ (Figure 7).

These analytical solutions can be followed away from γ_0 using numerical continuation [13]. Figure 8 shows the resulting bifurcation diagram typical of $\nu_\beta < \nu < \nu_\alpha$ in Region III$^-$. In this and all subsequent bifurcation diagrams we plot solutions in terms of their norms

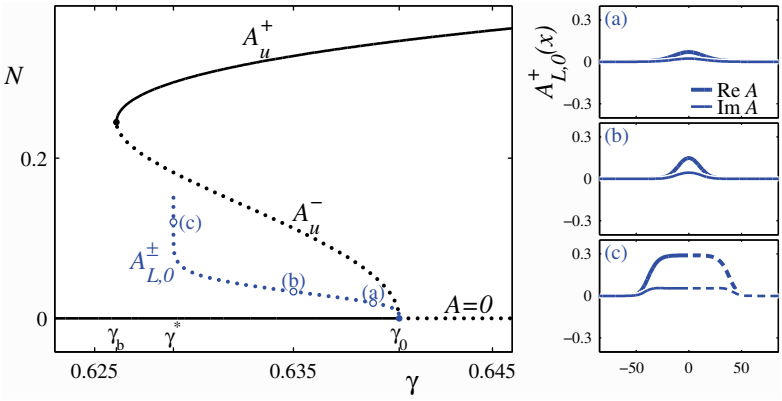

Figure 8. *Bifurcation diagram for $\nu_\beta < \nu < \nu_\alpha$ in Region* III$^-$*, showing the branches of localized states $A_{L,0}^\pm$ found by continuing the solution (3.12) away from γ_0, as well as the uniform states $A_u^\pm$. Solid (dotted) lines correspond to stable (unstable) solutions. Right panels show profiles of $A_{L,0}^+$ at locations* (a), (b), *and* (c), *respectively; panel* (c) *shows a broad homoclinic orbit near $\gamma^* \approx 0.6289$ decomposed into a pair of nearly heteroclinic connections, one connecting $A = 0$ to A_u^+ (solid line) and the other connecting A_u^+ to $A = 0$ (dashed line). Parameters: $\mu = -0.5$, $\alpha = 1$, $\beta = 2$, $\nu = 0.4$ with* (a) $\gamma = 0.639$, (b) $\gamma = 0.635$, (c) $\gamma = 0.6289$.

$$N = \sqrt{\frac{1}{L}\int_{-L/2}^{L/2} \{|A|^2 + |\partial_x A|^2\}\, \mathrm{d}x}, \tag{3.13}$$

where L is the large but finite spatial period used in the numerical computations. Typically $L = 200$. Figure 8 shows not only the uniform phase-locked states $A_u^\pm$ but also the branches of spatially localized solutions $A_{L,0}^\pm$ found by continuing the analytical result (3.12) away from γ_0. Solutions along these branches are always even in x, $A_{L,0}^\pm(-x) = A_{L,0}^\pm(x)$. In addition the two branches of solutions are related by the symmetry $A_{L,0}^+(x) = -A_{L,0}^-(x)$ and therefore always have identical norms in the bifurcation diagram. The right panels in Figure 8 show sample solutions along the $A_{L,0}^+$ branch. Near γ_0 the profile is broad (Figure 8(a)). As γ decreases away from γ_0, the solution first contracts in x forming a well-localized state (Figure 8(b)). However, as γ approaches the value γ^*, these localized states broaden again, with $A_{L,0}^+$ spending more and more "time" near the uniform value A_u^+. The resulting broad homoclinic orbit can be thought of as a pair of nearly heteroclinic orbits, the first connecting $A = 0$ to A_u^+ and the second connecting A_u^+ back to $A = 0$ (Figure 8(c)). We refer to this pair of heteroclinic connections as a heteroclinic *cycle*. Numerical branch following reveals that the branches of localized states $A_{L,0}^\pm$ approach γ^* monotonically from above; as a result the $A_{L,0}^\pm$ solutions remain *unstable* to an amplitude (even) mode throughout their range of existence. In $\gamma < \gamma^*$ the broad localized states of the type shown in Figure 8(c) evolve in time by decreasing their width and eventually collapsing to the (stable) uniform profile $A = 0$. In contrast, in $\gamma > \gamma^*$ states of this type grow in width, filling more and more of the domain with the (stable) uniform phase-locked state A_u^+.

The point γ^* at which a heteroclinic cycle is present is analogous to the so-called Maxwell point in the theory of variational systems [7, 45], where it corresponds to the equal energy case. It turns out that the multiplicity of steady states near γ^* is determined by the spatial

eigenvalues of the two states connected by the cycle and hence is independent of the type of system.

3.1.4. Localized states bifurcating from $\gamma = \gamma_a$. Recall that for $\nu > \nu_\alpha$ the four spatial eigenvalues of the trivial state form a complex quartet when $\gamma < \gamma_a$, collide at $\lambda = \pm ik_a$ when $\gamma = \gamma_a$, and then split but remain imaginary when $\gamma > \gamma_a$. For this case, weakly nonlinear analysis in the vicinity of γ_a (see Appendix B) reveals that there is a branch of small amplitude spatially periodic solutions given by

$$A_{P,a}(x) = (\eta_a + i)\sqrt{\frac{\gamma_a - \gamma}{b_a}}\cos(k_a x + \varphi), \tag{3.14}$$

where the phase φ is arbitrary, $b_a \equiv 6\eta_a(\beta - \alpha)$, and, since $\alpha > 0$,

$$\eta_a = \alpha + \rho_\alpha > 0 \tag{3.15}$$

(see (B.7) in Appendix B). Consequently this bifurcation is supercritical whenever $\beta < \alpha$; in this case no additional *localized* states bifurcate from γ_a. This is the case in Regions I^- and II^- of Figure 3. In contrast, when $\beta > \alpha$ (Region III^-), the bifurcation to spatially periodic states is subcritical, and localized spatial *oscillations* of the form

$$A_{L,a}(x) = (\eta_a + i)\sqrt{\frac{\gamma_a - \gamma}{b_a/2}}\,\mathrm{sech}\left(\sqrt{\frac{\gamma_a - \gamma}{a_a}}x\right)\cos(k_a x + \varphi) \tag{3.16}$$

bifurcate from $A = 0$ simultaneously with the spatially periodic states and in the same direction. Here $a_a \equiv 2\rho_\alpha^2 k_a^2/\gamma_a > 0$. Bifurcations of this type occur in Figure 7 in the region $\nu > \nu_\alpha$ with the localized oscillations present below the line $\gamma = \gamma_a$. Within the asymptotic analysis, the phase φ in (3.16) is again arbitrary, but terms beyond all orders select solutions with the phases $\varphi = 0, \pi/2, \pi, 3\pi/2$ [8, 31]. In the following we therefore distinguish between families of even ($A_{L,a}^{\mathrm{even}}$; $\varphi = 0, \pi$) and odd ($A_{L,a}^{\mathrm{odd}}$; $\varphi = \pi/2, 3\pi/2$) parity homoclinic solutions.

The analytical solutions in (3.14) and (3.16) can be followed away from γ_a using numerical continuation, as shown in Figure 9. The left panel of the figure shows the branch of spatially periodic states $A_{P,a}$ as well as the branches of both even and odd localized states $A_{L,a}$. The branch of uniform phase-locked states $A_u^\pm$ is shown for reference. The right panels show sample solutions along the two branches of localized states. The small amplitude localized states are broad near γ_a (Figure 9(a),(c)); as γ decreases away from γ_a, the envelope of these states contracts in x, forming well-localized packets (Figure 9(b),(d)). As γ decreases toward γ^*, the profiles of both even and odd states broaden. Near γ^* the even localized states $A_{L,a}^{\mathrm{even}}$ can be thought of as a pair of nearly heteroclinic orbits, the first of which connects $A = 0$ to A_u^+ with the second connecting A_u^+ back to $A = 0$ (Figure 9(c)). In contrast, $A_{L,a}^{\mathrm{odd}}$ near γ^* consists of three parts: a pair of nearly heteroclinic orbits connecting $A = 0$ to $\pm A_u^+$ on either side of a heteroclinic connection between A_u^+ and $-A_u^+$ (Figure 9(f)). The numerical results again suggest that at γ^* there exist heteroclinic cycles connecting $A = 0$ and $\pm A_u^+$. As in Figure 8, the branches of localized states approach γ^* monotonically from above, and the solutions are always unstable. The $A_{L,a}^{\mathrm{even}}$ branch is unstable to a single amplitude (even) mode, while the $A_{L,a}^{\mathrm{odd}}$ branch is unstable to two modes, an amplitude (odd) mode and a phase (even)

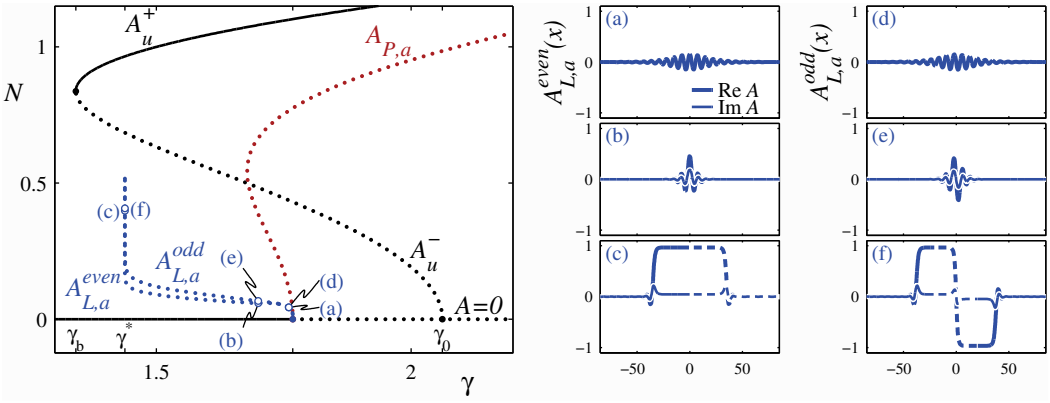

Figure 9. *Bifurcation diagram for $\nu > \nu_\alpha$ in Region* III$^-$*, showing branches of odd and even parity localized states $A_{L,a}$ found by continuation of the solutions (3.16) away from γ_a, as well as the spatially periodic states $A_{P,a}$ and the uniform states $A_u^\pm$. Solid (dotted) lines correspond to stable (unstable) solutions.* (a)–(f) *Profiles of $A_{L,a}$ at the locations indicated in the left panel. Panel* (c) *shows that the broad homoclinic orbits present near $\gamma^* \approx 1.437$ on the $A_{L,a}^{\rm even}$ branch can be thought of as pairs of nearly heteroclinic connections between $A = 0$ and A_u^+ (solid and dashed lines). Panel* (f) *shows that the corresponding odd parity states take the form of a pair of nearly heteroclinic connections between $A = 0$ and $\pm A_u^+$ (solid lines), with a nearly heteroclinic orbit from A_u^+ to $-A_u^+$ (dashed) in between. Parameters: $\mu = -0.5$, $\alpha = 1$, $\beta = 2$, $\nu = 2$, with* (a),(d) $\gamma = 1.76$, (b),(e) $\gamma = 1.70$, (c),(f) $\gamma = 1.437$.

mode. The $A_{P,a}$ states are likewise always unstable; although the nature of this instability varies throughout Region III$^-$, the unstable modes typically correspond to long wavelength disturbances.

The heteroclinic cycles identified in the bifurcation diagrams in Figures 8 and 9 occur along the line γ^* in Figure 7, corresponding to Region III$^-$; the line emerges from the tangency at ν_β that creates the saddle-node bifurcation and passes continuously from $\nu_\beta < \nu < \nu_\alpha$ (Figure 8) to $\nu > \nu_\alpha$ (Figure 9).

3.1.5. Small amplitude states for $\alpha < 0$. When $\alpha < 0$ as in Regions IV$^-$ and V$^-$, the critical value ν_α is negative. This change in sign requires a reinterpretation of the equations derived above. In this case the dispersion relation (3.5) predicts that the Turing bifurcation of the $A = 0$ state at γ_a is present when $\nu < \nu_\alpha$ instead of $\nu > \nu_\alpha$. Figures 10 and 11 show the (ν, γ) plane for Regions IV$^-$ and V$^-$, respectively, with γ_a plotted as a solid line in $\nu < \nu_\alpha$, where it corresponds to a bifurcation point. Because the analysis at γ_a performed in Appendix B now applies in $\nu < \nu_\alpha$, the expression for η_a in (B.7) reduces to

$$\eta_a = \alpha - \rho_\alpha < 0. \tag{3.17}$$

Moreover, when $\nu > \nu_\alpha$, the spatial eigenvalues at γ_0 are real, and the collision of eigenvalues at γ_a occurs on the real axis; localized states are therefore expected in $\gamma < \gamma_0$ (as in Figure 5(a)). In contrast, when $\nu < \nu_\alpha$, the eigenvalues at γ_0 are imaginary and the collision at γ_a occurs on the imaginary axis. In this case localized states are expected in $\gamma < \gamma_a$ (as in Figure 5(b)).

The change in sign of η_a also affects the bifurcations from γ_a present in $\alpha < 0$. As $\beta > \alpha$ everywhere in this quadrant the bifurcation to the spatially periodic states $A_{P,a}$ is supercritical

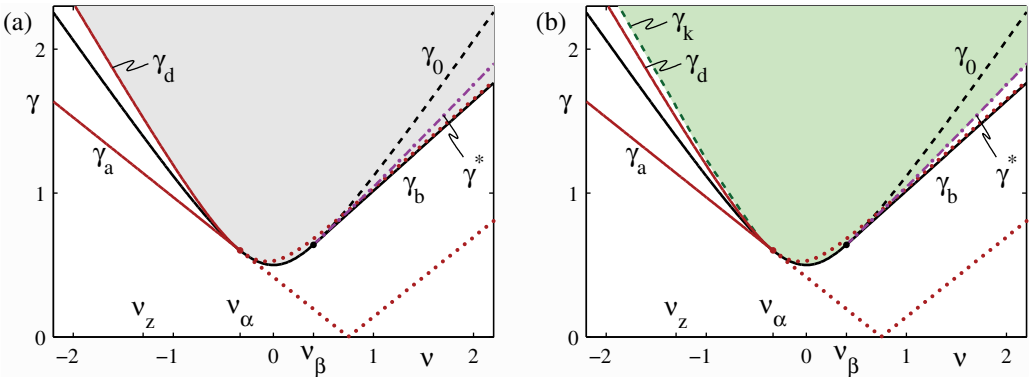

Figure 10. *The (ν,γ) plane in Region* IV^-. *In* (a) *shading indicates the presence of stable uniform states A_u^+, while in* (b) *it indicates the SIF region. The line γ_k in* (b) *corresponds to saddle-node bifurcations of large amplitude fronts referred to as kinks. Parameters: $\mu=-0.5$, $\alpha=-1.5$, $\beta=1.25$.*

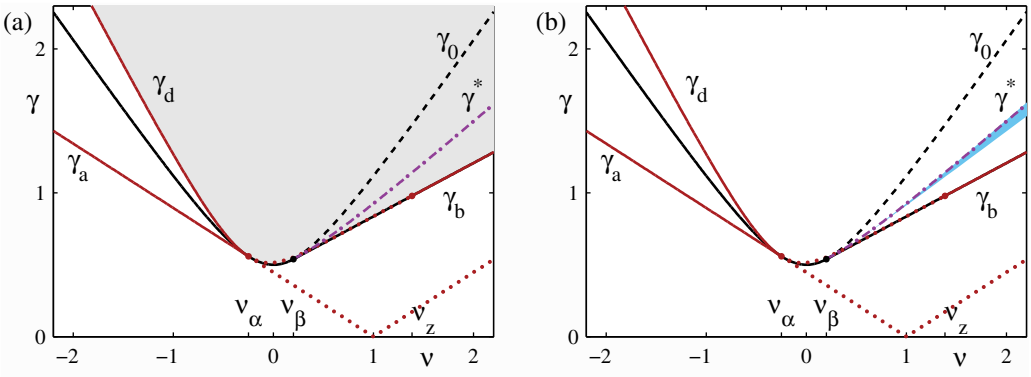

Figure 11. *The (ν,γ) plane in Region* V^-. *In* (a) *shading indicates the presence of stable uniform states A_u^+, while in* (b) *it indicates the SSO region. Parameters: $\mu=-0.5$, $\alpha=-2$, $\beta=2.5$.*

throughout Regions IV^- and V^-. Moreover, no bifurcations to localized spatial oscillations of the form (3.16) can take place.

Expression (3.12) remains valid in $\alpha<0$: in both Regions IV^- and V^-, $\nu_\beta>\nu_\alpha$ and hence a branch of small amplitude single-peaked localized states bifurcates subcritically at γ_0 whenever $\nu>\nu_\beta$; such states are therefore present in $\gamma<\gamma_0$ (see Figures 10 and 11). Thus the only small amplitude localized states in Regions IV^- and V^- are those associated with γ_0.

We can follow the branches of analytically known small amplitude states away from γ_0 using numerical continuation. In Regions IV^- and V^- this branch behaves like the corresponding branch in Figure 8 and approaches γ^* monotonically whenever ν is near ν_β. However, new behavior is found when $\nu\gg\nu_\beta$ (Figure 12): the branch of localized states $A_{L,0}^{\pm}$ now approaches γ^* in an oscillatory fashion, undergoing an infinite sequence of saddle-node bifurcations as it winds toward it; cf. [28]. At each saddle-node bifurcation the stability of the localized states changes: the localized states near γ_0 are unstable, but there is a region surrounding γ^*, between the first and second saddle-node bifurcations, within which there is a finite multiplicity

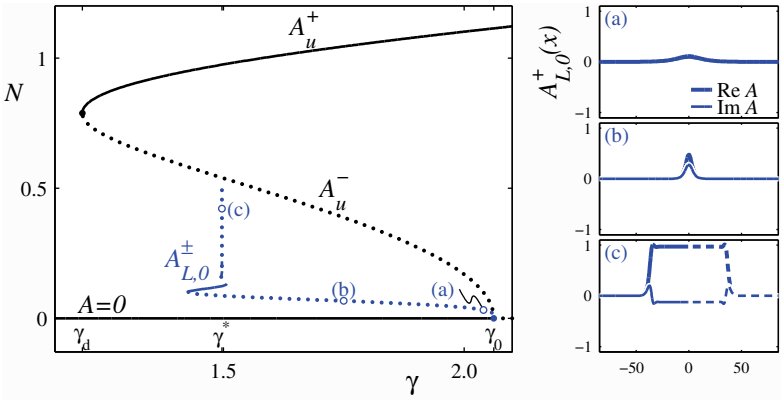

Figure 12. *Bifurcation diagram for $\nu \gg \nu_\beta$ in Region V^-, showing the branches of localized states $A_{L,0}^{\pm}$ found by continuing the solution (3.12) away from γ_0, as well as the uniform states $A_u^{\pm}$. Solid (dotted) lines correspond to stable (unstable) solutions. A closeup of the behavior near $\gamma^* \approx 1.496$ is shown in Figure 13. (a)–(c) Profiles of $A_{L,0}^+$ at the locations indicated in the left panel. Parameters: $\mu = -0.5$, $\alpha = -2$, $\beta = 2.5$, $\nu = 2$; (a) $\gamma = 2.04$, (b) $\gamma = 1.75$, (c) $\gamma = 1.496$.*

of *stable* localized states (Figure 13). We label this region SSO since it contains states that correspond in the physical system (2.1) to stable standard oscillons, i.e., stable localized states that are biasymptotic to $A = 0$ as $x \to \pm\infty$.

The location of the SSO states in the (ν, γ) plane in Region V^- is shown in Figure 11(b) and takes the form of a wedge straddling γ^*, increasing in width as ν increases. The emergence of γ^* from the tangency at ν_β is difficult to make out in Figure 11(b); a closeup for a different set of parameters elsewhere in Region V^- is shown in Figure 14. Near ν_β, in the domain labeled (a) in Figure 14, the branch of localized states $A_{L,0}^{\pm}$ approaches γ^* monotonically from γ_0. The SSO region appears only when ν exceeds ν_β sufficiently, in the domain labeled (b) in Figure 14. Numerically we find that the SSO region first appears near the crossing of γ^* and the curve γ_d (to be defined in the next section). Moreover, there is good theoretical reason to believe that the SSO region in fact emerges from this codimension-two point, although it is initially exponentially thin and hence numerically invisible. There is a similar SSO

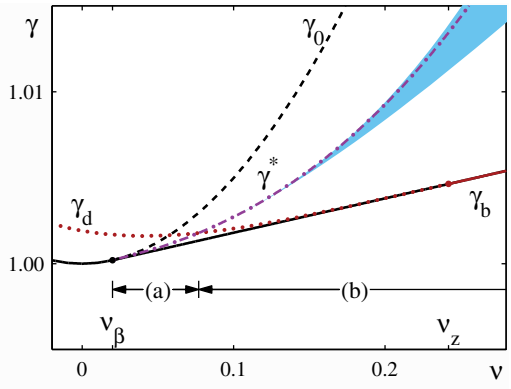

Figure 14. *Closeup of the SSO region in the (ν,γ) plane in Region* V^-. *In region* (a) $\gamma^* < \gamma_d$ *and the approach of small amplitude localized states to* γ^* *is monotonic; in* (b) $\gamma^* > \gamma_d$ *and the approach is via a series of saddle-node bifurcations, the first two of which define the boundaries of the SSO region (shaded). Parameters:* $\mu = -1$, $\alpha = -5$, $\beta = 50$.

region present in Region IV^-, but it is orders of magnitude thinner than the one shown for Region V^-.

3.2. Large amplitude states in $z > 0$. In the previous subsection we found it convenient to consider separately the small amplitude behavior in $\alpha > 0$ and $\alpha < 0$. In this section we turn to a study of *large amplitude* states, discussing separately the cases $z > 0$ and $z < 0$, where

$$z(\alpha,\beta) \equiv -\alpha(1-\beta^2) + 2\beta \tag{3.18}$$

(see below). The former spans Regions II^-–IV^- in the (α,β) plane of Figure 3, while the latter inequality characterizes Regions I^- and V^-.

3.2.1. Stability of $A = A_u^{\pm}$. The stability of the uniform phase-locked states in time is determined by linearizing (3.1) about these states and looking for solutions of the form e^{ikx+st}. The resulting dispersion relation is

$$\begin{aligned} &s^2 - 2s\left(\mu - k^2 - 2|A_u^{\pm}|^2\right) + (1+\alpha^2)k^4 + 2\left[2(1+\alpha\beta)|A_u^{\pm}|^2 - (\mu+\alpha\nu)\right]k^2 \\ &+ 4\left[(\mu+\beta\nu)|A_u^{\pm}|^2 + \gamma^2 - \gamma_0^2\right] = 0. \end{aligned} \tag{3.19}$$

Consider first the stability near γ_0, where the uniform phase-locked states bifurcate from $A = 0$. The amplitude of these states near this point is given by

$$|A_u^{\pm}(\gamma)|^2 = -\frac{\gamma_0(\gamma-\gamma_0)}{\beta(\nu-\nu_\beta)} + \dots. \tag{3.20}$$

This expression is valid both in the subcritical case ($\gamma < \gamma_0$, $\nu > \nu_\beta$), in which A_u^- bifurcates from γ_0, and in the supercritical case ($\gamma > \gamma_0$, $\nu < \nu_\beta$), in which A_u^+ bifurcates from γ_0. For small wavenumbers the growth rate near this bifurcation is given by

$$s(k,\gamma) \approx -\frac{\alpha}{\mu}(\nu-\nu_\alpha)k^2 + \frac{2\gamma_0}{\mu}(\gamma-\gamma_0). \tag{3.21}$$

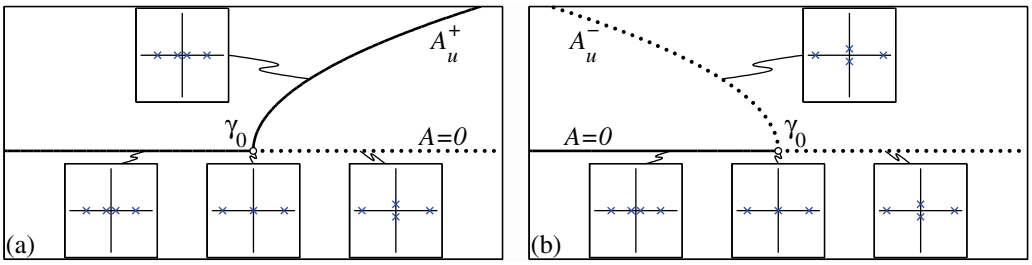

Figure 15. *Temporal stability of $A = 0$ and the uniform phase-locked states $A_u^\pm$ near γ_0 when $\alpha > 0$, $\nu < \nu_\alpha$, and the bifurcation at γ_0 is* (a) *supercritical or* (b) *subcritical: Solid (dotted) lines represent stable (unstable) solutions. The insets show the spatial eigenvalues λ of these states in the complex λ plane.*

Thus, when the bifurcation is subcritical, the A_u^- state which emerges from γ_0 is unstable to the $k = 0$ mode, as shown in Figure 15(b). When the bifurcation is supercritical, the A_u^+ state that emerges from γ_0 inherits the stability of the $A = 0$ state from $\gamma < \gamma_0$: when $\alpha > 0$, it is stable when $\nu < \nu_\alpha$ and unstable when $\nu > \nu_\alpha$. An example of the former is shown in Figure 15(a).

We next analyze the dispersion relation near the saddle-node bifurcation of uniform phase-locked states at $\gamma = \gamma_b$, present in $\nu > \nu_\beta$. At this point the amplitude $|A_u(\gamma_b)|$ of these states is given by

$$|A_u(\gamma_b)|^2 = \frac{\beta(\nu - \nu_\beta)}{\rho_\beta^2}, \tag{3.22}$$

while nearby it is

$$|A_u^\pm|^2 = |A_u(\gamma_b)|^2 \pm \frac{\sqrt{2\gamma_b(\gamma - \gamma_b)}}{\rho_\beta} + \dots. \tag{3.23}$$

The dispersion relation near the saddle-node, valid for small k, reduces to

$$s(k,\gamma) \approx -\frac{z(\nu - \nu_z)k^2 \pm 2\rho_\beta^3 |A_u(\gamma_b)|^2 \sqrt{2\gamma_b(\gamma - \gamma_b)}}{\rho_\beta^2(2|A_u(\gamma_b)|^2 - \mu)}, \tag{3.24}$$

where

$$\nu_z \equiv -\frac{(1-\beta^2) + 2\alpha\beta}{z}\mu \tag{3.25}$$

and z is as defined in (3.18). The "+" sign in this expression refers to the upper branch A_u^+, and the "−" sign to the lower branch A_u^-. Once again the A_u^- branch is always unstable with respect to the $k = 0$ mode. Since $\mu < 0$ and $z > 0$, the A_u^+ branch is stable near the saddle-node when $\nu > \nu_z$ but is unstable when $\nu < \nu_z$. The resulting stability assignments in the neighborhood of the saddle-node of uniform phase-locked states are shown in Figure 16.

It follows that the behavior of the system at a given value of ν depends on the location of ν_z relative to ν_β. In Region II$^-$ (Figure 6), ν_z is greater than ν_β; consequently, for $\nu_\beta < \nu < \nu_z$

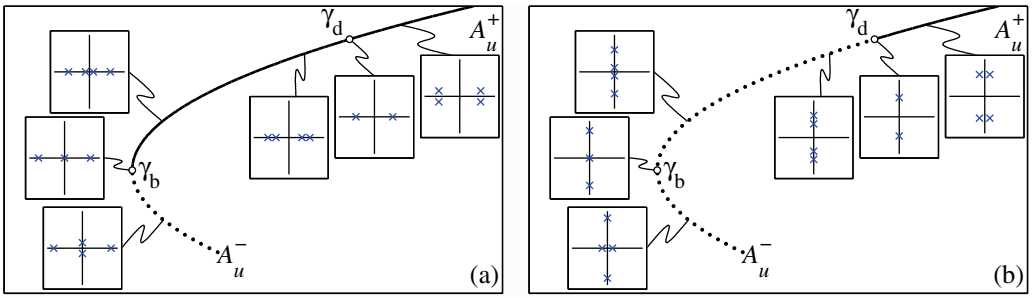

Figure 16. *Temporal stability of the uniform phase-locked states: Solid (dotted) lines represent stable (unstable) solutions. The insets show the spatial eigenvalues of the uniform states in a neighborhood of γ_b and γ_d. When $z > 0$,* (a) *corresponds to $\nu > \nu_z$ and* (b) *to $\nu < \nu_z$, and vice versa for $z < 0$.*

the behavior near the saddle-node is described by Figure 16(b), while for $\nu > \nu_z$ it is described by Figure 16(a). In contrast, in Regions III$^-$ (Figure 7) and IV$^-$ (Figure 10), ν_z is less than ν_β, and the behavior shown in Figure 16(a) applies whenever a saddle-node is present ($\nu > \nu_\beta$).

Since the A_u^+ state is necessarily stable at large γ, the presence of instability near γ_b implies the presence of a further bifurcation which stabilizes the A_u^+ state as γ increases. This bifurcation is a Turing bifurcation and occurs at $\gamma = \gamma_d$ (Figure 16(b)), where

$$\gamma_d^2 = \gamma_b^2 + \frac{\left\{ z(\mu^2 + \nu\nu_z) + \mathrm{sgn}[\alpha - \beta]\mu\rho_\alpha\rho_\beta^2\gamma_0 \right\}^2}{4\mu^2\rho_\beta^2(\alpha - \beta)^2}; \tag{3.26}$$

the associated wavenumber is given by

$$k_d = \frac{\sqrt{\mu + \alpha\nu - 2|A_u^+(\gamma_d)|^2(1 + \alpha\beta)}}{\rho_\alpha}. \tag{3.27}$$

These expressions apply when the A_u^+ state emerges from a supercritical bifurcation at γ_0 as well: an initially unstable state ($\nu > \nu_\alpha$) stabilizes as γ increases at γ_d.

In Region II$^-$ (Figure 6), the Turing bifurcation is present in $\nu_\alpha < \nu < \nu_z$. The curve $\gamma = \gamma_d$ is tangent at ν_α to the line $\gamma = \gamma_a$ (and hence also to the curve $\gamma = \gamma_0$), corresponding to the simultaneous creation of both Turing instabilities (of $A = 0$ and $A = A_u^\pm$) at γ_0. At ν_z the curve $\gamma = \gamma_d$ is tangent to the line $\gamma = \gamma_b$, corresponding to the annihilation of the Turing bifurcation as it merges with the saddle-node of uniform phase-locked states. Between these tangencies γ_d corresponds to bifurcations and hence forms the lower boundary of the stable uniform phase-locked states within the resonance tongue. In Figure 6 we indicate this portion of γ_d with a solid line (barely visible) to distinguish it from portions where it does not correspond to bifurcations (shown dotted). In some places in Figure 6 the $\gamma = \gamma_d$ curve is difficult to distinguish from the other curves present; this is especially true at large values of ν where $\gamma_d - \gamma_b \ll 1$.

In Region III$^-$ (Figure 7), the Turing bifurcation is absent. The curve $\gamma = \gamma_d$ always lies above γ_0, but no tangencies are present. Finally, in Region IV$^-$ (Figure 10), the Turing bifurcation reappears along with the tangency of $\gamma = \gamma_d$ to $\gamma = \gamma_a$ (and $\gamma = \gamma_0$) at ν_α. In this

case the bifurcations are present in $\nu < \nu_\alpha$ (solid line), and at the tangency the two Turing bifurcations merge and annihilate. At large ν the curve $\gamma = \gamma_d$ (dotted) approaches $\gamma = \gamma_b$ and becomes difficult to distinguish.

3.2.2. Spatial eigenvalues of $A = A_u^\pm$. In this subsection we study the spatial eigenvalues of the uniform phase-locked states to identify the parameter regimes with possible exponentially localized states biasymptotic to $A = A_u^\pm$. These eigenvalues are determined by linearizing (2.2) about $A_u^\pm$ and satisfy

$$(1+\alpha^2)\lambda^4 + 2\lambda^2\left[\mu + \alpha\nu - 2(1+\alpha\beta)|A_u^\pm|^2\right] + 4\left[(\mu+\beta\nu)|A_u^\pm|^2 + \gamma^2 - \gamma_0^2\right] = 0. \tag{3.28}$$

As was the case above when considering the stability in time, we first examine the spatial eigenvalues near γ_0 where the uniform phase-locked states bifurcate from $A = 0$. At γ_0 there are two zero eigenvalues and two order one eigenvalues given by

$$\lambda = \pm\Lambda_0 \equiv \pm\frac{\sqrt{-2\alpha(\nu-\nu_\alpha)}}{\rho_\alpha}. \tag{3.29}$$

When $\alpha > 0$, these eigenvalues are real if $\nu < \nu_\alpha$ and imaginary if $\nu > \nu_\alpha$, in agreement with the eigenvalue analysis along the $A = 0$ branch described in section 3.1.2. Using (3.20) for the amplitude of the uniform phase-locked states near $\gamma = \gamma_0$, the small spatial eigenvalues along this branch are given approximately by

$$\lambda^2 = \frac{4\gamma_0(\gamma-\gamma_0)}{\rho_\alpha^2\Lambda_0^2} \tag{3.30}$$

and hence are of the same sign as Λ_0^2 when $\gamma > \gamma_0$ and of the opposite sign when $\gamma < \gamma_0$. Thus a supercritical bifurcation to uniform phase-locked states at γ_0 implies that the zero eigenvalues split "toward" the large eigenvalues $\pm\Lambda_0$ and all four eigenvalues are either real or imaginary (the eigenvalue structure (i) or (iii) in section 3.1.2). In contrast, when this bifurcation is subcritical, the zero eigenvalues split in the direction "opposite" to the large eigenvalues, and so two are real and two are imaginary (the eigenvalue structure (iv) in section 3.1.2). These spatial eigenvalues are shown in the insets in Figure 15 for the case $\nu < \nu_\alpha$, where Λ_0 is real; a similar figure holds in the case $\nu > \nu_\alpha$, where Λ_0 is imaginary.

For the case shown in Figure 15(a), the spatial eigenvalues of the trivial state are such that no localized states biasymptotic to $A = 0$ can exist in $\gamma > \gamma_0$. But in this same range of γ the eigenvalues of the uniform phase-locked state A_u^+ can support localized states, and indeed, as shown in the next section, localized states in the form of *fronts* bifurcate supercritically from γ_0 whenever the eigenvalue structure in Figure 15(a) applies.

We next compute the eigenvalues of the uniform phase-locked states near the saddle-node bifurcation at $\gamma = \gamma_b$. At the saddle-node, (3.28) has a pair of zero eigenvalues and a pair of order one eigenvalues given by

$$\lambda = \pm\Lambda_b \equiv \pm\frac{\sqrt{2z(\nu-\nu_z)}}{\rho_\alpha\rho_\beta}. \tag{3.31}$$

Since $z > 0$ these eigenvalues are real when $\nu > \nu_z$ (Figure 16(a)) and imaginary when $\nu < \nu_z$ (Figure 16(b)). Using (3.23) for the amplitude along the $A_u^{\pm}$ branches near the saddle-node, the zero eigenvalues become

$$\lambda^2 = \pm \frac{4|A_u(\gamma_b)|^2}{\Lambda_b^2} \frac{\rho_\beta}{\rho_\alpha^2} \sqrt{2\gamma_b(\gamma - \gamma_b)}. \tag{3.32}$$

Here the "+" sign refers to the upper branch A_u^+, and the "−" sign to the lower branch A_u^-. As shown in Figure 16, along the A_u^+ branch the zero eigenvalues split "toward" the large eigenvalues and hence all four are either real or imaginary, while along the A_u^- branch the zero eigenvalues split in the "opposite" direction, and two eigenvalues are always real and two are always imaginary. We conclude that when the bifurcation to uniform phase-locked states is subcritical, the eigenvalues of the A_u^- states are always of type (iv). Thus we do not expect localized states involving A_u^-. On the other hand, a branch of localized states involving A_u^+ may emerge from the saddle-node at $\gamma = \gamma_b$ when the eigenvalue structure is of the type shown in Figure 16(a) but not in the case shown in Figure 16(b).

The eigenvalue analysis predicts one final bifurcation that can occur along the A_u^+ branch of uniform phase-locked states: the four eigenvalues, which are either all real or all imaginary, collide pairwise at $\gamma = \gamma_d$. The spatial eigenvalues at this collision are $\lambda = \pm ik_d$. In the case in which the bifurcation to uniform phase-locked states at γ_0 is subcritical and the A_u^+ branch emerges from the saddle-node at γ_b, the collision occurs on the imaginary axis whenever the eigenvalues $\pm\Lambda_b$ lie on the imaginary axis, as in Figure 16(b). If the eigenvalues $\pm\Lambda_b$ are real, the collision occurs instead on the real axis, as in Figure 16(a). In contrast, when the A_u^+ branch emerges directly from a supercritical bifurcation at γ_0, the eigenvalue collision occurs on the imaginary axis when the eigenvalues $\pm\Lambda_0$ are imaginary, as in Figure 5(b), and on the real axis when they are real, as in Figure 5(a). When the collision at γ_d occurs on the real axis, it corresponds to a global bifurcation, the Belyakov–Devaney point. When the collision at γ_d occurs on the imaginary axis, it corresponds to a local bifurcation point; this is precisely the Turing bifurcation at γ_d identified in section 3.2.1. In addition to identifying the appearance of spatially extended Turing patterns, the eigenvalue analysis suggests that spatially localized states that approach A_u^+ may also emerge from this bifurcation point into $\gamma > \gamma_d$. Thus localized states may emerge *either* from γ_b *or* from γ_d but not both.

A comparison of the eigenvalue structure in Figures 5(a) and 16(a) shows that bifurcations that occur at γ_0 and γ_b are similar in nature; at both bifurcation points there are two zero eigenvalues and two real eigenvalues, and localized states may exist nearby in $\gamma < \gamma_0$ or $\gamma > \gamma_b$, where the eigenvalue structure is of type (i). A comparison of Figures 5(b) and 16(b) shows that the bifurcations that can occur at γ_a and γ_d are also similar. Both are reversible Hopf bifurcations with 1:1 resonance [26], and localized states may exist in $\gamma < \gamma_a$ or $\gamma > \gamma_d$, where the eigenvalue structure is of type (ii). However, the small amplitude localized states that bifurcate from γ_a and γ_0 are biasymptotic to $A = 0$, while the large amplitude states that bifurcate from γ_b and γ_d are biasymptotic to A_u^+. As such, the former correspond to standard oscillons, while the latter represent new states we refer to as reciprocal oscillons [57].

3.2.3. Fronts bifurcating from $\gamma = \gamma_0$. In section 3.1.3 we examined the "small amplitude" spatially localized states that bifurcate from $A = 0$ at γ_0 whenever the bifurcation

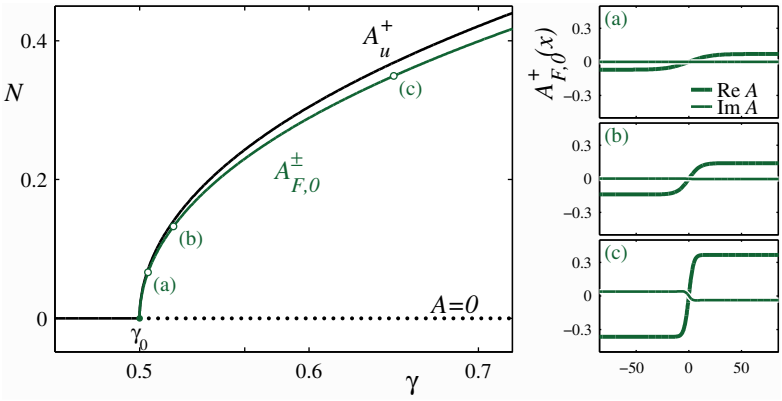

Figure 17. *Bifurcation diagram for $\nu < \nu_\alpha$ in Region* II^-*, showing the branches of front-like states $A_{F,0}^{\pm}$ found by continuing the solution (3.33) away from γ_0, together with the uniform states A_u^+. The norm of $A_{F,0}^{\pm}$ has been rescaled to distinguish it from the uniform states. Solid (dotted) lines correspond to stable (unstable) solutions.* (a)–(c) *Sample front profiles. Parameters:* $\mu = -0.5$, $\alpha = 2$, $\beta = 1$, $\nu = 0$; (a) $\gamma = 0.505$, (b) $\gamma = 0.52$, (c) $\gamma = 0.65$.

to the uniform phase-locked states is subcritical ($\nu > \nu_\beta$). These states are biasymptotic to $A = 0$ as $x \to \pm\infty$. In this section we examine the so-called *large amplitude* states that bifurcate from $A = 0$ at γ_0 whenever the bifurcation to the uniform phase-locked states is supercritical ($\nu < \nu_\beta$). Appendix A shows that such states are present in $\gamma > \gamma_0$ in Region II^- when $\nu < \nu_\alpha$ (Figure 6), in Region III^- when $\nu < \nu_\beta$ (Figure 7), and in Region IV^- when $\nu_\alpha < \nu < \nu_\beta$ (Figure 10) and take the form

$$A_{F,0}^{\pm}(x) = \pm(\eta_0 + i)\sqrt{\frac{\gamma - \gamma_0}{-b_0}}\tanh\left(\sqrt{\frac{\gamma - \gamma_0}{-2a_0}}x\right), \tag{3.33}$$

where $a_0 < 0$, $b_0 < 0$. The "+" branch refers to fronts which asymptote to the uniform phase-locked state A_u^+ as $x \to \infty$ and to $-A_u^+$ as $x \to -\infty$, while the reverse is true for the "−" branch. Thus both solutions have odd parity under spatial reflection and are *fronts*.

The analytical solutions (3.33) can be followed away from γ_0 using numerical continuation. Since heteroclinic cycles never form at these values of ν, the fronts extend to arbitrarily large γ (Figure 17). Near γ_0 the fronts are broad (Figure 17(a)) but become more localized as γ increases (Figure 17(b),(c)). In the following we refer to these fronts as Ising fronts. Such fronts are typically (although not necessarily) monotonic in x and are linearly stable to all perturbations, even and odd.

3.2.4. Localized states bifurcating from $\gamma = \gamma_b$. The weakly nonlinear analysis performed in Appendix C shows that when $\nu > \nu_z$ a branch of spatially localized states exists near the saddle-node bifurcation at $\gamma = \gamma_b$. These states are biasymptotic to A_u^+ and are given by

$$A_{L,b}(x) = A_u^+ - 3\Upsilon_1(\xi_b + i)\sqrt{\gamma - \gamma_b}\,\mathrm{sech}^2\left\{\left(\frac{\Upsilon_1}{2a_b/b_b}\right)^{1/2}(\gamma - \gamma_b)^{1/4}\,x\right\}; \tag{3.34}$$

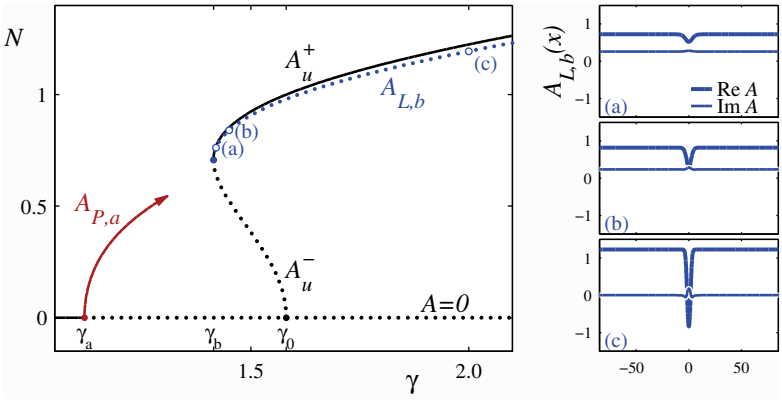

Figure 18. *Bifurcation diagram for $\nu > \nu_z$ in Region* II^-*, showing the branch of localized states $A_{L,b}$ found by numerical continuation of the solution* (3.34) *away from γ_b, as well as the spatially periodic states $A_{P,a}$ and the uniform states $A_u^{\pm}$. The norm of $A_{L,b}$ has been rescaled to distinguish it from the uniform states. Solid (dotted) lines correspond to stable (unstable) solutions.* (a)–(c) *Solution profiles at the locations indicated in the left panel. Parameters: $\mu = -0.5$, $\alpha = 2$, $\beta = 1$, $\nu = 1.5$, with* (a) $\gamma = 1.42$, (b) $\gamma = 1.45$, (c) $\gamma = 2$.

the constants in this expression are defined in Appendix C. There is a similar branch of localized states biasymptotic to $-A_u^+$ given by $-A_{L,b}(x)$. In Regions III^- and IV^- $\nu_z < \nu_\beta$, and hence the condition $\nu > \nu_z$ automatically holds whenever a saddle-node is present. A branch of localized states of this type therefore emerges from γ_b when $\nu > \nu_z$ in Region II^- (Figure 6) but is present whenever there is a saddle-node in Region III^- (Figure 7) and Region IV^- (Figure 10).

The analytical solution (3.34) can be followed away from γ_b using numerical continuation. The behavior away from the saddle-node depends critically on whether or not a heteroclinic cycle forms as γ increases away from γ_b. In the absence of such a cycle the branch of localized states simply extends to arbitrarily large γ, a situation that occurs when $\nu > \nu_z$ in Region II^-, as shown in Figure 18. The solution profile near γ_b is broad and forms a shallow dip in an otherwise uniform A_u^+ background (Figure 18(a)). Away from the saddle-node the solution contracts in x, forming a well-defined hole in the A_u^+ background (Figure 18(c)), but remains unstable throughout owing to a single unstable amplitude mode of even parity. The supercritical branch of stable spatially periodic states $A_{P,a}$ is shown for clarity only near γ_a.

When a heteroclinic cycle is present, the branch of localized states emerging from the saddle-node can approach γ^* either monotonically or in an oscillatory fashion involving a sequence of saddle-node bifurcations. In Region IV^- only the former is observed (Figure 19), while in Region III^- both possibilities may occur (Figure 20). The heteroclinic cycle that forms with increasing γ is *identical* to that responsible for the termination of the small amplitude states, as can be seen by comparing, for example, the profiles in Figure 20(c) and Figure 9(c),(f); this is a manifestation of the reciprocity already noted in [12, 27].

When the approach to γ^* is monotonic, the localized states are always unstable to a single amplitude (even) mode. On the other hand, when the approach is oscillatory (observed only in Region III^-), the stability changes at successive saddle-node bifurcations, as illustrated in Figure 21. As a result multiple stable *reciprocal oscillons* are present in a region straddling

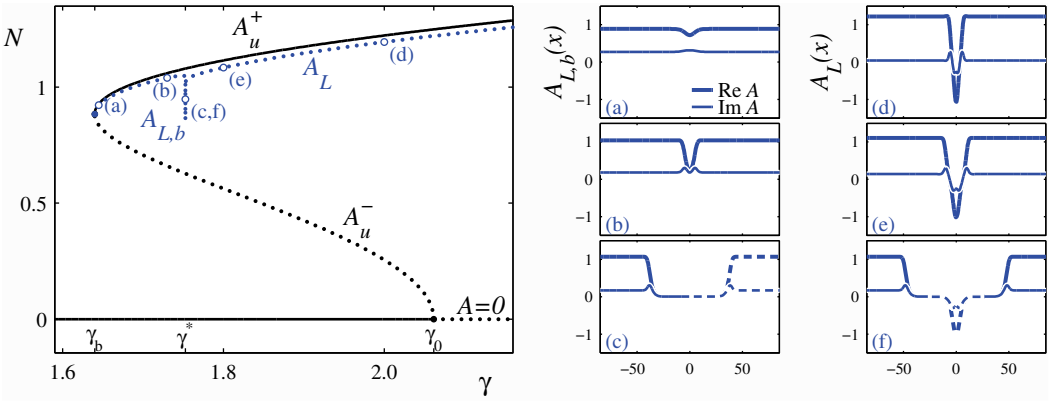

Figure 19. *Bifurcation diagram for $\nu > \nu_\beta$ in Region* IV$^-$*, showing the branch of localized states $A_{L,b}$ found by numerical continuation of the solution (3.34) away from γ_b, as well as a branch A_L found using the homotopy method and the uniform states $A_u^\pm$. The norms of the localized states have been rescaled to distinguish them from the uniform states. Parameters: $\mu = -0.5$, $\alpha = -1.5$, $\beta = 1.25$, $\nu = 2$, with* (a) $\gamma = 1.645$, (b) $\gamma = 1.730$, (c),(f) $\gamma = 1.752$, (d) $\gamma = 2$, (e) $\gamma = 1.8$.

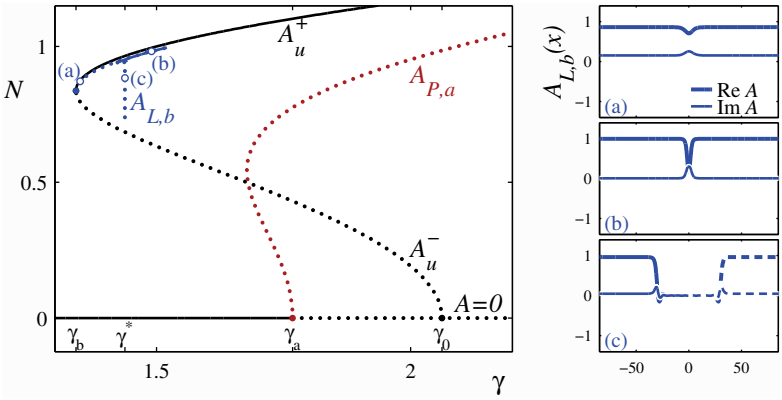

Figure 20. *Bifurcation diagram for $\nu \gg \nu_\beta$ in Region* III$^-$*, showing the branch of localized states $A_{L,b}$ found by numerical continuation of the solution (3.34) away from γ_b, as well as the spatially periodic states $A_{P,a}$ and the uniform states $A_u^\pm$. The norm of $A_{L,b}$ has been rescaled to distinguish it from the uniform states. Solid (dotted) lines correspond to stable (unstable) solutions. A closeup of the behavior near $\gamma^* \approx 1.437$ is shown in Figure 21.* (a)–(c) *Solution profiles at the locations indicated in the left panel. Parameters: $\mu = -0.5$, $\alpha = 1$, $\beta = 2$, $\nu = 2$, with* (a) $\gamma = 1.35$, (b) $\gamma = 1.49$, (c) $\gamma = 1.437$.

γ^*; in Figure 21 we label this region SRO. The extent of the SRO region in the (ν, γ) plane in Region III$^-$ is shown in Figure 7(b). The SRO region takes the form of a wedge straddling the line γ^* and increases in width as ν increases. As with the SSO region described in the previous section, the SRO region is not created at ν_β together with the line γ^* but appears only when ν sufficiently exceeds ν_β. A closeup of this behavior is shown in Figure 22 for a different set of parameters elsewhere in Region III$^-$. In this figure it is easier to see that the SRO region first appears only after the line γ^* crosses the line $\gamma = \gamma_a$.

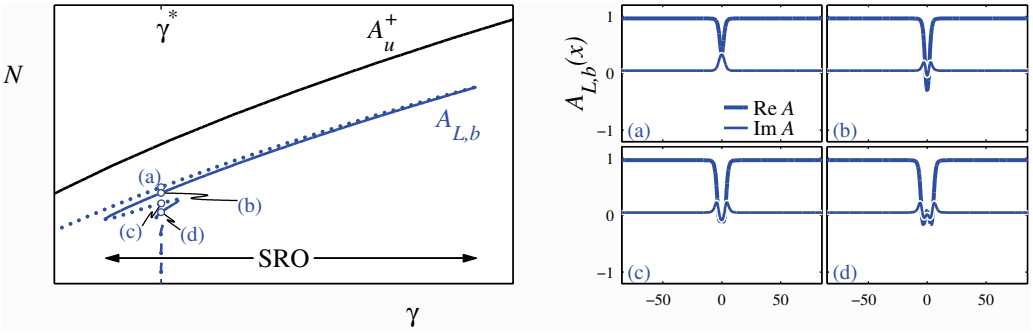

Figure 21. *Detail of Figure 20, including sample profiles near $\gamma = \gamma^*$ (see text). In the left panel solid (dotted) lines correspond to stable (unstable) solutions.*

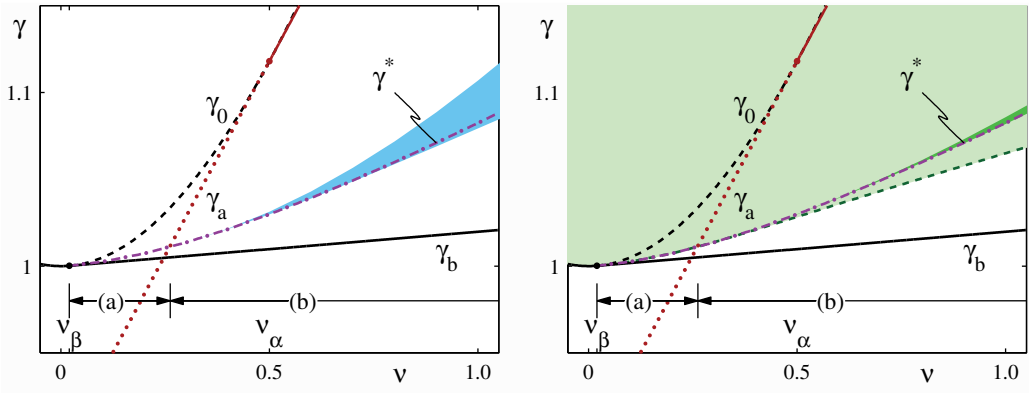

Figure 22. *Detail of the crossing of γ^* and γ_a in the (ν, γ) plane of Region III$^-$. In the domain labeled* (a)*, $\gamma^* > \gamma_a$ and the approach of large amplitude localized states and fronts to γ^* is monotonic; in* (b)*, $\gamma^* < \gamma_a$ and the approach is via a series of saddle-node bifurcations. Left panel: The SRO region (shaded) defined by the first two saddle-node bifurcations on the branch of localized states. Right panel: The SIF region (lightly shaded) extends down to the first saddle-node bifurcation on the front branch, while the SSF region (dark) extends from the second saddle-node to the third. Parameters: $\mu = -1$, $\alpha = 2$, $\beta = 50$.*

3.2.5. Localized states bifurcating from $\gamma = \gamma_d$. A collision of spatial eigenvalues on the imaginary axis at γ_d corresponds to a bifurcation point analogous to γ_a. For this case weakly nonlinear analysis in the vicinity of γ_d (Appendix D) reveals that there is a branch of spatially periodic solutions given by

$$A_{P,d}(x) = A_u^+ + 2(\xi_d + i)\sqrt{\frac{\gamma - \gamma_d}{b_d}}\cos(k_d x + \varphi) \tag{3.35}$$

and a branch of localized spatial oscillations of the form

$$A_{L,d}(x) = A_u^+ + 2(\xi_d + i)\sqrt{\frac{\gamma - \gamma_d}{b_d/2}}\,\mathrm{sech}\left\{\sqrt{\frac{\gamma - \gamma_d}{a_d}}x\right\}\cos(k_d x + \varphi)\,, \tag{3.36}$$

both of which bifurcate simultaneously from γ_d. Two similar branches also bifurcate at γ_d from the $-A_u^+$ branch. The expressions for ξ_d, a_d, and b_d are unwieldy (see Appendix D)

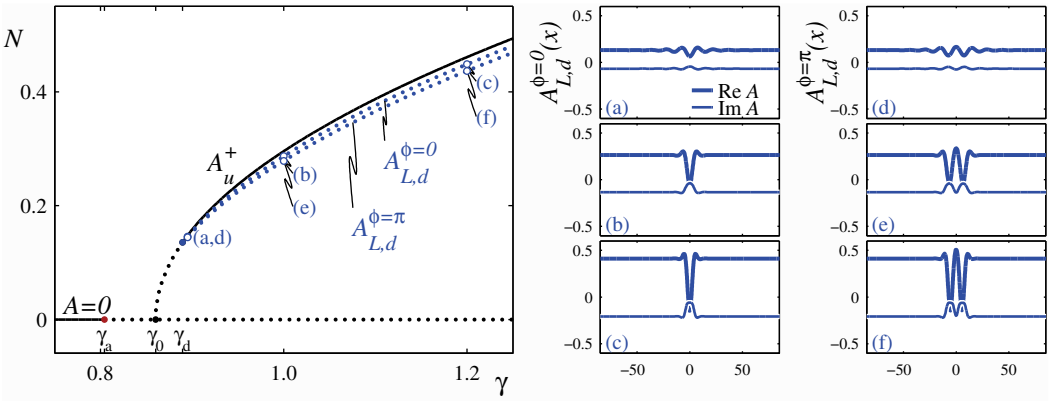

Figure 23. *Bifurcation diagram for $\nu < \nu_\alpha$ in Region* IV$^-$*, showing the two branches of localized states $A_{L,d}^{\varphi=0}$ and $A_{L,d}^{\varphi=\pi}$, as well as the branch of uniform phase-locked states A_u^+. For clarity the branches of spatially periodic states $A_{P,a}$ and $A_{P,d}$ which bifurcate from γ_a and γ_d, respectively, are omitted. The norms of the localized states have been rescaled to distinguish them from the uniform states. Solid (dotted) lines correspond to stable (unstable) solutions.* (a)–(c) *Sample localized profiles along $A_{L,d}^{\varphi=0}$.* (d)–(f) *Sample localized profiles along $A_{L,d}^{\varphi=\pi}$. Parameters: $\mu = -0.5$, $\alpha = -1.5$, $\beta = 1.25$, $\nu = -0.7$, with* (a),(d) $\gamma = 0.895$, (b),(e) $\gamma = 1$, (c),(f) $\gamma = 1.2$.

but can easily be evaluated for specific parameter choices. We find that $a_d, b_d > 0$ for all values of ν at which the collision at γ_d occurs on the imaginary axis. Thus, whenever γ_d is a bifurcation point, both $A_{P,d}$ and $A_{L,d}$ emerge into $\gamma > \gamma_d$. This is the case in Region II$^-$ when $\nu_\alpha < \nu < \nu_z$ and in Region IV$^-$ when $\nu < \nu_\alpha$; as already noted, γ_d never corresponds to a bifurcation in Region III$^-$.

The phase φ in (3.35) is arbitrary. Within the asymptotic analysis the phase φ in (3.36) is also arbitrary, but terms beyond all orders select solutions with phases $\varphi = 0, \pi$. We refer to these two solutions as $A_{L,d}^{\varphi=0}$ and $A_{L,d}^{\varphi=\pi}$, respectively. These states are distinct, unrelated by symmetry, and *even* in x. Odd states of the type present in (3.16) are excluded here since these localized states represent small perturbations of a *nontrivial* uniform background state.

The two branches of solutions described analytically by (3.36) can be followed away from the bifurcation point using numerical continuation. Since these solutions never apply when a heteroclinic cycle is present, the corresponding solution branch extends to arbitrarily large γ, as shown in Figure 23. The localized states are broad near γ_d (Figure 23(a),(d)) but contract in x as γ increases, forming well-localized packets. At large γ the $\varphi = 0$ solution corresponds to a single hole in the uniform A_u^+ background (Figure 23(c)), while the $\varphi = \pi$ solution corresponds to two adjacent holes (Figure 23(f)); we think of the latter as a bound state of two holes. Both branches are unstable throughout: the $\varphi = 0$ solutions are unstable to a single amplitude (even) mode, while the $\varphi = \pi$ solutions are unstable to both an amplitude (even) mode and a phase (odd) mode.

3.2.6. Additional large amplitude branches. All the branches of states presented thus far were found by numerically continuing an approximate analytical solution away from a local bifurcation. Some of these branches terminate in global bifurcations at γ^*. In this section we show that there are, in addition, branches of large amplitude localized states

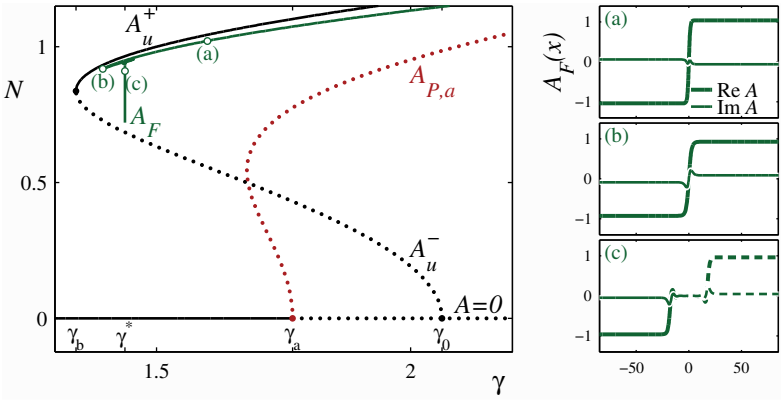

Figure 24. *Bifurcation diagram for $\nu \gg \nu_\beta$ in Region* III$^-$*, showing the branches of fronts A_F, as well as the spatially periodic states $A_{P,a}$ and the uniform states $A_u^\pm$. The norm of A_F has been rescaled to distinguish it from the uniform states. Solid (dotted) lines correspond to stable (unstable) solutions. A closeup of the behavior near $\gamma^* \approx 1.437$ is shown in Figure 25.* (a)–(c) *Sample localized profiles along A_F. The wide profile in* (c) *near γ^* can be thought of as a pair of nearly heteroclinic orbits between $A = 0$ and $\pm A_u^+$ (solid and dashed lines). Parameters: $\mu = -0.5$, $\alpha = 1$, $\beta = 2$, $\nu = 2$, with* (a) $\gamma = 1.6$, (b) $\gamma = 1.394$, (c) $\gamma = 1.437$.

and fronts for which we have no approximate analytical solution. We locate these branches using a homotopy method: starting from an analytically known local solution, we follow the corresponding solution branch to a large value of γ; we then change another parameter such as α or ν at fixed large γ to move into a regime where no analytical solution exists; finally, we follow this branch of large amplitude states back toward small γ. In the following we use this technique to locate new classes of both localized and front-like states, with a particular interest in locating stable states in the neighborhood of the line γ^*.

We find that the behavior of the large amplitude front-like states present at large γ depends on the presence or absence of γ^*. When such a point is present, as in Region III$^-$ for $\nu > \nu_\beta$, the branch of fronts may approach γ^* from above either monotonically or through a series of saddle-node bifurcations. Numerically we observe that the former occurs when $\gamma^* > \gamma_a$, a condition that holds only very close to ν_β. The latter occurs when $\gamma^* < \gamma_a$ and is the case for all $\nu \gg \nu_\beta$. A bifurcation diagram with this behavior is shown in Figure 24. In this case, the fronts at large γ are simple monotonic (Ising) transitions from A_u^+ to $-A_u^+$, but as one passes between adjacent saddle-nodes the fronts develop extra structure near their midpoint, and we refer to the resulting profiles as *structured* fronts. The Ising fronts are stable at large γ, but stability switches at each saddle-node. Thus stable Ising fronts (SIFs) exist for all γ above the first saddle-node, and stable structured fronts (SSFs) exist between the second and third saddle-nodes. These regions are labeled SIF and SSF in the closeup shown in Figure 25.

In the absence of γ^* our numerics suggest that the branch of Ising fronts always terminates, as γ decreases, in a saddle-node bifurcation at $\gamma = \gamma_k$ involving a second branch of front-like states that also comes in from large γ. These new states resemble kinks [24] and are always unstable with respect to an amplitude (odd) mode. An example of this behavior taken from Region II$^-$ is shown in Figure 26. These kink fronts differ fundamentally from the structured fronts created near γ^*, despite the fact that both are nonmonotonic transitions between $\pm A_u^+$.

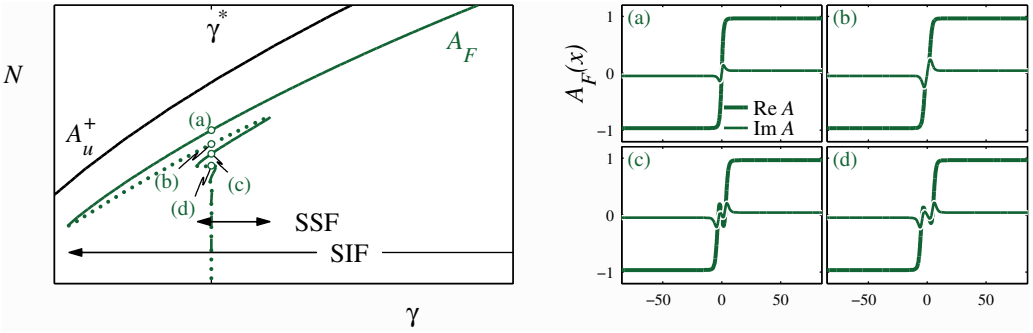

Figure 25. *Detail from Figure 24 of the A_F branch as it approaches γ^*. The significance of the regions SIF and SSF is explained in the text.*

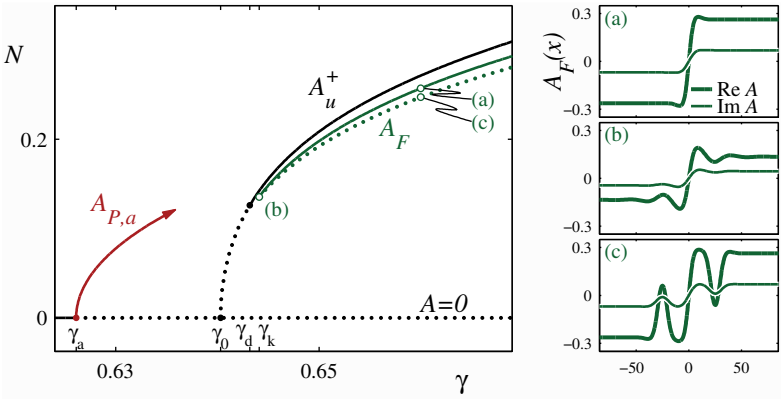

Figure 26. *Bifurcation diagram for $\nu_\alpha < \nu < \nu_\beta$ in Region* II^-*, showing the branch of front states A_F, as well as the spatially periodic states $A_{P,a}$ and the uniform states $A_u^\pm$. The norm of A_F has been rescaled to distinguish it from the uniform states. Solid (dotted) lines correspond to stable (unstable) solutions.* (a)–(c) *Sample localized profiles. Parameters: $\mu = -0.5$, $\alpha = 2$, $\beta = 1$, $\nu = 0.4$, with* (a),(c) $\gamma = 0.66$, (b) $\gamma = 0.644$.

The latter result when an Ising front develops extra structure near the midpoint at $A = 0$, while the former are the result of nucleation as the nontrivial states on either side of the front develop holes which are bound to the front.

In Region II^- (Figure 6) there is no γ^* line in the (ν, γ) plane and the only stable fronts are monotonic. In $\nu < \nu_\alpha$ the SIF region extends down to γ_0, where the fronts $A_{F,0}^\pm$ bifurcate directly from $A = 0$. In $\nu > \nu_\alpha$ the lower boundary of the SIF region consists of the line of saddle-node bifurcations where the monotonic fronts collide with the kinks. This saddle-node bifurcation always appears to lie (slightly) above γ_d, although in $\nu > \nu_z$ both this saddle-node and γ_d approach γ_b, and we can no longer determine the precise relation between the boundary of the SIF region and γ_d.

Figure 7(c) shows the region of existence of stable fronts in Region III^- and the associated line γ^*. The SIFs extend down to γ_0 in $\nu < \nu_\beta$. Above ν_β the behavior is difficult to make out in Figure 7(c) but easier to see in Figure 22, corresponding to a value of the parameters elsewhere in Region III^-. In the domain directly above ν_β, labeled (a) in this figure, the

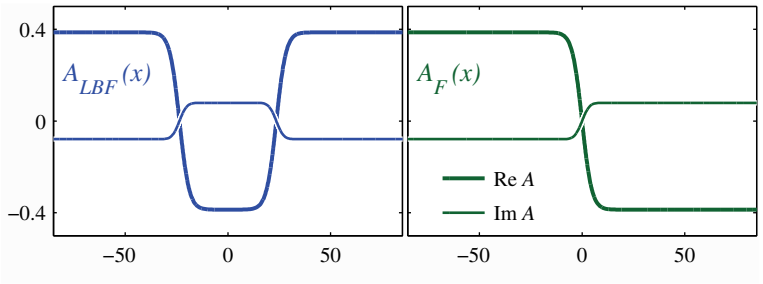

Figure 27. *Comparison of the profiles of an LBF and an (Ising) front that coexist at the same value of the parameters in Region* I^-. *Parameters:* $\mu = -0.5$, $\alpha = 2$, $\beta = 0.5$, $\nu = -0.2$, $\gamma = 0.712$.

approach to γ^* is monotonic and the SIF region extends down only as far as γ^*. In the domain labeled (b) the approach of the branch of fronts to γ^* is through a series of saddle-nodes and the SIF region extends beyond γ^* to the first of these, which lies above γ_b. In the latter case Region III^- also contains an SSF region. The regime of existence is difficult to make out in Figure 7(c), but in Figure 22 it is clear that the SSF region occupies a thin wedge around the line γ^* in the domain labeled (b). A comparison of Figures 7(b) and 7(c) (or the closeups in Figure 22) shows the intimate relation between the SRO and SSF regions: both are associated with nonmonotonic approach of a branch of large amplitude states to γ^* and are present at identical values of ν, although the widths of the regions (as determined by the locations of the saddle-nodes) are different.

Figure 10(b) does the same for Region IV^-. In $\nu_\alpha < \nu < \nu_\beta$ the SIF region extends down to γ_0, where the fronts $A^{\pm}_{F,0}$ bifurcate directly from $A = 0$. Below ν_α the boundary of this region consists of the line of saddle-nodes γ_k where the monotonic fronts collide with the kinks; again this saddle-node always lies above γ_d. Above ν_β the large amplitude fronts always approach γ^* monotonically from above, and the line γ^* forms the boundary of the SIF region.

The homotopy method can also be applied to the localized states. In Region II^-, the branch of large amplitude localized states $A_{L,d}$ that emerges from γ_d in $\nu_\alpha < \nu < \nu_z$ and the branch of $A_{L,b}$ that emerges from γ_b when $\nu > \nu_z$ each extends to large γ, where the profiles resemble deep holes in a uniform A^+_u background. When the localized states are continued numerically in ν below ν_α and then followed back to small γ we find that this hole deepens and broadens as the localized state fills with $-A^+_u$. Eventually the localized state becomes wide enough that it resembles a pair of bound fronts between $\pm A^+_u$. We refer to such solutions as localized bound fronts (LBFs), A_{LBF}. A profile on the A_{LBF} branch in Region I^- is shown in Figure 27 along with the Ising front at the same value of the parameters; the profiles are nearly identical over the entire width of the front. The separation between the two fronts increases as γ approaches γ_d from above. Although the numerical results are inconclusive, we conjecture that this branch terminates at γ_d in a global bifurcation analogous to the Belyakov–Devaney bifurcation. In this case we have two symmetrically related fixed points so that the "single-pulse" orbit which persists in both $\gamma < \gamma_d$ and $\gamma > \gamma_d$ is the front connecting $\pm A^+_u$. We interpret the LBFs as the simplest of the infinite multiplicity of multipulse states expected to exist in $\gamma > \gamma_d$.

LBFs are also present in Region III$^-$, though only above the Belyakov–Devaney point γ_d. As a result we find no additional localized states in the neighborhood of γ^* since it always lies far below γ_d.

In Region IV$^-$ the branch of large amplitude localized states $A_{L,b}$ that emerge from γ_b in $\nu > \nu_\beta$ approaches γ^* monotonically from below, while the branch $A_{L,d}$ that emerges from γ_d in $\nu < \nu_\alpha$ extends to large γ. The latter can be followed in ν not only into the domain $\nu_\alpha < \nu < \nu_\beta$, where no analytical results apply, but also into $\nu > \nu_\beta$ corresponding to the previously inaccessible range of parameter space above the line γ^*. When numerically continued back toward small γ we find two types of behavior. At values of ν such that $\gamma_d > \gamma^*$, the resulting solutions resemble the LBFs and are again found numerically only above γ_d. This is so for $\nu_\alpha < \nu < \nu_\beta$ as well as at some values of ν slightly above ν_β. When ν exceeds ν_β sufficiently that $\gamma^* > \gamma_d$, the branch of localized states approaches γ^* monotonically from above. It may be of interest to recall that in this same region the *small amplitude* localized states $A^{\pm}_{L,0}$ approach this same γ^* in a series of saddle-node bifurcations (Figure 12). These new large amplitude localized states, labeled A_L in Figure 19, exist in addition to those that bifurcate from the saddle-node at γ_b and approach γ^* from below, and are everywhere unstable to an amplitude mode. The A_L profile at γ^* consists of a heteroclinic cycle involving three parts (Figure 19(f)): a front from A^+_u to $A = 0$, a localized state biasymptotic to $A = 0$, and another front from $A = 0$ to A^+_u. This limiting profile is distinct from the limiting profile (Figure 19(c)) along the $A_{L,b}$ branch that also terminates at γ^*, although the segments of these profiles resembling fronts between A^+_u and $A = 0$ are identical.

3.3. Large amplitude states in $z < 0$. When $z < 0$, as in Regions I$^-$ and V$^-$, the expressions presented above remain valid, but we must reinterpret the results. Specifically, in (3.31) the order one eigenvalues at γ_b are now real when $\nu < \nu_z$ and in this case large amplitude localized states biasymptotic to A^+_u are expected to emerge from the saddle-node into $\gamma > \gamma_b$ (as in Figure 16(a)). The collision of eigenvalues at γ_d occurs on the imaginary axis and corresponds to a bifurcation point when $\nu > \nu_z$ (as in Figure 16(b)).

In Region I$^-$, ν_z, as defined in (3.25), is always less than ν_β, and the behavior near the saddle-node is necessarily of the type shown in Figure 16(b). In this region the Turing bifurcations of the $A = 0$ and A^+_u states are created in the tangency of γ_d and γ_a to γ_0 at ν_α, and γ_d remains a bifurcation point in all $\nu > \nu_\alpha$, where it forms the boundary of the stable region of uniform phase-locked states within the resonance tongue. The large amplitude localized states and fronts are similar to those found in Region II$^-$, including the LBFs in $\nu < \nu_\alpha$ found using the homotopy method. Like Region II$^-$, Region I$^-$ contains no heteroclinic cycles, and no SRO or SSF regions are present.

The behavior in Region V$^-$ resembles very closely that of Region IV$^-$. The one notable exception is that in Region IV$^-$ the Turing bifurcation at γ_d was present only in $\nu < \alpha$, while in Region V$^-$ it is also present in $\nu > \nu_z$ where it defines the boundary of the region of stable uniform phase-locked states. Nevertheless the large amplitude states observed in Region V$^-$ match those described previously for Region IV$^-$, including the necessarily monotonic approach of both localized states and fronts to γ^*.

3.4. Pinning near γ^*. Thus far we have identified numerically two types of behavior near γ^*: a branch of states can approach γ^* either monotonically or through a series of saddle-node

bifurcations. We have exhibited examples of both types of behavior in our discussion of the termination of small and large amplitude localized states, and of fronts. In this subsection we show that the type of behavior observed is determined by the spatial eigenvalues of the spatially uniform solutions connected by the heteroclinic cycles present at γ^* [28].

We consider first the case of large amplitude localized states, such as those that emerge from γ_b, shown in Figures 19 and 20. Near the saddle-node at γ_b these states represent small perturbations of the A_u^+ state, and these grow in amplitude as γ approaches γ^*. Near this point the inner region of the localized state approaches $A = 0$ and we can think of the localized state as a combination of two fronts, one from A_u^+ to $A = 0$ and a second from $A = 0$ back to A_u^+. If the eigenvalues of the $A = 0$ state are complex, the approach to $A = 0$ will be via a decaying oscillation in x; the departure from $A = 0$ will likewise be via a growing oscillation in x. These oscillatory tails can be seen in the profile shown in Figure 20(c). Such oscillations are responsible for the mutual "pinning" of the fronts that is, in turn, responsible for the series of saddle-node bifurcations that must occur as the fronts move apart and the heteroclinic cycle is approached. When the fronts are close to one another the interaction between them is strong, and the pinning interval is therefore broad; when the fronts are far apart they interact only weakly and the distance between successive saddle-node bifurcations shrinks. The widest of these pinning intervals is the SRO region labeled in Figure 21. When the eigenvalues of the $A = 0$ state are instead real, the approach to (and departure from) the $A = 0$ state is exponential, and no oscillatory tails are present (Figure 19(b)). In this case pinning is absent, and the branch of localized states approaches γ^* monotonically.

There are three regions with γ^* lines: Regions III$^-$, IV$^-$, and V$^-$. In Regions IV$^-$ (Figure 10) and V$^-$ (Figure 11), the line γ^* always lies in $\nu > \nu_\beta$ and always lies between γ_a and γ_0, in a region where the eigenvalues of $A = 0$ are real. In these two regions large amplitude localized states experience no pinning, and the branches of these states must therefore approach γ^* monotonically. In Region III$^-$ (Figure 7), the line γ^* falls above γ_a when it is first created at ν_β, but as ν increases γ^* crosses γ_a somewhere in the range $\nu_\beta < \nu < \nu_\alpha$ and lies below γ_a in $\nu > \nu_\alpha$. This crossing is shown in detail in Figure 22. In a very small range in ν below this crossing, labeled (a) in the figure, the eigenvalues of $A = 0$ are real and there is no pinning; above this crossing, in the range labeled (b), the eigenvalues are complex, resulting in pinning and an associated SRO interval. The width of this interval increases from zero as ν increases beyond the crossing point.

We can also use the same pinning argument to understand the creation of the SSF region shown in Figure 7(c) and in the right panel of Figure 22. The monotonic fronts that exist at large γ split as γ approaches γ^*, creating a broad inner region which fills with the $A = 0$ state (Figure 24(c)). When the spatial eigenvalues of this state are complex the fronts experience pinning and the approach of the branch of fronts to γ^* will be via a series of saddle-node bifurcations which define the SSF region. Because these same eigenvalues are responsible for the SRO region of the large amplitude localized states, we expect the SSF and SRO regions to be present in the *same* range of values of ν, as confirmed by Figure 22.

A similar argument applies in the case of small amplitude localized states biasymptotic to $A = 0$, but in this case it is the A_u^+ (or $-A_u^+$) state which fills the inner region near γ^*. As a result the behavior near γ^*, shown, for example, in Figures 8 and 12, is determined by the spatial eigenvalues of A_u^+. In Region III$^-$ the line γ^* always lies below γ_d, and the eigenvalues

of A_u^+ at γ^* are therefore real. It follows that in this region the small amplitude localized states cannot exhibit pinning and hence that the corresponding solution branch must approach γ^* monotonically, as in Figures 8 and 9. In Regions IV$^-$ and V$^-$ the γ^* line falls below γ_d when it is first created in the tangency at ν_β but crosses γ_d as ν increases. This crossing is shown in detail in Figure 14. It follows that when ν is sufficiently larger than ν_β, the approach to γ^* becomes oscillatory, resulting in the SSO region shown in Figure 11(b).

3.5. Another type of pinning. In the preceding subsections we have seen a number of examples of what might be called classical pinning regions. The fundamental object responsible for this behavior is a heteroclinic cycle between two distinct states, the $A = 0$ and $A = A_u^+$ uniform states [28]. The LBFs can likewise be understood in terms of pinning, but in this case the fundamental fronts are connections between $\pm A_u^+$ found in the SIF regions. As such the resulting homoclinic orbits could be called *homoclinic* cycles because the two states visited by the trajectory are related by symmetry. If the spatial eigenvalues of the state A_u^+ are complex, the two fronts will possess oscillatory tails that will interact and lead to preferred separations. This notion is consistent with the numerical observation that these LBF states are only found above γ_d, where the spatial eigenvalues are complex. Even when γ_d does not correspond to a bifurcation point, the spatial eigenvalues below γ_d are real and no pinning can take place.

There are two important observations that distinguish this case from the previous results. First, the heteroclinic orbits responsible for the classical pinning regions exist only along the line γ^*, whereas the orbits responsible for the LBF states exist throughout the entire SIF region. Thus, while the line γ^* organizes the regions SSO, SRO, and SSF, it is less clear what organizes the various LBF states. Second, due to symmetry, the Ising fronts that exist within the SIF region do not drift. As such the pinning force does not oppose any natural tendency of the bound fronts to drift but selects only the preferred separations.

It is also worth mentioning the states which result when the unstable kink fronts described above are evolved in time. The holes on either side of the front deepen into a stable state which resembles five bound Ising fronts (the original front plus two from the deepening of each hole). Numerical simulations show that other stable states consisting of three or seven bound Ising fronts also exist within much of the SIF regions. It is easy to imagine a large multiplicity of fronts and localized states created in this manner. Thus although the focus of this paper is on the stable states associated with the pinning of fronts near the γ^* line, it is clear that bound fronts play an important role in the full enumeration of stable solutions to (2.2).

3.6. Multipulse branches near $\gamma = \gamma^*$. We have already seen that the region around γ^* contains a large multiplicity of states associated with the pinning of fronts as some branches wind toward γ^*. This region also contains a large multiplicity of branches beyond those already discussed, referred to as multipulse branches [29]. Figure 9 shows two heteroclinic cycles emerging monotonically from γ^* toward small amplitude. The simplest of these is $A_{L,a}^{\text{even}}$, consisting of two bound heteroclinic connections from $A = 0$ to A_u^+ (Figure 9(c)). The second slightly more complicated cycle, $A_{L,a}^{\text{odd}}$, consists of three parts: a heteroclinic connection from $A = 0$ to A_u^+, followed by a connection from A_u^+ to $-A_u^+$, and finally a connection from $-A_u^+$ back to $A = 0$ (Figure 9(f)). The existence of the front between A_u^+ and $-A_u^+$ at γ^* is a result of pinning and is responsible for the series of saddle-nodes as the large amplitude Ising

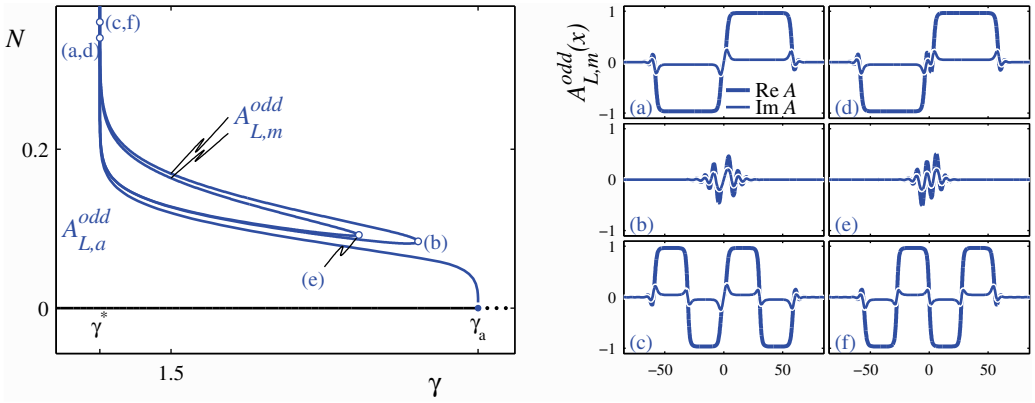

Figure 28. *Bifurcation diagram for $\nu \gg \nu_\beta$ in Region* III$^-$*, showing branches of odd multipulse states $A^{\rm odd}_{L,m}$ together with the branch $A^{\rm odd}_{L,a}$ of odd single-pulse states. Parameters:* $\mu = -0.5$, $\alpha = 1$, $\beta = 2$, $\nu = 2$; (a),(c),(d),(f) $\gamma = 1.437$; (b) $\gamma = 1.715$; (e) $\gamma = 1.663$.

fronts approach γ^* (Figure 25). In fact, the connection between A^+_u and $-A^+_u$ in Figure 9(f) is identical to the front profile shown in Figure 25(a). There are actually (infinitely) many fronts connecting $\pm A^+_u$ at γ^*, each of which can be used to assemble a different heteroclinic cycle at this point. All cycles assembled in this way consist of two pulses and are odd. Figures 28(a),(d) show two examples, assembled using the fronts shown in panels (b) and (c) of Figure 25, respectively. Figure 28 also shows the result of continuing these cycles numerically away from γ^* and toward small amplitude. The cycle $A^{\rm odd}_{L,a}$ is the only odd branch that terminates in a local bifurcation at γ_a. Both of the other branches of odd states shown in the figure terminate at saddle-node bifurcations in $\gamma^* < \gamma < \gamma_a$. The other branches that collide at these saddle-nodes also trace back to γ^*; these are also odd but consist of four pulses—not two. These four-pulse states can each be decomposed into a heteroclinic cycle made of five fronts. The profile shown, for example, in Figure 28(c) consists of a front from $A = 0$ to A^+_u, followed by three fronts between A^+_u and $-A^+_u$, and finally a front from $-A^+_u$ back to $A = 0$. Of the three intermediate fronts, two correspond to the profile shown in Figure 25(a) and the third to the profile shown in Figure 25(b). We refer to these odd parity localized multipulse states in general as $A^{\rm odd}_{L,m}$.

Pinning also causes the branch of large amplitude localized states $A_{L,b}$ shown in Figure 20 to approach γ^* in a series of saddle-node bifurcations, resulting in an infinite series of orbits homoclinic to A^+_u at γ^*. These profiles are shown in Figure 21. These homoclinic orbits can be used to assemble additional heteroclinic cycles at γ^* which have even parity, corresponding to even multipulse localized states $A^{\rm even}_{L,m}$. The profiles of two such cycles are shown in Figures 29(a),(d) and are assembled using the localized states shown in Figures 21(a),(b), respectively. Figure 29 shows the result of numerically continuing these even heteroclinic cycles away from γ^*; the branch $A^{\rm even}_{L,a}$ is shown for reference. As before, we find that the branches of two-pulse states terminate in $\gamma^* < \gamma < \gamma_a$ in saddle-node bifurcations involving other branches which, when followed back to γ^*, correspond to even heteroclinic cycles that are yet more complex. For example, the profile shown in Figure 29(c) consists of five parts: a homoclinic orbit to

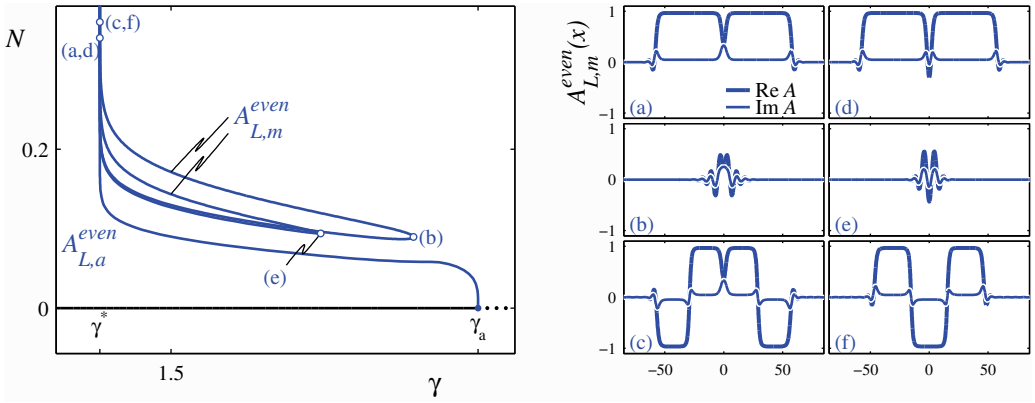

Figure 29. *Bifurcation diagram for $\nu \gg \nu_\beta$ in Region* III$^-$*, showing branches of even multipulse states $A^{\rm even}_{L,m}$ together with the branch $A^{\rm even}_{L,a}$ of even single-pulse states. A_u^+ sandwiched between two heteroclinic fronts connecting $\pm A_u^+$ and two more heteroclinic connections from A_u^- to $A = 0$.

The description of multipulse states is more complicated when $\nu < \nu_\alpha$ and the bifurcation from $A = 0$ to localized states occurs at γ_0 instead of γ_a, and depends on the location of γ^* relative to γ_a. When $\gamma^* < \gamma_a$, the multipulse states in the neighborhood of γ^* can be assembled as described above, but when these states are numerically continued into $\gamma > \gamma^*$, they do not collide pairwise in saddle-node bifurcations. Instead the multipulse branches all terminate at the Belyakov–Devaney point γ_a, which lies between γ^* and γ_0. As the branches approach γ_a, the distance between the individual pulses that make up each profile is large and they interact only weakly. When instead $\gamma^* > \gamma_a$, the large amplitude localized states and fronts approach γ^* monotonically. In this case no small amplitude multipulse states are present.

The results in Figures 28 and 29 give a glimpse of the large number of complex multipulse localized states biasymptotic to $A = 0$ that are present near γ^* when the large amplitude states experience pinning. Likewise, at parameter values for which the small amplitude localized states experience pinning ($\gamma_d < \gamma^*$) it is possible to assemble these pieces into complex heteroclinic cycles that asymptote to $\pm A_u^+$. These can be followed away from γ^* to large amplitude. An example is shown in Figure 19. Evidently the A_L profile shown in Figure 19(f) can now be interpreted as a *heteroclinic* cycle to A_u^+ involving three parts: two fronts on either side of a localized state. Although many complex heteroclinic cycles can be assembled in this manner, we find numerically that it is difficult to continue all but the simplest ones away from γ^*. Should any multipulse branches of this type exist in $\gamma < \gamma^*$, we expect that they terminate pairwise above γ_d when this is a Turing bifurcation and at γ_d when it is a Belyakov–Devaney point.

4. Self-excited oscillatory regime. In this section we describe solutions to (3.1) in the self-excited oscillatory case, $\mu > 0$. In this case we refer to the five regions of the (α, β) plane shown in Figure 3 as Regions I$^+$–V$^+$. As in the damped case, the bifurcation to uniform

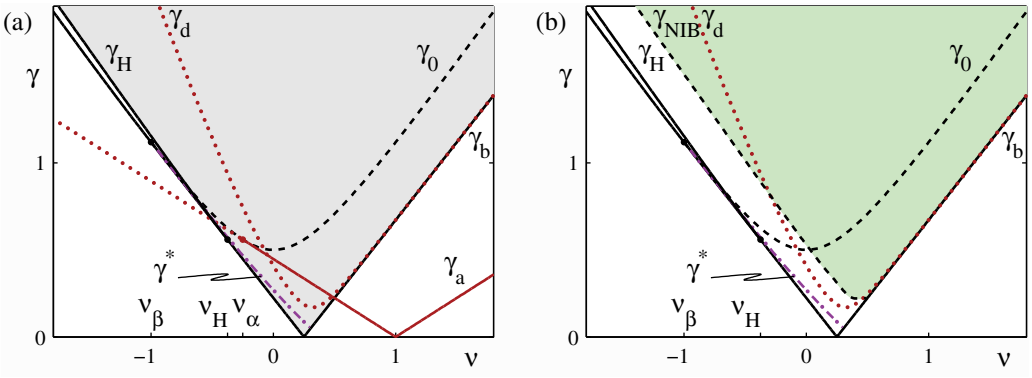

Figure 30. *The (ν,γ) plane in Region I^+. In* (a) *shading indicates the presence of stable uniform states A_u^+. In* (b) *the curve $\gamma=\gamma_{NIB}$ marks the location of the nonequilibrium Ising–Bloch bifurcation which forms the left boundary of the SIF region (shaded). Parameters: $\mu=0.5$, $\alpha=2$, $\beta=0.5$. For these parameters, $\nu_z=2.75$ and falls outside the range shown.*

phase-locked states at γ_0 is supercritical when $\nu<\nu_\beta$ and subcritical when $\nu>\nu_\beta$. But in the self-excited case $\nu_\beta<0$, and the boundary of the resonance tongue in the (ν,γ) plane differs qualitatively from that in the damped case, extending down to $\gamma_b=0$ at $\nu=\beta\mu$ (Figure 2(b)). Each region is described below. For each region we describe the stability of the uniform solutions in both t and x. We next consider the effect of the sign change in μ on the analytical predictions of localized states and fronts, and then present numerical results which show the extent in the (ν,γ) plane of stable states of either type.

4.1. Region I^+. The resonance tongue in this region is shown in Figure 30(a). When $\mu>0$ the $A=0$ state is always unstable to a range of wavenumbers owing to the presence of a $k=0$ Hopf bifurcation; the A_u^- state is also everywhere unstable. However, we expect that when $|\mu|$ is small the effect of changing the sign of μ should be confined to small amplitude states. Indeed, we find that the A_u^+ state remains stable at sufficiently large γ, although it may lose stability with decreasing γ. This loss of stability defines a (new) boundary of the resonance tongue and may arise in one of two ways. When $\nu<\nu_H$,

$$\nu_H\equiv-\frac{(1-\beta^2)}{2\beta}\mu, \tag{4.1}$$

the uniform phase-locked states A_u^+ lose stability at a $k=0$ Hopf bifurcation that occurs at $\gamma=\gamma_H$, where

$$\gamma_H^2=\gamma_b^2+\rho_b^2\left[\frac{\mu}{2}-|A_u^+(\gamma_b)|^2\right]^2. \tag{4.2}$$

The curve $\gamma=\gamma_H$ is shown in Figure 30(a) and forms the lower stability boundary for the uniform phase-locked states when $\nu<\nu_H$. At $\nu=\nu_H$ this curve is tangent to γ_b, and the Hopf bifurcation turns into a Takens–Bogdanov bifurcation. Note that $\nu_H>\nu_\beta$ for all values of β, independent of α. It follows that the above description of the Hopf bifurcation in Region I^+

also applies in Regions II^+–V^+. The dispersion relation (3.19) shows that the Hopf bifurcation occurs when

$$\mu - 2|A_u^+(\gamma_H)|^2 = 0 \tag{4.3}$$

and hence only in $\mu > 0$.

The second possibility is that, as γ decreases, the A_u^+ state loses stability with respect to a Turing bifurcation at $\gamma = \gamma_d$. Equation (3.26) for the location of this bifurcation remains valid in $\mu > 0$ and applies provided the critical wavenumber k_d in (3.27) is real. In Region I^+ the Turing bifurcation is present in $\nu > \nu_z$, at which point the curve $\gamma = \gamma_d$ is tangent to the line $\gamma = \gamma_b$. Between ν_H and ν_z the uniform phase-locked states remain stable down to the boundary of the resonance tongue at the saddle-node at γ_b. Thus the A_u^+ phase-locked state is stable in a subregion of the resonance tongue defined by $\gamma > \gamma_H$ when $\nu < \nu_H$, $\gamma > \gamma_b$ when $\nu_H < \nu < \nu_z$, and $\gamma > \gamma_d$ when $\nu > \nu_z$.

The analysis of the spatial eigenvalues in the damped case also applies to the self-excited case. Since $\alpha > 0$ in Region I^+, the spatial eigenvalue structure shown in Figure 5(a) applies to the $A = 0$ state when $\nu < \nu_\alpha$, and that shown in Figure 5(b) applies when $\nu > \nu_\alpha$. The spatial eigenvalues of the uniform phase-locked states in $\nu < \nu_\beta$, where A_u^+ bifurcates supercritically from γ_0, are shown in Figure 15(a). Since $z < 0$ in Region I^+, the spatial eigenvalues in the neighborhood of the saddle-node are as shown in Figure 16(b) whenever $\nu_\beta < \nu < \nu_z$ and, as shown in Figure 16(a), whenever $\nu > \nu_z$. Of course, the stability assignments in these figures do not necessarily carry over to the case $\mu > 0$.

Figure 30 also shows the location of the line $\gamma = \gamma^*$ at which heteroclinic connections between $A = 0$ and $A = A_u^+$ are present. The location of this line in the (ν, γ) plane differs qualitatively from the $\mu < 0$ case. As before, the line emerges from the tangency at ν_β, but because of the location of ν_β and the orientation of the resonance tongue, it extends toward smaller γ as ν increases and then terminates in a codimension-two point at which $\gamma^* = \gamma_b$, slightly above $\nu = \beta\mu$, where $\gamma_b = 0$. However, the line always lies below γ_d, and hence the spatial eigenvalues of the uniform phase-locked state A_u^+ at $\gamma = \gamma^*$ are real (of type (i)). As a result we do not expect localized solutions biasymptotic to $A = 0$ to exhibit pinning as the branch approaches γ^* and the profile fills with the A_u^+ state. The spatial eigenvalues of the $A = 0$ state at γ^* are also of type (i) near the tangency at ν_β, but γ^* crosses $\gamma = \gamma_a$ somewhere in $\nu_\beta < \nu < \nu_\alpha$, implying that in part of the domain in ν the spatial eigenvalues of the trivial state at γ^* are of type (ii). Thus the pinning which was responsible for the SRO and SSF regions in $\mu < 0$ may create similar structures in $\mu > 0$ as well.

Several of the analytical solutions described in section 3 also apply in Region I^+. We begin with the states bifurcating from the $A = 0$ state even though we expect these to inherit the instability of this state. The solution (3.14) describing the spatially periodic extended states $A_{P,a}$ bifurcating from γ_a is valid in Region I^+ when $\nu > \nu_\alpha$, but the sign of η_a and hence the nature of the bifurcation depends on the value of ν relative to $\alpha\mu$. This critical value corresponds to the point at which $\gamma_a(\nu) = 0$ and is easily located graphically in Figure 30. Below this value, the general expression for η_a in (B.7) reduces to $\eta_a = \alpha + \rho_\alpha > 0$, and the bifurcation to spatially periodic states is subcritical. Above $\nu = \alpha\mu$ we have instead $\eta_a = \alpha - \rho_\alpha < 0$, and the bifurcation is supercritical. In the former case there is in addition a subcritical bifurcation from γ_a to spatially localized states $A_{L,a}$ as described by (3.16); in the latter no such

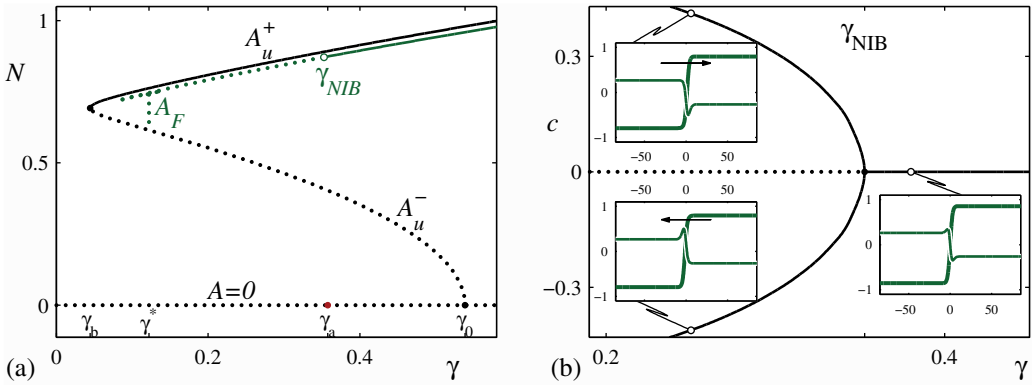

Figure 31. (a) *Bifurcation diagram in Region* I^+ *at a value of* ν *such that* $\gamma^* < \gamma_a$*, showing the branches of fronts* A_F *as well as the uniform states* $A_u^{\pm}$*. localized states are present. When ν lies below ν_α but above ν_β, (3.12) describes the branch of small amplitude spatially localized states $A_{L,0}^{\pm}$ which emerge subcritically from γ_0.

The branches of localized states, $A_{L,0}$ and $A_{L,a}$, can be followed away from their respective bifurcation points using numerical continuation. For values of ν for which heteroclinic cycles are present, $A_{L,0}$ and $A_{L,a}$ always approach γ^* monotonically in a manner very similar to that shown in Figures 8 and 9. This is consistent with the expectation based on the spatial eigenvalues of the A_u^+ state. However, the stability of these localized states in Region I^+ is different from that in the $\mu < 0$ case. As before, there is an unstable amplitude mode with a localized eigenfunction, but now there is in addition an infinite spectrum of unstable modes with extended eigenfunctions, corresponding to instabilities inherited from the background $A = 0$ state. There is also a range in ν, above the termination of the γ^* line but below $\nu = \alpha\mu$, in which the $A_{L,a}$ branch emerges subcritically from γ_a but no heteroclinic cycle is present. In this case the branch of localized states interacts instead with a secondary branch of spatially periodic states that bifurcate from the subcritical $A_{P,a}$ states. The details of this interaction and the (unstable) stationary states that result are beyond the scope of this paper but resemble related behavior already studied in the context of the Swift–Hohenberg equation [8].

An examination of the large amplitude localized states reveals several new examples of interesting behavior. Large amplitude Ising fronts are found in Region I^+ using the homotopy method described above. The starting point for this method is the branch of fronts $A_{F,0}$ in (3.33) which bifurcate supercritically from γ_0 when $\nu < \nu_\beta$ and extend to arbitrarily large γ. At other values of ν, the behavior of the branch of fronts as γ decreases depends on whether or not a heteroclinic cycle forms. When it does, the branch of fronts approaches γ^* either monotonically (near ν_β, where $\gamma^* > \gamma_a$ and the spatial eigenvalues of $A = 0$ are real) or in a series of saddle-nodes (when $\gamma^* < \gamma_a$ and these eigenvalues are complex). An example of the

latter is shown in Figure 31(a). The front profiles that make up this branch look similar to those shown in Figure 24. At large γ these correspond to monotonic Ising fronts between A_u^+ and $-A_u^+$ but near γ^* the profiles become structured and eventually approach a heteroclinic cycle involving the state $A = 0$ as the branch approaches γ^* in a series of saddle-nodes. But in Region I^+, all the fronts that exist near γ^* are unstable due to a nonequilibrium Ising–Bloch (NIB) bifurcation [11] at $\gamma_{NIB} > \gamma^*$, where the Ising fronts lose stability with respect to an (even) phase mode. Below γ_{NIB} stability is transferred to a pair of counterpropagating Bloch fronts, distinguished from the stationary Ising fronts by their lack of odd parity. As shown in Figure 31(b) the speed c of the resulting Bloch fronts increases as the square root of the distance from γ_{NIB} [11].

The motion of the Bloch fronts is shown in Figure 32. When two such fronts traveling in opposite directions collide, they annihilate; fronts traveling in the same direction move at identical speeds and therefore never collide. We surmise that the pinning mechanism discussed in section 3.5 for Ising fronts also applies to Bloch fronts, although a detailed description of this mechanism will be given elsewhere. We have, however, found examples of Bloch fronts whose drift velocity is identically zero (i.e., pinned Bloch fronts) and in the neighborhood of such states identified stationary localized states similar to the LBF states described above (Figure 27) but resembling bound Bloch fronts.

At sufficiently large values of ν where no heteroclinic cycle forms, the branch of Ising fronts annihilates instead with a branch of kinks in a saddle-node bifurcation, as shown previously in Figure 26. The region of existence of SIFs in Region I^+ is shown in Figure 30(b). Above $\nu \approx 0.5$ the Ising fronts are stable all the way down to the saddle-node, where they join with the kinks. Below this value of ν the fronts always lose stability with respect to an NIB bifurcation prior to the saddle-node bifurcation. The line $\gamma = \gamma_{NIB}$ is shown in Figure 30(b) and forms the boundary of the SIF region. The figure shows that the NIB bifurcation prevents the formation of a wedge of *stable* structured front (SSF) states around γ^*.

A similar story applies with regard to the large amplitude localized states in Region I^+. When $\nu_\beta < \nu < \nu_z$ and the eigenvalue structure near the saddle-node is of the type shown in

Figure 16(a), (3.34) describes the branch of localized states biasymptotic to A_u^+ which bifurcate from the saddle-node at γ_b. Above ν_z the spatial eigenvalues of the uniform phase-locked states are as shown in Figure 16(b), and in this case γ_d is a bifurcation point producing the states described by (3.35) and (3.36). We find numerically that in this region the coefficients a_d and b_d are again strictly positive and hence that the bifurcation at γ_d is always subcritical, with the spatially periodic and localized states emerging into $\gamma > \gamma_d$. In either case the global behavior of the $A_{L,b}$ and $A_{L,d}$ branches depends on whether a heteroclinic cycle forms. When no such cycle forms, these branches extend to arbitrarily large γ and are always unstable. In contrast, when it does form, the branch of localized states approaches the associated γ^* either monotonically or in a series of saddle-nodes as in the example shown in Figure 20. But unlike the earlier examples, in Region I^+ the branch of localized states does not change stability at each saddle-node: as expected the broad localized states resembling heteroclinic cycles between $A = A_u^+$ and $A = 0$ inherit the instability of the $A = 0$ state, but even the narrow profiles, such as the analogue of the profile shown in Figure 21(b), are unstable. In time these unstable localized states evolve into deeper localized states that split into two (Bloch) fronts and drift away from each other. Thus, despite the multiplicity of localized states present in this region, no wedge of *stable* reciprocal oscillons (SROs) around γ^* results.

4.2. Region II^+. The behavior in Region II^+ mimics that of Region I^+, including the presence and general orientation of the line γ^*. The one notable difference is that the Turing bifurcation of the uniform phase-locked states A_u^+ at γ_d is absent in this region. Thus the large amplitude localized states always bifurcate from the saddle-node at γ_b. But the important conclusions regarding the presence of the NIB bifurcation, the extent of the SIF region, and the lack of SSF and SRO regions still apply.

4.3. Region III^+. The resonance tongue in Region III^+ is shown in Figure 33(a). The existence and stability of the uniform phase-locked states are similar to those in Region I^+. At large γ these are stable. Above ν_H the stable region extends all the way to the boundary of the resonance tongue at γ_b, while below ν_H the stable region extends only down to γ_H, where the uniform state loses stability with respect to a Hopf bifurcation. In Region III^+ the Turing bifurcation at γ_d, present when ν lies between ν_α and ν_z, falls below the Hopf bifurcation and is therefore never part of the boundary of the stable uniform states.

The γ^* line in Region III^+ is drastically different when compared to Regions I^+ and II^+. In this case it is created in a codimension-two point at which $\gamma^* = \gamma_b$ and extends to arbitrarily large γ as ν increases. Because γ^* always lies below γ_a, the spatial eigenvalues of $A = 0$ at γ^* are complex. As a result branches of large amplitude localized states approach γ^* in a series of saddle-nodes. Unlike Regions I^+ and II^+, in Region III^+ *some* of the resulting localized states are stable despite the instability of the $A = 0$ state [47]. The shaded region in Figure 33(b) shows the location of this truncated SRO region. At large values of ν the branch of large amplitude localized states $A_{L,b}$ that emerges from the saddle-node at γ_b resembles that in Figure 20, including stability assignments: the branch is initially unstable with respect to a single (even) amplitude mode, and gains and loses stability repeatedly at successive saddle-node bifurcations as the branch winds toward γ^*. However, when the localized state becomes sufficiently wide, it loses stability in a Hopf bifurcation to an oscillatory mode with a spatially localized eigenfunction. Provided this instability occurs below the second saddle-node, the

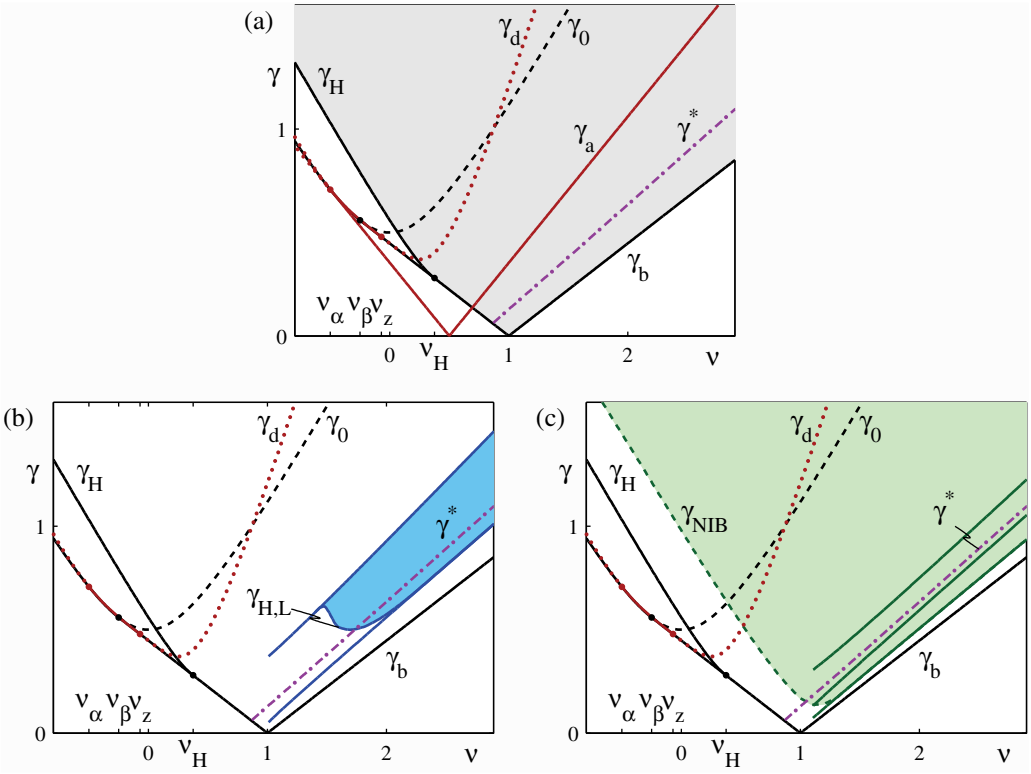

Figure 33. *The (ν,γ) plane in Region III^+. In* (a) *shading indicates the presence of stable uniform states A_u^+. In* (b) *shading indicates the SRO region, while in* (c) *it indicates the SIF region. The three unlabeled lines in* (c) *mark the first three saddle-nodes as the fronts approach γ^*. An SSF region exists near the γ^* line, between the second and third saddle-node, at larger values of ν. Parameters: $\mu = 0.5$, $\alpha = 1$, $\beta = 2$.*

SRO region spans the entire range between the first and second saddle-nodes. At large ν the Hopf bifurcation does in fact occur far "down" the $A_{L,b}$ branch, but as ν decreases this instability occurs farther "up" the branch. Figure 34 shows a bifurcation diagram at a value of ν sufficiently small that the Hopf bifurcation lies between the first two saddle-nodes. In this case the truncated SRO region extends only from the first saddle-node down to the localized Hopf bifurcation, labeled $\gamma_{H,L}$. Figure 33(b) shows that the line of localized Hopf bifurcations $\gamma = \gamma_{H,L}$ forms the boundary of the SRO region in the (ν,γ) plane. At sufficiently small ν the SRO region is completely absent because the Hopf bifurcation occurs before the first saddle-node. For reference, the location of the first two saddle-nodes is still indicated in the figure even when they do not correspond to the boundary of the SRO region.

The behavior of the fronts in Region III^+ is shown in Figure 33(c). In $\nu < \nu_\alpha$ the fronts $A_{F,0}$ emerge supercritically from γ_0 and extend to arbitrarily large γ. Using the homotopy method, we find that at large positive values of ν, where heteroclinic cycles are present, the complex eigenvalues of the $A = 0$ state result in front pinning and hence in the creation of structured fronts. At intermediate values of ν the branch of fronts terminates, as γ decreases, slightly above γ_b; here the branch becomes difficult to track numerically, and the nature of this bifurcation remains unclear. The fronts are stable at large γ and either lose stability in

an NIB bifurcation as γ decreases or, when ν is sufficiently large, remain stable down to the first saddle-node associated with the pinning region. As with the large amplitude localized states, the SSF region is truncated at small values of ν by a Hopf bifurcation. This bifurcation moves farther down the branch as ν increases and, at large values of ν (larger than the domain shown in Figure 33(c)), an SSF region does appear.

Although in this paper we are primarily interested in time-independent solutions of (2.2), it is noteworthy that some of the unstable localized states near γ^* are found to evolve in time into structures that remain spatially localized but are time-periodic. These oscillations are

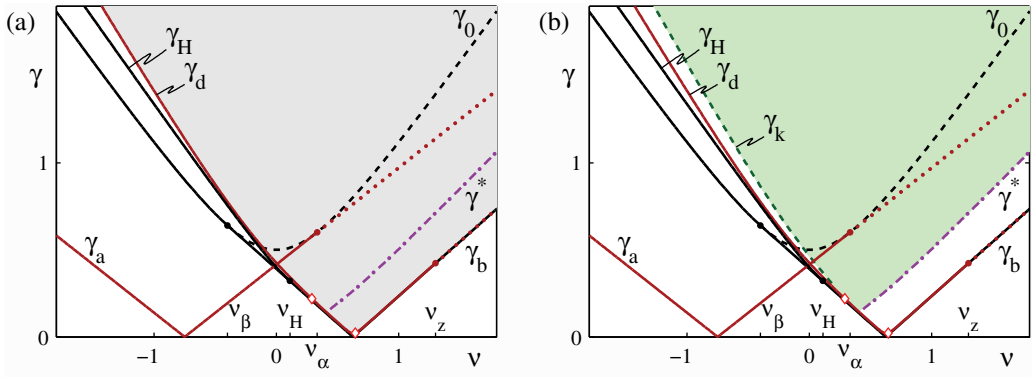

Figure 36. *The (ν,γ) plane in Region* IV$^+$. *In* (a) *shading indicates the presence of stable uniform states A_u^+, while in* (b) *it indicates the SIF region. confined to the inhomogeneous part of the profile, while the uniform part remains stationary (Figure 34(b)). Such states belong to the branch of localized periodic solutions (not shown) that emerges from the localized Hopf bifurcation at $\gamma_{H,L}$. In addition, the Hopf instability of the fronts in the neighborhood of γ^* leads to localized oscillating fronts (Figure 35). In either case the frequency of the oscillations is not in general rationally related to the driving frequency, and hence states of this type correspond to multifrequency oscillations of the observable w in the original system.

4.4. Region IV$^+$. The resonance tongue in Region IV$^+$, shown in Figure 36(a), resembles that in Region III$^+$, as does the location of the line $\gamma = \gamma^*$ in $\nu > \beta\mu$. However, since $\alpha < 0$ in Region IV$^+$ (and in Region V$^+$), the critical value ν_α is now positive, and the analytical result (3.14) describing the bifurcation at γ_a to spatially periodic states is valid in $\nu < \nu_\alpha$. In this range, the line $\gamma = \gamma_a$ is shown as a solid line to indicate that it corresponds to bifurcation points. For $\nu < \alpha\mu$, η_a reduces to $\alpha - \sqrt{1+\alpha^2} < 0$ and the bifurcation to spatially periodic states at γ_a is supercritical, while for $\nu > \alpha\mu$, η_a reduces to $\alpha + \sqrt{1+\alpha^2} > 0$ and the bifurcation is subcritical. In the former case no localized states are present near γ_a, while in the latter case there is in addition a subcritical bifurcation to spatially localized states $A_{L,a}$ as described by (3.16). Likewise, in $\nu > \nu_\alpha$ there is a subcritical bifurcation to spatially localized states $A_{L,0}$, as described by (3.12), which emerge from γ_0.

The uniform phase-locked states A_u^+ exist in $\gamma > \gamma_0$, $\nu < \nu_\beta$ and in $\gamma > \gamma_b$, $\nu > \nu_\beta$. The locations of the Hopf (γ_H, present in $\nu < \nu_H$) and Turing (γ_d, present in $\nu < \nu_z$) bifurcations of the uniform phase-locked states, as defined in (4.2) and (3.26), respectively, are also shown in the figure. An inspection reveals that γ_d always lies above γ_H. As a result the boundary of the stable uniform phase-locked states in $\nu < \nu_z$ is γ_d, and the Hopf bifurcation does not play an important role. Above ν_z the uniform states remain stable all the way to the saddle-node at γ_b.

Likewise, the spatial eigenvalues of the uniform phase-locked states are of the type shown in Figure 16(b) whenever $\nu < \nu_z$, in the range where γ_d is a bifurcation point. The spatially

periodic states $A_{P,d}$ described by (3.35) bifurcate subcritically (into $\gamma > \gamma_d$) over most of the domain. There is, however, a range of ν values for which this bifurcation is supercritical ($\gamma < \gamma_d$), as indicated in Figure 36(a). In the former case the coefficients a_d, b_d defined in Appendix D are both positive, and there is in addition a branch of spatially localized states $A_{L,d}$, given by (3.36), that emerges subcritically from γ_d. In the latter case $a_d > 0$ while $b_d < 0$, and no localized states bifurcate from γ_d. When $\nu > \nu_z$, the spatial eigenvalues in the neighborhood of γ_d and γ_b are described instead by Figure 16(a). In this case the localized states $A_{L,b}$ given by (3.34) emerge from the saddle-node.

The γ^* line for this region is also shown in the figure and emerges from a codimension-two point defined by $\gamma^* = \gamma_d$ that lies slightly below $\nu = \beta\mu$ (at which $\gamma_b = 0$). In contrast, in Region III$^+$ the analogous codimension-two point occurs at $\gamma^* = \gamma_b$. It is clear from the figure that the codimension-two point lies between the two $\diamond$'s where no localized states are known analytically, although a supercritical bifurcation to spatially periodic solutions $A_{P,d}$ is present. Because the γ^* line lies above γ_d in a region with complex spatial eigenvalues of the A_u^+ state, we expect branches of small amplitude localized states near γ^* to experience pinning. While this is confirmed numerically, these SSO-like states inherit the instability of the $A = 0$ background and are always unstable. Over the domain shown in the figure (up to about $\nu = 2$) the γ^* line lies below γ_a, in a region with complex spatial eigenvalues of the $A = 0$ state. Thus branches of large amplitude fronts and localized states near γ^* are expected to exhibit pinning. At larger values of ν the γ^* line crosses above γ_a, the spatial eigenvalues become real, and pinning cannot occur.

We consider first the behavior of the large amplitude localized states, found numerically by continuing one of the analytically known solutions. The localized states $A_{L,d}$ that emerge from γ_d below the leftmost $\diamond$ in the figure extend to arbitrarily large γ since, at these values of ν, no heteroclinic cycles form. The localized states $A_{L,d}$ that emerge from γ_d above the rightmost $\diamond$ in the figure, and the localized states $A_{L,b}$ that emerge from γ_b when $\nu > \nu_z$, always approach a heteroclinic cycle and do so as expected either in a series of saddle-node bifurcations or monotonically. These solutions are unstable near their creation at γ_d or γ_b to a single amplitude mode; as γ increases, an additional localized Hopf mode destabilizes the solutions below the γ^* line, thereby eliminating a potential SRO region.

As for the fronts, these exist at large γ and can be found using the homotopy method described above. Several types of behavior are observed as γ decreases. Below $\nu \approx 0.2$ the Ising fronts terminate in a saddle-node bifurcation involving kink fronts. Above $\nu \approx 0.5$ a heteroclinic cycle is present and the Ising fronts approach γ^* as expected either in a series of saddle-node bifurcations or monotonically. Between these two limits the behavior remains unclear. The Ising fronts are stable at large γ. At large negative values of ν these fronts remain stable down to the saddle-node bifurcation, where this branch merges with (unstable) kinks. At less negative values the Ising fronts appear to lose stability above this saddle-node to an NIB bifurcation. At large positive values of ν the Ising fronts also always lose stability with decreasing γ, this time to a localized Hopf mode. The Hopf instability occurs above the first saddle-node when the approach to γ^* is through a series of saddle-nodes and above γ^* when the approach is monotonic. As a result the boundary of the SIF region near γ^* consists of the line of localized Hopf bifurcations, and the structured fronts that may be present near γ^* are all unstable.

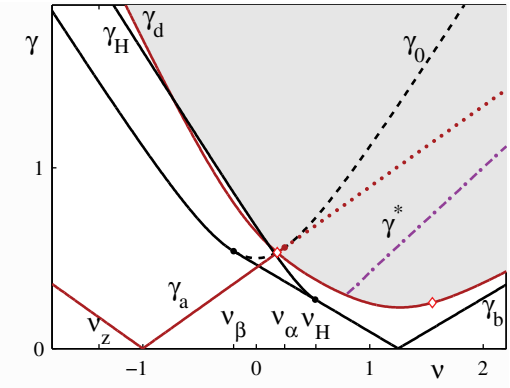

Figure 37. *The* (ν, γ) *plane in Region* V^+. *Parameters:* $\mu = 0.5$, $\alpha = -2$, $\beta = 2.5$.

In summary, Region IV^+ exhibits pinning of both small and large amplitude states near the γ^* line, leading to a multiplicity of spatially localized but *unstable* states in its vicinity, in regions resembling the SSO, SRO, and SSF regions already identified for $\mu < 0$.

4.5. Region V^+. The resonance tongue in Region V^+ is shown in Figure 37 and resembles Region IV^+. The main difference relates to γ_d. First, the tangency at ν_z is now absent, and hence γ_d is always a bifurcation point. It follows that the localized states $A_{L,b}$ emerging from the saddle-node at γ_b are never present in this region. Instead the branches of localized states $A_{L,d}$ emerge subcritically from γ_d, but only outside of the region marked by the two $\diamond$'s in the figure. Between these two points the bifurcation to spatially periodic states $A_{P,d}$ is supercritical, and no localized states are predicted by local analysis. The second major difference compared to Region IV^+ is that now the line γ_H of Hopf bifurcations of the uniform phase-locked states intersects the line γ_d (twice). Hence, there is a range in ν where the boundary of the stable uniform solutions is made up of γ_H instead of γ_d. The codimension-two points at which $\gamma_d = \gamma_H$ have not been studied, but an analogous interaction between a Turing bifurcation and a Hopf bifurcation of the $A = 0$ state has been considered [58, 59] and is known to create interesting dynamics.

The behavior of the fronts and localized states observed by continuing these states numerically also resembles that described for Region IV^+. Both large and small amplitude states approach the γ^* line in a series of saddle-nodes creating SSO-like, SRO-like, and SSF-like regions, but the resulting states are always unstable because the respective branch undergoes a localized Hopf or an NIB bifurcation before reaching γ^*.

5. Discussion and conclusions. The present study was largely motivated by the discovery in several distinct systems of subharmonic spatially localized temporal oscillations called oscillons [4, 40, 44, 52]. The experiments indicate that oscillons of this type are present inside the 2:1 resonance tongue, and it is natural in these circumstances to examine the vicinity of the boundary of this region, where homogeneous phase-locked oscillations coexist with the trivial state. This coexistence region is produced in response to the forcing and is found even in systems exhibiting supercritical dynamics in the absence of forcing. In the absence of primitive equations describing chemical or granular media, we have chosen to examine the

possible existence of spatially localized structures within the framework of the forced complex Ginzburg–Landau (FCGL) equation. This equation can be viewed as the normal form for periodically forced oscillations near the 2:1 resonance in extended dissipative systems. As such the FCGL equation describes the large-scale dynamics of all extended systems driven sufficiently close to the onset of a primary oscillatory instability by a sufficiently weak periodic force sufficiently close to the 2:1 temporal resonance. Within this equation the oscillon problem reduces to the study of time-independent spatially localized solutions for the amplitude of these oscillations; i.e., the background oscillation at half the forcing frequency is factored out. If this is restored and the corresponding states are recovered from (2.1), we see that the localized structures we have called standard oscillons do indeed resemble the type of localized temporal oscillation observed in the experiments, while the reciprocal oscillons resemble holes in a background that also oscillates with half the forcing frequency. Likewise, the Ising fronts [11] become phase kinks, connecting two nontrivial states oscillating exactly out of phase.

5.1. Summary of the results. Our study employs the technique of spatial dynamics. We have seen that this approach coupled with numerical branch following provides a powerful technique for analyzing problems of this type. The spatial dynamics approach allows us to view spatially periodic states as periodic orbits in space and identifies spatially localized states with homoclinic (oscillons) or heteroclinic (fronts) orbits. More importantly, this approach leads one to focus on the spatial eigenvalues of the spatially homogeneous states, and these in turn allow one to identify the parameter regimes where localized structures are likely and to interpret the large multiplicity of coexisting states as a consequence of a mechanism we refer to as pinning. The same mechanism is, in addition, responsible for stabilizing some of these states against time-dependent perturbations. As shown in the appendices, we have used bifurcations in the spatial eigenvalues to construct analytically both spatially periodic and spatially localized states, which can in turn be used to initialize numerical continuation. These techniques led us to identify parameter regimes in which the various localized structures are all organized around a special point in parameter space corresponding to the formation of a heteroclinic cycle in space. We have called this point γ^*. Among the results from our analysis are the following:

1. Identification of two distinct types of "small amplitude" oscillons, referred to collectively as standard oscillons. Both are biasymptotic to the rest state $A = 0$ as $x \to \pm\infty$. The first of these bifurcates from $A = 0$ at the phase-locking threshold γ_0 and resembles a single bump; near the heteroclinic cycle at γ^* these may be stable (SSO region in Regions IV^- and V^-). The second consists of localized spatial oscillations of even or odd parity that emerge from the Turing bifurcation at γ_a and are never stable.
2. Identification of two distinct types of "large amplitude oscillons," biasymptotic to A_u^+ or $-A_u^+$ as $x \to \pm\infty$, referred to collectively as reciprocal oscillons. The first of these emerges from the boundary of the fundamental 2:1 resonance tongue at γ_b and resembles a hole in a uniform background; near γ^* these may be stable (SRO region in Regions III^- and III^+). The second type is an even parity localized spatial oscillation on a uniform background that emerges from the Turing bifurcation at γ_d and is never stable.
3. Identification of two classes of large amplitude front-like states called Ising fronts and

Table 1

Summary of the behavior in the various regions of the (α, β) plane. Each region is defined uniquely by columns 2–5. In column 6 "yes" ("no") indicates the presence (absence) of a γ^* line. In column 7 "yes" indicates that an SSO region forms around a part of the γ^* line, "no" indicates that an SSO region is absent (either because there is no pinning at γ^*, or because additional instabilities eliminate stable standard oscillons), while "." indicates the absence of an SSO region due to the absence of the γ^* line. The same notation is used in column 8 to indicate the existence of SRO and SSF regions around γ^*. The final column emphasizes that an SIF region is always present, regardless of the presence of γ^*.

Region		sgn(μ)	sgn(α)	sgn($\alpha-\beta$)	sgn(z)	γ^* line	SSO region	SRO/SSF regions	SIF region
I^-		$-$	$+$	$+$	$-$	no	.	.	yes
II^-	(Fig. 6)	$-$	$+$	$+$	$+$	no	.	.	yes
III^-	(Fig. 7)	$-$	$+$	$-$	$+$	yes	no	yes	yes
IV^-	(Fig. 10)	$-$	$-$	$-$	$+$	yes	yes	no	yes
V^-	(Fig. 11)	$-$	$-$	$-$	$-$	yes	yes	no	yes
I^+	(Fig. 30)	$+$	$+$	$+$	$-$	yes	no	no	yes
II^+		$+$	$+$	$+$	$+$	yes	no	no	yes
III^+	(Fig. 33)	$+$	$+$	$-$	$+$	yes	no	yes	yes
IV^+	(Fig. 36)	$+$	$-$	$-$	$+$	yes	no	no	yes
V^+	(Fig. 37)	$+$	$-$	$-$	$-$	yes	no	no	yes

structured fronts, respectively; the latter possess internal structure in the front region (cf. [61]). These states are stable in regions called SIF (present in all five regions of the (α, β) plane) and SSF (present only in Regions III^- and III^+), respectively. The SRO and SSF regions overlap, while the SSO region is present for distinct parameter values.

4. Identification of a heteroclinic cycle at γ^* between the trivial and the phase-locked states A_u^+ in the subcritical region of the fundamental 2:1 resonance tongue, and elucidation of its role as an organizing center not only for the standard oscillons, but also for reciprocal oscillons and structured fronts. In addition, a variety of more complex states referred to as multipulse states also emanates from the vicinity of γ^*.
5. Detailed discussion of the differences between the damped ($\mu < 0$) and self-excited ($\mu > 0$) cases, and in particular between the stability properties of the localized structures in these two cases; identification of stable large amplitude fronts even in the absence of a heteroclinic cycle, including pinned and moving Bloch fronts.

The existence and stability results for localized states are summarized in the broadest terms in Table 1. Regions I–V are defined in terms of analytically accessible properties of the spatially uniform phase-locked states only. As a result, the existence and stability regions of some of the other states may extend across the region boundaries.

5.2. Connection to experiments. The standard oscillons observed, for example, in vertically vibrated granular media [52] resemble the single bump standard oscillons identified in the FCGL equation (2.2). In the first explanation of this phenomenon, a second field was required to stabilize states of this type [51]. The present work shows that this type of standard oscillon can be stable in damped driven systems even in the absence of a second field (SSO region in Regions IV^- and V^-).

In contrast, experiments on the optically forced BZ reaction [40, 44] have revealed the

presence of spot-like structures embedded in a background state that oscillates 180° out of phase with the spot. These states resemble the states we have called reciprocal oscillons and, in particular, the states $A_{L,b}$ and A_L shown in Figures 18(c) and 19(d),(e), respectively. However, our results indicate that these states are unstable unless the parameters are chosen to lie in Region III$^+$, close to γ^*, with $\nu \gg \nu_\beta$ (Figure 33(b)). Thus it may be more likely that the observed spots may in fact correspond to the bound fronts A_{LBF} shown in Figure 27, should states of this type prove to be stable.
