Existing experiments on the BZ system [40] also reveal that the diameter of the observed reciprocal oscillons is comparable to the width of the Ising fronts connecting out-of-phase spatially homogeneous oscillations. The experiments reveal, moreover, that the reciprocal oscillons exist in a narrow parameter range near the onset of labyrinthine patterns, which in turn form as finite amplitude patterns near the boundary of the 2:1 resonance tongue [4, 60]. These results are in qualitative agreement with simulations of a modified version of (2.2) that includes interfacial tension [4]. In a companion paper [57] we present results of numerical integration of (2.2) in time in two spatial dimensions. These results suggest that the reciprocal oscillons and front-like structures described here in one spatial dimension possess analogues in two spatial dimensions and show that stable spot-like states and stable front-like phase kinks may indeed have similar widths and that both are found within the pinning region identified in one spatial dimension. We use these results to conjecture that the observed labyrinthine patterns are in fact the result of a transverse instability [4, 21, 22, 58] of the front-like states associated with the reciprocal oscillons in the pinning region. This aspect of the problem will be pursued in a future publication.

5.3. Future directions. From a broader theoretical perspective, the properties of the FCGL equation summarized above resemble those discussed at greater length for the Swift–Hohenberg equation (see [7] and references therein). This equation is also a bistable reversible fourth order system in space. However, there are important differences between the two sets of equations, the most significant being the fact that the Swift–Hohenberg equation is variational. Although the FCGL equation can be reduced to the Swift–Hohenberg equation in specific parameter regimes [4], in other regimes the stability properties of the two systems will in general differ. In particular, as we have seen in this paper, the FCGL equation can exhibit persistent time dependence, unlike the Swift–Hohenberg equation.

Although the Swift–Hohenberg equation is known to exhibit bistability between uniform states of the type studied in this paper, recent work on this equation has focused on the consequences of bistability between the trivial state and a spatially *periodic* state. As a result, the fronts that bound a spatially localized state at either side can lock to the underlying spatial structure, and the heteroclinic bifurcation opens out into a pinning *region*. This pinning region is defined by pairs of branches of localized states that snake back and forth across the Maxwell point, giving rise to a characteristic "snakes-and-ladders" structure [7, 8]. In contrast, when the bistability is between two spatially homogeneous states, pinning arises only from the oscillating *tails*. In this case the bounding fronts interact ever more weakly as the distance between them increases, and the pinning region necessarily collapses to the Maxwell point. Thus no true snaking occurs. Our study of the FCGL equation indicates that the variational structure, while helpful in the physical interpretation of the pinning region [8], is not a prerequisite for its presence in more general forced dissipative systems.

Indeed, our results indicate that similar behavior will be present in other systems exhibiting bistability between two spatially uniform states, provided that the system is reversible under spatial reflection and of fourth or higher order in space. The reversibility property renders the homoclinic connections corresponding to the standard and reciprocal oscillons structurally stable (codimension-zero) while making the creation of the heteroclinic cycle between $A = 0$ and $A = A_u^+$ of codimension one and hence is responsible for making the behavior associated with the pinning or snaking region of codimension one. In contrast, in nonreversible systems such as those describing traveling pulses in the comoving frame [62], homoclinic connections to homogeneous equilibria such as $A = 0$ and $A = A_u^+$ are of codimension one, while the formation of a pair of heteroclinic connections is of codimension two. Despite this difference, the behavior near each global connection, once formed, resembles that described here for the FCGL equation [62].

The detailed survey of spatially localized oscillations presented in this paper provides the necessary theoretical background for future experimental and theoretical explorations of spatially extended parametrically driven dissipative systems and their association with structured fronts, Bloch fronts, and labyrinthine patterns.

Appendix A. Weakly nonlinear analysis near $\gamma = \gamma_0$. At $\gamma = \gamma_0$ the $A = 0$ state has two zero spatial eigenvalues and two nonzero spatial eigenvalues. In the following we assume that $\mu < 0$ and note that when $\alpha > 0$ and $\nu > \nu_\alpha$ the two nonzero eigenvalues are imaginary. In this case we do not expect localized states nearby (Figure 5(b)). On the other hand, if $\alpha > 0$, $\nu < \nu_\alpha$, the two nonzero eigenvalues are real and for $\gamma < \gamma_0$ the zero eigenvalues split along the real axis (Figure 5(a)). Thus localized states may exist in $\gamma < \gamma_0$. To find these states we write $\gamma = \gamma_0 + \epsilon^2\delta$, where $\epsilon \ll 1$ and δ is an order one quantity. Writing $A \equiv U + iV$, the appropriate expansion of the fields U and V is

$$\begin{bmatrix} U \\ V \end{bmatrix} = \epsilon \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} + \epsilon^3 \begin{bmatrix} u_3 \\ v_3 \end{bmatrix} \cdots , \tag{A.1}$$

where all quantities depend on x via the slow spatial variable $X \equiv \epsilon x$ only. With these scalings the linear operator in (3.1) becomes $\mathcal{L} = \mathcal{L}_0 + \epsilon^2\mathcal{L}_2$, where

$$\mathcal{L}_0 = \begin{bmatrix} \mu + \gamma_0 & -\nu \\ \nu & \mu - \gamma_0 \end{bmatrix}, \quad \mathcal{L}_2 = \begin{bmatrix} \delta & 0 \\ 0 & -\delta \end{bmatrix} + \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \partial_{XX}, \tag{A.2}$$

while the nonlinear operator becomes $\mathcal{N}(U, V) = \epsilon^2\mathcal{N}(u_1, v_1) + \ldots$.

At order ϵ stationary solutions to (3.1) satisfy

$$\mathcal{L}_0 \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \tag{A.3}$$

implying that

$$\begin{bmatrix} u_1 \\ v_1 \end{bmatrix} = \begin{bmatrix} \eta_0 \\ 1 \end{bmatrix} B(X), \tag{A.4}$$

where $\eta_0 \equiv (\gamma_0 - \mu)/\nu$ and $B(X)$ is a real-valued function of X. At order ϵ^3 we obtain

$$\mathcal{L}_0 \begin{bmatrix} u_3 \\ v_3 \end{bmatrix} = -\{\mathcal{L}_2 + \mathcal{N}(u_1, v_1)\} \begin{bmatrix} u_1 \\ v_1 \end{bmatrix}. \tag{A.5}$$

Since $\mathcal{L}_0$ is singular, (A.5) requires a solvability condition. The required condition is obtained by taking the scalar product of the equation with the adjoint null eigenvector of $\mathcal{L}_0$, viz.,

$$\Xi_0 = \begin{bmatrix} -\eta_0 & 1 \end{bmatrix}. \tag{A.6}$$

The result can be written in the form

$$a_0 B_{XX} = \delta B + b_0 B^3, \tag{A.7}$$

where $a_0 = \alpha(\nu - \nu_\alpha)/\gamma_0$, $b_0 = 2\beta(\nu - \nu_\beta)(\gamma_0 - \mu)/\nu^2$. This equation admits spatially homogeneous solutions $B = \sqrt{-\delta/b_0}$ or, equivalently,

$$\begin{bmatrix} U \\ V \end{bmatrix} = \begin{bmatrix} \eta_0 \\ 1 \end{bmatrix} \sqrt{\frac{\gamma_0 - \gamma}{b_0}} + \ldots, \tag{A.8}$$

where the omitted terms are of higher order in $|\gamma_0 - \gamma|$. This solution bifurcates supercritically when $b_0 < 0$ (i.e., $\nu < \nu_\beta$) and corresponds then to the A_u^+ states discussed in section 2. When $b_0 > 0$ (i.e., $\nu > \nu_\beta$) the bifurcation is subcritical and the homogeneous solutions then correspond to the A_u^- states.

Equation (A.7) also admits several different space-dependent solutions. Based on the eigenvalue analysis, we expect localized states only when $\nu < \nu_\alpha$, corresponding to $a_0 < 0$. When, in addition, $b_0 < 0$ (i.e., $\nu < \nu_\beta$), there is a supercritical bifurcation to front-like states of the form

$$\begin{bmatrix} U \\ V \end{bmatrix} = \begin{bmatrix} \eta_0 \\ 1 \end{bmatrix} \sqrt{\frac{\gamma - \gamma_0}{-b_0}} \tanh\left(\sqrt{\frac{\gamma - \gamma_0}{-2a_0}} x\right) + \ldots. \tag{A.9}$$

In contrast, when $b_0 > 0$ (i.e., $\nu > \nu_\beta$), there is a subcritical bifurcation to localized states of the form

$$\begin{bmatrix} U \\ V \end{bmatrix} = \begin{bmatrix} \eta_0 \\ 1 \end{bmatrix} \sqrt{\frac{\gamma_0 - \gamma}{b_0/2}} \operatorname{sech}\left(\sqrt{\frac{\gamma_0 - \gamma}{-a_0}} x\right) + \ldots. \tag{A.10}$$

Solutions of the latter type exist only if $\alpha < \beta$, i.e., in Region III (since $\alpha > 0$, by assumption). Evidently at fixed values of the parameters α, β, μ, ν at most one of these solution branches can be present.

Equation (A.7) has localized solutions analogous to (A.9) and (A.10) even when $a_0 > 0$ ($\nu > \nu_\alpha$) where localized states are not expected. This expectation is confirmed by the numerics: the approximate solutions constructed by the above method when $a_0 > 0$ cannot be extended away from $\gamma = \gamma_0$ and do not represent valid solutions of the original FCGL equation (2.2).

A similar discussion applies when $\alpha < 0$ but is omitted.

Appendix B. Weakly nonlinear analysis near $\gamma = \gamma_a$. At $\gamma = \gamma_a$ the four spatial eigenvalues of the $A = 0$ state collide at $\lambda = \pm ik_a$, each of double multiplicity, where

$$k_a \equiv \frac{\sqrt{\alpha(\nu - \nu_\alpha)}}{\rho_\alpha}. \tag{B.1}$$

As in the previous appendix we assume that $\mu < 0$, $\alpha > 0$. In this case, k_a is real when $\nu > \nu_\alpha$ and the eigenvalue collision occurs on the imaginary axis: below γ_a the eigenvalues form a complex quartet and above γ_a they are imaginary (Figure 5(b)). In the theory of reversible systems this situation is referred to as the reversible Hopf bifurcation [26], although here it takes place in space instead of time. The theory predicts the presence of localized states in $\gamma < \gamma_a$, consisting of oscillations with wavenumber k_a modulated on a large scale owing to the small real part of λ. In contrast, when $\nu < \nu_\alpha$, the wavenumber k_a is imaginary and the eigenvalue collision occurs on the real axis; thus no bifurcation occurs (Figure 5(a)).

To find the localized states expected when $\nu > \nu_\alpha$, we set $\gamma = \gamma_a + \epsilon^2\delta$, where $\epsilon \ll 1$ and δ is an order one quantity, and allow all quantities to depend on both the short scale x and the long scale $X = \epsilon x$. The appropriate expansion of the fields is

$$\begin{bmatrix} U \\ V \end{bmatrix} = \epsilon \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} + \epsilon^2 \begin{bmatrix} u_2 \\ v_2 \end{bmatrix} + \epsilon^3 \begin{bmatrix} u_3 \\ v_3 \end{bmatrix} \cdots . \tag{B.2}$$

With this scaling the linear operator in (3.1) becomes $\mathcal{L} = \mathcal{L}_0 + \epsilon\mathcal{L}_1 + \epsilon^2\mathcal{L}_2$, where

$$\mathcal{L}_0 = \begin{bmatrix} \mu + \gamma_a & -\nu \\ \nu & \mu - \gamma_a \end{bmatrix} + \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \partial_{xx}, \tag{B.3}$$

$$\mathcal{L}_1 = 2 \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \partial_x \partial_X, \quad \mathcal{L}_2 = \begin{bmatrix} \delta & 0 \\ 0 & -\delta \end{bmatrix} + \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \partial_{XX}, \tag{B.4}$$

while the nonlinear operator becomes $\mathcal{N}(U, V) = \epsilon^2\mathcal{N}(u_1, v_1) + \ldots$.

At order ϵ stationary solutions to (3.1) satisfy

$$\mathcal{L}_0 \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \tag{B.5}$$

and hence

$$\begin{bmatrix} u_1 \\ v_1 \end{bmatrix} = \begin{bmatrix} \eta_a \\ 1 \end{bmatrix} B(X)\, e^{ik_a x} + c.c., \tag{B.6}$$

where $B(X)$ is a complex-valued function of X and

$$\eta_a \equiv \alpha + \mathrm{sgn}(\nu - \alpha\mu)\rho_\alpha. \tag{B.7}$$

Since $\alpha > 0$ and $\nu > \nu_\alpha$, the argument of sgn(.) is always positive, and

$$\eta_a = \alpha + \rho_\alpha > 0. \tag{B.8}$$

Expression (B.1) for k_a is also obtained at this order.

The order ϵ^2 terms in (3.1) are

$$\mathcal{L}_0 \begin{bmatrix} u_2 \\ v_2 \end{bmatrix} = -\mathcal{L}_1 \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} \tag{B.9}$$

or

$$\mathcal{L}_0 \begin{bmatrix} u_2 \\ v_2 \end{bmatrix} = -2i\rho_\alpha k_a \begin{bmatrix} 1 \\ \eta_a \end{bmatrix} B_X e^{ik_a x} + c.c. \tag{B.10}$$

The solvability condition for this equation is obtained by taking the scalar product with the adjoint null eigenvector,

$$\mathbf{\Xi}_a = \begin{bmatrix} -\eta_a & 1 \end{bmatrix} e^{-ik_a x} + c.c., \tag{B.11}$$

and integrating over the real line. Since this condition is automatically satisfied, we solve (B.10) and obtain

$$\begin{bmatrix} u_2 \\ v_2 \end{bmatrix} = \begin{bmatrix} \eta_a \\ 1 \end{bmatrix} C(X) e^{ik_a x} + 2ik_a \frac{\rho_\alpha^2}{\gamma_a} \begin{bmatrix} 0 \\ 1 \end{bmatrix} B_X e^{ik_a x} + c.c., \tag{B.12}$$

where $C(X)$ is an arbitrary complex-valued function that may be set to zero.

Proceeding to order ϵ^3, we obtain

$$\mathcal{L}_0 \begin{bmatrix} u_3 \\ v_3 \end{bmatrix} = -\left\{\mathcal{L}_2 + \mathcal{N}(u_1, v_1)\right\} \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} - \mathcal{L}_1 \begin{bmatrix} u_2 \\ v_2 \end{bmatrix}. \tag{B.13}$$

The solvability condition for this equation takes the form

$$a_a B_{XX} = -\delta B - b_a B|B|^2, \tag{B.14}$$

where $a_a = 2\rho_\alpha^2 k_a^2/\gamma_a$, $b_a = 6\eta_a(\beta - \alpha)$. The spatially periodic solution $B = \sqrt{-\delta/b_a}\, e^{i\varphi}$, or, equivalently,

$$\begin{bmatrix} U \\ V \end{bmatrix} = 2 \begin{bmatrix} \eta_a \\ 1 \end{bmatrix} \sqrt{\frac{\gamma_a - \gamma}{b_a}} \cos\left(k_a x + \varphi\right), \tag{B.15}$$

is always present when $\nu > \nu_\alpha$ and bifurcates subcritically when $b_a > 0$ (i.e., $\beta > \alpha$) or supercritically when $b_a < 0$ (i.e., $\beta < \alpha$). The phase φ is arbitrary and is a result of spatial translation invariance of (2.2).

In addition to the periodic states, there are two other types of solutions that are possible, depending on the sign of the coefficient b_a. When $b_a < 0$ (i.e., $\beta < \alpha$), there is a supercritical bifurcation to front-like states of the form

$$\begin{bmatrix} U \\ V \end{bmatrix} = 2 \begin{bmatrix} \eta_a \\ 1 \end{bmatrix} \sqrt{\frac{\gamma - \gamma_a}{-b_a}} \tanh\left(\sqrt{\frac{\gamma - \gamma_a}{2a_a}} x\right) \cos\left(k_a x + \varphi\right). \tag{B.16}$$

These fronts connect two out-of-phase periodic states of the type described by (B.15). However, despite their intrinsic interest, solutions of this type cannot be computed by our techniques, and their role in the dynamics of (2.2) remains unclear. Solutions of this type are therefore omitted from all bifurcation diagrams.

In contrast, when $b_a > 0$ (i.e., $\beta > \alpha$), there is a subcritical bifurcation to localized states of the form

$$\begin{bmatrix} U \\ V \end{bmatrix} = 2 \begin{bmatrix} \eta_a \\ 1 \end{bmatrix} \sqrt{\frac{\gamma_a - \gamma}{b_a/2}} \operatorname{sech}\left(\sqrt{\frac{\gamma_a - \gamma}{a_a}} x\right) \cos\left(k_a x + \varphi\right), \tag{B.17}$$

and no front-like states are present. The spatial phase φ remains arbitrary at the level of (B.14), but this is no longer the case when terms beyond all orders are included. These terms select the phases $\varphi = 0, \pi/2, \pi, 3\pi/2$; these correspond to odd ($\phi = \pi/2, 3\pi/2$) and even ($\phi = 0, \pi$) solutions of (B.17); cf. [8].

Appendix C. Weakly nonlinear analysis near $\gamma = \gamma_b$. In this appendix we assume that $\mu < 0$, $z > 0$. In this case a saddle-node bifurcation involving the uniform phase-locked states A_u^+ and A_u^- occurs at $\gamma = \gamma_b$ whenever $\nu > \nu_\beta$. At this point the uniform state has two zero spatial eigenvalues and two nonzero spatial eigenvalues, and the nonzero eigenvalues are real provided $\nu > \nu_z$ (Figure 16(a)). Along the A_u^+ branch the zero eigenvalues split along the real axis, and localized states may exist in the form of orbits homoclinic to A_u^+. To find these states we write $\gamma = \gamma_b + \epsilon^2\delta$, where $\epsilon \ll 1$ and $\delta > 0$ is an order one quantity. With $A = U + iV$ the localized states of interest can be written in the form

$$\begin{bmatrix} U \\ V \end{bmatrix} = \begin{bmatrix} U \\ V \end{bmatrix}^+ + \begin{bmatrix} u \\ v \end{bmatrix}, \tag{C.1}$$

where the first term is the uniform phase-locked state A_u^+ and the second corresponds to the space-dependent terms that decay to zero as $x \to \pm\infty$.

Based on the scaling defined above the uniform phase-locked states A_u^+ can be approximated by the series

$$\begin{bmatrix} U \\ V \end{bmatrix}^+ = \begin{bmatrix} U_0 \\ V_0 \end{bmatrix} + \epsilon \begin{bmatrix} U_1 \\ V_1 \end{bmatrix} + \epsilon^2 \begin{bmatrix} U_2 \\ V_2 \end{bmatrix} + \dots, \tag{C.2}$$

where

$$\begin{bmatrix} U_0 \\ V_0 \end{bmatrix} = \begin{bmatrix} \eta_b \\ 1 \end{bmatrix} \Upsilon_0, \qquad \begin{bmatrix} U_1 \\ V_1 \end{bmatrix} = \sqrt{\delta} \begin{bmatrix} \xi_b \\ 1 \end{bmatrix} \Upsilon_1, \tag{C.3}$$

$$\eta_b = \beta + \operatorname{sgn}(\nu - \beta\mu)\rho_\beta, \quad \xi_b = \frac{\eta_b \nu + (1 - \beta\eta_b)|A_u(\gamma_b)|^2}{\nu - (\beta + \eta_b)|A_u(\gamma_b)|^2}, \tag{C.4}$$

$$\Upsilon_0 = \frac{|A_u(\gamma_b)|}{\sqrt{1 + \eta_b^2}}, \quad \Upsilon_1 = \operatorname{sgn}[\xi_b\eta_b + 1]\sqrt{\frac{\eta_b}{(\xi_b\eta_b + 1)(\xi_b - \eta_b)}}. \tag{C.5}$$

Since $\mu < 0$ and $\nu > \nu_\beta$, the argument of sgn(.) in (C.4) is always positive, and η_b reduces to

$$\eta_b = \beta + \rho_\beta. \tag{C.6}$$

The sign of the coefficient Υ_1 in (C.5) is chosen to ensure that the expansion in (C.2) corresponds to the A_u^+ state; the opposite sign yields the A_u^- state.

The second term in (C.1) can be expanded as

$$\begin{bmatrix} u \\ v \end{bmatrix} = \epsilon \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} + \epsilon^2 \begin{bmatrix} u_2 \\ v_2 \end{bmatrix} + \dots, \tag{C.7}$$

where all quantities depend on x via the slow spatial scale $X \equiv \epsilon^{1/2} x$. The linear operator in (3.1) takes the form $\mathcal{L} = \mathcal{L}_0 + \epsilon \mathcal{L}_1 + \epsilon^2 \mathcal{L}_2$, where

$$\mathcal{L}_0 = \begin{bmatrix} \mu + \gamma_b & -\nu \\ \nu & \mu - \gamma_b \end{bmatrix}, \quad \mathcal{L}_1 = \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \partial_{XX}, \quad \mathcal{L}_2 = \begin{bmatrix} \delta & 0 \\ 0 & -\delta \end{bmatrix}, \tag{C.8}$$

while the nonlinear terms take the form $\mathcal{N} = \mathcal{N}_0 + \epsilon \mathcal{N}_1 + \epsilon^2 \mathcal{N}_2 + \dots$, where

$$\mathcal{N}_0 = -\begin{bmatrix} U_0 & V_0 \end{bmatrix} \begin{bmatrix} U_0 \\ V_0 \end{bmatrix} \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix}, \quad \mathcal{N}_1 = -2 \begin{bmatrix} U_0 & V_0 \end{bmatrix} \begin{bmatrix} U_1 + u_1 \\ V_1 + v_1 \end{bmatrix} \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix}, \tag{C.9}$$

$$\mathcal{N}_2 = -\left\{ \begin{bmatrix} U_1 + u_1 & V_1 + v_1 \end{bmatrix} \begin{bmatrix} U_1 + u_1 \\ V_1 + v_1 \end{bmatrix} + 2 \begin{bmatrix} U_0 & V_0 \end{bmatrix} \begin{bmatrix} U_2 + u_2 \\ V_2 + v_2 \end{bmatrix} \right\} \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix}. \tag{C.10}$$

At order ϵ^0 stationary solutions to (3.1) satisfy

$$\{\mathcal{L}_0 + \mathcal{N}_0\} \begin{bmatrix} U_0 \\ V_0 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \tag{C.11}$$

an equality that holds by virtue of the definition of U_0 and V_0. At order ϵ we obtain

$$\{\mathcal{L}_0 + \mathcal{N}_0\} \begin{bmatrix} U_1 + u_1 \\ V_1 + v_1 \end{bmatrix} = -\{\mathcal{L}_1 + \mathcal{N}_1\} \begin{bmatrix} U_0 \\ V_0 \end{bmatrix}. \tag{C.12}$$

The X-independent terms in this equation cancel by virtue of the definition of U_1 and V_1, leaving

$$\left\{ \mathcal{L}_0 + \mathcal{N}_0 - 2 \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \begin{bmatrix} U_0^2 & U_0 V_0 \\ U_0 V_0 & V_0^2 \end{bmatrix} \right\} \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{C.13}$$

Thus

$$\begin{bmatrix} u_1 \\ v_1 \end{bmatrix} = \begin{bmatrix} \xi_b \\ 1 \end{bmatrix} B(X), \tag{C.14}$$

where $B(X)$ is an unknown real-valued function of X.

Proceeding to order ϵ^2, we obtain

$$\{\mathcal{L}_0+\mathcal{N}_0\}\begin{bmatrix}U_2+u_2\\V_2+v_2\end{bmatrix}=-\{\mathcal{L}_1+\mathcal{N}_1\}\begin{bmatrix}U_1+u_1\\V_1+v_1\end{bmatrix}-\{\mathcal{L}_2+\mathcal{N}_2\}\begin{bmatrix}U_0\\V_0\end{bmatrix}. \tag{C.15}$$

Again the X-independent terms cancel. The solvability condition for this equation is obtained by taking the scalar product with

$$\Xi_b=\begin{bmatrix}-\eta_b & 1\end{bmatrix} \tag{C.16}$$

to eliminate the u_2, v_2 terms, leaving

$$a_b B_{XX}=b_b\left(2V_1B+B^2\right), \tag{C.17}$$

where

$$a_b=1+\alpha\xi_b+\alpha\eta_b-\eta_b\xi_b,\quad b_b=-\frac{\Upsilon_0(1+\eta_b^2)}{\Upsilon_1^2}. \tag{C.18}$$

The latter quantity is always negative. Equation (C.17) admits spatially homogeneous solutions $B=-2V_1$, or

$$\begin{bmatrix}U\\V\end{bmatrix}=\begin{bmatrix}U_0\\V_0\end{bmatrix}-\epsilon\begin{bmatrix}U_1\\V_1\end{bmatrix}+\dots, \tag{C.19}$$

corresponding to the other branch of uniform phase-locked states, A_u^-. In addition, (C.17) admits a branch of X-dependent localized states

$$B(X)=-3\Upsilon_1\sqrt{\delta}\,\mathrm{sech}^2\left\{\left(\frac{\Upsilon_1\sqrt{\delta}}{2a_b/b_b}\right)^{1/2}X\right\} \tag{C.20}$$

corresponding to

$$\begin{bmatrix}U\\V\end{bmatrix}=\begin{bmatrix}U\\V\end{bmatrix}^{+}-3\Upsilon_1\sqrt{\gamma-\gamma_b}\begin{bmatrix}\xi_b\\1\end{bmatrix}\mathrm{sech}^2\left\{(\gamma-\gamma_b)^{1/4}\left(\frac{\Upsilon_1}{2a_b/b_b}\right)^{1/2}x\right\}. \tag{C.21}$$

The two spatial eigenvalues of the $B=0$ state in (C.17) correspond to those described previously in (3.32), providing a relation between the eigenvalue analysis and asymptotic analysis:

$$\frac{\Upsilon_1 b_b}{2a_b}=\frac{|A_u(\gamma_b)|^2}{\Lambda_b^2}\frac{\rho_\beta}{\rho_\alpha^2}\sqrt{2\gamma_b}. \tag{C.22}$$

It follows that the solution (C.21) exists whenever the order one spatial eigenvalues at the saddle-node bifurcation are real, which is consistent with the assumptions made at the beginning of this appendix. In addition, (C.22) yields a useful relation between the sign of Λ_b^2 and

the signs of Υ_1 and a_b.

Appendix D. Weakly nonlinear analysis near $\gamma = \gamma_d$. In this appendix we assume that $\mu < 0$ and $z > 0$. In this case, when the bifurcation at γ_0 is supercritical, the four spatial eigenvalues of the A_u^+ branch are either all real or all imaginary between γ_0 and γ_d, and likewise between γ_b and γ_d when the bifurcation at γ_0 is subcritical. At γ_d these eigenvalues collide pairwise on either the real or the imaginary axis and form a complex quartet for $\gamma > \gamma_d$. When this collision occurs on the imaginary axis, γ_d corresponds to a bifurcation from which localized states may emerge in the form of orbits homoclinic to A_u^+ in $\gamma > \gamma_d$. To find these states we write $\gamma = \gamma_d + \epsilon^2\delta$, where $\epsilon \ll 1$ and δ is an order one quantity. With $A = U + iV$ the localized states of interest can be written

$$\begin{bmatrix} U \\ V \end{bmatrix} = \begin{bmatrix} U \\ V \end{bmatrix}^+ + \begin{bmatrix} u \\ v \end{bmatrix}, \tag{D.1}$$

where the first term corresponds to the uniform phase-locked states and the second to the x-dependent terms, which decay to zero as $x \to \pm\infty$.

Based on the scaling defined above, the uniform phase-locked states A_u^+ can be approximated by the series

$$\begin{bmatrix} U \\ V \end{bmatrix}^+ = \begin{bmatrix} U_0 \\ V_0 \end{bmatrix} + \epsilon^2 \begin{bmatrix} U_2 \\ V_2 \end{bmatrix} + \dots, \tag{D.2}$$

while the x-dependent terms can be expanded as

$$\begin{bmatrix} u \\ v \end{bmatrix} = \epsilon \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} + \epsilon^2 \begin{bmatrix} u_2 \\ v_2 \end{bmatrix} + \epsilon^3 \begin{bmatrix} u_3 \\ v_3 \end{bmatrix} + \dots. \tag{D.3}$$

All quantities in (D.3) depend on both the short spatial scale x and the long spatial scale $X \equiv \epsilon x$. The linear operator in (3.1) takes the form $\mathcal{L} = \mathcal{L}_0 + \epsilon\mathcal{L}_1 + \epsilon^2\mathcal{L}_2$, where

$$\mathcal{L}_0 = \begin{bmatrix} \mu + \gamma_d & -\nu \\ \nu & \mu - \gamma_d \end{bmatrix} + \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \partial_{xx}, \tag{D.4}$$

$$\mathcal{L}_1 = 2 \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \partial_{Xx}, \quad \mathcal{L}_2 = \begin{bmatrix} \delta & 0 \\ 0 & -\delta \end{bmatrix} + \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \partial_{XX}, \tag{D.5}$$

while the nonlinear terms take the form $\mathcal{N} = \mathcal{N}_0 + \epsilon\mathcal{N}_1 + \epsilon^2\mathcal{N}_2 + \epsilon^3\mathcal{N}_3 + \dots$, where

$$\mathcal{N}_0 = -(U_0^2 + V_0^2) \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix}, \tag{D.6}$$

$$\mathcal{N}_1 = -2(u_1U_0 + v_1V_0) \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix}, \tag{D.7}$$

$$\mathcal{N}_2 = -\left\{ \begin{bmatrix} u_1 & v_1 \end{bmatrix} \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} + 2 \begin{bmatrix} U_0 & V_0 \end{bmatrix} \begin{bmatrix} U_2 + u_2 \\ V_2 + v_2 \end{bmatrix} \right\} \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix}, \tag{D.8}$$

$$\mathcal{N}_3 = -2\left\{ \begin{bmatrix} U_0 & V_0 \end{bmatrix} \begin{bmatrix} u_3 \\ v_3 \end{bmatrix} + \begin{bmatrix} u_1 & v_1 \end{bmatrix} \begin{bmatrix} U_2 + u_2 \\ V_2 + v_2 \end{bmatrix} \right\} \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix}. \tag{D.9}$$

At order ϵ^0 stationary solutions to (3.1) satisfy

$$\{\mathcal{L}_0+\mathcal{N}_0\}\begin{bmatrix}U_0\\V_0\end{bmatrix}=\begin{bmatrix}0\\0\end{bmatrix}, \tag{D.10}$$

implying that

$$\begin{bmatrix}U_0\\V_0\end{bmatrix}=\begin{bmatrix}\eta_d\\1\end{bmatrix}\Upsilon_0, \tag{D.11}$$

where

$$\eta_d=\frac{\nu-\beta|A_u^+(\gamma_d)|^2}{\mu+\gamma_d-|A_u^+(\gamma_d)|^2},\quad \Upsilon_0=\frac{|A_u^+(\gamma_d)|}{\sqrt{1+\eta_d^2}}. \tag{D.12}$$

At order ϵ we obtain

$$\{\mathcal{L}_0+\mathcal{N}_0\}\begin{bmatrix}u_1\\v_1\end{bmatrix}=-\mathcal{N}_1\begin{bmatrix}U_0\\V_0\end{bmatrix} \tag{D.13}$$

or

$$\mathcal{M}\begin{bmatrix}u_1\\v_1\end{bmatrix}=\begin{bmatrix}0\\0\end{bmatrix}, \tag{D.14}$$

where

$$\mathcal{M}\equiv\mathcal{L}_0+\mathcal{N}_0-2\begin{bmatrix}1&-\beta\\\beta&1\end{bmatrix}\begin{bmatrix}U_0^2&U_0V_0\\U_0V_0&V_0^2\end{bmatrix}. \tag{D.15}$$

The critical wavenumber k_d given in (3.27) is determined by the solvability condition for this equation. With this condition satisfied, the solution is

$$\begin{bmatrix}u_1\\v_1\end{bmatrix}=\begin{bmatrix}\xi_d\\1\end{bmatrix}\left\{Be^{ik_dx}+\bar{B}e^{-ik_dx}\right\}, \tag{D.16}$$

where

$$\xi_d=\frac{\nu-\alpha k_d^2-\beta|A_u^+(\gamma_d)|^2+2(U_0V_0-\beta V_0^2)}{\mu+\gamma_d-k_d^2-|A_u^+(\gamma_d)|^2-2(U_0^2-\beta U_0V_0)} \tag{D.17}$$

and $B(X)$ is a complex-valued function of X.

Proceeding to order ϵ^2, we obtain

$$\{\mathcal{L}_0+\mathcal{N}_0\}\begin{bmatrix}U_2+u_2\\V_2+v_2\end{bmatrix}=-\{\mathcal{L}_1+\mathcal{N}_1\}\begin{bmatrix}u_1\\v_1\end{bmatrix}-\{\mathcal{L}_2+\mathcal{N}_2\}\begin{bmatrix}U_0\\V_0\end{bmatrix}. \tag{D.18}$$

The X-independent terms can be written in the form

$$\mathcal{M}\begin{bmatrix}U_2\\V_2\end{bmatrix}=-\begin{bmatrix}\delta&0\\0&-\delta\end{bmatrix}\begin{bmatrix}U_0\\V_0\end{bmatrix}. \tag{D.19}$$

It follows that the solution for U_2, V_2 takes the form

$$\begin{bmatrix} U_2 \\ V_2 \end{bmatrix} = \delta \begin{bmatrix} \tau_d \\ 1 \end{bmatrix} \Upsilon_2, \tag{D.20}$$

where the constants τ_d and Υ_2 are determined by solving (D.19):

$$\begin{bmatrix} \tau_d \\ 1 \end{bmatrix} \Upsilon_2 = -\mathcal{M}^{-1} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} U_0 \\ V_0 \end{bmatrix}. \tag{D.21}$$

Here $\mathcal{M}^{-1}$ refers to the inverse of $\mathcal{M}$ after setting the ∂_{xx} terms in this operator to zero. We do not give the explicit form for these constants, but they can be easily evaluated numerically for any set of parameter values.

The remaining X-dependent terms in (D.18) are

$$\mathcal{M} \begin{bmatrix} u_2 \\ v_2 \end{bmatrix} = -2 \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \partial_{xX} \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} + \left\{ 2 \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \begin{bmatrix} u_1^2 & u_1 v_1 \\ u_1 v_1 & v_1^2 \end{bmatrix} + (u_1^2 + v_1^2) \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \right\} \begin{bmatrix} U_0 \\ V_0 \end{bmatrix}. \tag{D.22}$$

With the Ansatz

$$\begin{bmatrix} u_2 \\ v_2 \end{bmatrix} = s_0 \begin{bmatrix} \chi_0 \\ 1 \end{bmatrix} |B_1|^2 + s_1 \begin{bmatrix} \chi_1 \\ 1 \end{bmatrix} \left\{ i B_X e^{ik_d x} - i \bar{B}_X e^{-ik_d x} \right\} + s_2 \begin{bmatrix} \chi_2 \\ 1 \end{bmatrix} \left\{ B_1^2 e^{2ik_d x} + \bar{B}_1^2 e^{-2ik_d x} \right\} \tag{D.23}$$

the coefficients s_i and χ_i are determined by solving (D.22) at each order in $e^{nik_d x}$ $(n = 0, 1, 2)$. For the $n = 0$ terms, the x-derivatives in the $\mathcal{M}$ operator vanish. If we call the resulting operator $\mathcal{M}_0$, the $n = 0$ part of the solution is given by

$$s_0 \begin{bmatrix} \chi_0 \\ 1 \end{bmatrix} = 2\mathcal{M}_0^{-1} \left\{ 2 \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \begin{bmatrix} \xi_d^2 & \xi_d \\ \xi_d & 1 \end{bmatrix} + (\xi_d^2 + 1) \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \right\} \begin{bmatrix} U_0 \\ V_0 \end{bmatrix}. \tag{D.24}$$

Similarly, for the $n = 2$ terms we define $\mathcal{M}_2$ by replacing ∂_{xx} in $\mathcal{M}$ by $-4k_d^2$. Then

$$s_2 \begin{bmatrix} \chi_2 \\ 1 \end{bmatrix} = \mathcal{M}_2^{-1} \left\{ 2 \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \begin{bmatrix} \xi_d^2 & \xi_d \\ \xi_d & 1 \end{bmatrix} + (\xi_d^2 + 1) \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \right\} \begin{bmatrix} U_0 \\ V_0 \end{bmatrix}. \tag{D.25}$$

Since the operator $\mathcal{M}_1$, defined by replacing ∂_{xx} in $\mathcal{M}$ by $-k_d^2$, is singular, the two components of the $n = 1$ equation,

$$s_1 \mathcal{M}_1 \begin{bmatrix} \chi_1 \\ 1 \end{bmatrix} + 2k_d \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \begin{bmatrix} \xi_d \\ 1 \end{bmatrix} = 0, \tag{D.26}$$

are linearly related, leading to the relation

$$s_1 = -2k_d \frac{\begin{bmatrix} 1 & 0 \end{bmatrix} \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \begin{bmatrix} \xi_d \\ 1 \end{bmatrix}}{\begin{bmatrix} 1 & 0 \end{bmatrix} \mathcal{M}_1 \begin{bmatrix} \chi_1 \\ 1 \end{bmatrix}}, \tag{D.27}$$

where χ_1 is arbitrary (subject to $\chi_1 \neq \xi_d$). Without loss of generality, we choose $\chi_1 = 0$.

Finally, at order ϵ^3 we obtain

$$\{\mathcal{L}_0 + \mathcal{N}_0\} \begin{bmatrix} u_3 \\ v_3 \end{bmatrix} = -\{\mathcal{L}_1 + \mathcal{N}_1\} \begin{bmatrix} U_2 + u_2 \\ V_2 + v_2 \end{bmatrix} - \{\mathcal{L}_2 + \mathcal{N}_2\} \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} - \mathcal{N}_3 \begin{bmatrix} U_0 \\ V_0 \end{bmatrix}. \tag{D.28}$$

The solvability condition at this order is obtained by multiplying this equation by the adjoint null eigenvector of $\mathcal{M}_1$ and integrating over x. This vector is given by

$$\begin{bmatrix} \Xi_d & 1 \end{bmatrix} e^{-ik_d x}, \tag{D.29}$$

where

$$\Xi_d = -\frac{\nu - \alpha k_d^2 - \beta |A_u^+(\gamma_d)|^2 - 2(\beta U_0^2 + U_0 V_0)}{\mu + \gamma_d - k_d^2 - |A_u^+(\gamma_d)|^2 - 2(U_0^2 - \beta U_0 V_0)}. \tag{D.30}$$

The resulting equation can be written

$$a_d B_{XX} = \delta B - b_d B |B|^2, \tag{D.31}$$

where

$$a_d = -f_1/f_2, \qquad b_d = -f_3/f_2, \tag{D.32}$$

and

$$f_1 = \begin{bmatrix} \Xi_d & 1 \end{bmatrix} \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \begin{bmatrix} \xi_d \\ 1 \end{bmatrix} - 2k_d s_1 \begin{bmatrix} \Xi_d & 1 \end{bmatrix} \begin{bmatrix} 1 & -\alpha \\ \alpha & 1 \end{bmatrix} \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \tag{D.33}$$

$$\begin{aligned} f_2 = \Upsilon_0 \Upsilon_2 \begin{bmatrix} \Xi_d & 1 \end{bmatrix} \Bigg\{ & -2 \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \begin{bmatrix} \tau_d \eta_d & \tau_d \\ \eta_d & 1 \end{bmatrix} - 2 \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \begin{bmatrix} \eta_d \tau_d & \eta_d \\ \tau_d & 1 \end{bmatrix} \\ & - 2(\eta_d \tau_d + 1) \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \Bigg\} \begin{bmatrix} \xi_d \\ 1 \end{bmatrix} + \begin{bmatrix} \Xi_d & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} \xi_d \\ 1 \end{bmatrix}, \end{aligned} \tag{D.34}$$

$$\begin{aligned} f_3 = -2\Upsilon_0 \begin{bmatrix} \Xi_d & 1 \end{bmatrix} \Bigg\{ & \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \left\{ s_0 \begin{bmatrix} \chi_0 \\ 1 \end{bmatrix} + s_2 \begin{bmatrix} \chi_2 \\ 1 \end{bmatrix} \right\} \begin{bmatrix} \xi_d & 1 \end{bmatrix} \\ & + \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \begin{bmatrix} \xi_d \\ 1 \end{bmatrix} \left\{ s_0 \begin{bmatrix} \chi_0 & 1 \end{bmatrix} + s_2 \begin{bmatrix} \chi_2 & 1 \end{bmatrix} \right\} \\ & + \left\{ s_0(1 + \xi_d \chi_0) + s_2(1 + \xi_d \chi_2) \right\} \begin{bmatrix} 1 & -\beta \\ \beta & 1 \end{bmatrix} \Bigg\} \begin{bmatrix} \eta_d \\ 1 \end{bmatrix} \\ & - 3(1 + \xi_d^2) \begin{bmatrix} \Xi_d & 1 \end{bmatrix} \begin{bmatrix} 1 & -\beta \\ \beta & -1 \end{bmatrix} \begin{bmatrix} \xi_d \\ 1 \end{bmatrix}. \end{aligned} \tag{D.35}$$

The solutions to (D.31) depend on the signs of the coefficients a_d and b_d. Regardless of the sign of a_d, there is always a solution of the form $B = \sqrt{\delta/b_d} e^{i\varphi}$, corresponding to spatially periodic states:

$$\begin{bmatrix} U \\ V \end{bmatrix} = \begin{bmatrix} U \\ V \end{bmatrix}^+ + 2 \begin{bmatrix} \xi_d \\ 1 \end{bmatrix} \sqrt{\frac{\gamma - \gamma_d}{b_d}} \cos(k_d x + \varphi). \tag{D.36}$$

When $b_d > 0$ these periodic states bifurcate subcritically, toward $\gamma > \gamma_d$; when $b_d < 0$ the bifurcation is supercritical, toward $\gamma < \gamma_d$. Equation (D.31) also has localized solutions of the form

$$\begin{bmatrix} U \\ V \end{bmatrix} = \begin{bmatrix} U \\ V \end{bmatrix}^{+} + 2 \begin{bmatrix} \xi_d \\ 1 \end{bmatrix} \sqrt{\frac{\gamma - \gamma_d}{b_d/2}} \operatorname{sech}\left\{ \sqrt{\frac{\gamma - \gamma_d}{a_d}} x \right\} \cos\left(k_d x + \varphi\right). \tag{D.37}$$

When both a_d and b_d are positive, these solutions bifurcate subcritically, toward $\gamma > \gamma_d$; when these coefficients are both negative, (D.31) suggests that the corresponding solutions bifurcate supercritically, toward $\gamma < \gamma_d$. However, based on the spatial eigenvalue analysis, we expect localized solutions only for $\gamma > \gamma_d$, and indeed no localized solutions to (2.2) in $\gamma < \gamma_d$ have been found. Thus the localized solutions of (D.31) correspond to solutions of (2.2) only when a_d and b_d are both positive.

Acknowledgments. A. Yochelis thanks Vered Rom-Kedar and the Department of Applied Mathematics and Computer Science, Weizmann Institute of Science, where some of this work was carried out.

Tangency Bifurcations of Global Poincaré Maps*

Clare M. Lee†, Pieter J. Collins‡, Bernd Krauskopf†, and Hinke M. Osinga†

Abstract. One tool to analyze the qualitative behavior of a periodic orbit of a vector field in $\mathbb{R}^n$ is to consider the Poincaré return map to an $(n-1)$-dimensional section. The image under the Poincaré map of a point on this section that lies near the periodic orbit is obtained by following the flow of the vector field until the next (local) intersection. It is well known that the Poincaré map defined on a section transverse to a periodic orbit is a diffeomorphism locally near the periodic orbit. However, in practice one often considers the Poincaré map not only locally but also on a much larger global and typically unbounded section. Generically, there are then points where the flow is tangent to the section, and these give rise to discontinuities of the Poincaré map. In fact, the orbits of some points may not even return to the section, in which case the Poincaré map is not defined at all. In this paper we study tangency bifurcations of invariant manifolds of Poincaré maps on global sections of vector fields in $\mathbb{R}^2$ and $\mathbb{R}^3$. At such a bifurcation the manifold becomes tangent to the section, which results in a qualitative change of the Poincaré map while the underlying flow itself does not undergo a bifurcation. Using tools from singularity theory, we present normal forms of the codimension-one tangency bifurcations in the neighborhood of the respective tangency point. The study of these bifurcations is motivated by and illustrated with the examples of the (unforced) Van der Pol oscillator and a system modeling a semiconductor laser with optical injection. Finally, we present a framework for the generalization of our normal-form results to arbitrary dimension and codimension.

1. Introduction.

In 1892 Henri Poincaré introduced the idea of a return map of a vector field—today generally referred to as a *Poincaré map*—while he was studying a restriction of the three-body problem [35, 36]. His aim was to find the motion of three bodies (one having negligible mass compared with the other two—for example, the Sun, Earth, and Moon) given only their initial positions, velocities, and masses. His work was fundamental for both the local and global analysis of nonlinear dynamical systems. In particular, he studied periodic orbits and their stability and introduced the first return map to a given local section as a new tool. In this setting the section in phase space is chosen transverse to the periodic orbit, and one considers the map that is defined locally on the section by following the flow until it

returns back to the section. The periodic orbit of the system corresponds to a fixed point of this Poincaré map. Since the Poincaré map is a diffeomorphism (a smooth map with a smooth inverse) in a neighborhood of this fixed point, the existence and stability analysis of periodic orbits in the full phase space reduces to the study of fixed points of local diffeomorphisms. This fact is used in the bifurcation analysis of periodic orbits in standard textbooks such as [17, 27, 39].

Today, the Poincaré map is a much-used tool in theoretical studies and in the evaluation of experiments alike. Generally speaking, one studies attractors and other invariant sets that one obtains by considering only the intersection points of the flow with a prespecified section. One way of obtaining such a representation is to plot measured quantities (for example, position, velocity, voltage, or current) whenever a designated quantity has a particular value, for example, when it crosses its average. Another common choice is to consider a section in the space of the first derivative of the flow and to plot the position of successive maxima/minima of the system; such maps can be seen, for example, in [1, 37]. In this way, one can illustrate classic transitions, such as the period-doubling route to chaos or the break-up of an invariant torus.

The above discussion already shows that in practice one typically chooses a suitable and typically unbounded section—we speak of a global section in this context. A common choice of global section is a (hyper)plane defined by one of the variables having a fixed value. The key point is that the first return map to the global section is not only defined locally with respect to an invariant set, which is why we refer to it as a *global Poincaré map*.

A special case is that of a stroboscopic map of a periodically forced system with angular frequency ω; well-known examples (see, for example, [17, 39]) include the forced damped pendulum and the forced Van der Pol and the forced Duffing oscillators. A periodically forced system can be written as an autonomous vector field by considering time t as another variable, which is, hence, periodic with period $2\pi/\omega$. The Poincaré section is then taken at $t = 2\pi/\omega$ so that the Poincaré map records the variables at regular time intervals. In a mechanical experiment, this can be achieved by stroboscopic illumination with the forcing frequency; hence we have the name stroboscopic map; see, for example, [6, 21]. Since the section is effectively taken in time and not in space, each orbit intersects the global section defined by $t = 2\pi/\omega$ and does so transversely. This means that the stroboscopic map is a well-defined global diffeomorphism on the entire section.

By contrast, for a vector field that is not periodically forced one cannot find a global section on which the Poincaré map is a global diffeomorphism. Given a general autonomous vector field and any global section Σ, there exists a nonempty set of codimension one—which we call the *tangency locus*—where the vector field is tangent to Σ; that is, the flow is not transverse to the section. Furthermore, there may be orbits that do not return to the section in forward or backward time. These two obstructions were already known to Birkhoff [3], who considered the problem of finding a Poincaré map in the context of Hamiltonian systems. His goal was to find a so-called complete section that is intersected by all trajectories so that the Poincaré map gives information about the entire dynamics. Birkhoff's result is that the Poincaré map is well defined, smooth, and complete if the section is such that the tangency locus is invariant under the first return; one also speaks of a Birkhoff section [11]. In this case it is sufficient to consider the Poincaré map on a compact region that is bounded by the tangency locus. For a

two-degree-of-freedom Hamiltonian system one obtains an area preserving map of the plane by means of restricting to a fixed-energy surface. However, for arbitrary Hamiltonian systems the condition that the tangency locus is invariant under the first return is not necessarily satisfied. To deal with this more general Hamiltonian situation, Dullin and Wittek [11] generalized Birkhoff's result by constructing what they call a W-section, which guarantees a weaker form of completeness in the sense that orbits either return to the W-section in finite time or have a limit in the W-section as time goes to infinity. Analyzing the properties of the associated Poincaré map requires the study of geometric properties of the flow in phase space in relation to the energy surface [4].

We consider here the properties of the Poincaré map on a global section of a general autonomous vector field, by which we mean that it does not have any special properties such as a Hamiltonian structure or preserved symmetries. Typically, there are regions of the section where the Poincaré first return map can be defined locally as a diffeomorphism by considering the kth return map to the global section for a suitable fixed k. Such regions are bounded by the tangency locus. Namely, the kth return map is discontinuous across the tangency locus. This fact was used in [22] to explain the emergence of an increasing number of discontinuities of the one-dimensional map approximation associated with a chaotic attractor, such as that of the Rössler system. However, when one allows the number of intersections k with the section to vary across the tangency locus, then the Poincaré map can be extended as a continuous map to an adjacent region. How the number k must be changed to ensure continuity of the Poincaré map can be determined from the condition that the integration time be continuous; see also [11]. This idea was used in [10] to compute one-dimensional invariant manifolds of the global Poincaré map across the tangency locus. By continuing orbit segments (with the associated integration time) as two-point boundary value problems it is possible to compute one-dimensional invariant manifolds of the global Poincaré map across the tangency locus without the need for manually changing the number k of returns to the section; see [13] for details and examples.

The specific topic addressed in this paper is the characterization of bifurcations of a global Poincaré map that do not correspond to bifurcations of the underlying flow. Such topological changes of the Poincaré map can be brought about either by changing a system parameter so that an invariant object changes in such a way that its intersection with the section is affected, or equivalently by changing the position of the section in the flow. Indeed, one needs to take some care to avoid drawing wrong conclusions from topological changes of phase portraits in a given section. A concrete example is the appearance of extra branches of intersections with a fixed section of a one-parameter family of periodic orbits. This may simply be due to the periodic orbit changing shape in the full phase space, which does not correspond to a bifurcation of the flow. The emergence of extra branches in a given section typically happens, for example, when the orbit approaches a saddle-focus equilibrium [16]. Another example is the intersection of an invariant torus with a section, which can take different forms, as is discussed in detail in section 4.

The invariant set in the Poincaré section may be even more complicated in applications. An example is the study by Peikert and Sadlo [32, 33] of one-dimensional invariant manifolds in a two-dimensional section through a vortex ring associated with a river power plant. The authors refer to "seemingly ring-shaped lobes [as] an artifact of the slice plane which does

not follow well the curved center line of the structure" [33, sect. 5.2]. Indeed, such "lobes" arise due to the way the section intersects a corresponding two-dimensional manifold, and this depends on the exact position of the section. In particular, the study of changes of the invariant set with the position of the section is important for the interpretation of experimental measurements, such as two-dimensional sections through a vortex structure by means of a laser sheet [14].

We consider here the bifurcations of a smooth invariant manifold of dimension ℓ as it interacts with a global section of a generic vector field with an n-dimensional phase space. We call these bifurcations *tangency bifurcations*, because they are generated by orbits that are tangent to the section at the bifurcation point. We analyze the tangency bifurcations locally, which means that there are no equilibria in the section. Therefore, we may consider a flowbox in a suitable neighborhood of the bifurcation point, which is simply a domain in phase space that is bounded by orbit segments and transverse codimension-one in- and out-sets. We use the flowbox theorem [31] to "straighten out" the flow by mapping it to the standard flowbox with parallel flow. Subsequently, we apply coordinate changes to map the section to a standard form as motivated by singularity theory; the key is to show that the coordinate changes can be chosen to preserve the flow lines in the standard flowbox. As a result, we obtain normal forms for the unfoldings of tangency bifurcations in terms of parameterized families of curved sections in the standard flowbox. Specifically, we treat all tangency bifurcations of codimension one for $n \leq 3$ and then discuss how the notion of a tangency bifurcation can be generalized for arbitrary n and ℓ.

Singularity theory has been used to classify special classes of dynamical systems, including impacting systems [9], piecewise-smooth systems [41], noninvertible maps (endomorphisms) of the plane [12, 18, 26], flows on manifolds with boundary [34, 38, 40], and diffeomorphisms with curves [5]. As is the case for any specific class of systems, singularity theory suggests normal forms, but it needs to be adapted to the situation at hand. In the case of a tangency bifurcation of a global Poincaré map, as studied here, this means the required coordinate transformation needs to map the section and the manifold to suitable normal forms, while also mapping the flow to the standard flow in the flowbox. In the absence of an invariant manifold (or when it is comprised of a single trajectory) we can make use of work by Sotomayor and Teixeira, who study generic flows on a manifold with a codimension-one boundary, namely, two-dimensional flows in [40] and three-dimensional flows in [38]. Sotomayor and Teixeira work in a completely general setting and investigate what conditions on the vector field and the section are needed for structural stability of the interaction between the flow and the boundary. We remark that by considering different ways of "completing" the flow on the other side of the boundary or Poincaré section, the results of Sotomayor and Teixeira and those presented here can also be applied to piecewise-smooth systems (where one defines a second flow as one wishes) [41] and to reversible systems (where the other flow is induced by an involution) [42]. Because in our setup the global section plays the role of their boundary, we can use the genericity results in [38, 40] for the context of tangency bifurcation of a global Poincaré map.

There are a number of ways in which our work differs from that of Sotomayor and Teixeira. First, they do not consider the flow on the "outside" of the boundary, while we are interested in the flow on both sides of the section. More importantly, we consider bifurcations of a "local piece" of an invariant one- or two-dimensional manifold in a local flowbox around a

bifurcation point. This piece of manifold could be part of a periodic orbit, invariant torus, or a stable or unstable manifold of a saddle object. While the tangency bifurcation remains locally the same, its global manifestation depends on the type of invariant manifold one is considering. For example, Sotomayor and Teixeira consider as separate the two cases that a periodic orbit or a one-dimensional separatrix has a tangency with the boundary, which we interpret as manifestations of the same interaction with the global section. Finally, two-dimensional invariant manifolds were not considered in [38]. By contrast, we present unfoldings of all tangency bifurcations of a two-dimensional invariant manifold with a two-dimensional Poincaré section. To this end, we first map the invariant manifold to a horizontal plane in the standard flowbox so that the section is deformed to a smooth surface. Our proofs then detail how to construct suitable coordinate transformations in the standard flowbox, where we distinguish between the direction of the flow and directions perpendicular to the flow. As a result, we obtain a normal form of the respective tangency bifurcation, which is unfolded by moving a smooth surface (that is, the section) up and down. We remark that, if one disregards the special direction given by the flow, tangencies between two smooth surfaces in $\mathbb{R}^3$ (or manifolds of codimension one, more generally) can be phrased in the language of divergent diagrams of smooth maps [29]. Here the manifold and the section are viewed as level sets of two smooth maps from $\mathbb{R}^3$ to $\mathbb{R}$, and singularity theory applied to this context yields normal forms as presented here. We stress again that the normal-form results obtained in [29] are not immediately applicable to tangency bifurcation of Poincaré maps because one must also show that the required coordinate changes can be chosen to respect the flow in the flowbox. Furthermore, the fact that the invariant manifold actually consists of trajectories is important: a tangency along a trajectory has different consequences for the Poincaré map than a tangency in the parameter direction.

In contrast to the mentioned theoretical studies, we not only present the unfoldings of the tangency bifurcations abstractly in a flowbox but also illustrate them with concrete examples of vector fields arising in applications. Specifically, we use the two-dimensional unforced Van der Pol oscillator to explain why a discontinuity arises in a kth return map and how a quadratic tangency bifurcation manifests itself for the classic case of a periodic orbit. Tangency bifurcations of two-dimensional invariant manifolds are illustrated with the example of a three-dimensional vector field model of a semiconductor laser with optical injection [44]. Specifically, we show how quadratic and cubic tangencies occur naturally in the intersection of a family of invariant tori with a planar section. Finally, we present a geometric model that explains how the cubic tangency as observed in a planar section for the injection laser can be transformed into the normal form in a flowbox.

This paper is organized as follows. In section 2 we discuss the motivation behind this paper and outline the problems that arise from globalizing a local Poincaré map; here we also provide formal definitions. In section 3 we consider the quadratic tangency bifurcation with a global section of a two-dimensional flow; this case is illustrated with the Van der Pol oscillator. Section 4 then deals with quadratic tangencies of invariant manifolds with a two-dimensional section of a three-dimensional flow; a model of a semiconductor laser with optical injection serves as a concrete example. In section 5 we consider the case of a cubic tangency bifurcation of a three-dimensional flow; what this bifurcation looks like in practice is again illustrated with the example of a semiconductor laser with optical injection. Section 6 discusses the

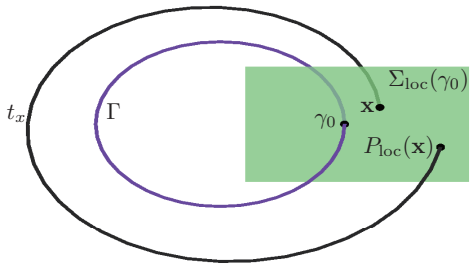

Figure 1. *A periodic orbit Γ intersecting a local section $\Sigma_{\rm loc}(\gamma_0)$ at the point γ_0. The local Poincaré map $P_{\rm loc}$ takes $\mathbf{x}$ to the next local intersection $P_{\rm loc}(\mathbf{x})$ with $\Sigma_{\rm loc}(\gamma_0)$.*

general case of a tangency bifurcation of an ℓ-dimensional manifold with a global section of an n-dimensional flow. Finally, in section 7 we draw some conclusions and discuss directions for future research.

2. Background and motivation.

Many readers will be familiar with the concept of a Poincaré map defined on a local section transverse to a periodic orbit. Consider a vector field

$$\dot{\mathbf{x}} = f(\mathbf{x}, \lambda), \quad \mathbf{x} \in X, \quad \lambda \in \mathbb{R}^m, \tag{2.1}$$

where X is the phase space, λ is a (vector-valued) parameter, and $f : X \to X$ is sufficiently smooth. For the purposes of this paper $X = \mathbb{R}^n$, where we mostly consider the cases $n = 2$ or $n = 3$. The flow associated with (2.1) is denoted by Φ, so that the orbit or trajectory through x is defined as

$$\mathcal{O}(x) = \{\Phi^t(x) \mid t \in \mathbb{R}\}. \tag{2.2}$$

We assume now that (2.1) has a periodic orbit Γ for some value of λ. Note that generically Γ is part of a (λ-dependent) family, but for the moment we consider the parameter λ as fixed. To obtain the standard definition of a local Poincaré map $P_{\rm loc}$, one chooses an $(n-1)$-dimensional submanifold Σ that intersects Γ transversely at an intersection point γ_0. The Poincaré map is then defined in some neighborhood $\Sigma_{\rm loc}(\gamma_0)$ of γ_0; see, for example, [27, 31]. A point $\mathbf{x} \in \Sigma_{\rm loc}(\gamma_0)$ is taken by the flow Φ to the next intersection of the forward trajectory $\{\Phi^t(\mathbf{x}) \mid \forall t \geq 0\}$ with $\Sigma_{\rm loc}(\gamma_0)$; see also Figure 1. That is,

$$\begin{aligned} P_{\rm loc} : \Sigma_{\rm loc}(\gamma_0) &\to \Sigma'_{\rm loc}(\gamma_0), \\ \mathbf{x} &\mapsto P_{\rm loc}(\mathbf{x}) := \Phi^{t_x}(\mathbf{x}), \end{aligned} \tag{2.3}$$

where $t_{\mathbf{x}} = \min\{t > 0 \mid \Phi^t(\mathbf{x}) \in \Sigma'_{\rm loc}(\gamma_0)\}$ is the time to the next local intersection and $\Sigma'_{\rm loc}(\gamma_0)$ is a neighborhood of $\Sigma_{\rm loc}(\gamma_0)$ such that $\Sigma_{\rm loc}(\gamma_0) \subseteq \Sigma'_{\rm loc}(\gamma_0)$. Note that γ_0 is a fixed point of $P_{\rm loc}$ and that $t_{\mathbf{x}}$ is close to the period of the periodic orbit Γ. Since the section Σ is chosen transverse to Γ at γ_0, it is always possible to choose $\Sigma_{\rm loc}(\gamma_0)$ such that $P_{\rm loc}$ is a well-defined diffeomorphism on $\Sigma_{\rm loc}(\gamma_0)$. Locally near γ_0 the dynamics of the vector field f are equivalent to the dynamics of $P_{\rm loc}$ on $\Sigma_{\rm loc}(\gamma_0)$ so that the local Poincaré map allows the study of basic bifurcations of the periodic orbit Γ; see, for example, [17, 27, 39].

In many applications, on the other hand, one is interested in more general invariant sets, including invariant tori and chaotic attractors. Therefore, one often considers some suitably chosen "large" and generally unbounded *global section* in phase space. For the purpose of this paper, we call Σ a global section if it is the image of a smooth embedding

$$F : \mathbb{R}^{n-1} \to \mathbb{R}^n, \tag{2.4}$$

where we assume that $F(\mathbb{R}^{n-1})$ divides the phase space $\mathbb{R}^n$ into two disjoint parts, that is to say, $|F(x)| \to \infty$ as $|x| \to \infty$. In other words, a global section $\Sigma = F(\mathbb{R}^{n-1})$ is a smooth manifold of dimension $n-1$ that is unbounded in all directions. Specifically, Σ is the unbounded image of the real line for $n = 2$ and of a two-dimensional plane for $n = 3$. It is common in applications to choose Σ simply as an $(n-1)$-dimensional hyperplane.

The *global Poincaré map* on the global section Σ is then defined as in (2.3), except that we now consider P on the entire global section Σ, that is,

$$\begin{aligned} P &: \Sigma \to \Sigma, \\ \mathbf{x} &\mapsto P(\mathbf{x}) := \Phi^{t_{\mathbf{x}}}(\mathbf{x}), \end{aligned} \tag{2.5}$$

where $t_{\mathbf{x}}$ is the time to first intersection with Σ; note that P is well defined at $\mathbf{x}$ if $0 \leq \inf\{t > 0 \mid \Phi^t(\mathbf{x}) \in \Sigma\} < \infty$.

As can already be inferred from Figure 1, a global section Σ typically has $k \geq 2$ intersections with a periodic orbit Γ. (Note that generically there is an even number of points in $\Gamma \cap \Sigma$.) In other words, the local Poincaré map P_{loc} defined on $\Sigma_{\text{loc}}(\gamma_0)$ coincides with the restriction to $\Sigma_{\text{loc}}(\gamma_0)$ of the kth iterate of the global Poincaré map as defined by (2.5). Indeed, P^k is a local diffeomorphism near any of the (transverse) intersection points of Γ with Σ.

It turns out that the global Poincaré map as defined by (2.5) is a diffeomorphism on the whole of Σ that describes the entire dynamics on $\mathbb{R}^n$ only under rather severe conditions (see, for example, [3, 30]), namely, only when

1. the flow Φ of (2.1) is transverse to Σ at every point $\mathbf{x} \in \Sigma$;
2. the forward orbit and the backward orbit through every point $\mathbf{x} \in \Sigma$ both have another intersection with Σ; and
3. every orbit of (2.1) intersects Σ.

In the literature Σ is often referred to as a global Poincaré section when these conditions are satisfied; see, for example, [45]. This is not to be confused with our notion of a global (i.e., nonlocal) section as defined in (2.4). Indeed, the above conditions are typically not satisfied for a global section in our sense.

Theorem 2.1. *For a generic vector field it is not possible to find a global Poincaré section Σ to which all points return and that is everywhere transverse to the flow, unless the phase space is a fibration over the circle.*

Theorem 2.1 is proved in [45] in two basic steps; see also [3, 7, 11, 30]. The first step is to show that if a global Poincaré section with the above properties exists, then the phase space X is topologically equivalent to the suspension manifold $[0,1] \times \Sigma/\!\sim$. Here, the quotient is taken with respect to the equivalence relation $\sim$, where $(0, x_1) \sim (1, x_2)$ for $x_1, x_2 \in \Sigma$ if $x_2 = P(x_1)$. The second step of the proof is to show that if Σ is a smooth manifold on which P is a diffeomorphism, then $[0,1] \times \Sigma/\!\sim$ can be written as a fibration over $\mathbb{S}^1$.

An immediate consequence of Theorem 2.1 is the following. Consider a generic vector field on $\mathbb{R}^n$. Then the vector field is equivalent to a periodically forced system if and only if one can find a global section $\Sigma = F(\mathbb{R}^{n-1})$ on which the Poincaré map is a diffeomorphism. In other words, diffeomorphisms on $\mathbb{R}^{n-1}$ correspond to periodically forced vector fields on $\mathbb{R}^n$ (written in autonomous form where time t is one of the axes). Indeed, periodically forced vector fields form an important subclass with well-known examples such as the forced damped pendulum, the forced Van der Pol equations, and the forced Duffing oscillator [17, 39]. The global Poincaré map in the sense discussed here is given as the stroboscopic map, that is, as the time-$2\pi/\omega$ map. The fact that the stroboscopic map is a global diffeomorphism is a particularly nice property of periodically forced vector fields. However, as was discussed above, this property is very special.

For a general (that is, not a periodically forced) vector field, there are points where the vector field is tangent to the global section Σ. This can already be deduced from the case of a section through a periodic orbit Γ. If one considers two consecutive (transverse) intersection points γ_0 and γ_1 of Γ with Σ, then the flow points in opposite directions (with respect to Σ) near γ_0 and γ_1, respectively. By continuity of the vector field, we must have at least one point on Σ where the vector field is tangent to the section. We define the *tangency locus* C as

$$C := \{\mathbf{x} \in \Sigma \mid f(\mathbf{x}) \cdot \vec{n}_\Sigma(\mathbf{x}) = 0\}, \tag{2.6}$$

where $\vec{n}_\Sigma(\mathbf{x})$ is the unit normal to Σ at the point $\mathbf{x}$. Note that if Σ is a hyperplane, the normal $\vec{n}_\Sigma(\mathbf{x})$ does not depend on $\mathbf{x}$. For the remainder of this paper we assume that $C \neq \emptyset$. It follows from the implicit function theorem [43] that C consists of smooth codimension-one submanifolds of Σ, provided that 0 is a regular point of $f(\mathbf{x}) \cdot \vec{n}_\Sigma(\mathbf{x})$. That is, for a one-dimensional section Σ ($n = 2$) the tangency locus C is generically a set of isolated points. For a two-dimensional section Σ ($n = 3$) it consists of smooth curves. Furthermore, in a two-dimensional section Σ there may be points of C where the flow has a cubic tangency (that is, a cusp singularity) with Σ; such points are generically isolated. These genericity statements follow from results by Sotomayor and Teixeira in [38, 40] on flows on two- and three-dimensional manifolds with boundary.

The importance of the tangency locus C lies in the realization that any kth-return map to Σ for any $k \geq 0$, that is, the Poincaré map P as defined by (2.5) or its kth iterate, is discontinuous across C; this was already noted by Birkhoff [3] in the context of Hamiltonian systems. The reason for this discontinuity is that the number of intersections with the section Σ changes due to the tangency; see also section 3.1. We remark that a kth-return map can be extended continuously across C, namely, by changing the number of global intersections and considering the $(k \pm 1)$st-return map in the adjoining region. The required number of global intersections is determined by the condition that the time $t_{\mathbf{x}}$ to the next (local) intersection depends continuously on the point $\mathbf{x}$ across C [10]; see also [11]. This approach of extending a Poincaré map across C by continuation of the entire orbit segment from Σ back to Σ, which includes the integration time $t_{\mathbf{x}}$, is especially useful when one wants to compute invariant manifolds of global Poincaré maps [13]. Note that a thus extended Poincaré map is only continuous across C but not smooth; see the discussion of Figure 3 in section 3.1. In other words, the existence of a tangency locus is indeed an obstacle to finding a Poincaré map that is a global diffeomorphism.

We consider here tangency bifurcations of the Poincaré map P on a global section Σ, which are characterized by the interaction of an invariant manifold M with the tangency locus $C \subset \Sigma$. The first step is to define an appropriate notion of topological equivalence.

Definition 2.2. *We are given two flows on two open neighborhoods U_1 and U_2 of $\mathbb{R}^n$ and $(n-1)$-dimensional smooth sections $\Sigma_1 \subset U_1$ and $\Sigma_2 \subset U_2$ with tangency loci C_1 and C_2, respectively. Suppose, further, that there are ℓ-dimensional invariant manifolds $M_1 \subset U_1$ and $M_2 \subset U_2$. We say that the flow on U_1 is* Σ-M-topologically equivalent *to that on U_2 if there exists a homeomorphism $h : U_1 \to U_2$ such that*

(E1) *h maps orbits in U_1 to orbits in U_2 and respects the direction of time;*
(E2) *h maps Σ_1 to Σ_2 and C_1 to C_2; and*
(E3) *h maps M_1 to M_2.*

Note that (E2) and (E3) ensure that $h|_{\Sigma_1}$ maps $M_1 \cap \Sigma_1$ to $M_2 \cap \Sigma_2$. For notational convenience, we refer to Σ-M-topological equivalence simply as topological equivalence in what follows. Similarly, we refer to the orbits of a flow on an open neighborhood U relative to $\Sigma, M \subset U$ simply as a phase portrait. Here we also assume that Σ divides U into two disjoint parts; this, by our definition of a global section, is satisfied for any sufficiently small U.

Following standard ideas of bifurcation theory [17, 27], we say that a phase portrait is structurally stable if any sufficiently close phase portrait is topologically equivalent. Here closeness between phase portraits is given by the C^1-topology of the underlying vector fields and the C^1-distance between the respective sections and invariant manifolds; compare with [38, 40]. Consequently, a bifurcation takes place when a phase portrait is not structurally stable, and it is of codimension $c \in \mathbb{N}$ if it is structurally stable in a c-parameter family (but not in a $(c-1)$-parameter family); one also speaks of an unfolding. Here two parameterized families of systems are topologically equivalent if the phase portraits of the two unfoldings are topologically equivalent according to Definition 2.2 and the underlying family of homeomorphisms can be chosen to depend continuously on the parameters.

Clearly bifurcations of the underlying flow in the usual sense (meaning that (E1) is violated) are also bifurcations of the Poincaré map P in the sense of Definition 2.2; these bifurcations are covered by standard bifurcation theory. However, there are new types of bifurcations in the sense of Definition 2.2, namely, those that correspond to violation of (E2) and/or (E3). Our interest here is in a class of such bifurcations—the tangency bifurcations—which are due to a qualitative change of $M \cap \Sigma$. In this paper we restrict to tangency bifurcations in $\mathbb{R}^n$ for $n \leq 3$ of codimension one, meaning that they occur structurally stably in one-parameter families. Tangency bifurcations do not involve equilibria in Σ so that we can consider the phase portrait in a flowbox near the interaction of the invariant manifold with the section. A flowbox does not contain any equilibria and is characterized by an in-set I and an out-set O transverse to the flow, with "sides" that consist of orbit segments. This is possible because a flow without equilibria is transient [34]; that is, each orbit leaves a compact connected manifold in finite positive and negative time. According to the flowbox theorem [31], the vector field in any given flowbox is conjugate (by means of a coordinate transformation that is as smooth as the vector field f) to parallel flow in the standard flowbox, which we define here for definiteness as

$$\left\{ \begin{array}{rcl} \dot{u} & = & 1, \\ \dot{v} & = & 0, \end{array} \right. \tag{2.7}$$

where $u \in [-1,1]$ and $v \in [-1,1]^{n-1}$. It follows that the standard in-set and the standard out-set are

$$I = \{u = -1\} \quad \text{and} \quad O = \{u = +1\}. \tag{2.8}$$

The basic idea behind transforming a given flowbox to the standard flowbox is that the flow lines are "straightened out." In the present setting, this means that the section Σ becomes curved. In other words, a normal form as considered here consists of a suitable family of curved sections that interact with a fixed invariant manifold, which is determined by a prespecified subset of the in-set I.

3. Two-dimensional flows.

We begin by explaining the main concepts with a concrete example in section 3.1, before presenting a general normal-form result in section 3.2.

3.1. The (unforced) Van der Pol oscillator.

As a concrete motivating example we consider the (unforced) Van der Pol oscillator [20, 39] of an RLC circuit, which is defined as the two-dimensional vector field

$$\begin{cases} \dot{x} &= y, \\ \dot{y} &= a(1-x^2)y - x, \end{cases} \tag{3.1}$$

where $a = 0.25$ is used throughout this paper. For this value of a, system (3.1) has an attracting periodic orbit Γ. As the global section we choose the horizontal line

$$\Sigma = \Sigma_s := \{(x,y) \in \mathbb{R}^2 \mid y = s\} \tag{3.2}$$

for some constant $s \in \mathbb{R}$. Figure 2 shows how the global section Σ (green) for $s = 1$ intersects the periodic orbit Γ (purple) transversely in two points, γ_0 and γ_1. Recall that a transverse intersection of Σ with Γ always leads to at least two intersection points, regardless of the choice of Σ. Near γ_0 the flow is upward through Σ, while near γ_1 it points down; at the points C the flow is tangent to Σ. Using (3.1) and (3.2), the points C at which the flow is tangent to Σ satisfy

$$\dot{y}|_{y=s} = 0 \quad \Leftrightarrow \quad \big(a(1-x^2)y - x\big)\big|_{y=s} = 0$$

so that

$$C = C(s) = \begin{cases} \{(0,0)\} & \text{if } s = 0, \\ \left\{\left(\frac{1 \pm \sqrt{1+4a^2s^2}}{-2as}, s\right)\right\} & \text{if } s \neq 0. \end{cases}$$

As is clear from this formula, changing the section a little (that is, a sufficiently small change of $s \neq 0$) does not lead to a qualitative change of the tangency set C. The two tangency points $(-2 \pm \sqrt{5}, 1)$ for $s = 1$ are labeled C in Figure 2. From the figure we can observe that the first intersection with Σ of the forward orbit $\mathcal{O}^+(\mathbf{x})$ of a point $\mathbf{x}$ below Σ (except for the equilibrium at the origin) always lies to the left of the tangency point $(-2 + \sqrt{5}, 1)$. In fact, in this case $\mathcal{O}^+(\mathbf{x})$ also always lies to the right of the other tangency point $(-2 - \sqrt{5}, 1)$. By contrast, the forward orbit of a point $\mathbf{x}$ above Σ intersects either to the left of $(-2 - \sqrt{5}, 1)$ or to the right of $(-2 + \sqrt{5}, 1)$, which depends on whether the orbit starts to the right or to the left of the backward orbit of the tangency point $(-2 - \sqrt{5}, 1)$. Note that this backward orbit divides the space into orbits that intersect Σ and orbits that miss.

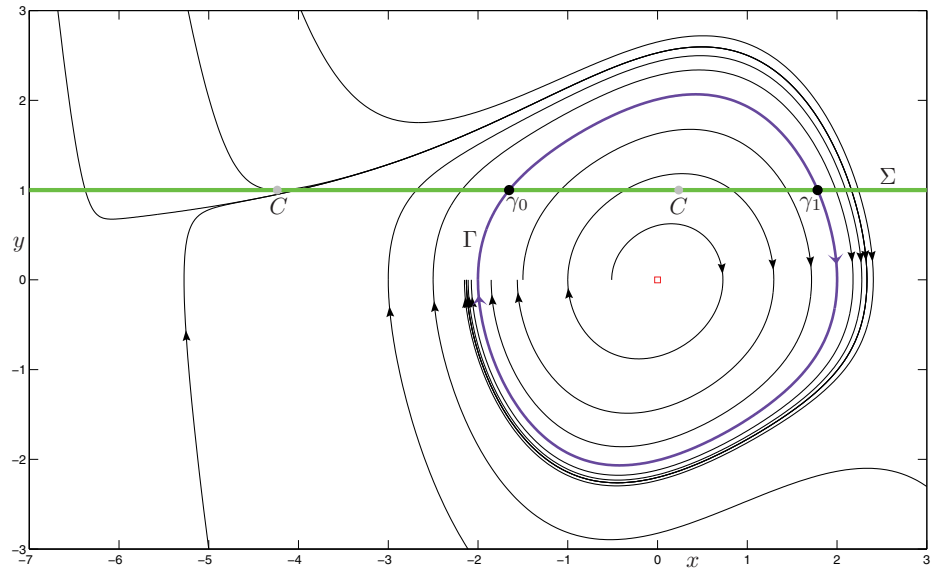

Figure 2. *Phase portrait of the (unforced) Van der Pol oscillator (3.1) for $a = 0.25$ with a global section Σ_1 (green line) at $y = 1$. The periodic orbit Γ (purple) intersects Σ_1 at the two points γ_0 and γ_1. The flow is tangent to Σ at the points denoted by C.*

Near γ_0 we can define a local Poincaré map P_{loc} on a local section $\Sigma_{\text{loc}}(\gamma_0) \subset \Sigma$, and similarly we can define P_{loc} near γ_1 on $\Sigma_{\text{loc}}(\gamma_1) \subset \Sigma$. Since there are two transverse intersections of Γ with Σ, we have $P_{\text{loc}} = P^2$ on both $\Sigma_{\text{loc}}(\gamma_0)$ and $\Sigma_{\text{loc}}(\gamma_1)$, where P is the global Poincaré map as defined by (2.5). Figure 3 illustrates that P^2 is indeed not a continuous map on the whole of Σ but is discontinuous at C. To see this we consider the tangency point $c := (-2 + \sqrt{5}, 1) \in C$. The image $P^2(c + \delta)$ of any point $c + \delta \in \Sigma_s$ for $\delta \geq 0$ lies closer to γ_1 than $c + \delta$. (The only exception is $P^2(\gamma_1) = \gamma_1$.) Note that $P^2(c)$ is the limit of $P^2(c + \delta)$ as $\delta \to 0$ and it lies closer to γ_1 than c. Now consider a point $c - \epsilon \in \Sigma$ for $\epsilon > 0$ small. As is shown in Figure 3, the image $P^2(c - \epsilon)$ lies closer to γ_0 than $c - \epsilon$. In the limit of $\epsilon \to 0$ the image $P^2(c-\epsilon)$ converges to $P^1(c)$ rather than to $P^2(c)$. Hence, P^2 is discontinuous across c.

It is straightforward to see that the discontinuity of P^2 is due to a discontinuity of the global Poincaré map P itself. Namely, we have that

$$\lim_{\epsilon \to 0} P(c - \epsilon) = c \neq P(c) = \lim_{\delta \to 0} P(c + \delta).$$

Note that this involves a discontinuity of the integration time, namely, the first-return time $t_{(c-\epsilon)}$ associated with $P(c - \epsilon)$ goes to 0 for $\epsilon \to 0$, while there is a nonzero integration time associated with the orbit segment connecting c with $P(c)$. As can be seen from Figure 3, the continuous extension of $P_{\text{loc}} = P^2$ from $\Sigma_{\text{loc}}(\gamma_1)$ across the point c to $\Sigma_{\text{loc}}(\gamma_0)$ is the map P^3. In particular, for this extension the integration time back to a local neighborhood of the section is continuous; see also [10, 13].

We now consider the interaction of the family of sections Σ_s with the periodic orbit Γ, that is, with an invariant manifold of the flow. As is shown in Figure 4, a codimension-one

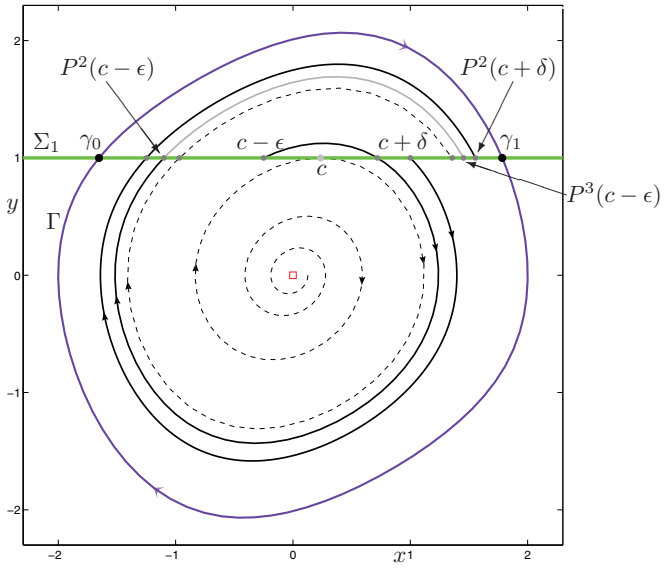

Figure 3. *Illustration of the discontinuity of P^2 for the Van der Pol oscillator (3.1) across a tangency point $c \in \Sigma_1$; compare with Figure 2.*

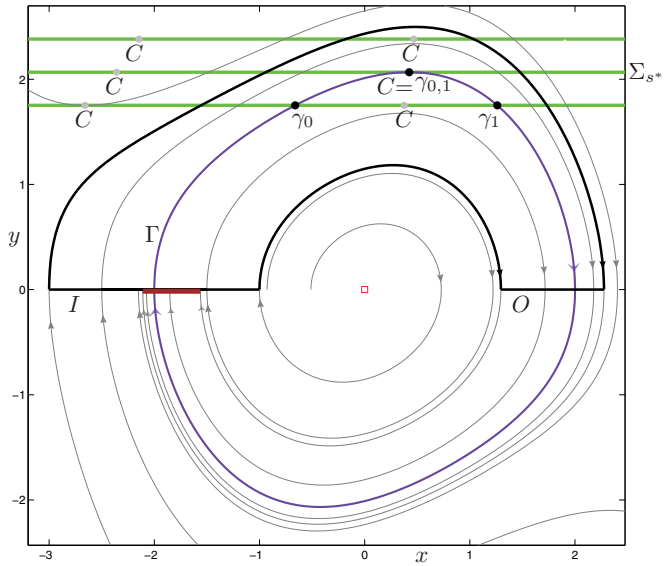

Figure 4. *A flowbox for the Van der Pol oscillator (3.1) near the quadratic tangency of the periodic orbit Γ with the section Σ_{s^*}; the three topologically different choices for Σ_s (green lines) are $s = 1.7518$, $s = 2.0670$, and $s = 2.3822$; compare with Figure 2.*

bifurcation of the Poincaré map occurs for the specific value s^* of s where Γ has a quadratic tangency with the section Σ_{s^*}; numerically we find that $s^* \approx 2.0670$. For $s < s^*$ there are

two transverse intersection points of Γ with Σ_s, as is the case in Figures 2 and 3. For $s > s^*$, on the other hand, Γ has no intersections at all with Σ_s so that the Poincaré map P does not give any information on the dynamics of Γ in this case.

To analyze the situation we consider a flowbox that includes part of the periodic orbit Γ near the tangency point with Σ; see Figure 4, where the flowbox is indicated by thick black lines. Note that the periodic orbit Γ inside the flowbox is simply a particular orbit that is determined by a single point of the in-set I. The fact that Γ is a periodic orbit cannot be deduced from the flowbox alone. Rather, one needs to take into account the global map R from O back to I, which is a contraction in this case since Γ is an attracting orbit. In Figure 4 the image $R(O)$ of the out-set is the thick brown segment on the in-set I.

The idea is now to consider only the flow inside the flowbox of Figure 4. For $s = 1.7518$ the section Σ_s intersects Γ in the two points γ_0 and γ_1, as for the case $s = 1$ of section 3.1. Orbits inside the flowbox that are sufficiently close to Γ intersect Σ_s twice, but orbits below the tangency point C in the flowbox do not intersect Σ_s at all. For $s = s^* \approx 2.0670$, orbits above Γ intersect Σ_s, but orbits below Γ (that is, below the point C in the flowbox) do not. This is due to the nontransverse quadratic tangency of Γ with Σ_{s^*}. Finally, for $s = 2.3822$, the periodic orbit Γ does not intersect the section Σ_s so that points sufficiently close to Γ do not intersect Σ_s either. The overall situation concerning the periodic orbit Γ follows when one takes the map R from O to I into account. Namely, under repeated re-entry into the flowbox all orbits eventually intersect Σ_s infinitely often for $s < s^*$, while all orbits eventually do not return to Σ_s for $s > s^*$. We stress that this division is determined locally inside the flowbox by the quadratic tangency between Γ and Σ_s at $s^* \approx 2.0670$.

3.2. Normal form of the quadratic tangency bifurcation. Generically, a tangency of an orbit of a vector field is quadratic [40], and we have the following result.

Proposition 3.1. *In any sufficiently small flowbox, the phase portrait near a quadratic tangency of an orbit of a flow in $\mathbb{R}^2$ with a global section is topologically equivalent to the phase portrait in the standard flowbox (2.7) for $n = 2$ given by the section*

$$\Sigma = \{(u, v) \mid v = 2\,u^2\}. \tag{3.3}$$

The proof of Proposition 3.1 can be found in [40] for the related situation of a flow on a two-dimensional manifold with boundary. Note that singularity theory guarantees that there is a smooth map that maps the section and the tangent orbit to the standard flowbox as stated. It requires an extra step to show that this map can be chosen in such a way that orbits map to orbits.

The local dynamics within the standard two-dimensional flowbox, that is, for $(u, v) \in [-1, 1]^2$, can be described by giving the transfer map ρ_I from the in-set I to the section Σ, the transfer map ρ_Σ from Σ to itself, and the transfer map ρ_O from Σ to the out-set O. Since not all orbits hit Σ, the map ρ_I is not everywhere defined; similarly, ρ_Σ is not defined for points that have no local returns to Σ. We have the following explicit formulae:

$$u = \rho_I(v) = \begin{cases} -\sqrt{v/2} & \text{for } 0 \le v \le 1, \\ \text{undefined} & \text{for } -1 \le v < 0, \end{cases} \tag{3.4}$$

$$\rho_\Sigma(u) = \begin{cases} -u & \text{for } -1 \le u \le 0, \\ \text{undefined} & \text{for } 0 < u \le 1, \end{cases}$$

$$v = \rho_O(u) = \begin{cases} 2u^2 & \text{for } 0 \le u \le 1, \\ \text{undefined} & \text{for } -1 \le u < 0. \end{cases}$$

Similarly, the associated transfer times are

$$\begin{aligned} \tau_I(v) &= 1 - \sqrt{v/2} \quad \text{for } 0 \le v \le 1, \\ \tau_\Sigma(u) &= 2u \quad \text{for } -1 \le u \le 0, \\ \tau_O(v) &= 1 - 2u^2 \quad \text{for } 0 \le u \le 1. \end{aligned} \tag{3.5}$$

For a general flow with quadratic tangency, (3.4) and (3.5) are normal forms that give the leading-order components of the respective transfer maps. The singularities of the above transfer maps expose the local dynamics within the flowbox. Notice that ρ_I has a quadratic singularity at $v = 0$ due to the grazing of the trajectory at the minimum of the parabolic section Σ, that is, at C.

We now consider the case that the flowbox contains a one-dimensional invariant manifold that has a quadratic tangent with a particular section, as was the case for the Van der Pol system in Figure 4. This *quadratic tangency bifurcation* is of codimension one, where we require the standard genericity condition that the dependence on the parameter is smooth and that the manifold crosses the section with positive speed. We have the following normal-form result.

Proposition 3.2. *In any sufficiently small flowbox, the unfolding of a quadratic tangency of a one-dimensional invariant manifold of a flow in $\mathbb{R}^2$ with a global section is topologically equivalent to the unfolding in the standard flowbox (2.7) for $n = 2$ given by the one-parameter family of sections*

$$\Sigma_s = \{(u, v + s) \mid v = 2\,u^2\}, \tag{3.6}$$

where the invariant manifold is the line

$$M = \{(u, v) \mid v = 0\}.$$

Proof. Suppose that the unfolding parameter of the quadratic tangency is η and the bifurcation takes place at $\eta = 0$. According to Proposition 3.1, any phase portrait of the unfolding in a flowbox near the quadratic tangency point is topologically equivalent to that given by $\widetilde{\Sigma} = \Sigma_0$ in the standard flowbox (2.7) for $n = 2$. Therefore, the invariant manifold (which is simply a single orbit) is mapped to a straight flowline $\widetilde{M} = \{v = s(\eta)\}$ in the standard flowbox, where $s(0) = 0$; furthermore, genericity of the dependence on η implies that $\frac{ds}{d\eta}(0) \neq 0$ so that $s(\eta)$ unfolds the bifurcation. The result follows by applying the coordinate change $(u, v) \mapsto (u, v - s(\eta))$, which maps $\widetilde{M}$ to M and $\widetilde{\Sigma}$ to $\Sigma_{-s(\eta)}$. The thus constructed η-family of coordinate changes is continuous by the genericity assumption on η. ∎

Figure 5 illustrates the quadratic tangency bifurcation of Proposition 3.2 by showing the standard flowbox (2.7) with the parabolic section given by (3.6). Figure 5(a) shows the generic case $M \cap \Sigma_s = \emptyset$, panel (b) is at the tangency where $M \cap \Sigma_s = C$ for $s = 0$, and panel (c) is the generic case $M \cap \Sigma_s = \{m_0, m_1\}$. Note that the in-set I (that is, the v-space) acts as the parameter space, because the relative position of M and Σ_s is uniquely determined by $M \cap I$ relative to the projection of C onto I; compare with Figure 4.

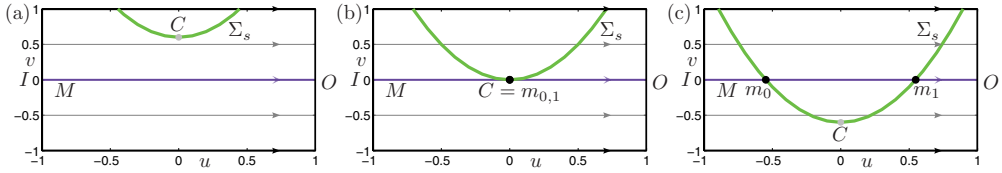

Figure 5. *Unfolding of a quadratic tangency of an invariant manifold M (purple) with a global section (green) given by the family of parabolic sections Σ_s in the standard flowbox for $s = 0.6$ (a), $s = 0$ (b), and $s = -0.6$ (c).*

3.3. Global manifestations of a quadratic tangency. The example of a quadratic tangency bifurcation of the Van der Pol system as discussed in section 3.1 is a specific global manifestation of this bifurcation. Namely, the invariant manifold M of Proposition 3.2 is actually a segment of the attracting periodic orbit Γ. This means that there is a map R from the out-set O back to the in-set I and that this map is a contraction. Therefore, the first return map P on Σ_s near a quadratic tangency of Γ is given by

$$P(u) = \begin{cases} \rho_\Sigma(u) & \text{for} \quad -1 \le u \le 0, \\ \rho_I \circ R \circ \rho_O(u) & \text{for} \quad 0 < u \le 1, \end{cases} \tag{3.7}$$

where u is the coordinate in the standard flowbox. It is now possible to determine the second return map as

$$P^2(u) = \begin{cases} \rho_I \circ R \circ \rho_O \circ \rho_\Sigma(u) & \text{for} \quad -1 \le u \le 0, \\ \rho_\Sigma \circ \rho_I \circ R \circ \rho_O(u) & \text{for} \quad 0 < u \le 1. \end{cases} \tag{3.8}$$

Note that P and P^2 have two branches, namely, one defined on the interval from I to C and one on the interval from C to O.

Figure 6 shows P and P^2 in a flowbox of the Van der Pol system (3.1) before, at, and after the tangency of the periodic orbit Γ that was illustrated in Figure 4. The two branches have been computed with numerical continuation, where the beginning point was varied along Σ_s toward C from the in-set and from the out-set, respectively. In all panels the endpoints of a branch that have an image under the map are shown as gray dots. The purple dots denote the intersection points $\gamma_{0,1}$ of $\Gamma \cap \Sigma_s$. Note that the slopes of all branches are less than 1 in absolute value, because the periodic orbit Γ is attracting.

We first discuss the consequence of the quadratic tangency for the first return map P, which is shown in the left column of Figure 6. Before the quadratic tangency the section Σ_s is above the periodic orbit Γ so that $\Gamma \cap \Sigma_s = \emptyset$. As a result, the points on Σ_s in the interval $[C, P^{-1}(C))$ do not return to the section under P; see panel (a1). At the quadratic tangency for $s = s^* \approx 2.0670$ the section Σ_s intersects Γ tangentially in a single point, which is a fixed point of P. Note from panel (b1) that P is continuous and both left and right differentiable; however, these derivatives differ at the point $\Sigma_s \cap \Gamma$ (purple dot). After the quadratic tangency, shown in panel (c1), the first return map P is well defined everywhere but is discontinuous at the tangency locus C. Furthermore, P has an attracting period-two orbit, namely, the two intersection points $\gamma_{0,1}$ (purple dots) of Γ with Σ_s. Note that during this entire transition the

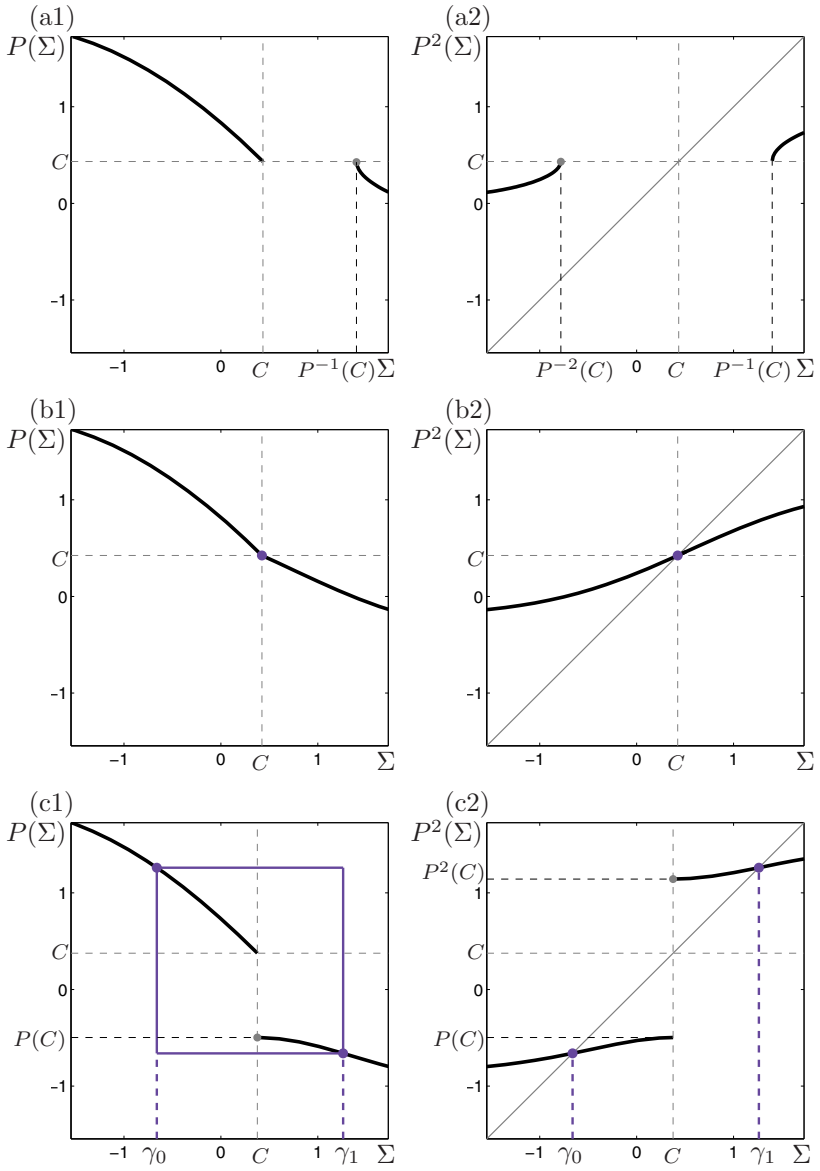

Figure 6. *The first return map P (left column) and second return map P^2 (right column) for the Van der Pol oscillator (3.1) on the sections Σ_s before, at, and after a quadratic tangency; compare with Figure 4. Rows* (a)–(c) *are for $s \approx 2.1359$, $s \approx 2.0670$, and $s \approx 1.7518$, respectively.*

left branch (from I to C) remains virtually unchanged, while the right branch (from C to O) changes topologically owing to the changing nature of $\rho_I \circ R \circ \rho_O$ with s.

The second return map P^2 is simply the second iterate of P; it is shown in the right column of Figure 6. Before the quadratic tangency, points in the interval $(P^{-2}(C), P^{-1}(C)]$ do not have an image under P^2; see panel (a2). At the tangency, the two branches come together in a fixed point (purple dot), at which P^2 is continuous and smooth. After the tangency bifurcation, the map P^2 is well defined everywhere but discontinuous at C. The intersection

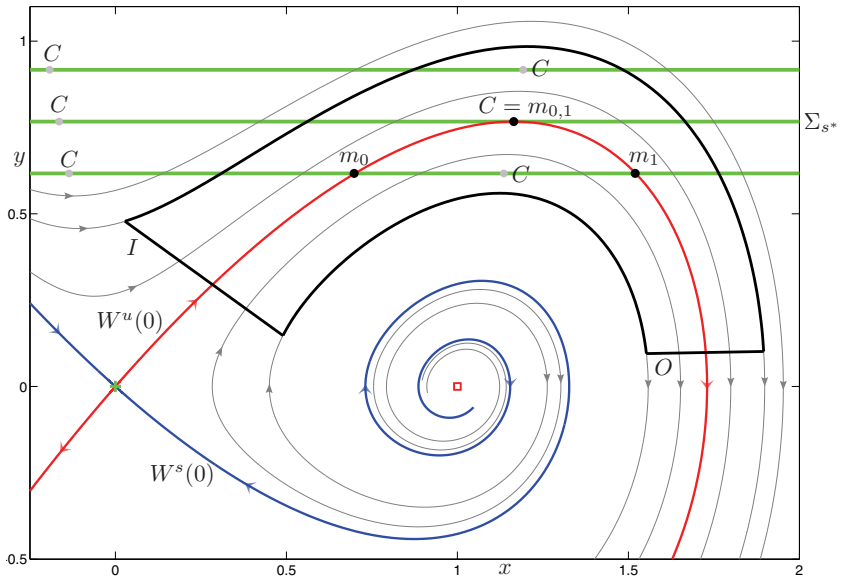

Figure 7. *Phase portrait of the vector field (3.9) for $\lambda = 0.25$ with the stable manifold $W^s(0)$ (blue) and the unstable manifold $W^u(0)$ (red) of the origin. Also shown are three different choices of horizontal global section Σ_s, before, at, and after a tangency of $W^u(0)$ with Σ_s, namely, for $s = 0.6169$, 0.7669, and 0.9169, respectively. The black flowbox shows that this bifurcation unfolds as described by the normal form.*

points $\gamma_{0,1}$ (purple dots) of Γ with Σ_s are fixed points under P^2. Indeed, the restrictions of P^2 to the neighborhoods $\Sigma_{\text{loc}}(\gamma_0)$ or $\Sigma_{\text{loc}}(\gamma_1)$ give the respective local Poincaré maps P_{loc}. Note that in these transitions both branches of P^2 are changing, because they both depend on the map R that describes the flow outside the flowbox.

As we have seen, the properties of P and P^2 depend on the map R from the out-set back to the in-set. In case of a repelling periodic orbit Γ, the map R^{-1} from the in-set back to the out-set is a contraction. Therefore, the respective maps P and P^2 can be obtained from Figure 6 by reversing the roles of in-set and out-set. Geometrically, this corresponds to a reflection in the antidiagonal of the respective panels.

An altogether different global situation arises when the invariant manifold M inside the flowbox is not a segment of a periodic orbit. A generic and dynamically relevant situation is that M is a segment of a global stable or unstable manifold of an equilibrium. As a concrete example we consider the vector field

$$\begin{cases} \dot{x} &= y, \\ \dot{y} &= \lambda y + x - x^2, \end{cases} \tag{3.9}$$

which was introduced in [19] as a system with a homoclinic bifurcation. For $\lambda = 0.25$ the phase portrait of (3.9) is as in Figure 7. The system has a saddle point at the origin with stable manifold $W^s(0)$ (blue) and unstable manifold $W^u(0)$ (red) as shown in Figure 7. We consider a family of horizontal sections $\Sigma_s = \{(x, y) \mid y = s\}$ (green), which has a tangency with $W^u(0)$ for $s^* \approx 0.7669$. When one restricts one's attention to a suitable flowbox (boldface curves),

then this tangency unfolds as described by the normal form in Proposition 3.2; compare with Figure 5. However, the invariant manifold M inside the flowbox is now a segment of $W^u(0)$ so that points of the out-section O move off to infinity. Hence, there exists no map R from O back to I and the intersection points m_0 and m_1 do not correspond to fixed points of the first return map P. In fact, the map P is defined only from I to C, where it is as shown in the left column of Figure 6.

Note that Teixeira [40] considered the related situations that a periodic orbit or a separatrix interacts with the boundary of a two-dimensional flow. However, he treated these two global situations as different cases. By contrast, we take the point of view that the local bifurcation mechanism in a suitable flowbox is actually the same, while the global dynamics is determined by the exact nature of the invariant manifold that is involved in the tangency with the section (or boundary) inside the flowbox.

4. Quadratic tangency bifurcation in three-dimensional flows. An invariant manifold of a three-dimensional flow can be either one- or two-dimensional. Therefore, there are more possibilities for interactions of an invariant manifold with a two-dimensional section. As before, we discuss interactions in the context of a family of two-dimensional sections Σ_s at a regular point of the critical locus C, that is, at a generic tangency point between a three-dimensional flow and the section. To this end, we consider the standard flowbox (2.7) for $n = 3$, where we take $(v_1, v_2) = v \in [-1, 1]^2$ as coordinates. We start with a straightforward generalization of Proposition 3.2.

Corollary 4.1. *In a sufficiently small flowbox, the unfolding of a quadratic tangency of a one-dimensional invariant manifold of a flow in $\mathbb{R}^3$ with a global section is topologically equivalent to the unfolding in the standard flowbox (2.7) for $n = 3$ given by the one-parameter family of sections*

$$\Sigma_s = \{(u, v_1, v_2 + s) \mid v_2 = 2\,u^2\}, \tag{4.1}$$

where the invariant manifold is the line

$$M = \{(u, v) \mid (v_1, v_2) = (0, 0)\}.$$

Note that this bifurcation is of codimension one, because it involves the interaction of a one-dimensional manifold with a one-dimensional fold curve C in $\mathbb{R}^3$. In the standard flowbox the section Σ_s is a parabolic cylinder with the straight line $C = C(s) = \{(u, v_1, v_2 + s) \mid u = 0 \text{ and } v_2 = 0\}$, along which the flow has a quadratic tangency. This represents the generic situation inside a flowbox in the absence of cusp points on C, that is, in a sufficiently small neighborhood of a generic quadratic tangency point; see also [38, Figure 5.1]. Note further that this unfolding reduces to the case for $n = 2$ of Proposition 3.2 by means of considering the two-dimensional slice for $v_1 = 0$. Therefore, the form of the transfer map ρ_I from the in-set I to the section Σ, the transfer map ρ_Σ from Σ to itself, and the transfer map ρ_O from Σ to the out-set O are as given in (3.4).

The more interesting possibility for $n = 3$ is the interaction of a two-dimensional invariant manifold M with a two-dimensional global section near a quadratic tangency of a single orbit. In this setting we do not consider the details of the dynamics on the part of M inside the flowbox but simply consider M as a smooth family of one-dimensional orbit segments. We

say that there is a *codimension-one quadratic tangency bifurcation* between the two surfaces M and Σ at the point $\mathbf{x}^* = M \cap \Sigma$ if $M \cap I$ has a quadratic tangency with the projection (along flowlines) of C onto I. As a genericity condition we require that the dependence on the parameter is smooth and that M crosses Σ with positive speed. Note that this definition is general and does not depend on the choice of flowbox. The two cases of the quadratic tangency bifurcation are distinguished by whether $M \cap I$ lies in the region to which Σ projects or not, which we refer to as the *saddle case* and the *minimax case*, respectively.

Proposition 4.2. *In any sufficiently small flowbox, the unfolding of a quadratic tangency of a two-dimensional invariant manifold of a flow in $\mathbb{R}^3$ with a global section is topologically equivalent to the unfolding in the standard flowbox (2.7) for $n = 3$ given by the one-parameter family of sections*

$$\Sigma_s = \{(u, v_1, v_2 + s) \mid v_2 = 2\,u^2 \pm 2\,v_1^2\}, \tag{4.2}$$

where the invariant manifold is the plane

$$M = \{(u, v_1, v_2) \mid v_2 = 0\}.$$

The plus sign in (4.2) gives the minimax case and the minus sign the saddle case of the bifurcation.

Proof. Suppose that the unfolding parameter of the quadratic tangency is η and the bifurcation takes place at $\eta = 0$. In light of Corollary 4.1 we may consider a manifold $\widetilde{M}$ in the standard flowbox with $\Sigma_{s(\eta)}$ as given by (4.1) such that the quadratic tangency for $\eta = 0$ takes place at the origin. Then $\widetilde{M} \cap I$ is (locally and for sufficiently small η) given by a function $\mu_\eta : v_1 \to v_2$ on the in-set I with a single minimum or maximum. Hence, the u-independent coordinate change $(u, v_1, v_2) \mapsto (u, v_1, v_2 - \mu_\eta(v_1) - s(\eta))$ maps $\widetilde{M}$ to the plane $\{v_2 = 0\}$. As a result, the image $\widetilde{\Sigma}_{s(\eta)}$ under this transformation is either a paraboloid or a saddle surface, where $s(\eta)$ is the v_2-value (vertical distance) of the maximum, the minimum, or the saddle point, respectively. Therefore, for each η there exists a v_2-dependent coordinate change of v_1 that leaves the origin invariant and a v_2-dependent coordinate change of u (as in the proof of Proposition 3.1) that together bring $\widetilde{\Sigma}_{s(\eta)}$ to the normal form given by (4.2). Again, a rescaling of time ensures that $\dot{u} = 1$. The thus constructed η-family of coordinate changes is continuous by the genericity assumption on η. ∎

From a singularity theory point of view, the two cases determined by the sign in (4.2) are the well-known transitions through a minimum or maximum (minimax for short), and through a saddle [2, 15, 46]. In particular, these are the only two generic cases, and the unfolding given in Proposition 4.2 applies in both cases. However, there is an additional ingredient that is important in the present context: one also needs to consider the direction of the flow on either side of the tangency locus C.

The minimax and the saddle cases of the quadratic tangency of Proposition 4.2 are illustrated in Figures 8 and 9, respectively. In these figures, the left-hand columns show the curve $M \cap I = \{v_2 = 0\}$ in the in-set I with the projection of Σ_s (green region) that is bounded by the projection $\widehat{C}$ of the fold curve C; any orbit in the green region intersects Σ twice in the flowbox. The middle columns show the section Σ_s (green) and the manifold M (pink) in the three-dimensional flowbox; the tangency locus C is the fold curve given by $u = 0$ in

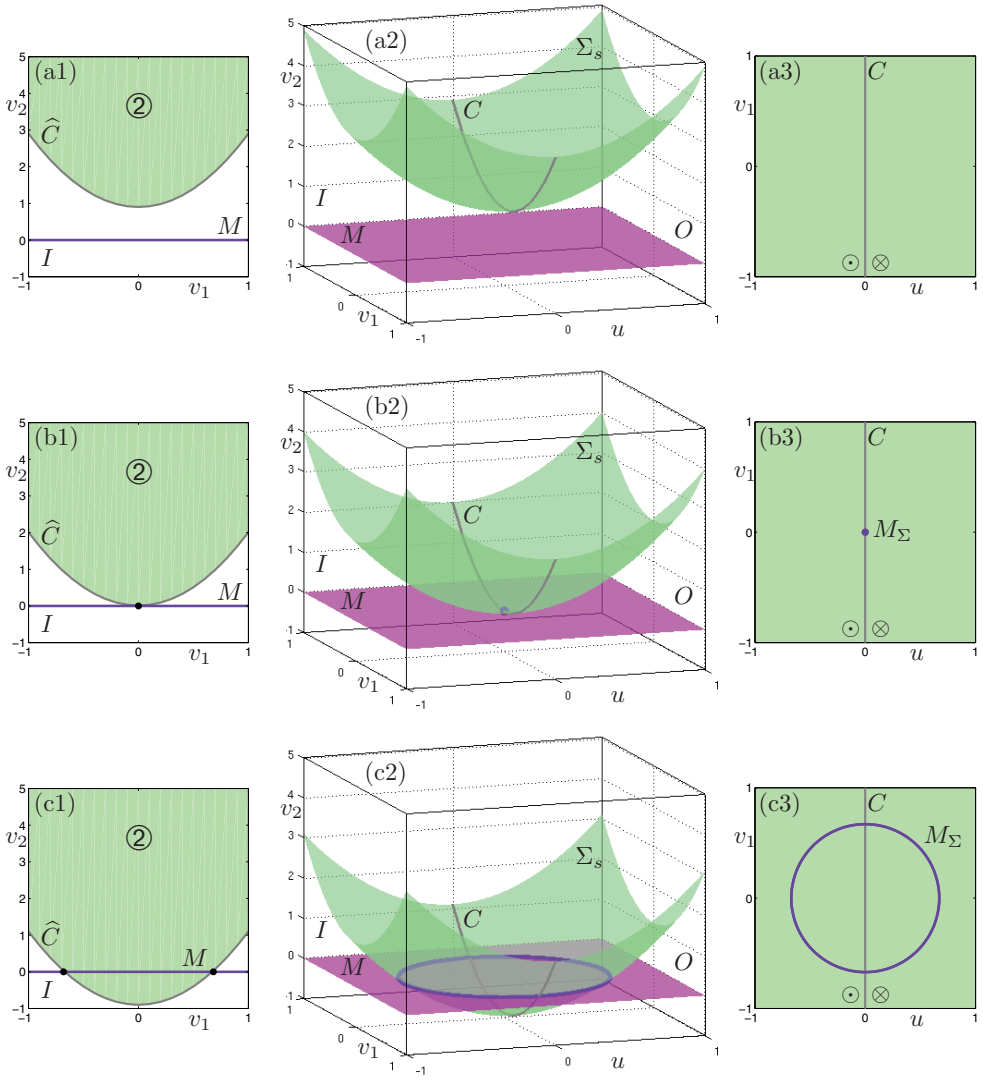

Figure 8. *The minimax case of the quadratic tangency bifurcation, as described by the plus sign in (4.2), before* (a)*, at* (b)*, and after* (c) *the bifurcation. The left column shows $M \cap I = \{v_2 = 0\}$ relative to the projection curve $\widehat{C}$ that bounds the projection of Σ_s (green region) onto the in-set I; the symbol ② indicates that there are two intersections with Σ in the green region. The middle column shows the section Σ_s (green) and the planar two-dimensional manifold M (pink), and the right column shows the intersection M_Σ in Σ_s. The tangency locus C (gray curve) separates the regions where the flow is upward (⊙) and downward (⊗). Rows* (a)–(c) *are for $s = 0.9$, $s = 0.0$, and $s = -0.9$, respectively.*

both cases. The right-hand columns show the corresponding intersections M_Σ (purple) in the global section Σ_s. The direction of the flow through Σ_s is indicated: the symbol ⊙ denotes upward flow and the symbol ⊗ downward flow (with respect to the normal to the section). Rows (a) through (c) are before, at, and after the respective bifurcations.

The minimax transition creates a topological circle M_Σ; see Figure 8(c). This circle is

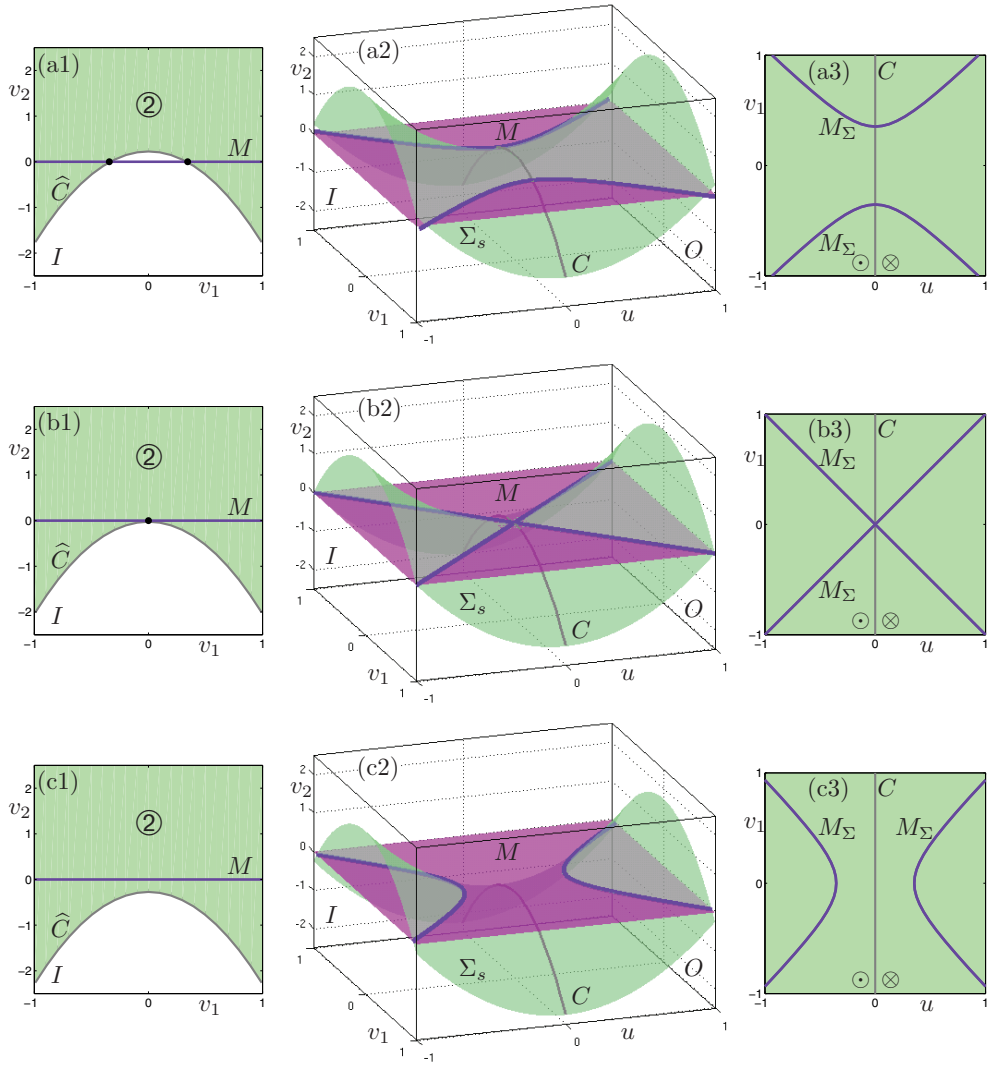

Figure 9. *The saddle case of the quadratic tangency bifurcation, as described by the minus sign in (4.2), before* (a)*, at* (b)*, and after* (c) *the bifurcation. The left column shows $M \cap I = \{v_2 = 0\}$ relative to the projection curve $\widehat{C}$ that bounds the projection of Σ_s (green region) onto the in-set I; the symbol ② indicates that there are two intersections with Σ in the green region. The middle column shows the section Σ_s (green) and the planar two-dimensional manifold M (pink), and the right column shows the intersection M_Σ in Σ_s. The tangency locus C (gray curve) separates the regions where the flow is upward ($\odot$) and downward ($\otimes$). Rows* (a)–(c) *are for $s = 0.25$, $s = 0.0$, and $s = -0.25$, respectively.*

divided by C into two parts: points on the left half of M_Σ are mapped under the flow to the right half of M_Σ; the points on $M_\Sigma \cap C$ intersect Σ only once inside the flowbox. By contrast, in the saddle transition we have that $M_\Sigma \neq \emptyset\ \forall s$; see Figure 9. The intersection of M with Σ_s in row (a) consists of two arcs that both cross C. Points on each arc to the left of C return to Σ_s on the same arc to the right of C, namely, at the same value of v_1. At the moment of the

saddle transition in row (b) the two arcs of M_Σ meet on C to form a cross. In row (c) M_Σ consists of two arcs in a different way; namely, there is an arc in the region of upward flow and one arc in the region of downward flow; points on the left arc are mapped diffeomorphically to the right arc.

4.1. Intersection of an invariant two-torus with a plane. As for the case $n = 2$ in section 3.2, the question arises as to how the minimax and the saddle transitions in a flowbox manifest themselves for a given three-dimensional vector field. This depends again on whether there is a map R from the two-dimensional out-set O back to the two-dimensional in-set I. A natural setting in which such a map may occur is that the segment M inside the flowbox is part of an invariant two-torus $\mathbb{T}$ of the underlying flow. In this case, the map R leaves M invariant, meaning that $M \cap O$ is mapped back to $M \cap I$. When the torus is attracting, R contracts the v_2-direction of the standard flowbox.

Importantly, bifurcations of the Poincaré map on a section can be brought about either by changes to the section or by changes to the torus itself. To show this, we consider a simple geometric example, given by the unit circle

$$\Gamma = \{(x, y, z) \in \mathbb{R}^3 \mid x = \cos\theta,\ y = 0,\ z = \sin\theta, \quad \text{where } 0 \le \theta < 2\pi\} \tag{4.3}$$

in the (x, z)-plane, surrounded by a tube of radius r that forms the torus

$$\begin{aligned}\mathbb{T} = \{(x, y, z) \in \mathbb{R}^3 \mid x = (1 + r\cos\phi)\cos\theta,\ y = r\sin\phi,\\ z = (1 + r\cos\phi)\sin\theta, \quad \text{where } 0 \le \theta, \phi < 2\pi\}.\end{aligned} \tag{4.4}$$

We may consider $\mathbb{T}$ and Γ as a geometric model of an invariant torus surrounding a periodic orbit of an unspecified vector field, as long as $\mathbb{T}$ does not have self-intersections, that is, for $0 < r < 1$. We now consider the family of global planar sections $\Sigma_s = \{(x, y, z) \in \mathbb{R}^3 \mid z = s\}$. While we are not specifying an underlying flow, we make the assumption that the tangency locus $C \subset \Sigma_s$ is given by the condition $x = 0$; note that this is consistent with the desired invariance of $\mathbb{T}$ and Γ. For specificity we further assume that the flow is upward ($\odot$) on Σ_s for $x < 0$ and downward ($\otimes$) for $x > 0$.

The situation for $r = 0.5$ and $s = 0.5$ is shown in Figure 10(a) in (x, y, z)-space, while panel (b) shows the invariant objects in the planar section Σ_s. Note that for the specific example of $\mathbb{T}$ as defined by (4.4) the family of intersection curves $\mathbb{T}_\Sigma$ comprises part of the family of Cassini ovals [28]. In particular, for these values of r and s the set $\mathbb{T}_\Sigma$ is a lemniscate, which means that Figure 10 shows a saddle transition of $\mathbb{T}_\Sigma$ locally near C; compare with Figure 9. This codimension-one situation can be unfolded in two different ways, namely, either by changing the section Σ, that is, by varying s, or by varying the radius r of the torus. In the former case, the section moves up and down through the torus $\mathbb{T}$ and the periodic orbit Γ. As is shown in the accompanying animation (69972_01.gif [8.13MB]), apart from the saddle transition at $s = 0.5$, one also encounters a quadratic tangency of Γ for $s = 1$ and a minimax transition of $\mathbb{T}$ for $s = 1$. On the other hand, when $\mathbb{T}_{0.5}$ remains fixed and the radius r of $\mathbb{T}$ is changed, then only the saddle transition is unfolded; see the accompanying animation (69972_02.gif [3.85MB]).

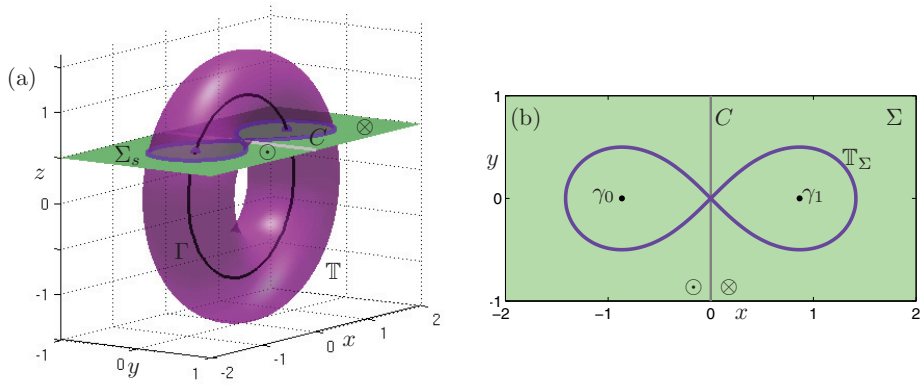

Figure 10. *Saddle transition in the geometric example (4.3)–(4.4) of an invariant torus $\mathbb{T}$ (pink) surrounding a periodic orbit Γ (black curve) with the planar section $\Sigma_{0.5}$ (green) when the radius of $\mathbb{T}$ is $r = 0.5$; the intersections $\mathbb{T}_\Sigma = \mathbb{T} \cap \Sigma_s$ are shown in purple and $\Gamma \cap \Sigma_s$ is indicated by black dots. Along C the flow is tangent to Σ, and the symbols $\odot$ and $\otimes$ indicate where the flow is upward and downward, respectively. The bifurcation unfolds when either the section or the radius r is changed, as is illustrated in the accompanying animations (69972_01.gif [8.13MB] and 69972_02.gif [3.85MB]).*

4.2. Saddle transitions in a semiconductor laser system. To demonstrate how quadratic tangencies arise in a practical example, we consider the model of a semiconductor laser with optical injection given by the equations

$$\begin{cases} \dot{E} = K + \left(\frac{1}{2}(1 + i\alpha)\, n - i\omega\right) E, \\ \dot{n} = -2\gamma n - (1 + 2Bn)\left(|E|^2 - 1\right), \end{cases} \tag{4.5}$$

where $E = E_x + iE_y$ is the complex electric field and n is the population inversion. The parameters α, B, and γ characterize the material properties of the laser, ω is the detuning, and K the injection field strength; see [44] for further details. In this paper $\alpha = 2$, $B = 0.015$, $\gamma = 0.035$, and $\omega = 0.43$ are used throughout, while K is varied.

As was done in [44], we choose the fixed global section

$$\Sigma = \{(E, n) \in \mathbb{C} \times \mathbb{R} \mid n = -0.1\}. \tag{4.6}$$

By numerical integration of (4.5) it can be found quite easily that, for a range of the injection strength K around 0.1139, the Poincaré map on Σ shows attracting invariant curves surrounding points of an unstable period-six orbit $\{\gamma_0, \ldots \gamma_5\}$; see Figure 11. As can be seen from the panels of this figure, the number of invariant curves, labeled $\mathbb{T}_\Sigma$, changes with K.

One might be tempted to think that the change in the number of invariant curves is due to a bifurcation of the vector field (4.5), but this is not the case. Instead, there are several saddle transitions involving an underlying attracting invariant torus $\mathbb{T}$; see Figure 12. The torus $\mathbb{T}$ has been obtained by integrating from a suitable initial condition (after omitting transients), because the dynamics on it appears to be quasi-periodic (or of very high period); Figure 12 shows $\mathbb{T}$ (mauve) computed as a single orbit over 60,000 time steps of size 0.01; the repelling

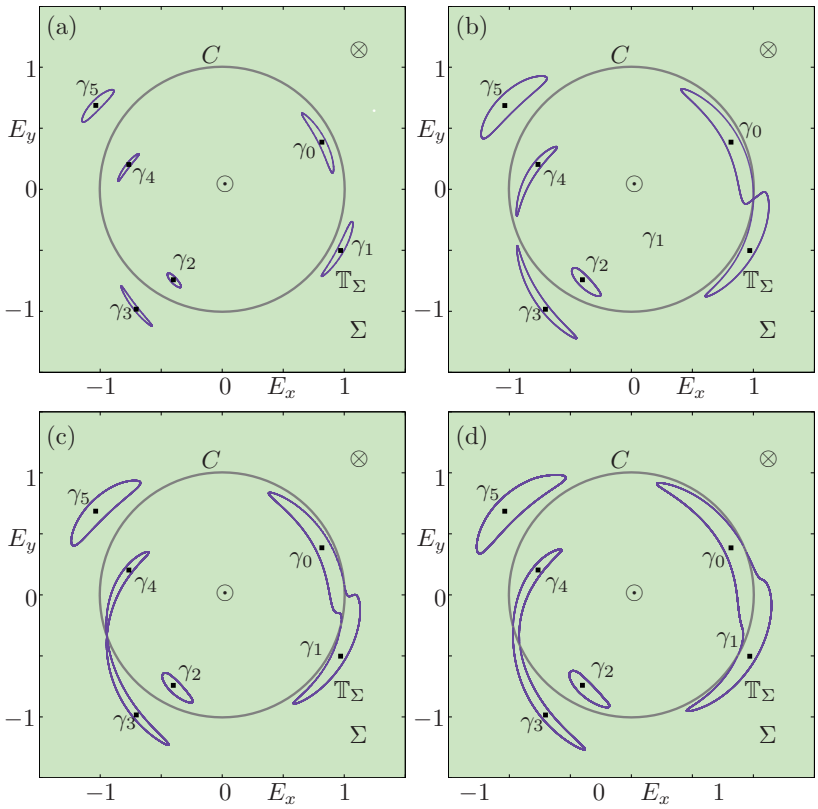

Figure 11. *The Poincaré map of* (4.5) *in the fixed section* Σ *defined by* (4.6) *has a number of attracting invariant curves, labeled* $\mathbb{T}_\Sigma$*, that surround points of an unstable period-six orbit* $\Gamma_\Sigma = \{\gamma_0, \dots \gamma_5\}$*. The number of invariant curves in* $\mathbb{T}_\Sigma$ *depends on the value of the injection strength* K*. Also shown is the circular tangency locus* C *given by* (4.7) *that divides* Σ *into two regions with upward* ($\odot$) *and downward* ($\otimes$) *flow. From* (a)–(d) K *takes the values* 0.1139, 0.11392468, 0.1139281, *and* 0.11395*; compare with Figure* 12.

periodic orbit Γ inside $\mathbb{T}$ is also shown; it was found as a fixed point of the sixth return map to the section Σ. Indeed, as is shown in Figure 12, there are exactly six intersections of Γ (black) and Σ (green).

To compare with the theory, note that the flow of (4.5) is tangent to Σ along the tangency locus

$$C = \left\{ (E, n) \in \Sigma \;\middle|\; |E|^2 = \Delta(-0.1) \right\}, \tag{4.7}$$

where

$$\Delta(n) := 1 - \frac{2\gamma n}{1 + 2Bn}. \tag{4.8}$$

Hence, C is a circle in Σ that is centered at $(0, 0, -0.1)$ with radius $\sqrt{\Delta(n)} \approx 1.0035$ for the given system parameters. We conclude from (4.5) that the flow points in the positive n-direction ($\odot$) inside C and in the negative n-direction ($\otimes$) outside C.

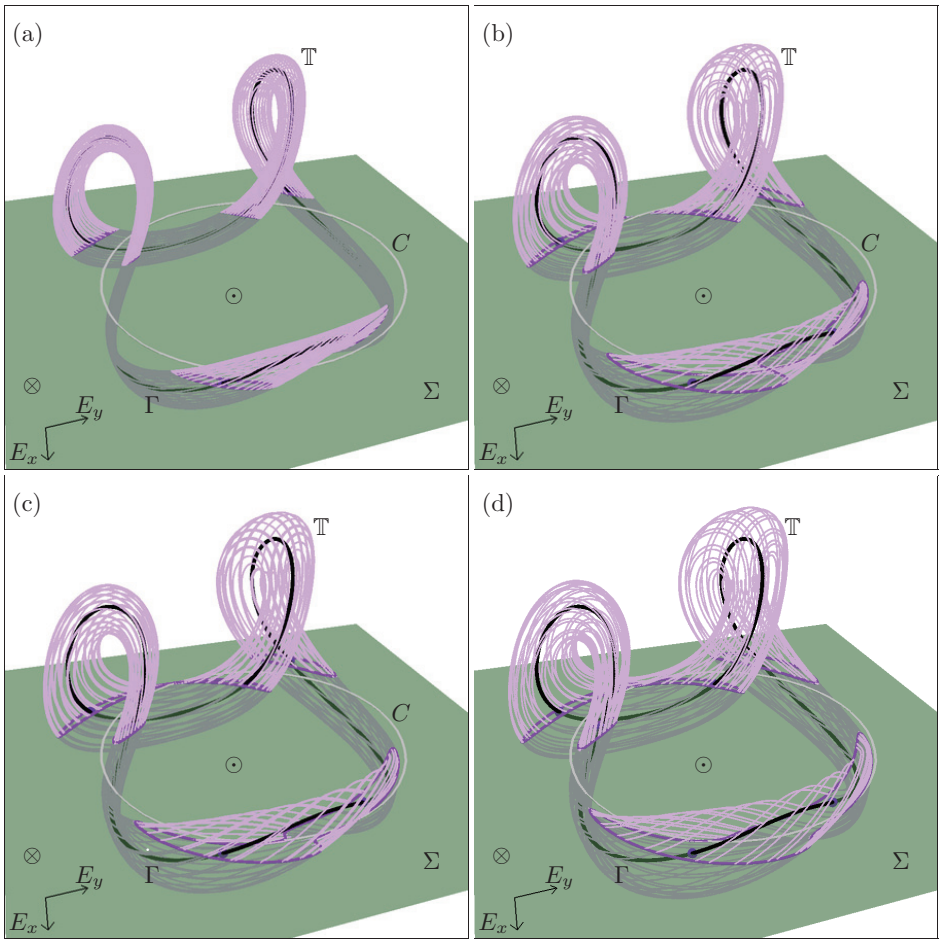

Figure 12. *The sets $\mathbb{T}_\Sigma$ and Γ_Σ in Figure 11 of the Poincaré map of (4.5) on the section Σ defined by (4.6) are intersections of an attracting invariant torus $\mathbb{T}$ and a repelling periodic orbit Γ of the flow. Also shown is the circular tangency locus C given by (4.7) that divides Σ into two regions with upward ($\odot$) and downward ($\otimes$) flow. From* (a)–(d) *K takes the values* 0.1139, 0.11392468, 0.1139281, *and* 0.11395.

In Figures 11 and 12 the parameter K is varied from (a) to (d) with the same values being used in the corresponding panels of the two figures. In panel (a) the intersection $\mathbb{T}_\Sigma$ consists of six disjoint invariant circles, each surrounding an intersection point γ_i. Under the first return map P on Σ each invariant circle is mapped to another invariant circle in $\mathbb{T}_\Sigma$. Note that a circle outside C is mapped to one inside C, and vice versa. Panels (b) of Figures 11 and 12 show the first saddle transition, where the invariant circles around γ_0 and γ_1 join to form a single invariant circle; locally the situation is topologically equivalent to Figures 10 and 9(b). While each component of $\mathbb{T}_\Sigma$ in Figure 11(a) maps to itself under the sixth return of P, this is no longer true after the saddle transition in Figure 11(b). After the bifurcation, as shown in Figure 11(c), the part inside C of the large component of $\mathbb{T}_\Sigma$ that surrounds γ_0 and γ_1 is mapped under P to the part of the same component that lies outside C. On the other hand, the outside part of this component is mapped under P^5 back to the inside part. Note

that panels (c) of Figures 11 and 12 also show the next saddle transition of the two invariant circles surrounding γ_3 and γ_4. Panels (d) of Figures 11 and 12 show the situation after the second saddle transition with the set of four circles in Σ that is invariant under P; two of the invariant circles now surround a pair of points of Γ_Σ.

As can be seen from the three-dimensional images of Figure 12, the invariant torus $\mathbb{T}$ does not appear to undergo any bifurcations (meaning that it remains a normally hyperbolic invariant manifold). The topological changes of the invariant set $\mathbb{T}_\Sigma$ of the Poincaré map shown in Figure 11 are entirely due to the fact that the torus changes its "thickness" with the injection strength K, which leads to saddle transitions. This is exactly the mechanism that was discussed with the simple geometric example in section 4.1 and in animation (69972_02.gif [3.85MB]).

5. Cubic tangency bifurcation in three-dimensional flows. In this section we discuss a different and final codimension-one tangency bifurcation of a two-dimensional invariant manifold of a three-dimensional flow. We identify and characterize this bifurcation in a planar section of the semiconductor laser system (4.5) in the next section. We then discuss the geometry with a simpler geometric model in section 5.2 and finally derive the normal form in section 5.3.

However, first we introduce a new geometric object—the *extended critical locus* denoted $\mathcal{C}$—to help understand the geometry of the flow. Suppose that we have as part of the setup a one-parameter family Σ_s of sections such that the bifurcation occurs at $\mathbf{x}^* \in \Sigma_{s^*}$. (If, as in the laser system, we are starting with only a single section Σ, then we define the family Σ_s in a natural way by moving it in the direction of the unit normal vector $\vec{n}_\Sigma(\mathbf{x})$, formally $\Sigma_s = \{\mathbf{x} + s\,\vec{n}_\Sigma(\mathbf{x}) \mid \mathbf{x} \in \Sigma\}$ and $\Sigma = \Sigma_{s^*}$; note that for sufficiently small s each Σ_s is a global section in the sense of (2.4).) The extended critical locus $\mathcal{C}$ is now defined as the union of the critical tangency loci $C(s)$ of the sections Σ_s, that is,

$$\mathcal{C} = \bigcup_s C(s). \tag{5.1}$$

We assume here that the dependence of Σ_s on s is smooth so that $\mathcal{C}$ is a smooth codimension-one submanifold of the phase space $\mathbb{R}^n$. Therefore, $\mathcal{C}$ is of the same dimension as the section Σ (i.e., it is a surface for $n = 3$), and $\mathcal{C} \cap \Sigma = C$. Generically, the extended critical locus is transverse to Σ_s, and, hence, knowing properties of the flow through $\mathcal{C}$ gives new geometric insight. We define the tangency locus D on $\mathcal{C}$ by

$$D := \{\mathbf{x} \in \mathcal{C} \mid f(\mathbf{x}) \cdot \vec{n}_\mathcal{C}(\mathbf{x}) = 0\}, \tag{5.2}$$

where $\vec{n}_\mathcal{C}(\mathbf{x})$ is the unit normal to $\mathcal{C}$ at the point $\mathbf{x}$. As with C on Σ the tangency locus D generically consists of codimension-one submanifolds (i.e., curves for $n = 3$) that divide $\mathcal{C}$ into regions with opposite directions of the flow.

5.1. Cubic tangency bifurcation in the semiconductor laser system. When the parameter K of the semiconductor laser system equation (4.5) is increased to values beyond those shown in Figure 11, then one encounters the codimension-one bifurcation of the invariant torus $\mathbb{T}$ that is illustrated in Figures 13 and 14.

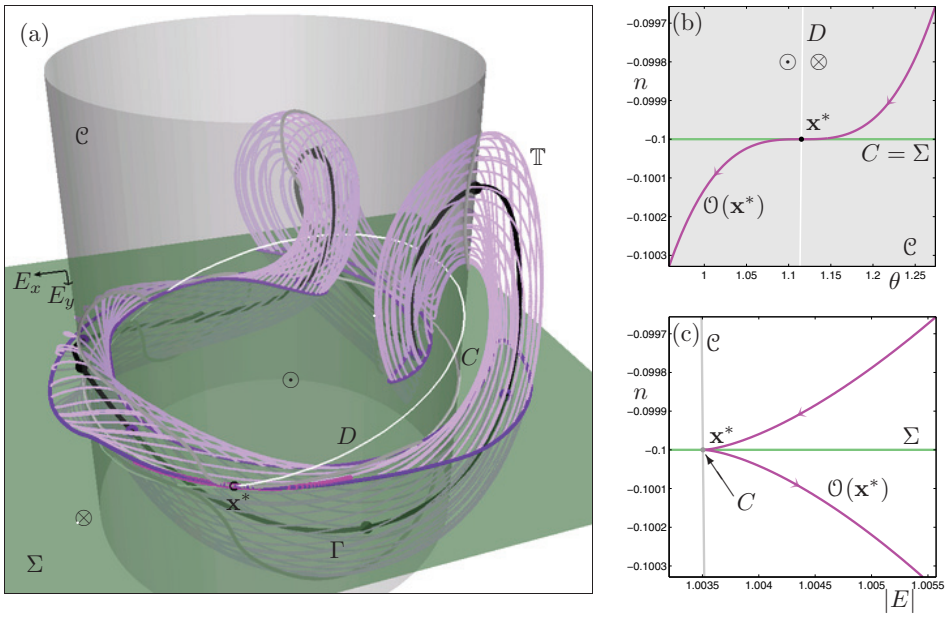

Figure 13. *Panel* (a) *shows the invariant torus* $\mathbb{T}$ *(mauve) of* (4.5) *at the moment of the cubic tangency bifurcation at* $\mathbf{x}^* \approx (0.44162, 0.90111, -0.1)$ *for* $K \approx 0.1140145$*; compare with Figure* 14(b)*. Also shown are the section* Σ *(green), the extended critical locus* $\mathcal{C}$ *(gray), and the respective intersection curves with* $\mathbb{T}$*. A segment of the orbit* $\mathcal{O}(\mathbf{x}^*)$ *(magenta curve) is shown in panel* (b) *in the* (θ, n)*-plane and in panel* (c) *in the* $(|E|, n)$*-plane (where* $E = |E|e^{i\theta}$*); notice the large difference in scales between* n *and* θ *in panel* (b)*.*

Figure 13(a) is a three-dimensional image of the surfaces $\mathbb{T}$, Σ, and $\mathcal{C}$ at the moment of bifurcation for $K \approx 0.1140145$. The extended tangency locus $\mathcal{C}$ was computed by considering the family of sections

$$\Sigma_s = \{(E, n) \in \mathbb{C} \times \mathbb{R} \mid n = s\},$$

where $\Sigma = \Sigma_{s^*}$ for $s^* = -0.1$. It follows from (4.7) and (4.8) that

$$\mathcal{C} = \left\{(E, n) \in \mathbb{C} \times \mathbb{R} \;\mid\; |E|^2 = \Delta(n)\right\}, \tag{5.3}$$

which is a cone. Furthermore, we find that

$$D = \left\{(E, n) \in \mathcal{C} \mid E_x = -\frac{n}{2K}\Delta(n),\; E_y = \sqrt{\Delta(n) - \frac{n^2}{4K^2}\Delta(n)^2}\right\}, \tag{5.4}$$

where n is chosen such that $E_y \in \mathbb{R}$, that is, $|n| \leq 2k/\sqrt{\Delta(n)}$. The cone $\mathcal{C}$ is the gray surface in Figure 13(a) that is divided by D (closed white curve) into two parts. The flow points from the inside of $\mathcal{C}$ to the outside above D and from the outside of $\mathcal{C}$ to the inside below D.

At the moment of bifurcation, illustrated in Figure 13, the torus $\mathbb{T}$ crosses the section Σ at the intersection point $\mathbf{x}^* \in C \cap D$ of C and D. Therefore, $\mathbb{T}_\Sigma$ is tangent to C in Σ and $\mathbb{T}_\mathcal{C}$ is tangent to C in $\mathcal{C}$; see row (b) of Figure 14. Figure 13(a) shows a relevant segment of $\mathcal{O}(\mathbf{x}^*)$ (magenta curve). Notice that this orbit segment remains very close to Σ and that it is

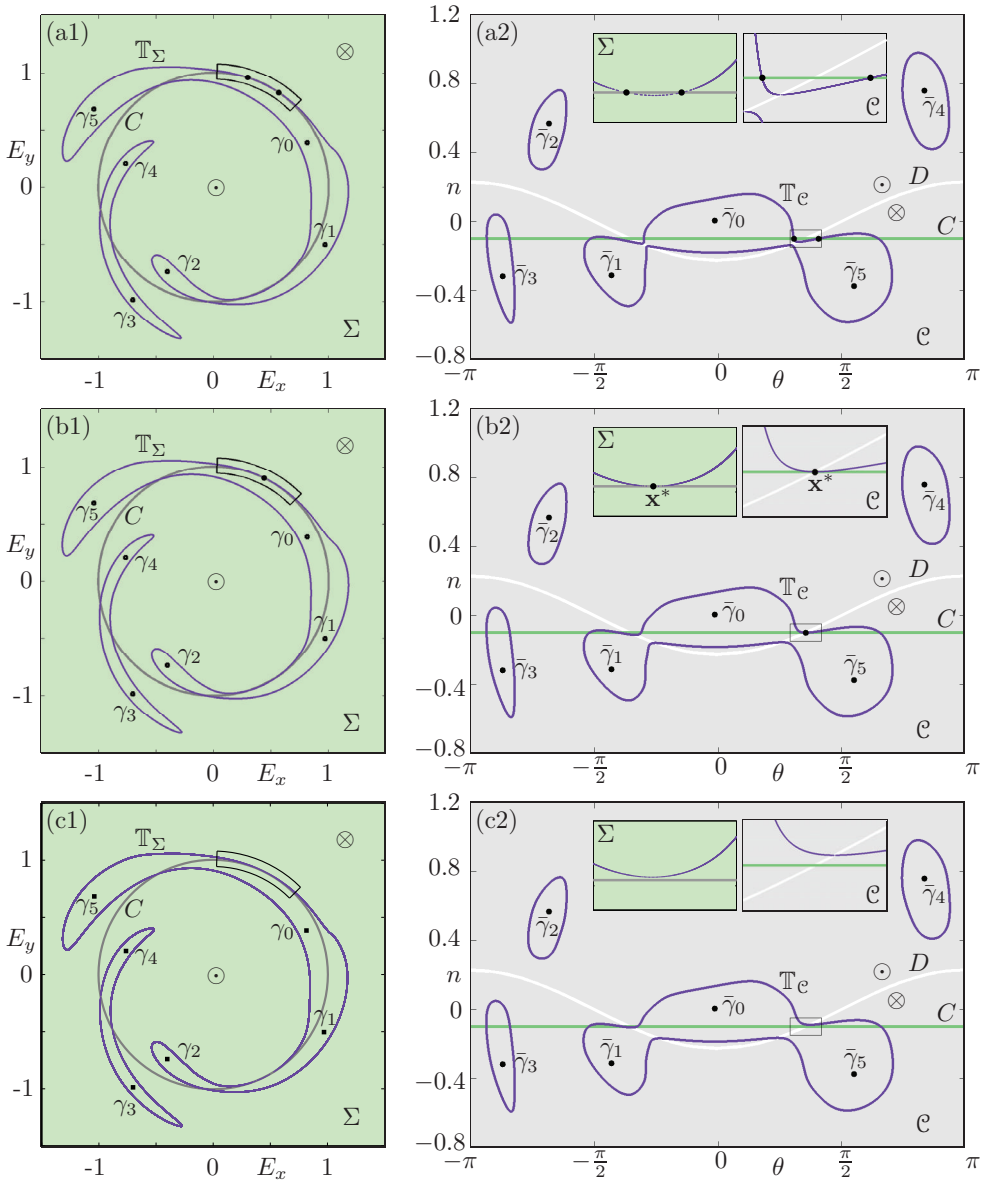

Figure 14. *Cubic tangency bifurcation for* (4.5). *The three rows show the situation before, at, and after the bifurcation. The left column shows the interaction of* $\mathbb{T}_\Sigma$ *with* C *in* Σ, *and the right column the interaction of* $\mathbb{T}_\mathcal{C}$ *with* D *in* $\mathcal{C}$; *the subpanels show enlargements near the tangency points in* Σ *(green subpanel) and* $\mathcal{C}$ *(gray subpanel) in the indicated regions. Rows* (a)–(c) *are for* $K = 0.1140105$, 0.1140145, *and* 0.1140185, *respectively; compare with Figure* 13(a).

very difficult to judge its position relative to other flow lines. Therefore, Figure 13(b) and (c) show the orbit through $\mathbf{x}^*$ in the radial and angular projections of $E = |E|e^{i\theta}$, that is, in the (θ, n)-plane and in the $(|E|, n)$-plane, respectively. In these projections one can clearly see the determining property of this orbit: it has a cubic tangency with the section Σ at $\mathbf{x}^*$, which is why we refer to this bifurcation as the *codimension-one cubic tangency bifurcation*.

What happens when one moves through the cubic tangency bifurcation for $K \approx 0.1140145$ is illustrated in Figure 14, where the green panels on the left show $\mathbb{T}_\Sigma$ in Σ and the gray panels on the left show $\mathbb{T}_\mathcal{C}$ in $\mathcal{C}$. Note that $\mathcal{C}$ has been "unrolled" and is shown in the (θ, n)-plane. Also shown are enlargements near the bifurcation point in Σ (green subpanel) and in $\mathcal{C}$ (gray subpanel), respectively; here $\mathbb{T}_\Sigma$ is plotted relative to the curve C, which appears as a straight line in the green subpanels. As is shown in the left column of Figure 14 and the associated green subpanels, the curve $\mathbb{T}_\Sigma$ moves relative to the curve C in the section Σ. At the same time we see in the right column of Figure 14 and the associated gray subpanels that $\mathbb{T}_\mathcal{C}$ moves relative to the curve $C = \Sigma \cap \mathcal{C}$ in the extended tangency locus $\mathcal{C}$. In Figure 14(a) there are two intersections between $\mathbb{T}_\Sigma$ and C and two between $\mathbb{T}_\mathcal{C}$ and C. Points on the part of $\mathbb{T}_\Sigma$ around γ_5 that lie outside C return to points on one of two separate arcs of $\mathbb{T}_\Sigma$, namely, the large arc inside C near γ_0 or the small piece between the two intersection points with C that is shown in the enlarged area of the section. Figure 14(b) is at the moment of cubic tangency bifurcation when the invariant manifold $\mathbb{T}_\Sigma$ has a quadratic tangency with the tangency locus C at the point $\mathbf{x}^*$. At the same time $\mathbb{T}_\mathcal{C}$ has a quadratic tangency with C at $\mathbf{x}^*$. Even though this bifurcation of the Poincaré map does not change the invariant curve $\mathbb{T}_\Sigma$, it does make a difference to the dynamics on the global section, because it changes the number of segments of $\mathbb{T}_\Sigma$ on either side of the tangency locus C. After the bifurcation, $\mathbb{T}_\Sigma$ and $\mathbb{T}_\mathcal{C}$ no longer intersect C; see Figure 14(c). This means that now the part of $\mathbb{T}_\Sigma$ around γ_5 that lies outside C returns to a single arc of $\mathbb{T}_\Sigma$ inside C.

It is generally quite difficult to find orbits with cubic tangencies with a section. Therefore, the insight that a cubic tangency bifurcation takes place when a two-dimensional invariant manifold $\mathbb{T}$ passes through a point in $C \cap D$ is very useful from a practical point of view (even though this is only a necessary and not a sufficient condition). Namely, the set $C \cap D$ consists generically of isolated points that can be calculated analytically. In particular, a cubic tangency bifurcation can occur only when $C \cap D \neq \emptyset$. One readily computes that for $|n| \leq 2k/\sqrt{\Delta(n)}$ the curves D and C intersect in two points, which are given by

$$C \cap D = \left(\frac{0.1}{2K}\Delta(n),\ \pm\sqrt{\Delta(n) - \frac{0.01}{4K^2}\Delta(n)^2},\ -0.1 \right) \approx \left(\frac{0.05035}{K},\ \pm\frac{1}{2}\sqrt{4.02808 - \frac{0.01014}{K^2}},\ -0.1 \right) \tag{5.5}$$

for the fixed values $\alpha = 2$, $B = 0.015$, $\gamma = 0.035$, and $\omega = 0.43$ used here, and for $s = s^* = -0.1$. Indeed, for $\Sigma_{-0.1}$ there are exactly two points in $C \cap D$. At the bifurcation for $K \approx 0.1140145$ we have $C \cap D \approx \{(0.44162, \pm 0.90111, -0.1)\}$, and $\mathbb{T}$ crosses the point $\mathbf{x}^* \approx (0.44162, 0.90111, -0.1)$; see Figures 13(a) and 14.

We finally remark that $C \equiv D$ is not generic in our context, but it occurs stably in Hamiltonian vector fields. In fact, this geometric situation was identified (but not in terms of C and D) by Birkhoff [3] as the one that allows the construction of a complete Poincaré section. Namely, for $C \equiv D$ the curve $C \subseteq \Sigma$ is invariant under the flow and orbits are spiraling around C.

5.2. A helical tube with a cubic tangency bifurcation. To get geometric insight into how a cubic tangency bifurcation can be "straightened out" to a normal form in the standard flowbox, we now consider a concrete geometric model of a simplified curved flow. To this end, we consider the family of sections

$$\Sigma_s = \{(x, y, z) \in \mathbb{R}^3 \mid z = s\} \tag{5.6}$$

in $\mathbb{R}^3$, where we further assume that the flow is such that

$$C = C(s) = \{(x, y, s) \in \Sigma_0 \mid y = 0\} \tag{5.7}$$

so that the flow points up for $y > 0$ and down for $y < 0$. Therefore,

$$\mathcal{C} = \{(x, y, z) \in \mathbb{R}^3 \mid y = 0\}. \tag{5.8}$$

To specify the flow further, we consider a helix Γ of radius 1 in $\mathbb{R}^3$ given by

$$\Gamma = \Gamma(\theta) = \{(x, y, z) \in \mathbb{R}^3 \mid x = \theta,\ y = \cos\theta,\ z = \sin\theta\}, \tag{5.9}$$

with period 2π as parameterized by $\theta \in \mathbb{R}$. We assume that the flow leaves Γ invariant. Notice that Γ spirals around C and intersects Σ in infinitely many points for $|s| < 1$.

The next step of the construction is to consider a one-parameter family of invariant tubes around Γ. To obtain a generic situation, the radius (around the respective points of Γ) of the tube must vary with the angular parameter θ. We consider here a standard tube that consists of circles of radius $k\,r(\theta)$ that lie in the plane spanned by the normal $N(\theta)$ and the binormal $B(\theta)$ of Γ at $x = \theta$. The parameter k is the "gross radius" in the sense that changing k changes the size of the tube but not its shape, which is given by $r(\theta)$; note that k plays the same role geometrically as the injection strength K in the laser system (4.5). We assume that $r(\theta)$ does not have extra periodicity or symmetries. Furthermore, $r(\theta)$ is such that there are no self-intersections or other bifurcations such as saddle transitions too near the bifurcation point. A function $r(\theta)$ that satisfies all conditions and the resulting formula of $\mathbb{T}$ can be found in Appendix A.

The helix Γ and the tube $\mathbb{T}$ are shown in Figure 15 for three different values of k. Also shown are the section $\Sigma = \Sigma_{-0.1804} = \{(x, y, z) \in \mathbb{R}^3 \mid z = -0.1804\}$ and the extended critical locus $\mathcal{C}$. The value $s = -0.1804$ for the height of the section Σ was determined so that there is a cubic tangency bifurcation for the fixed value $k = 0.2$; namely, it occurs at $\theta = 6.94193$. The intersection curves $\mathbb{T}_\Sigma$ and $\mathbb{T}_\mathcal{C}$ in Σ and $\mathcal{C}$, respectively, are shown in Figure 16. In Figures 15 and 16 the rows (a)–(c) show the situation before, at, and after the bifurcation. Figures 15 and 16 also show the critical locus D of $\mathcal{C}$. Since we do not specify an underlying flow, the curve D must also be constructed in a consistent way. In particular, D must go through the point of cubic tangency and be consistent with the positions of $\mathbb{T}_\mathcal{C}$. These requirements are met by D as defined in Appendix A, where the flow through $\mathcal{C}$ is in the direction of negative y above D and in the direction of positive y below D.

As can be seen from Figures 15 and 16, the planes Σ and $\mathcal{C}$, the tangency locus D, and the invariant objects Γ and $\mathbb{T}$ form a consistent geometrical model for the cubic tangency bifurcation. By consistency we mean here that the conditions we place on the unspecified

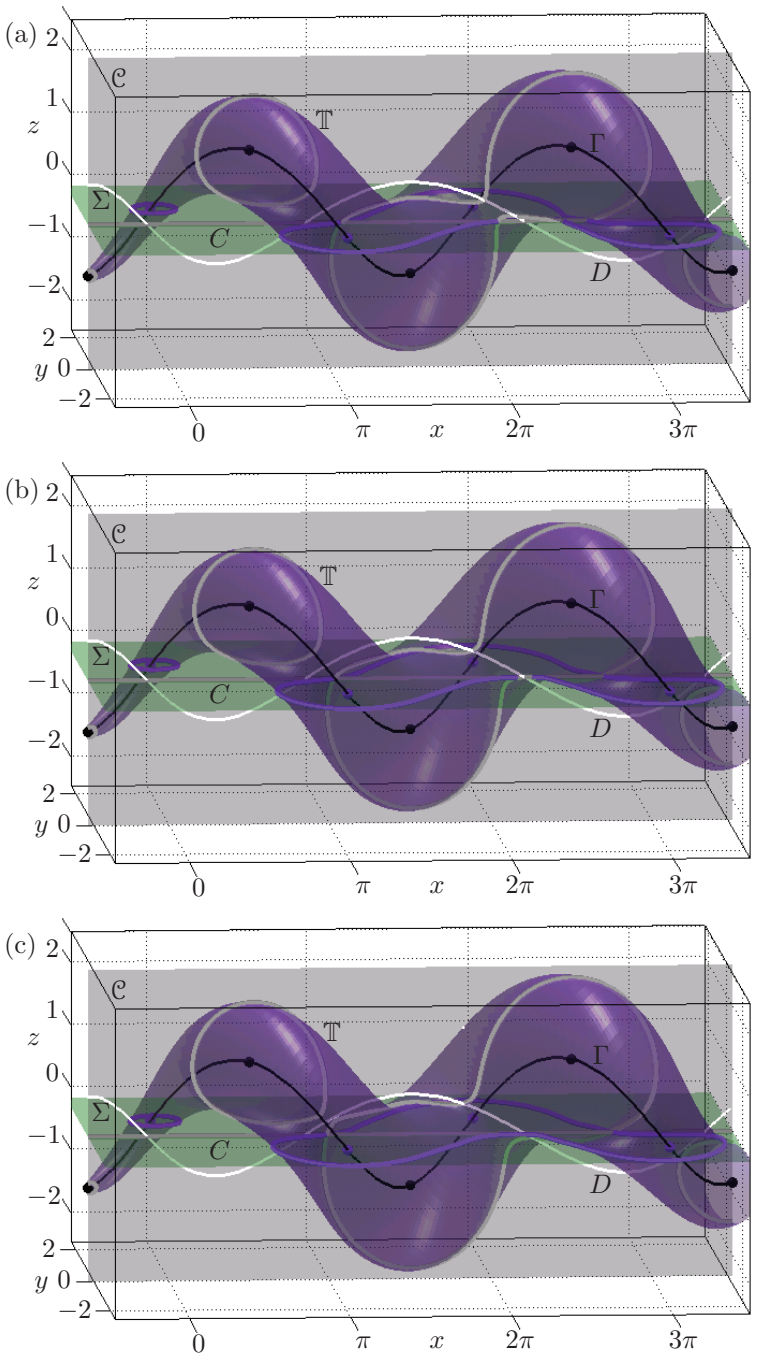

Figure 15. *Geometrical model of a cubic tangency bifurcation, consisting of a helical orbit Γ surrounded by a tube $\mathbb{T}$ of varying radius that spirals around the tangency locus C of a section Σ; also shown is the extended critical locus $\mathcal{C}$. Panels* (a)–(c) *are before, at, and after the bifurcation, namely, for $k = 0.19$, 0.2, and 0.21, while the section is given by $z = -0.1804$; see also Figure 16.*

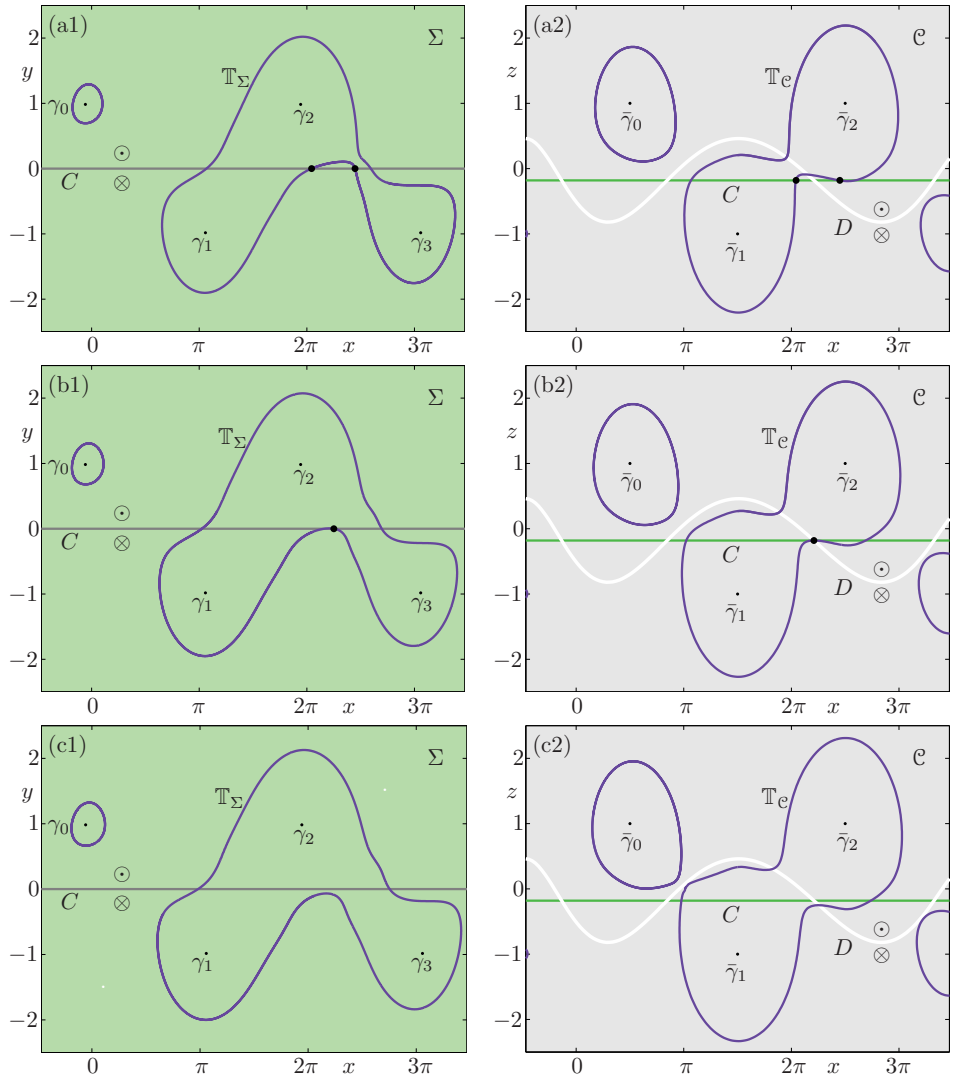

Figure 16. *The geometrical model of a cubic tangency bifurcation shown in the section* Σ *(left column) and in the plane* $\mathcal{C}$ *(right column). Panels* (a)–(c) *are before, at, and after the bifurcation, namely, for* $k = 0.19$, 0.2, *and* 0.21*; see also Figure* 15.

flow during the geometric construction are such that they can be realized by an actual flow; compare with Figure 14. As for the laser system in section 5.1, the bifurcation is unfolded by changing the gross radius of the invariant manifold $\mathbb{T}$, as specified by the parameter k in (A.1). (Note that the cubic tangency bifurcation could also be unfolded by moving the section, that is, by changing the parameter s in (5.6).) The key feature in the section Σ is the single closed component $\mathbb{T}_\Sigma$ that surrounds three points $\gamma_1, \gamma_2, \gamma_3 \in \Gamma_\Sigma$; see Figure 16 (left column). Before the bifurcation the closed component of $\mathbb{T}_\Sigma$ has four intersections with C; at the cubic tangency bifurcation the two innermost of them come together to a single point; and after the bifurcation there are only two intersection points (which is the minimal

number for a component of $\mathbb{T}_\Sigma$ that surrounds three points of Γ_Σ). In the plane $\mathcal{C}$ the object of interest is the single closed component $\mathbb{T}_\mathcal{C}$ that surrounds only two points $\overline{\gamma}_1, \overline{\gamma}_2 \in \Gamma_\mathcal{C}$; see Figure 16 (right column). Before the bifurcation the closed component of $\mathbb{T}_\mathcal{C}$ has four intersections with $\Sigma \cap \mathcal{C}$ (note that the situation in row (a) is close to a saddle transition), at the cubic tangency bifurcation the two innermost of them come together to a single point, and after the bifurcation there are only two intersection points (which is again the minimal number for a component of $\mathbb{T}_\mathcal{C}$ that surrounds two points of $\Gamma_\mathcal{C}$).

5.3. Normal form of the cubic tangency bifurcation. To obtain the normal form of the cubic tangency bifurcation in a three-dimensional flowbox we consider a small neighborhood of the bifurcation in phase space. The idea is then to "untwist" the helical structure of the flow, which means that the section Σ and the extended critical locus $\mathcal{C}$ deform to smooth surfaces. The key realization is that, owing to the cubic tangency of the orbit involved, in the normal form one needs to consider a section Σ that has a cusp singularity when projected along the orbits onto the in-set I (or the out-set O). The result in the absence of an invariant manifold was proved by Sotomayor and Teixeira [38, Figure 5.2] in the context of vector fields on a three-dimensional manifold with a codimension-one boundary. It can be phrased as follows in the present context.

Proposition 5.1. *In any sufficiently small flowbox the phase portrait near a cubic tangency of an orbit of a flow in $\mathbb{R}^3$ with a global section is topologically equivalent to the phase portrait in the standard flowbox (2.7) for $n = 3$ given by the section*

$$\Sigma = \{(u, v_1, v_2) \in \mathbb{R}^3 \mid v_1\, u - u^3 + v_2 = 0\}. \tag{5.10}$$

In order to understand the geometry of the flow in the standard flowbox and to help make the link with the previous sections, we now construct the extended tangency locus $\mathcal{C}$. Since $\vec{n}_\Sigma((0,0,0)) = (0,0,1)$, we embed the section Σ of (5.10) into the one-parameter family of sections

$$\Sigma_s = \{(u, v_1, v_2 + s) \in \mathbb{R}^3 \mid v_1\, u - u^3 + v_2 = 0\} \tag{5.11}$$

so that $\Sigma = \Sigma_0$. One readily finds that the tangency locus of Σ_s is

$$C = C(s) = \{(u, v_1, v_2 + s) \in \Sigma_s \mid v_1 = 3u^2,\ v_2 = -2u^3\}. \tag{5.12}$$

The projection $\widehat{C}$ of C onto the in-set I along the u-direction (the direction of the flow) has two branches that meet at a cusp point at $(v_1, v_2) = (0, s) \in I$. It follows that the extended critical locus $\mathcal{C}$ of the family Σ_s is the parabolic surface

$$\mathcal{C} = \{(u, v_1, v_2) \in \mathbb{R}^3 \mid v_1 = 3u^2\}. \tag{5.13}$$

Furthermore, the flow is tangent to $\mathcal{C}$ along the tangency locus

$$D = \{(u, v_1, v_2) \in \mathcal{C} \mid u = 0,\ v_1 = 0\},$$

where the flow is directed into the parabolic cylinder bounded by $\mathcal{C}$ for $u < 0$ and out of the parabolic cylinder for $u > 0$.

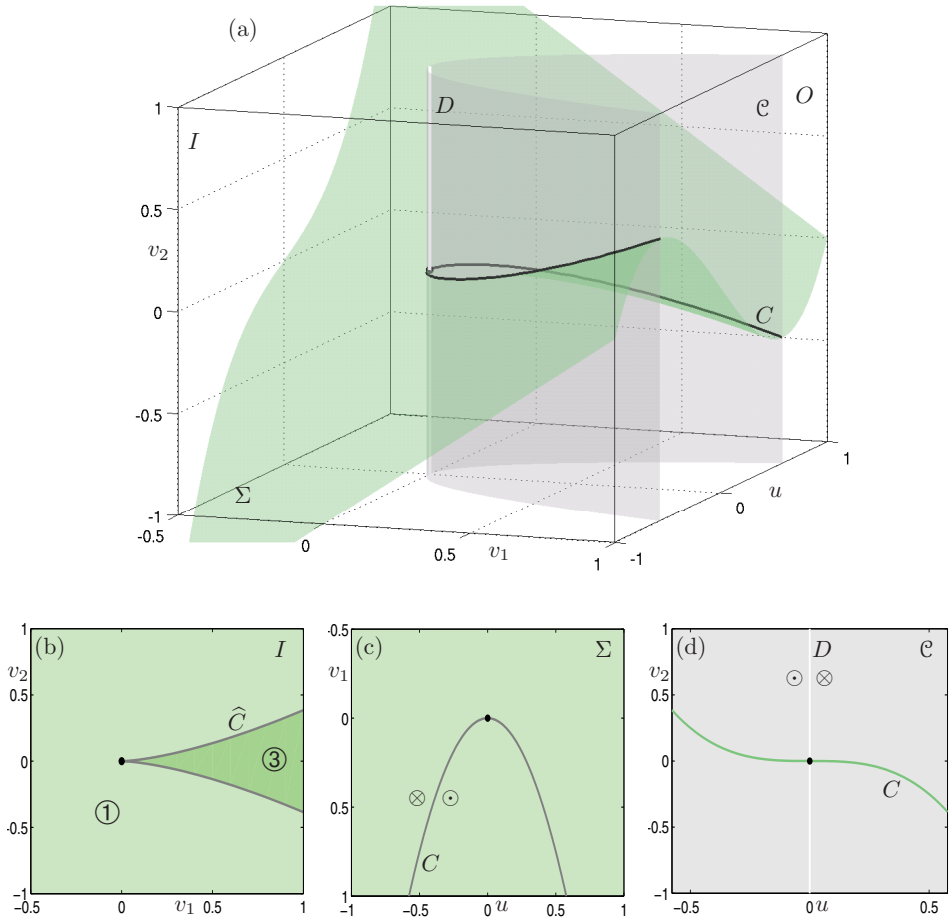

Figure 17. *Panel* (a) *depicts the cuspidal section* $\Sigma = \Sigma_0$ *(green) of* (5.11) *and the extended critical locus* $\mathcal{E}$ *inside the standard flowbox. Panel* (b) *shows the projection of* C *and* Σ *onto the in-set* I*; the symbols* ① *and* ③ *indicate the regions with one and three intersections with* Σ*, respectively. Panel* (c) *shows the curve* C *in* Σ*, and panel* (d) *the curves* C *and* D*. The direction of the flow is indicated by the symbols* $\odot$ *and* $\otimes$*.*

Figure 17(a) shows the section $\Sigma = \Sigma_0$ and the extended critical locus $\mathcal{E}$ inside the standard flowbox. Figures 17(b)–(d) show respective images on I, Σ, and $\mathcal{E}$. The projection curve $\widehat{C}$ divides the in-set I into two regions, labeled ① and ③ in Figure 17(b). Any orbit starting inside region ③ of I has three intersections with Σ while it "winds around" the curve C in (u, v_1, v_2)-space. (Rather, in the flowbox C winds around the straight orbit segment.) Similarly, orbits starting in region ① intersect Σ only once. Moreover, any orbit with $v_1 > 0$ intersects the parabolic surface $\mathcal{E}$ twice; compare with Figure 17(d). In other words, the geometry shown in Figure 17 is indeed topologically equivalent to that near a cubic tangency as discussed in sections 5.1 and 5.2.

We now present the normal form of the cubic tangency bifurcation. This bifurcation is of codimension one under the genericity conditions that the invariant manifold is in general position with respect to the section Σ at the moment of cubic tangency, the dependence on

the parameter is smooth, and the manifold crosses the section with positive speed.

Proposition 5.2. *In any sufficiently small flowbox, the unfolding of a cubic tangency of a two-dimensional invariant manifold of a flow in* $\mathbb{R}^3$ *with a global section is topologically equivalent to the unfolding in the standard flowbox* (2.7) *for* $n = 3$ *given by the one-parameter family of sections defined in* (5.11)*, where the invariant manifold is the plane*

$$M = \{(u, v_1, v_2) \mid v_1 = -v_2\}. \tag{5.14}$$

Proof. Suppose that the unfolding parameter of the quadratic tangency is η and the bifurcation takes place for $\eta = 0$. According to Proposition 5.1, any phase portrait of the unfolding in a flowbox near the cubic tangency point is topologically equivalent to that given by $\Sigma = \Sigma_0$ in the standard flowbox (2.7) for $n = 3$. Therefore, the invariant manifold is mapped to a surface $\widetilde{M}(\eta)$. The curve $\widetilde{M}(\eta) \cap I$ is (locally and for sufficiently small η) given by a function $\mu_\eta : v_1 \to v_2$ on the in-set I. Since $\widetilde{M}(0)$ is in general position, we have that $\frac{d\mu}{d\eta}(0) \neq 0$, meaning that the tangent vector to $\widetilde{M}(0) \cap I$ at the origin $(v_1, v_2) = (0, 0) \in I$ has both a v_1- and a v_2-component. Due to continuity on η, the same is true for $\widetilde{M}(\eta) \cap I$ for sufficiently small η. Therefore, the curve $\widetilde{M}(\eta) \cap I$ is locally a graph over the antidiagonal $(v_1, -v_1)$ of I, and it intersects the v_2-axis of I at a well-defined height $\mu_\eta(0) = s(\eta)$, where $s(0) = 0$. The u-independent coordinate change

$$(v_1, v_2) \mapsto (v_1, v_2 - v_1 - \mu(v_1))$$

maps $\widetilde{M}(\eta)$ to M as given by (5.14). Due to genericity of the dependence of $\widetilde{M}$ on η, we have that $\frac{d\mu}{d\eta}(0) = \frac{ds}{d\eta} \neq 0$, which implies that the image $\widetilde{\Sigma}(\eta)$ of Σ under this coordinate change is a surface with a generic cusp at $(u, v_1, v_2) = (0, 0, -s(\eta))$. As in the proof of Proposition 4.2, the surface $\widetilde{\Sigma}(\eta)$ can be brought to the required form (5.11) by a u-independent coordinate change that leaves M invariant. The overall η-family of coordinate changes is continuous by the genericity assumption on η. ∎

The important realization is that the manifold M of the normal form in the standard flowbox needs to be in general position relative to the cusp surface, which means that it must have nonnegative components in both the v_1- and the v_2-directions. This is ensured by the choice of the "diagonal" manifold M defined in (5.14). Note that a horizontal manifold (given by $v_2 = 0$) would always intersect the curve C in exactly one point, while a vertical manifold (given by $v_1 = 0$) would always intersect C at the cusp point. Both situations are not generic. Furthermore, for generic M as given in the normal form by (5.14), the cubic tangency bifurcation can alternatively be unfolded by moving the manifold M up and down. This is exactly the mechanism leading to a cubic tangency of an invariant torus when its gross radius changes as in sections 5.1 and 5.2.

In Figure 18 the unfolding given by Proposition 5.2 is presented in (u, v_1, v_2)-space, and in Figure 19 on the in-set I, the section Σ_s, and the extended critical locus $\mathcal{C}$; see also the accompanying animation (69972_03.gif [21.3MB]). Before the cubic tangency bifurcation, the invariant manifold M_Σ in Σ_s has two intersections with the curve C. Similarly, the intersection curve $M_\mathcal{C}$ in $\mathcal{C}$ intersects C twice. At the moment of bifurcation both M_Σ and $M_\mathcal{C}$ have quadratic tangencies with C in Σ_s and $\mathcal{C}$, respectively. Notice that these tangencies

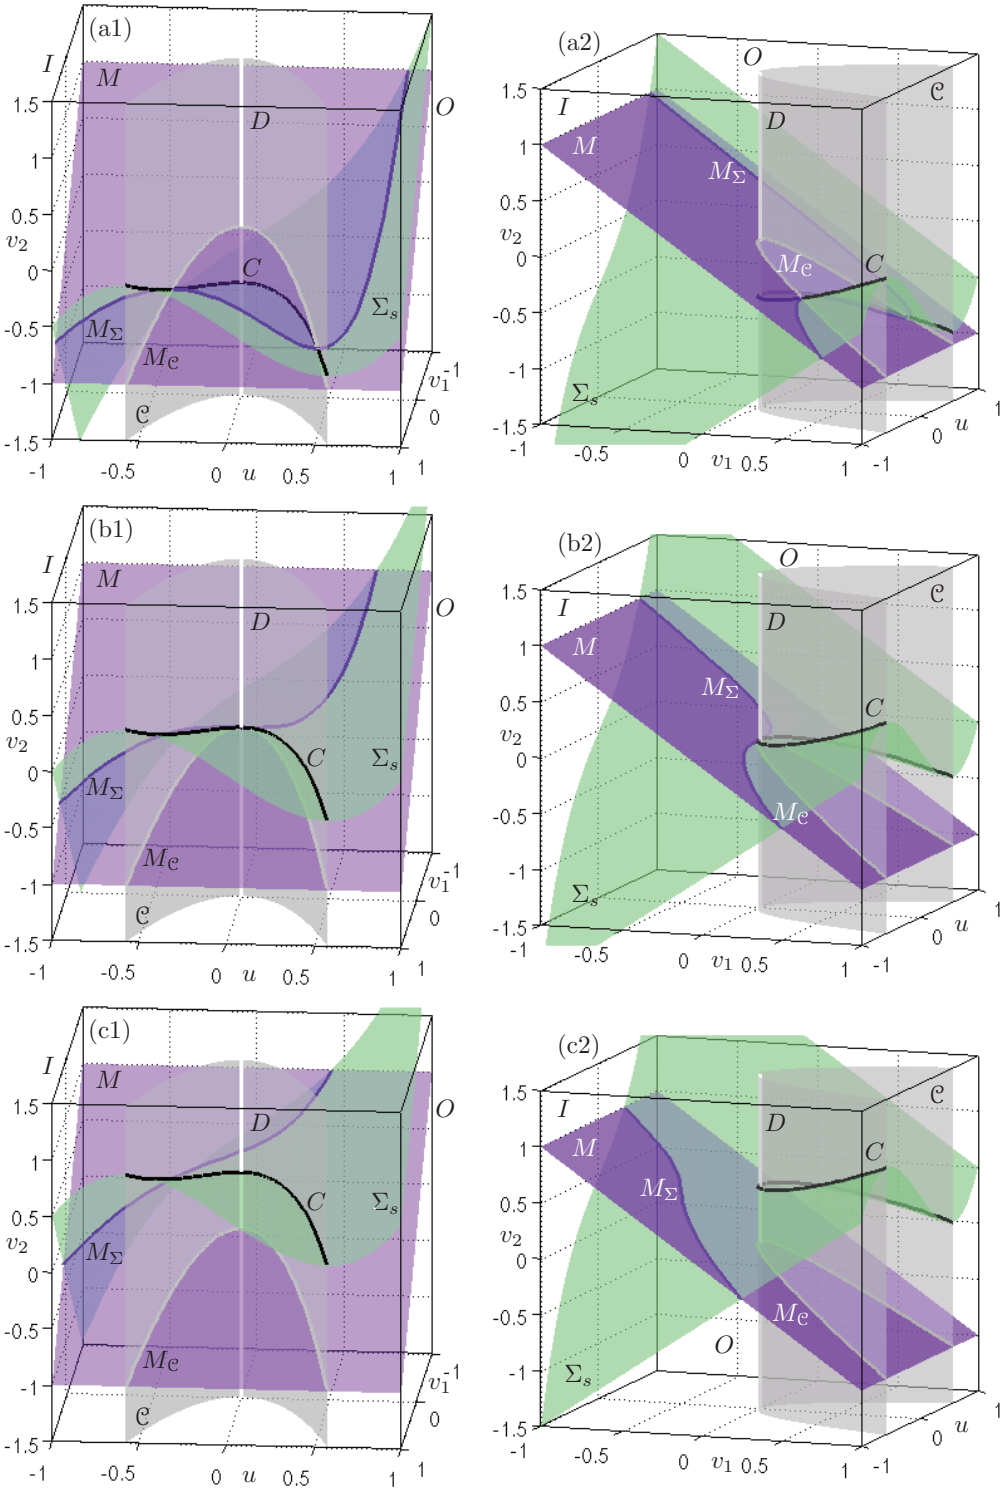

Figure 18. *Unfolding of the cubic tangency bifurcation in normal form in the standard flowbox, presented from two different viewpoints. Rows* (a)–(c) *show the invariant manifold* M *(purple), the section* Σ_s *(green), and the extended critical locus* $\mathcal{C}$ *(gray) before, at, and after the bifurcation. Also shown are the tangency loci* C *and* D*. From* (a)–(c) $s = -0.5$, $s = 0$, *and* $s = 0.5$*; see also Figure* 19 *and animation* (69972_03.gif [21.3MB]).

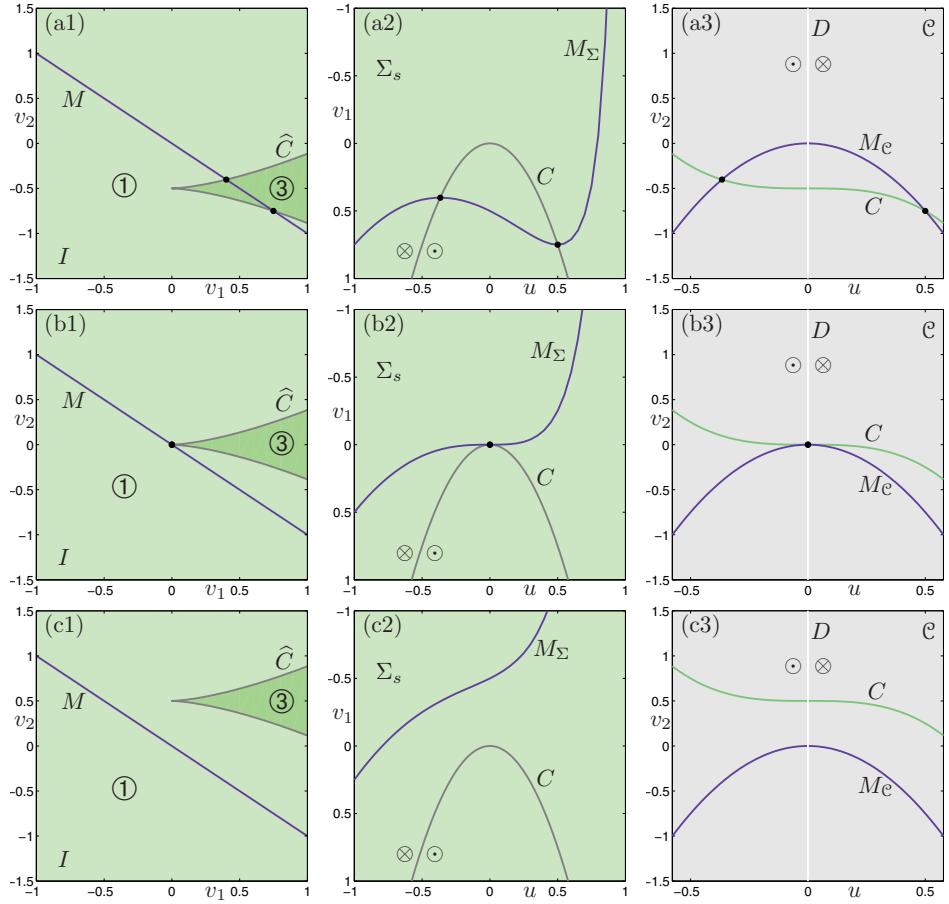

Figure 19. *Unfolding of the cubic tangency bifurcation projected onto the in-set I (left column), on the section Σ_s (middle column), and on the extended critical locus $\mathcal{C}$ (right column); compare with Figure 17. From* (a)–(c) *$s = -0.5$, $s = 0$, and $s = 0.5$; see also Figure 18 and animation* (69972_03.gif [21.3MB]).

indeed occur at the point $C \cap D$ as noted previously. After the bifurcation, neither M_Σ nor $M_{\mathcal{C}}$ intersect C. The comparison of Figure 19 with the corresponding Figure 14 of a cubic tangency bifurcation in the semiconductor laser system (4.5) demonstrates how the unfolding manifests itself in a concrete example.

6. Tangency bifurcations in higher dimension and of higher codimension. The unfoldings in the previous sections of the codimension-one tangency bifurcations of a manifold M with a global section Σ of flows in $\mathbb{R}^2$ and $\mathbb{R}^3$ give only a hint of the many possibilities for tangency bifurcations of a fixed codimension in $\mathbb{R}^n$ for any n. The key realization is that there are two "sources" of codimension: the order of contact with Σ of the orbit $\mathcal{O}(\mathbf{x}^*)$ of the tangency point $\mathbf{x}^*$ and possible codimension associated with tangencies of M and Σ at $\mathbf{x}^*$ in other directions. The first example of a tangency bifurcation with both types of tangencies is the codimension-one quadratic tangency in $\mathbb{R}^3$ in section 4.

Classifying and unfolding tangency bifurcations of higher codimension and for $n > 3$ is beyond the scope of this paper. However, we now give a general framework for this task, which

is based on a more detailed consideration of the intersection of the tangent spaces $T_M(\mathbf{x}^*)$ and $T_\Sigma(\mathbf{x}^*)$.

Definition 6.1. *Let M be an invariant manifold of dimension ℓ of a vector field f on $\mathbb{R}^n$ with a given planar $(n-1)$-dimensional global section Σ. Suppose that the following conditions are satisfied:*

(B1) *There is a point $\mathbf{x}^* \in M \cap \Sigma$ such that the orbit $\mathcal{O}(\mathbf{x}^*)$ has a tangency of degree $d \in \mathbb{N}$ with Σ at $\mathbf{x}^*$, where we assume that the tangency is at least quadratic, that is, $d \geq 2$.*

(B2) *The dimension of the orthogonal complement N of $f(\mathbf{x}^*)$ in $T_M(\mathbf{x}^*) \cap T_\Sigma(\mathbf{x}^*)$ is p.*

(B3) *The point $\mathbf{x}^*$ is a critical point of codimension q of the restriction $\vartheta|_N$ to N of the local chart $\vartheta : T_M(\mathbf{x}^*) \to \mathbb{R}^n$ of the manifold M at $\mathbf{x}^*$.*

Then we say that M and Σ have a d-tangency with singularity dimension p and singularity codimension q *at $\mathbf{x}^*$ (or d-p-q-tangency for short).*

The singularity codimension q is defined only for $p > 0$, meaning that $p = 0$ if and only if $q = 0$. Furthermore, by construction of N there must be a tangency (quadratic or of higher degree) along each of the base vectors of N so that $q \geq p$. From the data specified in Definition 6.1 one can determine the overall codimension.

Proposition 6.2. *The codimension c of a d-p-q-tangency of an ℓ-dimensional invariant manifold $M \subset \mathbb{R}^n$ with a global section is $c = d + q - \ell$, where $p < \ell < n$.*

Proof. For M and Σ in general position, $\dim(\Sigma \cap M) = \ell - 1$, independently of n. Furthermore, by (B1) and (B3) the point $\mathbf{x}^*$ is a critical point of codimension $(d-1)+q$ of the restriction of the chart ϑ to $f(\mathbf{x}^*) \oplus N = T_M(\mathbf{x}^*) \cap T_\Sigma(\mathbf{x}^*)$. Therefore, the codimension of the bifurcation is $c = (d-1) + q - (l-1)$. ■

Proposition 6.2 has some interesting immediate consequences. First, it shows that we indeed presented all codimension-one d-p-q-tangency bifurcations for $n \leq 3$; namely,

1. the 2-0-0-tangency for $\ell = 1$ is the quadratic tangency of a one-dimensional manifold in $\mathbb{R}^2$ and in $\mathbb{R}^3$ of Proposition 3.2 and Corollary 4.1, respectively;
2. the 2-1-1-tangency for $\ell = 2$ is the quadratic tangency of a two-dimensional manifold in $\mathbb{R}^3$ of Proposition 4.2; and
3. the 3-0-0-tangency for $n = 3$ and $\ell = 2$ is the cubic tangency of a two-dimensional manifold in $\mathbb{R}^3$ of Proposition 5.2.

Similarly, we can list all codimension-two tangency bifurcations for $n \leq 3$, which are as follows:

1. the 3-0-0-tangency for $\ell = 1$ is the cubic tangency of a one-dimensional manifold in $\mathbb{R}^2$ and in $\mathbb{R}^3$;
2. the 2-1-2-tangency for $\ell = 2$ is the quadratic tangency of a two-dimensional manifold with a cubic tangency in the one-dimensional N-direction;
3. the 3-1-1-tangency for $\ell = 2$ is the cubic tangency of a two-dimensional manifold with a quadratic tangency in the one-dimensional N-direction; and
4. the 4-0-0-tangency for $\ell = 2$ is a tangency of order four of an orbit on a two-dimensional manifold.

An important new element of codimension-two tangency bifurcations is that they cannot be unfolded solely by moving the section Σ (because Σ is of codimension one in $\mathbb{R}^n$). Of the cases above, only the unfolding for $\ell = 1$, that is, the codimension-two cubic 3-0-0-tangency, is straightforward.

Proposition 6.3. *In any sufficiently small flowbox, the unfolding of a cubic tangency of*

a one-dimensional invariant manifold of a flow in $\mathbb{R}^3$ *with a global section is topologically equivalent to the unfolding in the standard flowbox* (2.7) *for* $n = 3$ *given by the one-parameter family of sections* (5.11) *that interacts with the one-parameter family of manifolds*

$$M = \{(u, v_1, v_2) \mid v_1 = \lambda \text{ and } v_2 = 0\}.$$

This result follows from Proposition 5.1 in the same way that Proposition 3.2 follows from Proposition 3.1, namely, by the construction of a parameter-dependent coordinate change. Proposition 6.3 says that the unfolding of the codimension-two cubic tangency of a one-dimensional manifold in $\mathbb{R}^3$ (and, therefore, in all dimensions $n \geq 2$ and including $n = 2$) is given by the standard unfolding of a cusp bifurcation. Namely, the phase portrait is determined by the relative position of the point $M_I = (0, \lambda)$ in the in-set I relative to projection $\widehat{C}(s)$ of the fold curve; see Figure 17. Crossing one of the two branches of $\widehat{C}(s)$ corresponds to a codimension-one quadratic tangency that unfolds as given by Corollary 4.1. At the central codimension-two point the manifold passes exactly through the cusp point in I.

Suppose now that M is actually a segment of a periodic orbit Γ, meaning that there is a map R from the out-set O back to the in-set I that leaves M invariant. Then the number of intersections of Γ with Σ changes by two when Γ crosses C, even if this happens at the cusp point.

7. Conclusions and discussion. We considered the class of tangency bifurcations, which are bifurcations that one finds generically in global Poincaré maps but that are not due to bifurcations of the underlying vector field. Tangency bifurcations involve the interaction of an invariant manifold with the tangency locus of the section, which is nonempty unless the system is effectively periodically forced. Specifically, we presented a complete treatment of codimension-one tangency bifurcations of flows in $\mathbb{R}^2$ and $\mathbb{R}^3$, that is, for one-dimensional and two-dimensional global sections. We presented their normal forms in the standard flowbox by specifying suitable families of curved smooth sections that interact with straight invariant manifolds of appropriate dimension. Our approach is similar in spirit to that taken by Sotomayor and Teixeira, who considered flows on manifolds with one- and two-dimensional boundaries. The additional ingredients needed here are further coordinate transformations to "straighten out" the invariant manifold but such that the flowlines in the flowbox remain unchanged.

With the examples of the two-dimensional unforced Van der Pol oscillator and a three-dimensional model of a semiconductor laser with optical injection, we demonstrated how the codimension-one tangency bifurcations manifest themselves in a specific vector field. Namely, we studied the interactions of periodic orbits and invariant tori with the tangency locus of a given planar section. As is the case generically, the respective bifurcations of the Poincaré map can be brought about by either changing some system parameter or moving the section. The quadratic tangencies of one- or two-dimensional invariant manifolds with a planar section could be associated with the respective normal forms in the flowbox in a relatively straightforward manner. In the case of a cubic tangency, on the other hand, the operation of "straightening out" the flow to obtain the normal form in the flowbox is quite complicated. Therefore, a simplified geometric model at an intermediate step was constructed to help understand the normal-form transformation geometrically.

As we have shown for the concrete example of an attracting periodic orbit, a tangency bifurcation may give rise to a global topological change of the corresponding Poincaré map. Here, the properties of the map from the out-set back to the in-set become important. Similarly, one can study the consequences of tangency bifurcations of two-dimensional Poincaré maps in three-dimensional vector fields. However, there are more possibilities for the map from the out-set back to the in-set, because it is now two-dimensional as well. One example would be that the map has a repelling fixed point surrounded by an invariant curve, which would correspond to the case that the invariant manifold inside the flowbox is part of an invariant torus. Section 4.1 hints at bifurcations of the two-dimensional Poincaré map in the case that the flow on the torus is rational or irrational. However, the situation may be quite complicated if there are equilibria on the smooth torus. The classical example is the Cherry flow [8, 23], which gives rise to discontinuity of the Poincaré map on the invariant curve; in fact, the points where all iterates of this Poincaré map are defined form a Cantor set. A discussion of topological changes of two-dimensional Poincaré maps is left for future work.

The unfoldings presented here were shown to fit naturally into a general framework for the classification of tangency bifurcations of arbitrary codimension. The general idea is that a tangency of degree $d \geq 2$ of an orbit on the manifold is accompanied by other possible tangencies of the manifold in the directions normal to this orbit. This point of view provides a clear direction for the future study of tangency bifurcations in higher-dimensional spaces and of higher codimension. We already listed the codimension-two tangency bifurcations of a two-dimensional manifold in $\mathbb{R}^3$, and the construction of their unfoldings is an interesting challenge. Another important next step and the subject of our ongoing research is the study of tangency bifurcations in $\mathbb{R}^4$. This study starts with the tangency bifurcations of codimension one, as they are encountered naturally when a single parameter of the vector field is changed, or the section is moved. The normal forms that need to be developed involve intersections of hypersurfaces in $\mathbb{R}^4$, which is very hard to imagine and visualize. This difficulty can be overcome by considering the corresponding surfaces in the three-dimensional in-set of the flow box. Note that it will be a real challenge to identify and visualize tangency bifurcations in three-dimensional sections in concrete vector fields arising from applications.

Another topic of ongoing research is the classification of different mechanisms in which points or regions are created in the global section for which the flow never returns back to the section. In other words, the issue is to find bifurcations that create new sets of the section where the Poincaré map is not defined. As we already demonstrated in section 3.3, such bifurcations may be due to interactions between the global section and stable and unstable manifolds of equilibria and other invariant sets that do not lie in the section. Already for the case of three-dimensional flows, the study of these bifurcations in applications requires the use of numerical techniques for the computation of two-dimensional global invariant manifolds, such as those in [13, 24, 25].

Appendix A. Details of the helical tube construction. A standard tube of radius $k\,r(\theta)$ around the helix (5.9) is given by

$$\mathbb{T} = \{\Gamma(\theta) + k\,r(\theta)\,(N(\theta)\cos\phi + B(\theta)\sin\phi) \quad \text{for } \theta \in \mathbb{R},\ 0 \leq \phi < 2\pi\}\,, \tag{A.1}$$

where $N(\theta)$ is the normal and $B(\theta)$ the binormal at $x = \theta$. From (5.9) it follows that the

tangent, normal, and binormal are

$$T = \left(\frac{1}{\sqrt{2}}, -\frac{\sin\theta}{\sqrt{2}}, \frac{\cos\theta}{\sqrt{2}}\right), \quad N = (0, \cos\theta, \sin\theta), \quad B = \left(\frac{1}{\sqrt{2}}, \frac{\sin\theta}{\sqrt{2}}, -\frac{\cos\theta}{\sqrt{2}}\right).$$

Therefore, the helical tube (A.1) takes the form

$$\mathbb{T} = \left\{(x,y,z) \in \mathbb{R}^3 \mid x = \theta + k\, r(\theta)\frac{\sin\phi}{\sqrt{2}},\ y = \cos\theta + k\, r(\theta)\left(\cos\theta\cos\phi + \frac{\sin\theta\sin\phi}{\sqrt{2}}\right),\right.$$
$$\left. z = \sin\theta + k\, r(\theta)\left(\sin\theta\cos\phi - \frac{\cos\theta\sin\phi}{\sqrt{2}}\right) \text{ for } \theta \in \mathbb{R},\ 0 \le \phi < 2\pi\right\}.$$

A function $r(\theta)$ that satisfies the requirements mentioned in section 5.2 is

$$r(\theta) = \left(\sin^2\theta - \left(\frac{2\theta - 3\pi}{2\pi}\right)^2 - \frac{1}{2}\left(\frac{4\theta - 14\pi}{7\pi}\right)^2 + \frac{4}{5}\exp\left(\frac{11\pi}{4} - \theta\right) + 6\right).$$

For $K = 0.2$ we find a cubic tangency bifurcation with the plane $\Sigma = \Sigma_{-0.1804}$ at $\mathbf{x}^* \approx (6.94193, 0, -0.1804) \in C \subset \Sigma$. The curve $D \subset \mathcal{C}$ can now be constructed by observing the condition that it goes through $\mathbf{x}^*$ and is in general position with respect to the components of $\mathbb{T}_{\mathcal{C}}$. The definition

$$D = D(\theta) = \left\{(\theta, 0, z) \in \mathcal{C} \mid z = -0.64\sin\left(\frac{16\theta\pi^2 - 111.0709\pi^2}{-0.34\,(2\theta - 3\pi)^2 + 22.4\pi^2}\right) + 0.1804\right\}$$

meets these requirements, as can be seen from Figure 16. Note that the choice of $r(\theta)$ and D are by no means unique. The formulae presented here are indeed quite involved, but they allow one to compute all objects of interest while being consistent with the existence of an underlying flow.

Acknowledgments. The authors thank M. A. Teixeira and J. Sotomayor for helpful discussions.

Synchronous Chaos in Coupled Map Lattices with General Connectivity Topology*

Jonq Juang† and Yu-Hao Liang†

Abstract. The purpose of the paper is to address the synchronous chaos in coupled map lattices with general connectivity topology. Our main results contain the following. First, the master stability functions also hold for general connectivity topology with coupling through a nonlinear function that needs to be exactly the individual chaotic map. Second, the synchronization curve, composed of pieces of transverse Lyapunov exponent curves, is constructed. Third, necessary and sufficient conditions on coupling strength for yielding the synchronous chaos of the system are given. Moreover, the coupling strength d_c giving the fastest convergence rate of the initial values toward the synchronous state is explicitly obtained. It is also proved that such d_c is independent of the choice of the individual map. Finally, our results here can be applied to address questions of wavelength bifurcations and size instability.

Key words. stable synchronization, Lyapunov exponents, wavelength bifurcation, coupled map lattices

1. Introduction.

A particularly interesting form of dynamical behavior occurs in networks of coupled systems or oscillators when all of the individual systems or oscillators acquire identical chaotic behavior. Such behavior of a network models many systems of interest in physics, biology, and engineering. A central dynamical question is: When is such synchronous behavior stable, especially in regard to coupling strengths in the network? Much progress in this direction has been made in lattices of coupled chaotic systems. Indeed, many results [1], [2], [3], [4], [5], [6], [7], [8], [9], [10], [11], [12], [13], [14] give analytical criteria for determining the range of coupling strength to acquire locally or even globally stable synchronization. On the other hand, to the best of our knowledge, there are no general results for global synchronization in coupled map lattices (CMLs). There are, however, globally synchronous results for some special cases (see, e.g., [15]). As to the study of local synchronization in CMLs, the notion of master stability functions (MSFs) that allows one to isolate the contribution of the network structure in terms of the eigenvalues of the coupling matrix was introduced in [8], [16], [17], [18], [19] to determine the possible range of coupling strength. This function then defines a region of stably synchronous state in terms of the coupling strength and the eigenvalues of the coupling matrix. Most of the work done in finding such a region of stability of the synchronous state is numerical. In a few certain cases, such as when the coupling matrix is symmetric, the MSFs can be further reduced to a number of inequalities [20], [21], [22], [23]

$$h_{\max} + \ln|1 + d\lambda_i| < 0, \quad i = 2, \ldots, m. \tag{1.1}$$

Here $h_{\max}$ is the largest Lyapunov exponent of the individual map, λ_i are the nonzero eigenvalues of the $m \times m$ coupling matrix, and d is the coupling strength. The Gershgorin disk theory is then applied to obtain some sufficient conditions [23] on the coupling strength for local synchronization. The reason for the huge gap between the theory developed in the lattices of coupled chaotic systems and that of CMLs lies mostly in the fact that it is more natural to have a nonlinear coupling between oscillators in the CMLs. This is because a nonlinear coupling within suitable range of the coupling strength tends to yield an invariant region for the corresponding CMLs while linear coupling cannot. It should be noted that there is no such problem for the lattices of coupled chaotic systems. It should also be mentioned that all the analytical results of the lattices of the coupled chaotic systems stated above are linearly coupled.

The purpose of this paper is to give the best possible results for the local synchronization of the CMLs. Indeed, we first prove that (1.1) holds true for general connectivity topology with a limitation that the nonlinear coupling needs to be the individual chaotic map as well. Second, the synchronization curve, composed of pieces of transverse Lyapunov exponent curves, is derived. With the help of the synchronization curve, we give necessary and sufficient conditions on yielding synchronization of the CMLs. Such conditions then lead to the identification of the optimal coupling strength interval for acquiring synchronization of the CMLs. The optimal interval is to be termed the *synchronization interval* of the CMLs. Moreover, the coupling strength d_c, called the *center* of the *synchronization interval* and giving the fastest convergence rate of the initial values toward the synchronous state, can be identified. Such d_c is independent of the choice of the individual map. Like the applications, our work here can also be used to analytically quantify how the small-world scheme improves the synchronizability of the network [24], [25], [26], [27]. Furthermore, our results here can be applied to address questions of wavelength bifurcations [28], [29], [30], [31], [32] and size instability [32]. For CMLs or coupled chaotic systems, the following four scenarios are possible as the coupling varies: (i) no synchronization; (ii) the presence of short wavelength bifurcations (SWBs); (iii) the presence of intermediate wavelength bifurcations (IWBs); and (iv) the presence of long wavelength bifurcations (LWBs). Our main results give the following. First, if the coupling matrix has only real eigenvalues, then only (i) and (ii) are possible. Second, if the coupling matrix has complex eigenvalues, then all four scenarios are possible. Third, the critical values for which wavelength bifurcations occur as well as the exact number of oscillators capable of sustaining stably synchronous chaos can be explicitly computed. Finally, the minimum coupling value where all wavelength modes become de-excited enough to induce the stability of the synchronous state is also explicitly given.

We conclude this introductory section by mentioning the organization of the paper. The main results are contained in section 2. Three types of coupling matrices are provided in section 3 as illustrations and applications to our main results. Some concluding remarks about future research are addressed in section 4.

2. Main results. Consider a network of CMLs consisting of m oscillators. The equations of the motion then read

$$\boldsymbol{x}_i(n+1) = \boldsymbol{f}(\boldsymbol{x}_i(n)) + d\left(\sum_{k=1}^{m} g_{ik}\boldsymbol{h}(\boldsymbol{x}_k(n))\right), \quad i = 1, \ldots, m. \tag{2.1}$$

Here $\boldsymbol{f}:\mathbb{R}^l\to\mathbb{R}^l$, $l\geq 1$, represents the individual chaotic map, and $\boldsymbol{h}:\mathbb{R}^l\to\mathbb{R}^l$ is an arbitrary nonlinear function describing how each oscillator's variables are used in the coupling. The quantities g_{ij} are the coupling weights between the oscillators i and j. To consider the notion of synchronization, we assume that $\sum_{k=1}^m g_{ik}=0$ for each i, and 0 is the simple eigenvalue of the coupling matrix $\boldsymbol{G}=(g_{ij})$. The quantity d represents the coupling strength of the CMLs (2.1). To have an invariant region for CMLs (2.1), one usually chooses $\boldsymbol{h}$ as $\boldsymbol{f}$. Such nonlinear coupling between oscillators is what makes (2.1) harder to treat analytically. In vector-matrix form with $\boldsymbol{h}=\boldsymbol{f}$, (2.1) becomes

$$\boldsymbol{x}(n+1)=\boldsymbol{F}(\boldsymbol{x}(n))+d(\boldsymbol{G}\otimes\boldsymbol{I})\boldsymbol{F}(\boldsymbol{x}(n)), \tag{2.2}$$

where $\otimes$ denotes the Kronecker product, $\boldsymbol{x}(n)=(\boldsymbol{x}_1(n),\dots,\boldsymbol{x}_m(n))^T$, and $\boldsymbol{F}(\boldsymbol{x}(n))=(\boldsymbol{f}(\boldsymbol{x}_1(n)),\dots,\boldsymbol{f}(\boldsymbol{x}_m(n)))^T$.

To study the stability of the synchronous state $\{\boldsymbol{x}_i=\boldsymbol{s}\ \forall i\}$ of CML (2.2), we consider the variational equation of (2.2):

$$\begin{aligned}\boldsymbol{\xi}(n+1)&=D\boldsymbol{F}(\boldsymbol{s}(n))\boldsymbol{\xi}(n)+d(\boldsymbol{G}\otimes\boldsymbol{I})D\boldsymbol{F}(\boldsymbol{s}(n))\boldsymbol{\xi}(n)\\ &=\left[\boldsymbol{I}\otimes D\boldsymbol{f}(\boldsymbol{s}(n))+d\left(\boldsymbol{G}\otimes\boldsymbol{I}\right)\left(\boldsymbol{I}\otimes D\boldsymbol{f}\left(\boldsymbol{s}(n)\right)\right)\right]\boldsymbol{\xi}(n),\end{aligned} \tag{2.3a}$$

where $\boldsymbol{\xi}=(\boldsymbol{\xi}_1,\dots,\boldsymbol{\xi}_m)$ and each $\boldsymbol{\xi}_i$ is the perturbation to the ith oscillator. Let $\boldsymbol{J}=\boldsymbol{P}^{-1}\boldsymbol{G}\boldsymbol{P}$, where $\boldsymbol{J}=[0]\oplus\boldsymbol{J}_1\oplus\cdots\oplus\boldsymbol{J}_p$ is the real Jordan canonical form of $\boldsymbol{G}$. Applying the change of variables $\boldsymbol{\eta}=(\boldsymbol{P}^{-1}\otimes\boldsymbol{I})\boldsymbol{\xi}$, we get

$$\boldsymbol{\eta}(n+1)=\left[(\boldsymbol{I}+d\boldsymbol{J})\otimes D\boldsymbol{f}(\boldsymbol{s}(n))\right]\boldsymbol{\eta}(n),$$

or, equivalently, in block diagonal form,

$$\begin{aligned}\boldsymbol{\eta}_i(n+1)&=\left[(\boldsymbol{I}+d\boldsymbol{J}_i)^n\otimes D\boldsymbol{f}^n(\boldsymbol{s}(1))\right]\boldsymbol{\eta}_i(1)\\ &=:\boldsymbol{A}_i(n)\boldsymbol{\eta}_i(1).\end{aligned} \tag{2.3b}$$

Let $\sigma(\boldsymbol{A})$ denote the spectrum of $\boldsymbol{A}$. Then $\sigma(\boldsymbol{A}_i(n)\boldsymbol{A}_i^*(n))$ equals

$$\begin{aligned}&\sigma([(\boldsymbol{I}+d\boldsymbol{J}_i)^n\otimes D\boldsymbol{f}^n(\boldsymbol{s}(1))]\,[(\boldsymbol{I}+d\boldsymbol{J}_i^*)^n\otimes(D\boldsymbol{f}^n(\boldsymbol{s}(1)))^*])\\ &=\sigma([(\boldsymbol{I}+d\boldsymbol{J}_i)^n\,(\boldsymbol{I}+d\boldsymbol{J}_i^*)^n]\otimes[D\boldsymbol{f}^n(\boldsymbol{s}(1))\cdot(D\boldsymbol{f}^n(\boldsymbol{s}(1)))^*])\\ &=\sigma((\boldsymbol{I}+d\boldsymbol{J}_i)^n\,(\boldsymbol{I}+d\boldsymbol{J}_i^*)^n)\cdot\sigma(D\boldsymbol{f}^n(\boldsymbol{s}(1))\cdot(D\boldsymbol{f}^n(\boldsymbol{s}(1)))^*)\\ &=\sigma((\boldsymbol{I}+d\bar{\boldsymbol{J}}_i)^n\,(\boldsymbol{I}+d\bar{\boldsymbol{J}}_i^*)^n)\cdot\sigma(D\boldsymbol{f}^n(\boldsymbol{s}(1))\cdot(D\boldsymbol{f}^n(\boldsymbol{s}(1)))^*),\end{aligned}$$

where $\bar{\boldsymbol{J}}=[0]\oplus\bar{\boldsymbol{J}}_1\oplus\cdots\oplus\bar{\boldsymbol{J}}_p$ is the Jordan canonical form of $\boldsymbol{G}$. Consequently, the Lyapunov exponents of (2.2) are

$$h_j+\lim_{n\to\infty}\frac{\ln\sqrt{\lambda_{k,i}}}{n}.$$

Here h_j are the Lyapunov exponents of the individual system $\boldsymbol{f}$, and $\lambda_{k,i}$ are the eigenvalues of $(\boldsymbol{I}+d\boldsymbol{J}_{\lambda_i})^n(\boldsymbol{I}+d\boldsymbol{J}_{\lambda_i}^*)^n$, where $\boldsymbol{J}_{\lambda_i}$ is a Jordan block of matrix $\boldsymbol{G}$ and λ_i is an eigenvalue of

$\boldsymbol{G}$. Let the size of matrix $\boldsymbol{J}_{\lambda_i}$ be $k_i \times k_i$, and let $\boldsymbol{N} = \boldsymbol{J}_{\lambda_i} - \lambda_i \boldsymbol{I}$. It should be noted that for sufficiently large n,

$$\begin{aligned}(\boldsymbol{I} + d\boldsymbol{J}_{\lambda_i})^n &= ((1 + d\lambda_i)\boldsymbol{I} + d\boldsymbol{N})^n = (1 + d\lambda_i)^n (\boldsymbol{I} + \alpha \boldsymbol{N})^n \\ &= (1 + d\lambda_i)^n \left(\boldsymbol{I} + \sum_{j=1}^{k_i - 1} \binom{n}{j} \alpha^j \boldsymbol{N}^j \right) \\ &=: (1 + d\lambda_i)^n \boldsymbol{T}_i,\end{aligned}$$

where $\alpha = d/(1 + d\lambda_i)$. Clearly, the order of the magnitude of each entry of $\boldsymbol{T}_i \boldsymbol{T}_i^*$ is at most $\mathrm{O}(n^{2k_i - 2})$. We conclude, via the Gershgorin disk theorem, that all eigenvalues of $\boldsymbol{T}_i \boldsymbol{T}_i^*$ are of the order $\mathrm{O}(n^{2k_i - 2})$. Consequently, the Lyapunov exponents of (2.2) are

$$h_j + \ln |1 + d\lambda_i|. \tag{2.4}$$

We summarize the above as follows.

Theorem 2.1. *Let $\boldsymbol{G} = (g_{ij})$ be the coupling matrix satisfying that all its row sums are zero and zero is a simple eigenvalue. Then the synchronous state of CML (2.2) is (locally) stable provided that*

$$h_{max} + \ln |1 + d\lambda_i| < 0, \quad i = 2, \ldots, m, \tag{2.5}$$

where $h_{\max}$ is the largest Lyapunov exponent of the individual map $\boldsymbol{f}$ and $\lambda_i \in \sigma(\boldsymbol{G}) - \{0\}$, $i = 2, \ldots, m$. That is to say, if d satisfies the inequalities in (2.5), then for any initial values of (2.2) that are sufficiently close to the synchronous state $\{\boldsymbol{x}_i = \boldsymbol{s}\ \forall i\}$, we have that each of the oscillators $\boldsymbol{x}_i(n)$ tends to the same state as n goes to infinity. Otherwise, CML (2.2) will not acquire local synchronization.

Remark. (i) The decoupling form (2.3b) of variational equation (2.3a) was first observed and proposed by Pecora and Carroll [8]. (ii) If the identity matrix $\boldsymbol{I}$ in (2.2) is replaced by a diagonal matrix $\boldsymbol{D}$ with some but not all diagonal elements being zero, then the corresponding system (2.2) is called a partial-state coupling. The partial-state coupling also finds applications in various fields. For instance, in self-pulsating laser diode equations (see, e.g., [33]), only the photon density can be coupled with the electron density of the active region. Moreover, in the case of coupled chaotic systems, the systems that are partial-state coupled may exhibit different dynamic behavior. For instance, it is well known (see, e.g., [7]) that for the coupled Lorentz systems, only if the x-component or y-component is coupled will the resulting system achieve synchronization.

We shall assume from here on that the real parts of the eigenvalues of $\mathbf{G}$ are nonpositive. To find the range of the coupling d so that (2.5) is fulfilled, we need to solve the following min max problem:

$$\begin{aligned}\min_{d \in \mathbb{R}} \max_{2 \le i \le m} |1 + d\lambda_i| &= \min_{d > 0} \max_{2 \le i \le m_1} |1 + d\lambda_i| \\ &=: \min_{d > 0} \max_{2 \le i \le m_1} r_i(d) =: \min_{d > 0} r(d).\end{aligned} \tag{2.6}$$

Here m_1 is the number of eigenvalues lying in upper complex plane or on the real axis. The curves $r_i(d)$ are termed the ith mode of the transverse Lyapunov exponent curves. The equalities above are due to the facts that $|1+d\lambda_i| = |1+d\bar{\lambda}_i|$, the real parts of the eigenvalues of $\mathbf{G}$ are nonpositive, and (2.5) is violated whenever $d \le 0$. Without loss of generality, we may assume that those distinct nonzero eigenvalues are λ_i, $i = 2, \ldots, m_1$, with $0 < |\lambda_2| \le \cdots \le |\lambda_{m_1}|$. The coupling value $d := d_c$ solving the min max problem (2.6) is the optimal choice of the coupling in the sense that it gives the fastest convergence rate of the initial values toward the synchronous state. To understand how $r(d)$ is formed, we need to know the ordering of $r_i(d)$. For $d > 0$, direct computations yield

$$\begin{aligned} r_i(d) &= \left[|\lambda_i|^2 d^2 + 2\,\mathrm{Re}(\lambda_i) d + 1\right]^{\frac{1}{2}} \\ &= \left[|\lambda_i|^2 \left(d - \frac{\mathrm{Re}(-\lambda_i)}{|\lambda_i|^2}\right)^2 + \frac{|\lambda_i|^2 - \mathrm{Re}^2(\lambda_i)}{|\lambda_i|^2}\right]^{\frac{1}{2}} \\ &=: \left[|\lambda_i|^2 (d - c_i)^2 + \tan^2\theta_i\right]^{\frac{1}{2}}. \end{aligned} \tag{2.7a}$$

Moreover, $r_i(d) \ge r_j(d)$ if and only if

$$\mathrm{Re}(\lambda_i) \ge \mathrm{Re}(\lambda_j) \quad \text{if } |\lambda_i| = |\lambda_j|, \tag{2.7b}$$

and

$$(|\lambda_i|^2 - |\lambda_j|^2)(d - d_{ij}) \ge 0 \quad \text{if } |\lambda_i| \ne |\lambda_j|, \tag{2.7c}$$

where

$$d_{ij} = \frac{2(\mathrm{Re}(-\lambda_i) - \mathrm{Re}(-\lambda_j))}{|\lambda_i|^2 - |\lambda_j|^2}. \tag{2.7d}$$

Let $A_i = \{j : 2 \le j \le m_1 \text{ and } |\lambda_i| = |\lambda_j|\}$. Then $\max_{j\in A_i} |1 + d\lambda_j| = |1 + d\lambda_k|$, where k is chosen so that $\mathrm{Re}(\lambda_k) \ge \mathrm{Re}(\lambda_j)\ \forall j \in A_i$. This gives that within each of the index set A_i, their corresponding quantities $|1+d\lambda_i|$ are well ordered for any $d > 0$. Consequently, to solve (2.6), we may assume, without loss of generality, that $0 < |\lambda_2| < \cdots < |\lambda_{m_1}|$ from here on. Using the terminology in [32], we see that the numbers 2 and m_1 correspond to the longest and shortest wavelength modes, respectively. The numbers in between 2 and m_1 are to be called intermediate wavelength modes. Since $d_{ij} = d_{ji}$ for any i and j we consider only d_{ij} with $i > j$. Our reduction process is now complete.

The following procedures are proposed to determine the "actual" node points of $r(d)$ from the candidate set $\{d_{ij} : i > j\}$.

(A) Set $k_0 = 0$, and $k_1 = \max\{l \mid \mathrm{Re}(\lambda_i) \le \mathrm{Re}(\lambda_l)\ \forall i = 2 \ldots, m_1\}$. Let k_2 be the largest index so that $0 < d_{k_2 k_1} \le d_{k k_1}\ \forall k_1 < k \le m_1$.

(B) Let k_3 be the largest index so that $d_{k_2 k_1} < d_{k_3 k_2} \le d_{k k_2}\ \forall k_2 < k$. The process can be continued until $k_p = m_1$ for some $p \le m_1$.

The next result shows that $\{k_i\}_{i=1}^{p}$ is the set of "actual" node points of $r(d)$.

Theorem 2.2. *Let $\boldsymbol{G}$ be given as in Theorem 2.1. Assume that the real parts of the eigenvalues of $\boldsymbol{G}$ are nonpositive. Then $r(d) = r_{k_i}(d)$ whenever $d_{k_i k_{i-1}} \le d \le d_{k_{i+1}k_i}$, $i = 1, \ldots, p$. Here $d_{k_1,k_0} = 0$ and $d_{k_{p+1}k_p} = \infty$.*

Proof. Denote $I_j = [d_{k_j k_{j-1}}, d_{k_{j+1}k_j}]$. It then follows from (2.7c) that if $i > j$ and $d_{ij} > 0$, then $r_i(d) > r_j(d)$ whenever $d > d_{ij}$ and $r_i(d) < r_j(d)$ whenever $0 < d < d_{ij}$. We then conclude that

(2.8a) (i) the ordering of $r_i(d)$ and $r_j(d)$ remains the same until both curves meet;

(2.8b) (ii) if $r_i(d^*) > r_j(d^*)$ for some $d^* > 0$ with $i > j$, then $r_i(d) > r_j(d)$ $\forall d \ge d^*$.

Using the first inequality in (2.7a), we have that $r(d) = r_{k_1}(d)$ for $\epsilon_1 > d \ge 0$. Here ϵ_1 is sufficiently small. It then follows from (2.8a), (2.8b), and procedure (A) that $r(d) = r_{k_1}(d)$ on I_1. Upon using (2.8a), we conclude that $r(d) = r_{k_2}(d)$ for $d \in (d_{k_2k_1}, d_{k_2k_1} + \epsilon_2)$. Here ϵ_2 is sufficiently small. Similarly, $r(d) = r_{k_2}(d)$ on I_2. We omit the proof of the remaining assertions of the theorem due to the similarity. ∎

Note that not all c_{k_i} given in (2.7a) could be critical points of $r(d)$. In fact, the critical points of $r(d)$ may not even come from the set $\{c_{k_i}\}$. We next identify the "actual" critical points of $r(d)$. Our next main result shows that $r(d)$ has exactly one critical point.

Theorem 2.3. *The curve $r(d)$ has a unique critical point d_c that solves the min max problem (2.6). Moreover, the optimal range of coupling d to sustain stably synchronous chaos of (2.2) is (d_l, d_r). Here d_l and d_r, $d_l < d_r$, are the intersection points (if any exist) of the straight line $y = e^{-h_{\max}}$ and the curve $y = r(d)$. Consequently, CML (2.2) acquires local synchronization if and only if $d \in (d_l, d_r)$.*

Proof. We break up the proof of the theorem into the following three steps.

Step I. We first claim that the number of c_{k_i} lying in the interior $\overset{\circ}{I}_i$ of I_i is at most one. Indeed, suppose there exist $c_{k_a} \in \overset{\circ}{I}_a$ and $c_{k_b} \in \overset{\circ}{I}_b$ with $c_{k_a} < c_{k_b}$. Then the following hold true: (i) $r_{k_a}(c_{k_b}) > r_{k_a}(c_{k_a})$. (ii) $r_{k_a}(c_{k_a}) > r_{k_b}(c_{k_a})$. (iii) $r_{k_b}(c_{k_a}) > r_{k_b}(c_{k_b})$. Inequalities (i) and (iii) hold true since c_{k_a} and c_{k_b} are, respectively, the minimum points of $r_{k_a}(d)$ and $r_{k_b}(d)$. The fact that $r_{k_a}(d)$ lies above all other curves on I_a leads to inequality (ii). Combining these inequalities, we have that $r_{k_a}(c_{k_b}) > r_{k_b}(c_{k_b})$, which is in contradiction to the fact that r_{k_b} is the maximum curve on I_{k_b}.

Step II. We next show that if $c_{k_i} \in \overset{\circ}{I}_i$, then $r(d)$ is decreasing on $(0, c_{k_i})$ and increasing on (c_{k_i}, ∞). Indeed, for $d \in I_{i+1}$, $r(d) = r_{k_{i+1}}(d) > r_{k_i}(d) > r_{k_i}(d_{k_{i+1}k_i}) = r_{k_{i+1}}(d_{k_{i+1}k_i})$. Using the conclusion in Step I and the fact that $r^2_{k_i}(d)$ is parabolic, we conclude that $r_{k_{i+1}}(d)$ must be increasing on I_{i+1}. On the other hand, $r_{k_{i-1}}(d)$ must be decreasing on I_{i-1} since $r_{k_{i-1}}(d) > r_k(d) > r_{k_i}(d_{k_ik_{i-1}}) = r_{k_{i-1}}(d_{k_ik_{i-1}})$. The monotonicity of $r(d)$ on each interval I_j, $1 \le j \le m_1$, can be similarly determined.

Step III. Since $r(d)$ is decreasing initially on I_1 and increasing eventually on I_p, there must be at least one critical point. If such points do not lie in the set of node points, then $r(d)$ has a unique critical point. Suppose $c_{k_i} \notin \overset{\circ}{I}_i$ $\forall i = 1, \ldots, p$. Then $r(d)$ is monotonic on each interval I_i. Suppose $r(d)$ first changes its monotonicity at $d_{k_{l+1}k_l}$ for some l. Then an argument similar to that given in Step II shows that once $r(d)$ becomes increasing on I_{l+1}, it will stay increasing the rest of the way. We have just completed the proof of the theorem. ∎

Remark. (i) If the straight line $y = e^{-h_{\max}}$ and the curve $y = r(d)$ do not intersect, then CML (2.2) will not achieve synchronization for any coupling strength. Suppose d_r and d_l exist. Then, as soon as d exceeds d_r, a certain wavelength mode is excited, which, in turn, causes the instability of the synchronous state. The illustration in Examples 2 and 3 shows that the excited wavelength mode could be either the shortest wavelength mode, the intermediate wavelength mode, or the longest wavelength mode. In any event, d_r is the exact critical value where wavelength bifurcation occurs. On the other hand, d_l is the exact critical value where all wavelength modes become de-excited enough to induce the stability of the synchronous state. (ii) Such $r(d)$ is called the *synchronization curve* of CML (2.2), and the interval (d_l, d_r), if it exists, is termed the *synchronization interval* of CML (2.2). Clearly, $d_c \in (d_l, d_r)$ and depends only on the connectivity topology.

Theorem 2.4. *Suppose the coupling matrix* $\mathbf{G}$ *has nonpositive real eigenvalues. Denote by* $\{\lambda_i\}_{i=2}^{m_1}$ *the distinct nonzero eigenvalues of* $\mathbf{G}$. *Then*

$$r(d) = \begin{cases} \lambda_2(d), & d \in [0, d_{m_1 2}] = I_1, \\ \lambda_{m_1}(d), & d \in (d_{m_1 2}, \infty) = I_2, \end{cases}$$

and $d_c = d_{m_1 2} = \frac{-2}{\lambda_2 + \lambda_{m_1}}$. *Consequently, depending on the quantity of* $h_{\max}$, *either CML* (2.2) *achieves no synchronization or SWB occurs as* d *varies. Furthermore, if* d_l *and* d_r *exist, then the* synchronization interval *of the corresponding CMLs is* $\left(\frac{1-e^{-h_{\max}}}{-\lambda_2}, \frac{1+e^{-h_{\max}}}{-\lambda_{m_1}}\right)$.

Proof. It is easily seen that $k_1 = 2$ and $k_2 = m_1$ since $d_{ij} = \frac{-2}{\lambda_i + \lambda_j}$. Thus, $r(d)$ is as asserted. The proof then follows from the facts that $c_{m_1} = -\frac{1}{\lambda_{m_1}} < \frac{-2}{\lambda_2 + \lambda_{m_1}} < -\frac{1}{\lambda_2} = c_2$ and $d_c = d_{m_1 2}$. Solving equations $y = r(d)$ and $y = e^{-h_{\max}}$, we have that d_l and d_r are as claimed. ∎

3. Illustrations and applications.

We illustrate our theorems with the following examples.

Example 1. Let the oscillators be diffusively coupled with periodic boundary conditions. For such $\mathbf{G}$, $m_1 = m$, $-\lambda_{m_1} = 4\sin^2 \frac{[\frac{m}{2}]\pi}{m}$, and $-\lambda_2 = 4\sin^2 \frac{\pi}{m}$.

Let $f(x) = 4x(1-x)$, $0 \le x \le 1$. Then $h_{\max} = \ln 2$, and the corresponding candidates for d_l and d_r are, respectively, $\frac{1}{8}\sin^{-2}\frac{\pi}{m}$ and $\frac{3}{8}\sin^{-2}\frac{[\frac{m}{2}]\pi}{m}$. However, $d_l \le d_r$ only if $m \le 5$. Hence, we conclude that the maximum number of oscillators to sustain synchronous chaos is 5.

We next compare our results with those obtained in [23], [34]. Their sufficient conditions on the coupling strength for obtaining stable synchronization are, respectively, given as follows: $\frac{1-e^{-h_{\max}}}{m} < d\, g_{ij} < \frac{1+e^{-h_{max}}}{m}$ and $\left(\sum_{k=1,\, k\neq i}^{m} |g_{ki} - g_{ji}|\right) + \left|\frac{1}{d} + g_{ii} - g_{ji}\right| < \frac{1}{d}e^{-h_{\max}}$ $\forall i, j$ with $i \neq j$. However, the first inequality above fails to find any suitable coupling strength provided that $\boldsymbol{G}$ has zero off-diagonal elements. If $\boldsymbol{G}$ is given as above with $m \ge 4$ and $f(x) = 4x(1-x)$, then the second inequality also fails to find any suitable coupling strength.

Example 2. Consider synchronization in a directed ring of $2K$ nearest neighbor coupled oscillators [19] with $K = 2$ and $m = 9$. Specifically, the coupling matrix $\boldsymbol{G}$ under consideration is a circulant matrix of the form

$$\boldsymbol{G} = \mathrm{circ}(-30,\ 13,\ 2,\ 0,\ \ldots,\ 0,\ 5.4,\ 9.6).$$

The spectrum of $\boldsymbol{G}$ is $\{-30+13e^{\frac{2(j-1)\pi}{9}i}+2e^{\frac{4(j-1)\pi}{9}i}+5.4e^{\frac{14(j-1)\pi}{9}i}+9.6e^{\frac{16(j-1)\pi}{9}i} : j = 1, \ldots, 9\}$. Here $\lambda_2 \approx -11.4024 + 1.1629i$, $\lambda_3 \approx -33.0293 + 2.1855i$, $\lambda_4 \approx -45 + 5.8890i$, and $\lambda_5 \approx -45.5683 + 3.3483i$. Direct computations yield that $d_{42} \approx 0.0348 < d_{52} < d_{32}$, $d_{54} \approx 0.0406$, and $c_5 < c_4 < d_{42} < d_{54} < c_2$ (see Figure 1). Consequently,

$$r(d) = \begin{cases} r_2(d), & d \in I_1 = [0, d_{42}], \\ r_4(d), & d \in I_2 = [d_{42}, d_{54}], \\ r_5(d), & d \in I_3 = [d_{54}, \infty], \end{cases}$$

the node points of $r(d)$ are d_{42} and d_{54}, and the critical point of $r(d)$ occurs at d_{42}. Let $f_\mu(x) = \mu x(1-x)$. For $\mu = 4$, since $e^{-h_{max}} = e^{-\ln 2} = 0.5 < r(d_{42})$, the *synchronization interval* does not exist. As μ varies from $\mu_\infty \approx 3.57$ to $\mu = 4$, scenarios (i), (ii), and (iii) described in the introductory section can be clearly observed from the figure.

On the other hand, the maximum number of oscillators on such connectivity topology to sustain stably synchronous chaos is 7. The claim above is done by checking the intersection of the equations $y = \frac{1}{2}$ and $y = r(d)$ $\forall m \leq 8$.

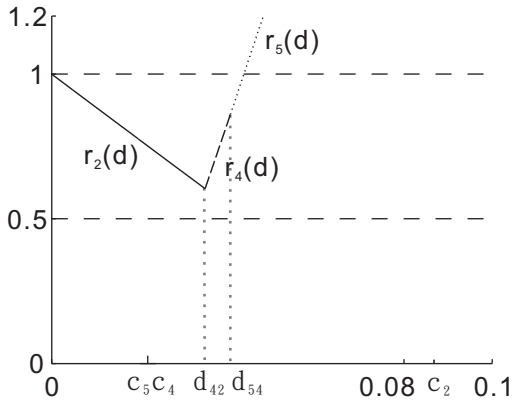

Figure 1. *Graph of $r(d)$ in Example 2. Here $d_{42} \approx 0.0348$, $d_{54} \approx 0.0406$, $r(d_{42}) \approx 0.6040$, $r(d_{54}) \approx 0.8604$, $c_5 \approx 0.02182$, $c_4 \approx 0.02185$, and $c_2 \approx 0.0868$. The critical point of $r(d)$ is d_{42}.*

Example 3. The following example shows that LWB is also possible. Let $\boldsymbol{G}$ be given as follows:

$$\begin{pmatrix} -30 & 3 & 12 & 5 & 10 \\ 10 & -30 & 3 & 12 & 5 \\ 5 & 10 & -30 & 3 & 12 \\ 12 & 5 & 10 & -30 & 3 \\ 3 & 12 & 5 & 10 & -30 \end{pmatrix}.$$

The spectrum of $\boldsymbol{G}$ is $\{0, -35.2639+10.7719i =: \lambda_2, -39.7361+2.5429i =: \lambda_3, \bar{\lambda}_2, \bar{\lambda}_3\}$. Then the graph of $r(d)$ is demonstrated in Figure 2. Consider $f(x) = 4x(1-x)$. Then the longest wavelength mode becomes excited to induce instability as d is increased beyond d_r.

Example 4. To illustrate the accuracy of our theorems, *synchronization intervals* established in Theorem 2.4 are compared with those obtained by the computer simulation. In particular, theoretically and numerically predicted *synchronization intervals* for three exam-

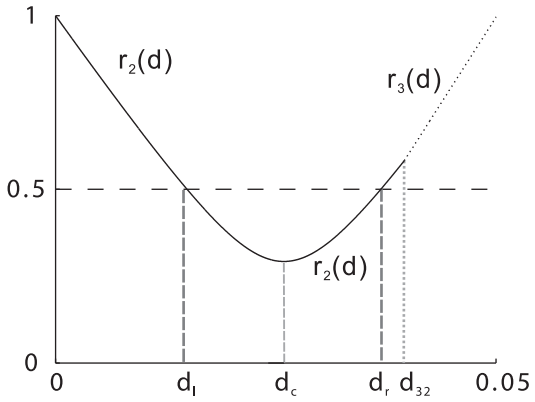

Figure 2. *Graph of $r(d)$ in Example 3. Here $d_{32} \approx 0.0396$, $c_2 \approx 0.0259$, $c_3 \approx 0.0251$, $d_l \approx 0.0149$, and $d_r \approx 0.0369$. The critical point of $r(d)$ is c_2.*

ples above are almost identical. Such comparisons are recorded in Figure 3. They are "almost" identical. This simulation is set up so that the differences between the initial values $\boldsymbol{x}_i$ are within 10^{-5}. Synchronization is achieved when their differences are within 10^{-15}.

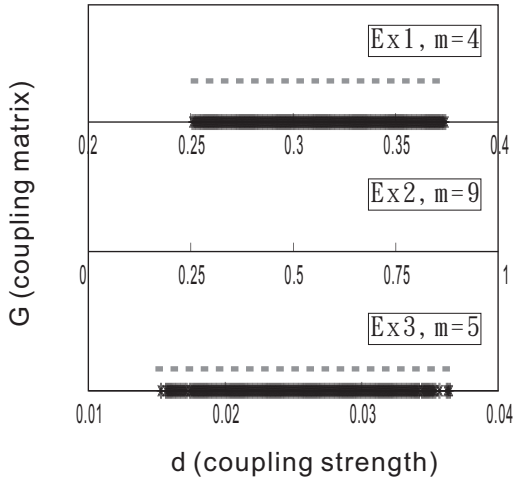

Figure 3. *Three typical* synchronization intervals *for coupled logistic map with various coupling matrices are shown. Solid (bold) lines are synchronization intervals obtained by computer simulation. Dotted (fine) lines are synchronization intervals predicted by our theorems. All are scaled for clear visualization.*

4. Conclusions. We conclude this paper by mentioning the difficulty one might face by applying our methods to more general cases, $\boldsymbol{D} \neq \boldsymbol{I}$ or $\boldsymbol{h} \neq \boldsymbol{f}$, and a possible approach to solving them.

Our main results in this paper are based on the study of the inequalities in (2.5). However, in the case that $\boldsymbol{D} \neq \boldsymbol{I}$ or $\boldsymbol{h} \neq \boldsymbol{f}$, it seems to be a nontrivial matter to find their corresponding inequalities such as (2.5). One possible approach is to find the lower and upper bounds of the Lyapunov exponents of (2.2), where both bounds have expressions similar to those in (2.4).

Acknowledgment. The authors would like to thank the referees for their helpful comments.

On Synchronization and Traveling Waves in Chains of Relaxation Oscillators with an Application to Lamprey CPG*

Péter L. Várkonyi† and Philip Holmes‡

Abstract. We study chains of relaxation-type neural oscillators with local excitatory coupling. Phase reductions suggest that such networks typically exhibit traveling waves, but relaxation oscillators often synchronize. We examine these behaviors using the phase response and fast threshold modulation (FTM) theories, which respectively describe network behavior for infinitesimally weak and moderate coupling. Surprisingly, the two different approximations yield quantitatively consistent predictions for chains with one-way coupling. Specifically, approaching the relaxation limit, such chains can exhibit waves with vanishing phase differences (i.e., synchrony) propagating in the coupling direction, *or* waves with persistent phase differences traveling against the coupling direction. These results provide novel support for the finding that caudo-rostral coupling dominates in the lamprey central pattern generator (CPG), and they suggest that recent models may underestimate the role of network effects in burst generation.

Key words. fast threshold modulation, phase reduction, relaxation oscillators, synchronization, traveling waves

1. Introduction.

Phase reduction theory, originally developed by Malkin [30, 31] and independently rediscovered by Winfree [43] (cf. [14]), provides a method for the simplification and analysis of networks of coupled oscillators, including those composed of spontaneously oscillatory spiking or bursting neurons. Augmented by the averaging theorem [15] for weakly coupled systems, it allows one to reduce N sets of M ordinary differential equations (ODEs), each set describing an oscillator having a hyperbolic (attracting) limit cycle, to a system of N ODEs approximating the phases of each oscillator along its limit cycle. See [18] and [19] for more recent statements of Malkin's theorem. Phase reduction always applies for sufficiently weak coupling, but it often extends to stronger coupling [11].

According to this theory, chains of oscillators with local coupling generically exhibit traveling waves, except for symmetrical bidirectional coupling or special types of interactions such as coupling of neural oscillators via gap junctions [7, 22, 23]. However, the interaction of relaxation oscillators seems to be exceptional: they phase-lock with zero phase-difference,

(i.e., they synchronize) in cases where one would expect traveling waves [35, 36]. This synchrony is robust against perturbations: while phase oscillators compensate for perturbations by changing their phase relations, relaxation oscillators typically compensate via changes in waveforms.

There are at least two explanations for this behavior. Phase reduction neglects the effects of nonlinearities in coupling: it requires that orbits perturbed by coupling remain sufficiently close to unperturbed limit cycles at all times, which holds for *sufficiently weak* coupling $\epsilon \ll 1$. Relaxation oscillators combine fast and slow dynamics (i.e., two characteristic time-scales with ratio $\mu \ll 1$), and in this case phase reduction requires *extremely weak* coupling: $\epsilon \ll \mu$ [19]. In relevant ranges of μ, the oscillators' interactions are typically dominated by higher order effects that are not captured by phase theory. Fast threshold modulation (FTM) theory [35, 36] was introduced to explain this behavior. Motivated by synaptic coupling of neural oscillators, it applies to moderate or strong coupling: $\mu \ll \epsilon$.

Despite the apparent contrast between relaxation and phase oscillators, and the limited applicability of phase reduction to the former, phase theory can also account for synchronization of relaxation oscillators [19], and its predictions agree qualitatively with those of FTM theory. The reason for this unexpected behavior is that the function $H(\psi)$ describing the effect of coupling between two oscillators is discontinuous at certain points with respect to their phase difference ψ.

In this paper we apply phase reduction for weak coupling ($\epsilon \ll \mu \ll 1$) and a combination of FTM and phase theory for relaxation-type oscillators ($\mu \ll \epsilon \ll 1$). We ask if a given system exhibits traveling waves or synchrony and compare predictions of the two methods, thereby shedding light on behaviors expected under variations in coupling strength ϵ. Both approaches are required to obtain a global picture of the behavior of coupled chains, and we show that their predictions are *quantitatively* similar in chains with one-way coupling, despite the different mechanisms. In section 2 we analyze a pair of oscillators with one-way coupling in the phase reduction limit and outline a generalization to unidirectionally coupled oscillator chains, and section 3 is an analogous study of the FTM limit. In these sections we describe an interesting property of traveling wave solutions: in the limit $\mu \to 0$ waves propagating in the coupling direction approach synchronous dynamics, but counterpropagating waves persist (Theorems 2.1 and 3.1). These results provide quantitative conditions for traveling waves versus synchrony in arrays of unidirectionally coupled relaxation oscillators. The behavior of bidirectionally coupled chains is also briefly discussed at the end of each section. In section 4 we demonstrate that most, but not all, simple oscillators exhibit the first behavior: synchrony is more common in the relaxation limit than traveling waves, and we provide a sufficient condition for this in Theorem 4.1. Section 5 contains illustrative examples of both behaviors.

In section 6, we apply these results to the neural central pattern generator (CPG) of the lamprey. Recent lamprey CPG models [39, 27, 26] are double chains of relaxation-type bursters in which the burst frequency is adjusted by neuro-modulators that tune the slow time-scale μ so that the relaxation limit is approached as swimming speed decreases. Simulations indicate that these models exhibit synchrony in the relaxation limit and that phase lags between neighboring units depend strongly on swimming frequency, being small at low frequency and larger at high frequency. In contrast, the animal exhibits quasi–frequency-independent phase patterns. As we will show, this shortcoming could be eliminated if the model's parameters

were adjusted to generate traveling waves in the relaxation limit. The paper concludes with section 7. We relegate many technical details in the proofs of Theorems 2.1 and 3.1 to a series of appendices. Background on CPGs can be found in [8], and background on phase and relaxation oscillator models can be found in [21, 23].

2. Relaxation oscillators in the phase limit. We consider a pair of identical relaxation oscillators O_1, O_2, each with one slow variable x_j and one fast one y_j. The time-scale ratio is set by the parameter $0 < \mu \ll 1$, and $\mu \to 0$ is the relaxation limit. If O_1 receives weak coupling ($\epsilon \ll \mu$) from O_2 in the fast variable, the ODEs for O_1 are

$$\dot{x_1} = f(x_1, y_1), \tag{2.1}$$

$$\dot{y_1} = \frac{1}{\mu}\left[g(x_1, y_1) + \epsilon h(x_1, y_1, x_2, y_2)\right], \tag{2.2}$$

while those of O_2 are the same, but without the coupling term h. Henceforth we assume that the fast equation (2.2) has a cubic-shaped nullcline or *slow manifold* $g = 0$, and that for $\epsilon = 0$ a stable hyperbolic limit cycle Γ of period T exists, on which x_j slowly decreases (resp., increases) near the lower (resp., upper) branch of $g = 0$; see Figure 1. Henceforth, in describing a single oscillator, we typically drop the subscripts.

In section 2.1 we summarize the results of Izhikevich [19] and prepare for section 2.2. There we prove our first theorem, extending the leading order phase response curve (PRC) expressions of [19] to the next order and providing explicit estimates of the width and height of PRC peaks in terms of fractional powers of μ (Figure 5).

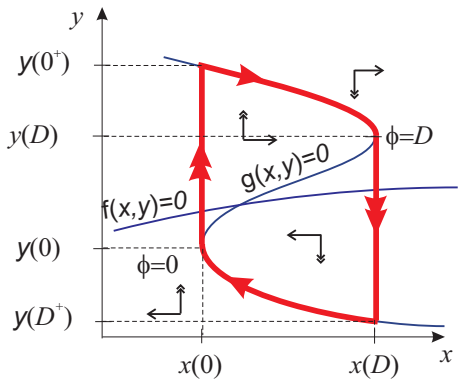

Figure 1. *Schematic phase portrait of a 2D relaxation oscillator with cubic-shaped nullcline (thin curve). Arrows show directions of the vectorfield; ϕ denotes the phase along the limit cycle (thick curve); $\phi = 0, D$ denote phase values at the instantaneous jumps; and $x(0)$, $y(0)$, $y(0^+)$, etc. denote the coordinates of the corresponding points in phase space. Oscillators are assumed to be active on the upper branch $\phi \in (0, D)$ and silent on the lower branch $\phi \in (D, 0)$.*

2.1. Phase reduction and previous results. Like any ODE with a stable hyperbolic limit cycle, (2.1)–(2.2) can be reduced to a phase description [18]. We define the phase $\phi = \phi(x, y)$ along Γ such that the periodic solution satisfies $\dot{\phi} = 2\pi/T \stackrel{\text{def}}{=} \omega$, and we let $x(\phi)$, $y(\phi)$, etc. denote coordinates of points on Γ. The system of four coupled ODEs may then be

reduced to the phase equations

$$\dot{\phi_1} = \omega + \frac{\epsilon}{\mu}\tilde{h}(\phi_1, \phi_2)z(\phi_1) + \mathcal{O}(\epsilon^2), \quad \dot{\phi_2} = \omega, \tag{2.3}$$

where $\tilde{h}(\phi_1, \phi_2) = h(x_1(\phi_1), y_1(\phi_2), x_2(\phi_2), y_2(\phi_2))$ denotes the coupling function evaluated on Γ. Here the PRC $z(\phi)$ represents the sensitivity of O_1 to perturbations from O_2, and $z(\phi) > 0$ (resp., $z(\phi) < 0$) means that an excitatory signal ($h > 0$) received at $(x(\phi), y(\phi))$ speeds up (resp., slows down) O_1. In deriving the PRC one expands about Γ in a Taylor series, thereby neglecting nonlinear ($O(\epsilon^2)$) coupling effects. See [10, 3] for recent examples of explicit PRC computations.

After introducing the phase difference $\psi = \phi_1 - \phi_2$, (2.3) can be averaged over the period T and subtracted to yield

$$\dot{\psi} = \frac{\epsilon}{2\pi\mu}\int_0^{2\pi} \tilde{h}(\varphi + \psi, \varphi)z(\varphi + \psi)\, d\varphi + O(\epsilon^2) \stackrel{\text{def}}{=} H(\psi) + O(\epsilon^2). \tag{2.4}$$

Zeros of H correspond to phase differences at which the oscillators phase-lock ($\psi = \text{const}$), and stable phase-locking occurs if $H(\psi) = 0$ and $dH(\psi)/d\psi < 0$. For details, see [18, 17].

While in general PRCs must be computed numerically, in [19, section 2] analytical formulae were derived for (2.1)–(2.2) in the limit $\mu \to 0$, as follows. Let $z^*(\phi) \stackrel{\text{def}}{=} z(\phi)/\mu$; subscripts x and y denote partial derivatives, $\phi^{(1)} = 0$ and $\phi^{(2)} = D$ denote phase values at the jumps, $y(\phi^{(j)}) = y(0), y(D)$ denote the value of y immediately before a jump, and $y(\phi^{(j)+}) = y(0^+), y(D^+)$ denotes its value immediately after it (Figure 1). If $\phi \neq \phi^{(j)}$, $j \in \{1, 2\}$, then

$$z^*(\phi) = -\frac{\omega f_y(x(\phi), y(\phi))}{f(x(\phi), y(\phi))g_y(x(\phi), y(\phi))}, \tag{2.5}$$

and near the jumps $\phi = \phi^{(j)}$,

$$z^*(\phi) = \frac{\delta(\phi - \phi^{(j)})\,\omega^2}{g_x(x(\phi^{(j)}), y(\phi^{(j)}))}\left[\frac{1}{f(x(\phi^{(j)}), y(\phi^{(j)}))} - \frac{1}{f(x(\phi^{(j)}), y(\phi^{(j)+}))}\right]. \tag{2.6}$$

Equation (2.5) follows from linearization in the neighborhood of the slow parts of Γ on the upper and lower branches of the $g = 0$ nullcline, and it may be derived from the adjoint formulation of the PRC [18], as in [19, (2.9)]. Equation (2.6) is found by considering the jumps from $y(0)$ to $y(0^+)$ and $y(D)$ to $y(D^+)$ (Figure 1; cf. [19, (2.4)]). The delta functions at $\phi^{(j)}$ play a central role in explaining the behavior of coupled relaxation oscillators; see Figure 2.

To formulate our results, we supplement (2.5)–(2.6) with the following conditions:

(i) The coupling term $h \equiv 1$ while O_2 is near the upper branch of its $g = 0$ nullcline (for $\mu \to 0$ this implies $\phi \in (0, D)$), and $h \equiv 0$ near the lower branch. During jumps, $0 \leq h \leq 1$.

(ii) $\partial f(x, y)/\partial y > 0$ at arbitrary points $(x(\phi), y(\phi))$ along the limit cycle.

(iii) The duty cycle $D/(2\pi) \leq 0.5$ (time spent on the upper (active) branch is not more than that spent on the lower branch).

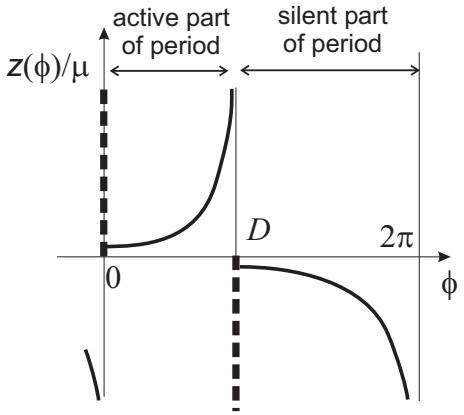

Figure 2. *Schematic PRC for a relaxation oscillator in the limit $\mu \to 0$ as derived in [19]. The function has singularities and delta functions (thick dashed lines) at $\phi = 0, D$. The sign of the delta functions is always as shown. The sign of the continuous parts is as shown if condition* (ii) *holds.*

Condition (i) simplifies the notion that oscillators have active (e.g., bursting) and silent (e.g., refractory) states; it has been used by other authors (e.g., [35, 36, 19]). Condition (ii) requires that $f(x, y)$ is strictly monotonic in y, which is true for most oscillator models, and it implies that the sign of z^* is as shown in Figure 2, due to the following facts:

(1) On the limit cycle of Figure 1, $f(x(0), y(0)) < 0$, $f(x(0), y(0^+)) > 0$, and $g_x(x(0), y(0)) < 0$, so (2.6) implies that the peak in z^* at $\phi = 0$ is positive. Similarly, the peak at $\phi = D$ is negative.

(2) Attractivity of the upper and lower branches of the $g = 0$ nullcline implies that $g_y < 0$; $f > 0$ on the upper branches and $f < 0$ on the lower branches, and $f_y > 0$, by condition (ii). Thus (2.5) gives positive and negative PRC values during the active and silent parts of the limit cycle, respectively.

Under condition (i), (2.4) simplifies to

$$H(\psi) = \frac{\epsilon}{2\pi} \int_{\psi}^{D+\psi} z^*(\phi)\, d\phi; \tag{2.7}$$

the resulting function $H(\psi)$ is shown in Figure 3, in which its key properties are also summarized. In particular, H is discontinuous: when $\phi^{(i)}$ enters or leaves the interval of integration $[\psi, D + \psi]$ in (2.7), the delta functions in (2.6) introduce step changes. If the decreasing step at $\psi = 0$ passes through 0, then $H(\psi)$ has a root at 0, corresponding to synchronization, which is robust against perturbations such as adding a constant to H. This fact was advanced in [19] to explain why weakly coupled relaxation oscillators tend to synchronize.

Note that the properties of $H(\psi)$ shown in Figure 3 require condition (iii); for $D > \pi$, H may have arbitrarily many roots or possibly none at all. Condition (iii) holds for the majority of important relaxation oscillators, and it appears elsewhere in the literature [24]. We also remark that, since $\lim_{\phi \to \phi^{(i)}} g_y = 0$ and $g_y \backsim (\phi^{(i)} - \phi)^{1/2}$, the rescaled PRC $z^*(\phi)$ in (2.5) has integrable singularities at $\phi = \phi^{(j)}$.

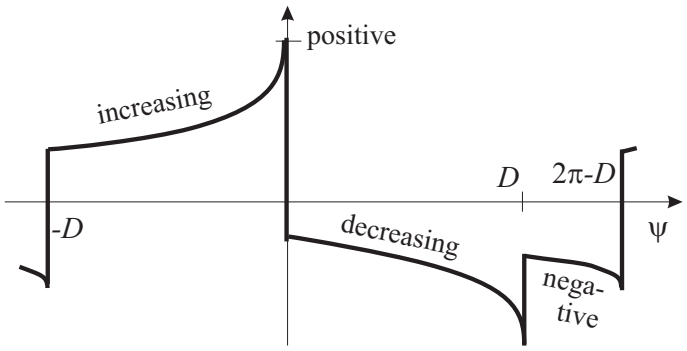

Figure 3. *Schematic coupling function $H(\psi)$ for a relaxation oscillator with weak one-way coupling in the limit $\epsilon \ll \mu \to 0$, as derived in* [19]. *If conditions* (i)–(iii) *hold, the qualitative form of H and the directions of the steps are as shown.*

2.2. Phase-locking and synchrony. While the discontinuity of H at $\psi = 0$ often yields synchronization, this is not the only possibility: if $\text{sign}(H(0^+)) = \text{sign}(H(0^-))$, the oscillators do not synchronize, although phase-locking can occur at $\psi \neq 0$ if H has nonzero roots. This latter case corresponds to traveling waves in a chain (see section 2.3). Here we state a result that shows that phase-locked solutions with $\psi = \Delta(\mu) \leq 0$ behave differently from those with $\Delta(\mu) > 0$, thereby distinguishing the two behaviors.

Theorem 2.1. *Let $H_\mu(\psi)$ denote the averaged coupling function at a given value of μ, and let $(x, y) = (\xi, \upsilon(\xi))$ denote the equation of the active branch of the slow manifold. Assume that the phase-shift $\Delta(\mu)$ satisfies $dH_\mu(\psi)/d\psi|_{\Delta(\mu)} < 0 = H_\mu(\Delta(\mu))$.*

(a) *If conditions* (i)–(iii) *hold and*

$$-\int_{x(0)}^{x(D)} \frac{f_y(\xi,\upsilon(\xi))}{f^2(\xi,\upsilon(\xi))g_y(\xi,\upsilon(\xi))}\,d\xi + \frac{1}{g_x(x(D),y(D))}\left[\frac{1}{f(x(D),y(D))} - \frac{1}{f(x(D),y(D+))}\right] > 0, \tag{2.8}$$

then $0 < \lim_{\mu\to 0}\Delta(\mu) < \pi$; i.e., O_1 leads O_2.

(b) *If conditions* (i)–(iii) *hold and* (2.8) *is false, then $\Delta(\mu) \backsim -\mu^{2/3}$ for small μ and $\lim_{\mu\to 0}\Delta(\mu) = 0$; i.e., the oscillators synchronize.*

Proof. We extend the results of [19] to the case $0 < \mu \ll 1$. The limit cycle consists of three parts, known in singular perturbed and boundary layer theory as the outer, inner, and intermediate limits [2]; see Figure 4.

1. Evolution along slow manifolds: These episodes occupy time $O(1)$, and the PRCs are well approximated by (2.5); thus $z^*(\phi) = O(1)$.
2. Transition from slow motion to jumps at the knees of the $g = 0$ nullcline: These take time $O(\mu^{2/3})$ [2], and, as shown below, the phase response converges to (2.6) in the relaxation limit; thus $z^*(\phi) = O(\mu^{-2/3})$.
3. Fast jumps of duration $O(\mu)$ between slow manifolds: Here $z^*(\phi) = O(1)$, as in case 1.

These statements follow from the arguments of [19], summarized in section 2.1, with the crucial additional fact, shown in Appendix A, that the delta function in (2.6) derives from

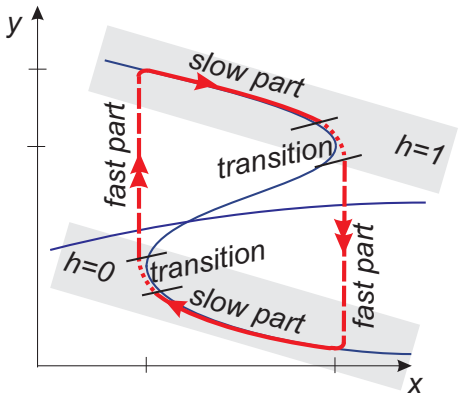

Figure 4. *Characteristic segments of the limit cycle of a relaxation oscillator: Slow motion along nullclines, fast jumps, and transition. Coupling h is assumed constant (≡ 0 or 1) near the slow nullclines, shown shaded.*

perturbations during transition and *not* during the fast jump. Intuitively, perturbations can advance the jump as solutions approach the fold, but perturbations in the fast variable have little effect during the jump ($z \backsim O(\mu)$, i.e., $z^* \backsim O(1)$), due to the $O(\mu^{-1})$ speed of the dynamics. The resulting PRC is shown in Figure 5.

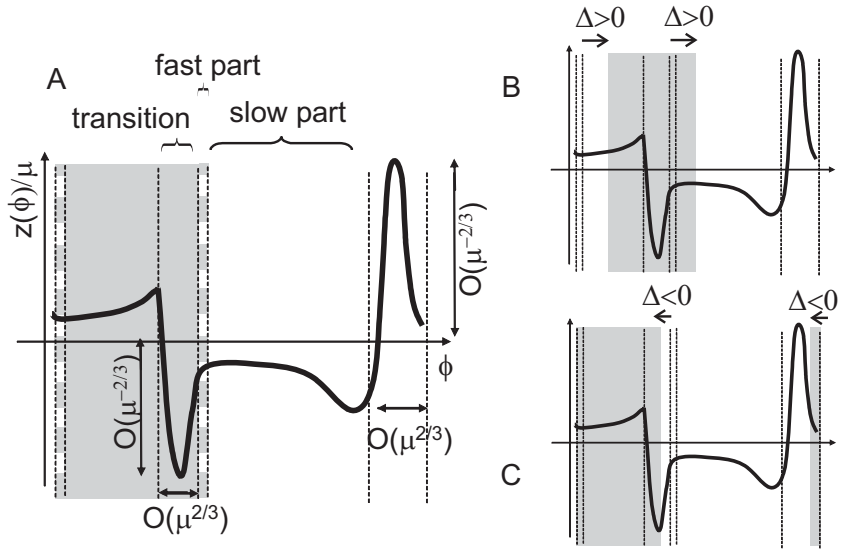

Figure 5. A: *PRCs for relaxation oscillators with* $0 \neq \mu \ll 1$. *Grey denotes the active part of the period* $h \equiv 1$, *white the silent part* $h \equiv 0$, *and striped, far from the nullclines, h not defined by condition* (i). *For synchrony,* $H(0)$ *is the integral of* z^* *over the grey interval.* B: *For small* $\psi > 0$, $H(\psi)$ *is the integral over a domain shifted rightward compared to the case* $\psi = 0$. C: *For small* $\psi < 0$, *the integration domain is shifted leftward and includes the peaks of* z^*.

If the two oscillators are in synchrony ($\psi = 0$), O_1 receives a coupling signal during both the slow and transitional parts near the *upper nullcline* according to condition (i); there is no input during slow and transition parts near the lower nullcline. Condition (i) does not

determine h during the fast jumps, since the state is far from both nullclines. However, the integral of z^* during these episodes is only $O(\mu)$ ($\sim$ the jump duration), so its contribution to H vanishes as $\mu \to 0$; cf. (2.7). Thus, if μ is sufficiently close to 0, $H_\mu(0)$ is well approximated by the integral of z^* over the slow and transition parts on the upper branch, and using (2.5)–(2.7), we obtain

$$H_\mu(0) = \frac{\epsilon\omega^2}{2\pi}\left[\int_0^D \frac{-f_y(x(\phi),y(\phi))}{\omega f(x(\phi),y(\phi))g_y(x(\phi),y(\phi))}\,d\phi \right. \\ \left. + \frac{1}{g_x(x(D),y(D))}\left(\frac{1}{f(x(D),y(D))} - \frac{1}{f(x(D),y(D^+))}\right)\right] + \mathcal{O}(\mu); \tag{2.9}$$

see also Figure 5(A).

Due to (2.1) and (2.3), we have $d\phi = dx \cdot \omega/f$; hence (2.9) is equal to the left-hand side of (2.8) modulo the $O(\mu)$ term and the $\epsilon\omega^2/2\pi$ factor. Thus, case (a) of Theorem 2.1 corresponds to $\lim_{\mu\to 0} H_\mu(0) > 0$. If $\psi = 0$ at $t = 0$, ψ increases according to (2.4), and the limits of integration in (2.7) must be moved rightward to locate a zero of $H(\psi)$, as in Figure 5(B). At that point the limits do not intersect the peaks of the PRC, implying that H has finite slope just above $\psi = 0$. The conclusion of part (a) follows from this fact.

On the other hand, if $H(0) < 0$, the domain of integration must be shifted to the left and will intersect the PRC's peaks; see Figure 5(C). A negative peak of width $O(\mu^{2/3})$ and slope $O(\mu^{-2/3})$, which shrinks to a vertical step in the relaxation limit of Figure 2, lies just below $\psi = 0$. $\Delta(\mu)$ cannot lie elsewhere than at this steep part, since conditions (i)–(iii) imply that at all other points $H(\psi)$ is either negative or increasing; see Figure 3. ■

We remark that if only condition (i) holds, we still have $\lim_{\mu\to 0}\Delta(\mu) \neq 0$ in case (a). In case (b), conditions (i)–(ii) without (iii) imply the existence of the synchronous solution but do not imply its uniqueness. Condition (i) without (ii)–(iii) means that the oscillators often but not always synchronize.

2.3. Oscillator chains in the phase reduction limit. The behavior of coupled pairs of phase oscillators generalizes to that of chains. Here we review basic results based on [22, 25] and outline some consequences of Theorem 2.1.

Consider a chain of n identical oscillators. For one-way nearest-neighbor coupling and if $H(\psi)$ crosses 0, phase differences between adjacent oscillators are equal to those between a coupled pair, being determined by the stable zeros of H. For two-way coupling ($H_1(\psi)$ and $H_2(\psi)$) in a long chain ($n >> 1$), one direction is typically dominant and phase relations are unaffected by connections in the other, except near boundaries. In special cases (e.g., $H_1 \approx H_2$) neither direction dominates and phase differences may be nonuniform. If the coupling is translation-symmetric and close but not necessarily adjacent oscillators are coupled, then the chain mimics the behavior of a reduced network with nearest-neighbor connections.

Thus, our analysis of a pair of units also explains the behavior of a wide class of chains. Case (a) of Theorem 2.1 ($0 < \lim_{\mu\to 0}\Delta(\mu) < \pi$) means that the unit that receives coupling is advanced in phase compared to the other. Analogously, a chain exhibits traveling waves propagating against the coupling direction (against the dominant direction for two-way coupling), and, according to the theorem, such traveling waves persist in the relaxation limit $\mu \to 0$. In contrast, case (b) corresponds to a phase lag of the unit receiving coupling that vanishes

in the relaxation limit. The corresponding phenomenon in chains is a traveling wave that propagates in the (dominant) coupling direction and approaches synchrony in the relaxation limit.

3. Relaxation oscillators in the FTM limit. We again consider the system (2.1)–(2.2), but now under the assumption $\mu \ll \epsilon \ll 1$. FTM theory describes the interaction of relaxation oscillators that exhibit sufficiently fast jumps simultaneously ($\mu \ll \epsilon$). It neglects interactions during the periods of slow dynamics, so most FTM results have been qualitative in nature. Here we augment these results by combining FTM with phase reduction theory, assuming $\epsilon \ll 1$ so that the latter applies except near jumps. We retain the notation of section 2 with phase ϕ along the unperturbed limit cycle Γ and $(x(\phi), y(\phi))$ denoting points in the phase plane.

3.1. FTM theory. FTM theory and the synchronization of relaxation oscillators are described in detail in [35] via the example of a mutually coupled pair. (Chains and other networks are considered in [36].) Here we perform a similar analysis of a pair with one-way coupling.

Since ϵ is large compared to μ, we consider an unperturbed limit cycle ($h \equiv 0$) and a separate, perturbed limit cycle for $h \equiv 1$; see Figure 6(A). Since O_2 receives no coupling signal it follows the former. Input to O_1 is either 1 or 0, depending on the state of O_2, so O_1 intermittently switches between the two cycles. Jumps are assumed to be instantaneous. (In phase reduction, one considers only the unperturbed limit cycle, but "jumps" are not instantaneous.)

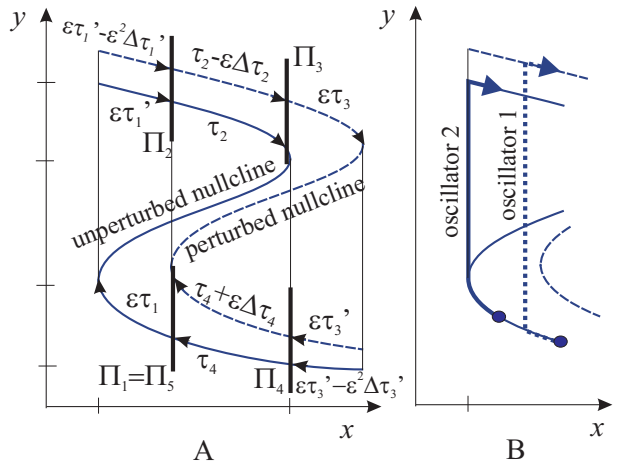

Figure 6. A: *Unperturbed (solid) and perturbed (dashed) nullclines.* Π_i *and* τ_i *represent Poincaré sections and times required to pass certain trajectories, respectively, as used in Appendix B.* B: *An example of FTM interaction:* O_2 *(solid) slightly leads* O_1 *(dashed); when* O_2 *jumps up,* O_1 *switches to the perturbed nullcline, leading to a synchronous jump.*

To illustrate FTM interaction, assume that the oscillators are almost synchronized and moving on the silent branch with O_1 slightly lagging behind O_2. When O_2 reaches the knee and jumps, it sends O_1 to the perturbed limit cycle, thereby causing a synchronous jump, after which O_1 takes the lead. See Figure 6(B). Similarly, synchronous jumps occur if O_1 slightly leads O_2 prior to jumping down. This typically results in rapid and robust synchronization.

The example shows that oscillators with FTM interaction can compensate for deviations from perfect synchrony by keeping fast jumps synchronous and modulating their locations. However, while FTM interactions at jumps act to synchronize the units, accumulating interactions during slow phases may shift them apart. The relative strength of the two effects determines whether synchronization occurs.

The fact that the phase equation (2.3) is not applicable near jumps is illustrated by the following example. Consider two impulsive perturbations, each of strength and duration $\mathcal{O}(\epsilon)$, delivered when O_1 is on the orbit segment of length $\epsilon\tau_1$ in Figure 6(A). Either one alone immediately moves the state to the upper branch, causing an $\mathcal{O}(\epsilon)$ phase change, large compared to its size of $\mathcal{O}(\epsilon^2)$ (strength $\times$ duration). However, if the impulses act successively, the second has an effect of only $\mathcal{O}(\epsilon^2)$. The implicit assumption of phase reduction theory, that successive perturbations are additive, is violated.

3.2. Phase-locking and synchrony. Examples like those above show that the notion of phase difference is unclear, so we introduce the following definitions to categorize different types of T-periodic interactions of pairs of oscillators under FTM:

(a) *Oscillator* O_j *leads* O_i if O_i is silent when O_j jumps up and O_i is active when O_j jumps down.

(b) *The oscillators alternate* if when either jumps up or down, the other is silent, or, alternatively, if when either jumps up or down, the other is active. Only the first case is possible under condition (iii).

(c) *The oscillators synchronize* if the time intervals that O_i spends in its active state are a subset of those spent by O_j in its active state or vice versa. This includes the case when jumps up and/or down are synchronous.

We can now state an analogue of Theorem 2.1.

Theorem 3.1. *Assume that two oscillators in the FTM limit ($\epsilon \to 0$, $\mu/\epsilon \to 0$) each have stable T-periodic solutions. Then*

(a) *if conditions* (i)–(iii) *and inequality* (2.8) *hold, O_1 leads O_2; and*

(b) *if conditions* (i)–(iii) *hold but inequality* (2.8) *does not, the oscillators synchronize.*

Proof. The lengthy proof is given in Appendix B. It relies primarily on defining a function H_{FTM}, analogous to H of section 2, which predicts the relative dynamics, and showing that H_{FTM} has the same shape in the limit $\epsilon \to 0$, $\mu/\epsilon \to 0$ as H does in the limit $\mu \to 0$, $\epsilon/\mu \to 0$. ■

In case (b) of Theorem 3.1 synchrony implies either that the jump in O_2 initiates an immediate jump in O_1 or that one of the oscillators jumps up earlier and jumps down later than the other. If there are synchronous jumps, it is intuitively clear that for small but nonzero μ this results in a small lag of the driven oscillator. Thus cases (b) of Theorems 2.1 and 3.1 are closely related. In contrast, if there is synchrony as defined above but no synchronous jumps, relations between the two theorems are less clear. However, in Appendix C we illustrate that the latter scenario is nongeneric for $\epsilon \to 0$.

There are some differences between the phase and FTM limits. For phase oscillators, $\Delta \backsim \mu^{2/3}$, as shown in Theorem 2.1(b). In the FTM case the $O(\mu)$ duration of fast jumps implies that $\Delta \backsim \mu$. We illustrate this by a numerical example in section 5.

3.3. Oscillator chains in the FTM case. As in phase response theory, the behavior of a unidirectionally coupled pair has implications for chains with one-way, nearest-neighbor coupling; i.e., in cases (a) and (b), chains typically exhibit traveling waves against and in the coupling direction, respectively, and in the relaxation limit synchrony results in case (b) but not in case (a). We suspect that more diffuse localized couplings can be reduced to the nearest-neighbor case, although we are unaware of specific studies of this type.

The behavior of chains FTM-coupled in both directions is less transparent than in case of phase-coupling. Oscillator pairs and arrays with *symmetrical* bidirectional FTM-coupling typically exhibit synchrony, and in contrast to phase-interaction, this is robust against perturbations of the coupling symmetry [35, 36]. These results indicate that asymmetrically coupled arrays (significantly stronger in one direction than in the other) are probably more likely to synchronize than those with unidirectional connections. Quantitative conditions for synchrony versus traveling waves for two-way coupling appear to be unknown. As we show in section 4, traveling wave behavior is much rarer than synchrony in one-way arrays. The above facts suggest that it is even rarer when connections in both directions are present.

4. Why do most oscillators synchronize? It was shown in sections 2 and 3 that oscillators can, but need not, synchronize in the relaxation limit $\mu \to 0$. As described in this section, we examined several simple two-dimensional relaxation oscillator models of neural oscillators and found that all exhibited synchrony. This suggests that inequality (2.8) of Theorem 2.1 is false for many examples. The following theorem provides a sufficient condition for this and hence for synchronization. Two oscillators satisfying conditions (i)–(iii) above and (iv) and (v) below always synchronize in the relaxation limit by Theorems 2.1 and 3.1.

Theorem 4.1. *Suppose that* (2.1)–(2.2) *satisfy condition* (ii)*, and additionally, at all points* (x, y) *on the "active" branch of the slow manifold* $g = 0$*, the following conditions hold.*

- *Condition* (iv): $f_x(x, y) \le 0$.
- *Condition* (v): $g_x(x, y) \le g_x(x(D), y(D))$.

Then inequality (2.8) *is false.*

Proof (by contradiction). The integral in (2.8) (or (2.9)) is evaluated along $g = 0$, on which an infinitesimal displacement $(d\xi, d\upsilon)$ satisfies

$$g_x(\xi, \upsilon)\, d\xi + g_y(\xi, \upsilon)\, d\upsilon = 0 \quad \text{or} \quad d\xi = -\frac{g_y(\xi, \upsilon)\, d\upsilon}{g_x(\xi, \upsilon)}. \tag{4.1}$$

We use (4.1) to change the variable of integration in (2.8) from ξ to υ, replacing $(\xi, \upsilon(\xi))$ by $(\xi(\upsilon), \upsilon)$, where $\xi(\upsilon)$ denotes the inverse of $\upsilon(\xi)$. Since $g_x < 0$ on the active nullcline, due to $g_x(x(D), y(D)) < 0$ and condition (v), this inverse is well defined in the case of interest. Inequality (2.8) becomes

$$\begin{aligned} &-\int_{y(D)}^{y(0+)} \frac{f_y(\xi(\upsilon), \upsilon)}{f^2(\xi(\upsilon), \upsilon) g_x(\xi(\upsilon), \upsilon)}\, d\upsilon \\ &+ \frac{1}{g_x(x(D), y(D))} \left[\frac{1}{f(x(D), y(D))} - \frac{1}{f(x(D), y(D^+))} \right] > 0. \end{aligned} \tag{4.2}$$

To show that (4.2) is false we first replace $g_x(x, y)$ in the integrand by the constant term $g_x(x(D), y(D))$, using the facts that $g_x(x, y) \le g_x(x(D), y(D)) < 0$ and $f_y < 0$ (condition (ii)),

which together imply that

$$\int_{y(D)}^{y(0+)} \frac{f_y(\xi(\upsilon),\upsilon)}{f^2(\xi(\upsilon),\upsilon)g_x(\xi(\upsilon),\upsilon)}\,d\upsilon \le \int_{y(D)}^{y(0+)} \frac{f_y(\xi(\upsilon),\upsilon)}{f^2(\xi(\upsilon),\upsilon)g_x(x(D),y(D))}\,d\upsilon.$$

We then multiply the resulting expression by the strictly positive quantity $-g_x(x(D),y(D))$ to deduce that, if (4.2) holds, then also

$$\int_{y(D)}^{y(0+)} \frac{f_y(\xi(\upsilon),\upsilon)}{f^2(\xi(\upsilon),\upsilon)}\,d\upsilon - \frac{1}{f(x(D),y(D))} + \frac{1}{f(x(D),y(D^+))} > 0,$$

which in turn implies that

$$\int_{y(D)}^{y(0+)} \frac{f_y(\xi(\upsilon),\upsilon)}{f^2(\xi(\upsilon),\upsilon)}\,d\upsilon - \frac{1}{f(x(D),y(D))} > 0, \tag{4.3}$$

where we use $1/f(x(D),y(D^+)) < 0$, since $f < 0$ on the "silent" branch of the slow manifold.

Next, using the chain rule and appealing to condition (iv) and the fact that $\xi(\upsilon)$ is a decreasing function, we have

$$\frac{df(\xi(\upsilon),\upsilon)}{d\upsilon} = f_y + f_x\frac{d\xi(\upsilon)}{d\upsilon} \ge f_y. \tag{4.4}$$

Equation (4.4) allows us to replace the partial derivative in the integrand of (4.3) by the total derivative and further to express it as an exact differential,

$$\int_{y(D)}^{y(0+)} \frac{df(\xi(\upsilon),\upsilon)/dy}{f^2(\xi(\upsilon),\upsilon)}\,d\upsilon = -f^{-1}(x_a(\upsilon),\upsilon)\big|_{y(D)}^{y(0+)}, \tag{4.5}$$

where $x_a(\upsilon)$ denotes points on the active branch and we use the fact that $(f^{-1})' = -f'/f^2$. Our inequality now reads

$$-f^{-1}(x_a(\upsilon),\upsilon)\big|_{y(D)}^{y(0+)} - \frac{1}{f(x(D),y(D))} = \frac{-1}{f(x(0),y(0+))} > 0. \tag{4.6}$$

But this is false, since $f(x,y) > 0$ on the active branch, providing our contradiction. ■

Theorem 4.1 applies to many oscillator models with unidirectional coupling that satisfies condition (i). We analyzed the van der Pol oscillator [37] and neuron models of FitzHugh–Nagumo [12, 33], Hindmarsh–Rose [16], Morris–Lecar [32], and Rinzel [34], as well as a two-dimensional spike-rate description of the bursting half-center in the lamprey from [42, p. 209], obtaining the results summarized in Table 1. We also checked inequality (2.8) (in some cases numerically) and found that it was false in every case, in four of which Theorem 4.1 applies. This suggests that it is not easy to find relaxation oscillators that do not synchronize. Nonetheless, in the next section we provide an example of this apparently rare behavior.

5. A numerical example. To demonstrate the above results, we now analyze a pair of van der Pol oscillators in Lienard variables [28, Chap. XI], [29], with one-way excitatory coupling. At the end of the section simulation results of chains are also shown. The uncoupled units include a parameter p that can be varied to produce two characteristic behaviors. $p = 0$ corresponds to the classical van der Pol oscillator. Oscillator 1 is described by

$$\begin{aligned} \dot{x_1} &= f(x_1, y_1) = y_1, \\ \mu \dot{y_1} &= g(x_1, y_1) + \epsilon h(y_2) \end{aligned} \tag{5.1}$$

$$= \left(y_1 - y_1^3/3 - x_1\right) \cdot \left(1 + (p \cdot x_1)^4\right) + \epsilon \left\{ \begin{array}{lll} 1 & \text{if} & y_2 > 0 \\ 0 & \text{if} & y_2 \le 0 \end{array} \right\}, \tag{5.2}$$

and the equations of oscillator 2 are the same but lack the coupling term $\epsilon\{\ldots\}$. The coupling obeys condition (i) and the uncoupled oscillators satisfy conditions (ii), (iii), and (iv) since $f_y \equiv 1$, the duty cycle is exactly 1/2 due to the symmetry of the vectorfield, and $f_x \equiv 0$. For $p = 0$, they also satisfy (v), because $g_x \equiv -1$. Thus they synchronize in the relaxation limit $\mu \to 0$ with extremely weak coupling (by Theorems 2.1 and 4.1) as well as with moderate coupling (by Theorems 3.1 and 4.1).

If $p \neq 0$, the S-shaped fast nullclines of (5.2) remain the same, but $g(x, y)$ becomes steeper as $|x_j|$ increases so that condition (v) does not hold and Theorem 4.1 cannot be applied. Numerical evaluations show that inequality (2.8) fails for $p < p_{cr} \approx 2.36$ but holds for $p \geq p_{cr}$. In the latter case, Theorems 2.1 and 3.1 predict persistent phase-shifts as $\mu \to 0$.

The oscillator pair was simulated with $\epsilon = 0.5$ and various values of μ and p. In every case, the system converged to a stable periodic orbit with period T equal to that of an uncoupled unit. The jth increasing zero-crossing of $y_1(t)$ and $y_2(t)$ (i.e., times t_{ij} when $y_i(t_{ij}) = 0$, $\dot{y}_i t_{ij} > 0$) were detected and the phase-shift Δ was determined according to

$$\Delta = \lim_{j \to \infty} \frac{t_{2j} - t_{1j}}{T}. \tag{5.3}$$

For weakly coupled relaxation oscillators ($\epsilon, \mu \to 0$), the respective meanings of $\pi > \Delta > 0$, $\Delta = 0$, and $-\pi < \Delta < 0$ are that the driven oscillator leads, is synchronous with, and lags behind the driver. Here ϵ is not very small, so $\Delta \approx 0$, but $\neq 0$ might also correspond

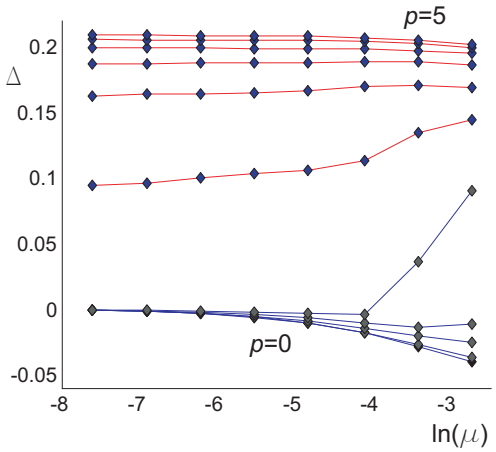

Figure 7. *Dependence of phase-shift between the coupled pair of oscillators* Δ *on* μ*. From bottom to top,* $p = 0, 0.5, 1, \ldots, 5$*. For small p, the shift is negative (the driven oscillator lags) and vanishes at the relaxation limit* $\mu \to 0$*; for large p the shift is positive and persists in the relaxation limit. Note that* $p = 2$ *is small in this regard, although it shows different behavior from the* $p < 2$ *cases for larger* μ *(fifth curve from the bottom).*

to synchrony (cf. the definition of synchrony in section 3.2). Nevertheless Δ is still a good indicator of the phase difference.

Figure 7 illustrates the dependence of Δ on μ for different values of p, showing that $\Delta(\mu)$ curves below 0, for small μ converge to 0 as $\mu \to 0$. Curves above 0, however, converge to a strictly positive limit. This corresponds to one of our main findings: if the driven oscillator leads the driver, the phase difference persists in the relaxation limit, but if the driver leads, the difference vanishes.

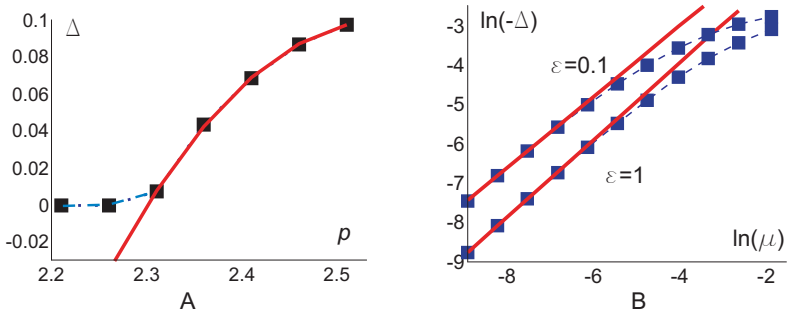

Figure 8. A: *Phase-shift* Δ *as function of p for* $\mu = 10^{-3}$*,* $\epsilon = 0.5$ *(squares), and a fitted quadratic curve* $\bar{\Delta}(p)$ *(solid line).* B: *Dependence of* Δ *on* μ *for* $p = 0$ *plotted on logarithmic scales for* $\epsilon = 1$ *and at* $\epsilon = 0.1$ *(squares). Linear regression in the range* $\mu = 10^{-4} \ldots 10^{-3}$ *reveals* $ln(-\Delta) \approx 0.98 \ln(\mu) + 0.04$ *and* $ln(-\Delta) \approx 0.90 \ln(\mu) + 0.67$*, respectively (solid lines).*

Figure 8(A) shows the numerically derived function $\Delta(p)$ for $\mu = 10^{-3}$ and $\epsilon = 0.5$. A quadratic fit for $\Delta > 0$ yields $\bar{\Delta}(p) = -1.646p^2 + 8.382p - 10.572$, whose root at $\bar{p}_{cr} \approx 2.301$ lies within 3% of $p_{cr} \approx 2.36$ predicted by inequality (2.8). The difference is primarily due to

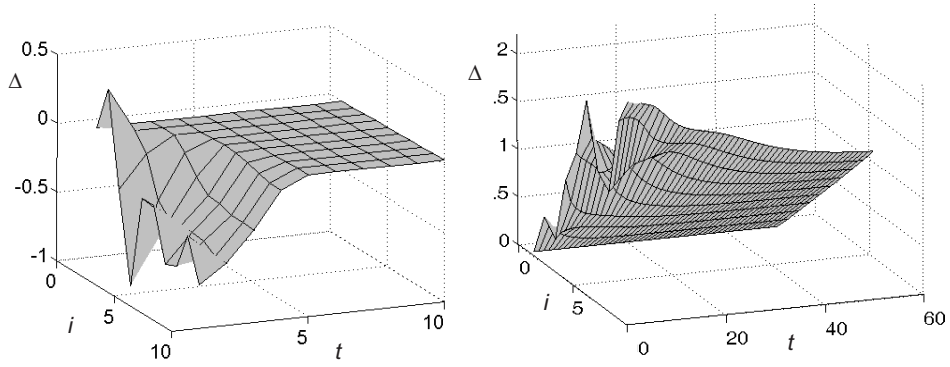

Figure 9. *Dynamics of a chain of* 10 *oscillators at* $p = 0$ *(left) and* 3 *(right). Each oscillator* i *is driven by its neighbor* $i-1$*;* t *denotes time normalized by the period of an uncoupled unit.* Δ *denotes the phase difference between units* i *and* 1*. the relatively strong coupling.

We also determine numerically how Δ scales with μ for small p to examine $\lim_{\mu \to 0} \Delta = 0$. The predictions of sections 2.2 and 3.2 are $\Delta \backsim \mu^{2/3}$ for phase-oscillator interactions and $\Delta \backsim \mu^{1}$ for FTM interactions. According to simulations with $p = 0$, the exponent is approximately 0.97 in the range $\mu = 10^{-4} \ldots 10^{-3}$ if $\epsilon = 1$ and 0.90 if $\epsilon = 0.1$ (Figure 8(B)). These results reflect the fact that our parameter values are appropriate for FTM ($\mu << \epsilon << 1$); but they also show that the exponent decreases as ϵ decreases, moving toward the phase-approximation value, which holds for $\epsilon << \mu << 1$.

We close this section by illustrating the two types of behavior for chains. The two panels of Figure 9 show the spatio-temporal dynamics of phase-shifts along a chain of 10 unidirectionally coupled units. For $p = 0$ (left panel), the network rapidly synchronizes, while for $p = 3$ uniform phase-shifts develop on a longer time-scale. The final states agree with the predictions of Theorem 2.1. (The reason for the radically different decay times of transients is explained in [35].)

6. Applications to the lamprey CPG. The central pattern generator (CPG) of the lamprey has been a focus of research for over thirty years. Fictive swimming experiments [9] show that the CPG without muscles or afferent (feedback) inputs produces rhythms similar to real swimming: traveling waves of activation (motoneuron bursts) propagate from head to tail on both sides in antiphase. The wavelength remains approximately constant and equal to body length over a considerable speed range.

The components of the CPG and their interconnectivities have been partially determined [5], and a reduced network with three classes of neurons, representing one or a few segments of the animals' CPG, has been proposed; see Figure 10(A). Each segment has bilateral symmetry, with mutual inhibition between hemisegments. The entire CPG is modeled as a chain of such units [21, 23], intersegmental connections being of the same type as intrasegmental ones, but with strengths decreasing rapidly with distance. For simplicity here we assume only nearest-neighbor connections, but our results can be extended to more

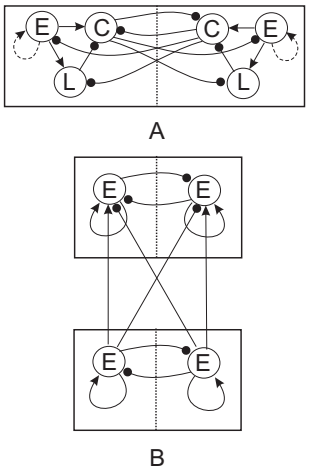

Figure 10. A: *Simplified structure of a segmental unit of the lamprey CPG first proposed by* [6]. *E, L, and C represent small groups of excitatory, crossed inhibitory, and lateral inhibitory neurons, respectively, and arrows and circles denote excitatory and inhibitory synapses. Bilaterally symmetric halves of the network are coupled by inhibition. The dashed self-excitatory connection occurs in some but not all models.* B: *A simplified network with E cells alone approximates the dynamics of cell-based rhythm generation (cf.* [38]*); two segmental units are shown.*

widespread connections, provided that they are short relative to the size of the full network.

Several models have implemented the network architecture of Figure 10(A), and two different pattern-generating mechanisms have been proposed [13]: rhythms being generated by network connections, or by small groups of bursting cells. Simple *network-based* models [4, 40] were able to reproduce the constant wavelength-swimming speed behavior, albeit over a limited frequency range. The *cell-based* mechanism inspired a series of detailed model studies [26, 39, 27] which encompass a wider frequency range, but with frequency-dependent wavelengths (small at low frequencies, large at high frequencies).

The core of the cell-based networks is a double chain of relaxation-type oscillators (Figure 10(B); see also [38]), each representing a small group of intrinsic bursters. The fast and the slow variables represent average activity (firing rate) and spike-rate adaptation due to slow calcium currents, respectively. In these models, swimming frequency is adjusted through serotonin concentration determining the speed of the slow dynamics, i.e., μ. (Other, less important, parameters also change with frequency, but we ignore these effects.) Thus, when swimming speed decreases, the speeds of the slow and the fast dynamics separate, approaching a relaxation limit. The tendency of chains of relaxation oscillators to synchronize offers a straightforward explanation for the wavelength-frequency behavior of these networks, and, as we now show, the results of sections 2–4 yield more precise predictions on cell-based CPG models.

The double chains of Figure 10 differ from the single chains studied in sections 2.3 and 3.3, but their behavior can be predicted in a similar manner by considering a pair of segments comprising four oscillators, as in Figure 10(B). Specifically, we assume condition (i) above, that the hemisegments remain out of phase, and we denote the strengths of intersegmental excitatory and inhibitory connections by ϵ_e and ϵ_i, respectively. Phase response theory

then yields the averaged coupling function $H_{\mu\,pair}$ governing intersegmental phase differences (cf. (2.4)) at given values of μ by superposing the contributions of the excitatory and inhibitory connections. In the relaxation limit $\lim_{\mu\to 0} H_{\mu\,pair} \stackrel{\text{def}}{=} H_{0\,pair}$ we obtain

$$\lim_{\mu\to 0} H_{\mu\,pair} \stackrel{\text{def}}{=} H_{0\,pair}(\psi) = \frac{1}{2\pi}\left[\epsilon_e \int_{\psi}^{D+\psi} z^*(\phi)\,d\phi - \epsilon_i \int_{\psi+\pi}^{D+\psi+\pi} z^*(\phi)\,d\phi\right]. \tag{6.1}$$

Equation (6.1) is the analogue of (2.7) with a second term $-\epsilon_i \int \ldots$ due to inhibition between the segments. Its consequence is a somewhat weaker and (in part (a)) more technical analogue of Theorem 2.1.

Theorem 6.1. *Let $(x, y) = (\xi, \upsilon(\xi))$ and $(x, y) = (\xi, \zeta(\xi))$, respectively, denote points on the active and silent branches of the $\dot{y} = 0$ nullcline. Assume that $\Delta(\mu)$ satisfies $dH_{\mu\,pair}(\psi)/d\psi|_{\Delta(\mu)} < 0 = H_{\mu\,pair}(\Delta(\mu))$.*

(a) *If conditions* (i)–(iii) *hold, and*

$$\begin{aligned} &-\epsilon_e \int_{x(0)}^{x(D)} \frac{f_y(\xi,\upsilon(\xi))}{f^2(\xi,\upsilon(\xi))g_y(\xi,\upsilon(\xi))}\,d\xi \\ &+\epsilon_i \int_{x(\pi)}^{x(\pi+D)} \frac{f_y(\xi,\zeta(\xi))}{f^2(\xi,\zeta(\xi))g_y(\xi,\zeta(\xi))}\,d\xi \\ &+\epsilon_e \frac{1}{g_x(x(D),y(D))}\left[\frac{1}{f(x(D),y(D))} - \frac{1}{f(x(D),y(D+))}\right] > 0, \end{aligned} \tag{6.2}$$

then for a coupling function of the form $H_{0\,pair}(\phi) = \Xi(\phi) + c$ (where Ξ is an arbitrary 2π periodic function and c is an arbitrary constant), there exists $\delta > 0$ independent of c such that if $|\Delta(0)| < \delta$, then $\Delta(0) > 0$.

(b) *If conditions* (i)–(iii) *hold, Δ is unique modulo 2π, and inequality* (6.2) *is false, then $\Delta(\mu) \backsim -\mu^{2/3}$ for small μ, and $\Delta(0) = 0$; i.e., the driven segment lags the driver and the segments synchronize in the relaxation limit.*

Proof (sketch). The proof of Theorem 6.1 is similar to that of Theorem 2.1, so we outline only the main points and differences between them.

Referring to (6.1) and the proof of Theorem 2.1, and noting that (6.2) has no "boundary" term due to inhibitory connections ϵ_i, since for duty cycle $D/(2\pi) < 0.5$ and $\phi_{ij} \approx 0$ the driven oscillator jumps when the inhibitory driver is inactive, we see that the left-hand side of inequality (6.2) is equal to $H_{0\,pair}(0)$. Hence, cases (a) and (b) of the theorem respectively correspond to $H_{0\,pair}(0) > 0$ and ≤ 0. The first term $\epsilon_e \int \ldots$ in (6.1) has a jump at $\phi = 0$, at the top of which it is positive, and this term is continuous on the left side of the jump provided that $-D < \phi < 0$ (see the proof of Theorem 2.1). The second term $-\epsilon_i \int \ldots$ is positive and continuous in ϕ if $|\phi| < (\pi - D)$ because z^* is negative and integrable in the interval $D < \phi < 2\pi$; cf. Figure 3. Hence, $H_{0\,pair}(\phi)$ itself has a jump at 0, is positive at the top of the jump ($H_{0\,pair}(0^-) > 0$), and is continuous in the interval $(-\min\{D, \pi - D\}, 0)$.

In case (b), at the bottom of the jump $H_{0\,pair}(0^+)$ is negative as in Theorem 2.1, so it has a stable root at 0, and because of uniqueness, $\Delta(0) = 0$. For μ small but positive, $\Delta(\mu) \backsim -\mu^{2/3}$ for the same reason as in Theorem 2.1. In case (a) at the bottom of the jump $H_{0\,pair}(0^+)$ is already positive, and thus $H_{0\,pair}(0^-) > s > 0$, where s denotes the magnitude

of the jump, which is independent of the constant c in the definition of $H_{0\,pair}$. On the negative side of 0, there is an interval in which $H_{0\,pair}(\phi)$ is continuous (see above). Thus by definition there exists δ (again independent of c) such that for arbitrary $0 < 0 - \phi < \delta$, we have $|H_{0\,pair}(0^-) - H_{0\,pair}(\phi)| < s$, yielding $H_{0\,pair}(\phi) > 0$. Thus if $|\Delta(0)| < \delta$, $\Delta(0)$ must be positive. ■

The implication of part (a) is that if $|\Delta(0)| << 1$, then $\Delta(0) > 0$; the driven segment leads the driver. Hence the statement in part (a) is similar to, and more specific than, part (a) of Theorem 2.1. Theorem 6.1 has two restrictions in addition to those of Theorem 2.1—the uniqueness of Δ in part (b) and its closeness to zero in part (a)—but neither affects its applicability to lamprey CPGs. Uniqueness means that the CPG has a unique stable traveling wave solution in agreement with the observation that the lamprey exhibits a single robust pattern of motion. It is also reasonable that $|\Delta(0)| << 1$ since the lamprey's notocord has $\mathcal{O}(100)$ segments, so intersegmental phase differences must be $\mathcal{O}(0.01 \times 2\pi)$ if wavelength is to equal body length.

Phase response theory does not always apply to the lamprey CPG, because intersegmental coupling is not necessarily weak, so FTM interactions may be more appropriate. Much as Theorem 2.1 has an analogous statement in Theorem 3.1, an analogue of Theorem 6.1 holds under the assumption of FTM interactions. Here we give an informative but inexact version, without proof.

Theorem 6.2. *Assume that two pairs of oscillators in the FTM limit ($\epsilon_{e,i} \to 0$, $\mu/\epsilon_{e,i} \to 0$) each have stable T-periodic solutions. Let Δ_{FTM} denote the time difference between activation of the ipsilateral driven and driver oscillators (positive if the driven activates first). Then,*

(a) *if conditions* (i)–(iii) *and inequality* (6.2) *hold and $|\Delta_{FTM}| << 1$, then the driven oscillators lead the drivers; and*

(b) *if conditions* (i)–(iii) *hold but inequality* (6.2) *fails and the network has only one stable T-periodic solution, then the oscillators synchronize (away from the relaxation limit, the driven segment lags the driver).*

Provided that the CPG has unidirectional intersegmental coupling, the consequences of Theorems 6.1–6.2 for the lamprey are as follows.

1. If inequality (6.2) fails, neighboring segments display a negative phase difference that vanishes in the relaxation limit. A chain will therefore exhibit waves that propagate in the direction of the intersegmental coupling, with wavelength approaching zero in the relaxation limit. Hence, in such models the wavelength is usually an increasing function of μ, instead of a constant with frequency. This behavior was seen in previous numerical simulations.

2. If inequality (6.2) holds, segments have positive phase differences that persist in the relaxation limit and traveling waves will propagate against the coupling direction, with approximately constant wavelength as μ is varied. Hence, intersegmental connections must be directed from tail to head to obtain head-to-tail traveling waves.

Our first important finding is that, if (6.2) holds, a double chain of oscillators can combine the advantages of previous cell- and network-based CPG models, namely, wide frequency-range and constant wavelengths. Theorem 4.1 implies that single chains rarely satisfy the analogous inequality (2.8), but the presence of an additional positive term $\epsilon_i \int \dots$ in (6.2), due to cross-inhibitory connections, provides more flexibility. On the other hand, as shown in section 3.3, the bidirectional coupling in the real network promotes synchrony under the

assumption of FTM interactions. Hence finding "well-behaved" models is difficult, but probably not hopeless, since the high number of ad hoc parameters in such models allows wide freedom for improvement. The failure of such an attempt would suggest that the cell-based mechanism is an oversimplification and that more sophisticated models, perhaps combining both rhythm-generating mechanisms, are required.

It is also worth noting that caudo-rostral (tail-to-head) coupling is required to produce waves that travel from head to tail. This confirms previous studies [41, 20] that used completely different arguments to show that ascending is stronger than descending coupling in the lamprey notocord.

7. Conclusions. This paper concerns coupled sets of planar relaxation oscillators. We focus on pairs of oscillators with unidirectional coupling but draw conclusions for two-way coupling and linear chains of oscillators. Our main theorems, Theorems 2.1 and 3.1, provide sufficient conditions for persistent phase lags and for synchrony in the limits of weak coupling and of large time-scale separation, using phase response theory and FTM theory, respectively. The key step involves estimation of an inequality (2.8) arising from the averaged coupling function.

Theorem 4.1 provides a sufficient condition for synchrony, and in section 4 we show that several models of bursting neurons satisfy this condition, which we conjecture to be the typical case. However, counterexamples can be found, as demonstrated in section 5. Finally, in section 6 we extend these results to the double chains featured in models of CPGs for swimming in lamprey, providing analogues of Theorems 2.1 and 3.1 in Theorems 6.1 and 6.2. These results partially explain why cell-based models of relaxation type approach synchrony as swimming speed decreases, violating the experimental observation of near-constant phase lags over a wide speed range, but they also offer hope that parameterizations that permit the observed behavior may be found.

More generally, the results in this paper reveal interesting relations between phase response and FTM theory, which apply in the distinctly different limits of weak coupling ($1 \gg \mu \gg \epsilon \to 0$) and strong time-scale separation ($1 \gg \epsilon \gg \mu \to 0$). In particular, we construct a composed Poincaré return map in the latter relaxation limit that is the analogue of the averaged coupling function in the former limit. This map is used to demonstrate that the tendency of unidirectionally coupled pairs or arrays of oscillators to synchronize is unaffected by extreme changes of the ratio ϵ/μ despite evident differences between the resultant coupling mechanisms. However, we also find that the rates of convergence to synchrony scale differently as perfect time-scale separation ($\mu \to 0$) is approached. In case of FTM interaction, our study raises further questions regarding the behavior of bidirectionally but asymmetrically coupled arrays as well as that of arrays with multiple (non–nearest-neighbor) coupling. A similar approach to the present one may be helpful in studying synchronization properties of such networks.

Appendix A. Theorem 2.1: The PRC at jumps. Here we locally approximate the PRC near jumps, showing that relaxation oscillators have large phase response values during transition, shortly before (but not during) jumps. This fact is central in the proof of Theorem 2.1.

We assume small but nonzero μ, in which case the stable limit cycle Γ of the ODEs (2.1)–(2.2) is close to but not exactly the same as that shown in Figure 1. Since notation like $x(\phi)$

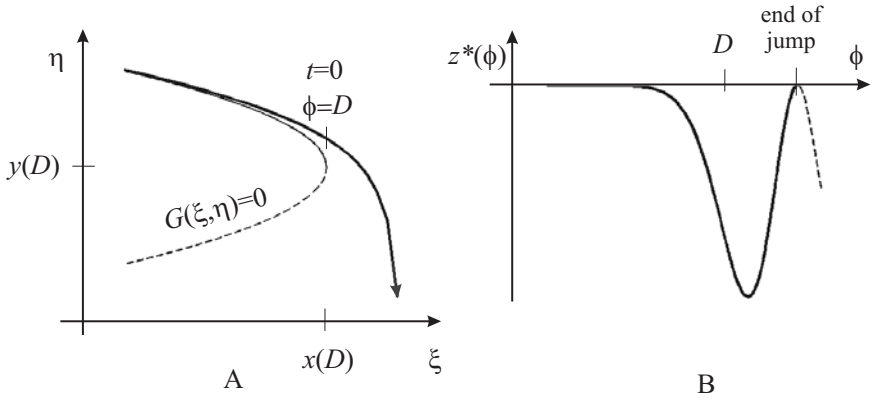

Figure 11. A: *An orbit in the neighborhood of a downward jump.* B: *The PRC near the jump.*

has been used to denote coordinates on Γ as $\mu \to 0$, we now use different notation ξ and η for the slow and the fast variables, respectively. We define time t and phase ϕ such that $t = 0$ and $\phi = D$ when $\xi = x(D)$; see Figure 11(A).

Leading order terms in the PRC near jumps at nondegenerate (quadratic) turning points are determined by the local approximation

$$\dot{x} \approx f(x(D), y(D)), \tag{A.1}$$

$$\mu\dot{y} \approx g_x(x(D), y(D))\,[x - x(D)] + \frac{g_{yy}(x(D), y(D))}{2}\,[y - y(D)]^2\,. \tag{A.2}$$

These ODEs have an explicit solution in terms of Airy functions and their derivatives [1], denoted below by Ai, Bi, Ai', and Bi':

$$\xi(t) = x(D) + ft, \tag{A.3}$$

$$\eta(\xi) = y(D) + \mu^{1/3}\left(\frac{4fg_x}{g_{yy}^2}\right)^{1/3}\frac{Ai'(\zeta) + a \cdot Bi'(\zeta)}{Ai(\zeta) + a \cdot Bi(\zeta)}, \tag{A.4}$$

where a is an arbitrary constant, the arguments $(x(D), y(D))$ have been suppressed (i.e., $f = f(x(D), y(D))$, etc.), and ζ is a rescaled version of ξ,

$$\zeta = -\mu^{-2/3}\left(\frac{g_x g_{yy}}{2f^2}\right)^{1/3}(\xi - x(D)). \tag{A.5}$$

The parameter a is determined by the asymptotic boundary condition that for $\xi \to -\infty$ the orbit follows the upper branch of the $g = 0$ nullcline, implying that $\eta(\xi) > y(D)$; see Figure 11(A). We note that $\xi \to -\infty$ corresponds to $\zeta \to \infty$ by (A.5), the limiting values of $Ai(\zeta)$, $Ai'(\zeta)$, $Bi(\zeta)$, and $Bi'(\zeta)$ are $+0$, -0, $+\infty$, and $+\infty$, respectively, and, from the nullcline geometry, $f > 0 > g_x$. Using these facts in (A.4), $\lim_{\xi\to-\infty}\eta(\xi) > y(D)$ implies that $a = 0$. The orbit gradually leaves the nullcline and η goes to minus infinity at $\zeta = A \approx -2.3381$, which is a zero of the function Ai. The term $\mu^{1/3}$ in (A.4) implies that, for small μ, η remains close to zero for most values of ζ and suddenly grows just before ζ reaches its critical value.

By definition, the PRC represents the (linear) advancing or retarding effect of a small, instantaneous perturbation $\Delta\eta$ in the fast variable. Such a perturbation results in a switch to another trajectory with $a \approx \Delta\eta \cdot da/d\eta$. The η-coordinate of the perturbed trajectory goes to infinity at $\zeta = \zeta_{end}(a)$. We assume that $\zeta_{end}(a)$ corresponds, via (A.5), to the rescaled slow coordinate ξ_{end} when the jump is finished and slow motion begins on the lower branch of the nullcline; as already noted, $\zeta_{end}(0) = A$. The perturbation changes this by

$$\Delta\xi_{end} = \Delta\eta \frac{da}{d\eta}\frac{d\zeta_{end}}{da}\frac{d\xi}{d\zeta} + \mathcal{O}(\Delta\eta^2). \tag{A.6}$$

To compute the effect of the perturbation, note that during the jump the slow variable evolves according to $\dot{\xi} \approx f(x(D), y(D))$, so that the jump duration increases by $\Delta\xi_{end}/f(x(D), y(D))$. After the jump, the orbit reverses direction in ξ: $\dot{\xi} \approx f(x(D), y(D^+)) < 0$. Thus positive $\Delta\xi$ has a further retarding effect of duration $\Delta\xi_{end}/f(x(D), y(D^+))$. The sum of these two terms represents the "time-response" to the perturbation, and a final scaling factor $d\phi/dt = \omega$ yields the local PRC

$$\begin{aligned}\Delta\phi = -\Delta\eta \frac{da}{d\eta}\frac{d\zeta_{end}}{da}\frac{d\xi}{d\zeta}\omega \left[f^{-1}(x(D), y(D)) - f^{-1}(x(D), y(D^+))\right] \\ + \mathcal{O}(\Delta\mu^2),\end{aligned} \tag{A.7}$$

where the minus sign implies that positive values correspond to shortening of the period.

We compute the components of the product in (A.7) one by one. First, $d\xi/d\zeta$ comes directly from (A.5):

$$\frac{d\xi}{d\zeta} = -\mu^{2/3}\left(\frac{2f^2}{g_x g_{yy}}\right)^{1/3}. \tag{A.8}$$

We find $da/d\eta = (d\eta/da)^{-1}$ using (A.4):

$$\begin{aligned}\frac{da}{d\eta} &= \left[\left(\frac{4\mu f g_x}{g_{yy}^2}\right)^{1/3} \frac{Bi'(\zeta)(Ai(\zeta) + a\,Bi(\zeta)) - Bi(\zeta)(Ai'(\zeta) + a\,Bi'(\zeta))}{(Ai(\zeta) + a\,Bi(\zeta))^2}\bigg|_{a=0}\right]^{-1} \\ &= \left[\left(\frac{4\mu f g_x}{g_{yy}^2}\right)^{1/3} \frac{Bi'(\zeta)\,Ai(\zeta) - Bi(\zeta)\,Ai'(\zeta)}{Ai(\zeta)^2}\right]^{-1}.\end{aligned} \tag{A.9}$$

The term $Bi'(\zeta)\,Ai(\zeta) - Bi(\zeta)\,Ai'(\zeta)$ is constant. The fact that its derivative is 0 follows from the definition of Airy functions: $v\,Ai(v) = Ai''(v)$, $v\,Bi(v) = Bi''(v)$. This straightforward calculation is omitted. Hence we may replace ζ by the constant $A \approx -2.3381$ defined above and use $Ai(A) = 0$ to obtain

$$\frac{da}{d\eta} = -\left[\left(\frac{4\mu f g_x}{g_{yy}^2}\right)^{1/3} \frac{Bi(A)\,Ai'(A)}{Ai(\zeta)^2}\right]^{-1}. \tag{A.10}$$

Finally, we determine $d\zeta_{end}/da$. $\zeta_{end}(a)$ denotes the location of the singularity in (A.4): it is the solution of

$$Ai(\zeta) + a\,Bi(\zeta) = 0. \tag{A.11}$$

Thus we have

$$\frac{d\zeta_{end}}{da} = \left[\frac{da}{d\zeta_{end}}\right]^{-1} = \left[-\frac{d\left[Ai(\zeta)/Bi(\zeta)\right]}{d\zeta}\bigg|_{\zeta=A}\right]^{-1}$$
$$= \frac{Bi^2(A)}{Ai(A)\,Bi'(A) - Ai'(A)\,Bi(A)} = -\frac{Bi(A)}{Ai'(A)}. \tag{A.12}$$

Substituting (A.3), (A.5), (A.8), (A.10), and (A.12) into (A.7), we obtain the PRC in terms of t:

$$\frac{\Delta\phi}{\Delta\eta} \approx \left[\frac{\mu f(x(D),y(D))g_{yy}(x(D),y(D))}{2g_x^2(x(D),y(D))}\right]^{1/3} Ai'^{-2}(A)$$
$$\times\, Ai^2\left(-\mu^{-2/3}\left(\frac{g_x(x(D),y(D))g_{yy}(x(D),y(D))f(x(D),y(D))}{2}\right)^{1/3} t\right)$$
$$\times\, \omega\left[\frac{1}{f(x(D),y(D))} - \frac{1}{f(x(D),y(D^+))}\right]. \tag{A.13}$$

Finally, replacing t by $\phi = \phi_0 + \omega t$, we obtain the approximate PRC $z(\phi)$ during the transition and jump. Note that in spite of its apparent complexity, the formula (A.13) contains only constants and a scaled Ai^2 function, so that we may write

$$z^*(\phi) = \frac{z(\phi)}{\mu} \approx B\mu^{-2/3}\, Ai^2\left(C\mu^{-2/3}(\phi - \phi_0)\right), \tag{A.14}$$

where B, C are $O(1)$ constants. See also Figure 11(B).

This formula demonstrates that large PRC values occur during transition, while the oscillator state is near the upper nullcline. (These correspond to the delta function in the relaxation limit; see (2.6).) The analogous result for the upward jump can be derived in the same way. In that case, the large values occur during transition at the lower nullcline. We remark, without explicit computations, that the integral of this approximation of the phase-response function from $-\infty$ to the end of the jump is equal to the coefficient of the delta function in (2.6).

Appendix B. Proof of Theorem 3.1. The proof is divided into five parts. In the first, notation and concepts are introduced; these include four mappings H_i representing the interactions of the oscillators during the four segments of their limit cycles (slow motions on the upper and lower nullcline branches, and jumps). In the second part we analyze the functions H_i. These results are used in the third part to demonstrate that the only possible forms of T-periodic interactions are synchrony or O_1 leading O_2. The fourth part contains the proof that if O_1 leads, then inequality (2.8) holds, and in the last part we show the converse in the case of synchrony.

B.1. Notation. Let $t_j^{(1)}, \ldots, t_j^{(5)}$ denote the times at which the state of O_j successively crosses the Poincaré sections $\Pi_1, \Pi_2, \ldots, \Pi_5 = \Pi_1$ defined in Figure 6(A). We shall construct a return map

$$\epsilon H_{FTM}(t_2^{(1)} - t_1^{(1)}) = \left[t_2^{(5)} - t_1^{(5)}\right] - \left[t_2^{(1)} - t_1^{(1)}\right], \tag{B.1}$$

which describes the time-shift during one cycle due to coupling, normalized by the coupling strength ϵ. Phase-locked solutions correspond to zeros of H_{FTM}, and their stability requires $0 \leq \epsilon\, dH_{FTM}(t)/dt \leq 2$. Thus, H_{FTM} is a similar predictor of dynamics to the coupling function $H(\psi)$ in the phase limit, although the stability condition differs. We assemble the maps H_i, $i = 1, 2, 3, 4$,

$$\epsilon H_i(t_2^{(i)} - t_1^{(i)}) = \left[t_2^{(i+1)} - t_1^{(i+1)}\right] - \left[t_2^{(i)} - t_1^{(i)}\right], \tag{B.2}$$

the composition of which defines

$$\begin{aligned} H_{FTM}(t) = {} & H_1(t) + H_2(t + \epsilon H_1(t)) \\ & + H_3(t + \epsilon H_2(t + \epsilon H_1(t))) \\ & + H_4(t + \epsilon H_3(t + \epsilon H_2(t + \epsilon H_1(t)))). \end{aligned} \tag{B.3}$$

In Figure 6(A), we introduce notation for the times required to travel along certain trajectories in the phase space. We use these to express the functions H_i for small ϵ in the next subsection. The notation reflects the scaling of these lengths; e.g., $\epsilon\Delta\tau_2$ in Figure 6(A) is $\mathcal{O}(\epsilon)$ because it represents the effect of a perturbation of strength $\mathcal{O}(\epsilon)$ and duration $\mathcal{O}(1)$.

B.2. The functions H_i. We shall use condition (iii), which implies that $\tau_4 > \tau_2$ if ϵ is sufficiently small. We also note that the functions H_i are invariant under translation by the period of the unperturbed limit cycle: $T = \epsilon(\tau_1 + \tau_1') + \tau_2 + \tau_4$.

To construct $H_1(t)$ we exploit the nature of FTM interactions. For $\epsilon\tau_1' \leq t \leq \tau_4$, O_1 receives no input between Π_1 and Π_2, so it travels on its unperturbed limit cycle, yielding $H_1(t) \equiv 0$. At $t = 0$, $H_1(0) = \epsilon\Delta\tau_1'$. If $-\epsilon\tau_1 - \tau_2 \leq t \leq -\epsilon\tau_1$, O_1 follows the perturbed limit cycle, so $H_1(t) \equiv (\tau_1 + \tau_1')$. For $-\epsilon\tau_1 \leq t \leq 0$, O_1 switches to the perturbed limit cycle from the curve of length $\epsilon\tau_1$, as shown in Figure 6(B). On the intervals $(-\epsilon\tau_1, 0)$ and $(0, \epsilon\tau_1')$, $H_1(t)$ is approximately linear (for $\epsilon \ll 1$). See Figure 12(A). The mapping $H_3(t)$ is generated in much the same way (Figure 12(C)).

To approximate $H_2(t)$ we use condition (ii), which implies that orbits move faster on the upper branch of the perturbed nullcline than on the unperturbed one: $\Delta\tau_2$ is positive. Thus for $t = 0$, O_1 receives input along the upper nullcline and arrives at Π_3 before O_2, so $H_2(0) = \Delta\tau_2$. The same argument holds if t is slightly negative, but if t is further decreased, the coupling signal turns off before O_1 reaches Π_3, until at $t = -\tau_2$ O_1 reaches Π_3 entirely on the unperturbed limit cycle. Thus $H_2(t) \equiv 0$ for $t < -\tau_2$, and it increases monotonically for $-\tau_2 < t$. See Figure 12(B).

O_1 receives input while traveling between Π_2 and Π_3, if $t \in (0, \epsilon\tau_1')$, so $H_2(t) \equiv \Delta\tau_2$ in this interval. If, however, t is increased further, O_1 has no input when crossing Π_2, and it first follows the unperturbed nullcline and jumps to the perturbed one if $t \in (\epsilon\tau_1', \epsilon\tau_1' + \tau_2)$; the bigger t is, the later this jump occurs. Thus H_2 decreases in this interval. If $t > \epsilon\tau_1' + \tau_2$, again $H_2(t) \equiv 0$.

Similar arguments lead to $H_4(t)$ (Figure 12(D)). $H_4(t) \equiv 0$ for $t \in (-\epsilon\tau_1, 0)$, because O_1 travels on the unperturbed nullcline. Because of condition (ii), traveling on the perturbed nullcline is always slower; thus $H_4(t)$ is nonpositive. It is monotonically decreasing in $(0, \tau_2 + \epsilon\tau_1')$, at which point O_1 starts on the perturbed limit cycle but switches along the

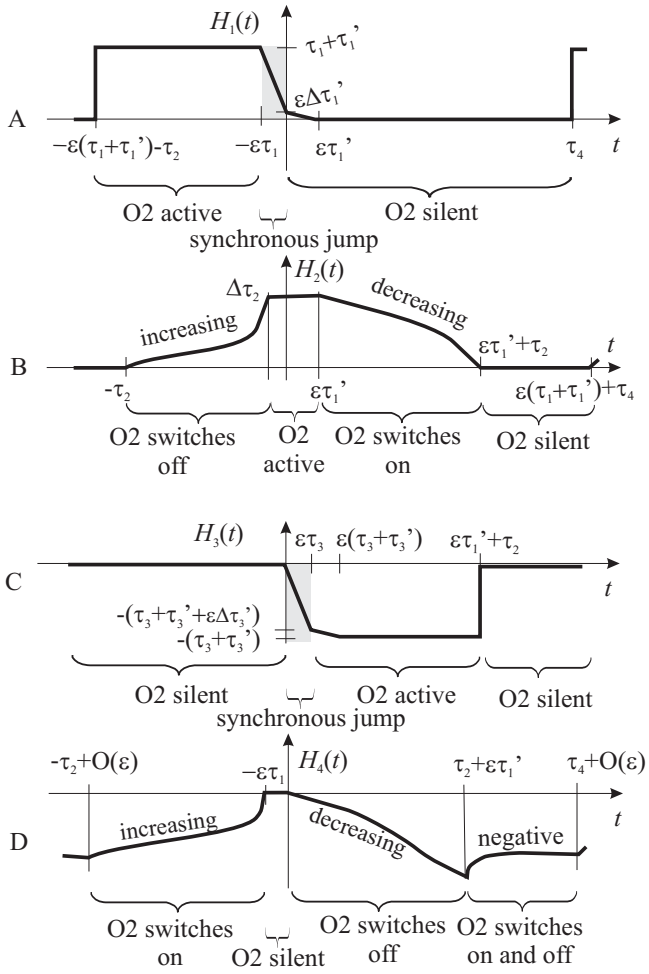

Figure 12. *The maps H_i.* A: O_2 active/silent *implies that O_2 is active/silent when O_1 jumps up;* synchronous jump *means that the upward jump of O_2 initiates an immediate jump in O_1.* B: O_2 active/silent *applies for the time interval in which O_1 travels from Π_2 to Π_3; O_2* switches on/off *means that O_2 is silent/active when O_1 crosses Π_2 but switches on/off before O_1 reaches Π_3. Analogous notation is used in* C *and* D.

way. The bigger t is, the longer it travels before switching to the unperturbed nullcline. H_4 has another, increasing part, corresponding to traveling on the unperturbed nullcline initially and switching to the perturbed one at some point (the bigger t, the later this happens), and a fourth region, marked "negative" in Figure 12(D), corresponding to starting and arriving on the unperturbed nullcline and spending an interval of length $\tau_2 + \epsilon\tau_1'$ on the other nullcline in between.

B.3. Possible forms of T-periodic dynamics. Here we show that on any stable T-periodic solution of the coupled oscillator pair, either O_1 and O_2 are in synchrony or O_1 leads O_2. We thereby exclude alternating dynamics or leading by O_2.

First assume that the oscillators alternate, so that, while O_2 is active, O_1 moves between Π_3 and Π_4. Thus, $t + \epsilon H_3(t + \epsilon H_2(t + \epsilon H_1(t))) \in (\tau_2 + O(\epsilon), \tau_4 + O(\epsilon))$: the interval marked

negative in Figure 12(D). This implies that

$$t \in (\tau_2 + O(\epsilon),\, \tau_4 + O(\epsilon)), \tag{B.4}$$

and while (B.4) holds, we can deduce the following.

1. From (B.4) and the fact that O_2 is silent when O_1 jumps up, $H_1(t) \equiv 0$ for sufficiently small ϵ.
2. Because O_2 is silent when O_1 is on its upper nullcline, $H_2(t + \epsilon H_1(t)) \equiv 0$.
3. Because O_2 is silent when O_1 jumps down, $H_3(t + \epsilon H_2(t + \epsilon H_1(t))) \equiv 0$.
4. From (B.4), $H_4(t + \epsilon H_3(t + \epsilon H_2(t + \epsilon H_1(t)))) < 0$.

Thus, $H_{FTM} < 0$ by (B.3). Since T-periodic solutions require $H_{FTM}(t) = 0$, this is a contradiction.

Assume now that O_2 leads O_1. In this case, the following hold:

1. O_2 is active when O_1 jumps up, corresponding to the $H_1(t) = \text{const} > 0$ part of H_1.
2. O_2 turns off before O_1 reaches Π_3, corresponding to the increasing part of H_2.
3. O_2 is silent when O_1 is between Π_3 and Π_4, implying that $H_3(t+\epsilon H_2(t+\epsilon H_1(t))) \equiv 0$.
4. O_2 turns on before O_1 reaches Π_1, corresponding to the increasing part of H_4.

In the interval of t that satisfies these requirements, all four functions are constant or increasing, implying that $H_{FTM}(t)$ itself is constant or increasing and hence that T-periodic solutions, if any exist, are unstable, from section B.1. This is again a contradiction.

Thus, we have proven that the only possible stable T-periodic solutions are synchrony or leading of O_1. In the next two subsections, we show that, if ϵ is sufficiently small, inequality (2.8) determines which case occurs.

B.4. If O_1 leads, then inequality (2.8) holds. Assume now that $H_{FTM}(t) = 0$ and O_1 leads. In this case O_2 is silent when O_1 is between Π_1 and Π_2, so that $H_1(t) < \epsilon\,\Delta\tau_1'$; see Figure 12(A). Similarly, O_2 is active when O_1 lies between Π_3 and Π_4, implying that $H_3(t + \epsilon H_2(t + \epsilon H_1(t))) < -(\tau_3 + \tau_3') + \epsilon\Delta\tau_3'$; see Figure 12(C). Combining these with the global inequalities $H_2 \le \Delta\tau_2$ and $H_4 \le 0$, (B.3) yields

$$0 = H_{FTM}(t) < \epsilon\Delta\tau_1' - (\tau_3 + \tau_3') + \epsilon\Delta\tau_3' + \Delta\tau_2. \tag{B.5}$$

The $\mathcal{O}(\epsilon)$ terms vanish as $\epsilon \to 0$; limiting values of the $\mathcal{O}(1)$ terms are found below.

For $\epsilon \ll 1$ (weak coupling) $\epsilon\Delta\tau_2$ is equal to the (appropriately scaled) linear phase-response to continuous ϵ perturbation during slow motion on the upper branch ($0 < \phi < D$); i.e., as shown in section 2,

$$\lim_{\epsilon\to 0} \Delta\tau_2 = \int_{x(0)}^{x(D)} \frac{f_y(\chi, y_a(\chi))}{f^2(\chi, y_a(\chi)) g_y(\chi, y_a(\chi))}\, d\chi. \tag{B.6}$$

We obtain $(\tau_3 + \tau_3')$ in the $\epsilon \to 0$ limit by approximating the ODEs defining O_1 at the upper right knee $[x(D), y(D)]$ by (A.1)–(A.2), derived in Appendix A. Substituting $h = 1$ and solving

$$g(x, y) + \epsilon \cdot 1 = 0 \quad \text{and} \quad g_y(x, y) = 0 \tag{B.7}$$

shows that the perturbation ϵh shifts the knee to the right by $\epsilon/g_x(x(D), y(D))$. Thus,

$$\epsilon\tau_3 \approx -\frac{\epsilon}{f(x(D), y(D))g_x(x(D), y(D))}, \tag{B.8}$$

$$\text{and} \quad \epsilon\tau_3' \approx \frac{\epsilon}{f(x(D), y(D^+))g_x(x(D), y(D))}, \tag{B.9}$$

yielding

$$\tau_3 + \tau_3' \approx \frac{1}{g_x(x(D), y(D))}\left[\frac{1}{f(x(D), y(D))} - \frac{1}{f(x(D), y(D^+))}\right]. \tag{B.10}$$

Substituting (B.6) and (B.10) into (B.5), we find that (2.8) holds in the $\epsilon \to 0$ limit. ■

Note that (B.10) represents the effect of FTM interactions but that it also agrees with predictions of phase reduction theory; cf. (2.6). This is the main reason that condition (2.6) holds in both the phase and the FTM limits.

B.5. Inequality (2.8) is false in case of synchrony. First we substitute the inequalities $H_1 \geq 0$ and $H_3 \geq -(\tau_3 + \tau_3')$ (cf. Figures 12(A,C)) into (B.3) to obtain

$$0 = H_{FTM}(t) \geq H_2(t + \epsilon H_1(t)) - (\tau_3 + \tau_3') + H_4(t + \epsilon H_3(t + \epsilon H_2(t + \epsilon H_1(t)))). \tag{B.11}$$

$H_2(t + H_1(t))$ is estimated by noting that, in case of synchrony, at least one of the following holds:

1. Upward jumps are synchronous.
2. Downward jumps are synchronous.
3. O_1 jumps up earlier and jumps down later than O_2.
4. O_2 jumps up earlier and jumps down later than O_1.

The first case yields $|t| \leq \epsilon\tau_1$; cf. Figure 12(A). Since $|H_1| \leq \tau_1 + \tau_1'$, we also have $|t + \epsilon H_1(t)| \leq \epsilon(\tau_1 + 2\tau_1')$; i.e., for arbitrary $\delta_1 > 0$, sufficiently small ϵ guarantees $|t + \epsilon H_1(t)| \leq \delta_1$. In the limit $\epsilon \to 0$, H_2 is determined exactly by phase theory. Moreover, H_2 is continuous because it describes interactions that occur only during slow dynamics and not during jumps. Appealing to continuity, we see that for arbitrary $\delta_2 > 0$, we may pick δ_1 sufficiently small that $|H_2(v) - H_2(0)| \leq \delta_2$ for all $|v| \leq \delta_1$. Thus, for ϵ sufficiently small, we conclude that

$$H_2(t + \epsilon H_1(t)) \geq \Delta\tau_2 - \delta_2. \tag{B.12}$$

Analogous arguments can be applied in the other three cases, and one can show in the same way that for sufficiently small ϵ, $|H_4(t + \epsilon H_3(t + \epsilon H_2(t + \epsilon H_1(t)))) - H_4(0)| \leq \delta_2$ also holds, implying that

$$H_4(t + \epsilon H_3(t + \epsilon H_2(t + \epsilon H_1(t)))) \geq -\delta_2. \tag{B.13}$$

Substituting inequalities (B.12)–(B.13) into (B.11), we obtain

$$0 = H_{FTM}(t) \geq \Delta\tau_2 - (\tau_3 + \tau_3') - 2\delta_2, \tag{B.14}$$

which holds for arbitrarily small δ_2 and so yields

$$0 \geq \Delta\tau_2 - (\tau_3 + \tau_3'). \tag{B.15}$$

Finally, using (B.6) and (B.10) in (B.15), we conclude that (2.8) cannot hold. ■

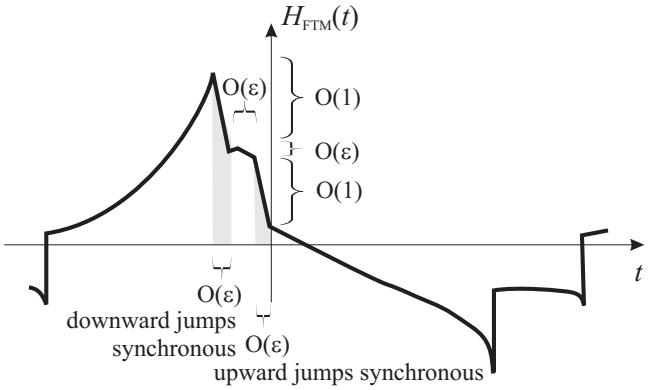

Figure 13. *An example of the composed map H_{FTM}. The proof of Theorem 3.1 relies on the fact that for $\epsilon \to 0$, the shape of H_{FTM} is similar to that of H in Figure 3. H_{FTM} has one or two steep, decreasing steps (two are shown here), inherited from H_1 and H_3. If there are two, they are separated by a plateau of width $O(\epsilon)$. A root of H_{FTM} in either steep part means that at least one jump is synchronous; a root in the plateau corresponds to synchronous activity in which neither jump is synchronous (cf. section 3.2). The latter is atypical in the limit $\epsilon \to 0$, as shown in Appendix C.*

Appendix C. Synchrony under weak coupling. The mappings H_2 and H_4 introduced in Appendix B have finite steepness, but H_1 and H_3 have $O(\epsilon^{-1})$-steep decreasing steps, corresponding to synchronous jumps of the two oscillators. The exact shape of the mapping H_{FTM} is model-specific, but in all cases it will also have one or two inherent steep parts due to (B.3), as shown in the example of Figure 13. According to the definition of section 3.2, the T-periodic orbits of the two oscillators are synchronous if one or both jumps coincide, or if one oscillator jumps up earlier but jumps down later than the other. These cases respectively correspond to two steep segments of H_{FTM} and the small plateau between them (if such a plateau exists). The width and height of the plateau is $O(\epsilon)$, and it vanishes in the limit $\epsilon \to 0$. Thus, synchronous activity typically means that either upward or downward jumps are synchronous.

Neimark–Sacker Bifurcations in Planar, Piecewise-Smooth, Continuous Maps*

D. J. W. Simpson and J. D. Meiss†

Abstract. The multipliers of a fixed point of a piecewise-smooth, continuous map may change discontinuously as the fixed point crosses a discontinuity under smooth variation of parameters. We study the case when the multipliers "jump" from inside to outside the unit circle, and we assume the map is two-dimensional and piecewise-affine. The resulting dynamics is sometimes similar to the Neimark–Sacker bifurcation of a smooth map in which an attracting periodic or quasiperiodic orbit is created as the fixed point loses stability. However, the bifurcation is often much more complex, with multiple (chaotic) attractors, saddles, and repellors created or destroyed.

Key words. piecewise-smooth systems, resonance tongues, border-collision bifurcations

1. Introduction.

A dynamical system $F : M \to M$ is *piecewise-smooth* if it is everywhere smooth (i.e., C^k for some $k \in \mathbb{N}$) except on some codimension-one boundaries, called *switching manifolds*, that divide M into countably many regions. Such systems provide useful models for physical situations involving nonsmooth behavior such as impacts or rapid switching. Indeed, they are used in a wide variety of fields such as vibro-impacting systems and systems with friction [34, 5, 20, 25], circuitry including relay control systems [37, 4, 33], economics [27, 19], biology, and physiology [29, 17].

The theory of bifurcations in smooth dynamical systems is extensive and well grounded [18, 35]. However, the majority of this theory does not apply to piecewise-smooth systems. This paper is concerned with piecewise-smooth, continuous maps that are everywhere continuous but have a discontinuous Jacobian on the switching manifolds. As a fixed point of such a map crosses a switching manifold as a system parameter is varied, its associated multipliers may change discontinuously. The "jump" in multipliers may alter the stability of the fixed point. The resulting bifurcation is now called a *border-collision bifurcation*, a term coined by Nusse and Yorke [23] but originally called a C-bifurcation by Feigin whose work can be found in [9]. We study the two-dimensional case when complex multipliers jump from inside to outside the unit circle at the bifurcation. We show that this bifurcation exhibits diverse dynamical behavior, some of which is akin to that of a Neimark–Sacker bifurcation in a smooth map, some of which is like that of other border-collision bifurcations, and some of which are phenomena that to our knowledge have not been described previously.

Piecewise-smooth maps have two major applications. They appear as models of physical systems with both discrete and nonsmooth behavior, such as switching circuits and economics; second, they appear mathematically as Poincaré maps of piecewise-smooth flows with oscillatory behavior—see, for instance, work on *grazing bifurcations* and *sliding bifurcations* [8, 37, 16, 2]. They also provide a normal form for the so-called *corner-collision bifurcation* [7]. It is therefore of great interest to understand border-collision bifurcations in such maps.

To investigate local behavior near a border-collision bifurcation, it is first important to study the piecewise-linear approximation of the map at the bifurcation. The resulting piecewise-affine, continuous map provides a local approximation to a piecewise-smooth map near a differentiable point on a switching manifold. We can choose coordinates $z \in \mathbb{R}^n$ such that the local switching manifold becomes the plane $z_1 = 0$ and the piecewise-affine map takes the form

$$z' = \begin{cases} A_1 z + \mu c, & z_1 \le 0, \\ A_2 z + \mu c, & z_1 \ge 0, \end{cases} \tag{1}$$

where A_1 and A_2 are real-valued $n \times n$ matrices and $c \in \mathbb{R}^n$. In order for the map to be continuous, all columns of the two matrices A_i must be equal except for the first. It is assumed the fixed point crosses the switching manifold nontangentially, and thus $z^* = \mu(I - A_i)^{-1}c$ has $z_1^* = 0$ only when $\mu = 0$.

The work of Feigin [9] has provided an invaluable framework for the existence of fixed points and periodic solutions on either side of border-collision bifurcations for (1). Let σ_i^+ [σ_i^-] denote the number of real multipliers of A_i greater than 1 [less than -1] for $i = 1, 2$ (A_i may also have complex-valued multipliers). Feigin showed that

1. assuming A_1 and A_2 do not have a multiplier 1, then if $\sigma_1^+ + \sigma_2^+$ is even, (1) has a unique fixed point $\forall\ \mu \in \mathbb{R}$ continuously crossing the switching manifold at the origin when $\mu = 0$, and if $\sigma_1^+ + \sigma_2^+$ is odd, two fixed points exist for one sign of μ, colliding and annihilating at the origin when $\mu = 0$; and
2. assuming A_1 and A_2 do not have a multiplier -1, then if $\sigma_1^- + \sigma_2^-$ is odd, a period two cycle exists for one sign of μ colliding with the fixed point at the origin when $\mu = 0$, and if $\sigma_1^- + \sigma_2^-$ is even, the map (1) exhibits no 2-cycles.

The dynamics of one-dimensional, piecewise-affine, continuous maps with a single switching manifold are well understood [3, 8]. For example, it has been proved that in this case multiple attractors cannot coexist and every aperiodic attractor is chaotic [8].

For the two-dimensional case, we let $z = (x, y)$ and choose coordinates so that the locally smooth switching manifold corresponds to the y-axis. Following [23], the local map may be generically transformed by an affine change of coordinates to the canonical form $(x', y') = F_\mu(x, y; \tau_L, \tau_R, \delta_L, \delta_R)$, where F_μ is defined by

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{cases} A_L \begin{bmatrix} x \\ y \end{bmatrix} + \mu \begin{bmatrix} 1 \\ 0 \end{bmatrix}, & x \le 0, \\ A_R \begin{bmatrix} x \\ y \end{bmatrix} + \mu \begin{bmatrix} 1 \\ 0 \end{bmatrix}, & x \ge 0, \end{cases} \tag{2}$$

where

$$A_L = \begin{bmatrix} \tau_L & 1 \\ -\delta_L & 0 \end{bmatrix}, \quad A_R = \begin{bmatrix} \tau_R & 1 \\ -\delta_R & 0 \end{bmatrix}. \tag{3}$$

Again, the second columns of the two matrices are equal since the map is assumed continuous. The parameters of the normal form are simply the traces, $\tau_{L,R}$ and determinants, $\delta_{L,R}$, of the matrices $A_{L,R}$.

The normal form (2) has several simple properties that we will use below.

- The map F_μ is a homeomorphism of $\mathbb{R}^2$ if and only if $\delta_L\delta_R > 0$.
- If $\delta_L, \delta_R > 0$, the inverse is simply related to the original map by

$$F_\mu^{-1}(x, y; \tau_L, \tau_R, \delta_L, \delta_R) = F_{-\mu}\left(y, x; \frac{\tau_R}{\delta_R}, \frac{\tau_L}{\delta_L}, \frac{1}{\delta_R}, \frac{1}{\delta_L}\right). \tag{4}$$

  Thus the dynamical properties of F for positive μ are the same as those of F^{-1} for negative μ for a different combination of parameter values.
- The map has the scaling symmetry

$$F_{\lambda\mu}(\lambda x, \lambda y; \tau_L, \tau_R, \delta_L, \delta_R) = \lambda F_\mu(x, y; \tau_L, \tau_R, \delta_L, \delta_R) \ \forall\ \lambda > 0. \tag{5}$$

  Consequently, if $\mathcal{I}$ is an invariant set under F_μ, then $\lambda\mathcal{I}$ is an invariant set for $F_{\lambda\mu}$, $(\lambda > 0)$. Therefore, every bounded invariant set collapses onto the origin as $\mu \to 0$, and it is sufficient to consider only $\mu \in \{1, 0, -1\}$.

The canonical form (2) can have complex dynamics including multiple strange or quasi-periodic attractors, and the spectrum of its possible behaviors have not been completely classified. Partial classifications have been presented for the dissipative case, $|\delta_L|, |\delta_R| < 1$ [2], and for the case that the multipliers of the fixed point near the border-collision bifurcation remain real-valued [9].

In this paper, we will study the case in which the map has complex eigenvalues, in particular, when A_L corresponds to an attracting focus and A_R to a repelling focus. This is the case where one might expect an analogue of the Neimark–Sacker bifurcation to occur when a fixed point crosses the switching manifold.

In section 2 we describe basic properties of the canonical form map, (6), that we investigate. Periodic solutions are described by symbolic dynamics in section 2.1. Here we construct a linear system (10) to solve for periodic solutions and deduce their stability. We consider border-collision bifurcations of periodic solutions and then in section 2.2 define rotation numbers for general orbits.

Basic dynamics of the map (6) are described in section 3. We give a comparison to the smooth Neimark–Sacker bifurcation and show the effect of nonlinear terms. In section 3.1, via geometrical arguments, we prove the existence of an attracting set for some limiting cases and show that this set persists for nearby parameter values.

Particularly for the case of complex multipliers, it is of interest to compute regions in parameter space within which periodic solutions of a particular rotation number exist and are attracting. As with the case of circle maps, such regions are called resonance tongues (or Arnold tongues). In contrast to smooth systems, resonance tongues in piecewise-smooth

systems exhibit a distinctive lens-chain structure. This was first observed for a one-dimensional piecewise-linear circle map [36] and has been observed for the canonical form (2) in [38] and for other two-dimensional piecewise-linear maps [32, 15]. We will discuss these structures in detail in sections 3.2–3.5.

Complicated and unusual dynamics are described in section 4. In section 4.1 we provide an example where the fixed point is a saddle on the switching manifold and no invariant circle is created at the bifurcation. Multiple attractors are discussed in section 4.2; see also section 4.6 for additional complications.

The loss of stability of a periodic solution via an associated multiplier attaining the value -1 is detailed in section 4.3, and the loss of stability via a complex conjugate pair of associated multipliers crossing the unit circle is discussed in section 4.5. Period-doubled solutions appear far from basic periodic solutions due to the absence of quadratic and higher order terms in the canonical form. In a codimension-two situation we observe resonance tongues with reducible rotation numbers emanating from codimension-two points. Resonance tongues with reducible rotation numbers are discussed in section 4.4. These resonance tongues do not seem to form lens-chains. Conclusions are presented in section 5.

2. A two-dimensional map. In this paper we will study the map (2) when multipliers associated with the fixed point are complex-valued and jump from inside to outside the unit circle at the border-collision bifurcation. Thus we assume that A_L and A_R, (3), have eigenvalues $r_L e^{\pm 2\pi i \omega_L}$ and $\frac{1}{s_R} e^{\pm 2\pi i \omega_R}$, respectively, where $r_L, s_R \in (0,1)$ and without loss of generality $\omega_L, \omega_R \in (0, \frac{1}{2})$. Note that this corresponds to the case that $0 < \delta_L = r_L^2 < 1$ and $1 < \delta_R = 1/s_R^2$ so that the map (2) is an orientation preserving homeomorphism. With these new parameters, the normal form becomes

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{cases} \begin{bmatrix} 2r_L \cos(2\pi\omega_L) & 1 \\ -r_L^2 & 0 \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} + \mu \begin{bmatrix} 1 \\ 0 \end{bmatrix}, & x \le 0, \\ \begin{bmatrix} \frac{2}{s_R} \cos(2\pi\omega_R) & 1 \\ -\frac{1}{s_R^2} & 0 \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} + \mu \begin{bmatrix} 1 \\ 0 \end{bmatrix}, & x \ge 0. \end{cases} \tag{6}$$

We will denote this map $(x', y') = f_\mu(x, y; r_L, s_R, \omega_L, \omega_R)$.

We may compute the existence of fixed points and 2-cycles by applying Feigin's analysis. Both A_L and A_R have no real-valued eigenvalues; hence, in the form (1), $\sigma_1^+ = \sigma_2^+ = \sigma_1^- = \sigma_2^- = 0$, and thus (6) has a unique fixed point $\forall\ \mu \in \mathbb{R}$, and the map has no period-two orbits for any values of the parameters. Explicitly, the fixed point is

$$\begin{bmatrix} x^* \\ y^* \end{bmatrix} = \begin{cases} \dfrac{\mu}{r_L^2 - 2r_L \cos(2\pi\omega_L) + 1} \begin{bmatrix} 1 \\ -r_L^2 \end{bmatrix}, & \mu \le 0, \\ \dfrac{\mu}{s_R^2 - 2s_R \cos(2\pi\omega_R) + 1} \begin{bmatrix} s_R^2 \\ -1 \end{bmatrix}, & \mu \ge 0. \end{cases} \tag{7}$$

The fixed point moves from the left-half plane (LHP) when $\mu < 0$, where it is a stable focus, to the origin at $\mu = 0$, and then to the right-half plane (RHP) when $\mu > 0$, where it is an unstable focus.

Since (6) is a homeomorphism, its inverse is given by the symmetry (4). Explicitly, we have

$$f_\mu^{-1}(x,y) = \begin{cases} \begin{bmatrix} 0 & -s_R^2 \\ 1 & 2s_R\cos(2\pi\omega_R) \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} - \mu \begin{bmatrix} 0 \\ 1 \end{bmatrix}, & y \le 0, \\ \begin{bmatrix} 0 & -\frac{1}{r_L^2} \\ 1 & \frac{2}{r_L}\cos(2\pi\omega_L) \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} - \mu \begin{bmatrix} 0 \\ 1 \end{bmatrix}, & y \ge 0. \end{cases} \tag{8}$$

2.1. Periodic solutions. Each orbit of (6) can be coded by a symbol sequence that gives its itinerary relative to the switching manifold. We will denote an orbit of (6) by a sequence $z^{(t)} = (x^{(t)}, y^{(t)})$, where $z^{(t+1)} = f_\mu(z^{(t)})$. The *symbol sequence* for an orbit is a sequence $\mathcal{S} = \{\mathcal{S}_t \in \{\mathsf{L}, \mathsf{R}\} : t \in \mathbb{Z}\}$, where

$$\mathcal{S}_t = \begin{cases} \mathsf{L}, & x^{(t)} \le 0, \\ \mathsf{R}, & x^{(t)} \ge 0. \end{cases} \tag{9}$$

Note that we allow the selection of either L or R when $x^{(t)} = 0$; however, since the map is continuous on the switching manifold, this ambiguity will not cause difficulties.

A period-n orbit, $\{z^{(0)}, z^{(1)}, \dots, z^{(n-1)}\}$, with $x^{(i)} \neq 0$ for each i, is defined by symbol sequence of length n that is unique up to a cyclic permutation. Given a periodic symbol sequence, the orbit is determined by the linear system

$$\begin{aligned} z^{(1)} &= A_{\mathcal{S}_0} z^{(0)} + b, \\ z^{(2)} &= A_{\mathcal{S}_1} z^{(1)} + b, \\ &\vdots \\ z^{(0)} &= A_{\mathcal{S}_{n-1}} z^{(n-1)} + b, \end{aligned}$$

where $b = (\mu, 0)^{\mathsf{T}}$. Elimination of the points $z^{(1)}, \dots, z^{(n-1)}$ gives

$$(I - M_{\mathcal{S}}) z^{(0)} = P_{\mathcal{S}} b, \tag{10}$$

where

$$M_{\mathcal{S}} = A_{\mathcal{S}_{n-1}} \dots A_{\mathcal{S}_0}, \tag{11}$$

$$P_{\mathcal{S}} = I + A_{\mathcal{S}_{n-1}} + A_{\mathcal{S}_{n-1}} A_{\mathcal{S}_{n-2}} + \dots + A_{\mathcal{S}_{n-1}} \dots A_{\mathcal{S}_1}. \tag{12}$$

We will call (10) the *n-cycle solution system*. If $(I - M_{\mathcal{S}})$ is nonsingular for a given period-n symbol sequence $\mathcal{S}$, (10) has the unique solution

$$z^{(0)} = (I - M_{\mathcal{S}})^{-1} P_{\mathcal{S}} b. \tag{13}$$

If, in addition, the consistency conditions (9) are satisfied, the period-n orbit exists and is said to be *admissible*; otherwise, it is *virtual* (terminology widely used in piecewise-smooth system theory [8]).

Stability of an admissible orbit that has no points on the switching manifold is easily determined. In this case, there exists a neighborhood of $z^{(0)}$ within which all points follow the symbol sequence $\mathcal{S}$ for at least n iterates. Moreover if $w^{(0)}$ is an element of this neighborhood, then

$$w^{(n)} = M_{\mathcal{S}} w^{(0)} + P_{\mathcal{S}} b. \tag{14}$$

Note that $z^{(0)}$ is the unique fixed point of this linear system; thus the stability of the n-cycle is determined by $M_{\mathcal{S}}$. For instance, the n-cycle is stable if and only if both multipliers of $M_{\mathcal{S}}$ lie inside the unit circle. For this reason we call $M_{\mathcal{S}}$ the *stability matrix* of $\mathcal{S}$.

Suppose now that an admissible n-cycle has one point on the switching manifold, say, $z^{(0)}$; that is, $x^{(0)} = 0$ and $x^{(i)} \neq 0 \; \forall \; i \neq 0$. Then there is a neighborhood of $z^{(0)}$ such that all points in this neighborhood located on one side of the switching manifold (say, the LHP) follow the symbol sequence $\mathcal{S}$ for n steps, whereas all points in the neighborhood on the other side follow the symbol sequence $\mathcal{S}^*$ for n steps, where $\mathcal{S}^*$ differs from $\mathcal{S}$ only in the first component. Thus for any $w^{(0)}$ in the neighborhood, we have

$$w^{(n)} = \begin{cases} M_{\mathcal{S}} w^{(0)} + P_{\mathcal{S}} b, & w_1^{(0)} \leq 0, \\ M_{\mathcal{S}^*} w^{(0)} + P_{\mathcal{S}^*} b, & w_1^{(0)} \geq 0. \end{cases} \tag{15}$$

Note that $P_{\mathcal{S}^*} = P_{\mathcal{S}}$ and $M_{\mathcal{S}^*}$ differs from $M_{\mathcal{S}}$ in only the first column; thus (15) is a piecewise-affine continuous map of the form (1). Hence, using Feigin's results, the problem of the existence of n-cycles and $2n$-cycles near the bifurcation is reduced to counting the number of real multipliers of $M_{\mathcal{S}}$ and $M_{\mathcal{S}^*}$ greater than 1 and less than -1.

We call $P_{\mathcal{S}}$ the *border-collision matrix* of $\mathcal{S}$ in view of the following lemma.

Lemma 1. *Suppose* $(I - M_{\mathcal{S}})$ *is nonsingular and* $\mu \neq 0$. *Then the point* $z^{(0)} = (I - M_{\mathcal{S}})^{-1} P_{\mathcal{S}} (\mu, 0)^{\mathsf{T}}$ *lies on the switching manifold if and only if* $P_{\mathcal{S}}$ *is singular.*

Proof. We introduce the map

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{cases} A_L \begin{bmatrix} x \\ y \end{bmatrix} + b, & x \leq 0, \\ A_R \begin{bmatrix} x \\ y \end{bmatrix} + b, & x \geq 0, \end{cases} \tag{16}$$

which is equivalent to (6) when $b = (b_1, b_2)^{\mathsf{T}} = (\mu, 0)^{\mathsf{T}}$. This map displays the same dynamics when $b = (\mathrm{sign}(b_1 + b_2), 0)^{\mathsf{T}}$ since the shift transformation $(x, y) \mapsto (x, y) + (0, -b_2)$ transforms $b = (b_1, b_2)^{\mathsf{T}}$ to $(b_1 + b_2, 0)^{\mathsf{T}}$, and a positive scaling (preserving the sign of x) transforms b to $(\mathrm{sign}(b_1 + b_2), 0)^{\mathsf{T}}$. Thus for any $b \in B = \{(b_1, b_2)^{\mathsf{T}} \mid \mu(b_1 + b_2) > 0\}$, $b_1 + b_2$ has the same sign as μ, and thus (16) exhibits the same dynamical structure as (6). In particular, if the periodic orbit with symbol sequence $\mathcal{S}$ for (6) has the point $z^{(0)}$ on the switching manifold, then the corresponding point for the map (16), $(I - M_{\mathcal{S}})^{-1} P_{\mathcal{S}} b$, will also lie on the switching manifold. Thus if $z^{(0)}$ lies on the switching manifold, then $(I - M_{\mathcal{S}})^{-1} P_{\mathcal{S}} B$ is a subset of the switching manifold. But B is a two-dimensional set; therefore, $P_{\mathcal{S}}$ is singular.

Let

$$K = \{(k, -k)^{\mathsf{T}} \mid k \in \mathbb{R}\}. \tag{17}$$

Note that $\forall b \in K$, the above shift transformation transforms b to the origin; hence in this case (16) has a unique fixed point z^*, which lies on the switching manifold. Clearly this point is a solution to the n-cycle solution system of $\mathcal{S}$; thus $z^* = (I - M_{\mathcal{S}})^{-1} P_{\mathcal{S}} b$. Now suppose that $P_{\mathcal{S}}$ is singular. If $b \in \text{null}(P_{\mathcal{S}}) \cap K$, $P_{\mathcal{S}} b = 0$, and hence $z^* = 0$. But for the origin to be a fixed point of (16) we must have $b = 0$. Thus $\text{null}(P_{\mathcal{S}}) \cap K = \{0\}$. It follows that $P_{\mathcal{S}}$ maps K onto $P_{\mathcal{S}}\mathbb{R}^2$. Thus $\exists b \in K$ such that $P_{\mathcal{S}} b = P_{\mathcal{S}}(\mu, 0)^{\mathsf{T}}$. The map (16) with this b has $z^* = (I - M_{\mathcal{S}})^{-1} P_{\mathcal{S}} b$ on the switching manifold. Thus $z^{(0)}$ for (6) also lies on the switching manifold. ■

The next lemma is useful for describing dynamics near where $M_{\mathcal{S}}$ has an eigenvalue 1.

Lemma 2. *Suppose $P_{\mathcal{S}}$ is nonsingular and $\mu \neq 0$. Then the n-cycle solution system (10) has a solution if and only if $(I - M_{\mathcal{S}})$ is nonsingular.*

Proof. Clearly if $(I - M_{\mathcal{S}})$ is nonsingular, (10) has the unique solution (13). Suppose $(I - M_{\mathcal{S}})$ is singular. Following the argument in Lemma 1, for any $b \in K$, (17), the map (16) has a unique fixed point z^* and $(I - M_{\mathcal{S}})z^* = P_{\mathcal{S}} b$. Thus $P_{\mathcal{S}} K \subset \text{rng}(I - M_{\mathcal{S}})$, the range of $(I - M_{\mathcal{S}})$, but $P_{\mathcal{S}}$ is nonsingular; thus we must have $P_{\mathcal{S}} K = \text{rng}(I - M_{\mathcal{S}})$. Finally, $(\mu, 0)^{\mathsf{T}} \notin K$; therefore, (10) has no solution. ■

The above lemmas and discussion can easily be extended to higher dimensional piecewise-affine maps.

2.2. Rotation numbers. The rotation number (or winding number) of an orbit of a map is a characterization of the average increase in angle per iteration. It is most easily defined for maps on circles or annuli. The rotation number for a map on $\mathbb{R}^2$ can be defined relative to a fixed point, z^*, if one exists, because removing z^* from the plane leaves an annulus. An alternative, intrinsic definition is called the "self-rotation number" [10]. The first definition is dependent upon the choice of z^*, but since (6) has a unique fixed point for any combination of parameter values, it is natural to define the rotation number about this point.

Since orbits of (6) rotate in a clockwise direction about z^*, we define the angle $\phi : \mathbb{R}^2 \setminus \{z^*\} \to (-\pi, \pi]$ as

$$\begin{aligned} \phi(z) &= \text{polar angle of } (x - x^*) - \mathrm{i}(y - y^*) \\ &= \text{atan2}(y^* - y, x - x^*), \end{aligned} \tag{18}$$

where atan2 is the two argument arctangent. To compute the rotation number we simply average the changes in ϕ over the iterations of the map. Let $\Delta\phi : \mathbb{R}^2 \setminus \{z^*\} \to [0, 2\pi)$ be

$$\Delta\phi(z) = \phi(f(z)) - \phi(z) \mod 2\pi; \tag{19}$$

then the rotation number of an orbit is

$$\rho(z^{(0)}) = \lim_{n\to\infty} \frac{1}{2\pi n} \sum_{i=0}^{n-1} \Delta\phi(z^{(i)}) \tag{20}$$

if this limit exists. It can be shown [30] that, for any point in $\mathbb{R}^2 \setminus \{z^*\}$ the limit (20) exists even if the orbit is unbounded and that

$$0 < \rho(z) < \frac{1}{2}. \tag{21}$$

Clearly if $z^{(0)}$ belongs to a period-n orbit, the rotation number is rational: $\rho = m/n$. If (6) has an invariant circle, then since f_μ is a homeomorphism, so is its restriction to the circle. Since any invariant circle bounds an invariant disk, the Brouwer fixed point theorem implies that the disk must contain a fixed point, which must be z^*, since the fixed point of (6) is unique. This is consistent with (21), which implies that the rotation number of the circle is nonzero. The usual definition for the rotation number on a circle [18, 6] coincides with (20). Furthermore, all points on the invariant circle have the same rotation number [18, 6].

3. Resonance tongues and basic dynamics. Recall that a Neimark–Sacker bifurcation in a sufficiently smooth map generically occurs when an attracting fixed point has a complex pair of multipliers, say, $\lambda(\mu) = r(\mu)e^{2\pi i\omega(\mu)}$ and $\bar{\lambda}(\mu)$, that cross the unit circle, at, say, $\mu = 0$ [18]. If the map satisfies a nondegeneracy assumption and $\lambda^n(0) \neq 1$ for $n = 1$, 2, 3, or 4, then an invariant circle is created or destroyed as μ crosses zero. The circle emerges from the fixed point with a size $O(|\mu|^{\frac{1}{2}})$. The criticality of the bifurcation is determined by cubic terms in the normal form; when it is *supercritical* the invariant circle is stable and exists when $|\lambda(\mu)| > 1$, and when it is *subcritical* the opposite is true. For small μ, dynamical behavior on the circle is determined by the rotation number $\omega(\mu)$. If $\omega(\mu) = \frac{m}{n}$ with $\gcd(m, n) = 1$ and $n > 4$, the motion is called *weakly resonant* or *mode locked* and there generically exist two or more period-n orbits on the invariant circle. When $n \leq 4$, the dynamics is *strongly resonant* and an invariant circle need not exist [18]. When $\omega(\mu)$ is irrational, all orbits on the circle are dense and quasiperiodic.

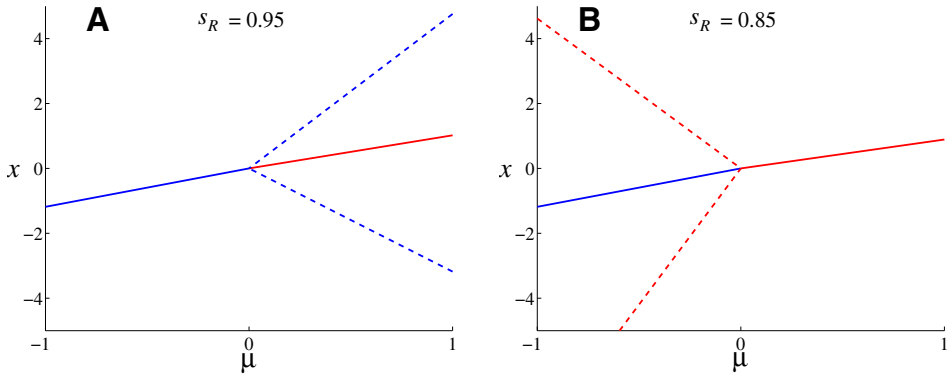

Figure 1. *Bifurcation diagrams of (6) when $\omega_L = \omega_R = 0.16$, $r_L = 0.9$. In panel A, $s_R = 0.95$; in panel B, $s_R = 0.85$. Blue (red) lines denote stable (unstable) solutions. Solid lines correspond to the fixed point, and dashed lines correspond to the maximum and minimum values of a periodic solution. Phase portraits corresponding to panel A are shown in Figure 2.*

The behavior of the piecewise-smooth map (6) can be much more complicated when μ crosses zero. However, for some parameter values, its behavior is similar to the classical Neimark–Sacker bifurcation; two example bifurcation diagrams for (6) are shown in Figure 1. For panel A of the figure, when $\mu < 0$, the stable fixed point is a global attractor; see Figure 2, panel A. When $\mu > 0$, the fixed point is unstable and is encircled by a stable invariant circle with rotation number $\rho \approx 0.1601$ whose basin appears to be the entire phase space except for the fixed point (see Figure 2, panel B). Consequently, this bifurcation is analogous to a

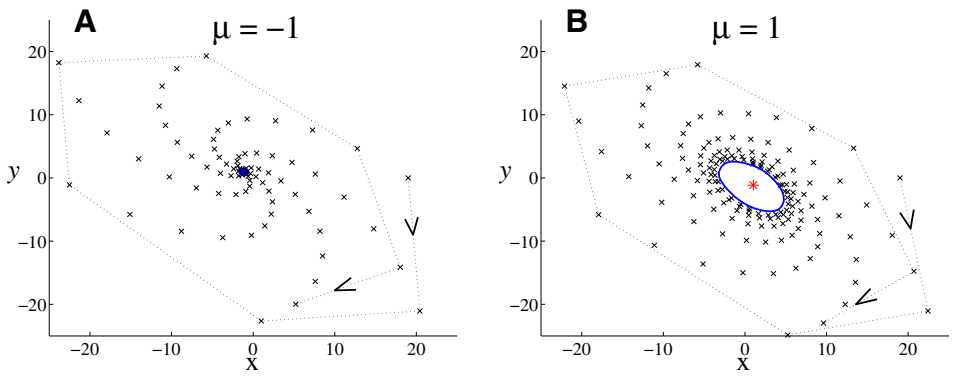

Figure 2. *Phase portraits of (6) with the same parameter values as those in Figure 1, panel A. In both panels one orbit is shown and the first few iterates are connected to illustrate the direction of motion. The fixed point is indicated by an asterisk.*

supercritical Neimark–Sacker bifurcation. An important difference is that, unlike in smooth systems, the size of the invariant circle grows linearly with respect to μ. This is a simple consequence of the scaling symmetry (5) and is common in other bifurcations in piecewise-smooth systems [20, 8]—for example, the discontinuous Andronov–Hopf bifurcation [31].

By contrast, the bifurcation in panel B of Figure 1 is analogous to a subcritical Neimark–Sacker bifurcation. When $\mu < 0$, there is an unstable invariant circle whose radius shrinks linearly to zero as $\mu \to 0^-$. Points inside the circle are attracted to the stable fixed point, whereas the forward orbits of points outside the circle are unbounded. When $\mu > 0$, the orbit of every initial condition, except for the unstable fixed point, is unbounded.

A fundamental question regarding the map (6) is: What governs the criticality of the Neimark–Sacker-like bifurcation? As will be shown later, the answer is not simple. For instance, there may exist no invariant circles for any value of μ (see section 4.1), or both supercritical and subcritical behavior may be observed together (see section 4.6).

Numerical simulations suggest that (6) does not exhibit strong resonance. We have not observed significantly different dynamical phenomena when $\omega_L = \omega_R = 1/3$ or $1/4$ in (6).

The addition of nonlinear terms to (6) does not affect structurally stable dynamics (e.g., when the created orbits are hyperbolic) for sufficiently small values of μ. For instance, bifurcation diagrams are shown in Figure 3 for the map

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = f_\mu(x, y) - \begin{bmatrix} x^2 \\ 0 \end{bmatrix}. \tag{22}$$

In panel A of Figure 3, the parameter values of panel A of Figure 1 are used. For small $\mu > 0$, we find an attracting invariant circle which grows in amplitude approximately linearly with respect to μ. For larger values of μ, the nonlinear map develops a stable 6-cycle.

In panel B, parameters are chosen such that the piecewise-affine map, (6), has a stable 3-cycle for $\mu > 0$. For small $\mu > 0$, the nonlinear map exhibits the same 3-cycle, which initially grows at the same linear rate as for the piecewise-affine map. However, as μ is increased, the 3-cycle undergoes a period-doubling cascade. The cascade is comprised of usual smooth

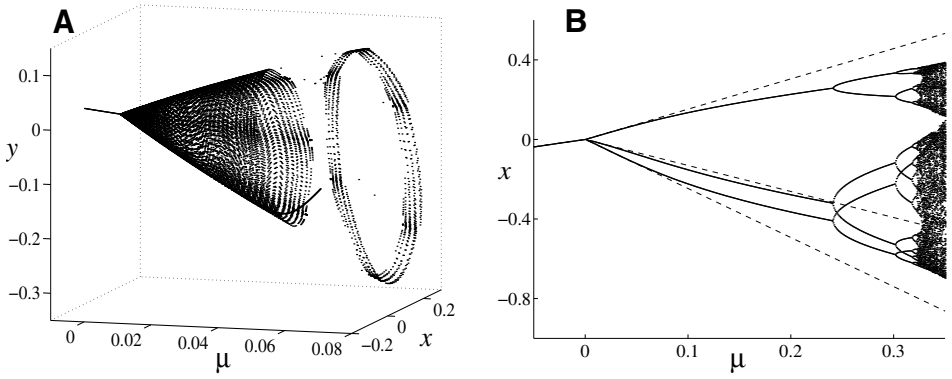

Figure 3. *Bifurcation diagrams of the nonlinear map, (22), computed numerically by plotting forward orbits after transients have decayed. In panel A the parameter values are the same as those in Figure 1, panel A; in panel B, $\omega_L = \omega_R = 0.4$, $r_L = 0.2$, and $s_R = 0.7$. In panel B, the corresponding bifurcation diagram of (6) is superimposed (shown as dashed lines).*

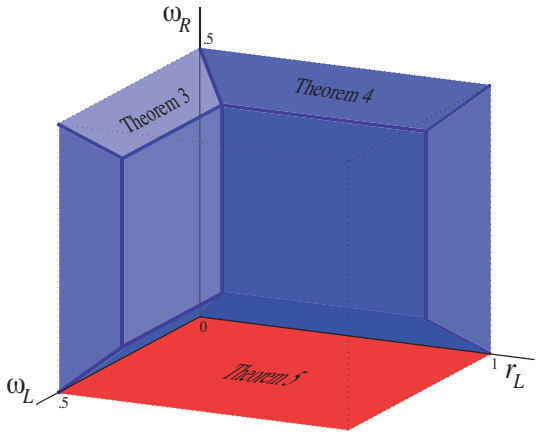

Figure 4. *Schematic summary of the results of section 3.1. Regions in parameter space are shaded blue where it is known that there exists an asymptotically stable invariant set and red where no attractor exists. The regions are labeled by their corresponding theorems in section 3.1.*

period-doubling bifurcations, where the attracting set is bounded away from the switching manifold.

The rest of this section describes the dynamics of (6) when $\mu = 1$ under variation of the remaining four parameters.

3.1. Limiting parameter values. Here we prove the existence or absence of an attractor for some limiting values of the parameters. This is summarized in Figure 4. There are two limiting domains in this figure, small r_L and small ω_L, for which we prove there exists an asymptotically stable invariant set in Theorems 3 and 4. The third limit in Figure 4 corresponds to $\omega_R = 0$ for which we prove in Theorem 5 almost all orbits are unbounded. Numerical results for regions in the figure where the theorems do not apply are given in the

remaining subsections. Throughout this section we let $f = f_1$ denote the map (6), with $\mu = 1$.

Theorem 3. *Consider* (6) *with* $\mu = 1$ *and assume* $0 < s_R < 1$, $0 < \omega_L$, $\omega_R < 1/2$ *as usual. Then there is an* $\varepsilon > 0$ *such that whenever* $0 \le r_L < \varepsilon$, *the map has an asymptotically stable invariant set.*

Proof. First suppose $r_L = 0$. Since $\mu = 1$, the unique fixed point of (6) lies in the RHP. The fixed point is an unstable focus; thus any point in the RHP other than the fixed point maps into the LHP in finitely many steps. Moreover, if $z = (x, y)$ is the first point in the LHP, then it is easy to see that $y < 0$. The image of this point is $f(z) = (y + 1, 0)$, with an x component less than one. If this image is still in the LHP, then the second iterate $f^2(z) = (1, 0) \in$ RHP. Consequently, any point in the LHP maps into the RHP in at most two steps.

Thus the forward orbit of every point other than the fixed point intersects the segment $\mathcal{I} = \{(x, 0) \mid x \in [0, 1]\}$. Since $\mathcal{I}$ is compact, there is an $N \in \mathbb{N}$ such every point in $\mathcal{I}$ maps back into $\mathcal{I}$ in at most N steps. Hence

$$\Omega = \bigcup_{i=0}^{N} f^i(\mathcal{I})$$

is a compact, bounded, forward invariant set of f. Note that $z^* \notin \Omega$. Let Σ be any compact neighborhood of Ω, $\Omega \subset \mathrm{int}(\Sigma)$, that does not contain the fixed point. Since Σ is compact, every point in Σ maps to $\mathcal{I}$; thus there is an $\hat{N} \in \mathbb{N}$ such that $f^{\hat{N}}(\Sigma) \subset \Omega$, i.e., Σ is a trapping set for $f^{\hat{N}}$.

When r_L is small, a similar construction must hold: since (6) depends continuously on r_L, there is an $\varepsilon > 0$ such that whenever $0 \le r_L < \varepsilon$, Σ is still a trapping set for $f^{\hat{N}}$. Let

$$\Lambda = \bigcap_{i=0}^{\infty} f^i(\Sigma). \tag{23}$$

Then Λ is an attracting set for (6); it is necessarily asymptotically stable and invariant. ∎

The attracting set (23) may not be an "attractor" as it need not be minimal or chain-transitive [24, 28]. Indeed, we will see in section 3.2 that f can have multiple attractors.

Theorem 4. *Consider* (6) *with* $\mu = 1$ *and* $0 < r_L$, $s_R < 1$, $0 < \omega_R < 1/2$ *as usual. Then there is an* $\varepsilon > 0$ *such that whenever* $0 \le \omega_L < \varepsilon$, *the map has an asymptotically stable invariant set.*

Proof. When $\omega_L = 0$, the left half of (6) becomes

$$z' = A_L z + \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad A_L = \begin{bmatrix} 2r_L & 1 \\ -r_L^2 & 0 \end{bmatrix}.$$

This affine map has a unique (virtual) fixed point $z_L^* = \frac{1}{(1-r_L)^2}(1, -r_L^2)^\mathsf{T}$ in the RHP; see panel A of Figure 5. A_L has a repeated eigenvalue r_L and a single eigenvector $(1, -r_L)^\mathsf{T}$. The one-dimensional invariant manifold E^{r_L} of the virtual fixed point intersects the y-axis at $\frac{r_L}{1-r_L} > 0$. Observe that E^{r_L} separates orbits of the left-half map (i.e., if z is below (above) E^{r_L}, then so is z'). Let $\Xi = \{(x, y) \mid x, y \ge 0,\ y \le r_L(\frac{1}{1-r_L} - x)\}$; see Figure 5, panel A.

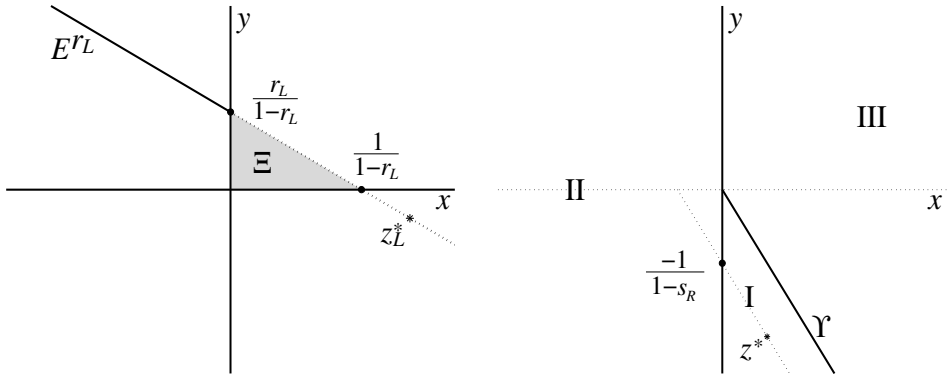

Figure 5. *Partitions of phase space when $\mu = 1$, applied in Theorems 4 and 5. In panel A, $\omega_L = 0$; in panel B, $\omega_R = 0$.*

Consider the forward orbit of any $z \in \Xi$ under the full map (6). Since the map in the RHP corresponds to an unstable focus, z maps to a point $\hat{z}$ in the LHP in finitely many steps, and since for any $x > 0$, $y' = -\frac{1}{s_R^2}x < 0$, $\hat{z}$ lies below the x-axis. Every point in the LHP below E^{r_L} maps into the RHP below E^{r_L} in finitely many steps. Since for any $x < 0$, $y' = -r_L^2 x > 0$, the first iterate in the RHP will lie above the x-axis and thus in Ξ. Since Ξ is compact, there is an $N \in \mathbb{N}$ such that $\forall\ z \in \Xi$, $f^n(z) \in \Xi$ for some $n \le N$. Hence,

$$\Omega = \bigcup_{i=0}^{N} f^i(\Xi)$$

is a compact, bounded, forward invariant set for f.

Following the argument in Theorem 3, this implies that for $0 \le \omega_L < \epsilon$ there is an attracting set Λ, (23) for f, where Σ is a neighborhood of Ω. ■

Theorem 5. *Consider (6) with $\mu = 1$ and the limiting case $\omega_R = 0$. Assume that the remainder of the parameter values satisfy $0 < r_L$, $s_R < 1$, $0 < \omega_L < 1/2$ as usual. Then the forward orbit of any point other than the fixed point is unbounded.*

Proof. When $\omega_R = 0$, the right half of (6) becomes

$$z' = A_R z + \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad A_R = \begin{bmatrix} \frac{2}{s_R} & 1 \\ -\frac{1}{s_R^2} & 0 \end{bmatrix}.$$

This affine map has a unique fixed point $z^* = -\frac{1}{(1-s_R)^2}(s_R^2, -1)^\mathsf{T}$ in the RHP. A_R has a repeated eigenvalue $\frac{1}{s_R}$ and a single eigenvector $(s_R, -1)^\mathsf{T}$ whose associated one-dimensional invariant manifold Σ intersects the y-axis at $-\frac{1}{1-s_R} < 0$. Let Υ be the line parallel to Σ which passes through the origin. We use Υ to partition phase space into three regions, as shown in panel B of Figure 5. Region III, the set $\{(x, y) \mid x \ge 0,\ x > -s_R y\}$, is forward invariant for (6) because for any z in region III, $z' = (\frac{2}{s_R}x + y + 1, -\frac{1}{s_R^2}x)^\mathsf{T}$; that is,

$$x' = \frac{2}{s_R}x + y + 1 > \frac{2}{s_R}x - \frac{1}{s_R}x + 1 \Rightarrow x' > \frac{1}{s_R}x > 0.$$

Using $x = -s_R^2 y'$, we see that $x' > -s_R y'$, and hence z' is in region III. Since the map in the LHP corresponds to a virtual stable focus, and since for any $x < 0$, $y' = -r_L^2 x > 0$, every point in region II is mapped into region III in finitely many iterations. Thus the forward orbit of any point either starts in the RHP and remains there or enters region III via the LHP in finitely many steps and remains in region III. In any case, the tail of the forward orbit is contained in the RHP, and since dynamics in the RHP are governed by an unstable linear map, the forward orbit of every point except z^* is unbounded. ■

The limiting case, $s_R = 1$, has been described previously in [32, 26, 13]; we will discuss it further in section 3.3.

3.2. Resonance tongues when $\mu = 1$. Figures 6, 7, and 8 show numerically computed regions of existence of stable periodic orbits with periods shown in the color bar at the bottom of Figure 6. As is commonly observed in piecewise smooth systems, these "resonance tongues" usually have the form of a chain of lens-shaped regions [37, 27]. The rotation number of each lens-chain is fixed, and, as we will discuss below, within a given chain, the symbol sequence changes from lens to lens. The tongues emanate from $s_R = 1$, and their sizes are ordered by the Farey sequence, as indicated along the top of Figure 6. In some places tongues overlap corresponding to the coexistence of multiple stable periodic solutions.

The figures are computed on a grid of 1024 frequency values and 128 values of s_R. For each set of parameters, we numerically check the admissibility conditions (9) and the stability conditions (that the multipliers of the stability matrix (11) lie inside the unit circle) for periodic orbits up to period 30 with certain symbol sequences described below. If no stable n-cycle was found, we compute N iterates along the forward orbit of the point $z = (M, 0)$ for N up to 10^4. If $\max_{i=0}^{n} |x^{(i)}|$ appeared to grow steadily as $n \to N$, this orbit is declared to be unbounded, and the corresponding point is shaded white. Otherwise the point is shaded black and presumably corresponds to bounded motion with a period larger than 30. Because the orbits for small ω appear to range over a large domain, we used $M = 10^{12}$.

In some cases, multiple attracting periodic solutions may exist, and our algorithm simply assigns a color based on the first periodic orbit that it finds; see section 4.2.

In Figure 6, notice that when $\omega_R = 0$, there are no stable solutions for any value of s_R as foreseen by Theorem 5. Similarly, when $\omega_L = 0$ (as seen in the lower two diagrams when $\omega_R = -\phi$), there is a stable solution for all values of s_R in accordance with Theorem 4. In Figure 8, notice that the diagram corresponding to the smaller value of r_L has stable orbits over a larger range of parameter space, as would be expected from Theorem 3.

3.3. Dynamics near $s_R = 1$. We first describe the dynamics for the case $s_R = 1$, corresponding to the top edge of the figures. When $\mu = 1$, the fixed point z^*, (7), lies in the RHP and is a center. Points sufficiently near z^* rotate around it with rotation number ω_R on invariant ellipses contained in the RHP. The largest of this family of nested ellipses has one point on the switching manifold. The boundary of the region in phase space within which this rigid rotation occurs has a geometry dependent upon the rationality of ω_R [32]. When ω_R is irrational, the boundary is the largest ellipse. When $\omega_R = m/n$ is rational, the boundary is an invariant n-sided polygon $\mathcal{P}$. In this case there are points in the region bounded by the largest ellipse and $\mathcal{P}$. These points simply belong to m/n-cycles contained in the RHP.

Numerically we have observed that the boundary attracts nearby points outside the region,

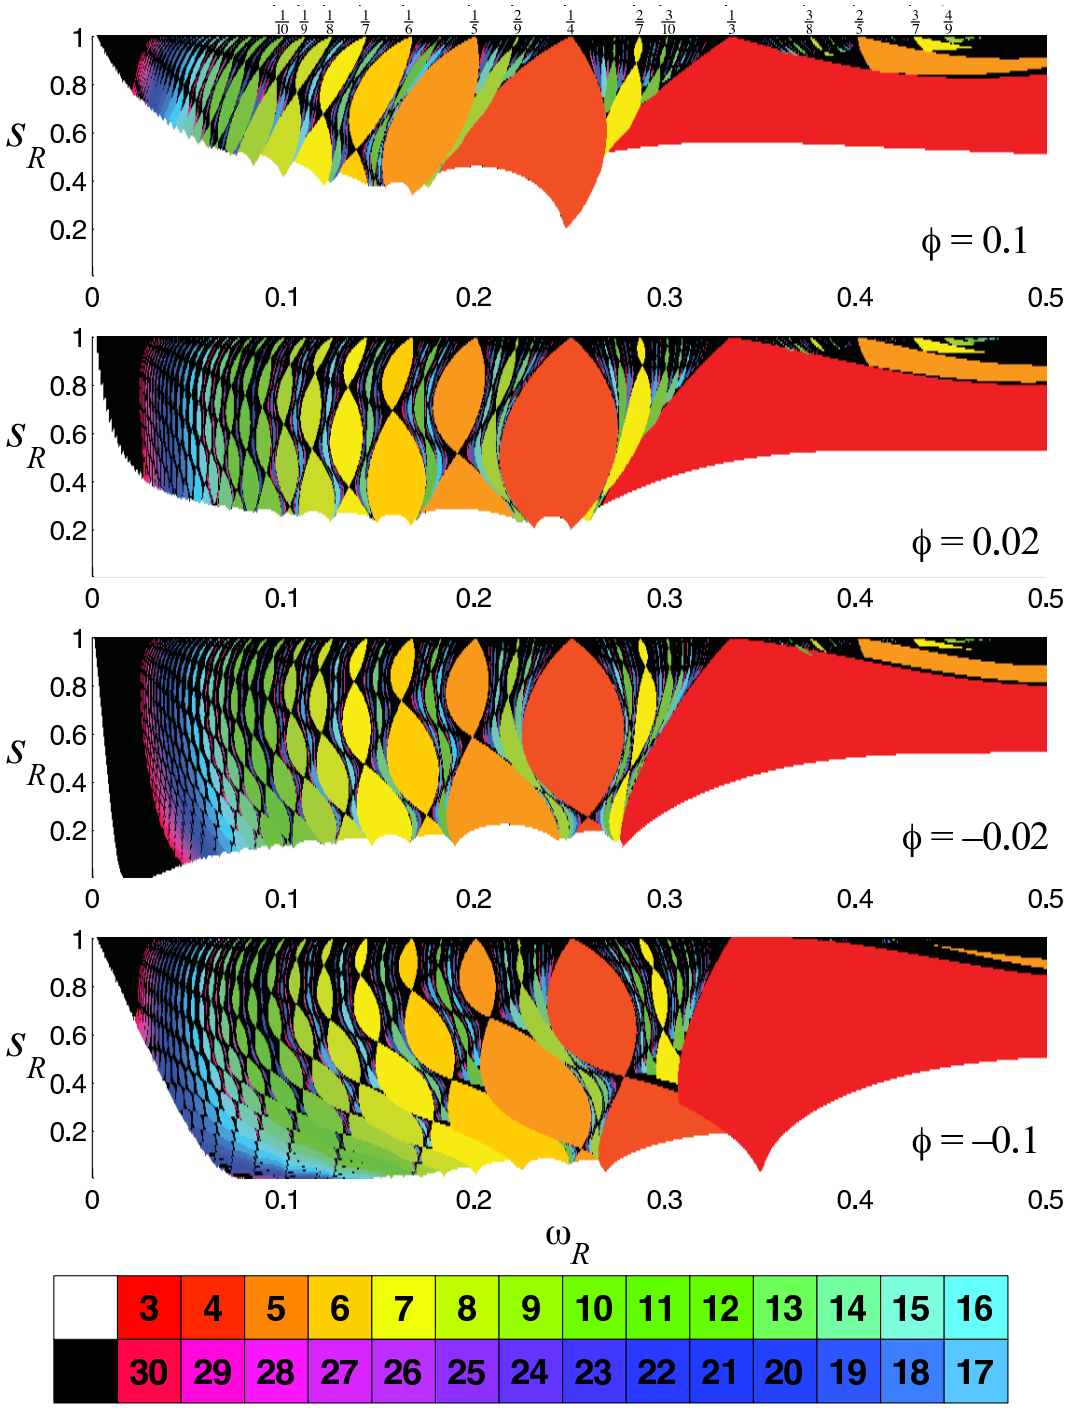

Figure 6. *Resonance tongues for $\mu = 1$, $r_L = 0.2$, $\omega_L = \omega_R + \phi$ for four different values of ϕ. Each colored region corresponds to the existence of a stable periodic orbit with period shown in the color bar at the bottom. White regions correspond to unbounded orbits and black regions to orbits with period larger than 30.*

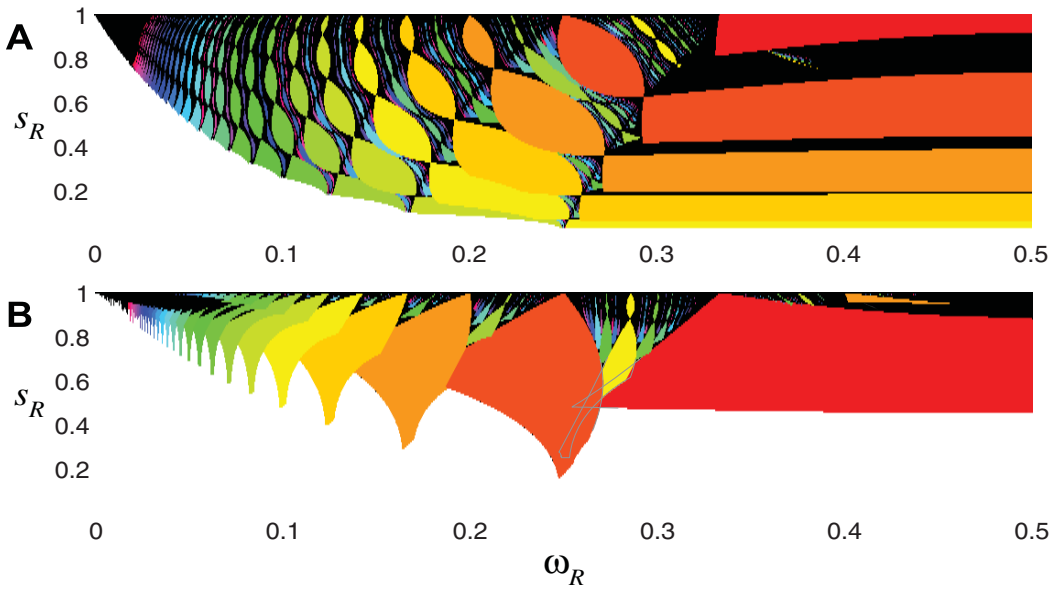

Figure 7. *Resonance tongues of* (6) *for* $\mu = 1$. *In panel A,* $r_L = 0.3$, $\omega_L = 0.09$*; in panel B,* $r_L = 0.16$, $\omega_L = 0.38$. *In panel B, the overlapping of the* 1/3, 1/4, *and* 2/7 *tongues is emphasized. The color scheme is the same as that in Figure* 6.

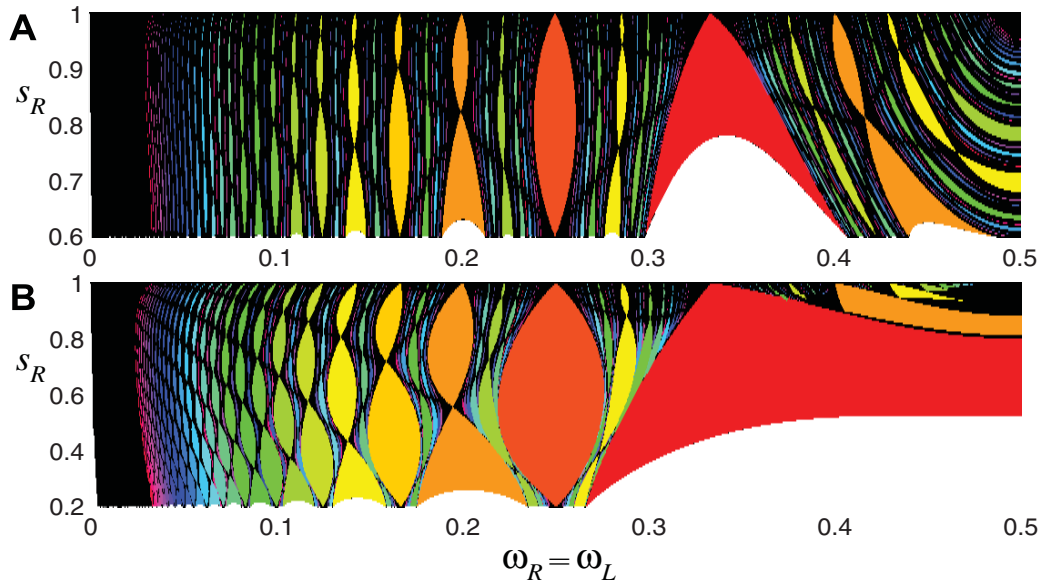

Figure 8. *Resonance tongues of* (6) *for equal polar angles, i.e.,* $\omega_L = \omega_R$, *when* $\mu = 1$. *In panel A,* $r_L = 0.6$*; in panel B,* $r_L = 0.2$. *The color scheme is the same as that in Figure* 6.

prompting the following conjecture.

Conjecture 1. *Consider* (6) *with* $\mu = 1$ *and assume that* $0 < r_L < 1$, $0 < \omega_L$, $\omega_R < 1/2$

as usual. Then there is an $\varepsilon > 0$ such that whenever $1 - \varepsilon < s_R \leq 1$, the map has an asymptotically stable invariant set.

Note that other attractors may exist when $s_R = 1$. For example, in panel A of Figure 7, the period-three cycle exists $\forall \omega_R > \frac{1}{3}$ when $s_R = 1$. For these values there will also be an invariant polygon or ellipse with rotation number ω_R.

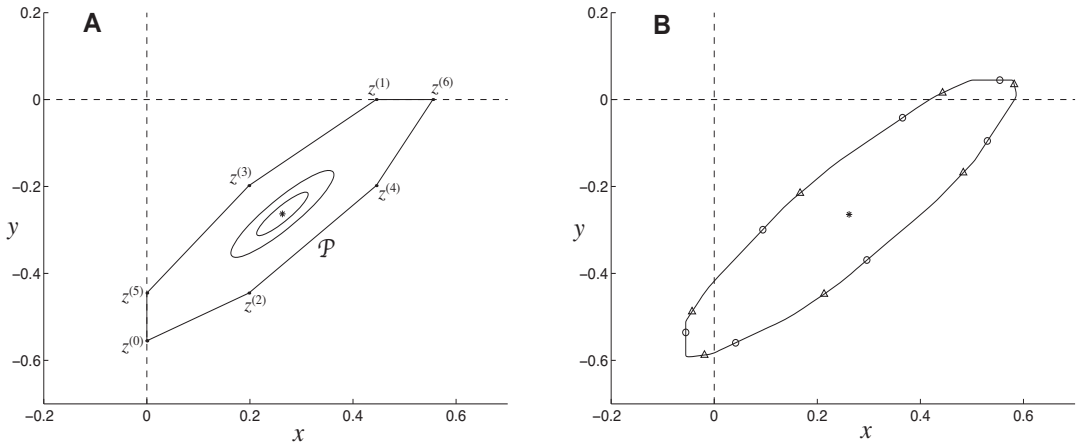

Figure 9. *Phase portraits of (6) when $\mu = 1$, $\omega_L = \omega_R = 3/7$, $r_L = 0.9$, and $s_R = 1$ in panel A and $s_R = 0.995$ in panel B. The fixed point z^* is indicated by an asterisk. In panel A, we show the invariant heptagon $\mathcal{P}$ and two of the uncountably many invariant ellipses near the center z^*, each consisting of infinitely many 3/7-cycles. In panel B, the right-half map is no longer area preserving; $\mathcal{P}$ appears to become an invariant circle attracting from both sides. The stable (saddle) 3/7-cycle is indicated by triangles (circles).*

When $\omega_R = m/n$ is rational, the bounding polygon $\mathcal{P}$ has one side on the switching manifold; see Figure 9. Denote the vertices of $\mathcal{P}$ by $\{z^{(i)} \mid i = 0, \ldots, n-1\}$, so that each $z^{(i)}$ maps to $z^{(i+1)}$. Suppose that $z^{(0)} = (0, y^{(0)})$ and $z^{(d)} = (0, y^{(d)})$ are the two points on the switching manifold and without loss of generality that $y^{(0)} < y^{(d)}$. Since the rotation number is m/n, $z^{(1)}$ is the mth vertex clockwise from $z^{(0)}$; thus $z^{(i)}$ is the $(im \bmod n)$th vertex clockwise from $z^{(0)}$. Since $z^{(d)}$ is adjacent to $z^{(0)}$, $dm \bmod n = 1$. In other words, d is the multiplicative inverse of m modulo n, which—as is well known—exists if and only if m/n is an irreducible fraction [14]. For example, when $m/n = 3/7$, $d = 5$ since $5 \times 3 \bmod 7 = 15 \bmod 7 = 1$; see Figure 9. Alternatively d may be computed via the Farey tree. If m_1/n_1 and m_2/n_2 are the Farey neighbors of m/n ($m_1 + m_2 = m$ and $n_1 + n_2 = n$), then $mn_i \bmod n = \pm 1$ for $i = 1, 2$; thus d is either n_1 or n_2.

The n-cycle $\{z^{(i)}\}$ may be thought of as having a symbol sequence $\mathcal{S}$, where $\mathcal{S}_0 = \mathcal{S}_d = \mathsf{L}$ and the remaining $(n-2)$ elements equal R. Each of the conditions $x^{(0)} = 0$ and $x^{(d)} = 0$ defines a codimension-one manifold in parameter space that forms a boundary for the lens that emanates from $s_R = 1$. Within the lens there exist both stable and saddle orbits with rotation number m/n. These orbits collide and annihilate on the boundaries in a border-collision bifurcation. The stable orbits have symbol sequence $\mathcal{S}$, whereas the saddle orbits have one point in the LHP and $(n-1)$ points in the RHP. An example of a phase portrait showing these two orbits and the invariant circle formed from the unstable manifolds of the saddle is shown in panel B of Figure 9.

3.4. Resonance tongue boundaries. More generally, the codimension-one boundaries of resonance tongues correspond to either a border-collision bifurcation or a loss of stability. In the first case, one point on the attracting n-cycle collides with the switching manifold. The resulting border-collision bifurcation may be classified by Feigin's analysis, as discussed in section 2.1. Typically we find that the stable n-cycle annihilates with a saddle-type n-cycle that coexists within the lens, but this is not always the case (see section 4.4). A second possible codimension-one boundary corresponds to the loss of stability of the attracting cycle when one or more multipliers of its stability matrix $M_{\mathcal{S}}$ leaves the unit circle. In codimension-one situations this can happen in exactly three ways: a real multiplier may pass through 1 or -1 or a complex conjugate multiplier pair may cross the unit circle.

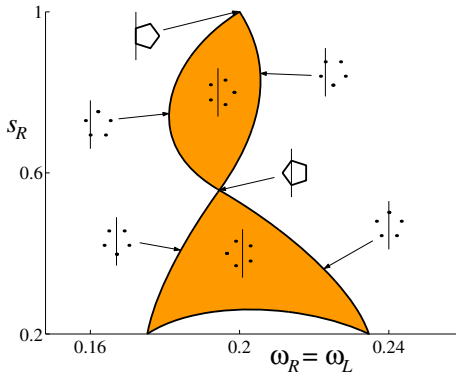

Figure 10. *The 2/5-resonance tongue of (6) with $\mu = 1$, $r_L = 0.2$, as seen in Figure 8, panel B. Shown are schematic phase portraits of the stable 2/5-cycle in relation to the switching manifold.*

As an example, Figure 10 illustrates the lens-chain for the 2/5 orbit and also shows phase portraits of the stable cycle in the two lenses and on their boundaries. In the upper lens, two points of the stable 2/5-cycle lie in the LHP; in the lower lens three points lie in the LHP. The left and right boundaries correspond to border-collision bifurcations along which the stable cycle collides and annihilates with a saddle cycle. Along the bottom boundary a multiplier associated with the stable cycle passes through 1.

Interestingly, this last bifurcation does not resemble a saddle-node bifurcation in a smooth system. If the stability matrix $M_{\mathcal{S}}$ has a multiplier $\lambda^* = 1$, then $I - M_{\mathcal{S}}$ is singular. By Lemma 2, the system (10) has no solution provided that the border-collision matrix $P_{\mathcal{S}}$ (12) is nonsingular. In this case, as $\lambda^* \to 1^-$, the n-cycle becomes unbounded. Of course, this is a somewhat artificial consequence of the lack of nonlinear terms in (6). Note that the saddle cycle exists on both sides of the $\lambda^* = 1$ bifurcation curve.

If Conjecture 1 holds, the bounding invariant polygon $\mathcal{P}$ for $s_R = 1$ is an attracting invariant set, and so it persists as such a set, typically as an invariant circle for $s_R < 1$. There are many ways in which an invariant circle of planar, piecewise-affine continuous maps can break up [32, 39]. For instance, the stable and unstable manifolds of the saddle cycle may transversely intersect, replacing the invariant circle with a homoclinic tangle [32, 38, 39]. The invariant circle consisting of a stable and saddle cycle and the unstable invariant manifolds of the saddle may disappear upon collision and annihilation of the cycles in a border-collision

bifurcation. Also, a loss of stability of the stable cycle may lead to the destruction of the invariant circle [32, 21]. These mechanisms are similar to those that occur in smooth maps [1].

The symbol sequence of an m/n periodic orbit $\{z^{(i)} \mid i = 0, \ldots, n-1\}$ that lies on an invariant circle may be determined by the same process as when $s_R = 1$. Assume the invariant circle intersects the switching manifold twice and that the m/n-cycle has l points in the LHP and $(n-l)$ points in the RHP. If $z^{(0)}$ is the first point in the cycle along the invariant circle to the left of its lower intersection with the switching manifold, then the points in the LHP are $z^{(0)}, z^{(d)}, z^{(2d \bmod n)}, \ldots, z^{((l-1)d \bmod n)}$, where $dm \bmod n = 1$ as before. Therefore, $\mathcal{S}_0 = \mathcal{S}_d = \cdots = \mathcal{S}_{(l-1)d \bmod n} = \mathsf{L}$ and $\mathcal{S}_i = \mathsf{R}$ otherwise.

Stable n-cycles associated with the topmost lens in a tongue are comprised of two points in the LHP and $(n-2)$ points in the RHP. Numerically we have observed that other lenses correspond to stable n-cycles with one more point in the LHP than the connected lens above. The saddle n-cycle has one fewer point in the LHP and one more point in the RHP than its stable counterpart.

Figure 8 shows resonance tongues when $\omega_L = \omega_R$ for two different fixed values of r_L. Lens-chains emanate from $s_R = 1$ and may extend to $s_R = r_L$. If n is odd, we have observed that the bottom-most lens corresponds to stable n-cycles with $\frac{n+1}{2}$ points in the LHP and the boundary of this lens intersects $s_R = r_L$ at one point. Alternatively, if n is even, the bottom-most lens corresponds to stable n-cycles with $\frac{n}{2}$ points in the LHP and there are possibly two intersection points of the boundary of this lens with $s_R = r_L$. The boundary curve connecting these two points bends above $s_R = r_L$ as in Figure 10 and corresponds to the associated stability matrix having a multiplier 1. We were unable to find any stable solutions when $s_R < r_L$, prompting the following conjecture.

Conjecture 2. *Suppose $\mu = 1$, $0 < \omega_L = \omega_R < 1/2$, and $0 < s_R < r_L < 1$. Then (6) has no stable solutions.*

3.5. Shrinking points. As in [36], we call points where resonance tongues have zero width *shrinking points*. Since this corresponds to the intersection of two border-collision-bifurcations, there is a period-n orbit, $\{z^{(i)}\}$, that has two points on the switching manifold. As a result of the piecewise-affine structure of the map, line segments connecting $z^{(i)}$ and $z^{(i+d)}$ map to one another and hence form an invariant n-gon comprised of uncountably many m/n-cycles; see Figure 11 for an example. If $\mathcal{S}$ is the symbol sequence of these cycles, then $(I - M_{\mathcal{S}})$ is singular at the shrinking point. Note that Lemma 2 does not apply here since $P_{\mathcal{S}}$ is singular; the n-cycle solution system (10) has uncountably many solutions.

Denote the two vertices of the n-gon on the switching manifold by $w_1 = (0, y_1)$ and $w_2 = (0, y_2)$ and assume without loss of generality that $y_1 < y_2$. Since these points are on a periodic orbit, $f^s(w_1) = w_2$ for some s. For example, in Figure 11, $s = 5$. The polygon persists as an attracting invariant set as parameters are continuously varied, though it will no longer necessarily contain only periodic orbits. When the polygon persists as an invariant circle, the points of intersection of the invariant circle with the switching manifold, w_1 and w_2, also vary continuously. Moreover, it is a codimension-one phenomenon for w_1 to map into w_2 in s iterations. Thus there exists a curve in two-dimensional parameter space along which $f^s(w_1) = w_2$. We call such a curve a *shrinking point curve*. These curves also exist for one-dimensional piecewise-linear circle maps, and in [36], the authors were able to obtain

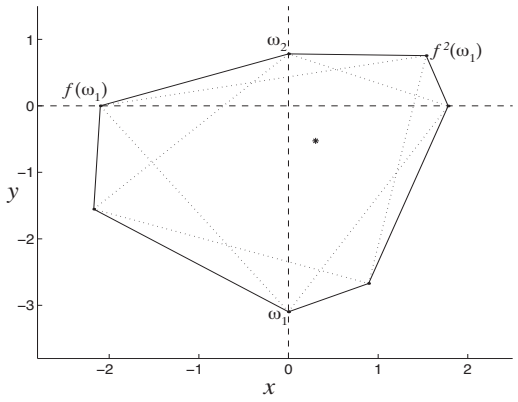

Figure 11. *A phase portrait of (6) for parameter values ($r_L = 0.6$, $s_R \approx 0.7583$, $\omega_L = \omega_R \approx 0.2841$) corresponding to a shrinking point on the 2/7-resonance tongue. The invariant circle is a heptagon that consists entirely of 2/7-cycles. As when $s_R = 1$, the vertices map to one another as do the sides. The stable fixed point is indicated by an asterisk. The dotted lines connect the vertices with their images.*

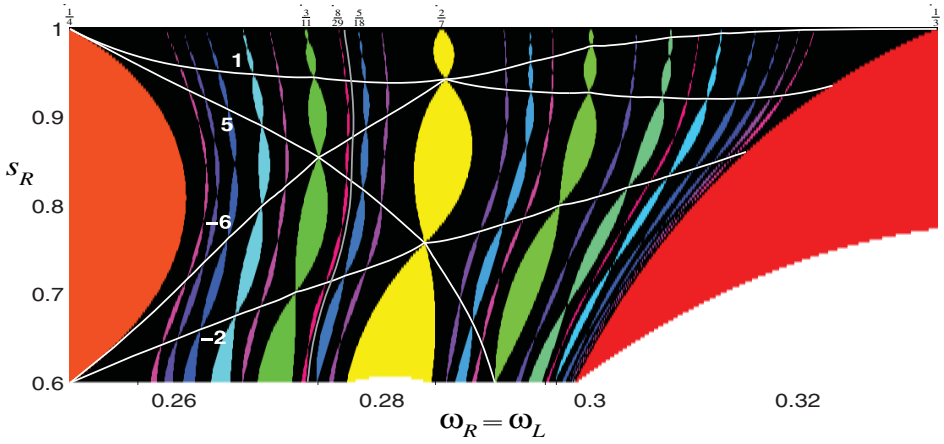

Figure 12. *A magnification of panel A of Figure 8. The white curves are shrinking point curves for $s = -6$, -2, 1, and 5. The gray curve corresponds to stable solutions for which the rotation number is $\frac{1}{2+\gamma} \approx 0.2764$, where γ is the golden ratio.*

analytical expressions.

Shrinking point curves can be computed numerically by first finding an approximate invariant circle by the algorithm described in [12] and then estimating the points w_1 and w_2 by interpolation. We then vary the parameters to minimize $|f^s(w_1) - w_2|$ for some fixed s; an example is shown in Figure 12.

For instance, when $s = 5$, we obtain a curve that extends from the top of the 1/4-resonance region to the bottom of the 3/10-resonance region, as shown in Figure 12. This curve intersects the 2/7-resonance region at which point the associated 2/7-polygon appears as in Figure 11. As seen in this figure, w_1 maps into w_2 upon five iterations of (6). At this point w_2 maps into w_1 in two iterations; hence the shrinking point curve for which $s = -2$ also crosses this point.

Similarly the curves for $s = 1$ and $s = -6$ intersect at the upper shrinking point of the 2/7 lens-chain.

In addition to invariant circles with rational rotation numbers, we can approximately find irrational circles by following a sequence of rational lens-chains whose rotation numbers limit on a given irrational number. For example, in Figure 12, the gray one-dimensional curve corresponds to the existence of an invariant circle whose rotation number is computed to be $\frac{1}{2+\gamma}$, where γ is the golden ratio, within an error of 10^{-10}. Note that this curve is sandwiched between resonance tongues whose rotation numbers correspond to the Farey sequence

$$\frac{1}{3}, \frac{1}{4}, \frac{2}{7}, \frac{3}{11}, \frac{5}{18}, \frac{8}{29} \to \frac{1}{2+\gamma} \approx 0.2764.$$

Resonance tongues associated with the first six rotation numbers in this sequence are shown in Figure 12.

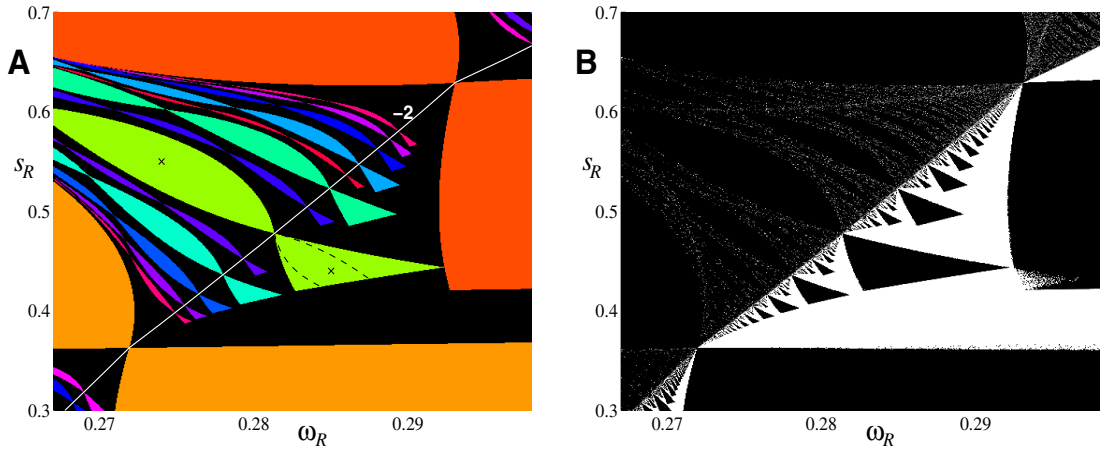

Figure 13. *Panel A shows a magnification of panel A of Figure 7 ($r_L = 0.3$, $\omega_L = 0.09$, and $\mu = 1$). The white curve is the shrinking point curve with $s = -2$; the dashed black curves correspond to first homoclinic tangencies. Phase portraits for parameter values indicated by crosses are shown in Figure 14. Panel B shows numerically calculated Lyapunov exponents over the same parameter range. Black (white) areas correspond to negative (positive) Lyapunov exponents. Gray areas correspond to numerically computed Lyapunov exponents with a magnitude less than* 0.0005.

To distinguish between regular and chaotic orbits, we numerically computed Lyapunov exponents for initial conditions on a 512×512 grid in parameter space; see Figure 13. To create panel B, for each choice of parameter values, we iterated a randomly chosen initial condition for 10^4 steps after removing transients. When there are multiple attractors, the value we compute for the Lyapunov exponent depends upon which basin of attraction the initial random point is located. For example, the black and white area centered at $(\omega_R, s_R) = (0.294, 0.43)$ corresponds to the coexistence of a stable 1/4-cycle and a chaotic attractor born in a flip bifurcation of a 2/9-cycle.

If there exists an attracting invariant circle with an irrational rotation number, the map restricted to the circle is semiconjugate to rigid rotation [6]. Thus, in this case, orbits on the circle are quasiperiodic and have zero Lyapunov exponent. For this reason the upper-left

half of Figure 13, panel B, contains many data points for which the numerically computed Lyapunov exponent has a value within 0.0005 of zero. These grey curves also seem to fall between the lens-chains corresponding to rational rotation numbers, which is consistent with their rotation number being irrational.

The line that runs diagonally through Figure 13 is the $s = -2$ shrinking point curve. To the left of this curve, there appear to be no chaotic solutions, or at least they are very much less common. Figure 14 shows stable and unstable invariant manifolds of the saddle 2/9-cycle on either side of the shrinking point curve. In panel A the associated eigenvalues of both the stable and saddle 2/9-cycles are positive and the unstable manifolds form an attracting invariant circle. In panel B the associated eigenvalues of the stable 2/9-cycle are negative and the unstable manifolds spiral into the stable 2/9-cycle. We have observed a similar situation near the shrinking point curve for all lens-chains shown in Figure 13, panel A; thus we believe Figure 14 illustrates a typical scenario.

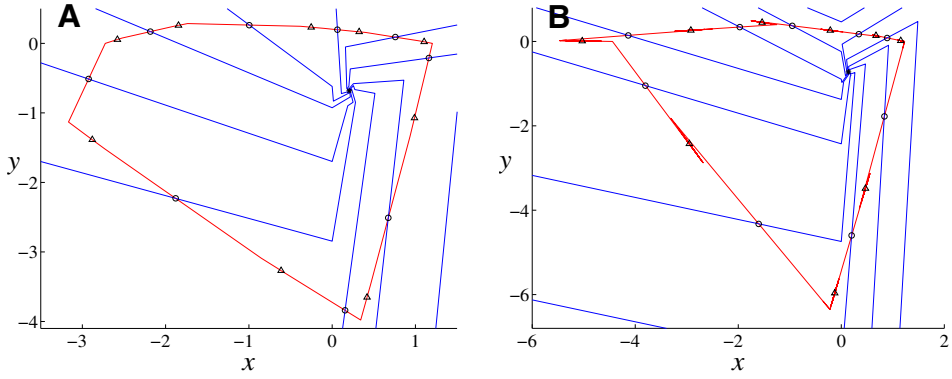

Figure 14. *Stable (blue) and unstable (red) invariant manifolds of a saddle* 2/9*-cycle of* (6) *when* $r_L = 0.3$, $\omega_L = 0.09$, *and* $\mu = 1$. *In panel A,* $\omega_R = 0.274$ *and* $s_R = 0.55$. *In panel B,* $\omega_R = 0.285$ *and* $s_R = 0.44$. *Triangles (circles) denote stable (saddle)* 2/9*-cycles.*

Variation of the parameters of panel B toward a border-collision bifurcation leads to a collision of the stable and unstable manifolds of the saddle cycle. Beyond curves of first tangency (shown in Figure 13) the invariant circle no longer exists. The stable and unstable manifolds intersect transversely forming a homoclinic tangle.

4. More complex phenomena. Despite its simple appearance, the map (6) exhibits an extremely rich array of behavior beyond that described in section 3. Via an example, in section 4.1 we examine the border-collision bifurcation when no invariant circle is created. In section 4.2 we look at multiple attractors. As mentioned in section 3.4, there are three paths by which stable periodic orbits generically lose stability. The first is via an associated real-valued multiplier crossing 1, as detailed in section 3.4. In section 4.3 we detail the case when the crossing occurs at -1. We observe non–lens-chain structures, and these are expounded in section 4.4. The third scenario, that of a complex conjugate pair of multipliers crossing the unit circle, is looked at in section 4.5. Section 4.6 introduces more exotic border-collision bifurcations occurring at $\mu = 0$.

4.1. Saddle fixed points for $\mu = 0$. The white regions in Figure 8 correspond to parameter values where no attractor exists when $\mu = 1$. Here we describe the corresponding border-collision bifurcation that occurs at $\mu = 0$. We find that no invariant circle is created; thus the bifurcation bears little relation to a Neimark–Sacker bifurcation in a smooth system.

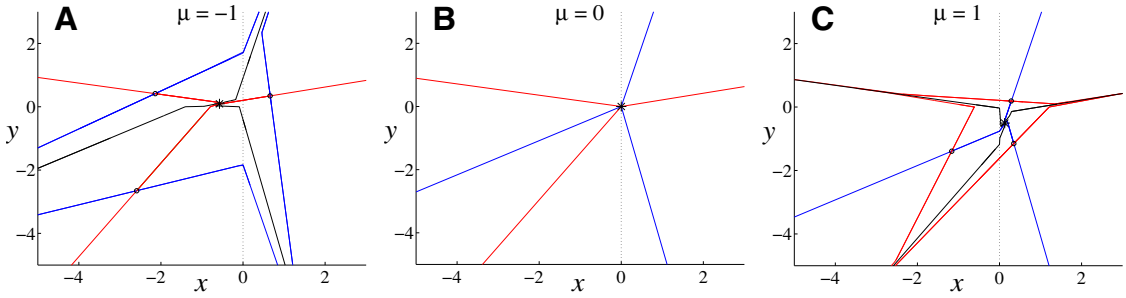

Figure 15. *Stable (blue) and unstable (red) manifolds of a period-3 saddle (indicated by circles) for (6) when $\omega_L = \omega_R = 0.38$, $r_L = 0.4$, $s_R = 0.5$ for $\mu = -1, 0, 1$. The fixed point is indicated with an asterisk.*

As an example, in Figure 15 we show phase portraits for $\mu = -1, 0, 1$. When $\mu = -1$, the unique fixed point of (6) lies in the LHP and is stable. However, its basin of attraction is not the entire plane: there is a period-three saddle with the symbol sequence LLR. The one-dimensional piecewise-linear stable manifolds of this orbit (the blue curves) form the boundary of the basin of attraction for the fixed point. Orbits of points in the interior of the complement of this region are unbounded. When $\mu = 1$, the opposite situation occurs: the fixed point lies in the RHP and is a repellor. The unstable manifolds (red curves) of a period-three orbit with symbol sequence RRL form the boundary for the basin of repulsion of the fixed point.

The LLR orbit that exists when $\mu < 0$ is destroyed at $\mu = 0$; however, its unstable manifolds persist as an invariant set of piecewise-linear curves contained in the basin of repulsion; these are the black curves in panel C of Figure 15. These manifolds extend to infinity and connect to the fixed point. Similarly, the stable manifolds of the RRL 3-cycle become an invariant set of piecewise-linear curves in the basin of attraction of the fixed point when $\mu = 1$.

When $\mu = 0$, the two period-three orbits collide with the fixed point at the origin. The stable manifolds of the RRL orbit and the unstable manifolds of the LLR orbit become stable and unstable manifolds of the origin, which is now a saddle with six hyperbolic sectors.

We believe the above dynamical behavior is generic. When $\omega_L = \omega_R$ and the origin is of saddle type for $\mu = 0$, we expect n stable invariant rays and n unstable invariant rays to emanate from the origin, as we have observed above for $n = 3$. In general, when $\omega_L \neq \omega_R$, more complications may arise.

4.2. Multiple attractors. The overlapping of resonance tongues corresponds to the coexistence of multiple stable periodic cycles. Multiple attractors in piecewise-smooth maps have been described previously; see, for instance, [38, 32, 11, 22, 21]. An overlap is shown, for example, in panel B of Figure 7 near $\omega_R = 0.27$ and $s_R = 0.5$. Two examples of the phase space for this situation are shown in Figure 16. For example, for the parameters of panel A, there exist simultaneous stable period-three and period-four cycles. For this case there are also saddle period-three and period-four cycles, and the stable manifold of the latter saddle

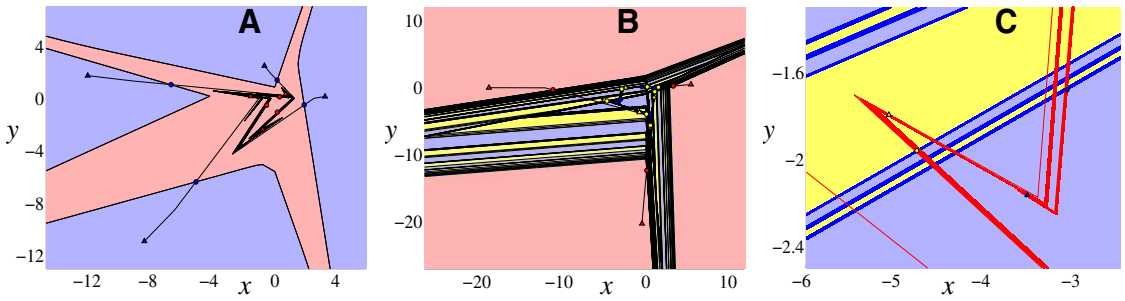

Figure 16. *Attractors and their basins of attraction for (6) $\mu = 1$ and $(r_L, s_R, \omega_L, \omega_R) = (0.45, 0.55, 0.2, 0.4)$ in panel A and $(0.16, 0.52, 0.38, 0.265)$ in panel B. Stable (saddle) periodic orbits are indicated by triangles (circles) and shaded red for period 3, blue for period 4, and yellow for period 7. Panel C is a magnification of panel B; here stable (unstable) invariant manifolds are colored blue (red).*

forms the boundary between the basins of attraction of the two stable orbits.

The coexistence of three attractors is illustrated in panel B of Figure 16; these correspond to the mutual intersection of the 1/3, 1/4, and 2/7 resonance tongues as seen in Figure 7, panel B. The one-dimensional stable manifold of the period-three saddle forms the boundary of the basin of attraction of the stable 3-cycle. However, the boundary between the remaining two basins is more complicated. The stable manifolds of the period-four and period-seven saddles transversely intersect the unstable manifolds of all three saddles forming a collection of homoclinic and heteroclinic orbits. The stable manifolds of the period-four and period-seven saddles appear to accumulate and form a fractal boundary between the two basins. We note that we have been able to find up to six coexisting attractors for the map (6) (specifically when $(\mu, r_L, s_R, \omega_L, \omega_R) = (1, 0.68, 0.8, 0.38, 0.27)$ there exist attractors with symbolic sequences $\mathsf{LRLL}(\mathsf{RLL})^k$ for $k = 7, \ldots, 12$); we believe that arbitrarily many distinct stable solutions can coexist.

4.3. Flip bifurcations of periodic solutions. An attracting periodic orbit of (6) can lose stability by a period-doubling or flip bifurcation. Suppose that an n-cycle with symbol sequence $\mathcal{S}$ has a stability matrix $M_{\mathcal{S}}$, with one multiplier inside the unit circle and one multiplier near -1; call it λ_{PD}. As described in section 2.1, if no points of the n-cycle lie on the switching manifold, there is a neighborhood of its initial condition with the same symbol sequence for the first n iterates; recall (14). Let $v_{\mathsf{PD}}^{(0)}$ denote the eigenvector of $M_{\mathcal{S}}$ at $z^{(0)}$ associated with λ_{PD}. Since $v_{\mathsf{PD}}^{(0)}$ corresponds to the dynamically slow direction of the periodic orbit, orbits of (6) that start sufficiently close to the periodic orbit approach the image vectors $v_{\mathsf{PD}}^{(i)}$ associated with λ_{PD} for each $z^{(i)}$. This is illustrated in Figure 17.

When $\lambda_{\mathsf{PD}} = -1$, points on the slow eigenvectors that are sufficiently close to the period-n orbit return to themselves after $2n$ iterations; therefore, there exists a segment of $2n$-cycles with a symbol sequence equal to the concatenation of $\mathcal{S}$ with itself, which we will denote $\mathcal{S}_{\mathsf{PD}}$.

This family of $2n$-cycles has a "first" point of intersection with the switching manifold. Let $q_\delta = z^{(0)} + \delta v_{\mathsf{PD}}$; then for $\lambda_{\mathsf{PD}} = -1$ the orbits of q_δ have the symbol sequence $\mathcal{S}_{\mathsf{PD}}$ providing $\delta \in [0, \delta_{\max}]$ for some $\delta_{\max} > 0$. Moreover, a single point on the $2n$-cycle will generically touch the switching manifold at $\delta_{\max}$. Without loss of generality, we can assume that a permutation

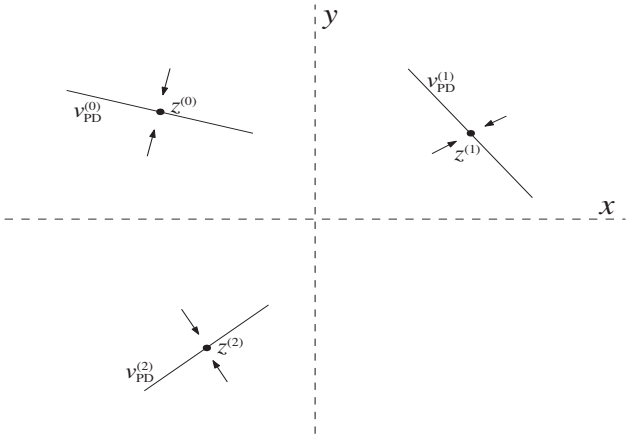

Figure 17. *Schematic showing an n-cycle and its associated slow eigenvectors in a neighborhood of the n-cycle.*

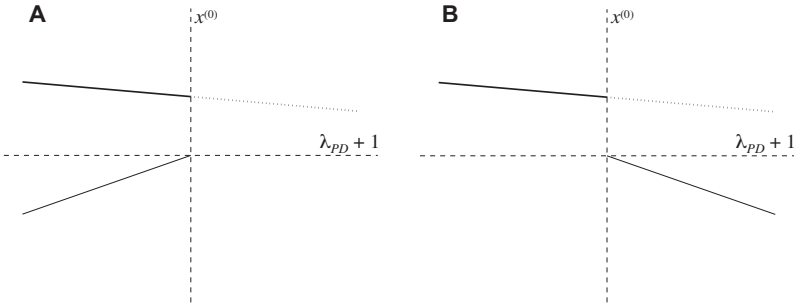

Figure 18. *Schematics of bifurcation diagrams about a flip bifurcation of (6). The solid (dotted) line corresponds to a stable (unstable) n-cycle. The thin line corresponds to a $2n$-cycle of unknown stability.*

of the orbit is selected so that the point that hits the switching manifold first is $q_{\delta_{\max}}$. Thus, when $\lambda_{\mathsf{PD}} = -1$, there is a period-$2n$ orbit with symbol sequence $\mathcal{S}_{\mathsf{PD}}$ that has its first point on the switching manifold.

Since the first symbol is ambiguous, we can also declare that this orbit has a switching manifold with its first symbol flipped; call this sequence $\mathcal{S}_{\mathsf{PD}^*}$. This orbit is an admissible solution of the system (10) with sequence $\mathcal{S}_{\mathsf{PD}^*}$.

The x-component of this solution will typically change and will have the correct sign, corresponding to $\mathcal{S}_{\mathsf{PD}^*}$ for only one sign of $\lambda_{\mathsf{PD}} + 1$: this will correspond to an admissible, isolated period-$2n$ orbit. This $2n$-cycle will coexist with either the stable n-cycle, as sketched in panel A, or the unstable n-cycle, as sketched in panel B of Figure 18. We have not been able to derive a general result regarding the stability of the period-doubled cycle; however, it appears most often to be unstable (see section 4.4 for a stable example).

For the case that the doubled cycle is unstable and exists for $\lambda_{\mathsf{PD}} < -1$, we have observed that it is typically embedded in a complicated attractor. In some cases, this attractor coincides

with the doubled cycle when it is created and grows in size as $\lambda_{\mathsf{PD}}+1$ decreases; see panel A of Figure 19. Alternatively, the attractor can be large and contain the n-cycle when it is created; see panel B of Figure 19. In both cases the Lyapunov exponent for the attractor appears to be positive ($\gamma_L \approx 0.0747$ in panel A and $\gamma_L \approx 0.0129$ in panel B), suggesting that the attractor is chaotic. As the parameters are varied further, the multiple-piece attractor may undergo merging [21].

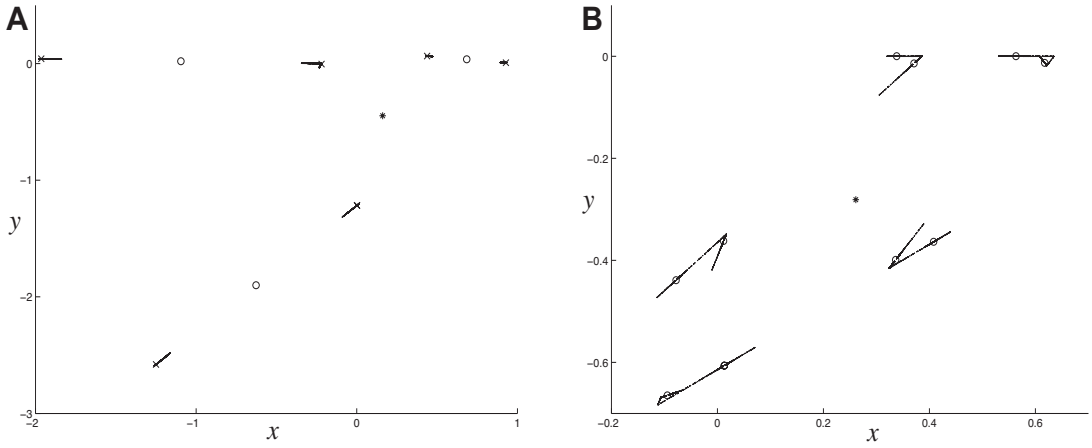

Figure 19. *Phase portraits of* (6) *when* $\lambda_{\mathsf{PD}} \approx -1.01$, $\mu = 1$. *In panel A,* $n = 3$*; in panel B,* $n = 10$. *An unstable fixed point is indicated by an asterisk. A saddle* n*-cycle is indicated by circles. In panel A, a saddle* $2n$*-cycle is indicated by crosses. In both panels, a complicated attractor is indicated by dots. The parameter values are* $(r_L, s_R, \omega_L, \omega_R) = (0.18202, 0.6, 0.09, 0.38)$ *in panel A and* $(r_L, s_R, \omega_L, \omega_R) = (0.0193, 0.964, 0.38, 0.41)$ *in panel B.*

So far we have assumed that a single point, $q_{\delta_{\max}}$, on the period-$2n$ orbit with $\lambda_{\mathsf{PD}} = -1$ hits the switching manifold. By varying another parameter, it is possible to have two such points on the switching manifold, say, $q^{(i)}_{\delta_{\max}}$ and $q^{(j)}_{\delta_{\max}}$, when $\lambda_{\mathsf{PD}} = -1$; this corresponds to a codimension-two bifurcation.

In this case there will be two curves that cross at the codimension-two point; these correspond to the vanishing of the x-components of each $q_{\delta_{\max}}$ individually. These two curves divide the neighborhood of the codimension-two point into four quadrants. In one quadrant there will be no admissible period-$2n$ orbit, and in two quadrants exactly one of the two new orbits will be admissible; one will have a symbol sequence with the ith symbol in PD flipped and the other with the jth symbol flipped. In the final quadrant, a new period-$2n$ switching manifold will be admissible—that corresponding to flipping *both* the ith and jth symbols.

In Figure 20 we show two examples where the doubly flipped period-$2n$ orbits are stable. In these cases the primary orbits, 1/3 and 2/5, respectively, are seen to lose stability with $\lambda_{\mathsf{PD}} = -1$, and there is a narrow tongue corresponding to stable orbits with rotation numbers 2/6 and 4/10, respectively, that emanates from a codimension-two point on the period-doubling curve. Interestingly, there also exist additional resonance tongues in the neighborhood of this codimension-two point. These appear in sequences with rotation numbers $2k/6k$ for k up to 7 in panel A and rotation numbers $4k/10k$ for k up to 3 in panel B. We have been unable to locate resonance tongues corresponding to larger values of k. In panel A the doubled

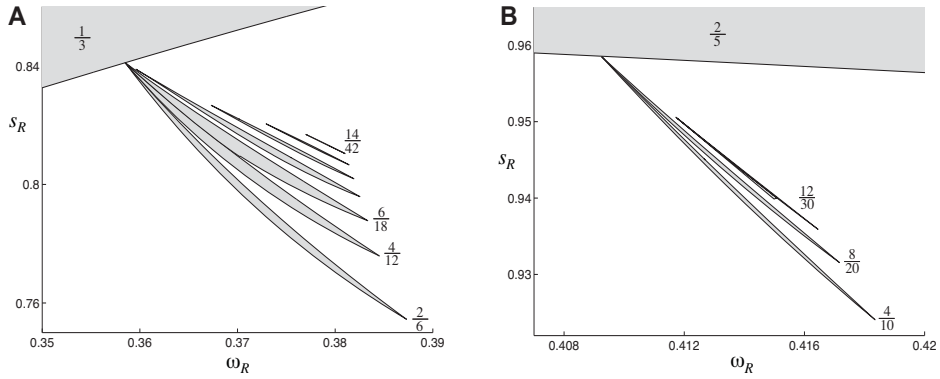

Figure 20. *Magnifications of panels A and B of Figure 7 near codimension-two flip bifurcations of (6). The shaded regions correspond to the existence of a stable orbit with the rotation numbers shown.*

orbits have symbol sequences $(\mathsf{LLR})^{2k-1}\mathsf{RRR}$; note that only the first three tongues in the sequence appear to emanate from the codimension-two point. In panel B the doubled orbits have symbol sequences $(\mathsf{LRLRR})^{2k-1}\mathsf{RRRRR}$, and only the first two tongues emanate from the codimension-two point.

4.4. Reducible rotation numbers. The rotation number of an n-cycle of the map (6) is a fraction m/n, where m is the number of times the orbit revolves around the fixed point in n steps. In this section we discuss the case in which m/n is a reducible fraction and describe new codimension-one bifurcations that do not seem to exist for the irreducible case. Furthermore, we will see that resonance regions associated with reducible rotation numbers do not appear to exhibit the familiar lens-chain structure.

An example with reducible rotation numbers is shown in Figure 21. Here there are three separate, adjoining resonance tongues. The tongue (abe) corresponds to parameters for which there exists a stable 3/9-cycle with symbol sequence LRLLRRRRL. The right-hand boundary of this region, (a-e), corresponds to a flip bifurcation. To the right of this boundary the 3/9-cycle exists but is not attracting. Throughout this tongue there also exists a saddle 3/9-cycle that collides and annihilates with the stable cycle in a usual border-collision bifurcation on the boundary (a-b).

The boundary (b-e) also corresponds to a border-collision bifurcation; however, here the 3/9-cycle persists above the boundary. Above this boundary the 3/9-cycle has symbol sequence RRLLRRRRL and is stable to the right of the boundary (d-i), which corresponds to a flip bifurcation. Along (b-d) a 6/18-cycle is created that exists above the boundary and is stable to the right of (c-g), which also corresponds to a flip bifurcation. This period-doubled cycle has a symbol sequence that is the concatenation of the symbol sequences of the two stable 3/9-cycles. Finally, the boundaries (g-h) and (f-i) correspond to border-collision bifurcations beyond which saddles of the same rotation number continue to exist.

Of all the border-collision boundaries that we have so far discussed, the boundary (d-e) is the only one for which stable n-cycles exist on both sides of the bifurcation. Also, of all the

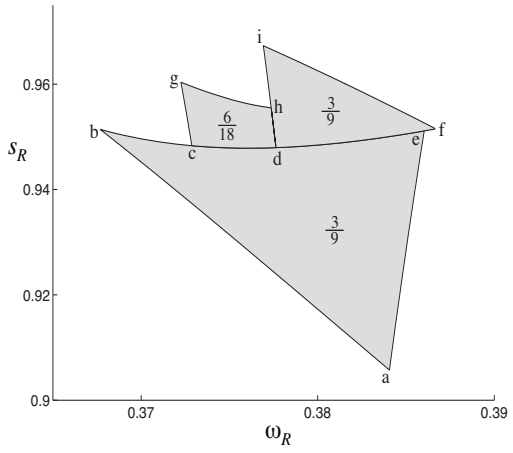

Figure 21. *Resonance tongues of* (6) *for* $\mu = 1$, $r_L = 0.475$, $\omega_L = 0.09$. *The bottom and upper right tongues correspond to a stable* 3/9*-cycle. The upper left tongue corresponds to a stable* 6/18*-cycle.*

codimension-one flip bifurcation boundaries so far discussed, the boundary (d-h) is the only one along which the period-doubled solution is stable. We have observed scenarios similar to Figure 21 for different rotation numbers. We conclude that periodic solutions for which the rotation number is a reducible fraction appear to exhibit a wider variety of codimension-one bifurcations than those with a rotation number that is irreducible. In particular, we do not see the familiar lens-chain structure.

4.5. Neimark–Sacker bifurcations of periodic solutions. Just as the fixed point can undergo a Neimark–Sacker bifurcation, so can a periodic orbit. When this bifurcation does not coincide with a border collision, the stability matrix $M_{\mathcal{S}}$ will have a pair of complex eigenvalues on the unit circle so that $\det(M_{\mathcal{S}}) = 1$. By (11) this corresponds to $r_L^l = s_R^{n-l}$, where l is the number of L's in $\mathcal{S}$. As an example, this bifurcation occurs for the period-three orbit LLR, when $(\mu, r_L, s_R, \omega_L) = (1, 0.5, 0.25, 0.25)$ and any $\omega_R \in (\hat{\omega}, \frac{1}{2})$, where $\hat{\omega} = \frac{1}{2\pi}\cos^{-1}(\frac{19}{32}) \approx 0.3512$. If the complex multiplier pair of an m/n orbit crosses the unit circle at $e^{2\pi i \frac{p}{q}}$ for an irreducible fraction p/q, there will exist uncountably many period-qn orbits with rotation numbers qm/qn at the bifurcation. Generically one of these cycles has two points on the switching manifold. In a similar manner as for the codimension-two flip bifurcation described in section 4.3, a qm/qn-resonance tongue emanates from this codimension-two Neimark–Sacker point in parameter space. However, we have not found an example with (6) for which the qn-cycle is stable.

4.6. Further complications. We have mostly considered the case $\mu > 0$ for the map (6). However, using the symmetry property (4), each stable (unstable) solution for $\mu > 0$ corresponds to an unstable (stable) solution of the same period and rotation number for $\mu < 0$ if the R and L parameters are exchanged. For some choices of parameter values, nontrivial periodic orbits can be observed for both signs of μ. For example, in panel A of Figure 22, we see an unstable 4-cycle for $\mu < 0$ and a stable 3-cycle for $\mu > 0$. Alternatively, a stable n-cycle can coexist with the stable fixed point. For example, in panel B of Figure 22, a stable 5-cycle coexists with the stable fixed point for $\mu < 0$, and a stable period-six orbit is created

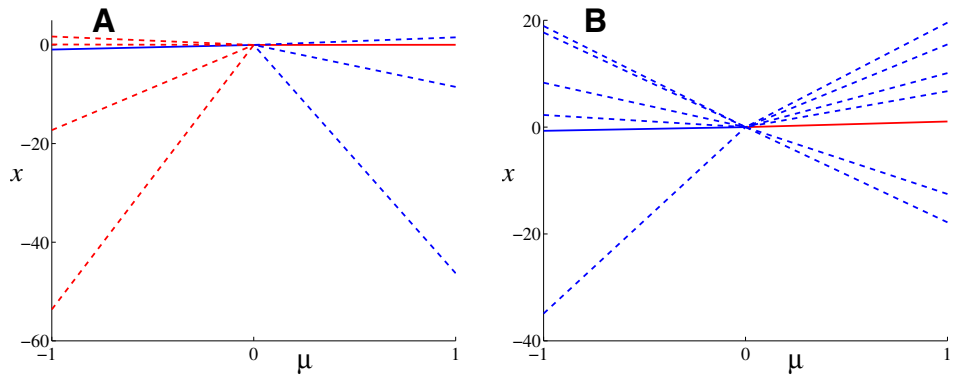

Figure 22. *Bifurcation diagrams of* (6) *for* $(r_L, s_R, \omega_L, \omega_R) = (0.2, 0.7, 0.49, 0.12)$ *in panel A and* $(0.25, 0.18, 0.25, 0.38)$ *in panel B. Blue (red) lines denote stable (unstable) solutions, solid lines correspond to the fixed point, and dashed lines correspond to periodic orbits.*

for $\mu > 0$.

Recall also from section 4.2 that multiple attractors may coexist. Similarly stable and unstable solutions with different periods may coexist, and various combinations of these phenomena may occur. The bifurcation at $\mu = 0$ may be extremely complex.

5. Conclusion. In this paper we have studied border-collision bifurcations of fixed points in planar, piecewise-smooth, continuous maps for the case that the multipliers are complex and "jump" from inside to outside the unit circle.

We investigated a piecewise-linear approximation (6), which we believe preserves local dynamics under the addition of nonlinear terms, except at higher codimension points such as at the boundaries of resonance tongues. For example, at shrinking points nonlinear terms may dramatically affect dynamics. The map (6) is a homeomorphism with a single fixed point that is stable for $\mu < 0$ and unstable for $\mu > 0$. We have found a large variety of periodic, quasiperiodic, and chaotic attractors for this system. Typically these attractors are created at the bifurcation, exist for one sign of μ, and grow in size linearly with respect to μ. These features are commonly observed in piecewise-smooth systems [8, 20] but are not typical in smooth systems. We have seen that, unlike the one-dimensional case, [8], multiple attractors may coexist in our two-dimensional map. Also, attractors may coexist with repellors; the bifurcation at $\mu = 0$ may be very complicated.

For some parameter values the border-collision bifurcation is analogous to that of a Neimark–Sacker bifurcation in a smooth map: an invariant circle is created that may be stable or unstable. As the parameters of the map are varied, the invariant circle may be destroyed. Though we investigated some of the ways in which this may occur, we have not given a complete classification.

Periodic orbits are classified by their symbol sequence $\mathcal{S}$ and rotation number m/n. Stable m/n-cycles exist in parameter regions (resonance tongues) that are bounded by curves of border-collision bifurcations or loss of stability. When m/n is an irreducible fraction, the resonance tongue has the form of a chain of lenses (also seen by [37, 27]); each lens corresponds to cycles with a particular symbol sequence. When m/n is reducible, lenses of the

associated resonance tongue may connect along intervals rather than at points. We observe a wider variety of border-collision bifurcations at boundaries of tongues with reducible rotation numbers.

There are many directions by which our investigations may be extended. For example, if we do not require that the multipliers of the fixed point are complex, just that they both jump from inside the unit circle to outside, we expect more complications to arise. In particular, for this case the map need not be a homeomorphism. We would like to extend our results here to higher dimensional maps; however, a center-manifold analysis cannot be applied to this bifurcation problem in the usual manner, and we are unaware of a theory of dimension reduction in piecewise-smooth systems.

Acknowledgment. We would like to thank Holger Dullin for many helpful discussions.

Master-Slave Global Stochastic Synchronization of Chaotic Oscillators*

Maurizio Porfiri† and Roberta Pigliacampo†

Abstract. We study global synchronization of coupled chaotic systems with random intermittent coupling. We use stochastic Lyapunov stability theory and partial averaging techniques to show that global synchronization is possible if the switching period is sufficiently small and if the oscillators globally synchronize under a time-averaged coupling. We study mean square and almost sure global synchronization, and we determine quantitative bounds for the exponential rate of decay of the synchronization error. We focus on master-slave synchronization, where two dynamical systems are coupled via a directed feedback that randomly switches among a finite set of given constant functions at a prescribed time rate. We apply the proposed approach to the synchronization of Chua circuits.

Key words. master-slave synchronization, global synchronization, stochastic synchronization, chaos, Chua circuit, exponential stability

1. Introduction.

Chaos synchronization is a topic of great interest, due to its observation in a huge variety of phenomena of different natures. In many biological systems, synchronization plays an important role in self-organization of organisms' groups [11]. Examples of synchronization include communication among fireflies [10, 37], locomotion of animals [14], molecular and cellular activity [26], and cardiac stimulation [23, 29, 46]. The study of neural activity [48, 58, 68] and brain disorders [3, 57] is a correlated issue as well. Other examples of synchronization can be found in ecological systems [6], meteorology [18], chemistry [26, 39], gas-liquid bubbling dynamics [61, 66], and optics [59, 67]. Many reviews on chaos synchronization are currently available; see, for example, [2, 7, 13, 25, 47, 52, 54].

In the literature, different paradigms have been proposed to enforce synchronization of two or more coupled chaotic oscillators. We mention, among the others, peer-to-peer coupling [4, 24, 56, 60, 64], back-stepping [8], generalized synchronization [71, 72], phase synchronization [7], and master-slave synchronization [12, 22, 28, 33, 34, 43, 49, 50, 51, 65, 72, 73]. In this work, we focus on master-slave synchronization. In this case, one system acts as a "master" by driving the other system that behaves consequently as a "slave."

Most of the research efforts on chaos synchronization focus on time-invariant coupling [2, 7, 13, 25, 47, 52, 54]. Nevertheless, experimental and numerical evidence on master-slave synchronization shows that synchronization can also be achieved using time-varying intermittent feedback coupling [22, 33, 72, 73]. In [22], experimental results on synchronization

†Mechanical and Aerospace Engineering Department, Polytechnic University, Brooklyn, NY 11201 (mporfiri@poly.edu, rpigli01@utopia.poly.edu).

of two periodically coupled chaotic circuits are presented. In [33, 72], the slave system is driven by a sequence of samples of the master's state. In [73], the signal transmission from the master to the slave system is adaptively controlled. That is, the driving signal is transmitted only when it is expected to reduce the synchronization error.

In this work, we establish sufficient conditions for global exponential synchronization of coupled chaotic systems with random intermittent coupling. We associate to the stochastic system a partially averaged system describing synchronization under time-constant coupling. We transform the synchronization problem into a nonlinear stochastic stability problem by describing the system's dynamics through the synchronization error. We present a general framework for assessing global exponential stability of switched stochastic systems from global exponential stability of their time-averaged counterparts. Under certain regularity conditions, we show that global exponential synchronization of intermittently coupled oscillators is possible if the oscillators exponentially synchronize under a time-constant average coupling and if the coupling is switching sufficiently quickly. In addition, we provide a rigorous estimate for the slowest fast-switching rate that guarantees global synchronization. We particularize our findings to linearly coupled oscillators, where intermittent coupling is made possible through a switching linear state feedback. The switching feedback gain changes randomly over time while assuming values among a finite set of constant values. For this configuration, global exponential synchronization of the partially averaged system can be studied using well-established and manageable techniques based on Lyapunov stability theory and Gerschgorin's theorem, such as those presented in [34].

Synchronization of oscillator networks under intermittent fast-switching coupling is also studied in [4, 56, 64] in case of peer-to-peer synchronization. In [56, 64], only local asymptotic synchronization results based on linearized dynamics are presented, while this work and [4] focus on global synchronization by retaining the nonlinear nature of the coupled systems. In [4], a new type of small-world network of cells with chaotic oscillators is investigated. Cells are coupled through a time-varying network that consists of a fixed, so-called *pristine network* and intermittent links between any pair of cells that are used to describe small-world dynamical effects. As shown by the authors, intermittent links facilitate synchronization of the oscillator network by reducing the synchronization threshold. Time-varying interconnections are considered as binary independent identically distributed random variables. That is, they do not influence each other, they have the same probability to be present, and when they are on, they share the same strength. In addition, time-varying interconnections are allowed to change only simultaneously and at equally spaced instants of time, thereby fixing the switching rate of the time-varying network to a constant value. The authors determine rigorous bounds for the strength of the intermittent coupling and the switching rate to guarantee global asymptotic synchronization of the oscillator network for almost all the switching sequences, that is, global asymptotic almost sure synchronization. The claims are proved by showing that, under some general hypotheses, there exists an autonomous quadratic Lyapunov function for the synchronization error dynamics that asymptotically goes to zero for almost all the switching sequences. The autonomous quadratic Lyapunov function is constructed from a thorough analysis of the synchronization problem over the time-averaged network topology based on the connection graph stability method [5].

In this paper, we extend the mathematical tools presented in [4] to global exponential

synchronization of coupled oscillators. Beyond analyzing almost sure synchronization, we also focus on mean square synchronization. That is, we derive conditions for the second moment of the error dynamics to converge to zero. Mean square and almost sure convergence of stochastic processes are in general not equivalent [30, 69]. For example, if a stochastic process takes on increasingly large values with decreasing probability and the rate of increase is sufficiently fast, then it may converge almost surely while its moments diverge; see, for example, [42]. Derived results on mean square synchronization can be potentially useful in assessing the effects of perturbations and unmodeled dynamics on synchronizability of oscillator networks; see, for example, the approaches outlined in [17, 70]. We provide rigorous bounds for the exponential rate of decay of the synchronization error dynamics. In particular, we analyze the exponential rate of convergence to zero of the error second moment and of the probability of the error norm to be larger than a threshold value. Estimating these convergence rates can be potentially useful in assessing the coupling performance and in optimizing the design of time-varying coupling strategies. In addition, unlike [4], we consider time-varying interconnections that can in principle assume a variety of values and change at a nonconstant but bounded switching rate. One of the main contributions of our work is Theorem 2.4, which extends recent results on Lyapunov stability theory [1] and averaging methods [27, 53] for deterministic dynamical systems to stochastic systems. Theorem 2.4 applies to a large class of nonautonomous candidate Lyapunov functions, including the autonomous quadratic candidate Lyapunov functions considered in [4]. In addition, it yields general conditions for exponential stability of stochastic nonautonomous nonlinear systems that include as a special case the results in [4].

The system studied in this paper finds many practical applications. For example, in communication and signal processing, chaotic behavior can be used for message encryption and secure communication [16, 19, 20, 32, 35, 45]. Higher communication efficiency can be potentially achieved through sporadic transmission of the driving signal. This is particularly useful when the available resources are shared and the amount of information that can be transmitted is limited.

We organize the paper as follows. In section 2, we present our general results on stability of nonlinear stochastic systems. In section 3, we apply these results to the master-slave synchronization problem. As a sample case, in section 4 we consider the case of two stochastically coupled Chua circuits. Section 5 is left for conclusions.

2. Global exponential stability through fast-switching. We consider the integral equation in $\mathbb{R}^n$

$$x(t) = x(\sigma_k) + \int_{\sigma_k}^{t} f(x(\xi), \xi, \Omega) d\xi, \tag{2.1}$$

where $t \in [\sigma_k, \sigma_{k+1})$, $\sigma_k = k\varepsilon$, $\varepsilon > 0$, $k \in \mathbb{Z}^+$, and n is a positive integer. The function f is defined in $\mathbb{R}^n \times \mathbb{R}^+ \times \Theta$ and is piecewise continuous with respect to t. Here, Ω is a discrete random variable taking values in the finite set $\Theta = \{\omega_1, \ldots, \omega_N\}$, with N a positive integer. We assume that the origin is an equilibrium of every sample system; that is, $f(0, t, \omega) = 0$ for every $t \in \mathbb{R}^+$ and every $\omega \in \Theta$. We further assume that for every $\omega \in \Theta$ the function $f_\omega(\bullet, \bullet) = f(\bullet, \bullet, \omega)$ is globally Lipschitz in $\mathbb{R}^+$, with Lipschitz constant $L_{\omega,\varepsilon}$. In addition, we

require that $L_{\omega,\varepsilon} \leq L$, where L is a constant independent of ω and ε. We note that (2.1) describes a Markovian nonlinear nonhomogeneous jump system; see, for example, [15]. We study the solutions of (2.1) for $t \geq t_0 \in \mathbb{R}^+$ and initial conditions $x(t_0) = x_0$.

In what follows, we use $\mathsf{E}[\bullet]$ to indicate expectation, we denote probability with $P\{\bullet\}$, and we use "a.s." for abbreviating "almost sure" or "with probability one"; see, for example, [30]. We refer to $\| \bullet \|$ as the Euclidean norm in $\mathbb{R}^n$ or the corresponding induced norm in $\mathbb{R}^{n\times n}$. We use the superscript T for matrix transposition. For brevity, we refer to the stability of the origin as the system stability.

In this section, we establish sufficient conditions for global stability of the stochastic system (2.1). To this aim, we recall the definitions of global mean square exponential stability (see, for example, [21, 44]) and global almost sure exponential stability (see, for example, [44]). As stated in section 1, mean square stability and almost sure stability are in general not equivalent. The relationship between these concepts in stochastic observer design has been studied in [69], whereas a comparison between them in the analysis of asynchronous systems with Poisson transitions can be found in [42].

Definition 2.1. *The system* (2.1) *is globally mean square exponentially stable if there exist* $\alpha \geq 0$ *and* $\beta > 0$ *such that for any* $x_0 \in \mathbb{R}^n$ *and* $t_0 \in \mathbb{R}^+$

$$\mathsf{E}[\|x(t)\|^2] \leq \alpha \|x_0\|^2 e^{-\beta(t-t_0)}$$

$\forall t \geq t_0$.

Definition 2.2. *The system* (2.1) *is globally almost surely exponentially stable if there exist a constant* $\zeta \geq 0$ *and a positive bounded random variable* ϱ *such that for any* $x_0 \in \mathbb{R}^n$ *and* $t_0 \in \mathbb{R}^+$

$$\|x(t)\| \leq \varrho e^{-\zeta(t-t_0)}$$

a.s. $\forall t \geq t_0$.

From classical Lyapunov stability theory, it is well known that a deterministic dynamical system is uniformly asymptotically stable if there exists a positive definite decrescent candidate Lyapunov function whose time derivative along the solutions of the system is strictly negative definite; see, for example, [36]. In [1], this condition is relaxed, and it is shown that if the candidate Lyapunov function decreases when evaluated at a discrete sequence of time instants, the system is uniformly asymptotically stable. In this case, the time derivative of the Lyapunov function can assume positive and negative values. The following theorem extends the results of [1] from the deterministic to the stochastic case and serves as a preliminary result to establish our main claim, that is, Theorem 2.4.

Theorem 2.3. *Consider the system* (2.1)*, and suppose that there exists a function* $V : \mathbb{R}^n \times \mathbb{R}^+ \to \mathbb{R}$ *such that* $\forall (x,t) \in \mathbb{R}^n \times \mathbb{R}^+$

$$\lambda_{min}\|x\|^2 \leq V(x,t) \leq \lambda_{max}\|x\|^2 \tag{2.2}$$

with λ_{min} *and* λ_{max} *positive nonzero real constants. Assume also that there exists* ν*, with* $0 < \nu \leq 1$*, such that*

$$\mathsf{E}[V(x(\sigma_{k+1}),\sigma_{k+1})|x(\sigma_k)] - V(x(\sigma_k),\sigma_k) \leq -\nu V(x(\sigma_k),\sigma_k) \tag{2.3}$$

for every $k \in \mathbb{Z}^+$. Then, (2.1) is globally mean square exponentially stable and globally almost surely exponentially stable.

Proof. See Appendix A. ∎

Remark 1. *In the literature, different definitions of almost sure exponential stability for stochastic differential equations of the kind of (2.1) have been proposed; see, for example, [44, 40]. In this work we use the definition of [44], which, loosely speaking, enforces the exponential stability of almost all the sample systems in the deterministic sense. On the other hand, the exponential stability notion introduced in [40] implies that the probability that $\|x(t)\|$ is greater than or equal to a given quantity decreases with an exponential decay. A detailed discussion on the differences among used stability notions for stochastic systems can be found in [38]. For completeness, in Appendix A we also show that under the hypotheses of Theorem 2.3, (2.1) is globally almost surely exponentially stable in the sense of [40].*

We associate to (2.1) the partially averaged system

$$\dot{x}(t) = \overline{f}(x(t), t) = \mathsf{E}[f(x(t), t, \Omega)]. \tag{2.4}$$

Equation (2.4) represents a deterministic nonautonomous nonlinear system. We notice that the origin is an equilibrium of the partially averaged system; that is, $\overline{f}(0, t) = 0$ for every $t \in \mathbb{R}^+$. If (2.4) is globally exponentially stable, by the converse theorem of Lyapunov (see [36, Theorem 3.12]) we know that there exists a function V that is bounded by quadratic forms of x and whose time derivative is strictly negative definite along the system trajectories; see, for example, (2.5) and (2.6) below. In the following theorem, we show that if V satisfies further regularity conditions and the switching period is sufficiently small, the original system (2.1) is globally mean square exponentially stable and globally almost surely exponentially stable.

Theorem 2.4. *Consider the system (2.1) and the associated partially averaged system (2.4), and suppose that there exists a function $V(x, t)$ which satisfies the following conditions:*

1. *There exist positive real numbers λ_{min} and λ_{max} such that for every $(x, t) \in \mathbb{R}^n \times \mathbb{R}^+$*

$$\lambda_{min}\|x\|^2 \leq V(x, t) \leq \lambda_{max}\|x\|^2. \tag{2.5}$$

2. *There exists $w > 0$ such that for every $(x, t) \in \mathbb{R}^n \times \mathbb{R}^+$*

$$\frac{\partial V}{\partial t}(x, t) + \frac{\partial V}{\partial x}(x, t)\overline{f}(x, t) \leq -w\|x\|^2. \tag{2.6}$$

3. *$\forall t \in \mathbb{R}^+$, $\frac{\partial V}{\partial x}(0, t) = 0$ and $\frac{\partial V}{\partial x}$ is globally Lipschitz with Lipschitz constant C_v. Moreover, for every $t \in \mathbb{R}^+$, $\frac{\partial^2 V}{\partial x \partial t}(0, t) = 0$ and $\frac{\partial^2 V}{\partial x \partial t}$ is globally Lipschitz with Lipschitz constant C_{vt}.*

There exists an $\varepsilon^* > 0$ such that $\forall \varepsilon < \varepsilon^*$ system (2.1) is globally mean square exponentially stable and globally almost surely exponentially stable. The function $V(x, t)$ is called a Lyapunov function.

Proof. The derivative of V along the solution of (2.1) is

$$\dot{V}(x(t), t) = \frac{\partial V}{\partial t}(x(t), t) + \frac{\partial V}{\partial x}(x(t), t) f(x(t), t, \Omega). \tag{2.7}$$

For every nonnegative integer k, we define

$$\Delta V(\sigma_{k+1},\sigma_k)=\mathsf{E}[V(x(\sigma_{k+1}),\sigma_{k+1})|x(\sigma_k)]-V(x(\sigma_k),\sigma_k). \tag{2.8}$$

From (2.1), (2.7), and (2.8) we have

$$\begin{aligned}\Delta V(\sigma_{k+1},\sigma_k)&=\mathsf{E}\left[\int_{\sigma_k}^{\sigma_{k+1}}\dot{V}(x(t),t)dt\right]\\&=\mathsf{E}\left[\int_{\sigma_k}^{\sigma_{k+1}}\frac{\partial V}{\partial t}(x(t),t)+\frac{\partial V}{\partial x}(x(t),t)f(x(t),t,\Omega)dt\right]\\&=\mathsf{E}\left[\int_{\sigma_k}^{\sigma_{k+1}}\frac{\partial V}{\partial x}(x(t),t)f(x(t),t,\Omega)-\frac{\partial V}{\partial x}(x(\sigma_k),t)f(x(\sigma_k),t,\Omega)dt\right]\\&\quad+\mathsf{E}\left[\int_{\sigma_k}^{\sigma_{k+1}}\frac{\partial V}{\partial t}(x(t),t)-\frac{\partial V}{\partial t}(x(\sigma_k),t)dt\right]\\&\quad+\mathsf{E}\left[\int_{\sigma_k}^{\sigma_{k+1}}\frac{\partial V}{\partial t}(x(\sigma_k),t)+\frac{\partial V}{\partial x}(x(\sigma_k),t)f(x(\sigma_k),t,\Omega)dt\right].\end{aligned} \tag{2.9}$$

We seek an upper bound for the absolute values of the three terms in the summation above. We start our analysis by considering the first and second terms. Using the Lipschitz conditions on f_ω and on the first and second derivatives of V and following the argument of [53, parts II and III of the proof of Theorem 2] for each realization ω of Ω, we have

$$\begin{aligned}&\left|\int_{\sigma_k}^{\sigma_{k+1}}\frac{\partial V}{\partial x}(x(t),t)f(x(t),t,\omega)\right.\\&\qquad\left.-\frac{\partial V}{\partial x}(x(\sigma_k),t)f(x(\sigma_k),t,\omega)dt\right|\le 2L_{\omega,\varepsilon}^2C_ve^{2\varepsilon L_{\omega,\varepsilon}}\varepsilon^2\|x(\sigma_k)\|^2,\\&\left|\int_{\sigma_k}^{\sigma_{k+1}}\frac{\partial V}{\partial t}(x(t),t)-\frac{\partial V}{\partial t}(x(\sigma_k),t)dt\right|\le L_{\omega,\varepsilon}C_{vt}e^{2\varepsilon L_{\omega,\varepsilon}}\varepsilon^2\|x(\sigma_k)\|^2.\end{aligned}$$

Since $\sum_{i=1}^N P\{\Omega=\omega_i\}=1$ and $L_{\omega,\varepsilon}\le L$ for each ω and ε, the absolute value of the first term of the summation (2.9) is less than or equal to

$$2L^2C_ve^{2\varepsilon L}\varepsilon^2\|x(\sigma_k)\|^2.$$

In addition, the absolute value of the second term is less than or equal to

$$LC_{vt}e^{2\varepsilon L}\varepsilon^2\|x(\sigma_k)\|^2.$$

Now, we consider the third term on the right side of (2.9):

$$\begin{aligned}&\mathsf{E}\left[\int_{\sigma_k}^{\sigma_{k+1}}\frac{\partial V}{\partial t}(x(\sigma_k),t)+\frac{\partial V}{\partial x}(x(\sigma_k),t)f(x(\sigma_k),t,\Omega)dt\right]\\&\qquad=\mathsf{E}\left[\int_{\sigma_k}^{\sigma_{k+1}}\frac{\partial V}{\partial t}(x(\sigma_k),t)+\frac{\partial V}{\partial x}(x(\sigma_k),t)\overline{f}(x(\sigma_k),t)dt\right]\\&\qquad\quad+\mathsf{E}\left[\int_{\sigma_k}^{\sigma_{k+1}}\frac{\partial V}{\partial x}(x(\sigma_k),t)\{f(x(\sigma_k),t,\Omega)-\overline{f}(x(\sigma_k),t)\}dt\right].\end{aligned}$$

By hypothesis, (2.6) provides a bound for the integrand in the first term in the summation above, while the second term is equal to zero. Using the above computed bounds in (2.9), we find

$$\Delta V(\sigma_{k+1}, \sigma_k) \leq [g(\varepsilon) - w\varepsilon]\|x(\sigma_k)\|^2, \tag{2.10}$$

where the function $g(\varepsilon)$ is defined by

$$g(\varepsilon) = (2L^2 C_v e^{2\varepsilon L} + LC_{vt} e^{2\varepsilon L})\varepsilon^2. \tag{2.11}$$

Noticing that $g(0) = 0$ and $g'(0) = 0$, we have that there exists $\varepsilon^* > 0$ such that

$$\Delta V(\sigma_{k+1}, \sigma_k) \leq -\overline{w}\|x(\sigma_k)\|^2, \tag{2.12}$$

where $\overline{w} = [w\varepsilon - g(\varepsilon)] > 0$ for every $\varepsilon < \varepsilon^*$. In conclusion, if the switching period ε is sufficiently small, (2.5), (2.8), and (2.12) imply that the hypotheses of Theorem 2.3 are satisfied. Thus the claim follows. ■

Remark 2. *We assumed that ε is a fixed period of time. This hypothesis can be relaxed. In fact, Theorem 2.4 can be generalized considering not equally spaced switching instants. If the maximum time distance between two adjacent switching events is ε_{max}, (A.9) in Theorem 2.3 still holds with $\gamma = e^{L\varepsilon_{max}}$, while Theorem 2.4 holds with $\varepsilon_{max} \leq \varepsilon^*$.*

Remark 3. *Theorem 2.4 applies to a large class of candidate Lyapunov functions, including autonomous quadratic functions of the type $V(x,t) = x^T Px$, where P is a symmetric positive definite constant matrix. Autonomous quadratic candidate Lyapunov functions are considered in [4]. In this case, conditions 1 and 3 of Theorem 2.4 are automatically satisfied. In fact, (2.5) holds for $\lambda_{min} = \min\{\lambda(P)\}$ and $\lambda_{max} = \max\{\lambda(P)\}$, since P is a constant matrix (here, $\lambda(\bullet)$ indicates the spectrum of the matrix). Furthermore, condition 3 of Theorem 2.4 is satisfied with $C_v = 2\|P\|$ and $C_{vt} = 0$. The claims of Theorem 2.4 imply as a special case the global almost sure asymptotic stability results proved in [4] for the class of small-world networks considered therein.*

3. Master-slave synchronization.

3.1. Problem statement.

We consider the master system

$$\dot{x}(t) = Ax(t) + g(x(t)) + u(t), \tag{3.1}$$

where $x(t) \in \mathbb{R}^n$ is the state vector, $u(t) \in \mathbb{R}^n$ is the input vector, $A \in \mathbb{R}^{n\times n}$ is a constant matrix, g is a nonlinear function, n is a positive integer, and $t \in \mathbb{R}^+$ indicates the time variable. We construct a slave system for (3.1):

$$\dot{\widetilde{x}}(t) = A\widetilde{x}(t) + g(\widetilde{x}(t)) + u(t) + K(t)(x(t) - \widetilde{x}(t)). \tag{3.2}$$

System (3.2) is unidirectionally coupled to the master system (3.1) through the feedback gain matrix function $K(t)$. We consider the case where $K(t)$ is a piecewise constant signal that, in every time interval $[\sigma_k, \sigma_{k+1})$, with $\sigma_k = k\varepsilon$, $\varepsilon > 0$, and $k \in \mathbb{Z}^+$, equals the random variable $\mathfrak{K}_k$. We assume that the random variables $\mathfrak{K}_k$ are independent and identically distributed discrete

random variables that take values in the finite set $\{K_1, K_2, \ldots, K_N\}$, with N a positive integer. We refer to $\mathfrak{K}$ as the common random variable describing the full set of random variables $\{\mathfrak{K}_k\}_{k=0}^{\infty}$. Following [34], we assume that

$$g(x) - g(\widetilde{x}) = M_{x,\widetilde{x}}(x - \widetilde{x})$$

for some bounded matrix $M_{x,\widetilde{x}}$, whose elements depend on x and $\widetilde{x}$. As discussed in [34], this condition applies to a large variety of chaotic systems. We note that assuming the matrix $M_{x,\widetilde{x}}$ is bounded does not imply that the oscillators' states are bounded.

We express the system of equations (3.1) and (3.2) in terms of the error function $e = x - \widetilde{x}$:

$$\begin{aligned} \dot{e}(t) &= Ae(t) + g(x(t)) - g(\widetilde{x}(t)) - K(t)e(t) \\ &= (A - K(t))e(t) + M_{x(t),x(t)-e(t)}e(t). \end{aligned} \tag{3.3}$$

The stochastic nonautonomous nonlinear system in (3.3) can be written in the form (2.1), where f is defined by

$$f(e, t, \mathfrak{K}) = (A - \mathfrak{K} + M_{x(t),x(t)-e})e. \tag{3.4}$$

We say that the two oscillators in (3.1) and (3.2) globally mean square synchronize if the error system in (3.3) is globally mean square exponentially stable; see Definition 2.1. Similarly, we say that the two oscillators in (3.1) and (3.2) globally almost surely synchronize if the error system in (3.3) is globally almost surely exponentially stable; see Definition 2.2.

We note that, for $i = 1, \ldots, N$, the function $f_i = f(\bullet, \bullet, K_i)$ is globally Lipschitz in $\mathbb{R}^+$ with Lipschitz constant $L_i = \|A\| + m + \|K_i\|$, where $\|M\| \leq m$. In addition, the Lipschitz constants L_i are bounded by $L = \|A\| + m + \max_{1\leq i\leq N}\{\|K_i\|\}$. We further notice that $f(0, t, K_i) = 0\ \forall t \in \mathbb{R}^+$.

3.2. Global stochastic synchronization. In this section, we combine the general findings of section 2 on stochastic stability of nonlinear systems with available results on synchronizability of deterministic master-slave systems to provide sufficient conditions for global synchronization of the master-slave system described by (3.1) and (3.2) under fast-switching conditions. In particular, we make use of the results of [34], where a criterion for assessing global exponential stability of (3.3) is given in the case of constant feedback gain.

We associate to the system (3.3) the partially averaged system

$$\dot{e}(t) = (A + M_{x(t),x(t)-e(t)})e(t) - \overline{K}e(t), \tag{3.5}$$

where $\overline{K} = \mathsf{E}[K(t)] = \sum_{i=1}^{N} p_i K_i$ is the time-averaged constant feedback gain. Here, p_i indicates the probability of $K(t)$ assuming value K_i, that is, $p_i = P\{\mathfrak{K} = K_i\}$.

Global exponential stability of (3.5), that is, global exponential synchronization of the master-slave system under constant feedback coupling $\overline{K}$, can be enforced using the results of [34]. For clarity, we restate here the main theorem of [34] adapted to the present notation.

Theorem 3.1. *The system* (3.5) *is globally exponentially stable if the feedback gain matrix* $\overline{K}$ *is chosen such that*

$$\bar{l}_i(\xi, t) \leq -w < 0, \quad i = 1, 2, \ldots, n,$$

for every $\xi \in \mathbb{R}^n$ *and* $t \in \mathbb{R}^+$, *where the* $\bar{l}_i(\xi, t)$*'s are the eigenvalues of the matrix*

$$Q(\xi, t) = (A - \overline{K} + M_{x(t),x(t)-\xi})^T P + P(A - \overline{K} + M_{x(t),x(t)-\xi})$$

and P *is a positive definite symmetric constant matrix. A Lyapunov function for* (3.5) *can be constructed as*

$$V(e) = e^T P e \tag{3.6}$$

with

$$\dot{V}(e(t)) = e^T(t) Q(e(t), t) e(t) \leq -w\|e(t)\|^2. \tag{3.7}$$

The Lyapunov function (3.6) constructed for the partially averaged system can be used to assess the stability of the stochastic system. In fact, (3.7) is equivalent to (2.6), and conditions 1 and 3 of Theorem 2.4 are automatically satisfied as observed in Remark 3. Equation (2.12), specified for the case at hand, reads

$$2L^2 C_v e^{2L\varepsilon}\varepsilon^2 - w\varepsilon = 0, \tag{3.8}$$

and it yields the sought value of ε^*. By applying Theorem 2.4, we claim that the system (3.3) is globally mean square exponentially stable and globally almost surely exponentially stable $\forall \varepsilon < \varepsilon^*$. We summarize the above arguments in the following corollary.

Corollary 3.2. *Consider the system* (3.3) *and the corresponding partially averaged system* (3.5). *If the feedback gain matrix* $K(t)$ *is chosen such that*

$$\bar{l}_i(\xi, t) \leq -w < 0, \quad i = 1, 2, \ldots, n, \tag{3.9}$$

for every $\xi \in \mathbb{R}^n$ *and* $t \in \mathbb{R}^+$, *where the* $\bar{l}_i(\xi, t)$*'s are the eigenvalues of the matrix*

$$Q(\xi, t) = (A - \overline{K} + M_{x(t),x(t)-\xi})^T P + P(A - \overline{K} + M_{x(t),x(t)-\xi}) \tag{3.10}$$

and P *is a positive definite symmetric constant matrix, then there exists an* $\varepsilon^* > 0$ *such that* $\forall \varepsilon < \varepsilon^*$ *the system* (3.3) *is globally mean square exponentially stable and globally almost surely exponentially stable. The time duration* ε^* *is the nonzero solution of* (3.8).

Remark 4. *The conditions of Corollary* 3.2 *do not generally constrain the structure of the feedback gain matrices* $\{K_1, \ldots, K_N\}$. *In the special case where the feedback gains* $\{K_1, \ldots, K_N\}$ *and the probabilities* $\{p_1, \ldots, p_N\}$ *lead to a diagonal time-averaged feedback gain matrix* $\overline{K}$ *and the matrix* P *is diagonal, inequalities* (3.9) *may be directly enforced using Gerschgorin's theorem, as illustrated in* [34].

Remark 5. *The type of intermittent coupling considered in this paper has been also analyzed in the framework of consensus theory* [31, 55]. *However, in consensus theory, the individual systems' dynamics is linear, while in the present case the coupled systems are strongly nonlinear.*

4. Case study: Synchronization of two chaotic Chua circuits. As an example, we apply our results to synchronization of Chua circuits; see, for example, [62]. A Chua circuit system is described by

$$\begin{cases} \dot{x_1} &= a(x_2 - x_1 - h(x_1)), \\ \dot{x_2} &= x_1 - x_2 + x_3, \\ \dot{x_3} &= -bx_2, \end{cases} \tag{4.1}$$

where $a > 0$, $b > 0$, and the nonlinear function h has the form

$$h(x_1) = m_1 x_1 + \frac{1}{2}(m_0 - m_1)\{|x_1 + 1| - |x_1 - 1|\} \tag{4.2}$$

with $m_0 < 0$ and $m_1 < 0$. We define

$$h(x_1) - h(\widetilde{x}_1) = w_{x_1,\widetilde{x}_1}(x_1 - \widetilde{x}_1), \tag{4.3}$$

where $w_{x_1,\widetilde{x}_1}$ depends on x_1 and $\widetilde{x}_1$ and is bounded by $m_0 \leq w_{x_1,\widetilde{x}_1} \leq m_1$; see, for example, [34].

We consider the case where $K(t)$ is a diagonal matrix. Following (3.2), the slave system of (4.1) is constructed as follows:

$$\begin{cases} \dot{\widetilde{x}}_1 &= a(\widetilde{x}_2 - \widetilde{x}_1 - h(\widetilde{x}_1)) + k_1(t)(x_1 - \widetilde{x}_1), \\ \dot{\widetilde{x}}_2 &= \widetilde{x}_1 - \widetilde{x}_2 + \widetilde{x}_3 + k_2(t)(x_2 - \widetilde{x}_2), \\ \dot{\widetilde{x}}_3 &= -bx_2 + k_3(t)(x_3 - \widetilde{x}_3). \end{cases} \tag{4.4}$$

Combining (4.1) and (4.4), we obtain (3.3) with

$$A = \begin{bmatrix} -a & a & 0 \\ 1 & -1 & 1 \\ 0 & -b & 0 \end{bmatrix}, \quad K(t) = \begin{bmatrix} k_1(t) & 0 & 0 \\ 0 & k_2(t) & 0 \\ 0 & 0 & k_3(t) \end{bmatrix}, \quad g(x) = \begin{bmatrix} -ah(x) \\ 0 \\ 0 \end{bmatrix}.$$

We observe that $g(x) - g(\widetilde{x}) = M_{x,x-e}e$ with

$$M_{x,x-e} = \begin{bmatrix} -aw_{x_1,x_1-e_1} & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \tag{4.5}$$

and $\|M\| \leq a|m_0|$.

We associate to the system (3.3) the partially averaged system

$$\dot{e} = Ae + M_{x,x-e}e - \overline{K}e, \tag{4.6}$$

where

$$\overline{K} = \begin{bmatrix} \overline{k}_1 & 0 & 0 \\ 0 & \overline{k}_2 & 0 \\ 0 & 0 & \overline{k}_3 \end{bmatrix}. \tag{4.7}$$

By choosing $P = I$ and by setting

$$\begin{aligned} \overline{k}_1 &\geq \frac{1}{2}(1 - a - 2am_0 + w), \\ \overline{k}_2 &\geq \frac{1}{2}(a - 1 + |1 - b| + w), \\ \overline{k}_3 &\geq \frac{1}{2}(|1 - b| + w), \end{aligned} \tag{4.8}$$

the partially averaged system is globally exponentially stable [34]. This follows directly from Gerschgorin's theorem, as anticipated in Remark 4. We also have $C_v = 2$, and $L = \|A\| + a|m_0| + \max_{1\leq i\leq N}\{\|K_i\|\}$. Equation (3.8) gives the value of ε^* that ensures the global mean square exponential stability and the global almost sure exponential stability of the stochastic system $\forall \varepsilon < \varepsilon^*$.

Here, we present a few numerical results that illustrate how two stochastically coupled Chua circuits synchronize for a sufficiently fast switching rate. We select $a = 9.78$, $b = 14.97$, $m_0 = -1.31$, and $m_1 = -0.75$ in order to have chaotic behavior of the system [34]. We let $K(t)$ switch randomly between the two constant matrices K_1 and K_2, where K_1 is the zero matrix and

$$K_2 = \begin{bmatrix} 20 & 0 & 0 \\ 0 & 27.5 & 0 \\ 0 & 0 & 20 \end{bmatrix}. \tag{4.9}$$

For these parameters we have $\|A\| = 18.89$, $\max_{1\leq i\leq N}\{\|K_i\|\} = \|K_2\| = 27.5$, and $L = 59.20$. Selecting $p_1 = 0.6$ and $p_2 = 0.4$, w can be chosen from (4.8) to be equal to 0.5. From (3.8) we have that for $\varepsilon \leq \varepsilon^* = 3.56 \times 10^{-5}$ the system synchronizes globally mean square exponentially and globally almost surely exponentially. Figure 1 depicts the trajectories of the master and slave systems on the x_1-x_2 and x_1-x_3 planes for $\varepsilon = 10^{-5}$. This figure shows that the two systems synchronize even if the initial conditions are significantly different.

5. Conclusions. In this paper, we presented a general criterion for global synchronization of randomly coupled chaotic oscillators. We focus on the case of two oscillators in master-slave configuration. The two systems are coupled through a stochastic unidirectional feedback that is realized through a switching function that switches randomly among a finite set of constant values. Using tools based on Lyapunov stability and partial averaging we showed that, under suitable regularity conditions, the synchronization characteristics of the partially averaged system are inherited by the stochastic system. Our findings are illustrated through numerical simulations on Chua circuits. The proposed approach can be applied to global synchronization of complex networks and seems particularly promising for analyzing pinning-controllability (see, for example, [63]) with intermittent control.

The main claim on stochastic stability of this work, Theorem 2.4, applies to a large class of stochastic nonautonomous nonlinear systems and Lyapunov functions. In particular, it can be applied to autonomous quadratic Lyapunov functions, such as those studied in [4]. In addition, our main claim yields strong conditions on global exponential stability that include, as a special case, the asymptotic stability results derived in [4].

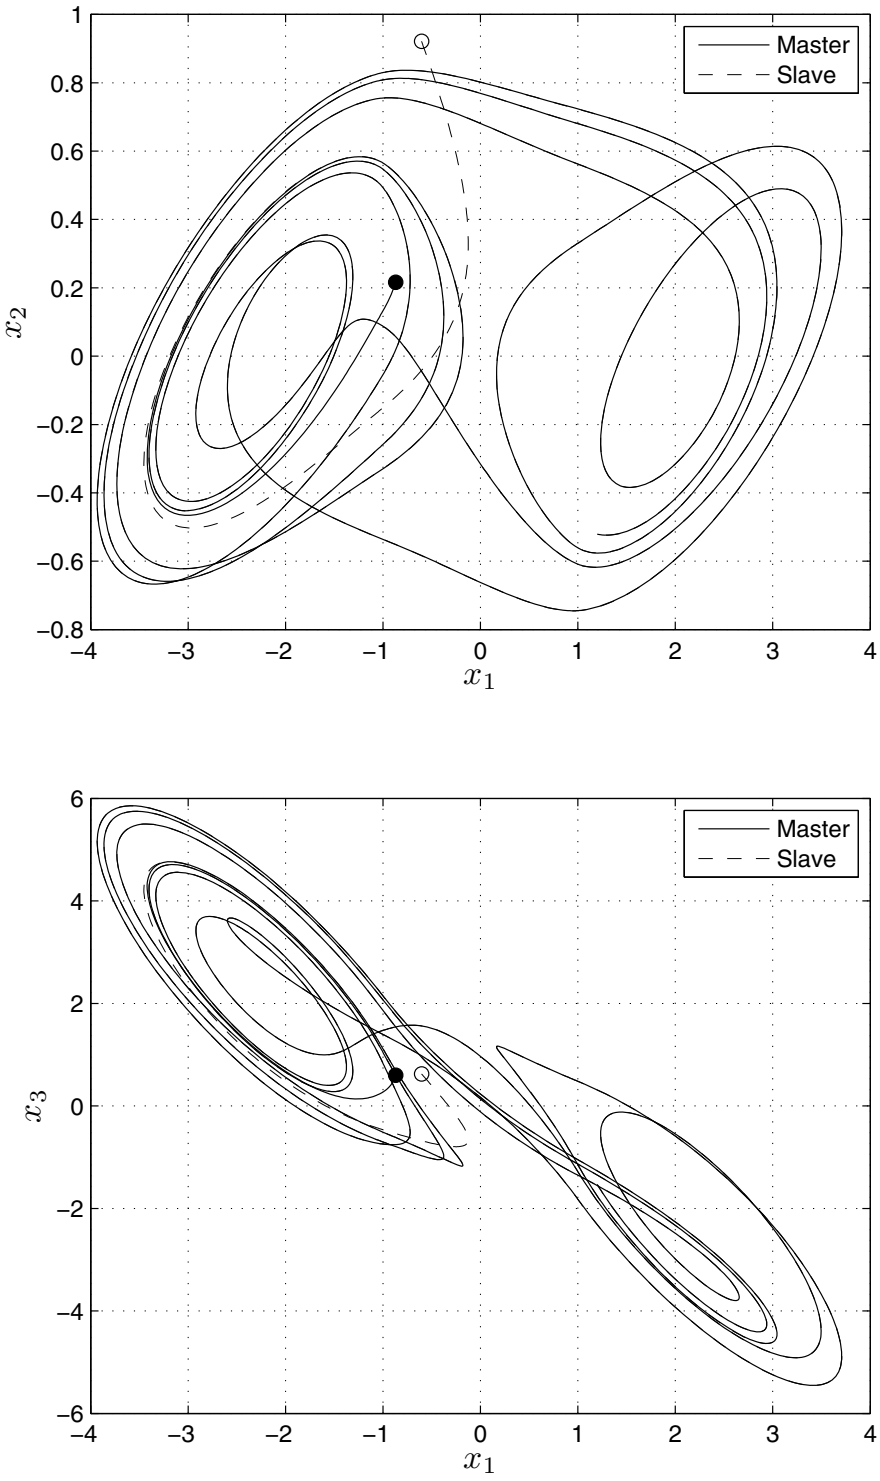

Figure 1. *Trajectories of the master and slave systems in the x_1-x_2 and x_1-x_3 planes.*

Appendix A. Proof of Theorem 2.3.

Proof. We start by proving the global mean square exponential stability. Consider arbitrary initial time $t_0 \in \mathbb{R}^+$ and initial condition $x_0 \in \mathbb{R}^n$. We define the index $\hat{k}$ so that $t_0 \in [\sigma_{\hat{k}-1}, \sigma_{\hat{k}})$. Specifying (2.3) at the $\hat{k}$th and $(\hat{k}+1)$th switching instants, we have

$$\mathsf{E}[V(x(\sigma_{\hat{k}+1}), \sigma_{\hat{k}+1})|x(\sigma_{\hat{k}})] \leq (1-\nu)V(x(\sigma_{\hat{k}}), \sigma_{\hat{k}}), \tag{A.1}$$

$$\mathsf{E}[V(x(\sigma_{\hat{k}+2}), \sigma_{\hat{k}+2})|x(\sigma_{\hat{k}+1})] \leq (1-\nu)V(x(\sigma_{\hat{k}+1}), \sigma_{\hat{k}+1}). \tag{A.2}$$

By taking the conditional expected value of (A.2) we obtain

$$\mathsf{E}[\mathsf{E}[V(x(\sigma_{\hat{k}+2}), \sigma_{\hat{k}+2})|x(\sigma_{\hat{k}+1})]|x(\sigma_{\hat{k}})] \leq (1-\nu)\mathsf{E}[V(x(\sigma_{\hat{k}+1}), \sigma_{\hat{k}+1})|x(\sigma_{\hat{k}})]. \tag{A.3}$$

Using the smoothing lemma (see, for example, Lemma 1.1 on page 474 in [30]) and inequality (A.1) in (A.3), we find

$$\mathsf{E}[V(x(\sigma_{\hat{k}+2}), \sigma_{\hat{k}+2})|x(\sigma_{\hat{k}})] \leq (1-\nu)^2 V(x(\sigma_{\hat{k}}), \sigma_{\hat{k}}).$$

We explicitly note that the hypotheses of the smoothing lemma are verified since (2.1) defines a Markov process.

Iterating the argument above for any positive integer $n > \hat{k}$, we obtain

$$\mathsf{E}[V(x(\sigma_n), \sigma_n)|x(\sigma_{\hat{k}})] \leq (1-\nu)^{n-\hat{k}} V(x(\sigma_{\hat{k}}), \sigma_{\hat{k}}). \tag{A.4}$$

By using the bounds in (2.2), (A.4) gives

$$\mathsf{E}[\|x(\sigma_n)\|^2|x(\sigma_{\hat{k}})] \leq \lambda_{max}/\lambda_{min}(1-\nu)^{n-\hat{k}}\|x(\sigma_{\hat{k}})\|^2. \tag{A.5}$$

Inequality (A.5) can be used to derive an upper bound for the unconditioned expected value that is needed to assess the global mean square exponential stability according to Definition 2.1. Since $\hat{k}$ defines a given instant of time and x_0 is a prescribed initial condition, $x(\sigma_{\hat{k}})$ is a finite-state random variable taking values in $\{x_1(\sigma_{\hat{k}}), \ldots, x_N(\sigma_{\hat{k}})\}$, where N is the cardinality of the event set Θ. From the definition of conditional expectation (see, for example, [9]), we have

$$\mathsf{E}[\|x(\sigma_n)\|^2] = \sum_{i=1}^{N} \mathsf{E}[\|x(\sigma_n)\|^2|x_i(\sigma_{\hat{k}})]P\{x_i(\sigma_{\hat{k}})\}, \tag{A.6}$$

where $P\{x_i(\sigma_{\hat{k}})\}$ is the probability that $x_i(\sigma_{\hat{k}})$ is the realization of the random variable $x(\sigma_{\hat{k}})$. Hence, using inequality (A.5), equation (A.6) yields

$$\mathsf{E}[\|x(\sigma_n)\|^2] \leq \sum_{i=1}^{N} \frac{\lambda_{max}}{\lambda_{min}}(1-\nu)^{n-\hat{k}}\|x_i(\sigma_{\hat{k}})\|^2 P\{x_i(\sigma_{\hat{k}})\}. \tag{A.7}$$

In order to assess the global mean square exponential stability, we need to analyze the system dynamics inside every switching interval. Given a generic switching interval $[\sigma_k, \sigma_{k+1})$

and an instant $\bar{t} \in [\sigma_k, \sigma_{k+1})$, using the triangle inequality $\forall t \geq \bar{t}$ in $[\sigma_k, \sigma_{k+1})$, equation (2.1) yields

$$\|x(t)\| \leq \|x(\bar{t})\| + \int_{\bar{t}}^{t} \|f(x(\xi), \xi, \Omega)\| d\xi. \tag{A.8}$$

Since the functions f_ω are globally Lipschitz in $\mathbb{R}^+$ and all the corresponding Lipschitz constants are bounded by a constant L, (A.8) yields

$$\|x(t)\| \leq \|x(\bar{t})\| + \int_{\bar{t}}^{t} L\|x(\xi)\| d\xi.$$

Using the Gronwall–Bellman inequality (see, for example, [36]), we have

$$\|x(t)\| \leq \gamma \|x(\bar{t})\| \tag{A.9}$$

with $\gamma = e^{L\varepsilon}$. Therefore, using (A.9) in (A.7), we find that $\forall t \in [\sigma_n, \sigma_{n+1})$

$$\mathsf{E}[\|x(t)\|^2] \leq \gamma^2 \mathsf{E}[\|x(\sigma_n)\|^2] \leq \gamma^2 \sum_{i=1}^{N} \frac{\lambda_{max}}{\lambda_{min}} (1-\nu)^{n-\hat{k}} \|x_i(\sigma_{\hat{k}})\|^2 P\{x_i(\sigma_{\hat{k}})\}. \tag{A.10}$$

Inequality (A.9) can also be used to find an upper bound for $\|x(\sigma_{\hat{k}})\|$ in terms of the initial conditions. In fact, since $t_0 \in [\sigma_{\hat{k}-1}, \sigma_{\hat{k}})$ for the definition of $\hat{k}$, from (A.9) we obtain

$$\|x(\sigma_{\hat{k}})\| \leq \gamma \|x(t_0)\|. \tag{A.11}$$

Finally, using (A.11) to bound the right side of (A.10), we obtain

$$\begin{aligned} \mathsf{E}[\|x(t)\|^2] &\leq \gamma^4 \sum_{i=1}^{N} \frac{\lambda_{max}}{\lambda_{min}} (1-\nu)^{n-\hat{k}} \|x(t_0)\|^2 P\{x_i(\sigma_{\hat{k}})\} \\ &\leq \gamma^4 \frac{\lambda_{max}}{\lambda_{min}} (1-\nu)^{n-\hat{k}} \|x(t_0)\|^2 \\ &\leq \alpha \|x(t_0)\|^2 e^{-\beta(t-t_0)}, \end{aligned} \tag{A.12}$$

where we defined

$$\alpha = \gamma^4 (1-\nu)^{-2} \lambda_{max}/\lambda_{min}, \quad \beta = -\ln(1-\nu)/\varepsilon. \tag{A.13}$$

Therefore, according to Definition 2.1, the system (2.1) is globally mean square exponentially stable.

In the second part of the proof, we establish the global almost sure exponential stability. Following [44], we let χ be a positive real number such that $\chi \leq \beta$, where β is defined in (A.13). From the Markov inequality (see, for example, [30, Theorem 1.1, p. 120]), we have

$$P\left\{ \sup_{t \in [\sigma_{n-1}, \sigma_n)} \|x(t)\|^2 > e^{-(\beta-\chi)(\sigma_{n-1}-t_0)} \right\} \leq e^{(\beta-\chi)(\sigma_{n-1}-t_0)} \mathsf{E}\left[\sup_{t \in [\sigma_{n-1}, \sigma_n)} \|x(t)\|^2 \right]. \tag{A.14}$$

Using (A.12) in (A.14), we find

$$P\left\{\sup_{t\in[\sigma_{n-1},\sigma_n)}\|x(t)\|^2 > e^{-(\beta-\chi)(\sigma_{n-1}-t_0)}\right\} \le \alpha\|x(t_0)\|^2 e^{-\chi(\sigma_{n-1}-t_0)}. \tag{A.15}$$

By taking the infinite summation with respect to n of both sides of (A.15) and by noticing that $e^{-\chi\varepsilon}$ is less than one, we find

$$\sum_{n=\hat{k}}^{\infty} P\left\{\sup_{t\in[\sigma_{n-1},\sigma_n)}\|x(t)\|^2 > e^{-(\beta-\chi)(\sigma_{n-1}-t_0)}\right\} < \infty. \tag{A.16}$$

Thus, by directly applying the Borel–Cantelli lemma (see, for example, [41, Lemma 1, p. 192]), we obtain that

$$\sup_{\sigma_n>k\ge\sigma_{n-1}}\|x(t)\| \le e^{-1/2(\beta-\chi)(\sigma_{n-1}-t_0)} \tag{A.17}$$

holds a.s. for all but finitely many n. Hence, for any sample system, there exists a positive integer n_0 such that (A.17) holds a.s. for any $n > n_0$. Therefore, for any $n > n_0$ and $t \in [\sigma_{n-1}, \sigma_n)$, the following inequality holds a.s.:

$$\|x(t)\| \le e^{-1/2(\beta-\chi)(\sigma_{n-1}-t_0)} \le e^{1/2(\beta-\chi)\varepsilon} e^{-1/2(\beta-\chi)(t-t_0)}. \tag{A.18}$$

By repetitively applying the Gronwall–Bellman inequality in (A.9) and by using (A.18), we finally find that $\forall t \ge t_0$ the following inequality holds a.s.:

$$\|x(t)\| \le \gamma^{n_0-\widehat{k}+1} e^{1/2(\beta-\chi)\varepsilon}\|x(t_0)\| e^{-1/2(\beta-\chi)(t-t_0)}, \tag{A.19}$$

which proves the global almost sure exponential stability of (2.1) according to Definition 2.2.

For completeness, we also show that (2.1) is globally almost surely exponentially stable in the sense of [40]. We notice that, since (2.3) holds and $V(x(\sigma_k), \sigma_k)$ is a positive quantity, the sequence of $V(x(\sigma_k), \sigma_k)$ is a supermartingale; see, for example, Definition 2.4 in [30]. Therefore, we can apply the supermartingale inequality (see, for example, [41, Proposition 1, p. 31]) and obtain that for every $\eta > 0$

$$P\left\{\sup_{\infty>k\ge n} V(x(\sigma_k), \sigma_k) \ge \eta\right\} \le \frac{\mathsf{E}[V(x(\sigma_n), \sigma_n)|x(\sigma_{\hat{k}})]}{\eta}. \tag{A.20}$$

Substituting (A.4) into (A.20) and using condition (2.5), we find

$$P\left\{\sup_{\infty>k\ge n}\|x(\sigma_k)\|^2 \ge \frac{\eta}{\lambda_{min}}\right\} \le \frac{\lambda_{max}}{\eta}(1-\nu)^{n-\hat{k}}\|x(\sigma_{\hat{k}})\|^2. \tag{A.21}$$

Using (A.9) in (A.21), we obtain the following inequality for the continuous time process $x(t)$:

$$P\left\{\sup_{\infty>(t-t_0)\ge T}\|x(t)\|^2 \ge \frac{\eta}{\lambda_{min}}\right\} \le \frac{\gamma^2\lambda_{max}}{\eta}(1-\nu)^{n-\hat{k}}\|x(t_0)\|^2, \tag{A.22}$$

where T is an arbitrary time duration and the index n satisfies $n = \hat{k} + \lfloor T/\varepsilon \rfloor$, where $\lfloor \bullet \rfloor$ refers to the integer division. By defining the positive quantity $\mu = \gamma\sqrt{\eta/\lambda_{min}}$ and expressing the left-hand side of (A.22) in terms of the supremum of $\|x(t)\|$, we obtain

$$P\left\{\sup_{\infty>(t-t_0)\geq T}\|x(t)\| \geq \mu\right\} \leq \frac{\lambda_{max}\gamma^4}{\lambda_{min}\mu^2}(1-\nu)^{n-\hat{k}}\|x(t_0)\|^2. \tag{A.23}$$

Replacing the constants α and β defined in (A.13) into (A.23), we finally derive the following bound on the exponential rate of decay of the probability that $\|x(t)\|$ is larger than μ:

$$P\left\{\sup_{\infty>(t-t_0)\geq T}\|x(t)\| \geq \mu\right\} \leq \frac{\alpha}{\mu^2}\|x(t_0)\|^2 e^{-\beta T}. \tag{A.24}$$ ■

Acknowledgments. The authors would like to thank Ms. Francesca Fiorilli and Dr. Davide Spinello for their careful review of the manuscript.

A Computer-Assisted Proof of Σ_3-Chaos in the Forced Damped Pendulum Equation*

Balázs Bánhelyi†, Tibor Csendes†, Barnabas M. Garay‡, and László Hatvani§

Abstract. The present paper is devoted to studying Hubbard's pendulum equation

$$\ddot{x} + 10^{-1}\dot{x} + \sin(x) = \cos(t).$$

Using rigorous/interval methods of computation, the main assertion of Hubbard on chaos properties of the induced dynamics is raised from the level of experimentally observed facts to the level of a theorem completely proved. A special family of solutions is shown to be chaotic in the sense that, on consecutive time intervals $(2k\pi, 2(k+1)\pi)$ $(k \in \mathbb{Z})$, individual members of the family can freely "choose" between the following possibilities: the pendulum crosses the bottom position exactly once clockwise or does not cross the bottom position at all or crosses the bottom position exactly once counterclockwise. The proof follows the topological index/degree approach by Mischaikow, Mrozek, and Zgliczynski. The new feature of this paper is a definition of the transition graph for which the periodic orbit lemma—the key technical result of the approach mentioned above—turns out to be a consequence of Brouwer's fixed point theorem. The role of wholly automatic versus "trial-and-error with human overheads" computer procedures in detecting chaos is also discussed.

Key words. forced damped pendulum, Σ_3-chaos, computer-assisted proof, transition graph, interval arithmetic

1. Introduction and the main results.

The complexity of the solutions to the forced damped pendulum equation

$$m\ell\ddot{x} + b\dot{x} + mg\sin(x) = A\cos(\omega t)$$

and of related systems is one of the most frequently studied problems in dynamics. For certain values of the parameters, small perturbation theory can be applied to prove chaotic behavior.

However, a purely theoretical approach can hardly lead to a proof for chaos if small perturbation methods break down such as in the case where

$$\ddot{x} + 10^{-1}\dot{x} + \sin(x) = \cos(t) \tag{1.1}$$

(i.e., for parameters $m\ell = mg = A = \omega = 1$ and $b = 10^{-1}$) investigated by Hubbard [24]. Based on numerical experiments and the accompanying abstract considerations mimicking Smale's geometric horseshoe construction, Hubbard [24] made the existence of Σ_3-chaos—both on Poincaré sections of the 2π-solution mapping and also in more natural terms of the dynamics—quite plausible. His main result can be stated as follows.

Theorem H (Hubbard [24]). *Suppose we are given a bi-infinite sequence* $\{\varepsilon_k\}_{k\in\mathbf{Z}} \in \{-1;0;1\}^{\mathbb{Z}}$, *arbitrarily chosen. Then the pendulum governed by* (1.1) *has at least one motion that corresponds to the bi-infinite sequence* $\{\varepsilon_k\}_{k\in\mathbb{Z}}$ *in the sense that, during the time interval* $(2k\pi, 2(k+1)\pi)$, *the pendulum bob*

- *crosses the bottom position exactly once clockwise if and only if* $\varepsilon_k = -1$,
- *does not cross the bottom position at all if and only if* $\varepsilon_k = 0$, *or*
- *crosses the bottom position exactly once counterclockwise if and only if* $\varepsilon_k = 1$

and does not point downward at the time instants $t = 2k\pi$, $k \in \mathbf{Z}$.

The first aim of this paper is to interpret Hubbard's observation within the Mischaikow–Mrozek framework of computer-assisted proofs for horseshoe-type chaos. We use the word "observation" because, as is written on page 755 of [24], "no statement is proved anywhere." Hubbard arranges numerical evidence according to the framework of symbolic dynamics. We complete his work by filling in the gaps via refinements of some of his theoretical arguments (in particular, by introducing the small quadrangles L_ℓ, M_ℓ, R_ℓ, $\ell \in \mathbb{Z}$) and performing the necessary rigorous interval arithmetic computations. We will show that Theorem H is a consequence of a technical result based on Figure 10 in Hubbard [24], which shows images and preimages of three large quadrangles, the convex hulls of the smaller sets $L_\ell \cup M_\ell \cup R_\ell$, $\ell = -1, 0, 1$. In short, the observation is turned into a theorem.

Theorem 1.1. *There exist compact pairwise disjoint quadrangles*

$$L_0, M_0, R_0 \subset \left\{(x, \dot{x}) \in \mathbf{R}^2 \;\middle|\; 0 < x < 2\pi\right\}$$

with the following properties. Given a bi-infinite sequence $\{\varepsilon_k\}_{k\in\mathbb{Z}} \in \{-1;0;1\}^{\mathbb{Z}}$, *there exists a solution* $x = x(\{\varepsilon_k\}_{k\in\mathbb{Z}}) : \mathbf{R} \to \mathbf{R}$ *to* (1.1) *such that*

$$(x(2k\pi), \dot{x}(2k\pi)) \in \begin{cases} L_{\sigma_k} & \text{if} \quad \varepsilon_k = -1, \\ M_{\sigma_k} & \text{if} \quad \varepsilon_k = 0, \\ R_{\sigma_k} & \text{if} \quad \varepsilon_k = 1, \end{cases} \tag{1.2}$$

where $\sigma_{k+1} = \sigma_k + \varepsilon_k$, $k \in \mathbb{Z}$ *with* $\sigma_0 = 0$, *and*

$$L_\ell = L_0 + (2\ell\pi, 0), \quad M_\ell = M_0 + (2\ell\pi, 0), \quad R_\ell = R_0 + (2\ell\pi, 0), \quad \ell \in \mathbb{Z}. \tag{1.3}$$

Quadrangles L_0, M_0, and R_0 are shown in Figure 2. Property (1.2) means that the horizontal $2\ell\pi$-translates L_ℓ, M_ℓ, R_ℓ of the carefully chosen quadrangles L_0, M_0, R_0 are visited by trajectories of the Poincaré mapping

$$\Pi : \mathbb{R}^2 \to \mathbb{R}^2, \quad (x(0), \dot{x}(0)) \to (x(2\pi), \dot{x}(2\pi))$$

in the given order prescribed by the bi-infinite sequence $\{\varepsilon_k\}_{k\in\mathbb{Z}}$. The underlying circle of abstract topological results on transition graphs and iterates of continuous mappings are the

key parts of the landmark paper by Mischaikow and Mrozek [30] and of the great number of contributions that followed. The essence of the Mischaikow–Mrozek approach is to prove the existence of an abundance of combinatorially different periodic orbits and then, by using the density of periodic orbits in the shift dynamics, to pass to the existence of horseshoe-type chaos. The main technical tool is represented by what we call Lemma 2.1 in section 2 below. Lemma 2.1 relates to transition graphs and periodic orbits in two dimensions and constitutes the main step in proving Theorem 1.1.

The second aim of this paper is to provide an elementary proof of a higher-dimensional generalization of Lemma 2.1. Higher-dimensional versions of Lemma 2.1 were given by Gidea and Zgliczynski [21] and Pireddu and Zanolin [37]. The underlying definitions of the transition graphs in [21] and [37] (the latter being motivated by [25]) are different. However, both proofs are based on Brouwer degree arguments. Here we will give a third definition of the transition graph in higher dimensions—the two-dimensional case having been settled by Papini and Zanolin [34]—where a simple application of Brouwer's fixed point theorem suffices. This implies, in particular, that in some of the earliest computer-assisted proofs for horseshoe-type chaos [30], [52], [53], [54], Conley index and/or Brouwer degree arguments can be replaced by applications of Brouwer's fixed point theorem. See also Remark 1.

The computer-assisted parts of the proofs of Theorems 1.1 and H were performed in the LINUX and Cygwin environments, on a typical modern PC. We used the PROFIL/BIAS [27] programming environment which supports interval arithmetics and the Validated Numerical ODE (VNODE) package by Nedialkov [32], [33]. Our basic references for rigorous/interval computation and set-valued numerics are [1] and [13], respectively.

The computer program used for the proof can be downloaded from the Web page http://www.inf.u-szeged.hu/~banhelyi/FDP together with a short introduction and screenshots of the installation procedure.

This paper is organized as follows. Section 2 begins with a definition of the transition graph in two dimensions, goes on to state Lemma 2.1, and ends with a proof of Theorem 1.1. Theorem H and a higher-dimensional generalization of Lemma 2.1 are proved in sections 4 and 5, respectively. Connections to a four-dimensional neural networks model are investigated in section 6. Section 3 is devoted to a discussion of the role of the computer in chaos detection.

The results on symbolic dynamics and various forms of the pendulum equation can be found in a variety of papers. Two early results in this direction concern the standard pendulum equation with damping and variable length (but without an external forcing term) $\ddot{x} + b\dot{x} + (1 + c\sin(\mu t))\sin(x) = 0$. They were obtained by applying Melnikov's approach [48] and a computer-assisted version of the shooting method [23], respectively. The concept of a chaotic oscillation for the case $b = 0$ was defined in [17]. For the singularly perturbed van der Pol equation $\varepsilon\ddot{x} + \varphi(x)\dot{x} + \varepsilon x = p(t)$, where φ and p are piecewise constant, the existence of embedded symbolic dynamics was proved by Levi [28] in 1981. He used Newhouse's abstract results on homoclinic bifurcations.

From the enormous (and still mathematically sound) literature on chaos in electrical circuits, we refer the reader to the computer-assisted proofs of Galias [18] for chaos in Chua's circuit as well as to the computer-assisted proof of Yang and Li [47] for chaos in Josephson junctions.

Chaos results for the time-periodic nonlinear Hill equation $\ddot{x} + q(t)g(x) = 0$ were obtained

by topological and variational methods. The slightly more general time-periodic equations $\ddot{x}+b\dot{x}+q(t)g(x)=0$ and $\ddot{x}+\partial W(t,x)/\partial x=h(t)$ were investigated in [7] and [6], respectively. For details, generalizations, and more references, see the survey by Papini and Zanolin [35]. Note that Hubbard's pendulum equation (1.1) is not included in their discussions of theoretical and computational results, however.

2. Transition graph and chaos associated. For $j\in\mathbb{Z}$, define

$$\begin{aligned} Q_j &= \{(x_1,x_2)\in\mathbb{R}^2 \mid 3j+1\le x_1\le 3j+2,\ 0\le x_2\le 1\},\\ \lambda_j &= \{x\in Q_j \mid x_1=3j+1\},\quad \rho_j=\{x\in Q_j \mid x_1=3j+2\},\\ E_j &= \{(x_1,x_2)\in\mathbb{R}^2 \mid 3j+1\le x_1\le 3j+2,\ |2x_2-1|>1\}. \end{aligned}$$

Let $X=\cup_{j\in\mathbb{Z}}Q_j\subset\mathbb{R}^2$, and consider a continuous mapping $\varphi: X\to\mathbb{R}^2$ with coordinate functions φ_1,φ_2. The *transition graph* $\mathcal{G}(\varphi)$ *of* φ is defined as a directed graph with vertex set $\mathbf{V}(\mathcal{G})=\mathbb{Z}$. For $j,\tilde{j}\in\mathbf{V}(\mathcal{G})$, the pair $(j,\tilde{j})$ belongs to the edge set $\mathbf{E}(\mathcal{G})$ of $\mathcal{G}(\varphi)$ if

$$\varphi(Q_j)\subset\mathbb{R}^2\setminus \mathrm{cl}(E_{\tilde{j}}) \tag{2.1}$$

and one of the following conditions holds true:

$$\varphi_1(x)<3\tilde{j}+1 \quad\text{for}\quad x\in\lambda_j \quad\text{and}\quad \varphi_1(x)>3\tilde{j}+2 \quad\text{for}\quad x\in\rho_j \tag{2.2}$$

or

$$\varphi_1(x)>3\tilde{j}+2 \quad\text{for}\quad x\in\lambda_j \quad\text{and}\quad \varphi_1(x)<3\tilde{j}+1 \quad\text{for}\quad x\in\rho_j. \tag{2.3}$$

Sets Q_j,λ_j,ρ_j,E_j $(j=0,1,2)$ as well as relation $(0,2)\in\mathbf{E}(\mathcal{G})$ are shown in Figure 1. We write $\mathbf{V}=\mathbf{V}(\mathcal{G})=\mathbb{Z}$ and $\mathbf{E}=\mathbf{E}(\mathcal{G})$ in the following. For $N\in\mathbb{N}$, the directed graph $\mathcal{C}=\mathcal{C}(j_0,j_1,\dots,j_N)$ is a *directed* $(N+1)$*-circle in* $\mathcal{G}(\varphi)$ if $\mathbf{V}(\mathcal{C})=\{j_0,j_1,\dots,j_N\}\subset\mathbb{Z}$ and, with the convention $j_{N+1}=j_0$, $\mathbf{E}(\mathcal{C})=\{(j_k,j_{k+1})\}_{k=0}^{N}\subset\mathbf{E}$. The directed graph $\mathcal{P}=\mathcal{P}(\{j_k\mid k\in\mathbb{Z}\})$ is a *directed bi-infinite path in* $\mathcal{G}(\varphi)$ if $\mathbf{V}(\mathcal{P})=\{j_k\mid k\in\mathbb{Z}\}\subset\mathbb{Z}$ and $\mathbf{E}(\mathcal{P})=\{(j_k,j_{k+1})\}_{k\in\mathbb{Z}}\subset\mathbf{E}$. The definition of directed finite and infinite paths (i.e., paths having a root vertex) in $\mathcal{G}(\varphi)$ follows a similar pattern and will not be included here.

Lemma 2.1. *Let $\mathcal{C}=\mathcal{C}(j_0,j_1,\dots,j_N)$ be a directed circle in the transition graph $\mathcal{G}(\varphi)$. Then there is a finite sequence of points $\{q_k\}_{k=0}^{N}\subset X$ such that, with the convention $q_{N+1}=q_0$,*

$$q_{k+1}=\varphi(q_k) \quad\textit{and}\quad q_k\in Q_{j_k},\quad k=0,1,\dots,N.$$

Actually, Lemma 2.1 comes from the paper by Mischaikow and Mrozek [30]. As stated above, it is a version of the main result in Zgliczynski [52]. The formulation and the proof of a higher-dimensional generalization of Lemma 2.1 will be postponed until section 5.

Corollary 2.2. *Let $\mathcal{P}=\mathcal{P}(\{j_k\}_{k\in\mathbb{Z}})$ be a directed bi-infinite path in the transition graph $\mathcal{G}(\varphi)$. Assume that either*

(A) *every directed infinite path in $\mathcal{P}$ has infinitely many different vertices*

or

(B) *$\mathcal{G}$ (as a directed graph) is connected.*

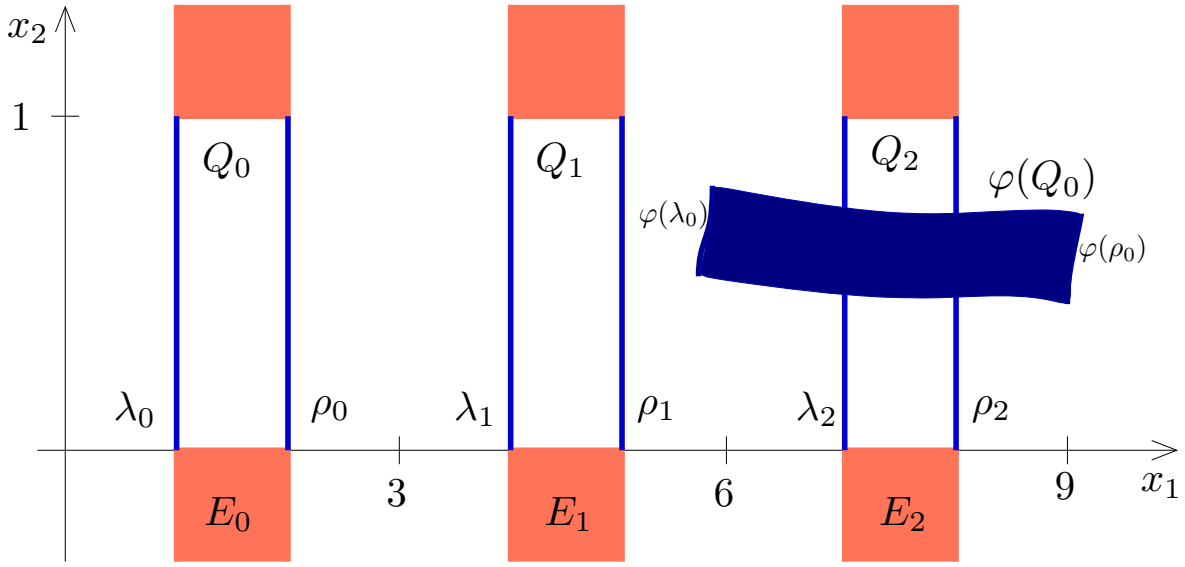

Figure 1. *Notation used to define the transition graph in two dimensions.*

Then there is a bi-infinite sequence of points $\{q_k\}_{k\in\mathbb{Z}} \subset X$ *with the property that*

$$q_{k+1} = \varphi(q_k) \quad \textit{and} \quad q_k \in Q_{j_k}, \quad k \in \mathbb{Z}.$$

Proof. Case (A). Choose a positive integer $\ell = L$ and consider the finite path with consecutive vertices $(j_{-L}, j_{-L+1}, \dots, j_L) \in \mathbb{Z}^{2L+1}$. Next, choose an integer $M > L$ such that $j_M \neq j_k$ for $k = -L, \dots, L$. Redefining φ on Q_{j_M}, we may assume that $(j_M, j_{-L}) \in \mathbf{E}$. Thus the extended finite sequence $(j_{-L}, \dots, j_L, j_{L+1}, \dots, j_M) \in \mathbf{V}^{L+1+M}$ forms the set of consecutive vertices of a directed circle in $\mathcal{G}(\varphi)$. Applying Lemma 2.1, we conclude there must exist a finite sequence of points $\{q_k^L\}_{|k|\le L} \subset X$ such that

$$q_{k+1}^L = \varphi(q_k^L) \quad \text{for} \quad k = -L, \dots, L-1 \quad \text{and} \quad q_k^L \in Q_{j_k} \quad \text{for} \quad k = -L, \dots, L.$$

Repeating the previous considerations for $\ell = L+1, L+2, \dots$, a standard Bolzano–Weierstrass subsequence argument in the limiting process $\ell \to \infty$ leads to the desired result.

Case (B). The connectedness of $\mathcal{G}$ is equivalent to the property that every directed finite path in $\mathcal{P}$ is contained in a directed circle of $\mathcal{G}(\varphi)$. Consequently, with some minor modifications, the argument we applied in proving case (A) can be repeated here. ■

Corollary 2.2 asserts the existence of a φ-trajectory which visits the Q_j's in the prescribed order: a directed bi-infinite path of type (A) or (B) of the transition graph is shadowed by a φ-trajectory. Directed $(N+1)$-circles in $\mathcal{G}(\varphi)$ are shadowed by $(N+1)$-periodic φ-trajectories. This is the essence of Lemma 2.1.

Remark 1. If $N = 0$, then Lemma 2.1 simplifies to the Colorado fixed point theorem in [3]. If the vertical coordinate is missing, then Lemma 2.1 simplifies to a well-known result in one-dimensional dynamics (see, for example, Lemma III.1.4 in [40]) whose proof is based solely on the intermediate value theorem. The proof of a higher-dimensional generalization

of Lemma 2.1 in section 5 mimics the standard derivation of the Miranda theorem from Brouwer's fixed point theorem [36]. Note that the Miranda theorem is nothing else but the higher-dimensional counterpart of the intermediate value theorem. It is known to be equivalent to Brouwer's fixed point theorem and to many other important results in topology [51]. Its history can be traced back to Poincaré and Bohl. Not long ago, the Miranda theorem appeared as a root test in numerical analysis and interval computation [16], [15], [42] as well as in chaos theory for two-dimensional mappings [34], [4]. The "rectangular nature" of the Miranda theorem fits in beautifully with the rectangles used to define the transition graph as well as the rectangles used in rigorous/interval computation.

Remark 2. Observe that Lemma 2.1 remains valid if the right-hand side of inclusion (2.1) is weakened to $\mathbb{R}^2 \setminus E_{\tilde{j}}$ and the strict inequalities in (2.2) and (2.3) are replaced by their nonstrict counterparts. (In fact, for $\ell = 1, 2, \dots$, it is elementary to construct a modified map $\varphi^\ell : X \to \mathbb{R}^2$ satisfying $|\varphi_\ell - \varphi| < 1/\ell$ for which Lemma 2.1 (as stated above) applies. Allowing $\ell \to \infty$, the existence of the desired φ-periodic trajectory follows from the Bolzano–Weierstrass argument.) The reason for stating Lemma 2.1 in the form presented above is to make the result stable with respect to small perturbations. Actually, if the conditions of Lemma 2.1 are met, and a continuous mapping $\tilde{\varphi} : \cup_{j\in\mathbb{Z}} Q_j \to \mathbb{R}^2$ satisfies $\max\{|\varphi(q) - \tilde{\varphi}(q)| \mid q \in \cup_{k=0}^{N} Q_{j_k}\} \le \eta$ with η sufficiently small, then the $(N+1)$-tuple $(j_0, j_1, \dots, j_N) \in \mathbb{Z}^{N+1}$ forms a directed circle in $\mathcal{G}(\tilde{\varphi})$ as well. As we shall see below, it is exactly this robustness property of the transition graph which makes Lemma 2.1 so suitable in computer-assisted proofs for horseshoe-type chaos. Stability in small perturbations in turn ensures stability in numerical approximations, including those with rounding errors.

Now we shall return to (1.1), which was studied by Hubbard [24].

In what follows we will demonstrate how Corollary 2.2 applies and how it leads to a complete proof of Theorem 1.1. The strategy is to find a bi-infinite sequence of pairwise disjoint compact sets $\{K_j\}_{j\in\mathbb{Z}}$ in the Poincaré plane $\{(x, \dot{x}) \in \mathbb{R}^2\}$ such that, up to a coordinate transformation h, Corollary 2.2 applies to the associated Poincaré mapping $\Pi : (x(0), \dot{x}(0)) \to (x(2\pi), \dot{x}(2\pi))$ of (1.1). We need a homeomorphism h of the Poincaré plane onto the standard plane $\{(x_1, x_2) \in \mathbb{R}^2\}$ such that, for

$$\varphi = h\Pi h^{-1}|X : X \to \mathbb{R}^2 \quad \text{with} \quad Q_j = h(K_j), \quad j \in \mathbb{Z},$$

Corollary 2.2 directly applies. Here, of course, $X = \cup_{j\in\mathbb{Z}} Q_j$, and $h\Pi h^{-1}|X$ means the restriction of $h\Pi h^{-1}$ to X. Since Π is 2π-periodic in the x variable and the number of different ε_k's is three, the bi-infinite sequence $\{K_j\}_{j\in\mathbb{Z}}$ is sought as a collection of the horizontal $2\ell\pi$-translates of the three specially chosen quadrangles L_0, M_0, R_0 (compare the notation in (1.3) and see Figure 2) with

$$K_{3\ell} = L_0 + (2\ell\pi, 0), \quad K_{3\ell+1} = M_0 + (2\ell\pi, 0), \quad K_{3\ell+2} = R_0 + (2\ell\pi, 0), \quad \ell \in \mathbb{Z}.$$

Given a bi-infinite sequence $\{\varepsilon_k\}_{k\in\mathbb{Z}} \in \{-1; 0; 1\}^{\mathbb{Z}}$, it is essential that the directed bi-infinite path $\mathcal{P} = \mathcal{P}(\{j_k\}_{k\in\mathbb{Z}})$ with $j_k = 3\sigma_k + 1 + \varepsilon_k$ (where—as defined in Theorem 1.1—$\sigma_0 = 0$ and $\sigma_{k+1} = \sigma_k + \varepsilon_k$ for $k \in \mathbb{Z}$) be a subgraph of $\mathcal{G}(\varphi)$. Applying Corollary 2.2, trajectories satisfying (1.2) correspond to the directed bi-infinite path $\mathcal{P} = \mathcal{P}(\{j_k\}_{k\in\mathbb{Z}})$ and vice versa.

Proof of Theorem 1.1. The successful realization of the strategy outlined above depends on the careful choice of the quadrangles L_0, M_0, R_0 and of the coordinate transformation

h. Noting the horizontal 2π-translation invariance property of the collection $\{K_j\}_{j\in\mathbb{Z}}$, the continuous mapping $\varphi = h\Pi h^{-1}|X$ is prescribed to be 9-periodic with respect to the x_1 variable. This can be guaranteed by requiring that the coordinate functions of homeomorphism $h : \{(x, \dot{x}) \in \mathbb{R}^2\} \to \{(x_1, x_2) \in \mathbb{R}^2\}$ satisfy

$$h_1(x + 2\pi, \dot{x}) = 9 + h_1(x, \dot{x}) \quad \text{and} \quad h_2(x + 2\pi, \dot{x}) = h_2(x, \dot{x}). \tag{2.4}$$

The existence of quadrangles L_0, M_0, R_0 that lead to a *transition graph suitably complex* depends on the inner structure of the Poincaré mapping.

Following Hubbard [24], define quadrangles $K_0 = L_0$, $K_1 = M_0$, $K_2 = R_0$ as

$$K_j = \operatorname{conv}\{V_{ul}^{K_j}, V_{ur}^{K_j}, V_{ll}^{K_j}, V_{lr}^{K_j}\}, \quad j = 0, 1, 2,$$

which are the closed convex hulls of their respective upper left, upper right, lower left, and lower right vertices. (The letters L, M, and R stand for left, middle, and right, respectively.) The coordinates of these vertices are

$$\begin{aligned} V_{ul}^{L_0} &= (1.000,\ -0.985), & V_{ur}^{L_0} &= (1.970,\ -0.208),\\ V_{ll}^{L_0} &= (1.226,\ -1.350), & V_{lr}^{L_0} &= (2.226,\ -0.516),\\ V_{ul}^{M_0} &= (2.436,\ 0.166), & V_{ur}^{M_0} &= (2.481,\ 0.201),\\ V_{ll}^{M_0} &= (2.758,\ -0.123), & V_{lr}^{M_0} &= (2.796,\ -0.092),\\ V_{ul}^{R_0} &= (3.197,\ 0.775), & V_{ur}^{R_0} &= (3.800,\ 1.258),\\ V_{ll}^{R_0} &= (3.398,\ 0.389), & V_{lr}^{R_0} &= (4.412,\ 1.202). \end{aligned}$$

See Figure 2. For details on how the individual vertices were found, see the third paragraph of section 3 below.

Now consider the broken line in Figure 2, namely,

$$\mathcal{L}_1 = \{\text{the vertical half-line below } W_1^1\} \cup [W_1^1, W_1^2] \cup \{\text{the vertical half-line above } W_1^2\},$$

where

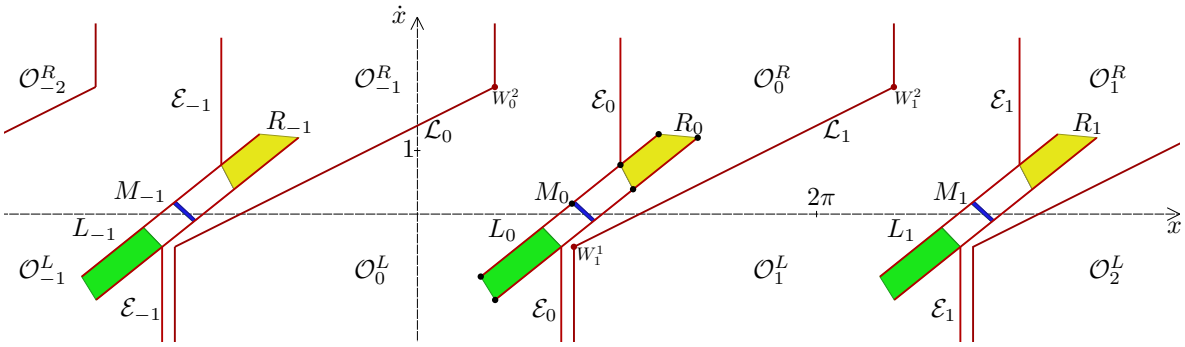
$$W_1^1 = (w_1^1, w_2^1) = V_{lr}^{L_0} + (0.2, 0), \qquad W_1^2 = (w_1^2, w_2^2) = (7.5, 2),$$

and $[W_1^1, W_1^2]$ stands for the closed line segment between W_1^1 and W_1^2. The open strip between $\mathcal{L}_1$ and the translated broken line $\mathcal{L}_0 = \mathcal{L}_1 + (-2\pi, 0)$ shall be denoted by $\mathcal{S}_0$. Now with "conv" standing for the closed convex hull of the points in braces, define

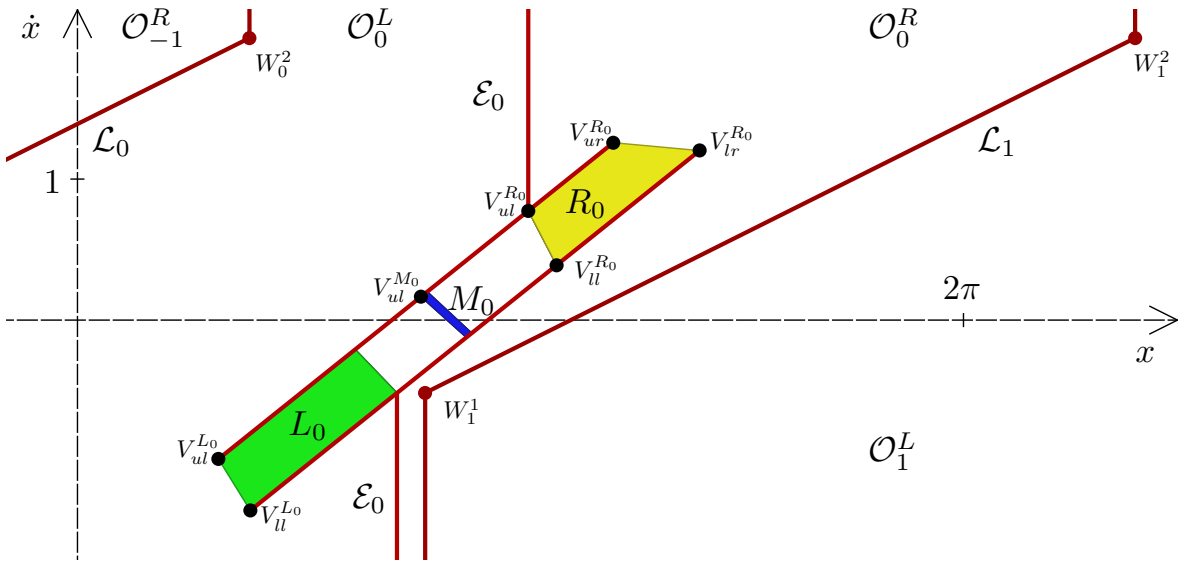
$$\begin{aligned} \mathcal{D}_0 = \{&\text{the vertical half-line below } V_{lr}^{L_0}\} \cup L_0 \cup \operatorname{conv}\{V_{ur}^{L_0}, V_{ul}^{M_0}, V_{ll}^{M_0}, V_{lr}^{L_0}\}\\ &\cup M_0 \cup \operatorname{conv}\{V_{ur}^{M_0}, V_{ul}^{R_0}, V_{ll}^{R_0}, V_{lr}^{M_0}\} \cup R_0 \cup \{\text{the vertical half-line above } V_{ul}^{R_0}\}. \end{aligned}$$

The open strips between $\mathcal{D}_0$ and $\mathcal{L}_0$ (resp., $\mathcal{L}_1$) will be denoted by $\mathcal{O}_0^L$ (resp., $\mathcal{O}_0^R$). The union of the right-hand side boundary of the strip $\mathcal{O}_0^L$ and the left-hand side boundary of the strip $\mathcal{O}_0^R$ will be denoted by $\mathcal{B}_0$. Finally, we let

$$\mathcal{E}_0 = \mathcal{B}_0 \setminus \{(V_{ul}^{L_0}, V_{ll}^{L_0}) \cup (V_{ur}^{R_0}, V_{lr}^{R_0})\},$$



(a) The entire region considered



(b) Focusing just on the middle three quadrangles

Figure 2. *Notation used in proving Theorem 1.1.*

where, for example, $(V_{ul}^{L_0}, V_{ll}^{L_0})$ stands for the open line segment connecting $V_{ul}^{L_0}$ and $V_{ll}^{L_0}$. (The closed line segment connecting $V_{ul}^{L_0}$ and $V_{ll}^{L_0}$, for example, will be denoted by $[V_{ul}^{L_0}, V_{ll}^{L_0}]$. Note that $\mathcal{E}_0$ is the union of ten closed line segments and two closed half-lines. See Figure 2 again.)

The crucial properties responsible for the edge structure of the transition graph are

$$\Pi(R_{-1}),\ \Pi(M_0),\ \Pi(L_1)\ \subset\ \mathcal{S}_0 \setminus \mathcal{E}_0, \tag{2.5}$$

$$\Pi([V_{ul}^{R_{-1}}, V_{ll}^{R_{-1}}]),\ \Pi([V_{ul}^{M_0}, V_{ll}^{M_0}]),\ \Pi([V_{ur}^{L_1}, V_{lr}^{L_1}])\ \subset\ \mathcal{O}_0^L, \tag{2.6}$$

$$\Pi([V_{ur}^{R_{-1}}, V_{lr}^{R_{-1}}]),\ \Pi([V_{ur}^{M_0}, V_{lr}^{M_0}]),\ \Pi([V_{ul}^{L_1}, V_{ll}^{L_1}])\ \subset\ \mathcal{O}_0^R. \tag{2.7}$$

See Figure 3, which shows the sets $\Pi(L_0)$ (a translated copy of $\Pi(L_1)$), $\Pi(M_0)$, and $\Pi(R_0)$ (a translated copy of $\Pi(R_{-1})$). The subset relations (2.5), (2.6), and (2.7) will be checked by

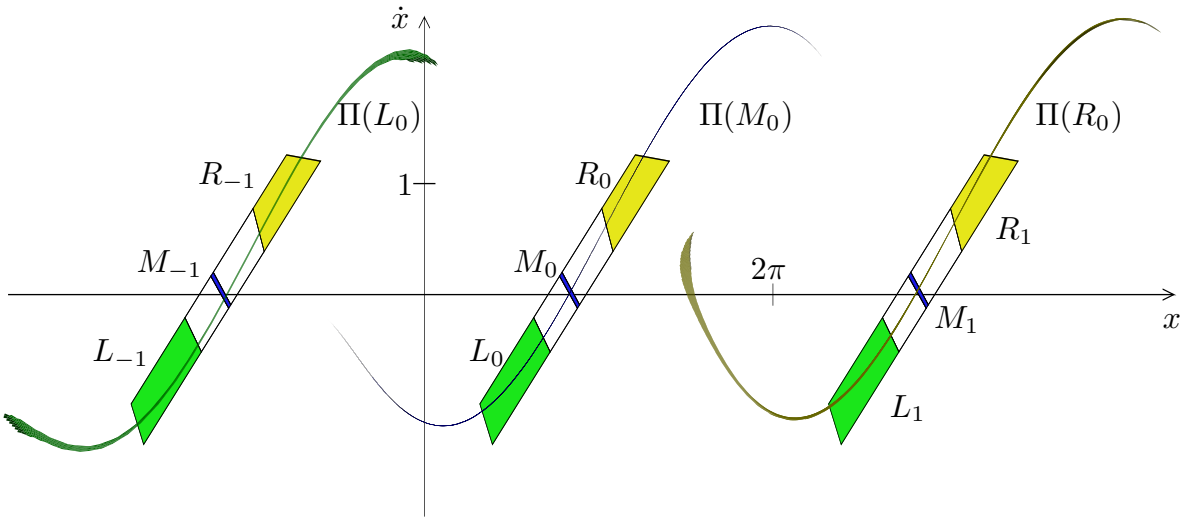


Figure 3. *Images of the specially chosen quadrangles under* Π.

computer. Note that the sets $\mathcal{S}_0 \setminus \mathcal{E}_0$, $\mathcal{O}_0^L$, and $\mathcal{O}_0^R$ are open and all nine sets $\Pi(R_{-1}), \dots, \Pi([V_{ul}^{L_1}, V_{ll}^{L_1}])$ on the respective left-hand sides are compact. Hence inclusions (2.5), (2.6), and (2.7) remain valid if the entire construction is repeated with the sets $\mathcal{D}_0$, $\mathcal{B}_0$, and $\mathcal{E}_0$ slightly thicker, that is, if $\mathcal{D}_0$, $\mathcal{B}_0$, and $\mathcal{E}_0$ are replaced by their closed neighborhoods $\mathcal{D}$, $\mathcal{B}$, and $\mathcal{E}$, suitably chosen.

Next we will start constructing a homeomorphism h subject to condition (2.4). We also require that $Q_j = h(K_j)$ with

$$(3j+1,1) = h(V_{ul}^{K_j}), \quad (3j+2,1) = h(V_{ur}^{K_j}), \quad j = 0,1,2,$$
$$(3j+1,0) = h(V_{ll}^{K_j}), \quad (3j+2,0) = h(V_{lr}^{K_j}), \quad j = 0,1,2$$

(i.e., the corresponding vertices are mapped to each other), and

$$\operatorname{cl}(E_0 \cup E_1 \cup E_2) \subset h(\mathcal{E}), \qquad \{(x_1,x_2) \in \mathbb{R}^2 \mid x_1 = 0\} = h(\mathcal{L}_0). \tag{2.8}$$

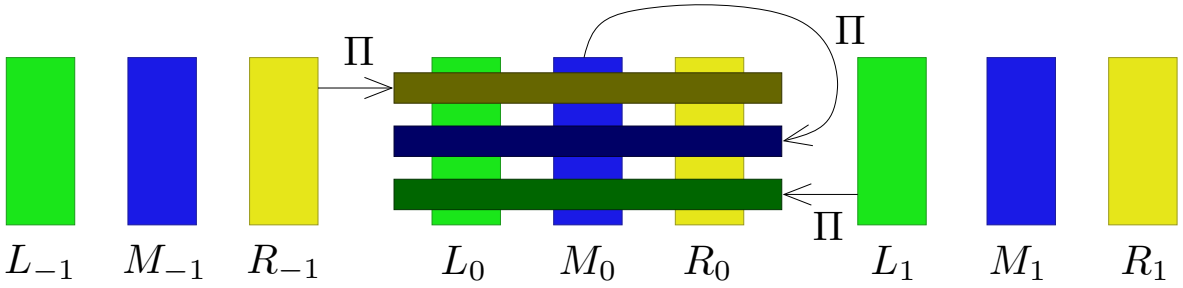
Due to the piecewise linear boundaries of the sets involved, the construction of h is elementary. We have a fair amount of freedom in choosing h. Advanced results of two-dimensional topology are not needed for this. Note that, by translation symmetry, the broken line $\mathcal{L}_1$ is mapped onto the line of the equation $x_1 = 9$.

Recall that $X = \cup_{j\in\mathbb{Z}} Q_j$. Then property (2.5) and the inclusion in (2.8) imply that

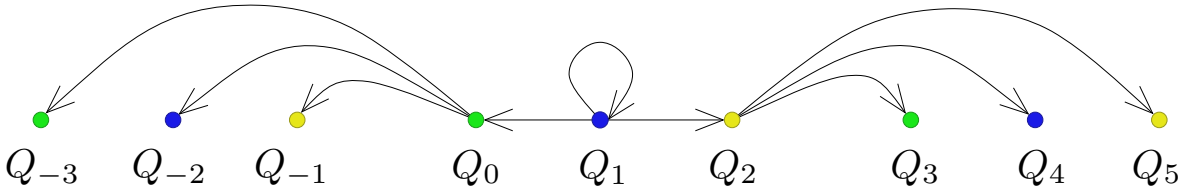
$$\varphi(X) \subset \mathbb{R}^2 \setminus \operatorname{cl}\left(\cup_{j\in\mathbb{Z}} E_j\right).$$

Using (2.6), (2.7), we conclude that the transition graph of φ is as follows. The vertex set of $\mathcal{G}(\varphi)$ is obviously $\mathbf{V} = \mathbb{Z}$, and $\mathcal{G}(\varphi)$ is 3-periodic in the sense that $(j,\tilde{j}) \in \mathbf{E}$ if and only if $(j+3, \tilde{j}+3) \in \mathbf{E}$. The edges starting from the vertex subset $\{0,1,2\}$ are like those shown in Figure 4(a):

$$(0,-3);(0,-2);(0,-1);(1,0);(1,1);(1,2);(2,3);(2,4);(2,5).$$



(a) A segment of the 3-periodic transition graph $\mathcal{G}(\varphi)$



(b) Σ_3-chaos in the quotient dynamics of Π

Figure 4. *Combinatorial complexity in Hubbard's forced damped pendulum equation.*

Thus we arrive at the schematic phase portrait of the Poincaré mapping depicted in Figure 4(b).

Given a bi-infinite sequence $\{\varepsilon_k\}_{k\in\mathbb{Z}} \in \{-1;0;1\}^{\mathbb{Z}}$, a quick analysis of the transition graph $\mathcal{G}(\varphi) = \mathcal{G}(h\Pi h^{-1}|X)$ shows that the directed bi-infinite path $\mathcal{P} = \mathcal{P}(\{j_k\}_{k\in\mathbb{Z}})$ with $j_k = 3\sigma_k + 1 + \varepsilon_k$ (where—as defined in Theorem 1.1—$\sigma_0 = 0$ and $\sigma_{k+1} = \sigma_k + \varepsilon_k$ for $k \in \mathbb{Z}$) is a subgraph of $\mathcal{G}(\varphi)$. Trajectories satisfying (1.2) correspond to the directed bi-infinite path $\mathcal{P} = \mathcal{P}(\{j_k \mid k \in \mathbb{Z}\})$ and vice versa.

This provides all the necessary points for proving Theorem 1.1. Apply Corollary 2.2, and then we are done. ∎

The derivation of Theorem 1.1 follows the main argument in the Mischaikow–Mrozek framework for computer-assisted proofs. (Note that the invertibility of Π was not exploited, but it will be needed for the backward invariance of the set Λ in Corollary 2.3 below.) For the geometric background and details on the role of the computer, see section 3.

It is not hard to reformulate Theorem 1.1 in the language of symbolic dynamics [49], [40]. In fact, recall that $Q_j = h(K_j)$, and let $\Theta \subset X$ be the closure of all periodic points of φ that shadow the directed circles of $\mathcal{G}(\varphi)$. The set Θ is backward and forward invariant under φ. For $x \in \Theta$, the formula

$$(c(x))_k = j_k \quad \text{whenever} \quad \varphi^k(x) \in Q_{j_k} \quad \text{and} \quad k \in \mathbb{Z}$$

defines a continuous itinerary mapping $c : \Theta \to \mathbb{Z}^{\mathbf{Z}}$. The inverse of a homeomorphism h lifts everything to the Poincaré plane. Clearly $\Lambda = h^{-1}(\Theta)$ is backward and forward invariant under the Poincaré mapping Π, and, for $\lambda = (x, \dot{x}) \in \Lambda$ with $d(\lambda) = c(h(\lambda))$,

$$(d(\lambda))_k = j_k \quad \text{whenever} \quad \Pi^k(\lambda) \in K_{j_k}, \quad k \in \mathbb{Z}.$$

Letting S denote the shift operator on $\mathbb{Z}^{\mathbb{Z}}$, we may conclude that

$$c(\varphi(x)) = Sc(x) \quad \text{for each} \quad x \in \Theta \qquad \text{and} \qquad d(\Pi(\lambda)) = Sd(\mathbf{x}) \quad \text{for each} \quad \lambda \in \Lambda.$$

The entire construction is based on the horizontal 2π-translation symmetry of Π. The respective quotient maps are continuous and satisfy

$$\bar{d}(\bar{\Pi}(\bar{\lambda})) = \bar{S}\bar{d}(\bar{\lambda}) \qquad \text{for each} \quad \bar{\lambda} \in \bar{\Lambda}.$$

The quotient transition graph $\mathcal{G}(\bar{\varphi})$ is the complete directed graph on three vertices and thus the modulo 3 itinerary map $\bar{d} : \bar{\Lambda} \to \{0,1,2\}^{\mathbb{Z}}$ is onto. In particular, note that

$$(\bar{d}(\bar{\lambda}))_k = 1 + \varepsilon_k \quad \text{for} \quad \bar{\lambda} \in \bar{\Lambda} = \Lambda \cap \left\{(x, \dot{x}) \in \mathbf{R}^2 \;\middle|\; 0 < x < 2\pi\right\}, \quad k \in \mathbb{Z}.$$

The quotient results can be expressed in compact form as a corollary.

Corollary 2.3 (a continuation of Theorem 1.1). *The modulo 2π Poincaré mapping $\bar{\Pi}$ on $\bar{\Lambda}$ is semiconjugate to the shift operator $\bar{S}$ on Σ_3, the space of three symbols.*

In fact, as suggested by Hubbard [24], $\bar{d}$ is plausibly one-to-one, and thus $\bar{\Pi}|\bar{\Lambda}$ and $\bar{S}$ are conjugate. See Figure 3 again and compare it with Figures 4(a) and 4(b).

3. Chaos detection by computer. What the computer is used for in the Mischaikow–Mrozek framework of computer-assisted proofs for chaos is *to check certain subset relations* (like (2.5), (2.6), (2.7)) and, above all, *to find the subset relations to be checked*—in essence, to find a collection of "rectangular" subsets of the phase space like L_0, M_0, R_0 such that the associated transition graph has at least two different, but intersecting, circles. The hard part is to find the subset relations to be checked. If small perturbation arguments do not help, one cannot get by without a computer. The checking part is much easier and sometimes, in exceptional cases, like the equation $\ddot{x} + x = \sin(\sqrt{2}t) + 2^{-1}(|5x+1| - |5x-1|)$ [38], it can be done by hand. Still, the proof in [38] is computer-assisted. The successful collection of "rectangular" subsets is the result of trial-and-error computer experimentation with human overheads.

It is natural to ask to what extent the task of finding the successful subset relations can be left to the computer. The required subset relations determine a constrained satisfaction problem [10], and techniques of global optimization [39] apply. If we want to look for three quadrangles, the search domain of the optimization procedure is a subset of a 24-dimensional parameter space (eight dimensions for each quadrangle based on the coordinate pairs of the four vertices; the search for a successful collection of the "forbidden sets" $\mathcal{L}_0$, $\mathcal{L}_1$, and $\mathcal{E}_0$ requires the introduction of some additional parameters). And the smaller the search domain, the better. However, a "small" search domain corresponds to a "good" initial guess which can only be obtained from some a priori known theoretical or numerical results on the details of the dynamics. Typical candidates for members of a successful collection are quadrangles situated on the unstable manifold of a transversal homoclinic saddle.

In an interesting paper devoted to Hénon mapping with the classical parameters $a = 1.4$ and $b = 0.3$, Galias [19] describes the configuration of 29 polygons which leads to the rigorous entropy estimate $h(\mathcal{H}) > 0.430\ldots$, which is quite close to the generally accepted value of $h(\mathcal{H}) = 0.465\ldots$. All 29 polygons are narrow quadrangles—or quadrangles with some vertices

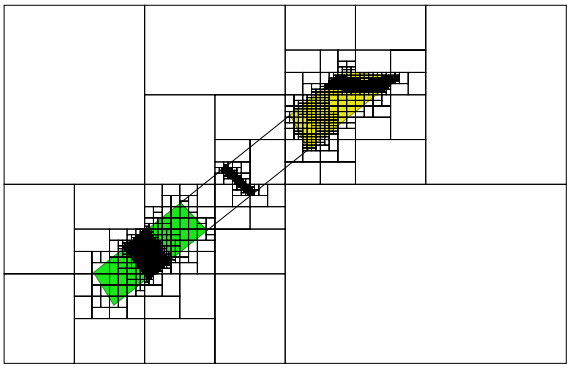
"chopped off"—situated along the unstable manifold of the homoclinic saddle. They were found by hand, based on an earlier search for periodic points of low periods. The well-known and highly automatized GAIO package [12], [13] is used to construct 247 GAIO polygons in a forthcoming paper by Day, Frongillo, and Trevino [11] proving the slightly better estimate of $h(\mathcal{H}) > 0.4318\ldots$. (If a global search is performed just on finding 29 or 247 segments of the unstable manifold, one needs 58 or 494 parameters, respectively. The second number is far too much for optimization methods currently available for this type of problem.) Nevertheless, it remains an open question whether a bootstrap application of global optimization procedures, keeping the number of parameters under 10, say, at each step of the gradual improvements along the consecutive local searches, can achieve a better estimate. We feel that it is not inappropriate here to call to the attention of the reader a forthcoming paper [5] of ours, where, within a 17-dimensional parameter space, the full power of the optimization method [4] is exploited. The main result is that $\mathcal{H}^k$, the kth iterate of Hénon's mapping with the classical parameters $a = 1.4$ and $b = 0.3$, has an embedded copy of the Σ_2 dynamics if and only if $k = 2$, $k = 4$, or $k \geq 6$. This is guaranteed by Smale's abstract theory of transversal homoclinic saddles only for $k \geq k_0$ sufficiently large. (Incidentally, all existence proofs (like [31], [14], [20]) for a transversal homoclinic saddle in the dynamics of $\mathcal{H}$ are, to the best of our knowledge, in some way or other, computer-assisted.)

In proving Theorem 1.1, the vertices of quadrangles L_0, M_0, R_0 (as well as of the "forbidden sets" $\mathcal{L}_0, \mathcal{L}_1, \mathcal{E}_0$) were chosen in the way shown in Hubbard [24]. Though the coordinates of the individual vertices were not explicitly given by him, it was straightforward to adjust them based on Figure 10 of his paper. This adjustment was made by hand. According to our estimates, our method [10] would have required several months of CPU time. Actually, what Hubbard works with are just three large quadrangles, the convex hulls of which we define as the sets $L_\ell \cup M_\ell \cup R_\ell$, $\ell = -1, 0, 1$, and the "forbidden sets" are not mentioned by him at all. At first sight, it is quite plausible that the twelve vertices $V_{ul}^{L_0}, \ldots, V_{lr}^{R_0}$ lie on the circumference of Hubbard's large quadrangle. However, we could not find such an arrangement. This indicates the differences between nonrigorous and rigorous computation. Just like the Hénon mapping $\mathcal{H}$, the Poincaré mapping Π of Hubbard's pendulum equation (1.1) also has a homoclinic saddle. This saddle point is

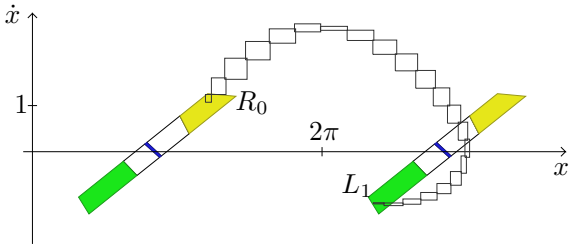
$$P = (2.634\ldots, 0.026\ldots) \quad \text{with eigenvalues} \quad \mu_1 = 321.836\ldots \quad \text{and} \quad \mu_2 = 0.001\ldots$$

(all our computations being rigorous). Of course P represents an unstable 2π-periodic solution which has bifurcated from the upward/top equilibrium position $x = \pi$, $\dot{x} = 0$ of the damped unforced pendulum. Equation (1.1) has a second, asymptotically stable, 2π-periodic solution which corresponds to the sink $Q = (4.236\ldots, 0.392\ldots)$ of the Poincaré mapping with eigenvalues $\mu_{1,2} = -0.725\cdots \pm i\,0.129\ldots$ and which has bifurcated from the bottom equilibrium position $x = 0$, $\dot{x} = 0$ of the damped unforced pendulum. Computer-assisted reasoning shows there are no further 2π-periodic solutions. Note that P is contained in M_0, and its unstable manifold intersects the carefully chosen quadrangles in the rather strange order of $R_{-1}, M_{-1}, L_{-1}, L_0, M_0, R_0, L_1, M_1, R_1$.

Unstable and stable manifolds of P intersect each other outside P. Apparently, this is a transversal intersection. But we did not verify transversality by rigorous computation. The reason is that transversality by itself, though guaranteeing the existence of a topological



(a) A typical detail in the computer-assisted part of proving Theorem 1.1



(b) A typical detail in the computer-assisted part of proving Theorem H

Figure 5. *Checking inclusions by interval computation.*

horseshoe, contains less information about the dynamics than a transition graph with carefully chosen "rectangular" subsets. The next logical step forward should be, rather, the verification of the Conley–Moser invariant cone field conditions [49] leading (if it is really the case) to transversality as well as to the conjugacy between $\bar{\Pi}|\bar{\Lambda}$ and $\bar{S}$. Unfortunately, *the verification of inclusions* (2.5), (2.6), (2.7) *takes almost an hour on a typical modern PC.* See Figure 5(a). Because of this, we think that there is little hope of checking the invariant cone field conditions in a reasonable amount of time. Nevertheless, the semiconjugacy of $\bar{\Pi}|\bar{\Lambda}$ to $\bar{S}$ established in Corollary 2.3 is not much worse than the conjugacy we expected. Semiconjugacy to $\bar{S}$ means that the dynamics is at least as complex as the full shift on the space of three symbols, while conjugacy would mean that the dynamics of $\bar{\Pi}|\bar{\Lambda}$ is just as complex as the one belonging to $\bar{S}$. What can be shown is that $m(\bar{\Lambda})$, the Lebesgue measure of $\bar{\Lambda}$, is zero. (This is clear because $\bar{\Pi}(\bar{\mathcal{C}}) \subset \bar{\mathcal{C}}$ for $\bar{\mathcal{C}} = \{(x, \dot{x}) \in \mathbb{R}^2 \mid 0 \le x < 2\pi,\ |\dot{x}| \le 12\}$, $\bar{\Lambda} \subset \cap_{k=0}^{\infty} \bar{\Pi}^k(\bar{\mathcal{C}})$, and $\bar{\Pi}$ contracts areas by a factor of $e^{-\pi/5}$, due to damping and the Liouville theorem [24].) Questions on additional chaos properties in Hubbard's pendulum equation (1.1)—like the Wada property experimentally observed by Hubbard [24] or fine ergodic properties like the existence of a unique Sinai–Ruelle–Bowen (SRB) measure (found for the Lorenz equation by Tucker [46]) and mixing (found for the Lorenz equation by Luzzato, Melbourne, and Paccaut [29])—remain open.

In conclusion, we note that the existence of a transition graph with two different but intersecting circles is implicit in a paper by Stoffer and Palmer [44] on shadowing. In essence, they prove that the existence of two hyperbolic periodic orbits which come sufficiently near each other without remaining too close for a long time (e.g., those whose minimal periods are highly nonresonant) implies the existence of an embedded horseshoe. This corresponds to the Levinson phenomenon which motivated Smale to construct the geometric horseshoe [43], [28]. For a comparison between the shadowing and the topological approach in computer-assisted proofs for chaos, see the recent paper by Coomes, Kocak, and Palmer [9].

4. Chaos in natural terms of the dynamics. The one-to-one correspondence between a set of the solutions to Hubbard's pendulum equation (1.1) and the set of all bi-infinite

sequences on three symbols manifests itself in natural terms of the dynamics.

Focusing on the pendulum, the quadrangles L_0, M_0, R_0 remain hidden, even to the most observant viewer. What can be easily seen are high speeds or low speeds, the number of consecutive clockwise or counterclockwise returns, changes in the direction of swing and/or rotation, and movements across the upper and/or lower vertical positions. When systematizing a range of dynamical behavior, the mind has a tendency to consider the consecutive occurrences of alternative, easily discernible events like a heads-or-tails sequence in coin-tossing.

Theorems H and 1.1 should be interpreted from this point of view. Any possible order of the mutually exclusive alternatives can occur. Both observations describe the same combinatorial aspect of Σ_3-chaos—the existence of "coin-tossing" (coins with three sides) label sequences [26] for itineraries. However, the alternatives in Theorem 1.1 are hard to observe whereas the alternatives in Theorem H are quite transparent. There exist uncountably many solutions of Hubbard's pendulum equation which can be distinguished from each other based on their combinatorially different qualitative behavior. This is what we might call combinatorial chaos in natural terms of the dynamics. Previous examples include symbolic dynamics in terms of consecutive return times in Alekseev's three-body system [2], [24]; consecutive maxima and minima in the Lorenz systems [22]; the number of sign changes in consecutive time intervals of equal length [7], [45]; and multibumps in bursting oscillations [41]. Their natural place is in the vicinity of bifurcating homoclinic/heteroclinic orbit connections.

Proof of Theorem H. In order to prove Theorem H, we need to examine what the solution map $(x(0), \dot{x}(0)) \to (x(t), \dot{x}(t))$ does between the Poincaré sections at $t_0 = 0$ and $t_1 = 2\pi$.

First, consider the collection of motions of the forced damped pendulum with initial position $(x(0), \dot{x}(0)) \in R_0$ and final position $(x(2\pi), \dot{x}(2\pi)) \in L_1 \cup M_1 \cup R_1$. It is not hard to check by rigorous/interval computation that $0 < x(t) < 4\pi$, whenever $0 \le t \le 2\pi$, and

$$\big\{(x(t), \dot{x}(t)) \in \mathbb{R}^2 \;\big|\; 0 \le t \le 2\pi\big\} \cap \big\{(x, \dot{x}) \in \mathbb{R}^2 \;\big|\; x = 2\pi \text{ and } \dot{x} \le 0\big\} = \emptyset.$$

Applying the intermediate value theorem, it follows that $x(t^*) = 2\pi$ for some $t^* \in (0, 2\pi)$, $x(t) \in (0, 2\pi)$ for $t \in [0, t^*)$, and $x(t) \in (2\pi, 4\pi)$ for $t \in (t^*, 2\pi]$. In other words, during the time interval $(0, 2\pi)$, the pendulum bob crosses the bottom position exactly once counterclockwise and does not point downward at the time instants $t_0 = 0$ and $t_1 = 2\pi$. This holds true for motions of the pendulum with initial position $(x(0), \dot{x}(0)) \in R_0$ and final position $(x(2\pi), \dot{x}(2\pi)) \in L_1 \cup M_1 \cup R_1$ (but not for all motions with initial position $(x(0), \dot{x}(0)) \in R_0$). This holds true especially for all $\sigma_0 = 0$, $\varepsilon_0 = 1$ (and, a fortiori, $\sigma_1 = 1$, $\varepsilon_1 \in \{-1, 0, 1\}$) motions of the pendulum described by Theorem 1.1. Parts of the necessary computations in subcase $\sigma_0 = 0$, $\varepsilon_0 = 1$, $\sigma_1 = 1$, $\varepsilon_1 = -1$ are shown in Figure 5(b).

The remaining cases $\sigma_0 = 0$, $\varepsilon_0 = 0$ and $\sigma_0 = 0$, $\varepsilon_0 = -1$ were settled in a similar way. *The total CPU time requested was under two minutes on a typical modern PC.* ∎

The connection between symbolic dynamics and oscillation patterns in (1.1) is worth further investigation. We would like to know whether symbolic dynamics appears regarding crossing the bottom *and the top* equilibrium positions.

5. Lemma 2.1 in a higher dimension. A simple proof. Let m, n be fixed nonnegative integers, and let $\mathbf{V} \subset \mathbb{Z}$ be a finite or countably infinite indexing set. Next, let the boundary and interior of a compact set S in a Euclidean space $\mathbb{R}^k$ be denoted by ∂S and $\mathrm{int}(S)$,

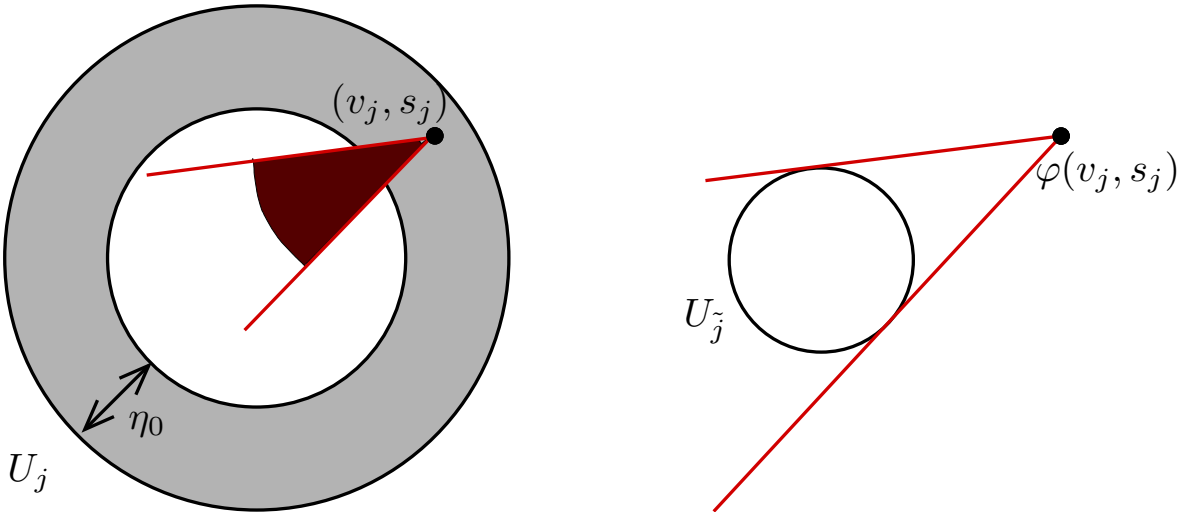


Figure 6. *Condition* (5.2) *for fixed* $(v_j, s_j) \in \{u_j \in U_j \mid d(u_j, \partial U_j) \le \eta_0\} \times S_j$.

respectively. The closed neighborhood of radius $R > 0$ of a point p and a set S in $\mathbb{R}^k$ will be denoted by $\mathcal{B}^k[p, R]$ and $\mathcal{B}^k[S, R]$, respectively. The norm and scalar product in $\mathbb{R}^k$ shall be denoted by $\|\cdot\|$ and $\langle\cdot,\cdot\rangle$.

Now consider the collection of rectangular sets of the form

$$Q_j = \left\{x = (u, s) \in \mathbb{R}^m \times \mathbb{R}^n \;\middle|\; u \in U_j,\ s \in S_j\right\}, \quad j \in \mathbf{V},$$

where $\{U_j\}_{j\in\mathbf{V}}$ and $\{S_j\}_{j\in\mathbf{V}}$ are compact topological balls in $\mathbb{R}^m$ and in $\mathbb{R}^n$, respectively. Note that S_j is a retract of $\mathbb{R}^n$. Let $r_j : \mathbb{R}^n \to S_j$ be a retraction, where $j \in \mathbf{V}$.

Next, let $X = \cup_{j\in\mathbf{V}} Q_j \subset \mathbb{R}^m \times \mathbb{R}^n$ and consider a continuous mapping $\varphi : X \to \mathbb{R}^m \times \mathbb{R}^n$ with coordinate functions φ_u, φ_s. Afterward, suppose that $Q_j \cap Q_k = \emptyset$ for $j \ne k$ and that $\left\{j \in \mathbf{V} \;\middle|\; Q_j \cap \left\{(u, s) \in \mathbb{R}^m \times \mathbb{R}^n \;\middle|\; \|u\| + \|s\| < R\right\} \ne \emptyset\right\}$ is finite for any $R > 0$.

The *transition graph* $\mathcal{G}(\varphi)$ *of* φ is defined as a directed graph with vertex set $\mathbf{V}$. For $j, \tilde{j} \in \mathbf{V}$, the pair $(j, \tilde{j})$ belongs to the edge set $\mathbf{E}$ of $\mathcal{G}(\varphi)$ if

$$\varphi(Q_j) \subset \mathbb{R}^m \times \mathbb{R}^n \setminus U_{\tilde{j}} \times (\mathbb{R}^n \setminus S_{\tilde{j}}) \tag{5.1}$$

and, for some positive constants $\eta_0 = \eta_0(j, \tilde{j})$ and $\kappa_0 = \kappa_0(j, \tilde{j})$, one of the following two conditions holds true:

$$\begin{aligned} &v_j + \kappa(u_{\tilde{j}} - \varphi_u(v_j, s_j)) \in U_j \quad \text{whenever} \\ &v_j \in U_j,\ d(v_j, \partial U_j) \le \eta_0,\ s_j \in S_j,\ u_{\tilde{j}} \in U_{\tilde{j}},\ \text{and}\ 0 \le \kappa \le \kappa_0, \end{aligned} \tag{5.2}$$

or

$$\begin{aligned} &v_j - \kappa(u_{\tilde{j}} - \varphi_u(v_j, s_j)) \in U_j \quad \text{whenever} \\ &v_j \in U_j,\ d(v_j, \partial U_j) \le \eta_0,\ s_j \in S_j,\ u_{\tilde{j}} \in U_{\tilde{j}},\ \text{and}\ 0 \le \kappa \le \kappa_0. \end{aligned} \tag{5.3}$$

The definition of the transition graph in section 2 is more restrictive. If $m = n = 1$, then condition (5.1) is equivalent to $\varphi(Q_j) \subset \mathbb{R}^2 \setminus E_{\tilde{j}}$, a weakening of condition (2.1) discussed in Remark 2. Similarly, with $\eta_0 = 1 - \vartheta_0$ and κ_0 suitably chosen (it is enough to make both $\vartheta_0 > 0$ and $\kappa_0 = \kappa_0(\vartheta_0) > 0$ sufficiently small), conditions (5.2) and (5.3) are implied by conditions (2.2) and (2.3), respectively.

With the notion of the transition graph redefined in $\mathbb{R}^m \times \mathbb{R}^n$, $m, n \geq 1$, the wording of Lemma 2.1 in a higher dimension coincides with that of the original Lemma 2.1 verbatim. Now we turn to the proof of this generalization. Conditions (5.2) and (5.3) will be clarified and analyzed later.

Proof of Lemma 2.1 in $\mathbb{R}^m \times \mathbb{R}^n$. The strategy is to rewrite the system of equations

$$x_{k+1} = \varphi(x_k) \quad \text{and} \quad x_k \in Q_{j_k}, \quad k = 0, 1, \ldots, N,$$

as a fixed point equation $(x_0, x_1, \ldots, x_N) = \mathcal{F}(x_0, x_1, \ldots, x_N)$ in the product space $\prod_{k=0}^{N} Q_{j_k} \subset (\mathbb{R}^m \times \mathbb{R}^n)^{N+1}$ and to check that all conditions of Brouwer's fixed point theorem are satisfied.

Choose a positive constant

$$\kappa^* \leq \min_{k=0,1,\ldots,N} \kappa_0(j_k, j_{k+1}) \quad \text{such that} \quad \kappa^* C^* \leq \min_{k=0,1,\ldots,N} \eta_0(j_k, j_{k+1}),$$

where

$$C^* = \max_{k=0,1,\ldots,N} \max\bigl\{ \|u_{k+1} - \varphi_u(x_k)\| \;\big|\; u_{k+1} \in U_{j_{k+1}},\, x_k \in Q_{j_k} \bigr\}.$$

For $(x_0, x_1, \ldots, x_N) \in \prod_{k=0}^{N} Q_{j_k}$, coordinatewise we set

$$(\mathcal{F}(x_0, x_1, \ldots, x_N))_k = (u_k + \varepsilon_k \kappa^* (u_{k+1} - \varphi_u(x_k)), r_{j_k}(\varphi_s(x_{k-1}))) \in \mathbb{R}^m \times \mathbb{R}^n.$$

Here ε_k depends on the pair $(j, \tilde{j}) = (j_k, j_{k+1})$ taking $\varepsilon_k = 1$ if condition (5.2) applies and $\varepsilon_k = -1$ if condition (5.3) applies, where $k = 0, 1, \ldots, N$.

Since $x_{N+1} = x_0$, $x_{-1} = x_N$ by convention, we shift the index values in the $\mathbb{R}^n$-coordinate and see that the fixed point equation $(x_0, x_1, \ldots, x_N) = \mathcal{F}(x_0, x_1, \ldots, x_N)$ in $\prod_{k=0}^{N} Q_{j_k}$ is equivalent to the system of equations

$$u_{k+1} = \varphi_u(x_k) \quad \text{and} \quad s_{k+1} = r_{j_{k+1}}(\varphi_s(x_k)), \quad k = 0, 1, \ldots, N. \tag{5.4}$$

In view of condition (5.1), the first identity in (5.4) implies that $\varphi_s(x_k) \in S_{j_{k+1}}$. Hence $r_{j_{k+1}}(\varphi_s(x_k)) = \varphi_s(x_k)$, and system (5.4) simplifies to

$$u_{k+1} = \varphi_u(x_k) \quad \text{and} \quad s_{k+1} = \varphi_s(x_k), \quad \text{i.e.,} \quad x_{k+1} = \varphi(x_k), \quad k = 0, 1, \ldots, N.$$

It is clear that $\prod_{k=0}^{N} Q_{j_k}$ is a compact topological ball in $(\mathbb{R}^m \times \mathbb{R}^n)^{N+1}$ and $\mathcal{F} : \prod_{k=0}^{N} Q_{j_k} \to (\mathbb{R}^m \times \mathbb{R}^n)^{N+1}$ is a continuous function. Here all that remains is for us to prove that

$$(\mathcal{F}(x_0, x_1, \ldots, x_N))_k \in Q_{j_k} \quad \text{whenever} \quad (x_0, x_1, \ldots, x_N) \in \prod_{k=0}^{N} Q_{j_k},$$

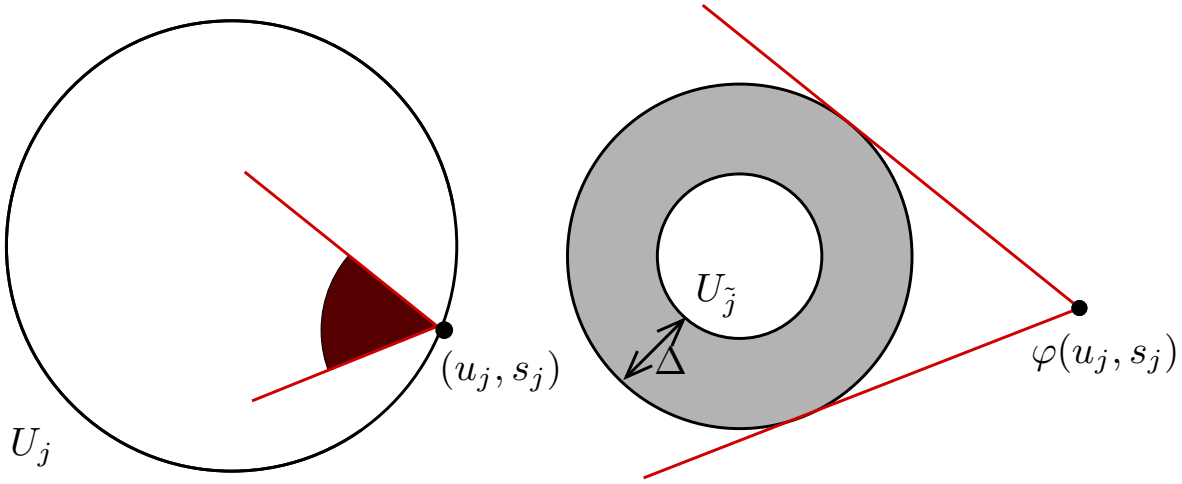

Figure 7. *Condition* (5.6) *for fixed* $(u_j, s_j) \in \partial U_j \times S_j$.

$k = 0, 1, \ldots, N$. Since $r_{j_k}(\varphi_s(x_{k-1})) \in S_{j_k}$, we can go to the $\mathbb{R}^m$-coordinate and just check that

$$u_k + \varepsilon_k \kappa^*(u_{k+1} - \varphi_u(x_k)) \in U_{j_k} \quad \text{if} \quad x_k = (u_k, s_k) \in Q_{j_k} \text{ and } u_{k+1} \in U_{j_{k+1}}. \tag{5.5}$$

If $u_k \in U_{j_k}$ with $d(u_k, \partial U_{j_k}) \le \eta_0(j_k, j_{k+1})$, then—depending on the value of ε_k—(5.5) reduces to (5.2) or (5.3) with $\kappa = \kappa^*$. On the other hand, if $u_k \in U_{j_k}$ with $d(u_k, \partial U_{j_k}) > \eta_0(j_k, j_{k+1})$, then (5.5) follows from the inequality $\kappa^* \|u_{k+1} - \varphi_u(x_k)\| \le \kappa^* C^* \le \eta_0(j_k, j_{k+1})$, $k = 0, 1, \ldots, N$. ■

From a geometric point of view, both condition (5.2) and the alternative condition (5.3) imply that $U_{\tilde{j}}$ is "surrounded by" $\varphi_u(\partial U_j \times S_j)$. In the special case, $U_j = U_{\tilde{j}} = \mathcal{B}^m[0, 1]$ and $S_j = \mathcal{B}^m[0, 1]$ (compact unit balls in the respective Euclidean spaces), so condition (5.2) is a consequence of the inequality

$$\langle \varphi_u(u, s) - \tilde{u},\, u \rangle > 0 \quad \text{whenever } u, \tilde{u} \in \mathbb{R}^m,\ s \in \mathbb{R}^n,\ \|u\| = 1,\ \|\tilde{u}\|, \|s\| \le 1,$$

which resembles certain geometric conditions in various versions of Brouwer's fixed point theorem [51].

The remaining part of this section will be devoted to a technical analysis of conditions (5.2) and (5.3). By a symmetry argument, this analysis reduces to investigating (5.2). Condition (5.2) will be replaced by the slightly stronger condition (5.6), which is stable with respect to small perturbations of φ_u, including numerical approximations with rounding errors. A second advantage of (5.6) over (5.2) is that condition (5.6) can be readily checked. To see this, compare Figure 7 with Figure 6. Overall, condition (5.6) is better suited to computer-assisted proofs than (5.2). The section ends with the somewhat more convenient and transparent condition (5.8), where uniformity with respect to λ is not required.

Proposition 5.1. *Condition* (5.2) *is a consequence of a simpler requirement. It is that there*

exist positive constants $\lambda_0 = \lambda_0(j,\tilde{j})$ *and* $\Delta = \Delta(j,\tilde{j})$ *such that*

$$u_j + \lambda(w_{\tilde{j}} - \varphi_u(u_j, s_j)) \in U_j \quad \text{whenever} \tag{5.6}$$
$$u_j \in \partial U_j,\ s_j \in S_j,\ w_{\tilde{j}} \in \mathcal{B}^m[U_{\tilde{j}}, \Delta],\ \text{and}\ 0 \le \lambda \le \lambda_0.$$

Proof. We omit indices $j, \tilde{j}$ in the following and write $U = U_j$, $S = S_j$, and $W = U_{\tilde{j}}$.

Now suppose that condition (5.6) is satisfied but (5.2) is not. Then there are sequences $\{v_\ell\} \subset U$, $\{s_\ell\} \subset S$, $\{w_\ell\} \subset W$, $\{\kappa_\ell\} \subset \mathbb{R}^+$, which have the following properties:

$$p_\ell = v_\ell + \kappa_\ell(w_\ell - \varphi_u(v_\ell, s_\ell)) \notin U \quad \text{for} \quad \ell = 1, 2, \dots \tag{5.7}$$

and both $v_\ell \to \partial U$ and $\kappa_\ell \to 0$ as $\ell \to \infty$.

Since $v_\ell \in U$ and $p_\ell \notin U$, there exists a $\kappa_\ell^* \in [0, \kappa_\ell)$ such that

$$z_\ell = v_\ell + \kappa_\ell^*(w_\ell - \varphi_u(v_\ell, s_\ell)) \in \partial U \quad \text{for} \quad \ell = 1, 2, \dots.$$

With the construction, $0 < \kappa_\ell - \kappa_\ell^* \le \lambda_0$, and (by using the uniform continuity of mapping φ_u on the compact set $U \times S$) $\|\varphi_u(z_\ell, s_\ell) - \varphi_u(v_\ell, s_\ell)\| \le \Delta$ for ℓ large enough. In view of condition (5.6), we conclude that

$$p_\ell = z_\ell + (\kappa_\ell - \kappa_\ell^*)[(w_\ell + \varphi_u(z_\ell, s_\ell) - \varphi_u(v_\ell, s_\ell)) - \varphi_u(z_\ell, s_\ell)] \in U$$

for large enough ℓ, which contradicts (5.7). ∎

Proposition 5.2. *Actually, condition* (5.6) *is a consequence of a simpler requirement. It is that there exists a positive constant* $\delta = \delta(j,\tilde{j})$ *such that*

$$u_j + \mu(w_{\tilde{j}} - \varphi_u(u_j, s_j)) \in \operatorname{int}(U_j) \quad \text{whenever} \tag{5.8}$$
$$u_j \in \partial U_j,\ s_j \in S_j,\ w_{\tilde{j}} \in \mathcal{B}^m[U_{\tilde{j}}, \delta],\ \text{and}\ 0 < \mu \le \mu_0\ \text{with some}\ \mu_0 = \mu_0(u_j, s_j, w_{\tilde{j}}).$$

Proof. As before, we write $U = U_j$, $S = S_j$, and $W = U_{\tilde{j}}$.

Fix $u^* \in \partial U$, $s^* \in S$, and $w^* \in W$. By compactness, it is sufficient to demonstrate the existence of two positive constants $\tau = \tau(u^*, s^*, w^*)$ and $\lambda^* = \lambda^*(u^*, s^*, w^*)$ such that, given $u \in \partial U$, $s \in S$, and $w \in \mathcal{B}^m[W, \delta]$ with $\|u - u^*\| \le \tau$, $\|s - s^*\| \le \tau$, $\|w - w^*\| \le \tau$, the following holds true:

$$u + \lambda(w - \varphi_u(u, s)) \in U \quad \text{whenever} \quad 0 \le \lambda \le \lambda^*.$$

By continuity, there is a $\sigma \in (0, \delta)$ such that, for arbitrary $w \in \mathcal{B}^m[w^*, \sigma]$ and $q \in U \cap \mathcal{B}^m[u^*, \sigma]$,

$$\tilde{w} - \varphi_u(q, s^*) = w - \varphi_u(u^*, s^*) \quad \text{for some} \quad \tilde{w} \in \mathcal{B}^m[w^*, \delta]. \tag{5.9}$$

In view of condition (5.8) with $(u^*, s^*, w^*) = (u_j, s_j, w_{\tilde{j}})$, we may assume that

$$u^* + \alpha_+^*(w^* - \varphi_u(u^*, s^*)) \in \operatorname{int}(U) \cap \partial\mathcal{B}^m[u^*, \sigma] \quad \text{for some} \quad \alpha_+^* > 0.$$

As a corollary, a simple geometric argument implies the existence of a constant $\eta \in (0, \sigma)$ such that, for arbitrary $p \in \mathcal{B}^m[u^*, \eta]$ and $w \in \mathcal{B}^m[w^*, \eta]$,

$$p + \alpha_+(w - \varphi_u(u^*, s^*)) \in \operatorname{int}(U) \cap \partial\mathcal{B}^m[u^*, \sigma] \quad \text{for some} \quad \alpha_+ = \alpha_+(p, w) > 0,$$

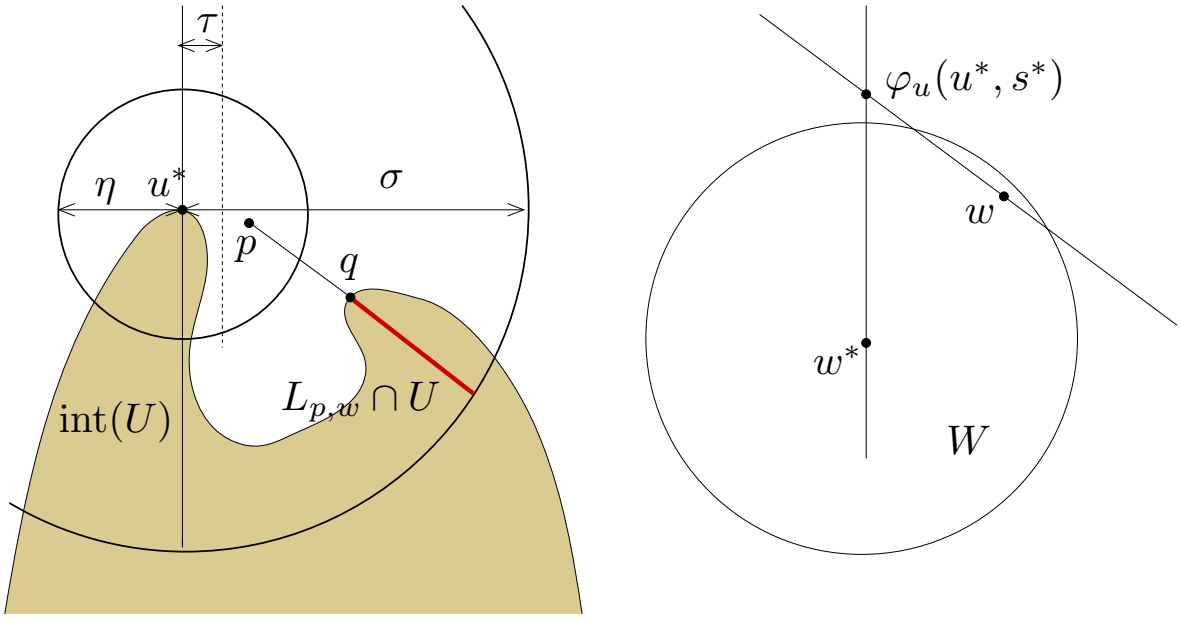

Figure 8. *Illustration of the proof of Proposition 5.2.*

where α_+ is unique, the function $(p, w) \to \alpha_+(p, w)$ is continuous, and $\alpha_+(u^*, w^*) = \alpha_+^*$. For future use, we note that

$$\alpha_* = \inf\{\alpha_+(p, w) \mid p \in \mathcal{B}^m[u^*, \eta],\ w \in \mathcal{B}^m[w^*, \eta]\} > 0$$

by compactness. Now consider the straight line segment

$$L_{p,w} = \{p + \lambda(w - \varphi_u(u^*, s^*)) \mid \lambda \geq 0\} \cap \mathcal{B}^m[u^*, \sigma],$$

and assume that $q = p + \gamma_0(w - \varphi_u(u^*, s^*)) \in \partial U \cap L_{p,w}$ for some $\gamma_0 < \alpha_+$. Applying property (5.9), condition (5.8) (with $(q, s^*, \tilde{w}) = (u_j, s_j, w_{\tilde{j}})$) implies that

$$p + \gamma(w - \varphi_u(u^*, s^*)) = q + (\gamma - \gamma_0)(\tilde{w} - \varphi_u(q, s^*)) \in \operatorname{int}(U)$$

for $\gamma > \gamma_0$, where $|\gamma - \gamma_0|$ is small. By an elementary connectedness argument in one dimension, we infer that $L_{p,w} \cap U$ is a compact interval with an endpoint on $\partial\mathcal{B}^m[u^*, \sigma]$. See Figure 8.

Similarly, observe that there exists a constant $\tau \in (0, \eta)$ such that, for arbitrary $w \in \mathcal{B}^m[w^*, \tau]$, $u \in U \cap \mathcal{B}^m[u^*, \tau]$, and $s \in S \cap \mathcal{B}^n[s^*, \tau]$,

$$\hat{w} - \varphi_u(u^*, s^*) = w - \varphi_u(u, s) \quad \text{for some} \quad \hat{w} \in \mathcal{B}^m[w^*, \eta]. \tag{5.10}$$

If, in particular, $u \in \partial U \cap \mathcal{B}^m[u^*, \tau]$, $s \in S \cap \mathcal{B}^n[s^*, \tau]$, and $w \in \mathcal{B}^m[w^*, \tau]$, then by property (5.10)

$$\{u + \lambda(w - \varphi_u(u, s)) \mid \lambda \geq 0\} \cap \mathcal{B}^m[u^*, \sigma] = L_{u,\hat{w}}$$

for some $\hat{w} \in \mathcal{B}^m[w^*, \eta]$. Since $u \in \partial U \subset U$ and $L_{u,\hat{w}} \cap U$ is a compact interval with an endpoint on $\partial\mathcal{B}^m[u^*, \sigma]$, we conclude that $L_{u,\hat{w}} \subset U$. Hence $u + \lambda(w - \varphi_u(u, s)) \in U$ for $0 \leq \lambda \leq \alpha_+(u, \hat{w})$, and thus $\lambda^* = \lambda^*(u^*, s^*, w^*)$ can be chosen for $\alpha_* > 0$. ∎

We do not know whether $\mathrm{int}(U_j)$ in (5.8) can actually be replaced by U_j. On the other hand, simple examples confirm that Proposition 5.1 does not hold true for $\Delta = 0$.

6. Lemma 2.1 and a recent four-dimensional example of Yang and Li [50]. As we mentioned earlier, conditions (5.2) and (5.3) can be readily checked for $m = 1$, but they are more complicated for $m > 1$. Regardless of the value of the positive integer n, condition (5.1) remains rather simple. It follows that for small, multidimensional perturbations of one-dimensional mappings which "contract" in the new directions, the $m = 1$, $n \geq 1$ case of Lemma 2.1 can be applied without difficulty. For example, Lemma 2.1 can be applied for the family of mappings investigated in [54] and simplifies the proofs therein.

As for the $m > 1$ case, it is reasonable to suppose that a twofold application of Lemma 2.1 leads to a rigorous proof of the existence of chaotic behavior in a recent four-dimensional neural network example of Yang and Li [50]. Our conjecture is supported by analyzing the figures in that paper.

We will now consider the autonomous system of ordinary differential equations [50]

$$\begin{aligned}
\dot{x}_1 &= -x_1 + 2.10f(x_1) + 2.50f(x_2),\\
\dot{x}_2 &= -x_2 - 2.60f(x_1) + 1.00f(x_2) + 3.00f(x_3),\\
\dot{x}_3 &= -x_3 - 2.80f(x_2) + 0.50f(x_3) - 1.10f(x_4),\\
\dot{x}_4 &= -100x_4 + 100f(x_3) + 160f(x_4),
\end{aligned} \tag{6.1}$$

which models a cellular neural network of Chua–Roska type [8] with $f(x_i) = 2^{-1}(|x_i + 1| - |x_i - 1|)$, $x_i \in \mathbb{R}$, $i = 1, 2, 3, 4$. A horseshoe in an appropriate Poincaré mapping Π was found by Yang and Li [50] numerically, via nonrigorous computation. Their paper does not say how the 14 coefficients/weights on the right-hand side of the above system of ordinary differential equations were chosen. The nice Figure 4 in [50] suggests that the successful Poincaré section was chosen by a trial-and-error process with human overheads.

Now we would like to show that, with the underlying sets properly chosen, the transition graph $\mathcal{G}(\Pi)$ is the complete directed graph on two vertices. The argument will be based on the case $m = 2$, $n = 1$ of the higher-dimensional generalization of Lemma 2.1 and, of course, on the geometric information contained in [50].

Simplified and schematic variants of Figures 7, 5, and 8 of [50] are presented here as Figures 9, 10, and 11, respectively. The two vertical prisms with quadrilateral bases in [50] correspond to our cylinders $\mathcal{C}_U = U \times S$ and $\mathcal{C}_W = W \times S$, while the vertical edges of the prisms correspond to the points A_ℓ and B_ℓ, $\ell = 1, 2, 3, 4$, respectively. The prisms are strongly contracted in the vertical direction. As for the two horizontal directions within, mapping Π is a modest expansion. Applied to our situation, the crucial observation in [50] is that vertical segments on the jacket of $\mathcal{C}_U$ and of $\mathcal{C}_W$ (i.e., segments of the form $\{A\} \times S$ and $\{B\} \times S$ with $A \in \partial U$ and $B \in \partial W$) are mapped onto "almost vertical" curves on $\partial\Pi(\mathcal{C}_U)$ and on $\partial\Pi(\mathcal{C}_W)$, respectively. This explains why $\Pi(\mathcal{C}_U)$ and $\Pi(\mathcal{C}_W)$ can be regarded as cylinders and implies that condition (5.6) or its alternative counterpart (i.e., there exist positive constants λ_0 and Δ such that

$$\begin{aligned}
&u_j - \lambda(w_{\tilde{j}} - \varphi_u(u_j, s_j)) \in U_j \quad \text{whenever}\\
&u_j \in \partial U_j,\ s_j \in S_j,\ w_{\tilde{j}} \in \mathcal{B}^m[U_{\tilde{j}}, \Delta],\ \text{and}\ 0 \leq \lambda \leq \lambda_0)
\end{aligned} \tag{6.2}$$

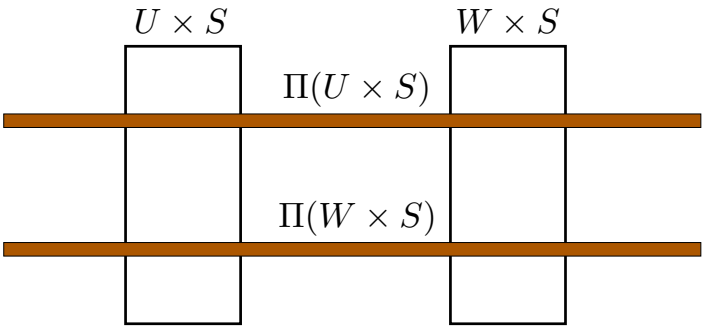

Figure 9. *The front view of the four cylinders* $\mathcal{C}_U = U \times S$, $\mathcal{C}_W = W \times S$, $\Pi(\mathcal{C}_U)$, *and* $\Pi(\mathcal{C}_W)$.

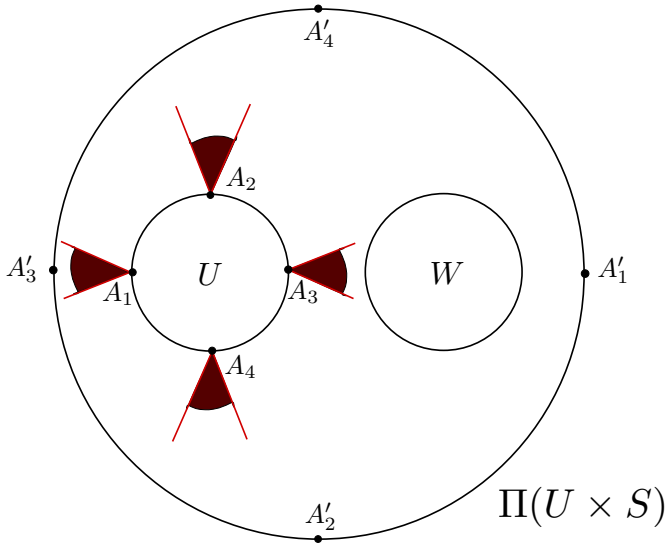

Figure 10. *The upper view of the cylinders* $\mathcal{C}_U = U \times S$, $\Pi(\mathcal{C}_U)$, *and* $\mathcal{C}_W = W \times S$.

has to be checked only for a single $s = s^* \in S$. There is no loss of generality in assuming that $S = [-1, 1] \subset \mathbb{R}$ and $s^* = 0$. For brevity, we write $A'_\ell = \Pi_u(A_\ell, 0)$ and $B'_\ell = \Pi_u(B_\ell, 0)$, $\ell = 1, 2, 3, 4$. The relative position of the four cylinders and the 2×8 special points in Figures 9, 10, and 11 are exactly like the computer pictures in [50].

In what follows we will show that Lemma 2.1 applies in this situation. We do this by examining if and how, with $U_j = U, W$ and $U_{\tilde{j}} = U, W$, the alternative pair of conditions (5.6) and (6.2) is satisfied. The final result will be that, with vertex set $\mathbf{V}(\mathcal{G}) = \{C_U, C_W\}$, the edge set of the transition graph $\mathcal{G}(\Pi)$ is $\mathbf{E}(\mathcal{G}) = \{(C_U, C_U), (C_U, C_W), (C_W, C_U), (C_W, C_W)\}$.

For a fixed $\ell \in \{1, 2, 3, 4\}$, the angular sector at A_ℓ in Figure 10 describes the two cones

$$\{A_\ell + \lambda(u - A'_\ell) \in \mathbb{R}^2 \mid u \in \mathcal{B}^2[U, \Delta] \text{ and } 0 \le \lambda \le \lambda_0\}$$

and

$$\{A_\ell + \lambda(w - A'_\ell) \in \mathbb{R}^2 \mid w \in \mathcal{B}^2[W, \Delta] \text{ and } 0 \le \lambda \le \lambda_0\}.$$

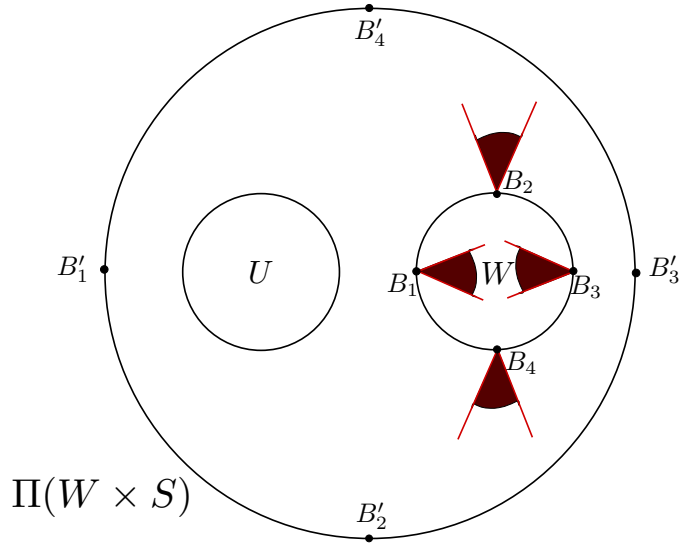

Figure 11. *The upper view of the cylinders $\mathcal{C}_W = W \times S$, $\Pi(\mathcal{C}_W)$, and $\mathcal{C}_U = U \times S$.*

(For the sake of simplicity, these two cones have been drawn in Figure 10 as a single angular sector with vertex A_ℓ for every ℓ. And, like all of figures in this section, the small positive constants Δ and λ_0 remain unspecified.) Based on the direction of these angular sectors, it seems plausible that condition (6.2) is satisfied for $\varphi = \Pi$, $S_j = [-1, 1]$, $U_j = U$, and $U_{\tilde{j}} = U, W$. Regarding the proof of Lemma 2.1, Proposition 5.1 implies that condition (5.5) is satisfied for $\varphi = \Pi$, $S_{j_k} = [-1, 1]$, $U_{j_k} = U$, $\varepsilon_k = -1$, and $U_{j_{k+1}} = U, W$.

Similarly, for $\ell = 1, 2, 3, 4$, the angular sector at B_ℓ in Figure 11 describes the two cones (or the union of the two cones)

$$\{B_\ell + \lambda(u - B'_\ell) \in \mathbb{R}^2 \mid u \in \mathcal{B}^2[U, \Delta] \text{ and } 0 \le \lambda \le \lambda_0\}$$

and

$$\{B_\ell + \lambda(w - B'_\ell) \in \mathbb{R}^2 \mid w \in \mathcal{B}^2[W, \Delta] \text{ and } 0 \le \lambda \le \lambda_0\}.$$

Unfortunately, neither condition (5.6) nor (6.2) is satisfied, and, if left unchanged, the proof of Lemma 2.1 breaks down in the present situation. However, the direction of the four angular sectors in Figure 11 suggests a simple way out.

Together with a combinatorial modification, the proof of Lemma 2.1 still holds true. The $\mathbb{R}^m = \mathbb{R}^2$ coordinate

$$u_k + \varepsilon_k \kappa^*(u_{k+1} - \varphi_u(x_k)) = u_k + \varepsilon_k \kappa^*(u_{k+1} - \Pi_u(x_k)) \in \mathbb{R}^2$$

of $(\mathcal{F}(x_0, x_1, \dots, x_N))_k$, $k = 0, 1, \dots, N$, is to be replaced by

$$(u^1_k + \varepsilon^1_k \kappa^*(u^1_{k+1} - \Pi^1_u(x_k)),\ u^2_k + \varepsilon^2_k \kappa^*(u^2_{k+1} - \Pi^2_u(x_k))) \in \mathbb{R} \times \mathbb{R},$$

where superscript 1 (resp., 2) stands for the first (= horizontal) (resp., second (= vertical)) coordinate in Figures 10 and 11, and

$$\varepsilon^1_k = \varepsilon^2_k = -1 \qquad \text{if} \quad U_{j_k} = U \quad \text{and} \quad U_{j_{k+1}} = U, W,$$

and

$$\varepsilon_k^1 = 1,\ \varepsilon_k^2 = -1 \qquad \text{if} \quad U_{j_k} = W \quad \text{and} \quad U_{j_{k+1}} = U, W.$$

No other changes are needed for the proof. After this refinement of the choice of parameter ε_k, condition (5.5) will be satisfied again.

We feel justified in concluding that, eventually, the argument outlined above leads to a rigorous proof for the existence of embedded Σ_2 dynamics in (6.1). At present, several details are missing. It is not enough to check the alternative conditions for two times four points in a simplified and schematic situation. The relation between the original dynamics creating Figures 7, 5, and 8 of [50] and its simplified representation in Figures 9, 10, and 11 has to be analyzed rigorously. This task is parallel to the one we performed in section 2 for Hubbard's forced damped pendulum equation (1.1).

Acknowledgment. The authors are grateful for the suggestions and comments of the referees that helped improve the paper.

A Method for Determining Most Probable Errors in Nonlinear Lightwave Systems*

Elaine T. Spiller† and William L. Kath‡

Abstract. We present a method for computing bit-error ratios in soliton-based lightwave systems. The method uses soliton perturbation theory and calculus of variations to find approximate versions of the most probable paths through sample space leading to errors, combined with importance-sampled Monte Carlo simulations of the full set of equations around these approximate paths to compute the actual error rates. As a specific example, the method is applied to a differential phase-shift-keyed lightwave system. For this example the method not only computes the bit-error ratio but also predicts the set of failure modes leading to large pulse distortions, thus illuminating the specific manner in which errors occur.

Key words. solitons, perturbation theory, calculus of variations, rare events, importance sampling, lightwave systems, phase-shift keying, bit-error ratio

1. Introduction.

In-line optical amplification and nonlinear propagation are two of the primary features of modern long-distance lightwave communication systems. Optical amplification adds spontaneous emission noise to the signal [1], and nonlinearities present in the system can distort the combined signal plus noise during propagation [2], causing the output statistics to differ significantly from Gaussian random variables. Because the ultimate performance of such communication systems is often limited by noise, it is desirable to be able to predict how often errors occur. This is a challenging task, both because of the complicated interaction between signal and noise and because system designers typically require that errors be *rare events*, e.g., a bit-error ratio of 1 error per 10^9 bits or more.

Monte Carlo methods are one standard way to compute error probabilities, but doing so for such rare events is, of course, beyond the capability of standard methods. Recently, however, the application of both importance-sampled Monte Carlo [3, 4, 5, 6] and multicanonical Monte Carlo methods [7, 8, 9, 10, 11, 12] has demonstrated that it is possible to successfully overcome the limitations of standard Monte Carlo simulations for studying rare events in lightwave communication systems. Other methods are possible, of course [13, 14], and the development of new techniques is a subject of current active research. A common theme of

such methods is the biasing of the noise used in the simulations so that samples from the region(s) of state space where the sought-after rare events (i.e., errors) occur arise much more frequently than they would normally. Once one accounts for the biasing, one can efficiently compute probability distribution functions (pdfs) that are accurate far down into the tails. Multicanonical Monte Carlo employs an iterative numerical procedure to determine the biasing toward the desired regions of state space, while importance-sampled Monte Carlo relies on physical or mathematical insight to accomplish this task.

A challenge associated with implementing importance sampling is in choosing a biasing distribution that is close to optimal, i.e., a biasing that *efficiently* samples from the regions of state space where the events of interest are most likely to occur [15]. Previously we have presented numerical results demonstrating that this can be done to simulate noise-induced transmission impairments in phase-modulated communication systems [16]. The purpose of this paper is to describe in detail the methods used to produce such numerical simulations, specifically, how the structure of the nonlinear Schrödinger (NLS) equation and results from approximate methods (in this case, soliton perturbation theory) can be used to guide importance-sampled Monte Carlo simulations of rare events in phase-modulated lightwave communications systems. Essentially, the search for an efficient biasing distribution breaks down into two optimization problems: At an individual amplifier, what is the most likely noise realization that will lead to a specified parameter change? And, over the entire transmission length, what combination of parameter changes at each amplifier is most likely to lead to large signal distortions and, ultimately, errors? The resolution of these questions not only allows the error rate to be computed but also provides insight into how errors arise.

This paper is organized as follows: in section 2 we present the NLS equation and review soliton perturbation theory. We also give an overview of some modulation formats, in particular, the manner in which information is encoded onto a uniform sequence of optical pulses. In section 3 we discuss some background concerning importance-sampled Monte Carlo simulations and present the solution to the optimal biasing problem at one amplifier. In section 3.2 we describe the full optimal biasing problem for a specific modulation format known as differential phase-shift keying (DPSK). The biasing problem is formulated here using a continuous approximation of the governing evolution equations and is thus an extension of previous versions which employed discrete approximations [3, 4]. This new version of the biasing problem allows more complicated problems to be treated, since they can be solved via calculus of variations. The resulting boundary value problem yields multiple solutions which we describe in detail and which we interpret as possible error modes. In section 5 we discuss the implementation of the importance-sampled Monte Carlo method for the differential phase-shift-keyed problem and present the results of simulations.

2. Formulation. A basic schematic of the differential phase-shift-keyed transmission system to be analyzed and simulated is included in Figure 1. In general terms, the system consists of a long length of fiber with a transmitter at the beginning and a receiver at the end [17]. The components of the transmitter are a laser acting as a source of pulses and a Mach–Zehnder modulator to encode data upon them. This data stream is then launched into the optical fiber. Because the signal experiences loss as it propagates, a gain element is usually inserted every few tens of kilometers to compensate for the loss [17]. Thus, the combination of propagation with loss followed by gain typically must be repeated a number of times to

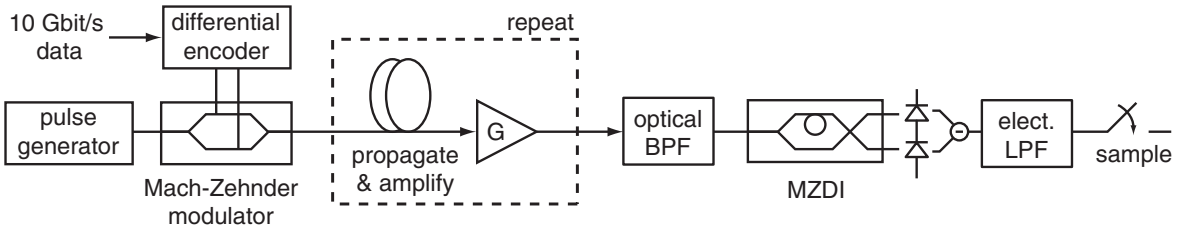

Figure 1. *Basic schematic of a differential phase-shift-keyed transmission system. For a specific description of the elements, please see the text.*

achieve the desired total optical transmission distance. A final set of components filters out noise and recovers the signal; here the elements of the receiver are an optical band-pass filter, a Mach–Zehnder delay interferometer, an electrical low-pass filter, and an electrical sampler.

2.1. Model of a soliton-based lightwave system. The longest part of the system is the optical fiber with periodic amplification. We will model this propagation using the NLS equation with periodically added noise [2]:

$$\frac{\partial u}{\partial z} = \frac{i}{2}\frac{\partial^2 u}{\partial t^2} + i|u|^2 u + \sum_{k=1}^{N_{\text{amp}}} n_k(t)\delta(z - kz_{\text{a}}). \tag{2.1}$$

Here u represents the optical signal's electromagnetic field envelope, z and t are dimensionless distance and retarded time, N_{amp} is the total number of amplifiers, and z_{a} is the dimensionless distance between them. As is customary in the optics literature, z is considered to be the propagation variable, and the "initial condition" (i.e., input signal) is the time-varying electric field envelope profile defined at the beginning of the fiber span, $z = 0$. The model also includes white Gaussian noise added by each amplifier,

$$\begin{aligned} \langle n_i(t)\rangle &= 0, \\ \langle n_i(t) n_j^*(t')\rangle &= \sigma^2 \delta_{ij}\delta(t - t'). \end{aligned} \tag{2.2}$$

This accounts for the effect of photons which are spontaneously emitted at each amplifier and which subsequently experience gain along with the signal (hence the name amplified spontaneous emission (ASE) noise [1]). Here * represents the complex conjugate, and σ^2 is the noise variance; physically, $\sigma^2 = (G-1)^2 \eta_{\text{sp}} T_{\text{w}} \gamma / D\, G \ln G$, where G is the amplifier (power) gain, η_{sp} is the amplifier's spontaneous emission factor, T_{w} is the pulse width, and γ and D are the fiber's nonlinear and dispersion coefficients [2]. The assumption of delta-correlated noise is not physically realistic because as written it contains infinite power, so this should be interpreted merely as a shorthand for the case where the noise spectrum has a bandwidth much larger than that of the signal [1]. Note that in (2.1) we have already averaged out the deterministic power fluctuations caused by loss and amplification [18] in order to more easily focus on the detrimental effects of ASE noise.

In the absence of noise, (2.1) has the well-known soliton solution given by [19]

$$u(t, z) = A \operatorname{sech}(A[t - T]) \exp(i\Omega[t - T] + i\varphi). \tag{2.3}$$

Here A, T, Ω, and φ are, respectively, the amplitude, position, frequency, and phase of the pulse. In the absence of noise A and Ω are constant and T and φ evolve according to $dT/dz = \Omega$ and $d\varphi/dz = (A^2 + \Omega^2)/2$. Note that the parameters in this solution arise from the invariances of the NLS equation [20], and so if a perturbation such as noise alters one or more of these parameters, the solution with changed parameters is a perfectly valid solution of the NLS equation. Thus, it is precisely because of these invariances that noise-induced perturbations can build into large deviations over long propagation distances.

2.2. Differential phase-shift keying (DPSK). A modulation format is the method by which information is encoded on an otherwise periodic optical signal. On-off keying (OOK), i.e., sending a single pulse of light to represent a logical "1" and none for a logical "0," is one traditional encoding format used in lightwave communication systems. An alternative method is phase-shift keying, where information is encoded on the optical signal's phase while the amplitude remains constant [21, 22, 23]. Differential phase-shift keying is a slight variant of this, in which information is encoded on the *phase difference* between two adjacent pulses. We will consider a binary differential phase-shift-keyed system where the transmitter consists of a source that produces an identical sequence of pulses followed by a modulator that encodes no phase difference between pulses to represent a logical "1" and a π phase difference to represent a logical "0." (The reverse could also be used, of course.)

At the receiver in a differential phase-shift-keyed system, the signal is detected, and adjacent bit slots[1] are compared to determine if the received signal represents a "1" or a "0." This step must also be modeled, because we are ultimately interested in calculating the probability of an error, i.e., the probability that a "1" was sent and a "0" was detected, or vice-versa. From an engineering perspective, it is difficult to directly measure the absolute phase of a pulse; it is substantially easier to interfere two adjacent pulses and calculate the resulting optical intensity as a voltage. In practice one does this with a device comprised of a Mach–Zehnder delay interferometer followed by a balanced detector, as shown in Figure 1.

A Mach–Zehnder delay interferometer splits the signal into two copies and delays one relative to the other by one bit period, T_b. The two optical signals are then both constructively and destructively interfered. This process is repeated for each pair of received optical pulses. The balanced detector produces a voltage by subtracting the intensity of the destructively interfered signal from the intensity of the constructively interfered signal. Therefore, if at the end of transmission $u(t)$ is the optical field envelope and $u(t - T_\mathrm{b})$ is the version delayed by T_b, then the voltage after interference and balanced detection (but before electrical filtering) is given by

$$V(t) = |u(t) + u(t - T_\mathrm{b})|^2 - |u(t) - u(t - T_\mathrm{b})|^2. \tag{2.4}$$

With this encoding format, the threshold voltage is at $V = 0$ and a positive voltage at the output of the detector in the center of a bit slot represents a "1," while a negative voltage represents a "0." Note that the zero voltage threshold corresponds to a phase difference of $\pi/2$ between the two pulses, independent of their amplitudes.

Figure 2 is a schematic outline of the detection process for a back-to-back signal, i.e., when detection immediately follows encoding without transmission. The top two plots are

[1] A bit slot is one of the finite-width temporal windows into which an optical signal is divided.

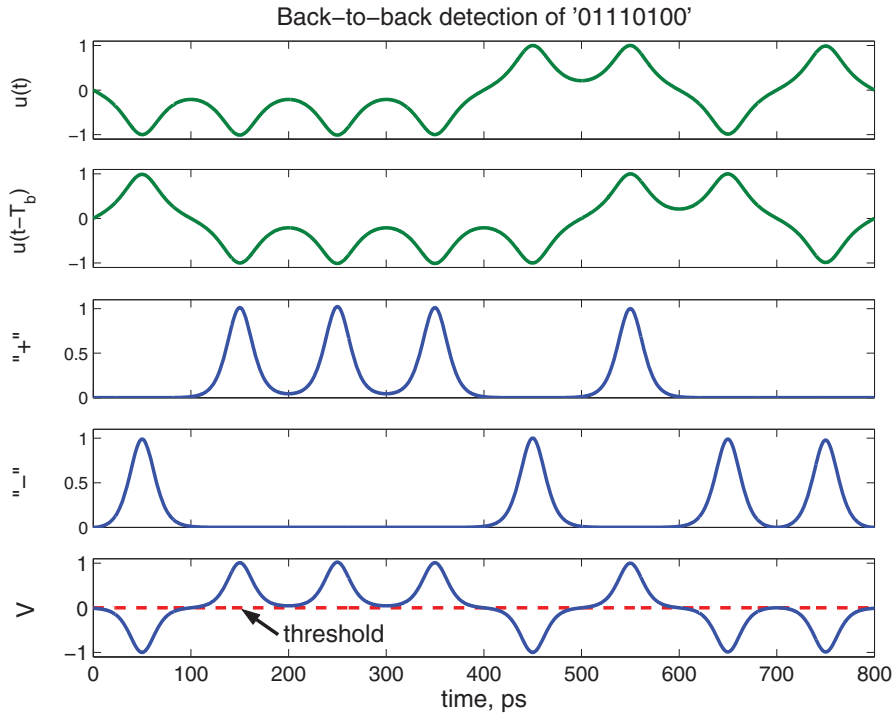

Figure 2. *In order from top to bottom: (The modulus of) the original and delayed optical signals (green), the constructively and destructively interfered electrical signals, and the output voltage V (blue), all in arbitrary units. The detection process is described in the text. On this plot, $V = 0$, and the signal is assumed to be periodic; the detection threshold (dashed red) is also included.*

the optical signal and the optical signal delayed one bit slot within the Mach–Zehnder delay interferometer. The next two plots are the output from the Mach–Zehnder delay interferometer, i.e., the electrical power of the two constructively and destructively interfered signals, respectively. The bottom plot is their difference and the detector's output voltage. The voltage threshold is also included on this plot; within each bit slot, a detected voltage above threshold is considered to be a "1," while each voltage below threshold is considered a "0." It is assumed that the detector samples the output voltage at the center of a given bit slot. This process is the same when transmission over a significant distance occurs between encoding and detection, although the received optical signal is then distorted by propagation and ASE noise. In practice (and in the simulations described in section 5) the signal is additionally filtered optically before the Mach–Zehnder delay interferometer and electrically just after; this is done to remove as much of the noise as possible. In what follows, the goal is to compute the pdf of the output voltage V and the resulting bit-error rate.

2.3. Soliton perturbation theory and noise-induced parameter changes. Consider a soliton solution, u_s, of the form given in (2.3), and a perturbation to it, δu. If we linearize the NLS equation about u_s, then the eigenmodes and generalized eigenmodes of the linear operator, $\mathcal{L}$, relate perturbations in the solution to changes in the soliton parameters [2, 24, 25]. Here we consider such a decomposition at the kth amplifier where the perturbation in the

underlying soliton solution, $u_s(t, kz_a)$, is comprised of noise, i.e., $\delta u(t, kz_a) = n_k(t)$. We then have [2, 24, 25]

$$n_k(t) = \delta A_k f_A + \delta\Omega_k f_\Omega + \delta T_k f_T + \delta\varphi_k f_\varphi + R(t, kz_a), \tag{2.5}$$

where f_K is the mode (or generalized mode) of $\mathcal{L}$ corresponding to the parameter $K \in \{A, \Omega, T, \varphi\}$, δK_k is the change in that parameter, and $R(t, kz_a)$ is the remainder of the perturbation, which manifests itself as dispersive radiation [2, 19, 24, 25]. In order to isolate the noise-induced change to a single parameter at the kth amplifier, one takes the inner product of (2.5) with the adjoint mode associated with the parameter of interest.[2] Thus, a noise-induced parameter change at the kth amplifier has the form

$$\delta K_k = \mathrm{Re} \int n_k(t) \underline{f}_K^* \, dt, \tag{2.6}$$

where * denotes the complex conjugate, and $\underline{f}_K$ is the adjoint or generalized adjoint mode of the linearized operator associated with parameter $K \in \{A, \Omega, T, \varphi\}$ [2, 3, 4, 24, 25].

We are interested in the instances when noise-induced parameter changes during propagation lead to significant distortion of the received signal. Although noise-induced parameter changes at each amplifier are small, several of these changes can combine to produce large deviations at the output. Combining the relation in (2.6) for the noise-induced parameter changes at each amplifier with how they vary between amplifiers in the absence of perturbations, we can write equations describing their evolution along the transmission line [2],

$$A_k = A_{k-1} + \delta A_k, \tag{2.7a}$$

$$T_k = T_{k-1} + z_a\Omega_{k-1} + \delta T_k, \tag{2.7b}$$

$$\Omega_k = \Omega_{k-1} + \delta\Omega_k, \tag{2.7c}$$

$$\varphi_k = \varphi_{k-1} + \frac{z_a}{2}(A_{k-1}^2 + \Omega_{k-1}^2) + \delta\varphi_k, \tag{2.7d}$$

where again z_a represents the distance between amplifiers. From the soliton solution given in (2.3), one can see that the additional changes to the phase and position arise because the rates at which they advance in the absence of perturbations depend upon the amplitude and frequency. In this notation φ is the phase of a pulse at the pulse center and $\delta\varphi_k$ represents direct phase perturbations at the kth amplifier. Note that A_k is the amplitude just after the kth amplifier and δA_k is the noise-induced amplitude change, which will depend on the soliton parameters from the previous amplifier (the $(k-1)$st, or the initial parameters if $k = 1$).

It is also useful to write the output voltage given by (2.4) in terms of the soliton parameters at the output. At the center of the bit slot, $t = 0$, and in the absence of position shifts ($T = 0$) and added noise, this voltage is

$$V = A_1^\circ A_2^\circ \cos(\varphi_1^\circ - \varphi_2^\circ), \tag{2.8}$$

where A_1°, A_2°, φ_1°, and φ_2° are the amplitudes and phases of two adjacent pulses of the output signal, i.e., evaluated at $z = z_{\mathrm{final}}$.

[2]Here we use the inner product $\langle v, w\rangle = \mathrm{Re} \int v^* w \, dt$.

3. Importance sampling. Recall that our objective is to find the probability of rare events in a nonlinear differential phase-shift-keyed lightwave system by direct simulation. To calculate the probability of an outcome, y, in a desired region, $\mathcal{R}$, one needs to compute the integral

$$P = Pr(y \in \mathcal{R}) = \int I(y(\boldsymbol{x}))p(\boldsymbol{x})\, d\boldsymbol{x}, \tag{3.1}$$

where I is an indicator function that is 1 when y is in $\mathcal{R}$ and 0 otherwise, and p is the pdf of the random variables $\boldsymbol{X}$ upon which the system's output depends. One can approximate this integral with a Monte Carlo quadrature given by

$$\hat{P} = \frac{1}{N}\sum_{k=1}^{N} I(y(\boldsymbol{X}_k)), \tag{3.2}$$

where $\boldsymbol{X}_k$ are random samples drawn from the distribution $p(\boldsymbol{x})$. Unfortunately, if P is very small (say, $P < 10^{-7}$), then standard Monte Carlo simulations require an unreasonably large number of samples to capture even a single event in this region, let alone a sufficient quantity to accurately approximate the integral.

To overcome this shortfall of Monte Carlo estimation we will utilize a variance reduction technique known as *importance sampling* [5, 26]. The main idea of importance sampling is to perform Monte Carlo quadrature by sampling from an alternative probability distribution, $p^*(\boldsymbol{x})$, that concentrates samples in the region of interest, $\mathcal{R}$, much more efficiently than the original distribution $p(\boldsymbol{x})$. However, if we draw random variables from $p^*(\boldsymbol{x})$, then we need to correct our statistics using the *likelihood ratio*, $L(\boldsymbol{x}) = p(\boldsymbol{x})/p^*(\boldsymbol{x})$, in order to obtain an unbiased result. Thus, (3.1) and (3.2) become

$$P = Pr(y \in \mathcal{R}) = \int I(y(\boldsymbol{x}))L(\boldsymbol{x})p^*(\boldsymbol{x})\, d\boldsymbol{x} \tag{3.3}$$

and

$$\hat{P}^* = \frac{1}{N}\sum_{k=1}^{N} I(y(\boldsymbol{X}_k^*))L(\boldsymbol{X}_k^*), \tag{3.4}$$

respectively, where the samples $\boldsymbol{X}_k^*$ are drawn from the distribution $p^*(\boldsymbol{x})$. Equations (3.1) and (3.3) are equivalent, but (3.4) will better estimate the probability P if the distribution $p^*(\boldsymbol{x})$ is chosen wisely. The challenge of effectively implementing importance-sampled Monte Carlo is to find a useful biasing distribution $p^*(\boldsymbol{x})$, i.e., one that can efficiently generate samples in $\mathcal{R}$ [15].

We wish to bias the noise in Monte Carlo simulations of this nonlinear lightwave system so that desired rare events occur more frequently than would normally be the case. If one corrects biased simulations with the likelihood ratio, the results are as if unbiased simulations had been run. In this manner we can accurately simulate rare events and compute pdfs of some quantity of interest far down into the tails. The difficulty, however, is that the number of random variables needed to simulate such systems is necessarily very large—in the tens or even hundreds of thousands. Because the dimensionality of the random state space is quite large,

it can be quite difficult to locate the specific regions that are most likely to produce errors. To bypass this problem, we use low-dimensional approximations of the system dynamics to determine the most probable manner in which perturbations can produce large deviations, and then we use this information to bias the noise and guide full importance-sampled Monte Carlo simulations of the full system. We will accomplish this by dividing the problem into two subproblems: the optimal biasing at a single amplifier and the optimal biasing across all amplifiers.

3.1. Optimal biasing at a single amplifier. First, we briefly summarize the method of biasing the ASE noise by changing the mean of individual Gaussian random variables associated with the noise added at the amplifiers as suggested by Moore, Biondini, and Kath [3], and as discussed in detail in [4]. The first step is to determine how to optimally bias a pulse at a single amplifier in order to achieve a desired parameter change.

The semianalytical approach is based upon some mathematical and physical insight. Studies exploring the growth of noise-induced phase jitter indicate that the variance in a pulse's phase is driven both directly and also by amplitude jitter that couples through self-phase modulation [27, 28]. (Determining the mean and variance alone, of course, is not sufficient information to calculate error probabilities when the distributions are non-Gaussian.) Both types of noise-induced fluctuations arise because solutions of the NLS equation cannot resist changes in the directions associated with the soliton parameters, as they arise from invariances of the equation [20]: any solution with different parameters is itself a perfectly valid solution. Thus, large phase and amplitude variations can build up from smaller ones, and these lead to significant deviations in the detected output voltage.

In what follows, we will neglect perturbations to the pulse's position (or timing) and frequency because we will consider the case of a system with small dispersion. In this limit, amplitude and phase fluctuations dominate. The first step in the analysis, then, is to determine the optimal biasing that produces the sought-after phase and amplitude changes at a single amplifier. When we perform the simulations we will use a discretized version of the NLS equation and the noise driving it, but to simplify the notation here we will describe the procedure using continuous functions of time. Following (2.1), at an amplifier a perturbation $\Delta u = n_k(t)$ is produced in the propagating signal by the noise. In the simulations, however, instead of using the unbiased noise $n_k(t) \equiv X(t)$, we will use a random variable of the form $X^*(t) = X(t) + b(t)$, where $b(t)$ is the biasing. The goal, again, is to choose the biasing $b(t)$ to make errors occur much more frequently than would be the case otherwise, and then to correct the estimate of these events' probabilities using the likelihood ratio.

The problem of finding the optimal biasing $b(t)$ has the same form for each of the four soliton parameters, so we will present it for the general parameter K, where $K \in \{A, T, \Omega, \varphi\}$. Recall that a parameter change, ΔK, due to a perturbation is the projection of the perturbation onto the adjoint or generalized adjoint mode of the linearized NLS equation associated with that parameter. In addition, maximizing the probability of achieving a desired outcome in the case of Gaussian noise is equivalent to maximizing the log-likelihood, i.e., minimizing the negative of the exponent. Thus, we want to minimize

$$\int_{-\infty}^{\infty} \langle |X(t) + b_K(t)|^2 \rangle \, dt = \sigma^2 + \int_{-\infty}^{\infty} |b_K(t)|^2 \, dt, \tag{3.5}$$

subject to the constraint of achieving (on average) a desired parameter change ΔK, i.e.,

$$\Delta K = \mathrm{Re}\int_{-\infty}^{\infty} \langle \underline{u}_K^*(t)(X(t)+b_K(t))\rangle\, dt = \mathrm{Re}\int_{-\infty}^{\infty} \underline{u}_K^*(t) b_K(t)\, dt = \text{constant}. \tag{3.6}$$

To solve this optimization problem, we reformulate it as a Lagrange multiplier problem:

$$F[b_K(t), b_K^*(t)] = \int_{-\infty}^{\infty} |b_K(t)|^2\, dt + \lambda\left[\Delta K - \mathrm{Re}\int_{-\infty}^{\infty} \underline{u}_K^* b_K(t)\, dt\right]. \tag{3.7}$$

To minimize F we take its functional derivative with respect to b_K and find the stationary point, $\delta F/\delta b_K = 0$. We see that F is minimized when

$$b_K(t) = \lambda \underline{u}_K(t), \tag{3.8}$$

which gives

$$\lambda = \frac{\Delta K}{\displaystyle\int_{-\infty}^{\infty} |\underline{u}_K(t)|^2\, dt}. \tag{3.9}$$

Thus, combining (3.8) and (3.9), we have the optimal functions to bias the soliton amplitude and phase,

$$b_A(t) = \frac{\Delta A}{\displaystyle\int_{-\infty}^{\infty} |\underline{u}_A|^2\, dt}\, \underline{u}_A(t), \tag{3.10a}$$

$$b_\varphi(t) = \frac{\Delta \varphi}{\displaystyle\int_{-\infty}^{\infty} |\underline{u}_\varphi|^2\, dt}\, \underline{u}_\varphi(t). \tag{3.10b}$$

Note that the latter equation is valid if $\Omega = 0$.

3.2. Optimal biasing across all amplifiers. The next question to address is how the changes across all of the amplifiers along the full transmission line should be arranged in order to best achieve a targeted output voltage. Is it more probable for large perturbations to occur at just a few amplifiers or for them to occur in a more distributed manner?

To answer this question, we will assume that the biasing function at each amplifier is a linear combination of the optimal biasing functions determined in the previous section and let the coefficients vary from amplifier to amplifier. Note that these adjoint eigenmodes are functions of time, but they also depend explicitly upon the parameters (A, T, Ω, φ) of the underlying soliton at each amplifier. The desired optimal biasing over all amplifiers then has the form

$$B_n = \alpha_n \underline{u}_A + \beta_n \underline{u}_\varphi, \tag{3.11}$$

where $1 \le n \le N_{\text{amp}}$. The goal then reduces to determining the optimal values of α_n and β_n at each amplifier along the transmission line.

Recall that the output voltage depends on the amplitudes and phases of two adjacent pulses. If we label two such adjacent pulses (1) and (2), we have, at the center of the bit slot,

$$V = A^{(1)}A^{(2)}\cos(\varphi^{(1)} - \varphi^{(2)}). \tag{3.12}$$

As a result, we must expand the biasing to include the adjoint modes associated with the amplitudes and phases of both adjacent pulses, i.e.,

$$B_n = \alpha_n^{(1)}\underline{u}_A^{(1)} + \beta_n^{(1)}\underline{u}_\varphi^{(1)} + \alpha_n^{(2)}\underline{u}_A^{(2)} + \beta_n^{(2)}\underline{u}_\varphi^{(2)}. \tag{3.13}$$

To simplify the optimization problem, we will assume that, during propagation, terms labeled (1) do not overlap in time with terms labeled (2), which means that all inner products of $\underline{u}_K^{(1)}$ and $\underline{u}_K^{(2)}$ are zero; i.e., $\langle \underline{u}_K^{(1)}, \underline{u}_K^{(2)} \rangle = \text{Re}\int_{-\infty}^{\infty} \underline{u}_K^{*(1)}\underline{u}_K^{(2)}\,dt = 0$ for $K \in \{A, \varphi\}$.

The goal, then, is the same as before: to choose the appropriate combination of biasing functions such that the probability of a desired rare event at the end of transmission is maximized, subject to the constraint that the biasing will achieve a desired output voltage. Again, because the noise is Gaussian, this is equivalent to minimizing the overall norm of the biasing functions; i.e., we wish to minimize

$$\sum_{n=1}^{N_{\text{amp}}} \|B_n\|^2 = \sum_{n=1}^{N_{\text{amp}}} (\alpha_n^{(1)})^2\|\underline{u}_A^{(1)}\|^2 + (\beta_n^{(1)})^2\|\underline{u}_\varphi^{(1)}\|^2 + (\alpha_n^{(2)})^2\|\underline{u}_A^{(2)}\|^2 + (\beta_n^{(2)})^2\|\underline{u}_\varphi^{(2)}\|^2 \tag{3.14}$$

subject to

$$A_{N_{\text{amp}}}^{(1)}A_{N_{\text{amp}}}^{(2)}\cos(\varphi_{N_{\text{amp}}}^{(1)} - \varphi_{N_{\text{amp}}}^{(2)}) = V^{\circ}. \tag{3.15}$$

In reality, (3.15) will not exactly represent the voltage at the output due to pulse distortions that occur during propagation and because of filtering, which has not been included in the analysis. It will be highly correlated with the output voltage, however, and thus sufficient to guide the biasing of the full simulations.

In this problem we have an additional constraint that the soliton parameters, A and φ, vary from amplifier to amplifier as dictated by soliton perturbation theory. For example, the amplitude at a particular amplifier is the value at the previous amplifier plus the noise-induced amplitude change. The phase at an amplifier, however, is the value at the previous amplifier plus the noise-induced phase change *plus* the amplitude-induced phase change that has accumulated between amplifiers. In addition, the adjoint eigenmodes at each amplifier depend on the soliton parameters, since the norms of the amplitude and phase adjoint eigenmodes are given by

$$\|\underline{u}_A\|^2 = \int_{-\infty}^{\infty} |\underline{u}_A|^2\,dt = 2A, \tag{3.16a}$$

$$\|\underline{u}_\varphi\|^2 = \int_{-\infty}^{\infty} |\underline{u}_\varphi|^2\,dt = \frac{\pi^2 + 12}{18A}. \tag{3.16b}$$

Thus, the goal is to minimize

$$\sum_{n=1}^{N_{\text{amp}}} 2A_n^{(1)}(\alpha_n^{(1)})^2 + \frac{\pi^2+12}{18A_n^{(1)}}(\beta_n^{(1)})^2 + 2A_n^{(2)}(\alpha_n^{(2)})^2 + \frac{\pi^2+12}{18A_n^{(2)}}(\beta_n^{(2)})^2 \tag{3.17}$$

subject to

$$V^\circ = A_1^\circ A_2^\circ \cos(\varphi_1^\circ - \varphi_2^\circ), \tag{3.18a}$$

$$A_n^{(k)} = A_{n-1}^{(k)} + \langle \underline{u}_{A_{n-1}}^{(k)}, B_n \rangle, \tag{3.18b}$$

$$\varphi_n^{(k)} = \varphi_{n-1}^{(k)} + \frac{1}{2}(A_{n-1}^{(k)})^2 z_{\text{a}} + \langle \underline{u}_{\varphi_{n-1}}^{(k)}, B_n \rangle, \quad k = 1, 2. \tag{3.18c}$$

Here, A_n and φ_n represent the values of the amplitude and phase, respectively, just after the nth amplifier. The $^\circ$ symbol denotes evaluation at $z = z_L$, i.e., $A_k^\circ = A_{N_{\text{amp}}}^{(k)}$. The last terms on the right-hand sides of (3.18b) and (3.18c) represent the biased noise B_n added at the nth amplifier projected onto the amplitude and phase modes; recall that they depend on the parameter values before the amplifier, i.e., those from just after the $(n-1)$st amplifier (or the initial parameter values if at the first amplifier).

It is not clear how to solve the discrete constrained minimization problem given by (3.17) and (3.18) even approximately, as was done previously in less complicated situations [3, 4]. We therefore follow an alternative approach in which the discrete problem is approximated by a continuous version. Equations (3.18b) and (3.18c) can be rewritten, for example, as

$$\frac{A_n^{(k)} - A_{n-1}^{(k)}}{z_{\text{a}}} = \frac{2\alpha_n^{(k)}}{z_{\text{a}}} A_{n-1}^{(k)}, \tag{3.19a}$$

$$\frac{\varphi_n^{(k)} - \varphi_{n-1}^{(k)}}{z_{\text{a}}} = \frac{1}{2}(A_{n-1}^{(k)})^2 + \frac{\beta_n^{(k)}}{z_{\text{a}}} \frac{\pi^2+12}{18A_{n-1}^{(k)}}, \tag{3.19b}$$

which shows that their continuous approximations should be

$$\frac{dA_k}{dz} = \frac{2\alpha_k}{z_{\text{a}}} A_k, \tag{3.20a}$$

$$\frac{d\varphi_k}{dz} = \frac{1}{2}A_k^2 + \frac{\beta_k}{z_{\text{a}}} \frac{\pi^2+12}{18A_k}, \quad k = 1, 2. \tag{3.20b}$$

The continuous version of the problem therefore reduces to minimizing a functional with differential equation constraints, which can be solved using calculus of variations [29]. In Lagrange multiplier form the problem is

$$\begin{aligned} F = \int_0^{z_L} \sum_{j=1}^{2} \Bigg[& 2A_j\alpha_j^2 + \frac{\pi^2+12}{18A_j}\beta_j^2 + \lambda_j^A(z)\left(\frac{dA_j}{dz} - \frac{2\alpha_j}{z_a}A_j\right) \\ & + \lambda_j^\varphi(z)\left(\frac{d\varphi_j}{dz} - \frac{1}{2}A_j^2 - \frac{\pi^2+12}{18z_aA_j}\beta_j\right)\Bigg] dz + \lambda_{V^\circ}(A_1^\circ A_2^\circ \cos(\varphi_1^\circ - \varphi_2^\circ) - V^\circ). \end{aligned} \tag{3.21}$$

Each λ above is a Lagrange multiplier and is labeled to refer to its corresponding constraint (all four evolution equations—two equations for each pulse—from soliton perturbation theory and the targeted output voltage). Where z_a remains in this approximation, it is a finite parameter.

To find the most likely soliton parameter paths that lead to large voltage distortions, we thus obtain a boundary value problem given by the Euler–Lagrange equations associated with the functional F,

$$\frac{d^2A_1}{dz^2} - \frac{1}{2A_1}\left(\frac{dA_1}{dz}\right)^2 - \frac{\pi^2+12}{18}\frac{\beta^2}{A_1} + 2g\beta A_1^2 = 0, \tag{3.22a}$$

$$\frac{d^2A_2}{dz^2} - \frac{1}{2A_2}\left(\frac{dA_2}{dz}\right)^2 - \frac{\pi^2+12}{18}\frac{\beta^2}{A_2} - 2g\beta A_2^2 = 0, \tag{3.22b}$$

$$A_1(0) = 1, \tag{3.22c}$$

$$A_2(0) = 1, \tag{3.22d}$$

$$\sin(\varphi)\frac{dA_1}{dz}(1) + 2\beta\cos(\varphi) = 0, \tag{3.22e}$$

$$\sin(\varphi)\frac{dA_2}{dz}(1) + 2\beta\cos(\varphi) = 0, \tag{3.22f}$$

$$\frac{g}{2}\int_0^1 \left(A_1^2 - A_2^2\right) dz + \frac{\pi^2+12}{18z_a}\beta\int_0^1 \left(\frac{1}{A_1} + \frac{1}{A_2}\right) dz = \varphi, \tag{3.22g}$$

$$A_1(1)A_2(1)\cos\varphi = V^\circ. \tag{3.22h}$$

Here, we have eliminated the Lagrange multipliers from the equations, as well as α_1 and α_2. Because the functional depends upon the phases only through the phase difference $\varphi \equiv \varphi_1^\circ - \varphi_2^\circ$, the resulting Euler equations also involve only this difference. In turn, this leads to $\beta_1 = -\beta_2 \equiv \beta$. In the above, we have rescaled $z \to z_L\, z$ for numerical convenience so that the distance varies from $z = 0$ to $z = 1$. We have also rescaled $A \to A_0\, A$, where A_0 is the initial amplitude of the pulse, so that in the rescaled equations the initial amplitude is unity. It is then natural to rescale $\beta \to A_0\beta/z_L$ and introduce $g = A_0^2 z_L$ as an effective nonlinear parameter. In the remainder of this paper, when we discuss the phase we will refer to the relative phase, i.e., the phase difference between adjacent pulses, unless explicitly mentioned otherwise. Note that (3.22g) is merely the integrated form of the evolution equation for this phase difference. In the above we have assumed that the initial phase difference between the pulses is zero; i.e., we have assumed that a "1" was initially encoded. For simplicity, we will focus on this particular case in what follows. The case of a "0," i.e., two pulses with an initial π phase difference, is almost identical.

Thus, the continuous optimization problem has been reduced to a coupled boundary value problem describing the "optimal" evolution of the amplitude and phase parameters, i.e., a problem whose solution gives the most probable paths leading to a specified output voltage. It should be reemphasized that the paths obtained from the solution of this problem will not be directly used to approximate the probability of the sought-after output voltage. Instead, they will be used to guide simulations of the full NLS equation; i.e., they will be used to bias the noise in such a way to induce parameter fluctuations lying close to these paths. The

biasing, of course, is accounted for by updating the likelihood ratio. The approximations made in calculating these optimal paths are thus not detrimental because the randomness associated with the importance-sampled Monte Carlo simulations allows for a search of state space around these paths. Another view of this is that the low-dimensional description of the problem given by soliton perturbation theory is merely used to determine the most significant regions of state space. Then, full importance-sampled Monte Carlo simulations of the NLS equation are used to sample the rare events of interest and directly calculate the probability of occurrence of the sought-after rare events.

Before continuing, it is useful to consider some general features of (3.22). If $\beta = 0$, one can see that evolution equations for the two amplitudes are the same. Thus, the output phase is zero, $\varphi = 0$, and the boundary conditions are satisfied. In this case, one can solve the equations exactly and obtain

$$A_1 = A_2 = A(z) = (1 - cz)^2. \tag{3.23}$$

The constant c is related to the targeted output voltage by $c = 1 - \sqrt[4]{V}$. This solution identifies *one* most probable manner in which large voltage changes can be achieved. In this way, however, errors are not obtained since a change of sign of the voltage must occur for this to happen. This suggests that *another* optimal pulse distortion mode exists—one that can achieve negative output voltages.

Predictions based upon the growth of the phase variance indicate that large phase fluctuations at the output do occur. If these phase fluctuations are large enough, the cosine term in the formula for the output voltage will change sign, leading to an error. There are additional mathematical indications that another error mode should exist. If one uses perturbation theory to solve (3.22) for small β, one obtains a consistency result of the form $\varphi \approx m \sin(\varphi)$, where m is a constant depending upon g and $V°$. If $m > 1$, this problem has a bifurcation to solutions with either positive or negative output phase.

4. Pulse distortion modes. We therefore look numerically for solutions where φ is nonzero and specifically for solutions with an output phase that is at least $\pi/2$ so that a change of sign of output voltage occurs. To find them, we let β parameterize the family of solutions and use the numerical continuation and bifurcation package AUTO [30] incorporated into XPP [31] to solve (3.22).

The first solution to be obtained numerically is the one described by (3.23) that produces *correlated* amplitude fluctuations. For this mode, large changes in the output voltage are most likely to occur when, on average, the amplitudes of two adjacent pulses decrease together. Again, there is no phase difference between the two pulses at output produced by this mode. Figure 3 shows typical amplitude and phase solution paths for this correlated pulse distortion mode.

In addition, the numerical solution of the equations with AUTO also reveals a bifurcation to *anticorrelated* amplitude and phase changes; this bifurcation occurs as the output voltage is reduced. In this case, on average, one pulse's amplitude increases, which advances its phase through self-phase modulation, while the adjacent pulse's amplitude decreases, retarding its phase. Consequently, this distortion mode can result in a nonzero output phase difference. This anticorrelated pulse distortion mode can lead to negative targeted output voltages and

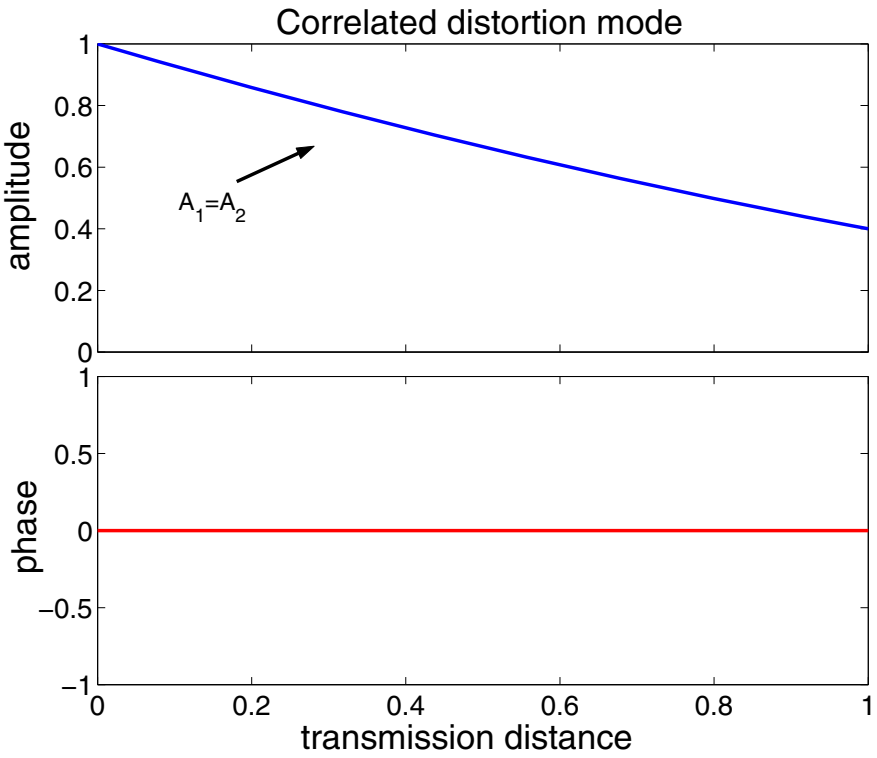

Figure 3. *Typical mean path that amplitudes of adjacent pulse and their phase difference are most likely to take on average to reach a desired output voltage when pulse variations are correlated. For this mode it is most likely that the amplitudes of two adjacent pulses decrease (or increase) together resulting in no phase change. The horizontal axis represents the fraction of total transmission distance.*

thus produce errors. Figure 4 shows typical solution paths for the this particular distortion mode; the other solution is symmetric under the interchange of A_1 and A_2 and a change of sign of φ.

In the descriptions of the pulse distortion modes above we have not yet addressed the issue of which of the two modes is more probable. We will see shortly that correlated fluctuations are most probable when the voltage is large, i.e., near its initial value. Anticorrelated fluctuations, on the other hand, become more probable as the voltage decreases, and especially when the voltage is near zero, i.e., near the threshold at which an error occurs. There is also a transition region of voltage values where these two distortion modes are of approximately equal importance, and the location and width of this region varies, to a certain extent, from problem to problem depending on the physical system parameters. Specifically, when changes to the physical parameters alter the effective nonlinear coefficient, g, then the location of the bifurcation point on the solution curve associated with (3.23) from which the second solution appears will vary.

To measure the importance of a pulse distortion mode for a given output voltage we will calculate a quantity that we refer to as the *biasing strength*. The biasing strength, denoted as $\mathcal{S}$, is merely a measure of the size of the minimum functional which was used to obtain the optimal biasing across all amplifiers. Recall that this functional is essentially the sum over all

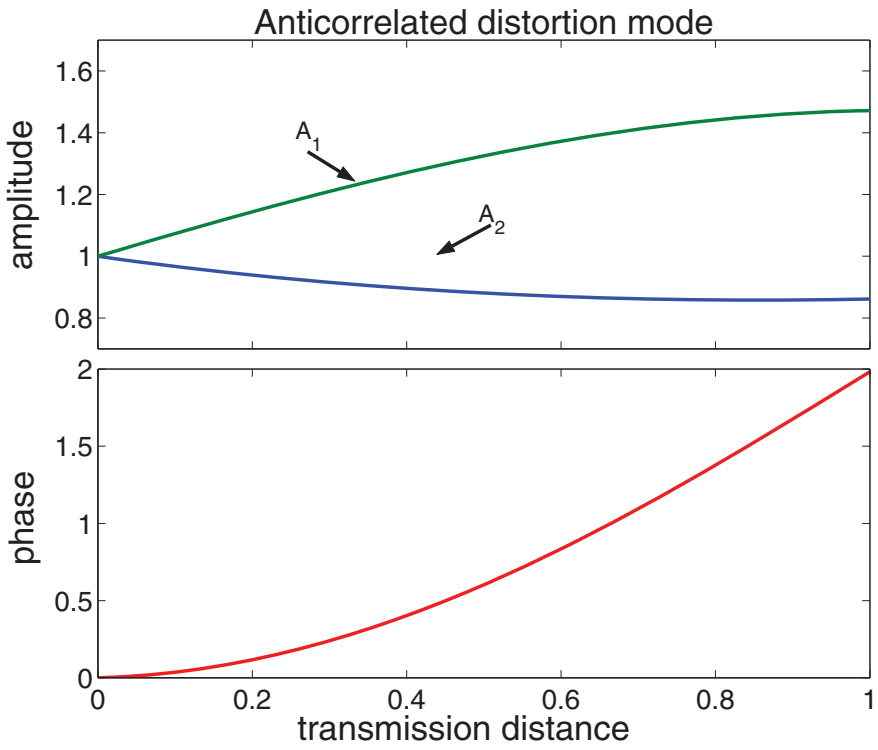

Figure 4. *Typical mean path that amplitudes of adjacent pulses and their phase difference are most likely to take, on average, to reach a desired output voltage in the case of anticorrelated noise-induced perturbations. In this case, we can see that one pulse's amplitude tends to increase while the neighboring pulse's amplitude tends to decrease. The opposite phase changes produced by these amplitude changes, plus equal and opposite direct noise-induced phase changes, lead to a large output phase difference. The horizontal axis represents fraction of total transmission distance.*

amplifiers of the norms of the biasing applied to the mean ASE noise,

$$\mathcal{S} = \sum_{n=1}^{N_{\text{amp}}} \|B_n\|^2, \tag{4.1}$$

so that it is a measure of the total amount of noise. Recall that the ASE noise is modeled as white zero-mean Gaussian noise. Thus, when we bias the mean of the ASE noise at each amplifier using B_n, the probability of a resulting outcome is proportional to the negative exponential of the biasing strength, $\mathcal{S}$; i.e., $\mathcal{S}$ is essentially the negative of the log-likelihood associated with the Gaussian noise. Thus, smaller biasing strengths correspond to more likely events.

In Figure 5 we have plotted a bifurcation diagram summarizing the optimal biasing solutions of (3.22), with $\mathcal{S}$ included. The precise details of these curves are expected to depend somewhat upon the nonlinearity coefficient, g. Here they are plotted for $g = 2.076$, which is the effective nonlinearity of the physical system discussed later in this paper. The curve labeled "correlated" corresponds to the correlated pulse distortion mode and represents solutions similar to Figure 3. The curve labeled "anticorrelated" corresponds to the anticorrelated pulse

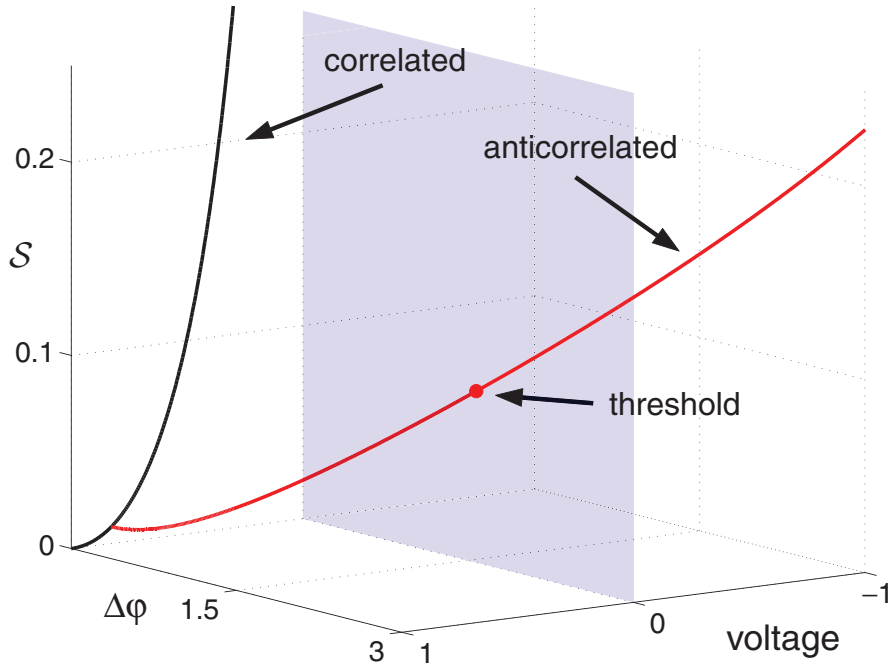

Figure 5. *General representation of the solution curves of the optimal biasing equations for $g = 2.076$. The axes represent output phase, output voltage, and biasing strength, $\mathcal{S}$. The error threshold ($V = 0$) is also highlighted for reference. As anticipated, the curve of correlated solutions has positive output voltage and cannot reach threshold. The anticorrelated solution curve passes through threshold, so anticorrelated amplitude changes are the mechanism most likely to produce errors in this differential phase-shift-keyed lightwave system. Near the bifurcation point (in the lower left-hand corner), the distortions due to each mode have approximately equal importance.*

distortion mode and represents solutions similar to those in Figure 4. These solution curves predict that only the anticorrelated distortion mode can achieve voltages beyond threshold, i.e., output voltages that correspond to errors.

5. Biasing for the soliton-based differential phase-shift-keyed system. Now that we know how to optimally bias the noise at each amplifier, we will use this biasing to guide importance-sampled Monte Carlo simulations. As previously stated, the goal of these simulations is to accurately determine the probability of noise-induced output voltage distortions and errors when errors are extremely rare events. The reason we do full simulations is that the optimal biasing functions and optimal parameter paths that we have calculated are only approximate. By doing full nonlinear simulations, any errors due to linear approximations are avoided. The approximations need not be perfect, of course, because they are used only to guide the full simulations, and thus the full importance-sampled Monte Carlo simulations can still correctly determine the probabilities associated with the rare events.

The outline of the process used to perform one trial of an importance-sampled Monte Carlo simulation of the differential phase-shift-keyed lightwave system is as follows (please note that computational details of these steps are carefully explained in section 6.2):

1. Generate the initial differential phase-shift-keyed signal.

2. Propagate the signal numerically to the next amplifier.
3. Extract the soliton parameters for one pair of adjacent pulses from the noisy signal.
4. Compute the adjoint eigenmodes of the NLS equation linearized about the solitons determined in the previous step using the appropriate analytic formulas [2].
5. Generate zero-mean Gaussian white noise with variance prescribed by (2.2).
6. Bias the mean of the random variables with an optimal linear combination of adjoint eigenmodes determined by the solution of (3.22).
7. Update the likelihood ratio. (Each amplifier's noise is independent, and hence the overall likelihood ratio is the product of the individual likelihood ratios.)
8. Repeat steps 2–7 until the end of transmission line is reached.
9. Apply any desired optical filter, detect the signal, convert it to a voltage with a balanced Mach–Zehnder delay interferometer, and apply the electrical filter.
10. Update the desired statistics of the output voltage signal.

A typical simulation has several biasing directions, i.e., targeted output voltages, per biasing mode (correlated or anticorrelated targeted amplitude changes). Several thousand trials are performed for each direction and the results are combined using multiple importance sampling [5, 26, 32]. In this manner the pdf of the output voltage can be computed well down into the tails. To validate results from the importance-sampled Monte Carlo simulations, we can compare them, at least for not-too-small probabilities, to results from standard Monte Carlo simulations. We also keep track of the coefficient of variation, the sample mean divided by the sample standard deviation, for each bin [5]. Good agreement between the biased and unbiased simulations, and a coefficient of variation that decreases smoothly like $1/\sqrt{N}$ with the number of trials N, are indications that the results from the importance-sampled Monte Carlo simulations are accurate.

For importance-sampled Monte Carlo simulations to be implemented properly, *all* important biasing directions should be included. For example, if one were to bias to target only anticorrelated variations, the simulation would not converge properly for larger probabilities—the pdf would not "visually" converge (would not be smooth and/or the tails might drop off rapidly), the pdf might not agree properly with the unbiased simulations (in the region where unbiased simulations are valid), and/or the coefficient of variation would contain large fluctuations. These large fluctuations would occur in voltage regions where correlated variations are the more likely events, because they would still occur occasionally even though the less likely anticorrelated events had been targeted, and when they did occur they would dominate the probability distribution.

Important biasing directions must not be overlooked. For example, for the anticorrelated biasing directions, one must consider *both* the amplitude of pulse (1) increasing with the amplitude of pulse (2) decreasing *and* the amplitude of pulse (2) increasing with the amplitude of pulse (1) decreasing as distinct biasing directions even if they target the same output voltage. Both cases, of course, will produce the same output phase difference on average. If only one of the cases were considered for each targeted voltage, however, the simulation would miss *half* of the most probable events.

As an example of how the random sampling around the biasing paths works, Figure 6 shows random paths of amplitude and phase from approximately 30 samples where the noise has been biased to follow an anticorrelated path to produce a low voltage. This figure demonstrates

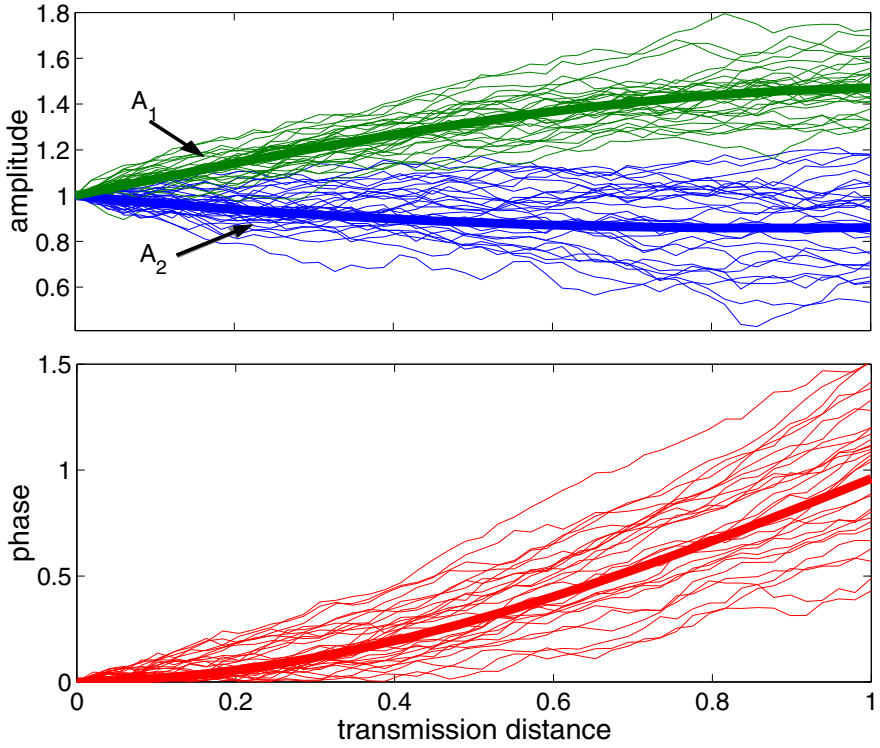

Figure 6. *Simulation showing the random paths (jagged, thin lines) from approximately* 30 *biased samples near a typical anticorrelated optimal biasing direction (smooth, bold curves). The amplitude parameters are plotted in the top figure (green for* A_1*, blue for* A_2*), while the phase difference is plotted in the bottom figure. The horizontal axis represents the normalized transmission distance.*

that the importance-sampled Monte Carlo scheme outlined above successfully biases noise to induce larger-than-normal amplitude and phase fluctuations in the manner predicted by soliton perturbation theory. It also demonstrates how the randomness of biased Monte Carlo simulations enables a search of state space near the predicted optimal path. In this manner, even if the predicted optimal path is not exact, the random nature of the simulation enables the most probable path through state space to a desired rare event to be properly sampled.

6. Simulation of an example differential phase-shift-keyed system.

6.1. System parameters. As a test of the method, we simulate a 10 Gbit/s soliton-based differential phase-shift-keyed transmission system, which means that each pulse lies within a 100 ps bit slot. This bit rate has been of interest for communication applications [22, 23]. Here we assume a fiber loss of 0.21 dB/km, a nonlinear coefficient of 1.7 $(\text{W-km})^{-1}$, an average dispersion of 0.15 ps^2/km, and 30 ps full-width half-max (FWHM) pulses. The FWHM is the time interval over which the instantaneous power is larger than 1/2 of its maximum. A related parameter, the pulse width, T_{w}, is used to nondimensionalize time. This scaling factor varies from pulse shape to pulse shape, but for hyperbolic secant pulses, $T_{\text{w}} = T_{\text{FWHM}}/1.76$.

We assume further that the amplifiers are spaced every 80 km, and we use a spontaneous emission factor $\eta_{\text{sp}} = 1.25$. The total transmission distance is 4,000 km, and the average power

is 0.1 mW (the pulse peak power is 0.3 mW). This choice of parameters results in a system with an optical signal to noise ratio of 14.5 dB (using a .2 nm filter). It is worth reiterating at this point that we have averaged over deterministic power fluctuations as described in section 2.1 after (2.2). At the end of transmission the signal is filtered using a 50 GHz optical bandpass filter, detected using a balanced Mach–Zehnder delay interferometer, and then filtered electrically by a Bessel filter with a bandwidth that is 80% of the bit rate.

6.2. Numerical parameters and implementation. In the split-step numerical simulations the pseudorandom bit pattern "01110100" (or a cyclic permutation) is used, encoded using a π phase change between adjacent pulses to represent a "0" and no phase change for a "1." This 8-bit pattern contains all possible 3-bit combinations. Spatial evolution steps are taken to be 1/5th of the amplifier spacing. Time is discretized by dividing each bit slot by 64. Thus, 64 Fourier modes describe each pulse, and $N = 512$ Fourier modes describe the time-periodic 8-bit sequence.

To simulate the noise, $n_k(t)$, we generate independently and identically distributed unit Gaussian random variables, X_i, $i = 1, \ldots, 2N$, and then scale them by an appropriate standard deviation. Random variables must be added to both the real and imaginary parts of the field at each time point (or to each frequency component), resulting in the factor of two above. The variance of the numerical noise is set to be equal to the variance of the ASE noise determined by physical parameters, σ^2 (see (2.2) and [4]). Because the noise $n_k(t)$ is delta-correlated, we must have

$$\int \langle n_k(t) n_k^*(t') \rangle \, dt = \sigma^2. \tag{6.1}$$

We wish to find a scaling factor, a, which when applied to standard Gaussians makes them satisfy the equivalent relationship in the discrete case, namely,

$$\sum_i \langle aX_i \, aX_j \rangle \Delta t \approx a^2 \langle X_j^2 \rangle \Delta t = \sigma^2/2. \tag{6.2}$$

(The factor of 1/2 here is because $n_k(t)$ contains both real and imaginary parts, each contributing half of the total.) Thus, we see that the numerical standard deviation a should be $\sigma/\sqrt{2\Delta t}$.

The optical bandpass filter is implemented by taking the product of the output signal and a Gaussian (again, 50 GHz) in the frequency domain and then transforming the filtered optical signal back to the time domain. For the electrical filter, we use a 5th order Bessel filter (which is a causal approximation of a perfect time delay) and apply the filter in the frequency domain of the optical intensity. The mean delay associated with the filter is removed before detection. Note that these filters are incorporated into the simulation because such filters are typically used in practice to eliminate as much noise as possible from the output signal.

To bias the noise at each amplifier, one must "extract" the underlying soliton from a noisy pulse. This underlying pulse is the soliton about which the NLS equation is linearized at each amplifier. Recall that a soliton solution of the NLS equation is determined by four parameters: amplitude, timing, frequency, and phase. In order to find the underlying soliton, one must determine at least approximate values for these parameters. Given a pulse, one

can approximate the soliton parameters by using moment integrals [4], which arise from the invariances of the NLS equation's Lagrangian. For example, given part of a signal $u(t, z_k)$ that represents one bit slot, one can calculate an approximate soliton amplitude with the equation

$$A(z_k) = \frac{1}{2} \int |u|^2 \, dt. \tag{6.3}$$

Similar moment integrals can be used to find the other parameters (for the phase, no exact local definition is available, but ad hoc versions can be created). For a very noisy pulse, however, it is possible that the moment integral given by (6.3) will overestimate the amplitude. One can improve parameter estimates by filtering the high frequency components of the pulse to remove some of the noise before calculating the moment integrals [4].

Recall that the parameters are used to construct the underlying soliton and associated linearized modes. These modes are used to bias the noise added to the signal, and more precise biasing leads to faster statistical convergence of the importance-sampled Monte Carlo simulations. To this end iterative improvement to the soliton parameter estimates can also be obtained. Once initial approximations for the soliton parameters have been found, one can compute the residual $\delta u = u(t, z) - u_s(t, z)$. Next, one can project the residual δu onto the adjoint eigenmodes of the NLS equation linearized about the approximate soliton. If these projections are not close to zero (as compared to some tolerance), then the underlying soliton has not been estimated properly. To remedy this, one can update the parameter estimates by the projected amounts and repeat the process until sufficient accuracy is achieved.

For the simulations presented here, 340,000 biased Monte Carlo trials were performed. More precisely, we targeted 17 different output voltages so that the entire voltage range of interest is covered; for each of these 17 "biasing directions" 20,000 trials were used, and the results were combined with multiple importance sampling [5, 26, 32]. The simulation cycles through the eight possible pulse pairs from the bit pattern given above. That is, for each importance-sampled Monte Carlo trial, an individual pair of pulses was targeted (i.e., the noise was biased for that pair and not for the other six pulses). The resulting voltage (associated with each particular pulse pair biased for a given trial) is sampled at the center of the corresponding bit slot, and the pdf of the output voltage is computed by dividing the output voltage range into 80 bins. Two pdfs are computed per simulation—one conditioned on a "0" having been sent initially and another conditioned on a "1" having been sent initially.

6.3. Simulation results. In Figure 7 we plot the probability density functions computed from the importance-sampled Monte Carlo simulation of the soliton differential phase-shift-keyed lightwave system with the physical parameters described previously. Also plotted are the results from an unbiased Monte Carlo simulation that used 10^7 trials. Two overall pdfs are plotted—one conditioned on a "1" having been sent initially and another conditioned on a "0" having been sent. Note the importance-sampled results lie on top of the unbiased simulations in the region where the latter give results, but go down more than 10 orders of magnitude farther in probability. The simulation clearly shows that importance sampling outperforms standard Monte Carlo simulations by many orders of magnitude. In the figure we also plot the individual contributions to the combined pdf from the trials that targeted the correlated distortion mode and the trials that targeted the anticorrelated distortion mode.

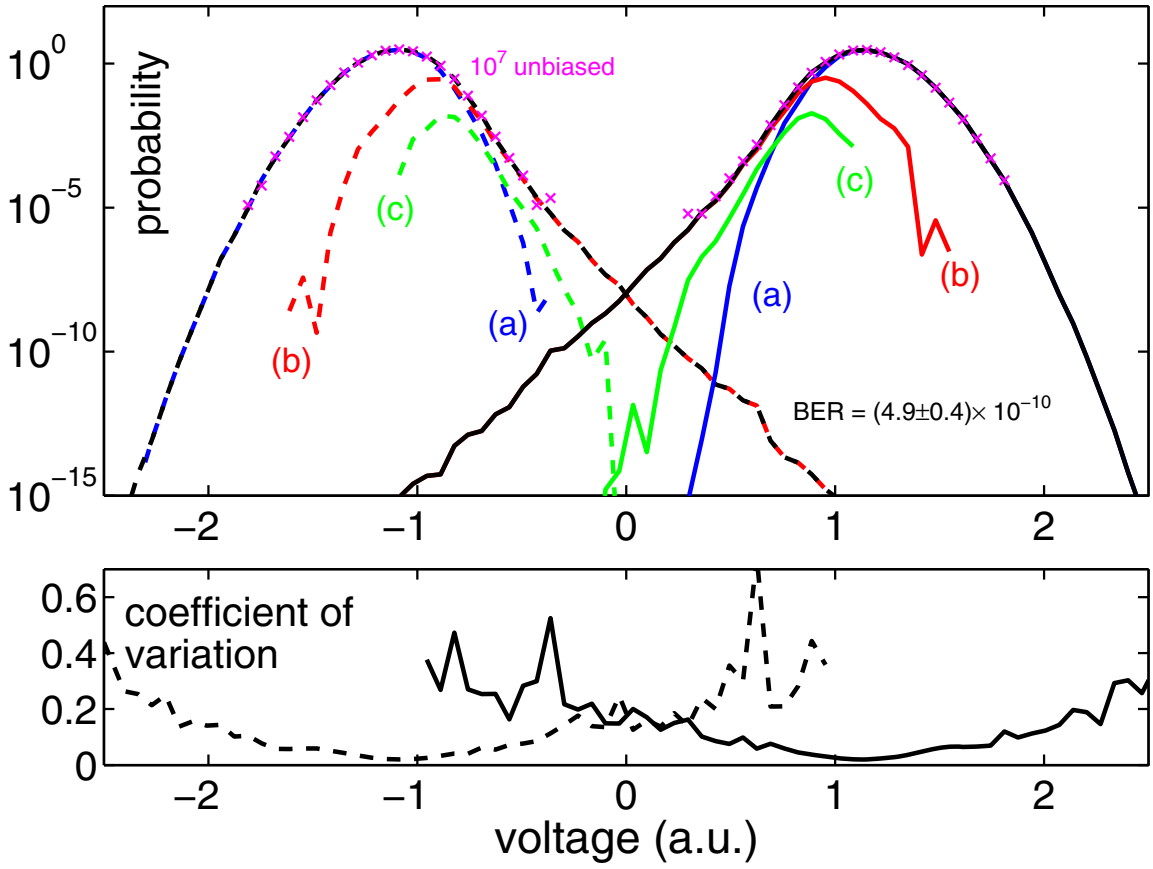

Figure 7. *Top: Black curves represent probability distribution functions (pdfs) for output voltage, conditioned on either a "1" (solid) or a "0" (dashed) being sent initially. The lower curves indicate individual contributions to the total probability from each of the two predicted distortion modes discussed previously and the one-pulse distortion mode—*(a) *correlated amplitude variations;* (b) *anticorrelated phase and amplitude variations;* (c) *single pulse variations. The contributions from each of these modes are combined to compute the overall pdfs (black curves). Bottom: The coefficient of variation for the importance sampling simulation. (The C.V., or relative variance, is the ratio of the sample standard deviation divided to the mean; the smaller the relative variance, the more accurate the estimate is likely to be.)*

In some regions the overall pdfs come primarily from one of the two modes, and so one of the individual curves overlaps the overall pdf in these regions. In particular, the pdfs at large voltages, $|V| > 1.5$, are comprised only of the contributions from correlated amplitude variations, i.e., the curves labeled (a). Similarly, the pdfs near and past the threshold at zero voltage are comprised solely of the contribution from anticorrelated amplitude and phase variations, i.e., curves labeled (b); thus, for these system parameters this distortion mode solely determines the bit-error ratio.

For this particular simulation we also biased the noise in an additional direction not predicted by the biasing theory for a pair of pulses; the contribution from these trials is represented by curve (c). The impetus for including this additional biasing direction, which targets changes in the output voltage due to variations in a single pulse, rather than a pair of

pulses, was to speed up convergence of the simulation and reduce the size of the coefficient of variation. Including this additional biasing direction did not significantly change the resulting pdf but did lower the total number of trials needed to achieve a desired (small) coefficient of variation at moderately small probabilities. In this case, the optimal biasing problem is equivalent to (3.14) and (3.15), except that the amplitude of one of the pulses is constant. As a result, the boundary value problem that one must solve to optimize the biasing problem is equivalent to (3.22) when one eliminates the equations governing the evolution of A_2 and its boundary conditions and replaces the A_2 in the other instances with $A_2 = 1$. This single pulse biasing mode exhibits solutions similar to the anticorrelated distortion mode, in that the voltage distortion is most likely to occur if the pulse's amplitude decreases, causing a phase retardation. There is no equivalent to the correlated distortion mode in the singe-pulse case, however. The result of the single-pulse biasing shows a contribution to the overall pdf that is smaller than that from the other two modes. This explains why this solution did not show up when solving the pair-pulse biasing problem (3.22); it is not a local extremum of the function given by (3.21). Nevertheless, the contribution to the overall pdf from this mode is a noticeable fraction of the total, which is why including it speeds up the convergence of the simulations.

To further illustrate the character of the large variation modes that were included in the simulation, Figure 8 shows specific simulation trials for each. These amplitude, phase, and voltage profiles were recorded when a particular voltage threshold was crossed (a different threshold was used for each type of distortion). The amplitude and phase curves are shown after optical filtering, while the voltage curve is shown after electrical filtering. Modes (a), (b), and (c) are examples of the result of correlated, anticorrelated, and single-pulse amplitude and phase variations, respectively, corresponding to Figure 7. In each case it is clear that the actual pulse fluctuations show deviations from the optimal biasing paths; e.g., the amplitude profiles shown in mode (a) are neither identical nor smooth; it is only the *mean* biasing that is described properly using soliton perturbation theory. It is also worth noting that although one particular voltage bit slot has been targeted, the fluctuations also produce significant deviations in nearby bit slots. Thus, each fluctuation produces a particular pattern of correlated deviations in the voltage signal.

For these system parameters, the individual pdfs for the one and zero voltage rails cross in Figure 7 at a value just below 10^{-8}. The probability of an error is the average of the probability that a "0" was sent and a "1" was detected and the probability that a "1" was sent and a "0" was detected. Integrating the area under the parts of the pdfs that lie beyond the zero voltage point (the decision threshold) and multiplying by 1/2 (the probability of a "1" or a "0" being sent) gives a total bit-error ratio of $(4.9 \pm .4) \times 10^{-10}$ for these parameters. To calculate the variance in this multiple importance-sampled simulation, we used the method of Biondini, Kath, and Menyuk [5].

As a comparison, we have performed another set of Monte Carlo simulations where a noiseless signal is propagated and a comparable amount of white Gaussian noise is then added at the end of the transmission line. This is a standard approximation valid when the noise does not interact with the signal during propagation, but only at the detector [33]. In this simulation, the amount of white Gaussian noise added at the end of the transmission line was adjusted so that the optical signal to noise ratio at the end was the same as for the

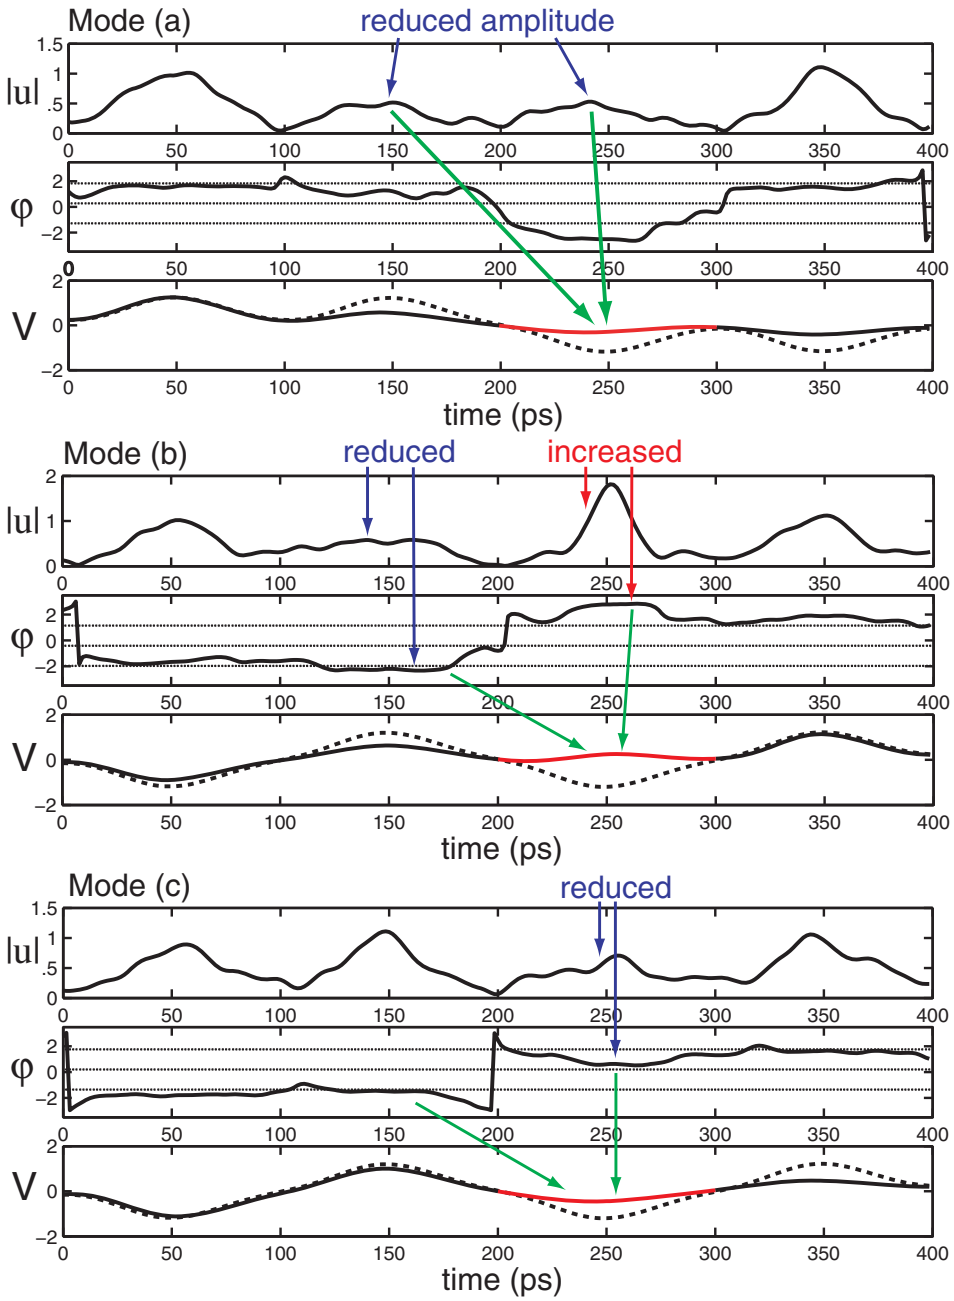

Figure 8. *Single-trial examples of each of the error modes. Modes* (a), (b), *and* (c) *correspond to correlated, anticorrelated, and single-pulse amplitude and phase variations, respectively. The dashed lines correspond to the voltage of the undistorted signal. Note that a different sequence of pulses was targeted in case* (a) *than in* (b) *and* (c). *In each case, reductions or increases in amplitude and phase are indicated. The optical pulses that combine to produce the specific targeted voltage bit slot are also indicated.*

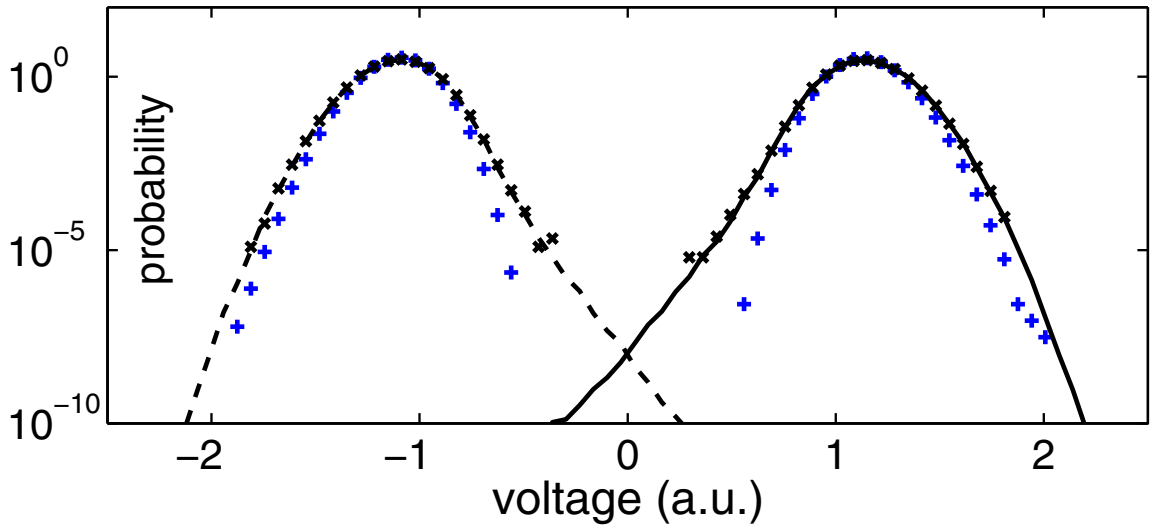

Figure 9. *Comparison between full importance-sampled Monte Carlo simulations (black curves, as in Figure 7) and another set of unbiased Monte Carlo simulations where a noiseless signal is propagated and then a comparable amount of noise is added at the end of the transmission line just before detection (+ signs; see text for more details). Black ×'s are pdfs from unbiased Monte Carlo simulations of the full nonlinear system, as in Figure 7. The results show that neglecting the interaction between signal and noise during propagation can significantly underestimate the bit-error ratio.*

full simulations. The result is shown by the + signs in Figure 9; the main simulation results from Figure 7 are also included for comparison purposes. For this comparison simulation, 10^9 unbiased Monte Carlo trials were used (more trials are possible in this case; since only one nonlinear propagation is necessary, it is a much simpler simulation). Although this number of trials is insufficient to actually estimate a bit-error ratio, it is clear that the pdfs conditioned on either a "1" or a "0" being sent will cross at a probability that falls significantly below the value seen in the full importance-sampled simulations. This demonstrates that estimates which neglect the interaction between signal and noise during propagation (including those based upon assuming Gaussian statistics for the received "1"s and "0"s [34]) can significantly underestimate the actual bit-error ratio.

7. Discussion. We have presented a method for computing errors in soliton-based lightwave systems. The method uses soliton perturbation theory and calculus of variations to find approximate versions of the most probable paths through sample space leading to errors, followed by importance-sampled Monte Carlo simulations of the full set of equations around these approximate paths to compute the actual error rates. A specific example differential phase-shift-keyed lightwave system was simulated, and the system's bit-error ratio was computed. The method predicts the most probable ways in which large pulse distortions occur, thus providing an explanation as to the specific manner in which errors occur.

One of the main difficulties associated with simulating such systems is the large dimensionality of the state space. Recall that 512 Fourier modes were used for the simulations of the example system in section 6, meaning that 1,024 independent Gaussian random variables are added at each amplifier. With a total distance of 4,000 km, and an amplifier spacing of

80 km, this gives 50 amplifiers, and thus a total of 51,200 Gaussian random variables. This is just an example, of course, and it is possible that even more variables might be used in other cases. Ultimately we are searching for regions in a very large-dimensional state space that produce large deviations in a *single* output quantity, the voltage, and furthermore, we want to determine which of these regions are the most probable.

The large dimensionality of the state space associated with such problems can make finding the regions most likely to contribute to errors difficult. The only sure way of doing so, of course, is by an exhaustive search of state space, something that is clearly beyond the capability of existing computational methods and hardware. In the present case, we have employed low-dimensional approximations of the system dynamics and analytical methods to guide the simulations to the locations of such regions. In this we regard the mathematical structure imposed by the equations describing the system as constraints which limit the regions of state space in which errors may occur.

By contrast, when iterative methods such as the multicanonical Monte Carlo method are used, a performance measure is monitored (such as the voltage at the center of the bit slot), and each set of simulations is analyzed in order to determine directions in state space for further exploration. To do this no analytical approximations are needed, of course, and so in one sense such iterative methods are more straightforward. For such methods to work, however, the regions of state space that produce one set of voltage values should be contiguous with regions that produce values with slightly smaller probabilities, something that is difficult to verify a priori in any specific application. If this is not the case, of course, then iterative sampling may fail to locate these newer values. In the present case, although it requires a nontrivial effort to construct the analytical approximation used to guide the biasing, the insight provided by the analytic approach gives one much more confidence that nothing has been missed when one preforms the Monte Carlo sampling.

A detailed comparison between the two approaches is beyond the scope of the present work, of course. We hope to make such a comparison in the future, however, and thus further clarify the pros and cons associated with the application of each type of method of simulating lightwave systems.

Acknowledgments. The authors would like to thank Gino Biondini, Curtis Menyuk, Colin McKinstrie, Richard Moore, and John Zweck for many helpful discussions.

C^1 Approximation of Vector Fields Based on the Renormalization Group Method*

Hayato Chiba†

Abstract. The renormalization group (RG) method for differential equations is one of the perturbation methods for obtaining solutions which approximate exact solutions for a long time interval. This article shows that, for a differential equation associated with a given vector field on a manifold, a family of approximate solutions obtained by the RG method defines a vector field which is close to the original vector field in the C^1 topology under appropriate assumptions. Furthermore, some topological properties of the original vector field, such as the existence of a normally hyperbolic invariant manifold and its stability, are shown to be inherited from those of the RG equation. This fact is applied to the bifurcation theory.

Key words. renormalization group method, singular perturbation method, bifurcation theory

1. Introduction.

The renormalization group (RG) method for differential equations is one of the perturbation methods for obtaining solutions which approximate exact solutions for a long time interval. In their papers [1, 2], Chen, Goldenfeld, and Oono established the RG method for ODEs of the form

$$\dot{x} = \frac{dx}{dt} = f(t,x) + \varepsilon g(t,x), \quad x \in \mathbf{R}^n, \tag{1.1}$$

where $\varepsilon > 0$ is a small parameter. For this equation, the method for deriving approximate solutions of the form

$$x(t) = x_0(t) + \varepsilon x_1(t) + \varepsilon^2 x_2(t) + \cdots \tag{1.2}$$

is called the *naive expansion* or the *regular perturbation method*, where $x_i(t)$'s are governed by inhomogeneous linear ODEs obtained by putting (1.2) into (1.1) and equating the coefficients of ε^i of both sides of (1.1). It is well known that approximate solutions constructed by the naive expansion are valid only in a time interval of $O(1)$ in general, since secular terms diverge as $t \to \infty$. Many techniques for obtaining approximate solutions which are valid in a long time interval have been developed until now; these are collectively called singular perturbation methods.

The RG method proposed by Chen, Goldenfeld, and Oono is one of the singular perturbation methods that look like the variation-of-constant method, in which the secular terms

included in $x_1(t), x_2(t), \dots$ of (1.2) are renormalized into the integral constant of $x_0(t)$. The ODE to be satisfied by the renormalized integral constant is called the *RG equation*. Chen, Goldenfeld, and Oono showed that the RG method unifies the conventional singular perturbation methods, such as the multiscale method, the boundary layer technique, WKB analysis, and the reductive perturbation method, by giving explicit examples. Though the multiscale method requires occasionally fractional power laws or logarithmic functions of ε in the expansion of $x(t)$, the RG method needs only a power-series expansion of $x(t)$ in ε, and it starts with the naive expansion of $x(t)$ to reach the same result the multiscale method does.

Kunihiro [3, 4] interpreted the RG method as a theory of envelopes for approximate solutions constructed by the naive expansion. His insight revealed why the RG method works well. Nozaki and Oono [5] and Goto, Masutomi, and Nozaki [6] proposed a proto-RG equation or translational Lie group method to renormalize secular terms up to arbitrary order and to obtain higher order approximate solutions. Ei, Fujii, and Kunihiro [7] apply the RG method to obtain approximate center manifolds and slow manifolds. Ziane [8] and DeVille et al. [9] proved that an orbit constructed on the RG method approximates an exact solution for a long time interval. Further, DeVille et al. [9] showed that if the unperturbed part of a given ODE is linear and diagonalizable, the RG equation for the ODE is equivalent to the normal form of the vector field.

Despite the active interest in the RG method, little attention has been paid to date to the question of whether a family of approximate solutions to exact solutions of the original ODE (vector field), which is obtained by varying initial values, forms a well-defined vector field or not. Put another way, a question to be asked is whether approximate solutions intersect with one other or not. Further, the RG method has been applied to differential equations only on the Euclidean space but has not yet been extended to a method applicable to differential equations on manifolds.

In the present paper, it is shown that for a given vector field of the form $f(t,x)+\varepsilon g(t,x)$ on an arbitrary manifold, approximate solutions obtained by the RG method define a vector field which is close to the original vector field in the C^1 topology on appropriate assumptions of boundedness for the flow of $f(t,x)$ and for other functions. This implies that the approximate vector field works well in investigating properties of the original vector field that are persistent under C^1 perturbation. In particular, if the approximate vector field has a normally hyperbolic invariant manifold, then the original vector field is expected also to have an invariant manifold because the Fenichel theory ensures that normally hyperbolic invariant manifolds are persistent under C^1 perturbation. In fact, it is shown that the existence of an invariant manifold and its stability are inherited from those of the RG equation since the flow of the RG equation is proved to be conjugate to that of the approximate vector field. In view of this, it is desirable that the RG equation be easier to solve than the original equation. In fact, it will be proved that the RG equation has larger symmetry than the original equation. This method will be applied in the bifurcation theory to show that a periodic orbit emerges far away from a fixed point, which is an example of the global bifurcation other than the ordinary Hopf bifurcation.

In particular, the RG method is applied to a time-dependent linear equation of the form

$$\dot{x} = F(t)x + \varepsilon G(t)x, \quad x \in \mathbf{R}^n, \tag{1.3}$$

where $F(t)$ and $G(t)$ are $n \times n$ matrix functions. On appropriate assumptions, the stability of the trivial solution $x = 0$ of (1.3) is shown to coincide with that of the RG equation for (1.3), which is a time-*independent* linear equation. By using this result, synchronous solution of coupled oscillators is shown to be stable.

This paper is organized as follows: Section 2 presents basic facts and definitions in dynamical systems. Section 3 contains a simple example of the RG method. In section 4, a main theorem on approximate vector fields is proved. Section 5 gives a few properties of the RG equation in term of symmetries. In section 6, an invariant manifold of a given equation is shown to be inherited from its RG equation. In section 7, the RG method is applied to time-dependent linear equations (1.3). In Appendix A, we discuss the higher order RG equation to prove Theorem 6.1.

2. Notation. Let f be a time-independent C^r vector field on a C^r manifold M and $\varphi : \mathbf{R} \times M \to M$ its flow. We denote by $\varphi_t(x_0) \equiv x(t)$, $t \in \mathbf{R}$, a solution to the ODE $\dot{x} = f(x)$ through $x_0 \in M$, which satisfies $\varphi_t \circ \varphi_s = \varphi_{t+s}$, $\varphi_0 = \mathrm{id}_M$, where id_M denotes the identity map of M. For a fixed $t \in \mathbf{R}$, $\varphi_t : M \to M$ defines a diffeomorphism of M. We assume φ_t is defined for all $t \in \mathbf{R}$.

For a time-dependent vector field, let $x(t, \tau, \xi)$ denote a solution to an ODE $\dot{x}(t) = f(t, x)$ through ξ at $t = \tau$, which defines a flow $\varphi : \mathbf{R} \times \mathbf{R} \times M \to M$ by $\varphi_{t,\tau}(\xi) = x(t, \tau, \xi)$. For fixed $t, \tau \in \mathbf{R}$, $\varphi_{t,\tau} : M \to M$ is a diffeomorphism of M satisfying

$$\varphi_{t,t'} \circ \varphi_{t',\tau} = \varphi_{t,\tau}, \quad \varphi_{t,t} = \mathrm{id}_M. \tag{2.1}$$

Conversely, a family of diffeomorphisms $\varphi_{t,\tau}$ of M, which are C^1 with respect to t and τ, satisfying the above equality for any $t, \tau \in \mathbf{R}$ defines a time-dependent vector field on M through

$$f(t, x) = \frac{d}{d\tau}\Big|_{\tau=t} \varphi_{\tau,t}(x). \tag{2.2}$$

3. A brief review of the renormalization group method. Before describing a general theory of the RG method in the next section, we review the RG method for obtaining approximate solutions of an ODE with a simple example.

Let us consider an ODE

$$\ddot{x} + x + \varepsilon x^3 = 0, \quad x \in \mathbf{R}, \ |\varepsilon| << 1. \tag{3.1}$$

Assume that the ODE admits a solution of the form $x(t) = x_0(t) + \varepsilon x_1(t) + O(\varepsilon^2)$. Then the substitution provides

$$\ddot{x}_0 + \varepsilon \ddot{x}_1 + x_0 + \varepsilon x_1 + \varepsilon (x_0 + \varepsilon x_1)^3 + O(\varepsilon^2) = 0.$$

Expanding this into a power series in ε and equating the coefficients of $\varepsilon^0, \varepsilon^1$ to zero, respectively, we get

$$\ddot{x}_0 + x_0 = 0, \tag{3.2}$$

$$\ddot{x}_1 + x_1 = -x_0^3. \tag{3.3}$$

We denote a general solution of the former whose initial time is $t = 0$ by

$$x_0(t, 0, A) = Ae^{it} + \overline{A}e^{-it}, \quad A \in \mathbf{C}. \tag{3.4}$$

Then (3.3) and (3.4) are put together to give

$$\ddot{x}_1 + x_1 = -(A^3 e^{3it} + 3|A|^2 Ae^{it} + 3|A|^2 \overline{A}e^{-it} + \overline{A}^3 e^{-3it}).$$

A special solution of this equation, whose initial time is $t = \tau$, is written as

$$x_1(t, \tau; A) = \frac{A^3}{8}e^{3it} + \frac{3i}{2}|A|^2 A(t - \tau)e^{it} + \text{c.c.}, \tag{3.5}$$

where c.c. is the complex conjugate of the first two terms of the right-hand side. Note that a secular term arises which diverges to infinity as $t \to \infty$. The reason for taking the initial time $t = \tau$ is that we want to construct a family of curves parameterized by τ since approximate solutions obtained by the RG method are given as envelopes of the family (see Kunihiro [3, 4]).

Now let us define $\hat{x}$ as

$$\hat{x}(t, \tau; A) = x_0(t, 0, A) + \varepsilon x_1(t, \tau; A).$$

Then $\hat{x}$ is an approximate solution to (3.1) on short time intervals. Indeed, $\hat{x}$ satisfies the equation

$$\ddot{\hat{x}} + \hat{x} + \varepsilon\hat{x}^3 = 3\varepsilon^2(Ae^{it} + \overline{A}e^{-it})^2 \left(\frac{A^3}{8}e^{3it} + \frac{3i}{2}|A|^2 A(t - \tau)e^{it} + \text{c.c.}\right) + O(\varepsilon^3), \tag{3.6}$$

which implies that if A is bounded and t is sufficiently close to τ, then $\hat{x}$ approximates to an exact solution of (3.1) well. This procedure for obtaining a local approximate solution is called *naive expansion*.

The RG method employs two additional steps to obtain solutions approximating to exact solutions on a long time intervals. At first, we regard the constant A as a differentiable function of τ and differentiate $\hat{x}$ with respect to τ at t:

$$\begin{aligned}\frac{d\hat{x}}{d\tau}\Big|_{\tau=t}(t, \tau, A(\tau)) &= \frac{\partial x_0}{\partial A}\frac{dA}{d\tau}\Big|_{\tau=t} + \varepsilon\frac{\partial x_1}{\partial \tau}\Big|_{\tau=t} + \varepsilon\frac{\partial x_1}{\partial A}\frac{dA}{d\tau}\Big|_{\tau=t} \\ &= A'e^{it} + \overline{A}'e^{-it} + \varepsilon\left(-\frac{3i}{2}|A|^2 Ae^{it} + \frac{3A^2}{8}A'e^{3it} + \text{c.c.}\right).\end{aligned}$$

We impose the condition on $A(t)$ that $d\overline{x}/d\tau|_{\tau=t} = 0$, which is called the *RG condition*. Then we obtain the following ODE for $A(t)$:

$$\frac{dA}{dt} = \varepsilon\frac{3i}{2}|A|^2 A + O(\varepsilon^2).$$

Truncating the higher order term $O(\varepsilon^2)$, we obtain the *RG equation*

$$\frac{dA}{dt} = \varepsilon\frac{3i}{2}|A|^2 A, \tag{3.7}$$

which is solved by

$$A(t) := A(t,a,\theta) = \frac{1}{2}a\exp i\left(\frac{3\varepsilon}{8}a^2t+\theta\right), \tag{3.8}$$

where a,θ are arbitrary constants. With this $A(t)$, we define $X(t,a,\theta)$ by

$$X(t,a,\theta) := \hat{x}(t,t,A(t,a,\theta)). \tag{3.9}$$

Then this $X(t)$ gives a solution which approximates an exact solution of (3.1) for a long time interval. The condition $d\overline{x}/d\tau|_{\tau=t}=0$ means that the curve $X(t,a,\theta)=\hat{x}(t,t;A(t,a,\theta))$ is an envelope for the family of curves $\{\hat{x}(t,\tau;A(\tau,a,\theta))\}_{\tau\in\mathbf{R}}$ (see Kunihiro [3, 4]). Our general definition of the RG equation is shown in the next section.

4. Main theorem. In this section, under appropriate assumptions, we prove that a family of orbits constructed by the RG method defines a vector field which approximates the original vector field in the C^1 topology. Though we show Theorem 4.4 for vector fields on Euclidean space, it can be easily extended to vector fields on an arbitrary manifold. See Remark 4.5.

Let $f(t,x)$ and $g(t,x)$ be C^4 and C^3 time-dependent vector fields on $\mathbf{R}^n$, respectively, and consider an ODE

$$\dot{x}(t) = f(t,x)+\varepsilon g(t,x) \tag{4.1}$$

and its unperturbed system

$$\dot{x}_0(t) = f(t,x_0). \tag{4.2}$$

We denote a general solution to the latter by

$$x_0(t) := x_0(t,0,A) = \varphi^0_{t,0}(A), \tag{4.3}$$

whose initial value is $x_0(0)=A\in\mathbf{R}^n$ at $t=0$, and where φ^0 is its flow. With this x_0, we further consider an ODE

$$\dot{x}_1(t) = \frac{\partial f}{\partial x}(t,x_0)x_1+g(t,x_0). \tag{4.4}$$

A general solution to this equation is written as

$$x_1 = (D\varphi^0_{t,0})_A\circ(D\varphi^0_{\tau,0})_A^{-1}h(\tau,A)+(D\varphi^0_{t,0})_A\int_\tau^t(D\varphi_{s,0})_A^{-1}g(s,\varphi^0_{s,0}(A))ds, \tag{4.5}$$

where τ is an initial time, $h(\tau,A)$ is an initial value, and $(D\varphi^0_{t,0})_A$ is the derivative of $\varphi^0_{t,0}$ at A. In what follows, we denote by $\mathbf{R}_{\geq T}$ the set of the real numbers which are larger than or equal to $T\in\mathbf{R}$: $\mathbf{R}_{\geq T}=\{t\in\mathbf{R}\mid t\geq T\}$. Set $\mathbf{R}_{\geq T}=\mathbf{R}$ if $T=-\infty$.

Definition 4.1. *A function $p(t)$ is said to be Krylov–Bogolyubov–Mitropolskii (KBM) on $\mathbf{R}_{\geq T}$ if the number*

$$\lim_{t\to\infty}\frac{1}{t-t_0}\int_{t_0}^t p(s)ds \tag{4.6}$$

converges for all $t_0 \geq T$.

The notation of KBM vector fields was introduced in [14] and used in DeVille et al. [9] to define the RG equation. Note that periodic functions and almost periodic functions are KBM on $\mathbf{R}$ (see Fink [13]).

The next definition is proposed by DeVille et al. [9].

Definition 4.2. *Suppose that* $(D\varphi^0_{t,0})^{-1}_A g(t, \varphi^0_{t,0}(A))$ *is KBM on* $\mathbf{R}_{\geq T}$ *for each* $A \in \mathbf{R}^n$. *Then a* C^3 *function* $R : \mathbf{R}^n \to \mathbf{R}^n$ *defined by*

$$R(A) = \lim_{t\to\infty} \frac{1}{t-T} \int_T^t (D\varphi^0_{s,0})^{-1}_A g(s, \varphi^0_{s,0}(A)) ds \tag{4.7}$$

is called the resonance *or* secular *part for the solution* x_1 *defined by* (4.5).

By using (4.7), equation (4.5) is rewritten as

$$x_1 = (D\varphi^0_{t,0})_A \circ (D\varphi^0_{\tau,0})^{-1}_A h(\tau, A) + (D\varphi^0_{t,0})_A \int_\tau^t \left((D\varphi^0_{s,0})^{-1}_A g(s, \varphi^0_{s,0}(A)) - R(A)\right) ds + (D\varphi^0_{t,0})_A R(A)(t-\tau).$$

Define the initial value $h(\tau, A)$ to be

$$h(\tau, A) := (D\varphi^0_{\tau,0})_A \int^\tau \left((D\varphi^0_{s,0})^{-1}_A g(s, \varphi^0_{s,0}(A)) - R(A)\right) ds, \tag{4.8}$$

where $\int^\tau$ is the indefinite integral, whose integral constant is fixed arbitrarily. Then, x_1 is expressed as

$$\begin{aligned} x_1 := x_1(t, \tau; A) &= (D\varphi^0_{t,0})_A \int^t \left((D\varphi^0_{s,0})^{-1}_A g(s, \varphi^0_{s,0}(A)) - R(A)\right) ds + (D\varphi^0_{t,0})_A R(A)(t-\tau) \\ &= h(t, A) + (D\varphi^0_{t,0})_A R(A)(t-\tau). \end{aligned} \tag{4.9}$$

In perturbation theory, the second term of the right-hand side is called the *secular term*. The reason for defining the initial value $h(\tau, A)$ as (4.8) is that we want to divide x_1 into two terms: one is the secular term which diverges as $t \to \infty$, and the other is the bounded term $h(t, A)$ (see also the norm conditions (N) below). With this $x_1(t, \tau; A)$, we associate a curve defined by

$$\hat{x}(t) := \hat{x}(t, \tau; A) = x_0(t, 0, A) + \varepsilon x_1(t, \tau; A), \tag{4.10}$$

which provides a locally approximate solution of (4.1). Now we define the RG equation.

Definition 4.3. *Suppose that* $(D\varphi^0_{t,0})^{-1}_A g(t, \varphi^0_{t,0}(A))$ *is KBM on* $\mathbf{R}_{\geq T}$ *for each* $A \in \mathbf{R}^n$. *Then, the equation defined by*

$$\frac{dA}{dt} = \varepsilon R(A), \quad A \in \mathbf{R}^n, \tag{4.11}$$

is called the RG equation *for* $f + \varepsilon g$, *and the vector field* $\varepsilon R(A)$ *on* $\mathbf{R}^n$ *is called the* RG vector field *for* $f + \varepsilon g$. *We denote by* φ^{RG}_t *the flow generated by the RG vector field.*

In the literature, the RG equation is defined so that its solution $A := A(t)$ may satisfy $d\hat{x}/d\tau|_{\tau=t}(t,\tau;A(\tau)) = 0$. According to our definition of the RG vector field, $d\hat{x}/d\tau|_{\tau=t}$ is calculated as

$$\frac{d\hat{x}}{d\tau}\Big|_{\tau=t}(t,\tau;A(\tau)) = \varepsilon^2 \frac{\partial x_1}{\partial A}(t,t;A(t))R(A(t)). \tag{4.12}$$

The higher order term $O(\varepsilon^2)$ is truncated; (4.12) then implies that solutions to (4.11) satisfy $d\hat{x}/d\tau|_{\tau=t}(t,\tau;A(\tau)) = 0$.

To state our main theorem, we assume the following norm conditions (N) for the functions $f(t,x)$, $g(t,x)$, $x_0(t,0,A)$, and $h(t,A) = x_1(t,t;A)$ on $\mathbf{R}_{\geq T} \times \mathbf{R}^n$. These conditions will be used to prove that the vector field F_ε defined in (4.16) is sufficiently close to the original vector field $f + \varepsilon g$ in the C^1 topology (see (4.18), (4.19)).

Norm conditions (N). Let $K \subset \mathbf{R}^n$ be an arbitrary compact subset. We assume that there exists T such that $(D\varphi^0_{t,0})^{-1}_A g(t, \varphi^0_{t,0}(A))$ is KBM on $\mathbf{R}_{\geq T}$ for each $A \in K$ and the following functions are bounded uniformly on $\mathbf{R}_{\geq T} \times K$:
(N1) $h(t,A)$,
(N2) $\partial^2 f/\partial x^2$, $\partial f/\partial x$, $\partial g/\partial x$, $x_0(-t,0,A)$, $(\partial x_0/\partial A)^{-1}$, $\partial^2 x_0/\partial A^2$, $\partial h/\partial A$, $\partial h^2/\partial A^2$,
(N3) f, $\partial^2 f/\partial x \partial t$, $\partial^3 f/\partial x^3$, $\partial^3 f/\partial x^2 \partial t$, g, $\partial^2 g/\partial x^2$, $\partial^2 g/\partial x \partial t$, $\partial^3 x_0/\partial A^3$, $\partial^3 h/\partial A^3$.

In section 6 and Appendix A, we consider a system of the form

$$\dot{x} = Fx + \varepsilon g(t,x), \quad x \in \mathbf{R}^n, \tag{4.13}$$

where F is a diagonalizable $n \times n$ constant matrix, all of whose eigenvalues lie on the imaginary axis. In this case, the following are sufficient conditions for this system to satisfy the norm conditions (N1) to (N3):

(i) $g(t,x)$ is polynomial in x and periodic in t.
(ii) $g(t,x)$ is polynomial in x and almost periodic in t, the set of whose Fourier exponents has no accumulation points.

See Appendix A for the proof. The case where F has eigenvalues on the left half plane will be treated in a forthcoming paper. In Example 4.7, we show another example satisfying norm conditions (N) whose unperturbed part is nonlinear.

In what follows, we fix an open subset $U \subset \mathbf{R}^n$ such that $\overline{U}$ is compact. Define $\alpha_t : U \to \mathbf{R}^n$ to be

$$\alpha_t(A) = x_0(t,0,A) + \varepsilon h(t,A) \tag{4.14}$$

for all $t \in \mathbf{R}_{\geq T}$. The set U is defined so that α_t is a diffeomorphism on U (see the proof of Theorem 4.4(i) below). Note that the smaller $|\varepsilon|$ is, the larger set U we can take.

Our main theorem is stated as follows.

Theorem 4.4. *Let f, g, $x_0(t,0,A)$, $x_1(t,\tau;A)$ be vector fields and solutions to differential equations defined in (4.1) to (4.4) and (4.9), respectively. Let $\varepsilon R(A)$ be the RG vector field for $f + \varepsilon g$, and denote its integral curves, whose initial time is t_0 and initial value is $\xi \in U$, by $A(t) := A(t,t_0,\xi) = \varphi^{RG}_{t-t_0}(\xi)$. Then, there exist $\varepsilon_0 > 0$ such that the following hold for all $|\varepsilon| < \varepsilon_0$:*

(i) *Suppose that the norm condition* (N1) *is satisfied. Then,*

$$\Phi_{t,t_0} := \alpha_t \circ \varphi^{RG}_{t-t_0} \circ \alpha_{t_0}^{-1} : \alpha_{t_0}(U) \to \mathbf{R}^n \tag{4.15}$$

defines a flow on $U_\varepsilon := \{(t,x) \mid t \in \mathbf{R}_{\geq T},\ x \in \alpha_t(U)\}$ *associated with a time-dependent vector field*

$$F_\varepsilon(t,x) := \frac{d}{da}\Big|_{a=t} \Phi_{a,t}(x). \tag{4.16}$$

The integral curves of F_ε *are put in the form*

$$X(t,t_0;\xi) := \hat{x}(t,t;A(t,t_0,\xi)), \tag{4.17}$$

where $\hat{x}$ *is defined by* (4.10).

(ii) *Suppose that the norm conditions* (N1)–(N2) *are satisfied. Then, there exists a non-negative constant* L_1 *such that the vector field* F_ε *defined by* (4.16) *satisfies an inequality*

$$\sup_{U_\varepsilon} ||f + \varepsilon g - F_\varepsilon|| < \varepsilon^2 L_1. \tag{4.18}$$

(iii) *Suppose that the norm conditions* (N1)–(N3) *are satisfied. Then, there exists a non-negative constant* L_2 *such that the vector field* F_ε *satisfies an inequality*

$$\sup_{U_\varepsilon} ||D_{t,x} f + \varepsilon D_{t,x} g - D_{t,x} F_\varepsilon|| < \varepsilon^2 L_2, \tag{4.19}$$

where $D_{t,x} f = (\partial f/\partial t, \partial f/\partial x)$ *and* $||D_{t,x} f|| = ||\partial f/\partial x|| + ||\partial f/\partial t||$. *In particular,* F_ε *is sufficiently close to* $f + \varepsilon g$ *in the* C^1 *topology if* $|\varepsilon|$ *is sufficiently small.*

Proof of (i). Since $h(t,x)$ is bounded on $\mathbf{R}_{\geq T} \times U$ by the norm condition (N1), $\varepsilon h(t,x)$ can be sufficiently close to a null function as a C^3 function of x for sufficiently small ε. Since the flow $\varphi^0_{t,0}$ is a C^4 diffeomorphism and since the set of diffeomorphisms is open in the space of C^1 maps in the C^1 topology, it follows that for a sufficiently small ε, the map α_t given by (4.14) is a diffeomorphism from U into $\mathbf{R}^n$ for each $t \in \mathbf{R}_{\geq T}$. Therefore, the map $\Phi_{t,t_0} : \alpha_{t_0}(U) \to \mathbf{R}^n$ defined by (4.15) is a diffeomorphism from $\alpha_{t_0}(U)$ into $\mathbf{R}^n$ as well and satisfies $\Phi_{t,t'} \circ \Phi_{t',t_0} = \Phi_{t,t_0}$, $\Phi_{t,t} = id_{\alpha_t(U)}$. This shows that Φ_{t,t_0} is a flow associated with a vector field F_ε defined by (4.16). Then, it turns out that

$$\Phi_{t,t_0}(\alpha_{t_0}(\xi)) = \alpha_t \circ \varphi^{RG}_{t-t_0}(\xi) = \alpha_t(A(t,t_0,\xi)) = \hat{x}(t,t;A(t,t_0,\xi)) = X(t,t_0;\xi),$$

which implies that $X(t,t_0;\xi)$ gives an integral curve of F_ε, namely,

$$\frac{dX}{dt}(t,t_0;\xi) = F_\varepsilon(t, X(t,t_0;\xi)). \tag{4.20}$$

This ends the proof. ■

Proof of (ii), (iii). Denote $h(t,A)$ as $h_t(A)$. The vector field $F_\varepsilon(t,x)$ is calculated as

$$\begin{aligned}
F_\varepsilon(t,x) &= \frac{d}{da}\Big|_{a=t}\left((\varphi^0_{a,0}+\varepsilon h_a)\circ\varphi^{RG}_{a-t}\circ\alpha_t^{-1}(x)\right)\\
&= \frac{d}{da}\Big|_{a=t}(\varphi^0_{a,0}+\varepsilon h_a)\circ\alpha_t^{-1}(x)+(D\varphi^0_{t,0}+\varepsilon Dh_t)_{\alpha_t^{-1}(x)}\frac{d}{da}\Big|_{a=t}\varphi^{RG}_{a-t}\circ\alpha_t^{-1}(x)\\
&= f(t,x_0(t,0,\alpha_t^{-1}(x)))+\varepsilon\frac{\partial f}{\partial x}(t,x_0(t,0,\alpha_t^{-1}(x)))x_1(t,t;\alpha_t^{-1}(x))+\varepsilon g(t,x_0(t,0,\alpha_t^{-1}(x)))\\
&\quad+\varepsilon\frac{d}{da}\Big|_{a=t}x_1(t,a,\alpha_t^{-1}(x))+\varepsilon(D\varphi^0_{t,0}+\varepsilon Dh_t)_{\alpha_t^{-1}(x)}R(\alpha_t^{-1}(x))\\
&= f(t,x_0(t,0,\alpha_t^{-1}(x)))+\varepsilon g(t,x_0(t,0,\alpha_t^{-1}(x)))\\
&\quad+\varepsilon\frac{\partial f}{\partial x}(t,x_0(t,0,\alpha_t^{-1}(x)))h_t(\alpha_t^{-1}(x))+\varepsilon^2(Dh_t)_{\alpha_t^{-1}(x)}R(\alpha_t^{-1}(x)).
\end{aligned}$$

On account of $\alpha_t(x)=x_0(t,0,x)+\varepsilon h_t(x)$, the above equation is expanded as

$$\begin{aligned}
F_\varepsilon(t,x) &= f(t,x)+\varepsilon\frac{df}{d\varepsilon}\Big|_{\varepsilon=0}(t,x_0(t,0,\alpha_t^{-1}(x)))+\frac{\varepsilon^2}{2}\frac{d^2f}{d\varepsilon^2}\Big|_{\varepsilon=\theta_1\varepsilon}(t,x_0(t,0,\alpha_t^{-1}(x)))+\varepsilon g(t,x)\\
&\quad+\varepsilon^2\frac{dg}{d\varepsilon}\Big|_{\varepsilon=\theta_2\varepsilon}(t,x_0(t,0,\alpha_t^{-1}(x)))+\varepsilon\frac{\partial f}{\partial x}(t,x)h_t((\varphi^0_{t,0})^{-1}(x))\\
&\quad+\varepsilon^2\frac{\partial f}{\partial x}(t,x)\frac{dh_t}{d\varepsilon}\Big|_{\varepsilon=\theta_3\varepsilon}(\alpha_t^{-1}(x))\\
&\quad+\varepsilon^2\frac{d}{d\varepsilon}\Big|_{\varepsilon=\theta_4\varepsilon}\left(\frac{\partial f}{\partial x}(t,x_0(t,0,\alpha_t^{-1}(x)))\right)h_t(\alpha_t^{-1}(x))+\varepsilon^2(Dh_t)_{\alpha_t^{-1}(x)}R(\alpha_t^{-1}(x)),
\end{aligned}$$

where $0<\theta_1,\theta_2,\theta_3,\theta_4<1$ are constants in the Taylor formula. The second term of the right-hand side of the above is calculated as

$$\begin{aligned}
\frac{df}{d\varepsilon}\Big|_{\varepsilon=0}(t,x_0(t,0,\alpha_t^{-1}(x))) &= \frac{\partial f}{\partial x}(t,x)\frac{\partial x_0}{\partial A}(t,0,(\varphi^0_{t,0})^{-1}(x))\frac{d}{d\varepsilon}\Big|_{\varepsilon=0}\alpha_t^{-1}(x)\\
&= -\frac{\partial f}{\partial x}(t,x)h_t((\varphi^0_{t,0})^{-1}(x)).
\end{aligned}$$

Therefore, we obtain

$$\begin{aligned}
F_\varepsilon(t,x)-f(t,x)-\varepsilon g(t,x) &= \frac{\varepsilon^2}{2}\frac{d^2f}{d\varepsilon^2}\Big|_{\varepsilon=\theta_1\varepsilon}(t,x_0(t,0,\alpha_t^{-1}(x)))+\varepsilon^2\frac{dg}{d\varepsilon}\Big|_{\varepsilon=\theta_2\varepsilon}(t,x_0(t,0,\alpha_t^{-1}(x)))\\
&\quad+\varepsilon^2\frac{\partial f}{\partial x}(t,x)\frac{dh_t}{d\varepsilon}\Big|_{\varepsilon=\theta_3\varepsilon}(\alpha_t^{-1}(x))\\
&\quad+\varepsilon^2\frac{d}{d\varepsilon}\Big|_{\varepsilon=\theta_4\varepsilon}\left(\frac{\partial f}{\partial x}(t,x_0(t,0,\alpha_t^{-1}(x)))\right)h_t(\alpha_t^{-1}(x))\\
&\quad+\varepsilon^2(Dh_t)_{\alpha_t^{-1}(x)}R(\alpha_t^{-1}(x)).
\end{aligned}\tag{4.21}$$

We have to estimate the norm of the right-hand side of the above equation. At first, $df/d\varepsilon$ is given by

$$\frac{df}{d\varepsilon}(t, x_0(t, 0, \alpha_t^{-1}(x)))$$

$$= -\frac{\partial f}{\partial x}(t, x_0(t, 0, \alpha_t^{-1}(x)))\frac{\partial x_0}{\partial A}(t, 0, \alpha_t^{-1}(x))\left(\frac{\partial}{\partial A}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)^{-1} h_t(\alpha_t^{-1}(x)). \tag{4.22}$$

Note that equations

$$\alpha_t^{-1}(x) = (\varphi_{t,0}^0 + \varepsilon h_t)^{-1}(x) = (id + \varepsilon(\varphi_{t,0}^0)^{-1} \circ h_t)^{-1} \circ (\varphi_{t,0}^0)^{-1}(x), \tag{4.23}$$

$$x_0(t, 0, \alpha_t^{-1}(x)) = \varphi_{t,0}^0 \circ \alpha_t^{-1}(x) = (id - \varepsilon h_t \circ \alpha_t^{-1})(x), \tag{4.24}$$

$$\frac{\partial x_0}{\partial A}(t, 0, \alpha_t^{-1}(x))\left(\frac{\partial}{\partial A}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)^{-1}$$

$$= id - \varepsilon\left(\frac{\partial h_t}{\partial A}\right)_{\alpha_t^{-1}(x)} \sum_{k=0}^{\infty}\left(-\varepsilon\left(\frac{\partial x_0}{\partial A}\right)_{\alpha_t^{-1}(x)}^{-1} \circ \left(\frac{\partial h_t}{\partial A}\right)_{\alpha_t^{-1}(x)}\right)^k \circ \left(\frac{\partial x_0}{\partial A}\right)_{\alpha_t^{-1}(x)}^{-1} \tag{4.25}$$

hold and the left-hand sides of the above three equations are bounded by the norm conditions (N1)–(N2). Therefore, the right-hand side of (4.22) is bounded uniformly in $\mathbf{R}_{\geq T}$. To show the boundedness of the first term of the right-hand side of (4.21), it is sufficient to show that the derivative of each factor of the right-hand side of (4.22) is bounded. They are calculated as

$$\frac{d}{d\varepsilon}\frac{\partial f}{\partial x}(t, x_0(t, 0, \alpha_t^{-1}(x)))$$

$$= -\frac{\partial^2 f}{\partial x^2}(t, x_0(t, 0, \alpha_t^{-1}(x)))\frac{\partial x_0}{\partial A}(t, 0, \alpha_t^{-1}(x))\left(\frac{\partial}{\partial A}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)^{-1} h_t(\alpha_t^{-1}(x)), \tag{4.26}$$

$$\frac{d}{d\varepsilon}\frac{\partial x_0}{\partial A}(t, 0, \alpha_t^{-1}(x))$$

$$= -\frac{\partial^2 x_0}{\partial A^2}(t, 0, \alpha_t^{-1}(x))\left(\frac{\partial}{\partial A}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)^{-1} h_t(\alpha_t^{-1}(x)), \tag{4.27}$$

$$\frac{d}{d\varepsilon}\left(\frac{\partial}{\partial A}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)^{-1} \tag{4.28}$$

$$= -\left(\frac{\partial}{\partial A}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)^{-1} \frac{d}{d\varepsilon}\left(\frac{\partial}{\partial A}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)\left(\frac{\partial}{\partial A}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)^{-1},$$

$$\frac{d}{d\varepsilon}\left(\frac{\partial}{\partial A}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)$$

$$= \left(\frac{\partial h_t}{\partial A}\right)_{\alpha_t^{-1}(x)} - \left(\frac{\partial^2}{\partial A^2}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)\left(\frac{\partial}{\partial A}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)^{-1} h_t(\alpha_t^{-1}(x)), \tag{4.29}$$

$$\frac{d}{d\varepsilon}h_t(\alpha_t^{-1}(x))$$

$$= -\left(\frac{\partial h_t}{\partial A}\right)_{\alpha_t^{-1}(x)}\left(\frac{\partial}{\partial A}(\varphi_{t,0}^0 + \varepsilon h_t)_{\alpha_t^{-1}(x)}\right)^{-1} h_t(\alpha_t^{-1}(x)). \tag{4.30}$$

By the norm conditions and (4.23), (4.24), and (4.25), these are bounded uniformly in $\mathbf{R}_{\geq T}$. Therefore, the first term of the right-hand side of (4.21) is bounded.

The boundedness of the second term of the right-hand side of (4.21) is verified from (4.22) by using g instead of f, and the boundedness of the other terms of the right-hand side of (4.21) is verified from (4.26), (4.30), and the norm conditions (N1)–(N2). This proves Theorem 4.4(ii). Theorem 4.4(iii) is verified by differentiating both sides of (4.21) with respect to x, t and estimating the norm as above. This calculation is elementary and is omitted here. ■

Remark 4.5. Though we have treated the vector field F_ε on an open set of $\mathbf{R}^n$, the vector field F_ε may be defined in the case of an arbitrary manifold M. Let $\{U_i\}_{i\in\Lambda}$ be an open covering of M such that each $\overline{U}_i$ is compact. We identify U_i with an open subset on $\mathbf{R}^n$. Suppose that $U_i \cap U_j \neq \emptyset$ and let $\psi_{ij} : U_i \cap U_j \to U_i \cap U_j$ be a coordinate transformation function from U_i to U_j. Let $\varepsilon R^i(A)$ and $\varepsilon R^j(A)$ be the RG vector fields constructed on U_i and U_j, respectively, and let $\varphi_t^{RG(i)}$, $\varphi_t^{RG(j)}$ be respective flows. By (4.7), it is easy to verify that $R^i(A) = (D\psi_{ij})^{-1}R^j(\psi_{ij}(A))$ and $\varphi_t^{RG(i)} = \psi_{ij}^{-1} \circ \varphi_t^{RG(j)} \circ \psi_{ij}$. Let F_ε^i, F_ε^j be approximate vector fields constructed on U_i, U_j defined by (4.16), respectively. Then F_ε^i is transformed by the coordinate transformation as follows:

$$\begin{aligned} D\psi_{ij}F_\varepsilon^i(t,x) &= D\psi_{ij}\frac{d}{da}\Big|_{a=t}\Phi_{a,t}(x) \\ &= \frac{d}{da}\Big|_{a=t}\psi_{ij}\circ\alpha_t\circ\varphi_{t-t_0}^{RG(i)}\circ\alpha_{t_0}^{-1}(x) \\ &= \frac{d}{da}\Big|_{a=t}\psi_{ij}\circ(x_0+\varepsilon h)\circ\psi_{ij}^{-1}\circ(\psi_{ij}\circ\varphi_{t-t_0}^{RG(i)}\circ\psi_{ij}^{-1}) \\ &\qquad\qquad \circ(\psi_{ij}\circ(x_0+\varepsilon h)\circ\psi_{ij}^{-1})^{-1}(\psi_{ij}(x)), \end{aligned}$$

where $\psi_{ij}\circ x_0(t,0,\psi_{ij}^{-1}(x))$ and $\psi_{ij}\circ h(t,\psi_{ij}^{-1}(x)) = \psi_{ij}\circ x_1(t,t,\psi_{ij}^{-1}(x))$ are coordinate representations on U_j of $x_0(t,0,x)$ and of $x_1(t,t,x)$, respectively, which are represented in the coordinates on U_i. This means that

$$D\psi_{ij}F_\varepsilon^i(t,x) = F_\varepsilon^j(t,\psi_{ij}(x)), \quad x\in U_i. \tag{4.31}$$

Let $\{\rho_i\}_{i\in\Lambda}$ be a partition of unity subordinate to the cover $\{U_i\}_{i\in\Lambda}$ and define $F_\varepsilon(t,x) := \sum_{i\in\Lambda}\rho_i(x)F_\varepsilon^i(t,x)$; then F_ε is a well-defined vector field on M which approximates to $f+\varepsilon g$.

Remark 4.6. Now that we have the approximate vector field $F_\varepsilon(t,x) = f(t,x)+\varepsilon g(t,x)+O(\varepsilon^2)$, the Gronwall inequality immediately proves the error estimate for approximate solutions.

Let $x(t,t_0)$ be a solution of (4.1) satisfying the norm conditions (N) whose initial time is t_0. Let $X(t,t_0;\xi)$ be a curve defined by (4.17). Suppose that $x(t_0,t_0) = X(t_0,t_0;\xi) \in \alpha_t(U)$. Then, there exist positive constants ε_0, T, C such that the inequality

$$||x(t,t_0) - X(t,t_0;\xi)|| < C\varepsilon, \quad 0 < t < T/\varepsilon, \tag{4.32}$$

holds for $0 < \varepsilon < \varepsilon_0$.

This fact was essentially proved in Ziane [8] and DeVille et al. [9]. Note that DeVille et al. also treated the case that the norm conditions (N) are not satisfied—for example,

$g(t,x) = x/\sqrt{t}$. The above fact is also followed by putting $m = 1$ and replacing e^{Ft} by $(D\varphi^0_{t,0})_A$ in the proof of Theorem A.8, in which the error estimate for a higher order case by using the higher order RG equation is proved.

In the next example, the RG method is applied to a vector field whose unperturbed part is nonlinear. Application to vector fields with linear unperturbed parts will be treated in section 6.

Example 4.7. Consider a system on $\{(x,y) \mid x > 0,\ y \in \mathbf{R}\} \subset \mathbf{R}^2$,

$$\begin{cases} \dot{x} = xy + \varepsilon xy^2, \\ \dot{y} = -\log x + \varepsilon y, \end{cases} \tag{4.33}$$

where $\varepsilon \in \mathbf{R}$ is a small constant. Note that unperturbed part is nonlinear. In order to obtain approximate solutions to (4.33), we apply the RG method. The unperturbed system of (x_0, y_0) is written as $\dot{x}_0 = x_0 y_0$, $\dot{y}_0 = -\log x_0$. Its general solution, whose initial value is $(x_0(0), y_0(0)) = (A, B)$, is given by

$$x_0(t) = e^{B\sin t + (\log A)\cos t}, \quad y_0(t) = B\cos t - (\log A)\sin t. \tag{4.34}$$

The RG equation defined by (4.11) is calculated as

$$\frac{d}{dt}\begin{pmatrix} A \\ B \end{pmatrix} = \frac{\varepsilon}{2}\begin{pmatrix} A\log A \\ B \end{pmatrix}, \tag{4.35}$$

which is solved as

$$A(t) = \exp\left(pe^{\varepsilon t/2}\right), \quad B(t) = qe^{\varepsilon t/2}, \tag{4.36}$$

where $p, q \in \mathbf{R}$ are arbitrary constants. On the other hand, $h(t, A, B)$ defined by (4.8) is given by $h(t, A, B) = (D\varphi^0_{t,0})_{(A,B)} M(t)$, where

$$(D\varphi^0_{t,0})_{(A,B)} = \begin{pmatrix} \cos t \cdot e^{B\sin t + (\log A)\cos t}/A & \sin t \cdot e^{B\sin t + (\log A)\cos t} \\ -\sin t/A & \cos t \end{pmatrix}, \tag{4.37}$$

(4.38)

$$M(t) = \begin{pmatrix} \dfrac{A(\log A)^2 - AB^2}{3}\sin^3 t + \dfrac{2AB\log A}{3}\cos^3 t - \dfrac{AB}{2}\sin^2 t + AB^2\sin t - \dfrac{A\log A}{4}\sin^2 t \\ \dfrac{(\log A)^2 - B^2}{3}\cos^3 t - \dfrac{2B\log A}{3}\sin^3 t - \dfrac{\log A}{2}\sin^2 t - (\log A)^2\cos t + \dfrac{B}{4}\sin 2t \end{pmatrix}.$$

It is easy to verify that the norm conditions (N) are satisfied. According to (4.17) with the present $A(t), B(t)$, an approximate solution to (4.33) is given by

$$\begin{pmatrix} X(t) \\ Y(t) \end{pmatrix} = \begin{pmatrix} e^{B(t)\sin t - (\log A(t))\cos t} \\ B(t)\cos t - (\log A(t))\cos t \end{pmatrix} + \varepsilon h(t, A(t), B(t)). \tag{4.39}$$

Note that the RG vector field $\frac{\varepsilon}{2}(x\log x, y)$ commutes with the vector field $(xy, -\log x)$, which is the unperturbed part of (4.33) with respect to the Lie bracket product. This fact is proved generally in the next section.

5. RG vector fields with symmetry. In this section, we consider an autonomous equation on a manifold M:

$$\dot{x} = f(x) + \varepsilon g(x), \quad x \in M. \tag{5.1}$$

For this equation, we suppose that $(D\varphi_s^0)_A^{-1} g(\varphi_s^0(A))$ is KBM on $\mathbf{R}_{\geq T}$ and the RG equation for $f + \varepsilon g$

$$\frac{dA}{dt} = \varepsilon R(A) = \varepsilon \lim_{t\to\infty} \frac{1}{t-T} \int_T^t (D\varphi_s^0)_A^{-1} g(\varphi_s^0(A)) ds \tag{5.2}$$

is defined, where φ^0 is a flow of $f(x)$ satisfying $\varphi_{t+t'}^0 = \varphi_t^0 \circ \varphi_{t'}^0$.

Assume that a Lie group G acts on the manifold M. If a vector field f on M satisfies

$$(Da)_x f(x) = f(ax) \quad \forall a \in G, \forall x \in M, \tag{5.3}$$

then f is called *invariant* under the action of G, where $(Da)_x$ is the derivative at x of the map determined by $a : M \to M$ at x.

Proposition 5.1. *If vector fields f and g are invariant under the action of a Lie group G, then so is the RG vector field for $f + \varepsilon g$.*

Proof. For all $a \in G$, $R(aA)$ is calculated as

$$\begin{aligned} R(aA) &= \lim_{t\to\infty} \frac{1}{t-T} \int_T^t (D\varphi_s^0)_{aA}^{-1} g(\varphi_s^0(aA)) ds \\ &= \lim_{t\to\infty} \frac{1}{t-T} \int_T^t (Da)_A (D\varphi_s^0)_A^{-1} (Da)_A^{-1} g(a\varphi_s^0(A)) ds \\ &= (Da)_A \lim_{t\to\infty} \frac{1}{t-T} \int_T^t (D\varphi_s^0)_A^{-1} (Da)_A^{-1} (Da)_A g(\varphi_s^0(A)) ds = (Da)_A R(A). \end{aligned}$$

This proves the proposition. ∎

The next proposition was proved by Ziane [8] for the case that $f(t,x)$ is a linear vector field.

Proposition 5.2. *The RG vector field $\varepsilon R(A)$ for $f + \varepsilon g$ commutes with f with respect to the Lie bracket product. Equivalently, $R(A)$ satisfies*

$$(D\varphi_t^0)_A R(A) = R(\varphi_t^0(A)) \tag{5.4}$$

for all $t \in \mathbf{R}$ and all $A \in M$.

Proof. For all $s' \in \mathbf{R}$ and for all $A \in M$, $R(\varphi_{s'}^0(A))$ is calculated as

$$\begin{aligned} R(\varphi_{s'}^0(A)) &= \lim_{t\to\infty} \frac{1}{t-T} \int_T^t (D\varphi_s^0)_{\varphi_{s'}^0(A)}^{-1} g(\varphi_s^0 \circ \varphi_{s'}^0(A)) ds \\ &= \lim_{t\to\infty} \frac{1}{t-T} \int_T^t (D\varphi_{s'}^0)_A \circ (D\varphi_s^0)_A^{-1} \circ (D\varphi_{s'}^0)_A^{-1} g(\varphi_{s+s'}^0(A)) ds \\ &= (D\varphi_{s'}^0)_A \lim_{t\to\infty} \frac{1}{t-T} \int_T^t (D\varphi_{s+s'}^0)_A^{-1} g(\varphi_{s+s'}^0(A)) ds. \end{aligned}$$

Putting $s+s'=s''$ provides

$$\begin{aligned}R(\varphi^0_{s'}(A)) =&(D\varphi^0_{s'})_A \lim_{t\to\infty}\frac{1}{t-T}\int_{T+s'}^{t+s'}(D\varphi^0_{s''})_A^{-1}g(\varphi^0_{s''}(A))ds''\\ =&(D\varphi^0_{s'})_A R(A)+(D\varphi^0_{s'})_A \lim_{t\to\infty}\frac{1}{t-T}\int_{t}^{t+s'}(D\varphi^0_{s''})_A^{-1}g(\varphi^0_{s''}(A))ds''\\ &-(D\varphi^0_{s'})_A \lim_{t\to\infty}\frac{1}{t-T}\int_{T}^{T+s'}(D\varphi^0_{s''})_A^{-1}g(\varphi^0_{s''}(A))ds''\\ =&(D\varphi^0_{s'})_A R(A).\end{aligned}$$

This proves the proposition. ■

Propositions 5.1 and 5.2 show that if vector fields f and g are invariant under the action of a Lie group G, then the RG vector field $\varepsilon R(A)$ is invariant under the action of G and the one-parameter group $\{\varphi^0_t\}_{t\in\mathbf{R}}$. In this sense, the RG vector field has a simpler structure than the original vector field $f+\varepsilon g$.

6. Invariant manifolds.

In this section, we consider an equation of the form

$$\dot{x}=Fx+\varepsilon g(x),\quad x\in\mathbf{R}^n, \tag{6.1}$$

where F is a diagonalizable $n\times n$ constant matrix, all of whose eigenvalues lie on the imaginary axis, and where g is a polynomial vector field on $\mathbf{R}^n$. Note that in this situation, the norm conditions (N) are satisfied.

Theorem 6.1. *If the RG vector field $\varepsilon R(x)$ for (6.1) has a boundaryless compact normally hyperbolic invariant manifold N, then (6.1) also has a normally hyperbolic invariant manifold N_ε for sufficiently small $\varepsilon>0$. This invariant manifold N_ε is diffeomorphic to N, and its stability coincides with that of N.*

We will prove this theorem in Appendix A, while we give a brief sketch of the proof below.

Suppose that the RG vector field has a normally hyperbolic invariant manifold N. Then, the approximate vector field $F_\varepsilon(t,x)$ defined by (4.16) has a normally hyperbolic invariant manifold $\tilde{N}$ which is diffeomorphic to $\mathbf{R}\times N$ in the (t,x) space since the flow of the approximate vector field is related to the flow of the RG vector field through (4.15). Now we need Fenichel's theorem.

Theorem (Fenichel [10]). *Let M be a C^r manifold ($r\geq 1$) and $\mathcal{X}^r(M)$ the set of C^r vector fields on M with the C^1 topology. Let f be a C^r vector field on M, and suppose that $N\subset M$ is a boundaryless compact connected normally hyperbolic f-invariant manifold. Then, the following hold:*

(i) *There is a neighborhood $\mathcal{U}\subset\mathcal{X}^r(M)$ of f such that there exists a normally hyperbolic g-invariant C^r manifold $N_g\subset M$ for all $g\in\mathcal{U}$.*

(ii) *N_g is diffeomorphic to N and the diffeomorphism $h:N_g\to N$ is close to the identity $\mathrm{id}:N\to N$ in the C^1 topology.*

See [10, 11, 12] for the proof of the theorem and the definition of normal hyperbolicity. Since the approximate vector field $F_\varepsilon(t,x)$ is C^1 close to the original vector field $Fx+\varepsilon g(x)$, we expect that Fenichel's theorem concludes that the original vector field $Fx+\varepsilon g(x)$ has

an invariant manifold which is diffeomorphic to $\mathbf{R} \times N$ in the (t, x) space. Since (6.1) is an autonomous equation, $Fx + \varepsilon g(x)$ has an invariant manifold which is diffeomorphic to N in the x space.

The above argument needs to be modified because the approximate vector field is a time-dependent vector field even if the original vector is independent of t, while Fenichel's theorem holds for time-independent vector fields. In Appendix A, we define the higher order RG equation to refine the error estimate of the approximate vector field to prove Theorem 6.1.

Note that for the case of compact normally hyperbolic invariant manifolds with boundary, Fenichel's theorem is modified as follows: If a vector field f has a compact connected normally hyperbolic invariant manifold N with a boundary, then a vector field g, which is C^1 close to f, has a *locally* invariant manifold N_g which is diffeomorphic to N. In this case, an orbit of the flow of g through a point on N_g may go out from N_g through its boundary. According to this theorem, Theorem 6.1 has to be modified so that N_ε is locally invariant if N has a boundary.

Example 6.2. Consider the system on $\mathbf{R}^2$:

$$\begin{cases} \dot{x} = y - x^3 + \varepsilon x, \\ \dot{y} = -x. \end{cases} \tag{6.2}$$

The unperturbed system $\dot{x} = y - x^3$, $\dot{y} = -x$ has the origin as a fixed point which is *not* hyperbolic. By using Theorem 6.1, we show the occurrence of the Hopf bifurcation at $\varepsilon = 0$, and a stable periodic orbit appears for $\varepsilon > 0$.

Changing the coordinate by $(x, y) = (\varepsilon X, \varepsilon Y)$, we obtain

$$\begin{cases} \dot{X} = Y + \varepsilon(X - \varepsilon X^3), \\ \dot{Y} = -X. \end{cases} \tag{6.3}$$

We want to regard the term $\varepsilon^2 X^3$ as a *first* order term with respect to ε since, at this time, we define only the *first* order RG equation while the higher order RG equation will be defined in Appendix A. To do so, define the function $\varepsilon_0(t)$ by $\varepsilon_0(t) \equiv \varepsilon$, and rewrite (6.3) as

$$\begin{cases} \dot{X} = Y + \varepsilon(X - \varepsilon_0 X^3), \\ \dot{Y} = -X, \\ \dot{\varepsilon}_0 = 0. \end{cases} \tag{6.4}$$

Then this system takes the form (6.1). The RG method is applicable to (6.4). Substitute $X = X_0 + \varepsilon X_1$, $Y = Y_0 + \varepsilon Y_1$ into (6.4) and equate the coefficients of $\varepsilon^0, \varepsilon^1$ to zero, respectively. Then we get

$$\begin{cases} \dot{X}_0 = Y_0, \\ \dot{Y}_0 = -X_0, \end{cases} \quad \begin{cases} \dot{X}_1 = Y_1 + X_0 - \varepsilon_0 X_0^3, \\ \dot{Y}_1 = -X_1. \end{cases} \tag{6.5}$$

We denote a solution to the former by

$$X_0(t) = Ae^{it} + \overline{A}e^{-it}, \quad A \in \mathbf{C}. \tag{6.6}$$

With this $X_0(t)$, a special solution to the latter defined by (4.9), whose initial time is $t = \tau$, is written as

$$X_1(t) = \frac{1}{2}(A - 3\varepsilon_0 A|A|^2)(t-\tau)e^{it} + \frac{3i}{8}A^3 e^{3it} + \text{c.c.}, \tag{6.7}$$

where c.c. is the complex conjugate of the first two terms of the right-hand side. Therefore, the RG equation for (6.3) is given by

$$\frac{dA}{dt} = \frac{1}{2}\varepsilon(A - 3\varepsilon_0 A|A|^2). \tag{6.8}$$

Substituting $A = re^{i\theta}$ into the above equation provides

$$\begin{cases} \dot{r} = \dfrac{\varepsilon}{2}(r - 3\varepsilon_0 r^3), \\ \dot{\theta} = 0. \end{cases} \tag{6.9}$$

Fixed points of this system are $r = 0$ and $r = \sqrt{1/3\varepsilon_0} := r_0$, when $\varepsilon_0 > 0$. Further, we obtain

$$\frac{d}{dr}\Big|_{r=r_0} \frac{\varepsilon}{2}(r - 3\varepsilon_0 r^3) = \frac{\varepsilon}{2}\left(1 - 9\varepsilon_0 \cdot \frac{1}{3\varepsilon_0}\right) = -\varepsilon < 0.$$

This means that the RG equation (6.9) has a circle $\{r = r_0\}$ as a stable normally hyperbolic invariant manifold (the set of fixed points) if $\varepsilon > 0$. By Theorem 6.1, the system (6.2) also has a stable periodic orbit if $\varepsilon > 0$ is sufficiently small. This proves that the Hopf bifurcation occurs for (6.2). Note that the radius of the invariant circle for the RG equation is of order $O(1/\sqrt{\varepsilon})$. In the original coordinate (x, y), the radius of the periodic orbit for the system (6.2) is of order $O(\sqrt{\varepsilon})$. Indeed, the periodic solution is approximately given by $x(t) = 2\sqrt{\varepsilon/3}\cos t$ in the (x, y) coordinate.

We can show that the second order RG equation defined in Definition A.5 for (6.3) is given as $\dot{r} = \varepsilon(r - 3\varepsilon r^3)/2$, $\dot{\theta} = -\varepsilon^2/8$. Thus we can obtain the same result as above without introducing ε_0 by using the second order RG equation, although it provides a modification to the motion in the θ direction.

We have just seen in Example 6.2 that the RG method can be used on problems in which there is an ordinary Hopf bifurcation. In the next example, we show that the RG method can also be used for systems in which a limit cycle is created far away from a fixed point, namely, with $O(1)$ radius.

Example 6.3. Consider the system on $\mathbf{R}^2$

$$\begin{cases} \dot{x} = y + \varepsilon(x - x^3), \\ \dot{y} = -x. \end{cases} \tag{6.10}$$

Substituting $x = x_0 + \varepsilon x_1$, $y = y_0 + \varepsilon y_1$ into (6.10) and equating the coefficients of $\varepsilon^0, \varepsilon^1$ to zero, respectively, we get

$$\begin{cases} \dot{x}_0 = y_0, \\ \dot{y}_0 = -x_0, \end{cases} \qquad \begin{cases} \dot{x}_1 = y_1 + x_0 - x_0^3, \\ \dot{y}_1 = -x_1. \end{cases} \tag{6.11}$$

We denote a solution to the former by

$$x_0(t) = Ae^{it} + \overline{A}e^{-it}, \quad A \in \mathbf{C}. \tag{6.12}$$

With this $x_0(t)$, a special solution to the latter defined by (4.9), whose initial time is $t = \tau$, is written as

$$x_1(t) = \frac{1}{2}(A - 3A|A|^2)(t-\tau)e^{it} + \frac{3i}{8}A^3 e^{3it} + \text{c.c.}, \tag{6.13}$$

where c.c. is the complex conjugate of the first two terms of the right-hand side. Therefore, the RG equation for (6.10) is given by

$$\frac{dA}{dt} = \frac{1}{2}\varepsilon(A - 3A|A|^2). \tag{6.14}$$

Substituting $A = re^{i\theta}$ into the above equation provides

$$\begin{cases} \dot{r} = \dfrac{\varepsilon}{2}(r - 3r^3), \\ \dot{\theta} = 0. \end{cases} \tag{6.15}$$

Fixed points of this system are $r = 0$ and $r = \sqrt{1/3} := r_0$, when $\varepsilon > 0$. It is easy to verify that $r = r_0$ is the stable fixed point. Therefore, the system (6.10) has a stable periodic orbit if $\varepsilon > 0$ is sufficiently small. Note that since the radius of the invariant circle for the RG equation is of $O(1)$, the radius of the periodic orbit of the system (6.10) is also of $O(1)$. This can be verified numerically. For each ε, points $y_0 > 0$ at which the periodic orbit for the system (6.10) crosses the y axis are calculated numerically to provide Figure 1. The radius y_0 is almost independent of ε when $\varepsilon > 0$ is sufficiently small.

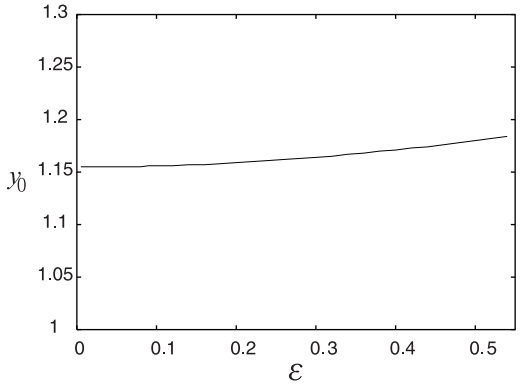

Figure 1. *The radius y_0 of the periodic orbit of the system (6.10) for each ε.*

7. Linear equations.

We apply the RG method to a time-dependent linear equation

$$\dot{x} = F(t)x + \varepsilon G(t)x, \quad x \in \mathbf{R}^n, \tag{7.1}$$

where $F(t)$ and $G(t)$ are $n \times n$ matrix functions which are of C^1 class with respect to t. A solution to the equation $\dot{x}_0 = F(t)x_0$ is denoted by $x_0(t, 0, v) = X(t)v$, where $X(t)$ is the

fundamental matrix and $v \in \mathbf{R}^n$ is an initial value. We assume that $X(t)^{-1}G(t)X(t)$ is KBM on $t \geq 0$, and we define a constant matrix

$$R := \lim_{t\to\infty} \frac{1}{t}\int_0^t X^{-1}(s)G(s)X(s)ds. \tag{7.2}$$

We call it a *secular matrix* for (7.1). Then, a special solution to an equation $\dot{x}_1 = F(t)x_1 + G(t)x_0(t,0,v)$ defined by (4.9) is given by

$$x_1(t,\tau;v) = X(t)\widetilde{G}(t)v + X(t)(t-\tau)Rv,\ \ \widetilde{G}(t) = \int^t (X(s)^{-1}G(s)X(s) - R)ds, \tag{7.3}$$

and the RG equation for (7.1) is given by a linear equation

$$\dot{v} = \varepsilon Rv,\ \ v \in \mathbf{R}^n. \tag{7.4}$$

If $X(t)$ and $\widetilde{G}(t)$ are bounded in $t \geq 0$, then Theorem 4.4(i) holds and the flow Φ_{t,t_0} defined by (4.15) is put in the form

$$\Phi_{t,t_0} = X(t)(I + \varepsilon\widetilde{G}(t))e^{\varepsilon R(t-t_0)}(I + \varepsilon\widetilde{G}(t_0))^{-1}X(t_0)^{-1}, \tag{7.5}$$

where I is the $n \times n$ identity matrix. Accordingly, the approximate vector field F_ε defined by (4.16) is expressed as

$$F_\varepsilon(t,x) = F(t)x+\varepsilon G(t)X(t)(I+\varepsilon\widetilde{G}(t))^{-1}X(t)^{-1}x+\varepsilon^2 X(t)\widetilde{G}(t)R(I+\varepsilon\widetilde{G}(t))^{-1}X(t)^{-1}x. \tag{7.6}$$

The following proposition means that the stability of $X(t)^{-1}x(t)$ is inherited from that of the RG equation if $\varepsilon > 0$ is sufficiently small. In fact, the proposition shows that if real parts of all eigenvalues of R are negative, then $||X(t)^{-1}x(t)|| \to 0$ as $t \to \infty$ for an arbitrary solution $x(t)$ of (7.1), and that if there exists an eigenvalue of R whose real part is positive, then there exists a solution $x(t)$ of (7.1) such that $||X(t)^{-1}x(t)|| \to \infty$ as $t \to \infty$.

Proposition 7.1. *Suppose that $X(t)$ and $\widetilde{G}(t)$ defined in (7.3) are bounded in $t \geq 0$. Let R be a secular matrix for (7.1) and $\lambda_1, \dots, \lambda_n$ its eigenvalues. Then, for each integer k with $1 \leq k \leq n$, there exist positive constants D_1, D_2, t_0, a positive valued function $\phi(\varepsilon)$ with $\phi(\varepsilon) \to 0$ as $\varepsilon \to 0$, and a solution $x(t)$ of (7.1) such that the inequality*

$$D_2 e^{\varepsilon \mathrm{Re}(\lambda_k)t - 2\varepsilon\phi(\varepsilon)t} \leq ||X(t)^{-1}x(t)|| \leq D_1 e^{\varepsilon \mathrm{Re}(\lambda_k)t + 2\varepsilon\phi(\varepsilon)t} \tag{7.7}$$

holds for $t \geq t_0$.

Proof. Since $\widetilde{G}(t) = \int_0^t (X(s)^{-1}G(s)X(s) - R)ds$ is bounded, $(I + \varepsilon\widetilde{G}(t))^{-1}$ is expanded into the Neumann series as $(I + \varepsilon\widetilde{G}(t))^{-1} = \sum_{n=0}^\infty (-\varepsilon)^n \widetilde{G}(t)^n$. With this expansion inserted into (7.6), $F_\varepsilon(t,x)$ is rewritten as

$$F_\varepsilon(t,x) = F(t)x + \varepsilon G(t)x + \varepsilon^2 H(t,\varepsilon)x, \tag{7.8}$$

$$H(t,\varepsilon) := \sum_{n=0}^\infty (-\varepsilon)^n \left(X(t)\widetilde{G}(t)R\widetilde{G}(t)^n X(t)^{-1} - G(t)X(t)\widetilde{G}(t)^{n+1}X(t)^{-1}\right). \tag{7.9}$$

Let us rewrite (7.1) as

$$\dot{x} = F_\varepsilon(t,x) - \varepsilon^2 H(t,\varepsilon)x. \tag{7.10}$$

Introducing a new function $y(t)$ by $x(t) = X(t)y(t)$, we verify that y satisfies the differential equation

$$\dot{y} = \widetilde{F}_\varepsilon(t)y - \varepsilon^2 \widetilde{H}(t,\varepsilon)y, \tag{7.11}$$

where

$$\widetilde{F}_\varepsilon(t) := \varepsilon X(t)^{-1}G(t)X(t) + \varepsilon^2 X(t)^{-1}H(t,\varepsilon)X(t), \tag{7.12}$$

$$\widetilde{H}(t,\varepsilon) := \sum_{n=0}^{\infty}(-\varepsilon)^n \left(\widetilde{G}(t)R\widetilde{G}(t)^n - X(t)^{-1}G(t)X(t)\widetilde{G}(t)^{n+1}\right), \tag{7.13}$$

and further that the flow of the linear vector field $\widetilde{F}_\varepsilon(t)y$ is given by

$$\widetilde{\Phi}_{t,t_0} = (I + \varepsilon\widetilde{G}(t))e^{\varepsilon R(t-t_0)}(I + \varepsilon\widetilde{G}(t_0))^{-1}. \tag{7.14}$$

To prove the proposition, we can suppose that the secular matrix R is put in the Jordan form. In fact, if we change the variable x in (7.1) by $x \mapsto Px$, where P is an arbitrary nonsingular constant matrix, then $F(t)$, $G(t)$, and $X(t)^{-1}G(t)X(t)$ are brought into $P^{-1}F(t)P$, $P^{-1}G(t)P$, and $P^{-1}X(t)^{-1}G(t)X(t)P$, respectively. This means that R turns into $P^{-1}RP$. In what follows, we assume that R is of the Jordan form

$$R = \begin{pmatrix} \lambda_1 & p_1 & & & \\ & \lambda_2 & p_2 & & \\ & & \ddots & \ddots & \\ & & & \lambda_{n-1} & p_{n-1} \\ & & & & \lambda_n \end{pmatrix}, \tag{7.15}$$

where λ_i $(i = 1,\dots,n)$ are the eigenvalues of R such that $\mathrm{Re}(\lambda_1) \le \cdots \le \mathrm{Re}(\lambda_n)$ and where p_i $(i = 1,\dots,n-1)$ are either 0 or 1.

Now let us fix an integer $k < n$ such that $\mathrm{Re}(\lambda_{k+1}) - \mathrm{Re}(\lambda_k) > 0$. The case that $n = k$ and the case that there are no such $k < n$ are treated later. Define matrices $Q_1(t), Q_2(t)$ to be upper triangle matrices

$$Q_1(t) = \left(\begin{array}{ccc|ccc} e^{\varepsilon\lambda_1 t} & & * & & & \\ & \ddots & & & 0 & \\ & & e^{\varepsilon\lambda_k t} & & & \\ \hline & & & 0 & & \\ & & & & \ddots & \\ & & & & & 0 \end{array}\right), \quad Q_2(t) = \left(\begin{array}{ccc|ccc} 0 & & & & & \\ & \ddots & & & 0 & \\ & & 0 & & & \\ \hline & & & e^{\varepsilon\lambda_{k+1}t} & & * \\ & & & & \ddots & \\ & & & & & e^{\varepsilon\lambda_n t} \end{array}\right)$$

such that $Q_1(t) + Q_2(t) = e^{\varepsilon Rt}$. Then, a solution $y(t)$ to (7.11) satisfies an integral equation

$$\begin{aligned} y(t) = \widetilde{\Phi}_{t,0}\boldsymbol{e}_k &- \varepsilon^2 \int_0^t (I + \varepsilon\widetilde{G}(t))Q_1(t-s)(I + \varepsilon\widetilde{G}(s))^{-1} \circ \widetilde{H}(s,\varepsilon)y(s)ds \\ &+ \varepsilon^2 \int_t^\infty (I + \varepsilon\widetilde{G}(t))Q_2(t-s)(I + \varepsilon\widetilde{G}(s))^{-1} \circ \widetilde{H}(s,\varepsilon)y(s)ds, \end{aligned} \tag{7.16}$$

where $\boldsymbol{e}_1, \dots, \boldsymbol{e}_n$ are the canonical bases of $\mathbf{R}^n$. The first term of the right-hand side of the above is written as $\widetilde{\Phi}_{t,0}\boldsymbol{e}_k = (I+\varepsilon\widetilde{G}(t))(q_1(t)e^{\varepsilon\lambda_k t}, \dots, q_{k-1}(t)e^{\varepsilon\lambda_k t}, e^{\varepsilon\lambda_k t}, 0, \dots, 0)^t$, where $q_i(t)$ $(i = 1, \dots, k-1)$ are monomials of t whose degrees are at most $k-1$. The fact that $\widetilde{G}(t) = \int_0^t (X(s)^{-1}G(s)X(s) - R)ds$ is bounded uniformly in t implies that $(I+\varepsilon\widetilde{G}(t))^{\pm 1}$ and $X(t)^{-1}G(t)X(t)$ are also bounded uniformly in t, and thereby so is $\widetilde{H}(t,\varepsilon)$. Consequently, there exist positive constants C_0, C_1 such that

$$||\widetilde{H}(t,\varepsilon)|| \le C_0, \quad ||(I+\varepsilon\widetilde{G}(t))^{\pm 1}|| \le C_1. \tag{7.17}$$

Further, there exist positive constants C_2, C_3 and a positive valued function $\phi(\varepsilon)$ satisfying $\phi(\varepsilon) \to 0$ as $\varepsilon \to 0$ such that

$$\begin{aligned} ||Q_1(t)|| &\le \frac{C_2}{\phi(\varepsilon)^n} e^{\varepsilon \mathrm{Re}(\lambda_k)t + \varepsilon\phi(\varepsilon)t} \quad \text{for } t \ge 0, \\ ||\widetilde{\Phi}_{t,0}\boldsymbol{e}_k|| &\le \frac{C_1C_2}{\phi(\varepsilon)^n} e^{\varepsilon \mathrm{Re}(\lambda_k)t + \varepsilon\phi(\varepsilon)t} \quad \text{for } t \ge 0, \\ ||Q_2(t)|| &\le \frac{C_3}{\phi(\varepsilon)^n} e^{\varepsilon \mathrm{Re}(\lambda_{k+1})t - \varepsilon\phi(\varepsilon)t} \quad \text{for } t \le 0. \end{aligned} \tag{7.18}$$

Indeed, if $\varepsilon t \ge 1$, there exists a constant C such that $||Q_1(t)|| \le C\varepsilon^n t^n e^{\varepsilon \mathrm{Re}(\lambda_k)t}$. Suppose that there exists a function $q(\varepsilon)$ such that

$$||Q_1(t)|| \le C\varepsilon^n t^n e^{\varepsilon \mathrm{Re}(\lambda_k)t} \le Cq(\varepsilon) e^{\varepsilon \mathrm{Re}(\lambda_k)t + \varepsilon\phi(\varepsilon)t}.$$

This inequality is equivalent to the inequality $\varepsilon t \le q(\varepsilon)^{1/n} e^{\varepsilon\phi(\varepsilon)t/n}$, and it is easy to verify that this inequality holds when $q(\varepsilon) = (n/(\phi(\varepsilon)e))^n$. Putting $C_2 = C(n/e)^n$, we obtain $||Q_1(t)|| \le \frac{C_2}{\phi(\varepsilon)^n} e^{\varepsilon \mathrm{Re}(\lambda_k)t + \varepsilon\phi(\varepsilon)t}$ for $\varepsilon t \ge 1$. This inequality also holds when $0 \le \varepsilon t < 1$ because $||Q_1(t)|| \le Ce^{\varepsilon \mathrm{Re}(\lambda_k)t}$ holds if $0 \le \varepsilon t < 1$. The inequalities for $||\widetilde{\Phi}_{t,0}\boldsymbol{e}_k||$ and $||Q_2(t)||$ above are verified in a similar way.

We define a sequence of functions $\{y_m(t)\}_{m\ge 0}$ by

$$\begin{aligned} y_0(t) &= \widetilde{\Phi}_{t,0}\boldsymbol{e}_k, \\ y_{m+1}(t) &= y_0(t) - \varepsilon^2 \int_0^t (I+\varepsilon\widetilde{G}(t))Q_1(t-s)(I+\varepsilon\widetilde{G}(s))^{-1} \circ \widetilde{H}(s,\varepsilon)y_m(s)ds \\ &\quad + \varepsilon^2 \int_t^\infty (I+\varepsilon\widetilde{G}(t))Q_2(t-s)(I+\varepsilon\widetilde{G}(s))^{-1} \circ \widetilde{H}(s,\varepsilon)y_m(s)ds. \end{aligned}$$

We need two lemmas to prove the proposition.

Lemma 7.2. *Let $\phi(\varepsilon) = \varepsilon^{1/(2n+2)}$ and fix $\varepsilon > 0$ small so that $\mathrm{Re}(\lambda_{k+1}) - \mathrm{Re}(\lambda_k) - 3\phi(\varepsilon) > 0$. Then there exists a constant $0 < p < 1$ such that*

$$||y_m(t) - y_{m-1}(t)|| \le p^m e^{\varepsilon \mathrm{Re}(\lambda_k)t + 2\varepsilon\phi(\varepsilon)t}, \quad m = 1, 2, \dots, \tag{7.19}$$

for $t \ge 0$.

Proof. We prove (7.19) by induction. For $m = 1$, the quantity $||y_1(t) - y_0(t)||$ is estimated as follows:

$$\begin{aligned}
||y_1 - y_0|| &\le \varepsilon^2 \int_0^t ||I + \varepsilon\widetilde{G}(t)|| \cdot ||Q_1(t-s)|| \cdot ||(I + \varepsilon\widetilde{G}(s))^{-1}|| \cdot ||\widetilde{H}(s,\varepsilon)|| \cdot ||y_0(s)||ds \\
&\quad + \varepsilon^2 \int_t^\infty ||I + \varepsilon\widetilde{G}(t)|| \cdot ||Q_2(t-s)|| \cdot ||(I + \varepsilon\widetilde{G}(s))^{-1}|| \cdot ||\widetilde{H}(s,\varepsilon)|| \cdot ||y_0(s)||ds \\
&\le \frac{\varepsilon^2 C_0 C_1^3 C_2^2}{\phi(\varepsilon)^{2n}} \int_0^t e^{\varepsilon \mathrm{Re}(\lambda_k)t + \varepsilon\phi(\varepsilon)t} e^{\varepsilon\phi(\varepsilon)s} ds \\
&\quad + \frac{\varepsilon^2 C_0 C_1^3 C_2 C_3}{\phi(\varepsilon)^{2n}} \int_t^\infty e^{\varepsilon \mathrm{Re}(\lambda_{k+1})t - \varepsilon\phi(\varepsilon)t} e^{-\varepsilon \mathrm{Re}(\lambda_{k+1})s + \varepsilon \mathrm{Re}(\lambda_k)s + 3\varepsilon\phi(\varepsilon)s} ds \\
&\le \frac{\varepsilon C_0 C_1^3 C_2}{\phi(\varepsilon)^{2n+1}} \left(C_2 + \frac{C_3\phi(\varepsilon)}{\mathrm{Re}(\lambda_{k+1}) - \mathrm{Re}(\lambda_k) - 3\phi(\varepsilon)} \right) e^{\varepsilon \mathrm{Re}(\lambda_k)t + 2\varepsilon\phi(\varepsilon)t} \\
&= \varepsilon^{1/(2n+2)} C_0 C_1^3 C_2 \left(C_2 + \frac{C_3\phi(\varepsilon)}{\mathrm{Re}(\lambda_{k+1}) - \mathrm{Re}(\lambda_k) - 3\phi(\varepsilon)} \right) e^{\varepsilon \mathrm{Re}(\lambda_k)t + 2\varepsilon\phi(\varepsilon)t}.
\end{aligned}$$

Define

$$p = \varepsilon^{1/(2n+2)} C_0 C_1^3 C_2 \left(C_2 + \frac{C_3\phi(\varepsilon)}{\mathrm{Re}(\lambda_{k+1}) - \mathrm{Re}(\lambda_k) - 3\phi(\varepsilon)} \right); \tag{7.20}$$

then (7.19) holds for $m = 1$. Further, if ε is sufficiently small, the inequality $0 < p < 1$ holds. With this p, if we suppose that (7.19) holds, then we can verify that $||y_{m+1} - y_m|| \le p^{m+1} e^{\varepsilon \mathrm{Re}(\lambda_k)t + 2\varepsilon\phi(\varepsilon)t}$ by the same calculation as above. ∎

This lemma implies that the sequence $\{y_m(t)\}_{m\ge 0}$ converges to a solution of (7.11).

Lemma 7.3. *Under the same conditions as Lemma 7.2, there exist positive constants D_1 and t_0 such that*

$$||y_m(t)|| \le D_1 e^{\varepsilon \mathrm{Re}(\lambda_k)t + 2\varepsilon\phi(\varepsilon)t}, \quad m = 0, 1, \ldots, \tag{7.21}$$

for $t \ge t_0$.

Proof. We prove the lemma by induction. When $m = 0$, the above inequality is clear if $D_1 \ge C_1 C_2/\phi(\varepsilon)^n$. Suppose that the above inequality holds for m; then

$$\begin{aligned}
||y_{m+1}|| &\le ||y_0|| + \varepsilon^2 \int_0^t ||I + \varepsilon\widetilde{G}(t)|| \cdot ||Q_1(t-s)|| \cdot ||(I + \varepsilon\widetilde{G}(s))^{-1}|| \cdot ||\widetilde{H}(s,\varepsilon)|| \cdot ||y_m(s)||ds \\
&\quad + \varepsilon^2 \int_t^\infty ||I + \varepsilon\widetilde{G}(t)|| \cdot ||Q_2(t-s)|| \cdot ||(I + \varepsilon\widetilde{G}(s))^{-1}|| \cdot ||\widetilde{H}(s,\varepsilon)|| \cdot ||y_m(s)||ds \\
&= D_1 e^{\varepsilon \mathrm{Re}(\lambda_k)t + \varepsilon\phi(\varepsilon)t} + \frac{\varepsilon^2 C_0 C_1^2 C_2 D_1}{\phi(\varepsilon)^n} \int_0^t e^{\varepsilon \mathrm{Re}(\lambda_k)t + \varepsilon\phi(\varepsilon)t} e^{\varepsilon\phi(\varepsilon)s} ds \\
&\quad + \frac{\varepsilon^2 C_0 C_1^2 C_3 D_1}{\phi(\varepsilon)^n} \int_t^\infty e^{\varepsilon \mathrm{Re}(\lambda_{k+1})t - \varepsilon\phi(\varepsilon)t} e^{-\varepsilon \mathrm{Re}(\lambda_{k+1})s + \varepsilon \mathrm{Re}(\lambda_k)s + 3\varepsilon\phi(\varepsilon)s} \\
&\le D_1 e^{\varepsilon \mathrm{Re}(\lambda_k)t + \varepsilon\phi(\varepsilon)t} + \frac{\varepsilon C_0 C_1^2 C_2 D_1}{\phi(\varepsilon)^{n+1}} e^{\varepsilon \mathrm{Re}(\lambda_k)t + 2\varepsilon\phi(\varepsilon)t} \\
&\qquad + \frac{\varepsilon C_0 C_1^2 C_3 D_1}{\phi(\varepsilon)^n (\mathrm{Re}(\lambda_{k+1}) - \mathrm{Re}(\lambda_k) - 3\phi(\varepsilon))} e^{\varepsilon \mathrm{Re}(\lambda_k)t + 2\varepsilon\phi(\varepsilon)t}
\end{aligned}$$

$$\leq D_1 e^{\varepsilon \mathrm{Re}(\lambda_k)t + 2\varepsilon\phi(\varepsilon)t} \left(e^{-\varepsilon\phi(\varepsilon)t} + \frac{\varepsilon^{n/(2n+2)}}{C_1 C_2} p \right),$$

where p is defined by (7.20). Since $0 < p < 1$, we can take sufficiently large t_0 and sufficiently small ε such that

$$0 < e^{-\varepsilon\phi(\varepsilon)t} + \frac{\varepsilon^{n/(2n+2)}}{C_1 C_2} p < 1$$

for $t \geq t_0$. This proves the lemma. ■

We return to the proof of Proposition 7.1. By taking the limit $m \to \infty$ in (7.21), we obtain a solution $y(t) = y^{(k)}(t)$ of (7.11) satisfying the right part of the inequality (7.7) when $k \neq n$. If there exist eigenvalues $\lambda_{k'}$ of R satisfying $\mathrm{Re}(\lambda_{k'}) = \mathrm{Re}(\lambda_k)$, we repeat the above discussion with $\boldsymbol{e}_{k'}$ instead of $\boldsymbol{e}_k$ included in (7.16). Then we obtain a solution $y^{(k')}(t)$ of (7.11), which is linearly independent of $y^{(k)}(t)$, satisfying the right part of the inequality (7.7). To prove the same inequality for $k = n$, instead of (7.16), we use the integral equation

$$y(t) = \widetilde{\Phi}_{t,0}\boldsymbol{e}_n - \varepsilon^2 \int_0^t (I + \varepsilon\widetilde{G}(t)) e^{\varepsilon R(t-s)} (I + \varepsilon\widetilde{G}(s))^{-1} \circ \widetilde{H}(s,\varepsilon) y(s) ds. \tag{7.22}$$

The same procedure as above applied to this equation yields the right part of inequality (7.7) for $k = n$.

We proceed to prove the left part of inequality (7.7). Let $y^{(k)}(t)$ be a solution of (7.11) which satisfies the right part of inequality (7.7), and denote the fundamental matrix to (7.11) by Y, whose column vectors are $y^{(1)}(t), \ldots, y^{(n)}(t)$. Define a matrix Z by $Z = Y^{-t}$, where Y^{-t} is the abbreviation of $(Y^{-1})^t$; this notation will be used in what follows. Each column vector $z^{(1)}(t), \ldots, z^{(n)}(t)$ of Z satisfies an adjoint equation of (7.11):

$$\dot{z} = -(\widetilde{F}_\varepsilon(t) - \varepsilon^2 \widetilde{H}(t,\varepsilon))^t z. \tag{7.23}$$

Since the flow of the linear vector field $-(\widetilde{F}_\varepsilon)^t z$ is given by $\widetilde{\Phi}_{t,t_0}^{-t} = (I + \varepsilon\widetilde{G}(t))^{-t} e^{-\varepsilon R^t (t-t_0)} (I + \varepsilon\widetilde{G}(t_0))^t$, we can prove that there exists a solution $z(t) = u^{(k)}(t)$ of (7.23) such that

$$||u^{(k)}(t)|| \leq D_1' e^{-\varepsilon \mathrm{Re}(\lambda_k)t + 2\varepsilon\phi(\varepsilon)t}, \quad k = 1, \ldots, n, \quad t \geq t_0, \tag{7.24}$$

by the same procedure as that for the proof of the inequality (7.7), where D_1' is some positive constant. Let U be the fundamental matrix for (7.23) whose column vectors are $u^{(1)}(t), \ldots, u^{(n)}(t)$. By the uniqueness of solutions of (7.23), there exists a constant matrix K such that $U = ZK$. Let k_{ij} be the (i,j) component of K. Since $Y^t U = K$, the inequality $|k_{ii}| = |(y^{(i)}(t), u^{(i)}(t))| \leq ||y^{(i)}(t)|| \cdot ||u^{(i)}(t)||$ holds, which then proves the left part of inequality (7.7) if $k_{ii} \neq 0$, where $(\ ,\ )$ denotes the standard inner product of the $\mathbf{R}^n$. If $k_{ii} = 0$, we define $\widetilde{u}^{(k)}(t)$ by $\widetilde{u}^{(k)}(t) = u^{(k)}(t) + \sum_{i=k+1}^n \alpha_i u^{(i)}(t)$, with $\alpha_i \in \mathbf{R}$. And we define a matrix $\widetilde{U}$ whose column vectors are $\widetilde{u}^{(1)}(t), \ldots, \widetilde{u}^{(n)}(t)$. Each $\widetilde{u}^{(k)}(t)$ satisfies the inequality (7.24) for some constant D_1'. Then there exists a constant matrix $\widetilde{K}$ such that $Y^t \widetilde{U} = \widetilde{K}$, and we can assume that its diagonal component $k_{ii} \neq 0$ by defining $\alpha_i \in \mathbf{R}$ appropriately. This ends the proof of Proposition 7.1. ■

Corollary 7.4. *Consider an equation* $\dot{x} = Fx + \varepsilon G(t)x$ *with* $x \in \mathbf{R}^n$, *where* F *is an* $n \times n$ *constant matrix and* $G(t)$ *is an* $n \times n$ *matrix which is of* C^1 *class with respect to* t. *Suppose that all eigenvalues of* F *lie on the imaginary axis, and suppose that* $G(t)$ *and* $\widetilde{G}(t)$ *defined by* (7.3) *are bounded in* $t \in \mathbf{R}$. *If* $\varepsilon > 0$ *is sufficiently small, then the stability of a trivial solution* $x(t) \equiv 0$ *coincides with that of a trivial solution of the RG equation* $\dot{v} = \varepsilon R v$, *where* R *is a secular matrix for* $Fx + \varepsilon G(t)x$.

In the above corollary, the boundedness of $G(t)$ and $\widetilde{G}(t)$ are satisfied if $G(t)$ is a periodic or almost periodic function in t whose Fourier exponents do not have accumulation points in $\mathbf{R}$.

Example 7.5. Let us consider the Mathieu equation:

$$\ddot{y} = -(a + 2\varepsilon \cos t)y, \tag{7.25}$$

where a and ε are positive parameters. It is well known that there exists an area in the (a, ε) plane such that the origin is an unstable fixed point for (7.25) if (a, ε) is in this area. We calculate the area approximately by the RG method.

Let $a = a_0 + \varepsilon a_1$ and $y = y_0 + \varepsilon y_1$. Substituting them into (7.25) and comparing the coefficients of ε^0 and ε^1 in both sides of (7.25) provides

$$\ddot{y}_0 = -b^2 y_0, \tag{7.26}$$

$$\ddot{y}_1 = -b^2 y_1 - a_1 y_0 - 2\cos t \cdot y_0, \tag{7.27}$$

where $a_0 = b^2$. A general solution to the former is given by

$$y_0(t) = Ae^{ibt} + \overline{A}e^{-ibt}, \quad A \in \mathbf{C}. \tag{7.28}$$

With this y_0, (7.27) is rewritten as

$$\ddot{y}_1 = -b^2 y_1 - \left(a_1 A e^{ibt} + A e^{i(1+b)t} + \overline{A} e^{i(1-b)t} + \text{c.c.}\right). \tag{7.29}$$

If $b = 1/2$ (i.e., $a_0 = 1/4$), the secular term appears for all a_1. In fact, the equation

$$\ddot{y}_1 = -\frac{1}{4} y_1 - \left(a_1 A e^{it/2} + A e^{3it/2} + \overline{A} e^{it/2} + \text{c.c.}\right) \tag{7.30}$$

admits a special solution given by

$$y_1(t, \tau; A) = i(a_1 A + \overline{A})(t - \tau)e^{it/2} + \frac{A}{2} e^{3it/2} + \text{c.c.}, \tag{7.31}$$

where the initial time has been chosen to be $t = \tau$. Then, the RG equation for (7.25) is given by

$$\dot{A} = i\varepsilon(a_1 A + \overline{A}). \tag{7.32}$$

Putting $A = B + iC$, $B, C \in \mathbf{R}$, we break up (7.32) into

$$\begin{cases} \dot{B} = \varepsilon(1 - a_1)C, \\ \dot{C} = \varepsilon(1 + a_1)B. \end{cases} \tag{7.33}$$

A general solution to this equation is given by

$$B(t) = \begin{cases} pe^{\varepsilon\sqrt{1-a_1^2}t} + qe^{-\varepsilon\sqrt{1-a_1^2}t} & (|a_1| \le 1), \\ pe^{i\varepsilon\sqrt{a_1^2-1}t} + qe^{-i\varepsilon\sqrt{a_1^2-1}t} & (|a_1| > 1), \end{cases} \tag{7.34}$$

where $p, q \in \mathbf{R}$ are arbitrary constants. This shows that the origin is an unstable fixed point for the RG equation (7.33) if $|a_1| < 1$. This proves the instability of the fixed point of the Mathieu equation (7.25) if $a = 1/4 + \varepsilon a_1 + O(\varepsilon^2)$, $|a_1| < 1$.

Example 7.6. Consider the coupled Mathieu equations

$$\begin{cases} \ddot{x} = -(a + 2\varepsilon\cos t)x - \varepsilon p(x-y) - \varepsilon q(\dot{x}-\dot{y}), \\ \ddot{y} = -(a + 2\varepsilon\cos t)y - \varepsilon p(y-x) - \varepsilon q(\dot{y}-\dot{x}), \end{cases} \tag{7.35}$$

where $\varepsilon > 0$ and $a, p, q \in \mathbf{R}$ are constants. Put $u = x + y$; then the equation for $u(t)$ is the Mathieu equation (7.25). In Example 7.5, we proved that if $a = 1/4$, the trivial solution $u = 0$ of the Mathieu equation (7.25) is unstable. In what follows, we assume that $a = 1/4$. Put $z = x - y$. Then z satisfies the equation

$$\ddot{z} = -\frac{1}{4}z + \varepsilon(-2q\dot{z} - 2pz - 2\cos t \cdot z). \tag{7.36}$$

Put further $z = z_0 + \varepsilon z_1$, where z_0 is subjected to the unperturbed equation $\ddot{z}_0 = -\frac{1}{4}z_0$ and has a general solution of the form $z_0(t) = Ae^{it/2} + \overline{A}e^{-it/2}$. With this $z_0(t)$, the equation for z_1 proves to be given by

$$\ddot{z}_1 = -\frac{1}{4}z_1 - iqAe^{it/2} - 2pAe^{it/2} - Ae^{3it/2} - \overline{A}e^{it/2} + \text{c.c.}, \tag{7.37}$$

where c.c. denotes the complex conjugate of the last four terms of the right-hand side. A special solution of this equation, whose initial time is $t = \tau$, is given by

$$z_1(t) = i(iqA + 2pA + \overline{A})(t-\tau)e^{it/2} + \frac{A}{2}e^{3it/2} + \text{c.c.} \tag{7.38}$$

Therefore, the RG equation for (7.36) is put in the form

$$\dot{A} = i\varepsilon(iqA + 2pA + \overline{A}), \quad A \in \mathbf{C}. \tag{7.39}$$

Put $A = \alpha + i\beta$, $\alpha, \beta \in \mathbf{R}$. Then the above equation is rewritten as

$$\frac{d}{dt}\begin{pmatrix} \alpha \\ \beta \end{pmatrix} = \varepsilon \begin{pmatrix} -q & -2p+1 \\ 2p+1 & -q \end{pmatrix} \begin{pmatrix} \alpha \\ \beta \end{pmatrix}. \tag{7.40}$$

Eigenvalues of the matrix in the right-hand side of the above equation are $\lambda_\pm = -q \pm \sqrt{1-4p^2}$. Therefore, the stability of the trivial solution $(\alpha, \beta) = (0, 0)$ of the RG equation is as given in Figure 2.

Corollary 7.4 shows that the stability of the trivial solution $z(t) = 0$ of (7.36) coincides with that of the stability of $(\alpha, \beta) = (0, 0)$. This proves that if $\mathrm{Re}(\lambda_\pm) < 0$, then $|x(t) - y(t)| \to 0$ as $t \to \infty$, although each $|x(t)|, |y(t)|$ diverges as $t \to \infty$.

A numerical solution to (7.35) for $\varepsilon = 0.01$, $x(0) = 0.5$, $y(0) = 0.1$ is presented in Figure 3.

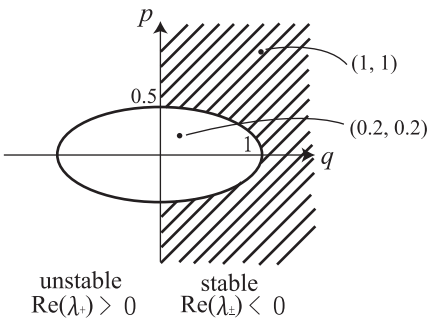

Figure 2. *The trivial solution* $(\alpha, \beta) = (0, 0)$ *is stable on the shaded area.*

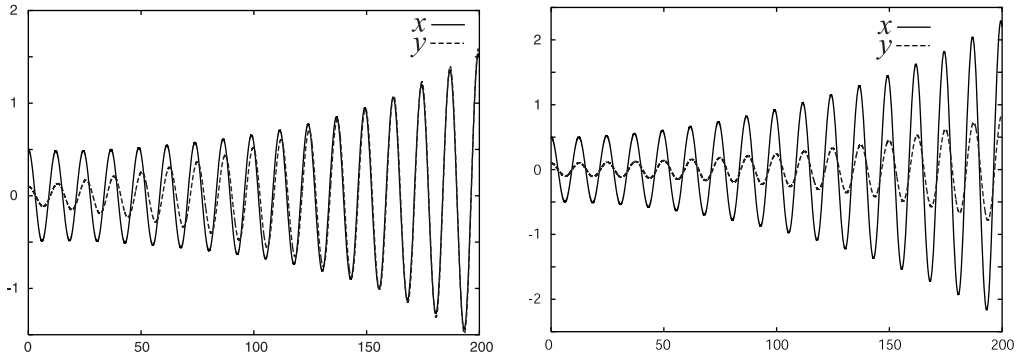

Figure 3. *Numerical results for* (7.35). *The synchronous solution* $x(t) = y(t)$ *is* (a) *stable if* $p = q = 1$, (b) *unstable if* $p = q = 0.2$.

Appendix A. Higher order RG equation. In this appendix, we define the higher order RG equation for constructing an approximate vector field which is $O(\varepsilon^{m+1})$ close to a given original vector field. The result is used in proving Theorem 6.1.

Let F be a diagonalizable $n \times n$ matrix, all of whose eigenvalues lie on the imaginary axis, and let $g_1(t, x), \ldots, g_m(t, x)$ be C^∞ vector fields on $\mathbf{R} \times \mathbf{R}^n$ which are polynomial in x and periodic in t. Consider an ODE

$$\dot{x} = Fx + \varepsilon g_1(t, x) + \varepsilon^2 g_2(t, x) + \cdots + \varepsilon^m g_m(t, x), \quad x \in \mathbf{R}^n, \tag{A.1}$$

where $\varepsilon \in \mathbf{R}$ is a small parameter. Put $x = x_0 + \varepsilon x_1 + \cdots + \varepsilon^m x_m$. Then the above equation is rewritten as

$$\dot{x}_0 + \varepsilon \dot{x}_1 + \cdots + \varepsilon^m \dot{x}_m = F(x_0 + \varepsilon x_1 + \cdots + \varepsilon^m x_m) + \sum_{i=1}^{m} \varepsilon^i g_i(t, x_0 + \varepsilon x_1 + \cdots + \varepsilon^m x_m). \tag{A.2}$$

Expanding the right-hand side of the above equation with respect to ε and equating the coefficients of each ε^i of both sides of the above, we obtain ODEs for $x_0, x_1, \ldots, x_m$,

$$\dot{x}_0 = Fx_0, \tag{A.3}$$

$$\dot{x}_1 = Fx_1 + G_1(t, x_0), \tag{A.4}$$

$$\vdots$$

$$\dot{x}_i = Fx_i + G_i(t, x_0, x_1, \dots, x_{i-1}), \tag{A.5}$$

$$\vdots$$

$$\dot{x}_m = Fx_m + G_m(t, x_0, x_1, \dots, x_{m-1}), \tag{A.6}$$

where G_i is some smooth function of $t, x_0, x_1, \dots, x_{i-1}$ which is periodic in t. For example, G_1, G_2, and G_3 are given by

$$G_1(t, x_0) = g_1(t, x_0), \tag{A.7}$$

$$G_2(t, x_0, x_1) = \frac{\partial g_1}{\partial x}(t, x_0)x_1 + g_2(t, x_0), \tag{A.8}$$

$$G_3(t, x_0, x_1, x_2) = \frac{1}{2}\frac{\partial^2 g_1}{\partial x^2}(t, x_0)x_1^2 + \frac{\partial g_1}{\partial x}(t, x_0)x_2 + \frac{\partial g_2}{\partial x}(t, x_0)x_1 + g_3(t, x_0), \tag{A.9}$$

respectively. We have to solve the above equations. At first, we denote by $x_0(t, 0, A) = X(t)A$ a solution of the unperturbed part $\dot{x}_0 = Fx_0$, where $X(t) = e^{Ft}$ is the fundamental matrix and $A \in \mathbf{R}^n$ is an initial value. With this x_0, by a discussion similar to that in section 4, a solution of (A.4) is given by

$$x_1(t, \tau; A) = h_t^{(1)}(A) + X(t)R_1(A)(t - \tau), \tag{A.10}$$

where $h_t^{(1)}(A)$ and $R_1(A)$ are defined by

$$R_1(A) = \lim_{t\to\infty} \frac{1}{t}\int^t X(s)^{-1}G_1(s, X(s)A)ds, \tag{A.11}$$

$$h_t^{(1)}(A) = X(t)\int^t \left(X(s)^{-1}G_1(s, X(s)A) - R_1(A)\right)ds, \tag{A.12}$$

respectively. The integral constants of the indefinite integrals in (A.11), (A.12) and (A.13), (A.14) below are fixed arbitrarily. By choosing these integral constants appropriately, we can reduce the RG equation. This will be done in a forthcoming paper. Note that since $X(t)$ and $G_1(t, x)$ are almost periodic in t, $X(t)^{-1}G_1(t, X(t)A)$ is bounded uniformly in $t \in \mathbf{R}$ and $R_1(A)$ is well defined. With this x_0 and x_1, we solve the equation for x_2, as will be shown in Proposition A.1. This process is performed step by step until a solution x_m to (A.6) is obtained.

Proposition A.1. *Define functions $R_i(A)$ and $h_t^{(i)}(A)$, $i = 2, \dots, m$, by*

$$R_i(A) := \lim_{t\to\infty} \frac{1}{t}\int^t \Bigg(X(s)^{-1}G_i(s, X(s)A, h_s^{(1)}(A), \dots, h_s^{(i-1)}(A)) - X(s)^{-1}\sum_{k=1}^{i-1}(Dh_s^{(k)})_A R_{i-k}(A)\Bigg)ds, \tag{A.13}$$

$$h_t^{(i)}(A) := X(t)\int^t \Big(X(s)^{-1} G_i(s, X(s)A, h_s^{(1)}(A), \dots, h_s^{(i-1)}(A)) - X(s)^{-1}\sum_{k=1}^{i-1} (Dh_s^{(k)})_A R_{i-k}(A) - R_i(A)\Big) ds. \tag{A.14}$$

Then, the curve defined by

$$x_i := x_i(t,\tau;A) = h_t^{(i)}(A) + y_1^{(i)}(t,A)(t-\tau) + y_2^{(i)}(t,A)(t-\tau)^2 + \cdots + y_i^{(i)}(t,A)(t-\tau)^i \tag{A.15}$$

gives a solution to (A.5) *for* $i = 1, 2, \dots, m$, *where* $y_1^{(i)}, \dots, y_i^{(i)}$ *are defined by*

$$y_1^{(i)}(t,A) = X(t)R_i(A) + \sum_{k=1}^{i-1} (Dh_t^{(k)})_A R_{i-k}(A), \tag{A.16}$$

$$y_j^{(i)}(t,A) = \frac{1}{j}\sum_{k=1}^{i-1} \frac{\partial y_{j-1}^{(k)}}{\partial A}(t,A) R_{i-k}(A), \quad j = 2, 3, \dots, i-1, \tag{A.17}$$

$$y_i^{(i)}(t,A) = \frac{1}{i}\sum_{k=1}^{i-1} \frac{\partial y_{i-1}^{(k)}}{\partial A}(t,A) R_{i-k}(A) = \frac{1}{i}\frac{\partial y_{i-1}^{(i-1)}}{\partial A}(t,A) R_1(A), \tag{A.18}$$

$$y_j^{(i)}(t,A) = 0, \quad j > i. \tag{A.19}$$

Proof. We prove Proposition A.1 by induction. Assume that $x_1, \dots, x_{i-1}$ defined by (A.15) are solutions of (A.5) for $i = 1, 2, \dots, i-1$. In order to prove that x_i defined by (A.15) is a solution of (A.5), we substitute (A.15) into (A.5) to obtain

$$\begin{aligned} &Fh_t^{(i)}(A) + G_i(t, X(t)A, h_t^{(1)}(A), \dots, h_t^{(i-1)}(A)) - \sum_{k=1}^{i-1} (Dh_t^{(k)})_A R_{i-k}(A) - X(t)R_i(t) \\ &+ \sum_{k=1}^{i} \dot{y}_k^{(i)}(t,A)(t-\tau)^k + \sum_{k=1}^{i} y_k^{(i)}(t,A) k (t-\tau)^{k-1} \\ &\quad = Fh_t^{(i)}(A) + F\sum_{k=1}^{i} y_k^{(i)}(t,A)(t-\tau)^k + G_i(t, x_0, x_1, \dots, x_{i-1}). \end{aligned} \tag{A.20}$$

It is easy to verify that $G_i(t, x_0, x_1, \dots, x_{i-1})$ with $x_0, x_1, \dots, x_{i-1}$ defined by (A.15) is a polynomial in $t-\tau$ whose degree is at most $i-1$. We denote it by

$$G_i(t, x_0, \dots, x_{i-1}) = \sum_{k=0}^{i-1} \widetilde{G}_i^{(k)}(t, x_0, \dots, x_{i-1})(t-\tau)^k. \tag{A.21}$$

Note that $\widetilde{G}_i^{(0)}(t, x_0, \dots, x_{i-1}) = G_i(t, X(t)A, h_t^{(1)}(A), \dots, h_t^{(i-1)}(A))$. Equating the coefficients of $(t-\tau)^k$ of both sides of (A.20) with (A.21), we obtain

$$y_1^{(i)}(t,A) = \sum_{k=1}^{i-1} (Dh_t^{(k)})_A R_{i-k}(A) + X(t)R_i(A), \tag{A.22}$$

$$\dot{y}_k^{(i)}(t,A) + (k+1)y_{k+1}^{(i)}(t,A) = Fy_k^{(i)}(t,A) + \widetilde{G}_i^{(k)}(t,x_0,\dots,x_{i-1}),\ \ k=1,\dots,i-1, \tag{A.23}$$

$$\dot{y}_i^{(i)}(t,A) = Fy_i^{(i)}(t,A). \tag{A.24}$$

These equations can determine $y_1^{(i)}, y_2^{(i)}, \dots, y_i^{(i)}$. Equation (A.22) gives (A.16). From (A.23) for $k=1$, we obtain

$$\begin{aligned}
2y_2^{(i)}(t,A) &= Fy_1^{(i)}(t,A) - \dot{y}_1^{(i)}(t,A) + \widetilde{G}_i^{(1)}(t,x_0,\dots,x_{i-1}) \\
&= \sum_{k=1}^{i-1} F(Dh_t^{(k)})_A R_{i-k}(A) + FX(t)R_i(A) \\
&\quad - \sum_{k=1}^{i-1} \frac{\partial}{\partial t}(Dh_t^{(k)})_A R_{i-k}(A) - \frac{\partial}{\partial t}X(t)R_i(A) + \widetilde{G}_i^{(1)}(t,x_0,\dots,x_{i-1}) \\
&= \sum_{k=1}^{i-1} F(Dh_t^{(k)})_A R_{i-k}(A) - \sum_{k=1}^{i-1} \frac{\partial}{\partial A}\Bigg(Fh_t^{(k)}(A) + G_k(t,X(t)A,h_t^{(1)}(A),\dots,h_t^{(k-1)}(A)) \\
&\quad - \sum_{j=1}^{k-1}(Dh_t^{(j)})_A R_{k-j}(A) - X(t)R_k(A)\Bigg) R_{i-k}(A) + \widetilde{G}_i^{(1)}(t,x_0,\dots,x_{i-1}) \\
&= \sum_{k=1}^{i-1} \frac{\partial}{\partial A}\Bigg(\sum_{j=1}^{k-1}(Dh_t^{(j)})_A R_{k-j}(A) + X(t)R_k(A)\Bigg) R_{i-k}(A) \\
&\quad + \widetilde{G}_i^{(1)}(t,x_0,\dots,x_{i-1}) - \sum_{k=1}^{i-1}\frac{\partial}{\partial A}G_k(t,X(t)A,h_t^{(1)}(A),\dots,h_t^{(k-1)}(A))R_{i-k}(A) \\
&= \sum_{k=1}^{i-1} \frac{\partial}{\partial A} y_1^{(k)}(t,A)R_{i-k}(A) \\
&\quad + \widetilde{G}_i^{(1)}(t,x_0,\dots,x_{i-1}) - \sum_{k=1}^{i-1}\frac{\partial}{\partial A}G_k(t,X(t)A,h_t^{(1)}(A),\dots,h_t^{(k-1)}(A))R_{i-k}(A).
\end{aligned} \tag{A.25}$$

If the equality

$$\widetilde{G}_i^{(1)}(t,x_0,\dots,x_{i-1}) = \sum_{k=1}^{i-1}\frac{\partial}{\partial A}G_k(t,X(t)A,h_t^{(1)}(A),\dots,h_t^{(k-1)}(A))R_{i-k}(A) \tag{A.26}$$

holds, then (A.17) for $j=2$ is obtained. The left-hand side of the above is calculated as

$$\begin{aligned}
\widetilde{G}_i^{(1)}(t,x_0,\dots,x_{i-1}) &= -\frac{\partial}{\partial \tau}\Big|_{\tau=t} G_i(t,x_0,\dots,x_{i-1}) \\
&= -\sum_{j=1}^{i-1}\lim_{\tau\to t}\frac{\partial G_i}{\partial x_j}(t,x_0,\dots,x_{i-1})\frac{\partial}{\partial \tau}\Big|_{\tau=t} x_j(t,\tau;A) \\
&= \sum_{j=1}^{i-1}\lim_{\tau\to t}\frac{\partial G_i}{\partial x_j}(t,x_0,\dots,x_{i-1})\Bigg(X(t)R_j(A) + \sum_{k=1}^{j-1}(Dh_t^{(k)})_A R_{j-k}(A)\Bigg).
\end{aligned} \tag{A.27}$$

The right-hand side of (A.26) is calculated as

$$\begin{aligned}
&\sum_{k=1}^{i-1}\frac{\partial}{\partial A}G_k(t,X(t)A,h_t^{(1)}(A),\dots,h_t^{(k-1)}(A))R_{i-k}(A)\\
&=\sum_{k=1}^{i-1}\sum_{j=1}^{k-1}\lim_{\tau\to t}\frac{\partial G_k}{\partial x_j}(t,x_0,\dots,x_{i-1})(Dh_t^{(j)})_A R_{i-k}(A)\\
&\quad+\sum_{k=1}^{i-1}\lim_{\tau\to t}\frac{\partial G_k}{\partial x_0}(t,x_0,\dots,x_{i-1})X(t)R_{i-k}(A). \qquad \text{(A.28)}
\end{aligned}$$

Now we need a simple lemma.

Lemma A.2. *For integers i,j with $i>j$, the equality*

$$\frac{\partial G_i}{\partial x_j}=\frac{\partial G_{i-1}}{\partial x_{j-1}}=\cdots=\frac{\partial G_{i-j}}{\partial x_0} \qquad \text{(A.29)}$$

holds.

We will prove this lemma after the proof of Proposition A.1 is completed. According to Lemma A.2, (A.27) and (A.28) are brought into

(A.30)

$$\widetilde{G}_i^{(1)}(t,x_0,\dots,x_{i-1})=\sum_{j=1}^{i-1}\lim_{\tau\to t}\frac{\partial G_{i-j}}{\partial x_0}(t,x_0,\dots,x_{i-1})\left(X(t)R_j(A)+\sum_{k=1}^{j-1}(Dh_t^{(k)})_A R_{j-k}(A)\right),$$

and

$$\begin{aligned}
&\sum_{k=1}^{i-1}\frac{\partial}{\partial A}G_k(t,X(t)A,h_t^{(1)}(A),\dots,h_t^{(k-1)}(A))R_{i-k}(A)\\
&=\sum_{k=1}^{i-1}\sum_{j=1}^{k-1}\lim_{\tau\to t}\frac{\partial G_{k-j}}{\partial x_0}(t,x_0,\dots,x_{i-1})(Dh_t^{(j)})_A R_{i-k}(A)\\
&\quad+\sum_{k=1}^{i-1}\lim_{\tau\to t}\frac{\partial G_k}{\partial x_0}(t,x_0,\dots,x_{i-1})X(t)R_{i-k}(A), \qquad \text{(A.31)}
\end{aligned}$$

respectively. This proves (A.26), and (A.17) for $j=2$ is verified.

By using (A.23), $y_3^{(i)},\dots,y_{i-1}^{(i)},y_i^{(i)}$ are calculated in the same way as above, and (A.17) and (A.18) are proved, but we omit the detailed calculation here. Next, we have to show that $y_i^{(i)}$ given by (A.18) satisfies (A.24). To show this, according to $y_1^{(1)}(t,A)=X(t)R_1(t)$, we rewrite (A.18) as

$$\begin{aligned}
y_i^{(i)}(t,A)&=\frac{1}{i}\frac{\partial y_{i-1}^{(i-1)}}{\partial A}R_1(A)\\
&=\frac{1}{i(i-1)}\frac{\partial}{\partial A}\left(\frac{\partial y_{i-2}^{(i-2)}}{\partial A}R_1(A)\right)R_1(A)
\end{aligned}$$

$$
\begin{aligned}
&= \ \vdots \\
&= \frac{1}{i!}\frac{\partial}{\partial A}\left(\frac{\partial}{\partial A}\left(\cdots\frac{\partial}{\partial A}\left(\frac{\partial y_1^{(1)}}{\partial A}R_1(A)\right)\cdots\right)R_1(A)\right)R_1(A)\\
&= X(t)\frac{1}{i!}\frac{\partial}{\partial A}\left(\frac{\partial}{\partial A}\left(\cdots\frac{\partial}{\partial A}\left(\frac{\partial R_1}{\partial A}R_1(A)\right)\cdots\right)R_1(A)\right)R_1(A).
\end{aligned}
$$

Since $X(t)$ is the fundamental matrix of the equation $\dot{y} = Fy$, $y_i^{(i)}$ satisfies (A.24). Therefore, x_i defined by (A.15) satisfies (A.5). This ends the proof of Proposition A.1. ■

Proof of Lemma A.2. By definition, $G_i(t, x_0, \ldots, x_{i-1})$ is written as

$$
G_i(t, x_0, \ldots, x_{i-1}) = \sum_{k=1}^{i-1} \frac{1}{k!}\frac{d^k}{d\varepsilon^k}\Big|_{\varepsilon=0} g_{i-k}(t, \textstyle\sum_{l=0}^m \varepsilon^l x_l) + g_i(t, x_0).
$$

On the other hand, $G_{i-1}(t, x_0, \ldots, x_{i-2})$ is rewritten as

$$
\begin{aligned}
G_{i-1}(t, x_0, \ldots, x_{i-2}) &= \sum_{k=0}^{i-2} \frac{1}{k!}\frac{d^k}{d\varepsilon^k}\Big|_{\varepsilon=0} g_{i-k-1}(t, \textstyle\sum_{l=0}^m \varepsilon^l x_l)\\
&= \sum_{k=1}^{i-1} \frac{1}{(k-1)!}\frac{d^{k-1}}{d\varepsilon^{k-1}}\Big|_{\varepsilon=0} g_{i-k}(t, \textstyle\sum_{l=0}^m \varepsilon^l x_l).
\end{aligned}
$$

To show the equality $\partial G_i/\partial x_j = \partial G_{i-1}/\partial x_{j-1}$, it is sufficient to prove the equality

$$
\frac{\partial}{\partial x_j}\frac{1}{k!}\frac{d^k}{d\varepsilon^k}\Big|_{\varepsilon=0} g_{i-k}(t, \textstyle\sum_{l=0}^m \varepsilon^l x_l) = \frac{\partial}{\partial x_{j-1}}\frac{1}{(k-1)!}\frac{d^{k-1}}{d\varepsilon^{k-1}}\Big|_{\varepsilon=0} g_{i-k}(t, \textstyle\sum_{l=0}^m \varepsilon^l x_l) \tag{A.32}
$$

for $k = 1, 2, \ldots, i-1$. For simplicity, we denote $g_{i-k}(t, x)$ by $g(x)$. Consider the trivial equality

$$
\frac{\partial}{\partial x_j} g(\textstyle\sum_{l=0}^m \varepsilon^l x_l) = \varepsilon \frac{\partial}{\partial x_{j-1}} g(\textstyle\sum_{l=0}^m \varepsilon^l x_l), \quad j = 1, \ldots, m. \tag{A.33}
$$

Expanding both sides of the above equation with respect to ε, we obtain

$$
\begin{aligned}
&\frac{\partial}{\partial x_j}\left(\sum_{p=0}^{k} \frac{\varepsilon^p}{p!}\frac{d^p}{d\varepsilon^p}\Big|_{\varepsilon=0} g(\textstyle\sum_{l=0}^m \varepsilon^l x_l) + \widetilde{R}(\varepsilon, x_0, \ldots, x_m)\right)\\
&= \varepsilon\frac{\partial}{\partial x_{j-1}}\left(\sum_{p=0}^{k} \frac{\varepsilon^p}{p!}\frac{d^p}{d\varepsilon^p}\Big|_{\varepsilon=0} g(\textstyle\sum_{l=0}^m \varepsilon^l x_l) + \widetilde{R}(\varepsilon, x_0, \ldots, x_m)\right),
\end{aligned}
$$

where $\widetilde{R}$ is some function satisfying $\widetilde{R} \sim o(|\varepsilon|^{k+1})$. Equating the coefficients of ε^k of both sides of the above, we obtain (A.32). This ends the proof of Lemma A.2. ■

Remark A.3. Proposition A.1 also holds for a time-dependent matrix $F(t)$ as long as the fundamental matrix $X(t)$ of $F(t)$ is periodic in t. Further, for Proposition A.1, we do not

need to assume that functions g_i in (A.1) are polynomial in x. These assumptions are used to prove statements below.

Lemma A.4. *For* (A.1)*, functions* $h_t^{(i)}(A)$ *with* $i = 1, 2, \dots, m$ *defined by* (A.12) *and* (A.14) *are bounded uniformly in* t*.*

To prove this lemma, we need a theory of almost periodic functions. Indeed, we can show that functions $h_t^{(i)}(A)$ are almost periodic functions. This fact also holds even if the $g_i(t,x)$'s in (A.1) are not periodic in t but almost periodic in t as long as the set of Fourier exponents of the $g_i(t,x)$'s does not have accumulation points in $\mathbf{R}$. See Fink [13] for the definitions and basic facts of almost periodic functions.

Proof of Lemma A.4. We prove the proposition by induction. At first, note that $G_1(t,x_0)$ defined by (A.7) is almost periodic uniformly in x_0 because it is periodic in t and polynomial in x_0. Therefore, a function $X(t)^{-1}G_1(t,X(t)A)$ included in (A.12) is almost periodic uniformly in A (see Theorem 2.11 of Fink [13]). Each component of the vector-valued function $X(t)^{-1}G_1(t,X(t)A)$ is of the form $\sum_{k=1}^{p} b_k(t)e^{i\xi_k t}$, where $b_k(t)$ are some periodic functions and $\xi_k \in \mathbf{R}$ are some constants. Since each $b_k(t)$ can be expanded as a Fourier series in the ordinary sense, the set of Fourier exponents of $\sum_{k=1}^{p} b_k(t)e^{i\xi_k t}$ does not have accumulation points on $\mathbf{R}$. Since the Fourier coefficient corresponding to the zero Fourier exponent, if it exists, is $R_1(A)$ defined by (A.11), $X(t)^{-1}G_1(t,X(t)A) - R_1(A)$ does not have a zero as a Fourier exponent. Therefore, $\int^t (X(s)^{-1}G_1(s,X(s)A) - R_1(A))ds$ is almost periodic (we use Theorem 4.12 of Fink [13]), and this proves Lemma A.4 for $h_t^{(1)}(A)$.

Suppose that Lemma A.4 holds for $h_t^{(1)}(A), \dots, h_t^{(i-1)}(A)$. Like the above, the integrand in (A.14) is almost periodic uniformly in A because $G_1(t,x_0,\dots,x_{i-1})$ is periodic in t and polynomial in $x_0,\dots,x_{i-1}$. Since $X(s)A, h_s^{(1)}(A), \dots, h_s^{(i-1)}(A)$, the set of whose Fourier exponents has no accumulation points by the assumption of induction, are almost periodic the set of Fourier exponents of the function

$$p(s,A) := X(s)^{-1}G_i(s,X(s)A,h_s^{(1)}(A),\dots,h_s^{(i-1)}(A)) - X(s)^{-1}\sum_{k=1}^{i-1}(Dh_s^{(k)})_A R_{i-k}(A)$$

included in (A.14) does not have accumulation points. Since $R_i(A)$ defined by (A.13) gives the Fourier coefficient corresponding to the zero Fourier exponent of $p(s,A)$, if it exists, there exists $M > 0$ such that all Fourier exponents λ of the integrand in (A.14) satisfy $|\lambda| \geq M$. Then Theorem 4.12 of Fink [13] proves that $h_t^{(i)}(A)$ is almost periodic. ■

Definition A.5. *Along with* $R_1(A), \dots, R_m(A)$ *defined by* (A.11) *and* (A.13)*, we define the* mth order RG equation *for* (A.1) *by*

$$\dot{A} = \varepsilon R_1(A) + \varepsilon^2 R_2(A) + \cdots + \varepsilon^m R_m(A), \quad A \in \mathbf{R}^n, \tag{A.34}$$

and we call $\varepsilon R_1(A) + \cdots + \varepsilon^m R_m(A)$ *the* mth order RG vector field *for* (A.1)*. We denote by* $\varphi_t^{(m)}$ *the flow generated by the* m*th order RG vector field.*

Fix an open set $U \subset \mathbf{R}^n$ such that $\overline{U}$ is compact. Define the map α_t to be

$$\alpha_t(A) := X(t)A + \varepsilon h_t^{(1)}(A) + \varepsilon^2 h_t^{(2)}(A) + \cdots + \varepsilon^m h_t^{(m)}(A) \tag{A.35}$$

for all $t \in \mathbf{R}$. Now we are in a position to restate Theorem 4.4 in the present situation.

Theorem A.6. *Let $\varphi_t^{(m)}$ be the flow of the mth order RG equation for (A.1) and α_t the map defined by (A.35). Then, there exists $\varepsilon_0 > 0$ such that the following holds for all $|\varepsilon| < \varepsilon_0$: A map*

$$\Phi_{t,t_0} := \alpha_t \circ \varphi_{t-t_0}^{(m)} \circ \alpha_{t_0}^{-1} : \alpha_{t_0}(U) \to \mathbf{R}^n \tag{A.36}$$

defines a flow on $U_\varepsilon := \{(t,x) \mid t \in \mathbf{R},\ x \in \alpha_t(U)\}$ associated with a time-dependent vector field

$$F_\varepsilon(t,x) := \frac{d}{da}\Big|_{a=t} \Phi_{a,t}(x). \tag{A.37}$$

Further, there exists a vector field $\widetilde{F}_\varepsilon(t,x)$, which is bounded in t and bounded as $\varepsilon \to 0$, satisfying

$$F_\varepsilon(t,x) = Fx + \varepsilon g_1(t,x) + \cdots + \varepsilon^m g_m(t,x) + \varepsilon^{m+1}\widetilde{F}_\varepsilon(t,x). \tag{A.38}$$

Proof. The proof of the fact that the map Φ_{t,t_0} defines a flow is the same as that of Theorem 4.4(i). We prove (A.38). The vector field defined by (A.37) is calculated as

$$\begin{aligned}
F_\varepsilon(t,x) &= \frac{d}{da}\Big|_{a=t} \alpha_a \circ \varphi_{a-t}^{(m)} \circ \alpha_t^{-1}(x) \\
&= \frac{d}{da}\Big|_{a=t} \left(x_0(a,0,\alpha_t^{-1}(x)) + \varepsilon x_1(a,a;\alpha_t^{-1}(x)) + \cdots + \varepsilon^m x_m(a,a;\alpha_t^{-1}(x))\right) \\
&\quad + \left(X(t) + \varepsilon (Dh_t^{(1)})_{\alpha_t^{-1}(x)} + \cdots + \varepsilon^m (Dh_t^{(m)})_{\alpha_t^{-1}(x)}\right) \\
&\quad \circ \left(\varepsilon R_1(\alpha_t^{-1}(x)) + \cdots + \varepsilon^m R_m(\alpha_t^{-1}(x))\right) \\
&= \frac{d}{da}\Big|_{a=t} \left(x_0(a,0,\alpha_t^{-1}(x)) + \varepsilon x_1(a,t;\alpha_t^{-1}(x)) + \cdots + \varepsilon^m x_m(a,t;\alpha_t^{-1}(x))\right) \\
&\quad + \frac{d}{da}\Big|_{a=t} \left(\varepsilon x_1(t,a;\alpha_t^{-1}(x)) + \cdots + \varepsilon^m x_m(t,a;\alpha_t^{-1}(x))\right) \\
&\quad + \left(X(t) + \varepsilon (Dh_t^{(1)})_{\alpha_t^{-1}(x)} + \cdots + \varepsilon^m (Dh_t^{(m)})_{\alpha_t^{-1}(x)}\right) \\
&\quad \circ \left(\varepsilon R_1(\alpha_t^{-1}(x)) + \cdots + \varepsilon^m R_m(\alpha_t^{-1}(x))\right).
\end{aligned} \tag{A.39}$$

Since $x_i(a,t;\alpha_t^{-1}(x))$ is a solution of (A.5), it satisfies

$$\begin{aligned}
&\frac{d}{da}\Big|_{a=t} x_i(a,t;\alpha_t^{-1}(x)) \\
&= Fx_i(t,t;\alpha_t^{-1}(x)) + G_i(t,x_0(t,0,\alpha_t^{-1}(x)),\dots,x_{i-1}(t,t;\alpha_t^{-1}(x))) \\
&= Fh_t^{(i)}(\alpha_t^{-1}(x)) + G_i(t,x_0,h_t^{(1)}(\alpha_t^{-1}(x)),\dots,h_t^{(i-1)}(\alpha_t^{-1}(x))).
\end{aligned} \tag{A.40}$$

And, according to (A.15) and (A.16), the equality

$$\frac{d}{da}\Big|_{a=t} x_i(t,a;\alpha_t^{-1}(x)) = -y_1^{(i)}(t,\alpha_t^{-1}(x)) = -X(t)R_i(\alpha_t^{-1}(x)) - \sum_{k=1}^{i-1} (Dh_t^{(k)})_{\alpha_t^{-1}(x)} R_{i-k}(\alpha_t^{-1}(x)) \tag{A.41}$$

holds. Substituting (A.40) and (A.41) into (A.39), we obtain

(A.42)

$$\begin{aligned} &F_\varepsilon(t,x)\\ &= Fx_0(t,0,\alpha_t^{-1}(x)) + \sum_{k=1}^{m} \varepsilon^k \left(Fh_t^{(k)}(\alpha_t^{-1}(x)) + G_k(t,x_0,h_t^{(1)}(\alpha_t^{-1}(x)),\dots,h_t^{(k-1)}(\alpha_t^{-1}(x))) \right)\\ &\qquad + O(\varepsilon^{m+1})\\ &= Fx + \varepsilon g_1(t,x) + \cdots + \varepsilon^m g_m(t,x) + O(\varepsilon^{m+1}). \end{aligned}$$

It is hard to write out the term $O(\varepsilon^{m+1})$ explicitly. However, it is easy to prove that the term $O(\varepsilon^{m+1})$ is bounded uniformly in t, because it consists of the almost periodic functions $X(t)$, $g_i(t,x)$, $h_t^{(i)}$, α_t^{-1}. This ends the proof of Theorem A.6. ■

Theorem 6.1 follows immediately as a corollary of the next theorem.

Theorem A.7. *Consider an autonomous equation*

$$\dot{x} = Fx + \varepsilon g_1(x) + \cdots + \varepsilon^m g_m(x), \quad x \in \mathbf{R}^n, \tag{A.43}$$

where F is a diagonalizable $n\times n$ constant matrix, all of whose eigenvalues lie on the imaginary axis, and where $g_1,\dots,g_m$ are polynomial vector fields on $\mathbf{R}^n$. Suppose that its mth order RG vector field satisfies

$$R_1(A) = \cdots = R_{k-1}(A) = 0, \quad R_k(A) \neq 0, \quad k \leq 2m. \tag{A.44}$$

If the vector field $R_k(A)$ has a compact normally hyperbolic invariant manifold N, then (A.43) also has a normally hyperbolic invariant manifold N_ε for sufficiently small $\varepsilon > 0$. The N_ε is diffeomorphic to N and its stability coincides with that of N.

Proof. Before proving the theorem, we point out that the condition $k \leq 2m$ is not essential because we can take $m \in \mathbf{N}$ sufficiently large. Let us denote by $F_\varepsilon(t,x)$ the approximate vector field for (A.43) defined by (A.37). From Theorem A.6, we can rewrite (A.43) as

$$\dot{x} = F_\varepsilon(t,x) - \varepsilon^{m+1}\widetilde{F}_\varepsilon(t,x). \tag{A.45}$$

On account of (A.36), the RG vector field $\varepsilon^k R_k(x) + \cdots + \varepsilon^m R_m(x)$ satisfies the equation

$$\begin{aligned} \varepsilon^k R_k(x) + \cdots + \varepsilon^m R_m(x) &= \frac{d}{da}\Big|_{a=t} \alpha_a^{-1} \circ \Phi_{a,t} \circ \alpha_t(x)\\ &= \frac{d\alpha_a^{-1}}{da}\Big|_{a=t}(\alpha_t(x)) + (D\alpha_t^{-1})_{\alpha_t(x)} \frac{d}{da}\Big|_{a=t} \Phi_{a,t} \circ \alpha_t(x)\\ &= -(D\alpha_t)_x^{-1} \frac{d\alpha_t}{dt}(x) + (D\alpha_t)_x^{-1} F_\varepsilon(t,\alpha_t(x)). \end{aligned} \tag{A.46}$$

Introducing a new function $y(t)$ by $x(t) = \alpha_t \circ y(t)$ and substituting it into (A.45), we obtain

$$\frac{d\alpha_t}{dt}(y(t)) + (D\alpha_t)_{y(t)}\dot{y}(t) = F_\varepsilon(t,\alpha_t(y(t))) - \varepsilon^{m+1}\widetilde{F}_\varepsilon(t,\alpha_t(y(t))).$$

This equation is put together with (A.46) to yield

$$\dot{y} = \varepsilon^k R_k(y) + \cdots + \varepsilon^m R_m(y) - \varepsilon^{m+1}(D\alpha_t)_y^{-1} \circ \widetilde{F}_\varepsilon(t, \alpha_t(y)). \tag{A.47}$$

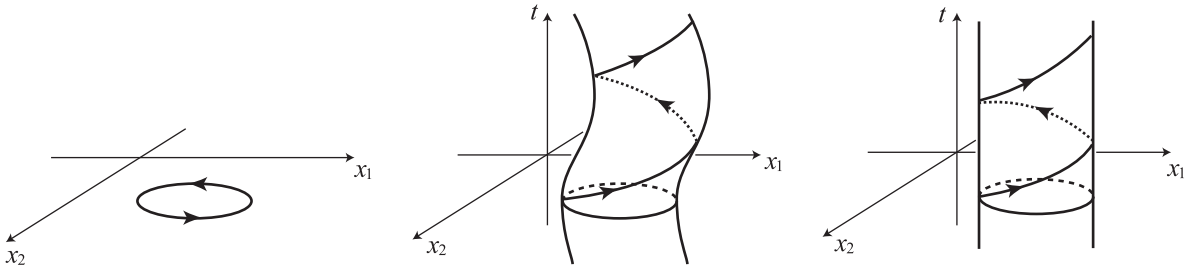
We introduce a newly scaled time s by $t = s/\varepsilon^k$. Then the above equation is rewritten as

$$\frac{dy}{ds} = R_k(y) + \varepsilon R_{k+1}(y) + \cdots + \varepsilon^{m-k} R_m(y) - \varepsilon^{m-k+1}(D\alpha_{s/\varepsilon^k})_y^{-1} \circ \widetilde{F}_{\varepsilon^k}(s/\varepsilon^k, \alpha_{s/\varepsilon^k}(y)). \tag{A.48}$$

Since α_t, $(D\alpha_t)_y$, and $\widetilde{F}_\varepsilon(t, y)$ are bounded uniformly in $t \in \mathbf{R}$, $(D\alpha_{s/\varepsilon^k})_y^{-1} \circ \widetilde{F}_{\varepsilon^k}(s/\varepsilon^k, \alpha_{s/\varepsilon^k}(y))$ is also bounded as $s \to \pm\infty$ and $\varepsilon \to 0$. Therefore, the time-dependent vector field $H(s, y)$ defined by the right-hand side of the above equation is sufficiently close to the vector field $R_k(y)$ in the C^1 topology if $\varepsilon > 0$ is sufficiently small.

Now we use Fenichel's theorem. We regard the vector field $R_k(y)$ on $\mathbf{R}^n$ as a vector field on $\mathbf{R} \times \mathbf{R}^n$ by putting $R_k(t, y) := R_k(y)$. If $R_k(y)$ has a normally hyperbolic invariant manifold N, then $R_k(t, y)$ has a normally hyperbolic invariant manifold $\mathbf{R} \times N$ in (t, y) space. Since $H(s, y)$ is sufficiently close to $R_k(t, y)$ as a vector field on $\mathbf{R} \times \mathbf{R}^n$ in the C^1 topology, $H(s, y)$ also has a normally hyperbolic invariant manifold $\widetilde{N}_\varepsilon$ which is diffeomorphic to $\mathbf{R} \times N$. Since $x(t) = \alpha_t \circ y(t)$ and since $D\alpha_t$ is bounded, (A.43) for $x(t)$ has a normally hyperbolic invariant manifold $\hat{N}_\varepsilon$ which is diffeomorphic to $\mathbf{R} \times N$ in (t, x) space.

Since (A.43) is autonomous, the manifold $\hat{N}_\varepsilon$ must be straight along the time axis (see Figure 4). Consequently, (A.43) has a normally hyperbolic invariant manifold on $\mathbf{R}^n$ which is diffeomorphic to N. ■



flow of $R_k(x)$ flow of (A.48) flow of (A.43)

Figure 4. *The case that $R_k(x)$ has an invariant circle. In this case, the flows of (A.48) and (A.43) have invariant cylinders in the (t, x) space.*

Let $A(t)$ be a solution of the mth order RG equation (A.34) for (A.1), and define the curve $\tilde{x}(t)$ to be

$$\tilde{x}(t) := \alpha_t(A(t)) = X(t)A(t) + \varepsilon h_t^{(1)}(A(t)) + \cdots + \varepsilon^m h_t^{(m)}(A(t)). \tag{A.49}$$

Then, $\tilde{x}(t)$ is an integral curve of the approximate vector field $F_\varepsilon(t, x)$ defined by (A.37), and it gives an approximate solution for (A.1).

Theorem A.8. *There exist positive constants ε_0, C, T and a compact subset $V = V(\varepsilon) \subset \mathbf{R}^n$ including the origin such that for all $|\varepsilon| < \varepsilon_0$, every solution $x(t)$ of (A.1) and $\widetilde{x}(t)$ defined*

by (A.49) *with* $x(0) = \widetilde{x}(0) \in V$ *satisfies the inequality*

$$||x(t) - \widetilde{x}(t)|| < C\varepsilon^m \quad \textit{for } 0 \le t \le T/\varepsilon. \tag{A.50}$$

Proof of Theorem A.8. Suppose that $||x(0)|| < K$. At first, we show that there exists $T > 0$ such that $||x(t)|| < 2K$ for $0 \le t \le T/\varepsilon$. We rewrite (A.1) as the integral equation

$$x(t) = e^{Ft}x(0) + e^{Ft}\int_0^t e^{-Fs}\varepsilon g(s, x(s), \varepsilon)ds, \tag{A.51}$$

where $g(t, x, \varepsilon) := g_1(t, x) + \varepsilon g_2(t, x) + \cdots + \varepsilon^{m-1}g_m(t, x)$. Choose $t \ge 0$ so that $||x(s)|| < 2K$ if $0 \le s \le t$. Then, there exists a positive constant $K' > 0$ such that $||g(s, x(s), \varepsilon)|| < K'$ and the inequality

$$\begin{aligned} ||x(t)|| &\le ||x(0)|| + \int_0^t \varepsilon ||g(s, x(s), \varepsilon)||ds \\ &\le K + \int_0^t \varepsilon K' ds = K\left(1 + \frac{K'}{K}\varepsilon t\right) \end{aligned}$$

holds. When $0 \le t \le K/(K'\varepsilon)$, we have $||x(t)|| < 2K$ so that we put $T := K/K'$ for the existence of T.

By Theorem A.6, an approximate solution $\widetilde{x}(t)$ satisfies an ODE

$$\dot{\widetilde{x}}(t) = F_\varepsilon(t, \widetilde{x}) = F\widetilde{x} + \varepsilon g_1(t, \widetilde{x}) + \cdots + \varepsilon^m g_m(t, \widetilde{x}) + \varepsilon^{m+1}\widetilde{F}_\varepsilon(t, \widetilde{x}). \tag{A.52}$$

Fix a positive number K such that the closed ball B_{2K} of radius $2K$ centered at the origin is included in the open set $\alpha_t(U)$, where U is an open set on which α_t is a diffeomorphism. Then, we can verify that $||\widetilde{x}(t)|| < 2K$ if $||\widetilde{x}(0)|| < K$ and if $0 \le t \le T/\varepsilon$ in the same way as above.

For $x(t)$ and $\widetilde{x}(t)$ such that $x(0) = \widetilde{x}(0), ||x(0)|| < K$, we put $\xi(t) = \alpha_t^{-1} \circ x(t)$, $\eta(t) = \alpha_t^{-1} \circ \widetilde{x}(t)$. They satisfy respective ODEs

$$\dot{\xi}(t) = \varepsilon R_1(\xi) + \varepsilon^2 R_2(\xi) + \cdots + \varepsilon^m R_m(\xi) + \varepsilon^{m+1}\widetilde{G}_\varepsilon(t, \xi), \tag{A.53}$$

$$\dot{\eta}(t) = \varepsilon R_1(\eta) + \varepsilon^2 R_2(\eta) + \cdots + \varepsilon^m R_m(\eta), \tag{A.54}$$

where $\widetilde{G}_\varepsilon$ is a smooth function which is bounded uniformly in $t \in \mathbf{R}$ and bounded as $\varepsilon \to 0$ for each $\xi \in \mathbf{R}^n$. Let W be the image of the closed ball B_{2k} under the map α_t^{-1}. Then $\xi(t)$ and $\eta(t)$ are sitting in the compact set W if $0 \le t \le T/\varepsilon$. Let $L_1 > 0$ be a Lipschitz constant for $R_1(\xi) + \varepsilon R_2(\xi) + \cdots + \varepsilon^{m-1}R_m(\xi)$ on W and suppose that $\sup_{t\in\mathbf{R}, \xi\in W} ||\widetilde{G}_\varepsilon(t, \xi)|| < L_2$. Then, for $0 \le t \le T/\varepsilon$, the inequality

$$||\xi(t) - \eta(t)|| \le \varepsilon L_1 \int_0^t ||\xi(s) - \eta(s)||ds + \varepsilon^{m+1}L_2 t \tag{A.55}$$

holds. Then, the Gronwall inequality implies that

$$||\xi(t) - \eta(t)|| \le \frac{L_2}{L_1}\varepsilon^m(e^{\varepsilon L_1 t} - 1) \le \frac{L_2}{L_1}\varepsilon^m(e^{L_1 T} - 1), \ \ 0 \le t \le T/\varepsilon. \tag{A.56}$$

This shows that there exists a positive constant C such that $||x(t) - \widetilde{x}(t)|| = ||\alpha_t \circ \xi(t) - \alpha_t \circ \eta(t)|| \leq C\varepsilon^m$ holds if $0 \leq t \leq T/\varepsilon$. ■

The next theorem is a simple extension of Propositions 5.1 and 5.2.

Theorem A.9. *Consider an autonomous equation* (A.43).

(i) *If vector fields Fx and $g_1(x), g_2(x), \ldots$ are invariant under the action of a Lie group G, then the mth order RG equation is also invariant under the action of G.*

(ii) *The mth order RG equation commutes with the linear vector field Fx with respect to the Lie bracket product. Equivalently, each $R_i(A)$, $i = 1, 2, \ldots$, satisfies*

$$X(t)R_i(A) = R_i(X(t)A), \quad A \in \mathbf{R}^n. \tag{A.57}$$

Proof of Theorem A.9. Recall that G_i in (A.5) is independent of t since (A.43) is autonomous.

(i) We prove by induction that $R_i(A)$ and $h_t^{(i)}(A)$, $i = 1, 2, \ldots$, are invariant under the action of a Lie group G. Since $aX(t)A = X(t)aA$ and $ag_1(x) = g_1(ax)$ hold for all $a \in G$, $R_1(aA)$ is brought into the form

$$\begin{aligned} R_1(aA) &= \lim_{t\to\infty} \frac{1}{t} \int^t X(s)^{-1} G_1(X(s)aA) ds \\ &= a \lim_{t\to\infty} \frac{1}{t} \int^t X(s)^{-1} G_1(X(s)A) ds = aR_1(A). \end{aligned}$$

And the invariance of $h_t^{(1)}$, $h_t^{(1)}(aA) = ah_t^{(1)}(A)$, is verified in a similar way. Suppose that $R_k(aA) = aR_k(A)$ and $h_t^{(k)}(aA) = ah_t^{(k)}(A)$ hold for $k = 1, 2, \ldots, i-1$. Then, it is easy to verify that

$$(Dh_t^{(k)})_{aA} = a(Dh_t^{(k)})_A a^{-1}, \tag{A.58}$$

$$G_k(X(t)aA, h_t^{(1)}(aA), \ldots, h_t^{(k-1)}(aA)) = aG_k(X(t)A, h_t^{(1)}(A), \ldots, h_t^{(k-1)}(A)) \tag{A.59}$$

for $k = 1, 2, \ldots, i-1$. This and (A.13), (A.14) imply that $R_i(aA) = aR_i(A)$ and $h_t^{(i)}(aA) = ah_t^{(i)}(A)$.

(ii) We prove by induction that $R_i(X(t)A) = X(t)R_i(A)$ and $h_t^{(i)}(X(t')A) = h_{t+t'}^{(i)}(A)$ hold for $i = 1, 2, \ldots$. For all $s' \in \mathbf{R}$, $R_1(X(s')A)$ takes the form

$$\begin{aligned} R_1(X(s')A) &= \lim_{t\to\infty} \frac{1}{t} \int^t X(s)^{-1} G_1(X(s)X(s')A) ds \\ &= X(s') \lim_{t\to\infty} \frac{1}{t} \int^t X(s+s')^{-1} G_1(X(s+s')A) ds. \end{aligned}$$

Putting $s + s' = s''$, we verify that

$$\begin{aligned} R_1(X(s')A) &= X(s') \lim_{t\to\infty} \frac{1}{t} \int^{t+s'} X(s'')^{-1} G_1(X(s'')A) ds'' \\ &= X(s')R_1(A) + X(s') \lim_{t\to\infty} \frac{1}{t} \int_t^{t+s'} X(s'')^{-1} G_1(X(s'')A) ds'' \\ &= X(s')R_1(A). \end{aligned}$$

Next, $h_t^{(1)}(X(s')A)$ is calculated as

$$\begin{aligned} h_t^{(1)}(X(s')A) &= X(t)\int^t \left(X(s)^{-1}G_1(X(s)X(s')A) - R_1(X(s')A)\right) ds \\ &= X(t)X(s')\int^t \left(X(s')^{-1}X(s)^{-1}G_1(X(s)X(s')A) - R_1(A)\right) ds \\ &= X(t+s')\int^t \left(X(s+s')^{-1}G_1(X(s+s')A) - R_1(A)\right) ds. \end{aligned}$$

Putting $s+s'=s''$ provides

$$h_t^{(1)}(X(s')A) = X(t+s')\int^{t+s'} \left(X(s'')^{-1}G_1(X(s'')A) - R_1(A)\right) ds'' = h_{t+s'}^{(1)}(A). \tag{A.60}$$

Suppose that $R_k(X(t)A) = X(t)R_i(A)$ and $h_t^{(k)}(X(t')A) = h_{t+t'}^{(k)}(A)$ hold for $k = 1, 2, \ldots, i-1$. Then, $R_i(X(s')A)$ is calculated as

$$\begin{aligned} R_i(X(s')A) &= \lim_{t\to\infty}\frac{1}{t}\int^t \Bigg(X(s)^{-1}G_i(X(s)X(s')A, h_s^{(1)}(X(s')A), \ldots, h_s^{(i-1)}(X(s')A)) \\ &\qquad - X(s)^{-1}\sum_{k=1}^{i-1}(Dh_s^{(k)})_{X(s')A}R_{i-k}(X(s')A)\Bigg) ds \\ &= X(s')\lim_{t\to\infty}\frac{1}{t}\int^t \Bigg(X(s+s')^{-1}G_i(X(s+s')A, h_{s+s'}^{(1)}(A), \ldots, h_{s+s'}^{(i-1)}(A)) \\ &\qquad - X(s+s')^{-1}\sum_{k=1}^{i-1}(Dh_{s+s'}^{(k)})_A R_{i-k}(A)\Bigg) ds. \end{aligned}$$

Putting $s+s'=s''$ provides

$$\begin{aligned} R_i(X(s')A) &= X(s')\lim_{t\to\infty}\frac{1}{t}\int^{t+s'} \Bigg(X(s'')^{-1}G_i(X(s'')A, h_{s''}^{(1)}(A), \ldots, h_{s''}^{(i-1)}(A)) \\ &\qquad - X(s'')^{-1}\sum_{k=1}^{i-1}(Dh_{s''}^{(k)})_A R_{i-k}(A)\Bigg) ds'' \\ &= X(s')R_i(A) + X(s')\lim_{t\to\infty}\frac{1}{t}\int_t^{t+s'} \Bigg(X(s'')^{-1}G_i(X(s'')A, h_{s''}^{(1)}(A), \ldots, h_{s''}^{(i-1)}(A)) \\ &\qquad - X(s'')^{-1}\sum_{k=1}^{i-1}(Dh_{s''}^{(k)})_A R_{i-k}(A)\Bigg) ds'' \\ &= X(s')R_i(A). \end{aligned}$$

We can show that $h_t^{(i)}(X(t')A) = h_{t+t'}^{(i)}(A)$ in a similar way. ■

Stability Analysis of Two-Dimensional Pool-Boiling Systems*

M. Speetjens†, A. Reusken‡, S. Maier-Paape§, and W. Marquardt¶

Abstract. In this paper we consider a model for pool-boiling systems known from the literature. This model involves only the temperature distribution within the heater and models the heat exchange with the boiling medium via a nonlinear boundary condition imposed on the fluid-heater interface. The model allows multiple homogeneous (i.e., spatially constant) and multiple heterogeneous steady-state solutions. The structure of this family of steady-state solutions has been studied by means of a bifurcation analysis in two recent papers by Speetjens, Reusken, and Marquardt [*Commun. Nonlinear Sci. Numer. Simul.*, 13 (2008), pp. 1475–1494; *Commun. Nonlinear Sci. Numer. Simul.*, 13 (2008), pp. 1518–1537]. The present study concentrates on stability properties of these steady-state solutions. To this end, a generic linear and a case-specific nonlinear stability analysis are performed which show that only the homogeneous steady-state solutions of complete nucleate or complete film boiling are linearly stable. All heterogeneous steady-state solutions appear linearly unstable. These stability results are consistent with laboratory observations.

Key words. pool boiling, stability, bifurcation analysis, numerical simulation

1. Introduction.

Pool boiling refers to boiling processes that lean on natural convection as a means for heat transfer through the boiling medium and is the key mode of thermal transport in many practical applications. Local heat-transfer phenomena near heating walls in industrial boiling equipment (e.g., evaporators and kettle reboilers) are essentially pool-boiling processes [3]. Furthermore, pool boiling is emerging as a novel cooling technique for electronics components [4]. Despite its importance, many aspects of (pool) boiling remain largely unexplored to date, mainly due to the immense complexity of the process induced by the intricate interplay between hydro- and thermodynamics. Studies on boiling known in the literature are mainly experimental and empirical. Theoretical investigations of fundamental phenomena in pool boiling, on the other hand, are scarce. This is the primary motivation for our recent studies, reported in [1] and [2], as well as for the follow-up study presented in this paper.

The central topic of the present study is the stability behavior of pool-boiling systems. Laboratory experiments indicate that, without active control, pool-boiling systems allow only two stable steady-state solutions, namely nucleate boiling and film boiling [5, 6, 7, 8]. Other states belong to the transition-boiling regime and are inherently unstable. Nucleate boiling is, as opposed to film boiling, an efficient and safe mode of heat transfer and the sought-after boiling mode in most practical applications [9]. However, for typical operating conditions, the system admits both nucleate boiling and film boiling as steady states [1], and, consequently, the stable state eventually attained by the system is a priori unclear. Whether a given unstable state in the transition-boiling regime evolves towards either the nucleate-boiling or the film-boiling state is of major practical importance, though. This is intimately related to the stability properties of boiling states. Stability analyses of pool-boiling systems are hitherto restricted to highly idealized models such as, for instance, heated wires [10, 11, 12], heated foils [13], heated cylinders with homogeneous boiling conditions [14, 15], and rectangular "thick" heaters with artificial heterogeneous boiling conditions [13]. Similar studies for more sophisticated models including both realistic heater geometries and realistic heterogeneous boiling conditions are not known in the literature. This is the impetus for the study presented in this paper.

The stability analysis in this paper concerns the stability properties of the multiple heterogeneous boiling states that have been found in [1] for a spatially two-dimensional (2D) heater. Key to the modelling approach is the phenomenological connection between the local state of aggregation of the boiling medium and the local temperature at the fluid-heater interface at mesoscopic length and time scales:[1] "lower" and "higher" temperatures correspond to the liquid and vapor phases, respectively. This allows a description of the (qualitative) behavior of the pool-boiling problem entirely in terms of the temperature field within the heater. Thus the pool-boiling problem is reduced to a heat-transfer problem for the heater with a nonlinear heat-flux relation at the interface between the heater and the boiling medium. This heater-only model is based on the approach used in [13, 14]. Section 2 provides a concise description. Further details can be found in [1].

The nonlinear heat-transfer model resembles nonlinear evolution equations of parabolic type (e.g., reaction-diffusion and pattern-formation equations) known from mathematical physics [17, 18]. The dynamics of such systems are typically dominated by a global attractor, consisting of the steady-state solutions and their heteroclinic connections, to which initial conditions converge if time evolves [18]. Said resemblance suggests that the pool-boiling model may exhibit similar dynamical behavior. However, in the pool-boiling model the nonlinearity of the problem is due to the nonlinear heat-flux condition at the heater-fluid interface and is not due to a nonlinearity in the partial differential equation itself as in "conventional" nonlinear parabolic evolution equations. Thus the concepts known for the latter problem class cannot be applied directly to the pool-boiling problem. We are unaware of rigorous mathematical studies on, e.g., existence, smoothness, and asymptotic stability of solutions of problems involving nonlinear boundary conditions such as our pool-boiling problem. A rigorous mathematical analysis is beyond the present scope, however. Instead, preliminary

[1]Here mesoscopic means locally averaged in space and time over intervals larger than bubble dimensions and bubble lifetimes in order to smooth out microscopic short-term fluctuations [16].

results are given that indicate the existence of a global attractor consisting of steady-state solutions and their heteroclinic connections (section 3.1). This strongly suggests dynamical behavior akin to that of "conventional" nonlinear evolution equations and justifies a study on the existence of (multiple) steady-state solutions and their stability properties.

The set of steady-state solutions of the 2D boiling problem has been studied extensively in [1]; an extension to the three-dimensional (3D) case is given in [2]. The present study investigates the stability properties of these steady states by a linear stability analysis. This analysis hinges on linearization of the nonlinear problem at a given steady-state solution. Treatment of the resulting linearized model with a separation-of-variables technique results in a linear eigenvalue problem that governs the eigenmodes and corresponding eigenvalues (i.e., temporal growth rates) of steady-state solutions (section 3.2.1). Analysis of this eigenvalue problem yields generic stability properties (section 3.2.2). The eigenmodes and eigenvalues of a given steady state can be computed (approximately) using a Fourier-collocation discretization method (section 3.2.3). The generic linear stability analysis and the eigenmode decomposition are demonstrated for a representative set of steady-state solutions (section 4.1). A brief recapitulation of steady-state solutions determined in [1] is given in section 3.3. Numerical simulation of the *non*linear evolution of linearly unstable steady states is performed by a spectral algorithm. These simulations validate the linear analysis and yield first insight into the *non*linear (in)stability behavior (section 4.2). Conclusions are drawn in section 5.

2. Model problem. The stability of pool-boiling systems is investigated in terms of a model problem considered in [1]. An extensive discussion and motivation of this model is provided in that paper. Here we restrict ourselves to a concise description of the nondimensional formulation of this model.

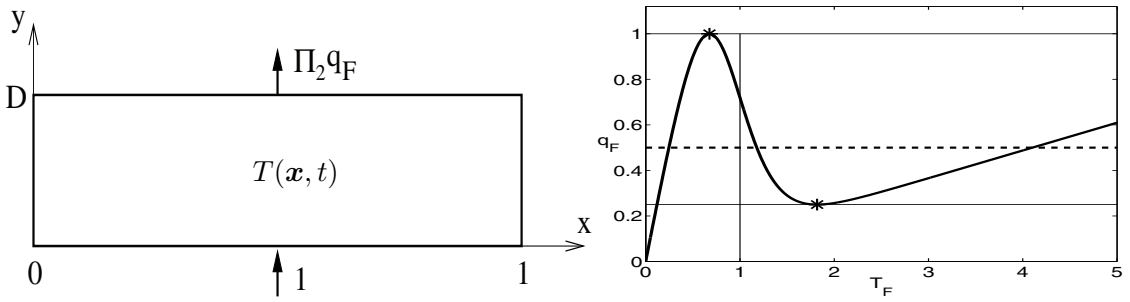
We consider the heat transfer within the 2D rectangular heater $\mathcal{D} := [0,1] \times [0,D]$ (Figure 1(a)). Its boundary is given by $\Gamma = \partial\mathcal{D} = \Gamma_H \cup \Gamma_A \cup \Gamma_F$ and comprises the boundary segments Γ_H: $y = 0$ (constant heat supply), Γ_A: $x = 0, 1$ (adiabatic sidewalls), and Γ_F: $y = D$ (nonconstant heat extraction by boiling process). The heat transfer within $\mathcal{D}$ is modeled by

$$\begin{aligned} \frac{\partial T}{\partial t} &= \kappa \nabla^2 T \qquad && \text{in } \ \mathcal{D} \times [0, t_{\text{end}}], \\ T(\boldsymbol{x}, 0) &= T_0(\boldsymbol{x}) \qquad && \text{for } \ \boldsymbol{x} := (x, y) \in \mathcal{D}, \\ \frac{\partial T}{\partial \nu} &= g(\boldsymbol{x}, T) \qquad && \text{on } \ \Gamma, \end{aligned} \tag{2.1}$$

with ν the outward normal of Γ. The boundary condition on Γ introduces a nonlinearity due to the dependence of g on $T(x, D, t) =: T_F(x, t)$. Note that T_F denotes the value of T at the fluid-heater interface Γ_F. The function g is given by

$$g(\boldsymbol{x}, Z) = \begin{cases} 0 & \text{for } x = 0 \text{ or } x = 1, \\ 1/\Lambda & \text{for } y = 0, \\ -\Pi_1 \, q_F(Z; \Pi_2, \Pi_3)/\Lambda & \text{for } y = D. \end{cases} \tag{2.2}$$

The function $T = T(\boldsymbol{x}, t)$ is the nondimensional temperature excess (i.e., the temperature relative to the boiling point of the medium). System parameters are D (aspect ratio of the heater), Λ (nondimensional thermal conductivity), κ (nondimensional thermal diffusivity),



(a) *Heater configuration.* (b) *Heat-flux function.*

Figure 1. *Nondimensional model problem:* (a) *heater configuration and* (b) *heat-flux function* q_F. *The dashed line represents the normalized heat supply* Π_1^{-1}.

and Π_1 (nondimensional critical heat flux of boiling process), all of which are positive. The nonlinear heat-flux function $q_F(\cdot;\Pi_2,\Pi_3)$ accounts for the heat exchange between the heater and the boiling medium. This function is specified in the appendix and introduces two further control parameters, viz. Π_2 and Π_3, resulting in a total of six parameters. However, physical considerations suggest $\Lambda D/\kappa = |1-\Pi_1|$, and thus the model contains five independent control parameters.

Physical considerations further suggest that the heat-flux function q_F, which describes the *local* heat exchange between fluid and heater, should be qualitatively similar to the so-called boiling curve. The latter describes the *global* heat exchange between fluid and heater obtained via averaging over the fluid-heater interface Γ_F. Therefore, as before [1] we use a heat-flux function schematically shown in Figure 1(b), which has the typical shape of a boiling curve; see the appendix for an explicit expression. The heat-flux function is parameterized by Π_2 (ratio of extremal heat fluxes) and Π_3 (ratio of extremal temperatures) and consists of three distinct regimes that correspond to one of the local boiling modes and associated mesoscopic states: nucleate boiling (left of local maximum; fluid-rich state); transition boiling (in between both extrema; transitional state); film boiling (right of local minimum; vapor-rich state).[2]

Important to note is that, despite being of the same shape, imposition of the heat-flux function q_F on the fluid-heater interface Γ_F is not equivalent to imposition of the boiling curve on Γ_F. Heat-flux function q_F describes the *local* heat flux as a function of the *local* interface temperature and holds for both homogeneous and heterogeneous interface states. The boiling curve, on the other hand, describes the *mean* heat flux as a function of the *mean* interface temperature and strictly holds only for homogeneous interface states. (Homogeneous states satisfying q_F automatically satisfy the boiling curve and form a subset of the total set of solutions to the proposed model.) The local nature of q_F is essential for the present model to admit the (multiple) heterogeneous boiling states that characterize physical boiling systems.

3. Unsteady pool-boiling problem: Generic analysis. The nonlinear heat-transfer model (2.1) bears resemblance to nonlinear parabolic problems known from mathematical physics [18]. However, a fundamental difference is that in the heat-transfer model (2.1) the nonlinearity resides in the boundary condition rather than in the partial differential equation itself.

[2]Further physical background for this heater-only model is given by [1].

This is a direct consequence of the finite thickness ($D > 0$) of the present heater configuration and distinguishes our problem from "thin" ($D \to 0$) configurations. For vanishing D the model reduces to a partial differential equation with a nonlinear source term (see, e.g., [13]), and generic concepts for the analysis of parabolic systems—in particular of the reaction-diffusion type [17]—can be applied. Examples of such approaches to pool-boiling systems are in [10, 11, 12, 13].

Rather than providing a rigorous mathematical analysis, which is beyond the present scope, in this section we indicate that concepts similar to those introduced for "conventional" parabolic evolution equations [18] can be applied to the pool-boiling problem, too. We assume that solutions of the pool-boiling problem fulfill all the regularity conditions that admit application of such concepts. We note that the results of the generic analysis and those of the case study in section 4 are in good agreement.

3.1. Generic dynamical behavior. The dynamical behavior of an evolutionary (parabolic) system is commonly investigated based on its corresponding weak formulation [18]. We use the Sobolev space $H^1(\mathcal{D})$ and the notation

$$(u,v)_{L^2(\mathcal{D})} := \int_{\mathcal{D}} uv \, dx \, dy, \quad B(T,\varphi) := \int_{\mathcal{D}} \nabla T \cdot \nabla \varphi \, dx \, dy.$$

For the heat-transfer problem (2.1) the weak formulation is as follows: find $u = u(t) = T(\cdot,t) \in H^1(\mathcal{D})$ with $\frac{du(t)}{dt} \in L^2(\mathcal{D})$ such that

$$\left(\frac{du(t)}{dt}, \varphi\right)_{L^2(\mathcal{D})} = \int_{\partial\mathcal{D}} g(\boldsymbol{x},u)\,\varphi \, d\sigma - \kappa B(u,\varphi) \quad \text{for all } \varphi \in H^1(\mathcal{D}). \tag{3.1}$$

If a solution u of (3.1) is sufficiently smooth, it clearly provides an L_2-solution of (2.1). Conversely, regular solutions to (2.1) naturally are solutions to (3.1).

The weak formulation describes the evolution of the system from its initial state $u(0)$ to its current state $u(t)$; i.e., $u(t) = \Phi_t(u(0))$ defines a flow. Thus the weak formulation (3.1) defines a dynamical system for the weak solution $u(t)$. Existence and uniqueness of a solution of (3.1) depend on smoothness and growth properties of g. This topic is not studied in the present paper. We *assume* that g is such that the following property holds.

Property 1. *System* (3.1) *results in a global semiflow:* $\Phi_t : H^1(\mathcal{D}) \to H^1(\mathcal{D})$, $t \in [0,\infty)$.

The dynamical system (3.1) has a gradient structure; i.e., the functional $E : H^1(\mathcal{D}) \to \mathbb{R}$,

$$E(u) := \frac{\kappa}{2} B(u,u) - \int_{\partial\mathcal{D}} G(\boldsymbol{x},u)\, d\sigma, \tag{3.2}$$

with $G(\boldsymbol{x},u)$ such that $D_u G(\boldsymbol{x},u) = g(\boldsymbol{x},u)$, defines an energy or Lyapunov function for the solutions u of (3.1). Under certain smoothness and growth assumptions on g we have $DE(u) \in \mathcal{L}\big(H^1(\mathcal{D}),\mathbb{R}\big)$ and

$$DE(u)[\varphi] = \kappa B(u,\varphi) - \int_{\partial\mathcal{D}} g(\boldsymbol{x},u)\,\varphi \, d\sigma \quad \text{for all } u,\varphi \in H^1(\mathcal{D}). \tag{3.3}$$

Along a solution curve $u(t)$ of (3.1) the energy E decays monotonically in time:

$$\frac{d}{dt}\left[E(u(t))\right] = DE(u)\left[\frac{du}{dt}\right] = -\left(\frac{du}{dt}, \frac{du}{dt}\right)_{L^2(\mathcal{D})} \leq 0, \tag{3.4}$$

with equality (for a range of t-values) only if $u(t) = T(\cdot, t) = T_\infty(\cdot)$ is a steady-state solution. This property implies a loss of energy of solutions $u(t) = T(\cdot, t)$ with progressing time. This already provides important information on the long-term dynamical behavior, namely that for any initial condition u_0 the corresponding solution converges to a steady-state solution.

Our case study for the pool-boiling problem further indicates the existence of a global attractor $\mathcal{A}$ for the semiflow $\Phi_\cdot$, i.e., a strictly positive invariant subset of $H^1(\mathcal{D})$, which is compact and attracts all bounded subsets of $H^1(\mathcal{D})$ (cf. [18], Definition I. 1.3). We *assume* the following property to guarantee this existence.

Property 2. *Assume that the global semiflow $\Phi_\cdot$ generated by (3.1) has some compactness property, e.g., in the sense of* [18, *Theorem* I. 1.12 *or* I. 1.13]*, and further assume the existence of a bounded set $M \subset H^1(\mathcal{D})$, which attracts all bounded sets in $H^1(\mathcal{D})$.*

In order to elucidate the consequences of the above properties we introduce the following notation. Let $\mathcal{E}$ be the set of equilibria:

$$\mathcal{E} = \left\{u \in H^1(\mathcal{D}) \colon\ \Phi_t(u) = u \quad \text{for all } t \geq 0\right\}.$$

For $u_0, v_0 \in \mathcal{E}$ let $\mathcal{C}(u_0, v_0)$ be the set of heteroclinic connections between u_0 and v_0, i.e., all full orbits that approach u_0 as $t \to -\infty$ and v_0 as $t \to \infty$. Using these notions we can formulate the following result.

Theorem 3.1. *We assume Properties 1 and 2. Then the semiflow $\Phi_\cdot$ possesses a global compact attractor $\mathcal{A}$. This global attractor equals the unstable set of $\mathcal{E}$; i.e., it consists of full orbits which approach the set of steady-state solutions for $t \to -\infty$. If, furthermore, $\mathcal{E}$ is discrete, then the global attractor consists of steady-state solutions $u(t) = T(\cdot, t) = T_\infty(\cdot) \in H^1(\mathcal{D})$ of (3.1), i.e.,*

$$\kappa B(T_\infty, \varphi) = \int_{\partial\mathcal{D}} g(\boldsymbol{x}, T_\infty)\, \varphi \, d\sigma \quad \textit{for all } \varphi \in H^1(\mathcal{D}), \tag{3.5}$$

and their heteroclinic connections

$$\mathcal{A} = \left(\bigcup_{u_0 \in \mathcal{E}} \{u_0\}\right) \cup \bigcup_{u_0, v_0 \in \mathcal{E}} \mathcal{C}(u_0, v_0). \tag{3.6}$$

Proof. [18, Theorems I.1.1 and VII.4.1]. ∎

In general, unstable steady-state solutions u_0 have a stable manifold $\mathcal{M}_s(u_0) = \{w \in H^1(\mathcal{D}) : \Phi_t(w) \to u_0 \text{ for } t \to \infty\}$ with a finite nonzero codimension. Therefore it is most likely for a generic initial condition u_0 to lie in the stable manifold of a stable equilibrium $g \in \mathcal{E}$. Hence in realistic systems due to physical imperfections as well as numerical simulations due to rounding errors the evolution process basically always converges towards a stable steady state.

Isolation of the global attractor of the boiling problem requires identification of its steady-state solutions and determination of the corresponding stability properties. The steady-state solutions have been studied extensively in [1]; a brief recapitulation is given in section 3.3. The present paper concerns the corresponding stability properties. Section 3.2 gives a generic linear stability analysis; section 4 demonstrates and validates this linear analysis by way of numerical simulation of the nonlinear evolution of unstable steady-state solutions. This also offers first insight into the nonlinear stability behavior of the system. Moreover, it may enable a more detailed investigation of the structure of the attractor by the approach proposed in [19] along the lines of the analysis of the Cahn–Hilliard equation in [20] and [21].

3.2. Linear stability analysis of steady-state solutions.

3.2.1. Linearized heat-transfer model. The stability analysis of steady-state solutions that we present is based on the linear theory of stability; cf. [22, section I.6]. To determine stability of a steady-state solution $T_\infty(\boldsymbol{x})$, one subjects this steady-state solution to a small initial perturbation $v_0(\boldsymbol{x}) = v(\boldsymbol{x}, 0)$. We assume that for the nonlinear problem (2.1) the *principle of linearized stability* holds (cf. [23]); i.e., solutions of the nonlinear problem in a neighborhood of a steady-state solution T_∞ and of the linearized problem (linearization at T_∞) have the same qualitative behavior. This assumption justifies the analysis of stability properties of the nonlinear problem by means of a stability analysis of the linearized problem. In this paper, unless stated otherwise explicitly, the notions stable and unstable are always meant in the sense of this linear theory of stability.

For the stability analysis we introduce the linearization of (2.1). Let $T_\infty(\boldsymbol{x})$ be a regular steady-state solution of (2.1); i.e., T_∞ satisfies the following Laplace equation with a nonlinear Neumann boundary condition:

$$\nabla^2 T_\infty = 0 \quad \text{in } \mathcal{D}, \qquad \frac{\partial T_\infty}{\partial \nu} = g(\boldsymbol{x}, T_\infty) \quad \text{on } \Gamma = \partial\mathcal{D} \tag{3.7}$$

(g as in (2.2)). Properties of the nonlinear steady-state problem (3.7) are derived in [1] and summarized in section 3.3. The corresponding linearized problem at T_∞ for the perturbation $v(\boldsymbol{x}, t)$ induced by an initial perturbation $v_0(\boldsymbol{x})$ is given by

$$\begin{aligned} \frac{\partial v}{\partial t} &= \kappa \nabla^2 v && \text{in } \mathcal{D} \times [0, t_{\text{end}}], \\ v(\boldsymbol{x}, 0) &= v_0(\boldsymbol{x}) && \text{for } \boldsymbol{x} \in \mathcal{D}, \\ \frac{\partial v}{\partial \nu} &= f(\boldsymbol{x}) v && \text{on } \Gamma. \end{aligned} \tag{3.8}$$

The Neumann boundary condition is given by

$$f(\boldsymbol{x}) = \begin{cases} 0 & \text{on } \Gamma \setminus \Gamma_F, \\ -\gamma(x) & \text{on } \Gamma_F, \end{cases} \tag{3.9}$$

with

$$\gamma(x) = \frac{\Pi_1}{\Lambda} \frac{dq_F}{dZ} \left(T_{F,\infty}(x) \right), \qquad x \in [0, 1], \tag{3.10}$$

where $T_{F,\infty}(x) := T_\infty(x, D)$ is the steady-state temperature profile at the fluid-heater interface Γ_F. Thus the original nonlinear condition on Γ_F simplifies to a standard linear Neumann condition with an x-dependent coefficient determined by the interface temperature $T_{F,\infty}(x)$ of the steady-state solution.

As ansatz (based on separation of variables) we seek solutions of (3.8) of the form

$$v(\boldsymbol{x}, t) = \mathrm{e}^{-\kappa\mu t}\psi(\boldsymbol{x}). \tag{3.11}$$

Substitution of (3.11) into (3.8) leads to the following linear elliptic eigenvalue problem for ψ:

$$\nabla^2\psi + \mu\psi = 0 \quad \text{in} \quad \mathcal{D}, \tag{3.12}$$

$$\frac{\partial\psi}{\partial\nu} = 0 \quad \text{on} \quad \Gamma \setminus \Gamma_F, \tag{3.13}$$

$$\frac{\partial\psi}{\partial\nu} + \gamma(x)\psi = 0 \quad \text{on} \quad \Gamma_F. \tag{3.14}$$

The weak formulation of this eigenvalue problem is as follows: determine $\mu_n \in \mathbb{R}$, $\psi_n \in H^1(\mathcal{D})$ such that

$$-B(\psi_n, \varphi) - \int_{\Gamma_F} \gamma\,\psi_n\,\varphi\,d\sigma + \mu_n \int_{\mathcal{D}} \psi_n\,\varphi\,dx\,dy = 0 \quad \text{for all } \varphi \in H^1(\mathcal{D}). \tag{3.15}$$

The eigenpairs that solve this problem are denoted by (μ_n, ψ_n), $n = 1, 2, \ldots$. The eigenfunctions are scaled such that $\|\psi_n\|_{L^2(\mathcal{D})} = 1$. Whether, for generic γ (e.g., $\gamma \in L^\infty(\Gamma_F)$), the eigenfunctions $(\psi_n)_{n\geq 1}$ form a complete orthogonal basis of $L^2(\mathcal{D})$ is an open question. We do not study this topic in the present paper. Instead, we assume that these eigenfunctions span a space that is sufficiently large such that it makes sense to restrict the choice of the initial perturbations $v_0(\boldsymbol{x})$ to this space. We obtain the following representation for the unique solution v of (3.8) induced by an initial perturbation $v_0 \in \operatorname{span}\{\psi_n \mid n \geq 1\}$:

$$\text{Let} \quad v_0(\boldsymbol{x}) = \sum_{k=0}^{\infty} \eta_k\psi_k, \quad \text{with} \quad \eta_k = (v_0, \psi_k)_{L^2(\mathcal{D})}; \tag{3.16}$$

$$\text{then} \quad v(\boldsymbol{x}, t) = \sum_{k=1}^{\infty} \eta_k \mathrm{e}^{-\kappa\mu_k t}\psi_k(\boldsymbol{x}). \tag{3.17}$$

Note that the eigenvalues μ_k depend (via γ) on T_∞ yet *not* on the perturbation v_0.

Representation (3.17) implies that the steady-state solution T_∞ of (2.1) is linearly stable w.r.t. all perturbations of the form (3.16) if all μ_k are nonnegative. Conversely, T_∞ is an unstable steady-state solution if at least one μ_k is negative. Relation (3.15), in turn, implies that $\mu_k \geq 0$ for all k if $\gamma \geq 0$. Thus it follows that $\gamma \geq 0$ on the fluid-heater interface Γ_F is a sufficient condition for linear stability of the steady-state solution.

3.2.2. Analysis of the eigenvalue problem. The stability properties of steady-state solutions T_∞ of (2.1) are directly related to the eigenvalues of problem (3.12)–(3.14). In this section we study this eigenvalue problem.

We use an approach based on Fourier analysis. First, for a *fixed* $\mu \in \mathbb{R}$ we consider the problem (3.12)–(3.13) and apply separation of variables to construct bivariate Fourier modes that satisfy (3.12)–(3.13). Let $\phi(\boldsymbol{x}) = \alpha(x)\beta(y)$. An elementary computation shows that $c\,\alpha(x)\beta(y)$, $c \in \mathbb{R} \setminus \{0\}$, solves (3.12)–(3.13) if and only if

$$\alpha(x) = \cos(n\pi x), \qquad \beta(y) = \cosh\bigl(\sqrt{(n\pi)^2 - \mu}\, y\bigr), \quad n = 0, 1, 2, \ldots.$$

Note that for $z < 0$ we have $\cosh(\sqrt{z}) = \cosh(i\sqrt{|z|}) = \cos(\sqrt{|z|})$. We now make the ansatz that the whole solution space of (3.12)–(3.13) is obtained by superposition of these Fourier modes; i.e., all solutions of (3.12)–(3.13) lie in the space

$$S_\mu := \left\{ \psi(\boldsymbol{x}) = \sum_{n=0}^{\infty} A_n \cos(n\pi x) \cosh(\sqrt{\alpha_{n,\mu}}\, y), \quad A_n \in \mathbb{R},\ \alpha_{n,\mu} := (n\pi)^2 - \mu \right\}.$$

If we take the boundary condition (3.14) into account, then the solutions of (3.12)–(3.14) form a subspace of S_μ. A function $\phi(\boldsymbol{x}) = \sum_{n=0}^{\infty} A_n \cos(n\pi x) \cosh(\sqrt{\alpha_{n,\mu}}\, y) \in S_\mu$ solves (3.14) if and only if

$$\sum_{n=0}^{\infty} A_n \sqrt{\alpha_{n,\mu}} \sinh(\sqrt{\alpha_{n,\mu}}\, D) \cos(n\pi x) + \gamma(x)\phi(x, D) = 0 \quad \text{for all} \quad x \in [0, 1]. \tag{3.18}$$

Thus the problem of finding the eigenvalues of (3.12)–(3.14) is transformed to the problem of finding μ such that (3.18) has a nontrivial solution $\phi_F(x) := \phi(x, D)$. Note that the latter problem is spatially *one*-dimensional (1D). Furthermore, for $z < 0$ we have $\sqrt{z}\sinh(\sqrt{z}) = -\sqrt{|z|}\sin(\sqrt{|z|})$, and thus for all $\alpha_{n,\mu} \in \mathbb{R}$ (3.18) is real. We will solve this equation using a univariate Fourier analysis. To this end some notation is introduced. Let $\mathcal{F} : L^2([0, 1]) \to \ell^2$ be the Fourier transform:

$$\mathcal{F}\left(\sum_{n=0}^{\infty} c_n \cos(n\pi \cdot) \right) = (c_n)_{n \geq 0}.$$

For $\mathbf{c}, \mathbf{d} \in \ell^2$ the elementwise multiplication is denoted by $\mathbf{c} * \mathbf{d} = (c_n d_n)_{n \geq 0}$. Furthermore, we write for $\phi \in S_\mu$ restricted to fluid-heater interface Γ_F

$$\begin{aligned} \phi_F(x) := \phi(x, D) &= \sum_{n=0}^{\infty} A_n \cosh(\sqrt{\alpha_{n,\mu}}\, D) \cos(n\pi x) = \sum_{n=0}^{\infty} \widetilde{\phi}_n \cos(n\pi x), \\ \widetilde{\phi}_n &:= A_n \cosh(\sqrt{\alpha_{n,\mu}}\, D). \end{aligned} \tag{3.19}$$

Using this, (3.18) can be rewritten as follows: find $\phi_F(x) = \sum_{n=0}^{\infty} \widetilde{\phi}_n \cos(n\pi x)$ such that

$$\sum_{n=0}^{\infty} \sqrt{\alpha_{n,\mu}} \tanh(\sqrt{\alpha_{n,\mu}}\, D) \widetilde{\phi}_n \cos(n\pi x) + \gamma(x)\phi_F(x) = 0 \quad \text{for all} \quad x \in [0, 1]. \tag{3.20}$$

For $z < 0$ we have $\sqrt{z}\tanh(\sqrt{z}) = -\sqrt{|z|}\tan(\sqrt{|z|})$. Define

$$\mathbf{d}_\mu \in \ell^2, \quad (d_\mu)_n := \sqrt{\alpha_{n,\mu}} \tanh(\sqrt{\alpha_{n,\mu}}\, D), \quad n = 0, 1, \ldots.$$

Then problem (3.20) has the following compact formulation: find ϕ_F such that

$$J_\mu \phi_F := \mathcal{F}^{-1}\big(\mathbf{d}_\mu * \mathcal{F}\phi_F\big) + \gamma\phi_F = 0. \tag{3.21}$$

In this formulation it is implicitly assumed that a solution ϕ_F is sufficiently smooth such that $\mathbf{d}_\mu * \mathcal{F}\phi_F \in \text{range}(\mathcal{F})$. The linear operator J_μ is well defined on a dense subspace of $L^2([0,1])$. We are interested in values for μ for which (3.21) has a nontrivial solution ϕ_F. Furthermore, we are interested in the sign of these eigenvalues μ, as they determine the stability of corresponding steady-state solutions. In the analysis below we distinguish two cases: constant and nonconstant γ. For $\gamma(x) = \gamma =$ constant the relevant properties of μ can be determined analytically. For the general case of a smooth but not necessarily constant function $\gamma(x)$ certain properties can still be derived analytically. However, for full insight we must resort to discretization of (3.21) and study its properties via numerical computations. Note that, for brevity, ϕ hereafter refers to both the full and the boundary solutions; its meaning readily follows from the context.

Homogeneous temperature on fluid-heater interface: Constant γ. If $\gamma(x) = \gamma$ is constant, the following holds.

Theorem 3.2. *There exist sequences $(z_k^+)_{k\in\mathbb{N}}$ with $z_k^+ \in [(k-1)\pi, (k-\frac{1}{2})\pi)$, $k \geq 1$, and $(z_k^-)_{k\in\mathbb{N}}$ with $z_1^- < 0$, $z_{k+1}^- \in [(k-\frac{1}{2})\pi, k\pi)$, $k \geq 1$, such that the following holds. If (μ, ϕ), with $\phi \neq 0$, solves (3.21), then $\mu \in (\mu_{k,n})_{k,n\in\mathbb{N}}$ with $\mu_{k,n}$ defined by*

$$\mu_{k,n} = z_k^+ + (n\pi)^2 \quad \textit{if } \gamma \geq 0, \tag{3.22}$$

$$\mu_{k,n} = z_k^- + (n\pi)^2 \quad \textit{if } \gamma < 0. \tag{3.23}$$

For all k, n, the pair $\mu = \mu_{k,n}$, $\phi(x) = \cos(n\pi x)$ is a solution of (3.21).

Proof. Note that

$$\begin{aligned} & \mathcal{F}^{-1}\big(\mathbf{d}_\mu * \mathcal{F}\phi\big) + \gamma\phi = 0 \\ \Leftrightarrow\quad & \mathbf{d}_\mu * \mathcal{F}\phi + \gamma\mathcal{F}\phi = 0 \\ \Leftrightarrow\quad & \text{for all } n: \ (d_\mu)_n + \gamma = 0 \ \text{ or } \ \widetilde{\phi}_n = (\mathcal{F}\phi)_n = 0. \end{aligned}$$

Take an $n \in \mathbb{N}$ such that $\widetilde{\phi}_n \neq 0$. Then $(d_\mu)_n + \gamma = 0$ must hold. We consider the equation

$$\mu \to (d_\mu)_n + \gamma = \sqrt{\alpha_{n,\mu}}\tanh\big(\sqrt{\alpha_{n,\mu}}\,D\big) + \gamma = 0, \quad \alpha_{n,\mu} = (n\pi)^2 - \mu. \tag{3.24}$$

Thus we look for the roots of the function $g(z) := \sqrt{z}\tanh(\sqrt{z}\,D) + \gamma$. For $z > 0$ and $\gamma \geq 0$ the equation $g(z) = 0$ has no solution. For $z > 0$ and $\gamma < 0$ there is a unique root $z^* > 0$. Define $z_1^- := -z^*$. This induces a corresponding $\mu_1 := z_1^- + (n\pi)^2$ that solves (3.24). For $z \leq 0$ we have $g(z) = -\sqrt{-z}\tan(\sqrt{-z}\,D) + \gamma$. An elementary analysis shows that for $\gamma \geq 0$ the equation $g(z) = 0$ has negative roots z^* with $-z^* =: z_k^+ \in [(k-1)\pi, (k-\frac{1}{2})\pi)$ for $k = 1, 2, \ldots$. For $\gamma < 0$ the equation $g(z) = 0$ has negative roots z^* with $-z^* =: z_{k+1}^- \in [(k-\frac{1}{2})\pi, k\pi)$ for $k = 1, 2, \ldots$. Due to $-z = -\alpha_{n,\mu} = \mu - (n\pi)^2$ we obtain corresponding solutions of (3.24): $\mu_k = z_k^+ + (n\pi)^2$, $k = 1, 2, \ldots$, for the case $\gamma \geq 0$ and $\mu_k = z_k^- + (n\pi)^2$, $k = 2, 3, \ldots$, for the case $\gamma < 0$. Combining the results for the cases $z > 0$ and $z \leq 0$ reveals that all possible roots

of (3.24) are given by (3.22)–(3.23). If we take $\widetilde{\phi}_n = 1$, $\widetilde{\phi}_m = 0$ for all $m \neq n$, then $(\mu_{k,n}, \phi)$ with $\phi(x) = \cos(n\pi x)$ solves (3.21). ■

Remark 1. Relation (3.22) implies that for the case $\gamma \geq 0$ all eigenvalues $\mu = \mu_{k,n}$ of (3.12)–(3.14) are positive. Relation (3.23) yields that for the case $\gamma < 0$ there always exists some integer $n_0 > 0$ such that $\mu_{1,n} < 0$ for all $0 \leq n \leq n_0$. *Thus Theorem 3.2 describes the linear stability properties of the pool-boiling problem in case of constant γ. Steady-state solutions for which $\gamma \geq 0$ holds are linearly stable, whereas steady-state solutions for which $\gamma < 0$ holds are unstable.*

Remark 2. Using Theorem 3.2 and the representation (3.19) we obtain that the eigenfunction corresponding to $\mu = \mu_{k,n}$ is given by $\phi(x, y) = \cos(n\pi x)\cosh(\sqrt{(n\pi)^2 - \mu_{k,n}}\, y)$. Note that $(n\pi)^2 - \mu_{k,n} = -z_k^+$ for $\gamma \geq 0$ and $(n\pi)^2 - \mu_{k,n} = -z_k^-$ for $\gamma < 0$. Hence, for $\gamma \geq 0$ an eigenfunction corresponding to $\mu = \mu_{k,n}$ is given by $\phi(x, y) = \cos(n\pi x)\cos(\sqrt{z_k^+}\, y)$, and for $\gamma < 0$ we obtain $\phi(x, y) = \cos(n\pi x)\cosh(\sqrt{-z_1^-}\, y)$ if $k = 1$ and $\phi(x, y) = \cos(n\pi x)\cos(\sqrt{z_k^-}\, y)$ if $k \geq 2$.

Heterogeneous temperature on fluid-heater interface: Nonconstant γ. The linear operator J_μ in (3.21) is *symmetric* on its domain in $L^2([0, 1])$. This allows a general analysis using real eigenvalues and energy arguments. We introduce the notation $I := [0, 1]$ and $\gamma_{min} := \min_{x \in I} \gamma(x)$. We derive a similar stability condition as before.

Theorem 3.3. *Assume that $\gamma_{min} \geq 0$ holds. Then for all solutions (μ, ϕ) of (3.21), with $\phi \neq 0$, we have $\mu \geq 0$.*

Proof. If $\mu, \phi \neq 0$ satisfies (3.21), we attain

$$\big(\mathcal{F}^{-1}(\mathbf{d}_\mu * \mathcal{F}\phi), \phi\big)_{L^2(I)} + (\gamma\phi, \phi)_{L^2(I)} = 0. \tag{3.25}$$

Suppose $\mu < 0$. Then $\alpha_{n,\mu} = (n\pi)^2 - \mu > 0$ for all n, and thus $(d_\mu)_n > 0$ for all n. This implies, with $c_n := \|\cos(n\pi x)\|_{L^2(I)}$, that

$$\big(\mathcal{F}^{-1}(\mathbf{d}_\mu * \mathcal{F}\phi), \phi\big)_{L^2(I)} = \sum_{n=0}^{\infty} (d_\mu)_n c_n^2 \widetilde{\phi}_n^2 > 0.$$

Combined with $(\gamma\phi, \phi)_{L^2(I)} \geq \gamma_{min}(\phi, \phi)_{L^2(I)} \geq 0$, this results in a contradiction with (3.25). ■

Below we derive properties of eigenvalues $\mu < 0$, i.e., eigenvalues for which corresponding unstable stationary solutions exist. Due to Theorem 3.3 these exist only if $\gamma_{min} < 0$ holds.

Lemma 3.4. *Let $\mu < 0$ be such that $J_\mu\phi = 0$ for a $\phi \neq 0$; i.e., (3.21) holds. Then $\mu \in [\mu^*, 0)$ holds, where $\mu^* < 0$ is the unique solution of*

$$\lambda^*(\mu^*) = 0, \qquad \lambda^*(\mu) = \sqrt{-\mu}\tanh\big(\sqrt{-\mu}\, D\big) + \gamma_{min}. \tag{3.26}$$

Proof. Due to $\gamma_{min} < 0$ relation (3.26) has a unique solution. Through $J_\mu\phi = 0$ we arrive at

$$\big(\mathcal{F}^{-1}(\mathbf{d}_\mu * \mathcal{F}\phi), \phi\big)_{L^2(I)} + (\gamma\phi, \phi)_{L^2(I)} = 0. \tag{3.27}$$

For $\mu < \mu^*$ and arbitrary $\phi \neq 0$ we have

$$\begin{aligned}\big(\mathcal{F}^{-1}(\mathbf{d}_\mu * \mathcal{F}\phi), \phi\big)_{L^2(I)} &\geq (d_\mu)_0 \|\phi\|^2_{L^2(I)} = \sqrt{-\mu}\tanh\big(\sqrt{-\mu}\,D\big)\|\phi\|^2_{L^2(I)} \\ &> \sqrt{-\mu^*}\tanh\big(\sqrt{-\mu^*}\,D\big)\|\phi\|^2_{L^2(I)} \\ &= \gamma_{min}\|\phi\|^2_{L^2(I)} \geq -(\gamma\phi, \phi)_{L^2(I)}.\end{aligned}$$

Hence (3.27) cannot hold for $\mu < \mu^*$. ∎

Lemma 3.4 implies that negative eigenvalues must lie in the finite interval $\mu \in [\mu^*, 0)$. The result in the following theorem characterizes the number of negative eigenvalues in this interval.

Theorem 3.5. *Let $\mu^* \leq \mu_1 < \mu_2 < \cdots < \mu_s < 0$ be all μ_i such that $J_{\mu_i}\phi_i = 0$ for some $\phi_i \neq 0$. Assume that for all i the null space of J_{μ_i} is 1D. Let Σ_J be the number of strictly negative eigenvalues (the "index") of $J_0 =: J$ and assume that for each of these eigenvalues the corresponding eigenspace is 1D. Then $s = \Sigma_J$ holds.*

Proof. Let $\lambda(\mu), v(\mu)$ be an eigenpair of J_μ, i.e., $J_\mu v(\mu) = \lambda(\mu)v(\mu)$, with $\|v(\mu)\|_{L^2(I)} = 1$. This implies that

$$\lambda(\mu) = \big(\lambda(\mu)v(\mu), v(\mu)\big)_{L^2(I)} = \big(J_\mu v(\mu), v(\mu)\big)_{L^2(I)}.$$

Differentiation w.r.t. μ is denoted by a prime. Using the symmetry of J_μ we obtain

$$\begin{aligned}\lambda'(\mu) &= \big(J'_\mu v(\mu), v(\mu)\big)_{L^2(I)} + 2\big(J_\mu v(\mu), v'(\mu)\big)_{L^2(I)} \\ &= \big(J'_\mu v(\mu), v(\mu)\big)_{L^2(I)} + 2\lambda(\mu)\big(v(\mu), v'(\mu)\big)_{L^2(I)} \\ &= \big(J'_\mu v(\mu), v(\mu)\big)_{L^2(I)}.\end{aligned}$$

The last equality follows from differentiation of $\|v(\mu)\|^2_{L^2(I)} = 1$ w.r.t. μ. The linear operator J'_μ is given by $J'_\mu\phi = \mathcal{F}^{-1}\big(\hat{\mathbf{d}}_\mu * \mathcal{F}\phi\big)$, with

$$(\hat{d}_\mu)_n = \frac{d}{d\mu}(d_\mu)_n = \frac{d}{d\mu}\Big[\sqrt{(n\pi)^2 - \mu}\tanh(\sqrt{(n\pi)^2 - \mu}\,D)\Big].$$

An elementary computation yields that $-c_0 \leq (\hat{d}_\mu)_n < 0$ holds, where c_0 is a constant independent of n and μ. Thus $-c_0 \leq \big(J'_\mu v(\mu), v(\mu)\big)_{L^2(I)} = \lambda'(\mu) \leq 0$ holds for all $\mu \leq 0$. This means that $\lambda(\mu)$ is a decreasing function with a bounded derivative. For $J_{\mu_i}\phi_i = 0$, $\phi_i \neq 0$ (with a 1D null space), this implies a unique eigenvalue curve $\lambda(\mu)$ which passes through μ_i, i.e., $\lambda(\mu_i) = 0$. Due to the monotonicity of $\lambda(\mu)$ this curve must intersect the negative y-axis, resulting in a corresponding negative eigenvalue of J_0. This implies $s \leq \Sigma_J$. Conversely, let ξ be a negative eigenvalue of J_0. Then there is a unique eigenvalue curve $\lambda(\mu)$ with $\lambda(0) = \xi$. Due to Lemma 3.4 this curve must intersect the μ-axis in the interval $[\mu^*, 0)$. Hence, a unique corresponding $\mu_i \in [\mu^*, 0)$ exists such that $\lambda(\mu_i) = 0$. This implies $\Sigma_J \leq s$. ∎

From Theorem 3.5 it follows that steady-state solutions with $\gamma_{min} < 0$ and $\Sigma_J > 0$ are always unstable. The necessary condition for instability $\gamma_{min} < 0$ is satisfied only if the fluid-heater temperature falls (at least locally) within the transition regime; this implies a fundamental relation between transition boiling and instability.

The results of Theorem 3.5 induce a method for computing the number of negative eigenvalues $\mu \in [\mu^*, 0)$. This number equals the number of negative eigenvalues of the operator $J = J_0$. For the general case of a smooth but nonconstant γ the eigenvalues of J_μ cannot be determined analytically. Thus we apply a discretization method (section 3.2.3) for numerical approximation. Using a sufficiently high resolution, this allows us to determine the correct number of negative eigenvalues (i.e., the same number as for the continuous problem). Moreover, an accurate approximation of the negative continuous eigenvalues can be computed. The resolution needed is not very high due to the fact that the eigenfunctions corresponding to the negative eigenvalues are dominated by low-frequency modes. This is explained in the following remark.

Remark 3. Consider ϕ with $\|\phi\|_{L^2(I)} = 1$ and $\xi < 0$ such that $J\phi = \xi\phi$. Represent ϕ in the cosine basis as $\phi(x) = c_0 + \sum_{n=1}^{\infty} c_n \sqrt{2}\cos(n\pi x)$ (with $\|\phi\|^2_{L^2(I)} = \sum_{n=0}^{\infty} c_n^2 = 1$). Then

$$\left(\mathcal{F}^{-1}(\mathbf{d}_0 * \mathcal{F}\phi), \phi\right)_{L^2(I)} + (\gamma\phi, \phi)_{L^2(I)} = \xi(\phi, \phi)_{L^2(I)} < 0$$

holds, and

$$\begin{aligned}\sum_{n=0}^{\infty} c_n^2 n\pi \tanh(n\pi) &= \left(\mathcal{F}^{-1}(\mathbf{d}_0 * \mathcal{F}\phi), \phi\right)_{L^2(I)} \\ &= -(\gamma\phi, \phi)_{L^2(I)} \le \|\gamma\|_{L^\infty(I)} \|\phi\|^2_{L^2(I)} = \|\gamma\|_{L^\infty(I)}.\end{aligned}$$

Thus c_n must become "smaller" for "larger" n, meaning that, in this sense, the eigenfunction ϕ is dominated by low-frequency modes.

3.2.3. Discretization method. As explained above, the problem of finding eigenvalues of (3.12)–(3.14) has been transformed to the problem of finding μ such that (3.21) has a nontrivial solution. If for some μ an eigenvalue $\lambda(\mu)$ of J_μ equals zero, this μ is an eigenvalue of (3.12)–(3.14). For a general smooth function γ the eigenvalue curves $\lambda(\mu)$ of the operator J_μ cannot be determined analytically. We introduce a discretization method that is used to discretize J_μ and thus determine the eigenvalue curves approximately. We use a Fourier-collocation method [24]: determine $\phi_F(x) := \sum_{n=0}^{N} \widetilde{\phi}_n \cos(n\pi x)$ such that

$$\sum_{n=0}^{N} \{\sqrt{\alpha_{n,\mu}} \tanh(\sqrt{\alpha_{n,\mu}} D) + \gamma(x_k)\} \widetilde{\phi}_n \cos(n\pi x_k) = 0 \quad \text{for all } 0 \le k \le N \tag{3.28}$$

holds, with $x_k = k/N$, $k = 0, \ldots, N$, the collocation points. Note that this is a discrete version of the continuous problem in (3.20). The $N+1$ equations (3.28) for the $N+1$ unknowns $\widetilde{\phi}_n$ can be represented in a compact matrix-vector formulation. To this end we introduce some notation. Let $\boldsymbol{\phi} = (\phi_0, \ldots, \phi_N)^T$ be the vector of nodal values $\phi_n := \phi_F(x_n)$. The latter relate to the truncated Fourier spectrum $\widetilde{\boldsymbol{\phi}} = (\widetilde{\phi}_0, \ldots, \widetilde{\phi}_N)^T$ via

$$\boldsymbol{\phi} = \boldsymbol{V}\,\widetilde{\boldsymbol{\phi}}, \qquad \widetilde{\boldsymbol{\phi}} = \boldsymbol{V}^{-1}\boldsymbol{\phi}, \tag{3.29}$$

with

$$\boldsymbol{V} := \begin{bmatrix} 1 & \cos(\pi x_0) & \ldots & \cos(N\pi x_0) \\ \vdots & \vdots & & \vdots \\ 1 & \cos(\pi x_N) & \ldots & \cos(N\pi x_N) \end{bmatrix} = \boldsymbol{V}^T. \tag{3.30}$$

The relation

$$\boldsymbol{V}^{-1} = \frac{2}{N}\,\boldsymbol{D}\,\boldsymbol{V}\,\boldsymbol{D}, \qquad \boldsymbol{D} = \operatorname{diag}\left(\frac{1}{2}, 1, \ldots, 1, \frac{1}{2}\right) \tag{3.31}$$

holds; i.e., the matrix $\sqrt{\frac{2}{N}}\boldsymbol{V}\boldsymbol{D}$ is orthogonal. Define

$$\boldsymbol{K}_\mu = \boldsymbol{V}\boldsymbol{K}_{S,\mu}\boldsymbol{V}^{-1}, \quad \boldsymbol{K}_{S,\mu} = \operatorname{diag}\big(\sqrt{\alpha_{n,\mu}}D\tanh(\sqrt{\alpha_{n,\mu}}D)\big)_{0\le n\le N}, \tag{3.32}$$

$$\boldsymbol{Q} = \operatorname{diag}\big(D\gamma(x_n)\big)_{0\le n\le N}. \tag{3.33}$$

Note that $\boldsymbol{K}_{S,\mu}$ and $\boldsymbol{Q}$ are both diagonal matrices. The discrete problem (3.28) can be formulated in matrix-vector form as

$$\boldsymbol{J}_\mu\boldsymbol{\phi} = \boldsymbol{0}, \qquad \boldsymbol{J}_\mu := \boldsymbol{K}_\mu + \boldsymbol{Q}. \tag{3.34}$$

In spectral form this becomes

$$\boldsymbol{J}_{S,\mu}\widetilde{\boldsymbol{\phi}} = \boldsymbol{0}, \quad \boldsymbol{J}_{S,\mu} := \boldsymbol{V}^{-1}\boldsymbol{J}_\mu\boldsymbol{V} = \boldsymbol{K}_{S,\mu} + \boldsymbol{Q}_S, \quad \boldsymbol{Q}_S := \boldsymbol{V}^{-1}\boldsymbol{Q}\boldsymbol{V}. \tag{3.35}$$

The eigenvalues μ and eigenfunctions ϕ_F are approximated by those $\mu \in \mathbb{R}$ and $\boldsymbol{\phi} \in \mathbb{R}^{N+1}$ for which $\boldsymbol{\phi}$ is a nontrivial null-vector of $\boldsymbol{J}_\mu$.

Numerical tests for the case study in section 4 revealed that in these (approximate) eigenfunctions, for sufficiently high N, the Fourier coefficients decay exponentially with increasing wave number n. This is consistent with Remark 3 in that the low-frequency modes are indeed dominant. In all our experiments we use a resolution with $N = 128$. This resolution allows a correct determination of the number of negative eigenvalues μ as well as an accurate approximation of their numerical value.

3.3. Steady-state solutions. A detailed analysis of the steady-state behavior of the pool-boiling problem is given in [1]. The approach is in essence similar to that adopted above. The nonlinear 2D steady-state problem (3.7) is reduced to a 1D boundary model via the method of separation of variables. This 1D model is solved (approximately) through numerical approximation with a Fourier-collocation discretization method. The issues relevant in the present context are summarized below.

Application of separation of variables to (3.7) yields a (formal) representation of the solution of the Laplace equation and the linear Neumann boundary conditions on $\Gamma \setminus \Gamma_F$. This results in

$$T_\infty(x,y) = \sum_{n=0}^{\infty} \widetilde{T}_n \frac{\cosh(n\pi y)}{\cosh(n\pi D)}\cos(n\pi x) + \frac{D-y}{\Lambda}, \tag{3.36}$$

which can easily be checked by substitution. The coefficients $\widetilde{T}_n$ form the spectrum of the Fourier cosine expansion

$$T_{F,\infty}(x) := T_\infty(x,D) = \sum_{n=0}^{\infty} \widetilde{T}_n \cos(n\pi x) \tag{3.37}$$

of the temperature profile at the fluid-heater interface Γ_F. These coefficients are determined by the nonlinear Neumann boundary condition on Γ_F. Substitution of (3.36) into the nonlinear boundary condition on Γ_F leads to

$$\sum_{n=0}^{\infty} n\pi \tanh(n\pi D)\widetilde{T}_n \cos(n\pi x) + \eta(T_{F,\infty}(x))T_{F,\infty}(x) - \frac{1}{\Lambda} = 0, \tag{3.38}$$

for all $x \in [0,1]$, where $\eta(T_F) = \frac{\Pi_1}{\Lambda}\frac{q_F(T_F)}{T_F}$ is the scaled heat-transfer coefficient. The nonlinear equation (3.38) is the characteristic equation that determines the particular properties of the steady-state solutions of (3.7). Note the resemblance to relation (3.20).

The reduced steady-state problem (3.38) admits trivial and nontrivial solutions. Trivial solutions are homogeneous interface temperatures, for which $T_{F,\infty}(x) = \widetilde{T}_0$ and $\widetilde{T}_n = 0$ for $n \geq 1$ holds. Then the nonlinear condition (3.38) simplifies to

$$q_F(\widetilde{T}_0) = \Pi_1^{-1}. \tag{3.39}$$

Thus homogeneous solutions coincide with intersection(s) between the heat-flux function q_F and the normalized heat supply given by Π_1^{-1} (Figure 1(b)). Nontrivial, i.e., heterogeneous, solutions $T_{F,\infty}(x)$ that satisfy (3.38) cannot be determined analytically. However, certain properties of such solutions (if they exist) can be derived. One important property, proved in [1], is that such solutions always occur *as conjugate pairs*

$$T_{F,\infty}(x) \quad \text{and} \quad T^*_{F,\infty}(x) := T_{F,\infty}(x + 1/k) \quad \text{for a} \quad k \in \mathbb{N}. \tag{3.40}$$

This means that if $T_{F,\infty}(x)$ is a solution, then (for a certain $k \in \mathbb{N}$) the shifted function $T_{F,\infty}(x + 1/k)$ is a solution, too. This implies nonuniqueness of heterogeneous solutions. Homogeneous steady-state solutions can easily be determined by a standard root-finding method applied to (3.39). Heterogeneous steady-state solutions are computed (approximately) by using a Fourier-collocation discretization method, as described in section 3.2.3, applied to (3.38). This results in a nonlinear system of equations of the form

$$\boldsymbol{\mathcal{G}}(\boldsymbol{T}) := \big(\boldsymbol{K} + \boldsymbol{M}(\boldsymbol{T})\big)\boldsymbol{T} - \boldsymbol{G} = \boldsymbol{0}, \tag{3.41}$$

$\boldsymbol{T} = (T_0, \ldots, T_N)^T$, $T_n := T_{F,\infty}(x_n)$, $\boldsymbol{K} = \boldsymbol{K}_0$, as in (3.32) and

$$\boldsymbol{M} = \operatorname{diag}\big(\eta_n\big)_{0\leq n\leq N}, \quad \eta_n := \eta(T_{F,\infty}(x_n)), \quad \boldsymbol{G} = (1/\Lambda, \ldots, 1/\Lambda)^T. \tag{3.42}$$

The discrete system (3.41) defines a nonlinear set of equations that is solved by a continuation procedure. To this end we introduce a parameterized heat-flux function

$$q_F(T_F; P) := C_D\big(F_1 - PF_2H(C_DT_F - 1)\big)T_F, \quad 0 \leq P \leq 1 \tag{3.43}$$

(cf. (A.1)). In this modified heat-flux function the degree of nonlinearity is controlled through the nonlinearity parameter P. For $P = 0$ function (3.43) reduces to a linear form; for $P = 1$ the physical heat-flux $q_F(T_F)$ is recovered. This P-dependence of q_F induces a P-dependence

of the matrix $\boldsymbol{M}$ via the function η. This is expressed by the notation $\boldsymbol{M}_P$. The continuation procedure is applied to the function

$$P \to \boldsymbol{\mathcal{G}}(\boldsymbol{T}, P) := \big(\boldsymbol{K} + \boldsymbol{M}_P(\boldsymbol{T})\big)\boldsymbol{T} - \boldsymbol{G} = \boldsymbol{0}. \tag{3.44}$$

For each $P \in [0,1]$ the set of *homogeneous* solutions of this system can be easily computed. Starting on a branch of homogeneous solutions, the continuation algorithm determines (pitchfork) bifurcations at which the conjugate solution pairs (3.40) branch off from the homogeneous branch. An extensive treatment of these bifurcation results is given in [1]. In section 4.1 a bifurcation diagram for a representative case study is given.

4. Unsteady boiling problem: An illustrative case study. In this section the concepts introduced above are demonstrated by means of a representative case study. Unless indicated otherwise, the fixed parameter set $\Lambda = 0.2$, $D = 0.2$, $\Pi_2 = 4$, $\Pi_1 = 2$, and $\Pi_3 = 0.37$ (corresponding with $W = 1$; see appendix) is used. The steady-state solutions and corresponding *linear* stability properties are treated in section 4.1. The *nonlinear* (long-term) evolution of perturbed unstable steady-state solutions is investigated in section 4.2 via numerical simulation of (2.1). These results give a numerical validation of the linear stability analysis (section 4.1) and provide insight into the nonlinear stability behavior (section 4.2).

4.1. Steady-state solutions and their linear stability properties.

4.1.1. Homogeneous steady-state solutions. Homogeneous solutions are determined through relation (3.39) and coincide with the intersections between the heat-flux function q_F (solid line) and the normalized heat supply given by Π_1^{-1} (dashed line) in Figure 1(b). Three nondegenerate situations can occur:

Regime $\Pi_1 > \Pi_2$. Relation (3.39) admits one steady-state solution $T_{F,\infty}$ in the nucleate-boiling regime (Figure 2(a)). The local positive slope of the boiling curve ($\dot{q}_F := dq_F/dT > 0$) implies $\gamma > 0$, and thus by Theorem 3.2 we have stability of $T_{F,\infty}$.

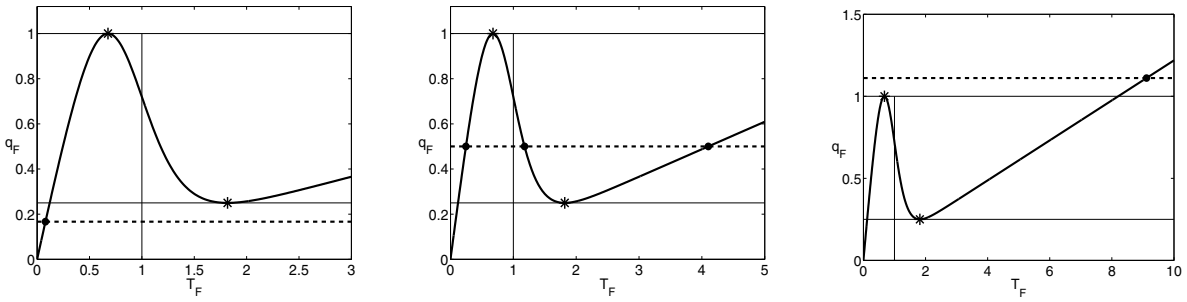
Regime $1 < \Pi_1 < \Pi_2$. Relation (3.39) yields three steady-state solutions (Figure 2(b)): $T_{F,\infty}^{(1)}$ (nucleate boiling); $T_{F,\infty}^{(2)}$ (transition boiling); $T_{F,\infty}^{(3)}$ (film boiling). For $T_{F,\infty}^{(1,3)}$ we have $\gamma > 0$ (due to $\dot{q}_F > 0$), and thus by Theorem 3.2 we have stability of these steady-state solutions. For $T_{F,\infty}^{(2)}$ we have $\dot{q}_F < 0$ and thus $\gamma < 0$. From Theorem 3.2 we conclude that $T_{F,\infty}^{(2)}$ is unstable.

Regime $\Pi_1 < 1$. Relation (3.39) has one steady-state solution $T_{F,\infty}$ in the film-boiling regime (Figure 2(c)). From $\gamma > 0$ and Theorem 3.2 we conclude that this solution is stable.

Cases $\Pi_1 = \Pi_2$ and $\Pi_1 = 1$ are the degenerate cases through which the system switches between one and three homogeneous solutions.

4.1.2. Heterogeneous steady-state solutions.

Steady-state behavior. The study of [1] strongly suggests that heterogeneous solution pairs (3.40) emerge only from pitchfork bifurcations that occur on branches of homogeneous solutions. For *homogeneous* solutions, $\boldsymbol{T} = T_F = \text{constant}$, the Jacobian w.r.t. T of $\boldsymbol{\mathcal{G}}(\boldsymbol{T}; P)$ is



(a) $\Pi_1 > \Pi_2$ (b) $1 < \Pi_1 < \Pi_2$ (c) $\Pi_1 < 1$

Figure 2. *Homogeneous steady-state solution(s) as a function of the system parameters* Π_1 *and* Π_2*. The solutions (dots) coincide with the intersections between the heat-flux function* q_F *(solid lines) and normalized heat supply* Π_1^{-1} *(dashed lines).*

given by

$$\frac{\partial \boldsymbol{\mathcal{G}}(\boldsymbol{T};P)}{\partial \boldsymbol{T}} =: \hat{\boldsymbol{J}}_P(\boldsymbol{T}) = \boldsymbol{V}\boldsymbol{\Lambda}_P\boldsymbol{V}^{-1}, \qquad \boldsymbol{\Lambda}_P = \operatorname{diag}\big(n\pi\tanh(n\pi D) + \gamma_P(T_F)\big)_{0\le n\le N}, \tag{4.1}$$

with $\gamma_P(Z) = \frac{\Pi_1}{\Lambda}\frac{\partial q_F(Z;P)}{\partial Z}$. Note that for $P = 1$ (i.e., $q_F(Z;1) = q_F(Z)$) *this Jacobian is equal to the matrix* $\boldsymbol{J}_0$ in (3.34): $\hat{\boldsymbol{J}}_1 = \boldsymbol{J}_0$. The origin of this identity lies in the fact that for $\mu = 0$ the *linear* eigenvalue problem (3.12)–(3.14) (which has a corresponding discrete boundary operator $\boldsymbol{J}_0$ as in (3.34)) is the same as the *linearization* of the stationary problem in (3.7) (which has a corresponding discrete boundary operator $\hat{\boldsymbol{J}}_1$ as in (4.1)).

The eigenvalues and corresponding eigenvectors of $\hat{\boldsymbol{J}}_P$ are given by

$$\lambda_n = n\pi\tanh(n\pi D) + \gamma_P(T_F), \quad \boldsymbol{v}_n = (\cos(n\pi x_0),\dots,\cos(n\pi x_N))^T, \quad 0 \le n \le N. \tag{4.2}$$

The eigenvector $\boldsymbol{v}_n$ coincides with the nth Fourier mode. The Jacobian is singular if one or more of its eigenvalues λ_n vanish. Because $n\pi\tanh(n\pi D) \ge 0$ for all $n \ge 0$, this can happen only if $\gamma(T_F) \le 0$. Thus a bifurcation on a homogeneous solution branch can occur only for those T_F for which the boiling curve has a negative slope. Only the intersection $T_F^{(2)}$ satisfies this criterion. This explains why bifurcations are restricted to the $T_F^{(2)}$-branch in the bifurcation diagram (Figure 3). This implies that bifurcations—and thus multiple (heterogeneous) solutions—can occur only for surface temperature values in the transition range of the boiling curve. Figure 3 shows the bifurcation diagram as a function of the nonlinearity parameter P [1]. The heavy curves are the solution branches corresponding to the homogeneous solutions $T_{F,\infty}^{(1,2,3)}$. The lower (nearly horizontal) branch coincides with the intersection $T_{F,\infty}^{(1)}$ that exists for all $0 \le P \le 1$; the upper branch, with turning point at P_B (here $P_B \approx 0.926$), coincides with the two intersections $T_{F,\infty}^{(2,3)}$ that exist only in the interval $P_B \le P \le 1$. The lower and upper legs of this upper branch (connected at the turning point) correspond to $T_{F,\infty}^{(2)}$ and $T_{F,\infty}^{(3)}$, respectively. The solid curves are the heterogeneous solution branches that originate from pitchfork bifurcations (dots) on the $T_{F,\infty}^{(2)}$-branch and from left to right correspond with the single vanishing eigenvalue $\lambda_n = 0$ for $n = 1, 2, 3$. The corresponding

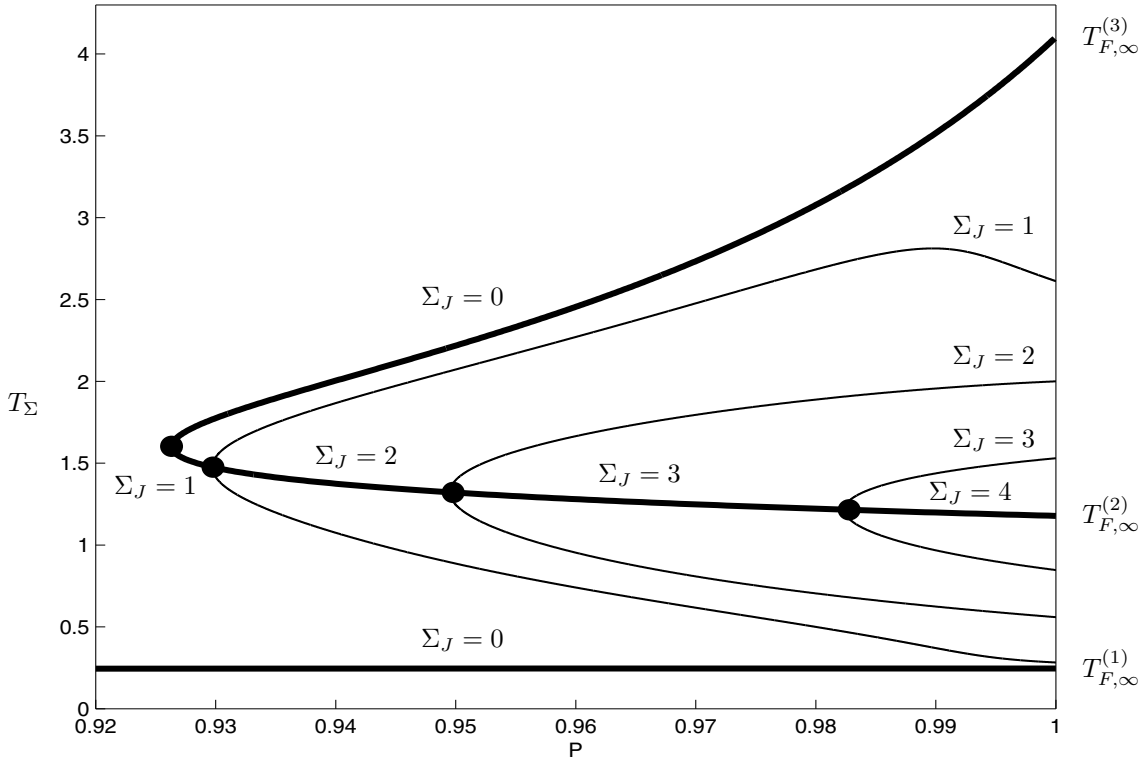


Figure 3. *Bifurcation diagram for the nonlinearity parameter P. Heavy curves correspond to homogeneous solutions; normal curves correspond to heterogeneous solutions. Filled circles represent bifurcations. The leftmost bifurcation is the tangent bifurcation that leads to multiple homogeneous solutions; the bifurcations from which the heterogeneous branches emerge are pitchfork bifurcations. Included also is the corresponding index Σ_J (section 4.1.3).*

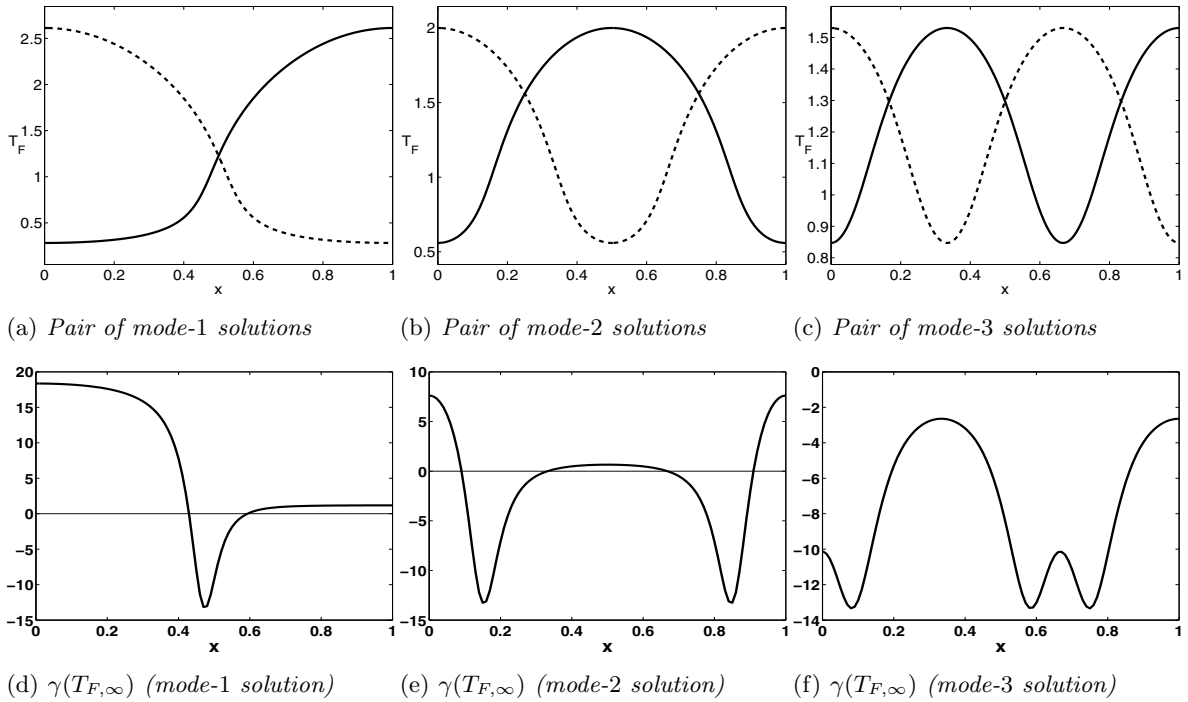
eigenvector $\boldsymbol{v}_n$ determines the form of the bifurcating heterogeneous solution and equals the nth Fourier mode. These heterogeneous solutions that originate from the bifurcation point corresponding to λ_n are called "mode-n" solutions. The lower and upper legs in a pitchfork bifurcation correspond to $T_{F,\infty}$ and its conjugate $T_{F,\infty}^*$, respectively; cf. (3.40).

The final states ($P = 1$) in the bifurcation diagram (Figure 3) correspond to the physically meaningful steady-state solutions to the boiling problem (2.1). Figure 4 (top row) shows the boundary profiles $T_{F,\infty}$ associated with the pairs of steady-state mode-n solutions, where solid and dashed lines indicate $T_{F,\infty}$ and its conjugate $T_{F,\infty}^*$, respectively. Figure 4 (bottom row) gives the profiles of the function $\gamma(x)$ from (3.10) corresponding to $T_{F,\infty}$.

4.1.3. Qualitative linear stability properties. Theorems 3.3 and 3.5 state that the qualitative stability (i.e., stable or unstable) of the heterogeneous mode-n solutions depends on γ_{min} and the index Σ_J. The boundary profiles (Figure 4) show that for all cases we have $\gamma < 0$—and hence transition boiling—on one or more sections of the boundary Γ_F (Figures 4(d)–(f)). This implies that $\gamma_{min} < 0$ and thus rules out unconditional stability (Theorem 3.3); stability properties depend on the quantity Σ_J as defined in Theorem 3.5. We generalize the definition of Σ_J by defining Σ_J as the P-dependent number of negative eigenvalues of the



(a) *Pair of mode-1 solutions* (b) *Pair of mode-2 solutions* (c) *Pair of mode-3 solutions*

(d) $\gamma(T_{F,\infty})$ *(mode-1 solution)* (e) $\gamma(T_{F,\infty})$ *(mode-2 solution)* (f) $\gamma(T_{F,\infty})$ *(mode-3 solution)*

Figure 4. *Heterogeneous steady-state (mode-n) solutions of the boiling problem. The top row gives the boundary profiles $T_{F,\infty}$ (solid) and $T^*_{F,\infty}$ (dashed) of the pairs of mode-n solutions. The bottom row gives coefficient γ corresponding with $T_{F,\infty}$; $\gamma < 0$ indicates regions of transition boiling.*

Jacobian $\hat{\boldsymbol{J}}_P$ from (4.1). The identity $\hat{\boldsymbol{J}}_1 = \boldsymbol{J}_0$ means that for $P = 1$ this generalized Σ_J coincides with the Σ_J as defined in Theorem 3.5 (provided that the resolution is high enough to determine the correct number of negative eigenvalues; cf. Remark 3). Thus the linear stability properties of the steady-state solutions follow directly from the bifurcation analysis visualized in Figure 3. On the homogeneous branches Σ_J can be easily computed using (4.2). Computational analysis reveals that on the heterogeneous solution branches no further bifurcations occur, apart from the pitchfork bifurcation points at the intersection with the homogeneous branch. Thus Σ_J remains constant along a heterogeneous branch, meaning that Σ_J for $P = 1$ (the relevant quantity for Theorem 3.5) equals Σ_J at the underlying bifurcation. The value for Σ_J at $P = 1$ is computed numerically. The values for Σ_J corresponding with each solution branch are indicated in Figure 3. For all heterogeneous solutions we have $\Sigma_J > 0$ at $P = 1$, and, thus, due to Theorem 3.5, *all heterogeneous solutions are unstable.* Moreover, Σ_J—and thereby the number of unstable modes (Theorem 3.5)—increases with each bifurcation. In this sense mode-n solutions become more unstable for higher n. The change of the value of Σ_J at the bifurcation points and its effect on the linear stability properties are closely related to the "exchange of stability principle"; cf. [23].

The linear stability analysis shows that the pool-boiling problem is linearly bistable. The homogeneous nucleate-boiling ($T_F^{(1)}$) and film-boiling ($T_F^{(3)}$) states are the only stable states; other steady states are always unstable. The bistability implies that the system has two basins of attraction, associated with the two stable states $T_F^{(1)}$ and $T_F^{(3)}$, divided by a separatrix

formed by the *stable* manifolds of the *unstable* solutions [19].

The bistability established above is entirely consistent with laboratory experiments on physical boiling systems [6, 25, 26]. The homogeneous nucleate-boiling and film-boiling states are the only hitherto known stable states of such systems and thus are the only steady-state solutions that may occur naturally. The bistability admits the boiling system (for specific perturbations) to transit from nucleate to film boiling and vice versa via intermediate—and highly unstable—heterogeneous states. The triggering mechanisms behind such transitions and the ensuing evolution of the boiling states remain ill understood to date, however. Consequently, prevention of, in particular, the transition from nucleate to film boiling, or "burnout" [16], remains *the* key challenge in industrial boiling processes (section 1). The bistability furthermore implies the absence of stable homogeneous boiling states outside the nucleate-boiling and film-boiling regimes. This poses formidable challenges for reproducible measurements of the boiling curve in the transition-boiling regime; namely, boiling conditions are assumed homogeneous along the entire boiling curve (section 2). Active stabilization of transition boiling during boiling-curve measurements offers a way for attainment of such conditions [27]. However, it appears that accomplishment of homogeneous transition boiling is not always possible, despite successful stabilization. This significantly complicates boiling-curve measurements, which implicitly assume a homogeneous state.

4.1.4. Quantitative linear stability properties. The *unstable* heterogeneous solutions develop into essentially unsteady states in the case of some nonzero initial perturbation $v_0(\boldsymbol{x})$. In practice, such perturbations are always present. Hence, the heterogeneous steady-state solutions cannot be sustained by the system and must undergo some evolution in time. This evolution depends largely on the unstable eigenmode(s) $\psi_k(\boldsymbol{x})$, i.e., for which the corresponding eigenvalue μ_k is negative, according to (3.17).

Figure 5 gives the sequence of eigenvalues $\mu_1 < \mu_2 < \cdots$ corresponding with the mode-n solutions ($n = 1, 2, 3$). The number of negative eigenvalues equals $n = \Sigma_J$, consistent with the values of the index Σ_J in Figure 3. Furthermore, the magnitude $|\mu_k|$ of the negative eigenvalues grows—implying higher growth rates of perturbations—with increasing n. Figure 6 shows the boundary profiles of the unstable eigenmodes $\psi_k(\boldsymbol{x})$, with corresponding μ_k-values as indicated, associated with the mode-n solutions. Figure 7 gives the three unstable modes of the mode-3 solution in the whole domain $\mathcal{D}$. Note that due to the maximum principle the extrema of ψ_k occur at the boundary of $\mathcal{D}$. The mode-1 solution has only one unstable eigenmode. This mode dominates the evolution of the instability, largely independent of the initial perturbation. The mode-2 and mode-3 solutions have multiple unstable eigenmodes with associated eigenvalues of comparable magnitude, and, consequently, the space spanned by these modes has dimension larger than one. Thus the evolution of the instability becomes essentially dependent upon the initial perturbation and allows a much richer spatial structure compared to the mode-1 case.

4.1.5. The role of heater properties in the stability behavior. The inherent instability of transition boiling greatly hampers reliable and reproducible laboratory experiments on boiling heat transfer under transition conditions. The heater properties are important design parameters for such transition experiments [14]. Our pool-boiling model enables examination

of the role of the heater properties in the stability behavior of pool-boiling systems under representative conditions (i.e., heterogeneous boiling states on realistic heaters) and may thus be beneficial for the design of laboratory experiments. To this end a short exploratory study, as a prelude to future work, is given below.

In the present model the heater properties are described by the parameters Λ (thermal conductivity) and D (heater thickness). In the case study we investigate the changes in stability properties of the heterogeneous solutions induced by variation of Λ or D. The instability is quantified in terms of the eigenvalue $\mu_1 < 0$ of the most unstable eigenmode. Figure 8 gives μ_1 as a function of Λ (panel (a)) and D (panel (b)) for the mode-n heterogeneous steady-state solutions (symbols), the homogeneous transition solution $T_F^{(2)}$ (with $\mu_1 = z_1^-$ as in Theorem 3.2), and the lower bound μ_* according to (3.26). The dashed vertical line indicates the parameter value used in the case study. (The plots actually show $-\mu$ so as to facilitate the logarithmic scale.) Both graphs reveal that the number of mode-n solutions decreases with both increasing Λ and increasing D. Beyond $\Lambda \approx 1.2$ mode-n solutions have vanished altogether; beyond $D \approx 0.1$ the system settles for three mode-n solutions and effectively becomes independent of the heater thickness for $D \gtrapprox 0.5$. Thus increasing thermal conductivity and/or the heater thickness promotes homogeneity and uniqueness of boiling states. This is consistent with results in [1].

In Figure 8(a) one can observe the bifurcation of mode-n profiles from the $T_F^{(2)}$-profile with decreasing thermal conductivity Λ. (For D essentially the same happens. This is less apparent in Figure 8(b), though.) The instability of the mode-n solutions is stronger (in the sense that $|\mu_1|$ increases) for larger n, and $T_F^{(2)}$ appears to be the most unstable solution. Physically, this may be explained by the fact that the portion of the interface on which the temperature is in the transition regime (i.e., where $\gamma < 0$) grows with n and is maximal for the homogeneous state $T_F^{(2)}$.

The mode-n solutions for $n > 1$ become more unstable (larger $|\mu_1|$) for increasing Λ and/or D. For the homogeneous solution $T_F^{(2)}$, on the other hand, this lessens the instability. For the mode-1 solution $|\mu_1|$ exhibits a nonmonotonic dependence on Λ and on D. These observations reveal that the dependence of the stability behavior on changes in the heater properties is related to the kind of steady-state solution. For the mode-n ($n > 1$) solutions, increasing heater thickness D and/or thermal conductivity Λ amplifies instability, whereas for the homogeneous solution $T_F^{(2)}$ this dampens instability.

The above results strongly suggest that, despite significant quantitative variations in μ_1, the instability itself remains under all conditions and that, in consequence, the existence of stable heterogeneous solutions for specific heater properties is therefore highly unlikely. Laboratory experiments support this assertion (consult [14] for a survey). This consolidates the widely accepted observation that active stabilization, via, e.g., the methodology by [6], is essential for detailed experimental studies on homogeneous boiling states in the transition region and on any heterogeneous boiling state. Moreover, this confirms that the stability analysis of [28] is erroneous, as already pointed out by [15]. Haramura [28] studied the stability of homogeneous boiling states on the fluid-heater interface of a 3D heater with constant heating in the transition boiling regime (i.e., $\gamma < 0$) and derived critical conditions for which the homogeneous boiling state supposedly becomes unstable. These critical conditions are in contradiction to findings in previous studies (e.g., [14, 8]) as well as to those in the present study.

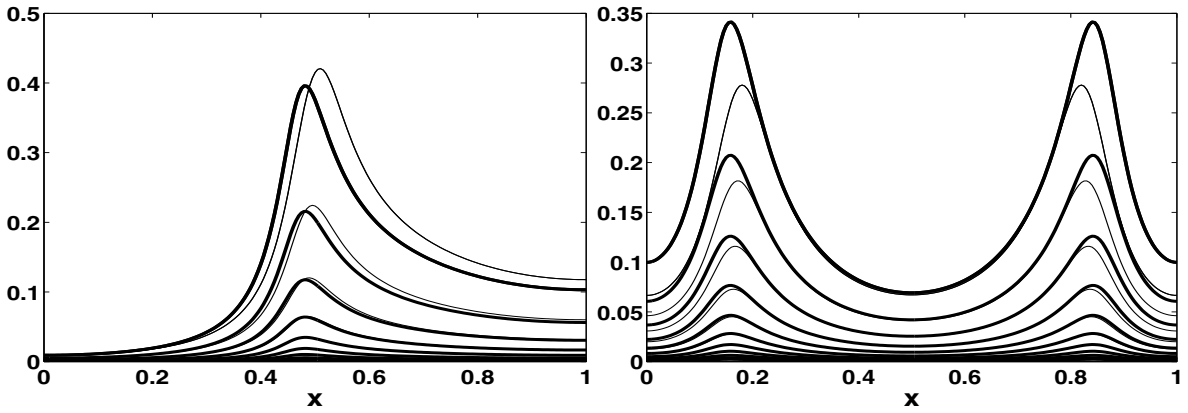
4.2. Evolution of perturbed unstable steady-state solutions. The *nonlinear* long-term evolution of perturbed unstable steady-state solutions, i.e., the *nonlinear* (in)stability behavior, can be determined via numerical simulation of (2.1). We used a spectral tau method based on Fourier (x) and Chebyshev (y) expansion of $T(\boldsymbol{x}, t)$ for spatial discretization in combination with a second-order Crank–Nicolson time-marching scheme [24]. The nonlinearity on the interface Γ_F has been dealt with by Picard iteration [29].

Numerical studies of (2.1) serve two purposes, namely, validation of the linear stability analysis (section 3.2) and gaining first insight into the nonlinear stability behavior of the pool-boiling system. These two topics are addressed in section 4.2.1 and section 4.2.2, respectively.

4.2.1. Validation of the linear stability analysis. The spectral scheme proposed above is used for the numerical simulation of the linearized heat-transfer model (3.8). Tests with various identical initial conditions $v_0(\boldsymbol{x})$ for each of the steady-state solutions T_∞ reveal that solutions $v(\boldsymbol{x}, t)$ obtained through the linear model (3.8) and the expansion (3.17) coincide within machine accuracy. This validates the eigenmode decomposition (3.17).

A second issue is a comparison of the evolution of the perturbation $v(\boldsymbol{x}, t)$ in the *non*linear model (2.1) and in the eigenmode decomposition (3.17). Tests reveal that in both cases the stability properties are qualitatively the same: heterogeneous steady-state solutions are unstable, and the homogeneous nucleate-boiling and film-boiling states are stable. This provides strong evidence that the pool-boiling system is *non*linearly bistable as well.

Quantitative validation of the linear stability analysis and establishment of a range of validity of the linear approximation follow from investigation of two representative heterogeneous cases, namely, the steady-state mode-1 and mode-2 solutions. As initial perturbation we take $v_0(\boldsymbol{x}) = \epsilon\psi_1(\boldsymbol{x})$, with $\epsilon = 0.01$ and ψ_1 the first eigenfunction (normalized) of (3.12)–(3.14).



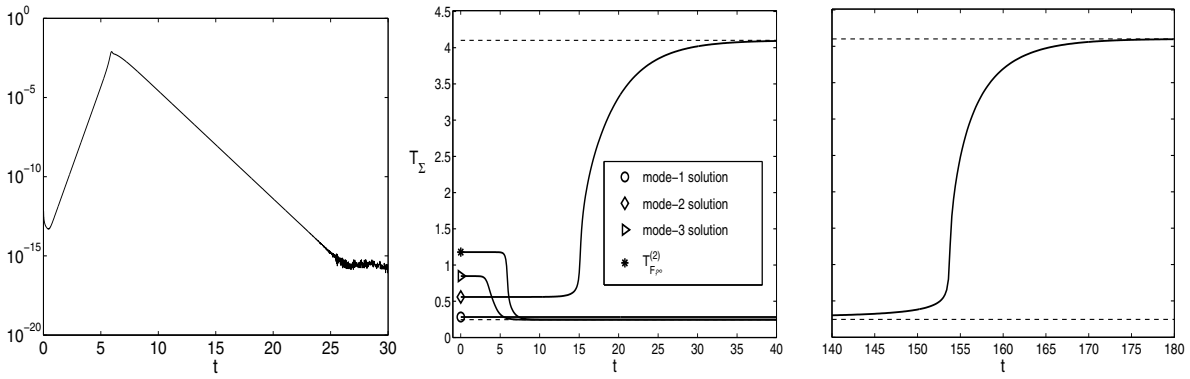
(a) *Mode-1 solution* (b) *Mode-2 solution*

Figure 9. *Solutions $v(\boldsymbol{x},t)$ of the linear approximation (3.11) (heavy lines) and of the nonlinear model (thin lines) for the mode-1 (panel (a)) and mode-2 (panel (b)) steady-state solutions. Initial perturbation is $v_0(\boldsymbol{x}) = 0.01\psi_1(\boldsymbol{x})$. The curves correspond to time steps $\Delta t = 5$ (mode-1) and $\Delta t = 0.5$ (mode-2).*

Figure 9 shows the profiles at the interface Γ_F at several time instances t corresponding with the solutions to the nonlinear model and the linearized problem. (For the nonlinear model we give the departure $v(\boldsymbol{x},t) = T(\boldsymbol{x},t) - T_\infty(\boldsymbol{x})$ from the initial state.) The more pronounced peaks correspond with more advanced time levels. The results show a good agreement between linear approximation and nonlinear evolutions for a significant time interval.

4.2.2. Nonlinear stability analysis. The present case study involves the following unstable steady-state solutions: the homogeneous solution $T^{(2)}_{F,\infty}$ in the transition-boiling regime and the three pairs of mode-n solutions. Perturbations are not imposed explicitly but are due to rounding errors in the machine representation of the initial condition. This implies a machine-dependent yet reproducible perturbation. These small perturbations are sufficient to trigger evolution of the unstable states. We use the functionals $T_\Sigma = \sum_n \widetilde{T}_n$ and $\mathcal{K}(k\Delta t) = \|\mathbb{T}^k - \mathbb{T}^{k-1}\|/\|\mathbb{T}^k\|$, where $\mathbb{T}^k$ is the matrix consisting of all coefficients in the discrete Fourier–Chebyshev series of the solution at $t = k\Delta$, as measures for quantifying the evolution. The mode-n solutions always occur as pairs (3.40). We consider only one solution of this pair (lower legs of the heterogeneous branches in Figure 3).

Figure 10(a) demonstrates the dynamical behavior of the system during transition from unstable to stable steady states via the measure of unsteadiness $\mathcal{K}(t)$ for the unstable homogeneous solution $T^{(2)}_{F,\infty}$. The progression clearly reveals that the evolution of the temperature field accelerates (i.e., $\mathcal{K}(t)$ grows continuously) up to a turning point at $t \approx 6$, where the situation reverses and a deceleration sets in that continues until a stable steady state is reached at $t \approx 25$. (The erratic evolution beyond $t \approx 25$ is due to fluctuations around the steady state at machine-accuracy level.) The mode-n solutions exhibit essentially similar behavior as that shown in Figure 10(a); differences are entirely quantitative in that turning points and attainment of stable steady states occur at different instances in time. Figure 10(b) gives the evolution from unstable to stable steady states in terms of the functional $T_\Sigma(t)$ (split into two frames.) The unstable homogeneous solution $T^{(2)}_{F,\infty}$ and the mode-3 solutions progress towards



(a) $\mathcal{K}(t)$ *for* $T^{(2)}_{F,\infty}$. (b) *Progression towards one of the two stable steady states.*

Figure 10. *Evolution of perturbed unstable steady-state solutions towards a stable state. Panel* (a) *shows the initial acceleration and subsequent deceleration of the evolution with the measure of unsteadiness* $\mathcal{K}(t)$ *for the unstable homogeneous solution* $T^{(2)}_{F,\infty}$. *Panel* (b) *gives the progression of the unstable states (as indicated) towards one of the two stable steady states (dashed lines) in terms of the functional* $T_\Sigma(t)$. *(Split into two frames, the right frame concerns only the mode-*1 *solution.) Only the parent solution* T_F *of each conjugate pair* (3.40) *is included.*

the stable steady-state solution $T^{(1)}_{F,\infty}$ in the nucleate-boiling regime (lower dashed line); the mode-1 and mode-2 solutions progress towards the stable steady-state solution $T^{(3)}_{F,\infty}$ in the film-boiling regime (upper dashed line). The sharp transitions of the evolutions occur around the aforementioned turning points and reflect the fact that the changeover from unstable to stable states happens rather abruptly within a relatively narrow time window. Moreover, this changeover takes place earlier, suggesting stronger instability, with decreasing length scales of the heterogeneous features (higher n) of the mode-n solutions. This is in qualitative agreement with experimental observations [9].

Figure 11 gives the evolutions of the profiles of the interface temperature T_F for each of the unstable steady-state solutions in Figure 10(b) at equidistant time intervals, where the arrows indicate progression in time. (Time intervals are different for each case and are set proportional to the duration of the entire evolution.) The heavy dashed profiles correspond with the intermediate state at the respective turning points; the lower and upper dashed lines indicate the stable nucleate-boiling and film-boiling states, respectively. The evolution of the profiles nicely illustrates the progression towards either the nucleate-boiling state (panels (a) and (d)) or the film-boiling state (panels (b) and (c)). Note that for the unstable homogeneous case $T^{(2)}_{F,\infty}$ (panel (a)) the profile remains homogeneous throughout the evolution. Moreover, the expansion and subsequent condensation of the profiles before and after the turning point (heavy dashed lines) demonstrate the initial acceleration and the subsequent deceleration of the evolution. The acceleration phase of the mode-n solutions is characterized by rapid smoothing of the heterogeneous features (panels (b)–(d)); during the subsequent deceleration phase the (approximately) homogeneous intermediate state gradually tends to the ultimate stable state.

5. Conclusions. In this paper we consider a 2D nonlinear heat-transfer problem as a model for pool-boiling systems. The model problem involves only the temperature distribu-

tion within the heater and models the heat exchange with the boiling medium via a nonlinear boundary condition imposed at the fluid-heater interface. This results in a linear parabolic partial differential equation (heat equation) with a nonlinear Neumann boundary condition at the fluid-heater interface. Important information about the (qualitative) behavior of this dynamical system can be obtained from its steady-state solutions and the corresponding stability properties. The steady-state behavior has been studied in [1]. The main topic of the present study is the corresponding stability behavior. To this end a linear (short-term) and a nonlinear (long-term) stability analysis are performed.

In the linear stability analysis the linearized heat-transfer model is, by separation of space

and time, reduced to a nonlinear eigenvalue problem that depends only on the two spatial variables. Separation of the two spatial variables subsequently leads to a nonlinear spatially *one*-dimensional problem for the eigenvalues. Analysis of the latter problem yields generic stability properties for steady-state solutions. These are demonstrated and validated by numerical simulations in a representative case study. One of the main conclusions is that the (linearized as well as nonlinear) system is bistable: all steady-state solutions, except the homogeneous nucleate-boiling and film-boiling states, are inherently unstable. Perturbed unstable states always progress towards one of these two stable states. Our study furthermore strongly suggests that these stability properties are qualitatively independent of heater properties (thermal conductivity Λ and thickness D). Changes in heater properties affect the stability properties of the system only in a quantitative manner. Thus the present study rigorously demonstrates the bistability of pool-boiling systems, which is consistent with laboratory experiments [6] and other theoretical studies [10, 12, 14, 13].

The numerical simulations for the case study provide evidence that there is a strong analogy between the nonlinear heat-transfer problem and generic nonlinear parabolic evolution equations, which typically have a nonlinearity in the partial differential equation. This analogy suggests the fundamental property that the dynamical behavior of the system is dominated by a global attractor made up of steady-state solutions and corresponding heteroclinic connections (section 3.1). Both the linear and nonlinear stability behavior that we observe in the pool-boiling system indicate that this property holds. Although many stability results, based on both theoretical analysis and numerical experiments, are derived in this paper, a complete rigorous mathematical analysis of the dynamics of the pool-boiling model is not yet available.

Recent studies revealed that the steady-state behavior and the mathematical structure of 3D pool-boiling problems is essentially similar to that of the simplified 2D case considered here [2]. This means that the stability behavior found in the present work in principle extends to the 3D case. Moreover, the present analysis may form the basis for future research on active stabilization of unstable heterogeneous boiling states by extending the model with a temperature-control loop similar to that proposed in [14].

Appendix. Heat-flux function. The heat-flux function $q_F(Z;\Pi_2,\Pi_3)$ is given by

$$q_F(Z) = h(Z)Z, \tag{A.1}$$

with

$$h(Z) = C_D\left\{F_1 - F_2 H(C_D Z - 1)\right\}, \qquad H(\zeta) = \frac{1}{2}\left[\tanh\left(\frac{2\zeta}{W}\right) + 1\right]. \tag{A.2}$$

The function $H(\zeta)$ is a smoothed Heaviside function. The parameter $W > 0$ controls the width of the transient (from $H = 0$ to $H = 1$) around $\zeta = 0$ and is specified a priori. The value of W indirectly sets the physical parameter Π_3. The coefficient C_D rescales the argument Z such that the single deflection point of q_F coincides with $Z = 1$; i.e., $q_F''(1) = 0$. Its value is defined implicitly through

$$2\frac{dH}{d\zeta}(C_D - 1) + C_D\frac{d^2H}{d\zeta^2}(C_D - 1) = 0 \tag{A.3}$$

and thus depends only on W. It can be shown that q_F as in (A.1) possesses a local maximum and minimum at $Z_{max} < 1$ and $Z_{min} > 1$, respectively. Introduction of the scaling factors F_1 and F_2, which scale q_F such that the conditions

$$q_F'(Z_{max}) = 0, \quad q_F'(Z_{min}) = 0, \quad q_F(Z_{max}) = 1, \quad q_F(Z_{min}) = \Pi_2^{-1} \tag{A.4}$$

are fulfilled, then results in a heat-flux function that is consistent with the physical boiling curve. For given Π_2 and W the conditions (A.4) result in four nonlinear equations that can be solved for the four unknowns $(F_1, F_2, Z_{min}, Z_{max})$.

Regularity Properties of Critical Invariant Circles of Twist Maps, and Their Universality*

Arturo Olvera† and Nikola P. Petrov‡

Abstract. We accurately compute the golden and silver critical invariant circles of several area-preserving twist maps of the cylinder. We define some functions related to the invariant circle and to the dynamics of the map restricted to the circle (for example, the conjugacy between the circle map giving the dynamics on the invariant circle and a rigid rotation on the circle). The global Hölder regularities of these functions are low (some of them are not even once differentiable). We present several conjectures about the universality of the regularity properties of the critical circles and the related functions. Using a Fourier analysis method developed by de la Llave and one of the authors, we compute numerically the Hölder regularities of these functions. Our computations show that—within their numerical accuracy—these regularities are the same for the different maps studied. We discuss how our findings are related to some previous results: (a) to the constants giving the scaling behavior of the iterates on the critical invariant circle (discovered by Kadanoff and Shenker) and (b) to some characteristics of the singular invariant measures connected with the distribution of iterates. Some of the functions studied have pointwise Hölder regularity that has different values at different points. Our results give convincing numerical support to the fact that the points with different Hölder exponents of these functions are interspersed in the same way for different maps, which is a strong indication that the underlying twist maps belong to the same universality class. In particular, the numerical results on the regularity of the so-called big conjugacies imply that the Hölder spectra of the functions conjugating the dynamics on the critical invariant circle to a rigid rotation are the same. This, in turn, shows that the invariant measures on the critical circles have the same singularity spectra.

1. Introduction.

It has been known since the late 1970s and early 1980s that many objects at the boundary of chaotic behavior exhibit remarkable scaling properties and that, furthermore, these properties are "universal." Such properties are exhibited by unimodal maps of the interval [1, 2] and [3] (reprinted in [59]), critical maps of the circle [4] (reprinted in [59]), critical KAM tori [5, 6], and other systems. These observations have been explained in terms of a renormalization group analysis, following a methodology that had been developed earlier in the study of critical phenomena in statistical mechanics and field theory [7, 8, 9], [10]

(reprinted as a book [11]), and [12] (reprinted in [61]).

The scale invariance of the critical objects affects many of their properties. Notably, the Hölder regularity of the critical objects (or some functions related to them) tends to have a low and fractional value. Presumably the values of the regularities are related to exponents and geometric properties of the renormalization group fixed points which describe the critical objects.

Furthermore, the observation that critical objects can be divided into "universality classes" such that all objects in a given class "look the same" can be tested numerically. One way to do this is to define certain functions related to the critical objects—typically these functions are not very regular (in some cases not even once differentiable)—and to test numerically whether the regularities of these functions are the same for different objects. Another—even more sensitive—test for universality is to take two functions, say h_1 and h_2, from the same class, and to study the regularity of functions such as $H_{1,2} := h_1 \circ h_2^{-1}$—for h_1 and h_2 belonging to the same universality class, one can expect $h_1 \circ h_2^{-1}$ to be more regular than h_1 and h_2^{-1}. From the fact that $H_{1,2}$ is more regular than h_1 and h_2^{-1} one can also draw important conclusions about the pointwise Hölder regularity of the functions h_i. If the Hölder regularity of the functions h_i has different values at different points (as in the case we consider), then one can conclude that the points at which the function h_1 has certain values of the pointwise Hölder exponent are interspersed in the same way as the corresponding points for the function h_2 (for more precise statements, see sections 2.6 and 5.3).

The idea of using the regularity of a function as an indicator for the universality class was tested in [13] in the case of noncritical and critical (with different degree of criticality) circle maps, in which the empirical results are accompanied by an extensive mathematical theory. A substantial part of the effort in [13] was to develop implementations of methods known in harmonic analysis (finite differences, Littlewood–Paley theory, wavelet analysis) to assess the regularity of the objects numerically.

In the present paper, we extend the methodology of [13] to the study of critical invariant circles of area-preserving twist maps. Invariant circles in dynamical systems are among the most important objects that organize the long-term behavior of the system, and the critical ones are especially important because of their role as "last barriers to chaos" (for readable reviews see, e.g., [14] or, with more emphasis on the mathematical aspects, the recent book [15]). Critical invariant circles have been studied extensively since the early 1980s [5, 6, 10, 12].

We accurately compute the golden critical invariant circles of several standard-like area-preserving twist maps and some functions related to the dynamics of the iterates of the maps on these circles. Then we apply methods developed in [13] to study the Hölder regularity of these functions and some universality aspects. We also perform some computations in the case of critical invariant circles with rotation number equal to the silver mean.

In section 2 we give some background on twist maps and their critical invariant circles, define the functions that are the objects of our numerical study, and present several precise conjectures concerning the properties of the critical invariant circles and the functions introduced. Section 3 is devoted to a discussion of the numerical methods used to compute critical invariant circles and to assess Hölder regularity of functions. We collect our results in section 4, and in section 5 we discuss their significance and relationship with previous studies.

2. Critical invariant circles of twist maps.

2.1. Twist maps. Let $\mathbb{T} := \mathbb{R}/\mathbb{Z}$ stand for the circle. We will be concerned with maps F of the (infinite) cylinder $\mathbb{T} \times \mathbb{R}$,

$$F : \mathbb{T} \times \mathbb{R} \to \mathbb{T} \times \mathbb{R} : (\theta, r) \mapsto F(\theta, r) =: (\theta', r') \ ,$$

which satisfy the following properties:

- *Area preservation.* The map F preserves the oriented area: $\det DF = 1$.
- *Zero-flux.* The oriented area between a homotopically nontrivial circle and its image under F is 0. (In our situation, this is equivalent to saying that every nontrivial circle intersects its image.)
- *Twist condition.* For any fixed value of θ, $\frac{\partial \theta'}{\partial r} > 0$.

A map of the cylinder can be identified with a map $\tilde{F} : \mathbb{R}^2 \to \mathbb{R}^2$ (called a *lift* of F) which satisfies

$$\tilde{F}(\theta + 1, r) = \tilde{F}(\theta, r) + (1, 0) \ .$$

Often one does not need to keep the distinction.

The maps which we will use in our numerical studies are of the form $(\theta', r') := F(\theta, r)$ with

$$\begin{aligned} \theta' &= (\theta + r') \bmod 1 \ , \\ r' &= r + \lambda V(\theta) \ , \end{aligned} \tag{2.1}$$

where λ is a parameter and $V : \mathbb{T} \to \mathbb{R}$ is a function satisfying $\int_0^1 V(\theta)\, d\theta = 0$. In particular, many numerical studies have been devoted to studying (2.1) with

$$V(\theta) = -\frac{1}{2\pi} \sin 2\pi\theta \ , \tag{2.2}$$

in which case we will call the map F the *Taylor–Chirikov* map. In our studies we used six functions V (given in section 4.1), all of them odd. The fact that the functions V are odd allows us to use the technique of the symmetry lines described in section 3.1 in order to compute periodic orbits of F. Of course, one would expect that the same results hold for any V, not only for odd ones.

Given an orbit $\mathcal{X} = \{(\theta_n, r_n) = F^n(\theta_0, r_0) \mid n = 0, 1, 2, \ldots\}$, we define its *rotation number*, $\rho(\mathcal{X})$, as the limit

$$\rho(\mathcal{X}) := \lim_{n \to \pm\infty} \frac{\tilde{\theta}_n - \theta_0}{n}$$

whenever this limit exists; here $\tilde{\theta}_n$ is the projection to the first argument of the nth iterate of the point (θ_0, r_0) under a lift $\tilde{F}$ of F. In contrast to the situation for circle maps, the rotation number depends on the orbit (and it may happen that some orbits do not have a rotation number).

We say that an orbit is *well-ordered* when, for every k and l, the function of n defined as $e(n) = \theta_{n+k} - l - \theta_n$ has the same sign. Every well-ordered orbit has a rotation number (the converse, however, is not true).

It is also easy to see that if a bounded orbit is well-ordered and $\rho(\theta_0, r_0)$ is irrational, the closure of the orbit, $\overline{\{(\theta_n, r_n)\}_{n=0}^{\infty}}$, is a perfect set (i.e., every point is an accumulation point of points in the set); in other words, in this case the orbit is either a homotopically nontrivial circle or a Cantor set.

A set $U \subseteq \mathbb{T} \times \mathbb{R}$ is *invariant* if $U = F(U)$.

The following result plays an important role [15, Chap. 2].

Theorem 2.1. *If F is as above, for every $\rho \in \mathbb{R}$ there exists a well-ordered orbit with rotation number ρ.*

2.2. Invariant circles of twist maps—rigorous results. The proof of the following theorem can be found in [16] (reprinted in [60]) and [17] (reprinted in [61]). We refer to [15] and [18] for a detailed exposition.

Theorem 2.2. *Let U be an open simply connected invariant set containing one of the ends of the cylinder. Then the boundary, ∂U, of the set U is an invariant circle which is the graph of a Lipschitz function. In other words, ∂U can be written as $r = R(\theta)$, where $R : \mathbb{T} \to \mathbb{R}$ is a Lipschitz function.*

For the map (2.1), the Lipschitz constant of the function R can be bounded by an expression which involves only the Lipschitz constant of the function F in a neighborhood of the circle ∂U.

In particular, we have the following corollary.

Corollary 2.1. *Any homotopically nontrivial invariant circle is the graph of a Lipschitz function R.*

A number ρ is said to be *Diophantine* if, for each $m, n \in \mathbb{N} \setminus \{0\}$, for some $C > 0$, and for some $d > 2$, it satisfies

$$\left|\rho - \frac{m}{n}\right| > \frac{C}{n^d} \ .$$

In the case when the map F is close to integrable and its rotation number ρ is Diophantine, one can apply the Kolmogorov–Arnold–Moser theory to obtain that there exists an analytic invariant circle such that the orbits on it have rotation number ρ.

Golden, respectively, *silver*, invariant circles are those with rotation number equal to the *golden mean*,

$$\sigma_{\mathrm{G}} := [1, 1, 1, \ldots] = \frac{\sqrt{5} - 1}{2} \ , \tag{2.3}$$

respectively, to the *silver mean*, $\sigma_{\mathrm{S}} := [2, 2, 2, \ldots.] = \sqrt{2} - 1$. Here we have used the notation $\rho = [a_1, a_2, a_3, \ldots] = 1/(a_1 + 1/(a_2 + 1/(a_3 + \cdots)))$ for the continued fraction expansion of $\rho \in (0, 1)$ [19].

There are rigorous results that guarantee the nonexistence of invariant circles of F of the form (2.1).

Theorem 2.3.

(i) *If $\sup_\theta |\lambda V(\theta)| > 1$, then (2.1) has no invariant circles.*

(ii) *If $\sup_\theta |V'(\theta)| = 1$ (which holds for the function (2.2)), then for $|\lambda| > \frac{4}{3}$ the map (2.1) has no invariant circles.*

(iii) *For V given by (2.2), the map (2.1) has no golden invariant circles for $|\lambda| > \frac{63}{64} = 0.984375\ldots.$*

(iv) *For V given by (2.2), the map (2.1) has no golden invariant circles for $|\lambda| > 0.9718$.*

Part (i) of Theorem 2.3 is elementary: if $\lambda \sup_\theta |V(\theta)| > 1$, then there will exist points $(\theta^*, r^*) \in \mathbb{T}\times\mathbb{R}$ such that $F(\theta^*, r^*) = (\theta^*, r^*+1)$, which, when iterated, gives that $F^n(\theta^*, r^*) = (\theta^*, r^*+n)$—the unbounded growth of the second coordinate of $F^n(\theta^*, r^*)$ with n implies that a topologically nontrivial invariant circle cannot exist. (These orbits are called "Chirikov accelerator modes" [20].)

Part (ii) can be found in [17], and parts (iii) and (iv) are proved by computer-assisted methods in [21] and [22], respectively.

It is widely believed that the following conjecture holds.

Conjecture 2.1. *For a Diophantine number ρ and for a map F of the form (2.1), there is a number $\Lambda(\rho)$ such that when $|\lambda| > \Lambda(\rho)$, there is no invariant circle with rotation number ρ, and when $|\lambda| < \Lambda(\rho)$, there exists an analytic invariant circle with rotation number ρ. The invariant circle becomes critical when $|\lambda| = \Lambda(\rho)$.*

Since our paper is devoted to homotopically nontrivial invariant circles, we will usually omit the words "homotopically nontrivial."

2.3. Functions related to the critical invariant circles. We are interested in describing the critical invariant circles with rotation number ρ which are in the boundary of existence. Postponing for the moment issues about how these objects can actually be computed, we point out that, to a given critical invariant circle γ of rotation number ρ, we can associate

- the function $R : \mathbb{T} \to \mathbb{R}$ such that the critical invariant circle γ is the graph of R:

$$\gamma = \{(\theta, r) \in \mathbb{T} \times \mathbb{R} \, : \, r = R(\theta)\} \; ; \tag{2.4}$$

- the *advance map* $g : \mathbb{T} \to \mathbb{T}$ defined by

$$F(\theta, R(\theta)) = (g(\theta), R \circ g(\theta)) \; ; \tag{2.5}$$

- the *hull map* $\Psi : \mathbb{T} \to \mathbb{T} \times \mathbb{R}$, which gives a representation of the invariant circle γ in such a way that the dynamics on γ becomes a rotation by ρ, i.e.,

$$F \circ \Psi(\theta) = \Psi(\theta + \rho) \; ; \tag{2.6}$$

- the map $h = \pi_1 \circ \Psi : \mathbb{T} \to \mathbb{T}$ (where $\pi_1 : \mathbb{T} \times \mathbb{R} \to \mathbb{T}$ is the projection onto $\mathbb{T}$), which conjugates the advance map to a rotation by ρ:

$$g \circ h(\theta) = h(\theta + \rho) \; ; \tag{2.7}$$

- the map $h^{-1} : \mathbb{T} \to \mathbb{T}$, which is the inverse of the map h defined in (2.7).

We note the following rigorous results.

Theorem 2.2 guarantees that the function R is Lipschitz. It is an easy consequence of the implicit function theorem that g should be as regular as R. Nevertheless, it is useful to compute the regularities of both g and R independently to assess the reliability of the numerical methods used.

Because of (2.7), it is clear that the regularity of g is not smaller than the minimum of the regularities of h and h^{-1}.

2.4. The "big" conjugacies. Let ρ be a Diophantine number, F_i $(i = 1, 2)$ be area-preserving twist maps, and γ_i be the critical invariant circle of F_i with rotation number ρ. Let g_{γ_i} and h_{γ_i} be the associated advance map (2.5) and conjugacy (2.7), respectively. We introduce the conjugating functions

$$G_{\gamma_1,\gamma_2} := g_{\gamma_1} \circ g_{\gamma_2}^{-1} : \mathbb{T} \to \mathbb{T} ,$$
$$H_{\gamma_1,\gamma_2} := h_{\gamma_1} \circ h_{\gamma_2}^{-1} : \mathbb{T} \to \mathbb{T} .$$

We will call these functions "big" conjugacies to distinguish them from the "small" conjugacies h that conjugate the projected dynamics on the critical circles to a rigid rotation (2.7). Note that the "big" conjugacies satisfy

$$G_{\gamma_1,\gamma_2} \circ G_{\gamma_2,\gamma_3} = G_{\gamma_1,\gamma_3} , \quad H_{\gamma_1,\gamma_2} \circ H_{\gamma_2,\gamma_3} = H_{\gamma_1,\gamma_3} .$$

Below we discuss one aspect of the definition of the big conjugacies that will be important in our computations.

Since there is no "origin" on the circle $\mathbb{T}$, one has a certain amount of freedom in the definition of some maps. For example, if the function Ψ is a hull map (i.e., satisfies (2.6)), then the function $\tilde{\Psi}$ defined as $\tilde{\Psi}(\theta) = \Psi(\theta + \zeta)$ will also satisfy (2.6) for any choice of the constant ζ. Similarly, the map h (2.7) that conjugates the advance map g to a rigid rotation can be redefined by composing it on the right with a rotation, and the resulting map, $\tilde{h}(\theta) = h(\theta + \zeta)$, will also conjugate g to a rigid rotation. Naturally, all important properties of the maps h and $\tilde{h}$—in particular, their Hölder regularity—will be the same. However, one cannot use this freedom liberally when studying the big conjugacies. To understand the reason for this, consider the map h defined by (2.7) for some twist map F. Naturally, the map $h \circ h^{-1}$ is the identity map, so it is C^∞. However, for any nonzero ζ in the definition of $\tilde{h}$, there is no guarantee that the map $h \circ \tilde{h}^{-1}$ will be C^∞. This is due to the fact that the regularity of h may be different at different points, and while in $h \circ h^{-1}$ these "irregularities" cancel out, in $h \circ \tilde{h}^{-1}$ the action of h does not necessarily "undo" the irregularities caused by $\tilde{h}^{-1}$. In section 2.5 we explain in detail how we choose ζ in order to avoid the "spurious" irregularities of the big conjugacy.

In section 2.6 we formulate some conjectures about the regularity of the big conjugacies, and in the conclusion (section 5.3) we discuss the implications for the pointwise Hölder spectra of the functions h_i.

2.5. Big conjugacies and symmetries. Consider two functions h_{γ_1} and h_{γ_2} corresponding to the critical circles γ_1 and γ_2 of the twist maps F_1 and F_2. If F_1 and F_2 happen to belong to the same "universality class" (see section 2.6), then one would expect that the big conjugacy H_{γ_1,γ_2} will be more regular than the functions h_{γ_1} and $h_{\gamma_2}^{-1}$. To avoid introducing spurious irregularities in H_{γ_1,γ_2}, we use the symmetries of the map h that come from the symmetries of the F [23], [24] (reprinted in [61]), and [25].

It is well known that if the function V is odd, then the map F given by (2.1) can be written as a composition of two involutions:

$$F = I_1 \circ I_0 , \qquad I_0^2 = I_1^2 = \mathrm{Id} , \tag{2.8}$$

where

$$I_0(\theta, r) = (-\theta, r + \lambda V(\theta)) \ , \quad I_1(\theta, r) = (-\theta + r, r) \ . \tag{2.9}$$

From (2.8) we have $I_0 \circ F = F^{-1} \circ I_0$ and $I_1 \circ F = F^{-1} \circ I_1$. Acting on (2.6) with I_0 from the left, we obtain

$$F^{-1} \circ (I_0 \circ \Psi)(\theta) = (I_0 \circ \Psi)(\theta + \rho) \ . \tag{2.10}$$

On the other hand, if we define the function $L : \mathbb{T} \to \mathbb{T} \times \mathbb{R}$ by $L(\theta) := \Psi(-\theta)$, then (2.6) can be written as

$$F^{-1} \circ L(\theta) = L(\theta + \rho) \ . \tag{2.11}$$

Comparing (2.10) and (2.11), we see that L and $I_0 \circ \Psi$ can differ only by a shift in the argument; i.e., there has to exist a constant ζ such that $I_0 \circ \Psi(\theta) = L(\theta + \zeta) = \Psi(-\theta - \zeta)$. This, together with (2.9) and $h = \pi_1 \circ \Psi$, implies

$$h(\theta) = -h(-\theta - \zeta) \ .$$

This implies that $h(-\frac{\zeta}{2}) = 0$, and the numerical value of ζ can be found from the computed values of h. Setting $\tilde{h}(\theta) := h(\theta - \frac{\zeta}{2})$, we obtain that $\tilde{h}$ is an odd function. In what follows, we will assume that the appropriate value of ζ has been subtracted, and we will omit the tilde over h.

2.6. Universality. In this section, we formulate precisely some conjectures on the behavior of critical invariant circles described by a nontrivial fixed point of the renormalization group. It seems quite possible that these conjectures can be proved as conditional theorems assuming existence and certain properties of this fixed point.

One of the most striking predictions of the renormalization group theory is that many characteristics of the critical invariant circles are largely independent of the details of the map. This is captured by the notion of universality.

Definition 2.1. *We say that a numerical characteristic is* universal *when it takes the same value in an open set of maps. We say that a property is* universal *when it holds for an open set of maps.*

The open sets alluded to in Definition 2.1 are called *domains of universality.*

For the case that we will be concerned with, the description of the domains of universality in terms of properties of the nontrivial fixed points of the renormalization operator is still debated, but there are indications that the domain of universality is not the whole space [26, 27, 28].

Conjecture 2.2. *The existence of one and only one nontrivial fixed point of the renormalization operator is a universal property.*

This conjecture has been known for a long time [12]. Recently in [29] it has been shown how this conjecture can be formulated in terms of some other conjectured properties related to the transversal intersection of some manifolds with the unstable invariant manifold of the nontrivial fixed point. Even the formulation of the subsequent conjectures depends on Conjecture 2.2.

An important new development is the computer-assisted proof [30] of the existence of a nontrivial fixed point of the renormalization group associated with the breakup of the golden invariant torus (the proof in [30] is based on renormalization of time-dependent Hamiltonians developed in [31] and earlier papers of the same author).

The concept of universality is rather natural when one wants to study properties that depend on the speed at which the set of maps converges to the fixed point under the renormalization operator. In particular, regularity of conjugacies depends on this speed of convergence and, hence, should be a universal quantity (more precise formulations are given in [32]). To formulate the conjectures below, we will need the following definition.

Definition 2.2. *For $\kappa = n + \chi$ with $n \in \mathbb{Z}$, $\chi \in (0,1)$, we say that the function $K : \mathbb{T} \to \mathbb{R}$ has* (global) Hölder exponent *κ and write $K \in \Lambda_\kappa(\mathbb{T})$ when K is n times differentiable and, for some constant $C > 0$,*

$$|D^n K(\theta) - D^n K(\tilde{\theta})| \le C|\theta - \tilde{\theta}|^\chi$$

for all $\theta, \tilde{\theta} \in \mathbb{T}$.

For the case of an integer value of κ, this definition is more complicated, but we will omit it since in the applications considered in this paper κ is not an integer.

Now we formulate several conjectures concerning the regularities of the functions introduced in sections 2.3 and 2.4.

Conjecture 2.3. *The regularity, $\kappa(R)$, of the critical invariant circle is a universal number.*

Conjecture 2.4. *The regularities $\kappa(g)$, $\kappa(h)$, and $\kappa(h^{-1})$ are universal numbers.*

Conjecture 2.5. *For pairs of critical circles γ_1 and γ_2, the regularities $\kappa(G_{\gamma_1,\gamma_2})$ and $\kappa(H_{\gamma_1,\gamma_2})$ are universal numbers.*

Directly from the definition of Hölder regularity, one can see that if $\kappa(\phi)$ and $\kappa(\psi)$ are between 0 and 1, then $\kappa(\phi \circ \psi) \ge \kappa(\phi)\,\kappa(\psi)$. This implies that

$$\kappa(H_{\gamma_1,\gamma_2}) = \kappa(h_{\gamma_1} \circ h_{\gamma_2}^{-1}) \ge \kappa(h_{\gamma_1})\,\kappa(h_{\gamma_2}^{-1})\ . \tag{2.12}$$

For all critical invariant circles γ_i that we studied, we obtained numerically that $\kappa(h_{\gamma_i}) < 1$ and $\kappa(h_{\gamma_i}^{-1}) < 1$, so (2.12) yields that H_{γ_1,γ_2} is not less regular than $\kappa(h_{\gamma_1})\,\kappa(h_{\gamma_2}^{-1})$. For γ_1 and γ_2 in the same universality class, however, we expect more—because of "cancellation" of the "singularities" of h_{γ_1} and $h_{\gamma_2}^{-1}$, we state our final conjecture.

Conjecture 2.6. *The following inequalities hold for $i = 1, 2$:*

$$\kappa(h_{\gamma_i}) < \kappa(H_{\gamma_1,\gamma_2})\ , \qquad \kappa(h_{\gamma_i}^{-1}) < \kappa(H_{\gamma_1,\gamma_2})\ .$$

3. Description of the numerical methods.

In this section we first describe the methods used for numerical computation of invariant circles and the related functions described in sections 2.3 and 2.4. Then we briefly discuss the method we use to compute the Hölder regularity of the functions.

3.1. Computing critical invariant circles.

We need to compute (homotopically nontrivial) critical invariant circles of twist maps of the form (2.1) with a Diophantine rotation number. We approximate such invariant circles by well-ordered periodic orbits (whose existence is guaranteed by Theorem 2.1). Consider a sequence $\{\mathcal{X}^{(j)}\}_{j\in\mathbb{N}}$ of well-ordered periodic orbits whose rotation numbers, $\{\rho_j\}_{j\in\mathbb{N}}$, constitute a sequence of rational numbers which converge

to a Diophantine number ρ. Then the limit of these periodic orbits will be a well-ordered invariant set $\mathcal{X}_\rho$ of rotation number ρ; the existence of this set is guaranteed by the Aubry–Mather theory [33, Chap. 13], [15, Chap. 2]. The set $\mathcal{X}_\rho$ can be a continuous curve which is a graph of a Lipschitz function under appropriate conditions (Theorem 2.2) or an orbit homeomorphic to a Cantor set (Cantorus). In the former case, the rotation number uniquely determines the invariant circle (see Remark 4.2), while in the latter case there may exist different Cantor sets with the same rotation number.

We approximate a Diophantine number ρ by the rational numbers given by finite truncations of the continued fraction expansion of ρ. In the case of the golden mean σ_{G} (2.3), these rational approximants are ratios $\rho_m = Q_{m-1}/Q_m$ of consecutive Fibonacci numbers Q_m. The limit of the periodic orbits with rotation numbers ρ_m is the invariant set $\mathcal{X}_\rho$ we are looking for [24].

The problem of computing well-ordered orbits with a prescribed rational rotation number ρ_m is greatly simplified if the function $V(\theta)$ in (2.1) is odd. In this case the task of finding a periodic orbit is reduced to a one-dimensional problem because the map F can be written as the composition of two involutions as in (2.8); if such a decomposition is possible, the map F is said to be *reversible*. If F is reversible, there exists a set of lines in the (θ, r) space—called *symmetry lines*—that are invariant with respect to the involutions I_0 and I_1 (2.9). It can be shown that any periodic orbit has two points that belong to one of the symmetry lines; hence we can find these points (and, therefore, the periodic orbits that contain them) by using a one-dimensional root finder [24]. Using the fact that the periodic orbits computed in this way are well ordered, we can implement a numerical procedure to compute periodic orbits of several million points that approximate the invariant set $\mathcal{X}_\rho$.

We are interested in studying the properties of area-preserving twist maps of the form (2.1). When the parameter λ in (2.1) is equal to 0, the corresponding twist map acts on each point (θ, r) as a rigid rotation in the θ-direction, $F(\theta, r) = (\theta + r, r)$, and hence the phase space is foliated by invariant circles of the form $\{r = \text{const}\}$. For small values of $|\lambda|$, KAM theory guarantees the existence of invariant circles with Diophantine rotation numbers. According to Conjecture 2.1, there is an upper bound $\Lambda(\rho)$ on the values of $|\lambda|$ such that for $|\lambda| < \Lambda(\rho)$ there exists an invariant circle with rotation number ρ (some rigorous upper bounds on $\Lambda(\rho)$ are given in Theorem 2.3). To find an accurate numerical approximation of the critical value, $\Lambda(\rho)$, of λ for which the invariant circle of rotation number ρ disintegrates, we applied an empirical method known as the "residue criterion" proposed in [24], developed in [34], and partially justified rigorously in [35, 36]. The main idea of this method is to determine the value of λ such that the residue of all the approximating periodic orbits reaches the same value. Let R_m be the residue of a periodic orbit which is the mth approximant to an invariant circle with rotation number ρ. If $\lim_{m\to\infty} R_m = 0$, then there exists an invariant circle with rotation number ρ; if $\lim_{m\to\infty} R_m = \infty$, then the invariant set $\mathcal{X}_\rho$ is a Cantor set. A critical invariant circle is obtained at the value of λ for which R_m tends to a finite value as $m \to \infty$ (see Remark 4.2).

3.2. Studying Hölder regularity numerically. In this section we describe briefly the method we employed to study Hölder regularity, referring the reader to [13] for details, additional references, and an assessment of the numerical accuracy of various numerical methods for computing regularity.

In this paper, we will use only the method developed in [13] that was found to be the most accurate for studying Hölder regularity—the so-called continuous Littlewood–Paley (CLP) method. Here we do not use the wavelet-based methods implemented in [13]. The CLP method has been used in [37, 25, 38].

3.2.1. Theoretical basis of the CLP method. The CLP method is based on the following result (which can be found in [39, Chap. 5, Lemma 5]).

Theorem 3.1 (CLP). *The function $K \in L^\infty(\mathbb{T})$ is in $\Lambda_\kappa(\mathbb{T})$ if and only if for some integer $\eta > \kappa$ there exists a constant $C > 0$ such that for any $t > 0$*

$$\left\| \left(\frac{\partial}{\partial t} \right)^\eta \mathrm{e}^{-t\sqrt{-\Delta}} K \right\|_{L^\infty(\mathbb{T})} \leq C t^{\kappa - \eta} , \tag{3.1}$$

where Δ is the one-dimensional Laplace operator: $\Delta K(\theta) = K''(\theta)$.

Remark 3.1. If the above result holds for some integer $\eta > \alpha$, then it holds for all integers $\tilde{\eta} > \alpha$.

Remark 3.2. The operator $\mathrm{e}^{-t\sqrt{-\Delta}}$ is a convolution with the Poisson kernel: $\mathrm{e}^{-t\sqrt{-\Delta}} K = P_{\exp(-2\pi t)} * K$. The function $u(\theta, t) := \mathrm{e}^{-t\sqrt{-\Delta}} K(\theta)$ is a solution of Laplace's equation, $u_{\theta\theta} + u_{tt} = 0$, on the half-cylinder $(\theta, t) \in \mathbb{T} \times (0, \infty)$, with Dirichlet boundary condition $u(\theta, 0) = K(\theta)$.

Remark 3.3. The mathematical theory requires only that (3.1) be an upper bound. In our numerical experiments, however, this bound is saturated for a significant range of values of t. This fact is very possibly a consequence of the self-similarity at small scales of the functions we consider (which is at the basis of the renormalization group description). This saturation was also observed for the functions considered in [13, 37, 25, 38].

3.2.2. Remarks on the numerical implementation. To use the CLP method, we need to repeatedly apply fast Fourier transform (FFT), which is easiest to do if the values of the function K in (3.1) are known at 2^N equally spaced points in the interval $[0, 1)$ for some positive integer N. However, as we describe in section 4, we do not have control over the set of points at which the values of K can be computed (where K stands for any of the functions R, g, h, h^{-1}, H, G). Hence, the first step in applying the CLP method would be the computation of the values of K on an evenly spaced grid. If we accurately know the values of K at M points in $[0, 1)$, we can expect that, by using some interpolation method, we will be able to obtain the approximate values of K on $2^N \approx M$ equidistant points, $\{2^{-N} j\}_{j=0}^{2^N - 1}$. To compute the approximate values of K on the equidistant grid, we used cubic spline interpolation. Using interpolation poses the question of whether the interpolated values faithfully represent the true values of K. Naturally, the answer to this question is no, but, practically, if M is large enough, the interpolated values will be very close to the true values, which will allow us to accurately compute many Fourier coefficients of K. The degree of "contamination" of the Fourier spectra due to the interpolation depends on the uniformity of the distribution of the M points at which the value of K is accurately known (see Remark 4.3).

To apply the CLP method numerically, we observe that the operator $(\frac{\partial}{\partial t})^\eta \mathrm{e}^{-t\sqrt{-\Delta}}$ used in Theorem 3.1 is diagonal in a Fourier series representation: if $K(\theta) = \sum_{k \in \mathbb{Z}} \hat{K}_k \mathrm{e}^{-2\pi i k \theta}$, then

$$\left(\frac{\partial}{\partial t}\right)^{\eta} \mathrm{e}^{-t\sqrt{-\Delta}} K(\theta) = \sum_{k\in\mathbb{Z}} (-2\pi|k|)^{\eta}\, \mathrm{e}^{-2\pi t|k|}\, \hat{K}_k\, \mathrm{e}^{-2\pi i k\theta} \ . \tag{3.2}$$

Having computed the values of the spline interpolant to the function K on an equally spaced grid, applying (3.1) is easy. Namely, we fix some values of the parameters η and t, perform FFT to find $\hat{K}_k$, and compute the Fourier coefficients of $(\frac{\partial}{\partial t})^{\eta}\, \mathrm{e}^{-t\sqrt{-\Delta}} K$. Then we apply inverse FFT to find the values of $(\frac{\partial}{\partial t})^{\eta}\, \mathrm{e}^{-t\sqrt{-\Delta}} K$ at the equally spaced set of points $\{2^{-N} j\}_{j=0}^{2^N-1}$; among these values we find the one with maximum absolute value—this value we take for the numerical value of the left-hand side of (3.1). For a fixed value of η, we repeat this procedure for many values of t (we used several hundred values of t in our computations). According to (3.1), if we plot

$$\log \left\| \left(\frac{\partial}{\partial t}\right)^{\eta} \mathrm{e}^{-t\sqrt{-\Delta}} K \right\|_{L^{\infty}(\mathbb{T})} \quad \text{versus} \quad \log t \ , \tag{3.3}$$

the points should lie below a straight line of slope $\kappa - \eta$. As pointed out in Remark 3.3 (see also Remark 4.4) the points on the log-log plot should not only be below this straight line, but should also be close to it. We perform linear regression to find the slope of this line, from which we find κ.

4. Numerical results.

4.1. Twist maps studied. We study numerically a set of one-parameter families of area-preserving twist maps of the form (2.1), each family having a different function V. Within each family we find numerically the value $\Lambda(\sigma_{\mathrm{G}})$ of the parameter λ for which the golden (resp., silver) invariant circle is critical. The set of functions V that we selected—all of them odd (so that we can use the symmetry lines technique as explained in section 3.1)—consists of the following:

1. The standard (Taylor–Chirikov) map:

$$V_1(\theta) = -\frac{1}{2\pi} \sin 2\pi\theta \ . \tag{4.1}$$

2. The "standard map with two harmonics":

$$V_2(\theta) = -\frac{1}{2\pi} \left[\sin(2\pi\theta) - 0.03 \sin(6\pi\theta)\right] . \tag{4.2}$$

3. The "critical standard map with two harmonics":

$$V_3(\theta) = -\frac{1}{2\pi} \left[\sin(2\pi\theta) - \frac{1}{2} \sin(6\pi\theta)\right] . \tag{4.3}$$

   For this choice of coefficients, the first three derivatives of $V(\theta)$ at $\theta = 0$ are zero.

4. The "0.2-analytic map":

$$V_4(\theta) = -\frac{1}{2\pi} \frac{\sin(2\pi\theta)}{1 - 0.2\cos(2\pi\theta)} \ . \tag{4.4}$$

   This map has infinitely many nonzero Fourier coefficients. It would be very interesting to study this map when the coefficient of the cosine function in the denominator is close to 1, but then it would be extremely difficult to compute periodic orbits.

5. The "0.4-analytic map":

$$V_5(\theta) = -\frac{1}{2\pi}\frac{\sin(2\pi\theta)}{1-0.4\cos(2\pi\theta)} \ . \tag{4.5}$$

6. The "tent map":

$$V_6(\theta) = \sum_{j=1}^{17} c_j \sin(2\pi j\theta) \ , \tag{4.6}$$

where $c_j = (-1)^{\frac{j+1}{2}}\frac{4}{\pi^2 j^2}$ for j odd and $c_j = 0$ for j even are the Fourier coefficients of the function

$$\mathcal{V}(\theta) = \begin{cases} -4\theta & \text{for } 0 \le \theta < \frac{1}{4} \ , \\ 4\theta - 2 & \text{for } \frac{1}{4} \le \theta < \frac{3}{4} \ , \\ 4 - 4\theta & \text{for } \frac{3}{4} \le \theta < 1 \ . \end{cases}$$

The function V_6 is close to the piecewise linear continuous function $\mathcal{V}$.

Our numerical experiments were performed with the twist maps coming from the above six functions $V(\theta)$ and the corresponding values $\Lambda(\sigma_{\mathrm{G}})$, following the six steps below. All numerical values here are given for rotation number golden mean; for silver mean the algorithm is analogous.

1. As discussed in section 3.1, the invariant circle of rotation number σ_{G} can be obtained as a limit of periodic orbits of rotation numbers equal to ratios of consecutive Fibonacci numbers, $\rho_m = Q_{m-1}/Q_m$. We chose to compute hyperbolic periodic orbits and found the values of $\Lambda(\sigma_{\mathrm{G}})$ by applying Greene's residue criterion [24].
2. The highest approximant to the critical invariant circle that we computed was a periodic orbit with rotation number $Q_{29}/Q_{30} = 832040/1346269$. The value of $\Lambda(\sigma_{\mathrm{G}})$ was determined by using the condition that the difference $|R_{30} - R_{29}|$ of the residues of the periodic orbits with periods Q_{29} and Q_{30} be zero (in practice, we wanted this difference to be smaller than 10^{-10}); this procedure is related to Greene's residue criterion (see Remark 4.2 below). The periodic orbits were computed with an error not exceeding 10^{-23}.
3. We computed the hyperbolic periodic orbit $\{(\theta_m, r_m)\}_{m=0}^{M-1}$ of period $M = Q_{30}$. The values of the advance map g (2.5) at the points θ_m ($m = 0, 1, \ldots, M-1$) were then computed by $g(\theta_m) = \theta_{m+1}$ (here and below, we take mod 1 wherever needed). The values of the conjugacy h at the points $m\sigma_{\mathrm{G}}$ (these points correspond to m applications of the rigid rotation by σ_{G} to 0) are given by $h(m\sigma_{\mathrm{G}}) = \theta_m$ and, similarly, $h^{-1}(\theta_m) = m\sigma_{\mathrm{G}}$.
4. In our Fourier analysis–based CLP method we need to deal with periodic functions, so we compute the "periodized" versions, $g - \mathrm{Id}$, $h - \mathrm{Id}$, and $h^{-1} - \mathrm{Id}$, of the functions g, h, and h^{-1}. Then we sort the periodized functions with respect to their argument; the function R is already periodic, so we just sort its values.
5. The periodic functions are passed to the cubic spline interpolation routine to find approximations to the values of the corresponding functions on a uniformly spaced grid of 2^N points; we used $N = 20$ (so that $2^{20} = 1048576$ is roughly equal to the length, Q_{30}, of the periodic orbit).

6. The interpolated values of the functions are given to the CLP algorithm to compute their Hölder regularity. We used integer values of η in (3.1) from 1 to 5, and for each analyzed function chose the value of η that gave the best straight line on the log-log plot (3.3). The log-log plots for the other values of η were used as a consistency check.

In sections 4.4.1 and 4.4.2 we give the results on the regularity of the functions related to the critical invariant circles with rotation numbers σ_{G} and σ_{S}, respectively (for σ_{S}, we used only the functions V_1 and V_2).

Remark 4.1. In computing the big conjugacies H_{γ_1,γ_2}, we had to take special care to preserve the symmetries of the maps h. For each critical circle we studied, we needed to find the appropriate value of the constant ζ and shift the argument of the corresponding function h as explained in section 2.5.

Remark 4.2. Greene's residue criterion [24] was defined using elliptic periodic orbits, but one can obtain similar results using hyperbolic orbits (in this case the residue's value is negative; for rotation number golden mean it is $\lim_{m\to\infty} R_m \approx -0.255426$); see [34]. According to the Aubry–Mather theory, the hyperbolic periodic orbits are minimizing, while the elliptic ones are minimax orbits [15]. Each invariant circle is a minimizing orbit, and it is the limit set of a sequence of minimizing periodic orbits whose rotation numbers converge to the rotation number of the invariant circle. For any sequence of periodic orbits with rotation number $\frac{p_n}{q_n}$ that converges to ω (the rotation number of the invariant circle), the hyperbolic and the elliptic orbits that belong to this sequence are interleaved: any elliptic orbit with rotation number $\frac{p_{n+1}}{q_{n+1}}$ is bounded by two hyperbolic orbits with rotation number $\frac{p_n}{q_n}$ and $\frac{p_{n-1}}{q_{n-1}}$, respectively. Hence, the sequence of elliptic periodic orbits and the sequence of hyperbolic periodic orbits converge to the same invariant circle. We conjectured that the regularity of invariant circles computed with elliptic and hyperbolic periodic orbits is the same, and performed some numerical experiments that supported this conjecture. We use hyperbolic periodic orbits to compute the regularity of critical invariant curves because our numerical methods for computing the orbits are more robust for hyperbolic orbits than for the elliptic ones.

4.2. Critical invariant circles—visual explorations. In Figure 1 we show the critical invariant circles which, by the definition (2.4), are graphs of the functions R corresponding to the six twist maps studied. The graphs of the "periodized versions" of the advanced maps, $g - \mathrm{Id}$; the conjugacies, $h - \mathrm{Id}$; and their inverses, $h^{-1} - \mathrm{Id}$, are plotted in Figures 2, 3, and 4, respectively.

Figure 5 illustrates the self-similar nature of the functions h; needless to say, the insets are true zooms of parts of the graph of the function.

Figure 6 shows the graphs of several periodized big conjugacies $H - \mathrm{Id}$; it is obvious that these functions are smoother than the "small" conjugacies h.

4.3. Fourier spectra, CLP method. Figure 7 depicts $\log_{10}$ of the modulus of the kth Fourier coefficient of a periodized conjugacy $(h - \mathrm{Id})$ versus $\log_{10} k$; here h is the conjugacy corresponding to the twist map F with V_3 (4.3). The horizontal distance between two adjacent high peaks is approximately equal to $|\log_{10} \sigma_{\mathrm{G}}| \approx 0.209$, which is a manifestation of the self-similarity at small scales. The $\log_{10}$-$\log_{10}$ plots of the Fourier spectra of the functions $(g - \mathrm{Id})$ and $(h^{-1} - \mathrm{Id})$ for the same map F are given in Figure 8.

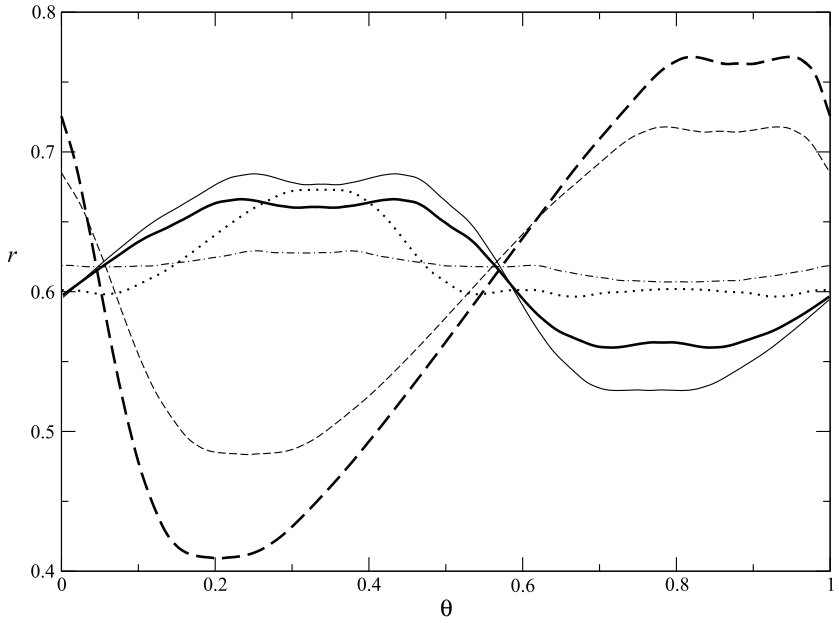

Figure 1. *Critical invariant circles, $r = R(\theta)$, of the maps corresponding to the maps $V_1, V_2, \ldots, V_6$ given by (4.1)–(4.6) (V_1 = thin solid line, V_2 = thick solid line, V_3 = dotted line, V_4 = thin dashed line, V_5 = thick dashed line, V_6 = dotted-dashed line).*

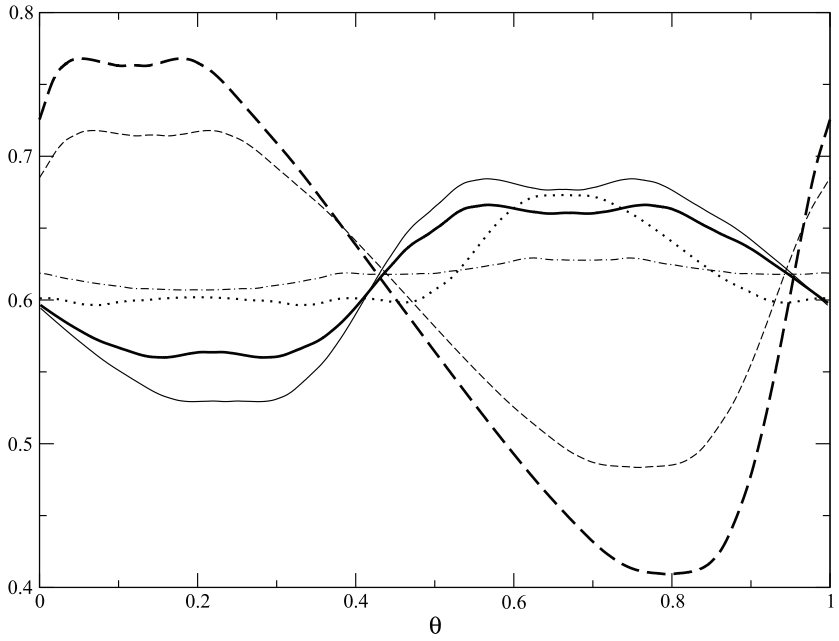

Figure 2. *"Periodized" advance maps $g - \mathrm{Id}$ (notation same as in Figure 1).*

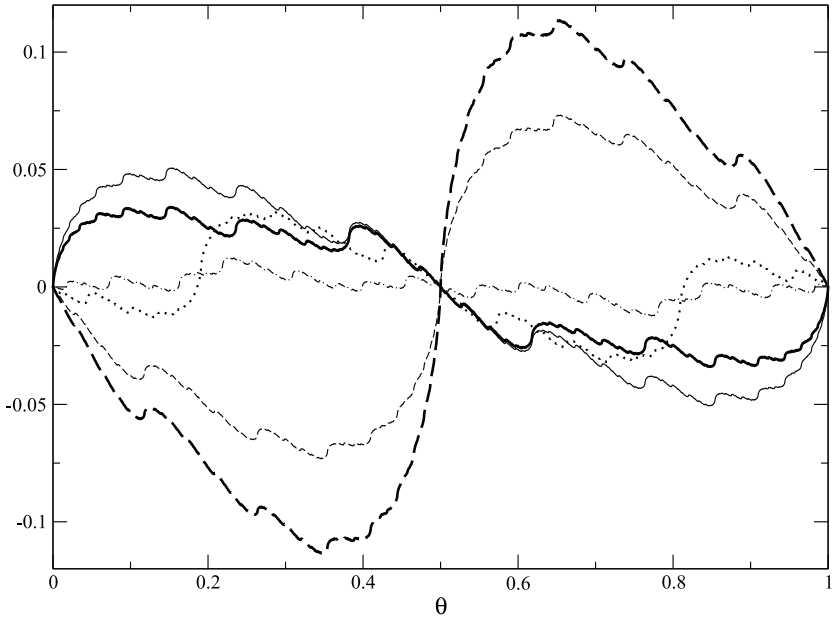

Figure 3. *"Periodized" conjugacies* $h - \mathrm{Id}$ *(notation same as in Figure 1).*

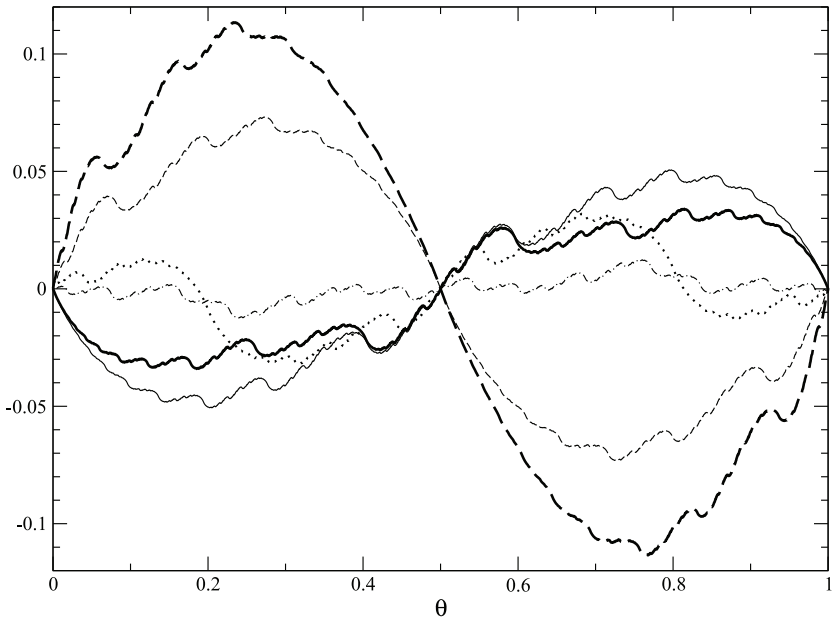

Figure 4. *"Periodized" inverse conjugacies* $h^{-1} - \mathrm{Id}$ *(notation same as in Figure 1).*

Remark 4.3. Note that the spectrum of h is very accurate even at length-scales $\sim 10^{-6}$, while the spectrum of h^{-1} is quite noisy. As explained in sections 3.2.2 and 4.1, the main reason for this is that the exact values of h are known at the points $(m\sigma_{\mathrm{G}})$ mod 1, which are almost uniformly distributed on $\mathbb{T}$. On the other hand, we know the exact values of g and h^{-1} at the

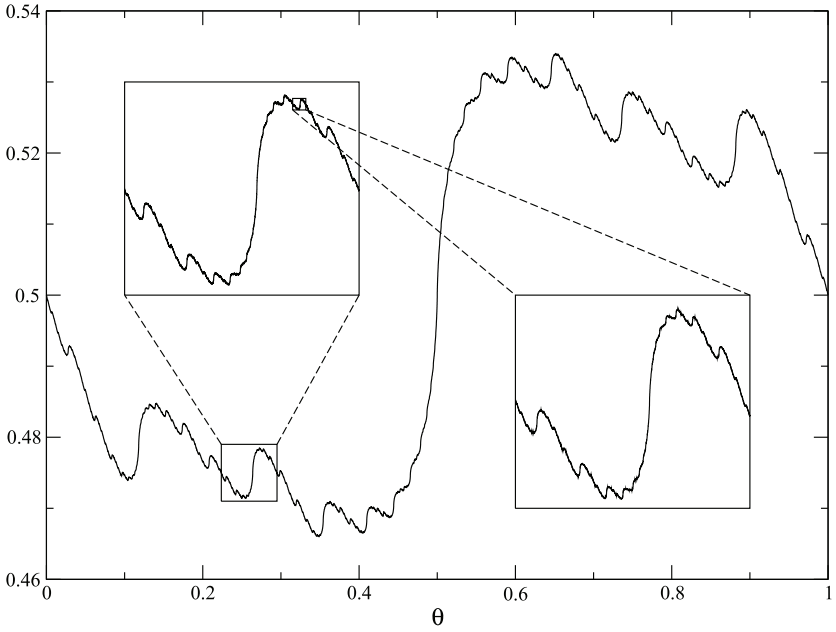

Figure 5. *Zooming in the graph of the function* $h - \mathrm{Id}$ *corresponding to the map* V_2 (4.2).

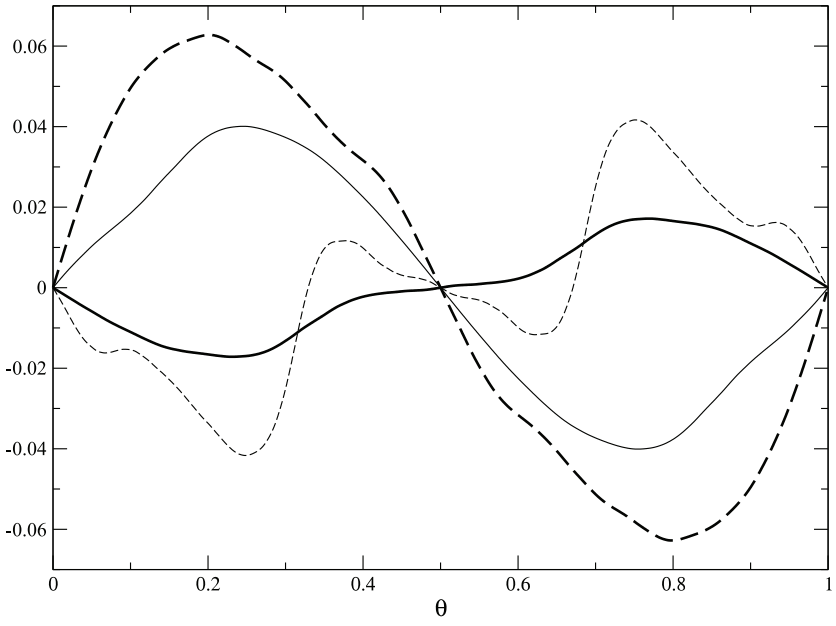

Figure 6. *"Periodized" big conjugacies* $H - \mathrm{Id}$.

very nonuniformly distributed points of the form $g^m(\theta_0)$ (because the underlying invariant measure is singular; see section 5.2), which results in the presence of big gaps between these points and, hence, distorted values of the spline interpolant.

In Figure 9 we show several plots of $\log_{10}$ of the left-hand side of (3.1) versus $\log_{10} t$.

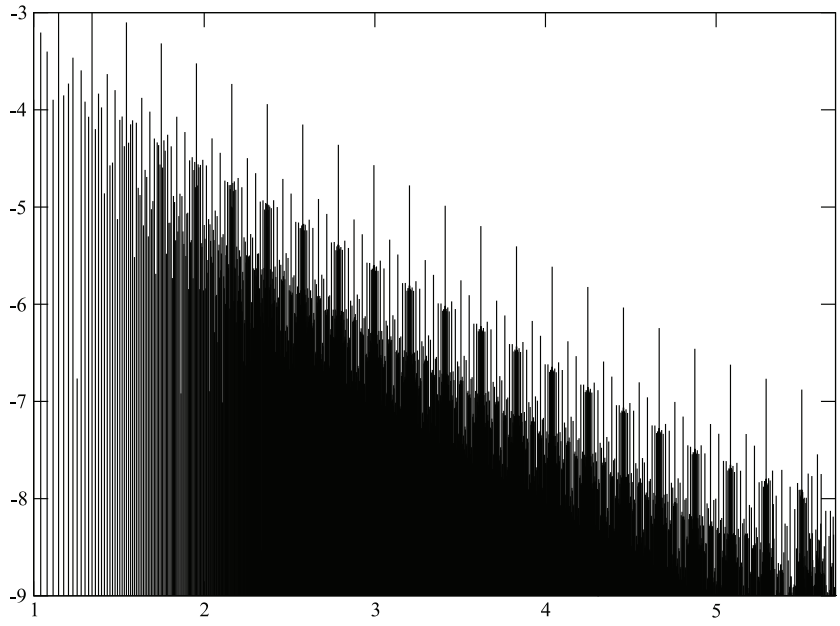

Figure 7. *Plot of* $\log_{10}|(\widehat{h-\mathrm{Id}})_k|$ *versus* $\log_{10} k$*, where* h *corresponds to the map* F *coming from the function* V_3 (4.3).

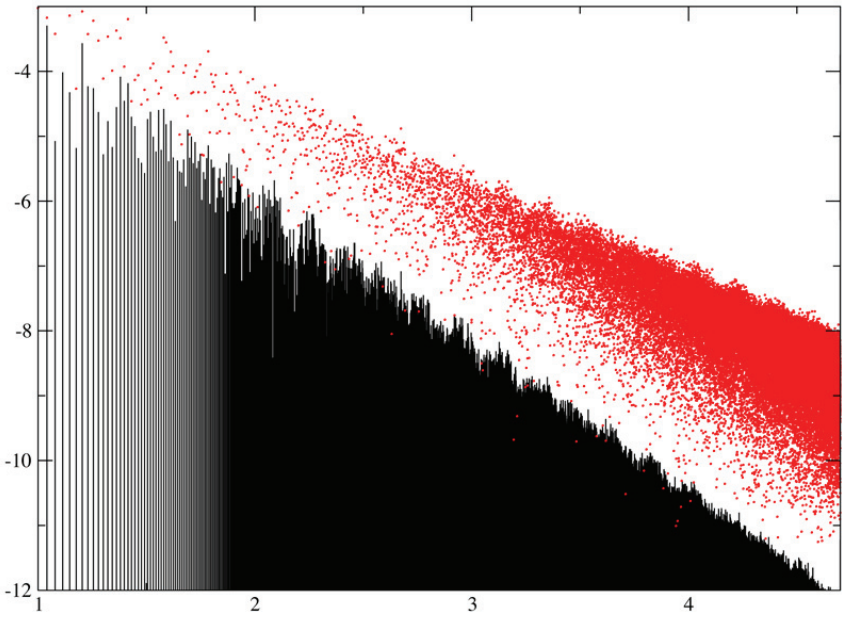

Figure 8. *Plot of* $\log_{10}|(\widehat{g-\mathrm{Id}})_k|$ *and* $\log_{10}|(\widehat{h^{-1}-\mathrm{Id}})_k|$ *versus* $\log_{10} k$*, for the same map* F *as in Figure 7. The impulses correspond to* $(g-\mathrm{Id})$*, and the dots above them to* $(h^{-1}-\mathrm{Id})$.

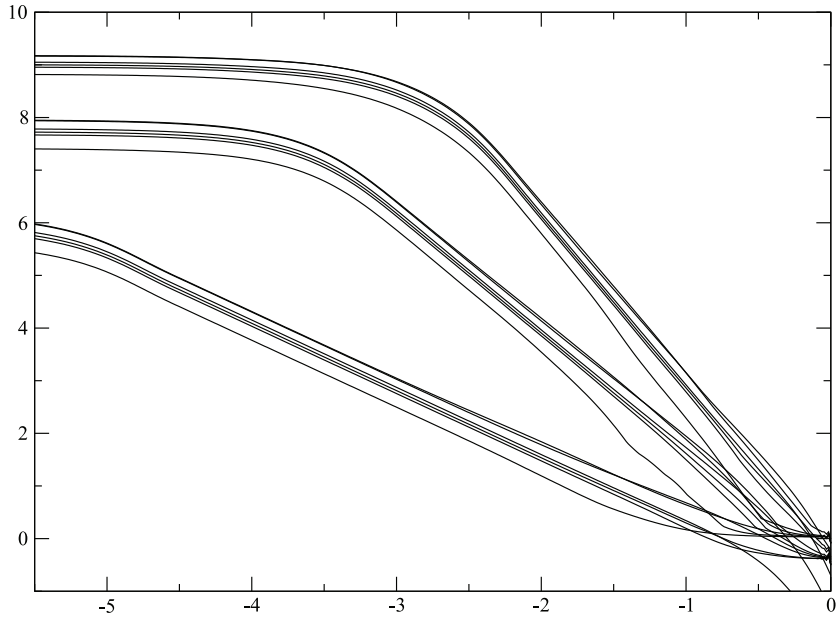

Figure 9. *Plots of* $\log_{10} \|(\frac{\partial}{\partial t})^\eta \, \mathrm{e}^{-t\sqrt{-\Delta}} K\|_{L^\infty(\mathbb{T})}$ *versus* $\log_{10} t$ *for the functions* $K = (h - \mathrm{Id})$ *for the twist maps coming from* $V_1, \ldots, V_6$ *for* $\eta = 2$ *(shallowest lines),* $\eta = 3$*, and* $\eta = 4$ *(steepest lines).*

The six lines in each group of lines of similar slope correspond to the six different choices (4.1)–(4.6) of functions V, and the lines in each group come from the same value of η in (3.1). Each of the "lines" in the figure in fact consists of 400 points (visually indistinguishable). The computer time spent on the CLP analysis is of the order of one minute per point (we used 2^{20} Fourier coefficients to compute each of these points).

We computed the regularity by performing linear regression on the points on graphs like the one in Figure 9, in the regions where the points follow more or less a straight line. As one can see from this figure, for t close to 1 (i.e., $\log_{10} t \approx 0$), the graphs for different functions are not straight lines, then as t decreases they form more or less straight lines, and as t decreases further, these lines level out. This behavior can be understood intuitively from (3.2)—for $t \approx 1$ the high-k Fourier coefficients are strongly suppressed by the factor $(-2\pi|k|)^\eta \, \mathrm{e}^{-2\pi t|k|}$, so the CLP method still does not "feel" the asymptotic self-similarity of the functions at small length-scales; at the other extreme, the leveling out of the lines for very small t comes from the fact that in our computations we use a finite—albeit very large—number of Fourier coefficients.

Remark 4.4. The "straight lines" in Figure 9 are not really straight (which has been noticed in different contexts in [13, 25]). We show this effect in Figure 10, which was created as follows. We took the six lines for $\eta = 2$ from Figure 9, and for each of them we computed the slope of the line as a function of the horizontal coordinate in the figure, $\log_{10} t$. To compute this slope, we took each pair of adjacent points on the line and found the slope of the straight line connecting these points. The distance between two consecutive peaks in Figure 9 is $|\log_{10} \sigma_{\mathrm{G}}|$; more interestingly, as $\log_{10} t$ becomes more negative, the lines tend to the same wavy line, until all lines reach saturation around $\log_{10} t \approx -4.5$.

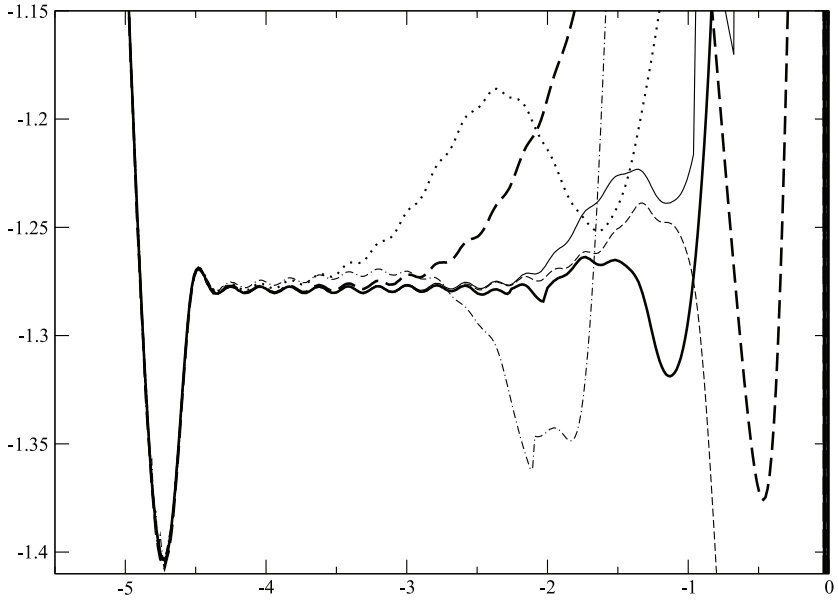

Figure 10. *Slope of the lines on Figure 9 as a function of* $\log_{10} t$ *(see text). The notation is the same as in Figure 1.*

Table 1

Regularities of the functions R, g, h, and h^{-1} *for the golden critical invariant circles of maps F corresponding to different functions V.*

F with	$\kappa(R)$	$\kappa(g)$	$\kappa(h)$	$\kappa(h^{-1})$
V_1	1.83(9)	1.83(9)	0.722(1)	0.92(1)
V_2	1.79(6)	1.75(9)	0.721(1)	0.92(1)
V_3	1.83(4)	1.84(3)	0.724(2)	0.93(2)
V_4	1.86(8)	1.86(8)	0.722(1)	0.92(1)
V_5	1.85(5)	1.85(5)	0.724(2)	0.93(1)
V_6	1.85(15)	1.88(12)	0.726(3)	0.93(2)

4.4. Hölder regularities—numerical results.

4.4.1. Hölder regularities for rotation number golden mean. Table 1 summarizes our numerical results. The first column gives the map V used in the numerical computations (for the six functions V given by (4.1)–(4.6)). In the other columns we give the values of the (global) Hölder exponent κ of the function R (representing the invariant circle as a graph in the (θ, r)-plane), the advance map g, the conjugacy h, and its inverse h^{-1}, coming from the (dynamics on) the golden critical invariant circle of the corresponding area-preserving twist map F. The notation used is the following: 1.85(15) stands for 1.85 ± 0.15, and 0.726(3) for 0.726 ± 0.003. Note that, within the numerical error, $\kappa(R) = \kappa(g)$, as expected.

We also computed the Hölder regularities of all big conjugacies H between each of the six functions $h_1, \ldots, h_6$ (coming from $V_1, \ldots, V_6$) with all other h_j's. We applied the CLP method to find that the regularity of all thirty functions H studied is

$$\kappa(H) = 1.80 \pm 0.15 \ . \tag{4.7}$$

4.4.2. Hölder regularities for rotation number silver mean. We computed the regularity of the maps R_j, g_j, h_j, and h_j^{-1} $(j = 1, 2)$ for the twist maps with the functions V_1 and V_2, as well as the regularity of the "big conjugacies" $H_{1,2}$ and $H_{2,1}$, for the critical invariant circle with rotation number the *silver mean*, $\sigma_S = [2, 2, 2, \ldots]$. The regularities for V_1 and V_2 were numerically the same, so we give only one value; similarly for $H_{1,2}$ and $H_{2,1}$. Here are the results for the regularities (the subscript S stands for "silver"):

$$\begin{aligned}
\kappa(R_S) &= 1.70 \pm 0.15 \ , \\
\kappa(g_S) &= 1.75 \pm 0.15 \ , \\
\kappa(h_S) &= 0.715 \pm 0.015 \ , \\
\kappa(h_S^{-1}) &= 0.87 \pm 0.02 \ , \\
\kappa(H_S) &= 1.80 \pm 0.15 \ .
\end{aligned}$$

5. Discussion and conclusion. In sections 5.1 and 5.2 we point out some relationships between our results and previous studies related to universal scaling factors and singular measures. In the final section 5.3, we recapitulate our findings.

5.1. Hölder regularity and scaling factors. Here we will explain how the scaling of the distances of closest returns of the iterates of a point gives bounds on the Hölder regularity of some of the functions we study. Our analysis here is reminiscent of the analysis in [13, sect. 8.2]. The numerical values below are for rotation number the golden mean.

We start by recalling the crucial observation of Kadanoff and Shenker [5, 6] (see also [10, sect. 4.4]) of the existence of universal scalings in the distribution of the iterates of the Taylor–Chirikov map on the critical invariant circle γ in neighborhoods of certain points of γ. Let $\theta_{\rm rar} \in \mathbb{T}$ stand for the value around which the iterates of the function g are most rarefied (in our notation $\theta_{\rm rar} = \frac{1}{2}$, while in [6] $\theta_{\rm rar} = 0$). Let $\theta_{\rm den} \in \mathbb{T}$ stand for the value around which the iterates of the function g are most dense (in our notation $\theta_{\rm den} = 0$, while in [6] it is $\theta_{\rm den} = \frac{1}{2}$). Since by Theorem 2.2 the function R is Lipschitz, around the points $(\theta_{\rm rar}, R(\theta_{\rm rar}))$ and $(\theta_{\rm den}, R(\theta_{\rm den}))$, the iterates of any point on γ under F are most rarefied, respectively, dense. Shenker and Kadanoff found that the critical invariant circle in a neighborhood of $\theta_{\rm rar}$ is asymptotically invariant under simultaneous scalings in both the θ- and r-directions, with scaling factors

$$\alpha_0 \approx -1.414836 \quad (\text{in } \theta) \ , \qquad \beta_0 \approx -3.0668882 \quad (\text{in } r)$$

(see also the bounds on these values in Stirnemann [40]). This implies that, for large n,

$$\frac{g^{Q_{n+1}}(\theta_{\rm rar}) - \theta_{\rm rar}}{g^{Q_n}(\theta_{\rm rar}) - \theta_{\rm rar}} \approx \alpha_0^{-1} \ , \qquad \frac{R(g^{Q_{n+1}}(\theta_{\rm rar})) - R(\theta_{\rm rar})}{R(g^{Q_n}(\theta_{\rm rar})) - R(\theta_{\rm rar})} \approx \beta_0^{-1} \ . \tag{5.1}$$

The scaling around $\theta_{\rm den}$ is a bit more complicated—it is called "step-3" scaling for obvious reasons:

$$\frac{g^{Q_{n+3}}(\theta_{\rm den}) - \theta_{\rm den}}{g^{Q_n}(\theta_{\rm den}) - \theta_{\rm den}} \approx \alpha_3^{-1} \ , \qquad \frac{R(g^{Q_{n+3}}(\theta_{\rm den})) - R(\theta_{\rm den})}{R(g^{Q_n}(\theta_{\rm den})) - R(\theta_{\rm den})} \approx \beta_3^{-1} \ , \tag{5.2}$$

where the "step-3" scaling factors are

$$\alpha_3 \approx -4.84581 \quad (\text{in } \theta) \ , \qquad \beta_3 \approx -16.8597 \quad (\text{in } r) \ .$$

To understand heuristically why these scalings give restrictions on the Hölder regularity of R, set $\Delta\theta := g^{Q_{n+1}}(\theta_{\rm rar}) - \theta_{\rm rar}$, $\Delta r := R(g^{Q_{n+1}}(\theta_{\rm rar})) - R(\theta_{\rm rar})$ for some large value of n. Then if the local Hölder exponent of R at $\theta = \theta_{\rm rar}$ is κ, we will have $|\Delta r| \sim |\Delta\theta|^\kappa$. If the graph of R is asymptotically invariant around $(\theta_{\rm rar}, R(\theta_{\rm rar}))$ with respect to the scalings (5.1), we will have $|\beta_0\,\Delta r| \sim |\alpha_0\,\Delta\theta|^\kappa$. "Dividing out" the last two relationships, we obtain $|\beta_0| \sim |\alpha_0|^\kappa$, i.e., $\kappa \sim \frac{\log|\beta_0|}{\log|\alpha_0|}$. This argument (which can easily be made rigorous) implies that the (global) Hölder exponent of R does not exceed $\frac{\log|\beta_0|}{\log|\alpha_0|} \approx 3.22945$. The scaling (5.2) yields a tighter bound on the Hölder regularity of R:

$$\kappa(R) \le \frac{\log|\beta_3|}{\log|\alpha_3|} \approx 1.7901\ . \tag{5.3}$$

Note that the fact that the scaling (5.2) is "step-3" (as opposed to "step-1") is irrelevant for the bounds on the Hölder regularity.

To obtain bounds on $\kappa(h)$ and $\kappa(h^{-1})$, we use Lemma 8.1 from [13], which says that if the function h conjugates f_1 and f_2, $h\circ f_1 = f_2 \circ h$, and if for some sequence of positive integers Q_n the functions f_j $(j = 1, 2)$ behave in a neighborhood of the fixed point $\theta_{\rm fix} = h(\theta_{\rm fix})$ of h as

$$f_j^{Q_n}(\theta_{\rm fix}) = \theta_{\rm fix} + C_j\eta_j^{-n} + o(\eta_j^{-n})$$

for some constants η_j and C_j, then $\kappa(h) \le \frac{\log|\eta_2|}{\log|\eta_1|}$. Applying this to the definition of h and using the well-known fact that $(Q_n\,\sigma_{\rm G}) \bmod 1 \le C\sigma_{\rm G}^n$, we obtain the bounds

$$\kappa(h) \le \frac{\log|\alpha_0^{-1}|}{\log|\sigma_{\rm G}|} \approx 0.721125\ , \qquad \kappa(h^{-1}) \le \frac{\log|\sigma_{\rm G}^3|}{\log|\alpha_3^{-1}|} \approx 0.91478\ . \tag{5.4}$$

A comparison with Table 1 suggests that these bounds are saturated.

5.2. Conjugacies and singular measures. The functions whose Hölder regularity we study are defined through high iterates of maps. For example, the graph of the function R defined by (2.4) is nothing but the critical invariant circle γ of F which is densely filled by the iterates $F^n(\theta_0, r_0)$ of some point $(\theta_0, r_0) \in \gamma$. Here we discuss how some characterizations of the singularities in the distribution of the iterates of F on γ are related to the Hölder regularity of some of the functions considered.

Hentschel and Procaccia [41] pointed out the importance of the *generalized (Rényi) dimensions* $D(q)$ of a singular measure for dynamical systems; these quantities have been defined previously in the context of probability theory by Rényi [42]. Halsey et al. in their seminal paper [50] related heuristically the Rényi dimension of a singular measure to the *spectrum of singularities* $f(\alpha)$. We recall that $f(\alpha)$ is the Hausdorff dimension of the set E_α of points where the measure has singularity of strength α. The spectrum $f(\alpha)$ is a function supported on the interval $[\alpha_{\min}, \alpha_{\max}]$, where $\alpha_{\min} = D(\infty)$ (resp., $\alpha_{\max} = D(-\infty)$) describes the scaling behavior of the measure in the region where the measure is most dense, respectively, most rarefied.

Let (θ_0, r_0) be an arbitrary point on the critical invariant circle γ of the area-preserving twist map F. Then the distribution of the iterates in a very long orbit, $\{F^n(\theta_0, r_0)\}_{n=0}^K$,

approaches as $K \to \infty$ the "density" of the measure on γ that is invariant with respect to the restriction of the map F onto γ. (We put "density" in quotation marks because for singular measures this is not a function but a set of Dirac δ-distributions.) This invariant measure on γ induces an invariant measure μ_g of the map g on $\mathbb{T}$. It is easy to see that (2.7) implies that

$$h^{-1}(\theta) = \int_0^\theta d\mu_g$$

(for an appropriately chosen ζ in the redefinition of h as in section 2.5). This relationship implies that the spectrum of singularities $f(\alpha)$ of the measure μ_g is the same as the *Hölder spectrum* $f_{\mathrm{H}}(\alpha)$ of the function h^{-1}. By definition, $f_{\mathrm{H}}(\alpha)$ is the Hausdorff dimension of the set where the local Hölder exponent of the function is equal to α; for a readable account we refer the reader to Jaffard [43, 44]. The (global) Hölder regularity $\kappa(\phi)$ of a function ϕ is equal to the lowest end, $\alpha_{\min}$, of the support of the Hölder spectrum, $f_{\mathrm{H}}(\alpha)$, of ϕ.

Osbaldestin and Sarkis [45] applied the method of [50] to determine numerically the functions $f(\alpha)$ and $D(q)$ of the invariant measure μ_g coming from the distribution of iterates of the Taylor–Chirikov map F on the golden invariant circle. They found that

$$\alpha_{\min} = D(\infty) \approx 0.915\ , \qquad \alpha_{\max} = D(-\infty) \approx 1.387 \approx \frac{1}{0.720}\ .$$

Comparing these with the values in Table 1, the reader should recognize that their $\alpha_{\min}$ is nothing but our $\kappa(h^{-1})$, while $\alpha_{\max}$ is equal to the inverse of the regularity of the conjugacy h.

Burić, Mudrinić, and Todorović [46, 47] studied numerically the Taylor–Chirikov map and the map (2.1) with $V(\theta) = \frac{1}{2}\sin 2\pi\theta + \frac{1}{4}\sin 4\pi\theta$ for rotation numbers with continued fraction expansions of the form $[S, 1^\infty] := [S, 1, 1, 1, \ldots]$, $[S, 2^\infty]$, $[S, 3^\infty]$, $[S, 4^\infty]$, where S stands for some short string of positive integers. They found that $f(\alpha)$ and $D(q)$ depend only on the tail but do not depend on the initial part S or on whether the Taylor–Chirikov map or the other map was used in their numerics.

Other papers related to numerical computations of singular measures on critical invariant circles of area-preserving twist maps are Shi and Hu [48, 49], where the methods of [50] (reprinted in [59]) were used, and Hunt et al. [51], where the authors used the thermodynamic formalism developed in [52] (reprinted in [59]) to compute the information dimension $D(1)$ of the standard map for different rotation numbers.

5.3. Conclusion. We accurately computed the golden critical invariant circles for six twist maps of the form (2.1) and the global Hölder regularity κ of some functions related to the dynamics on these circles, as well as regularities of the functions associated with the silver critical invariant circles of two twist maps. Our numerical experiments lend credibility to Conjectures 2.3, 2.4, and 2.5 concerning the universality of the regularities of the functions R, g, h, h^{-1}, and H (see Table 1 and (4.7)). Yamaguchi and Tanikawa [53] found numerically that the golden invariant circle (given by the function R) of the Taylor–Chirikov map is differentiable, but R' is not of bounded variation; our studies significantly narrow the numerical bounds on $\kappa(R)$ for this and other maps.

Our results seem to indicate that the regularities of R, h, and h^{-1} saturate the upper bounds (5.3) and (5.4) coming from previous studies of scaling exponents.

Our finding that $\kappa(H)$ is greater than $\kappa(h)$ and $\kappa(h^{-1})$ by a comfortable margin (cf. Conjecture 2.6) has an interesting consequence. As discussed in section 5.2, the Hölder regularity of h and h^{-1} is different at different points, and for each $\alpha \in (\alpha_{\min}, \alpha_{\max})$, the set E_α (where the pointwise Hölder exponent of h^{-1} is α) has Hausdorff dimension $f_H(\alpha)$ strictly between 0 and 1. Previous numerical studies indicated that $f_H(\alpha)$ are the same for different maps F. Our finding shows that the "irregularities" of functions h coming from different maps F are interspersed in the same way in $[0, 1]$ for all twist maps studied. Note that this does not mean that for a certain value of α the sets E_α are *the same* for different F in the same universality class—only the way all sets E_α for different α are interwoven is universal.

Perhaps it would be interesting for the reader to compare the results of the present paper with those on regularity of nontwist maps [25]. One has to keep in mind, however, that, while—according to Theorem 2.2—the critical invariant circles for twist maps are graphs (in polar coordinates), in the case of nontwist maps this is not so. Therefore, some of the objects we studied here (i.e., the functions R and g) do not have analogues for nontwist maps.

It would be interesting to apply wavelet-maxima methods for pointwise regularity [54, 55] (see also the rigorous analysis in [43, 44]) to the problem studied in this paper and to compare the results of the wavelet analysis with the results about the singular invariant measures.

The case of more general Bryuno numbers also deserves attention (see, e.g., [56, 57]). However, we do not think that numerical studies of the regularities of functions related to twist maps with such rotation numbers are feasible at present for several reasons. Most importantly, the accuracy of the results on regularity behaves like the logarithm of the computational effort and of the size of the data arrays needed in the computations; note that Figure 9 is in log-log scale. Also, the inherent "oscillations" around the straight line in that figure (shown in Figure 10) contribute to the numerical error in the determination of the averaged slopes. Achieving higher precision in computing the regularity will require computing the parameters of the twist map with a very high accuracy, which in turn will necessitate very long runs of the programs.

As a by-product of our studies, we have computed millions of Fourier coefficients of the functions h and noticed some self-similarity properties that to the best of our knowledge have not been observed before. Currently we are working on understanding these properties.

Acknowledgments. We would like to express our gratitude to Rafael de la Llave, who introduced the authors of the present paper to each other, suggested the problem, and took an active part in the early stages of this research. We have profited immensely from his expert advice and friendly prodding throughout our work on the paper.

We also thank the referees whose constructive suggestions helped us clarify some important points.

Our computations were carried out on the computers of IIMAS-UNAM and the Department of Mathematics of the University of Texas. A.O. would like to thank Ana Pérez for computational support. We used the doubledouble software developed by Keith Briggs, and the convenient plotting tool Grace [58] (a descendant of ACE/gr developed by Paul J. Turner). We express our thanks to all these people and organizations.

Chaotic Braided Solutions via Rigorous Numerics: Chaos in the Swift–Hohenberg Equation*

Jan Bouwe van den Berg† and Jean-Philippe Lessard‡

Abstract. We prove that the stationary Swift–Hohenberg equation has chaotic dynamics on a critical energy level for a large (continuous) range of parameter values. The first step of the method relies on a computer assisted, rigorous, continuation method to prove the existence of a periodic orbit with certain geometric properties. The second step is topological: we use this periodic solution as a skeleton, through which we braid other solutions, thus forcing the existence of infinitely many braided periodic orbits. A semiconjugacy to a subshift of finite type shows that the dynamics is chaotic.

Key words. forcing, chaos, pattern formation, computer-assisted proof, Swift–Hohenberg

1. Introduction.

Finding analytic solutions of nonlinear, parameter dependent, ordinary differential equations (ODEs) is in general an extremely difficult task—most of the time impossible. The use of numerical techniques then becomes a useful path to adopt in order to understand the dynamics of a given nonlinear ODE. One may obtain insight not just through simulations; today the numerical output can also be used to rigorously extract coarse topological information from the systems, often revealing complicated dynamics. In particular, proving the existence of chaos in nonlinear dynamical systems in such a way has become quite popular (see [1, 14, 17, 26, 33, 35, 36]). One may interpret these results as forcing-type theorems, since a finite number of computable objects can be used to draw conclusions about the existence of infinitely many other objects. In this paper we propose a novel approach along those lines to prove existence of chaos for a class of problems with a special structure, namely, so-called second-order Lagrangian dynamical systems with the Twist property. This is a class of variational problems that lead to fourth-order ODEs. In particular, the well-known Swift–Hohenberg equation, one of standard models for pattern formation, falls into this class of problems.

A common feature of the proofs in [1, 17, 26, 35, 36] is the use of interval arithmetic to integrate the flow over sets and look for images of these rigorously integrated sets on some

prescribed Poincaré sections. In contrast, our proof requires only proving the existence of *a single periodic solution* of a certain type. This will be done via validated continuation (cf. [15, 18]). One important advantage of this validated continuation method is that it becomes natural to prove the existence of chaos for a continuous range of parameter values.

We focus our attention on the Swift–Hohenberg equation, a fourth-order parabolic partial differential equation (PDE), traditionally written as

$$\frac{\partial U}{\partial T} = -\left(\frac{\partial^2}{\partial X^2} + 1\right)^2 U + \alpha U - U^3, \tag{1}$$

which is widely used as a model for pattern formation due to a finite wavelength instability, such as in Rayleigh–Bénard convection (see, e.g., [11, 32]). The onset of instability is at $\alpha = 0$. The Swift–Hohenberg equation was originally devised to describe the behavior of systems at, and just beyond, the onset of a supercritical finite wavelength instability, and it has since served as a universal model equation in the study of pattern formation, where the parameter α is not necessarily taken to be small (see, e.g., [9, 21, 28, 31]). Stationary profiles satisfy the ODE

$$-U'''' - 2U'' + (\alpha - 1)U - U^3 = 0, \tag{2}$$

which has a constant of integration, called the *energy*

$$E = U'''U' - \frac{1}{2}U''^2 + U'^2 - \frac{\alpha - 1}{2}U^2 + \frac{1}{4}U^4 + \frac{(\alpha - 1)^2}{4},$$

which has been normalized so that, for $\alpha > 1$, the nontrivial homogeneous states $U = \pm\sqrt{\alpha - 1}$ have energy $E = 0$. The dynamics of (2) has been studied extensively, especially for small $\alpha > 0$, but many questions remain open for larger values of the parameter. Numerical simulations suggest chaotic behavior for most $\alpha > 0$, but this has so far not been verified rigorously. In particular, although both shooting methods (e.g., [2, 7, 8, 27]) and variational methods (e.g., [6, 22, 24, 29]) have been used extensively to study (2) and related fourth-order equations, they have not succeeded in revealing chaos for the Swift–Hohenberg ODE.

The energy level $E = 0$ is special in the sense that it is a singular energy level, and it contains the nontrivial homogeneous states $U = \pm\sqrt{\alpha - 1}$. Those equilibria are stable solutions of the PDE (1) for $\alpha > \frac{3}{2}$, and saddle-foci for the ODE (2) in the same parameter range. It is well known that saddle-foci may act as organizing centers for complicated dynamics [16, 23], and this inspires us to focus our attention on the dynamics in the energy level $E = 0$. Our main result is to establish rigorously that the Swift–Hohenberg ODE has chaotic dynamics in the energy level $E = 0$ for a large continuous range of parameter values.

Proposition 1. *The dynamics of the Swift–Hohenberg ODE* (2) *on the energy level* $E = 0$ *is chaotic for all* $\alpha \geq 2$.

Before we discuss the method of proof, let us comment on some generalizations of this result. First, the method is amenable to a larger class of equations, namely, second-order Lagrangians with the Twist property; see [3]. Second, the result is stable in the sense that for energy levels arbitrarily close to 0, chaos can be proved via a few adjustments of the arguments. We will comment on both generalizations when appropriate but will keep the

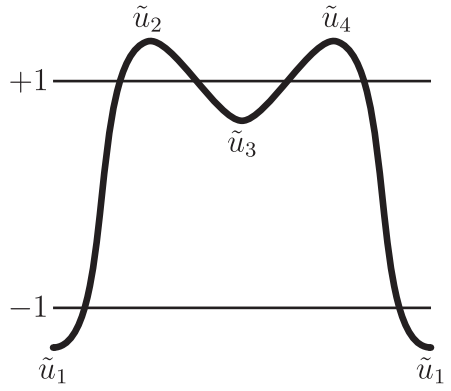

Figure 1. *Sketch of a periodic solution $\widetilde{u}$ satisfying the geometric properties $\mathcal{H}$.*

focus firmly on Proposition 1 to reduce technical details. Finally, the parameter range $\alpha \geq 2$ can be extended somewhat using our method but certainly not to cover the entire range $\alpha > 0$, as will be explained below.

We now turn to the method behind Proposition 1. Rather than working directly with (2), we first perform a change of coordinates that compactifies the parameter range as well as makes the notation more convenient. The new variables are

$$y = \frac{X}{\sqrt[4]{\alpha - 1}}, \qquad u(y) = \frac{U(X)}{\sqrt{\alpha - 1}}, \qquad \nu = \frac{2}{\sqrt{\alpha - 1}}. \tag{3}$$

The parameter range $\alpha \geq 2$ corresponds to $\nu \in (0, 2]$, and the differential equation becomes

$$-u'''' - \nu u'' + u - u^3 = 0, \tag{4}$$

while the expression for the energy is now

$$E = u'''u' - \frac{1}{2}u''^2 + \frac{\nu}{2}u'^2 + \frac{1}{4}(u^2 - 1)^2. \tag{5}$$

Equation (4), and variants with different nonlinearities, have been thoroughly investigated (see [10] and [28] and the references therein), but the parameter range under scrutiny here, namely, $\nu \geq 0$, remains much less explored than the range $\nu < 0$, mainly because most methods are somewhat less powerful for positive ν. An exception are the braid invariants introduced in [19], which are especially suited to deal with positive ν, and which we will indeed exploit in section 2.

In the method presented in this paper, chaos is forced by the existence of a single periodic solution $\widetilde{u}$ with specific geometric properties, much like a period-3 solution of an interval map implies chaos [25] (or a pseudo-Anosov braid in the context of surface homeomorphisms [34]). The periodic solution we are looking for needs to satisfy the following geometric properties (see also Figure 1):

$$\mathcal{H} \begin{cases} (H_1) & \widetilde{u} \text{ has exactly four monotone laps and extrema } \{\widetilde{u}_i\}_{i=1}^4; \\ (H_2) & \widetilde{u}_1 \text{ and } \widetilde{u}_3 \text{ are minima, and } \widetilde{u}_2 \text{ and } \widetilde{u}_4 \text{ are maxima;} \\ (H_3) & \widetilde{u}_1 < -1 < \widetilde{u}_3 < 1 < \widetilde{u}_2, \widetilde{u}_4; \\ (H_4) & \widetilde{u} \text{ is symmetric in its minima } \widetilde{u}_1 \text{ and } \widetilde{u}_3. \end{cases}$$

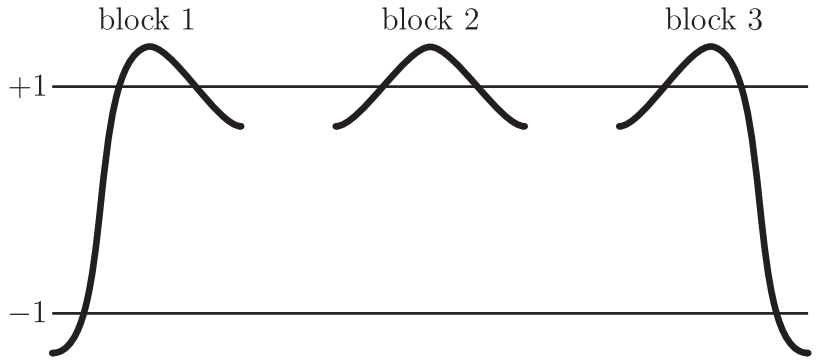

Figure 2. *Building blocks for the solutions that lead to the chaos of Theorem 2.*

Let the extrema $\widetilde{u}_i$ be attained in $\widetilde{y}_i$; then the last condition can be reformulated as

$$\widetilde{u}(\widetilde{y}_1 + y) = \widetilde{u}(\widetilde{y}_1 - y) \qquad \text{and} \qquad \widetilde{u}(\widetilde{y}_3 + y) = \widetilde{u}(\widetilde{y}_3 - y).$$

In particular, this implies that $\widetilde{u}_2 = \widetilde{u}_4$. We should note that condition H_4 is in fact not necessary for the results below to hold, but it simplifies the exposition.

As said before, such periodic solutions can be used to prove chaos when the equilibria $u = \pm 1$ are saddle-foci, i.e., when $\nu < \sqrt{8}$.

Theorem 2 (forcing). *Let $\nu \in [0, \sqrt{8})$, and suppose there exists a periodic solution $\widetilde{u}$ of (4) at the energy level $E = 0$ satisfying the geometric conditions $\mathcal{H}$. Then (4) is chaotic on the energy level $E = 0$ in the sense that there exists a two-dimensional Poincaré return map which has a compact invariant set on which the topological entropy is positive.*

The construction of the chaotic invariant set hinges on an application of Conley index theory for discretized braids [19] which will be adapted to our specific situation. The formulation in terms of discretized braids and the computation of the Conley index for well-chosen neighborhoods, whose construction involves the special periodic solution $\widetilde{u}$, is presented in section 2, together with all details of the proof of Theorem 2. Let us briefly discuss some intuition behind the result. The set of solutions of (4) that leads us to chaotic dynamics is obtained by putting the three building blocks in Figure 2 together. The order of the blocks should follow the intuition coming from Figure 2; i.e., blocks 1 and 2 may be followed by block 2 or 3, while block 3 can only be followed by block 1. The sequence of building blocks may be chosen arbitrarily as long as these rules are obeyed, and the different possibilities are sufficiently complicated to lead to chaos. The final technical step in proving chaos is then to find a semiconjugacy to a subshift of finite type; see section 2.1.

It is important to note that the only hypothesis that needs to be verified in order to prove the existence of chaos in (4) at $E = 0$ is the existence of the periodic solution $\widetilde{u}$ satisfying $\mathcal{H}$. This will be done via rigorous numerics, or computer assisted (interval arithmetic) calculations, together with a set of analytic estimates of the "tail" terms, i.e., the remainder terms not covered by the finite dimensional reduction. The construction leads to the existence of the periodic solution with the required geometric properties for a large range of parameter values.

Theorem 3 (rigorous computation). *For every $\nu \in [0,2]$ (4) has a periodic solution at energy level $E = 0$ satisfying the geometric properties $\mathcal{H}$.*

The change of variables (3) directly converts Theorems 2 and 3 into Proposition 1.

Numerical simulations suggest that although the parameter range in Theorem 3 (and hence Proposition 1) can be increased somewhat, the solution $\widetilde{u}$ with the described geometric behavior in fact disappears in a saddle-node bifurcation at some critical value $\nu_* > 2$ ($\nu_* \approx 2.03$). Hence, one has to find a different mechanism to force chaos if one wants to prove a similar result for the parameter range $\nu > 2$ (or, e.g., $\alpha \in (0,2]$).

We are going to employ Fourier transformation, a finite dimensional reduction, and a Newton-like operator, which we will prove is a contraction map via rigorous estimation of the tail term. This method has been successfully used in [15] and [18], but here we need to extend it considerably in three crucial aspects. First, the requirement $E = 0$ means that, besides satisfying the differential equation, the solution must obey an additional requirement. This means that the period of the periodic solution cannot be fixed a priori, and instead is another unknown. The extra equation leads, at a more technical level, to the need for better convolution estimates (see Appendix A), as will be explained later. Second, rigorous continuation is required in order to obtain results not for isolated values of ν (cf. [15, 18, 38]) but for the entire parameter interval $\nu \in [0,2]$. Note that in [13], a result about an entire parameter interval was also obtained, but at a much more computationally expensive price. Third, the geometric condition $\mathcal{H}$ needs to be verified rigorously to be able to combine the computational effort with the topological argument from Theorem 2, so that $\widetilde{u}$ forces chaotic dynamics.

We give a brief outline of the arguments here; full details can be found in section 3. Let $\frac{2\pi}{L}$ be the a priori unknown period of the solution $\widetilde{u}$, and let the local minima be attained at $y = 0$ and $y = \frac{\pi}{L}$. The symmetry condition H_4 implies that $u'(0) = 0$; hence evaluating the energy constraint (5) at $y = 0$ reduces (5) to

$$u''(0) = \frac{1}{\sqrt{2}}\big(u(0)^2 - 1\big), \tag{6}$$

where we have used that, since we look for solutions satisfying $\mathcal{H}$, we may assume that $u(0) < 1$ is a nondegenerate minimum; hence $u''(0) > 0$. In view of the symmetries, the Ansatz

$$u(y) = a_0 + 2\sum_{l=1}^{\infty} a_l \cos(lLy)$$

is natural, and it reduces (4) to (with $a_{-k} \equiv a_k$)

$$g_k \overset{\text{def}}{=} \left[1 + \nu L^2 k^2 - L^4 k^4\right] a_k - \sum_{\substack{k_1+k_2+k_3=k \\ k_i \in \mathbb{Z}}} a_{k_1} a_{k_2} a_{k_3} = 0 \qquad \text{for all } k \geq 0,$$

while (6) becomes

$$e \overset{\text{def}}{=} -2L^2 \sum_{l=1}^{\infty} l^2 a_l - \frac{1}{\sqrt{2}} \left[a_0 + 2\sum_{l=1}^{\infty} a_l\right]^2 + \frac{1}{\sqrt{2}} = 0.$$

The first sum in the above expression requires a faster than cubic decay of the sequence a_l, which leads to the need for improved convolution estimates (proved in Appendix A), since the bounds previously used in [12, 13, 14, 15, 18] turn out to be impractical in the current context. With the notation $x = (L, a_0, a_1, a_2, \ldots)$ and $f(x, \nu) = (e, g_0, g_1, g_2, \ldots)$, we are thus looking for a solution of $f(x, \nu) = 0$. In this formulation, and using a finite dimensional reduction, we may now use the classical predictor-corrector algorithm for following a continuous branch. However, we need to add a validation step (see [15]) and interval arithmetic to make this into a mathematically rigorous proof. We stress that the interval arithmetic, although necessary and time consuming, is of much less practical importance than the analytic error estimates due to the finite dimensional reduction. Using this finite dimensional reduction, we can, with the help of a computer, for fixed $\bar{\nu}$ find an approximate solution $\bar{x}$ of $f(x, \bar{\nu}) = 0$, as well as an approximate solution $\dot{x}$ of $\partial_x f(\bar{x}, \bar{\nu})\dot{x} + \partial_\nu f(\bar{x}, \bar{\nu}) = 0$. We also compute an approximate inverse J of $\partial_x f(\bar{x}, \bar{\nu})$. Via rigorous estimates on the remainder terms we show that

$$T(x, \Delta_\nu) = x - Jf(x, \bar{\nu} + \Delta_\nu)$$

is a contraction map on a small ball around $\bar{x} + \Delta_\nu \dot{x}$ in an appropriate Banach space for all sufficiently small Δ_ν. Repeating this for many small parameter intervals leads us to the existence of a symmetric periodic solution for all $\nu \in [0, 2]$, and, once we have verified the geometric conditions $\mathcal{H}$, to a proof of Theorem 3. It should be clear from the reformulation above that it is quite natural to do parameter continuation. In fact, we expect to find a *continuous* branch of solutions parametrized by ν. Although continuity is easy to verify for each continuation step separately, and indeed this property is used in section 4 to reduce the number of computations required, we do not need a globally (i.e., for all $\nu \in [0, 2]$) continuous branch for our proof. We refer the reader to [5] for a general overview of obtaining globally continuous branches of solutions using these techniques in the more general context of pseudo–arc-length continuation.

Let us comment on further developments. We prove here that the Poincaré return map from Theorem 2, which is in fact the map that follows solutions from one local minimum to the next (see section 2.1), has topological entropy of at least 0.48. It is possible to obtain better bounds on the entropy, still based on the existence of the periodic solution $\widetilde{u}$, using the $u \to -u$ mirror symmetry, but we will not go into the details here. Furthermore, an analysis along the lines of [4] may lead to statements about the size of the attractor for boundary value problems associated to the PDE (1), all enabled by the rigorous establishment of a single periodic solution with the geometric properties $\mathcal{H}$. This is currently under investigation.

The outline of this paper is as follows. As already noted, it suffices to prove Theorems 2 and 3, which together imply Proposition 1. The forcing theorem, Theorem 2, is proved in section 2. The method that leads to the existence of the special solution described in Theorem 3 is explained in detail in section 3. Furthermore, section 4 deals with the verification of the geometric properties $\mathcal{H}$. The analytic estimates in sections 3 and 4 lead to an algorithm, in which a finite set of inequalities needs to be checked, which is left to a computer program (with interval arithmetic). The estimates together with the output from the computer program prove Theorem 3. The appendix contains some general and rather sharp convolution estimates needed for the analytic bounds on the remainder terms.

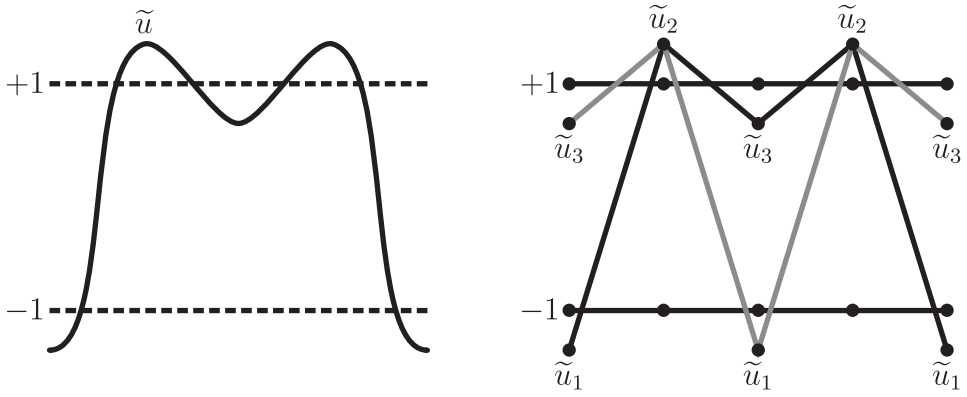

Figure 3. *Left: Sketch of the solution $\widetilde{u}$. Right: Discretized version $\{\widetilde{u}_i\}_{i=1}^4$ and a shift $\{\widetilde{u}_{i+2}\}_{i=1}^4$.*

Additional files come with the paper. The MATLAB functions *SH_continuation.m*, *SH_rigorous_continuation.m*, *SH_mesh_generator.m*, *SH_geometric_properties.m*, and *SH_run_proof.m* (70912_01.zip [14KB]) rigorously verify Procedures 16 and 21. Furthermore, the accompanying animation (70912_02.gif [1.32MB]) shows the evolution of the rigorously computed periodic solution, as we move the parameter from $\nu = 0$ to $\nu = 2$. In section 3.1, details about the computer implementation of the rigorous verification of Procedures 16 and 21 are given, together with a brief description of the MATLAB functions.

2. Forcing theorem. In this section we assume, as in Theorem 2, that $\nu \in [0, \sqrt{8})$ and that there exists a periodic solution $\widetilde{u}$ of (4) at $E = 0$ with the geometric properties $\mathcal{H}$. The idea behind the proof is that we code periodic solutions u of (4) at $E = 0$ by their extrema (see Figure 3). This leads to a discretization of the problem. If $u' = 0$, then, by (5), $u'' = \pm\frac{1}{\sqrt{2}}(u^2 - 1)$. Hence, extrema are nondegenerate except at $u = \pm 1$, and we are going to avoid those values, so we may for the moment assume all extrema to be nondegenerate. We denote the sequence of extrema of u by $\{u_i\}_{i\in\mathbb{Z}}$, where u_i represents a local minimum for odd i and a local maximum for even i (see also Figure 3).

For $\nu \geq 0$ our system is a so-called Twist system on $E = 0$, as defined and proved in [3]. The fact that the energy level is singular (contains equilibria) leads to some technical complications, but we shall overcome them relatively easily in our present context. We can therefore use the braid theory for discretized parabolic equations from [19]. The results on Twist systems that are needed in this paper are summarized in the next lemma; its proof can be found in [3] and [19, Thm. 37].

Lemma 4. *Let $\nu \geq 0$. There exist functions $\mathcal{R}_i \in C^1(\Omega_i; \mathbb{R})$ with domains*

$$\Omega_i = \left\{(u, v, w) \in \mathbb{R}^3 \;\middle|\; (-1)^i u < (-1)^i v,\ (-1)^i w < (-1)^i v,\ \text{and } u, v, w \neq \pm 1\right\},$$

with the following properties:

(a) *$\mathcal{R}_{i+2} = \mathcal{R}_i$, so there are really only two different functions in play.*

(b) *$(\mathcal{R}_i)_{i\in\mathbb{Z}}$ is a* parabolic recurrence relation*; i.e., it has the monotonicity property*

$$\partial_{u_{i-1}}\mathcal{R}_i > 0 \qquad \text{and} \qquad \partial_{u_{i+1}}\mathcal{R}_i > 0. \tag{7}$$

(c) *Define*

$$\Omega = \big\{(u_i)_{i\in\mathbb{Z}} \;\big|\; (u_{i-1}, u_i, u_{i+1}) \in \Omega_i \text{ for all } i\big\}.$$

A sequence $(u_i)_{i\in\mathbb{Z}} \in \Omega$ *solves*

$$\mathcal{R}_i(u_{i-1}, u_i, u_{i+1}) = 0 \qquad \text{for all } i$$

if and only if *it corresponds to solution of* (4) *at* $E = 0$ *with nondegenerate extrema* u_i. *An analogous statement holds for semi-infinite sequences* $(u_i)_{i\geq i_0}$ *which solve* $\mathcal{R}_i(u_{i-1}, u_i, u_{i+1}) = 0$ *for all* $i \geq i_0 + 1$.

The shapes of the domains Ω_i reflect the fact that minima are preceded and followed by maxima (and vice versa). The lemma thus implies that instead of looking for (periodic) solutions of (4) at $E = 0$ with nondegenerate extrema, we may try to find (periodic) sequences u_i that solve $\mathcal{R}_i = 0$. We remark that Lemma 4 (and the method in this paper) extends to a more general class of fourth-order ODEs, namely, those derived from a second-order Lagrangian satisfying the Twist property; see [3]. The Twist property, in essence, means that there are unique monotone solutions of the ODE between extremal values u_i and u_{i+1}.

We want to exploit the fact that the energy level $E = 0$ contains the equilibria $u = \pm 1$. However, these solutions do not correspond to a proper sequence of extrema. The linearization around the equilibria is going to help us resolve this issue. Namely, for $-\sqrt{8} < \nu < \sqrt{8}$ the equilibria ± 1 are saddle-foci, and this leads to the following fact (formulated here for the equilibrium $+1$).

Lemma 5. *Let* $-\sqrt{8} < \nu < \sqrt{8}$. *For any* $\varepsilon > 0$ *there exists a sequence* $\{u_i^\varepsilon\}_{i=1}^\infty$,

$$0 < (-1)^i(u_i^\varepsilon - 1) < \varepsilon,$$

which satisfies

$$\mathcal{R}_i(u_{i-1}^\varepsilon, u_i^\varepsilon, u_{i+1}^\varepsilon) = 0 \qquad \text{for } i \geq 2.$$

Notice that we do not claim that $\mathcal{R}_1(u_0^\varepsilon, u_1^\varepsilon, u_2^\varepsilon) = 0$; we did not even define u_0^ε.

Proof. The idea is that the u_i^ε are the extrema of an orbit in the stable manifold of $+1$, which is contained in the energy level $E = 0$. That $u_i^\varepsilon - 1$ alternates sign follows from the fact that the equilibrium $+1$ is a saddle-focus: it is easy to check that for $-\sqrt{8} < \nu < \sqrt{8}$ the *linearized* equation (i.e., $u = 1 + v$ with $v'''' + \nu v'' + 2v + O(v^2) = 0$) has solutions of the form

$$1 + Ce^{-\lambda_r x}\cos(\lambda_i x + \phi),$$

with C and ϕ arbitrary (with $\lambda_r, \lambda_i > 0$ depending on ν). In particular, the stable manifold of the linearized problem intersects the hyperplane $\{u' = 0\}$ in the line

$$\ell = \big\{(1 + v, 0, -\sqrt{2}\,v, 2\sqrt{2}\lambda_r v) \;\big|\; v \in \mathbb{R}\big\}.$$

For the nonlinear equation we need to invoke the stable manifold theorem. Let us denote the stable manifold by $W^s(+1)$ and the local stable manifold by $W^s_{\text{loc}} = W^s(+1) \cap B_{\varepsilon_0}(+1)$ for $\varepsilon_0 > 0$ chosen sufficiently small (so that the following arguments hold). By the stable manifold theorem, the local stable manifold intersects the hyperplane $\{u' = 0\}$ in a curve tangent to ℓ, and thus

$$W^s_{\text{loc}} \cap \{u' = 0\} \subset \big\{(1 + v, 0, -\sqrt{2}\,v + O(v^2), 2\sqrt{2}\lambda_r v + O(v^2)) \;\big|\; v \in \mathbb{R}\big\} \cap B_{\varepsilon_0}(+1).$$

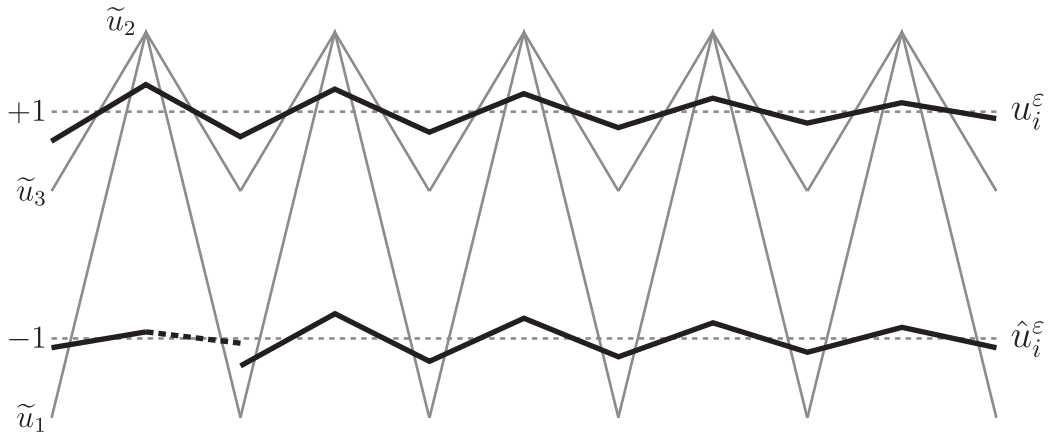

Figure 4. *The "up-down" setting including the oscillating tails in the local stable manifolds of* ± 1.

In particular, for ε_0 sufficiently small, for solutions u in the local stable manifold it holds that if $u' = 0$ and $u > 1$, then $u'' < 0$, whereas if $u' = 0$ and $u < 1$, then $u'' > 0$. This shows that all solutions in the local stable manifold have successive extrema on alternating sides of $u = 1$. Now pick one orbit in the local stable manifold and denote its extrema by $\{u_i^{\varepsilon_0}\}_{i=1}^{\infty}$, with $u_1^{\varepsilon_0}$ a local minimum. Then $0 < (-1)^i(u_i^{\varepsilon_0} - 1) < \varepsilon_0$, and $u_i^{\varepsilon_0} \to 1$ as $i \to \infty$ (exponentially fast, in fact). For $\varepsilon < \varepsilon_0$ we may choose $u_i^\varepsilon = u_{i+2n(\varepsilon)}^{\varepsilon_0}$ for some $n(\varepsilon) \in \mathbb{N}$ sufficiently large. ■

We can use the symmetry to obtain an analogous result near -1. To be explicit, $\bar{u}_i^\varepsilon = -u_{i+1}^\varepsilon$ satisfies $0 < (-1)^i(\bar{u}_i^\varepsilon + 1) < \varepsilon$. For "technical" reasons to become clear later, we will need to shift this solution, modulo the $2p$-periodicity:

$$\hat{u}_i^\varepsilon = \bar{u}_{i-2 \bmod 2p}^\varepsilon. \tag{8}$$

In fact, we have not yet chosen the period of the sequences/solutions under scrutiny, but we will do so shortly. See Figure 4 for an illustration of u_i^ε and $\hat{u}_i^\varepsilon$. Notice that $\hat{u}_i^\varepsilon$ does not "close" at $i = 3$. Nevertheless, this will not stop us from putting it to use below.

To study solutions of $\mathcal{R}_i = 0$ we introduce an artificial new time variable s and consider $u_i(s)$ evolving according to the flow $u_i' = \mathcal{R}_i$. Clearly, we want to find stationary points, and we are going to construct isolating neighborhoods for the flow (any $p \in \mathbb{N}$)

$$\frac{du_i}{ds} = \mathcal{R}_i(u_{i-1}, u_i, u_{i+1}), \qquad i = 1, \dots, 2p, \tag{9}$$

where we identify $u_0 = u_{2p}$ and $u_1 = u_{2p+1}$. The monotonicity property (7) implies that this flow has the decreasing intersection-number property: if two solutions are represented as piecewise linear functions (as in most of the figures), then the number of intersections can only decrease as time s increases.

To build the isolating neighborhoods for (9), consider first the solution $\widetilde{u}$ with geometric properties $\mathcal{H}$. Since it is a periodic solution of (4) at $E = 0$, it follows from Lemma 4(c) that

(recall that $\widetilde{u}_2 = \widetilde{u}_4$)

$$\begin{aligned}\mathcal{R}_1(\widetilde{u}_2, \widetilde{u}_1, \widetilde{u}_2) &= 0,\\ \mathcal{R}_2(\widetilde{u}_1, \widetilde{u}_2, \widetilde{u}_3) &= 0,\\ \mathcal{R}_1(\widetilde{u}_2, \widetilde{u}_3, \widetilde{u}_2) &= 0,\\ \mathcal{R}_2(\widetilde{u}_3, \widetilde{u}_2, \widetilde{u}_1) &= 0.\end{aligned}$$

Next, we choose

$$\varepsilon = \frac{1}{2}\max\{-1 - \widetilde{u}_1,\ \widetilde{u}_2 - 1,\ 1 - \widetilde{u}_3\}.$$

Although not strictly necessary for understanding the arguments that follow, it is worth mentioning that in the setting of discretized braids described in [19], we are going to use a skeleton consisting of four strands (see Figure 3, right, and Figure 4): $v_i^1 = \widetilde{u}_i$ and $v_i^2 = \widetilde{u}_{i+2}$, and $v_i^3 = u_i^\varepsilon$ and $v_i^4 = \hat{u}_i^\varepsilon$. To be precise, both v^1 and v^2 are defined for all $i \in \mathbb{Z}$ and are 4-periodic. Furthermore, v^3 is defined for all $i \geq 1$ (though not periodic), while v^4 is defined for $i = 0, \ldots, 2p+1$, with $v_0^4 = v_{2p}^4$ and $v_{2p+1}^4 = v_1^4$. All four strands satisfy

$$\mathcal{R}_i(v_{i-1}, v_i, v_{i+1}) = 0 \qquad \text{for } i = 1, \ldots, 2p,$$

with the *exception* of v^3 at $i = 1$ and v^4 at $i = 2, 3$. Below we will make sure that these points do not come into play in the construction of isolating neighborhoods.

Consider a finite, but arbitrarily long, sequence

$$\mathbf{a} = \{\mathbf{a}_j\}_{j=1}^N, \qquad \mathbf{a}_j \geq 2. \tag{10}$$

Let the period of the sequences (u_i) be $p = \sum_{j=1}^N \mathbf{a}_j$. Now that p is fixed, the meaning of $\hat{u}_i^\varepsilon$ in (8) is settled. We define the set of partial sums

$$\mathcal{A} = \left\{ \sum_{j=1}^{n-1} \mathbf{a}_j \;\middle|\; n = 1, \ldots, N \right\}.$$

Note that $0 \in \mathcal{A}$. Now define the set (neighborhood) $U_\mathbf{a} \subset \mathbb{R}^{2p}$ as a product of intervals

$$U_\mathbf{a} = \{u_i \in I_i,\ i = 1, \ldots, 2p\},$$

where the intervals are given by

$$\begin{aligned} I_i &= [u_i^\varepsilon, \widetilde{u}_2] && \text{if } i \text{ is even;}\\ I_i &= [\widetilde{u}_3, u_i^\varepsilon] && \text{if } i \text{ is odd and } \frac{i-1}{2} \notin \mathcal{A};\\ I_i &= [\widetilde{u}_1, \hat{u}_i^\varepsilon] && \text{if } i \text{ is odd and } \frac{i-1}{2} \in \mathcal{A}. \end{aligned}$$

Notice that $U_\mathbf{a}$ is contained in the domain of definition Ω of $\mathcal{R}$, since ± 1 are not in any of the intervals I_i, and the "up-down" criterion is also satisfied (the intervals I_i for odd i lie strictly

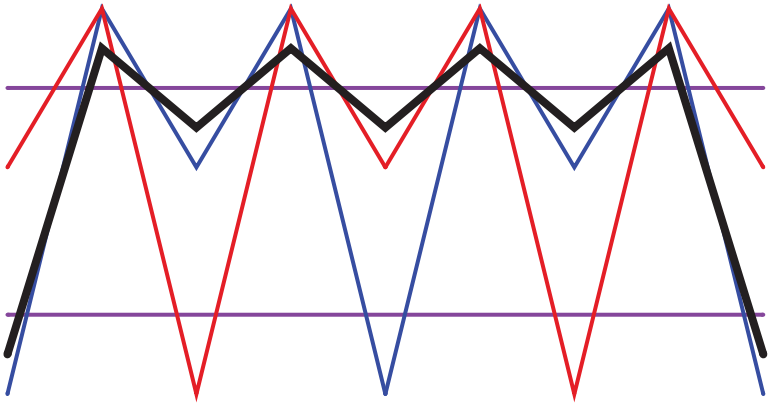

Figure 5. *The thin colored lines denote the skeleton, where we represent u^ε and $\hat{u}^\varepsilon$ by constants for convenience. The thick black lines represent the free strand, which is in $U_{\mathbf{a}}$ for $\mathbf{a} = (4)$, $p = 4$. One can check that on the boundary of $U_{\mathbf{a}}$ the number of crossings with at least one of the skeletal strands decreases; hence the flow points outward on the boundary $\partial U_{\mathbf{a}}$.*

below the ones for even i). It is useful to review the intervals in the context of Figure 4 and to look at Figure 6 for an example with $\mathbf{a} = 243$.

We now prove that every $U_{\mathbf{a}}$ contains an equilibrium of (9), still under the assumption that $\widetilde{u}$ is a periodic solution of (4) at $E = 0$ with geometric properties $\mathcal{H}$.

Lemma 6. *For any* $\mathbf{a}$ *defined in* (10) *the set* $U_{\mathbf{a}}$ *contains an equilibrium, corresponding to a periodic solution of* (4) *on* $E = 0$.

Proof. The case $\mathbf{a} = 222\ldots2 = 2^q$ is exceptional, since the point $(\widetilde{u}_1, \widetilde{u}_2, \widetilde{u}_3, \widetilde{u}_2)^q$, corresponding to the periodic solution $\widetilde{u}$, lies on the boundary of (the closed set) $U_{222\ldots2}$.

For all other $\mathbf{a}$, the corresponding solution lies in the interior of $U_{\mathbf{a}}$. The proof follows from the general theory in [19]. Namely, suppose from now on that $\mathbf{a} \neq 222\ldots2$. Then $U_{\mathbf{a}}$ is an isolating block for the flow in the sense of the Conley index, and the flow points outward everywhere on the boundary. This is relatively easy to check on the codimension 1 boundaries of $U_{\mathbf{a}}$, i.e., exactly one of the u_i lies on the boundary of I_i, while all the others are in the interior; for the higher codimension boundaries, see [19]. For the following arguments it may be helpful for the reader to consult Figure 5.

Let us consider one of the sides of the $2p$-cube $U_{\mathbf{a}}$. For example, $u_i = u_i^\varepsilon$ for some even i; i.e., u_i is on the lower boundary of I_i. Since $u_{i-1} < u_{i-1}^\varepsilon$, and $u_{i+1} < u_{i+1}^\varepsilon$ on the codimension 1 piece of this side, we infer from the monotonicity (7) that

$$\frac{du_i}{ds} = \mathcal{R}_i(u_{i-1}, u_i, u_{i+1}) < \mathcal{R}_i(u_{i-1}^\varepsilon, u_i^\varepsilon, u_{i+1}^\varepsilon) = 0.$$

Hence the flow points outward. And when $u_i = \widetilde{u}_2$ for some even i (the upper boundary point of I_i), then, since $\mathbf{a}_j \geq 2$, either $\frac{i-1}{2} \notin \mathcal{A}$ or $\frac{i+1}{2} \notin \mathcal{A}$, or both. Let us consider the case $\frac{i-1}{2} \notin \mathcal{A}$ (the other case is analogous); then $u_{i-1} > \widetilde{u}_3$ and $u_{i+1} > \widetilde{u}_1$ (assuming again that $(u_i)_{i=1}^{2p}$ is in a codimension 1 boundary). Hence

$$\frac{du_i}{ds} = \mathcal{R}_i(u_{i-1}, u_i, u_{i+1}) > \mathcal{R}_2(\widetilde{u}_3, \widetilde{u}_2, \widetilde{u}_1) = 0,$$

and thus the flow points outward again. All other (codimension 1) boundaries can be dealt with analogously.

We should note that, by construction of the neighborhoods in combination with the definition of u^ε and $\hat{u}^\varepsilon$, we avoid the three points where the skeleton does not satisfy the recurrence relation. In particular, no part of the boundary $\partial U_{\mathbf{a}}$ lies in the hyperplanes $u_1 = u_1^\varepsilon$ (since $u_1 < -1$) or $u_2 = \hat{u}_2^\varepsilon$ or $u_3 = \hat{u}_3^\varepsilon$ (since $\mathbf{a}_1 \geq 2$; hence $u_2, u_3 > \widetilde{u}_3$). We leave the remaining details to the reader.

As said before, for the higher codimension boundaries we refer the reader to [19, Prop. 11, Thm. 15]. We can now conclude that since $U_{\mathbf{a}}$ is a $2p$-cube and the flow points outward on $\partial U_{\mathbf{a}}$, its Conley index is homotopic to a $2p$-sphere, and the nonvanishing of its Euler characteristic implies that there has to be a stationary point in the interior of $U_{\mathbf{a}}$ [19, Lem. 36] corresponding to a solution of (4) by Lemma 4(c). ■

Remark 7. A similar result holds for energy levels close to $E = 0$. The main difference is that the infinite sequences u_i^ε, consisting of the extrema of a solution in the stable manifold of 1, is not available in energy levels $E \neq 0$. Nevertheless, an analogous construction can be set up for E sufficiently close to 0, *provided* the sequences $\mathbf{a} = \{\mathbf{a}_j\}_{j=1}^N$ are now chosen with $2 \leq \mathbf{a}_j \leq N_E < \infty$, where N_E tends to infinity as E approaches 0. For $E > 0$ (and small) an additional difficulty arises, because the Twist property (and hence Lemma 4) does not immediately follow from the results in [3]. However, perturbation methods can be used to show that the Twist property persists for small $E > 0$, at least away from the equilibria $u = \pm 1$. The details are beyond the scope of the current paper.

Remark 8. When the symmetry condition H_4 is dropped, then the definition of $U_{\mathbf{a}}$ needs to be modified to accommodate for the fact that $\widetilde{u}_2 \neq \widetilde{u}_4$. The shape of the set $U_{\mathbf{a}}$ will be more complicated than just a single $2p$-cube. Namely, one needs to consider the appropriate discretized braid class; see [19]. Nevertheless, the results in [19] show that the Conley index of this braid class is again homotopic to a sphere, and Lemma 6 and the results in the next section remain valid in the nonsymmetric setting.

2.1. Topological entropy. In this section we construct a semiconjugacy from a Poincaré section of the flow to a subshift of finite type with positive entropy, and thereby we finish the proof of Theorem 2. This process involves a couple of somewhat technical steps.

First, we look at an alternative coding, which is more convenient when examining the entropy. We extend any sequence $\mathbf{a} = \{\mathbf{a}_j\}_{j=1}^N$, $\mathbf{a}_j \geq 2$, periodically to a bi-infinite sequence: $\mathbf{a}_{j+N} = \mathbf{a}_j$. To such a periodic sequence we associate a bi-infinite sequence of 0's and 1's:

$$\mathbf{b} = \cdots 01^{\mathbf{a}_{-2}-1}01^{\mathbf{a}_{-1}-1}01^{\mathbf{a}_0-1}.01^{\mathbf{a}_1-1}01^{\mathbf{a}_2-1}0\cdots .$$

Notice, in particular, that $\mathbf{b}_0 = 0$. This coding is also indicated in Figure 6. It is not hard to see that the sequences $\mathbf{b}$ are in the symbol space Σ_B generated by the adjacency matrix

$$B = \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}.$$

We now interpret $U_{\mathbf{a}}$ as an *infinite* product of intervals, and in terms of $\mathbf{b}$ the intervals making up the neighborhood $U_{\mathbf{a}} = U_{\mathbf{b}}$ are given by ($i \in \mathbb{Z}$)

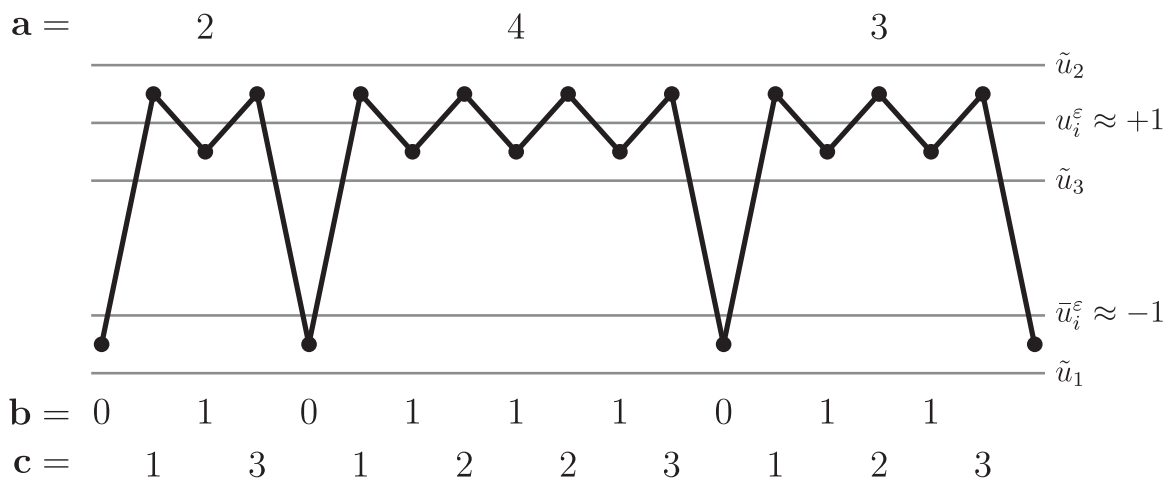

Figure 6. *A schematic example of a pattern in $U_{\mathbf{a}}$. At the top is the coding* $\mathbf{a}$*, and below are the corresponding codings* $\mathbf{b}$ *and* $\mathbf{c}$*, which are used in the discussion of the entropy.*

$$
\begin{aligned}
I_i &= [u_i^\varepsilon, \widetilde{u}_2] && \text{if } i \text{ is even,}\\
I_i &= [\widetilde{u}_3, u_i^\varepsilon] && \text{if } i \text{ is odd and } b_{\frac{i+1}{2}} = 0,\\
I_i &= [\widetilde{u}_1, \hat{u}_i^\varepsilon] && \text{if } i \text{ is odd and } b_{\frac{i+1}{2}} = 1.
\end{aligned}
$$

Let $u_{\mathbf{a}} = u_{\mathbf{b}}$ be the periodic solutions of (4) at $E = 0$ corresponding to the stationary points in $U_{\mathbf{a}} = U_{\mathbf{b}}$, which was found in Lemma 6.

An arbitrary periodic sequence in Σ_B might not have a $b_0 = 0$, but for any periodic sequence $\mathbf{b} \neq 1^\infty$ in Σ_B we can find a periodic solution of (4) at $E = 0$ in $U_{\mathbf{b}}$ by using an appropriate shift.

It is now time to set up the semiconjugacy from a Poincaré map of the flow to the shift-map σ on Σ_B. It is not difficult to check that the sets $\mathcal{C} \subset \{E = 0\} \subset \mathbb{R}^4$ of all orbits, varying over all possible periodic $\mathbf{a}$'s or $\mathbf{b}$'s, is uniformly bounded. Taking the closure of this set, we obtain a compact invariant set $\overline{\mathcal{C}}$ for the ODE. Notice that it may include the equilibrium solution $u \equiv 1$.

Next we choose a Poincaré section. The energy level $E = 0$ is a three-dimensional subset of the phase space $\mathbb{R}^4$. A local minimum in $E = 0$ is defined by the values of u and u''', since $u'' = \frac{1}{\sqrt{2}}|u^2 - 1|$. The Poincaré section is therefore defined as the two-dimensional subset

$$\mathcal{P} = \left\{ (u, 0, \tfrac{1}{\sqrt{2}}|u^2 - 1|, u''') \;\middle|\; u, u''' \in \mathbb{R} \right\},$$

and the return map $\mathcal{T} : \mathcal{P} \to \mathcal{P}$ follows solutions from one minimum to the next. For the special point $\pm\mathbf{1} = (\pm 1, 0, 0, 0) \in \mathcal{P}$ we define $\mathcal{T}(\pm\mathbf{1}) = \pm\mathbf{1}$.

Lemma 9. *For any $\nu > -\sqrt{8}$ the Poincaré return map $\mathcal{T}$ is well defined on $\mathcal{P}$, and $\mathcal{T}$ is continuous.*

Proof. That $\mathcal{T}$ is well defined follows from the fact that any solution $u \not\equiv 1$ in $E = 0$ has infinitely many extrema, which was proved in, e.g., [28, Lem. 3.1.2]. That $\mathcal{T}$ is continuous

away from $\pm\mathbf{1}$ follows from the methods in the proof of Lemmas 3.1.3 and 3.1.4 in [28]. There, only symmetric settings were considered, but the method prevails in the nonsymmetric setting. Continuity of $\mathcal{T}$ at $\pm\mathbf{1}$ follows from the fact that the equilibria are either saddle-foci ($|\nu| < \sqrt{8}$) or centers ($\nu \geq \sqrt{8}$). Roughly speaking, the closer an orbit starts to ± 1, the more extrema near ± 1 it has. It is not hard to deduce continuity at $\pm\mathbf{1}$ from this. ■

By construction and Lemma 9, the return map $\mathcal{T}$, defined on $\mathcal{P}$, has a compact invariant set $\Lambda = \mathcal{P} \cap \overline{\mathcal{C}}$. For $\lambda \in \Lambda$, we denote by $u^\lambda(y)$ the solution with *initial data* λ.

Lemma 10. *Let $\lambda \in \Lambda$, and let u^λ be the associated solution of (4). Suppose $u^\lambda \not\equiv 1$. Then u^λ has only nondegenerate extrema, with the maxima in $(1, \widetilde{u}_2]$ and the minima either in $[\widetilde{u}_3, 1)$ or in $[\widetilde{u}_1, -1)$.*

Proof. We write $u = u^\lambda$. All solutions in $\overline{\mathcal{C}}$ can be approximated arbitrarily closely (on compact intervals) by the periodic solutions found in Lemma 6. Nondegenerate extrema persist, whereas degenerate extrema ($u' = u'' = 0$) in $E = 0$ must lie on the lines $u = \pm 1$. Hence, the bounds on the extrema follow immediately from the definitions of $U_{\mathbf{a}}$ and I_i, once we have excluded degenerate extrema, i.e., inflection points on $u = \pm 1$.

To rule out inflection points we argue by contradiction (see also [28, Lem. 3.1.5]). Suppose $u \in \overline{\mathcal{C}}$ has an inflection point, say, $u'(0) = u''(0) = 0$. Hence $u(0) = \pm 1$ and $u'''(0) \neq 0$ (if $u'''(0) = 0$, then $u \equiv 1$ by uniqueness of the initial value problem). We consider the case $u(0) = 1$ and $u'''(0) > 0$; the other three cases are ruled out in an analogous manner. Let $\{u_n\}_{n=1}^\infty$ be a sequence of periodic solutions found in Lemma 6, such that $u_n \to u$ in C^3 on any bounded interval. Then by the implicit function theorem, for large enough n, there exist points y_n such that $\lim_{n\to\infty} y_n = 0$ and $u_n''(y_n) = 0$. We know that $u_n'(y_n) \neq 0$, since the u_n have only nondegenerate extrema.

We now consider two cases: either $u_n'(y_n) > 0$ or $u_n'(y_n) < 0$ for infinitely many $n \in \mathbb{N}$. In the former case we argue as follows. Taking a subsequence we may assume that $u_n'(y_n) > 0$ for all n. We conclude from $E = 0$ and $u_n''(y_n) = 0$ that

$$u_n'''(y_n) + \frac{\nu}{2} u_n'(y_n) = -\frac{(u_n(y_n)^2 - 1)^2}{4u_n'(y_n)} \leq 0.$$

Taking the limit $n \to \infty$ in the above inequality leads to $u'''(0) + \frac{\nu}{2} u'(0) \leq 0$, which contradicts the assumption that u has an inflection point at $y = 0$ with $u'''(0) > 0$.

In the latter case, we may assume that $u_n'(y_n) < 0$ for all n. Since in the inflection point $u'''(0) > 0$, it follows that $u'(y) > 0$ for $y \neq 0$ sufficiently small. This means that for n large enough there are sequences $y_n^1 < y_n < y_n^2$ of local maxima and minima of u_n, respectively, such that $y_n^{1,2} \to 0$ as $n \to \infty$. Since the periodic solutions u_n have their extrema on alternating sides of $+1$ by construction, there is a sequence $y_n^3 \in (y_n^1, y_n^2)$ such that $u_n(y_n^3) = 1$ and $u_n'(y_n^3) < 0$. We conclude from $E = 0$ and $u_n(y_n^3) = 1$ that

$$u_n'''(y_n^3) + \frac{\nu}{2} u_n'(y_n^3) = \frac{u_n''(y_n^3)^2}{u_n'(y_n^3)} \leq 0,$$

and we reach a contradiction as before by taking the limit $n \to \infty$ in this inequality, thereby concluding the proof. ■

To define the semiconjugacy $\rho : \Lambda \to \Sigma_B$ we consider the solution $u^\lambda(y)$ of (4) with initial data $\lambda \in \Lambda$. If $u^\lambda \equiv 1$, we define $\rho(\lambda) = 1^\infty$. Otherwise, let u_i^λ be the sequence of extrema

of u^λ, indexed such that u_1^λ is the minimum corresponding to $\lambda \in \mathcal{P}$. By Lemma 10, this sequence lies in $U_{\mathbf{b}_\lambda}$ for some $\mathbf{b}_\lambda \in \Sigma_B$, and we define $\rho(\lambda) = \mathbf{b}_\lambda$.

It follows from Lemmas 9 and 10 that the map ρ is continuous (also in the point $+\mathbf{1}$, if $+\mathbf{1}$ happens to lie in Λ). Moreover, $\rho \circ \mathcal{T} = \sigma \circ \rho$ by construction and the properties of the return map (where σ is the shift map). Finally, ρ is surjective. Namely, all *periodic* sequences in Σ_B have corresponding solutions in $\overline{\mathcal{C}}$ (and thus in Λ), and since the set of periodic sequences is dense in Σ_B and Λ is compact, surjectivity follows. Hence, ρ defines a semiconjugacy, and it follows (e.g., [30]) that the topological entropy of the map $\mathcal{T}$ on Λ is positive:

$$h_{\text{top}}(\mathcal{T}|_\Lambda) \geq h_{\text{top}}(\sigma|_{\Sigma_B}) = \log\left(\frac{1+\sqrt{5}}{2}\right).$$

This finishes the proof of Theorem 2.

Remark 11. There is another way to make a coding that was already alluded to in the introduction. The profile between two successive minima can, qualitatively, have three shapes (see Figure 2):

$$\begin{aligned} u_i < -1 \quad &\text{and} \quad u_{i+2} > -1, \qquad \text{coded by } \mathbf{c}_i = 1; \\ u_i > -1 \quad &\text{and} \quad u_{i+2} > -1, \qquad \text{coded by } \mathbf{c}_i = 2; \\ u_i > -1 \quad &\text{and} \quad u_{i+2} < -1, \qquad \text{coded by } \mathbf{c}_i = 3. \end{aligned}$$

This new coding $\mathbf{c}$ is also indicated in Figure 6. The corresponding adjacency matrix is

$$\begin{pmatrix} 0 & 1 & 1 \\ 0 & 1 & 1 \\ 1 & 0 & 0 \end{pmatrix}.$$

This of course does not improve the bound on the entropy of $\mathcal{T}$, but the slightly more complicated coding $\mathbf{c}$, using "up-down" building blocks, is more intuitively related to the shape of solutions, as expressed in Figure 2.

3. Rigorous continuation. We are going to restrict our attention to symmetric periodic solutions u satisfying $\mathcal{H}$. Hence, let

$$u(y) = a_0 + 2\sum_{l=1}^{\infty} a_l \cos(lLy), \tag{11}$$

with L an a priori unknown variable. Since $u'(0) = 0$, and the energy (5) is a conserved quantity along the orbits of (4), we get that

$$\begin{aligned} E &= u'''(0)u'(0) - \frac{1}{2}u''(0)^2 + \frac{\nu}{2}u'(0)^2 + \frac{1}{4}(u^2-1)^2 \\ &= -\frac{1}{2}\left[u''(0) - \frac{1}{\sqrt{2}}\big(u(0)^2-1\big)\right]\left[u''(0) + \frac{1}{\sqrt{2}}\big(u(0)^2-1\big)\right]. \end{aligned}$$

Since we look for u such that $E = 0$, $u(0) < -1$, and $u''(0) > 0$, the energy condition boils down to

$$u''(0) - \frac{1}{\sqrt{2}}[u(0)^2 - 1] = 0. \tag{12}$$

Substituting the expansion (11) of $u(y)$ into (12), we obtain

$$e(L,a) \stackrel{\text{def}}{=} -2L^2 \sum_{l=1}^{\infty} l^2 a_l - \frac{1}{\sqrt{2}} \left[a_0 + 2 \sum_{l=1}^{\infty} a_l \right]^2 + \frac{1}{\sqrt{2}} = 0. \tag{13}$$

Plugging the expansion (11) into (4) and computing the inner product of the resulting equations with each $\cos(kLx)$, $k \geq 0$, we get

$$g_k(L,a,\nu) \stackrel{\text{def}}{=} [1 + \nu L^2 k^2 - L^4 k^4] a_k - \sum_{\substack{k_1+k_2+k_3=k \\ k_i \in \mathbb{Z}}} a_{k_1} a_{k_2} a_{k_3} = 0, \tag{14}$$

where $a = (a_0, a_1, \ldots)$. Define $x = (x_{-1}, x_0, x_1, \ldots) = (L, a_0, a_1, a_2, \ldots)$, and $g = (g_0, g_1, g_2, \ldots)^T$, as well as

$$f(x,\nu) = \begin{bmatrix} e(x) \\ g(x,\nu) \end{bmatrix}. \tag{15}$$

To simplify the presentation, we use the notation $f_{-1} = e$ and $f_k = g_k$ for $k \geq 0$. Now, since we want to use rigorous numerical methods to find pairs (x,ν) such that $f(x,\nu) = 0$, we need to consider a finite dimensional projection of (15). Define $x_F = (x_{-1}, x_0, \ldots, x_{m-1}) = (L, a_0, \ldots, a_{m-1}) \in \mathbb{R}^{m+1}$,

$$e^{(m)}(x_F) \stackrel{\text{def}}{=} -2L^2 \sum_{l=1}^{m-1} l^2 a_l - \frac{1}{\sqrt{2}} \left[a_0 + 2 \sum_{l=1}^{m-1} a_l \right]^2 + \frac{1}{\sqrt{2}},$$

and

$$g^{(m)}(x_F,\nu) \stackrel{\text{def}}{=} [g_0(x_F,\nu), \ldots, g_{m-1}(x_F,\nu)]^T.$$

The *Galerkin projection* of (15) is defined by

$$f^{(m)}(x_F,\nu) \stackrel{\text{def}}{=} \begin{bmatrix} e^{(m)}(x_F) \\ g^{(m)}(x_F,\nu) \end{bmatrix}.$$

It is important to note that $f^{(m)}$ has both a finitely truncated domain and a finitely truncated codomain.

We now describe how we can modify the classical, numerical, predictor-corrector algorithm for following a continuous branch of solutions to fit our setting. Suppose that, at parameter value $\nu = \nu_0$, we have used a Newton-like iteration method to numerically find $\bar{x}_F$ such that

$$f^{(m)}(\bar{x}_F, \nu_0) \approx 0. \tag{16}$$

Throughout this paper, Df represents the derivative of f with respect to the x_F- or x-variable. If $(\bar{x}_F, \nu_0)$ is a solution of $f^{(m)}(x_F,\nu) = 0$ such that the Jacobian matrix $Df^{(m)}(\bar{x}_F, \nu_0)$ is invertible, then, by the implicit function theorem, there exists a unique one-dimensional local continuum of solutions (x_F,ν) such that the solution x_F is locally a function of the parameter

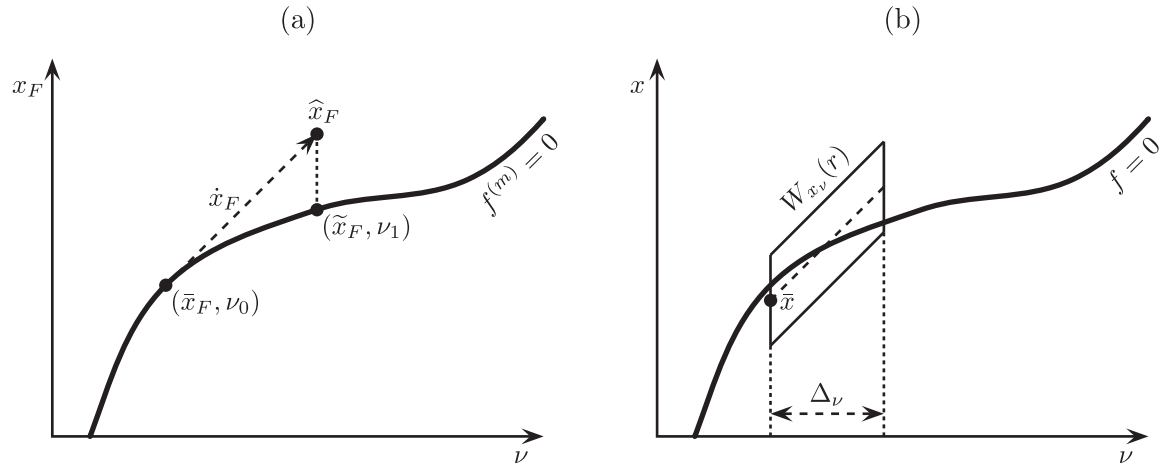

Figure 7. (a) *Sketch of the predictor-corrector algorithm for the truncated problem* $f^{(m)}(x_F, \nu) = 0$. (b) *The neighborhood* $W_{x_\nu}(r)$ *in which we find solutions of the full problem* $f(x, \nu) = 0$.

ν (near ν_0). Moreover, as a computational counterpart, we may numerically find a *tangent* vector $\dot{x}_F$ to the solution curve at $(\bar{x}_F, \nu_0)$, i.e.,

$$Df^{(m)}(\bar{x}_F, \nu_0)\dot{x}_F + \frac{\partial f^{(m)}}{\partial \nu}(\bar{x}_F, \nu_0) \approx 0. \tag{17}$$

We can then use this tangent vector to obtain a *predictor* $\widehat{x}_F = \bar{x}_F + (\nu_1 - \nu_0)\dot{x}_F$ for the solution at a parameter value ν_1 close to ν_0. The *corrector* then consists of iterating a Newton-like map, with initial point $\widehat{x}_F$, to converge to the zero $\widetilde{x}_F$ of $f^{(m)}(x_F, \nu_1)$; see also Figure 7(a). There are two essential problems to overcome in this scheme. First, the result for the finite dimensional truncation needs to be "lifted" to the infinite dimensional setting. This lifting is carried out via "validated continuation" [15], with a final interval arithmetic step. Second, the described method leads to a discrete set of solutions (x, ν), whereas we aim for solutions for a *continuous* range of parameter values, and we describe our approach below.

Denote by $\bar{x}_F = (\bar{L}, \bar{a}_0, \bar{a}_1, \ldots, \bar{a}_{m-1})$ and $\dot{x}_F = (\dot{L}, \dot{a}_0, \dot{a}_1, \ldots, \dot{a}_{m-1})$ the approximate solutions of (16) and (17), respectively, and define their infinite extensions $\bar{x} = (\bar{x}_F, 0, 0, 0, \ldots)$ and $\dot{x} = (\dot{x}_F, 0, 0, 0, \ldots)$. We define the "linear part" of g_k as

$$\mu_k(L, \nu) \stackrel{\text{def}}{=} 1 + \nu L^2 k^2 - L^4 k^4.$$

Furthermore, let the $(m+1) \times (m+1)$ matrix J_F be the numerically computed inverse of $Df^{(m)}(\bar{x}_F, \nu_0)$, and let 0_F be the $1 \times (m+1)$ row vector $(0, 0, \ldots, 0)$. We define the linear operator on sequence spaces

$$A \stackrel{\text{def}}{=} \begin{bmatrix} J_F & 0_F^T & 0_F^T & 0_F^T & \cdots \\ 0_F & \mu_m(\bar{L}, \nu_0)^{-1} & 0 & 0 & \cdots \\ 0_F & 0 & \mu_{m+1}(\bar{L}, \nu_0)^{-1} & 0 & \cdots \\ 0_F & 0 & 0 & \mu_{m+2}(\bar{L}, \nu_0)^{-1} & \\ \vdots & \vdots & \vdots & & \ddots \end{bmatrix}, \tag{18}$$

which acts as an *approximate inverse* of the linear operator $Df(\bar{x}, \nu_0)$. We shall always make sure that m is sufficiently large, so that $\mu_m(\bar{L}, \nu_0) < 0$. For ν close to ν_0, we consider the Newton-like operator

$$T_\nu(x) \stackrel{\text{def}}{=} x - A \cdot f(x, \nu). \tag{19}$$

To formalize this approach, it is convenient to use a functional analytic setting. As weight functions we define, for $s > 0$,

$$\omega_k^s = \begin{cases} 1, & k = -1, 0, \\ k^s, & k \geq 1. \end{cases} \tag{20}$$

In general, one can play around with these weight functions (and the norm below); for the problem in this paper, we have found the choice (20) to be appropriate, because it leads to a proof. These weight functions are used in the norms

$$\|x\|_s = \sup_{k=-1,0,1,\ldots} |x_k \omega_k^s| \tag{21}$$

and the sequence spaces

$$\Omega^s = \{x, \|x\|_s < \infty\},$$

consisting of sequences with algebraically decaying tails. For the first sum in (13) to make sense, we shall require that $s > 3$.

Lemma 12. *We have the following:*

(a) *The sequence space Ω^s with norm $\|\cdot\|_s$ is a Banach space for all s. The injections $\Omega^{s_1} \hookrightarrow \Omega^{s_2}$ are compact for all $s_1 > s_2$.*

(b) *Let $s > 3$. The map $T(x, \nu)$ is continuous from $\Omega^s \times \mathbb{R}$ to Ω^{s+2}, and $T(x, \nu)$ is compact from $\Omega^s \times \mathbb{R}$ to Ω^s.*

(c) *Let $s_0 > 3$ and fix ν. Zeros of $f(x, \nu)$, or, equivalently, fixed points of $T(x, \nu)$, that are in Ω^{s_0}, are in Ω^s for all $s \geq s_0$.*

(d) *Let $s > 3$. A sequence $x = (L, a_0, a_1, \ldots) \in \Omega^s$ is a zero of f, or a fixed point of T,* if and only if *u given by (11) is a periodic solution of (4) at energy level $E = 0$, with period $\frac{2\pi}{L}$, and symmetric in $y = 0$ and $y = \frac{\pi}{L}$.*

Proof. We only outline the proofs; the reader may quite easily fill in the details.

Part (a) follows from standard functional analytic arguments. For part (b), observe that, for any $s > 1$, the weighted discrete convolution $k^s |\sum_{k_1+k_2+k_3=k} a_{k_1} a_{k_2} a_{k_3}|$ is uniformly bounded if $k^s |a_k|$ is uniformly bounded; see, for example, Appendix A. It then follows that $g_k = -L^4 k^4 a_k + O(k^2)$. Since $\mu_k = -L^4 k^4 + O(k^2)$, the composition $[A \cdot f(x, \nu)]_k = x_k + O(k^{-2})$ as $k \to \infty$, and we conclude that T maps $\Omega^s \times \mathbb{R}$ to Ω^{s+2} for $s > 3$ (one needs $s > 3$ for the first sum in (13) to be well defined). Continuity of T is straightforward to verify, and the compact injections from part (a) then imply the compactness statement in (b).

Concerning part (c), the equivalence of zeros of f and fixed points of T is obvious, and the remainder of the statement follows immediately from parts (a) and (b) by using that $x = T(x)$. Finally, since the tail of a fixed point of T decays faster than any algebraic rate, all sums may be differentiated term by term; hence u defined by (11) is a solution of

the differential equation (periodic, with energy $E = 0$). On the other hand, any (periodic) solution of the differential equation is C^∞; hence the tail of its Fourier transform decays faster than any algebraic rate, and thus, by standard arguments, the Fourier transform solves $g = 0$, and part (d) follows. ∎

Lemma 12(d) shows that the problem of finding (symmetric) periodic solutions of (4) at $E = 0$ is equivalent to studying fixed points of T. We will find balls in Ω^s on which T, for fixed ν, is a contraction mapping, thus leading to solutions of (4). Let us define the ball of radius r, centered at the origin,

$$W(r) \stackrel{\text{def}}{=} [-r, r]^2 \times \prod_{k=1}^{\infty} \left[-\frac{r}{k^s}, \frac{r}{k^s}\right]. \tag{22}$$

For $\Delta_\nu = \nu - \nu_0$ small, we define the *predictors based at* ν_0 by

$$x_\nu = \bar{x} + \Delta_\nu \dot{x}.$$

For ν close to ν_0 we define the ball centered at x_ν by

$$W_{x_\nu}(r) = x_\nu + W(r).$$

We look for fixed points of T inside these balls/neighborhoods; see also Figure 7(b). To show that T is a contraction mapping, we need bounds Y_k and Z_k for all $k = -1, 0, 1, 2, \ldots$, such that, with $\Delta_\nu = \nu - \nu_0$,

$$\left|[T_\nu(x_\nu) - x_\nu]_k\right| \le Y_k(\Delta_\nu), \tag{23}$$

and

$$\sup_{w, w' \in W(r)} \left|[DT_\nu(x_\nu + w')w]_k\right| \le Z_k(r, \Delta_\nu). \tag{24}$$

We will find such bounds in sections 3.2 and 3.3, respectively. Notice that $Y_k \ge 0$ and $Z_k \ge 0$. Although this is not a restriction, we will, in this paper, consider only $\Delta_\nu \ge 0$, since we will initiate the continuation at the parameter value $\nu = 0$ and finish at $\nu = 2$; hence we do continuation in one direction only.

Variants of the following lemma were also used in [13, 15, 18, 37].

Lemma 13. *Fix $s > 3$ and $\nu = \nu_0 + \Delta_\nu$. If there exists an $r > 0$ such that $\|Y + Z\|_s < r$, with $Y = (Y_{-1}, Y_0, Y_1, \ldots)$ and $Z = (Z_{-1}, Z_0, Z_1, \ldots)$ the bounds as defined in (23) and (24), then there is a unique $\widetilde{x}_\nu \in W_{x_\nu}(r)$ such that $f(\widetilde{x}_\nu, \nu) = 0$.*

Proof. We outline the proof, which can be found in more detail in [15] and [37]. The mean value theorem (applied componentwise), combined with the assumption $\|Y + Z\|_s < r$, implies that $T(\cdot, \nu)$ maps $W_{x_\nu}(r)$ into itself. Since $Y_k \ge 0$ and $Z_k \ge 0$, it follows that $\|Z\|_s \le \|Y + Z\|_s < r$. We infer from the mean value theorem that the Lipschitz constant of $T(\cdot, \nu)$ on $W_{x_\nu}(r)$ can be estimated above by $\|Z\|_s / r < 1$, so that T is a contraction mapping. Finally, zeros of f correspond to fixed point of T; hence an application of the Banach fixed point theorem concludes the proof. ∎

In order to verify the hypotheses of Lemma 13 in a computationally efficient way, we introduce the notion of *radii polynomials*. Namely, as will become clear in sections 3.2 and 3.3, the functions $Y_k(\Delta_\nu)$ and $Z_k(r,\Delta_\nu)$ are polynomials in their independent variables. Also, for sufficiently large k, say, $k \geq M$, one may choose

$$Y_k = 0 \qquad \text{and} \qquad Z_k = \widehat{Z}_M \left(\frac{M}{k}\right)^s$$

for some $\widehat{Z}_M(r,\Delta_\nu) > 0$. This leads us to the following definition.

Definition 14. *Let $Y_k(\Delta_\nu) = 0$ and $Z_k(r,\Delta_\nu) = \widehat{Z}_M(r,\Delta_\nu)\left(\frac{M}{k}\right)^s$ for all $k \geq M$. We define the $M+2$* radii polynomials *$\{p_{-1}, p_0, \ldots, p_{M-1}, p_M\}$ by*

$$p_k(r,\Delta_\nu) \stackrel{\text{def}}{=} \begin{cases} Y_k(\Delta_\nu) + Z_k(r,\Delta_\nu) - \frac{r}{\omega_k^s}, & k = -1, 0, \ldots, M-1, \\ \widehat{Z}_M(r,\Delta_\nu) - \frac{r}{\omega_M^s}, & k = M. \end{cases}$$

The usefulness of the radii polynomials p_k follows from the observation that the polynomials Y_k and Z_k have a few exceptionally small terms. Namely, it turns out that they are *roughly* of the form (to be made precise in sections 3.2 and 3.3)

$$\begin{aligned} Y_k &\sim \delta_1 + \delta_2 \Delta_\nu + O(\Delta_\nu^2), \\ Z_k &\sim \delta_3 r + O(\Delta_\nu r, r^2), \end{aligned}$$

where the δ_1, δ_2, and δ_3 are small, because of the choice of $\bar{x}$, the choice of $\dot{x}$, and the choice of the linear operator A in the Newton-like map T, respectively. It is easy to see that the zeroth-order term of Z_k vanishes. Hence, the radii polynomials are roughly of the form

$$p_k(r,\Delta_\nu) \sim (\delta_1 + \Delta_\nu \delta_2) - \left(\frac{1}{\omega_k^s} - \delta_3\right) r + O(r^2, \Delta_\nu r, \Delta_\nu^2),$$

so that one may anticipate them to be negative for small r (but not too small) for a reasonably large range of Δ_ν.

Lemma 15. *Let $s > 3$ and let $Y_k(\Delta_\nu) = 0$ and $Z_k(r,\Delta_\nu) = \widehat{Z}_M(r,\Delta_\nu)\left(\frac{M}{k}\right)^s$ for all $k \geq M$. Suppose that there exists an $r > 0$ such that $p_k(r,\Delta_\nu) < 0$ for all $k = -1, \ldots, M$; then the hypotheses of Lemma 13 are satisfied for $\nu = \nu_0 + \Delta_\nu$.*

Proof. Let $s > 3$, $r > 0$, and $\nu = \nu_0 + \Delta_\nu$ such that $p_k(r,\Delta_\nu) < 0$ for all $k = -1, 0, \ldots, M$. Since $Y_k + Z_k = \widehat{Z}_M\left(\frac{M}{k}\right)^s$ for $k \geq M$, by definition of the radii polynomials, we get that

$$\begin{aligned} \|Y + Z\|_s &= \sup_{k=-1,0,1,\ldots} |[Y_k(\Delta_\nu) + Z_k(r,\Delta_\nu)]\omega_k^s| \\ &= \max_{k=-1,0,\ldots,M} \{p_k(r,\Delta_\nu)\omega_k^s + r\} < r. \end{aligned}$$

∎

Combining Lemmas 13 and 15, it should now become clear that proving the existence of zeros of f, and hence periodic solutions of (4) at $E = 0$, is *computable*, since only a finite number of polynomial inequalities need to be verified. There is one final observation to be made. The Y_k and the Z_k are monotonically increasing in the variable $\Delta_\nu \geq 0$, that is,

$Y_k(\Delta_\nu^0) \le Y_k(\Delta_\nu^1)$ and $Z_k(r,\Delta_\nu^0) \le Z_k(r,\Delta_\nu^1)$ for $0 \le \Delta_\nu^0 \le \Delta_\nu^1$. As a consequence, the same property holds for the radii polynomials: if $0 \le \Delta_\nu^0 \le \Delta_\nu^1$, then $p_k(r,\Delta_\nu^0) \le p_k(r,\Delta_\nu^1)$ for all $k = -1,\dots,M$. Hence, if the hypotheses in Lemma 13 are satisfied for some $\Delta_\nu^0 > 0$, then they are satisfied for all $\Delta_\nu \in [0,\Delta_\nu^0]$; hence there are corresponding periodic solutions of (4) for all $\nu \in [\nu_0, \nu_0 + \Delta_\nu^0]$.

For what follows we recall that the construction of the radii polynomials p_k involves Y_k and Z_k, defined in (26) and (31), respectively, as well as M_0 and $\widehat{Z}_M$, defined in (30) and (32), respectively. Furthermore, because the coefficients of the polynomials Y_k and Z_k are all positive, there is at most one interval in the positive half line on which p_k is negative. With these considerations in mind, the following procedure leads to a proof of the existence part of Theorem 3. The geometric properties $\mathcal{H}$ will be checked in Procedure 21 in section 4.

Procedure 16. *To check the hypotheses in Lemma 15 on the interval $\nu \in [0,2]$ we proceed as follows.*

1. *Choose minimum and maximum step-sizes $0 < \Delta_{\min} < \Delta_{\max}$. Initiate $s > 3$, $m \in \mathbb{N}$, $M \ge \max\{3m-2, 6\}$, $\nu_0 = 0$, $\Delta_\nu \in [\Delta_{\min}, \Delta_{\max}]$, $\Delta_\nu^0 = 0$, and an approximate zero $\widehat{x}_F$ of $f^{(m)}(x_F, 0)$. Calculate the analytic estimates $(\alpha_k,\ k = 0,\dots,M)$ that are independent of everything.*
2. *With a classical Newton iteration, find near $\widehat{x}_F$ an approximate solution $\bar{x}_F$ of $f^{(m)}(x_F, \nu_0) = 0$. Calculate an approximate solution $\dot{x}_F$ of (17). Use the first component of $\bar{x}_F$ to calculate with interval arithmetic $M_0(\bar{L}, \nu_0)$ and check that $M_0 \le M$ (this is never a problem in practice).*
3. *Compute, using interval arithmetic, the coefficients of the radii polynomials p_k, $k = -1,\dots,M$. This is the computationally most expensive step, since it involves the coefficients in Tables 1, 3, and 4 and in particular requires the calculation of convolution terms.*
4. *Calculate numerically $I = [I_-, I_+] \overset{\text{def}}{=} \bigcap_{k=-1}^{M} \{r \ge 0 \mid p_k(r,\Delta_\nu) \le 0\}$.*
   - *If $I = \varnothing$, then go to Step 6.*
   - *If $I \ne \varnothing$, then let $r = \min\{\frac{11}{10} I_-, \frac{I_- + I_+}{2}\}$. Compute with interval arithmetic $p_k(r,\Delta_\nu)$. If $p_k(r,\Delta_\nu) < 0$ for all $k = -1,\dots,M$, then go to Step 5; else go to Step 6.*
5. *Update $\Delta_\nu^0 \leftarrow \Delta_\nu$ and $r_0 \leftarrow r$. If $\frac{10}{9}\Delta_\nu \le \Delta_{\max}$, then update $\Delta_\nu \leftarrow \frac{10}{9}\Delta_\nu$ and go to Step 4; else go to Step 7.*
6. *If $\Delta_\nu^0 > 0$, then go to Step 7; else if $\frac{9}{10}\Delta_\nu \ge \Delta_{\min}$, then update $\Delta_\nu \leftarrow \frac{9}{10}\Delta_\nu$ and go to Step 4; else go to Step 8.*
7. *The continuation step has succeeded. Store, for future reference, $\bar{x}_F$, $\dot{x}_F$, r_0, ν_0, and Δ_ν^0. Determine ν_1 approximately equal to, but interval arithmetically less than, $\nu_0 + \Delta_\nu^0$. If $\nu_1 \ge 2$, then terminate the procedure* successfully*; else make the updates $\nu_0 \leftarrow \nu_1$, $\Delta_\nu \leftarrow \Delta_\nu^0$, $\widehat{x}_F \leftarrow \bar{x}_F + \Delta_\nu^0 \dot{x}_F$, and $\Delta_\nu^0 \leftarrow 0$, and go to Step 2 for the next continuation step.*
8. *The continuation step has failed. Either decrease $\Delta_{\min}$ and return to Step 6 or increase s or M and return to Step 3; or increase m and return to Step 2. Alternatively, terminate the procedure* unsuccessfully *at $\nu = \nu_0$ (although with success on $[0,\nu_0]$).*

Note that computing I using interval arithmetic would be expensive, since we would need to compute each set $\{r \ge 0 \mid p_k(r,\Delta_\nu) \le 0\}$ $(k = -1,\dots,M-1)$ using interval arithmetic.

Since we need only to get one radius $r \in I$, we chose to approximate I with floating point arithmetic, pick a point r in the approximation of I, and finally prove that $r \in I$ using interval arithmetic. During the procedure, a sequence of intervals $[\nu_0, \nu_0 + \Delta_\nu^0]$ covering $[0, 2]$ is stored, together with the variables defining the neighborhoods $W_{x_\nu}(r_0)$. In section 4, the balls $W_{x_{\nu_0}}(r_0)$ will be used in Procedure 21 (and Lemma 22) to check the geometric conditions $\mathcal{H}$. Concerning the usefulness of the procedure in practice, the proof of the pudding is in the eating.

Lemma 17. *Let $s = 4$, $m = 43$, $M = 127$, $\Delta_{\min} = 10^{-10}$, and $\Delta_{\max} = 2$. Then we can choose an approximate zero $\widehat{x}_F = \widehat{x}_F^*$ of $f^{(m)}(x_F, 0)$ such that Procedure 16 terminates* successfully. *Hence there are periodic solutions of (4) at $E = 0$ for all $\nu \in [0, 2]$.*

The choice of $\widehat{x}_F^*$ is made in such a way that the solutions found satisfy the geometric conditions $\mathcal{H}$. This is checked using Procedure 21.

Proof. A MATLAB computer program successfully performing Procedure 16 accompanies the paper. In particular, we never end up in Step 8 of the procedure. Concerning the implementation, the only difficult evaluations are the convolution terms, which can be computed in a very efficient way using the fast Fourier transform combined with interval arithmetic; see [18]. More details about the implementation are given in section 3.1. ∎

3.1. Implementation. In this section, we discuss in detail the implementation of the rigorous verification of Procedure 16 and Procedure 21 (which checks the geometric properties $\mathcal{H}$; see section 4). First, as seen in [15], the errors induced by the floating point computations of the coefficients of the radii polynomials are small. Hence, finding a positive r at which all radii polynomials are negative without interval arithmetic gives significant confidence about the success of Procedure 16. On top of that, the computational efficiency of floating point arithmetic in MATLAB allows for fast computations. With this in mind, we wrote a preliminary function called *SH_continuation.m*, which verifies, without interval arithmetic, that Procedure 16 performs successfully. Using the values given in Lemma 17, we obtained 13068 successful nonrigorous steps in a bit more than 7 minutes. In Figure 8, we plot the evolution of Δ_ν as the parameter ν runs from 0 to 2.

This being done, and armed with confidence, we then aimed for the proof. First we wrote *SH_rigorous_continuation.m*, the equivalent of *SH_continuation.m*, in the MATLAB interval arithmetic package *Intlab* (see [20]). We did not try to optimize for speed in the interval arithmetic setting, since we preferred to keep the changes with respect to the floating point version *SH_continuation.m* limited. The speed of the interval arithmetic is thus rather slow, and we decided to distribute the computations over 20 different computers, each running 3 simultaneous calculations. Hence, we used the 13068 output points from *SH_continuation.m* to generate a nonuniform mesh $\{(\nu_j, x_j) \mid j = 1, \dots, 61\}$ of the branch under study, where $\nu_1 = 0$ and $\nu_{61} = 2$. The function *SH_mesh_generator.m* picks 61 points out of the 13068 defining the discrete branch. Note that we do not need to define x_{61}, since at this point we have already reached $\nu = 2$. This mesh is stored in the file *SH_mesh_points.mat*. Then, for each $j = 1, \dots, 60$, we called the function *SH_run_proof*(j). This function first starts *Intlab*, loads *SH_mesh_points.dat*, and then rigorously verifies Procedure 16 between the parameter values ν_j and ν_{j+1}, using *SH_rigorous_continuation.m* with the initial point x_j as input. Finally, it verifies, by running the interval arithmetic function *SH_geometric_properties.m*, that the periodic orbits rigorously generated by *SH_rigorous_continuation*(x_j, ν_j, ν_{j+1}) satisfy the geo-

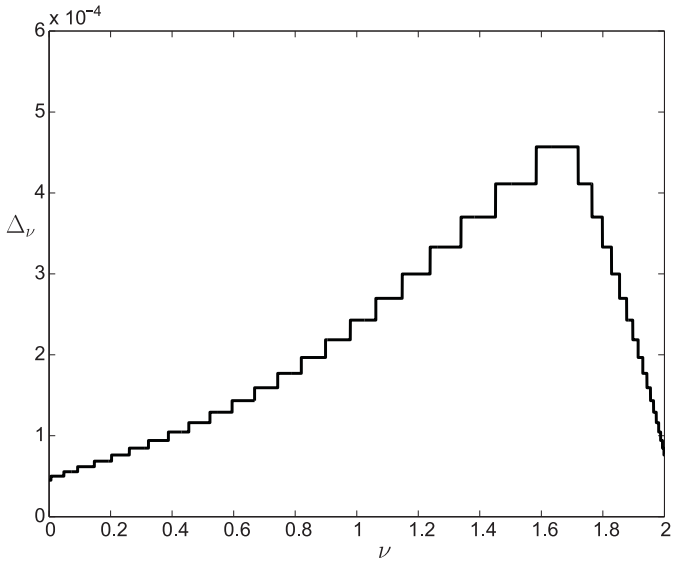

Figure 8. *The step size Δ_ν as a function of the parameter $\nu \in [0,2]$. The step size increases at first, but it then decreases as we approach a saddle-node bifurcation.*

metric properties $\mathcal{H}$, as described in section 4. Thus, the proof of Lemma 17 (and Lemma 22) was finished when all 60 runs ended successfully. The total running time was around 12 hours.

3.2. The bounds $Y_k(\Delta_\nu)$.

Recalling (19) and (23), in this section we want to find bounds

$$\left|[-A \cdot f(x_\nu, \nu)]_k\right| \leq Y_k(\Delta_\nu).$$

We use the following notation. For an arbitrary vector $y_F = (y_{-1}, y_0, y_1, \ldots, y_{m-1})$, the infinite extension is $y = (y_{-1}, y_0, y_1, \ldots, y_{m-1}, 0, 0, 0, \ldots)$. For an infinite sequence $z = (z_{-1}, z_0, z_1, \ldots)$, the finite restriction is $z_F = (z_{-1}, z_0, z_1, \ldots, z_{m-1})$, whereas $z_I = (0, 0, \ldots, 0, z_m, z_{m+1}, z_{m+2}, \ldots)$ denotes the infinite tail. Similar notation is used for vectors/sequences of which the index starts at 0 rather than -1—in particular, the vectors $\bar{a}_F = (\bar{a}_0, \bar{a}_1, \ldots, \bar{a}_{m-1})$ and $\dot{a}_F = (\dot{a}_0, \dot{a}_1, \ldots, \dot{a}_{m-1})$. Also, absolute values of vectors, infinite sequences, and matrices are taken componentwise, e.g., $|x| = (|x_{-1}|, |x_0|, |x_1|, |x_2|, \ldots)$. Furthermore, we use the convolutions

$$(a * b * c)_k = \sum_{\substack{k_1+k_2+k_3=k \\ k_1,k_2,k_3 \in \mathbb{Z}}} a_{|k_1|} b_{|k_2|} c_{|k_3|},$$

which is of course the standard convolution when taking $a_{-k} \equiv a_k$, and (with the extension convention)

$$(a_F * b_F * c_F)_k = (a * b * c)_k = \sum_{\substack{k_1+k_2+k_3=k \\ |k_i|<m}} a_{|k_1|} b_{|k_2|} c_{|k_3|},$$

which vanishes for $k \geq 3m - 2$.

Table 1

The nonzero coefficients in the expansion (25) of f_k. In particular, $d^4_{-1} = d^5_{-1} = 0$. Notice that for $k \geq m$ the only nonvanishing terms are the convolution terms. Furthermore, for $k \geq 3m-2$ all coefficients are 0.

$k = -1$	
d^1_{-1}	$-2\bar{L}^2 \sum_{l=1}^{m-1} l^2 \dot{a}_l - 4\bar{L}\dot{L} \sum_{l=1}^{m-1} l^2 \bar{a}_l - \sqrt{2}\left(\bar{a}_0 + 2\sum_{l=1}^{m-1} \bar{a}_l\right)\left(\dot{a}_0 + 2\sum_{l=1}^{m-1} \dot{a}_l\right)$
d^2_{-1}	$-4\bar{L}\dot{L} \sum_{l=1}^{m-1} l^2 \dot{a}_l - 2\dot{L}^2 \sum_{l=1}^{m-1} l^2 \bar{a}_l - \frac{1}{2}\sqrt{2}\left(\dot{a}_0 + 2\sum_{l=1}^{m-1} \dot{a}_l\right)^2$
d^3_{-1}	$-2\dot{L}^2 \sum_{l=1}^{m-1} l^2 \dot{a}_l$
$k = 0, 1, 2, \ldots$	
d^1_k	$\left(1 + \nu_0 \bar{L}^2 k^2 - \bar{L}^4 k^4\right) \dot{a}_k + \left((2\nu_0 \bar{L}\dot{L} + \bar{L}^2)k^2 - 4\bar{L}^3 \dot{L} k^4\right) \bar{a}_k - 3(\bar{a} * \bar{a} * \dot{a})_k$
d^2_k	$\left((2\nu_0 \bar{L}\dot{L} + \bar{L}^2)k^2 - 4\bar{L}^3 \dot{L} k^4\right) \dot{a}_k + \left((\nu_0 \dot{L}^2 + 2\bar{L}\dot{L})k^2 - 6\bar{L}^2 \dot{L}^2 k^4\right) \bar{a}_k - 3(\bar{a} * \dot{a} * \dot{a})_k$
d^3_k	$\left((\nu_0 \dot{L}^2 + 2\bar{L}\dot{L})k^2 - 6\bar{L}^2 \dot{L}^2 k^4\right) \dot{a}_k + \left(\dot{L}^2 k^2 - 4\bar{L}\dot{L}^3 k^4\right) \bar{a}_k - (\dot{a} * \dot{a} * \dot{a})_k$
d^4_k	$\left(\dot{L}^2 k^2 - 4\bar{L}\dot{L}^3 k^4\right) \dot{a}_k - \dot{L}^4 k^4 \bar{a}_k$
d^5_k	$-\dot{L}^4 k^4 \dot{a}_k$

Exploiting that f is a vector of polynomials in the components of x and ν, we write

$$f_k(x_\nu, \nu) = f_k(\bar{x} + \Delta_\nu \dot{x},\ \nu_0 + \Delta_\nu) = f_k(\bar{x}, \nu_0) + \sum_{i=1}^{5} d^i_k(\bar{x}, \dot{x}, \nu_0)\Delta^i_\nu. \tag{25}$$

Here the constants d^i_k are listed in Table 1.

For the zeroth-order term we have for the finite part $f_F(\bar{x}, \nu_0) = f^{(m)}(\bar{x}_F, \nu_0)$, which is very small, since $\bar{x}_F$ is a numerical zero of $f^{(m)}(x_F, \nu_0)$. The choice of $\dot{x}_F$ given by (17) implies that the first-order term d^1_F is also small, since

$$f_F(x_\nu, \nu) = f^{(m)}(\bar{x}_F, \nu_0) + \left[Df^{(m)}(\bar{x}_F, \nu_0)\dot{x}_F + \frac{\partial f}{\partial \nu}^{(m)}(\bar{x}_F, \nu_0)\right]\Delta_\nu + O(\Delta^2_\nu).$$

For the tail ($k \geq m$) we have $f_k(\bar{x}, \nu_0) = -(\bar{a} * \bar{a} * \bar{a})_k = -(\bar{a}_F * \bar{a}_F * \bar{a}_F)_k$, which vanishes for $k \geq 3m - 2$.

Using the vectors d^i from Table 1, this leads to bounds $Y_k(\Delta_\nu)$ as listed below, with $\Delta_\nu \geq 0$:

$$Y_F = |J_F \cdot f^{(m)}(\bar{x}_F, \nu_0)| + \sum_{i=1}^{5} \left|J_F \cdot d^i_F\right| \Delta^i_\nu \tag{26a}$$

for $k = -1, 0, 1, \ldots, m-1$;

$$Y_k = \frac{|(\bar{a} * \bar{a} * \bar{a})_k| + 3|(\bar{a} * \bar{a} * \dot{a})_k|\Delta_\nu + 3|(\bar{a} * \dot{a} * \dot{a})_k|\Delta^2_\nu + |(\dot{a} * \dot{a} * \dot{a})_k|\Delta^3_\nu}{|\mu_k(\bar{L}, \nu_0)|} \tag{26b}$$

for $m \le k \le 3m-3$; and

$$Y_k = 0 \tag{26c}$$

for $k \ge 3m-2$.

3.3. The bounds $Z_k(r, \Delta_\nu)$. In this section we construct bounds

$$\sup_{w,w' \in W(r)} \left| [DT_\nu(x_\nu + w')w]_k \right| \le Z_k(r, \Delta_\nu).$$

We will use the notation introduced at the start of section 3.2. Furthermore, at several instances, we employ a computational parameter M, and although not necessary, we choose the same value of M every time for simplicity.

Recall that J_F is a numerical inverse of $Df^{(m)}(\bar{x}_F, \nu_0)$. To simplify the exposition, we introduce an almost inverse of the operator A defined in (18):

$$A^\dagger \stackrel{\text{def}}{=} \begin{bmatrix} Df^{(m)}(\bar{x}_F, \nu_0) & 0_F^T & 0_F^T & 0_F^T & \cdots \\ 0_F & \mu_m(\bar{L}, \nu_0) & 0 & 0 & \cdots \\ 0_F & 0 & \mu_{m+1}(\bar{L}, \nu_0) & 0 & \cdots \\ 0_F & 0 & 0 & \mu_{m+2}(\bar{L}, \nu_0) & \\ \vdots & \vdots & \vdots & & \ddots \end{bmatrix}.$$

We split $Df_\nu(x_\nu + w')w$ into two pieces:

$$Df_\nu(x_\nu + w')w = A^\dagger w + \left[Df_\nu(x_\nu + w') - A^\dagger\right]w$$

and hence

$$DT_\nu(w' + x_\nu)w = [I - AA^\dagger]w - A\left[Df_\nu(x_\nu + w') - A^\dagger\right]w, \tag{27}$$

where the first term will be very small. For $w, w' \in W(r)$ we consider $v, v' \in W(1)$ defined by $w = rv$ and $w' = rv'$. Similar to section 3.2, we expand the expression $[Df_\nu(x_\nu + w') - A^\dagger]w$ in terms of r and Δ_ν:

$$\left([Df_\nu(x_\nu + w') - A^\dagger]w\right)_k = \sum_{i=1}^{5} \sum_{j=0}^{5-i} c_k^{i,j}(\bar{x}, \dot{x}, v, v', \nu_0) r^i \Delta_\nu^j. \tag{28}$$

Here the constants $c_k^{i,j}$ are listed in Table 2. Since $A^\dagger$ does not depend on r or Δ_ν, it is involved only in the calculation of the coefficient $c_k^{1,0}$. In particular, for the finite part,

$$c_F^{1,0} = Df_F(\bar{x}, \nu_0)v - Df^{(m)}(\bar{x}_F, \nu_0)v_F,$$

and for the tail ($k \ge m$),

$$c_k^{1,0} = Df_k(\bar{x}, \nu_0)v - \mu_k(\bar{L}, \nu_0)v_k.$$

The other coefficients $c_k^{i,j}$ can be easily generated with the help of a computer (e.g., with Maple). Here we have rearranged the terms in the output somewhat to make the formulas in

Table 2

The nonzero coefficients in the expansion (28). In the expression for $c_k^{1,0}$ we have used the notation $v_I = (0, 0, \dots, 0, v_m, v_{m+1}, v_{m+2}, \dots)$.

$k = -1$	
$c_{-1}^{1,0}$	$-2\bar{L}^2 \sum_{l=m}^{\infty} l^2 v_l - \sqrt{2}\left(\bar{a}_0 + 2\sum_{l=1}^{m-1} \bar{a}_l\right)\left(2\sum_{l=m}^{\infty} v_l\right)$
$c_{-1}^{1,1}$	$-4\left(\dot{L}\sum_{l=1}^{m-1} l^2 \bar{a}_l + \bar{L}\sum_{l=1}^{m-1} l^2 \dot{a}_l\right) v_{-1} - 4\bar{L}\dot{L}\sum_{l=1}^{\infty} l^2 v_l - \sqrt{2}\left(\dot{a}_0 + 2\sum_{l=1}^{m-1} \dot{a}_l\right)\left(v_0 + 2\sum_{l=1}^{\infty} v_l\right)$
$c_{-1}^{1,2}$	$-4\dot{L} v_{-1} \sum_{l=1}^{m-1} l^2 \dot{a}_l - 2\dot{L}^2 \sum_{l=1}^{\infty} l^2 v_l$
$c_{-1}^{2,0}$	$-4\left(v'_{-1}\sum_{l=1}^{m-1} l^2 \bar{a}_l + \bar{L}\sum_{l=1}^{\infty} l^2 v'_l\right) v_{-1} - 4\bar{L} v'_{-1} \sum_{l=1}^{\infty} l^2 v_l - \sqrt{2}\left(v'_0 + 2\sum_{l=1}^{\infty} v'_l\right)\left(v_0 + 2\sum_{l=1}^{\infty} v_l\right)$
$c_{-1}^{2,1}$	$-4\left(v'_{-1}\sum_{l=1}^{m-1} l^2 \dot{a}_l + \dot{L}\sum_{l=1}^{\infty} l^2 v'_l\right) v_{-1} - 4\dot{L} v'_{-1} \sum_{l=1}^{\infty} l^2 v_l$
$c_{-1}^{3,0}$	$-4 v'_{-1} v_{-1} \sum_{l=1}^{\infty} l^2 v'_l - 2(v'_{-1})^2 \sum_{l=1}^{\infty} l^2 v_l$
$k = 0, 1, 2, \dots$	
$c_k^{1,0}$	$\begin{cases} -3\,(\bar{a} * \bar{a} * v_I)_k & \text{for } 0 \le k \le m-1, \\ -3\,(\bar{a} * \bar{a} * v)_k & \text{for } k \ge m \end{cases}$
$c_k^{1,1}$	$-k^2\left[(4k^2\bar{L}^3\dot{L} - \bar{L}^2 - 2\nu_0\bar{L}\dot{L})v_k + 2\big((6k^2\bar{L}^2\dot{L} - \bar{L} - \nu_0\dot{L})\bar{a}_k + (2k^2\bar{L}^3 - \nu_0\bar{L})\dot{a}_k\big)v_{-1}\right] - 6\,(\bar{a} * \dot{a} * v)_k$
$c_k^{1,2}$	$-k^2\left[(6k^2\bar{L}^2\dot{L}^2 - 2\bar{L}\dot{L} - \nu_0\dot{L}^2)v_k + 2\big((6k^2\bar{L}\dot{L}^2 - \dot{L})\bar{a}_k + (6k^2\bar{L}^2\dot{L} - \bar{L} - \nu_0\dot{L})\dot{a}_k\big)v_{-1}\right] - 3\,(\dot{a} * \dot{a} * v)_k$
$c_k^{1,3}$	$-k^2\dot{L}\left[(4k^2\bar{L}\dot{L}^2 - \dot{L})v_k + 2\big(2k^2\dot{L}^2\bar{a}_k + (6k^2\bar{L}\dot{L} - 1)\dot{a}_k\big)v_{-1}\right]$

$c_k^{2,0}$	$-2k^2\left[(2k^2\bar{L}^3 - \nu_0\bar{L})(v'_{-1}v_k + v'_k v_{-1}) + (6k^2\bar{L}^2 - \nu_0)\bar{a}_k v'_{-1} v_{-1}\right] - 6\,(\bar{a} * v' * v)_k$
$c_k^{2,1}$	$-2k^2\left[(6k^2\bar{L}^2\dot{L} - \bar{L} - \nu_0\dot{L})(v'_{-1}v_k + v'_k v_{-1}) + ((12k^2\bar{L}\dot{L} - 1)\bar{a}_k + (6k^2\bar{L}^2 - \nu_0)\dot{a}_k)v'_{-1}v_{-1}\right] - 6\,(\dot{a} * v' * v)_k$
$c_k^{2,2}$	$-2k^2\left[(6k^2\bar{L}\dot{L}^2 - \dot{L})(v'_{-1}v_k + v'_k v_{-1}) + (6k^2\dot{L}^2\bar{a}_k + (12k^2\bar{L}\dot{L} - 1)\dot{a}_k)v'_{-1}v_{-1}\right]$
$c_k^{2,3}$	$-4k^4\dot{L}^2\left[\dot{L}(v'_{-1}v_k + v'_k v_{-1}) + 3\dot{a}_k v'_{-1} v_{-1}\right]$
$c_k^{3,0}$	$-k^2 v'_{-1}\left[(6k^2\bar{L}^2 - \nu_0)(v'_{-1}v_k + 2v'_k v_{-1}) + 12k^2\bar{L}\bar{a}_k v'_{-1} v_{-1}\right] - 3\,(v' * v' * v)_k$
$c_k^{3,1}$	$-k^2 v'_{-1}\left[(12k^2\bar{L}\dot{L} - 1)(v'_{-1}v_k + 2v'_k v_{-1}) + 12k^2(\dot{L}\bar{a}_k + \bar{L}\dot{a}_k)v'_{-1}v_{-1}\right]$
$c_k^{3,2}$	$-6k^4\dot{L} v'_{-1}\left[\dot{L}(v'_{-1}v_k + 2v'_k v_{-1}) + 2\dot{a}_k v'_{-1} v_{-1}\right]$
$c_k^{4,0}$	$-4k^4(v'_{-1})^2\left[\bar{L}(v'_{-1}v_k + 3v'_k v_{-1}) + \bar{a}_k v'_{-1} v_{-1}\right]$
$c_k^{4,1}$	$-4k^4(v'_{-1})^2\left[\dot{L}(v'_{-1}v_k + 3v'_k v_{-1}) + \dot{a}_k v'_{-1} v_{-1}\right]$
$c_k^{5,0}$	$-k^4(v'_{-1})^3\left[v'_{-1}v_k + 4v'_k v_{-1}\right]$

Table 2 more aesthetically pleasing. However, such cosmetic changes are of course not needed for any *practical* purposes.

We now compute uniform upper bounds for the $c_k^{i,j}$, i.e., $C_k^{i,j} \ge 0$, such that

$$\left|c_k^{i,j}(\bar{x}, \dot{x}, v, v', \nu_0)\right| \le C_k^{i,j}(\bar{x}, \dot{x}, \nu_0) \qquad \text{for all } v, v' \in W(1). \tag{29}$$

The most involved are the convolution terms, and we have a dedicated lemma to estimate

those. Although the formulas are quite cumbersome, the numbers defined below are easily calculated with a computer. We introduce the computational parameter $M \in \mathbb{N}$, arbitrary for now, and we define

$$\gamma_M \stackrel{\text{def}}{=} 2\left[\frac{M}{M-1}\right]^s + \left[\frac{4\ln(M-2)}{M} + \frac{\pi^2-6}{3}\right]\left[\frac{2}{M}+\frac{1}{2}\right]^{s_*-2},$$

where s_* is the largest integer such that $s_* \le s$, and

$$\beta_k \stackrel{\text{def}}{=} \begin{cases} 4 + \frac{1}{2^{2s-1}(2s-1)}, & k=0, \\ 2\left[2+\frac{1}{2^s}+\frac{1}{3^s}+\frac{1}{3^{s-1}(s-1)}\right] + \sum_{k_1=1}^{k-1} \frac{k^s}{k_1^s(k-k_1)^s}, & k=1,2,\ldots,M-1, \\ 2\left[2+\frac{1}{2^s}+\frac{1}{3^s}+\frac{1}{3^{s-1}(s-1)}\right] + \gamma_M, & k=M. \end{cases}$$

Using this, we set

$$\alpha_k = \frac{6\beta_M}{(M+k)^s(M-1)^{s-1}(s-1)} + 3\sum_{j=M}^{M+k-1} \frac{\beta_{j-k}}{j^s(j-k)^s} \qquad \text{for } k=0,1,\ldots,M-1,$$

while for $k=M$ we define

$$\alpha_M \stackrel{\text{def}}{=} \beta_0 + \sum_{j=1}^{M-1} \frac{\beta_j}{j^s}\left[1+\frac{1}{\left[1-\frac{j}{M}\right]^s}\right] + \beta_M\left[2+\frac{1}{2^s}+\frac{1}{3^s}+\frac{1}{3^{s-1}(s-1)}+\frac{1}{(M-1)^{s-1}(s-1)}+\gamma_M\right].$$

We introduce, for infinite sequence $a=(a_0,a_1,a_2,\ldots)$, the notation

$$|a|_M = (|a|_0, |a|_1, \ldots, |a|_{M-1}).$$

Analogous to (21) and (22), but now for sequences with index starting at 0 rather than -1, we define

$$\|a\|_s^0 \stackrel{\text{def}}{=} \sup_{k=0,1,\ldots} |a_k\omega_k^s| = \sup\{|a_0|, |a_1|, 2^s|a_2|, 3^s|a_3|, 4^s|a_4|, \ldots\}$$

and

$$W^0(r) \stackrel{\text{def}}{=} \{a,\ \|a\|_s^0 \le r\} = [-r,r] \times \prod_{k=1}^{\infty}\left[-\frac{r}{k^s}, \frac{r}{k^s}\right].$$

Lemma 18. *Let $M \ge 6$, and let a, b, and c lie in the balls $W^0(A_a)$, $W^0(A_b)$, and $W^0(A_c)$. Then for $k=0,1,\ldots,M-1$ we have*

$$(a*b*c)_k \in \left\{\left(|a|_M * |b|_M * |c|_M\right)_k + A_aA_bA_c\alpha_k\right\}[-1,1],$$

while for $k \ge M$ we have

$$(a*b*c)_k \in A_aA_bA_c\frac{\alpha_M}{k^s}[-1,1].$$

Proof. The proof is a special case of the general convolution estimates in Appendix A, with $p = 3$, $M_1 = M$, and the notation $\beta_k = \alpha_k^{(2)}$, $\alpha_k = 3\varepsilon_k^{(3)}$, and $\alpha_M = \alpha_M^{(3)}$. ∎

We are now ready to estimate the coefficients $c_k^{i,j}(\bar{x}, \dot{x}, v, v', \nu_0)$, but we first introduce a bit more notation, namely, in view of Lemma 18,

$$Q_k(a,b,c) \stackrel{\text{def}}{=} \begin{cases} \left(|a|_M * |b|_M * |c|_M\right)_k + \|a\|_s^0 \|b\|_s^0 \|c\|_s^0 \alpha_k, & k = 0, 1, \dots M-1, \\ \|a\|_s^0 \|b\|_s^0 \|c\|_s^0 \frac{\alpha_M}{k^s}, & k \geq M. \end{cases}$$

Furthermore, for $s > 1$, we use the notation

$$\zeta(s, l_0) \stackrel{\text{def}}{=} \sum_{l=l_0}^{\infty} \frac{1}{l^s} \qquad \text{and} \qquad \zeta(s) \stackrel{\text{def}}{=} \zeta(s,1) = \sum_{l=1}^{\infty} \frac{1}{l^s}$$

and their estimates (which require only a finite computation) for $l_0 \leq M$,

$$\zeta_M(s, l_0) \stackrel{\text{def}}{=} \sum_{l=l_0}^{M} \frac{1}{l^s} + \frac{1}{(M-1)^{s-1}(s-1)} \qquad \text{and} \qquad \zeta_M(s) \stackrel{\text{def}}{=} \zeta_M(s,1)$$

so that $\zeta(s, l_0) \leq \zeta_M(s, l_0)$ and $\zeta(s) \leq \zeta_M(s)$. Finally, let

$$\mathbb{I} \stackrel{\text{def}}{=} \left(1, 1, \frac{1}{2^s}, \frac{1}{3^s}, \frac{1}{4^s}, \dots\right) \qquad \text{and} \qquad \mathbb{I}_I \stackrel{\text{def}}{=} \left(0, 0, \dots, 0, \frac{1}{m^s}, \frac{1}{(m+1)^s}, \dots\right).$$

With this notation in place, and using Lemma 18, the bounds $C_k^{i,j}(\bar{x}, \dot{x}, \nu_0)$ satisfying (29), listed in Table 3, are now straightforward to derive. For fixed k, these constants $C_k^{i,j}$ each involve only a finite computation, but there are of course still infinitely many values of k to consider. Notice first that for $k \geq m$ many terms in Table 3 vanish, since only the first m elements of $\bar{a}$ and $\dot{a}$ are nonzero. For the same reason, calculating $\|\bar{a}\|_s^0$ and $\|\dot{a}\|_s^0$ is a finite computation. Moreover, many terms can be estimated using the fact that, for any $A_1, A_2 \in \mathbb{R}$,

$$\left|A_1 + \frac{A_2}{k^2}\right| \leq \max\left\{\left|A_1 + \frac{A_2}{M^2}\right|, |A_1|\right\} \qquad \text{for all } k \geq M.$$

It follows from these considerations and Lemma 18 that

$$C_k^{i,j} \leq \widehat{C}_M^{i,j}\, k^{4-s} \qquad \text{for } k \geq M \geq \min\{m, 6\},$$

where the $\widehat{C}_M^{i,j}$ are listed in Table 4.

To conclude the calculation of Z_k we need an estimate on

$$|\mu_k(\bar{L}, \nu_0)| = \bar{L}^4 k^4 \left|1 - \frac{\nu_0}{\bar{L}^2 k^2} + \frac{1}{\bar{L}^4 k^4}\right|$$

for large k. Let

$$M_0(\bar{L}, \nu_0) \stackrel{\text{def}}{=} \begin{cases} 0 & \text{for } \nu_0 \leq 0, \\ \sqrt{2\nu_0}/\bar{L} & \text{for } \nu_0 > 0. \end{cases} \tag{30}$$

Table 3

The uniform bounds $C_k^{i,j}(\bar{x},\dot{x},\nu_0)$ on the coefficients $c_k^{i,j}(\bar{x},\dot{x},v,v',\nu_0)$. For $k=0$ one should read $k^{2-s}=0$ and $k^{4-s}=0$, irrespective of s.

Then it is not hard to check that

$$|\mu_k(\bar{L},\nu_0)| \geq \frac{\bar{L}^4k^4}{2} \qquad \text{for } k \geq M_0.$$

Using the vectors $C^{i,j}$ and the numbers $\widehat{C}_M^{i,j}$ from Tables 3 and 4, and in view of (27), this leads to bounds $Z_k(r,\Delta_\nu)$ as listed below, with $M \geq \min\{M_0, m, 6\}$ and $\Delta_\nu \geq 0$:

$$Z_F = |I - J_F \cdot Df^{(m)}(\bar{x}_F,\nu_0)| \cdot \mathbb{I}_F\, r + \sum_{i=1}^{5}\sum_{j=0}^{5-i}\left|J_F\right| \cdot C_F^{i,j}\, r^i\, \Delta_\nu^j \tag{31a}$$

for $k = -1, 0, 1, \ldots, m-1$;

$$Z_k = \frac{1}{|\mu_k(\bar{L},\nu_0)|}\sum_{i=1}^{5}\sum_{j=0}^{5-i} C_k^{i,j}\, r^i\, \Delta_\nu^j \tag{31b}$$

for $m \le k \le M-1$; and

$$Z_k = \frac{2}{\bar{L}^4}\frac{1}{k^s}\sum_{i=1}^{5}\sum_{j=0}^{5-i} \widehat{C}_M^{i,j}\, r^i\, \Delta_\nu^j \tag{31c}$$

for $k \ge M$. Finally, for the purpose of Definition 14 and Lemma 15, we set

$$\widehat{Z}_M \overset{\text{def}}{=} \frac{2}{\bar{L}^4 M^s}\sum_{i=1}^{5}\sum_{j=0}^{5-i} \widehat{C}_M^{i,j}\, r^i\, \Delta_\nu^j, \tag{32}$$

so that $Z_k = \widehat{Z}_M\big(\frac{M}{k}\big)^s$.

4. Verification of the geometric properties $\mathcal{H}$. We now put ourselves in the situation of a single, successful, rigorous continuation step, where we have found an $r > 0$ such that the set ($s > 3$)

$$W_{x_\nu}(r) = x_\nu + W(r) \qquad \text{with } x_\nu = \bar{x} + (\nu-\nu_0)\dot{x}, \tag{33}$$

centered at the predictor based at ν_0, contains a unique fixed point $\widetilde{x}^\nu$ of $T(x,\nu)$ for each parameter value $\nu \in [\nu_0,\nu_1]$. We write $\widetilde{x}^\nu = (\widetilde{L}^\nu, \widetilde{a}_0^\nu, \widetilde{a}_1^\nu, \widetilde{a}_2^\nu, \ldots)$. The functions $\widetilde{u}^\nu$ defined via (11) are periodic solutions of (4) with period $2\pi/\widetilde{L}^\nu$, which are symmetric in $y=0$ and $y=\pi/\widetilde{L}^\nu$. For convenience, we incorporate the period of the periodic solution in the definition of the geometric condition as follows:

$$\mathcal{H}_{\widetilde{L}}\ \begin{cases} (H_1) & \widetilde{u} \text{ has exactly four monotone laps and extrema } \{\widetilde{u}_i\}_{i=1}^4 \text{ on } [0, 2\pi/\widetilde{L}], \\ (H_2) & \widetilde{u}_1 \text{ and } \widetilde{u}_3 \text{ are minima, and } \widetilde{u}_2 \text{ and } \widetilde{u}_4 \text{ are maxima,} \\ (H_3) & \widetilde{u}_1 < -1 < \widetilde{u}_3 < 1 < \widetilde{u}_2, \widetilde{u}_4, \\ (H_4) & \widetilde{u}(x) \text{ is symmetric in its minima } \widetilde{u}_1 \text{ and } \widetilde{u}_3. \end{cases}$$

We need to make sure that the unique zero of f in W_{x_ν} satisfies these properties. The following lemma will help us in the verification process, since it shows that we need only to check the conditions for *one* parameter value along any continuous branch of solutions.

Lemma 19. *Let $\widetilde{u}^\nu$, $\nu_0 \le \nu \le \nu_1$, be periodic solutions of (4) at the energy level $E=0$ with period $2\pi/\widetilde{L}^\nu$, which are symmetric in $y=0$ and $y=\pi/\widetilde{L}^\nu$. Suppose that $\widetilde{u}^\nu$ and $\widetilde{L}^\nu$ depend continuously on ν; i.e., $\widetilde{u}^\nu$ depends continuously on ν as a C^3-function on compact intervals. If $\widetilde{u}^{\nu_0}$ satisfies $\mathcal{H}_{\widetilde{L}^{\nu_0}}$, then $\widetilde{u}^\nu$ satisfies $\mathcal{H}_{\widetilde{L}^\nu}$ for all $\nu \in [\nu_0,\nu_1]$.*

Proof. To reduce clutter, we remove all tildes from the notation. By symmetry, we need only to consider the interval $[0,\pi/L^\nu]$. Let

$$N = \big\{\nu \in [\nu_0,\nu_1] \;\big|\; u^\nu \text{ satisfies } \mathcal{H}_{L^\nu}\big\}.$$

By assumption, $\nu_0 \in N$. We will show that N is both open and closed (in the relative topology), i.e., connected; hence $N = [\nu_0,\nu_1]$ as asserted.

It is relatively easy to see that N is open. Namely, for $\nu \in N$ the extrema of u^ν do not lie on the lines $u = \pm 1$. It then follows from the energy identity $E = 0$ that the extrema of u^ν are all nondegenerate. Hence, the conditions $H_{1,2,3,4}$ are open conditions (under the symmetry assumption in the lemma).

To prove that N is closed is a bit more involved. Let $\{\nu_n\}_{n=1}^\infty \subset N$ be a sequence converging to $\nu_* \in [\nu_0, \nu_1]$. Our goal is to show that $\nu_* \in N$. We denote $u^n = u^{\nu_n}$ and $u_* = u^{\nu_*}$. Let the extrema $u^n_{1,2,3}$ be attained in $y^n_{1,2,3}$. Clearly, we have that $y^n_1 = 0$ and $y^n_3 = \pi/L^\nu_n$, while, taking a subsequence, we may additionally assume that y^n_2 converges to some y^*_2 as $n \to \infty$. Denote also $y^*_1 = 0$ and $y^*_3 = \pi/L^{\nu_*}$. By C^3-continuity, we have $u'_*(y^*_{1,2,3}) = 0$, and

$$u_*(y^*_1) \le -1 \le u_*(y^*_3) \le 1 \le u_*(y^*_2). \tag{34}$$

In fact, the inequalities are strict. We prove this for the last inequality $u_*(y^*_2) > 1$; the other cases are analogous. Suppose, by contradiction, that $u_*(y^*_2) = 1$. Since $u'_*(y^*_2) = 0$, it follows from $E = 0$ that $u''_*(y^*_2) = 0$. By continuity,

$$\max_y u_*(y) = \lim_{n\to\infty} \max_y u^n(y) = \lim_{n\to\infty} u^n(y^n_2) = u_*(y^*_2) = 1.$$

This implies that $u'''_*(y^*_2) = 0$. Uniqueness of the initial value problem for the ODE then says that $u_*(y) = 1$ for all y, which contradicts $u_*(y^*_1) \le -1$. Similarly one can show that all the other inequalities in (34) are strict; hence u_* has at least four extrema on $[0, 2\pi/L^{\nu_*}]$, and those satisfy H_3.

The final step is to prove that u_* does not have more than four monotone laps. We argue once more by contradiction. Recall that $y^*_2 = \lim_{n\to\infty} y^n_2$. Suppose there is a point $z \in (0, \pi/L^{\nu_*})$ with $u'_*(z) = 0$, and $z \ne y^*_2$. If $u''_*(z) \ne 0$, then, by the implicit function theorem, this extremum persists for u^n for n sufficiently large, leading to more than four monotone laps of u^n, contradicting the fact that u^n satisfies the geometric conditions. Hence, it must be that $u''_*(z) = 0$, and thus $u_*(z) = \pm 1$, since $E = 0$. Moreover, since $u_* \not\equiv \pm 1$, we must have $u'''_*(z) \ne 0$. Let us consider the case $u_*(z) = 1$ and $u'''_*(z) > 0$; all other (three) cases are analogous.

We thus have

$$u_*(z) = 1, \quad u'_*(z) = 0, \quad u''_*(z) = 0, \quad u'''_*(z) > 0. \tag{35}$$

Clearly $u'_*(y) > 0$ for y sufficiently close but not equal to z. By continuity, we have $(u^n)'(z \pm \varepsilon) > 0$ for ε sufficiently small and n large enough. By the implicit function theorem, for large enough n, there exist points $z_n \in [z-\varepsilon, z+\varepsilon]$ such that $\lim_{n\to\infty} z_n = z$ and $(u^n)''(z_n) = 0$, and $(u^n)'(z_n) \ne 0$, since u^n has no additional extrema in $(0, L^{\nu_n})$ besides y^n_2. In fact, $(u^n)'(z_n) > 0$, since, if $(u^n)'(z_n) < 0$, then u^n would have two extrema in $[z-\varepsilon, z+\varepsilon]$, leading to more than four monotone laps of u^n, which is a contradiction. Hence $(u^n)'(z_n) > 0$.

We conclude from $E = 0$ and $(u^n)''(z_n) = 0$ that

$$\Big[(u^n)'''(z_n) + \frac{\nu_n}{2}(u^n)'(z_n)\Big](u^n)'(z_n) = -\frac{1}{4}(u^n(z_n)^2 - 1)^2.$$

Since $(u^n)'(z_n) > 0$, this means that

$$(u^n)'''(z_n) + \frac{\nu_n}{2}(u^n)'(z_n) \le 0.$$

Finally, we take the limit $n \to \infty$ in the above inequality to obtain

$$u_*'''(z) + \frac{\nu_*}{2} u_*'(z) \leq 0,$$

which contradicts (35). Hence u_* indeed has exactly four monotone laps on $[0, 2\pi/L^{\nu_*}]$, implying that $\nu_* \in N$ and that N is closed. ∎

We now need only to show that the geometric properties are satisfied at $\nu = \nu_0$, since the solutions depend continuously on ν.

Lemma 20. *The fixed point $\widetilde{x}_\nu \in \Omega^s$ depends continuously on ν for $\nu \in [\nu_0, \nu_1]$. Similarly, the corresponding periodic solutions $\widetilde{u}_\nu$ depend continuously on ν as C^3-functions on compact intervals.*

Proof. Recall that we are dealing with a single continuation step $\nu \in [\nu_0, \nu_1]$, so that the neighborhoods on which T is a contraction mapping are given by (33). The assertion now follows from the continuity and compactness properties of the map T, described in Lemma 12, using standard functional analytic arguments. ∎

To check that $\widetilde{u}^{\nu_0}$ has the properties $\mathcal{H}_{\widetilde{L}^{\nu_0}}$, we follow the procedure outlined below. To reduce clutter, we often drop ν_0 from the notation. We introduce the variables $z = \widetilde{L}^{\nu_0} y$ and $v(z) = \widetilde{u}^{\nu_0}(y)$, so that

$$v(z) = \widetilde{a}_0 + 2 \sum_{k=1}^{\infty} \widetilde{a}_k \cos(kz).$$

This way, we separate the shape of the solution from the period; only the shape is important for the geometric conditions. Clearly, $v'(0) = v'(\pi) = 0$, and v is symmetric in those extrema.

We recall that $\bar{x} = (\bar{L}, \bar{a}_0, \bar{a}_1, \ldots, \bar{a}_{m-1}, 0, 0, \ldots)$, while the fixed point is given by $\widetilde{x} = (\widetilde{L}, \widetilde{a}_0, \widetilde{a}_1, \widetilde{a}_2, \ldots)$. We have $\widetilde{a}_k \in \mathbf{a}_k$, where the intervals are given by

$$\mathbf{a}_k \stackrel{\text{def}}{=} \begin{cases} [\bar{a}_0 - r,\, \bar{a}_0 + r], & k = 0, \\ [\bar{a}_k - \frac{r}{k^s},\, \bar{a}_k + \frac{r}{k^s}], & k = 1, \ldots, m-1, \\ [-\frac{r}{k^s}, \frac{r}{k^s}], & k \geq m. \end{cases}$$

Consider $z \in \mathbf{z} \stackrel{\text{def}}{=} [z^-, z^+] \subset \mathbb{R}$. Then, using interval arithmetic, we can compute rigorous interval enclosures of $v(z)$, $v'(z)$, and $v''(z)$:

$$\begin{aligned} v(z) \in\ & \mathbf{v}[\mathbf{z}] \stackrel{\text{def}}{=} \mathbf{a}_0 + 2 \sum_{k=1}^{m-1} \mathbf{a}_k \cos(k\mathbf{z}) + \frac{2r}{(m-1)^{s-1}(s-1)}[-1,1], \\ v'(z) \in\ & \mathbf{v}'[\mathbf{z}] \stackrel{\text{def}}{=} -2 \sum_{k=1}^{m-1} \mathbf{a}_k\, k \sin(k\mathbf{z}) + \frac{2r}{(m-1)^{s-2}(s-2)}[-1,1], \\ v''(z) \in\ & \mathbf{v}''[\mathbf{z}] \stackrel{\text{def}}{=} -2 \sum_{k=1}^{m-1} \mathbf{a}_k\, k^2 \cos(k\mathbf{z}) + \frac{2r}{(m-1)^{s-3}(s-3)}[-1,1]. \end{aligned}$$

We now use the following procedure (see also Figure 9). Note that we know a priori that $v'(0) = v'(\pi) = 0$.

Procedure 21. *Checking that $\widetilde{u}^{\nu_0}$ satisfies $\mathcal{H}_{\widetilde{L}^{\nu_0}}$ is equivalent to verifying that v satisfies $\mathcal{H}_\pi$. We proceed as follows.*

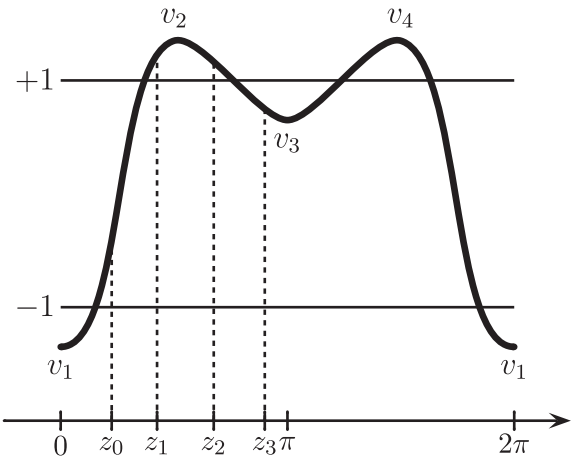

Figure 9. *Illustration of the procedure to make sure that v satisfies $\mathcal{H}_\pi$, i.e., the periodic solution $\widetilde{u}^{\nu_0}$ satisfies the geometric conditions $\mathcal{H}_{\tilde{L}_0^\nu}$. The extrema are denoted by $v_i = \widetilde{u}_i^{\nu_0}$.*

1. *Verify that* $\mathbf{v}[0] \subset (-\infty, -1)$. *That implies that* $\widetilde{u}_1^{\nu_0} = v(0) < -1$.
2. *Find an (approximately largest)* $z_0 > 0$ *such that* $\mathbf{v}''[0, z_0] \subset (0, \infty)$. *Hence, there is a unique extremum in* $[0, z_0]$, *namely, a minimum, at* $z = 0$.
3. *Find an (approximately largest)* $z_1 > z_0$ *such that* $\mathbf{v}'[z_0, z_1] \subset (0, \infty)$. *Hence, the interval* $[z_0, z_1]$ *does not contain any extremum.*
4. *Verify that* $\mathbf{v}[z_1] \subset (1, \infty)$.
5. *Find an (approximately largest)* $z_2 > z_1$ *such that both* $\mathbf{v}[z_1, z_2] \subset (1, \infty)$ *and* $\mathbf{v}''[z_1, z_2] \subset (-\infty, 0)$.
6. *Verify that* $\mathbf{v}'[z_2] \subset (-\infty, 0)$. *That implies that there is a unique extremum* z_* *in* $[z_1, z_2]$, *namely, a maximum* $\widetilde{u}_2^{\nu_0} = v(z_*) > 1$.
7. *Find an (approximately largest)* $z_3 > z_2$ *such that* $\mathbf{v}'[z_2, z_3] \subset (-\infty, 0)$. *Hence, the interval* $[z_2, z_3]$ *does not contain any extremum.*
8. *Verify that* $\mathbf{v}''[z_3, \pi] \subset (0, \infty)$ *and* $\mathbf{v}[\pi] \subset (-1, 1)$. *That implies that there is a unique extremum in* $[z_3, \pi]$, *namely, a minimum* $\widetilde{u}_3^{\nu_0} = v(\pi) \in (-1, 1)$ *at* $z = \pi$.

Combining Lemma 19 with Procedure 21 leads to the required result.

Lemma 22. *The choice of the approximate zero* $\widehat{x}_F^*$ *of* $f^{(m)}(x_F, 0)$ *in Lemma 17 can be made such that for each of the resulting intervals* $[\nu_0, \nu_0 + \Delta_\nu^0]$ *covering* $[0, 2]$, *which were extracted in Procedure 16, Procedure 21 is successful at* ν_0. *Hence the solutions found in Lemma 17 via Procedure 16 satisfy the geometric conditions* $\mathcal{H}$.

The animation (70912_02.gif [1.32MB]) accompanying this paper shows the changing shape of the periodic solution $\widetilde{u}^\nu$ as the parameter ν increases from 0 to 2.

Proof. A MATLAB computer program (*SH_geometric_properties.m*; see also section 3.1) successfully performing Procedure 21 accompanies the paper. The numerical implementation of Procedure 21 is rather straightforward. Steps 1, 4, and 6 and the second part of Step 8 are mere evaluations of a function using interval arithmetic. Steps 2, 3, 5, and 7 and the first part of Step 8 are all implemented in the same fashion. For instance, we describe here what is done in the implementation of Step 3. First, we consider a mesh $\{x_0, \dots, x_n\}$ of the interval

$[z_0, \pi]$, and we find the largest $k \in \{1, \dots, n\}$ for which we have that $\mathbf{v}'[x_{i-1}, x_i] \subset (1, \infty)$ for all $i \in \{1, \dots, k\}$. We then let $z_1 = x_i$. Note that the smaller the mesh size, the nearer z_1 will be to a zero of v'. Every verification thus requires a series of evaluations of $\mathbf{v}$, $\mathbf{v}'$, and $\mathbf{v}''$ using interval arithmetic. In the implementation, we chose the mesh size to be 0.01. ■

In conclusion, Theorem 3 is a consequence of Lemmas 17 and 22, which are based on Procedures 16 and 21, respectively.

Appendix A. Estimates for infinite convolution sums with power decay. In this section, we present two lemmas that are fundamental in the construction of the radii polynomials. Let $s \geq 2$ be a real number and $M \geq 6$ a natural number.

We introduce an improvement of general estimates for infinite convolution sums with power decay of the form

$$\sum_{k_1+\cdots+k_p=k} a^{(1)}_{k_1} \cdots a^{(p)}_{k_p}, \tag{36}$$

introduced in [12, 14] and used in [13, 15, 18] (the special case $p = 2$ was considered earlier in [38]). Most of the estimates used in the above papers are corollaries of Lemma 5.8 in [14].

Lemma 23 (from [14]). *Let $A > 0$ and $s \geq 2$. Let $\{a_k\}_{k\in\mathbb{Z}}$ be such that $a_{-k} = a_k$, $a_0 \in A[-1, 1]$, and $a_k \in \frac{A}{|k|^s}$ for all $k \in \mathbb{Z} \setminus \{0\}$. Let $\alpha = \frac{2}{s-1} + 2 + 3.5 \cdot 2^s$. Then*

$$\sum_{\sum n_i=k} a_{n_1} \cdots a_{n_p} \subseteq \begin{cases} \alpha^{p-1} A^p[-1, 1], & k = 0, \\ \frac{\alpha^{p-1}A^p}{|k|^s}[-1, 1], & k \neq 0. \end{cases}$$

Observe that the coefficient α provided by Lemma 23 grows exponentially in s. One reason for being interested in getting tighter analytic estimates for sums of the form (36) comes from the fact that, in solving (13) and (14), we need $p = 3$ and $s \geq 4$. If we use the bounds given by Lemma 23, the computational cost of the rigorous continuation will dramatically increase, since we will need to use a very large computational parameter M. A lower bound on M (depending on the α of Lemma 23) can actually be found in [18, section 2.2].

In this appendix we consider general values of the degree p of the convolution and the decay power s, since the specific case is hardly any simpler than the general one. Moreover, the general convolution estimates may be of use for future applications of the method laid out in this paper.

Throughout this appendix we assume that $a_{-k} = a_k$ for all $k \in \mathbb{Z}$. Since

$$\sum_{\substack{k_1+\cdots+k_p=-k \\ k_i\in\mathbb{Z}}} a^{(1)}_{k_1} \cdots a^{(p)}_{k_p} = \sum_{\substack{k_1+\cdots+k_p=k \\ k_i\in\mathbb{Z}}} a^{(1)}_{k_1} \cdots a^{(p)}_{k_p},$$

we consider only the cases $k \in \mathbb{N}$. Note that the estimates are also applicable to the situation where $a_{-k} = -a_k$ for all k.

Before introducing the new general estimates, we need the following result.

Lemma 24. *Let $s \geq 2$, and let s_* be the largest integer such that $s_* \leq s$. Let, for $k \geq 4$,*

$$\gamma_k \overset{\text{def}}{=} 2\left[\frac{k}{k-1}\right]^s + \left[\frac{4\ln(k-2)}{k} + \frac{\pi^2 - 6}{3}\right]\left[\frac{2}{k} + \frac{1}{2}\right]^{s_*-2}. \tag{37}$$

Then, for $k \geq 4$,

$$\sum_{k_1=1}^{k-1} \frac{k^s}{k_1^s (k-k_1)^s} \leq \gamma_k.$$

Proof. First observe that

$$\begin{aligned}
\sum_{k_1=1}^{k-1} \frac{k^s}{k_1^s (k-k_1)^s} &= 2\left[\frac{k}{k-1}\right]^s + \sum_{k_1=2}^{k-2} \frac{k^s}{k_1^s (k-k_1)^s} \\
&= 2\left[\frac{k}{k-1}\right]^s + k^{s-1} \sum_{k_1=2}^{k-2} \frac{(k-k_1)+k_1}{k_1^s (k-k_1)^s} \\
&= 2\left[\frac{k}{k-1}\right]^s + k^{s-1} \left[\sum_{k_1=2}^{k-2} \frac{1}{k_1^s (k-k_1)^{s-1}} + \sum_{k_1=2}^{k-2} \frac{1}{k_1^{s-1} (k-k_1)^s}\right] \\
&= 2\left[\frac{k}{k-1}\right]^s + 2\sum_{k_1=2}^{k-2} \frac{k^{s-1}}{k_1^{s-1} (k-k_1)^s}.
\end{aligned}$$

We now set, using the above,

$$\begin{aligned}
\phi_k^{(s)} &\stackrel{\text{def}}{=} \sum_{k_1=2}^{k-2} \frac{k^{s-1}}{k_1^{s-1} (k-k_1)^s} \\
&= \frac{1}{2} \sum_{k_1=2}^{k-2} \frac{k^s}{k_1^s (k-k_1)^s}.
\end{aligned}$$

We obtain the recurrence inequality

$$\begin{aligned}
\phi_k^{(s)} &= \sum_{k_1=2}^{k-2} \frac{k^{s-1}}{k_1^{s-1} (k-k_1)^s} = k^{s-2} \sum_{k_1=2}^{k-2} \frac{(k-k_1)+k_1}{k_1^{s-1} (k-k_1)^s} \\
&= k^{s-2} \left[\sum_{k_1=2}^{k-2} \frac{1}{k_1^{s-1} (k-k_1)^{s-1}} + \sum_{k_1=2}^{k-2} \frac{1}{k_1^{s-2} (k-k_1)^s}\right] \\
&= \frac{1}{k} \sum_{k_1=2}^{k-2} \frac{k^{s-1}}{k_1^{s-1} (k-k_1)^{s-1}} + \sum_{k_1=2}^{k-2} \frac{k^{s-2}}{k_1^{s-2} (k-k_1)^s} \\
&\leq \frac{1}{k} \sum_{k_1=2}^{k-2} \frac{k^{s-1}}{k_1^{s-1} (k-k_1)^{s-1}} + \frac{1}{2} \sum_{k_1=2}^{k-2} \frac{k^{s-2}}{k_1^{s-2} (k-k_1)^{s-1}} \\
&= \left[\frac{2}{k} + \frac{1}{2}\right] \phi_k^{(s-1)}.
\end{aligned}$$

Hence, since $\frac{k}{k_1(k-k_1)} \leq 1$ for $2 \leq k_1 \leq k-2$ and $k \geq 4$,

$$\phi_k^{(s)} \leq \phi_k^{(s_*)} \leq \phi_k^{(2)} \left[\frac{2}{k} + \frac{1}{2}\right]^{s_*-2},$$

where s_* is the largest integer such that $s_* \leq s$, and

$$\begin{aligned}\phi_k^{(2)} &= \sum_{k_1=2}^{k-2} \frac{k}{k_1(k-k_1)^2} = \sum_{k_1=2}^{k-2} \frac{1}{k_1(k-k_1)} + \sum_{k_1=2}^{k-2} \frac{1}{(k-k_1)^2} \\ &= \frac{2}{k}\sum_{k_1=2}^{k-2} \frac{1}{k_1} + \sum_{k_1=2}^{k-2} \frac{1}{k_1^2} \leq \frac{2}{k}\ln(k-2) + \frac{\pi^2}{6} - 1.\end{aligned}$$

By combining the above inequalities, we conclude that

$$\sum_{k_1=1}^{k-1} \frac{k^s}{k_1^s(k-k_1)^s} \leq 2\left[\frac{k}{k-1}\right]^s + \left[\frac{4\ln(k-2)}{k} + \frac{\pi^2-6}{3}\right]\left[\frac{2}{k}+\frac{1}{2}\right]^{s_*-2} = \gamma_k. \qquad \blacksquare$$

Note that the estimates will be given via a recurrent definition in p, i.e., the power of the nonlinearity. Hence, we begin by getting explicitly the estimates for the case $p = 2$. Throughout this note, we use $M \geq 6$ as a computational parameter; its use is primarily to make all the estimates computable in practice.

A.1. Estimates for the quadratic nonlinearity.

Lemma 25 (quadratic estimates). *Let $s \geq 2$ and $M \geq 6$. Define*

$$\alpha_k^{(2)} \overset{\text{def}}{=} \begin{cases} 4 + \frac{1}{2^{2s-1}(2s-1)} & \text{for } k = 0, \\ 2\left[2 + \frac{1}{2^s} + \frac{1}{3^s} + \frac{1}{3^{s-1}(s-1)}\right] + \sum_{k_1=1}^{k-1} \frac{k^s}{k_1^s(k-k_1)^s} & \text{for } 1 \leq k \leq M-1, \\ 2\left[2 + \frac{1}{2^s} + \frac{1}{3^s} + \frac{1}{3^{s-1}(s-1)}\right] + \gamma_k & \text{for } k \geq M. \end{cases}$$

Let $A_1, A_2 > 0$ such that $a_0^{(i)} \in A_i[-1,1]$ and $a_k^{(i)} \in \frac{A_i}{|k|^s}[-1,1]$ for all $k \neq 0$ and for $i = 1, 2$. Suppose that $a_{-k}^{(i)} = a_k^{(i)}$. Then

$$\sum_{\substack{k_1+k_2=k \\ k_i \in \mathbb{Z}}} a_{k_1}^{(1)} a_{k_2}^{(2)} \in \begin{cases} \alpha_0^{(2)} A_1 A_2\,[-1,1], & k = 0, \\ \frac{\alpha_k^{(2)} A_1 A_2}{|k|^s}\,[-1,1], & k \neq 0. \end{cases}$$

Proof. Let $k = 0$. Then

$$\begin{aligned}\sum_{\substack{k_1+k_2=0 \\ k_i \in \mathbb{Z}}} a_{k_1}^{(1)} a_{k_2}^{(2)} &= \sum_{k_1<0} a_{k_1}^{(1)} a_{-k_1}^{(2)} + a_0^{(1)} a_0^{(2)} + \sum_{k_1>0} a_{k_1}^{(1)} a_{-k_1}^{(2)} \\ &= a_0^{(1)} a_0^{(2)} + 2\sum_{k_1=1}^{\infty} a_{k_1}^{(1)} a_{k_1}^{(2)} \\ &\in A_1 A_2 \left[1 + 2\sum_{k_1=1}^{\infty} \frac{1}{k_1^{2s}}\right][-1,1] \\ &\subseteq A_1 A_2 \left[4 + \frac{1}{2^{2s-1}(2s-1)}\right][-1,1] \\ &= \alpha_0^{(2)} A_1 A_2\,[-1,1].\end{aligned}$$

Now consider $k \in \{1, \dots, M-1\}$. Then

$$\begin{aligned}\sum_{\substack{k_1+k_2=k\\ k_i\in\mathbb{Z}}} a^{(1)}_{k_1}a^{(2)}_{k_2} &= \sum_{k_1=-\infty}^{-1} a^{(1)}_{k_1}a^{(2)}_{k-k_1} + a^{(1)}_0 a^{(2)}_k + \sum_{k_1=1}^{k-1} a^{(1)}_{k_1}a^{(2)}_{k-k_1} + a^{(1)}_k a^{(2)}_0 + \sum_{k_1=k+1}^{\infty} a^{(1)}_{k_1}a^{(2)}_{k-k_1}\\ &\in A_1A_2\left[\frac{2}{k^s} + 2\sum_{k_1=1}^{\infty}\frac{1}{k_1^s(k+k_1)^s} + \frac{1}{k^s}\sum_{k_1=1}^{k-1}\frac{k^s}{k_1^s(k-k_1)^s}\right][-1,1]\\ &\subset A_1A_2\left[\frac{2}{k^s} + \frac{2}{k^s}\sum_{k_1=1}^{\infty}\frac{1}{k_1^s} + \frac{1}{k^s}\sum_{k_1=1}^{k-1}\frac{k^s}{k_1^s(k-k_1)^s}\right][-1,1]\\ &\subseteq \frac{\alpha^{(2)}_k A_1A_2}{k^s}[-1,1],\end{aligned}$$

where we, quite arbitrarily, have bound the infinite sum $\sum_{k_1=1}^{\infty}\frac{1}{k_1^s}$ using an integral estimate after the third term. For the case $k \geq M$, we do the same analysis as in the case $k \in \{1, \dots, M-1\}$, and we use the upper bound γ_k from Lemma 24. ■

Remark 26. For any $k \geq M \geq 6$, we have that $\alpha^{(2)}_k \leq \alpha^{(2)}_M$.

Proof. For $k \geq 6$, the fact that $\frac{\ln(k-1)}{(k+1)} \leq \frac{\ln(k-2)}{k}$ implies that $\gamma^{(s)}_{k+1} \leq \gamma^{(s)}_k$. The conclusion then follows from the definition $\alpha^{(2)}_k$ for $k \geq M \geq 6$. ■

A.2. Estimates for a general nonlinearity. Let $p \geq 3$ be the degree of the nonlinearity, $s \geq 2$ the decay of the coefficients, and $M \geq 6$ a natural number. We compute the general estimates recursively. Hence, we first suppose that for every $k \geq 0$, we know explicitly $\alpha^{(p-1)}_k > 0$ such that

$$\sum_{\substack{k_1+\cdots+k_{p-1}=k\\ k_i\in\mathbb{Z}}} a^{(1)}_{k_1}\cdots a^{(p-1)}_{k_{p-1}} \in \begin{cases}\alpha^{(p-1)}_0\left(\prod_{i=1}^{p-1}A_i\right)[-1,1], & k=0,\\ \frac{\alpha^{(p-1)}_k}{|k|^s}\left(\prod_{i=1}^{p-1}A_i\right)[-1,1], & k\neq 0,\end{cases}$$

and such that $\alpha^{(p-1)}_k \leq \alpha^{(p-1)}_M$ for all $k \geq M$. We define

$$\alpha^{(p)}_k \overset{\text{def}}{=} \begin{cases}\alpha^{(p-1)}_0 + 2\sum_{k_p=1}^{M-1}\frac{\alpha^{(p-1)}_{k_p}}{k_p^{2s}} + \frac{2\alpha^{(p-1)}_M}{(M-1)^{2s-1}(2s-1)} & \text{for } k=0,\\ \sum_{k_p=1}^{M-k-1}\frac{\alpha^{(p-1)}_{k+k_p}k^s}{k_p^s(k+k_p)^s} + \alpha^{(p-1)}_M\left(1+\frac{1}{2^s}+\frac{1}{3^s}+\frac{1}{3^{s-1}(s-1)}\right)\\ \quad + \alpha^{(p-1)}_k + \sum_{k_p=1}^{k-1}\frac{\alpha^{(p-1)}_{k_p}k^s}{k_p^s(k-k_p)^s} + \alpha^{(p-1)}_0 + \sum_{k_p=1}^{M-1}\frac{\alpha^{(p-1)}_{k_p}k^s}{(k+k_p)^s k_p^s}\\ \quad + \frac{\alpha^{(p-1)}_M}{(M-1)^{s-1}(s-1)} & \text{for } 1\leq k\leq M-1,\\ \alpha^{(p-1)}_M\left[2+\frac{1}{2^s}+\frac{1}{3^s}+\frac{1}{3^{s-1}(s-1)}+\frac{1}{(M-1)^{s-1}(s-1)}+\gamma_k\right]\\ \quad + \alpha^{(p-1)}_0 + \sum_{k_p=1}^{M-1}\frac{\alpha^{(p-1)}_{k_p}}{k_p^s}\left[1+\frac{1}{\left[1-\frac{k_p}{M}\right]^s}\right] & \text{for } k\geq M.\end{cases}$$

Lemma 27. *For $i = 1, \dots, p$, let $A_i > 0$ such that $a_0^{(i)} \in A_i[-1,1]$ and $a_k^{(i)} \in \frac{A_i}{|k|^s}[-1,1]$ for all $k \neq 0$. Suppose that $a_{-k}^{(i)} = a_k^{(i)}$. Then*

$$\sum_{\substack{k_1+\cdots+k_p=k \\ k_i\in\mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_p}^{(p)} \in \begin{cases} \alpha_0^{(p)} \left(\prod_{i=1}^p A_i\right)[-1,1], & k = 0, \\ \frac{\alpha_k^{(p)}}{|k|^s} \left(\prod_{i=1}^p A_i\right)[-1,1], & k \neq 0. \end{cases}$$

Proof. Several times throughout the proof, we use that $\alpha_k^{(p-1)} \leq \alpha_M^{(p-1)}$ for all $k \geq M$. For $k = 0$,

$$\begin{aligned} \sum_{\substack{k_1+\cdots+k_p=0 \\ k_i\in\mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_p}^{(p)} &= \sum_{k_p=-\infty}^{-1} a_{k_p}^{(p)} \sum_{\substack{k_1+\cdots+k_{p-1}=-k_p \\ k_i\in\mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_{p-1}}^{(p-1)} \\ &\quad + a_0^{(p)} \sum_{\substack{k_1+\cdots+k_{p-1}=0 \\ k_i\in\mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_{p-1}}^{(p-1)} \\ &\quad + \sum_{k_p=1}^{\infty} a_{k_p}^{(p)} \sum_{\substack{k_1+\cdots+k_{p-1}=-k_p \\ k_i\in\mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_{p-1}}^{(p-1)} \\ &\in \left(\prod_{i=1}^p A_i\right) \left[\sum_{k_p=1}^{\infty} \frac{\alpha_{k_p}^{(p-1)}}{k_p^{2s}} + \alpha_0^{(p-1)} + \sum_{k_p=1}^{\infty} \frac{\alpha_{k_p}^{(p-1)}}{k_p^{2s}}\right][-1,1] \\ &\subseteq \left(\prod_{i=1}^p A_i\right) \left[\alpha_0^{(p-1)} + 2\sum_{k_p=1}^{M-1} \frac{\alpha_{k_p}^{(p-1)}}{k_p^{2s}} + \frac{2\alpha_M^{(p-1)}}{(M-1)^{2s-1}(2s-1)}\right][-1,1] \\ &= \alpha_0^{(p)} \left(\prod_{i=1}^p A_i\right)[-1,1]. \end{aligned}$$

For any $k \geq 1$,

$$\begin{aligned} \sum_{\substack{k_1+\cdots+k_p=k \\ k_i\in\mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_p}^{(p)} &= \sum_{k_p=-\infty}^{-1} a_{k_p}^{(p)} \sum_{\substack{k_1+\cdots+k_{p-1}=k-k_p \\ k_i\in\mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_{p-1}}^{(p-1)} \\ &\quad + a_0^{(p)} \sum_{\substack{k_1+\cdots+k_{p-1}=k \\ k_i\in\mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_{p-1}}^{(p-1)} + \sum_{k_p=1}^{k-1} a_{k_p}^{(p)} \sum_{\substack{k_1+\cdots+k_{p-1}=k-k_p \\ k_i\in\mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_{p-1}}^{(p-1)} \\ &\quad + a_k^{(p)} \sum_{\substack{k_1+\cdots+k_{p-1}=0 \\ k_i\in\mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_{p-1}}^{(p-1)} + \sum_{k_p=k+1}^{\infty} a_{k_p}^{(p)} \sum_{\substack{k_1+\cdots+k_{p-1}=k-k_p \\ k_i\in\mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_{p-1}}^{(p-1)} \end{aligned}$$

$$\in \left(\prod_{i=1}^{p} A_i\right)\left[\sum_{k_p=1}^{\infty}\frac{\alpha_{k+k_p}^{(p-1)}}{k_p^s(k+k_p)^s}+\frac{\alpha_k^{(p-1)}}{k^s}+\sum_{k_p=1}^{k-1}\frac{\alpha_{k_p}^{(p-1)}}{k_p^s(k-k_p)^s}+\frac{\alpha_0^{(p-1)}}{k^s}+\sum_{k_p=1}^{\infty}\frac{\alpha_{k_p}^{(p-1)}}{(k+k_p)^s k_p^s}\right][-1,1].$$

Consider $k\in\{1,\dots,M-1\}$. Since $\alpha_{k_p}^{(p-1)}\le\alpha_M^{(p-1)}$ for all $k_p\ge M$, we have

$$\begin{aligned}\sum_{k_p=1}^{\infty}\frac{\alpha_{k+k_p}^{(p-1)}}{k_p^s(k+k_p)^s}&=\sum_{k_p=1}^{M-k-1}\frac{\alpha_{k+k_p}^{(p-1)}}{k_p^s(k+k_p)^s}+\sum_{k_p=M-k}^{\infty}\frac{\alpha_{k+k_p}^{(p-1)}}{k_p^s(k+k_p)^s}\\&\le\sum_{k_p=1}^{M-k-1}\frac{\alpha_{k+k_p}^{(p-1)}}{k_p^s(k+k_p)^s}+\alpha_M^{(p-1)}\sum_{k_p=M-k}^{\infty}\frac{1}{k_p^s(k+k_p)^s}\\&\le\sum_{k_p=1}^{M-k-1}\frac{\alpha_{k+k_p}^{(p-1)}}{k_p^s(k+k_p)^s}+\alpha_M^{(p-1)}\sum_{k_p=1}^{\infty}\frac{1}{k_p^s(k+k_p)^s}\\&\le\frac{1}{k^s}\left[\sum_{k_p=1}^{M-k-1}\frac{\alpha_{k+k_p}^{(p-1)}k^s}{k_p^s(k+k_p)^s}+\alpha_M^{(p-1)}\left(1+\frac{1}{2^s}+\frac{1}{3^s}+\frac{1}{3^{s-1}(s-1)}\right)\right].\end{aligned}$$

Similarly,

$$\sum_{k_p=1}^{\infty}\frac{\alpha_{k_p}^{(p-1)}}{(k+k_p)^s k_p^s}\le\frac{1}{k^s}\left[\sum_{k_p=1}^{M-1}\frac{\alpha_{k_p}^{(p-1)}k^s}{(k+k_p)^s k_p^s}+\frac{\alpha_M^{(p-1)}}{(M-1)^{s-1}(s-1)}\right].$$

Recalling the definition of $\alpha_k^{(p)}$ for the cases $k\in\{1,\dots,M-1\}$, we get that

$$\sum_{\substack{k_1+\cdots+k_p=k\\k_i\in\mathbb{Z}}}a_{k_1}^{(1)}\cdots a_{k_p}^{(p)}\in\frac{\alpha_k^{(p)}}{k^s}\left(\prod_{i=1}^{p}A_i\right)[-1,1].$$

Consider now $k\ge M$; then

$$\sum_{k_p=1}^{\infty}\frac{\alpha_{k+k_p}^{(p-1)}}{k_p^s(k+k_p)^s}+\frac{\alpha_k^{(p-1)}}{k^s}\le\frac{\alpha_M^{(p-1)}}{k^s}\left[2+\frac{1}{2^s}+\frac{1}{3^s}+\frac{1}{3^{s-1}(s-1)}\right].$$

Using Lemma 24, we get that

$$\sum_{k_p=1}^{k-1} \frac{\alpha_{k_p}^{(p-1)}}{k_p^s(k-k_p)^s} = \sum_{k_p=1}^{M-1} \frac{\alpha_{k_p}^{(p-1)}}{k_p^s(k-k_p)^s} + \frac{1}{k^s} \sum_{k_p=M}^{k-1} \frac{k^s \alpha_{k_p}^{(p-1)}}{k_p^s(k-k_p)^s}$$
$$\leq \frac{1}{k^s} \sum_{k_p=1}^{M-1} \frac{\alpha_{k_p}^{(p-1)}}{k_p^s\left(1-\frac{k_p}{k}\right)^s} + \frac{\alpha_M^{(p-1)}}{k^s} \sum_{k_p=M}^{k-1} \frac{k^s}{k_p^s(k-k_p)^s}$$
$$\leq \frac{1}{k^s} \left[\sum_{k_p=1}^{M-1} \frac{\alpha_{k_p}^{(p-1)}}{k_p^s\left(1-\frac{k_p}{M}\right)^s} + \alpha_M^{(p-1)} \gamma_k \right].$$

Also,

$$\sum_{k_p=1}^{\infty} \frac{\alpha_{k_p}^{(p-1)}}{(k+k_p)^s k_p^s} \leq \frac{1}{k^s} \left[\sum_{k_p=1}^{M-1} \frac{\alpha_{k_p}^{(p-1)}}{k_p^s} + \frac{\alpha_M^{(p-1)}}{(M-1)^{s-1}(s-1)} \right].$$

Combining the three above inequalities, we finally have that

$$\sum_{\substack{k_1+\cdots+k_p=k \\ k_i \in \mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_p}^{(p)}$$
$$\in \frac{1}{k^s} \left(\prod_{i=1}^{p} A_i \right) \left[\alpha_0^{(p-1)} + \sum_{k_p=1}^{M-1} \frac{\alpha_{k_p}^{(p-1)}}{k_p^s} \left(1 + \frac{1}{\left(1-\frac{k_p}{M}\right)^s} \right) \right.$$
$$\left. + \alpha_M^{(p-1)} \left(2 + \tfrac{1}{2^s} + \tfrac{1}{3^s} + \tfrac{1}{3^{s-1}(s-1)} + \tfrac{1}{(M-1)^{s-1}(s-1)} + \gamma_k \right) \right] [-1,1]$$
$$= \frac{\alpha_k^{(p)}}{k^s} \left(\prod_{i=1}^{p} A_i \right) [-1,1]. \quad \blacksquare$$

Remark 28. For any $k \geq M \geq 6$, we have that $\alpha_k^{(p)} \leq \alpha_M^{(p)}$.

Proof. The proof is identical to that of Remark 26. $\blacksquare$

A.3. Comparison of the general estimates. We now compare the new estimates with the ones given by Lemma 23 for different values of p and s. Since the only difference in the estimates is α^{p-1} versus $\alpha_k^{(p)}$, these are the quantities we compare in Table 5. In particular, the new estimates lead to an improvement of a factor 10^2 for the values $p = 3$ and $s = 4$ used in this paper, while for higher values of p and s they become even more beneficial. For the computation, we fixed $M = 100$; in the case $p \geq 3$, increasing M would make the $\alpha_k^{(p)}$ smaller still.

A.4. Refinement for $k \in \{0, \ldots, M-1\}$. We present a corollary of Lemma 27 which gives better bounds for $0 \leq k \leq M-1$.

Corollary 29. *Let $p \geq 3$ be the degree of the nonlinearity, $s \geq 2$ the decay of the coefficients, and $M \geq 6$ a natural number. Consider another computational number $M_1 \geq M$. Let the $\{\alpha_k^{(p-1)}\}_{k \in \{0,\ldots,M_1\}}$ be defined in Lemma 27. For $i = 1, \ldots, p$, let $A_i > 0$ be such that*

Table 5
Comparison of the estimates α^{p-1} versus $\alpha_k^{(p)}$ used in Lemmas 23 and 27.

p	s	k	α^{p-1}	$\alpha_k^{(p)}$
2	4	10	$5.87 \cdot 10^{1}$	$6.65 \cdot 10^{0}$
3	4	30	$3.44 \cdot 10^{3}$	$4.44 \cdot 10^{1}$
3	4	90	$3.44 \cdot 10^{3}$	$4.31 \cdot 10^{1}$
3	5	30	$1.31 \cdot 10^{4}$	$4.20 \cdot 10^{1}$
3	7	30	$2.03 \cdot 10^{5}$	$4.12 \cdot 10^{1}$
3	10	30	$1.29 \cdot 10^{7}$	$4.26 \cdot 10^{1}$
3	50	30	$1.55 \cdot 10^{31}$	$1.68 \cdot 10^{2}$
4	4	10	$2.02 \cdot 10^{5}$	$3.28 \cdot 10^{2}$
4	5	10	$1.50 \cdot 10^{6}$	$3.17 \cdot 10^{2}$
4	7	10	$9.13 \cdot 10^{7}$	$3.59 \cdot 10^{2}$
5	10	10	$1.65 \cdot 10^{14}$	$3.98 \cdot 10^{3}$
5	20	10	$1.81 \cdot 10^{26}$	$1.82 \cdot 10^{5}$
10	25	20	$4.25 \cdot 10^{72}$	$1.75 \cdot 10^{8}$
20	50	90	$2.07 \cdot 10^{296}$	$5.01 \cdot 10^{15}$

$a_0^{(i)} \in A_i[-1,1]$ *and* $a_k^{(i)} \in \frac{A_i}{|k|^s}[-1,1]$ *for all* $k \neq 0$, *and let* $|a|_{M_1}^{(i)} = \left(|a_0^{(i)}|, \dots, |a_{M_1-1}^{(i)}|\right)$. *Suppose that* $a_{-k}^{(i)} = a_k^{(i)}$. *For* $k \in \{0, \dots, M-1\}$, *define*

$$\varepsilon_k^{(p)} = \frac{2\alpha_{M_1}^{(p-1)}}{(M_1+k)^s(M_1-1)^{s-1}(s-1)} + \sum_{k_p=M_1}^{M_1+k-1} \frac{\alpha_{k_p-k}^{(p-1)}}{k_p^s(k_p-k)^s}.$$

Then we have that, for $k \in \{0, \dots, M-1\}$,

$$\left(a^{(1)} * \cdots * a^{(p)}\right)_k \in \left[\left(|a|_{M_1}^{(1)} * \cdots * |a|_{M_1}^{(p)}\right)_k + \left(\prod_{i=1}^{p} A_i\right) p\varepsilon_k^{(p)}\right][-1,1].$$

Proof. First notice that

$$\begin{aligned}\left(a^{(1)} * \cdots * a^{(p)}\right)_k &= \sum_{\substack{k_1+\cdots+k_p=k \\ k_i \in \mathbb{Z}}} a_{k_1}^{(1)} \cdots a_{k_p}^{(p)} \\ &= \sum_{\substack{k_1+\cdots+k_p=k \\ |k_i|<M_1}} a_{k_1}^{(1)} \cdots a_{k_p}^{(p)} + \sum_{\substack{k_1+\cdots+k_p=k \\ \max\{|k_1|,\dots,|k_p|\} \geq M_1}} a_{k_1}^{(1)} \cdots a_{k_p}^{(p)}.\end{aligned}$$

We have that

$$\sum_{\substack{k_1+\cdots+k_p=k\\ |k_p|\geq M_1}} a^{(1)}_{k_1}\cdots a^{(p)}_{k_p} = \sum_{k_p=-\infty}^{-M_1} a^{(p)}_{k_p} \sum_{k_1+\cdots+k_{p-1}=k-k_p} a^{(1)}_{k_1}\cdots a^{(p-1)}_{k_{p-1}} + \sum_{k_p=M_1}^{\infty} a^{(p)}_{k_p} \sum_{k_1+\cdots+k_{p-1}=k-k_p} a^{(1)}_{k_1}\cdots a^{(p-1)}_{k_{p-1}}$$

$$\in \left(\prod_{i=1}^{p} A_i\right) \sum_{k_p=M_1}^{\infty} \left[\frac{\alpha^{(p-1)}_{k+k_p}}{k_p^s(k+k_p)^s} + \frac{\alpha^{(p-1)}_{k_p-k}}{k_p^s(k_p-k)^s}\right][-1,1]$$

$$\subseteq \left(\prod_{i=1}^{p} A_i\right) \left[2\alpha^{(p-1)}_{M_1} \sum_{k_p=M_1}^{\infty} \frac{1}{k_p^s(k+k_p)^s} + \sum_{k_p=M_1}^{M_1+k-1} \frac{\alpha^{(p-1)}_{k_p-k}}{k_p^s(k_p-k)^s}\right][-1,1]$$

$$\subseteq \left(\prod_{i=1}^{p} A_i\right) \left[\frac{2\alpha^{(p-1)}_{M_1}}{(M_1+k)^s(M_1-1)^{s-1}(s-1)} + \sum_{k_p=M_1}^{M_1+k-1} \frac{\alpha^{(p-1)}_{k_p-k}}{k_p^s(k_p-k)^s}\right][-1,1].$$

Recalling the definition of $\varepsilon^{(p)}_k$, we can conclude that

$$\left(a^{(1)} * \cdots * a^{(p)}\right)_k \in \left[\left(|a|^{(1)}_{M_1} * \cdots * |a|^{(p)}_{M_1}\right)_k + \left(\prod_{i=1}^{p} A_i\right) p\varepsilon^{(p)}_k\right][-1,1]. \qquad \blacksquare$$

Existence of a Reversible T-Point Heteroclinic Cycle in a Piecewise Linear Version of the Michelson System*

Victoriano Carmona†, Fernando Fernández-Sánchez†, and Antonio E. Teruel‡

Abstract. The proof of the existence of a global connection in differential systems is generally a difficult task. Some authors use numerical techniques to show this existence, even in the case of continuous piecewise linear systems. In this paper we give an analytical proof of the existence of a reversible T-point heteroclinic cycle in a continuous piecewise linear version of the widely studied Michelson system. The principal ideas of this proof can be extended to other piecewise linear systems.

Key words. piecewise linear systems, heteroclinic orbits, invariant manifolds

1. Introduction.

The existence of global connections in a differential system usually forces a complex dynamical behavior in a neighborhood of such connections. For instance, under the presence of a homoclinic cycle to a saddle-focus equilibrium point satisfying an eigenvalue ratio condition, the celebrated works of Shil'nikov [26, 27] ensure the existence of infinitely many periodic orbits of saddle type accumulating to the homoclinic cycle.

Moreover, the existence of a global connection in a differential system implies the appearance of subsidiary connections for certain perturbations of the system. For example, an analysis of the bifurcation structure of homoclinic cycles and subsidiary connections can be found in [15].

Heteroclinic cycles are also organizing centers of a very complex dynamic [10, 11, 12, 14]. In particular, Dumortier, Ibañez, and Kokubu [11] conjecture the existence of an infinite set of bifurcation phenomena, called a *cocoon* bifurcation [20], accumulating at a reversible T-point, that is, a point of the parameter space where a special kind of heteroclinic cycle satisfying some nondegeneracy condition appears. Furthermore, they explain the occurrence of such bifurcation phenomena as a consequence of the presence of this global connection.

Unfortunately, for nonlinear differential systems it is not easy to guarantee the existence of a global connection. Even though this is possible, some other extra conditions, for instance,

the nondegeneracy conditions in the case of a reversible T-point heteroclinic cycle, cannot always be verified in a rigorous way. For example, the existence of a heteroclinic cycle in the Michelson system [25, 28], having an explicit expression for one of its heteroclinic orbits, is known [16, 18]. Nevertheless, the genericity conditions that determine if such a heteroclinic cycle is a reversible T-point heteroclinic cycle remain to be verified [11].

On the other hand, there are a lot of papers devoted to the existence of global connections in piecewise linear differential systems [2, 8, 9, 22, 23, 24]. Many of these works require numerical arguments to show the existence of the global connections. However, in [22], the authors provide an analytical proof of the existence of a homoclinic cycle in a three-dimensional piecewise linear system. In a similar way, in the present work we pay attention to the existence of a reversible T-point heteroclinic cycle in piecewise linear systems.

Now, some ideas for establishing the main result of the paper are introduced. The Michelson system is the one-parameter family of autonomous three-dimensional differential systems

$$\begin{cases} \dot{x} = y, \\ \dot{y} = z, \\ \dot{z} = d^2 - y - \dfrac{1}{2}x^2, \end{cases} \tag{1.1}$$

where the dot stands for the derivative with respect to t and, without loss of generality, we can assume that $d \geq 0$. This family appears in the study of traveling wave solutions of the one-dimensional Kuramoto–Sivashinsky equation [25]. It also arises in the analysis of the unfolding of the nilpotent singularity of codimension three [10, 13].

For $d \neq 0$ the Michelson system has two equilibrium points, $\mathbf{p}_\pm = (\pm d\sqrt{2}, 0, 0)$, which are of saddle-focus type. The stable manifold $W^s(\mathbf{p}_+)$ of $\mathbf{p}_+$ (respectively, the unstable manifold $W^u(\mathbf{p}_-)$ of $\mathbf{p}_-$) is one-dimensional and the unstable manifold $W^u(\mathbf{p}_+)$ of $\mathbf{p}_+$ (respectively, the stable manifold $W^s(\mathbf{p}_-)$ of $\mathbf{p}_-$) is two-dimensional.

The vector field $\mathbf{f}$ associated to the Michelson system (1.1) satisfies the following important properties that affect the solution set:

- The divergence of $\mathbf{f}$ is identically zero. Therefore, the family is volume-preserving.
- The vector field $\mathbf{f}$ is invariant under the linear involution $\mathbf{R}(x, y, z) = (-x, y, -z)$ and sign reverse; that is,
$$\mathbf{R}(\mathbf{f}(\mathbf{x})) = -\mathbf{f}(\mathbf{R}(\mathbf{x})),$$
where $\mathbf{x} = (x, y, z)^T$.

From the second property, the following dynamical consequences are obtained:

- Let $\phi(t; \mathbf{p})$ denote the flow of system (1.1). The equality $\phi(t; \mathbf{R}(\mathbf{p})) = \mathbf{R}(\phi(-t; \mathbf{p}))$ holds, and we say that the family is time-reversible with respect to the linear involution $\mathbf{R}$.
- If $\mathbf{p}$ is a point on the y-axis, then $\mathbf{R}(\mathbf{p}) = \mathbf{p}$. Therefore, the orbit through $\mathbf{p}$ is reversible with respect to $\mathbf{R}$, that is, $\phi(t; \mathbf{p}) = \mathbf{R}(\phi(-t; \mathbf{p}))$, and the y-axis is called the reversibility axis.
- By the reversibility, the stable and unstable manifolds of $\mathbf{p}_-$ satisfy $W^s(\mathbf{p}_-) = \mathbf{R}\left(W^u(\mathbf{p}_+)\right)$ and $W^u(\mathbf{p}_-) = \mathbf{R}\left(W^s(\mathbf{p}_+)\right)$, respectively.

An interesting object of the dynamics of the Michelson system which has been widely studied (see [11, 16, 19, 20] and the references therein) is the so-called reversible T-point

heteroclinic cycle. Following [11], we say that the Michelson system (1.1) has a reversible T-point heteroclinic cycle $\Gamma = \{\mathbf{p}_+\} \cup \rho_\pm \cup \{\mathbf{p}_-\} \cup \rho_\mp$ for the parameter value d_0 if the following hold:

(a) The two-dimensional manifolds $W^u(\mathbf{p}_+)$ and $W^s(\mathbf{p}_-)$ have a transversal intersection along the heteroclinic orbit $\rho_\pm$.

(b) As the parameter d is varied around d_0 the heteroclinic orbit $\rho_\mp$ unfolds generically. That is, the one-dimensional manifolds $W^u(\mathbf{p}_-)$ and $W^s(\mathbf{p}_+)$ intersect at $\rho_\mp$ for $d = d_0$ and the "distance" between $W^u(\mathbf{p}_-)$ and $W^s(\mathbf{p}_+)$ measured in a transverse plane is diffeomorphic to $\mu = d - d_0$.

The value d_0 is usually called a reversible T-point. Note that some authors [11] use the name Bykov cycle to refer to a T-point heteroclinic cycle [3, 4, 5].

By abuse of notation, we can call the orbit $\rho_\mp$ a one-dimensional heteroclinic orbit, because this orbit corresponds to the one-dimensional invariant manifolds of the singular points, and the orbit $\rho_\pm$ a two-dimensional heteroclinic orbit because it is contained in the intersection set of the two-dimensional invariant manifolds of the singular points.

From several recent works it is possible to discern that piecewise linear systems are able to reproduce the dynamics of differentiable systems. Thus, it is natural to wonder if a suitable continuous piecewise linear version of the Michelson system with a reversible T-point exists.

An easy way to obtain a continuous piecewise linear system from the Michelson system is to perform, for $d \neq 0$, the change of variables $x \to x/d^2$, $y \to y/d^2$, $z \to z/d^2$ followed by the change of function $x^2 \to |x|$. This procedure transforms system (1.1) into

$$\begin{cases} \dot{x} = y, \\ \dot{y} = z, \\ \dot{z} = 1 - y - c|x|, \end{cases} \tag{1.2}$$

where $c = \frac{d^2}{2}$. Note that this system is also volume-preserving and time-reversible with respect to the involution $\mathbf{R}$.

Due to the lack of differentiability of the piecewise linear vector fields, the generic tools of the analysis of differentiable systems cannot be applied. Therefore, the techniques used in [11] for the Michelson system are useless for our piecewise linear continuous version. Nevertheless, we also show that some dynamical aspects of the Michelson system remain in our piecewise linear version.

System (1.2) is formed by two linear systems separated by the plane $\{x = 0\}$, called the separation plane, and it can be written in a matricial form as

$$\dot{\mathbf{x}} = \begin{cases} A^+\mathbf{x} + \mathbf{e}_3 & \text{if } x \geq 0, \\ A^-\mathbf{x} + \mathbf{e}_3 & \text{if } x \leq 0, \end{cases} \tag{1.3}$$

with

$$A^+ = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ -c & -1 & 0 \end{pmatrix}, \quad A^- = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ c & -1 & 0 \end{pmatrix}, \quad \text{and} \quad \mathbf{e}_3 = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}.$$

In the half-space $\{x < 0\}$, the system has exactly one equilibrium point $\mathbf{p}_- = (-1/c, 0, 0)^T$ which is a saddle-focus point. Let $\lambda > 0$ and $\alpha \pm \mathrm{i}\,\beta$ be the eigenvalues of the Jacobian matrix

at $\mathbf{p}_-$. This clearly implies that

$$c = \lambda(1+\lambda^2), \quad \alpha = -\frac{\lambda}{2}, \quad \beta = \frac{\sqrt{4+3\lambda^2}}{2}. \tag{1.4}$$

By the reversibility with respect to $\mathbf{R}$, there exists exactly one saddle-focus equilibrium $\mathbf{p}_+ = (1/c, 0, 0)^T$ in the half-space $\{x > 0\}$ whose eigenvalues are given by $-\lambda$ and $-\alpha \pm \mathrm{i}\,\beta$.

Using the expression of the parameter c given in (1.4), system (1.2) can be written as

$$\begin{cases} \dot{x} = y, \\ \dot{y} = z, \\ \dot{z} = 1 - y - \lambda(1+\lambda^2)|x|, \end{cases} \tag{1.5}$$

and the parameter $\lambda > 0$ can be chosen as the fundamental parameter of the family.

In the particular case of piecewise linear systems, global connections can be classified attending to the number of intersections with the separation plane. Using the notation introduced above, we say that a reversible T-point heteroclinic cycle Γ of system (1.5) is (n, m) if the one-dimensional heteroclinic orbit $\rho_\mp$ intersects the separation plane $\{x = 0\}$ at exactly n points and the two-dimensional heteroclinic orbit $\rho_\pm$ intersects $\{x = 0\}$ at exactly m points.

Obviously, the reversibility of system (1.5) forces n to be odd. As we will see later, due to the local linear shape of the one-dimensional invariant manifolds, n has to be different than one. So, the $(3, 1)$ reversible T-point heteroclinic cycle can be considered to be the simplest one and its existence will be the main goal of this work, as it is summarized in the following theorem.

Theorem 1.1. *There exists a value $\lambda_1 \in (1/2, 1)$ such that the piecewise linear version (1.5) of the Michelson system has a $(3, 1)$ reversible T-point heteroclinic cycle Γ for $\lambda = \lambda_1$.*

Some numerical computations allow us to obtain $\lambda_1 \approx 0.65153556$. In fact, its boundary values $1/2$ and 1 do not have any dynamical meaning, and they have been chosen for the sake of simplicity of the handmade calculations involved in the proof.

Piecewise linear system (1.5) has been obtained from the Michelson system by using a natural transformation. This transformation preserves not only the look of the equations but also the properties of reversibility and volume-preservation. We must emphasize that this is not casual. In fact, considering a piecewise linear continuous system with separation plane $\{x = 0\}$ and two saddle-focus equilibria, and assuming the reversibility, volume-preservation, and nondegeneracy conditions, the unique system that can be obtained is (1.5) except for linear changes of variables and time. More precisely, a piecewise linear continuous system with separation plane $\{x = 0\}$ under the hypothesis of observability can be written as

$$\begin{cases} \dot{x} = t^{\pm} x - y, \\ \dot{y} = m^{\pm} x - z, \\ \dot{z} = d^{\pm} x - 1, \end{cases} \tag{1.6}$$

where parameters t^+, m^+, and d^+ correspond to the linear system in the half-space $\{x > 0\}$ while t^-, m^-, and d^- correspond to the linear system in the half-space $\{x < 0\}$. Observability is a nondegeneracy condition, which means that the dynamics of the system cannot be uncoupled [6, 7]. The reversibility condition with respect to $\mathbf{R}$ implies that $t^- = -t^+$,

$m^- = m^+$, and $d^- = -d^+$. On the other hand, system (1.6) is volume-preserving if and only if $t^+ = t^- = 0$. Now, the existence of two saddle-focus equilibria forces the parameters d^+ and m^+ to be positive. Hence, system (1.6) is really

$$\begin{cases} \dot{x} = -y, \\ \dot{y} = mx - z, \\ \dot{z} = d|x| - 1, \end{cases}$$

where $d = d^+ > 0$ and $m = m^+ > 0$. The trivial linear change of variables and time,

$$X = -m^{3/2}x, \quad Y = my, \quad Z = m^{3/2}x - m^{1/2}z, \quad \tau = m^{1/2}t,$$

transforms the system into

$$\begin{cases} X' = Y, \\ Y' = Z, \\ Z' = 1 - Y - \frac{d}{m^{3/2}}|X|, \end{cases}$$

where the prime stands for the derivative with respect to τ. This is the piecewise linear version of the Michelson system previously obtained.

The rest of the paper is devoted to the proof of Theorem 1.1, and it is organized as follows. In section 2 we describe the basic geometric elements of the problem. In section 3 we prove the existence, for every λ in a semi-infinite interval, of a two-dimensional heteroclinic orbit with exactly one intersection point with the plane $\{x = 0\}$. For one of these values of λ, there exists a one-dimensional heteroclinic orbit with exactly three intersection points with $\{x = 0\}$, as is proved in section 4. From this follows the existence of a simple heteroclinic cycle Γ. In section 5 we prove that Γ satisfies the nondegeneracy conditions of a reversible T-point heteroclinic cycle.

2. Some geometric elements of the flow. In this section we describe the behavior of the flow crossing the plane $\{x = 0\}$ and the basic elements of the linear dynamics locally contained in the half-spaces $\{x < 0\}$ and $\{x > 0\}$.

For every point $\mathbf{p} = (x_\mathbf{p}, y_\mathbf{p}, z_\mathbf{p})^T \in \mathbb{R}^3$ we denote by $\mathbf{x}_\mathbf{p}(t;\lambda) = (x_\mathbf{p}(t;\lambda), y_\mathbf{p}(t;\lambda), z_\mathbf{p}(t;\lambda))^T$ the solution of the system (1.5) with parameter λ and initial condition $\mathbf{x}_\mathbf{p}(0;\lambda) = \mathbf{p}$. The corresponding orbit is denoted by $\gamma_\mathbf{p}$.

If $x_\mathbf{p} = 0$ and $y_\mathbf{p} > 0$, then the orbit $\gamma_\mathbf{p}$ crosses transversally the plane $\{x = 0\}$ with $x_\mathbf{p}(-t;\lambda) < 0$ and $x_\mathbf{p}(t;\lambda) > 0$ for $t > 0$ small enough. If $x_\mathbf{p}(t;\lambda)$ vanishes in $(0, +\infty)$, then we define the flying time $t^+_\mathbf{p}$ as the positive value such that $x_\mathbf{p}(t^+_\mathbf{p};\lambda) = 0$ and $x_\mathbf{p}(t;\lambda) > 0$ in $(0, t^+_\mathbf{p})$. In such a case, we define the Poincaré map Π_+ at the point $\mathbf{p}$ as $\Pi_+(\mathbf{p}) = (0, y_\mathbf{p}(t^+_\mathbf{p};\lambda), z_\mathbf{p}(t^+_\mathbf{p};\lambda))^T$. Note that the Poincaré map Π_+ depends only on the linear system $\dot{\mathbf{x}} = A^+\mathbf{x} + \mathbf{e}_3$ given in (1.3).

If $x_\mathbf{p} = 0$ and $y_\mathbf{p} < 0$, then the orbit $\gamma_\mathbf{p}$ crosses transversally the plane $\{x = 0\}$ with $x_\mathbf{p}(-t;\lambda) > 0$ and $x_\mathbf{p}(t;\lambda) < 0$ for $t > 0$ small enough. If $x_\mathbf{p}(t;\lambda)$ vanish in $(0, +\infty)$, then we define the flying time $t^-_\mathbf{p}$ as the positive value such that $x_\mathbf{p}(t^-_\mathbf{p};\lambda) = 0$ and $x_\mathbf{p}(t;\lambda) < 0$ in $(0, t^-_\mathbf{p})$. In such a case, we define the Poincaré map Π_- at the point $\mathbf{p}$ as $\Pi_-(\mathbf{p}) = (0, y_\mathbf{p}(t^-_\mathbf{p};\lambda), z_\mathbf{p}(t^-_\mathbf{p};\lambda))^T$. This map depends only on the linear system $\dot{\mathbf{x}} = A^-\mathbf{x} + \mathbf{e}_3$.

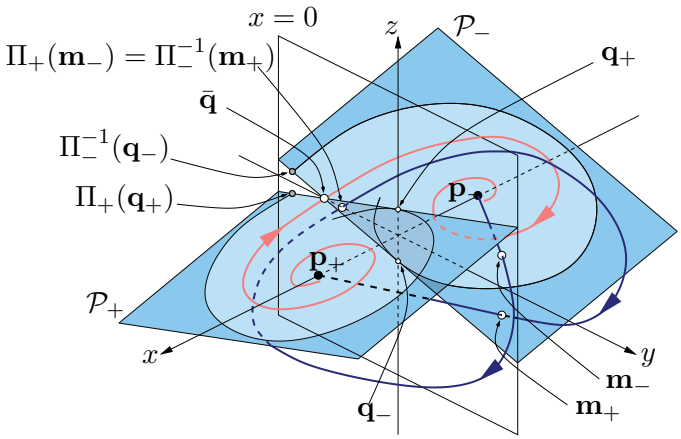

Figure 1. *Some geometric elements of the flow.*

If $\mathbf{p}$ belongs to the z-axis, i.e., $x_\mathbf{p} = 0$ and $y_\mathbf{p} = 0$, then $\mathbf{p}$ is called a contact point of the flow of system (1.5) with the plane $\{x = 0\}$ because the vector field at this point is tangent to the plane. Following [21], the first coordinate of the Taylor expansion of $\mathbf{x}_\mathbf{p}(t;\lambda) - \mathbf{p}$ at $t = 0$ is

$$\mathbf{e}_1^T\left(\mathbf{x}_\mathbf{p}(t;\lambda) - \mathbf{p}\right) = z_\mathbf{p}\frac{t^2}{2} + \frac{t^3}{3!} + \mathbf{e}_1^T\mathbf{x}_\mathbf{p}^{(4)}(\xi;\lambda)\frac{t^4}{4!}.$$

Hence, if $z_\mathbf{p} < 0$, then orbit $\gamma_\mathbf{p}$ is locally contained in the half-space $\{x \le 0\}$; if $z_\mathbf{p} > 0$, then $\gamma_\mathbf{p}$ is locally contained in the half-space $\{x \ge 0\}$; and if $z_\mathbf{p} = 0$, then $\gamma_\mathbf{p}$ crosses the plane $\{x = 0\}$ from the half-space $\{x < 0\}$ to the half-space $\{x > 0\}$.

Now we describe the basic elements of the linear dynamics in every half-space; all this information is summarized in Figure 1.

The stable manifold $W^s(\mathbf{p}_+)$ of $\mathbf{p}_+$ contains the half-line $\mathcal{L}_+ = \{\mathbf{p}_+ + \mu(1, -\lambda, \lambda^2) : -\frac{1}{\lambda(1+\lambda^2)} \le \mu < \infty\}$ generated by the eigenvector associated to the eigenvalue $-\lambda$ of the matrix A^+. The half-line $\mathcal{L}_+$ and the plane $\{x = 0\}$ intersect at the point

$$\mathbf{m}_+ = \left(0, \frac{1}{1+\lambda^2}, -\frac{\lambda}{1+\lambda^2}\right)^T.$$

The unstable two-dimensional manifold $W^u(\mathbf{p}_+)$ is locally contained in the half-plane

$$\mathcal{P}_+ = \left\{\lambda\left(1+\lambda^2\right)x - \lambda^2 y + \lambda z = 1 : x \ge 0\right\},$$

which is called the focal half-plane of $\mathbf{p}_+$. This half-plane is obtained from the eigenvectors associated to the complex eigenvalues of A^+. The half-plane $\mathcal{P}_+$ and the separation plane $\{x = 0\}$ intersect along the straight line

$$\mathcal{D}_+ = \left\{-\lambda^2 y + \lambda z = 1\right\}.$$

Let us emphasize that not every point in $\mathcal{D}_+$ belongs to the unstable manifold $W^u(\mathbf{p}_+)$; see Figure 1. The intersection point of $\mathcal{D}_+$ and the z-axis is $\mathbf{q}_+ = \left(0, 0, \frac{1}{\lambda}\right)^T$. Since $\mathbf{q}_+$ is a contact

point, the orbit $\gamma_{\mathbf{q}_+}$ is tangent to the separation plane $\{x = 0\}$ at $\mathbf{q}_+$. Thus, the segment $\mathcal{S}_+ \subset \mathcal{D}_+$ with endpoints $\mathbf{q}_+$ and $\Pi_+(\mathbf{q}_+)$ is contained in $W^u(\mathbf{p}_+)$.

The unstable manifold $W^u(\mathbf{p}_-)$ of $\mathbf{p}_-$ contains the half-line $\mathcal{L}_- = \{\mathbf{p}_- - \mu(1, \lambda, \lambda^2) : -\frac{1}{\lambda(1+\lambda^2)} \leq \mu < \infty\}$ generated by the eigenvector associated to the eigenvalue λ of the matrix A^-. The half-line and the plane $\{x = 0\}$ intersect at the point

$$\mathbf{m}_- = \left(0, \frac{1}{1+\lambda^2}, \frac{\lambda}{1+\lambda^2}\right)^T.$$

The stable two-dimensional manifold $W^s(\mathbf{p}_-)$ is locally contained in the half plane

$$\mathcal{P}_- = \left\{\lambda\left(1+\lambda^2\right)x + \lambda^2 y + \lambda z = -1 : x \leq 0\right\},$$

which is called the focal half-plane of $\mathbf{p}_-$. This half-plane is obtained from the eigenvectors associated to the complex eigenvalues of A^-. The half-plane $\mathcal{P}_-$ and the separation plane $\{x = 0\}$ intersect along the straight line

$$\mathcal{D}_- = \left\{\lambda^2 y + \lambda z = -1\right\}.$$

Let us emphasize that not every point in $\mathcal{D}_-$ belongs to the stable manifold $W^s(\mathbf{p}_-)$. The intersection point of $\mathcal{D}_-$ and the z-axis is $\mathbf{q}_- = \left(0, 0, -\frac{1}{\lambda}\right)^T$. Since $\mathbf{q}_-$ is a contact point, the orbit $\gamma_{\mathbf{q}_-}$ is tangent to the separation plane $\{x = 0\}$ at $\mathbf{q}_-$. Thus, the segment $\mathcal{S}_- \subset \mathcal{D}_-$ with endpoints $\mathbf{q}_-$ and $\Pi_-^{-1}(\mathbf{q}_-)$ is contained in $W^s(\mathbf{p}_-)$.

3. Existence of a two-dimensional heteroclinic orbit. In this section we prove the existence of a simple two-dimensional heteroclinic orbit $\rho_\pm$, that is, a heteroclinic orbit $\rho_\pm \subset W^u(\mathbf{p}_+) \cap W^s(\mathbf{p}_-)$ which intersects the plane $\{x = 0\}$ at exactly one point $\bar{\mathbf{q}}$.

A necessary and sufficient condition for the existence of the orbit $\rho_\pm$ is $\bar{\mathbf{q}} \in \mathcal{S}_- \cap \mathcal{S}_+$. This implies that $\bar{\mathbf{q}} = \left(0, -\lambda^{-2}, 0\right)^T$, because it is the intersection point of the straight lines $\mathcal{D}_+$ and $\mathcal{D}_-$. We now proceed to look for the values of the parameter λ for which the point $\bar{\mathbf{q}}$ belongs to $\mathcal{S}_-$ and, by reversibility, to $\mathcal{S}_+$.

By definition, the segment $\mathcal{S}_-$ is defined by the endpoints $\mathbf{q}_-$ and $\Pi_-^{-1}(\mathbf{q}_-)$. Since the third coordinate of $\mathbf{q}_-$ is negative and $\bar{\mathbf{q}}$ has the third coordinate equal to zero, then $\bar{\mathbf{q}} \in \mathcal{S}_-$ if and only if the third coordinate of $\Pi_-^{-1}(\mathbf{q}_-)$ is nonnegative. Therefore, system (1.5) has a simple two-dimensional heteroclinic orbit $\rho_\pm$ if and only if there exist $t_0 > 0$ and $\lambda_0 > 0$ such that $(t; \lambda) = (t_0; \lambda_0)$ is a solution of the system

$$\begin{cases} x_{\mathbf{q}_-}(-t; \lambda) = 0, \\ z_{\mathbf{q}_-}(-t; \lambda) \geq 0, \end{cases} \tag{3.1}$$

with

$$x_{\mathbf{q}_-}(-t; \lambda_0) < 0 \text{ for every } t \in (0, t_0). \tag{3.2}$$

We emphasize that condition (3.2) ensures that the point $\mathbf{x}_{\mathbf{q}_-}(-t_0; \lambda_0)$ is the preimage of $\mathbf{q}_-$ by the Poincaré map Π_-.

Taking into account condition (3.2), the expressions of $x_{\mathbf{q}_-}$ and $z_{\mathbf{q}_-}$ in (3.1) can be obtained by integrating the linear system in the half-space $\{x < 0\}$ in backward time with initial condition $\mathbf{x}(0;\lambda) = \mathbf{q}_-$. Thus, system (3.1) can be written as

(3.3)
$$\begin{cases} x_{\mathbf{q}_-}(-t;\lambda) = -\dfrac{1}{\lambda(1+\lambda^2)}\left[1 - e^{\frac{\lambda}{2}t}\left(\cos\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right) - \dfrac{\lambda}{\sqrt{4+3\lambda^2}}\sin\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right)\right)\right] = 0, \\ z_{\mathbf{q}_-}(-t;\lambda) = -\dfrac{1}{\lambda}e^{\frac{\lambda}{2}t}\left[\cos\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right) + \dfrac{\lambda}{\sqrt{4+3\lambda^2}}\sin\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right)\right] \geq 0. \end{cases}$$

Using the function $\varphi(\tau,\gamma) = 1 - e^{\gamma\tau}(\cos(\tau) - \gamma\sin(\tau))$ defined in [1], system (3.3) can be rewritten as

$$\begin{cases} -\dfrac{1}{\lambda(1+\lambda^2)}\varphi\left(-\frac{\sqrt{4+3\lambda^2}}{2}t, -\frac{\lambda}{\sqrt{4+3\lambda^2}}\right) = 0, \\ -\dfrac{1}{\lambda}e^{\frac{\lambda}{2}t}\left(1 - \varphi\left(\frac{\sqrt{4+3\lambda^2}}{2}t, -\frac{\lambda}{\sqrt{4+3\lambda^2}}\right)\right) \geq 0. \end{cases}$$

Hence, the existence of a solution $(t;\lambda) = (t_0;\lambda_0)$ of (3.1) satisfying inequality (3.2) is equivalent to the existence of a solution $(t;\lambda) = (t_0;\lambda_0)$ of system

$$\begin{cases} \varphi\left(-\frac{\sqrt{4+3\lambda^2}}{2}t, -\frac{\lambda}{\sqrt{4+3\lambda^2}}\right) = 0, \\ \varphi\left(\frac{\sqrt{4+3\lambda^2}}{2}t, -\frac{\lambda}{\sqrt{4+3\lambda^2}}\right) \geq 1 \end{cases} \tag{3.4}$$

with $t_0 > 0$, $\lambda_0 > 0$ and such that

$$\varphi\left(-\frac{\sqrt{4+3\lambda_0^2}}{2}t, -\frac{\lambda_0}{\sqrt{4+3\lambda_0^2}}\right) > 0 \tag{3.5}$$

for every t in $(0,t_0)$.

In the next result, whose proof is direct, we compile elementary properties of function $\varphi(\tau,\gamma)$, some of which can be found in [1].

Lemma 3.1. *Function $\varphi(\tau,\gamma) = 1 - e^{\gamma\tau}(\cos(\tau) - \gamma\sin(\tau))$ satisfies the following properties.*

(i) $\varphi(-\tau,-\gamma) = \varphi(\tau,\gamma)$.

(ii) $\frac{\partial\varphi}{\partial\tau} = (1+\gamma^2)e^{\gamma\tau}\sin(\tau)$ *and* $\frac{\partial^2\varphi}{\partial\tau^2} = (1+\gamma^2)e^{\gamma\tau}(\cos(\tau) + \gamma\sin(\tau))$.

(iii) *For every fixed $\gamma > 0$ the function $\varphi(\tau,\gamma)$ reaches its local maxima and minima values, respectively, at $\tau_{2k+1} = (2k+1)\pi$ and $\tau_{2k} = 2k\pi$ with $k \in \mathbb{Z}$. Moreover, $\varphi(\tau_{2k+1},\gamma) = 1 + e^{\gamma\tau_{2k+1}}$ and $\varphi(\tau_{2k},\gamma) = 1 - e^{\gamma\tau_{2k}}$.*

(iv) *There exists a unique function $\hat{\tau}_1 : (0,+\infty) \to (\pi,2\pi)$ such that $\varphi(\hat{\tau}_1(\gamma),\gamma) = 0$, $\varphi(\tau,\gamma) > 0$ for $\tau \in (0,\hat{\tau}_1(\gamma))$ and $\varphi(\tau,\gamma) < 0$ for $\tau \in (\hat{\tau}_1(\gamma),2\pi)$.*

(v) $\frac{\partial\varphi}{\partial\gamma} = e^{\gamma\tau}(-\tau\cos(\tau) + (1+\gamma\tau)\sin(\tau))$.

(vi) *There exists a unique function $\hat{\tau}_2 : (0,+\infty) \to (-2\pi,-\pi)$ such that $\varphi(\hat{\tau}_2(\gamma),\gamma) = 1$ and $\varphi(\tau,\gamma) > 1$ for $\tau \in (\hat{\tau}_2(\gamma),-\pi)$.*

The shape of functions $\hat{\tau}_1$ and $\hat{\tau}_2$ introduced in the previous lemma are described in the next result. Some of these properties are shown in Figure 2.

Lemma 3.2. *The following properties of functions $\hat{\tau}_1$ and $\hat{\tau}_2$, defined in Lemma 3.1, hold.*

(i) *The function $\hat{\tau}_1$ is differentiable, $\frac{d\hat{\tau}_1}{d\gamma} < 0$, $\lim_{\gamma\searrow 0}\hat{\tau}_1(\gamma) = 2\pi$, and $\lim_{\gamma\nearrow\infty}\hat{\tau}_1(\gamma) = \pi$.*

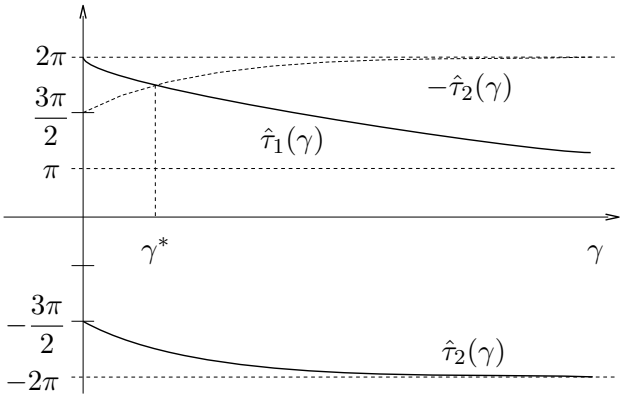

Figure 2. *Qualitative behavior of functions $\hat{\tau}_1$ and $\hat{\tau}_2$.*

(ii) *The function $\hat{\tau}_2$ is differentiable, $\frac{d\hat{\tau}_2}{d\gamma} < 0$, $\lim_{\gamma\searrow 0}\hat{\tau}_2(\gamma) = -\frac{3\pi}{2}$, and $\lim_{\gamma\nearrow\infty}\hat{\tau}_2(\gamma) = -2\pi$.*

(iii) *There exists a unique value $\gamma^* > 0$ such that $-\hat{\tau}_2(\gamma^*) = \hat{\tau}_1(\gamma^*)$. This value satisfies $\gamma^* < \frac{1}{\sqrt{19}}$. Moreover, $-\hat{\tau}_2(\gamma) < \hat{\tau}_1(\gamma)$ in $(0,\gamma^*)$ and $-\hat{\tau}_2(\gamma) > \hat{\tau}_1(\gamma)$ in $(\gamma^*,+\infty)$.*

(iv) *If $0 < \gamma < \gamma^*$, then $\varphi(-\hat{\tau}_1(\gamma),\gamma) < 1$, and $\varphi(-\hat{\tau}_1(\gamma),\gamma) > 1$ if $\gamma > \gamma^*$.*

Proof. (i) Since $\hat{\tau}_1(\gamma) \in (\pi, 2\pi)$, by the implicit function theorem it follows that $\hat{\tau}_1$ is a differentiable function and

$$\left.\frac{d\hat{\tau}_1}{d\gamma}\right|_\gamma = \frac{\hat{\tau}_1(\gamma)e^{-\gamma\hat{\tau}_1(\gamma)} - \sin(\hat{\tau}_1(\gamma))}{(1+\gamma^2)\sin(\hat{\tau}_1(\gamma))} < 0.$$

Taking the limit as γ tends to zero in the implicit expression $\varphi(\hat{\tau}_1(\gamma),\gamma) = 0$, it is easy to check that $\lim_{\gamma\searrow 0}\cos(\hat{\tau}_1(\gamma)) = 1$ and $\lim_{\gamma\nearrow\infty}\sin(\hat{\tau}_1(\gamma)) = 0$. Hence, $\lim_{\gamma\searrow 0}\hat{\tau}_1(\gamma) = 2\pi$ and $\lim_{\gamma\nearrow\infty}\hat{\tau}_1(\gamma) = \pi$.

(ii) This statement follows by the same arguments as in the previous item.

(iii) By the definition of φ and $\hat{\tau}_2$ it follows that, for every $\gamma > 0$, $\cos(\hat{\tau}_2(\gamma)) = \gamma\sin(\hat{\tau}_2(\gamma))$ and $\hat{\tau}_2(\gamma) \in \left(-2\pi, -\frac{3\pi}{2}\right)$. Fixing $\gamma = \frac{1}{\sqrt{19}}$ it is easy to obtain

$$\cos\left(\hat{\tau}_2\left(\frac{1}{\sqrt{19}}\right)\right) = \frac{1}{2\sqrt{5}} \quad \text{and} \quad \sin\left(\hat{\tau}_2\left(\frac{1}{\sqrt{19}}\right)\right) = \frac{\sqrt{19}}{2\sqrt{5}}.$$

This clearly gives $\varphi\left(-\hat{\tau}_2\left(\frac{1}{\sqrt{19}}\right), \frac{1}{\sqrt{19}}\right) = 1 - \frac{1}{\sqrt{5}}e^{-\frac{\hat{\tau}_2\left(\frac{1}{\sqrt{19}}\right)}{\sqrt{19}}}$, which is negative because of $\hat{\tau}_2(\gamma) < -\frac{3\pi}{2}$.

On the other hand, since $\varphi\left(\hat{\tau}_1\left(\frac{1}{\sqrt{19}}\right), \frac{1}{\sqrt{19}}\right) = 0$ and $\varphi\left(\tau, \frac{1}{\sqrt{19}}\right)$ is a monotone decreasing function for $\tau \in (\pi, 2\pi)$ (see Lemma 3.1(iii)), then $\hat{\tau}_1\left(\frac{1}{\sqrt{19}}\right) < -\hat{\tau}_2\left(\frac{1}{\sqrt{19}}\right)$.

Following statements (i) and (ii) in this lemma, the auxiliary function $h(\gamma) = \hat{\tau}_1(\gamma) + \hat{\tau}_2(\gamma)$ satisfies that $h'(\gamma) < 0$ for every $\gamma > 0$ and $\lim_{\gamma\searrow 0} h(\gamma) = \frac{\pi}{2} > 0$. Since $h\left(\frac{1}{\sqrt{19}}\right) < 0$, there

exists a value $\gamma^* \in \left(0, \frac{1}{\sqrt{19}}\right)$ such that $h(\gamma^*) = 0$, $h(\gamma) > 0$ for $0 < \gamma < \gamma^*$, and $h(\gamma) < 0$ for $\gamma > \gamma^*$.

(iv) If $0 < \gamma < \gamma^*$, then $-2\pi < -\hat{\tau}_1(\gamma) < \hat{\tau}_2(\gamma) < -\frac{3\pi}{2}$; see statement (iii). Therefore, by using that $\partial\varphi/\partial\tau > 0$ in $\tau \in (-2\pi, -\frac{3\pi}{2})$ (Lemma 3.1(ii)), it follows that $\varphi(-\hat{\tau}_1(\gamma), \gamma) < \varphi(\hat{\tau}_2(\gamma), \gamma) = 1$. The other inequality of the statement follows in a similar way. ■

The boundary value $\frac{1}{\sqrt{19}}$ appearing in statement (iii) of Lemma 3.2 has only computational meaning. In fact, it has been chosen to obtain the value $1/2$ in the statement of Theorem 1.1.

In the next result we prove the existence of a simple two-dimensional heteroclinic orbit in the piecewise linear differential system (1.5) for every value of the parameter λ greater than a certain value λ^*.

Proposition 3.3. *There exists a value λ^* in $(0, \frac{1}{2})$ such that*

(i) *if $\lambda \geq \lambda^*$, system (1.5) has a two-dimensional heteroclinic orbit with exactly one intersection point with the plane $\{x = 0\}$, and*

(ii) *if $\lambda < \lambda^*$, system (1.5) has no two-dimensional heteroclinic orbits with exactly one intersection point with the plane $\{x = 0\}$.*

Proof. For the sake of simplicity, let us consider the change of variables

$$\tau = \frac{\sqrt{4 + 3\lambda^2}}{2} t, \quad \gamma = \frac{\lambda}{\sqrt{4 + 3\lambda^2}}. \tag{3.6}$$

In these new variables, system (3.4) and condition (3.5) can be written as

$$\begin{cases} \varphi(-\tau, -\gamma) = 0, \\ \varphi(\tau, -\gamma) \geq 1, \end{cases} \quad \text{and} \quad \begin{cases} \varphi(-\bar{\tau}, -\gamma) > 0 \\ \text{for every } \bar{\tau} \text{ in } (0, \tau). \end{cases} \tag{3.7}$$

Hence, the existence of a solution $(\tau_0; \gamma_0)$ to (3.7) is equivalent to the existence of a two-dimensional heteroclinic orbit with exactly one intersection point with the plane $\{x = 0\}$. According to this, the proof of this proposition is reduced to the analysis of the existence of a solution to system (3.7).

Let γ^* be the value defined in Lemma 3.2(iii). Since $0 < \gamma^* < \frac{1}{\sqrt{19}}$, the corresponding value λ^* given by (3.6) is real and positive and satisfies $0 < \lambda^* < \frac{1}{2}$. Let us prove that this is the value λ^* for which both statements of the proposition hold.

(i) For $\lambda_0 \geq \lambda^*$, the corresponding value γ_0 given by (3.6) satisfies $\gamma_0 \geq \gamma^*$. Thus, using Lemmas 3.1(i) and 3.2(iv), we obtain $\varphi(\hat{\tau}_1(\gamma_0), -\gamma_0) \geq 1$. On the other hand, from Lemma 3.1(i) and (iv), we have $\varphi(-\hat{\tau}_1(\gamma_0), -\gamma_0) = 0$ and $\varphi(-\tau, -\gamma_0) > 0$ for every $\tau \in (0, \hat{\tau}_1(\gamma_0))$. That is, $(\hat{\tau}_1(\gamma_0); \gamma_0)$ is the desired solution of system (3.7).

(ii) For $\lambda_0 < \lambda^*$, the corresponding value γ_0 given by (3.6) satisfies $\gamma_0 < \gamma^*$. Note that the unique solution $\bar{\tau}$ of $\varphi(-\tau, -\gamma_0) = 0$ which satisfies $\varphi(-\tau, -\gamma_0) > 0$ for every $\tau \in (0, \bar{\tau})$ is $\bar{\tau} = \hat{\tau}_1(\gamma_0)$; see Lemma 3.1(i) and (iv). Because of $\gamma_0 < \gamma^*$ we have $\varphi(\hat{\tau}_1(\gamma_0), -\gamma_0) < 1$; see Lemma 3.2(iv). Consequently, we concluded that the system (3.7) does not have any solutions. ■

Note that a value λ satisfying the statements of Proposition 3.3 has to be unique in $\lambda > 0$. Moreover, the value $\lambda^* \approx 0.41527324$ can be numerically obtained.

4. Existence of a one-dimensional heteroclinic orbit. In this section we prove the existence of a simple one-dimensional heteroclinic orbit $\rho_{\mp}$, that is, a heteroclinic orbit $\rho_{\mp} = W^u(\mathbf{p}_-) = W^s(\mathbf{p}_+)$ which intersects the plane $\{x = 0\}$ at exactly three points. Two of these points are necessarily $\mathbf{m}_-$ and $\mathbf{m}_+$.

An equivalent condition for the existence of a simple one-dimensional heteroclinic orbit is $\Pi_+(\mathbf{m}_-) = \Pi_-^{-1}(\mathbf{m}_+)$. Due to reversibility, this occurs if and only if the point $\Pi_+(\mathbf{m}_-)$ belongs to the reversibility axis, that is, when the first and third coordinates of $\Pi_+(\mathbf{m}_-)$ are equal to zero. Therefore, system (1.5) has a simple one-dimensional heteroclinic orbit if and only if the system

$$\begin{cases} x_{\mathbf{m}_-}(t;\lambda) = 0, \\ z_{\mathbf{m}_-}(t;\lambda) = 0 \end{cases} \tag{4.1}$$

has a solution $(t_1;\lambda_1)$ such that $t_1 > 0$, $\lambda_1 > 0$, and

$$x_{\mathbf{m}_-}(t;\lambda_1) > 0 \text{ for every } t \in (0,t_1). \tag{4.2}$$

Note that condition (4.2) ensures that the point $\mathbf{x}_{\mathbf{m}_-}(t_1;\lambda_1)$ is the image of $\mathbf{m}_-$ by the Poincaré map Π_+.

Now, to prove the existence of solutions of system (4.1) we are going to simplify its equations. Integrating $\dot{\mathbf{x}} = A^+\mathbf{x} + \mathbf{e}_3$ in forward time with initial condition $\mathbf{x}(0;\lambda) = \mathbf{m}_-$, system (4.1) can be written as

$$\begin{cases} \dfrac{e^{-\lambda t}\left[(1+\lambda^2)\sqrt{4+3\lambda^2} + 2e^{\frac{3}{2}\lambda t}\lambda^2\sqrt{4+3\lambda^2}\cos\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right) - 6e^{\frac{3}{2}\lambda t}\lambda^3\sin\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right)\right]}{\lambda\sqrt{4+3\lambda^2}(1+\lambda^2)(1+3\lambda^2)} = \dfrac{1}{\lambda(1+\lambda^2)}, \\ \dfrac{e^{-\lambda t}\lambda\left[-(1+\lambda^2)\sqrt{4+3\lambda^2} + 2e^{\frac{3}{2}\lambda t}(1+2\lambda^2)\sqrt{4+3\lambda^2}\cos\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right) - 2\lambda e^{\frac{3}{2}\lambda t}\sin\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right)\right]}{\sqrt{4+3\lambda^2}(1+\lambda^2)(1+3\lambda^2)} = 0. \end{cases}$$

Adding $\frac{\lambda(1+\lambda^2)}{2e^{\frac{\lambda}{2}t}}$ times the first equation to $\frac{(1+\lambda^2)}{2\lambda e^{\frac{\lambda}{2}t}}$ times the second one gives

$$\cos\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right) - \frac{\lambda}{\sqrt{4+3\lambda^2}}\sin\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right) = \frac{1}{2e^{\frac{\lambda}{2}t}}. \tag{4.3}$$

Moreover, multiplying the second equation by $\frac{1}{\lambda}e^{\lambda t}(1+\lambda^2)(1+3\lambda^2)$, adding $1+\lambda^2$ to both sides of the obtained expression, and multiplying the result by $\frac{1}{2}e^{-\frac{3}{2}\lambda t}$, we get

$$(1+2\lambda^2)\cos\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right) - \frac{\lambda}{\sqrt{4+3\lambda^2}}\sin\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right) = \frac{1+\lambda^2}{2e^{\frac{3}{2}\lambda t}}. \tag{4.4}$$

Now, the trigonometric functions are determined by solving the system given by (4.3) and (4.4),

$$\begin{aligned} \cos\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right) &= \frac{1+\lambda^2-e^{\lambda t}}{4\lambda^2 e^{\frac{3}{2}\lambda t}}, \\ \sin\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right) &= \frac{\sqrt{4+3\lambda^2}}{4\lambda^3 e^{\frac{3}{2}\lambda t}}(1+\lambda^2-e^{\lambda t}(1+2\lambda^2)), \end{aligned} \tag{4.5}$$

and thus

$$\cos\left(\tfrac{\sqrt{4+3\lambda^2}}{2}t\right)^2+\sin\left(\tfrac{\sqrt{4+3\lambda^2}}{2}t\right)^2$$
$$=\frac{4\lambda^6}{1+\lambda^2}e^{3\lambda t}-(1+4\lambda^2+3\lambda^4)e^{2\lambda t}+(2+6\lambda^2+3\lambda^4)e^{\lambda t}-(1+\lambda^2)^2+1$$

or, equivalently,

$$\frac{4\lambda^6}{1+\lambda^2}e^{3\lambda t}-(1+4\lambda^2+3\lambda^4)e^{2\lambda t}+(2+6\lambda^2+3\lambda^4)e^{\lambda t}-(1+\lambda^2)^2=0. \tag{4.6}$$

Let us consider the system given by (4.3) and (4.6). Note that every solution of system (4.1) is a solution of system (4.3) and (4.6), but the converse is not necessarily true. In the following lemma we establish the conditions on a solution of system (4.3) and (4.6) for being a solution of system (4.1).

Lemma 4.1. *Let $(t_1;\lambda_1)$ be a solution of system (4.3) and (4.6), with $t_1>0$ and $\lambda_1>0$. Then, $(t_1;\lambda_1)$ is a solution of system (4.1) if and only if $(2k-1)\pi<\frac{\sqrt{4+3\lambda_1^2}}{2}t_1<2k\pi$ with $k\in\mathbb{N}$.*

Proof. Suppose that $(t_1;\lambda_1)$ is a solution of system (4.1). Since $t_1>0$ and $\lambda_1>0$, from (4.5) it is clear that $\sin(\frac{\sqrt{4+3\lambda_1^2}}{2}t_1)<0$. Thus, the argument $\frac{\sqrt{4+3\lambda_1^2}}{2}t_1$ belongs to $((2k-1)\pi,2k\pi)$ with $k\in\mathbb{N}$.

For the other implication, let us consider the system

$$\begin{cases} X-\dfrac{\lambda_1}{\sqrt{4+3\lambda_1^2}}Y &= \dfrac{1}{2e^{\frac{\lambda_1}{2}t_1}},\\ X^2+Y^2 &= 1, \end{cases} \tag{4.7}$$

whose equations correspond to a straight line and a circle. Hence, it has at most two different solutions. Since the straight line defined by the first equation contains a point with $X=1$ and $Y>0$, at most one of such solutions has a negative second coordinate.

Note that

$$(X,Y)=\left(\frac{1+\lambda_1^2-e^{\lambda_1 t_1}}{4\lambda_1^2e^{\frac{3}{2}\lambda_1 t_1}},\frac{\sqrt{4+3\lambda_1^2}}{4\lambda_1^3e^{\frac{3}{2}\lambda_1 t_1}}(1+\lambda_1^2-e^{\lambda_1 t_1}(1+2\lambda_1^2))\right)$$

is a solution of system (4.7) with $Y<0$. On the other hand, since $(t_1;\lambda_1)$ is a solution of system (4.3) and (4.6), then

$$(\tilde{X},\tilde{Y})=\left(\cos\left(\frac{\sqrt{4+3\lambda_1^2}}{2}t_1\right),\sin\left(\frac{\sqrt{4+3\lambda_1^2}}{2}t_1\right)\right)$$

is also a solution of system (4.7) with $\tilde{Y}<0$. Therefore, we conclude that $(\tilde{X},\tilde{Y})=(X,Y)$, which means that $(t_1;\lambda_1)$ is a solution of (4.5) or, equivalently, a solution of (4.1). ∎

In the next result we prove that system (4.1) has at least a solution $(t_1;\lambda_1)$ which also satisfies some important conditions to verify inequality (4.2).

Lemma 4.2. *System* (4.1) *has a solution* $(t_1;\lambda_1)$ *satisfying*

$$\frac{1}{2}<\lambda_1<1 \quad \textit{and} \quad \pi<\frac{\sqrt{4+3\lambda_1^2}}{2}t_1<2\pi.$$

Proof. Let us define $\psi(s,\lambda)=\frac{4\lambda^6}{1+\lambda^2}s^3-(1+4\lambda^2+3\lambda^4)s^2+(2+6\lambda^2+3\lambda^4)s-(1+\lambda^2)^2$ and $\tau=\frac{\sqrt{4+3\lambda^2}}{2}t$. Thus, system (4.3) and (4.6) can be written as

$$\begin{cases} f_1(\tau,\lambda)=\varphi\left(\tau,\frac{\lambda}{\sqrt{4+3\lambda^2}}\right)-\dfrac{1}{2}=0,\\ f_2(\tau,\lambda)=\psi\left(e^{\frac{2\lambda}{\sqrt{4+3\lambda^2}}\tau},\lambda\right)=0, \end{cases} \tag{4.8}$$

where φ is the function defined in Lemma 3.1.

From Lemma 4.1, the proof is complete by showing the existence of a solution $(\tau_1;\lambda_1)$ of system (4.8) in $(\pi,2\pi)\times(\frac{1}{2},1)$. We will obtain such a solution by applying the Poincaré–Miranda theorem [17], which is an n-dimensional extension of Bolzano's theorem.

The definition of φ makes it obvious that $f_1(\pi,\lambda)>0$ and $f_1(2\pi,\lambda)<0$ for every $\lambda>0$. In particular, it is true for $\lambda\in[\frac{1}{2},1]$. That is, function f_1 takes different signs at the vertical sides of the rectangle $[\pi,2\pi]\times[\frac{1}{2},1]$.

Let us now analyze the sign of function $f_2(\tau,\lambda)$ at the horizontal sides of $[\pi,2\pi]\times[\frac{1}{2},1]$ by studying the cubic polynomials $\psi(s,1)$ and $\psi(s,\frac{1}{2})$. Since the derivative of $\psi(s,1)$ with respect to s is positive in $\mathbb{R}$ and $\psi(1,1)=1$, we have $\psi(s,1)>1$ for every $s\in(1,+\infty)$. Therefore, $f_2(\tau,1)>1$ for every $\tau>0$ and, in particular, $f_2(\tau,1)>0$ for every $\tau\in[\pi,2\pi]$.

For the last side of the rectangle, straightforward computations show that the derivative of $\psi(s,\frac{1}{2})$ with respect to s vanishes at two values $s_1<1<s_2$, where s_2 is a local minimum. Taking into account that $\psi(1,\frac{1}{2})=-\frac{1}{80}$ and $\psi(27,\frac{1}{2})=-\frac{41003}{80}$, it follows that $\psi(s,\frac{1}{2})<0$ for $s\in[1,27]$. Note that, for $\lambda=\frac{1}{2}$ and $\tau\in[\pi,2\pi]$, the exponential function $e^{\frac{2\lambda}{\sqrt{4+3\lambda^2}}\tau}$ takes values in $[1,27]$, as is easy to check from inequalities $4\pi<3\sqrt{19}$ and $e<3$. Therefore, $f_2(\tau,\frac{1}{2})<0$ for every $\tau\in[\pi,2\pi]$.

The lemma follows by the Poincaré–Miranda theorem. ∎

To conclude the proof of the existence of a simple one-dimensional heteroclinic orbit for system (1.5), it remains only to check that the solution $(t_1;\lambda_1)$ of system (4.1), given in Lemma 4.2, also satisfies condition (4.2). This is done in the following result.

Proposition 4.3. *For* $\lambda=\lambda_1$, *the system* (1.5) *has a simple one-dimensional heteroclinic orbit.*

Proof. From Lemma 4.2, there exists a solution $(t_1;\lambda_1)$ of system (4.1). Integrating $\dot{\mathbf{x}}=A^+\mathbf{x}+\mathbf{e}_3$ in forward time with initial condition $\mathbf{x}(0;\lambda)=\mathbf{m}_-$, we obtain the following expression for the second coordinate of the solution:

$$y_{\mathbf{m}_-}(t;\lambda)=\frac{2e^{\frac{1}{2}\lambda t}\lambda^2\sqrt{4+3\lambda^2}\cos\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right)+2e^{\frac{1}{2}\lambda t}\lambda(2+3\lambda^2)\sin\left(\frac{\sqrt{4+3\lambda^2}}{2}t\right)}{\sqrt{4+3\lambda^2}(1+\lambda^2)(1+3\lambda^2)}+\frac{e^{-\lambda t}}{(1+3\lambda^2)}. \tag{4.9}$$

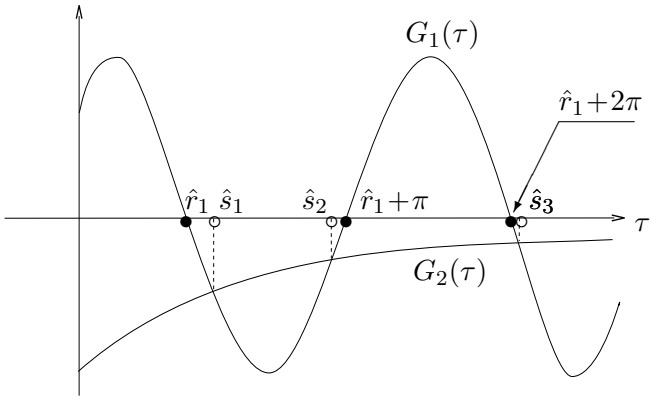

Figure 3. *Qualitative behavior of functions G_1 and G_2.*

Remember that, in our system, $\dot{x}_{\mathbf{m}_-}(t;\lambda) = y_{\mathbf{m}_-}(t;\lambda)$. Thus, using (4.5) to simplify $y_{\mathbf{m}_-}(t_1;\lambda_1)$, we obtain

$$\dot{x}_{\mathbf{m}_-}(t_1;\lambda_1) = \frac{e^{-\lambda_1 t_1} - 1}{\lambda_1^2} < 0.$$

On the other side, $\dot{x}_{\mathbf{m}_-}(0;\lambda_1) > 0$.

Assume that $(t_1;\lambda_1)$ does not satisfy condition (4.2). Therefore, there exists a value in $(0,t_1)$ where $x_{\mathbf{m}_-}(t;\lambda_1)$ vanishes. From $\dot{x}_{\mathbf{m}_-}(0;\lambda_1) > 0$ and $\dot{x}_{\mathbf{m}_-}(t_1;\lambda_1) < 0$ it may be concluded that the derivative $\dot{x}_{\mathbf{m}_-}(t;\lambda_1)$, that is, $y_{\mathbf{m}_-}(t;\lambda_1)$, has to vanish at least at three values s_1, s_2, s_3 such that $0 < s_1 < s_2 < s_3 < t_1$. For simplicity of notation, we consider the change $\tau = \frac{\sqrt{4+3\lambda_1^2}}{2}t$. Let $\hat{s}_1, \hat{s}_2, \hat{s}_3, \tau_1$ denote the respective values of s_1, s_2, s_3, t_1 by this change. Therefore, $0 < \hat{s}_1 < \hat{s}_2 < \hat{s}_3 < \tau_1$.

From (4.9), the equality $y_{\mathbf{m}_-}(t;\lambda_1) = 0$ is equivalent to $G_1(\tau) = G_2(\tau)$, where

$$\begin{aligned} G_1(\tau) &= \frac{\lambda_1^2}{1+\lambda_1^2}\cos(\tau) + \frac{\lambda_1(2+3\lambda_1^2)}{\sqrt{4+3\lambda_1^2}(1+\lambda_1^2)}\sin(\tau), \\ G_2(\tau) &= -\frac{1}{2}\exp\left(\frac{-3\lambda_1}{\sqrt{4+3\lambda_1^2}}\tau\right). \end{aligned} \tag{4.10}$$

The qualitative behavior of G_1 and G_2 is shown in Figure 3.

Since $G_2(\tau) < 0$ for every τ and $G_1(0) > 0$, there exists an $\hat{r}_1 \in (0, \hat{s}_1)$ where $G_1(\hat{r}_1) = 0$, $G_1(\tau) < 0$ for $\tau \in \bigcup_{k=0}^{\infty} I_k$, where $I_k = (\hat{r}_1 + 2k\pi, \hat{r}_1 + (2k+1)\pi)$. On the other hand, the second derivative G_2'' is always negative while the second derivative G_1'' is positive in every interval I_k with $k = 0, 1, 2, \ldots$. Therefore, in each interval I_k there may exist at most two values where G_1 and G_2 coincide.

We conclude that $\hat{s}_3 > \hat{r}_1 + 2\pi$. In particular, $\tau_1 > 2\pi$ and, equivalently, $\frac{\sqrt{4+3\lambda_1^2}}{2}t_1 > 2\pi$, which contradicts Lemma 4.2. Thus, the proposition follows. ■

From Propositions 3.3 and 4.3 we conclude that for $\lambda = \lambda_1$ system (1.5) has a simple two-dimensional heteroclinic orbit $\rho_\pm$ and a simple one-dimensional heteroclinic orbit $\rho_\mp$. That is, for $\lambda = \lambda_1$ system (1.5) has a $(3,1)$ heteroclinic cycle $\Gamma = \mathbf{p}_+ \cup \rho_\pm \cup \mathbf{p}_- \cup \rho_\mp$.

5. Existence of a reversible T-point heteroclinic cycle. In this section we finish the proof of Theorem 1.1. It remains only to verify that the heteroclinic cycle Γ, obtained in section 4 for $\lambda = \lambda_1$, satisfies the two following conditions, which are equivalent to those stated at the definition of a reversible T-point heteroclinic cycle:

(i) Manifolds $W^u(\mathbf{p}_+)$ and $W^s(\mathbf{p}_-)$ intersect transversally along the two-dimensional heteroclinic orbit $\rho_\pm$.

(ii) The difference between the third coordinates of $\Pi_+(\mathbf{m}_-)$ and $\Pi_-^{-1}(\mathbf{m}_+)$ is diffeomorphic to $\mu = \lambda - \lambda_1$ (note that the distance between two points in the plane $\{x = 0\}$ which are symmetric with respect to $\mathbf{R}$ is two times the absolute value of the third coordinate of any of them).

Statement (i) is a direct consequence of the transversality of manifolds $W^u(\mathbf{p}_+)$ and $W^s(\mathbf{p}_-)$ at $\{x = 0\}$ and the differentiability of the flow.

To verify condition (ii), it is necessary only to prove that the third coordinate of $\Pi_+(\mathbf{m}_-)$ is diffeomorphic to $\mu = \lambda - \lambda_1$.

Let $t^+_{\mathbf{m}_-}(\lambda)$ be the flying time of the solution through the point $\mathbf{m}_-$ for each λ in a neighborhood of λ_1. In particular, $t^+_{\mathbf{m}_-}(\lambda_1) = t_1$, where t_1 is defined in Lemma 4.2. The third coordinate of $\Pi_+(\mathbf{m}_-)$, as a function of λ, can be written as $h(\lambda) = z_{\mathbf{m}_-}(t^+_{\mathbf{m}_-}(\lambda); \lambda)$. Notice that $h(\lambda)$ is analytical because the solution depends only on the linear system in the half-space $\{x > 0\}$ and the orbit through $\Pi_+(\mathbf{m}_-)$ is transversal to the plane $\{x = 0\}$ for $\lambda = \lambda_1$. Thus, since $h(\lambda_1) = 0$, to conclude that $h(\lambda)$ is diffeomorphic to $\mu = \lambda - \lambda_1$ it is sufficient to prove that $h'(\lambda_1) \neq 0$.

Proposition 5.1. *Function $h(\lambda) = z_{\mathbf{m}_-}(t^+_{\mathbf{m}_-}(\lambda); \lambda)$ satisfies $h'(\lambda_1) < 0$.*

Proof. The first derivative $h'(\lambda_1)$ is given by

$$\left.\frac{dh}{d\lambda}\right|_{\lambda_1} = \dot{z}_{\mathbf{m}_-}(t_1; \lambda_1) \left.\frac{dt^+_{\mathbf{m}_-}}{d\lambda}\right|_{\lambda_1} + \left.\frac{\partial z_{\mathbf{m}_-}(t; \lambda)}{\partial \lambda}\right|_{(t_1;\lambda_1)}.$$

Since the derivative $\dot{x}_{\mathbf{m}_-}(t_1; \lambda_1) = y_{\mathbf{m}_-}(t_1; \lambda_1)$ does not vanish, the function $t^+_{\mathbf{m}_-}(\lambda)$ is implicitly defined by the equation $x_{\mathbf{m}_-}(t; \lambda) = 0$ in a neighborhood of $(t_1; \lambda_1)$. Moreover, $t^+_{\mathbf{m}_-}(\lambda)$ is analytical and

$$\left.\frac{dt^+_{\mathbf{m}_-}}{d\lambda}\right|_{\lambda_1} = -\frac{\left.\dfrac{\partial x_{\mathbf{m}_-}(t; \lambda)}{\partial \lambda}\right|_{(t_1;\lambda_1)}}{y_{\mathbf{m}_-}(t_1; \lambda_1)}.$$

On the other hand, since $z_{\mathbf{m}_-}(t; \lambda)$ is the third coordinate of the solution of system (1.5) with initial condition $\mathbf{m}_-$, we have

$$\dot{z}_{\mathbf{m}_-}(t_1; \lambda_1) = -\lambda_1(1 + \lambda_1^2)x_{\mathbf{m}_-}(t_1; \lambda_1) - y_{\mathbf{m}_-}(t_1; \lambda_1) + 1 = -y_{\mathbf{m}_-}(t_1; \lambda_1) + 1.$$

Therefore, substituting into the expression of $dh/d\lambda$, we obtain

$$\left.\frac{dh}{d\lambda}\right|_{\lambda_1} = \frac{y_{\mathbf{m}_-}(t_1; \lambda_1) - 1}{y_{\mathbf{m}_-}(t_1; \lambda_1)} \left.\frac{\partial x_{\mathbf{m}_-}(t; \lambda)}{\partial \lambda}\right|_{(t_1;\lambda_1)} + \left.\frac{\partial z_{\mathbf{m}_-}(t; \lambda)}{\partial \lambda}\right|_{(t_1;\lambda_1)}.$$

Integrating the linear system $\dot{\mathbf{x}} = A^+\mathbf{x} + \mathbf{e}_3$ with initial condition $\mathbf{m}_-$ and taking into account that $x_{\mathbf{m}_-}(t_1;\lambda_1) = 0$ and $z_{\mathbf{m}_-}(t_1;\lambda_1) = 0$, the following equalities hold:

$$\begin{aligned}
y_{\mathbf{m}_-}(t_1;\lambda_1) &= \frac{e^{-\lambda_1 t_1} - 1}{\lambda_1^2},\\
\left.\frac{\partial x_{\mathbf{m}_-}(t;\lambda)}{\partial\lambda}\right|_{(t_1;\lambda_1)} &= \frac{\lambda_1 t_1}{\lambda_1^2(1+3\lambda_1^2)(1+\lambda^2)(4+3\lambda^2)}\Big(9\lambda_1^4(e^{-\lambda_1 t_1}-1) + 18\lambda^2(e^{-\lambda_1 t_1}-1)\\
&\qquad + 9e^{-\lambda_1 t_1} - 5\Big)\\
&\quad + \frac{2}{\lambda_1^2(1+3\lambda_1^2)(1+\lambda^2)(4+3\lambda^2)}\Big(3\lambda_1^2(2e^{-\lambda_1 t_1}-3) + 7(e^{-\lambda_1 t_1}-1)\Big),\\
\left.\frac{\partial z_{\mathbf{m}_-}(t;\lambda)}{\partial\lambda}\right|_{(t_1;\lambda_1)} &= \frac{3\lambda_1 t_1}{\lambda_1^2(1+3\lambda_1^2)(1+\lambda^2)(4+3\lambda^2)}\Big(3\lambda_1^6 + \lambda_1^4(7-e^{-\lambda_1 t_1}) + \lambda_1^2(5-2e^{-\lambda_1 t_1})\\
&\qquad + 1 - e^{-\lambda_1 t_1}\Big)\\
&\quad + \frac{2}{\lambda_1^2(1+3\lambda_1^2)(1+\lambda^2)(4+3\lambda^2)}\Big(3\lambda_1^4(e^{-\lambda_1 t_1}-1) + \lambda_1^2(3e^{-\lambda_1 t_1}-2)\\
&\qquad + 1 - e^{-\lambda_1 t_1}\Big).
\end{aligned}$$

Straightforward computations show that

$$\left.\frac{dh}{d\lambda}\right|_{\lambda_1} = -\frac{2}{\lambda_1^2(1+3\lambda_1^2)(1+\lambda^2)(4+3\lambda^2)(e^{\lambda_1 t_1}-1)}P(t_1,\lambda_1),$$

where

$$\begin{aligned}
P(t_1,\lambda_1) &= 3(e^{\lambda_1 t_1} + e^{-\lambda_1 t_1} - 2)\lambda_1^5 t_1 + 3(4e^{\lambda_1 t_1} + e^{-\lambda_1 t^*} - 4)\lambda_1^4 + 2(2e^{\lambda_1 t_1} + 3e^{-\lambda_1 t_1} - 6)\lambda^3 t_1\\
&\quad + 9(2e^{\lambda_1 t_1} + e^{-\lambda_1 t_1} - 3)\lambda_1^2 + (e^{\lambda t_1} + 3e^{-\lambda_1 t_1} - 4\lambda_1 t_1) + 6(e^{\lambda_1 t_1} + e^{-\lambda_1 t_1} - 2).
\end{aligned}$$

From Lemma 4.2 we have $\frac{1}{2} < \lambda_1 < 1$ and $\frac{2\pi}{\sqrt{7}} < t_1 < \frac{8\pi}{\sqrt{19}}$. Therefore, $\frac{\pi}{\sqrt{7}} < \lambda_1 t_1 < \frac{8\pi}{\sqrt{19}}$ and $3 < e^{\lambda_1 t_1}$. This implies that the coefficients of λ^5, λ^4, λ^3, and λ^2 in the expression of $P(\lambda_1, t_1)$ are positive. Moreover, $e^{\lambda t_1} + 3e^{-\lambda_1 t_1} - 4\lambda_1 t_1 > -\lambda_1 t_1 > -\frac{8\pi}{\sqrt{19}}$, and $6(e^{\lambda_1 t_1} + e^{-\lambda_1 t_1} - 2) > 6$. Since $6\sqrt{19} > 8\pi$, it follows that $P(\lambda_1, t_1) > 0$, which proves the proposition. ■

From Proposition 5.1 we finish the proof of Theorem 1.1.

Acknowledgments. The authors would like to thank Dr. E. Freire, Dr. E. Ponce, and Dr. F. Torres for useful discussions.

Localized Hexagon Patterns of the Planar Swift–Hohenberg Equation*

David J. B. Lloyd†, Björn Sandstede†, Daniele Avitabile‡, and Alan R. Champneys‡

Abstract. We investigate stationary spatially localized hexagon patterns of the two-dimensional (2D) Swift–Hohenberg equation in the parameter region where the trivial state and regular hexagon patterns are both stable. Using numerical continuation techniques, we trace out the existence regions of fully localized hexagon patches and of planar pulses which consist of a strip filled with hexagons that is embedded in the trivial state. We find that these patterns exhibit snaking: for each parameter value in the snaking region, an infinite number of patterns exist that are connected in parameter space and whose width increases without bound. Our computations also indicate a relation between the limits of the snaking regions of planar hexagon pulses with different orientations and of the fully localized hexagon patches. To investigate which hexagons among the one-parameter family of hexagons are selected in a hexagon pulse or front, we derive a conserved quantity of the spatial dynamical system that describes planar patterns which are periodic in the transverse direction and use it to calculate the Maxwell curves along which the selected hexagons have the same energy as the trivial state. We find that the Maxwell curve lies within the snaking region, as expected from heuristic arguments.

1. Introduction.

Localized stationary structures play an important role in many biological, chemical, and physical processes (see, for instance, the textbooks [45, 72, 74]). Such structures have been observed in a variety of experiments ranging from vertically vibrated granular materials [38, 89], liquid crystals [15], binary-fluid convection [8, 65], autocatalytic chemical reactions such as the Belousov–Zhabotinsky system [31, 90], electrochemical systems [1, 6], and localized microstructures in solidification [48] to nonlinear optical devices [63, 77, 86]. Localized patterns have also been found in many nonlinear models such as those derived from magnetohydrodynamics [12], flame fronts [39], lasers [56], vibrated granular materials [36, 88], neural networks [54, 55], and cellular buckling [47] as well as in the Swift–Hohenberg equation [26, 28, 29, 44, 80], which often serves as a paradigm for general pattern-forming systems [30, 37].

In this paper, we consider stationary solutions of the Swift–Hohenberg equation [30, 85]

$$u_t = -(1+\Delta)^2 u - \mu u + \nu u^2 - u^3, \tag{1.1}$$

where $x \in \mathbb{R}$ for the one-dimensional (1D) version and $(x, y) \in \mathbb{R}^2$ in the planar case. We

focus on the region $\nu \geq 0$ since the case $\nu < 0$ is then recovered upon replacing u by $-u$. The trivial state $u = 0$ is stable for $\mu > 0$ and destabilizes at $\mu = 0$ with respect to perturbations that have nonzero finite spatial wavelength. At $\mu = 0$, hexagons bifurcate in a transcritical bifurcation from $u = 0$ for each $\nu > 0$, while rolls bifurcate in a subcritical pitchfork bifurcation from $u = 0$ provided $\nu > \nu_r := \sqrt{27/38}$ [44]. While the bifurcating hexagons and rolls are initially unstable for $\mu > 0$, they stabilize in a subsequent saddle-node bifurcation, leading to bistability between the nontrivial patterns and the trivial state for $\mu > 0$. The bistability of trivial and patterned states opens up the possibility of finding fully localized stationary patches of hexagons or rolls such as those shown in Figure 1. It is patterns of this type that we shall focus on in this paper.

We first review briefly the situation in one dimension and refer the reader to section 2 for a more extensive discussion. In one space dimension, the Swift–Hohenberg equation exhibits localized structures, as shown in Figure 2. The patterns shown there are connected in parameter space, and their width increases as we move up on the bifurcation curve: this scenario is referred to as *snaking* [92]. There are several interesting questions one may ask about the patterns shown in Figure 2: can we predict for which values of μ these structures exist, and can we determine a priori which periodic pattern is selected to form the localized structure?

We begin with the second question: the steady-state equation

$$-(1 + \partial_x^2)^2 u - \mu u + \nu u^2 - u^3 = 0 \tag{1.2}$$

of the 1D Swift–Hohenberg equation exhibits, in the relevant parameter region, a one-parameter family of periodic patterns for each fixed (μ, ν). To decide which one of these makes up the core of the localized structure, we consider a front that connects the trivial state to a periodic pattern: this front corresponds to a heteroclinic orbit of the ordinary differential equation (1.2) that connects $u = 0$ to a periodic orbit. It turns out that the ODE (1.2) admits the first integral

$$\mathcal{H}(u) = u_{xxx} u_x - \frac{u_{xx}^2}{2} + u_x^2 + \frac{(1 + \mu)u^2}{2} - \frac{\nu u^3}{3} + \frac{u^4}{4} \tag{1.3}$$

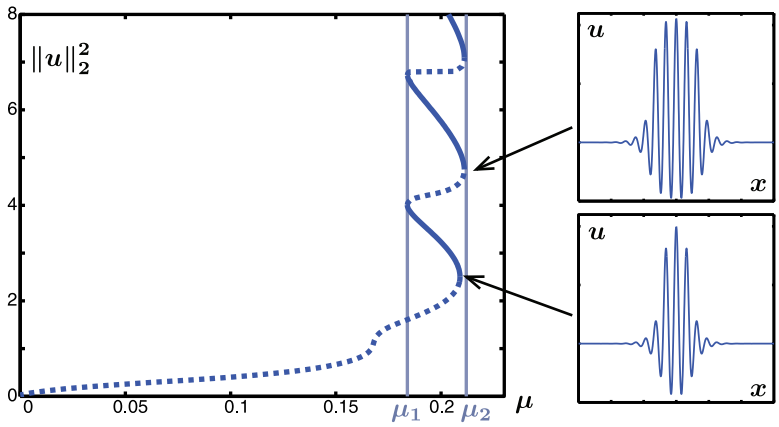

Figure 2. *A partial bifurcation diagram of localized stationary patterns in the 1D Swift–Hohenberg equation (1.1) is shown for $\nu = 1.6$ (other solution branches are given in Figure 8). Dotted blue lines indicate (temporally) unstable solutions, while solid blue lines denote stable solutions. At each fold along the snake, a pair of new rolls is formed in the pulse. The left and right fold bifurcations approach the vertical asymptotes $\mu_1 = 0.181$ and $\mu_2 = 0.211$, and the Maxwell point is $\mu_M = 0.2$.*

so that the value $[\mathcal{H}(u)](x)$ of $\mathcal{H}$ along a solution $u(x)$ of (1.2) does not change as a function of x. In particular, if we evaluate $\mathcal{H}$ along our front, we find that $\mathcal{H}$ must vanish along the limiting periodic pattern as it vanishes at $u = 0$. Generically, $\mathcal{H}$ will vanish only at finitely many periodic orbits in the family of periodic patterns and will therefore serve as a selection principle that involves only the periodic patterns.

We now address the first question, namely, for which parameter values stationary fronts exist. We recall that the Swift–Hohenberg equation (1.1) posed on $\mathbb{R}^d$ with $1 \le d \le 3$ is a gradient system,

$$u_t = -\nabla \mathcal{E}(u),$$

in $H^2(\mathbb{R}^d)$, where the energy functional $\mathcal{E}$ is given by

$$\mathcal{E}(u) = \int_{\mathbb{R}^d} \left[\frac{[(1+\Delta)u]^2}{2} + \frac{\mu u^2}{2} - \frac{\nu u^3}{3} + \frac{u^4}{4} \right] \mathrm{d}\mathbf{x}, \qquad \mathbf{x} \in \mathbb{R}^d, \tag{1.4}$$

and the gradient $\nabla \mathcal{E}(u) = \frac{\delta \mathcal{E}}{\delta u}(u)$ of $\mathcal{E}$ with respect to u is computed in $L^2(\mathbb{R}^d)$. In particular, $\mathcal{E}$ decreases strictly in time along solutions of (1.1) unless the solution is stationary. We record that the existence of the first integral $\mathcal{H}$ given above is actually a consequence of the translation invariance of the integrand of $\mathcal{E}$. While we cannot evaluate the energy functional along periodic patterns as they are not localized, whence the integral in (1.4) may not exist, we may, however, define a local energy by integrating over one spatial period of the underlying periodic pattern. We may then expect, on a heuristic level, that stationary interfaces between the trivial state and the periodic pattern can exist only when their local energies coincide; otherwise, one of the states would invade the other one to decrease energy, thus leading to moving fronts. This gives a heuristic criterion that allows us to determine for which values of μ stationary fronts can exist: for each μ, compute the periodic pattern $u_*(\mu)$ for which $\mathcal{H}(u_*(\mu)) = 0$, calculate its local energy $\mathcal{E}(u_*(\mu))$, and then find μ so that $\mathcal{E}(u_*(\mu)) = 0$. The

corresponding parameter value μ_{M} is referred to as the Maxwell point. It was first pointed out by Pomeau [73] that stationary fronts should exist not only at the Maxwell point $\mu = \mu_{\mathrm{M}}$ but in an entire interval that contains μ_{M} where fronts are pinned or locked. Consequently, we expect to find localized roll patches in an entire interval, and this is what happens in Figure 2. The specific pinning mechanism leading to Figure 2 was elucidated in [26, 52, 92] and will be discussed in section 2.

We now turn to the planar Swift–Hohenberg equation (1.1). Several numerical observations of localized spots and hexagon patches of (1.1) have been documented in the literature [26, 44, 78]. Localized square patterns have also been observed in the Swift–Hohenberg equation when an additional nonlinear gradient term is added [44, 79]. In addition, localized stripes and spots have been found in the cubic-quintic Swift–Hohenberg equation

$$u_t = -(1+\Delta)^2 u - \mu u + \nu u^3 - u^5. \tag{1.5}$$

Close to our approach is the paper [63], in which a complex Ginzburg–Landau equation with a saturable nonlinearity was studied in a cavity-soliton context. In [63], the steady-state equation was solved numerically as a boundary-value problem, and the bifurcation diagram was traced out for various localized patterns, including hexagon patches, using continuation techniques. However, the authors continued solutions only up to the first fold and not beyond.

The aim of this paper is to investigate hexagon fronts and fully localized hexagon patches in the two-dimensional (2D) Swift–Hohenberg equation (1.1). We have three main results. The first is the construction of a conserved quantity $\mathcal{H}$ for the 2D Swift–Hohenberg equation: the existence of $\mathcal{H}$ is a consequence of Noether's theorem since the integrand of the energy functional $\mathcal{E}$ is invariant under translations, i.e., does not depend explicitly on x.

Proposition 1 (conserved quantity for the 2D Swift–Hohenberg equation). *If $u(x,y)$ is a smooth solution of the planar Swift–Hohenberg equation (1.1) which is spatially periodic with period ℓ in the y-variable, then the quantity*

$$\mathcal{H}(u) = \int_0^\ell \left[u_{xxx}u_x - \frac{u_{xx}^2}{2} + u_x^2 + \frac{(1+\mu)u^2}{2} - \frac{\nu u^3}{3} + \frac{u^4}{4} - u_{xy}^2 - u_y^2 + \frac{u_{yy}^2}{2} \right] \mathrm{d}y \tag{1.6}$$

does not depend on x.

As in the 1D case, the first integral $\mathcal{H}$ provides a selection principle for hexagons: if we find a planar front that connects hexagons to the trivial state and is periodic in the transverse direction (see Figure 3), then $\mathcal{H}$ must vanish when evaluated along a single hexagon in the far field of the front. This selection principle together with the local energy $\mathcal{E}$ will allow us to compute Maxwell points for the planar Swift–Hohenberg equation (1.1). Our second result shows that, for each fixed $\nu > 0$, and all sufficiently small $\mu > 0$, there is a unique small-amplitude hexagon pattern along which $\mathcal{H}$ vanishes. We refer the reader to section 3.3 for a stronger result.

Proposition 2 (existence of hexagons with $\mathcal{H} = 0$). *For each fixed $\nu > 0$, there is a number $\mu_0 > 0$ so that the planar Swift–Hohenberg equation (1.1) admits a unique small-amplitude hexagon solution $u_*(\mu)$ that satisfies $\mathcal{H}(u_*(\mu)) = 0$ for each $\mu \in (0, \mu_0)$. These hexagons satisfy $u_*(0) = 0$, have wavenumber $\kappa_*(\mu)$ with $\kappa_*(0) = 1$, and depend smoothly on μ.*

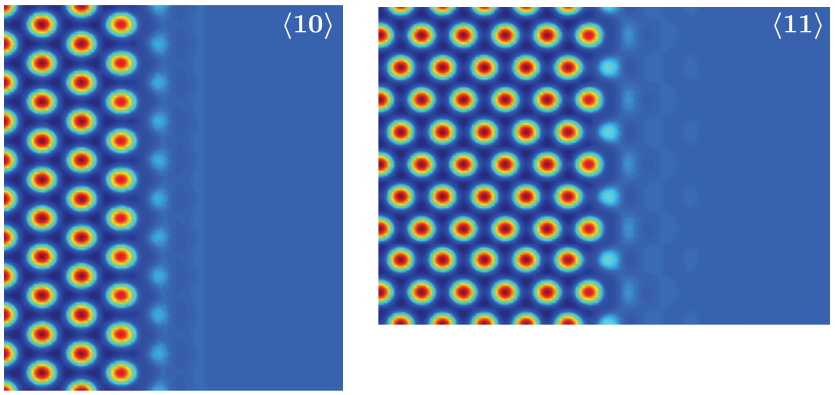

Figure 3. *Color plots of two stationary fronts are shown for the planar Swift–Hohenberg equation (1.1): Both fronts connect hexagons to the trivial state along the horizontal x-direction, are periodic in the vertical y-direction, and differ in the way in which their interfaces are aligned in a fixed hexagonal lattice.*

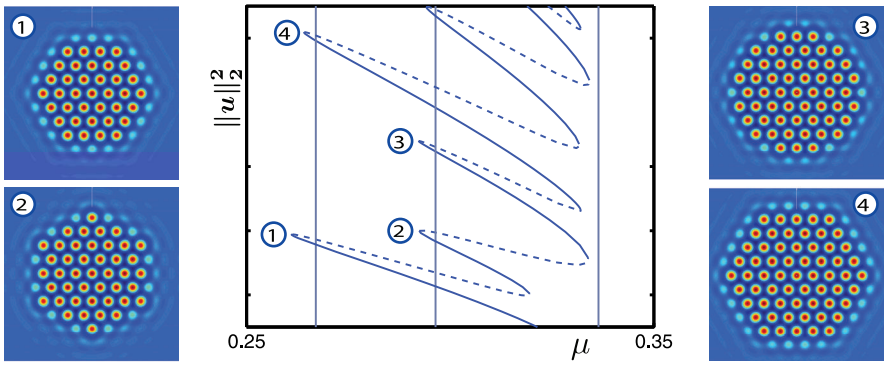

Figure 4. *Part of the bifurcation curve corresponding to localized hexagon patches of (1.1) with $\nu = 1.6$ is shown. Color plots of representative solutions are shown in panels 1–4. The entire snaking curve and color plots of the associated stationary solutions can be viewed in the accompanying animation (70762_01.mpg [10.8MB]).*

Our third result is a comprehensive numerical study of localized hexagon patches in the planar Swift–Hohenberg equation (1.1). Instead of giving a detailed list of these results, which can be found in section 5, we focus here on the observation that these localized structures snake.

Observation 1 (snaking of localized hexagon patches). *Localized hexagon patches of the Swift–Hohenberg equation exist and snake in a wedge-shaped region in the (μ, ν)-parameter plane. The shape of the hexagon patches changes along the snaking curve: their interfaces resemble planar hexagon fronts with different orientations with respect to a fixed hexagonal lattice; see Figures 3 and 4. The saddle-node bifurcations of the localized hexagon patches are aligned with saddle-nodes of planar hexagon fronts, which are shown as vertical lines in Figure 4.*

The remainder of this paper is organized as follows. We begin in section 2 with a review of snaking in one space dimension as this case motivated our paper to a large extent. We also review known results about regular hexagons and planar hexagon fronts. In section 3,

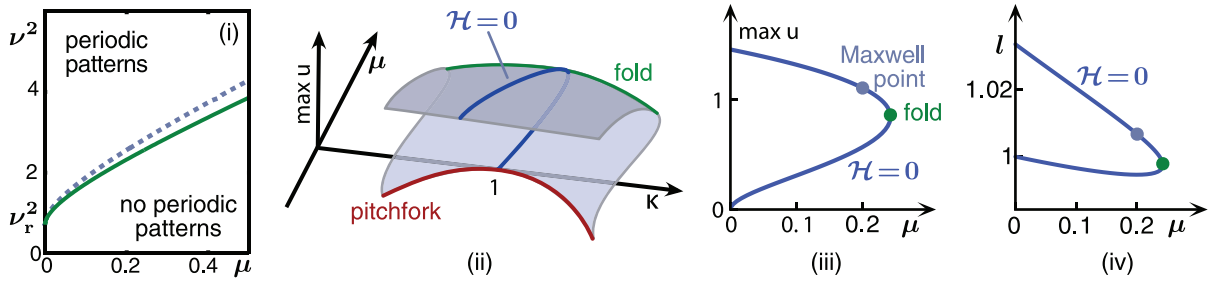

Figure 5. *Panel* (i) *contains the numerically computed fold bifurcation curve of* 1*D rolls of* (2.1) *with wavenumber* $\kappa = 1$ *(solid green) and the Maxwell curve (dotted grey) along which rolls with* $\mathcal{H} = 0$ *and* $\mathcal{E} = 0$ *exist. The schematic picture in panel* (ii) *indicates that, for fixed* $\nu > \nu_r$*, rolls exist for any wavenumber* κ *close to one. Panels* (iii) *and* (iv) *contain numerical bifurcation diagrams of the rolls that satisfy* $\mathcal{H} = 0$ *for* $\nu = 1.6$*: Shown are the amplitude and the wavelength* $l = 1/\kappa$ *(so that* $l = 1$ *corresponds to a period of* 2π*). The Maxwell point* $\mathcal{E} = 0$ *occurs on the upper branch, where rolls are stable.*

we discuss selection principles for hexagons and prove Propositions 1 and 2. We outline in section 4 the numerical algorithms that we used to compute planar hexagon fronts and localized hexagon patches and comment on their implementation. Our main results can be found in section 5, where we discuss fully localized hexagon and rhomboid patches. We end in section 6 with conclusions and a discussion.

Throughout this paper, we use color plots to illustrate the profiles of stationary planar patterns and refer the reader to the caption of Figure 1 for an explanation of what these plots represent. Two-parameter bifurcation diagrams are always drawn using (μ, ν^2) rather than (μ, ν), which makes the diagrams more legible.

2. Review of 1D snaking and planar hexagons.

2.1. Snaking in one space dimension.

Recall the steady-state equation

$$-(1+\partial_x^2)^2 u - \mu u + \nu u^2 - u^3 = 0, \qquad x \in \mathbb{R}, \tag{2.1}$$

of the 1D Swift–Hohenberg equation (1.1). Equation (2.1) has two important features that we shall exploit: it is invariant under the reflection $x \mapsto -x$ and admits the first integral $\mathcal{H}$ given in (1.3).

At $\mu = 0$, the trivial state $u = 0$ undergoes a pitchfork bifurcation to even spatially periodic patterns with period 2π or wavenumber $\kappa = 1$. These patterns bifurcate supercritically with $\mu < 0$ when $\nu < \nu_r := \sqrt{27/38}$ and subcritically with $\mu > 0$ when $\nu > \nu_r$. To accommodate the switch from super- to subcritical at $\nu = \nu_r$, a fold of periodic patterns with wavenumber $\kappa = 1$ emerges from $(\mu, \nu) = (0, \nu_r)$ into the positive half-plane, as shown in Figure 5(i). In fact, even periodic patterns bifurcate for any wavenumber κ close to one along a curve of pitchfork bifurcations, as indicated in Figure 5(ii) for a fixed $\nu > \nu_r$.

We are interested in standing localized structures such as those shown in Figure 2. As argued in section 1, the Maxwell curve predicts parameter regions where these structures may exist [11, 68, 70]: recall that Maxwell points are found by calculating, for each given (μ, ν), the periodic roll pattern $u_{\rm per}(\mu, \nu)$ that has vanishing first integral $\mathcal{H} = 0$ and subsequently adjusting the parameters so that the energy $\mathcal{E}(u_{\rm per}(\mu, \nu))$, computed over one period of $u_{\rm per}$,

vanishes as well. This can be done numerically, and the result [17, 19] is the Maxwell curve shown in Figure 5(i) which emerges from the codimension-two point $(0, \nu_r)$, where the bifurcation to rolls changes from super- to subcritical. We give two arguments that show that the Maxwell curve can emerge only from this point. First, small-amplitude rolls are unstable at subcritical bifurcations, while they bifurcate for $\mu < 0$ at supercritical bifurcations: in neither case can we find stable rolls for $\mu > 0$ that coexist with the stable trivial state. Alternatively, the normal form at pitchfork bifurcations is $\mu w - aw^3 = 0$, and the associated energy $\mathcal{E}(w) = \mu w^2/2 - aw^4/4$ does not vanish at the bifurcating state when $a \neq 0$.

Around the Maxwell curve, a pinning region exists where stable localized patterns can be found [73]. We shall now briefly review two different approaches that explain why this pinning region is present and why snaking occurs.

Asymptotics beyond all orders. Near the codimension-two point $(\mu, \nu) = (0, \nu_r)$ with $\nu_r = \sqrt{27/38}$, the snaking behavior in (1.1) can be explained by the interaction between the underlying periodic state and the slowly varying envelope which forms the localized structure. On the level of amplitude equations, the fast scale of the underlying periodic pattern is ignored, and these amplitude equations then predict that stationary pulses exist only at the Maxwell point. In the works [11, 13], the fast scale was formally reintroduced at lowest order into the amplitude equation, and the effect on locking and pinning was analyzed. This approach predicts an exponentially small width of the order $\exp(-\pi/|\nu - \nu_r|^2)$ of the locking region in the parameter μ when $\nu > \nu_r$ is fixed with $|\nu - \nu_r| \ll 1$ but does not capture the precise asymptotic behavior in ν. A consistent asymptotic analysis beyond all orders was recently carried out in [25, 52] which gives the precise asymptotic behavior of the width of the locking region in the parameter μ as a function of ν as ν approaches ν_r. Multiple scale expansions that capture the different scaling regimes near the bifurcation point and the Maxwell curve in one step, albeit without addressing terms beyond all orders, were introduced earlier in [16, 17]; in addition, the wavelength correction along the Maxwell curve was calculated in [17, (3.27)].

Dynamical-systems geometry. The second approach we shall discuss is of a more geometric nature and due to [92, 26]. We rewrite the fourth-order steady-state equation (2.1) as the first-order system

$$U_x = F(U; \mu, \nu), \qquad U = (u, u_x, u_{xx}, u_{xxx}) \in \mathbb{R}^4, \tag{2.2}$$

where we regard x as the time-like evolution variable. Recall that (2.2) has the first integral $\mathcal{H}$ from (1.3). The reflection invariance $x \mapsto -x$ of (2.1) means that (2.2) is reversible with reverser $\mathcal{R}U := (u, -u_x, u_{xx}, -u_{xxx})$: if $U(x)$ is a solution, so is $\mathcal{R}U(-x)$. Reversible solutions $U(x)$ of (2.2), which by definition satisfy $U(0) \in \operatorname{Fix}\mathcal{R}$, correspond to even solutions $u(x)$ of (2.1).

The trivial state $u = 0$ and the even periodic patterns $u_{per}(x)$ of (2.1) correspond to the equilibrium $U = 0$ and reversible periodic orbits $U_{per}(x)$, respectively, of (2.2). If the trivial state $u = 0$ and the rolls $u_{per}(x)$ are temporally stable with respect to the Swift–Hohenberg equation, then the corresponding solutions $U = 0$ and $U_{per}(x)$ of (2.2) are hyperbolic. If, for instance, $U = 0$ were not hyperbolic, then the matrix $F_U(0; \mu, \nu)$ would have a purely imaginary eigenvalue $\mathrm{i}\omega$, and $u(x, t) = \mathrm{e}^{\mathrm{i}\omega x}$ would satisfy the linearization of (1.1) about $u = 0$, which contradicts temporal stability. A similar argument applies to purely imaginary Floquet exponents of $U_{per}(x)$, which are related to the dispersion relation of $u_{per}(x)$: if the

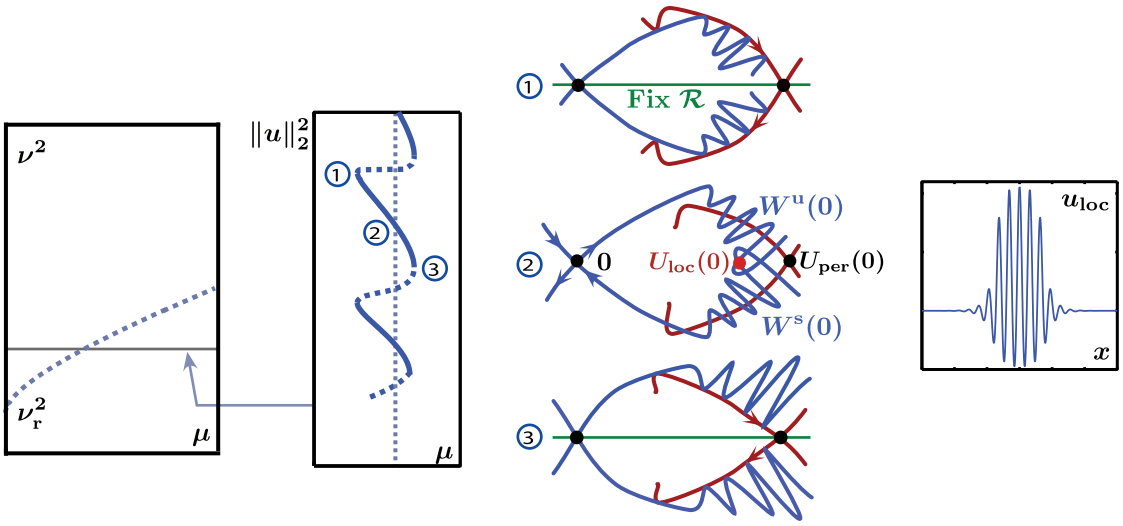

Figure 6. *The leftmost panel shows the Maxwell curve in the (μ, ν^2)-parameter space, while the center-left panel shows the bifurcation diagram for a fixed value of ν. The three pictures in the center-right panel illustrate the geometry of the stable and unstable manifolds of the equilibrium $U = 0$ and the periodic orbit $U_{\rm per}$ in a two-dimensional Poincaré section (see text for further details): The tangles of the unstable and stable manifolds of $U = 0$ are caused by the expansion and contraction near the periodic orbit and are therefore more pronounced near the periodic orbit. The localized pattern shown in the rightmost panel corresponds to the intersection $U_{\rm loc}$ of the stable and unstable manifolds of $U = 0$ near the periodic orbit $U_{\rm per}$.*

rolls $u_{\rm per}(x)$ are spectrally stable, then the periodic orbit $U_{\rm per}(x)$ will have only two Floquet exponents at zero; see [66, 67, 82, 83] and [81, sect. 3.4.2] for further details. In summary, we can identify the localized patterns $u_{\rm loc}(x)$ shown in Figure 2 with homoclinic orbits of (2.2) that lie in the intersections of the stable and unstable manifolds of $U = 0$ which come close to the hyperbolic periodic orbit $U_{\rm per}(x)$.

To visualize this situation better, we restrict (2.2) to the three-dimensional invariant zero level set $\mathcal{H}^{-1}(0)$ of the first integral $\mathcal{H}$. Next, we choose a two-dimensional Poincaré section Σ in the three-dimensional set $\mathcal{H}^{-1}(0)$ at the point $U_{\rm per}(0)$ on the periodic orbit $U_{\rm per}(x)$. The fixed-point space $\mathrm{Fix}\,\mathcal{R}$ of the reverser $\mathcal{R}$ becomes a line in the section Σ which can be used to identify symmetric orbits: note that the phase diagrams will be symmetric under the reverser $\mathcal{R}$. We now make the assumption that the unstable manifold of $U = 0$ intersects the stable manifold of the periodic orbit $U_{\rm per}(x)$ transversely in the section Σ and that the parameter μ moves these manifolds transversely through each other,[1] as shown in Figure 6. Numerical computations in [42] confirmed this assumption in the snaking regime of a reversible system of two coupled second-order equations. Figure 6 illustrates the resulting geometry which explains why the existence region of localized structures is an interval in parameter space. The end points of the intervals correspond to parameter values where fronts that connect the trivial state to the patterned state disappear in saddle-node bifurcations. Figure 7 explains in more detail why the localized structures get broader as we move up along the snaking curve.

[1]Due to reversibility, the same is then true for the stable manifold of $U = 0$ and the unstable manifold of $U_{\rm per}(x)$.

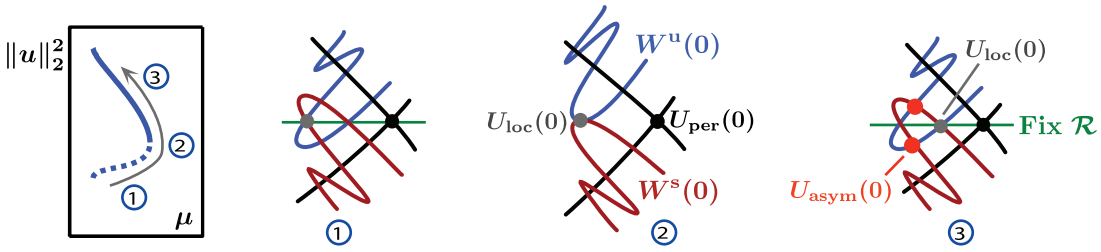

Figure 7. *As we move upward on the snaking curve, μ first increases and then decreases. Geometrically, the localized structure moves from one branch of the invariant manifolds through a saddle-node bifurcation to the adjacent branch. In doing so, it moves closer to the periodic orbit: Thus, it spends more "time" x near U_{per} and therefore broadens in space. As a result, its norm increases, which explains the structure of the snaking curve. Besides saddle-node bifurcations, the localized structures also undergo pitchfork bifurcations, which result in two asymmetric structures explained further in the text and in Figure 8.*

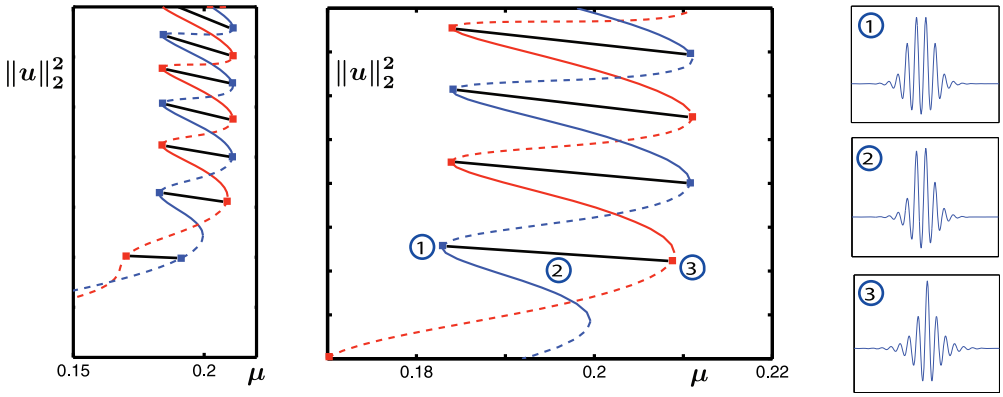

Figure 8. *The left and center panels contain the bifurcation diagrams of asymmetric localized structures that bifurcate at pitchfork bifurcations from even localized structures [20, 22]: Solutions along the curved branches are even with minima (blue) or maxima (red) at $x = 0$, while solutions along the horizontal ladders (black) are asymmetric. Panels 1–3 contain the graphs of selected solution profiles $u(x)$.*

As can be seen from Figure 7, the reflection symmetry $x \mapsto -x$ of the Swift–Hohenberg equation has another interesting consequence: each saddle-node bifurcation of an even localized structure is accompanied by a pitchfork bifurcation at which two asymmetric structures bifurcate. In the Swift–Hohenberg equation, these asymmetric states and the associated bifurcation diagrams were recently computed numerically in [20, 22], and we reproduce their numerical computations in Figure 8. As shown in Figure 8, the asymmetric structures connect two different families of even localized structures in parameter space. We give now a brief heuristic explanation of this phenomenon and refer the reader to [10] for a rigorous approach. Here and in [10], we assume that the parameter μ unfolds the intersection of $W^u(0)$ and $W^s(U_{per})$ as indicated in Figure 6 and that the resulting bifurcation diagram of even localized structures is as shown in Figure 8. Each symmetric periodic orbit $U_{per}(x)$ intersects the fixed-point space $\mathrm{Fix}\,\mathcal{R}$ precisely twice, and the two intersection points correspond to maxima and minima of u_{per}. Even localized structures arise as intersections of the unstable manifold $W^u(0)$ with $\mathrm{Fix}\,\mathcal{R}$ near either the maximum or the minimum of U_{per}. In the Swift–Hohenberg

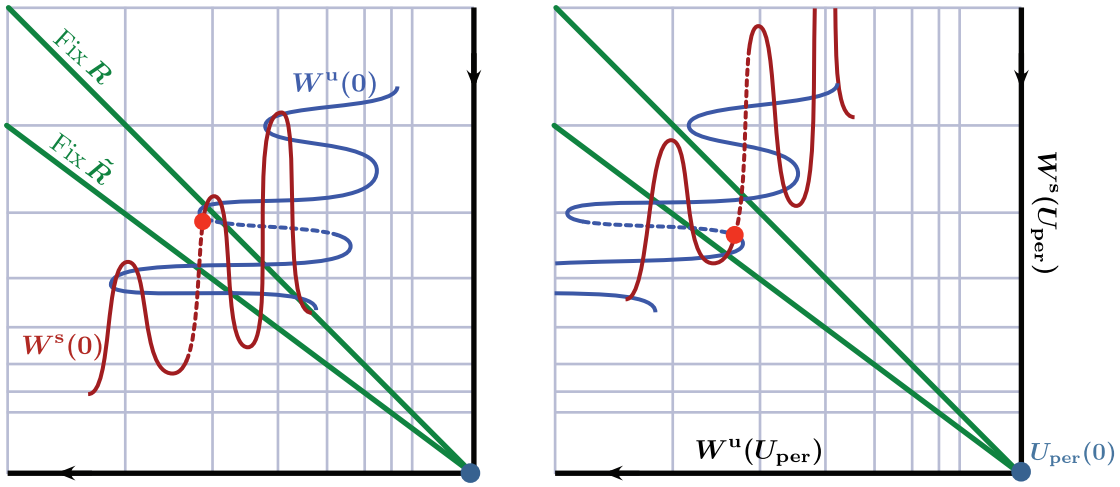

Figure 9. *Shown is the dynamics of the linearized Poincaré map near the periodic orbit U_{per}. On the left, the parameter μ is close to the pitchfork bifurcation in $\mathrm{Fix}\,\mathcal{R}$ that creates an asymmetric localized structure $U_{\mathrm{asym}}(0)$ (red bullet). As μ is increased, we assume that $W^{\mathrm{u}}(0)$ is moved to the left and, correspondingly, by reversibility, $W^{\mathrm{s}}(0)$ is moved upward. Following their intersection $U_{\mathrm{asym}}(0)$, which occurs along the branches plotted with dashes, we observe that it ends at a second pitchfork bifurcation in $\mathrm{Fix}\,\tilde{\mathcal{R}}$. Thus, the asymmetric localized structures connect, in parameter space, even solutions with a minimum at $x = 0$ to even solutions with a maximum at $x = 0$. The points $U_{\mathrm{asym}}(0)$ stay on the same horizontal and vertical segments of the invariant manifolds, and their distance from $U_{\mathrm{per}}(0)$ therefore does not change much: In particular, their L^2-norm cannot change by too much, which explains why the ladders are approximately horizontal. See also the accompanying animation* (70762_02.mov [533KB]).

equation, numerical evidence suggests that both these structures exist; see Figure 8. To capture them, we can work with two different Poincaré sections $\Sigma_{\max}$ and $\Sigma_{\min}$, placed at the maximum and minimum, or else work with a second reverser $\tilde{\mathcal{R}} := \Pi\mathcal{R}\Pi^{-1}$ near the section $\Sigma := \Sigma_{\min}$, where $\Pi : \Sigma_{\max} \to \Sigma_{\min}$ is the first-return map induced by the flow of (2.2). We choose the latter approach as it allows us to visualize the entire dynamics in one section. We straighten out the invariant manifolds of U_{per} and use the linearized Poincaré map near the symmetric orbit U_{per}. Using the assumptions made above on the unfolding of the intersections with respect to the parameter μ, we obtain the diagrams shown in Figure 9 which reproduce the numerically observed ladder structure geometrically.

We now turn to a discussion of the shape of the snaking region in the (μ, ν)-parameter space. Figure 6 indicates that snaking occurs in an interval in μ that is bounded by fold bifurcations of heteroclinic orbits which connect $U = 0$ to the rolls $U_{\mathrm{per}}(x)$. To demarcate the snaking region in (μ, ν)-space, we should therefore continue these fold bifurcations in parameter space, which is a difficult numerical task as we would need to find simultaneously periodic solutions, their Floquet eigenfunctions, and the heteroclinic orbits at a structurally unstable saddle-node bifurcation (see [53] for a recent numerical approach to this problem). Instead, we continue fold bifurcations of localized rolls in the parameters (μ, ν). As shown in Figure 10, these fold curves do not reach the codimension-two point $(\mu, \nu) = (0, \nu_{\mathrm{r}})$ but instead collide pairwise in cusp bifurcations. Continuing fold curves of localized rolls therefore gives a good approximation of the snaking region which fails, however, near the codimension-two

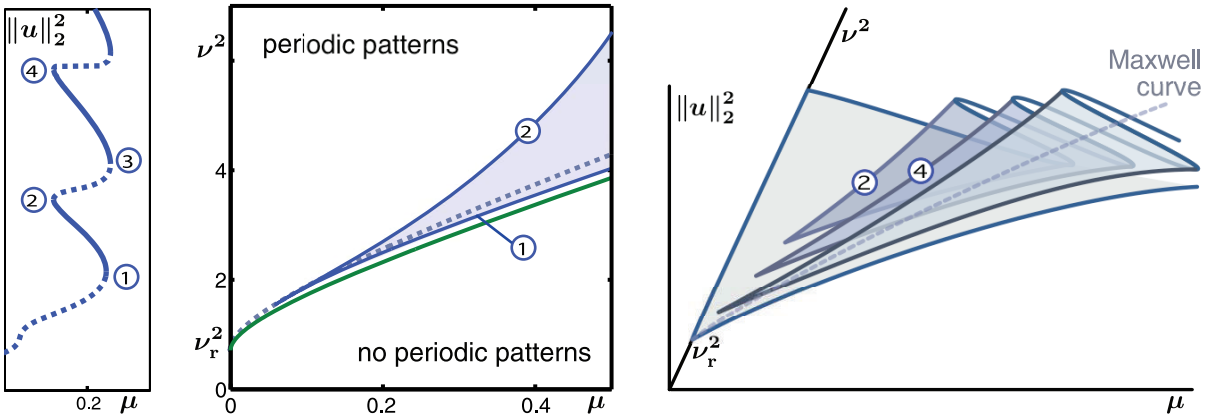

Figure 10. *The middle panel contains the numerically computed fold curves of localized rolls of (2.1) associated with the folds labeled (1) and (2) in the left panel: The two fold curves collide in a cusp bifurcation. The right panel contains a schematic illustration of the sheet of localized rolls: Fold curves of localized rolls will collide pairwise in cusps, and we believe that the sequence of cusps approaches the codimension-two point $(0, \nu_r)$ along the Maxwell curve.*

point.

2.2. Regular hexagonal patterns. We briefly review known results on the existence and stability of regular hexagons [33, 40, 41, 49] (see also [35, sect. 2] for a review), which can be tiled to cover the entire plane.

The planar Swift–Hohenberg equation

$$u_t = -(1+\Delta)^2 u - \mu u + \nu u^2 - u^3, \qquad \mathbf{x} = (x, y) \in \mathbb{R}^2 \tag{2.3}$$

is equivariant under the action of the Euclidean symmetry group $\mathbb{E}(2)$ which consists of rotations, translations, and reflections of the plane. Thus, we may seek stationary solutions to this equation that are invariant under a given fixed subgroup of $\mathbb{E}(2)$. We focus on hexagons with wavenumber $\kappa = 1$ and consider therefore the planar hexagonal lattice $\mathcal{L}$,

$$\mathcal{L} = \{n_1 l_1 + n_2 l_2 + n_3 l_3 \in \mathbb{R}^2;\, n_1, n_2, n_3 \in \mathbb{Z}\},$$

where

$$l_1 = 2\pi\left(1, \frac{1}{\sqrt{3}}\right), \qquad l_2 = 2\pi\left(0, -\frac{2}{\sqrt{3}}\right), \qquad l_3 = 2\pi\left(-1, \frac{1}{\sqrt{3}}\right);$$

see Figure 11. It is convenient to retain the lattice vector l_3 even though it is redundant. Hexagons are time-independent solutions $u(\mathbf{x})$ of (2.3) which are invariant under the subgroup $\mathbb{D}_6$ of $\mathbb{E}(2)$ and which are $\mathcal{L}$-periodic so that

$$u(\mathbf{x} + l) = u(\mathbf{x}) \qquad \forall l \in \mathcal{L},\ \forall \mathbf{x} \in \mathbb{R}^2.$$

To find hexagons, it is convenient to use the dual lattice $\mathcal{L}^*$ defined via

$$\mathcal{L}^* = \{n_1 k_1 + n_2 k_2 + n_3 k_3 \in \mathbb{R}^2;\, n_1, n_2, n_3 \in \mathbb{Z}\}$$

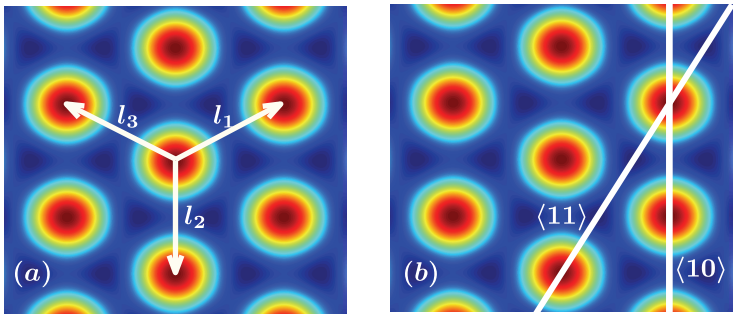

Figure 11. *Shown are color plots of regular hexagons on the lattice $\mathcal{L}$ together with the lattice vectors l_1, l_2, and l_3 in panel* (a) *and with two lines with Bravais–Miller indices* $\langle 10\rangle$ *and* $\langle 11\rangle$ *in panel* (b).

with

$$k_1 = (-1, 0), \qquad k_2 = \left(\frac{1}{2}, \frac{\sqrt{3}}{2}\right), \qquad k_3 = \left(\frac{1}{2}, -\frac{\sqrt{3}}{2}\right),$$

which allows us to represent $\mathcal{L}$-periodic solutions of (2.3) by the Fourier series

$$u(\mathbf{x}, t) = \sum_{k\in\mathcal{L}^*} \hat{u}_k(t) \mathrm{e}^{\mathrm{i}k\cdot\mathbf{x}}.$$

We now restrict our attention to hexagons that bifurcate from $u = 0$. Linearizing (2.3) about $u = 0$ gives the linear operator $-(1+\Delta)^2-\mu$. Posed on appropriate spaces of $\mathcal{L}$-periodic functions, the first instability occurs at $\mu = 0$, where an eigenvalue of algebraic multiplicity six, with eigenfunctions $\exp(\pm \mathrm{i}k_j \cdot \mathbf{x})$ for $j = 1, 2, 3$, crosses into the right half-plane. On the resulting six-dimensional center manifold, we can parametrize solutions as

(2.4)
$$u(\mathbf{x}, t) = A_1(t)\mathrm{e}^{-\mathrm{i}x} + A_2(t)\mathrm{e}^{\mathrm{i}(x+\sqrt{3}y)/2} + A_3(t)\mathrm{e}^{\mathrm{i}(x-\sqrt{3}y)/2} + h(A_1, A_2, A_3, \overline{A}_1, \overline{A}_2, \overline{A}_3; \mu, \nu) + \text{c.c.},$$

where the function h represents the higher-order contributions to the center manifold. The flow on the center manifold can be calculated for $|\mu| \ll 1$ and $|\nu| \ll 1$ by evaluating the Swift–Hohenberg equation on the elements of the center manifold and projecting the resulting expression back onto the center eigenspace.[2] The result is

(2.5)
$$\begin{aligned}
\dot{A}_1 &= -\mu A_1 + \alpha_1 \overline{A}_2\overline{A}_3 + \alpha_2 A_1|A_1|^2 + \alpha_3 A_1(|A_2|^2 + |A_3|^2) + r(A_1, A_2, A_3),\\
\dot{A}_2 &= -\mu A_2 + \alpha_1 \overline{A}_1\overline{A}_3 + \alpha_2 A_2|A_2|^2 + \alpha_3 A_2(|A_1|^2 + |A_3|^2) + r(A_2, A_3, A_1),\\
\dot{A}_3 &= -\mu A_3 + \alpha_1 \overline{A}_2\overline{A}_1 + \alpha_2 A_3|A_3|^2 + \alpha_3 A_3(|A_2|^2 + |A_1|^2) + r(A_3, A_1, A_2),
\end{aligned}$$

plus the complex conjugated equations of six ODEs for the complex amplitudes A_j, where the coefficients α_j are real and are given by

$$\alpha_1 = 2\nu + \mathrm{O}(|\mu|(|\mu| + |\nu|)), \qquad \alpha_2 = -3 + \mathrm{O}(|\mu| + |\nu|), \qquad \alpha_3 = -6 + \mathrm{O}(|\mu| + |\nu|),$$

[2] If ν is small, then the function h is not needed for the calculation of the cubic terms of the reduced vector field: The coefficients in (2.5) for arbitrary ν can be found in [44].

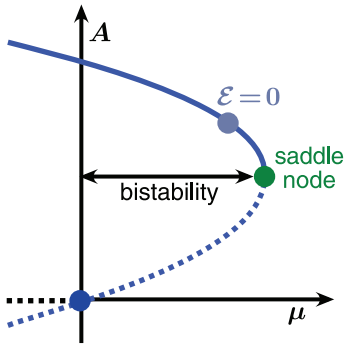

Figure 12. *The bifurcation diagram of hexagons with critical wavenumber $\kappa = 1$ in the Swift–Hohenberg equation is shown for fixed $0 < \nu \ll 1$. Solid lines correspond to stable patterns, while dotted lines correspond to unstable ones. The hexagons undergo a saddle-node bifurcation at amplitude $A = \nu/15 + \mathrm{O}(\nu^2)$ when $\mu = \nu^2/15 + \mathrm{O}(\nu^3)$. The energy $\mathcal{E}$ vanishes only for $\mu = \mu_{\mathcal{E}}$ given in (2.9) for the hexagons with amplitude $A = 4\nu/45 + \mathrm{O}(\nu^2)$ on the upper branch.*

and the remainder term $r(z) = \mathrm{O}(|z|^4)$ is of higher order. Equivariance of the Swift–Hohenberg equation and invariance of the hexagonal lattice with respect to rotations by $\pi/3$, reflections, and translations manifest themselves in the equivariance of the reduced system with respect to the transformations

$$\begin{aligned}
\sigma &: (A_1, A_2, A_3) \mapsto (\overline{A}_3, \overline{A}_1, \overline{A}_2),\\
\rho &: (A_1, A_2, A_3) \mapsto (A_1, A_3, A_2),\\
\tau_a &: (A_1, A_2, A_3) \mapsto (\mathrm{e}^{\mathrm{i}a_1} A_1, \mathrm{e}^{-\mathrm{i}(a_1+\sqrt{3}a_2)/2} A_2, \mathrm{e}^{\mathrm{i}(-a_1+\sqrt{3}a_2)/2} A_3),
\end{aligned}$$

respectively. Hexagons are invariant under $\mathbb{D}_6$ and therefore lie, in particular, in the one-dimensional intersection of the fixed-point spaces of σ^2 and σ^3, which is given by $A := A_1 = A_2 = A_3 \in \mathbb{R}$. As an intersection of fixed-point spaces, the line $A_1 = A_2 = A_3 \in \mathbb{R}$ is invariant under (2.5), and hexagons can therefore be found as nontrivial equilibria of the differential equation

$$\dot{A} = -\mu A + 2\nu A^2 - 15A^3 + \mathrm{O}((|\mu| + |\nu|)(|\mu| + |A|)|A|^2 + |A|^4) \tag{2.6}$$

which exist for

$$\mu = 2\nu A - (15 + \mathrm{O}(|\nu| + |A|))A^2. \tag{2.7}$$

The stability of these hexagons with respect to $\mathcal{L}$-periodic perturbations is calculated by considering the linearization of (2.5) about the hexagons [23, 40]. The resulting bifurcation diagram of hexagons is plotted for $\nu > 0$ in Figure 12; other solution branches corresponding to mixed modes, which bifurcate in secondary bifurcations, and rolls exist but are not shown in Figure 12. The hexagons with $A > 0$ shown in Figure 12 are up-hexagons: our focus is on $\mu, \nu > 0$, and we shall therefore encounter only up-hexagons in the rest of this paper. When $\nu < 0$, the bifurcation diagram in Figure 12 does not change except that A is reflected via $A \mapsto -A$: in this case, localized hexagon patterns consist of down-hexagons, though

the bifurcation diagrams shown in the remainder of the paper would not change due to the symmetry $(u,\nu)\mapsto(-u,-\nu)$.

We now calculate the energy $\mathcal{E}(u)$ given in (1.4) along the hexagon branch (2.7). Substituting

$$u(x,y)=2A\left[\cos(x)+\cos((x+\sqrt{3}y)/2)+\cos((x-\sqrt{3}y)/2)\right]$$

into (1.4) and integrating over the fundamental domain $[0,4\pi]\times[0,4\pi/\sqrt{3}]$, we find that the energy of the hexagons with wavenumber $\kappa=1$ is given by

$$\mathcal{E}=\frac{8\pi^2A^3}{\sqrt{3}}(4\nu-45A)+\mathrm{O}((|\nu|+|A|)A^4), \tag{2.8}$$

which vanishes precisely when $A=4\nu/45+\mathrm{O}(\nu^2)$, which corresponds to the parameter curve

$$\mu_{\mathcal{E}}=\frac{8\nu^2}{135}+\mathrm{O}(\nu^3). \tag{2.9}$$

For fixed $\nu>0$, the energy (2.8) along the bifurcating hexagons is strictly larger than zero for $0<|A|\ll 1$.

Throughout this section, we considered only hexagons with wavenumber $\kappa=1$. Hexagons with wavenumbers κ close to one bifurcate for $\mu=-(1-\kappa^2)^2$, and these can be captured by an analogous analysis upon using the arguments $(\kappa x,\kappa y)$ in place of (x,y) in the right-hand side of (2.4).

2.3. Planar hexagon fronts. We now discuss planar stationary hexagon fronts that connect hexagons to the trivial state. As illustrated in Figure 3, these fronts can have different orientations with respect to the hexagonal lattice $\mathcal{L}$, which can be classified using the Bravais–Miller index [5].

Definition 1 (Bravais–Miller index). *Fix the hexagonal lattice $\mathcal{L}$. The Bravais–Miller index $\langle n_1\,n_2\,n_3\rangle$ of a line in the plane is given by the reciprocals n_j of the intercepts of the line with the lines $\mathbb{R}l_j$ generated by the lattice vectors l_j (assigning the reciprocal $n_j=0$ if the line does not intersect $\mathbb{R}l_j$). Negative indices $-n$ with $n>0$ are conventionally written as $\overline{n}:=-n$. Since $n_1+n_2+n_3=0$, we may write the index using only two indices: our choice is $\langle n_1\,n_2\rangle$, and we refer the reader to Figure 11(b) for examples.*

If a hexagon front has a straight interface, we assign the Bravais–Miller index of its interface to it. Two examples of Bravais–Miller indices are given in Figure 11(b), and the corresponding hexagon fronts are shown in Figure 3. We shall present more detailed numerical results for the existence of fronts with these orientations later in the paper.

For μ close to zero, stationary fronts between hexagons and the trivial state can be found using a formal multiscale expansion as carried out in [60], though we note that this approach cannot capture the expected pinning and locking of these fronts. To construct stationary $\langle 10\rangle$ fronts, we substitute the ansatz

$$u(x,y)=\epsilon\left(A_1(\epsilon x)\mathrm{e}^{-\mathrm{i}x}+A_2(\epsilon x)\left[\mathrm{e}^{\mathrm{i}(x+\sqrt{3}y)/2}+\mathrm{e}^{\mathrm{i}(x-\sqrt{3}y)/2}\right]+\text{c.c.}\right)$$

into (2.3), set $\mu = \epsilon^2\tilde{\mu}$ and $\nu = \epsilon\tilde{\nu}$, and expand in powers of ϵ. To leading order, we obtain the system

$$
\begin{aligned}
0 &= 4\partial_X^2 A_1 - \tilde{\mu}A_1 + 2\tilde{\nu}\overline{A}_2^2 - 3A_1|A_1|^2 - 12A_1|A_2|^2,\\
0 &= \partial_X^2 A_2 - \tilde{\mu}A_2 + 2\tilde{\nu}\overline{A}_1\overline{A}_2 - 9A_2|A_2|^2 - 6A_2|A_1|^2,
\end{aligned}
\tag{2.10}
$$

where the nonlinearity on the right-hand side comes from (2.5) upon setting $A_2 = A_3$. A similar ODE can be derived for $\langle 11\rangle$ fronts and, in fact, for fronts of any given orientation [60].

Stationary fronts with index $\langle 10\rangle$ that connect the trivial state to hexagons with wavenumber $\kappa = 1$ correspond to heteroclinic orbits of (2.10) that connect $(A_1, A_2) = (0, 0)$ to the hexagon solutions $(A_1, A_2) = (\tilde{A}, \tilde{A})$, where $A = \epsilon\tilde{A}$ is an equilibrium of (2.6). Equation (2.10) admits the first integral

$$
\begin{aligned}
\mathcal{H}(A_1, A_2) = {}& 2|\partial_X A_1|^2 + |\partial_X A_2|^2 - \tilde{\mu}\left(\frac{|A_1|^2}{2} + |A_2|^2\right)\\
&+ \tilde{\nu}(\overline{A}_1\overline{A}_2^2 + A_1A_2^2) - \frac{3}{4}|A_1|^4 - 6|A_1|^2|A_2|^2 - \frac{9}{2}|A_2|^4,
\end{aligned}
\tag{2.11}
$$

which is constant along solutions of (2.10). In particular, heteroclinic orbits between $(0, 0)$ and $(\tilde{A}, \tilde{A})$ can exist only when $\mathcal{H}(\tilde{A}, \tilde{A}) = \mathcal{H}(0, 0) = 0$, which gives the condition

$$
\mathcal{H}(\tilde{A}, \tilde{A}) = -\frac{3\tilde{\mu}}{2}\tilde{A}^2 + 2\tilde{\nu}\tilde{A}^3 - \frac{45}{4}\tilde{A}^4 = 0
$$

that we need to solve for $\tilde{A}$. Using (2.7) and interpreting the results in the original unscaled parameters, we arrive at the condition

$$
\mu_{\mathrm{M}} = \frac{8\nu^2}{135} + \mathrm{O}(\nu^3),
\tag{2.12}
$$

along which $\mathcal{H}$ vanishes at the bifurcating hexagons with wavenumber $\kappa = 1$. Equation (2.9) shows that the energy $\mathcal{E}$ vanishes at the same hexagons for the same parameter values, to the order in which we computed them. Thus, the curve defined by (2.12) gives the Maxwell curve, which provides a heuristic criterion for the existence of planar fronts but does not account for pinning and locking phenomena.

The analysis reviewed here is valid only in the limit $(\mu, \nu) \to 0$ and does not address the wavenumber selection as we fixed $\kappa = 1$. In section 3, we will construct a conserved quantity $\mathcal{H}$ which defines the Maxwell curve for general parameter values and prove Proposition 3 on the selection of hexagons that satisfy $\mathcal{H} = 0$. In section 5.2, we shall compare the predictions made by the Maxwell curve (2.12) and its extension from section 3 with numerical computations for the full 2D Swift–Hohenberg equation.

3. Spatial dynamics, and selection principles for hexagons. In this section, we prove Propositions 1 and 2.

3.1. Proof of Proposition 1. Proposition 1 states that if $u(x,y)$ is a bounded solution of the planar stationary Swift–Hohenberg equation

$$-(1+\Delta)^2 u - \mu u + \nu u^2 - u^3 = 0, \qquad (x,y) \in \mathbb{R}^2, \tag{3.1}$$

which is spatially periodic with period ℓ in the y-variable, then the quantity

$$\mathcal{H}(u) = \int_0^\ell \left[u_{xxx}u_x - \frac{u_{xx}^2}{2} + u_x^2 + \frac{(1+\mu)u^2}{2} - \frac{\nu u^3}{3} + \frac{u^4}{4} - u_{xy}^2 - u_y^2 + \frac{u_{yy}^2}{2} \right] \mathrm{d}y \tag{3.2}$$

does not depend on x. This can, of course, be verified directly by computing the derivative of (3.2) with respect to x and using (3.1), and we omit this straightforward calculation.

Instead, we outline how the first integral $\mathcal{H}$ can be derived in the first place from the translation invariance of the Lagrangian associated with (3.1) and refer the reader to [2, 3] and [24, Ch. 15] for a general abstract approach. We start with a general energy functional[3]

$$\mathcal{E}(u) = \int_{\mathbb{R}^d} \mathcal{L}(u(\mathbf{x}), \nabla u(\mathbf{x}), \Delta u(\mathbf{x}))\, \mathrm{d}\mathbf{x}, \qquad \mathbf{x} = (x_1, \dots, x_d) \in \mathbb{R}^d,$$

where $\mathcal{L}(q,p,r) : \mathbb{R} \times \mathbb{R}^d \times \mathbb{R} \to \mathbb{R}$ is a given smooth function that does not depend explicitly upon $\mathbf{x}$. The Euler–Lagrange equation associated with the energy functional $\mathcal{E}$ reflects the extremum condition $\nabla\mathcal{E}(u) = \frac{\delta\mathcal{E}}{\delta u}(u) = 0$, where the gradient with respect to u is calculated in the L^2-scalar product, and is given by

$$\mathcal{L}_q(u, \nabla u, \Delta u) - \nabla \cdot \mathcal{L}_p(u, \nabla u, \Delta u) + \Delta \mathcal{L}_r(u, \nabla u, \Delta u) = 0, \qquad \mathbf{x} = (x_1, \dots, x_d) \in \mathbb{R}^d, \tag{3.3}$$

where the partial derivatives $\mathcal{L}_q$, $\mathcal{L}_p$, and $\mathcal{L}_r$ of the function $\mathcal{L}(q,p,r)$ are evaluated at $(u(\mathbf{x}), \nabla u(\mathbf{x}), \Delta u(\mathbf{x}))$. Assume now that $u(\mathbf{x})$ is a smooth solution of the Euler–Lagrange equation (3.3). We compute

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}x_1}\left[\mathcal{L}(u, \nabla u, \Delta u)\right] &= \mathcal{L}_q u_{x_1} + \mathcal{L}_p \cdot \nabla u_{x_1} + \mathcal{L}_r \Delta u_{x_1} \\
&\overset{(3.3)}{=} (\nabla \cdot \mathcal{L}_p - \Delta \mathcal{L}_r) u_{x_1} + \mathcal{L}_p \cdot \nabla u_{x_1} + \mathcal{L}_r \Delta u_{x_1} \\
&= u_{x_1} \nabla \cdot \mathcal{L}_p + \nabla u_{x_1} \cdot \mathcal{L}_p + \mathcal{L}_r \Delta u_{x_1} - (\Delta \mathcal{L}_r) u_{x_1} \\
&= \nabla \cdot (u_{x_1} \mathcal{L}_p) + \nabla \cdot (\mathcal{L}_r \nabla u_{x_1} - u_{x_1} \nabla \mathcal{L}_r).
\end{aligned}$$

Thus, we have established the existence of a conservation law for the Euler–Lagrange equation.

Lemma 1. *Assume that $u(\mathbf{x})$ is a smooth solution of the Euler–Lagrange equation (3.3) associated with the Lagrangian $\mathcal{L}(q,p,r)$; then the conservation law*

$$\partial_{x_1}\mathcal{L}(u, \nabla u, \Delta u) - \nabla \cdot \left[u_{x_1} \mathcal{L}_p(u, \nabla u, \Delta u) + \mathcal{L}_r(u, \nabla u, \Delta u) \nabla u_{x_1} - u_{x_1} \nabla \mathcal{L}_r(u, \nabla u, \Delta u) \right] = 0 \tag{3.4}$$

is satisfied for all $\mathbf{x} \in \mathbb{R}^d$.

[3] In section 3.1, we use $\mathcal{L}$ exclusively for the Lagrangian; in all other sections, this letter refers to the hexagonal lattice.

We now return to the planar Swift–Hohenberg equation (3.1), which is the Euler–Lagrange equation associated with the energy functional

$$\mathcal{E}(u) = \int_{\mathbb{R}^2} \mathcal{L}(u, \nabla u, \Delta u)\, \mathrm{d}x\, \mathrm{d}y$$

for the Lagrangian

$$\mathcal{L}(q, p, r) := \frac{(q+r)^2}{2} + \frac{\mu q^2}{2} - \frac{\nu q^3}{3} + \frac{q^4}{4}, \tag{3.5}$$

where $(q, p, r) \in \mathbb{R} \times \mathbb{R}^2 \times \mathbb{R}$. Lemma 1 asserts that (3.4) is met for any smooth solution $u(x, y)$ of (3.1). If we further assume that $u(x, y)$ is periodic with period ℓ in y, then we can integrate (3.4) in y over $[0, \ell]$ and use periodicity in y to find that the equation

$$\partial_x \int_0^\ell [\mathcal{L}(u, \nabla u, \Delta u) - u_x \mathcal{L}_{p_1}(u, \nabla u, \Delta u) - \mathcal{L}_r(u, \nabla u, \Delta u) u_{xx} + u_x \partial_x \mathcal{L}_r(u, \nabla u, \Delta u)]\, \mathrm{d}y = 0$$

is met for all x, where we write $p = (p_1, p_2)$. In particular, along such solutions,

$$\int_0^\ell [\mathcal{L}(u, \nabla u, \Delta u) - u_x \mathcal{L}_{p_1}(u, \nabla u, \Delta u) - \mathcal{L}_r(u, \nabla u, \Delta u) u_{xx} + u_x \partial_x \mathcal{L}_r(u, \nabla u, \Delta u)]\, \mathrm{d}y$$

does not depend on x. Substituting the expression for $\mathcal{L}$ from (3.5), we find that the integral above coincides with the expression (3.2) for $\mathcal{H}$, as claimed.

3.2. Spatial dynamics. As in the 1D situation, the quantity $\mathcal{H}(u)$ given in (3.2) determines which hexagons can be connected by a stationary planar front to the trivial state. We use spatial dynamics to gain further insight into why snaking should occur for stationary planar fronts. We focus on fronts that connect hexagons to the trivial state and that are spatially periodic along the interface.

Thus, assume that $u(x, y)$ is a smooth solution of (3.1) which is periodic in y with positive minimal period ℓ. We define the wavenumber

$$\kappa = \frac{2\pi}{\ell}$$

and introduce the rescaling $\phi = \kappa y$. With this rescaling, $\phi \in [0, 2\pi]$ corresponds to $y \in [0, \ell]$, and the planar Swift–Hohenberg equation (3.1) becomes

$$\partial_x^4 u + 2\kappa^2 \partial_x^2 \partial_\phi^2 u + \kappa^4 \partial_\phi^4 u + 2(\partial_x^2 u + \kappa^2 \partial_\phi^2 u) + (1+\mu)u - \nu u^2 + u^3 = 0. \tag{3.6}$$

Exploiting that we are now interested in solutions with period 2π in ϕ, we write this equation as a first-order system in x and obtain

$$U_x = \mathcal{A}(\mu, \kappa) U + \mathcal{N}(U; \nu), \qquad U \in \mathcal{U}, \tag{3.7}$$

where

$$\mathcal{A}(\mu, \kappa) = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -\kappa^4 \partial_\phi^4 - 2\kappa^2 \partial_\phi^2 - (1+\mu) & 0 & -2 - 2\kappa^2 \partial_\phi^2 & 0 \end{pmatrix}, \qquad \mathcal{N}(U; \nu) = \begin{pmatrix} 0 \\ 0 \\ 0 \\ \nu U_1^2 - U_1^3 \end{pmatrix},$$

and $U(x) = U(x)(\varphi)$ is, for each fixed x, a function of φ that lies in $\mathcal{U} := H^3(S^1) \times H^2(S^1) \times H^1(S^1) \times L^2(S^1)$, where S^1 is the interval $[0, 2\pi]$ with the end points identified. Equation (3.7) is reversible with respect to the reverser

$$\mathcal{R}U = \mathcal{R}(U_1, U_2, U_3, U_4)^t = (U_1, -U_2, U_3, -U_4)^t,$$

which corresponds to reflections in x, and admits the first integral

$$\mathcal{H}(U; \mu, \nu, \kappa) = \int_0^{2\pi} \Big[U_2 U_4 - \frac{U_3^2}{2} + U_2^2 + \frac{(1+\mu)U_1^2}{2} - \frac{\nu U_1^3}{3} + \frac{U_1^4}{4} - \kappa^2(\partial_\phi U_2)^2 - \kappa^2(\partial_\phi U_1)^2 + \frac{\kappa^4(\partial_\phi^2 U_1)^2}{2} \Big] \mathrm{d}\phi, \tag{3.8}$$

which is simply (3.2) with y rescaled and $(u, u_x, u_{xx}, u_{xxx})$ replaced by U. Even though the system (3.7) is ill-posed in the sense that (3.7) may not have a solution for a given initial condition, we can still apply the theory developed in [71, 82, 83] to show that stable and unstable manifolds of equilibria and periodic orbits of (3.7) exist. These manifolds are infinite-dimensional, but the results in [10, 71, 83] imply that the geometric situation for (3.7) is analogous to the 1D situation.

The existence of the first integral $\mathcal{H}$ implies that if there is a heteroclinic orbit of (3.7) that connects $U = 0$ to a periodic orbit, then $\mathcal{H}$ must vanish along the heteroclinic orbit and on the periodic orbit. In particular, if we seek stationary fronts between the trivial state and regular hexagons, then for each fixed (μ, ν) there will typically be a unique regular hexagon, with a uniquely selected wavenumber κ, that satisfies the condition $\mathcal{H} = 0$. Under appropriate existence and transversality assumptions on the heteroclinic orbits that correspond to such fronts, we can use spatial dynamics to prove the existence of transverse homoclinic orbits, corresponding to planar hexagon pulses with the same selected hexagonal wavenumber, and of complex snaking bifurcation diagrams, and we refer the reader to [10] for details.

For fully localized hexagon patches such as those shown in Figures 1(a) and 4, spatial dynamics may not work: while we can view the radial variable as the evolution variable, it is not clear how appropriate function spaces can be set up that allow for the increasingly finer hexagon structure in the angular variable. Nevertheless, we may formally move along the radial direction from the center of a localized hexagon patch toward infinity and consider the interface between regular hexagons and the trivial state at the patch boundary: if this boundary becomes approximately planar as the patch grows, as seems to be the case for the hexagon patches that we present later in this paper, then we should expect, on a formal level, that the selection principle for hexagon fronts applies to localized patches, too: the existence region of localized hexagon patches should therefore be centered around the Maxwell curve of the planar hexagon fronts between trivial state and regular hexagons. Furthermore, the hexagons inside the hexagon patch should satisfy $\mathcal{H} = 0$, which selects their wavenumber.

So far, we have focused on planar hexagon fronts between the trivial state and regular hexagons as these are relevant for localized hexagon patches. However, other stationary planar hexagon fronts exist, and we outline now how they arise and what their spatial profiles look like. Assume that we found a transversely constructed heteroclinic orbit of (3.7) between

regular hexagons and the trivial state for the parameter values (μ_0, ν_0) and the wavenumber κ_0. If we vary the wavenumber κ near κ_0 while keeping (μ_0, ν_0) fixed, then the assumed transversality implies that the heteroclinic orbit will persist. However, this orbit will now connect the trivial state to frustrated hexagons that have minimal period $\ell = 2\pi/\kappa$ in the y-direction but are slightly compressed or expanded in the x-direction to accommodate the condition $\mathcal{H} = 0$ on the new cross-section $[0, \ell]$. The planar hexagon fronts constructed in this fashion live on the domain $\mathbb{R} \times [0, \ell]$ with periodic boundary conditions in the y-variable. Periodic boundary conditions allow us to view these fronts as planar hexagon fronts on the domains $\mathbb{R} \times [-n\ell, n\ell]$ for arbitrary positive integers n on the plane: the resulting fronts connect the trivial state to frustrated hexagon patterns that are periodic with minimal period ℓ in the transverse y-direction. The corresponding Maxwell curves will depend on ℓ (or κ), and we therefore obtain an entire family of Maxwell curves.

3.3. Regular hexagons. We prove Proposition 2, which states that, for each fixed ν, there is a unique branch of regular hexagons which bifurcate from $u = 0$ at $\mu = 0$ along which the first integral $\mathcal{H}$ from (3.2) vanishes. The wavelength of these selected hexagons may vary along the branch and therefore needs to be treated as an unknown which will adjust itself to satisfy the constraint $\mathcal{H} = 0$. This is a special case of the more general problem of finding solutions to Hamiltonian systems with a prescribed value of the Hamiltonian [9, 14, 18, 69, 75, 76]. Indeed, we prove Proposition 2 by applying the following general bifurcation theorem.

Theorem 3.1 (see [9, Theorem 2.2]). *Let $\mathcal{X}$, $\mathcal{Y}$, and $\mathcal{Z}$ be Banach spaces. Let $\psi \in \mathcal{Z}^*$, $\mathcal{F} \in \mathcal{C}^\omega(\mathcal{X} \times \mathbb{R}^2, \mathcal{Y})$, and $\mathcal{H} \in \mathcal{C}^\omega(\mathcal{X} \times \mathbb{R}^2, \mathcal{Z})$, and consider the equation*

$$\begin{pmatrix} \mathcal{F}(u, \mu, \kappa) \\ \psi(\mathcal{H}(u, \mu, \kappa)) \end{pmatrix} = 0, \tag{3.9}$$

where $u \in \mathcal{X}$ and $(\mu, \kappa) \in \mathbb{R}^2$. We assume that $u = 0$ is a solution of (3.9) for all (μ, κ) with $\mathcal{H}_u(0, \mu, \kappa) \equiv 0$. Furthermore, assume that $\mathcal{F}_u(0, \mu_0, \kappa_0) \in L(\mathcal{X}, \mathcal{Y})$ is Fredholm[4] with index zero with $\mathrm{N}(\mathcal{F}_u(0, \mu_0, \kappa_0)) = \mathbb{R}\hat{u} \neq \{0\}$. We write $\mathcal{X} = \mathbb{R}\hat{u} \oplus \hat{\mathcal{X}}$, $\hat{\mathcal{Y}} := \mathrm{R}(\mathcal{F}_u(0, \mu_0, \kappa_0))$, and $\mathcal{Y} = \mathbb{R}\hat{v} \oplus \hat{\mathcal{Y}}$ and denote by $P : \mathcal{Y} \to \hat{\mathcal{Y}}$ the projection along $\hat{v}$. We assume now that $\psi(\mathcal{H}_{uu}(0, \mu_0, \kappa_0)[\hat{u}, \hat{u}]) = 0$ and that the operator $D \in L(\hat{\mathcal{X}} \times \mathbb{R}^2, \hat{\mathcal{Y}} \times \mathbb{R}^2)$ given by

$$D := \begin{pmatrix} P\mathcal{F}_u(0, \mu_0, \kappa_0) & P\mathcal{F}_{u\mu}(0, \mu_0, \kappa_0)[\hat{u}, 1] & P\mathcal{F}_{u\kappa}(0, \mu_0, \kappa_0)[\hat{u}, 1] \\ 0 & (1-P)\mathcal{F}_{u\mu}(0, \mu_0, \kappa_0)[\hat{u}, 1] & (1-P)\mathcal{F}_{u\kappa}(0, \mu_0, \kappa_0)[\hat{u}, 1] \\ \psi(\mathcal{H}_{uu}[\hat{u}, \cdot]) & \psi(\mathcal{H}_{uu\mu}[\hat{u}, \hat{u}, 1]) & \psi(\mathcal{H}_{uu\kappa}[\hat{u}, \hat{u}, 1]) \end{pmatrix} \tag{3.10}$$

is an isomorphism. Under these assumptions, $(0, \mu_0, \kappa_0)$ is a bifurcation point for (3.9), and there is an interval I containing 0 and a unique analytic branch $(u, \mu, \kappa)(s)$ of solutions of (3.9), defined for $s \in I$, which satisfies $(u, \mu, \kappa)(0) = (0, \mu_0, \kappa_0)$ and $\|u(s) - s\hat{u}\|_{\mathcal{X}} = \mathrm{O}(s^2)$ as $s \to 0$.

We now set up an appropriate framework that allows us to appeal to the preceding theorem to prove Proposition 2. We first rescale (x, y) by setting $x = X/\kappa$ and $y = Y/\kappa$. In the rescaled

[4] A linear operator L is called Fredholm if its null space $\mathrm{N}(L)$ is finite-dimensional, its range $\mathrm{R}(L)$ is closed, and the range $\mathrm{R}(L)$ has finite codimension. In this case, the Fredholm index is defined to be the difference $\dim \mathrm{N}(L) - \operatorname{codim} \mathrm{R}(L)$.

variables, the Swift–Hohenberg equation is given by

$$(1+\kappa^2\Delta)^2 u + \mu u - \nu u^2 + u^3 = 0.$$

We are interested in regular hexagons and therefore seek, as in section 2.2, solutions with $\mathbb{D}_6$-symmetry. In addition, we require that solutions be centered at the origin to reduce the multiplicity of solutions. Thus, we set

$$\begin{aligned}
\mathcal{X} = \Big\{ & u \in \mathcal{C}^4(\mathbb{R}^2,\mathbb{R});\ u(X,Y) = u(X,Y+4\pi/\sqrt{3}) = u(X+2\pi,Y+2\pi/\sqrt{3}),\\
& u(X,Y) = u((X+\sqrt{3}Y)/2,(-\sqrt{3}X+Y)/2) \quad \forall (X,Y) \Big\},\\
\mathcal{Y} = \Big\{ & u \in \mathcal{C}^0(\mathbb{R}^2,\mathbb{R});\ u(X,Y) = u(X,Y+4\pi/\sqrt{3}) = u(X+2\pi,Y+2\pi/\sqrt{3}),\\
& u(X,Y) = u((X+\sqrt{3}Y)/2,(-\sqrt{3}X+Y)/2) \quad \forall (X,Y) \Big\},\\
\mathcal{Z} = {} & \mathcal{C}^0(\mathbb{R},\mathbb{R})
\end{aligned}$$

and define

$$\begin{aligned}
\mathcal{F}(u,\mu,\kappa) &:= (1+\kappa^2\Delta)^2 u + \mu u - \nu u^2 + u^3,\\
\mathcal{H}(u,\mu,\kappa) &:= \int_0^{\frac{4\pi}{\sqrt{3}}} \left[\kappa^4 \left(u_{XXX} u_X - \frac{u_{XX}^2}{2} \right) + \kappa^2 u_X^2 + \frac{(1+\mu)u^2}{2} - \frac{\nu u^3}{3} + \frac{u^4}{4} \right.\\
&\qquad \left. - \kappa^4 u_{XY}^2 - \kappa^2 u_Y^2 + \frac{\kappa^4 u_{YY}^2}{2} \right] \mathrm{d}Y,\\
\psi\mathcal{H}(u,\mu,\kappa) &:= \mathcal{H}(u,\mu,\kappa)\big|_{X=0}.
\end{aligned}$$

The required regularity assumptions are then met, and it is clear that $u=0$ is a solution for all (μ,κ) with $\mathcal{H}_u(0,\mu,\kappa) \equiv 0$. We calculate the derivatives

$$\begin{aligned}
\mathcal{F}_u(0,\mu,\kappa)[v] &= (1+\kappa^2\Delta)^2 v + \mu v,\\
\mathcal{F}_{u\mu}(0,\mu,\kappa)[v] &= v,\\
\mathcal{F}_{u\kappa}(0,\mu,\kappa)[v] &= 4\kappa^3\Delta^2 v + 2\kappa\Delta v,\\
\mathcal{H}_{uu}(0,\mu,\kappa)[v,w] &= \int_0^{\frac{4\pi}{\sqrt{3}}} [\kappa^4(v_X w_{XXX} + v_{XXX} w_X - v_{XX} w_{XX}) + 2\kappa^2 v_X w_X + (1+\mu) vw\\
&\qquad - 2\kappa^4 v_{XY} w_{XY} - 2\kappa^2 v_Y w_Y + \kappa^4 v_{YY} w_{YY}]\,\mathrm{d}Y,\\
\mathcal{H}_{uu\mu}(0,\mu,\kappa)[v,w] &= \int_0^{\frac{4\pi}{\sqrt{3}}} vw\,\mathrm{d}Y,\\
\mathcal{H}_{uu\kappa}(0,\mu,\kappa)[v,w] &= \int_0^{\frac{4\pi}{\sqrt{3}}} [4\kappa^3(v_X w_{XXX} + v_{XXX} w_X - v_{XX} w_{XX}) + 4\kappa v_X w_X\\
&\qquad - 8\kappa^3 v_{XY} w_{XY} - 4\kappa v_Y w_Y + 4\kappa^3 v_{YY} w_{YY}]\,\mathrm{d}Y.
\end{aligned}$$

The analysis reviewed in section 2.2 implies that we should pick $(\mu_0,\kappa_0) = (0,1)$, for which $\mathcal{F}_u(0,0,1)$ has a one-dimensional null space spanned by

$$\hat{u}(X,Y) = \cos(X) + \cos((X+\sqrt{3}Y)/2) + \cos((X-\sqrt{3}Y)/2).$$

We may set $\hat{v} := \hat{u}$ and use the L^2-inner product on the fundamental periodicity domain $[0, 4\pi] \times [0, 4\pi/\sqrt{3}]$ to define complements $\hat{\mathcal{X}}$ and $\hat{\mathcal{Y}}$ of $\mathbb{R}\hat{u}$ in $\mathcal{X}$ and $\mathcal{Y}$, as $\mathcal{F}_u(0, 0, 1)$ is symmetric with respect to this inner product.

Substituting these expressions, we find that $\mathcal{H}_{uu}(0, 0, 1)[\hat{u}, \hat{u}] = 0$. Furthermore, we find that the operator D defined in (3.10) is given by

$$D = \begin{pmatrix} P\mathcal{F}_u(0,0,1) & 0 & 0 \\ 0 & 1 & 2 \\ \star & 4\pi\sqrt{3} & -8\pi\sqrt{3} \end{pmatrix} \in L(\hat{\mathcal{X}} \times \mathbb{R}^2, \hat{\mathcal{Y}} \times \mathbb{R}^2).$$

In particular, this operator is invertible, and we obtain the following result, which is formulated again in the original spatial variables.

Proposition 3 ($\mathcal{L}$-periodic hexagons with $\mathcal{H} = 0$). *Fix any ν; then there exist an interval $I \subset \mathbb{R}$ and a unique branch $s \mapsto (u, \mu, \kappa)(s)$ of nontrivial $\mathcal{L}$-periodic hexagons of the Swift–Hohenberg equation (3.1) with zero constraint (3.8) and aspect ratio $\kappa(s)$, which are defined and smooth for $s \in I$. Moreover, $(u, \mu, \kappa)(0) = (0, 0, 1)$ and*

(3.11)
$$\Big\| [u(s)](x,y) - s\Big[\cos(\kappa(s)x) + \cos(\kappa(s)(x + \sqrt{3}y)/2) + \cos(\kappa(s)(x - \sqrt{3}y)/2)\Big] \Big\|_{\mathcal{C}^4} = \mathrm{O}(s^2)$$

as $s \to 0$.

For $\nu > 0$, (2.7) and (3.11) imply that $\mu(s) > 0$ for all sufficiently small $s > 0$, as claimed in Proposition 2.

4. Numerical algorithms.

In this section, we describe the numerical algorithms, and their implementation, that we used to compute regular hexagons, planar hexagon pulses, and localized hexagon patches.

Though we will rely on continuation methods for most of our computations, we shall also occasionally employ an initial value problem solver, which we discuss first. Afterward, we outline the computation of regular hexagons and the associated hexagon Maxwell curve. This information will guide us as to where we may find hexagon pulses and localized hexagon structures in the Swift–Hohenberg equation. We then move on to the computation of planar hexagon pulses that are periodic in the transverse direction. Last, we present the numerical methods for the computation of localized hexagon patches: these methods are designed to take advantage of the $\mathbb{D}_6$-symmetry of localized structures and allow us to compute localized structures that extend over large spatial regions. The computations of localized hexagon patches were also repeated with other methods to check the reliability of the numerical results.

The actual computations were carried out on FINCH, a dual core 2.7 GHz PowerPC G5 with 4GB of RAM, and PHOENIX, a server with two 3GHz dual core Xeon processors with 8GB of RAM, both running Mac OS 10.4.

4.1. The initial value problem solver.

To quickly find solutions of the Swift–Hohenberg equation, investigate the stability of patterns with respect to small symmetry-breaking perturbations, and confirm the solutions obtained from our other numerical solvers, we employ an initial value problem solver for the Swift–Hohenberg equation (1.1), which we shall now discuss briefly. First, we use the 2D Fourier transform to reduce the initial value problem

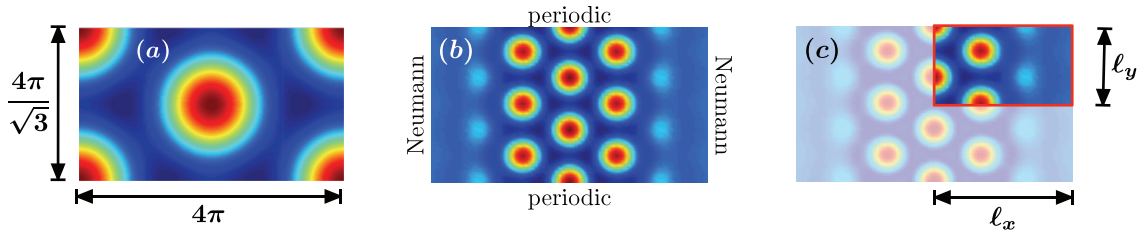

Figure 13. *Regular hexagons are computed with Neumann boundary conditions on the domain* $\Omega_{\rm hex}$ *shown in panel* (a). *Reflection-symmetric planar hexagon pulses are defined on the domain shown in panel* (b) *with Neumann conditions in the horizontal* x*-direction and periodic boundary conditions in the vertical* y*-direction. Panel* (c) *illustrates the computational domain* $\Omega = (0, \ell_x) \times (0, \ell_y)$ *with Neumann conditions.*

on a rectangular box with periodic boundary conditions to a system of ODEs. The resulting ODE system is truncated at a sufficiently large Fourier mode and solved in time using the first-order exponential time-stepping algorithm developed in [27]. We implemented this solver in MATLAB. Computations are done on domains of size 60×60 with 256×256 and 512×512 Fourier modes. Typical time steps are 0.01 and 0.001.

4.2. Regular hexagons and Maxwell curves. To find regular hexagons, we proceed initially as in section 3.3. It has been shown in [62, 61] that regular hexagons can be computed in a rectangular box with Neumann boundary conditions provided the ratio of the lengths of the sides of the rectangle is an integer multiple of $\sqrt{3}$. Thus, we introduce new independent coordinates $X = \kappa x$ and $Y = \kappa y$ and use the rescaled Swift–Hohenberg equation

$$\mathcal{F}(u; \mu, \nu, \kappa) = (1 + \kappa^2 \Delta)^2 u + \mu u - \nu u^2 + u^3 = 0, \qquad (X, Y) \in \Omega_{\rm hex} \tag{4.1}$$

on the computational domain $\Omega_{\rm hex} = (0, 4\pi) \times (0, 4\pi/\sqrt{3})$ with Neumann boundary conditions; see Figure 13(a).

For the computation of Maxwell curves, we add the constraints

$$\mathcal{H}(u; \mu, \nu, \kappa) = \int_0^{\frac{4\pi}{\sqrt{3}}} \left[-\frac{\kappa^4 (u_{XX})^2}{2} + \frac{(1+\mu)u^2}{2} - \frac{\nu u^3}{3} + \frac{u^4}{4} - \kappa^2 (u_Y)^2 + \frac{\kappa^4 (u_{YY})^2}{2} \right]_{X=0} \mathrm{d}Y = 0, \tag{4.2}$$

which ensures that the first integral $\mathcal{H}$ vanishes, and

$$\mathcal{E}(u; \mu, \nu, \kappa) = \int_{\Omega_{\rm hex}} \left[\frac{[(1 + \kappa^2 \Delta)u]^2}{2} + \frac{\mu u^2}{2} - \frac{\nu u^3}{3} + \frac{u^4}{4} \right] \mathrm{d}X \, \mathrm{d}Y = 0, \tag{4.3}$$

which enforces zero energy. Note that several terms in the original expression (3.2) for $\mathcal{H}$ vanish on account of the Neumann conditions $u_X(0, Y) = u_{XXX}(0, Y) = 0$. The choice of our computational domain means that we accurately compute the energy of two full hexagons in (4.3); see Figure 13(a).

We expect that the equation $\mathcal{F}(u; \mu, \nu, \kappa) = 0$ has a locally unique regular zero u for each fixed (μ, ν, κ) in appropriate regions[5] in parameter space. We can also use (4.1) together with

[5]For instance, for μ close to zero, due to the results in section 2.2; see also Proposition 3.

the constraints (4.2)–(4.3) in a numerical continuation framework where we expect to find a curve of solutions (u, μ, ν, κ) that depend on an arclength parameter s. Since the resulting Maxwell curves do not exhibit any folds in the parameter μ, we can, in fact, compute this curve by stepping in the parameter μ.

For the actual computations, we evaluate derivatives using spectral differentiation as in [87, sect. 3] and compute the integrals in the constraints (4.2)–(4.3) using the periodic trapezoid rule [87, sect. 12]. We now briefly outline how this is done in our context. We choose the mesh $X_i = 4\pi i/N$ and $Y_j = 4\pi j/N\sqrt{3}$ for $i, j = 1, \dots N$ and write $u_{ij} = u(X_i, Y_j)$ on this mesh. A convenient way of evaluating first-order derivatives and the Laplacian is via Kronecker products: if A is an $m \times n$ matrix and B is a $p \times q$ matrix, then the Kronecker product $A \otimes B$ is an $mp \times nq$ matrix which consists of $m \times n$ blocks, where each block is a $p \times q$ matrix. The (i, j)th block is given by $a_{ij}B$. Introducing the step size $h = 2\pi/N$, the spectral differentiation matrices for functions of one variable are given by

$$D_N = \text{toeplitz}\left[0, \left(\frac{(-1)^j}{2\tan(jh/2)}\right)_{j=1,\dots,N-1}\right]$$

for the first derivative and by

$$D_N^{(2)} = \text{toeplitz}\left[-\frac{\pi^2}{3h^2} - \frac{1}{6}, \left(-\frac{(-1)^j}{2\sin^2(jh/2)}\right)_{j=1,\dots,N-1}\right]$$

for the second derivative [87, sect. 3], where toeplitz$[v]$ denotes the symmetric Toeplitz matrix (a matrix whose entries are constant along each diagonal) formed by the row vector $v \in \mathbb{R}^N$. Using Kronecker products, we can now set up the $N^2 \times N^2$ differentiation matrices for $u(X, Y)$ which are given by

$$D_{X,N} = I \otimes \left(\frac{1}{4}\right) D_N, \quad D_{Y,N} = \left(\frac{\sqrt{3}}{4}\right) D_N \otimes I, \quad \Delta_N = I \otimes \left(\frac{1}{4}\right)^2 D_N^{(2)} + \left(\frac{\sqrt{3}}{4}\right)^2 D_N^{(2)} \otimes I,$$

corresponding, respectively, to the first-order derivatives ∂_X and ∂_Y and to the Laplacian Δ.

The above procedure results in a finite-dimensional system. We solve this system in MATLAB using the nonlinear Newton trust-region solver FSOLVE. For (μ, ν) close to zero, we choose

$$u(X, Y) = A[\cos(X) + \cos((X + \sqrt{3}Y)/2) + \cos((X - \sqrt{3}Y)/2)]$$

as an initial guess, where a good approximation for the amplitude A can be obtained from normal-form theory by solving (2.7). MATLAB's Newton trust-region solver has the advantage of often achieving global convergence even when starting from poor initial guesses. We have frequently obtained better convergence by solving initially only the Swift–Hohenberg equation, without the integral constraints (4.2)–(4.3), with $\kappa = 1$ and ν fixed. Afterward, using this solution as initial data, we solve the Swift–Hohenberg equation together with one or both of the integral constraints by including one or two of the parameters κ and ν as unknowns. Once we have a solution to (4.1)–(4.3), we continue it in μ by stepping in the parameter μ and solving (4.1)–(4.3) for (u, ν, κ) for each fixed μ. We use $18 \cdot 18 = 324$ interpolation points in the box $\Omega_{\text{hex}} = (0, 4\pi) \times (0, \frac{4\pi}{\sqrt{3}})$ and compute solutions within an absolute tolerance of 10^{-4}. The entire Maxwell curve was computed in a couple of minutes.

4.3. Numerical continuation of planar hexagon pulses. In this section, we discuss the computation of stationary planar hexagon pulses with Bravais–Miller indices $\langle 10\rangle$ and $\langle 11\rangle$ such as those shown in Figure 3. The interfaces in these solutions are vertical, and the overall patterns are periodic in the transverse y-direction and reflection symmetric.

Hence, we will focus on computing stationary solutions $u(x,y)$ of the planar Swift–Hohenberg equation that are periodic in the y-direction and are symmetric under reflections in x and y so that $u(-x,y) = u(x,y) = u(x,-y)$ for all (x,y). These solutions therefore satisfy

$$(1+\Delta)^2 u + \mu u - \nu u^2 + u^3 = 0, \qquad (x,y) \in \Omega, \tag{4.4}$$

on $\Omega = (0,\ell_x)\times(0,\ell_y)$ with Neumann boundary conditions

$$u_x|_{\{x=0,\ell_x\}} = u_{xxx}|_{\{x=0,\ell_x\}} = u_y|_{\{y=0,\ell_y\}} = u_{yyy}|_{\{y=0,\ell_y\}} = 0 \tag{4.5}$$

on $\partial\Omega$; see Figure 13. We need to choose ℓ_x large enough to avoid boundary effects (we used $\ell_x = 50$), while ℓ_y is chosen in such a way as to accommodate hexagon interfaces with $\langle 10\rangle$ or $\langle 11\rangle$ orientation: we pick $\ell_y = 4\pi n/\sqrt{3}$ for interfaces with index $\langle 10\rangle$ and $\ell_y = 2\pi n$ for interfaces with index $\langle 11\rangle$. The choice of $n \in \mathbb{N}$ allows us to compute patterns for several wavelengths in the vertical y-direction.

Fixing the length ℓ_y of the domain in the y-direction may frustrate the hexagons: since regular hexagons can no longer choose their wavenumber freely to satisfy the constraint $\mathcal{H} = 0$, the patterned state will typically consist of frustrated hexagons that have a fixed period ℓ_y/N in the y-variable for some integer N to accommodate the fixed length in the y-direction, while their wavelength in the x-direction adjusts itself to satisfy the constraint $\mathcal{H} = 0$; the resulting frustrated hexagons are therefore slightly compressed or elongated in the x-direction and no longer $\mathbb{D}_6$-symmetric. We could add the constraint (4.2) and allow ℓ_y to vary so that regular hexagons always fit into the domain. Since we have found that the regular hexagons for which $\mathcal{H} = 0$ have wavenumbers κ very close to $\kappa = 1$, we believe that the effect of fixing ℓ_y on the selected patterns is negligible. However, the snaking limits of the planar hexagon pulses may coincide better with the snaking limits of the localized hexagon patches had we elected to allow ℓ_y to vary.

To solve (4.4)–(4.5) numerically, we used a 13-point finite difference stencil for the spatial discretization. We implemented the resulting system in the continuation framework PARACONT [7], a module built on top of the continuation module LOCA of the package Trilinos, which is written and maintained by Sandia Laboratories [43]. Since Trilinos does not currently offer a direct solver for LOCA that works on parallel processors, we employed a multilevel preconditioner on a coarse level so that an exact sparse linear solve is done. The computations were carried out on the domain $\Omega = (0,\ell_x)\times(0,\ell_y)$ with $\ell_x = 50$. We used $\ell_y = 20\pi/\sqrt{3}$ for $\langle 10\rangle$ pulses and $\ell_y = 10\pi$ for $\langle 11\rangle$ pulses and worked with both 128×256 and 256×256 mesh points for both computations.

We remark that localized pulses on long cylinders $(0,\ell_x)\times S^1$ have been computed previously in the von Karman–Donnell equations, a coupled system of elliptic PDEs that describe equilibria of axially compressed cylindrical shells [46, 59]. The approach adopted there was to carry out a Fourier decomposition in the angular direction leading to a large system of ODEs that were solved with the boundary-value solver AUTO97.

4.4. Numerical continuation of localized hexagon patches. We now turn to the computation and continuation of planar localized hexagon patches such as the ones presented in Figures 1(a) and 4. We focus on the computation of patterns with $\mathbb{D}_6$-symmetry. Since we found that sparse Cartesian meshes give a preference to $\mathbb{D}_4$-symmetric square patterns, we discretize the planar Swift–Hohenberg equation in polar coordinates. In particular, we found that a spectral Fourier discretization in the angular coordinate combined with an adaptive collocation mesh in the radial coordinate appears to be a very efficient method for computing localized hexagon patches.

In the following, we will outline our approach for computing localized patterns with an arbitrary $\mathbb{D}_{2k}$-symmetry.[6] Restricting ourselves to solutions with $\mathbb{D}_{2k}$-symmetry allows us to compute them on the first quadrant $\Omega = \{x, y > 0\}$ with Neumann boundary conditions, which is advantageous for various reasons. First, it factors out, in a natural fashion and without the need for introducing additional constraints, the continuous translation and rotation symmetries in $\mathbb{E}(2)$ of the Swift–Hohenberg equation, whose presence would otherwise yield a singular Jacobian, which is problematic for Newton solvers. Second, computing solely on the first quadrant greatly reduces the size of the discretized system. Third, as already mentioned, we can center localized solutions at the origin and compute efficiently in polar coordinates. The main disadvantage of computing on the first quadrant is that temporal stability cannot be deduced and bifurcations to $\mathbb{D}_{2k+1}$ patterns cannot be detected. Overall, we believe that the advantages outweigh the disadvantage of potentially failing to detect instabilities during continuation as these can often be identified a posteriori by direct numerical simulations.

We therefore consider the stationary planar Swift–Hohenberg equation

$$(1 + \Delta_{r,\theta})^2 u + \mu u - \nu u^2 + u^3 = 0 \tag{4.6}$$

written in polar coordinates $(r, \theta) \in (0, \infty) \times [0, 2\pi)$, where

$$\Delta_{r,\theta} u = u_{rr} + \frac{u_r}{r} + \frac{u_{\theta\theta}}{r^2}.$$

Polar coordinates are singular at $r = 0$, and we need to find appropriate boundary conditions at the origin to remove this singularity. To do this, we follow [84]. Assuming that u is a sufficiently localized solution, we multiply (4.6) by another localized function v and subsequently integrate over (r, θ) to arrive at the weak formulation

$$\begin{aligned} &\int_0^{2\pi}\int_0^{\infty} \left[\Delta u \Delta v - 2\nabla u \nabla v + (1+\mu)uv - \nu u^2 v + u^3 v\right] r \,\mathrm{d}r \,\mathrm{d}\theta \\ &= \int_0^{2\pi}\int_0^{\infty} \left[\left(\frac{(ru_r)_r}{r} + \frac{u_{\theta\theta}}{r^2}\right)\left(\frac{(rv_r)_r}{r} + \frac{v_{\theta\theta}}{r^2}\right) - 2\left(u_r v_r + \frac{u_\theta v_\theta}{r^2}\right)\right. \\ &\qquad \left. + (1+\mu)uv - \nu u^2 v + u^3 v\right] r \,\mathrm{d}r \,\mathrm{d}\theta = 0 \end{aligned} \tag{4.7}$$

of (4.6). The boundary conditions at $r = 0$ which make the bilinear form (4.7) meaningful are

$$u_r|_{(0,\theta)} = (ru_r)_r|_{(0,\theta)} = u_\theta|_{(0,\theta)} = u_{\theta r}|_{(0,\theta)} = u_{\theta\theta}|_{(0,\theta)} = (u_{\theta\theta})_r|_{(0,\theta)} = 0 \qquad \forall \theta \in [0, 2\pi).$$

[6] This method can be extended to localized $\mathbb{D}_{2k+1}$-symmetric patterns, but we do not go into the details here.

Since $(ru_r)_r = ru_{rr} + u_r$, the conditions above reduce to

$$u_r(0,\theta) = u_{\theta\theta}(0,\theta) = u_{\theta\theta r}(0,\theta) = 0 \qquad \forall \theta \in [0, 2\pi). \tag{4.8}$$

We now expand $u(r,\theta)$ in a Fourier series which we truncate at order $N \in \mathbb{N}$ to get a finite-dimensional system. Thus, we set

$$u(r,\theta) = \sum_{n=-N}^{N} a_n(r) \mathrm{e}^{-\mathrm{i}n\theta}, \tag{4.9}$$

where N is the truncation order, and $a_n(r)$ is complex-valued for each n. The Laplacian becomes

$$\Delta_{r,\theta} u = \sum_{n=-N}^{N} \left[\partial_r^2 a_n + \frac{\partial_r a_n}{r} - \frac{n^2 a_n}{r^2} \right] \mathrm{e}^{-\mathrm{i}n\theta}.$$

Substituting these expressions, we find that the truncated planar Swift–Hohenberg equation (4.6) can be written as

$$\begin{aligned} &\partial_r^4 a_n + \frac{2\partial_r^3 a_n}{r} - \frac{\partial_r^2 a_n}{r^2} + \frac{\partial_r a_n}{r^3} - \frac{2n^2 \partial_r^2 a_n}{r^2} + \frac{2n^2 \partial_r a_n}{r^3} - \frac{4n^2 a_n}{r^4} + \frac{n^4 a_n}{r^4} \\ &+ 2\left(\partial_r^2 a_n + \frac{\partial_r a_n}{r} - \frac{n^2 a_n}{r^2} \right) + (1+\mu) a_n - \nu \sum_{p+q=n} a_p a_q + \sum_{p+q+s=n} a_p a_q a_s = 0, \end{aligned} \tag{4.10}$$

while the boundary conditions (4.8) at the origin reduce to

$$\begin{aligned} \partial_r a_0\big|_{r=0} = \partial_r^3 a_0\big|_{r=0} = 0, \\ a_n\big|_{r=0} = \partial_r a_n\big|_{r=0} = 0 \qquad \forall n \neq 0. \end{aligned}$$

Solutions $u(r,\theta)$ with $\mathbb{D}_{2k}$-symmetry are invariant under the reflection $\theta \mapsto -\theta$ and the rotation $\theta \mapsto \theta - \pi$ so that

$$u(r,\theta) = u(r,-\theta) \quad \text{and} \quad u(r,\theta) = u(r,\theta-\pi)$$

for all (r,θ). These identities imply that

$$a_n = a_{-n} \quad \text{and} \quad a_n = (-1)^n a_n \quad \forall n,$$

for the coefficients $a_n(r)$ of the Fourier representation (4.9) of u. The first of these two conditions implies that we need to compute the coefficients a_n only for $n \geq 0$, while the second condition implies that all odd Fourier coefficients a_{2n+1} must vanish identically. The two summations in (4.10) can then be simplified by noting that

$$\begin{aligned} \sum_{p+q=n} a_p a_q &= \sum_{p=-N}^{N} a_{|p|} a_{|n-p|}, \\ \sum_{p+q+s=n} a_p a_q a_s &= \sum_{p=-N}^{N} \sum_{q=-N}^{N} a_{|p|} a_{|q|} a_{|n-p-q|}. \end{aligned}$$

So far, we have considered solutions with an arbitrary $\mathbb{D}_{2k}$-symmetry. From now on, we restrict ourselves to solutions with $\mathbb{D}_6$-symmetry, such as hexagons. Such solutions are in addition invariant under rotations by an angle of $\pi/3$, which is equivalent to requiring that

$$a_n = \mathrm{e}^{\mathrm{i}n\pi/3} a_n \qquad \forall n.$$

The only nonzero modes that can satisfy this constraint are those for which $n = 6m$ for some $m \in \mathbb{Z}$. Hence, for the purpose of computing localized $\mathbb{D}_6$-symmetric solutions, we need to consider only the Fourier modes $a_{6m}(r)$: note that the space spanned by these modes is the fixed-point space under the $\mathbb{D}_6$-action and therefore invariant under the evolution of (4.10). Thus, we set

$$A_m(r) := a_{6m}(r), \qquad |m| \le M,$$

with $N = 6M$ and write (4.10) as the first-order system

$$\begin{aligned}
\partial_r A_m &= B_m,\\
\partial_r B_m &= C_m,\\
\partial_r C_m &= D_m,\\
\partial_r D_m &= -\frac{2D_m}{r} + \frac{C_m}{r^2} - \frac{B_m}{r^3} + \frac{2(6m)^2 C_m}{r^2} - \frac{2(6m)^2 B_m}{r^3}\\
&\quad + \frac{4(6m)^2 A_m}{r^4} - \frac{(6m)^4 A_m}{r^4}\\
&\quad - 2\left(C_m + \frac{B_m}{r} - \frac{(6m)^2 A_m}{r^2}\right) - (1+\mu) A_m\\
&\quad + \nu \sum_{p=-M}^{M} A_{|p|} A_{|m-p|} - \sum_{p=-M}^{M} \sum_{q=-M}^{M} A_{|p|} A_{|q|} A_{|m-p-q|}
\end{aligned} \tag{4.11}$$

with boundary conditions

$$\begin{aligned}
\partial_r A_0\big|_{r=0} = D_0\big|_{r=0} &= 0,\\
A_m\big|_{r=0} = C_m\big|_{r=0} &= 0 \qquad \forall m \neq 0,\\
A_m\big|_{r=R} = B_m\big|_{r=R} &= 0 \qquad \forall m,
\end{aligned} \tag{4.12}$$

where R indicates the radial domain $(0, R)$ on which we compute solutions.

Both the domain truncation parameter R and the Fourier truncation parameter M must be set to suitably large values to ensure that the Neumann boundary conditions at $r = R$ do not influence the localized patterns and to make sure that the Fourier modes can resolve the angular dependence of the computed patterns. Close to $(\mu, \nu) = 0$, the localized patterns are small in amplitude but are also well spread out: this requires both R and M to be large. Specifically, we expect that the number of Fourier modes required to resolve a localized hexagon patch corresponds roughly to the number of hexagon rings one wishes to interpolate: if we wish to compute a hexagon patch of radius R, then it will have approximately R hexagons, or more, located on its interface. To resolve these R hexagons, we need at least $M \approx R$ Fourier modes in the angular variable, and this is indeed what we find in our numerical computations.

A major problem is acquiring good initial data for continuation. We use two different methods for preparing good initial guesses for the boundary-value problem (4.11)–(4.12). The first method is to use an initial value problem solver and find a stable stationary localized hexagon patch by direct numerical simulations: as we can first compute the Maxwell curve, we do know where to look for stable hexagon patches. Our experience was, however, that convergence to stationary solutions tends to be very slow. Instead, we have found that it is better to discretize the boundary-value problem (4.11)–(4.12) in the radial variable using a Chebyshev decomposition with an infinite mapping in the radial coordinate r that bunches the collocation points near the origin, as in [57]. We then use MATLAB's Newton trust-region solver FSOLVE starting from initial data of the form

$$u(x,y) = a\,\mathrm{sech}(b\sqrt{x^2+y^2})\left[\cos(x)+\cos((x+\sqrt{3}y)/2)+\cos((x-\sqrt{3}y)/2)\right],$$

where a is chosen to be close to or greater than the maximum height of a single hexagon cell and b determines the size of the localized hexagon patch. This procedure gives excellent convergence results and allows us to obtain accurate starting data for subsequent continuation in parameters.

As already mentioned, initial data for hexagon patches were computed using MATLAB's Newton trust-region solver. To continue these solutions, we implemented the boundary-value problem (4.11)–(4.12) in AUTO-07P [34]. Within AUTO-07P, we computed the L^2-norm of solutions by appending an additional equation together with another parameter that corresponds to the value of the L^2-norm of a solution; we exclude this additional equation from the calculation of the pseudoarclength. The Jacobian of the right-hand side of (4.11) was supplied in analytic form to speed up the computation. We use standard AUTO-07P tolerances and choose the collocation mesh size NTST between 200 and 400. The radial domain truncation parameter R was set to $R = 80, 100, 200$, while the number of angular Fourier modes was taken to be $M = 20, 30, 40$. The computation of the full hexagon snake took up to one day on PHOENIX.

Hexagon patches have been computed previously in [63] in the context of nonlinear optics. In fact, the authors there computed and continued several different localized states and traced out the beginning of the snaking diagram. They discretized the underlying PDE on an equidistant mesh, used the fast Fourier transform for evaluating the spatial derivatives, and solved the resulting large system of algebraic equations using Newton's method. This method tends to be computationally expensive (their computations required the use of 300 servers with 500MHz processors) since the mesh requires a large number of modes even in the tails of the localized pattern.

5. Localized hexagon and rhomboid patches: Numerical results.

In this section, we present our numerical results. We emphasize that the computational domains of numerical solutions are typically much larger than the domains visible in the figures presented below as we frequently cropped images to highlight the features of the localized patterns.

5.1. Regular hexagons and Maxwell curves.

We first compute regular hexagons of the planar Swift–Hohenberg equation that satisfy $\mathcal{H} = 0$ as solutions to (4.1)–(4.2) with $\nu = 1.6$. As discussed in section 3, only these hexagons can be connected to the trivial state by a

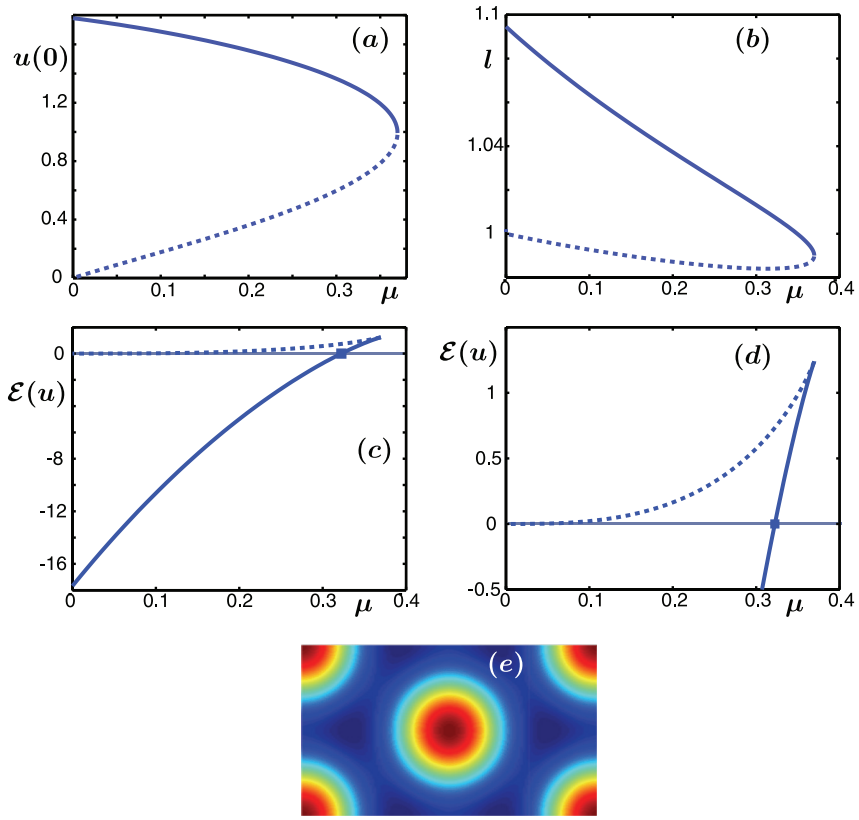

Figure 14. *We computed regular hexagons with $\mathcal{H} = 0$ as solutions of (4.1)–(4.2) with $\nu = 1.6$. Stable hexagons are plotted in solid lines, and unstable ones are plotted in dashed lines. We plot the amplitude $u(0,0)$ at the origin in panel* (a)*, the wavelength $l = 1/\kappa$ of the hexagons in* (b)*, and the energy $\mathcal{E}(u)$ along the branch in* (c)–(d)*. The Maxwell point $\mathcal{E}(u) = 0$ occurs at $\mu = \mu_{\rm M} = 0.3224$ on the stable branch. Compared with the trivial state, stable regular hexagons have less energy to the left and higher energy to the right of the Maxwell point. Panel* (e) *contains a color plot of the regular hexagons $u(x, y)$ on the domain $[0, 4\pi l] \times [0, 4\pi l/\sqrt{3}]$ at the Maxwell point.*

stationary planar front. The bifurcation diagram shown in Figure 14(a) is qualitatively similar to that found in section 2.2 in the normal-form analysis for $|\nu| \ll 1$: regular hexagons bifurcate off the trivial solution at $\mu = 0$ and are initially unstable but regain stability in a saddle-node bifurcation. Figure 14(b) contains a plot of the wavelength $l := 1/\kappa$ of the hexagons with $\mathcal{H} = 0$ as μ is varied. The energy $\mathcal{E}(u)$ of these hexagons, computed over two hexagons, is shown in Figure 14(c)–(d) as a function of μ. In particular, the Maxwell point, where $\mathcal{E} = 0$, occurs at $\mu = \mu_{\rm M} = 0.3224$, and we plot the computed hexagon at the Maxwell point in Figure 14(e). We remark that the dependence of the wavelength and the energy on the parameter μ is qualitatively similar for hexagons and 1D rolls; see Figure 5(iii)–(iv) or [19, Figure 2] for results on rolls.

Next, we solve (4.1)–(4.3) for (u, μ, ν, κ), which gives the hexagon Maxwell curve along which hexagons with zero energy $\mathcal{E} = 0$ and zero first integral $\mathcal{H} = 0$ exist. As discussed in section 3, this curve serves as a guide to where hexagon fronts and pulses as well as fully

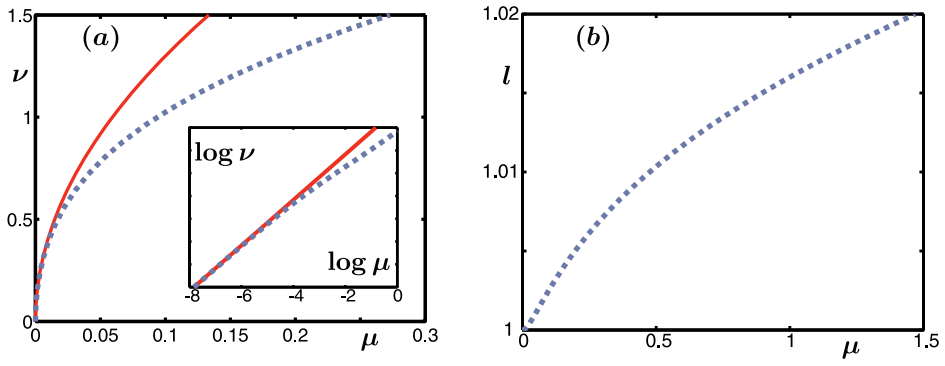

Figure 15. *In panel* (a)*, we plot the Maxwell curve along which the regular hexagons of* (4.1) *satisfy the constraints* $\mathcal{H} = 0$ *and* $\mathcal{E} = 0$ *from* (4.2) *and* (4.3)*, respectively: The numerical result is dashed, while the analytic prediction* $\mu = \mu_{\mathrm{M}} = 8\nu^2/135$*, valid in the limit* $\nu \to 0$*, is plotted as a solid line. Panel* (b) *gives the wavelength* $l = 1/\kappa$ *of the corresponding hexagons.*

localized hexagon patches can be expected. In Figure 15, we plot both the hexagon Maxwell curve in (μ, ν)-parameter space and the dependence of the wavelength $l = 1/\kappa$ of the selected hexagons on the parameter μ. As predicted by the theory outlined in section 2.3, the Maxwell curve emerges from the codimension-two point $(\mu, \nu) = (0, 0)$ and agrees well with the analytic prediction $\mu_{\mathrm{M}} = 8\nu^2/135$ given in (2.12). The wavelength of the hexagons increases along the Maxwell curve. We remark that, for $0 \leq \mu \leq 0.6$, the Maxwell curve agrees well with the curve obtained from setting $\mathcal{E} = 0$ and allowing arbitrary values for $\mathcal{H}$ while keeping $\kappa = 1$ fixed (we do not show a comparison of these curves though).

As shown in Figure 14(d), stable regular hexagons have less energy than the trivial state to the left of the Maxwell curve and higher energy to its right. Thus, we expect that hexagons will invade the trivial state for μ sufficiently far to the left of the Maxwell curve, while the trivial state will invade hexagons for μ sufficiently far to its right.

5.2. Planar hexagon pulses: Bifurcation diagram for $\nu = 1.6$. Throughout this section, we fix $\nu = 1.6$ and recall that the hexagon Maxwell point is given by $\mu = 0.3224$.

We compute planar hexagon pulses of the Swift–Hohenberg equation with Bravais–Miller indices $\langle 10 \rangle$ and $\langle 11 \rangle$. Example plots of these solutions for $\mu = 0.31$ are given in Figure 3. Since we fixed the computational domain in these computations, all hexagons are slightly compressed by the same fraction in the y-direction instead of being fully $\mathbb{D}_6$-symmetric: each vertical slice $u(x, \cdot)$ of the planar hexagon pulse $u(x, y)$ must satisfy $\mathcal{H} = 0$ for each x, and since regular hexagons cannot adjust their wavelength in the y-direction to accommodate this condition due to the fixed domain dimension, the selected patterns are slightly frustrated hexagons. The frustrated hexagons are still periodic in both the x- and the y-directions, but their wavelengths in the x- and y-directions are no longer in a $\sqrt{3} : 1$ ratio as those of regular hexagons.

Upon varying μ, we find that planar $\langle 10 \rangle$ hexagon pulses snake as shown in Figure 16. Upon passing through a pair of fold bifurcations, the pulses acquire an additional full column of hexagons and thereby widen in the horizontal x-direction. As outlined in section 3.2, we can consider the planar Swift–Hohenberg equation as a dynamical system in an unbounded

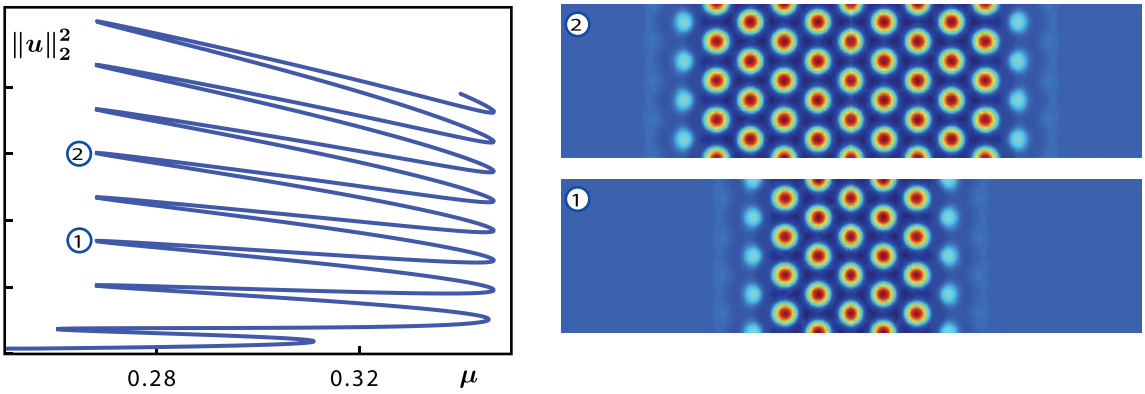

Figure 16. *The left panel contains the bifurcation diagram of planar* $\langle 10 \rangle$ *hexagon pulses, while two selected profiles at the labeled parameter values are shown in the right two panels.*

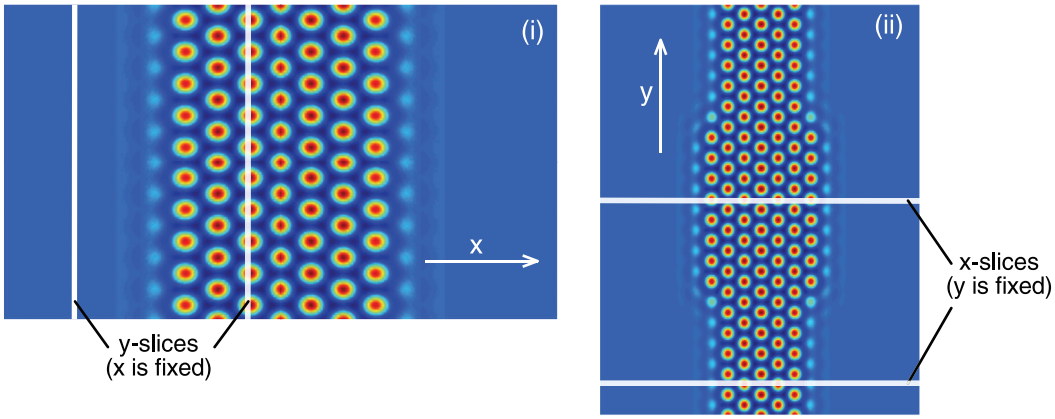

Figure 17. *Panel* (i) *contains a color plot of a planar* $\langle 10 \rangle$ *hexagon pulse. We view* x *as the evolution variable which is used to evolve* y*-slices forward and backward: The left* y*-slice corresponds to an equilibrium of the resulting spatial dynamical system in* x *(the profile in the* y*-slice does not change when* x *is varied nearby), while the* y*-slice in the hexagon region corresponds to a periodic orbit (the profile changes periodically in* x *when the* y*-slice is moved to the left and right). Thus, we can interpret a planar* $\langle 10 \rangle$ *hexagon pulse as a homoclinic orbit that passes close to a periodic orbit which is formed of hexagons, and we therefore expect snaking on account of the results in sections 2.1 and 3.2. Panel* (ii) *contains a color plot of an almost-planar hexagon pulse. Here, we view* y *as the evolution variable which propagates* x*-slices up- and downward. The two indicated* x*-slices correspond to two different periodic orbits: Their profiles change periodically when* y *is varied, but the horizontal extent of the hexagon regions is different for the two profiles. We can therefore interpret an almost-planar hexagon pulse as a homoclinic orbit in the* y*-dynamics which connects the periodic orbit at the top and bottom to itself and which passes near a second periodic orbit. The results in sections 2.1 and 3.2 imply again that snaking should occur.*

direction provided we restrict ourselves to a bounded cross-section in the remaining spatial variable. To explain the snaking of planar $\langle 10 \rangle$ pulses, we treat the x-variable as our time-like variable and restrict y to a bounded interval with Neumann boundary conditions. As can be seen from Figure 17(i), a planar hexagon pulse corresponds to a homoclinic orbit of the trivial state $U = 0$ which passes close to a periodic orbit in the x-dynamics that is formed of

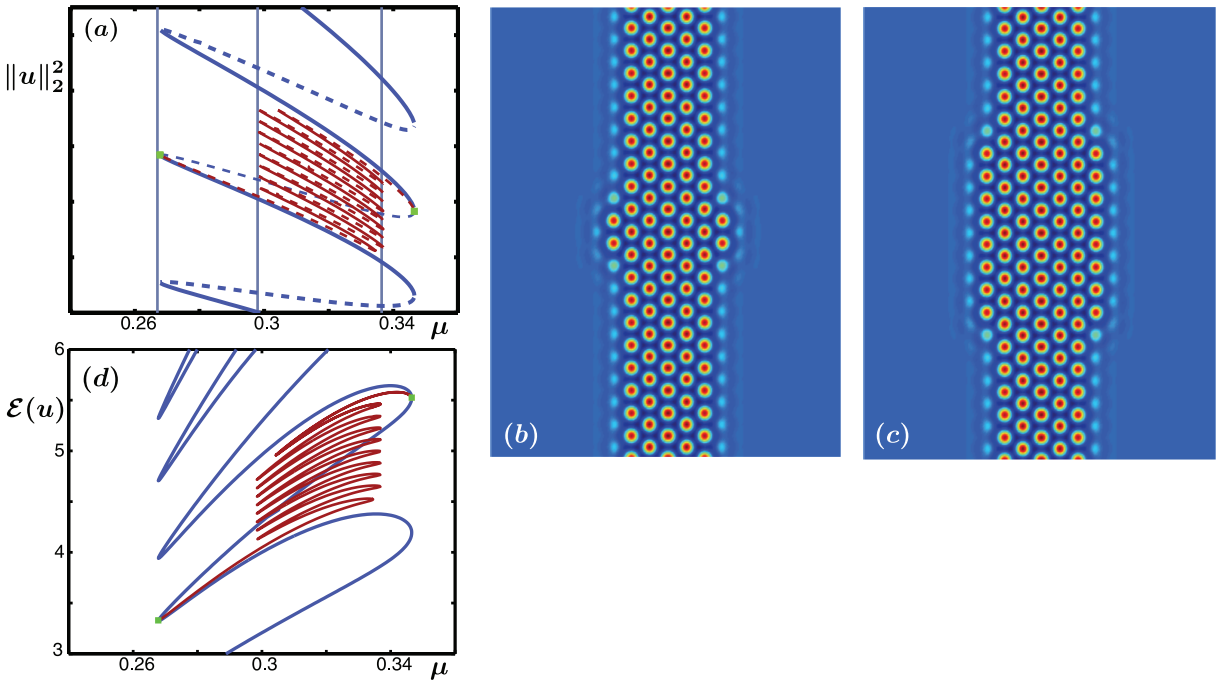

Figure 18. *In panel* (a)*, the bifurcation diagrams of planar* $\langle 10 \rangle$ *hexagon pulses (blue) and the bifurcating almost-planar pulses (red) are shown, where stable pulses are indicated by solid lines and unstable ones by dashed lines. Panels* (b)–(c) *are color plots of two different almost-planar hexagon pulses for* $\mu = 0.3$ *along the smaller red snaking diagram. In panel* (d)*, we plot the energy* $\mathcal{E}(u)$*, computed as an integral over the entire computational domain, along the branches.*

hexagons. Thus, we are in the situation discussed in sections 2.1 and 3.2 and expect snaking to set in [10]. As already alluded to in section 3.2, the scenario we just described persists if we change the height of the y-interval: the selected hexagons will become slightly frustrated, and, accordingly, the Maxwell point may change slightly, but the resulting planar hexagon pulses will continue to snake.

As shown in Figure 18(a), planar $\langle 10 \rangle$ pulses undergo additional pitchfork bifurcations near each fold. Figure 18(b)–(c) shows that the patterns bifurcating at the pitchfork bifurcations are almost-planar hexagon pulses: at onset, either one or two hexagon cells appear in new columns to the left and right at the center of the $\langle 10 \rangle$ pulse. As we move along the bifurcating branch, the almost-planar hexagon pulses begin to snake, and, at each fold, additional pairs of hexagon cells are added symmetrically above and below the already added hexagon cells until the entire column is filled. At this point, the branch of almost-planar pulses terminates in a second pitchfork bifurcation at the planar $\langle 10 \rangle$ hexagon pulses. Almost-planar hexagon pulses undergo only a finite number of folds due to the finite height of the computational domain. Similar to the case of planar pulses, the left and right fold bifurcations of almost-planar hexagon pulses line up. To explain the snaking of almost-planar pulses, we consider the y-variable as our time-like variable and restrict x to a large bounded interval with Neumann boundary conditions; see Figure 17(ii). In this spatial-dynamics interpretation, an almost-planar hexagon pulse corresponds to a homoclinic orbit

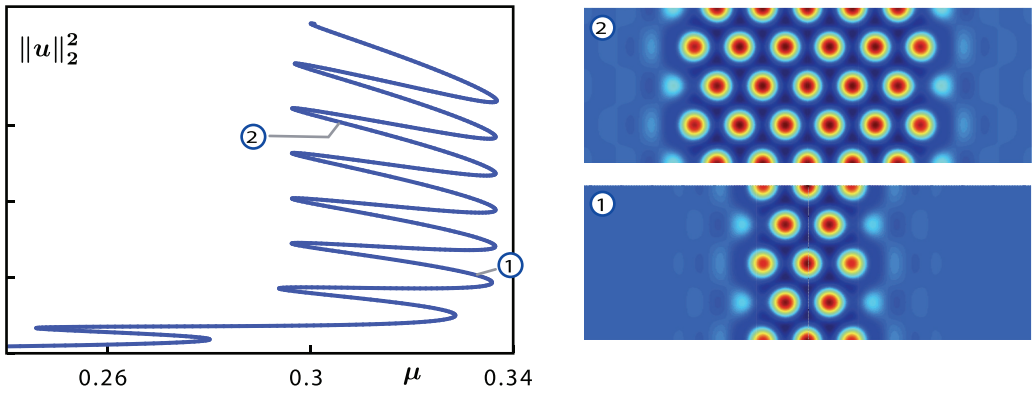

Figure 19. *The left panel contains the bifurcation diagram of planar* $\langle 11 \rangle$ *hexagon pulses. Two selected profiles are shown on the right.*

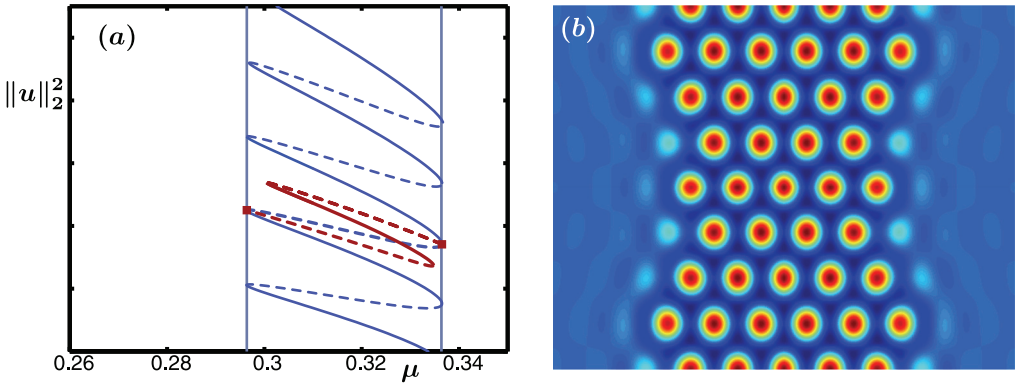

Figure 20. *The bifurcation diagrams of planar* $\langle 11 \rangle$ *hexagon pulses (blue) and the bifurcating almost-planar pulses (red) are plotted in panel* (a). *Panel* (b) *is a color plot of an almost planar* $\langle 11 \rangle$ *pulse for* $\mu = 0.309$.

of a periodic orbit that passes close to a second periodic orbit as y increases. Each periodic orbit in the y-dynamics consists of a localized hexagon pulse in the x-variable with a different number of hexagons in its center. Homoclinic orbits between periodic orbits will snake in the same fashion as the homoclinic orbits between equilibria that we discussed in section 2.1.

We now turn to a discussion of planar $\langle 11 \rangle$ hexagon pulses which also snake (see Figure 19) and exhibit pitchfork bifurcations to almost-planar $\langle 11 \rangle$ pulses, as shown in Figure 20. The almost-planar $\langle 11 \rangle$ hexagon pulses undergo only two folds since the computational domain allows only eight hexagons in the y-direction: there would be more folds if the height ℓ_y of the computational domain used in Figure 13 were larger.

Figure 21 contains the bifurcation diagrams of both planar $\langle 10 \rangle$ and $\langle 11 \rangle$ hexagon pulses. This figure shows that the orientation of the hexagon pulse has a significant effect on the width of the snaking region. The different vertical lines along which the folds line up will play an important role later when we discuss fully localized hexagon patches. We believe that there are many other hexagon pulses with orientations different from $\langle 10 \rangle$ and $\langle 11 \rangle$. The other

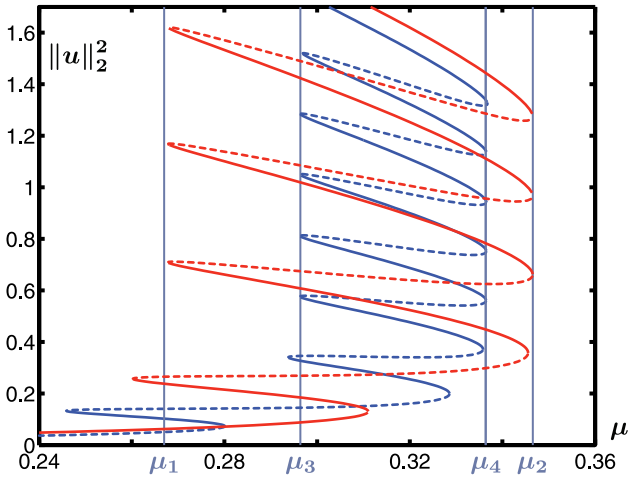

Figure 21. *The bifurcation diagrams of planar hexagon pulses with Bravais–Miller indices* $\langle 10\rangle$ *(in red) and* $\langle 11\rangle$ *(in blue) are shown. The* $\langle 10\rangle$ *pulse snakes between the limits* $\mu_1 = 0.267$ *and* $\mu_2 = 0.3454$*, while the* $\langle 11\rangle$ *pulse snakes between* $\mu_3 = 0.2964$ *and* $\mu_4 = 0.3364$*. The stability of the branches alternates between unstable (dashed) and stable (solid) at each fold.*

planar hexagon pulses will have larger Bravais–Miller indices, and we expect heuristically that these interfaces have higher energy. These pulses can be computed in exactly the same fashion as the $\langle 10\rangle$ and $\langle 11\rangle$ pulses, but we have not carried out these computations at present. The existence of infinitely many planar hexagon pulses with different orientations can also be inferred from an energy argument. At the Maxwell point, a single hexagon cell has zero energy, and so any combination of the hexagon cells that lie on the hexagon lattice can be used to create differently oriented pulses. We expect the resulting pulses to pin or lock to produce snaking regions similar to those found for $\langle 10\rangle$ and $\langle 11\rangle$ pulses.

Finally, we briefly address the nature of the pitchfork bifurcations to almost-planar hexagon pulses that occur near each fold bifurcation. We begin with the fold bifurcation: the eigenfunction $v_0(x, y)$ associated with the fold eigenvalue $\lambda = 0$ is periodic in the y-variable with minimal period $\ell = 4\pi/\sqrt{3}$ for $\langle 10\rangle$ and $\ell = 4\pi$ for $\langle 11\rangle$ pulses. Now consider the planar pulse on the entire plane and apply Floquet–Bloch theory (see, for instance, [67, Theorem 2.1]): we find a one-parameter family $\lambda(\gamma)$ of eigenvalues, defined for all γ sufficiently close to zero, whose eigenfunctions are of the form $v(x, y; \gamma)e^{i\gamma y}$, where $v(x, y; \gamma)$ has period ℓ in the y-variable. For $\gamma = 0$, we recover the fold eigenvalue $\lambda(0) = 0$ with eigenfunction $v(x, y; 0) = v_0(x, y)$. Next, we consider domains of height $N\ell$ in the y-direction for large integers $N \gg 1$ with periodic boundary conditions in y: this is the situation shown in Figure 16. The eigenfunctions we found on the plane fit into this domain provided $\gamma = \gamma_n := 2\pi n/N\ell$ for integers $n \geq 0$. The smallest nonzero value of γ is $\gamma_1 = 2\pi/N\ell$: the associated eigenvalue $\lambda(\gamma_1) = O(1/N)$ is close to zero for $N \gg 1$, and its eigenfunction

$$v(x, y; \gamma_1)e^{i\gamma_1 y} = [v_0(x, y) + O(1/N)]e^{2\pi i y/N\ell}$$

is a harmonic modulation of the fold eigenfunction in the y-direction. Figure 22 shows a $\langle 10\rangle$ hexagon pulse and the associated fold and pitchfork eigenfunctions on a domain with

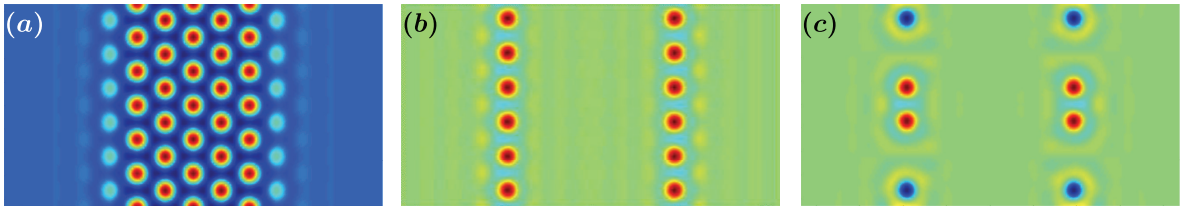

Figure 22. *Shown are color plots of a planar* $\langle 10 \rangle$ *hexagon pulse at a fold bifurcation in* (a)*, the associated fold eigenfunction in* (b)*, and the pitchfork eigenmode that leads to almost-planar hexagon pulses in* (c)*.*

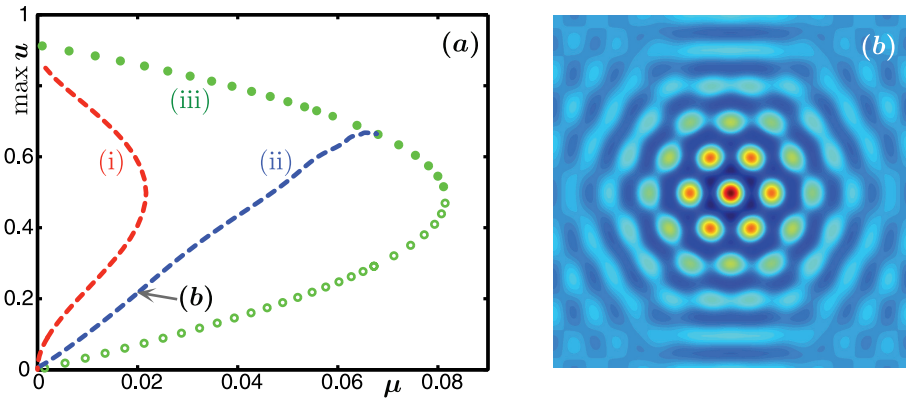

Figure 23. *Localized radial pulses* (i)*, localized hexagon patches* (ii)*, and regular hexagons* (iii) *with wavenumber* $\kappa = 1$ *of the planar Swift–Hohenberg equation* (1.1) *with* $\nu = 0.9$ *are shown in panel* (a)*. Dashed solutions and regular hexagons with open bullets are unstable, while regular hexagons with filled bullets are stable. Note that neither branch* (i) *nor* (ii) *terminates at the branch* (iii) *of regular hexagons (see text for details). Panel* (b) *contains a color plot of a localized hexagon patch for* $\mu = 0.02$*.*

$N = 6$: the pitchfork eigenfunction is indeed a cosine modulation of the fold eigenfunction with maximal period in y, as claimed.

5.3. Localized hexagon patches. In this section, we discuss our results for localized hexagon patches of the planar Swift–Hohenberg equation (1.1). We shall also report on numerical results for localized radial pulses.[7] We focus first on two different representative slices $\nu = 0.9$ and $\nu = 1.6$ of the bifurcation diagram in (μ, ν)-parameter space before we consider the full diagram in (μ, ν)-space and comment on the special value $\nu = 1.049$ that separates regions of qualitatively similar behavior.

5.3.1. Bifurcation diagram for $0 < \nu < 1.049$. We first consider the region where $0 < \nu < 1.049$ and illustrate our results in Figure 23 for $\nu = 0.9$. We find localized radial pulses, localized hexagon patches, and regular hexagons. All these solutions bifurcate from $u = 0$ at $\mu = 0$ and are initially unstable. Regular hexagons stabilize in a fold bifurcation and later cross into the left half-plane $\mu < 0$. Localized radial pulses gain stability with respect to radial perturbations at the first fold bifurcation but continue to be unstable with respect to hexagonal perturbations. They cross with nonzero amplitude into the left half-plane, where

[7] Existence results for these localized radial solutions are proved in [58].

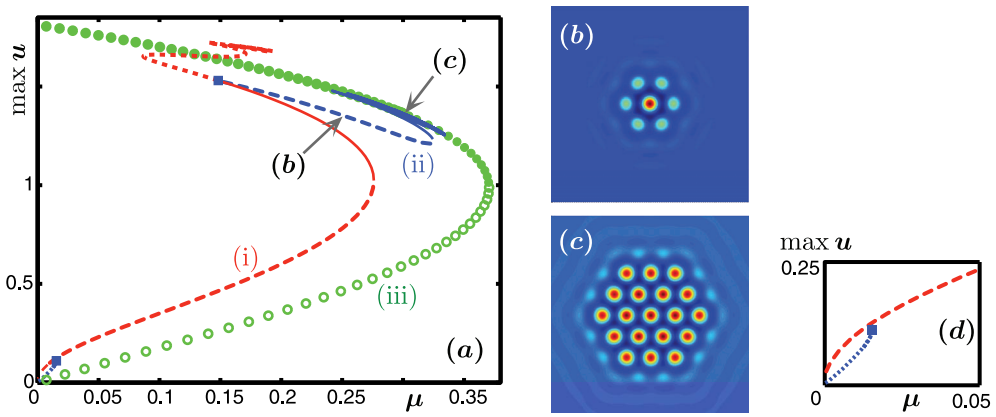

Figure 24. *Localized radial pulses* (i)*, localized hexagon patches* (ii)*, and regular hexagons* (iii) *with wavenumber* $\kappa = 1$ *of the planar Swift–Hohenberg equation* (1.1) *with* $\nu = 1.6$ *are shown in panel* (a)*; the area near the origin is enlarged in panel* (d)*. Dashed solutions and regular hexagons with open bullets are unstable, while solutions along solid lines and regular hexagons with filled bullets are stable. Panels* (b) *and* (c) *are color plots of localized hexagon patches for* $\mu = 0.25$ *near the bifurcation off the radial pulse* (b) *and for* $\mu = 0.3$ *on the snaking curve* (c)*.*

they turn into nonlocalized target patterns. The unstable localized hexagon patches appear to begin to snake for $\mu \approx 0.065$, but we were only able to continue through the first fold. The Maxwell point of regular hexagons for $\nu = 0.9$ is $\mu = \mu_{\mathrm{M}} \approx 0.07$.

5.3.2. Bifurcation diagram for $1.049 < \nu < 2.23$. In Figure 24, we summarize the bifurcation diagram for $\nu = 1.6$, where localized hexagon patches have previously been found in [78] via direct numerical simulations. The localized hexagon patches that arise in this parameter region tend to be highly localized, and the numerical methods described in section 4 should therefore work particularly well. Other previous direct numerical simulations have shown that temporally stable localized radial pulses exist in this region of parameter space: our numerical continuation methods will corroborate these findings and establish a strong link between localized radial and hexagonal structures.

As shown in Figure 24, radial pulses bifurcate off the trivial solution at $\mu = 0$ and are initially unstable with respect to radial and hexagonal perturbations. Also bifurcating at $\mu = 0$ are unstable localized hexagon patches which disappear in a subcritical pitchfork bifurcation of the radial pulse at $\mu \approx 0.015$: from this point onward, the radial pulses are unstable only with respect to radial perturbations. Subsequently, the radial pulses stabilize in a saddle-node bifurcation at $\mu \approx 0.276$ and later on, for $\mu \approx 0.15$, undergo a second subcritical bifurcation to unstable localized hexagon patches. The radial pulses continue on and begin to snake. The unstable localized hexagon patches that bifurcate at the second pitchfork bifurcation of the radial pulses gain stability in a fold bifurcation at $\mu \approx 0.325$ and begin to snake around the hexagon Maxwell point $\mu_{\mathrm{M}} \approx 0.3222$. While snaking, the localized hexagon patches become wider until they fill the entire domain. In addition to these localized patterns, unstable regular hexagons also bifurcate from the trivial solution at $\mu = 0$ and stabilize in a fold bifurcation at $\mu \approx 0.37$. As can be seen from Figure 24(a), the localized hexagon patterns snake close to the regular hexagons.

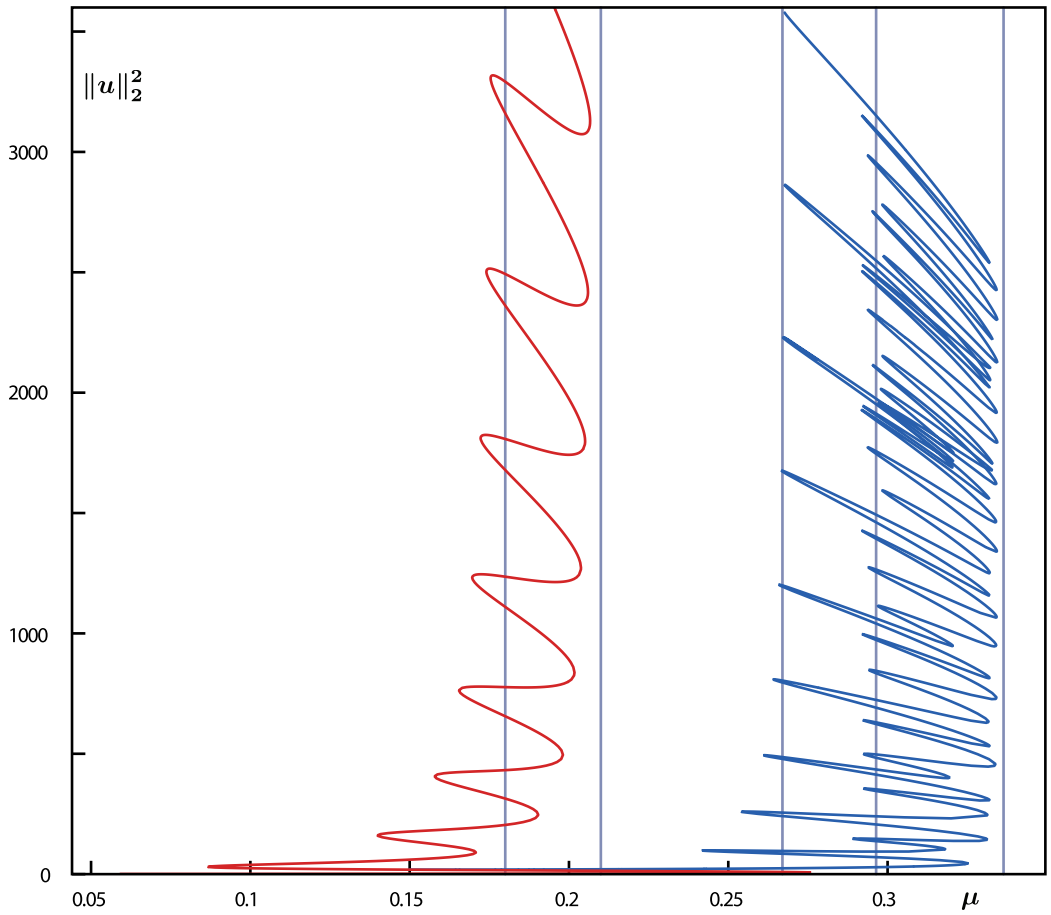

Figure 25. *The snaking curves of radial pulses (left, in red) and fully localized hexagon patches (right, in blue) are plotted for $\nu = 1.6$. Radial solutions are computed on a disk of radius $R = 100$: The fold asymptotes of $1D$ rolls are indicated by vertical grey lines, and the Maxwell point of $1D$ rolls occurs at $\mu_{\mathrm{M}} = 0.2$. The localized hexagon patches are computed with $M = 19$ angular Fourier modes on a domain of radius $R = 80$: The fold asymptotes of planar $\langle 10 \rangle$ and $\langle 11 \rangle$ hexagon pulses are plotted as vertical grey lines, and the hexagon Maxwell point occurs for $\mu_{\mathrm{M}} \approx 0.3222$. The hexagon snaking curve and the associated solution profiles can be viewed in the accompanying animation* (70762_01.mpg [10.8MB]).

We focus now on the snaking behavior of localized hexagon patches. The bifurcation curves of localized radial and hexagon patterns are shown in Figure 25. In particular, we see that the snaking of localized hexagon patches is qualitatively very different from the snaking of the radial pulses and, in fact, also from the snaking of planar hexagon fronts, whose diagram is shown in Figure 21. Indeed, the fold bifurcations of radial pulses and planar hexagon pulses occur near two well-defined limiting values, while the folds of localized hexagon patches align themselves along at least three distinct vertical asymptotes.

The spatial shapes of the fully localized hexagon patches along the snaking curve can be viewed in the accompanying animation (70762_01.mpg [10.8MB]). It is clear from the movie that the localized hexagon structures change in a complicated fashion as the parameter μ is

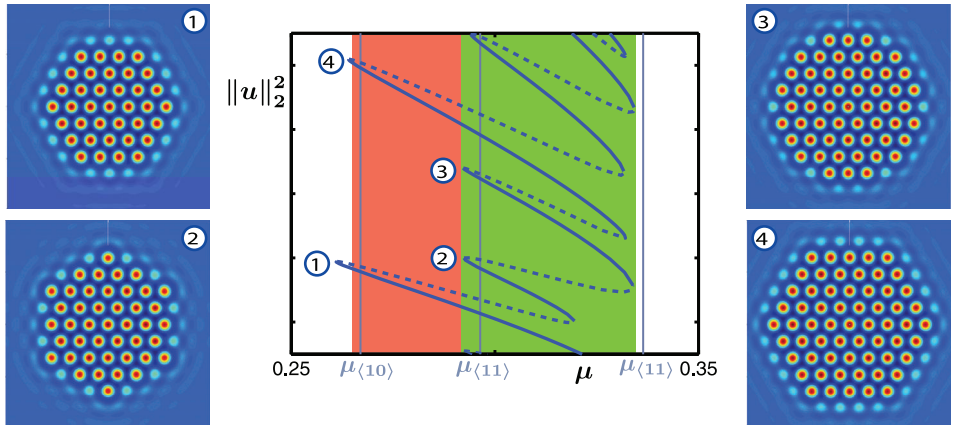

Figure 26. *The center panel contains part of the bifurcation diagram of localized hexagon patches for* $\nu = 1.6$. *Stable and unstable solutions are plotted in solid and dashed lines, respectively. The vertical lines in grey correspond to the fold limits of planar* $\langle 10\rangle$ *and* $\langle 11\rangle$ *hexagon pulses. Panels* 1–4 *contain color plots of the hexagon patches at the inner and outer left folds.*

varied, and we shall now discuss some of the features visible in the movie in more detail and attempt to identify the underlying mechanisms.

In Figure 26, we plot a few selected spatial profiles along a small segment of the bifurcation curve. We note that localized structures alternately lose and regain stability at consecutive folds. Moving along the bifurcation branch from panel (1) to panel (4) in Figure 26, we see that the localized structure acquired an additional ring of hexagons and thus grew from four to five rings. The process of adding rings is much more complicated than simply adding a new full ring at each fold. First, as shown in panel (2), a single hexagon is added at the center of each side: note that the faces of the resulting localized structure resemble the planar $\langle 11\rangle$ hexagon pulses encountered in section 5.2 and that the addition of the single hexagon occurs at a fold that aligns itself with the snaking curve of $\langle 11\rangle$ pulses. Next, in panel (3), hexagons are added symmetrically to either side of the centered hexagon cell created previously in panel (2): this happens again near an inner fold. The final step is to add an additional pair of hexagons symmetrically to either side of the previously created hexagons to complete the row: this occurs near the fold corresponding to a $\langle 10\rangle$ pulse. The faces of the "superhexagon" structure in panels (1) and (4) resemble planar hexagon pulses with $\langle 10\rangle$ orientation. In summary, as the snake in Figure 26 is traversed, new hexagon cells emerge symmetrically on each face, starting at the center of each face. This cellular growth is reminiscent of the bifurcation diagram of almost-planar $\langle 10\rangle$ pulses shown in Figure 18.

Figure 27 contains a sequence of pictures of localized hexagon structures further up on the snaking curve to illustrate the transition from a localized structure with nine hexagon rings to a pattern with ten rings. Comparing panels (1) and (2), we find that two new hexagon cells appear in the center of each face: there are two new hexagon cells, rather than just one, as the number of hexagons in the outermost row in Figure 27(1) is odd, rather than even, as for the four-ring structure in Figure 26. While cells are added in the center, the corners of the superhexagon structure recede and disappear, which did not happen for four-ring structures.

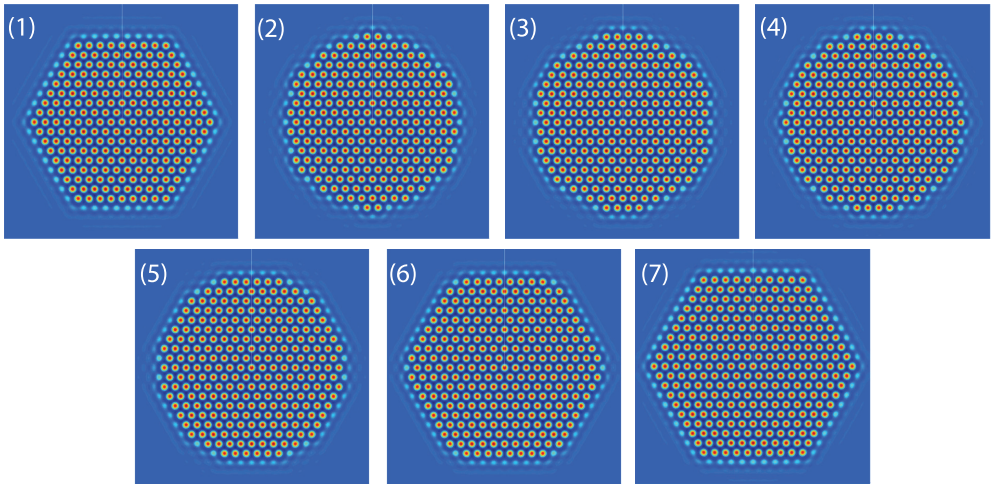

Figure 27. *Color plots of localized hexagon patches at the leftmost folds are shown to illustrate the growth from a* 9*-ring hexagon patch to a* 10*-ring patch. The computations are done on a domain of radius* $R = 100$ *with* $M = 40$ *angular Fourier modes.*

In panel (3), the diagonal faces resemble planar $\langle 11 \rangle$ pulses which move forward to complete the superhexagon visible in panel (7) as we move along the bifurcation curve. The removal of the six cells in the corners of the superhexagon in panels (1)–(2) leads to a reduction of the L^2-norm of the localized structures, which creates the apparent self-intersections of the bifurcation curve visible in Figure 25.

The results discussed above indicate that localized hexagon patches expand initially by adding one or two new hexagon cells at the center of each face. In Figure 28, we compare the bifurcation curves of almost-planar $\langle 10 \rangle$ hexagon pulses with one and two cells to the relevant segments of the snaking curve of localized hexagon patches. The parameter values for the first two folds along the bifurcation curves agree well, but the bifurcation curves of almost-planar pulses and localized hexagon patches separate soon after. On a heuristic level, we believe that hexagon patches do not grow by adding full rows because it costs too much energy to grow hexagons at the corners where two adjacent faces join up. This belief is supported by the observation that the corner hexagons actually recede, as is visible in panels (1)–(2) of Figure 27. Thus, even though cells initially emerge at the centers of each face, the overall growth mechanism is clearly more global, which is why the bifurcation curves of the almost-planar $\langle 10 \rangle$ hexagon pulses agree with the snaking curve of hexagon patches only initially.

We believe that infinitely many planar hexagon fronts with different Bravais–Miller indices play a role in forming the bifurcation diagram shown in Figure 25, though we were not able to go up far enough on the bifurcation curve to identify additional vertical asymptotes that may belong to planar hexagons with different indices. It is remarkable, though, that all rightmost folds seem to line up near the asymptote coming from the planar $\langle 11 \rangle$ hexagon pulse. Most of these folds seem to involve structures that resemble either planar $\langle 11 \rangle$ or almost-planar $\langle 10 \rangle$ pulses. On a heuristic level, it appears that growing these structures involves the same mechanism, and we illustrate this further in Figure 29. However, hexagons emerge along the

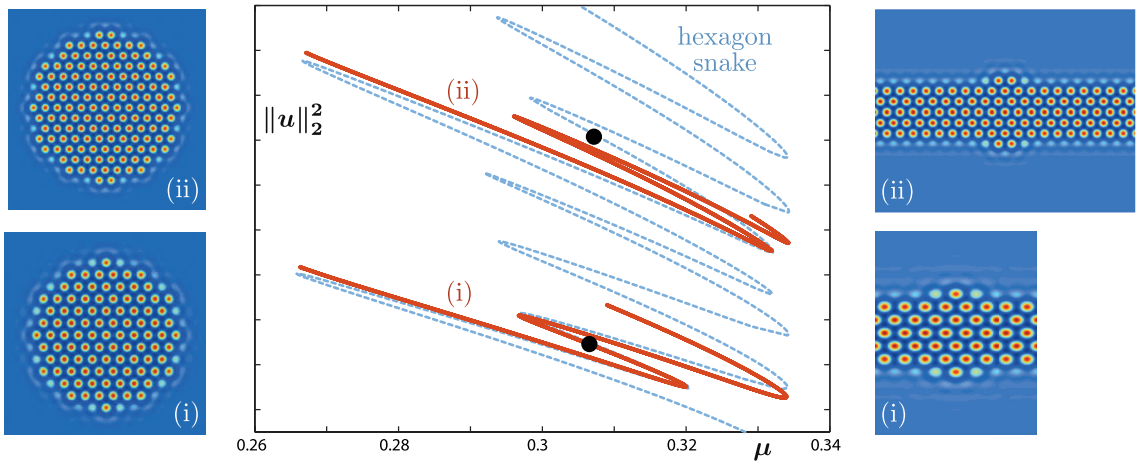

Figure 28. *In the middle panel, we plot part of the hexagon snake from Figure 25 and overlay the snaking curves of almost-planar* $\langle 10 \rangle$ *hexagon pulses for which initially one cell* (i) *or two cells* (ii) *emerge at the center. We rescaled the vertical coordinate of the snaking curves of the almost-planar pulses linearly to allow a comparison with the hexagon data. The remaining panels show color plots of localized hexagon patches (left) for parameter values indicated by bullets in the middle panel and representative almost-planar pulses (right) on the curves* (i) *and* (ii).

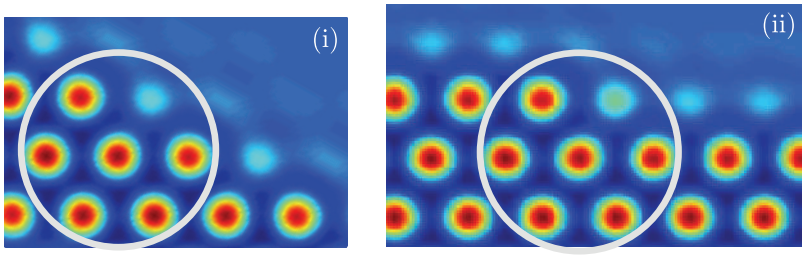

Figure 29. *We plot a rotated planar* $\langle 11 \rangle$ *hexagon pulse in panel* (i) *and an almost-planar* $\langle 10 \rangle$ *hexagon pulse in panel* (ii). *The circles enclose incomplete hexagon structures: Along the next fold in the snaking curve, the missing hexagon in the circle will be filled in.*

entire interface of a planar $\langle 11 \rangle$ pulse, while only a single hexagon is added to an almost-planar $\langle 10 \rangle$ structure.

In section 3.2, we showed that regular hexagon cells in a stationary planar hexagon front satisfy $\mathcal{H} = 0$ for the conserved quantity $\mathcal{H}$ that we defined in (3.8). The condition $\mathcal{H} = 0$ selects the wavenumber of these hexagons. In section 3.2, we stated our belief that this selection criterion for the wavenumber should also apply to localized hexagon patches. In Figure 30, we compare the wavenumbers of regular hexagons for which $\mathcal{H} = 0$ with the wavenumbers of the hexagon cells at the center of localized hexagon patches. We find that the wavenumbers of the center hexagon cells in localized hexagon patches get closer to the predicted wavenumbers as we move up on the snaking curve.

The different vertical asymptotes visible in Figure 26 have interesting consequences for

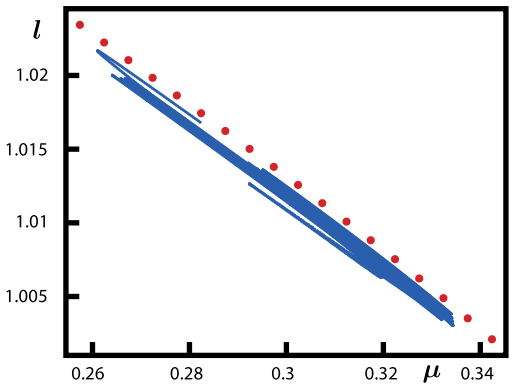

Figure 30. *Plotted are the wavelengths $l = 1/\kappa$ of the regular hexagons for which $\mathcal{H} = 0$ (red bullets) and of the hexagon cells located at the center of the localized hexagon patches (blue dots) as functions of μ for $\nu = 1.6$. The wavelength $l = 1$ corresponds to a spatial period of 2π.*

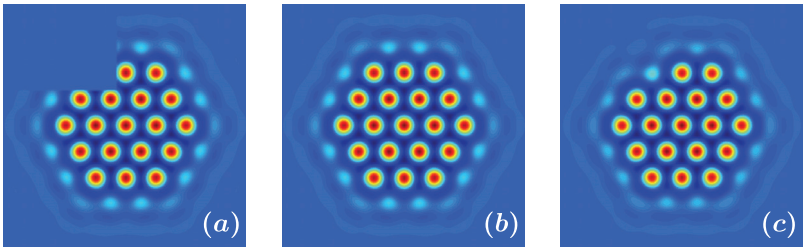

Figure 31. *We illustrate the temporal evolution of localized hexagon structures in the Swift–Hohenberg equation (1.1) with $\nu = 1.6$. The initial condition is shown in panel* (a)*. The solutions at time $t = 100$ are shown in panel* (b) *for $\mu = 0.27$ inside the red region of Figure 26 and in panel* (c) *for $\mu = 0.3$ inside the green region of Figure 26.*

the temporal dynamics of the Swift–Hohenberg equation. As indicated in Figure 26, we divide the μ-parameter space into two intervals, shown in red and green, depending on whether we are to the left or right of the folds that are aligned with the leftmost asymptote of the planar $\langle 11 \rangle$ hexagon pulse. These regions seem to be intimately linked with different self-completion behaviors of localized hexagon patches. We choose the pattern shown in Figure 31(a) as our initial condition and solve the planar Swift–Hohenberg equation. For μ in the red region, to the left of the leftmost $\langle 11 \rangle$ fold, the solution evolves in time toward the completed superhexagon shown in Figure 31(b): since $\langle 11 \rangle$ pulses do not exist in this parameter region, the pattern evolves in time so that all interfaces are $\langle 10 \rangle$ pulses. In contrast, for μ in the green region to the right of the leftmost $\langle 11 \rangle$ fold, the solution converges in time to a localized hexagon patch that is not $\mathbb{D}_6$-symmetric: stable $\langle 11 \rangle$ pulses exist in this region, and the interface of the pattern finds it easier to evolve toward an $\langle 11 \rangle$ pulse rather than a $\langle 10 \rangle$ pulse. Phrased in terms of the bifurcation diagram of Figure 26, the solution moves upward to the stable $\mathbb{D}_6$-symmetric pattern on the hexagon bifurcation curve for parameters in the red region. In contrast, the solution evolves to an asymmetric hexagon patch for parameters in the green region: it appears as if the asymmetric patterns block the evolution toward symmetric patches. We conjecture

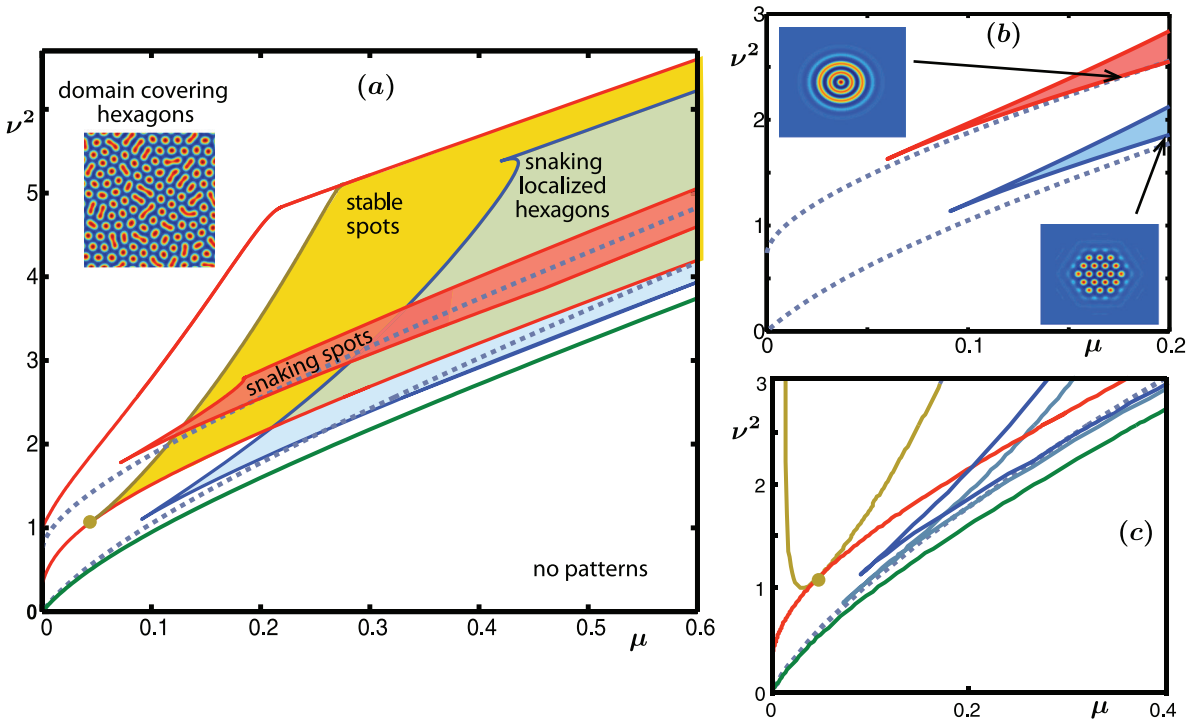

Figure 32. *This figure summarizes our numerical results for radial and hexagonal patterns in the planar Swift–Hohenberg equation* (1.1). *Dashed grey curves correspond to* 1*D roll and* 2*D hexagonal Maxwell curves, the green curve corresponds to the disappearance of regular hexagons with wavenumber* $\kappa = 1$ *in a fold bifurcation, and red curves correspond to fold bifurcations of localized radial spots. The existence region of stable spots is shown in yellow in panel* (a). *Panels* (a)–(c) *also indicate the snaking regions of spots and localized hexagon patches that are delimited by the first pair of fold bifurcations of these patterns: As discussed in the main text, we expect that there is a sequence of fold curves which disappear in a sequence of cusps that accumulate at the origin, so that the full snaking regions are expected to extend along the two Maxwell curves all the way to the* ν*-axis. Panel* (c) *contains four such fold bifurcation curves of localized hexagon patches that are aligned along the hexagon Maxwell curve and which disappear at two cusp bifurcations. Panel* (c) *also contains the pitchfork bifurcation curves of localized hexagon patches from spots in yellow and the fold bifurcation curve of spots in red: These curves meet at the mode interaction point* $(\mu, \nu^2) = (0.048, 1.1)$ $(\nu = 1.049)$.

that these asymmetric hexagon patches may bifurcate from $\mathbb{D}_6$-symmetric hexagon patches in a planar version of ladders, similar to those observed in one space dimension in [19, 20, 22] which we reproduced in Figure 8.

5.3.3. Bifurcation diagram in (μ, ν)-parameter space. Using numerical continuation, we have also traced out partial bifurcation diagrams for localized patterns of the planar Swift–Hohenberg equation in the parameters (μ, ν). These results are summarized in Figure 32 and presented in schematic form in Figure 33.

Regular hexagons exist above the green curve in Figure 32(a). We find that localized hexagon patches seem to bifurcate from the trivial state $u = 0$ along the entire positive ν-axis into the positive quadrant $\mu > 0$. Hexagon patches also bifurcate from localized radial spots along a pitchfork bifurcation curve, where symmetry is broken from O(2) to $\mathbb{D}_6$. Overall, we

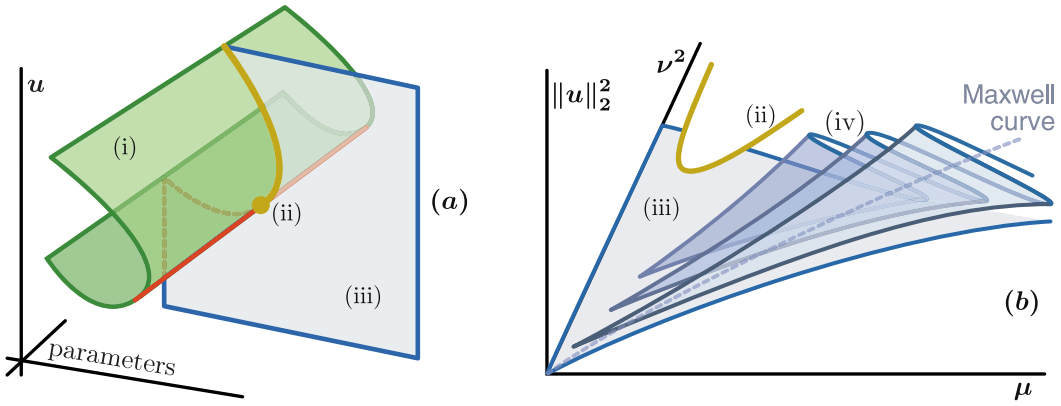

Figure 33. *Schematic illustrations of the bifurcation diagram of localized hexagon patches are shown. Panel* (a) *shows the sheet of localized radial spots* (i) *which undergo pitchfork bifurcations to localized hexagon patches along the yellow curve* (ii). *In panel* (b), *localized hexagon patches* (iii) *bifurcate from* $u = 0$ *at* $\mu = 0$ *and from spots along the pitchfork bifurcation curve* (ii). *The hexagon patches begin to snake* (iv) *near the hexagonal Maxwell curve (shown in dotted grey) in an infinite sequence of fold bifurcations that disappear closer to the origin in a sequence of cusps. See Figure* 32(c) *for the corresponding numerical results.*

obtain a connected surface along which localized hexagon patches exist; see Figure 33 for a schematic picture and Figures 23 and 24 for numerical computations. Localized spots are stable in a wedge delimited by the fold and pitchfork bifurcation curves that emerge from the mode interaction point $(\mu, \nu) = (0.048, 1.049)$ $(\nu^2 = 1.1)$ in Figure 32(a).

Localized hexagon patches snake in a wedge-like region which is aligned with the hexagon Maxwell curve and appears to extend all the way to the origin, where the bifurcation to regular hexagons changes from super- to subcritical, as outlined in Figure 33(b). In Figure 32(c), we show four numerically continued fold bifurcation curves of localized hexagon patches which disappear in two cusp bifurcations. For $\nu \leq 0.9$, localized hexagon patches are spread out so far and fold bifurcations occur so close to each other that we were not able to continue beyond the first fold: these numerical difficulties prevented us from further probing the sequence of fold and cusp bifurcations. Spots also snake, and we show in Figure 32(a) the region delimited by the first two fold bifurcation curves along their snaking curve together with the cusp at which the fold curves collide and disappear. Again, we expect that the snaking region of spots extends along the Maxwell curve associated with 1D rolls to the codimension-two point $(\mu, \nu) = (0, \sqrt{27/38})$, where the bifurcations to rolls change from super- to subcritical.

In Figure 26, we observed that the leftmost snaking limit of the hexagon patches coincides with the leftmost fold of the planar $\langle 10 \rangle$ hexagon pulses. To illuminate this feature further, we show in Figure 34 the snaking region of fully localized hexagon patches and, for comparison, the snaking regions of planar $\langle 10 \rangle$ and $\langle 11 \rangle$ hexagon pulses in panels (a) and (b), respectively. For $\mu < 0.35$, the leftmost fold curve of the $\langle 10 \rangle$ pulses aligns itself with the leftmost boundary of the hexagon patches, while the rightmost fold curve of the $\langle 11 \rangle$ pulses aligns itself with the rightmost boundary of the hexagon patches.

We see in Figure 32 that a cusp forms at $(\mu, \nu^2) \approx (0.4205, 5.4173)$ on the upper fold curve on the wedge belonging to localized hexagon patches. This upper cusp is similar to that found in [19, 20, 22] for 1D structures and indicates that a new Maxwell curve crosses into

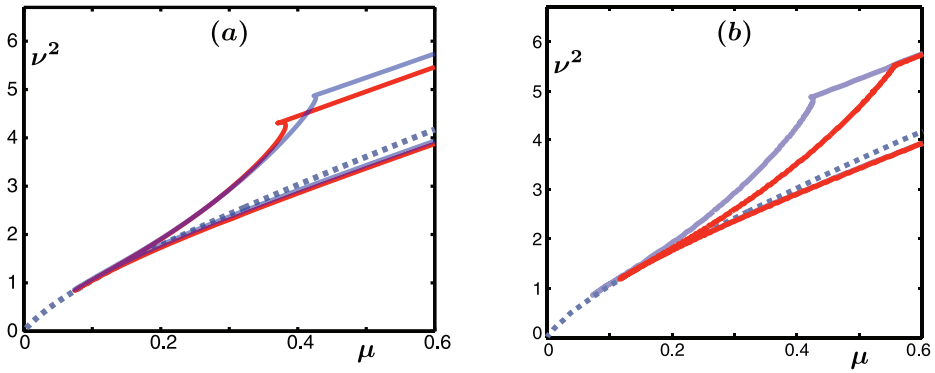

Figure 34. *Comparison of the snaking region of localized hexagon patches (blue) and the snaking regions of planar* $\langle 10 \rangle$ *hexagon pulses (red) in panel* (a) *and* $\langle 11 \rangle$ *hexagon pulses (red) in panel* (b)*. The hexagon Maxwell curve is also shown (dashed grey).*

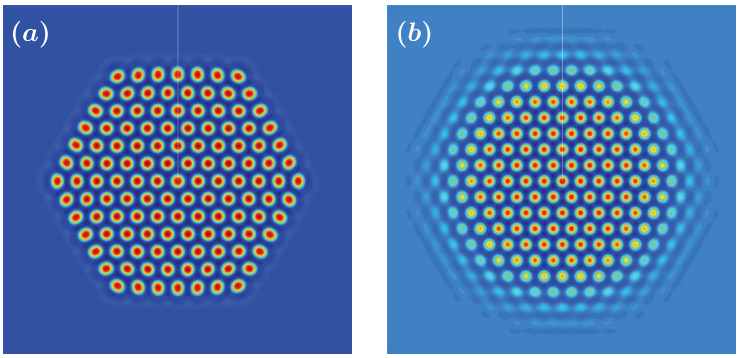

Figure 35. *Panels* (a) *and* (b) *contain color plots of localized hexagon patches for* $(\mu, \nu^2) = (0.7, 6.2355)$ *and* $(\mu, \nu^2) = (0.0738, 0.8612)$*, respectively.*

the snaking region. We plot a localized hexagon patch further up on the upper fold curve for $(\mu, \nu^2) = (0.7, 6.2355)$ in Figure 35(a): note that the individual hexagon cells on the outer ring are elongated. For comparison, we plot in Figure 35(b) the localized hexagon patch at the lower cusp at $(\mu, \nu^2) = (0.0738, 0.8612)$.

5.4. Localized rhomboid patches. We also investigated fully localized rhomboid patches. These solutions have an interior cellular hexagonal structure, but, as shown in Figure 36(b), the overall patch does not possess hexagonal symmetry: the underlying cellular pattern is shifted by half a spatial period so that the center of the localized patch does not coincide with the center of an interior hexagon. Unlike localized hexagon patches, localized rhomboids bifurcate from a pair of localized hexagons, which in turn bifurcate from the trivial state. Hexagon pairs, triplets, and rhomboids consisting of four hexagons have previously been computed in [63]. The snaking diagram of the localized rhomboid patches, shown in Figure 36(a), appears to be qualitatively similar to the snaking diagram of localized hexagon patches shown in Figure 25. There seem to be roughly three snaking limits: the leftmost limit corresponds to the completion of a superrhomboid, shown in Figure 36(b), while the other two snaking limits

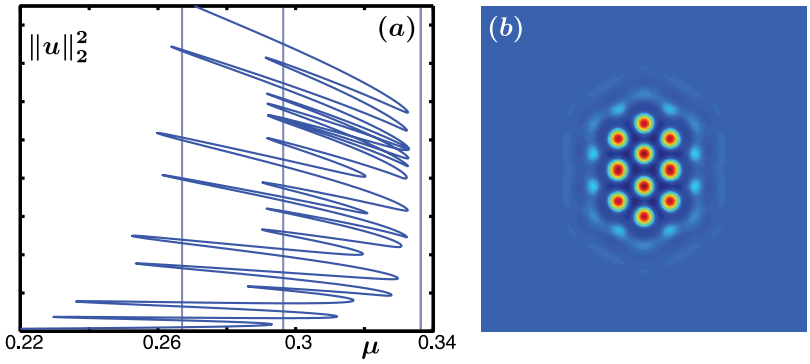

Figure 36. *Panel* (a) *contains the bifurcation diagram of localized rhomboid patches for* $\nu = 1.6$*, while the rhomboidal structure itself is shown as a color plot in panel* (b) *for* $\mu = 0.2817$*. The vertical lines are the asymptotes of the fold bifurcations of* $\langle 10 \rangle$ *and* $\langle 11 \rangle$ *hexagon pulses shown in Figure 26. The computations were carried out on a square domain with dimensions* 80×80*.*

correspond to the emergence of individual hexagons along the sides of the localized structure, as in the case of hexagon patches. Further up the snake, the leftmost folds get closer to the folds of the planar $\langle 10 \rangle$ hexagon pulses. Similar to the case of hexagon patches, the bifurcation curves of localized rhomboids intersect as individual corner cells are suppressed, leading to a decrease of the overall L^2-norm. We computed the localized rhomboids on a large square box with Neumann boundary conditions rather than with polar coordinates as we did for localized hexagon patches: in particular, we are confident that the damping of the corner cells is not due to boundary conditions or numerical errors.

We believe that the localized hexagon and rhomboid patches are connected in parameter space by bifurcation curves of asymmetric patterns similar to those found in [19, 21] for 1D structures. These ladders will effectively shift the cellular pattern between the localized hexagon and rhomboid patches.

6. Conclusions and discussion.

Summary. We briefly summarize our main findings. First, we provided a selection principle for hexagons that can appear as asymptotic states in planar fronts that connect to the trivial state $u = 0$. Any such hexagon must satisfy $\mathcal{H} = 0$, where the function $\mathcal{H}$ is a first integral of the spatial dynamical system that describes solutions $u(x, y)$ of the Swift–Hohenberg equation that are periodic in the transverse y-direction. The expression (1.6) of $\mathcal{H}$ was derived from a conservation law that arises, via Noether's theorem, due to the translation symmetry of the Lagrangian of the energy (1.4) of the Swift–Hohenberg equation. Using a theorem proved in [9], we also showed that a unique branch of regular hexagons along which $\mathcal{H} = 0$ bifurcates from the trivial state at $\mu = 0$: these hexagons have a uniquely selected wavelength.

In section 3.2, we gave a spatial-dynamics formulation of solutions of the Swift–Hohenberg equation that are periodic in one of the two spatial variables. This formulation implies that planar hexagon pulses, such as those shown in Figures 16 and 19, will exist in open regions of parameter space provided they are transversely constructed, a condition we expect to hold generically. This indicates that snaking should occur for planar hexagon pulses, and we found numerically in section 5.2 that snaking does indeed occur for hexagons pulses with two differ-

ent orientations, namely, with Bravais–Miller indices $\langle 10 \rangle$ and $\langle 11 \rangle$. We also computed and continued almost-planar hexagon pulses which bifurcate from the planar hexagon pulses in pitchfork bifurcations near each fold bifurcation: these almost-planar pulses appear prominently in the snaking diagram of localized hexagon patches.

Heuristically, we expect that the snaking regions are centered around the hexagon Maxwell curve which corresponds to the curve in (μ, ν)-parameter space along which hexagons exist that satisfy $\mathcal{H} = 0$ and that have the same energy, $\mathcal{E}(0) = 0$, as the trivial state $u = 0$. Indeed, only when the trivial state and the hexagons have roughly the same energy can we expect that stationary interfaces between them exist; otherwise, one of the states will invade the other one to reduce the overall energy. Our numerical computations confirmed this heuristic picture and showed furthermore that the Maxwell curve emerges from the codimension-two point where the bifurcation to hexagons changes from super- to subcritical, as it is there that we can expect regions of bistability to exist.

Our main numerical findings consist of the continuation results of localized hexagon and rhomboid patches in the Swift–Hohenberg equation. Our computations suggest that infinitely many hexagon and rhomboid patches coexist in open parameter regions. The localized hexagon patches lie on the same solution branch and increase in width as we move along the branch. Strikingly, the hexagon patches do not grow by adding a full ring of hexagons at each fold but instead seem to follow, at least initially, the almost-planar hexagon pulses with indices $\langle 10 \rangle$ and $\langle 11 \rangle$ that we computed in section 5.2. Overall, we found a rich snaking structure with several, possibly infinitely many, vertical asymptotes for fold bifurcations of localized structures, compared with only two asymptotes for planar hexagon pulses and 1D structures. We identified three asymptotes as arising from fold bifurcations of planar hexagon pulses with indices $\langle 10 \rangle$ and $\langle 11 \rangle$. However, we did not identify an overarching mechanism that predicts how hexagon patches might grow as we move up further along the branch.

We also investigated self-completion of asymmetric hexagon patches and found evidence that self-completion occurs only to the left of the snaking region of the $\langle 11 \rangle$ fronts. The self-completion study was motivated by results in [4, 6], where this process was addressed by using interaction theory for localized spots. The alternative explanation put forward here is based on the existence regions of planar hexagon fronts with different orientations. Though we do not have any conclusive evidence, we do not believe that the hexagon structures found in our paper can be viewed as bound states of localized spots: Figure 24, for instance, shows that localized hexagon patches can exist well outside the existence region of localized spots.

Finally, we mention that Figure 32 contains various results on localized radial structures. In particular, the branch of localized hexagon patches that bifurcates from the trivial state at $(\mu, \nu) = 0$ and later begins to snake splits, for larger values of ν, into two branches which begin or end at pitchfork bifurcations of localized radial structures. We refer the reader to [58] for a more detailed analytical and numerical study of these radial spots.

Open problems. We now outline what we believe to be interesting questions for further research on multidimensional localized patterns and refer the reader to [50] for another recent list of open problems in this area.

A major goal is to uncover the mechanism that underlies the snaking behavior of localized hexagon patches and to prove that it does occur in the Swift–Hohenberg equation. Currently, there do not seem to be any methods available that can be used to carry out such a compre-

hensive analysis. Thus, we discuss first a number of more modest open problems that may give better insight into certain aspects of hexagon snaking.

Snaking of planar hexagon pulses seems more amenable to an analytic approach. On a formal level, asymptotics beyond all orders has recently been used in [25, 52] to predict the snaking width for the 1D structures shown in Figure 2 near the codimension-two point $(\mu, \nu) = 0$. The idea behind this approach is to look more closely into the derivation of the amplitude equations (2.10) which govern the existence of 1D pulses. In the standard derivation, anisotropic terms that depend on the small scale x, rather than the large scale $X = \epsilon x$, are neglected. In [25, 52], these terms and their effect on the remaining modes through the nonlinearity are taken into account, and an analysis of the resulting exponentially small coupling terms between rolls and the 1D pulse gave an extremely accurate prediction for the snaking region in the 1D setting. The same approach may perhaps work in the planar case to capture the interaction terms between small-scale hexagons and large-scale hexagon pulses with different Bravais–Miller indices.

The energy functional of the Swift–Hohenberg equation may also help to illuminate snaking of hexagon pulses. Our numerical results indicate that the widths of the snaking regions of planar hexagon pulses depend on the orientation of their interfaces, i.e., on their Bravais–Miller indices, and it may be possible to capture this effect through an appropriate interfacial energy. Along the same lines, the growth of cells along an interface for almost-planar hexagon pulses appears qualitatively similar to the growth of interface boundaries in polycrystalline structures. Numerical studies of polycrystalline structures in [64] via two-dimensional Ising models have shown that the orientation of interfaces in hexagonal lattices has a significant effect on the propagation speed of these interfaces. In the context of the Swift–Hohenberg equation, the speeds of planar $\langle 10 \rangle$ and $\langle 11 \rangle$ fronts outside the pinning region may be similar to those seen in Ising models.

Another approach to understanding snaking of planar hexagon pulses is to assume that there exists a generic planar hexagon front for a certain value of μ which disappears, as μ decreases or increases beyond a certain threshold, via a saddle-node bifurcation as indicated in Figure 6. Instead of using geometric methods to prove that this results in snaking of planar hexagon pulses, an analytic result via Lin's method could be used to generalize the intuitive picture given in Figure 6 for two-dimensional Poincaré sections to the infinite-dimensional spatial-dynamics setting of section 3.2. This analysis has recently been carried out in [10], where it was also shown that it captures asymmetric ladder structures.

While an analysis of snaking of hexagon patches seems currently out of reach, it may be possible to say more about the underlying mechanisms by carrying out more comprehensive numerical studies. The numerical methods we have used significantly reduce the computational cost required to compute fully localized 2D patterns by using an adaptive mesh and by taking into account the symmetry of localized hexagon patches. However, the computation of larger patterns requires a less expensive way of computing hexagon patches. We believe that implementing triangular finite elements in Trilinos should result in a significant speed-up. In addition, we do not expect that the core region of hexagon patches changes much as the patterns grow. Thus, it might be possible to work with an annular region as the computational domain where the boundary conditions on the inner boundary are chosen to ensure compatibility with previously computed hexagon patches. This should lead to a further reduction of

the size of the system.

Other localized 2D patterns. Last, we comment on other localized planar structures.

In [78], fully localized stripe patches were observed in the cubic-quintic Swift–Hohenberg equation

$$u_t = -(1+\Delta)^2 u - \mu u + \nu u^3 - u^5. \tag{6.1}$$

These patterns, reproduced in Figure 1(b), are clearly anisotropic. To describe them, one could use, as in [32], the Newell–Whitehead–Segel equation

$$4\left(\partial_X - \frac{\mathrm{i}}{2}\partial_{YY}^2\right)^2 A = \epsilon A - |A|^2 A + |A|^4 A$$

for the envelope function $A(X,Y)$ of stripes that are parallel to the y-direction, where $(X,Y) = (\epsilon^{1/2}x, \epsilon^{1/4}y)$. This equation admits localized fronts $A_1(X)$ and $A_2(Y)$ with different spatial widths. The front $A_1(X)$ occurs at the 1D Maxwell point found in the normal-form analysis of the 1D cubic-quintic Swift–Hohenberg equation (6.1): this front corresponds to an "equilibrium to periodic orbit" connection for the associated spatial dynamical system, and we therefore expect snaking and the growth of additional rolls along the x-direction as an equation parameter is varied. The front $A_2(Y)$ in the Y-direction, on the other hand, corresponds to an "equilibrium to equilibrium" connection, and we do not expect snaking to occur; instead, we expect that the bifurcation curve converges, in an oscillatory fashion, to a single vertical asymptote [51]. This latter behavior is precisely what was observed in [78] in numerical simulations of fully localized stripe patterns.

Another interesting Swift–Hohenberg model is

$$u_t = -(1+\Delta)^2 u - \mu u + \nu u^3 - u^5 + \alpha\nabla\cdot[|\nabla u|^2\nabla u].$$

The last term in the above equation gives preference to patterns with square symmetry, and localized patches of squares have indeed been found in direct numerical simulations [44, 79]. We expect that these patches exhibit snaking and predict that localized square patches of square shape grow by adding new cells starting from the middle of each face.

Localized pentagonal structures have also been observed numerically in [91, Figure 10(a)–(b)] in a model of driven optical cavities. Our numerical methods could be extended easily to compute and continue these structures by expanding u as a Fourier series

$$u(r,\theta) = \sum_{n\in\mathbb{Z}} a_n(r)\mathrm{e}^{5ni\theta}$$

using five-fold symmetric terms. Pentagons do not tile the plane, so the question of snaking for localized pentagons would be interesting.

Acknowledgments. We are grateful to John Burke, Edgar Knobloch, Paul Matthews, Arnd Scheel, and Thomas Wagenknecht for many helpful comments and discussions. We also thank José Antonio Medina Hernández, Gregory Kozyreff, and the anonymous referees for many comments that helped us improve the presentation of this paper. David Lloyd and Björn Sandstede thank the Newton Institute for its hospitality during the theme programme "Pattern Formation in Large Domains" in Autumn 2005, and Björn Sandstede gratefully acknowledges a Royal Society Wolfson Research Merit Award.

Neuronal Networks with Gap Junctions: A Study of Piecewise Linear Planar Neuron Models*

S. Coombes†

Abstract. The presence of gap junction coupling among neurons of the central nervous systems has been appreciated for some time now. In recent years there has been an upsurge of interest from the mathematical community in understanding the contribution of these direct electrical connections between cells to large-scale brain rhythms. Here we analyze a class of exactly soluble single neuron models, capable of producing realistic action potential shapes, that can be used as the basis for understanding dynamics at the network level. This work focuses on planar piecewise linear models that can mimic the firing response of several different cell types. Under constant current injection the periodic response and phase response curve (PRC) are calculated in closed form. A simple formula for the stability of a periodic orbit is found using Floquet theory. From the calculated PRC and the periodic orbit a phase interaction function is constructed that allows the investigation of phase-locked network states using the theory of weakly coupled oscillators. For large networks with global gap junction connectivity we develop a theory of strong coupling instabilities of the homogeneous, synchronous, and splay states. For a piecewise linear caricature of the Morris–Lecar model, with oscillations arising from a homoclinic bifurcation, we show that large amplitude oscillations in the mean membrane potential are organized around such unstable orbits.

Key words. piecewise linear models, gap junctions, Floquet theory, coupled-oscillator theory, phase-density function

1. Introduction.

Gap junctions allow for direct communication between cells. They are typically formed from the juxtaposition of two hemichannels (connexin proteins) and allow the free movement of ions or molecules across the intercellular space separating the plasma membrane of one cell from another. Gap junction coupling is known to occur between many cell types, including, for example, pancreatic-β cells [21], heart cells [23], and astrocytes [9]. It is no understatement to say that they are now believed to be ubiquitous throughout the central nervous system [16]. Indeed it has been appreciated for some time that they exist between inhibitory neurons of the neocortex [35]. As well as being found in the neocortex [36, 4, 39, 34], they occur in many other brain regions, including the hippocampus [34], inferior olivary nucleus in the brain stem [75], the spinal cord [71], and the thalamus [47], and have recently been shown to form axo-axonic connections between *excitatory* cells in the hippocampus (on mossy fibers) [41]. Without the need for receptors to recognize chemical messengers, gap junctions are much faster than chemical synapses at relaying signals. The

synaptic delay for a chemical synapse is typically in the range 1–100 ms, while the synaptic delay for an electrical synapse may be only about 0.2 ms. There is now little doubt that gap junctions play a substantial role in the generation of neural rhythms, both functional [3, 46, 8] and pathological [82, 24], and that they may subserve system level computations [62].

The presence of gap junctional coupling in a neuronal network necessarily means that neurons directly "feel" the shape of action potentials (APs) from other neurons to which they are connected. From a modeling perspective one must therefore be careful to work with single neuron models that have an accurate representation of an AP shape. To date there is now a zoo of single neuron models that can accurately reflect these shapes for different neuronal cell types (see, for example, [49]). Typically such models, being based around that of Hodgkin–Huxley [44], are high dimensional and can often only be analyzed using perturbative techniques, such as geometric singular perturbation theory (see [72] for a review). When combined with an initial reduction of the model, say, using the techniques in [54], this has proven a remarkably powerful approach for gaining insight into single neuron behavior. However, it does not necessarily pave the way for tractable network studies. In this case, starting from a one-dimensional integrate-and-fire (IF) type model is often advocated [11]. However, since the IF model does not generate an AP shape, it must be augmented in some way as in [15, 37], leading one naturally to consider the spike-response model [38]. However, in this case the AP is considered to have a universal shape, triggered as the voltage reaches a constant voltage threshold. This does not quite capture the dynamics of a truly excitable system (with gating variables), where instead one would expect a state-dependent threshold and a variable AP shape. Thus we are naturally led to a search for planar models possessing one voltage and one gating variable that can mimic the behavior of high dimensional conductance-based models. Perhaps the most famous example of such a model is the FitzHugh–Nagumo model [31], which has many of the same characteristics as the Hodgkin–Huxley model. In this case analytical progress has been possible with one further step, namely, the introduction of piecewise linear (PWL) nullclines. This gives rise to the so-called McKean model [64], for which a number of results about the existence and stability of periodic orbits are now known [83, 84]. In this paper we introduce a broader class of PWL models that can mimic the behavior of many common cell types and describe how to analyze periodic orbits explicitly. Importantly we show that the study of such models does indeed allow for mathematical studies of the rich dynamical behavior seen in large networks with strong gap junction coupling. In this sense our work is complementary to many other theoretical studies that focus on *weak coupling* [74, 69, 7, 61, 56, 26] as well as *computational* studies with strong coupling [55, 60, 3, 76].

One of the main motivations for pursuing the work in this paper is that it may underpin the development of a tractable firing rate model of neural tissue possessing gap junctions. Necessarily this must require an understanding of strong coupling if gap induced variations in firing rate are of interest. With the exception of work by van Vreeswijk [81] (for synaptic interactions), results for strong coupling are rare. Hence, although we focus on the special case of PWL neuron models, this is useful as it allows us to gain some specific insight into dynamics in the strong coupling regime. Moreover, some of the techniques we develop here, notably for determining the stability of the asynchronous state in a strongly gap junction coupled global network, are valid not just for PWL systems but also for more general limit cycle oscillator networks. The more detailed structure of this paper is as follows. In section 2

we introduce the class of PWL models that we study throughout the paper. In particular, we focus on two distinct examples, one of which is the McKean model and the other a new PWL model that caricatures the conductance-based Morris–Lecar model with oscillations generated via a homoclinic bifurcation [68]. Next, in section 3, we show how to analyze periodic orbits that arise in such models under constant current injection. This includes the construction of orbits, the determination of their stability, and the calculation of the phase response curve (PRC) for the orbit. Stability is analyzed using Floquet theory and shown to lead to a simple formula for the nonzero Floquet exponent. Network studies are pursued in section 4 for two important cases: (i) weak coupling, and (ii) strong coupling. In the former case we show how to calculate the phase interaction function for a network in closed form using a Fourier representation. This is used to investigate phase-locked states in both small and large networks. Focusing on synchronous and splay states in globally coupled networks, we further show how to treat the case of strong coupling. Our results for existence and stability recover those of the weak coupling theory in the appropriate limit. In section 5 we use this strong coupling theory to understand large amplitude oscillations seen in the mean field signal of networks of Morris–Lecar neurons with gap junction coupling [42]. Finally, in section 6 we discuss natural extensions of the work in this paper.

2. Piecewise linear neuron models. The excitable properties of neural cells can often be summarized simply by determining their firing rate response to constant current injection. Broadly speaking one then classifies a neuron as being either Type I or Type II. Type I is obtained when repetitive APs are generated with an arbitrarily low frequency, whereas in Type II APs emerge at a nonzero frequency. In this latter case it is natural to think of oscillations as arising through a Hopf bifurcation. Indeed, from the seminal experimental and modeling work of Hodgkin and Huxley, this is known to be the case for the squid giant axon. Thus, although the original Hodgkin–Huxley model consists of four nonlinear ordinary differential equations (ODEs), it is not surprising that alternative planar models can also be invoked to fit at least the firing rate response. The classic example is the FitzHugh–Nagumo model [31], though others such as those obtained by a systematic reduction of the Hodgkin–Huxley equations are known [1]. These planar models are described by two coupled nonlinear ODEs—one for voltage and the other for a single effective gating variable. The nullcline for the voltage variable has a cubic shape typical of many excitable systems. Although powerful geometric techniques may be brought to bear on such planar models, their analysis in closed form is precluded by the presence of the cubic nonlinearity. This has motivated the introduction and study of PWL caricatures, such as the McKean model [64, 79]. The equations for a single two-dimensional McKean neuron take the form

$$C\dot{v} = f(v) - w + I, \tag{2.1}$$

$$\dot{w} = g(v, w), \tag{2.2}$$

where the functions $f(v)$ and $g(v, w)$ are given by

$$f(v) = \begin{cases} -v, & v < a/2, \\ v - a, & a/2 \le v \le (1+a)/2, \\ 1 - v, & v > (1+a)/2, \end{cases} \tag{2.3}$$

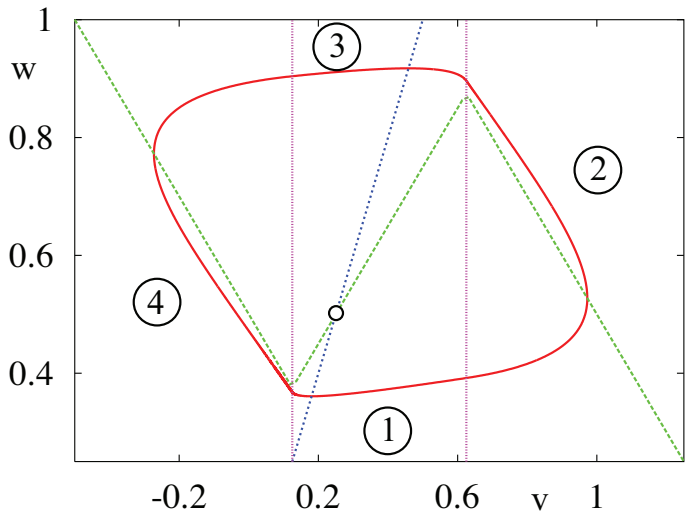

Figure 1. *The phase plane for the McKean model has a nullcline with a piecewise linear cubic shape (dashed green line) corresponding to $\dot{v}=0$ and a linear one associated with $\dot{w}=0$ (dotted blue line). Parameters are $C=0.1$, $I=0.5$, $\gamma=0.5$, and $a=0.25$. The red line corresponds to a stable periodic orbit.*

$$g(v,w)=v-\gamma w. \tag{2.4}$$

Here, $C>0$, $\gamma>0$, I is a constant drive, and $f(v)$ is a PWL caricature of the cubic FitzHugh–Nagumo nonlinearity $f(v)=v(1-v)(v-a)$, while $g(v,w)$ describes the linear dynamics of the gating variable. Another popular choice for $f(v)$ is the function $f(v)=-v+\Theta(v-a)$, where Θ is the Heaviside step function. The analysis of this latter nonlinearity has been pursued in detail by Tonnelier [78, 80]. A phase-plane plot of the McKean model is shown in Figure 1. Generating Type I behavior, often associated with either a homoclinic bifurcation or a saddle-node on an invariant cycle (SNIC) [27], necessarily requires the introduction of a nonlinear dynamics for the gating variable, as in the Morris–Lecar model or the cortical neuron model of Wilson [85]. A PWL idealization of the Morris–Lecar model has already been introduced by Tonnelier and Gerstner [80], and since the nullcline of the gating variable in the Wilson model has a quadratic shape, it too is easy to caricature. Indeed, many of the shapes for $g(v,w)$ underlying a Type I response appear to be described with the simple continuous choice

$$g(v,w)=\begin{cases}(v-\gamma_1 w+b^*\gamma_1-b)/\gamma_1, & v<b,\\ (v-\gamma_2 w+b^*\gamma_2-b)/\gamma_2, & v\geq b,\end{cases} \tag{2.5}$$

with $-a/2<b^*<(1-a)/2$ and $a/2<b<(1+a)/2$. Here we take $\gamma_2>0$, though we allow γ_1 to take both positive and negative values. Another natural choice, though this time discontinuous, is $g(v,w)=v-\gamma w+\Theta(v-b)$, which has been used to caricature the Morris–Lecar model in particular [80]. Note that (up to a constant shift) we recover the PWL McKean model with the choice $\gamma_1=\gamma=\gamma_2$ in (2.5). An example with dynamics that is bistable between a fixed point and a limit cycle is shown in Figure 2. Here the emergence of low frequency oscillations is associated with a homoclinic bifurcation, whereby the amplitude

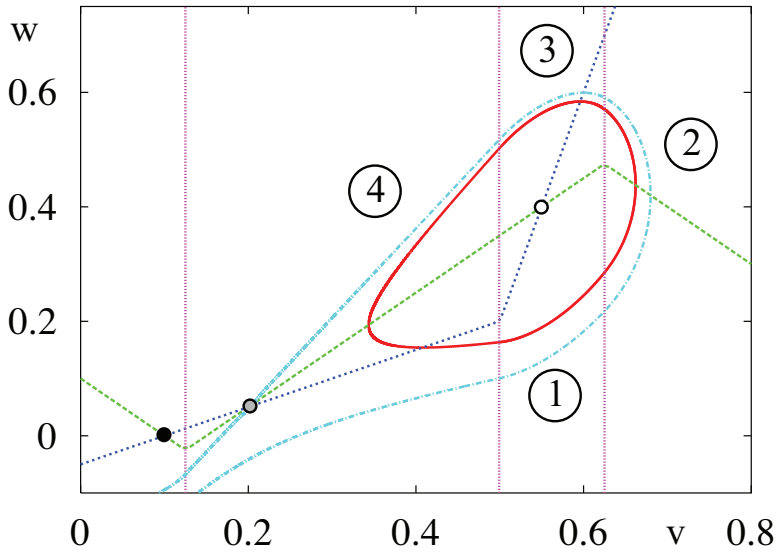

Figure 2. *The phase plane for the piecewise linear Morris–Lecar (PML) model with* $\gamma_1 = 2$, $\gamma_2 = 0.25$, $C = 0.825$, $I = 0.1$, $a = 0.25$, $b = 0.5$, *and* $b^* = 0.2$. *The pale blue line passing through the saddle (gray filled circle) is the separatrix between the stable fixed point (black filled circle) and the stable limit cycle (in red).*

of the periodic orbit grows with a decrease in I and collides with a saddle point. We regard this model as a PWL caricature of the Morris–Lecar neuron, with oscillations arising from a homoclinic bifurcation, and as such shall refer to it as the PML model. On a technical point it is important to note that it is not possible to have a smooth SNIC with a PWL model, since it would not contain any quadratic parts (necessary to define a saddle-node bifurcation). One such example would be the nonlinear IF neuron, described by Karbowski and Kopell [52] with subthreshold dynamics $\dot{v} = |v| + I$. Throughout the rest of this paper we shall work with the PWL model defined by (2.3) and (2.5), though we stress here that the techniques we develop work for all of the PWL choices for $f(v)$ and $g(v, w)$ that we have discussed above.

3. Periodic orbits. Much can be said about the dynamics of models of PWL planar systems defined by (2.3) and (2.5). For the special case that $f(v) = -v + \Theta(v - a)$ and $g(v, w) = v$ Tonnelier [78] has shown how to use the method of harmonic balance [2] to obtain information about periodic orbits. Here we present an alternative approach that can tackle more general choices for f and g. In essence we solve the system in each of its linear regimes and demand continuity of solutions to construct orbits of the full nonlinear flow. To see how we do this it is first convenient to consider a two-dimensional linear system of the form

$$\dot{z} = Az + b, \qquad z = \begin{bmatrix} v \\ w \end{bmatrix}, \tag{3.1}$$

where the 2×2 matrix A has components a_{ij}, $i, j = 1, 2$, and b is a constant 2×1 input vector. The solution to (3.1) may be written in the form

$$z(t) = G(t)z(0) + K(t)b, \qquad G(t) = \mathrm{e}^{At}, \qquad K(t) = \int_0^t G(s)\mathrm{d}s. \tag{3.2}$$

If A has real eigenvalues $\lambda_\pm$, such that $Aq_\pm = \lambda_\pm q_\pm$ with $q_\pm \in \mathbb{R}^2$, given by

$$\lambda_\pm = \frac{\mathrm{Tr}\, A \pm \sqrt{(\mathrm{Tr}\, A)^2 - 4 \det A}}{2}, \tag{3.3}$$

then we may "diagonalize" and write $G(t)$ in the computationally useful form $G(t) = P\mathrm{e}^{\Lambda t}P^{-1}$, where $\Lambda = \mathrm{diag}(\lambda_+, \lambda_-)$, $P = [q_+, q_-]$, and $q_\pm = [(\lambda_\pm - a_{22})/a_{21}, 1]^T$. If A has complex eigenvalues $\rho \pm i\omega$, then the associated complex eigenvector is q such that $Aq = (\rho + i\omega)q$, $q \in \mathbb{C}^2$. In this case $G(t) = \mathrm{e}^{\rho t}P\mathcal{R}_{\omega t}P^{-1}$, where

$$\mathcal{R}_\theta = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix}, \qquad P = [\mathrm{Im}(q), \mathrm{Re}(q)] = \begin{bmatrix} 0 & 1 \\ \widehat{\omega} & \widehat{\rho} \end{bmatrix}, \tag{3.4}$$

with $\widehat{\omega} = \omega/a_{12}$ and $\widehat{\rho} = (\rho - a_{11})/a_{12}$. Note that ρ and ω may be written using the invariance of Tr and det as $\rho = (a_{11} + a_{22})/2$, $\omega^2 = a_{11}a_{22} - a_{12}a_{21} - \rho^2 > 0$. The explicit form for $G(t)$, necessary for carrying out computations, is given in Appendix A.

To specify a periodic orbit of the PWL model of choice it is convenient to break the solution into pieces such that on each piece the dynamics is governed by a linear dynamical system. As a concrete example we will focus on the type of periodic orbits shown in Figures 1 and 2. In both these examples we need only consider four distinct pieces, labeled by $\mu = 1, \ldots, 4$. We denote the time spent in each of these four states as T_μ. For each piece we write $z_\mu(t) = G_\mu(t)z_\mu(0) + K_\mu(t)b_\mu$ with the forms for G_μ and K_μ given by (3.2) under the replacement of A by A_μ. For the McKean model we have that $A_1 = A_3$, $A_2 = A_4$, where

$$A_1 = \begin{bmatrix} 1/C & -1/C \\ 1 & -\gamma \end{bmatrix}, \qquad A_2 = \begin{bmatrix} -1/C & -1/C \\ 1 & -\gamma \end{bmatrix}, \tag{3.5}$$

with

$$b_1 = \begin{bmatrix} (I-a)/C \\ 0 \end{bmatrix}, \quad b_2 = \begin{bmatrix} (1+I)/C \\ 0 \end{bmatrix}, \quad b_4 = \begin{bmatrix} I/C \\ 0 \end{bmatrix}, \tag{3.6}$$

and $b_3 = b_1$. For the PML model defined by (2.5)

$$A_1 = \begin{bmatrix} 1/C & -1/C \\ 1/\gamma_2 & -1 \end{bmatrix}, \qquad A_2 = \begin{bmatrix} -1/C & -1/C \\ 1/\gamma_2 & -1 \end{bmatrix}, \qquad A_4 = \begin{bmatrix} 1/C & -1/C \\ 1/\gamma_1 & -1 \end{bmatrix}, \tag{3.7}$$

with

$$b_1 = \begin{bmatrix} (I-a)/C \\ b^* - b/\gamma_2 \end{bmatrix}, \quad b_2 = \begin{bmatrix} (1+I)/C \\ b^* - b/\gamma_2 \end{bmatrix}, \quad b_4 = \begin{bmatrix} (I-a)/C \\ b^* - b/\gamma_1 \end{bmatrix}, \tag{3.8}$$

$A_3 = A_1$, and $b_3 = b_1$. Introducing two voltage thresholds v_{th}^1 and v_{th}^2, where $(v_{\mathrm{th}}^1, v_{\mathrm{th}}^2) = (a/2, (1+a)/2)$ for the McKean model and $(v_{\mathrm{th}}^1, v_{\mathrm{th}}^2) = (b, (1+a)/2)$ for the PML model, means that we can parameterize a periodic orbit by choosing initial data such that $z_1(0) = (v_{\mathrm{th}}^1, w^*)$ (with w^* as yet undetermined) and $z_{\mu+1}(0) = G_\mu(T_\mu)z_\mu(0) + K_\mu(T_\mu)b_\mu$ for $\mu = 1, 2, 3$. The "times-of-flight" T_μ are determined by solving the threshold crossing conditions $v_1(T_1) = v_{\mathrm{th}}^2$, $v_2(T_2) = v_{\mathrm{th}}^2$, $v_3(T_3) = v_{\mathrm{th}}^1$, and $v_4(T_4) = v_{\mathrm{th}}^1$. A periodic solution can then be found by solving

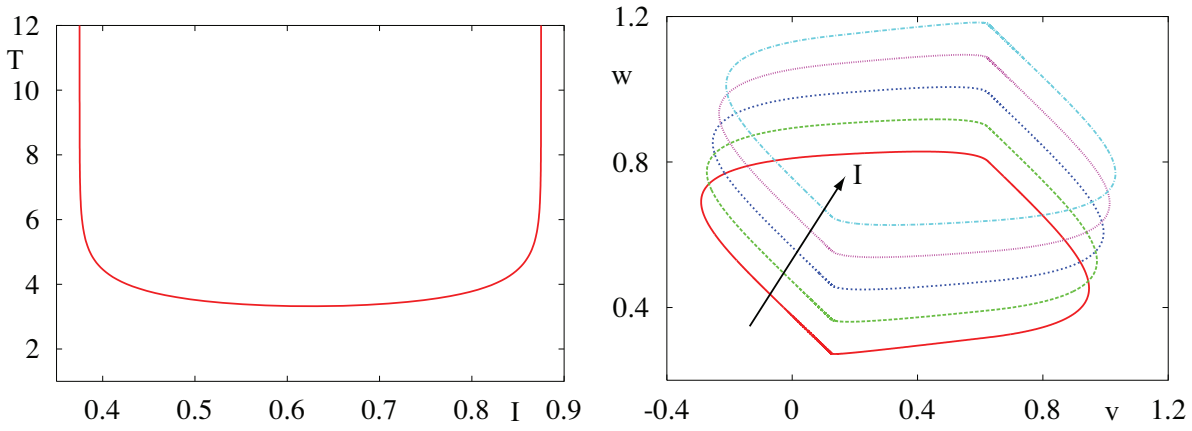

Figure 3. *McKean model. Left: Period of solution as a function of background drive I. Right: Shape of orbits for $I = 0.4, 0.5, 0.6, 0.7, 0.8$. Other parameters are as in Figure 1.*

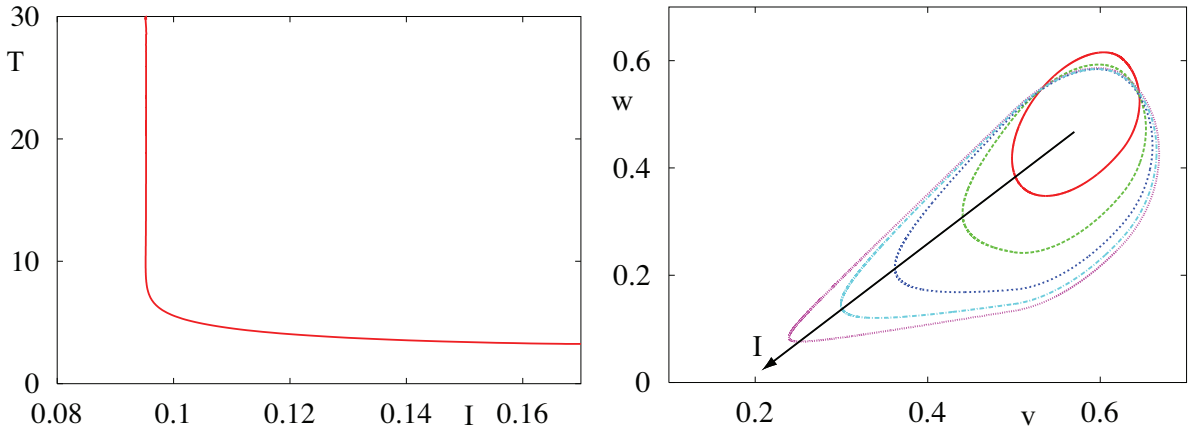

Figure 4. *PML model. Left: Period of solution as a function of background drive I. Right: Shape of orbits for I ranging from 0.17 to 0.09. Other parameters are as in Figure 2.*

$w_4(T_4) = w_1(0)$, thus yielding w^* and the period $T = \sum_{\mu=1}^{4} T_\mu$. In Figure 3 we plot the period and orbit shape as a function of the external drive I obtained using the prescription above. A similar plot for the PML model is shown in Figure 4. In contrast to the McKean model, the firing rate of the PML model at the onset of repetitive behavior increases from zero, as expected for a system with a homoclinic bifurcation.

Three other types of periodic solution are also possible. Two of these involve only a single threshold crossing—namely, one which crosses through the section $v = v_{\rm th}^1$ but not $v = v_{\rm th}^2$ and another which crosses through $v = v_{\rm th}^2$ but not $v = v_{\rm th}^1$. Calling these the *sub-* and *supra*threshold periodic orbits, respectively, we may solve each using the approach (and notation) above. The subthreshold orbit is specified by the restriction $\mu = \{1, 4\}$ with $z_1(0) = (v_{\rm th}^1, w^*)$, subject to $v_1(T_1) = v_{\rm th}^1 = v_4(T_4)$ and $w_4(T_4) = w_1(0)$, so that $T = T_1 + T_4$. The suprathreshold orbit is specified by the restriction $\mu = \{2, 3\}$ with $z_2(0) = (v_{\rm th}^2, w^*)$, subject to $v_2(T_2) = v_{\rm th}^2 = v_3(T_3)$ and $w_3(T_3) = w_2(0)$, so that $T = T_2 + T_3$. Examples of

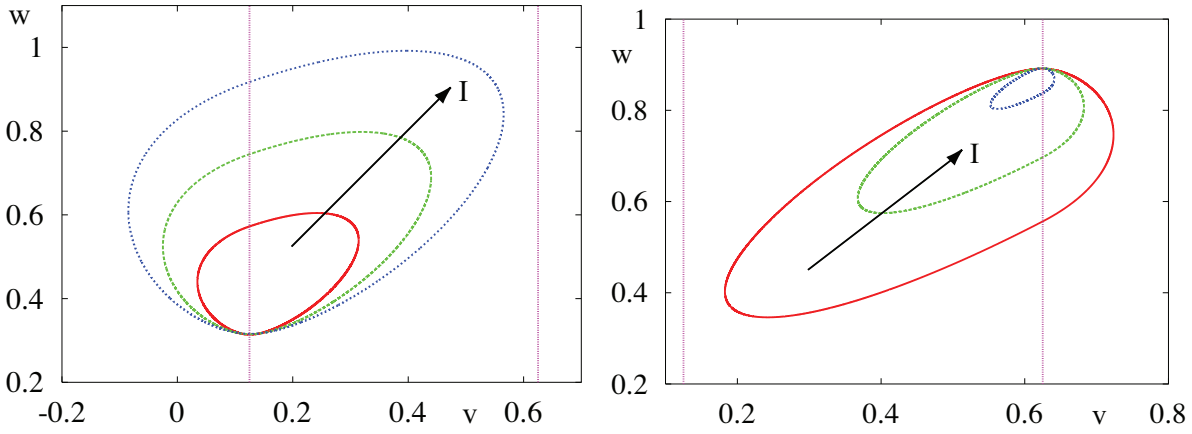

Figure 5. *McKean model. Left:* Subthreshold *orbits with* $C = 1$, $\gamma = 0.4$, *and* $I = 0.475, 0.5, 0.525$. *All these subthreshold orbits have a common period. Right:* Suprathreshold *orbits with* $C = 1$, $\gamma = 0.7$, *and* $I = 0.47, 0.49, 0.51$. *All these suprathreshold orbits have a common period. Other parameters are as in Figure* 1.

such orbits are shown in Figure 5. The final type of orbit does not cross any thresholds and is defined simply by $v(T) = v_{\rm th}$ and $v(T) = v(0)$ for some section $v_{\rm th}$ through the orbit. We shall call such an orbit *harmonic*, because its shape will be determined by a linear system of ODEs. Note, however, that it will exist only at an isolated point in parameter space, namely, where the coefficient matrix A has purely complex eigenvalues ($\mathrm{Tr}\, A = 0$, $\det A > 0$).

3.1. Phase response curve. It is common practice in neuroscience to characterize a neuronal oscillator in terms of its phase response to a perturbation. This gives rise to the notion of a so-called phase response curve (PRC). For a detailed discussion of PRCs we refer the reader to [29, 30, 45]. It suffices to say that there are three main ways to calculate PRCs, attributed to Winfree, Kuramoto, and Malkin. A nice comparison of these three approaches can be found in [50]. For concreteness we shall follow the exposition in [13] for the Malkin adjoint method. Consider a dynamical system $\dot{z} = F(z)$ with a T-periodic solution $Z(t) = Z(t+T)$ and introduce an infinitesimal perturbation Δz_0 to the trajectory $Z(t)$ at time $t = 0$. This perturbation evolves according to the linearized equation of motion:

$$\frac{\mathrm{d}\Delta z}{\mathrm{d}t} = DF(Z(t))\Delta z, \qquad \Delta z(0) = \Delta z_0. \tag{3.9}$$

Here $DF(Z)$ denotes the Jacobian of F evaluated along Z. Introducing a time-independent phase shift $\Delta\theta$ as $\theta(Z(t) + \Delta z(t)) - \theta(Z(t))$, we have to first order in Δz that

$$\Delta\theta = \langle Q(t), \Delta z(t)\rangle, \tag{3.10}$$

where $\langle\cdot,\cdot\rangle$ defines the standard inner product, and $Q = \nabla_Z\theta$ is the gradient of θ evaluated at $Z(t)$. Taking the time-derivative of (3.10) gives

$$\left\langle \frac{\mathrm{d}Q}{\mathrm{d}t}, \Delta z \right\rangle = -\left\langle Q, \frac{\mathrm{d}\Delta z}{\mathrm{d}t} \right\rangle = -\langle Q, DF(Z)\Delta z\rangle = -\left\langle DF^T(Z)Q, \Delta z\right\rangle. \tag{3.11}$$

Since the above equation must hold for arbitrary perturbations, we see that the gradient $Q = \nabla_Z \theta$ satisfies the linear equation

$$\frac{\mathrm{d}Q}{\mathrm{d}t} = D(t)Q, \qquad D(t) = -DF^T(Z(t)), \tag{3.12}$$

subject to the conditions $\nabla_{Z(0)}\theta \cdot F(Z(0)) = 1/T$ and $Q(t) = Q(t+T)$. The first condition simply guarantees that $\dot{\theta} = 1/T$ (at any point on the periodic orbit), and the second enforces periodicity. The (vector) PRC, R, is related to Q according to the simple scaling $R = QT$. In general (3.12) must be solved numerically to obtain the PRC, say, using the *adjoint* routine in XPP [25]. However, for PWL models $DF(Z)$ is piecewise constant, and we can obtain a solution in closed form. Introducing a labeling as for the periodic orbit in section 3, we rewrite (3.12) in the form $\dot{Q}_\mu = D_\mu Q_\mu$, where $D_\mu = -A_\mu^T$. The solution of each subsystem is given by $Q_\mu(t) = G_\mu^T(T_\mu - t)Q_\mu(T_\mu)$ with $Q_\mu(T_\mu) = Q_{\mu+1}(0)$ for $\mu = 1, 2, 3$. Denoting $Q_4(T_4) = (q_1, q_2)$, we have the relation

$$\frac{q_1}{\mu}\left[f(v_{\mathrm{th}}^1) - w^* + I\right] + q_2 g(v_{\mathrm{th}}^1, w^*) = \frac{1}{T}. \tag{3.13}$$

Periodicity is ensured by choosing $Q_1(0) = Q_4(T_4)$. After introducing the 2×2 matrix $\Gamma = G_1^T(T_1)G_2^T(T_2)G_3^T(T_3)G_4^T(T_4)$, this periodicity condition takes the form

$$(\Gamma_{11} - 1)q_1 + \Gamma_{12}q_2 = 0. \tag{3.14}$$

Hence (3.13) and (3.14) define a pair of linear equations for (q_1, q_2) that we may write in the form

$$\Psi \begin{bmatrix} q_1 \\ q_2 \end{bmatrix} = \begin{bmatrix} 1/T \\ 0 \end{bmatrix}, \qquad \Psi = \begin{bmatrix} (f(v_{\mathrm{th}}^1) - w^* + I)/\mu & g(v_{\mathrm{th}}^1, w^*) \\ \Gamma_{11} - 1 & \Gamma_{12} \end{bmatrix}. \tag{3.15}$$

This is easily solved, with, say, Cramer's rule, giving $q_i = \det(\Psi_i)/\det(\Psi)$, where

$$\Psi_1 = \begin{bmatrix} 1/T & g(v_{\mathrm{th}}^1, w^*) \\ 0 & \Gamma_{12} \end{bmatrix}, \qquad \Psi_2 = \begin{bmatrix} (f(v_{\mathrm{th}}^1) - w^* + I)/\mu & 1/T \\ \Gamma_{11} - 1 & 0 \end{bmatrix}. \tag{3.16}$$

Similarly we may also construct the PRCs for the sub- and suprathreshold orbits (though we omit the details here). Note that the discussion above assumes that the underlying dynamical system is described by a continuous vector field, so that we are free to choose any point on the orbit to fix the condition $\dot{\theta} = 1/T$. For discontinuous systems such as would arise in the singular limit $C = 0$ or with a discontinuous choice of $g(v, w)$, then conditions (3.13) and (3.14) are not sufficient. Techniques for tackling relaxation style oscillations that arise in the former case have been developed in [48, 17], while the latter case can easily be treated by writing down the matching conditions to fix $\dot{\theta} = 1/T$ at any jump discontinuities in $g(v, w)$. Plots of two example PRCs constructed using the above approach are shown in Figure 6.

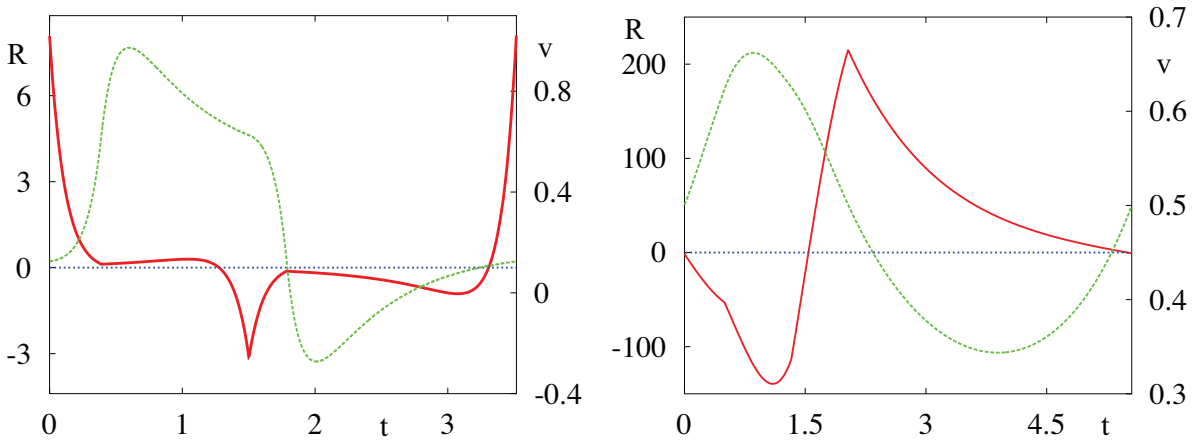

Figure 6. *PRC (first component of $Q(t)$ scaled by T). The dashed line shows the underlying shape of the periodic voltage solution. Left: McKean model PRC with parameters as in Figure 1. Right: PML model with parameters as in Figure 2.*

3.2. Stability: Floquet theory. The natural way to determine the stability of a periodic orbit is to use Floquet theory (see, for example, [14]). The linearized equations describing the evolution of perturbations around the periodic orbit are given by (3.9). Note that with the use of a time-ordering operator $\mathcal{T}$ we may write the fundamental matrix solution of this T-periodic system as

$$G(t) = \mathcal{T}\left\{\exp\left[\int_0^t DF(Z(s))\mathrm{d}s\right]\right\}, \tag{3.17}$$

where $\mathcal{T}D(t)D(s) = \Theta(t-s)D(t)D(s)+\Theta(s-t)D(s)D(t)$. Let μ_k be the (distinct) eigenvalues of $G(T)$, and write $\sigma_k = \ln(\mu_k)/T \bmod 2\pi i$. It follows that the periodic orbit will be stable if all the Floquet exponents have negative real part, namely, $\mathrm{Re}\,\sigma_k < 0$ for all $k = 1, 2$. Note that one of the Floquet exponents is always zero since it corresponds to perturbations along the periodic orbit (i.e., $\dot{Z}$ is a solution of (3.9) with a Floquet multiplier equal to unity). For PWL models time-ordering is not an issue (since DF is piecewise constant), and we have that $G(T) = G_4(T_4)G_3(T_3)G_2(T_2)G_1(T_1) = \Gamma^T$.

We now make use of the well-known result $\mu_1\mu_2 = \exp(\int_0^T \mathrm{Tr}\, DF(s)\mathrm{d}s)$ to obtain $(\sigma_1, \sigma_2) = (0, \sigma)$, where

$$\sigma = \frac{1}{T}\sum_{\mu=1} T_\mu \,\mathrm{Tr}\, A_\mu. \tag{3.18}$$

The nonzero exponent for the sub- and suprathreshold orbit is given by (3.18) with $T_2 = T_3 = 0$ and $T_1 = T_4 = 0$, respectively. For a harmonic splay state we have simply that $\sigma = \mathrm{Tr}\, A_1$. Periodic solutions are stable if $\sigma < 0$. For example, a periodic solution of the McKean model has a nonzero Floquet exponent $\sigma = (T_1 - T_2 + T_3 - T_4)/(CT) - \gamma$. Note that in the singular limit $C \to 0$ we expect $T_{1,3} \to 0$, so that $\sigma \leq 0$. Hence, any periodic orbits that persist in this limit will be stable. For the PML model $\sigma = (T_1 - T_2 + T_3 + T_4)/(CT) - 1$. Some example plots of the nonzero Floquet exponent as a function of the external drive I are shown in Figure 7.

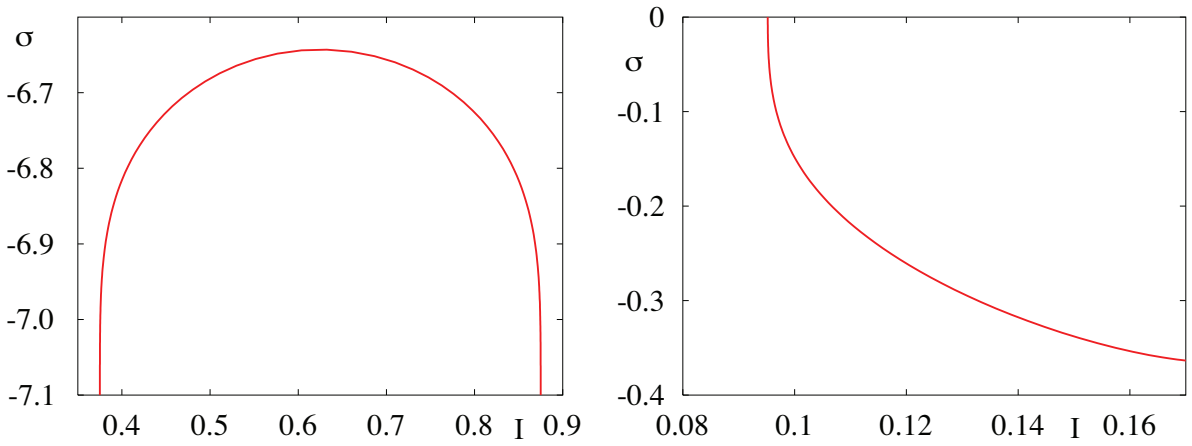

Figure 7. *Plot of the Floquet exponent σ. Left: Result for the McKean model using the solution branch of Figure 3 (left). Right: Result for the PML model using the solution branch of Figure 4 (left). Since $\sigma < 0$, the solution branches in these two examples are stable.*

4. Gap junction coupling.

To model the direct gap junction coupling between two cells, one labeled *post* and the other *pre*, we introduce an extra current to the right-hand side of (2.1) of the form

$$I_{\text{gap}} = g_{\text{gap}}(v_{\text{pre}} - v_{\text{post}}), \tag{4.1}$$

where g_{gap} is the conductance of the gap junction. Indexing neurons in a network with the label $i = 1, \ldots, N$ and defining a gap junction conductance strength between neurons i and j as g_{ij} means that neuron i experiences a drive of the form $N^{-1}\sum_{j=1}^{N} g_{ij}(v_j - v_i)$. For a phase-locked state then $z_i(t) = z(t - \phi_i T)$, $z(t) = z(t + T)$ (for some constant phases $\phi_i \in [0, 1)$), and we have N equations distinguished by the driving terms $N^{-1}\sum_{j=1}^{N} g_{ij}(v(t + (\phi_i - \phi_j)T) - v(t))$. In this section we pursue two approaches for studying networks of identical PWL neurons with such coupling terms. The first is the more familiar coupled-oscillator approach, valid for weak coupling. The second approach exploits a Fourier representation to obtain closed form solutions for splay states with arbitrary coupling strength.

4.1. Weak coupling.

The theory of weakly coupled oscillators [57, 28] is now a standard tool of dynamical systems theory and has been invoked by several authors to study networks with gap junctions [69, 61, 70, 26, 63, 53]. It has also previously been used to study networks of McKean neurons in the singular limit $C \to 0$ [17, 22]. We introduce a time-dependent phase along the T-periodic orbit of an uncoupled neuron such that $\dot{\theta}_i(t) = 1/T$ for $i = 1, \ldots, N$, with $\theta_i \in [0, 1)$. In the presence of weak coupling (small g_{ij}), the dynamics for a gap junction coupled network then takes the form

$$\frac{\mathrm{d}\theta_i}{\mathrm{d}t} = \frac{1}{T} + \frac{1}{N}\sum_{j=1}^{N} g_{ij} H(\theta_j - \theta_i), \qquad i = 1, \ldots, N, \tag{4.2}$$

where $H(\theta)$ is the so-called phase interaction function. For gap junction coupling this is given by

$$H(\theta) = \frac{1}{T}\int_0^T Q^T(t)(v(t+\theta T) - v(t), 0)\mathrm{d}t, \tag{4.3}$$

where $v(t)$ is a periodic solution of (2.1) and (2.2), and $Q(t)$ is the associated adjoint. It is convenient to introduce Fourier series for the 2×1 vectors z and Q and write

$$z(t) = \sum_n z_n \mathrm{e}^{2\pi i n t/T}, \qquad Q(t) = \sum_n Q_n \mathrm{e}^{2\pi i n t/T}. \tag{4.4}$$

The phase interaction function then has the series representation

$$H(\theta) = \sum_n R_n v_{-n}[\mathrm{e}^{-2\pi i n\theta} - 1], \tag{4.5}$$

where v_n denotes the first component of z_n and R_n is the first component of Q_n. The Fourier coefficients z_n and Q_n may be obtained in closed form by taking Fourier transforms of the solutions for $z(t)$ and $Q(t)$. A straightforward calculation, using the forms of $z(t)$ and $Q(t)$ derived in sections 3 and 3.1, gives

$$z_n = \frac{1}{T}\sum_{\mu=1}^4 \left[\alpha_\mu^n z_\mu(0) + \gamma_\mu^n b_\mu\right] \mathrm{e}^{-2\pi i n\nu_\mu}, \qquad Q_n = \frac{1}{T}\sum_{\mu=1}^4 \beta_\mu^n Q_\mu(T_\mu)\mathrm{e}^{-2\pi i n\nu_\mu}, \tag{4.6}$$

where $(\nu_1, \nu_2, \nu_3, \nu_4) = (0, T_1, T_1+T_2, T_1+T_2+T_3)/T$ and the coefficients α_μ^n, β_μ^n, and γ_μ^n are given explicitly by

$$\alpha_\mu^n = \int_0^{T_\mu} G_\mu(t)\mathrm{e}^{-2\pi i n t/T}\mathrm{d}t, \quad \beta_\mu^n = \int_0^{T_\mu} G_\mu^T(T_\mu - t)\mathrm{e}^{-2\pi i n t/T}\mathrm{d}t, \quad \gamma_\mu^n = \int_0^{T_\mu} K_\mu(t)\mathrm{e}^{-2\pi i n t/T}\mathrm{d}t. \tag{4.7}$$

Computationally useful forms for these matrix coefficients are given in Appendix B. Writing $H(\theta)$ as the Fourier series $\sum_n H_n \mathrm{e}^{2\pi i n\theta}$, we have that $H_n = R_{-n}v_n$ for $n \neq 0$ and $H_0 = -\sum_{n\neq 0} H_n$. From the structure of (4.7) given in Appendix B we see that the Fourier coefficients for the orbit and the response function decay as $1/n$, and hence those of the phase interaction function decay as $1/n^2$. Examples of phase interaction functions constructed using the above prescription are shown in Figure 8.

We define a phase-locked solution to be of the form $\theta_i(t) = \phi_i + \Omega t$, where ϕ_i is a constant phase and Ω is the collective frequency of the coupled oscillators. Substitution into the averaged system (4.2) gives

$$\Omega = \frac{1}{T} + \frac{1}{N}\sum_{j=1}^N g_{ij} H(\phi_j - \phi_i), \qquad i = 1, \ldots, N. \tag{4.8}$$

After choosing some reference oscillator, these N equations determine the collective frequency Ω and $N-1$ relative phases. In order to analyze the local stability of a phase-locked solution $\Phi = (\phi_1, \ldots, \phi_N)$, we linearize the system by setting $\theta_i(t) = \phi_i + \Omega t + \widetilde{\theta}_i(t)$ and expand to first order in $\widetilde{\theta}_i$ to obtain

$$\frac{\mathrm{d}\widetilde{\theta}_i}{\mathrm{d}t} = \frac{1}{N}\sum_{j=1}^N \widehat{\mathcal{H}}_{ij}(\Phi)\widetilde{\theta}_j, \qquad \widehat{\mathcal{H}}_{ij}(\Phi) = g_{ij}H'(\phi_j - \phi_i) - \delta_{i,j}\sum_{k=1}^N g_{ik}H'(\phi_k - \phi_i), \tag{4.9}$$

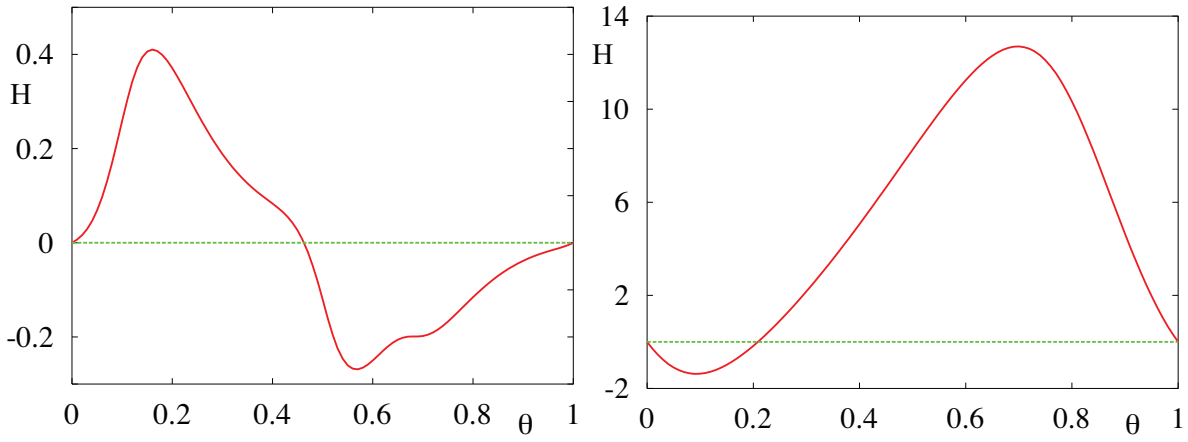

Figure 8. *Phase interaction functions corresponding to Figure 6. Left: McKean model. Right: PML model.*

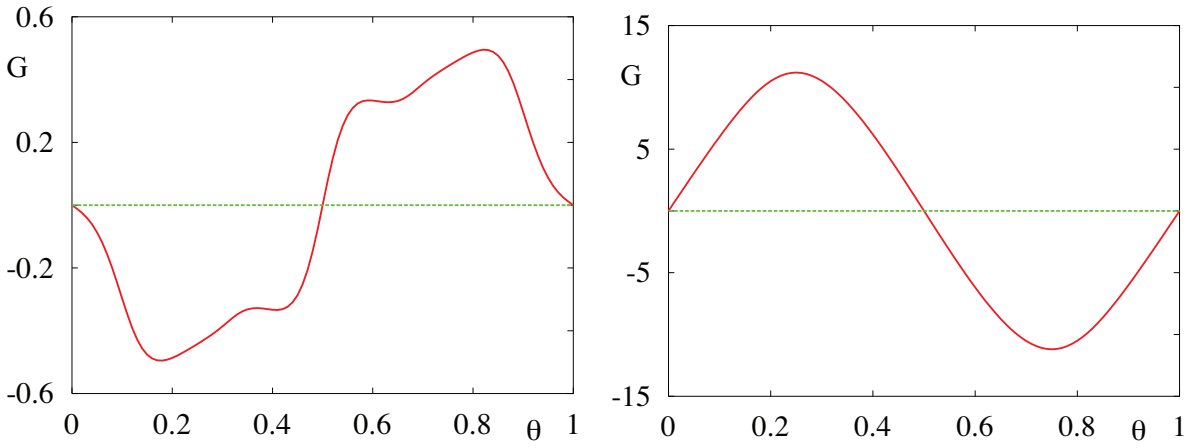

Figure 9. *Phase interaction function between two neurons; $G(\theta) = H(-\theta) - H(\theta)$ corresponding to Figure 8. Left: McKean model. Right: PML model.*

where $H'(\phi) = \mathrm{d}H(\phi)/\mathrm{d}\phi$. One of the eigenvalues of the Jacobian $\widehat{\mathcal{H}}$ is always zero, and the corresponding eigenvector points in the direction of the flow, that is, $(1, 1, \ldots, 1)$. The phase-locked solution will be stable provided that all other eigenvalues have a negative real part. For two neurons, with $g_{ij} = g$, a phase-locked state is defined by $G(\phi) = 0$, where $G(\phi) = g[H(-\phi) - H(\phi)]$ and ϕ is the relative phase between the two. The condition for stability is simply $G'(\phi) < 0$. By symmetry the phase-locked state ($\phi = 0$) and the antisynchronous state ($\phi = 1/2$) are guaranteed to exist. In Figure 9 we plot $G(\phi)$ for the phase interaction functions of Figure 8. In this example we see that the McKean model admits a stable synchronous solution, while the PML model admits a stable antisynchronous solution.

For globally coupled networks with $g_{ij} = g$ the system (4.2) is $\mathbf{S}_N \times \mathbf{T}^1$ equivariant. By the equivariant branching lemma maximally symmetric solutions describing synchronous, splay, and cluster states are expected to be generic [5]. For the synchronous state, defined by $\phi_i(t) = 0$, the collective frequency is given simply as $\Omega = 1/T$, and $\widehat{\mathcal{H}}_{ij}(\Phi) = gH'(0)[1 - N\delta_{ij}]$.

Hence, there is a single zero eigenvalue and an eigenvalue $\lambda = -gH'(0)$ of multiplicity $N-1$. For the examples in Figure 8 we see that the McKean model has a stable synchronous solution, while the PML model, with oscillations generated by a homoclinic bifurcation, does not. If the underlying single neuron model has an oscillation generated by a SNIC bifurcation (for which the PRC is well known), then synchrony is stable [26, 50]. For a splay state of the form $\phi_i = i/N$ the eigenvalues of $\widehat{\mathcal{H}}$ are given by $\lambda_n = g\sum_j H'(j/N)(\mathrm{e}^{2\pi inj/N}-1)/N$ for $n = 0,\dots,N-1$. Such solutions are often called merry-go-round states, since all oscillators in the network pass through some fixed phase at regularly spaced time intervals of T/N. For a recent review of the stability of cluster states (in which subsets of the oscillator population synchronize, with oscillators belonging to different clusters behaving differently) we refer the reader to [40, 12]. We shall not focus on them further here.

In the limit $N \to \infty$ we have the useful result that (for global coupling) network averages may be replaced by time averages:

$$\lim_{N\to\infty} \frac{1}{N}\sum_{j=1}^{N} F(jT/N) = \frac{1}{T}\int_0^T F(t)\mathrm{d}t = F_0 \tag{4.10}$$

for some T-periodic function $F(t) = F(t+T)$. Hence in the large N limit the collective frequency of a splay state (global coupling) is given by $\Omega = 1/T + gH_0$, with eigenvalues

$$\lambda_n = \frac{g}{T}\int_0^T H'(t/T)\mathrm{e}^{2\pi int/T}\mathrm{d}t = -2\pi ingH_{-n}. \tag{4.11}$$

Hence a splay state is stable if $-ng\,\mathrm{Im}\,H_n < 0$, where we have used the fact that since $H(\theta)$ is real, then $\mathrm{Im}\,H_{-n} = -\mathrm{Im}\,H_n$. A numerical examination of the eigenvalues (4.11) (using the analytical expressions for H_n obtained via (4.6)) for the phase interaction functions shown in Figure 8 shows that the splay state is unstable for both these examples. One natural way to stabilize the splay state is to include some synaptic coupling as in the work of [37, 26]. Another mechanism is to include noise, as originally noted by Kuramoto [57]. If we consider the addition of zero mean white noise with variance σ^2 to the voltage dynamics, then the phase-reduced system also feels an additive zero mean white noise source, though with variance σ_θ^2 given by $\sigma_\theta^2 = \sigma^2\int_0^T [R(t)]^2\,\mathrm{d}t/T$. For a globally coupled network the asynchronous state is stable if $-ng\,\mathrm{Im}\,H_n < \sigma_\theta^2 n^2$ for all $n \neq 0$ [58]. This nicely shows us that if the eigenvalues associated with the deterministic model stray slightly into the right-hand complex plane, then a small amount of noise can be used to compensate and restabilize the splay state. However, since this is an argument that relies upon weak coupling, then it can necessarily work only if the unstable eigenvalues are sufficiently close to the imaginary axis.

4.2. Beyond weak coupling. Here we develop techniques for the study of the synchronous and splay states in the strong coupling regime for global coupling ($g_{ij} = g$ for all i,j). First, we show how to construct such solutions, extending techniques used in our weak coupling analysis, and use this to explore the effect of gap junction strength on network firing rates. Second, we show how to analyze the stability of the synchronous solution using Floquet theory and that of the splay state using a phase-density formalism.

4.2.1. Existence and stability of a synchronous state. A synchronous network solution exists whenever a periodic orbit for an isolated oscillator exists ($g = 0$) and has the period of the uncoupled isolated oscillator. However, stability will depend on the value of coupling g. For convenience we define a matrix $A_\mu(g) = A_\mu - B(g)$ with

$$B(g) = \frac{g}{C}J, \qquad J = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}. \tag{4.12}$$

Following reasoning similar to that in [40] the $2N$ Floquet multipliers are given as the eigenvalues of a $2N \times 2N$ matrix $G(T)$, where $G(T)$ has the form of (3.17), with DF given by

$$DF = \begin{bmatrix} A(g) + \frac{1}{N}B(g) & \frac{1}{N}B(g) & \frac{1}{N}B(g) & \dots & \frac{1}{N}B(g) \\ \frac{1}{N}B(g) & A(g) + \frac{1}{N}B(g) & \frac{1}{N}B(g) & \dots & \frac{1}{N}B(g) \\ \vdots & & \ddots & & \\ \frac{1}{N}B(g) & \frac{1}{N}B(g) & \dots & A(g) + \frac{1}{N}B(g) & \frac{1}{N}B(g) \\ \frac{1}{N}B(g) & \frac{1}{N}B(g) & \dots & \frac{1}{N}B(g) & A(g) + \frac{1}{N}B(g) \end{bmatrix}, \tag{4.13}$$

where $A(g) = A_\mu(g)$. Here μ is chosen according to $\mu = \mu_1$ if $t \in [0, T_1)$, $\mu = \mu_2$ if $t \in [T_1, T_2)$, $\mu = \mu_3$ if $t \in [T_2, T_3)$, and $\mu = \mu_4$ if $t \in [T_3, T_4)$, defining four distinct *phases* of the orbit. On each of these four phases $DF = DF_\mu$ is independent of time. The matrix DF_μ is block circulant, with a generating row given by $[A_\mu(g) + B(g)/N \; B(g)/N \; \dots \; B(g)/N]$, and can be diagonalized by Fourier transform. Introducing the 2-component vector q_n, $n = 0, \dots, N-1$, the components of the eigenvectors of DF_μ can be listed as a set of N 2-component vectors with entries

$$q_n e^{2\pi i n m/N}, \qquad n, m = 0, \dots, N-1, \tag{4.14}$$

where q_0 is an eigenvector of A_μ and $q_{n\neq 0}$ is an eigenvector of $A_\mu(g)$. Hence, we may calculate $G(T) = G_4(T_4)G_3(T_3)G_2(T_2)G_1(T_1)$ using the representation $G_\mu(T_\mu) = P_\mu \exp(\Lambda_\mu T_\mu) P_\mu^{-1}$, where P_μ is the matrix of eigenvectors of DF_μ and Λ_μ is the corresponding diagonal matrix of eigenvalues, comprising the two eigenvalues of A_μ and $N-1$ copies of the two eigenvalues of $A_\mu(g)$. However, motivated by these observations, there is a much simpler way of calculating the Floquet multipliers that avoids the computation of $G(T)$ (and its eigenstructure).

We write the N-dimensional linearized system of equations in the form $\dot{Z} = DF\, Z$. First consider the two-dimensional system $\dot{z} = A(g)z$. By direct inspection we see that

$$Z = \begin{bmatrix} z \\ -z \\ 0 \\ \vdots \\ 0 \end{bmatrix}, \quad \begin{bmatrix} z \\ 0 \\ -z \\ \vdots \\ 0 \end{bmatrix}, \dots, \begin{bmatrix} z \\ 0 \\ 0 \\ \vdots \\ -z \end{bmatrix} \tag{4.15}$$

are linearly independent solutions of $\dot{Z} = DF\, Z$. Hence the two Floquet multipliers of $\dot{z} = A(g)z$ are also Floquet multipliers of $\dot{Z} = DF\, Z$, with $N-1$ degeneracy. Now con-

sider the two-dimensional system $\dot{z} = Az$. Again by direct inspection we see that

$$Z = \begin{bmatrix} z \\ z \\ z \\ \vdots \\ z \end{bmatrix} \tag{4.16}$$

is also a solution of $\dot{Z} = DF\,Z$, with two Floquet multipliers. Hence we can account for all the $2N$ Floquet multipliers (including the one which is unity). Using the analysis of section 3.2 the three relevant Floquet exponents are given by (3.18) and the pair (σ_1, σ_2), where $\sigma_k = \ln(\mu_k)/T \bmod 2\pi i$. Here the μ_k are the two (distinct) eigenvalues of $G(T) = G_4(T_4)G_3(T_3)G_2(T_2)G_1(T_1)$, where $G_\mu(T_\mu) = \exp(A_\mu(g)T_\mu)$ is a 2×2 matrix. Hence the synchronous network state is stable if an uncoupled isolated oscillator has a stable periodic orbit ($\sigma < 0$, and see (3.18)) and if the absolute values of the eigenvalues of $G(T)$ are less than unity. The condition for eigenvalues to cross the unit circle along the real axis is $\det[G(T) \pm I] = 0$, and off of the real axis we have the condition $\det G(T) = 1$. This latter condition is equivalent to $\sum_\mu T_\mu \operatorname{Tr} A_\mu(g) = 0$. For the examples in section 4.1 we find that the McKean model supports a stable synchronous state for weak coupling and that this stability persists with increasing g. For the PML model the synchronous state is unstable for weak g and can restabilize with increasing g when $\det[G(T) - I] = 0$. For the parameters of Figure 2 this occurs at $g \sim 0.45$.

4.2.2. Existence and stability of a splay state. Here we will focus on a globally coupled network in the large N limit. We first rewrite the coupling term for a splay state, $(v_i(t), w_i(t)) = (v(t - iT/N),\, w(t - iT/N))$ with $(v(t), w(t)) = (v(t + T),\, w(t + T))$, as

$$\lim_{N\to\infty} \frac{1}{N} \sum_{j=1}^{N} v(t + jT/N) = \frac{1}{T} \int_0^T v(t)\mathrm{d}t, \tag{4.17}$$

which is independent of both i and t. Hence, for a splay state every neuron in the network is described by the same dynamical system, namely,

$$C\dot{v} = f(v) - gv - w + I + gv_0, \qquad \dot{w} = g(v, w), \tag{4.18}$$

where $v_0 = T^{-1} \int_0^T v(t)\mathrm{d}t$. We note that because of the dependence on v_0 (4.18) is an advanced-retarded differential delay equation (see Appendix D for a general numerical method of solution). In the notation of section 3 we write $\dot{z}_\mu = A_\mu(g)z_\mu + b_\mu(g)$, where $b_\mu(g) = b_\mu + b$, with

$$b = \frac{g}{C} J z_0, \qquad z_0 = \begin{bmatrix} v_0 \\ w_0 \end{bmatrix}. \tag{4.19}$$

The same techniques as deployed in section 3 can be invoked to obtain a formal solution describing a T-periodic orbit. In doing so we see that the generalization of (4.6) expresses the

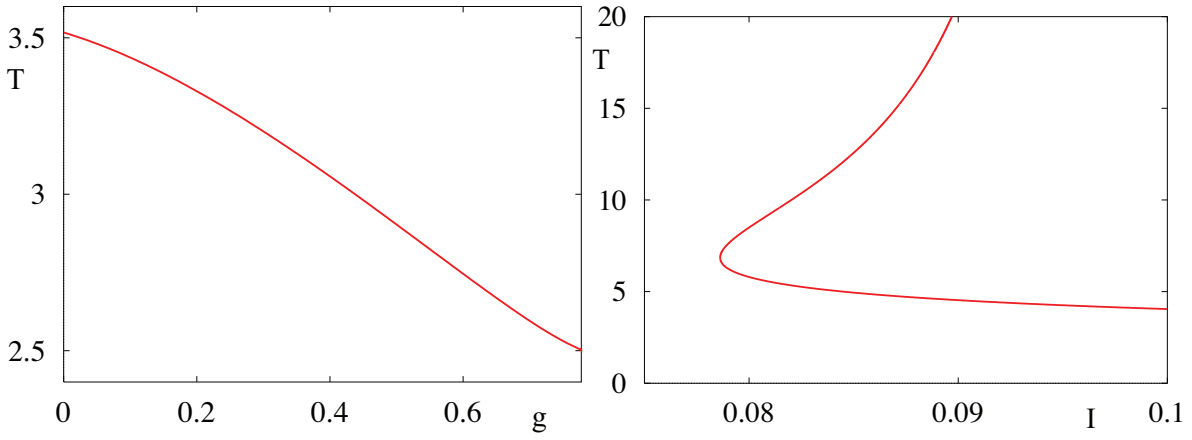

Figure 10. *Period of the splay state as a function of the coupling strength g. Left: McKean model with parameters as in Figure 1. Right: Period of PML model with g = 0.1 as a function of drive I and other parameters as in Figure 2. Note the coexistence of long and short period splay states.*

solution in terms of itself via the dependence of $b_\mu(g)$ on the Fourier component z_0. Setting $n = 0$ in this equation gives a self-consistent expression for z_0 given by

$$z_0 = \frac{1}{T}\sum_{\nu=1}^{4}\left\{\alpha_\nu^0(g)z_\nu(0) + \gamma_\nu^0(g)b_\nu(g)\right\}, \tag{4.20}$$

where $\alpha_\mu^n(g)$ and $\gamma_\mu^n(g)$ are the natural generalizations of α_μ^n and γ_μ^n (obtained under the replacement of $G_\mu(t) = \exp(A_\mu t)$ by $\exp(A_\mu(g)t)$ in (4.7)). Equation (4.20) may be rearranged to obtain an explicit equation for z_0 in the form $z_0 = Mz_1(0)$, where the 2×2 matrix M is a function of system parameters and the unknowns w^* and T_μ. The threshold crossing conditions may then be solved for as before to determine w^* and T_μ. The elements of α_μ^0 are given explicitly by $K_\mu(T_\mu)$, and those of γ_μ^0 are given in Appendix C. The dependence of the period on the strength of coupling g is shown in Figure 10. Typically we find that if a splay state exists for $g = 0$, then with increasing g its period decreases. However, in some parameter regimes it can also begin to increase again, as originally noted in [26]. Interestingly for the PML model it is easy to find parameter regimes where there is a coexistence of solutions, as in Figure 10, right. Note that in this example with $I < 0.09$ (where there are two solutions) the splay state does not exist at $g = 0$ so that weak coupling theory cannot tell us anything about either existence or stability.

In general the stability of a phase-locked state can be determined by determining the $2N$ Floquet exponents of the linearized system. Indeed, pursuing this approach for a splay state, we would find a similar coefficient matrix as in (4.13) with diagonal entries not equal to each other, but rather phase shifted, making analytical progress more cumbersome. However, for large N we may pursue an alternative phase reduction technique for networks of limit cycle oscillators with synaptic coupling developed by van Vreeswijk [81] and later used to study resonate-and-fire networks [66]. To do this we first write the coupling term $N^{-1}\sum_{j=1}^{N} v_j(t)$ in a more convenient form for studying perturbations of the mean field; namely, we write

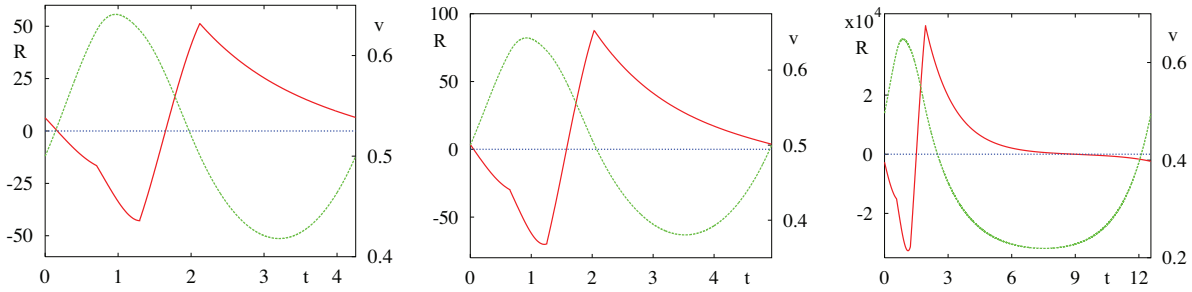

Figure 11. *The PRC of the splay state for the PML model for three different points on the solution branch shown in Figure 10, right. Left:* $I = 0.095$. *Middle:* $I = 0.085$, *lower branch. Right:* $I = 0.085$, *upper branch.*

$$\lim_{N\to\infty}\frac{1}{N}\sum_{j=1}^{N}v_j(t)=\lim_{N\to\infty}\frac{1}{N}\sum_{j=1}^{N}\sum_{m\in\mathbb{Z}}u(t-T_j^m), \tag{4.21}$$

where $T_j^m = mT + jT/N$. Here $u(t) = 0$ for $t < 0$ and is chosen such that $v(t) = \sum_{m\in\mathbb{Z}} u(t - mT)$, ensuring that $v(t) = v(t + T)$. For arbitrary values of T_j^m the coupling term (4.21) is time-dependent, and we may write it in the form

$$E(t)=\int_0^\infty f(t-s)u(s)\mathrm{d}s,\qquad f(t)=\lim_{N\to\infty}\frac{1}{N}\sum_{j,m}\delta(t-T_j^m), \tag{4.22}$$

where we recognize $f(t)$ as a firing rate. We now consider perturbations of the mean field such that $E(t)$ (the average membrane voltage) is split into a stationary part (arising from the splay state) and an infinitesimal perturbation. Namely, we write $E(t) = v_0 + \epsilon(t)$, with small $\epsilon(t)$. Since this perturbation to the oscillator defined by (4.18), the *splay* oscillator, is small, we may use phase reduction techniques to study the stability of the splay state.

In terms of a phase $\theta \in [0, 1)$ along the asynchronous state, we may write the evolution of this phase variable in response to a perturbation in the mean field as

$$\frac{\mathrm{d}\theta}{\mathrm{d}t}=\frac{1}{T}+g\Gamma(\theta)\epsilon(t), \tag{4.23}$$

where $\Gamma(\theta)$ is the (g-dependent) voltage component of the adjoint for the splay oscillator. This can again be calculated in closed form using the techniques developed in section 3.1. Some examples of splay state PRCs are shown in Figure 11. In fact, we need to treat N phase variables θ_i, each described by an equation of the form (4.23), which are coupled by the dependence of $\epsilon(t)$ on these variables. To make this more explicit we write

$$\epsilon(t)=\int_0^\infty \delta f(t-s)u(s)\mathrm{d}s \tag{4.24}$$

and use a phase-density description to calculate the dependence of the perturbed firing rate δf on the phases. We define a phase-density function as the fraction of neurons in the interval $[\theta, \theta + \mathrm{d}\theta]$, namely, $\rho(\theta, t) = N^{-1}\sum_j \delta(\theta_j(t) - \theta)$. Introducing the flux $J(\theta, t) = \rho(\theta, t)\dot{\theta}$, we

have the continuity equation

$$\frac{\partial \rho}{\partial t} = -\frac{\partial J}{\partial \theta}, \tag{4.25}$$

with boundary condition $J(1,t) = J(0,t)$. The firing rate is the flux through $\theta = 1$, so that $f(t) = J(1,t)$. Considering perturbations around the splay state, $(\rho, J) = (1, T^{-1})$, means writing $\rho(\theta,t) = 1 + \delta\rho(\theta,t)$, with a corresponding perturbation of the flux that takes the form $\delta J(\theta,t) = \delta\rho(\theta,t)/T + g\Gamma(\theta)\epsilon(t)$. In fact, the analysis that follows applies to the *asynchronous* state and not just the splay state. The distinction between the splay and asynchronous states is subtle; in the splay state, the phases are distributed along a cycle with phase differences of $1/N$ between two adjacent phases. In the asynchronous state, the definition is simply $\rho(\theta,t) = \rho_0(\theta)$, namely, that the phase density function is independent of time.

Differentiation of $\delta J(\theta,t)$ gives the partial differential equation

$$\partial_t \delta J(\theta,t) = -\frac{1}{T}\partial_\theta \delta J(\theta,t) + g\Gamma(\theta)\epsilon'(t), \tag{4.26}$$

where

$$\epsilon(t) = \int_0^\infty u(s)\delta J(1, t-s)\mathrm{d}s. \tag{4.27}$$

Assuming a solution of the form $\delta J(\theta,t) = \mathrm{e}^{\lambda t}\delta J(\theta)$ gives

$$\epsilon(t) = \delta J(1)\mathrm{e}^{\lambda t}\widetilde{u}(\lambda), \tag{4.28}$$

where $\widetilde{u}(\lambda) = \int_0^\infty u(t)\mathrm{e}^{-\lambda t}\mathrm{d}t$ is the Laplace transform of $u(t)$. In this case $\epsilon'(t) = \lambda\epsilon(t)$. Equation (4.26) then reduces to the ODE

$$\frac{\mathrm{d}}{\mathrm{d}\theta}\delta J(\theta)\mathrm{e}^{\lambda T\theta} = g\lambda T\Gamma(\theta)\delta J(1)\widetilde{u}(\lambda)\mathrm{e}^{\lambda T\theta}. \tag{4.29}$$

Integrating (4.29) from $\theta = 0$ to $\theta = 1$ and using the fact that $\delta J(1) = \delta J(0)$ yields an implicit equation for λ as

$$\frac{1}{\widetilde{u}(\lambda)} - \frac{g\lambda T}{\mathrm{e}^{\lambda T} - 1}\int_0^1 \Gamma(\theta)\mathrm{e}^{\lambda\theta T}\mathrm{d}\theta = 0. \tag{4.30}$$

By taking the Laplace transform of $v(t) = \sum_m u(t - mT)$, we have that

$$\widetilde{u}(\lambda) = (1 - \mathrm{e}^{-\lambda T})\widetilde{v}(\lambda). \tag{4.31}$$

Hence, we may write λ as the solution to $\mathcal{E}(\lambda) = 0$, where

$$\mathcal{E}(\lambda) = \frac{\mathrm{e}^{\lambda T}}{\widetilde{v}(\lambda)} - g\lambda T\int_0^1 \Gamma(\theta)\mathrm{e}^{\lambda\theta T}\mathrm{d}\theta. \tag{4.32}$$

Since $1/\widetilde{v}(0) = 0$, we see that $\mathcal{E}(0) = 0$, as expected. Writing $\lambda = \nu + i\omega$, we may find the pair (ν,ω) by the simultaneous solution of $\mathcal{E}_{\mathrm{R}}(\nu,\omega) = 0$ and $\mathcal{E}_{\mathrm{I}}(\nu,\omega) = 0$, where $\mathcal{E}_{\mathrm{R}}(\nu,\omega) =$

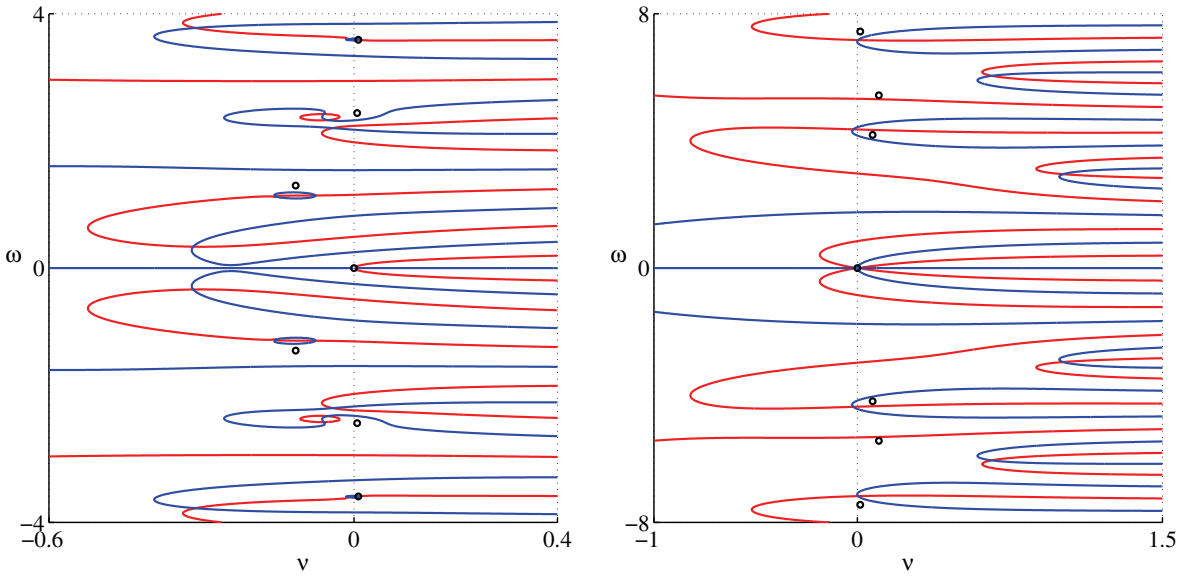

Figure 12. *Spectrum for the splay state in the PML model. Eigenvalues are at the positions where the red and blue curves intersect. The small circles denote the predictions from weak coupling theory. Parameters are as in Figure 2. Left: $I = 0.1$, $g = 0.01$. Note the unstable mode with $\omega \sim \pm 3.6$. As expected, eigenvalues from the weak coupling theory are close to the zeros of the full stability function. Right: Spectrum for the splay state with $g = 0.1$, $C = 0.9$, $I = 0.085$. In this case predictions from weak coupling theory break down. Note the occurrence of a double-zero eigenvalue signaling a bifurcation to a branch of solutions with $T_2 = 0$ (i.e., orbits tangential to $v = v_{th}^2$).*

$\mathrm{Re}\,\mathcal{E}(\nu + i\omega)$ and $\mathcal{E}_{\mathrm{I}}(\nu, \omega) = \mathrm{Im}\,\mathcal{E}(\nu + i\omega)$. In terms of the Fourier coefficients for $\Gamma(\theta)$ and $v(t)$, we may obtain a useful representation for (4.32) using

$$\int_0^1 \Gamma(\theta) \mathrm{e}^{\lambda\theta T} \mathrm{d}\theta = (\mathrm{e}^{\lambda T} - 1) \sum_n \frac{R_n}{2\pi i n + \lambda T}, \tag{4.33}$$

$$\widetilde{v}(\lambda) = T \sum_n \frac{v_{-n}}{2\pi i n + \lambda T}. \tag{4.34}$$

Examples of the spectrum obtained from the zeros of $\mathcal{E}(\lambda)$, for the PML model, are shown in Figure 12. In all cases we find the splay state is unstable.

For small g we expect to recover the stability result obtained using weakly coupled oscillator theory (see section 4.1). To check this we consider solutions of the form $2\pi i n + \lambda T = 2\pi i n g R_n v_{-n} T$ for $n \neq 0$ and $g \ll 1$. In this case we have that

$$\frac{\mathcal{E}(\lambda)}{g} = \frac{1}{\sum_n 1/(2\pi i n R_n)} - (\lambda T)^2 \sum_n \frac{R_n}{2\pi i n + \lambda T}. \tag{4.35}$$

Using the facts that R_n decays as $1/n$ (and so is an odd function of n) and λ scales with g, we may write

$$\sum_{n,m} \frac{1}{2\pi i n R_n} \frac{R_m}{2\pi i m + \lambda T} \approx \sum_n \frac{1}{2\pi i n (2\pi i n + \lambda T)} = \frac{1}{\mathrm{e}^{\lambda T} - 1} \int_0^1 S(\theta) \mathrm{e}^{\lambda\theta T} d\theta, \tag{4.36}$$

where we introduce the function $S(\theta) = \sum_n S_n e^{2\pi i n\theta}$, with $S_n = 1/(2\pi i n)$. Recognizing $S(\theta)$ as the Fourier series for the sawtooth function $S(\theta) = S(\theta+1)$ with $S(\theta) = -\theta$ for $\theta \in [0,1)$, we may evaluate (4.36) as $1/(\lambda T)^2$. Using (4.36) in (4.35) shows that $\mathcal{E}(\lambda_n) = 0$, where $\lambda_n = 2\pi i n - 2\pi i n g H_{-n}$, and we recover the stability condition for weak coupling, namely, $-ng \operatorname{Im} H_n < 0$ for $n \neq 0$.

5. Mean field rhythms. We are now in an ideal position to explore observations of Han, Kurrer, and Kuramoto [42, 43] concerning large amplitude oscillations seen in the average membrane potential of globally gap junction coupled Morris–Lecar networks. These novel rhythms were interpreted as cyclic transitions between coherent and incoherent network states and described as "bursting." However, to distinguish this from the type of behavior commonly associated with fast-slow systems [18], we shall not use this terminology here. For the rest of this section we focus on the PML model. We begin our discussion by analyzing the homogeneous fixed point behavior of the network. Using arguments similar to those in section 4.2.1, we may easily construct conditions for the stability of the fixed point (v^{ss}, w^{ss}). Considering the case $b < v^{ss} < (1+a)/2$, we have that

$$v^{ss} = \frac{a - I + b_s - b/\gamma_2}{1 - g - 1/\gamma_2}, \qquad w^{ss} = \frac{v^{ss}}{\gamma_2} + b_s - \frac{b}{\gamma_2}. \tag{5.1}$$

If it exists, this homogeneous steady state is independent of C. The conditions for network stability of this homogeneous state are $\operatorname{Tr} A_1 = 1/C - 1 < 0$ and $\operatorname{Tr} A_1(g) = (1-g)/C - 1 < 0$. Thus a homogeneous network state (if it exists) is stable only for $C > 1$ and unstable otherwise. Note, however, that when $\operatorname{Tr} A_1(g) = 0$, namely, $C = C_H = 1 - g$, we expect the existence of a harmonic splay state (since the dynamics is governed by a purely linear system with imaginary eigenvalues). Generically the results in sections 4.2.1 and 4.2.2 show that both the synchronous and splay states will be unstable for the PML model. However, knowledge of these states and the stability of the network steady state can be used to understand the original observations in [42, 43] regarding oscillations in the mean membrane potential. These authors suggested that such states could be viewed as being pushed and pulled between the unstable synchronous state and the unstable fixed point. However, in light of the work presented here, we now see that such oscillations may also occur as oscillations around an unstable orbit that can be either a fixed point or a splay state. We illustrate this idea with the aid of Figure 13. In each of the upper panels we show plots of the unstable orbits that exist for $C < C_H$, $C = C_H$, and $C > C_H$, with $C < 1$. For $C < C_H$ there is an unstable splay state that "sits" between the unstable synchronous state and the unstable homogeneous steady state. Direct numerical simulations show that the network fluctuates around the splay state, cycling between the other two unstable states. A similar behavior occurs at $C = C_H$, though the network can fluctuate around and between three coexisting unstable splay states. For $C > C_H$ the network dynamics fluctuates around the unstable homogeneous steady state. In Figure 14 we show an example of large amplitude oscillations in the mean membrane potential with a value of C just less than $C = 1$, beyond which point the homogeneous steady state is stable.

6. Discussion. Motivated by the desire to understand the dynamics of neuronal networks with gap junction coupling, we have developed a number of results for planar PWL neuron models. We focus on these as they are minimal models capable of generating AP shapes.

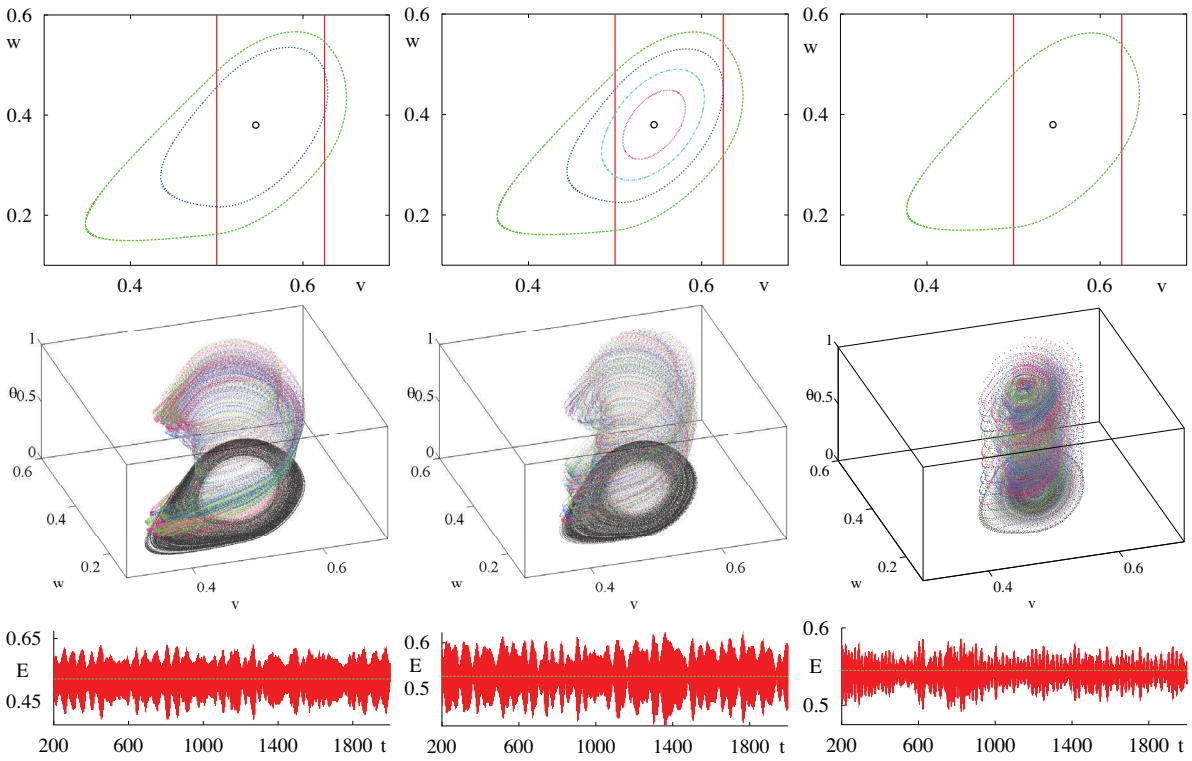

Figure 13. *Top: A family of coexisting unstable orbits in the PML model; synchronous (green), splay (blue), subthreshold splay (light blue), and harmonic splay (red). Here* $g = 0.1$, $I = 0.085$, *and other parameters are as in Figure 2. Left:* $C < 1 - g$ $(C = 0.89)$. *Middle:* $C = 1 - g$ $(C = 0.9)$. *Right:* $C > 1 - g$ $(C = 0.91)$. *Middle: Numerical simulation (after dropping transients) with* $N = 100$ *neurons showing a pseudo–color plot of the triple* (θ, v_i, w_i), *where* $\theta = t/\Delta \bmod 1$ *for some fixed* Δ. *Initial data is chosen to lie between the splay and synchronous state. Left: The network cycles between the unstable synchronous state and the unstable splay state.* Δ *is chosen as the mean of the synchronous and splay period. Middle: The network cycles between the unstable synchronous state and the unstable harmonic splay state.* Δ *is chosen as the mean of the synchronous and harmonic splay period. Right: The network cycles between the unstable synchronous state and the unstable fixed point.* Δ *is chosen as the period of the synchronous state. Bottom: Mean field signal* $E(t)$ *showing large amplitude fluctuations. Left: Fluctuations around the splay state (with* $v_0 = 0.52107$*). Middle: Fluctuations around the splay state (with* $v_0 = 0.52583$*). Right: Fluctuations around the fixed point (with* $v_0 = 0.545$*).*

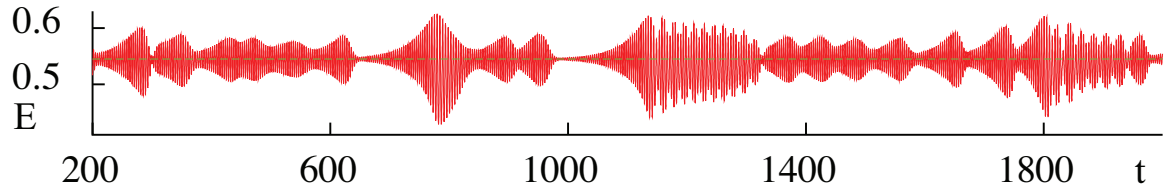

Figure 14. *Time varying mean field behavior organized around the unstable fixed point. Parameters are as in Figure 13, right, with* $C = 0.95$.

Unlike synaptically coupled networks, the shape of an AP is all-important in a gap junction coupled network as it is communicated directly between cells. For any PWL planar single

neuron model we have shown how to build periodic orbits in a self-consistent way, by piecing together trajectories from neighboring regions of phase space. Moreover, this procedure naturally lends itself to the construction of the associated PRC. The stability of periodic orbits has been established using Floquet theory, which in this case generates closed form expressions for the nonzero exponent of the orbit. As well as paving the way for the more obvious weakly coupled network analysis, we have found that the simplicity of the PWL model can allow for studies in the strong coupling regime, albeit for global coupling. In illustration of the utility of studying PWL networks, we have further shown how this can underpin a systematic explanation of the original observations of Han, Kurrer, and Kuramoto [42] on the generation of exotic mean field signals in networks of Morris–Lecar neurons with gap junction coupling.

Looking forward, it is worth mentioning here a number of possible extensions of the work in this paper that will lead to a deeper understanding of the role of gap junctions in shaping brain rhythms. As we have stressed, the techniques in this paper are general and are applicable to many PWL systems. In particular, it would be valuable to study Type I models which rely on a SNIC to generate their firing rate response [33, 32]. The cortical neuron model of Wilson [85] is a classic example of this, and its quadratic recovery variable is easily caricatured by choosing the parameter γ_1 in (2.5) to be negative. For systems with local chain-like coupling it may also prove possible to adapt techniques in [65] to study both synchronization and transient dynamics. Another natural step is to endow the purely gap junction coupled networks that we have described here with synaptic interactions. At the level of weak coupling the coupled oscillator theory that we have described here is naturally generalized along the lines of [26, 53]. Another mechanism available to neurons for the initiation of a firing event is that of anode break excitation, whereby a neuron can fire on release from a hyperpolarized state. The planar models that we have considered here are capable of such behavior, and thus when connected by inhibitory synapses emergent network periodic orbits might also be analyzed in a PWL fashion. In the strong coupling regime the challenge of studying phase-locked states that are neither synchronous nor splay effectively reduces to the problem of studying ODEs with delays. The techniques for doing this for PWL systems are relatively well developed in the engineering community, and one may therefore revisit the work in this paper, making explicit use of Lambert functions to define trajectories [6, 86]. In light of the recent interest in the analysis of gap junctions between dendritic trees [73], it would be interesting to explore the possibility of moving away from point neuron models, as studied here, to models with a spatially extended character [10]. For dendrites without active processes, the tools for doing this have been partially developed in [19]. However, of all the possible next steps, we regard the development of a tissue level firing rate model that can properly treat gap junction coupling as the major challenge facing the mathematical neuroscience community. Although at the level of fast voltage variables it is natural to think of gap junction coupling between nearest neighbors as generating a diffusive coupling, it is not clear that it is appropriate to simply add diffusive terms to existing rate models [77], such as the Wilson–Cowan, Amari, or Liley models (recently reviewed in [20]), since the state variables in these examples have no direct interpretation as fast voltage variables. In future work we hope to combine ideas from mean field dynamics, particularly those in [51, 67], with "equation-free" modeling [59] to tackle this challenge.

Appendix A. For real eigenvalues of A, we have the explicit form for $G(t)$ in section 3:

$$
\begin{aligned}
G_{11}(t) &= \frac{1}{\lambda_+ - \lambda_-}\left\{\lambda_+ \mathrm{e}^{\lambda_+ t} - \lambda_- \mathrm{e}^{\lambda_- t} - a_{22}\left[\mathrm{e}^{\lambda_+ t} - \mathrm{e}^{\lambda_- t}\right]\right\},\\
G_{12}(t) &= -\frac{\lambda_+ - a_{22}}{\lambda_+ - \lambda_-}\frac{\lambda_- - a_{22}}{a_{21}}\left[\mathrm{e}^{\lambda_+ t} - \mathrm{e}^{\lambda_- t}\right],\\
G_{21}(t) &= \frac{a_{21}}{\lambda_+ - \lambda_-}\left[\mathrm{e}^{\lambda_+ t} - \mathrm{e}^{\lambda_- t}\right],\\
G_{22}(t) &= \frac{1}{\lambda_+ - \lambda_-}\left\{\lambda_+ \mathrm{e}^{\lambda_- t} - \lambda_- \mathrm{e}^{\lambda_+ t} + a_{22}\left[\mathrm{e}^{\lambda_+ t} - \mathrm{e}^{\lambda_- t}\right]\right\}.
\end{aligned} \tag{A.1}
$$

The matrix $K(t)$ may then be calculated as

$$
\begin{aligned}
K_{11}(t) &= \frac{1}{\lambda_+ - \lambda_-}\left\{\mathrm{e}^{\lambda_+ t} - \mathrm{e}^{\lambda_- t} - a_{22}\left[\frac{\mathrm{e}^{\lambda_+ t}-1}{\lambda_+} - \frac{\mathrm{e}^{\lambda_- t}-1}{\lambda_-}\right]\right\},\\
K_{12}(t) &= -\frac{\lambda_+ - a_{22}}{\lambda_+ - \lambda_-}\frac{\lambda_- - a_{22}}{a_{21}}\left[\frac{\mathrm{e}^{\lambda_+ t}-1}{\lambda_+} - \frac{\mathrm{e}^{\lambda_- t}-1}{\lambda_-}\right],\\
K_{21}(t) &= \frac{a_{21}}{\lambda_+ - \lambda_-}\left[\frac{\mathrm{e}^{\lambda_+ t}-1}{\lambda_+} - \frac{\mathrm{e}^{\lambda_- t}-1}{\lambda_-}\right],\\
K_{22}(t) &= \frac{1}{\lambda_+ - \lambda_-}\left\{\frac{\lambda_+}{\lambda_-}\left[\mathrm{e}^{\lambda_- t}-1\right] - \frac{\lambda_-}{\lambda_+}\left[\mathrm{e}^{\lambda_+ t}-1\right] + a_{22}\left[\frac{\mathrm{e}^{\lambda_+ t}-1}{\lambda_+} - \frac{\mathrm{e}^{\lambda_- t}-1}{\lambda_-}\right]\right\}.
\end{aligned} \tag{A.2}
$$

For complex eigenvalues of A, we have the explicit form for $G(t)$:

$$
G(t) = \frac{\mathrm{e}^{\rho t}}{\widehat{\omega}}\begin{bmatrix} \widehat{\omega}\cos\omega t - \widehat{\rho}\sin\omega t & \sin\omega t \\ -(\widehat{\rho}^2+\widehat{\omega}^2)\sin\omega t & \widehat{\omega}\cos\omega t + \widehat{\rho}\sin\omega t \end{bmatrix}. \tag{A.3}
$$

The matrix $K(t)$ may then be calculated as

$$
K(t) = \frac{1}{\widehat{\omega}}\begin{bmatrix} \widehat{\omega}K_R(t) - \widehat{\rho}K_I(t) & K_I(t) \\ -(\widehat{\rho}^2+\widehat{\omega}^2)K_I(t) & \widehat{\omega}K_R(t) + \widehat{\rho}K_I(t) \end{bmatrix}, \tag{A.4}
$$

where

$$
K_R(t) = \frac{1}{\rho^2+\omega^2}\left\{\rho\left[\mathrm{e}^{\rho t}\cos(\omega t) - 1\right] + \omega \mathrm{e}^{\rho t}\sin(\omega t)\right\}, \tag{A.5}
$$

$$
K_I(t) = \frac{1}{\rho^2+\omega^2}\left\{\omega\left[1 - \mathrm{e}^{\rho t}\cos(\omega t)\right] + \rho \mathrm{e}^{\rho t}\sin(\omega t)\right\}. \tag{A.6}
$$

Appendix B. Computationally useful forms for the matrix elements in (4.7) are as follows:

$$
\alpha_\mu^n = P_\mu \Psi_\mu^n P_\mu^{-1}, \tag{B.1}
$$

$$
\beta_\mu^n = \widetilde{P}_\mu \Psi_\mu^{-n} \widetilde{P}_\mu^{-1} \mathrm{e}^{-2\pi i n T_\mu/T}, \tag{B.2}
$$

$$
\gamma_\mu^n = P_\mu \widetilde{\Psi}_\mu^n P_\mu^{-1}, \tag{B.3}
$$

where

$$\Psi_\mu^n = \operatorname{diag}\left(\frac{e^{(\lambda_+^\mu - 2\pi i n/T)T_\mu}-1}{\lambda_+^\mu - 2\pi i n/T}, \frac{e^{(\lambda_-^\mu - 2\pi i n/T)T_\mu}-1}{\lambda_-^\mu - 2\pi i n/T}\right), \tag{B.4}$$

$$\widetilde{\Psi}_\mu^n = \operatorname{diag}(1/\lambda_+^\mu, 1/\lambda_-^\mu)\left[\Psi_\mu^n + \frac{e^{-2\pi i n T_\mu/T}-1}{2\pi i n/T} I\right], \qquad n \neq 0, \tag{B.5}$$

$$\widetilde{\Psi}_\mu^0 = \operatorname{diag}(1/\lambda_+^\mu, 1/\lambda_-^\mu)\operatorname{diag}\left(\frac{e^{\lambda_+^\mu T_\mu}-1}{\lambda_+^\mu} - T_\mu, \frac{e^{\lambda_-^\mu T_\mu}-1}{\lambda_-^\mu} - T_\mu\right), \tag{B.6}$$

with P_μ and $\widetilde{P}_\mu$ as the matrix of eigenvectors of A_μ and A_μ^T, respectively, with associated eigenvalues $\lambda_\pm^\mu$. From the structure of Ψ_μ^n and $\widetilde{\Psi}_\mu^n$ above we see that α_μ^n, β_μ^n, and γ_μ^n all decrease as $1/n$.

Appendix C. In section 4.2.2 the elements of γ_μ^0 are calculated explicitly by noting that $\gamma_\mu^0 = \int_0^{T_\mu} K_\mu(t)\mathrm{d}t$. The structure of $K_\mu(t)$ for real and imaginary eigenvalues of the associated matrix A_μ are given by (A.2) and (A.4), respectively. Denoting $\int_0^t K(s)\mathrm{d}s$ by $F(t)$ gives

$$\begin{aligned}
F_{11}(t) &= \frac{1}{\lambda_+ - \lambda_-}\left\{\frac{e^{\lambda_+ t}-1}{\lambda_+} - \frac{e^{\lambda_- t}-1}{\lambda_-} - a_{22}\left[\frac{1}{\lambda_+}\left[\frac{e^{\lambda_+ t}-1}{\lambda_+} - t\right] - \frac{1}{\lambda_-}\left[\frac{e^{\lambda_- t}-1}{\lambda_-} - t\right]\right]\right\},\\
F_{12}(t) &= -\frac{\lambda_+ - a_{22}}{\lambda_+ - \lambda_-}\frac{\lambda_- - a_{22}}{a_{21}}\left[\frac{1}{\lambda_+}\left[\frac{e^{\lambda_+ t}-1}{\lambda_+} - t\right] - \frac{1}{\lambda_-}\left[\frac{e^{\lambda_- t}-1}{\lambda_-} - t\right]\right],\\
F_{21}(t) &= \frac{a_{21}}{\lambda_+ - \lambda_-}\left[\frac{1}{\lambda_+}\left[\frac{e^{\lambda_+ t}-1}{\lambda_+} - t\right] - \frac{1}{\lambda_-}\left[\frac{e^{\lambda_- t}-1}{\lambda_-} - t\right]\right],\\
F_{22}(t) &= \frac{1}{\lambda_+ - \lambda_-}\left\{\frac{\lambda_+}{\lambda_-}\left[\frac{e^{\lambda_- t}-1}{\lambda_-} - t\right] - \frac{\lambda_-}{\lambda_+}\left[\frac{e^{\lambda_+ t}-1}{\lambda_+} - t\right]\right.\\
&\quad \left. + a_{22}\left[\frac{1}{\lambda_+}\left[\frac{e^{\lambda_+ t}-1}{\lambda_+} - t\right] - \frac{1}{\lambda_-}\left[\frac{e^{\lambda_- t}-1}{\lambda_-} - t\right]\right]\right\}
\end{aligned} \tag{C.1}$$

for real $\lambda_\pm$ and

$$F(t) = \frac{1}{\widehat{\omega}}\begin{bmatrix}\widehat{\omega}F_R(t) - \widehat{\rho}F_I(t) & F_I(t)\\ -(\widehat{\rho}^2 + \widehat{\omega}^2)F_I(t) & \widehat{\omega}F_R(t) + \widehat{\rho}F_I(t)\end{bmatrix}, \tag{C.2}$$

where

$$F_R(t) = \frac{1}{\rho^2 + \omega^2}\left\{\rho\left[K_R(t) - t\right] + \omega K_I(t)\right\}, \tag{C.3}$$

$$F_I(t) = \frac{1}{\rho^2 + \omega^2}\left\{\omega\left[t - K_R(t)\right] + \rho K_I(t)\right\} \tag{C.4}$$

for complex $\lambda_\pm$. The matrices $\gamma_\mu^0 = F_\mu(T_\mu)$ may then be calculated using the above forms for $F(t)$ (under the replacement of $\lambda_\pm$ by $\lambda_\pm^\mu$).

Appendix D. For a splay state we may rewrite the advanced-retarded system of equations (4.18) as a set of ODEs by introducing

$$X_-(t) = \frac{1}{T}\int_0^t v(t)\mathrm{d}t, \qquad X_+(t) = \frac{1}{T}\int_t^T v(t)\mathrm{d}t. \tag{D.1}$$

After rescaling time as $\tau = t/T$ we may write

$$\frac{C}{T}\frac{\mathrm{d}v}{\mathrm{d}\tau} = f(v) - gv - w + I + g(X_- + X_+), \tag{D.2}$$

$$\frac{1}{T}\frac{\mathrm{d}w}{\mathrm{d}\tau} = g(v,w), \tag{D.3}$$

$$\frac{\mathrm{d}X_-}{\mathrm{d}\tau} = v, \tag{D.4}$$

$$\frac{\mathrm{d}X_+}{\mathrm{d}\tau} = -v, \tag{D.5}$$

subject to the boundary conditions $v(0) = v_{\rm th} = v(1)$, $w(0) = w^* = w(1)$, $X_-(0) = 0$, $X_-(1) = v_0$, $X_+(0) = v_0$, and $X_+(1) = 0$ (for some voltage section $v_{\rm th}$). We have four ODEs with seven boundary conditions which we may treat as a boundary value problem for the free parameters (v_0, w^*, T). For general choices of f and g it is natural to use numerical shooting for the solution of this problem. Alternatively, for the PWL models discussed in this paper we may analytically construct solutions according to the prescription described in section 4.2.2.

Acknowledgments. I would like to thank Bard Ermentrout and three anonymous referees for useful comments that have improved the presentation of the work in this paper.

The Geometry of Slow Manifolds near a Folded Node*

M. Desroches†, B. Krauskopf†, and H. M. Osinga†

Abstract. This paper is concerned with the geometry of slow manifolds of a dynamical system with one fast and two slow variables. Specifically, we study the dynamics near a folded-node singularity, which is known to give rise to so-called canard solutions. Geometrically, canards are intersection curves of two-dimensional attracting and repelling slow manifolds, and they are a key element of slow-fast dynamics. For example, canard solutions are associated with mixed-mode oscillations, where they organize regions with different numbers of small oscillations. We perform a numerical study of the geometry of two-dimensional slow manifolds in the normal form of a folded node in $\mathbb{R}^3$. Namely, we view the part of a slow manifold that is of interest as a one-parameter family of orbit segments up to a suitable cross-section. Hence, it is the solution of a two-point boundary value problem, which we solve by numerical continuation with the package AUTO. The computed family of orbit segments is used to obtain a mesh representation of the manifold as a surface. With this approach we show how the attracting and repelling slow manifolds change in dependence on the eigenvalue ratio μ associated with the folded-node singularity. At $\mu = 1$ two primary canards bifurcate and secondary canards are created at odd integer values of μ. We compute 24 secondary canards to investigate how they spiral more and more around one of the primary canards. The first sixteen secondary canards are continued in μ to obtain a numerical bifurcation diagram.

Key words. slow-fast systems, singular perturbation, canard solution, boundary value problem, invariant manifolds

1. Introduction.

Multiple time scale systems are characterized by the property that certain variables evolve on vastly different time scales, which means that the systems may display dynamics that is composed of slow and fast elements. The occurrence of different time scales is quite natural in many applications, including chemical reaction dynamics [10, 33, 35, 37, 39], cell modeling [15, 43, 44], electronic circuits [13, 48, 49], and laser dynamics [16, 21]. The first example of slow-fast dynamics was discovered by Van der Pol [48, 49] in the 1920s. He considered an electrical circuit with a triode valve where the current is a cubic function of the voltage. The mathematical model of this circuit is known today as the Van der Pol equations. It shows sustained, very nonharmonic oscillations when the nonlinear damping is large. In this case the periodic solution is composed of slow motion that closely follows attracting segments of the underlying cubic curve (which forms one of the nullclines), followed by fast jumps as the trajectory reaches either of the two folds of this curve. At the jumps one of

the variables barely changes until the trajectory reaches another attracting segment of cubic curve. Van der Pol called these periodic solutions *relaxation oscillations*. Models showing relaxation oscillations quite similar to that of the Van der Pol equations have been found in other application areas. A well-known example is the FitzHugh–Nagumo system, which also has two time scales and a cubic nonlinearity. It was derived independently by FitzHugh [24] and Nagumo [38] as a simplified planar version of the famous Hodgkin–Huxley equations for the action potential of the giant axon of a squid in terms of transmembrane currents [31].

At the end of the 1970s, Benoît et al. [5] found and analyzed even more unusual periodic solutions in the Van der Pol equations with an added external constant forcing term; they called these periodic solutions *canards*. A canard orbit has the special property that it follows at least one unstable segment of the underlying cubic nullcline. In other words, the trajectory does not jump at the respective fold. Canard orbits account for a sudden increase in the amplitude of the attracting periodic orbit in the transition from harmonic oscillations to relaxation oscillations. This change is known as a *canard explosion*, a term that was first introduced by Brøns and Bar-Eli [7]. A canard explosion and the associated canards are extremely difficult to observe in two-dimensional slow-fast systems, because the transition happens in an exponentially small parameter interval.

In three-dimensional slow-fast systems canards may exist in much larger regions of the system parameters. They have been found in numerous slow-fast systems. For example, canards explain sudden changes in amplitude and period of oscillatory behavior in chemical reactions [10, 33, 35, 37, 39]; they organize the dynamics in models of coupled neurons and also play an important role in intracellular activities [15, 43, 44]; canards have been studied for their role in diffusion-induced instabilities [10, 41]; and Guckenheimer et al. [6, 29] recently performed an extensive study of a reduced hybrid model of the (periodically) forced Van der Pol equations which revealed relaxation oscillations and canard orbits of different types. A related phenomenon in slow-fast systems are *mixed-mode oscillations*, which consist of large-amplitude excursions followed by small-amplitude motions that are typically of (relatively) high frequency. This type of oscillation has been found in chemical and biological systems, and the connection between mixed-mode oscillations and canards has been clarified recently [9, 35, 44, 50]; see also the special issue [8].

For the theoretical study of canards in three-dimensional phase space, one considers a dynamical system with two slow and one fast variable of the form

$$\left\{\begin{array}{rcl} \dot{u}_1 &=& g_1(u_1,u_2,v,\varepsilon),\\ \dot{u}_2 &=& g_2(u_1,u_2,v,\varepsilon),\\ \varepsilon\dot{v} &=& f(u_1,u_2,v,\varepsilon). \end{array}\right. \tag{1.1}$$

Here g_1, g_2, and f are sufficiently smooth functions, and $\varepsilon > 0$ is a small parameter that separates the different time scales. Since ε is small, the variables u_1 and u_2 move on a slower time scale than the fast variable v. The equivalent of the cubic nullcline of the Van der Pol equations is now the surface—called the *critical manifold*—that is given as the v-nullcline of (1.1). The critical manifold has repelling parts and attracting parts, which meet along one-dimensional fold curves. As for the Van der Pol equations, the slow dynamics takes place close to the critical manifold. When a fold is reached two things can happen. The trajectory may jump at the fold curve toward another attracting sheet of the critical manifold. If a global

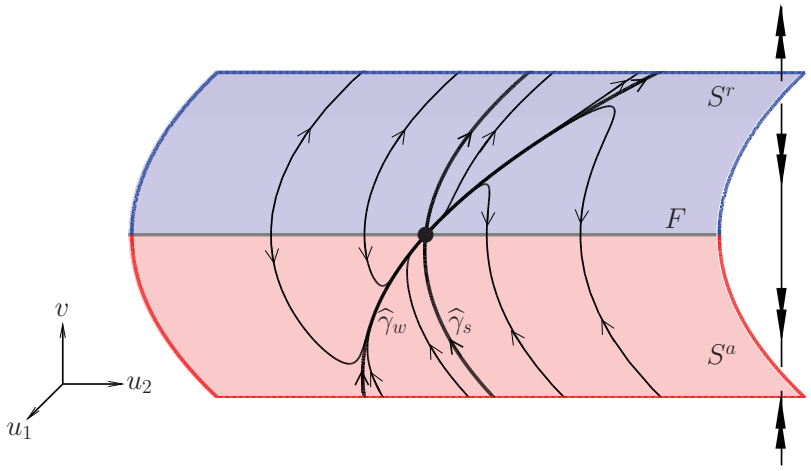

Figure 1. *Sketch of a folded critical manifold S consisting of an attracting sheet S^a (red) and a repelling sheet S^r (blue) that meet at a fold curve F. The sketched flow on S is the generic slow flow near a folded node (black dot); shown are two singular canards $\widehat{\gamma}_s$ and $\widehat{\gamma}_w$ and some other trajectories of the slow flow. The action of the fast flow is shown along one fast fiber.*

return mechanism is present, e.g., the critical manifold is S-shaped with two fold curves, such jumps give rise to classical relaxation oscillations [36, 46]. The other possibility is that the trajectory is a canard solution that does not jump at the fold curve but instead stays near the repelling part of the critical manifold for a certain amount of time.

Since the beginning of the 1980s different analytical techniques have been applied to the study of canard solutions. Initially, nonstandard analysis [3, 4, 5] and matched asymptotic expansions [19, 36] were used. Dumortier and Roussarie showed in their seminal work [17, 18, 42] that (standard) nonlinear analysis can be applied to the study of canards. Underlying this approach is the realization that canards can be understood via the dynamics of the system near folds of the critical manifold. Of specific interest here are (isolated) points on fold curves where the direction of flow changes from pointing toward the fold to pointing away from the fold. These points, called *folded singularities*, are key to the understanding of canard solutions.

We are concerned here with the case of a *folded node*, which is a type of folded singularity that has been identified as an organizing center for the creation of canard solutions. Figure 1 shows the dynamics for $\varepsilon = 0$ near a folded node on a regular fold curve F along which the attracting sheet S^a and the repelling sheet S^r of the critical manifold join. At the folded node (black dot), the direction of the flow on the critical manifold changes. This allows for the existence of canard solutions on the critical manifold that cross F at the folded node with nonzero speed and then follow the repelling sheet S^r. These canards for $\varepsilon = 0$ are referred to as *singular canards*, and they occur in an entire region that is bounded by the repelling part of the fold curve F (to the left of the folded node) and the special canard solution $\widehat{\gamma}_s$ in Figure 1. The main question now is: What can be said about the dynamics near a folded node when $\varepsilon > 0$? According to a well-known result by Fenichel [22, 23], away from the fold curve F the attracting and repelling sheets give rise to an *attracting slow manifold* S^a_ε and a *repelling slow manifold* S^r_ε for $\varepsilon > 0$, respectively. Importantly, for $\varepsilon > 0$ the two surfaces S^a_ε and S^r_ε do not

connect along the fold curve, but rather intersect, generically transversely, in one-dimensional solution curves. These curves are referred to as *maximal canards*, as they stay close to the repelling part of the critical manifold for a certain amount of time. In other words, finding the structure of canard solutions near the folded node is equivalent to understanding the geometry of the two-dimensional surfaces S^a_ε and S^r_ε.

Canards near a folded node are best analyzed in a normal form setting. Normal forms for all types of folded singularities, including the folded node, were derived by Il'yashenko; see Arnol′d et al. [2, part I, chapter 4] and also the topological classification of Takens [47]. Benoît [4] completely analyzed the case of a folded saddle and also considered the case of a folded node. He proved the existence of two maximal canards under a nonresonance condition with tools of nonstandard analysis and found secondary canards with spiraling behavior by numerical integration. Szmolyan and Wechselberger [45] considered all cases of folded singularities. For the folded node they proved the existence of primary canards by using geometric singular perturbation theory in combination with blow-up transformations. The existence of secondary canards depends on the eigenvalue ratio of the Jacobian at the folded node, which we denote μ with $1 \leq \mu < \infty$; precise details are given in section 2. Guckenheimer and Haiduc [28] proved that for any fixed μ there is a finite number of secondary canards near a folded node, and this number goes to infinity as both $\mu \to \infty$ and $\varepsilon \to 0$. Wechselberger [50] studied how secondary canards bifurcate from the weak primary canard, and he sketched the underlying bifurcation structure. Both Guckenheimer and Haiduc [28] and Wechselberger [50] find canards numerically by computing the one-dimensional intersection curves of the attracting and repelling slow manifolds in a two-dimensional cross-section with a shooting approach (integration from a line of initial conditions far from the fold curve); the canards are then identified as crossings of the two curves.

Our goal is to compute and visualize the slow manifolds as surfaces and the canards as trajectories in $\mathbb{R}^3$ to obtain additional geometric insight into the dynamics near a folded node. To this end, we consider the normal form as used in [50], which is given as the three-dimensional vector field

$$\left\{ \begin{array}{rcl} \dot{x} &=& \frac{1}{2}\mu y - (\mu+1)z, \\ \dot{y} &=& 1, \\ \dot{z} &=& x + z^2. \end{array} \right. \tag{1.2}$$

In (1.2) the folded node is at the origin and the parameter μ is the ratio of the eigenvalues of the Jacobian matrix of the so-called desingularized reduced flow evaluated at the folded node. Note that, as a result of a parameter dependent blow-up procedure, (1.2) does not depend on ε. Nevertheless, this normal form describes how the attracting and repelling slow manifolds intersect near a folded node. Specifically, for any μ system (1.2) has an attracting slow manifold C^- and a repelling slow manifold C^+ that intersect in the maximal canards one wants to study; see section 2 for more information on the derivation and meaning of the normal form.

Specifically, we compute in this paper the slow manifolds C^- and C^+ of (1.2) as surfaces in $\mathbb{R}^3$. This is achieved by representing a piece of interest of a slow manifold as a one-parameter family of orbit segments that satisfy suitably chosen boundary conditions. The resulting boundary value problem is solved with the continuation and collocation routines of

the package AUTO [14]. This setup is very flexible and accurate, because it is based on the continuation of two-point boundary value problems [34]. It allows us to adjust the boundary conditions to emphasize certain local features of the underlying dynamics in the vicinity of the folded node. With our method we obtain a very precise visualization of the behavior of the slow manifolds. In particular, we are able to capture in detail the complexity of their intersections, that is, the canards. For increasing μ, the two surfaces rotate more and more around the weak primary canard (the perturbation of $\widehat{\gamma}_w$ in Figure 1), which leads to the creation of secondary canards at odd integer values of μ. Our method allows us to detect canards and to continue them as solutions of a boundary value problem in the parameter μ. We compute up to 24 secondary canards and show how they spiral around the weak primary canard. Furthermore, we continue sixteen secondary canards in μ to obtain a numerical bifurcation diagram.

Note that very few attempts have been made so far to produce accurate computations of slow manifolds as surfaces. Milik et al. [35] visualize slow manifolds in the normal form of a folded saddle-node; in this special case (of codimension one) the system decouples into a one-parameter family of two-dimensional systems, so that the slow manifolds can be built up from individual one-dimensional stable and unstable manifolds (which can be found by integration). Ginoux and Rossetto derive an implicit equation that provides local approximations of slow manifolds as the locus where the torsion vanishes [25, 26]. Both methods are quite different from our approach. Our boundary value problem formulation allows one not only to compute slow manifolds as global objects in a specified region of interest but also to detect canards and follow them in system parameters. More generally, computing invariant manifolds by continuation and collocation as solution families subject to suitable boundary conditions is a very flexible method [34] which is particularly well suited for slow-fast systems [20]. Our method is not restricted to the normal form setting but can be used more widely, for example, for the study of canards in the self-coupled FitzHugh–Nagumo system [11].

The outline of this paper is as follows. In the next section we present some technical background material. We briefly review slow-fast systems in section 2.1, explain the blow-up method in section 2.2, and then discuss some known properties of the normal form (1.2) in section 2.3. Section 3 explains in detail how to compute slow manifolds as collections of orbit segments. In section 4 we show how the slow manifolds change with μ, and section 5 is devoted to the detection and continuation of the secondary canards. In section 6 we show that the geometry of the slow manifolds does not change topologically when the normal form is perturbed. We conclude with a summary and outlook in section 7.

2. Background on the folded node.

In this section we recall some basic facts about singularly perturbed dynamical systems, folded singularities, and the blow-up method to analyze them. We consider the three-dimensional normal form (1.2), as studied, for example, by Benoît [3, 4], Guckenheimer and Haiduc [28], and Wechselberger [50]. Following [50], we show how the normal form is derived from a generic three-dimensional system with a folded node at the origin and present some useful properties of (1.2).

2.1. Slow-fast dynamical systems.

The *slow-time system* (1.1) defines a vector field using the slow time t. An alternative way of writing (1.1) is to introduce the fast time $\tau = \frac{t}{\varepsilon}$, which

gives the *fast-time system*

$$\left\{\begin{array}{rcl} u_1' &=& \varepsilon g_1(u_1,u_2,v,\varepsilon),\\ u_2' &=& \varepsilon g_2(u_1,u_2,v,\varepsilon),\\ v' &=& f(u_1,u_2,v,\varepsilon), \end{array}\right. \tag{2.1}$$

where the prime indicates the derivative with respect to the fast time τ. This rescaling of time is valid only for $\varepsilon > 0$ and does not modify the geometry of the trajectories. The main question is whether it is possible to understand the dynamics for small $\varepsilon > 0$ by considering the two limits of (1.1) and (2.1) given by $\varepsilon = 0$.

The limit of the slow-time system (1.1) for $\varepsilon = 0$ is known as the *reduced system* or *slow subsystem*

$$\left\{\begin{array}{rcl} \dot{u}_1 &=& g_1(u_1,u_2,v,0),\\ \dot{u}_2 &=& g_2(u_1,u_2,v,0),\\ 0 &=& f(u_1,u_2,v,0). \end{array}\right. \tag{2.2}$$

System (2.2) is a set of differential algebraic equations on the slow time scale, namely, two differential equations constrained by the algebraic equation $f = 0$. This condition defines the *critical manifold*

$$S := \left\{(u_1,u_2,v) \in \mathbb{R}^3 \mid f(u_1,u_2,v,0) = 0\right\}, \tag{2.3}$$

on which the dynamics of the reduced system (2.2) takes place. Typically, it is not possible to solve for S as a function of u_1 and u_2, but we may assume that S is locally a graph over, say, u_2 and v. Then we can describe the flow of the reduced system (2.2) on S as a projection onto the (u_2, v)-plane. Namely, by differentiating the algebraic equation $f = 0$ with respect to time, we obtain

$$\left\{\begin{array}{rcl} \dot{u}_2 &=& g_2(u_1,u_2,v,0),\\ -f_v\dot{v} &=& f_{u_1}g_1 + f_{u_2}g_2, \end{array}\right. \tag{2.4}$$

where $u_1 = s(u_2, v)$ is uniquely defined by the condition $(u_1, u_2, v) \in S$. We then rescale (2.4) by $-f_v$ to obtain the vector field

$$\left\{\begin{array}{rcl} \dot{u}_2 &=& -f_v g_2(u_1,u_2,v,0),\\ \dot{v} &=& f_{u_1}g_1 + f_{u_2}g_2, \end{array}\right. \tag{2.5}$$

with $u_1 = s(u_2, v)$, which generates a *slow flow* on S.

The limit of the fast-time system (2.1) for $\varepsilon = 0$ is known as the *layer system* or *fast subsystem*

$$\left\{\begin{array}{rcl} u_1' &=& 0,\\ u_2' &=& 0,\\ v' &=& f(u_1,u_2,v,0). \end{array}\right. \tag{2.6}$$

The variables u_1 and u_2 are constants in system (2.6) and enter the equation for v as parameters. Hence, the layer system is a two-parameter family of differential equations on the fast

time scale. The critical manifold S also plays a key role in the layer system, namely, as a manifold of equilibria.

The idea of geometric singular perturbation theory [23, 32] is to understand the dynamics of system (1.1) with $\varepsilon > 0$ sufficiently small by splitting the motion into its fast and slow components. The fast dynamics of (1.1) is described by the layer system (2.6), meaning that trajectories behave like solutions of (2.6) until they get close to S. On the slow time scale, solutions are well approximated by the reduced system (2.2); in particular, trajectories remain confined to an ε-neighborhood of S. The overall dynamics can indeed be understood in this way if the critical manifold S is *normally hyperbolic*. This means that the dynamics in the direction normal to the manifold dominates the dynamics in the tangent direction [30]. Due to results by Fenichel [22, 23], a normally hyperbolic critical manifold S persists under small perturbations as a nearby normally hyperbolic invariant manifold S_ε for the singularly perturbed system (1.1). Since S is a manifold of equilibria for (2.6), the normally hyperbolic points on S are those points for which all eigenvalues associated with the directions normal to S do not lie on the imaginary axis.

In the vicinity of points where normal hyperbolicity fails, the singularly perturbed problem can give rise to very complex dynamics. In order to study what happens when S is not normally hyperbolic, we consider the projection of S onto the (u_1, u_2)-plane of slow variables. The critical manifold S consists of regular points where $f_v \neq 0$ and critical points of the projection where $f_v = 0$. According to singularity theory [1], regular points are generic and they correspond to points where S is normally hyperbolic. Moreover, a generic critical point is a fold point, and together the fold points form a codimension-one submanifold F of S. Along F two sheets of S meet. In $\mathbb{R}^3$ there may be cusp points (degenerate folds), but they are generically isolated. We focus here on fold points and their influence on the dynamics of system (1.1).

Specifically, we consider a critical manifold S with (locally) a nonempty fold curve that does not contain cusp points. Therefore, S can be written as $S = S^a \cup F \cup S^r$, where S^a and S^r refer to the attracting and repelling sheets of S, respectively, that meet at F; formally

$$\begin{aligned} S^a &= \{(u_1, u_2, v) \in S \mid f_v(u_1, u_2, v) < 0\}, \\ F &= \{(u_1, u_2, v) \in S \mid f_v(u_1, u_2, v) = 0\}, \\ S^r &= \{(u_1, u_2, v) \in S \mid f_v(u_1, u_2, v) > 0\}. \end{aligned} \tag{2.7}$$

System (2.4) is singular along F, while the desingularized system (2.5) governs the dynamics in the vicinity of the critical manifold S. Note that the rescaling by $-f_v$ that achieves this desingularization changes the direction of time where $f_v > 0$, that is, on the repelling sheet S^r of the critical manifold S.

Roughly speaking, the original system (1.1) is governed by system (2.5) when it evolves almost on the attracting sheet S^a. The situation changes when a trajectory reaches the fold curve F, that is, when f_v becomes zero. In the generic situation, that is, if $\dot{v} \neq 0$, the prominent dynamics switches to the fast dynamics (2.6) and the trajectory escapes from S along a fast fiber parallel to the v-axis. The condition $\dot{v} = f_{u_1} g_1 + f_{u_2} v_2 \neq 0$ is called the *normal switching condition* [36] and means geometrically that the reduced flow projected onto the (u_1, u_2)-plane is not tangent to the fold curve F. The point on the fold curve F where the change of dynamics occurs is called a *jump point*. If S is S-shaped, that is, there are

two separate attracting sheets and two fold curves connected to a repelling sheet, then the presence of jump points typically leads to the existence of relaxation oscillations [36, 46]; a detailed discussion of this phenomenon is given in [29] for the forced Van der Pol system.

A point on F with $f_{u_1} g_1 + f_{u_2} v_2 = 0$ is called a *folded singularity*. At such a point it is possible for a trajectory to pass through F and not escape along a fast fiber. According to the topological type of the singularity as an equilibrium of system (2.6), one has generically *folded nodes*, *folded saddles*, and *folded foci*. Locally, the dynamics near a folded singularity can be described by normal forms. The case of a folded-node singularity is sketched in Figure 1, and several trajectories of the slow flow associated with the normal form (1.2) are shown. Notice the change of direction of the slow flow across the fold curve F. As a result, some initial conditions on S^a are attracted to regular points on F, which leads to a jump. However, an entire wedge exists, bounded by the singular canard $\widehat{\gamma}_s$ and a half-line on F that ends at the folded node, where trajectories converge to the folded node and pass through to follow the repelling sheet S^r. This wedge is called the *funnel region* [47], and it is responsible for the generic existence of canard solutions in systems with $\varepsilon > 0$.

2.2. Blow-up of the folded node. One can apply the method of blow-up in the setting of geometric singular perturbation theory [17, 18, 42]. The general idea is to rescale the variables of the original problem together with the singular parameter ε. In this way, one can transform a singularly perturbed system into a regularly perturbed system that is defined on a higher-dimensional phase space. In what follows we assume that the fold curve F is the u_2-axis, which can be achieved by a (nonlinear) coordinate transformation.

The slow manifolds S^a_ε and S^r_ε correspond to ε-leaves of three-dimensional attracting and repelling center manifolds M_a and M_r of the extended system

$$\left\{ \begin{array}{rcl} u_1' &=& \varepsilon g_1(u_1, u_2, v, \varepsilon), \\ u_2' &=& \varepsilon g_2(u_1, u_2, v, \varepsilon), \\ v' &=& f(u_1, u_2, v, \varepsilon), \\ \varepsilon' &=& 0. \end{array} \right. \tag{2.8}$$

The linearization of the extended system (2.8) has all eigenvalues equal to zero at the folded node. Hence, one cannot apply center manifold theory at points on F and describe the behavior of the slow manifolds in a neighborhood of F. A good way of overcoming this difficulty is to apply a blow-up transformation at the folded node, which is a degenerate singularity of system (2.8). Roughly speaking, the blow-up method is a well-chosen coordinate transformation that desingularizes such a degenerate singularity. It was originally developed for planar vector fields [18] but has been adapted to the case of three-dimensional singularly perturbed systems [45, 50]. The change of coordinates transforms the degenerate singularity at the origin into a sphere $\mathbb{S}^3$ that contains points with (at least) one nonzero eigenvalue. Then the general methods of dynamical systems are applicable—in particular, center manifold theory; see [45] for a detailed exposition of the blow-up in this specific context.

In the case of a three-dimensional singularly perturbed system with a folded node at the origin, the desingularizing transformation is defined by

$$u_1 = \rho^2 x, \quad u_2 = \rho y, \quad v = \rho z, \quad \varepsilon = \rho^2 \bar{\varepsilon},$$

where $(x, y, z, \bar{\varepsilon}) \in \mathbb{S}^3$ and $\rho \in [0, \rho_0]$ is a new radial parameter. The analysis on the sphere is now done using charts that yield so-called *directional rescalings* obtained by setting one coordinate in $\mathbb{S}^3$ equal to ± 1 and desingularizing the vector field in these charts. As is explained in [50], the possible intersections between the slow manifolds, that is, the existence of maximal canards, are best studied using the chart $\bar{\varepsilon} = 1$, denoted κ_2, which describes the situation on the blown-up locus. As a main result, the blow-up extends the normal hyperbolicity of the slow manifolds S^a_ε and S^r_ε to the blown-up sphere. After desingularization, the system in κ_2 is given by

$$\left\{\begin{array}{rcl} \dot{x} &=& \frac{1}{2}\mu y - (\mu+1)z + O(\rho), \\ \dot{y} &=& 1, \\ \dot{z} &=& x + z^2 + O(\rho). \end{array}\right. \tag{2.9}$$

By definition of the directional rescaling in chart κ_2 we have $\rho = \sqrt{\varepsilon}$.

The role of (2.9) is as follows. By Fenichel's theorems, for any fixed $\varepsilon > 0$ sufficiently small, the slow manifolds S^a_ε and S^r_ε exist outside a neighborhood of the fold curve F. These manifolds have extensions into the neighborhood of F, that is, into the blown-up locus; see [9, 45, 50] for the technical details. The great benefit of the blow-up transformation in chart κ_2 is that for $\varepsilon \to 0$ the extensions on the blown-up locus tend to invariant manifolds $C^\pm$ of (2.9) for $\rho = 0$, which is the normal form (1.2). Therefore, the normal form acts as a "germ" in the sense that intersections of C^+ and C^- are "seeds" that give rise to actual canards of (1.1) for $\varepsilon > 0$. Consequently, the geometry of the manifolds $C^\pm$ contains all the relevant information regarding the corresponding "true" slow manifolds S^r_ε and S^a_ε of system (1.1), respectively. Indeed, the study of the geometry of $C^\pm$ is the main topic of this paper. Note that from now on we refer to $C^\pm$ simply as repelling and attracting slow manifolds and to their intersections as canards (rather than their seeds).

2.3. Properties of the normal form. An important property of the normal form (1.2) is its invariance under the time-reversing symmetry $(x, y, z, t) \mapsto (x, -y, -z, -t)$. Therefore, it suffices to concentrate on the attracting slow manifold C^-; the repelling slow manifold C^+ is given by the symmetry. The manifolds $C^\pm$ connect at infinity (the boundary of the blown-up locus) with the respective sheets of the critical manifold of the underlying slow-fast system (1.1). Therefore, in the limit $x \to -\infty$, the manifold C^- converges to the upper sheet of the parabolic cylinder

$$S := \{(x, y, z) \in \mathbb{R}^3 \mid x + z^2 = 0\}. \tag{2.10}$$

Furthermore, the interactions of C^+ with C^- take place in the vicinity of the origin, that is, near the fold curve $F := \{(0, y, 0) \in \mathbb{R}^3\}$ of S.

A main advantage of (1.2) is that it possesses two explicit canard solutions of algebraic growth, γ_s and γ_w, given as

$$\begin{array}{rcl} \gamma_s(t) &=& \left(-\frac{\mu^2}{4}t^2 + \frac{\mu}{2},\ t,\ \frac{\mu}{2}t\right), \\ \gamma_w(t) &=& \left(-\frac{1}{4}t^2 + \frac{1}{2},\ t,\ \frac{1}{2}t\right). \end{array} \tag{2.11}$$

We refer to γ_s as the *strong canard* and to γ_w as the *weak canard*, because they correspond to the strong and the weak eigendirections of the linearization of system (1.2) at the folded node, respectively. The maximal canards γ_s and γ_w are extensions on the blown-up locus of the singular canards $\widehat{\gamma}_s$ and $\widehat{\gamma}_w$ shown in Figure 1, respectively. Note that the geometry of $C^{\pm}$ for $\mu > 1$ and for $1/\mu \in [0,1]$ is topologically the same (where the roles of γ_s and γ_w are interchanged); recall that μ denotes the ratio of the eigenvalues of system (2.5) projected onto the (y,z)-plane and linearized at the origin. Therefore, we consider here the changes of the slow manifolds $C^{\pm}$ as a function of μ only for $\mu \geq 1$.

It has been proved that $C^{\pm}$ intersect transversely along γ_s and γ_w when μ is not an integer [4, 45]. For integer values of μ the manifolds C^+ and C^- intersect transversely along γ_s and tangentially along γ_w. A new canard is created from the weak canard γ_w at every odd integer value of the parameter μ (for $\mu \geq 3$) [50]. The bifurcating canards η_i are called *secondary canards*. It was analytically proved in [45] that the slow manifolds C^- and C^+ spiral $\lfloor \mu \rfloor$ times around the weak canard γ_w (here $\lfloor q \rfloor$ denotes the integer part of the real number q). Due to the time-reversing symmetry of the normal form, this implies that C^- and C^+ make $\lfloor \frac{\mu-1}{2} \rfloor$ full rotations around each other. Each one of these full rotations ends in a transverse intersection along a secondary canard. Hence, away from the resonances $\mu \in \mathbb{N}$, there are $\lfloor \frac{\mu-1}{2} \rfloor$ secondary canards that successively make one additional complete revolution around γ_w. More precisely, η_i makes $i + \frac{1}{2}$ rotations around γ_w; see section 5. Geometrically, we can think of the strong canard γ_s as the secondary canard η_0, because γ_s makes a half-rotation around γ_w. The order is such that γ_w is always located between $\eta_{\lfloor \frac{\mu-1}{2} \rfloor}$ and $\eta_{\lfloor \frac{\mu-1}{2} \rfloor - 1}$.

3. Computing slow manifolds.

The main underlying idea of our approach is that one can compute (a finite part of) a two-dimensional invariant manifold of a system of ordinary differential equations as a collection of orbit segments by numerical continuation of a one-parameter family of two-point boundary value problems. This approach can be applied in a wide variety of contexts [34]. Below we explain how we use it to compute $C^{\pm}$ for the normal form; see [11] for details on how to compute $C^{\pm}$ for systems not in the normal form.

3.1. Slow manifolds as collections of orbit segments.

As is common in numerical continuation, we consider a vector field of the form

$$\dot{\mathbf{u}} = T\mathbf{g}(\mathbf{u}, \lambda), \tag{3.1}$$

where $\mathbf{g} : \mathbb{R}^n \times \mathbb{R}^p \to \mathbb{R}^n$ is sufficiently smooth and $T \in \mathbb{R}$ and $\lambda \in \mathbb{R}^p$ are parameters. The parameter T is the total integration time. It appears explicitly as a free parameter on the right-hand side of (3.1), so that an orbit segment $\mathbf{u}(t)$ is always represented over the interval $[0,1]$. By imposing suitable boundary conditions on solutions of (3.1) we can characterize any k-dimensional invariant submanifold in $\mathbb{R}^n \times \mathbb{R}^p$. To be more precise, we consider the boundary conditions

$$\begin{cases} \mathbf{u}(0) \in L, \\ \mathbf{u}(1) \in \Sigma, \end{cases} \tag{3.2}$$

where L is a one-dimensional submanifold and Σ is a codimension-one submanifold of $\mathbb{R}^n$. One needs $(n-1)$ boundary conditions to restrict $\mathbf{u}(0)$ to the curve L and one boundary

condition to restrict $\mathbf{u}(1)$ to the $(n-1)$-dimensional manifold Σ. Hence, the total number of boundary conditions in (3.2) is n. That is, with T as a free parameter, (3.1)–(3.2) define a one-parameter family of well-posed two-point boundary value problems that represent orbit segments starting at L and ending in the section Σ; see, for example, [12]. The family is parametrized by the position of $\mathbf{u}(0)$ on L, and T is the integration time to reach Σ from L. Depending on the choice of L and Σ, this general setup can be used to compute different types of dynamical objects, including two-dimensional invariant manifolds [34] and their one-dimensional intersection curves with the section Σ [20].

In the present setting the phase space is three-dimensional, and our goal is to find appropriate definitions for L and Σ so that (3.1)–(3.2) define $C^{\pm}$ as surfaces in a region of interest. Since C^+ can be found from C^- by symmetry in (1.2), we explain here only the computation of C^-. The family of orbit segments obtained by continuation of (3.1)–(3.2) defines (part of) the two-dimensional manifold C^-, provided the one-dimensional submanifold L satisfies $L \subset C^-$ [23, 50]. We do not know C^-, but we do know that in the half-space $\{x \leq -\xi\}$ with $\xi > 0$ sufficiently large, C^- is well approximated by

$$S^a = \{(x, y, z) \in \mathbb{R}^3 \mid x + z^2 = 0,\ z < 0\},$$

that is, by the lower sheet of the parabolic cylinder S given in (2.10). Therefore, we define

$$L = L^-_\xi := \{(-\xi, s, -\sqrt{\xi}) \mid s \in \mathbb{R}\}, \tag{3.3}$$

which is the line on S^a with $x = -\xi$. The interesting dynamics takes place near the origin on the fold curve F of S, so a suitable choice for Σ is a plane transverse to F. We define

$$\Sigma = \Sigma_\alpha := \{y = \alpha\}, \tag{3.4}$$

where $\alpha \geq 0$. The two-point boundary value problem (3.1)–(3.2) for the choices (3.3) and (3.4) defines a one-parameter family of orbit segments that lie on C^- in good approximation, provided ξ is large enough.

3.2. Finding a first orbit segment on the slow manifold. To start the continuation we must provide a first orbit segment that solves (3.1) subject to the boundary conditions (3.2). For the normal form (1.2) two explicit canard solutions are known, which we can use to start a computation. Note that neither one of the two explicit solutions has a point in common with the lower sheet S^a of the parabolic cylinder S, which means that it is not possible to choose ξ such that the two explicit canard solutions contain segments that start on L^-_ξ and solve the boundary value problem (3.1)–(3.2). However, we use the explicit solutions only to start the Newton iteration; that is, we select a suitable explicit solution segment such that Newton's method converges to a solution of (3.1)–(3.2).

To be concrete, we start from the strong canard γ_s given in (2.11) and consider the initial orbit segment

$$\mathbf{u}(t) = \gamma_s(tT + t_0), \qquad 0 \leq t \leq 1, \tag{3.5}$$

for some start time t_0 and total integration time T. We choose $t_0 < 0$ such that the x-coordinate of $\gamma_s(t_0)$ is equal to $-\xi$, that is,

$$-\frac{\mu^2}{4}t_0^2 + \frac{\mu}{2} = -\xi.$$

In order to satisfy the second boundary condition $\mathbf{u}(1) \in \Sigma_\alpha$, we need

$$\gamma_s(T + t_0) \in \Sigma_\alpha \Leftrightarrow T + t_0 = \alpha.$$

Note that the start time t_0 must be negative, because the y-coordinate acts as time in the normal form (1.2), and we wish to preserve the direction of time. Therefore, we have

$$t_0 = -\sqrt{\frac{2\mu + 4\xi}{\mu^2}} \quad \text{and} \quad T = \alpha + \sqrt{\frac{2\mu + 4\xi}{\mu^2}}. \tag{3.6}$$

The solution segment (3.5) only approximately satisfies the boundary condition $\mathbf{u}(0) \in L_\xi^-$; namely, the difference between the z-coordinates of $\mathbf{u}(0) = \gamma_s(t_0)$ and the point on L_ξ^- at $s = t_0$ is

$$\frac{\mu}{2}\sqrt{\frac{2\mu + 4\xi}{\mu^2}} - \sqrt{\xi} = \frac{\mu}{2\left(\sqrt{\frac{\mu}{2} + \xi} + \sqrt{\xi}\right)}. \tag{3.7}$$

This difference is small, provided $\xi \gg \mu$, and decreases as $\xi \to \infty$. Hence, if ξ is large enough, we expect that Newton's method converges, and the first correction step of the continuation leads to a solution of (3.1)–(3.2). We remark that for a slow-fast system that is not in normal form an explicit solution is generally not known. This difficulty can be overcome with a homotopy approach, as is demonstrated in [11].

3.3. Computation of C^- from L_ξ^- to Σ_α. The computed part of C^- depends on the two user-specified parameters ξ and α that define L_ξ^- and Σ_α, respectively. The parameter ξ controls the accuracy of the computation in that it determines the initial distance between C^- and S^a. By construction, an orbit segment satisfying (3.1)–(3.2) converges to an actual orbit segment on C^- in the limit $\xi \to \infty$. It is a very difficult task beyond the scope of this paper to find an explicit ξ-dependent error bound for the approximation of C^- and how it depends on μ. To derive a practical measure for the accuracy of the computations presented here, we make use of the fact that the strong canard γ_s is given as an explicit solution (2.11). As mentioned in section 3.2, the orbit segment (3.5) of γ_s is the start solution for Newton's method, and we use the difference between $\gamma_s(tT + t_0)$ and the approximate solution $\mathbf{u}^*(t)$ as an indication of the overall approximation error. Namely, we consider the pointwise difference between $\gamma_s(tT + t_0)$ and $\mathbf{u}^*(t)$ with $0 \le t \le 1$ and ensure that it is sufficiently small. At $t = 0$ this difference is given by (3.7), and it decreases exponentially for $t > 0$; this decrease is particularly fast due to the difference in time scales. Specifically, we consider only the difference in the z-coordinate and require that

$$|\, \gamma_s(tT + t_0) - \mathbf{u}^*(t) \,|_z < 10^{-5}$$

for all t with $\mathbf{u}_x^*(t) > -\frac{1}{2}\xi$. In other words, this condition ensures the accuracy of the second and relevant part of the orbit segment, and we found that it is satisfied with $\xi = 100$ for all $\mu \le 8.5$ that we consider in this paper. For larger μ, also ξ needs to be increased; namely, we use $\xi = 200$ for $\mu = 14.5$, $\xi = 400$ for $\mu = 25.5$, and $\xi = 1000$ for $\mu = 49.5$.

The parameter α determines the location of the section Σ_α. Its choice depends on which aspect of $C^\pm$ is of interest. A natural choice is $\alpha = 0$, such that the folded node (the origin) is contained in Σ_α. This means that C^- and C^+ are computed both up to Σ_0, which emphasizes their intersection curves $C_0^\pm = C^\pm \cap \Sigma_0$. Note that these intersection curves have been computed before by shooting methods (numerical integration of initial values of S^a); see, for example, [28, 27, 50]. By contrast, we compute the curves $C_0^\pm$ as well as the surfaces $C^\pm$ themselves with the collocation and continuation routines of the package AUTO [14]. The main advantage of using collocation, as opposed to a shooting method, is that the size of the continuation step is determined by taking the entire orbit segment into account instead of the initial condition alone. This feature is particularly useful for slow-fast systems, which are extremely sensitive to changes of the initial condition [20]. Specifically, we compute the one-dimensional curves $C_0^\pm$ with an adaptation of the software MANBVP [20], where orbit segments are generated according to the local curvature of C_0^-. The two-dimensional surfaces $C^\pm$ are computed with an AUTO run with a fixed continuation step size, which ensures a uniform distribution of mesh points on the surface.

In order to investigate how C^- and C^+ intersect near the folded node at the origin, we consider orbit segments computed up to Σ_α with $\alpha > 0$. By symmetry, C^+ ends in $\Sigma_{-\alpha}$, so that the two slow manifolds are seen to interact in the region $-\alpha \le y \le \alpha$. To visualize the geometry of this interaction it is convenient to show only the "ribbons" of C^- and C^+ in between the planes $\Sigma_{-\alpha}$ and Σ_α. To this end, we clip each orbit segment of the computed manifold C^- where it intersects $\Sigma_{-\alpha}$. We then determine a mesh with a fixed number of mesh points that are uniformly distributed according to arclength along clipped orbit segments. The resulting ribbons of $C^\pm$ can readily be visualized; see section 4.

3.4. Illustration of the method. Figure 2 illustrates our method for the normal form (1.2) with $\mu = 1.2$. Figure 2(a) shows an approximation of the attracting slow manifold C^- for $\alpha = 0$; that is, we computed a collection of orbit segments that start on L_{100}^-, the straight red line in Figure 2(a), and end in Σ_0, the (x, z)-plane shown in green. The bold red curve in Σ_0 is the intersection C_0^- of C^- with Σ_0, and a small segment of its symmetrical image C_0^+ (blue curve, not labeled) is also shown. We started the continuation from the solution segment (bold black curve) $\gamma_s(tT + t_0)$, $t \in [0, 1]$, of the explicitly known strong canard γ_s with t_0 and T as defined in (3.6). The continuation is done in two directions parametrized by the y-coordinate along L_{100}^-, where we start at $y = t_0 < 0$.

Let us first focus on the continuation run where y increases, because this part generates most of the intersection curve C_0^-. Note that it is natural to stop the continuation when $y = 0$ is reached. (This is detected by a user-defined function in AUTO; the solution family exists for $y > 0$, but then T becomes negative.) Notice from Figure 2(a) that the curve C_0^- is very close to the lower branch of the parabola $S \cap \Sigma_0 = \{x + z^2 = 0\}$. At the scale of Figure 2(a) it is difficult to see what happens near the folded node; an enlarged view of $C_0^\pm$ is presented in the next section.

During the second continuation run, when y is decreasing, we encounter the orbit segment between L_{100}^- and Σ_0 that corresponds to the weak canard γ_w, for which we have an explicit expression given in (2.11). Note that, due to the symmetry of the normal form, any intersection of the curve C_0^- with the line $z = 0$ in the section Σ_0 corresponds to a canard. Hence, by imposing the user-defined function $\mathbf{u}_z(1) = 0$ as part of the continuation of the one-parameter

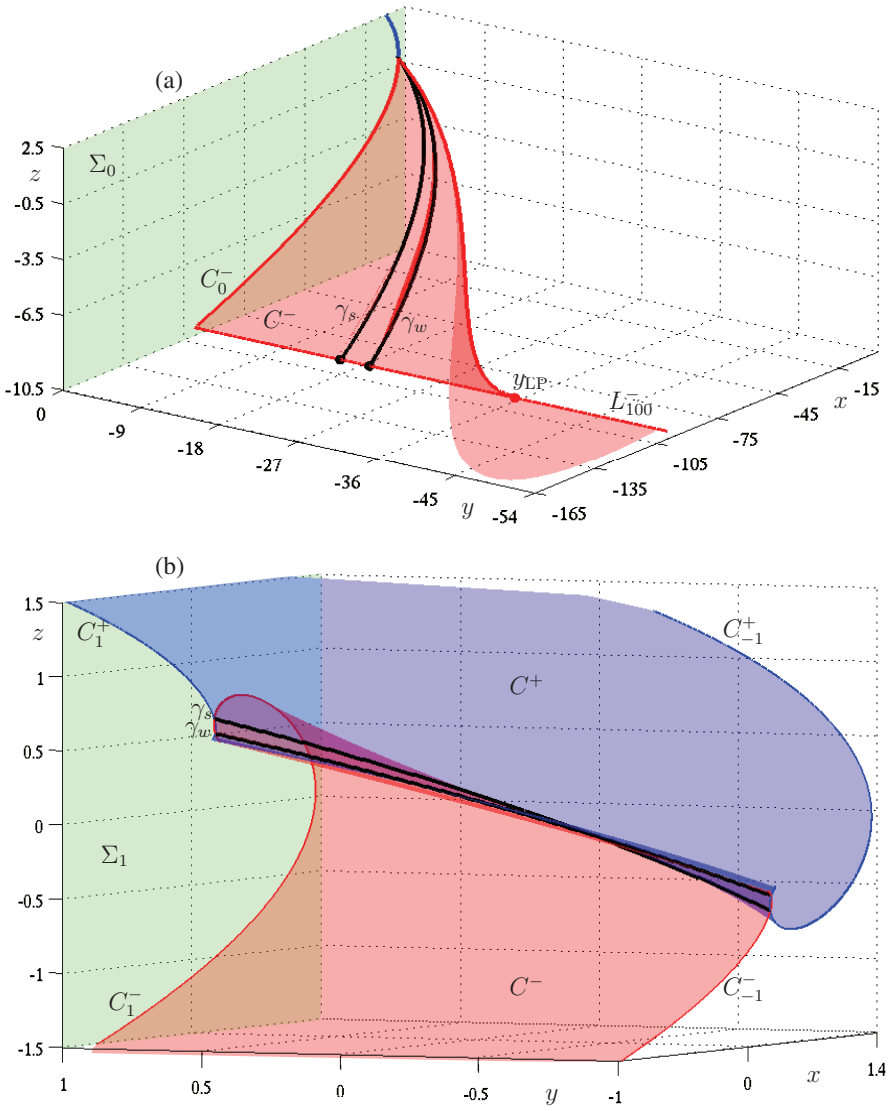

Figure 2. *Global overview of the slow manifolds for $\mu = 1.2$. Panel* (a) *shows the attracting slow manifold C^- (red surface) computed from the line of initial conditions L_{100}^- (red line) up to section Σ_0; panel* (b) *shows the parts of C^- and C^+ (red and blue surfaces, respectively) in between the sections Σ_{-1} and Σ_1. The two primary canards γ_s and γ_w have been highlighted as bold black curves; the red bold curve (panel* (a) *only) is the orbit starting at the intersection point $y_{\rm LP}$ between L_{100}^- and the x-nullcline. We also show the intersection curves $C_\alpha^\pm$ of the slow manifolds $C^\pm$ with the sections Σ_0 and $\Sigma_{\pm 1}$. See also the accompanying animation* (70881_01.gif [5.9MB]) *of the computation of C^- for $\mu = 8.5$.*

family that solves (3.1)–(3.2), AUTO [14] automatically detects these canard solutions of the normal form (1.2); a more detailed discussion is provided in section 5. The actual canard solutions are obtained by concatenating the detected orbit segment on C^-, which ends in Σ_0 on the line $z = 0$, with its symmetrical copy on C^+ on the other side of Σ_0.

As y decreases further, we encounter another special solution during the continuation, which is shown as the bold red curve in Figure 2(a) that starts at the point labeled y_{LP} on L_{100}^{-}. The point

$$y_{\mathrm{LP}} = -\frac{2(\mu+1)}{\mu}\sqrt{\xi}$$

is the unique point where the x-direction of the vector field (1.2) vanishes on L_{100}^{-}; that is, $y_{\mathrm{LP}} \approx 36.777$ is the intersection of L_{100}^{-} with the x-nullcline for $\mu = 1.2$. If L_{100}^{-} were exactly on C^{-}, then all initial conditions on L_{100}^{-} beyond y_{LP}, that is, with y-coordinates less than y_{LP}, would lie on (backward-extended) orbit segments that intersect L_{100}^{-} at y-coordinates larger than y_{LP}. This behavior corresponds exactly to the case that an (un)stable manifold in a Poincaré section crosses the locus where the flow is tangent to the section; see [20] for more details.

In practice L_{100}^{-} lies only approximately on C^{-} and solutions beyond y_{LP} do not lie exactly on the computed approximation of C^{-} but still very close to it. Hence, it appears as though a new part of C^{-} is obtained, which manifests itself as a very sharp fold, or "crease," on the approximation of C^{-}. From a computational point of view, the continuation makes sense only for $\mathbf{u}(0) \in [0, y_{\mathrm{LP}}]$, because continuation beyond y_{LP} produces a second approximation of the same part of C^{-}. Figure 2(a) does show a computation of C^{-} past y_{LP} to illustrate what happens. Note that $y_{\mathrm{LP}} \to -\infty$ as $\xi \to \infty$, that is, in the limit where L_{ξ}^{-} converges to a line on C^{-}, the point y_{LP} no longer exists.

Figure 2(b) demonstrates how the ribbons of $C^{\pm}$ in between Σ_1 and Σ_{-1} can be used as a means of visualizing the interaction of the two manifolds. For clarity, the intersection curves $C_1^{\pm}$ and $C_{-1}^{\pm}$ are shown as well. The geometry of $C^{\pm}$ is further enhanced by including the strong and weak canards γ_s and γ_w, respectively.

4. Geometry of the slow manifolds. We now study the slow manifolds $C^{\pm}$ for different values of the parameter μ. We use both $\alpha = 0$ and $\alpha > 0$ in the method from section 3 to illustrate not only the intersection curves $C_0^{\pm}$ of $C^{\pm}$ with Σ_0, as was done in [50], but also the geometry of the two-dimensional slow manifolds $C^{\pm}$ themselves. A main goal is to see how maximal canards arise as new intersection curves between C^{-} and C^{+}. In all figures the attracting slow manifold C^{-} is colored red, the repelling slow manifold C^{+} is blue, the section Σ_α is green, and the strong canard γ_s and the weak canard γ_w are black. As μ is increased, secondary canards appear, which we label successively as η_i. We adopted a particular color coding for these secondary canards: η_1 is orange, η_2 is magenta, η_3 is cyan, and we repeat these successive colors for each group of three consecutive secondary canards after η_3.

4.1. Geometry of $C^{\pm}$ up to Σ_0. We begin with a series of images for $\mu = 1$, $\mu = 1.2$, $\mu = 2.5$, $\mu = 3.5$, and $\mu = 8.5$ that illustrate the behavior of $C^{\pm}$ up to the section Σ_0; see Figures 3(a),(b), 4(a),(b), and 5(a), respectively. Each figure shows a three-dimensional view in a neighborhood of the folded node of C^{+} and C^{-}, computed up to Σ_0, together with the corresponding intersections in the plane Σ_0. To facilitate comparison and analysis, the viewpoint and aspect ratio are identical for all three-dimensional pictures, although the ranges along the axes vary.

Figure 3(a) shows the case $\mu = 1$, which acts as the starting point where $C^{\pm}$ have a nontransverse, tangent intersection along a single orbit. The first two (maximal) canards γ_s

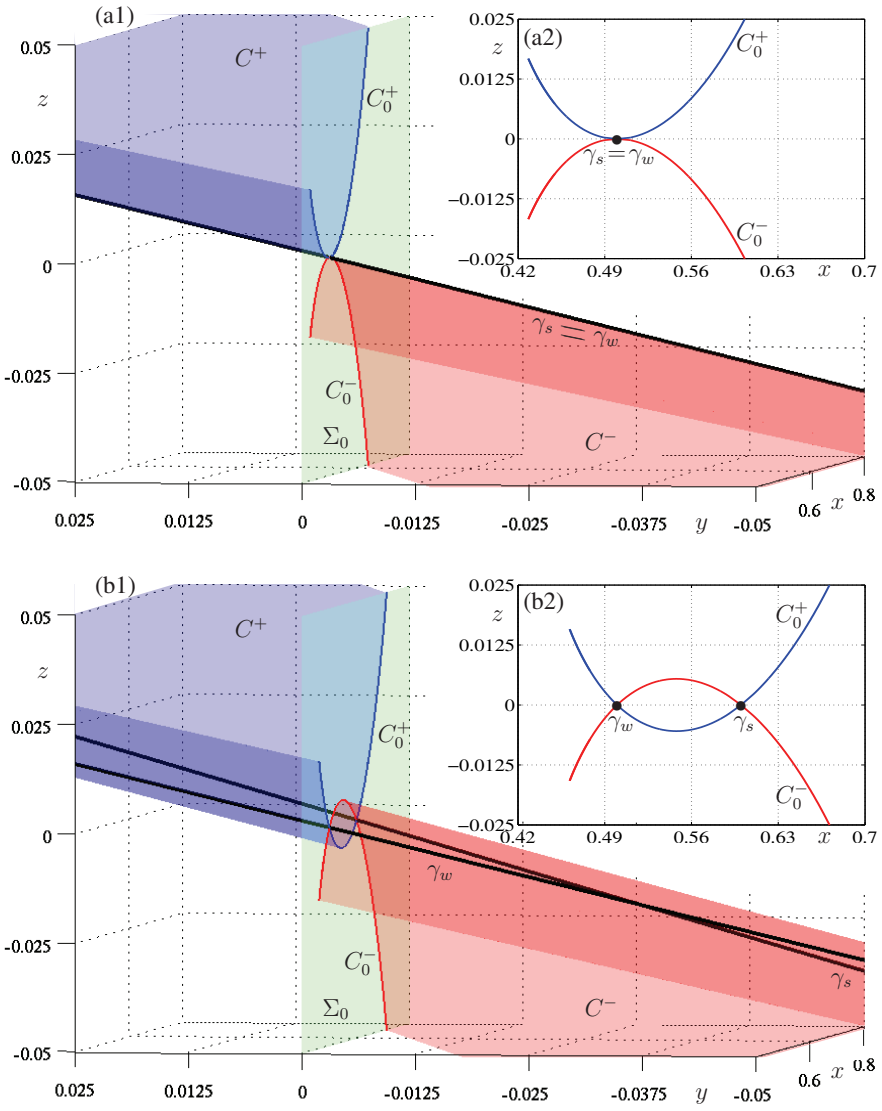

Figure 3. *Local three-dimensional views of the slow manifolds $C^{\pm}$ computed up to section Σ_0; the inset panels show their intersections $C_0^{\pm}$ with Σ_0. Panels* (a) *are for $\mu = 1$ and panels* (b) *are for $\mu = 1.2$. The weak canard γ_w and the strong canard γ_s are shown as black curves and their intersections with Σ_0 are denoted by black dots. See also Figures 4 and 5.*

and γ_w are created as μ is increased. They are shown in Figure 3(b) for $\mu = 1.2$; see also Figure 2. Note that γ_s and γ_w are now two distinct orbits of the normal form (1.2) in which the slow manifolds $C^{\pm}$ intersect transversely. The case $\mu = 1.2$ is representative of all values $1 < \mu < 2$. Notice in Figure 3 the parts of $C_0^{\pm}$ to the left of γ_w, which correspond to the part of $C^{\pm}$ between γ_w and the orbit of the point y_{LP}. We remark that these parts, which we call the tips of $C_0^{\pm}$, exist for all values of μ, but they rapidly become so small that they are invisible in Figures 4 and 5(a).

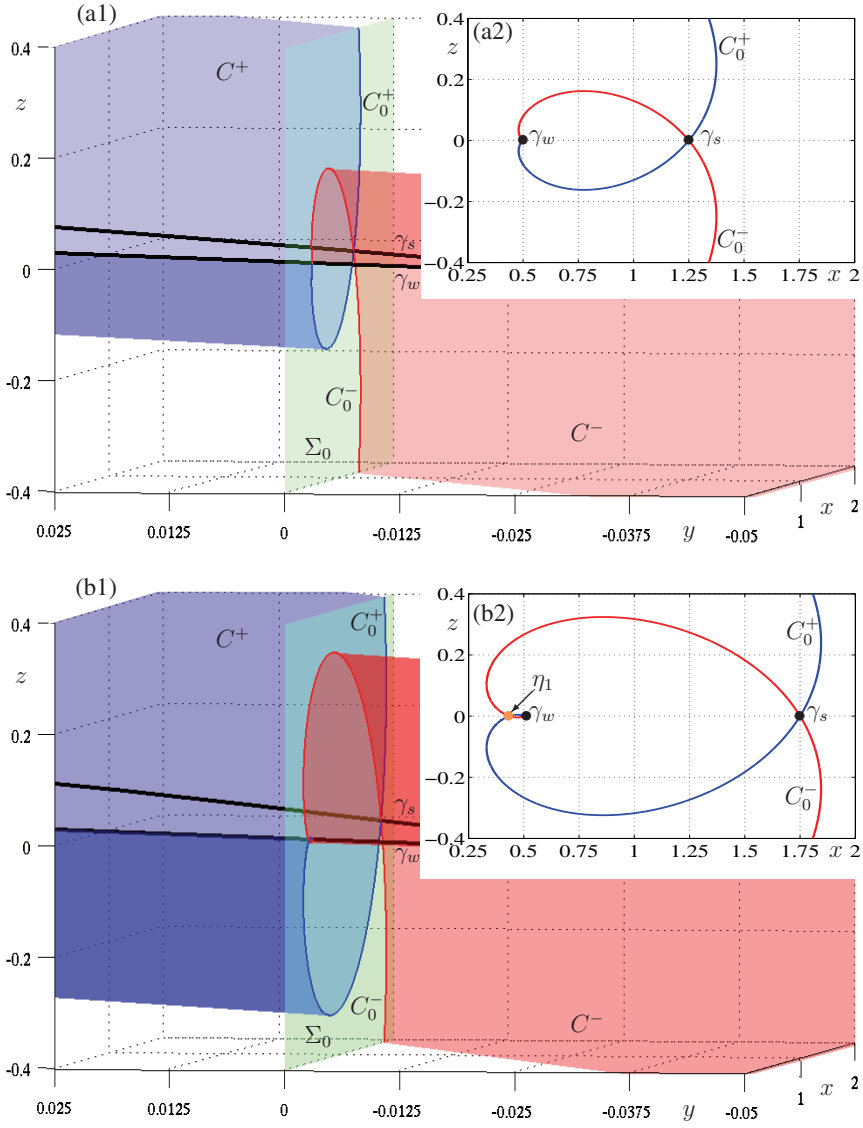

Figure 4. *Local three-dimensional views of the slow manifolds $C^{\pm}$ computed up to section Σ_0; the inset panels show their intersections $C_0^{\pm}$ with Σ_0. Panels* (a) *are for $\mu = 2.5$ and panels* (b) *are for $\mu = 3.5$. Note the existence of the first secondary canard η_1 (orange dot) in panel* (b2)*, which appears in a transcritical bifurcation at $\mu = 3$. See also Figures 3 and 5.*

A qualitative change occurs at $\mu = 2$. Figure 4(a) shows the situation for $\mu = 2.5$. As can be observed particularly in panel (a2), the tips of $C_0^{\pm}$ have rotated around so that they now point inside the region delimited by γ_s and γ_w. Indeed, these tips rotate continuously with μ. At $\mu = 2$ the tangent bundles $T_{\gamma_w} C^{\pm}$ coincide and the directions in Σ are parallel to the z-axis; that is, $C_0^{\pm}$ both have a vertical tangency vector at $\gamma_w(0)$. Numerical evidence in [50] suggests that near $\mu = 2$, and indeed near all even μ, there are (very) short branches of canards that

correspond to intersection points of the tip of C_0^- with C_0^+ and vice versa. For $\mu = 3$ the tips have rotated so that the tangent bundles $T_{\gamma_w}C^\pm$ coincide again, but $C_0^\pm$ now both have a tangency vector parallel to the x-axis, and a transcritical bifurcation occurs that results in a secondary canard (again, there are very short branches associated with intersections of the tips of $C_0^\pm$). As shown in [50], transcritical bifurcations occur for all odd integer values of $\mu \geq 3$. Figure 4(b) shows a phase portrait for $\mu = 3.5$ with the first secondary canard η_1 (orange curve). As can be seen clearly in Figure 4(b2), there are now three intersection points of $C_0^\pm$ in Σ_0. Note that γ_w is located between η_1 and γ_s on the x-axis.

Figure 5(a) shows the situation for $\mu = 8.5$, where we have three secondary canards, denoted η_1 (orange), η_2 (magenta), and η_3 (cyan). It gives an idea of how the secondary canards appear as a result of the spiraling motion of $C^\pm$ around the weak canard γ_w; this is particularly visible for $C_0^\pm$ in Σ_0, shown in Figure 5(a2) and in the accompanying animation (70881_02.gif [3.7MB]). The figure also illustrates the fact that $C^\pm$ make $\lfloor \frac{\mu-1}{2} \rfloor$ full rotations around γ_w.

4.2. Ribbons of $C^\pm$ near the folded singularity. Figures 3, 4, and 5(a) give a good insight into the topological changes of the geometry of $C^\pm$. After the bifurcation of maximal canards at $\mu = 1$, all secondary maximal canards bifurcate from γ_w in transcritical bifurcations at odd integer values of μ. To bring out this behavior more clearly, we also compute ribbons of $C^\pm$ in between $\Sigma_{-\alpha}$ and Σ_α for suitable $\alpha > 0$. Figure 5(b) shows $C^\pm$ in between Σ_{-1} and Σ_1, along with the intersection curves γ_s, γ_w (black curves), η_1 (orange), and η_2 (magenta); note that η_3 is not shown in this picture, because it cannot be distinguished from γ_w at this scale. The intersection curves $C_{-1}^\pm$ and $C_1^\pm$ in the bounding sections Σ_{-1} and Σ_1 give an idea of how C^- and C^+ spiral out past the origin in forward and backward time, respectively.

Figure 6 shows $C^\pm$ for much larger values of μ, namely, for $\mu = 25.5$ and $\mu = 49.5$ in panels (a) and (b), respectively. The slow manifolds spiral out faster as μ increases; hence, we now show ribbons of $C^\pm$ only in between $\Sigma_{-0.5}$ and $\Sigma_{0.5}$. The figure shows the increased complexity of $C^\pm$ with many more intersection curves that form additional secondary canards. For $\mu = 25.5$ there are twelve secondary canards that wind around γ_w; only the first four are labeled in Figure 6(a). For $\mu = 49.5$ there are 24 secondary canards, but again only η_1, η_2, η_3, and η_4 are labeled in Figure 6(b). Due to the increased spiraling amplitude of the intersection curves $C_{-0.5}^\pm$ and $C_{0.5}^\pm$, the strong canard and the secondary canards now lie further away from the weak canard than for $\mu = 25.5$ (or any $\mu < 49.5$); see also the accompanying animation (70881_03.gif [1.3MB]).

Figure 7 illustrates the increasing complexity with μ by showing $C^\pm$ for $\mu = 8.5$, $\mu = 14.5$, $\mu = 25.5$, and $\mu = 49.5$. Here we rotated the slow manifolds $C^\pm$ about the z-axis with the visualization package Geomview [40] to generate common enlarged views centered around the weak canard γ_w. In this way, one obtains a good impression of the spiraling behavior of the secondary canards around γ_w and how their positions and distances to γ_w change with μ. Figure 7(a) shows that for $\mu = 8.5$ the manifolds C^- and C^+ intersect in the two secondary canards η_1 and η_2. For $\mu = 14.5$ there are a total of six secondary canards, four of which, η_1 to η_4, are shown in Figure 7(b). Note how the distance of η_1 and η_2 from the central weak canard γ_w (black curve) is now much larger for $\mu = 14.5$; in a way, this creates space for η_3 and η_4 to spiral around γ_w as well. For $\mu = 25.5$ there are twelve secondary canards in total, but only η_1 to η_4 are labeled in Figure 7(c). Similarly, for $\mu = 49.5$ in Figure 7(d) there

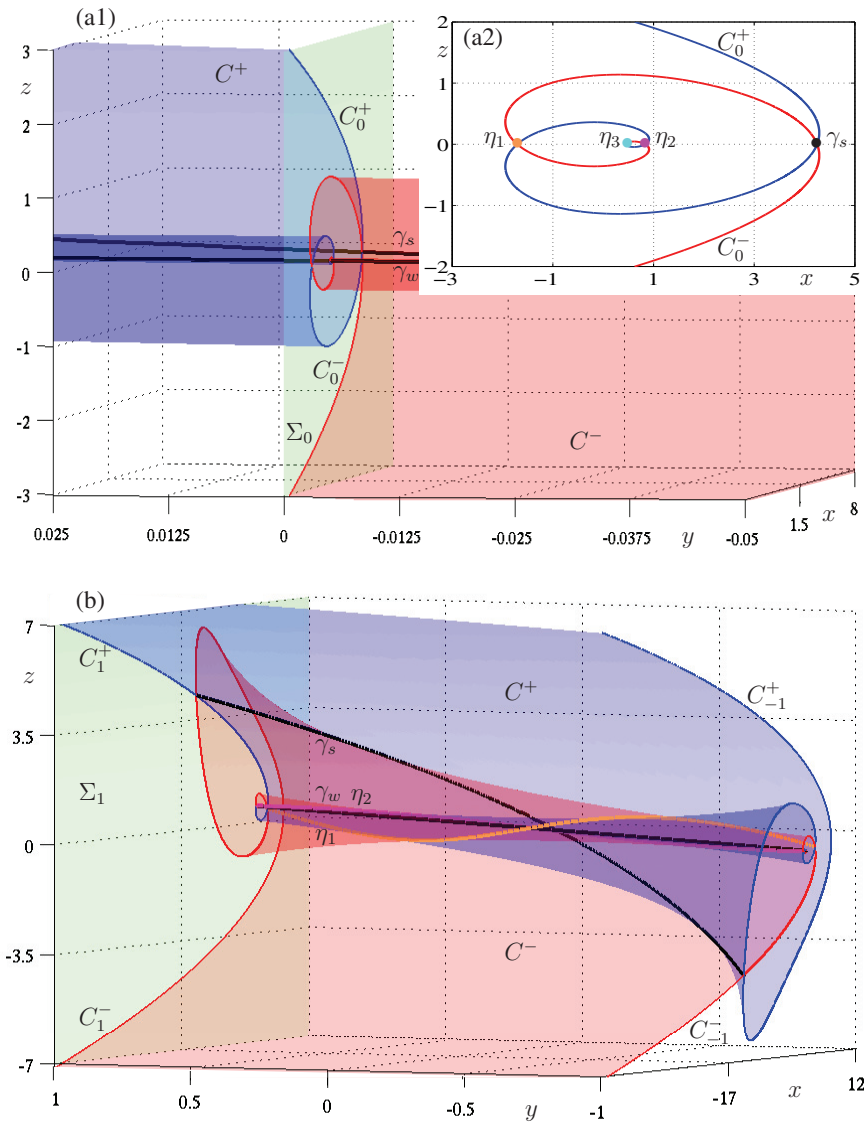

Figure 5. *Local three-dimensional views of the slow manifolds $C^\pm$ for $\mu = 8.5$ computed up to section Σ_0 in panels* (a)*; the inset panel* (a2) *shows their intersections $C_0^\pm$ with Σ_0. See also Figures 3 and 4 and the accompanying animation* (70881_02.gif [3.7MB]). *Panel* (b) *shows the ribbons of $C^\pm$ in between Σ_{-1} and Σ_1 along with the corresponding intersection curves $C_{-1}^\pm$ and $C_1^\pm$. There are three secondary canards η_1, η_2, and η_3, indicated by colored dots in Σ_0 in panel* (a2).

are 24 secondary canards, of which the first nine are clearly visible, while only η_1 to η_4 are labeled.

5. Geometric study of the secondary canards. As we have seen, the secondary canards arise as intersections of the slow manifolds C^- and C^+. We now find them directly as special orbits within the boundary value problem setup in section 3. This allows us to visualize and

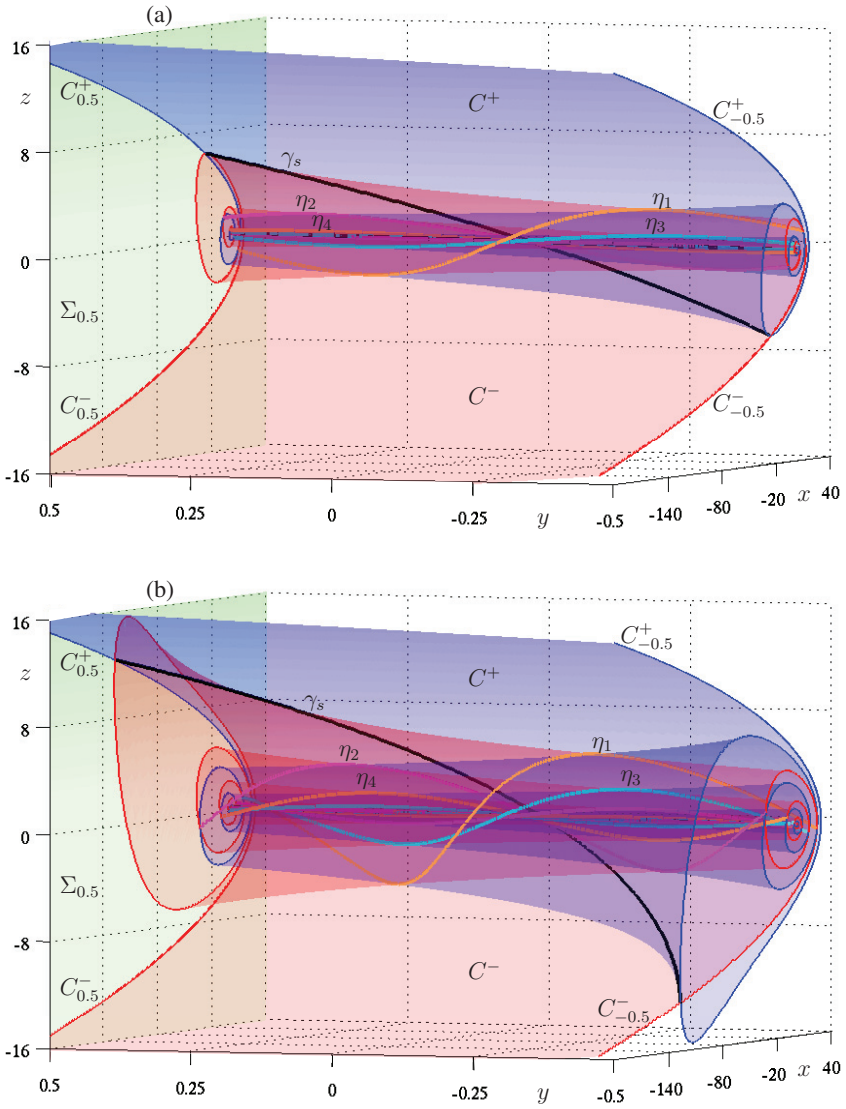

Figure 6. *Three-dimensional views of the ribbons of $C^{\pm}$ in between $\Sigma_{-0.5}$ and $\Sigma_{0.5}$, together with all maximal canards and the intersection curves $C^{\pm}_{\pm 0.5}$. Panel* (a) *is for $\mu = 25.5$, with twelve secondary canards, and panel* (b) *is for $\mu = 49.5$, with 24 secondary canards. See also Figures* 2(a) *and* 5(b) *and the accompanying animation* (70881_03.gif [1.3MB]).

discuss their spiraling behavior with respect to the weak canard γ_w. Furthermore, we continue the secondary canards in the parameter μ to reveal an overall bifurcation diagram.

5.1. Detection of secondary canards. During the continuation of (3.1)–(3.2) for fixed μ, the end points $\mathbf{u}(1) \in \Sigma_0$ of the computed orbit segments oscillate about the z-axis; see, for example, Figure 5(a2). Secondary canards are detected by the condition that the z-coordinate $\mathbf{u}_z(1)$ satisfies $\mathbf{u}_z(1) = 0$, which is done during the continuation by monitoring a user-defined function in AUTO. Recall that the point $\mathbf{u}_z(1)$ is a function of the y-coordinate $\mathbf{u}_y(0)$ of the

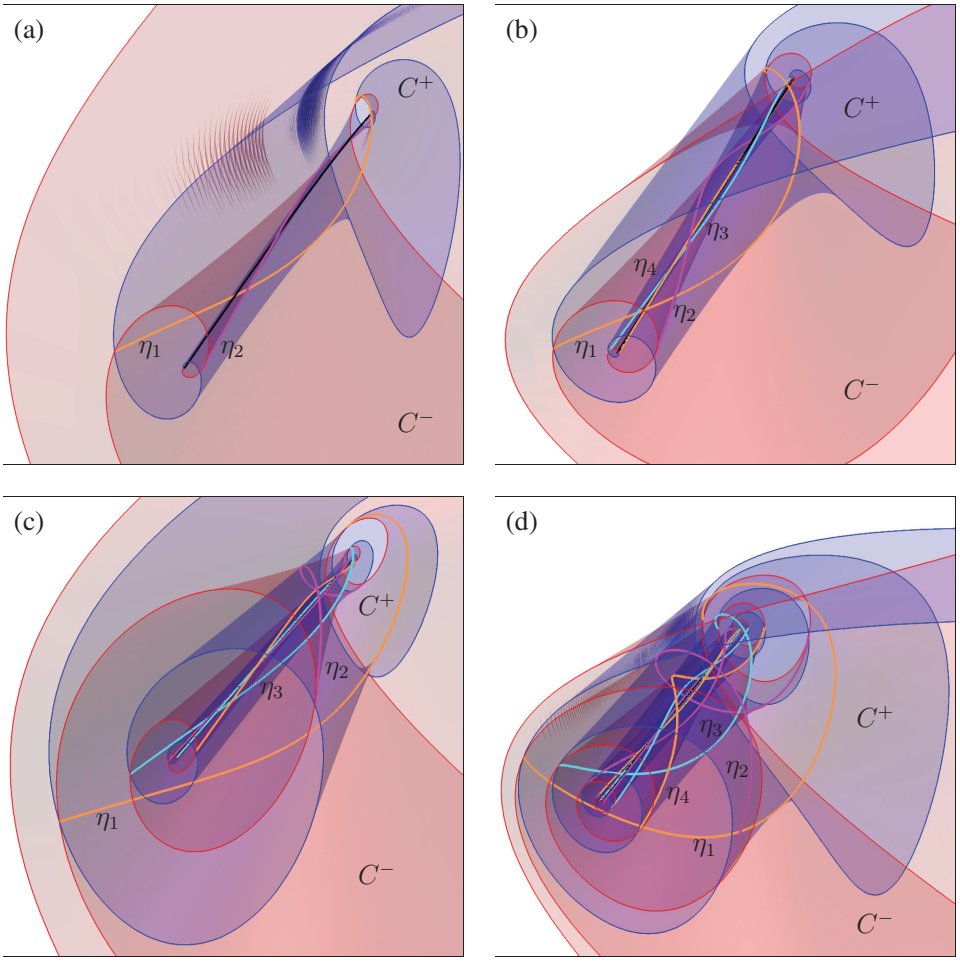

Figure 7. *Different views of the attracting and repelling slow manifolds C^- and C^+, respectively, to illustrate the spiraling dynamics of the secondary canards around the weak canard γ_w (black curve). The parameter μ is 8.5 in panel* (a)*, $\mu = 14.5$ in panel* (b)*, $\mu = 25.5$ in panel* (c)*, and $\mu = 49.5$ in panel* (d)*.*

point $\mathbf{u}(0)$ that varies along L_ξ^-.

Figure 8 shows the graph of $\mathbf{u}_z(1)$ as a function of $\mathbf{u}_y(0)$ for $\mu = 49.5$, where we show data for the run that starts from the strong canard γ_s for which we have $\mathbf{u}_y(0) = t_0 \approx -1.29$. Due to the spiraling nature of C_0^-, the graph oscillates with a rapidly decreasing amplitude; note that the continuation is in the direction of negative $\mathbf{u}_y(0)$. The enlargement in the inset of Figure 8 shows the oscillation of $\mathbf{u}_z(1)$ in the region where η_{12} to η_{15} are detected and the oscillation amplitude has decreased to values of order 10^{-4}. Numerically it becomes increasingly difficult to detect where $\mathbf{u}_z(1)$ changes sign when the oscillation amplitude becomes very small. In other words, for large μ, as in Figure 8, for $\mu = 49.5$, it is quite a challenge to detect the secondary canards that lie very close to γ_w.

For all values of μ in this paper we start the continuation with the AUTO accuracy settings

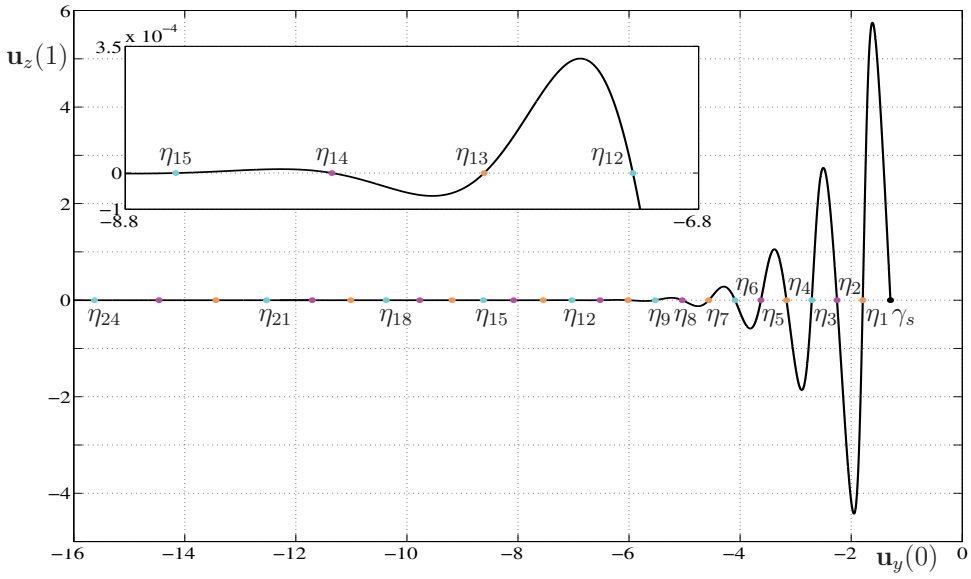

Figure 8. *Graph of the z-coordinate* $\mathbf{u}_z(1)$ *of the end point* $\mathbf{u}(1) \in \Sigma_0$ *of the computed orbit segments on* C^- *for* $\mu = 49.5$ *as a function of the y-coordinate* $\mathbf{u}_y(0)$ *of the point* $\mathbf{u}(0) \in L^-_\xi$*, where we used* $\xi = 1000$*. The continuation starts from the strong canard* γ_s*, and secondary canards* η_i *are detected when* $\mathbf{u}_z(1) = 0$*.*

Table 1

AUTO accuracy parameters as used during the detecting the secondary canards of (1.2)*. Row* (a) *is our regular accuracy setting, and row* (b) *is the increased accuracy as used for* $\mu = 49.5$*. Here* NTST *is the number of mesh points,* NCOL *the number of collocation points,* DSMIN *and* DSMAX *are the minimal and maximal stepsizes for the continuation, and* EPSS *is the relative arclength convergence criterion for the detection of special solutions; all other AUTO accuracy parameters are set to their default values.*

	NTST	NCOL	DS	DSMIN	DSMAX	EPSS
(a)	200	4	0.001	5×10^{-4}	0.01	10^{-4}
(b)	400	6	0.001	10^{-7}	0.01	10^{-7}

as shown in row (a) of Table 1. This is sufficient for the reliable detection of the η_i even for $\mu = 25.5$, but for the case $\mu = 49.5$ shown in Figure 8 the detection stops when extrema of $\mathbf{u}_z(1)$ are less than 10^{-9} in modulus. At this stage the secondary canards η_1 to η_{17} have been detected reliably. The next four secondary canards η_{18} to η_{21} are found in a second run, where we increase the accuracy parameters to the settings given in row (b) of Table 1. Nevertheless, the detection of η_{22} to η_{24} is very difficult even with the increased accuracy settings, because $\mathbf{u}_z(1)$ is now consistently below 10^{-15} in modulus. Since we are reaching the limit of machine precision, spurious roots of $\mathbf{u}_z(1)$ are reported, out of which we need to select η_{22} to η_{24}. This can be done by taking into consideration the distance between roots in $\mathbf{u}_y(0)$, which leads to a selection that is consistent with the detected secondary canards η_1 to η_{21}; see Figure 11(d).

Once a secondary canard has been detected for a fixed value of μ as a zero of $\mathbf{u}_z(1)$, it can be continued in the parameter μ by imposing $\mathbf{u}_z(1) = 0$ as an additional boundary condition. In this way, we can compute μ-dependent families of detected secondary canards.

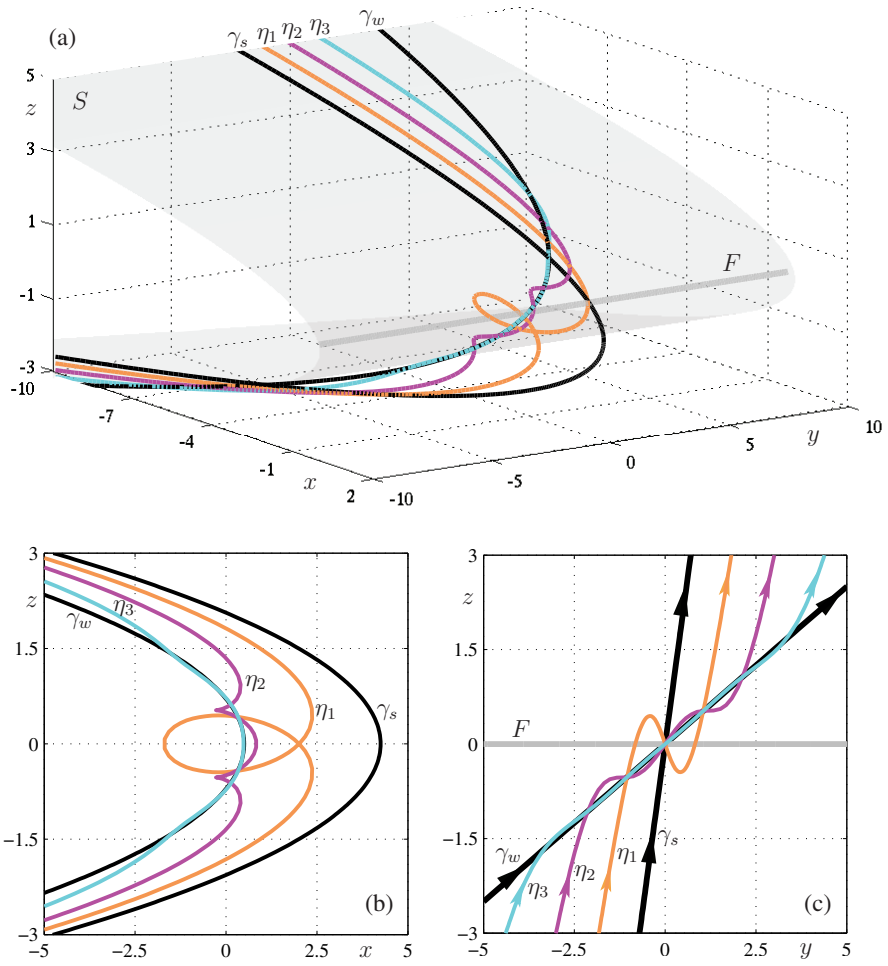

Figure 9. *Spiraling behavior of the secondary canards of* (1.2) *with* $\mu = 8.5$. *Panel* (a) *shows the primary canards* γ_s *and* γ_w *(black) and the three secondary canards* η_1, η_2, *and* η_3; *also shown for orientation is the parabolic cylinder* S *with its fold curve* F. *Panels* (b) *and* (c) *show the projections onto the* (x, z)- *and* (y, z)-*planes, respectively.*

We remark here that the oscillations of $\mathbf{u}_z(1)$ near a fixed canard increase as μ is increased. Hence, canards η_i for large i can be detected reliably for larger μ and then continued back into the range of lower values of μ.

5.2. Spiraling behavior of the secondary canards. To explain the spiraling of the secondary canards around the weak canard, we concentrate on the case $\mu = 8.5$, for which there are three secondary canards, η_1 to η_3. They are shown in Figure 9 together with the primary canards γ_s and γ_w (black curves). Figure 9(a) is a three-dimensional view of the canards, where we also show for orientation the parabolic cylinder S (grey) with its fold curve F (thick grey line). The secondary canards η_i lie seemingly parallel to γ_s for $|x|$ large but follow γ_w near F. With increasing i the η_i lie closer to γ_w as they spiral increasingly around it. Figures

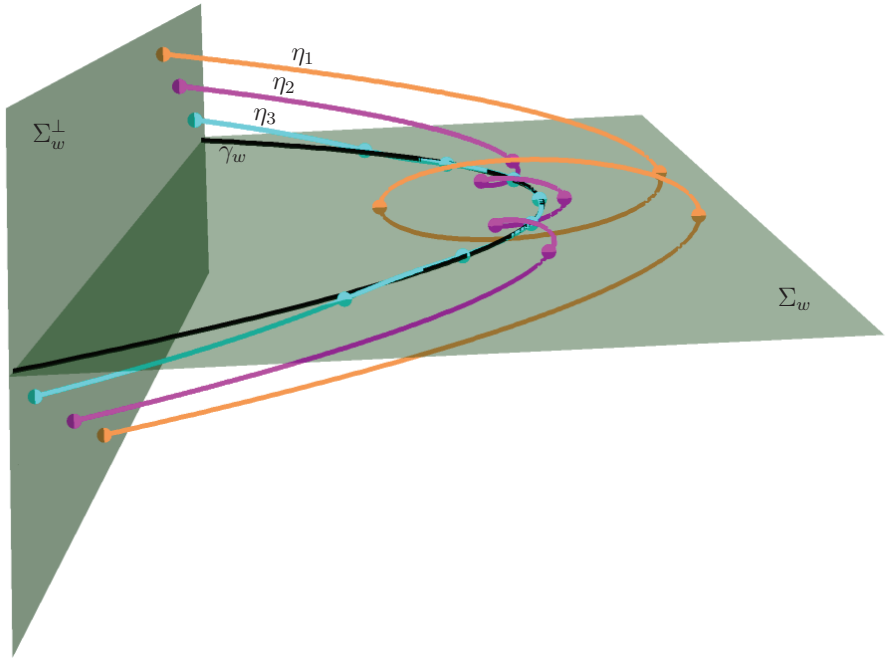

Figure 10. *Detailed view of the three secondary canards and γ_w for $\mu = 8.5$. The weak canard γ_w lies in the plane Σ_w and the three secondary canards start and end in a suitable plane $\Sigma_w^\perp$ perpendicular to Σ_w. The intersections of the secondary canards with Σ_w are marked by dots to emphasize the rotations around γ_w.*

9(b) and (c) are projections of the primary and secondary canards onto the (x, z)- and (y, z)-planes, respectively. Figure 9(b) illustrates how each new secondary canard makes one more full rotation around the weak canard γ_w. Figure 9(c) focuses on the (slow) dynamics of the secondary canards in the neighborhood of the fold.

Figure 10 is a visualization with the package Geomview [40] in the spirit of a wire and cardboard model to bring out the spiraling of the secondary canards η_1 to η_3 around γ_w. Namely, shown are the plane $\Sigma_w = \{y = 2z\}$ that contains γ_w and the plane $\Sigma_w^\perp = \{x = -10\}$ that is perpendicular to Σ_w chosen so that all spiraling behavior is captured. The secondary canards η_1 to η_3 start on $\Sigma_w^\perp$ below Σ_w and return to $\Sigma_w^\perp$ above Σ_w. Notice that η_1 has three intersection points (yellow dots), η_2 has five intersection points (magenta dots), and η_3 has seven intersection points (blue dots) with Σ_w. This illustrates the theoretical results that η_i makes $\lfloor \frac{\mu-1}{2} \rfloor$ rotations around γ_w. Figure 10 also illustrates that the secondary canards η_i lie successively closer to γ_w in the region of the fold.

The spiraling character of a secondary canard η_i does not depend on the value of μ. When a secondary canard is created in a transcritical bifurcation closest to γ_w at an odd integer value of μ, its rotating property is fixed. This is illustrated in Figure 11 with projections onto the (y, x)-plane of all canards for $\mu = 8.5$, $\mu = 14.5$, $\mu = 25.5$, and $\mu = 49.5$, respectively. For each case we chose a region of the (y, x)-plane that allows for a comparison between the panels; specifically, the x-maximum of γ_s is fixed, and the y-range is adjusted so that the last secondary canard is seen to "leave" γ_w. Figure 11(a) for $\mu = 8.5$ should be compared directly

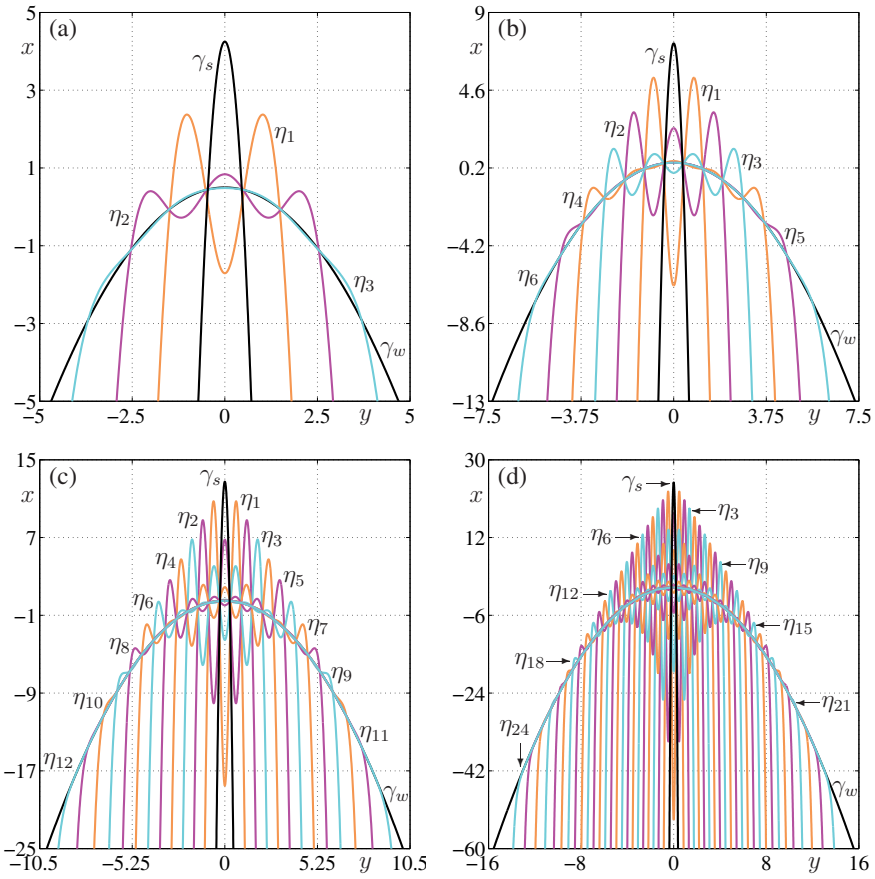

Figure 11. *Representation in the (y, x)-plane of the primary and secondary canards for four different values of μ. From panel* (a) *to panel* (d) *$\mu = 8.5$, $\mu = 14.5$, $\mu = 25.5$, and $\mu = 49.5$, respectively; the shown parts of the (y, x)-plane are chosen so that the maximum of γ_s appears in the same location and all the computed canards are covered.*

with Figure 9. There are six secondary canards in Figure 11(b), twelve in Figure 11(c), and 24 in Figure 11(d). Overall, the secondary canards run parallel to (have the same slope as) the strong canard γ_s for large $|x|$ and then spiral around γ_w. Observe that the maxima of the η_i appear to line up along a curve that connects γ_w to the maximum of γ_s; an initial investigation showed that this curve is not a straight line. It would be an interesting challenge to study limiting features of the canards in a suitably rescaled (y, x)-plane for μ tending to ∞.

5.3. Continuation of the secondary canards in μ. It is a particular advantage of our boundary value problem setup that secondary canards can be continued in the parameter μ. Figure 12 shows the result of the continuation of the secondary canards η_1 to η_{16}, where we plot the x-coordinate $\mathbf{u}_x(1)$ of the end point in Σ_0. Also shown in this bifurcation diagram are the primary canards γ_w and γ_s. They are determined from (2.11) as the straight lines $\mathbf{u}_x(1) = \frac{1}{2}$ and $\mathbf{u}_x(1) = \frac{\mu}{2}$, respectively, which intersect transversely at $\mu = 1$. The continuation was

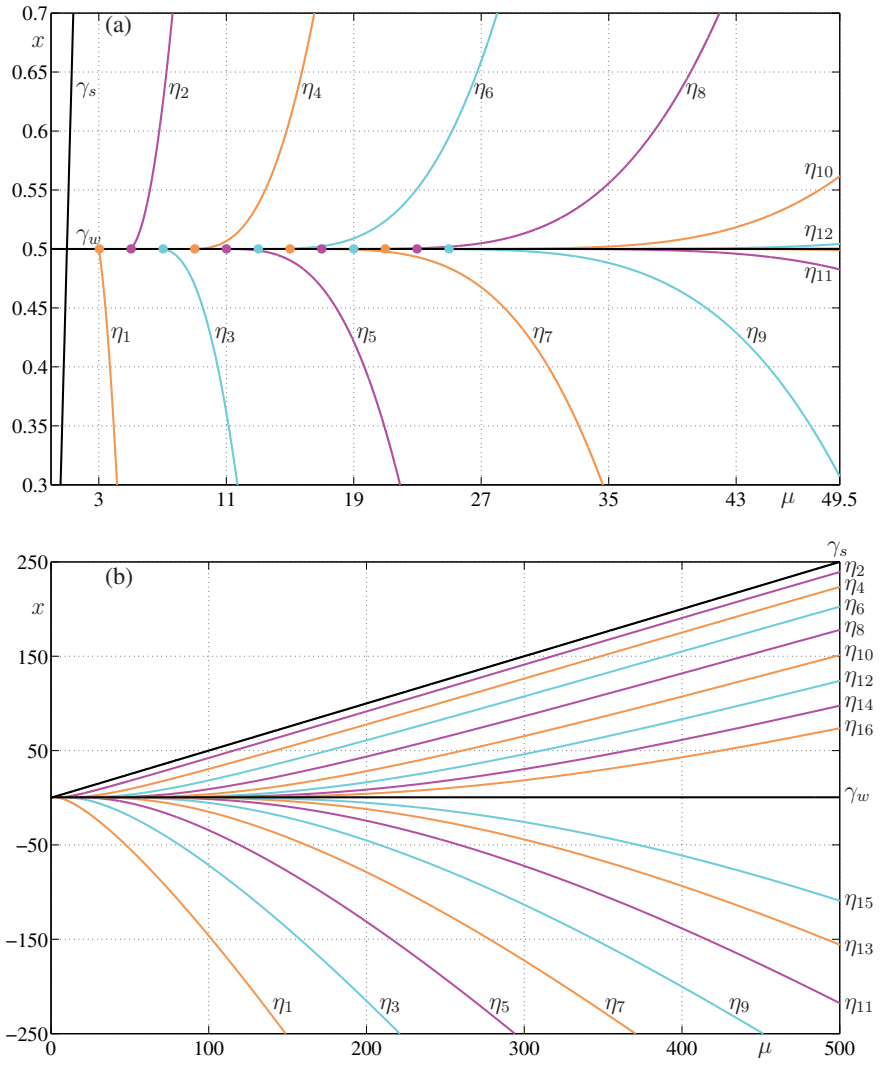

Figure 12. *Continuation in μ of η_i for $1 \le i \le 16$. Shown are the projections of η_i onto the (μ, x)-plane with γ_s and γ_w included for reference. Panel* (a) *shows how the first twelve secondary canards bifurcate from γ_w at odd integer values of μ; the bifurcation points for η_1 to η_{12} are indicated by thick colored dots. Panel* (b) *shows a larger view of the continuation up to $\mu = 500$.*

started by detecting all twelve secondary canards for $\mu = 25.5$, where we used $\xi = 1000$ to ensure sufficient accuracy for their continuation for $\mu > 25.5$. Figure 12(a) shows how η_1 to η_{12} bifurcate from γ_w at odd integer values. Figure 12(b) shows all sixteen branches η_i for the much larger μ-range up to $\mu = 500$.

The computed Figure 12 should be compared with the sketch provided in [50, Fig. 17]. Wechselberger showed in [50] that the bifurcation diagram is organized by transcritical bifurcations at odd μ-values. Notice that, on the scale of Figure 12(a), the branches η_i for $i > 3$

appear to be tangent to the branch γ_w, rather than making an angle with it as one would expect in a transcritical bifurcation. This illustrates the fact that the angle of the branch η_i with the branch γ_w decreases extremely rapidly with i; see the proofs of [50, Propositions 3.2 and 3.3]. It may be of interest to note that on the scale of Figure 12(b) the branches η_i for even i appear to have the same slope for large μ as the branch γ_s. By contrast, on this scale one cannot conjecture any convergence of the slopes of the branches η_i for odd i.

According to [50], there are two quite subtle features of the bifurcation diagram whose computation is beyond the scope of this paper. First, there are very short branches η_i that exist for μ just before the transcritical bifurcations. We found that the numerical calculation becomes so sensitive that it already stops before the associated transcritical bifurcation point is reached. Second, numerical evidence in [50] suggests that there are also very small branches of secondary canards associated with pitchfork bifurcations at even μ-values. In contrast to all other canards, these secondary canards occur in symmetric pairs and do not intersect the x-axis in Σ_0. Hence, they would need to be detected directly as an intersection of C_0^- and C_0^+.

6. Beyond the normal form. It is in the nature of a normal form that (1.2) has special properties. Specifically C^- and C^+ are each other's images under a symmetry operation. From a computational point of view, this means that only C^- needs to be computed. Furthermore, secondary canards can be detected and continued by considering the condition $\mathbf{u}_z(1) = 0$. However, for a system that is not in normal form the symmetry of the normal form is typically lost. Hence, in general the attracting and repelling slow manifolds must be computed separately as the solution families of two different two-point boundary value problems. As a consequence, the primary and the secondary canards must be detected as intersection points of the curves C_0^- and C_0^+.

As an example, we show here what the slow manifolds look like in the perturbation of the normal form (1.2) that is given by (2.9) for small nonzero ρ, that is,

$$\left\{\begin{array}{rcl} \dot{x} &=& \frac{1}{2}\mu y - (\mu+1)z + \rho, \\ \dot{y} &=& 1, \\ \dot{z} &=& x + z^2 + \rho. \end{array}\right. \tag{6.1}$$

Note that the slow manifolds of (6.1) can be computed with the same boundary conditions as those of (1.2). As before, we require that the orbit segments start on the line L_ξ^- defined by (3.3). For the computation of the repelling slow manifold, we reverse time in (6.1) and consider

$$L_\xi^+ := \{(-\xi, s, \sqrt{\xi}) \mid s \in \mathbb{R}\},$$

which lies on the upper sheet of the parabolic cylinder S. Furthermore, we require the orbit segments to end in a transverse section Σ_α given by (3.4) with $\alpha = 0$ or $\alpha = \pm 1$.

We consider here the case $\mu = 8.5$ and $\rho = 0.316$ and fix $\xi = 100$ as before. For this value of ρ, the explicitly known solution γ_s of the unperturbed system (1.2) is not a suitable start solution for Newton's method. Therefore, starting from γ_s, we first compute the ρ-dependent family of orbit segments that solve (6.1) subject to the boundary conditions (3.2). Here we fix the parameter s that defines the position on L_ξ^- to the value (given by γ_s) of

$$s = t_0 = -\sqrt{\frac{2\mu + 4\xi}{\mu^2}}$$

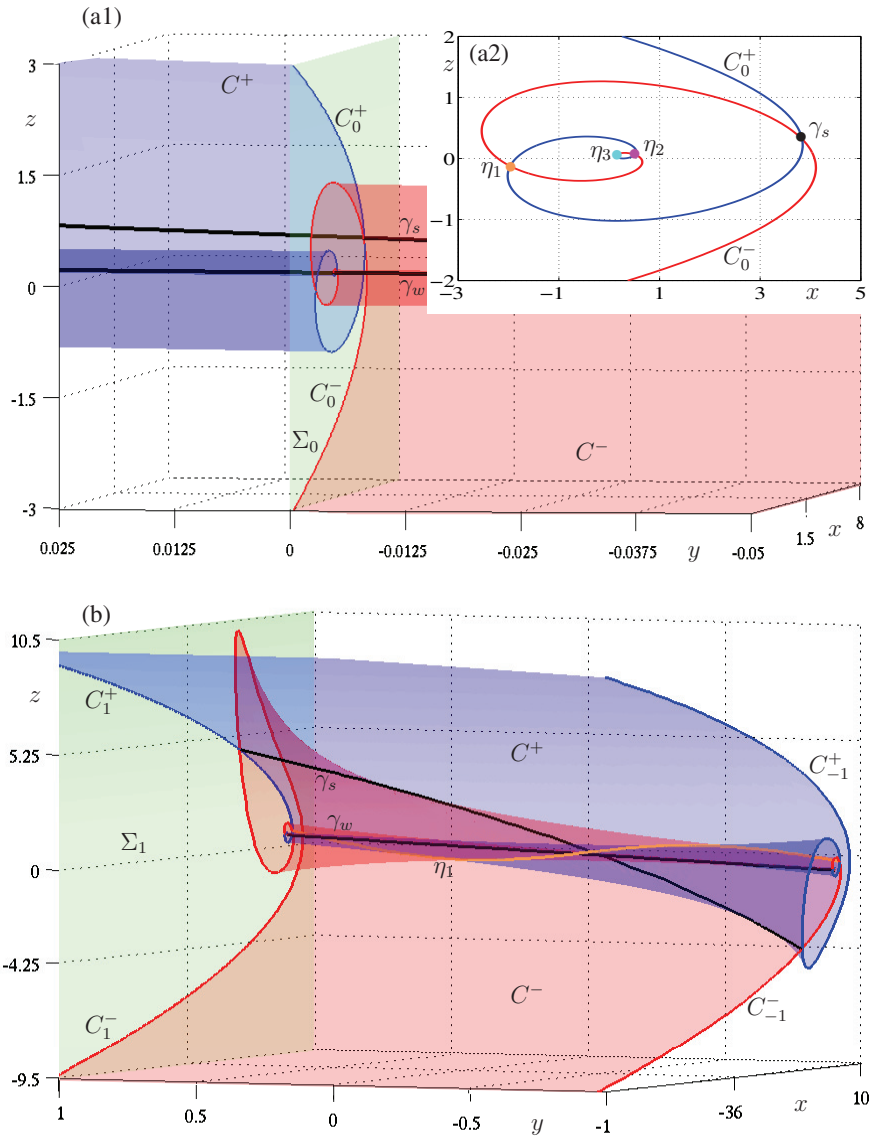

Figure 13. *Slow manifolds and canard solutions of (2.9) with $\mu = 8.5$ and $\rho = 0.316$. The manifolds are smooth deformations of the equivalent manifolds for $\rho = 0$, but the attracting and repelling slow manifolds are no longer related by symmetry; compare with Figure 5.*

as defined in (3.6). When $\rho = 0.316$ is reached, a first orbit segment on C^- has been found; a first orbit segment on C^+ is found similarly by starting a continuation in ρ from the part of γ_s that connects L_ξ^+ to Σ_α. We now fix ρ and continue in s to sweep out C^- and C^+, respectively.

Figure 13 shows the slow manifolds of (6.1) for $\mu = 8.5$ and $\rho = 0.316$. This figure should be compared with Figure 5 for $\rho = 0$; for ease of comparison we use the same viewpoints in both figures. In Figure 13 the slow manifolds C^- and C^+ have deformed and are no longer

each other's images under a symmetry operation. Nevertheless, the situation is topologically the same as that for $\rho = 0$ in Figure 5. Namely, C^- and C^+ intersect in the same way in the primary canards γ_s and γ_w and the secondary canards η_1 to η_3; see Figure 13(a2) and (b). In particular, the rotating behavior of η_1 to η_3 around γ_w is preserved. The canards are found by detecting orbit segments on C^- and C^+ that end at the same point in Σ_0 (within the accuracy of the computation). Concatenation of the two respective orbit segments results in the representation of the secondary canard as a solution that starts on L_ξ^- and ends at L_ξ^+. After applying a Newton step to get an exact solution to this boundary value problem, detected canards can be continued in a system parameter.

7. Conclusion. We performed a study of slow manifolds and associated canard solutions in a three-dimensional normal form of a slow-fast system with a folded node. Specifically, we computed the two-dimensional attracting and repelling slow manifolds as one-parameter families of orbit segments that satisfy appropriate boundary conditions. This approach also allows us to detect and continue the canard solutions themselves. The visualization of these geometric objects for different values of the normal form parameter μ (the ratio of eigenvalues at the folded node) provided unprecedented insight into the geometry of the dynamics near a folded node. We discussed in detail how the secondary canards spiral around the weak primary canard and presented the first computed bifurcation diagram showing branches of the secondary canards as a function of μ.

The numerical continuation of solution families of a well-posed boundary value problem can be performed very accurately. In our computations we use the continuation and boundary value solver routines of AUTO, which uses pseudoarclength continuation and collocation with piecewise-polynomial approximations. Hence, the boundary value problems we define are solved subject to established error bounds. Therefore, the accuracy of our calculations of slow manifolds and canard solutions comes down to determining how the choice of boundary condition influences the distance of the approximation from the real object. In our setup we define approximating orbit segments by requiring that they start on a suitable line (sufficiently far away from the origin) on a parabolic cylinder. Numerical checks ensured that the pointwise distance to the true slow manifolds along selected orbit segments is sufficiently small. The detection and continuation of canard solutions generally works very well with our method, but there remain numerical difficulties near bifurcation points. A more detailed error analysis, which would be very useful in this context, remains a challenging subject for further investigation.

While this paper concentrates on the normal form of a folded node, our boundary value problem approach to computing slow manifolds and canard solutions can be applied more widely. This was demonstrated with the example of a perturbation of the normal form that breaks the underlying symmetry. In [11] we computed slow manifolds and canard solutions in the self-coupled FitzHugh–Nagumo model, which required the implementation of a homotopy approach to generating initial approximate orbits on the attracting and repelling slow manifolds. In this way, we were able to identify sectors between different secondary canards that correspond to mixed-mode oscillations with different numbers of small oscillations.

In the near future we plan to use our computational approach to investigate other slow-fast systems arising in applications, especially those showing mixed-mode oscillations. This

is relatively straightforward for the case of three-dimensional vector field models with a clear splitting of the phase space into slow and fast variables, such as the self-coupled FitzHugh–Nagumo model [11] or the forced Van der Pol system [6, 29]. However, we believe that the computation of invariant manifolds would also be a very helpful tool in situations where there is no obvious split of the system into slow and fast variables. The goal here would be to identify slow and fast components of the dynamics numerically and to use this knowledge to unravel the geometry of slow manifolds and associated canard solutions.

Acknowledgments. The authors thank John Guckenheimer and Martin Wechselberger for helpful discussions.

Asymptotics of a Slow Manifold*

J. Vanneste†

Abstract. Approximately invariant elliptic slow manifolds are constructed for the Lorenz–Krishnamurthy model of fast-slow interactions in the atmosphere. As is the case for many other two-time-scale systems, the various asymptotic procedures that may be used for this construction diverge, and there are no exactly invariant slow manifolds. Valuable information can however be gained by capturing the details of the divergence: this makes it possible to define exponentially accurate slow manifolds, identify one of these as optimal, and predict the amplitude and phase of the fast oscillations that appear for trajectories started on it. We demonstrate this for the Lorenz–Krishnamurthy model by studying the slow manifolds obtained using a power-series expansion procedure. We develop two distinct methods to derive the leading-order asymptotics of the late coefficients in this expansion. Borel summation is then used to define a unique slow manifold, regarded as optimal, which is piecewise analytic in the slow variables. This slow manifold is not analytic on a Stokes surface: when slow solutions cross this surface, they switch on exponentially small fast oscillations through a Stokes phenomenon. We show that the form of these oscillations can be recovered from the Borel summation. The approach that we develop for the Lorenz–Krishnamurthy model has a general applicability; we sketch how it generalizes to a broad class of two-time-scale systems.

Key words. slow manifold, exponential asymptotics, atmospheric waves

1. Introduction.

Dynamical systems with two time scales appear in a wide variety of applications, particularly in physics and chemistry. A central concept in their analysis is that of a slow manifold [28, 18, 19]. Slow manifolds are nearly invariant submanifolds of the state space of these systems near which the dynamics is slow; their dimension is the number of slow variables, and they are defined by constraints slaving fast variables to slow ones (see, e.g., [25]). The advantages of identifying slow manifolds in two-time-scale systems are obvious: projecting the dynamics onto a slow manifold leads to a dynamical system of reduced dimensionality; this system approximates the full dynamics while filtering out the fast behavior, and it can therefore be integrated efficiently.

The fast behavior we are concerned with in this paper consists of rapid undamped oscillations. In this case, the slow manifolds are elliptic and hence fragile. Specifically, if $\epsilon \ll 1$ is the small parameter characterizing the separation between fast and slow time scales, the slow manifold that exists for $\epsilon = 0$ cannot be expected to persist as an invariant object when $\epsilon \neq 0$. This is of course in contrast to the normally hyperbolic case, for which persistence can be established [13]. Even though elliptic slow manifolds are generally not exactly invariant, they

†School of Mathematics and Maxwell Institute, University of Edinburgh, King's Buildings, Edinburgh EH9 3JZ, UK (J.Vanneste@ed.ac.uk).

can be approximately so to a very high degree of accuracy. Indeed, systematic asymptotic procedures make it possible to improve this accuracy, estimated by the angle between the vector field and the manifold, systematically order-by-order in ϵ. For analytic vector fields, it is possible to construct slow manifolds with $O(\epsilon^n)$ accuracy for arbitrary $n \in \mathbb{N}$ and even, by optimal truncation, to achieve exponential accuracy [15, 11, 35, 25, 12, 27].

The nonexistence of exactly invariant slow manifolds reflects the fact that fast activity cannot be completely filtered out by a suitable projection of the initial conditions. In other words, in the elliptic situation, fast oscillations are typically generated by the slow dynamics, however well the initial data are prepared. The noninvariance is also manifested by the divergence of the asymptotic procedures used in the construction of slow manifolds. The two aspects are related: the nature of the divergence—the manner in which the coefficients of ϵ^n in the power-series expansions defining slow manifolds grow with n—encodes the generation of (exponentially small) oscillations. Thus, capturing the details of the divergence provides a means of describing these oscillations. It also gives a way of analyzing the differences between the various slow manifolds that are obtained near optimal truncation. One of the motivations here is to distinguish, among these slow manifolds differing by exponentially small terms, a unique one, enjoying special properties.

The exponential accuracy of elliptic slow manifolds, the divergence of the asymptotic procedures used in their construction, and the connection between this divergence and the generation of fast oscillations are the themes of this paper. Although these have a general appeal for a broad class of two-time-scale systems, we mainly explore them in a specific context, and for a specific model. The context is geophysical fluid dynamics. Because of the fast rotation of the earth, the midlatitude atmosphere and oceans are typical two-time-scale systems, with the corresponding small parameter—the Rossby number—taking values of the order of 0.1 and 0.01 in the atmosphere and the oceans, respectively. Furthermore, the nature of the forcing is such that the fast degrees of freedom, consisting of inertia-gravity waves, are often only weakly excited. As a result, the notion of a slow manifold is eminently relevant. (See, e.g., [34, 31] and references therein for more background.)

The specific model that we analyze is the Lorenz five-component model [21], often referred to as the Lorenz–Krishnamurthy (LK) model [23]. This model, governed by five ordinary differential equations, was devised by Lorenz in order to explore the concept of slow manifolds and study their invariance. Since it was proposed, it has become one of the main testbeds for the study of slow manifolds, reduced models (termed "balanced models" in this context), spontaneous wave generation, etc., in geophysical fluid dynamics [21, 22, 23, 9, 10, 14, 32, 6, 7, 8, 17, 29, 30].

Several asymptotic procedures have been proposed for the derivation of slow manifolds in the LK model (e.g., [20, 32]). Since their divergence properties are identical, we concentrate here on a particularly simple one (see [34] for a detailed discussion). Specifically, a slaving relation, which defines the slow manifold by relating the fast variables to the slow ones, is postulated and introduced into the dynamical equations. An approximate solution of the resulting partial differential equation is then sought as a series expansion in powers of the small parameter ϵ. The coefficients in this series, which we term "slaving coefficients," are functions of the slow variables. Our main aim is to capture their late form, that is, to obtain the asymptotics of the coefficient of ϵ^n as $n \to \infty$. Two alternative approaches are

discussed. These are interchangeable in the case of the LK model, but one or the other may be preferable for more complicated models. Remarkably, the leading-order asymptotics of the slaving coefficients can be determined in closed form, up to a single constant which is readily estimated by solving a recurrence relation numerically. The accuracy of the asymptotic result is established by a comparison with the slaving coefficients computed numerically for a range of values of the slow variables.

We emphasize that our asymptotic results give a precise description of the manner in which the power-series expansion defining the slow manifolds diverges as $n \to \infty$. This makes it possible to go beyond the standard optimal truncation arguments (e.g., [11, 35]), which only provide bounds on the accuracy of the slow manifold, and delve into the dynamics of the exponentially small terms. Specifically, we use the Borel summation of the divergent power series [3, 2] to define a unique manifold, which we term the "optimal slow manifold." This is defined in a piecewise manner, with discontinuities across codimension-one surfaces. Trajectories started on the optimal slow manifold move away from it by an exponentially small distance when they cross these surfaces, and fast oscillations develop. The amplitude and phase of these oscillations can be determined from the late behavior of the slaving coefficients. In previous work [29], we derived this amplitude and phase by considering the dynamics along specific trajectories. The present approach recovers these results by taking a more geometric perspective, which views the slow manifold as a single object rather that a collection of slow trajectories.

The analysis we carry out for the LK model is representative of a more general treatment applicable to more complicated two-time-scale systems. We make this plain by also considering a broad class of such systems and sketching how the theory developed for the LK model generalizes to this class. The results presented are largely formal, and they make a number of simplifying assumptions, in particular about the nature of the singularities of slow trajectories in the complex time plane. Nevertheless, they provide a first glimpse into the relationship between these singularities, the divergence of the asymptotic procedures used for constructing slow manifolds, and the generation of fast oscillations.

This paper is organized as follows. The LK model is introduced in section 2. There we discuss a systematic approach for the construction of slow manifolds of increasing accuracy. As mentioned, this approach relies on expanding in power-series of ϵ the relations which define the slow manifolds by slaving fast variables to slow variables. The coefficients of ϵ^n in this expansion—the slaving coefficients—satisfy recurrence relations involving partial derivatives with respect to the slow variables. The nonlinearity of the LK model, involving only quadratic terms, is simple enough that the slaving coefficients are homogeneous polynomials in the slow variables. It is therefore easy to derive them by solving simple algebraic recurrences for the coefficients of these polynomials. Section 3 focuses on these coefficients, which we refer to as polynomial coefficients to distinguish them from the slaving coefficients. Specifically, we examine the form of the polynomial coefficients for large n. Two asymptotic results are obtained. The first result gives a Gaussian approximation to the slaving coefficients. The second, more general, result improves on this approximation in the same manner as the large-deviation theory, for the probability density of sums of random numbers improves on the central-limit theorem. Section 4 then considers the large-n asymptotics of the slaving coefficients themselves. The asymptotic behavior is obtained using two different approaches, one based on

the polynomial coefficients and the other directly considering the partial differential equation satisfied by the slaving coefficients. The results are exploited in section 5, where we discuss the resummation of the divergent series defining the slow manifolds. There, we use Borel summation (e.g., [3, 2]) to define a unique slow manifold which we regard as optimal. The slaving relation for this slow manifold is given as an integral which is clearly discontinuous across certain surfaces in the slow space. Examining the dynamics across these surfaces, we demonstrate that it is characterized by the generation of exponentially small fast oscillations whose form is encoded in the Borel sum. General two-time-scale systems with elliptic slow manifolds are considered in section 6. The paper concludes with a discussion in section 7.

2. Formulation.

2.1. Model. We consider the model devised by Lorenz [21] and variously referred to as the Lorenz five-component model or as the LK model [23]. In its conservative form, on which we will focus, it can be written as the set of five ordinary differential equations

$$\dot{u} = -vw + \epsilon bvy, \tag{2.1}$$

$$\dot{v} = uw - \epsilon buy, \tag{2.2}$$

$$\dot{w} = -uv, \tag{2.3}$$

$$\epsilon\dot{x} = -y, \tag{2.4}$$

$$\epsilon\dot{y} = x + buv \tag{2.5}$$

for the five dependent variables (u, v, w, x, y). This model, obtained by truncation of the rotating shallow-water equations, governs the dynamics of a triad of vortical modes, with amplitudes (u, v, w), coupled to a gravity mode described by (x, y). The two parameters b and ϵ of the model control the strength of the coupling and the gravity-wave frequency, respectively.

Following Camassa [9] and Bokhove and Shepherd [6], we note that the constancy of the $u^2 + v^2$, obvious from (2.1)–(2.2), can be used to reduce the dimension of the LK model from 5 to 4. Specifically, letting

$$u = u_0 \cos\phi \quad \text{and} \quad v = u_0 \sin\phi \tag{2.6}$$

reduces (2.1)–(2.5) to the two degree-of-freedom Hamiltonian system

$$\dot{\phi} = w - \epsilon by, \tag{2.7}$$

$$\dot{w} = -u_0^2 \sin(2\phi)/2, \tag{2.8}$$

$$\epsilon\dot{x} = -y, \tag{2.9}$$

$$\epsilon\dot{y} = x + bu_0^2 \sin(2\phi)/2. \tag{2.10}$$

Here, $u_0^2 = u^2 + v^2$ is a constant which could be set to 1 by scaling.

In the form (2.7)–(2.10), the LK model can be recognized as describing the dynamics of a pendulum (making an angle 2ϕ with the vertical), coupled in some way to a spring of extension x. This interpretation is useful in developing some intuition about the dynamics of the model; it also makes transparent the relationship between the LK model and mechanical

models such as the swinging spring (or elastic pendulum; see, e.g., [24]). In what follows, we mostly use the original formulation (2.1)–(2.5), which gives a more compact form to various mathematical expressions; however, we often use the variable ϕ in place of (u, v) to display functions of (u, v, w) in the reduced, two-dimensional space (ϕ, w).

We are interested in the dynamics of the LK model when $\epsilon \ll 1$. In this regime, there is a large separation between the $O(1)$ time scale of evolution of the slow variables (u, v, w) and the $O(\epsilon)$ time scale of the fast variables (x, y). We also assume that $b = O(1)$. In the geophysical context, these assumptions correspond to the quasi-geostrophic regime, in which fast gravity waves interact only weakly with the much slower vortical motion, termed "balanced motion." In the mechanical interpretation of the LK model, $\epsilon \ll 1$ indicates that the spring is stiff, so that its frequency ϵ^{-1} far exceeds that of the pendulum.

The large time-scale separation implies the existence of slow manifolds. For the LK model, these are three-dimensional submanifolds of the state space, parameterized by (u, v, w), which are nearly invariant and near which the motion is slow. The dynamics in the neighborhood of such slow manifolds is approximately devoid of the fast oscillations which characterize the dynamics elsewhere in the state space. The slow manifolds are elliptic, since linearizing the fast dynamics gives the purely imaginary eigenvalues $\pm i\epsilon^{-1}$. Therefore, they cannot be expected to be invariant when $\epsilon \neq 0$. Nevertheless, their accuracy, measured by the difference between the angle made by the vector field $(\dot{u}, \dot{v}, \dot{w}, \dot{x}, \dot{y})$ and the slow manifold, can be very high indeed: systematic improvement procedures make it possible to define slow manifolds with exponentially small errors.

The main interest of slow manifolds is that they allow a simplified description of the dynamics. Projecting the vector field onto a slow manifold leads to a reduced system of slow equations for (u, v, w) which approximates well the full dynamics for initial conditions near the slow manifold. Reduced models obtained in this manner are termed "balanced models" in the geophysical context, where they have proved highly successful.

It is clear from (2.4)–(2.5) that a slow manifold for the LK model can be defined as the graph

$$x = -buv \quad \text{and} \quad y = 0. \tag{2.11}$$

The corresponding balanced model is then given by (2.1)–(2.3) with $y = 0$. The slow manifold (2.11) is only a leading-order approximation; starting with Lorenz [21], many authors have considered how this can be improved. In the next sections, we examine in detail a simple asymptotic procedure of the type described by Warn et al. [34] which leads to an arbitrary $O(\epsilon^n)$ accuracy. Our aim is to capture the manner in which this procedure diverges so as to define a slow manifold with a better-than-exponential accuracy.

2.2. Slow manifolds. Slow manifolds can be sought by introducing the so-called slaving relations

$$x = X(u, v, w; \epsilon) \quad \text{and} \quad y = Y(u, v, w; \epsilon) \tag{2.12}$$

for unknown functions X and Y into (2.4)–(2.5). Eliminating the time derivatives by means of (2.1)–(2.3) gives what Lorenz [20] termed the "superbalance equation," namely,

$$\epsilon\left[\frac{\partial X}{\partial u}(-vw+\epsilon bvy)+\frac{\partial X}{\partial v}(uw-\epsilon buy)-\frac{\partial X}{\partial w}uv\right]=-Y, \tag{2.13}$$

$$\epsilon\left[\frac{\partial Y}{\partial u}(-vw+\epsilon bvy)+\frac{\partial Y}{\partial v}(uw-\epsilon buy)-\frac{\partial Y}{\partial w}uv\right]=X+buv. \tag{2.14}$$

These are two coupled partial differential equations for X and Y for which approximate solutions can be found using iteration or expansion in powers of ϵ. Here we employ the latter method which is more suited to deriving explicit results. To some extent the method used is irrelevant, since the slow manifolds obtained by different means coincide up to terms smaller than the accuracy of the methods. Nevertheless, specific methods may have some advantage: for instance, the iterative procedure proposed in [25] guarantees that all equilibria of the system near the slow manifold lie exactly on it. The expansion used here does not have this property.

Inspection of (2.13)–(2.14) indicates that power-series expansions of the slaving relations (2.12) take the form

$$x=\sum_{n=0}^{N}\epsilon^{2n}X_n(u,v,w)\quad\text{and}\quad y=\sum_{n=0}^{N}\epsilon^{2n+1}Y_n(u,v,w), \tag{2.15}$$

where the functions of the slow variables X_n and Y_n are termed slaving coefficients. These are homogenous polynomials in u, v, and w of degree $2n+2$ and $2n+3$, respectively. We make their specific form explicit by writing

$$X_n(u,v,w)=(2n)!\sum_{i,j=0}C_{ij}^n\,u^{2i+1}v^{2j+1}w^{2k}, \tag{2.16}$$

with $k=n-i-j\geq 0$, and

$$Y_n(u,v,w)=(2n+1)!\sum_{i,j=0}D_{ij}^n\,u^{2i}v^{2j}w^{2k+1}, \tag{2.17}$$

with $k=n+1-i-j\geq 0$. In defining the coefficients C_{ij}^n and D_{ij}^n, we have introduced the normalization factors $(2n)!$ and $(2n+1)!$ which roughly capture the dominant growth of X_n and Y_n with n. We refer to C_{ij}^n and D_{ij}^n as polynomial coefficients and emphasize that, unlike the slaving coefficients X_n and Y_n which they generate, they are simply numbers (for fixed b).

Substituting (2.15)–(2.17) into (2.13)–(2.14) leads to the following recurrence relations for C_{ij}^n and D_{ij}^n:

$$\begin{aligned}(2n+1)D_{ij}^n&=(2i+1)C_{i(j-1)}^n-(2j+1)C_{(i-1)j}^n+(2k+2)C_{(i-1)(j-1)}^n\\&\quad-b\sum_{m=0}^{n-1}\sum_{p,q=0}^{m}\frac{(2m)!(2n-2m-1)!}{(2n)!}C_{pq}^m\\&\qquad\times\left[(2p+1)D_{(i-p)(j-q-1)}^{n-m-1}-(2q+1)D_{(i-p-1)(j-q)}^{n-m-1}\right],\end{aligned} \tag{2.18}$$

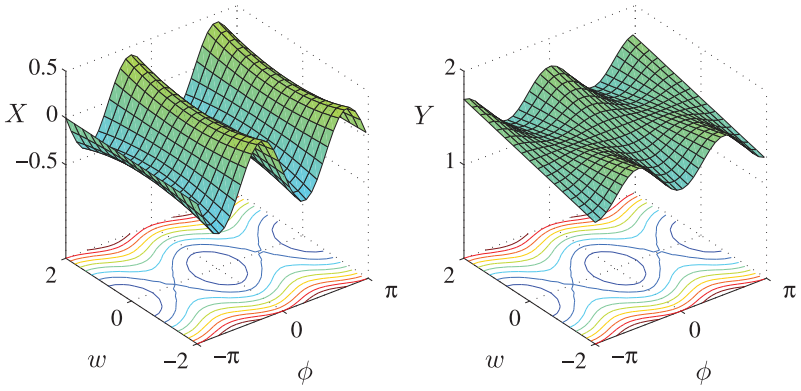

Figure 1. *Approximate slow manifold with $O(\epsilon^3)$ accuracy: The slaving functions $X(u,v,w)$ and $Y(u,v,w)$ are plotted as functions of ϕ (with $u=\cos\phi$ and $v=\sin\phi$) and w for $\epsilon=0.2$ and $b=0.5$. Approximate slow trajectories are plotted in the (ϕ,w)-plane.*

where $k=n+1-i-j$, and

$$
\begin{aligned}
2nC_{ij}^n &= -2(i+1)D_{(i+1)j}^{n-1} + 2(j+1)D_{i(j+1)}^{n-1} - (2k+1)D_{ij}^{n-1} \\
&\quad + b\sum_{m=0}^{n-2}\sum_{p,q=0}^{m+1} \frac{(2m+1)!(2n-2m-3)!}{(2n-1)!} D_{pq}^m \\
&\qquad \times \left[2pD_{(i-p+1)(j-q)}^{n-m-2} - 2qD_{(i-p)(j-q+1)}^{n-m-2}\right],
\end{aligned}
\tag{2.19}
$$

where $k=n-i-j$. The initial condition for this iteration is provided by the leading-order slow manifold (2.11) which gives

$$
C_{00}^0 = -b. \tag{2.20}
$$

The successive D_{ij}^n and C_{ij}^n are then calculated from (2.18)–(2.19), with the convention that $D_{ij}^n=0$ for $i<0$, $j<0$, or $i+j>n+1$, and $C_{ij}^n=0$ for $i<0$, $j<0$, or $i+j>n$. The first few coefficients are

$$
D_{00}^0 = 0, \quad D_{10}^0 = b, \quad D_{01}^0 = -b \tag{2.21}
$$

and

$$
C_{00}^1 = -2b, \quad C_{10}^1 = -b/2, \quad C_{01}^1 = b/2. \tag{2.22}
$$

For larger n, the coefficients are easily computed numerically for fixed b. The numerical results presented in this paper rely on such computations carried out for n up to 100.

The slow manifold corresponding to (2.20)–(2.22), for which the superbalance equation is approximated within an $O(\epsilon^3)$ error, is shown in Figure 1. The approximations to X and Y are shown as a function of ϕ and w, with $u_0=1$ in (2.6), $\epsilon=0.2$, and $b=0.5$. The figure also shows approximate trajectories in the plane of the slow variables (ϕ,w); lifting them to the slow manifold gives an approximation to full trajectories.

The series (2.15) diverge as $N \to \infty$. In this paper we examine more precisely the nature of this divergence by considering the late behavior of the slaving coefficients X_n and Y_n as $n \to \infty$. A possible approach, attempted by Warn [33] for a simplifed model, consists in deriving approximations for the polynomial coefficients C_{ij}^n and D_{ij}^n as $n \to \infty$ from the recurrence relations (2.18)–(2.19). This is carried out in the next section.

3. Late behavior of C_{ij}^n and D_{ij}^n. We consider the behavior of C_{ij}^n and D_{ij}^n for large n. Numerical computations of these coefficients suggest the asymptotic forms

$$C_{ij}^n \sim (-1)^{j+1} f(\xi,\eta) \quad \text{and} \quad D_{ij}^n \sim (-1)^j g(\xi,\eta), \tag{3.1}$$

where

$$\xi = n^{-1/2}(i - n/3) \quad \text{and} \quad \eta = n^{-1/2}(j - n/3). \tag{3.2}$$

The two functions $f(\xi,\eta)$ and $g(\xi,\eta)$ introduced in (3.1) are smooth and localized, peaking at $(\xi,\eta) = (0,0)$ and decreasing rapidly for $|\xi| \to \infty$ and $|\eta| \to \infty$. Thus, the coefficients C_{ij}^n and D_{ij}^n are maximum for $i \approx n/3$ and $j \approx n/3$, and $O(1)$ only in a "core" region where $\xi, \eta = O(1)$. As we now show, it is not difficult to derive explicit expressions for $f(\xi,\eta)$ and $g(\xi,\eta)$ in this core region.

3.1. Core: $\xi, \eta = O(1)$. We first note that the nonlinear terms in the recurrence relations (2.18)–(2.19) (the last two lines in each of these equations) can be neglected in the limit $n \to \infty$; provided that C_{ij}^n and D_{ij}^n remain $O(1)$ as $n \to \infty$, this is a valid approximation because of the rapid decrease of the ratios of factorials. Neglecting the nonlinear terms, we obtain two sets of first-order linear recurrence relations and, by elimination of D_{ij}^n, a single set of second-order recurrence relations for C_{ij}^n. Substituting the form (3.1) and using Taylor expansions to write, for instance,

$$\begin{aligned} C_{(i+1)j}^n &\sim (-1)^{j+1} f(\xi + n^{-1/2}, \eta) \\ &\sim (-1)^{j+1} \left[f(\xi,\eta) + n^{-1/2} \frac{\partial f}{\partial \xi}(\xi,\eta) + \frac{1}{2n} \frac{\partial^2 f}{\partial \xi^2}(\xi,\eta) + \cdots \right] \end{aligned}$$

leads to a partial differential equation for $f(\xi,\eta)$. The first nontrivial term appears at order $O(n^{-1})$ and is given by

$$4\left(\frac{\partial^2 f}{\partial \xi^2} + \frac{\partial^2 f}{\partial \eta^2} - \frac{\partial^2 f}{\partial \xi \partial \eta} \right) + 45\left(\xi \frac{\partial f}{\partial \xi} + \eta \frac{\partial f}{\partial \eta} \right) + 90 f = 0.$$

Separating variables, it is easily verified that the only solution decreasing to 0 for large $|\xi|$ and $|\eta|$ is the Gaussian

$$f(\xi,\eta) = \Lambda \mathrm{e}^{-15(\xi^2 + \xi\eta + \eta^2)/2}, \tag{3.3}$$

where the constant Λ remains to be determined. From the linearization of (2.18) and from (3.1), we also deduce that

$$g(\xi,\eta) = f(\xi,\eta). \tag{3.4}$$

With these results, the form of C_{ij}^n and D_{ij}^n for large n is known up to the single number Λ which depends solely on b and needs to be determined numerically. This is conveniently done by considering the behavior of the solutions $(u(t), v(t), w(t), x(t), y(t))$ of the LK model near their poles in the complex t-plane. This approach makes contact with the exponential-asymptotics treatment of solutions of the LK models in [29].

Let $t_* \in \mathbb{C}$ be one of the poles of the solutions (as discussed below, these are poles of Jacobi elliptic functions, but their location is unimportant at this point). At a distance from such a pole, the dependent variables can be expanded in inverse powers of $t - t_*$ as

$$u = \sum_{n=0}^{\infty} \frac{\epsilon^{2n} \hat{U}_n}{(t-t_*)^{2n+1}}, \quad v = \sum_{n=0}^{\infty} \frac{\epsilon^{2n} \hat{V}_n}{(t-t_*)^{2n+1}}, \quad w = \sum_{n=0}^{\infty} \frac{\epsilon^{2n} \hat{W}_n}{(t-t_*)^{2n+1}}, \tag{3.5}$$

$$x = \sum_{n=0}^{\infty} \frac{\epsilon^{2n} \hat{X}_n}{(t-t_*)^{2n+2}}, \quad \text{and} \quad y = \sum_{n=0}^{\infty} \frac{\epsilon^{2n+1} \hat{Y}_n}{(t-t_*)^{2n+3}}. \tag{3.6}$$

Note that the coefficients $\hat{X}_n$ and $\hat{Y}_n$ are just (complex) numbers, unlike X_n and Y_n, which are functions of (u, v, w). Substituting (3.5)–(3.6) into (2.1)–(2.5) gives a set of five first-order recurrence relations for the coefficients $(\hat{U}_n, \hat{V}_n, \hat{W}_n, \hat{X}_n, \hat{Y}_n)$. Observing that

$$u \sim -\mathrm{i}/(t-t_*), \quad v \sim 1/(t-t_*), \quad w \sim -\mathrm{i}/(t-t_*) \tag{3.7}$$

is a possible leading-order behavior near t_*, we find the initial conditions

$$\hat{U}_0 = -\mathrm{i}, \quad \hat{V}_0 = 1, \quad \hat{W}_0 = -\mathrm{i}, \quad \hat{X}_0 = \mathrm{i}b, \quad \text{and} \quad \hat{Y}_0 = 2\mathrm{i}b \tag{3.8}$$

for these recurrence relations. There are other possible behaviors near the poles that are alternatives to (3.7). These are obtained by changing the signs of a pair of (u, v, w) and hence of $(\hat{U}_0, \hat{V}_0, \hat{W}_0)$ and correcting the signs of $(\hat{X}_0, \hat{Y}_0)$ accordingly. (Such an alternative choice is made in [29].)

With the initial conditions (3.8) and for fixed b, it is straightforward to compute $(\hat{U}_n, \hat{V}_n, \hat{W}_n, \hat{X}_n, \hat{Y}_n)$ numerically. The value of Λ can then be inferred from their behavior for $n \gg 1$. Specifically, the late form of $\hat{X}_n$ can be verified to be

$$\hat{X}_n \sim \mathrm{i}(-1)^n (2n+1)! \kappa \tag{3.9}$$

for some constant κ. This constant is easily estimated from the $\hat{X}_n$ obtained numerically by approximating the relation

$$\kappa = \lim_{n\to\infty} \frac{\mathrm{i}(-1)^{n+1} \hat{X}_n}{(2n+1)!}$$

for a large but finite n (cf. [29]).

Now, the asymptotic form (3.1)–(3.3) of C_{ij}^n provides an alternative expression for the right-hand side of (3.9). To obtain it, we substitute the leading-order behavior of u, v, and w near t_* given in (3.7) into the expansion (2.15)–(2.16) of the slaving relation $x = X(u, v, w; \epsilon)$. This reduces to

$$x \sim \mathrm{i} \sum_{n=0}^{\infty} \frac{(-1)^{n+1} (2n)! \epsilon^{2n}}{(t-t_*)^{2n+2}} \sum_{i,j=0}^{n} (-1)^j C_{ij}^n.$$

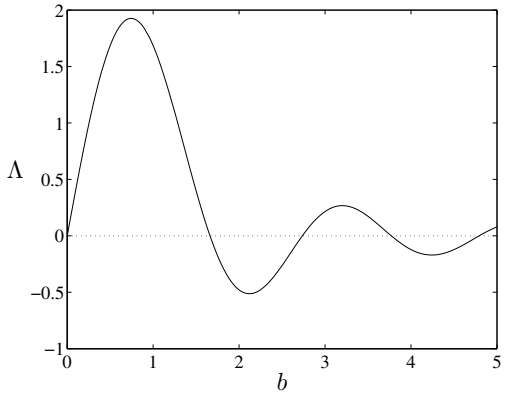

Figure 2. *Prefactor* Λ *in the asymptotics* (3.1)–(3.3) *of* C_{ij}^n *as a function of* b.

Comparing with (3.6) then gives

$$\hat{X}_n \sim \mathrm{i}(-1)^{n+1}(2n)! \sum_{i,j=0}^{n} (-1)^j C_{ij}^n.$$

The right-hand side can now be evaluated using the form (3.1)–(3.3) of C_{ij}^n. Approximating the sums by integrals, we obtain

$$\begin{aligned}\hat{X}_n &\sim \mathrm{i}(-1)^n(2n)!n\Lambda \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mathrm{e}^{-15(\xi^2+\eta^2+\xi\eta)/2}\,\mathrm{d}\xi\,\mathrm{d}\eta \\ &\sim \mathrm{i}(-1)^n(2n+1)!\frac{2\pi\Lambda}{15\sqrt{3}}.\end{aligned}$$

This is a second expression for the late behavior of $\hat{X}_n$. Identifying with (3.9) leads to the relation

$$\Lambda = \frac{15\sqrt{3}}{2\pi}\kappa. \tag{3.10}$$

Thus, like κ, Λ can be obtained numerically by computing the coefficients $\hat{X}_n$ for $n \gg 1$ from the five recurrence relations for $(\hat{U}_n, \hat{V}_n, \hat{W}_n, \hat{X}_n, \hat{Y}_n)$. The results of this computation carried out for values of b in the range $(0, 5)$ are shown in Figure 2. For the value $b = 0.5$ which we use often in what follows, we find that $\Lambda = 1.6858\cdots$. Note that Λ vanishes for certain values of b; for these, the growth of the functions X_n and Y_n is slower than in the generic case $\Lambda \neq 0$, and it can be captured only by continuing the expansion beyond the leading-order term considered here.

With our estimate for the prefactor Λ, we now have the complete form of the leading-order asymptotics of C_{ij}^n and D_{ij}^n for $n \gg 1$ in the core region $\xi, \eta = O(1)$. This is compared in Figure 3 with the values of $(-1)^{j+1}C_{ij}^n$ computed numerically from the recurrence relations (2.16)–(2.19) for $n = 40$, 70, and 100. The figure confirms the asymptotic results and illustrates how the discrete dependence of C_{ij}^n on i and j asymptotes to the continuous dependence

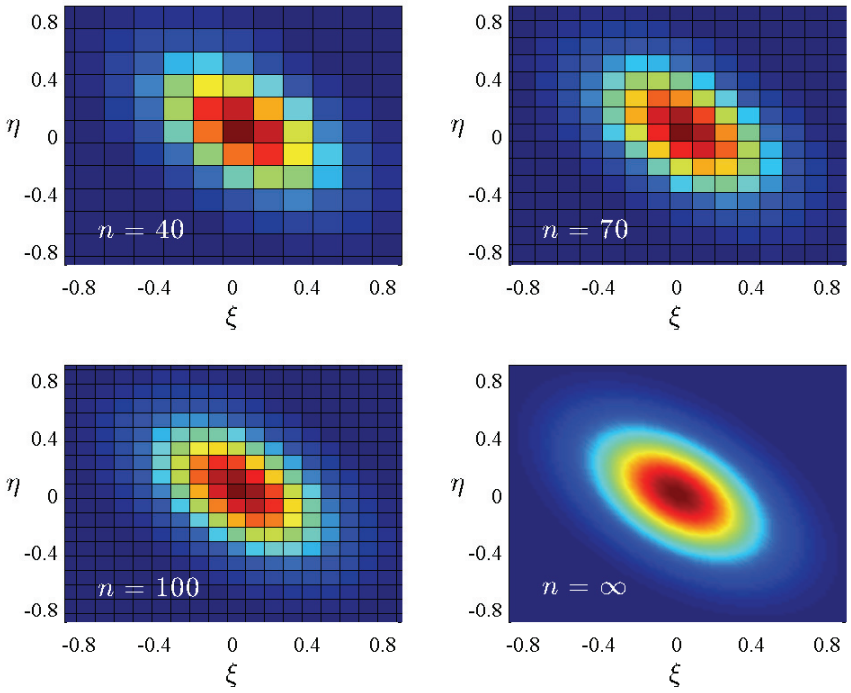

Figure 3. *Coefficients* $(-1)^{j+1}C_{ij}^n$ *as functions of* $\xi = n^{-1/2}(i - n/3)$ *and* $\eta = n^{-1/2}(j - n/3)$ *for* $n = 40$, 70, *and* 100, *and for* $b = 0.5$. *The last panel shows the asymptotic form for* $n \to \infty$.

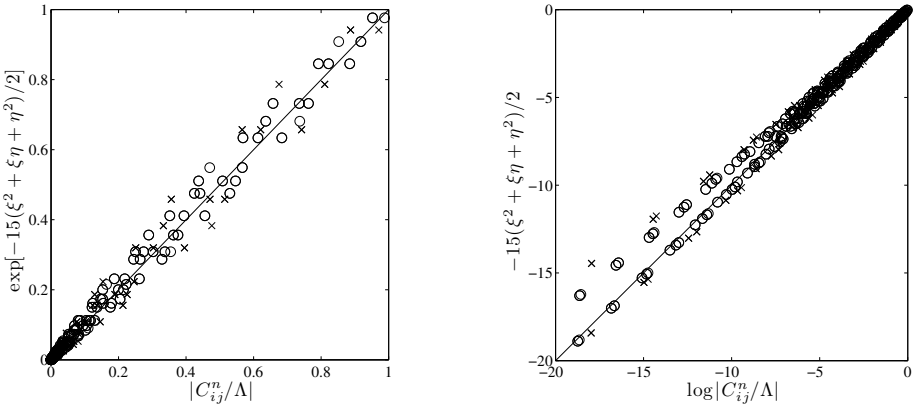

Figure 4. *Scatter plot of* $(-1)^{j+1}C_{ij}^n/\Lambda$, *with* Λ *estimated numerically, against* $\exp[-15(\xi^2 + \xi\eta + \eta^2)/2]$ *for* $b = 0.5$, *and* $n = 40$ $(\times)$ *and* $n = 100$ $(\circ)$. *The same data are plotted in linear coordinates (left panel) and in logarithmic coordinates (right panel).*

on ξ and η as $n \to \infty$. To give a more precise comparison between numerical and asymptotic results than afforded by the color-scale Figure 3, we show in Figure 4 scatter plots of $(-1)^{j+1}C_{ij}^n$, normalized by Λ, against its asymptotic limit $\exp[-15(\xi^2+\xi\eta+\eta^2)/2]$. This con-

firms the match between asymptotic and numerical results. It also shows that the convergence toward the asymptotic behavior is rather slow.

A noticeable feature of Figure 4 is the cloud of points for small values of C_{ij}^n. These correspond to indices i and j far from the core values $i, j \approx n/3$ or, in other words, to $|\xi|, |\eta| \gg 1$. In this tail region, we cannot expect the asymptotics (3.1)–(3.3) to be valid. Even though C_{ij}^n and D_{ij}^n are exponentially small there, the tail region is important for the evaluation of the coefficients X_n and Y_n from the sums (2.16)–(2.17). Indeed, for $u, v, w \in \mathbb{R}$, the largest terms in these sums are not those for which $\xi, \eta = O(1)$ but rather those for which $\xi, \eta = O(n^{1/2})$. This is because the factors $u^{2i+1}v^{2j+1)}w^{2k}$ in the sum (2.16), for instance, depend exponentially on n in the core region, since $i, j, k = O(n)$ there. Thus the asymptotic results derived so far, although providing valid estimates for the coefficients C_{ij}^n and D_{ij}^n where they are $O(1)$, are not sufficiently accurate to estimate X_n and Y_n from (2.16)–(2.17).

The situation is analogous to that encountered in probability theory when studying the distribution of the sum of random variables. The central-limit theorem provides a Gaussian approximation for the core of the distribution, but this approximation fails in the tails. These can be essential, however, for instance, if the expectation of the exponential of the sum is to be estimated. It is therefore necessary to go beyond the central-limit theorem and use the theory of large deviations, which gives an estimate of the distribution valid in the tails. Here, similarly, it is necessary to derive an approximation for C_{ij}^n and D_{ij}^n for $n \gg 1$ when $\xi, \eta = O(n^{1/2})$. This is done next.

3.2. Tail: $\xi, \eta = O(n^{1/2})$.

We start with the "large-deviation" ansatz

$$C_{ij}^n = (-1)^{j+1} A(a, b, n) \mathrm{e}^{-nG(a,b)}, \tag{3.11}$$

where

$$a = \frac{i}{n} - \frac{1}{3} \quad \text{and} \quad b = \frac{j}{n} - \frac{1}{3}.$$

Here the functions A and G need to be determined to satisfy the recurrence relations (2.18)–(2.19). The dependence of A on n is assumed to be such that its partial derivatives (denoted by subscripts) satisfy $A_a, A_b = O(1)$ as $n \to \infty$. We will be concerned only with determining the function G which governs the dominant, or controlling, behavior of C_{ij}^n. This function satisfies

$$G(0,0) = G_a(0,0) = G_b(0,0) = 0.$$

This is necessary to recover the Gaussian form given in (3.1) and (3.3)–(3.4) when $a = n^{-1/2}\xi = O(n^{-1/2})$ and $b = n^{-1/2}\eta = O(n^{-1/2})$. More specifically,

$$G(a, b) \sim \frac{15}{2}\left(a^2 + ab + b^2\right) \quad \text{as} \quad a, b \to 0. \tag{3.12}$$

Introducing (3.11) into (2.18)–(2.19) and retaining only the leading-order term yields a nonlinear differential equation for G which is too lengthy to reproduce here. It can, however, be much simplified by introducing the Legendre transform

$$S(p, q) = \sup_{a,b} \left(ap + bq - G(a, b)\right), \tag{3.13}$$

with $p = G_a(a,b)$ and $q = G_b(a,b)$. In terms of S, with p and q as independent variables, the equation satisfied by G takes the form

$$\left[(1-\mathrm{e}^{-p})S_p + (1-\mathrm{e}^{-q})S_q - \frac{1}{3}(1+\mathrm{e}^{-p}+\mathrm{e}^{-q})\right]^2 = \mathrm{e}^{S-2p/3-2q/3}.$$

Taking the square root, we obtain

$$(1-\mathrm{e}^{-p})S_p + (1-\mathrm{e}^{-q})S_q = \frac{1}{3}(1+\mathrm{e}^{-p}+\mathrm{e}^{-q}) - \mathrm{e}^{S/2-p/3-q/3}. \tag{3.14}$$

The sign choice is justified by considering this equation for small p and q. Assuming that S is quadratic, (3.14) reduces to

$$pS_p + qS_q + \frac{S}{2} = \frac{1}{9}\left(p^2 - pq + q^2\right) + \cdots,$$

where $\cdots$ denotes cubic- and higher-order terms. Solving gives

$$S(p,q) \sim \frac{2}{45}\left(p^2 - pq + q^2\right) \quad \text{as} \quad p,q \to 0, \tag{3.15}$$

which is the Legendre transform of (3.12), as expected.

The nonlinear equation (3.14) can be solved explicitly. Let

$$P = \frac{1}{2}\log\left[(\mathrm{e}^p - 1)(\mathrm{e}^q - 1)\right], \quad Q = \frac{1}{2}\log\left(\frac{\mathrm{e}^p - 1}{\mathrm{e}^q - 1}\right), \tag{3.16}$$

and

$$S(p,q) = \hat{S}(P,Q) + P - \frac{1}{3}(p+q). \tag{3.17}$$

We note that the branches of the logarithms in (3.16) need to be specified: a suitable choice takes $-\pi/2 < \arg(\mathrm{e}^p - 1) \le 3\pi/2$ and $-3\pi/2 < \arg(\mathrm{e}^q - 1) \le \pi/2$ so that $P(-p,-q) = P(p,q)$ and $Q(-p,-q) = Q(p,q) + \mathrm{i}\pi$ for $p,q > 0$. Introducing the variable transformation (3.16)–(3.17) into (3.14) leads to the simpler equation

$$\hat{S}_P = -\frac{\mathrm{e}^{(\hat{S}+P)/2}}{\left[\left(1+\mathrm{e}^{P+Q}\right)\left(1+\mathrm{e}^{P-Q}\right)\right]^{1/2}}$$

involving a P-derivative only. Integrating gives the solution

$$\hat{S}(P,Q) = -2\log\left(\frac{1}{2}\int^P \frac{\mathrm{e}^{P'/2}}{\left[\left(1+\mathrm{e}^{P'+Q}\right)\left(1+\mathrm{e}^{P'-Q}\right)\right]^{1/2}}\,\mathrm{d}P' + C(Q)\right), \tag{3.18}$$

where the function $C(Q)$ remains to be determined. It can be shown that $C(Q) = 0$ if the lower limit of integration in (3.18) is taken as $-\infty$ so that

$$\hat{S}(P,Q) = -2\log\left(\frac{1}{2}\int_{-\infty}^P \frac{\mathrm{e}^{P'/2}}{\left[\left(1+\mathrm{e}^{P'+Q}\right)\left(1+\mathrm{e}^{P'-Q}\right)\right]^{1/2}}\,\mathrm{d}P'\right). \tag{3.19}$$

Indeed, this choice ensures that the limiting behavior (3.15) is recovered for $p, q \to 0$. To verify this, note that $P \to -\infty$ and hence $\exp(P) \to 0$ as $p, q \to 0$. The denominator of the integrand in (3.19) can then be expanded, leading to

$$\begin{aligned}\hat{S}(P,Q) &= -2\log\left(\frac{1}{2}\int_{-\infty}^{P} \mathrm{e}^{P'/2}\left[1-\mathrm{e}^{P'}\cosh Q+\mathrm{e}^{2P'}\left(\frac{1}{4}+\frac{3}{4}\cosh(2Q)\right)+\cdots\right]\mathrm{d}P'\right)\\ &= -P+\frac{2}{3}\mathrm{e}^{P}\cosh Q-\frac{2}{5}\mathrm{e}^{2P}\left(\frac{1}{4}+\frac{3}{4}\cosh(2Q)\right)+\frac{1}{9}\mathrm{e}^{2P}\cosh^2 Q+\cdots.\end{aligned}$$

On using the approximations $\exp(P+Q) = p + p^2/2 + \cdots$, $\exp(P-Q) = q + q^2/2 + \cdots$, $\exp(2P) = pq + \cdots$, and $\exp(2Q) = p/q + \cdots$, this further simplifies to

$$\hat{S}(P,Q) = -P + \frac{1}{3}(p+q) + \frac{2}{45}\left(p^2 - pq + q^2\right) + \cdots.$$

Introducing this result into (3.17) reduces $S(p,q)$ to the form (3.15), as required.

With (3.19) established, the derivation of the large-n behavior of C_{ij}^n for $\xi, \eta = O(n^{-1/2})$ is complete: $S(p,q)$ can be calculated from (3.17), and the function $G(a,b)$ follows by inverting the Legendre transform (3.13). If the asymptotic form of C_{ij}^n is used only to approximate the coefficients $X_n(u,v,w)$, as is done in the next section, the inversion step is in fact not necessary since the X_n can be expressed directly in terms of $S(p,q)$.

4. Late behavior of X_n and Y_n. In this section, we present two approaches for the derivation of the asymptotic form of the slaving coefficients X_n and Y_n for $n \gg 1$. One approach relies on our approximation (3.11) for C_{ij}^n; the other considers the superbalance equation (2.13)–(2.14) directly. We start with the latter approach, which turns out to be somewhat simpler.

4.1. From the superbalance equation. From (2.13)–(2.14), and assuming that the linear terms dominate for large n, we have that

$$X_{n+1} \sim -\left(vw\frac{\partial}{\partial u} + uw\frac{\partial}{\partial v} - uv\frac{\partial}{\partial w}\right)^2 X_n \tag{4.1}$$

as $n \to \infty$. This recurrence relation can be solved using characteristics: let $(U,V,W)(t)$ be the solutions of the leading-order slow equations, namely,

$$\dot{U} = -VW, \tag{4.2}$$

$$\dot{V} = UW, \tag{4.3}$$

$$\dot{W} = -UV, \tag{4.4}$$

with initial conditions $(U,V,W)(0) = (u,v,w)$. Then the solution of (4.1) can be written as

$$X_n(u,v,w) \sim (-1)^n \left.\frac{\mathrm{d}^{2n}}{\mathrm{d}t^{2n}}\right|_{t=0} \tilde{X}_0(U(t),V(t),W(t)). \tag{4.5}$$

Here $\tilde{X}_0$ is an unknown polynomial, determined by the early iterations when the nonlinear terms neglected in (4.1) are significant. The details of $\tilde{X}_0$ do not matter: what controls the

right-hand side of (4.5) for large n are the singularities of $(U,V,W)(t)$ nearest the origin of the complex t-plane (e.g., [5]). Let t_* and $\bar{t}_*$, where the overbar denotes complex conjugation, be these singularities, and assume they are poles of order r. These poles should be thought of as functions of the slow variables: $t_* = t_*(u,v,w)$. Then, as $t \to t_*$,

$$\tilde{X}_0 \sim \frac{C}{(t-t_*)^r}, \tag{4.6}$$

where C is a constant which may depend on t_*. The complex conjugate behavior holds as $t \to \bar{t}_*$. These behaviors control the late asymptotics of X_n. From (4.5)–(4.6), we obtain the asymptotics in the explicit form

$$X_n \sim \frac{(-1)^n(2n+r-1)!C}{(r-1)!(-t_*)^{2n+r}} + \text{c.c.}$$

Comparison with (3.6) and (3.9) then shows that

$$r = 2 \quad \text{and} \quad C = \mathrm{i}\kappa$$

for trajectories $(U(t),V(t),W(t))$ consistent with (3.7). It follows that

$$X_n \sim \frac{(-1)^n(2n+1)!\mathrm{i}\kappa}{t_*^{2n+2}} + \text{c.c.} \tag{4.7}$$

The relationship $t_* = t_*(u,v,w)$ can be made completely explicit using the solution of (4.2)–(4.4). In what follows, we assume that $|w| \geq |u|$. This means that we consider the open trajectories in the (ϕ,w)-plane represented in Figure 1. (The case $|w| < |u|$, corresponding to closed trajectories, is treated similarly, by swapping the roles of u and w.) Defining

$$u_0 = \pm\sqrt{u^2+v^2} \quad \text{and} \quad w_0 = \pm\sqrt{v^2+w^2},$$

with the signs those of u and w, respectively, the solution of (4.2)–(4.4) can be written in terms of Jacobi elliptic functions as

$$U(t) = u_0\,\mathrm{cn}(w_0(t-t_0);k), \tag{4.8}$$

$$V(t) = u_0\,\mathrm{sn}(w_0(t-t_0);k), \tag{4.9}$$

$$W(t) = w_0\,\mathrm{dn}(w_0(t-t_0);k), \tag{4.10}$$

where the modulus $k = u_0/w_0 \leq 1$ (e.g., [1, Ch. 16]). The constant t_0 is determined by the initial conditions $(U,V,W)(0) = (u,v,w)$. With $\phi(u,v)$ defined as in (2.6) and taken in $(-\pi,\pi)$, we find that

$$t_0 = -\frac{1}{w_0}F(\phi(u,v);k), \tag{4.11}$$

where F denotes the elliptic integral of the first kind, defined as

$$F(\phi;k) = \int_0^\phi (1-k^2\sin^2\sigma)^{-1/2}\,\mathrm{d}\sigma$$

(e.g., [1, Ch. 17]).

Now, the poles of the elliptic functions in (4.8)–(4.10) are located on the lattice

$$t_* = t_0 + 2r\frac{K(k)}{w_0} + \mathrm{i}(2s+1)\frac{K(k')}{w_0}, \quad r, s \in \mathbb{Z}, \tag{4.12}$$

where $k'^2 = 1 - k^2$ and $K(k) = F(\pi/2; k)$ denotes the complete elliptic integral of the first kind ([1, Ch. 17]). The poles nearest the origin clearly have $s = 0$ or $s = -1$. We choose to denote by t_* the pole corresponding to $s = 0$; the pole corresponding to $s = -1$ is its complex conjugate $\bar{t}_*$. With this convention, the poles nearest the origin are given by t_* and $\bar{t}_*$, with

$$t_* = t_0 + 2r\frac{K(k)}{w_0} + \mathrm{i}\frac{K(k')}{w_0}. \tag{4.13}$$

Here,

$$r = \begin{cases} -1 & \text{for} \quad \phi \in (-\pi, -\pi/2), \\ 0 & \text{for} \quad \phi \in (-\pi/2, \pi/2), \\ 1 & \text{for} \quad \phi \in (\pi/2, \pi), \end{cases}$$

since, according to (4.11), t_0 is a monotonic function of ϕ in $(-\pi, -\pi/2)$, $(-\pi/2, \pi/2)$, and $(\pi/2, \pi)$, which satisfies $t_0 = \mp K(k)/w_0$ for $\phi = \pm\pi/2$ and $t_0 = \mp 2K(k)/w_0$ for $\phi = \pm\pi$. Substituting (4.13) into (4.7) gives the completely explicit form

$$X_n \sim \frac{(-1)^n(2n+1)!\mathrm{i}\kappa w_0^{2n}}{\left(F(\phi(u,v);k) - 2rK(k) - \mathrm{i}K(k')\right)^{2n+2}} + \text{c.c.} \tag{4.14}$$

for the late asymptotics of X_n. An analogous expression can be derived for Y_n.

Three remarks are in order. The first concerns the sign of the right-hand side of (4.14). Near the pole with $r = 0$, the behavior of the solution (4.8)–(4.10) is consistent with (3.7), as assumed in the derivation. Near the poles with $r = \pm 1$, the signs of $U(t)$ and $V(t)$ are opposite those in (3.7), but the sign of X_n remains unchanged because the transformation $(u, v, w, x, y) \mapsto (-u, -v, w, x, y)$ leaves (2.1)–(2.5) invariant. The second remark concerns the discontinuous behavior of X_n at $\phi(u, v) = \pm\pi/2$, that is, for $u = 0$. This is immediately remedied by noting that the two pairs of complex-conjugate poles with $r = 0$ and $r = \mp 1$ both contribute to X_n at the same order in a neighborhood of size $O(n^{-1})$ of $\phi = \pm\pi/2$. Adding the two contributions then leads to an approximation for X_n that is continuous at $\phi = \pm\pi/2$. The third remark is that the factorial growth of X_n described by (4.14) means that the asymptotic series (2.15) defining the slow manifold is of Gevrey type of order 1; the divergence of this type of series and their resummability is well understood (e.g., [2]).

The asymptotic result (4.14) is illustrated by Figure 5, which compares the asymptotic and numerical estimates of $X_n/(2n)!$ as a function of ϕ for fixed $u_0 = 1$, $w = 2$, and $b = 0.5$. Since X_n is a π-periodic function of ϕ, it is plotted only for $\phi \in [0, \pi)$. The upper panel of the figure corresponds to $n = 5$ and the lower panel to $n = 20$. For $n = 5$, we show two asymptotic estimates: the first takes into account only the pair of complex-conjugate poles nearest the origin; the second takes into account the two nearest pairs. As remarked above, the latter approximation eliminates the discontinuity at $\phi = \pi/2$; it also matches the

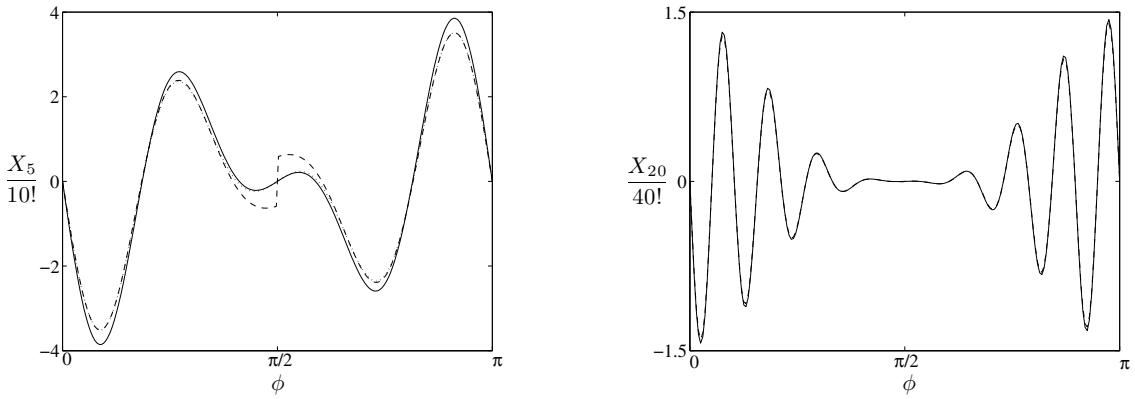

Figure 5. *Estimates of $X_n(u, v, w)$ as a function of ϕ for $w = 2$ and $b = 0.5$: Numerical results (solid curves) are compared with asymptotic results (dashed curve) for $n = 5$ and $n = 20$. For $n = 5$ the asymptotic result obtained by taking into account two poles is also shown (dotted curve).*

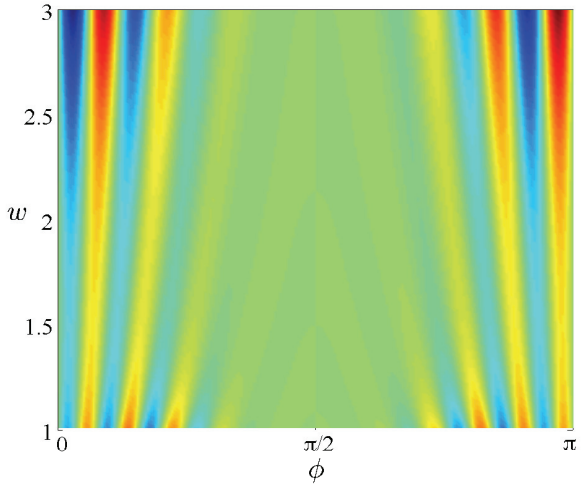

Figure 6. *X_{20} as a function of ϕ and w for $u_0 = 1$ and $b = 0.5$. (X_{20} has been normalized by w^{23} for the clarity of the picture.)*

numerical results remarkably well. For $n = 20$, the match is already excellent with a single pair of complex-conjugate poles, and the curves are indistinguishable.

To illustrate further the manner in which the coefficients X_n depend on ϕ and w, we show in Figure 6 results of the numerical computation of X_{20} for $\phi \in [0, \pi)$ and $w \in [1, 3)$. The values of X_{20} increase rapidly with w; in order to make the dependence on ϕ visible in the color scale for the smaller values of w, we have plotted X_n/w^α rather than X_n, with the parameter α chosen as $\alpha = 23$ to minimize the variations in color in the w direction. A completely indistinguishable picture would have been produced had we used the asymptotic estimate for X_{20} in place of the numerical results.

4.2. From the coefficients C_{ij}^n. We now present a derivation of the asymptotics (4.14) alternative to that of the previous section. This relies on the results of section 3 providing the asymptotics of the polynomial coefficients C_{ij}^n with sufficient accuracy that the sums (2.16)–(2.17) can be estimated. A possible advantage of this approach is that it is less dependent on the exact solution of the leading-order balanced model (4.2)–(4.4) and hence on the integrability of that model.

To obtain the asymptotics of X_n from that of C_{ij}^n, we introduce (3.11) into (2.16) to find that

$$X_n(u,v,w) \asymp (2n)! \sum_{i,j=0} A(a,b)(-1)^{j+1} \mathrm{e}^{-nG(a,b)} u^{2i+1} v^{2j+1} w^{2k}, \tag{4.15}$$

with $k = n - i - j$. In this section, we concentrate on the controlling behavior of X_n for $n \gg 1$ and ignore order-one prefactors. This is indicated by the symbol $\asymp$. The oscillations introduced by the factor $(-1)^{j+1}$ in the sum make the validity of the expression questionable for $v \in \mathbb{R}$. However, one can use it safely, for instance, if $\nu = \mathrm{i}v \in \mathbb{R}$, and then use an analytic continuation argument for $v \in \mathbb{R}$. We proceed in this formal manner. Approximating the sums in (4.15) by integrals over a and b gives

$$X_n \asymp (2n)! n^2 (u\nu w)^{2n/3} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} A(a,b) \mathrm{e}^{n[2a\log(u/w) + 2b\log(\nu/w) - G(a,b)]} \,\mathrm{d}a\,\mathrm{d}b. \tag{4.16}$$

The integrals can be approximated by Laplace's method to obtain

$$X_n \asymp (2n)! n (u\nu w)^{2n/3} \mathrm{e}^{S(p,q)}, \tag{4.17}$$

where S is the Legendre transform of G defined in (3.13),

$$p = \log\left(\frac{u}{w}\right)^2 \quad \text{and} \quad q = \log\left(\frac{\nu}{w}\right)^2.$$

Several simplifications occur upon using the variable transformation (3.16)–(3.17): this reduces (4.17) to the form

$$X_n \asymp (2n+1)! \left[(w^2 - u^2)(w^2 - \nu^2)\right]^{n/2} \mathrm{e}^{n\hat{S}(P,Q)}, \tag{4.18}$$

where

$$P = \frac{1}{2} \log \frac{(w^2 - u^2)(w^2 - \nu^2)}{w^4} \quad \text{and} \quad Q = \frac{1}{2} \log \frac{w^2 - u^2}{w^2 - \nu^2}. \tag{4.19}$$

At this point, we can reintroduce $\mathrm{i}v$ in place of ν and take $v \in \mathbb{R}$. Doing so, we analytically continue the function given by the integral in (4.16) for $v \in \mathrm{i}\mathbb{R}$ to $v \in \mathbb{R}$. This provides an approximation to at least one branch of (4.15) thought of as an analytic function of v in the complex plane minus possible branch cuts. Note that the arguments of the logarithm in P and Q are both positive if we assume, as in section 4.1, that $|w| \geq |u|$. However, for our choice of branch for the definition of P and Q, $\arg(\mathrm{e}^p - 1) = \arg(u^2/w^2 - 1) = \pi$, $\arg(\mathrm{e}^q - 1) = \arg(-v^2/w^2 - 1) = -\pi$, and hence

$$P = \frac{1}{2} \log \frac{(w^2 - u^2)(w^2 + v^2)}{w^4} \quad \text{and} \quad Q = \frac{1}{2} \log \frac{w^2 - u^2}{w^2 + v^2} + \mathrm{i}\pi. \tag{4.20}$$

We now consider the integral appearing in the expression (3.18) for $\hat{S}$, namely,

$$I = \int_{-\infty}^{P} \frac{\mathrm{e}^{P'/2}}{\left[\left(1+\mathrm{e}^{P'+Q}\right)\left(1+\mathrm{e}^{P'-Q}\right)\right]^{1/2}}\,\mathrm{d}P', \tag{4.21}$$

and note that the factor $1+\mathrm{e}^{P'-Q}$ in the denominator changes sign in the integration range for $P' = Q - \mathrm{i}\pi < P$. We introduce the change integration variable from P' to z', with

$$z'^2 = \frac{1+\mathrm{e}^{Q-P'}}{1-\mathrm{e}^{2Q}},$$

which maps $P' = -\infty$ to $z' = \infty$, $P' = Q - \mathrm{i}\pi$ to $z' = 0$, and $P' = P$ to $z' = z$, where

$$z^2 = \frac{1+\mathrm{e}^{Q-P}}{1-\mathrm{e}^{2Q}} = (v/u_0)^2, \tag{4.22}$$

with the last equality following from (4.20). The change of variables makes it possible to express I in terms of elliptic integrals as

$$\begin{aligned} I &= \left(\int_{Q-\mathrm{i}\pi}^{P} + \int_{-\infty}^{Q-\mathrm{i}\pi}\right) \frac{\mathrm{e}^{P'/2}}{\left[\left(1+\mathrm{e}^{P'+Q}\right)\left(1+\mathrm{e}^{P'-Q}\right)\right]^{1/2}}\,\mathrm{d}P' \\ &= -\mathrm{e}^{Q/2}\left[F(\phi(u,v);k) \pm \mathrm{i}K'(k)\right], \end{aligned}$$

where the $\pm$ sign depends on a branch choice and $\phi(u,v) = \sin^{-1}(v/u_0)$ is assumed to be in $(-\pi/2, \pi/2)$. In writing this expression we recover the parameter k appearing in section 4.1 from the computation

$$1 - \mathrm{e}^{2Q} = \frac{u^2+v^2}{v^2+w^2} = \frac{u_0^2}{w_0^2} = k^2 \tag{4.23}$$

using (4.20). Similarly, we compute $\mathrm{e}^{Q/2} = \mathrm{i}(w^2-u^2)^{1/4}(w^2+v^2)^{-1/4}$ and finally reduce (4.18) to

$$X_n \asymp \frac{(2n+1)!(-1)^n w_0^{2n}}{\left[F(\phi(u,v);k) \pm \mathrm{i}K'(k)\right]^{2n}}. \tag{4.24}$$

Once the two complex-conjugate contributions are taken into account, this is consistent with (4.14) when $-\pi/2 < \phi < \pi/2$. For $-\pi < \phi < -\pi/2$ and $\pi/2 < \phi < \pi$, other branch choices must be made in (4.21) to recover (4.14).

5. Resummation. Our main aim for examining the late asymptotics of the coefficients X_n and Y_n is to control the divergence of the power-series expansion of the slaving relation (2.12) defining the slow manifold. This makes it possible to ascertain how a unique slow manifold can be defined, which, although not invariant, is optimal in a certain sense. A natural way of achieving this is by using Borel resummation. As we now show, the Borel summation [2] of the divergent series (2.15) provides a natural definition of a unique, piecewise-continuous slow manifold, with discontinuities across what might be termed Stokes surface.

We define the Borel transform of $X(u,v,w;\epsilon)$ by the series

$$B_X(u,v,w;\xi) = \sum_{n=0}^{\infty} \frac{X_n(u,v,w)}{(2n+1)!}\xi^{2n+1}. \tag{5.1}$$

The asymptotics (4.7) of X_n ensures that this series converges for $|\xi| < |t_*|$. Analytic continuation can then be used to define B_X for larger $|\xi|$. Formally, X can be recovered from its Borel transform by Laplace transform, according to

$$X(u,v,w;\epsilon) = \epsilon^{-2}\int_0^{\infty} \mathrm{e}^{-\xi/\epsilon} B_X(u,v,w;\xi)\,\mathrm{d}\xi, \tag{5.2}$$

as a term-by-term integration indicates. We now propose to define the optimal slow manifold for the LK model by this relation and its counterpart for $Y(u,v,w;\epsilon)$. A crucial point is that we choose the integration contour in (5.2) to be the positive real line for all values of (u,v,w). A consequence is that the optimal slow manifold defined in this manner is not analytic and indeed is not even continuous in (u,v,w). This is unavoidable since the analytic continuation of (5.2) that may be obtained by suitably deforming the contour of integration in the complex plane picks up fast oscillations across certain surfaces in the (u,v,w)-space. We discuss this next.

The loss of analyticity in X arises when singularities of B_X in the ξ-plane cross the positive real axis. The singularities of B_X are, in turn, controlled by the asymptotics of X_n for $n \gg 1$. Taking (4.7) into account, we observe that B_X has poles for $\xi = \pm \mathrm{i}t_*$, with the behavior

$$B_X(u,v,w;\xi) \sim \pm\sum_{n=0}^{\infty} (-1)^n \mathrm{i}\kappa \frac{\xi^{2n+1}}{t_*^{2n+2}} = \pm\frac{\mathrm{i}\kappa\xi}{\xi^2+t_*^2} \tag{5.3}$$

near these. Here, as in section 4, t_* is a function of the slow variables: $t_* = t_*(u,v,w)$. The sign in (5.3) should be taken as $+$ if the behavior of x near the pole is in agreement with (3.7) and as $-$ if the sign of x is opposite. (Note that all poles t_* of $(u(t),v(t),w(t),x(t),y(t))$, not only those nearest the origin, lead to contributions of this form, although the latter have a dominant role.) Thus, we conclude from (5.3) that the optimal slow manifold is discontinous for values of (u,v,w) such that there are poles t_* with $\operatorname{Re} t_* = 0$. Taking the location (4.12) of the poles t_* into account, this is seen to occur for $\phi = -\pi, 0, \pi$, that is, when $v = 0$. A simple picture therefore emerges of an optimal slow manifold analytic everywhere in (u,v,w) except on the surface $v = 0$, which can be termed Stokes surface. Across this surface, a Stokes phenomenon occurs, and $X(u,v,w;\epsilon)$ and $Y(u,v,w;\epsilon)$ jump. Not surprisingly, the jumps are associated with the generation of fast oscillations.

Let us examine this more closely by considering a trajectory of the slow system crossing the Stokes surface $v = 0$. For definiteness, we consider the crossing corresponding to $\dot v > 0$, i.e., $\phi = 0$ (the crossing with $\dot v < 0$, i.e., $\phi = \pm\pi$, is identical modulo a few sign changes). For $v < 0$, the relevant poles of the slow solution (4.8)–(4.10) have $\operatorname{Re} t_* > 0$. Considering only the poles closest to the real axis, and taking $\operatorname{Im} t_* > 0$ by convention, the location of the poles of the function B_X in the ξ-plane (the Borel plane) is as represented on the left panel of Figure 7, with four poles at $\pm\mathrm{i}t_*$ and $\pm\mathrm{i}\bar t_*$. As v increases toward 0, $\operatorname{Re} t_*$ decreases, and the

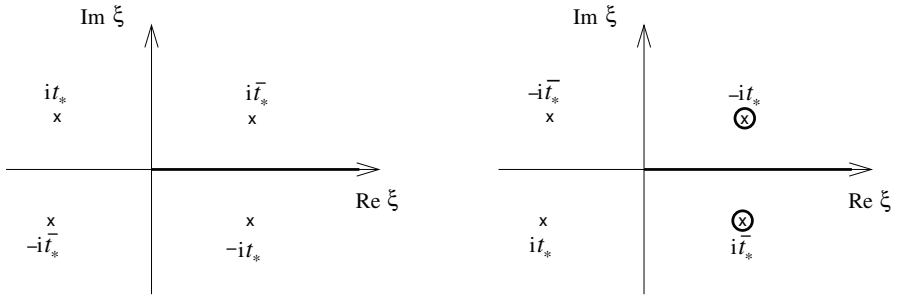

Figure 7. *Location of the poles of B_X in the complex ξ-plane for $v < 0$ (left panel), and for $v > 0$ (right panel). The optimal slow manifold, defined by as the integral of $\exp(-\xi/\epsilon)B_X$ along the positive real axis of ξ, is not analytic for $v = 0$: The optimal slow manifold for $v > 0$ differs from the analytic continuation of the manifold defined for $v < 0$ by the contributions of the two poles encircled in the right panel.*

poles move toward the real line, which they cross when $v = 0$. Thereafter, there is a difference between the function X defined by (5.2) for $v > 0$ and the function obtained by analytically continuing X from $v < 0$. The difference is the contribution of the two poles $-\mathrm{i}t_*$ and $\mathrm{i}\bar{t}_*$ that have crossed the integration contour. This contribution, computed from (5.2)–(5.3) (with the + sign) as the residue

$$X_{\mathrm{pole}}(u, v, w; \epsilon) = \frac{\pi\kappa}{\epsilon^2}\mathrm{e}^{\mathrm{i}t_*/\epsilon} + \text{c.c.} = \frac{2\pi\kappa}{\epsilon^2}\mathrm{e}^{-\operatorname{Im} t_*/\epsilon}\cos(\operatorname{Re} t_*/\epsilon), \tag{5.4}$$

corresponds to fast gravity oscillations. This is made obvious by evaluating (5.4) along the slow trajectory. To leading order in ϵ, the slow trajectory is given by

$$u(t) \sim u_0\,\mathrm{cn}(w_0 t; k), \quad v(t) \sim u_0\,\mathrm{sn}(w_0 t; k), \quad w(t) \sim w_0\,\mathrm{dn}(w_0 t; k). \tag{5.5}$$

Introducing this into (5.4) leads to

$$x_{\mathrm{pole}}(t) = X_{\mathrm{pole}}(u(t), v(t), w(t); \epsilon) = \frac{2\pi\kappa}{\epsilon^2}\mathrm{e}^{-K(k')/(\epsilon w_0)}\cos(t/\epsilon), \tag{5.6}$$

since $-\pi/2 < \phi < \pi/2$ and $t_* = -t + \mathrm{i}K(k')/w_0$, in the simple case considered with $\dot{v} > 0$. This pole contribution clearly corresponds to fast oscillations that appear when v goes through 0 and have exponentially small amplitudes, proportional to $\exp(-K(k')/(\epsilon w_0))$. The expression (5.6) coincides with that obtained in [29] using a different approach (up to a sign change arising from a different sign combination in (5.5)). The computations carried out in that paper, comparing (5.6) with results of the numerical integration of the LK system, confirms the validity of this expression.

Physically, the pole contribution represents gravity waves that are generated spontaneously by the slow balanced motion and cause the exact trajectories to move away from the optimal slow manifold by an exponentially small amount. Note that we have considered only the leading-order contribution associated with the pole t_*. In the full problem, there are not only corrections to the amplitude and phase in (5.6), but also terms with higher frequencies n/ϵ, $n > 1$, which appear as a result of the nonlinearities of the LK model.

6. General slow manifold. In this section, we briefly discuss how some of the results obtained above for the LK model generalize to a broad class of two-time-scale systems. The systems that we consider can be written in the form

$$\frac{\partial \mathsf{s}}{\partial t} = \mathsf{N}_\mathsf{s}(\mathsf{s},\mathsf{f}), \tag{6.1}$$

$$\frac{\partial \mathsf{f}}{\partial t} + \frac{1}{\epsilon}\mathcal{L}(\mathsf{s})\mathsf{f} = \mathsf{N}_\mathsf{f}(\mathsf{s},\mathsf{f}), \tag{6.2}$$

where s denotes the vector of slow variables and f the vector of fast variables. Here $\mathsf{N}_\mathsf{s}(\mathsf{s},\mathsf{f})$ and $\mathsf{N}_\mathsf{f}(\mathsf{s},\mathsf{f})$ are vector-valued functions of s and f, analytic in finite regions around $\operatorname{Im}\mathsf{s} = 0$ and $\operatorname{Im}\mathsf{f} = 0$. They are assumed to be of order one, and could depend on ϵ, but we have ignored this dependence. The matrix $\mathcal{L}(\mathsf{s})$ governs the linear dynamics of the fast variables; it is assumed to be analytic in s and skew symmetric. The eigenvalues $\pm\mathrm{i}\omega_k(\mathsf{s})$, $k = 1, 2, \ldots$, of $\mathcal{L}(\mathsf{s})$ are assumed to satisfy

$$1 < \omega_1(\mathsf{s}) < \omega_2(\mathsf{s}) < \cdots < \omega_n(\mathsf{s}).$$

The boundedness from below by a constant, which can be set to 1 by suitably defining ϵ, is crucial to ensure the time-scale separation between the variables s and f. Note that the fact that $\omega_k \neq 0$ implies that the dimension of f is even. The LK model is of the form (6.1)–(6.2), with $\mathsf{s} = (u, v, w)$, $\mathsf{f} = \epsilon(x, y)$, and $\mathcal{L}(\mathsf{s})$ given by the 2×2 canonical symplectic matrix.

The system (6.1)–(6.2) clearly has an elliptic slow manifold which, to leading order, is simply given by $\mathsf{f} = 0$. More accurate slow manifolds can be obtained by seeking a relationship

$$\mathsf{f} = \mathsf{F}(\mathsf{s};\epsilon) \tag{6.3}$$

slaving the fast variables to the slow ones. Introducing (6.3) into (6.2) and using (6.1) to eliminate the time derivative leads to the superbalance equation

$$\epsilon\mathsf{N}_\mathsf{s}(\mathsf{s},\mathsf{F}(\mathsf{s}))\cdot\partial_\mathsf{s}\mathsf{F}(\mathsf{s}) + \mathcal{L}(\mathsf{s})\mathsf{F}(\mathsf{s}) = \epsilon\mathsf{N}_\mathsf{f}(\mathsf{s},\mathsf{F}(\mathsf{s})), \tag{6.4}$$

where $\cdot$ denotes summation over the components of s. An approximation solution F can be derived by iteration or expansion in powers of ϵ. Here we use the latter procedure and write F as the formal series

$$\mathsf{F}(\mathsf{s};\epsilon) = \sum_{n=0}^{\infty} \epsilon^{n+1}\mathsf{F}^{(n)}(\mathsf{s}). \tag{6.5}$$

The successive $\mathsf{F}^{(n)}$ are then determined from a recurrence relation, starting with $\mathsf{F}^{(0)}(\mathsf{s}) = \mathcal{L}(\mathsf{s})^{-1}\mathsf{N}_\mathsf{f}(\mathsf{s},0)$.

6.1. Late behavior of $\mathsf{F}^{(n)}$. We now consider the asymptotics of $\mathsf{F}^{(n)}$ for $n \gg 1$. In the absence of detailed information on the nature of the terms N_s and N_f in (6.1)–(6.2), we cannot write $\mathsf{F}^{(n)}$ as polynomials in s, as is the case for the LK model (and, more generally, for any model where N_s and N_f are polynomials in s and f). However, it remains possible to infer the late behavior of $\mathsf{F}^{(n)}$ directly from the superbalance equation (6.4) following the approach taken for the LK model in section 4.1.

Introducing the expansion (6.5) into (6.4) and considering the coefficient of ϵ^{n+2}, say, leads to a recurrence relation for $\mathsf{F}^{(n)}$. It would be very tedious to write down this recurrence explicitly; however, our interest is in the behavior of the solution $\mathsf{F}^{(n)}$ for $n \gg 1$ only. It is therefore sufficient to consider the dominant terms in the recurrence relation; these correspond to the balance

$$\mathcal{L}(\mathsf{s})\mathsf{F}^{(n+1)}(\mathsf{s}) \sim \mathsf{N}_{\mathsf{s}}(\mathsf{s},0)\cdot\partial_{\mathsf{s}}\mathsf{F}^{(n)}(\mathsf{s}). \tag{6.6}$$

To see this, assume that $\mathsf{F}^{(n)}$ depends on n like $(n+r-1)!/a^n$ for some n-independent parameters $r \geq 0$ and $a(\mathsf{s})$, as is confirmed below. The controlling behavior of the terms retained in (6.6) (i.e., the fastest dependence on n) is then proportional to $(n-r)!$. One of the terms neglected in (6.6) is $\mathsf{F}^{(n)}(\mathsf{s})\cdot\partial_{\mathsf{f}}\mathsf{N}_{\mathsf{f}}(\mathsf{s},0)$, with controlling behavior $(n+r-1)!$, and hence smaller by a factor $1/n$ than the terms retained. All the other terms are nonlinear in $\mathsf{F}^{(n)}$ and give contributions also behaving like $(n+r-1)!$ or smaller. We demonstrate this for the quadratic terms that arise in the expansion of the first term in (6.4). Ignoring irrelevant constants, these give a contribution at $O(\epsilon^{n+2})$ of the form

$$\sum_{k=0}^{n-1}\mathsf{F}^{(n-1-j)}(\mathsf{s})\partial_{\mathsf{s}}\mathsf{F}^{(j)}(\mathsf{s}) = \mathsf{F}^{(0)}(\mathsf{s})\partial_{\mathsf{s}}\mathsf{F}^{(n-1)}(\mathsf{s}) + \sum_{k=0}^{n-2}\mathsf{F}^{(n-1-j)}(\mathsf{s})\partial_{\mathsf{s}}\mathsf{F}^{(j)}(\mathsf{s}).$$

The first term on the right-hand side behaves like $(n+r-1)!$. The controlling behavior of each of the terms in the remaining sum can be bounded by $(n+r-2)!$, so that, together, they also yield a contribution bounded by (a multiple of) $(n+r-1)!$. All the nonlinear terms neglected in (6.6) can be treated using a similar argument relying on the fact that multiple sums of powers of $\mathsf{F}^{(j)}$ are dominated by the terms involving the coefficients $\mathsf{F}^{(j)}$ with the largest possible indices j.

Now, the late behavior of $\mathsf{F}^{(n)}$ can be captured by solving the approximate recurrence relation (6.6). To do this, we define

$$\mathbf{v} = \mathsf{N}_{\mathsf{s}}(\mathsf{s},0)\cdot\partial_{\mathsf{s}}, \tag{6.7}$$

which we will think of either as a differential operator or as a vector field in the space of the slow variables s. The dynamics associated with this vector field is that of the simplest balanced model, obtained by substituting the lowest-order slaving relation $\mathsf{f}=0$ into (6.1). The approximate recurrence relation (6.6) can be rewritten in terms of $\mathbf{v}$ as

$$\mathcal{L}(\mathsf{s})\mathsf{F}^{(n+1)}(\mathsf{s}) \sim -\mathbf{v}\mathsf{F}^{(n)}(\mathsf{s}). \tag{6.8}$$

This can be solved using the method of characteristics. We denote by

$$\mathsf{S}(t) = \exp(t\mathbf{v})\mathsf{s}$$

the solution of

$$\dot{\mathsf{S}} = \mathbf{v}(\mathsf{S}) \quad \text{with} \quad \mathsf{S}(0) = \mathsf{s}.$$

Thus $\exp(t\mathbf{v})$ gives the approximate slow trajectory obtained on the leading-order slow manifold $\mathsf{f} = 0$. In terms of this trajectory, we integrate (6.8) as

$$\mathsf{F}^{(n+1)}(\mathsf{s}) \sim -\mathcal{L}(\mathsf{s})^{-1} \left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0} \mathsf{F}^{(n)}(\mathrm{e}^{t\mathbf{v}}\mathsf{s}).$$

This gives the general solution of (6.6) and hence the leading-order form of the late coefficients as

$$\mathsf{F}^{(n)}(\mathsf{s}) \sim (-1)^n \mathcal{L}(\mathsf{s})^{-n} \left.\frac{\mathrm{d}^n}{\mathrm{d}t^n}\right|_{t=0} \tilde{\mathsf{F}}^{(0)}(\mathrm{e}^{t\mathbf{v}}\mathsf{s};\mathsf{s}), \tag{6.9}$$

where $\tilde{\mathsf{F}}_0$ is an unknown (vector) function, determined by the early behavior of the recurrence, when the approximation (6.6) does not hold.

As in the case of the LK model, the large-n behavior of $\mathsf{F}^{(n)}$ is controlled by the singularities of the function $\psi(t;\mathsf{s}) = \tilde{\mathsf{F}}^{(0)}(\mathrm{e}^{t\mathbf{v}}\mathsf{s};\mathsf{s})$ nearest the origin of the complex t-plane. It is difficult to make general statements about the nature of these singularities, since $\mathrm{e}^{t\mathbf{v}}\mathsf{s}$ is the solution of a nonlinear, typically nonintegrable system of ordinary differential equations. Poles, branch points, essential singularities, but also more complicated behavior such as natural boundaries are all possible. Here, we restrict our attention to the simplest situation, where the singularities nearest the real t-axis are a pair of complex-conjugate poles t_* and $\bar{t}_*$. It should be emphasized that these poles depend on s, though we do not make this explicit. Near t_*, ψ takes the form

$$\psi(t;\mathsf{s}) = \tilde{\mathsf{F}}^{(0)}(\mathrm{e}^{t\mathbf{v}}\mathsf{s};\mathsf{s}) \sim \frac{\mathsf{g}}{(t-t_*)^r}, \tag{6.10}$$

where g is a time-independent vector, depending on s only through t_*. In a manner similar to that used to determine κ (or Λ) for the LK model, it should be relatively easy to determine g by considering solutions of (6.1)–(6.2) in the limit $t \to t_*$ as expansions in powers of $(t-t_*)^{-1}$.

Introducing (6.10) into (6.9) and taking the complex-conjugate pole into account give

$$\mathsf{F}^{(n)}(\mathsf{s}) \sim \frac{(n+r-1)!}{(r-1)!(-t_*)^{n+r}} \mathcal{L}(\mathsf{s})^{-n}\mathsf{g} + \text{c.c.} \tag{6.11}$$

Now, for generic g,

$$\mathcal{L}(\mathsf{s})^{-n}\mathsf{g} \sim \frac{\alpha \mathsf{e}_1}{(\mathrm{i}\omega_1)^n} + \frac{\beta \bar{\mathsf{e}}_1}{(-\mathrm{i}\omega_1)^n}. \tag{6.12}$$

Here $\pm\mathrm{i}\omega_1$ are the lowest eigenvalues of $\mathcal{L}(\mathsf{s})$, and e_1 and its complex conjugate $\bar{\mathsf{e}}_1$ are the associated eigenvectors, normalized so that $\bar{\mathsf{e}}_1 \cdot \mathsf{e}_1 = 1$, where $\cdot$ denotes the (non-Hermitian) scalar product. The constants α and β are given by $\alpha = \bar{\mathsf{e}}_1 \cdot \mathsf{g}$ and $\beta = \mathsf{e}_1 \cdot \mathsf{g}$. Taking (6.12) into account reduces (6.11) to

$$\mathsf{F}^{(n)}(\mathsf{s}) \sim \frac{(\mathrm{i})^n(-1)^r(n+r-1)!}{(r-1)!\omega_1^n t_*^{n+r}} \left(\alpha \mathsf{e}_1 + (-1)^n \beta \bar{\mathsf{e}}_1\right) + \text{c.c.} \tag{6.13}$$

In this expression, the dependence on s of the right-hand side is through that of t_*, α, β, ω_1, and e_1. If $\mathcal{L}$ is independent of s, however, ω_1 and e_1 are constant, and α and β depend on s

through t_* only. This is the situation of the LK model. Note that (6.13) indicates that the slow manifold is again determined by an asymptotic series of Gevrey type of order 1. Note also that (6.13) has the form $(n+r-1)!/a^n$ assumed to obtain the approximate recurrence relation (6.6).

6.2. Resummation. Once the asymptotic behavior (6.13) is determined, it is possible to use the Borel summation of the divergent series (6.5) to define a unique optimal slow manifold piecewise. Specifically, we define

$$\mathsf{B}_\mathsf{F}(\mathsf{s};\xi) = \sum_{n=0}^{\infty} \frac{\mathsf{F}^{(n)}(\mathsf{s})}{(n+r-1)!}\xi^{n+r-1}, \tag{6.14}$$

which, according to (6.13), converges for $|\xi| < |\omega_1 t_*|$. The formal inversion is given by

$$\mathsf{F}(\mathsf{s};\epsilon) = \frac{1}{\epsilon^r}\int_0^\infty \mathrm{e}^{-\xi/\epsilon}\mathsf{B}_\mathsf{F}(\mathsf{s};\xi)\,\mathrm{d}\xi, \tag{6.15}$$

as is readily verified. Like for the LK model, we can choose to define an optimal slow manifold by this expression, insisting that the contour of integration be the positive real line. This slow manifold is discontinuous for the values of s such that the poles of $\mathsf{B}_\mathsf{F}(\mathsf{s};\xi)$ in ξ lie on the positive real line. The poles of $\mathsf{B}_\mathsf{F}(\mathsf{s};\xi)$ are found from (6.13) to be located at $\pm\mathrm{i}t_*$ and $\pm\mathrm{i}\bar{t}_*$. Thus the Stokes surfaces, across which the optimal slow manifold is discontinuous, are simply defined by the condition $\operatorname{Re} t_* = 0$.

The analytic continuation of (6.15) across the Stokes surface includes fast oscillations, as we now demonstrate. From (6.13), we obtain that the behavior of $\mathsf{B}_\mathsf{F}(\mathsf{s};\xi)$ near the poles $\xi = \pm\mathrm{i}t_*$ is of the form

$$\mathsf{B}_\mathsf{F}(\mathsf{s},\xi) \sim \frac{(-1)^r\mathrm{i}\omega_1}{(r-1)!}\left(\frac{\xi}{t_*}\right)^{r-1}\left(\frac{\alpha}{\xi+\mathrm{i}\omega_1 t_*}\mathsf{e}_1 - \frac{\beta}{\xi-\mathrm{i}\omega_1 t_*}\bar{\mathsf{e}}_1\right). \tag{6.16}$$

A similar expression gives the behavior near the complex-conjugate poles $\xi = \pm\mathrm{i}\bar{t}_*$. When a Stokes surface is crossed, the difference between the value of F on the optimal slow manifold and that on the full trajectory is given by the contribution of the poles which cross the positive real axis when $\operatorname{Re} t_* = 0$. Taking $\omega_1 \operatorname{Im} t_* > 0$ for definiteness, these poles are $-\mathrm{i}\omega_1 t_*$ and $\mathrm{i}\omega_1\bar{t}_*$. Computing their contribution using the residue theorem gives

$$\mathsf{F}_{\mathrm{pole}}(\mathsf{s};\epsilon) = \pm\frac{2\pi\mathrm{i}(\mathrm{i}\omega_1)^r}{\epsilon^r(r-1)!}\mathrm{e}^{\mathrm{i}\omega_1 t_*/\epsilon}\alpha\mathsf{e}_1 + \mathrm{c.c.}, \tag{6.17}$$

where the sign depends on the direction in which $-\mathrm{i}t_*$ crosses the positive real axis when $\operatorname{Re} t_* = 0$. Evaluating this expression along the approximate slow solutions $\mathsf{s}(t) = \mathrm{e}^{\mathbf{v}t}\mathsf{s}(0)$ confirms that the pole contribution corresponds to fast oscillations. Their amplitude is the exponentially small $\epsilon^{-r}\exp(-\omega_1 \operatorname{Im} t_*)$, their frequency is the lowest frequency ω_1/ϵ, and their polarization (relative size of the various components of f) is fixed by the eigenvector of $\mathcal{L}(s)$ associated with the eigenvalue $\mathrm{i}\omega_1$. The other frequencies $\omega_k > 0$, $k \neq 1$, give contributions that are smaller than (6.17) by the exponentially small factors $\exp[(\omega_1 - \omega_k)\operatorname{Im} t_*/\epsilon]$.

7. Discussion. In this paper, we have examined in detail the divergence of the asymptotic procedures leading to approximately invariant slow manifolds for the Lorenz–Krishnamurthy (LK) model. This divergence was initially observed by Lorenz [20] and was considered in some of the subsequent literature [32, 33]. Here we derive an explicit expression for the leading-order behavior of the slaving coefficients X_n as $n \to \infty$. This makes it possible to employ Borel summation to define a unique slow manifold. In this manner, we resolve the ambiguity that exists for finite-accuracy slow manifolds which are not uniquely defined even for fixed accuracy ϵ^n. The Borel summation requires a choice of integration contour in the Laplace integral that defines it. Our choice is the obvious one which minimizes the oscillations that appear in the slaved fast variables along slow trajectories. The oscillations are not completely eliminated, however: as the trajectories approach the Stokes surface, oscillations appear with the characteristic error-function switching on, which characterizes the Stokes phenomenon [4]. The definition of the slow manifold that we propose ensures that the oscillations are reduced to subexponential levels away from the Stokes surfaces.

We emphasize that our optimal slow manifold differs from Lorenz's slowest invariant manifold [20]. The latter is a truly invariant manifold consisting of periodic orbits. These periodic orbits exist because the slow system with $\epsilon = 0$ is integrable: its phase space is foliated by periodic orbits, most of which persist when $\epsilon \neq 0$ (see [6, 25, 16]). The periodic orbits with $\epsilon \neq 0$ contain exponentially small fast oscillations, with the same amplitude as the oscillations switched on by the Stokes phenomenon that we consider here. In fact, it is easy to obtain an approximation for these orbits from our results. This is achieved by adding oscillations to a solution which starts on the optimal slow manifold. The amplitude and phase of these oscillations are chosen such that after a period of the slow solution, when extra oscillations have been switched on by (two) Stokes phenomena, the complete solution returns to its initial value. This is a consistent approximation because, to leading order, the added oscillations are an approximate solution of the LK equations, and because their (exponentially) small amplitudes make their superposition possible.

We have limited our computations to the leading asymptotics of the slaving coefficients X_n and Y_n for $n \gg 1$. As a result, our estimate for the pole contributions associated with the spontaneous generation of oscillations approximates only the leading-order part of these oscillations. In other words, our computations are carried out to an exponential accuracy that is sufficient to capture the dominant part of the oscillations only. Higher accuracy would require obtaining several terms in the large-n expansion of X_n. A complete expansion for X_n includes terms of different origins. In particular, it includes contributions from all the poles t_* associated with the slow dynamics rather than from those nearest the real axis only. Furthermore, because of the nonlinearity of the recurrence relations for X_n, contributions mixing the different poles arise.

We present two approaches for the determination of the asymptotics of the slaving coefficients. The first, which applies the method of characteristics to the superbalance equation, is readily generalized formally to a large class of two-time-scale systems. This approach makes plain the connection between the exponential asymptotics carried out in [29] for solutions of the LK model and that carried out here for the slow manifold as a whole. In essence, it treats slow manifolds as unions of slow trajectories; in doing so, it turns the problem of exponential asymptotics for the partial differential equation that is the superbalance equation into a

problem of exponential asymptotics for ordinary differential equations. Practical use of this approach requires computing the location of the poles of the leading-order slow trajectories in the complex time plane. For integrable systems such as the LK model, this is possible very explicitly; however, this can be much more problematic for more complex, nonintegrable models. Our second approach relies on the observation that the slaving coefficients X_n and Y_n are polynomials in the slow variables; it concentrates then on first obtaining the asymptotics for the corresponding polynomial coefficients and then summing these. It is clear that the integrability of the LK model underlies the fact that the polynomial coefficients can be obtained in quite an explicit form. It is however possible that this type of approach remains useful in nonintegrable problems, provided that the slaving coefficients continue to take polynomial forms. Of course, some numerical work may be required—for instance, evaluating the function G (or its Legendre transform) governing the asymptotics.

We conclude by noting that the control of late coefficients together with Borel summation have been used for two-time-scale systems in the context of averaging [26]. Slow manifolds are of course closely related to averaging, and averaging order-by-order provides a means of constructing slow manifolds, at least for single-frequency systems, when the difficulties associated with resonances do not arise [15]. In this context, the control of the divergence of asymptotics series can be used as an alternative to the more standard iterative approach, with an incomplete Laplace transform in the Borel summation used in place of the optimal truncation argument to bound error terms by exponentially small quantities. In this paper, we use Borel summation as a practical tool in situations simple enough that the late coefficients in the asymptotic expansions not only can be bounded but also can be approximated accurately.

Novel Vehicular Trajectories for Collective Motion from Coupled Oscillator Steering Control*

Margot Kimura† and Jeff Moehlis†

Abstract. We consider a model for vehicle motion coordination for three vehicles that uses coupled oscillator steering control. Prior work on such models has focused primarily on sinusoidal coupling functions, which typically give behavior in which individual vehicles move either in straight lines or in circles. We show that other, more exotic trajectories are possible when more general coupling functions are considered. Such trajectories are associated with periodic orbits in the steering control subsystem. The proximity of these periodic orbits to heteroclinic bifurcations allows for a detailed characterization of the properties of the vehicular trajectories.

Key words. collective motion, coupled oscillators

1. Introduction.

Many organisms display ordered collective motion [7], such as geese flying in a Chevron-shaped formation [22], wildebeests herding on the Serengeti plains of Africa [32], locusts swarming in sub-Saharan Africa [34], and fish schooling [28]. Collective motion is also of great interest and importance for engineering applications such as formation control of unmanned vehicles and spacecraft [18, 29, 31], cooperative robotics [8], and sensor networks [9]. Much recent work in the engineering community involves formulating and studying interaction rules which allow a population to operate in a particular collective motion state; e.g., [10, 14, 17, 18, 21, 24, 31].

In the present paper, we consider the "LPS model" for vehicle motion coordination developed by Leonard, Paley, and Sepulchre [25, 26, 27, 29, 30, 31]; cf. [19]. This considers N Dubins-type vehicles [11] which are identical, move with constant unit speed, and are globally (all-to-all) coupled:

$$\begin{aligned} \dot{r}_n &= e^{i\theta_n}, \\ \dot{\theta}_n &= u_n(r,\theta), \qquad n = 1,\dots,N. \end{aligned} \tag{1.1}$$

Here the complex vector r_n denotes the position of vehicle n with respect to the origin, while the angle θ_n denotes the orientation of its (unit) velocity vector with respect to the positive real axis. Since $r_n = x_n + iy_n$, with $(x_n, y_n) \in \mathbb{R}^2$, we will hereafter use the following equivalent

equations for the velocity of each vehicle:

$$\begin{aligned} \dot{x}_n &= \cos(\theta_n), \\ \dot{y}_n &= \sin(\theta_n). \end{aligned} \tag{1.2}$$

It can be shown that the system in (1.1) is invariant to rigid group rotation and translation for controllers $u_n(r,\theta)$ that are functions of only the relative positions and headings of the vehicles, defined as $r_m - r_n$ and $\theta_m - \theta_n$, respectively [25, 26, 27, 29, 30, 31]; cf. [19].

The steering control $u_n(r,\theta)$ of the vehicles can be decomposed as

$$u_n(r,\theta) = \underbrace{\omega_0 + u_n^{head}(\theta)}_{u_n^{phase}(\theta)} + u_n^{spac}(r,\theta), \qquad n = 1,\dots,N, \tag{1.3}$$

where $\omega_0 \in \mathbb{R}$ is a constant, the heading controller u_n^{head} depends only on the relative orientation of the vehicles and governs the relative directions, and the spacing controller u_n^{spac} is used to attract the vehicles to a given spatial formation. Following [27, 29, 31], we call $u_n^{phase}(\theta)$ the *phase controller*. When the phase controller depends only on the differences $\theta_m - \theta_n$, a useful connection with the coupled oscillator literature (e.g., [5, 6, 33]) is possible.

Constructing the spacing controller is more challenging in general, since it must be designed to stabilize a specific formation. In [26, 27, 29, 30, 31], a controller that stabilizes a circular formation and a proof of stabilization are given. The basic idea is to design a potential function which is minimized when the vehicles are in the desired configuration. Then, for $u_n^{head} = 0$, it is possible to construct a Lyapunov function to demonstrate that the desired formation is asymptotically stable. For the overall system, one can use a composite Lyapunov function, made up of a linear combination of the Lyapunov functions used for the spacing and heading controls, to prove the stability of the overall desired configuration [25, 26, 27, 29, 30, 31].

The benefits of this type of model for controlling the motion of a group of vehicles are clear: the model takes advantage of results from research on coupled oscillators and translates them into a simple but robust law governing individual vehicle motion that produces the desired overall group motion.

Most of the previous work on the LPS model has assumed a sinusoidal coupling function for the phase controller:

$$u_n^{phase} = \omega_0 + \frac{k}{N}\sum_{j=1}^{N} \sin(\theta_m - \theta_n). \tag{1.4}$$

With this phase controller alone (i.e., $u_n^{spac} = 0$), the system converges asymptotically to a synchronized phase arrangement for $k > 0$, and a phase-balanced solution for $k < 0$ [23, 25, 27, 29]. Both of these phase-space solutions lead to vehicular trajectories that are either straight lines or circles, depending on the value of ω_0: for $\omega_0 \neq 0$, the trajectories converge to circles, and for $\omega_0 = 0$, the trajectories converge to straight lines.

In this paper, we explore the effects of more general coupling functions to see what other types of coordinated motion are possible for this model using the phase controller alone. We

will show that one can get trajectories that are much more exotic than straight lines or circles, and which may be advantageous in situations where one wants a relatively complicated trajectory that is a natural result of the phase controller, rather than having to piece a similar trajectory together with existing methods. The trajectories from our phase controller are characterized by almost regular, Spirograph-like shapes, where the vehicles spend some time circling one section of space before moving on to another area, eventually tracing out an annulus, which may be useful in applications where one wants a robot to patrol an appropriately shaped space while periodically doing a more careful search of a subsection of that space. These trajectories are related to heteroclinic cycles for the coupled oscillator system; see [3, 16] for related heteroclinic orbits in systems of N coupled identical oscillators; cf. [4, 5]. To simplify our analysis, we will restrict the system to three vehicles. (A discussion of more general coupling functions for two vehicles is given in [20].)

We begin with an analysis of the general phase control and then present a detailed analysis of the resulting trajectories for a specific coupling function. Sections 2 and 3 consider the case of all-to-all coupling, while section 4 considers a different coupling topology. Our conclusion is given in section 5.

2. Identical all-to-all coupling: Phase dynamics.

2.1. Equations and symmetry. A system of three identical oscillators with all-to-all identical phase-difference coupling is given by

$$\dot{\theta}_n = \omega_0 + k \sum_{m \neq n} f(\theta_m - \theta_n), \qquad n = 1, 2, 3, \tag{2.1}$$

where $\theta_n \in [0, 2\pi)$ and the coupling function f is 2π-periodic. This system of equations is equivariant with respect to the group $S_3 \times T^1$, where S_3 is the six-element permutation group generated by

$$\begin{aligned} \sigma_1 &: (\theta_1, \theta_2, \theta_3) \to (\theta_2, \theta_1, \theta_3), \\ \sigma_2 &: (\theta_1, \theta_2, \theta_3) \to (\theta_2, \theta_3, \theta_1), \end{aligned} \tag{2.2}$$

and T^1 is the circle group with action

$$\tau_\phi : (\theta_1, \theta_2, \theta_3) \to (\theta_1 + \phi,\, \theta_2 + \phi,\, \theta_3 + \phi) \tag{2.3}$$

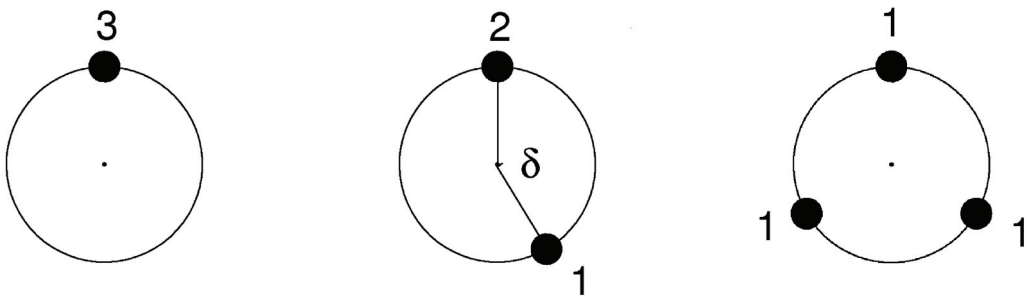
for all $\phi \in [0, 2\pi)$. This means that if $(\theta_1(t), \theta_2(t), \theta_3(t))$ is a solution to (2.1), then, for any $\gamma \in S_3 \times T^1$, so is $\gamma \cdot (\theta_1(t), \theta_2(t), \theta_3(t))$.

Equation (2.1) can be reduced to a two-dimensional system by introducing the 2π-periodic variables $\psi_1 = \theta_1 - \theta_2$ and $\psi_2 = \theta_1 - \theta_3$:

$$\begin{aligned} \dot{\psi}_1 &= \dot{\theta}_1 - \dot{\theta}_2 = k[f(-\psi_1) + f(-\psi_2) - f(\psi_1) - f(\psi_1 - \psi_2)], \\ \dot{\psi}_2 &= \dot{\theta}_1 - \dot{\theta}_3 = k[f(-\psi_1) + f(-\psi_2) - f(\psi_2) - f(\psi_2 - \psi_1)]. \end{aligned} \tag{2.4}$$

Equation (2.4) inherits equivariance with respect to the actions obtained from (2.2) and (2.3) on the ψ variables:

$$\begin{aligned} \hat{\sigma}_1 &: (\psi_1, \psi_2) \to (-\psi_1,\, \psi_2 - \psi_1), \\ \hat{\sigma}_2 &: (\psi_1, \psi_2) \to (\psi_2 - \psi_1,\, -\psi_1). \end{aligned} \tag{2.5}$$



(a) S_3 Solution (b) $S_2 \times S_1$ Solution (c) Z_3 Solution

Figure 1. *Phase-locked solutions guaranteed to exist for any coupling function f. The locations of the dots on the phase circle are determined by the values of θ for the oscillators, with the number indicating how many oscillators share the same phase. These solutions are labeled according to their isotropy subgroup, as described in the text.*

Note that $\hat{\tau}_\phi : (\psi_1, \psi_2) \to (\psi_1, \psi_2)$ acts as the identity for all ϕ. The actions $\hat{\sigma}_1$ and $\hat{\sigma}_2$ generate the permutation group S_3. We will sometimes find it convenient to think of ψ_1 and ψ_2 as being restricted to $[0, 2\pi)$, and other times it will be useful to allow them to take any real value.

2.2. Solutions and bifurcations. Phase-locked solutions are characterized by each pair of θ variables always differing by a fixed value. Thus in the ψ variables, phase-locked solutions correspond to fixed points. The symmetry and stability properties of phase-locked solutions are discussed below. As convenient, we will discuss these solutions in either the θ or the ψ variables. The three types of phase-locked solutions shown in Figure 1 are guaranteed to exist for any coupling function f of the form of (2.1), given a simple nondegeneracy condition [4, 5, 6]. These are labeled according to their isotropy subgroup, which is the set of elements of $S_3 \times T^1$ that leave the solution unchanged [15]. We note that the existence of a fixed point at (ψ_1^*, ψ_2^*) implies the existence of fixed points at $(\psi_1^* + 2\pi j,\ \psi_2^* + 2\pi m)$ for all $j \in \mathbb{Z}$ and $m \in \mathbb{Z}$.

The S_3 solutions: Fixed points at $(\psi_1^*, \psi_2^*) = (0, 0)$.

Symmetry. This phase-locked solution is invariant under the symmetry $S_3 = \langle \sigma_1, \sigma_2 \rangle$ in the θ variables, and $S_3 = \langle \hat{\sigma}_1, \hat{\sigma}_2 \rangle$ in the ψ variables; hence it has the name "S_3 solution." Since it corresponds to $\theta_1 = \theta_2 = \theta_3$, it is also sometimes referred to as the "in-phase" or "synchronous" solution.

Stability analysis and bifurcations. The Jacobian for (2.4) at the fixed point $(\psi_1^*, \psi_2^*) = (0, 0)$ has a double eigenvalue $\lambda_{1,2} = -3kf'(0)$. Thus, the stability of the fixed point depends solely on the sign of the real part of $kf'(0)$: if $kf'(0)$ is positive (resp., negative), then the S_3 solution is stable (resp., unstable).

Suppose that there is a bifurcation parameter which causes the shape of the coupling function f to change. It is immediately evident that the stability of the S_3 fixed point changes if the value $kf'(0)$ passes through zero as this parameter is varied. Because the fixed point at $(\psi_1^*, \psi_2^*) = (0, 0)$ will persist for all f, this corresponds to an S_3-symmetric transcritical

bifurcation. Assuming that there are no fixed points on the invariant lines $\psi_1 = 0$, $\psi_2 = 0$, or $\psi_1 = \psi_2$, for $(\psi_1, \psi_2) \in [0, 2\pi)$, at this bifurcation, a triangular heteroclinic connection appears between the fixed points at $(\psi_1^*, \psi_2^*) = (0, 0)$, $(2\pi, 0)$, and $(0, 2\pi)$. Since these points are identified by the 2π-periodicity of ψ_1 and ψ_2, this can also be referred to as a homoclinic connection. Thus, the authors of [4] call this an $\mathbb{S}_3$ transcritical/homoclinic bifurcation, or $\mathbb{S}_{3\text{THB}}$. If the heteroclinic loop is attracting at the bifurcation, the system will have a stable limit cycle very close to the triangle on the side of the bifurcation where the S_3 solution is unstable. Such a bifurcation will occur in the example below.

The $S_2 \times S_1$ solutions: Fixed points at $(\psi_1^*, \psi_2^*) = (0,\ 2\pi - \delta)$, $(2\pi - \delta,\ 0)$, and (δ, δ) for $\delta \in (0, 2\pi)$.

Symmetry. Arguments in [5, 6] imply that, provided $f'(0) \neq 0$, there must exist a $\delta \in (0, 2\pi)$ such that there is a phase-locked solution with two oscillators in phase and one oscillator shifted by the phase δ. The phase-locked solution corresponding to $(\psi_1^*, \psi_2^*) = (0,\ 2\pi - \delta)$ is invariant under the group $S_2 = \langle \sigma_1 \rangle$ in the θ variables, and $S_2 = \langle \hat{\sigma}_1 \rangle$ in the ψ variables. Following [5], this is referred to as an $S_2 \times S_1$ solution: the S_2 corresponds to the permutation just mentioned, and the S_1 refers to the identity permutation acting on the other oscillator. The other phase-locked solutions are related to this one by symmetry and are invariant under conjugate subgroups.

Stability analysis and bifurcations. The Jacobian at the fixed point $(2\pi - \delta,\ 0)$ has eigenvalues $\lambda_1 = k[-f'(\delta) - 2f'(-\delta)]$ and $\lambda_2 = k[-2f'(0) - f'(\delta)]$. Note that the symmetry-related fixed points at $(2\pi - \delta,\ 0)$ and (δ, δ) have the same stability. These points can be sinks, sources, or saddles.

Bifurcations occur when either $f'(\delta) + 2f'(-\delta) = 0$ or $f'(\delta) + 2f'(0) = 0$. Depending on the relative values of $f'(\delta)$, $f'(-\delta)$, and $f'(0)$ for different parameters of f, the fixed points' stability can change to or from a sink, source, or saddle in a pitchfork or saddle-node bifurcation; cf. [4]. Such solutions are involved in the $\mathbb{S}_{3\text{THB}}$ bifurcation described above, and can also be involved in the related global saddle-node heteroclinic bifurcation identified in [2].

The Z_3 solutions: Fixed points at $(\psi_1^*, \psi_2^*) = (\frac{2\pi}{3}, \frac{4\pi}{3})$ and $(\frac{4\pi}{3}, \frac{2\pi}{3})$.

Symmetry. The fixed point $(\psi_1^*, \psi_2^*) = (\frac{2\pi}{3}, \frac{4\pi}{3})$ corresponds to a solution for which $\theta_1 = \theta_2 + \frac{2\pi}{3}$ and $\theta_2 = \theta_3 + \frac{2\pi}{3}$. This is typically called the "splay state" because θ_1, θ_2, and θ_3 are equally spaced around the unit circle. This solution is invariant under the three-element cyclic group Z_3 generated by

$$(\theta_1, \theta_2, \theta_3) \to \left(\theta_2 + \frac{2\pi}{3},\ \theta_3 + \frac{2\pi}{3},\ \theta_1 + \frac{2\pi}{3}\right) \tag{2.6}$$

and hence is called the "Z_3 solution." In terms of the ψ variables, this solution is invariant under $\langle \hat{\sigma}_2 \rangle$, which is isomorphic to the group Z_3. The fixed point $(\psi_1^*, \psi_2^*) = (\frac{4\pi}{3}, \frac{2\pi}{3})$ is invariant under the group Z_3 generated by

$$(\theta_1, \theta_2, \theta_3) \to \left(\theta_3 + \frac{2\pi}{3},\ \theta_1 + \frac{2\pi}{3},\ \theta_2 + \frac{2\pi}{3}\right) \tag{2.7}$$

in the θ variables and $\langle \hat{\sigma}_2 \hat{\sigma}_1 \rangle$ in the ψ variables.

Stability analysis and bifurcations. The Jacobian at this fixed point $(\frac{2\pi}{3}, \frac{4\pi}{3})$ has eigenvalues $\lambda_{1,2} = k[-\frac{3}{2}(f'(\frac{2\pi}{3}) + f'(\frac{4\pi}{3})) \pm \frac{3i}{2}|f'(\frac{4\pi}{3}) - f'(\frac{2\pi}{3})|]$. Thus, unless $f'(\frac{4\pi}{3}) = f'(\frac{2\pi}{3})$,

this fixed point will be either a spiral sink or a spiral source. At $f'(\frac{2\pi}{3})+f'(\frac{4\pi}{3})=0$, the fixed point switches between a spiral sink and a spiral source, which is an indication of a Hopf bifurcation, as found in [4].

2.3. An example. As an example, we now consider the coupling function

$$f(\varphi)=\mu_1\sin(\varphi)+\mu_2\cos(\varphi)+\mu_3\sin(2\varphi), \tag{2.8}$$

which will provide a spectrum of novel trajectories when applied to vehicle motion coordination using the LPS model. While the coupling function given by (2.8) provides a nice example for our analysis of these interesting trajectories, the phenomena that produce the trajectories we consider are fairly generic, and so we expect to see similar bifurcations in the phase space and trajectories for the vehicles for other appropriate coupling functions [3, 16].

The above analysis predicts that both a $\mathbb{S}_{\text{3THB}}$ bifurcation involving the S_3 and $S_2\times S_1$ solutions and, independently, a Hopf bifurcation involving the Z_3 solutions will occur at $\mu_1+2\mu_3=0$ for the system (1.1) with coupling function (2.8). Numerical bifurcation analysis using XPPAUT [12] shows that for $\mu_2=1$, $\mu_3=-0.06$, and $k=1$ and when treating μ_1 as the bifurcation parameter, the Hopf bifurcation is subcritical, and that the branch of unstable periodic orbits turns around in a saddle-node bifurcation of periodic orbits to give stable periodic orbits; see Figure 2. This figure also illustrates that the phase space for the system can be divided into two triangles bounded by the invariant lines $\psi_1=0$, $\psi_1=2\pi$, $\psi_2=0$, $\psi_2=2\pi$, and $\psi_1=\psi_2$. Trajectories in these triangles are related by symmetry, and the resulting vehicular trajectories are identical. Thus, without loss of generality, we will assume that all initial conditions are chosen such that the system moves in the lower right triangle.

3. Identical all-to-all coupling: Vehicular trajectories. We now illustrate the richness of possible vehicular trajectories for (1.1) with identical all-to-all phase-difference steering control by considering the coupling function given in (2.8) with parameters $\mu_1=0.1$, $\mu_2=1$, and $\mu_3=-0.06$; see Figure 2(c) for the corresponding reduced phase-space system. If the system converges to the stable Z_3 solution, then the vehicles will move either in circles or in straight lines, depending on the value of ω_0, with each instantaneously moving in a direction at an angle of $\pm\frac{2\pi}{3}$ with respect to the others. Such motion has been found for the LPS model with the coupling function $f(\theta)=\sin(\theta)$ [25, 26, 27, 29, 30, 31]. However, if the system converges to the stable limit cycle, then the vehicles can display more exotic trajectories, such as the trajectory shown in Figure 3. Thus, we will focus our analysis on the solutions that converge to the stable limit cycle. As we will demonstrate later, these exotic trajectories are products of a stable limit cycle in the reduced phase system, so one can expect to see qualitatively similar trajectories for other appropriate coupling functions and coupling topologies.

Motion along the limit cycle is not uniform: the system slows near each of the fixed points and moves quickly in regions away from a fixed point. As will be explained in the following, it is from this nonuniform motion that the trajectories get their peculiar shapes. We first present an explanation of the vehicular motion in an intuitive way, and then validate the intuition with results from numerical simulations, which were done using a fourth-order variable-timestep Runge–Kutta algorithm. Without loss of generality, we will restrict discussion to the motion of vehicle 1 (denoted v_1) only. The motion of vehicle 2 (v_2) and vehicle 3 (v_3) is identical to but out of phase with the motion of v_1; this is summarized in Table 1.

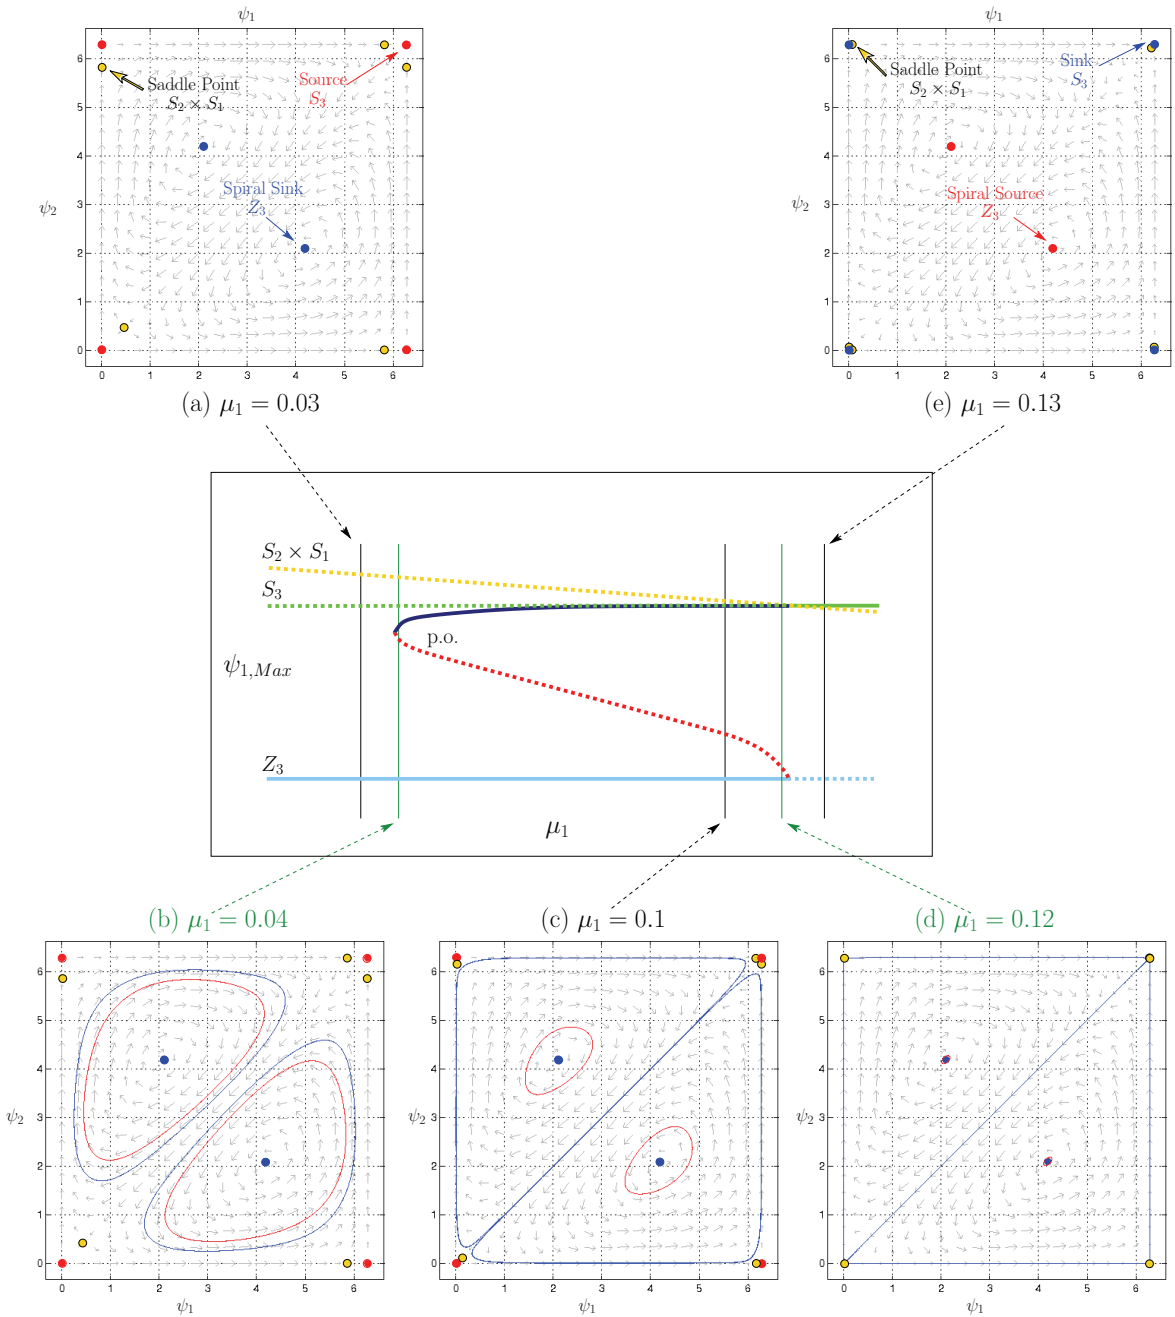


Figure 2. *The bifurcation diagram in terms of μ_1, showing the phase portraits at several values of μ_1 of interest for $\mu_2 = 1$ and $\mu_3 = -0.06$. In the (ψ_1, ψ_2) plane, yellow dots represent saddle points, red shows sources or unstable periodic orbits, and blue represents sinks or stable periodic orbits. Solid (resp., dashed) lines in the bifurcation diagram indicate stable (resp., unstable) solutions.*

3.1. The intuitive description. The overall vehicle motion in Figure 3 can be decomposed into identical units, each of which contains a cluster and a tail. We will name the tail

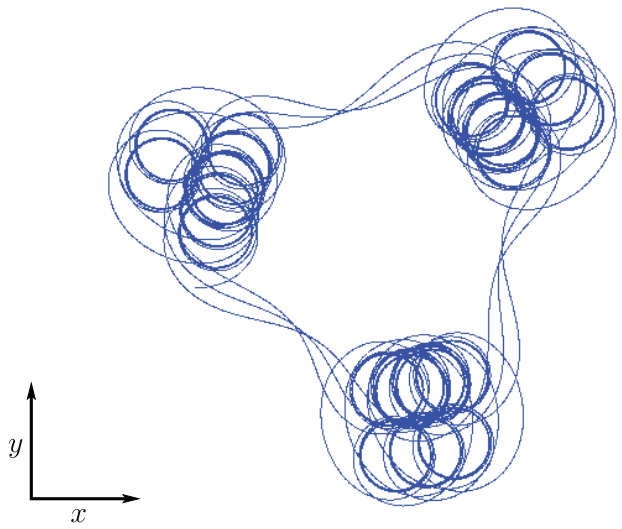

Figure 3. *An example trajectory for vehicle 1 (v_1) with parameters $\mu_1 = 0.1$, $\mu_2 = 1$, $\mu_3 = -0.06$, $\omega_0 = k = 1$. This trajectory is taken over many cycles of the periodic orbit in the (ψ_1, ψ_2) plane.*

Table 1

Relative phase and resulting behavior of all three vehicles in terms of position in the (ψ_1, ψ_2) plane. Here, $\uparrow$ means "increase(s)," and $\downarrow$ means "decrease(s)." The definition of "excursion" is given in the text.

Box	ψ behavior	θ behavior	Vehicle motion
1	$\psi_1 \uparrow$ to $\approx 2\pi$ $\psi_2 \approx 0$	θ_1 & $\theta_3 \uparrow$ at the same rate θ_2 temporarily $\downarrow$	v_1 & v_3: short excursion v_2: long excursion
2	$\psi_2 \uparrow$ to $\approx 2\pi$ $\psi_1 \approx 2\pi$	θ_1 & $\theta_2 \uparrow$ at the same rate θ_3 temporarily $\downarrow$	v_1 & v_2: short excursion v_3: long excursion
3	$\psi_1 \approx \psi_2 \downarrow$ together to ≈ 0	θ_2 & $\theta_3 \uparrow$ at the same rate θ_1 temporarily $\downarrow$	v_2 & v_3: short excursion v_1: long excursion

connecting the units a *long excursion*. Each cluster can be further broken down to show two general types of behavior: small approximately circular orbits, which we will call *small orbits*, and the roughly semicircular excursions that connect the small orbits, which we will refer to as *short excursions*. The vehicle path in a single unit can be described as a cycle through a small orbit followed by a short excursion to another small orbit, followed by a second short excursion to a third small orbit, followed by a long excursion to the next cluster. This is illustrated in Figure 4.

We can understand this behavior by dividing the periodic orbit into six boxes, as labeled in Figure 4. Simulations show that when the system in the (ψ_1, ψ_2) plane is in a lettered box (i.e., near a fixed point), the vehicles move in a small orbit, and when the system is in a numbered box, the vehicles undergo an excursion. This is expected, since the vehicles would move in a circle if the system were actually at the fixed point (i.e., generically, at a fixed point, $\dot{\theta}_j = \text{constant} \neq 0$). Therefore, one can intuitively expect the vehicles to show switching behavior between small orbits and excursions as the system moves in the (ψ_1, ψ_2) plane.

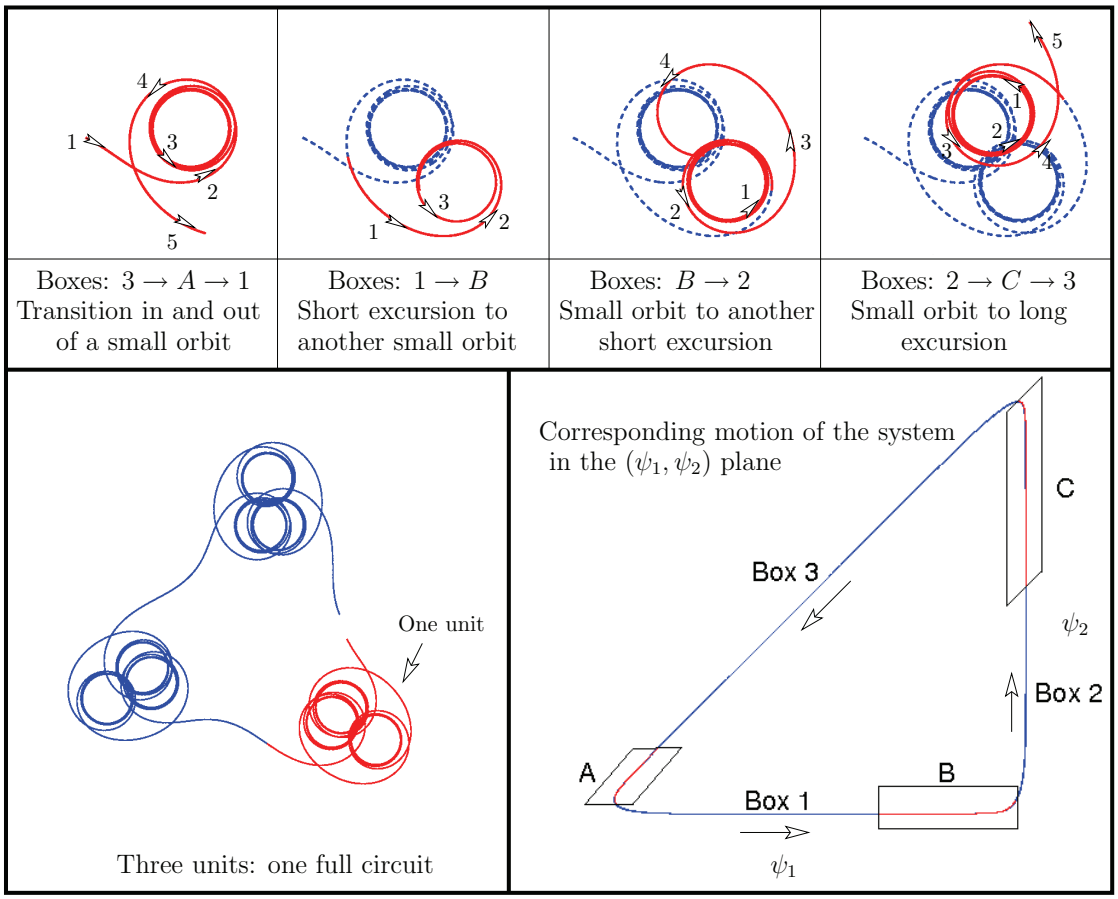

Figure 4. *Behavior of v_1 in the (x, y) plane with corresponding position of the system in the (ψ_1, ψ_2) plane. The top explains the motion of v_1 within one unit: Follow the ordered arrows in the time-series of pictures. The bottom-left panel shows one full circuit of vehicle motion, and the bottom-right panel shows the various boxes in the (ψ_1, ψ_2) plane.*

3.2. Numerical analysis and validation.

3.2.1. Box definition. To validate the above intuition, we need to be more precise about the boundaries of the boxes. Since the vehicles are always moving in a smooth and roughly circular trajectory, it is natural to define the boxes in terms of the instantaneous radius of curvature of the vehicles' trajectories. This was calculated from simulation data for each point by finding the radius of the circle defined by that point and its two neighboring points; see Figure 5.

The lettered boxes were chosen by calculating where the radius of curvature for v_1 was within 0.01 of the minima of each trough, as seen in Figure 6. Boxes 1, 2, and 3 are then defined as the intervening lengths of the periodic orbit in the (ψ_1, ψ_2) plane.

3.2.2. Approximate solutions. Within each box, we present an approximate solution with a few simplifying assumptions.

Near a fixed point (i.e., in a lettered box), the behavior of the system is approximately

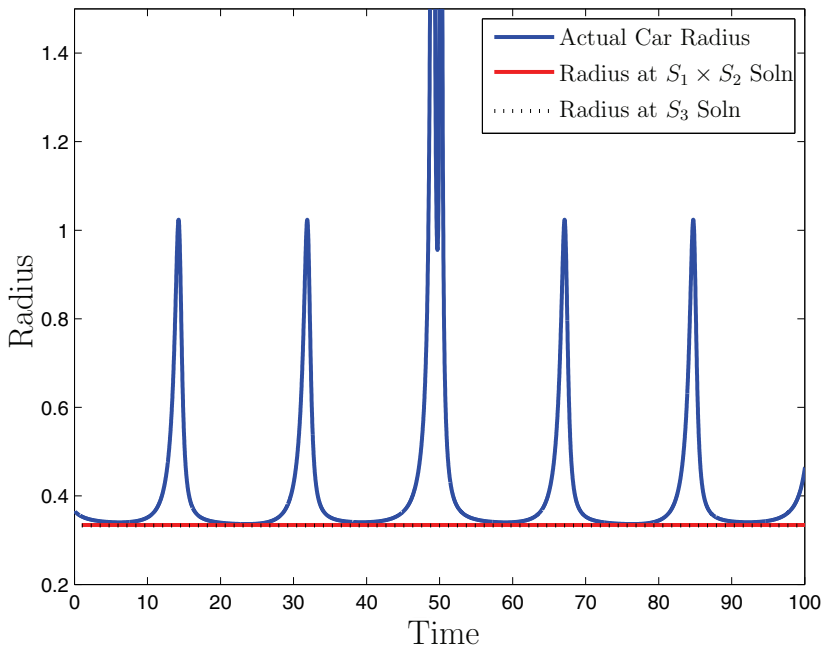

Figure 5. *Measurements of the radius of curvature for v_1 moving in the trajectory shown in Figure 3 with the approximations at each nearby fixed point. It is evident from the periodic flat troughs that the radius of curvature of the vehicles' motion spends a significant amount of time at an approximately constant value. Moreover, the value of that constant value is very close to the radius of curvature the vehicles' motion would have if the system were at the $S_2 \times S_1$ solution. See Figure 6 for an enlargement.*

the same as if the system were actually at the fixed point. At a fixed point, we have $\dot{\theta}_1 = \dot{\theta}_2 = \dot{\theta}_3 \equiv \varpi$, where ϖ is a constant. This is easily integrated, giving

$$\theta_i(t) = \varpi t + \theta_{0i}.$$

This corresponds to the following equations in the (x, y) plane:

$$\dot{x}_i = \cos(\varpi t + \theta_{0i}),$$
$$\dot{y}_i = \sin(\varpi t + \theta_{0i}).$$

These equations can also be integrated, yielding

$$x_i = \tfrac{1}{\varpi} \sin(\varpi t + \theta_{0i}),$$
$$y_i = -\tfrac{1}{\varpi} \cos(\varpi t + \theta_{0i}),$$

corresponding to motion in a circle of radius $\frac{1}{\varpi}$.

For the particular coupling function discussed in the example above, $\varpi = \omega_0 + 2k\mu_2$. Plugging in $\omega_0 = k = \mu_2 = 1$, we find that the vehicles move in circles with radius $\frac{1}{3}$ if the system is at an S_3 solution. When the system is at one of the $S_2 \times S_1$ solutions, found for

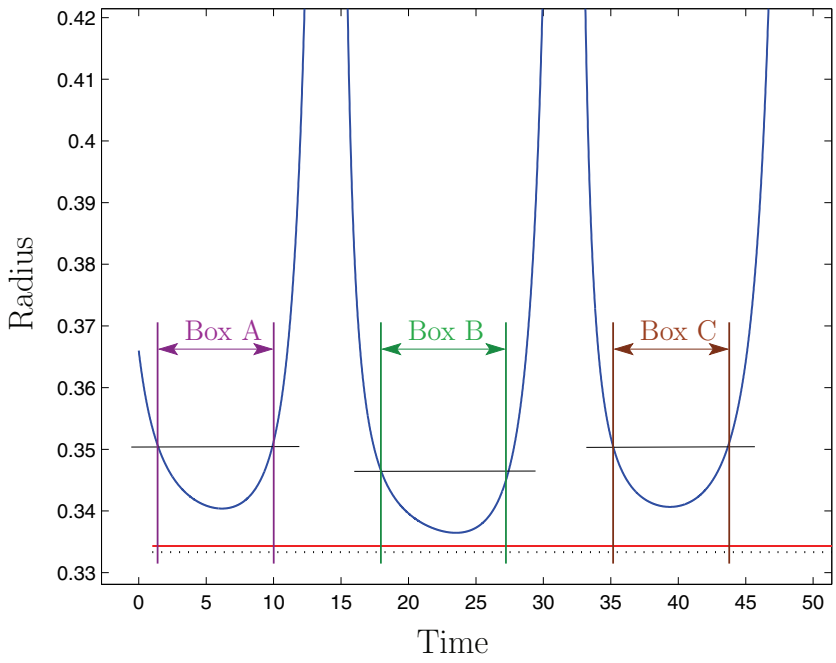

Figure 6. *An enlargement of Figure 5, showing how close the actual instantaneous radius of curvature of v_1 comes to the approximated values, and how the radius of curvature defines the location of the lettered boxes. The dotted line represents what the radius of curvature would be at the S_3 solution, and the red solid line represents the radius at the $S_2 \times S_1$ solution. The line segments show where the radius of curvature of v_1 is within 0.01 of its minimum for each box. The edges of the boxes correspond to the intersections of these line segments with the radius of curvature of v_1. The numbered boxes are then assigned as the intervening spaces between lettered boxes.*

these parameters to be at $(0.11511, 0.11511)$, $(0, 2\pi - 0.11511)$, or $(2\pi - 0.11511, 0)$, the radius of the motion of v_1 is approximately 0.334317. As one can see in Figure 6, the approximation that the system is at an $S_2 \times S_1$ fixed point is very close to the results obtained from the actual simulation.

In the numbered boxes, we can approximate the behavior of the system by noting that in Box 1, $\psi_2 \approx 0$, in Box 2, $\psi_1 \approx 0$, and in Box 3, $\psi_1 \approx \psi_2$ and both decrease from a value close to 2π to a value close to 0 at about the same rate.

Taking $\psi_2 = 0$ (which is approximately true in Box 1) in (2.4), we obtain $\dot{\psi}_2 = 0$ and

$$\dot{\psi}_1 = \dot{\theta}_1 - \dot{\theta}_2 = k[f(-\psi_1) + f(0) - 2f(\psi_1)], \tag{3.1}$$

a one-dimensional differential equation. Similarly, taking $\psi_1 = 2\pi = 0$ (which is approximately true in Box 2) in (2.4) gives the same formula as (3.1) but with $\psi_1 \to \psi_2$. Finally, taking $\psi_1 = \psi_2 \equiv \psi$ (which is approximately true in Box 3), we obtain

$$\dot{\psi}_1 = \dot{\psi}_2 = \dot{\psi} = k[2f(-\psi) - f(0) - f(\psi)], \tag{3.2}$$

which is related to (3.1) through $\psi_1 \to -\psi$.

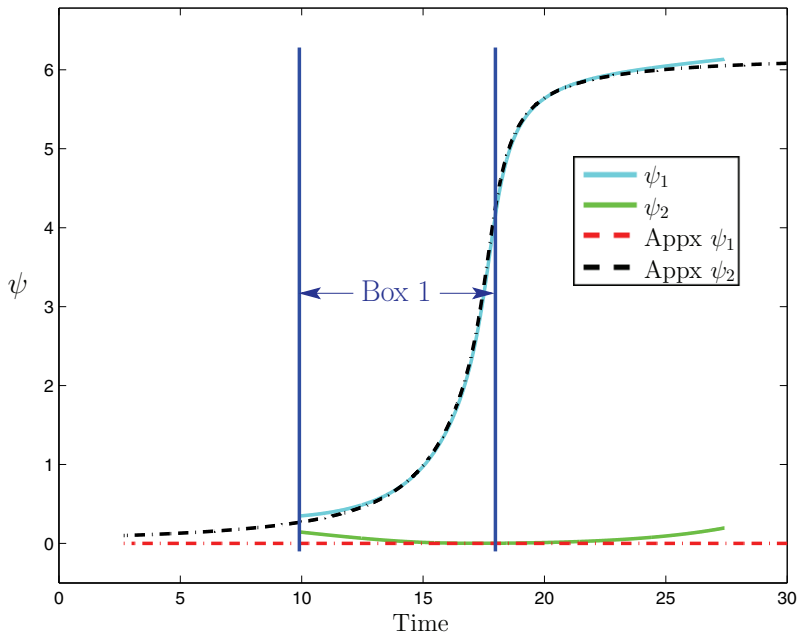

Figure 7. *Demonstration of the validity of the approximation leading to (3.1): The graphs of the approximate solutions in Box 1 and actual simulation data show that the assumptions made are reasonable.*

Numerical integration of the approximate equations very closely matches the data from simulation in all three boxes; see Figures 7 and 8 for Boxes 1 and 3, respectively. (The approximate solutions are nearly identical in Boxes 1 and 2, so only the simulation for Box 1 is shown.)

3.2.3. The Spirograph kaleidoscope. The ω_0 and k terms effectively control the curvature of the individual trajectories and the speed at which the system moves through the (ψ_1, ψ_2) plane, respectively. The shape of the vehicular trajectories, even in transients, depends only on the ratio $\frac{\omega_0}{k}$, as can be seen most easily in an equivalent form of (2.1):

$$\dot{\theta}_n = k\left(\frac{\omega_0}{k} + \sum_{m \neq n} f(\theta_m - \theta_n)\right), \qquad n = 1, 2, 3. \tag{3.3}$$

In this form, it is clear that the variable k simply scales time, while the actual dynamics depend only on the constant $\frac{\omega_0}{k}$, which can be thought of as the effective natural frequency. Since we have constrained our vehicles to have constant unit velocity, the only way that the vehicles can compensate for a larger (resp., smaller) k (with appropriately scaled ω_0), which would make the vehicles move more quickly (resp., slowly), is to produce a smaller (resp., larger), scaled, version of the exact same pattern, even in transients. This effect is demonstrated in Figure 9.

There are many possible trajectories found by varying the $\frac{\omega_0}{k}$ ratio, which have a base shape

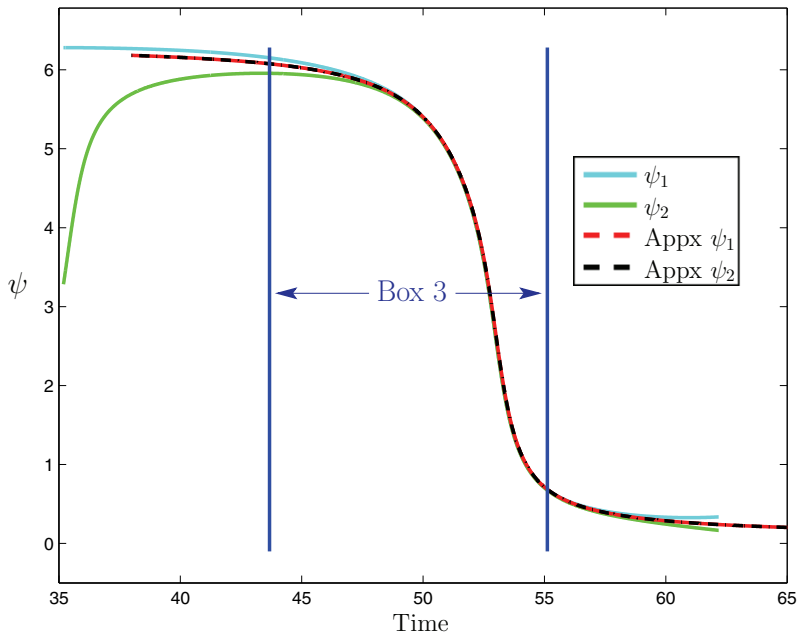

Figure 8. *Demonstration of the validity of the approximation leading to (3.2): The graphs of the approximate solutions in Box 3 and actual simulation data show that the assumptions made are reasonable.*

resembling a pattern from a Spirograph.[1] It is possible to obtain a regular overall trajectory (global) shape with any number of sides that either passes through the approximate center of the polygon, or travels exclusively along the edges. In other words, the radius of the global shape can be made to be anywhere between zero and infinity. Moreover, as one steps through the possible values of $\frac{\omega_0}{k}$, the radius runs continuously from zero through infinity and back to zero again, providing a kaleidoscope-like effect. Recognition of this trend allows one to look at a trajectory for a given set of parameters, and to be able to expect roughly what the trajectories will look like for neighboring values of $\frac{\omega_0}{k}$.

To sample over the different types of trajectories possible for $\omega_0 > 0$ and $k > 0$, we first held $\omega_0 = 1$ and varied k from 0 to 1, and then held $k = 1$ and varied ω_0 from 0 to 1. Some example trajectories are shown in Figures 10 and 11. From simulations, we have found that the global radius goes to infinity when $\frac{\omega_0}{k} \approx 0.1292 + 0.1189n$, where n is an integer.

4. The Arbiter configuration. We have also found interesting phase dynamics and vehicular trajectories for coupling topologies other than all-to-all. Here we focus on the coupling topology shown in Figure 12, which we have nicknamed the "Arbiter" configuration.

[1]A "Spirograph" is a toy invented by Denys Fisher and was first introduced to the United States in 1966 by Kenner, Inc. The name "Spirograph" is a trademark of Hasbro, Inc. The toy allows the user to create intricate designs: The user puts a pen on a point within a circle, which rotates around the inside or outside of another shape, typically also a circle. The geometric curves produced by a Spirograph are mathematically known as hypotrochoids and epitrochoids [1]. An interactive applet demonstrating what patterns are possible with a Spirograph can be found at [13].

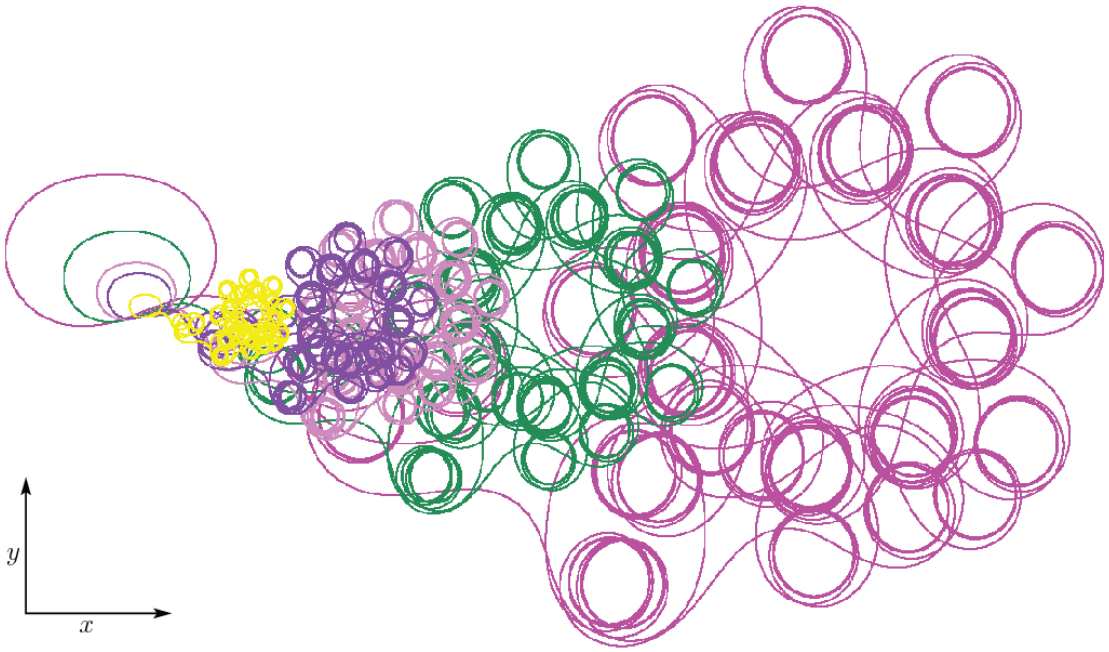

Figure 9. *Five trajectories with the same initial conditions in (x, y) and (ψ_1, ψ_2), and with the same ratio $\frac{\omega_0}{k}$, but with different values of k (and appropriately scaled ω_0).*

The equations for the Arbiter configuration for $N = 3$ are

$$\begin{aligned} \dot{\theta}_1 &= \omega_0 + k[f(\theta_2 - \theta_1) + f(\theta_3 - \theta_1)], \\ \dot{\theta}_2 &= \omega_0 + kf(\theta_1 - \theta_2), \\ \dot{\theta}_3 &= \omega_0 + kf(\theta_1 - \theta_3). \end{aligned} \tag{4.1}$$

Transforming (4.1) into the ψ coordinates as in section 2.3 gives

$$\begin{aligned} \dot{\psi}_1 &= k[f(-\psi_1) + f(-\psi_2) - f(\psi_1)], \\ \dot{\psi}_2 &= k[f(-\psi_1) + f(-\psi_2) - f(\psi_2)]. \end{aligned} \tag{4.2}$$

It is evident that the (ψ_1, ψ_2) equations are equivariant under permutation of ψ_1 and ψ_2, and that the lines $\psi_1 = 2\pi n$ and $\psi_2 = 2\pi n$, where n is an integer, are no longer invariant. The system does have an invariant line at $\psi_1 = \psi_2$. Along this line, $\psi_1 = \psi_2 \equiv \psi$, and we see that if there exists a δ^* such that $2f(-\delta^*) - f(\delta^*) = 0$, then there will be at least one fixed point on the invariant line at $(\psi_1, \psi_2) = (\delta^*, \delta^*)$. An argument for the existence of such a δ^* under quite general conditions follows.

4.1. Existence of $S_2 \times S_1$ solutions with $\psi_1 = \psi_2$. Letting

$$c_1(\delta) = 2f(-\delta), \qquad c_2(\delta) = f(\delta), \tag{4.3}$$

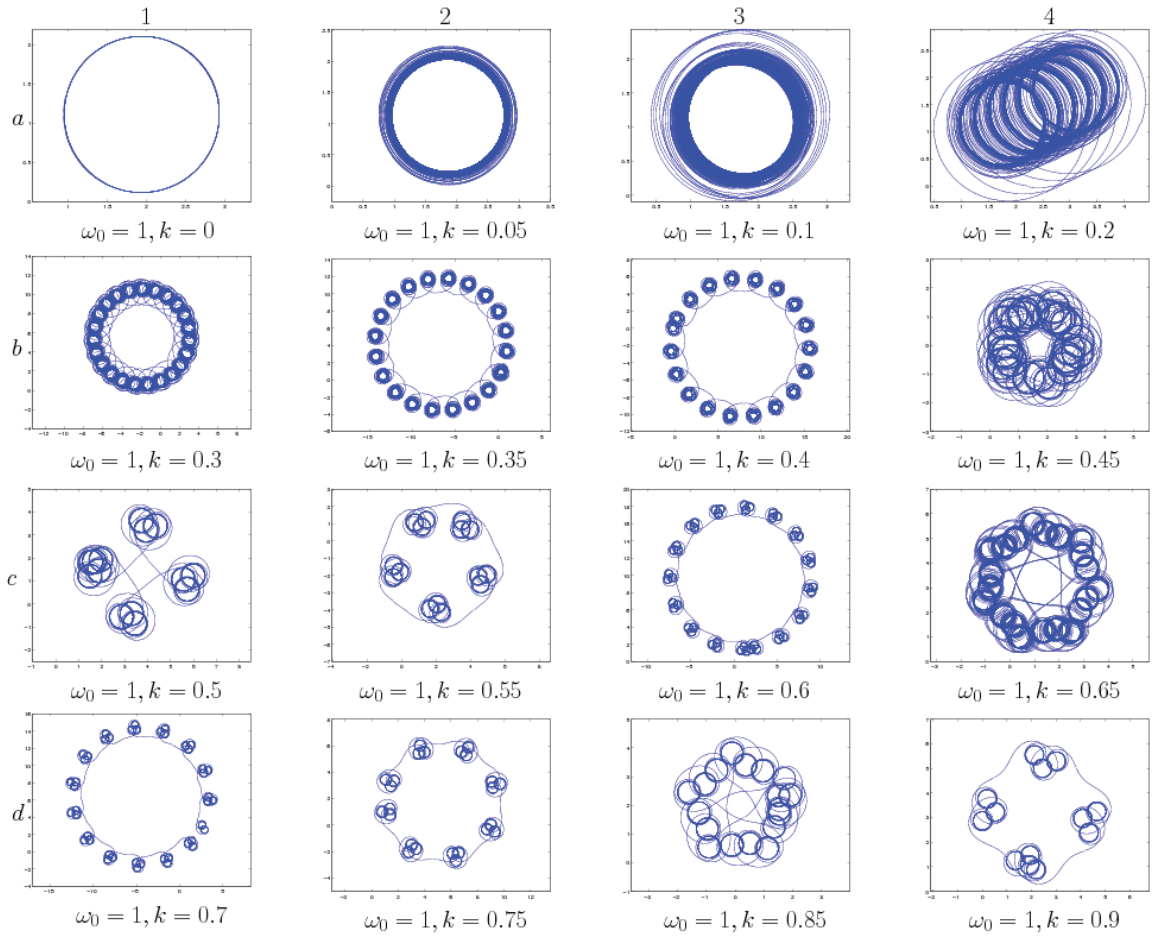

Figure 10. *A few examples of vehicular trajectories for v_1 from coupling function (2.8) with $\mu_1 = 0.1$, $\mu_2 = 1$, and $\mu_3 = -0.06$, while holding $\omega_0 = 1$ and varying k from 0 to a value close to 1.*

a valid δ^* will satisfy

$$c_1(\delta^*) = c_2(\delta^*). \tag{4.4}$$

If $|f(\delta)| \geq 0$ for all δ, it is possible that no such δ exists: for example, take $f(\delta) = 1$. Therefore, we assume that there exists a $\phi_1 \neq 0$ such that $f(\phi_1) = 0$, but $f'(\phi_1) \neq 0$. Then, by periodicity of f, there must be a $\phi_2 \neq 0$ such that $f(\phi_2) = 0$ but $f'(\phi_2) \neq 0$.

If $f(0) \neq 0$, without loss of generality, we can assume that $c_1(0) > c_2(0) > 0$. This implies that $c_1(2\pi) > c_2(2\pi) > 0$. Now,

$$\begin{aligned}
&\min[c_2(\delta)] = \min[f(\delta)] \equiv \beta,\\
&\min[c_1(\delta)] = \min[2f(-\delta)] = \min[2f(\delta)] = 2[\min f(\delta)] = 2\beta,
\end{aligned}$$

where $\beta < 0$, as shown in Figure 13. This implies that there exists a δ^{**} such that $c_1(\delta^{**}) < c_2(\delta^{**})$. Therefore, by the intermediate value theorem, there must be at least two valid values

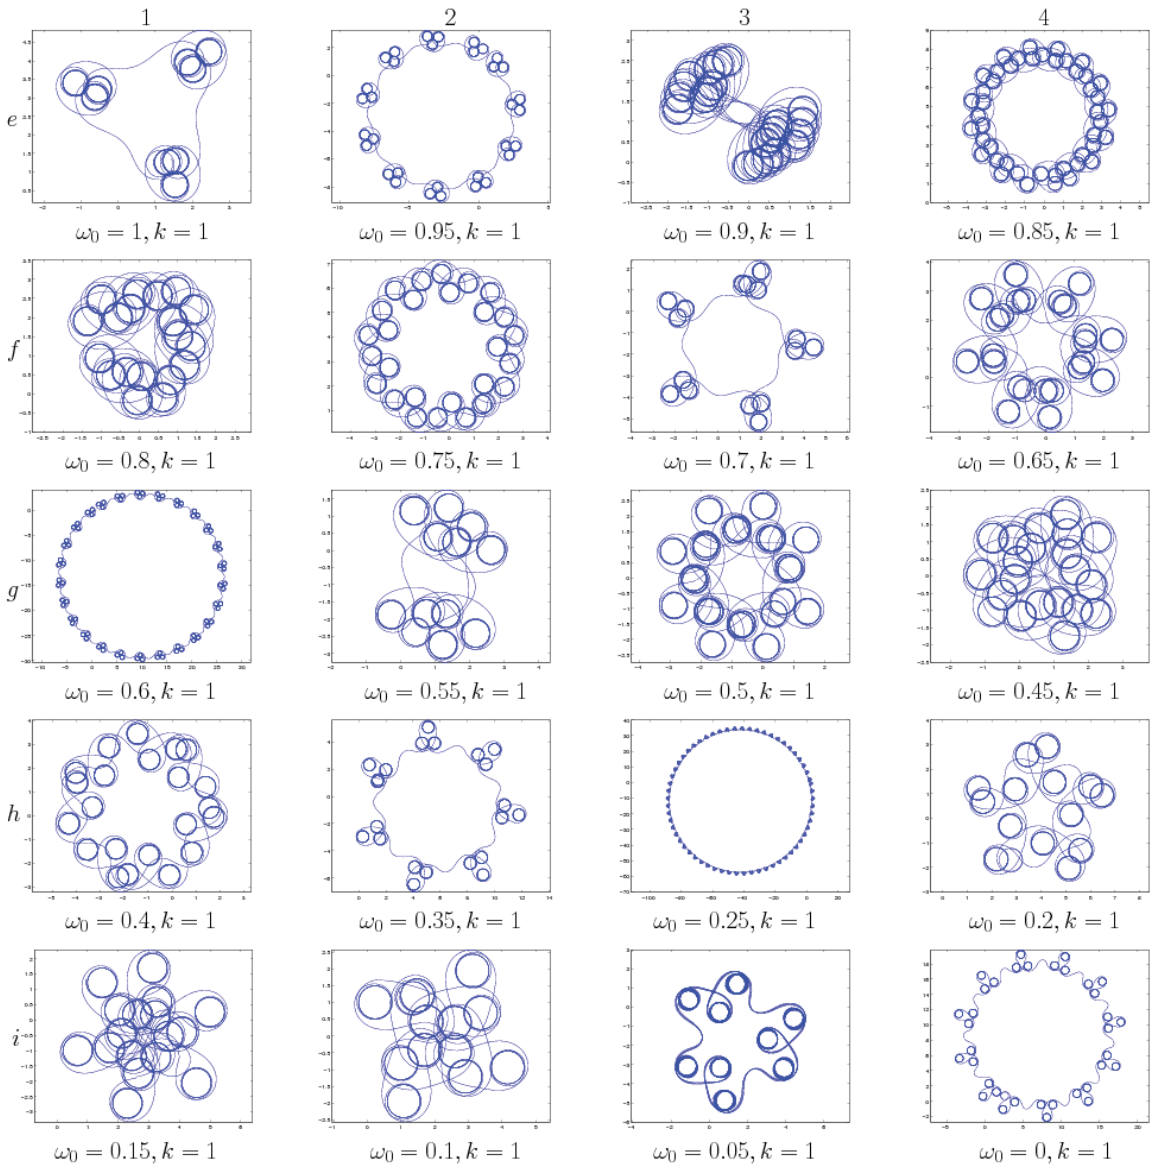

Figure 11. *A continuation of Figure 10: A few example vehicular trajectories for v_1 holding $k = 1$ and varying ω_0 from 1 to 0.*

$\delta^*_{1,2}$ such that $c_1(\delta^*_1) = c_2(\delta^*_1)$ and $c_1(\delta^*_2) = c_2(\delta^*_2)$. Furthermore, all further viable values for δ^* will occur in pairs.

A similar argument can be made to prove the existence of a $\delta^* \in (0, 2\pi)$ if $f(0) = 0$ (corresponding to the existence of an S_3-symmetric fixed point) provided that there exists a $\phi_1 \neq 0$ such that $f(\phi_1) = 0$ and $f'(\phi_1) \neq 0$.

4.2. Example. Using the example coupling function (2.8) with $\mu_1 = 0.1$, $\mu_2 = 1$, $\mu_3 = -0.06$, and $k = 1$, we find that the system has saddle points at $(\psi^*_1, \psi^*_2) = (4.29213, 4.29213)$

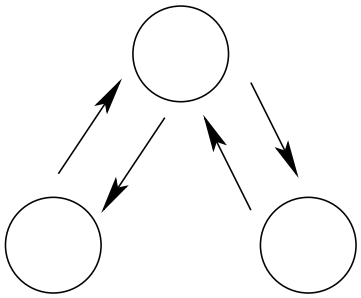

Figure 12. *The Arbiter configuration. Here the arrows indicate the coupling between agents.*

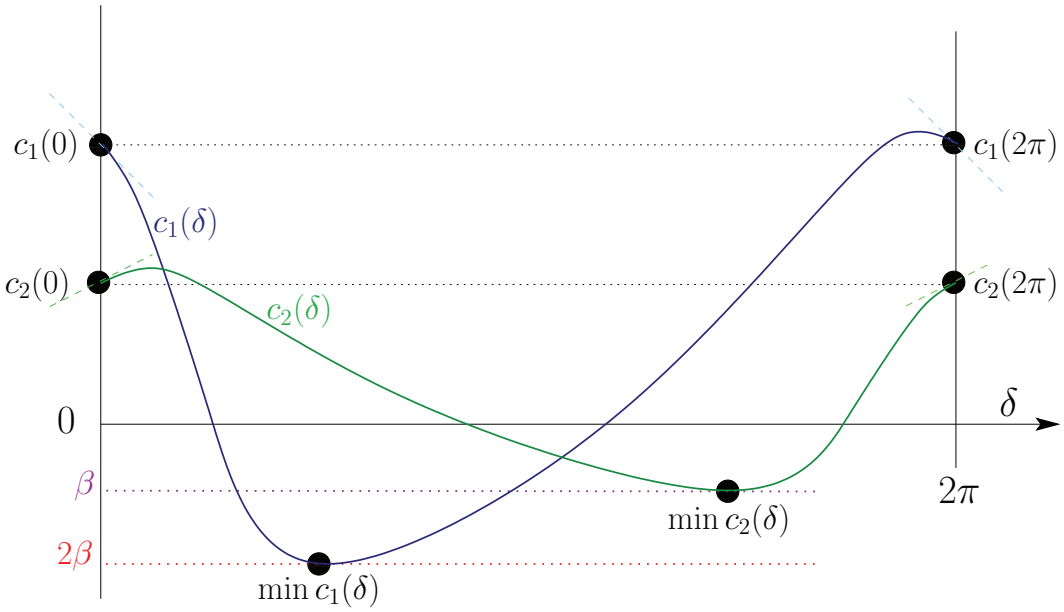

Figure 13. *Illustration of the argument that given the constraints mentioned in the text, there must be at least two possible values for δ^*. Without loss of generality, we can set $c_1(0) > c_2(0) > 0$, which gives $c_1(2\pi) > c_2(2\pi) > 0$ by periodicity. However, by noting that $\min[f(-\delta)] = \min[f(\delta)]$, it is clear that $\min[c_1(\delta)] = 2\min[c_2(\delta)]$. Therefore, $c_1(\delta)$ and $c_2(\delta)$ must cross in at least two points. The points where the two functions cross are viable values for δ^*, and this proves the existence of the $S_2 \times S_1$ solutions.*

and $(1.35235, 1.35235)$, which are guaranteed to exist from the above argument, and spiral sinks at $(\psi_1^*, \psi_2^*) = (4.8432, 1.63105)$ and $(1.63105, 4.8432)$. For these parameters, there are also two symmetry-related stable periodic orbits in the (ψ_1, ψ_2) coordinates; see Figure 14. The vehicular trajectories corresponding to motion along several cycles of one of the stable periodic orbits is shown in Figure 15, which is reminiscent of the trajectories found in section 2.3. For the same reasons as in section 3.2.3, one can also produce a variety of trajectories by varying the values of ω_0 and k, as shown in Figure 16.

We find that at least one stable periodic orbit exists in the (ψ_1, ψ_2) system between the saddle-node bifurcations of limit cycles at $\mu_1 = \pm 0.115681$. (For some parameters, there are two symmetry-related periodic orbits.) Within this range, there are several global bifurcations

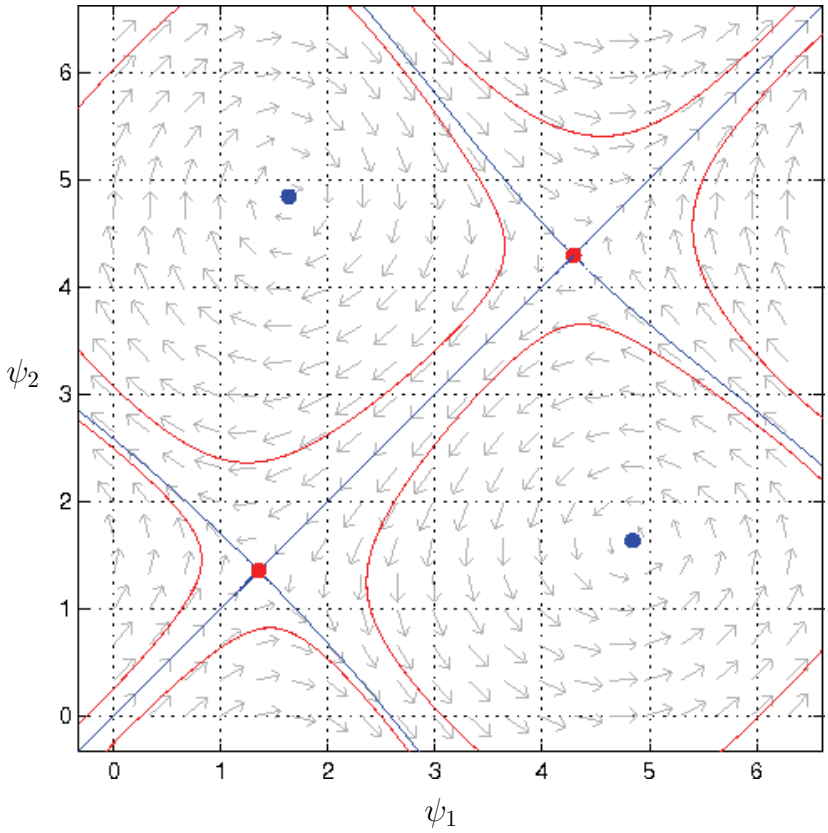

Figure 14. *The (ψ_1, ψ_2) plane for the Arbiter coupling topology with $N = 3$, and coupling function (2.8) with $\mu_1 = 0.1$, $\mu_2 = 1$, $\mu_3 = -0.06$, $\omega_0 = 1$, $k = 1$. The existence of stable periodic orbits suggests that this system may provide interesting patterns of vehicular motion.*

involving the $S_2 \times S_1$ fixed points on the line $\psi_1 = \psi_2$. The details of these bifurcations are outside of the scope of our present study, but we do note that it would be possible to interpret the vehicular motion in terms of visits near and between the fixed points, as was done in section 3.

5. Conclusion. In this paper, we considered a model for vehicle motion coordination developed by Leonard, Paley, and Sepulchre which uses coupled oscillator steering control. We showed that novel trajectories are possible using only the phase controller when coupling functions more general than sinusoidal are considered. Such trajectories are associated with periodic orbits in the steering control subsystem, and the proximity of these periodic orbits to heteroclinic bifurcations allowed a detailed characterization of the properties of the vehicular trajectories.

Similar trajectories are expected to be possible for such systems with $N > 3$ vehicles. An attempt to understand the details of such trajectories would likely benefit from previous studies of phase-locked solutions for coupled oscillator systems with phase-difference coupling [5, 6, 33] and heteroclinic orbits for such systems [3, 16].

The trajectories described in this paper may have applications in sensor area covering

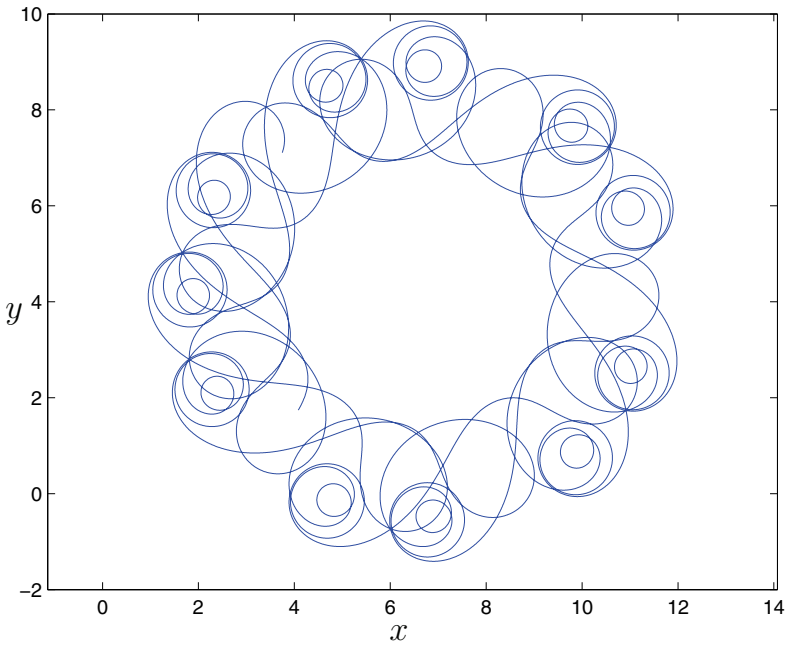

Figure 15. *Motion of v_1 using the Arbiter coupling topology with $N = 3$ corresponding to the motion of the system along a stable periodic orbit in Figure 14.*

problems in which one is particularly interested in certain regions of an annulus in the plane, with the option of either passing through the center or moving along the circumference of the area to be covered. For example, the trajectory shown in 1c of Figure 10 may be useful for the case where one wants agents to carefully patrol four evenly distributed areas as well as check the area in the center of those four areas periodically. If one desires to check sections of a circular area but is not interested in the area in the center of the sections, a trajectory such as 2e of Figure 11 may be appropriate. Should the areas inside the circular area be of higher interest than the perimeter, then a trajectory such as 2n of Figure 16 may be of interest. If one desires to patrol an annulus evenly in sections, a trajectory similar to 4e or 2f of Figure 11 may be useful. Most parameter values provide trajectories where an almost regular polygon-like global trajectory drifts around the center of pattern; thus, over time, the trajectories eventually cover an annulus. An example of this can be found in plot 3e of Figure 11—this is a "polygon" with slightly more than 2 sides, that is drifting around, and will eventually fill out an annulus. These patterns may be useful for applications where it is desirable for a robot patrolling an annulus-shaped space to not only periodically thoroughly investigate subregions of the space, but to also be relatively difficult to predict.

Despite the fact that the system is very stable in the reduced phase space, the trajectories described here are quite sensitive to variations in the parameters of the coupling equations. Should these trajectories prove to be potentially useful for a particular area coverage problem, it may be worthwhile to investigate the use of spacing control, and to make the global behavior robust to uncertainty and perturbations in the parameters.

A Hamiltonian Analogue of the Meandering Transition*

Claudia Wulff†

Abstract. In this paper a Hamiltonian analogue of the well-known meandering transition from rotating waves to modulated rotating and modulated traveling waves in systems with the Euclidean symmetry of the plane is presented. In non-Hamiltonian systems, for example, in spiral wave dynamics, this transition is a Hopf bifurcation in a corotating frame, as external parameters are varied, and modulated traveling waves occur only at certain resonances. In Hamiltonian systems, for example, in systems of point vortices in the plane, the conserved quantities of the system, angular and linear momentum, are natural bifurcation parameters. Depending on the symmetry properties of the momentum map, either modulated traveling waves do not occur, or, in contrast to the dissipative case, modulated traveling waves are the typical scenario near rotating waves, as momentum is varied. Systems with the symmetry group of a sphere and with the Euclidean symmetry group of three-dimensional space are also treated.

Key words. meandering transition, resonance drift, symmetric Hamiltonian systems

1. Introduction.

The meandering transition in spiral wave dynamics is a transition from rigidly rotating to meandering and drifting spiral waves. In symmetry terms, it is a bifurcation from rotating waves to modulated rotating and modulated traveling waves in systems with SE(2)-symmetry. Here SE(2) is the special Euclidean group of motions of the plane. Rotating waves are solutions which become stationary in a corotating frame and are examples of relative equilibria. Modulated rotating and modulated traveling waves are solutions which become periodic in a corotating/comoving frame and are examples of relative periodic orbits (RPOs). In non-Hamiltonian systems, the meandering bifurcation corresponds, in a rotating frame, to a Hopf bifurcation induced by changing an external parameter. Typically the bifurcating relative periodic orbits are modulated rotating waves, and modulated traveling waves occur only at certain resonances. See, for example, [3, 8, 10, 27, 30, 31] and the references therein.

In this paper the first ever analysis of the Hamiltonian analogue of this meandering transition is presented. Examples of Hamiltonian systems where such a transition occurs are rotating point vortices on the plane [1, 2, 21, 25, 29] or rotating rigid bodies in ideal fluids [15]. In a Hamiltonian system it is natural to study the persistence and bifurcation of the rotating wave to nearby momentum levels since the momentum map is a conserved quantity and hence an internal parameter of the system.

The differential equations near Hamiltonian relative equilibria in symmetry-adapted local

coordinates from [26] are used to study the transition from rotating waves to modulated rotating and modulated traveling waves on nearby momentum levels in Hamiltonian systems with SE(2)-symmetry. Thereby a Hamiltonian analogue of the meandering transition of spiral waves is obtained.

It is shown that, depending on the symmetry properties of the momentum map, either modulated traveling waves are typical near rotating waves, as momentum is varied (cf. sections 4.2 and 4.3), or modulated traveling waves do not occur; see section 4.4 and in particular Proposition 4.10. As far as I am aware, for the first time, rotating waves and transitions to relative periodic orbits are continued in the cocycle parameter which determines the symmetry properties of the momentum map. These results hold under conditions which are generically satisfied.

The transition from rotating waves to modulated traveling waves occurring in the meandering transition is an example of resonance drift, as analyzed in [31]; see also [4] and [6]. Resonance drift occurs if there is a discontinuity of the average drift velocities of the bifurcating relative periodic orbits at the relative equilibrium. In the case of the meandering transition it is a discontinuous jump between a rotational and a translational velocity. This phenomenon is also discussed in systems with spherical symmetry SO(3) and in systems with the Euclidean symmetry SE(3) of motions in three-dimensional space; see sections 5.1 and 5.2.

The meandering transition is a transition from relative equilibria to relative periodic orbits. In non-Hamiltonian systems it is a Hopf bifurcation of the symmetry reduced dynamics. The Hamiltonian analogue of a Hopf bifurcation is a Lyapunov center bifurcation. In this paper Lyapunov center bifurcations for the reduced Hamiltonian system on the symplectic slice are proved to obtain families of RPOs nearby elliptic relative equilibria; see Proposition 4.6, Theorems 4.11 (a), 5.1 (b), and 5.2 (c), and Propositions 5.3 (b) and 5.6.

The technically most complicated parts of the paper are the results on bifurcation from relative equilibria to RPOs which lie outside the symplectic leaf of the original equilibrium of the reduced dynamics; see Theorems 4.3, 5.2 (b), and 5.5. Here Lyapunov center type theorems are proved for the symmetry reduced system which is a Poisson system and not a Hamiltonian system. It is shown that in this case resonance drift occurs.

Related results in the literature are the following: Persistence results for generic Hamiltonian relative equilibria and relative periodic orbits of noncompact group actions, extending earlier results for compact symmetry groups, can be found in [32, 33]. See also Ortega and Ratiu [23] and Montaldi and Tokieda [20] and references therein for results on bifurcations of Hamiltonian relative equilibria.

Relative Lyapunov center bifurcations from Hamiltonian relative equilibria with isotropy to RPOs, which lie on nearby energy level sets, have been obtained by Ginzburg and Lerman [9] (see also references therein). Ortega [22] studies persistence of the bifurcating RPOs to nearby energy level sets and to those nearby momentum values which correspond to the isotropy subgroup of the relative equilibrium. Instead, in this article, the group is assumed to act freely, and the main focus is the bifurcation of relative equilibria to RPOs on all nearby momentum level sets.

The paper is organized as follows: In section 2 the meandering transition for dissipative systems is reviewed. In section 3 symmetric Hamiltonian systems are introduced and the equations near relative equilibria from [26] are reviewed. In section 4 a Hamiltonian analogue

of the meandering transition is presented using the equations near Hamiltonian relative equilibria from section 3. First Euclidean symmetric Hamiltonian systems with an equivariant momentum map for the standard coadjoint action are studied. Then systems with Euclidean symmetry for which the momentum map has a cocycle are considered. Finally, in section 5, the Hamiltonian analogue of the meandering transition is discussed for systems with spherical symmetry and for systems with the Euclidean symmetry group of three-dimensional space.

2. Meandering transition for dissipative systems. In this section the notions of relative equilibria and relative periodic orbits of general symmetric differential equations are defined. Suitable symmetry-adapted coordinates near relative equilibria are introduced, and the differential equations are given in these coordinates. Then the results are applied to dissipative systems with the Euclidean symmetry of the plane, and the meandering transition for dissipative systems is reviewed. Note that in this paper the terms "dissipative systems," "non-Hamiltonian systems," and "general systems" are used interchangeably. Most of the material of this section is basically contained in [8, 10, 31]. Only Remark 2.2 (c) is a new result.

2.1. Relative equilibria and relative periodic orbits of general systems. Let us consider an ordinary differential equation on a finite-dimensional manifold $\mathcal{M}$

$$\dot{x}(t) = f(x(t)) \tag{2.1}$$

with flow $\Phi_t(x_0) = x(t; x_0)$, $x(0) = x_0$. Let a finite-dimensional Lie group Γ act properly and smoothly on $\mathcal{M}$. For simplicity it is assumed that the Γ-action is *free*, that is,

$$\Gamma_x = \{\gamma \in \Gamma,\ \ \gamma x = x\} = \{\mathrm{id}\}$$

for all $x \in \mathcal{M}$. The vectorfield (2.1) is taken to be Γ-*equivariant*, i.e.,

$$\gamma f(x) = f(\gamma x) \quad \text{for all } \gamma \in \Gamma.$$

A solution $x(t)$ with initial condition $x(0) = x_0$ lies on a *relative equilibrium* Γx_0 whenever the group orbit Γx_0 is invariant under the flow of (2.1), i.e., if $x(t; x_0) \in \Gamma x_0$ for all t. This means that

$$f(x_0) = \xi_0 x_0 := \left(\frac{\mathrm{d}}{\mathrm{d}s} \exp(s\xi_0).x_0\right)\Big|_{s=0}$$

for some $\xi_0 \in \mathbf{g}$. Here $\mathbf{g} = \mathcal{T}_{\mathrm{id}}\Gamma$ is the Lie algebra of Γ. The element ξ_0 is called the *drift velocity* of the relative equilibrium at x_0. Note that the trajectory through x_0 becomes an equilibium in a frame moving with velocity ξ_0. If ξ_0 is an infinitesimal rotation, then the relative equilibrium is called a *rotating wave* (RW). Note that at the point γx_0 of the relative equilibrium Γx_0 the drift velocity is determined by the equation

$$f(\gamma x_0) = \gamma f(x_0) = \gamma \xi_0 x_0 = (\mathrm{Ad}_\gamma \xi_0) x_0$$

and is therefore given by $\mathrm{Ad}_\gamma \xi_0$. Here $\mathrm{Ad}_\gamma : \mathbf{g} \to \mathbf{g}$ and

$$\mathrm{Ad}_\gamma \eta = \gamma \eta \gamma^{-1}, \quad \mathrm{ad}_\xi \eta = \frac{\mathrm{d}}{\mathrm{d}t} \mathrm{Ad}_{\exp(t\xi)} \eta|_{t=0} = [\xi, \eta], \quad \gamma \in \Gamma,\ \eta, \xi \in \mathbf{g}, \tag{2.2}$$

are the *adjoint action* of Γ and $\mathbf{g}$ and the *infinitesimal adjoint action* of $\mathbf{g}$ on $\mathbf{g}$.

An example of such a finite-dimensional manifold $\mathcal{M}$ with SE(2)-equivariant vectorfield (2.1) on it is the center manifold near a rotating spiral $\mathrm{SE}(2)x_0$ in a reaction-diffusion system; see, e.g., [27]. Here $\mathrm{SE}(2) = \mathrm{SO}(2) \ltimes \mathbb{R}^2$ is the special Euclidean symmetry of rotations and translations in the plane with group multiplication defined in (2.5) below.

By the slice theorem of Palais [24] sufficiently small neighborhoods $\mathcal{U}$ of the group orbit Γx_0 have the bundle structure $\mathcal{U} = \Gamma \times \mathcal{N}$. Here $\mathcal{N} \subseteq \mathcal{T}_{x_0}\mathcal{M}$ is a local section, also called *slice*, transversal to Γx_0 at x_0; see Figure 1.

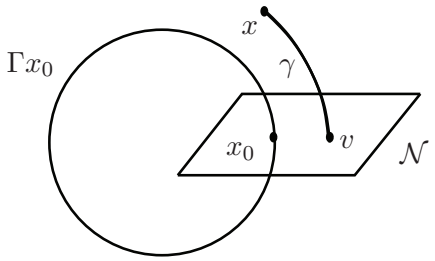

Figure 1. *Palais coordinates near* Γx_0.

To analyze the dynamics near, and bifurcations from, relative equilibria, it has proved very useful to model the flow in a Γ-invariant neighborhood $\mathcal{U}$ of the relative equilibrium by differential equations on the space $\Gamma \times \mathcal{N}$:

$$\dot{\gamma} = \gamma f_\Gamma(v), \quad \dot{v} = f_\mathcal{N}(v), \tag{2.3}$$

where $f_\Gamma : \mathcal{N} \to \mathbf{g}$ and $f_\mathcal{N} : \mathcal{N} \to \mathcal{N}$. Any $x \in \mathcal{U}$ takes the form $x \simeq (\gamma, v) \in \Gamma \times \mathcal{N}$, and the point x_0 corresponds to $x_0 \simeq (\mathrm{id}, 0)$. Then $f_\mathcal{N}(0) = 0$; i.e., the relative equilibrium Γx_0 of (2.1) becomes an equilibrium of the $\dot{v}$-equation. Moreover, $f_\Gamma(0) = \xi_0$. Note that the equations (2.3) have skew-product form: the $\dot{v}$-equation, which is called the *slice equation*, does not depend on the group variable γ. It describes the symmetry-reduced dynamics, whereas the $\dot{\gamma}$-equation describes the drift dynamics on the group Γ. These results are due to Krupa [14] for compact Lie groups and to Fiedler et al. [8] for noncompact Lie groups. For later use, the linearization $L_0 = \mathrm{D}f(x_0) - \xi_0$ of the relative equilibrium Γx_0 at x_0 in the frame moving with the velocity ξ_0 in symmetry-adapted coordinates is

$$L_0 = \begin{pmatrix} \mathrm{ad}_{\xi_0} & \mathrm{D}_v f_\Gamma(0) \\ 0 & \mathrm{D}_v f_\mathcal{N}(0) \end{pmatrix}. \tag{2.4}$$

The point $x_0 \in \mathcal{M}$ lies on a relative periodic orbit $\mathcal{P}$ of (2.1) if $x(t; x_0) = \Phi_t(x_0)$ is periodic in the space of group orbits $\mathcal{M}/\Gamma$. This means that there exist $T_0 > 0$ and $\gamma_0 \in \Gamma$ such that $\Phi_{T_0}(x_0) = \gamma_0 x_0$; see Figure 2. The infimum of the numbers T_0 with this property is the *relative period* of the RPO. The corresponding group element γ_0 is called the *drift symmetry* of the RPO with respect to x_0; cf. [33, 34]. The relative periodic orbit itself is defined to be the submanifold of $\mathcal{M}$ given by

$$\mathcal{P} \;=\; \{\gamma \Phi_t(x_0) \mid \gamma \in \Gamma,\, t \in \mathbb{R}\}.$$

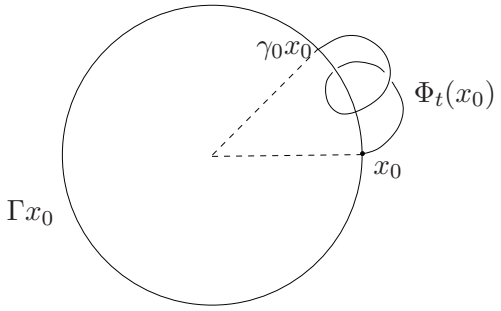

Figure 2. *A relative periodic orbit.*

If γ_0 is a translation, the RPO is called a *modulated traveling wave* (MTW); if γ_0 is a nonvanishing translation, it is a proper modulated traveling wave. If γ_0 is a (nonvanishing) rotation, the RPO is called a (proper) *modulated rotating wave* (MRW); see Figure 3. Any $\xi_0 \in \mathbf{g}$ such that $\gamma_0 = \exp(T_0\xi_0)$ is called an *average drift velocity* of the RPO at x_0. Note that the trajectory through x_0 becomes T_0-periodic in a frame moving with velocity ξ_0.

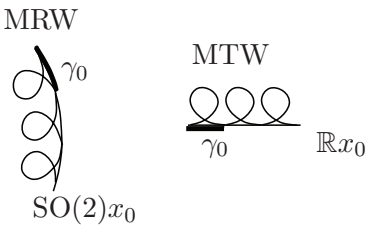

Figure 3. *Drift symmetries of modulated rotating and modulated traveling waves.*

2.2. The meandering transition for dissipative systems. Let Γ be the Euclidean symmetry of the plane consisting of rotations and translations

$$\Gamma = \mathrm{SE}(2) = \mathrm{SO}(2) \ltimes \mathbb{R}^2,$$

where the semidirect product is defined as

$$(\phi_1, a_1)(\phi_2, a_2) = (\phi_1 + \phi_2, a_1 + R_{\phi_1} a_2), \qquad \phi_i \in \mathrm{SO}(2),\ a_i \in \mathbb{R}^2,\ i = 1, 2. \tag{2.5}$$

Here R_ϕ is a rotation by ϕ in $\mathbb{R}^2$. Let us assume that the relative equilibrium $\mathrm{SE}(2)x_0$ is a rotating wave with rotation frequency ω_0^{rot}. Then the $\dot{\gamma}$-equation in (2.3), which models the drift dynamics near the rotating wave, takes the following form:

$$\dot{\phi} = f_\phi(v), \quad \dot{a} = R_\phi f_a(v). \tag{2.6}$$

Moreover, $f_\phi(0) = \omega_0^{\mathrm{rot}}$ is the rotation frequency of the rotating wave and $f_a(0) = 0$. As in the general case, the rotating wave $\mathrm{SE}(2)x_0$ becomes an equilibrium of the slice equation:

$f_{\mathcal{N}}(0) = 0$. These equations were first formulated by Barkley [3] and then derived by Fiedler et al. [8] and Golubitsky, LeBlanc, and Melbourne [10].

Let us now assume that both $f_{\mathcal{N}}(\cdot, \mu)$ and $f_\Gamma(\cdot, \mu) = (f_\phi(\cdot, \mu), f_a(\cdot, \mu))$ depend on an external parameter $\mu \in \mathbb{R}$. In a meandering transition the symmetry-reduced system undergoes a Hopf bifurcation. Suppose that this bifurcation occurs for $\mu = 0$; let $\pm i\omega_0^{\mathrm{Hopf}}$ be the Hopf eigenvalues of $\mathrm{D}_v f_{\mathcal{N}}(0, 0)$. Assume that $\pm i\omega_0^{\mathrm{Hopf}}$ are simple eigenvalues and that $\mathrm{D}f_{\mathcal{N}}(0, 0)$ has no other eigenvalues in $i\omega_0^{\mathrm{Hopf}}\mathbb{Z}$. Let $v_{\mathrm{RW}}(\mu) \approx 0$ be the equilibrium of $f_{\mathcal{N}}(\cdot, \mu)$, $\mu \approx 0$, such that $v_{\mathrm{RW}}(\mu)$ is smooth in μ and $v_{\mathrm{RW}}(0) = 0$. Then $x_{\mathrm{RW}}(\mu) \simeq (\mathrm{id}, v_{\mathrm{RW}}(\mu))$ lies on a rotating wave of (2.1). Let $\lambda(\mu)$ be the eigenvalue of $\mathrm{D}_v f_{\mathcal{N}}(v_{\mathrm{RW}}(\mu), \mu)$ such that $\lambda(\mu)$ is smooth in μ and $\lambda(0) = i\omega_0^{\mathrm{Hopf}}$. Assume that the usual transversality condition

$$\left(\mathrm{Re}\,\frac{\partial}{\partial \mu}\lambda(\mu)\right)\Big|_{\mu=0} \neq 0 \tag{2.7}$$

for a Hopf bifurcation is satisfied. Then there is a smooth path $v(s)$, $s \geq 0$, of points on periodic solutions of the $\dot{v}$-equation with period $T(s) \approx T_0^{\mathrm{Hopf}} = 2\pi/\omega_0^{\mathrm{Hopf}}$ and parameter $\mu(s)$ such that $v(0) = 0$, $T(0) = T_0^{\mathrm{Hopf}}$, $\mu(0) = 0$.

The periodic orbit through $v(s)$ of the slice equation corresponds to a relative periodic orbit $\mathcal{P}(s)$ through $x(s) \simeq (\mathrm{id}, v(s))$ of the original ODE (2.1) with drift symmetry $\gamma(s) = (\phi(s), a(s))$. Here $\phi(s)$ and $a(s)$ are obtained by integrating (2.6) from 0 to $T(s)$. There are two cases:

(a) If $\phi(s) \neq 0 \bmod 2\pi$, then $x(s)$ lies on a modulated rotating wave, and this is the typical case.

(b) If $\phi(s) = 0 \bmod 2\pi$, then $x(s)$ lies on a modulated traveling wave.

Note that

$$\phi(s) \approx \omega_0^{\mathrm{rot}} T_0^{\mathrm{Hopf}} = \frac{\omega_0^{\mathrm{rot}}}{\omega_0^{\mathrm{Hopf}}} 2\pi.$$

Hence case (b) occurs if $\omega_0^{\mathrm{rot}}/\omega_0^{\mathrm{Hopf}} \in \mathbb{Z}$, i.e., if there is a resonance between the rotation frequency ω_0^{rot} and the Hopf frequency ω_0^{Hopf} of the rotating wave Γx_0; see [3, 8, 10, 31]. In the case of two real parameters $\mu \in \mathbb{R}^2$ the following proposition holds true; see also Figure 4.

Proposition 2.1 (see [31, Example 3.6]). *Let $\mu \in \mathbb{R}^2$, and let $\mathrm{SE}(2)x_0$ be a rotating wave at $\mu = 0$ at which a resonant Hopf bifurcation occurs: $\omega_0^{\mathrm{rot}}/\omega_0^{\mathrm{Hopf}} \in \mathbb{Z}$. Then under some nondegeneracy conditions (detailed in the proof below) a path $\mathcal{P}_{\mathrm{MTW}}(s)$, $s \geq 0$, of modulated traveling waves at parameters $\mu_{\mathrm{MTW}}(s)$ bifurcates from the rotating wave $\mathrm{SE}(2)x_0$.*

Proof. Denote the rotation frequency of the rotating wave $\mathrm{SE}(2)x_{\mathrm{RW}}(\mu)$ at parameter μ by $\omega^{\mathrm{rot}}(\mu)$. The transversality condition (2.7) for Hopf bifurcation ensures that coordinates in parameter space $\mu \in \mathbb{R}^2$ can be chosen such that $\mu_1 = 0$ is the Hopf line near $\mu = 0$, i.e., such that $\lambda(0, \mu_2) = i\omega^{\mathrm{Hopf}}(\mu_2)$ for some smooth function $\omega^{\mathrm{Hopf}}(\mu_2)$ with $\omega^{\mathrm{Hopf}}(0) = \omega_0^{\mathrm{Hopf}}$. Periodic orbits bifurcating from this Hopf line are then parametrized by μ_2 and $s \geq 0$. Let $v(s, \mu_2)$ lie on a periodic orbit with parameters s, μ_2 such that $v(s, \mu_2)$ is smooth in its parameters and $v(0, \mu_2) = v_{\mathrm{RW}}(0, \mu_2)$. Let $T(s, \mu_2)$ be the period of the periodic orbit through $v(s, \mu_2)$. Modulated traveling waves satisfy $F(s, \mu_2) = \phi(T(s, \mu_2)) = 0$. This equation can be solved near 0 for $\mu_2(s)$ by the implicit function theorem if $\frac{\partial F}{\partial \mu_2}(0) \neq 0$. This condition holds

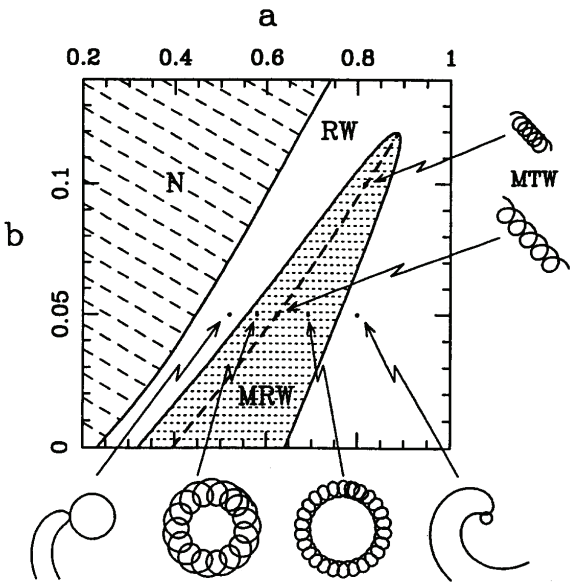

Figure 4. *Phase diagram for the spiral wave dynamics for a reaction-diffusion system depending on the parameters a, b. Reprinted Figure 1 from [3] with permission, copyright 1994 by the American Physical Society.*[1] *Shown are regions containing N: no spiral waves; RW: stable rigidly rotating waves; MRW: modulated rotating waves; MTW: modulated traveling waves (dashed curve). Spiral tip paths illustrate states at six points. Small portions of spiral waves are shown for the two rotating wave cases.*

true if the nondegeneracy condition

$$\frac{\partial}{\partial \mu_2}\left(\frac{\omega^{\mathrm{rot}}(\mu_2)}{\omega^{\mathrm{Hopf}}(\mu_2)}\right)\Big|_{\mu_2=0} \neq 0 \tag{2.8}$$

is satisfied. Then $v(s, \mu_2(s))$ lies on modulated traveling wave $\mathcal{P}_{\mathrm{MTW}}(s)$. ■

Remarks 2.2. (a) In [31] (see also [6] for compact groups) resonances of the form $\omega_\Gamma/\omega_\mathcal{N} = k \in \mathbb{Z}\backslash\{0\}$ between a nonvanishing imaginary eigenvalue $\pm i\omega_\Gamma$ of ad_{ξ_0} and an eigenvalue $\pm i\omega_\mathcal{N}$ of $\mathrm{D}_v f_\mathcal{N}(0)$ are shown to be necessary for *resonance drift* to occur. Resonance drift means that RPOs $\mathcal{P}(s)$ bifurcate with average drift velocities $\xi(s)$ at $x(s) \in \mathcal{P}(s)$ which cannot be chosen to converge to the drift velocity ξ_0 of the relative equilibrium, i.e., $x(s) \to x_0$ as $s \to 0$, but $\lim_{s\to 0} \xi(s) \neq \xi_0$. From the form of the linearization $L_0 = \mathrm{D}f(x_0) - \xi_0$ about a relative equilibrium Γx_0 in a corotating frame (see (2.4)), it follows that resonance drift is caused by resonances between drift dynamics and the symmetry-reduced dynamics. In Proposition 2.1 above, resonance drift occurs with $\omega_\Gamma = \omega_0^{\mathrm{rot}}$ and $\omega_\mathcal{N} = \omega_0^{\mathrm{Hopf}}$. Proposition 2.1 is a special case of [31, Proposition 3.4], which treats resonance drift for general Lie groups Γ.

(b) In the case of spherical symmetry $\Gamma = \mathrm{SO}(3)$ modeling, for example, rotating spiral waves of reaction-diffusion systems on the sphere, resonance drift caused by resonant Hopf

[1]Readers may view, browse, and/or download material for temporary copying purposes only, provided these uses are for noncommercial personal purposes. bifurcation has been studied in [31, 7, 4]. In this case generically there is a path $(x(s), \mu(s))$ in two-dimensional parameter space $\mu(s) \in \mathbb{R}^2$ such that $\mathrm{SO}(3)x(s)$ is a modulated rotating wave at parameter $\mu(s)$ with an average drift velocity $\xi(s)$ at $x(s)$ which is orthogonal to the drift velocity $\xi_0 \in \mathrm{so}(3) \in \mathcal{T}_{\mathrm{id}}\mathrm{SO}(3)$ of the rotating wave $\mathrm{SO}(3)x_0$ at $x_0 = \lim_{s\to 0} x(s)$. The proof of this result is very similar to the proof of Proposition 2.1: For any $R \in \mathrm{SO}(3)$ write

$$R = \exp\left(\sum_{i=1}^{3} \phi_i \xi_i\right). \tag{2.9}$$

Here ξ_i, $i = 1, 2, 3$, are infinitesimal rotations such that $\exp(\phi_i \xi_i)$, $i = 1, 2, 3$, is a rotation by the angle ϕ_i around the e_i axis (often $\mathrm{so}(3)$ is identified with $\mathbb{R}^3$ and ξ_i with e_i, $i = 1, 2, 3$). Assume, as before, that the Hopf line is at $\mu_1 = 0$. Let $R(s, \mu_2)$ be the drift symmetry of the modulated rotating wave at $x(s, \mu_2)$. Assume, without loss of generality, that the rotating wave through $x_{\mathrm{RW}}(\mu)$ has a rotation velocity $\xi_{\mathrm{RW}}(\mu) || \xi_3$ so that $\xi_{\mathrm{RW}}(\mu) = \omega^{\mathrm{rot}}(\mu) e_3$. Then the modulated rotating waves to be found satisfy the equation $F(s, \mu_2) = \phi_3(s, \mu_2) = 0$. This equation can be solved if (2.8) holds. The bifurcating modulated rotating waves $\mathcal{P}(s)$ have average drift velocities in the (x_1, x_2)-plane. For a Hamiltonian analogue see section 5.1.

(c) Resonance drift also occurs for relative equilibria of systems with the Euclidean symmetry group $\Gamma = \mathrm{SE}(3) = \mathrm{SO}(3) \ltimes \mathbb{R}^3$ of rotations and translations in three-dimensional space; cf. [5]. An example would be a Hopf bifurcation from a rigidly rotating and translating scroll wave $\mathrm{SE}(3)x_0$ of a reaction-diffusion system on $\mathbb{R}^3$; see, e.g., [30]. The group multiplication on $\Gamma = \mathrm{SE}(3) = \mathrm{SO}(3) \ltimes \mathbb{R}^3$ is analogous to (2.5): For $(R_1, a_1), (R_2, a_2) \in \mathrm{SO}(3) \ltimes \mathbb{R}^3$ it is given by

$$(R_1, a_1)(R_2, a_2) = (R_1 R_2, a_1 + R_1 a_2), \qquad R_1, R_2 \in \mathrm{SO}(3),\ a_1, a_2 \in \mathbb{R}^3.$$

Note that (R, a) is a rotation around the rotation axis of R about the point

$$c = (\mathrm{id} - R)^+ a \in \mathbb{R}^3$$

combined with a translation along the axis of R. Here A^+ denotes the Moore–Penrose pseudoinverse of A; i.e., $x = A^+ b$ satisfies $\|Ax - b\|_2 = \min$, $A \in \mathrm{Mat}(n)$, $x, b \in \mathbb{R}^n$. Let $\xi_0 = (\xi_0^r, \xi_0^a)$ be the drift velocity of the relative equilibrium $\mathrm{SE}(3)x_0$ at x_0 and assume that $\xi_0^r \neq 0$. Without loss of generality, choose x_0 in its group orbit such that $\xi_0^r \in \mathrm{so}(3) \simeq \mathbb{R}^3$ (see part (b) for this identification) is parallel to ξ_0^a and to e_3, and write $\xi_0^r = \omega_0^{\mathrm{rot}} e_3$, where $\omega_0^{\mathrm{rot}} \neq 0$. Align the family of relative equilibria $\mathrm{SE}(3)x_{\mathrm{RE}}(\mu)$ with $x_{\mathrm{RE}}(0) = x_0$ such that their drift velocity $\xi_{\mathrm{RE}}(\mu)$ at $x_{\mathrm{RE}}(\mu)$ also satisfies $\xi_{\mathrm{RE}}^r(\mu) = \omega^{\mathrm{rot}}(\mu) e_3$. If the Hopf frequency ω_0^{Hopf} satisfies $\omega_0^{\mathrm{rot}}/\omega_0^{\mathrm{Hopf}} \in \mathbb{Z}$ and this resonance is passed transversely as in (2.8), then, as in part (b), there is a curve $\mathcal{P}(s)$ of relative periodic orbits through $x(s) \approx x_0$ with drift symmetry $\gamma(s) = (R(s), a(s))$ at $x(s)$ satisfying $\phi_3(s) = 0 \bmod 2\pi$. Here $R(s)$ is determined by $\phi_i(s)$, $i = 1, 2, 3$, as in (2.9). These RPOs rotate and translate along a vector in the (x_1, x_2)-plane. The point around which they rotate approaches infinity as $s \to 0$.

(d) Note that for the groups $\Gamma = \mathrm{SE}(2)$, $\Gamma = \mathrm{SO}(3)$, and $\Gamma = \mathrm{SE}(3)$ considered above, resonance drift can occur only near relative equilibria with nonvanishing rotational velocity. Otherwise, the linear map ad_{ξ_0} has no eigenvalues in $\mathrm{i}\mathbb{R}\backslash\{0\}$, but this is necessary for resonance drift; cf. part (a) and [31].

3. Dynamics near Hamiltonian relative equilibria. As in the dissipative case, the meandering transition in Hamiltonian systems is studied by analyzing the equations near relative equilibria (2.3). Therefore, in this section symmetric Hamiltonian systems and the structure of the equations (2.3) for Hamiltonian systems are reviewed. Then these results are applied to Hamiltonian systems with Euclidean symmetry for later use in the analysis of the Hamiltonian meandering transition. Most of the material of this section is taken from [12, 18, 26, 28].

3.1. Symmetric Hamiltonian systems. In this section a brief introduction to symmetric Hamiltonian differential equations is given (see, e.g., [12, 18] for more details). The starting point is a Hamiltonian ordinary differential equation on a smooth finite-dimensional symplectic manifold $\mathcal{M}$ with a symplectic form (i.e., a nondegenerate, closed 2-form) Ω_x, $x \in \mathcal{M}$. A Hamiltonian vector field

$$\dot{x} = f_H(x) \tag{3.1}$$

is generated by a smooth function (the *Hamiltonian*) $H : \mathcal{M} \mapsto \mathbb{R}$ via the relationship

$$\Omega_x(f_H(x), v) = \mathrm{D}H(x)v, \qquad x \in \mathcal{M},\ v \in \mathcal{T}_x\mathcal{M}. \tag{3.2}$$

Example 3.1. The simplest example is a Hamiltonian system

$$\dot{x} = \mathbb{J}\mathrm{D}_x H(x)$$

on $\mathcal{M} = \mathbb{R}^{2n}$, where

$$\mathbb{J} = \begin{pmatrix} 0 & \mathrm{id} \\ -\mathrm{id} & 0 \end{pmatrix}$$

and $H : \mathcal{M} \to \mathbb{R}$ is a smooth Hamiltonian. Then the symplectic form Ω is the standard symplectic form given by $\Omega(u, v) = \langle \mathbb{J}^{-1}u, v\rangle$, and $\mathbb{J}$ is called the symplectic structure matrix. By the Darboux theorem (see, e.g., [18]), locally every Hamiltonian system has this form in suitable coordinates.

Let us assume that a finite-dimensional Lie group Γ acts *symplectically* on $\mathcal{M}$, i.e., that

$$\Omega_{\gamma x}(\gamma u, \gamma v) = \Omega_x(u, v) \qquad \text{for all}\ \ x \in \mathcal{M},\ \ \gamma \in \Gamma,\ \ u, v \in \mathcal{T}_x\mathcal{M}.$$

If H is invariant under the action of Γ, then the vector field f_H is Γ-equivariant.

Let $\mathbf{g}^*$ denote the dual of the Lie algebra $\mathbf{g}$ of Γ. By Noether's theorem, for each continuous symmetry $\xi \in \mathbf{g}$ locally there is a conserved quantity $\mathbf{J}(\xi)(\cdot)$ of (3.1). The function $\mathbf{J}(\xi)$ is linear in ξ, so that $\mathbf{J}$ maps into $\mathbf{g}^*$ (see, e.g., [18]). It is assumed that $\mathbf{J}$ exists globally on $\mathcal{M}$.

Example 3.2. The dynamics of N point vortices $(z_1, \dots, z_N) \in \mathbb{R}^{2N}$, $z_j = (x_j, y_j)$, $j = 1, \dots, N$, on the plane is given by the following Hamiltonian system [1, 2, 21]:

$$k_i\dot{x}_i = \frac{\partial H}{\partial y_i}, \quad k_i\dot{y}_i = -\frac{\partial H}{\partial x_i}, \quad i = 1, \dots, N, \tag{3.3}$$

where $k_i \neq 0$, $k = 1, \dots, N$. The Hamiltonian H

$$H(z_1, \dots, z_N) = -\frac{1}{\pi}\sum_{\substack{i,j=0 \\ i<j}}^{N} k_i k_j \ln|z_i - z_j|$$

of (3.3) is invariant under the action of the special Euclidean group of the plane $\Gamma = \mathrm{SE}(2) = \mathrm{SO}(2) \ltimes \mathbb{R}^2$ on $\mathbb{R}^{2N}$, given by

$$(R_\varphi, a) \cdot (z_1, \dots, z_N) := (R_\varphi z_1 + a, \dots, R_\varphi z_N + a)$$

for $R_\varphi \in \mathrm{SO}(2)$ and $a \in \mathbb{R}^2$. The symplectic form

$$\Omega(z_1, \dots, z_N) = \sum_{i=1}^{N} k_i \mathrm{d}x_i \wedge \mathrm{d}y_i$$

is SE(2)-invariant. The Hamiltonian system (3.3) can be obtained from Euler's equations for ideal fluids by modeling the point vortices as δ-distributions; see, e.g., [2]. In this example the space of momenta is $\mathbf{g}^* = \mathrm{se}(2)^* = \mathrm{so}(2)^* \oplus (\mathbb{R}^2)^*$. By Noether's theorem, $\mathbf{J}(x) = (\mathbf{J}^\phi(x), \mathbf{J}^a(x))$ is conserved. Here the angular momentum $\mathbf{J}^\phi$ and linear momentum $\mathbf{J}^a = (\mathbf{J}^{a_1}, \mathbf{J}^{a_2})$ are given by

$$\mathbf{J}^\phi(x) = -\frac{1}{2}\sum_{i=1}^{N} k_i |z_i|^2, \quad \mathbf{J}^{a_1} = \sum_{i=1}^{N} k_i y_i, \quad \mathbf{J}^{a_2} = -\sum_{i=1}^{N} k_i x_i. \tag{3.4}$$

In the following transitions from relative equilibria to relative periodic orbits are studied when the conserved quantities angular and linear momentums are varied. In contrast to dissipative systems, external parameters are not needed for the study of bifurcations. These transitions are studied by analyzing the symmetry-reduced equations (2.3) for Hamiltonian systems. As in the general case (see section 2.1), the reduction by the symmetry group is achieved by transforming the dynamics into a comoving frame. As a consequence, in the symmetry-reduced system the momentum is moving with the velocity of the comoving frame and might not be conserved anymore. Therefore, to compute the reduced system in the Hamiltonian case, first the action of the symmetry group on the space of momenta is investigated.

3.2. Symmetries of momentum maps. Let us assume that $\mathbf{J}$ commutes with $\gamma \in \Gamma$,

$$\mathbf{J}(\gamma x) = \gamma \mathbf{J}(x), \quad \gamma \in \Gamma, \tag{3.5}$$

and, unless otherwise stated, that the action on momentum space $\mathbf{g}^*$ is the coadjoint action, so that the momentum map is Ad^*-equivariant:

$$\gamma \mathbf{J}(x) = (\mathrm{Ad}^*_\gamma)^{-1} \mathbf{J}(x), \quad \gamma \in \Gamma. \tag{3.6}$$

The *coadjoint action* of Γ on $\mathbf{g}^*$ is given by $\gamma\mu := (\mathrm{Ad}^*_\gamma)^{-1}\mu$, where $\mathrm{Ad}_\gamma : \mathbf{g} \to \mathbf{g}$ from (2.2) is the adjoint action. The *infinitesimal coadjoint action* of $\mathbf{g}$ on $\mathbf{g}^*$ is defined by

$$\xi\mu = -\mathrm{ad}^*_\xi \mu, \tag{3.7}$$

with ad_ξ as in (2.2). The *isotropy subgroup* of $\mu \in \mathbf{g}^*$ is denoted by

$$\Gamma_\mu = \{\gamma \in \Gamma,\ \mathrm{Ad}^*_\gamma \mu = \mu\}$$

and its Lie algebra by $\mathbf{g}_\mu$.

Example 3.3. As an example the adjoint and coadjoint action for the Euclidean group are computed. They are needed later for the computation of the drift dynamics near Hamiltonian rotating waves.

Let $\gamma = (\phi, a)$, $\hat{\gamma} = (\hat{\phi}, \hat{a})$. Then

$$\begin{aligned}\gamma\hat{\gamma}\gamma^{-1} &= (\phi, a)(\hat{\phi}, \hat{a})(\phi, a)^{-1} = (\phi + \hat{\phi}, R_\phi \hat{a} + a)(\phi, a)^{-1} \\ &= (\phi + \hat{\phi}, R_\phi \hat{a} + a)(-\phi, -R_{-\phi} a) = (\hat{\phi}, -R_{\hat{\phi}} a + R_\phi \hat{a} + a) \\ &= (\hat{\phi}, R_\phi \hat{a} + (\mathrm{id} - R_{\hat{\phi}}) a).\end{aligned}$$

Letting $\hat{\phi} = \xi^\phi \epsilon$ and $\hat{a} = \xi^a \epsilon$ and differentiating with respect to ϵ at $\epsilon = 0$, one gets, with $\xi = (\xi^\phi, \xi^a) = (\xi^\phi, \xi^a_1, \xi^a_2) \in \mathbb{R}^3$,

$$\mathrm{Ad}_\gamma \xi = \gamma \xi \gamma^{-1} = (\phi, a)(\xi^\phi, \xi^a)(\phi, a)^{-1} = (\xi^\phi, (R_\phi \xi^a)_1 + \xi^\phi a_2, (R_\phi \xi^a)_2 - \xi^\phi a_1).$$

Using $\mathrm{ad}_\xi = \frac{\mathrm{d}}{\mathrm{d}t} \mathrm{Ad}_{\exp(t\xi)}|_{t=0}$, the adjoint actions of SE(2) on se(2) and the infinitesimal adjoint action of se(2) on se(2) are obtained:

$$\mathrm{Ad}_\gamma = \begin{pmatrix} 1 & 0 & 0 \\ a_2 & \cos\phi & -\sin\phi \\ -a_1 & \sin\phi & \cos\phi \end{pmatrix}, \quad \mathrm{ad}_\xi = \begin{pmatrix} 0 & 0 & 0 \\ \xi^a_2 & 0 & -\xi^\phi \\ -\xi^a_1 & \xi^\phi & 0 \end{pmatrix}. \tag{3.8}$$

The coadjoint action of SE(2) and se(2) and the infinitesimal coadjoint action of se(2) on se(2)* are obtained by transposing and inverting Ad_γ and by transposition and multiplication by -1 of ad_ξ:

$$(\mathrm{Ad}^*_\gamma)^{-1} = \begin{pmatrix} 1 & -(R_{-\phi} a)_2 & (R_{-\phi} a)_1 \\ 0 & \cos\phi & -\sin\phi \\ 0 & \sin\phi & \cos\phi \end{pmatrix}, \quad -\mathrm{ad}^*_\xi = \begin{pmatrix} 0 & -\xi^a_2 & \xi^a_1 \\ 0 & 0 & -\xi^\phi \\ 0 & \xi^\phi & 0 \end{pmatrix}. \tag{3.9}$$

From these equations it can be seen that the isotropy subgroup Γ_μ of $\mu \in \mathrm{se}(2)^*$ is $\Gamma_\mu = \Gamma = \mathrm{SE}(2)$ if and only if $\mu^a = 0$ and that $\Gamma_\mu \simeq \mathbb{R}$ for $\mu^a \neq 0$.

Remark 3.4. In the case of zero total circulation $\mathcal{K} := \sum_{i=1}^N k_i = 0$ the momentum map $\mathbf{J}$ for the planar vortex dynamics from (3.4) is Ad*-equivariant (see [2]); but, if $\mathcal{K} \neq 0$, then, instead of (3.6), the equivariance condition (3.5) now holds for the action

$$\gamma \cdot_\kappa \mu := \mathrm{Ad}^*_{\gamma^{-1}} \mu + \kappa(\gamma) \tag{3.10}$$

of Γ on $\mathbf{g}^*$. Here

$$\kappa(\phi, a) = \mathcal{K}(-\tfrac{1}{2}|a|^2, a_2, -a_1) \in \mathrm{se}(2)^* \tag{3.11}$$

is called a *cocycle*; see [18]. In other words, (3.5) now becomes

$$\mathbf{J}(\gamma x) = \gamma \cdot_\kappa \mathbf{J}(x) \quad \text{for all} \quad \gamma \in \Gamma. \tag{3.12}$$

The *infinitesimal cocycle* $K : \mathbf{g} \times \mathbf{g} \to \mathbb{R}$ corresponding to the cocycle κ is defined as

$$K(\xi) = \frac{\mathrm{d}}{\mathrm{d}t}\kappa(e^{t\xi})|_{t=0} \in \mathbf{g}^*,$$

and in this case it is given by

$$K(\xi,\eta) = \mathcal{K}\left\langle \xi^a, \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right) \eta_a \right\rangle = \mathcal{K}(-\xi_1^a\eta_2^a + \xi_2^a\eta_1^a). \tag{3.13}$$

The infinitesimal action of the Lie algebra $\mathbf{g}$ of Γ on $\mathbf{g}^*$ is defined as

$$\xi \cdot_K \mu = \frac{\mathrm{d}}{\mathrm{d}t}\exp(t\xi) \cdot_\kappa \mu|_{t=0} = -\mathrm{ad}^*_\xi\mu + K(\xi). \tag{3.14}$$

The isotropy subgroup of $\mu \in \mathbf{g}^*$ with respect to the cocycle action (3.10) is denoted by Γ^κ_μ. Its Lie algebra is denoted by $\mathbf{g}^K_\mu = \mathcal{T}_{\mathrm{id}}\Gamma^\kappa_\mu$. For later use, note that $\gamma = (\phi, a) \in \Gamma^\kappa_\mu$ for $\mu \in \mathrm{se}(2)^*$ if and only if

$$(R_\phi - \mathrm{id})\mu^a = \mathcal{K}\begin{pmatrix} -a_2 \\ a_1 \end{pmatrix}. \tag{3.15}$$

Hence for a nonvanishing cocycle the isotropy subgroup of every $\mu \in \mathbf{g}^*$ is conjugate to $\mathrm{SO}(2)$.

Let x_0 lie on a relative equilibrium Γx_0 with drift velocity $\xi_0 \in \mathbf{g}$ at x_0, so that $\Phi_t(x_0) = \exp(t\xi_0)x_0$. Since momentum is conserved,

$$\mu_0 = \mathbf{J}(x_0) = \mathbf{J}(\Phi_t(x_0)) = \mathbf{J}(\exp(t\xi_0)x_0) = \exp(t\xi_0)\mu_0,$$

and therefore μ_0 is fixed by ξ_0:

$$\xi_0\mu_0 = 0. \tag{3.16}$$

Such pairs $(\xi, \mu) \in \mathbf{g} \oplus \mathbf{g}^*$ are called *velocity-momentum pairs*. Note that the action of ξ_0 on μ_0 in (3.16) is the infinitesimal coadjoint action (3.7), or the infinitesimal action with cocycle (3.14), depending on the symmetry property of the momentum map.

Similarly, if $x_0 = \gamma_0^{-1}\Phi_{T_0}(x_0)$ lies on a relative periodic orbit with drift symmetry γ_0 and momentum $\mu_0 = \mathbf{J}(x_0)$, then μ_0 is fixed by γ_0:

$$\gamma_0\mu_0 = \mu_0. \tag{3.17}$$

Such pairs $(\gamma, \mu) \in \Gamma \times \mathbf{g}^*$ are called *drift-momentum pairs*.

3.3. Dynamics near Hamiltonian relative equilibria. For a symplectic manifold $\mathcal{M}$ with Ad^*-equivariant momentum map the normal space $\mathcal{N}$ to the group orbit Γx_0 at $x_0 \in \mathcal{M}$ from section 2.1 can be decomposed as

$$\mathcal{M}/\Gamma \simeq \mathcal{N} \;=\; \mathcal{N}_0 \oplus \mathcal{N}_1 \;\cong\; \mathbf{g}^*_{\mu_0} \oplus \mathcal{N}_1.$$

Here

$$\mathbf{g}_{\mu_0} = \mathcal{T}_{\mathrm{id}}\Gamma_{\mu_0} = \{\xi \in \mathbf{g} : \mathrm{ad}^*_\xi\mu_0 = 0\}$$

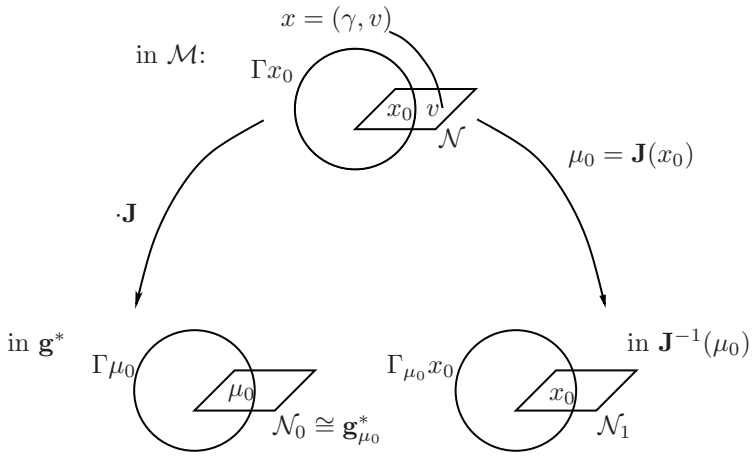

Figure 5. *Symplectic slice theorem.*

is the isotropy subalgebra of the momentum $\mu_0 = \mathbf{J}(x_0)$ of x_0. The space $\mathcal{N}_0$ is isomorphic to a section transverse to the momentum group orbit $\Gamma\mu_0$ at μ_0. To see that $\mathcal{N}_0 \simeq \mathbf{g}^*_{\mu_0}$, let $\mathbf{n}_{\mu_0}$ be a complement to $\mathbf{g}_{\mu_0}$ in $\mathbf{g}$ and let $\operatorname{ann}(\mathbf{n}_{\mu_0})$ denote the annihilator of $\mathbf{n}_{\mu_0}$ in $\mathbf{g}^*$. Then $\mathcal{T}_{\mu_0}\Gamma\mu_0 = \mathbf{g}\mu_0 = \operatorname{ann}(\mathbf{g}_{\mu_0})$, and so $\operatorname{ann}(\mathbf{n}_{\mu_0}) \cong \mathbf{g}^*_{\mu_0}$ is a section transverse to $\Gamma\mu_0$ at μ_0. The *symplectic normal space* or *symplectic slice* $\mathcal{N}_1$ at x_0 is a slice to the Γ_{μ_0} orbit of x_0 in the momentum level set $\mathbf{J}^{-1}(\mu_0)$; cf. Figure 5. Moreover, there is a choice of slice $\mathcal{N}$ such that the coordinate transformation $x \to (\gamma, \nu, w) \in \Gamma \times \mathcal{N}_0 \oplus \mathcal{N}_1$, where x lies in some Γ-invariant neighborhood $\mathcal{U}$ of Γx_0, is symplectic with symplectic form $\Omega_{\Gamma\times\mathcal{N}}$ on $\Gamma \times \mathcal{N}$ given by $\Omega_{\Gamma\times\mathcal{N}} = \Omega_{\Gamma\times\mathbf{g}^*_{\mu_0}} + \Omega_{\mathcal{N}_1}$. Here $\Omega_{\mathcal{N}_1}$ is the symplectic form on $\mathcal{N}_1$ and $\Omega_{\Gamma\times\mathbf{g}^*_{\mu_0}}$ the symplectic form on $\Gamma \times \mathbf{g}^*_{\mu_0}$, obtained by restriction of the symplectic form on $\mathcal{T}^*\Gamma \simeq \Gamma \times \mathbf{g}^*$. In these coordinates the momentum map becomes

$$\mathbf{J}(\gamma, \nu, w) = \gamma(\mu_0 + \nu); \tag{3.18}$$

see [11, 17] and also [26]. Let $\mathbb{J}_{\mathcal{N}_1}$ be the structure matrix of the symplectic form on $\mathcal{N}_1$.

One more technical assumption is needed: In this paper, unless otherwise stated, it is assumed that μ_0 is *split*; i.e., there is a $\Gamma^{\mathrm{id}}_{\mu_0}$-invariant complement to $\mathbf{g}_{\mu_0}$ in $\mathbf{g}$. Here $\Gamma^{\mathrm{id}}_{\mu_0}$ is the identity component of Γ_{μ_0}. This condition is always satisfied for compact groups and also for the special Euclidean group of the plane; see [26]. For the general case see [26].

Theorem 3.5 (see [26, Theorem 3.1]). *Let, as above, (γ, v), $v = (\nu, w) \in \mathcal{N}$, $\gamma \in \Gamma$, parametrize a Γ-invariant neighborhood $\mathcal{U}$ of the relative equilibrium Γx_0 with momentum $\mu_0 = \mathbf{J}(x_0)$. Let $h(\nu, w)$ be the restriction of the Hamiltonian H to the slice $\mathcal{N} = \mathbf{g}^*_{\mu_0} \oplus \mathcal{N}_1$, and let μ_0 be split. Assume that the momentum map is Ad^*-equivariant. Then $\gamma(t) \in \Gamma$, $\nu(t) \in \mathbf{g}^*_{\mu_0}$, $w(t) \in \mathcal{N}_1$, where $x(t) \simeq (\gamma(t), \nu(t), w(t)) \in \mathcal{U}$ solves (3.1), satisfy the differential equations*

$$\dot\gamma = \gamma\, \mathrm{D}_\nu h(\nu, w), \quad \dot\nu = \mathrm{ad}^*_{\mathrm{D}_\nu h(\nu,w)}\nu, \quad \dot w = \mathbb{J}_{\mathcal{N}_1}\mathrm{D}_w h(\nu, w). \tag{3.19}$$

As in the non-Hamiltonian case, the relative equilibrium Γx_0 corresponds to the equilibrium $v = (0, 0) \in \mathcal{N}$ of the slice equation on $\mathcal{N}$. The first equation describes the motion of

the body frame. Here $\mathrm{D}_\nu h$ is the velocity of the body frame, and $\mathrm{D}_\nu h(0,0) = \xi_0$ is the drift velocity of the relative equilibrium Γx_0 at x_0. The second equation describes the motion of the momenta in body coordinates, and the last equation models the shape dynamics.

From a comparison of (3.19) with the equations near relative equilibria in the general case (2.3), it becomes apparent that in the Hamiltonian case $v = (\nu, w)$ and

$$f_\Gamma(v) = \mathrm{D}_\nu h(\nu, w), \quad f_\mathcal{N}(v) = \begin{pmatrix} \mathrm{ad}^*_{\mathrm{D}_\nu h}(\nu) \\ \mathbb{J}_{\mathcal{N}_1} \mathrm{D}_w h(\nu, w) \end{pmatrix}.$$

So the slice equation $\dot v = f_\mathcal{N}(v)$ now consists of the two differential equations for $\dot\nu$ and $\dot w$. Moreover,

$$\mathrm{D} f_\mathcal{N}(0) = \begin{pmatrix} \mathrm{ad}^*_{\xi_0}|_{\mathbf{g}^*_{\mu_0}} & 0 \\ \mathbb{J}_{\mathcal{N}_1} \mathrm{D}^2_{\nu w} h(0) & \mathbb{J}_{\mathcal{N}_1} \mathrm{D}^2_w h(0) \end{pmatrix}. \tag{3.20}$$

The energy $h(\nu, w)$ is a conserved quantity of the slice equation which is a *Poisson system*; see [18]. Any function $C(\nu, w)$ which is a conserved quantity of the slice equation for all choices of Hamiltonians $h(\nu, w)$ is called a *Casimir* of the slice equation. Note that the flow-invariant *symplectic leaves* of the slice equation are given by $\Gamma^{\mathrm{id}}_{\mu_0} \nu_0 \times \mathcal{N}_1$, where $\nu_0 \in \mathcal{N}_0$.

Note for later reference that (3.20) is true for nonsplit μ as well if the infinitesimal coadjoint action ad^*_ξ restricted to $\mathrm{ann}(\mathbf{n}_{\mu_0}) \simeq \mathbf{g}^*_{\mu_0}$ in $\mathrm{ad}^*_{\xi_0}|_{\mathbf{g}^*_{\mu_0}}$ is replaced by the corresponding action on $\mathbf{g}_{\mu_0}$. For split μ_0, both these actions coincide; see [26].

Remark 3.6. With the notation from (3.7), the $\dot\nu$-equation can be rewritten as

$$\dot\nu = -\mathrm{D}_\nu h(\nu, w)\nu.$$

As shown in [28], Theorem 3.5 remains true in the case of a momentum map which is symmetric with respect to a cocycle action if the infinitesimal coadjoint action in the $\dot\nu$-equation is replaced by the corresponding action (3.14) with a cocycle. Then the $\dot\nu$-equation becomes

$$\dot\nu = -\mathrm{D}_\nu h(\nu, w) \cdot_K \nu \tag{3.21}$$

provided that μ_0 is split for the action of Γ^κ on $\mathbf{g}$, i.e., if there is a $(\Gamma^\kappa_{\mu_0})^{\mathrm{id}}$-invariant complement $\mathbf{n}^K_{\mu_0}$ to $\mathbf{g}^K_{\mu_0}$ in $\mathbf{g}$, where $(\Gamma^\kappa_{\mu_0})^{\mathrm{id}}$ is the identity component of $\Gamma^\kappa_{\mu_0}$. Moreover, as before, $\mathcal{N}_0 \simeq \mathrm{ann}(\mathbf{n}^K_{\mu_0}) \simeq (\mathbf{g}^K_{\mu_0})^*$.

Remark 3.7. For later use, let us consider parameter dependent Hamiltonian systems

$$\dot x = f(x, \mathcal{K}), \tag{3.22}$$

where f is defined by

$$\Omega(x, \mathcal{K})(f(x, \mathcal{K}), v) = \mathrm{D}_x H(x, \mathcal{K})v, \qquad x \in \mathcal{M},\ v \in \mathcal{T}_x\mathcal{M}.$$

Assume that the symplectic form $\Omega(\mathcal{K})$, the Hamiltonian $H(\cdot, \mathcal{K})$, and the momentum map $\mathbf{J}(\cdot, \mathcal{K})$ depend smoothly on a parameter $\mathcal{K}$. Then Theorem 3.5 still applies, and the sections $\mathcal{N}_0(\mathcal{K})$, $\mathcal{N}_1(\mathcal{K})$, as well as the Hamiltonian $h(\nu, w, \mathcal{K})$, depend smoothly on $\mathcal{K}$, as long as the dimensions of $\mathcal{N}_0(\mathcal{K})$ and $\mathcal{N}_1(\mathcal{K})$ are constant. See the proofs in [11, 17] and [26].

Example 3.8. For later use, let us derive the differential equations (3.19) near rotating waves of Hamiltonian systems (3.1) with symmetry group $\Gamma = \mathrm{SE}(2)$, in the case of an Ad^*-equivariant momentum map. Let x_0 lie on a rotating wave so that $\Phi_t(x_0) = \exp(t\xi_0)x_0$, $\xi_0 \in \mathrm{so}(2)$, $\mu_0 = \mathbf{J}(x_0)$. From (3.16) it follows that $0 = -\mathrm{ad}^*_{\xi_0}\mu_0$, with $\mathrm{ad}^*_{\xi_0}$ from (3.9). Therefore, $\mu_0^a = 0$, so that the rotating wave through x_0 has vanishing linear momentum. Then $\Gamma_{\mu_0} = \mathrm{SE}(2)$; see Example 3.3. Hence $\mathcal{N}_0 \simeq \mathbf{g}^*_{\mu_0} \simeq \mathrm{se}(2)^*$, and so the equations (3.19) for SE(2)-equivariant Hamiltonian systems are

$$
\begin{array}{rcll}
\dot\phi &=& \mathrm{D}_{\nu^\phi}h, \quad \dot a = R_\phi \mathrm{D}_{\nu^a}h, & \Leftrightarrow \quad \dot\gamma = \gamma \mathrm{D}_\nu h(\nu, w), \\
\dot\nu^\phi &=& \nu_1^a \mathrm{D}_{\nu_2^a}h(\nu,w) - \nu_2^a \mathrm{D}_{\nu_1^a}h(\nu,w) & \\
\dot\nu_1^a &=& \nu_2^a \mathrm{D}_{\nu^\phi}h(\nu,w) & \Leftrightarrow \quad \dot\nu = \mathrm{ad}^*_{\mathrm{D}_\nu h}\nu, \\
\dot\nu_2^a &=& -\nu_1^a \mathrm{D}_{\nu^\phi}h(\nu,w) & \\
\dot w &=& \mathbb{J}_{\mathcal{N}_1}\mathrm{D}_w h(\nu,w). &
\end{array}
\tag{3.23}
$$

Example 3.9. Also, for later use, let us consider the equations (3.21) for Hamiltonian systems (3.22) which have a momentum map $\mathbf{J}(\cdot, \mathcal{K})$ with cocycle (3.11), $\mathcal{K} \neq 0$. From (3.10) and (3.11) it follows that the momentum μ_0 can always be translated such that $\mu_0^a = 0$. For $\mu_0^a = 0$ one has $\xi = (\xi^\phi, \xi^a) \in \mathbf{g}^K_{\mu_0}$ if and only if $\xi^a = 0$, and so

$$\Gamma^\kappa_{\mu_0} = \mathrm{SO}(2) \times \{0\} \subseteq \mathrm{SE}(2).$$

For $\xi^a = 0$ the infinitesimal cocycle (3.13) vanishes. Hence $\{(0, \xi^a) \in \mathrm{se}(2),\ \xi^a \in \mathbb{R}^2\}$ is a $\Gamma^\kappa_{\mu_0}$-invariant complement to $\mathbf{g}^K_{\mu_0} = \mathrm{so}(2)$ in se(2), and μ_0 is split. Consequently, $\mathcal{N}_0 \simeq (\mathbf{g}^K_{\mu_0})^* = \mathrm{so}(2)^*$, and $\dot\nu = 0$ in (3.21).

4. The meandering transition in Hamiltonian systems.

In this section a Hamiltonian analogue of the meandering transition for dissipative systems, which was described in section 2.2 above, is presented, using the equations near Hamiltonian relative equilibria (3.19) from section 3. First Euclidean symmetric Hamiltonian systems with an Ad^*-equivariant momentum map are studied (sections 4.1–4.3). Then systems with Euclidean symmetry for which the momentum map has a cocycle are considered (section 4.4).

4.1. Persistence of rotating waves.

In this section and in sections 4.2–4.3 it is assumed that (3.1) has the symmetry group $\Gamma = \mathrm{SE}(2)$ and an Ad^*-equivariant momentum map.

As a prerequisite for the analysis of the transition from rotating waves to modulated rotating waves and modulated traveling waves, the persistence of nondegenerate rotating waves to nearby momentum values is studied.

Definition 4.1. *A relative equilibrium* Γx_0 *of* (3.1) *is called* nondegenerate *if* $\mathrm{D}^2_w h(0)$ *is invertible. Here* $h(\nu, w)$ *is the Hamiltonian in the symmetry-adapted coordinates near* x_0 *from* (3.19).

Note that a relative equilibrium is typically nondegenerate. The next proposition shows that nondegenerate rotating waves persist to nearby angular momentum.

Proposition 4.2. *Let* $\mathrm{SE}(2)x_0$ *be a nondegenerate rotating wave of an* SE(2)*-equivariant Hamiltonian system* (3.1) *with* Ad^**-equivariant momentum map* $\mathbf{J}(\cdot)$*, and let* $\mu_0 = \mathbf{J}(x_0)$*. Then there is a one-parameter family* $\mathrm{SE}(2)x_{\mathrm{RW}}(\nu^\phi)$ *of rotating waves nearby parametrized*

by angular momentum $\mu^\phi = \mu_0^\phi + \nu^\phi$ *with vanishing linear momentum such that* $x_{\mathrm{RW}}(\nu^\phi) \simeq (\mathrm{id}, (\nu^\phi, 0, 0)^T, w_{\mathrm{RW}}(\nu^\phi))$ *is smooth in* ν^ϕ *and* $x(0) = x_0$, $w_{\mathrm{RW}}(0) = 0$.

Proof. Rotating waves are equilibria of the slice equation, i.e., of the (ν, w)-system of (3.23). Using the nondegeneracy assumption, the equation $0 = \dot{w} = \mathbb{J}_{\mathcal{N}_1} \mathrm{D}_w h(\nu, w)$ can be solved by the implicit function theorem for $w_{\mathrm{RW}}(\nu)$ such that $w_{\mathrm{RW}}(0) = 0$. For rotating waves the linear momentum has to vanish; see Example 3.8. Hence $\nu^a = 0$ in any rotating wave. From the $\dot{\nu}$-equation of (3.23) then $\dot{\nu}^\phi = 0$, $\dot{\nu}^a = 0$ follows. Hence $x_{\mathrm{RW}}(\nu^\phi) \simeq (\mathrm{id}, (\nu^\phi, 0, 0)^T, w_{\mathrm{RW}}(\nu^\phi))$ lies on a rotating wave of (3.1) for all $\nu^\phi \approx 0$. By (3.18), $\mathbf{J}(x_{\mathrm{RW}}(\nu^\phi)) = \mu_0 + \nu = (\mu_0^\phi + \nu^\phi, 0)$. ∎

A persistence theory for generic nondegenerate relative equilibria of Hamiltonian systems with general noncompact symmetry group has been developed in [32]; see also [20] for an example of nonpersistence of rotating waves to nonvanishing linear momentum in point vortex dynamics. The above proposition could also be proved by applying the results of [32] to the example $\Gamma = \mathrm{SE}(2)$. However, the direct proof given above is more elementary.

4.2. Bifurcation of modulated traveling waves. The following theorem states that typically rotating waves of Euclidean equivariant Hamiltonian systems with Ad^*-equivariant momentum map persist to modulated traveling waves at nearby linear momenta $\mu^a \neq 0$. Consequently resonance drift occurs generically.

Theorem 4.3. *Let* $\mathrm{SE}(2)x_0$ *be a nondegenerate rotating wave of an* $\mathrm{SE}(2)$*-equivariant Hamiltonian system* (3.1) *with* Ad^**-equivariant momentum map. Denote its rotation frequency by* $\omega_0^{\mathrm{rot}} = \xi_0^\phi$ *and assume that* $\omega_0^{\mathrm{rot}} \neq 0$. *If all eigenvalues* $\mathrm{i}\omega_0$ *of* $\mathbb{J}_{\mathcal{N}_1} \mathrm{D}_w^2 h(0)$ *satisfy*

$$\omega_0 / \omega_0^{\mathrm{rot}} \notin \mathbb{Z}, \tag{4.1}$$

then the rotating wave $\mathrm{SE}(2)x_0$ *persists as a modulated traveling wave* $\mathcal{P}_{\mathrm{MTW}}(\nu^\phi, r^a)$ *to all nearby momentum values* $\mu = (\mu_0^\phi + \nu^\phi, \nu^a)$, $r^a = \|\nu^a\|$. *Moreover, there is a smooth function* $x_{\mathrm{MTW}}(\nu^\phi, r^a) \in \mathcal{P}_{\mathrm{MTW}}(\nu^\phi, r^a)$ *such that* $x_{\mathrm{MTW}}(\nu^\phi, 0) = x_{\mathrm{RW}}(\nu^\phi)$. *Here* $\mathrm{SE}(2)x_{\mathrm{RW}}(\nu^\phi)$ *is the family of rotating waves from Proposition 4.2. The relative period* $T_{\mathrm{MTW}}(\nu^\phi, r^a)$ *of the modulated traveling wave* $\mathcal{P}_{\mathrm{MTW}}(\nu^\phi, r^a)$ *is close to* $T_{\mathrm{MTW}}(0) = \frac{2\pi}{|\omega_0^{\mathrm{rot}}|}$, *and the translation drift* $\gamma_{\mathrm{MTW}}(\nu^\phi, r^a) = (0, a_{\mathrm{MTW}}(\nu^\phi, r^a))$ *of the modulated traveling wave at* $x_{\mathrm{MTW}}(\nu^\phi, r^a)$ *satisfies* $a_{\mathrm{MTW}}(\nu^\phi, 0) = 0$.

Proof. The rotating wave $\mathrm{SE}(2)x_0$ is treated as a periodic orbit of period $T_0 = \frac{2\pi}{\omega_0^{\mathrm{rot}}}$. Introduce polar coordinates $\nu^a = (r^a \cos\phi^a, r^a \sin\phi^a)$. Then (3.23) implies that $r^a = \|\nu^a\|_2$ is a conserved quantity (Casimir) of the slice equation. Since the slice equation also conserves energy, the set

$$\mathcal{N}_{E,r^a} = \{(\nu, w) \in \mathcal{N},\ h(\nu, w) = E,\ \|\nu^a\|_2 = r^a\}$$

is flow-invariant. From $\dot{\phi}^a = \mathrm{D}_{\nu^\phi} h(\nu, w) \approx \omega_0^{\mathrm{rot}} \neq 0$ for $(\nu, w) \approx 0$ it can be deduced that for $E \approx E_0 = H(x_0)$, $r^a > 0$, $r^a \approx 0$, the section

$$\mathcal{S}_{E,r^a} = \{(\nu, w) \in \mathcal{N}_{E,r^a},\ \phi^a = 0,\ (\nu, w) \approx 0\}$$

is tranversal to the flow in $\mathcal{N}_{E,r^a}$. Let $\Pi(E, r^a, \cdot) : \mathcal{S}_{E,r^a} \to \mathcal{S}_{E,r^a}$ be the Poincaré map to the Poincaré section $\mathcal{S}_{E,r^a}$. Since $\mathrm{D}_{(\nu,w)} h(0) = (\xi_0, 0)$ with $\xi_0^\phi = \omega_0^{\mathrm{rot}} \neq 0$, the sections $\mathcal{S}_{E,r^a}$, $E \approx E_0$, $r^a \approx 0$, can be parametrized as

$$\mathcal{S}_{E,r^a} = \{(\nu^\phi, w),\ \nu^\phi = \nu^\phi(E, r^a, w),\ w \in \mathcal{N}_1\}.$$

Hence $\Pi(E, r^a, \cdot)$ can be considered as a map from $\mathcal{N}_1$ to itself. By assumption $ki\omega_0^{\mathrm{rot}}$, $k \in \mathbb{Z}$, is not an eigenvalue of $\mathbb{J}_{\mathcal{N}_1} \mathrm{D}_w^2 h(0)$. Therefore,

$$\mathrm{D}_w \Pi(E_0, 0, 0) - \mathrm{id} = \exp\left(\frac{2\pi}{|\omega_0^{\mathrm{rot}}|} \mathbb{J}_{\mathcal{N}_1} \mathrm{D}_w^2 h(0)\right) - \mathrm{id}$$

is invertible, and so there is a fixed point $w(E, r^a)$ of $\Pi(E.r^a, \cdot)$ for each $E \approx E_0$, $r^a \approx 0$. As $\mathrm{D}_{\nu^\phi} h(0) = \omega_0^{\mathrm{rot}} \neq 0$, this family of fixed points can be parametrized by ν^ϕ and r^a instead of E and r^a.

The periodic orbits of the slice equation through $v(\nu^\phi, r^a) = (\nu(\nu^\phi, r^a), w(\nu^\phi, r^a))$, where $\nu(\nu^\phi, r^a) = (\nu^\phi, r^a, 0)$, correspond to relative periodic orbits $\mathcal{P}_{\mathrm{MTW}}(\nu^\phi, r^a)$ of (3.1) through $x_{\mathrm{MTW}}(\nu^\phi, r^a) \simeq (\mathrm{id}, v(\nu^\phi, r^a))$ with momentum

$$\mathbf{J}(x_{\mathrm{MTW}}(\nu^\phi, r^a)) = \mu_0 + \nu(\nu^\phi, r^a) = (\mu_0^\phi + \nu^\phi, r^a, 0);$$

see (3.18). For vanishing linear momentum $r^a = 0$ they reduce to the rotating waves $\mathrm{SE}(2)x_{\mathrm{RW}}(\nu^\phi)$ from Proposition 4.2.

By (3.17), any RPO with drift $\gamma = (\phi, a)$ and momentum μ satisfies $(\mathrm{Ad}_\gamma^*)^{-1}\mu = \mu$, with $(\mathrm{Ad}_\gamma^*)^{-1}$ as in (3.9). Because of (3.9), the condition $\mu^a \neq 0$ implies $\phi = 0$ so that the RPOs $\mathcal{P}_{\mathrm{MTW}}(\nu^\phi, r^a)$ are modulated traveling waves for $r^a \neq 0$. ∎

4.3. Bifurcation of modulated rotating waves. In this section the existence of modulated rotating waves near elliptic rotating waves is proved by the Lyapunov center theorem.

Definition 4.4. *A relative equilibrium Γx_0, $x_0 \simeq (\mathrm{id}, (\nu, w) = (0, 0))$, of a Γ-equivariant Hamiltonian system (3.1) is called* elliptic *if all eigenvalues of the linearization $\mathbb{J}_{\mathcal{N}_1} \mathrm{D}_w^2 h(0)$ of the $\dot{w}$-dynamics of (3.19) lie in $\mathrm{i}\mathbb{R} \setminus \{0\}$ and* nonresonant *if all its eigenvalues are simple and no eigenvalue $\mathrm{i}\omega_j$ is an integer multiple of another eigenvalue $\mathrm{i}\omega_k$ for $\omega_j \neq \omega_k$.*

Note that any stable relative equilibrium is elliptic and that relative equilibria are elliptic for an open range of parameters (until a Hamiltonian Hopf bifurcation of the $\dot{w}$-equation of (3.19) occurs).

Definition 4.5. *Let Γx_0, $x_0 \simeq (\mathrm{id}, (\nu, w) = (0, 0))$, be an elliptic relative equilibrium of (3.1), and denote the eigenvalues of $\mathbb{J}_{\mathcal{N}_1} \mathrm{D}_w^2 h(0)$ by $\pm\mathrm{i}\omega_j$, $j = 1, \dots, d$, $d := \frac{1}{2} \dim \mathcal{N}_1$. The signs of the normal frequencies ω_j are chosen such that*

$$h(0, w) = \sum_{j=1}^{d} \frac{\omega_j}{2} \langle w_j, w_j \rangle + O(\|w\|^3). \tag{4.2}$$

Here $w = (w_1, \dots, w_d)$, $w_j \in \mathbb{R}^2$, are suitable coordinates on $\mathcal{N}_1$. The sign of ω_j is called the Krein signature *of ω_j. There is an $m : n$-*resonance *between the normal frequencies ω_j and ω_k if $m\omega_j = n\omega_k$, $m, n \in \mathbb{Z}$.*

Proposition 4.6. *Let $\mathrm{SE}(2)x_0$ be a nonresonant elliptic rotating wave of an $\mathrm{SE}(2)$-equivariant Hamiltonian system (3.1) with Ad^*-equivariant momentum map. Let ω_0^{rot} be its rotation frequency, let $H(x_0) = E_0$ be its energy, and let $\mu_0 = \mathbf{J}(x_0)$ be its momentum at x_0. Denote the eigenvalues of $\mathbb{J}_{\mathcal{N}_1} \mathrm{D}_w^2 h(0)$ by $\pm\mathrm{i}\omega_j$, $j = 1, \dots, \frac{1}{2} \dim \mathcal{M} - 3$. Then there are $(\frac{1}{2} \dim \mathcal{M} - 3)$-many two-dimensional families $\mathcal{P}_j(\nu^\phi, s)$ of RPOs, $j = 1, \dots, \frac{1}{2} \dim \mathcal{M} - 3$, of (3.1), where*

$s \geq 0$, $\nu^\phi \approx 0$, with angular momentum $\mu_0^\phi + \nu^\phi$, with vanishing linear momentum, with energy $E = H(x_{\mathrm{RW}}(\nu^\phi)) \pm s^2$ (depending on the Krein signature of ω_j), and with relative periods $T_j(\nu^\phi, s)$ such that $T_j(0,0) = 2\pi/|\omega_j|$. Moreover, there are smooth functions $x_j(\nu^\phi, s)$ with $x_j(\nu^\phi, s) \in \mathcal{P}_j(\nu^\phi, s)$, $x_j(\nu^\phi, 0) = x_{\mathrm{RW}}(\nu^\phi)$. If $\omega_0^{\mathrm{rot}}/\omega_j \notin \mathbb{Z}$ for all normal frequencies ω_j, then all these RPOs are proper modulated rotating waves for $(\nu^\phi, s) \approx 0$. Proper modulated rotating waves do not persist to nonzero linear momenta.

Proof. First note that proper modulated rotating waves have a drift symmetry $\gamma = (\phi, a)$ with $\phi \neq 0 \bmod 2\pi$. This implies, because of (3.17) and (3.9), that the linear momentum ν^a of a proper modulated rotating wave vanishes. Equation (3.23) implies that $\dot\nu^\phi \equiv 0$, $\dot\nu^a \equiv 0$ at $\nu^a = 0$. So proper modulated rotating waves near x_0 correspond to nonlinear normal modes of the ν^ϕ-dependent $\dot w$-equation of (3.23) at $\nu^a = 0$. Note that $\mathcal{N}_1$ has dimension

$$\dim \mathcal{N}_1 = \dim \mathcal{M} - 2 \dim \mathrm{SE}(2) = \dim \mathcal{M} - 6.$$

By the Lyapunov center theorem (see, e.g., [19]) there are $d = \frac{\dim \mathcal{N}_1}{2}$ families of periodic orbits $w_j(\nu^\phi, s)$, $j = 1, \dots, d$, of the $\dot w$-equation of (3.23) such that $w_j(\nu^\phi, 0) = w_{\mathrm{RW}}(\nu^\phi)$, with $w_{\mathrm{RW}}(\nu^\phi)$ from Proposition 4.2. Let $\mathrm{i}\omega_j(\nu^\phi)$ be the eigenvalue of $\mathbb{J}_{\mathcal{N}_1} \mathrm{D}_w^2 h((\nu^\phi, 0, 0), w_{\mathrm{RW}}(\nu^\phi))$ such that $\omega_j(0) = \omega_j$. Since $\partial_s w_j(\nu^\phi, 0)$ lies in the real eigenspace of $\mathbb{J}_{\mathcal{N}_1} \mathrm{D}_w^2 h((\nu^\phi, 0, 0), w_{\mathrm{RW}}(\nu^\phi))$ to the eigenvalue $\mathrm{i}\omega_j(\nu^\phi)$ (see, e.g., [19]), and since $\mathrm{D}_w h((\nu^\phi, 0, 0), w_{\mathrm{RW}}(\nu^\phi)) = 0$, the energy of the periodic orbits is

$$h((\nu^\phi, 0, 0), w_j(\nu^\phi, s)) = H(x_{\mathrm{RW}}(\nu^\phi)) + \omega_j(\nu^\phi) s^2 + O(s^3).$$

Therefore, s can be rescaled to achieve that the periodic orbit $w_j(\nu^\phi, s)$ has energy $H(x_{\mathrm{RW}}(\nu^\phi))$ $\pm s^2$ depending on the sign of ω_j; see (4.2). Then $x_j(\nu^\phi, s) = (\mathrm{id}, (\nu^\phi, 0, 0), w_j(\nu^\phi, s))$ lies on an RPO $\mathcal{P}_j(\nu^\phi, s)$ of (3.1). Its momentum is

$$\mathbf{J}(x_j(\nu^\phi, s)) = (\mu_0^\phi + \nu^\phi, 0, 0)$$

by (3.18). The drift symmetry $\gamma_j(\nu^\phi, s) = (\phi_j(\nu^\phi, s), a_j(\nu^\phi, s))$ of the RPO at $x_j(\nu^\phi, s)$ satisfies $\phi_j(0,0) = 2\pi\omega_0^{\mathrm{rot}}/\omega_j$, and so $\phi_j(0,0) \neq 0 \bmod 2\pi$ if $\omega_0^{\mathrm{rot}}/\omega_j \notin \mathbb{Z}$. In this case $\phi_j(\nu^\phi, s) \neq 0 \bmod 2\pi$ for $(\nu^\phi, s) \approx 0$, and the RPOs $\mathcal{P}_j(\nu^\phi, s)$ are indeed proper modulated rotating waves for $(\nu^\phi, s) \approx 0$. ∎

Example 4.7. Let us now study a Hamiltonian analogue of the meandering transition for point vortices with vanishing total circulation $\mathcal{K} = 0$. In this case the momentum map of the point vortex system (3.3) is Ad^*-equivariant; cf. Remark 3.4. Let us start with a configuration of rigidly rotating point vortices. Such a configuration is a rotating wave of (3.3). Synge [29] and later Aref [1] showed the existence of rotating waves of 3 vortices with vanishing total circulation. Patrick [25] constructed rotating wave solutions with vanishing total circulation for $N \geq 3$ vortices. Let us assume that the rotating wave is nondegenerate and that the nonresonance condition (4.1) is satisfied (this assumption is trivially satisfied for 3 vortices, since then $\mathcal{N}_1 = \{0\}$). Then it persists as a translating and precessing configuration, i.e., as a modulated traveling wave, to nonzero linear momentum. Moreover if the rotating wave is elliptic and nonresonant, then there are $(\frac{1}{2} \dim \mathcal{M} - 3) = (N - 3)$ different 2-parameter families of rotating and precessing configurations of vortices nearby, which are modulated

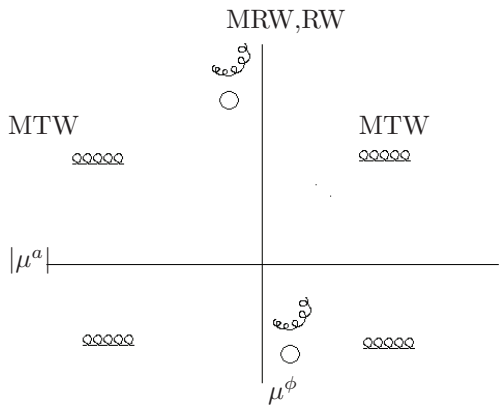

Figure 6. *Bifurcation diagram for the Hamiltonian meandering transition of point vortex dynamics in the case of vanishing circulation. RW: Rotating waves. MRW: Modulated rotating waves. MTW: Modulated traveling waves.*

rotating waves (Patrick [25] shows stability of the rotating waves of 4 vortices with vanishing total circulation, which he constructed. This implies that these rotating waves are elliptic, and, since $\mathcal{N}_1$ is 2-dimensional, they are also nonresonant).

Figure 6 shows the bifurcation diagram of the Hamiltonian meandering transition for point vortex dynamics in the case of an Ad^*-equivariant momentum map (for momentum maps with cocycle see section 4.4). This diagram should be compared with the corresponding bifurcation diagram of the dissipative meandering transition, Figure 4.

Note that, in contrast to the meandering/drifting transition in dissipative systems, here modulated traveling waves are the typical scenario as momentum is varied. Modulated rotating waves occur only for zero-linear momentum and so are a codimension two phenomenon in the three parameters' angular and linear momentums.

Example 4.8. Another example where a Hamiltonian meandering transition occurs is the Kirchhoff model of an underwater vehicle; see [13, 15]. In this case the configuration space is the Euclidean group $\mathrm{SE}(3) = \mathrm{SO}(3) \ltimes \mathbb{R}^3$ of three-dimensional space modeling the angle and position of the underwater vehicle, and the phase space $\mathcal{M} = \mathcal{T}^*\mathrm{SE}(3)$ is 12-dimensional. In the case of noncoincident centers of gravity and buoyancy the symmetry group is

$$\Gamma = \mathrm{SO}_3(2) \ltimes \mathbb{R}^3 = \mathrm{SE}(2) \times \mathbb{R}_3.$$

Here $\mathrm{SO}_3(2)$ denotes the group of rotations around the axis of gravity, which is chosen as the third coordinate axis (i.e., as the e_3-axis), and $\mathbb{R}_3$ is the group of translations along the e_3-axis. Near a vertically falling and spinning relative equilibrium the dynamics is given by the slice equations near a rotating wave of a Euclidean equivariant system (3.23), but now there is an additional equation

$$\dot{\nu}_3^a \equiv 0$$

in the slice and a corresponding equation

$$\dot{a}_3 = \mathrm{D}_{\nu_3^a} h(\nu, w)$$

for the group dynamics, where $\nu = (\nu^\phi, \nu^a)$, $\nu^a = (\nu^a_1, \nu^a_2, \nu^a_3)$. Assume that this relative equilibrium is nondegenerate and satisfies the nonresonance condition (4.1). Then it persists as translating RPO with nonvertical linear drift to horizontal linear momentum. Let the relative equilibrium be elliptic and nonresonant (from [15, section 4.4.2] it follows that these conditions are satisfied at least for an open range of parameters). Then there are two 3-parameter families of RPOs, parametrized by (ν^ϕ, ν^a_3, s), which fall, rotate, and precess.

4.4. Hamiltonian meandering transition for momentum maps with cocycle. In this section the analogue of the meandering transition of dissipative systems is considered for Hamiltonian systems where the momentum map has a nonvanishing cocycle of the form that occurs in point vortex dynamics. The limiting behavior for a vanishing cocycle is studied, and in this way the meandering transition for momentum maps with cocycle is related to the results of sections 4.1–4.3 on the meandering transition for Hamiltonian systems with Ad^*-equivariant momentum map.

Let us consider a parameter dependent SE(2)-symmetric Hamiltonian system (3.22). Assume that the symplectic form $\Omega(\mathcal{K})$, the Hamiltonian $H(\cdot, \mathcal{K})$, and the momentum map $\mathbf{J}(\cdot, \mathcal{K}) : \mathcal{M} \to \mathrm{se}(2)^*$ depend smoothly on a parameter $\mathcal{K}$. Moreover, assume that the momentum map is Ad^*-equivariant for $\mathcal{K} = 0$ and has the cocycle (3.11) for $\mathcal{K} \neq 0$; see (3.10), (3.12). An example of such a momentum map is the momentum map (3.4) for the point vortex dynamics (3.3).

As in the analysis of the Hamiltonian meandering transition for Ad^*-equivariant momentum maps (see section 4.1), first the persistence of rotating waves to nearby momentum values is studied. Moreover, the behavior of the rotating waves in the limit of vanishing cocycle is analyzed in the following theorem.

Theorem 4.9. *Consider a Hamiltonian system with* SE(2)*-symmetry for which the momentum map* $\mathbf{J}(\cdot, \mathcal{K})$ *has a nonvanishing cocycle satisfying* (3.11), (3.12). *Then the following hold:*

(a) *For* $\mathcal{K} \neq 0$ *all relative equilibria are rotating waves. Any nondegenerate rotating wave* $\mathrm{SE}(2)x_0$ *persists to all nearby momentum values as a one-parameter family* $\mathrm{SE}(2)x_{\mathrm{RW}}(\nu)$, $\nu \in (\mathbf{g}^K_{\mu_0})^*$, $x_{\mathrm{RW}}(0) = x_0$.

(b) *The center of rotation* $c(\mathcal{K})$ *of any smooth family* $\mathrm{SE}(2)x_{\mathrm{RW}}(\mathcal{K})$, $\mathcal{K} \neq 0$, $\mathcal{K} \approx 0$, *of rotating waves with fixed linear momentum* $\mu^a \neq 0$ *and rotation frequency* $\omega^{\mathrm{rot}}(\mathcal{K})$, *such that* $\lim_{\mathcal{K}\to 0} \omega^{\mathrm{rot}}(\mathcal{K}) = \omega^{\mathrm{rot}}_0 \neq 0$, *tends to infinity, as* $\mathcal{K} \to 0$, *according to*

$$\|c(\mathcal{K})\| = \frac{\|\mu^a\|}{\mathcal{K}}.$$

(c) *Assume that there is a nondegenerate rotating wave* $\mathrm{SE}(2)x_0$ *at* $\mathcal{K} = 0$ *with momentum* $\mu_0 = (\mu^\phi_0, 0)$ *and rotation frequency* $\omega^{\mathrm{rot}}_0 \neq 0$. *Then this rotating wave can be continued to a rotating wave* $\mathrm{SE}(2)x_{\mathrm{RW}}(\nu^\phi, \mathcal{K})$ *for small* $\mathcal{K} \neq 0$, $\nu^\phi \neq 0$, *such that* $\mathbf{J}^\phi(x_{\mathrm{RW}}(\nu^\phi, \mathcal{K}), \mathcal{K}) = \mu^\phi_0 + \nu^\phi$ *and* $\mathbf{J}^a(x_{\mathrm{RW}}(\nu^\phi, \mathcal{K}), \mathcal{K}) = 0$.

Part (b) of this theorem implies that for $\mathcal{K} = 0$ rotating waves exist only for vanishing linear momentum; see Proposition 4.2.

Proof of Theorem 4.9. (a) If the momentum map for a Hamiltonian system with SE(2)-symmetry has a nonvanishing cocycle, then $\Gamma^\kappa_\mu \simeq \mathrm{SO}(2)$ for all $\mu \in \mathrm{se}(2)^*$, as shown in Remark 3.4. Hence $\mathbf{g}^K_\mu \simeq \mathrm{so}(2)$ for all $\mu \in \mathrm{se}(2)^*$, and by (3.16) all relative equilibria are

rotating waves. Moreover, in Example 3.9 it was shown that $\dot\nu \equiv 0$ in (3.21), $\nu \in (\mathbf{g}_\mu^K)^*$. For a nondegenerate rotating wave $\mathrm{SE}(2)x_0$ the matrix $\mathrm{D}_w^2 h(0)$ is invertible. Therefore, there is a path $w_{\mathrm{RW}}(\nu)$ of equilibria of the $\dot w$-equation near $w_{\mathrm{RW}}(0) = 0$. These equilibria correspond to rotating waves $\mathrm{SE}(2)x_{\mathrm{RW}}(\nu)$, $x_{\mathrm{RW}}(\nu) \simeq (\mathrm{id}, \nu, w_{\mathrm{RW}}(\nu))$, of (3.1) for all nearby momenta $\mathrm{SE}(2)\mathbf{J}(x_{\mathrm{RW}}(\nu), \mathcal{K}) = \mathrm{SE}(2)(\mu_0 + \nu)$, where $\mu_0 = \mathbf{J}(x_0, \mathcal{K})$.

(b) Let $\mathrm{SE}(2)x_{\mathrm{RW}}(\mathcal{K})$ be an rotating wave with momentum μ and drift velocity $\xi = \xi(\mathcal{K}) = (\xi^\phi, \xi^a)(\mathcal{K})$. Differentiating (3.15) and identifying $\mathbb{R}^2$ with $\mathbb{C}$ and $\mathrm{so}(2)$ with $\mathbb{R}$, one obtains that

$$(\xi^\phi, \xi^a) \in \mathbf{g}_\mu^K \quad \Leftrightarrow \quad \mathcal{K}\xi^a = \xi^\phi \mu^a. \tag{4.3}$$

Let $(\phi, a)x = e^{\mathrm{i}\phi}x + a$, $x \in \mathbb{R}^2 \simeq \mathbb{C}$. Then $x(t) = \exp(t(\xi^\phi, \xi^a))x_0$ satisfies the differential equation $\dot x(t) = \mathrm{i}\xi^\phi x(t) + \xi^a$. Solving this and setting $t = 1$, one gets

$$\exp(\xi^\phi, \xi^a)x_0 = e^{\mathrm{i}\xi^\phi}x_0 + \frac{1}{\mathrm{i}\xi^\phi}(e^{\mathrm{i}\xi^\phi} - 1)\xi^a.$$

Therefore, $\exp(\xi^\phi, \xi^a)$ is a rotation with center

$$c = \mathrm{i}\frac{\xi^a}{\xi^\phi} = \mathrm{i}\frac{\mu^a}{\mathcal{K}} = \frac{1}{\mathcal{K}}(-\mu_2^a, \mu_1^a)^T. \tag{4.4}$$

This proves (b).

(c) Let us reduce only by the $\mathrm{SO}(2) \times \{0\}$-symmetry. Then the system

$$\dot{\tilde\nu} = 0, \quad \dot{\tilde w} = \mathbb{J}_{\tilde{\mathcal{N}}_1} \mathrm{D}_{\tilde w}\tilde h(\tilde\nu, \tilde w, \mathcal{K})$$

is obtained on the slice $\tilde{\mathcal{N}}$ transverse to the $\mathrm{SO}(2)$-orbit $\mathrm{SO}(2)x_0$ at x_0, with $\tilde\nu = \nu^\phi$. By (3.8), (3.9) the matrix $\mathrm{ad}_{\xi_0} = -\mathrm{ad}_{\xi_0}^*$ has simple eigenvalues 0 and $\pm\mathrm{i}\omega_0^{\mathrm{rot}}$. By (2.4) and (3.20), at $\mathcal{K} = 0$ the linearization of the slice equation $\mathrm{D}f_{\tilde{\mathcal{N}}}(0,0)$ has one simple eigenvalue 0 corresponding to the equation $\dot{\tilde\nu} = 0$. Therefore, $\mathrm{D}_{\tilde w}^2\tilde h(0,0,0)$ is invertible, and so the rotating wave $\mathrm{SO}(2)x_0$ is nondegenerate. By Remark 3.7 the $\dot{\tilde w}$-equation is smooth in $\mathcal{K}$. So there is a smooth two-parameter family $\tilde w_{\mathrm{RW}}(\tilde\nu, \mathcal{K})$ of equilibria of the $\dot{\tilde w}$-equation. This gives a family $\mathrm{SE}(2)x_{\mathrm{RW}}(\nu^\phi, \mathcal{K})$, $x_{\mathrm{RW}}(\nu^\phi, \mathcal{K}) \simeq (\mathrm{id}, \nu^\phi, \tilde w_{\mathrm{RW}}(\nu^\phi, \mathcal{K}))$, of rotating waves of (3.1). By (3.18) their angular momentum is $\mathbf{J}^\phi(x_{\mathrm{RW}}(\nu^\phi, \mathcal{K}), \mathcal{K}) = \mu_0^\phi + \nu^\phi$. Since only a reduction by the $\mathrm{SO}(2)$-symmetry has been carried out, the rotating waves through $x_{\mathrm{RW}}(\nu^\phi, \mathcal{K})$ have drift velocities $\xi_{\mathrm{RW}}(\nu^\phi, \mathcal{K})$ with $\xi_{\mathrm{RW}}^a(\nu^\phi, \mathcal{K}) = 0$. Moreover, $\xi_{\mathrm{RW}}^\phi(\nu^\phi, \mathcal{K}) \approx \omega_0^{\mathrm{rot}} \neq 0$ for $\mathcal{K} \approx 0$. Therefore, (4.3) implies that $\mathbf{J}^a(x_{\mathrm{RW}}(\nu^\phi, \mathcal{K}), \mathcal{K}) = 0$. ■

The next proposition shows that in the case of a momentum map with cocycle (3.11) all RPOs are modulated rotating waves.

Proposition 4.10. *Consider a Hamiltonian system with* $\mathrm{SE}(2)$*-symmetry for which the momentum map* $\mathbf{J}(\cdot, \mathcal{K})$ *has a nonvanishing cocycle satisfying* (3.11), (3.12)*. Then the following hold:*

(a) *For* $\mathcal{K} \neq 0$ *all RPOs are modulated rotating waves.*

(b) *Any smooth family* $\mathcal{P}(\mathcal{K})$ *of proper modulated rotating waves of* (3.1)*, i.e., of RPOs with drift symmetry* $\gamma(\mathcal{K}) = (\phi(\mathcal{K}), a(\mathcal{K}))$*, where* $\phi(\mathcal{K}) \neq 0 \bmod 2\pi$ *for all* $\mathcal{K} \neq 0$*,* $\mathcal{K} \approx 0$*, with fixed linear momentum* $\mu^a \neq 0$ *has a center of rotation* $c(\mathcal{K})$ *diverging to* ∞ *for* $\mathcal{K} \to 0$ *according to* $\|c(\mathcal{K})\| = \frac{\|\mu^a\|}{\mathcal{K}}$.

Proof. (a) Similarly as in the proof of Theorem 4.9 (a), this follows from the fact that $\Gamma_\mu^\kappa \simeq \mathrm{SO}(2)$ for all $\mu \in \mathrm{se}(2)^*$, as shown in Remark 3.4. This, together with (3.17), implies that all RPOs are modulated rotating waves.

(b) This statement is proved similarly as Theorem 4.9 (b). By (3.15), the center of rotation $c(\mathcal{K}) = R_{\phi(\mathcal{K})}c(\mathcal{K}) + a(\mathcal{K})$ of the drift symmetry $\gamma(\mathcal{K}) = (\phi(\mathcal{K}), a(\mathcal{K}))$, $\phi(\mathcal{K}) \neq 0 \bmod 2\pi$, of the RPO is given by (4.4), and so $c(\mathcal{K}) \to \infty$ as $\mathcal{K} \to 0$ for $\mu^a \neq 0$. ∎

In the next theorem the transition from rotating waves to modulated rotating waves and modulated traveling waves is studied in the limit $\mathcal{K} \to 0$.

Theorem 4.11. *Let* $\mathrm{SE}(2)x_{\mathrm{RW}}(\mathcal{K})$ *be a nondegenerate rotating wave of a Hamiltonian system* (3.1) *which has a momentum map* $\mathbf{J}(\cdot, \mathcal{K})$ *with cocycle satisfying* (3.10), (3.11)*. Fix the momentum* $\mu_0 = \mathbf{J}(x_{\mathrm{RW}}(\mathcal{K}), \mathcal{K})$ *of* $x_{\mathrm{RW}}(\mathcal{K})$ *independent of* $\mathcal{K}$*. Then the following hold true.*

(a) *Fix* $\mathcal{K} \neq 0$*. Assume that the rotating wave* $\mathrm{SE}(2)x_{\mathrm{RW}}(\mathcal{K})$ *is elliptic and nonresonant in the sense of Definition 4.4, with normal frequencies* ω_j*,* $j = 1, \dots, \frac{1}{2}\dim\mathcal{M} - 2$*. Then there are* $(\frac{1}{2}\dim\mathcal{M} - 2)$ *many two-dimensional families* $\mathcal{P}_j(\nu, s, \mathcal{K})$ *of modulated rotating waves such that there are functions* $x_j(\nu, s, \mathcal{K}) \in \mathcal{P}_j(\nu, s, \mathcal{K})$ *which are smooth in* $s \geq 0$*,* $\mathcal{K}$*, and* $\nu \in (\mathbf{g}_{\mu_0}^K)^* \simeq \mathrm{so}(2)^*$ *with* $x_j(\nu, 0, \mathcal{K}) = x_{\mathrm{RW}}(\nu, \mathcal{K})$*. Here* $x_{\mathrm{RW}}(\nu, \mathcal{K})$ *lies on a rotating wave with momentum* $\mu_0 + \nu$*. The modulated rotating wave through* $x_j(\nu, s, \mathcal{K})$ *has relative period* $T_j(\nu, s, \mathcal{K})$ *with* $T_j(0, 0, \mathcal{K}) = 2\pi/|\omega_j|$*, energy* $H(x_j(\nu, s, \mathcal{K}), \mathcal{K}) = H(x_{\mathrm{RW}}(\nu, \mathcal{K}), \mathcal{K}) \pm s^2$ *(depending on the Krein signature of* ω_j*), and momentum* $\mathbf{J}(x_j(\nu, s, \mathcal{K}), \mathcal{K}) = \mu_0 + \nu$*,* $j = 1, \dots, \frac{1}{2}\dim\mathcal{M} - 2$.

(b) *Assume that there is a rotating wave* $\mathrm{SE}(2)x_0$ *at* $\mathcal{K} = 0$ *with rotation frequency* ω_0^{rot} *which is elliptic and nonresonant in the sense of Definition 4.4, and that* $\omega_0^{\mathrm{rot}}/\omega_j \notin \mathbb{Z}$ *for all eigenvalues* $\mathrm{i}\omega_j$ *of* $\mathbb{J}_{\mathcal{N}_1}\mathrm{D}_w^2 h(0, 0, 0)$*. Then the* $(\frac{1}{2}\dim\mathcal{M} - 3)$ *families* $\mathcal{P}_j(\nu^\phi, s)$ *of modulated rotating waves near* $\mathrm{SE}(2)x_0$ *from Proposition 4.6 at* $\mathcal{K} = 0$ *can be continued to small* $\mathcal{K} \neq 0$ *and correspond to families* $\mathcal{P}_j(\nu, s, \mathcal{K})$ *from part* (a) *with* $\nu = \nu^\phi$.

(c) *Assume that the rotating wave* $\mathrm{SE}(2)x_0$ *at* $\mathcal{K} = 0$ *is elliptic and nonresonant and that* $\omega_j/\omega_0^{\mathrm{rot}} \notin \mathbb{Z}$ *for all eigenvalues* $\mathrm{i}\omega_j$ *of* $\mathbb{J}_{\mathcal{N}_1}\mathrm{D}_w^2 h(0, 0, 0)$*. Then for* $\mathcal{K} \neq 0$*,* $\mathcal{K} \approx 0$*, one of the families* $\mathcal{P}(\nu, s, \mathcal{K})$ *from* (a) *corresponds to an eigenvalue* $\mathrm{i}\omega(\mathcal{K})$ *of* $\mathbb{J}_{\mathcal{N}_1(\mathcal{K})}\mathrm{D}_w^2 h(0, w_{\mathrm{RW}}(0, \mathcal{K}), \mathcal{K})$ *which depends smoothly on* $\mathcal{K}$ *such that* $\omega(0) = \omega_0^{\mathrm{rot}}$*. Here* ω_0^{rot} *is the rotation frequency of the rotating wave* $\mathrm{SE}(2)x_0$ *at* $\mathcal{K} = 0$*,* $\mathcal{N}_1(\mathcal{K})$ *is the symplectic normal space at the rotating wave through* $x_{\mathrm{RW}}(0, \mathcal{K}) \simeq (\mathrm{id}, 0, w_{\mathrm{RW}}(0, \mathcal{K})) \in \Gamma \times \mathcal{N}_0(\mathcal{K}) \oplus \mathcal{N}_1(\mathcal{K})$*,* $\mathcal{N}_0(\mathcal{K}) \simeq (\mathbf{g}_{\mu_0}^K)^*$*, and* $h(\nu, w, \mathcal{K})$ *is the Hamiltonian in symmetry-adapted coordinates at* $x_{\mathrm{RW}}(0, \mathcal{K})$ *for the cocycle parameter* $\mathcal{K}$*. As* $\mathcal{K} \to 0$*, this family converges to the family of modulated traveling waves from Theorem 4.3.*

Proof. (a) Fix $\mathcal{K} \neq 0$. Then, as shown in Example 3.9, $\mathcal{N}_0 = \mathcal{N}_0(\mathcal{K})$ is one-dimensional, and so $\mathcal{N}_1 = \mathcal{N}_1(\mathcal{K})$ has dimension $\dim\mathcal{M} - 4$. By the Lyapunov center theorem (see, e.g., [19]) applied to the ν-dependent $\dot{w}$-equation on $\mathcal{N}_1 = \mathcal{N}_1(\mathcal{K})$, there are $\frac{1}{2}\dim\mathcal{N}_1 = (\dim\mathcal{M} - 4)/2$ many families of nonlinear normal modes through $w_j(\nu, s, \mathcal{K})$. These give families of RPOs $\mathcal{P}_j(\nu, s, \mathcal{K})$ of (3.22) through $x_j(\nu, s, \mathcal{K}) \simeq (\mathrm{id}, \nu, w_j(\nu, s, \mathcal{K}))$ with momentum $\mathbf{J}(x_j(\nu, s, \mathcal{K})) = \mu_0 + \nu$; see (3.18). The statement about the energy of the RPOs is proved as in Proposition 4.6.

It was shown in Remark 3.4 that $\Gamma_\mu^\kappa \simeq \mathrm{SO}(2)$ for all $\mu \in \mathrm{se}(2)^*$. Hence (3.17) implies that all these RPOs are modulated rotating waves. This proves part (a).

(b) Let us reduce by SO(2)-symmetry only. The dynamics on the slice $\tilde{\mathcal{N}}(\mathcal{K})$ is then $\dot{\tilde{\nu}} \equiv 0$, $\tilde{\nu} = \nu^\phi \in \mathrm{so}(2)^*$, and $\dot{\tilde{w}} = \mathbb{J}_{\tilde{\mathcal{N}}_1(\mathcal{K})} \mathrm{D}_{\tilde{w}} \tilde{h}(\tilde{\nu}, \tilde{w}, \mathcal{K})$. Because of (3.8), (3.9), the matrix $\mathrm{ad}_{\xi_0} = -\mathrm{ad}_{\xi_0}^*$ has simple eigenvalues $0, \pm \mathrm{i}\omega_0^{\mathrm{rot}}$. Therefore, by (2.4) and (3.20), the equilibrium $\tilde{w} = 0$ of the $\dot{\tilde{w}}$-equation at $\tilde{\nu} = 0$, $\mathcal{K} = 0$, is elliptic; moreover, its linearization has, in addition to the eigenvalues $\pm \mathrm{i}\omega_j$, $j = 1, \dots, \frac{1}{2}\dim \mathcal{N}_1$, double eigenvalues $\pm \mathrm{i}\omega_0^{\mathrm{rot}}$. Let us apply the Lyapunov center theorem to the $\dot{\tilde{w}}$-equation. This gives relative normal modes $\tilde{w}_j(\tilde{\nu}, s, \mathcal{K})$ for all nonresonant normal frequencies. These correspond to all imaginary eigenvalues $\pm \mathrm{i}\omega_j$ with eigenvectors in the original symplectic normal space $\mathcal{N}_1$ for the full SE(2)-group action. Since by Remark 3.7 the $\dot{\tilde{w}}$-equation is smooth in $\mathcal{K}$, this gives $\frac{1}{2}\dim \mathcal{N}_1 = (\dim \mathcal{M} - 6)/2$ smooth families $\mathcal{P}_j(\nu^\phi, s, \mathcal{K})$ of RPOs through $x_j(\nu^\phi, s, \mathcal{K}) \simeq (\mathrm{id}, \tilde{\nu}, \tilde{w}_j(\nu^\phi, s, \mathcal{K}))$, $j = 1, \dots \frac{1}{2}\dim \mathcal{N}_1$, with momentum $\mathbf{J}(x_j(\nu^\phi, s, \mathcal{K})) = (\mu_0^\phi + \nu^\phi, 0)$; see (3.18). These RPOs are modulated rotating waves, since the system was reduced only by SO(2)-symmetry.

(c) Let $\mathcal{K} = 0$. Then (3.20) and (3.9) imply that the linearization of the $\dot{\nu}$-equation has eigenvalues $\pm \mathrm{i}\omega_0^{\mathrm{rot}}$ and 0, where the real eigenspace of $\pm \mathrm{i}\omega_0^{\mathrm{rot}}$ is given by $\{\nu = (0, \nu^a), \nu^a \in \mathbb{R}^2\} \subseteq \mathrm{se}(2)^*$. Compared to the slice equation (3.23) near rotating waves of momentum maps without cocycle, for $\mathcal{K} \neq 0$ the $\mathcal{N}_0(\mathcal{K})$ component of the slice $\mathcal{N}(\mathcal{K})$ is only one-dimensional instead of three-dimensional. Since $\mu_0^a = \mathbf{J}^a(x_0, 0) = 0$ and $\mu_0 = \mathbf{J}(x_{\mathrm{RW}}(\mathcal{K}), \mathcal{K})$ is fixed, Remark 3.9 implies that $\nu = \nu^\phi$ for $\mathcal{K} \neq 0$ and that then $\dot{\nu} \equiv 0$. For $\mathcal{K} \neq 0$ the eigenvalue $\pm \mathrm{i}\omega_0^{\mathrm{rot}}$ of $\mathrm{D}f_{\mathcal{N}}(0)$ perturbs into eigenvalues $\pm \mathrm{i}\omega(\mathcal{K})$ of $\mathrm{D}f_{\mathcal{N}(\mathcal{K})}(v_{\mathrm{RW}}(\mathcal{K}))$. Here $v_{\mathrm{RW}}(\mathcal{K})$ is the equilibrium of the slice equation at momentum μ_0 and cocycle parameter $\mathcal{K}$ corresponding to the relative equilibrium $x_{\mathrm{RW}}(\nu^\phi, \mathcal{K})$ at $\nu^\phi = 0$ from Theorem 4.9 (c). Since $\mathrm{D}f_{\mathcal{N}(\mathcal{K})}(v_{\mathrm{RW}}(\mathcal{K}))$ vanishes when restricted to $\mathcal{N}_0(\mathcal{K})$, it follows that $\pm \mathrm{i}\omega(\mathcal{K})$ are eigenvalues of $\mathrm{D}f_{\mathcal{N}_1(\mathcal{K})}(v_{\mathrm{RW}}(\mathcal{K}))$. By the Lyapunov center theorem and due to the nonresonance condition $\omega_j/\omega_0^{\mathrm{rot}} \notin \mathbb{Z}$, this gives one more family of nonlinear relative normal modes for $\mathcal{K} \neq 0$, $\mathcal{K} \approx 0$. It will now be shown that this additional family of RPOs converges to the family $\mathcal{P}(\nu^\phi, r^a)$ of modulated traveling waves from Theorem 4.3 as $\mathcal{K} \to 0$.

The proof of Theorem 4.3 can be extended to the case $\mathcal{K} \approx 0$, $\mathcal{K} \neq 0$. It is convenient to work in the slice coordinates $(\nu, w) \in \mathcal{N} = \mathcal{N}_0 \oplus \mathcal{N}_1$ at $\mathcal{K} = 0$, even when perturbations to cocycle parameters $\mathcal{K} \neq 0$ are considered. For any $\mathcal{K} \approx 0$ the dynamics on the slice $\mathcal{N}$ does not depend on γ and the energy $h(\nu, w, \mathcal{K})$ is still a conserved quantity. But note that the Poisson structure on $\mathcal{N}$ changes, and in particular $|\nu^a|^2$ is not a conserved quantity anymore. By (3.9), for $\mathcal{K} = 0$ the momentum group orbits $\mathrm{SE}(2)\mu$ are cylinders around the μ^ϕ-axis. For $\mathcal{K} \neq 0$, due to (3.10) and (3.11), they are paraboloids, centered along the μ^ϕ-axis. A Casimir, i.e., a function satisfying $C(\gamma \cdot_\kappa \mu) = C(\mu)$, where $\gamma \cdot_\kappa \mu$ is defined in (3.10), is given by $C(\mu^\phi, \mu^a) = \|\mu^a\|^2 + 2\mathcal{K}\mu^\phi$. Let $\mathbf{J}^a(\nu, w, \mathcal{K})$ and $\mathbf{J}^\phi(\nu, w, \mathcal{K})$ be the linear and angular momenta on the slice $\mathcal{N}$. Since the momentum map depends smoothly on $\mathcal{K}$, these maps are smooth in all variables. Then

$$C(\nu, w, \mathcal{K}) = \|\mathbf{J}^a(\nu, w, \mathcal{K})\|^2 + 2\mathcal{K}\mathbf{J}^\phi(\nu, w, \mathcal{K}) \tag{4.5}$$

is a conserved quantity for the slice equation. For $\mathcal{K} = 0$ one has $\mathbf{J}^a(\nu, w, \mathcal{K} = 0) = \nu^a$, $\mathbf{J}^\phi(\nu, w, \mathcal{K} = 0) = \nu^\phi$. Therefore, for $\mathcal{K} \approx 0$ the Casimir $C(\nu, w, \mathcal{K})$ is a small perturbation

of $C(\nu,w,\mathcal{K})|_{\mathcal{K}=0} = \|\nu^a\|^2$. The rotating waves through $x_{\mathrm{RW}}(\nu^\phi,\mathcal{K})$ from Theorem 4.9 (c) have energy $E_{\mathrm{RW}}(\nu^\phi,\mathcal{K}) = H(x_{\mathrm{RW}}(\nu^\phi,\mathcal{K}))$ with $\frac{\partial E_{\mathrm{RW}}}{\partial \nu^\phi}(0,0) = \omega_0^{\mathrm{rot}} \neq 0$. So they can be parametrized by $(E,\mathcal{K})$ instead of $(\nu^\phi,\mathcal{K})$ for $E \approx E_0 = H(x_0)$ and $\mathcal{K} \approx 0$. Let $x_{\mathrm{RW}}(E,\mathcal{K}) = (\mathrm{id}, \nu_{\mathrm{RW}}(E,\mathcal{K}), w_{\mathrm{RW}}(E,\mathcal{K})) \in \Gamma \times \mathcal{N}$ be the family of rotating waves near $x_0 \simeq (\mathrm{id},0,0)$. Then $\nu^a_{\mathrm{RW},1}(E,0) = 0$, $\nu^a_{\mathrm{RW},2}(E,0) = 0$ by Proposition 4.2. Since the slice equation conserves energy, the energy level sets $\mathcal{N}_{E,\mathcal{K}}$ of the slice $\mathcal{N}$ at cocycle parameter $\mathcal{K}$ are flow-invariant. Moreover, as $\mathrm{D}_{\nu^\phi} h(0) = \omega_0^{\mathrm{rot}}$, $\omega_0^{\mathrm{rot}} \neq 0$, they can be parametrized by

$$\begin{aligned}\mathcal{N}_{E,\mathcal{K}} &= \{(\nu,w) \in \mathcal{N}, \quad h(\nu,w,\mathcal{K}) = E\}\\ &= \{(\nu,w) \in \mathcal{N}, \quad \nu^\phi = \nu^\phi(E,\nu^a,w,\mathcal{K})\},\end{aligned}$$

where $E \approx E_0 = H(x_0)$, $\nu^a \approx 0$, $\mathcal{K} \approx 0$, $w \approx 0$. As in the proof of Theorem 4.3,

$$\begin{aligned}\mathcal{S}_{E,\mathcal{K}} = \{(\nu,w) \in \mathcal{N}, \quad \nu_2^a = \nu^a_{\mathrm{RW},2}(E,\mathcal{K}), \quad \nu_1^a > \nu^a_{\mathrm{RW},1}(E,\mathcal{K}),\\ \nu^\phi = \nu^\phi(E,\nu^a,w,\mathcal{K}), \quad w \in \mathcal{N}_1, \quad w \approx 0, \quad \nu^a \approx 0\}\end{aligned}$$

is a Poincaré section in $\mathcal{N}_{E,\mathcal{K}}$ for $E \approx E_0$, $\mathcal{K} \approx 0$. Denote $s = \nu_1^a - \nu^a_{\mathrm{RW},1}(E,\mathcal{K})$. Let us now look for fixed points of the Poincaré map $\Pi(E,s,w,\mathcal{K})$ which maps $\mathcal{S}_{E,\mathcal{K}}$ to itself.

Decompose $\Pi(E,s,w,\mathcal{K}) = (\Pi_0(E,s,w,\mathcal{K}), \Pi_1(E,s,w,\mathcal{K}))$, where $\Pi_1(\cdot)$ is the w-component ($w \in \mathcal{N}_1$) and $\Pi_0(\cdot)$ the s-component of Π. Due to the nonresonance condition, $\Pi_1(E,s,w,\mathcal{K}) = w$ can be solved for $\mathcal{K} \approx 0$, $s \approx 0$, $E \approx E_0 = H(x_0)$, by the implicit function theorem to obtain $w(E,s,\mathcal{K})$. Inserting this into Π_0, one obtains one scalar fixed point equation $s = \hat{\Pi}(E,s,\mathcal{K})$. This equation is satisfied due to the existence of the Casimir (4.5): Let $\hat{s} = \hat{\Pi}(E,s,\mathcal{K})$. Inserting $w = w(E,s,\mathcal{K})$ into (4.5), a function $C(E,s,\mathcal{K}) = s^2 + O(\mathcal{K})$ is obtained. Any equilibrium (ν,w) of the slice equation on $\mathcal{N}$ satisfies

$$\mathrm{D}\, C(\nu,w) \,||\, \mathrm{D}\, h(\nu,w)$$

or

$$\mathrm{D}(C|_{h=E}) = 0,$$

where $E = h(\nu,w)$. The equilibria corresponding to rotating waves of (3.1) are at $s = 0$, and therefore $\mathrm{D}_s C(E,0,\mathcal{K}) \equiv 0$. Moreover, $\mathrm{D}_s^2 C(E_0,0,0) = 2$, where $E_0 = H(x_0)$. So $s \to C(E,s,\mathcal{K})$ is monotonically increasing for $s \geq 0$, $E \approx E_0$, $\mathcal{K} \approx 0$, and one can solve for $s(E,C,\mathcal{K})$. Hence $\hat{s} = s$, and a family $(\nu,w)(E,C,\mathcal{K})$ of periodic orbits of the slice equation is obtained. This gives a family $\mathcal{P}(E,C,\mathcal{K})$ of RPOs of (3.22). Changing the parametrization of the RPOs $\mathcal{P}(E,C,\mathcal{K})$ from (E,C) back to (ν^ϕ,s), the notation of the theorem is recovered. Let $(\phi,a)(\nu^\phi,s,\mathcal{K})$ by the drift symmetry of the RPO $\mathcal{P}(\nu^\phi,s,\mathcal{K})$ at $x(\nu^\phi,s,\mathcal{K}) \simeq (\mathrm{id},(\nu,w)(\nu^\phi,s,\mathcal{K}))$. Note that for $\mathcal{K} = 0$, (3.18) gives $s = r^a$ and $\mathbf{J}(x(\nu^\phi,r^a,0)) = (\mu_0^\phi + \nu^\phi, r^a, 0)$. By (3.17) and (3.9) for $r^a \neq 0$ and $\mathcal{K} = 0$ all RPOs are modulated traveling waves. Therefore, $\phi(\nu^\phi,s,\mathcal{K}) \to 0$ as $\mathcal{K} \to 0$ and the RPOs $\mathcal{P}(\nu^\phi,s,\mathcal{K})$ become modulated traveling waves in the limit of vanishing cocycle. ■

5. Extensions to systems with other symmetry groups. In this section the Hamiltonian analogue of the meandering transition is discussed for systems with spherical symmetry and for systems with the Euclidean symmetry group of three-dimensional space. See Remarks 2.2 (b) and (c) for the corresponding dissipative case.

5.1. Hamiltonian meandering transition with spherical symmetry. In this section it is assumed that the Hamiltonian system (3.1) has spherical symmetry $\Gamma = \mathrm{SO}(3)$. Then persistence of rotating waves to modulated rotating waves at nearby momentum values is studied. Thereby the analogue of Remark 2.2 (b) is studied in the Hamiltonian context. The results can be applied to rotating point vortices on the sphere; see, e.g., [16].

For $\mu_0 = 0$ the momentum isotropy subalgebra is $\mathbf{g}_{\mu_0} = \mathrm{so}(3)$ and for $\mu_0 \neq 0$ (the typical case) it is $\mathbf{g}_{\mu_0} = \mathrm{so}(2)$. Let us first consider the generic case of a rotating wave with momentum $\mu_0 \neq 0$.

Theorem 5.1. *Let $\mathrm{SO}(3)x_0$ be a nondegenerate rotating wave with nonvanishing momentum μ_0 and drift velocity ξ_0. Align x_0 such that $\mu_0 = (0, 0, \mu_{0,3})$, $\xi_0 = (0, 0, \omega_0^{\mathrm{rot}})^T$. Then the following hold true:*

(a) *The rotating wave $\mathrm{SO}(3)x_0$ persists to every nearby momentum. Moreover, there is a one-dimensional family of rotating waves $\mathrm{SO}(3)x_{\mathrm{RW}}(\nu)$, $\nu \approx 0$, such that $x_{\mathrm{RW}}(\nu)$ is smooth and $x_{\mathrm{RW}}(0) = x_0$. The rotating wave through $x_{\mathrm{RW}}(\nu)$ has drift velocity $\xi_{\mathrm{RW}}(\nu)||e_3$, with $\xi_{\mathrm{RW}}(0) = \xi_0$, and momentum $\mathbf{J}(x_{\mathrm{RW}}(\nu)) = (0, 0, \mu_{0,3} + \nu)$.*

(b) *Let the rotating wave $\mathrm{SO}(3)x_0$ be elliptic and nonresonant in the sense of Definition 4.4 and denote its normal frequencies by ω_j. Then there are $(\frac{1}{2}\dim\mathcal{M} - 2)$ two-dimensional families $\mathcal{P}_j(\nu, s)$, $j = 1, \ldots \frac{1}{2}\dim\mathcal{M} - 2$, $\nu \approx 0$, $s \geq 0$, of modulated rotating waves nearby such that there are smooth functions $x_j(\nu, s) \in \mathcal{P}_j(\nu, s)$ with $x_j(\nu, 0) = x_{\mathrm{RW}}(\nu)$ (where $x_{\mathrm{RW}}(\nu)$ is from (a)). These modulated rotating waves have energy $H(x_j(\nu, s)) = H(x_{\mathrm{RW}}(\nu)) \pm s^2$ (depending on the Krein signature of ω_j), momentum $\mathbf{J}(x_j(\nu, s)) = (0, 0, \mu_{0,3} + \nu)$, relative period $T_j(\nu, s)$, such that $T_j(0, 0) = \frac{2\pi}{|\omega_j|}$, and average drift velocity $\xi_j(\nu, s)||e_3$ at $x_j(\nu, s)$, with $\xi_j(0, 0) = \xi_0$.*

So resonance drift cannot occur near rotating waves of SO(3)-symmetric Hamiltonian systems with nonvanishing angular momentum.

Proof of Theorem 5.1. If $\mu_0 \neq 0$, then $\mathcal{N}_0 \simeq \mathbf{g}_{\mu_0}^* \simeq \mathrm{so}_3(2)^*$ is one-dimensional. Here $\mathrm{so}_3(2)$ corresponds to infinitesimal rotations around the e_3-axis. So the $\dot{\nu}$-equation of (3.19) just becomes $\dot{\nu} = 0$.

(a) A nondegenerate rotating wave $\mathrm{SO}(3)x_0$ persists as equilibrium $w_{\mathrm{RW}}(\nu)$ of the $\dot{w}$-equation for $\nu \approx 0$. This gives a rotating wave of (3.1) through $x_{\mathrm{RW}}(\nu) \simeq (\mathrm{id}, \nu, w_{\mathrm{RW}}(\nu))$ with nonvanishing momentum $\mathbf{J}(x_{\mathrm{RW}}(\nu)) = (0, 0, \mu_{0,3} + \nu)$, $\nu \approx 0$; cf. (3.18). Due to SO(3)-equivariance the rotating wave persists to all nearby momenta.

(b) By the Lyapunov center theorem there are $\frac{1}{2}\dim(\mathcal{N}_1)$ families $w_j(\nu, s)$ of periodic orbits of the $\dot{w}$-equation, parametrized by ν and s. Here $\dim\mathcal{N}_1 = \dim\mathcal{M} - 4$. These give points $x_j(\nu, s) = (\mathrm{id}, \nu, w_j(\nu, s))$ on modulated rotating waves $\mathcal{P}_j(\nu, s)$ with $x_j(\nu, 0) = x_{\mathrm{RW}}(\nu)$ and with momentum $\mathbf{J}(x_j(\nu, s)) = \mu_0 + \nu = (0, 0, \mu_{0,3} + \nu_3)$; see (3.18). Let $\mathrm{SO}_3(2)$ be the group of rotations around e_3 with Lie algebra $\mathrm{so}_3(2)$. Since $\mathbf{J}(x_j(\nu, s)) \neq 0$ and $\mathbf{J}(x_j(\nu, s))||e_3$, by (3.17) the drift symmetry $R_j(\nu, s)$ of the RPO at $x_j(\nu, s)$ lies in $\mathrm{SO}_2(3)$, and so the average drift velocity $\xi_j(\nu, s)$ at $x_j(\nu, s)$ is in $\mathrm{so}_3(2)$. ∎

Next let us consider the case that the rotating wave $\mathrm{SO}(3)x_0$ has zero angular momentum $\mu_0 = 0$. In this case resonance drift typically occurs, as the following theorem shows.

Theorem 5.2. *Consider a nondegenerate rotating wave $\mathrm{SO}(3)x_0$ with momentum $\mu_0 = \mathbf{J}(x_0) = 0$ and nonvanishing drift velocity $\xi_0 \neq 0$. Choose x_0 such that $\xi_0 = (0, 0, \omega_0^{\mathrm{rot}})^T$, where ω_0^{rot} is the rotation frequency of the rotating wave at x_0. Then the following hold true.*

(a) *There is a one-parameter family* $\mathrm{SO}(3)x_{\mathrm{RW}}(\nu_3)$ *of rotating waves nearby,* $\nu_3 \approx 0$*, with momentum* $\mathbf{J}(x_{\mathrm{RW}}(\nu_3)) = (0,0,\nu_3)$ *and drift velocity* $\xi_{\mathrm{RW}}(\nu_3)||e_3$ *at* $x_{\mathrm{RW}}(\nu_3)$*, such that* $\xi_{\mathrm{RW}}(0) = \xi_0$*. Moreover, the rotating wave* $\mathrm{SO}(3)x_0$ *persists to all nearby momentum values.*

(b) *Assume that* $\mathbb{J}_{\mathcal{N}_1}\mathrm{D}_w^2 h(0)$ *has no eigenvalues in* $\mathrm{i}\omega_0^{\mathrm{rot}}\mathbb{Z}$*. Then there is a two-parameter family* $\mathcal{P}_{\mathrm{MRW}}(\nu_2,\nu_3)$*,* $\nu_2 \geq 0$*,* $\nu_3 \approx 0$*, of modulated rotating waves of* (3.1) *such that* $x_{\mathrm{MRW}}(\nu_2,\nu_3) \in \mathcal{P}_{\mathrm{MRW}}(\nu_2,\nu_3)$ *is smooth in* (ν_2,ν_3) *and* $x_{\mathrm{MRW}}(0,\nu_3) = x_{\mathrm{RW}}(\nu_3)$*. The modulated rotating wave at* $x_{\mathrm{MRW}}(\nu_2,\nu_3)$ *has drift symmetry* $\gamma_{\mathrm{MRW}}(\nu_2,\nu_3)$*, relative period* $T(\nu_2,\nu_3)$*, and momentum* $\mathbf{J}(x_{\mathrm{MRW}}(\nu_2,\nu_3)) = (0,\nu_2,\nu_3)$*, and* $x_{\mathrm{MRW}}(0,0) = x_0$*,* $T(0,0) = 2\pi/|\omega_0^{\mathrm{rot}}|$*,* $\gamma_{\mathrm{MRW}}(0) = \mathrm{id}$*. This family contains a one-parameter family* $\mathcal{P}(\nu_2,0)$ *of modulated rotating waves which have an average drift velocity* $\xi(\nu_2,0)$ *at* $x_{\mathrm{MRW}}(\nu_2,0)$ *parallel to the* e_2*-axis.*

(c) *Assume that the rotating wave* $\mathrm{SO}(3)x_0$ *is elliptic and nonresonant in the sense of Definition* 4.4 *and that* $\mathbb{J}_{\mathcal{N}_1}\mathrm{D}_w^2 h(0)$ *has no eigenvalues* $\mathrm{i}\omega_j$ *with* $\omega_0^{\mathrm{rot}}/\omega_j \in \mathbb{Z}$*. Then there are* $(\frac{1}{2}\dim\mathcal{M} - 3)$ *more two-parameter families* $\mathcal{P}_j(\nu_3,s)$*,* $j = 1,\dots\frac{1}{2}\dim\mathcal{M} - 3$*, of modulated rotating waves near the rotating wave and there are smooth functions* $x_j(\nu_3,s) \in \mathcal{P}_j(\nu_3,s)$ *with* $x_j(\nu_3,0) = x_{\mathrm{RW}}(\nu_3)$ *(where* $x_{\mathrm{RW}}(\nu_3)$ *is from part* (a)*). The modulated rotating wave* $\mathcal{P}_j(\nu_3,s)$ *has momentum* $\mathbf{J}(x_j(\nu_3,s)) = (0,0,\nu_3)$ *at* $x_j(\nu_3,s)$*, energy* $H(x_j(\nu_3,s)) = H(x_{\mathrm{RW}}(\nu_3)) \pm s^2$ *(depending on the Krein signature of* ω_j*), relative period* $T_j(\nu_3,s)$ *such that* $T_j(0,0) = 2\pi/|\omega_j|$*, and average drift velocity* $\xi_j(\nu_3,s)||e_3$*,* $s \geq 0$*, with* $\xi_j(0,0) = \xi_0$*,* $j = 1,\dots\frac{1}{2}\dim\mathcal{M} - 3$*.*

Proof. If the rotating wave $\mathrm{SO}(3)x_0$ has momentum $\mu_0 = 0$, then $\mathbf{g}_{\mu_0} = \mathrm{so}(3)$. In this case $\nu \in \mathrm{so}(3)^* \simeq \mathbb{R}^3$ and the $\dot{\nu}$-equation from (3.19) becomes

$$\dot{\nu} = \nu \times \mathrm{D}_\nu h(\nu, w). \tag{5.1}$$

(a) Since the $\dot{\nu}$ equation has nontrivial dynamics, let us reduce only by the symmetry group

$$\tilde{\Gamma} = \{\gamma \in \mathrm{SO}(3), \quad \mathrm{Ad}_\gamma \xi_0 = \xi_0\} = \mathrm{SO}_3(2),$$

which is the group of rotations around the e_3-axis. The corresponding slice is denoted by $\widetilde{\mathcal{N}} = \widetilde{\mathcal{N}}_0 \oplus \widetilde{\mathcal{N}}_1$. Then $\tilde{\nu} \in \widetilde{\mathcal{N}}_0$ is given by $\tilde{\nu} = \nu_3$ and $\dot{\tilde{\nu}} = 0$. Note that $\dim\widetilde{\mathcal{N}}_1 = \dim\mathcal{N}_1 + 4$. Let $\tilde{h}(\tilde{\nu},\tilde{w})$ be the Hamiltonian in the bundle coordinates $(\tilde{\gamma},\tilde{\nu},\tilde{w}) \in \tilde{\Gamma} \times \widetilde{\mathcal{N}}_0 \oplus \widetilde{\mathcal{N}}_1$. The matrix $\mathrm{ad}^*_{\xi_0}$ has eigenvalues $\pm\mathrm{i}\omega_0^{\mathrm{rot}}$ with real eigenspace $\{\nu = (\nu_1,\nu_2,0) \in \mathrm{so}(3)^*\}$ and a simple eigenvalue 0. Because of (2.4) and (3.20), the eigenvalues of the linearization $\mathbb{J}_{\widetilde{\mathcal{N}}_1}\mathrm{D}^2_{\tilde{w}}\tilde{h}(0)$ of the equilibrium $0 \in \widetilde{\mathcal{N}}_1$ corresponding to the rotating wave $\mathrm{SO}(3)x_0$ are given by the eigenvalues of $\mathbb{J}_{\mathcal{N}_1}\mathrm{D}_w^2 h(0)$ and by the eigenvalues $\pm\mathrm{i}\omega_0^{\mathrm{rot}}$ of multiplicity two. Hence the rotating wave is nondegenerate when considered as a rotating wave of a Hamiltonian system with $\mathrm{SO}_3(2)$-symmetry. Therefore, $\dot{\tilde{w}} = 0$ for $\tilde{w}(\tilde{\nu})$ can be solved using the nondegeneracy condition. This gives rotating waves $\mathrm{SO}(3)x_{\mathrm{RW}}(\tilde{\nu})$, $x_{\mathrm{RW}}(\tilde{\nu}) \simeq (\mathrm{id},\tilde{\nu},\tilde{w}(\tilde{\nu}))$ for the original $\mathrm{SO}(3)$-equivariant Hamiltonian system (3.1). Since only a reduction by $\mathrm{SO}_3(2)$-symmetry was carried out, these rotating waves have drift velocities $\xi_{\mathrm{RW}}(\nu_3)||e_3$, where $\xi(0) = \xi_0 \neq 0$. Then (3.16) implies that also $\mathbf{J}(x(\nu_3))||e_3$. This proves part (a).

(b) The rotating waves through $x_{\mathrm{RW}}(\nu_3) \simeq (\gamma_{\mathrm{RW}}(\nu_3),\nu_{\mathrm{RW}}(\nu_3),w_{\mathrm{RW}}(\nu_3))$ from part (a) have, by (3.18), momentum

$$\mathbf{J}(x_{\mathrm{RW}}(\nu_3)) = (0,0,\nu_3) = \gamma_{\mathrm{RW}}(\nu_3)\nu_{\mathrm{RW}}(\nu_3)$$

and energy $E_{\mathrm{RW}}(\nu_3) = h(\nu_{\mathrm{RW}}(\nu_3), w_{\mathrm{RW}}(\nu_3))$, where

$$E'_{\mathrm{RW}}(0) = \mathrm{D}_\nu h(0)\nu'_{\mathrm{RW}}(0) = \omega_0^{\mathrm{rot}} \neq 0.$$

Therefore, they can be parametrized by energy E instead of ν_3. Let $x_{\mathrm{RW}}(E) \simeq (\gamma_{\mathrm{RW}}(E), \nu_{\mathrm{RW}}(E), w_{\mathrm{RW}}(E))$ again denote the corresponding path of rotating waves. Let $\omega^{\mathrm{rot}}(E)$ be the rotation frequency of the rotating wave $\mathrm{SO}(3)x_{\mathrm{RW}}(E)$. Since the slice equation conserves the energy $h(\nu, w)$ the energy level sets $\mathcal{N}_E$ of $\mathcal{N}$ are flow-invariant. Because of $\mathrm{D}_\nu h(0) = (0, 0, \omega_0^{\mathrm{rot}})$, $\omega_0^{\mathrm{rot}} \neq 0$, and $\mathrm{D}_w h(0) = 0$, they can be parametrized for $E \approx E_0 = h(0)$, similarly as in the proof of Theorem 4.3, by

$$\mathcal{N}_E = \{(\nu, w) \in \mathcal{N}, \quad h(\nu, w) = E\} = \{(\nu, w) \in \mathcal{N}, \quad \nu_3 = \nu_3(\nu_1, \nu_2, w, E)\}.$$

Then $\nu_3(\nu_{\mathrm{RW},1}(E), \nu_{\mathrm{RW},2}(E), w_{\mathrm{RW}}(E), E) = \nu_{\mathrm{RW},3}(E)$. Let us now consider the equilibrium $v_{\mathrm{RW}}(E) := (\nu_{\mathrm{RW}}(E), w_{\mathrm{RW}}(E))$ of the slice equation as periodic orbit with period $T^{\mathrm{rot}}(E) = \frac{2\pi}{|\omega^{\mathrm{rot}}(E)|}$. The matrix $\mathrm{ad}^*_{\xi_0}$ has a pair $\pm\mathrm{i}\omega_0^{\mathrm{rot}}$ of nonvanishing imaginary eigenvalues with real eigenspace spanned by the vectors $\{(\nu_1, \nu_2, 0),\ \nu_1, \nu_2 \in \mathbb{R}\} \subseteq \mathrm{so}(3)^*$. By (3.20), the linearization of the slice equation $\mathrm{D}_v f_{\mathcal{N}}(v_{\mathrm{RW}}(E))$ at $E = E_0$ also has this pair of eigenvalues which perturbs to the eigenvalues $\pm\mathrm{i}\omega^{\mathrm{rot}}(E)$ of $\mathrm{D}_v f_{\mathcal{N}}(v_{\mathrm{RW}}(E))$ for $E \approx E_0$. Consequently,

$$\begin{aligned}\mathcal{S}_E = \{(\nu, w) \in \mathcal{N}_E,\ \nu_1 = \nu_{\mathrm{RW},1}(E),\ \nu_2 > \nu_{\mathrm{RW},2}(E),\ \nu_2 \approx \nu_{\mathrm{RW},2}(E),\\ \nu_3 = \nu_3(\nu_{\mathrm{RW},1}(E), \nu_2, w, E),\ w \approx w_{\mathrm{RW}}(E)\}\end{aligned}$$

is a section transverse to the flow of the slice equation at $v_{\mathrm{RW}}(E)$ inside the energy level set $\mathcal{N}_E$ to the energy $E \approx E_0$. Let $s := \nu_2 - \nu_{\mathrm{RW},2}(E)$. The corresponding Poincaré map is denoted by $\Pi(\cdot, E) : \mathcal{S}_E \to \mathcal{S}_E$. Decompose $\Pi(\cdot, E) = (\Pi_0(\cdot, E), \Pi_1(\cdot, E))$, where Π_0 maps into the ray $s \geq 0$ and Π_1 into $\mathcal{N}_1$. By assumption there is no k : 1-resonance between ω_0^{rot} and any normal frequency on $\mathcal{N}_1$. Therefore, the equation $\Pi_1(s, w, E) = w$ can be solved for $w(s, E)$, such that $w(0, E) = w_{\mathrm{RW}}(E)$ for $E \approx E_0$. Plugging this into Π_0 a map $\tilde{\Pi}(\cdot, E)$ from the ray $s \geq 0$ into itself is obtained. The $\dot{\nu}$-equation (5.1) conserves the Casimir $C^R(\nu, w) = \|\nu\|_2^2$. Define $\nu_3(s, E) := \nu_3(\nu_{\mathrm{RW},1}(E), s+\nu_{\mathrm{RW},2}(E), w(s, E), E)$. Then $\hat{s} = \hat{\Pi}(s, E)$ satisfies $C(\hat{s}, E) = C(s, E)$, where

$$C(s, E) = (\nu_{\mathrm{RW},1}(E))^2 + (\nu_{\mathrm{RW},2}(E) + s)^2 + (\nu_3(s, E))^2.$$

The path of relative equilibria $\mathrm{SO}(3)x_{\mathrm{RW}}(E)$ corresponds to $(s, E) = (0, E)$. Note that

$$\mathrm{D}\, h(v_{\mathrm{RW}}(E)) \mid\mid \mathrm{D}\, C^R(v_{\mathrm{RW}}(E))$$

and that $\mathrm{D}\, C^R|_{h(v)=E} = 0$ at $v = v_{\mathrm{RW}}(E)$. As a result of this, $\mathrm{D}_s C(0, E) \equiv 0$. Moreover, from $\mathrm{D}_\nu h(0) = \omega_0^{\mathrm{rot}} e_3$ and $\mathrm{D}_w h(0) = 0$, it follows that $\mathrm{D}_s \nu_3(0, E_0) = 0$, and therefore $\mathrm{D}_s^2 C(0, E_0) = 2$. Hence $s \to C(s, E)$ is injective for $s \geq 0$, $s \approx 0$, for any fixed $E \approx E_0$. Consequently $\hat{s} = s$, and so $v(s, E) := (\nu(s, E), w(s, E))$, with $\nu(s, E) = (\nu_{\mathrm{RW},1}(E), s + \nu_{\mathrm{RW},2}(E), \nu_3(s, E))^T$, lies on a periodic orbit of the slice equation with period $T(s, E) \approx T(0, E) = \frac{2\pi}{|\omega^{\mathrm{rot}}(E)|}$.

Changing the parametrization back from E to ν_3, a two-parameter family $v(s, \nu_3) = (\nu(s, \nu_3), w(s, \nu_3))$ of periodic orbits of the slice equation with periods $T(s, \nu_3)$ is obtained, satisfying $T(0, \nu_3) = T^{\mathrm{rot}}(0, \nu_3)$. These give points $\hat{x}(s, \nu_3) \simeq (\gamma_{\mathrm{RW}}(\nu_3), v(s, \nu_3))$ on modulated rotating waves of the full Hamiltonian system (3.1) with momentum $\hat{\mu}(s, \nu_3) = \gamma_{\mathrm{RW}}(\nu_3)\nu(s, \nu_3)$;

see (3.18). At the rotating waves $\hat{\mu}(0,\nu_3) = \nu_3$ and hence $\mathrm{D}_{\nu_3}\hat{\mu}(0,\nu_3) \equiv e_3$. Moreover, $\gamma_{\mathrm{RW}}(0) = \mathrm{id}$ implies that $\mathrm{D}_s\hat{\mu}(0,0) \equiv e_2$. So smooth functions $\hat{\phi}_2(s,\nu_3)$, $\hat{\phi}_3(s,\nu_3)$ can be found such that $\hat{\gamma}(s,\nu_3) = \exp(\hat{\phi}_2(s,\nu_3)\xi_2 + \hat{\phi}_3(s,\nu_3)\xi_3)$ (with the notation from (2.9)) satisfies $(\hat{\gamma}(s,\nu_3)\hat{\mu}(s,\nu_3))_1 = 0$ and $\hat{\phi}_2(0,\nu_3) = 0$, $\hat{\phi}_3(0,\nu_3) = 0$. Let $\gamma(s,\nu_3) = \hat{\gamma}(s,\nu_3)\gamma_{\mathrm{RW}}(\nu_3)$. Then $x(s,\nu_3) \simeq (\gamma(s,\nu_3), v(s,\nu_3))$ lies on an RPO with momentum $\mu(s,\nu_3)$ such that $\mu_1(s,\nu_3) = 0$. Then s can be replaced by ν_2 and (ν_2,ν_3) can be tranformed such that $x(\nu_2,\nu_3)$ has momentum $\mu(\nu_2,\nu_3) = \mathbf{J}(x(\nu_2,\nu_3)) = (0,\nu_2,\nu_3)$, $\nu_2 \geq 0$.

The condition (3.17) implies that the drift symmetry $\gamma(\nu_2,\nu_3)$ at the RPO through $x(\nu_2,\nu_3)$ satisfies $\gamma(\nu_2,\nu_3)\mu(\nu_2,\nu_3) = \mu(\nu_2,\nu_3)$, where $\gamma(0) = \mathrm{id}$. Therefore, $\gamma(\nu_2,\nu_3)$ is a rotation around the vector $\mu(\nu_2,\nu_3)$ in the (x_2,x_3)-plane. Moreover, for $\nu_3 = 0$ the modulated rotating wave $\mathcal{P}(\nu_2,0)$ rotates around the e_2-axis with momentum $\mu(\nu_2) = (0,\nu_2,0)$ at $x(\nu_2,0)$.

(c) By assumption there is no $k:1$-resonance between any of the eigenvalues of $\mathbb{J}_{\mathcal{N}_1}\mathrm{D}^2_w h(0)$ and between the eigenvalues of $\mathbb{J}_{\mathcal{N}_1}\mathrm{D}^2_w h(0)$ and $\mathrm{i}\omega_0^{\mathrm{rot}}$. Hence for all normal frequencies on $\mathcal{N}_1$, part (c) follows from the Lyapunov center theorem applied on the space $\tilde{\mathcal{N}}_1$, after symmetry reduction by $\mathrm{SO}_3(2)$ as in part (a). ∎

5.2. Hamiltonian meandering transition with the Euclidean symmetry of three-dimensional space. In this section the Hamiltonian analogue of the resonance drift of Remark 2.2 (c) is studied. The symmetry group is again $\Gamma = \mathrm{SE}(3) = \mathrm{SO}(3) \ltimes \mathbb{R}^3$. Similarly as in (3.8), (3.9), the adjoint and coadjoint actions for $\Gamma = \mathrm{SE}(3)$ are

$$\begin{aligned} \mathrm{Ad}_{(R,a)}\xi &= (\, R\xi^r \,,\, R\xi^a - R\xi^r \times a \,)\,, \\ \mathrm{Ad}^*_{(R,a)^{-1}}\mu &= (\, R\mu^r + a \times R\mu^a \,,\, R\mu^a \,)\,, \end{aligned} \tag{5.2}$$

where $(R,a) \in \mathrm{SO}(3) \ltimes \mathbb{R}^3$; see, e.g., [15, 26]. So typically, when $\mu^a \neq 0$, then $\Gamma_\mu \simeq \mathrm{SO}(2) \times \mathbb{R}$. In this case resonance drift is not possible.

Proposition 5.3. *Let $\mathrm{SE}(3)x_0$ be a nondegenerate relative equilibrium with generic momentum value μ_0 satisfying $\mu_0^a \neq 0$ and with drift velocity ξ_0. Align x_0 such that $\xi_0^a || e_3$, $\xi_0^r || e_3$. Then the following hold true.*

(a) *There is a two-parameter family $\mathrm{SE}(3)x_{\mathrm{RE}}(\nu_3^r,\nu_3^a)$ of relative equilibria of (3.1) with $x_{\mathrm{RE}}(0,0) = x_0$. The relative equilibrium at $x_{\mathrm{RE}}(\nu_3^r,\nu_3^a)$ has angular momentum $\mathbf{J}^r(x_{\mathrm{RE}}(\nu_3^r,\nu_3^a)) = (0,0,\mu^r_{0,3} + \nu_3^r)$, linear momentum $\mathbf{J}^r(x_{\mathrm{RE}}(\nu_3^r,\nu_3^a)) = (0,0,\mu^a_{0,3} + \nu_3^a)$, and drift velocity $\xi_{\mathrm{RE}}(\nu_3^r,\nu_3^a)$, which satisfies $\xi^r_{\mathrm{RE}}(\nu_3^r,\nu_3^a) || e_3$, $\xi^a_{\mathrm{RE}}(\nu_3^r,\nu_3^a) || e_3$.*

(b) *Let the relative equilibrium $\mathrm{SE}(3)x_0$ be elliptic and nonresonant in the sense of Definition 4.4 and denote its normal frequencies by ω_j, $j = 1,\dots,\frac{1}{2}\dim\mathcal{M} - 4$. Then there are $(\frac{1}{2}\dim\mathcal{M} - 4)$ families of RPOs $\mathcal{P}_j(\nu_3^r,\nu_3^a,s)$, $s \geq 0$, and smooth functions $x_j(\nu_3^r,\nu_3^a,s) \in \mathcal{P}_j(\nu_3^r,\nu_3^a,s)$ such that $x_j(\nu_3^r,\nu_3^a,0) = x_{\mathrm{RE}}(\nu_3^r,\nu_3^a)$. The RPO at $x_j(\nu_3^r,\nu_3^a,s)$ has momentum*

$$\mathbf{J}^r(x_j(\nu_3^r,\nu_3^a,s)) = (0,0,\mu^r_{0,3} + \nu_3^r), \quad \mathbf{J}^a(x_j(\nu_3^r,\nu_3^a,s)) = (0,0,\mu^a_{0,3} + \nu_3^a),$$

energy $H(x_j(\nu_3^r,\nu_3^a,s)) = H_{\mathrm{RE}}(\nu_3^r,\nu_3^a)) \pm s^2$ (depending on the Krein signature of ω_j), relative period $T_j(\nu_3^r,\nu_3^a,s)$, such that $T_j(0,0,0) = 2\pi/|\omega_j|$, and average drift velocity $\xi_j(\nu_3^r,\nu_3^a,s)$ at $x_j(\nu_3^r,\nu_3^a,s)$, which satisfies $\xi_j^r(\nu_3^r,\nu_3^a,s) || e_3$, $\xi_j^a(\nu_3^r,\nu_3^a,s) || e_3$, $\xi_j(0,0) = \xi_0$.

Proof. (a) Note that, by (5.2), $\xi_0^a || e_3$, $\xi_0^r || e_3$ implies $\mu_0^a || e_3$, $\mu_0^r || e_3$. The Lie-group $\Gamma_{\mu_0} \simeq \mathrm{SO}_3(2) \times \mathbb{R}_3$ is abelian; therefore, $\dot{\nu} \equiv 0$ holds in the equations (3.19) near a relative equilibrium

$\mathrm{SE}(3)x_0$ with generic momentum value. By the nondegeneracy condition, $\dot{w} = 0$ can be solved for $w_{\mathrm{RE}}(\nu)$ to obtain relative equilibria through $x_{\mathrm{RE}}(\nu) \simeq (\mathrm{id}, \nu, w_{\mathrm{RE}}(\nu))$. The statement about the momentum of $x_{\mathrm{RE}}(\nu)$ follows from (3.18), and the statement about the velocity $\xi_{\mathrm{RE}}(\nu)$ from (3.16) and (5.2).

(b) The Lyapounov center theorem can be applied on the ν-dependent $\dot{w}$-equation. The statements about the momentum of the families of RPOs follows from (3.18). The fact that their drift symmetry lies in $\mathrm{SO}_3(2) \times \mathbb{R}_3$, and hence their average drift velocity in $\mathrm{so}_3(2) \times \mathbb{R}_3$, follows from (3.17) and the fact that $\Gamma_{\mu_0} \simeq \mathrm{SO}_3(2) \times \mathbb{R}_3$; see part (a). ∎

The situation is different if the relative equilibrium $\mathrm{SE}(3)x_0$ has a nongeneric momentum value $\mu_0 = \mathbf{J}(x_0)$. In what follows, it is shown that in this case resonance drift occurs generically.

If $\mu_0^a = 0$, then (5.2) implies that $\Gamma_{\mu_0} \simeq \mathrm{SO}(2) \ltimes \mathbb{R}^3$. Let us assume, without loss of generality, that $\mu_0^r || e_3$. Then the drift velocity $\xi_0 = (\xi_0^r, \xi_0^a)$ of the relative equilibrium at x_0 satisfies $\xi_0^r || e_3$. Choose x_0 in its $\mathrm{SE}(3)$ orbit such that also $\xi_0^a || e_3$. The momentum value μ_0 is nonsplit, and the $\dot{\nu}$-equation of (3.19) for $\nu = (\nu^r, \nu^a) \in \mathrm{so}(2)^* \oplus (\mathbb{R}^3)^*$ is nontrivial; see [26]. It can be easily checked that the functions

$$C^a(\mu) = \|\mu^a\|^2 \quad \text{and} \quad C^r(\mu) = \langle \mu^a, \mu^r \rangle \tag{5.3}$$

are invariant under the coadjoint action (5.2). These restrict to the functions $C^a(\nu) = \|\nu^a\|^2$ and $C^r(\nu) = \nu_3^a(\mu_3^r + \nu^r)$ on the slice $\mathcal{N}_0 \simeq \mathrm{so}(2)^* \oplus (\mathbb{R}^3)^*$ and are Casimirs, i.e., conserved quantities of the $\dot{\nu}$-equation.

In the following proposition persistence of a relative equilibrium with vanishing linear momentum is studied, as a prerequisite for the analysis of the Hamiltonian meandering transition.

Proposition 5.4. *Let $\mathrm{SE}(3)x_0$ be a nondegenerate relative equilibrium with momentum value $\mu_0 = (\mu_0^r, 0)$, $\mu_0^r || e_3$, and with drift velocity $\xi_0 = (\xi_0^r, \xi_0^a)$, where $\xi_0^r \neq 0$, $\xi_0^r || e_3$, $\xi_0^a || e_3$. Then there exists a two-dimensional family of relative equilibria $\mathrm{SE}(3)x_{\mathrm{RE}}(\nu^r, \nu_3^a)$ of (3.1) such that $x_{\mathrm{RE}}(\nu^r, \nu_3^a)$ is smooth in its parameters and $x_{\mathrm{RE}}(0) = x_0$, $\xi_{\mathrm{RE}}(0,0) = \xi_0$. The relative equilibrium through $x_{\mathrm{RE}}(\nu^r, \nu_3^a)$ has angular momentum $\mathbf{J}^r(x_{\mathrm{RE}}(\nu^r, \nu_3^a)) = \mu_0^r + \nu^r e_3$, linear momentum $\mathbf{J}^a(x_{\mathrm{RE}}(\nu^r, \nu_3^a)) = \nu_3^a e_3$, and drift velocity $\xi_{\mathrm{RE}}(\nu^r, \nu_3^a)$, where $\xi_{\mathrm{RE}}^r(\nu^r, \nu_3^a) = \omega^{\mathrm{rot}}(\nu^r, \nu_3^a) e_3$, $\xi_{\mathrm{RE}}^a(\nu^r, \nu_3^a) || e_3$.*

Proof. This proposition is an application of a persistence result for general noncompact symmetry groups; see [32, Example 5.3(a)]. But it can also be proved in an elementary way: Because of (2.4), (3.20), the linearization L_0 at x_0 has, by our nondegeneracy condition and the form of ad_{ξ_0} from (5.2), a four-dimensional kernel corresponding to two zero eigenvalues of ad_{ξ_0}. Therefore, let us reduce only by the abelian symmetry group $\tilde{\Gamma} = \mathrm{SO}_3(2) \times \mathbb{R}_3$ of rotations around and translations along the e_3-axis. This gives the reduced system

$$\dot{\tilde{\nu}} = 0, \quad \dot{\tilde{w}} = \mathbb{J}_{\widetilde{\mathcal{N}}_1} \mathrm{D}_{\tilde{w}} \tilde{h}(\tilde{\nu}, \tilde{w}) \tag{5.4}$$

on the slice $\widetilde{\mathcal{N}} = \widetilde{\mathcal{N}}_0 \oplus \widetilde{\mathcal{N}}_1$, where $\tilde{\nu} = (\nu^r, \nu_3^a) \in \widetilde{\mathcal{N}}_0 \simeq \mathrm{so}_3(2)^* \oplus \mathbb{R}_3^*$. Since $\mathbb{J}_{\widetilde{\mathcal{N}}_1} \mathrm{D}_{\tilde{w}}^2 \tilde{h}(0)$ is invertible, the equation $0 = \mathbb{J}_{\widetilde{\mathcal{N}}_1} \mathrm{D}_{\tilde{w}} h(\tilde{\nu}, \tilde{w})$ can be solved for $\tilde{w}(\tilde{\nu})$ by the implicit function theorem. This gives relative equilibria $\mathrm{SE}(3)x_{\mathrm{RE}}(\nu^r, \nu_3^a)$ of (3.1), where $x_{\mathrm{RE}}(\nu^r, \nu_3^a) \simeq (\mathrm{id}, \tilde{\nu}, \tilde{w}(\tilde{\nu}))$. The drift velocity $\xi_{\mathrm{RE}}(\nu^r, \nu_3^a)$ of the relative equilibrium at $x_{\mathrm{RE}}(\nu^r, \nu_3^a)$ lies in the Lie algebra of $\tilde{\Gamma}$

and therefore satisfies $\xi^r_{\mathrm{RE}}(\nu^r,\nu^a_3)=\omega^{\mathrm{rot}}_{\mathrm{RE}}(\nu^r,\nu^a_3)e_3$ and $\xi^a_{\mathrm{RE}}(\nu^r,\nu^a_3)||e_3$. The statement about the momentum of $x_{\mathrm{RE}}(\nu^r,\nu^a_3)$ follows from (3.18). ■

In this case resonance drift occurs as the following theorem shows.

Theorem 5.5. *Let, as before,* $\mathrm{SE}(3)x_0$ *be a nondegenerate relative equilibrium with momentum* $\mu_0=(\mu^r_0,0)$, $\mu^r_0||e_3$, $\mu^r_0\neq 0$, *and with nonvanishing rotational velocity vector* $\xi^r_0\neq 0$ *such that* $\xi^r_0=\omega^{\mathrm{rot}}_0e_3$, $\xi^a_0||e_3$. *Assume that* $\mathbb{J}_{\mathcal{N}_1}\mathrm{D}^2_w h(0)$ *has no eigenvalue in* $\mathrm{i}\omega^{\mathrm{rot}}_0\mathbb{Z}$. *Then the following hold:*

(a) *There is a three-dimensional manifold* $\mathcal{P}(\nu^r,\nu^a_2,\nu^a_3)$ *of RPOs such that* $x(\nu^r,\nu^a_2,\nu^a_3)\in\mathcal{P}(\nu^r,\nu^a_2,\nu^a_3)$ *is a smooth function of its parameters,* $\nu^a_2\geq 0$, $\nu^r\approx 0$, $\nu^a_3\approx 0$, *and* $x(\nu^r,0,\nu^a_3)=x_{\mathrm{RE}}(\nu^r,\nu^a_3)$. *The RPO through* $x(\nu^r,\nu^a_2,\nu^a_3)$ *has angular momentum* $\mathbf{J}^r(x(\nu^r,\nu^a_2,\nu^a_3))=\mu^r_0+\nu^re_3$, *linear momentum* $\mathbf{J}^a(x(\nu^r,\nu^a_2,\nu^a_3))=(0,\nu^a_2,\nu^a_3)$, *and relative period* $T(\nu^r,\nu^a_2,\nu^a_3)$ *with* $T(\nu^r,0,\nu^a_3)=2\pi/|\omega^{\mathrm{rot}}(\nu^r,\nu^a_3)|$. *Here* $\omega^{\mathrm{rot}}(\nu^r,\nu^a_3)$ *is the rotation frequency of the relative equilibrium* $\mathrm{SE}(3)x_{\mathrm{RE}}(\nu^r,\nu^a_3)$ *from Proposition* 5.4.

(b) *This family contains a two-dimensional submanifold* $x(\nu^r,\nu^a_2,0)$ *at* $\nu^a_3=0$ *which has an average rotational drift velocity* $\xi^r(\nu^r,\nu^a_2,0)$ *with* $\xi^r_3(\nu^r,\nu^a_2,0)=0$.

Note that the RPO through $x(\nu^r,\nu^a_2,0)$ rotates around and translates along a vector parallel to e_2, whereas the original relative equilibrium through x_0 rotates around and translates along the e_3 direction.

Proof of Theorem 5.5. Let $\nu^r\approx 0$, $\nu^a_3\approx 0$. Near the relative equilibria through $x_{\mathrm{RE}}(\nu^r,\nu^a_3)\simeq(\gamma_{\mathrm{RE}}(\nu^r,\nu^a_3),\nu_{\mathrm{RE}}(\nu^r,\nu^a_3),w_{\mathrm{RE}}(\nu^r,\nu^a_3))$ from Proposition 5.4, let us change coordinates on the slice $\mathcal{N}=\mathcal{N}_0\oplus\mathcal{N}_1$, $\mathcal{N}_0\simeq\mathrm{so}(2)^*\oplus(\mathbb{R}^3)^*$, from $v=(\nu^r,\nu^a_1,\nu^a_2,\nu^a_3,w)$ to $(E,C^r,\nu^a_1,\nu^a_2,w)$ as follows: first let

$$\nu^a_3(\nu^r,C^r)=\frac{C^r}{\nu^r+\mu^r_{0,3}}.$$

Here $C^r(\mu+\nu)=\langle\nu^a,\mu^r_0+\nu^re_3\rangle$ is the Casimir from (5.3) restricted to elements of the form $\mu_0+\nu$, where $\nu\in\mathcal{N}_0\simeq\mathrm{so}_3(2)^*\oplus(\mathbb{R}^3)^*$. Then, by the implicit function theorem, using that $\mathrm{D}_{\nu^r}h(0)=\omega^{\mathrm{rot}}_0\neq 0$, $\mathrm{D}_wh(0)=0$, $\mathrm{D}_{\nu^a}h(0)||e_3$, and $\mathrm{D}_{\nu^r}\nu^a_3(0,0)=0$, one obtains

$$\nu^r=\nu^r(E,C^r,\nu^a_1,\nu^a_2,w)$$

for $E\approx E_0=H(x_0)$, $C^r\approx 0$, where $E=h((\nu^r,\nu^a_1,\nu^a_2,\nu^a_3(\nu^r,C^r)),w)$. Solving $E=h(\nu_{\mathrm{RE}}(\nu^r,\nu^a_3(\nu^r,C^r)),w_{\mathrm{RE}}(\nu^r,\nu^a_3(\nu^r,C^r)))$ by the implicit function theorem for ν^r, the family of relative equilibria $\mathrm{SE}(3)x_{\mathrm{RE}}(E,C^r)$, $x_{\mathrm{RE}}(E,C^r)\simeq(\gamma_{\mathrm{RE}}(E,C^r),v_{\mathrm{RE}}(E,C^r))$, $v_{\mathrm{RE}}(E,C^r)=(\nu_{\mathrm{RE}}(E,C^r),w_{\mathrm{RE}}(E,C^r))$ is obtained, parametrized by the conserved quantities (E,C^r). Then, since $\omega^{\mathrm{rot}}_0\neq 0$ and $\xi^r_0=\omega^{\mathrm{rot}}_0e_3$, by (3.20) and (5.2), for $C^r\approx 0$, $E\approx E_0$, the section

$$\begin{aligned}\mathcal{S}_{E,C^r}=\{(\nu,w)\in\mathcal{N},\ &\nu^a_3=\nu^a_3(\nu^r,C^r),\ \nu^r=\nu^r(E,C^r,\nu^a_1,\nu^a_2,w),\\ &\nu^a_1=\nu^a_{\mathrm{RE},1}(E,C^r),\ \nu^a_2>\nu^a_{\mathrm{RE},2}(E,C^r),\\ &\nu^a_2\approx\nu^a_{\mathrm{RE},2}(E,C^r),\ w\approx w_{\mathrm{RE}}(E,C^r)\}\end{aligned}$$

is transversal to the flow of (3.1) in the flow-invariant manifold

$$\mathcal{N}_{E,C^r}:=\{(\nu,w)\in\mathcal{N},\ h(\nu,w)=E,\ C^r(\nu)=C^r\}.$$

Consider the Poincaré map $(s,w) \to \Pi(E,C^r,s,w)$ from $\mathcal{S}_{E,C^r}$ to itself, where $s = \nu_2^a - \nu_{\mathrm{RE},2}(E,C^r)$. At $(E,C^r,s,w) = (E_0,0,0,0)$ the Poincaré return time is $T(0) = \frac{2\pi}{|\omega_0^{\mathrm{rot}}|}$. Due to the nonresonance assumption the equation $\Pi_1(E,C^r,s,w) = w$ can be solved for $w(E,C^r,s)$ such that $w(E,C^r,0) = w_{\mathrm{RE}}(E,C^r)$. Here Π_1 is the $\mathcal{N}_1$ component of Π. What follows is a proof that $\hat{x}(E,C^r,s) = (\gamma_{\mathrm{RE}}(E,C^r), \nu(E,C^r,s), w(E,C^r,s))$ lies on an RPO. Here

$$
\begin{aligned}
\nu(E,C^r,s) &= (\nu^r(E,C^r,s), \nu^a(E,C^r,s)),\\
\nu^r(E,C^r,s) &= \nu^r(E,C^r,\nu^a_{\mathrm{RE},1}(E,C^r), s+\nu^a_{\mathrm{RE},2}(E,C^r), w(E,C^r,s)),\\
\nu_3^a(E,C^r,s) &= \nu_3^a(\nu^r(E,C^r,s),C^r),\\
\nu^a(E,C^r,s) &= (\nu^a_{\mathrm{RE},1}(E,C^r), s+\nu^a_{\mathrm{RE},2}(E,C^r), \nu_3^a(E,C^r,s)).
\end{aligned}
\tag{5.5}
$$

By construction, $\hat{x}(E,C^r,0) = x_{\mathrm{RE}}(E,C^r)$. Define

$$C^a(E,C^r,s) = \|\nu^a(E,C^r,s)\|^2.$$

The equilibria $v_{\mathrm{RE}}(E,C^r)$ of the slice equation are at $s=0$. The fact that $\mathrm{D}_{(\nu,w)}h$ is a linear combination of $\mathrm{D}_{(\nu,w)}C^a$ and $\mathrm{D}_{(\nu,w)}C^r$ at any equilibrium of the slice equation then implies that

$$\mathrm{D}_s C^a(E,C^r,0) = 0.$$

Moreover, $\mathrm{D}_s\nu_3^a(0,0,0) = 0$ since $\nu_3^a(\nu^r, C^r=0) \equiv 0$. This together with (5.5) gives

$$\mathrm{D}_s^2 C^a(E_0,0,0) = 2.$$

So for small positive s and fixed $E \approx E_0$, $C^r \approx 0$, the function $s \to C^a(E,C^r,s)$ is injective. This proves that there is a coordinate transformation from (E,C^r,s) to the conserved quantities (E,C^r,C^a). Therefore, $\hat{x}(E,C^r,s)$ lies on an RPO $\mathcal{P}(E,C^r,s)$ of (3.1), as claimed. Let us now change coordinates back from (E,C^r,s) to (ν^r,s,ν_3^a) and denote the corresponding function again by $\hat{x}(\nu^r,s,\nu_3^a) \simeq (\gamma_{\mathrm{RE}}(\nu^r,\nu_3^a), \nu(\nu^r,s,\nu_3^a), w(\nu^r,s,\nu_3^a)) \in \mathcal{P}(\nu^r,s,\nu_3^a)$.

It is now shown that a smooth function $\hat{\gamma}(\nu^r,s,\nu_3^a)$ can be found such that

$$x(\nu^r,s,\nu_3^a) \simeq (\gamma(\nu^r,s,\nu_3^a), v(\nu^r,s,\nu_3^a)),$$

where

$$\gamma(\nu^r,s,\nu_3^a) = \hat{\gamma}(\nu^r,s,\nu_3^a)\gamma_{\mathrm{RE}}(\nu^r,\nu_3^a) \quad \text{and} \quad v(\nu^r,s,\nu_3^a) = (\nu(\nu^r,s,\nu_3^a), w(\nu^r,s,\nu_3^a)),$$

satisfies

$$\mathbf{J}_1^a(x(\nu^r,s,\nu_3^a)) = 0, \quad \mathbf{J}_1^r(x(\nu^r,s,\nu_3^a)) = 0, \quad \mathbf{J}_2^r(x(\nu^r,s,\nu_3^a)) = 0, \tag{5.6}$$

and $\hat{\gamma}(\nu^r,0,\nu_3^a) = \mathrm{id}$. First note that this holds true at $s=0$ by Proposition 5.4. For $s \neq 0$, let

$$\hat{\gamma}(\nu^r,s,\nu_3^a) = (\hat{R}(\nu^r,s,\nu_3^a), \hat{a}(\nu^r,s,\nu_3^a)),$$

and $\hat{\mu}(\nu^r,s,\nu_3^a) = \mathbf{J}(\hat{x}(\nu^r,s,\nu_3^a))$. Then $\mathbf{J}^a(x_{\mathrm{RE}}(\nu^r,\nu_3^a)) = \nu_3^a e_3$ implies that $\mathrm{D}_{\nu_3^a}\hat{\mu}^a(0,0,0) = e_3$. From $\gamma_{\mathrm{RE}}(0,0) = \mathrm{id}$ one further gets $\mathrm{D}_s\hat{\mu}^a(0,0,0) = e_2$. Therefore, smooth functions $\hat{\phi}_2(\nu^r,s,\nu_3^a)$, $\hat{\phi}_3(\nu^r,s,\nu_3^a)$ can be found such that $\hat{\phi}_j(\nu^r,0,\nu_3^a) = 0$, $j=2,3$, and

$$(\hat{R}(\nu^r,s,\nu_3^a)\hat{\mu}^a(\nu^r,s,\nu_3^a))_1 = 0,$$

where, as in (2.9),

$$\hat{R}(\nu^r, s, \nu_3^a) = \exp(\hat{\phi}_2(\nu^r, s, \nu_3^a)\xi_2 + \hat{\phi}_3(\nu^r, s, \nu_3^a)\xi_3).$$

In this way the first equation of (5.6) is satisfied. Then ν_3^a and $\nu_2^a = s$ can be rescaled such that

$$\mathbf{J}^a(x(\nu^r, \nu_2^a, \nu_3^a)) = (0, \nu_2^a, \nu_3^a).$$

Let

$$\tilde{\mu}(\nu^r, \nu_2^a, \nu_3^a) = \mathrm{Ad}^*_{(\hat{R}(\nu^r, \nu_2^a, \nu_3^a), 0)^{-1}} \hat{\mu}(\nu^r, \nu_2^a, \nu_3^a).$$

Note that $\tilde{\mu}^a(\nu^r, \nu_2^a, \nu_3^a) = (0, \nu_2^a, \nu_3^a)^T$ has been achieved by choosing $\hat{R}(\nu^r, \nu_2^a, \nu_3^a)$. Moreover, (5.2) gives

$$\mathrm{Ad}_{(0,\hat{a})^{-1}} \tilde{\mu}^r = \tilde{\mu}^r + (\nu_3^a \hat{a}_2 - \nu_2^a \hat{a}_3, -\nu_3^a \hat{a}_1, \nu_2^a \hat{a}_1)^T.$$

Let $\hat{a}_2 \equiv 0$. When $\nu_2^a \neq 0$, then $\hat{a}_3 = \hat{a}_3(\nu^r, \nu_2^a, \nu_3^a)$ can be chosen such that

$$(\mathrm{Ad}^*_{(0,\hat{a}(\nu^r, \nu_2^a, \nu_3^a))^{-1}} \tilde{\mu}^r(\nu^r, \nu_2^a, \nu_3^a))_1 = 0,$$

thus satisfying the second equation of (5.6). If $\nu_2^a = 0$, i.e., at the relative equilibria, $\tilde{\mu}^r(\nu^r, 0, \nu_3^a) = \nu^r e_3$ anyway, and when $\nu_2^a \to 0$, then $\hat{a}_3 \to \mathrm{D}_{\nu_2^a} \tilde{\mu}_1^r(\nu^r, 0, \nu_3^a)$. Moreover, the equation

$$(\mathrm{Ad}^*_{(0,\hat{a}(\nu^r, \nu_2^a, \nu_3^a))^{-1}} \tilde{\mu}^r(\nu^r, \nu_2^a, \nu_3^a))_2 = 0,$$

and hence the last equation of (5.6), can be satisfied by choosing $\hat{a}_1(\nu^r, \nu_2^a, \nu_3^a)$ appropriately whenever $\nu_3^a \neq 0$. When $\nu_3^a = 0$, then $C^r = 0$ and $\nu_{\mathrm{RE}}(\nu^r, 0) = (\nu^r, 0)$. In particular, $\nu_{\mathrm{RE},1}^a(\nu^r, 0) = 0$, and so also $\nu_1^a(\nu^r, s, 0) = 0$ (see (5.5)). Therefore, $\hat{R}(\nu^r, s, 0) = \mathrm{id}$ and $\tilde{\mu}_2^r(\nu^r, \nu_2^a, 0) = 0$. Consequently, when $\nu_2^a \to 0$, then $\hat{a}_2 \to \mathrm{D}_{\nu_2^a} \tilde{\mu}_2^r(\nu^r, \nu_2^a, 0)$. Hence a smooth function $\hat{a}(\nu^r, \nu_2^a, \nu_3^a)$ has been found such that $\mu^r(\nu^r, \nu_2^a, \nu_3^a) := \mathrm{Ad}^*_{(0,\hat{a})^{-1}} \tilde{\mu}^r(\nu^r, \nu_2^a, \nu_3^a) \,||\, e_3$. For $\nu_2^a = 0$ the equality $\mu^r(\nu^r, 0, \nu_3^a) = \mu_0^r + \nu^r e_3$ holds. So coordinates can be changed such that $\mu^r(\nu^r, \nu_2^a, \nu_3^a) = \mu_0^r + \nu^r e_3$ for all $\nu_2^a \geq 0$, $\nu_2^a \approx 0$. This proves part (a) of the proposition.

For part (b), let $\gamma(\nu^r, \nu_2^a, \nu_3^a) = (R(\nu^r, \nu_2^a, \nu_3^a), a(\nu^r, \nu_2^a, \nu_3^a))$ be the drift symmetry of the RPO $\mathcal{P}(\nu^r, \nu_2^a, \nu_3^a)$ at $x(\nu^r, \nu_2^a, \nu_3^a)$, and write, as in (2.9), $R(\nu^r, \nu_2^a, \nu_3^a) = \exp(\sum_{i=1}^3 \phi_i \xi_i)$, where $\phi_i = \phi_i(\nu^r, \nu_2^a, \nu_3^a)$. Then $\phi_3(\nu^r, \nu_2^a, \nu_3^a) = 0$ at $\nu_3^a = 0$ needs to be satisfied. Equations (3.17) and (5.2) imply that $R(\nu^r, \nu_2^a, \nu_3^a)\mathbf{J}^a(x(\nu^r, \nu_2^a, \nu_3^a)) = \mathbf{J}^a(x(\nu^r, \nu_2^a, \nu_3^a))$, where $\mathbf{J}^a(x(\nu^r, \nu_2^a, \nu_3^a)) = (0, \nu_2^a, \nu_3^a)$. Therefore, $\sum_{i=1}^3 \phi_i \xi_i = \hat{\phi}(0, \nu_2^a, \nu_3^a)^T$ for some $\hat{\phi} \in \mathbb{R}$, where ξ_i is identified with $e_i \in \mathbb{R}^3$ and $\mathrm{so}(3)$ and $(\mathbb{R}^3)^*$ with $\mathbb{R}^3$. Because of this, $\phi_3 = 0$ for $\nu_3^a = 0$. ∎

In addition to the family of RPOs from the above theorem, there may be additional families of RPOs which rotate and translate about the same axis (without loss of generality the e_3-axis) as the relative equilibrium.

Proposition 5.6. *Let, as before,* $\mathrm{SE}(3)x_0$ *be a relative equilibrium of an* $\mathrm{SE}(3)$*-equivariant Hamiltonian system* (3.1)*, with momentum* $\mu_0 = (\mu_0^r, 0)$*,* $\mu_0^r \neq 0$*, and with nonvanishing rotational velocity vector* $\xi_0^r \neq 0$*. Choose* x_0 *such that* $\mu_0^r || e_3$*,* $\xi_0^r = \omega_0^{\mathrm{rot}} e_3$*,* $\xi_0^a || e_3$*. Assume that the relative equilibium is nonresonant and elliptic in the sense of Definition* 4.4 *and that* $\omega_0^{\mathrm{rot}}/\omega_j \notin \mathbb{Z}$ *for all eigenvalues* $\mathrm{i}\omega_j$ *of* $\mathbb{J}_{\mathcal{N}_1} \mathrm{D}_w^2 h(0)$*. Then there are three-dimensional manifolds* $\mathcal{P}_j(\nu^r, s, \nu_3^a)$ *of RPOs,* $j = 1, \ldots \frac{1}{2} \dim \mathcal{M} - 5$*, and smooth functions* $x_j(\nu^r, s, \nu_3^a) \in \mathcal{P}_j(\nu^r, s, \nu_3^a)$

such that $x_j(\nu^r, 0, \nu_3^a) = x_{\mathrm{RE}}(\nu^r, \nu_3^a)$ *(with* $x_{\mathrm{RE}}(\nu^r, \nu_3^a)$ *from Proposition 5.4). Moreover, the RPO through* $x_j(\nu^r, s, \nu_3^a)$ *has momentum* $(\mu_0^r + \nu^r e_3, \nu_3^a e_3)$*, energy* $H(x_j(\nu^r, s, \nu_3^a)) = H(x_{\mathrm{RE}}(\nu^r, \nu_3^a)) \pm s^2$ *(depending on the Krein signature of* ω_j*), relative period* $T_j(\nu^r, s, \nu_3^a)$*, where* $T_j(0,0,0) = 2\pi/|\omega_j|$*, and average drift velocity*

$$\xi_j(\nu^r, s, \nu_3^a) = (\xi_{j,3}^r(\nu^r, s, \nu_3^a)e_3, \xi_{j,3}^a(\nu^r, s, \nu_3^a)e_3), \xi_j(0,0,0) = \xi_0.$$

Proof. Let us, as in the proof of Proposition 5.4, reduce only by the symmetry group $\tilde{\Gamma} = \mathrm{SO}_3(2) \times \mathbb{R}_3$. The statement then follows by applying the Lyapunov center theorem on the $\dot{\tilde{w}}$-equation of (5.4). ∎

Conclusion and future directions. In this paper a Hamiltonian analogue of the well-known meandering transition from rotating waves to modulated rotating waves and modulated traveling waves in systems with Euclidean symmetries has been studied. This transition occurs, for example, in a finite-dimensional system of point vortices. Similar effects have been analyzed in systems with spherical symmetry and with the Euclidean symmetry of three-dimensional space. It remains a challenging open problem to extend these results to infinite-dimensional Hamiltonian systems such as PDE models of vortex dynamics.

Abstract. We study (i) traveling wave solutions, (ii) the formation and spatial spread of synchronous oscillations, and (iii) the effects of variations of threshold in a system of integro-differential equations which describe the activity of large-scale networks of excitatory neurons on spatially extended domains. The independent variables are the activity level u of a population of excitatory neurons which have long range connections, and a recovery variable v. In the integral component of the equation for u the firing rate function is the Heaviside function, and the coupling function w is positive. Thus, there is no inhibition in the system. There is a critical value of the parameter β ($\beta_* > 0$) that appears in the equation for v, at which the eigenvalues $\mu^{\pm}$ of the linearization of the system around the rest state $(u, v) = (0, 0)$ change from real to complex. We focus on the range $\beta > \beta_*$, where $\mu^{\pm}$ are complex, and analyze properties of wave fronts and 1-pulse and 2-pulse waves when the connection function w is asymmetric. For wave fronts we demonstrate how an initial stimulus evolves into two solutions which propagate in opposite directions with different speeds and shapes. For 1-pulse waves our main theoretical result (Theorem 4.2) shows that there is a range of $\beta > \beta_*$ where two families of waves exist, each consisting of infinitely many solutions. The waves in these two families also propagate in opposite directions with different speeds and shapes. There is a critical value $\theta^* > 0$ such that if $\theta > \theta^*$, then 1-pulse waves can propagate only in one direction. In addition, there is a second critical β value, $\beta^* > \beta_*$, where bulk oscillations come into existence and the system becomes bistable. When $\beta \geq \beta_*$ we show how an initial stimulus evolves into a solution with large amplitude oscillations that spread out uniformly from the point of stimulus. The asymmetry in w causes the rate of spread of the "region of synchrony" to be more rapid to the right of the point of stimulus than to the left. When $\theta > \theta^*$ we construct a "unidirectional" circuit where synchronization in one region can trigger synchronization in a distant, second region. However, when synchronization is initially triggered in the second region, it cannot spread to the first region.

1. Introduction.

Functional behavior of the central nervous system includes such diverse phenomena as information processing from different receptor zones, sleep, and the control of vital autonomic functions [29, 30, 40]. These processes require cooperation between ensembles of cells organized into large-scale, spatially extended neuronal networks. The physical laws that govern the behavior of large-scale networks are different from those for a system consisting of small numbers of cells [15, 26, 34, 56]. In the study of spatially extended neuronal networks

†Department of Mathematics, University of Pittsburgh, Pittsburgh, PA 15260 (troy@math.pitt.edu).

considerable attention has been given to (i) traveling waves of activity, (ii) the formation and spatial spread of synchronous oscillations, and (iii) the effects of variations in the threshold of excitation. This includes both experimental [28, 3, 4, 5, 10, 18, 23, 31, 33, 36, 39, 37, 45, 46, 49, 53, 61, 57, 60] and theoretical [1, 12, 13, 14, 17, 2, 19, 20, 24, 25, 22, 32, 35, 38, 40, 42, 58, 59, 62] studies.

In this paper we investigate traveling waves, the spread of synchronous oscillations, and the effects of variations in threshold in the excitable, spatially extended model

$$\begin{aligned} \tfrac{\partial u(x,t)}{\partial t} &= -u(x,t) - v(x,t) + \textstyle\int_{-\infty}^{\infty} w(x-x')f(u(x',t)-\theta)dx' + \zeta(x,t), \\ \tfrac{\partial v(x,t)}{\partial t} &= \epsilon(\beta u(x,t) - v(x,t)). \end{aligned} \tag{1.1}$$

Systems of this form were introduced by Pinto and Ermentrout [42] to model the spread of excitation waves in slices of brain cortex in which synaptic inhibition is pharmacologically blocked [7, 10, 31, 61]. The variable u denotes the activity level of the population of excitatory neurons with long range connections; v represents a negative feedback recovery mechanism in which "the negative feedback could represent spike frequency adaptation, synaptic depression or some other process that limits excitation of the network" [42]. The function $\zeta(x,t)$ represents external input to the system. The parameters ϵ and β are positive and control the rate of change of v; θ is a positive constant which denotes the threshold level for u. We assume that the coupling function w is strictly positive. Thus, there is no inhibition in the system. We also assume that w is continuous, integrable, and either symmetric, i.e.,

$$w(x) = w(-x) \quad \forall x \in (-\infty, \infty), \tag{1.2}$$

or asymmetric, i.e.,

$$w(x) \neq w(-x) \quad \text{for some} \quad x \in (-\infty, \infty). \tag{1.3}$$

The firing rate function f is nonnegative and sigmoidal-shaped. In order to allow for comparison of our results with those of previous studies, we follow [2, 19, 42, 48, 58] and set

$$f(u-\theta) = H(u-\theta) = \begin{cases} 1 & \forall u \geq \theta, \\ 0 & \forall u < \theta, \end{cases} \tag{1.4}$$

and

$$w(x) = \frac{1}{2}e^{-|x|+\kappa x}, \quad 0 \leq \kappa \leq 1, \quad \text{and} \quad x \in \mathrm{R}. \tag{1.5}$$

We will make use of the observation that if $\kappa > 0$, then

$$w(x) > w(-x) \quad \forall x \in (-\infty, \infty). \tag{1.6}$$

In our numerical studies we employ two methods to initiate a solution such as a traveling wave. The first is to set the external stimulus to zero, i.e., $\zeta(x,0) \equiv 0$, and let $(u(x,0), v(x,0))$ be a perturbation from the rest state $(0,0)$ which has the typical form

$$(u(x,0), v(x,0)) \equiv (Ae^{-Bx^2}, 0), \quad x \in \mathrm{R},\ A > 0, \text{ and } B > 0. \tag{1.7}$$

Equivalently, we could set $(u(x,0),v(x,0)) = (0,0)$ and set $\zeta(x,0) = Ae^{-Bx^2}$.

Goals. We investigate the dynamics of (1.1) when w is asymmetric and the eigenvalues $\mu^{\pm}$ of the linearization of (1.1) around the rest state $(u,v) = (0,0)$ are *complex*. Section 2 shows how $\mu^{\pm}$ change from real to complex as β passes through the critical value $\beta_* = \frac{(\epsilon-1)^2}{4\epsilon}$ from below. As β increases from β_* the imaginary part of $\mu^{\pm}$ increases and solutions of the linearization oscillate with increasing frequency. In turn, this causes the dynamics of (1.1) to become more complicated. Thus, we study how the structure of families of traveling waves changes as β increases from β_*. There is a critical value $\beta^* > \beta_*$ where bulk oscillations appear and (1.1) becomes bistable. When $\beta \geq \beta^*$ we investigate the formation and spatial spread of synchronous oscillations. To put our investigation into perspective we summarize previous results in (A)–(C) below. Our specific aims are described in (D).

(A) *Symmetric couplings and real eigenvalues.* Pinto et al. [42, 43, 44] analyzed 1-pulse waves in parameter regimes where w is symmetric and $\mu^{\pm}$ are *real*. Richardson, Schiff, and Gluckman [48] make use of the results in [44] to study the effects of raising electric fields on 1-pulse waves in the mammalian cortex. The stability of solutions in the real eigenvalue setting has been studied in [12, 44, 50].

(B) *Asymmetric couplings and real eigenvalues.* Pinto and Troy [47] analyzed 1-pulse waves when w is asymmetric and $\mu^{\pm}$ are real. The asymmetry in w causes an initial stimulus of the form (1.7) to evolve into two 1-pulse waves which propagate in opposite directions with different amplitudes and speeds. Thus, traveling waves have a preferred direction of propagation when the coupling is asymmetric. In agreement with these theoretical results, we give experimental evidence which indicates that 1-pulse waves in the barrel cortex have a preferred direction of propagation.

(C) *Symmetric couplings and complex eigenvalues.* Troy and Shusterman [58] investigated (1.1) in parameter regimes where the coupling is the symmetric function $w(x) = \frac{1}{2}e^{-|x|}$ and $\beta > \beta_*$ where $\mu^{\pm}$ are *complex*. We analyzed one-dimensional wave fronts, single-pulse waves, and multipulse wave trains. We also explained why multipulse waves are expected to exist only in the complex eigenvalue regime. In two dimensions we analyzed the periodic formation of waves, as well as the mechanisms responsible for the formation of spiral waves. Spiral waves were recently discovered in tangential slices of rat brain tissue [31]. Thus, in the complex eigenvalue setting the dynamics of (1.1) are richer than in the real eigenvalue case. Furthermore, these dynamics closely resemble electrophysiological phenomena observed in clinical and experimental studies [40].

(D) *Specific aims: Asymmetric couplings and complex eigenvalues.* In this paper we extend the results described in (A)–(C) and investigate the dynamics of (1.1) when w is asymmetric and the eigenvalues $\mu^{\pm}$ are complex. Our goals are summarized in I–III below.

I. *Traveling waves.* Single-pulse and multipulse traveling activity waves have been observed in feline cortex [3, 4, 5], in the brain of freely moving mice [18], in tangential and coronal brain slice experiments [31, 61], and in seizure propagation across cortical regions [39, 60]. In sections 3–5 we analyze wave fronts, 1-pulse waves, and 2-pulse waves when $\beta > \beta_*$ and $w(x) = \frac{1}{2}e^{-|x|+\kappa x}$, where $\kappa \neq 0$. Wave front solutions cross the threshold level $u = \theta$ precisely once, whereas N-pulse waves cross threshold exactly 2N times. For a fixed initial stimulus we find that, as β increases, there is a natural evolution from wave fronts to 1-pulse waves, and subsequently to 2-pulse waves. Our main theoretical result (Theorem 4.2)

shows that there is a range of $\beta > \beta^*$ where two families of 1-pulse waves exist, each consisting of infinitely many coexisting solutions. The waves in these two families propagate in opposite directions with different speeds and shapes. Infinite families of solutions with such diverse properties do not exist when w is asymmetric and $\mu^{\pm}$ are real. Similar properties hold for wave fronts and 2-pulse waves. Because the eigenvalues are complex, technical difficulties make proofs more challenging than in the real eigenvalue case. These difficulties lead to open problems which are stated as we proceed.

II. *Synchronous oscillations.* There is a second critical value $\beta^* > \beta_*$ where spatially independent bulk oscillations come into existence (section 6). When $\beta \geq \beta^*$ the system (1.1) is bistable since these oscillations are stable and coexist with the stable rest state $(u, v) = (0, 0)$. An initial stimulus of the form (1.7) can evolve into a solution which exhibits large amplitude oscillations that spread out uniformly from the point of stimulus. The asymmetry in w causes the rate of spread of the "region of synchrony" to be more rapid to the right of the point of stimulus than to the left. Eventually, however, the solution oscillates uniformly over the entire spatial region. We also show how an initial stimulus can evolve into a stable 1-pulse wave which coexists with synchronous oscillations and the stable rest state. In section 6 we compare our theoretical results with clinical observations of epileptiform events.

III. *Variations in threshold.* In 1936 Hill [28] suggested that the value of threshold might change in response to the state of neuronal tissue. Following Hill's theoretical ideas, Coombes and Owen [13, 14] studied the effects of a state dependent threshold on bump-type solutions in a scalar Wilson–Cowan-type model in which w is of Mexican hat type; i.e., $w(x)$ is symmetric about $x = 0$ and changes sign on $(-\infty, \infty)$. Recently, Kowai, Lazar, and Metherate [35] have given experimental evidence which shows that the threshold of excitation can indeed change. In particular, when they expose axons of thalamocortical mouse neurons to nicotine, the threshold of excitation *decreases* and the firing rate of the neurons *doubles*. In [54] it is suggested that this causes "an increase in the amount of sensory information reaching the cortex," and that "this is a major reason that nicotine enhances cognitive functioning." It is also pointed out that in schizophrenia there is poor communication between the thalamus and the cortex, and therefore the high incidence of smoking in schizophrenics might be a method of self-medication. In our analysis of traveling waves and synchrony we investigate the effects of both increasing and decreasing the threshold θ, and also the strength κ of the asymmetric coupling. In agreement with [35] we find that the amplitudes and speeds of traveling waves *increase* dramatically as θ *decreases*. Because w is asymmetric there is a critical value θ^* such that waves can be transmitted in only one direction when $\theta > \theta^*$. In section 6 we investigate how variations in threshold can affect synchrony. As a first step toward understanding how communication between spatial regions can become inhibited when threshold is too high, we let $\theta > \theta^*$ and study how synchronization in one region can influence synchronization in a distant region. For this we construct a simple "unidirectional neuronal circuit" in which $\theta > \theta^*$ so that waves propagate only to the right. In this setting synchronization in one region causes the formation of a train of waves which propagate to the right and ultimately trigger a second, distant region to undergo synchronization. However, because $\theta > \theta^*$, synchronization in the second region is inhibited from emitting left propagating waves; hence the first region remains at rest.

Conclusions and directions for future research are given in section 7.

2. Traveling waves. Following [44, 58], we set $\zeta(x,t) = 0$ and look for traveling wave solutions of (1.1) of the form $(u,v) = (U(z), V(z))$, where $z = x + ct$. These satisfy

$$\begin{aligned} cU'(z) &= -U - V + \textstyle\int_{-\infty}^{\infty} w(z-z')H(U(z')-\theta)dz', \\ cV'(z) &= \epsilon(\beta U - V), \end{aligned} \tag{2.1}$$

where

$$w(z-z') = \frac{1}{2}e^{-|z-z'|+\kappa(z-z')}, \quad 0 \le \kappa < 1. \tag{2.2}$$

Our main focus is on the regime $\kappa \neq 0$, where the coupling is asymmetric. For simplicity we restrict our attention to the case $\kappa > 0$. It is easily verified that (2.1) is equivalent to

$$c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U = c\frac{d}{dz}\int_{-\infty}^{\infty} w(z-z')H(U-\theta)dz' + \epsilon\int_{-\infty}^{\infty} w(z-z')H(U-\theta)dz'. \tag{2.3}$$

Linearizing (2.3) around the rest state $U = 0$ leads to

$$c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U = 0. \tag{2.4}$$

The eigenvalues associated with (2.4) are

$$\mu^{\pm} = \frac{\lambda^{\pm}}{c} = \frac{-(\epsilon+1) \pm \mathrm{i}\sqrt{4\beta\epsilon - (\epsilon-1)^2}}{2c}. \tag{2.5}$$

We restrict our attention to the regime $0 < \epsilon < 1$. From this and (2.5) it follows that

$$\mu^{\pm} \text{ are real} \iff 0 < \beta \le \beta_* = \frac{(\epsilon-1)^2}{4\epsilon}. \tag{2.6}$$

Remarks. (i) When $\mu^{\pm}$ are real one expects to find only wave fronts or single-pulse waves [42, 43, 44, 48, 58]. Our interest is in the regime $\beta > \beta^*$, where $\mu^{\pm}$ are complex and the dynamics of (1.1) are richer. For example, when w is symmetric we previously found the coexistence of families of multipulse waves in one space dimension and periodic waves and rotating waves in two dimensions [58].

(ii) We have followed [44, 58] and let the independent variable have the form $z = x + ct$. Thus, when $c > 0$, solutions of (2.1)–(2.2) correspond to traveling waves of (1.1) which propagate "to the left" as t increases. If $z = x - ct$, then traveling wave solutions propagate "to the right."

Previous studies analyzed traveling waves when w is symmetric [2, 19, 20, 42, 44, 48, 58]. In this setting it can be assumed that $c > 0$, since a wave traveling with speed $c > 0$ can be transformed into a wave traveling in the opposite direction with the same shape, and with speed $-c < 0$. Here we study traveling waves when $\mu^{\pm}$ are complex and the w is asymmetric. Our numerical experiments in the next three sections show that an initial perturbation from rest can cause two waves to form which propagate in opposite directions with different speeds and shapes. We will make use of the quantities

$$\alpha = \mathrm{Re}(\mu^{\pm}) = \frac{-(\epsilon+1)}{2c} \quad \text{and} \quad \gamma = \mathrm{Im}(\mu^{\pm}) = \frac{\sqrt{4\epsilon\beta - (\epsilon-1)^2}}{2c}. \tag{2.7}$$

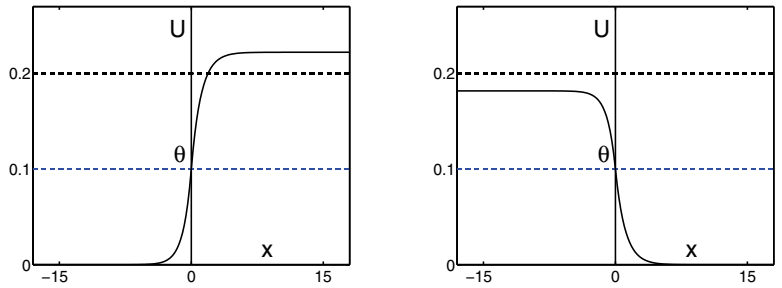

Figure 1. *Left panel: Stationary front solution of* (3.8)–(3.9)*, with* $U(\infty) = \frac{2\theta}{1-\kappa} = .23$ *when* $(\theta, \kappa) = (.1, .15)$ *and* $\beta = \beta_1 = \frac{0.5}{(\kappa+1)\theta} - 1 = 3.35$*. Right panel: Solution with* $U(-\infty) = \frac{2\theta}{1+\kappa} = .173$ *when* $\beta = \beta_2 = \frac{.5}{(1-\kappa)\theta} - 1 = 4.88$.

Our investigation indicates that stable traveling waves exist when

$$0 < \epsilon, \kappa < 1, \quad 0 < \theta < \min\left(\frac{2\epsilon}{(1-\kappa^2)(\epsilon+1)^2}, \frac{1}{4(\epsilon+1)}\right), \quad \beta > \beta_* = \frac{(\epsilon-1)^2}{4\epsilon}. \tag{2.8}$$

The first two sets of inequalities in (2.8) are mild restrictions which allow technical arguments to be completed, and the third inequality means that $\mu^{\pm}$ are complex. Throughout the paper we perform numerical experiments for parameters which satisfy (2.8). An important implication of (2.8) is that

$$\beta_* = \frac{(\epsilon-1)^2}{4\epsilon} < \beta_1 = \frac{1}{2(1+\kappa)\theta} - 1 < \beta_2 = \frac{1}{2(1-\kappa)\theta} - 1 \tag{2.9}$$

when $|\kappa|$ is small. In section 3 we will see that distinct branches of wave fronts come into existence at the critical values $\beta_1 = \frac{1}{2(1+\kappa)\theta} - 1$ and $\beta_2 = \frac{1}{2(1-\kappa)\theta} - 1$. Our analysis of 1-pulse waves in section 4 shows that infinitely many wave speeds are possible at $\beta = \beta_1$ and $\beta = \beta_2$. 2-pulse solutions are described in section 5. When $\mu^{\pm}$ are complex, underlying oscillatory terms lead to technical difficulties which make the completion of existence proofs especially challenging. These difficulties suggest open problems which are discussed as we proceed.

3. Wave fronts. We analyze wave front solutions when w is asymmetric. Although the discussion appears lengthy, it is necessary to give complete details in order to obtain a global understanding of the structure of solutions. Our study focuses on the following:

A. The construction of two families of stationary solutions with speed $c = 0$ (Figure 1).
B. Properties of wave fronts when $c > 0$. In this case a family of solutions bifurcates from a stationary solution (Figure 1, right panel) as c *increases* from $c = 0$.
C. Properties of wave fronts when $c < 0$. In this case a family of wave fronts with different speeds and shapes bifurcates from a second stationary solution (Figure 1, left panel) as c *decreases* from $c = 0$.
D. The effects of changing the threshold θ.
E. Open problems.

A. *Stationary solutions.* We set $c = 0$ and $w(x) = \frac{1}{2}e^{-|x-x'|+\kappa(x-x')}$ in (2.3) and investigate the existence of stationary wave front solutions of the form

$$U(x) = \frac{1}{2(\beta+1)} \int_{-\infty}^{\infty} e^{-|x-x'|+\kappa(x-x')} H\left(U(x') - \theta\right) dx'. \tag{3.1}$$

We find that there is a range of parameters for which two different solutions exist.

The first stationary solution. The first solution (Figure 1, left panel) satisfies

$$\begin{cases} U(x) \text{ and } U'(x) \text{ are continuous } \forall x \in (-\infty, \infty), \\ U(x) < \theta \ \forall x < 0,\ U(0) = \theta, \\ U(x) > \theta \ \forall x \in (0, \infty). \end{cases} \tag{3.2}$$

Without loss of generality we have assumed that $U(0) = \theta$ in (3.2) since (3.1) is translationally invariant. Then (3.2) reduces (3.1) to

$$U(x) = \frac{1}{2(\beta+1)} \int_{0}^{\infty} e^{-|x-x'|+\kappa(x-x')} dx'. \tag{3.3}$$

Solving (3.2)–(3.3) gives

$$U(x) = \begin{cases} \frac{0.5}{(\kappa+1)(\beta+1)} e^{(1+\kappa)x} & \forall x \le 0, \\ \frac{0.5}{\beta+1} \left(\frac{2}{1-\kappa^2} - \frac{e^{(\kappa-1)x}}{1-\kappa} \right), & x > 0, \end{cases} \tag{3.4}$$

where β, κ, θ satisfy

$$0 < \kappa < 1, \quad 0 < \theta < 1, \quad \beta = \beta_1 = \frac{0.5}{(\kappa+1)\theta} - 1. \tag{3.5}$$

This and (2.9) imply that

$$\beta_* < \beta_1 < \frac{1}{2\theta} - 1 \ \forall \kappa \in (0,1), \quad \beta_1 \to \frac{1}{2\theta} - 1 \text{ as } \kappa \to 0^+, \quad \beta_1 \to \frac{1}{4\theta} - 1 \text{ as } \kappa \to 1^-. \tag{3.6}$$

It follows from (3.4)–(3.5) that

$$\begin{cases} U'(x) > 0 \ \forall x \in (-\infty, \infty), \\ (U(x), U'(x)) \to \left(\frac{2\theta}{1-\kappa}, 0 \right) \text{ as } x \to \infty, \\ (U(x), U'(x)) \to (0,0) \text{ as } x \to -\infty. \end{cases} \tag{3.7}$$

The second stationary solution. The second solution (Figure 1, right panel) satisfies

$$\begin{cases} U(x) \text{ and } U'(x) \text{ are continuous } \forall x \in (-\infty, \infty), \\ U(x) > \theta \ \forall x \in (-\infty, 0),\ U(0) = \theta, \\ U(x) < \theta \ \forall x > 0. \end{cases} \tag{3.8}$$

Conditions (3.8) reduce (3.1) to

$$U(x) = \frac{1}{2(\beta+1)} \int_{-\infty}^{0} e^{-|x-x'|+\kappa(x-x')} dx'. \tag{3.9}$$

Solving (3.8)–(3.9) gives

$$U(x) = \begin{cases} \frac{.5}{\beta+1}\left(\frac{2}{1-\kappa^2} - \frac{e^{(1+\kappa)x}}{1+\kappa}\right), & x < 0, \\ \frac{.5}{(\beta+1)(1-\kappa)} e^{(\kappa-1)x} & \forall x \geq 0. \end{cases} \tag{3.10}$$

Conditions (3.8) hold when β, κ, θ, a satisfy

$$0 < \kappa < 1, \quad 0 < \theta < 1, \quad \beta = \beta_1 = \frac{.5}{(1-\kappa)\theta} - 1. \tag{3.11}$$

This implies that

$$\beta_1 > \frac{1}{2\theta} - 1 \ \forall \kappa \in (0,1), \quad \beta_1 \to \frac{1}{2\theta} - 1 \text{ as } \kappa \to 0^+, \quad \beta_1 \to +\infty \text{ as } \kappa \to 1^-. \tag{3.12}$$

Finally, it follows from (3.10)–(3.11) that U satisfies (3.8), and also

$$\begin{cases} U'(x) < 0 \ \forall x \in (-\infty, \infty), \\ (U(x), U'(x)) \to \left(\frac{2\theta}{1+\kappa}, 0\right) \text{ as } x \to -\infty, \\ (U(x), U'(x)) \to (0,0) \text{ as } x \to +\infty. \end{cases} \tag{3.13}$$

B. *Properties of wave fronts when $c > 0$.* In this and the next two sections we show how distinct branches of solutions bifurcate from the stationary solutions constructed above as c passes through $c = 0$. When $c > 0$ wave front solutions satisfy

$$\begin{cases} U(z) \text{ and } U'(z) \text{ are continuous } \forall z \in (-\infty, \infty), \\ U(z) < \theta \ \forall z < 0, \\ (U(z), U'(z)) \to (0,0) \text{ as } z \to -\infty, \\ U(0) = \theta, \quad U(z) > \theta \ \forall z > 0, \quad U'(z) \to 0 \text{ as } z \to \infty. \end{cases} \tag{3.14}$$

Again, without loss of generality we have assumed that $U(0) = \theta$ in (3.2) since (2.3) is translationally invariant. When conditions (3.14) hold, equation (2.3) reduces to

$$c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U = \frac{c}{2}\frac{d}{dz}\int_0^\infty e^{-|z-z'|+\kappa(z-z')}dz' + \frac{\epsilon}{2}\int_0^\infty e^{-|z-z'|+\kappa(z-z')}dz'. \tag{3.15}$$

This further reduces to

$$c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U = g(z), \tag{3.16}$$

where

$$g(z) = \begin{cases} .5(c + \frac{\epsilon}{1+\kappa})e^{(1+\kappa)z} & \forall z \leq 0, \\ .5(c - \frac{\epsilon}{1-\kappa})e^{-(1-\kappa)z} + \frac{\epsilon}{1-\kappa^2} & \text{if} \quad z > 0. \end{cases} \tag{3.17}$$

A combination of analysis and numerical experiments suggests that two branches of solutions coexist when $c > 0$ (Figure 2). To understand how these results are obtained, we investigate the following:

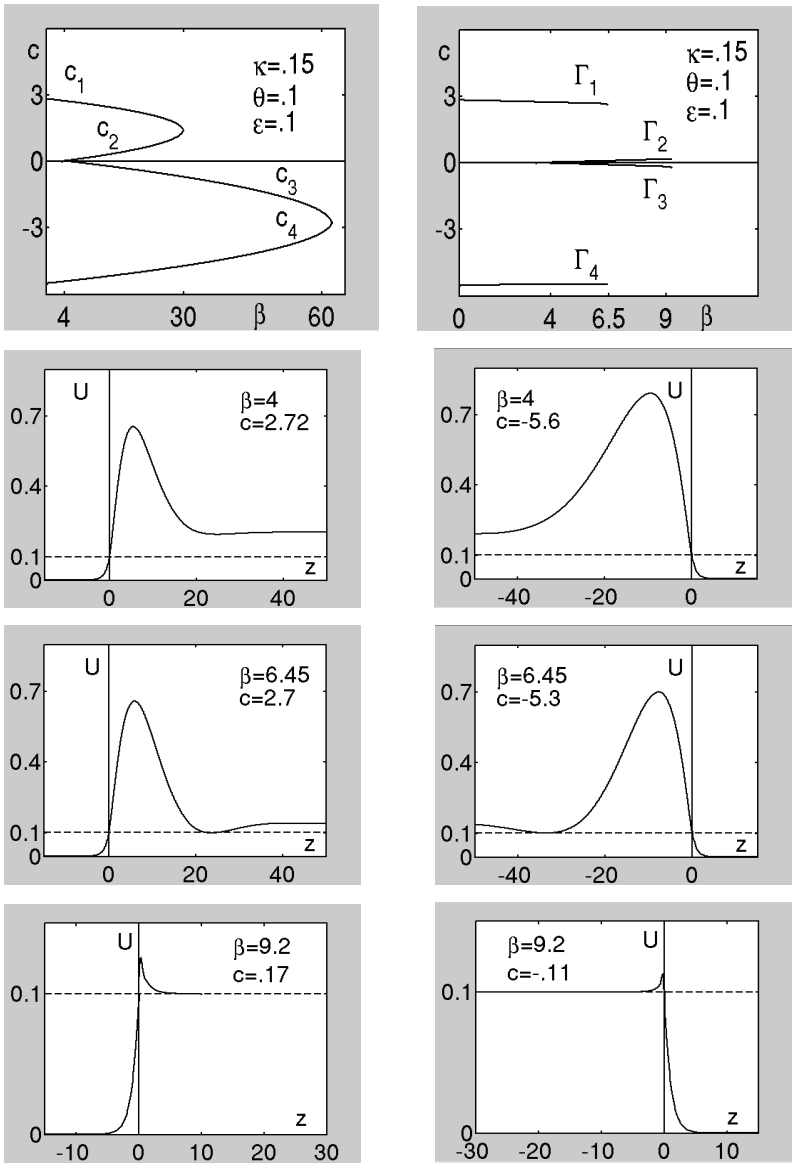

Figure 2. *Upper left:* c_1, c_2, c_3, *and* c_4 *versus* β *when* $(\epsilon, \theta, \kappa) = (.1, .1, .15)$. *Upper right:* Γ_1, Γ_2, Γ_3, *and* Γ_4 *in the* (β, c) *plane when* $(\epsilon, \theta, \kappa) = (.1, .1, .15)$. *Second row: Solutions at* $\beta = 4$ *on* Γ_1 *(left) and* Γ_4 *(right). Third row: Solutions at the right endpoints of* Γ_1 *(left) and* Γ_4 *(right), where* $\beta \approx 6.45$. *Fourth row: Solutions at the right endpoints of* Γ_2 *(left) and* Γ_3 *(right), where* $\beta = \frac{1}{(1-\kappa^2)\theta} - 1 \approx 9.2$.

(i) Analysis of solutions on $(-\infty, 0]$.
(ii) Analysis of solutions on $(0, \infty)$.
(iii) Numerical evidence for the existence of solutions.

(i) *Analysis of solutions on* $(-\infty, 0]$. On $(-\infty, 0]$ the solution of (3.16) is

$$U_0(z) = b_1 e^{\alpha z} \cos(\gamma z) + b_2 e^{\alpha z} \sin(\gamma z) + P_0(z), \tag{3.18}$$

where b_1 and b_2 are constants, and $P_0(z)$ is the particular solution

$$P_0(z) = \frac{.5(\epsilon + (1+\kappa)c)}{(1+\kappa)((1+\kappa)^2c^2 + (1+\kappa)(1+\epsilon)c + \epsilon(\beta+1))} e^{(1+\kappa)z} \quad \forall z \le 0. \tag{3.19}$$

The oscillatory terms $b_1 e^{\alpha z}\cos(\gamma z)$ and $b_2 e^{\alpha z}\sin(\gamma z)$ in (3.18) are due to $\mu^{\pm}$ being complex. Recall from (2.7) that $\alpha = \mathrm{Re}(\mu^{\pm}) < 0$ when $c > 0$. Thus, to satisfy the condition $U_0(-\infty) = U_0'(-\infty) = 0$, we conclude that $b_1 = b_2 = 0$, and (3.18)–(3.19) reduce to

$$U_0(z) = \frac{.5(\epsilon + (1+\kappa)c)}{(1+\kappa)((1+\kappa)^2c^2 + (1+\kappa)(1+\epsilon)c + \epsilon(\beta+1))} e^{(1+\kappa)z} \quad \forall z \le 0. \tag{3.20}$$

Substituting $U_0(0) = \theta$ into (3.20) gives the algebraic equation

$$\frac{.5(\epsilon + (1+\kappa)c)}{(1+\kappa)((1+\kappa)^2c^2 + (1+\kappa)(1+\epsilon)c + \epsilon(\beta+1))} = \theta. \tag{3.21}$$

It follows from (3.20)–(3.21) that

$$U_0(z) = \theta e^{(1+\kappa)z} < \theta \quad \forall z \le 0. \tag{3.22}$$

(ii) *Analysis of solutions on* $(0,\infty)$. When $z > 0$ the first step in analyzing solutions is to solve (3.21) for wave speed c. This gives the two positive values (Figure 2, upper left panel)

$$c_1 = \frac{.5 - \theta(1+\kappa)(\epsilon+1) + \sqrt{\left(.5 - \theta(1+\kappa)(1+\epsilon)\right)^2 - 4\epsilon\theta(1+\kappa)\left(\theta(1+\kappa)(\beta+1) - .5\right)}}{2\theta(1+\kappa)^2}, \tag{3.23}$$

$$c_2 = \frac{.5 - \theta(1+\kappa)(\epsilon+1) - \sqrt{\left(.5 - \theta(1+\kappa)(1+\epsilon)\right)^2 - 4\epsilon\theta(1+\kappa)\left(\theta(1+\kappa)(\beta+1) - .5\right)}}{2\theta(1+\kappa)^2}. \tag{3.24}$$

Recall from (2.8) that $0 < \epsilon < 1$ and $0 < \theta < \frac{1}{4(\epsilon+1)}$. This and (3.23)–(3.24) imply that

$$\begin{cases} c_1 > 0 \text{ if } 0 < \beta < \frac{1}{2\theta(1+\kappa)} - 1 + \frac{1}{4\epsilon\theta^2(1+\kappa)^2}\left(.5 - \theta(1+\kappa)(1+\epsilon)\right)^2, \\ c_2 = 0 \text{ if } \beta = \frac{1}{2\theta(1+\kappa)} - 1, \\ c_2 > 0 \text{ if } \frac{1}{2\theta(1+\kappa)} - 1 < \beta \le \frac{1}{2\theta(1+\kappa)} - 1 + \frac{1}{4\epsilon\theta^2(1+\kappa)^2}\left(.5 - \theta(1+\kappa)(1+\epsilon)\right)^2, \\ c_1 \text{ and } c_2 \text{ are complex if } \beta > \frac{1}{2\theta(1+\kappa)} - 1 + \frac{1}{4\epsilon\theta^2(1+\kappa)^2}\left(.5 - \theta(1+\kappa)(1+\epsilon)\right)^2. \end{cases} \tag{3.25}$$

When $z > 0$ the solution of (3.16) is

$$U_1 = k_1 e^{\alpha z}\cos(\gamma z) + k_2 e^{\alpha z}\sin(\gamma z) + P_1(z), \tag{3.26}$$

where $\alpha < 0$ and $\gamma > 0$ are defined in (2.7), and $P_1(z)$ is the particular solution

$$P_1(z) = \frac{.5((1-\kappa)c - \epsilon)}{(1-\kappa)((1-\kappa)^2c^2 - (1-\kappa)(1+\epsilon)c + \epsilon(\beta+1))} e^{-(1-\kappa)z} + \frac{1}{(\beta+1)(1-\kappa^2)}, \tag{3.27}$$

where $c = c_1$ or $c = c_2$. To preserve continuity at $z = 0$ we require that $(U_1(0), U_1'(0)) = (U_0(0), U_0'(0))$. This and (3.26)–(3.27) show that k_1 and k_2 are uniquely defined by

$$k_1 = \theta - P_1(0) \quad \text{and} \quad k_2 = \frac{1}{\gamma}\left(\theta(1-\alpha) - P_1{}'(0) + \alpha P_1(0)\right). \tag{3.28}$$

(iii) *Numerical evidence for the existence of solutions.* To complete the proof that a solution satisfies all of the conditions in (3.14) for a traveling wave front we need only to show that

$$U_1(z) > \theta \ \ \forall z > 0 \quad \text{and} \quad \lim_{z\to\infty} U_1'(z) = 0. \tag{3.29}$$

To gain insight we let $\epsilon = .1$ and $\beta > \beta_* = 2.025$ and solve the initial value problem

$$\begin{aligned} u_t(x,t) &= -u - v + \tfrac{1}{2}\textstyle\int_{-120}^{120} e^{-|x-x'|+\kappa(x-x')} H(u(x',t)-\theta)dx', \\ v_t(x,t) &= \epsilon(\beta u - v), \\ u(x,0) &= e^{-x^2}, \quad \text{and} \quad v(x,0) = 0 \quad \forall x \in [-120, 120], \end{aligned} \tag{3.30}$$

where (θ, κ) satisfy (3.30). The limits $(-\infty, \infty)$ in the integral term have been replaced with $[-120, 120]$. Other choices for initial conditions give results similar to those described below. A second approach which leads to wave formation is to initially keep u and v at their resting levels, i.e., $u(x,0) = v(x,0) = 0$, and perturb the system with an external stimulus applied to the right side of the equation for u. To solve (3.30) we approximate the integral term with a Riemann sum, with step size $\Delta x = .1$, and use an explicit Euler time step $\Delta t = .05$. When $\beta > \beta_*$ the solution of (3.30) evolves into a traveling wave front (Figure 2), a single-pulse wave (Figures 4 and 6), or an N-pulse wave (Figure 7). Our numerical study of wave fronts suggests that (3.29) does not hold at every point along the curves c_1 and c_2 (Figure 2, upper left). However, (3.29) does hold along two connected subbranches Γ_1 and Γ_2 of these curves (Figure 2, upper right). Below we describe Γ_1 and Γ_2.

The lower branch Γ_2. When $c = c_2$ it follows from (3.26), (3.27), and (3.28) that

$$\begin{aligned} U_1(z) = {} & k_1 e^{\alpha z}\cos(\gamma z) + k_2 e^{\alpha z}\sin(\gamma z) \\ & + \frac{.5((1-\kappa)c_2 - \epsilon)}{(1-\kappa)((1-\kappa)^2 c_2^2 - (1-\kappa)(1+\epsilon)c_2 + \epsilon(\beta+1))} e^{-(1-\kappa)z} + \frac{1}{(\beta+1)(1-\kappa^2)}. \end{aligned} \tag{3.31}$$

If $U_1(z) > \theta \ \forall z > 0$, then (3.31) implies that $U_1'(z) \to 0$ as $z \to \infty$, and therefore both conditions in (3.29) hold. Thus, it is sufficient to show that

$$U_1(z) > \theta \quad \forall z > 0. \tag{3.32}$$

It is difficult to prove (3.32) since the oscillatory component $k_1 e^{\alpha z}\cos(\gamma z) + k_2 e^{\alpha z}\sin(\gamma z)$ of (3.31) can cause $U_1(z)$ to dip below the threshold level θ at some point in $(0, \infty)$. However, our numerical experiments indicate that there is a branch Γ_2 (Figure 2) of solutions satisfying

$$U(z) = \begin{cases} \theta e^{(1+\kappa)z} < \theta & \forall z < 0, \\ U_1(z) > \theta & \forall z > 0. \end{cases} \tag{3.33}$$

Along Γ_2 it follows from (3.23) and (3.25) that

$$c_2 \to 0^+ \text{ as } \beta \to \left(\frac{1}{2(1+\kappa)\theta} - 1\right)^+. \tag{3.34}$$

Thus, the left end of Γ_2 begins at $\beta = \frac{1}{2(1+\kappa)\theta} - 1$ where $c_2 = 0$ and U is the stationary solution defined by (3.4) (Figure 1, left panel). To determine the right end of Γ_2 we substitute the condition $U(\infty) \geq \theta$ into (3.33) and obtain $U(\infty) = \frac{1}{(1-\kappa^2)(\beta+1)} \geq \theta$. This implies that Γ_2 cannot extend past $\beta = \frac{1}{(1-\kappa^2)\theta} - 1$. Figure 2 (fourth row, left panel) shows the solution at the right endpoint of Γ_2 when $(\epsilon, \theta, \kappa) = (.1, .1, .15)$. For each $\beta \in [\frac{1}{2(1+\kappa)\theta} - 1, \frac{1}{(1-\kappa^2)\theta} - 1]$ our computations indicate that $U(z) > \theta \ \forall z > 0$; hence we conjecture that the interval of existence of Γ_2 is $[\frac{1}{2(1+\kappa)\theta} - 1, \frac{1}{(1-\kappa^2)\theta} - 1]$. Our study also suggests that all solutions on Γ_2 are unstable.

The upper branch Γ_1. Let Γ_1 denote the upper branch of wave fronts when $c = c_1$ (Figure 2). This branch extends to the left of $\beta = \beta_*$ down to $\beta = 0$. When $0 < \beta \leq \beta_*$ the eigenvalues $\mu^{\pm}$ are real, and solutions on Γ_1 are monotone for large z. When $\beta > \beta_*$ the eigenvalues $\mu^{\pm}$ are complex and solutions have the form

$$U(z) = \begin{cases} \theta e^{(1+\kappa)z} & \forall z \leq 0, \\ k_1 e^{\alpha z}\cos(\gamma z) + k_2 e^{\alpha z}\sin(\gamma z) + \frac{.5((1-\kappa)c_1 - \epsilon)e^{-(1-\kappa)z}}{(1-\kappa)((1-\kappa)^1 c_1^2 - (1-\kappa)(1+\epsilon)c_1 + \epsilon(\beta+1))} & \\ \qquad + \frac{1}{(1-\kappa^2)(\beta+1)} & \forall z > 0, \end{cases} \tag{3.35}$$

where α, γ, k_1, and k_2 are evaluated at $c = c_2$. To complete the proof we need to show that $U(z) > \theta \ \forall z > 0$. This is difficult to prove, even in the real eigenvalue regime, since U can dip below θ at a positive z value. In Figure 2 (second row, left) we set $\beta = 4$ and see that $U(z)$ is a wave front since $U(z) > \theta \ \forall z > 0$. In the third row, left panel, we set $\beta = 6.45$ and see that $U(z)$ is not a wave front since it is tangent to $U = \theta$ at $z \approx 21$. When $\beta > 6.45$ the function U cannot be a wave front since it dips below θ at a positive z value. We conjecture that the interval of existence of Γ_1 is approximately $(0, 6.45)$ (Figure 2, first row, right). Our study suggests that solutions on Γ_1 are stable.

C. *Properties of wavefronts when* $c < 0$. When $c < 0$ we investigate solutions which satisfy

$$\begin{cases} U(z) \text{ and } U'(z) \text{ are continuous } \forall z \in (-\infty, \infty), \\ U(z) > \theta \ \forall z < 0, \quad U'(z) \to 0 \text{ as } z \to -\infty, \\ U(0) = \theta, \quad U(z) < \theta \ \forall z > 0, \\ (U(z), U'(z)) \to (0,0) \text{ as } z \to \infty. \end{cases} \tag{3.36}$$

When conditions (3.36) hold, (2.3) reduces to

$$c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U = \frac{c}{2}\frac{d}{dz}\int_{-\infty}^{0} e^{-|z-z'|+\kappa(z-z')}dz' + \frac{\epsilon}{2}\int_{-\infty}^{0} e^{-|z-z'|+\kappa(z-z')}dz'. \tag{3.37}$$

This further reduces to

$$c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U = g(z), \tag{3.38}$$

where

$$g(z) = \begin{cases} -.5(c + \frac{\epsilon}{1+\kappa})e^{(1+\kappa)z} + \frac{\epsilon}{1-\kappa^2} & \forall z \le 0, \\ -.5(c - \frac{\epsilon}{1-\kappa})e^{-(1-\kappa)z} & \text{if} \quad z > 0. \end{cases} \tag{3.39}$$

As in the case $c > 0$, we devote the remainder of this section to the following:

(iv) Analysis of solutions on $[0, \infty)$.
(v) Analysis of solutions on $(-\infty, 0)$.
(vi) Numerical evidence for the existence of solutions.

(iv) *Analysis of solutions on* $[0, \infty)$. Proceeding as above, we find that the solution of (3.38) is

$$U_2(z) = \frac{.5(\epsilon - (1-\kappa)c)}{(1-\kappa)((1-\kappa)^2c^2 + -(1-\kappa)(1+\epsilon)c + \epsilon(\beta+1))} e^{-(1-\kappa)z} \quad \forall z > 0. \tag{3.40}$$

Substituting the condition $U_2(0) = \theta$ into (3.40), we obtain

$$\frac{.5(\epsilon - (1-\kappa)c)}{(1-\kappa)((1-\kappa)^2c^2 - (1-\kappa)(1+\epsilon)c + \epsilon(\beta+1))} = \theta. \tag{3.41}$$

It follows from (3.40)–(3.41) that

$$U_2(z) = \theta e^{-(1-\kappa)z} < \theta \quad \forall z \ge 0. \tag{3.42}$$

Next, solving (3.41) for wave speed c gives the two negative values (Figure 2)

$$c_3 = \frac{\theta(1-\kappa)(\epsilon+1) - .5 + \sqrt{\left(.5 - \theta(1-\kappa)(1+\epsilon)\right)^2 - 4\epsilon\theta(1-\kappa)\left(\theta(1-\kappa)(\beta+1) - .5\right)}}{2\theta(1-\kappa)^2}, \tag{3.43}$$

$$c_4 = \frac{\theta(1-\kappa)(\epsilon+1) - .5 - \sqrt{\left(.5 - \theta(1-\kappa)(1+\epsilon)\right)^2 - 4\epsilon\theta(1-\kappa)\left(\theta(1-\kappa)(\beta+1) - .5\right)}}{2\theta(1-\kappa)^2}. \tag{3.44}$$

(v) *Analysis of solutions on* $(-\infty, 0)$. When $z < 0$ the solution of (3.16) is

$$U_3 = k_1 e^{\alpha z}\cos(\gamma z) + k_2 e^{\alpha z}\sin(\gamma z) + P_2(z), \tag{3.45}$$

where $\alpha < 0$ and $\gamma > 0$ are defined in (2.7), and $P_2(z)$ is the particular solution

$$P_2(z) = \frac{-.5((1+\kappa)c + \epsilon)}{(1+\kappa)((1+\kappa)^2c^2 + (1+\kappa)(1+\epsilon)c + \epsilon(\beta+1))} e^{(1+\kappa)z} + \frac{1}{(\beta+1)(1-\kappa^2)}, \tag{3.46}$$

where $c = c_3$ or $c = c_4$. To preserve continuity at $z = 0$ we require that $(U_3(0), U_3'(0)) = (U_2(0), U_2'(0))$. This and (3.45)–(3.46) show that k_1 and k_2 are uniquely defined by

$$k_1 = \theta - P_2(0) \quad \text{and} \quad k_2 = \frac{1}{\gamma}\left(\theta(1-\alpha) - P_2'(0) + \alpha P_2(0)\right). \tag{3.47}$$

(vi) *Numerical evidence for the existence of solutions.* As in the case $c > 0$, to complete the proof that a solution satisfies all of the conditions in (3.14) for a wave front it suffices to show that

$$U_3(z) > \theta \quad \forall z < 0. \tag{3.48}$$

Our numerical experiments suggest that conditions (3.48) are not satisfied at every point along the curves c_3 and c_4 (Figure 2). However, (3.48) does hold along two subbranches Γ_3 and Γ_4 of these curves (Figure 2). Below we briefly describe properties of solutions along Γ_3 and Γ_4.

The branch Γ_3. When $c = c_3 < 0$ it follows from (3.45), (3.46), and (3.47) that

$$\begin{aligned} U_2(z) &= k_1 e^{\alpha z}\cos(\gamma z) + k_2 e^{\alpha z}\sin(\gamma z) \\ &\quad - \tfrac{.5((1+\kappa)c_3+\epsilon)}{(1+\kappa)((1+\kappa)^2c_3^2+(1+\kappa)(1+\epsilon)c_3+\epsilon(\beta+1))}e^{(1+\kappa)z} + \tfrac{1}{(\beta+1)(1-\kappa^2)}. \end{aligned} \tag{3.49}$$

Our numerical experiments indicate that there is a branch Γ_3 (Figure 2) of solutions satisfying

$$U(z) = \begin{cases} \theta e^{-(1-\kappa)z} < \theta & \forall z \geq 0, \\ U_2(z) > \theta & \forall z < 0. \end{cases} \tag{3.50}$$

Along Γ_3 it follows from (3.43) that

$$c_3 \to 0^+ \text{ as } \beta \to \left(\frac{1}{2(1-\kappa)\theta} - 1\right)^+. \tag{3.51}$$

Thus, the left end of Γ_3 begins at $\beta = \frac{1}{2(1-\kappa)\theta} - 1$ where $c_3 = 0$ and U is the stationary solution defined by (3.4) (Figure 1, right panel). To determine the right end of Γ_3 we substitute the condition $U(\infty) \geq \theta$ into (3.50) and obtain $U(\infty) = \frac{1}{(1-\kappa^2)(\beta+1)} \geq \theta$. This implies that Γ_3 cannot extend past $\beta = \frac{1}{(1-\kappa^2)\theta} - 1$. Figure 2 (fourth row, right panel) shows the solution at the right endpoint of Γ_3 when $(\epsilon, \theta, \kappa) = (.1, .1, .15)$. For each $\beta \in [\frac{1}{2(1-\kappa)\theta} - 1, \frac{1}{(1-\kappa^2)\theta} - 1]$ our computations indicate that $U(z) > \theta$ $\forall z < 0$; hence we conjecture that the interval of existence of Γ_3 is $[\frac{1}{2(1-\kappa)\theta} - 1, \frac{1}{(1-\kappa^2)\theta} - 1]$. Our study also suggests that all solutions on Γ_3 are unstable.

Comparisons. To obtain Γ_2 we set $(\epsilon, \theta, \kappa) = (.1, .1, .15)$ and let β increase from the upper critical value $\beta = \frac{1}{2(1+\kappa)\theta} - 1$ where $c_2 = 0$ and the solution is the stationary front defined by (3.4). Γ_3 is found by letting β increase from the lower critical value $\beta = \frac{1}{2(1-\kappa)\theta} - 1$ where $c_3 = 0$ and the solution is the stationary front defined by (3.10). The eigenvalues $\mu^{\pm}$ are complex at $\beta = \frac{1}{2(1+\kappa)\theta} - 1$ and $\beta = \frac{1}{2(1-\kappa)\theta} - 1$ since $(\epsilon, \theta, \kappa)$ satisfy (2.8). It is interesting to contrast these bifurcation results with [2], where a similar phenomenon is found when the coupling is symmetric (i.e., $\kappa = 0$) and (ϵ, θ) are chosen so that $\mu^{\pm}$ are real. In that study (θ, β) are kept fixed and counterpropagating fronts bifurcate from the stationary solution as ϵ varies. It would be interesting to analytically determine if a similar phenomenon occurs here where w is asymmetric and $\mu^{\pm}$ are complex.

The branch Γ_4. We let Γ_4 denote the upper branch of wave fronts when $c = c_4 < 0$ (Figure 2). As in the case $c > 0$, this branch extends below $\beta = \beta_*$ down to $\beta = 0$. Solutions on Γ_4 have the form

$$U(z) = \begin{cases} \theta e^{-(1-\kappa)z} & \forall z > 0, \\ k_1 e^{\alpha z}\cos(\gamma z) + k_2 e^{\alpha z}\sin(\gamma z) - \frac{.5((1+\kappa)c_4+\epsilon)e^{(1+\kappa)z}}{(1+\kappa)((1+\kappa)^2c_4^2+(1+\kappa)(1+\epsilon)c_4+\epsilon(\beta+1))} & \\ \qquad + \frac{1}{(1-\kappa^2)(\beta+1)} & \forall z \le 0, \end{cases} \tag{3.52}$$

where α, γ, k_1, and k_2 are evaluated at $c = c_4$. To complete the proof of existence we need to show that $U(z) > \theta\ \forall z < 0$. Again, this is difficult to prove since U can dip below θ at a negative value of z. In Figure 2 (second row, right panel) we set $\beta = 4$ and see that $U(z)$ is a wave front since $U(z) > \theta\ \forall z < 0$. In the third row, right panel, we set $\beta = 6.45$ and see that $U(z)$ is not a wave front since it is tangent to $U = \theta$ at $z \approx -21$. When $\beta > 6.45$ the function U cannot be a wave front since it dips below θ at a finite value of z. Thus, we conjecture that the interval of existence of Γ_4 is approximately $(0, 6.45)$. Our study suggests that all solutions on Γ_4 are stable.

D. *The effects of changing the threshold θ.* We study how variations in θ affect wave front formation when $\mu^{\pm}$ are complex and w is asymmetric. Figures 2 and 3 illustrate the differences in the behavior of solutions when $\theta = .1$ and $\theta = .2$, and lead to the following conjectures:

(i) There is an interval of β values, approximately $0 < \beta < 6.75$ when $(\epsilon, \kappa, \theta) = (.1, .15, .1)$, and a second interval $0 < \beta < 4.05$ when $(\epsilon, \kappa, \theta) = (.1, .15, .2)$, over which two stable wave fronts coexist, which propagate in opposite directions, with different speeds and amplitudes.

(ii) At fixed $(\epsilon, \kappa, \beta)$ the speeds and amplitudes *decrease* as θ increases.

(iii) At fixed (ϵ, κ) the values of β at the right endpoints of $\Gamma_1, \ldots, \Gamma_4$ decrease as θ increases.

E. *Open problems.* It remains an open problem to prove the existence of wave fronts along the branches $\Gamma_1, \ldots, \Gamma_4$ described above. Whether $\mu^{\pm}$ are real or complex, new methods are needed in order to overcome the technical difficulties in showing that solutions satisfy $U(z) = \theta$ only once on the interval $(-\infty, \infty)$. Although generalizations and insightful approximations have previously been given [2, 42], this property has not yet been verified for any set of parameters or couplings, even in the real eigenvalue regime. In [58] we considered parameter values where $\mu^{\pm}$ are *real* and developed a comparison method which addresses these issues when w is symmetric. It is hoped that extensions of our techniques will help complete existence proofs when w is asymmetric, and for a wider range of rate functions and parameter values. The proof of stability of solutions along Γ_1 and Γ_4, and the instability of solutions along Γ_2 and Γ_3, also remains an open problem. It is possible that this might be accomplished by extensions of Evans function methods developed in [12, 44, 50].

4. 1-pulse traveling waves.

We analyze 1-pulse traveling waves when w is asymmetric and $\mu^{\pm}$ are complex. Our study consists of the following:

A. The proof of nonexistence of stationary, 1-pulse solutions.

B. Positive and negative wave speeds: the statement and proof of Theorem 4.2 concerning the coexistence of two families of infinitely many 1-pulse waves.

C. The effects of changing the threshold and the identification of θ^*.

A. *Nonexistence of stationary solutions.* In the previous section we showed how two distinct families of wave fronts come into existence by means of a bifurcation from stationary solutions when $\kappa \neq 0$. In [58] we demonstrated how a branch of 1-pulse traveling waves

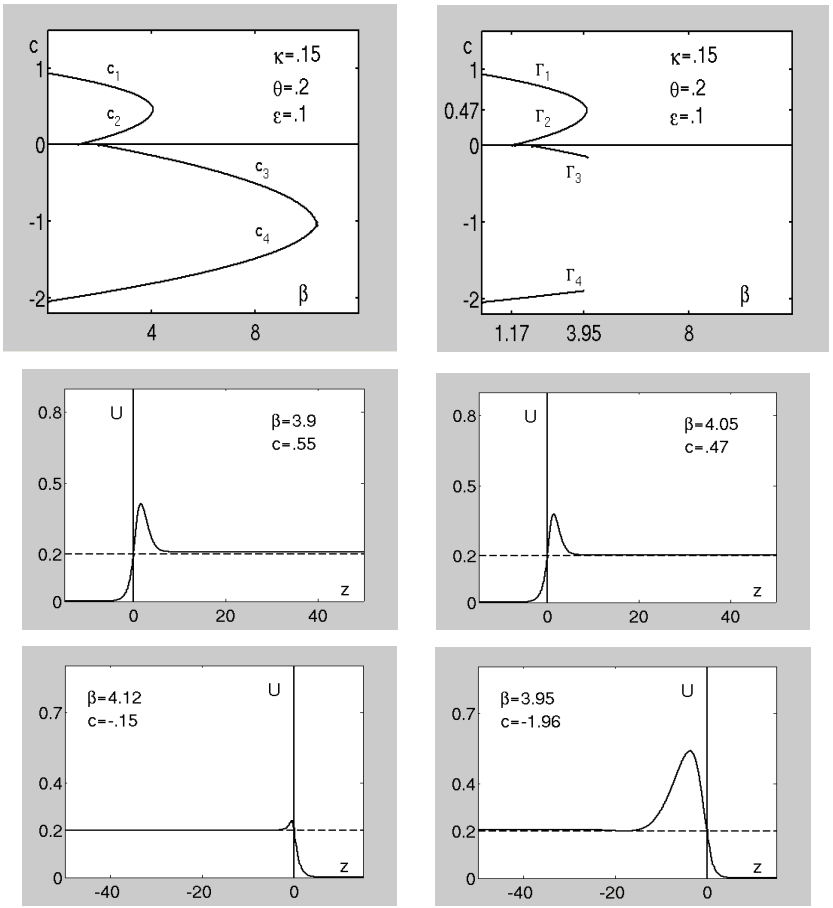

Figure 3. *Upper left:* c_1, c_2, c_3, *and* c_4 *versus* β *when* $(\epsilon, \theta, \kappa) = (.1, .2, .15)$. *Upper right:* Γ_1, Γ_2, Γ_3, *and* Γ_4 *in the* (β, c) *plane. Second row: Solutions at* $\beta = 3.9$ *on* Γ_1 *(left) and at* $\beta = 4.05$, *the right endpoint where* Γ_1 *meets* Γ_2 *(right). Third row: Solutions at the right endpoints of* Γ_3 *where* $\beta \approx 4.12$ *(left) and* Γ_4 *where* $\beta \approx 3.95$ *(right). It is conjectured that solutions on* Γ_1 *and* Γ_4 *stable, and those on* Γ_2 *and* Γ_3 *are unstable.*

bifurcates from a stationary solution when $\kappa = 0$ and the coupling is symmetric. Theorem 4.1 below shows that there is a fundamental difference when we consider asymmetric couplings. In particular, we prove that there is no stationary 1-pulse solution for the class of asymmetric couplings satisfying the general condition

$$w(x) - w(-x) > 0 \ \ \forall x \in (-\infty, \infty) \quad \text{or} \quad w(x) - w(-x) < 0 \ \ \forall x \in (-\infty, \infty). \tag{4.1}$$

The function $w(x) = \frac{1}{2} e^{-|x| + \kappa x}$ which we study in this paper falls within this class. Thus, for couplings satisfying condition (4.1), a family of 1-pulse waves cannot come into existence by means of a bifurcation from a stationary solution.

Theorem 4.1. *If* w *satisfies* (4.1), *then* (2.3) *does not have a stationary* 1*-pulse solution.*

Proof. If a stationary solution U exists, then $c = 0$ and (2.3) reduces to

$$U(x) = \frac{1}{\beta + 1} \int_{-\infty}^{\infty} w(x - x') dx'. \tag{4.2}$$

We assume, for contradiction, that $U(x)$ satisfies

$$\begin{cases} U(x) \text{ and } U'(x) \text{ are continuous } \forall x \in (-\infty, \infty), \\ U(x) < \theta \ \forall x < 0, \quad U(0) = \theta, \\ U(x) > \theta \ \forall x \in (0, a), \quad \text{for some } a > 0, \\ U(a) = \theta, \quad U(x) < \theta \ \forall x > a, \\ (U(x), U'(x)) \to 0 \text{ as } |x| \to \infty. \end{cases} \tag{4.3}$$

Without loss of generality we have assumed that $U(0) = \theta$ in (4.3) since (4.2) is translationally invariant. Conditions (4.3) reduce (4.2) to

$$U(x) = \frac{1}{\beta + 1} \int_0^a w(x - x')dx'. \tag{4.4}$$

The substitution $\eta = x - x'$ changes (4.4) into

$$U(x) = \frac{1}{\beta + 1} \int_{x-a}^{x} w(\eta)d\eta. \tag{4.5}$$

Setting $x = 0$ and $x = a$ in (4.5), we conclude from (4.3) that

$$U(0) = \frac{1}{\beta + 1} \int_{-a}^{0} w(\eta)d\eta = \theta \quad \text{and} \quad U(a) = \frac{1}{\beta + 1} \int_0^a w(\eta)d\eta = \theta. \tag{4.6}$$

From this it follows that $\int_{-a}^{0} w(\eta)d\eta = \int_0^a w(\eta)d\eta$; hence

$$\int_0^a [w(\eta) - w(-\eta)]d\eta = 0. \tag{4.7}$$

However, condition (4.1) implies that either

$$\int_0^a [w(\eta) - w(-\eta)]d\eta > 0 \quad \text{or} \quad \int_0^a [w(\eta) - w(-\eta)]d\eta < 0, \tag{4.8}$$

which contradicts (4.7). This completes the proof.

B. *Positive and negative wave speeds.* In this section we study properties of 1-pulse traveling waves for both positive and negative wave speeds.

Positive wave speeds. When $c > 0$ we investigate the existence of 1-pulse waves which satisfy

$$\begin{cases} U(z) \text{ and } U'(z) \text{ are continuous } \forall z \in (-\infty, \infty), \\ U(z) < \theta \ \forall z < 0, \quad U(0) = \theta, \\ U(z) > \theta \ \forall z \in (0, a), \quad \text{for some } a = a(c) > 0, \\ U(a) = \theta \quad \text{and} \quad U(z) < \theta \ \forall z \in (a, \infty), \\ (U(z), U'(z)) \to (0, 0) \text{ as } |z| \to \infty. \end{cases} \tag{4.9}$$

Again we have assumed that $U(0) = \theta$ since (2.3) is translationally invariant. When conditions (4.9) hold, (2.3) reduces to

$$c^2U'' + c(1 + \epsilon)U' + \epsilon(\beta + 1)U = c\frac{d}{dz} \int_0^a w(z - z')dz' + \epsilon \int_0^a w(z - z')dz'. \tag{4.10}$$

Because $w(x) = \frac{1}{2}e^{-|x|+\kappa x}$, (4.10) can be written in the equivalent form

$$c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U = f(z), \tag{4.11}$$

where

$$f(z) = \begin{cases} \frac{.5}{1+\kappa}\left(c(1+\kappa)+\epsilon\right)\left(1-e^{-(1+\kappa)a}\right)e^{(1+\kappa)z} & \forall z \le 0, \\ .5\left(c+\frac{\epsilon}{\kappa-1}\right)e^{(\kappa-1)z} - .5\left(c+\frac{\epsilon}{\kappa+1}\right)e^{(\kappa+1)(z-a)} + \frac{\epsilon}{1-\kappa^2} & \text{if} \quad 0 < z < a, \\ \frac{.5}{1-\kappa}(\epsilon - c(1-\kappa))(e^{(1-\kappa)a}-1)e^{-(1-\kappa)z} & \forall z \ge a. \end{cases} \tag{4.12}$$

Negative wave speeds. When $c < 0$, a 1-pulse traveling wave satisfies

$$\begin{cases} U(z) \text{ and } U'(z) \text{ are continuous } \forall z \in (-\infty, \infty), \\ U(z) < \theta \ \forall z \in (-\infty, a), \quad \text{for some } a = a(c) < 0,\ U(a) = 0, \\ U(z) > \theta \ \forall z \in (a, 0), \quad U(0) = \theta, \\ U(z) < \theta \ \forall z > 0, \\ (U(z), U'(z)) \to (0,0) \text{ as } |z| \to \infty. \end{cases} \tag{4.13}$$

When conditions (4.13) hold, (2.3) reduces to

$$c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U = c\frac{d}{dz}\int_a^0 w(z-z')dz' + \epsilon\int_a^0 w(z-z')dz'. \tag{4.14}$$

Because $w(x) = \frac{1}{2}e^{-|x|+\kappa x}$, (4.14) can be written in the equivalent form

$$c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U = h(z), \tag{4.15}$$

where

$$h(z) = \begin{cases} \frac{.5}{1-\kappa}\left(c(1-\kappa)-\epsilon\right)\left(e^{(1-\kappa)a}-1\right)e^{-(1-\kappa)z} & \forall z \ge 0, \\ .5\left(c-\frac{\epsilon}{1-\kappa}\right)e^{-(1-\kappa)(z-a)} - .5\left(c+\frac{\epsilon}{\kappa+1}\right)e^{(\kappa+1)z} + \frac{\epsilon}{1-\kappa^2} & \text{if} \quad a < z < 0, \\ \frac{.5}{1+\kappa}(\epsilon + c(1+\kappa))(e^{-(1+\kappa)a}-1)e^{(1+\kappa)z} & \forall z \le a. \end{cases} \tag{4.16}$$

We prove the following theorem.

Theorem 4.2. *Let (ϵ, θ) satisfy (2.8). If $\kappa > 0$ is small and $\beta = \frac{1}{2(1-\kappa^2)\theta} - 1$, then the following hold.*

(i) *There are infinitely many $c \in (c_2, c_1)$ and $a(c) > 0$ and solutions U of (4.11)–(4.12) such that*

$$\begin{aligned} &U(z) = \theta e^{(1+\kappa)z}\ \forall z < 0, \quad U(0) = U(a(c)) = \theta, \quad \textit{and} \quad U'(0) = 1+\kappa, \\ &(U(z), U'(z)) \to (0,0) \quad \textit{as} \quad z \to \infty. \end{aligned} \tag{4.17}$$

(ii) *There are infinitely many $c \in (c_4, c_3)$ and $a(c) < 0$ and solutions U of (4.11)–(4.12) such that*

$$\begin{aligned} &U(z) = \theta e^{-(1-\kappa)z}\ \forall z > 0, \quad U(a(c)) = U(0) = \theta, \quad \textit{and} \quad U'(0) = \kappa - 1, \\ &(U(z), U'(z)) \to (0,0) \quad \textit{as} \quad z \to -\infty. \end{aligned} \tag{4.18}$$

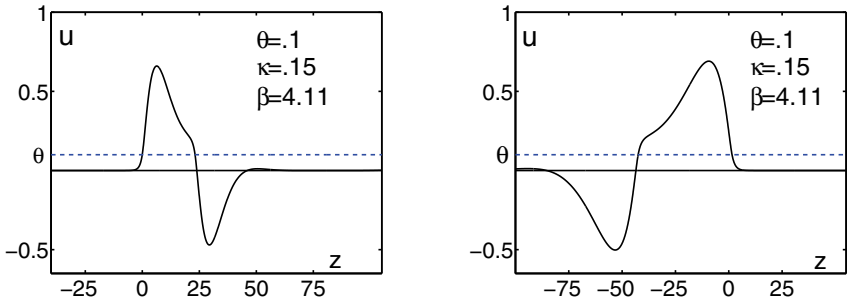

Figure 4. *1-pulse waves when* $\epsilon = \theta = .1$ *and* $\beta = \frac{1}{2\theta(1-\kappa^2)} - 1 \approx 4.11$ *(see Theorem 4.2). Left panel:* $c \approx 2.27$ *and* $a \approx 24$. *Right panel:* $c \approx -5.65$ *and* $a \approx -43$. *Clicking on the first panel displays the accompanying movie* (70988_01.mpg [1.4MB]).

Remarks. (i) The proof of Theorem 4.2 relies heavily on sine and cosine terms which arise due to $\mu^{\pm}$ being complex. Such terms are not present in the real eigenvalue case, and therefore we conjecture that Theorem 4.2 does not hold when $\mu^{\pm}$ are real.

(ii) The positive wave speed solutions described in Theorem 4.2 have monotone tails as $z \to -\infty$ and oscillatory tails as $z \to \infty$. By contrast, the speeds and amplitudes of the negative wave speed solutions are larger than those of the positive speed solutions (see Figure 4); they have oscillatory tails as $z \to -\infty$ and monotone tails as $z \to \infty$. The oscillatory tails are due to $\mu^{\pm}$ being complex.

(iii) To prove that the solutions in Theorem 4.2 are 1-pulse waves we must also prove that $z = 0$ and $z = a(c)$ are the *only* solutions of $U(z) = \theta$, and that $(U(z), U'(z)) \to (0,0)$ as $z \to \infty$. Because $\mu^{\pm}$ are complex, technical difficulties arise which make the verification of these properties a challenging problem which remains open.

Proof of Theorem 4.2. We prove part (i) for the case $c > 0$. The details for the case $c < 0$ are similar and are omitted for brevity. On the interval $(-\infty, 0)$ the system (4.11)–(4.12) reduces to

$$c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U = \frac{.5}{1+\kappa}\left(c(1+\kappa)+\epsilon\right)(1-e^{-(1+\kappa)a})e^{(1+\kappa)z} \quad \forall z \le 0. \tag{4.19}$$

The general solution of (4.19) is

$$\begin{aligned} U_3(z) &= k_1 e^{\alpha z}\cos(\gamma z) + k_2 e^{\alpha z}\sin(\gamma z) \\ &\quad + \tfrac{.5((1+\kappa)c+\epsilon)(1-e^{-(1+\kappa)a})}{(1+\kappa)((1+\kappa)^2c^2+(1+\kappa)(1+\epsilon)c+\epsilon(\beta+1))}e^{(1+\kappa)z}. \end{aligned} \tag{4.20}$$

We need to show that there are values $c \in (c_2, c_1)$ and $a > 0$ such that

$$U_3(z) < \theta \ \ \forall z \in (-\infty, 0), \quad U_3(-\infty) = U_3'(-\infty) = 0, \quad \text{and} \quad U_3(0) = \theta. \tag{4.21}$$

Recall from (2.7) that $\alpha = \mathrm{Re}(\mu^{\pm}) < 0$. Thus, to satisfy $U_3(-\infty) = U_3'(-\infty) = 0$ we conclude that $k_1 = k_2 = 0$, and therefore

$$U_3(z) = \frac{.5((1+\kappa)c+\epsilon)(1-e^{-(1+\kappa)a})}{(1+\kappa)((1+\kappa)^2c^2+(1+\kappa)(1+\epsilon)c+\epsilon(\beta+1))}e^{(1+\kappa)z}. \tag{4.22}$$

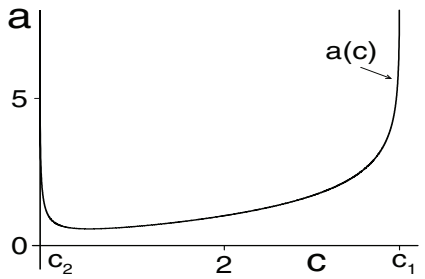

Figure 5. *Graph of $a(c)$ versus c when $(\epsilon,\theta,\kappa)=(.1,.1,.15)$ and $\beta=\frac{1}{2(1-\kappa^2)\theta}-1\approx 4.11$.*

Substituting the continuity requirement $U_3(0)=\theta$ into (4.22) gives

$$\frac{.5((1+\kappa)c+\epsilon)(1-e^{-(1+\kappa)a})}{(1+\kappa)((1+\kappa)^2c^2+(1+\kappa)(1+\epsilon)c+\epsilon(\beta+1))}=\theta. \tag{4.23}$$

Combining (4.22) and (4.23) gives $U_3(z)=\theta e^{(1+\kappa)z}\ \forall z\le 0$.

The interval $(0,a)$. On the interval $(0,a)$ the system (4.11)–(4.12) reduces to

$$c^2U''+c(1+\epsilon)U'+\epsilon(\beta+1)U=.5\left(c+\frac{\epsilon}{\kappa-1}\right)e^{(\kappa-1)z}-.5\left(c+\frac{\epsilon}{\kappa+1}\right)e^{(\kappa+1)(z-a)}+\frac{\epsilon}{1-\kappa^2}. \tag{4.24}$$

The general solution of (4.24) is

$$U_4(z)=m_1e^{\alpha z}\cos(\gamma z)+m_2e^{\alpha z}\sin(\gamma z)+P_4(z), \tag{4.25}$$

where α and γ are defined in (2.7), and P_4 is the particular solution

$$\begin{aligned}P_4(z)=&\tfrac{.5(c(1-\kappa)-\epsilon)e^{(\kappa-1)z}}{(1-\kappa)((1-\kappa)^2c^2-(1+\epsilon)(1-\kappa)c+\epsilon(\beta+1))}\\&-\tfrac{.5(\epsilon+c(1+\kappa))e^{(\kappa+1)(z-a)}}{(1+\kappa)((1+\kappa)^2c^2+(1+\epsilon)c(1+\kappa)+\epsilon(\beta+1))}+\tfrac{1}{(\beta+1)(1-\kappa^2)}.\end{aligned} \tag{4.26}$$

Continuity at $z=0$ requires that $(U_4(0),U_4'(0))=(U_3(0),U_3'(0))=(\theta,(1+\kappa)\theta)$. Combining this with (4.25) and (4.26) shows that the coefficients m_1 and m_2 in (4.25) are defined by

$$m_1=\theta-P_4(0)\quad\text{and}\quad m_2=\frac{1}{\gamma}\left(\theta(1+\kappa-\alpha)-P_4'(0)+\alpha P_4(0)\right). \tag{4.27}$$

Next, solve (4.23) for $e^{-(1+\kappa)a}$ and get

$$e^{-(1+\kappa)a(c)}=\frac{.5(\epsilon+c(1+\kappa))-\theta(1+\kappa)\left((1+\kappa)^2c^2+(1+\epsilon)c(1+\kappa)+\epsilon(\beta+1)\right)}{.5(\epsilon+c(1+\kappa))}. \tag{4.28}$$

It follows from (3.21) that the right side of (4.28) is zero at $c=c_1$ and $c=c_2$ and that (Figure 5)

$$a(c)>0\ \ \forall c\in(c_2,c_1)\quad\text{and}\quad\lim_{c\to c_2^+}a(c)=\lim_{c\to c_1^-}a(c)=\infty. \tag{4.29}$$

We will use (4.29) to help prove that there exist values $c \in (c_2, c_1)$ and $a = a(c) > 0$ such that

$$U_4(a(c)) = \theta. \tag{4.30}$$

Substituting (4.25) into (4.30) gives

$$m_1 e^{\alpha a(c)} \cos(\gamma a(c)) + m_2 e^{\alpha a(c)} \sin(\gamma a(c)) + P_4(a(c)) = \theta. \tag{4.31}$$

Thus, it remains to show that there are infinitely many $c \in (c_2, c_1)$ such that the function

$$g(c) = m_1 e^{\alpha a(c)} \cos(\gamma a(c)) + m_2 e^{\alpha a(c)} \sin(\gamma a(c)) + P_4(a(c)) - \theta \tag{4.32}$$

satisfies $g(c) = 0$. The first step is to write (4.28) as

$$\frac{.5(\epsilon + c(1+\kappa))}{(1+\kappa)^2 c^2 + (1+\epsilon)(1+\kappa)c + \epsilon(\beta+1)} = \frac{.5(\epsilon + c(1+\kappa))e^{-(1+\kappa)a}}{(1+\kappa)^2 c^2 + (1+\epsilon)(1+\kappa)c + \epsilon(\beta+1)} + \theta(1+\kappa). \tag{4.33}$$

Substituting (4.33) into (4.26) and using the hypothesis $\beta = \frac{1}{2(1-\kappa^2)\theta} - 1$, we obtain

$$\begin{aligned} P_4(a(c)) - \theta = {} & e^{-(1-\kappa)a(c)} \left(\tfrac{.5(c(1-\kappa)-\epsilon)}{(1-\kappa)(1-\kappa)^2 c^2 - (1+\epsilon)(1-\kappa)c + \epsilon(\beta+1)} \right) \\ & - e^{-(1+\kappa)a(c)} \left(\tfrac{.5(\epsilon + c(1+\kappa))}{(1+\kappa)(1+\kappa)^2 c^2 + (1+\epsilon)(1+\kappa)c + \epsilon(\beta+1)} \right). \end{aligned} \tag{4.34}$$

Next, substitute (4.34) into (4.32) and get

$$g(c) = e^{\alpha a(c)} g_1(c), \tag{4.35}$$

$$\begin{aligned} g_1 = {} & m_1 \cos(\gamma a(c)) + m_2 \sin(\gamma a(c)) + e^{-(1+\alpha-\kappa)a(c)} \left(\tfrac{.5(c(1-\kappa)-\epsilon)}{(1-\kappa)(1-\kappa)^2 c^2 - (1+\epsilon)(1-\kappa)c + \epsilon(\beta+1)} \right) \\ & - e^{-(1+\alpha+\kappa)a(c)} \left(\tfrac{.5(\epsilon + c(1+\kappa))}{(1+\kappa)(1+\kappa)^2 c^2 + (1+\epsilon)(1+\kappa)c + \epsilon(\beta+1)} \right). \end{aligned} \tag{4.36}$$

Because $e^{\alpha a(c)} > 0$, it suffices to show that $g_1(c)$ changes sign infinitely often on (c_2, c_1). To analyze $g_1(c)$ we need to determine the limiting behavior, as $c \to c_1^-$, of the terms on the right side of (4.36). For this we need the five basic estimates developed below.

(i) *The behavior of $e^{-(1+\alpha-\kappa)a(c)}$ and $e^{-(1+\alpha+\kappa)a(c)}$ as $c \to c_1^-$.* From (2.7) it follows that

$$\lim_{c \to c_1^-} (1 + \alpha - \kappa) = \frac{2c_1(1-\kappa) - 1 - \epsilon}{2c_1}. \tag{4.37}$$

It follows from (3.23), and the hypothesis $\beta = \frac{1}{2(1-\kappa^2)\theta} - 1$, that

$$c_1 = \frac{.5 - \theta(1+\kappa)(\epsilon+1) + \sqrt{(.5 - \theta(1+\kappa)(1+\epsilon))^2 - \frac{2\epsilon\theta\kappa(1+\kappa)}{1-\kappa}}}{2\theta(1+\kappa)^2}. \tag{4.38}$$

We substitute (4.38) into (4.37) and conclude from an algebraic manipulation, and the restriction $0 < \theta < \frac{1}{4(\epsilon+1)}$ given in (2.8), that

$$\lim_{(c,\kappa) \to (c_1^-, 0)} (1 + \alpha - \kappa) = \frac{1 - 3\theta(1+\epsilon)}{1 - 2\theta(1+\epsilon)} > 0. \tag{4.39}$$

From (4.39) and continuity it follows that if $\kappa > 0$ is small, then

$$\lim_{c\to c_1^-}(1+\alpha-\kappa) > 0. \tag{4.40}$$

Thus, if $\kappa > 0$ is small, then (4.29) and (4.40) imply that

$$\lim_{c\to c_1^-} e^{-(1+\alpha-\kappa)a(c)} = \lim_{c\to c_1^-} e^{-(1+\alpha+\kappa)a(c)} = 0. \tag{4.41}$$

(ii) *The behavior of $\gamma a(c)$ as $c \to c_1^-$.* Recall that $\beta = \frac{1}{2(1-\kappa^2)\theta} - 1$. This and (2.7)–(2.8) imply that

$$\gamma = \frac{(\epsilon+1)}{2c\sqrt{(1-\kappa^2)\theta}}\sqrt{\frac{2\epsilon}{(\epsilon+1)^2} - (1-\kappa^2)\theta} > 0 \quad \forall c \in [c_2, c_1] \text{ and } \forall \kappa \in [0,1). \tag{4.42}$$

From this and (4.29) we conclude that $\gamma a(c)$ is continuous in c and that

$$\gamma a(c) > 0 \ \forall c \in (c_2, c_1) \quad \text{and} \quad \lim_{c\to c_1^-} \gamma a(c) = \infty \ \forall \kappa \in [0,1). \tag{4.43}$$

(iii) *The behavior of $(1-\kappa)^2c^2 - (1+\epsilon)(1-\kappa)c + \epsilon(\beta+1)$ as $c \to c_1^-$.* We show that

$$\lim_{c\to c_1^-}\left((1-\kappa)^2c^2 - (1+\epsilon)(1-\kappa)c + \epsilon(\beta+1)\right) > 0 \quad \forall \kappa \in [0,1). \tag{4.44}$$

It follows from (2.8) that the discriminant of the limiting term

$$(1-\kappa)^2c_1^2 - (1+\epsilon)(1-\kappa)c_1 + \epsilon(\beta+1) \tag{4.45}$$

satisfies

$$\text{discriminant} = (1-\kappa)^2\left((1+\epsilon)^2 - 4\epsilon(\beta+1)\right) < 0 \quad \forall \kappa \in [0,1),$$

since $\epsilon > 0$ and $\beta > \frac{(\epsilon-1)^2}{4\epsilon}$. This and continuity imply that (4.44) holds.

(iv) *The behavior of m_1 as $c \to c_1^-$.* We show that m_1 is bounded away from 0 as $c \to c_1^-$ when $\kappa > 0$ is small. Since $a(c) \to \infty$ as $c \to c_1^-$, it follows from (4.26) and the definition of m_1 given in (4.27) that m_1 is continuous in κ and c, and

$$\lim_{c\to c_2^-} m_1 = \theta - \frac{.5(c_1(1-\kappa)-\epsilon)}{(1-\kappa)\left((1-\kappa)^2c_1^2 - (1+\epsilon)(1-\kappa)c_1 + \epsilon(\beta+1)\right)} - \frac{1}{(\beta+1)(1-\kappa^2)}. \tag{4.46}$$

We solve (3.21) for c^2, substitute the resultant expression into (4.46), and obtain the limiting value

$$\lim_{(\kappa,c)\to(0,c_1^-)} m_1 = \frac{\theta(\epsilon - 2\theta(1+\epsilon)c_1)}{(.5 - 2\theta(1+\epsilon))c_1 + .5\epsilon} - \frac{1}{\beta+1}, \tag{4.47}$$

where, by (3.23), c_1 has the limiting value

$$c_1 = \frac{.5 - \theta(1+\epsilon)}{\theta} > 0. \tag{4.48}$$

Substituting (4.48) into the numerator of the first term in (4.47) gives the limiting value

$$\lim_{(\kappa,c)\to(0,c_1^-)} m_1 = \frac{\theta(-1+2\theta(1+\epsilon)^2)}{(.5-2\theta(1+\epsilon))c_1+.5\epsilon} - \frac{1}{\beta+1}. \tag{4.49}$$

Recall from (2.8) that $0<\epsilon<1$ and $0<\theta<\frac{1}{4(\epsilon+1)}$. This implies that $-1+2\theta(1+\epsilon)^2 < .5(\epsilon-1)<0$ and $.5-2\theta(1+\epsilon)>0$. Thus, the first term in (4.49) is negative, and therefore

$$\lim_{(\kappa,c)\to(0,c_1^-)} m_1 < -\frac{1}{\beta+1} = -2\theta. \tag{4.50}$$

Finally, it follows from (4.50) and continuity that if $\kappa>0$ is small, then

$$\lim_{c\to c_1^-} m_1 < -2\theta. \tag{4.51}$$

(v) *The behavior of $g_1(c)$.* We now use the estimates given above to determine the behavior of $g_1(c)$ when $\kappa>0$ is small. It follows from (4.43) that, for small $\kappa>0$, there is an increasing sequence $\{c_n\}$ such that

$$c_n \to c_2^- \text{ as } n\to\infty \quad \text{and} \quad \gamma a(c_n) = 2n\pi \text{ for large } n. \tag{4.52}$$

Let $c=c_n$ in (4.36). Then $\sin(\gamma a(c_n))=0$, $\cos(\gamma a(c_n))=1$, and (4.36) reduces to

$$\begin{aligned} g_1(c_n) = m_1 &+ e^{-(1+\alpha-\kappa)a(c_n)}\left(\tfrac{.5(c_n(1-\kappa)-\epsilon)}{(1-\kappa)(1-\kappa)^2c_n^2-(1+\epsilon)(1-\kappa)c_n+\epsilon(\beta+1)}\right) \\ &- e^{-(1+\alpha+\kappa)a(c_n)}\left(\tfrac{.5(\epsilon+c_n(1+\kappa))}{(1+\kappa)(1+\kappa)^2c_n^2+(1+\epsilon)(1+\kappa)c_n+\epsilon(\beta+1)}\right). \end{aligned} \tag{4.53}$$

Combining the estimates in (4.41), (4.44), (4.51), and (4.52), we conclude from (4.53) that

$$g_1(c_n) < -\theta \text{ for } n >> 1. \tag{4.54}$$

Likewise, for small $\kappa>0$, there is an increasing sequence $\{c^n\}$ such that

$$c^n \to c_2^- \text{ as } n\to\infty \quad \text{and} \quad \gamma a(c^n) = (2n+1)\pi \text{ for } n >> 1. \tag{4.55}$$

Let $c=c^n$ in (4.36). Then $\sin(\gamma a(c^n))=0$ and $\cos(\gamma a(c^n))=-1$. From this, (4.41), (4.44), (4.51), and (4.55) it follows that

$$g_1(c^n) > \theta \text{ for large } n >> 1. \tag{4.56}$$

It follows from (4.54) and (4.56) and continuity that $g_1(c)$, and therefore $g(c)$, have infinitely many zeros on (c_1,c_2) when $\kappa>0$ is small. Thus, we have proved that there are infinitely many $c\in(c_1,c_2)$ and $a(c)>0$, and corresponding solutions U of (2.3), such that

$$U(z) = \begin{cases} \theta e^{(1+\kappa)z} & \forall z\le 0, \\ U_4(z), & 0<z<a(c), \end{cases} \tag{4.57}$$

where $U_4(z)$ is defined in (4.25)–(4.26) and satisfies

$$U_4(0) = U_4(a(c)) = \theta \quad \text{and} \quad U_4'(0) = 1 + \kappa. \tag{4.58}$$

This completes the first part of the proof of (4.17). It remains to show that the solution satisfies $(U(z), U'(z)) \to (0,0)$ as $z \to \infty$. This is addressed below.

The interval (a, ∞). On the interval (a, ∞) the system (4.11)–(4.12) reduces to

$$c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U = \frac{.5}{1-\kappa}(\epsilon - c(1-\kappa))(e^{(1-\kappa)a} - 1)e^{-(1-\kappa)z} \quad \forall z > a. \tag{4.59}$$

The general solution of (4.59) is

$$U_5(z) = q_1 e^{\alpha z}\cos(\gamma z) + q_2 e^{\alpha z}\sin(\gamma z) + P_5(z), \tag{4.60}$$

where α and γ are defined in (2.7), and P_5 is the particular solution

$$P_5(z) = \tfrac{(\epsilon - c(1-\kappa))(e^{(1-\kappa)a}-1)e^{-(1-\kappa)z}}{(1-\kappa)((1-\kappa)^2c^2 - (1+\epsilon)(1-\kappa)c + \epsilon(\beta+1))}. \tag{4.61}$$

The coefficients q_1 and q_2 in (4.60) are uniquely defined by the continuity conditions

$$U_5(a(c)) = U_4(a(c)) = \theta \quad \text{and} \quad U_5'(a(c)) = U_4'(a(c)). \tag{4.62}$$

Finally, it follows from (4.60)–(4.61) and the fact that $\alpha < 0$ that

$$(U_5(z), U_5'(z)) \to (0,0) \text{ as } z \to \infty. \tag{4.63}$$

This completes the proof of part (i) of Theorem 4.2.

C. *The effects of changing threshold and the identification of* θ^*. To understand how solutions change as θ varies we proceed as in section 3 and compare the behavior of solutions when $\theta = .1$ and $\theta = .2$. For these values our numerical experiments suggest that all conditions for a 1-pulse wave are satisfied along a branch Λ_1 of solutions when $c > 0$, and also along a second branch Λ_2 when $c < 0$. Solutions along Λ_1 and Λ_2 are stable and propagate in opposite directions with different speeds and amplitudes. Figure 6 (top row) illustrates these branches when $(\epsilon, \kappa) = (.1, .15)$.

(i) *The case* $\theta = .1$. Figure 6 (second row, first panel) shows two solutions which coexist at the right endpoints of Λ_1 and Λ_2, where $\beta \approx 12.75$.

(ii) *The case* $\theta = .2$. The middle panel of the second row shows two solutions which coexist when $\beta = 3.35$. The right endpoint of Λ_1 occurs at $\beta \approx 3.5$, where the positive wave speed solution ceases to exist. When $\beta > 3.5$ the negative wave speed solution continues to exist until $\beta \approx 7.5$, where the branch Λ_2 comes to an end. The third panel illustrates the solution at $\beta = 7.5$.

Our experiments lead to the following conjectures whose proofs remain open problems:

- At fixed $(\epsilon, \kappa, \beta)$ the amplitudes and speeds of 1-pulse solutions *decrease* as θ *increases*.
- At fixed (ϵ, κ) the right endpoint of Λ_1 decreases more rapidly than the right endpoint of Λ_2 as θ increases. Thus, there is an interval I of β values such that if $\beta \in$ I is fixed, then a critical value $\theta^* = \theta^*(\epsilon, \kappa, \beta)$ exists such that there are two stable solutions when $0 < \theta \leq \theta^*$ and only one solution when $\theta > \theta^*$.

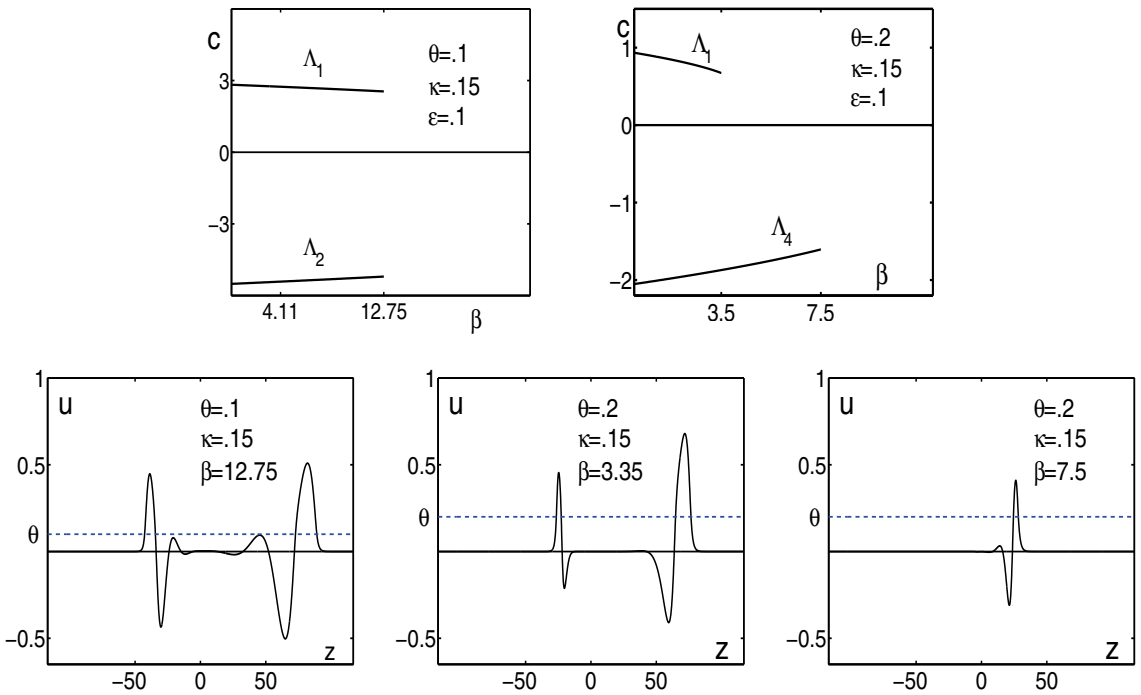

Figure 6. *First row: Bifurcation curves Λ_1 and Λ_2 in the (β, c) plane for families of 1-pulse waves when $(\epsilon, \kappa, \theta) = (.1, .15, .1)$ (left) and $(\epsilon, \kappa, \theta) = (.1, .15, .2)$ (right). Second row: Solutions at specific points along Λ_1 and Λ_2. Please click on each figure in the second row to display the accompanying movie* (70988_02.mpg [2.64MB], 70988_03.mpg [2.1MB], and 70988_04.mpg [1.41MB]).

Experimental implications. By controlling the electric field in disinhibited slices of mammalian cortex, Richardson, Schiff, and Gluckman [48] can determine properties of 1-pulse waves for different values of threshold. Our results show that, when threshold has a low value, an appropriate stimulus causes waves to form which propagate in opposite directions with different amplitudes and speeds. The methods in [48] might allow one to determine if similar properties hold for low electric field values and also whether there is a critical value of the field where one of the waves disappears. This, together with an analysis of the speeds and amplitudes of waves as a function of electric field strength, could provide a plausible method to obtain a measure of the asymmetry in the connectivity between neuronal groups.

5. 2-pulse waves. To understand how 2-pulse waves form when $\beta > \beta_*$, we analyze the linearization of (2.3) around the rest state $U = 0$:

$$c^2 H'' + c(1+\epsilon)H' + \epsilon(\beta+1)H = 0. \tag{5.1}$$

When $\mu^{\pm}$ are complex the general solution of (5.1) is

$$H(z) = b_1 e^{\alpha z} \sin(\gamma z) + b_2 e^{\alpha z} \cos(\gamma z), \tag{5.2}$$

where

$$\alpha = \mathrm{Re}(\mu^{\pm}) = \frac{-(\epsilon+1)}{2c} < 0 \quad \text{and} \quad \gamma = \mathrm{Im}(\mu^{\pm}) = \frac{\sqrt{4\epsilon\beta - (\epsilon-1)^2}}{2c} > 0. \tag{5.3}$$

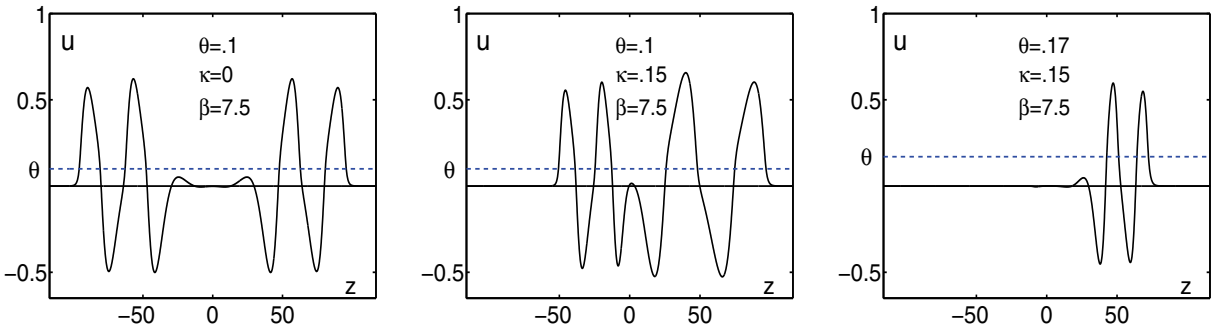

Figure 7. *2-pulse waves when* $\beta = 7.5$ *and* $(\epsilon, \theta, \kappa) = (.1, .1, 0)$ *(left),* $(\epsilon, \theta, \kappa) = (.1, .1, .15)$ *(middle), and* $(\epsilon, \theta, \kappa) = (.1, .17, .15)$ *(right). In the right panel the wave propagates only to the right since* $\theta = .17 > \theta^*$ *when* $(\epsilon, \kappa) = (.1, .15)$. *Click on each panel to display the accompanying movie* (70988_05.mpg [3.51MB], 70988_06.mpg [2.94MB], and 70988_07.mpg [2.73MB]).

It follows from (5.2)–(5.3) that the frequency of oscillation of $H(z)$ increases as β increases from β_*. In turn, this causes solutions of (1.1) to become more oscillatory as β increases, making it increasingly likely that an initial perturbation will evolve into a 2-pulse traveling wave. It follows from (2.3) that a 2-pulse traveling wave satisfies

$$\begin{aligned} c^2U'' + c(1+\epsilon)U' + \epsilon(\beta+1)U &= c\tfrac{d}{dz}\textstyle\int_0^a w(z-z')dz' + \epsilon\int_0^a w(z-z')dz' \\ &\quad + c\tfrac{d}{dz}\textstyle\int_b^d w(z-z')dz' + \epsilon\int_b^d w(z-z')dz', \end{aligned} \tag{5.4}$$

where

$$\begin{cases} U(0) = U(a) = U(b) = U(d) = \theta \text{ for some } d > b > a > 0, \\ U(z) \neq \theta \text{ if } z \notin \{0, a, b, d\}, \\ (U(z), U'(z)) \to (0,0) \text{ as } |z| \to \infty. \end{cases} \tag{5.5}$$

In Figure 7 we consider the representative parameter set $\epsilon = .1$ and $\beta = 7.5$ and illustrate three different types of 2-pulse waves. For this we solve the initial value problem

$$\begin{aligned} &u_t(x,t) = -u - v + \tfrac{1}{2}\textstyle\int_{-120}^{120} e^{-|x-x'|+\kappa(x-x')}H(u(x',t)-\theta)dx', \\ &v_t(x,t) = \epsilon(\beta u - v), \\ &u(x,0) = .6e^{-x^2}, \quad \text{and} \quad v(x,0) = 0 \quad \forall x \in [-120, 120]. \end{aligned} \tag{5.6}$$

In the left panel we let $\theta = .1$ and set $\kappa = 0$ so that w is symmetric. The initial stimulus splits into two 2-pulse waves which propagate outward from $x = 0$. The wave propagating to the left has the same speed and shape as the wave propagating to the right. In the second panel we keep $\theta = .1$ and set $\kappa = .15$ so that w is asymmetric. The initial stimulus again splits into two waves. The wave traveling to the left is slower than the one traveling to the right, and its shape is also different. In the third panel we keep $\kappa = .15$ and raise θ to $\theta = .17$. Once again, the initial perturbation splits into two waves which begin to propagate outward from the $x = 0$. However, because $\theta = .17 > \theta^*$, the "weaker" wave propagating to the left cannot be sustained, and it quickly shrinks and collapses onto the steady state $(u, v) = (0, 0)$. The

wave propagating to the right persists indefinitely. We note that (i) other choices for initial conditions give the same results, and (ii) similar properties were observed for 1-pulse waves (see Figures 4 and 6).

For general $N \geq 2$ a simple extension of (5.4)–(5.5) gives the criteria satisfied by N-pulse traveling waves. In particular, it is necessary to prove that the solution intersects $U = \theta$ exactly 2N times. However, as with 1-pulse waves, the nonlocal terms in the equation lead to technical difficulties in proving this key property, and therefore existence proofs remain a challenging open problem. Finally, we note that our numerical study suggests that the traveling waves in Figure 7 are all stable as solutions of (1.1). It would be of interest to develop Evans function methods to prove this conjecture.

6. Synchronous oscillations. In this section we investigate the formation and spread of uniformly synchronous oscillations when β increases past a second critical value $\beta^* > \beta_*$ where (1.1) becomes bistable. In particular, we show how β^* arises and study the following when $\beta \geq \beta^*$:

A. Bistability: The coexistence of bulk oscillations and a stable rest state.
B. Synchrony: The formation of uniformly synchronous oscillations which spread outward from a point of stimulus.
C. The coexistence of synchronous oscillations and 1-pulse waves.
D. How synchronization in one region can trigger synchronization in another.

A. *Bistability: The coexistence of bulk oscillations and a stable rest state.* Our goal here is to show that there is a critical value β^* where spatially independent bulk oscillations come into existence. Such solutions depend only on the variable t and satisfy

$$\begin{aligned} \tfrac{du}{dt} &= -u - v + f(u-\theta)\textstyle\int_{-\infty}^{\infty} w(\eta)d\eta, \\ \tfrac{dv}{dt} &= \epsilon(\beta u - v). \end{aligned} \tag{6.1}$$

In [58] we considered symmetric couplings and showed that periodic solutions of (6.1) come into existence at a critical β^*. Figure 8 illustrates how this happens for the parameter set $(\epsilon, \theta, \kappa) = (.1, .1, 0)$. In the first row we let $\beta = 12.6$ and see that the solution with initial condition $(u(0), v(0)) = (.4, 0)$ returns to the rest state $(u, v) = (0, 0)$ as $t \to \infty$. The same behavior occurs when $0 < \beta < 12.6$, and for all other initial conditions. Thus, the rest state is globally stable when $0 < \beta \leq 12.6$. At $\beta = \beta^* \approx 12.61$ a periodic solution comes into existence (second row, right panel). Its trajectory forms a closed loop in the (u, v) plane and intersects the $u' = 0$ nullcline at the "threshold point" $(u, v) = (\theta, -\theta)$ (left panel). This property causes the periodic solution to be semistable. That is, solutions of (6.1) whose initial conditions lie outside its trajectory approach a translate of the periodic solution as $t \to \infty$, and solutions with initial conditions inside the trajectory satisfy $(u, v) \to (0, 0)$ as $t \to \infty$. As β increases from β^* a family of stable periodic orbits bifurcates from the periodic solution at β^*. The third row shows such a solution at $\beta = 17$. Our study shows that this mechanism also occurs when $\kappa \neq 0$, and over a wide range of θ, which includes the critical value θ^*. For small $\theta > 0$ a phase plane approach can be used to prove the existence of periodic solutions. General proofs remain open.

B. *Synchrony.* When $\beta \geq \beta^*$ our numerical experiments on the full system (1.1) show that uniformly synchronous oscillations can form and spread outward from a point of stimulus. In

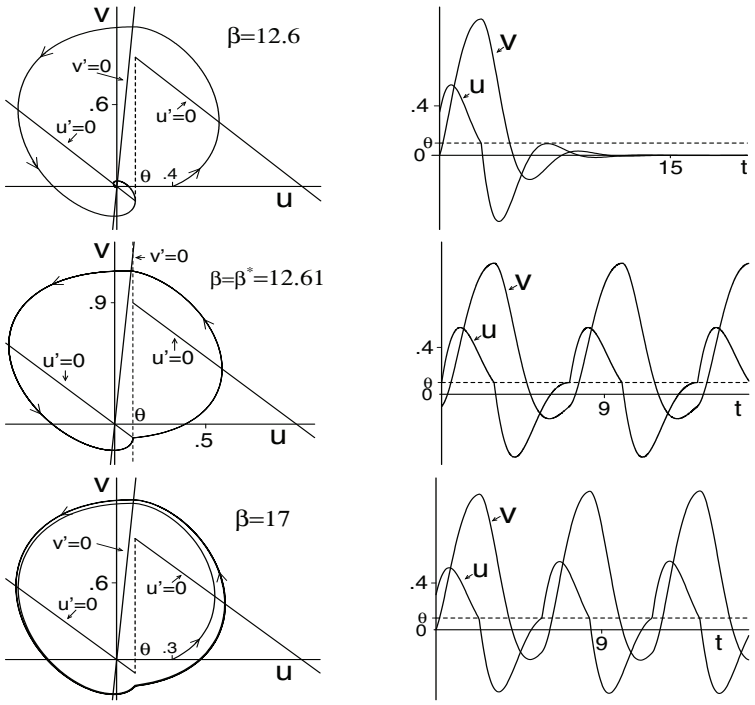

Figure 8. *Bulk oscillations: Solutions of* (6.1) *graphed in the* (u, v) *phase plane (left column), and* u *and* v *as functions of* t *(right column). Parameter values:* $(\epsilon, \theta, \kappa) = (.1, .1, 0)$.

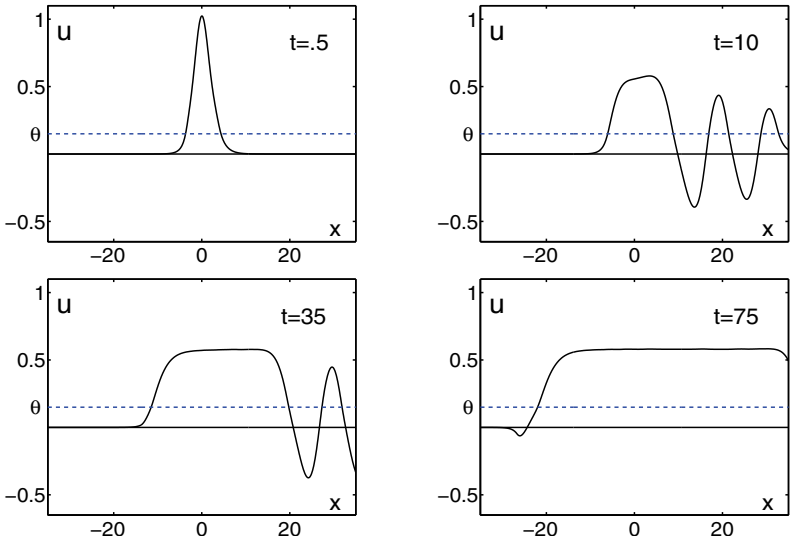

Figure 9. *The formation and spread of uniformly synchronous oscillations in response to the initial stimulus* $(u(x,0), v(x,0)) = (.6e^{-x^2}, 0)$ *when* $(\epsilon, \theta, \kappa, \beta) = (.1, .15, .15, 17)$. *Clicking on the first image displays the accompanying movie* (70988_08.mpg [3.17MB]).

Figure 9 we set $(\beta, \epsilon, \theta, \kappa) = (17, .1, .15, .15)$ and consider the initial condition

$$(u(x,0),v(x,0)) = (.6e^{-x^2},0), \quad x \in \mathrm{R}. \tag{6.2}$$

The stimulus (6.2) is sufficiently strong so that the bulk oscillations affect the solution and cause it to begin oscillating at the center of the stimulus. The oscillations are spatially uniform and in phase over an ever expanding "region of synchrony." Our study suggests the following:

(i) During each oscillation the region of synchrony expands outward by an amount proportional to the speed of a 1-pulse wave.

(ii) During each oscillation the expanding region sheds a traveling wave. Since $\theta > \theta^*$ for our choice of parameters, these waves can propagate only to the right.

Because of the asymmetry in w, the expansion of the region of synchrony is most rapid in the direction to the right of the point of initial stimulus and less rapid to the left. Eventually, however, the solution oscillates uniformly over the entire spatial region, and with the same period as the bulk oscillation. There are similarities between the theoretical spread of a region of synchrony and clinical observations of epileptiform events. Milton and Jung [40, pp. 346–347] point out that "during a seizure there is a propagation of synchrony over the cortical surface" (see Figures 5.7 and 5.8 in [40]) and that optical imaging shows wave-like properties of epileptic propagation. In electocorticographic studies, Towel et al. [57] show how spatially uniform synchronous oscillations develop in a region behind the leading edge of a seizure as it propagates across the cortex (see Figures 6.2, 6.5, and 6.11 in [57]). Milton [39, pp. 18–19] notes that a seizure spreads relatively slowly when compared with spike propagation rates. Our numerical study indicates that the region of synchrony also spreads slowly, at a rate which is only a fraction of the speed of a traveling wave. An important challenge for future research is to extend the methods in [58] and derive a theoretical formula for the rate of expansion which takes into account asymmetric couplings as well as variations in the threshold θ.

C. *The coexistence of synchronous oscillations and 1-pulse waves.* Wright and Sergejew [60] have demonstated the presence of traveling waves in EEG studies of seizure propagation. In [58] we found that a similar phenomenon occurs theoretically; i.e., 1-pulse traveling waves can form in the same parameter regime as synchronous oscillations when $\kappa = 0$ and $\theta > 0$ is small. Here we examine the robustness of this property when $\kappa \neq 0$ and for larger values of θ. For this we consider the representative parameter set $(\beta, \epsilon, \theta, \kappa) = (17, .1, .15, .15)$. At these values the system is bistable, and synchronous oscillations form and spread outward in response to a sufficiently strong initial stimulus. However, synchrony is not always the outcome. For example, Figure 10 illustrates how the solution with the smaller amplitude initial perturbation

$$(u(x,0),v(x,0)) = (.18e^{-x^2},0), \quad x \in \mathrm{R}, \tag{6.3}$$

evolves into a 1-pulse wave. It propagates only to the right since $\kappa = .15$ and $\theta = .15 > \theta^*$. Our study suggests that synchronous oscillations and stable 1-pulse waves coexist for a broad range of parameters. Proofs remain an open problem.

D. *How synchronization in one region can trigger synchronization in another.* We investigate how synchronous oscillations in one region can spread and initiate synchronization in distant regions. This aspect of our study is motivated by two diverse settings.

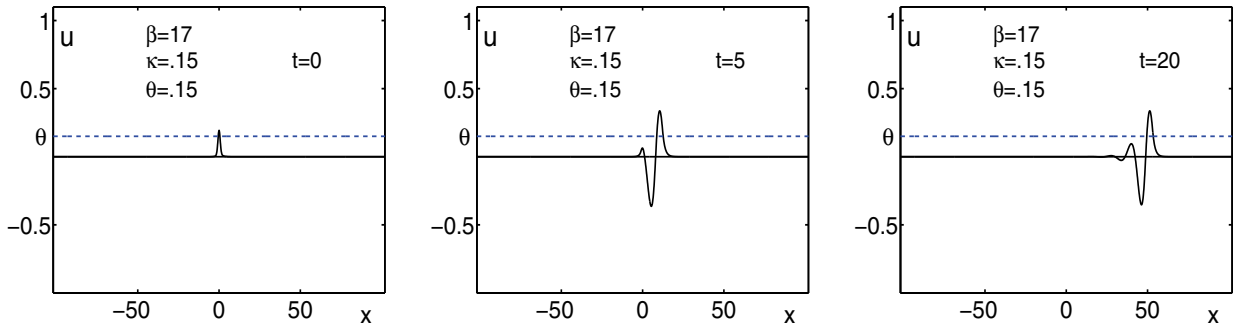

Figure 10. *A small amplitude stimulus* $(u(x,0),v(x,0)) = (.18e^{-x^2},0)$ *evolves into a* 1*-pulse wave when* $(\beta,\epsilon,\theta,\kappa) = (17,.1,.15,.15)$. *Its speed* $c \approx |c_4| = .257$ *is computed from* (3.43). *Clicking on the first panel displays the accompanying movie* (70988_09.mpg [1.73MB]).

(i) In section 1 we described recent experiment results which show that exposure to nicotine reduces the threshold of excitation in thalamocortical mouse neurons and that this dramatically increases their firing rates [35, 54]. It is suggested that in the brains of schizophrenics, the poor communication between thalamus and cortex might be improved by such lowering of threshold.

(ii) Chkhenkeli and Milton [8] describe how seizures in one region of the brain can trigger seizure onset in another. In particular, they give evidence which shows how rhythmic oscillations in the amygdala can trigger a seizure in the hippocampus (see Figure 3.4 in [8]). They also show how a seizure which starts in the hippocampus does not necessarily spread to the amygdala (see Figure 3.4 in [8]).

Our goal here is to understand how similar phenomena occur in our model when $\kappa \neq 0$ and the threshold θ varies. In particular, we find that when θ increases past the critical value θ^*, synchronization in one region can trigger the onset of synchronization in another, but the reverse is not true. To see how this happens we let β vary as a function of x and define

$$\beta(x) = \begin{cases} 17 & \forall x \in [-100,-35), \\ 10 & \forall x \in [-35,35), \\ 17 & \forall x \in [35,100]. \end{cases} \tag{6.4}$$

As in B and C above, we set $(\epsilon,\theta,\kappa) = (.1,.15,.15)$. Since $\beta = 17$ in $[-100,35)$ and $[35,100]$ the results of part B show that spatially uniform synchronous oscillations can develop in these intervals. However, since $\beta = 10 < \beta^*$ when $x \in [-35,35)$, synchronization cannot occur in this interval. Thus, the interval $[-35,35)$ forms a "buffer" region separating the two outer intervals where synchronization can occur. Furthermore, $\theta > \theta^*$ for our choice of parameters; hence waves can propagate only to the right in any of the three subintervals. To understand the behavior of this "unidirectional neuronal circuit," we performed three simple experiments.

I. In the first row of Figure 11 a small initial stimulus centered at $x = -50$ evolves into a 1-pulse wave propagating to the right (left panel). When the wave enters the interval $[-35,35)$ its amplitude and speed increase since β has the lower value $\beta = 10$ (middle panel). As the wave crosses into the interval $[35,100]$ it is not sufficient to trigger synchronization. Instead, its amplitude and speed *decrease* and the wave passes through the interval $[35,100]$ as time t

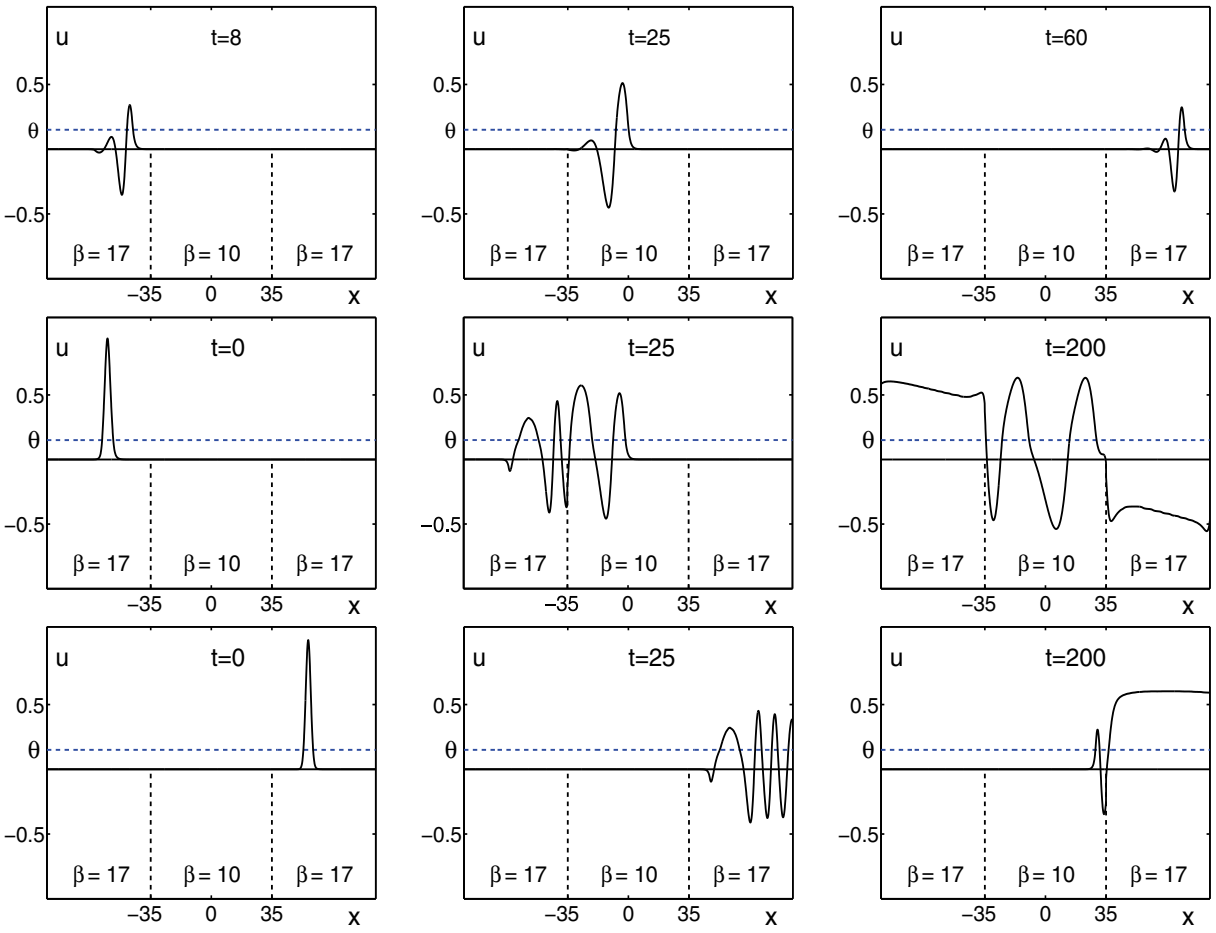

Figure 11. *First row: A small amplitude stimulus* $(u(x,0), v(x,0)) = (.18e^{-(x+50)^2}, 0)$ *evolves into a* 1*-pulse wave. The wave propagates through the entire circuit without triggering any part of it to undergo synchronization. Parameters are* $(\epsilon, \theta, \kappa) = (.1, .15, .15)$. *Second row: A larger amplitude stimulus* $(u(x,0), v(x,0)) = (e^{-(x+50)^2}, 0)$ *triggers synchronization in the interval* $[-100, -35)$. *The train of waves emitted by the synchronizing region propagates through the circuit and initiates synchronization in the interval* $[35, 100]$. *Third row: A stimulus* $(u(x,0), v(x,0)) = (e^{-(x-50)^2}, 0)$ *triggers synchronization in the interval* $[35, 100]$. *Since waves cannot propagate to the left, there can be no initiation of synchronization in the left end interval* $[-100, -35)$. *Click on the first figure in each row to display the accompanying movie* (70988_10.mpg [1.64MB], 70988_11.mpg [16.1MB], and 70988_12.mpg [4.02MB]).

increases (right panel). Thus, a small amplitude stimulus centered in the interval $[-100, -35)$ evolves into a 1-pulse wave which propagates through the entire circuit without triggering synchronization.

II. In the second row a stimulus centered at $x = -50$ (left panel) is sufficiently strong to trigger the formation and spread of synchronous oscillations in the interval $[-100, -35)$. During each cycle the region of synchrony expands by a small amount and a wave is emitted. Thus, a train of waves is created. These waves propagate to the right and enter $[-35, 35)$, where their amplitudes and speeds increase (middle panel). As the waves pass the point

$x = 35$ they are sufficient to initiate synchronization in the interval $[35, 100]$ (right panel). Thus, synchronization in the region $[-100, -35)$ causes the formation of a train of waves which eventually trigger synchronization in the region $[35, 100]$.

Remark. We have found that at least three waves must pass the point $x = 35$ in order to initiate synchronization in the region $[35, 100]$. To test this we found that the initial stimulus $(u(x, 0), v(x, 0)) = (10e^{-(x+20)^2}, 0)$ evolves into a 2-pulse wave which propagates to the right and passes right on through the interval $[35, 100]$ without initiating synchronization.

III. In the third row we test whether synchronous oscillations in the right end interval $[35, 100]$ can ultimately trigger synchronous oscillations in the left end interval $[-100, 35)$. An initial stimulus centered at $x = 50$ (left panel) initiates synchronous oscillations which spread uniformly over the entire interval $[35, 100]$ (second and third panels). However, our choice of parameters does not allow for left propagating waves; hence there is no initiation of synchronous oscillations in $[-100, -35)$ where the solution remains in the rest state $u = v = 0$.

Remarks. The results described above in I–III still hold when β has different values in the outer intervals $[-100, 35)$ and $[35, 100]$. In this setting, when synchronous oscillations are initiated in these intervals, their frequencies do not necessarily entrain. Analytical proofs of the numerical experiments described in parts A–D remain a challenging open problem.

7. Conclusions. In this paper we analyzed the dynamic behavior of a system of integro-differential equations that models the activity of excitatory neurons on large-scale, spatially extended domains. The independent variables represent the activity level of a population of excitatory neurons with long range connections (u) and recovery (v). We considered positive, asymmetric coupling functions (w) and a Heaviside firing rate (f).

There is a critical value of the parameter β ($\beta_* > 0$) that appears in the equation for v, at which the eigenvalues $\mu^{\pm}$ of the linearization of the system around the rest state $(u, v) = (0, 0)$ change from real to complex. If $0 < \beta \leq \beta_*$, then $\mu^{\pm}$ are real and both wave fronts and 1-pulse traveling waves can exist. In [58] we explained why multipulse waves are not expected in the real eigenvalue case. By contrast, when $\beta > \beta_*$ and $\mu^{\pm}$ are complex, the range of behavior is much richer. For example, our analysis provides evidence for the coexistence of at least two distinct families of stable wave fronts. Because w is asymmetric, these solutions propagate in opposite directions with different speeds and shapes. We have also found a range of $\beta > \beta_*$ where two families of 1-pulse traveling wave solutions exist (Theorem 4.2). Each family consists of infinitely many coexisting solutions, and solutions in the two families propagate in opposite directions with different speeds and shapes. In addition, we study the effects of variations of threshold θ on the dynamics of the system. As θ increases, the speeds and amplitudes of the waves in each family decrease until a critical value $\theta^* > 0$ is reached where solutions in the first family disappear. That is, left propagating 1-pulse waves cease to exist when $\theta > \theta^*$. In addition there is a range $\theta > \theta^*$ where 2-pulse waves can propagate only in one direction. This phenomenon does not occur when the coupling is a symmetric function. To our knowledge this is the first description of such unidirectional wave propagation in this class of nonlocal model.

There is a a second critical value $\beta^* > \beta_*$ where (1.1) becomes bistable and a family of spatially independent bulk oscillations comes into existence. These solutions influence the global dynamics of (1.1). For example, when $\beta \geq \beta^*$ a strong initial stimulus evolves into uniformly synchronous oscillations which spread outward from the point of stimulus. However,

a weak stimulus does not trigger synchronization and merely evolves into a 1-pulse traveling wave. We also study how variations in θ affect the spread of synchrony. In particular, we let $\kappa > 0$ be fixed and allow $\beta > \beta^*$ to be a function of the spatial coordinate x. We then raise θ to a value above the critical value θ^* so that waves propagate only to the right. In the resulting unidirectional circuit we show how synchronization in one region can trigger synchronization in a second, distant region. However, when synchronization is triggered in the second region, it cannot spread to the first region and the first region remains at rest.

In all cases formidable technical difficulties preclude the completion of the final step of existence proofs. It remains an open problem to extend our methods so that existence proofs can be completed for a wider range of parameters, and also for more general coupling and firing rate functions.

Our numerical experiments were performed when the firing rate is the Heaviside function. To test the robustness of our results we have considered more general, sigmoidal-shaped firing rates of the form

$$f(u) = \frac{1}{1 + Ke^{-r(u-\theta)}}, \quad K > 0,\ r > 0, \tag{7.1}$$

and

$$f(u) = Ke^{-\frac{r}{(u-\theta)^2}} H(u-\theta), \quad K > 0,\ r > 0. \tag{7.2}$$

With f given by (7.1) or (7.2), our numerical results continue to hold when M is of moderate size and R is large (e.g., $K \approx 1$ and $R \geq 50$). It remains an open problem to determine the maximal range of parameters, firing rate, and coupling functions over which the numerical results are valid.

Our theoretical results might have important implications for experimental and clinical neurophysiology. In particular, our finding that the dynamics of (1.1) undergo qualitative transitions when $\mu^{\pm}$ become complex, or θ exceeds θ^*, offers a plausible explanation of trailing-end instabilities and wave speed variations observed in cortical experiments [35, 45, 46]. Further explanation of observed variability in cortical waves might be provided by our findings that the asymmetry in w leads to the coexistence of entire families of traveling waves which propagate in opposite directions with different shapes and speeds. The unpredictable variation in trailing ends and wave speeds could be caused by solutions switching from one member of the family to another. A possible biophysical mechanism of such switching may involve a variable neurohormonal concentration affecting neuronal recovery and strength of intercellular connections [31].

Our observation that bifurcations of the system behavior occur at the critical values $\beta = \beta_*$ or $\theta = \theta^*$ also has important practical correlates. It predicts that by pushing the system above or below one of these values one can qualitatively change the system behavior and obtain a broad range of dynamical phenomena. One experimental example of such macrobehavior is an evoked response, which might persist long after the stimulus [46]. Understanding the cellular mechanisms responsible for such important functional changes in neuronal networks requires further study.

Acknowledgments. The author thanks Brent Doiron and Vladimir Shusterman for useful discussions during the preparation of the manuscript.

TC-HAT ($\widehat{\text{TC}}$): A Novel Toolbox for the Continuation of Periodic Trajectories in Hybrid Dynamical Systems*

Phanikrishna Thota† and Harry Dankowicz‡

Abstract. This paper describes the underlying formulation and functionality of the newly developed software program $\widehat{\text{TC}}$ ("TC-HAT"), to perform bifurcation analysis of systems in which continuous-in-time dynamics are interrupted by discrete-in-time events, often referred to as *hybrid dynamical systems*. Boundary-value-problem formulations corresponding to single- and two-parameter continuations of periodic trajectories and selected associated codimension-one bifurcations in such systems are presented. Finally, the capabilities of the program are illustrated by performing bifurcation analysis of a few example hybrid dynamical systems.

Key words. hybrid dynamical systems, bifurcation analysis, continuation software, TC-HAT

1. Introduction.

A combination of theoretical and computational tools for bifurcation analysis of dynamical systems offers distinct advantages to brute-force forward-time simulation [29]. Such a combination enables prediction of behavior and response without the need for a vast collection of simulations based at distinct initial conditions. More importantly, it may offer an understanding of, and an underlying explanation for, changes in behavior and response that are not available through simple simulation. Such analysis may further establish the existence of structure in the response of a dynamical system that would not be accessible to forward-time simulation. This may, in turn, enable a critical evaluation of the validity of the output of computer simulations.

A comprehensive bifurcation analysis of a dynamical system seeks to establish the existence of characteristic classes of responses, such as equilibria or periodic responses. In each case, this involves locating and tracking families of such responses under variations in system parameters in a process known as *continuation* [2, 10, 12, 17, 18, 19, 28, 34, 37, 38, 40, 44]. The study of the robustness of particular system responses further emphasizes parameter values where such families merge or terminate or where the stability characteristics of the corresponding responses change. Here, characteristic normal forms may be used to establish universal unfoldings of the associated *bifurcation structure* of response families [26]. In turn, these unfoldings provide guidance for further continuation.

Hybrid dynamical systems describe a class of mathematical models in which the continuous evolution of continuous and discrete state variables is punctuated by discontinuous changes in these variables and in the description of their future evolution. In mechanical engineering applications, hybrid dynamical systems occur in typical models of impacts (corresponding to instantaneous jumps in system velocities) or dry friction (including distinct conditions of sustained stick or slip) [31, 33, 35, 54]. In models of electrical circuitry, hybrid systems represent idealized versions of nonlinear circuit elements, such as diodes and transistors. Similarly, switched feedback strategies occur commonly in control applications. Finally, models of biochemical systems, including those describing biomolecular reactions, often include chemical switches and other triggered events, for example, the mitotic halving of the cell mass [51].

Hybrid dynamical systems exhibit bifurcations of the same fundamental nature as those observed in smooth systems, including saddle-node, Hopf, and period-doubling bifurcations. In contrast to smooth systems, however, hybrid dynamical systems also exhibit *discontinuity-induced bifurcations* associated with changes in the hybrid time history of the reference response. For example, *grazing bifurcations*, associated with the onset of zero-relative-velocity contact in systems with impact-like discontinuities, are known to be associated with strong instabilities and complicated sequences of postgrazing bifurcations.

Analytical tools for the study of discontinuity-induced bifurcations of periodic trajectories include the discontinuity-mapping technique pioneered by Nordmark and collaborators [9, 14, 41, 42, 50]. This method introduces a unique correction to the prebifurcation description of the local dynamics and an effective normal-form description of the postbifurcation behavior. In particular, the technique allows one to resolve the degree of singularity associated with the discontinuity-induced bifurcation and to establish the existence of nearby families of periodic trajectories with distinct hybrid time histories.

A number of computational tools are available for bifurcation analysis of characteristic classes of response, such as equilibria, periodic trajectories, homo- or heteroclinic trajectories between equilibria and/or periodic trajectories, quasiperiodic trajectories on invariant tori, and stable and unstable manifolds. These include general algebraic and two-point boundary-value solvers for ordinary differential equations, such as AUTO (and specialized drivers, such as HOMCONT [4, 6] and SLIDECONT [11]), MATCONT [13], and SYMPERCON [53]; boundary-value solvers for delay differential equations, such as DDE-BIFTOOL [20] and PDDE-CONT [48]; tools for large-scale systems, such as LOCA [45]; and implementations in MATLAB [5, 27].

The purpose of this paper is to establish a working definition of hybrid dynamical systems that is amenable to bifurcation analysis and to the implementation of continuation algorithms for periodic responses in such systems. In particular, selected boundary-value-problem formulations are proposed that enable single- and two-parameter continuations of periodic responses and some associated bifurcations. The formulation and its implementation in the Fortran-based software application $\widehat{\text{TC}}$ ("TC-HAT") provides a semiautomated tool for computational bifurcation analysis of periodic responses that complements the functionality present in the packages mentioned above.

The manuscript is organized as follows. Section 2 formulates a working definition of a hybrid dynamical system in terms of its essential components and its solutions. Several fundamental boundary-value-problem formulations are given in section 3. Section 4 reviews the general orthogonal collocation scheme employed in AUTO with particular emphasis on the

modifications necessary to accommodate hybrid dynamics and presents some specific comments on the implementation and usage of $\widehat{\text{TC}}$. A series of model examples is presented in section 5 to illustrate the formalism. Finally, a concluding discussion in section 6 highlights a number of desirable additions to the $\widehat{\text{TC}}$ functionality that would enable a more comprehensive study of the solution structure of hybrid dynamical systems. This section also summarizes drawbacks in the present implementation that may affect computational accuracy and that would be successfully addressed through a reimplementation of the boundary-value-problem formulations in a stand-alone hybrid system continuation application.

2. Hybrid dynamical systems.

2.1. General setup. In this paper (cf. Thota [49] and Kang et al. [32]), a *hybrid dynamical system* assumes the existence of a state space $\mathbb{X}$ of dimension n and an associated smooth vector-valued function $\mathbf{f}_{\mathfrak{m}} : \mathbb{X} \to \mathbb{X}$ known as the *vector field*, indexed by a *mode variable* $\mathfrak{m}$ in some finite set of modes $\mathfrak{M}$. Moreover, denote by $\mathfrak{E}$ a finite collection of *events*, and associate to each element $\mathfrak{e} \in \mathfrak{E}$ a pair $\pi_{\mathfrak{e}} = (\mathfrak{m}, \mathfrak{m}')$ of elements of $\mathfrak{M}$, a smooth *event function* $h_{\mathfrak{e}} : \mathbb{X} \to \mathbb{R}$, and a smooth *jump function* $\mathbf{g}_{\mathfrak{e}} : \mathbb{X} \to \mathbb{X}$. Then, a pair of modes $(\mathfrak{m}_{\text{in}}, \mathfrak{m}_{\text{out}})$ and a pair of states $(\mathbf{x}_{\text{in}}, \mathbf{x}_{\text{out}})$ are said to be *connected* by the event $\mathfrak{e}$ if

$$\pi_{\mathfrak{e}} = (\mathfrak{m}_{\text{in}}, \mathfrak{m}_{\text{out}}), \tag{2.1}$$

$\mathbf{x}_{\text{in}}$ is a point on the *event surface*

$$\{\mathbf{x} \mid h_{\mathfrak{e}}(\mathbf{x}) = 0,\ \partial_{\mathbf{x}} h_{\mathfrak{e}}(\mathbf{x}) \cdot \mathbf{f}_{\mathfrak{m}_{\text{in}}}(\mathbf{x}) \leq 0\},$$

i.e.,

$$h_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) = 0, \tag{2.2}$$

and

$$\mathbf{g}_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) = \mathbf{x}_{\text{out}} \tag{2.3}$$

(cf. Figure 1).

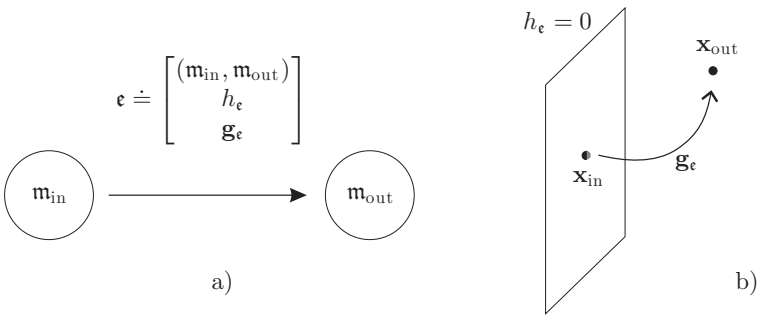

Figure 1. *The event $\mathfrak{e}$ results in a change in mode from $\mathfrak{m}_{\text{in}}$ to $\mathfrak{m}_{\text{out}}$ and a jump in state from $\mathbf{x}_{\text{in}}$ to $\mathbf{x}_{\text{out}}$.*

A *solution* of (or *trajectory* of) the corresponding dynamical system on a finite interval of time $[t_0, t_N]$ is a sequence $\xi = \{\mathbf{x}_j : [t_{j-1}, t_j] \to \mathbb{X}\}_{j=1}^{N}$ of N smooth curves, an associated

sequence of modes $\{\mathfrak{m}_j\}_{j=1}^{N}$, and an associated sequence of events $\{\mathfrak{e}_j\}_{j=1}^{N-1}$, such that the corresponding tangent vector at $\mathbf{x}_j(t)$ equals $\mathbf{f}_{\mathfrak{m}_j}(\mathbf{x}_j(t))$, i.e., in the case of $\mathbb{X} = \mathbb{R}^n$,

$$\frac{d}{dt}\mathbf{x}_j(t) = \mathbf{f}_{\mathfrak{m}_j}(\mathbf{x}_j(t)), \tag{2.4}$$

and such that, for $j \in [1, N-1]$, the pair of modes $(\mathfrak{m}_j, \mathfrak{m}_{j+1})$ and the pair of states $(\mathbf{x}_j(t_j), \mathbf{x}_{j+1}(t_j))$ are connected by the event $\mathfrak{e}_j$, i.e.,

$$h_{\mathfrak{e}_j}(\mathbf{x}_j(t_j)) = 0 \tag{2.5}$$

and

$$\mathbf{g}_{\mathfrak{e}_j}(\mathbf{x}_j(t_j)) = \mathbf{x}_{j+1}(t_j). \tag{2.6}$$

The concatenation $\mathbf{\Sigma} = \{\mathfrak{m}_1, \mathfrak{e}_1, \mathfrak{m}_2, \mathfrak{e}_2, \ldots, \mathfrak{m}_{N-1}, \mathfrak{e}_{N-1}, \mathfrak{m}_N\}$ will be called the solution's *signature* (cf. [36]). It is clear that this definition encapsulates the case of a smooth dynamical system, for which $\mathfrak{M}$ consists of a single element and $\mathfrak{E}$ is empty. A solution of a hybrid dynamical system will be said to be *simple* in the case that the signature has only a single element and *hybrid* otherwise.

2.2. The hybrid flow. Denote by $\mathbf{\Phi}_{\mathfrak{m}}$ the flow function corresponding to the vector field $\mathbf{f}_{\mathfrak{m}}$. Then, for $j \in [1, N-1]$ it follows that

$$\mathbf{\Phi}_{\mathfrak{m}_j}(\mathbf{x}_j(t_{j-1}), t_j - t_{j-1}) = \mathbf{x}_j(t_j), \tag{2.7}$$

where $T_j \overset{\text{def}}{=} t_j - t_{j-1}$ is the *time-of-flight* of the jth segment. As in smooth systems, the Jacobian $\partial_{\mathbf{x}}\mathbf{\Phi}_{\mathfrak{m}}(\mathbf{x}, t)$ is obtained as the solution to the variational initial-value problem

$$\frac{d}{dt}\partial_{\mathbf{x}}\mathbf{\Phi}_{\mathfrak{m}}(\mathbf{x}, t) = \partial_{\mathbf{x}}\mathbf{f}_{\mathfrak{m}}(\mathbf{\Phi}_{\mathfrak{m}}(\mathbf{x}, t)) \cdot \partial_{\mathbf{x}}\mathbf{\Phi}_{\mathfrak{m}}(\mathbf{x}, t), \tag{2.8}$$

$$\partial_{\mathbf{x}}\mathbf{\Phi}_{\mathfrak{m}}(\mathbf{x}, 0) = Id, \tag{2.9}$$

where Id denotes the $n \times n$ identity matrix. Moreover, differentiation of $\mathbf{f}_{\mathfrak{m}}(\mathbf{\Phi}_{\mathfrak{m}}(\mathbf{x}, t))$ with respect to time shows that

$$\mathbf{f}_{\mathfrak{m}}(\mathbf{\Phi}_{\mathfrak{m}}(\mathbf{x}, t)) = \partial_{\mathbf{x}}\mathbf{\Phi}_{\mathfrak{m}}(\mathbf{x}, t) \cdot \mathbf{f}_{\mathfrak{m}}(\mathbf{x}) \tag{2.10}$$

and, in particular, that

$$\mathbf{f}_{\mathfrak{m}_j}(\mathbf{x}_j(t_j)) = \partial_{\mathbf{x}}\mathbf{\Phi}_{\mathfrak{m}_j}(\mathbf{x}_j(t_{j-1}), t_j - t_{j-1}) \cdot \mathbf{f}_{\mathfrak{m}_j}(\mathbf{x}_j(t_{j-1})). \tag{2.11}$$

An event $\mathfrak{e}$ with $\pi_{\mathfrak{e}} = (\mathfrak{m}_{\text{in}}, \mathfrak{m}_{\text{out}})$ is *transversal* if

$$\partial_{\mathbf{x}}h_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) \cdot \mathbf{f}_{\mathfrak{m}_{\text{in}}}(\mathbf{x}_{\text{in}}) < 0. \tag{2.12}$$

In this case, the function

$$F(\mathbf{x}, t) = h_{\mathfrak{e}}(\mathbf{\Phi}_{\mathfrak{m}_{\text{in}}}(\mathbf{x}, t)) \tag{2.13}$$

satisfies the conditions

$$F(\mathbf{x}_{\text{in}}, 0) = h_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) = 0 \tag{2.14}$$

and

$$\partial_t F(\mathbf{x}_{\text{in}}, 0) = \partial_{\mathbf{x}} h_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) \cdot \mathbf{f}_{\mathfrak{m}_{\text{in}}}(\mathbf{x}_{\text{in}}) < 0. \tag{2.15}$$

From the implicit function theorem it follows that there exists a unique smooth function $\tau_{\mathfrak{e}}(\mathbf{x})$ for $\mathbf{x} \approx \mathbf{x}_{\text{in}}$, such that

$$\tau_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) = 0, \tag{2.16}$$

$$h_{\mathfrak{e}}(\mathbf{\Phi}_{\mathfrak{m}_{\text{in}}}(\mathbf{x}, \tau_{\mathfrak{e}}(\mathbf{x}))) \equiv 0, \tag{2.17}$$

and

$$\partial_{\mathbf{x}} \tau_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) = -\frac{\partial_{\mathbf{x}} h_{\mathfrak{e}}(\mathbf{x}_{\text{in}})}{\partial_{\mathbf{x}} h_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) \cdot \mathbf{f}_{\mathfrak{m}_{\text{in}}}(\mathbf{x}_{\text{in}})}. \tag{2.18}$$

For $\mathbf{x} \approx \mathbf{x}_{\text{in}}$ the *discontinuity mapping*

$$\mathbf{D}_{\mathfrak{e}}(\mathbf{x}) = \mathbf{\Phi}_{\mathfrak{m}_{\text{out}}}(\mathbf{g}_{\mathfrak{e}}(\mathbf{\Phi}_{\mathfrak{m}_{\text{in}}}(\mathbf{x}, \tau_{\mathfrak{e}}(\mathbf{x}))), -\tau_{\mathfrak{e}}(\mathbf{x})) \tag{2.19}$$

satisfies the conditions

$$\mathbf{D}_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) = \mathbf{g}_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) = \mathbf{x}_{\text{out}} \tag{2.20}$$

and

$$\partial_{\mathbf{x}} \mathbf{D}_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) = \partial_{\mathbf{x}} \mathbf{g}_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) + \frac{(\mathbf{f}_{\mathfrak{m}_{\text{out}}}(\mathbf{x}_{\text{out}}) - \partial_{\mathbf{x}} \mathbf{g}_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) \cdot \mathbf{f}_{\mathfrak{m}_{\text{in}}}(\mathbf{x}_{\text{in}})) \cdot \partial_{\mathbf{x}} h_{\mathfrak{e}}(\mathbf{x}_{\text{in}})}{\partial_{\mathbf{x}} h_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) \cdot \mathbf{f}_{\mathfrak{m}_{\text{in}}}(\mathbf{x}_{\text{in}})} \tag{2.21}$$

(cf. [1, 39]). In particular,

$$\partial_{\mathbf{x}} \mathbf{D}_{\mathfrak{e}}(\mathbf{x}_{\text{in}}) \cdot \mathbf{f}_{\mathfrak{m}_{\text{in}}}(\mathbf{x}_{\text{in}}) = \mathbf{f}_{\mathfrak{m}_{\text{out}}}(\mathbf{x}_{\text{out}}). \tag{2.22}$$

Now suppose that ξ denotes a solution sequence of length N with $T_j \neq 0$ for all $1 \leq j \leq N$ and an associated signature $\mathbf{\Sigma}$ with all transversal events. Then, for every $\mathbf{x} \approx \mathbf{x}_1(t_0)$, $\tilde{t}_0 \approx t_0$, and $\tilde{t}_N \approx t_N$, the above analysis establishes the existence of a sequence $\tilde{\xi} = \left\{\tilde{\mathbf{x}}_j : \left[\tilde{t}_{j-1}, \tilde{t}_j\right] \to \mathbb{X}\right\}_{j=1}^{N}$ of N smooth curves with $\tilde{\mathbf{x}}_1(\tilde{t}_0) = \mathbf{x}$, such that conditions (2.4)–(2.6) hold with $\mathbf{x}$ and t replaced by $\tilde{\mathbf{x}}$ and $\tilde{t}$, respectively. In particular, it follows that $\tilde{\mathbf{x}}_j(\tilde{t}_j) = \mathbf{\Phi}_{\mathfrak{m}_j}(\tilde{\mathbf{x}}_j(\tilde{t}_{j-1}), \tilde{t}_j - \tilde{t}_{j-1})$. Associate with ξ and the signature $\mathbf{\Sigma}$ the *hybrid flow*

$$\mathbf{\Phi}_{\xi,\mathbf{\Sigma}} \overset{\text{def}}{=} \mathbf{\Phi}_{\mathfrak{m}_N}(\cdot, T_N) \circ \mathbf{D}_{\mathfrak{e}_{N-1}} \circ \mathbf{\Phi}_{\mathfrak{m}_{N-1}}(\cdot, T_{N-1}) \circ \mathbf{D}_{\mathfrak{e}_{N-2}} \circ \cdots \circ \mathbf{\Phi}_{\mathfrak{m}_2}(\cdot, T_2) \circ \mathbf{D}_{\mathfrak{e}_1} \circ \mathbf{\Phi}_{\mathfrak{m}_1}(\cdot, T_1) \tag{2.23}$$

defined for $\mathbf{x} \approx \mathbf{x}_1(t_0)$ and such that

$$\tilde{\mathbf{x}}_N\left(\tilde{t}_0 + \sum_{i=1}^{N} T_i\right) = \mathbf{\Phi}_{\xi,\mathbf{\Sigma}}(\tilde{\mathbf{x}}_1(\tilde{t}_0)). \tag{2.24}$$

To linear order it follows that

$$\tilde{\mathbf{x}}_N\left(\tilde{t}_0+\sum_{i=1}^{N}T_i\right)-\mathbf{x}_N\left(t_0+\sum_{i=1}^{N}T_i\right)=\partial_{\mathbf{x}}\boldsymbol{\Phi}_{\xi,\boldsymbol{\Sigma}}\left(\mathbf{x}_1\left(t_0\right)\right)\cdot\left(\tilde{\mathbf{x}}_1\left(\tilde{t}_0\right)-\mathbf{x}_1\left(t_0\right)\right), \tag{2.25}$$

where

$$\partial_{\mathbf{x}}\boldsymbol{\Phi}_{\xi,\boldsymbol{\Sigma}}\left(\mathbf{x}_1\left(t_0\right)\right)=\partial_{\mathbf{x}}\boldsymbol{\Phi}_{\mathfrak{m}_N}\left(\mathbf{x}_N\left(t_{N-1}\right),T_N\right)\cdot\prod_{j=N-1}^{1}\partial_{\mathbf{x}}\mathbf{D}_{\mathfrak{e}_j}\left(\mathbf{x}_j\left(t_j\right)\right)\cdot\partial_{\mathbf{x}}\boldsymbol{\Phi}_{\mathfrak{m}_j}\left(\mathbf{x}_j\left(t_{j-1}\right),T_j\right). \tag{2.26}$$

Equations (2.11) and (2.22) imply that

$$\partial_{\mathbf{x}}\boldsymbol{\Phi}_{\xi,\boldsymbol{\Sigma}}\left(\mathbf{x}_1\left(t_0\right)\right)\cdot\mathbf{f}_{\mathfrak{m}_1}\left(\mathbf{x}_1\left(t_0\right)\right)=\mathbf{f}_{\mathfrak{m}_N}\left(\mathbf{x}_N\left(t_N\right)\right), \tag{2.27}$$

i.e., that deviations in the initial condition along the initial vector field result in deviations of the terminal point along the final vector field.

The above discussion pertains to the a posteriori characterization of a sequence of curves and an associated signature as a solution to a hybrid dynamical system. The question of how to generate such a solution a priori requires a definition of the forward dynamics of a hybrid dynamical system. For this purpose, associate with each mode $\mathfrak{m}\in\mathfrak{M}$ an *event map* $\iota_{\mathfrak{m}}:\mathbb{X}\to\mathfrak{E}$, such that $\pi_{\iota_{\mathfrak{m}}(\mathbf{x})}=(\mathfrak{m},\cdot)$. Then, given a state vector $\mathbf{x}_j\left(t_{j-1}\right)$ and an associated mode $\mathfrak{m}_j$ at $t=t_{j-1}$, apply the flow $\boldsymbol{\Phi}_{\mathfrak{m}_j}$ until the earliest time $t=t_j$ that condition (2.5) is satisfied for some event function $h_{\mathfrak{e}}$, for which $\pi_{\mathfrak{e}}=(\mathfrak{m}_j,\cdot)$. Proceed to apply the event map $\iota_{\mathfrak{m}_j}$ to yield $\mathfrak{e}_j=\iota_{\mathfrak{m}_j}\left(\mathbf{x}_j\left(t_j\right)\right)$, $\mathbf{x}_{j+1}\left(t_j\right)=\mathbf{g}_{\mathfrak{e}_j}\left(\mathbf{x}_j\left(t_j\right)\right)$, and $\mathfrak{m}_{j+1}$, where $\pi_{\mathfrak{e}_j}=(\mathfrak{m}_j,\mathfrak{m}_{j+1})$. Append the curve segment $\mathbf{x}_j\left(t\right)$ for $t\in[t_{j-1},t_j]$ and $\mathfrak{m}_j$ and $\mathfrak{e}_j$ to the solution sequence ξ and the signature $\boldsymbol{\Sigma}$, respectively. Repeat this construction as many times as desired. Degenerate situations may occur if two event functions are reached simultaneously, in which case priority must be given on an ad hoc, domain-specific basis.

It is clear that there may not exist a solution with an initial condition $\mathbf{x}_0$ and a prescribed signature. This, however, is of no concern to the above construction of the sequence $\tilde{\xi}$, since this presupposes an existing trajectory with signature $\boldsymbol{\Sigma}$ and transversal intersections of the corresponding event surfaces. On the other hand, it is certainly possible that trajectories may exist with a given signature that could not occur during forward simulation of the hybrid dynamical system. To ensure consistency between the a posteriori characterization of trajectories and the a priori generation of such trajectories using the transition function, care and domain-specific knowledge is required.

2.3. The hybrid Poincaré map. Suppose again that the event $\mathfrak{e}$ with $\pi_{\mathfrak{e}}=(\mathfrak{m}_{\text{in}},\mathfrak{m}_{\text{out}})$ is *transversal*, such that $h_{\mathfrak{e}}=0$ is a local Poincaré section for trajectory segments based at nearby initial conditions and governed by the $\mathbf{f}_{\mathfrak{m}_{\text{in}}}$ vector field. Then, for $\mathbf{x}\approx\mathbf{x}_{\text{in}}$, the *projection*

$$\mathbf{P}_{\mathfrak{e}}\left(\mathbf{x}\right)=\boldsymbol{\Phi}_{\mathfrak{m}_{\text{in}}}\left(\mathbf{x},\tau_{\mathfrak{e}}\left(\mathbf{x}\right)\right) \tag{2.28}$$

satisfies the conditions

$$h_{\mathfrak{e}}\left(\mathbf{P}_{\mathfrak{e}}\left(\mathbf{x}\right)\right)=0, \tag{2.29}$$

$$\mathbf{P}_{\mathfrak{e}}\left(\mathbf{x}_{\text{in}}\right)=\mathbf{x}_{\text{in}}, \tag{2.30}$$

and

$$\partial_{\mathbf{x}}\mathbf{P}_{\mathfrak{e}}\left(\mathbf{x}_{\text{in}}\right)=Id-\frac{\mathbf{f}_{\mathfrak{m}_{\text{in}}}\left(\mathbf{x}_{\text{in}}\right)\cdot\partial_{\mathbf{x}}h_{\mathfrak{e}}\left(\mathbf{x}_{\text{in}}\right)}{\partial_{\mathbf{x}}h_{\mathfrak{e}}\left(\mathbf{x}_{\text{in}}\right)\cdot\mathbf{f}_{\mathfrak{m}_{\text{in}}}\left(\mathbf{x}_{\text{in}}\right)}. \tag{2.31}$$

In particular,

$$\partial_{\mathbf{x}}\mathbf{P}_{\mathfrak{e}}\left(\mathbf{x}_{\text{in}}\right)\cdot\mathbf{f}_{\mathfrak{m}_{\text{in}}}\left(\mathbf{x}_{\text{in}}\right)=\mathbf{0}. \tag{2.32}$$

Consider again the sequence $\xi=\{\mathbf{x}_j:[t_{j-1},t_j]\to\mathbb{X}\}_{j=1}^{N}$ of N smooth curves with associated signature $\mathbf{\Sigma}$ and all transversal events. Associate with ξ and $\mathbf{\Sigma}$ the *hybrid Poincaré map*

$$\mathbf{P}_{\xi,\mathbf{\Sigma}}\overset{\text{def}}{=}\mathbf{g}_{\mathfrak{e}_{N-1}}\circ\mathbf{P}_{\mathfrak{e}_{N-1}}\circ\mathbf{\Phi}_{\mathfrak{m}_{N-1}}\left(\cdot,T_{N-1}\right)\circ\mathbf{g}_{\mathfrak{e}_{N-2}}\circ\mathbf{P}_{\mathfrak{e}_{N-2}}\circ\mathbf{\Phi}_{\mathfrak{m}_{N-2}}\left(\cdot,T_{N-2}\right)\circ\cdots\circ\mathbf{g}_{\mathfrak{e}_1}\circ\mathbf{P}_{\mathfrak{e}_1}\circ\mathbf{\Phi}_{\mathfrak{m}_1}\left(\cdot,T_1\right) \tag{2.33}$$

defined for $\mathbf{x}\approx\mathbf{x}_1\left(t_0\right)$ and such that

$$\tilde{\mathbf{x}}_N\left(\tilde{t}_{N-1}\right)=\mathbf{P}_{\xi,\mathbf{\Sigma}}\left(\tilde{\mathbf{x}}_1\left(\tilde{t}_0\right)\right) \tag{2.34}$$

for a nearby sequence $\tilde{\xi}=\left\{\tilde{\mathbf{x}}_j:\left[\tilde{t}_{j-1},\tilde{t}_j\right]\to\mathbb{X}\right\}_{j=1}^{N}$ of N smooth curves based at the point $\tilde{\mathbf{x}}_1\left(\tilde{t}_0\right)\approx\mathbf{x}_1\left(t_0\right)$. To linear order it follows that

$$\tilde{\mathbf{x}}_N\left(\tilde{t}_{N-1}\right)-\mathbf{x}_N\left(t_{N-1}\right)=\partial_{\mathbf{x}}\mathbf{P}_{\xi,\mathbf{\Sigma}}\left(\mathbf{x}_1\left(t_0\right)\right)\cdot\left(\tilde{\mathbf{x}}_1\left(\tilde{t}_0\right)-\mathbf{x}_1\left(t_0\right)\right),$$

where

$$\partial_{\mathbf{x}}\mathbf{P}_{\xi,\mathbf{\Sigma}}\left(\mathbf{x}_1\left(t_0\right)\right)=\prod_{j=N-1}^{1}\partial_{\mathbf{x}}\mathbf{g}_{\mathfrak{e}_j}\left(\mathbf{x}_j\left(t_j\right)\right)\cdot\partial_{\mathbf{x}}\mathbf{P}_{\mathfrak{e}_j}\left(\mathbf{x}_j\left(t_j\right)\right)\cdot\partial_{\mathbf{x}}\mathbf{\Phi}_{\mathfrak{m}_j}\left(\mathbf{x}_j\left(t_{j-1}\right),T_j\right). \tag{2.35}$$

Equations (2.11) and (2.32) imply that

$$\partial_{\mathbf{x}}\mathbf{P}_{\xi,\mathbf{\Sigma}}\left(\mathbf{x}_1\left(t_0\right)\right)\cdot\mathbf{f}_{\mathfrak{m}_1}\left(\mathbf{x}_1\left(t_0\right)\right)=\mathbf{0}, \tag{2.36}$$

i.e., that deviations in the initial condition along the initial vector field result in zero deviations of the outgoing state subsequent to the last event.

2.4. Periodic trajectories. A trajectory ξ of a hybrid dynamical system on a finite interval $[t_0,t_0+T]$ with signature $\mathbf{\Sigma}$ of length $2N-1$ will be said to be *periodic* with period T if $\mathbf{x}_1\left(t_0\right)=\mathbf{x}_N\left(t_0+T\right)$ and $\mathfrak{m}_N=\mathfrak{m}_1$. The same need to check for consistency with forward simulation as described in the general case naturally applies here. In particular, it is necessary to establish that the terminal state on the Nth segment does not trigger a nontrivial event.

For a periodic trajectory, the Jacobian $\partial_{\mathbf{x}}\mathbf{\Phi}_{\xi,\mathbf{\Sigma}}\left(\mathbf{x}_1\left(t_0\right)\right)$ is known as the *monodromy matrix* and describes the local stability properties of the trajectory. In particular, its eigenvalues are the celebrated *Floquet multipliers*, all of which (excluding the trivial eigenvalue at 1 with eigenvector equal to the initial vector field; cf. (2.27)) must lie within the unit circle in the complex plane to guarantee asymptotic orbital stability.

From the general statement

$$\mathbf{A}\cdot\mathbf{B}\cdot\mathbf{v}=\lambda\mathbf{v}\Rightarrow\mathbf{B}\cdot\mathbf{A}\cdot\mathbf{B}\cdot\mathbf{v}=\lambda\mathbf{B}\cdot\mathbf{v}, \tag{2.37}$$

it follows that if $\mathbf{v}$ is an eigenvector of $\partial_{\mathbf{x}}\mathbf{\Phi}_{\xi,\mathbf{\Sigma}}\left(\mathbf{x}_1\left(t_0\right)\right)$ with eigenvalue λ, then

$$\left(\prod_{j=N-1}^{1}\partial_{\mathbf{x}}\mathbf{D}_{\mathfrak{e}_j}\left(\mathbf{x}_j\left(t_j\right)\right)\cdot\partial_{\mathbf{x}}\mathbf{\Phi}_{\mathfrak{m}_j}\left(\mathbf{x}_j\left(t_{j-1}\right),T_j\right)\right)\cdot\mathbf{v} \tag{2.38}$$

is an eigenvector of the matrix

$$\left(\prod_{j=N-1}^{1}\partial_{\mathbf{x}}\mathbf{D}_{\mathfrak{e}_j}\left(\mathbf{x}_j\left(t_j\right)\right)\cdot\partial_{\mathbf{x}}\mathbf{\Phi}_{\mathfrak{m}_j}\left(\mathbf{x}_j\left(t_{j-1}\right),T_j\right)\right)\cdot\partial_{\mathbf{x}}\mathbf{\Phi}_{\mathfrak{m}_1}\left(\mathbf{x}_N\left(t_{N-1}\right),T_N\right) \tag{2.39}$$

with the same eigenvalue. This suggests redefining a *hybrid* periodic trajectory with N segments as the collection of all cyclic permutations of the sequence $\xi_{\circlearrowleft}=\{\mathbf{x}_j:[t_{j-1},t_j]\to\mathbb{X}\}_{j=1}^{N-1}$ of $N-1$ smooth curves obtained by prepending the final segment to the initial segment and relabeling the time partition. Specifically, associate with $\xi_{\circlearrowleft}$ the sequence of modes $\{\mathfrak{m}_j\}_{j=1}^{N-1}$ and the sequence of transitions $\{\mathfrak{e}_j\}_{j=1}^{N-1}$ such that, in addition to the conditions prescribed above for a general trajectory,

$$\pi_{\mathfrak{e}_{N-1}}=\left(\mathfrak{m}_{N-1},\mathfrak{m}_1\right), \tag{2.40}$$

the $(N-1)$th segment terminates at an intersection with the event surface

$$\left\{\mathbf{x}\mid h_{\mathfrak{e}_{N-1}}\left(\mathbf{x}\right)=0,\,\partial_{\mathbf{x}}h_{\mathfrak{e}_{N-1}}\left(\mathbf{x}\right)\cdot\mathbf{f}_{\mathfrak{m}_{N-1}}\left(\mathbf{x}\right)\leq 0\right\},$$

i.e.,

$$h_{\mathfrak{e}_{N-1}}\left(\mathbf{x}_{N-1}\left(t_{N-1}\right)\right)=0, \tag{2.41}$$

and the connectivity between the $(N-1)$th and 1st segments is given by the function $\mathbf{g}_{\mathfrak{e}_{N-1}}$, i.e.,

$$\mathbf{g}_{\mathfrak{e}_{N-1}}\left(\mathbf{x}_{N-1}\left(t_{N-1}\right)\right)=\mathbf{x}_1\left(t_0\right). \tag{2.42}$$

In this case, the *cyclic signature* equals the collection of all cyclic permutations of the sequence $\mathbf{\Sigma}_{\circlearrowleft}=\{\mathbf{I}_j\}_{j=1}^{N-1}$ consisting of pairs $\mathbf{I}_j=(\mathfrak{m}_j,\mathfrak{e}_j)$ or, equivalently, of triplets $\mathbf{I}_j=\left(\mathbf{f}_{\mathfrak{m}_j},h_{\mathfrak{e}_j},\mathbf{g}_{\mathfrak{e}_j}\right)$.

From this construction, it follows that the Floquet multipliers are the eigenvalues of the matrix

$$\partial_{\mathbf{x}}\mathbf{\Phi}_{\xi_{\circlearrowleft},\mathbf{\Sigma}_{\circlearrowleft}}\overset{\text{def}}{=}\prod_{j=N-1}^{1}\partial_{\mathbf{x}}\mathbf{D}_{\mathfrak{e}_j}\left(\mathbf{x}_j\left(t_j\right)\right)\cdot\partial_{\mathbf{x}}\mathbf{\Phi}_{\mathfrak{m}_j}\left(\mathbf{x}_j\left(t_{j-1}\right),T_j\right). \tag{2.43}$$

For any event $\mathfrak{e}$ with $\pi_{\mathfrak{e}}=(\mathfrak{m}_{\text{in}},\mathfrak{m}_{\text{out}})$ it is straightforward to show that

$$\left(\partial_{\mathbf{x}}\mathbf{D}_{\mathfrak{e}}\left(\mathbf{x}_{\text{in}}\right)-\partial_{\mathbf{x}}\mathbf{g}_{\mathfrak{e}}\left(\mathbf{x}_{\text{in}}\right)\cdot\partial_{\mathbf{x}}\mathbf{P}_{\mathfrak{e}}\left(\mathbf{x}_{\text{in}}\right)\right)\cdot\mathbf{v}\parallel\mathbf{f}_{\mathfrak{m}_{\text{out}}}\left(\mathbf{x}_{\text{out}}\right) \tag{2.44}$$

for all $\mathbf{v}$. Suppose, in particular, that $\mathbf{v}$ is an eigenvector of $\partial_{\mathbf{x}}\mathbf{\Phi}_{\xi_\circlearrowleft,\mathbf{\Sigma}_\circlearrowleft}$ with eigenvalue λ and transversal to $\mathbf{f}_{\mathfrak{m}_1}(\mathbf{x}_1(t_0))$. Then, there exists a scalar α such that

$$\partial_{\mathbf{x}}\mathbf{P}_{\xi_\circlearrowleft,\mathbf{\Sigma}_\circlearrowleft}(\mathbf{x}_1(t_0))\cdot\mathbf{v}=\partial_{\mathbf{x}}\mathbf{\Phi}_{\xi_\circlearrowleft,\mathbf{\Sigma}_\circlearrowleft}\cdot\mathbf{v}+\alpha\mathbf{f}_{\mathfrak{m}_1}(\mathbf{x}_1(t_0)), \tag{2.45}$$

and, consequently, $\lambda\mathbf{v}+\alpha\mathbf{f}_{\mathfrak{m}_1}(\mathbf{x}_1(t_0))$ is an eigenvector of $\partial_{\mathbf{x}}\mathbf{P}_{\xi_\circlearrowleft,\mathbf{\Sigma}_\circlearrowleft}(\mathbf{x}_1(t_0))$ with the same eigenvalue. In addition, from (2.36) it follows that $\mathbf{f}_{\mathfrak{m}_1}(\mathbf{x}_1(t_0))$ is an eigenvector of $\partial_{\mathbf{x}}\mathbf{P}_{\xi_\circlearrowleft,\mathbf{\Sigma}_\circlearrowleft}(\mathbf{x}_1(t_0))$ with eigenvalue 0. In the cyclic formulation, the Jacobian $\partial_{\mathbf{x}}\mathbf{P}_{\xi_\circlearrowleft,\mathbf{\Sigma}_\circlearrowleft}(\mathbf{x}_1(t_0))$ thus yields an equivalent description of the local stability properties of the trajectory.

2.5. An example oscillator. To illustrate the formalism introduced above, consider a mechanical system consisting of an oscillating mass m, termed the *impactor*, that is suspended within a frame and whose motion relative to the frame is harmonically excited by an external force (cf. Figure 2) with some known angular frequency ω and amplitude A. Here, the clearance between the frame and the impactor is designed so that collisions may occur with sufficient displacement of the impactor relative to the frame. Interactions between the frame and the impactor transmitted through the suspension are modeled with a combination of a linear elastic element with stiffness k and a linear dissipative element with damping coefficient c. Finally, collisions between the frame and the impactor are modeled as instantaneous impacts that, through the imposition of conservation of momentum and Newton's law of restitution, result in discontinuous-in-time changes in the impactor's velocity relative to the frame.

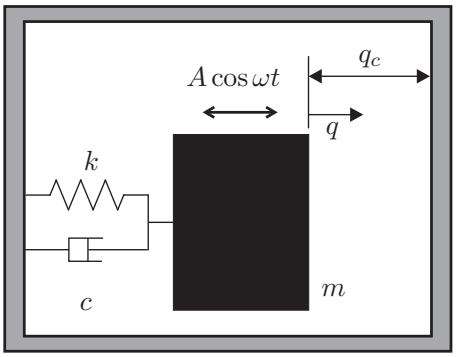

Figure 2. *The lateral motion of the impactor of mass m is harmonically excited with amplitude A and angular frequency ω. Instantaneous changes occur in the impactor's velocity $\dot{q}$ when q reaches q_c from below.*

The dynamics of the impactor may be formulated as a hybrid dynamical system in the following way. Denote by q the displacement of the impactor relative to the frame. The impactor motion is then governed by the linear differential equation

$$m\ddot{q}+c\dot{q}+kq=A\cos\omega t \tag{2.46}$$

as long as $q\leq q_c$ and such that if

$$\lim_{t\to t_c-}q(t)=q_c,\quad \lim_{t\to t_c-}\dot{q}(t)\geq 0 \tag{2.47}$$

for some time $t=t_c$, then

$$\lim_{t\to t_c+}q(t)=q_c,\quad \lim_{t\to t_c+}\dot{q}(t)=-e\lim_{t\to t_c-}\dot{q}(t), \tag{2.48}$$

where e is the coefficient of restitution. We omit from consideration situations in which the impactor remains in contact with the frame throughout a solution segment or solution signatures with infinite length.

Let

$$\mathbf{x} = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} \stackrel{\text{def}}{=} \begin{pmatrix} q \\ \dot{q} \\ \omega t \bmod 2\pi \end{pmatrix} \in \mathbb{R}^2 \times \mathbb{S}^1 \tag{2.49}$$

represent the state of the impactor. The smooth motion of the impactor is then governed by the vector field

$$\mathbf{f}_{\text{smooth}}(\mathbf{x}) = \begin{pmatrix} x_2 \\ \frac{1}{m}\left(A\cos x_3 - cx_2 - kx_1\right) \\ \omega \end{pmatrix} \tag{2.50}$$

and impacts between the impactor and the frame occur when

$$h_{\text{impact}}(\mathbf{x}) \stackrel{\text{def}}{=} q_c - x_1 = 0, \tag{2.51}$$

resulting in a discontinuous jump in state given by the state jump function

$$\mathbf{g}_{\text{impact}}(\mathbf{x}) = \begin{pmatrix} x_1 \\ -ex_2 \\ x_3 \end{pmatrix}. \tag{2.52}$$

Moreover, a discontinuous jump in the phase coordinate x_3 occurs when

$$h_{\text{phase}}(\mathbf{x}) \stackrel{\text{def}}{=} 2\pi - x_3 = 0 \tag{2.53}$$

and corresponds to the state jump function

$$\mathbf{g}_{\text{phase}}(\mathbf{x}) = \begin{pmatrix} x_1 \\ x_2 \\ x_3 - 2\pi \end{pmatrix}. \tag{2.54}$$

Finally, for purposes of detection of grazing events with the event surface corresponding to h_{impact}, consider the event function

$$h_{\text{turning}}(\mathbf{x}) \stackrel{\text{def}}{=} x_2 \tag{2.55}$$

and the associated state jump function

$$\mathbf{g}_{\text{identity}}(\mathbf{x}) = \mathbf{x} \tag{2.56}$$

(cf. Figure 3).

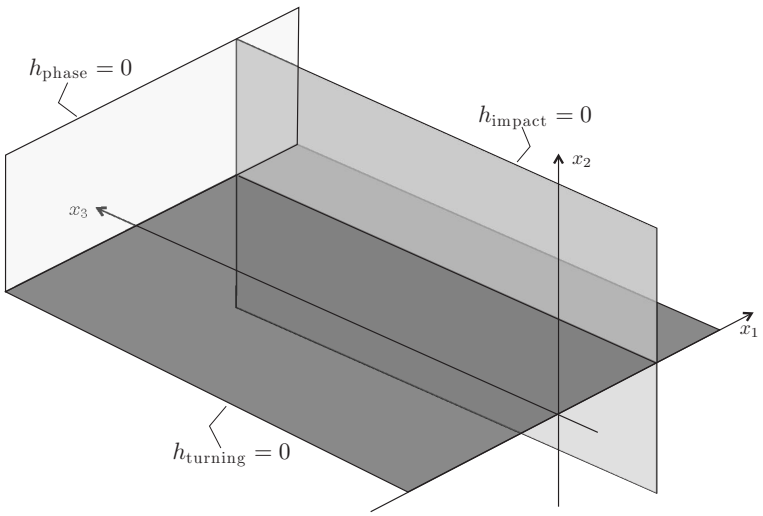

Figure 3. *A state-space schematic of the event surfaces describing the dynamics of the linear impact oscillator.*

Let $\mathfrak{M} = \{\mathfrak{smooth}\}$ and $\mathfrak{E} = \{\mathfrak{impact}, \mathfrak{phase}, \mathfrak{turning}\}$, such that $\mathbf{f}_{\mathfrak{smooth}} = \mathbf{f}_{\text{smooth}}$,

$$\mathfrak{impact} \doteq \begin{bmatrix} (\mathfrak{smooth}, \mathfrak{smooth}) \\ h_{\text{impact}} \\ \mathbf{g}_{\text{impact}} \end{bmatrix}, \tag{2.57}$$

$$\mathfrak{phase} \doteq \begin{bmatrix} (\mathfrak{smooth}, \mathfrak{smooth}) \\ h_{\text{phase}} \\ \mathbf{g}_{\text{phase}} \end{bmatrix}, \tag{2.58}$$

and

$$\mathfrak{turning} \doteq \begin{bmatrix} (\mathfrak{smooth}, \mathfrak{smooth}) \\ h_{\text{turning}} \\ \mathbf{g}_{\text{identity}} \end{bmatrix}, \tag{2.59}$$

corresponding to the *event graph* in Figure 4 showing the relationship between a mode and a given vector field as well as the event function and jump function associated with a given event. For example, $\mathfrak{e} = \mathfrak{impact}$ connects a solution segment governed by the vector field $\mathbf{f}_{\text{smooth}}$ and terminating at $\mathbf{x}_{\text{in}}$ on the event surface corresponding to h_{impact}, to the next solution segment based at $\mathbf{x}_{\text{out}}$ and again governed by the vector field $\mathbf{f}_{\text{smooth}}$, such that $\mathbf{x}_{\text{out}} = \mathbf{g}_{\text{impact}}(\mathbf{x}_{\text{in}})$. In the case of periodic trajectories, the dynamics of the hybrid system is captured by three distinct values of the index vector, namely,

$$\mathbf{I}_1 = (\mathfrak{smooth}, \mathfrak{impact}), \tag{2.60}$$

$$\mathbf{I}_2 = (\mathfrak{smooth}, \mathfrak{phase}), \tag{2.61}$$

$$\mathbf{I}_3 = (\mathfrak{smooth}, \mathfrak{turning}). \tag{2.62}$$

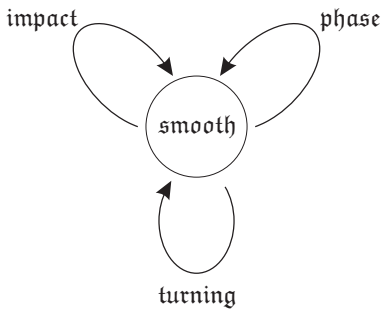

Figure 4. *Event graph corresponding to the linear impact oscillator.*

In particular, a solution will be termed *impacting* if its signature contains $\mathbf{I}_1$ and *nonimpacting* otherwise.

Consider, as an alternative, the state vector

$$\tilde{\mathbf{x}} = \begin{pmatrix} \tilde{x}_1 \\ \tilde{x}_2 \\ \tilde{x}_3 \\ \tilde{x}_4 \end{pmatrix} \in \mathbb{R}^4 \tag{2.63}$$

and the corresponding smooth vector field

$$\tilde{\mathbf{f}}_{\text{smooth}}(\tilde{\mathbf{x}}) = \begin{pmatrix} \tilde{x}_2 \\ \frac{1}{m}\left(A\tilde{x}_4 - c\tilde{x}_2 - k\tilde{x}_1\right) \\ \tilde{x}_3 + \omega\tilde{x}_4 - \tilde{x}_3\left(\tilde{x}_3^2 + \tilde{x}_4^2\right) \\ \tilde{x}_4 - \omega\tilde{x}_3 - \tilde{x}_4\left(\tilde{x}_3^2 + \tilde{x}_4^2\right) \end{pmatrix}, \tag{2.64}$$

event functions

$$\tilde{h}_{\text{impact}}(\tilde{\mathbf{x}}) = q_c - \tilde{x}_1, \tag{2.65}$$

$$\tilde{h}_{\text{phase}}(\tilde{\mathbf{x}}) = -\tilde{x}_3, \tag{2.66}$$

$$\tilde{h}_{\text{turning}}(\tilde{\mathbf{x}}) = \tilde{x}_2, \tag{2.67}$$

and state jump functions

$$\tilde{\mathbf{g}}_{\text{impact}}(\tilde{\mathbf{x}}) = \begin{pmatrix} \tilde{x}_1 \\ -e\tilde{x}_2 \\ \tilde{x}_3 \\ \tilde{x}_4 \end{pmatrix}, \tag{2.68}$$

$$\tilde{\mathbf{g}}_{\text{identity}}(\tilde{\mathbf{x}}) = \tilde{\mathbf{x}}. \tag{2.69}$$

It is straightforward to show that the surface $\tilde{x}_3^2 + \tilde{x}_4^2 - 1 = 0$ is invariant and globally attractive under the flow of the vector field $\tilde{\mathbf{f}}_{\text{smooth}}$. In particular, it can be easily seen that $\tilde{x}_3 = \sin(\omega t + \theta_0)$ and $\tilde{x}_4 = \cos(\omega t + \theta_0)$ on this surface.

Let $\mathfrak{M} = \{\mathfrak{smooth}\}$ and $\mathfrak{E} = \{\mathfrak{impact}, \mathfrak{phase}, \mathfrak{turning}\}$, such that $\tilde{\mathbf{f}}_{\mathfrak{smooth}} = \tilde{\mathbf{f}}_{\text{smooth}}$,

$$\mathfrak{impact} \doteq \begin{bmatrix} (\mathfrak{smooth}, \mathfrak{smooth}) \\ \tilde{h}_{\text{impact}} \\ \tilde{\mathbf{g}}_{\text{impact}} \end{bmatrix}, \tag{2.70}$$

$$\mathfrak{phase} \doteq \begin{bmatrix} (\mathfrak{smooth}, \mathfrak{smooth}) \\ \tilde{h}_{\text{phase}} \\ \tilde{\mathbf{g}}_{\text{identity}} \end{bmatrix}, \tag{2.71}$$

and

$$\mathfrak{turning} \doteq \begin{bmatrix} (\mathfrak{smooth}, \mathfrak{smooth}) \\ \tilde{h}_{\text{turning}} \\ \tilde{\mathbf{g}}_{\text{identity}} \end{bmatrix} \tag{2.72}$$

(cf. the event graph in Figure 4). In the case of periodic trajectories, the dynamics of the hybrid system is again captured by three distinct values of the index vector, namely,

$$\mathbf{I}_1 = (\mathfrak{smooth}, \mathfrak{impact}), \tag{2.73}$$

$$\mathbf{I}_2 = (\mathfrak{smooth}, \mathfrak{phase}), \tag{2.74}$$

$$\mathbf{I}_3 = (\mathfrak{smooth}, \mathfrak{turning}). \tag{2.75}$$

There is a one-to-one relationship between solutions to this hybrid dynamical system on $\tilde{x}_3^2 + \tilde{x}_4^2 - 1 = 0$ with $\theta_0 = 0$ and solutions to the original dynamical system. Solution segments for which $\tilde{x}_3^2 + \tilde{x}_4^2 - 1 \neq 0$, however, have no physical meaning. The introduction of the state variables $\tilde{x}_3$ and $\tilde{x}_4$ mimics the approach enabling the continuation of periodic trajectories of harmonically forced smooth dynamical systems in AUTO 97 effectively embedding $\mathbb{S}^1$ as a normally hyperbolic, attracting, invariant manifold of a smooth dynamical system in $\mathbb{R}^2$. Within the hybrid dynamical system formulation considered here, however, it is possible to consider an intrinsic parametrization in terms of the phase x_3, avoiding the need to artificially enlarge state space. This is particularly useful in the case of nonharmonic periodic or quasiperiodic forcing.

3. Boundary-value problems.

3.1. Periodic trajectories. The discussion below is focused on the task of finding a trajectory of a hybrid dynamical system with a prescribed signature satisfying the auxiliary boundary conditions

$$\mathbf{g}\left(\mathbf{x}_1\left(t_0\right), \mathbf{x}_N\left(t_N\right)\right) = \mathbf{0} \tag{3.1}$$

for some function $\mathbf{g}$ and any number of additional equations (typically generalized integral equations) that guarantee well-posedness.

As an example, in the case of a *periodic trajectory* of a hybrid dynamical system with a prescribed signature of length $2N - 1$, the auxiliary boundary condition corresponds to the connectivity condition

$$\mathbf{x}_1\left(t_0\right) - \mathbf{x}_N\left(t_N\right) = \mathbf{0}. \tag{3.2}$$

Together with an additional scalar condition, for example, the celebrated phase integral condition

$$\sum_{j=1}^{N} \int_{t_{j-1}}^{t_j} \mathbf{x}\left(t\right)^T \cdot \dot{\mathbf{x}}^*\left(t\right) dt = 0 \tag{3.3}$$

for some reference trajectory $\mathbf{x}^*\left(t\right)$, this yields a well-posed formulation for locating such a periodic trajectory (away from singularities). No such auxiliary boundary or integral conditions are necessary in the cyclic formulation in section 2.4.

The boundary-value formulation imposes only conditions of equality, e.g., the termination of trajectory segments on the zero-level surfaces of the corresponding event functions. It does not, however, automatically ensure that the event function is locally decreasing along the trajectory segment at the termination point. Solutions to the boundary-value formulation must therefore be postprocessed to agree with this condition.

3.2. Grazing/sliding bifurcations. Suppose that, for some value of a free parameter, a trajectory has been found that achieves approximate *grazing contact* at a point $\mathbf{x}_*$ along the jth segment with an event surface corresponding to the event function $h_{\mathcal{D}}$, such that

$$h_{\mathcal{P}}\left(\mathbf{x}_*\right) = 0 \tag{3.4}$$

and (without loss of generality)

$$\partial_{\mathbf{x}} h_{\mathcal{P}}\left(\mathbf{x}_*\right) \cdot \mathbf{f}_{\mathbf{I}_j}\left(\mathbf{x}_*\right) \tag{3.5}$$

is distinctly negative, where

$$h_{\mathcal{P}}\left(\mathbf{x}\right) \stackrel{\text{def}}{=} \partial_{\mathbf{x}} h_{\mathcal{D}}\left(\mathbf{x}\right) \cdot \mathbf{f}_{\mathbf{I}_j}\left(\mathbf{x}\right). \tag{3.6}$$

Then replace the jth segment with mode $\mathfrak{m}_j$, and the jth event $\mathfrak{e}_j$ with two segments with modes $\mathfrak{m}_{j'} = \mathfrak{m}_{j''} = \mathfrak{m}_j$ and terminating events $\mathfrak{e}_{j'}$ and $\mathfrak{e}_{j''}$, such that $\pi_{\mathfrak{e}_{j'}} = (\mathfrak{m}_j, \mathfrak{m}_j)$, $\pi_{\mathfrak{e}_{j''}} = (\mathfrak{m}_j, \mathfrak{m}_{j+1})$, $h_{\mathfrak{e}_{j'}} = h_{\mathcal{P}}$, $h_{\mathfrak{e}_{j''}} = h_{\mathfrak{e}_j}$, $\mathbf{g}_{\mathfrak{e}_{j''}} = \mathbf{g}_{\mathfrak{e}_j}$, and $\mathbf{g}_{\mathfrak{e}_{j'}}$ is the identity. The auxiliary boundary condition

$$h_{\mathcal{D}}\left(\mathbf{x}_j\left(t_j\right)\right) = 0 \tag{3.7}$$

serves to locate the parameter value and the trajectory corresponding to actual grazing contact.

The imposition of an additional boundary condition may also be used to detect codimension-one bifurcations in Filippov systems in which a trajectory segment terminates on the boundary of the sliding region [14]. Here, the event surface, termed the *switching manifold*, corresponding to the event function $h_{\text{switching}}$ locally separates two distinct regions of state space with vector fields $\mathbf{f}_>$ when $h_{\text{switching}} > 0$ and $\mathbf{f}_<$ when $h_{\text{switching}} < 0$. The *sliding region* is the subset on the switching manifold where

$$\partial_{\mathbf{x}} h_{\text{switching}} \cdot \mathbf{f}_< - \partial_{\mathbf{x}} h_{\text{switching}} \cdot \mathbf{f}_> > 0 \tag{3.8}$$

and

$$-1 \leq h_{\text{sliding}} \overset{\text{def}}{=} -\frac{\partial_{\mathbf{x}} h_{\text{switching}} \cdot \mathbf{f}_{>} + \partial_{\mathbf{x}} h_{\text{switching}} \cdot \mathbf{f}_{<}}{\partial_{\mathbf{x}} h_{\text{switching}} \cdot \mathbf{f}_{<} - \partial_{\mathbf{x}} h_{\text{switching}} \cdot \mathbf{f}_{>}} \leq 1. \tag{3.9}$$

The parameter values corresponding to the termination of the jth trajectory segment on the boundary of the sliding region may then be obtained using either of the auxiliary boundary conditions

$$h_{\text{sliding}}\left(\mathbf{x}_j\left(t_j\right)\right) = 1 \tag{3.10}$$

and

$$h_{\text{sliding}}\left(\mathbf{x}_j\left(t_j\right)\right) = -1. \tag{3.11}$$

3.3. Limit points. *Limit points* in the single-parameter continuation of boundary-value problems occur when the component of the tangent vector to the corresponding solution branch in the direction of the bifurcation parameter changes sign. Such limit points may be located by appending to the existing equations, the equations for the tangent vector to the trajectory branch, and imposing the condition that this component vanish. This functionality is standard in AUTO 97.

Specifically, let $\mu(s)$ and $\xi(s)$ represent the bifurcation parameter and a one-parameter family of solutions of a hybrid system with identical signature, all transversal intersections, and $t_j(s) - t_{j-1}(s) \neq 0$ for $1 \leq j \leq N$, such that $\mu'(0) = 0$. In particular, for $j \in [1, N-1]$,

$$\partial_t \mathbf{x}_j(t,s) - \mathbf{f}_{\mathfrak{m}_j}\left(\mathbf{x}_j(t,s), \mu(s)\right) = \mathbf{0}$$

for $t \in [t_{j-1}(s), t_j(s)]$ and

$$h_{\mathfrak{e}_j}\left(\mathbf{x}_j\left(t_j(s), s\right), \mu(s)\right) = 0, \tag{3.12}$$

$$\mathbf{x}_{j+1}\left(t_j(s), s\right) - \mathbf{g}_{\mathfrak{e}_j}\left(\mathbf{x}_j\left(t_j(s), s\right), \mu(s)\right) = \mathbf{0}. \tag{3.13}$$

Differentiation with respect to s and letting $s = 0$ then yield

$$\partial_t \partial_s \mathbf{x}_j^{lp}(t) - \partial_{\mathbf{x}} \mathbf{f}_{\mathfrak{m}_j}\left(\mathbf{x}_j^{lp}(t), \mu^{lp}\right) \cdot \partial_s \mathbf{x}_j^{lp}(t) = \mathbf{0}$$

and

$$\partial_{\mathbf{x}} h_{\mathfrak{e}_j}\left(\mathbf{x}_j^{lp}\left(t_j^{lp}\right), \mu^{lp}\right) \cdot \left[\partial_t \mathbf{x}_j^{lp}\left(t_j^{lp}\right) t_j^{lp\prime} + \partial_s \mathbf{x}_j^{lp}\left(t_j^{lp}\right)\right] = 0, \tag{3.14}$$

$$\partial_t \mathbf{x}_{j+1}^{lp}\left(t_j^{lp}\right) t_j^{lp\prime} + \partial_s \mathbf{x}_{j+1}^{lp}\left(t_j^{lp}\right) - \partial_{\mathbf{x}} \mathbf{g}_{\mathfrak{e}_j}\left(\mathbf{x}_j^{lp}\left(t_j^{lp}\right), \mu^{lp}\right) \cdot \left[\partial_t \mathbf{x}_j^{lp}\left(t_j^{lp}\right) t_j^{lp\prime} + \partial_s \mathbf{x}_j^{lp}\left(t_j^{lp}\right)\right] = \mathbf{0}, \tag{3.15}$$

where the superscript ^{lp} refers to limit point values at $s = 0$. Solving the second equation for $t_j^{lp\prime}$ and substituting into the third equation then yields

$$\partial_s \mathbf{x}_{j+1}^{lp}\left(t_j^{lp}\right) - \partial_{\mathbf{x}} \mathbf{D}_{\mathfrak{e}_j}\left(\mathbf{x}_j^{lp}\left(t_j^{lp}\right), \mu^{lp}\right) \cdot \partial_s \mathbf{x}_j^{lp}\left(t_j^{lp}\right) = \mathbf{0}. \tag{3.16}$$

It follows that, on each segment, $\partial_s \mathbf{x}_j^{lp}(t)$ is a solution to the variational equation that connects to the solution on the subsequent segment by premultiplication with the Jacobian $\partial_{\mathbf{x}} \mathbf{D}_{\mathfrak{e}_j}\left(\mathbf{x}_j^{lp}\left(t_j^{lp}\right), \mu^{lp}\right)$ of the corresponding discontinuity mapping.

In the case of periodic trajectories of a hybrid dynamical system with a prescribed signature of length $2N-1$, limit points correspond to *saddle-node bifurcations*, for which $\partial_{\mathbf{x}} \mathbf{\Phi}_{\xi_\circlearrowleft, \mathbf{\Sigma}_\circlearrowleft}$ has an eigenvector with eigenvalue 1 distinct from the initial vector field. To locate a saddle-node bifurcation point, consider an augmented hybrid dynamical system with state space $\tilde{\mathbb{X}} = \mathbb{X} \times \mathbb{X}$, mode set $\tilde{\mathfrak{M}} = \mathfrak{M}$, and event set $\tilde{\mathfrak{E}} = \mathfrak{E}$. Let the associated vector fields $\tilde{\mathbf{f}}_{\mathfrak{m}} : \tilde{\mathbb{X}} \to \tilde{\mathbb{X}}$ be given by

$$\tilde{\mathbf{f}}_{\mathfrak{m}}(\tilde{\mathbf{x}}) = \begin{pmatrix} \mathbf{f}_{\mathfrak{m}}(\mathbf{u}) \\ \mathbf{f}_{\mathfrak{m},\mathbf{x}}(\mathbf{u}) \cdot \mathbf{v} + \beta \mathbf{f}_{\mathfrak{m}}(\mathbf{u}) \end{pmatrix}, \quad \tilde{\mathbf{x}} = \begin{pmatrix} \mathbf{u} \\ \mathbf{v} \end{pmatrix}, \tag{3.17}$$

where β is an auxiliary free parameter whose value is subsequently found to equal 0. Moreover, let $\tilde{h}_{\mathfrak{e}}(\tilde{\mathbf{x}}) = h_{\mathfrak{e}}(\mathbf{u})$ and

$$\tilde{\mathbf{g}}_{\mathfrak{e}}(\tilde{\mathbf{x}}) = \begin{pmatrix} \mathbf{g}_{\mathfrak{e}}(\mathbf{u}) \\ \partial_{\mathbf{x}} \mathbf{D}_{\mathfrak{e}}(\mathbf{u}) \cdot \mathbf{v} \end{pmatrix}. \tag{3.18}$$

Together with the auxiliary boundary conditions

$$\mathbf{u}_1(t_0) - \mathbf{u}_m(t_m) = \mathbf{0}, \tag{3.19}$$

$$\mathbf{v}_1(t_0) - \mathbf{v}_m(t_m) = \mathbf{0} \tag{3.20}$$

and the integral conditions

$$\sum_{j=1}^{N} \int_{t_{j-1}}^{t_j} \|\mathbf{v}_j(t)\|^2 \, dt = 1, \tag{3.21}$$

$$\sum_{j=1}^{N} \int_{t_{j-1}}^{t_j} \mathbf{v}_j(t)^T \cdot \mathbf{f}_{\mathfrak{m}_j}(\mathbf{u}_j(t)) \, dt = 0, \tag{3.22}$$

this yields a well-posed formulation for locating the periodic trajectory and the corresponding eigenvector of $\partial_{\mathbf{x}} \mathbf{\Phi}_{\xi_\circlearrowleft, \mathbf{\Sigma}_\circlearrowleft}$. Here, the second integral condition ensures that the eigenvector is distinct from the initial vector field.

As will be discussed further below, the formulation above mimics the implementation of $\widehat{\text{TC}}$ and exploits existing features of the boundary-value problem solver for smooth dynamical systems in AUTO 97. An alternative, and somewhat simpler, formulation is afforded using the cyclic formulation and imposing the condition that $\partial_{\mathbf{x}} \mathbf{P}_{\xi_\circlearrowleft, \mathbf{\Sigma}_\circlearrowleft}(\mathbf{x}_1(t_0))$ has an eigenvector with eigenvalue 1. For this purpose, consider again an augmented hybrid dynamical system with state space $\tilde{\mathbb{X}} = \mathbb{X} \times \mathbb{X}$, mode set $\tilde{\mathfrak{M}} = \mathfrak{M}$, and event set $\tilde{\mathfrak{E}} = \mathfrak{E}$. Let the associated vector fields $\tilde{\mathbf{f}}_{\mathfrak{m}} : \tilde{\mathbb{X}} \to \tilde{\mathbb{X}}$ be given by

$$\tilde{\mathbf{f}}_{\mathfrak{m}}(\tilde{\mathbf{x}}) = \begin{pmatrix} \mathbf{f}_{\mathfrak{m}}(\mathbf{u}) \\ \mathbf{f}_{\mathfrak{m},\mathbf{x}}(\mathbf{u}) \cdot \mathbf{v} \end{pmatrix}, \quad \tilde{\mathbf{x}} = \begin{pmatrix} \mathbf{u} \\ \mathbf{v} \end{pmatrix}. \tag{3.23}$$

Moreover, let $\tilde{h}_{\mathfrak{e}}(\tilde{\mathbf{x}}) = h_{\mathfrak{e}}(\mathbf{u})$ and

$$\tilde{\mathbf{g}}_{\mathfrak{e}}(\tilde{\mathbf{x}}) = \begin{pmatrix} \mathbf{g}_{\mathfrak{e}}(\mathbf{u}) \\ \partial_{\mathbf{x}}\mathbf{g}_{\mathfrak{e}}(\mathbf{u}) \cdot \partial_{\mathbf{x}}\mathbf{P}_{\mathfrak{e}}(\mathbf{u}) \cdot \mathbf{v} \end{pmatrix}. \tag{3.24}$$

Then, the cyclic formulation and the integral condition

$$\sum_{j=1}^{N-1} \int_{t_{j-1}}^{t_j} \|\mathbf{v}_j(t)\|^2 \, dt = 1 \tag{3.25}$$

serve to locate the parameter values and the trajectory corresponding to the saddle-node bifurcation point. As $\mathbf{f}_{\mathfrak{m}_1}(\mathbf{x}_1(t_0))$ corresponds to an eigenvalue 0 of $\partial_{\mathbf{x}}\mathbf{P}_{\xi_{\circlearrowleft},\boldsymbol{\Sigma}_{\circlearrowleft}}(\mathbf{x}_1(t_0))$, there is no longer a need for the additional integral condition or the auxiliary parameter β.

3.4. Period-doubling bifurcations. Finally, consider the task of finding a periodic trajectory of a hybrid dynamical system with a prescribed signature in the presence of two free parameters, such that $\partial_{\mathbf{x}}\boldsymbol{\Phi}_{\xi_{\circlearrowleft},\boldsymbol{\Sigma}_{\circlearrowleft}}$ has an eigenvector with eigenvalue -1 corresponding to a *period-doubling bifurcation*. For this purpose, consider the augmented hybrid dynamical system with state space $\tilde{\mathbb{X}} = \mathbb{X} \times \mathbb{X}$, mode set $\tilde{\mathfrak{M}} = \mathfrak{M}$, event set $\tilde{\mathfrak{E}} = \mathfrak{E}$, and associated vector fields $\tilde{\mathbf{f}}_{\mathfrak{m}} : \tilde{\mathbb{X}} \to \tilde{\mathbb{X}}$, where

$$\tilde{\mathbf{f}}_{\mathfrak{m}}(\tilde{\mathbf{x}}) = \begin{pmatrix} \mathbf{f}_{\mathfrak{m}}(\mathbf{u}) \\ \mathbf{f}_{\mathfrak{m},\mathbf{x}}(\mathbf{u}) \cdot \mathbf{v} \end{pmatrix}, \quad \tilde{\mathbf{x}} = \begin{pmatrix} \mathbf{u} \\ \mathbf{v} \end{pmatrix}. \tag{3.26}$$

Moreover, let $\tilde{h}_{\mathfrak{e}}(\tilde{\mathbf{x}}) = h_{\mathfrak{e}}(\mathbf{u})$ and

$$\tilde{\mathbf{g}}_{\mathfrak{e}}(\tilde{\mathbf{x}}) = \begin{pmatrix} \mathbf{g}_{\mathfrak{e}}(\mathbf{u}) \\ \partial_{\mathbf{x}}\mathbf{D}_{\mathfrak{e}}(\mathbf{u}) \cdot \mathbf{v} \end{pmatrix}. \tag{3.27}$$

Then, the auxiliary boundary conditions

$$\mathbf{u}_1(t_0) - \mathbf{u}_m(t_m) = \mathbf{0}, \tag{3.28}$$

$$\mathbf{v}_1(t_0) + \mathbf{v}_m(t_m) = \mathbf{0} \tag{3.29}$$

and the integral condition

$$\sum_{j=1}^{m} \int_{t_{j-1}}^{t_j} \|\mathbf{v}_j(t)\|^2 \, dt = 1 \tag{3.30}$$

serve to locate the parameter values and the trajectory corresponding to the period-doubling bifurcation point.

Alternatively, let

$$\tilde{\mathbf{g}}_{\mathfrak{e}}(\tilde{\mathbf{x}}) = \begin{pmatrix} \mathbf{g}_{\mathfrak{e}}(\mathbf{u}) \\ \varkappa\partial_{\mathbf{x}}\mathbf{g}_{\mathfrak{e}}(\mathbf{u}) \cdot \partial_{\mathbf{x}}\mathbf{P}_{\mathfrak{e}}(\mathbf{u}) \cdot \mathbf{v} \end{pmatrix}, \tag{3.31}$$

where $\varkappa = -1$ when $\mathfrak{e} = \mathfrak{e}_{N-1}$ and $\varkappa = 1$ otherwise. In this case, the cyclic formulation and the integral condition

$$\sum_{j=1}^{N-1} \int_{t_{j-1}}^{t_j} \|\mathbf{v}_j(t)\|^2 \, dt = 1 \tag{3.32}$$

serve to locate the parameter values and the trajectory, for which $\partial_{\mathbf{x}} \mathbf{P}_{\xi_\circlearrowleft, \mathbf{\Sigma}_\circlearrowleft}(\mathbf{x}_1(t_0))$ has an eigenvector with eigenvalue -1.

4. $\widehat{\text{TC}}$ ("TC-HAT").

4.1. Functionality. $\widehat{\text{TC}}$ ("TC-HAT") is a novel Fortran-based software application developed by the authors that encompasses a set of basic tools for the bifurcation analysis of periodic trajectories of hybrid dynamical systems. In this regard, $\widehat{\text{TC}}$ was inspired by, and closely resembles in general code implementation, the existing software application SLIDECONT [11], developed by Fabio Dercole and Yuri Kuznetsov for the study of hybrid dynamical systems with sliding dynamics but no state-space jumps. As detailed below, $\widehat{\text{TC}}$ replaces and improves on some of the functionality of SLIDECONT but suffers, in other respects, from the same computational limitations regarding problem discretization. $\widehat{\text{TC}}$ (just like SLIDECONT) functions as a driver to a modified version of AUTO 97 [16], a Fortran-based software application for the bifurcation analysis of smooth dynamical systems. In particular, $\widehat{\text{TC}}$ exploits AUTO 97's general boundary-value-problem formulation to locate and continue periodic trajectories of hybrid dynamical systems and a selected set of codimension-one bifurcation points under variations in system parameters.

In its current form, $\widehat{\text{TC}}$ can perform the following specific tasks:

1. Single-parameter continuation of multisegment periodic trajectories of a hybrid dynamical system with a given signature.
2. Two-parameter continuation of multisegment periodic trajectories of a hybrid dynamical system with a given signature and with grazing incidence at the terminal point of the first segment with some event surface.
3. Two-parameter continuation of multisegment periodic trajectories of a hybrid dynamical system with a given signature and with the terminal point of the first segment intersecting a switching manifold in a Filippov system on the boundary of the sliding region.
4. Two-parameter continuation of multisegment periodic trajectories of a hybrid dynamical system with a given signature and corresponding to saddle-node or period-doubling bifurcation points.

SLIDECONT is able only to partially perform the above tasks for periodic trajectories with at most three distinct segments. In particular, SLIDECONT is not able to handle nontrivial state jump functions or characterize the Lyapunov stability (Floquet multipliers) of periodic trajectories. In the standard implementation of AUTO 97, the Lyapunov stability properties of a periodic orbit are determined through a computation of the eigenvalues of the Jacobian $\partial_{\mathbf{x}} \mathbf{\Phi}(\mathbf{x}_0, T)$, where $\mathbf{x}_0$ is a point on the periodic orbit and T is the period. Although SLIDECONT relies on a multisegment formulation similar to that described for $\widehat{\text{TC}}$ (see below),

it does not account for the corrections to the flow Jacobian imposed by the piecewise nature of the solution trajectory as in (2.21). In contrast, $\widehat{\text{TC}}$ ships with a modified version of AUTO 97 that includes these corrections and, consequently, is able to accurately characterize the linearized stability properties of periodic trajectories of hybrid dynamical systems.

The ability to correctly compute the eigenvalues of $\partial_{\mathbf{x}}\mathbf{\Phi}_{\xi_\circlearrowleft,\mathbf{\Sigma}_\circlearrowleft}$ implies that $\widehat{\text{TC}}$ (with the help of AUTO 97) can detect bifurcations associated with the crossing of the unit circle of one or several eigenvalues, for example, saddle-node and period-doubling bifurcations. These form the starting points for the two-parameter continuations of task 4 which are implemented as new boundary-value formulations in the modified version of AUTO 97. Note that SLIDECONT is able to continue saddle-node bifurcations (for hybrid trajectories of up to three segments and without jumps) as per the generic formulation for limit points outlined above.

Similarly, $\widehat{\text{TC}}$ (and SLIDECONT for hybrid trajectories of up to three segments and without jumps) may be employed to detect the grazing contact of a trajectory segment with a properly identified event surface so as to enable subsequent two-parameter continuation as in task 2. In this case, it is typically necessary to cyclically reorder the trajectory segments in the grazing trajectory as well as to modify its signature so that grazing contact is imposed on the first trajectory segment and so that all termination points correspond to transversal intersections. In the continuation of periodic trajectories that graze an event surface corresponding to a mechanical-impact-like discontinuity, $\widehat{\text{TC}}$ is also able to detect and locate a selected set of characteristic codimension-two grazing bifurcations that serve as organizing centers for a variety of codimension-one bifurcation curves such as saddle-node, period-doubling, and grazing bifurcations (cf. Thota, Zhao, and Dankowicz [50]).

Finally, $\widehat{\text{TC}}$ (and SLIDECONT for hybrid trajectories of up to three segments and without jumps) may be employed to detect the crossing of the terminal point of a trajectory segment terminating on the switching manifold in a Filippov system with the boundary of the corresponding sliding region. Two-parameter continuation as in task 3 is then possible subsequent to reordering the trajectory segments so that the additional boundary condition is imposed on the first segment.

4.2. Discretization. Piecewise polynomial collocation methods provide an accurate and highly adaptive procedure for computing approximate solutions of boundary-value problems involving differential equations. In this method, approximants of the form of piecewise polynomials of some predetermined order are sought that satisfy the given differential equation at a discrete set of points in the interval of definition, the *collocation points*. The robustness of this method has made it an indisputable candidate in solving some of the difficult problems in differential equations [16, 22] (see also [3, 21]).

Following [16], denote by $\mathbf{x}(t)$ a solution on the interval $[0,1]$ of the differential equation

$$\frac{d\mathbf{x}}{dt} = \mathbf{f}(\mathbf{x}) \tag{4.1}$$

for some vector field $\mathbf{f}$. Introduce the partition

$$0 = t_0 < \cdots < t_{j-1} < \cdots < t_{j-i/m} = t_j - \frac{i}{m}\Delta_j < \cdots < t_j < \cdots < t_N = 1, \tag{4.2}$$

where

$$\Delta_j = t_j - t_{j-1}, \tag{4.3}$$

and suppose that the sequence $\mathbf{x}_0, \ldots, \mathbf{x}_{j-1}, \ldots, \mathbf{x}_{j-i/m}, \ldots, \mathbf{x}_j, \ldots, \mathbf{x}_N$ approximates the values of $\mathbf{x}(t)$ on this partition for some integers N and m, $j = 1, \ldots, N$, and $i = 0, \ldots, m$. On each interval $[t_{j-1}, t_j]$, define the Lagrange polynomials

$$l_{j,i}(t) = \prod_{k=0,\, k\neq i}^{m} \frac{t - t_{j-k/m}}{t_{j-i/m} - t_{j-k/m}}, \quad i = 0, \ldots, m \text{ and } j = 1, \ldots, N, \tag{4.4}$$

such that $l_{j,i}\left(t_{j-i/m}\right) = 1$ and $l_{j,i}\left(t_{j-k/m}\right) = 0$ for $k \neq i$. Then, the piecewise polynomial function $\mathbf{p}(t)$, such that

$$\mathbf{p}(t) = \sum_{i=0}^{m} l_{j,i}(t)\mathbf{x}_{j-i/m} \tag{4.5}$$

for $t \in [t_{j-1}, t_j]$, interpolates the values $\mathbf{x}_{j-i/m}$ for $j = 1, \ldots, N$ and $i = 0, \ldots, m$. Now, consider the mth order Legendre polynomial on the interval $[0, 1]$ and denote its roots by z_i, $i = 1, \ldots, m$. For each interval $[t_{j-1}, t_j]$, define $z_{j,i}$ as

$$z_{j,i} = t_{j-1} + z_i \Delta_j. \tag{4.6}$$

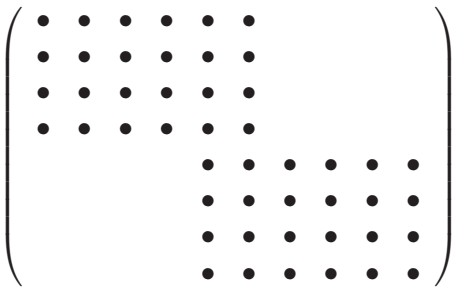
Then, an approximation to the solution to the original differential equation is obtained by seeking numerical values for the $mN + 1$ discrete approximants $\mathbf{x}_{j-i/m}$ for $j = 1, \ldots, N$, $i = 1, \ldots, m$, and $\mathbf{x}_N$ so that $\mathbf{p}$ satisfies the system of mN vector-valued equations

$$\mathbf{p}'(z_{j,i}) - \mathbf{f}(\mathbf{p}(z_{j,i})) = \mathbf{0} \tag{4.7}$$

for $j = 1, \ldots, N$ and $i = 1, \ldots, m$ and so that the associated boundary conditions are satisfied by $\mathbf{x}_0$ and $\mathbf{x}_N$.

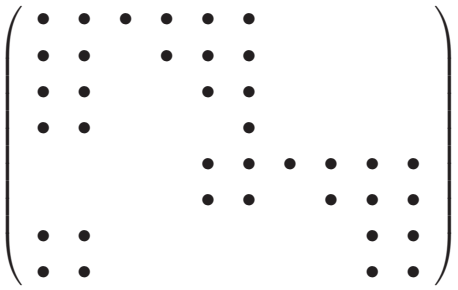
Suppose, for example, that $n = m = N = 2$. In this case, the linearization of (4.7) takes the form

(4.8)



where •'s denote nontrivial elements and zero elements have been omitted. Condensation of parameters and a subsequent step of nested dissection applied to an uncoupled subset of entries (see [16]) then yield a reduced matrix of the form

(4.9)



In particular, denote by P_0 and P_1 the 2×2 block matrices at the lower left and lower right, respectively, of this reduced matrix. It follows that, when evaluated on the converged solution,

$$P_0 \cdot \Delta \mathbf{x}_0 + P_1 \cdot \Delta \mathbf{x}_2 = 0, \tag{4.10}$$

i.e.,

$$\Delta \mathbf{x}_2 = -\left(P_1\right)^{-1} \cdot P_0 \cdot \Delta \mathbf{x}_0. \tag{4.11}$$

Hence, the matrix $-\left(P_1\right)^{-1} \cdot P_0$ gives the lowest-order relationship between perturbations in the initial point $\mathbf{x}_0$ and deviations in the corresponding terminal point $\mathbf{x}_2$.

For a multisegment trajectory of a hybrid dynamical system with solution sequence ξ and signature $\mathbf{\Sigma}$, the above formalism applies to each solution segment following the application of the time transformation

$$t \to t_{j-1} + tT_j \Rightarrow \mathbf{f}_{\mathfrak{m}_j} \to \frac{1}{T_j} \mathbf{f}_{\mathfrak{m}_j} \tag{4.12}$$

and the introduction of internal boundary conditions associated with the event sequence contained in $\mathbf{\Sigma}$. As described in previous sections, these couple the terminal point on the $(j-1)$st segment with the initial point on the jth segment and constrain the numerical values of the unknown times-of-flight T_j. As the coupling between distinct segments is imposed only on the boundary points, each segment may be treated independently from every other segment when formulating the piecewise polynomial approximant and the associated discretized differential equations. It follows that the sequence of matrix manipulations described previously can be applied for each segment independently of each other segment. Thus, the Jacobian $\partial_{\mathbf{x}} \mathbf{\Phi}_{\mathbf{I}_j} \left(\mathbf{x}_j \left(t_{j-1}\right), t_j - t_{j-1}\right)$ of the flow function that describes the sensitivity of the terminal point $\mathbf{x}_j \left(t_j\right)$ of the jth segment to changes in the initial point $\mathbf{x}_j \left(t_{j-1}\right)$ may again be obtained from the corresponding product $-\left(P_1\right)^{-1} \cdot P_0$.

A severely constrained implementation of the discretization scheme for a multisegment trajectory is afforded by the application of the same time partition to each solution segment. This fails to accommodate segment-specific error control and meshing algorithms, for example, in the case of solution segments with distinct curve characteristics. Instead, it corresponds to replacing the multipoint boundary-value problem with a regular two-point boundary-value problem for a single-segment trajectory of an augmented dynamical system with vector field

$$\mathbf{f} = \begin{pmatrix} \frac{1}{T_1} \mathbf{f}_{\mathfrak{m}_1} \\ \vdots \\ \frac{1}{T_N} \mathbf{f}_{\mathfrak{m}_N} \end{pmatrix} \tag{4.13}$$

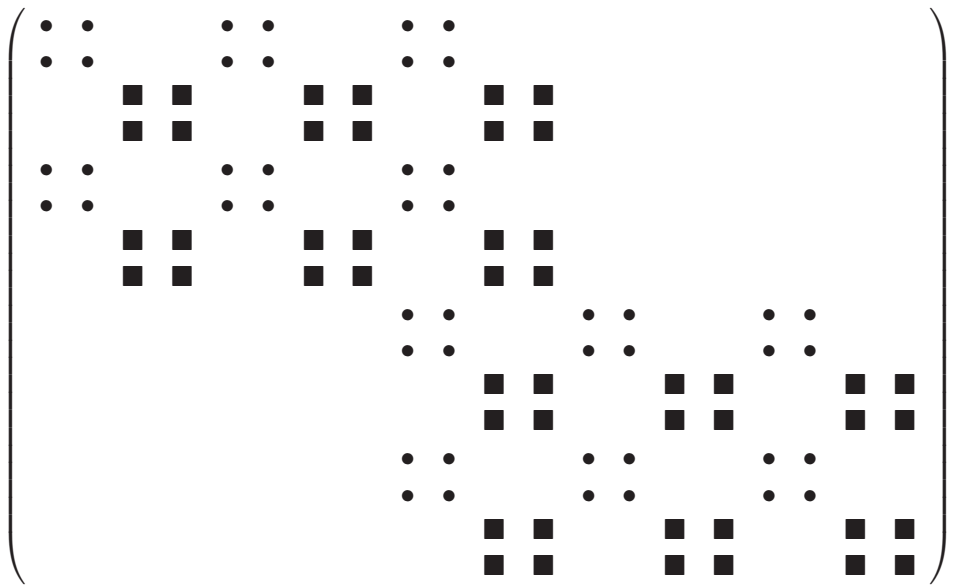
and solution

$$\mathbf{x}(t) = \begin{pmatrix} \mathbf{x}_1(t_0 + tT_1) \\ \vdots \\ \mathbf{x}_N(t_{N-1} + tT_N) \end{pmatrix}. \tag{4.14}$$

This also corresponds to the current implementation of $\widehat{\text{TC}}$ and SLIDECONT as these both rely on the two-point boundary-value solver contained in AUTO 97.

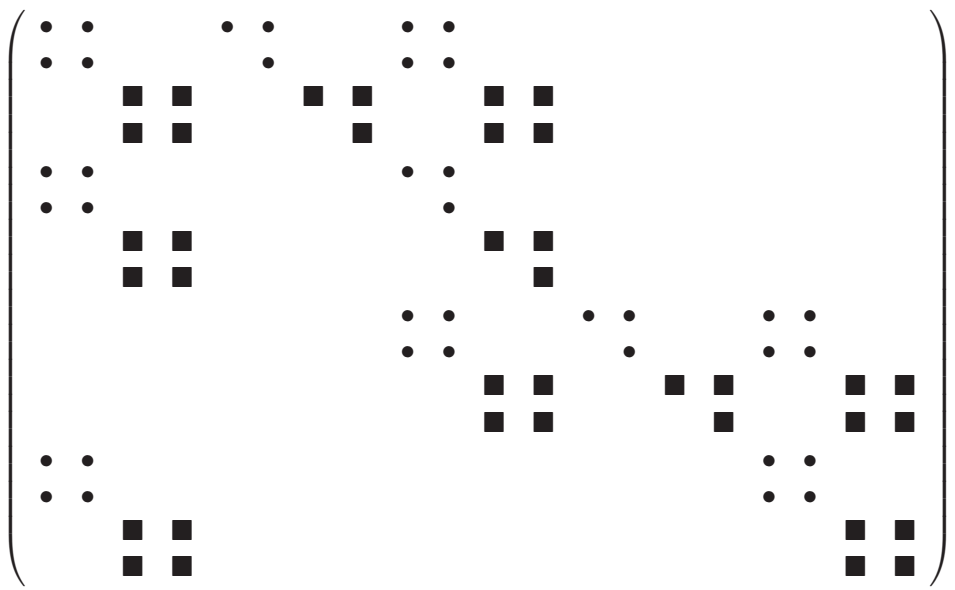
Suppose again that $n = m = N = 2$. Then, the linearization of (4.7) in the case of a two-segment trajectory takes the form

(4.15)



where •'s and ■'s denote nontrivial elements for the first and second segments, respectively, and zero elements have been omitted. Condensation of parameters and nested dissection as implemented in AUTO 97 then yields a reduced matrix of the form

(4.16)



In particular, denote by P_0 and P_1 the 4×4 block-diagonal matrices at the lower left and lower right, respectively, of this reduced matrix. It again follows that the matrix $-(P_1)^{-1}\cdot P_0$ gives the lowest-order relationship between perturbations in the initial point $\mathbf{x}_0$ and deviations in the corresponding terminal point $\mathbf{x}_2$ independently for each segment.

4.3. Usage. This section focuses on those aspects of $\widehat{\text{TC}}$ that distinguish it from AUTO 97. The section thus assumes some prior experience with the latter program. For further details on $\widehat{\text{TC}}$, see [49].

Essential information regarding the hybrid dynamical system is provided to $\widehat{\text{TC}}$ by the user in the <name>.f file.[1] This file contains the vector fields $\mathbf{f_I}$, the event functions $h_\mathbf{I}$, and the state jump functions $\mathbf{g_I}$ and, typically, their first (and, possibly, second) derivatives with respect to state variables and parameters. In addition, user-specific test functions may be included for monitoring during continuation. These may include event functions describing event surfaces with which the detection and two-parameter continuation of grazing incidence is desired or event functions describing the boundary of a sliding region on a switching manifold in a Filippov system for detection and continuation of selected sliding bifurcations.

Event functions corresponding to an identity state jump function may be introduced at liberty along a given trajectory of a hybrid dynamical system. This can be used to represent a trajectory by the value of some state variable on an event surface (cf. a Poincaré section) or to enforce a more accurate detection of grazing incidence (the latter necessarily occurring at a local extremum of the corresponding event function). In some instances, such as those where grazing occurs with an event surface at a point corresponding to a nontrivial jump in state space, an alternative signature may be intentionally employed to enable accurate detection and continuation of a grazing bifurcation curve (see below).

As with AUTO 97, continuation of periodic trajectories in $\widehat{\text{TC}}$ may be initialized with an approximate solution obtained by alternative means (for example, forward simulation) or from a previous run of $\widehat{\text{TC}}$. In contrast to the continuation of periodic trajectories in smooth systems, however, discontinuity-induced codimension-one bifurcations in hybrid dynamical systems are typically accompanied by a change in segment structure and length of signature. This necessitates an understanding of the trajectory branching associated with a given discontinuity-induced bifurcation and a subsequent reinitialization with a modified segment structure and signature. This may also be desirable prior to detecting a discontinuity-induced bifurcation as suggested above.

In the event that the initial solution trajectory is provided by the user, the time histories of the state variables for one complete time period of the periodic trajectory are contained in the <name>.dat file. As described in the previous section, each time interval $[t_{j-1}, t_j]$ is discretized by a segment-independent partition of the interval $[0, 1]$ (contained in the first column of the <name>.dat file) scaled to the length of the segment. The time history of the ith state variable along the jth segment is then contained in the $(1 + n\,(j-1) + i)$th column, where n is the state-space dimension of the hybrid dynamical system.

In the event that the initial solution trajectory is obtained from a previous continuation, the corresponding data is contained in a q.<name> file and labeled so as to enable further

[1] Here, <name> corresponds to the user-specified name of a file.

continuation. In the event that resegmentation is necessary, for example, when a discontinuity-induced bifurcation is associated with the birth of a branch of periodic trajectories with an additional segment, data in the q.<name> file may be extracted manually and modified externally as discussed in the previous paragraph.

To uniquely identify the continuation task to be undertaken, a number of numerical flags and continuation-specific parameter values must be provided by the user in the gc.<name> file. These include the state-space dimension of the hybrid dynamical system, the desired signature, the system parameters that will be allowed to vary during continuation (this list includes the segment times-of-flight), a segment-dependent list of event functions for which the detection of zero-crossings is desirable, and additional boundary conditions associated with continuation of grazing or sliding bifurcation curves.

5. Numerical examples.

5.1. A linear impact oscillator. To illustrate the methodology and functionality of $\widehat{\text{TC}}$ consider the first hybrid dynamical system discussed in section 2.5. Figure 5 shows a nonimpacting periodic trajectory of the hybrid dynamical system for $m = 1$, $c = 0.1$, $k = 1$, $q_c = 1$, $e = 0.8$, $\omega = 2.0$, and $A = 3.0$ with cyclic signature $\{\mathbf{I}_3, \mathbf{I}_2\}$. A segment of the corresponding branch of periodic trajectories under variations in ω with identical signature is shown in the left panel of Figure 6. Here, trajectories for which $\max x_1 > 1$ are inconsistent with the forward dynamics conditions and must be discarded. For $\omega = 1.998$ one finds a periodic trajectory that achieves grazing incidence with the event surface corresponding to h_{impact} at a point $\mathbf{x}^* = \begin{pmatrix} 1.0 & 0 & 3.075 \end{pmatrix}^T$. A two-parameter continuation of the corresponding grazing bifurcation curve under simultaneous variations in ω and A is shown in the right panel of Figure 6.

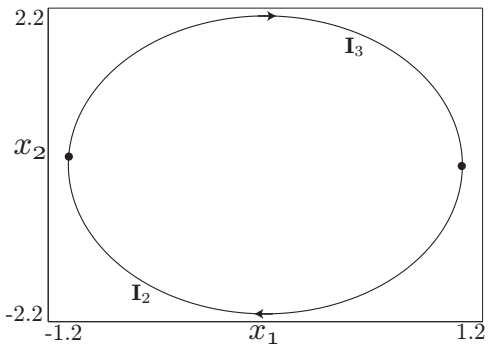


Figure 5. *A nonimpacting periodic trajectory of the linear oscillator for $\omega = 2.0$ and $A = 3.0$. Here and in the later figures, a dot on a periodic trajectory indicates the terminal point corresponding to a segment of that trajectory.*

Using the method of discontinuity mappings [8], it is possible to show that a unique branch of period-one impacting trajectories with a single impact per period emanates from the grazing curve under variations in A for all values of ω. To map out such a branch requires replacing the periodic trajectory with the equivalent trajectory with cyclic signature $\{\mathbf{I}_1, \mathbf{I}_2\}$. The result of such continuation for two distinct values of ω are shown in Figures 7 and 8. In each case, the

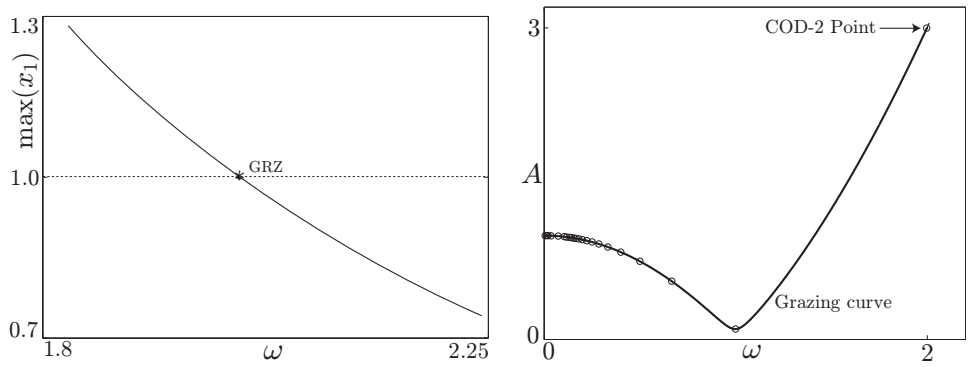

Figure 6. *Left panel: Diagram indicating the continuation of a nonimpacting periodic trajectory corresponding to the linear impact oscillator. Here,* $\widehat{\text{TC}}$ *detects the parameter value corresponding to a grazing incidence with the event surface* $h_{\text{impact}} = 0$ *that can be used as a starting solution to obtain a grazing curve. Right panel: Grazing curve in the* $(A$–$\omega)$ *space obtained using* $\widehat{\text{TC}}$*. The o's on the grazing curve correspond to the codimension-two bifurcation points, in particular to impact oscillators and detected by* $\widehat{\text{TC}}$*, that form organizing centers for a variety of codimension-one bifurcation curves* [50].

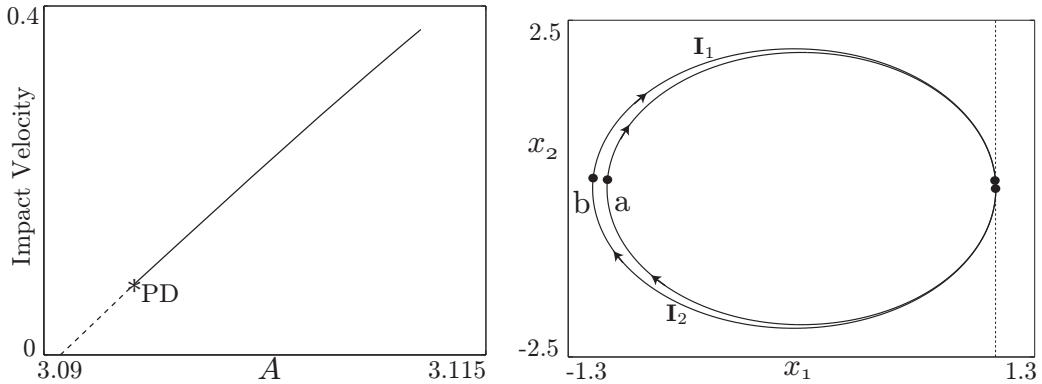

Figure 7. *Left panel: Bifurcation diagram indicating the continuation of an impacting periodic orbit as a function of* A *with a grazing periodic orbit as a starting solution for* $\omega = 2.0209$ *and* $A = 3.0909$*. This impacting periodic trajectory experiences a period-doubling bifurcation at* $A = 3.0951$ *resulting in a stable impacting trajectory. Right panel: Impacting periodic trajectories corresponding to the grazing incidence* (a) *and period-doubling bifurcation* (b) *points from the left panel.*

right panel shows two selected impacting periodic trajectories corresponding to the grazing and period-doubling bifurcation points and the grazing and saddle-node bifurcation points, respectively.

Figure 9 shows the results of two-parameter continuation of the saddle-node and period-doubling bifurcation curves under simultaneous variations in ω and A along with a segment of the grazing bifurcation curve. The former curves terminate at a point ($\omega = 1.9975$ and $A = 2.9966$) of quadratic contact with the grazing curve corresponding to a codimension-two grazing bifurcation point [23, 24, 30, 50].

In the case of the single-parameter continuation of impacting trajectories with cyclic signature $\{\mathbf{I}_1, \mathbf{I}_2\}$ from the grazing bifurcation curve considered above, the direction of continuation

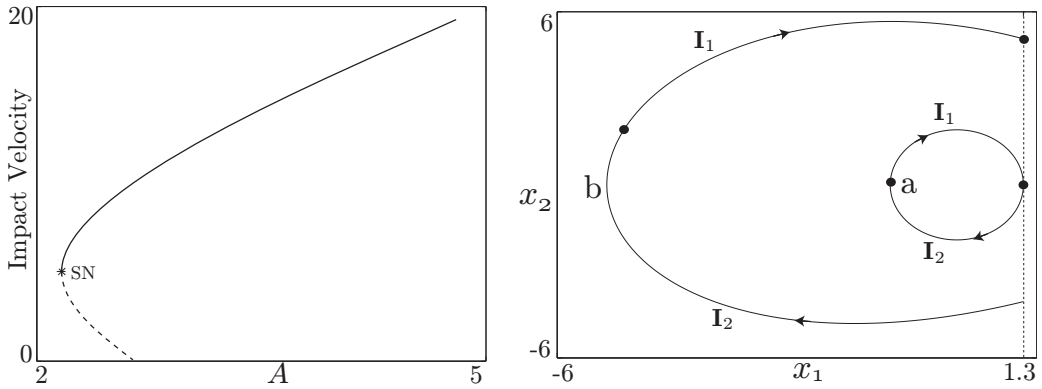

Figure 8. *Left panel: Bifurcation diagram indicating the continuation of an impacting periodic trajectory as a function of A with a grazing periodic trajectory as a starting solution for $\omega = 1.9086$ and $A = 2.6498$. This impacting periodic trajectory experiences a saddle-node bifurcation at $A = 2.1662$ resulting in a stable impacting trajectory. Right panel: Impacting periodic trajectories corresponding to the grazing incidence* (a) *and saddle-node bifurcation points* (b) *from the left panel.*

The saddle-node and period-doubling curves terminate at a joint tangential intersection with the grazing bifurcation curve.*

decides the validity of the solution trajectory obtained. As an example, continuation may result in convergence to a periodic trajectory similar to that shown in Figure 10. While this is a valid solution to the associated boundary-value problem, it is inconsistent with the requirement that event functions be locally decreasing along the corresponding trajectory segments at the corresponding termination points and should thus be discarded.

5.2. A Filippov system with impacts. As a second example, consider a mechanical system consisting of an oscillating mass m pressed against a rough horizontal surface with a corresponding maximum friction force of magnitude F_f [47]. Suppose that the motion of the mass relative to its environment is influenced by a combination of a linear elastic element with stiffness k and instantaneous impacts with coefficient of restitution e with a massive impactor with prescribed displacement time history $q_c(t)$ relative to the position of the mass corresponding to the unstretched length of the spring (cf. Figure 11).

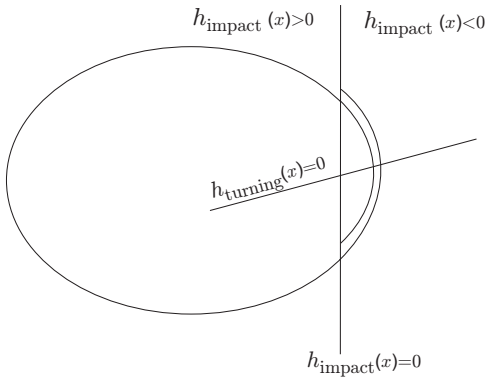

Figure 10. *Valid solution to the boundary value problem with no physical significance.*

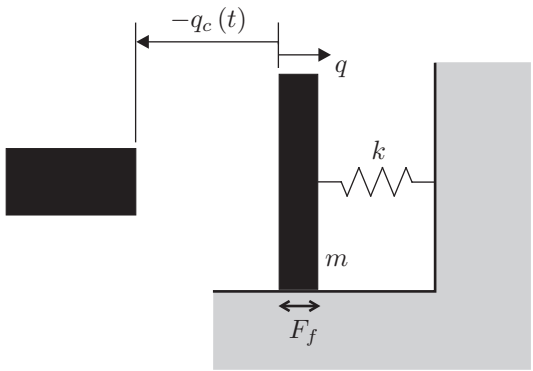

Figure 11. *The lateral motion of the oscillator of mass m is excited by impacts with a massive impactor with prescribed displacement time history $q_c(t)$.*

The dynamics of the oscillator may be formulated as a hybrid dynamical system in the following way. Denote by q the signed displacement of the oscillator relative to the position of unstretched length of the spring. The oscillator motion is then governed by the linear differential equation

$$m\ddot{q} + kq = F \tag{5.1}$$

as long as $q - q_c \geq 0$, where

$$F = \begin{cases} -F_f \frac{\dot{q}}{|\dot{q}|} & \text{for } \dot{q} \neq 0, \\ kq & \text{for } \dot{q} = 0 \text{ and } |kq| \leq F_f \end{cases} \tag{5.2}$$

and is otherwise defined so as to guarantee left-continuity with respect to time along a corresponding time history. Moreover, if

$$\lim_{t \to t_c -} q(t) = q_c(t_c), \quad \lim_{t \to t_c -} \dot{q}(t) \leq \dot{q}_c(t_c) \tag{5.3}$$

for some time $t = t_c$, then

$$\lim_{t \to t_c +} q(t) = q_c(t_c), \quad \lim_{t \to t_c +} \dot{q}(t) = -e \lim_{t \to t_c -} \dot{q}(t) + (1+e)\dot{q}_c(t_c), \tag{5.4}$$

where e is the coefficient of restitution. We again omit from consideration situations in which the oscillator remains in contact with the impactor throughout a solution segment or corresponds to signatures of infinite length.

Suppose that

$$q_c(t) = -b + a\sin\omega t \tag{5.5}$$

for $a, b > 0$, and let

$$\mathbf{x} = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} \stackrel{\text{def}}{=} \begin{pmatrix} q \\ \dot{q} \\ \omega t \ mod\ 2\pi \end{pmatrix} \in \mathbb{R}^2 \times \mathbb{S}^1 \tag{5.6}$$

represent the state of the oscillator. The smooth motion of the oscillator is then governed by the vector fields

$$\mathbf{f}_{\text{positive slip}}(\mathbf{x}) = \begin{pmatrix} x_2 \\ \frac{1}{m}(-F_f - kx_1) \\ \omega \end{pmatrix}, \tag{5.7}$$

$$\mathbf{f}_{\text{negative slip}}(\mathbf{x}) = \begin{pmatrix} x_2 \\ \frac{1}{m}(F_f - kx_1) \\ \omega \end{pmatrix}, \tag{5.8}$$

and

$$\mathbf{f}_{\text{stick}}(\mathbf{x}) = \begin{pmatrix} 0 \\ 0 \\ \omega \end{pmatrix}. \tag{5.9}$$

Impacts between the impactor and the frame occur when

$$h_{\text{impact}}(\mathbf{x}) \stackrel{\text{def}}{=} x_1 - q_c(x_3) = 0, \tag{5.10}$$

resulting in a discontinuous jump in state given by the state jump function

$$\mathbf{g}_{\text{impact}}(\mathbf{x}) = \begin{pmatrix} x_1 \\ -ex_2 + (1+e)\,\omega q_c'(x_3) \\ x_3 \end{pmatrix}. \tag{5.11}$$

Moreover, a discontinuous jump in the phase coordinate x_3 occurs when

$$h_{\text{phase}}(\mathbf{x}) \stackrel{\text{def}}{=} 2\pi - x_3 = 0 \tag{5.12}$$

and corresponds to the state jump function

$$\mathbf{g}_{\text{phase}}(\mathbf{x}) = \begin{pmatrix} x_1 \\ x_2 \\ 0 \end{pmatrix}. \tag{5.13}$$

Discontinuous changes in the vector field are associated with intersections of system trajectories with the event surface

$$h_{\text{stick}\pm}(\mathbf{x}) \stackrel{\text{def}}{=} \pm x_2 = 0. \tag{5.14}$$

Finally, for purposes of detection of grazing events with the event surface corresponding to h_{impact}, consider the event function

$$h_{\text{turning}}(\mathbf{x}) \stackrel{\text{def}}{=} x_2 - \omega q_c'(x_3) \tag{5.15}$$

and the associated state jump function

$$\mathbf{g}_{\text{identity}}(\mathbf{x}) = \mathbf{x} \tag{5.16}$$

(cf. Figure 12).

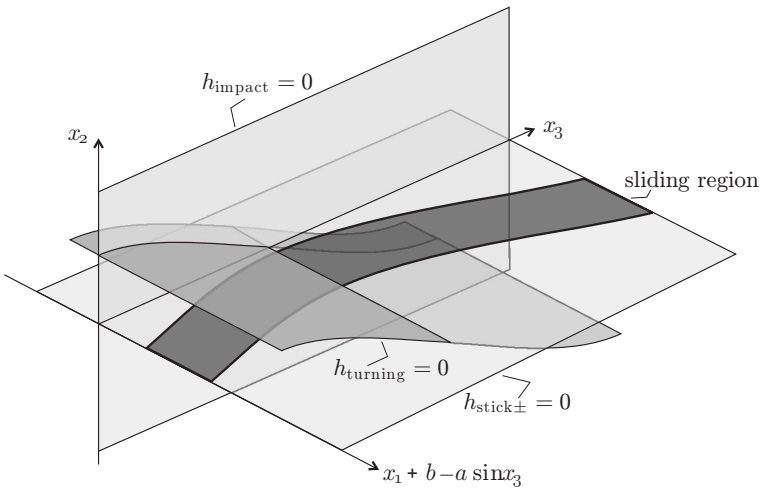

Figure 12. *A state-space schematic of the event surfaces describing the dynamics of the Filippov oscillator with impacts.*

A periodic trajectory of this hybrid dynamical system may be characterized in terms of a sequence of triplets of the form $(\mathbf{f}, h, \mathbf{g})$ corresponding to a solution segment governed by the vector field $\mathbf{f}$, terminating on the event surface corresponding to h, and connected to the next solution segment by the state jump function $\mathbf{g}$ as per the following list:

$$\mathbf{I}_1 = (\mathbf{f}_{\text{positive slip}}, h_{\text{impact}}, \mathbf{g}_{\text{impact}}), \tag{5.17}$$

$$\mathbf{I}_2 = (\mathbf{f}_{\text{positive slip}}, h_{\text{phase}}, \mathbf{g}_{\text{phase}}), \tag{5.18}$$

$$\mathbf{I}_3 = (\mathbf{f}_{\text{positive slip}}, h_{\text{stick}+}, \mathbf{g}_{\text{identity}}), \tag{5.19}$$

$$\mathbf{I}_4 = (\mathbf{f}_{\text{positive slip}}, h_{\text{turning}}, \mathbf{g}_{\text{identity}}), \tag{5.20}$$

$$\mathbf{I}_5 = (\mathbf{f}_{\text{negative slip}}, h_{\text{impact}}, \mathbf{g}_{\text{impact}}), \tag{5.21}$$

$$\mathbf{I}_6 = (\mathbf{f}_{\text{negative slip}}, h_{\text{phase}}, \mathbf{g}_{\text{phase}}), \tag{5.22}$$

$$\mathbf{I}_7 = (\mathbf{f}_{\text{negative slip}}, h_{\text{stick}-}, \mathbf{g}_{\text{identity}}), \tag{5.23}$$

$$\mathbf{I}_8 = (\mathbf{f}_{\text{negative slip}}, h_{\text{turning}}, \mathbf{g}_{\text{identity}}), \tag{5.24}$$

$$\mathbf{I}_9 = (\mathbf{f}_{\text{stick}}, h_{\text{impact}}, \mathbf{g}_{\text{impact}}), \tag{5.25}$$

$$\mathbf{I}_{10} = (\mathbf{f}_{\text{stick}}, h_{\text{phase}}, \mathbf{g}_{\text{phase}}), \tag{5.26}$$

$$\mathbf{I}_{11} = (\mathbf{f}_{\text{stick}}, h_{\text{turning}}, \mathbf{g}_{\text{identity}}) \tag{5.27}$$

(cf. Figure 13). In particular, a solution will be termed *impacting* if its signature contains $\mathbf{I}_1$, $\mathbf{I}_5$, and/or $\mathbf{I}_9$ and *nonimpacting* otherwise. Similarly, a solution will be termed *slipping* if its signature does not contain $\mathbf{I}_9$, $\mathbf{I}_{10}$, or $\mathbf{I}_{11}$, *sticking* if its signature contains only $\mathbf{I}_9$, $\mathbf{I}_{10}$, and/or $\mathbf{I}_{11}$, and a *stick-slip oscillation* otherwise.

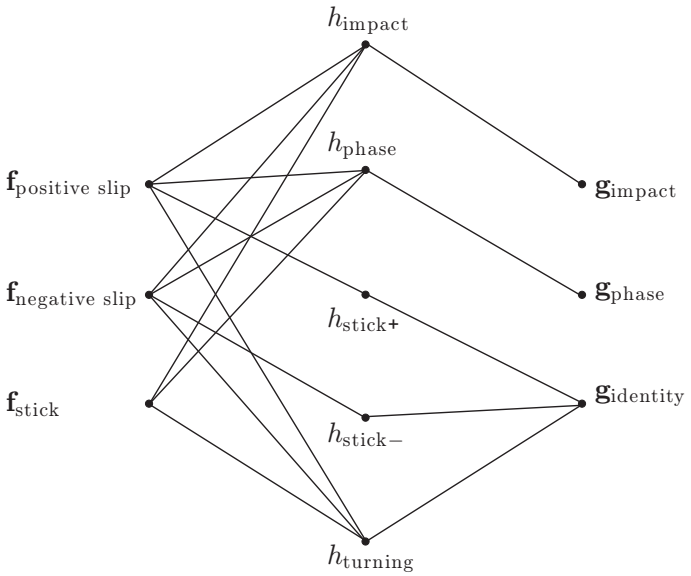

Figure 13. *Each branch of this graph based at an element in the leftmost column corresponds to the characterization of a solution segment of the Filippov system with impacts in terms of a triplet* $(\mathbf{f}, h, \mathbf{g})$.

This hybrid dynamical system is an example of a Filippov system with switching manifold given by the zero-level surface of $h_{\text{stick}+}$ (or, equivalently, $h_{\text{stick}-}$). Here, the sliding region is given by

$$-1 \leq h_{\text{sliding}}(\mathbf{x}) = \frac{kx_1}{F_f} \leq 1. \tag{5.28}$$

The vector field $\mathbf{f}_{\text{stick}}$ then corresponds to the *sliding vector field* (as per Utkin's equivalent control method [52]) along the sliding region.

The left panel of Figure 14 shows a periodic trajectory of the hybrid dynamical system for $m = 1$, $a = 1$, $\omega = 1$, $e = 0.9$, $k = 6$, $F_f = 0.7961$, and $b = 0.8471$ with cyclic signature $\{\mathbf{I}_9, \mathbf{I}_3, \mathbf{I}_7, \mathbf{I}_3, \mathbf{I}_{10}\}$. The corresponding branch of periodic trajectories under single-parameter variations in k is shown in the right panel of Figure 14. In particular, one end of the branch is seen to terminate at a point $k = 8.0544$, where the third segment of the periodic trajectory

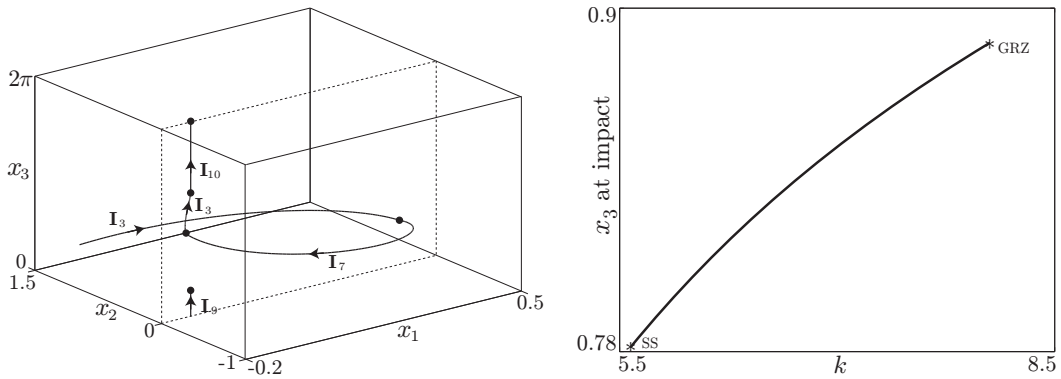

Figure 14. *Left panel: Periodic trajectory of the hybrid dynamical system for* $r = 0.9$, $k = 6$, $F_f = 0.7961$, *and* $b = 0.8471$. *Right panel: Single parameter continuation using the periodic trajectory in the left panel as an initial condition and varying* k.

achieves grazing incidence with the event surface corresponding to h_{impact}. Similarly, the other end of the branch terminates at $k = 5.5731$ as the third segment of the periodic trajectory terminates on the left boundary of the sliding region. The left and right panels of Figure 15 show the corresponding periodic trajectories.

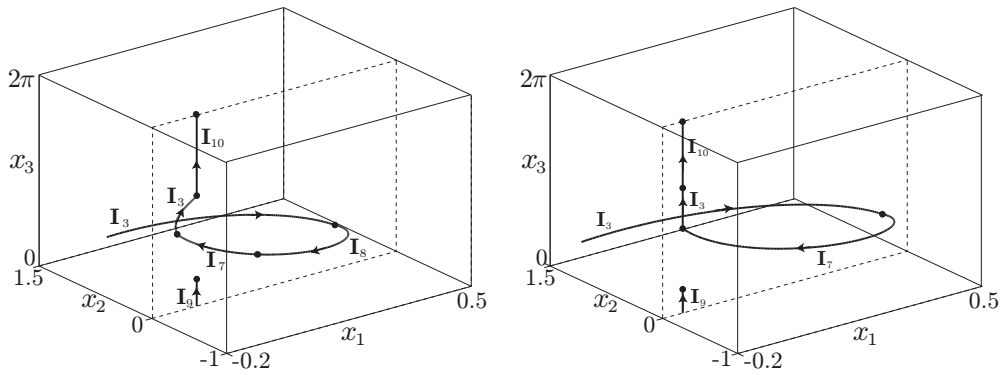

Figure 15. *Left panel: Periodic trajectory of the given hybrid dynamical system for* $k = 8.0544$ *that achieves grazing incidence with the event surface corresponding to* h_{impact}. *Right panel: Periodic trajectory of the given hybrid dynamical system for* $k = 5.5731$ *that intersects the switching manifold on the boundary of the sliding region.*

The dash-dotted curve in Figure 16 shows a two-parameter continuation of the grazing bifurcation curve under simultaneous variations in k and b based at an equivalent resegmentation with cyclic signature $\{\mathbf{I}_8, \mathbf{I}_7, \mathbf{I}_3, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ of the trajectory shown in the left panel of Figure 15. Resegmentation is here achieved by splitting the $\mathbf{I}_7$ segment into an $\mathbf{I}_8$ segment that terminates on the $h_{\text{turning}} = 0$ event surface followed by a truncated $\mathbf{I}_7$ segment and subsequently reordering the signature so that the additional boundary condition $h_{\text{impact}} = 0$ is applied to the terminal point of the first segment.

Two-parameter continuation of the sliding bifurcation curve under simultaneous variations in k and b based at the trajectory shown in the right panel of Figure 15 requires, at the very

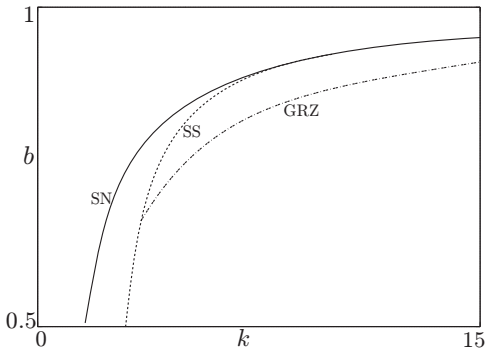

Figure 16. *Two parameter continuations of the grazing, sliding, and saddle-node bifurcation curves in the* (k, b) *parameter space.*

least, a reordering $\{\mathbf{I}_7, \mathbf{I}_3, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ of the cyclic signature so that the additional boundary condition $h_{\text{sliding}} = -1$ may be applied to the terminal point of the first segment. Some care is necessary, however, to ensure a nonsingular boundary-value problem. Specifically, in the limit as the $\mathbf{I}_7$ segment of the original periodic trajectory terminates on the left boundary of the sliding region, it follows from (5.7) and (5.9) that the subsequent $\mathbf{I}_3$ segment converges to a portion of the equilibrium trajectory $x_1 = -\frac{F_f}{k}$ and $x_2 = 0$ of the $\mathbf{f}_{\text{positive slip}}$ and $\mathbf{f}_{\text{stick}}$ vector fields, and terminates after a fixed time $\pi\sqrt{\frac{m}{k}}$ at a *nontransversal* event on $x_2 = 0$. In this limit, the cyclic signature $\{\mathbf{I}_7, \mathbf{I}_3, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ thus corresponds to a singular boundary-value problem and cannot be used for continuation of the sliding bifurcation.

A nonsingular boundary-value formulation may be obtained by replacing the terminal condition on the singular $\mathbf{I}_3$ segment with the condition that the segment's time-of-flight equal $\pi\sqrt{\frac{m}{k}}$. In this formulation, the correction matrix equation (2.21) corresponding to the singular $\mathbf{I}_3$ segment is given by the identity matrix. This permits two-parameter continuation of the sliding bifurcation curve under simultaneous variations in k and b (the dashed curve in Figure 16) and is consistent with subsequent one-parameter continuation under variations in k away from the sliding bifurcation curve using the original $\{\mathbf{I}_7, \mathbf{I}_3, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ boundary-value formulation.

Alternatively, a nonsingular boundary-value formulation may be obtained by replacing the terminal condition on the singular $\mathbf{I}_3$ segment with the condition that k be constant. This permits one-parameter continuation under variations in the segment's time-of-flight while retaining k among the unknowns of the boundary-value problem. For example, the singular $\mathbf{I}_3$ segment's time-of-flight may be reduced to zero while equivalently extending the subsequent $\mathbf{I}_{10}$ segment.

An alternative nonsingular boundary formulation may now be obtained by replacing the terminal condition on the singular $\mathbf{I}_3$ segment with the condition that the segment's time-of-flight equal 0. This again permits two-parameter continuation of the sliding bifurcation curve under simultaneous variations in k and b but is not consistent with subsequent one-parameter continuation away from the sliding bifurcation curve.

Finally, an equivalent resegmentation with cyclic signature $\{\mathbf{I}_7, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ may be obtained by replacing the consecutive $\mathbf{I}_3$ and $\mathbf{I}_{10}$ segments with a single extended $\mathbf{I}_{10}$ segment. This

is equivalent to eliminating the zero-length $\mathbf{I}_3$ segment obtained using the first alternative boundary-value formulation. This again permits two-parameter continuation of the sliding bifurcation curve under simultaneous variations in k and b and is consistent with subsequent one-parameter variation without the need for further resegmentation.

Indeed, a branch of periodic trajectories with cyclic signature $\{\mathbf{I}_7, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ can be shown to emanate from the sliding bifurcation point at $k = 5.5731$. A saddle-node bifurcation is found along this branch at $k = 4.9517$. The solid curve in Figure 16 shows the corresponding saddle-node bifurcation curve. It is curious to note that the grazing bifurcation curve appears to terminate on the sliding bifurcation curve at a point of transversal intersection, whereas the sliding bifurcation curve terminates on the saddle-node curve at a point of tangential contact. In the former case, the termination point is likely artificial, as a continuation with modified signature $\{\mathbf{I}_8, \mathbf{I}_7, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ should exist beyond this point. In contrast, the latter case is an example of a codimension-two sliding bifurcation (cf. [41]).

5.3. A heuristic cell-cycle model. As a final example, consider the biochemical reactions governing the activity of a set of biomolecules during distinct stages in the cell cycle of eukaryotes [51]. Here, the initiation of characteristic transitions during the cell cycle are reduced to variations in the concentrations of specific cyclin-enzyme dimers that catalyze the phosphorylation of key cell proteins. The activity of such cyclin/Cdk (cyclin-dependent kinase) dimers in the cell nucleus is controlled by a nonlinear feedback loop that regulates the availability of cyclin and various inhibitory agents. Specifically, the replication of DNA is triggered by increased levels of cyclin synthesis and reduced levels of cyclin degradation. Similarly, anaphase-promoting complexes (APCs) that enable the segregation of the chromatids during mitosis increase the level of cyclin degradation during telophase, returning the cell to its resting state.

Denote by x_1, x_2, and x_3 the concentrations of cyclin/Cdk dimers, active Cdh1/APCs, and the Cdh1/APC activator Cdc14, respectively. In this heuristic model, cyclin/Cdk dimers activate Cdc20/APCs while inhibiting Cdh1/APCs. Active Cdc20/APCs destroy an inhibitor of Cdc14, which in turn counters the inhibitory action of cyclin/Cdk on Cdh1/APCs. Finally, active Cdh1/APCs destroy cyclin. Denote by x_4 the cell mass, and suppose that during the cell's growth phase its rate of growth is independent of the concentrations of the biomolecules considered here. Cell division is assumed to be effectively instantaneous and triggered by the concentration of cyclin/Cdk dimers falling below a critical level x_1^*.

The dynamics of the cell-cycle model may be formulated as a hybrid dynamical system in the following way. Smooth variations in the state variables are governed by the vector field

$$\mathbf{f}_{\text{growth}}(\mathbf{x}) = \begin{pmatrix} k_1 - (k_2' + k_2'' x_2)\, x_1 \\ \frac{(k_3' + k_3'' x_3)(1 - x_2)}{J_3 + 1 - x_2} - \frac{k_4 x_1 x_2 x_4}{J_4 + x_2} \\ k_5' + k_5'' \frac{(x_1 x_4)^n}{J_5^n + (x_1 x_4)^n} - k_6 x_3 \\ \mu x_4 \left(1 - \frac{x_4}{x_4^*}\right) \end{pmatrix}, \tag{5.29}$$

where k_1, k_2', k_2'', k_3', k_3'', k_4, k_5', k_5'', and k_6 are rate constants, J_3, J_4, and J_5 are Michaelis–Menten constants (see [51]), n is some integer, μ is the linear growth rate in the limit of

$x_4 \ll x_4^*$, and x_4^* is the limiting cell mass in the absence of division events. Mitosis occurs when

$$h_{\text{mitosis}}(\mathbf{x}) = x_1 - x_1^*,$$

resulting in a discontinuous jump in state given by the state jump function

$$\mathbf{g}_{\text{mitosis}}(\mathbf{x}) = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4/2 \end{pmatrix}. \tag{5.30}$$

Let $\mathfrak{M} = \{\mathfrak{growth}\}$ and $\mathfrak{E} = \{\mathfrak{mitosis}\}$ such that $\mathbf{f}_{\mathfrak{growth}} = \mathbf{f}_{\text{growth}}$ and

$$\mathfrak{mitosis} \doteq \begin{bmatrix} (\mathfrak{growth}, \mathfrak{growth}) \\ h_{\text{mitosis}} \\ \mathbf{g}_{\text{mitosis}} \end{bmatrix} \tag{5.31}$$

and such that periodic trajectories have signatures consisting of one or several copies of the pair

$$\mathbf{I}_1 = (\mathfrak{growth}, \mathfrak{mitosis}). \tag{5.32}$$

The left panel of Figure 17 shows a periodic trajectory when $k_1 = 0.04$, $k_2' = 0.04$, $k_2'' = 1.0$, $k_3' = 1.0$, $k_3'' = 10.0$, $k_4 = 35.0$, $k_5' = 0.005$, $k_5'' = 0.2$, $k_6 = 0.1$, $J_3 = 0.04$, $J_4 = 0.04$, $J_5 = 0.3$, $n = 4$, $\mu = 0.01$, $m^* = 10.0$, and $x_1^* = 0.1$. A single-parameter continuation of this periodic trajectory with the cyclic signature $\{\mathbf{I}_1\}$ under variations in k_3'' is shown in the right panel of Figure 17. The corresponding branch of stable limit cycle terminates is limited by two saddle-node bifurcations at $k_3'' = 7.0213$ and $k_3'' = 45.1157$, respectively. A two-parameter continuation of the leftmost of these saddle-node bifurcations under simultaneous variations in k_3'' and k_5'' is shown in Figure 18.

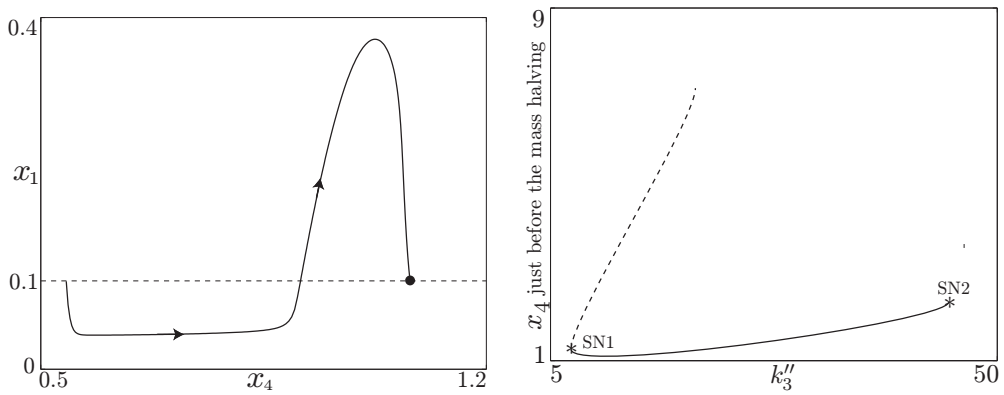

Figure 17. *Left panel: Periodic trajectory of the hybrid dynamical system for $k_3'' = 10$. Right panel: Single parameter continuation with varying k_3'' of the periodic trajectory shown in the left panel. Loci of saddle-node bifurcations SN1 and SN2 are evident in the figure.*

6. Discussion. The preponderance of physical and biological systems that are modeled with hybrid dynamical systems makes the task of providing user-friendly computational tools for bifurcation analysis pressing. The existing package SLIDECONT was a first step in this direction with emphasis on Filippov systems in the plane and with the ability to provide a comprehensive bifurcation analysis of equilibria and selected bifurcation analysis of periodic trajectories. The boundary-value formulation introduced here extends SLIDECONT's formulation to enable successful continuation of multisegment periodic trajectories in general hybrid dynamical systems and selected associated codimension-one bifurcations. It should be straightforward to arrive at similar formulations in the case of other codimension-one bifurcations associated with the eigenvalue spectrum, for example, torus bifurcations.

It should also be possible to modify the more general boundary-value formulation to accommodate efforts to locate and continue multisegment homo- and heteroclinic trajectories between equilibria and/or limit cycles in hybrid dynamical systems (cf. [7, 15, 25, 46]). A related challenge is the task of locating and continuing periodic trajectories of a hybrid dynamical system consisting of a countable set of segments with (at least) one point of accumulation of the switching times t_j. As in the case of homo- or heteroclinic trajectories, this necessitates omitting from the boundary-value formulation an infinite set of equations for $|t|$ larger than some critical T in the homo- or heteroclinic case and for t in some finite interval in the case of finite-time accumulation. In the latter case, however, rather than relying on a linear approximation of the stable and unstable manifolds, it becomes necessary to provide a connectivity condition between the accumulation point and the final nonignored event [43].

A more challenging task is that of *branch switching* between branches of distinct signature, in which domain-specific knowledge (as captured by the index jump function) is coupled with a local unfolding of singularities in parameter space corresponding to the intersection of distinct branches. Instances of such switching were discussed in the examples above (see also [32]) and relied in all cases on an understanding of the types of signature changes that could be achieved in a manner consistent with the conditions of forward simulation and with a continuous change in the segment structure. This poses a particular challenge in the case of singularities associated with the onset of grazing contact in systems with mechanical impact-like discontinuities. Here, infinitely many branches of periodic trajectories may emanate

continuously from the singularity. Methods of unfolding, such as the discontinuity-mapping technique [42], could then be used to provide tangent directions to the corresponding trajectory branches at the singularity.

The implementation of $\widehat{\text{TC}}$ as a driver for a modified version of AUTO 97 enables a range of automated continuation tasks without the need to recreate the necessary source code infrastructure. As AUTO 97 is designed to handle only two-point boundary-value problems, however, this necessitates a numerically ill-advised segment-independent time partition that is unable to adapt the partition of each segment to local properties. An obvious implication is the sudden growth of problem dimension that occurs, for example, with the addition of a solution segment with zero time-of-flight. As AUTO 97 implements direct matrix-equation solvers, this growth in dimension affects both CPU time as well as solution accuracy. There is also no direct attempt made to exploit the block structure of the linearized equations. More generally, the partition scheme will likely be dominated by features on the geometrically most complex segment, requiring unnecessarily fine discretization for other segments. These shortcomings are likely to become pronounced for solutions with long signatures. Collectively, these observations warrant a redesign of $\widehat{\text{TC}}$ that accommodates segment-specific meshing algorithms and that exploits the (sparse) structure of the linearized equations.

An exhaustive quantitative comparison of the numerical performance of the implementation of $\widehat{\text{TC}}$ within AUTO 97 is beyond the scope of this manuscript. A preliminary demonstration of the effect of the boundary-value formulation is afforded, e.g., by investigating the accuracy with which the switching-sliding bifurcation point is detected under single-parameter variations of k in the Filippov system with impacts discussed in section 5.2 using the different equivalent segmentations of the critical periodic trajectory. It follows directly from explicit expressions for the flows corresponding to the distinct vector fields $\mathbf{f}_{\text{stick}}$, $\mathbf{f}_{\text{positive slip}}$, and $\mathbf{f}_{\text{negative slip}}$ that periodic trajectories with cyclic signature $\{\mathbf{I}_7, \mathbf{I}_3, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ correspond to fixed points $\tilde{x}^*$ on the interval $[-1, 1]$ of the map

$$\tilde{x} \longmapsto \sqrt{(1+\tilde{x})^2 + \Omega^2\left(\tilde{a}^2 - \left(\tilde{b}+\tilde{x}\right)^2\right)} - 5, \tag{6.1}$$

where

$$\tilde{x} = \frac{kq_0}{F_f}, \quad \tilde{a} = \frac{ka}{F_f}, \quad \tilde{b} = \frac{kb}{F_f}, \quad \Omega = (1+e)\,\omega\sqrt{\frac{m}{k}}, \tag{6.2}$$

and q_0 is the initial position of the oscillator at the beginning of the $\mathbf{I}_9$ segment. In particular,

$$\tilde{x}^* = \frac{-4 - \tilde{b}\Omega^2 + \sqrt{16 - 24\Omega^2 + 8\tilde{b}\Omega^2 + \tilde{a}^2\Omega^4}}{\Omega^2} \tag{6.3}$$

corresponds to the branch shown in the right panel of Figure 14. The switching-sliding bifurcation then corresponds to

$$\Omega^2 = \frac{16}{\tilde{a}^2 - \left(\tilde{b}-1\right)^2}, \tag{6.4}$$

and the corresponding nonzero Floquet multiplier is given by

$$\frac{4\left(1-\tilde{b}\right)}{\tilde{a}^2-\left(\tilde{b}-1\right)^2}. \tag{6.5}$$

Similarly, periodic trajectories with cyclic signature $\{\mathbf{I}_7, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ correspond to fixed points $\tilde{x}^*$ on the interval $[-1, 1]$ of the map

$$\tilde{x} \longmapsto 3-\sqrt{(1+\tilde{x})^2+\Omega^2\left(\tilde{a}^2-\left(\tilde{b}+\tilde{x}\right)^2\right)}. \tag{6.6}$$

In particular,

$$\tilde{x}^* = \frac{4-\tilde{b}\Omega^2-\sqrt{16-8\Omega^2-8\tilde{b}\Omega^2+\tilde{a}^2\Omega^4}}{\Omega^2} \tag{6.7}$$

corresponds to the branch of four-segment trajectories emanating from the switching-sliding bifurcation curve and the corresponding nonzero Floquet multiplier is now given by

$$\frac{4\left(\tilde{b}-1\right)}{\tilde{a}^2-\left(\tilde{b}-1\right)^2}. \tag{6.8}$$

Table 1 shows the absolute difference between estimated values (k_5, λ_5) and (k_4, λ_4), respectively, of the value of k and the nonzero Floquet multiplier λ at the switching-sliding bifurcation point detected using $\widehat{\text{TC}}$ during single-parameter variation of periodic trajectories with cyclic signatures $\{\mathbf{I}_7, \mathbf{I}_3, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ and $\{\mathbf{I}_7, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ and those predicted from (6.4)–(6.5). Here, the AUTO 97 constants *NTST*, *NCOL*, *EPSL*, *EPSU*, and *EPSS* refer to the number of discretization intervals per segment, the number of collocation points per discretization interval, the convergence tolerance for free parameters and for solutions, and the continuation step size tolerance when locating special solutions, respectively.

Table 1

Absolute difference between estimated values (k_5, λ_5) and (k_4, λ_4), respectively, of the value of k and the nonzero Floquet multiplier λ at the switching-sliding bifurcation point detected using $\widehat{\text{TC}}$ during single-parameter variation of periodic trajectories with cyclic signatures $\{\mathbf{I}_7, \mathbf{I}_3, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ and $\{\mathbf{I}_7, \mathbf{I}_{10}, \mathbf{I}_9, \mathbf{I}_3\}$ and those predicted from (6.4)–(6.5). Here, $EPSL = EPSU = 10^{-6}$, $EPSS = 10^{-4}$, and $NCOL = 4$.

Realization of Critical Eigenvalues for Scalar and Symmetric Linear Delay-Differential Equations*

P.-L. Buono† and V. G. LeBlanc‡

Abstract. This paper studies the link between the number of critical eigenvalues and the number of delays in certain classes of delay-differential equations. There are two main results. The first states that for k purely imaginary numbers which are linearly independent over the rationals, there exists a scalar delay-differential equation depending on k fixed delays whose spectrum contains those k purely imaginary numbers. The second result is a generalization of the first result for delay-differential equations which admit a characteristic equation consisting of a product of s factors of scalar type. In the second result, the k eigenvalues can be distributed among the different factors. Since the characteristic equation of scalar equations contain only exponential terms, the proof exploits a toroidal structure which comes from the arguments of the exponential terms in the characteristic equation. Our second result is applied to delay coupled $\mathbf{D}_n$-symmetric cell systems with one-dimensional cells. In particular, we provide a general characterization of delay coupled $\mathbf{D}_n$-symmetric systems with an arbitrary number of delays and cell dimension.

Key words. bifurcation, delay-differential equations, symmetry, realizability

1. Introduction and background.

Delay-differential equations (DDEs) have been used as mathematical models for phenomena in population dynamics [21], physiology [12, 3], physics [23], climate modeling [26, 28], and engineering [27], among others. DDEs behave like abstract ordinary differential equations (ODEs) on an infinite-dimensional (Banach) phase space and many results which are known for ODEs on finite-dimensional spaces have analogues in the context of DDEs. Many scalar DDE models have been developed over the years, such as for Cheynes–Stokes respiration [12] and the regulation of hematopoiesis [12], the delayed Nicholson blowflies equation [18] in population dynamics, a two-delay model of an experiment on Parkinsonian tremor [2], and many more.

The bifurcation analysis of DDEs is done essentially in the same way as that of ODEs, although the technical details differ. Consider the neighborhood of an equilibrium solution of a nonlinear DDE; then the analysis of the linearization at the equilibrium point leads to stable, unstable, and center invariant subspaces where only the stable subspace is infinite-dimensional. There exist local invariant manifolds (stable, unstable, and center manifolds) tangent to the

corresponding invariant subspaces of the linearized equations about the equilibrium point on which the flow near the equilibrium is exponentially attracting (stable manifold), exponentially repelling (unstable manifold), or nonhyperbolic (center manifold). Now, bifurcations near equilibria are determined by the flow on the center manifold, and the dimension of this manifold is determined by the number of eigenvalues of the linearization on the imaginary axis.

The first result of our paper is Theorem 2.1 and goes as follows. Consider n nonzero imaginary numbers $i\omega_1, \ldots, i\omega_n$, where the imaginary parts $\omega_1, \ldots, \omega_n$ are positive and not rationally dependent. We show that there exists a scalar linear DDE depending on n discrete delays written

$$\dot{x} = \sum_{j=1}^{n} a_j x(t - \tau_j), \tag{1}$$

where $x \in \mathbb{R}$, $a_j \in \mathbb{R}$, and $\tau_j \in [0, \tau]$ for all $j = 1, \ldots, n$ such that the characteristic equation of (1), given by

$$\lambda - \sum_{j=1}^{n} a_j e^{-\lambda \tau_j} = 0, \tag{2}$$

has eigenvalues $\pm i\omega_1, \ldots, \pm i\omega_n$. This result generalizes explicit computations done in the case of one and two delays; see [20, 9, 1]. The proof is done by embedding the problem as a mapping which is solved by the implicit function theorem at a carefully chosen point. From the implicit function theorem, we are able to define a smooth mapping whose transversal intersection with a dense curve on an n-dimensional torus provides solutions. The incommensurability of the n frequencies enables us to define the dense curve on the n-torus. This type of argument using a dense curve on an n-dimensional torus was used in Choi and LeBlanc [7].

This result falls within the category of so-called realization theorems, for instance, the realization theorem of linear ODEs by linear DDEs obtained by Faria and Magalhães [11]. They show that for any finite-dimensional matrix B, a necessary and sufficient condition for the existence of a bounded linear operator $\mathcal{L}_0$ from $C([-\tau, 0], \mathbb{R}^n)$ into $\mathbb{R}^n$ with infinitesimal generator having spectrum containing the spectrum of B is that n be larger than or equal to the largest number of Jordan blocks associated with each eigenvalue of B. Other results in this direction are concerned with the realization of finite jets of ODEs on a finite-dimensional center manifold by DDEs; see [11, 7]. To our knowledge, the realization theorems in this paper are the first general results linking the number of critical eigenvalues of linear DDEs with the number of discrete delays.

The next significant result is an openness theorem, that is, the realization of n imaginary numbers (not necessarily rationally independent) as eigenvalues of a linear scalar DDE is valid in a neighborhood of any set of n rationally independent imaginary numbers. The proof of this theorem also relies on the implicit function theorem.

We then turn our attention to the context of symmetric systems of DDEs. Several examples of symmetric systems of DDEs [16, 24] have characteristic equations which decompose in factors, some of which have the same form as the characteristic equation (2). The decomposition of the characteristic equation is induced by the isotypic decomposition of the space,

and we present a general derivation of this decomposition. We show that isotypic components consisting of a unique one-dimensional complex irreducible representation contribute a factor of the form (2) in the characteristic equation, and so Theorem 2.1 can be applied directly to each such factor separately.

We present a generalization of Theorem 2.1 to the case where several factors of the characteristic equation have purely imaginary eigenvalues simultaneously. Theorem 2.4 shows that a set of n rationally independent purely imaginary complex numbers can be realized from several factors of the characteristic equation of a DDE with n delays given that two nondegeneracy conditions on the characteristic equation are satisfied. The statement of the theorem is independent of any symmetric structure, and the proof is a generalization of the proof of Theorem 2.1.

We illustrate the above result on $\mathbf{D}_n$-symmetric rings of n delay equations with delayed coupling. Hopf bifurcation from such symmetric networks has been studied by several authors [6, 10, 15, 16, 17, 24, 25, 29, 30]. We study only the case in which n is odd, since, for n even, one of the nondegeneracy conditions of Theorem 2.4 is not always satisfied, as we illustrate in a $\mathbf{D}_4$ example.

In order to apply Theorem 2.4 to this context, we derive an explicit form of the coupling matrix in terms of the connections in the graph representation of the ring for cells of any dimension and arbitrary numbers of connections and delays. This is a generalization of the networks considered in the articles listed in the previous paragraph. We specialize to the case of one-dimensional cells and show how Theorem 2.4 applies to $\mathbf{D}_n$-symmetric coupled cell systems with n odd.

The paper is organized as follows. The first section contains brief preliminary remarks, and then we state and prove our main result (Theorem 2.1) and the openness result (Theorem 2.2). Then we introduce the context leading to Theorem 2.4 and state this result. Section 3 is devoted to Γ-symmetric systems of DDEs, and the section begins with a general discussion. Section 3.1 presents a characterization of $\mathbf{D}_n$-symmetric rings of delay coupled cells with an arbitrary number of delays, and the characteristic equation in the case of one-dimensional cells is derived. Theorem 2.4 is applied to $\mathbf{D}_n$-symmetric rings of one-dimensional cells with n odd. Section 4 contains the proof of Theorem 2.4. We conclude with a discussion of open problems along the lines of those presented in this paper.

2. Realization theorems. We now discuss some aspects of the spectral theory of linear scalar DDEs. In fact, we just introduce the basic facts, in a nonabstract setting, needed for the statement of our first main theorem. For a complete treatment, see Diekmann et al. [9] or Hale and Verduyn-Lunel [20].

Consider the scalar DDE

$$\dot{x}(t) = \sum_{j=1}^{n} a_j x(t-\tau_j), \tag{3}$$

where $a_j \in \mathbb{R}$ and $\tau_j \in [0,\tau]$ for all $j = 1,\dots,n$ and $\tau > 0$. The characteristic equation for (3) can be obtained by substituting $x(t) = Ce^{\lambda t}$, where C is a constant, into the equation. Thus,

$$\lambda C e^{\lambda t} = \sum_{j=1}^{n} a_j C e^{\lambda(t-\tau_j)} = \sum_{j=1}^{n} a_j C e^{-\lambda\tau_j} e^{\lambda t},$$

and by rearranging the terms we obtain

$$\left(\lambda - \sum_{j=1}^{n} a_j e^{-\lambda\tau_j}\right) x(t) = 0.$$

So, $x(t)$ is a nonzero solution of (3) if and only if

$$\Delta(\lambda) := \lambda - \sum_{j=1}^{n} a_j e^{-\lambda\tau_j} = 0.$$

The complex number λ is an eigenvalue of equation (3) if it is a solution of the characteristic equation $\Delta(\lambda) = 0$.

The question we address in this paper is related to the number of imaginary eigenvalues (with incommensurable frequencies) which can satisfy $\Delta(\lambda) = 0$. The case $n = 1$ with one nonzero delay is a straightforward calculation and $\Delta(\lambda) = 0$ for only one nonzero imaginary eigenvalue λ; see [20]. The case $n = 2$ with $\tau_1 = 0$ and $\tau_2 \in (0, \tau]$ in (3) can be found in [9]. There, it is shown that $\Delta(\lambda) = 0$ can have at most two nonzero imaginary eigenvalues. The case $n = 2$ with $\tau_1, \tau_2 > 0$ is done in [1], where it is shown that $\Delta(\lambda) = 0$ can have at most two nonzero imaginary eigenvalues. We are now ready to state our first result.

Theorem 2.1. *Suppose* $\omega_1 > 0$, $\omega_2 > 0$, $\ldots$, $\omega_n > 0$ *are linearly independent over the rationals. Then there exist* $\tau_1 > 0$, $\tau_2 > 0$, $\ldots$, $\tau_n > 0$, $a_1 \in \mathbb{R}$, $a_2 \in \mathbb{R}$, $\ldots$, $a_n \in \mathbb{R}$ *such that the linear DDE*

$$\dot{x}(t) = a_1\, x(t-\tau_1) + a_2\, x(t-\tau_2) + \cdots + a_n\, x(t-\tau_n) \tag{4}$$

has solutions $x_j^{\pm}(t) = e^{\pm\, i\omega_j t}$ *for all* $j = 1, \ldots, n$.

Proof. A necessary and sufficient condition for the conclusion of the theorem to hold is that the algebraic system of $2n$ equations

$$\begin{aligned} \sum_{k=1}^{n} a_k\, e^{-i\omega_j\tau_k} &= i\omega_j, \qquad j = 1, \ldots, n, \\ \sum_{k=1}^{n} a_k\, e^{i\omega_j\tau_k} &= -i\omega_j, \quad j = 1, \ldots, n, \end{aligned} \tag{5}$$

has a solution in the $2n$ unknowns $(\tau_1, \tau_2, \ldots, \tau_n, a_1, a_2, \ldots, a_n)$. Although (5) is in complex form, since the second equation in (5) is just the complex conjugate of the first equation in (5), system (5) is equivalent to a system of $2n$ *real* equations. This fact is taken for granted throughout what follows, even though we continue to use complex notation.

It is useful to use the following matrix notation for (5):

$$\begin{pmatrix} P(\tau;\omega) \\ P(-\tau;\omega) \end{pmatrix} A^T = \begin{pmatrix} i\omega^T \\ -i\omega^T \end{pmatrix}, \tag{6}$$

where $\tau = (\tau_1, \ldots, \tau_n)$, $\omega = (\omega_1, \ldots, \omega_n)$, $A = (a_1, \ldots, a_n)$, superscript T denotes transpose, and $P(\tau;\omega) = P(\tau_1, \ldots, \tau_n; \omega_1, \ldots, \omega_n)$ is the $n \times n$ matrix whose entry at row j column k is

$$[\, P(\tau;\omega)\,]_{jk} = e^{-i\omega_j\tau_k}.$$

Note that $\overline{P(\tau;\omega)} = P(-\tau;\omega)$.

Instead of attempting to solve (6) directly, we adopt an approach based on the following fact. For $j,k = 1,\dots,n$, consider the exponents $\omega_j\tau_k$ in $P(\tau;\omega)$ taken modulo 2π. Since the ω_j are rationally independent, for $\tau_k \geq 0$, the vector $\tau_k\omega$ mod 2π generates a dense orbit, denoted by $\mathcal{O}_k$, on an n-torus $\mathbf{T}^n$, where $\mathbf{T} = \mathbb{R}/2\pi\mathbb{Z}$. If (τ, A) is a solution to (6), then τ produces a point on $V := (\mathbf{T}^n)^n$ via the dense orbits.

Thus, we embed the problem of finding solutions of (6) into the problem of finding solutions of a mapping F defined on V and which is an extension of (6). The idea is that an explicit solution of $F = 0$ is easily obtained, and we use the implicit function theorem to find a submanifold of solutions to $F = 0$. We then show that the structure of the dense orbits $\mathcal{O}_k$ on this submanifold yields an infinite number of solutions to $F = 0$ and therefore to (6).

Choose coordinates on V as follows:

$$V := \{\, \Phi = (\Phi^1,\dots,\Phi^n) \mid \Phi^j = (\varphi_1^j,\dots,\varphi_n^j) \in \mathbf{T}^n,\ j = 1,\dots,n \,\},$$

and consider the following mapping associated to (6):

$$F : V \times \mathbb{R}^n \longmapsto \mathbb{R}^{2n}$$

defined by

$$F(\Phi, A;\omega) = \begin{pmatrix} \widetilde{P}(\Phi) \\ \widetilde{P}(-\Phi) \end{pmatrix} A^T - i \begin{pmatrix} \omega^T \\ -\omega^T \end{pmatrix}, \tag{7}$$

where A and ω are as previously defined and $\widetilde{P}(\Phi)$ is the $n \times n$ matrix whose entry at row j column k is

$$\Big[\, \widetilde{P}(\Phi) \,\Big]_{jk} = \Big[\, \widetilde{P}(\Phi^1,\dots,\Phi^n) \,\Big]_{jk} = e^{-i\varphi_j^k}.$$

Letting $\Psi = \Phi^n$ is a convenient notation to use when applying the implicit function theorem, i.e.,

$$\Psi = (\psi_1,\dots,\psi_n) = \Phi^n = (\varphi_1^n,\dots,\varphi_n^n).$$

We write $V = V_\Phi \times V_\Psi$, where $V_\Phi \cong (\mathbf{T}^n)^{n-1}$ and $V_\Psi \cong \mathbf{T}^n$ so that

$$F : V_\Phi \times V_\Psi \times \mathbb{R}^n \longmapsto \mathbb{R}^{2n}$$

is written as $F(\Phi, \Psi, A;\omega)$ in (7) (we have relabeled $\Phi = (\Phi^1,\dots,\Phi^{n-1})$ to designate coordinates for $V_\Phi \cong (\mathbf{T}^n)^{n-1}$).

We now find an explicit solution to $F = 0$. If $\{e_1,\dots,e_n\}$ denotes the canonical basis of vectors in $\mathbb{R}^n$, we define the vectors $v_1,\dots,v_n$ by $v_1 = \sum_{k=1}^n e_k$, and for $j = 2,\dots,n$,

$$v_j = v_1 - \sum_{\ell=0}^{j-2} 2\, e_{n-\ell}.$$

By construction, the set $\{v_1,\dots,v_n\}$ is linearly independent, and so the $n \times n$ matrix $\mathcal{I}$, whose jth column is the vector v_j^T, is invertible.

Consider the following point in $V_\Phi \times V_\Psi$:

$$(\widehat{\Phi}, \widehat{\Psi}) = -\frac{\pi}{2}\left((v_1, \ldots, v_{n-1}), v_n\right);$$

then it is easy to compute that

$$\widetilde{P}(\widehat{\Phi}, \widehat{\Psi}) = i\mathcal{I}, \tag{8}$$

where $\widetilde{P}$ is as in (7). If we define

$$\widehat{A}^T \equiv (\hat{a}_1, \ldots, \hat{a}_n)^T = \mathcal{I}^{-1}\omega^T,$$

then

$$F(\widehat{\Phi}, \widehat{\Psi}, \widehat{A}; \omega) = 0.$$

Because the ω_j are rationally independent, it follows that the components $\hat{a}_k$ of $\widehat{A}$ are all nonzero.

We now show that we can use the implicit function theorem at the point $(\widehat{\Phi}, \widehat{\Psi})$. Define the $n \times n$ invertible matrix $\mathcal{U}_j$ to be the diagonal matrix whose kth diagonal element is the kth component of the vector v_j (in particular, $\mathcal{U}_1$ is the identity matrix). Note also that $\mathcal{U}_j^{-1} = \mathcal{U}_j$, $j = 1, \ldots, n$. We easily compute the derivative

$$J \equiv D_{(\Psi,A)}F(\widehat{\Phi}, \widehat{\Psi}, \widehat{A}; \omega) = \begin{pmatrix} \hat{a}_n\mathcal{U}_n & i\mathcal{I} \\ \hat{a}_n\mathcal{U}_n & -i\mathcal{I} \end{pmatrix},$$

which is invertible, and its inverse is easily computed as

$$J^{-1} = \begin{pmatrix} \frac{1}{2\hat{a}_n}\mathcal{U}_n & \frac{1}{2\hat{a}_n}\mathcal{U}_n \\ -\frac{i}{2}\mathcal{I}^{-1} & \frac{i}{2}\mathcal{I}^{-1} \end{pmatrix}.$$

By the implicit function theorem, there exist a neighborhood N of $\widehat{\Phi}$ in V_Φ and a unique smooth function

$$\begin{aligned} G : N &\longmapsto V_\Psi \times \mathbb{R}^n, \\ \Phi &\longmapsto G(\Phi) = (G_\Psi(\Phi), G_A(\Phi)) \end{aligned} \tag{9}$$

such that

$$G(\widehat{\Phi}) = (\widehat{\Psi}, \widehat{A})$$

and

$$F(\Phi, G(\Phi); \omega) \equiv 0 \quad \forall\, \Phi \in N. \tag{10}$$

Recall that $\mathcal{O}_k$ is the dense orbit generated by $\tau_k\omega$ mod 2π on the n-torus $\mathbf{T}^n$. Let $\mathcal{O}_\Phi \subset V_\Phi$ be the direct product of the dense orbits $\mathcal{O}_k$ for $k = 1, \ldots, n-1$ and $\mathcal{O}_\Psi$ be the dense orbit in V_Ψ. From (9), if $\Phi \in \mathcal{O}_\Phi$ and $\Psi = G_\Psi(\Phi) \in \mathcal{O}_\Psi$, then $A = G_A(\Phi)$ yields a solution to the original system of equations (6). Thus, to complete the proof, it remains to show that there exists a point $\Phi \in \mathcal{O}_\Phi$ which is mapped by G_Ψ to a point $\Psi \in \mathcal{O}_\Psi$.

We begin by showing that G_Ψ is regular at $\widehat{\Phi}$. An easy calculation shows that

$$K \equiv D_\Phi F(\widehat{\Phi}, \widehat{\Psi}, \widehat{A}; \omega) = \begin{pmatrix} \hat{a}_1 \mathcal{U}_1 & \hat{a}_2 \mathcal{U}_2 & \cdots & \hat{a}_{n-1} \mathcal{U}_{n-1} \\ \hat{a}_1 \mathcal{U}_1 & \hat{a}_2 \mathcal{U}_2 & \cdots & \hat{a}_{n-1} \mathcal{U}_{n-1} \end{pmatrix},$$

and implicit differentiation of (10) yields that

$$\begin{aligned} DG(\widehat{\Phi}) &= \begin{pmatrix} DG_\Psi(\widehat{\Phi}) \\ DG_A(\widehat{\Phi}) \end{pmatrix} = -J^{-1}K \\ &= \begin{pmatrix} -\frac{\hat{a}_1}{\hat{a}_n} \mathcal{U}_n \mathcal{U}_1 & -\frac{\hat{a}_2}{\hat{a}_n} \mathcal{U}_n \mathcal{U}_2 & \cdots & -\frac{\hat{a}_{n-1}}{\hat{a}_n} \mathcal{U}_n \mathcal{U}_{n-1} \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{0} \end{pmatrix}, \end{aligned} \tag{11}$$

where $\mathbf{0}$ denotes the $n \times n$ zero matrix. Consequently,

$$DG_\Psi(\widehat{\Phi}) = \begin{pmatrix} -\frac{\hat{a}_1}{\hat{a}_n} \mathcal{U}_n \mathcal{U}_1 & -\frac{\hat{a}_2}{\hat{a}_n} \mathcal{U}_n \mathcal{U}_2 & \cdots & -\frac{\hat{a}_{n-1}}{\hat{a}_n} \mathcal{U}_n \mathcal{U}_{n-1} \end{pmatrix}, \tag{12}$$

and it follows that the mapping

$$G_\Psi : N \longrightarrow V_\Psi$$

is regular at $\widehat{\Phi}$.

The density of $\mathcal{O}_k$ in $\mathbf{T}^n$ for $k = 1, \ldots, n-1$ implies that for every $\epsilon > 0$ there exists $(\tau_{1,\epsilon}, \ldots, \tau_{n-1,\epsilon})$ such that

$$\Phi^*_\epsilon = (\tau_{1,\epsilon}\omega, \ldots, \tau_{n-1,\epsilon}\omega) \bmod 2\pi$$

is in an ϵ-neighborhood of $\widehat{\Phi}$, and we define a small $(n-1)$-dimensional surface in V_Φ based at Φ^*_ϵ by

$$S^h_{\Phi^*_\epsilon} = \{(\tau_1\omega, \ldots, \tau_{n-1}\omega) \bmod 2\pi \mid \tau_j \in (\tau_{j,\epsilon} - h, \tau_{j,\epsilon} + h)\}$$

with ϵ, h small enough so that $S^h_{\Phi^*_\epsilon} \subset N$. Note that this surface is generated by small nonempty open intervals of $\mathcal{O}_k$ for $k = 1, \ldots, n-1$.

We now show that the image of $S^h_{\Phi^*_\epsilon}$ by G_Ψ has a nontrivial transversal intersection with $\mathcal{O}_\Psi$. To do this, we consider the function

$$\mathcal{T} : N \longrightarrow \mathbb{R}$$

defined by

$$\mathcal{T}(\Phi) = \det \begin{pmatrix} DG_\Psi(\Phi) \cdot W_1^T & DG_\Psi(\Phi) \cdot W_2^T & \cdots & DG_\Psi(\Phi) \cdot W_{n-1}^T & \omega^T \end{pmatrix}, \tag{13}$$

where

$$W_j := \frac{d}{dx_j}(x_1\omega, \ldots, x_j\omega, \ldots, x_{n-1}\omega)$$

for $j = 1, \dots, n-1$ are $n-1$ linearly independent vectors in $(\mathbb{R}^n)^{n-1}$. Obviously, $\mathcal{T}$ is continuous, and

$$\begin{aligned}
\mathcal{T}(\widehat{\Phi}) &= \det\left(-\tfrac{\hat{a}_1}{\hat{a}_n}\mathcal{U}_n\mathcal{U}_1\omega^T \quad -\tfrac{\hat{a}_2}{\hat{a}_n}\mathcal{U}_n\mathcal{U}_2\omega^T \quad \cdots \quad -\tfrac{\hat{a}_{n-1}}{\hat{a}_n}\mathcal{U}_n\mathcal{U}_{n-1}\omega^T \quad \mathcal{U}_n\mathcal{U}_n\omega^T \right) \\
&= \frac{(-1)^{n-1}}{\hat{a}_n^{n-1}} \det\mathcal{U}_n \det\left(\hat{a}_1\mathcal{U}_1\omega^T \quad \hat{a}_2\mathcal{U}_2\omega^T \quad \cdots \quad \hat{a}_{n-1}\mathcal{U}_{n-1}\omega^T \quad \mathcal{U}_n\omega^T \right) \\
&= \frac{(\omega_1\,\omega_2\,\cdots\,\omega_n)\,(\hat{a}_1\,\hat{a}_2\,\cdots\,\hat{a}_{n-1})}{\hat{a}_n^{n-1}} \det\mathcal{I} \\
&\neq 0.
\end{aligned}$$

It follows that there is a neighborhood $N' \subseteq N$ in which $\mathcal{T} \neq 0$. So, by choosing ϵ, h small enough such that $S^h_{\Phi^*_\epsilon} \subset N'$, the image of $S^h_{\Phi^*_\epsilon}$ by G_Ψ is transverse to $\mathcal{O}_\Psi$. The density of the orbit $\mathcal{O}_\Psi$ in V_Ψ guarantees that there are infinitely many intersections with $G_\Psi(\mathcal{S}^h_{\Phi^*_\epsilon})$ near the point $\widehat{\Psi} = G_\Psi(\widehat{\Phi})$. ■

The next theorem shows that the previous realization result holds for open sets near solutions found in Theorem 2.1.

Theorem 2.2. *Suppose $\omega_1 > 0$, $\omega_2 > 0$, …, $\omega_n > 0$ are linearly independent over the rationals. There exist a neigborhood $\mathcal{N}$ of $\omega = (\omega_1, \dots, \omega_n)$ in $\mathbb{R}^n$ and a smooth mapping*

$$\begin{aligned}
H: \quad \mathcal{N} &\longrightarrow \mathbb{R}^n \times \mathbb{R}^n, \\
\omega &\longmapsto H(\omega) = (\tau(\omega), A(\omega)) = ((\tau_1(\omega), \dots, \tau_n(\omega)), (a_1(\omega), \dots, a_n(\omega)))
\end{aligned}$$

such that

$$\begin{aligned}
\sum_{k=1}^{n} a_k(\omega)\, e^{-i\omega_j \tau_k(\omega)} &= i\omega_j, \qquad j = 1, \dots, n, \\
\sum_{k=1}^{n} a_k(\omega)\, e^{i\omega_j \tau_k(\omega)} &= -i\omega_j, \quad j = 1, \dots, n,
\end{aligned} \tag{14}$$

for all $\omega \in \mathcal{N}$.

Proof. We consider the system $F = 0$ given by (7). We have already shown in Theorem 2.1 that, for fixed ω linearly independent over the rationals, there exist infinitely many solutions to $F = 0$. We again use an implicit function theorem argument combined with the density of irrational torus flows.

Consider the mapping

$$\begin{aligned}
Q \quad &: \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}^n \longrightarrow \mathbb{R}^n \times \mathbb{R}^n, \\
&(\tau, A, \omega) \longmapsto Q(\tau, A, \omega) = F((\tau_1\omega, \dots, \tau_{n-1}\omega), \tau_n\omega, A; \omega),
\end{aligned} \tag{15}$$

where F is as in (7). Therefore,

(16)

$$D_\tau Q(\tau, A, \omega) = D_{((\Phi^1, \dots, \Phi^{n-1}), \Psi)} F((\tau_1\omega, \dots, \tau_{n-1}\omega), \tau_n\omega, A; \omega) \cdot \begin{pmatrix} \omega^T & 0 & 0 & \cdots & 0 \\ 0 & \omega^T & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & \omega^T \end{pmatrix},$$

where each 0 in the matrix above is an n-dimensional zero column vector; and

$$D_A Q(\tau, A, \omega) = D_A F((\tau_1\omega, \dots, \tau_{n-1}\omega), \tau_n\omega, A; \omega). \tag{17}$$

Thus, we wish to show that the $2n \times 2n$ matrix

$$\begin{pmatrix} D_\tau Q(\tau, A, \omega) & D_A Q(\tau, A, \omega) \end{pmatrix} \tag{18}$$

is invertible at the solutions to (5) we have found in Theorem 2.1.

For positive integers p and q, let $\mathrm{Mat}_{p,q}$ denote the space of $p \times q$ matrices. Consider the following mappings associated to (16), (17), and (18):

$$\mathcal{R}_1 : V_\Phi \times V_\Psi \times \mathbb{R}^n \times \mathbb{R}^n \longrightarrow \mathrm{Mat}_{2n,n}$$

defined by

$$\mathcal{R}_1(\Phi, \Psi, A, \omega) = D_{(\Phi,\Psi)} F(\Phi, \Psi, A; \omega) \cdot \begin{pmatrix} \omega^T & 0 & 0 & \cdots & 0 \\ 0 & \omega^T & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & \omega^T \end{pmatrix},$$

$$\mathcal{R}_2 : V_\Psi \times V_\Psi \times \mathbb{R}^n \times \mathbb{R}^n \longrightarrow \mathrm{Mat}_{2n,n}$$

defined by

$$\mathcal{R}_2(\Phi, \Psi, A, \omega) = D_A F(\Phi, \Psi, A; \omega),$$

and

$$\mathcal{R} : V_\Phi \times V_\Psi \times \mathbb{R}^n \times \mathbb{R}^n \longrightarrow \mathrm{Mat}_{2n,2n}$$

defined by

$$\mathcal{R}(\Phi, \Psi, A, \omega) = \begin{pmatrix} \mathcal{R}_1(\Phi, \Psi, A, \omega) & \mathcal{R}_2(\Phi, \Psi, A, \omega) \end{pmatrix}.$$

Now, a simple computation (similar to those done in the proof of Theorem 2.1) shows that

$$\mathcal{R}\left(-\frac{\pi}{2}(v_1, \dots, v_n), A, \omega\right) = \begin{pmatrix} \mathcal{Z} & i\mathcal{I} \\ \mathcal{Z} & -i\mathcal{I} \end{pmatrix},$$

where

$$\mathcal{Z} = \begin{pmatrix} a_1 \mathcal{U}_1 \omega^T & a_2 \mathcal{U}_2 \omega^T & \cdots & a_n \mathcal{U}_n \omega^T \end{pmatrix}.$$

If none of the a_j vanish, then the $n \times n$ matrix $\mathcal{Z}$ is invertible, since its determinant is

$$\det \mathcal{Z} = \prod_{j=1}^{n} a_j \omega_j \det \mathcal{I} \neq 0.$$

Thus,

$$\mathcal{R}\left(-\frac{\pi}{2}(v_1, \dots, v_n), A, \omega\right)^{-1} = \begin{pmatrix} \frac{1}{2}\mathcal{Z}^{-1} & \frac{1}{2}\mathcal{Z}^{-1} \\ -\frac{i}{2}\mathcal{I}^{-1} & \frac{i}{2}\mathcal{I}^{-1} \end{pmatrix}.$$

By continuity, there is thus a neighborhood $\mathcal{N}$ of the point $-\frac{\pi}{2}(v_1, \dots, v_n)$ in $V_\Phi \times V_\Psi$ in which $\mathcal{R}$ is invertible. By Theorem 2.1, there are infinitely many solutions of $Q = 0$ (see (15)) in $\mathcal{N}$, and the Jacobian matrix (18) is thus invertible at these solutions. We get the conclusion of Theorem 2.2 by the implicit function theorem. ∎

2.1. Example: $\mathbf{D}_3$-symmetric system. Theorem 2.1 is written in the context of scalar DDEs. However, in this section, we look at an example of a $\mathbf{D}_3$-symmetric system of DDEs where Theorem 2.1 can be applied and then proceed to explain the generalization of this theorem, which has applications to symmetric systems of DDEs.

Example 2.3. Let $\Gamma = \mathbf{D}_3$, the group generated by κ and γ, act on $\mathbb{R}^3$ as follows:

$$\kappa.(x_1, x_2, x_3) = (x_1, x_3, x_2), \qquad \gamma.(x_1, x_2, x_3) = (x_3, x_1, x_2).$$

Consider a linear $\mathbf{D}_3$-symmetric coupled cell system with delayed coupling where each cell is one-dimensional and has the form

$$\begin{aligned} \dot{x}_1 &= a_1 x_1(t-\tau_1) + a_2[x_2(t-\tau_2) + x_3(t-\tau_2)], \\ \dot{x}_2 &= a_1 x_2(t-\tau_1) + a_2[x_3(t-\tau_2) + x_1(t-\tau_2)], \\ \dot{x}_3 &= a_1 x_3(t-\tau_1) + a_2[x_1(t-\tau_2) + x_2(t-\tau_2)], \end{aligned} \tag{19}$$

where $x_i \in \mathbb{R}$ for $i = 1, 2, 3$ and $a_1, a_2, a_3 \in \mathbb{R}$. The characteristic equation of system (19) is obtained by substituting $(x_1, x_2, x_3) = (w_1 e^{\lambda t}, w_2 e^{\lambda t}, w_3 e^{\lambda t})$ into the equations. We obtain after simplification

$$\begin{aligned} \lambda w_1 &= a_1 e^{-\lambda\tau_1} w_1 + a_2 e^{-\lambda\tau_2}[w_2 + w_3], \\ \lambda w_2 &= a_1 e^{-\lambda\tau_1} w_2 + a_2 e^{-\lambda\tau_2}[w_3 + w_1], \\ \lambda w_3 &= a_1 e^{-\lambda\tau_1} w_3 + a_2 e^{-\lambda\tau_2}[w_1 + w_2], \end{aligned}$$

and rearranging the terms we have

$$\left[(\lambda - a_1 e^{-\lambda\tau_1})I - a_2 e^{-\lambda\tau_2} \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}\right] \begin{pmatrix} w_1 \\ w_2 \\ w_3 \end{pmatrix} = 0, \tag{20}$$

where I is the 3×3 identity matrix. Letting $\alpha = \lambda - a_1 e^{-\lambda\tau_1}$ and $\beta = -a_2 e^{-\lambda\tau_2}$ equation (20) becomes

$$\begin{pmatrix} \alpha & \beta & \beta \\ \beta & \alpha & \beta \\ \beta & \beta & \alpha \end{pmatrix} \begin{pmatrix} w_1 \\ w_2 \\ w_3 \end{pmatrix} = 0.$$

Let

$$\Delta(\lambda) = \begin{pmatrix} \alpha & \beta & \beta \\ \beta & \alpha & \beta \\ \beta & \beta & \alpha \end{pmatrix}.$$

We complexify $\mathbb{R}^3$ and look at the isotypic decomposition of $\mathbb{C}^3$ by the action of $\mathbf{D}_3$:

$$\mathbb{C}^3 = V_0 \oplus V_1 \oplus V_2,$$

where V_0 is the trivial representation of $\mathbf{D}_3$ and V_1, V_2 are the standard irreducible representations of $\mathbf{D}_3$ (all representations are one-dimensional complex). A basis for V_0 is $u_0 = (v, v, v)^t$,

a basis for V_1 is $u_1 = (v, e^{2\pi i/3}v, e^{4\pi i/3}v)^t$, and a basis for V_2 is $u_2 = (v, e^{4\pi i/3}v, e^{2\pi i/3}v)^t$. Therefore,

$$\Delta(\lambda)u_0 = (\alpha + 2\beta)u_0$$

and

$$\Delta(\lambda)u_1 = (\alpha - \beta)u_1, \qquad \Delta(\lambda)u_2 = (\alpha - \beta)u_2$$

since $e^{4\pi i/3} = \overline{e^{2\pi i/3}}$. Therefore, in the basis given by the isotypic decomposition of $\mathbb{C}^3$, $\Delta(\lambda)$ block diagonalizes so that we have

$$\begin{pmatrix} \alpha + 2\beta & 0 & 0 \\ 0 & \alpha - \beta & 0 \\ 0 & 0 & \alpha - \beta \end{pmatrix} \begin{pmatrix} \tilde{w}_1 \\ \tilde{w}_2 \\ \tilde{w}_3 \end{pmatrix} = 0.$$

Hence, the eigenvalues are solutions to

$$\det \Delta(\lambda) = (\alpha + 2\beta)(\alpha - \beta)^2 = (\lambda - a_1 e^{-\lambda\tau_1} - 2a_2 e^{-\lambda\tau_2})(\lambda - a_1 e^{-\lambda\tau_1} + a_2 e^{-\lambda\tau_2})^2 = 0.$$

Each factor of the characteristic equation is of the same form as the characteristic equation for a scalar DDE. Therefore, by letting $\tilde{a}_1 = a_1$ and $\tilde{a}_2 = 2a_2$ in $(\lambda - a_1 e^{-\lambda\tau_1} - 2a_2 e^{-\lambda\tau_2})$, Theorem 2.1 applies directly. The same is true for the factor $(\lambda - a_1 e^{-\lambda\tau_1} + a_2 e^{-\lambda\tau_2})$, where we let $\tilde{a}_1 = a_1$ and $\tilde{a}_2 = -a_2$. Hence, for any choice of a set of complex numbers $\Lambda = \{i\omega_1, i\omega_2\}$ with $\omega_1, \omega_2 > 0$ and rationally independent, there exists a linear $\mathbf{D}_3$ symmetric coupled cell system including Λ in its spectrum.

In the context of bifurcation theory, the symmetry properties of the critical eigenspace depend on which factor contains the critical eigenvalue, and this leads to different bifurcation behavior. Two imaginary eigenvalues in the first factor correspond to a nonresonant Hopf/Hopf mode interaction (without symmetry), while the second case leads to a nonresonant $\mathbf{D}_3$ Hopf/Hopf mode interaction. Details of the unfolding of these bifurcations can be found, respectively, in Kuznetsov [22] and Golubitsky, Stewart, and Schaeffer [14].

Note that Theorem 2.1 is not sufficient to guarantee the existence of a linear $\mathbf{D}_3$-symmetric coupled cell system with $i\omega_1$ satisfying the first factor and $i\omega_2$ satisfying the second factor simultaneously. We characterize this situation as follows. Let $b_1^1 = b_1^2 = 1$, $b_2^1 = 2$, and $b_2^2 = -1$, and for fixed rationally independent $i\omega_1, i\omega_2$ (with $\omega_1, \omega_2 > 0$) we look for a_1, a_2 and τ_1, τ_2 such that

$$\begin{aligned} a_1 b_1^1 e^{-i\omega_1\tau_1} + a_2 b_2^1 e^{-i\omega_1\tau_2} &= i\omega_1, \\ a_1 b_1^2 e^{-i\omega_2\tau_1} + a_2 b_2^2 e^{-i\omega_2\tau_2} &= i\omega_2, \end{aligned} \tag{21}$$

and their complex conjugate equations are satisfied. This is the context of the next theorem, which is a generalization of Theorem 2.1. We state this result in a general form below and postpone the proof to section 4, as it follows similar steps as the proof of Theorem 2.1.

Note that in the proof of Theorem 2.1, the matrix $\mathcal{I}$ defined in (8) is nonsingular by construction, and this is a crucial step in the argument. For this more general result we shall present, the matrix which holds a similar role is denoted by $\mathcal{I}_B$ since it is a matrix consisting of $\pm$ the constants b_k^j which appear in (21). The form of this matrix is not relevant for the

moment, and the structure of the matrix is described in section 4. We are now ready to state the theorem.

Theorem 2.4. *Consider the factors*

$$\prod_{j=1}^{r}\left(\lambda-\sum_{k=1}^{n}a_k b_k^j e^{-\lambda\tau_k}\right) \tag{22}$$

of a characteristic polynomial, where the constants $b_k^j \in \mathbb{R}\setminus\{0\}$ *are fixed for all* $j=1,\dots,r$, $k=1,\dots,n$, *and suppose that* $\det \mathcal{I}_B \neq 0$. *Suppose that*

$$\omega_1^1,\dots,\omega_{\ell_1}^1,\omega_1^2,\dots,\omega_{\ell_2}^2,\dots,\omega_1^r,\dots,\omega_{\ell_r}^r$$

are positive and linearly independent over the rationals where $\ell_1+\cdots+\ell_r=n$. *Then there exist* $\tau_1>0$, $\tau_2>0$, $\dots$, $\tau_n>0$, $a_1\in\mathbb{R}$, $a_2\in\mathbb{R}$, $\dots$, $a_n\in\mathbb{R}$ *such that for all* $j=1,\dots,r$,

$$\left(\lambda-\sum_{k=1}^{n}a_k b_k^j e^{-\lambda\tau_k}\right)=0$$

has roots $i\omega_\ell^j$ *for* $\ell=1,\dots,\ell_j$.

This theorem is applied in the following section to the case of $\mathbf{D}_n$-symmetrically coupled one-dimensional cell systems. If n odd, it is easy to show that $b_k^j\neq 0$ holds, but for n even, some of the b_k^j's can be zero, and in those cases, Theorem 2.4 cannot be applied directly.

Example 2.5. Consider the case of a $\mathbf{D}_4$-symmetric ring of DDEs given by

$$\dot{x}_i = a_1 x_i(t-\tau_1)+a_2[x_{i+1}(t-\tau_2)+x_{i-1}(t-\tau_2)],$$

where $i=1,\dots,4$ and the indices are taken modulo 4. A calculation similar to the $\mathbf{D}_3$ case above yields the characteristic equation

$$\det\Delta(\lambda)=(\lambda-a_1e^{-\lambda\tau_1}-2a_2e^{-\lambda\tau_2})(\lambda-a_1e^{-\lambda\tau_1})(\lambda-a_1e^{-\lambda\tau_1}+2a_2e^{-\lambda\tau_2})^2=0.$$

Here Theorem 2.4 cannot be applied if we include the second factor of the characteristic equation since the b_k^j coefficient of a_2 is null. However, Theorem 2.4 can be applied if we are looking for critical eigenvalues distributed among the first and third factors.

3. Linear Γ-symmetric DDEs. We now look at the case of Γ-equivariant linear retarded functional differential equations (RFDEs) depending on ℓ discrete delays. For the results of this section, we find it convenient to introduce the well-known abstract setting (see, for instance, Hale and Verduyn-Lunel [20]), which is adapted to the symmetric case. Let $C_n = C([-\tau,0],\mathbb{C}^n)$ be the Banach space of continuous functions from the interval $[-\tau,0]$, into $\mathbb{C}^n$ ($\tau>0$) endowed with the norm of uniform convergence. Consider the linear homogeneous RFDE

$$\dot{z}(t)=\mathcal{L}_0(z_t), \tag{23}$$

where $\mathcal{L}_0$ is a bounded linear operator from C_n into $\mathbb{C}^n$. We write

$$\mathcal{L}_0(\varphi) = \int_{-\tau}^{0} d\eta(\theta)\varphi(\theta),$$

where η is an $n \times n$ matrix-valued function of bounded variation defined on $[-\tau, 0]$. The characteristic equation is

$$\det \Delta(\lambda) = 0, \qquad \text{where } \Delta(\lambda) = \lambda I_n - \int_{-\tau}^{0} d\eta(\theta) e^{\lambda\theta}, \tag{24}$$

where I_n is the $n \times n$ identity matrix. Note that $e^{\lambda\theta} = e^{\lambda\theta} I_n$.

Suppose that Γ is a compact group of transformations acting linearly on $\mathbb{C}^n$. We say that (23) is Γ-*equivariant* if

$$\gamma \cdot \eta(\theta) = \eta(\theta) \cdot \gamma \quad \forall\, \gamma \in \Gamma,\ \theta \in [-\tau, 0]. \tag{25}$$

The group action of Γ on $\mathbb{C}^n$ induces an isotypic decomposition of $\mathbb{C}^n$:

$$\mathbb{C}^n = V_1 \oplus V_2 \oplus \cdots V_k,$$

where $V_i = U_i \oplus \cdots U_i$ for irreducible representations U_i of Γ and $U_i \not\cong U_j$ for $i \neq j$. Since $\eta(\theta)$ commutes with the action of Γ, then

$$\eta(\theta) V_i \subset V_i$$

for all $i = 1, \ldots, k$.

Therefore, $\Delta(\lambda)$ also commutes with the representation of Γ. Indeed, for all $\gamma \in \Gamma$,

$$\begin{aligned}
\Delta(\lambda)\gamma &= \lambda I \gamma - \left[\textstyle\int_{-\tau}^{0} d\eta(\theta) e^{\lambda\theta}\right] \gamma \\
&= \gamma\lambda I - \left[\textstyle\int_{-\tau}^{0} d\eta(\theta)\gamma e^{\lambda\theta}\right] \\
&= \gamma\lambda I - \left[\textstyle\int_{-\tau}^{0} \gamma d\eta(\theta) e^{\lambda\theta}\right] \\
&= \gamma\left(\lambda I - \textstyle\int_{-\tau}^{0} d\eta(\theta) e^{\lambda\theta}\right) = \gamma\Delta(\lambda).
\end{aligned}$$

Thus,

$$\Delta(\lambda) V_i \subset V_i$$

for all $i = 1, \ldots, k$, and in the orthogonal basis given by the isotypic decomposition, the matrix $\Delta(\lambda)$ block diagonalizes and we write

$$\Delta(\lambda) = \operatorname{diag}(\Delta_1(\lambda), \ldots, \Delta_k(\lambda)).$$

The characteristic equation then becomes

$$\det \Delta(\lambda) = \prod_{i=1}^{k} \det \Delta_i(\lambda).$$

Therefore, we are led to the following result.

Proposition 3.1. *Suppose that $V_i = U_i$ and U_i is a one-dimensional irreducible representation of Γ. Then*

$$\det \Delta_i(\lambda) = \lambda - \sum_{j=1}^{\ell} a_j e^{-\lambda \tau_j}.$$

Corollary 3.2. *Theorem 2.1 applies to factors of the characteristic equation which correspond to the context of Proposition 3.1.*

3.1. Delay coupled cell systems with $\mathbf{D}_n$-symmetry, n odd. Our goal is to apply Theorem 2.4 to delay coupled cell systems with $\mathbf{D}_n$-symmetry. We focus on the case of n odd because the assumption $b_k^j \neq 0$ is satisfied for all j, k. As Example 2.5 shows, when n is even one cannot apply Theorem 2.4 in all cases because some coefficients b_k^j may be zero. Therefore, we perform the following analysis on the case in which n is odd only. Note that these computations are valid in the case in which n is even with minor modifications.

Multiple authors [6, 10, 15, 16, 17, 24, 25, 29, 30] have studied Hopf bifurcation in $\mathbf{D}_n$-symmetric rings of cells with delayed coupling where each cell is one-dimensional. The differential equation systems in those papers have the following general form. For $i = 1, \ldots, n$, the dynamics of cell i is given, respectively, for n odd:

$$\dot{x}_i(t) = f(X_i) + g(x_{i+1}, \ldots, x_{i+(n-1)/2}, x_{i-(n-1)/2}, \ldots, x_{i-1}), \tag{26}$$

where $X_i = (x_i(t - s_1), \ldots, x_i(t - s_m))$, $x_j = x_j(t - \tau_j)$ for $j \neq i$, $f : \mathbb{R}^m \to \mathbb{R}$, $g : \mathbb{R}^{n-1} \to \mathbb{R}$ are smooth functions, $\tau_j, s_\ell \in [0, \tau]$ for all $j \neq i$, and $s = 1, \ldots, m$. Here, f is called the internal dynamics and g is the coupling function.

3.1.1. Characterization of delayed $\mathbf{D}_n$ networks. We introduce a more general notation for delayed symmetrically coupled cell systems inspired by recent work on (not necessarily symmetric) coupled cell systems of ODEs; see Golubitsky and Stewart [13] for a survey of the theory. Note that all the results of this section are straightforward generalizations of the nondelayed case.

Suppose that each cell in the system has phase space $\mathbb{R}^k$. We generalize system (26) to

$$\dot{X}_i(t) = f(\widetilde{X}_i, \widetilde{X}_{i+1}, \ldots, \widetilde{X}_{i+(n-1)/2}, \widetilde{X}_{i-(n-1)/2}, \ldots, \widetilde{X}_{i-1}), \qquad i = 1, \ldots, n, \tag{27}$$

where

$$\widetilde{X}_j = (X_j(t - \tau_1), \ldots, X_j(t - \tau_m)),$$

$f : (\mathbb{R}^{km})^n \to \mathbb{R}^k$ is a smooth function, and the position of $\widetilde{X}_k$ corresponds to the coupling from cell k to cell i and $\tau_j \geq 0$ for $j = 1, \ldots, m$. The following proposition is a straightforward consequence of the coupled cell system theory [13]. The proof is given for completeness.

Proposition 3.3. *Any delay coupled network of n-odd identical cells depending on m delays can be written as (27).*

Proof. Since the cells are identical, each cell has the same dimension k and the dynamics of all cells is given by the same function f. The function f has arguments coming from every other cell in the network corresponding to possible connections from these other cells, and those depend possibly on the m delays by the definition of $\widetilde{X}_j$. ∎

We say that cells j and k have *identical coupling* to cell i if

$$f(X_i,\dots,u,\dots,v,\dots)=f(X_i,\dots,v,\dots,u,\dots), \tag{28}$$

where u and v are permuted from positions j and k. We rewrite system (27) as

$$\dot{X}=F(\widetilde{X}), \tag{29}$$

where $X=(X_1,\dots,X_n)^t$,

$$\widetilde{X} \;=\; \widetilde{X}_i,\widetilde{X}_{i+1},\dots,\widetilde{X}_{i+(n-1)/2},\widetilde{X}_{i-(n-1)/2},\dots,\widetilde{X}_{i-1},$$

and $F:(\mathbb{R}^{km})^n\to\mathbb{R}^{nk}$ has the ith component given by the formulas above for $\dot{X}_i(t)$.

Consider the group $\mathbf{D}_n$, with generators ρ and κ acting on $\mathbb{R}^{kn}$ as follows:

$$\begin{aligned}\rho.(X_1,\dots,X_n)&=(X_n,X_1,X_2,\dots,X_{n-1}),\\ \kappa.(X_1,\dots,X_n)&=(X_1,X_n,\dots,X_{n+2-j},\dots,X_{(n+3)/2},X_{(n+1)/2},\dots,X_j,\dots,X_2).\end{aligned} \tag{30}$$

Without loss of generality we assume that our networks are transitive. That is, all cells in the network can be reached from any other cell via the coupling.

We now characterize the connections in the network so that the delay-differential system is $\mathbf{D}_n$-symmetric. We think of each cell in the network as having $[(n-1)/2]$ neighbors on each side and an opposite cell if n is even. Graphically, it is clear that an n-cell network is $\mathbf{D}_n$-symmetric if for all cells in the network, all connections to and from the jth neighbor on each side (or the opposite cell if n is even) are all the same; that is, the coupling term and its delay must be the same for all those connections. This idea is formalized in the next result.

Proposition 3.4. *A transitive network of n coupled identical cells with delays is $\mathbf{D}_n$-equivariant if and only if it satisfies the conditions below.*

(i) *Suppose that cell 1 receives an input from cell j with delay $\epsilon\in[0,\tau]$; then every cell i in the network ($i=2,\dots,n$) receives an input from cell $(i+j-1)$ mod n with delay ϵ identical to the one received by cell 1.*

(ii) *For every connection in part* (i)*, there is an identical connection from cell i to cell $(i+j-1)$ mod n with delay ϵ.*

Proof. The result is true for n odd and even but we give the proof only for n odd. We begin by looking at ρ-equivariance. Denote by $[w]_i$ the ith row of vector w. Then,

$$[\rho F(\widetilde{X})]_i=f(\widetilde{X}_{i-1},\widetilde{X}_i,\dots,\widetilde{X}_{i-2}),$$

and since $\rho X=(X_n,X_1,\dots,X_{n-1})$ we have

$$[F(\rho\widetilde{X})]_i=f(\widetilde{X}_{i-1},\widetilde{X}_i,\dots,\widetilde{X}_{i-2}).$$

Thus, ρ-equivariance holds automatically by the structure of the equations.

Suppose that cell 1 receives an input from cell j. We look at the system of equations (27) and focus on the possible coupling from cell $(i+j-1)$ mod n to cell i. Moreover, consider the possible connection from cell i to cell $(i-j+1)$ mod n. Note that the connections from $(i+j-1)$ mod n to i and from i to $(i-j+1)$ mod n are obtained by taking the index and

subtracting $j-1$. Finally, consider the possible connection from cell $(i-j+1)$ mod n to cell i. We now show that $F(\widetilde{X})$ is κ-equivariant (and so $\mathbf{D}_n$-equivariant) if and only if the connections defined above are identical. An easy computation shows that for all $i=1,\dots,n$ we have

$$[\kappa F(\widetilde{X})]_{n+2-i} = f(\widetilde{X}_i,\dots,\widetilde{X}_{i+j-1},\dots,\widetilde{X}_{i-j+1},\dots)$$

and

$$[F(\kappa\widetilde{X})]_{n+2-i} = f(\widetilde{X}_i,\dots,\widetilde{X}_{i-j+1},\dots,\widetilde{X}_{i+j-1},\dots),$$

where $n+2-i$ is taken modulo n for $i=1$.

We now show that parts (i) and (ii) imply κ-equivariance. If part (i) holds, the coupling from cell $(i+j-1)$ mod n to cell i and the coupling from cell i to cell $(i-j+1)$ mod n are identical. Then, by part (ii), the coupling from cell $(i-j+1)$ mod n to cell i is identical to the coupling from cell i to cell $(i-j+1)$ mod n. Therefore, the coupling from cells $(i+j-1)$ mod n and $(i-j+1)$ mod n to i are identical. By definition of identical coupling given by (28) we have that

$$f(\widetilde{X}_i,\dots,\widetilde{X}_{i-j+1},\dots,\widetilde{X}_{i+j-1},\dots) = f(\widetilde{X}_i,\dots,\widetilde{X}_{i+j-1},\dots,\widetilde{X}_{i-j+1},\dots).$$

Since the dynamics of all cells is given by the same function f, this is true for all $i=1,\dots,n$. Thus, F is κ-equivariant.

Suppose now that F is κ-equivariant. Equality of both sides of the equivariance condition implies that for all $i=1,\dots,n$, the couplings from cells $(i+j-1)$ mod n and $(i-j+1)$ mod n to i are identical. Since the dynamics of all cells is given by the same function f, the coupling from cell $(i+j-1)$ mod n to cell i guarantees an identical coupling from cell i to cell $(i-j+1)$ mod n, and this proves (i). But, the coupling from cell $(i-j+1)$ mod n to i is therefore identical to the coupling from cell i to cell $(i-j+1)$ mod n. Hence there is an identical two-way coupling between cells i and $(i-j+1)$ mod n, which proves (ii). ∎

3.1.2. General form of the characteristic equation. We now focus our attention on delay coupled cell systems where each cell is one-dimensional, that is, $k=1$. The results of this section are also easy generalizations of the nondelayed case. We split the linear and nonlinear parts of system (27) and write the result in abstract form:

$$\dot{X} = LX_t + H(X_t),$$

where $X_t \in C([-\tau,0],\mathbb{R}^n)$, $L : C([-\tau,0],\mathbb{R}^n) \to \mathbb{R}^n$ is a bounded linear map, and H is a nonlinear mapping. Thus, L is $\mathbf{D}_n$-equivariant, $\eta(\theta)$ is an $n\times n$ $\mathbf{D}_n$-equivariant matrix of bounded variation, and

$$L\phi = \int_{-\tau}^{0} d\eta(\theta)\phi.$$

Proposition 3.5. *The matrix $\eta(\theta)$ is symmetric ($\eta(\theta)=\eta(\theta)^T$) with the following properties:*
(1) *for all $j=1,\dots,n$, $\eta_{jj}(\theta)=p(\theta)$ for some function p, and*
(2) *for all i,k with $i\neq k$, $\eta_{ki}(\theta)=\eta_{(2+n-k)i}(\theta)=\eta_{k1}(\theta)$.*

Proof. We use Proposition 3.4 to obtain information on η. By part (ii), the matrix $\eta(\theta)$ is symmetric. From the structure of (27), we deduce that for all $j = 1, \dots, n$, $\eta_{jj}(\theta) = p(\theta)$ for some function $p(\theta)$. We denote by $\eta_{ji}(\theta)$ the element of η corresponding to the coupling from cell j to i. Consider $\eta_{j1}(\theta)$; then there is an identical connection from cell 1 to cell $2 + n - j$ by part (i) and so $\eta_{j1}(\theta) = \eta_{1(2+n-j)}(\theta)$. By part (ii), the connection from cell $2 + n - j$ to cell 1 is identical to its reciprocal and so $\eta_{j1}(\theta) = \eta_{(2+n-j)1}(\theta)$. By part (i), we then have $\eta_{ki}(\theta) = \eta_{(2+n-k)i}(\theta) = \eta_{k1}(\theta)$ since the connections to cell i are identical to the connections to cell 1. ∎

Remark 3.6. This result can be obtained for higher-dimensional cells with a proof essentially similar to this one, but with more cumbersome notation. We decided to restrict ourselves to the one-dimensional case as this is the one which we study in detail in what follows.

The diagonalization of the linear equation is obtained using the results at the beginning of section 3 and are analogous to calculations for the $\mathbf{D}_n$-symmetric ODEs found in Golubitsky, Stewart, and Schaeffer [14, Chapter XVIII]. The details are left to the reader. One obtains for $j = 0, \dots, n-1$

$$A_j(\theta) := p(\theta) + \sum_{k=2}^{(n+1)/2} 2\cos(2\pi(k-1)j/n)\eta_{k1}(\theta). \tag{31}$$

Note that $A_j(\theta) = A_{n-j}(\theta)$ for $j = 1, \dots, [n/2]$. The block diagonalization of η is given by the terms $A_j(\theta)$ for $j = 0, \dots, n-1$. Hence, in the basis given by the isotypic decomposition, we have

$$\Delta(\lambda) = \lambda I_n - \int_{-\tau}^{0} d\eta(\theta) e^{\lambda\theta} = \lambda I_n - \int_{-\tau}^{0} \operatorname{diag}(dA_0(\theta)e^{\lambda\theta}, \dots, dA_{n-1}(\theta)e^{\lambda\theta}).$$

Let $\Delta_j(\lambda) = \lambda - \int_{-\tau}^{0} dA_j(\theta)e^{\lambda\theta}$; then

$$\Delta(\lambda) = \operatorname{diag}(\Delta_0(\lambda), \dots, \Delta_{n-1}(\lambda)).$$

Therefore, the characteristic equation has the decomposition

$$\det \Delta(\lambda) = \det \Delta_0(\lambda) \prod_{j=1}^{(n-1)/2} [\det \Delta_j(\lambda)]^2 = 0. \tag{32}$$

For completeness, the reader can verify that the corresponding formula for n even is

$$\det \Delta(\lambda) = \det \Delta_0(\lambda) \det \Delta_{n/2}(\lambda) \prod_{j=1}^{n/2-1} [\det \Delta_j(\lambda)]^2 = 0, \tag{33}$$

where the A_j formula is slightly different from the one above.

3.1.3. Application of main theorems to the $\mathbf{D}_n$ case. It is straightforward that Theorem 2.1 can be applied to any of the factors of the characteristic equations (32) or (33). Recall from Example 2.5 that Theorem 2.4 can possibly be applied in the case in which n is even if the chosen factors of the characteristic equation satisfy $b_k^j \neq 0$ for all j, k. We do not pursue this case here.

To apply Theorem 2.4 in the $\mathbf{D}_n$ case with n odd, we need to verify that the coefficients b_k^j in the factors of the characteristic equation are nonzero and that the nondegeneracy condition $\det \mathcal{I}_B \neq 0$ is satisfied. In fact, as shown in section 4, $\det \mathcal{I}_B \neq 0$ if and only if the matrix

$$\mathcal{B} := \begin{bmatrix} b_1^1 & b_{1+\mu_1}^1 & \cdots & b_{1+\mu_{r-1}}^1 \\ b_1^2 & b_{1+\mu_1}^2 & \cdots & b_{1+\mu_{r-1}}^2 \\ \vdots & \vdots & \ddots & \vdots \\ b_1^r & b_{1+\mu_1}^r & \cdots & b_{1+\mu_{r-1}}^r \end{bmatrix}$$

is nonsingular, where ℓ_j is the number of imaginary eigenvalues satisfying the jth term of the product of the characteristic equation (22) and $\mu_j = \sum_{i=1}^{j} \ell_i$, where $\mu_r = n$ and $\mu_0 := 0$. Note that row j of $\mathcal{B}$ contains coefficients belonging to the jth factor of the characteristic equation (22). We apply Theorem 2.4 to $\mathbf{D}_n$-symmetric coupled cell systems depending on an arbitrary number of finite delays.

The characteristic equation is

$$\det \Delta(\lambda) = \det \Delta_0(\lambda) \prod_{j=1}^{(n-1)/2} [\det \Delta_j(\lambda)]^2 = 0. \tag{34}$$

We can write

$$\Delta_j(\lambda) = \lambda - F(\lambda) - G_j(\lambda),$$

where

$$F(\lambda) = \sum_{i=1}^{p} a_i e^{-\lambda \tau_i}$$

are the terms coming from the internal dynamics of each cell and

$$G_j(\lambda) = \sum_{k=2}^{(n+1)/2} \left[2 \cos\left(\frac{2\pi(k-1)j}{n} \right) \right] \sum_{t=1}^{m_k} \alpha_t^k e^{-\lambda s_t^k}$$

are the contributions from the coupling where m_k is the number of delayed terms in the connection from cell k to 1 and α_t^k are the respective coupling coefficients.

Example 3.7. As an example, consider a delay coupled $\mathbf{D}_5$-symmetric cell. Let $u_s(\theta) = 0$ if $\theta = [-\tau, -s]$ and $u_s(\theta) = 1$ for $\theta \in (-s, 0]$, where $\tau \geq s$ for all delays s, and suppose

$$\eta(\theta) = \begin{bmatrix} p(\theta) & \eta_{21}(\theta) & \eta_{31}(\theta) & \eta_{41}(\theta) & \eta_{51}(\theta) \\ \eta_{21}(\theta) & p(\theta) & \eta_{51}(\theta) & \eta_{31}(\theta) & \eta_{41}(\theta) \\ \eta_{41}(\theta) & \eta_{21}(\theta) & p(\theta) & \eta_{51}(\theta) & \eta_{31}(\theta) \\ \eta_{31}(\theta) & \eta_{41}(\theta) & \eta_{21}(\theta) & p(\theta) & \eta_{51}(\theta) \\ \eta_{51}(\theta) & \eta_{41}(\theta) & \eta_{31}(\theta) & \eta_{21}(\theta) & p(\theta) \end{bmatrix},$$

where

$$p(\theta)=\sum_{i=1}^{2} a_i u_{\tau_i}(\theta), \quad \eta_{21}(\theta)=\sum_{\ell=1}^{3} \alpha_\ell^2 u_{s_\ell^2}(\theta), \quad \text{and} \quad \eta_{31}(\theta)=\sum_{\ell=1}^{2} \alpha_\ell^3 u_{s_\ell^3}(\theta)$$

with the conditions $\eta_{41}(\theta)=\eta_{31}(\theta)$ and $\eta_{51}(\theta)=\eta_{21}(\theta)$ given by Proposition 3.5, part (2). Then,

$$F(\lambda)=\sum_{i=1}^{2} a_i e^{-\lambda\tau_i}$$

and

$$G_j(\lambda)=\sum_{k=2}^{3}\left[2\cos\left(\frac{2\pi(k-1)j}{n}\right)\right]\sum_{t=1}^{m_k}\alpha_t^k e^{-\lambda s_t^k},$$

where $m_2=3$ and $m_3=2$.

Thus, all coefficients b_j^k of $\mathcal{I}_B$ are nonzero and it is convenient to set b_1^j to be the coefficient of a_1; that is, $b_1^j=1$ for $j=0,1,2,\dots,(n+1)/2$, and we keep this convention for the remainder of the paper.

We suppose that the characteristic equation $\det\Delta(\lambda)=0$ has purely imaginary roots coming from all factors; then for $r=(n-1)/2$ we have

$$\mathcal{B}:=\begin{bmatrix} b_1^1 & b_{1+\mu_1}^1 & \cdots & b_{1+\mu_{r-1}}^1 \\ b_1^2 & b_{1+\mu_1}^2 & \cdots & b_{1+\mu_{r-1}}^2 \\ \vdots & \vdots & \ddots & \vdots \\ b_1^r & b_{1+\mu_1}^r & \cdots & b_{1+\mu_{r-1}}^r \end{bmatrix},$$

and we assign the coefficients $b_{1+\mu_j}^i$ as follows. We suppose that the first row corresponds to the factor for the trivial representation, which means that

$$b_{1+\mu_j}^1=2, \qquad j=1,2,\dots,(n-1)/2.$$

Then, we set the remaining coefficients of each row to be equal to $\left[2\cos\left(\frac{2\pi(k-1)j}{n}\right)\right]$ for $k=2,3,\dots,(n+1)/2$, where row $j+1$ has the coefficients of Δ_j for $j=1,2,\dots,(n-1)/2$. This leads to the matrix

(35)
$$\mathcal{B}=\begin{bmatrix} 1 & 2 & 2 & \cdots & 2 & 2 \\ 1 & 2\cos\left(\frac{2\pi}{n}\right) & 2\cos\left(\frac{4\pi}{n}\right) & \cdots & 2\cos\left(\frac{(n-3)\pi}{n}\right) & 2\cos\left(\frac{(n-1)\pi}{n}\right) \\ 1 & 2\cos\left(\frac{4\pi}{n}\right) & 2\cos\left(\frac{8\pi}{n}\right) & \cdots & 2\cos\left(\frac{2(n-3)\pi}{n}\right) & 2\cos\left(\frac{2(n-1)\pi}{n}\right) \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & 2\cos\left(\frac{(n-1)\pi}{n}\right) & 2\cos\left(\frac{2(n-1)\pi}{n}\right) & \cdots & 2\cos\left(\frac{(n-3)(n-1)\pi}{2n}\right) & 2\cos\left(\frac{(n-1)^2\pi}{2n}\right) \end{bmatrix}.$$

Let $i_1<i_2<\cdots<i_s$ be a set of indices chosen from $\{0,\dots,(n-1)/2\}$ defining a combination of factors from the characteristic equation (32). We now construct the $s\times s$

matrix $\mathcal{B}$ by removing rows and columns of (35) not in the set $\{i_1, i_2, \dots, i_s\}$. Suppose that $i_1, \dots, i_s$ are chosen from $\{1, \dots, (n-1)/2\}$; then the matrix $\mathcal{B}$ is symmetric ($\mathcal{B}^T = \mathcal{B}$) and has the form

(36)
$$\mathcal{B} = \begin{bmatrix} 2\cos\left(\frac{2\pi i_1^2}{n}\right) & 2\cos\left(\frac{2\pi i_2 i_1}{n}\right) & \cdots & 2\cos\left(\frac{2\pi i_{s-1} i_1}{n}\right) & 2\cos\left(\frac{2\pi i_s i_1}{n}\right) \\ 2\cos\left(\frac{2\pi i_1 i_2}{n}\right) & 2\cos\left(\frac{2\pi i_2^2}{n}\right) & \cdots & 2\cos\left(\frac{2\pi i_{s-1} i_2}{n}\right) & 2\cos\left(\frac{2\pi i_s i_2}{n}\right) \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 2\cos\left(\frac{2\pi i_1 i_{s-1}}{n}\right) & 2\cos\left(\frac{2\pi i_2 i_{s-1}}{n}\right) & \cdots & 2\cos\left(\frac{2\pi i_{s-1}^2}{n}\right) & 2\cos\left(\frac{2\pi i_s i_{s-1}}{n}\right) \\ 2\cos\left(\frac{2\pi i_1 i_s}{n}\right) & 2\cos\left(\frac{2\pi i_2 i_s}{n}\right) & \cdots & 2\cos\left(\frac{2\pi i_{s-1} i_s}{n}\right) & 2\cos\left(\frac{2\pi i_s^2}{n}\right) \end{bmatrix}.$$

In the other case, $i_1 = 0$ and the matrix is of the form

(37)
$$\mathcal{B} = \begin{bmatrix} 1 & 2 & \cdots & 2 & 2 \\ 1 & 2\cos\left(\frac{2\pi i_2^2}{n}\right) & \cdots & 2\cos\left(\frac{2\pi i_{s-1} i_2 - 1}{n}\right) & 2\cos\left(\frac{2\pi i_s i_2}{n}\right) \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & 2\cos\left(\frac{2\pi i_2 i_{s-1}}{n}\right) & \cdots & 2\cos\left(\frac{2\pi i_{s-1} i_{s-1}}{n}\right) & 2\cos\left(\frac{2\pi i_s i_{s-1}}{n}\right) \\ 1 & 2\cos\left(\frac{2\pi i_2 i_s}{n}\right) & \cdots & 2\cos\left(\frac{2\pi i_{s-1}^2}{n}\right) & 2\cos\left(\frac{2\pi i_s^2}{n}\right) \end{bmatrix}.$$

We can now state our result.

Theorem 3.8. *Consider a linear $\mathbf{D}_n$-symmetric coupled cell system with n odd depending on k delays $\tau_1, \dots, \tau_k$, and let $i_1 < i_2 < \cdots < i_s$ be indices chosen from $\{0, \dots, (n-1)/2\}$ defining a combination of factors from the characteristic equation (32). We assume that the matrix $\mathcal{B}$ given by (36) or (37) is nonsingular. Suppose*

$$\omega_1^1, \dots, \omega_{\ell_{i_1}}^1, \omega_1^2, \dots, \omega_{\ell_{i_2}}^2, \dots, \omega_1^s, \dots, \omega_{\ell_{i_s}}^s$$

are positive and linearly independent over the rationals, where $\ell_{i_1} + \cdots + \ell_{i_s} = k$. Then there exist $\tau_1 > 0, \dots, \tau_k > 0$ and real coefficients a_i such that for all $m = 1, \dots, s$

$$\det \Delta_{i_m}(\lambda) = 0$$

has solutions $i\omega_\ell^m$ for $\ell = 1, \dots, \ell_{i_m}$.

Proof. Since n is odd, the coefficients

$$b_k^j = 2\cos\left(\frac{2\pi(k-1)j}{n}\right)$$

are nonzero for all $k = 2, \ldots, (n+1)/2$ and $j = 0, \ldots, (n-1)/2$. Because $\mathcal{B}$ is assumed to be nonsingular, Theorem 2.4 applies and the result is obtained. ■

The condition that $\mathcal{B}$ is nonsingular does not always hold, as we show in the case $s = 2$. Consider the matrix (37) with $n = 9$ so that $i_2 \in \{1, 2, 3, 4\}$. Choosing $i_2 = 3$ we have the singular matrix

$$\mathcal{B} = \begin{pmatrix} 1 & 2 \\ 1 & 2 \end{pmatrix}.$$

We now show that $\mathcal{B}$ is nonsingular in the case $s = 2$ if the matrix is given by (36); that is,

$$\mathcal{B} = \begin{pmatrix} 2\cos\left(\frac{2\pi i_1^2}{n}\right) & 2\cos\left(\frac{2\pi i_1 i_2}{n}\right) \\ 2\cos\left(\frac{2\pi i_2 i_1}{n}\right) & 2\cos\left(\frac{2\pi i_2^2}{n}\right) \end{pmatrix}.$$

We compute

$$\begin{aligned} \det \mathcal{B} &= 4\left[\cos\left(\frac{2\pi i_1^2}{n}\right)\cos\left(\frac{2\pi i_2^2}{n}\right) - \cos\left(\frac{2\pi i_1 i_2}{n}\right)^2\right] \\ &= 2\left[\cos\left(\frac{2\pi(i_1^2+i_2^2)}{n}\right) + \cos\left(\frac{2\pi(i_1^2-i_2^2)}{n}\right) - \cos\left(\frac{4\pi i_1 i_2}{n}\right) - 1\right]. \end{aligned}$$

We show a few cases explicitly. First, the case $n = 3$ is not relevant since $i_1 < i_2$, $(n-1)/2 = 1$, and $i_1 \neq 0$. We show the case $n = 5$, where we must have $i_1 = 1$ and $i_2 = 2$. This implies that $i_1^2 + i_2^2 = 5$, and so

$$\det \mathcal{B} = 2\left[\cos\left(\frac{4\pi}{5}\right) - \cos\left(\frac{8\pi}{5}\right)\right] \neq 0.$$

We now turn to the general case and show that the determinant cannot vanish. Because the three cosines are projections of nth roots of unity on the real axis for n odd, then

$$\cos\left(\frac{2\pi(i_1^2+i_2^2)}{n}\right) + \cos\left(\frac{2\pi(i_1^2-i_2^2)}{n}\right) - \cos\left(\frac{4\pi i_1 i_2}{n}\right) \neq 1.$$

So if the determinant is to vanish, one of the cosines must be equal to 1. Since $i_1 < i_2$, there is only one option and we must have $i_1^2 + i_2^2 = n$. Thus, $i_1^2 = n - i_2^2$ and

$$\cos\left(\frac{2\pi(i_1^2-i_2^2)}{n}\right) = \cos\left(\frac{2\pi(n-2i_2^2)}{n}\right) = \cos\left(\frac{4\pi i_2^2}{n}\right).$$

If

$$\cos\left(\frac{4\pi i_2^2}{n}\right) - \cos\left(\frac{4\pi i_1 i_2}{n}\right) = 0,$$

this would imply $i_1 = i_2$, but we know that $i_1 < i_2$ and so $\det \mathcal{B}$ cannot vanish. We summarize this result in the next theorem.

Theorem 3.9. *Consider a linear $\mathbf{D}_n$-symmetric coupled cell system with n odd depending on k delays $\tau_1, \ldots, \tau_k$, and let $i_1 < i_2$ be indices chosen from $\{1, \ldots, (n-1)/2\}$ defining a combination of factors from the characteristic equation (32). Suppose*

$$\omega_1^1, \ldots, \omega_{\ell_{i_1}}^1, \omega_1^2, \ldots, \omega_{\ell_{i_2}}^2$$

are positive and linearly independent over the rationals, where $\ell_{i_1} + \ell_{i_2} = k$. Then there exist $\tau_1 > 0$, ..., $\tau_k > 0$ and real coefficients $a_1 \in \mathbb{R}$, ..., $a_p \in \mathbb{R}$ such that for $m = 1$ and $m = 2$

$$\det \Delta_{i_m}(\lambda) = 0$$

has solutions $i\omega_\ell^m$ for $\ell = 1, \ldots, \ell_{i_m}$.

4. Proof of Theorem 2.4. Before we present the proof of Theorem 2.4, we describe in the next lemma the form of the matrix $\mathcal{I}_B$ which appears in the proof and compute its determinant.

Lemma 4.1. *Let $\ell_1, \ldots, \ell_r$ be positive integers and define $\mu_j = \sum_{i=1}^{j} \ell_i$, where $\mu_r = n$ and $\mu_0 := 0$. Consider the $n \times n$ matrix*

$$\mathcal{I}_B := [A_1 \cdots A_j \cdots A_r]^T,$$

where

$$A_j = \begin{bmatrix} b_1^j & \cdots & b_{\mu_{j-1}}^j & b_{1+\mu_{j-1}}^j & b_{2+\mu_{j-1}}^j & \cdots & b_{\mu_j}^j & b_{\mu_j+1}^j & \cdots & b_n^j \\ b_1^j & \cdots & b_{\mu_{j-1}}^j & b_{1+\mu_{j-1}}^j & b_{2+\mu_{j-1}}^j & \cdots & -b_{\mu_j}^j & b_{\mu_j+1}^j & \cdots & b_n^j \\ \vdots & \cdots & \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \cdots & \vdots \\ b_1^j & \cdots & b_{\mu_{j-1}}^j & b_{1+\mu_{j-1}}^j & -b_{2+\mu_{j-1}}^j & \cdots & -b_{\mu_j}^j & b_{\mu_j+1}^j & \cdots & b_n^j \end{bmatrix}$$

is an $\ell_j \times n$ matrix and all elements are nonzero. Then,

$$\det \mathcal{I}_B = \pm \prod_{j=1}^{r} \left[(-2)^{\ell_j - 1} \prod_{s=2}^{\ell_j} b_{s+\mu_{j-1}}^j \right] \det \mathcal{B},$$

where

$$\mathcal{B} := \begin{bmatrix} b_1^1 & b_{1+\mu_1}^1 & \cdots & b_{1+\mu_{r-1}}^1 \\ b_1^2 & b_{1+\mu_1}^2 & \cdots & b_{1+\mu_{r-1}}^2 \\ \vdots & \vdots & \ddots & \vdots \\ b_1^r & b_{1+\mu_1}^r & \cdots & b_{1+\mu_{r-1}}^r \end{bmatrix}.$$

Proof. Substitute row k, denoted by R_k, of

$$A_j = \begin{bmatrix} b_1^j & \cdots & b_{\mu_{j-1}}^j & b_{1+\mu_{j-1}}^j & b_{2+\mu_{j-1}}^j & \cdots & b_{\mu_j}^j & b_{\mu_j+1}^j & \cdots & b_n^j \\ b_1^j & \cdots & b_{\mu_{j-1}}^j & b_{1+\mu_{j-1}}^j & b_{2+\mu_{j-1}}^j & \cdots & -b_{\mu_j}^j & b_{\mu_j+1}^j & \cdots & b_n^j \\ \vdots & \cdots & \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \cdots & \vdots \\ b_1^j & \cdots & b_{\mu_{j-1}}^j & b_{1+\mu_{j-1}}^j & -b_{2+\mu_{j-1}}^j & \cdots & -b_{\mu_j}^j & b_{\mu_j+1}^j & \cdots & b_n^j \end{bmatrix}$$

for $k = 2, \ldots, \ell_j$ by $R_k - R_1$. The matrix A_j becomes

$$\tilde{A}_j := \begin{bmatrix} b_1^j & \cdots & b_{\mu_{j-1}}^j & b_{1+\mu_{j-1}}^j & b_{2+\mu_{j-1}}^j & b_{3+\mu_{j-1}}^j & \cdots & b_{-1+\mu_j}^j & b_{\mu_j}^j & b_{\mu_j+1}^j & \cdots & b_n^j \\ 0 & \cdots & 0 & 0 & 0 & 0 & \cdots & 0 & -2b_{\mu_j}^j & 0 & \cdots & 0 \\ 0 & \cdots & 0 & 0 & 0 & 0 & \cdots & -2b_{-1+\mu_j}^j & -2b_{\mu_j}^j & 0 & \cdots & 0 \\ \vdots & \cdots & \vdots & \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \vdots & \cdots & \vdots \\ 0 & \cdots & 0 & 0 & 0 & -2b_{3+\mu_{j-1}}^j & \cdots & -2b_{-1+\mu_j}^j & -2b_{\mu_j}^j & 0 & \cdots & 0 \\ 0 & \cdots & 0 & 0 & -2b_{2+\mu_{j-1}}^j & -2b_{3+\mu_{j-1}}^j & \cdots & -2b_{-1+\mu_j}^j & -2b_{\mu_j}^j & 0 & \cdots & 0 \end{bmatrix}.$$

We compute the determinant of $\mathcal{I}_B$ by cofactor expansion starting with row 2 of $\tilde{A}_j$, which contains a unique nonzero element $-2b_{\mu_j}^j$. Denote by C_{ij} the (i,j)-cofactor matrix. The row $2+\mu_{j-1}$ of $C_{(2+\ell_{j-1},\mu_j)}$ has a unique nonzero element $-2b_{-1+\mu_j}$, and we perform a cofactor expansion along this row. The row $2+\mu_{j-1}$ of this new cofactor matrix also has a unique nonzero element $-2b_{-2+\mu_j}^j$, and we proceed with the same process removing successively columns $3+\mu_{j-1}$ to μ_j (and the appropriate rows) until the cofactor matrix has only two rows corresponding to the original $\tilde{A}_j$ matrix and the second row has the unique nonzero element $-2b_{2+\mu_{j-1}}$ which is used to perform a cofactor expansion. Performing this process successively on each matrix $\tilde{A}_j$ for $j = 1, \ldots, r$, leaves as a cofactor matrix the $r \times r$ matrix $\mathcal{B}$ defined in the statement. The formula in the lemma is written using $\mu_j = \mu_{j-1} + \ell_j$, and so the lemma is proved. ∎

We are now ready to prove our Theorem 2.4.

Proof of Theorem 2.4. The proof of this theorem is similar to the proof of Theorem 2.1. However, more notation is needed and the details of some calculations are more elaborate because we are now dealing with r factors of the characteristic equation and the vector ω is separated in r subvectors of possibly unequal length.

A necessary and sufficient condition for the conclusion of the theorem to hold is that the following algebraic system of $2n$ equations has a solution in the $2n$ unknowns $(\tau_1, \tau_2, \ldots, \tau_n,$

$a_1, a_2, \ldots, a_n$):

$$\text{(38)}\qquad \begin{cases} \displaystyle\sum_{k=1}^{n} a_k \left(b_k^1 e^{-i\omega_\ell^1 \tau_k}\right) = i\omega_\ell^1, & \ell = 1, \ldots, \ell_1, \\ \displaystyle\sum_{k=1}^{n} a_k \left(b_k^2 e^{-i\omega_\ell^1 \tau_k}\right) = i\omega_\ell^2, & \ell = 1, \ldots, \ell_2, \\ \qquad\vdots \\ \displaystyle\sum_{k=1}^{n} a_k \left(b_k^r e^{-i\omega_\ell^1 \tau_k}\right) = i\omega_\ell^r, & \ell = 1, \ldots, \ell_r, \end{cases}$$

$$\text{(39)}\qquad \begin{cases} \displaystyle\sum_{k=1}^{n} a_k \left(b_k^1 e^{i\omega_\ell^1 \tau_k}\right) = -i\omega_\ell^1, & k = 1, \ldots, \ell_1, \\ \displaystyle\sum_{k=1}^{n} a_k \left(b_k^2 e^{i\omega_\ell^1 \tau_k}\right) = -i\omega_\ell^2, & \ell = 1, \ldots, \ell_2, \\ \qquad\vdots \\ \displaystyle\sum_{k=1}^{n} a_k \left(b_k^r e^{i\omega_\ell^1 \tau_k}\right) = -i\omega_\ell^r, & \ell = 1, \ldots, \ell_r. \end{cases}$$

We introduce the following notation to describe the above system of equations in matrix form. Let

$$\omega = (\omega_1^1, \ldots, \omega_{\ell_1}^1, \ldots, \omega_1^r, \ldots, \omega_{\ell_r}^r),$$

and define (39) as

$$\text{(40)}\qquad \begin{pmatrix} P(\tau;\omega) \\ P(-\tau;\omega) \end{pmatrix} A^T = \begin{pmatrix} i\omega^T \\ -i\omega^T \end{pmatrix},$$

where $A = (a_1, \ldots, a_n)$, superscript T denotes transpose, and $P(\tau;\omega) = P(\tau_1, \ldots, \tau_n; \omega)$ is the $n \times n$ matrix of the form

$$P(\tau;\omega) = \begin{bmatrix} P_1(\tau;\omega) \\ P_2(\tau;\omega) \\ \vdots \\ P_r(\tau;\omega) \end{bmatrix},$$

whose entry at block j, row ℓ, and column k is

$$\left[P_j(\tau;\omega)\right]_{\ell k} = b_k^j e^{-i\omega_\ell^j \tau_k}.$$

Note that $\overline{P(\tau;\omega)} = P(-\tau;\omega)$.

As in the proof of Theorem 2.1, we use the fact that since the ω_ℓ^k are rationally independent, then $\omega\tau_k$ taken modulo 2π generates a dense orbit, denoted $\mathcal{O}_k$, on a torus $\mathbf{T}^n$.

Just as in Theorem 2.1, we embed the problem into a mapping F associated to (40). Let

$$V = \{\Phi = (\Phi^1, \ldots, \Phi^r) \mid \Phi^j = (\Phi_1^j, \ldots, \Phi_j^n),\ \Phi_j^k = (\varphi_{1k}^j, \ldots, \varphi_{\ell_j k}^j),\ j = 1, \ldots, r\},$$

and define

$$F : V \times \mathbb{R}^n \longmapsto \mathbb{R}^{2n}$$

as

$$F(\Phi^1, \dots, \Phi^r, A; \omega) = \begin{pmatrix} \widetilde{P}(\Phi^1, \dots, \Phi^r) \\ \widetilde{P}(-\Phi^1, \dots, -\Phi^r) \end{pmatrix} A^T - i \begin{pmatrix} \omega^T \\ -\omega^T \end{pmatrix}, \tag{41}$$

where A and ω are as previously defined and

$$\widetilde{P}(\Phi^1, \dots, \Phi^r) = \begin{bmatrix} \widetilde{P}_1(\Phi^1) \\ \widetilde{P}_2(\Phi^2) \\ \vdots \\ \widetilde{P}_r(\Phi^r) \end{bmatrix}$$

with

$$\left[\widetilde{P}_j(\Phi^1, \dots, \Phi^n) \right]_{\ell k} = b_k^j e^{-i\varphi_{\ell k}^j}$$

for $j = 1, \dots, r$, $\ell = 1, \dots, \ell_j$, and $k = 1, \dots, n$. The definition of $\widetilde{P}$ uses the following coordinates of V.

We single out some coordinates as follows to facilitate the use of the implicit function theorem. Let $\Psi_j = \Phi_n^j$ and $\Psi = (\Psi_1, \dots, \Psi_r)$, and we now write

$$\Phi = (\Phi_o^1, \dots, \Phi_o^{n-1}),$$

where

$$\Phi_o^j = (\Phi_1^j, \dots, \Phi_{n-1}^j).$$

Thus, the mapping (41) can be written as $F(\Phi, \Psi, A; \omega)$.

We now find an explicit solution of $F = 0$ using the vectors v_j defined in the proof of Theorem 2.1. Denote by $\mathcal{I}^\ell$ the (invertible) $\ell \times \ell$ matrix whose jth column is the vector v_j^T.

We define $\mu_0 := 0$, $\mu_j := \sum_{i=1}^j \ell_i$, and

$$\Theta_{\ell_j} := (\Phi_{1+\mu_{j-1}}^j, \dots, \Phi_{\mu_j}^j).$$

We use the following base point in V. For $j = 1, \dots, r$ define $\hat{\Phi}_j$ be the point given by

$$\hat{\Theta}_{\ell_j} = \frac{-\pi}{2}((v_1, \dots, v_{\ell_j - 1}), v_{\ell_j})$$

and $\hat{\Phi}_i^j = -\frac{\pi}{2} v_1$ for $i \notin \{\mu_{1+\mu_{j-1}}, \dots, \mu_j\}$. In particular, $\hat{\Phi}_{\mu_j}^j = -\frac{\pi}{2} v_{\ell_j}$.

We now evaluate $\widetilde{P}(\widehat{\Phi}, \widehat{\Psi})$ by computing $\widetilde{P}_j(\widehat{\Phi}, \widehat{\Psi})$ for $j = 1, \dots, r$:

$$\widetilde{P}_j(\widehat{\Phi}, \widehat{\Psi}) = i \begin{bmatrix} b_1^j & \cdots & b_{\mu_{j-1}}^j & b_{1+\mu_{j-1}}^j & b_{2+\mu_{j-1}}^j & \cdots & b_{\mu_j}^j & b_{\mu_j+1}^j & \cdots & b_n^j \\ b_1^j & \cdots & b_{\mu_{j-1}}^j & b_{1+\mu_{j-1}}^j & b_{2+\mu_{j-1}}^j & \cdots & -b_{\mu_j}^j & b_{\mu_j+1}^j & \cdots & b_n^j \\ \vdots & \cdots & \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \cdots & \vdots \\ b_1^j & \cdots & b_{\mu_{j-1}}^j & b_{1+\mu_{j-1}}^j & -b_{2+\mu_{j-1}}^j & \cdots & -b_{\mu_j}^j & b_{\mu_j+1}^j & \cdots & b_n^j \end{bmatrix}.$$

Thus,

$$\widetilde{P}(\widehat{\Phi},\widehat{\Psi}) = \begin{bmatrix} \widetilde{P}_1(\widehat{\Phi},\widehat{\Psi}) \\ \vdots \\ \widetilde{P}_j(\widehat{\Phi},\widehat{\Psi}) \\ \vdots \\ \widetilde{P}_r(\widehat{\Phi},\widehat{\Psi}) \end{bmatrix} := i\mathcal{I}_B,$$

where $\mathcal{I}_B$ is invertible by assumption. In particular, $\widetilde{P}(-\widehat{\Phi},-\widehat{\Psi}) = -i\mathcal{I}_B$. We define

$$\widehat{A}^T \equiv (\hat{a}_1,\ldots,\hat{a}_n)^T = \mathcal{I}_B^{-1}\omega^T,$$

which leads to the solution:

$$F(\widehat{\Phi},\widehat{\Psi},\widehat{A};\omega) = 0.$$

Because the ω_j are rationally independent, it follows that the components $\hat{a}_k$ of $\widehat{A}$ are all nonzero.

We now show that we can use the implicit function theorem at the point found above. We define the $\ell \times \ell$ invertible matrix $\mathcal{U}_j$ to be the diagonal matrix whose kth diagonal element is the kth component of the vector v_j (in particular, $\mathcal{U}_1$ is the identity matrix). Note also that $\mathcal{U}_j^{-1} = \mathcal{U}_j$, $j = 1,\ldots,r$. We compute

$$J \equiv D_{(\Psi,A)}F(\widehat{\Phi},\widehat{\Psi},\widehat{A};\omega) = \begin{pmatrix} \hat{U} & i\mathcal{I}_B \\ \hat{U} & -i\mathcal{I}_B \end{pmatrix},$$

where

$$\hat{U} = \operatorname{diag}(\hat{a}_n b_n^1 \mathcal{U}_1^1,\ldots,\hat{a}_n b_n^{r-1}\mathcal{U}_1^{r-1},\hat{a}_n b_n^r \mathcal{U}_{\ell_r}^r)$$

is an $n \times n$ matrix with diagonal blocks of dimensions $\ell_1 \times \ell_1$ to $\ell_r \times \ell_r$. By the implicit function theorem, there exist a neighborhood N of $\widehat{\Phi}$ in V_Φ and a unique smooth function

$$\begin{aligned} G : N &\longmapsto V_\Psi \times \mathbb{R}^n, \\ G : \Phi &\longmapsto G(\Phi) = (G_\Psi(\Phi), G_A(\Phi)) \end{aligned}$$

such that

$$G(\widehat{\Phi}) = (\widehat{\Psi},\widehat{A})$$

and

$$F(\Phi, G(\Phi);\omega) \equiv 0 \quad \forall\, \Phi \in N. \tag{42}$$

Now that we have identified a set of solutions for $F = 0$, we wish to identify within this set solutions which lie on the dense orbits $\mathcal{O}_k$.

We show now that G_Ψ is regular at $\widehat{\Phi}$. A computation shows that

$$K \equiv D_\Phi F(\widehat{\Phi},\widehat{\Psi},\widehat{A};\omega) = \begin{pmatrix} \hat{K} \\ \hat{K} \end{pmatrix},$$

where

$$\hat{K} = \operatorname{diag}(\hat{K}_1, \ldots, \hat{K}_r)$$

is an $n \times (n-1)n$ matrix where the block $\hat{K}_j$ has dimensions $\ell_j \times (n-1)\ell_j$ and is of the form

$$\hat{K}_j = \Big(\begin{array}{cccccccc} \hat{a}_1\, b_1^j\, \mathcal{U}_1^j & \cdots & \hat{a}_{1+\mu_{j-1}}\, b_{1+\mu_{j-1}}^j\, \mathcal{U}_1^j & \hat{a}_{2+\mu_{j-1}}\, b_{2+\mu_{j-1}}^j\, \mathcal{U}_2^j & \cdots & \hat{a}_{\mu_j}\, b_{\mu_j}^j\, \mathcal{U}_{\ell_j}^j \\ \hat{a}_{1+\mu_j} b_{1+\mu_j}^j \mathcal{U}_1^j & \cdots & \hat{a}_{n-1} b_{n-1}^j \mathcal{U}_1^j & & & & & \end{array} \Big).$$

The matrix J is invertible and its inverse is

$$J^{-1} = \begin{pmatrix} \frac{1}{2}\hat{U}^{-1} & \frac{1}{2}\hat{U}^{-1} \\ \frac{-i}{2}\mathcal{I}_B^{-1} & \frac{i}{2}\mathcal{I}_B^{-1} \end{pmatrix}.$$

Implicit differentiation of (42) yields

$$\begin{aligned} DG(\widehat{\Phi}) &= \begin{pmatrix} DG_\Psi(\widehat{\Phi}) \\ DG_A(\widehat{\Phi}) \end{pmatrix} = -J^{-1}K \\ &= \begin{pmatrix} \operatorname{diag}(\mathcal{M}_1, \ldots, \mathcal{M}_r) \\ * \end{pmatrix}, \end{aligned} \tag{43}$$

where $*$ is not important for our purposes and the first component is an $n \times (n-1)n$ matrix composed of $n-1$ block matrices

$$\mathcal{M}_j = \Big(\begin{array}{cccccccc} -\frac{\hat{a}_1 b_1^j}{\hat{a}_{\mu_j} b_{\mu_j}^j} (\mathcal{U}_1^j)^2 & \cdots & -\frac{\hat{a}_{1+\mu_{j-1}} b_{1+\mu_{j-1}}^j}{\hat{a}_{\mu_j} b_{\mu_j}^j} (\mathcal{U}_1^j)^2 & -\frac{\hat{a}_{2+\mu_{j-1}} b_{2+\mu_{j-1}}^j}{\hat{a}_{\mu_j} b_{\mu_j}^j} \mathcal{U}_1^j \mathcal{U}_2^j & \cdots \\ -\frac{\hat{a}_{\mu_j} b_{\mu_j}^j}{\hat{a}_{\mu_j} b_{\mu_j}^j} \mathcal{U}_1^j \mathcal{U}_{\ell_j}^j & -\frac{\hat{a}_{1+\mu_j} b_{1+\mu_j}^j}{\hat{a}_{\mu_j} b_{\mu_j}^j} (\mathcal{U}_1^j)^2 & \cdots & -\frac{\hat{a}_{n-1} b_{n-1}^j}{\hat{a}_{\mu_j} b_{\mu_j}^j} (\mathcal{U}_1^j)^2 & & & & \end{array} \Big)$$

of dimension $\ell_j \times (n-1)\ell_j$, where $j = 1, \ldots, r-1$. Recall that $\mu_r = n$, so that we have

$$\mathcal{M}_r = \Big(\begin{array}{cccccccc} -\frac{\hat{a}_1 b_1^r}{\hat{a}_{\mu_r} b_{\mu_r}^r} \mathcal{U}_{\ell_r}^r \mathcal{U}_1^r & \cdots & -\frac{\hat{a}_{\mu_{r-1}} b_{\mu_{r-1}}^r}{\hat{a}_{\mu_r} b_{\mu_r}^r} \mathcal{U}_{\ell_r}^r \mathcal{U}_1^r & -\frac{\hat{a}_{1+\mu_{r-1}} b_{1+\mu_{r-1}}^r}{\hat{a}_{\mu_r} b_{\mu_r}^r} \mathcal{U}_{\ell_r}^r \mathcal{U}_1^r \\ -\frac{\hat{a}_{2+\mu_{r-1}} b_{2+\mu_{r-1}}^r}{\hat{a}_{\mu_r} b_{\mu_r}^r} \mathcal{U}_{\ell_r}^r \mathcal{U}_2^r & \cdots & -\frac{\hat{a}_{n-1} b_{n-1}^r}{\hat{a}_{\mu_r} b_{\mu_r}^r} \mathcal{U}_{\ell_r}^r \mathcal{U}_{\ell_r-1}^r & & & & & \end{array} \Big).$$

Consequently,

$$DG_\Psi(\widehat{\Phi}) = \operatorname{diag}(\mathcal{M}_1, \ldots, \mathcal{M}_r) \tag{44}$$

is nonsingular and it follows that the mapping

$$G_\Psi : N \longrightarrow V_\Psi$$

is regular at $\widehat{\Phi}$.

From the density of $\mathcal{O}_k$ in $\mathbf{T}^n$ for $k = 1, \ldots, n-1$, we know that for every $\epsilon > 0$ there exists $(\tau_{1,\epsilon}, \ldots, \tau_{n-1,\epsilon})$ such that

$$\Phi_\epsilon^* = (\tau_{1,\epsilon}\omega, \ldots, \tau_{n-1,\epsilon}\omega) \bmod 2\pi$$

is in an ϵ-neighborhood of $\widehat{\Phi}$ in N, and we define a small $(n-1)$-dimensional surface in V_Φ based at Φ^*_ϵ by

$$S^h_{\Phi^*_\epsilon} = \{(\tau_1\omega, \dots, \tau_{n-1}\omega) \bmod 2\pi \mid \tau_j \in (\tau_{j,\epsilon} - h, \tau_{j,\epsilon} + h)\}$$

with $\epsilon, h > 0$ small enough so that $S^h_{\Phi^*_\epsilon} \subset N$. We now show that the image of $S^h_{\Phi^*_\epsilon}$ by G_Ψ has a nontrivial transversal intersection with $\mathcal{O}_\Psi$.

Consider the following $n-1$ vectors in $(\mathbb{R}^{\ell_1})^{n-1} \times (\mathbb{R}^{\ell_2})^{n-1} \times \cdots \times (\mathbb{R}^{\ell_r})^{n-1} \simeq (\mathbb{R}^n)^{n-1}$:

$$\begin{aligned}
W_1 &= (\omega^1, 0, \dots, 0; \omega^2, 0, \dots, 0; \dots; \omega^r, 0, \dots, 0),\\
W_2 &= (0, \omega^1, \dots, 0; 0, \omega^2, \dots, 0; \dots, 0, \omega^r, \dots, 0),\\
&\vdots\\
W_{n-2} &= (0, \dots, \omega^1, 0; 0, \dots, \omega^2, 0; \dots; 0, \dots, \omega^r, 0),\\
W_{n-1} &= (0, \dots, 0, \omega^1; 0, \dots, 0, \omega^2; \dots, 0, \dots, 0, \omega^r),
\end{aligned}$$

where 0 represents the 0 vector in the respective space $\mathbb{R}^{\ell_j}$, and we recall that

$$(\omega^1, \dots, \omega^r) = (\omega^1_1, \dots, \omega^1_{\ell_1}, \dots, \omega^r_1, \dots, \omega^r_{\ell_r}).$$

The set $\{W_1, \dots, W_{n-1}\}$ is linearly independent. We consider the function

$$\mathcal{T} : N \longrightarrow \mathbb{R}$$

defined by

$$\mathcal{T}(\Phi) = \det\begin{pmatrix} DG_\Psi(\Phi)\cdot W_1^T & DG_\Psi(\Phi)\cdot W_2^T & \cdots & DG_\Psi(\Phi)\cdot W_{n-1}^T & \omega^T \end{pmatrix}, \tag{45}$$

and recalling that $(\mathcal{U}^i_j)^2 = I$ for all j, i we compute

$$\begin{aligned}
\mathcal{T}(\hat{\Phi}) &= \det\begin{pmatrix} DG_\Psi(\hat{\Phi})\cdot W_1^T & DG_\Psi(\hat{\Phi})\cdot W_2^T & \cdots & DG_\Psi(\hat{\Phi})\cdot W_{n-1}^T & \omega^T \end{pmatrix}\\
&= \det(\alpha_{jk}),
\end{aligned} \tag{46}$$

where $j = 1, \dots, r$, $k = 1, \dots, n$. The elements of the matrix (α_{jk}) are

$$\alpha_{1k} = \begin{cases} -\frac{\hat{a}_k b^1_k}{\hat{a}_{\mu_1} b^1_{\mu_1}} \mathcal{U}^1_1 \mathcal{U}^1_k (\omega^1)^T, & k = 1, \dots, \ell_1,\\ -\frac{\hat{a}_k b^1_k}{\hat{a}_{\mu_1} b^1_{\mu_1}} (\mathcal{U}^1_1)^2 (\omega^1)^T, & k = 1 + \ell_1, \dots, n-1,\\ \frac{\hat{a}_{\mu_1} b^1_{\mu_1}}{\hat{a}_{\mu_1} b^1_{\mu_1}} (\mathcal{U}^1_1)^2 (\omega^1)^T, & k = n, \end{cases}$$

and for $j = 2, \dots, r-1$

$$\alpha_{jk} = \begin{cases} -\frac{\hat{a}_k b^j_k}{\hat{a}_{\mu_j} b^j_{\mu_j}} (\mathcal{U}^j_1)^2 (\omega^j)^T, & k = 1, \dots, \mu_{j-1}, \quad \text{and} \quad k = \mu_j + 1, \dots, n-1,\\ -\frac{\hat{a}_k b^j_k}{\hat{a}_{\mu_j} b^j_{\mu_j}} \mathcal{U}^j_1 \mathcal{U}^j_{k-\mu_{j-1}} (\omega^j)^T, & k = 1 + \mu_{j-1}, \dots, \mu_j,\\ \frac{\hat{a}_{\mu_j} b^j_{\mu_j}}{\hat{a}_{\mu_j} b^j_{\mu_j}} (\mathcal{U}^j_1)^2 (\omega^j)^T, & k = n, \end{cases}$$

and finally

$$\alpha_{rk} = \begin{cases} -\frac{\hat{a}_k b^r_k}{\hat{a}_{\mu_r} b^r_{\mu_r}} \mathcal{U}^r_{\ell_r} \mathcal{U}^r_1 (\omega^r)^T, & k = 1, \dots, \mu_{r-1}, \\ -\frac{\hat{a}_k b^r_k}{\hat{a}_{\mu_r} b^r_{\mu_r}} \mathcal{U}^r_{\ell_r} \mathcal{U}^r_{k-\mu_{r-1}} (\omega^r)^T, & k = 1 + \mu_{r-1}, \dots, \mu_r - 1, \\ \frac{\hat{a}_{\mu_r} b^r_{\mu_r}}{\hat{a}_{\mu_r} b^r_{\mu_r}} (\mathcal{U}^r_{\ell_r - 1})^2 (\omega^r)^T, & k = n, \end{cases}$$

where we recall that $\mu_r = n$. Note that the elements of the last column are rewritten so as to lead to the significant simplification of the determinant to the following form:

(47)
$$\mathcal{T}(\hat{\Phi}) = \frac{(-1)^{n-1} \omega^1_1 \cdots \omega^1_{\ell_1} \cdots \omega^r_1 \cdots \omega^r_{\ell_r} \hat{a}_1 \cdots \hat{a}_{n-1}}{(\hat{a}_{\mu_1} b^1_{\mu_1})^{\ell_1} \cdots (\hat{a}_{\mu_r} b^r_{\mu_r})^{\ell_r}} \det(\operatorname{diag}(\mathcal{U}^1_1, \mathcal{U}^2_1, \dots, \mathcal{U}^{r-1}_1, \mathcal{U}^r_{\ell_r})) \det \mathcal{I}'_B,$$

where

$$\mathcal{I}'_B = \begin{pmatrix} Q_1 \\ Q_2 \\ \vdots \\ Q_r \end{pmatrix},$$

and for $j = 1, \dots, r$

$$Q_j = \begin{bmatrix} b^j_1 & \cdots & b^j_{\mu_{j-1}} & b^j_{1+\mu_{j-1}} & b^j_{2+\mu_{j-1}} & \cdots & b^j_{\mu_j} & b^j_{\mu_j+1} & \cdots & \hat{a}_{\mu_j} b^j_{\mu_j} \\ b^j_1 & \cdots & b^j_{\mu_{j-1}} & b^j_{1+\mu_{j-1}} & b^j_{2+\mu_{j-1}} & \cdots & -b^j_{\mu_j} & b^j_{\mu_j+1} & \cdots & \hat{a}_{\mu_j} b^j_{\mu_j} \\ \vdots & \cdots & \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \cdots & \vdots \\ b^j_1 & \cdots & b^j_{\mu_{j-1}} & b^j_{1+\mu_{j-1}} & -b^j_{2+\mu_{j-1}} & \cdots & -b^j_{\mu_j} & b^j_{\mu_j+1} & \cdots & \hat{a}_{\mu_j} b^j_{\mu_j} \end{bmatrix}$$

is an $\ell_j \times n$ matrix. Moreover, $\det \mathcal{I}'_B \neq 0$ since $\det \mathcal{I}'_B = \hat{a}_n \det \mathcal{I}_B$ and $\hat{a}_n \neq 0$. Thus $\mathcal{T}(\hat{\Phi}) \neq 0$, and the conclusion is exactly the same as in Theorem 2.1; hence the theorem is proved. ∎

5. Conclusion. We have shown in this paper that n nonresonant eigenvalues on the imaginary axis can be realized by a scalar DDE with n delays. Moreover, the same is true for any collection of n imaginary eigenvalues in a neighborhood of an n-tuple of nonresonant imaginary eigenvalues. We have also shown how these results can be applied to nonscalar DDEs in the context of symmetric DDEs, where the characteristic equation decomposes according to the isotypic decomposition. We apply our result to delay coupled $\mathbf{D}_n$-symmetric cell systems with n odd.

There are several ways of extending the main result of our paper. One question we did not address in this paper is if n nonresonant nonzero imaginary eigenvalues constitute an upper bound for the realizability by a scalar equation with n delay. The case $n = 1$ is one such example since an easy calculation shows that we can have at most one imaginary eigenvalue on the imaginary axis. It is likely, but unknown, that this is also true for general n.

One may want to study whether k zero eigenvalues in a single Jordan block and ℓ nonresonant nonzero imaginary eigenvalues can be realized in a scalar DDE with $k + \ell$ delays. This problem may be feasible by modifying the proof of Theorem 2.1 since the nonresonance of the ℓ eigenvalues is again present. However, we expect the argument used in this paper to

break down for n nonzero imaginary eigenvalues with resonance. We can also study the same problem as in this paper but for higher-dimensional delay equations. One problem would be to find out if n nonresonant nonzero imaginary eigenvalues can be realized by an m-dimensional system with k delays. For instance, it is known that a pair of nonzero imaginary eigenvalues can be realized by a two-dimensional equation with one delay [8]. In this case $n = 2$, $m = 2$, $k = 1$, and so $n = mk$; is it possible to realize three nonresonant nonzero eigenvalues, or does the relationship $n = mk$ provide a bound to realizability in general?

Another problem which can be studied is whether a restriction in the class of delay equation can change the realizability. For instance, the characteristic equation for a general two-dimensional system with one-delay τ is

$$\lambda^2 + a\lambda + b\lambda e^{-\lambda\tau} + c + de^{-\lambda\tau} = 0,$$

while for a second-order equation with one delay in the feedback term we must set $b = 0$. We know in this case that two nonresonant nonzero imaginary eigenvalues can be realized by a second-order equation with a unique delay in the feedback term [4]. In fact, two imaginary eigenvalues with $1 : 2$ resonance have been found in such an equation [5]. The obvious question is to see if n nonresonant (and resonant) nonzero imaginary eigenvalues can be realized within the class of nth-order scalar equations with one delay in the feedback term.

An extension of our main result in a direction relevant for studying bifurcations is to find out whether the n nonresonant nonzero imaginary eigenvalues can be realized by a scalar delay equation such that the remaining eigenvalues have negative real parts; that is, the multiple Hopf point lies at the boundary of the stability region for the equilibrium solution. This is typically verified in stability analysis of specific equations. For scalar problems see Bélair and Campbell [1] for a thorough analysis of a two-delay case and a review of several other cases. Yuan and Campbell [31] study the stability regions for $\mathbf{D}_n$-symmetric rings of scalar cells with nearest neighbor delay coupling and simultaneously obtain the location of multiple Hopf bifurcation points at the boundary of the stability region.

Finally, let us mention the case of linear T-periodic equations with $N + 1$ delays:

$$\dot{x} = \sum_{j=0}^{N} a_j(t)x(t - \tau_j), \tag{48}$$

where each $a_j(t)$ is a T-periodic $n \times n$ matrix. Hale [19] states the following open problem:

> *Is it possible to give a precise upper bound in terms of N on the number of Floquet multipliers of (48) that can have moduli 1?*

If we restrict (48) to scalar equations, we can pose a possibly simpler problem which is related to the main result of our paper:

> *Is it possible to realize $N + 1$ complex numbers $e^{\pm i\omega_1}, \ldots, e^{\pm i\omega_{N+1}}$ with $\omega_1, \ldots, \omega_{N+1}$ positive and rationally independent as Floquet multipliers of the scalar equation (48)?*

This problem is automatically solved by Theorem 2.1 if a Floquet theorem can be applied to (48); that is, the Floquet exponents of the Floquet multipliers of (48) are eigenvalues of a scalar equation (1) with $N + 1$ delays. Such a theorem has not been proved in general; however, it may hold true given that some conditions are imposed on (48).

Acknowledgment. We would like to thank the referees for their suggestions concerning the contents and presentation of the paper.

Singular Hopf Bifurcation in Systems with Two Slow Variables*

John Guckenheimer†

Abstract. Hopf bifurcations have been studied intensively in two dimensional vector fields with one slow and one fast variable [É. Benoît et al., *Collect. Math.*, 31 (1981), pp. 37–119; F. Dumortier and R. Roussarie, *Mem. Amer. Math. Soc.*, 121 (577) (1996); W. Eckhaus, in *Asymptotic Analysis* II, Lecture Notes in Math. 985, Springer-Verlag, Berlin, 1983, pp. 449–494; M. Krupa and P. Szmolyan, *SIAM J. Math. Anal.*, 33 (2001), pp. 286–314; J. Guckenheimer, in *Normal Forms, Bifurcations and Finiteness Problems in Differential Equations*, NATO Sci. Ser. II Math. Phys. Chem. 137, Kluwer, Dordrecht, The Netherlands, 2004, pp. 295–316]. *Canard explosions* are associated with these *singular Hopf* bifurcations [S. M. Baer and T. Erneux, *SIAM J. Appl. Math.*, 46 (1986), pp. 721–739; S. M. Baer and T. Erneux, *SIAM J. Appl. Math.*, 52 (1992), pp. 1651–1664; B. Braaksma, *J. Nonlinear Sci.*, 8 (1998), pp. 457–490; Y. Lijun and Z. Xianwu, *J. Differential Equations*, 206 (2004), pp. 30–54], manifested by a very rapid growth in the amplitude of periodic orbits. There has been less analysis of Hopf bifurcations in slow-fast systems with two slow variables where singular Hopf bifurcation occurs simultaneously with *type* II *folded saddle-nodes* [A. Milik and P. Szmolyan, in *Multiple-Time-Scale Dynamical Systems*, IMA Vol. Math. Appl. 122, Springer-Verlag, New York, 2001, pp. 117–140; M. Wechselberger, *SIAM J. Appl. Dyn. Syst.*, 4 (2005), pp. 101–139]. This work contributes to our understanding of these Hopf bifurcations in five ways: (1) it computes the first Lyapunov coefficient of the bifurcation in terms of a normal form, (2) it describes global features of the flow that constrain the types of trajectories found in the system near the bifurcation, (3) it identifies codimension two bifurcations that occur as coefficients in the normal form vary, (4) it exhibits complex solutions that occur in the vicinity of the bifurcation for some values of the normal form coefficients, and (5) it identifies singular Hopf bifurcation as a mechanism for the creation of mixed-mode oscillations. A subtle aspect of the normal form is that terms of higher order contribute to the first Lyapunov coefficient of the bifurcation in an essential way.

Key words. Hopf bifurcation, mixed mode oscillation, singular perturbation

1. Introduction.

Slow-fast vector fields have the form

$$\begin{aligned} \varepsilon \dot{x} &= f(x, y, \varepsilon), \\ \dot{y} &= g(x, y, \varepsilon), \end{aligned} \tag{1.1}$$

with $x \in R^m$ as the fast variable, $y \in R^n$ as the slow variable, and ε as a small parameter that represents the ratio of time scales. The set of points satisfying $f = 0$ is the *critical manifold* of the system: slow motion of trajectories can occur only near the critical manifold. Fenichel theory [14] establishes that there are invariant slow manifolds of the system near portions of the critical manifold, where $D_x f$ is hyperbolic. Moreover, the trajectories on the

*Received by the editors March 14, 2008; accepted for publication (in revised form) by T. Kaper July 10, 2008; published electronically October 31, 2008.
http://www.siam.org/journals/siads/7-4/71852.html
†Mathematics Department, Cornell University, Ithaca, NY 14853 (jmg16@cornell.edu).

slow manifold approach trajectories of the *slow flow* $\dot{y} = g(h(y), y, 0)$ on the critical manifold where h is defined implicitly by $f(h(y), y, 0) = 0$. Points of the critical manifold where $D_x f$ is singular are called *fold* points. In much of the literature on slow-fast models of neural systems, the fold points are called "knees" [29].

Hopf bifurcation occurs in the following slow-fast system with one slow and one fast variable:

$$\begin{aligned} \varepsilon \dot{x} &= y - x^2/2 - x^3/3, \\ \dot{y} &= \mu - x. \end{aligned} \tag{1.2}$$

This system has an equilibrium point at $(\mu, \mu^2/2 + \mu^3/3)$ that undergoes a supercritical Hopf bifurcation as μ decreases through zero. The Hopf equilibrium is at the fold of the system. We also note that the slow flow along the critical manifold has a stable equilibrium on a stable branch of the critical manifold for $\mu > 0$ but an unstable equilibrium on the unstable branch of the critical manifold for $-1 < \mu < 0$. The periodic orbits that emerge from the Hopf bifurcation grow explosively from an amplitude that is $O(\varepsilon^{1/2})$ to an amplitude that is $O(1)$ over a range of values of μ that has length $O(\exp(-c/\varepsilon))$ for a constant $c > 0$ independent of ε. This *canard explosion* was discovered by Benoît et al. [7] and subsequently analyzed by Eckhaus [13], Dumortier and Roussarie [12], and others [23, 15].

Consider now another system with one slow and one fast variable:

$$\begin{aligned} \varepsilon \dot{x} &= y - x^2, \\ \dot{y} &= \mu - x + ay. \end{aligned} \tag{1.3}$$

This system also has a Hopf bifurcation, but it occurs when $x = \varepsilon a/2$, $y = \varepsilon^2 a^2/4$, and $\mu = \varepsilon a/2 - \varepsilon^2 a^3/4$. Its point of Hopf bifurcation is on the critical manifold but displaced from the fold by a distance that is $O(\varepsilon)$. When $a \neq 0$, the periodic orbits in the canard explosion of this system grow monotonically with variations of μ like those of system (1.2), but they become unbounded as μ varies over a finite interval. Whether the bifurcation is subcritical or supercritical is determined by the sign of a. When $a = 0$, the singular Hopf bifurcation at $\mu = 0$ is totally degenerate: system (1.3) has a family of periodic orbits that are level curves of the function $H(x, y) = \exp(-2y/\varepsilon)(y - x^2 + \varepsilon/2)$. In this case, the parabola $H = 0$ contains the stable and unstable slow manifolds of the system, and it bounds the family of periodic orbits.

The system (1.3) can be rescaled by $x = \varepsilon^{1/2} X$, $y = \varepsilon Y$, and $t = \varepsilon^{1/2} T$ to give

$$\begin{aligned} X' &= Y - X^2, \\ Y' &= \varepsilon^{-1/2}\mu - X + \varepsilon^{1/2} aY. \end{aligned} \tag{1.4}$$

This system can be transformed to the Hopf normal form

$$\begin{aligned} r' &= \frac{\varepsilon^{1/2} a}{16\sqrt{1 - \varepsilon a^2}} r^3 + o(r^3), \\ \theta' &= \sqrt{(1 - \varepsilon a^2)} + o(r) \end{aligned} \tag{1.5}$$

at the equilibrium.

System (1.3) is representative of generic singular Hopf bifurcations [2, 3, 8, 25] with one slow and one fast variable. There are three aspects of the bifurcation that are directly influenced by multiple time scales:

- The bifurcation occurs at a distance that is $O(\varepsilon)$ from a fold point.
- The periodic orbits emanating from the Hopf bifurcation undergo a canard explosion.
- The slow stable and unstable manifolds of the system cross each other as a varies.

Tangential intersections of the slow stable and unstable manifolds are not bifurcations in traditional terms, but rather a degeneracy in the slow-fast decomposition of the system [15] comparable to a homoclinic/heteroclinic bifurcation. Generically, such tangencies occur at different parameter values from those where the equilibrium point is on a fold curve or at the Hopf bifurcation parameter value. The crossing marks the transition from parameters at which the slow stable manifold converges to the equilibrium or periodic orbit and parameters for which it jumps along the fast direction after approaching the vicinity of the equilibrium. This transition is one of the most significant changes in dynamical behavior associated with the singular Hopf bifurcation.

Singular Hopf bifurcations with two slow variables and one fast variable are analogous to system (1.3) with a single slow variable. There are counterparts to each of the three properties listed above. Equilibrium points of a system with two slow variables lie on its two dimensional critical manifold. The folds of the critical manifold form a curve. A stable equilibrium point of the system (1.1) may approach and cross the fold curve in a generic manner when a single parameter is varied. If it does so, Hopf bifurcation occurs at a distance $O(\varepsilon)$ from the fold curve. Canard explosions also occur, but the dimension of the state space is now large enough to allow period-doubling and torus bifurcations as the periodic orbits grow. Section 3 gives examples of each of these bifurcations. In systems with two slow variables and one fast variable, the slow stable and unstable manifolds are each two dimensional and therefore can intersect transversally along a trajectory in the three dimensional state space. These intersections occur for open sets of parameters and are a common feature of systems near singular Hopf bifurcations. The location of the slow stable and unstable manifold intersections helps determine whether there are bounded attractors near the singular Hopf bifurcation.

This paper explores the dynamics of singular Hopf bifurcation via analysis of normal forms. Coordinate changes and scaling suggest a normal form analogous to (1.3), but the normal form has four coefficients that cannot be scaled to fixed values. If these coefficients are regarded as parameters (or *moduli*), then degenerate Hopf bifurcations occur in the system for some values of these coefficients. Regarding one of the coefficients as a second parameter, the theory of codimension two bifurcations [18] can be used to investigate the dynamics. In some cases, higher order terms in ε must be retained in a rescaled normal form to obtain nondegeneracy of the codimension two bifurcations.

Singular Hopf bifurcation with two slow variables has been studied previously in other papers [3, 8, 25, 27]. The normal form used by Braaksma [8] differs from the one used here: one difference is that Braaksma's normal form has "global returns" of trajectories that leave the vicinity of the equilibrium point in the flow. System (1.2) also has global returns but just one slow variable. This paper emphasizes the role of singular Hopf bifurcation in the creation of certain types of mixed-mode oscillations (MMOs). MMOs are oscillations in which there are small and large amplitude cycles in each period of the oscillation. Singular Hopf bifurca-

tions produce small oscillations near the equilibrium point that can be combined with global returns to create MMOs. MMOs appear to have been studied first in chemically reacting systems [4, 5, 22, 27] and then in lasers [21]. More recently, MMOs have been studied in neural oscillations [9], where they are sometimes associated with folded nodes [31, 33, 17] as well as singular Hopf bifurcations. Some of the subsidiary bifurcations analyzed here have been observed in the models of chemical oscillators, but their relationship to singular Hopf bifurcation does not seem to have been noticed previously. Section 4 discusses the "autocatalator" model analyzed by Petrov, Scott, and Showalter [28] and Milik and Szmolyan [27].

2. Coordinate changes and normal forms. The goal of this section is to derive a normal form for a generic system with two slow variables and one fast variable with an equilibrium point that crosses a simple fold transversally. We denote x as the fast variable and (y, z) as the slow variables. The fast equation for such a system near a simple fold can be reduced to $\varepsilon\dot{x} = y - x^2$ [1], perhaps using a rescaling of time. This is our starting point for deriving a normal form for singular Hopf bifurcation. We approximate the system by truncating nonlinear terms in the Taylor series expressions for $\dot{y}$ and $\dot{z}$. The truncated system is further reduced by noting that if $\dot{y} = \alpha + \beta x + \gamma y + \delta z$, then replacing z by $w = \alpha + \gamma y + \delta z$ makes $\dot{y} = \beta x + w$ while $\dot{w}$ is still an affine function of (x, y, z). We relabel w as z. Hopf bifurcation occurs when $\beta < 0$. Rescaling (x, y, z, t) by $(|\beta|^{1/2}, |\beta|, |\beta|^{3/2}, |\beta|^{-1/2})$ makes a further reduction to the case that $\beta = -1$. These coordinate transformations yield a truncated system of the form

$$\begin{aligned} \varepsilon\dot{x} &= y - x^2, \\ \dot{y} &= z - x, \\ \dot{z} &= -\mu - ax - by - cz. \end{aligned} \tag{2.1}$$

Note that a detailed study of higher degree normal forms for singular Hopf bifurcation with two slow variables does not appear in the literature. The term singular point is used in Arnold et al. [1] to refer to folded singularities [15] (pseudosingularities in Benoît [6]) that are regular points of the vector field (1.1) when $\varepsilon > 0$. A final rescaling $(x, y, z, t) = (\varepsilon^{1/2}X, \varepsilon Y, \varepsilon^{1/2}Z, \varepsilon^{1/2}T)$ and $(A, B, C) = (\varepsilon^{1/2}a, \varepsilon b, \varepsilon^{1/2}c)$ eliminates ε from the system:

$$\begin{aligned} X' &= Y - X^2, \\ Y' &= Z - X, \\ Z' &= -\mu - AX - BY - CZ. \end{aligned} \tag{2.2}$$

Our numerical studies and bifurcation analysis will be conducted largely with system (2.2). Note that A, B, and C tend to zero as $\varepsilon \to 0$ and that B tends to zero faster than A and C. The extent to which nonlinear terms in the equations for $\dot{y}$ and $\dot{z}$ that have order $\varepsilon^{1/2}$ following rescaling influence the dynamics described in this paper has not been investigated.

The "desingularized" slow flow of system (2.1) is

$$\begin{aligned} \dot{z} &= -2x(\mu + ax + bx^2 + cz), \\ \dot{x} &= z - x. \end{aligned} \tag{2.3}$$

This equation is obtained from (2.1) by setting $\varepsilon = 0$, differentiating the resulting equation $y - x^2 = 0$ to obtain $\dot{y} = 2x\dot{x}$, then eliminating $\dot{y}$ from the second equation and finally rescaling the equation by $2x$.

3. Normal form dynamics and flow maps. This section investigates the dynamics of the systems (2.1) and (2.2). As μ varies near zero in system (2.1), the equilibrium point crosses the fold curve of the critical manifold at the origin. This crossing has been called a *folded saddle-node type* II by Milik and Szmolyan [27] because the slow flow (2.3) has a degenerate equilibrium point at this parameter value. The bifurcation in the slow flow is a transcritical bifurcation. The origin is always a folded singularity (or pseudosingularity) that is a saddle when $\mu < 0$, a node when $0 < \mu < 1/8$, and a focus when $1/8 < \mu$. While the folded saddle-node appears as the main change in the dynamics of the slow flow, Hopf bifurcations of the systems (2.1) and (2.2) typically occur at nonzero values of μ. The equilibrium point of system (2.1) undergoes Hopf bifurcation at a value of μ that is $O(\varepsilon)$. Much of the analysis in this section is devoted to exploring this Hopf bifurcation and the family of periodic orbits emerging from it.

3.1. Hopf bifurcation. Equilibria of system (2.2) occur at points (X_e, X_e^2, X_e) with $\mu = -AX_e - BX_e^2 - CX_e$. The Jacobian at this equilibrium is the matrix

$$\begin{pmatrix} -2X_e & 1 & 0 \\ -1 & 0 & 1 \\ -A & -B & -C \end{pmatrix},$$

whose characteristic polynomial is

$$P(s) = s^3 + (C + 2X_e)s^2 + (B + 2X_eC + 1)s + (A + 2X_eB + C).$$

Thus Hopf bifurcation of the system occurs where $(B + 2X_eC + 1) > 0$ and

$$(C + 2X_e)(B + 2X_eC + 1) = (A + 2X_eB + C).$$

Note that $(B+2X_eC+1) > 0$ is satisfied when B and C are small. Thus, the Hopf bifurcation locus of system (2.2) is parametrized by the equations

$$\begin{aligned} A &= BC + 2X_eC^2 + 4X_e^2C + 2X_e, \\ \mu &= -AX_e - BX_e^2 - CX_e \end{aligned} \tag{3.1}$$

in terms of the equilibrium position X_e and the parameters B, C. If $B = 0$, then $A = 2X_eC^2 + 4X_e^2C + 2X_e$ and $\mu = -(2X_eC^2 + 4X_e^2C + 2X_e + C)X_e$. Since B is $O(\varepsilon)$ while A and C are $O(\varepsilon^{1/2})$, zero eigenvalues of the equilibrium occur near the origin only if $a + c$ is small in system (2.1).

The program Maple [26] has been used to compute the Hopf normal form of system (2.2). Consider first the case $B = 0$. System (2.2) can then be transformed to its Hopf normal form by rational coordinate changes if A, C, and μ are parametrized by X_e and ω, the magnitude of its imaginary eigenvalue. Whether the bifurcation is subcritical or supercritical is determined

by the sign of the first Lyapunov coefficient.[1] Maple yields the following expression for the first Lyapunov coefficient:

$$4\,\frac{{X_e}^3\left(12\,\omega^2{X_e}^2-4\,{X_e}^2-2\,\omega^2+\omega^4+1\right)}{\left(1-2\,\omega^2+\omega^4+12\,\omega^2{X_e}^2-8\,{X_e}^2+16\,{X_e}^4\right)\left(16\,{X_e}^4-8\,{X_e}^2+24\,\omega^2{X_e}^2-2\,\omega^2+\omega^4+1\right)}.$$

Substituting $\omega = \sqrt{1+2X_eC}$ and $X_e = 1/8\,\frac{-2\,C^2-2+2\,\sqrt{C^4+2\,C^2+1+4\,CA}}{C}$ gives the first Lyapunov coefficient in terms of A and C. The first Lyapunov coefficient is divisible by A and the leading order term of its Taylor series is $A/4$. The leading order term in the expansion of μ at the Hopf bifurcation is $-A(A+C)/2$. Following the rescaling of (2.1), the first Lyapunov coefficient is $O(\varepsilon^{1/2})$ and the value of μ is $O(\varepsilon)$.

Interestingly, there is a second term in the first Lyapunov coefficient of system (2.2) that is $O(\varepsilon^{1/2})$ in the case that $B \neq 0$ even though B is $O(\varepsilon)$. The coordinate transformations to Hopf normal form are rational if the system is parametrized by ω, X_e, and r, the magnitude of the real eigenvalue. Maple computes the first Lyapunov coefficient as a rational function P/Q of r, X_e, and ω. The leading terms in the Taylor series expansion of P and Q as functions of A, B, and C are $16C^5(2B + A^2 + AC + 2B^2)$ and $64C^5(A + C)$, respectively. If A and C are $O(\varepsilon^{1/2})$ and B is $O(\varepsilon)$, the first Lyapunov coefficient is $\frac{A}{4} + \frac{B}{2(A+C)} + o(\varepsilon^{1/2})$. Thus, even though B has higher order than A and C in terms of ε, it plays a significant role in the dynamics associated with the Hopf bifurcations of system (2.2).

Two different ways in which the nondegeneracy conditions for the Hopf bifurcation can fail are that the real eigenvalue r vanishes and that the first Lyapunov coefficient vanishes. Both of these degeneracies occur for small values of the parameters (A, B, C). When $r = 0$, a codimension two saddle-node Hopf bifurcation occurs if appropriate nondegeneracy conditions are met. The first Lyapunov coefficient vanishes along a surface in the parameter space that is asymptotic to $B = -A(A + C)/2$ as $\varepsilon \to 0$. This produces a *generalized* Hopf bifurcation, first analyzed by Bautin. The saddle-node Hopf and generalized Hopf bifurcations of system (2.2) are discussed in the next two subsections.

3.2. Saddle-node Hopf bifurcations. Saddle-node Hopf bifurcations (also called fold-Hopf bifurcations) occur at equilibria with both a zero eigenvalue and a pair of pure imaginary eigenvalues. The parameter values for which system (2.2) has such an equilibrium are given by $A = C(B - 1)$ and $\mu = BC^2/4$. Alternatively, these can be expressed by the equations $B = (A + C)/C$ and $\mu = C(A + C)/4$. Since B is of higher order than A and C in ε, these bifurcations are located where $A \approx -C$.

The truncated normal form of the saddle-node Hopf bifurcation [18] can be written in polar coordinates as

$$\begin{aligned}\dot r &= a_1 r z,\\ \dot z &= b_1 r^2 + b_2 z^2,\\ \dot\theta &= \omega.\end{aligned}$$

[1]The magnitude of the first Lyapunov coefficient depends upon the coordinates used in the eigenspace of the pure imaginary eigenvalues. Guckenheimer and Holmes [18] and Kuznetsov [24] use different coordinate systems that yield expressions which differ by a factor of 2. The expression here follows the conventions of Guckenheimer and Holmes [18].

The three coefficients a_1, b_1, b_2 determine the main features of the dynamics of its unfolding, for example, whether invariant tori occur close to the bifurcation. Maple calculations yield the expressions $\omega = 1 + B - C^2$ and

$$a_1 = \frac{C^2 - 1}{\omega^2},$$
$$b_1 = \frac{-B}{2\omega^2},$$
$$b_2 = \frac{-2B}{\omega^2}.$$

If $B > 0$, then all of these coefficients are negative, while if $B < 0$, then a_1 is negative and b_1, b_2 are both positive. Since $|b_i| < |a_1|$, these correspond to the cases IVb and III of Guckenheimer and Holmes [18, section 7.4]. Small invariant tori and chaotic solutions occur in generic unfoldings of case III.

3.3. Degenerate Hopf bifurcations. Hopf bifurcations are degenerate when their first Lyapunov coefficient vanishes [24]. Takens [32] described the unfolding of codimension two degenerate Hopf bifurcations, assuming that the second Lyapunov coefficient does not vanish. In the unfolding, the Hopf bifurcation makes a transition between subcritical and supercritical and there is a region with two periodic orbits that annihilate each other in a saddle-node of limit cycles bifurcation [18].

To find parameters where degenerate Hopf bifurcation might occur, we express the first Lyapunov coefficient as a rational function of X_e, A, B, C. Denote its numerator by P. We then compute the resultant of P and the Hopf polynomial $BC + 2X_e + 4CX_e^2 + 2X_eC^2 - A$ as functions of X_e to obtain a polynomial $R_H(A, B, C)$ that vanishes at degenerate Hopf points:

$$\begin{aligned}
R_H(A,B,C) = 256\,C^2(&-12\,A^2B - 15\,B^2A^2 + 20\,C^5A + 16\,C^2A^2 + 76\,C^4A^2 + 92\,C^3A^3\\
&+ 36\,C^2A^4 + 8\,C^7A + 16\,C^6A^2 + 8\,C^5A^3 + 8\,CA^3 + 16\,C^2B + 56\,BC^6\\
&+ 54\,C^4B - 120\,C^4B^2 - 65\,C^2B^2 + 36\,C^4B^5 + 91\,C^2B^4 + 8\,C^4B^3\\
&- 26\,C^6B^3 - 10\,C^4B^4 - 85\,C^6B^2 - 10\,C^8B^2 + 46\,C^2B^3 + 4\,B^2C^{10}\\
&- 32\,B^3C^8 + 55\,C^6B^4 + 26\,C^8B + 4\,C^{10}B + 8\,C^3A - 24\,B^2 - 24\,B^3\\
&+ 100\,C^3BA^3 - 144\,C^5B^3A - 124\,CB^3A - 156\,CB^2A + 22\,C^2BA^2\\
&- 32\,C^2B^3A^2 - 64\,CA^3B^2 + 60\,C^3B^4A + 76\,C^7AB - 52\,BCA^3\\
&+ 50\,BC^6A^2 + 4\,C^9AB - 95\,C^4B^2A^2 + 172\,C^3B^3A - 170\,C^3B^2A\\
&- 244\,C^5B^2A\\
&+ 128\,C^3BA + 148\,C^5BA + 4\,BCA + 192\,C^4BA^2\\
&- 210\,C^2B^2A^2 + 14\,C^7B^2A).
\end{aligned}$$

The leading order terms of $R_H(A, B, C)$ are

$$-1024\,C^2B\left(6\,B + 3\,A^2 - CA + 6\,B^2 - 4\,C^2\right),$$

implying that $B \approx (A+C)(4C-3A)/6$ at degenerate Hopf points with (A,B,C) small. For example, two approximate solutions of $R_H(A,B,C) = 0$ are $(-0.01, 0.00013335, 0.02)$ and $(-0.01, 0.00005, 0.02)$.

3.4. Periodic orbits. When $A = B = 0$ but $C \neq 0$, the family of periodic orbits at $\mu = 0$ is normally hyperbolic. Normal hyperbolicity implies that this surface of periodic orbits in (X, Y, Z, μ) space deforms but does not disappear when A and/or B are perturbed from zero. For most values of the parameters, the periodic orbits are isolated in the (X, Y, Z) state space. Continuation methods implemented in AUTO [11] and MATCONT [10] track the periodic orbits and locate saddle-node, period-doubling, and torus bifurcations as a single parameter is varied. Continuation methods further track curves of these bifurcations as two parameters are varied. This subsection presents some results obtained with MATCONT. Numerical integration has been used to check these continuation calculations and visualize complex trajectories from the family (2.2).

The first Lyapunov coefficient of the Hopf bifurcation in system (2.2) is $\frac{A}{4} + \frac{B}{2(A+C)} + o(\varepsilon^{1/2})$. When the first Lyapunov coefficient is negative, the bifurcation is supercritical, and stable periodic orbits emerge from the equilibrium. The periodic orbits can bifurcate as they grow in amplitude. Figure 1 shows four periodic orbits at the beginning of a period-doubling cascade computed with $(A,B,C) = (-0.05, -0.01, 0.1)$ and μ taking the values 0.0082, 0.0084, 0.0086, and 0.008618. As μ increases, three period-doubling bifurcations give successive transitions from the blue orbit to the green, then the red, and finally the thin blue orbit. The Hopf value of μ for these values of (A,B,C) is approximately 0.0008. Figure 2 shows a cross-section (green) to a quasi-periodic trajectory (blue) with parameter values $(A,B,C,\mu) = (-0.08, 0, 0.1, 0.001)$.

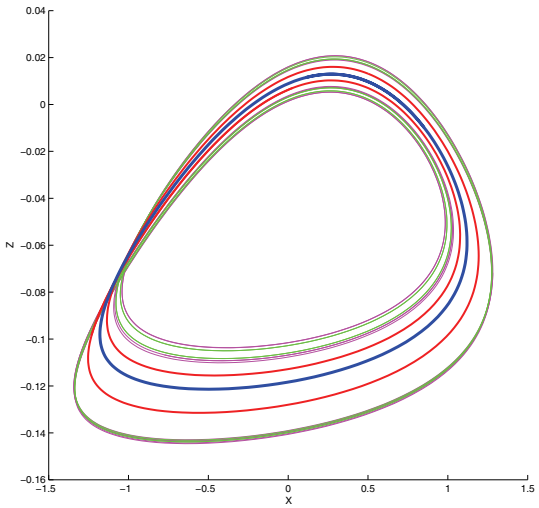

Figure 1. *Four periodic orbits of system (2.2) at the beginning of a period-doubling cascade, projected onto the (X,Z) plane. The heavy blue periodic orbit undergoes a period-doubling bifurcation to give rise to the red orbit. Two further period-doubling bifurcations yield the thin green and magenta. Parameter values are $(A,B,C) = (-0.05, -0.01, 0.1)$ and $\mu = 0.0082, 0.0084, 0.0086, 0.008618$ for the successive orbits.*

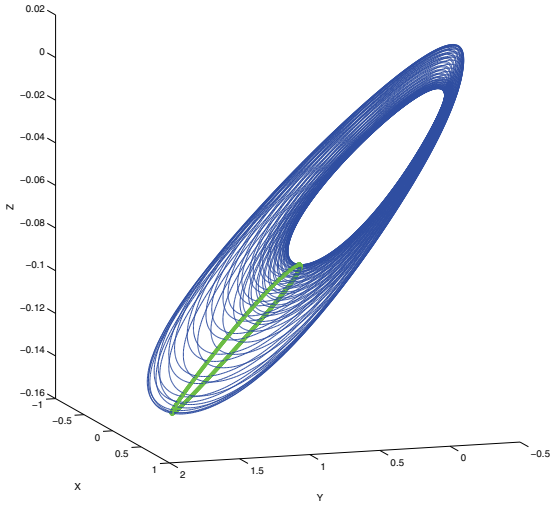

Figure 2. *A cross-section to a quasiperiodic trajectory of system (2.2). Parameter values are* $(A, B, C, \mu) = (-0.08, 0, 0.1, 0.001)$. *A portion of the trajectory is drawn as a blue curve. Intersections of the full computed trajectory with the plane* $X = 0$ *with* X *increasing are plotted in green.*

Figure 3 shows a bifurcation diagram for periodic orbits that emerge from a Hopf bifurcation as μ varies with $(A, B, C) = (-0.09, 0, 0.1)$. In this figure, the maximum and minimum values of x of the periodic orbits are plotted as a magenta curve. Points of period-doubling and torus bifurcations along this branch are marked and labeled "PD" and "T." Since $B = 0$, the system has a single equilibrium point, and the amplitude of the periodic orbits continues to grow as μ increases. The calculations are inconclusive as to whether this family of periodic orbits extends to ∞. When $B \neq 0$, system (2.2) has a second equilibrium on its critical manifold. If $A + C \neq 0$, then the second equilibrium is at finite distance from the origin. It appears that homoclinic orbits to this equilibrium can terminate families of periodic orbits. If $A + C \neq 0$, then the second equilibrium of system (2.1) is at finite distance from the origin and does not play a role in the local behavior of the singular Hopf bifurcation.

Branches of period-doubling and torus bifurcations with varying μ and B were computed with MATCONT 2.3.3 [10] and are shown in blue and green in Figure 4. Low order resonances of the torus bifurcations are marked by red dots. The three that occur for values of $\mu < 0.03$ are labeled with the order of the resonance; the point labeled R2 is the intersection of the two curves. The curve of torus bifurcations has a sharp bend near $\mu = 0.1$, where MATCONT detects several resonances of different orders as well as a fold of torus bifurcations very close to each other along the branch. The location of these resonances is indicated by the red marker at the right side of the figure.

4. Invariant manifolds. Invariant slow manifolds lie within an $O(\varepsilon)$ neighborhood of normally hyperbolic critical manifolds of slow-fast systems [14]. In typical settings, invariant manifolds are not unique, but their distance from each other is $O(\exp(-c/\varepsilon))$ for a suitable $c > 0$. The critical manifold $y = x^2$ of system (2.1) is normally hyperbolic away from the fold

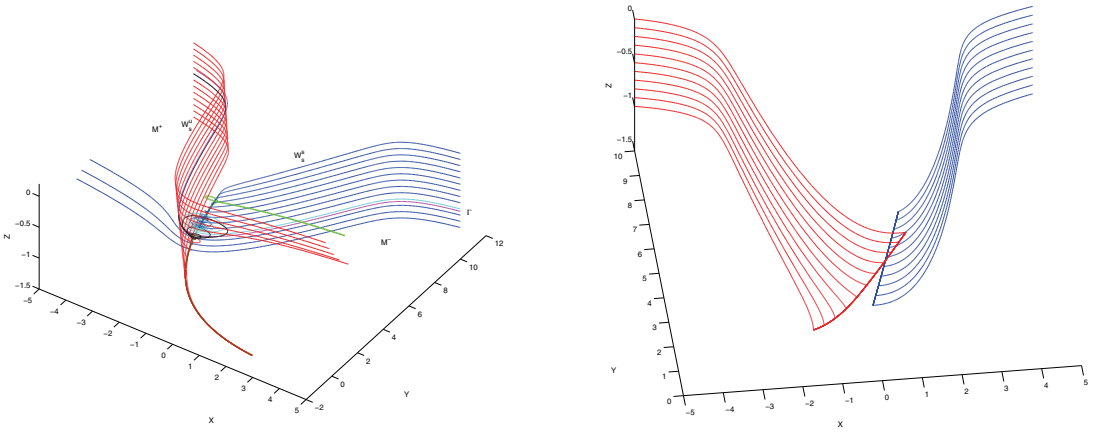
manifold are important objects in the phase portrait of the system. Away from the critical manifold, the vector field is almost parallel to the x axis. The critical manifold and the slow stable and unstable manifolds separate trajectories on which x decreases rapidly from those on which x increases rapidly. The region of trajectories flowing from $x = +\infty$ to the stable slow manifold W_s^s is denoted M^-, and the region of trajectories flowing toward $x = -\infty$ from the unstable slow manifold W_s^u is denoted M^+. On the fast time scale, trajectories are drawn toward W_s^s and away from W_s^u. In many cases, parts of W_s^s and W_s^u lie on the boundary of the domain of attraction for bounded attractors. This section visualizes these manifolds, examining their intersections with each other and with the stable and unstable manifolds of the equilibrium.

4.1. Intersections of stable and unstable slow manifolds. Numerical investigations are more convenient with the rescaled system (2.2) than with system (2.1). The stable and unstable slow manifolds of system (2.2) lie close to the parabolic cylinder $Y = X^2$ for large values of $|X|$, though the theory does not specify how large. The stable slow manifold W_s^s is computed by forward numerical integration starting with initial conditions on a curve parallel to the Z axis with X suitably larger than $\sqrt{Y}$, while the unstable slow manifold W_s^u is computed by backward numerical integration starting with initial conditions on a curve parallel to the Z axis with X suitably smaller than $-\sqrt{Y}$. In the examples below, the initial conditions are chosen with $X = \pm 5$ and $Y = 10$. These trajectories approach W_s^s and W_s^u exponentially fast, so beyond a transient they give good approximations to the manifolds. Estimates for

how close the trajectories are to W_s^s and W_s^u can be obtained by comparing their distance from trajectories with initial conditions on the critical manifold since the critical manifold lies on the opposite side of the slow manifolds from the curves of initial conditions.

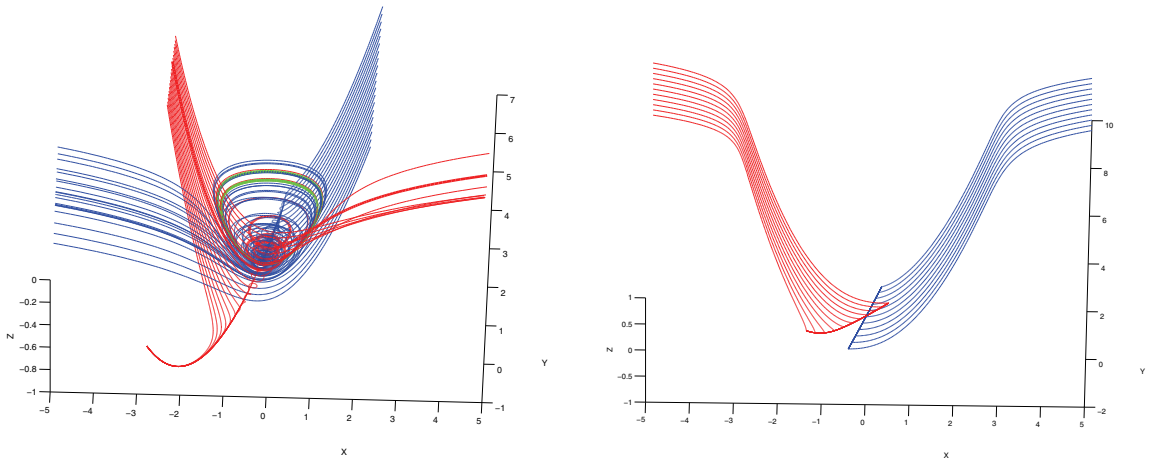
Figure 5(a) visualizes portions of the slow stable manifold W_s^s (blue) and the slow unstable manifold W_s^u (red) of system (2.2) as bundles of trajectories that begin on the lines $X = \pm 5$, $Y = 10$ until they reach $X = \mp 5$, $Y = 11$, or $T = 500$. Note that these stopping criteria extend the stable and unstable slow manifolds beyond the region where they lie close to the critical manifold. The parameter values used in Figure 5 are $(\mu, A, B, C) = (0, -0.05, -0.01, 0.1)$. The equilibrium is at the origin for these parameter values. It is on the fold curve and is stable with eigenvalues approximately $-0.0506, -0.0247 \pm 0.9934i$. The strong stable manifold of the equilibrium tangent to the eigenvector of its real eigenvalue is drawn in green. One branch of the strong stable manifold with X and Z negative approaches the slow unstable manifold while the other branch tends to ∞ in the X direction after its projection onto the (X, Y) plane makes a loop. The manifolds W_s^s and W_s^u appear to intersect transversally along a single trajectory Γ whose intersection with the plane $Z = X$ is depicted in Figure 5(b). In Figure 5(b), $Y' = Z - X = 0$ is the stopping criterion for the trajectories and piecewise



(a) (b)

Figure 5. (a) *Trajectories approaching and flowing along the slow stable manifold W_s^s are drawn in blue; trajectories approaching and flowing along the slow unstable manifold W_s^u are drawn in red. The initial conditions for these trajectories lie on the lines defined by $X = \pm 5$, $Y = 10$. The magenta curve approximates the intersection Γ of these two manifolds. The strong stable manifold of the equilibrium point is drawn in green. The equilibrium point is the forward limit set of the cyan trajectory and the dark blue trajectories above it. The blue trajectories below the magenta trajectory are unbounded, tending to $x = -\infty$ in finite time. Trajectories in the unstable manifold above the magenta trajectory tend to $x = +\infty$ as time decreases. The trajectories in the unstable manifold below the magenta trajectory tend to a branch of the strong stable manifold of the equilibrium which itself approaches the slow unstable manifold as time decreases. The slow unstable manifold W_s^u bounds the basin of attraction of the equilibrium point.* (b) *The same trajectories approaching W_s^s and W_s^u are drawn up to their intersection with the plane $Y' = Z - X = 0$. It is apparent that the intersection of these manifolds is transverse. The parameter values are $(\mu, A, B, C) = (0, -0.05, -0.01, 0.1)$.*

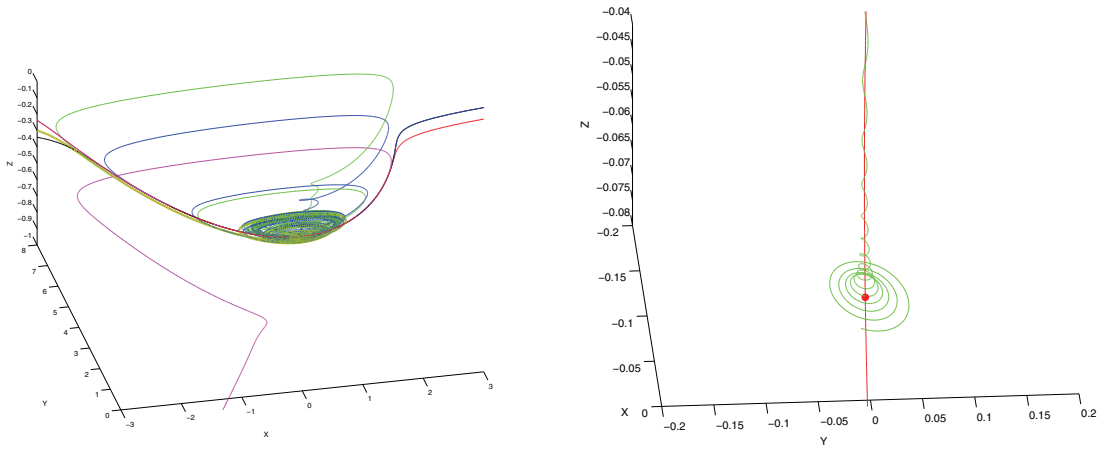
linear interpolations of the endpoints of these trajectories are drawn. An approximation to Γ is plotted as a magenta curve in Figure 5(a). Trajectories in W_s^s above Γ approach the equilibrium point, while trajectories below Γ tend to $-\infty$ along the X direction. The lowest trajectory in W_s^s above Γ is drawn in cyan to distinguish it from the others; the highest trajectory in W_s^u below Γ is drawn in black. In W_s^u, the trajectories above Γ tend to ∞ along the X direction while the trajectories below Γ spiral around the strong stable manifold of the equilibrium point. These observations motivate the conjecture that W_s^u is the boundary of the basin of attraction of the equilibrium point.



(a) (b)

Figure 6. (a) *Trajectories approaching and flowing along the slow stable manifold W_s^s are drawn in blue; trajectories approaching and flowing along the slow unstable manifold W_s^u are drawn in red. The initial conditions for these trajectories lie on the lines defined by $X = \pm 5$, $Y = 10$. A stable periodic orbit is drawn in green. All of the computed trajectories in W_s^s reach the plane $X = -5$ on their way to $X = -\infty$. The thick red trajectory shows that some of the trajectories in W_s^u that tend to $X = \infty$ oscillate before doing so.* (b) *The slow stable and unstable manifolds W_s^s and W_s^u intersect transversally. The parameter values are* $(\mu, A, B, C) = (0.0084, -0.05, -0.01, 0.1)$.

4.2. Intersections of the unstable slow manifold with the unstable manifold of the equilibrium point. As μ increases, the phase portraits of system (2.2) become more complicated. The equilibrium point has a supercritical Hopf bifurcation near $\mu = 0.0008$ and the periodic orbits born in this Hopf bifurcation enter a cascade of period-doubling bifurcations near $\mu = 0.008$, as illustrated in Figure 1. While μ increases, the asymptotic properties of the slow stable and unstable manifolds also change. Figure 6(a) visualizes portions of the slow stable (blue) and unstable (red) manifolds of system (2.2) as bundles of trajectories that begin on the lines $X = \pm 5$, $Y = 10$ and end on the plane defined by $Z' = 0$. The parameter values are $(\mu, A, B, C) = (0.0084, -0.05, -0.01, 0.1)$ used for the green period-doubled orbit displayed in Figure 1. This periodic orbit is also drawn in green here. As shown in Figure 6(b), the manifolds W_s^s and W_s^u intersect transversally, as they do when $\mu = 0$. However, in contrast to



(a) (b)

Figure 7. (a) *Three pairs of trajectories for system* (2.2) *with parameter values* $(\mu, A, B, C) = (0.003686, -0.05, -0.01, 0.1)$. *The black and blue trajectories are forward trajectories that approach the slow stable manifold* W_s^s*; the magenta and red trajectories are backward trajectories that approach the slow unstable manifold* W_s^u*; and the olive and green trajectories are forward trajectories starting close to the unstable manifold of the equilibrium point. Note that the olive and green trajectories approach* W_s^u *but then diverge from it in opposite directions.* (b) *A detailed view showing how the green trajectory spirals around the red stable manifold of the equilibrium point before approaching the periodic orbit.*

the situation with $\mu = 0$, trajectories above the intersection in W_s^s escape the bounded region containing the periodic orbits, and some trajectories above the intersection in W_s^u oscillate before they tend to $X = \infty$. The dynamical events that produce these qualitative changes in W_s^s and W_s^u as μ increases from 0 to 0.0084 are hardly clear.

For values of μ slightly larger than the Hopf bifurcation value, the equilibrium is a saddle with a two dimensional unstable manifold W_p^u bounded by the periodic orbit. As μ increases, W_p^u begins to spiral around the periodic orbit as the eigenvalues of its return map become complex. Near $\mu = 0.003686$, it appears that W_p^u begins to intersect W_s^u, the unstable slow manifold. Figure 7 presents evidence for this intersection. Figure 7(a) plots three pairs of trajectories, each of which is separated by the slow manifolds. The black and blue trajectories are forward trajectories with initial conditions $(5, 10, -0.704948)$ and $(5, 10, -0.704947)$. The black trajectory lies below the intersection of W_s^s and W_s^u and flows to $X = -\infty$, while the blue trajectory turns back toward positive values of X and then appears to spiral around the stable manifold of the equilibrium point before approaching the periodic orbit. The magenta and red trajectories have initial conditions $(-5, 10, -0.291832)$ and $(-5, 10, -0.291831)$ and are followed backward. The magenta orbit lies below the intersection of W_s^s and W_s^u and flows backward to $X = -\infty$ while the red trajectory flows backward to $X = \infty$. The olive and green trajectories have approximate initial conditions $(-0.073363697, 0.005235108, -0.072670595)$ and $(-0.073363704, 0.005235153, -0.072670597)$, points that lie close to the unstable manifold of the equilibrium. These trajectories approach the unstable slow manifold W_s^u and follow it to near its intersection with $Y = 6$ before separating. The olive trajectory then tends to

$X = -\infty$ while the green trajectory follows a similar path as the blue trajectory, spiraling around the stable manifold of the equilibrium and then approaching the periodic orbit. One might conjecture that the equilibrium point has a homoclinic orbit for a value of μ close to 0.003686. Figure 7(b) shows the green trajectory spiraling around the red stable manifold of the equilibrium point in more detail. However, the close approach of the trajectory to the equilibrium point does not imply that the parameters are close to those with a homoclinic orbit. As explained by Guckenheimer and Willms [19], the stable manifold of the equilibrium may be transversally stable as one moves away from the equilibrium, and large volumes of the state space may flow close to the stable manifold. This example demonstrates that qualitative changes in the intersections of invariant manifolds for system (2.2) typically occur at different parameter values than those where there are local bifurcations of the equilibrium point or periodic orbits of the system.

4.3. Intersections of the stable slow manifold with the stable manifold of the equilibrium point. When the equilibrium point has a one dimensional stable manifold, intersections of that manifold with the slow stable manifold might be expected to occur as codimension one bifurcations. This section presents evidence for this bifurcation by examining parameters with $A = B = \mu = 0$ and $C > 0$. For these parameters, the equilibrium is at the origin, the plane $Z = 0$ is invariant under the flow and time reversible, and there is a family of periodic orbits surrounding the origin and bounded by the parabola $Y - X^2 = -1/2$ in the plane $Z = 0$. The orbits below this parabola are unbounded, tending to $X = -\infty$ in finite time as t increases and to $X = \infty$ as t decreases. The family of periodic orbits is normally hyperbolic: each orbit has a strong stable manifold consisting of trajectories that tend toward it as $t \to \infty$. Figure 8(a) shows a branch of the stable manifold of the origin for six values of C, namely $(0.01, 0.1002, 0.1004, 0.1006, 0.1008, 0.101)$. Figure 8(b) shows the intersection of the stable manifolds with the plane $X = 3$ for 51 equally spaced values in the C interval $[0.01, 0.0101]$. Figure 8(c) shows the intersections from a much finer mesh of 5001 parameter values in this interval. It is evident that the stable manifold W^s_p of the origin oscillates in the (X, Y) plane as Z increases. These oscillations cease and X tends to ∞ for values of Z that depend upon C. Since trajectories tend to ∞ in finite time, the values of (Y, Z) typically approach finite limits along W^s_p. However, there are values of C where these limits appear to jump. These are produced by small ranges of C in which W^s_p crosses W^s_s. Figure 8(d) visualizes one crossing. The intersection of W^s_p with the plane $Y = 3$ is plotted in red as C varies through a regular mesh of 11 points in the interval $[0.01000965, 0.01000975]$. As C varies in this interval, the intersections of W^s_s with the plane $Y = 3$, drawn as a set of 11 blue curves in Figure 8(d), hardly move. The three dimensional manifold in (X, Y, Z, C) space swept out by W^s_s and the surface swept out by W^s_p clearly intersect transversally. When A, B, and μ are perturbed so that the equilibrium point becomes a saddle, the transverse intersection persists.

4.4. Contrasts between systems with one and two slow variables. The figures of this section hardly begin a systematic analysis of the global bifurcations of the invariant manifolds of system (2.2). Since the system likely has chaotic attractors for some parameter values, a complete analysis does not seem feasible. The behavior displayed here contrasts with the simpler two dimensional flows of singular Hopf bifurcations in systems with one slow variable and one fast variable. There, the slow stable and unstable manifolds are each a single trajectory

and the global bifurcation happens when the manifolds coincide. In the three dimensional setting investigated here, the slow stable and unstable manifolds are two dimensional and appear to intersect transversally in the vicinity of singular Hopf bifurcations. These intersections separate portions of the slow manifolds that turn in different directions. In some cases, parts of the manifolds become entangled with periodic orbits and the stable and unstable manifolds of the equilibrium. Sometimes the trajectories of these tangles remain bounded and sometimes they reemerge from the region of entanglement and proceed to $X = \pm\infty$. Further analysis of the intersections of these invariant sets is not pursued in this paper.

5. Mixed-mode oscillations in an example.

Mixed-mode oscillations (MMOs) have been observed and studied in chemical systems, for example, the Belousov–Zhabotinsky reac-

tion [20], and in the oxidation of carbon monoxide on platinum catalysts [22]. Several models have been proposed for these systems, but previous analysis has not identified that many of the properties seen in both the experimental data and models can be produced by singular Hopf bifurcations. Barkley [4] suggested that the minimum dimension of a system that fit the characteristics of MMOs in the Belousov–Zhabotinsky reaction was four. The more recent literature on MMOs in neural systems has focused upon MMOs produced by folded nodes [9, 30, 16], but some MMOs associated with singular Hopf bifurcations have characteristics that differ from those seen in the folded-node MMOs. Note that systems with singular Hopf bifurcations also have folded nodes, so singular Hopf bifurcations may produce MMOs that pass through folded nodes as well as ones that do not.

This section revisits one of the simplest models for MMOs—the autocatalator studied by Petrov, Scott, and Showalter [28] and Milik and Szmolyan [27]. The equations for this model are

$$\begin{aligned} \dot{a} &= \mu(\kappa + c) - ab^2 - a, \\ \varepsilon\dot{b} &= ab^2 + a - b, \\ \dot{c} &= b - c. \end{aligned} \tag{5.1}$$

In the studies of this system cited above, $\kappa = 2.5$ was held fixed and the parameters μ and/or ε were varied. The critical manifold of this system is given by $a = b/(1+b^2)$ and its fold curve is defined by $a = 1/2$, $b = 1$. At equilibrium points, $b = c$, so the equilibrium is on the fold curve when $b = c = 1$, $a = 1/2$, implying that $\mu = 1/(1+\kappa)$. In general, if we parametrize the equilibria of the system by c, then the curve of equilibrium points is given by $a = c/(1+c^2)$, $b = c$, $\mu = c/(c+\kappa)$. Computing the Jacobian of the system (5.1), we find that the criterion for Hopf bifurcation of the system is a polynomial expression that is affine in κ and quadratic in ε, so we can readily parametrize the Hopf bifurcation as a function of the variables c and ε. In addition to the equilibrium equations,

$$\begin{aligned} &\kappa_{hopf} \\ &= -\frac{c\left(9\,c^2\varepsilon + 2 - c^2 + 5\,\varepsilon + 6\,c^4\varepsilon + 5\,c^6\varepsilon^2 + 9\,c^4\varepsilon^2 + 7\,c^2\varepsilon^2 + 3\,c^6\varepsilon + 2\,\varepsilon^2 + c^8\varepsilon^2 + c^8\varepsilon - c^6\right)}{2 + 3\,c^4\varepsilon + 5\,c^6\varepsilon^2 + c^8\varepsilon^2 + 6\,c^2\varepsilon + 9\,c^4\varepsilon^2 + 7\,c^2\varepsilon^2 + 2\,c^6\varepsilon + c^8\varepsilon - c^2 + 4\,\varepsilon + 2\,\varepsilon^2 - c^6}. \end{aligned}$$

The function κ_{hopf} is singular at $c = 1, \varepsilon = 0$. For fixed κ, the Hopf criterion defines c as a smooth function of ε that vanishes at $c = 1$ and has slope $(3 + 2\kappa)/(1 + \kappa)$. Thus, there is indeed a singular Hopf bifurcation in this system. This does not appear in the analysis of Milik and Szmolyan [27] because they transform the parameters to set $\mu = \varepsilon\bar{\mu} + 1/(1+\kappa)$ and then use $\bar{\mu}$ and ε as the parameters they vary. In this representation, the Hopf bifurcations have parameter values that are close to $\bar{\mu} = 0.4375$ and are apparent as $\varepsilon \to 0$ only if $\bar{\mu}$ is also varied in the region near this Hopf value. Indeed, they do not analyze properties of the equilibrium point at all except at the values at which the Hopf bifurcation lies on the fold curve, a point termed a folded saddle-node in their work.

Petrov, Scott, and Showalter [28] studied the periodic orbits of system (5.1) using AUTO [11]. They work with two values of ε, namely, $\varepsilon = 0.01$ and $\varepsilon = 0.013$. For $\varepsilon = 0.013$, they observe that there is a supercritical Hopf bifurcation at $\mu \approx 0.29202$ and a second supercritical Hopf bifurcation at $\mu \approx 0.77372$. The first of these is the singular Hopf bifurcation: the

value of (a, b) is approximately $(0.49977, 1.031080)$. Petrov, Scott, and Showalter [28] observe that there is a narrow band of values of $\mu \in [0.297, 0.303]$ where the system has complex dynamics. The periodic orbits born at the singular Hopf bifurcation undergo a period-doubling cascade to a small amplitude chaotic attractor. Near $\mu = 0.29795$, the chaotic attractor disappears, and trajectories starting near the previous attractor approach a periodic MMO. Milik and Szmolyan use geometric and singular perturbation methods to study this system, producing return maps for some of the attractors. Figures 9 and 10 extend this analysis using the insights into the singular Hopf bifurcation described in this paper.

MMOs are formed from trajectories which concatenate small and large amplitude oscillations. In system (5.1), the large amplitude oscillations come from trajectories that pass "outside" the unstable slow manifold; i.e., they have larger values of a. To test whether trajectories with small amplitude oscillations flow to the outside of the unstable slow manifold, trajectories in the unstable manifold of the equilibrium were computed, similar to the calculations of the singular Hopf normal form illustrated in Figures 5, 6, and 7. Figures 9(a) and 9(b) display trajectories on the unstable manifold of the equilibrium point in blue and trajectories on the unstable slow manifold in red for parameter values $(\varepsilon, \kappa, \mu) = (0.013, 2.5, 0.2963)$ and $(\varepsilon, \kappa, \mu) = (0.013, 2.5, 0.2964)$, respectively. It appears that as μ increases from 0.2963 to 0.2964, the unstable manifold of the equilibrium point begins to intersect the unstable slow manifold. The intersection of these invariant manifolds seems to be intimately related to the formation of MMOs. Nonetheless, it is difficult to make definitive statements about these dynamics because the periodic orbits of the system have followed a period-doubling route to chaotic attractors for smaller values of μ, similar to the behavior displayed by the singular Hopf normal form (2.2) for parameters $(A, B, C) = (-0.05, -0.01, 0.1)$ and increasing μ (cf. Figure 1). Here, Petrov, Scott, and Showalter [28] showed that there are several families of MMOs as well as the small amplitude chaotic attractors in parameter ranges close to those displayed here.

Figure 9 suggests that intersections of the unstable slow manifold with the basins of small amplitude attractors are critical to the formation of MMOs. The value of ε used in this figure makes the system only moderately stiff. Figure 10 displays similar calculations for the smaller value $\varepsilon = 0.001$. Subfigure (a) shows trajectories in the unstable manifold of the equilibrium (blue) and the unstable slow manifold (blue) for $(\varepsilon, \kappa, \mu) = (0.001, 2.5, 0.2864)$. There is a stable periodic orbit, and this orbit forms the boundary of the unstable manifold of the equilibrium point. Subfigure (b) shows analogous information for $(\varepsilon, \kappa, \mu) = (0.001, 2.5, 0.2865)$. The stable periodic orbit persists, but some trajectories near the equilibrium point flow to the outside of the unstable slow manifold and generate MMOs. Figure 11 shows a portion of one of these MMOs as it passes close to the equilibrium point. The large amplitude excursions of the trajectory approach the stable manifold of the equilibrium point closely, and these are followed by slowly growing small amplitude oscillations similar to those that can appear in the aftermath of a subcritical Hopf bifurcation [19]. For these parameter values, the birth of MMOs is clearly the direct result of the intersections of the unstable slow manifold with the unstable manifold of the equilibrium.

6. Discussion. As a slow-fast system, the equations for singular Hopf bifurcation are reduced to a three dimensional vector field that can be rescaled so that the Hopf frequency

remains close to one as the singular perturbation parameter ε tends to zero. This scaling emphasizes the fast time scale whose singular limit is a vector field with an equilibrium point with pure imaginary and zero eigenvalues and a one parameter family of periodic orbits emanating from the equilibrium. Two coefficients of the Taylor expansion of the rescaled vector field, the real eigenvalue of its equilibrium and the first Lyapunov coefficient of its Hopf bifurcation, are $O(\varepsilon^{1/2})$. An interesting aspect of the normal form analysis is that an $O(\varepsilon)$ term in the Taylor expansion of the rescaled system still contributes to the first Lyapunov coefficient of the Hopf bifurcation at $O(\varepsilon^{1/2})$. The truncated normal form used in this paper includes this $O(\varepsilon)$ term. Thus the normal form has five parameters: the singular perturbation parameter, a primary parameter that drives the equilibrium point across the fold curve of the critical manifold, and three secondary parameters that can be regarded as moduli.

This paper highlights the complexity of Hopf bifurcation in multiple time scale systems with two slow variables and one fast variable. Numerical simulations and continuation calculations with the normal form demonstrate that periodic orbits near a singular Hopf bifurcation can have secondary bifurcations that produce quasiperiodic or chaotic trajectories of these systems in an $O(\varepsilon)$ neighborhood of the equilibrium undergoing Hopf bifurcation. The dependence of the secondary bifurcations on the moduli in the normal form is clearly very complicated. There are additional global bifurcations that separate parameter regimes with only small amplitude attractors from parameter regimes in which trajectories starting near the equilibrium can make large excursions. These transitions have been studied here by test-

ing for intersections of the two dimensional unstable manifold of the equilibrium point with the unstable slow manifold. From a pragmatic point of view, the boundary between trajectories that remain in the vicinity of the equilibrium point of the system and those that leave a neighborhood of the equilibrium point is an important aspect of the dynamics of singular Hopf bifurcation.

This paper is partly motivated by attempts to understand the mechanisms that create MMOs in slow-fast systems. MMOs have been observed in diverse physical systems and dynamical models. These MMOs appear to fall into different dynamical classes that have yet to be clearly delineated or analyzed. One class that has been identified and studied are MMOs associated with flow through a folded node [9, 16]. This paper identifies singular Hopf bifurcation as another mechanism for generating MMOs. As illustrated with the model chemical system (5.1), the intersections of the unstable slow manifold with the unstable manifold of a saddle-focus equilibrium point can produce MMOs. These intersections are a byproduct of singular Hopf bifurcation. The small oscillations of MMOs associated with singular Hopf bifurcation often begin with very small amplitude as they approach a saddle-focus equilibrium along its stable manifold and depart with growing oscillations along its unstable manifold. In contrast, the trajectories that pass through a folded node have oscillations that first decrease and then increase in amplitude. Figure 12 displays a trajectory of the system

$$\begin{aligned}\dot{x} &= y - x^2,\\ \dot{y} &= z - x,\\ \dot{z} &= -0.002\end{aligned}$$

with initial conditions $(50, 395, 0.16)$. The oscillations of this trajectory typify the small oscillations that one finds for MMOs produced by folded nodes. Compare this figure with Figure 11, showing an MMO associated with singular Hopf bifurcation in the autocatalator. In the normal form for the folded node, the numbers of oscillations with decreasing and increasing amplitude are equal. Further work to analyze the dynamical origins of MMOs from experimental observations of chemically reacting systems might be of interest [20]. It

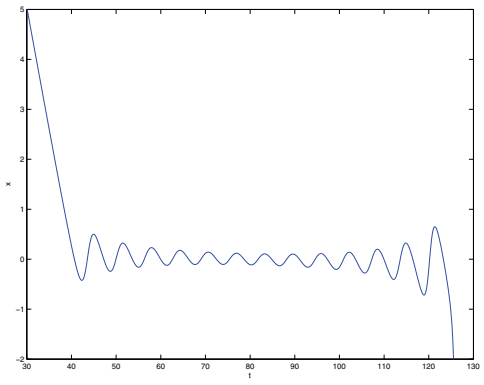

Figure 12. *Oscillations of a trajectory passing through a folded node.*

seems likely that MMOs associated with folded nodes and those associated with singular Hopf bifurcations both occur as well as MMOs that are far from these bifurcations.

Eulerian Equilibria of a Gyrostat in Newtonian Interaction with Two Rigid Bodies*

J. A. Vera†

Abstract. In this paper the noncanonical Hamiltonian dynamics of a gyrostat in the three body problem will be examined. By means of geometric-mechanics methods we will study the approximate dynamics that arises when we develop the potential in Legendre series and truncate the series to the second harmonics. Some relative equilibria, called Eulerian, of the dynamics of a gyrostat in Newtonian interaction with two rigid bodies will be studied. Taking advantage of the results obtained in previous papers, working on the reduced problem, we will study the bifurcations of these relative equilibria. The instability of Eulerian relative equilibria if the gyrostat is close to a sphere is proven. The rotational Poisson dynamics of the gyrostat placed in an Eulerian equilibrium and the study of the nonlinear stability of some equilibria are considered. The analysis is done in vectorial form avoiding the use of canonical variables and the tedious expressions associated with these variables. In this way, the classic results on equilibria of the three body problem, many of them obtained by other authors who had made used of more classic techniques, are generalized.

1. Introduction.

In the study of configurations of relative equilibria by differential geometry methods or by more classical methods we will mention here the papers of Wang, Krishnaprasad, and Maddocks [11], about the problem of a rigid body in a central Newtonian field, and Maciejewski [4], about the problem of two rigid bodies in mutual Newtonian attraction. These papers have been generalized to the case of two gyrostats by Mondéjar and Vigueras [5].

For the problem of three rigid bodies, we would like to mention that Vidyakin [9] and Dubochine [1] proved the existence of Euler and Lagrange configurations of equilibria when the bodies possess symmetries; Zhuravlev and Petrutskii [13] reviewed the results up to 1990. These works use canonical variables for the deduction of their results.

On the other hand, if a rigid solid model is used to represent celestial bodies instead of the point masses model, the possibility of internal or relative motions in the celestial bodies will not be considered. This hypothesis is not appropriate in many cases, as shown by Volterra [10] in his study on the variation of the latitude in the Earth's surface.

In relation to the previous point, let us remember what is known as a gyrostat, which is a mechanical system S, composed of a rigid body S', and other bodies S'' (deformable or rigid) connected to it, in such a way that their relative motion with respect to its rigid part

*Received by the editors October 7, 2006; accepted for publication (in revised form) by C. Wayne July 3, 2008; published electronically October 31, 2008. does not change the distribution of mass of the total system S (see Leimanis [3] for details). Examples of such systems are bodies that represent mobile internal cavities (for example, fluids) or bodies with coupled symmetrical rotors that can be activated by remote control.

In Vera [7] and a recent paper of Vera and Vigueras [8] we study the noncanonical Hamiltonian dynamics of $n+1$ bodies in Newtonian attraction, where n of them are rigid bodies with spherical distribution of mass or material points and the other body is a triaxial gyrostat. Using the symmetries of the system, we carried out two reductions, giving in each step the Poisson structure of the reduced space. Then, we obtained the equations of motion, the Casimir function of the system, and the equations that determine the equilibria and global conditions for the existence of the equilibria.

This paper is a concrete application of the general methods of [8] to the study of certain types of equilibria of a gyrostat in Newtonian attraction with two rigid bodies (see Figure 1). We describe the approximate dynamics that arises in a natural way when we take the Legendre development of the potential function and truncate this to the second harmonics. If the involved bodies are at much more mutual distances than the individual dimensions of the involved bodies, this approximate dynamics is a good description of the full dynamics of the problem.

Additionally, we suppose that the attitude dynamics of the two rigid bodies is the same as a rigid body in torque free motion. The two rigid bodies have revolution symmetry about the third axis of inertia. On the other hand, the Newtonian interaction of the gyrostat with the rigid bodies is the same as that of a material particle in Newtonian interaction with two rigid bodies. The Newtonian interaction among the two rigid bodies is the same as that of two material particles.

Under these hypotheses, we give global conditions on the existence of relative equilibria, and analogous to classic results on the topic (see [12] for details), we study the existence of relative equilibria that we will denominate of *Euler type* in the case in which S_1, S_2 are spherical or symmetrical bodies and S_0 is a gyrostat. Necessary and sufficient conditions for their existence in this approximate dynamics are obtained, and we give explicit expressions of the Eulerian equilibria, useful for the later study of their stability. A complete study of the number of the Eulerian equilibria is made when S_1, S_2 are spherical rigid bodies. Concerning to the stability of these equilibria, the instability of the Eulerian equilibria is proven.

On the other hand, the rotational Poisson dynamics of the gyrostat placed in an Eulerian equilibrium is considered. The nonlinear stability of some rotational equilibria, called cylindrical equilibria, is studied by means of the energy-Casimir method. By means of the tangent flow of this dynamics in the cylindrical equilibrium we obtain necessary conditions for the nonlinear stability of the cylindrical equilibria.

This analysis was done in vectorial form, giving to this problem a very compact treatment which avoids the use of canonical variables (Eulerian or Andoyer–Deprit variables) and the tedious expressions associated with these variables. This is a typical characteristic of the classic literature on these systems that the paper overcomes with this vectorial approach. Contrary to the canonical variables, this analysis is free of singularities.

We should note that the studied system has potential interest both in astrodynamics (dealing with spacecrafts) as well as in the understanding of the evolution of planetary systems recently found (and more to appear), where some of the planets may be modeled like gyrostats

rather than rigid bodies. In fact, the equilibria reported might well be compared with those taken for the "parking areas" of the space missions (GENESIS, SOHO, DARWIN, etc.) around the Eulerian points of the Sun-Earth and the Earth-Moon systems (see [2] for details).

To finish this introduction, we describe the structure of the article. The paper is organized into seven sections, two appendices, and the bibliography. In these sections we study the equations of motion, the Casimir function and integrals of the system, and the relative equilibria and the existence of Eulerian equilibria, in particular the study of the bifurcations of Eulerian equilibria in the approximate dynamics. The rotational Poisson dynamics of the gyrostat placed in an Eulerian equilibrium and the study of the stability of some equilibria are considered.

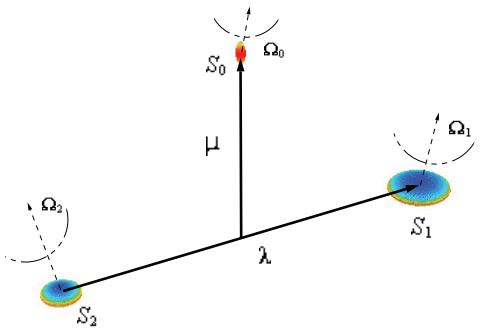

Figure 1. *Gyrostat in the three body problem.*

2. Equations of motion. Let S_0 be a gyrostat of mass m_0, and let S_1, S_2 be two symmetrical rigid bodies of masses m_1 and m_2, respectively; $\mathfrak{I} = \{\mathbf{O}, \mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3\}$ is an inertial reference frame; $\mathfrak{J} = \{\mathbf{C}_0, \mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3\}$ is a body frame fixed at the center of mass $\mathbf{C}_0$ of S_0 (see Vera and Vigueras [8] for details).

The following notation is used:

$$M_2 = m_1 + m_2, \quad M_1 = m_1 + m_2 + m_0, \quad g_1 = \frac{m_1 m_2}{M_2}, \quad g_2 = \frac{m_0 M_2}{M_1}.$$

For $\mathbf{u}, \mathbf{v} \in \mathbb{R}^3$, $\mathbf{u} \cdot \mathbf{v}$ is the dot product; $|\mathbf{u}|$ is the Euclidean norm of the vector $\mathbf{u}$; $\mathbf{u} \times \mathbf{v}$ is the cross product; $\mathbf{I}_{\mathbb{R}^3}$ is the identity matrix; and $\mathbf{0}$ is the zero matrix of order three. Consider $\mathbb{I}_0 = \operatorname{diag}(A_0, B_0, C_0)$ the diagonal tensor of inertia of the gyrostat and $\mathbb{I}_i = \operatorname{diag}(A_i, A_i, C_i)$ the diagonal tensors of inertia for the rigid bodies S_i, $i = 1, 2$. The generic expression $\mathbf{z} = (\mathbf{\Pi}_1, \mathbf{\Pi}_2, \mathbf{\Pi}_0, \boldsymbol{\lambda}, \mathbf{p}_{\boldsymbol{\lambda}}, \boldsymbol{\mu}, \mathbf{p}_\mu) \in \mathbb{R}^{21}$ is a vector of the twice reduced problem obtained by applying the symmetries of the system. The vector $\mathbf{z}$ is obtained by a Poisson reduction by means of the group $\mathbf{SO(3)}$ and a symplectic reduction by means of the translation group; see Vera and Vigueras [8] for details. The vector $\mathbf{\Pi}_0 = \mathbb{I}_0 \mathbf{\Omega}_0 + \mathbf{l}_r$ is the total rotational angular momentum vector of the gyrostat in the body frame, which is attached to its rigid part and whose axes have the direction of the principal axes of inertia of S_0; the vector $\mathbf{l}_r = (0, 0, l)$ is the constant gyrostatic momentum (this vector models the internal motions of the gyrostat) and $\mathbf{\Pi}_i = \mathbb{I}_i \mathbf{\Omega}_i$ $(i = 1, 2)$ are the total rotational angular

momentum vectors for the two rigid bodies. The elements $\boldsymbol{\lambda}$, $\boldsymbol{\mu}$, $\mathbf{p}_{\boldsymbol{\lambda}}$, and $\mathbf{p}_{\mu}$ are, respectively, the barycentric coordinates and the linear momenta expressed in the body frame $\mathfrak{J}$.

Following the results of Vera and Vigueras [8], according to the hypotheses formulated in the introduction of this paper, a good approximation to the potential of the system is expressed by

$$\mathcal{V} = \mathcal{V}_1 + \mathcal{V}_2,$$

where

$$\mathcal{V}_1 = -\left(\frac{Gm_1m_2}{|\boldsymbol{\lambda}|} + \frac{Gm_1m_0}{|\boldsymbol{\mu} - \frac{m_2}{M_2}\boldsymbol{\lambda}|} + \frac{Gm_2m_0}{|\boldsymbol{\mu} + \frac{m_1}{M_2}\boldsymbol{\lambda}|} \right),$$

$$\mathcal{V}_2 = -\frac{1}{2}\left(\frac{Gm_0\alpha_1}{|\boldsymbol{\mu} - \frac{m_2}{M_2}\boldsymbol{\lambda}|^3} + \frac{Gm_0\alpha_2}{|\boldsymbol{\mu} + \frac{m_1}{M_2}\boldsymbol{\lambda}|^3} - \frac{3Gm_0f_1}{|\boldsymbol{\mu} - \frac{m_2}{M_2}\boldsymbol{\lambda}|^5} - \frac{3Gm_0f_2}{|\boldsymbol{\mu} + \frac{m_1}{M_2}\boldsymbol{\lambda}|^5} \right),$$

and

$$\alpha_1 = 2A_1 + C_1, \quad \alpha_2 = 2A_2 + C_2,$$

$$f_1(\boldsymbol{\lambda}, \boldsymbol{\mu}) = \boldsymbol{\mu} \cdot \mathbb{I}_1\boldsymbol{\mu} - \frac{2m_2}{M_2}\boldsymbol{\lambda} \cdot \mathbb{I}_1\boldsymbol{\mu} + \left(\frac{m_2}{M_2}\right)^2 \boldsymbol{\lambda} \cdot \mathbb{I}_1\boldsymbol{\lambda},$$

$$f_2(\boldsymbol{\lambda}, \boldsymbol{\mu}) = \boldsymbol{\mu} \cdot \mathbb{I}_2\boldsymbol{\mu} + \frac{2m_1}{M_2}\boldsymbol{\lambda} \cdot \mathbb{I}_2\boldsymbol{\mu} + \left(\frac{m_1}{M_2}\right)^2 \boldsymbol{\lambda} \cdot \mathbb{I}_2\boldsymbol{\lambda}.$$

The Hamiltonian function of the system adopts the form

$$\mathcal{H}(\mathbf{z}) = \frac{|\mathbf{p}_{\boldsymbol{\lambda}}|^2}{2g_1} + \frac{|\mathbf{p}_{\boldsymbol{\mu}}|^2}{2g_2} + \frac{1}{2}\Pi_0^t\mathbb{I}_0^{-1}\Pi_0 - \mathbf{l}_r \cdot \mathbb{I}_0^{-1}\Pi + \frac{1}{2}\Pi_1^t\mathbb{I}_1^{-1}\Pi_1 + \frac{1}{2}\Pi_2^t\mathbb{I}_2^{-1}\Pi_2 + \mathcal{V}(\boldsymbol{\lambda}, \boldsymbol{\mu}).$$

Let $(\mathbf{M}, \{\ ,\ \}, \mathcal{H})$ with $\mathbf{M} = \mathbb{R}^{21}$ be the Poisson manifold, where $\{\ ,\ \}$ is the Poisson bracket defined by means of the Poisson tensor

$$\mathbf{B}(\mathbf{z}) = \begin{pmatrix} \widehat{\boldsymbol{\Pi}_1} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \widehat{\boldsymbol{\Pi}_2} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \widehat{\boldsymbol{\Pi}_0} & \widehat{\boldsymbol{\lambda}} & \widehat{\mathbf{p}_{\boldsymbol{\lambda}}} & \widehat{\boldsymbol{\mu}} & \widehat{\mathbf{p}_{\mu}} \\ \mathbf{0} & \mathbf{0} & \widehat{\boldsymbol{\lambda}} & \mathbf{0} & \mathbf{I}_{\mathbb{R}^3} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \widehat{\mathbf{p}_{\boldsymbol{\lambda}}} & -\mathbf{I}_{\mathbb{R}^3} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \widehat{\boldsymbol{\mu}} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I}_{\mathbb{R}^3} \\ \mathbf{0} & \mathbf{0} & \widehat{\mathbf{p}_{\mu}} & \mathbf{0} & \mathbf{0} & -\mathbf{I}_{\mathbb{R}^3} & \mathbf{0} \end{pmatrix}.$$

In $\mathbf{B}(\mathbf{z})$, $\widehat{\mathbf{v}}$ is considered to be the image of the vector $v \in \mathbb{R}^3$ by the standard isomorphism between the Lie algebras $\mathbb{R}^3$ and $\mathfrak{so}(3)$, i.e.,

$$\widehat{\mathbf{v}} = \begin{pmatrix} 0 & -v_3 & v_2 \\ v_3 & 0 & -v_1 \\ -v_2 & v_1 & 0 \end{pmatrix}.$$

The equations of the motion are given by

$$\frac{d\mathbf{z}}{dt} = \{\mathbf{z}, \mathcal{H}(\mathbf{z})\} = \mathbf{B}(\mathbf{z})\boldsymbol{\nabla}_{\mathbf{z}}\mathcal{H}(\mathbf{z}),$$

with $\boldsymbol{\nabla}_{\mathbf{u}}\mathcal{V}$ being the gradient of $\mathcal{V}$ with respect to an arbitrary vector $\mathbf{u}$.

Calculating $\{\mathbf{z}, \mathcal{H}(\mathbf{z})\}$, the following group of vectorial equations of motion can be written as

$$\begin{aligned}
&\frac{d\boldsymbol{\Pi}_0}{dt} = \boldsymbol{\Pi}_0 \times \boldsymbol{\Omega}_0 + \boldsymbol{\lambda} \times \boldsymbol{\nabla}_{\boldsymbol{\lambda}}\mathcal{V} + \boldsymbol{\mu} \times \boldsymbol{\nabla}_{\boldsymbol{\mu}}\mathcal{V},\\
&\frac{d\boldsymbol{\lambda}}{dt} = \frac{\mathbf{p}_{\boldsymbol{\lambda}}}{g_1} + \boldsymbol{\lambda} \times \boldsymbol{\Omega}_0, \quad \frac{d\mathbf{p}_{\boldsymbol{\lambda}}}{dt} = \mathbf{p}_{\boldsymbol{\lambda}} \times \boldsymbol{\Omega}_0 - \boldsymbol{\nabla}_{\boldsymbol{\lambda}}\mathcal{V},\\
&\frac{d\boldsymbol{\mu}}{dt} = \frac{\mathbf{p}_{\boldsymbol{\mu}}}{g_2} + \boldsymbol{\mu} \times \boldsymbol{\Omega}_0, \quad \frac{d\mathbf{p}_{\boldsymbol{\mu}}}{dt} = \mathbf{p}_{\boldsymbol{\mu}} \times \boldsymbol{\Omega}_0 - \boldsymbol{\nabla}_{\boldsymbol{\mu}}\mathcal{V},\\
&\frac{d\boldsymbol{\Pi}_1}{dt} = \boldsymbol{\Pi}_1 \times \boldsymbol{\Omega}_1, \quad \frac{d\boldsymbol{\Pi}_2}{dt} = \boldsymbol{\Pi}_2 \times \boldsymbol{\Omega}_2.
\end{aligned} \tag{1}$$

Important elements of $\mathbf{B}(\mathbf{z})$ are the associated Casimir functions. The vector

$$\mathbf{L}_0 = \boldsymbol{\Pi}_0 + \boldsymbol{\lambda} \times \mathbf{p}_{\boldsymbol{\lambda}} + \boldsymbol{\mu} \times \mathbf{p}_{\mu}$$

is a part of the total angular momentum $\mathbf{L}$ given by

$$\mathbf{L} = \boldsymbol{\Pi}_2 + \boldsymbol{\Pi}_1 + \mathbf{L}_0.$$

Then the following result can be concluded.

Proposition 1. *If φ_i $(i = 0, 1, 2)$ are real smooth functions, then $\varphi_0(\frac{|\mathbf{L}_0|^2}{2})$, $\varphi_i(\frac{|\boldsymbol{\Pi}_i|^2}{2})$ $(i = 1, 2)$ are Casimir functions of the Poisson tensor $\mathbf{B}(\mathbf{z})$. Furthermore, $\operatorname{Ker}\mathbf{B}(\mathbf{z}) = \langle \boldsymbol{\nabla}_{\mathbf{z}}\varphi_0, \boldsymbol{\nabla}_{\mathbf{z}}\varphi_1, \boldsymbol{\nabla}_{\mathbf{z}}\varphi_2 \rangle$. We also have $\frac{d\mathbf{L}}{dt} = \mathbf{0}$, which means the total angular momentum vector remains constant. If $\boldsymbol{\Pi}_0 = (\boldsymbol{\pi}_0^1, \boldsymbol{\pi}_0^2, \boldsymbol{\pi}_0^3)$, then $\boldsymbol{\pi}_0^3$ is an integral of the motion.*

3. Relative equilibria. If $\mathbf{z}_e = (\boldsymbol{\Pi}_2^e, \boldsymbol{\Pi}_1^e, \boldsymbol{\Pi}_0^e, \boldsymbol{\lambda}^e, \mathbf{p}_{\boldsymbol{\lambda}}^e, \boldsymbol{\mu}^e, \mathbf{p}_{\boldsymbol{\mu}}^e)$ is a generic relative equilibrium, the following vectorial equations are verified:

$$\begin{aligned}
&\boldsymbol{\Pi}_0^e \times \boldsymbol{\Omega}_0^e + \boldsymbol{\lambda}^e \times (\boldsymbol{\nabla}_{\boldsymbol{\lambda}}\mathcal{V})_e + \boldsymbol{\mu} \times (\boldsymbol{\nabla}_{\boldsymbol{\mu}}\mathcal{V})_e = \mathbf{0},\\
&\frac{\mathbf{p}_{\boldsymbol{\lambda}}^e}{g_1} + \boldsymbol{\lambda}^e \times \boldsymbol{\Omega}_0^e = \mathbf{0}, \quad \mathbf{p}_{\boldsymbol{\lambda}}^e \times \boldsymbol{\Omega}_0^e = (\boldsymbol{\nabla}_{\boldsymbol{\lambda}}\mathcal{V})_e,\\
&\frac{\mathbf{p}_{\boldsymbol{\mu}}^e}{g_2} + \boldsymbol{\mu}^e \times \boldsymbol{\Omega}_0^e = \mathbf{0}, \quad \mathbf{p}_{\boldsymbol{\mu}}^e \times \boldsymbol{\Omega}_0^e = (\boldsymbol{\nabla}_{\boldsymbol{\mu}}\mathcal{V})_e,\\
&\boldsymbol{\Pi}_1^e \times \boldsymbol{\Omega}_1^e = \mathbf{0}, \quad \boldsymbol{\Pi}_2^e \times \boldsymbol{\Omega}_2^e = \mathbf{0},
\end{aligned} \tag{2}$$

where $(\boldsymbol{\nabla}_{\boldsymbol{\lambda}}\mathcal{V})_e$ and $(\boldsymbol{\nabla}_{\boldsymbol{\mu}}\mathcal{V})_e$ are the values of $\boldsymbol{\nabla}_{\boldsymbol{\lambda}}\mathcal{V}$ and $\boldsymbol{\nabla}_{\boldsymbol{\mu}}\mathcal{V}$ at $\mathbf{z}_e$.

According to the relationships provided by Vera and Vigueras [8], the following results are obtained.

Lemma 2. *Whenever $\mathbf{z}_e = (\boldsymbol{\Pi}_2^e, \boldsymbol{\Pi}_1^e, \boldsymbol{\Pi}_0^e, \boldsymbol{\lambda}^e, \mathbf{p}_{\boldsymbol{\lambda}}^e, \boldsymbol{\mu}^e, \mathbf{p}_{\boldsymbol{\mu}}^e)$ is a relative equilibrium, the following relationships are satisfied:*

$$|\boldsymbol{\Omega}_0^e|^2|\boldsymbol{\lambda}^e|^2 - (\boldsymbol{\lambda}^e \cdot \boldsymbol{\Omega}_0^e)^2 = \frac{1}{g_1}(\boldsymbol{\lambda}^e \cdot (\boldsymbol{\nabla}_{\boldsymbol{\lambda}}\mathcal{V})_e),$$
$$|\boldsymbol{\Omega}_0^e|^2|\boldsymbol{\mu}^e|^2 - (\boldsymbol{\mu}^e \cdot \boldsymbol{\Omega}_0^e)^2 = \frac{1}{g_2}(\boldsymbol{\mu}^e \cdot (\boldsymbol{\nabla}_{\boldsymbol{\mu}}\mathcal{V})_e).$$

The previous two identities will be used to obtain necessary conditions for the existence of relative equilibria.

Certain relative equilibria will be studied assuming that vectors $\boldsymbol{\Omega}_0^e$, $\boldsymbol{\lambda}^e$, and $\boldsymbol{\mu}^e$ satisfy special geometric properties.

Definition 1. $\mathbf{z}_e$ *is said to be an* Eulerian relative equilibrium *when* $\boldsymbol{\lambda}^e$ *and* $\boldsymbol{\mu}^e$ *are proportional and* $\boldsymbol{\Omega}_e$ *is perpendicular to the straight line that they generate.*

From the above definitions, the following property is deduced.

Proposition 3. *In an Eulerian relative equilibrium, the forces that derive the potential do not exercise moments on the gyrostat.*

Next, necessary and sufficient conditions for the existence of Eulerian relative equilibria will be obtained.

4. Eulerian relative equilibria.

According to the relative position of the gyrostat S_0 with respect to S_1 and S_2, there are three possible equilibrium configurations: (a) $S_0S_2S_1$, (b) $S_2S_0S_1$, and (c) $S_2S_1S_0$ (see Figure 2 for details on the configuration $S_2S_1S_0$).

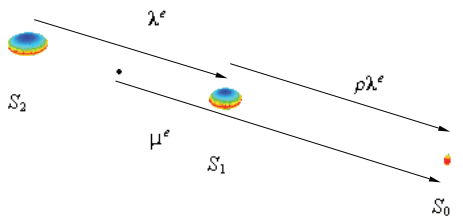

Figure 2. *Eulerian relative equilibria in configuration* $S_2S_1S_0$.

4.1. Necessary conditions of existence.

The following lemma is a direct consequence of the geometry of the problem.

Lemma 4. *If* $\mathbf{z}_e = (\boldsymbol{\Pi}_2^e, \boldsymbol{\Pi}_1^e, \boldsymbol{\Pi}_0^e, \boldsymbol{\lambda}^e, \mathbf{p}_{\boldsymbol{\lambda}}^e, \boldsymbol{\mu}^e, \mathbf{p}_{\mu}^e)$ *is a relative equilibrium of Euler type, then for the configuration* $S_0S_2S_1$

$$\left|\boldsymbol{\mu}^e - \frac{m_2}{M_2}\boldsymbol{\lambda}^e\right| = |\boldsymbol{\lambda}^e| + \left|\boldsymbol{\mu}^e + \frac{m_1}{M_2}\boldsymbol{\lambda}^e\right|.$$

In a similar way, for the configuration $S_2S_0S_1$

$$|\boldsymbol{\lambda}^e| = \left|\boldsymbol{\mu}^e - \frac{m_2}{M_2}\boldsymbol{\lambda}^e\right| + \left|\boldsymbol{\mu}^e + \frac{m_1}{M_2}\boldsymbol{\lambda}^e\right|.$$

Finally, for the configuration $S_2S_1S_0$

$$\left|\boldsymbol{\mu}^e + \frac{m_1}{M_2}\boldsymbol{\lambda}^e\right| = \left|\boldsymbol{\mu}^e - \frac{m_2}{M_2}\boldsymbol{\lambda}^e\right| + |\boldsymbol{\lambda}^e|.$$

If $\mathbf{z}_e$ is an Eulerian relative equilibrium, then

$$g_1|\mathbf{\Omega}_e^0|^2|\boldsymbol{\lambda}^e|^2 = \boldsymbol{\lambda}^e \cdot (\boldsymbol{\nabla}_{\boldsymbol{\lambda}}\mathcal{V})_e,$$
$$g_2|\mathbf{\Omega}_e^0|^2|\boldsymbol{\mu}^e|^2 = \boldsymbol{\mu}^e \cdot (\boldsymbol{\nabla}_{\boldsymbol{\mu}}\mathcal{V})_e,$$

with

$$\boldsymbol{\mu}^e - \frac{m_2}{M_2}\boldsymbol{\lambda}^e = \rho\boldsymbol{\lambda}^e, \quad \boldsymbol{\mu}^e + \frac{m_1}{M_2}\boldsymbol{\lambda}^e = (1+\rho)\boldsymbol{\lambda}^e, \quad \boldsymbol{\mu}^e = \frac{((1+\rho)m_2 + \rho m_1)}{M_2}\boldsymbol{\lambda}^e,$$

where $\rho \in (-\infty, -1)$ in the configuration (a), $\rho \in (-1, 0)$ in the configuration (b), and $\rho \in (0, +\infty)$ in the configuration (c). Moreover, it is possible to obtain

$$(\boldsymbol{\nabla}_{\boldsymbol{\lambda}}\mathcal{V})_e = h_1(\rho)\boldsymbol{\lambda}^e, \quad (\boldsymbol{\nabla}_{\boldsymbol{\mu}}\mathcal{V})_e = h_2(\rho)\boldsymbol{\lambda}^e$$

with

$$h_1(\rho) = \frac{Gm_1m_2}{|\boldsymbol{\lambda}^e|^3} + \frac{Gm_0m_1 sgn(1+\rho)}{M_2|\boldsymbol{\lambda}^e|^3}\left(\frac{m_2}{(1+\rho)^2} + \frac{\beta_2}{(1+\rho)^4|\boldsymbol{\lambda}^e|^2}\right) - \frac{Gm_0m_2 sgn(\rho)}{M_2|\boldsymbol{\lambda}^e|^3}\left(\frac{m_1}{\rho^2} + \frac{\beta_1}{\rho^4|\boldsymbol{\lambda}^e|^2}\right) \tag{3}$$

and

$$h_2(\rho) = \frac{Gm_0 sgn(1+\rho)}{|\boldsymbol{\lambda}^e|^3}\left(\frac{m_2}{(1+\rho)^2} + \frac{\beta_2}{|\boldsymbol{\lambda}^e|^2(1+\rho)^4}\right) + \frac{Gm_0 sgn(\rho)}{|\boldsymbol{\lambda}^e|^3}\left(\frac{m_1}{\rho^2} + \frac{\beta_1}{|\boldsymbol{\lambda}^e|^2\rho^4}\right), \tag{4}$$

where $\beta_1 = 3(C_1 - A_1)/2$, $\beta_2 = 3(C_2 - A_2)/2$, and

$$sgn(x) = \begin{cases} 1 & \text{if } x > 0, \\ -1 & \text{if } x \leq 0. \end{cases}$$

Now, from the identities

$$\boldsymbol{\lambda}^e \cdot (\boldsymbol{\nabla}_{\boldsymbol{\lambda}}\mathcal{V})_e = |\boldsymbol{\lambda}^e|^2 h_1(\rho),$$
$$\boldsymbol{\mu}^e \cdot (\boldsymbol{\nabla}_{\boldsymbol{\mu}}\mathcal{V})_e = \frac{((1+\rho)m_2 + \rho m_1)}{M_2}|\boldsymbol{\lambda}^e|^2 h_2(\rho),$$

the following equations are deduced:

$$|\mathbf{\Omega}_0^e|^2 = \frac{(m_1+m_2)h_1(\rho)}{m_1m_2},$$
$$|\mathbf{\Omega}_0^e|^2 = \frac{(m_0+m_1+m_2)h_2(\rho)}{m_0\left((1+\rho)m_2 + \rho m_1\right)}.$$

Then for an Eulerian relative equilibrium, ρ must be a real root of the following equation:

$$m_0(m_1+m_2)\left((1+\rho)m_2 + \rho m_1\right)h_1(\rho) = m_1m_2(m_0+m_1+m_2)h_2(\rho). \tag{5}$$

The following proposition summarizes all these results.

Proposition 5. *If* $\mathbf{z}_e = (\mathbf{\Pi}_2^e, \mathbf{\Pi}_1^e, \mathbf{\Pi}_0^e, \boldsymbol{\lambda}^e, \mathbf{p}_{\boldsymbol{\lambda}}^e, \boldsymbol{\mu}^e, \mathbf{p}_{\mu}^e)$ *is an Eulerian relative equilibrium, the equation* (5) *has at least one real root in which the functions* $h_1(\rho)$ *and* $h_2(\rho)$ *are given by the expressions* (3), (4). *The modulus of the angular velocity of the gyrostat is*

$$|\mathbf{\Omega}_0^e|^2 = \frac{(m_1+m_2)h_1(\rho)}{m_1 m_2}. \tag{6}$$

Remark 1. *When* $|\boldsymbol{\lambda}_e|$ *has a fixed value, if an Eulerian relative equilibrium exists, then* (5) *has real solutions. The number of real roots of* (5) *will depend, obviously, on the parameters which exist in the system.*

4.2. Sufficient conditions of existence. The following proposition indicates how to calculate solutions of (2).

Proposition 6. *When* $|\boldsymbol{\lambda}^e|$ *has a fixed value, let* ρ *be a solution of* (5), *where the functions* $h_1(\rho)$ *and* $h_2(\rho)$ *are given by the expressions* (3), (4). *Then* $\mathbf{z}_e = (\mathbf{\Pi}_2^e, \mathbf{\Pi}_1^e, \mathbf{\Pi}_0^e, \boldsymbol{\lambda}^e, \mathbf{p}_{\boldsymbol{\lambda}}^e, \boldsymbol{\mu}^e, \mathbf{p}_{\mu}^e)$ *are given by*

$$\boldsymbol{\lambda}^e = (\lambda^e, 0, 0), \quad \boldsymbol{\mu}^e = (\mu^e, 0, 0), \quad \mathbf{\Omega}_0^e = (0, 0, \omega_0^e),$$
$$\mathbf{p}_{\boldsymbol{\lambda}}^e = (0, g_1\omega_0^e\lambda^e, 0), \quad \mathbf{p}_{\boldsymbol{\mu}}^e = (0, g_2\omega_0^e\mu^e, 0), \quad \mathbf{\Pi}_0^e = (0, 0, C_0\omega_0^e + l),$$

where

$$\boldsymbol{\mu}^e = \frac{((1+\rho)m_1 + \rho m_2)}{M_2}\boldsymbol{\lambda}^e, \quad (\omega_0^e)^2 = \frac{(m_1+m_2)h_1(\rho)}{m_1 m_2}$$

is an Eulerian relative equilibrium. The total angular momentum of the system is expressed by

$$\mathbf{L} = (0, 0, C_2\omega_2^e + C_1\omega_1^e + C_0\omega_0^e + l + g_1(\omega_0^e)^2\lambda^e + g_2(\omega_0^e)^2\mu^e),$$

with l *being the gyrostatic momentum. The vectors* $\mathbf{\Pi}_2^e$, $\mathbf{\Pi}_1^e$ *verify the vectorial equations*

$$\mathbf{\Pi}_1^e \times \mathbf{\Omega}_1^e = \mathbf{0}, \quad \mathbf{\Pi}_2^e \times \mathbf{\Omega}_2^e = \mathbf{0}.$$

4.3. Eulerian relative equilibria when S_2 and S_1 are spherical rigid bodies. Consider the existence and number of solutions for Eulerian relative equilibria when S_2 and S_1 are spherical rigid bodies. In this case $C_1 = A_1$, $C_2 = A_2$, and (5) is equivalent to the following polynomial equation:

$$\begin{aligned}(m_1+m_2)\rho^5 + (3m_2+2m_1)\rho^4 + (3m_2 + m_1 + m_0(sgn(1+\rho)\\ - sgn(\rho)))\rho^3 + (m_2 - m_2 sgn(1+\rho) - m_1 sgn(\rho) - 3m_0 sgn(\rho))\rho^2\\ - (3sgn(\rho)m_0 + 2sgn(\rho)m_1)\rho - (m_0 sgn(\rho) + m_1 sgn(\rho)) = 0.\end{aligned} \tag{7}$$

This equation, by Descartes's rule of signs, has a unique real solution in the intervals $(-\infty, -1)$, $(-1, 0)$, and $(0, +\infty)$. Therefore, only one Eulerian relative equilibrium exists.

On the other hand,

$$|\mathbf{\Omega}_0^e|^2 = \frac{G(m_1+m_2)}{|\boldsymbol{\lambda}^e|^3}\left(1 + \frac{m_0}{(m_1+m_2)}\left(\frac{sgn(1+\rho)}{(1+\rho)^2} - \frac{sgn(\rho)}{\rho^2}\right)\right),$$

where ρ is the only solution of (7).

Proposition 5 gathers the results about Eulerian relative equilibria when S_2 and S_1 are spherical rigid bodies in the configurations (a), (b), and (c).

Proposition 7. 1. *If ρ is the unique positive root of the equation*

$$(m_1+m_2)\rho^5+(3m_2+2m_1)\rho^4+(3m_2+m_1)\rho^3 \\ -(3m_0+m_1)\rho^2-(3m_0+2m_1)\rho-(m_0+m_1)=0$$

with

$$|\mathbf{\Omega}_0^e|^2=\frac{G(m_1+m_2)}{|\boldsymbol{\lambda}^e|^3}\left(1+\frac{m_0}{(m_1+m_2)}\left(\frac{1}{(1+\rho)^2}-\frac{1}{\rho^2}\right)\right),$$

then $\mathbf{z}_e=(\mathbf{\Pi}_2^e,\mathbf{\Pi}_1^e,\mathbf{\Pi}_0^e,\boldsymbol{\lambda}^e,\mathbf{p}_{\boldsymbol{\lambda}}^e,\boldsymbol{\mu}^e,\mathbf{p}_{\mu}^e)$, given by

$$\boldsymbol{\lambda}^e=(\lambda^e,0,0),\quad \boldsymbol{\mu}^e=(\mu^e,0,0),\quad \mathbf{\Omega}_0^e=(0,0,\omega_0^e), \\ \mathbf{p}_{\boldsymbol{\lambda}}^e=(0,g_1\omega_0^e\lambda^e,0),\quad \mathbf{p}_{\boldsymbol{\mu}}^e=(0,g_2\omega_0^e\mu^e,0),\quad \mathbf{\Pi}_0^e=(0,0,C_0\omega_0^e+l), \tag{8}$$

is the unique solution of relative equilibrium of Euler type in the configuration $S_2S_1S_0$.

2. *If $\rho\in(-1,0)$ is the unique root of the equation*

$$(m_1+m_2)\rho^5+(3m_2+2m_1)\rho^4+(3m_2+m_1+2m_0)\rho^3 \\ +(3m_0+m_1)\rho^2+(3m_0+2m_1)\rho+(m_0+m_1)=0$$

with

$$|\mathbf{\Omega}_0^e|^2=\frac{G(m_1+m_2)}{|\boldsymbol{\lambda}^e|^3}\left(1+\frac{m_0}{(m_1+m_2)}\left(\frac{1}{(1+\rho)^2}+\frac{1}{\rho^2}\right)\right),$$

then $\mathbf{z}_e=(\mathbf{\Pi}_2^e,\mathbf{\Pi}_1^e,\mathbf{\Pi}_0^e,\boldsymbol{\lambda}^e,\mathbf{p}_{\boldsymbol{\lambda}}^e,\boldsymbol{\mu}^e,\mathbf{p}_{\mu}^e)$ given by (8) is the unique solution of relative equilibrium of Euler type in the configuration $S_2S_0S_1$.

3. *If $\rho\in(-\infty,-1)$ is the unique root of the equation*

$$(m_1+m_2)\rho^5+(3m_2+2m_1)\rho^4+(3m_2+m_1)\rho^3 \\ +(3m_0+m_1+2m_2)\rho^2+(3m_0+2m_1)\rho+(m_0+m_1)=0,$$

where

$$|\mathbf{\Omega}_0^e|^2=\frac{G(m_1+m_2)}{|\boldsymbol{\lambda}^e|^3}\left(1+\frac{m_0}{(m_1+m_2)}\left(\frac{1}{\rho^2}-\frac{1}{(1+\rho)^2}\right)\right),$$

then $\mathbf{z}_e=(\mathbf{\Pi}_2^e,\mathbf{\Pi}_1^e,\mathbf{\Pi}_0^e,\boldsymbol{\lambda}^e,\mathbf{p}_{\boldsymbol{\lambda}}^e,\boldsymbol{\mu}^e,\mathbf{p}_{\mu}^e)$ given by (8) is the unique solution of relative equilibrium of Euler type in the configuration $S_0S_2S_1$.

These results agree with the classical Newtonian three body problem; see [12] for details.

4.4. Eulerian relative equilibria when S_2 and S_1 are not spherical rigid bodies. In the present case, after carrying out the appropriate calculations, we reduce (5) to the study of the positive real roots of the nine degree equation

$$\beta_2 q(\rho)-m_1m_2a^2\rho^2(\rho+1)^2p(\rho)=0, \tag{9}$$

where

$$p(\rho) = (m_1+m_2)\rho^5 + (3m_2+2m_1)\rho^4 + (3m_2+m_1+m_0(sgn(1+\rho) - sgn(\rho)))\rho^3 + (m_2 - m_2 sgn(1+\rho) - m_1 sgn(\rho) - 3m_0 sgn(\rho))\rho^2 - (3sgn(\rho)m_0 + 2sgn(\rho)m_1)\rho - (m_0 sgn(\rho) + m_1 sgn(\rho)) \tag{10}$$

and

$$q(\rho) = m_0(ksgn(\rho)m_2 - sgn(1+\rho)m_1)\rho^5 + m_2(sgn(1+\rho)m_1 + 5sgn(\rho)m_0 k + km_1 sgn(\rho))\rho^4 + 2m_2 ksgn(\rho)(2m_1+5m_0)\rho^3 + 2m_2 ksgn(\rho)(3m_1+5m_0)\rho^2 + ksgn(\rho)m_2(4m_1+5m_0)\rho + ksgn(\rho)m_2(m_0+m_1),$$

where

$$\beta_1 = 3(C_1 - A_1)/2, \quad \beta_2 = 3(m_1+m_2)(C_2 - A_2)/2$$

with $\beta_1 = k\beta_2$, $a = |\boldsymbol{\lambda}_e|$, and $k \in \mathbb{R}$.

In order to study the number of real roots of the polynomial (9), the rational function

$$\beta_2 = R(\rho) = \frac{m_1 m_2 a^2 \rho^2 (\rho+1)^2 p(\rho)}{q(\rho)}$$

will be studied.

In practical applications m_0 is very small; then up to first order in m_0

$$\beta_2 = R_1(\rho) = \frac{a^2\rho^2(\rho+1)^2 p_1(\rho)}{q_1(\rho)} + o(m_0),$$

where

$$p_1(\rho) = \rho^5 + (2+\mu)\rho^4 + (1+2\mu)\rho^3 + (\mu - \mu sgn(1+\rho) - (1-\mu)sgn(\rho))\rho^2 - 2sgn(\rho)(1-\mu)\rho - (1-\mu)sgn(\rho)$$

and

$$q_1(\rho) = (sgn(1+\rho) + sgn(\rho)k)\rho^4 + 4sgn(\rho)k\rho^3 + 6sgn(\rho)k\rho^2 + 4sgn(\rho)k\rho + sgn(\rho)k,$$

where $\mu = \frac{m_2}{m_2+m_1}$.

The polynomial q_1 has no roots in $(0,+\infty)$ and $(-1,0)$ if $k > 0$ and $k < 0$, respectively. On the other hand, q_1 has only one root, ρ_1, in $(0,+\infty)$ and $(-1,0)$ if $k < 0$ and $k > 0$, respectively. ρ_0 will be denoted as the only root of p_1. The implicit curve $Res(k,\mu) = 0$, where Res is the resultant of the polynomials p_1 and q_1, is used to study the graph of R_1. When μ_0 has a fixed value, the only k_0 which verifies $Res(k_0,\mu_0) = 0$ exists according to the implicit function theorem. Consider the only root, $\widetilde{\rho_1} = \rho_0(\mu_0)$, of q_1 for k_0 and μ_0. The expressions

$$(\rho_{\max}, \xi_1(k) = R_1(\rho_{\max})), \quad (\rho_{\min}, \xi_2(k) = R_1(\rho_{\min}))$$

are the local maximum and minimum of the function R_1.

In the configuration $S_2S_1S_0$, for any value of μ fixed

$$\lim_{k\to+\infty}\xi_2(k)=0,\quad \lim_{k\to0^+}\xi_2(k)=-\infty$$

if $k>0$. For $k<0$

$$\lim_{k\to+\infty}\xi_1(k)=0,\quad \lim_{k\to0^+}\xi_2(k)=+\infty$$

if $\rho_1>\widetilde{\rho_1}$. If $\rho_1\le\widetilde{\rho_1}$, then R_1 is strictly increasing.

For the configuration $S_2S_0S_1$, if $\widetilde{\rho_1}\le\rho_1$ and $k>0$, then the function R_1 has just one minimum, which verifies

$$\lim_{k\to0^+}\xi_2(k)=\xi_0.$$

If $\rho_1<\widetilde{\rho_1}$, then

$$\lim_{k\to+\infty}\xi_2(k)=0.$$

If $k<0$, then R_1 verifies that

$$\lim_{k\to0^-}\xi_2(k)=\xi_0,\quad \lim_{k\to0^-}\xi_1(k)=+\infty,$$
$$\lim_{k\to-\infty}\xi_2(k)=0,\quad \lim_{k\to-\infty}\xi_1(k)=0.$$

The results for the configuration $S_0S_2S_1$ will be deduced from the configuration $S_2S_1S_0$.

According to these statements, the following proposition can be stated.

Proposition 8. *In the configuration $S_2S_1S_0$ for $k>0$,*

1. *if $\beta_2<R_1(\rho_{\min})$, then Eulerian relative equilibria do not exist.*
2. *If $\beta_2=R_1(\rho_{\min})$, a unique 2-parametric family of Eulerian relative equilibria exists.*
3. *If $R_1(\rho_{\min})<\beta_2<0$, two 2-parametric families of Eulerian relative equilibria exist.*
4. *If $\beta_2>0$, a unique 2-parametric family of Eulerian relative equilibria exists. For $k_0<k<0$ and $\beta_2>0$,*
5. *if $\beta_2\in(\xi_1(k),\xi_2(k))$, Eulerian relative equilibria do not exist.*
6. *If $\beta_2=\xi_1(k)$ or $\beta_2=\xi_2(k)$, then a unique 2-parametric family of Eulerian relative equilibria exists.*
7. *If $\beta_2>\xi_2(k)$, two 2-parametric families of Eulerian relative equilibria exist.*
8. *If $0<\beta_2<\xi_1(k)$, two 2-parametric families of Eulerian relative equilibria exist. For $k_0<k<0$ and $\beta_2<0$,*
9. *a unique 2-parametric family of Eulerian relative equilibria exists. For $k<k_0$ and $\beta_2>0$,*
10. *two 2-parametric families of Eulerian relative equilibria exist. For $k<k_0$ and $\beta_2<0$,*
11. *a unique 2-parametric family of Eulerian relative equilibria exists.*

Similar results are obtained for the configuration $S_2S_0S_1$. Figures 3, 4, 5, and 6 illustrate the bifurcations of the equilibria.

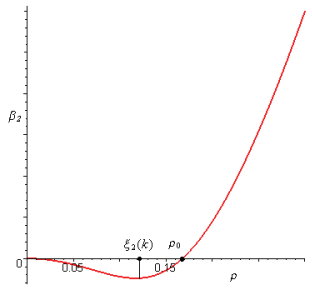

Figure 3. *Function $R_1(\rho)$ for the configuration $S_2S_1S_0$ and $k > 0$.*

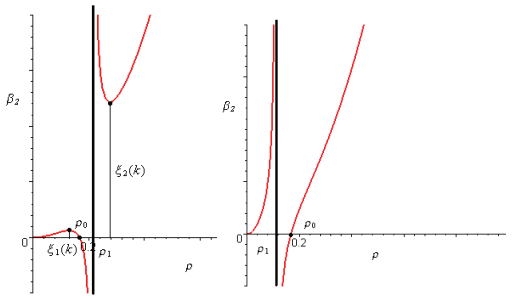

Figure 4. *Function $R_1(\rho)$ for the configuration $S_2S_1S_0$ for $k_0 < k < 0$ and $\beta_2 > 0$, $\beta_2 < 0$, respectively.*

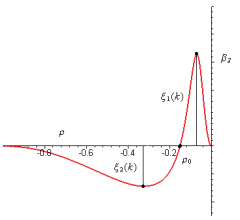

Figure 5. *Function $R_1(\rho)$ for the configuration $S_2S_0S_1$.*

5. Stability of Eulerian relative equilibria. The tangent flow of (1) in an Eulerian relative equilibrium $\mathbf{z}_e$ is expressed by

$$\frac{d\delta\mathbf{z}}{dt} = \mathfrak{U}(\mathbf{z}_e)\delta\mathbf{z},$$

with $\delta\mathbf{z} = \mathbf{z} - \mathbf{z}_e$ and $\mathfrak{U}(\mathbf{z}_e)$ being the Jacobian matrix of (1) in $\mathbf{z}_e$.

The characteristic polynomial $\mathfrak{U}(\mathbf{z}_e)$ is expressed as

$$P(X) = X^3(X^2+\Phi_0^2)(X^2+\Phi_1^2)(X^2+\Phi_2^2)(X^4+mX^2+n)(X^8+pX^6+qX^4+rX^2+s), \tag{11}$$

with $\Phi_i^2 = \frac{(C_i-A_i)\omega_i^e+l}{A_i}$. The coefficients present in the above polynomial are functions of the parameters of the problem and ρ, where ρ is taken as the root of (5).

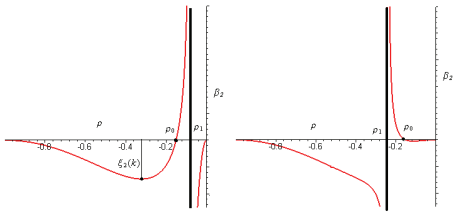

Figure 6. *Function $R_1(\rho)$ for the configuration $S_2S_0S_1$.*

5.1. S_2 and S_1 are spherical rigid bodies. The characteristic polynomial (11) of $\mathfrak{U}(\mathbf{z}_e)$ simplifies to

$$P(X) = X^5(X^2+\Phi_0^2)(X^2+\Phi_1^2)(X^2+\Phi_2^2)(X^2+(\omega_0^e)^2)^2(X^2+p)(X^4+qX^2+r) \tag{12}$$

with coefficients shown in Appendix B.

If $p \geq 0$, $q \geq 0$, $r \geq 0$, $q^2-4r \geq 0$, then $\mathbf{z}_e$ is spectrally stable. These conditions are not verified since $r < 0$.

Proposition 9. *If $\mathbf{z}_e$ is the only relative equilibrium in the configuration $S_0S_2S_1$ of the zero order approximate dynamics, then it is unstable.*

5.2. S_2 and S_1 are close to a sphere. The case in which S_i $(i=1,2)$ are close to a sphere will now be analyzed. In this case $C_i - A_i \approx 0$, and this is the reason why, by applying the implicit function theorem, $\mathbf{z}_e$ is unstable.

If $C_i - A_i$ is not close to zero, the coefficients of the polynomial (11) have very complicated expressions. Numeric calculations prove that linear stable Eulerian relative equilibria exist for certain values of the parameters $C_i - A_i$ $(i=1,2)$ (see Vera and Vigueras [8] for details). *These results are also applicable to configurations $S_2S_0S_1$ and $S_2S_1S_0$.*

6. Rotational Poisson dynamics in an Eulerian equilibrium. To describe the rotational Poisson dynamics in an Eulerian equilibrium, we consider the gyrostat fixed frame $\mathfrak{J} = \mathfrak{R}_{orb} = \{\mathbf{e}, \mathbf{b}, \mathbf{n}\}$ with origin in the mass center of the gyrostat. The versors $\mathbf{e}$ and $\mathbf{n}$ denote the radial and the orbital angular velocity directions, respectively, and $\mathbf{b} = \mathbf{n} \times \mathbf{e}$. We consider $\mathbf{\Omega}_{orb} = \mathbf{\Omega}_0 - \omega_0^e \mathbf{n}$ with ω_0^e given by (6). The rotational equations of the motion of a gyrostat placed in an Eulerian equilibrium are

$$\frac{d\mathbf{\Pi}_0}{dt} = \mathbf{\Pi}_0 \times \mathbf{\Omega}_0 + \mathfrak{M}, \quad \frac{d\mathbf{e}}{dt} = \mathbf{e} \times \mathbf{\Omega}_{\mathbf{orb}}, \quad \frac{d\mathbf{b}}{dt} = \mathbf{b} \times \mathbf{\Omega}_{\mathbf{orb}}, \quad \frac{d\mathbf{n}}{dt} = \mathbf{n} \times \mathbf{\Omega}_{\mathbf{orb}},$$

$\mathfrak{M}$ being the gravitational torque acting on the gyrostat. The following formula is verified for the gravitational torque:

$$\mathfrak{M} = \nabla_{\mathbf{e}} \mathcal{U},$$

with

$$\mathcal{U}(\mathbf{e}) = \frac{3k}{2} \mathbf{e} \cdot \mathbb{I}_0 \mathbf{e}.$$

The parameter k is given by

$$k = \frac{G}{|\boldsymbol{\lambda}^e|^3} \left(\frac{m_1}{|1+\rho|^3} + \frac{m_2}{|\rho|^3} \right),$$

and ρ is determined by (5).

Keeping in mind that $\mathbf{\Omega}_0 = \mathbb{I}_0^{-1}\mathbf{\Pi} - \mathbf{l}_r$ with $\mathbf{l}_r = \mathbb{I}^{-1}\widetilde{\mathbf{l}_r}$, the equations of motion are

$$\begin{aligned}
\frac{d\mathbf{\Pi}_0}{dt} &= \mathbf{\Pi}_0 \times \mathbb{I}_0^{-1}\mathbf{\Pi}_0 - \mathbf{\Pi}_0 \times \mathbf{l_r} + 3k\,\mathbf{e} \times \mathbb{I}\mathbf{e},\\
\frac{d\mathbf{e}}{dt} &= \mathbf{e} \times \left(\mathbb{I}_0^{-1}\mathbf{\Pi}_0 - \mathbf{l_r} - \omega_0^e\mathbf{n}\right),\\
\frac{d\mathbf{b}}{dt} &= \mathbf{b} \times \left(\mathbb{I}_0^{-1}\mathbf{\Pi}_0 - \mathbf{l_r} - \omega_0^e\mathbf{n}\right),\\
\frac{d\mathbf{n}}{dt} &= \mathbf{n} \times \left(\mathbb{I}_0^{-1}\mathbf{\Pi}_0 - \mathbf{l}_r\right).
\end{aligned}$$

As can be easily deduced, we obtain the closed system of nine equations of motion

$$\begin{aligned}
\frac{d\mathbf{\Pi}_0}{dt} &= \mathbf{\Pi}_0 \times \mathbb{I}^{-1}\mathbf{\Pi}_0 - \mathbf{\Pi}_0 \times \mathbf{l_r} + 3k\,\mathbf{e} \times \mathbb{I}\mathbf{e},\\
\frac{d\mathbf{e}}{dt} &= \mathbf{e} \times \left(\mathbb{I}^{-1}\mathbf{\Pi}_0 - \mathbf{l_r} - \omega_0^e\mathbf{n}\right),\\
\frac{d\mathbf{n}}{dt} &= \mathbf{n} \times \left(\mathbb{I}^{-1}\mathbf{\Pi}_0 - \mathbf{l}_r\right).
\end{aligned} \tag{13}$$

The system (13) is a Poisson system in $\mathbb{R}^9$. For it, given two arbitrary functions $f, g \in C^\infty(\mathbb{R}^9)$ and $\mathbf{u} \in \mathbb{R}^9$, we define the Poisson bracket $\{\cdot,\cdot\}$ by $\{f,g\} = (\nabla_{\mathbf{u}} f)^t \mathbf{\Gamma}(\mathbf{u}) \nabla_{\mathbf{u}} g$, where $\mathbf{u} = (\mathbf{\Pi}, \mathbf{e}, \mathbf{n})^t$ and $\mathbf{\Gamma}$ is

$$\mathbf{\Gamma}(\mathbf{u}) = \begin{pmatrix} \widehat{\mathbf{\Pi}} & \widehat{\mathbf{e}} & \widehat{\mathbf{n}} \\ \widehat{\mathbf{e}} & \mathbf{0} & \mathbf{0} \\ \widehat{\mathbf{n}} & \mathbf{0} & \mathbf{0} \end{pmatrix}.$$

Then, system (13) can be written as

$$\frac{d\mathbf{u}}{dt} = \mathbf{\Gamma}(\mathbf{u}) \boldsymbol{\nabla}_{\mathbf{u}} \mathcal{H}$$

with

$$\mathcal{H} = \frac{1}{2}\mathbf{\Pi}_0^t \mathbb{I}_0^{-1}\mathbf{\Pi}_0 - \mathbf{l_r} \cdot \mathbf{\Pi}_0 - \omega_0^e\,\mathbf{\Pi}_0 \cdot \mathbf{n} + \mathcal{U} \tag{14}$$

and $\mathcal{U}(\mathbf{e}) = \frac{3k}{2}\mathbf{e} \cdot \mathbb{I}\mathbf{e}$.

We can therefore conclude that (13) is a Hamiltonian system in the Poisson manifold $(\mathbb{R}^9, \{\cdot,\cdot\})$ with Hamiltonian function (14). The Poisson structure is noncanonical; that is, there exist nonconstant Casimir functions which are the following geometric integrals:

$$\Phi_1(\mathbf{u}) = \mathbf{e} \cdot \mathbf{e}, \quad \Phi_2(\mathbf{u}) = \mathbf{n} \cdot \mathbf{n}, \quad \Phi_3(\mathbf{u}) = \mathbf{e} \cdot \mathbf{n}.$$

6.1. Rotational equilibrium conditions. We know that a necessary and sufficient condition in order for $\mathbf{u}_e = (\mathbf{\Pi}_e, \mathbf{e}_e, \mathbf{n}_e)^t$ to be a equilibrium of the equations of motion (13) is that there must exist $\lambda_1, \lambda_2, \lambda_3 \in \mathbb{R}$ such that $\mathbf{d}(\widetilde{\mathcal{H}}) = \mathbf{d}(\mathcal{H} - \lambda_1\Phi_1 - \lambda_2\Phi_2 - \lambda_3\Phi_3) = \mathbf{0}$. From this, we deduce the following vectorial equations:

$$\begin{aligned} \mathbb{I}^{-1}\mathbf{\Pi}_0^e - \mathbf{l}_r - \omega_0^e\mathbf{n}_e &= \mathbf{0}, \\ 3k\mathbb{I}\mathbf{e}_e - 2\lambda_1\mathbf{e}_e - \lambda_3\mathbf{n}_e &= \mathbf{0}, \\ -\omega_0^e\mathbf{\Pi}_e - 2\lambda_2\mathbf{n}_e - \lambda_3\mathbf{e}_e &= \mathbf{0}. \end{aligned}$$

From these equations we obtain the relations

$$\mathbf{\Omega}_0^e = \omega_0^e\mathbf{n}_e, \quad \lambda_1 = \tfrac{3k}{2}\mathbf{e}_e \cdot \mathbb{I}_0^{-1}\mathbf{e}_e, \quad \lambda_2 = -\tfrac{\omega_0^e}{2}\mathbf{\Pi}_0^e \cdot \mathbf{n}_e, \quad \lambda_3 = 0.$$

We call *cylindrical equilibrium* to the following expression:

$$\begin{aligned} &\mathbf{\Pi}_0^e = (0, 0, C_0\omega_0^e + l), \quad \mathbf{e}_e = (1, 0, 0), && \mathbf{n}_e = (0, 0, 1), \\ &\lambda_1 = \frac{3k}{2A}, && \lambda_2 = -\frac{\omega_e(C_0\omega_0^e + l)}{2}, \quad \lambda_3 = 0. \end{aligned}$$

In this paper we obtain necessary and sufficient conditions for the nonlinear stability of the cylindrical equilibrium. Other equilibria and stability conditions are studied in an upcoming paper.

6.2. Necessary and sufficient conditions of stability of the cylindrical equilibrium. By means of the tangent flow of this dynamics in the cylindrical equilibrium, we obtain necessary conditions for the nonlinear stability. After some standard calculations we obtain the following expressions:

$$\begin{aligned} &C_0 - A_0 \geq 0, \\ &p = C_0[\omega_e^2(B_0 - C_0) + \omega_e l] + A[((\omega_0^e)^2 - 3k)(B_0 - A_0) + \omega_0^e l] \\ &+ [\omega_0^e(B_0 - C_0 - A_0) + l]^2 \geq 0, \\ &q = [(\omega_0^e)^2(B_0 - C_0) + \omega_e l][((\omega_0^e)^2 + 3k)(B_0 - A_0) + \omega_0^e l] \geq 0, \\ &p^2 - 4qC_0A_0 \geq 0. \end{aligned}$$

By means of the energy-Casimir method (see [6] for details), we obtain conditions for nonlinear stability of the cylindrical equilibria. Following the process, we will need to evaluate

$$\mathbf{d}^2(\widetilde{\mathcal{H}})(\mathbf{u}_e) = \begin{pmatrix} \mathbb{I}^{-1} & 0 & -\omega_0^e\mathbf{I}_{\mathbb{R}^3} \\ 0 & 3k\mathbb{I} - 2\lambda_1\mathbf{I}_{\mathbb{R}^3} & 0 \\ -\omega_0^e\mathbf{I}_{\mathbb{R}^3} & 0 & -2\lambda_2\mathbf{I}_{\mathbb{R}^3} \end{pmatrix}$$

with $\lambda_1 = 3k/2A$ and $\lambda_2 = -\omega_e(C\omega_e + l)/2$. This matrix restricted to

$$\mathbf{W} = \mathrm{Ker}(\mathbf{d}\Phi_1(\mathbf{u}_e)) \cap \mathrm{Ker}(\mathbf{d}\Phi_2(\mathbf{u}_e)) \cap \mathrm{Ker}(\mathbf{d}\Phi_3(\mathbf{u}_e))$$

is

$$\mathbf{d}^2(\widetilde{\mathcal{H}})_{|\mathbf{W}}(\mathbf{u}_e) = \begin{pmatrix} \frac{1}{A_0} & 0 & 0 & 0 & -\omega_0^e & 0 \\ 0 & \frac{1}{B_0} & 0 & 0 & 0 & -\omega_0^e \\ 0 & 0 & \frac{1}{C_0} & 0 & 0 & 0 \\ 0 & 0 & 0 & 3k(B_0 - A_0) & 0 & 0 \\ -\omega_0^e & 0 & 0 & 0 & 3k(C_0 - A_0) + \omega_0^e(C_0\omega_0^e + l) & 0 \\ 0 & -\omega_0^e & 0 & 0 & 0 & \omega_0^e(C_0\omega_0^e + l) \end{pmatrix}.$$

Using Sylvester's theorem, we obtain the following conditions for nonlinear stability of the cylindrical equilibrium:

$$\begin{aligned} &C_0 - A_0 > 0, \\ &(\omega_0^e)^2(B_0 - C_0) + \omega_0^e l > 0, \\ &((\omega_0^e)^2 + 3k)(B_0 - A_0) + \omega_0^e l > 0. \end{aligned}$$

7. Conclusions and future work. In this paper we have investigated some important periodic solutions of the dynamics of a gyrostat in Newtonian interaction with two symmetric rigid bodies. With the hypotheses formulated in the introduction, working in the double reduced space of configuration of the problem, both the equations of motion and those which determine the relative equilibria have been derived. The Eulerian relative equilibria have been completely determined by a polynomial equation of degree nine. The obtained results generalize those of [12, 1, 9]. The bifurcations of these equilibria have been carried out when m_0 is very small. The instability of Eulerian relative equilibria has been proven if the gyrostat S_0 is close to a sphere. The rotational Poisson dynamics of the gyrostat placed in an Eulerian equilibrium is considered. The nonlinear stability of some rotational equilibria, called cylindrical equilibria, is studied by means of the energy-Casimir method. By means of the tangent flow of this dynamics in the cylindrical equilibrium, we obtain necessary conditions for the nonlinear stability of the cylindrical equilibria. Diverse results, which had been obtained by means of classic methods in previous works, have been obtained and generalized in a different way. The methods employed in this work are suitable for use in similar problems. Numerous problems are open; among them, it is necessary to consider the study of the "inclined" relative equilibria, in which $\mathbf{\Omega}_0^e$ forms an angle $\alpha \neq 0$ and $\pi/2$ with the vector $\boldsymbol{\lambda}^e$.

Appendix A. Some numerical results. In order to obtain the values of $C_i - A_i$ $(i = 1, 2)$, the following relationships will be utilized:

$$\begin{aligned} C_1 - A_1 &= (1 - \mu)\left(\frac{e_{S_1}}{Z}\right)^2 J_2^{S_1}, \\ C_2 - A_2 &= \mu\left(\frac{e_{S_2}}{Z}\right)^2 J_2^{S_2}, \end{aligned}$$

where e_{S_i} and p_{S_i} represent the equatorial and polar radii of S_i $(i = 1, 2)$, $J_2^{S_i} = \frac{2}{5}\varepsilon_i$, respectively, and $\varepsilon_i = \frac{e_{S_i} - p_{S_i}}{e_{S_i}}$. S_1, S_2 are considered to be homogeneous ellipsoids. The distances are measured in kilometers.

Appendix B. Coefficients of the characteristic polynomial in Eulerian relative equilibria $S_0S_2S_1$.

The coefficients of the characteristic polynomial (12) are

$$\omega_e^2 = \frac{G((m_2+m_1)\rho^4 + (2m_1+2m_2)\rho^3 + (m_2+m_1)\rho^2 - 2m_0\rho - m_0)}{\lambda_e^3(1+\rho)^2\rho^2},$$

$$p = \frac{G((m_2+4m_0+m_1)\rho^3 + (3m_2+6m_0)\rho^2 + (4m_0+3m_2)\rho + m_0 + m_2)}{(1+\rho)^3\rho^3\lambda_e^3},$$

$$\begin{aligned} q = {} & \frac{G((-2m_1\rho^4 m_2 + (-2m_0m_1 + m_1^2 + m_2^2 - 2m_1m_2 - 2m_0m_2)\rho^3}{((1+\rho)^3\rho^3\lambda_e^3)} \\ & + \frac{(3m_2^2 + m_1m_2 - 6m_0m_1)\rho^2 + (-m_1m_2 + 3m_2^2 + 2m_0m_2 - 4m_0m_1)\rho}{((1+\rho)^3\rho^3\lambda_e^3)} \\ & + \frac{m_2^2 - m_0m_1 + m_0m_2 - m_1m_2))}{((1+\rho)^3\rho^3\lambda_e^3)}, \end{aligned}$$

$$r = \frac{G^2(a_1\rho^4 + a_2\rho^4 + a_3\rho^2 + a_4\rho + a_5)}{((1+\rho)^8\rho^8\lambda_e^9)}.$$

B.1. Coefficients a_i $(i = 1, \ldots, 5)$.

$$\begin{aligned} a_1 = {} & -42m_2^7m_1 - 48m_2^7m_0 - 147m_2^6m_1^2 - 336m_2^6m_1m_0 - 129m_2^6m_0^2 \\ & - 207m_2^5m_1^3 - 782m_2^5m_1^2m_0 - 673m_2^5m_1m_0^2 - 81m_2^5m_0^3 - 150m_2^4m_1^4 \\ & - 869m_2^4m_1^3m_0 - 1325m_2^4m_1^2m_0^2 - 378m_2^4m_1m_0^4 - 64m_2^3m_1^5 \\ & - 513m_2^3m_1^4m_0 - 1270m_2^3m_1^3m_0^2 - 702m_2^3m_1^2m_0^3 - 14m_2^2m_1^6 \\ & - 165m_2^2m_1^5m_0 - 610m_2^2m_1^4m_0^2 - 648m_2^2m_1^3m_0^3 - 24m_2m_1^6m_0 \\ & - 119m_2m_1^5m_0^2 - 297m_2m_1^4m_0^3 + 2m_1^6m_0^2 - 54m_1^5m_0^3, \end{aligned}$$

$$a_2 = -60m_2^7m_1 - 54m_2^7m_0 - 243m_2^6m_1^2 - 474m_2^6m_1m_0 - 173m_2^6m_0^2 - 399m_2^5m_1^3 - 1345m_2^5m_1^2m_0 - 999m_2^5m_1m_0^2 - 135m_2^5m_0^3 - 329m_2^4m_1^4 - 1846m_2^4m_1^3m_0 - 2223m_2^4m_1^2m_0^2 - 648m_2^4m_1m_0^3 - 138m_2^3m_1^5 - 1364m_2^3m_1^4m_0 - 2506m_2^3m_1^3m_0^2 - 1242m_2^3m_1^2m_0^3 - 24m_2^2m_1^6 - 536m_2^2m_1^5m_0 - 1530m_2^2m_1^4m_0^2 - 1188m_2^2m_1^3m_0^3 - 90m_2m_1^6m_0 - 477m_2m_1^5m_0^2 - 567m_2m_1^4m_0^3 - 56m_1^6m_0^2 - 108m_1^5m_0^3,$$

$$a_3 = -42m_2^7m_1 - 36m_2^7m_0 - 183m_2^6m_1^2 - 342m_2^6m_1m_0 - 93m_2^6m_0^2 - 349m_2^5m_1^3 - 1097m_2^5m_1^2m_0 - 630m_2^5m_1m_0^2 - 81m_2^5m_0^3 - 358m_2^4m_1^4 - 1776m_2^4m_1^3m_0 - 166m_2^4m_1^2m_0^2 - 405m_2^4m_1m_0^3 - 189m_2^3m_1^5 - 1614m_2^3m_1^4m_0 - 2256m_2^3m_1^3m_0^2 - 810m_2^3m_1^2m_0^3 - 31m_2^2m_1^6 - 827m_2^2m_1^5m_0 - 1683m_2^2m_1^4m_0^2 - 810m_2^2m_1^3m_0^3 - 6m_2m_1^7 - 228m_2m_1^6m_0 - 666m_2m_1^5m_0^2 - 405m_2m_1^4m_0^3 - 30m_1^7m_0 - 81m_1^5m_0^3 - 111m_1^6m_0^2,$$

Snaking of Multiple Homoclinic Orbits in Reversible Systems*

J. Knobloch† and T. Wagenknecht‡

Abstract. We study N-homoclinic orbits near a heteroclinic cycle in a reversible system. The cycle is assumed to connect two equilibria of saddle-focus type. Using Lin's method, we establish the existence of infinitely many N-homoclinic orbits for each N near the cycle. In particular, these orbits exist along snaking curves, thus mirroring the behavior of 1-homoclinic orbits. The general analysis is illustrated by numerical studies for a Swift–Hohenberg system.

Key words. bifurcation, multiple homoclinic orbits, heteroclinic cycle, homoclinic snaking, Lin's method

1. Introduction.

Spatially localized structures, such as solitary pulses, appear in many systems described by higher-order nonlinear partial differential equations (PDEs). Particular examples have been found in structural mechanics [11], nonlinear optics [20], and water wave problems [4]. A common feature of these cases is the onset of the localized patterns in a sequence of fold bifurcations, which are connected by a snaking curve.

In one spatial dimension this phenomenon can be explained by a sequence of bifurcations in the associated ordinary differential equation (ODE) for traveling waves. Localized patterns correspond to homoclinic solutions of this ODE, and it has been found that infinitely many of such orbits can exist near a heteroclinic cycle in the ODE. These homoclinic orbits all lie on a snaking curve, along which they undergo infinitely many fold bifurcations, while thereby getting wider and developing new oscillations about their center at each fold. An important requirement for this scenario to happen is the time-reversibility of the traveling-wave ODE.

In addition to time-reversibility, the type of the heteroclinic cycle plays an important role for the dynamics. Homoclinic snaking has been observed in a neighborhood of a heteroclinic cycle between an equilibrium p_1 and a saddle-focus equilibrium p_2 (EE cycle) and near cycles connecting an equilibrium p_1 and a periodic orbit P (EP cycle). The homoclinic orbits occurring along a snaking curve are asymptotic to p_1.

In the case of an EE cycle the snaking occurs locally around some critical value of a family parameter at which a codimension one heteroclinic cycle exists. This feature allows one to study the scenario using a local bifurcation analysis. In an earlier paper [14], it was shown rigorously by the authors that heteroclinic cycles between symmetric equilibria of saddle-focus type generate a snaking behavior. In contrast to that behavior, the snaking related to an EP

cycle is generically a global phenomenon in parameter space; that is, it can be observed in a region in parameter space. (This difference is also apparent in the shape of corresponding snaking curves (see Figures 1 and 7).) For a geometric explanation for why homoclinic snaking occurs in this case, we refer the reader to [23, 7]; see also [1] for a recent analytical description.

If p_1 is also of saddle-focus type, then general results by Häerterich [8] (see also [3, 18]) show that homoclinic orbits to p_1 will be accompanied by a plethora of N-homoclinic orbits, i.e., homoclinic orbits to p_1 that pass p_2 N times before closing the loop. For each N there exist infinitely many N-homoclinic orbits, which are distinguished by the times they spend near p_1. In the situation studied here, one may now expect these orbits to snake under variation of the parameter, too. Our goal is to describe this snaking.

More precisely, we understand a snaking curve as a graph $\{(\omega, \lambda(\omega)), \omega \in I\}$ that intersects a line $\{(\omega, \lambda^*), \omega \in I\}$ infinitely many times. Moreover, in the case of an EE cycle, $\lambda(\omega)$ tends to λ^* as ω tends to infinity. So, a snaking curve looks qualitatively similar to the one in Figure 1. Here ω is some intrinsic parameter characterizing the N-homoclinic orbit, taken from some infinite interval I, and $\lambda(\omega)$ is the family parameter of the ODE at which the N-homoclinic orbit exists. Roughly speaking, ω is the length of stay near p_2 during a certain passage of the N-homoclinic orbit near p_2. In the analysis in section 4, we will particularly focus on the case where ω is the first passage past p_2, and we will discuss other possibilities only briefly.

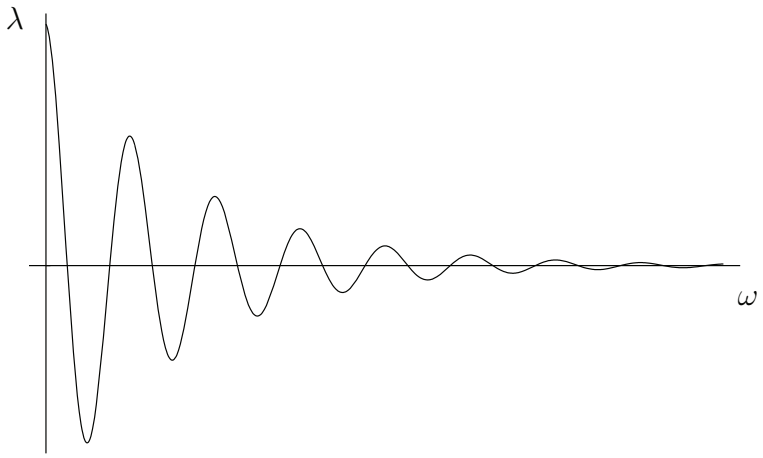

Figure 1. *Snaking curve for symmetric N-homoclinic orbits.*

This paper can be seen as a follow-up to [14], where we discussed 1-homoclinic orbits near an EE cycle. There it was also shown that p_2 has to be of saddle-focus type in order to find snaking behavior of 1-homoclinic orbits. Furthermore, it was shown there that p_1 has to be of saddle-focus type, too, if N-homoclinic orbits to this equilibrium are to exist.

Similar to the procedure in [14] we will use Lin's method [12, 17] to derive bifurcation equations for N-homoclinic orbits near the cycle. The general setup will be introduced in section 3. Under certain genericity assumptions it will be shown in section 4 that the cycle is accompanied by a multitude of N-homoclinic orbits, which exist on snaking curves. In section 5 we briefly discuss snaking near EP cycles. Numerical results for this case disclose

a remarkable difference in the behavior of 2-homoclinic orbits in comparison with the results for EE cycles, derived in the present paper.

Before the general bifurcation analysis, however, we will illustrate the problem we are interested in by numerical results for a generalized Swift–Hohenberg equation in the next section.

2. N-pulses in a generalized Swift–Hohenberg equation. We consider the generalized Swift–Hohenberg equation studied in [10]

$$\frac{\partial u}{\partial t} = ru - \left(\partial_x^2 + q_c^2\right)^2 u + vu^2 - gu^3. \tag{2.1}$$

Stationary localized solutions of this equation, that is, homoclinic solutions to 0 of the fourth-order equation

$$u'''' + 2q_c^2 u'' + (q_c^4 - r)u - vu^2 + gu^3 = 0, \tag{2.2}$$

have been discussed in detail in [2]. In particular, several snaking scenarios have been found to occur in (2.2).

We stress the fact that (2.2) is reversible. This means that there is a linear involution R such that the corresponding first-order system is invariant under the transformation $((u, u', u'', u'''), x) \mapsto (R(u, u', u'', u'''), -x)$. Here the involution R is defined by $(u, u', u'', u''') \mapsto (u, -u', u'', -u''')$. The reversibility plays an important role for the dynamics of (2.2). In particular, it leads to the robust existence of those homoclinic solutions, for which u is an even function. As is common, we will call such solutions *symmetric*. We refer the reader to section 3 for more general comments about reversible systems.

Note that, in addition to being reversible, (2.2) is also conservative and preserves a first integral. However, both in our computations for (2.2) and in the general analysis afterward, we will focus on symmetric homoclinics, and for these the reversibility of (2.2) is the most important property.

Following computations in [2], we set $q_c = 0.5$, $v = 0.75$, and $g = 1$ and consider (2.2) as an equation depending only on r. Then the 0 equilibrium is a saddle focus for all $r < 0$; i.e., the linear part of the vector field has a quadruple of complex eigenvalues. Furthermore, there are two additional equilibria $u_\pm = (3 \pm \sqrt{5 + 64r})/8$ if $r > -5/64$.

We compute symmetric homoclinic orbits to 0 by shooting for orbits in the unstable manifold of this equilibrium, which intersect the symmetry section $\mathrm{Fix}(R) = \{(u, u', u'', u''') : u' = u''' = 0\}$. The behavior and bifurcations of these orbits under variation of r are studied using the software package AUTO/HomCont [24].

Figure 2 shows a bifurcation diagram for a particular 1-homoclinic solution H_1. In this diagram we plot the L^2-norm of the solution vector (u, u', u'', u''') for H_1 against the parameter r. We see that H_1 emerges at $r = 0$ in a local bifurcation of the 0-equilibrium and then undergoes a sequence of fold bifurcations along a snaking curve which accumulate at $r^* = -1/16$.

Inspection of the solutions, contained in the accompanying boxes, shows that along the snaking curve the middle part of the homoclinic orbit approaches the equilibrium u_+, and

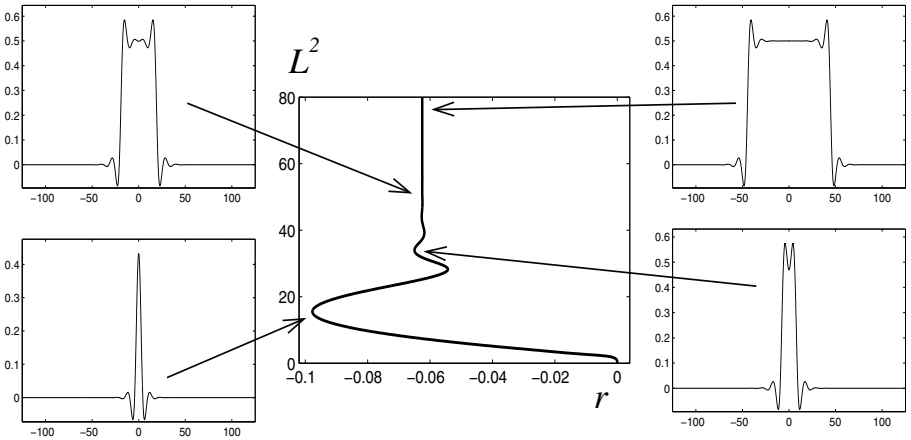

Figure 2. *Snaking curve for* 1*-homoclinic orbits of* (2.2).

indeed a heteroclinic cycle Γ between 0 and u_+ is found to exist at r^*; see also [2]. Note that Γ is invariant under R; it is the limit of symmetric homoclinic orbits.

Remark 2.1. *In all of the numerically obtained diagrams in this paper we plot the L^2-norm of the solution u against the parameter because this solution measure is numerically convenient. We note, however, that this norm is also directly related to the transition times, which will be used in the general analysis (compare with Figure 1). Indeed, the part of the solution that is close to u_+ is the one that predominantly contributes to its L^2-norm.*

Note that for $r = r^*$ there exist infinitely many homoclinic orbits to 0. Since 0 is of saddle-focus type for that parameter value, the results by Härterich [8] suggest the existence of N-homoclinic orbits to 0. These N-homoclinic orbits are computed using a homoclinic branch-switching method developed in [16]. We find a multitude of symmetric N-homoclinic orbits and consider only a few of them with $N = 2, 3$ here.

Figure 3 contains a bifurcation diagram for two symmetric 2-homoclinic orbits existing near the cycle Γ. As before, we plot the L^2-norm against the parameter r and find a snaking curve for each orbit, which accumulates at $r = r^*$. Note that the snaking curves in the diagram stop at some finite norm. This is caused by numerical difficulties in continuing the solutions.

Some solutions along the green curve are shown to the right of the diagram. As for H_1, we find that along the snaking curve the pulses widen, and their middle parts approach u_+. It is interesting to observe that the central part of the solutions between the pulses remains unchanged.

We note that the diagram in Figure 3 shows only half of the L^2-norm of the 2-homoclinic solutions, in order to allow for comparison with the snaking curve for the 1-homoclinic orbit. (The snaking curve for H_1 is shown in grey.) The green snaking curve is not close to the 1-homoclinic snaking curve, but we find a much better approximation in the red curve. This red curve corresponds to a 2-homoclinic solution for which the two pulses are further separated; compare also with the solution plots to the left of the diagram. This suggests that the snaking curves move closer together if the pulses become further separated. However, we encounter numerical difficulties in finding and continuing such solutions.

Next we discuss numerical results for 3-homoclinic orbits near Γ. In Figure 4 we present

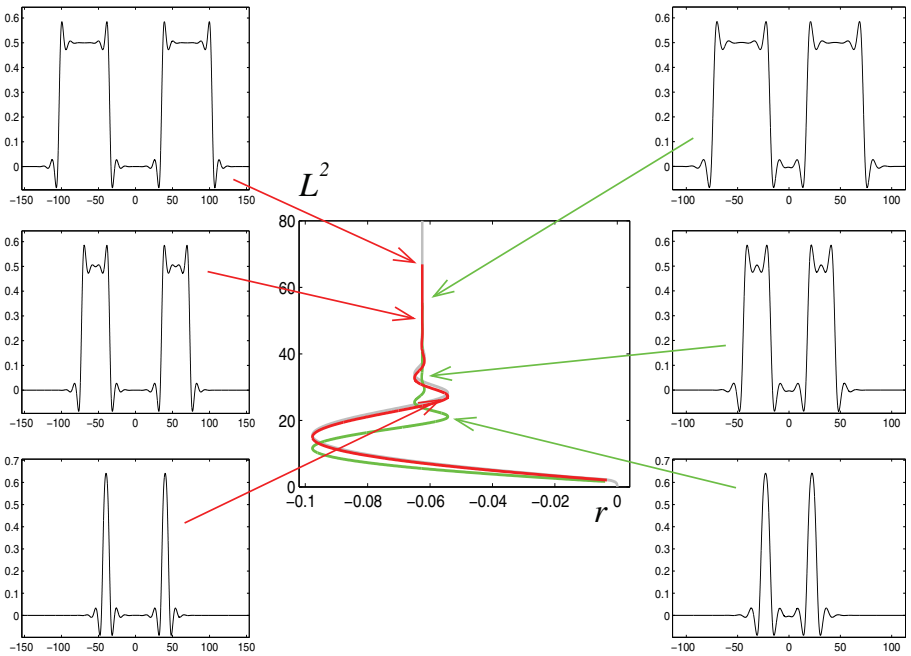

Figure 3. *Snaking curves for* 2*-homoclinic orbits of* (2.2).

two bifurcation diagrams for 3-homoclinic orbits near H_1. The orbits in this figure are created in saddle-node bifurcations and follow only parts of the snaking curve of H_1. Nevertheless, as the L^2-norm of the solutions increases, the curves approach the parameter value r^*.

But now the solution plots show that there are two different types of behavior along the snaking curves. Along the red snaking curves the outer pulses develop additional oscillations, whereas the middle pulse hardly changes. On the other hand, for orbits on the green curve it is the middle pulse that spreads out, and the outer pulses remain unchanged. In fact, solutions along the green curve approach a 2-*heteroclinic cycle* between 0 and u_+. The existence of such cycles will be investigated in section 4.4. We note that for both types of snaking the times separating the pulses are again virtually constant along all snaking curves.

As before, we rescale the L^2-norm of the 3-homoclinic orbits in Figure 4 to make the curves comparable with the one for H_1, whose snaking curve (in parts) is again shown in grey. Note that we again plot half of the L^2-norm of the solution vector, in order to accommodate the behavior along the red curves. This means that we plot an approximation to the L^2-norm of one of the outer pulses. Hence, there is a better match of the red and grey curves.

In summary, we have found 2- and 3-homoclinic orbits near H_1 which mirror the behavior of this 1-homoclinic solution in that they exist on snaking curves, along which certain pulses become wider and approach a steady state u_+. Furthermore, we expect to find different types of behavior along snaking curves for N-homoclinic orbits with $N > 2$.

3. Notation and setup. We aim to understand the numerical results above in a more general context and are thus interested in bifurcations from a heteroclinic cycle between two symmetric equilibria of saddle-focus type in the class of time-reversible systems. Let us

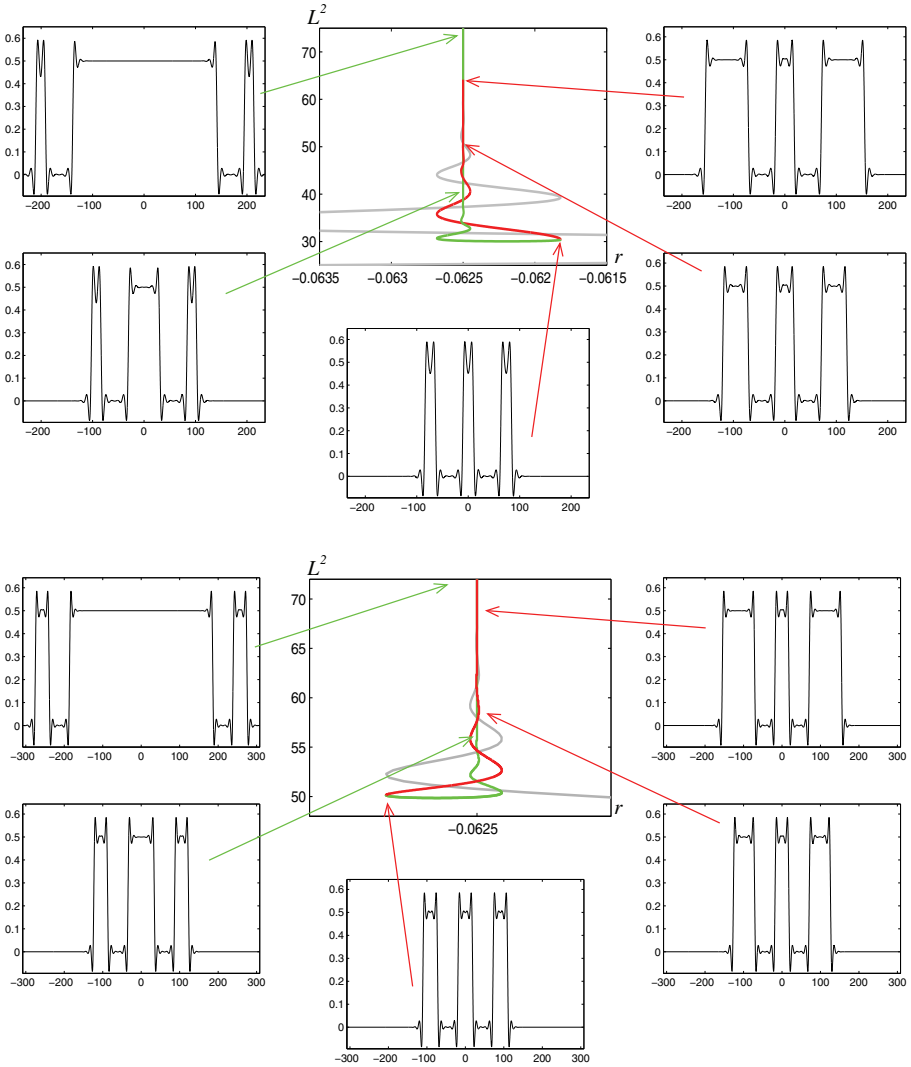

Figure 4. *Two bifurcation diagrams for 3-homoclinic orbits near the heteroclinic cycle. Two different types of snaking behavior are encountered along the red and green curves, respectively.*

describe this configuration in detail.

We consider a system of ODEs

$$\dot{x} = f(x, \lambda), \quad x \in \mathbb{R}^{2n}, \ \lambda \in \mathbb{R}, \tag{3.1}$$

with a smooth vector field f, which is assumed to be (time-)reversible; that is, the vector fields anticommute with some linear involution R:

$$Rf(x, \lambda) = -f(Rx, \lambda).$$

In a reversible system, the image RX of an orbit X is also an orbit. Orbits for which $RX = X$ are called *symmetric*. It is well known that orbits of a reversible system are symmetric if and

only if they intersect the fixed space $\mathrm{Fix}(R) := \{x \in \mathbb{R}^{2n} : Rx = x\}$ of the involution R. We refer the reader to [15, 21] for a collection of fundamental results about reversible systems.

We will be concerned with bifurcations from a heteroclinic cycle Γ in (3.1). More precisely, Γ is a collection of two equilibria p_1, p_2 and heteroclinic orbits connecting p_1 to p_2 and p_2 to p_1 in this order, respectively. Let us first discuss the equilibria.

We assume that (3.1) possesses two symmetric equilibria of saddle-focus type. More precisely, we assume that there are $p_1, p_2 \in \mathrm{Fix}(R)$ such that

$$f(p_k, 0) = 0, \quad k = 1, 2,$$

and the stable spectrum of $D_x f(p_k, 0)$ has the structure

$$\sigma^s(D_x f(p_k, 0)) = \{-\mu_k(0) \pm \varphi_k(0)i\} \cup \sigma_k^{ss}, \quad \text{with } \mu_k(0), \varphi_k(0) > 0. \tag{3.2}$$

In (3.2), σ_k^{ss} denotes the strong stable spectrum such that $\Re\mu < -\mu_k$ for all $\mu \in \sigma_k^{ss}$. Moreover, the principal eigenvalues $-\mu_k(0) \pm \varphi_k(0)i$ are assumed to be simple. Due to the symmetry of the equilibria p_k, we find for the unstable spectrum that

$$\sigma^u(D_x f(p_k, 0)) = -\sigma^s(D_x f(p_k, 0)). \tag{3.3}$$

By hyperbolicity the equilibria will persist as symmetric equilibria for small λ, and thus, with no loss of generality, we may assume that $f(p_k, \lambda) = 0$ for all λ. Furthermore, the leading eigenvalues of the linearized vector field vary smoothly with λ; this means that both $\mu_k(\cdot)$ and $\varphi_k(\cdot)$ are smooth functions of λ.

Let $W^{s(u)}(p_k, \lambda)$ denote the (un)stable manifold of p_k with respect to $f(p_k, \lambda)$. Again, due to the symmetry and hyperbolicity of the equilibria, these manifolds are n-dimensional; see also (3.3). Moreover, reversibility implies $W^s(p_k, \lambda) = RW^u(p_k, \lambda)$.

Finally, we assume the existence of a heteroclinic orbit $\Gamma_1 = \{\gamma_1(t) : t \in \mathbb{R}\}$ connecting p_1 to p_2 for $\lambda = 0$. By reversibility, this orbit is part of a heteroclinic cycle Γ, together with $\Gamma_2 = R\Gamma_1$ and the equilibria p_1 and p_2. Our analysis will require certain nondegeneracy conditions to be fulfilled. These will be imposed on Γ_1, and reversibility ensures that they are fulfilled along Γ_2, too.

First, we assume Γ_1 to be nondegenerate; that is, we assume

$$\dim\left(T_{\gamma_1(0)}W^u(p_1, 0) \cap T_{\gamma_1(0)}W^s(p_2, 0)\right) = 1, \tag{3.4}$$

where T_qM denotes the tangent space of a manifold M at the point q. As a consequence of (3.4), the equation $\dot{v} = -D_x f(\gamma_1(t), 0)^* v$ has a unique bounded solution ψ_1. We assume that both γ_1 and ψ_1 converge along the leading directions to the equilibria and zero, respectively; that is, we assume

$$\lim_{t\to-\infty} e^{\mu_1 t}\|\gamma_1(t) - p_1\| \neq 0, \qquad \lim_{t\to\infty} e^{\mu_2 t}\|\gamma_1(t) - p_2\| \neq 0, \tag{3.5}$$

$$\lim_{t\to-\infty} e^{\mu_2 t}\|\psi_1(t)\| \neq 0, \qquad \lim_{t\to\infty} e^{\mu_1 t}\|\psi_1(t)\| \neq 0. \tag{3.6}$$

Conditions (3.5) and (3.6) are known as nonorbit flip and noninclination flip conditions, respectively [18]; see also [13] for an equivalent geometric statement.

Finally, we also assume a generic unfolding of the heteroclinic connection Γ_1, which should break up under variation of the parameter λ. This can be ensured by assuming that a Melnikov integral M does not vanish [18]:

$$M := \int_{\infty}^{\infty} \langle \psi_1(t), D_\lambda f(\gamma_1(t), 0) \rangle \, dt \neq 0. \tag{3.7}$$

3.1. The main result. We are interested in N-homoclinic orbits to p_1 that lie in a sufficiently small neighborhood of the cycle Γ. Our main result reads as follows.

Theorem 3.1. *Consider* (3.1) *near the heteroclinic cycle* Γ *under the conditions set up in section* 3. *Let* $N \geq 1$ *be fixed.*

At $\lambda = 0$ *there exist countably many symmetric* N*-homoclinic orbits* $\mathcal{H}$ *to* p_1 *which can be continued on a snaking curve* $\lambda_{\mathcal{H}}(\cdot)$ *defined on* $(\Omega_{\mathcal{H}}, \infty)$. *The functions* $\lambda_{\mathcal{H}}$ *have countably infinitely many zeros, and* $|\lambda_{\mathcal{H}}(\omega)|$ *tends exponentially quickly to zero as* ω *tends to infinity.*

The graphs of $\lambda_{\mathcal{H}}$ are depicted in Figure 1. As already mentioned, we will prove Theorem 3.1 for the case where ω is the length of stay of the *first* passage of $\mathcal{H}$ near p_2. For a precise definition of ω, we refer the reader to section 4. However, the numerical results for 3-homoclinic orbits of (2.2) demonstrate that there are other possibilities for the choice of ω. We will discuss these issues briefly in section 4.4.

Note that for $N = 1$ the theorem has already been proved in [14]. In this case all symmetric 1-homoclinic orbits (to p_1) lie on the same snaking curve.

For $N > 1$ it turns out that the lengths of all the other passages near p_1 and p_2 remain bounded as ω tends to infinity. This phenomenon can also be observed in the numerical bifurcation diagrams; see, for example, Figure 4. Along the red branch in that figure, the outer pulses (representing the first and last passages near p_2) become and wider as the L^2-norm increases, while both the inner pulse and the time intervals, by which the pulses are separated, remain nearly unchanged.

Remark 3.2. *In addition, for fixed* N *there are infinitely many different snaking curves. For example, two* N*-homoclinic orbits* $\mathcal{H}$ *and* $\mathcal{H}'$ *(which might exist for the same* λ*) are not on the same snaking curve if their numbers of rotations around* p_1 *and* p_2 *are "too different."*

4. The analysis. We will analyze the existence of N-homoclinic orbits to p_1 using Lin's method [17, 12]. In a first step we determine *N-homoclinic Lin orbits* near the cycle Γ. An N-homoclinic Lin orbit to p_1 is a piecewise continuous orbit that starts in the unstable manifold of p_1, follows the cycle Γ, and finishes after N loops in the stable manifold of p_1. Thereby, the discontinuities are allowed to lie only in certain places and have well-defined jump directions. Figure 5 shows an impression of a 2-homoclinic Lin orbit near Γ.

4.1. Setup of the bifurcation equation. In the following we work exclusively in a neighborhood $\mathcal{U}$ of Γ. To define N-homoclinic Lin orbits precisely, let Σ_1 be a hyperplane intersecting Γ_1 transversally at $\gamma_1(0)$, and let $\Sigma_2 := R\Sigma_1$. We are concerned with four different types of partial orbits. First, let $X^- = \{x^-(t) : t \in (-\infty, 0]\}$, such that $x^-(0) \in \Sigma_1 \cap W^u(p_1, \lambda)$ and $x^-(t) \notin \Sigma_k$ for all $t < 0$. Similarly, let $X^+ = \{x^+(t) : t \in [0, \infty)\}$, such that $x^+(0) \in \Sigma_2 \cap W^s(p_1, \lambda)$ and $x^+(t) \notin \Sigma_k$ for all $t > 0$. Finally, for positive numbers ω_2^i, ω_1^j, we consider orbits $X_2^i = \{x_2^i(t) : t \in [0, 2\omega_2^i]\}$ and $X_1^j = \{x_1^j(t) : t \in [0, 2\omega_1^j]\}$, such that

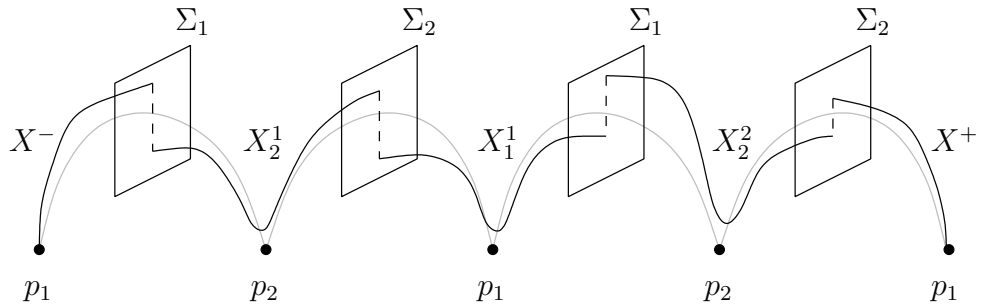

Figure 5. *A 2-homoclinic Lin orbit near the cycle* Γ. *The original heteroclinic orbits are shown in grey. Note that for the purpose of illustration* Γ *is shown as a heteroclinic chain.*

$$x_2^i(0) \in \Sigma_1,\ x_2^i\left(2\omega_2^i\right) \in \Sigma_2,\ \text{and}\ x_2^i(t) \notin \Sigma_2\ \text{for}\ t \in \left(0, 2\omega_2^i\right),$$
$$x_1^j(0) \in \Sigma_2,\ x_1^j\left(2\omega_1^j\right) \in \Sigma_1,\ \text{and}\ x_1^j(t) \notin \Sigma_1\ \text{for}\ t \in \left(0, 2\omega_1^j\right).$$

Now, we introduce a space $Z_1 \subset T_{\gamma_1(0)}\Sigma_1$, complementary to $T_{\gamma_1(0)}W^u(p_1,0)+T_{\gamma_1(0)}W^s(p_2,0)$. Note that because of (3.4) we have $\dim Z_1 = 1$. Furthermore, let $Z_2 = RZ_1 \subset \Sigma_2$. Then a collection of partial orbits

$$\mathcal{L} = \left(X^-, X_2^1, X_1^1, X_2^2, \ldots, X_1^{N-1}, X_2^N, X^+\right)$$

is called an N-homoclinic Lin orbit to p_1 if the jump between two consecutive partial orbits is parallel to Z_1 or Z_2, respectively.

Note that the lower index k of X_k^i indicates that this partial orbit passes p_k while the upper index i counts the number of passages past the equilibrium p_k. The indices in the corresponding quantities x_k^i and ω_k^i have the same meaning.

Lin orbits can be characterized by the times ω_2^i and ω_1^j, and by the parameter λ. More precisely, we have the following result.

Lemma 4.1 (see [17, 12]). *There are positive numbers* $\hat{\lambda}$ *and* $\hat{\omega}$ *such that for each* $|\lambda| < \hat{\lambda}$ *and each set* $\boldsymbol{\omega}_1 = \left\{\omega_1^1, \ldots, \omega_1^{N-1}\right\}$ *and* $\boldsymbol{\omega}_2 = \left\{\omega_2^1, \ldots, \omega_2^N\right\}$ *with*

$$\min\left\{\omega_1^j, \omega_2^i : j = 1, \ldots, N-1,\ i = 1, \ldots, N\right\} > \hat{\omega}$$

there exists a unique N*-homoclinic Lin orbit* $\mathcal{L}\left(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda\right)$ *as introduced above.*

The detection of N-homoclinic orbits near Γ now amounts to finding those Lin orbits without discontinuities (jumps), which are given by

$$\begin{aligned}
\Xi_1^1 &= x^-(0) - x_2^1(0),\\
\Xi_1^i &= x_1^{i-1}\left(2\omega_1^{i-1}\right) - x_2^i(0), \quad i = 2, \ldots, N,\\
\Xi_2^i &= x_2^i\left(2\omega_2^i\right) - x_1^i(0), \quad i = 1, \ldots, N-1,\\
\Xi_2^N &= x_2^N\left(2\omega_2^N\right) - x^+(0).
\end{aligned}$$

The lower index k of Ξ_k^i indicates in which cross-section the jump takes place, and the upper index i counts the jumps in these cross-sections.

Setting $\boldsymbol{\Xi}_1 = (\Xi_1^1, \dots, \Xi_1^N)$ and $\boldsymbol{\Xi}_2 = (\Xi_2^1, \dots, \Xi_2^N)$, we find by Lemma 4.1 that $\boldsymbol{\Xi}_i = \boldsymbol{\Xi}_i(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda)$. In order to detect actual N-homoclinic orbits to p_1 we have to solve the bifurcation equations

$$\boldsymbol{\Xi}_1(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda) = 0, \quad \boldsymbol{\Xi}_2(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda) = 0.$$

Within the general framework of Lin's method we can derive expressions for the terms $\boldsymbol{\Xi}_k$, $k = 1, 2$. We will do this for $\boldsymbol{\Xi}_1$ only, since it turns out that only this is needed when we focus on symmetric orbits.

For the jumps $\Xi_1^i = \Xi_1^i(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda)$ it has been shown in [17, 12] that

$$\Xi_1^i(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda) = \xi^\infty(\lambda) + \xi_1^i(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda),$$

where $\xi^\infty(\lambda)$ measures the splitting of $W^u(p_1, \lambda)$ and $W^s(p_2, \lambda)$ in the direction Z_1. Obviously, $\xi^\infty(0) = 0$, and according to assumption (3.7) we have $D\xi^\infty(0) \neq 0$. Hence, with no loss of generality we may assume that

$$\xi^\infty(\lambda) = \lambda.$$

While ξ^∞ depends only on λ, the terms ξ_1^i measure the influence of the finite transition times between the Σ_i, too. The leading terms in the ξ_1^i depend on the asymptotic behavior near the equilibria p_1 and p_2. Applying general results from [17, 12], we find the following lemma.

Lemma 4.2. *Assuming the nondegeneracy conditions (3.2), (3.5), and (3.6) the jumps ξ_1^i have the following representation:*

$$\begin{aligned}
\xi_1^1(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda) &= L_2(\omega_2^1, \lambda) + \mathcal{R}^1, \\
\xi_1^i(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda) &= L_1(\omega_1^{i-1}, \lambda) + L_2(\omega_2^i, \lambda) + \mathcal{R}^i, \quad i = 2, \dots, N,
\end{aligned}$$

where

$$\begin{aligned}
&L_k(\omega, \lambda) := c_k(\lambda) e^{-2\mu_k(\lambda)\omega} \sin\left(2\varphi_k(\lambda)\omega + \vartheta_k(\lambda)\right), \quad k = 1, 2, \\
&\mathcal{R}^1 = \mathcal{O}\left(e^{-2\alpha\mu_2(\lambda)\omega_2^1}\right), \quad \mathcal{R}^i = \mathcal{O}\left(e^{-2\alpha\mu_1(\lambda)\omega_1^{i-1}}\right) + \mathcal{O}\left(e^{-2\alpha\mu_2(\lambda)\omega_2^i}\right),
\end{aligned}$$

$i = 2, \dots, N$. Here α is some real number greater than one. The quantities c_1, c_2 and ϑ_1, ϑ_2 depend smoothly on λ, and we have $c_1(0) \neq 0$, $c_2(0) \neq 0$.

Also, from [17, 12] we know that the jumps ξ_k^i are differentiable, and moreover we have the following estimates of the derivatives.

Lemma 4.3. *Under the assumptions of Lemma 4.2, the mappings $\xi_1^i : \mathbb{R}^{N-1} \times \mathbb{R}^N \times \mathbb{R} \to \mathbb{R}$ are smooth and the partial derivatives $D_j\xi_1^i$, $j \in \{1, 2, 3\}$, can be estimated as follows:*

$$\begin{aligned}
D_j\xi_1^1(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda) &= D_j L_2(\omega_2^1, \lambda) + o\left(e^{-2\mu_2(\lambda)\omega_2^1}\right), \\
D_j\xi_1^i(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda) &= D_j\left(L_1(\omega_1^{i-1}, \lambda) + L_2(\omega_2^i, \lambda)\right) \\
&\quad + \mathcal{O}\left(e^{-2\alpha\mu_1(\lambda)\omega_1^{i-1}}\right) + \mathcal{O}\left(e^{-2\alpha\mu_2(\lambda)\omega_2^i}\right),
\end{aligned}$$

$i = 2, \dots, N$. Again α is some real number greater than one.

In the following we will focus on symmetric N-homoclinic orbits to p_1. Those orbits correspond to symmetric N-homoclinic Lin orbits to p_1, which are characterized by

$$\begin{aligned} &X^- = RX^+, \quad X_1^i = RX_1^{N-i}, \quad i = 1, \dots, \lfloor N/2 \rfloor, \quad \text{and} \\ &X_2^i = RX_2^{N+1-i}, \quad i = 1, \dots, \lfloor (N+1)/2 \rfloor, \end{aligned}$$

where $\lfloor r \rfloor$ denotes the integer part of the real number r. If N is even, then the partial orbit $X_1^{N/2}$ is symmetric and the N-homoclinic Lin orbit intersects $\operatorname{Fix} R$ near p_1, while for N odd $X_2^{(N+1)/2}$ is symmetric and the N-homoclinic Lin orbit intersects $\operatorname{Fix} R$ near p_2.

In particular, this implies that

$$\omega_1^i = \omega_1^{N-i}, \ i = 1, \dots \lfloor \tfrac{N}{2} \rfloor, \quad \text{and} \quad \omega_2^i = \omega_2^{N+1-i}, \ i = 1, \dots, \lfloor \tfrac{N+1}{2} \rfloor. \tag{4.1}$$

Taking these particulars of the transition times into consideration, we will henceforth write

$$\omega := \omega_2^1, \quad \boldsymbol{\omega} := (\omega_1^1, \dots, \omega_1^{\lfloor \frac{N}{2} \rfloor}, \omega_2^2, \dots, \omega_2^{\lfloor \frac{N+1}{2} \rfloor}).$$

Furthermore, the symmetry of an N-homoclinic Lin orbit implies

$$\Xi_1^i = R\,\Xi_2^{N+1-i}, \quad i = 1, \dots, N. \tag{4.2}$$

Hence, $\boldsymbol{\Xi}_1 = 0$ if and only if $\boldsymbol{\Xi}_2 = 0$, and the bifurcation equation for symmetric N-homoclinic orbits to p_1 reads

$$\boldsymbol{\Xi}(\omega, \boldsymbol{\omega}, \lambda) := \boldsymbol{\Xi}_1(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \lambda) = 0.$$

In what follows we just write Ξ^i instead of Ξ_1^i. With this notation we have

$$\begin{aligned} \Xi^1 &= \lambda + L_2(\omega_2^1, \lambda) + \mathcal{R}^1, \\ \Xi^i &= \lambda + L_1(\omega_1^{i-1}, \lambda) + L_2(\omega_2^i, \lambda) + \mathcal{R}^i, \quad i = 2, \dots, \lfloor \tfrac{N+1}{2} \rfloor, \\ \Xi^i &= \lambda + L_1(\omega_1^{N+1-i}, \lambda) + L_2(\omega_2^{N+1-i}, \lambda) + \mathcal{R}^i, \quad i = \lfloor \tfrac{N+1}{2} \rfloor + 1, \dots, N. \end{aligned} \tag{4.3}$$

Note that all Ξ^i and $\mathcal{R}^i$ depend on $(\omega, \boldsymbol{\omega}, \lambda)$.

4.2. Reformulation of the bifurcation equation.

We define

$$r_k^i := e^{-2\mu_k(0)\omega_k^i}, \quad r := r_2^1, \quad \mathbf{r} := (r_1^1, \dots, r_1^{\lfloor \frac{N}{2} \rfloor}, r_2^2, \dots, r_2^{\lfloor \frac{N+1}{2} \rfloor}). \tag{4.4}$$

We want to emphasize that by definition all r as well as all components of $\mathbf{r}$ are greater than zero.

With that we write the jumps as quantities depending on $(r, \mathbf{r}, \lambda)$:

$$\hat{\boldsymbol{\Xi}}(r, \mathbf{r}, \lambda) = (\hat{\Xi}^1(r, \mathbf{r}, \lambda), \dots, \hat{\Xi}^N(r, \mathbf{r}, \lambda)) := \boldsymbol{\Xi}(\omega(r), \boldsymbol{\omega}(\mathbf{r}), \lambda).$$

Corollary 4.4. *The $(r,\mathbf{r})$-dependent jumps read as follows:*

$$\begin{aligned}
\hat{\Xi}^1 &= \lambda + \hat{\mathcal{R}}^1,\\
\hat{\Xi}^i &= \lambda + \hat{L}_1(r_1^{i-1},\lambda) + \hat{L}_2(r_2^i,\lambda) + \hat{\mathcal{R}}^i, \quad i = 2,\dots,\lfloor\tfrac{N+1}{2}\rfloor,\\
\hat{\Xi}^i &= \lambda + \hat{L}_1(r_1^{N+1-i},\lambda) + \hat{L}_2(r_2^{N+1-i},\lambda) + \hat{\mathcal{R}}^i, \quad i = \lfloor\tfrac{N+1}{2}\rfloor + 1,\dots,N-1,\\
\hat{\Xi}^N &= \lambda + \hat{L}_1(r_1^1,\lambda) + \hat{\mathcal{R}}^N,
\end{aligned}$$

where $\hat{\mathcal{R}}^i = \hat{\mathcal{R}}^i(r,\mathbf{r},\lambda)$ and

$$\hat{L}_k(s,\lambda) := c_k(\lambda) s^{\frac{\mu_k(\lambda)}{\mu_k(0)}} \sin\left(-\frac{\varphi_k(\lambda)}{\mu_k(0)}\ln s + \vartheta_k(\lambda)\right), \quad k = 1,2,$$

and, with some $\alpha > 1$,

$$\begin{aligned}
\hat{\mathcal{R}}^1 &= \hat{L}_2(r,\lambda) + \mathcal{O}\big(r^\alpha\big),\\
\hat{\mathcal{R}}^i &= \mathcal{O}\left((r_1^{i-1})^\alpha\right) + \mathcal{O}\big((r_2^i)^\alpha\big), \quad i = 2,\dots,N-1,\\
\hat{\mathcal{R}}^N &= \hat{L}_2(r,\lambda) + \mathcal{O}\left((r_1^{N-1})^\alpha\right) + \mathcal{O}\big((r_2^N)^\alpha\big).
\end{aligned}$$

And similarly, we get estimates for the derivatives of the residual terms $\hat{\mathcal{R}}^i = \hat{\mathcal{R}}^i(r,\mathbf{r},\lambda)$ from Lemma 4.3.

Corollary 4.5. *The statement of Lemma 4.3 for the $(r,\mathbf{r})$-dependent jumps reads as follows:*

$$\begin{aligned}
&D_1\hat{\mathcal{R}}^1 = D_1\hat{L}_2(r,\lambda) + \mathcal{O}\big(r^{\alpha-1}\big), \quad D_2\hat{\mathcal{R}}^1 = \mathcal{O}\big(r^\alpha\big),\\
&D_3\hat{\mathcal{R}}^1 = D_3\hat{L}_2(r,\lambda) + \mathcal{O}\big(r^\alpha\big),\\
&D_2\hat{\mathcal{R}}^i = \mathcal{O}\left((r_1^{i-1})^{\alpha-1}\right) + \mathcal{O}\big((r_2^i)^{\alpha-1}\big), \quad i = 2,\dots,N,\\
&D_3\hat{\mathcal{R}}^i = \mathcal{O}\left((r_1^{i-1})^\alpha\right) + \mathcal{O}\big((r_2^i)^\alpha\big), \quad i = 2,\dots,N-1,\\
&D_3\hat{\mathcal{R}}^N = D_3\hat{L}_2(r,\lambda) + \mathcal{O}\left((r_1^{N-1})^\alpha\right) + \mathcal{O}\big((r_2^N)^\alpha\big).
\end{aligned}$$

Our goal is to rewrite the bifurcation equation $\hat{\boldsymbol{\Xi}} = 0$ as a fixed point equation. For this we introduce

$$\begin{aligned}
\hat{\mathbf{L}}(\mathbf{r},\lambda) &:= \big(\hat{L}_1(r_1^1,\lambda),\dots,\hat{L}_1(r_1^{\lfloor\frac{N}{2}\rfloor},\lambda),\hat{L}_2(r_2^2,\lambda),\dots,\hat{L}_2(r_2^{\lfloor\frac{N+1}{2}\rfloor},\lambda)\big)^T,\\
\hat{\boldsymbol{\mathcal{R}}} &:= \big(\hat{\mathcal{R}}^1,\dots,\hat{\mathcal{R}}^N\big)^T.
\end{aligned}$$

There is an invertible constant $(N\times N)$-matrix $\mathcal{M}$ such that

$$\hat{\boldsymbol{\Xi}}(r,\mathbf{r},\lambda) = \mathcal{M}\begin{pmatrix}\hat{\mathbf{L}}(\mathbf{r},\lambda)\\ \lambda\end{pmatrix} + \hat{\boldsymbol{\mathcal{R}}}(r,\mathbf{r},\lambda).$$

We comment on properties of $\mathcal{M}$ in the remark at the end of this section.

That $\hat{\boldsymbol{\Xi}}(r,\mathbf{r},\lambda) = 0$ is equivalent to

$$\begin{pmatrix}\hat{\mathbf{L}}(\mathbf{r},\lambda)\\ \lambda\end{pmatrix} = -\mathcal{M}^{-1}\hat{\boldsymbol{\mathcal{R}}}(r,\mathbf{r},\lambda). \tag{4.5}$$

In the next step we rewrite (4.5) into a fixed point equation. For that we choose $\hat{\mathbf{r}}$ such that $\hat{\mathbf{L}}(\hat{\mathbf{r}},0)=0$. Note that there are infinitely many candidates for such $\hat{\mathbf{r}}$ which accumulate at zero. However, for any such $\hat{\mathbf{r}}$ the partial derivative with respect to the first variable $D_1\hat{\mathbf{L}}(\hat{\mathbf{r}},0)$ is an invertible diagonal matrix $\mathcal{D}$, and the absolute values of the entries in the diagonal are either $|\frac{c_1(0)\varphi_1(0)}{\mu_1(0)}|$ or $|\frac{c_2(0)\varphi_2(0)}{\mu_2(0)}|$. We want to emphasize that these quantities do not depend on the particular choice of $\hat{\mathbf{r}}$ (as long as $\hat{\mathbf{L}}(\hat{\mathbf{r}},0)=0$).

With that, the Taylor expansion of $\hat{\mathbf{L}}$ at $(\mathbf{r},\lambda)=(\hat{\mathbf{r}},0)$ with second order residual term $\hat{\mathbf{L}}_{res,\hat{\mathbf{r}}}$ reads

$$\hat{\mathbf{L}}(\mathbf{r},\lambda)=\mathcal{D}(\mathbf{r}-\hat{\mathbf{r}})+D_2\hat{\mathbf{L}}(\hat{\mathbf{r}},0)\lambda+\hat{\mathbf{L}}_{res,\hat{\mathbf{r}}}(\mathbf{r},\lambda). \tag{4.6}$$

Combining (4.5) and (4.6), we find the following fixed point equation for $\mathbf{r}$ which is equivalent to $\hat{\boldsymbol{\Xi}}(r,\mathbf{r},\lambda)=0$:

$$\begin{aligned}\begin{pmatrix}\mathbf{r}\\ \lambda\end{pmatrix}&=\begin{pmatrix}\hat{\mathbf{r}}-\mathcal{D}^{-1}(D_2\hat{\mathbf{L}}(\hat{\mathbf{r}},0)\lambda+\hat{\mathbf{L}}_{res,\hat{\mathbf{r}}}(\mathbf{r},\lambda))\\ 0\end{pmatrix}-(\mathcal{M}\hat{\mathcal{D}})^{-1}\hat{\boldsymbol{\mathcal{R}}}(r,\mathbf{r},\lambda)\\ &=:\mathcal{T}_{\hat{\mathbf{r}}}(r,\mathbf{r},\lambda),\end{aligned} \tag{4.7}$$

where $\hat{\mathcal{D}}=\left(\begin{smallmatrix}\mathcal{D}&0\\0&1\end{smallmatrix}\right)$. The right-hand side $\mathcal{T}_{\hat{\mathbf{r}}}$ of this equation can be read as a mapping

$$\mathcal{T}_{\hat{\mathbf{r}}}:\mathbb{R}_+\times\mathbb{R}_+^{N-1}\times\mathbb{R}\to\mathbb{R}_+^{N-1}\times\mathbb{R}.$$

The lower index "+" denotes the restriction to positive numbers.

Remark 4.6. *Let $\mathcal{M}=(m_{i,j})$ be the above-defined $(N\times N)$-matrix. The entries $m_{i,j}$ are either one or zero. From the representation of $\hat{\boldsymbol{\Xi}}$ given in Corollary 4.4 we find that exactly the following entries are equal to one:*

$$\begin{aligned}&m_{1,N},\\ &m_{i,i-1},\quad m_{i,\lfloor\frac{N}{2}\rfloor+i-1},\quad m_{i,N},\quad i=2,\dots,\lfloor\tfrac{N+1}{2}\rfloor,\\ &m_{i,N+1-i},\quad m_{i,\lfloor\frac{N}{2}\rfloor+N-i},\quad m_{i,N},\quad i=\lfloor\tfrac{N+1}{2}\rfloor+1,\dots,N-1,\\ &m_{N,1},\quad m_{N,N}.\end{aligned}$$

To show that $\mathcal{M}$ is indeed nonsingular, we simply compute its determinant by using Laplace's formula. We expand alternately along the first or the last line of the corresponding minor arising in the course of this procedure. This finally yields that the absolute value of the determinant of $\mathcal{M}$ is equal to one; in more detail,

$$|\det\mathcal{M}|=\begin{cases}m_{1,N}\cdot m_{N,1}\cdot m_{2,\lfloor\frac{N}{2}\rfloor+1}\cdot m_{N-1,2}\cdot\dots\cdot m_{\lfloor\frac{N+1}{2}\rfloor,\lfloor\frac{N+1}{2}\rfloor-1}, & N\text{ even},\\ m_{1,N}\cdot m_{N,1}\cdot m_{2,\lfloor\frac{N}{2}\rfloor+1}\cdot m_{N-1,2}\cdot\dots\cdot m_{\lfloor\frac{N+1}{2}\rfloor,N-1}, & N\text{ odd}.\end{cases}$$

4.3. Proof of Theorem 3.1. Our goal is to solve the reformulated bifurcation equation (4.7) for $(\mathbf{r}_{\hat{\mathbf{r}}},\lambda_{\hat{\mathbf{r}}})(r)$ near $(\mathbf{r},\lambda)=(\hat{\mathbf{r}},0)$, $r\in(0,\epsilon)$. We will do this by applying the Banach fixed point theorem. Our strategy is as follows. First we construct for the "principal part"

$$\begin{pmatrix}\mathbf{r}\\ \lambda\end{pmatrix}=\begin{pmatrix}\hat{\mathbf{r}}-\mathcal{D}^{-1}(D_2\hat{\mathbf{L}}(\hat{\mathbf{r}},0)\lambda+\hat{\mathbf{L}}_{res,\hat{\mathbf{r}}}(\mathbf{r},\lambda))\\ 0\end{pmatrix}=:\mathcal{T}_{red,\hat{\mathbf{r}}}(r,\mathbf{r},\lambda)$$

of that equation a domain $\mathcal{C}_{\hat{\mathbf{r}}} \times \mathcal{B}_{\hat{\mathbf{r}}}$, which will be mapped contractively into itself by $\mathcal{T}_{red,\hat{\mathbf{r}}}$. Then we make clear that for small $\hat{\mathbf{r}}$ this can be carried forward to $\mathcal{T}_{\hat{\mathbf{r}}}$.

In the next step we consider $\hat{L}_k$, which represents the components of $\hat{\mathbf{L}}$. To simplify matters we omit the lower index k in further considerations:

$$\hat{L}(s,\lambda) := c(\lambda) s^{\frac{\mu(\lambda)}{\mu(0)}} \sin\left(-\frac{\varphi(\lambda)}{\mu(0)} \ln s + \vartheta(\lambda)\right).$$

The zeros s_n of $\hat{L}(\cdot,0)$ are explicitly given by $s_n = e^{-\frac{\mu(0)}{\varphi(0)}(n\pi - \vartheta(0))}$, $n \in \mathbb{Z}$. For our purpose we are interested only in those zeros which are close to $s = 0$, so we may assume $n \in \mathbb{N}$ sufficiently large.

Let $\delta := D_1\hat{L}(s_n, 0)$. Note that δ represents an element in the diagonal of $\mathcal{D}$ and that $|\delta|$ does not depend on n.

By $\hat{L}_{res,n}$ we denote the second-order residual term of the Taylor expansion of $\hat{L}$ at $(s_n, 0)$. Let $B[s,\rho]$ be the closed ball centered at s with radius ρ.

Lemma 4.7. *There are $\overline{\beta}, \overline{K} > 0$ such that for all sufficiently large $n \in \mathbb{N}$ the following estimates hold true: For all $s \in B[s_n, \rho_n]$, $\rho_n := s_n\overline{\beta}$, and all $\lambda \in B[0, l_{s_n}]$, $l_{s_n} = \overline{K} s_n$,*

$$|D_1\hat{L}_{res,n}(s_n\beta,\lambda)| < \frac{\delta}{3}, \quad |D_2\hat{L}_{res,n}(s_n\beta,\lambda)| < \frac{\delta}{3}, \tag{4.8}$$

and

$$\left|\delta^{-1}\left(D_2\hat{L}(s_n,0)\lambda + \hat{L}_{res,n}(s,\lambda)\right)\right| < \frac{2}{3}\rho_n. \tag{4.9}$$

Proof. First we prove the estimates regarding the derivatives of $L_{res,n}$. With $A(s,\lambda) := -\frac{\varphi(\lambda)}{\mu(0)} \ln s + \vartheta(\lambda)$ we get

$$\hat{L}_{res,n}(s,\lambda) = c(\lambda) s^{\frac{\mu(\lambda)}{\mu(0)}} \sin(A(s,\lambda)) - \delta(s - s_n) - D_2\hat{L}(s_n,0)\lambda,$$

and therefore

$$D_1\hat{L}_{res,n}(s,\lambda) = c(\lambda) s^{\frac{\mu(\lambda)}{\mu(0)}-1}\left[\tfrac{\mu(\lambda)}{\mu(0)} \sin(A(s,\lambda)) - \tfrac{\varphi(\lambda)}{\mu(0)} \cos(A(s,\lambda))\right] - \delta.$$

Obviously, $D_1\hat{L}_{res,n}(s_n,0) = 0$. Writing $s = s_n\beta$ one finds that there exist $\overline{\beta}$ and $\tilde{l}_{s_n}$ such that for all $\beta \in [1-\overline{\beta}, 1+\overline{\beta}]$ and all $\lambda \in B[0,\tilde{l}_{s_n}]$ the first estimate in (4.8) holds true. Note that for those β the corresponding $s = s_n\beta$ belong to $B[s_n, \rho_n]$.

For the derivative of $\hat{L}_{res,n}$ with respect to λ we find

$$\begin{aligned} D_2\hat{L}_{res,n}(s,\lambda) = {} & \left[c'(\lambda) s^{\frac{\mu(\lambda)}{\mu(0)}} + c(\lambda) s^{\frac{\mu(\lambda)}{\mu(0)}-1} \tfrac{\mu'(\lambda)}{\mu(0)}\right] \sin(A(s,\lambda)) \\ & + c(\lambda) s^{\frac{\mu(\lambda)}{\mu(0)}} \cos(A(s,\lambda)) D_2A(s,\lambda) - D_2\hat{L}(s_n,0). \end{aligned}$$

Because $\lim_{s\to+0} s^\alpha \ln s = 0$ for $\alpha > 0$, we have that $c(\lambda) s^{\frac{\mu(\lambda)}{\mu(0)}} \cos(A(s,\lambda)) D_2A(s,\lambda)$ tends to zero as $s \to 0$, uniformly in λ, and also that $\lim_{n\to\infty} D_2\hat{L}(s_n,0) = 0$. So, again we find that

there are a $\overline{\beta}$ and an $\tilde{l}_{s_n}$ such that for all $\beta \in [1-\overline{\beta}, 1+\overline{\beta}]$ and all $\lambda \in B[0, \tilde{l}_{s_n}]$ the estimate for $D_2\hat{L}_{res,n}$ holds true.

Note that indeed in both estimates $\tilde{l}_{s_n}$ may depend on n. The decisive term in this respect is $s^{\frac{\mu(\lambda)}{\mu(0)}-1}$. Using differentiability of μ at $\lambda = 0$, this term can be written as $s_n^{\mathcal{O}(\lambda)}\beta^{\mathcal{O}(\lambda)}$. If $|\lambda| < \overline{K}s_n$ for some $\overline{K}$, then $s_n^{\mathcal{O}(\lambda)}$ tends to 1 as n tends to infinity. This finally proves the estimates given in (4.8).

Our above consideration shows that $D_2\hat{L}(s_n, 0)$ remains bounded (as n tends to infinity) and that $D_2\hat{L}_{res,n}(s,\lambda)$ remains bounded if s and λ are close to zero. Applying the mean value theorem yields

$$\begin{aligned}|\hat{L}_{res,n}(s,\lambda)| &\le \sup_{\substack{s\in B[s_n,\rho_n]\\ \lambda\in B[0,l_{s_n}]}} |D_1\hat{L}_{res,n}(s,\lambda)|\,|s-s_n| + \sup_{\substack{s\in B[s_n,\rho_n]\\ \lambda\in B[0,l_{s_n}]}} |D_2\hat{L}_{res,n}(s,\lambda)|\,|\lambda| \\ &\le \tfrac{\delta}{3}(|s-s_n| + |\lambda|).\end{aligned}$$

Hence,

$$\left|\delta^{-1}\big(D_2\hat{L}(s_n,0)\lambda + \hat{L}_{res,n}(s,\lambda)\big)\right| \le |\delta|^{-1}\left(|D_2\hat{L}(s_n,0)|\,|\lambda| + \frac{\delta}{3}(|s-s_n|+|\lambda|)\right).$$

Recall that $|D_2\hat{L}(s_n,0)|$ tends to zero as $n \to \infty$, and therefore there is a K such that $|D_2\hat{L}(s_n,0)| < K$ for all sufficiently large n. Then with the particular

$$\overline{K} = \frac{\delta\overline{\beta}}{3}\left(K + \frac{\delta}{3}\right)^{-1},$$

(4.9) is also proved. ■

Now we return to the original fixed point equation (4.7). First we introduce some simplifying notation.

Let $\mathbf{r} := (r_1^1, \dots, r_1^{\lfloor\frac{N}{2}\rfloor}, r_2^2, \dots, r_2^{\lfloor\frac{N+1}{2}\rfloor}) \in \mathbb{R}_+^{N-1}$. We define projections π_k^i as follows:

$$\pi_k^i : \mathbb{R}_+^{N-1} \to \mathbb{R}_+, \quad \pi_k^i\big((r_1^1, \dots, r_1^{\lfloor\frac{N}{2}\rfloor}, r_2^2, \dots, r_2^{\lfloor\frac{N+1}{2}\rfloor})\big) = r_k^i.$$

Now let $\hat{\mathbf{L}}(\hat{\mathbf{r}}, 0) = 0$. By Lemma 4.7, each $\hat{r}_k^i$ has a $\rho_k^i = \hat{r}_k^i\overline{\beta}_k$ and a corresponding $B_k^i := B[\hat{r}_k^i, \rho_k^i]$ assigned to it. With these we define the cylinder

$$\mathfrak{C}_{\hat{\mathbf{r}}} := B_1^1 \times \cdots \times B_1^{\lfloor\frac{N}{2}\rfloor} \times B_2^2 \times \cdots \times B_2^{\lfloor\frac{N+1}{2}\rfloor}.$$

Further, we define

$$\overline{\beta} := \max\{\overline{\beta}_1, \overline{\beta}_2\}, \quad \underline{\beta} := \min\{\overline{\beta}_1, \overline{\beta}_2\}$$

and similarly

$$\overline{\rho}(\hat{\mathbf{r}}) := \max\{\rho_k^i\}, \quad \underline{\rho}(\hat{\mathbf{r}}) := \min\{\rho_k^i\}.$$

For $\mathbf{r} = (r^1, \dots, r^{N-1}) \in \mathbb{R}_+^{N-1} \subset \mathbb{R}^{N-1}$ we introduce

$$\overline{\mathbf{r}} := \max\{r^i,\, i = 1, \dots, N-1\} = \|\mathbf{r}\|, \quad \underline{\mathbf{r}} := \min\{r^i,\, i = 1, \dots, N-1\},$$

and with that we define

$$\kappa(\mathbf{r}) := \underline{\mathrm{r}}/\overline{\mathrm{r}} = \underline{\mathrm{r}}/\|\mathbf{r}\|.$$

From these definitions it follows that

$$\hat{\underline{\mathrm{r}}}\,\underline{\beta} \le \underline{\rho}(\hat{\mathbf{r}}) \le \overline{\rho}(\hat{\mathbf{r}}) \le \|\hat{\mathbf{r}}\|\overline{\beta}. \tag{4.10}$$

Therefore, $\sup\{\|\mathbf{r}\| : \mathbf{r} \in \mathfrak{C}_{\hat{\mathbf{r}}}\} \le \|\hat{\mathbf{r}}\|(1+\overline{\beta})$.

In accordance with Lemma 4.7 there is a constant $\hat{K}$ such that $l_{\hat{\underline{\mathrm{r}}}} = \hat{K}\underline{\rho}(\hat{\mathbf{r}})$. Finally, we define $\mathfrak{B}_{\hat{\mathbf{r}}} := B[0, l_{\hat{\underline{\mathrm{r}}}}]$.

Lemma 4.8. *Let $\kappa^* \in (0,1]$. There is an $\eta = \eta(\kappa^*)$ such that for all $\hat{\mathbf{r}}$ with $\kappa(\hat{\mathbf{r}}) \ge \kappa^*$, $\|\hat{\mathbf{r}}\| < \eta$, there is an ϵ_r such that for all $r \in (0, \epsilon_r)$ the fixed point equation (4.7) has a unique fixed point $(\mathbf{r}_{\hat{\mathbf{r}}}, \lambda_{\hat{\mathbf{r}}})(r) \in \mathfrak{C}_{\hat{\mathbf{r}}} \times \mathfrak{B}_{\hat{\mathbf{r}}}$. Moreover, $\mathbf{r}_{\hat{\mathbf{r}}}$ and $\lambda_{\hat{\mathbf{r}}}$ depend smoothly on r.*

Proof. First we show that there is an appropriate $\tilde{\eta}$ such that $\mathcal{T}_{\hat{\mathbf{r}}}(r,\cdot,\cdot)$ is a contraction on $\mathfrak{C}_{\hat{\mathbf{r}}} \times \mathfrak{B}_{\hat{\mathbf{r}}}$. We introduce for $(\mathbf{r},\lambda) \in \mathbb{R}^{N-1} \times \mathbb{R}$ the norm $\|(\mathbf{r},\lambda)\| := \|\mathbf{r}\| + |\lambda|$. Then, from the definition of $\mathcal{T}_{\hat{\mathbf{r}}}$ (see (4.7)) we find

$$\begin{aligned}\|D_{(2,3)}\mathcal{T}_{\hat{\mathbf{r}}}(r,\mathbf{r},\lambda)\| \le{}& \|\mathcal{D}^{-1}D_2\hat{\mathbf{L}}(\hat{\mathbf{r}},0)\| \\ &+ \max\{\|\mathcal{D}^{-1}\,D_1\hat{\mathbf{L}}_{res,\hat{\mathbf{r}}}(\mathbf{r},\lambda)\|,\ \|\mathcal{D}^{-1}\,D_2\hat{\mathbf{L}}_{res,\hat{\mathbf{r}}}(\mathbf{r},\lambda)\|\} \\ &+ \|(\mathcal{M}\hat{\mathcal{D}})^{-1}\|\,\|D_{(2,3)}\hat{\boldsymbol{\mathcal{R}}}(r,\mathbf{r},\lambda)\|.\end{aligned}$$

Since $\lim_{n\to\infty} D_2\hat{L}(s_n,0) = 0$, there is an η_1 such that $\|\hat{\mathbf{r}}\| < \eta_1/1+\overline{\beta}$ implies

$$\|\mathcal{D}^{-1}D_2\hat{\mathbf{L}}(\hat{\mathbf{r}},0)\| < \frac{1}{3}.$$

Moreover, due to Lemma 4.7, the constant η_1 can be chosen such that for $\|\hat{\mathbf{r}}\| < \eta_1/1+\overline{\beta}$ and $(\mathbf{r},\lambda) \in \mathfrak{C}_{\hat{\mathbf{r}}} \times \mathfrak{B}_{\hat{\mathbf{r}}}$ also

$$\|\mathcal{D}^{-1}\,D_1\hat{\mathbf{L}}_{res,\hat{\mathbf{r}}}(\mathbf{r},\lambda)\| < \frac{1}{3}, \quad \|\mathcal{D}^{-1}\,D_2\hat{\mathbf{L}}_{res,\hat{\mathbf{r}}}(\mathbf{r},\lambda)\| < \frac{1}{3}.$$

According to Corollary 4.5, there are an $\tilde{\epsilon}_r$ and an $\eta_2 < \eta_1$ such that for all $r < \tilde{\epsilon}_r$, all $\mathbf{r}$ with $\|\mathbf{r}\| < \eta_2$, and all $\lambda \in \mathcal{B}_{\hat{\mathbf{r}}}$, we have

$$\|(\mathcal{M}\mathcal{D})^{-1}\|\,\|D_{(2,3)}\hat{\boldsymbol{\mathcal{R}}}(r,\mathbf{r},\lambda)\| < \frac{1}{6}. \tag{4.11}$$

Therefore, if $\|\hat{\mathbf{r}}\|(1+\overline{\beta}) < \eta_2$, then (4.11) holds true for all $\mathbf{r} \in \mathfrak{C}_{\hat{\mathbf{r}}}$.

Thus, we have shown that if $\|\hat{\mathbf{r}}\| < \eta_2/1+\overline{\beta}$, then $\|D_{(2,3)}\mathcal{T}_{\hat{\mathbf{r}}}(r,\mathbf{r},\lambda)\| < 1$ for all $(\mathbf{r},\lambda) \in \mathfrak{C}_{\hat{\mathbf{r}}} \times \mathfrak{B}_{\hat{\mathbf{r}}}$, $r < \tilde{\epsilon}_r$. In other words, the mapping $\mathcal{T}_{\hat{\mathbf{r}}}(r,\cdot,\cdot)$ is a contraction on $\mathfrak{C}_{\hat{\mathbf{r}}} \times \mathfrak{B}_{\hat{\mathbf{r}}}$.

Next we verify that $\mathcal{T}_{\hat{\mathbf{r}}}(r,\cdot,\cdot)$ maps $\mathfrak{C}_{\hat{\mathbf{r}}} \times \mathfrak{B}_{\hat{\mathbf{r}}}$ into itself. Lemma 4.7 provides that for all $(\mathbf{r},\lambda) \in \mathfrak{C}_{\hat{\mathbf{r}}} \times \mathfrak{B}_{\hat{\mathbf{r}}}$

$$\left|\pi_k^i\big(\hat{\mathbf{r}} - \mathcal{D}^{-1}(D_2\hat{\mathbf{L}}(\hat{\mathbf{r}},0)\lambda + \hat{\mathbf{L}}_{res,\hat{\mathbf{r}}}(\mathbf{r},\lambda))\big)\right| < \tfrac{2}{3}\rho_k^i. \tag{4.12}$$

It remains (see (4.7)) to consider the term $(\mathcal{M}\hat{\mathcal{D}})^{-1}\hat{\boldsymbol{\mathcal{R}}}(r,\mathbf{r},\lambda)$. Let $(\mathbf{r},\lambda) \in \mathfrak{C}_{\hat{\mathbf{r}}} \times \mathfrak{B}_{\hat{\mathbf{r}}}$. In accordance with Corollary 4.4, there are constants C and $\hat{C}$ such that

$$\|\hat{\boldsymbol{\mathcal{R}}}(r,\mathbf{r},\lambda)\| \leq Cr + \hat{C}\|\hat{\mathbf{r}}\|^{\alpha}.$$

For any given $\hat{\mathbf{r}}$ we can choose $\epsilon_r = \epsilon_r(\hat{\mathbf{r}}) < \tilde{\epsilon}_r$ small such that

$$\|(\mathcal{M}\hat{\mathcal{D}})^{-1}\|\, Cr < \min\{(1/6)\underline{\rho}(\hat{\mathbf{r}}), (1/2)l_{\underline{\hat{\mathbf{r}}}}\}.$$

Further, due to (4.10) we find that $\underline{\rho}(\hat{\mathbf{r}}) \geq \underline{\beta}\kappa^*\|\hat{\mathbf{r}}\|$, and because of $l_{\underline{\hat{\mathbf{r}}}} = \hat{K}\underline{\rho}(\hat{\mathbf{r}})$ we have $l_{\underline{\hat{\mathbf{r}}}} \geq \hat{K}\underline{\beta}\kappa^*\|\hat{\mathbf{r}}\|$. Hence there is an $\eta_3 \leq \eta_2$ such that for $\hat{\mathbf{r}}$, $\|\hat{\mathbf{r}}\|(1+\overline{\beta}) < \eta_3$,

$$\|(\mathcal{M}\hat{\mathcal{D}})^{-1}\|\, \hat{C}\|\hat{\mathbf{r}}\|^{\alpha} < \min\{(1/6)\underline{\rho}(\hat{\mathbf{r}}), (1/2)l_{\underline{\hat{\mathbf{r}}}}\}.$$

This finally shows for those $\hat{\mathbf{r}}$ and $r < \epsilon_r$ that

$$\|(\mathcal{M}\hat{\mathcal{D}})^{-1}\|\, \|\hat{\boldsymbol{\mathcal{R}}}(r,\mathbf{r},\lambda)\| \leq \min\{(1/3)\underline{\rho}(\hat{\mathbf{r}}), l_{\underline{\hat{\mathbf{r}}}}\}.$$

Together with (4.12) this implies that $\mathcal{T}_{\hat{\mathbf{r}}}(r,\cdot,\cdot)$ maps $\mathfrak{C}_{\hat{\mathbf{r}}} \times \mathfrak{B}_{\hat{\mathbf{r}}}$ into itself.

Now we can apply the Banach fixed point theorem to prove the existence of $(\mathbf{r}_{\hat{\mathbf{r}}}, \lambda_{\hat{\mathbf{r}}})(r)$.

Finally, let $(\mathbf{r},\lambda) = \mathcal{T}_{\hat{\mathbf{r}}}(r,\mathbf{r},\lambda)$. Applying the implicit function theorem provides the smooth dependence of $(\mathbf{r}_{\hat{\mathbf{r}}}, \lambda_{\hat{\mathbf{r}}})$ on r. ∎

Remark 4.9. *The mapping $\hat{\boldsymbol{\Xi}}(\cdot,\mathbf{r},\lambda)$ and hence also $\mathcal{T}_{\hat{\mathbf{r}}}(\cdot,\mathbf{r},\lambda)$ can be continuously extended for $r = 0$. Lemma 4.8 remains true in this case. As a consequence of the uniform contraction principle (see [5]), we find that $(\mathbf{r},\lambda)(\cdot)$ is continuous in $r = 0$.*

To complete the proof of Theorem 3.1, we consider the function $\lambda_{\hat{\mathbf{r}}}$. Our above considerations show that, in particular,

$$\hat{\Xi}^1(r, \mathbf{r}_{\hat{\mathbf{r}}}(r), \lambda_{\hat{\mathbf{r}}}(r)) = \lambda_{\hat{\mathbf{r}}}(r) + \hat{L}_2(r, \lambda_{\hat{\mathbf{r}}}(r)) + \mathcal{O}(r^{\alpha}) \equiv 0.$$

Due to the structure of $\hat{L}_2$ the function $\lambda_{\hat{\mathbf{r}}}$ has infinitely many zeros. Moreover, it follows that $\lim_{r\to 0}\lambda_{\hat{\mathbf{r}}}(r) = 0$. Let r_0 be such that $\lambda_{\hat{\mathbf{r}}}(r_0) = 0$. Then $(r_0, \mathbf{r}_{\hat{\mathbf{r}}}(r_0))$ corresponds to an N-homoclinic orbit $\mathcal{H}_{\hat{\mathbf{r}}}(r_0)$ (to p_1) of the vector field $f(\cdot,0)$.

Let $\lambda_{\mathcal{H}_{\hat{\mathbf{r}}}(r_0)}(\omega) := \lambda_{\hat{\mathbf{r}}}(r(\omega))$, defined on some interval (a,∞). Then $\lambda_{\mathcal{H}_{\hat{\mathbf{r}}}(r_0)}$ has infinitely many zeros, and $|\lambda_{\mathcal{H}_{\hat{\mathbf{r}}}(r_0)}(\omega)|$ tends exponentially quickly to zero as ω tends to infinity.

To conclude, we return to the remark given at the end of section 3. The analysis in the proof of Lemma 4.8 was performed for fixed $\hat{\mathbf{r}}$. However, there is a sequence $(\hat{\mathbf{r}}_i)_{i\in\mathbb{N}}$ such that all $\hat{\mathbf{r}}_i$ are in accordance with the assumptions of Lemma 4.8, $\hat{\mathbf{r}}_i \to 0$, and $\mathfrak{C}_{\hat{\mathbf{r}}_i} \cap \mathfrak{C}_{\hat{\mathbf{r}}_j} = \emptyset$, $i \neq j$. With this, the sets $\mathcal{H}_{\hat{\mathbf{r}}_i}(r)$ and $\mathcal{H}_{\hat{\mathbf{r}}_j}(r)$ are disjoint for $i \neq j$, meaning that $\mathcal{H}_{\hat{\mathbf{r}}_i}(r)$ and $\mathcal{H}_{\hat{\mathbf{r}}_j}(r)$ are not on the same snaking curve.

4.4. Further homoclinic orbits. So far we have proved the existence of infinitely many N-homoclinic solutions to the equilibrium p_1 which lie on snaking curves and whose "outer" pulses become wider along the snaking curves. In what follows we denote the corresponding homoclinic orbits by $\mathcal{H}^{out}$. The numerical experiments for the generalized Swift–Hohenberg equation, however, show that there are also snaking curves different from the ones we described

so far analytically. In Figure 4 there are 3-homoclinic orbits depicted where the snaking is due to the middle part; in other words, the snaking curve is parametrized by ω_2^2. We denote these homoclinic orbits by $\mathcal{H}^{mid}$. In what follows we shall attempt to explain these observations in light of Theorem 3.1.

In the sketch of our further analysis, we restrict ourselves to the consideration of symmetric 3-homoclinic orbits and show that two different types of behavior along snaking curves can occur. However, the arguments are easily generalized to arbitrary N-homoclinic orbits, for which we expect to find $\lfloor (N+1)/2 \rfloor$ different types of behavior along snaking curves.

To simplify notation we write

$$(r_2^1, r_1^1, r_2^2) =: (r_1, r_2, r_3).$$

In accordance with Corollary 4.4 the bifurcation equation for 3-homoclinic orbits reads

$$\begin{aligned} 0 &= \hat{\Xi}^1 = \lambda + \hat{L}_2(r_1, \lambda) + \hat{\mathcal{R}}^1, \\ 0 &= \hat{\Xi}^2 = \lambda + \hat{L}_1(r_2, \lambda) + \hat{L}_2(r_3, \lambda) + \hat{\mathcal{R}}^2, \\ 0 &= \hat{\Xi}^3 = \lambda + \hat{L}_1(r_2, \lambda) + \hat{L}_2(r_1, \lambda) + \hat{\mathcal{R}}^3, \end{aligned} \tag{4.13}$$

where $\hat{\mathcal{R}}^1 = \mathcal{O}(r_1^\alpha)$, $\hat{\mathcal{R}}^2 = \mathcal{O}(r_2^\alpha) + \mathcal{O}(r_3^\alpha)$, and $\hat{\mathcal{R}}^3 = \mathcal{O}(r_2^\alpha) + \mathcal{O}(r_1^\alpha)$ for some $\alpha > 1$. In section 4.3 we have solved this equation for $(r_2, r_3, \lambda) = (r_2, r_3, \lambda)^{out}(r_1)$. The corresponding snaking curve is parametrized by $\omega_2^1 =: \omega_1$ (resp., r_1), which we call the *snaking parameter*. In the limit $r_1 \to 0$ (4.13) becomes

$$\begin{aligned} 0 &= \hat{\Xi}^1 = \lambda, \\ 0 &= \hat{\Xi}^2 = \lambda + \hat{L}_1(r_2, \lambda) + \hat{L}_2(r_3, \lambda) + \hat{\mathcal{R}}^2_{r_1=0}, \\ 0 &= \hat{\Xi}^3 = \lambda + \hat{L}_1(r_2, \lambda) + \hat{\mathcal{R}}^3_{r_1=0}. \end{aligned} \tag{4.14}$$

The lower index $r_1 = 0$ should indicate that these $\hat{\mathcal{R}}^{2/3}_{r_1=0}$ do not depend on r_1. We will call the orbits corresponding to solutions of (4.14) the *snaking limit*.

Roughly speaking, for $\omega_1 \to \infty$ ($r_1 \to 0$, respectively) the system (4.13) decouples: $\Xi^1 = \lambda = 0$ models the break-up of the original cycle Γ, and the solutions of $\Xi^2 = 0$, $\Xi^3 = 0$ correspond to symmetric 2-homoclinic orbits to p_2. Note that, in addition to the homoclinic orbits to p_1, there also exist a multitude of homoclinic orbits to p_2.

Let $\mathcal{H}^{out}_{\hat{\mathbf{r}}}(r_1)$ be the 3-homoclinic orbits belonging to the snaking curve $\lambda^{out}_{\hat{\mathbf{r}}}(r_1)$. Hence the snaking limit of $\mathcal{H}^{out}_{\hat{\mathbf{r}}}(r_1)$ for $r_1 \to 0$ (or, equivalently, for $\omega_1 \to \infty$) is the union of Γ and a particular (symmetric) 2-homoclinic orbit $\mathcal{H}_{2,2}(\hat{\mathbf{r}})$ to p_2. We write

$$\lim_{r \to 0} \mathcal{H}^{out}_{\hat{\mathbf{r}}}(r) = \Gamma \cup \mathcal{H}_{2,2}(\hat{\mathbf{r}}).$$

Indeed, this limit exists in the sense of the Hausdorff metric.

In the same way (4.13) can be solved for $(r_2, r_1, \lambda) = (r_2, r_1, \lambda)^{mid}(r_3)$. Then the corresponding snaking curve is parametrized by $\omega_2^2 =: \omega_3$ (resp., r_3). The right-hand side of (4.13) tends to the right-hand side of (4.15) as r_3 tends to zero:

$$
\begin{aligned}
0 = \hat{\Xi}^1 &= \lambda + \hat{L}_2(r_1, \lambda) + \hat{\mathcal{R}}^1_{r_3=0},\\
0 = \hat{\Xi}^2 &= \lambda + \hat{L}_1(r_2, \lambda) + \hat{\mathcal{R}}^2_{r_3=0},\\
0 = \hat{\Xi}^3 &= \lambda + \hat{L}_1(r_2, \lambda) + \hat{L}_2(r_1, \lambda) + \hat{\mathcal{R}}^3_{r_3=0}.
\end{aligned} \tag{4.15}
$$

Here, $\hat{\mathcal{R}}^1_{r_3=0} = \mathcal{O}\big((r_1)^\alpha\big)$, $\hat{\mathcal{R}}^2_{r_3=0} = \mathcal{O}\big((r_2)^\alpha\big)$, and $\hat{\mathcal{R}}^3_{r_3=0} = \mathcal{O}\big((r_2)^\alpha\big) + \mathcal{O}\big((r_1)^\alpha\big)$; now the $\hat{\mathcal{R}}$ do not depend on r_3.

Note that (4.15) is the bifurcation equation for 2-heteroclinic cycles connecting p_1 and p_2. First we make clear that near Γ there are infinitely many of these cycles. In the same way as outlined in section 4.2, system (4.15) can be written as a fixed point equation:

$$
(r_2, r_1, \lambda) = T_{\check{\mathbf{r}}}(r_2, r_1, \lambda). \tag{4.16}
$$

Let $\mathbf{r} := (r_2, r_1)$, and with that let $\check{\mathbf{r}}$ have the same meaning as $\hat{\mathbf{r}}$ in section 4.2. Using the arguments of the proof of Lemma 4.8, we find that (4.16) has a unique fixed point $(\mathbf{r}_{\check{\mathbf{r}}}, \lambda_{\check{\mathbf{r}}})$ in $\mathfrak{C}_{\check{\mathbf{r}}} \times [-\epsilon_{\check{\mathbf{r}}}, \epsilon_{\check{\mathbf{r}}}]$. (So, depending on the choice of $\check{\mathbf{r}}$ (4.16) has infinitely many solutions.)

Remark 4.10. *Note that if the vector field f is conservative, as in the example of the Swift–Hohenberg equation (2.2), then $\lambda_{\check{\mathbf{r}}} = 0$ for all $\check{\mathbf{r}}$. Indeed, for $\lambda \neq 0$ the equilibrium points p_1 and p_2 are in different level sets, and therefore they cannot be connected by a heteroclinic orbit.*

So, the snaking limit of $\mathcal{H}^{mid}_{\check{\mathbf{r}}}(r_3)$ is a 2-heteroclinic cycle. Note that this cycle depends on the particular choice of $\check{\mathbf{r}}$ which again is strongly related to the transition times near p_1 and p_2 (of both the cycle and the "nonsnaking part" of the considered 3-homoclinic orbit).

We can also discuss this behavior from a different perspective. Each of the symmetric 2-heteroclinic cycles can be seen as a primary cycle in its own right. Then, due to [14], there are 1-homoclinic orbits (to p_1) having this cycle as a snaking limit. But, related to Γ (in the present context), these orbits are the observed 3-homoclinic orbits.

Finally, we note that $\omega^1_1 =: \omega_2$ (resp., r_2) cannot serve as a snaking parameter; that is, the times separating the pulses stay almost constant along snaking curves. This follows from the fact that (4.13) cannot be solved for $(r_1, r_3, \lambda)(r_2)$, $r_2 \in (0, \epsilon)$. To see this let us assume the opposite. Then the corresponding snaking limit consists of two nonsymmetric 1-homoclinic orbits to p_1, which are R-images of each other, and a symmetric 1-homoclinic orbit to p_1. Indeed, $\hat{\boldsymbol{\Xi}} = (\hat{\Xi}^1, \hat{\Xi}^2, \hat{\Xi}^3)$ given in (4.13) can be extended continuously for $r_2 = 0$ and the corresponding limit provides the equations for those orbits. Further, the limit $\lim_{r_2 \to 0} (r_1, r_3, \lambda)(r_2)$ also exists (see Remark 4.9) and coincides with the solutions of (4.13) with $r_2 = 0$. But there are no nonsymmetric 1-homoclinic orbits near Γ: First note that nonsymmetric orbits come in pairs. In the language of section 4.1 both (nonsymmetric) 1-homoclinic orbits correspond to (different) 1-homoclinic Lin orbits $\{X^-, X^1_2, X^+\}$ with the same transition time ω_1. But, due to Lemma 4.1, there is only one (unique) Lin orbit for given transition time.

5. Conclusions.

In this paper we have studied the emergence of N-homoclinic orbits near heteroclinic cycles between equilibria of saddle-focus type (EE cycles) in reversible systems. Let us make some further comments and address topics for future research.

The complete bifurcation diagram for the SH equation. Our analysis has concerned the behavior for large transition times $\omega^i_{1,2}$, or, equivalently, small $r^i_{1,2}$, and has shown that for

each N there are infinitely many N-homoclinic orbits, which exist on distinct snaking curves near the cycle.

The numerical results for homoclinic orbits in the Swift–Hohenberg equation (2.2) show that two different snaking curves can be connected globally in that they can emerge in fold bifurcations close to a local bifurcation of the equilibrium at $r = 0$. This is illustrated in the results for 2-homoclinic orbits in Figure 3. Note that we do not show the other branches involved in the fold bifurcations in this figure.

A second possibility is revealed in the diagrams for 3-homoclinic orbits in Figure 4. Here, the red and green snaking curves merge in fold bifurcations close to the primary snaking curve. Such behavior seems to be in contrast to the results presented in section 4.3 above. In fact, due to our analysis in that section, both $r_2^{out}(r_1)$ and $r_3^{out}(r_1)$ are bounded away from zero as $r_1 \to 0$, as they stay in a neighborhood of $\hat{r}_2$ and $\hat{r}_3$. (We use the same notation as in section 4.4 above.) Therefore, for $r_1 \to 0$, we have that, in particular, $r_1 \ll r_3^{out}(r_1)$. Similarly we find that $r_3 \ll r_1^{mid}(r_3)$, as $r_3 \to 0$. Consequently the tails of the curves $\mathcal{H}_{\hat{\mathbf{r}}}^{out}(r_1)$ and $\mathcal{H}_{\check{\mathbf{r}}}^{mid}(r_3)$ do not intersect (independently on the concrete choice of $\hat{\mathbf{r}}$ and $\check{\mathbf{r}}$).

At the moment it is not clear whether fold bifurcations as in Figure 4, where the red and green branches meet, can be covered by our analysis. But we note that their analysis deserves further attention. For example, for 3-homoclinic orbits we have found that bifurcation curves $\mathcal{H}_{\check{\mathbf{r}}}^{mid}$ and $\mathcal{H}_{\hat{\mathbf{r}}}^{out}$ are globally connected. For N-homoclinic orbits with $N > 4$ there are more different types of snaking behavior and thus more possibilities for such global connections of snaking curves. It is of interest to investigate these bifurcation scenarios more closely.

Besides being reversible, (2.2) is also conservative, and thus nonsymmetric N-homoclinic solutions will also exist robustly near the primary orbit; see, for example, [3] for a related investigation. For the related case of snaking near an EP cycle (see also the last paragraph below), nonsymmetric solutions have recently been found to bifurcate in pitchfork bifurcations from the symmetric branches, creating a "snakes and ladder" structure; see [2]. Thus, our future work on N-homoclinic orbits will also include nonsymmetric solutions in order to see if similar structures can be found near EE cycles.

Stability of multipulses. For the related PDE (2.1) the N-homoclinic orbits discussed in this paper describe N-pulse solutions bifurcating from the fronts that connect the two equilibrium states. In this context the stability of the multipulses is of importance, since only stable patterns will be observed in numerical simulations or experiments. It is well known that the primary one-pulse solution alternates between being stable and unstable along the snaking curve and that this change of stability occurs when the fold points are crossed; see, for example, Figure 19 in [2]. In particular, note that at the bifurcation values, infinitely many stable 1-pulse homoclinic orbits exist.

The stability of N-pulse solutions near fronts or pulses is a more delicate issue. We only note here that stable N-pulse solution can exist near stable primary pulses. Of course, this cannot be investigated within the finite-dimensional framework of this paper, but methods are available to decide about stability rigorously; see [19].

For the Swift–Hohenberg equation simulations reveal striking similarities between the behavior of 1-pulse and 2-pulse solutions. Some results are presented in Figure 6, where we show the plots for 1- and 2-pulse orbits of (2.1). The simulations are based on a pseudospectral code with the linear terms integrated exactly using the ETD method [6] due to stiffness within

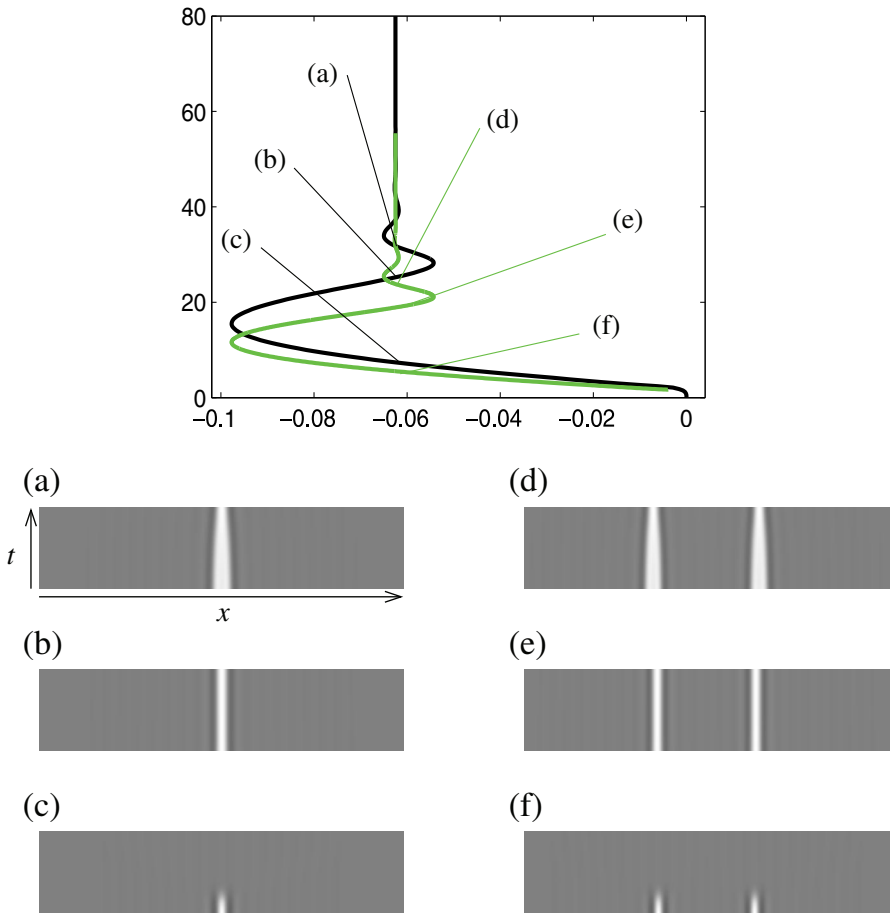

Figure 6. *Simulations of* 1*-pulse and* 2*-pulse solutions in the Swift–Hohenberg equation* (2.1).

the system. They have been performed for the critical parameter value $r = -0.0625$ over a time interval $t \in [0, 250]$. As initial profiles we have used perturbations of the 1-homoclinic orbit (panels (a)–(c)), and of the 2-homoclinic solutions along the green branch in Figure 3, panels (d)–(f).

The panels below the diagram in Figure 6 show the time evolution of the pulses viewed from the top with lighter regions corresponding to larger amplitudes. It can be seen that the pulses in panels (a), (d) and (c), (f), respectively, are unstable, with the amplitude of the pulses decaying to zero. Note that the decay in panels (a) and (d) is very slow. However, the pulses in panels (b) and (e) show stable behavior under the evolution in time. Because of the similarities in the evolution of 1-pulse and 2-pulse solutions, we can expect the emergence of infinitely many stable multipulse solutions in snaking scenarios in the Swift–Hohenberg equation.

N-homoclinic orbits near EP cycles. Finally, it is interesting to note that the behavior of N-homoclinic orbits reveals a striking difference in the dynamics near EE cycles and EP cycles. Note first that EP cycles can exist robustly in reversible systems, since the corresponding stable

and unstable manifolds can intersect transversally. Therefore, the fold points along snaking curves of homoclinic orbits in their neighborhood do not converge to a single parameter value but rather oscillate between two values which converge to the boundaries of the parameter interval in which the cycle exists; see also Figure 7.

This global character of bifurcations near an EP cycle makes a rigorous analytical treatment difficult. Recently, an analysis of 1-homoclinic orbits was presented in [1]. In addition, numerical results for N-homoclinic orbits near such a cycle have been described in [9, 22].

Below we present a corresponding result for the generalized Swift–Hohenberg equation (2.2). Similar to section 2 we view the equation as depending on r, this time setting $q_c = 0.5$, $v = 0.41$, and $g = 1$. And, as in that section, 1-homoclinic orbits to 0 are computed using shooting, and two-homoclinic orbits by the branch-switching method.

In Figure 7 we present a bifurcation diagram for symmetric 2-homoclinic orbits to 0 near an EP cycle, which exists for $r \in [-0.0146, -0.0125]$. This EP cycle generates two snaking curves of 1-homoclinic orbits, one which is shown in grey in the figure. In addition, the rescaled continuation curve for a 2-homoclinic orbit is shown in red in the figure. And although this curve follows (parts of) the snaking curve, we see a clear difference. In contrast to the EE cycle case the 2-homoclinic orbit does not exist on a snaking curve, but rather on an *isola* in the diagram.

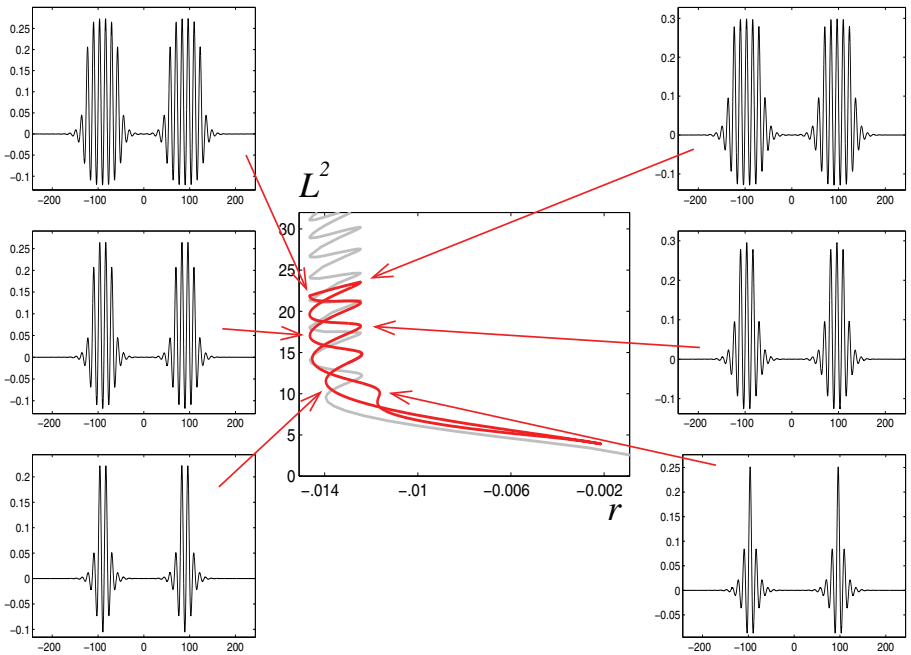

Figure 7. 2-*homoclinic orbits near an EP cycle exist along an isola in* (2.2).

A reason for this becomes apparent when we consider the plots for the 2-homoclinic solutions along the snaking curve. Moving up on the bifurcation curve, we see that the pulses of the solutions become wider, but in contrast to the EE cycle case, the pulses grow symmetrically about their center such that they do not stay separated but approach each other. (Note that instead of approaching an equilibrium solution the pulses now come close

to a periodic orbit such that they grow additional oscillations.) Hence, in the notation of section 4, the time ω_1^1 decreases along the snaking curve. And this process cannot be repeated ad infinitum, since the two pulses would have to meet, and therefore the 2-homoclinic orbit cannot follow the full snaking curve. Similar behavior has been found for different examples in [9, 22]. Indeed, so far, 2-homoclinic orbits near EP cycles have been found to lie only on isolas and not on snaking curves.

The precise character of these isolas is the subject of current research. General bifurcation results will be presented in a forthcoming paper. Furthermore, we also aim to understand the geometrical reason for the different behavior of N-homoclinic orbits near EE cycles and EP cycles, respectively.

Acknowledgments. We thank Steve Houghton for letting us use his numerical code for the PDE simulations. We are also grateful to the referees whose comments helped to improve the presentation of our results.

Hysteresis in a Rotating Differentially Heated Spherical Shell of Boussinesq Fluid*

Gregory M. Lewis† and William F. Langford‡

Abstract. A mathematical model of convection of a Boussinesq fluid in a rotating spherical shell is analyzed using numerical computations guided by bifurcation theory. The fluid is differentially heated on its inner spherical surface, with the temperature increasing from both poles to a maximum at the equator. The model is assumed to be both rotationally symmetric about the polar axis and reflectionally symmetric across the equator. This work is an extension to spherical geometry of previous work on the differentially heated rotating annulus. The spherical geometry is motivated by applications to planetary atmospheres. As the temperature gradient increases from zero, large Hadley cells extending from equator to poles form immediately. For larger temperature differences, two or three convection cells appear in each hemisphere. An organizing center is shown to exist, at which two saddle-node bifurcations come together in a codimension-2 hysteresis bifurcation (or cusp) point, providing a mechanism for hysteretic transitions between different cell patterns as the temperature gradient is varied.

Key words. cusp point, hysteresis bifurcation, flow transitions, Boussinesq fluid, flow in a rotating spherical shell, numerical computation, large-scale geophysical flow

1. Introduction.

The atmosphere of a planet may be idealized as a spherical shell of fluid surrounding the spherical surface of the planet. Many factors affect the circulation of the atmosphere; chief among these are the rotation of the planet, the differential heating of the surface and atmosphere by the planet's sun, and the thickness and composition of the atmosphere itself. In this paper we construct an idealized mathematical model of such a planet, ignoring all local variations of surface features such as oceans, continents, mountains, and glaciers. The symmetries of this model are exploited to make the computations more tractable.

On the inner boundary surface a temperature profile is prescribed to reflect the differential heating of the atmosphere by the sun, as follows. The average annual flux of solar radiation on a planet whose axis of rotation is tilted approximately 20° with respect to the plane that is perpendicular to the solar rays is nearly proportional to $-\cos(2\theta)$ (see [19]), where θ is the polar angle, which differs from the latitude only in its range (in particular, the latitude is given by $\pi/2 - \theta$). This flux is independent of the azimuthal variable φ and is a maximum at the

equator ($\theta = \pi/2$) and a minimum at the poles ($\theta = 0, \pi$). This profile is similar to the annual average of solar flux for many of the planets in our solar system, including Earth. Therefore, we choose the temperature on the inner boundary surface to be fixed at $T = T_r - \Delta T \cos(2\theta)$, where T_r is a reference temperature and the difference in the temperature from equator to pole is $2\Delta T$. On a real planet, a flux of radiation of this form would not result exactly in this prescribed temperature distribution on the surface, but we expect this model to capture the gross effects of the differential heating. In the model, the spherical shell is filled with a Boussinesq fluid, which means that its density varies linearly with temperature. Thus, the gravitational force acting radially inward drives convective motions of the fluid when $\Delta T > 0$.

We assume that both the inner and outer spheres are rigid, and that the fluid satisfies no-slip conditions on both boundaries. For the temperature at the outer sphere, we assume insulating boundary conditions. Inside the spherical shell, the fluid satisfies the Navier–Stokes equations in the Boussinesq approximation. Complete details of the model are given in section 2. The nonlinear equations for a steady state are solved using Newton iteration with Keller continuation from the trivial solution at $\Delta T = 0$. The linear stability problem is solved using the implicitly restarted Arnoldi method following a generalized Cayley transformation. The full methodology for analysis of the model is described in sections 3 and 4, and the results are presented in sections 5 and 6.

It is not possible in an Earth-bound laboratory to perform an experimental study of convection in a spherical shell as described here, because the gravitational force cannot be directed radially towards the common center of the spheres. (However, experiments to study spherical convection with a central force field under weightless conditions in a space lab are an interesting possibility; see, for example, [11, 3].) Many laboratory experiments have been performed on a differentially heated rotating cylindrical annulus, with Earth's gravity acting downward parallel to the cylinder axis and with centrifugal force acting radially. These experiments typically used water as the working fluid. Much has been learned about the dynamics of large-scale geophysical fluids from these laboratory experiments, even though the Reynolds number is significantly smaller in the experimental fluids than in actual geophysical flows [12, 24]. The Boussinesq approximation has been used as a basis for a mathematical model of the differentially heated rotating annulus, using laboratory-scale parameters and with water as the fluid [13, 20, 21]. The model has provided good agreement with the corresponding laboratory experiments.

Therefore, in this prototype mathematical model of a differentially heated rotating spherical shell of fluid, we adopt a philosophy of choosing the parameters of the fluid to be those of water and using the laboratory scale rather than the geophysical. In this way, the computations are tractable and the results obtained can be compared to both experiments and theoretical calculations for the better understood case of a differentially heated rotating annulus. This may provide insight into how the geometry of the system leads to the observed flow transitions, and may serve as a step towards understanding the dynamical structure of planetary systems. Although we have made quantitative choices for the fluid and the boundary conditions, we expect that these choices will have little effect on qualitative features of the results. This is supported by the numerous studies that have been performed on the differentially heated rotating annulus. Many experiments have been performed with different forms of heating, different geometries of the apparatus, and with different fluid properties,

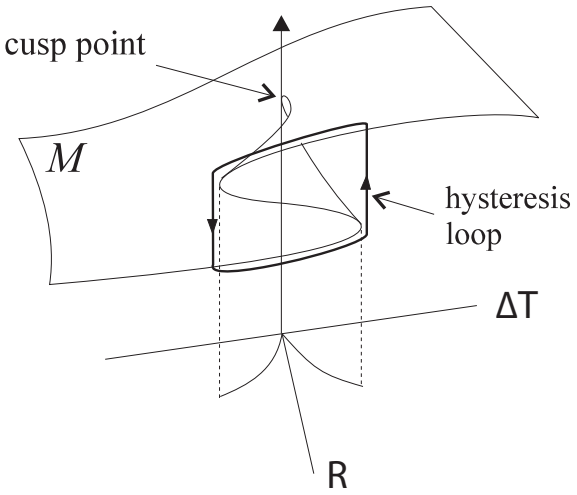

Figure 1. *The codimension-2 hysteresis bifurcation, showing the hysteresis loop as ΔT varies back and forth. The cusp shown in the $(R, \Delta T)$ parameter plane is the projection of the two curves of fold bifurcations onto this plane.*

and it is found that these have little qualitative effect on the types of transitions and form of the transition curves that are observed.

The goal of this paper is to determine the flow patterns, their stabilities and their transitions (bifurcations) for a differentially heated rotating spherical shell, consistent with our modeling assumptions. There are three bifurcation parameters of interest: the temperature difference ΔT, the shell gap width R, and the rotation rate Ω. The results presented in section 5 show that the qualitative features of the flow patterns do not change for moderate changes of Ω, although the stability with respect to non–rotationally symmetric perturbations is affected. However, for even very small $\Delta T > 0$, the fluid immediately begins to flow in a large stable convection cell with easterly flow toward the equator near the inner surface. This flow is similar to the Hadley cell, which exists in the atmosphere between approximately the equator and 30° latitude (in each hemisphere), except that it extends from equator to pole. In this paper, we refer to this convection cell as the Hadley cell. For larger values of ΔT, two or even three convection cells may appear between the equator and pole. The Hadley cell shrinks, always keeping one edge at the equator, while the additional cells appear between it and the pole. When a second cell exists next to the Hadley cell, it is characterized by a weaker counter-rotating flow, with a westerly component. The third cell, when it exists, has the same sense of rotation as the Hadley cell but lies near the pole. In every case, there is a region of high velocity azimuthal flow at high altitudes and midlatitudes, resembling Earth's *jet stream*.

Furthermore, we show that there exists a critical value of the pair $(R, \Delta T)$ that is a *hysteresis bifurcation point* (also called a *cusp point*); see Figure 1. This is a codimension-2 steady-state bifurcation that is well understood in mathematical bifurcation theory. The existence of this hysteresis point is demonstrated by an explicit calculation of its defining conditions in section 6, where the study of this hysteresis bifurcation is presented in detail. Only

its main features are outlined here. Figure 1 represents a generic hysteresis bifurcation. Here M is a manifold of steady states, existing for given parameters $(R, \Delta T)$, and the vertical axis represents the amplitude of a steady state (determined by the stream function in section 6). In a neighborhood of a hysteresis bifurcation point, the number of steady states (on M) can vary from one to three as the parameters $(R, \Delta T)$ vary. When three steady states coexist in Figure 1, the middle one is unstable, but all other steady states not on the fold lines in Figure 1 remain stable (attracting). Furthermore, there are abrupt upward and downward transitions at two *fold bifurcations* (also called limit points or saddle-node bifurcations), as shown in Figure 1, that occur at both ends of an interval of the bifurcation parameter ΔT, for appropriate fixed R. If ΔT is varied back and forth through this interval, the system traces a *hysteresis loop*, as shown in Figure 1. Between these two abrupt transitions there is an interval of ΔT that exhibits *bistability*; that is, two solutions are stable simultaneously.

1.1. Relationship to previous work. The fundamental problem of convection in spherical shells was formulated by Chandrasekhar [4, Chap. 6], who also solved the stability problem in the Boussinesq approximation for the spherically symmetric case, in terms of spherical harmonics. There is a large literature on spherically symmetric convection that is motivated by Earth's core and mantle, where the boundary conditions have full spherical symmetry (in particular, a constant temperature on the inner sphere); see, for example, [3, 5, 22, 31]. The present work differs from all of these because of the latitudinal temperature gradient.

Motivation for the present work is provided also by the classical Taylor–Couette experiment, in which the flow of a fluid (usually water) between two differentially rotating long coaxial cylinders is studied; see, for example, [2, 6, 8, 17]. In that experiment many interesting flow patterns may form, including *Taylor vortices*, which are invariant tori stacked coaxially between the cylinders in pairs with alternating clockwise and counterclockwise helical flows. There is no differential heating in the Taylor–Couette experiment; even so, the Taylor vortices resemble Hadley cells. Marcus and Tuckerman [25, 26] performed numerical simulations of the flow between two differentially rotating spheres (without heating) and found bifurcations to different numbers of cells that they called Taylor vortices, thus showing that Hadley-like cells may form even without differential heating, if the spheres are rotated differentially. See also [14].

2. Model equations. We use the Navier–Stokes equations in the Boussinesq approximation to model the fluid flow within the spherical shell. In the Boussinesq approximation, the variations of all fluid properties except the density are considered to be negligible, and the equation of state of the fluid is assumed to be

$$\rho = \rho_0 \left(1 - \alpha \left(T - T_r\right)\right), \tag{2.1}$$

where ρ is the density of the fluid, T is the temperature, α is the (constant) coefficient of thermal expansion, and ρ_0 is the density at a reference temperature T_r. The dimensionless quantity $\alpha\left(T - T_r\right)$ is assumed to be small. In the Boussinesq approximation the fluid is considered to be incompressible, which is a significant simplification.

The fluid is contained within a spherical shell with inner sphere of radius r_a and outer sphere of radius r_b. We assume gravity acts everywhere in the radial direction. The spherical shell rotates at rate Ω about the polar axis, and the inner and outer spheres rotate at the

same rate. The equations are written in spherical polar coordinates in a frame of reference corotating at rate Ω with the shell. The radial, polar, and azimuthal coordinates are denoted r, θ, and φ, respectively, with unit vectors $\mathbf{e}_r$, $\mathbf{e}_\theta$, and $\mathbf{e}_\varphi$.

The Navier–Stokes Boussinesq equations describing the evolution of the vector fluid velocity, $\mathbf{u} = \mathbf{u}(r,\theta,\varphi,t) = w\mathbf{e}_r + v\mathbf{e}_\theta + u\mathbf{e}_\varphi$, and the temperature of the fluid, $T = T(r,\theta,\varphi,t)$, are

$$\frac{\partial \mathbf{u}}{\partial t} = \nu\nabla^2\mathbf{u} - 2\boldsymbol{\Omega}\times\mathbf{u} + \left[g\mathbf{e}_r + \boldsymbol{\Omega}\times(\boldsymbol{\Omega}\times\mathbf{r})\right]\alpha\,(T - T_r) - \frac{1}{\rho_0}\nabla p - (\mathbf{u}\cdot\nabla)\,\mathbf{u}, \tag{2.2}$$

$$\frac{\partial T}{\partial t} = \kappa\nabla^2 T - (\mathbf{u}\cdot\nabla)\,T, \tag{2.3}$$

$$\nabla\cdot\mathbf{u} = 0, \tag{2.4}$$

where $\boldsymbol{\Omega} = \Omega\,(\cos\theta\mathbf{e}_r - \sin\theta\mathbf{e}_\theta)$ is the rotation vector, $\Omega = |\boldsymbol{\Omega}|$ is the rate of rotation about the polar axis, p is the pressure deviation from $p_0 = \rho_0 g(R - r) + \rho_0\Omega^2 r^2\sin^2\theta/2$, $\mathbf{r} = r\mathbf{e}_r + \theta\mathbf{e}_\theta + \varphi\mathbf{e}_\varphi$, ν is the kinematic viscosity, κ is the coefficient of thermal diffusivity, g is the gravitational acceleration, ∇ is the usual gradient operator in spherical coordinates, u is the azimuthal fluid velocity, often referred to as the zonal velocity, v is the polar fluid velocity, and w is the radial fluid velocity. The spatial domain is defined by $r_a < r < r_b$, $0 \le \varphi < 2\pi$, and $0 < \theta < \pi$. Thus, $\theta = 0, \pi$ correspond to the north and south poles of the shell, respectively, while $\theta = \pi/2$ corresponds to the equator. The equations can be rewritten in planetary coordinates by performing the change of variable $\theta \to \pi/2 - \theta$. The values of ν and κ are chosen to be those of the fluid at the reference temperature T_r, and it is assumed that the difference between the temperature of the fluid and T_r is everywhere small enough so that ν and κ can be considered as constants. We have included the effects of centrifugal buoyancy in the equations via the term $\boldsymbol{\Omega}\times(\boldsymbol{\Omega}\times\mathbf{r})$. All dimensional quantities are measured in CGS units.

As described in the introduction, the boundary conditions are

$$\begin{aligned} &\mathbf{u} = 0, \qquad T = T_r - \Delta T\cos(2\theta) \qquad \text{on} \quad r = r_a, \\ &\mathbf{u} = 0, \qquad \frac{\partial T}{\partial r} = 0 \qquad\quad \text{on} \quad r = r_b, \end{aligned} \tag{2.5}$$

with 2π-periodicity in the azimuthal variable φ.

In this paper we investigate flows that preserve the symmetries of the model, that is, flows that are invariant under rotation about the polar axis (i.e., axisymmetric flows) and that are invariant under reflection across the equator (i.e., across the line defined by $\theta = \pi/2$). Therefore, we study solutions of (2.2)–(2.5) in the form

$$\begin{aligned} &u = u(r,\theta,t) = u(r,\pi-\theta,t), \qquad v = v(r,\theta,t) = v(r,\pi-\theta,t), \\ &w = w(r,\theta,t) = w(r,\pi-\theta,t), \quad T = T(r,\theta,t) = T(r,\pi-\theta,t). \end{aligned} \tag{2.6}$$

The assumed symmetries significantly simplify the analysis. We may use the analysis of the symmetric system as a starting point for an analysis of the full system. Although it is not written explicitly, the solutions also depend on the parameters.

If we scale the radial coordinate as

$$r \to Rr', \tag{2.7}$$

where $R = r_b - r_a$ is the gap width, write the temperature as

$$T \to T' + T_r - \Delta T \cos(2\theta), \tag{2.8}$$

substitute these into (2.2)–(2.4), and drop the primes, we obtain the following axisymmetric equations describing the evolution of the fluid velocity $\mathbf{u} = w(r,\theta,t)\mathbf{e}_r + v(r,\theta,t)\mathbf{e}_\theta + u(r,\theta,t)\mathbf{e}_\varphi$, pressure deviation $p = p(r,\theta,t)$, and temperature deviation $T = T(r,\theta,t)$:

$$\begin{aligned}\frac{\partial u}{\partial t} &= \nu_s \nabla_0^2 u - \nu_s \frac{1}{r^2 \sin^2\theta} u - 2\Omega\left(\sin\theta w + \cos\theta v\right) \\ &\quad - \frac{1}{R}\left[\left(\mathbf{u}\cdot\nabla_0\right) u + \frac{\cos\theta}{r\sin\theta} uv + \frac{uw}{r}\right],\end{aligned} \tag{2.9}$$

$$\begin{aligned}\frac{\partial v}{\partial t} &= \nu_s \nabla_0^2 v - \nu_s\left(\frac{1}{r^2\sin^2\theta} v - \frac{2}{r^2}\frac{\partial w}{\partial \theta}\right) + 2\Omega\cos\theta u - \frac{1}{\rho_0 R r}\frac{\partial p}{\partial \theta} \\ &\quad - \left(\alpha\Omega^2 R r \sin\theta\cos\theta\right)\left(T - \Delta T\cos 2\theta\right) - \frac{1}{R}\left[\left(\mathbf{u}\cdot\nabla_0\right) v - \frac{\cos\theta}{r\sin\theta} u^2 + \frac{vw}{r}\right],\end{aligned} \tag{2.10}$$

$$\begin{aligned}\frac{\partial w}{\partial t} &= \nu_s \nabla_0^2 w - \nu_s\left(\frac{2}{r^2}\frac{\cos\theta}{\sin\theta} v + \frac{2}{r^2}\frac{\partial v}{\partial\theta} + \frac{2}{r^2} w\right) + 2\Omega\sin\theta u - \frac{1}{\rho_0 R r}\frac{\partial p}{\partial r} \\ &\quad - \alpha\left(\Omega^2 R r\sin^2\theta + g\right)\left(T - \Delta T\cos 2\theta\right) - \frac{1}{R}\left[\left(\mathbf{u}\cdot\nabla_0\right) w - \frac{1}{r}\left(u^2 + v^2\right)\right],\end{aligned} \tag{2.11}$$

$$\frac{\partial T}{\partial t} = \kappa_s \nabla_0^2 T + \frac{4\Delta T \kappa_s}{r^2}\left(\cos 2\theta + \cos^2\theta\right) + \frac{2\Delta T}{Rr}\sin 2\theta v - \frac{1}{R}\left(\mathbf{u}\cdot\nabla_0\right) T, \tag{2.12}$$

$$\nabla_0 \cdot \mathbf{u} = \frac{\partial w}{\partial r} + \frac{2}{r} w + \frac{1}{r}\frac{\partial v}{\partial\theta} + \frac{\cos\theta}{r\sin\theta} v \;=\; 0, \tag{2.13}$$

where $\nu_s = \nu/R^2$, $\kappa_s = \kappa/R^2$,

$$\nabla_0^2 = \frac{\partial^2}{\partial r^2} + \frac{2}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial\theta^2} + \frac{\cos\theta}{r^2\sin\theta}\frac{\partial}{\partial\theta},$$

$$\nabla_0 = \mathbf{e}_r\frac{\partial}{\partial r} + \mathbf{e}_\theta\frac{1}{r}\frac{\partial}{\partial\theta},$$

and

$$\left(\mathbf{u}\cdot\nabla_0\right) f = w\frac{\partial f}{\partial r} + \frac{v}{r}\frac{\partial f}{\partial\theta} \tag{2.14}$$

for any scalar function $f = f(r,\theta,t)$. The domain is now expressed as $r_a/R < r < r_b/R$, $0 \le \theta < \pi/2$, and the boundary conditions become

$$\begin{aligned}&\mathbf{u} = 0, \qquad T = 0 \qquad \text{on} \quad r = \frac{r_a}{R}, \\ &\mathbf{u} = 0, \qquad \frac{\partial T}{\partial r} = 0 \qquad \text{on} \quad r = \frac{r_b}{R}.\end{aligned} \tag{2.15}$$

The symmetry assumptions not only reduce the domain size (i.e., we now have $0 \le \theta \le \pi/2$), but also effectively introduce new boundary conditions at the equator and the pole. In order to satisfy the symmetries, there can be no flow of fluid or heat across the equator or the pole. In addition, the condition $u = 0$ at the pole is necessary to ensure that no discontinuity occurs in the fluid velocity at the pole. Thus, we have the additional boundary conditions

$$\begin{aligned} & u, v = 0, \qquad \frac{\partial w}{\partial \theta} = 0, \qquad \frac{\partial T}{\partial \theta} = 0 \qquad \text{on} \quad \theta = 0, \\ & v = 0, \qquad \frac{\partial u}{\partial \theta} = \frac{\partial w}{\partial \theta} = 0, \qquad \frac{\partial T}{\partial \theta} = 0 \qquad \text{on} \quad \theta = \frac{\pi}{2}. \end{aligned} \tag{2.16}$$

It is possible to write the equations completely in terms of dimensionless variables. However, this would not simplify the analysis, so we choose to work with the equations in the form (2.9)–(2.13). This follows previous numerical work on similar problems, e.g., [13, 30, 20].

3. Analysis.

3.1. Nonlinear equations for steady solution. The analysis begins with the computation of steady axisymmetric solutions that are invariant with respect to reflection across the equator; that is, we seek solutions of (2.9)–(2.13) that satisfy the boundary conditions (2.15)–(2.16) and are independent of time.

The method of stream functions is used to solve the steady equations. If v and w are written in terms of a (Stokes) stream function ξ, defined by

$$v = -\frac{1}{r \sin\theta} \frac{\partial \xi}{\partial r}, \qquad w = \frac{1}{r^2 \sin\theta} \frac{\partial \xi}{\partial \theta}, \tag{3.1}$$

then the incompressibility condition (2.13) is automatically satisfied [1]. After using (3.1) to replace v and w in the equations, the pressure terms can be eliminated. Subsequently, the steady solution can be found from the resulting three equations in the three unknown functions u, ξ, and T. These equations are found using the Maple symbolic computation software package and are sufficiently complicated that no insight is gained by explicitly writing them here. The boundary conditions for u and T are given by (2.15)–(2.16), as before, while the conditions on v and w will be satisfied if ξ satisfies the boundary conditions

$$\begin{aligned} & \xi = 0, \qquad \frac{\partial \xi}{\partial \theta} = 0, \qquad \frac{\partial^3 \xi}{\partial \theta^3} = 0 \quad \text{on} \quad \theta = 0, \\ & \xi = 0, \qquad \frac{\partial^2 \xi}{\partial \theta^2} = 0 \qquad \text{on} \quad \theta = \frac{\pi}{2}, \\ & \xi = 0, \qquad \frac{\partial \xi}{\partial r} = 0 \qquad \text{on} \quad r = \frac{r_a}{R}, \frac{r_b}{R}. \end{aligned} \tag{3.2}$$

The numerical algorithm to solve this system of nonlinear equations is described in section 4, and the steady axisymmetric solutions obtained are presented in section 5.

3.2. Linear stability analysis. The linear stability of a steady solution is defined in terms of the eigenvalues of the linearization of the dynamical equations about that solution. If the real parts of *all* the eigenvalues are negative, then all perturbations from the steady solution

will decay in the linearized equations. In this case, the solution is said to be linearly stable. If any of the eigenvalues has positive real part, then some small perturbations will grow, and the solution is linearly unstable. If there exist only eigenvalues with zero real part and negative real part, the solution is called neutrally stable. If the real part of an eigenvalue crosses the imaginary axis as a parameter is varied, then a qualitative change in the solution occurs; i.e., a bifurcation takes place. Flows corresponding to linearly stable steady solutions can be observed physically if the noise that is naturally present is sufficiently small. If a steady solution is linearly unstable, then the corresponding flow cannot be observed because some small perturbations due to the noise will tend to grow. Thus, it is expected that bifurcations correspond to transitions in the observed flow.

We compute the steady axisymmetric solution and its linear stability as the parameters of the system change, and we seek locations in the space of parameters where an eigenvalue crosses the imaginary axis. We are primarily interested in solutions that do not break the assumed symmetry, and therefore we initially require that this eigenvalue be associated with an eigenfunction that respects the symmetry.

If we write

$$u = u' + u_0, \qquad \xi = \xi' + \xi_0, \qquad T = T' + T_0, \tag{3.3}$$

where u_0, ξ_0, T_0 is a steady solution, and substitute into the three equations for u, ξ, and T, we obtain the perturbation equations in u', ξ', and T'. The trivial solution satisfies the perturbation equations, and it corresponds to u_0, ξ_0, T_0. If the perturbation equations are linearized and we assume that the unknown functions may be written as

$$u'(r,\theta,t) = e^{\lambda t}\psi_u(r,\theta), \quad \xi'(r,\theta,t) = e^{\lambda t}\psi_\xi(r,\theta), \quad T'(r,\theta,t) = e^{\lambda t}\psi_T(r,\theta), \tag{3.4}$$

then a linear eigenvalue problem is obtained. Consequently, the eigenvalues λ can be found from the generalized eigenvalue problem of the form

$$\lambda \mathbf{A}_0 \Psi = \mathbf{L}_0 \Psi, \tag{3.5}$$

where

$$\Psi = \begin{pmatrix} \psi_u \\ \psi_\xi \\ \psi_T \end{pmatrix}$$

is the eigenfunction and $\mathbf{A}_0$ and $\mathbf{L}_0$ are 3×3 matrices of linear differential operators.

The perturbations u', ξ', and T' correspond to axisymmetric perturbations. If all eigenvalues corresponding to these perturbations have negative real part, then the steady solution u_0, ξ_0, T_0 is a linearly stable solution of the axisymmetric equations (2.9)–(2.13). For this steady solution to be a corresponding linearly stable solution of the full three-dimensional model (2.2)–(2.4), we must also compute the eigenvalues corresponding to the nonaxisymmetric perturbations. To do this, we linearize the perturbation equations corresponding to the three-dimensional model, and we assume that the eigenfunctions have the form

$$\Phi(r,\theta,\varphi) = \hat{\Phi}_m(r,\theta)e^{im\varphi},$$

where $m = 1, 2, \ldots$ is the azimuthal wave number. Unlike in the axisymmetric case, it is not possible to solve this problem using a stream function approach. However, due to the form of the eigenfunctions, it is possible to use the incompressibility condition and the equation for the azimuthal velocity to eliminate the pressure and the azimuthal velocity, resulting in a generalized eigenvalue problem for each wave number m. The eigenvalue problem has the form (3.5) with $\hat{\Psi}_m$ replacing Ψ, and where

$$\hat{\Psi}_m = \begin{pmatrix} \hat{v}_m \\ \hat{w}_m \\ \hat{T}_m \end{pmatrix},$$

and the functions $\hat{v}_m, \hat{w}_m, \hat{T}_m$ depend only on r and θ.

To ensure the continuity of solutions, we require that, for $m \neq 1$, $\hat{v}_m, \hat{w}_m, \hat{T}_m$ vanish at the pole. Furthermore, to ensure that the solutions have continuous first derivatives at the pole, we also require that, for $m \neq 1$,

$$\frac{\partial \hat{v}_m}{\partial \theta} = \frac{\partial \hat{w}_m}{\partial \theta} = \frac{\partial \hat{T}_m}{\partial \theta} = 0 \qquad \text{on} \quad \theta = 0.$$

For $m = 1$, the condition of continuity also requires that $\hat{w}_1$ and $\hat{T}_1$ vanish at the pole. However, no such restriction applies to the meridional velocity, because the condition that $v(r, \theta, \varphi) = -v(r, \theta, \varphi + \pi)$ in the limit as $\theta \to 0$ allows for continuity in this case. However, to avoid the difficulty of computing nonzero solutions at $\theta = 0$, we look for stability only with respect to perturbations that satisfy $\hat{v}_1(r, \theta = 0) = 0$; this corresponds to perturbations that do not exhibit flow across the pole. We consider this additional boundary condition to be an additional simplifying assumption of the model. Furthermore, to reduce computational requirements we also compute the stability only with respect to perturbations that do not break the reflectional symmetry about the equator.

4. Numerical methods.

4.1. Discretization.

Because it is not possible to find analytic solutions for either the steady solution or the eigenvalue problem, the solutions are approximated numerically. Second order centered finite differencing is used to discretize the spatial derivatives. We approximate the value of the unknown functions at the locations of $N \times N$ uniformly spaced grid points in the interior of the domain. The values of T on the outer boundary, on the equator, and at the pole are not determined by the boundary conditions and must also be considered as unknowns. This leads to discretized solution vectors of size $3N^2 + 3N$. Discretization of the steady equations for u, ξ, and T leads to a system of nonlinear algebraic equations that can be solved by Newton iteration and Keller continuation (as explained in section 4.2) to find an approximation of the steady solution.

For the numerical approximation of the eigenvalues, the linearized perturbation equations are discretized, and thus the values of the steady solution are needed only at specific locations (the grid points) and the computed approximations are used. That is, the linearization is made about the approximate solution. Thus, upon discretization, the partial differential eigenvalue problem becomes a generalized matrix eigenvalue problem.

4.2. Solution techniques. We are interested in computing the steady solution for a wide range of parameter values. To do this, we implement pseudoarclength continuation with the Keller correction condition (see, e.g., [10]) and use a Newton method to solve the resulting equations. If a solution is known for a particular set of parameter values, then this method can be used effectively to follow solutions as a parameter is varied, i.e., to find a solution curve (with respect to the parameter).

Here, we know that for $\Delta T = 0$ the trivial solution satisfies the equations for u, ξ, and T. Thus, for ΔT small, the trivial solution is a reasonable prediction of the solution, and Newton's method is used for the correction. In pseudoarclength continuation, the parameter is considered as an unknown, and initial guesses of the solution are found by following the tangent, or a secant line approximation, to the solution curve. Increments are made approximately along the solution curve, and not by incrementing the parameter. The Keller condition ensures that the corrections to the initial guesses occur approximately perpendicularly to the tangent. This method is particularly useful because it is able to compute solutions along the solution curve even when there is a limit point on the curve, i.e., when the solution curve turns back on itself. In practice, the evaluation of the Jacobian is expensive, and therefore, in order to reduce the number of Jacobian evaluations, we use a quasi-Newton method in which the Jacobian is not updated on each iteration.

The generalized matrix eigenvalue problem that results from the discretization of (3.5) is solved in MATLAB using the implicitly restarted Arnoldi method [18], which is a memory-efficient iterative method for finding a specified number of the largest eigenvalues. A generalized Cayley transformation [10] is made so that the Arnoldi iteration finds the eigenvalues of interest. In particular, the generalized Cayley transformation

$$\mathbf{C}(\mathbf{L}, \mathbf{A}) = (\mathbf{L} - \alpha_1 \mathbf{A})^{-1} (\mathbf{L} - \alpha_2 \mathbf{A}) \tag{4.1}$$

maps eigenvalues λ of the generalized matrix eigenvalue problem $\lambda \mathbf{A} v = \mathbf{L} v$ to eigenvalues σ of the transformed matrix $\mathbf{C}(\mathbf{L}, \mathbf{A})$ such that the eigenvalues λ with $\text{Real}(\lambda) > (\alpha_1 + \alpha_2)/2$ are mapped to the eigenvalues σ with $|\sigma| > 1$, where α_1 and α_2 are the real parameters of the Cayley transformation. The parameters of the transformation can be chosen to improve convergence properties. The matrix $\mathbf{C}(\mathbf{L}, \mathbf{A})$ does not have to be formed explicitly, because the Arnoldi iteration only requires matrix-vector products involving $\mathbf{C}(\mathbf{L}, \mathbf{A})$ [18]. Thus, the full sparseness properties of $\mathbf{L}$ and $\mathbf{A}$ can be exploited, and computer memory requirements can be reduced.

5. Existence and stability results. The specific values of the parameters that are used in the computations are listed in Table 1. While these parameters remain fixed, we vary the gap width R (and thus $r_b \equiv r_a + R$), differential heating ΔT, and the rate of rotation Ω, and compute the azimuthal (or zonal) fluid velocity u, the stream function ξ, and temperature deviation T.

For $\Delta T = 0$, there is no movement of the fluid. However, for all $\Delta T > 0$ fluid motion is induced. For small values of $\Delta T > 0$ a single convection cell develops, which we call a Hadley cell. An example of such a solution for gap width $R = 3.4$ and rotation rate $\Omega = 0.01$ is plotted in Figure 2. In the figure, the stream function $\xi = \xi(r, \theta)$, the azimuthal (zonal) velocity $u = u(r, \theta)$, and the temperature deviation from the temperature on the inner

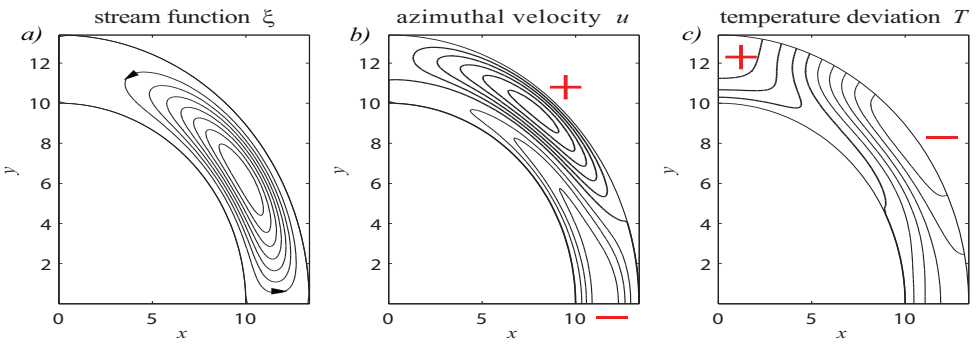

Figure 2. *An example of a single-cell circulation pattern observed for heating parameter $\Delta T = 0.0016$, gap width $R = 3.4$, and rotation rate $\Omega = 0.01$.* (a) *The stream function ξ—the flow tends to follow the contours;* (b) *the azimuthal (or zonal) velocity u; and* (c) *the temperature deviation T from the temperature prescribed on the lower boundary.*

boundary $T = T(r, \theta)$ are plotted on the unscaled domain $r_a \le r \le r_b$, $0 \le \theta \le \pi/2$. The figure represents a cross section of the solution at an arbitrary value of the azimuthal variable φ. The solution corresponding to the full equations (2.2)–(2.4) is obtained by rotating about the polar axis and reflecting across the equator. The "+" and "−" indicate the contours corresponding to positive and negative values of the functions, respectively. Contours of the stream function ξ and the azimuthal velocity that intersect the inner or outer boundary necessarily correspond to zeros of the function, while contours of the temperature deviation T that intersect the inner boundary correspond to zeros. The polar velocity v and the radial velocity w can be found from the stream function ξ using (3.1). In particular, the component of $\mathbf{u}$ that lies within a meridional plane is tangential to the contours represented in Figure 2(a), and thus the flow tends to follow these contours. More specifically, streamlines of the flow are restricted to lie on isosurfaces of ξ. The arrows in Figure 2(a) indicate the direction of the flow along the contours. In particular, in this flow, the fluid rises at the equator and falls at the pole. For this figure and all others that follow, we have taken $N = 40$.

The eigenvalues with the ten largest real parts associated with the axisymmetric eigenfunctions, as well as those associated with the eigenfunctions for each wave number m between 1 and 8, are approximated using the techniques described in section 3. It is found that all eigenvalues that are computed have negative real part. For the larger values of the wave

number m, the eigenvalues become more negative as the wave number is increased. Thus we expect that all eigenvalues associated with all wave numbers have negative real parts, and we conclude that the circulation pattern in Figure 2 is a linearly stable solution of the full three-dimensional equations.

If the heating parameter ΔT is increased further while keeping the gap width R fixed, a transition is observed. First, the flow passes through an intermediate stage, in which the stream function near the pole flattens. Then as ΔT is increased further, a three-cell pattern develops (see Figure 3). The three-cell pattern resembles the zonally (azimuthally) averaged circulation pattern observed in Earth's atmosphere, with a strong cell close to the equator (the Hadley cell), a weaker counter-rotating cell in the midlatitude (sometimes called the Ferrel cell), and finally an even weaker cell near the pole with the same direction of rotation as the Hadley cell [28]. Distinct differences between this pattern and that observed in Earth's atmosphere is that the equatorial cell extends to higher latitude than the Hadley cell of the atmosphere, and the middle cell does not extend to the inner sphere as does the corresponding cell of the atmosphere. However, as the differential heating ΔT is increased further, the middle cell does extend to the inner surface. The azimuthal velocity u is also similar to the azimuthally averaged azimuthal velocity observed in Earth's atmosphere, except that in the atmosphere the jet stream occurs at a somewhat lower latitude, and the negative velocity near the surface does not extend as far from the equator [28]. It is found that this solution is linearly stable to all axisymmetric and nonaxisymmetric perturbations considered, although stability to nonaxisymmetric perturbations is lost as the differential heating ΔT is increased.

It is of particular interest that, although there is clearly a transition in the flow pattern as ΔT is increased, there is no point at which the solution is neutrally stable; i.e., no eigenvalue crosses the imaginary axis. This is not entirely unexpected. Other studies in which flow transitions in systems with a lack of symmetry were investigated have revealed such behavior; for example, see [7, 23, 15, 29, 27]. Although such transitions have been observed in the absence of a corresponding nearby bifurcation (e.g., [7, 23]), they may be induced by a broken pitchfork bifurcation or a perturbed hysteresis bifurcation (see below). Therefore, we search for such a mechanism.

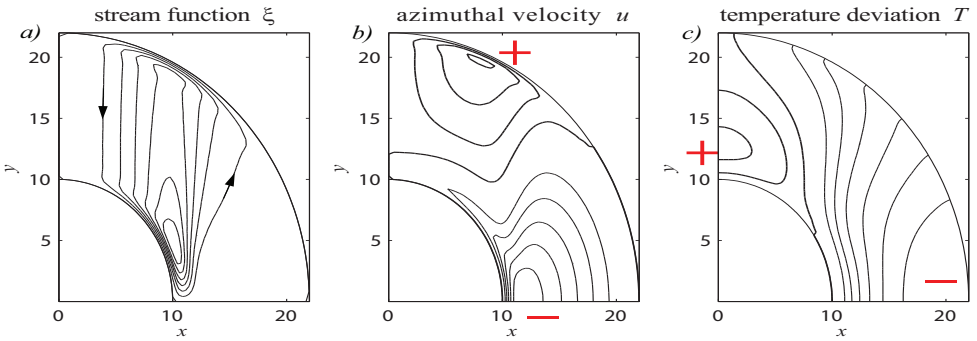

Figure 4. *An example of a single-cell circulation pattern observed for heating parameter* $\Delta T = 0.014$*, gap width* $R = 12$*, and rotation rate* $\Omega = 0.1$*.* (a) *The stream function* ξ*—the flow tends to follow the contours;* (b) *the azimuthal (or zonal) velocity* u*; and* (c) *the temperature deviation* T *from the temperature prescribed on the lower boundary.*

Although our full system has $SO(2) \times \mathbb{Z}_2$ symmetry, we are looking for solutions that preserve this symmetry, so we have used the symmetry to simplify the equations for u, ξ, and T. The simplified equations possess none of these symmetries. The symmetries of a system determine the types of bifurcation that are likely to occur, i.e., which types are generic for the system. For equations with no symmetry, saddle-node and Hopf bifurcations are generic and are expected to be observed if a real eigenvalue crosses through zero or a complex pair of eigenvalues crosses the imaginary axis, respectively, as a single parameter is varied.

The presence of a saddle-node bifurcation in itself cannot explain the observed transition, which occurs without a zero eigenvalue. However, such a transition may occur near an organizing center or bifurcation of codimension 2. This implies that it will be necessary to vary a second parameter to find it. The types of codimension-2 bifurcation points that could occur generically in a system like ours are the broken pitchfork bifurcation [9, 15, 29] and the hysteresis (or cusp) bifurcation [27] as described above and in [9, 16].

In order to clarify the origin of the observed transition, it is useful to explore the solutions at larger gap width and rate of rotation. If the gap width is increased to $R = 12$ and the rotation rate to $\Omega = 0.1$, then, when the heating ΔT is small enough, the linearly stable one-cell pattern is maintained, with a slight distortion of the stream function near the outer boundary and an increase in the retrograde velocity near the equator. An example is plotted in Figure 4. As the heating parameter ΔT is increased, there is a transition to a two-cell pattern (Figure 5), and again this transition occurs without an eigenvalue corresponding to an axisymmetric eigenfunction crossing the imaginary axis.

It is observed that as the gap width R and the rotation rate Ω are increased, the steady solutions become less stable to nonaxisymmetric perturbations. As a result, although this two-cell pattern is stable to axisymmetric perturbations, it is linearly unstable to nonaxisymmetric perturbations. The loss of stability to the nonaxisymmetric perturbations occurs as a Hopf bifurcation, and thus the bifurcating solution is expected to be a rotating wave with azimuthal wave number m. This implies that this two-cell solution will not be physically observable directly. However, because the loss of stability occurs near the one-cell to two-cell transition, it is possible that the rotating wave will inherit the θ and r dependence of the two-cell solution;

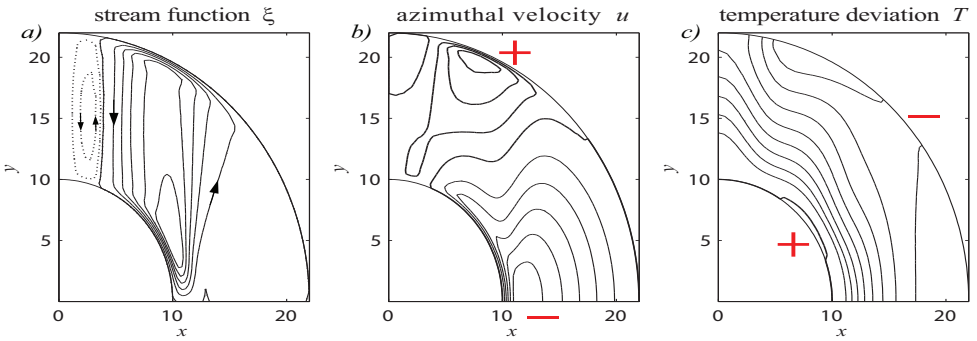

Figure 5. *An example of a two-cell circulation pattern observed for heating parameter $\Delta T = 0.016$, gap width $R = 12$, and rotation rate $\Omega = 0.1$.* (a) *The stream function ξ—the flow tends to follow the contours;* (b) *the azimuthal (or zonal) velocity u; and* (c) *the temperature deviation T from the temperature prescribed on the lower boundary. In* (a)*, the dashed lines represent contours at* 1/5 *of the value of the solid contours.*

i.e., an azimuthal average of the rotating wave will have a two-cell structure. We do not show this here, as it is secondary to our purpose for presenting this example. Regardless of the stability with respect to nonaxisymmetric perturbations, the two-cell pattern is a linearly stable solution of the axisymmetric equations, and it forms in qualitatively the same manner as the transition that is observed at lower R and Ω (see below for further discussion). Thus, an investigation of the transition to this flow, in the axisymmetric equations, will provide a mechanism for the transition. Below we consider solutions and stability only with respect to the axisymmetric equations.

As mentioned above, the transition at $R = 12$ and $\Omega = 0.1$ occurs without an eigenvalue corresponding to an axisymmetric eigenfunction crossing the imaginary axis. Because the eigenvalue with largest real part is real, this implies that there is no parameter value at which there is a zero eigenvalue. In Figure 6, we plot the real value of the (axisymmetric) eigenvalue with largest real part as a function of the heating parameter ΔT, and we plot a "bifurcation diagram" that indicates how the solutions change as ΔT changes, where the vertical axis is the L^2-norm of the stream function ξ. In the figure it can be seen that as the heating parameter ΔT increases, the value of the eigenvalue increases until it reaches a maximum that is negative, at which point it begins to decrease without ever reaching zero. Heuristically, it is observed that the development of the two-cell pattern begins to occur near this maximum.

If the gap width is increased to $R = 16.2$, then for small values of ΔT a linearly stable one-cell pattern is again observed; see Figure 7. A gap width of $R = 16.2$ corresponds to an aspect ratio $\eta = R/r_a = 1.35$. Although we are not necessarily interested in flows at large aspect ratio, they will help to explain the transition that is observed for smaller gap width.

As we increase the differential heating ΔT, again we see a transition from the one-cell to a two-cell pattern, shown in Figure 8. However, in this case, a real eigenvalue does cross the imaginary axis. In Figure 9, we plot both the real part of the eigenvalue with largest real part, as a function of ΔT, and the corresponding bifurcation diagram. The crossing of the imaginary axis by a real eigenvalue corresponds to a saddle-node bifurcation, also referred to as a limit point or fold. As the solution curve is followed past the bifurcation point, the solution becomes linearly unstable, and the value of ΔT begins to decrease. For a short interval,

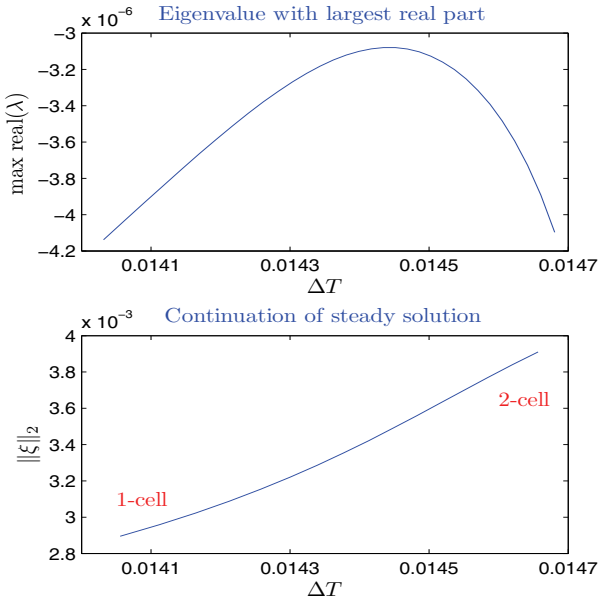

Figure 6. *Results for $R = 12$, $\Omega = 0.1$. (top) Real part of eigenvalue with largest real part versus ΔT, and (bottom) bifurcation diagram in ΔT; the vertical axis represents the L^2-norm of the stream function ξ.*

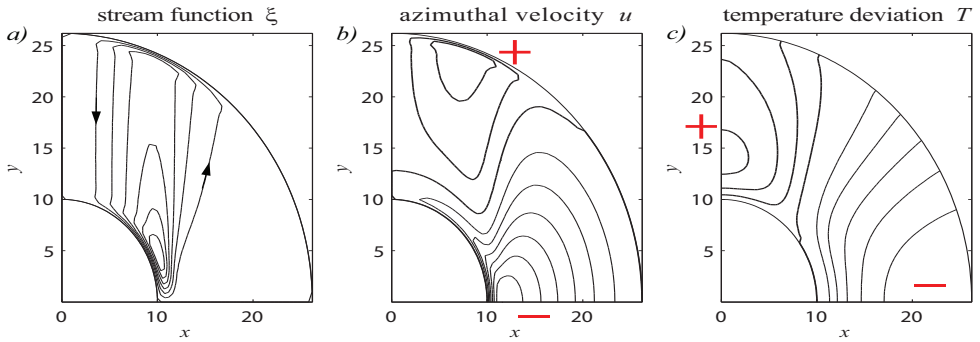

Figure 7. *An example of a single-cell circulation pattern observed for heating parameter $\Delta T = 0.013$, gap width $R = 16.2$, and rotation rate $\Omega = 0.1$.* (a) *The stream function ξ—the flow tends to follow the contours;* (b) *the azimuthal (or zonal) velocity u; and* (c) *the temperature deviation T from the temperature prescribed on the lower boundary.*

the real eigenvalue increases until it reaches a maximum, after which it begins to decrease. Subsequently, it again crosses the imaginary axis, and a second saddle-node bifurcation is observed. As we follow the curve past this point, the solution returns to being linearly stable, and ΔT once again begins to increase. This pair of saddle-node bifurcations results in an S-shaped bifurcation diagram. As we follow the solution curve, from the lower part of the S to the upper part of the S, the real part of the eigenvalue with largest real part traces out the loop seen in Figure 9. This form of solution curve results in a classical mechanism for hysteresis, as seen in the hysteresis loop shown in Figure 1.

6. Hysteresis bifurcation. The behavior observed in Figures 6 and 9 is indicative of a hysteresis (or cusp) bifurcation point. The typical behavior of a nonlinear system near a hysteresis point is as shown in Figure 1. It can be expected that at some critical value of the gap width $R = R_c$ a one-dimensional bifurcation diagram in ΔT will have a single vertical tangent, with slopes on either side being positive. For values of $R < R_c$ we expect no bifurcations as ΔT is increased (as in Figure 6), while for $R > R_c$ we expect a pair of saddle-node bifurcations (as in Figure 9). This behavior can be seen in Figure 1, where these different one-dimensional bifurcation diagrams in ΔT may be obtained as slices through M, taken with different values of constant R. Mathematically, a hysteresis or cusp bifurcation

point is determined by the following three conditions [16]:

1. There exists a steady solution.
2. There is a simple zero eigenvalue of the linearization of the equations about the steady solution.
3. The coefficient of the second order term of the normal form equations on the center manifold vanishes.

Therefore, in order to demonstrate that the observed behavior is indeed generated by a hysteresis bifurcation, it is necessary to show that each of the above three conditions is satisfied. Although it may seem that this would be a daunting task, in fact these conditions can be verified by an explicit calculation that can be performed numerically as follows; see [10, 16]. To elucidate these conditions and the means that we use to compute the hysteresis point, we write the equations for ξ, u, and T in the abstract form:

$$\dot{U} = LU + N(U,U), \tag{6.1}$$

where

$$U = \begin{pmatrix} \xi \\ u \\ T \end{pmatrix}$$

is the dependent variable, L is the linear operator such that LU is the linear part of the equations, $N(U,U)$ is the nonlinear part of the equations, and the dot represents differentiation with respect to time. Note that the nonlinear part N has only quadratic terms (from the Navier–Stokes equation), and thus we may write it in the bilinear form $N(U,U)$.

Assume that for some critical values of the parameters $(\Delta T, R) = (\Delta T_c, R_c)$ there is a steady solution U_0 of (6.1); i.e., U_0 satisfies

$$LU_0 + N(U_0,U_0) = 0. \tag{6.2}$$

Assume also that at $(\Delta T, R) = (\Delta T_c, R_c)$ the linearization L_0 about the steady solution U_0 has a simple zero eigenvalue $\lambda_0 = 0$, while all other eigenvalues have negative real part, where L_0 is given by

$$L_0 V = LV + N(V,U_0) + N(U_0,V). \tag{6.3}$$

That is, we have

$$L_0 \Psi = 0, \tag{6.4}$$

where Ψ is the eigenfunction corresponding to the zero eigenvalue.

Under certain conditions on L_0, the dependent variable U can be written in the form

$$U = w\Psi + \Phi, \tag{6.5}$$

where $w \in \mathbb{R}$ and thus $w\Psi \in \operatorname{span}\{\Psi\}$, and $\Phi \in E_s$. Here E_s is called the stable subspace and is the space spanned by all eigenfunctions corresponding to eigenvalues with negative real part.

If we write U as in (6.5), then under certain technical conditions a center manifold and normal form reduction can be performed on (6.1) to obtain the equation on the center manifold in normal form

$$\dot{w} = \beta_1 + \beta_2 w + a w^2 + c w^3 + O(w^4), \tag{6.6}$$

where a and c are coefficients of the normal form and β_1 and β_2 are unfolding parameters that are in general functions of the parameters ΔT and R. It can be shown that if $c \neq 0$, then neglecting the terms of $O(w^4)$ does not change the qualitative features of the solutions.

The center manifold and normal form theories state that for $(\Delta T, R)$ near $(\Delta T_c, R_c)$ and when the solutions are in some sense small, the dynamics of (6.1) can be deduced from (6.6). In particular, solutions of (6.6) are in one-to-one correspondence with those of (6.1).

Formulas for the coefficients of the normal form equation can be derived by performing a center manifold and normal form reduction in the general case [10, 16]. In particular, the coefficient of the second order term is given by

$$a = 1/2 \left\langle \Psi^*, N(\Psi, \Psi) \right\rangle, \tag{6.7}$$

where Ψ is the eigenfunction corresponding to λ_0, Ψ^* is the corresponding adjoint eigenfunction corresponding to λ_0, and

$$\langle U, V \rangle = \iint U \cdot V d\mathbf{r} \tag{6.8}$$

is the inner product on the domain.

For $a = 0$, a hysteresis bifurcation occurs when $\beta_1 = \beta_2 = 0$. For $\beta_2/c > 0$, there is a single solution to (6.6) for all β_1. For $\beta_2/c < 0$, there is a region in the two-dimensional parameter space (β_1, β_2) in which there are three solutions. The borders of this region are given asymptotically by the two curves

$$\beta_1 = \pm \frac{2}{3} \sqrt{\frac{-\beta_2}{c}} \beta_2. \tag{6.9}$$

As β_2 approaches zero, these two curves approach each other and meet in a cusp at $\beta_1 = \beta_2 = 0$. This is the origin of the name "cusp bifurcation."

In order to show that a hysteresis or cusp bifurcation occurs in the model, we need to show that the three aforementioned conditions are satisfied. That is, we must find parameter values $(\Delta T, R) = (\Delta T_c, R_c)$ such that the following three equations are satisfied:

$$L U_0 + N(U_0, U_0) = 0, \tag{6.10}$$

$$L_0 V = 0, \qquad \langle V, V \rangle = 1, \tag{6.11}$$

$$a = 1/2 \left\langle \Psi^*, N(\Psi, \Psi) \right\rangle = 0, \tag{6.12}$$

where L_0 is given by (6.3).

These equations have the unfortunate property that for some values of $\Delta T \neq \Delta T_c$, $R \neq R_c$, L_0 will not be singular, and thus (6.11) will not have a solution for any V. Therefore, it will

be convenient to use the following defining system [10]:

$$LU_0 + N(U_0, U_0) = 0, \tag{6.13}$$

$$g = 0, \tag{6.14}$$

$$g' = 0, \tag{6.15}$$

where g and g' are scalars given by

$$L_0 V + gB = 0, \qquad \langle C, V\rangle = 1, \tag{6.16}$$

$$L_0 V' + g'B = -N(V, V), \qquad \langle C, V'\rangle = 0, \tag{6.17}$$

and where B is not in the range of L_0, and C is not in the range of the adjoint operator L_0^*, which is defined by

$$\langle L_0 U, V\rangle = \langle U, L_0^* V\rangle$$

for all U and V.

Each of the three equations (6.13)–(6.15) corresponds to one of the hysteresis point defining conditions. Specifically, U_0 is a steady solution of (6.1) when (6.13) is satisfied. If we set $g = 0$ in (6.16) and there is a solution, then L_0 has a zero eigenvalue with corresponding eigenfunction V. Thus, the second hysteresis condition is satisfied when (6.14) is satisfied. In this case, when L_0 is not singular, there will still be a solution of (6.16), namely one for which $g \neq 0$. This is assured by choosing B not in the range of L_0. If we set $g' = 0$ in (6.17), and there is a solution, then we have that $N(V, V)$ must be in the range of L_0. If we also have $g = 0$, then from above we have that V is the eigenfunction of L_0 with zero eigenvalue; i.e., $V = \Psi$. Thus, if $N(V, V)$ is in the range of L_0, then, by the "Fredholm alternative" property of the adjoint, $N(V, V)$ must be orthogonal to the eigenfunction of L_0^* corresponding to the zero eigenvalue; i.e., we must have $\langle \Psi^*, N(\Psi, \Psi)\rangle = 0$, and thus the second order coefficient of the normal form vanishes. When L_0 is nonsingular, (6.17) has a solution regardless of g'. However, there is also the possibility that close to the cusp there are parameter values such that L_0 is singular, while $N(V, V)$ is not in the range of L_0; this occurs at the saddle-node bifurcations. Thus, there will be no solution of (6.17) for $g' = 0$. However, because B is not in the range of L_0, we are assured a solution with $g' \neq 0$.

In order to make the equations linear in V and V', we can choose the normalization conditions as shown. Solutions are assured when C is chosen to be not in the range of the adjoint operator L_0^*. In practice, because the kernel of L_0 is only one-dimensional, it is easy to choose B and C with the required properties.

It can be proved that when the system (6.13)–(6.15) has a solution, then not only is the nondegeneracy condition for a cusp bifurcation satisfied, but also the transversality condition [10]. Thus, we are assured that we have found a cusp bifurcation.

Upon discretization of (6.13)–(6.15) and (6.16)–(6.17) on an $N \times N$ grid, we obtain a system of nonlinear algebraic equations. For various values of N, we find that there are critical parameter values $(\Delta T, R) = (\Delta T_c, R_c)$ such that there are a U_0, g, and g' that satisfy the discretized system. Results are listed in Table 2. Although for small N it appears that we are not in the asymptotic range, the results for a higher value of N provide evidence of

Table 2

Critical parameter values at which the hysteresis bifurcation occurs, for various values of N. The results provide evidence of convergence.

N	ΔT	R
40	0.0143	16.0
80	0.0155	24.2
120	0.0163	27.8
160	0.0165	28.0

convergence. The large variation in R between the results at $N = 40$ and $N = 80$ is possibly caused by the nonlinear dependence of the equations on R; see (2.9)–(2.13). In particular, for large R, we expect that a large change in R is required to produce even a small change in behavior of the solutions. This could also be an indication that the boundary layers are not resolved sufficiently at low resolution to put us in the asymptotic range of the convergence. Regardless, the results provide evidence that a hysteresis bifurcation does in fact exist in the model with cusp point $(\Delta T_c, R_c) \approx (0.017, 28)$, and thus the lower resolution captures the correct qualitative behavior.

There is strong evidence that the transition from the one-cell to the two-cell pattern, which is observed at gap width $R = 12$ as the differential heating ΔT is increased, is associated with this cusp bifurcation. We also postulate that the transition from the one-cell to the three-cell pattern, which is observed at gap width $R = 3.4$ as the differential heating ΔT is increased, not only is the same mechanism, but is associated with the same bifurcation. This is evident if we consider the transition from the one-cell pattern for a sequence of gap widths R and rotation rates Ω that decrease from $R = 12$, $\Omega = 0.1$ to $R = 3.4$, $\Omega = 0.01$. For all transitions in this sequence, regardless of whether the transition results in a two-cell or three-cell pattern, the eigenvalue with largest real part behaves in the same manner (as shown in Figure 6) with only small quantitative changes. Furthermore, in all cases, the stream function component of the eigenfunctions corresponding to the eigenvalue with largest real part has a two-cell structure. The azimuthal velocity component of the eigenfunctions also shows little variation. There is nothing to indicate that there is another bifurcation that is taking place. That is, all solutions discussed above lie on a single solution manifold that is folded at the cusp point; see the manifold M in Figure 1. In [27], such a manifold is shown to connect qualitatively different solutions in a model of rotating convection in a cylinder with centrifugal buoyancy.

Furthermore, there is a smooth variation of the qualitative behavior as R is varied. For large R, the transition from a one-cell to two-cell pattern begins with a flattening of the stream function ξ near the pole, corresponding to a decrease in fluid velocity in this region, and is followed by the formation of the counter-rotating cell near the pole. The new cell is first observed as a small cell adjacent to the pole and grows as the differential heating ΔT is increased. Changes in the rotation rate Ω affect the stability of the solution to nonaxisymmetric perturbations but do not affect the qualitative features of the transition, and therefore, here, we refer only to changes in gap width R. If R is decreased, the flattening becomes more pronounced before the second cell is observed. When the cell is observed, it grows more quickly with ΔT than when the gap width is larger. If the differential heating is increased sufficiently, a transition from the two-cell pattern to a three-cell pattern is observed. For a

yet smaller gap width (e.g., $R = 3.4$), again the transition begins with a flattening. However, in this case, the second cell does not first appear adjacent to the pole but peeks out a small distance from the pole. This transitional stage is not in essence a two-cell pattern, because between the new cell and the pole there is a very weak (almost quiescent) region in which the fluid rotates in the same sense as the large cell near the equator.

The development of the two-cell pattern is easily explained in terms of the lowest order dynamics of the cusp bifurcation. To lowest order, the solution U to the perturbation equations will be given by $w\Psi$, where $w \in \mathbb{R}$ and Ψ is the eigenfunction corresponding to the eigenvalue with largest real part; see (6.5). Thus, to first order, the solution to the axisymmetric equations will be $w\Psi$ plus the solution about which we have linearized, i.e., the one-cell solution. Thus, because the stream function component of the eigenfunction Ψ has a two-cell structure, we expect that, to lowest order, the solution will also develop a two-cell structure. The development of the three-cell pattern in this context is not as easily explained. However, it may be possible that insight could be gained from a higher order computation.

We have already pointed out that the variation of the rotation rate Ω has relatively smaller qualitative effect on the solutions of the axisymmetric equations. Indeed, a cusp is observed if the rotation is held fixed at $\Omega = 0.01$ and only the gap width R is increased. We choose not to present this example because, in this case, an additional saddle-node bifurcation occurs at values of the differential heating slightly larger than where the cusp is observed. As the rotation rate is increased, this bifurcation moves further away from the cusp, and thus the example for $\Omega = 0.1$ more clearly indicates the origin of the observed transitions.

7. Discussion and conclusions. This work has shown that a Boussinesq fluid in a rotating spherical shell, differentially heated on its inner surface, can exhibit a variety of stable rotationally symmetric flow patterns. Distinctive features of these flow patterns include a Hadley cell with a flow pattern much like the Hadley cells of Earth, and a high azimuthal velocity jet stream located at high altitudes and midlatitudes, much like the jet stream in each hemisphere of Earth. For small values of the differential heating parameter $\Delta T > 0$, the Hadley cell exists and extends from equator to pole. For larger values of ΔT, first one then two or more additional convection cells may form between the Hadley cell and the pole in the mid- and polar latitudes. The first cell to form after the Hadley cell exhibits counter-rotating flow (westerly winds near the inner surface), and the third cell has Hadley-like rotation (easterly winds near the polar surface). The observed transitions are distinctly related to the spherical geometry of the system. This is evident because, in all models of differentially heated fluids in domains with cylindrical geometry, such transitions that do not break the rotational symmetry occur only at very high differential heating.

The features of the transitions are not affected by moderate changes in the rate of rotation Ω, although the solutions become less stable to nonaxisymmetric perturbations as Ω is increased. However, changes in the gap width R can induce significant changes. Mathematical analysis of the axisymmetric model demonstrates that it possesses a codimension-2 hysteresis (or cusp) bifurcation for a critical choice of the parameters $(R, \Delta T) = (R_c, \Delta T_c)$. In a neighborhood of this hysteresis point, for larger R, there exists a region of bistability in which two different states of the system are both linearly stable solutions of the axisymmetric equations. These two stable states are separated by a third unstable state. For such R (fixed), there exists an interval of values of ΔT exhibiting a hysteresis loop, as illustrated in Figure 1.

At each end of this interval, a small change in ΔT can cause a transition in the state of the system, to a qualitatively different flow pattern, e.g., one with a different number of convection cells.

The results of this paper lead to more questions than answers and will form the basis of much future work. In the model, changes in the Hadley cell have no influence on the temperature difference parameter ΔT. This is not the case in a real planetary system, where convection cells are known to act as "thermal conveyor belts." In the case of small ΔT and a large Hadley cell extending from equator to pole, this conveyor belt would have the effect of warming the polar region and cooling the equatorial region, thus *reducing* the temperature difference ΔT. This can be seen in the temperature deviation plots of Figures 2 and 4, in which the gradient of the temperature deviation is essentially opposite to the imposed differential heating. Therefore, the thermal conveyor belt function of a large Hadley cell enhances its persistence. On the other hand, if ΔT increases (for some other reason) to a value where the single Hadley cell is replaced by multiple cells, this would curtail the thermal conveyor belt acting from equator to pole. As a result, the polar regions would cool relative to the equatorial regions and ΔT would increase, pushing the system further to the right along the bifurcation curve. We conjecture that this feedback mechanism, from the convection cell flow back to the temperature difference ΔT, is present in real planetary atmospheres and implies a modification of the predictions of our model. The effect is most easily stated with reference to Figure 1: the interval of bistability in ΔT would lengthen and the cusp point would move to smaller values of R. In other words, the net effect of this thermal feedback would be to increase both the likelihood and the amplitude of the hysteresis behavior demonstrated in the model.

In addition, the model should be reconsidered to take into account the fact that the atmosphere of the earth is a strongly stratified compressible fluid, with properties very different from water. The vertical motion of a strongly stratified fluid is inhibited, thus causing an elongation (in θ) of the cells. The cells in a Boussinesq fluid typically have an aspect ratio close to 1, which implies that R must be rather large in order to see only three cells. In a strongly stratified fluid, a much smaller R (for a similar ΔT) would be sufficient to see a similar number of cells. Therefore, we predict that the phenomena exhibited in this model could exist in the atmosphere of a planet such as Earth, but for much smaller aspect ratios R/r_a. Thus, both the thermal feedback and the stratified fluid properties of real atmospheres, which have been neglected in this simple model, can be expected to amplify rather than inhibit the hysteresis mechanism demonstrated for the model.

In further work the model could be extended to physical dimensions on the scale of a planet such as Earth. Another future goal is an analysis of the nonaxisymmetric bifurcations that would lead to rotating waves, as well as analyses of spherical shell models that break the north-south reflectional symmetry or satisfy different boundary conditions.

Stable Synchrony in Globally Coupled Integrate-and-Fire Oscillators*

Yu-Chuan Chang† and Jonq Juang†

Abstract. A model of integrate-and-fire oscillators is studied. In the special case of identical oscillators, the model was first proposed and analyzed by Mirollo and Strogatz [*SIAM J. Appl. Math.*, 50 (1990), pp. 1645–1662]. We assume, as in Mirollo and Strogatz's model, that each oscillator x_i evolves according to a map f_i. Our main results are to demonstrate that the concavity structure of f_i plays an important role in determining whether Peskin's second conjecture holds true. Specifically, the following statements are proved. First, the system of convex oscillators (i.e., $f_i'' < 0$ for all i), in general, synchronizes when the oscillators are not quite identical. Second, the system of a certain class of concave oscillators (i.e., $f_i'' > 0$ for all i) will not achieve synchrony for initial conditions in a set of positive measure when the oscillators are nearly identical. Third, the system of concave oscillators may achieve synchrony under certain sufficient conditions, provided that the oscillators are not quite nonidentical and that its concavity is small.

Key words. stable synchrony, nonidentical oscillators, integrate-and-fire, concavity

1. Introduction.

Large assemblies of oscillator units can spontaneously evolve to a state of large scale organization. Synchronization is the best known phenomenon of this kind, where after some transient regime a coherent oscillatory activity of the set of oscillators emerges. This interesting phenomenon is quite common in many different disciplines such as engineering [62], physics [15, 35, 51], chemistry [36], as well as biology [61]. For example, in southeastern fireflies, thousands of individuals gathered on trees may flash in unison. Other examples of biological oscillators are the rhythmic activity of cells of the heart pacemaker [29, 40, 43, 55], of cells of the pancreas [48, 49], and of neural networks [9, 13, 20, 43, 45, 50]. Synchronization of oscillators has been studied in both phase-coupled models [3, 4, 5, 6, 11, 16, 17, 18, 19, 30, 33, 37, 38, 39, 42, 44, 52, 53, 55, 56, 57, 60, 58, 63], where the interaction between the oscillators is smooth and continuous in time, and pulse-coupled models [1, 7, 10, 12, 23, 24, 25, 27, 28, 31, 32, 36, 41, 46, 47, 57, 59], where the membrane voltage is discontinuously reset to a fixed value once it reaches a certain threshold. It should be noted that pulse-coupled models are of greater relevance for neuroscience applications since synaptic coupling is often spike mediated.

This paper deals with a population of integrate-and-fire oscillators with all-to-all pulse coupling. We begin with describing Peskin's model of n integrate-and-fire oscillators. Let the state of the ith oscillator be denoted by x_i, where x_i are subject to the dynamics $\frac{dx_i}{dt} =$

$-r_i x_i + I_i$, $0 \le x_i \le 1$, $i = 1, 2, \ldots, n$, with input $I_i > 0$, a normalized threshold 1, and leakiness $r_i \ge 0$. When $x_i = 1$, the ith oscillator fires and x_i jumps back to zero. As a consequence of the firing of the ith oscillator, the activation of any other oscillator j is incremented by the coupling $\omega_{i,j}$. Should no confusion arise, we write $\omega_{i,j}$ as ω_{ij}. This model was later generalized by Mirollo and Strogatz [41]. It was assumed that the state variable x_i evolves according to a map f_i. When x_i reaches the threshold, the oscillator fires and x_i jumps back instantly to zero, and the activation of any other oscillator j is incremented by the positive coupling ω_{ji}. Specifically, x_i evolve according to $x_i = f_i(\phi_i)$, where $f_i : [0,1] \to [0,1]$ is smooth and strictly increasing, i.e., $f_i' > 0$ on $(0,1)$. Here ϕ_i is a phase variable so that (i) $\frac{d\phi_i}{dt} = \frac{1}{T_i}$, where T_i is the cycle period for oscillator x_i when evolving freely; (ii) $\phi_i = 0$ when the oscillator is at its lowest state $x_i = 0$; and (iii) $\phi_i \equiv 1$ at the end of cycle when the oscillator reaches the threshold $x_i = 1$. Therefore, f_i satisfy $f_i(0) = 0$, $f_i(1) = 1$. These maps f_i are to be called evolution maps. The inverses of f_i are to be denoted by g_i. If $f_i \equiv f$, $T_i \equiv T$, and $\omega_{ij} \equiv \omega$ for all i, j, then the corresponding system is called identical. Otherwise, it is called nonidentical. To describe the dynamics of the model, let $\Phi^0 = (\phi_1^0, \phi_2^0, \ldots, \phi_n^0) \in \mathbb{R}^n$ be the initial condition of the oscillators. Here $0 = \phi_1^0 \le \phi_2^0 \le \cdots \le \phi_n^0 < 1$. Further, $\Phi^k = (\phi_{k_1}^k, \phi_{k_2}^k, \ldots, \phi_{k_n}^k)$, where $0 = \phi_{k_1}^k \le \phi_{k_2}^k \le \cdots \le \phi_{k_n}^k < 1$, is the state of n oscillators after the kth firing. Denote by $V_k(\Phi^0)$ the set of the indexes of oscillators reaching threshold simultaneously and thus firing the kth time at the same instance. After the $(k-1)$th firing, there will be at least one oscillator ready to fire at the next instance. Such an index set $V_k(\Phi^0)$ of the next firing oscillators is called the trigger set with respect to the initial condition Φ^0 at the kth stage. Let $U_k(\Phi^0)$ be the index set of oscillators which reach the threshold at the kth stage. Note that $U_k(\Phi^0) \supset V_k(\Phi^0)$. Hence, $U_k(\Phi^0)$ may contain the index of the oscillators which reach the threshold after receiving activations from other oscillators in $V_k(\Phi^0)$. Such a set $U_k(\Phi^0)$ is to be termed the spike set with respect to the initial condition Φ^0 at the kth stage. The terms for sets U_k and V_k were first used in [57]. Should no confusion arise, we shall write $V_k(\Phi^0)$ and $U_k(\Phi^0)$ as V_k and U_k, respectively. Immediately after the first firing, the resulting state $\Phi^1 = (\phi_{1_1}^1, \phi_{1_2}^1, \ldots, \phi_{1_n}^1)$, $0 = \phi_{1_1}^1 \le \phi_{1_2}^1 \le \cdots \le \phi_{1_n}^1 < 1$, is given by

$$\begin{aligned} \phi_{1_\ell}^1 &= g_{1_\ell}\left(f_{1_\ell}\left(\frac{T_{i_0}}{T_{1_\ell}}(1 - \phi_{i_0}^0) + \phi_{1_\ell}^0 \right) + \sum_{j \in U_1} \omega_{1_\ell, j} \right) \\ &=: g_{1_\ell}(f_{1_\ell}(\delta_{1_\ell}) + \omega_{1_\ell}), \qquad i_0 \in V_1 \text{ and } 1_\ell \in \{1, 2, \ldots, n\} - U_1 =: S_n - U_1. \end{aligned} \tag{1.1}$$

Note that the first firing consists of firings due to some oscillators reaching threshold simultaneously as well as any other oscillators then reaching threshold due to chain reaction of the earlier firings that are infinitesimally apart. All those chains of firings can be lumped into one set of "simultaneously firing" oscillators. The states $\Phi^k = (\phi_{k_1}^k, \phi_{k_2}^k, \ldots, \phi_{k_n}^k)$ of n oscillators after the kth firing can then be defined accordingly. If the cardinality of the spike set U_k, $k = 1, 2, \ldots, n$, is one, then we shall say that the system of n oscillators undergoes one *whole* cycle of firings or no *absorption* occurs for the system of n oscillators within one cycle of firings. For Peskin's model, $f_i(\phi) = \frac{I_i}{r_i}(1 - e^{-r_i T_i \phi})$ and $T_i = \ln(\frac{I_i}{I_i - r_i})/r_i$. Peskin conjectured that, first, for identical oscillators, the system approaches a state in which all oscillators are firing synchronously for almost all initial conditions and that, second, this remains true even when the oscillators are not quite identical. The first part of the conjecture was essentially proved

by Mirollo and Strogatz [41] with convex oscillators (i.e., $f_i'' < 0$). The second part of Peskin's conjecture was verified by Urbanczik and Senn [57] with flat oscillators (i.e., $f_i'' \equiv 0$). The key feature in those proofs relies on the nonconcavity of the evolution functions f_i. However, Bottani [8] numerically showed that even concave oscillators (i.e., $f_i'' > 0$) can synchronize, provided that the concavity is not too large. The purpose of this paper is two-fold. First, we prove the second part of Peskin's conjecture for the system of convex oscillators. Second, we prove Bottani's numerical results and more. Specifically, we shall show that for the system of n "identical" concave oscillators, no synchronization occurs for initial values in a set of positive measure, provided that $n = 3$ or n is even or phase responding curve $h(x) = g(f(x) + \omega)$ is concave upward. That is to say, in general, concave oscillators may synchronize for almost all initial conditions only if the concavity of the evolution maps is small. Indeed, we prove that the imbalance between the speeds and/or coupling strengths of the oscillators induces the synchronization of the system, provided that the concavity of the evolution maps is sufficiently small.

Since the work of Mirollo and Strogatz, current research into pulse-coupled or integrate-and-fire oscillators has become motivated by more elaborate questions (see, e.g., [25, 32, 47]). There have been many papers [7, 13, 25, 26, 39, 45, 46, 47] discussing those more advanced and complicated models. Some progress has also been made for more realistic biophysical models such as oscillators subject to small noise [36], constant delays [21], or a finite duration of synaptic response [2, 14, 22, 26].

We conclude this introductory section by mentioning the organization of the paper. Section 2 is devoted to the stability conditions for systems of two or more oscillators. In section 3, we derive the absorption conditions for systems of two or more oscillators. In particular, the necessary and sufficient condition for the absorption of two oscillators is given. This, in turn, provides some insight into the role that concavity of the evolution maps plays in determining the absorption process for systems of more than two oscillators. Some sufficient conditions for the absorption conditions for systems of more than two oscillators are derived. The main results of the paper are also recorded in this section.

2. Stable partial and full synchrony. Before beginning the analysis, we give an intuitive account of the way that synchrony develops as the system evolves: oscillators begin to clump together in "groups" that fire at the same time. For nonidentical oscillators, such groups of oscillators when they reach partial/full synchrony may break up again as the system continues to evolve. Consequently, it is desirable to find *stability conditions* for which a group of oscillators reaching the threshold at the same time will remain coordinated in the future. Such stable partial synchrony then gives rise to a positive feedback process, and thereby tends to grow by "absorbing" other oscillators. Absorptions reduce the number of groups until ultimately only one group remains—at that point the population is synchronized. The scenario above was first pointed out for a different system by Winfree [60], and the phrase "absorption" was coined by Mirollo and Strogatz [41]. With the characteristic of constant speed and equal coupling strengths, the system of identical oscillators always has the stability conditions satisfied. In this section, we shall derive stability conditions. The absorption conditions of the system are to be derived in section 3.

Unless otherwise stated, throughout this paper, the system of oscillators under consideration is either one of two types: convex or concave oscillators.

2.1. Stability conditions for two oscillators. We begin with the study of the system of two oscillators, which provides some insight as to why the system may or may not synchronize. The stability condition for two oscillators is to be derived in this subsection. To this end, we first need certain common properties shared by f and its inverse g.

Lemma 2.1. *Let $h_i : [0,1] \to [0,1]$ be smooth and strictly increasing maps with $h_i(0) = 0$ and $h_i(1) = 1$. Moreover, we assume that h_i have no inflection points and that $\lim_{x\to 0^+} xh_i'(1-x) = 0$ and $\lim_{x\to 0^+} xh_i'(x) = 0$. For each i, let two points, $A = (a_1, a_2)$ and $B = (b_1, b_2)$, be on $y = h_i(x)$ with $b_1 - a_1 \geq \omega_{\min}$. Here $\omega_{\min}$, the minimum of coupling strength, is defined to be*

$$\omega_{\min} = \min_{i,j} \omega_{ij}. \tag{2.1a}$$

Let m_h and M_h be, respectively, the minimum and maximum slope of the secant to h_i with the difference in x being at least $\omega_{\min}$. They are, respectively, defined as follows:

$$m_h = \min_i \left\{ \min \left\{ \frac{h_i(\omega_{\min})}{\omega_{\min}}, \frac{1 - h_i(1-\omega_{\min})}{\omega_{\min}} \right\} \right\} \tag{2.1b}$$

and

$$M_h = \max_i \left\{ \max \left\{ \frac{h_i(\omega_{\min})}{\omega_{\min}}, \frac{1 - h_i(1-\omega_{\min})}{\omega_{\min}} \right\} \right\}. \tag{2.1c}$$

Then

$$M_h \geq \frac{h_i(b_1) - h_i(a_1)}{b_1 - a_1} \geq m_h, \qquad m_h \leq 1 \text{ and } M_h \geq 1. \tag{2.2}$$

The equalities hold only if $b_1 - a_1 = \omega_{\min}$ and $a_1 = 0$ or $b_1 = 1$.

Proof. We illustrate only the case that $h_i''(x) > 0$ on $(0,1)$. Clearly, $\frac{h_i(a+x)-h_i(a)}{x} \geq \frac{h_i(x)}{x}$ for any $a \geq 0$, $x > 0$, and $1 \geq a + x \geq 0$. Moreover, $\frac{h_i(x)}{x}$ is increasing and bounded above by 1, and $\frac{1-h_i(1-x)}{x}$ is decreasing and bounded below by 1. Consequently, $M_h \geq \frac{1-h_i(1-\omega_{\min})}{\omega_{\min}} \geq \frac{h_i(b_1)-h_i(a_1)}{b_1-a_1} \geq \frac{h_i(\omega_{\min})}{\omega_{\min}} \geq m_h$. ∎

Remark 2.1.

1. *The geometric and physical meanings of m_h and M_h can be roughly interpreted as follows. Let the difference of two points in the vertical axis be the sum $\sum \omega_{ij}$ of certain coupling strengths due to the firings of certain oscillators; then the resulting difference in h is no smaller than $m_h \sum \omega_{ij}$ and no better than $M_h \sum \omega_{ij}$. See Figure 1.*
2. *Let $\omega_{\max} = \max_{i,j} \omega_{ij}$. An immediate application to Lemma 2.1 and Remark 2.1.1 is the following interpretation of the meaning of the quantities $M_g\omega_{\max}$ and $m_g\omega_{\min}$.*
   (a) *If an oscillator is within the distance $m_g\omega_{\min}$ of the threshold, then it will reach the threshold whenever it receives an activation jump due to the firings of other oscillators. On the other hand, if an oscillator is at least $M_g\omega_{\max}$ away from the threshold, then it will not reach the threshold whenever it receives an activation jump due to a single firing of another oscillator.*

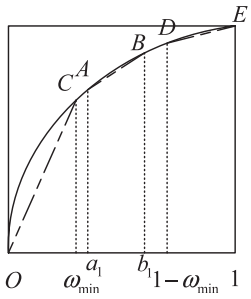

Figure 1. *Points O, C, A, B, D, and E are on a convex map $y = h(x)$. In this situation, $m_{\overline{OC}}$ is defined as the slope of $\overline{OC} = M_h$ and $m_{\overline{DE}} = m_h$. The assertions of Lemma 2.1 can easily be seen from the figure.*

(b) *If the ith oscillator has just received an impulse of strength ω_{ij} at x from the jth oscillator, then its phase jump, $g_i(f_i(x)+\omega_{ij})-x$, is at least $m_g\omega_{\min}$ and at most $M_g\omega_{\max}$ away from the origin.*

Theorem 2.2. *Let*

$$t_{\max} = \max_{i,j} \frac{T_i}{T_j}, \quad \Delta T = t_{\max} - 1, \quad \text{and} \quad \omega_{\min} = \min_{i,j} \omega_{ij}. \tag{2.3}$$

Suppose that f_i satisfy the same assumption as those maps h_i in Lemma 2.1. Let

$$m_g\omega_{\min} \geq \Delta T. \tag{2.4}$$

Then the system of two oscillators is stable.

Proof. Let $\Phi^0 = (\phi_1^0 = 0, \phi_2^0 = 0) \in \mathbb{R}^2$. We may assume that ϕ_2^0 has a greater speed $\frac{1}{T_2}$ and, hence, is the one that first reaches the threshold. Thus, $\phi_1^1 = g_1(f_1(\frac{T_2}{T_1})+\omega_{12})$. Therefore, $\phi_1^1 < 1$ if and only if $\frac{1-g_1(1-\omega_{12})}{\omega_{12}}\omega_{12} < 1 - \frac{T_2}{T_1}$. If $f_i''(x) > 0$, or equivalently, $g_i''(x) < 0$, and (2.4) holds, then we conclude, via (2.2), that $\phi_1^1 \geq 1$. Consequently, the assertion of the theorem holds. Suppose that $f_i''(x) < 0$, or equivalently, $g_i''(x) > 0$, and that (2.4) is satisfied. Then $\frac{1-g_1(1-\omega_{12})}{\omega_{12}}\omega_{12} \geq \frac{g_1(\omega_{12})}{\omega_{12}}\omega_{12} \geq m_g\omega_{\min} \geq \Delta T \geq 1 - \frac{T_2}{T_1}$. We have completed the proof of the theorem. ∎

The quantity ΔT is the phase difference between the fastest and slowest oscillators when evolving freely from their lowest state 0 toward the threshold. Therefore, if (2.4) holds, then two oscillators will remain firing synchronously according to Remark 2.1.2(a). To derive the stability condition and the absorption condition of the system, we make use of Lemma 2.1. From here on, we shall consider only the evolution maps that cannot turn "too" sharply at both ends. That is, the evolution maps f_i under consideration have the property that $\lim_{x\to 0^+} xf_i'(1-x) = 0$ and $\lim_{x\to 0^+} xf_i'(x) = 0$. It should be noted that each of the inverses of maps f_i cannot turn too sharply at both ends either.

2.2. Stable partial synchrony for n oscillators. To derive stable partial synchrony for n oscillators, we first need to derive conditions to exclude the possibility that one oscillator will run "too fast." The following proposition gives conditions that will prevent any oscillator from running too fast.

Proposition 2.3. *Let h_i be given as in Lemma 2.1, and let Δh and $\Delta\omega$ be given as follows:*

$$\Delta h = \max_{i,j} \max_{0\le\phi\le 1} |h_i(\phi) - h_j(\phi)| \tag{2.5a}$$

and

$$\Delta\omega = \max_{\substack{i,j\\ i\neq j}} \max_{T} \left(\sum_{\ell\in T} |\omega_{i\ell} - \omega_{j\ell}| \right), \tag{2.5b}$$

where $T \subset S_n - \{i,j\}$. If $n = 2$, then $\sum_{\ell\in T} |\omega_{i\ell} - \omega_{j\ell}|$ is to be interpreted as $|\omega_{ij} - \omega_{ji}|$.

1. *Let $\Phi^0 = (\phi_1^0, \dots, \phi_n^0)$ with ϕ_1^0 just reaching the threshold and being reset to zero. Assume $U_{k'}$, $k' = 1, 2, \dots, k$, are mutually exclusive and that $1, i \in S_n - \bigcup_{k'=1}^{k} U_{k'}$ with $\phi_i^0 \neq 0$. Suppose*

$$\begin{aligned} m_g^2 m_f \omega_{\min} &\ge \left(\sum_{j=0}^{k-1} \frac{1}{(m_f m_g)^j} \right) (M_g \Delta\omega + \Delta g + M_g(M_f(\Delta T + 1)\Delta T + \Delta f)) \\ &=: \left(\sum_{j=0}^{k-1} \frac{1}{(m_f m_g)^j} \right) \Delta. \end{aligned} \tag{2.6a}$$

   Then $\phi_i^{k'} \ge \phi_1^{k'}$, $k' = 1, 2 \dots, k$.
2. *Let*

$$m_g^2 m_f \omega_{\min} \ge \left(\sum_{j=0}^{n-1} \frac{1}{(m_f m_g)^j} \right) \Delta. \tag{2.6b}$$

   Suppose an oscillator has just reached the threshold. Then such an oscillator will not reach the threshold again until every other oscillator does. Moreover, suppose that the system of n oscillators undergoes one whole cycle of firings. Let the resulting phase of the system of oscillators be $\Phi^n = (\phi_{i_1}^n, \phi_{i_2}^n, \dots, \phi_{i_n}^n)$. Then the firing order for the next cycle with respect to the new initial condition Φ^n is preserved. That is, $\phi_{i_{k_2}}$ fires no earlier than $\phi_{i_{k_1}}$ does whenever $k_1 > k_2$.
3. *Let ϕ_i^m and ϕ_j^m be any two oscillators with $\phi_i^m = \phi_j^m < 1$ and $i, j \notin U_{m+1}$. Then the quantity Δ represents the maximum phase difference between these two oscillators after the next firing. That is, $|\phi_i^{m+1} - \phi_j^{m+1}| < \Delta$.*

Proof. Let δ_i and ω_i be given as in (1.1). Applying the mean value theorem, we get that

$$\begin{aligned} f_i(\delta_i) - f_i(\delta_1) &= f_i'(\xi) \left((1 - \phi_{i_0}^0) \frac{T_{i_0}}{T_i} \left(1 - \frac{T_i}{T_1} \right) + \phi_i^0 \right) \\ &\ge f_i'(\xi) \left((1 - \phi_{i_0}^0) \frac{T_{i_0}}{T_i} \left(1 - \frac{T_i}{T_1} \right) + g(\omega_{i1}) \right) \\ &\ge m_f m_g \omega_{\min} - M_f t_{\max} \Delta T. \end{aligned} \tag{2.7a}$$

Here $f_i'(\xi) = \frac{f_i(\delta_i)-f_i(\delta_1)}{\delta_i-\delta_1}$. The assumption that ϕ_1^0 just reach the threshold and Lemma 2.1 have been used to justify the inequalities in (2.7a). Using (2.5a), (2.5b), (2.6a), and (2.7a), we get that

$$\begin{aligned}\phi_i^1 - \phi_1^1 &= [g_i(f_i(\delta_i)+\omega_i) - g_i(f_i(\delta_i)+\omega_1)] + [g_i(f_i(\delta_i)+\omega_1) - g_i(f_i(\delta_1)+\omega_1)] \\ &\quad + [g_i(f_i(\delta_1)+\omega_1) - g_i(f_1(\delta_1)+\omega_1)] + [g_i(f_1(\delta_1)+\omega_1) - g_1(f_1(\delta_1)+\omega_1)] \\ &\geq \left(\sum_{j=1}^{k-1} \frac{1}{(m_f m_g)^j}\right)\Delta. \qquad \text{(2.7b)}\end{aligned}$$

Inductively, we have that

$$\begin{aligned}&\phi_i^{k'} - \phi_1^{k'} \geq \left(\sum_{j=k'}^{k-1} \frac{1}{(m_f m_g)^j}\right)\Delta, \quad k' = 1, 2, \ldots, k-1, \\ &\text{and } \phi_i^k - \phi_1^k \geq 0, \qquad \text{(2.8)}\end{aligned}$$

and the first part of the proposition follows. It should be noted that on the induction part, ϕ_i^0 in (2.7a) is to be replaced by $\phi_i^{k'-1} - \phi_1^{k'-1}$. Other parts of the estimates remain the same. Let Φ^0 be given. Suppose that the second assertion of the proposition were false. Then there exists a pair of indexes (i, j) such that the ith oscillator is the first oscillator reaching the threshold and the jth oscillator is the index of the first nonzero state oscillator that is outrun by the ith oscillator. To save notation, let the resulting phase state when the ith oscillator reaches the threshold be reset as ϕ_1^0, and the old index j be reset as j again. That is, ϕ_1^0 has just arrived at the threshold. Let k be the number of firings needed for ϕ_1^0 to reach the threshold. From how the indexes of 1 and j are chosen, we conclude that $k \leq n-1$ and that the spike sets associated with those firings are mutually disjoint. It follows from the first part of the proposition that if $\phi_1^k \geq 1$, then $\phi_i^k \geq \phi_1^k \geq 1$, a contradiction. We have just completed the proof of the first assertion of the second part of the proposition, and the second assertion of the second part of the proposition follows. To complete the proof of the last assertion of the proposition, we see that $\phi_i^{m+1} - \phi_j^{m+1}$ can be similarly expressed as those in (2.7b). The corresponding four terms in the brackets of (2.7b) are, respectively, bounded by $M_g\Delta\omega$, $M_g M_f t_{\max}\Delta T$, $M_g\Delta f$, and Δg. ■

We are now ready to state the stability conditions for synchrony.

Theorem 2.4. *Assume that the following stability condition holds:*

$$m_g^2 m_f \omega_{\min} \geq \max\left\{\sum_{j=0}^{n-1} \frac{1}{(m_f m_g)^j}, \sum_{j=0}^{n-2} (M_f M_g)^j\right\}\Delta. \qquad \text{(2.9)}$$

Then any group of oscillators which reaches the threshold simultaneously at some point will keep doing so in the future.

Proof. Let the ith and the jth oscillators be any two oscillators in the group spiking synchronously. Now reset both oscillators as $\phi_1^0 = \phi_2^0 = 0$. Suppose $1 \in U_{k+1}$ and $2 \notin \bigcup_{k'=1}^{k+1} U_{k'}$. It then follows from Proposition 2.3.2 that $U_{k'}$, $k' = 0, 1, \ldots, k+1$, are mutually

disjoint and that $k \le n-2$. Following from Proposition 2.3.3, we conclude that $|\phi_1^1 - \phi_2^1| \le \Delta$ and, inductively, $|\phi_1^k - \phi_2^k| \le (\sum_{j=0}^{k-1} \frac{1}{(M_f M_g)^j})\Delta$. Since $\phi_2^{k+1} = g_2(f_2(\frac{T_1}{T_2}(1-\phi_1^k)+\phi_2^k) + \sum_{\ell \in U_{k+1}} \omega_{2\ell})$, the index 2 being not in the set $\bigcup_{k'=1}^{k+1} U_{k'}$ implies that $\frac{T_1}{T_2}(1-\phi_1^k)+\phi_2^k < g_2(1-\sum_{\ell \in U_{k+1}} \omega_{2\ell})$. Upon using (2.2), we conclude that $m_g \omega_{\min} \le g_2'(\xi) \sum_{\ell \in U_{k+1}} \omega_{2\ell} < 1 - \frac{T_1}{T_2}(1-\phi_1^k) - \phi_2^k \le \Delta T + (\sum_{j=0}^{k-1} M_f M_g)\Delta \le (\sum_{j=0}^{n-2} M_f M_g)\Delta$, a contradiction to (2.9). ∎

Each of the terms in (2.9) can be verified analytically. Moreover, the inequality in (2.9) gives a measurement as to how not quite identical the system can be to get the stability condition. Roughly speaking, stability condition (2.9) amounts to saying that the total "weighted" measurements in how "nearly" identical the system is should be less than the minimum of the coupling strengths of the oscillators. In particular, the system of identical oscillators is always stable.

3. Absorption conditions.

In this section, we shall derive the conditions for which the absorption process of the system will forge ahead. In fact, we will show that the absorption process always occurs for a system of convex oscillators satisfying stability condition (2.9). On the other hand, the absorption process generally will not occur for a "nearly" identical system of concave oscillators. However, for a system of concave oscillators whose concavity is small, the absorption process is made possible by inducing an imbalance between the speeds and coupling strengths of the oscillators.

3.1. Absorption conditions for two oscillators.

We begin with the study of two oscillators. Let $\Phi^0 = (\phi_1^0, \phi_2^0)$ with $0 \le \phi_1^0 < \phi_2^0 < 1$. Assume that $U_1 = \{2\}$ and $U_2 = \{1\}$. Letting $\phi_2^0 = \phi$, the return map $R_2(\phi)$ is defined to be ϕ_2^2, the phase of the second oscillator immediately after the second firing. Specifically,

$$\phi_1^1 = g_1\left(f_1\left(\frac{T_2}{T_1}(1-\phi_2^0)+\phi_1^0\right)+\omega_{12}\right) =: h_1(\phi), \tag{3.1a}$$

$$\phi_2^2 = g_2\left(f_2\left(\frac{T_1}{T_2}(1-\phi_1^1)\right)+\omega_{21}\right) =: h_2(\phi_1^1), \tag{3.1b}$$

$$\phi_2^2 = h_2 h_1(\phi) =: R_2(\phi). \tag{3.1c}$$

Define the absorption map $A_2(\phi)$ as

$$A_2(\phi) = R_2(\phi) - \phi. \tag{3.1d}$$

The domain of the return map is the set of points for which $U_1 = \{2\}$ and $U_2 = \{1\}$. That is, no absorption occurs within one cycle of the firings whenever the initial values are in the domain of the return map. Now, $U_1 = \{2\}$ if and only if

$$\phi_2^0 > \ell_{12}, \quad \text{where } \ell_{ij} =: 1 - \frac{T_i}{T_j} g_i(1-\omega_{ij}), \tag{3.2a}$$

and $U_2 = \{1\}$ if and only if

$$\phi_1^1 > \ell_{21}. \tag{3.2b}$$

It should be noted that the positivity of ℓ_{ij} can be guaranteed by (2.4). The inequalities (3.2a) and (3.2b) amount to saying that there are limitations as to how close ϕ_2^0 can be to $0(=\phi_1^0)$ and $1(=\phi_1^0)$, respectively. To see why the second observation holds true, let

$$\gamma_{ij} = g_j(\omega_{ji}) - \ell_{ij}. \tag{3.3}$$

Note first that (3.2b) is equivalent to

$$f_1\left(\frac{T_2}{T_1}(1-\phi_2^0)+\phi_1^0\right)+\omega_{12} > f_1(\ell_{21}). \tag{3.4a}$$

If

$$\omega_{12} > f_1(\ell_{21}) \quad \text{or, equivalently,} \quad \gamma_{21} > 0, \tag{3.4b}$$

then ϕ_2^0 can be taken arbitrarily close to 1 from the left and (3.4a) still be satisfied. On the other hand, if $\gamma_{21} < 0$, then ϕ_2^0 cannot get too close to 1. In fact, $\phi_2^0 < h_1^{-1}(\ell_{21}) < 1$. Thus, the sign of γ_{21} determines how close ϕ_2^0 can be to 1 and therefore determines what is the boundary of the domain of the return map at the right end, which, in turn, influences the direction of the flow of the return map near the boundary of the domain. Such direction of the flow then determines whether the absorption process for the system of concave oscillators is to occur. (See Proposition 3.3.) We next show that for "nearly" identical oscillators the signs of γ_{ij} are determined by the concavity structure of the evolution maps.

Lemma 3.1. *Let ∇g be a measurement for the concavity of g_i, which is defined as follows:*

$$\nabla g = \min_i \left| \frac{g_i(\omega_{\max}) + g_i(1-\omega_{\max}) - 1}{\omega_{\max}} \right|. \tag{3.5}$$

Let $\widetilde{\Delta}\omega = \max_{i\neq j} |\omega_{ij} - \omega_{ji}|$. Assume that (2.4) and the following inequality, which is to be called the nearly identical condition, hold:

$$\omega_{\min}\nabla g > \Delta g + M_g\widetilde{\Delta}\omega + \Delta T. \tag{3.6}$$

Then $\gamma_{ij} < 0$ (resp., > 0) for all $i \neq j$, provided that $f_i'' < 0$ (resp., > 0) for all i.

Proof. Let $\widetilde{h}(x) =: \frac{h(x)+h(1-x)-1}{x}$. Here h is a map satisfying the assumptions of the maps given in Lemma 2.1. Then $\widetilde{h}(x)$ is increasing (resp., decreasing) on $(0,1)$, provided that $h''(x) > 0$ (resp., < 0). To see this, we have that $\widetilde{h}'(x) = \frac{x(h'(x)-h'(1-x))-(h(x)+h(1-x)-1)}{x^2} =: \frac{\widetilde{h_1}(x)}{x^2}$ and $\widetilde{h_1}'(x) = x(h''(x)+h''(1-x)) > 0$. Therefore, $\lim_{x\to 0^+}\widetilde{h_1}(x) = 0$, and so $\widetilde{h}(x)$ is increasing on $(0,1)$. The case for $h''(x) < 0$ can be similarly obtained. It is also clear that $\widetilde{h}(x) \leq 0$ (resp., ≥ 0) whenever $h''(x) > 0$ (resp., < 0). Consequently,

$$|-1+g_1(\omega_{12})+g_1(1-\omega_{12})| = \left|\frac{-1+g_1(\omega_{12})+g_1(1-\omega_{12})}{\omega_{12}}\omega_{12}\right| \leq \nabla g\omega_{\min}.$$

Suppose (3.6) holds. Then

$$\begin{aligned}\gamma_{ij} &= -1 + g_j(\omega_{ji}) + g_j(1-\omega_{ji}) + g_i(1-\omega_{ji}) - g_j(1-\omega_{ji}) \\ &\quad + g_i(1-\omega_{ij}) - g_i(1-\omega_{ji}) + \left(\frac{T_i}{T_j}-1\right)g_i(1-\omega_{ij}) < 0 \quad (\text{resp., } > 0),\end{aligned} \tag{3.7}$$

provided that $f_i''(x) < 0$ (resp., > 0), and the assertions of the lemma now follow. ∎

Remark 3.1.

1. *The consequences of Lemma 3.1 give that if the system of two oscillators is "nearly" identical in the sense that (3.6) are satisfied, then the domain of the absorption map A_2 is $(\frac{T_1}{T_2}\phi_1^0+\ell_{12}, h_1^{-1}(\ell_{21}))$ (resp., $(\frac{T_1}{T_2}\phi_1^0+\ell_{12}, 1)$), provided that $f_i'' < 0$ (resp., $f_i'' > 0$) for all i.*
2. *If ϕ_2^0 is not in the domain of the absorption map, then the two oscillators must fire simultaneously within one cycle of the firings. The corresponding system then will stay firing synchronously, provided that stability condition (2.4) is satisfied.*

The domain and monotonicity of the absorption map A_2 play an important role in determining whether the system is to forge ahead in the absorption process. The following lemma shows that the monotonicity of the absorption map depends on the concavity structure of f.

Lemma 3.2. *$\frac{\partial A_2}{\partial \phi} > 0$ (resp., < 0) on its domain, provided that $f_i'' < 0$ (resp., > 0) on $[0,1]$ for all i.*

Proof. We illustrate only the case that $f_i'' < 0$. The other cases can be similarly obtained. Applying the chain rule, we get

$$\begin{aligned}\frac{\partial R_2}{\partial \phi} &= \frac{\partial \phi_2^2}{\partial \phi} \\ &= g_2'\left(f_2\left(\frac{T_1}{T_2}(1-\phi_1^1)\right)+\omega_{21}\right) f_2'\left(\frac{T_1}{T_2}(1-\phi_1^1)\right) \\ &\quad \cdot g_1'\left(f_1\left(\frac{T_2}{T_1}(1-\phi_2^0)+\phi_1^0\right)+\omega_{12}\right) f_1'\left(\frac{T_2}{T_1}(1-\phi_2^0)+\phi_1^0\right).\end{aligned}$$

Using the facts that $g_i'' > 0$ and $g_i'(f_i(x)), f_i'(x) = 1$, $i = 1, 2$, we see immediately that $\frac{\partial R_2}{\partial \phi} > 1$, and hence $\frac{\partial A_2}{\partial \phi} > 0$. ∎

Proposition 3.3. *Assume that (2.4) is satisfied. Then the following statements hold:*

1. *Let (3.6) hold or $\gamma_{21} < 0$. Then $R_2(\phi)$ has a repelling fixed point, provided that $f_i'' < 0$ for all i. If $\gamma_{12} - \frac{T_1}{T_2}\phi_1^0 > 0$, then $R_2(\phi) - \phi > 0$ for all ϕ in its domain.*
2. *If $f_i'' > 0$ for all i and $\gamma_{21} < 0$, then $R_2(\phi) - \phi > 0$ for all ϕ in its domain.*
3. *Let $f_i'' > 0$ for all i. Assume that (3.6) holds. If $\phi_1^0 < \frac{T_1}{T_2}\gamma_{12}$, then $R_2(\phi)$ has a stable fixed point. If $\phi_1^0 > \frac{T_2}{T_1}\gamma_{12}$, then $R_2(\phi) - \phi < 0$ for all ϕ in its domain.*

Proof. Let $\phi = \frac{T_1}{T_2}\phi_1^0 + \ell_{12}$. Then

$$A_2(\phi) = \gamma_{12} - \frac{T_1}{T_2}\phi_1^0. \tag{3.8a}$$

Thus $A_2(\phi) < 0$, provided that $\gamma_{12} < 0$. On the other hand,

$$A_2(h_1^{-1}(\ell_{21})) = h_2(\ell_{21}) - h_1^{-1}(\ell_{21}) = 1 - h_1^{-1}(\ell_{21}) > 0, \tag{3.8b}$$

and the first part of the proposition now follows. The second part of the proposition is a direct consequence of Lemma 3.1, Lemma 3.2, and (3.8a). To complete the last part of the proposition, it remains to show that $A_2(1) < 0$ or, equivalently, $f_2(\frac{T_1}{T_2}(1 - g_1(\omega_{12}))) + \omega_{21} < 1$

or, equivalently, $\gamma_{12} > 0$, which follows from Lemma 3.1. We have just completed the proof of the proposition. ∎

Theorem 3.4.

1. *Assume that (2.4) holds. Then we have the following:*
   (a) *The system of two convex oscillators, in general, fires synchronously. Specifically, if $\gamma_{21} > 0$, then the synchrony of the system occurs for all initial values. Otherwise, that is, if $\gamma_{21} \le 0$, it synchronizes for almost all initial values. Consequently, for such a system, stability alone implies synchronization.*
   (b) *The system of two concave oscillators converges for all initial values to synchronous firing if and only if*

$$\gamma_{21} < 0 \quad \textit{or} \quad \gamma_{12} < 0. \tag{3.9}$$

   The inequalities in (3.9) are to be called the absorption condition for the system of two concave oscillators.
2. *Assume that (2.4) and (3.6) hold. Let $\phi_1^0 = 0$. Then the system of two concave oscillators will settle into a fixed nonfiring state if and only if ϕ_2^0 is in the domain of the absorption map A_2, that is, if $\ell_{12} < \phi_2^0 < 1$.*

Proof. To discuss synchrony for the system of two oscillators, we may just assume $\phi_1^0 = 0$. The statement 1(a) now follows from Proposition 3.3.1. The statement 2 follows easily from Proposition 3.3.3 and Lemma 3.1. It remains to prove statement 1(b). Consider the worst possible cases: (i) $\gamma_{21} < 0$ and $\gamma_{12} > 0$ or (ii) $\gamma_{21} > 0$ and $\gamma_{12} < 0$. The system will achieve synchronization at finite time for all initial conditions. To see this, we consider the case (ii). Let $\Phi^0 = (\phi_1^0, \phi_2^0)$ with $0 \le \phi_1^0 < \phi_2^0 < 1$. Then either Φ^1 is in synchrony or $\Phi^1 = (\phi_2^1, \phi_1^1)$ with $0 = \phi_2^1 < \phi_1^1 < 1$. Consequently, if no synchrony is achieved after the first firing, then the return map R_2 with respect to the initial phase state Φ^0 has a stable fixed point, while the return map R_2 with respect to the initial phase state Φ^1 has the property that $R_2(\phi) - \phi > 0$. However, the latter case will win out because it takes ϕ_1^1 finite time to reach the threshold and it takes ϕ_2^0 infinite time to reach the fixed point. On the other hand, if both γ_{21} and γ_{12} are nonnegative, then the corresponding return map has a stable fixed point. ∎

For the system of two convex oscillators, the associated return map is (volume) expanding; i.e., there exists some $r > 1$ such that $|A_2(\phi) - A_2(\overline{\phi})| > r|\phi - \overline{\phi}|$ for all $\phi \ne \overline{\phi}$ in the domain. Thus, the absorption is bound to happen except for the initial value being the fixed point of the absorption map. The sign of γ_{12} (or γ_{21}) then plays the role of determining whether the absorption map has a (repelling) fixed point or not. On the other hand, for the system of concave oscillators, the corresponding return map is (volume) contracting. If the flow of the return map at both ends of the domain points inward, which is the case for a nearly identical system (see Proposition 3.3.3), then its return map has a stable fixed point. As a result, the corresponding system converges to a nonfiring state. To make the system of concave oscillators fire synchronously, the flow of the return map at both ends has to point in the same direction, which in turn makes the absorption process go forward. The above scenario occurs whenever there is a certain degree of imbalance between oscillators (i.e., $\gamma_{12} < 0$ or $\gamma_{21} < 0$). To see this, note that $\gamma_{12} < 0$ is equivalent to $g_2(\omega_{21}) + \frac{T_1}{T_2} g_1(1 - \omega_{12}) < 1$. For identical concave oscillators, the inequality above will not be satisfied. Thus, to drive such a system into synchrony, the variations in the speed and/or the coupling strength cannot be too small.

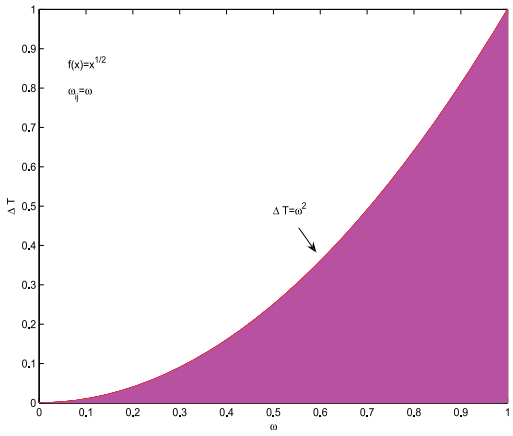

Figure 2. *The shaded area is the set of parameters satisfying* (3.10).

3.2. Feasible parameter and examples. For practical purposes, we consider how feasible it is to verify those stability and absorption conditions. Some numerical results are also provided to support the validity of the theorem. To simplify our calculations, we consider the following three cases: (i) $f_i(x) = \sqrt{x}$, $g_i(x) = x^2$, and $\omega_{12} = \omega_{21} = \omega$; (ii) $f_i(x) = x^2$, $g_i(x) = \sqrt{x}$, and $\omega_{12} = \omega_{21} = \omega$; (iii) $f_i(x) = x^2$, $g_i(x) = \sqrt{x}$, and $T_1 = T_2$.

Case (i): Since $m_g = \omega$, (2.4) becomes

$$\omega^2 \geq \Delta T. \tag{3.10}$$

In the $\omega - \Delta T$ plane, the equality in (3.10) is a parabola. As shown in Theorem 3.4, no absorption condition is needed to achieve synchrony for the system considered here. By choosing parameters randomly from the feasible region (see Figure 2), the numerical results (see Figure 3) indeed support our theory.

Case (ii): For case (ii), if (3.6) is satisfied, then no absorption occurs. Thus, the system in general will not fire synchronously unless ϕ_2^0 is too close to $\phi_1^0 = 0$. To see this, note that $\nabla g = \frac{\sqrt{\omega}+\sqrt{1-\omega}-1}{\omega}$, $m_g = \frac{1-\sqrt{1-\omega}}{\omega}$, and $\Delta g = \Delta\omega = 0$. The stability condition and (3.6) for the associated system then reduce to

$$(1 - \sqrt{1-\omega}) \geq \Delta T \tag{3.11}$$

and

$$\sqrt{\omega} + \sqrt{1-\omega} - 1 > \Delta T, \tag{3.12}$$

respectively. The feasible parameters region in the $\omega - \Delta T$ plane is nonempty (see Figure 4). Picking parameters from this region, we see, via Figure 5, that if $0 \leq \phi_2^0 < \ell_{12}$, then each of the corresponding systems will fire synchronously. Otherwise, they will settle into a nonfiring state. In fact, we choose various sets of parameters from different locations of the region, and all the corresponding systems behave as predicted in Theorem 3.4.2 (see Figure 5).

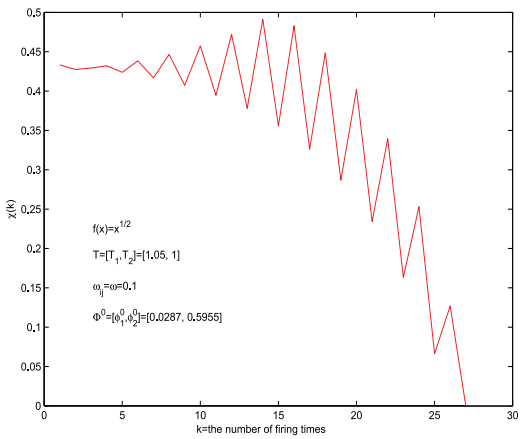

Figure 3. *The evolution of the synchronization order parameter $\chi(k)$ is defined as the sum of the minimum distances between any two oscillators at the kth stage* $= \sum_{i=1}^{n} \sum_{j=i+1}^{n} d(\phi_i^k, \phi_j^k)$, *where* $d(x, y) = \min(|x - y|, |x - y + 1|, |x - y - 1|)$. *If* $\chi(k) = 0$ *for some large* k, *then the system fires synchronously at finite time. If* $\lim_{k\to\infty} \chi(k) = 0$, *then the system fires synchronously eventually or asymptotically.*

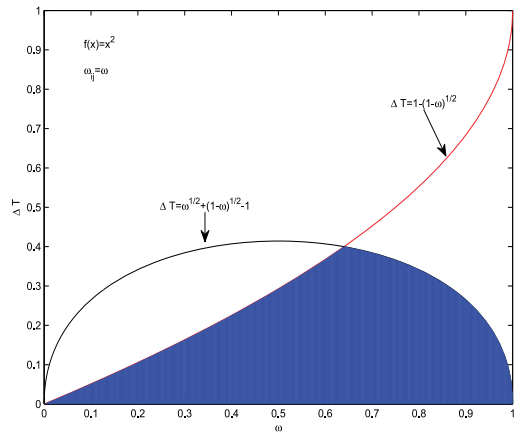

Figure 4. *The shaded area is the set of parameters satisfying* (3.11) *and* (3.12).

Case (iii): The absorption condition studied here is (3.9). Since $\Delta T = 0$, the stability condition is automatically satisfied. Moreover, (3.9) becomes

$$(\omega_{12})^{\frac{1}{2}} + (1 - \omega_{21})^{\frac{1}{2}} < 1. \tag{3.13}$$

The feasible parameters region in the ω_{21}-ω_{12} plane, as given in Figure 6, shows the "imbalance" between parameters ω_{12} and ω_{21}. The numerical results, as demonstrated in Figure 7, also support our theory.

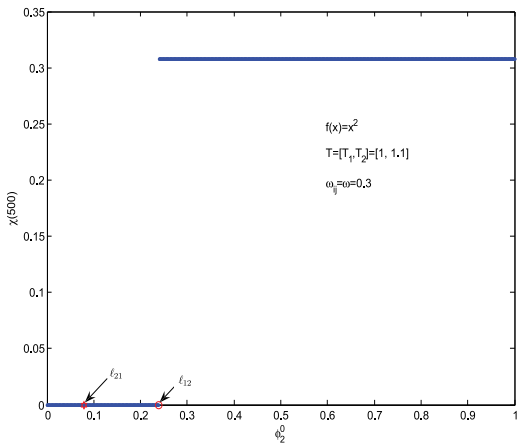

Figure 5. *Choosing parameters T_i and ω from the shaded part in Figure 4, we see that after 500 firings, the synchronization order parameter $\chi(500)$ is a step function with respect to the initial state ϕ_2^0. As predicted, if $\ell_{12} < \phi_2^0 < 1$, then the system settles into a nonfiring state. Otherwise, it fires synchronously.*

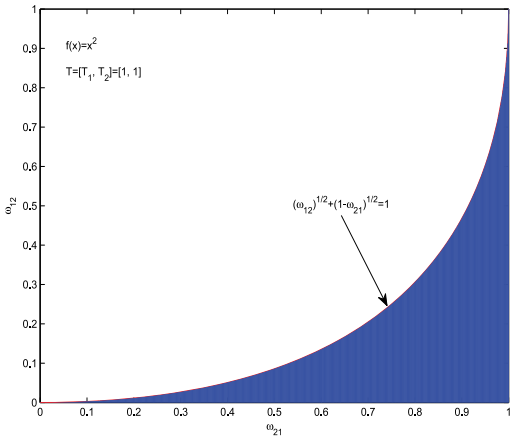

Figure 6. *The shaded area is the stability region for case* (iii).

3.3. Absorption conditions. To understand the absorption process of a system of more than two oscillators, we begin with defining the return map, which was originally defined in [41]. Throughout this section, we shall assume that stability condition (2.9) holds. Unlike the system of two oscillators, the corresponding return map under study in this section is now a high-dimensional map. Let the system of n oscillators undergo one whole cycle of firings. Assume that the resulting phase is denoted by $(\phi_1^0 = 0, \phi_2^0, \ldots, \phi_n^0)$. Let $\Phi^0 = (\phi_2^0, \ldots, \phi_n^0)$. Then the return map $R_n : \text{Domain}(R_n) =: A_n \subset \mathbb{R}^{n-1} \to \mathbb{R}^{n-1}$ is defined to be

$$R_n(\Phi^0) = \Phi^n = (\phi_2^n, \phi_3^n, \ldots, \phi_n^n) =: (r_{2,n}(\Phi^0), \ldots, r_{n,n}(\Phi^0)). \tag{3.14a}$$

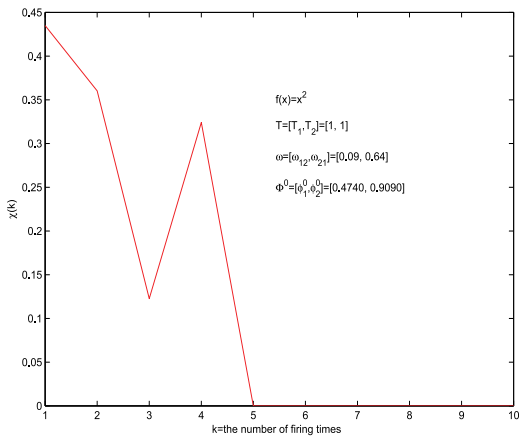

Figure 7. *Let the speed of the oscillators be* 1. *Pick the parameters* ω_{ij} *from the shaded region in Figure* 6. *The synchronization order parameter* $\chi(k)$ *reaches zero after* 5 *firings. The imbalance of parameters in activation gives the synchrony of the system.*

It should be noted, via Proposition 2.3.2, that the maps in (3.14a), (3.14b) are well defined. Moreover,

$$R_n(\Phi^0) = H_n \cdots H_2 H_1(\Phi^0), \tag{3.14b}$$

where

$$H_i = \tau_i \Sigma(\Phi). \tag{3.14c}$$

Here $\Phi = (\phi_2, \phi_3, \ldots, \phi_n)$,

$$\begin{aligned}\Sigma(\Phi) &= (\sigma_2, \sigma_3, \ldots, \sigma_n)\\ &=: \left(\frac{T_n}{T_1}(1-\phi_n), \frac{T_n}{T_2}(1-\phi_n)+\phi_2, \ldots, \frac{T_n}{T_{n-1}}(1-\phi_n)+\phi_{n-1}\right),\end{aligned}$$

and

$$\tau_i(\sigma_2, \sigma_3, \ldots, \sigma_n) = (g_1(f_1(\sigma_2)+\omega_{1,n}), \ldots, g_{n-1}(f_{n-1}(\sigma_{n-1})+\omega_{n-1,n})).$$

Note that we have implicitly relabeled the oscillators, so each of the image vectors $H_i(\Phi)$ represents the phases of the oscillators $1, 2, \ldots, n-1$. That is, the original oscillator 1 has become 2, oscillator 2 has become 3, ..., and oscillator n has become oscillator 1. It also follows from Proposition 2.3.3, Remark 2.1.2(b), and stability condition (2.9) that domain $(R_n) \subset S$, where $S = \{\Phi^0 = (\phi_2^0, \ldots, \phi_n^0) \in \mathbb{R}^{n-1} : 0 < \phi_2^0 < \phi_3^0 < \cdots < \phi_n^0 < 1\}$. In fact, the domain of the return map R_n is the set of points in S so that the spike sets $U_i = \{n-i+1\}$, $i = 1, 2, \ldots, n$. Having such spike sets is equivalent to the following inequalities:

$$\phi_{n-i+1}^{i-1} - \frac{T_{n-i}}{T_{n-i+1}}\phi_{n-i}^{i-1} > \ell_{n-i,\,n-i+1}, \qquad i = 1, 2, \ldots, n, \tag{3.15}$$

where $\ell_{n-i,\,n-i+1}$ are defined as in (3.2a) and T_0, $\ell_{0,1}$, and ϕ_0 are interpreted as T_n, $\ell_{n,1}$, and ϕ_n, respectively. Consequently, the domain A_n of the return map is

$$A_n = \{\Phi^0 \subset S : \text{the inequalities in (3.15) hold}\}. \tag{3.16a}$$

Since A_n is the finite intersection of open sets, it is open. Moreover, the domain A_k of H_k is the set of initial points satisfying the inequalities in (3.15) for $i = 1, 2, \ldots, k$. So A_i is the set of initial values that will have at least i firings before an absorption occurs. Then

$$A = \bigcap_{i=1}^{\infty} A_i = \text{the set of initial values that live forever without any absorptions.} \tag{3.16b}$$

We next state some properties of the return map $R_n : A_n \to S$. The first assertion of the theorem below is essentially due to Mirollo and Strogatz (see Theorem 3.1 of [41]).

Theorem 3.5. *Assume that stability condition (2.9) holds for a system of n oscillators. The following hold true:*

1. *Let $f_i'' < 0$ for all i. Then R_n is volume-expanding on A_n. Consequently, the set A has Lebesgue measure zero.*
2. *Let $f_i'' > 0$ for all i. Then R_n is volume-contracting on A_n.*

Proof. To prove the first assertion of the theorem, it suffices to show that the Jacobian determinant of R_n has absolute value greater than one. From (3.14b) and (3.14c) and the definitions of τ_i and Σ, $\det(DR_n) = \prod_{i=1}^n \det(DH_i) = \prod_{i=1}^n \det(D\tau_i)\det(D\Sigma)$. The map Σ is affine and satisfies $\sigma^n = I$, so $\det(D\Sigma) = \pm 1$. Note that $D\tau_i$ is a diagonal matrix; thus it is easily seen that $\det D\Sigma > 1$ under the assumption that each of the evolution maps is convex. Hence $|\det(DR)| > 1$. The arguments for proving the second assertion of the theorem are similar to those of the first. ∎

Since the return map of the system of convex oscillators is volume-expanding, the set of initial values that live forever without any absorptions has measure zero. Hence, it is the nature of the system of convex oscillators to grow by absorbing other oscillators. On the other hand, if the flow of the return map of the system of concave oscillators near the boundary of the domain points inward, such as that of identical concave oscillators, then the system converges to a fixed point, which is a nonfiring state. Hence, to break such a natural tendency of the system one has to introduce some imbalance between the parameters so as to make the direction of the flow point outward near a certain portion of the boundary, as in the case for two oscillators, where a necessary and sufficient condition has been established. Due to the technical difficulty of this, only sufficient conditions are established for systems of more than two oscillators. Such a result is stated in the following.

Theorem 3.6. *Let the number of concave oscillators under consideration be no less than three. Assume the following absorption condition, which is to say that the imbalance measurement is greater than or equal to the concavity of the inverse of the evolution maps:*

$$\frac{M_g}{m_g} \le \max_{0\le i\le n-1} \left(\frac{T_i \omega_{i,i+1}}{T_{i+1}\omega_{i+1,i}} \right). \tag{3.17}$$

Suppose that (2.9) and (3.17) hold. Then the absorption of the system must occur.

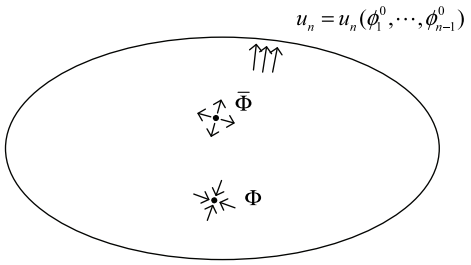

Figure 8. *A visualization of the claim in Step 3 of Theorem 3.6.*

Proof. Let $\max_{0\le i\le n-1} \frac{T_i\omega_{i,i+1}}{T_{i+1}\omega_{i+1,i}} = \frac{T_m\omega_{m,m+1}}{T_{m+1}\omega_{m+1,m}}$ for some m. Suppose that no absorption occurs after the first $(n-m)$ firings; then we may relabel oscillators so that the indexes $m+1,\dots,n,1,\dots,m$ of the oscillators become $1,2,\dots,n$, respectively. We then may assume that $\max_{0\le i\le n-1} \frac{T_i\omega_{i,i+1}}{T_{i+1}\omega_{i+1,i}} = \frac{T_n\omega_{n,1}}{T_1\omega_{1,n}}$. The proof the theorem then breaks into three steps. The first part is to prove that sufficient condition (3.17) is so given that the inequality in (3.15) with $i = n$ is violated whenever ϕ_n^0 is sufficiently close to 1 from the left. Consequently, if the system is to undergo one whole cycle of firings, ϕ_n^0 must stay away from 1. That is, $\phi_n^0 < u_n = u_n(\phi_1^0,\dots,\phi_{n-1}^0) < 1$ for some u_n depending on $\phi_1^0,\dots,\phi_{n-1}^0$ and being away from 1. Here $u_n = u_n(\phi_1^0,\dots,\phi_{n-1}^0)$ is a portion of the boundary of the domain of the return map described by $\phi_1^{n-1} - \frac{T_n}{T_1}\phi_n^{n-1} = \ell_{n,1}$. The second step of the proof is to show that the direction of the flow points outward to the boundary whenever ϕ_n^0 is sufficiently close to u_n from the left. Finally, to complete the proof the theorem, we need to show that the return map has no periodic points.

Step 1. Let ϕ_n^0 be sufficiently close to 1 from the left so that $\phi_1^1 - \phi_n^1 (= 0) < M_g\omega_{\min}$. We have used Lemma 2.1 to ensure that the above assertion can be done. Note that each of $g_i(f_i(\phi)+\omega)-\phi$, the phase jump at ϕ, is decreasing in ϕ. Hence, the phase jump is greater when the phase position ϕ is closer to the origin. Upon using Lemma 2.1, we conclude that

$$\begin{aligned}\phi_1^{n-1} - \frac{T_n}{T_1}\phi_n^{n-1} &< \phi_1^1 - \phi_n^1 + \left(1 - \frac{T_n}{T_1}\right)\\ &< M_g\omega_{1,n} + \left(1 - \frac{T_n}{T_1}\right) \le \frac{T_n}{T_1} m_g\omega_{n,1} + \left(1 - \frac{T_n}{T_1}\right) < \ell_{n,1}.\end{aligned}$$

We just proved that the boundary of the domain of the return map cannot get arbitrarily close to $\phi_n^0 = 1$. Note that if $n = 2$, then $\phi_2^1 = 0$, and so the first inequality above is not necessarily true.

Step 2. Suppose that ϕ_n^0 is close to u_n. Then $\phi_1^{n-1} - \frac{T_n}{T_1}\phi_n^{n-1}$ is close to $\ell_{n,1}$. Consequently, ϕ_n^n is close to 1. Therefore, $\phi_n^n > \phi_n^0$ whenever ϕ_n^0 is sufficiently close to u_n.

Step 3. Since R_n is volume-contracting, any of its periodic points, if one exists, must be stable. Assume, to the contrary, that there exists a periodic point Φ with period k. Let $\overline{R} = R_n^k$. Then Φ becomes a stable fixed point of $\overline{R}$. Moreover, the direction of the flow under $\overline{R}$ near the boundary of the domain still points outward. Consequently, there must exist a unstable fixed point $\bar{\Phi}$ of $\overline{R}$, a contradiction (see Figure 8).

Using Steps 1–3, we conclude that the direction of the flow of the return map points outward to the boundary u_n. Hence, the absorption must occur. We have just completed the proof of the theorem. ∎

From the proof of the above theorem as well as that of Theorem 3.4.1(b), it is easily concluded that for the system of concave oscillators to undergo the absorption process, the domain of the return map contains only the points for which their ϕ_n^0's must stay away from 1. This, in turn, makes the direction of flow near the boundary $u_n = u_n(\phi_1^0, \ldots, \phi_{n-1}^0)$ point outward. While the best possible condition to ensure such a scenario for the system of two concave oscillators can be obtained, it is not clear whether the condition that $\min_{1\le i\le n} \gamma_{i-1,i} < 0$ (here $\gamma_{0,1}$ is to be interpreted as $\gamma_{n,1}$) is the best absorption condition for the system of more than two oscillators. Nevertheless, if the concavity of a system is small, then the inequalities in (3.17) can be satisfied by inducing an imbalance between the speeds and weights of oscillators, which will be demonstrated in Proposition 3.7.

We next discuss the dynamics under iteration of the absorption maps. Assume an initial value Φ^0, not necessarily in the domain of the return map. Suppose after initial firings that the system forms k partially synchronous groups. Let the ith group, $1 \le i \le k$, contain k_i oscillators, where $\sum_{i=1}^{k} k_i = n$, and let these be treated as one new oscillator, denoted by $\overline{\phi}_i$. Clearly, when oscillator $\overline{\phi}_i$ is firing, the activation of each oscillator ϕ_j in the $(i+1)$th synchronous group, where $(\sum_{\ell=1}^{i} k_\ell) + 1 \le j \le \sum_{\ell=1}^{i+1} k_\ell =: \sigma_{i+1}$, is incremented by the positive coupling $\sum_{k=\sigma_{i-1}+1}^{\sigma_i} \omega_{jk} =: \widetilde{\omega}_{ji}$. For each j, $\sigma_{i-1} + 1 \le j \le \sigma_i$, we may define $\widetilde{\omega}_{ji+1}$ similarly. Since the ith and $(i+1)$th synchronous groups may contain more than one oscillator, the new cycle periods $\overline{T}_i$ and $\overline{T}_{i+1}$ of the new oscillators $\overline{\phi}_i$ and $\overline{\phi}_{i+1}$ are chosen as the minimum cycle periods among the oscillators in each group, i.e., $\overline{T}_i = \min_{\sigma_{i-1}+1\le i\le\sigma_i} T_i$ and $\overline{T}_{i+1} = \min_{\sigma_i+1\le i\le\sigma_{i+1}} T_i$. That is, the speed of each group is chosen to be the fastest speed among oscillators in the group. With $\overline{T}_i$ and $\overline{T}_j$ now being fixed, the corresponding new coupling strengths $\overline{\omega}_{i,i+1}$ and $\overline{\omega}_{i+1,i}$ are so chosen that

$$\max_{\sigma_{i-1}+1\le\ell\le\sigma_i} \left(\max_{\sigma_i+1\le j\le\sigma_{i+1}} \frac{\overline{T}_i \widetilde{\omega}_{\ell,i+1}}{\overline{T}_{i+1} \widetilde{\omega}_{j,i}} \right) = \frac{\overline{T}_i \overline{\omega}_{i,i+1}}{\overline{T}_{i+1} \overline{\omega}_{i+1,i}}. \tag{3.18}$$

The idea for such choices is to make the inequality (3.17) as easy as possible to satisfy. Due to the presence of the stability condition, we are allowed to make such choices. For these newly formed synchronous groups to continue their absorption process, we need to further assume that for any permissible set $\{k, k_1, k_2, \ldots, k_k\}$, where $2 < k \le n$ and $\sum_{i=1}^{k} k_i = n$,

$$\frac{M_g}{m_g} \le \max_{0\le i\le k-1} \left(\frac{\overline{T}_i \overline{\omega}_{i,i+1}}{\overline{T}_{i+1} \overline{\omega}_{i+1,i}} \right). \tag{3.19}$$

The right-hand side of the inequality above is to be called the imbalance measurement for the system of more than two oscillators. Note that the quantity $\frac{M_g}{m_g}$ is a measurement for the concavity of g. The closer $\frac{M_g}{m_g}$ is to 1, the more flat the g is. With such an absorption condition, the system continues to grow by absorption until it reaches full synchrony or reduces to two synchronous groups of oscillators. To ensure that these two synchronous groups continue to grow by absorption, we need to have a modified absorption condition for these two groups.

To this end, we assume that the first group consists of old oscillators $\phi_{\ell_1}, \dots, \phi_{\ell_2}$, where $1 \le \ell_1 < \ell_2 < n$ or $1 < \ell_1 < \ell_2 \le n$, while the second group contains the remaining oscillators. Then the parameters in γ_{12} and γ_{21}, as given in (3.3), need to be updated as well. Let $N_1 = \{\ell_1, \dots, \ell_2\}$ and $N_2 = \{1, 2, \dots, n\} - N_1$. Set $\widetilde{\omega}_{j1} = \sum_{i \in N_1} \omega_{ji}$, $j \in N_2$, and $\widetilde{\omega}_{j2} = \sum_{i \in N_2} \omega_{ji}$, $j \in N_1$. Define the new cycle periods of groups N_1 and N_2 to be the minimum cycle periods among the oscillators in each group. Denote such new periods by $\overline{T}_1$ and $\overline{T}_2$. Let

$$\gamma_{12}(\ell_1, \ell_2) = \min_{\substack{i \in N_1 \\ j \in N_2}} \left(g_j(\widetilde{\omega}_{j1}) - 1 + \frac{\overline{T}_1}{\overline{T}_2} g_i(1 - \widetilde{\omega}_{i2}) \right) \tag{3.20a}$$

and

$$\gamma_{21}(\ell_1, \ell_2) = \min_{\substack{j \in N_1 \\ i \in N_2}} \left(g_j(\widetilde{\omega}_{j2}) - 1 + \frac{\overline{T}_2}{\overline{T}_1} g_i(1 - \widetilde{\omega}_{i1}) \right). \tag{3.20b}$$

Then the absorption condition for any two sizes of synchronous groups of oscillators is

$$\min \left\{ \max_{\ell_1, \ell_2} \gamma_{12}(\ell_1, \ell_2), \max_{\ell_1, \ell_2} \gamma_{21}(\ell_1, \ell_2) \right\} < 0. \tag{3.20c}$$

The left-hand side of the inequality in (3.20c) is to be called the imbalance measurement for the system of two oscillators. With those absorption conditions on hand, one would expect the full synchrony of the system. The drawback of absorption conditions (3.19) and (3.20c) is that when n is large, there are enormously many cases needing to be checked. As a consequence, the question of nonemptiness of the set of parameters satisfying the constraints (3.19) and (3.20c) has to be addressed.

Proposition 3.7. *Let the coupling strengths $\omega_{ij} (= \omega)$ of a system of n oscillators all be equal. Let the period cycles of oscillators all be different. Assume that $\omega < \frac{2}{n}$ and that*

$$\frac{[\frac{n}{3}] + 1}{[\frac{n}{3}]} > t_{\max}. \tag{3.21}$$

Then the absorption conditions (3.19) *and* (3.20c) *are satisfied, provided that the concavity of the evolution maps is sufficiently small.*

Proof. With the speed of oscillators being all different, $t_{\max} > 1$. Suppose that the absorption occurs after the initial firings. Assume that the system evolves into k, $k > 2$, synchronous groups with sizes of groups being $k_1, k_2, \dots$, and k_k. If $k_1 = k_2 = \cdots = k_k$, then the system continues to grow by absorption, provided that $\frac{M_g}{m_g}$ is sufficiently close to 1. Suppose that the sizes of k synchronous groups are not all equal. Then there must exist an index i for which $\frac{\overline{\omega}_{i,i+1}}{\overline{\omega}_{i+1,i}} \ge ([\frac{n}{3}] + 1)/[\frac{n}{3}] > t_{\max}$. Here $[x]$ is the greatest integer that is equal to or less than x. Consequently, the imbalance measurement for this system is greater than one. The system then must reach full synchrony or reduce to the system of two synchronous groups, provided that the concavity of the evolution maps is small. In the case of the latter,

we assume that the sizes of these two groups N_1 and N_2 are ℓ and $n-\ell$, respectively, and let $f_i(x) = x$ for all i. Then (3.20c) reduces to

$$\gamma_{12}(\ell, n-\ell) = \ell\omega - \left(\frac{\overline{T}_i}{\overline{T}_j}\right)(n-\ell)\omega + \frac{\overline{T}_i}{\overline{T}_j} - 1, \qquad i \in N_1,\ j \in N_2,$$
$$\gamma_{21}(\ell, n-\ell) = (n-\ell)\omega - \left(\frac{\overline{T}_j}{\overline{T}_i}\right)\ell\omega + \frac{\overline{T}_j}{\overline{T}_i} - 1, \qquad i \in N_1,\ j \in N_2.$$

If n is even and $\ell = n - \ell$, then

$$\gamma_{12}(\ell, n-\ell) = \left(\frac{\overline{T}_i}{\overline{T}_j} - 1\right)\left(1 - \frac{n\omega}{2}\right) \quad \text{and} \quad \gamma_{21}(\ell, n-\ell) = \left(\frac{\overline{T}_j}{\overline{T}_i} - 1\right)\left(1 - \frac{n\omega}{2}\right).$$

Since $t_{\max} > 1$, either $\gamma_{12}(\ell, n-\ell)$ or $\gamma_{21}(\ell, n-\ell)$ is negative. If $n - \ell = \ell + \ell_1$, where $\ell_1 \geq 1$, then $\gamma_{12}(\ell, n-\ell) = (\frac{\overline{T}_i}{\overline{T}_j} - 1)(1 - \ell\omega) - \frac{\overline{T}_i}{\overline{T}_j}\ell_1\omega$. Suppose $\frac{\overline{T}_i}{\overline{T}_j} \leq 1$. Then $\gamma_{12}(\ell, n-\ell) < 0$. If $\frac{\overline{T}_i}{\overline{T}_j} > 1$, then $\gamma_{12}(\ell, n-\ell) < \Delta T - \omega_{\min} \leq 0$. The last inequality is justified by stability condition (2.4). The case that $\ell = (n-\ell) + \ell_1$, where $\ell_1 \geq 1$, can be similarly addressed. Therefore, the remaining two synchronous groups will achieve full synchrony, provided that the concavity of the evolution maps is small. ■

The result of the proposition supports the numerical observation of Bottani [8]. We next define phase responding function $h(x)$ and phase difference function $D(x)$. Both functions are helpful in determining the direction of the flow of the system near the boundary of the return map whenever the number of oscillators is greater than three. Assume that an oscillator receives an activation ω at x. Let the resulting phase $g(f(x) + \omega)$ be denoted by $h(x)$, and define $D(x)$ as

$$D(x) = h(x + a) - h(x). \tag{3.22}$$

Here $a > 0$ is a constant.

Proposition 3.8.

1. *Consider an identical system of three concave oscillators. That is, $f_i \equiv f$, $g_i \equiv g$, $T_i \equiv T$, and $\omega_{ij} = \omega$. Then the direction of the flow near the boundary of the domain of the return map points inward.*
2. *Suppose $h''(x) > 0$. Then $D(x)$ is increasing in x.*
3. *Consider an identical system of n concave oscillators. If $h''(x) > 0$, then*

$$\phi_n^0 - \phi_{n-1}^0 < \phi_n^n - \phi_{n-1}^{n-1} \tag{3.23}$$

whenever $\phi_n^0 - \phi_{n-1}^0$ is sufficiently close to $\ell_{ij} = 1 - g(1-\omega)$ from the left. Consequently, the direction of the flow of the system points inward near the boundary of the domain of the return map.

Proof. The boundary of the domain of the return map consists of three pieces of curves Γ_1, Γ_2, and Γ_3 defined by $\phi_{n-i+1}^{i-1} - \phi_{n-i}^{i-1} = 1 - g(1-\omega)$, $i = 1, 2, 3$, respectively. To prove the first part of the proposition, it suffices to show that for $i = 1, 2, 3$

$$\phi_{n-i+1}^{i-1} - \phi_{n-i}^{i-1} < \phi_{n-i+1}^{n+i-1} - \phi_{n-i}^{n+i-1} \tag{3.24}$$

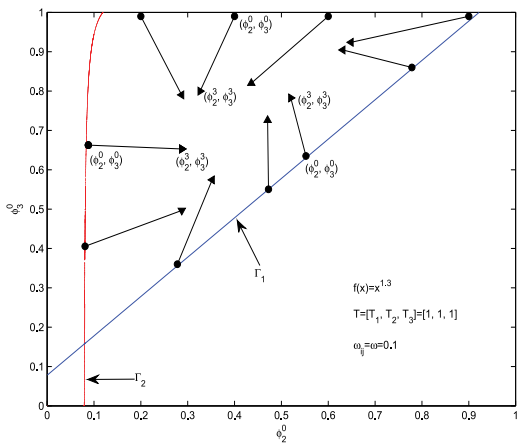

Figure 9. *The initial position and ending position of each arrow are* (ϕ_2^0, ϕ_3^0) *and* (ϕ_2^3, ϕ_3^3)*, respectively. The direction of the flow near the boundary of the domain of the return map indeed points inward as predicted.*

whenever $\phi_{n-i+1}^{i-1} - \phi_{n-i}^{i-1}$ are sufficiently close to $1-g(1-\omega)$. The inequalities in (3.24) amount to saying that $R(\phi_2^0, \phi_3^0) = (\phi_2^3, \phi_3^3)$ are moving further away from their respective boundaries whenever (ϕ_2^0, ϕ_3^0) are near Γ_1, Γ_2, and Γ_3, respectively (see Figure 9). To this end, we first prove that Γ_3 can be interpreted as $\phi_3^0 = 1$. For any $\phi_3^0 < 1$, we have that $\phi_1^1 > g(\omega)$. And so, for any $\phi_2^0 + 1 - g(1-\omega) < \phi_3^0 < 1$, we see that $\phi_1^2 - \phi_3^2 = \phi_1^1 - (\phi_3^2 - (\phi_1^2 - \phi_1^1)) > g(\omega) - (g(\omega) - (1 - g(1-\omega))) = 1 - g(1-\omega)$. We have used the fact that the phase jump function $h(x) - x$ is decreasing to justify the above inequality. Hence, Γ_3 can be interpreted as claimed. Now, if $\phi_3^0 - \phi_2^0 \approx (1 - g(1-\omega))^-$, then $\phi_2^1 \approx 1^-$, and so $\phi_3^2 - \phi_2^2 \approx (g(\omega))^+$. Here $\phi_2^2 = 0$. Consequently, $\phi_3^3 - \phi_2^3 = \phi_3^2 - ((\phi_2^3 - \phi_2^2) - (\phi_3^3 - \phi_3^2)) > g(\omega) - (g(\omega) - (1 - g(1-\omega))) = 1 - g(1-\omega)$. To prove (3.24) for $i = 1$, it remains to show that there exists an $\varepsilon > 0$ such that $\phi_3^3 - \phi_2^3 = 1 - g(1-\omega) + \varepsilon$ whenever (ϕ_2^0, ϕ_3^0) is near the boundary of Γ_1. To prove this, we need to make sure that $R(\phi_2^0, \phi_3^0)$ stay away from $1 - g(1-\omega)$ whenever (ϕ_2^0, ϕ_3^0) are near $\Gamma_1 \cap \Gamma_2$ and $\Gamma_1 \cap \Gamma_3$ (see Figure 9). Suppose that (ϕ_2^0, ϕ_3^0) is near the boundaries of Γ_1 and Γ_2. Then $\phi_1^2 \approx 1^-$. Thus, $\phi_3^3 - \phi_3^2 \approx g(2\omega) - g(\omega) = 1 - g(1-\omega) + \varepsilon$, where $\varepsilon > 0$. Similarly, if (ϕ_2^0, ϕ_3^0) is near the boundaries of Γ_1 and Γ_3, $\phi_3^3 - \phi_2^3$ is also bounded away from $1 - g(1-\omega)$. Hence, $\phi_3^3 - \phi_2^3$ is bounded away from $1 - g(1-\omega)$ whenever (ϕ_2^0, ϕ_3^0) is near the boundary of Γ_1. Similarly, one can prove that (3.24) holds for $i = 2, 3$. We have completed the first assertion of the proposition. The second assertion of the proposition is obvious. Suppose $\phi_n^0 - \phi_{n-1}^0 \approx (1 - g(1-\omega))^-$. Then $\phi_{n-1}^1 \approx 1^-$. Since $D(x)$ is increasing in x, $\phi_n^2 - \phi_{n-1}^2 \geq h(\omega) - h(0) = g(\omega)$. Inductively, we see that

$$\phi_n^n - \phi_{n-1}^n \geq g((n-1)\omega) - g((n-2)\omega) > 1 - g(1-\omega).$$

The second assertion of the proposition has been used repeatedly to justify the first inequality above. The second inequality above follows from (2.2). Therefore, (3.23) holds whenever ϕ_n^0 is sufficiently close to $1 - g(1-\omega)$. Hence, the direction of the flow of the system near the

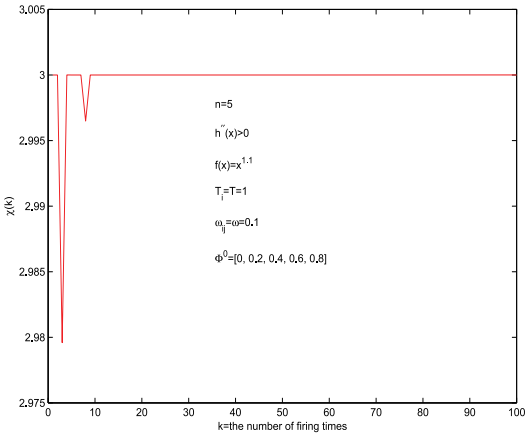

Figure 10. *For the choice of f, its phase responding function $h(x)$ is concave upward. The system in general does not synchronize as predicted in Proposition 3.8.3 and Theorem 3.9.2(b).*

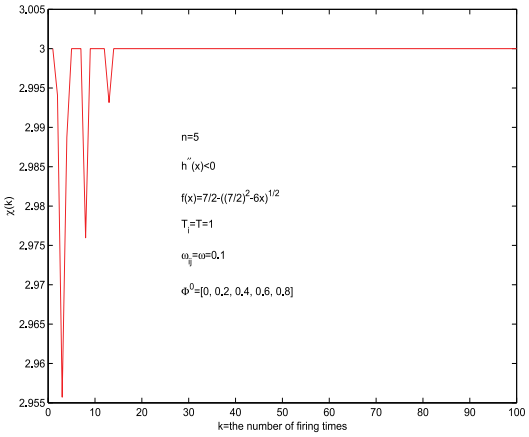

Figure 11. *For the choice of f, its phase responding function $h(x)$ is concave downward. Nevertheless, the system in general does not synchronize either.*

piece of boundary defined by $\phi_n^0 - \phi_{n-1}^0 = 1 - g(1-\omega)$ points inward. Similarly,

$$\phi_{n-i+1}^{i-1} - \phi_{n-i}^{i-1} < \phi_{n-i+1}^{n+i-1} - \phi_{n-i}^{n+i-1}, \qquad i = 2, \ldots, n,$$

whenever $\phi_{n-i+1}^{i-1} - \phi_{n-i}^{i-1}$ is close to $1 - g(1-\omega)$. We have just completed the proof of the proposition. ■

Two questions naturally arise from the proposition above. First, is the restriction $h''(x) > 0$ necessary for the validity of the second assertion of Proposition 3.8? Second, what kind of evolution maps with $f'' > 0$ satisfy the constraint $h''(x) > 0$? For the first question, we expect that the answer should be no (see Figures 10 and 11). However, we are unable to prove this.

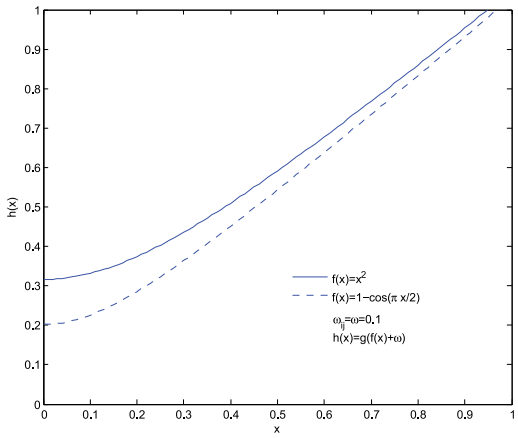

Figure 12. *Two graphs of $h(x)$ with two different f's are shown above. Their graphs are all concave upward.*

For the second question, we see in Figure 12, via the help of the computer, that $f(x) = x^r$, $r > 1$, and $f(x) = 1 - \cos(\pi x/2)$ satisfy $h''(x) > 0$.

We are now ready to state the main result of the paper.

Theorem 3.9.

1. *Suppose that stability condition (2.9) holds. Then the system of convex oscillators will achieve synchrony for all initial values, except possibly for those in a set of measure zero. In particular, the system of identical convex oscillators is to fire synchronously for all initial values, expect for those in a set of measure zero.*
2. (a) *The identical system with an even number of concave oscillators will not achieve full synchrony for certain initial values in a set of positive measure.*
   (b) *Suppose that the phase responding function $h(x)$ is concave upward. Then the identical system of concave oscillators will not synchronize for all initial values in the domain of its return map.*
   (c) *The identical system of three concave oscillators will not synchronize for all initial values in the domain of its return map.*
3. *Suppose that stability condition (2.9) and the absorption conditions (3.19) and (3.20c) are satisfied. Then the system of concave oscillators will achieve synchrony for all initial values.*

Proof. As shown in Theorem 3.5.1, the natural tendency of the system of convex oscillators is to grow by absorption regardless of their coupling strengths and speeds. Therefore, the system will continue to grow by absorption even though we need to update the new coupling strengths and speeds at each stage. The assertion of the first part of the theorem now follows. The third assertion of the theorem is now obvious. It remains to prove the second assertion of the theorem. To this end, let the number of oscillators be $2k$, and let ω and T be the constant coupling strength and constant cycle period, respectively. Pick $\Phi^0 = (\phi_1^0, \phi_2^0, \ldots, \phi_n^0)$

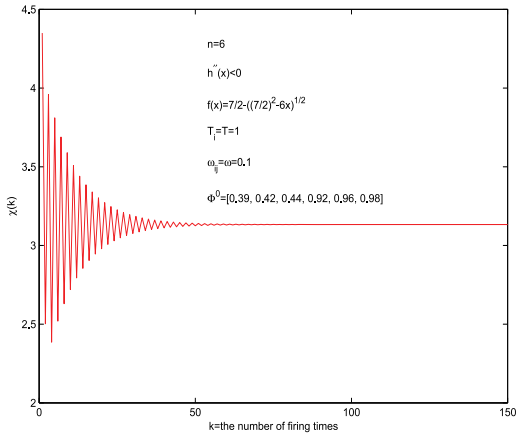

Figure 13. *The choice of f as above has the properties that $f''(x) > 0$ and $h''(x) < 0$. Since the number of oscillators chosen in this case is even, the numerical result demonstrated as above is consistent with the result of Theorem 3.9.2(a).*

to satisfy that

$$\phi_j^0 \in (1 - m_g\omega, 1),\ j = k+1, \dots, n, \text{ and} \tag{3.25}$$
$$\phi_1^0, \dots, \phi_k^0 \in (M_g(k+1)\omega - m_g\omega,\ M_g(k+1)\omega).$$

It then follows from Remark 2.1.2(a) that the system will reduce to two synchronous groups after initial firings. In fact, the first group contains oscillators $\phi_1^1, \dots, \phi_k^1$. The new coupling strengths for these two groups are equal. Denote by $\widetilde{\gamma}_{21}$ and $\widetilde{\gamma}_{12}$ the new corresponding γ_{21} and γ_{12}, respectively. Then $\widetilde{\gamma}_{21} = \widetilde{\gamma}_{12} = g(k\omega) + g(1 - k\omega) - 1 > 0$. Therefore, such a set of the initial values, which has a positive measure, will converge to a nonfiring state (see Figure 13). The assertions in 2(b) and 2(c) are now direct consequences of Proposition 3.8. We have just completed the second part of the theorem. ∎

The numerical stimulation suggests that a "nearly" identical system of any number of oscillators in general will not synchronize with or without the requirement that the phase responding curve be concave upward. Such a conjecture remains to be completed.

3.4. Examples and discussion. For the illustration of Theorem 3.9, the following three cases of systems of three oscillators are considered: (i) $f_i(x) = \sqrt{x}$, $\omega_{ij} = \omega$; (ii) $f_i(x) = x^{1.3}$ or $f_i(x) = \frac{7}{2} - \sqrt{(\frac{7}{2})^2 - 6x}$, $T_i = T$, and $\omega_{ij} = \omega$; (iii) $f_i(x) = x^r$, where $r > 1$, and $\omega_{ij} = \omega$.

Case (i): For this case, $m_g = \omega$, $m_f = \frac{1-\sqrt{1-\omega}}{\omega}$, $M_g = 2 - \omega$, and $M_f = \frac{1}{\sqrt{\omega}}$. Moreover, we have that $\frac{1}{m_g m_f} \geq M_g M_f$. Thus, as $n = 3$, equation (2.9) becomes

$$\frac{m_g^4 m_f^3 \omega}{(1 + m_f m_g + m_f^2 m_g^2) M_f M_g} \geq \Delta T(\Delta T + 1). \tag{3.26}$$

The corresponding feasible parameters region in $\omega - \Delta T$ is plotted in Figure 14. In the

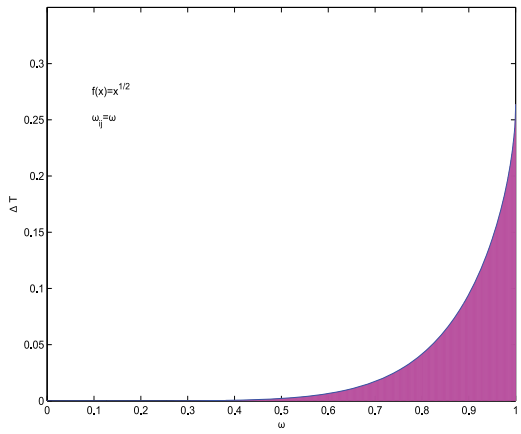

Figure 14. *The shaded part of the region is the set of parameters* $(\omega, \Delta T)$ *satisfying stability condition* (3.26).

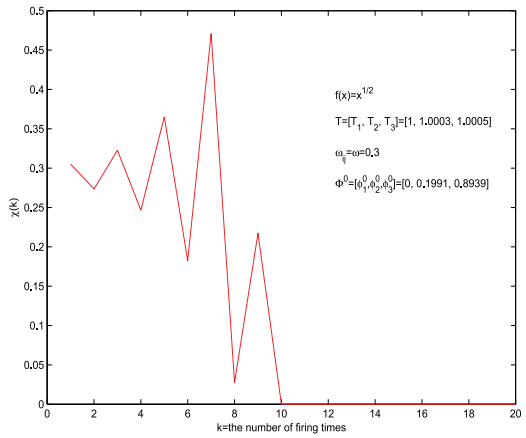

Figure 15. $\chi(t)$*, the synchronization order parameter, is defined in Figure* 3*. The parameters* ω_{ij} *and* T_i *are chosen so as to be from the stability region, Figure* 14*. With initial state being given as above, the system reaches full synchrony in* 10 *firings.*

numerical simulations, we pick randomly more than 20 sets of parameters with various sets of initial values; all the numerical results suggest the synchrony of the system. One such set of parameters and initial values and its corresponding numerical results are recorded in Figure 15.

Case (ii): The identical system is considered here. Let the number of oscillators be three. Figures 16 and 17 give the set of initial values not reaching synchrony, which contains the domain of the return map. Γ_3 is interpreted as $\phi_3^0 = 1$.

Case (iii): The case under consideration is the system of concave oscillators satisfying stability condition (2.9) and a modified absorption condition, which is stronger but easier to

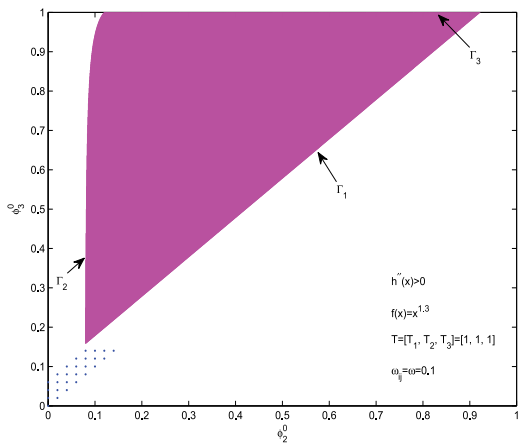

Figure 16. *The set of initial values reaching synchrony numerically is denoted by the dotted region. The points not in the dotted region, including the shaded region, will not acquire synchrony. In fact, the shaded region is the domain of the return map. This figure is consistent with the assertion of Theorems* 3.9.2(b) *and* 3.9.2(c).

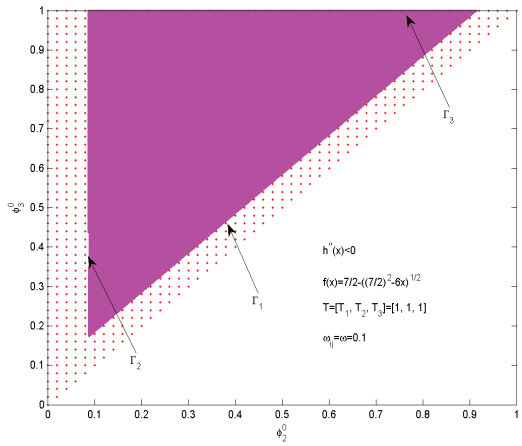

Figure 17. *The set of initial values reaching synchrony numerically is denoted by the dotted region. The points not in the dotted region, including the shaded region, will not acquire synchrony. In fact, the shaded region is the domain of the return map. This figure supports the assertion of Theorem* 3.9.2(c).

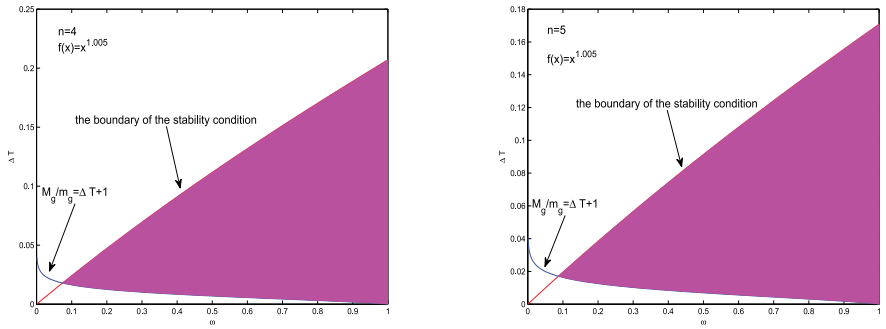
verify. Specifically, we consider the following absorption condition:

$$\frac{n}{n-2} > t_{\max} = \Delta T + 1 > \frac{M_g}{m_g}. \tag{3.27}$$

With such a stronger condition, the system will achieve full synchrony or reduce to two synchronous groups. However, in the case of the latter, to acquire full synchrony, the concavity of the evolution maps is still required to be sufficiently small. Numerically, we have that the



(a) The shaded part above is the region satisfied by both stability condition (2.9) and absorption conditions (3.27) for $n = 4$.

(b) The shaded part above is the region satisfied by both stability condition (2.9) and absorption conditions (3.27) for $n = 5$.

Figure 18.

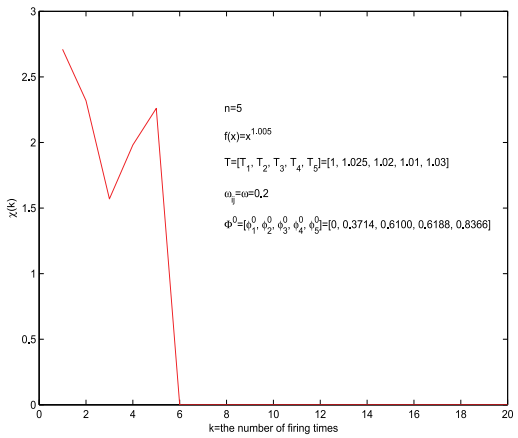


Figure 19. *Let $f(x) = x^{1.005}$. $\chi(t)$, the synchronization order parameter, is defined in Figure 3. The parameters ω_{ij} and T_i are so chosen to be in the stability region, Figure 18. Note that 5 is a prime number. Hence, when absorption occurs, the system breaks into a number of synchronous groups with their sizes being not all equal. Such an imbalance in coupling strength speeds the process of full synchrony. With initial state being given as above, the system reaches full synchrony in 6 firings.*

line $\left\{(\omega, \Delta T) : \Delta T = \frac{[\frac{n}{3}]+1}{[\frac{n}{3}]}\right\}$ does not intersect with the boundary of the stability condition. The parameter regions in the $\omega - \Delta T$ space satisfying (2.9) and (3.27) are, respectively, shown in the shaded regions in Figure 18(a) and (b). Picking the parameters from these regions, we see, in Figures 19 and 20, that the systems of both five and four concave oscillators reach full synchrony after a number of firings, provided that the concavity of the evolution maps is small. It should be mentioned that if n is a prime number, whenever the absorption occurs the system will acquire full synchrony in a short period of time. In this scenario, the imbalance in coupling strengths for the newly formed system is significant. In fact, it needs only six

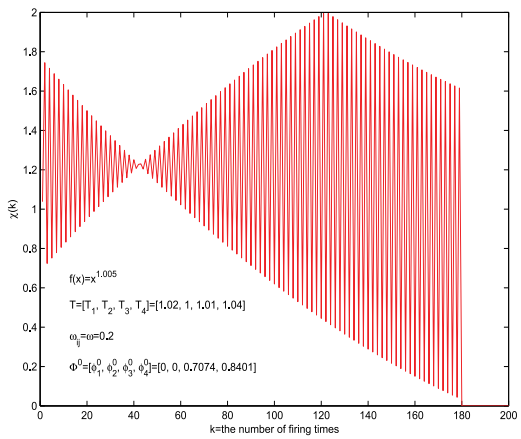

Figure 20. *With the evolution map, parameters, and initial state being given as above, the system reaches full synchrony in* 180 *firings. The reason that it takes so long for the system to synchronize is because* n *is an even number. When the absorption occurs, each of the synchronous groups may still have equal coupling strengths. Consequently, it takes longer for the system to synchronize since the imbalance in speed is insignificant.*

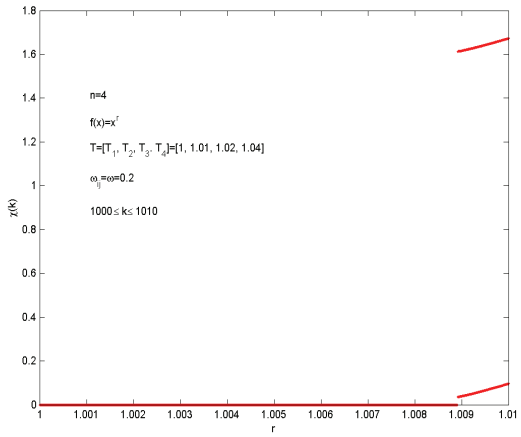

Figure 21. *The horizontal axis is the exponent of the evolution map of the form* $f(x) = x^r$, $r > 1$. *We plot* $\chi(k)$, $1000 \le k \le 1010$, *on the vertical axis.* 1000 *firings are needed to determine whether the corresponding system will achieve full synchrony or not. From the computer simulation, we see that the system will reach full synchrony, provided that* r *is roughly less than* 1.009.

firings to achieve full synchrony for $n = 5$. As for $n = 4$, the number of firings is 180 to secure synchrony. (See Figures 19 and 20, respectively.) To further support the validity of Proposition 3.7, we consider the evolution maps of the form $f(x) = x^r$, $r > 1$. The smaller r is, the smaller its concavity is. Treat r as a bifurcation parameter; Figures 21–23 show how we determine the smallest r that will make its corresponding system synchronize with various

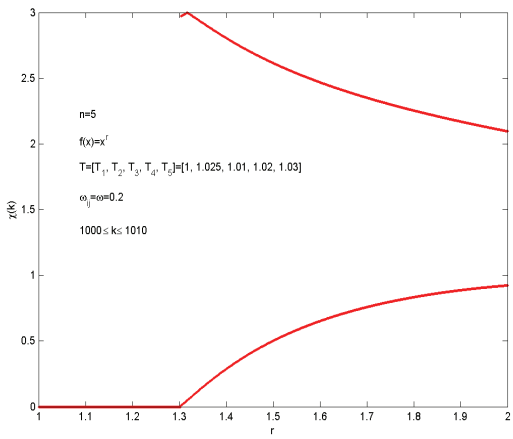

Figure 22. *Since* 5 *is a prime number, the imbalance measurement is "relatively" large if and when the system reduces to two synchronous groups. Therefore, the system is allowed to have a "larger" concavity at* $r \approx 1.3$.

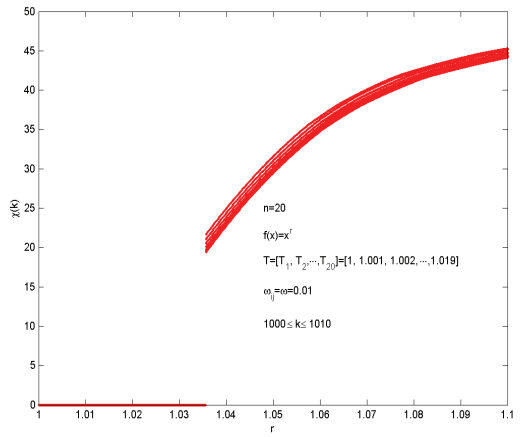

Figure 23. *With a greater number of oscillators present in the system, the computer simulation is consistent with the theory predicted in Proposition* 3.7.

choices of sizes of oscillators.

In conclusion, we prove stable synchrony for an integrate-and-fire model provided by Mirollo and Strogatz. Our results include the proof of Peskin's second conjecture. The next question is whether the results obtained here can be generalized to higher dimensional oscillators such as conductance-based models of neurons and/or phase-coupled networks via phase-response curves (see, e.g., [25] and the work cited therein). Note that the system presented here is just a special case for the phase-response curves approach. Nevertheless, the key ingredients for proving the full synchrony for those more current and advanced models should remain the same even though new technical difficulties might arise. For instance,

we still need to derive stability conditions so that the nonidentical system behaves like the identical system. We also need to have some kind of absorption conditions. For example, if the underlining model is dissipative, i.e., its time T-map decreases volume for all $T > 0$, then the natural tendency of the system would be to settle into a nonfiring state unless the direction of the flow of the "associated" return map points outward. If, on the other hand, the underlining model is volume-expanding, then the absorption process of the system tends to occur. It is certainly worthwhile to work on those problems.

Acknowledgments. The authors would like to thank the editor and referees for their helpful comments.

Algorithms for Rigorous Entropy Bounds and Symbolic Dynamics*

Sarah Day†, Rafael Frongillo‡, and Rodrigo Treviño§

Abstract. The aim of this paper is to introduce a method for computing rigorous lower bounds for topological entropy. The topological entropy of a dynamical system measures the number of trajectories that separate in finite time and quantifies the complexity of the system. Our method relies on extending existing computational Conley index techniques for constructing semiconjugate symbolic dynamical systems. Besides offering a description of the dynamics, the constructed symbol system allows for the computation of a lower bound for the topological entropy of the original system. Our overall goal is to construct symbolic dynamics that yield a high lower bound for entropy. The method described in this paper is algorithmic and, although it is computational, yields mathematically rigorous results. For illustration, we apply the method to the Hénon map, where we compute a rigorous lower bound of 0.4320 for topological entropy.

Key words. topological entropy, symbolic dynamics, Conley index, Hénon map, computer-assisted proof

1. Introduction.

There has been a significant increase in computer-assisted proofs in dynamical systems in the past ten years. Many of these studies use topological techniques and carry at heart ideas introduced by Conley [Con78] as well as extensions derived from them. Conley's ideas, which were generalizations of Morse's theory for gradient-like flows, have spawned two computational approaches for studying complicated dynamics in discrete dynamical systems. The first is the method of *correctly aligned windows* (also known as the method of *covering relations*), which traces its roots to work on *windows* introduced by Easton in [Eas75]. In this paper, we exploit the algorithmic nature of a second approach that relies on the more general tools of Conley index theory. While many of the algorithms for this approach were introduced in earlier works (see, e.g., [Szy95], [DJM04], [Day03] and references therein), it was necessary to develop additional techniques and algorithms for this project. In particular, we describe in section 3.1 extended techniques for locating a region of the domain to be used for computations, and present in section 3.2 a newly developed automated procedure for taking a computed Conley index and producing an appropriate representative symbolic dynamical system.

We use the computational techniques based on Conley index theory to build a semiconjugacy from a map $f : S \to S$, $S \subset \mathbb{R}^n$, to a symbolic dynamical system and obtain a

corresponding lower bound on the topological entropy (one measure of complexity) for the system. Since the symbols we use to construct the symbolic dynamics correspond to disjoint regions of the phase space $\mathbb{R}^n$, one benefit of this approach is that the symbolic dynamics offers a description of the dynamics on S, including information about the location of points along trajectories in S. Furthermore, the symbolic dynamics acts as a lower bound (via the semiconjugacy) for the dynamics of f on S; for any trajectory in the symbolic system there is at least one corresponding trajectory of f in S. It follows, as stated in Theorem 2.7, that the topological entropy of the symbolic system is a lower bound for the topological entropy of f. Since our goal is to compute a high lower bound, our approach relies on trying to maximize the complexity of the constructed symbolic system. We discuss our main approach for maximizing the complexity of the constructed system in section 3.

Topological entropy is a measurement that many have studied (see, e.g., [NBGM08], [AAC90], [ACE+87], [Col02], [Gal02]) using a variety of techniques. We see as the two main strengths in our approach the automation of our techniques and their independence from the typical constraint that stable and unstable manifolds are one-dimensional and restricted to the plane. Indeed, results in [DJM04] lead to entropy bounds for the infinite-dimensional Kot–Schaffer map in a way similar to the work described here, and in future work we plan to apply the automated techniques introduced in section 3 to this map to improve the bounds. In this paper, we apply our approach to the well-studied Hénon map in order to obtain results to compare with previous work in this area. We use our automated computational approach based on the ideas outlined above to construct a semiconjugacy between the dynamics on an appropriate subset of the Hénon attractor and a constructed symbolic dynamical system. Based on this construction, we give a rigorous lower bound of 0.4320 on the topological entropy of the Hénon map in Theorem 4.2. Section 4 also contains a comparison of this sample result with other work in this area.

This paper is organized in the following way. In section 2, we review the necessary background from dynamical systems and computational Conley index theory. Section 3 contains a detailed description of our extensions of this work to produce automated procedures for constructing complicated semiconjugate symbolic dynamics. Finally, in section 4 we apply these procedures to give sample results for the Hénon system.

2. Background.

In this section we review some basic definitions and ideas from dynamical systems theory and computational Conley index theory. We will state definitions and theorems which are relevant to our work, and refer the reader to [Rob95], [Con78], [MM02] and references therein for further development and details.

2.1. Symbolic dynamics and topological entropy.

Let $f : X \to X \subset \mathbb{R}^n$ be a continuous map. We will focus on maps that exhibit complicated dynamics on a compact subset $S \subset X$. Because the study of such maps and sets can be very complicated, they are often studied via a representation on a symbol space, giving rise to *symbolic dynamics*.

We focus on symbolic dynamics in the form of *subshifts of finite type*. Fix an integer $m \geq 2$, and let T be an $m \times m$ matrix with entries $t_{ij} \in \{0, 1\}$. The corresponding symbol space is

$$\Sigma_T := \{\mathbf{s} = (s_0 s_1 \ldots) \mid t_{s_k s_{k+1}} = 1 \text{ for all } k\}.$$

Although the matrix T is often referred to as the *adjacency matrix* in graph theory literature,

we will refer to T as the *symbol transition matrix* since it captures the allowed or admissible "transitions" between symbols. Finally, we define the *shift map* $\sigma_T : \Sigma_T \to \Sigma_T$ by

$$\sigma_T(\mathbf{s}) := \mathbf{s}', \quad \text{where } s'_i = s_{i+1}.$$

In this framework, (Σ_T, σ_T) is called a *subshift of finite type*, denoting both that we are working with only a finite list of (m) symbols and that only a subset of the set of all sequences on these m symbols is allowed by the symbol transition matrix T.

It is important to note that for an appropriate choice of metric on Σ_T, σ_T is a continuous map and $\sigma_T : \Sigma_T \to \Sigma_T$ is a dynamical system (see, e.g., [Rob95]). Subshifts of finite type are particularly nice in that dynamical objects of interest are often readily identifiable. For example, if one is looking for a period n orbit, then one checks that there is a symbol sequence $\mathbf{s}^* = (s_0, s_1, \ldots) \in \Sigma_T$ such that $s_{i+n} = s_i$ for all $i = 0, 1, \ldots$. If we view T as an adjacency matrix defining a directed graph, then $\mathbf{s}^*$ corresponds to an n-cycle, or cycle of length n, in the graph. For clarity, we include the following definition of the terms *cycle* and *simple cycle*.

Definition 2.1. *A* path *of length n in the directed graph G is a sequence of vertices $v_0, v_1, \ldots, v_n$ such that each pair (v_i, v_{i+1}) is an edge in G. If, in addition, $v_0 = v_n$, then $v_0, v_1, \ldots, v_n$ is a* cycle *of length n. Finally, a cycle $v_0, v_1, \ldots, v_n$ is a* simple cycle *provided that it contains no shorter cycles, namely, $v_i = v_j$ with $i \neq j$ if and only if $i, j \in \{0, n\}$.*

While subshifts of finite type and symbolic dynamical systems in general are nice to work with from a mathematical point of view, many interesting dynamical systems do not come in this form. Instead, as mentioned above, we may seek to represent a more general discrete dynamical system by symbolic dynamics. This representation often comes in the form of a *topological conjugacy* or *topological semiconjugacy*.

Definition 2.2. *A continuous map $\rho : X \to Y$ is a* topological semiconjugacy *between $f : X \to X$ and $g : Y \to Y$ if $\rho \circ f = g \circ \rho$ and ρ is surjective (onto). If, in addition, ρ is injective (one-to-one), then ρ is a* topological conjugacy.

Topological conjugacies preserve many properties of dynamical systems. One such example is the following theorem. (For more details, see [Dev89].)

Theorem 2.3. *Let ρ be a topological conjugacy between $f : X \to X$ and $g : Y \to Y$. Then $y \in Y$ is a periodic point of period n under g (i.e., $g^n(y) = y$) if and only if $\rho^{-1}(y)$ is a periodic point of period n under f.*

If f is topologically conjugate to a subshift of finite type, then we have a convenient list of trajectories of f given by the subshift. Indeed, in this case, the topological conjugacy acts as a coordinate transformation of the original system onto a decipherable (symbolic) system. In practice, such a complete description may be beyond our reach, and we instead construct topological semiconjugacies to appropriate subshifts of finite type. As illustrated by Theorem 2.7, these semiconjugate subshift systems offer lower bounds for the complexity of the dynamics of the original system.

One way to quantify the complexity of a given dynamical system is to compute its *topological entropy*. The following is based on Bowen's definition of topological entropy in [Bow71].

Definition 2.4. *Let $f : X \to X$ be a continuous map. A set $W \subset X$ is called (n, ϵ, f)-separated if for any two different points $x, y \in W$ there is an integer j with $0 \leq j < n$ so that the distance between $f^j(x)$ and $f^j(y)$ is greater than ϵ. Let $s(n, \epsilon, f)$ be the maximum*

cardinality of any (n, ϵ, f)*-separated set. The* topological entropy *of* f *is the number*

$$h_{top}(f) = \lim_{\epsilon \to 0} \limsup_{n \to \infty} \frac{\log(s(n, \epsilon, f))}{n}. \tag{2.1}$$

As a measurement of chaos, we say that a map f for which $h_{top}(f) > 0$ is chaotic, and, if $h_{top}(f) > h_{top}(g)$, then f is "more chaotic" than g.

Once again, we can turn to symbolic dynamics in order to perform concrete computations.

Theorem 2.5 (see Robinson [Rob95]). *Let* T *be a symbol transition matrix, and let* $\sigma_T : \Sigma_T \to \Sigma_T$ *be the associated subshift of finite type. Then*

$$h_{top}(\sigma_T) = \log(sp(T)),$$

where $sp(T)$ *is the spectral radius of* T*.*

In essence, (n, ϵ, σ_T)-separation is encoded in the representation of the system and may be computed directly from the symbol transition matrix T.

Computing the topological entropy of a system not given as a subshift proves to be more challenging. In this setting and from a computational perspective, (2.1) may appear daunting. For one thing, sensitive dependence on initial conditions, a property commonly associated with chaotic systems, makes careful, precise measurements of (n, ϵ, f)-separation for large n and small ϵ difficult if not impossible. One technique for dealing with this problem is to focus on computing periodic points up to some cut-off period N rather than length N segments of general trajectories. The problem of finding periodic points may be reduced to finding fixed points for a sufficiently high iterate of the map, and two different periodic orbits of period n are necessarily (n, ϵ, f)-separated for sufficiently small ϵ. One then checks that

$$\left\{ \frac{\log(\#\{\text{periodic points of period } n\})}{n} \right\}_{n \leq N}$$

appears to be converging. Galias employed this approach in his study of the Hénon map in [Gal01]. The question now becomes, "is N sufficiently large to yield a good approximation for topological entropy?" This leads us to a second fundamental obstacle to a mathematically rigorous computational approach—the need to obtain asymptotic measurements in both n and ϵ. In Theorem 2.7 we use a special construction of a semiconjugacy to a subshift system to overcome these difficulties and to compute a rigorous lower bound.

This construction relies on tools from *Conley index theory* discussed in section 2.2. We use these tools to build the subshift system with the *itinerary function* serving as the semiconjugacy linking the systems.

Definition 2.6. *Suppose that* $N \subset X$ *may be decomposed into* $m < \infty$ *disjoint, closed subsets* $(N = \cup_{i=1,\ldots,m} N_i)$*. Let* S *be the maximal invariant set in* N *(i.e.,* S *is the largest set such that* $S \subset N$ *and* $f(S) = S$*). Then* $f^j(S) \subset N$ *for all* $j = 0, 1, \ldots$*. Finally, let* T *be the* $m \times m$ *symbol transition matrix given by*

$$t_{ij} = \begin{cases} 1 & \text{if } f(S \cap N_j) \cap N_i \neq \emptyset, \\ 0 & \text{otherwise.} \end{cases}$$

The itinerary function $\rho : S \to \Sigma_T$ *is given by* $\rho(x) = s_0 s_1 \ldots$, *where* $s_j = i$ *for* $f^j(x) \in N_i$. *This function is continuous under the appropriate choice of metrics. (See* [Dev89], [Rob95] *for more details.)*

Finally, the following theorem allows us to use this semiconjugacy to obtain a lower bound for the topological entropy of the system under study.

Theorem 2.7. *Suppose that the itinerary function* ρ *is a semiconjugacy from* $f : S \to S$ *to* $\sigma_T : \Sigma_T \to \Sigma_T$ *for some* $S \subset X$ *and subshift of finite type* (σ_T, Σ_T) *with symbol transition matrix* T. *Then*

$$h_{top}(f) \geq \log(sp(T)) = h_{top}(\sigma_T),$$

where $sp(T)$ *is the spectral radius of* T.

Proof. Let $d(N_i, N_j) := \min_{x \in N_i,\, y \in N_j} d(x, y) > 0$ be the minimal distance between the two disjoint, closed sets N_i and N_j. Since there are only a finite number of these sets, $\epsilon_* := \min_{1 \leq i \neq j \leq m} d(N_i, N_j) > 0$.

For $\mathbf{s} = (s_0, s_1, \ldots) \in \Sigma_T$, call the sequence of n symbols, $B_n := (s_0, \ldots, s_{n-1})$, an *admissible* n*-block under* T. For each admissible n-block $B_n = (s_0, \ldots, s_{n-1})$, choose $x_{B_n} \in S$ such that $\rho(x_{B_n}) = (s_0, s_1, \ldots, s_{n-1}, s_n, \ldots) \in \Sigma_T$. Such a point exists in S since ρ maps S onto Σ_T. Furthermore, for $\epsilon < \epsilon_*$, the points chosen in S corresponding to two different admissible n-blocks must be (n, ϵ, f)-separated since, within n iterates, their itineraries carry them to two disjoint subsets of $S \cap N$, separated by a distance of at least ϵ_*.

We now have that for $\epsilon < \epsilon_*$, $s(n, \epsilon, f) \geq \#\{\text{admissible } n\text{-blocks under } T\}$. The asymptotic size of the set of admissible n-blocks may be computed as follows (see Theorem 1.9(b) in [Rob95]), to obtain the desired result:

$$\begin{aligned} h_{top}(f) &= \lim_{\epsilon \to 0} \limsup_{n \to \infty} \frac{\log(s(n, \epsilon, f))}{n} \\ &\geq \limsup_{n \to \infty} \frac{\log(\#\{\text{admissible } n\text{-blocks under } T\})}{n} \\ &= \log(sp(T)) \\ &= h_{top}(\sigma_T). \qquad \blacksquare \end{aligned} \tag{2.2}$$

Thus, we may bound the topological entropy of a map f from below by finding a semiconjugacy from f to an appropriate subshift of finite type. The higher the spectral radius of the symbol transition matrix T, the better the lower bound we achieve for the topological entropy of the original system.

2.2. Conley index theory. We now present some of the topological tools used to build the subshift of finite type required for Theorem 2.7. These tools are based on Conley index theory for which we now give definitions, facts, and theorems which are relevant to our work. A discussion of the implementation of these ideas in a computational framework follows in section 2.4.

Let $f : \mathbb{R}^n \to \mathbb{R}^n$ be a continuous map. A *trajectory through* $x \in \mathbb{R}^n$ is a sequence

$$\gamma_x := (\ldots, x_{-1}, x_0, x_1, \ldots) \tag{2.3}$$

such that $x_0 = x$ and $x_{n+1} = f(x_n)$ for all $n \in \mathbb{Z}$. We now define the *invariant set relative to* $N \subset \mathbb{R}^n$ as

$$Inv(N, f) := \{x \in N \mid \text{there exists a trajectory } \gamma_x \text{ with } \gamma_x \subset N\}. \tag{2.4}$$

One example of a relative invariant set is the domain $S = Inv(N, f)$ on which we defined the itinerary function ρ in Definition 2.6.

We are now ready to present some of the basic structures in Conley index theory.

Definition 2.8. *A compact set $N \subset \mathbb{R}^n$ is an* isolating neighborhood *if*

$$Inv(N, f) \subset int(N), \tag{2.5}$$

where $int(N)$ denotes the interior of N. S is an isolated invariant set *if $S = Inv(N, f)$ for some isolating neighborhood N.*

We use the next two definitions to encode the dynamics on an isolating neighborhood.

Definition 2.9. *Let $P = (P_1, P_0)$ be a pair of compact sets with $P_0 \subset P_1 \subset X$. The map induced on the pointed quotient space $(P_1/P_0, [P_0])$ is*

$$f_P(x) := \begin{cases} f(x) & \text{if } x, f(x) \in P_1 \setminus P_0, \\ [P_0] & \text{otherwise.} \end{cases} \tag{2.6}$$

Definition 2.10 (see [RS88]). *The pair of compact sets $P = (P_1, P_0)$ with $P_0 \subset P_1 \subset X$ is an* index pair *for f, provided that*

1. *the induced map, f_P, is continuous,*
2. *$\overline{P_1 \setminus P_0}$, the closure of $P_1 \setminus P_0$, is an isolating neighborhood.*

In this case, we say that P is an index pair for the isolated invariant set $S = Inv(\overline{P_1 \setminus P_0}, f)$.

The following definition is required for the definition of the Conley index.

Definition 2.11. *Two group homomorphisms, $\phi : G \to G$ and $\psi : G' \to G'$ on abelian groups G and G', are* shift equivalent *if there exist group homomorphisms $r : G \to G'$ and $s : G' \to G$ and a constant $m \in \mathbb{N}$ (referred to as the "lag") such that*

$$r \circ \phi = \psi \circ r, \quad s \circ \psi = \phi \circ s, \quad r \circ s = \psi^m, \quad \text{and} \quad s \circ r = \phi^m.$$

The shift equivalence class of ϕ, *denoted $[\phi]_s$, is the set of all homomorphisms ψ such that ψ is shift equivalent to ϕ.*

Definition 2.12. *Let $P = (P_1, P_0)$ be an index pair for the isolated invariant set $S = Inv(\overline{P_1 \setminus P_0}, f)$, and let $f_{P*} : H_*(P_1, P_0) \to H_*(P_1, P_0)$ be the map induced on the relative homology groups $H_*(P_1, P_0)$ from the map f_P. The* Conley index of S *is the shift equivalence class of f_{P*},*

$$Con(S, f) := [f_{P*}]_s. \tag{2.7}$$

The Conley index for the isolated invariant set S given in Definition 2.12 is well defined; namely, every isolated invariant set has an index pair, and the corresponding shift equivalence class remains invariant under different choices for this index pair (see, e.g., [MM02]).

So far we have passed from continuous maps to induced maps on relative homology. Our overall goal, however, is to describe the dynamics of our original map. Here we present

measurements based on the map on homology that may give us information about the original map. The first theorem is Ważewski's principle in the context of Conley index theory.

Theorem 2.13. *If* $Con(S, f) \neq [0]_s$, *then* $S \neq \emptyset$.

By requiring additional structure in the isolating neighborhood N of S, we can use a modification of Theorem 2.13 to study finer structure in S.

Corollary 2.14. *Let* $N \subset X$ *be the union of disjoint compact sets* $N_1, \ldots, N_m$, *and let* $S := Inv(N, f)$ *be the isolated invariant set relative to* N. *Let*

$$S' = Inv(N_1, f_{N_n} \circ \cdots \circ f_{N_1}) \subset S,$$

where f_{N_i} *denotes the restriction of the map* f *to the region* N_i. *If*

$$Con(S', f_{N_n} \circ \cdots \circ f_{N_1}) \neq [0]_s, \tag{2.8}$$

then $S' \neq \emptyset$. *More specifically, there exists a point in* S *whose trajectory under* f *travels through the regions* $N_1, \ldots, N_n$ *in the prescribed order.*

We here note that, given the hypotheses of Corollary 2.14, there is a nice technique for obtaining the index of S' given the computed index map f_{P*}, where $P = (P_1, P_0)$ is an index pair with $N = \overline{P_1 \setminus P_0}$. Using an approach developed by Szymczak in [Szy95], we set

$$f_P^{ij}(x) := \begin{cases} f(x) & \text{if } x \in N_i \text{ and } f(x) \in N_j, \\ [P_0] & \text{otherwise.} \end{cases} \tag{2.9}$$

Then $f_{P*}^{ij} : H_*(P_1, P_0 \cup (\cup_{l \neq i} N_l)) \to H_*(P_1, P_0 \cup (\cup_{l \neq j} N_l))$. Given f_{Pk} in matrix form representing the linear map on $H_k(P_1, P_0)$, we may label the columns/rows by location of the associated relative homology generators in the subgroups $H_k(P_1, P_0 \cup (\cup_{l \neq 1} N_l)), \ldots,$ $H_k(P_1, P_0 \cup (\cup_{l \neq n} N_l))$. To simplify notation, we say that generator g is in region N_i if $g \in H_k(P_1, P_0 \cup (\cup_{l \neq i} N_l))$. Then f_{Pk}^{ij} is the $n_j \times n_i$ submatrix with n_i columns corresponding to the n_i generators in N_i and n_j rows corresponding to the n_j generators in N_j. Furthermore, $(P_1, P_0 \cup (\cup_{l \neq 1} N_l))$ is an index pair for the isolated invariant set $S' = Inv(N_1, f_{N_n} \circ \cdots \circ f_{N_1})$ with index map $f_{P*}^{n1} \circ \cdots \circ f_{P*}^{12} : H_*(P_1, P_0 \cup (\cup_{l \neq 1} N_l)) \to H_*(P_1, P_0 \cup (\cup_{l \neq 1} N_l))$. Therefore,

$$Con(S', f_{N_n} \circ \cdots \circ f_{N_1}) = [f_{P*}^{n1} \circ \cdots \circ f_{P*}^{12}]_s. \tag{2.10}$$

Since the more general problem of determining whether the linear map $f_{Pk} : H_k(P_1, P_0) \to H_k(P_1, P_0)$ is not shift equivalent to 0 may be difficult, we here focus on a computable sufficient condition. Trace is preserved by shift equivalence, and we adopt the notation

$$\mathrm{tr}_k(Con(S, f)) := \mathrm{tr}(f_{Pk}),$$

where $\mathrm{tr}(f_{Pk})$ denotes the trace of the linear map $f_{Pk} : H_k(P_1, P_0) \to H_k(P_1, P_0)$. Then if $\mathrm{tr}_k(Con(S, f)) \neq 0$ for some k, $Con(S, f) \neq [0]_s$.

Corollary 2.15. *If* $\mathrm{tr}_k(Con(S', f_{N_{i_n}} \circ \cdots \circ f_{N_{i_1}})) \neq 0$ *for some* k, *then there exists* $x \in S'$ *with* $\rho(x) = i_1 i_2 \ldots i_n i_1 i_2 \ldots i_n \ldots$.

Taking this approach, we are close to showing something stronger, namely that there is a periodic orbit under f with the corresponding cyclic symbol sequence. This stronger statement relies on computing the Lefschetz number.

Definition 2.16. *Let S be an isolated invariant set. The* Lefschetz number of S *is defined as*

$$L(S,f) := \sum_k (-1)^k \operatorname{tr}(f_{Pk}), \tag{2.11}$$

where $P = (P_1, P_0)$ is an index pair for S.

The Lefschetz number is essential to the following theorem and its corollary.

Theorem 2.17. *Let S be an isolated invariant set. If*

$$L(S,f) \neq 0, \tag{2.12}$$

then S contains a fixed point.

For a proof, see [Szy96]. As before, a refinement of the approach allows us to study symbolic dynamics.

Corollary 2.18. *Let $N \subset X$ be the finite union of disjoint compact sets $N_1, \ldots, N_m$, and let $S := Inv(N, f)$. Let $S' = Inv(N_1, f_{N_n} \circ \cdots \circ f_{N_1}) \subset S$, where f_{N_i} denotes the map f restricted to the region N_i. If*

$$L(S', f_{N_n} \circ \cdots \circ f_{N_1}) \neq 0, \tag{2.13}$$

then $f_{N_n} \circ \cdots \circ f_{N_1}$ contains a fixed point in S' that corresponds to a periodic point of period n in S that under f travels through the regions $N_1, \ldots, N_n$ in order.

In what follows, we will develop algorithms based on Corollary 2.15 to construct and verify symbolic dynamics. However, in the special case where the index map f_{P*} is nontrivial on exactly one level (as occurs with the Hénon map), we may use Corollary 2.18 to show that the constructed semiconjugate symbolic system has the added stronger property that every periodic orbit in the symbolic system corresponds to a periodic orbit in the original system of the same period.

2.3. Multivalued and combinatorial maps. Now that we have the relevant tools from Conley index theory, we can begin applying them algorithmically to extract information about the dynamical system $f : X \to X$. In this section, we describe the construction of a combinatorial representation of f. The first step is to define a *multivalued map* F that will be used to incorporate bounded errors in the representation.

Definition 2.19. *The* multivalued map $F : X \rightrightarrows X$ *is a map from X to its power set; i.e., for all $x \in X$, $F(x) \subset X$. If, for a continuous single-valued map $f : X \to X$, $f(x) \in F(x)$ and $F(x)$ is acyclic (i.e., has the homology of a point) for all $x \in X$, then f is a* continuous selector of F, *and F is an* enclosure *of f.*

In what follows, we discuss how to construct an enclosure of the map under study. The purpose of the enclosure is to incorporate round-off and other errors that occur in computations. This construction requires rigorous small error bounds in order to create an enclosure whose images are not so large as to obscure all relevant dynamics. Given an appropriate enclosure, the topological tools from section 2.2 may be used to uncover dynamics of the underlying map. Furthermore, there are algorithms for both the construction of the enclosure and the computation of the Conley index. These algorithms require a further step—discretizing the domain in order to store it in the computer as a finite list of objects.

We begin by using the subdivision procedure implemented in the software package *GAIO* [DFJ01] to create a grid $\mathcal{G}$ on a compact (rectangular) region in X. In practice, the region chosen for representation is usually determined either experimentally through nonrigorous numerical simulations or analytically given a special structure or symmetry for the system (e.g., a compact attracting region). We partition a specified rectangular set $W = \prod_{k=1}^{n} [x_k^-, x_k^+] \subset \mathbb{R}^n$ into a *cubical grid*

$$\mathcal{G}^{(d)} := \left\{ \prod_{k=1}^{n} \left[x_k^- + \frac{i_k r_k}{2^d},\, x_k^- + \frac{(i_k+1) r_k}{2^d} \right] \;\middle|\; i_k \in \left\{ 0, \ldots, 2^d - 1 \right\} \right\},$$

where $r_k = x_k^+ - x_k^-$ is the radius of W in the kth coordinate and the depth d is a nonnegative integer. We call an element of the grid, $B = \prod_{k=1}^{n} \left[x_k^- + \frac{i_k r_k}{2^d},\, x_k^- + \frac{(i_k+1) r_k}{2^d} \right]$, a *box*. For a collection of boxes, $G \subset \mathcal{G} = \mathcal{G}^{(d)}$, define the *topological realization* of G as $|G| := \cup_{B \in G} B \subset \mathbb{R}^n$.

Constructing a useful *combinatorial enclosure* involves bounding all round-off and other errors. In our study of the Hénon map in section 4, we construct a combinatorial enclosure by computing images of $f(|G|)$ using interval arithmetic software. This produces a bounding box, $\tilde{f}(|G|)$, for the image $f(|G|)$, which is then intersected with the grid $\mathcal{G}$ to produce the combinatorial enclosure image

$$\mathcal{F}(G) := \{ G' \in \mathcal{G} : |G'| \cap \tilde{f}(|G|) \neq \emptyset \}.$$

This combinatorial enclosure, $\mathcal{F} : \mathcal{G} \rightrightarrows \mathcal{G}$, yields an enclosure $F = |\mathcal{F}|$ of f in the following way: define $|\mathcal{F}| : W \rightrightarrows W$, where $W = \cup_{G \in \mathcal{G}} |G|$,

$$|\mathcal{F}|(x) := \bigcup_{G \in \mathcal{G} \text{ with } x \in |G|} |\mathcal{F}(G)|. \tag{2.14}$$

More importantly, efficient algorithms exist for computing isolating neighborhoods, index pairs, and Conley indices for f from an appropriate combinatorial enclosure $\mathcal{F}$ of f.

2.4. Computational Conley index theory. Now we give algorithms for computing the isolating neighborhoods, index pairs, and Conley indices first introduced in section 2.2 in the setting of combinatorial enclosures.

Definition 2.20. *A* combinatorial trajectory *of a combinatorial enclosure $\mathcal{F}$ through $G \in \mathcal{G}$ is a bi-infinite sequence $\gamma_G = (\ldots, G_{-1}, G_0, G_1, \ldots)$ with $G_0 = G$, $G_n \in \mathcal{G}$, and $G_{n+1} \in \mathcal{F}(G_n)$ for all $n \in \mathbb{Z}$.*

Definition 2.21. *The* combinatorial invariant set *in $\mathcal{N} \subset \mathcal{G}$ for a combinatorial enclosure $\mathcal{F}$ is*

$$Inv(\mathcal{N}, \mathcal{F}) := \{ G \in \mathcal{G} : \textit{there exists a trajectory } \gamma_G \subset \mathcal{N} \}.$$

Definition 2.22. *The* combinatorial neighborhood *of $\mathcal{B} \subset \mathcal{G}$ is*

$$o(\mathcal{B}) := \{ G \in \mathcal{G} : |G| \cap |\mathcal{B}| \neq \emptyset \}.$$

This set, $|o(\mathcal{B})|$, sometimes referred to as a *one box neighborhood of $\mathcal{B}$ in $\mathcal{G}$*, is the smallest representable neighborhood of $|B|$ in the grid $\mathcal{G}$.

While there are different characterizations of isolation in the setting of combinatorial enclosures, we chose the following for this work.

Definition 2.23. *If*

$$o(Inv(\mathcal{N},\mathcal{F})) \subset \mathcal{N},$$

then $\mathcal{N} \subset \mathcal{G}$ *is a* combinatorial isolating neighborhood *under* $\mathcal{F}$.

Note that, by construction, the topological realization $|\mathcal{N}|$ of a combinatorial isolating neighborhood $\mathcal{N}$ under $\mathcal{F}$ is an isolating neighborhood under any continuous selector $f \in |\mathcal{F}|$. This definition is stronger than what is actually required to guarantee isolation on the topological level. It is, however, the definition that we will use in this work and is computable using the following approach.

Let $\mathcal{S} \subset \mathcal{G}$. Set $\mathcal{N} = \mathcal{S}$, and let $o(\mathcal{N})$ be the combinatorial neighborhood of $\mathcal{N}$ in $\mathcal{G}$. If $Inv(o(\mathcal{N}),\mathcal{F}) = \mathcal{N}$, then $\mathcal{N}$ is isolated under $\mathcal{F}$. If not, set $\mathcal{N} := Inv(o(\mathcal{N}),\mathcal{F})$ and repeat the above procedure. In this way, we grow the set $\mathcal{N}$ until either the isolation condition is met or the set grows to intersect the boundary of $\mathcal{G}$, in which case the algorithm fails to locate an isolating neighborhood in $\mathcal{G}$. This procedure is outlined in more detail in the following algorithm from [DJM04].

Algorithm 1 (Grow isolating neighborhood).

```
INPUT:  grid 𝒢, combinatorial enclosure ℱ on 𝒢, set 𝒮 ⊂ 𝒢
OUTPUT: a combinatorial isolating neighborhood 𝒩 containing 𝒮
        or 𝒩 = ∅ if the isolation condition is not met
𝒩 = grow_isolating_neighborhood(𝒢, ℱ, 𝒮)
    𝒢_boundary := {G ∈ 𝒢 : |G| ∩ ∂|𝒢| ≠ ∅};
    𝒩 := 𝒮;
    while Inv(o(𝒩),ℱ) ⊄ 𝒩 and 𝒩 ∩ 𝒢_boundary = ∅,
        𝒩 := Inv(o(𝒩),ℱ);
    end
    if 𝒩 ∩ 𝒢_boundary = ∅, return 𝒩;
    else return ∅;
    end
```

Once we have an isolating neighborhood for f, our next goal is to compute a corresponding index pair. The following definition of a *combinatorial index pair* again emphasizes our goal of using the combinatorial enclosure to compute structures for f.

Definition 2.24. *A pair* $\mathcal{P} = (\mathcal{P}_1,\mathcal{P}_0)$ *of cubical sets is a* combinatorial index pair *for a combinatorial enclosure* $\mathcal{F}$ *if the corresponding topological realization* $P = (P_1,P_0)$*, where* $P_i := |\mathcal{P}_i|$*, is an index pair for any continuous selector* $f \in |\mathcal{F}|$*. Namely,* $\overline{P_1 \setminus P_0} = |\mathcal{P}_1 \setminus \mathcal{P}_0|$ *is an isolating neighborhood under* f*, and the map* f_P*, as defined in Definition 2.9, is continuous.*

The following algorithm produces a combinatorial index pair associated with a combinatorial isolating neighborhood produced via Algorithm 1. While there are other algorithms for producing combinatorial index pairs, this algorithm works well with later index computations. For more details, see the description of *modified combinatorial index pairs* in [Day03].

Algorithm 2 (Build index pair).

```
INPUT:  grid 𝒢, combinatorial enclosure ℱ on 𝒢,
        combinatorial isolating neighborhood 𝒩 produced by Algorithm 1
```

```
OUTPUT: combinatorial index pair P = (P_1, P_0) with P_1 \ P_0 = N
[P_1, P_0] = build_index_pair(G, F, N)
    P_0 := ∅;
    New := F(N) ∩ o(N) \ N;
    while New ≠ ∅
        P_0 := P_0 ∪ New;
        New := (F(P_0) ∩ o(N)) \ P_0;
    end
    P_1 := N ∪ P_0;
    return [P_1, P_0];
```

We now have an isolating neighborhood $|\mathcal{N}|$ and corresponding index pair $P := (|\mathcal{P}_1|, |\mathcal{P}_0|)$ for f. What remains in computing the Conley index for the associated isolated invariant set, $S := Inv(|\mathcal{N}|, f)$, is to compute the map $f_{P*} : H_*(|\mathcal{P}_1|, |\mathcal{P}_0|) \to H_*(|\mathcal{P}_1|, |\mathcal{P}_0|)$. Once again, the combinatorial enclosure offers the appropriate computational framework, and we use the software program *homcubes* in [Pil98] to compute f_{P*}. This step is outlined in Algorithm 3.

Algorithm 3 (Compute index map).

```
INPUT:  grid G, combinatorial enclosure F on G,
        combinatorial index pair P = (P_1, P_0) produced by Algorithm 2
OUTPUT: relative homology groups H_*(|P_1|, |P_0|),
        the induced index map f_{P*} : H_*(|P_1|, |P_0|) → H_*(|P_1|, |P_0|),
        and the induced submaps {f^{ij}_{Pk}} on connected components
[f_{P*} H_*(|P_1|, |P_0|) {f^{ij}_{Pk}}] = compute_index_map(G, F, P_1, P_0)
    Q_1 = F(P_1);
    Q_0 = F(P_0);
    [f_{P*} H_*(|P_1|, |P_0|) {f^{ij}_{Pk}}] := homcubes(P_1, P_0, Q_1, Q_0, F);
    return [f_{P*} H_*(|P_1|, |P_0|) {f^{ij}_{Pk}}];
```

Algorithm 3 produces a sequence of matrices for the maps $f_{P0}, f_{P1}, \ldots, f_{Pn}$, where n is the dimension of the phase space X. For $k > n$, $f_{Pk} = 0$. The associated Conley index is $Con_*(S) = [f_{P*}]_s$ for $S := Inv(|\mathcal{P}_1 \setminus \mathcal{P}_0|, f)$. The submaps $f^{ij}_{Pk} : H_k(|\mathcal{P}_1|, |\mathcal{P}_0| \cup_{l \neq i} |\mathcal{N}_l|) \to H_k(|\mathcal{P}_1|, |\mathcal{P}_0| \cup_{l \neq j} |\mathcal{N}_l|)$, where $|\mathcal{N}_1|, \ldots, |\mathcal{N}_n|$ are the connected components of $|\mathcal{P}_1 \setminus \mathcal{P}_0|$, are given as submatrices of f_{Pk}. These are the maps required for Corollaries 2.14, 2.15, and 2.18. In the following section, we describe an algorithmic procedure for using this index information to construct the appropriate subshift of finite type.

3. Constructing and verifying complicated symbolic dynamics. Given $f : X \to X$, the general method we adopt for computing a lower bound on topological entropy consists of the following steps:

- constructing a fixed cubical grid $\mathcal{G}$ on a subset of X and a combinatorial enclosure $\mathcal{F}$ of f on $\mathcal{G}$ (section 2.3),
- locating a region of interest $\mathcal{S}$ in $\mathcal{G}$ (section 3.1),
- computing the associated Conley index (section 2.4),
- constructing semiconjugate symbolic dynamics (section 3.2),
- using the constructed symbolic dynamical system to compute a lower bound on the topological entropy of f (Theorem 2.7).

While many steps of this general procedure have been carried out in previous work (e.g., [DJM04] for the first four steps, and [Gal01] for the last step), we here seek to uncover far more complicated symbolic dynamics. This requires a more automated approach based on setting verifiable conditions for uncovering and proving the existence of cyclic symbolic dynamics and ignoring or giving up on the verification of dynamics that does not satisfy these conditions. Along these lines, we now give algorithms for locating a region of interest (section 3.1) and processing the resulting index information (section 3.2) that allow us to uncover more complicated dynamics than previously found using related techniques. This improved procedure produces the entropy bounds presented in section 4.

3.1. Locating a region of interest. We now turn to the second task in this list—that of locating the region of the grid where we will attempt to compute interesting symbolic dynamics. More specifically, the set that we are calling the *region of interest* will serve as the input, $\mathcal{S}$, for Algorithm 1. We show three different methods for locating regions of interest for the Hénon map in sections 4.1, 4.2, and 4.3. In this section, we focus on the method that, of these three, both is general (i.e., is not restricted to studies of the Hénon map) and yields high entropy bounds. This is the method followed in section 4.2. The first step in this approach is similar in spirit to the work of Cvitanović and others in using periodic orbits of low periods to approximate chaotic attractors. We begin by finding short cycles in the combinatorial enclosure (directed graph) $\mathcal{F}$. These short cycles correspond to possible periodic orbits of low period for f. We then add a level of complexity by searching for paths in the directed graph between these short cycles. From a dynamics point of view, these paths represent possible mixing between the periodic regions.

We construct a list of short cycles in $\mathcal{G}$ by setting ourselves a computational parameter `Max_Cycle_Length` $\in \mathbb{Z}^+$ and locating the cycles in $\mathcal{F}$ of length k with $1 \leq k \leq$ `Max_Cycle_Length`. These cycles are nonzero entries on the diagonal of $\mathcal{F}$ (when viewed as a transition matrix) raised to the kth power. The corresponding computed vertices in $\mathcal{F}$ are the regions in $\mathcal{G}$ that may contain period k points of f. Starting with $\mathcal{S} = \emptyset$, we begin adding the short cycles to $\mathcal{S}$ one by one, starting with the shortest. Just before adding a cycle to $\mathcal{S}$, we grow its isolating neighborhood using Algorithm 1 and then check that this neighborhood does not intersect the isolating neighborhood of the current collection. This corresponds to a possible increase in the number of symbols and/or the number of admissible transitions between symbols in the resulting constructed symbolic system and may eventually lead to a higher entropy bound. If this condition is not met, we do not add the cycle but move to the next cycle in the list, continuing until the list is exhausted. We next use breadth first search (BFS) to find shortest path, pairwise connections between the short cycles in $\mathcal{S}$ and add these connecting paths to $\mathcal{S}$. This procedure is outlined in Algorithm 4.

Algorithm 4 (Locating region of interest/joining low cycles).

```
INPUT:      grid 𝒢, combinatorial enclosure ℱ on 𝒢,
            computational parameter Max_Cycle_Length
OUTPUT:     region of interest 𝒮 ⊂ 𝒢
𝒮 = find_and_connect_low_cycles(𝒢, ℱ, Max_Cycle_Length)
   𝒮 = ∅;
   𝒩 = ∅;
```

```
for n = 1 : Max_Cycle_Length,
     for each length n cycle c in F,
          N_c = grow_isolating_neighborhood(G, F, c);
          if N_c ∩ N = ∅,
               S = S ∪ c;
               N = grow_isolating_neighborhood(G, F, N ∪ c);
          end
     end
end
S_c := S;
for each vertex v_i ∈ S_c,
     for each vertex v_j ∈ S_c,
          γ = shortest_path in F from v_i to v_j in G\o(o(S));
          S := S ∪ γ;
     end
end
return S;
```

Here, we explicitly compute cycles with lengths up to `Max_Cycle_Length`, which in practice is small. However, we obtain many new cycles by adding pairwise connections between the computed cycles. This allows us to uncover complicated dynamics without having to explicitly search for the long cycles that correspond to periodic orbits of high period. As illustration, Figure 1 depicts a subshift of finite type constructed from a region of interest consisting of a length 2 cycle, two length 4 cycles, and pairwise shortest connecting paths between these three objects. Note that the resulting subshift system contains infinitely many cycles (of lengths 5, 8, 10, and higher) and positive topological entropy.

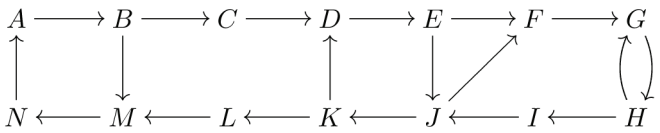

Figure 1. *Symbol transition graph constructed from a* 2*-cycle, two* 4*-cycles, and pairwise connections.*

While effective in computation of entropy bounds for the Hénon map (see section 4.2), this approach for the construction of the region of interest, $\mathcal{S}$, could be improved. Given a fixed combinatorial enclosure $\mathcal{F}$ on a grid $\mathcal{G}$, one goal would be to optimize the construction of $\mathcal{S}$ in order to produce a subshift of finite type with the highest possible entropy. As a first step along these lines, the relationship between the entropy bound and the maximal cycle length used in Algorithm 4 in a study of the Hénon map is depicted in Figure 5. In addition, there is a clear trade-off between refining the grid in order to find, isolate, and connect more low period cycles to produce a higher bound and the associated increase in computational cost. (The effect of refining the grid on increasing the bound is illustrated for the Hénon map in Figure 6.) Another improvement to these techniques related to this balance would involve making the computation of $\mathcal{G}$, and therefore $\mathcal{S}$, adaptive. The goal here would be to refine the grid in areas where new low-period periodic orbits and connec-

tions may be uncovered without having to recompute structures in the remainder of the space.

3.2. Processing index information. Recall that our goal is to compute complicated symbolic dynamics. If we are successful in locating an appropriate region of interest in the domain (one approach is described in section 3.1), the corresponding Conley index computed by the algorithms described in section 2.4 is given as a large matrix representing the map induced on an index pair consisting of many disjoint components.

From this index map, we wish to find a symbol transition matrix T such that f is semiconjugate to the subshift on Σ_T. We first use some properties of shift equivalence to simplify the computed index map. We then construct T from a collection of cycles, called *verified cycles*, that satisfy the hypotheses of Corollary 2.15.

3.2.1. Removing transient generators. We begin our processing of the index map $f_{P*} : H_*(P_1, P_0) \to H_*(P_1, P_0)$ by removing generators from $H_*(P_1, P_0)$ that do not correspond to asymptotic invariant behavior. More specifically, we utilize the fact that the Conley index, $\mathrm{Con}_*(S, f)$, is the shift equivalence class of f_{P*} to construct a new representative of the class obtained by removing generators $\alpha \in H_k(P_1, P_0)$ such that $f_{Pk}^l(\alpha) = 0$ or $\alpha \notin f_{Pk}^l(H_k(|\mathcal{P}_1|, |\mathcal{P}_0|))$ for some $l \in \mathbb{Z}$.

Note that since we are considering continuous maps f on $\mathbb{R}^n$, $f_{Pk} : H_k(P_1, P_0) \to H_k(P_1, P_0)$ are linear maps on (finite) vector spaces. We therefore choose to think of f_{Pk} as a square matrix. Suppose that f_{Pk} is similar to a matrix A, i.e., $f_{Pk} = B^{-1}AB$ for some invertible matrix B. Then, by setting $r = B$, $s = B^{-1}$, and $m = 0$ in Definition 2.11, we see that $[f_{Pk}]_s = [A]_s$. In what follows, B will be an appropriate reordering of the basis so that A takes on the block lower-triangular form required for the following theorem.

Theorem 3.1. *Let*

$$A = \begin{bmatrix} A_{11} & 0 & 0 \\ A_{21} & A_{22} & 0 \\ A_{31} & A_{32} & A_{33} \end{bmatrix}$$

be a 3×3 *block lower-triangular matrix, with square matrices* A_{ii} *on the diagonal. If* $A_{11}^l = 0$ *and* $A_{33}^l = 0$ *for some* l*, then* A *is shift equivalent to* A_{22}*.*

Proof. For $i = 1, 2, 3$, let $n_i \times n_i$ be the size of the square matrix A_{ii}, and define projection and inclusion maps respectively as follows:

$$\pi = \begin{bmatrix} 0_{n_{22} \times n_{11}} & I_{n_{22}} & 0_{n_{22} \times n_{33}} \end{bmatrix}$$

and

$$\iota = \pi^\top.$$

One can check that the maps $R := \pi A^l$ and $S := A^l \iota$ satisfy the conditions stated in Definition 2.11 to give the desired shift equivalence between A and A_{22} with lag constant $m = 2l$. ∎

The motivation for the previous theorem was to find a simpler representative for the shift equivalence class of f_{Pk}. This relies on finding a reordering of the basis for f_{Pk} that yields a similar matrix A satisfying the hypotheses of Theorem 3.1. In order to use existing efficient algorithms, we now turn to a graph interpretation of the $l \times l$ matrix f_{Pk}. More specifically,

we consider the directed graph $G = (V, E)$ with vertices $1, \dots, l$ and edges $(j, i) \in E$ if and only if $f_{Pk}(i, j) \neq 0$. Let

$$V_3 := \{v \in V \mid \text{any path starting at } v \text{ has length less than } l\}, \tag{3.1}$$

$$V_1 := \{v \in V \setminus V_3 \mid \text{any path ending at } v \text{ has length less than } l\}, \tag{3.2}$$

and

$$V_2 := V \setminus (V_1 \cup V_3). \tag{3.3}$$

Note that since there are l vertices, V_1 is the set of vertices that are not connected to cycles in backward time and V_3 is the set of all vertices that are not connected to cycles in forward time. The following two lemmas show that the partition $\{V_1, V_2, V_3\}$ of the vertex set V is useful for finding zeros in the matrix f_{Pk}.

Lemma 3.2. *The submatrix $f_{Pk}(V_1, V_2 \cup V_3)$ of f_{Pk} corresponding to the rows indexed by V_1 and columns indexed by $V_2 \cup V_3$ is the zero matrix of the appropriate size.*

Proof. Suppose that $f_{Pk}(w, v) \neq 0$ for $w \in V_1$ and $v \in V_2 \cup V_3$. Then (v, w) is an edge in the associated directed graph G. Since v is not in V_1, there exists a path $v_1, \dots, v_l, v$ in G. Then $v_1, \dots, v_l, v, w$ is a length $l + 1$ path in G, contradicting our assumption that $w \in V_1$. ∎

Lemma 3.3. *The submatrix $f_{Pk}(V_2, V_3)$ of f_{Pk} corresponding to the rows indexed by V_2 and columns indexed by V_3 is the zero matrix of the appropriate size.*

Proof. Suppose that $f_{Pk}(w, v) \neq 0$ for $w \in V_2$ and $v \in V_3$. Then (v, w) is an edge in the associated directed graph G. Since w is not in V_3, there exists a path $w, v_1, \dots, v_l$ in G. Then $v, w, v_1, \dots, v_l$ must also be a path in G, contradicting our assumption that $v \in V_3$. ∎

We have now shown that if we reorder the basis by listing the basis elements in V_1, followed by those in V_2, followed by those in V_3, we obtain the following block form (with rows and columns labeled by location in the specified sets):

$$f_{Pk} \sim A = \begin{array}{c} \\ V_1 \\ V_2 \\ V_3 \end{array} \begin{array}{c} \begin{array}{ccc} V_1 & V_2 & V_3 \end{array} \\ \begin{pmatrix} A_{11} & 0 & 0 \\ A_{21} & A_{22} & 0 \\ A_{31} & A_{32} & A_{33} \end{pmatrix} \end{array}.$$

What remains to show in order to use Theorem 3.1 is the following lemma.

Lemma 3.4. *The two matrices A_{11}^l and A_{33}^l are zero matrices of the appropriate sizes.*

Proof. We obtained the block lower-triangular matrix A by a reordering of the basis for the matrix f_{Pk}. Therefore, the associated directed graph G_A for A is the directed graph G with relabeled vertices. With a slight abuse of notation, we consider again the subsets V_1, V_2, V_3 in G_A to be the sets satisfying (3.2), (3.3), and (3.1), respectively. Interpreting nonzero entries of A to be weights on the corresponding edges, we may use powers of A to study paths in G_A. More specifically, $A^l(i, j) \neq 0$ implies that there exists a length l path from vertex j to vertex i in G_A (see, e.g., [Die05]). Now suppose that $A^l(i, j) = A_{11}^l(i, j) \neq 0$ for some $i, j \in V_1$. Then, by the above argument, there exists a length l path in G_A that ends at a vertex in V_1. This contradicts (3.2). Therefore, $A_{11}^l = 0$. A similar argument shows that $A_{33}^l(i, j) = 0$ for all $i, j \in V_3$. ∎

We now have that f_{Pk} is similar (and hence shift equivalent) to A which is shift equivalent to $\tilde{f}_{Pk} := A_{22}$ by Lemma 3.4 and Theorem 3.1. Therefore, we may take $\tilde{f}_{Pk}$ to be the new, possibly smaller representative of the Conley index

$$\mathrm{Con}(S, f) = [f_{Pk}]_s = [\tilde{f}_{Pk}]_s.$$

This procedure is outlined in Algorithm 5. Here, algorithms based on depth or breadth first search may be used to efficiently compute the required sets V_1, V_2, and V_3. As we will show in section 4 this technique may give a drastic decrease in the size of the representative index map.

Algorithm 5 (Remove transient generators).

INPUT: square matrix f_{Pk}
OUTPUT: shift equivalent (square) matrix $\tilde{f}_{Pk}$
$\tilde{f}_{Pk} =$ remove_transient_generators(f_{Pk})
$G = (V, E)$ is the directed graph associated with f_{Pk};
$V_3 = \{v \in V \mid$ any path starting at v is finite$\}$;
$V_1 = \{v \in V \mid$ any path ending at v is finite$\}$;
$V_2 = V \setminus (V_1 \cup V_3)$;
$\tilde{f}_{Pk} = f_{Pk}(V_2, V_2)$;
return $\tilde{f}_{Pk}$;

3.2.2. Cycle verification. We now automate a procedure for using Conley index computations to construct a semiconjugate subshift of finite type. As described in Theorem 3.6 below, we construct the subshift system from a collection of cycles that are *verified* using Corollary 2.15. As will be seen in section 4, the automation of this procedure becomes necessary as we build increasingly complicated subshifts of finite type. In particular, building a subshift system containing infinitely many periodic orbits may, in principle, lead to an infinite list of computations to verify that the hypotheses of Corollary 2.15 hold for each cycle. In the following approach, we present an algorithm which uses a finite list of computations to verify a possibly infinite set of cycles.

Given an index pair $P = (P_1, P_0)$, we begin by labeling each of the (m) disjoint regions of the isolating neighborhood $N := \overline{P_1 \setminus P_0}$. Let $N = \cup_{i=1}^{m} N_i$ with N_i closed and nonempty and $N_i \cap N_j = \emptyset$ for all $i \neq j$. By construction, each N_i has a corresponding cubical representation $\mathcal{N}_i \subset \mathcal{N}$. Recall that the associated itinerary function ρ is defined by $\rho(x) = (s_0 s_1 \ldots)$ with $s_j = i$ if $f^j(x) \in N_i$. Let $\tilde{T}$ be the matrix of admissible transitions between the regions N_i allowed by $\mathcal{F}$. More specifically, $\tilde{T}$ is the $m \times m$ matrix with entries

$$t_{ij} = \begin{cases} 1 & \text{if } \mathcal{F}(\mathcal{N}_j) \cap \mathcal{N}_i \neq \emptyset, \\ 0 & \text{otherwise.} \end{cases} \tag{3.4}$$

Then $\rho : \tilde{S} \to \Sigma_{\tilde{T}}$, where $\tilde{S} := Inv(N, f)$ and $\Sigma_{\tilde{T}}$ and $\sigma_{\tilde{T}} : \Sigma_{\tilde{T}} \to \Sigma_{\tilde{T}}$ are the subshift of finite type defined in section 2. As previously discussed, $\rho : \tilde{S} \to \Sigma_{\tilde{T}}$ may not be surjective, and hence $\sigma_{\tilde{T}} : \Sigma_{\tilde{T}} \to \Sigma_{\tilde{T}}$ may not be semiconjugate to $f : \tilde{S} \to \tilde{S}$. We will now construct a subshift system, $\sigma_T : \Sigma_T \to \Sigma_T$, with $\Sigma_T \subset \Sigma_{\tilde{T}}$, that we prove is semiconjugate via ρ to $f : S \to S$ with $S \subset \tilde{S}$.

Let $G = (V, E)$ be the directed graph associated with the symbol transition graph $\tilde{T}$ (viewed as an adjacency matrix). More specifically, the vertices are named for the regions N_i with $V = \{1, 2, \dots, m\}$, and the edge set $E := \{(j, i) \in V \times V \mid t_{ij} = 1\}$ represents the admissible transitions between regions. In our approach, we begin by removing all paths in G that are not contained in cycles. These paths correspond to dynamics that we will not check using index theory. A practical way to perform this step is to remove edges and vertices not contained in the strongly connected components (SCC) of G. We will now study Conley indices for periodic symbol sequences in $\Sigma_{\tilde{T}}$ represented by cycles in G.

As discussed in section 2.2, we consider restricted index maps

$$f_{Pk}^{ij} : H_k(P_1, P_0 \cup (\cup_{l \neq i} N_l)) \to H_k(P_1, P_0 \cup (\cup_{l \neq j} N_l)).$$

To do this, we first group the generators of $H_k(P_1, P_0)$ remaining after running Algorithm 5 by region. Again, thinking of f_{Pk} as a matrix with rows and columns corresponding to the generators of $H_k(P_1, P_0)$, we have that

$$f_{Pk}^{ij} := f_{Pk}(g_{N_j}, g_{N_i}), \tag{3.5}$$

where g_{N_i} are the (row/column) indices of generators in $H_k(P_1, P_0 \cup \bigcup_{l \neq i} N_l) \subset H_k(P_1, P_0)$. Here, f_{Pk}^{ij} is as an $n_j \times n_i$ matrix, where n_i and n_j are the number of generators in regions N_i and N_j, respectively. To simplify notation, for a path $p = (s_1, s_2, \dots, s_n)$, let

$$f_{Pk}^{p} := f_{Pk}^{s_{n-1}s_n} \circ \cdots \circ f_{Pk}^{s_1 s_2}. \tag{3.6}$$

Definition 3.5. *We say that a cycle $c = (s_1, s_2, \dots, s_n, s_1)$ in G is* verified *if, for some k,*

$$\operatorname{tr}(f_{Pk}^{c}) = \operatorname{tr}_k \operatorname{Con}(S', f_{N_{s_n}} \circ \cdots \circ f_{N_{s_1}}) \neq 0,$$

where $S' := Inv(N_{s_1}, f|_{N_{s_n} \to N_{s_1}} \circ \cdots \circ f|_{N_{s_1} \to N_{s_2}})$. Note that, by Corollary 2.15, $\rho^{-1}(\mathbf{s}) \neq \emptyset$, where $\mathbf{s} = (s_1 s_2 \dots s_n s_1 \dots s_n \dots)$ is the periodic symbol sequence corresponding to the verified cycle.

Before discussing our automated approach for verifying cycles, we give the following theorem to serve as motivation for this work.

Theorem 3.6. *Let Σ_T be the space of symbol sequences with symbol transition matrix T, and let $\operatorname{Per}(\Sigma_T)$ be the set of periodic symbol sequences in Σ_T under σ_T. Suppose that $\Sigma_T = \overline{\operatorname{Per}(\Sigma_T)}$ and for each $\mathbf{s} = (s_1 \dots s_n s_1 \dots s_n \dots) \in \operatorname{Per}(\Sigma_T)$ the corresponding cycle $c = (s_1, s_2, \dots, s_n, s_1)$ in G has been verified according to Definition 3.5. Then the itinerary function ρ is a semiconjugacy between $f : S \to S$ and $\sigma_T : \Sigma_T \to \Sigma_T$, where $S := \rho^{-1}(\Sigma_T) \subset \tilde{S}$.*

Proof. The itinerary function $\rho : \tilde{S} \to \Sigma_T$ is continuous and $\rho \circ f = \sigma_T \circ \rho$ (see section 2 and references therein). Furthermore, since each cycle in G corresponding to a periodic symbol sequence in Σ_T has been verified according to Definition 3.5, ρ maps onto $\operatorname{Per}(\Sigma_T)$. Since ρ is continuous, $\tilde{S} := Inv(N, f)$ is compact, and Σ_T is Hausdorff, ρ must map onto the closure of the set of of periodic symbol sequences, $\overline{\operatorname{Per}(\Sigma_T)} = \Sigma_T$. Therefore, $\rho : S \to \Sigma_T$ is a semiconjugacy. ∎

The list of cycles that may be verified according to Definition 3.5 relies implicitly on the form of f_P and, more specifically, on f_{Pk}^{ij} for $k = 0, 1, 2, \dots$ and $i, j \in \{1, \dots, m\}$. For the

examples studied in section 4, the homology maps f_{Pk} are trivial for all $k \neq 1$. Therefore, for these examples we fix $k = 1$, as any other choice will necessarily lead to a zero trace and failure to verify all cycles. For different systems, there may be more flexibility in the choice of k. Given a fixed k, the question of how the list of verified cycles relies on choices of i and j is far more subtle. We begin this discussion by fixing k and considering the case where each region contains exactly one homology generator ($n_i = 1$ for all $i = 1, \dots, m$). We will then discuss the more difficult case where some regions have multiple homology generators.

Note that if there is only one generator per region, then f_{Pk}^{ij} is a scalar for all admissible transitions $\tilde{t}_{ji} = 1$ in $\tilde{T}$. In this case, if $f_{Pk}^{ij} \neq 0$ for all admissible transitions, then for any admissible periodic symbol sequence $\mathbf{s} = (s_1 s_2 \dots s_n s_1 s_2 \dots s_n \dots)$ with corresponding cycle $c = (s_1 s_2 \dots s_n s_1)$, $\operatorname{tr}(f_{Pk}^c) \neq 0$, and therefore all cycles in G are verified. If, on the other hand, $f_{Pk}^{ij} = 0$ for some admissible transition, then any cycle c with edge (i, j) will have $\operatorname{tr}(f_{Pk}^c) = 0$ and cannot be verified using this approach. In this case, we remove this transition from the set of admissible transitions by removing the edge (i, j) from G and, correspondingly, by setting $t_{ji} = 0$ in T. In essence, cycle verification computations in the setting where there is exactly one homology generator per component boil down to a (finite) check that entries in f_{Pk} corresponding to admissible transitions in T are nonzero.

If there are regions that contain more than one generator of homology, then these computations become more complicated. In what follows, we will systematically process the cycles in G. In the first phase of the procedure, we process paths and cycles in $\mathcal{G}$ in an attempt verify cycles. Alternatively, one can think about identifying all cycles that may not be verified by our approach. Along these lines, we will label certain cycles as *unverifiable* and certain paths as *unconcatenable*. From these, we will identify a collection of edges that need to be removed from the graph so that all remaining cycles are verified cycles. Note that in what follows, labeling a path *unconcatenable* does not mean that cycles containing this path may not be verified according to Definition 3.5, only that we may not verify some such cycles using our prescribed list of finite computations. Let `Max_Iter` be a nonnegative integer that will serve as a computational parameter.

Definition 3.7. *Define the* edge set for a path $p = (v_0, \dots, v_n)$ *to be*

$$E(p) := \{(v_i, v_{i+1}) \in E(G) \mid i = 0, \dots, n-1\}$$

and the length of p *to be* $|p| = n$. *Consider a cycle* $c = (s, v_2, v_3, \dots, v_{n-1}, s)$ *starting and ending at vertex* s. *If* $\operatorname{tr}(f_{Pk}^c) = 0$, *then* c *is* unverifiable. *(See also Definition 3.5.)*

A path $p = (s, v_2, v_3, \dots, v_{n-1}, t)$ *from* s *to* t *of length* $|p| \leq$ `Max_Iter` *is* unconcatenable *if* $f_{Pk}^p = \mathbf{0}$.

For a path $p = (s, v_2, v_3, \dots, v_{n-1}, t)$ *from* s *to* t *of length* $|p| =$ `Max_Iter`, p *is* concatenable *if there exists a path* p' *from* s *to* t *with* $|p'| <$ `Max_Iter`, $E(p') \subseteq E(p)$, *and* $f_{Pk}^p = \alpha f_{Pk}^{p'} \neq \mathbf{0}$ *for some* $\alpha \neq 0$. *If no such path* p' *exists, then* p *is* unconcatenable.

Finally, an edge set E *is* prohibited *(at computational parameter* `Max_Iter`*) if at least one of the following holds:*

1. *there exists an unverifiable cycle* c *with* $|c| \leq$ `Max_Iter` *and* $E(c) \subseteq E$,
2. *there exists an unconcatenable path* p *with* $E(p) \subseteq E$.

Lemma 3.8. *If c is a cycle whose edge set $E(c)$ is not prohibited, then c is a verified cycle.*

Proof. Suppose that $|c| \leq$ `Max_Iter`. Since $E(c)$ is not prohibited, c must be a verified cycle.

Next, notice that in the natural partial ordering on edge sets, if E' is prohibited, then so is E for any E containing E'. Therefore, $E(c)$ must not contain any prohibited subsets. If $|c| >$ `Max_Iter`, then c is the concatenation of two paths, p_1 and p_2, where $|p_2| =$ `Max_Iter`. We will use the notation p_1p_2 to denote the concatenation of paths p_1 and p_2. Label the start/end vertices s_1, t_1 and s_2, t_2 of p_1 and p_2, respectively. Note that $s_1 = t_2$ and $t_1 = s_2$ by construction. Since $E(p_2) \subseteq E(c)$ is not prohibited, there exists a path p_2' from s_2 to t_2 with $E(p_2') \subseteq E(p_2)$, $|p_2'| <$ `Max_Iter`, and $f_{Pk}^{p_2} = \alpha f_{Pk}^{p_2'}$ for some $\alpha \neq 0$. Therefore,

$$\begin{aligned} f_{Pk}^{c} &= f_{Pk}^{p_2} f_{Pk}^{p_1} \\ &= \alpha f_{Pk}^{p_2'} f_{Pk}^{p_1} \\ &= \alpha f_{Pk}^{c'}, \end{aligned}$$

where $c' = p_1p_2'$ is a cycle with $E(c') = E(p_1) \cup E(p_2') \subseteq E(c)$ and length $|c'| \leq |c| - 1$. Continuing this process, we obtain a cycle $\tilde{c}$ with $|\tilde{c}| \leq$ `Max_Iter`, $E(\tilde{c}) \subseteq E(c)$, and $f_{Pk}^{c} = \tilde{\alpha} f_{Pk}^{\tilde{c}}$ for some $\tilde{\alpha} \neq 0$. Since $E(\tilde{c})$ cannot be prohibited, $\tilde{c}$ must be verifiable and

$$\operatorname{tr}(f_{Pk}^{c}) = \operatorname{tr}(\tilde{\alpha} f_{Pk}^{\tilde{c}}) = \tilde{\alpha} \operatorname{tr}(f_{Pk}^{\tilde{c}}) \neq 0.$$

Therefore, c is a verified cycle. ∎

Lemma 3.8 and Theorem 3.6 provide an outline of our approach for constructing the semiconjugate system. By Lemma 3.8, we know that all cycles that do not have prohibited edge sets are verified cycles and may be used to construct the semiconjugate system according to Theorem 3.6. In practice, we use the prohibited edge sets to identify a collection of edges to be removed from G, resulting in the desired semiconjugate system.

We now give an outline of our procedure for locating prohibited edge sets by collecting and testing appropriate matrix products along paths in G. The algorithm outputs a collection of minimal prohibited edge sets $\mathcal{B}$; that is, for any prohibited edge set E, there is a prohibited edge set $E' \in \mathcal{B}$ with $E' \subseteq E$.

Algorithm 6 (Find prohibited edge sets).

```
INPUT:   graph G, index map f_Pk, computational parameter Max_Iter;
OUTPUT:  list of minimal prohibited edge sets B
B = find_prohibited_edge_sets(G, {f_Pk}, Max_Iter)
  B = ∅;
  for all s,t ∈ V(G), E ⊂ E(G), set all M(s,t,E,k) = ∅;
  for all (s,t) ∈ E(G),
    if s == t and tr(f_Pk^st) == 0, B = B ∪ {(s,t)};
    else M(s,t,{(s,t)},1) = {f_Pk^st};
    end
  end
  for k = 1...Max_Iter,
    for s,t ∈ V(G), E ⊆ E(G), M ∈ M(s,t,E,k),
```

```
      for (t,u) ∈ E(G),
        E' = E ∪ (t,u);
        M' = f^{tu}_{Pk} M;
        if (M' == 0) or (s == u and tr(M') == 0),
          B = B ∪ {E'};
          set M(s',t',E'',ℓ) = ∅ for all s',t' ∈ V(G), E' ⊆ E'' ⊆ E(G), ℓ ≤ k;
        else if ∄M'' ∈ ⋃_{E''⊆E', ℓ<k} M(s,t,E'',ℓ), with M'' == αM' for some α ≠ 0,
          M(s,t,E',k+1) = M(s,t,E',k+1) ∪ {M'};
        end
      end
    end
  end
  B = B ∪ {E ⊂ E(G) | M(s,t,E,Max_Iter) ≠ ∅ and E minimal};
  return B;
```

In practice, it is more efficient to apply Algorithm 6 only to a subgraph of G that captures the behavior of the system in the regions with multiple homology generators. More specifically, we first study G restricted to the vertices for multiple generator regions and the neighboring single generator regions. This allows us to take advantage of the fact that f^p_{Pk} is a scalar for all paths p starting and ending at vertices for single generator regions. By removing enough edges so that there are no remaining prohibited edge sets in the subgraph, we can reduce the check that cycles remaining in G are verified to a check that the maps f^{ij}_{Pk} between single generator regions are nonzero. This is the approach we adopt for the results described in section 4.

For all cycles c in G that do not contain any prohibited edge sets (listed in $\mathcal{B}$), c is a verified cycle by Lemma 3.8. What remains for the construction of a subgraph G' of verified cycles is to remove enough edges so that we no longer have any cycles with prohibited edge sets. Since our goal is to obtain a high lower bound for entropy, we will select one edge from each prohibited edge set so that the removal of these edges results in the semiconjugate symbolic system with highest entropy. Again, since the list of prohibited edge sets is finite (and each prohibited edge set is finite), the computation of optimal edges to remove is finite. Removing the edges yields a graph in which all cycles may be verified using Corollary 2.15. By Theorem 3.6, the corresponding adjacency matrix, T, defines a semiconjugate symbolic system.

The following is an outline of the procedure for breaking prohibited edge sets.

Algorithm 7 (Break prohibited edge sets).

```
INPUT:  graph G, a list of prohibited edge sets B,
OUTPUT: graph G' in which all cycles may be verified via Corollary 2.15
G' = break_prohibited_edge_sets(G, B)
  if B = ∅, return G' = G;
  h_max = −1;
  E_c = ∅;
  for each set {e_1, e_2, ..., e_N}, where e_i is an edge on the ith cycle in B,
    let G' be the subgraph of G obtained by removing edges e_1, e_2, ..., e_N;
```

```
    let T(G') be the adjacency matrix for G';
    h = log(sp(T(G')));
    if h > h_max,
      h_max = h;
      E_c = {e_1, e_2, ..., e_N};
    end
  end
  let G' be the subgraph of G obtained by removing the edges in E_c;
  return G';
```

Combining Algorithms 6 and 7, Theorem 3.6 guarantees that the following algorithm produces a symbol transition matrix T with $\sigma : \Sigma_T \to \Sigma_T$ semiconjugate to $f : S \to S$. Noting that $f_{Pk}^{ij} = \mathbf{0}$ will cause the verification procedure to fail for any cycle containing edge (i, j), we will start with a graph G on the same vertex set with the edge set $E = \{(i, j) \mid f_{Pk}^{ij} \neq \mathbf{0}\}$.

Algorithm 8 (Build subshift).

```
INPUT:      index map f_Pk : H_k(|P_1|,|P_0|) → H_k(|P_1|,|P_0|),
            computational parameter Max_Iter
OUTPUT:     symbol transition matrix T for semiconjugate subshift of
            finite type
T = build_subshift(f_Pk, H_k(|P_1|,|P_0|), Max_Iter)
  f_Pk = remove_transient_generators(f_Pk);
  set m to be the number of disjoint components of H_k(|P_1|,|P_0|);
  V = {1, ..., m};
  E = {(i,j) ∈ V × V | f_Pk^ij ≠ 0};
  G = G(V, E);
  G = SCC(G); (removes all edges not contained in cycles)
  U = find_prohibited_edge_sets(G, f_Pk, Max_Iter);
  G' = break_prohibited_edge_sets(G, U);
  T is the adjacency matrix for graph G';
  return T;
```

4. An example: The Hénon map. As illustration, we now apply our techniques to the Hénon map

$$h(x, y) = (1 + y - ax^2, bx) \tag{4.1}$$

at the classical parameters a = 1.4, b = 0.3. Since its first appearance in [Hén76], there has been extensive research on the Hénon map. The first result concerning a real description of the chaotic dynamics of the Hénon map is [MS80], where the existence of a transverse homoclinic point, and hence the existence of horseshoe dynamics, is proved. In [Szy97], Szymczak used Conley index theory to give a computer-assisted proof of the existence of periodic orbits of all periods except three and five. In [Gal02], Galias employed the method of covering relations (related to Easton's windows) to give a computer-assisted proof of the existence of an infinite number of homoclinic and heteroclinic trajectories. [Gal02] also contains a result which gives

a rigorous lower bound for the topological entropy of the map $h_{top}(h) \geq 0.4300$. In [NBGM08], Newhouse et al. use the planar structure of the Hénon map to compute $h_{top}(h) \geq 0.46469$, the highest lower bound on the entropy for Hénon at the classical parameter values currently reported.

For this work, we use the *GAIO* software package to construct grids, $\mathcal{G}^{(d)}$, at discretization depths $0 \leq d \leq 12$, on the initial box $[-1.425, 1.425] \times [-0.425, 0.425]$ (see section 2.3). We then use the interval arithmetic package INTLAB [Cse99] to compute a combinatorial enclosure, $\mathcal{H}$, on $\mathcal{G}^{(d)}$ as

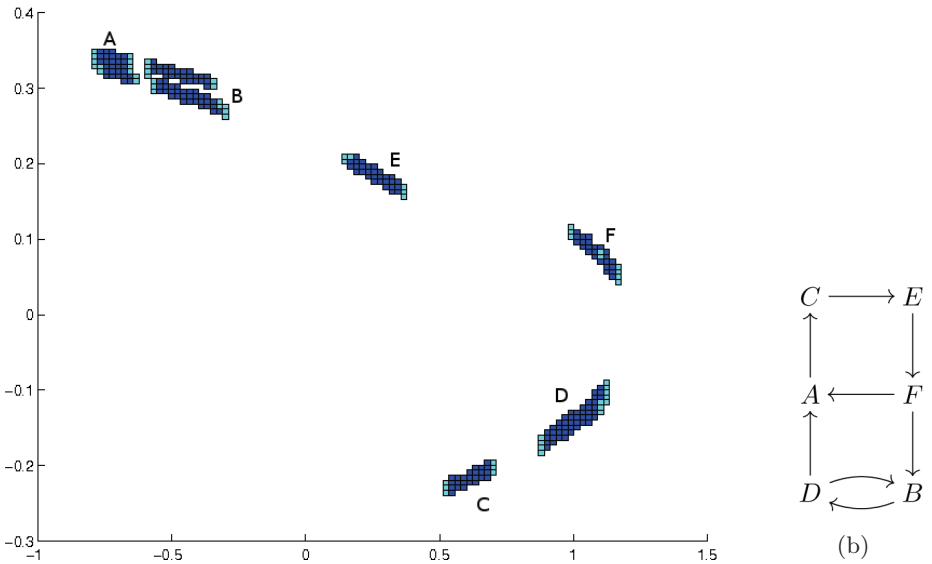
$$\mathcal{H}(I_1 \times I_2) = \{G \in \mathcal{G}^{(d)} \mid \tilde{h}(I_1, I_2) \cap G \neq \emptyset\},$$

where $I_1 \times I_2$ is an element in $\mathcal{G}^{(d)}$ in interval product notation and $\tilde{h}(I_1, I_2)$ denotes the rectangular image of $h(I_1, I_2)$ computed using (outward rounding) interval arithmetic. Finally, we use MATLAB scripts encoding the algorithms outlined throughout the paper to find and compute the required Conley index structures and subshifts of finite type. In the following sample results, we describe three different techniques for producing the region of interest $\mathcal{S} \subset \mathcal{G}^d$. Given $\mathcal{S}$, the main approach is the following.

Algorithm 9 (Main).

INPUT: grid $\mathcal{G}^d$, combinatorial enclosure $\mathcal{H}$ on $\mathcal{G}$,
region of interest $\mathcal{S}$, computational parameter Max_Iter
OUTPUT: lower bound on the topological entropy of h ENTROPY
ENTROPY = compute_entropy_lower_bound($\mathcal{G}^d$, $\mathcal{H}$, $\mathcal{S}$, Max_Iter)
  ENTROPY = 0;
  $\mathcal{N}$ = grow_isolating_neighborhood($\mathcal{S}$); (Algorithm 1)
  $[\mathcal{P}_1, \mathcal{P}_0]$ = build_index_pair($\mathcal{N}$); (Algorithm 2)
  f_{P*} = compute_index_map($\mathcal{P}_1$, $\mathcal{P}_0$, $\mathcal{H}$, $\mathcal{G}^d$); (Algorithm 3)
  for $k = 1 \ldots \dim(\mathcal{G}^d)$, with $f_{Pk} \neq 0$,
    T = build_subshift(f_{Pk}, $H_k(|\mathcal{P}_1|, |\mathcal{P}_0|)$, Max_Iter); (Algorithm 8)
    ENTROPY := max{ENTROPY, $\log(sp(T))$};
  end
  return ENTROPY;

4.1. Joining two short cycles. For purposes of illustration, we begin with a relatively simple example on the grid at depth $d = 7$. Although the resulting entropy lower bound, 0.2406, is small, this example provides us with matrices of reasonable sizes for depicting the results of various stages of the procedure. For this example, we locate a region of interest, $\mathcal{S}$, by searching the computed enclosure $\mathcal{H}$ on $\mathcal{G}^{(7)}$ for a cycle of length 2, a cycle of length 4, and shortest path connections from the 2-cycle to the 4-cycle and from the 4-cycle to the 2-cycle. $\mathcal{S}$ is the union of these four objects. Applying Algorithms 1 and 2 to $\mathcal{S}$ results in the index pair given in Figure 2.



(a) (b)

Figure 2. (a) *A combinatorial index pair,* $(\mathcal{P}_1, \mathcal{P}_0)$*, computed using Algorithms 1 and 2 for the Hénon map at depth* $d = 7$*. (*$\mathcal{P}_0$ *is the collection of boxes shown in cyan.)* (b) *The corresponding symbol transition graph produced by Algorithm 8.*

Theorem 4.1. *The topological entropy of the Hénon map* (4.1) *is bounded from below by* 0.2406.

Proof. The computed index map for the index pair depicted in Figure 2(a) is

$$h_{P,1} = \begin{array}{c} \\ A \\ B \\ B \\ B \\ B \\ C \\ D \\ E \\ F \\ F \end{array} \begin{array}{c} \begin{array}{cccccccccc} A & B & B & B & B & C & D & E & F & F \end{array} \\ \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \end{pmatrix} \end{array}.$$

The rows and columns are labeled by location of the corresponding homology generator in the labeled regions of the isolating neighborhood (see Figure 2(a)). Applying Algorithm 5 for removing transient generators to $h_{P,1}$ produces the shift equivalent matrix

$$A = \begin{array}{c} \\ A \\ B \\ B \\ C \\ D \\ E \\ F \\ F \end{array} \begin{array}{c} \begin{array}{cccccccc} A & B & B & C & D & E & F & F \end{array} \\ \begin{pmatrix} 0 & 0 & 0 & 0 & -1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \end{pmatrix} \end{array}.$$

This is the matrix labeled A_{22} in Theorem 3.1 and is obtained by an appropriate reordering of the basis. Note that this algorithm removed two of the homology generators in region B and, therefore, reduced the size of the representative of the shift equivalence class/Conley index.

As an example computation, using Corollary 2.15 to verify the cycle (B, D, B), we check that

$$\begin{aligned} \mathrm{tr}_1(Con(S', f|_{D\to B} \circ f|_{B\to D})) &= \mathrm{tr}\left(h_{P,1}^{DB} h_{P,1}^{BD}\right) \\ &= \mathrm{tr}_1\left(\begin{bmatrix} -1 \\ 0 \end{bmatrix} \begin{bmatrix} 1 & 1 \end{bmatrix}\right) \\ &= \mathrm{tr}_1\left(\begin{bmatrix} -1 & -1 \\ 0 & 0 \end{bmatrix}\right) \\ &\neq 0. \end{aligned}$$

Running Algorithm 8 on A to verify a collection of cycles results in the construction of a semiconjugate subshift system with symbol transition matrix

$$T = \begin{array}{c} \\ A \\ B \\ C \\ D \\ E \\ F \end{array} \begin{array}{c} \begin{array}{cccccc} A & B & C & D & E & F \end{array} \\ \begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix} \end{array}.$$

The corresponding symbol transition graph is given in Figure 2(b). Since the log of the spectral radius of T is greater than 0.2406, the result follows from Theorem 2.7. ∎

4.2. Joining low cycles (Algorithm 4). We now focus on improving the bound by refining the grid and using Algorithm 4 to compute a more complicated region of interest.

This approach results in the following theorem.

Theorem 4.2. *The topological entropy of the Hénon map* (4.1) *is bounded from below by* 0.4320.

Outline of proof. Given the enclosure $\mathcal{H}$ on $\mathcal{G}^{(12)}$, we use Algorithm 4 with Max_Cycle_Length = 7 to produce the region of interest $\mathcal{S}$. We then follow Algorithm 9. The index pair for $\mathcal{S}$ appears in Figure 3. Algorithm 3 returns an index map on 1521 relative homology gener-

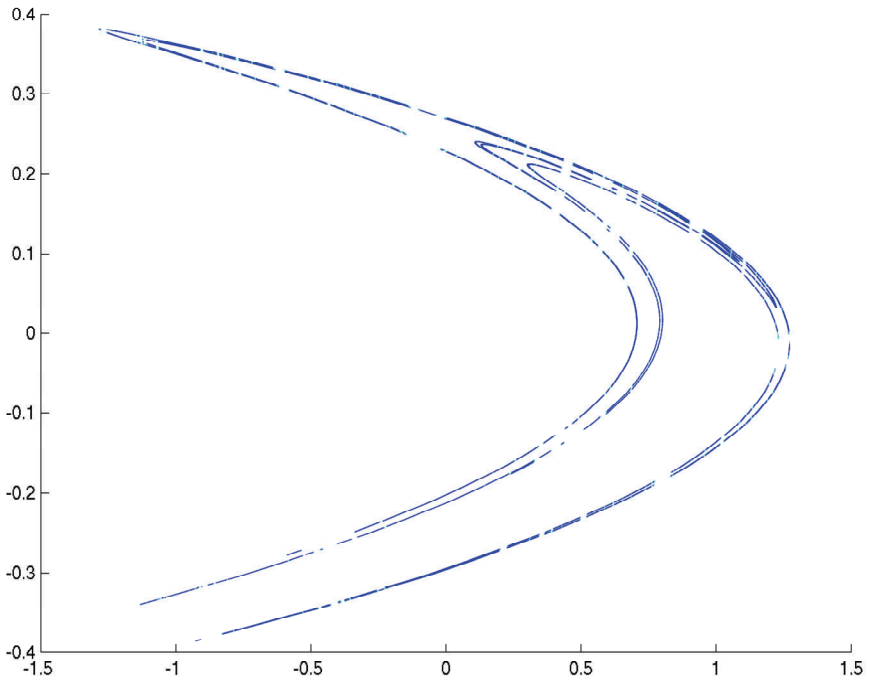


Figure 3. *The combinatorial index pair, $(\mathcal{P}_1, \mathcal{P}_0)$, constructed starting with Algorithm 4 for Theorem 4.2 at depth 12. ($\mathcal{P}_0$ is the collection of boxes shown in cyan.)*

ators. Algorithm 5 reduces this map to a shift equivalent map on 309 generators. Finally, Algorithm 8 produces a semiconjugate subshift of finite type with 247 symbols. The symbol transition matrix for the constructed subshift is depicted in Figure 4. The log of the spectral radius of T is bounded from below by 0.4320. The result then follows from Theorem 2.7. ■

For the above result computed on the grid $G^{(12)}$, we choose the maximal cycle length for Algorithm 4 to be Max_Cycle_Length = 7. This choice is made because choosing instead Max_Cycle_Length < 7 yields a lower bound than that given in Theorem 4.2, and choosing Max_Cycle_Length > 7 yields an entropy lower bound of 0. This behavior is depicted in Figure 5. The reason that choosing a large maximal cycle length leads to a 0 lower bound is that the corresponding isolating neighborhood produced by Algorithm 1 is a covering of the entire attractor, with corresponding trivial symbolic dynamics.

In principle, improving the bound requires only extra computational cost. Figure 6 shows the change in the computed entropy bound with increase in resolution of the grid (and corresponding increase in computational expense) for the Hénon map. The dip in the graph at depth 11 is of interest because, in general, we expect a monotonic increase in the computed entropy bound with increase in resolution of the grid. This nonmonotonic behavior indicates that our choice of region of interest, $\mathcal{S}$, in Algorithm 4 is indeed suboptimal. In fact, choosing $\mathcal{S}$ to be the boxes in $\mathcal{G}^{(11)}$ contained in the isolating neighborhood $\mathcal{N}$ returned by Algorithms 4 and 1 on $\mathcal{G}^{(10)}$ would yield the same entropy as that computed at depth 10, and so it is possible to compute a higher entropy bound at this resolution.

4.3. Fold preimage removal. A priori knowledge of the Hénon map suggests another approach for constructing the region of interest $\mathcal{S}$. We notice that indices for cycles traveling too close to the "fold" of the attractor (at approximately $(1.2717, -0.0207)$) are necessarily trivial. Here, the Hénon map loses hyperbolicity, and the resulting induced map on homology maps the corresponding generator to zero. Out of curiosity, we now take the opposite approach of removing boxes from the covering of the attractor in an attempt to find an isolating neighborhood with interesting associated symbolic dynamics. Here we start with a box covering of the maximal invariant set (in this case, Hénon's strange attractor) and remove a small box neighborhood of the fold. We then remove a fixed number of preimages of this collection of boxes from the covering of the maximal invariant set. This procedure is outlined in Algorithm 10. From the resulting region of interest, we grow an isolating neighborhood and construct and verify symbolic dynamics as outlined in Algorithm 9.

Algorithm 10 (Fold preimage removal for constructing $\mathcal{S}$).

INPUT: grid $\mathcal{G}^d$, combinatorial enclosure $\mathcal{H}$ on $\mathcal{G}^d$,
region $\mathcal{N}_f^0 \subset \mathcal{G}^d$ containing the fold point,
computational parameter Max_Preimage_Iter
OUTPUT: region of interest $\mathcal{S}$

$\mathcal{S}$ = fold_preimage_removal($\mathcal{G}^d$, $\mathcal{H}$, Max_Preimage_Iter)
$\mathcal{N}_f = \mathcal{N}_f^0$;
$\mathcal{S} = \mathcal{G}^d \setminus \mathcal{N}_f$;
for $i = 1 \ldots$ Max_Preimage_Iter,
Fold_Iter $= \mathcal{H}^{-1}(\mathcal{N}_f)$;
$\mathcal{S} = \mathcal{S} \setminus \mathcal{N}_f$;
end
return $\mathcal{S}$;

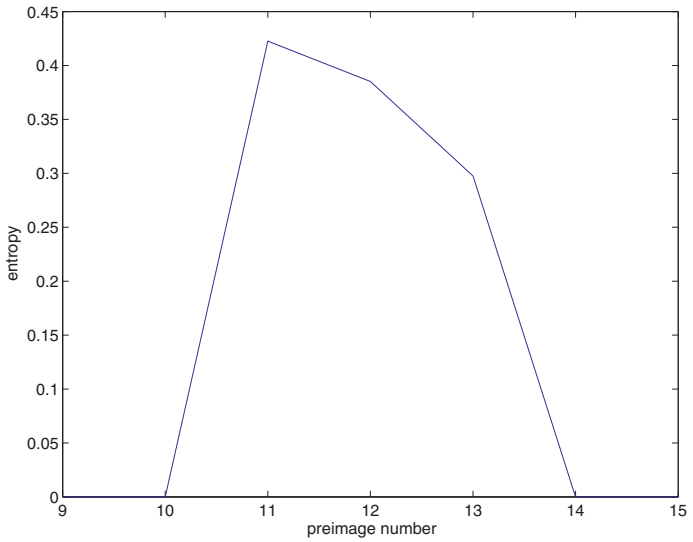

Figure 7. *Entropy lower bounds computed using the fold preimage removal technique for the Hénon map on grid* $\mathcal{G}^{(12)}$*. The horizontal axis gives the number,* `Max_Preimage_Iter`*, of preimages of the fold removed before growing the isolating neighborhood.*

Figure 7 depicts entropy bounds resulting from computations made starting with Algorithm 10 and various values of `Max_Preimage_Iter`. Removing too few preimages of the fold boxes (`Max_Preimage_Iter` small) does not yield interesting symbolic dynamics since we are unable to isolate this set at the given resolution. Removing too many preimages (`Max_Preimage_Iter` large) results in a subshift system consisting of disjoint cycles with 0 entropy. At depth 12, `Max_Preimage_Iter` $= 11$ provides the highest entropy bound, and this optimal constant increases at greater depths.

We obtain the following theorem by applying this third approach to the Hénon map.

Theorem 4.3 (fold and preimage removal). *The topological entropy of the Hénon map* (4.1) *is bounded from below by* 0.4225*.*

Outline of proof. Starting with a covering of the Hénon attractor by elements in $\mathcal{G}^{(12)}$, we use Algorithm 10 to remove `Max_Preimage_Iter` $= 11$ preimages (under $\mathcal{H}$) of $(1.2717, -0.0207) + [-0.04, 0.04] \times [-0.002, 0.002]$, a neighborhood of the "fold." We then use the resulting region of interest $\mathcal{S}$ together with $\mathcal{G}^{(12)}$, and $\mathcal{H}$ as the input for Algorithm 9. The computed index pair is shown in Figure 8. The homology map computed using Algorithm 3 is a map on 1281 generators of the first relative homology group. Algorithm 5 reduces the number of required generators to 191 by computing an appropriate shift equivalent index map. Finally, Algorithm 8 produces a topologically conjugate subshift on 129 symbols with topological entropy bounded from below by 0.4225. The result follows from Theorem 2.7. ∎

5. Concluding remarks.

We have described an automated, algorithmic method for studying the dynamics of a discrete dynamical system $f : X \to X$. The method not only constructs a semiconjugate subshift of finite type, but also uses this information to compute a rigorous lower bound on the topological entropy for the system. The essential ingredient to this ap-

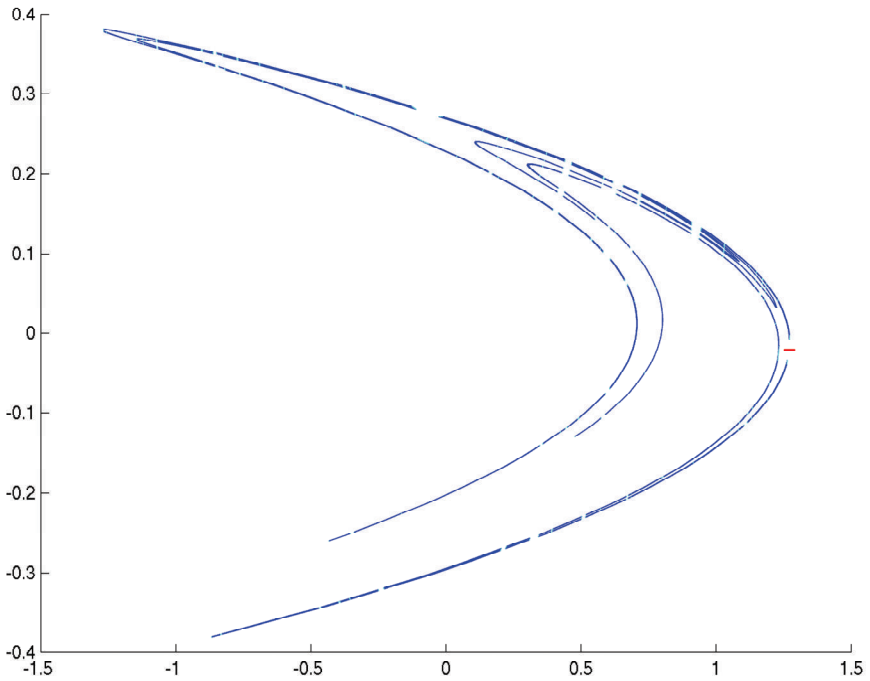

Figure 8. *The combinatorial index pair, $(\mathcal{P}_1, \mathcal{P}_0)$, constructed starting with Algorithm 10 at depth 12. ($\mathcal{P}_0$ is the collection of boxes shown in cyan.) The red rectangle shows the neighborhood of the fold point whose preimages were removed to construct the region of interest $\mathcal{S}$.*

proach is a computable "coarse" level of hyperbolicity in the map which is required to obtain a nontrivial Conley index. As the procedure stands, greater computational effort may be employed to improve the bounds. However, further analysis and optimization of the procedure described in section 3.1 for locating a region of interest should lead to even stronger results. A referee suggestion to consider more general sofic shifts rather than subshifts of finite type may also lead to the construction of semiconjugate symbolic dynamical systems with higher entropy.

The index processing techniques introduced in section 3.2 will enable further studies along these lines. As mentioned in the introduction, even infinite-dimensional systems may be studied in this manner. For such systems, it is necessary to incorporate both a dimension reduction for obtaining a computable system and analysis to overcome this reduction. These ideas are described in more detail in [DJM04] and would not, in principle, hinder entropy measurements of the type presented here.

Acknowledgments. The authors would like to thank Jim Wiseman and a referee for very helpful comments on the content and the structure of this paper.

Asymptotic Expansions of I-V Relations via a Poisson–Nernst–Planck System*

Nicole Abaid†‡, Robert S. Eisenberg§, and Weishi Liu†

Abstract. We investigate higher order matched asymptotic expansions of a steady-state Poisson–Nernst–Planck (PNP) system with particular attention to the I-V relations of ion channels. Assuming that the Debye length is small relative to the diameter of the narrow channel, the PNP system can be viewed as a singularly perturbed system. Special structures of the zeroth order inner and outer systems make it possible to provide an *explicit* derivation of higher order terms in the asymptotic expansions. For the case of zero permanent charge, our results concerning the I-V relation for two oppositely charged ion species are (i) the first order correction to the zeroth order linear I-V relation is generally *quadratic* in V; (ii) when the electro-neutrality condition is enforced at both ends of the channel, there is NO first order correction, but the second order correction is *cubic* in V. Furthermore (Theorem 3.4), up to the second order, the cubic I-V relation has (except for a very degenerate case) three distinct real roots that correspond to the bistable structure in the FitzHugh–Nagumo simplification of the Hodgkin–Huxley model.

Key words. singular perturbation, matched asymptotic expansion, I-V relations

1. Introduction.

The Poisson–Nernst–Planck (PNP) systems are basic electro-diffusion equations modeling, for example, ion flow through membrane channels and transport of holes and electrons in semiconductors (see, for example, [3, 4, 5, 10, 21, 32, 39, 18, 19, 34, 35]). In the context of ion flow through a membrane channel, the flow of ions is driven by their concentration gradients and by the electric field modeled together by the Nernst–Planck continuity equations, and the electric field is in turn determined by the concentrations through the Poisson equation. The PNP system describes the current flow at low resolution; that is, it is an approximate description of the transport process [3] appropriate when channel selectivity (between different chemical species of ions) is not of importance, as, for example, in the numerous classical studies of the *gramicidin channel* [51] most recently reviewed in [1, 2] (see also [16, 36, 37, 11, 25, 51, 17, 20]). Derivation from a Langevin model of ionic diffusion [42] shows how correlations are approximated in PNP systems and suggests extensions of the PNP approach to deal with selectivity arising from excess chemical potentials [13, 14, 6]. The bio-

logical properties of a channel called *permeation* can be described by the PNP equations. The biological properties called *selectivity* can be described by the extended PNP equations. Both permeation and selectivity are characterized by the current-voltage (I-V) relation measured experimentally under different ionic conditions.

The domain for the PNP system is a three-dimensional region including both the channel in the middle and the two baths at the ends of the tube. Thus there are some specifics regarding the domain geometry: the middle part of the domain representing the channel is much more narrow than the two ends that represent the two baths. A reasonable model of the domain would be a tubular-like region for the channel and two widely open conical regions for the baths. Another structure of the channel is its permanent charge, which is highly concentrated at the neck (center) of the channel. To capture the essence of the three-dimensional dynamics, one-dimensional PNP systems have been introduced with the key geometry ($h(x)$ in (1.1)) of the three-dimensional domain encoded in the equations. In particular, the following one-dimensional (steady-state) PNP system for n types of ion species was suggested by Nonner and Eisenberg in [32] and is derived in [42] and analyzed in [29] under the assumption that the characteristic radius of the channel is much smaller than its length:

$$\begin{aligned} &\frac{\epsilon^2}{h(x)}\frac{d}{dx}\left(h(x)\frac{d}{dx}\phi\right) = -\sum_{j=1}^{n}\alpha_j c_j - Q(x), \\ &\frac{dJ_k}{dx} = 0, \quad h(x)\frac{dc_k}{dx} + \alpha_k c_k h(x)\frac{d\phi}{dx} = -J_k, \quad k = 1, 2, \dots, n. \end{aligned} \tag{1.1}$$

Here the channel is normalized from $x = 0$ to $x = 1$; $h(x)$ is the scaled area function of the cross section of the channel at location x; $Q(x)$ is the permanent charge density; $\epsilon^2 = \lambda/r$, where λ is the Debye length and r is the characteristic radius of the channel; ϕ is the electric potential; and, for each $k = 1, 2, \dots, n$, c_k is the concentration, α_k is the valence, and J_k is the flux density (scaled by the diffusion constant) of the kth ion species. Note that J_k's are constant since we are considering the steady-state PNP system. The Debye length is customarily computed from the concentrations of ions on one side of the channel or the other, but we note for completeness that in some conditions the concentration of ions in the channel itself is quite different from that in the baths, and so the "local" Debye length (describing the inside of the channel) is quite different as well.

The baths are macroscopic regions in which the concentration of charges is nearly constant (because the dimensions of the reservoirs are macroscopic and so the total number of charges is hardly changed by the flows) and electrical potentials are nearly constant too. It is then natural to impose the following boundary conditions:

$$\phi(0) = V, \quad c_k(0) = L_k > 0; \quad \phi(1) = 0, \quad c_k(1) = R_k > 0. \tag{1.2}$$

Here V is the electric potential in the bath at the left end relative to that at the right end, and, for $k = 1, 2, \dots, n$, L_k and R_k are the concentrations of the kth ion species in the left and right baths, respectively.

In our one-dimensional setting, we model the region by a finite interval (normalized to $[0, 1]$). In this way, the interval can be partitioned into several subintervals so that the permanent charge takes large (in magnitude) values in the middle subintervals and small values away

from middle (zero near 0 and 1). There are other choices for the one-dimensional domain. For example, in [44], the whole real line is taken instead of a finite interval, and the boundary conditions are imposed at infinity. These two scalings correspond to different interpretations of relative ratios of different lengths involved in the biological problem. The mathematical treatment would be the same except at the boundaries. At this moment, it is not clear to us which interprets the biology better. Since the types of channels are so rich, we suspect that one scaling is better for certain types of channels and the other is better for other types.

With the setting in (1.1) and (1.2), the *I-V relation* means the dependence of the current $I = \sum \alpha_k J_k$ on the voltage V for fixed L_k's and R_k's. We remark that, in general, the I-V relation is NOT unique (see [30, 38, 39, 45, 46, 10] for $Q \neq 0$ and see [28] even for $Q = 0$). Understanding the nonuniqueness issue is critical for ion channels because nonuniqueness might explain the gating behavior of single channels, which switch suddenly and stochastically from one current level to another [16, 40, 31, 15]. Nonuniqueness is directly related to the stability of the corresponding steady states. The study of the stability problem is beyond the scope of this work. In section 3, we will consider special cases where the I-V relation is indeed unique.

System (1.1) together with the boundary condition (1.2) will be treated as a singular boundary value problem with $\epsilon \ll 1$ as the singular parameter. In, e.g., [5, 12, 27], the zeroth order I-V relation is explicitly obtained for two types of ion species and $Q = 0$ (see [10, 28] for a treatment of general situations and [44, 43] for a treatment using a three-dimensional PNP model). The zeroth order I-V relation, in this case, is linear. Experimental data show clearly a nonlinear I-V relation. But there is not much discussion on the nature of the nonlinearity except the famous Goldman–Hodgkin–Katz (GHK) I-V equation, which has been used to analyze experimental data for nearly 60 years but does not include such useful and necessary parameters as the charge of the channel protein.

It is our goal in this paper to examine higher order asymptotic expansions of the I-V relation. In particular, we are interested in higher order corrections to the zeroth order I-V relation. To obtain higher order asymptotic expansions of the I-V relation requires higher order asymptotic expansion of ϕ and c_k's. Both the classical matched asymptotic expansion method and the geometric singular perturbation method work well for the zeroth order term (see [5, 12, 27]) at least for the special case mentioned above. An advantage of the geometric method is that it also provides a rigorous justification directly of the validity of the zeroth order terms. But, for higher order terms, a direct application of the geometric singular perturbation theory seems not to work. Roughly speaking, it is not clear how to fully incorporate the information on the zeroth order terms in deriving systems for higher order terms. In fact, some natural approaches for higher order terms result in singularly perturbed systems that do not have the so-called *slow manifolds*. We therefore take the classical matched asymptotic expansion approach for higher order terms.

It is known that higher order terms satisfy linear but nonautonomous and nonhomogeneous systems. The homogeneous parts of the linear systems are the same and are nothing but the linearizations of the zeroth order nonlinear system along the zeroth order (inner and outer) solutions. Also known is the fact that it is generally impossible to get explicit solutions of a linear nonautonomous system. A special feature of the problem at hand is that the zeroth order nonlinear system possesses a complete set of integrals, and each integral provides an

integral for the linearization (see Propositions 2.1 and 2.2). It is this feature that allows us to carry out a detailed asymptotic analysis. Theoretically, any order of the asymptotic expansion can be found. But there are several technical difficulties even for obtaining the zeroth order terms; that is, one has to solve some nonlinear algebraic systems that are too complicated to expect explicit solutions in general. As a starting point, we will restrict ourselves to the simplest case where $n = 2$, $h = 1$, $Q = 0$, $\alpha_1 = -\alpha_2 = 1$. From the biological point of view, the most restrictive part of this constraint is $Q = 0$, since many channels have significant permanent charge. However, many channels are analyzed without consideration of permanent charge. The classical channel gramicidin, which has been simulated much more than any other channel we know of, has often been approximated that way [2, 51, 36, 37]. Maltoporin—one of the few channels with known high resolution crystallographic structure—has insignificant permanent charge [50, 24, 7, 49, 41]. Mathematically, this simplification allows us to obtain exact asymptotic expansions and, from those, explicit qualitative properties of I-V relations can be derived. Furthermore, a perturbation argument will allow one to generalize the result to cases where Q is small. Also, as mentioned above, we believe that the approach will work for general cases, say, a piecewise constant Q for quantitative results, particularly with the help of numerics. (This is a project that we will pursue in the future.) It should be clearly understood that some biological phenomena of importance—e.g., selectivity between cations—will not appear until three ions are considered, perhaps with different diffusion coefficients for each ionic type. Readers interested in more general cases may carry out the analysis along the lines of this paper with some extra analysis (see remarks in section 4).

For the special case where $n = 2$, $\alpha_1 = -\alpha_2 = 1$, $h = 1$, and $Q = 0$, our results give a *definite* nonlinear characterization of the I-V relations up to the second order ($O(\epsilon^2)$). More precisely, the first order correction to the zeroth order linear I-V relation is generally *quadratic* in V given in (3.20), but, when the electro-neutrality condition is imposed at both ends of the channel, the first order correction is *zero*. The second order correction is *cubic* in V even with the electro-neutrality condition (see formula (3.26)). Furthermore, the coefficient of the cubic term is always *negative* except for a highly degenerate case (see Theorem 3.4). The importance of this negative sign is that, up to the second order, the cubic I-V function has three distinct real roots—this agrees qualitatively with the I-V relation adopted in the FitzHugh–Nagumo simplification of the Hodgkin–Huxley systems. The existence of three roots of the I-V relation is responsible for the bistable structure in the FitzHugh–Nagumo system and may be related to the instabilities in biological channels called single channel gating [16, 40, 31, 15] and to the instabilities seen by [47, 48] in abiotic nanopores that have fixed structure. It should be pointed out that our analysis via the PNP system describes current flow through a single channel, and the FitzHugh–Nagumo equations (like the Hodgkin–Huxley system) describe an ensemble of channels in a biological membrane. The current through an ensemble of channels is determined by the current through a single channel and the gating process that determines the number of open channels. The FitzHugh–Nagumo equations have not yet been applied to abiotic channels of fixed structure [47, 48] as far as we know.

This paper is organized as follows. In section 2, we derive outer and inner systems for each order in the asymptotic expansions for a general situation. Starting in section 3, we restrict ourselves to the special case and examine the outer and inner expansions and matching. A treatment for the zeroth order is included in subsection 3.1 for completeness, and the first order

expansions and matching are detailed in subsection 3.2. In subsection 3.3, the analysis for the second order is carried out under the electro-neutrality assumption. Possible generalizations of our analysis and some general remarks are discussed in section 4.

For the reader's convenience, we provide a table of some notation to be used in this paper:

$x = 0$: the left end of the channel;
$x = 1$: the right end of the channel;
$\phi(x)$: the electric potential over the channel;
$0 = \phi(1)$: the reference of the potential set at the right end;
$V = \phi(0)$: the relative potential at the left end;
$c_k(x)$: the concentration of the kth ion species over the channel;
$L_k = c_k(0)$: the concentration of the kth ion species at the left end;
$R_k = c_k(1)$: the concentration of the kth ion species at the right end;
$Q(x)$: the permanent charge of the channel;
ε: the singular parameter related to the Debye length;
J_{kj}: the jth order in ε of the kth flux density;
$J_k = \sum_j \varepsilon^j J_{kj}$: the flux density of the kth ion species;
$T_j = \sum_k J_{kj}$: the jth order in ε of the diffusion flux density;
$I_j = \sum_k \alpha_k J_{kj}$: the jth order in ε of the current density;
$T = \sum_j \varepsilon^j T_j$: the diffusion flux density;
$I = \sum_j \varepsilon^j I_j$: the current density;
I-V relation: the dependence of I on V for fixed L_k, R_k, and Q.

2. Systems for asymptotic expansions. In this section, we derive the outer and inner systems for the asymptotic expansions and describe the matching principle to be employed. The outer systems govern the dynamics of ion flows within the channel, and the inner systems determine the potential boundary layers representing the effects of boundary conditions coming from the bath conditions. The matching principle then provides the interaction between the boundary conditions and the internal dynamics. In this sense, the boundary layers model the channel-bath interfaces. The process is standard but we will point out two special structures, (2.4) and Proposition 2.1, that allow us to obtain explicit information.

2.1. Outer systems for each order. We assume Q is constant and look for outer expansion of the form, for $k = 1, 2, \ldots, n$,

$$\begin{aligned} \phi(x;\epsilon) &= \phi_0(x) + \epsilon\phi_1(x) + \epsilon^2\phi_2(x) + \cdots, \\ c_k(x;\epsilon) &= c_{k0}(x) + \epsilon c_{k1}(x) + \epsilon^2 c_{k2}(x) + \cdots, \\ J_k &= J_{k0} + \epsilon J_{k1} + \epsilon^2 J_{k2} + \cdots. \end{aligned} \tag{2.1}$$

Substituting (2.1) into (1.1) and denoting the derivatives with respect to x by overdots, with the convention that $\phi_{-1} = \phi_{-2} = 0$, $\delta_0 = 1$, and $\delta_j = 0$ for $j \neq 0$, the jth order system is

$$\begin{aligned} \ddot{\phi}_{j-2} + h^{-1}(x)h_x(x)\dot{\phi}_{j-2} &= -\sum_{l=1}^{n} \alpha_l c_{lj} - \delta_j Q, \\ \dot{c}_{kj} &= -\sum_{p+q=j} \alpha_k c_{kp}\dot{\phi}_q - h^{-1}(x)J_{kj}. \end{aligned} \tag{2.2}$$

Upon introducing $u_j = h(x)\dot{\phi}_j$, system (2.2) becomes

$$\begin{aligned} \dot{\phi}_{j-2} &= h^{-1}(x)u_{j-2}, \\ \dot{u}_{j-2} &= -h(x)\sum_{l=1}^{n}\alpha_l c_{lj} - \delta_j h(x)Q, \\ \dot{c}_{kj} &= -h^{-1}(x)\sum_{p+q=j}\alpha_k c_{kp}u_q - h^{-1}(x)J_{kj}. \end{aligned} \tag{2.3}$$

An observation is that the homogeneous part for $\mathcal{C}_j = (c_{1j}, \dots, c_{nj})^T$ is

$$\dot{\mathcal{C}}_j = -\frac{u_0(x)}{h(x)}\mathcal{D}\mathcal{C}_j = -\dot{\phi}_0(x)\mathcal{D}\mathcal{C}_j, \tag{2.4}$$

where $\mathcal{D} = \operatorname{diag}\{\alpha_1, \dots, \alpha_n\}$ is a diagonal matrix. Once $\phi_0(x)$ is found, system (2.4) can be simply integrated:

$$\mathcal{C}_j(x) = \operatorname{diag}\left\{e^{-\alpha_1(\phi_0(x)-\phi_0(0))}, \dots, e^{-\alpha_n(\phi_0(x)-\phi_0(0))}\right\}\mathcal{C}_j(0).$$

Hence, system (2.3) can be solved by the method of variation of parameters.

2.2. Inner systems for each order. There will be two sets of inner systems, one at the boundary $x = 0$ and the other at the boundary $x = 1$.

2.2.1. Inner systems at the boundary $x = 0$. At the boundary $x = 0$, in terms of the inner variable $\xi = x/\epsilon$, let $\Phi(\xi;\epsilon) = \phi(\epsilon\xi;\epsilon)$, $C_k(\xi;\epsilon) = c_k(\epsilon\xi;\epsilon)$. System (1.1) becomes, for $k = 1, 2, \dots, n$,

$$\begin{aligned} h^{-1}(\epsilon\xi)\frac{d}{d\xi}\left(h(\epsilon\xi)\frac{d}{d\xi}\Phi\right) &= -\sum_{l=1}^{n}\alpha_l C_l - Q, \quad \frac{dJ_k}{d\xi} = 0, \\ h(\epsilon\xi)\frac{dC_k}{d\xi} + \alpha_k C_k h(\epsilon\xi)\frac{d\Phi}{d\xi} &= -\epsilon J_k. \end{aligned} \tag{2.5}$$

We look for the inner expansion of the form

$$\begin{aligned} \Phi(\xi;\epsilon) &= \Phi_0(\xi) + \epsilon\Phi_1(\xi) + \epsilon^2\Phi_2(\xi) + \cdots, \\ C_k(\xi;\epsilon) &= C_{k0}(\xi) + \epsilon C_{k1}(\xi) + \epsilon^2 C_{k2}(\xi) + \cdots, \\ J_k &= J_{k0} + \epsilon J_{k1} + \epsilon^2 J_{k2} + \cdots. \end{aligned} \tag{2.6}$$

Set

$$h(\epsilon\xi) = \sum_{p=0}\epsilon^p r_p^0 \xi^p, \quad h^{-1}(\epsilon\xi) = \sum_{p=0}\epsilon^p s_p^0 \xi^p,$$

where

$$r_p^0 = \frac{1}{p!}\frac{d^p h}{dx^p}(0) \quad \text{and} \quad s_p^0 = \frac{1}{p!}\frac{d^p h^{-1}}{dx^p}(0).$$

Denote by primes the derivatives with respect to ξ, and substitute (2.6) into (2.5) to get, for each $j = 0, 1, \ldots,$

$$\begin{aligned} &\sum_{p+q+l=j} s_p^0 \xi^p (r_q^0 \xi^q \Phi_l')' = -\sum_{l=1}^{n} \alpha_l C_{lj} - \delta_j Q, \\ &C_{kj}' = -\sum_{p+q=j} \alpha_k C_{kp} \Phi_q' - \sum_{p+q=j-1} s_p^0 \xi^p J_{kq}. \end{aligned} \tag{2.7}$$

By introducing $U_j = a_0 \Phi_j'$, we recast system (2.7) as

$$\begin{aligned} &\Phi_j' = s_0^0 U_j, \quad U_j' = -r_0^0 \sum_{l=1}^{n} \alpha_l C_{lj} - \delta_j r_0^0 Q, \\ &C_{kj}' = -s_0^0 \sum_{p+q=j} \alpha_k C_{kp} U_q - \sum_{p+q=j-1} s_p^0 \xi^p J_{kq}. \end{aligned} \tag{2.8}$$

For $j = 0$, the system is

$$\Phi_0' = s_0^0 U_0, \quad U_0' = -r_0^0 \sum_{l=1}^{n} \alpha_l C_{l0} - r_0^0 Q, \quad C_{k0}' = -s_0^0 \alpha_k C_{k0} U_0, \tag{2.9}$$

and, for all $j \geq 1$, system (2.8) has the same homogeneous part that is the linearization of the zeroth order system (2.9).

A specific structure of system (2.9) is revealed in the following.

Proposition 2.1. *The zeroth order inner system (2.9) has a complete set of $(n+1)$ first integrals given by, for $k = 1, 2, \ldots, n$,*

$$H_k = C_{k0} e^{\alpha_k \Phi_0}, \quad H_{n+1} = \frac{s_0^0}{2 r_0^0} U_0^2 - \sum_{l=1}^{n} C_{l0} + Q \Phi_0.$$

Proof. This can be verified directly (see also [28]). ∎

A crucial result is given below. We believe it is known but did not find a reference in the literature.

Proposition 2.2. *Consider an autonomous system*

$$z' = f(z), \quad z \in \mathbf{R}^m. \tag{2.10}$$

For a solution $z_0(t)$ of (2.10), consider the linearization along $z_0(t)$:

$$Z' = Df(z_0(t)) Z, \quad Z \in \mathbf{R}^m. \tag{2.11}$$

If a C^2 function $H : \mathbf{R}^m \to \mathbf{R}$ is an integral of system (2.10) (that is, $H(z(t))$ is independent of t for any solution $z(t)$ of (2.10)), then $G(Z, t) = \langle \nabla H(z_0(t)), Z \rangle$ is an integral of the linear system (2.11) (that is, $G(Z(t), t)$ is independent of t for any solution $Z(t)$ of (2.11)).

Proof. Since H is an integral of (2.10), $\frac{d}{dt}H(z(t)) = 0$ for all t, or

$$\langle \nabla H(z), f(z)\rangle = \sum_j \partial_j H(z) f_j(z) = 0$$

for all $z \in \mathbf{R}^m$. For any $k = 1, 2, \ldots, m$, take the partial derivative with respect to z_k to get

$$\sum_j \left(\partial^2_{kj} H(z) f_j(z) + \partial_j H(z) \partial_k f_j(z)\right) = 0. \tag{2.12}$$

As a consequence of (2.12), a computation gives that $\frac{d}{dt}G(Z(t), t) = 0$. ∎

As noted, the homogeneous part of (2.8) for $j \geq 1$ is the linearization of the zeroth order system (2.9); one can combine Propositions 2.1 and 2.2 to derive a complete set of integrals for the homogeneous part of (2.8). An application of variation of parameters allows one to get a closed form for the solutions of (2.8). For the general case presented in this section, certain technical difficulties arise in evaluating integrals explicitly. This is the main reason that, in section 3, we will restrict our analysis to a simple case.

2.2.2. Inner systems at the boundary $x = 1$. At the boundary $x = 1$, we use the inner variable $\xi = (-1 + x)/\epsilon$. Set $\Psi(\xi; \epsilon) = \phi(1 + \epsilon\xi; \epsilon)$ and $D_k(\xi; \epsilon) = c_k(1 + \epsilon\xi; \epsilon)$. We will then look for the inner expansion of the form:

$$\begin{aligned} \Psi(\xi;\epsilon) &= \Psi_0(\xi) + \epsilon\Psi_1(\xi) + \epsilon^2\Psi_2(\xi) + \cdots, \\ D_k(\xi;\epsilon) &= D_{k0}(\xi) + \epsilon D_{k1}(\xi) + \epsilon^2 D_{k2}(\xi) + \cdots, \\ J_k &= J_{k0} + \epsilon J_{k1} + \epsilon^2 J_{k2} + \cdots. \end{aligned} \tag{2.13}$$

In the same way as that for the boundary $x = 0$, one has, for each j,

$$\begin{aligned} \sum_{p+q+l=j} s^1_p \xi^p (r^1_q \xi^q \Psi'_l)' &= -\sum_{l=1}^{n} \alpha_l D_{lj} - \delta_j Q, \\ D'_{kj} &= -\sum_{p+q=j} \alpha_k D_{kp} \Psi'_q - \sum_{p+q=j-1} s^1_p \xi^p J_{kq}, \end{aligned} \tag{2.14}$$

where

$$r^1_p = \frac{1}{p!}\frac{d^p h}{dx^p}(1) \quad \text{and} \quad s^1_p = \frac{1}{p!}\frac{d^p h^{-1}}{dx^p}(1).$$

By introducing $V_j = r^1_0 \Psi'_j$, we get

$$\begin{aligned} \Psi'_j &= s^1_0 V_j, \quad V'_j = -r^1_0 \sum_{l=1}^{n} \alpha_l D_{lj} - \delta_j r^1_0 Q, \\ D'_{kj} &= -s^1_0 \sum_{p+q=j} \alpha_k D_{kp} V_q - \sum_{p+q=j-1} s^1_p \xi^p J_{kq}. \end{aligned} \tag{2.15}$$

2.3. Asymptotic matching principle. To piece together the inner solution and outer solution, one needs matching principles. There are two mainstreams in matching. One is the method of *intermediate matching* of Kaplun and Lagerstrom and the other is the *asymptotic matching principle* of Van Dyke (see [8, 9, 22, 23, 26]). The method of intermediate matching is based rigorously on the so-called *extension theorems*, but in general the implementation is more complicated than that of the asymptotic matching principle. The asymptotic matching principle, with a suitable hypothesis, can be also rigorously justified. It turns out that, for the problem handled in this paper, the so-called *outer manifold* is normally hyperbolic [10, 27], and Van Dyke's principle of asymptotic matching is justified (see, for example, [33]). We will thus use the asymptotic matching principle for our matching purpose.

To state the principle of asymptotic matching, we recall the notion of *kth order expansion operators* E_x^k and E_ξ^k in [26]: if, in terms of the outer variable x, $g(x;\epsilon) = \sum_{j=0}^{\infty} \epsilon^j g_j(x)$ and, in terms of the inner variable $\xi = x/\epsilon$, $f(\xi;\epsilon) = \sum_{j=0}^{\infty} \epsilon^j f_j(\xi)$, then

$$E_x^k(g(x;\epsilon)) = \sum_{j=0}^{k} \epsilon^j g_j(x), \quad E_\xi^k(f(\xi;\epsilon)) = \sum_{j=0}^{k} \epsilon^j f_j(\xi).$$

To match f and g up to the kth order at $x = 0$, one needs to express both $E_x^k(g(x;\epsilon))$ and $E_\xi^k(f(\xi;\epsilon))$ in the same variable. For example, to express $E_x^k(g(x;\epsilon)) = \sum_{j=0}^{k} \epsilon^j g_j(x)$ in terms of ξ, one replaces x by $\epsilon\xi$ in $g_j(x)$ and rewrites the expansion, say,

$$E_x^k(g(x;\epsilon)) = \sum_{j=0}^{k} \epsilon^j g_j(\epsilon\xi) = \sum_{j=0}^{\infty} \epsilon^j h_j(\xi);$$

in particular,

$$E_\xi^k E_x^k(g(x;\epsilon)) = \sum_{j=0}^{k} \epsilon^j h_j(\xi).$$

The kth order asymptotic matching principle for f and g at $x = 0$ is (see, for example, [8, 26]), in terms of the inner variable ξ,

$$E_\xi^k(f) = E_\xi^k E_x^k(g); \quad \text{that is,} \quad f_j(\xi) = h_j(\xi) \quad \text{for} \quad j = 0, 1, \ldots, k. \tag{2.16}$$

3. Matched asymptotic expansion: Case study. In this section, we will derive the matched asymptotic expansions for the case where $n = 2$, $\alpha_1 = -\alpha_2 = 1$, $Q = 0$, and $h = 1$. The zeroth order I-V relation turns out to be linear in V. While the first order correction is quadratic in V in general, it is zero when both ends are electro-neutral ($L_1 = L_2$ and $R_1 = R_2$). For this reason, we also carried out the analysis for the second order terms of the I-V relation under the electro-neutrality conditions and found that the I-V relation is a cubic in V.

For convenience, we set

$$I_j = \sum \alpha_k J_{kj} \qquad \text{and} \qquad T_j = \sum J_{kj}. \tag{3.1}$$

We point out that our main interest in the I-V relation is to derive the asymptotic expansion $I = I_0 + \epsilon I_1 + \epsilon^2 I_2 + \cdots$.

3.1. Zeroth order I-V relation. The zeroth order has been obtained in [5] using the asymptotic expansion method and in [27] using the geometric singular perturbation method. Here we rederive the zeroth order terms explicitly. This is crucial for an explicit formulation of higher order terms in the asymptotic expansions.

3.1.1. Zeroth order outer solution. From (2.3), the zeroth order outer system reads

$$0 = c_{10} - c_{20}, \quad \dot{c}_{10} = -c_{10}\dot{\phi}_0 - J_{10}, \quad \dot{c}_{20} = c_{20}\dot{\phi}_0 - J_{20}. \tag{3.2}$$

It is easy to solve system (3.2) to deduce

$$c_{10}(x) = c_{20}(x) = \frac{a_0 - T_0 x}{2}, \quad \phi_0(x) = b_0 + \frac{I_0}{T_0}\ln|a_0 - T_0 x| \tag{3.3}$$

for some constants a_0 and b_0 to be determined through matching. Here $I_0 = J_{10} - J_{20}$ and $T_0 = J_{10} + J_{20}$ from (3.1).

3.1.2. Zeroth order inner solution. At the boundary $x = 0$, the zeroth order inner system (2.8) is

$$\begin{aligned} &\Phi_0'(\xi) = U_0, \quad U_0'(\xi) = -C_{10} + C_{20}, \\ &C_{10}'(\xi) = -C_{10}U_0, \quad C_{20}'(\xi) = C_{20}U_0. \end{aligned} \tag{3.4}$$

In this case, Proposition 2.1 reads as follows.

Proposition 3.1. *System* (3.4) *has three first integrals given by*

$$H_1 = C_{10}e^{\Phi_0}, \quad H_2 = C_{20}e^{-\Phi_0}, \quad H_3 = \frac{1}{2}U_0^2 - C_{10} - C_{20}.$$

One can then solve system (3.4) explicitly (see [5, 27]) to get

$$\begin{aligned} &\Phi_0 = V + \frac{1}{2}\ln\frac{L_1}{L_2} + \ln\left(\frac{1 + le^{-\sqrt{M}\xi}}{1 - le^{-\sqrt{M}\xi}}\right)^2, \qquad U_0 = -\frac{4l\sqrt{M}e^{-\sqrt{M}\xi}}{1 - l^2e^{-2\sqrt{M}\xi}}, \\ &C_{10} = \sqrt{L_1L_2}\left(\frac{1 - le^{-\sqrt{M}\xi}}{1 + le^{-\sqrt{M}\xi}}\right)^2, \qquad C_{20} = \sqrt{L_1L_2}\left(\frac{1 + le^{-\sqrt{M}\xi}}{1 - le^{-\sqrt{M}\xi}}\right)^2, \end{aligned} \tag{3.5}$$

where

$$M = 2\sqrt{L_1L_2}, \quad l = \frac{L_2^{1/4} - L_1^{1/4}}{L_2^{1/4} + L_1^{1/4}}.$$

Similarly, at the boundary $x = 1$ with $\xi = (x - 1)/\epsilon$, we have

$$\begin{aligned} &\Psi_0(\xi) = \frac{1}{2}\ln\frac{R_1}{R_2} + \ln\left(\frac{1 + re^{\sqrt{N}\xi}}{1 - re^{\sqrt{N}\xi}}\right)^2, \qquad V_0(\xi) = \frac{4r\sqrt{N}e^{\sqrt{N}\xi}}{1 - r^2e^{2\sqrt{N}\xi}}, \\ &D_{10}(\xi) = \sqrt{R_1R_2}\left(\frac{1 - re^{\sqrt{N}\xi}}{1 + re^{\sqrt{N}\xi}}\right)^2, \qquad D_{20}(\xi) = \sqrt{R_1R_2}\left(\frac{1 + re^{\sqrt{N}\xi}}{1 - re^{\sqrt{N}\xi}}\right)^2, \end{aligned} \tag{3.6}$$

where

$$N = 2\sqrt{R_1R_2}, \quad r = \frac{R_2^{1/4} - R_1^{1/4}}{R_2^{1/4} + R_1^{1/4}}.$$

3.1.3. Zeroth order matching. In view of the matching principle (2.16), the matching conditions at the boundary $x = 0$ are

$$E^0_\xi E^0_x(c_k) = E^0_\xi(C_k) \quad \text{and} \quad E^0_\xi E^0_x(\phi) = E^0_\xi(\Phi).$$

From (3.3) and (3.5), we get

$$E^0_\xi E^0_x(c_k) = \frac{a_0}{2}, \quad E^0_\xi E^0_x(\phi) = b_0 + \frac{I_0}{T_0}\ln a_0,$$
$$E^0_\xi(C_k) = \sqrt{L_1 L_2}, \quad E^0_\xi(\Phi) = V + \frac{1}{2}\ln\frac{L_1}{L_2}.$$

The matching gives

$$a_0 = 2\sqrt{L_1 L_2} \quad \text{and} \quad b_0 = V + \frac{1}{2}\ln\frac{L_1}{L_2} - \frac{I_0}{T_0}\ln(2\sqrt{L_1 L_2}). \tag{3.7}$$

Similarly, the matching at the boundary $x = 1$ requires

$$a_0 - T_0 = 2\sqrt{R_1 R_2} \quad \text{and} \quad b_0 + \frac{I_0}{T_0}\ln(a_0 - T_0) = \frac{1}{2}\ln\frac{R_1}{R_2}. \tag{3.8}$$

We deduce, from (3.7) and (3.8), that

$$\begin{aligned} T_0 &= 2\sqrt{L_1 L_2} - 2\sqrt{R_1 R_2}, \\ I_0 &= \frac{2(\sqrt{L_1 L_2} - \sqrt{R_1 R_2})(2V + \ln(L_1 R_2) - \ln(L_2 R_1))}{\ln(L_1 L_2) - \ln(R_1 R_2)}. \end{aligned} \tag{3.9}$$

In particular, at the zeroth order, the I-V relation $I_0 = I_0(V)$ is *linear* in V. When $L_1 = L_2 = L$ and $R_1 = R_2 = R$ (electro-neutrality condition at both ends of the channel) hold, we have

$$T_0 = 2(L - R), \quad I_0 = \frac{2(L - R)}{\ln L - \ln R}V. \tag{3.10}$$

Note also that, as $L \to R$, we have $T_0 \to 0$ and $I_0 \to 2RV$.

3.2. First order I-V relation. Since the higher order outer systems (2.3) and inner systems (2.8) and (2.15) are nonautonomous, one cannot solve them explicitly in general. The upshot for our problem is that they can actually be solved explicitly. For inner systems, the solvability is due to Propositions 2.2 and 3.1.

3.2.1. First order outer solution. From (2.3), the first order outer system is

$$c_{11} = c_{21}, \quad \dot{c}_{11} = -(c_{10}\dot{\phi}_1 + c_{11}\dot{\phi}_0) - J_{11}, \quad \dot{c}_{21} = (c_{20}\dot{\phi}_1 + c_{21}\dot{\phi}_0) - J_{21}. \tag{3.11}$$

Recall, from (3.1), that $T_1 = J_{11} + J_{21}$ and $I_1 = J_{11} - J_{21}$. Using (3.3) for $(\phi_0(x), c_{10}(x), c_{20}(x))$, one solves system (3.11) to get

$$\begin{aligned} c_{11}(x) = c_{21}(x) &= \frac{a_1 - T_1 x}{2}, \\ \phi_1(x) &= b_1 + \frac{T_0 I_1 - I_0 T_1}{T_0^2}\ln|a_0 - T_0 x| + \frac{I_0(a_1 T_0 - a_0 T_1)}{T_0^2(a_0 - T_0 x)} \end{aligned}$$

for some unknown constants a_1 and b_1.

3.2.2. First order inner solution. The first order inner system (2.8) at $x = 0$ is

$$\begin{aligned} &\Phi_1' = U_1, \quad U_1' = -(C_{11} - C_{21}), \\ &C_{11}' = -(C_{10}U_1 + C_{11}U_0) - J_{10}, \quad C_{21}' = (C_{20}U_1 + C_{21}U_0) - J_{20}. \end{aligned} \tag{3.12}$$

As an application of Propositions 2.2 and 3.1, we have the next result.

Proposition 3.2. *The homogeneous part of* (3.12) *has the following integrals:*

$$\begin{aligned} G_1^h &= C_{11}e^{\Phi_0} + C_{10}e^{\Phi_0}\Phi_1, \\ G_2^h &= C_{21}e^{-\Phi_0} - C_{20}e^{-\Phi_0}\Phi_1, \\ G_3^h &= U_0U_1 - C_{11} - C_{21}. \end{aligned}$$

The full system (3.12) *has the following integrals:*

$$\begin{aligned} G_1 &= C_{11}e^{\Phi_0} + C_{10}e^{\Phi_0}\Phi_1 + J_{10}F_1(\xi), \\ G_2 &= C_{21}e^{-\Phi_0} - C_{20}e^{-\Phi_0}\Phi_1 + J_{20}F_2(\xi), \\ G_3 &= U_0U_1 - C_{11} - C_{21} - T_0\xi, \end{aligned}$$

where

$$\begin{aligned} F_1(\xi) &= \int_0^\xi e^{\Phi_0(s)}ds = -\sqrt{\frac{L_1}{L_2}}\frac{e^V}{\sqrt{M}}\left(\frac{4}{1 - le^{-\sqrt{M}\xi}} - \frac{4}{1-l} - \sqrt{M}\xi\right), \\ F_2(\xi) &= \int_0^\xi e^{-\Phi_0(s)}ds = -\sqrt{\frac{L_2}{L_1}}\frac{e^{-V}}{\sqrt{M}}\left(\frac{4}{1 + le^{-\sqrt{M}\xi}} - \frac{4}{1+l} - \sqrt{M}\xi\right). \end{aligned}$$

Proof. The first statement for the homogeneous part of system (3.12) follows from Propositions 2.2 and 3.1. The extra terms in the second statement are obtained by adding trial functions and forcing the resulting functions to be integrals of (3.12). This leads to

$$F_1(\xi) = \int_0^\xi e^{\Phi_0(s)}ds \quad \text{and} \quad F_2(\xi) = \int_0^\xi e^{-\Phi_0(s)}ds.$$

Direct integrations with Φ_0 in (3.5) give the explicit expressions for $F_1(\xi)$ and $F_2(\xi)$ as claimed. ∎

One can then use the integrals to solve system (3.12). Note that we have the initial conditions $\Phi_1(0) = 0$ and $C_{11}(0) = C_{21}(0) = 0$, but $U_1(0)$ has to be determined via matching. One finds, after careful integrations,

$$\begin{aligned} U_1(\xi) &= \frac{U_0(0)U_1(0) - (C_{10} - C_{20})\Phi_1 - J_{10}e^{-\Phi_0}F_1 - J_{20}e^{\Phi_0}F_2 + T_0\xi}{U_0}, \\ \Phi_1(\xi) &= -\frac{4l(T_0 + lI_0)}{M^{3/2}(1+l)(1-l)} - \frac{I_0}{M}\xi \\ &\quad + \frac{1}{2\sqrt{M}}\left(U_1(0) + \frac{I_0 + lT_0}{(1+l)(1-l)M}\right)e^{\sqrt{M}\xi} + o(e^{-\sqrt{M}\xi}). \end{aligned} \tag{3.13}$$

The term involving $e^{\sqrt{M}\xi}$ should disappear due to matching. Thus,

$$U_1(0) = -\frac{I_0 + lT_0}{(1+l)(1-l)M}.$$

In summary, we have

$$\begin{aligned}
\Phi_1(\xi) &= -\frac{4l(T_0 + lI_0)}{M^{3/2}(1+l)(1-l)} - \frac{I_0}{M}\xi + o(e^{-\sqrt{M}\xi}),\\
C_{11}(\xi) &= -\frac{2l(I_0 + lT_0)}{\sqrt{M}(1+l)(1-l)} - \frac{T_0}{2}\xi + o(e^{-\sqrt{M}\xi}),\\
C_{21}(\xi) &= -\frac{2l(I_0 + lT_0)}{\sqrt{M}(1+l)(1-l)} - \frac{T_0}{2}\xi + o(e^{-\sqrt{M}\xi}).
\end{aligned} \tag{3.14}$$

Similarly, at $x = 1$ with $x - 1 = \epsilon\xi$, we have

$$\begin{aligned}
\Psi_1(\xi) &= -\frac{4r(T_0 + rI_0)}{N^{3/2}(1+r)(1-r)} - \frac{I_0}{N}\xi + o(e^{-\sqrt{N}\xi}),\\
D_{11}(\xi) &= -\frac{2r(I_0 + rT_0)}{\sqrt{N}(1+r)(1-r)} - \frac{T_0}{2}\xi + o(e^{-\sqrt{N}\xi}),\\
D_{21}(\xi) &= -\frac{2r(I_0 + rT_0)}{\sqrt{N}(1+r)(1-r)} - \frac{T_0}{2}\xi + o(e^{-\sqrt{N}\xi}).
\end{aligned} \tag{3.15}$$

3.2.3. First order matching. We first consider the matching near $x = 0$. For the inner expansion, we have, from (3.5) and (3.14), for $k = 1, 2$,

$$\begin{aligned}
E^1_\xi(\Phi) &= E^1_\xi(\Phi_0(\xi) + \epsilon\Phi_1(\xi))\\
&= V + \frac{1}{2}\ln\frac{L_1}{L_2} - \epsilon\left(\frac{4l(T_0 + lI_0)}{M^{3/2}(1+l)(1-l)} + \frac{I_0}{M}\xi\right),\\
E^1_\xi(C_k) &= E^1_\xi(C_{k0}(\xi) + \epsilon C_{k1}(\xi))\\
&= \sqrt{L_1L_2} - \epsilon\left(\frac{2l(I_0 + lT_0)}{\sqrt{M}(1+l)(1-l)} + \frac{T_0}{2}\xi\right).
\end{aligned} \tag{3.16}$$

On the other hand, for the outer expansion, we have

$$\begin{aligned}
E^1_x(\phi) = E^1_x(\phi_0(x) + \epsilon\phi_1(x)) &= b_0 + \frac{I_0}{T_0}\ln a_0 - \frac{I_0}{a_0}x\\
&\quad + \epsilon\left(b_1 + \frac{T_0I_1 - I_0T_1}{T_0^2}\ln a_0 + \frac{I_0(a_1T_0 - a_0T_1)}{T_0^2a_0} + O(x)\right),\\
E^1_x(c_k) = E^1_x(c_{k0}(x) + \epsilon c_{k1}(x)) &= \left(\frac{a_0}{2} - \frac{T_0}{2}x\right) + \epsilon\left(\frac{a_1}{2} - \frac{T_1}{2}x\right).
\end{aligned}$$

Therefore, in terms of the inner variable ξ,

$$
\begin{aligned}
E^1_\xi E^1_x(\phi) &= b_0 + \frac{I_0}{T_0}\ln a_0 \\
&\quad + \epsilon\left(b_1 + \frac{T_0 I_1 - I_0 T_1}{T_0^2}\ln a_0 + \frac{I_0(a_1 T_0 - a_0 T_1)}{T_0^2 a_0} - \frac{I_0}{a_0}\xi\right), \\
E^1_\xi E^1_x(c_k) &= \frac{a_0}{2} + \epsilon\left(\frac{a_1}{2} - \frac{T_0}{2}\xi\right).
\end{aligned} \tag{3.17}
$$

The matchings $E^1_\xi(\Phi) = E^1_\xi E^1_x(\phi)$ and $E^1_\xi(C_k) = E^1_\xi E^1_x(c_k)$ imply, from (3.16) and (3.17),

$$
\begin{aligned}
a_0 &= M = 2\sqrt{L_1 L_2}, \qquad b_0 = V + \frac{1}{2}\ln\frac{L_1}{L_2} - \frac{I_0}{T_0}\ln a_0, \\
a_1 &= -\frac{4l(I_0 + lT_0)}{\sqrt{M}(1+l)(1-l)}, \\
b_1 &= -\frac{I_0(a_1 T_0 - a_0 T_1)}{T_0^2 a_0} - \frac{T_0 I_1 - I_0 T_1}{T_0^2}\ln a_0 \\
&\quad - \frac{4l(T_0 + lI_0)}{M^{3/2}(1+l)(1-l)}.
\end{aligned} \tag{3.18}
$$

Note that the relation for a_0 in (3.18) is consistent since $M = 2\sqrt{L_1 L_2}$.

Similarly, the matching near $x = 1$ gives

$$
\begin{aligned}
a_0 &= N + T_0 = 2\sqrt{R_1 R_2} + T_0, \qquad b_0 = \frac{1}{2}\ln\frac{R_1}{R_2} - \frac{I_0}{T_0}\ln(a_0 - T_0), \\
a_1 &= T_1 - \frac{4r(I_0 + rT_0)}{\sqrt{N}(1+r)(1-r)}, \\
b_1 &= -\frac{I_0(a_1 T_0 - a_0 T_1)}{2\sqrt{R_1 R_2}T_0^2} - \frac{T_0 I_1 - I_0 T_1}{T_0^2}\ln(2\sqrt{R_1 R_2}) \\
&\quad - \frac{4r(T_0 + rI_0)}{N^{3/2}(1+r)(1-r)}.
\end{aligned} \tag{3.19}
$$

As expected, one recovers (3.9) for T_0 and I_0 from the two expressions in (3.18) and (3.19) for a_0 and b_0. Using the two expressions for a_1 and b_1, we get

$$
\begin{aligned}
T_1 &= \frac{4r(I_0 + rT_0)}{\sqrt{N}(1+r)(1-r)} - \frac{4l(I_0 + lT_0)}{\sqrt{M}(1+l)(1-l)}, \\
I_1 &= T_0^{-1} I_0 T_1 - \frac{T_0^{-1} I_0(a_1 T_0 - a_0 T_1)}{\ln(R_1 R_2) - \ln(L_1 L_2)}\left(\frac{1}{\sqrt{R_1 R_2}} - \frac{1}{\sqrt{L_1 L_2}}\right) \\
&\quad - \frac{4rT_0(T_0 + rI_0)}{\sqrt{R_1 R_2 N}(1+r)(1-r)} + \frac{4lT_0(T_0 + lI_0)}{\sqrt{L_1 L_2 M}(1+l)(1-l)}.
\end{aligned} \tag{3.20}
$$

Note that T_1 is linear in I_0 and hence is linear in V; I_1 is quadratic in I_0 and hence is also quadratic in V. That is, the first order correction to the zeroth order linear I-V relation is *quadratic* in V in general.

What is interesting and potentially important is that, when $L_1 = L_2$ and $R_1 = R_2$ (electro-neutrality), one deduces that $T_1 = I_1 = 0$. That is, under the electro-neutrality condition at both ends, there is NO first order correction for the I-V relation.

3.3. Second order I-V relation with electro-neutrality. We now assume the electro-neutrality condition $L_1 = L_2$ and $R_1 = R_2$ and examine the I-V correction at the second order $O(\epsilon^2)$.

3.3.1. Second order outer expansion. The second order outer system (2.3) is

$$\begin{aligned} \ddot{\phi}_0 &= -c_{12} + c_{22}, \\ \dot{c}_{12} &= -(c_{12}\dot{\phi}_0 + c_{11}\dot{\phi}_1 + c_{10}\dot{\phi}_2) - J_{12}, \\ \dot{c}_{22} &= (c_{22}\dot{\phi}_0 + c_{21}\dot{\phi}_1 + c_{20}\dot{\phi}_2) - J_{22}. \end{aligned} \tag{3.21}$$

Note that, under the assumption $L_1 = L_2$ and $R_1 = R_2$, we have

$$a_1 = b_1 = T_1 = I_1 = c_{11}(x) = c_{21}(x) = \phi_1(x) = 0.$$

Upon using (3.3), one solves system (3.21) to get

$$\begin{aligned} c_{12}(x) &= \frac{a_2 - T_2 x}{2} + \frac{I_0^2 + 2I_0T_0}{4(a_0 - T_0x)^2}, \\ c_{22}(x) &= \frac{a_2 - T_2 x}{2} + \frac{I_0^2 - 2I_0T_0}{4(a_0 - T_0x)^2}, \\ \phi_2(x) &= b_2 - \frac{2I_0T_0}{3(a_0 - T_0x)^3} + \frac{I_0^3}{6T_0(a_0 - T_0x)^3} + \frac{I_0(a_2T_0 - a_0T_2)}{T_0^2(a_0 - T_0x)} \\ &\quad - \frac{I_0T_2}{T_0^2}\ln|a_0 - T_0x| + \frac{I_2}{T_0}\ln|a_0 - T_0x|, \end{aligned} \tag{3.22}$$

where a_2 and b_2 are unknown constants.

3.3.2. Second order inner expansion. The second order inner system (2.8) at $x = 0$ is

$$\begin{aligned} \Phi_2' &= U_2, \quad U_2' = -(C_{12} - C_{22}), \\ C_{12}' &= -(C_{10}U_2 + C_{11}U_1 + C_{12}U_0) - J_{11}, \\ C_{22}' &= (C_{20}U_2 + C_{21}U_1 + C_{22}U_0) - J_{21}. \end{aligned} \tag{3.23}$$

Similarly to the first order inner system, we have the following claim.

Proposition 3.3. *System* (3.23) *has the following integrals:*

$$\begin{aligned} G_1 &= C_{12}e^{\Phi_0} + C_{10}e^{\Phi_0}\Phi_2 + J_{11}F_1(\xi) + F_{12}(\xi), \\ G_2 &= C_{22}e^{-\Phi_0} - C_{20}e^{-\Phi_0}\Phi_2 + J_{21}F_2(\xi) - F_{22}(\xi), \\ G_3 &= U_0U_2 - C_{12} - C_{22} - T_1\xi + \frac{1}{2}U_1^2, \end{aligned}$$

where $F_1(\xi)$ *and* $F_2(\xi)$ *are given in Proposition* 3.2 *and*

$$F_{12}(\xi) = \int_0^\xi C_{11}(s)U_1(s)e^{\Phi_0(s)}ds, \qquad F_{22}(\xi) = \int_0^\xi C_{21}(s)U_1(s)e^{-\Phi_0(s)}ds.$$

Using $L_1 = L_2 = L$ and $R_1 = R_2 = R$, we have, from (3.5) and (3.6), that

$$\begin{aligned} &\Phi_0(\xi) = V, \quad U_0(\xi) = 0, \quad C_{10}(\xi) = C_{20}(\xi) = L, \\ &\Psi_0(\xi) = 0, \quad V_0(\xi) = 0, \quad D_{10}(\xi) = D_{20}(\xi) = R, \end{aligned}$$

and, from (3.14) and (3.15), that

$$\begin{aligned} &\Phi_1(\xi) = -\frac{I_0}{2L}\xi, \quad U_1(\xi) = -\frac{I_0}{2L}, \quad C_{11}(\xi) = C_{21}(\xi) = -\frac{T_0}{2}\xi, \\ &\Psi_1(\xi) = -\frac{I_0}{2R}\xi, \quad V_1(\xi) = -\frac{I_0}{2R}, \quad D_{11}(\xi) = D_{21}(\xi) = -\frac{T_0}{2}\xi. \end{aligned}$$

Also,

$$J_{11} = J_{21} = 0, \quad F_{12}(\xi) = \frac{I_0T_0}{8L}e^V\xi^2, \quad F_{22}(\xi) = \frac{I_0T_0}{8L}e^{-V}\xi^2.$$

Applying the integrals in Proposition 3.3, we can solve (3.23) with $\Phi_2(0) = C_{12}(0) = C_{22}(0) = 0$ to get

$$\Phi_2(\xi) = \left(\frac{I_0T_0}{8L^3} - A\right)e^{-\sqrt{2L}\xi} + Ae^{\sqrt{2L}\xi} - \frac{I_0T_0}{8L^3} - \frac{I_0T_0}{8L^2}\xi^2.$$

The matching will force $A = 0$. Thus, for $\xi \geq 0$,

$$\begin{aligned} \Phi_2(\xi) &= \frac{I_0T_0}{8L^3}\left(e^{-\sqrt{2L}\xi} - 1\right) - \frac{I_0T_0}{8L^2}\xi^2, \\ C_{12}(\xi) &= -\frac{I_0T_0}{8L^2}\left(e^{-\sqrt{2L}\xi} - 1\right), \quad C_{22}(\xi) = \frac{I_0T_0}{8L^2}\left(e^{-\sqrt{2L}\xi} - 1\right). \end{aligned} \tag{3.24}$$

Similarly, at $x = 1$, the second order inner solution is, for $\xi \leq 0$,

$$\begin{aligned} \Psi_2(\xi) &= \frac{I_0T_0}{8R^3}\left(e^{\sqrt{2R}\xi} - 1\right) - \frac{I_0T_0}{8R^2}\xi^2, \\ D_{12}(\xi) &= -\frac{I_0T_0}{8R^2}\left(e^{\sqrt{2R}\xi} - 1\right), \quad D_{22}(\xi) = \frac{I_0T_0}{8R^2}\left(e^{\sqrt{2R}\xi} - 1\right). \end{aligned} \tag{3.25}$$

3.3.3. Second order matching. From (3.22), in terms of $\xi = x/\epsilon$, the outer expansion at $x = 0$ is

$$\begin{aligned} E_\xi^2E_x^2(\phi) = b_0 &+ \frac{I_0}{T_0}\ln a_0 - \epsilon\frac{I_0}{a_0}\xi \\ &+ \epsilon^2\left(b_2 - \frac{I_0(2T_0 - I_0)(2T_0 + I_0)}{6T_0a_0^3} + \frac{I_0(a_2T_0 - a_0T_2)}{T_0^2a_0}\right. \\ &\left. + \frac{T_0I_2 - I_0T_2}{T_0^2}\ln a_0 - \frac{I_0T_0}{2a_0^2}\xi^2\right), \\ E_\xi^2E_x^2(c_1) = \frac{a_0}{2} &- \epsilon\frac{T_0}{2}\xi + \epsilon^2\left(\frac{a_2}{2} + \frac{I_0^2 + 2T_0I_0}{4a_0^2}\right), \\ E_\xi^2E_x^2(c_2) = \frac{a_0}{2} &- \epsilon\frac{T_0}{2}\xi + \epsilon^2\left(\frac{a_2}{2} + \frac{I_0^2 - 2T_0I_0}{4a_0^2}\right), \end{aligned}$$

and, in terms of $\xi = (x-1)/\epsilon$, the outer expansion at $x = 1$ is

$$\begin{aligned} E_\xi^2 E_x^2(\phi) &= b_0 + \frac{I_0}{T_0}\ln(a_0 - T_0) - \epsilon\frac{I_0}{a_0 - T_0}\xi \\ &\quad + \epsilon^2\left(b_2 - \frac{I_0(2T_0 - I_0)(2T_0 + I_0)}{6T_0(a_0 - T_0)^3} + \frac{I_0(a_2T_0 - a_0T_2)}{T_0^2(a_0 - T_0)}\right. \\ &\quad \left. + \frac{T_0I_2 - I_0T_2}{T_0^2}\ln(a_0 - T_0) - \frac{I_0T_0}{2(a_0 - T_0)^2}\xi^2\right), \\ E_\xi^2 E_x^2(c_1) &= \frac{a_0 - T_0}{2} - \epsilon\frac{T_0}{2}\xi + \epsilon^2\left(\frac{a_2 - T_2}{2} + \frac{I_0^2 + 2T_0I_0}{4(a_0 - T_0)^2}\right), \\ E_\xi^2 E_x^2(c_2) &= \frac{a_0 - T_0}{2} - \epsilon\frac{T_0}{2}\xi + \epsilon^2\left(\frac{a_2 - T_2}{2} + \frac{I_0^2 - 2T_0I_0}{4(a_0 - T_0)^2}\right). \end{aligned}$$

From (3.24) and (3.25), the inner expansion at $x = 0$ is

$$\begin{aligned} E_\xi^2(\Phi) &= V - \epsilon\frac{I_0}{2L}\xi - \epsilon^2\left(\frac{I_0T_0}{8L^3} + \frac{I_0T_0}{8L^2}\xi^2\right), \\ E_\xi^2(C_1) &= L - \epsilon\frac{T_0}{2}\xi + \epsilon^2\frac{I_0T_0}{8L^2}, \quad E_\xi^2(C_2) = L - \epsilon\frac{T_0}{2}\xi - \epsilon^2\frac{I_0T_0}{8L^2}, \end{aligned}$$

and the inner expansion at $x = 1$ is

$$\begin{aligned} E_\xi^2(\Psi) &= -\epsilon\frac{I_0}{2R}\xi - \epsilon^2\left(\frac{I_0T_0}{8R^3} + \frac{I_0T_0}{8R^2}\xi^2\right), \\ E_\xi^2(D_1) &= R - \epsilon\frac{T_0}{2}\xi + \epsilon^2\frac{I_0T_0}{8R^2}, \quad E_\xi^2(D_2) = R - \epsilon\frac{T_0}{2}\xi - \epsilon^2\frac{I_0T_0}{8R^2}. \end{aligned}$$

The matchings at $x = 0$ and at $x = 1$ then give

$$\begin{aligned} T_2 &= \frac{(L-R)^3(L+R)}{2L^2R^2(\ln L - \ln R)^2}, \\ I_2 &= \frac{(L-R)^4(L^2 + LR + R^2)}{3L^3R^3(\ln L - \ln R)^2}V - \frac{(L-R)^3(L^3 - R^3)}{3L^3R^3(\ln L - \ln R)^4}\nu_0^3 \\ &\quad + \frac{(L-R)^2(L^2 - R^2)}{2L^2R^2(\ln L - \ln R)^3}V^3. \end{aligned} \tag{3.26}$$

In particular, the second order correction $I_2(V)$ to the zeroth order I-V relation $I_0(V)$ is *cubic* in V. Note also that, as $L \to R$, one finds that $T_2 \to 0$ and $I_2 \to 0$.

Theorem 3.4. *If $L \neq R$, then, up to the order of ϵ^2, the I-V relation $I = I(V)$ in (3.26) is a cubic function with three distinct real roots.*

Proof. From (3.10) and (3.26), up to $O(\epsilon^2)$, $I = f(L, R; \epsilon)V - \epsilon^2 g(L, R)V^3$, where

$$\begin{aligned} f(L, R; \epsilon) &= \frac{2(L-R)}{\ln L - \ln R} + \epsilon^2\frac{(L-R)^4(L^2 + LR + R^2)}{3L^3R^3(\ln L - \ln R)^2}, \\ g(L, R) &= \frac{(L-R)^3(L^3 - R^3)}{3L^3R^3(\ln L - \ln R)^4} - \frac{(L-R)^2(L^2 - R^2)}{2L^2R^2(\ln L - \ln R)^3}. \end{aligned}$$

It is easy to see that $f(L,R;\epsilon) > 0$ for $L \neq R$ (and $f(R,R;\epsilon) = 2R$). It remains to show that $g(L,R) > 0$ for $L \neq R$. Note that $g(L,R) = g(R,L)$. Thus, it suffices to show $g(L,R) > 0$ for $L > R$. Assume now $L > R$ and rewrite $g(L,R)$ as

$$g(L,R) = \frac{(L-R)^3}{6L^3R^3(\ln L - \ln R)^4} h(L,R),$$

where $h(L,R) = 2(L^3 - R^3) - 3LR(L+R)(\ln L - \ln R)$. To show $h(L,R) > 0$ for $L > R$, we fix R and treat $h(L) = h(L,R)$ as a function of L. Then, a direct computation gives $h(R) = h'(R) = h''(R) = 0$ but $h'''(L) > 0$ for all L. Therefore, $h(L) > 0$ for $L > R$. ■

4. Some remarks. We investigated higher order asymptotic expansion of the I-V relation for biological channels via a one-dimensional steady-state Poisson–Nernst–Planck system. For the case of two oppositely charged ion species and zero permanent charge, we obtained explicit information on the I-V relation up to the second order. In particular, we found that the zeroth order I-V relation is *linear*, the first order correction to the zeroth order I-V relation is generally *quadratic*, and, with the electro-neutrality condition at both ends of the channel, there is NO first order correction but the second order correction is *cubic*. Furthermore, up to the second order, the cubic I-V relation has three real roots (Theorem 3.4), which is potentially related to the cubic-like feature of the average I-V relation of a population of channels in the FitzHugh–Nagumo simplification of the Hodgkin–Huxley model.

For second order terms, we only treated the electro-neutrality case because this is a natural biological assumption and the first order correction to the zeroth order linear I-V relation is zero. This occurs in the special case when the permanent charge Q is zero. In general, a realistic assumption is that Q is piecewise constant. To treat this general situation of Q, one can follow our approach to first work on each subinterval where Q is constant (see [10] for the zeroth order case). In doing so, one cannot assume the electro-neutrality condition since it is known to hold only at the two baths ($x = 0$ and $x = 1$). Another direction to be further explored is the case where three or more ion species are involved in the channel. We believe our analysis can be extended to those cases.

Acknowledgment. The authors thank the referees for their valuable comments and suggestions that helped improve the manuscript.

Separatrix Splitting in 3D Volume-Preserving Maps*

Héctor E. Lomelí† and Rafael Ramírez-Ros‡

Abstract. We construct a family of integrable volume-preserving maps in $\mathbb{R}^3$ with a two-dimensional heteroclinic connection of spherical shape between two fixed points of saddle-focus type. In other contexts, such structures are called Hill's spherical vortices or spheromaks. We study the splitting of the separatrix under volume-preserving perturbations using a discrete version of the Melnikov method. First, we establish several properties under general perturbations. For instance, we bound the topological complexity of the primary heteroclinic set in terms of the degree of some polynomial perturbations. We also give a sufficient condition for the splitting of the separatrix under some entire perturbations. A broad range of polynomial perturbations verify this sufficient condition. Finally, we describe the shape and bifurcations of the primary heteroclinic set for a specific perturbation.

Key words. separatrix splitting, volume-preserving maps, primary heteroclinic set, Melnikov method, bifurcations

1. Introduction.

A fundamental question in dynamical systems is the effect that small perturbations of a dynamical system cause on its unperturbed invariant sets. The most studied unperturbed invariant sets are tori and stable/unstable invariant manifolds of hyperbolic sets. Usually, the unperturbed dynamical system is integrable and has separatrices; that is, its stable and unstable invariant manifolds overlap. After a generic perturbation, the perturbed stable and unstable invariant manifolds intersect transversely, which gives rise to the onset of chaos, through the creation of Smale horseshoes. This phenomenon is known as the problem of splitting of separatrices. A widely used technique for detecting such intersections is the Melnikov method.

Our goal is to apply the Melnikov method to the splitting of separatrices in the discrete volume-preserving framework. Similar questions have been considered before. However, we believe this is the first time that detailed *analytical* results about the structure of the primary heteroclinic set and its bifurcations are established for *specific* maps. This represents a step forward with respect to previous works [23, 24], in which once a formula for the Melnikov function in terms of an infinite series is written down, the approach becomes mainly numerical, because of the technical difficulties that obstruct the analytical one. Here, we have overcome

some of these difficulties using basic tools: complex variable theory, quasi-elliptic functions, homology, and several algebraic tricks. Nevertheless, we have not been able to find an explicit expression of the Melnikov function in terms of elementary functions for any specific perturbation. In contrast, such explicit expressions (in terms of elliptic functions) have been known for almost twenty years in the discrete area-preserving setting [18, 13].

This study is interesting because volume-preserving maps are the simplest and most natural higher-dimensional versions of the much-studied class of area-preserving maps. The infinite-dimensional group of volume-preserving diffeomorphisms on $\mathbb{R}^3$ is at the core of the ambitious program to reformulate hydrodynamics [3]. Volume-preserving maps arise in a number of applications such as the study of the motion of Lagrangian tracers in incompressible fluids or of the structure of magnetic field lines [19, 20, 33, 30]. Experimental methods have only recently been developed that allow the visualization of particle trajectories in spatial fluids [28, 32].

Given a system with a heteroclinic connection between two hyperbolic fixed points, the Melnikov function computes the rate at which the distance between the manifolds changes with a perturbation. After the introduction of the Melnikov method for periodic perturbations of one-degree-of-freedom Hamiltonian systems, many different versions appeared, most of them in continuous settings (flows). For instance, there are versions for three-dimensional incompressible flows in [29, 6, 5].

There exist also discrete versions of this method, in which the Melnikov function is no longer an integral, but an infinite sum whose domain is the unperturbed connection. The first steps towards a discrete Melnikov theory were performed for area-preserving maps [17, 18, 13, 21], and next for symplectic maps [14], for twist maps [22], for general n-dimension diffeomorphisms [9, 7, 25], and for spatial billiard maps [15]. Finally, volume-preserving maps have been considered in [23, 24]. These papers deal with codimension-one heteroclinic connections between fixed points of saddle-focus type and between hyperbolic invariant circles. The current paper is a natural continuation and uses some of their ideas.

We shall construct a family of integrable volume-preserving maps $f : \mathbb{R}^3 \to \mathbb{R}^3$ with a two-dimensional heteroclinic connection between two fixed points. This family is derived from another family of integrable planar maps introduced by McMillan [27]. The same construction can be found in [23], but we have decided to study a completely new family to minimize the overlap with previous works. Additionally, the new family has a purely rational character, whereas the previous one contains trigonometric terms. In other words, our model can be used to explore numerically phenomena that are connected to the splitting of separatrices. In particular, numerical computations using a multiple-precision arithmetic are feasible.

The two-dimensional separatrix has a spherical shape, and the fixed points are its "north pole" p_+ and its "south pole" p_-. Our integrable maps depend on two parameters: a *characteristic exponent* $h > 0$ and a *frequency* $\omega \in \mathbb{T}$. These names refer to the fact that

$$\operatorname{spec}[Df(p_\pm)] = \left\{ \mathrm{e}^{\pm 2h}, \mathrm{e}^{\mp h + \mathrm{i}\omega}, \mathrm{e}^{\mp h - \mathrm{i}\omega} \right\}.$$

Thus, the fixed points are of saddle-focus type, the characteristic exponent measures the hyperbolicity of the map, and the frequency quantifies the rotation speed of the trajectories on the separatrix. There also exists a one-dimensional straight heteroclinic connection between

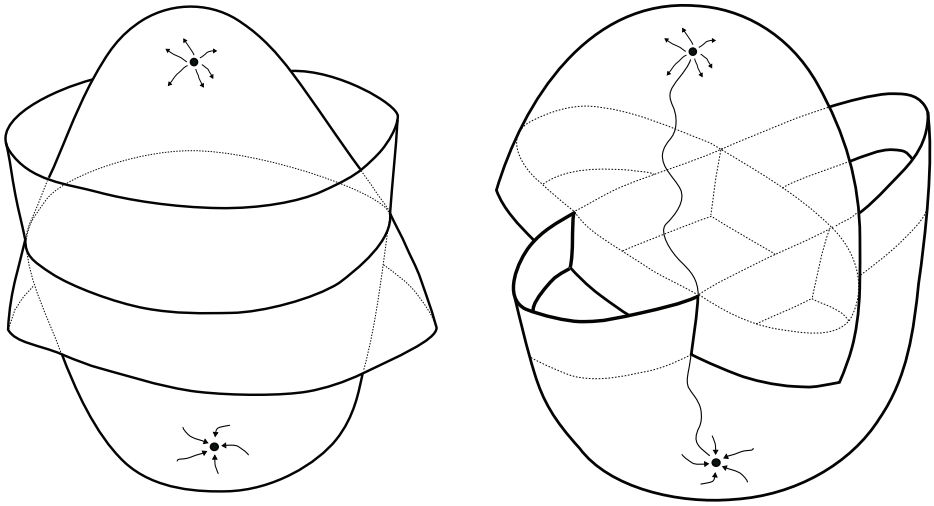

Figure 1. *In this figure we illustrate two possible intersections that appear as heteroclinic intersections of the stable and unstable manifolds that we will be considering. On the left, we have an* equatorial intersection. *On the right a* vertical intersection.

the fixed points. The same configuration appears in fluid dynamics under the name of *Hill's spherical vortex* or *bubble-type vortex breakdown* [33] and as a model for the magnetic field of stars. In a plasma physics context, the configuration is a confinement device that is called *spheromak* [26]. From a more theoretical point of view, we note that the integrable normal forms associated with families of volume-preserving flows with a *Hopf-zero singularity* have the same structure in the phase space [10].

In general, volume-preserving perturbations split the separatrix, but the perturbed stable and unstable manifolds still intersect along one-dimensional heteroclinic curves, which can be *vertical*, *equatorial*, or *bubble-type* ones. (This terminology is borrowed from [23].) Vertical curves are those heteroclinic intersections whose endpoints are both fixed points. Due to the rotational dynamics of the unperturbed map, these curves look like spirals connecting both poles when there is *swirl*; that is, when $\omega \neq 0$. On the contrary, equatorial and bubble-type curves are closed curves that do not approach the poles; in particular, they cannot appear in autonomous flows. The difference between equatorial and bubble-type curves is that the portions of the stable and unstable manifolds delimited by a bubble-type curve encircle a contractible region in $\mathbb{R}^3$; that is, a "bubble." See Remark 7 and Figure 1 for more details.

We shall describe the structure of the set of primary intersections under some perturbations. Roughly speaking, primary intersections are the sets of points where the stable and unstable manifolds "first" meet. In fact, primary intersections are the only intersections that can be followed by the perturbation. In the limit as $\epsilon \to 0$, they appear as zeroes of the Melnikov function. Therefore, nonprimary intersections are missed by standard Melnikov methods. See [23] for details.

First, we bound the topological complexity of the primary heteroclinic set in terms of the degree of volume-preserving polynomial perturbations of the form

$$f_\epsilon = (\mathrm{Id} + \epsilon\kappa) \circ f, \qquad \kappa(x, y, z) = (0, \alpha(x), \beta(x, y)).$$

In particular, it turns out that the primary heteroclinic set contains at most $2n$ vertical curves when $\alpha(x) \in \mathbb{R}_{n-1}[x]$ and $\beta(x,y) \in \mathbb{R}_n[x,y]$. Throughout this paper, we will use the notation $\mathbb{R}_m[x]$ for the set of degree-m polynomials in x with real coefficients and $\mathbb{R}_m[x,y]$ for the set of degree-m polynomials in x and y.

Next, we shall give a sufficient condition for the splitting of the separatrix under some entire perturbations. A broad range of polynomial perturbations verify this condition, for instance, those with $\kappa(x,y,z) = (0,0,\beta(x,y))$ for some even polynomial $\beta(x,y)$ of degree $4l+2$, provided that $\mathrm{e}^{4k\omega \mathrm{i}} \neq -1$ for $k = 1,\dots,2l+1$. In particular, nonresonant frequencies guarantee the breakdown of the unperturbed structure, which is in sharp contrast with some known principles in KAM (Kolmogorov–Arnold–Moser) theory.

Finally, we shall consider the perturbation with $\kappa(x,y,z) = (0,x,0)$. The primary heteroclinic set under this perturbation consists of four vertical curves for $\omega \neq \pm\pi/2$, whereas some heteroclinic bifurcations take place at $\omega = \pm\pi/2$. Unfortunately, we have found a complete proof of these facts only for $h \geq h_0 \approx 2.28$, but we conjecture, based on numerical experiments, that this picture holds for any $h > 0$. The previous upper bound on the number of vertical curves is optimal for this perturbation.

The proof of each analytical result is based on different tools. The bounds on the topological complexity follow from basic homology theory. The splitting result is obtained through the study of the complex singularities of the Melnikov function, an idea that goes back to Ziglin [35]. The part about bifurcations relies strongly on the fact that the Melnikov function can be expressed in terms of a quasi-elliptic function of order two. Additionally, each part has its own algebraic tricks.

We complete this introduction with a note on the organization of the paper. In section 2, we recall the Melnikov theory for volume-preserving maps. In section 3, we construct the family of integrable volume-preserving maps. In section 4, we derive an explicit expression for the Melnikov function associated with some volume-preserving perturbations. The next sections are devoted to bounding the topological complexity of the primary heteroclinic set and to establishing some sufficient conditions for the splitting. The study about the bifurcations of the primary heteroclinic set under the sample perturbation is contained in section 7. Some analytical details and numerical experiments are relegated to Appendices A and B, respectively.

2. The Melnikov theory for volume-preserving maps. In this section we shall briefly describe the Melnikov theory for volume-preserving maps developed in [23, 24, 25]. Let $f_\epsilon : \mathbb{R}^3 \to \mathbb{R}^3$ be a family of smooth volume-preserving maps such that the unperturbed map $f = f_0$ has two hyperbolic fixed points a and b whose stable and unstable invariant manifolds coincide, giving rise to a two-dimensional saddle connection $\Sigma = W^{\mathrm{u}}(a,f) \setminus \{a\} = W^{\mathrm{s}}(b,f) \setminus \{b\}$, where $W^{\mathrm{u}}(a,f)$ and $W^{\mathrm{s}}(b,f)$ denote the unstable invariant manifold of the point a and the stable invariant manifold of the point b, respectively. Both fixed points persist and remain hyperbolic for small ϵ. We want to study how the perturbed invariant manifolds $W^{\mathrm{u}}(a_\epsilon,f_\epsilon)$ and $W^{\mathrm{s}}(b_\epsilon,f_\epsilon)$ intersect.

Our goal is to describe the topology of the set of primary intersections $P_\epsilon \subset W^{\mathrm{u}}(a_\epsilon,f_\epsilon) \cap W^{\mathrm{s}}(b_\epsilon,f_\epsilon)$. We also try to elucidate when the separatrix Σ *splits* under the perturbation; that is, when there is no smooth family of saddle connections $\Sigma_\epsilon \subset W^{\mathrm{u}}(a_\epsilon,f_\epsilon) \cap W^{\mathrm{s}}(b_\epsilon,f_\epsilon)$ such that $\Sigma_0 = \Sigma$.

We recall some concepts that are going to be used below. A point ξ of a manifold Σ is a *regular point* of a smooth function $M : \Sigma \to \mathbb{R}$ when the differential form $\mathrm{d}M$ does not vanish at ξ, whereas $r \in \mathbb{R}$ is a *regular value* of M if every point in $M^{-1}(r)$ is a regular point. A zero of M is called *nondegenerate* when it is a regular point. If r is a regular value of M, then $M^{-1}(r)$ is a one-dimensional submanifold of Σ. On the contrary, $M^{-1}(r)$ can be much more complicated if 0 is a *singular value*, although its subset of regular points is also a one-dimensional submanifold of Σ. A diffeomorphism f is *symmetric* when there exists a diffeomorphism S such that $f \circ S = S \circ f$, and then S is called a *symmetry* of the map f. Analogously, f is *reversible* when there exists a diffeomorphism R such that $f \circ R = R \circ f^{-1}$, and then R is called a *reversor* of the map f and we denote by $\operatorname{Fix} R = \{\xi \in \mathbb{R}^3 : R(\xi) = \xi\}$ the set of its fixed points. These fixed points are called *symmetric* in the literature.

We collect in the following theorem the basic Melnikov-like results about this setup. See [23, 25].

Theorem 1. *Under the previous assumptions, there exists a smooth function $M : \Sigma \to \mathbb{R}$, called the* Melnikov function*, with the following properties:*

(i) *If ξ_0 is a nondegenerate zero of M, then $W^{\mathrm{u}}(a_\epsilon, f_\epsilon)$ and $W^{\mathrm{s}}(b_\epsilon, f_\epsilon)$ intersect transversely, for ϵ small enough, at a point $\xi_\epsilon = \xi_0 + \mathrm{O}(\epsilon) \in P_\epsilon$.*

(ii) *If 0 is a regular value of M, then the set of primary intersections P_ϵ is, for ϵ small enough, a one-dimensional submanifold of $\mathbb{R}^3$ such that $P_\epsilon = M^{-1}(0) + \mathrm{O}(\epsilon)$.*

(iii) *M is invariant by the unperturbed map: $M \circ f = M$.*

(iv) *If f_ϵ has a smooth family of*

1. *symmetries $S_\epsilon : \mathbb{R}^3 \to \mathbb{R}^3$ such that $S_0(\Sigma) = \Sigma$, then $M \circ S_0 = M$;*
2. *reversors $R_\epsilon : \mathbb{R}^3 \to \mathbb{R}^3$ such that $R_0(\Sigma) = \Sigma$, then $M \circ R_0 = -M$;*
3. *saddle connections $\Sigma_\epsilon \subset W^{\mathrm{u}}(a_\epsilon, f_\epsilon) \cap W^{\mathrm{s}}(b_\epsilon, f_\epsilon)$ with $\Sigma_0 = \Sigma$, then $M \equiv 0$.*

The Melnikov function is constructed in such a way that it measures the distance between the perturbed invariant manifolds $W^{\mathrm{u}}(a_\epsilon, f_\epsilon)$ and $W^{\mathrm{s}}(b_\epsilon, f_\epsilon)$ in first order. Because of this, the zero-level set $M^{-1}(0) \subset \Sigma$ is strongly related to the primary intersection set P_ϵ, and any change in its topology gives rise to some heteroclinic bifurcation. Further, a sufficient condition for the splitting of the separatrix is that the Melnikov function is not identically zero.

Symmetries, reversors, and symmetric heteroclinic points play an important role in the study of (primary) heteroclinic intersections; see [16]. For instance, the set of primary intersections is invariant by symmetries and reversors. Additionally, symmetric heteroclinic points persist under reversible perturbations. Concretely, if f_ϵ is R_ϵ-reversible and $\operatorname{Fix} R_0$ is a smooth curve that intersects transversely the saddle connection Σ at some point ξ_0, then there exists a unique point $\xi_\epsilon = \xi_0 + \mathrm{O}(\epsilon) \in P_\epsilon \cap \operatorname{Fix} R_\epsilon$.

Remark 1. If f_ϵ is not R_ϵ-reversible, but $f_\epsilon \circ R_\epsilon - R_\epsilon \circ f_\epsilon^{-1} = \mathrm{O}(\epsilon^2)$ and $R_0(\Sigma) = \Sigma$, then $M \circ R_0 = -M$. This has to do with the fact that the Melnikov function measures only first-order behaviors. We present an explicit example of this situation in Proposition 4.

In order to apply this theory, we must compute the Melnikov function. This is easier when the unperturbed map has a nondegenerate first integral $I : \mathbb{R}^3 \to \mathbb{R}$ and $f_\epsilon = (\mathrm{Id} + \epsilon\kappa) \circ f$ for some map $\kappa : \mathbb{R}^3 \to \mathbb{R}^3$. Under these assumptions, it is proved in [23, Lemma 8] that the Melnikov function is the absolutely convergent series

$$M = \sum_{k \in \mathbb{Z}} \langle \nabla I, \kappa \rangle \circ f^k. \tag{1}$$

This is the formula for Melnikov functions that we shall use in this paper.

We are interested only in perturbations that do not destroy the volume-preserving character of the unperturbed map f. This question has a simple answer: $f_\epsilon = (\mathrm{Id} + \epsilon\kappa) \circ f$ preserves volume if and only if the differential of the perturbation κ is nilpotent everywhere; see [23, Lemma 3]. This allows us to create simple examples of volume-preserving perturbations. For instance, we could take $\kappa(x, y, z) = (0, \alpha(x), \beta(x, y))$ or $\kappa(x, y, z) = (\gamma(y, z), \delta(z), 0)$ for any smooth functions $\alpha, \delta : \mathbb{R} \to \mathbb{R}$ and $\beta, \gamma : \mathbb{R}^2 \to \mathbb{R}$.

3. The maps. In this section we shall construct, following a methodology developed in [23], the perturbed volume-preserving maps f_ϵ that will be studied in the rest of the paper. As a starting point, we shall describe the unperturbed maps $f = f_0$ that form a family of integrable volume-preserving maps with a two-dimensional heteroclinic connection between a couple of hyperbolic fixed points. This integrable family is derived from another family of integrable planar standard-like maps introduced by McMillan [27].

Let $h > 0$ be the parameter of the family of planar standard-like maps. Then we consider the quantities $c = \cosh(h/2)$ and $s = \sinh(h/2)$, the rational transformation

$$z \mapsto \phi(z) = \frac{cz + s}{c + sz}, \tag{2}$$

and the area-preserving map

$$g(r, z) = \left(\phi\left(r + \phi^{-1}(z)\right) - z,\ r + \phi^{-1}(z)\right), \tag{3}$$

where $\phi^{-1}(z) = (cz - s)/(c - sz) = -\phi(-z)$ is the inverse transformation of (2). The phase portrait of this map is sketched in Figure 2. Its main dynamical properties are described in the next lemma.

Lemma 2. *The area-preserving map (3) has the following properties:*

(i) *The points $q_\pm = (0, \pm 1)$ are hyperbolic fixed points of g and*

$$\mathrm{spec}[Dg(q_\pm)] = \left\{\mathrm{e}^h, \mathrm{e}^{-h}\right\}.$$

(ii) *The function $J(r, z) = (c^2 - s^2z^2)r^2 + 2cs(z^2 - 1)r$ is a first integral, and the level $J^{-1}(0)$ contains two heteroclinic connections between the hyperbolic fixed points.*

(iii) *These heteroclinic connections are $\Gamma_0 = \left\{(r, z) \in \mathbb{R}^2 : r = 0,\ |z| < 1\right\}$ and*

$$\Gamma = \left\{(r, z) \in \mathbb{R}^2 : r = \phi(z) - \phi^{-1}(z) = \frac{2cs(1 - z^2)}{c^2 - s^2z^2},\ |z| < 1\right\}.$$

(iv) *The diffeomorphism $\gamma = (r, z) : \mathbb{R} \to \Gamma$, $z(t) = \tanh(t/2)$, $r(t) = z(t + h) - z(t - h)$ is a natural parametrization of the connection Γ; that is, $g(\gamma(t)) = \gamma(t + h)$.*

(v) *The map g is R-reversible and $R(\gamma(t)) = \gamma(-t)$, where $R(r, z) = (r, -z)$.*

Proof. It is a direct computation, so it is more enlightening to explain how these formulae are guessed. The canonical change of variables $(r, z) \mapsto (z, w = r + \phi^{-1}(z))$ transforms (3) into the planar standard-like map

$$\bar{g}(z, w) = (w, \psi(w) - z), \qquad \psi(w) = \phi(w) + \phi^{-1}(w) = \frac{2w}{c^2 - s^2w^2}$$

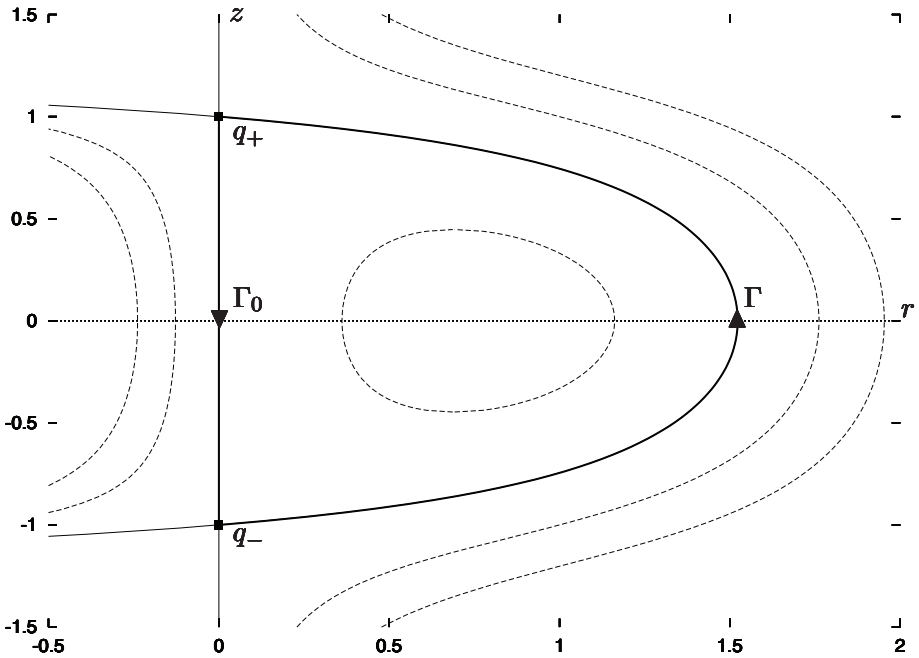

Figure 2. *The phase portrait of the area-preserving map (3) for $h = 2$. The solid squares denote the hyperbolic fixed points $q_\pm$. The thick lines denote the heteroclinic connections Γ_0 and Γ. The arrows denote the dynamics of the map on the connections.*

introduced by McMillan, which has similar properties [27, p. 232]. For instance,

$$\bar{J}(z,w) = s^2(z^2-1)(w^2-1) - (z-w)^2$$

is a known first integral of the McMillan map, and its zero-level set $\bar{J}^{-1}(0)$ contains two heteroclinic connections between the hyperbolic fixed points $\bar{q}_- = (-1,-1)$ and $\bar{q}_+ = (1,1)$. From the relation $\psi(z) = \phi(z) + \phi^{-1}(z)$, we get that

$$\bar{g}^k(z, \phi^{\pm 1}(z)) = \left(\phi^{\pm k}(z), \phi^{\pm(k+1)}(z)\right)$$

for all $k \in \mathbb{Z}$. Thus, using that $\phi : (-1,1) \to (-1,1)$ is a diffeomorphism such that $\lim_{k\to\pm\infty} \phi^k(z) = \pm 1$ for all $z \in (-1,1)$, we see that the heteroclinic connections are

$$\bar{\Gamma}_0 = \{w = \phi^{-1}(z)\}, \qquad \bar{\Gamma} = \{w = \phi(z)\}.$$

The change $(z,w) \mapsto (r = w - \phi^{-1}(z), z)$ transforms $\bar{\Gamma}_0$ into $\Gamma_0 = \{r = 0\}$ and $\bar{\Gamma}$ into $\Gamma = \{r = \phi(z) - \phi^{-1}(z)\}$. Finally, the natural parametrization follows from the relations $\phi(z(t)) = z(t+h)$ and $r(t) = \phi(z(t)) - \phi^{-1}(z(t)) = z(t+h) - z(t-h)$. ■

Next, we construct a volume-preserving map using the area-preserving map (3). The methodology consists, roughly speaking, of "rotating" the right half-plane $\{r > 0\}$ of Figure 2 around the vertical axis, using "canonical" cylindrical coordinates [23]. The map becomes fully three-dimensional if we introduce any nontrivial dynamics in the cylindrical angular variable

$\theta \in \mathbb{T} := \mathbb{R}/2\pi\mathbb{Z}$. For instance, a rigid rotation $\theta \mapsto \Theta = \theta + \omega$ suffices. See also Remark 2. The surface of revolution Σ obtained from the curve Γ is the two-dimensional heteroclinic connection we were looking for.

The construction would be a little obscure if we directly used the Cartesian coordinates (x, y, z). Hence, as an intermediate step, it is convenient to introduce the cylindrical angle $\theta \in \mathbb{T}$ and the cylindrical radius $\sqrt{2r} > 0$. That is, we will work with the canonical cylindrical coordinates (r, θ, z) defined by the relations

$$x = \sqrt{2r}\cos\theta, \qquad y = \sqrt{2r}\sin\theta, \qquad z = z. \tag{4}$$

The term canonical means that $\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z = \mathrm{d}r \wedge \mathrm{d}\theta \wedge \mathrm{d}z$. Consider the map $(r, \theta, z) \mapsto (R, \Theta, Z)$, given by

$$\Theta = \theta + \omega, \qquad (R, Z) = g(r, z), \tag{5}$$

where g is the area-preserving map (3). This map preserves volume, since

$$\mathrm{d}X \wedge \mathrm{d}Y \wedge \mathrm{d}Z = -\mathrm{d}R \wedge \mathrm{d}Z \wedge \mathrm{d}\Theta = -\mathrm{d}r \wedge \mathrm{d}z \wedge \mathrm{d}\theta = \mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z.$$

Let

$$\rho(r, z) = \begin{cases} \sqrt{(\phi(r + \phi^{-1}(z)) - z)/r}, & r \neq 0, \\ \sqrt{\phi'(\phi^{-1}(z))}, & r = 0. \end{cases}$$

This function $\rho(r, z)$ is analytic at $r = 0$ for $|z| < c/s$. Using coordinates (4) in the map defined by (5), we get that, in Cartesian coordinates, the map that we want is

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = f \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} \cos\omega & -\sin\omega & 0 \\ \sin\omega & \cos\omega & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \rho(r, z)x \\ \rho(r, z)y \\ r + \phi^{-1}(z) \end{pmatrix}, \tag{6}$$

where $r = (x^2 + y^2)/2$. We check, using formulation (6), that the map is well defined and analytic on $\{(0, 0, z) \in \mathbb{R}^3 : |z| < c/s\}$. This was not immediately clear from (4), since the change to cylindrical coordinates is singular at $r = 0$.

The map (6) is our unperturbed volume-preserving model. It depends on the *characteristic exponent* $h > 0$ and the *frequency* $\omega \in \mathbb{T}$. The characteristic exponent measures the hyperbolicity of the problem. In particular, numerical computations or analytical studies about separatrix splittings for small values of h will be hard, due to their exponential smallness. For instance, we have only been able to prove a conjecture presented in section 7 for $h \geq \log 16 - \log(\sqrt{113} - 9) \approx 2.282$.

The main dynamical properties of the integrable volume-preserving map (6) are described in the following lemma.

Lemma 3. *The volume-preserving map* (6) *has the following properties:*

(i) *The points* $p_\pm = (0, 0, \pm 1)$ *are hyperbolic fixed points of* f *such that*

$$\operatorname{spec}[Df(p_\pm)] = \left\{ \mathrm{e}^{\pm 2h}, \mathrm{e}^{\mp h + \mathrm{i}\omega}, \mathrm{e}^{\mp h - \mathrm{i}\omega} \right\}.$$

(ii) *The function* $I(x,y,z) = J((x^2+y^2)/2, z)$ *is a first integral of* f*, and the level* $I^{-1}(0)$ *contains two heteroclinic connections between the hyperbolic fixed points.*

(iii) *The heteroclinic connections are* $\Sigma_0 = \{(0,0,z) \in \mathbb{R}^3 : |z| < 1\}$ *and*

$$\Sigma = \left\{(x,y,z) \in \mathbb{R}^3 : x^2 + y^2 = \frac{4cs(1-z^2)}{c^2 - s^2 z^2},\ |z| < 1\right\}.$$

(iv) *The diffeomorphism* $\sigma : \mathbb{T} \times \mathbb{R} \to \Sigma$, $\sigma(\theta,t) = (x(\theta,t), y(\theta,t), z(t))$, *given by*

$$\left.\begin{array}{rcl} z(t) & = & \tanh(t/2), \\ r(t) & = & z(t+h) - z(t-h), \\ x(\theta,t) & = & \sqrt{2r(t)}\cos\theta, \\ y(\theta,t) & = & \sqrt{2r(t)}\sin\theta, \end{array}\right\} \tag{7}$$

is a natural parametrization of Σ*; that is,* $f(\sigma(\theta,t)) = \sigma(\theta+\omega, t+h)$.

(v) *The map* f *has the linear symmetry* $S(x,y,z) = (-x,-y,z)$ *and the involutive linear reversors* $R(x,y,z) = (x,-y,-z)$ *and* $T(x,y,z) = (-x,y,-z)$*. Additionally,* $S(\sigma(\theta,t)) = \sigma(\theta+\pi, t)$, $R(\sigma(\theta,t)) = \sigma(-\theta,-t)$, *and* $T(\sigma(\theta,t)) = \sigma(\pi-\theta,-t)$.

Proof. In the cylindrical coordinates (r,θ,z), the map f acts in the way described in (5). Therefore, these properties follow directly from the properties of the map g described in Lemma 2 and the fact that the involutions $\theta \mapsto -\theta$ and $\theta \mapsto \pi - \theta$ are reversors of the rigid rotations $\theta \mapsto \theta + \omega$. ■

Remark 2. We could have assumed that the frequency is not constant, but that it depends on the first integral: $\omega = \omega(I)$. In that case, since the expression of the Melnikov function only needs the values of the dynamics on the saddle connection Σ, only the value $\omega_0 = \omega(0)$ appears in the Melnikov computations.

The fixed sets of the reversors R and T are smooth curves. In fact, $\operatorname{Fix} R$ is the x-axis and $\operatorname{Fix} T$ is the y-axis. Additionally, each fixed set intersects the saddle connection transversely at a couple of opposite points, namely,

$$\Sigma \cap \operatorname{Fix} R = \{\xi^+, \xi^-\}, \qquad \Sigma \cap \operatorname{Fix} T = \{\zeta^+, \zeta^-\},$$

where $\xi^\pm = (\pm\eta, 0, 0)$, $\zeta^\pm = (0, \pm\eta, 0)$, and $\eta = 2\sqrt{s/c}$. Further, $\xi^+ = \sigma(0,0)$, $\xi^- = \sigma(\pi,0)$, $\zeta^+ = \sigma(\pi/2,0)$, and $\zeta^- = \sigma(3\pi/2,0)$. The question about when these symmetric heteroclinic points persist is answered in the following proposition.

Proposition 4. *Let* S, R, *and* T *be the symmetry and the reversors introduced in Lemma 3. Let* $\xi^\pm$ *and* $\zeta^\pm$ *be the symmetric heteroclinic points of the map (6) on the* x*-axis and* y*-axis, respectively. Let* P_ϵ *be the set of primary heteroclinic intersections of the perturbed map* $f_\epsilon = p_\epsilon \circ f$, *where* $p_\epsilon = \mathrm{Id} + \epsilon\kappa$ *and* $\kappa(x,y,z) = (0, \alpha(x), \beta(x,y))$.

(i) *If* $\alpha(x)$ *is odd and* $\beta(x,y)$ *is even, then* f_ϵ *is* S*-symmetric and* $S(P_\epsilon) = P_\epsilon$.

(ii) *If* $\beta(x,y)$ *is even in* y*, then* $f_\epsilon \circ R_\epsilon - R_\epsilon \circ f_\epsilon^{-1} = \mathrm{O}(\epsilon^2)$, *where* $R_\epsilon = p_\epsilon \circ R$*. If, in addition,* $\alpha(0) = 0$ *and* $\beta(0, \alpha(x)) = 0$, *then* f_ϵ *is* R_ϵ*-reversible,* $R_\epsilon(P_\epsilon) = P_\epsilon$, *and there exist points* $\xi_\epsilon^\pm = \xi^\pm + \mathrm{O}(\epsilon) \in P_\epsilon \cap \operatorname{Fix} R_\epsilon$.

(iii) *If* $\alpha(x)$ *is odd and* $\beta(x,y)$ *is even in* x*, then* $f_\epsilon \circ T_\epsilon - T_\epsilon \circ f_\epsilon^{-1} = \mathrm{O}(\epsilon^2)$, *where* $T_\epsilon = p_\epsilon \circ T$*. If, in addition,* $\alpha(0) = 0$ *and* $\beta(0, \alpha(x)) = 0$, *then* f_ϵ *is* T_ϵ*-reversible,* $T_\epsilon(P_\epsilon) = P_\epsilon$, *and there exist points* $\zeta_\epsilon^\pm = \zeta^\pm + \mathrm{O}(\epsilon) \in P_\epsilon \cap \operatorname{Fix} T_\epsilon$.

Proof. (i) If $\alpha(x)$ is odd and $\beta(x,y)$ is even, then $\kappa \circ S = S \circ \kappa$ and

$$p_\epsilon \circ S = (\mathrm{Id} + \epsilon\kappa) \circ S = S + \epsilon S \circ \kappa = S \circ (\mathrm{Id} + \epsilon\kappa) = S \circ p_\epsilon.$$

Therefore, $f_\epsilon \circ S = p_\epsilon \circ f \circ S = p_\epsilon \circ S \circ f = S \circ p_\epsilon \circ f = S \circ f_\epsilon$.

(ii) If $\beta(x,y)$ is even in y, then $\kappa \circ R = -R \circ \kappa$. Further, $p_\epsilon^{-1} = \mathrm{Id} - \epsilon\kappa + \mathrm{O}(\epsilon^2)$. Therefore, $R_\epsilon = (\mathrm{Id} + \epsilon\kappa) \circ R = R - \epsilon R \circ \kappa = R \circ (\mathrm{Id} - \epsilon\kappa) = R \circ p_\epsilon^{-1} + \mathrm{O}(\epsilon^2)$ and $f_\epsilon \circ R_\epsilon = p_\epsilon \circ f \circ R \circ p_\epsilon^{-1} + \mathrm{O}(\epsilon^2) = p_\epsilon \circ R \circ f^{-1} \circ p_\epsilon^{-1} + \mathrm{O}(\epsilon^2) = R_\epsilon \circ f_\epsilon^{-1} + \mathrm{O}(\epsilon^2)$.

If $\alpha(0) = 0$ and $\beta(0, \alpha(x)) = 0$, then $\kappa^2(x,y,z) = (0, \alpha(0), \beta(0, \alpha(x))) = 0$ and $p_\epsilon^{-1} = \mathrm{Id} - \epsilon\kappa$, so all the $\mathrm{O}(\epsilon^2)$ terms above vanish.

(iii) If $\alpha(x)$ is odd and $\beta(x,y)$ is even in x, then $\kappa \circ T = -T \circ \kappa$, so it suffices to replace R with T in the previous item. ∎

When R_ϵ and T_ϵ are true reversors, their fixed sets are

$$\begin{aligned} \operatorname{Fix} R_\epsilon &= \{(x,y,z) \in \mathbb{R}^3 : y = \epsilon\alpha(x)/2,\ z = \epsilon\beta(x, \epsilon\alpha(x)/2)/2\}, \\ \operatorname{Fix} T_\epsilon &= \{(x,y,z) \in \mathbb{R}^3 : x = 0,\ z = \epsilon\beta(0,y)/2\}, \end{aligned}$$

which are $\mathrm{O}(\epsilon)$-close to the x-axis and y-axis. (We have used that $\alpha(0) = 0$.)

4. The Melnikov function. Next, we want to derive an explicit expression for the Melnikov function associated with the volume-preserving perturbations

$$f_\epsilon = (\mathrm{Id} + \epsilon\kappa) \circ f, \qquad \kappa(x,y,z) = (0, \alpha(x), \beta(x,y)). \tag{8}$$

Other perturbations can also be studied. We do not aspire to be exhaustive.

If $\alpha(0) = \beta(0,0) = 0$, then $f_\epsilon(0,0,z) = f(0,0,z)$, and the one-dimensional heteroclinic connection Σ_0 is preserved under the perturbation (8). There is no similar persistence result for the two-dimensional heteroclinic connection Σ.

The first integral given in Lemma 3 is $I(x,y,z) = J(r,z)$, where $r = (x^2+y^2)/2$ and $J(r,z) = (c^2 - s^2z^2)r^2 + 2cs(z^2-1)r$. Additionally, $r = 2cs(1-z^2)/(c^2 - s^2z^2)$ on the saddle connection Σ. Finally, if the perturbation has the form (8), then the Melnikov function (1) can be written as

$$M : \Sigma \to \mathbb{R}, \qquad M(x,y,z) = \sum_{k \in \mathbb{Z}} m(x_k, y_k, z_k), \tag{9}$$

where $(x_k, y_k, z_k) = f^k(x,y,z)$ and

$$\begin{aligned} m(x,y,z) &= \langle \nabla I(x,y,z), \kappa(x,y,z) \rangle \\ &= \partial_y I(x,y,z)\alpha(x) + \partial_z I(x,y,z)\beta(x,y) \\ &= y\partial_r J(r,z)\alpha(x) + \partial_z J(r,z)\beta(x,y) \\ &= 2csy(1-z^2)\alpha(x) + 2szr(2c - sr)\beta(x,y). \end{aligned}$$

On the other hand, the natural parametrization $\sigma = (x,y,z) : \mathbb{T} \times \mathbb{R} \to \Sigma$ given in (7) provides a diffeomorphism between the saddle connection Σ and the cylinder $\mathbb{T} \times \mathbb{R}$, so that objects defined over Σ can be considered as depending on an angular variable $\theta \in \mathbb{T}$ and a

hyperbolic variable $t \in \mathbb{R}$. Henceforth, we will abuse the notation by not giving these objects new names. Thus, the Melnikov function (9) becomes

$$M : \mathbb{T} \times \mathbb{R} \to \mathbb{R}, \qquad M(\theta, t) = \sum_{k \in \mathbb{Z}} m(\theta + k\omega,\, t + kh), \tag{10}$$

where

$$\begin{aligned} m(\theta, t) &= \lambda(t) y(\theta, t) \alpha(x(\theta, t)) + \mu(t) \beta(x(\theta, t), y(\theta, t)) \\ &= \rho(t) \lambda(t) \alpha\big(\rho(t) \cos\theta\big) \sin\theta + \mu(t) \beta\big(\rho(t) \cos\theta, \rho(t) \sin\theta\big) \end{aligned} \tag{11}$$

and

$$\begin{aligned} r(t) &= z(t+h) - z(t-h) = \frac{2cs}{\cosh\left((t+h)/2\right) \cosh\left((t-h)/2\right)}, \\ \rho(t) &= \sqrt{2r(t)}, \\ \lambda(t) &= 2cs\left(1 - z(t)^2\right) = 4csz'(t) = \frac{2cs}{\cosh^2(t/2)}, \\ \mu(t) &= 2sz(t)r(t)\left(2c - sr(t)\right) = -4csr'(t). \end{aligned} \tag{12}$$

The rest of the paper deals with the computation and description of the zero-level set

$$Z = M^{-1}(0) = \{(\theta, t) \in \mathbb{T} \times \mathbb{R} : M(\theta, t) = 0\}$$

for several simple perturbations (8). In order to make that easier, we recall that the Melnikov function is invariant by the unperturbed map. In the current context, this implies that the Melnikov function M satisfies

$$M(\theta + \omega,\, t + h) = M(\theta, t) = M(\theta + 2\pi, t), \tag{13}$$

and therefore the zero-set Z is $(2\pi, 0)$ and (ω, h)-periodic. That is, if $(\theta^*, t^*) \in Z$, then $(\theta^* + \omega,\, t^* + h) \in Z$ and $(\theta^* + 2\pi, t^*) \in Z$.

A tilde will always denote the projection of a periodic object to the quotient torus,

$$\tilde{\tau}(\omega, h) = \tilde{\tau} := (\mathbb{T} \times \mathbb{R})/(\omega, h)\mathbb{Z} = \mathbb{R}^2/((2\pi, 0)\mathbb{Z} + (\omega, h)\mathbb{Z}), \tag{14}$$

which is diffeomorphic to the quotient of the saddle connection by the unperturbed map. The study of the projected set $\tilde{Z} = \tilde{M}^{-1}(0) \subset \tilde{\tau}$ is easier, because $\tilde{\tau}$ is compact.

The torus is represented in Figure 3 as the rectangle $[0, 2\pi] \times [0, h]$ with the appropriate identifications. We have not chosen the parallelogram shown in thin lines in that figure as the representation of the torus because its shape changes in ω, hindering posterior comparisons and the study of bifurcations that take place in ω.

Remark 3. Sometimes we will restrict ourselves to the case $\omega = 0$, which is called no-swirl in fluid dynamics. This is the simplest one, because then the quotient torus is a product: $\tilde{\tau}(0, h) = (\mathbb{R}/2\pi\mathbb{Z}) \times (\mathbb{R}/h\mathbb{Z})$, and the variable t is defined modulo h. Although the unperturbed map has just a two-dimensional dynamics for $\omega = 0$, it is still an interesting case—the perturbation will create a real three-dimensional dynamics.

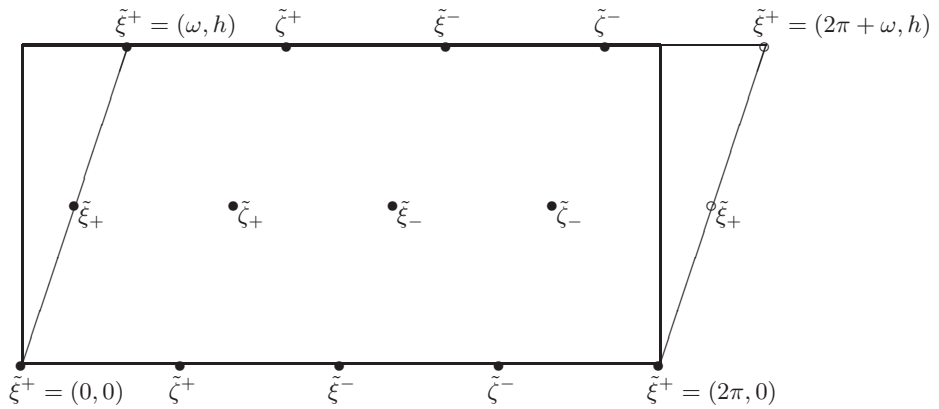

Figure 3. *A rectangular representation of the torus $\tilde{\tau}$ and the symmetric points described in Lemma 5 for $\omega = \pi/3$. Opposite sides of the rectangle are identified, although the identification of the horizontal ones is shifted by an amount equal to ω.*

Let us check that $\tilde{Z}$ contains at least eight *symmetric points* and has some useful symmetries and more periodicities when the perturbation preserves the symmetry and reversors of the unperturbed map. The symmetric points are shown in Figure 3.

Lemma 5. *Let $\tilde{Z}$ be the projection onto the torus (14) of the zero-level set of the Melnikov function (10).*

(i) *If $\alpha(x)$ is odd and $\beta(x, y)$ is even, then $\tilde{Z}$ is $(\pi, 0)$-periodic: $\tilde{Z} = \tilde{Z} + (\pi, 0)$.*
(ii) *If $\alpha(x)$ is even and $\beta(x, y)$ is odd, then $\tilde{Z}$ is $(\pi, 0)$-periodic: $\tilde{Z} = \tilde{Z} + (\pi, 0)$.*
(iii) *If $\beta(x, y)$ is even in y, then $\tilde{Z}$ contains (and is symmetric with regard to) the points $\tilde{\xi}^+ = (0, 0)$, $\tilde{\xi}^- = (\pi, 0)$, $\tilde{\xi}_+ = (\omega/2, h/2)$, and $\tilde{\xi}_- = (\pi + \omega/2, h/2)$.*
(iv) *If $\alpha(x)$ is odd and $\beta(x, y)$ is even in x, then $\tilde{Z}$ contains (and is symmetric with regard to) the points $\tilde{\zeta}^+ = (\pi/2, 0)$, $\tilde{\zeta}^- = (3\pi/2, 0)$, $\tilde{\zeta}_+ = (\pi/2 + \omega/2, h/2)$, and $\tilde{\zeta}_- = (3\pi/2 + \omega/2, h/2)$.*

Proof. We could write a geometric proof based on the geometric properties established in Proposition 4, but instead, we give a shorter analytic proof.

We consider the Melnikov function M as a function defined on the plane $\mathbb{R}^2$ with periods $(2\pi, 0)$ and (ω, h). Assume that M is odd with regard to a point $(\theta_0, t_0) \in \mathbb{R}^2$. Then $M^{-1}(0)$ contains (and is symmetric with regard to) the point (θ_0, t_0). But $M^{-1}(0)$ also contains (and is symmetric with regard to) the points $(\theta_0 + p, t_0 + q)$ for any semiperiod (p, q) of M, because

$$M(\theta_0 + p, t_0 + q) = -M(\theta_0 - p, t_0 - q) = -M(\theta_0 + p, t_0 + q).$$

The functions $r(t)$, $\rho(t)$, and $\lambda(t)$ given in (12) are even, whereas $\mu(t)$ is odd. Let m be the function defined in (11). Hence, the lemma is a consequence of the following observations:

(i) if $\alpha(x)$ is odd and $\beta(x, y)$ is even, then $m(\theta, t)$ is π-periodic in θ;
(ii) if $\alpha(x)$ is even and $\beta(x, y)$ is odd, then $m(\theta, t)$ is π-antiperiodic in θ;
(iii) if $beta(x, y)$ is even in y, then $m(\theta, t)$ is odd with regard to $(0, 0)$; and
(iv) if $\alpha(x)$ is odd and $\beta(x, y)$ is even in x, $m(\theta, t)$ is odd with regard to $(\pi/2, 0)$.

In this way, we conclude that the Melnikov function (10) verifies the conclusions of the lemma. ∎

Remark 4. One can obtain more symmetries or periodicities under more restrictive hypotheses. For instance, using basic trigonometric properties, one checks that Z is $(\pi/2, 0)$-periodic when $\kappa(x, y, z) = (0, x, 0)$ or when $\kappa(x, y, z) = (0, 0, \beta(x, y))$ for some $\beta(x, y)$ such that $\beta(x, y) = \beta(-y, x)$ or $\beta(x, y) = -\beta(-y, x)$.

Remark 5. It turns out that $\tilde{Z} \neq \emptyset$, even if the volume-preserving perturbation (8) has no symmetries. This has to do with the existence of an area form $\tilde{\eta}$ over the torus $\tilde{\tau}$ such that the integral of the two-form $\tilde{M}\tilde{\eta}$ vanishes. Therefore, the Melnikov function has to be zero at some points. This idea was used in [24]. We skip the details.

5. Bounds on the complexity of the primary heteroclinic set. First, we shall establish an upper bound on the cardinality of the horizontal sections of the zero-level set Z under polynomial perturbations of the form (8). These horizontal sections are defined as

$$Z_{t_0} = \{\theta \in \mathbb{T} : M(\theta, t_0) = 0\} = \{\theta \in \mathbb{T} : (\theta, t_0) \in Z\}, \qquad t_0 \in \mathbb{R}.$$

Proposition 6. *If $\alpha(x) \in \mathbb{R}_{n-1}[x]$ and $\beta(x, y) \in \mathbb{R}_n[x, y]$ for some integer $n \geq 1$, then either $Z_{t_0} = \mathbb{T}$ or $\#Z_{t_0} \leq 2n$.*

Proof. The function $m(\theta, t)$ given in (11) has the following simple forms under monomial perturbations. If $\alpha(x) = x^{i-1}$ and $\beta(x, y) = 0$, then $m(\theta, t) = (2r(t))^{i/2}\lambda(t)\cos^{i-1}\theta\sin\theta$, whereas if $\alpha(x) = 0$ and $\beta(x, y) = x^i y^j$, then $m(\theta, t) = (2r(t))^{(i+j)/2}\mu(t)\cos^i\theta\sin^j\theta$. Therefore, the Fourier expansion of $m(\theta, t)$ when $\alpha(x) \in \mathbb{R}_{n-1}[x]$ and $\beta(x, y) \in \mathbb{R}_n[x, y]$ has only the central $2n + 1$ harmonics. That is, $m(\theta, t) = \sum_{|j|\leq n} m_j(t)\mathrm{e}^{\mathrm{i}j\theta}$ for some coefficients $m_j(t)$. Thus the Fourier expansion of the Melnikov function (10) has the same form, since

$$\begin{aligned} M(\theta, t) &= \sum_{k\in\mathbb{Z}} m(\theta + k\omega,\, t + kh) \\ &= \sum_{|j|\leq n} \sum_{k\in\mathbb{Z}} m_j(t + kh)\mathrm{e}^{\mathrm{i}j(\theta+k\omega)} \\ &= \sum_{|j|\leq n} M_j(t)\mathrm{e}^{\mathrm{i}j\theta}, \end{aligned}$$

where $M_j(t) = \sum_{k\in\mathbb{Z}} \mathrm{e}^{\mathrm{i}jk\omega} m_j(t + kh)$. To end the proof, it suffices to note that any nonzero trigonometric polynomial like $M_{t_0}(\theta) := M(\theta, t_0) = \sum_{|j|\leq n} M_j(t_0)\mathrm{e}^{\mathrm{i}j\theta}$ has at most $2n$ different roots in $\mathbb{T}$. ∎

If $\omega = 0$, there exists a similar bound for the cardinal of the vertical sections. This new bound is obtained by using some elementary facts of the theory of elliptic functions. We recall that a function is *elliptic* when it is meromorphic in the whole complex plane and has two complex periods that are independent over the reals. The *order* of a nonconstant elliptic function is the number of its poles (or zeroes), counted with multiplicity, that lie in a cell. A *cell* of an elliptic function with periods p_1 and p_2 is a parallelogram with vertexes s, $s + p_1$, $s + p_1 + p_2$, and $s + p_2$ such that its sides do not contain either zeroes or poles. For a general background on elliptic functions, we refer to [34].

We realized in Remark 3 that the Melnikov function $M(\theta, t)$ is h-periodic in the vertical coordinate t when the frequency ω is zero. In that case, the vertical sections of the projected

zero-level set $\tilde{Z} = \tilde{M}^{-1}(0) \subset \tilde{\tau}$ defined as

$$\tilde{Z}^{\theta_0} = \{t \in \mathbb{R}/h\mathbb{Z} : \tilde{M}(\theta_0, t) = 0\} = \{t \in \mathbb{R}/h\mathbb{Z} : (\theta_0, t) \in \tilde{Z}\}$$

are subsets of the quotient space $\mathbb{R}/h\mathbb{Z}$.

Proposition 7. *Assume that the perturbation (8) is polynomial and $\omega = 0$. Let $\tilde{Z}^{\theta_0}$ be any vertical section which does not cover the whole set $\mathbb{R}/h\mathbb{Z}$. Let $l, n \in \mathbb{N}$.*

(i) *If $\alpha(x) \in \mathbb{R}_{2l-1}[x]$ is odd and $\beta(x, y) = 0$, then $\#\tilde{Z}^{\theta_0} \leq l$.*

(ii) *If $\alpha(x) = 0$ and $\beta(x, y) \in \mathbb{R}_{2n}[x, y]$ is even, then $\#\tilde{Z}^{\theta_0} \leq n + 1$.*

(iii) *If $\alpha(x) \in \mathbb{R}_{2l-1}[x]$ is odd and $\beta(x, y) \in \mathbb{R}_{2n}[x, y]$ is even, then $\#\tilde{Z}^{\theta_0} \leq \max(l, n + 2)$.*

Proof. These three items a based on the following formulae. If $\alpha(x) = x^{2j-1}$ and $\beta(x, y) = 0$, then $m(\theta, t) = (2r(t))^j \lambda(t) \cos^{2j-1}\theta \sin\theta$. If $\alpha(x) = 0$ and $\beta(x, y) = x^i y^{2j-i}$, then $m(\theta, t) = (2r(t))^j \mu(t) \cos^i\theta \sin^{2j-i}\theta$. Hence, if the polynomial $\alpha(x) \in \mathbb{R}_{2l-1}[x]$ is odd and the polynomial $\beta(x, y) \in \mathbb{R}_{2n}[x, y]$ is even, the function $m(\theta, t)$ has the form

$$m(\theta, t) = \lambda(t) \sum_{j=1}^{l} a_j(\theta)(r(t))^j + \mu(t) \sum_{j=1}^{n} b_j(\theta)(r(t))^j$$

for some trigonometric polynomials $a_j(\theta)$ and $b_j(\theta)$. Since $\omega = 0$, we get that

$$\tilde{M}^{\theta_0}(t) := \tilde{M}(\theta_0, t) = \sum_{j=1}^{l} a_j(\theta_0) A_j(t) + \sum_{j=1}^{n} b_j(\theta_0) B_j(t), \tag{15}$$

where $A_j(t) = \sum_{k\in\mathbb{Z}} \lambda(t + kh)(r(t + kh))^j$ and $B_j(t) = \sum_{k\in\mathbb{Z}} \mu(t + kh)(r(t + kh))^j$.

The functions $z(t)$, $r(t)$, $\lambda(t)$, and $\mu(t)$ are 2πi-periodic and meromorphic in $\mathbb{C}$. On the one hand, the poles of $z(t)$ are the points in the set $\pi\mathrm{i} + 2\pi\mathrm{i}\mathbb{Z}$, all of them simple, and so $\lambda(t) = 4csz'(t)$ has the same poles, but they are double ones. On the other hand, the poles of $r(t)$ are the points in the sets $\pm h + \pi\mathrm{i} + 2\pi\mathrm{i}\mathbb{Z}$, all of them simple, and so $\mu(t) = -4csr'(t)$ has the same poles, but they are double ones.

Thus, $A_j(t)$, $B_j(t)$, and $\tilde{M}^{\theta_0}(t)$ are elliptic functions with periods h and 2πi. Their poles are the points in the set $\pi\mathrm{i} + h\mathbb{Z} + 2\pi\mathrm{i}\mathbb{Z}$. Their orders are at most $\max(j, 2)$, $j + 2$, and $\max(l, n + 2)$, respectively. To end the common part of the proof, we note that $\tilde{M}^{\theta_0}(t)$ is nonconstant because $\tilde{Z}^{\theta_0} \neq \mathbb{R}/h\mathbb{Z}$.

(i) If $\beta(x, y) = 0$, the elliptic function (15) becomes $\tilde{M}^{\theta_0}(t) = \sum_{j=1}^{l} a_j(\theta_0) A_j(t)$, and its order is at most $\max(l, 2)$, so that it has at most $\max(l, 2)$ roots in a cell and $\#\tilde{Z}^{\theta_0} \leq \max(l, 2)$. We can substitute this last bound by $\#\tilde{Z}^{\theta_0} \leq l$ because if $\alpha(x) = x$ and $\omega = 0$, then either $\tilde{Z}^{\theta_0} = \mathbb{R}/h\mathbb{Z}$ or $\tilde{Z}^{\theta_0} = \emptyset$; see item (iv) of Theorem 17.

(ii) If $\alpha(x) = 0$, the elliptic function (15) becomes $\tilde{M}^{\theta_0}(t) = \sum_{j=1}^{n} b_j(\theta_0) B_j(t)$ and is odd, because $\mu(t)$ is odd and $r(t)$ is even. Its order is at most $n + 2$, but the rough bound $\#\tilde{Z}^{\theta_0} \leq n + 2$ can be improved using the symmetry. We get that $\tilde{M}^{\theta_0}(h/2 + \pi\mathrm{i}) = 0$, because

$$\tilde{M}^{\theta_0}(h/2 + \pi\mathrm{i}) = \tilde{M}^{\theta_0}(-h/2 + \pi\mathrm{i}) = \tilde{M}^{\theta_0}(-h/2 - \pi\mathrm{i}) = -\tilde{M}^{\theta_0}(h/2 + \pi\mathrm{i}).$$

This means that $\tilde{M}^{\theta_0}(t)$ has at most $n + 1$ real roots modulo h.

(iii) In this case, the bound $\#\tilde{Z}^{\theta_0} \leq \max(l, n+2)$ cannot be improved. ■

Remark 6. Proposition 6 also holds for the integrable trigonometric family of volume-preserving maps introduced in [23]. The proof does not requires any change. On the contrary, Proposition 7 cannot be directly translated into the trigonometric setting, because the complex singularities of the natural parametrization of the separatrix in that setting are more complicated.

Recall that in the introduction we had a brief discussion of the type of primary heteroclinic intersections that appear. In our case, by Theorem 1, it is enough to remember that primary intersections are the intersections that arise as the continuation of the nondegenerate zeroes of the Melnikov function.

Any vertical curve intersects the horizontal line $\{t = t_0\}$ in at least one point, so the number of vertical curves cannot be larger than the cardinal of the horizontal sections of the zero-level set. Therefore, as a by-product of Proposition 6, we get that there are at most $2n$ vertical curves when $\alpha(x) \in \mathbb{R}_{n-1}[x]$ and $\beta(x, y) \in \mathbb{R}_n[x, y]$. In fact, Propositions 6 and 7 have stronger consequences on the homology/homotopy classes of the heteroclinic intersections of the invariant manifolds.

We recall that $\tilde{Z}$ is the projection of the zero-level set $Z = M^{-1}(0)$ onto the torus $\tilde{\tau}$ defined in (14). Assume that 0 is a regular value of the Melnikov function. Then $\tilde{Z}$ is a submanifold of the torus, and its connected components are closed smooth curves. Therefore, once we have fixed an induced orientation on the torus, we can assign to each connected component $\tilde{\gamma}$ of $\tilde{Z}$ its homology class $[\tilde{\gamma}] \in H_1(\mathbb{T}^2) = \mathbb{Z}^2$.

In the case of the torus $\tilde{\tau}$, we will identify horizontal lines with the class $(1, 0)$ and vertical lines, generated by the vector (ω, h), with the class $(0, 1)$. Thus, $[\tilde{\gamma}] = (p, q) \in \mathbb{Z}^2$ means that $\tilde{\gamma}$ is a closed curve that wraps around the torus $|p|$ times in the horizontal direction and $|q|$ times in the vertical one. For instance, the set $\tilde{Z}$ has four connected components with homology class $(0, 1)$ or $(0, -1)$ in the subfigures 4(a)–4(d), whereas it has just two connected components with homology class $(1, -2)$ or $(-1, 2)$ in the subfigures 4(f)–4(i). Subfigure 4(e) is excluded because then 0 is a singular value of the Melnikov function.

Remark 7. With regard to the three types of heteroclinic curves mentioned in the introduction, we note that a connected component $\tilde{\gamma}$ such that $[\tilde{\gamma}] = (p, q)$ gives rise for ϵ small enough to vertical (resp., equatorial) (resp., bubble-type) curves when $q \neq 0$ (resp., $q = 0$ but $p \neq 0$) (resp., $p = q = 0$).

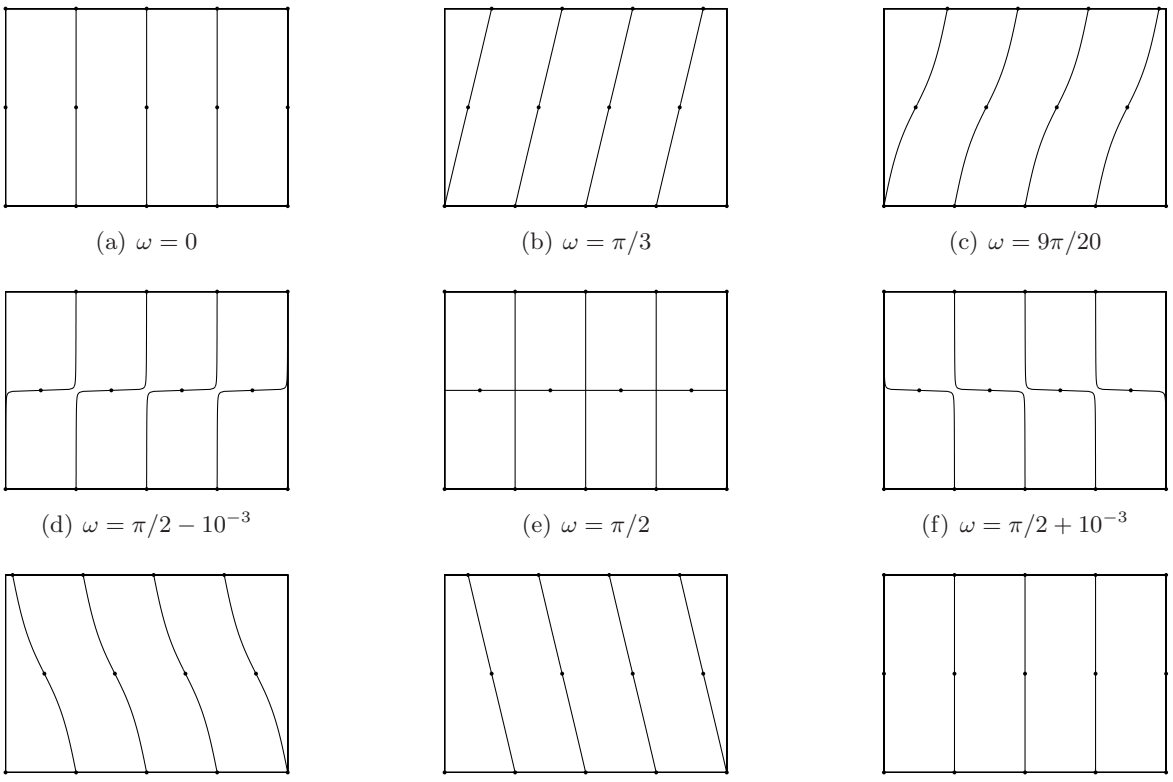
Remark 8. The first homology group and the first homotopy group (that is, the fundamental group) of a torus coincide: $H_1(\mathbb{T}^2) = \mathbb{Z}^2 = \pi_1(\mathbb{T}^2)$. Hence, we could use homotopy instead of singular homology.

We need the following result from Morse theory.

Lemma 8. *If $a \in \mathbb{R}$ is a regular value of a smooth function $f : X \to \mathbb{R}$ defined over a compact manifold X, the homology class of the level set $L_a = f^{-1}(a)$ is zero.*

Proof. It suffices to prove this for Morse functions, because Morse functions are dense and the homology class of a closed curve does not change under small perturbations.

Let a and b be two regular values of f such that $a < b$. Then L_a and L_b are the borders of the smooth manifold $f^{-1}([a, b])$, and so they have the same homology class. Let c be the maximum value of f. Since f is Morse, there exists a unique point $x \in X$ such that $f(x) = c$. This point is a nondegenerate maximum, and so if $\delta > 0$ is small enough, $c - \delta$ is a regular



(a) $\omega = 0$ (b) $\omega = \pi/3$ (c) $\omega = 9\pi/20$

(d) $\omega = \pi/2 - 10^{-3}$ (e) $\omega = \pi/2$ (f) $\omega = \pi/2 + 10^{-3}$

(g) $\omega = 11\pi/20$ (h) $\omega = 2\pi/3$ (i) $\omega = \pi$

Figure 4. *The only bifurcation of $\tilde{Z}$ in the range $0 \leq \omega \leq \pi$ under the perturbation $\kappa(x, y, z) = (0, x, 0)$ takes place at the singular frequency $\omega = \pi/2$. These pictures show this bifurcation for $h = 1$. The symmetric points move as the frequency ω varies.*

value and $L_{c-\delta}$ is just a small closed curve around x. Hence, $L_{c-\delta}$ is contractible, and its homology class is equal to zero. ■

The homology classes of the connected components of the projected zero-level set $\tilde{Z}$ are bounded in the following theorem. These bounds restrict the topological complexity of the primary heteroclinic set $P_\epsilon = Z + \mathrm{O}(\epsilon)$ for small values of ϵ.

Theorem 9. *Assume that 0 is a regular value of the Melnikov function associated with the perturbation (8). Let $\tilde{\gamma}_1, \ldots, \tilde{\gamma}_r$ be connected components of the projected zero-level set $\tilde{Z} = \tilde{M}^{-1}(0)$. Let $[\tilde{\gamma}_1] = (p_1, q_1)$, $\ldots$, $[\tilde{\gamma}_r] = (p_r, q_r)$ be their homology classes.*

(i) *The homology of $\tilde{Z}$ is zero: $\sum_j [\tilde{\gamma}_j] = \sum_j (p_j, q_j) = (0, 0)$.*

(ii) *If $\alpha(x) \in \mathbb{R}_{n-1}[x]$ and $\beta(x, y) \in \mathbb{R}_n[x, y]$, then $2\,|q_j| \leq \sum_j |q_j| \leq 2n$.*

(iii) *Assume that $\omega = 0$. Let $l, n \in \mathbb{N}$. Then we have the following:*

1. *If $\alpha(x) \in \mathbb{R}_{2l-1}[x]$ is odd and $\beta(x, y) = 0$, then $2\,|p_j| \leq \sum_j |p_j| \leq l$.*
2. *If $\alpha(x) = 0$ and $\beta(x, y) \in \mathbb{R}_{2n}[x, y]$ is even, then $2\,|p_j| \leq \sum_j |p_j| \leq n + 1$.*
3. *If $\alpha(x) \in \mathbb{R}_{2l-1}[x]$ is odd and $\beta(x, y) \in \mathbb{R}_{2n}[x, y]$ is even, then $2\,|p_j| \leq \sum_j |p_j| \leq \max(l, n + 2)$.*

Proof. (i) It suffices to apply Lemma 8 to the projected function $\tilde{M} : \mathbb{T}^2 \to \mathbb{R}$.

(ii) We are under the hypotheses of Proposition 6, and 0 is a regular value of the Melnikov function, so there exists some $t_* \in \mathbb{R}$ such that $\#Z_{t_*} \leq 2n$. On the contrary, $Z_{t_0} = \mathbb{T}$ for all $t_0 \in \mathbb{R}$, and the Melnikov function should be identically zero.

Using that $\tilde{Z} = \tilde{\gamma}_1 \amalg \cdots \amalg \tilde{\gamma}_r$ and that each curve $\tilde{\gamma}_j$ wraps $|q_j|$ times in the vertical direction, we get that $\sum_j |q_j| \leq \sum_j \#\left(\tilde{\gamma}_j \cap (\mathbb{T} \times \{t_*\})\right) = \#Z_{t_*} \leq 2n$. Next, we obtain the bound $2\,|q_j| = |q_j| + \left|\sum_{i \neq j} q_i\right| \leq \sum_i |q_i| \leq 2n$ from the identity $\sum_j q_j = 0$.

(iii) This follows in a similar way, but from Proposition 7. ∎

6. Splitting of separatrices. In this section we shall present two theorems about the splitting of the separatrix. In the first one, we shall establish a sufficient condition for the splitting of the separatrix under some entire perturbations, whereas in the second one we find a broad class of polynomial perturbations that split the separatrix. The sufficient condition is obtained through the study of the complex singularities of the Melnikov function. To be more precise, if the Melnikov function can be analytically extended for complex values of its variables and this extension has some nonremovable singularity, then the original Melnikov function cannot be identically zero and the separatrix splits.

For simplicity, we have restricted our study to perturbations of the form

$$f_\epsilon = (\mathrm{Id} + \epsilon\kappa) \circ f, \qquad \kappa(x, y, z) = (0, 0, \beta(x, y)) \tag{16}$$

for some nonzero even entire function $\beta(x, y)$. The study is a bit more cumbersome when the entire perturbation has the more general form (8) with $\alpha(x)$ odd and $\beta(x, y)$ even. If $\alpha(x)$ is not odd or $\beta(x, y)$ is not even, our current technique does not work, because ramified singularities are harder to deal with than isolated ones.

Theorem 10. *Let $B_\theta : \mathbb{C} \to \mathbb{C}$ be the entire function*

$$B_\theta(r) = \int_0^r \beta(\sqrt{2s}\cos\theta, \sqrt{2s}\sin\theta)\mathrm{d}s. \tag{17}$$

Let $r(t) = z(t + h) - z(t - h)$ with $z(t) = \tanh(t/2)$. If the function

$$\delta_\theta(t) = \delta_\theta^+(t) + \delta_\theta^-(t), \qquad \delta_\theta^\pm(t) = B_{\theta \pm \omega}(r(t \pm h)) \tag{18}$$

has a nonremovable singularity at $t = \pi\mathrm{i}$ for some $\theta \in \mathbb{T}$, then the separatrix splits.

We note that $z(t)$ is meromorphic and its poles are the points in the set $\pi\mathrm{i} + 2\pi\mathrm{i}\mathbb{Z}$. Hence, since the function $B_\theta(r)$ is entire and nonzero, the compositions $\delta_\theta^+(t)$ and $\delta_\theta^-(t)$ always have a nonremovable singularity at the point $t = \pi\mathrm{i}$. Our sufficient condition for the splitting is that the sum $\delta_\theta^+(t) + \delta_\theta^-(t)$ be still singular at $t = \pi\mathrm{i}$, which is generic.

Proof. The function $B_\theta(r)$ is entire because the parity of the perturbation $\beta(x, y)$ cancels the square roots that appear in (17).

The first step is to rewrite the Melnikov function in a more convenient form. Using that $\alpha(x) = 0$ and the relation $\mu(t) = -4cs r'(t)$, the Melnikov function (10) has the form $M(\theta, t) = -4cs(\Delta_\theta)'(t)$, where

$$\Delta_\theta(t) = \sum_{k \in \mathbb{Z}} \delta_\theta^{[k]}(t), \qquad \delta_\theta^{[k]}(t) = B_{\theta + k\omega}(r(t + kh)).$$

Using that $\delta_\theta(t) = \delta_\theta^{[1]}(t) + \delta_\theta^{[-1]}(t)$, we shall prove that the series $\Delta_\theta(t)$—and hence, the Melnikov function—has a nonremovable singularity at $t = \pi\mathrm{i}$ for some $\theta \in \mathbb{T}$.

Since the function $B_\theta(r)$ is entire, the composition $\delta_\theta^{[k]}(t) = B_{\theta+k\omega}(r(t+kh))$ is analytic but at the poles of the meromorphic function $r(t+kh)$, which are the points in the sets $\pm h - kh + \pi\mathrm{i} + 2\pi\mathrm{i}\mathbb{Z}$. Thus, the difference

$$\Delta_\theta(t) - \delta_\theta(t) = \sum_{k\neq\pm 1} \delta_\theta^{[k]}(t)$$

is analytic at $t = \pi\mathrm{i}$ for any $\theta \in \mathbb{T}$. On the other hand, by hypothesis, $\delta_\theta(t)$ has a nonremovable singularity at $t = \pi\mathrm{i}$ for some $\theta \in \mathbb{T}$. ■

Next, we find some concrete perturbations of the form (16) that split the separatrix. For simplicity, we shall deal with perturbations such that the computation of the singular parts of the functions $\delta_\theta^\pm(t)$ defined in (18) around their singularity $t = \pi\mathrm{i}$ can be easily analyzed. Polynomial perturbations are a natural choice. We need the following notation for the statement of the result. Given any $\beta(x,y) \in \mathbb{R}_n[x,y]$, we shall denote by $\sum_{l=0}^n \beta_l(x,y)$ its decomposition as a sum of homogeneous polynomials. That is, $\beta_l(\rho x, \rho y) = \rho^l \beta_l(x,y)$ for all $\rho \in \mathbb{R}$. Let $R_\varphi : \mathbb{R}^2 \to \mathbb{R}^2$ be the rotation

$$R_\varphi(x,y) = (x\cos\varphi - y\sin\varphi,\ x\sin\varphi + y\cos\varphi). \tag{19}$$

Proposition 11. *If $\beta(x,y) \in \mathbb{R}_{2n}[x,y]$ is even and $\beta_{2n} \circ R_{2\omega} \neq (-1)^n \beta_{2n}$, then the separatrix splits under the polynomial perturbation* (16).

Proof. The decomposition of the polynomial $\beta(x,y) \in \mathbb{R}_{2n}[x,y]$ has only even terms: $\beta(x,y) = \sum_{l=0}^n \beta_{2l}(x,y)$. Then the entire function $B_\theta : \mathbb{C} \to \mathbb{C}$ defined in (17) is the (not necessarily even) polynomial

$$B_\theta(r) = \sum_{l=0}^{n} \hat{B}_l(\theta) r^{l+1}, \qquad \hat{B}_l(\theta) = \frac{2^l \beta_{2l}(\cos\theta, \sin\theta)}{l+1}.$$

The point $t = \pi\mathrm{i}$ is a simple pole of the meromorphic function $z(t) = \tanh(t/2)$, and so it becomes a pole of order $n+1$ of the functions $\delta_\theta^+(t) = B_{\theta+\omega}(z(t+2h) - z(t))$ and $\delta_\theta^-(t) = B_{\theta-\omega}(z(t) - z(t-2h))$. In particular, there exist some Laurent coefficients $\hat{\delta}_1^\pm(\theta), \dots, \hat{\delta}_{n+1}^\pm(\theta)$ such that

$$\delta_\theta^\pm(t) = \frac{\hat{\delta}_{n+1}^\pm(\theta)}{(t-\pi\mathrm{i})^{n+1}} + \cdots + \frac{\hat{\delta}_1^\pm(\theta)}{t-\pi\mathrm{i}} + (\text{some analytic function at } t = \pi\mathrm{i}).$$

For instance, using that the residue of $z(t)$ at its poles is equal to 2, we get that the dominant Laurent coefficients are $\hat{\delta}_{n+1}^\pm(\theta) = (\mp 2)^{n+1} \hat{B}_n(\theta \pm \omega)$.

Finally, we note that if there exist some $\theta \in \mathbb{T}$ and some index $j = 1, \dots, n+1$ such that $\hat{\delta}_j^+(\theta) + \hat{\delta}_j^-(\theta) \neq 0$, then $\delta_\theta(t) = \delta_\theta^+(t) + \delta_\theta^-(t)$ has a nonremovable singularity at $t = \pi\mathrm{i}$ and the separatrix splits. The functional condition $\beta_{2n} \circ R_{2\omega} \neq (-1)^n \beta_{2n}$ is equivalent to the existence of some angle $\theta \in \mathbb{T}$ such that

$$\beta_{2n}(\cos(\theta+2\omega), \sin(\theta+2\omega)) \neq (-1)^n \beta_{2n}(\cos\theta, \sin\theta),$$

which is equivalent to the existence of θ such that $\hat{\delta}^+_{n+1}(\theta) + \hat{\delta}^-_{n+1}(\theta) \neq 0$. ■

Using this proposition, we shall obtain many polynomial perturbations that split the separatrix. To explain this, we introduce the complexified variables

$$z = x + y\mathrm{i}, \qquad \bar{z} = x - y\mathrm{i}. \tag{20}$$

In these variables, the functional equation $\beta_{2n} \circ R_{2\omega} = (-1)^n \beta_{2n}$ reads as $\tilde{\beta}_{2n} \circ \tilde{R}_{2\omega} = (-1)^n \tilde{\beta}_{2n}$. Here, $\tilde{R}_\varphi(z, \bar{z}) = (\mathrm{e}^{\varphi \mathrm{i}} z, \mathrm{e}^{-\varphi \mathrm{i}} \bar{z})$ and

$$\tilde{\beta}_{2n}(z, \bar{z}) = \sum_{k=-n}^{n} \tilde{\beta}^{[k]}_{2n} z^{n+k} \bar{z}^{n-k}$$

stand for the rotation (19) and the homogeneous polynomial $\beta_{2n}(x, y)$ in the complexified variables, respectively. The transformed polynomial $\tilde{\beta}_{2n}(z, \bar{z})$ is still a homogeneous polynomial of degree $2n$ because the change (20) is linear.

Lemma 12. *The functional equation $\beta_{2n} \circ R_{2\omega} = (-1)^n \beta_{2n}$ holds if and only if*

$$\tilde{\beta}^{[k]}_{2n} \left(\mathrm{e}^{4\omega k \mathrm{i}} - (-1)^n \right) = 0 \qquad \forall k = -n, \dots, n. \tag{21}$$

Proof. $\tilde{R}_{2\omega}(z, \bar{z}) = (\mathrm{e}^{2\omega \mathrm{i}} z, \mathrm{e}^{-2\omega \mathrm{i}} \bar{z})$ maps $z^{n+k} \bar{z}^{n-k}$ onto $\mathrm{e}^{4k\omega \mathrm{i}} z^{n+k} \bar{z}^{n-k}$. ■

Now we are ready to give precise statements about the splitting of the separatrix under polynomial perturbations of the form (16). For instance, we shall see that both *nonresonant frequencies* and *high-order resonant frequencies*—that is, $\omega/\pi \notin \mathbb{Q}$ or ω/π is an irreducible fraction with a high denominator—are strong obstructions for the persistence of the separatrix. A homogeneous polynomial $\beta_{2n}(x, y)$ of degree $2n$ is *rotationally invariant* when it has the form

$$\beta_{2n}(x, y) = \tilde{\beta}^{[0]}_{2n} z^n \bar{z}^n = \tilde{\beta}^{[0]}_{2n} |z|^{2n} = \tilde{\beta}^{[0]}_{2n} (x^2 + y^2)^n$$

for some constant $\tilde{\beta}^{[0]}_{2n} \in \mathbb{R}$. These polynomials are the only homogeneous ones that remain invariant under the action of the continuous group of rotations $R_\varphi : \mathbb{R}^2 \to \mathbb{R}^2$.

Theorem 13. *If $\beta(x, y)$ is an even polynomial of degree $2n$, then the perturbation (16) splits the separatrix in any of the following two cases:*

(i) *n odd and $\mathrm{e}^{4k\omega \mathrm{i}} \neq -1$ for $k = 1, \dots, n$; or*

(ii) *n even, $\beta_{2n}(x, y)$ not rotationally invariant, and $\mathrm{e}^{4k\omega \mathrm{i}} \neq 1$ for $k = 1, \dots, n$.*

Proof. From Proposition 11 and Lemma 12, we know that (21) is a necessary condition for the persistence of the separatrix. Let us check that this condition is incompatible with the two listed cases.

(i) If n is odd and $\mathrm{e}^{4k\omega \mathrm{i}} \neq -1$ for $k = 1, \dots, n$, condition (21) implies that $\tilde{\beta}^{[k]}_{2n} = 0$ for all $k = -n, \dots, n$. Therefore, the homogeneous polynomial $\beta_{2n}(x, y)$ is zero, which contradicts the fact that $\beta(x, y)$ has degree $2n$.

(ii) If n is even and $\mathrm{e}^{4k\omega \mathrm{i}} \neq 1$ for $k = 1, \dots, n$, then condition (21) implies that $\tilde{\beta}^{[k]}_{2n} = 0$ for all $k \neq 0$, which contradicts the fact that $\beta(x, y)$ has degree $2n$ and $\beta_{2n}(x, y)$ is not rotationally invariant. ■

It would be interesting to know whether there exist some entire perturbations of the form (16) that preserve the separatrix. Of course, such perturbations cannot verify the sufficient condition for splitting given in Theorem 10. We have not found any perturbation of this

kind, which is not so strange because in similar contexts, related with other McMillan maps, they simply do not exist. An area-preserving example of this situation can be found in [13], and a high-dimensional symplectic one in [14].

7. Bifurcations of the zero-level set in an example. In this section, we shall study the bifurcations in $\omega \in \mathbb{T}$ of the topological shape of the zero-set $Z \subset \mathbb{T} \times \mathbb{R}$ for the perturbation $\kappa(x, y, z) = (0, x, 0)$. We note that, according to Lemma 5 and Remark 4, Z contains (and is symmetric with regard to) the eight symmetric points shown in Figure 3 and it is also $(\pi/2, 0)$-periodic.

Based on detailed numerical computations and several analytical arguments, we conjecture that 0 is a singular value of the Melnikov function if and only if $\omega = \pm\pi/2$, and so the only bifurcations of $Z = M^{-1}(0)$ take place at those values. For instance, we show in Figure 4 the numerically computed shape of $\tilde{Z}$ for several values of the frequency in the range $0 \le \omega \le \pi$.

We give a dynamical interpretation of these Melnikov-like results. If $\omega \neq \pm\pi/2$, the set of primary intersections $P_\epsilon = Z + \mathrm{O}(\epsilon)$ consists of four vertical curves for ϵ small enough; see Theorem 1. Each curve has a symmetric twin, because P_ϵ is invariant under the axial symmetry $S(x, y, z) = (-x, -y, z)$. The fixed sets of the reversors are

$$\operatorname{Fix} R_\epsilon = \{(x, y, z) \in \mathbb{R}^3 : y = \epsilon x/2,\ z = 0\},$$
$$\operatorname{Fix} T_\epsilon = \{(x, y, z) \in \mathbb{R}^3 : x = 0,\ z = 0\}.$$

Hence, two heteroclinic vertical curves cross a curve $\mathrm{O}(\epsilon)$-close to the x-axis, and the other pair of heteroclinic curves cross the y-axis. The rotation number of these vertical curves is equal to ω in the range $-\pi/2 < \omega < \pi/2$, but it jumps to $\omega \mp \pi$ when the bifurcation values $\omega = \pm\pi/2$ are crossed. The shape of the primary set when $\omega = \pm\pi/2$ is not completely clear, because then 0 is a singular value of the Melnikov function and Theorem 1 cannot be applied. This is an open question.

The rest of the section is devoted to presenting some rigorous results supporting the previous conjecture, although we have found a complete proof only for $h \ge h_0 \approx 2.28$. Nevertheless, we have been able to prove the following results. If ω is a *regular frequency* (that is, if 0 is a regular value of the Melnikov function), then Z contains just four vertical curves. Otherwise, we say that ω is a *singular frequency* and Z contains the four vertical curves jointly with the images and preimages of exactly one horizontal straight line, in which case the degenerate zeroes of the Melnikov function are just the points in the intersections between the horizontal and vertical curves. The number of singular frequencies is finite. The frequencies $\omega = 0$ and $\omega = \pi$ are regular. The frequencies $\omega = \pm\pi/2$ are singular and are the only singular ones when the characteristic exponent is big enough: $h \ge h_0 := \log 16 - \log(\sqrt{113} - 9) \approx 2.28$.

In order to lighten the computations, we write the Melnikov function in its simplest form. Let $\chi : \mathbb{R} \to \mathbb{R}$ be the function

$$\chi(t) = \frac{4c^2 s^2}{\cosh((t+h)/2)\cosh^2(t/2)\cosh((t-h)/2)}. \tag{22}$$

Then, using that $\alpha(x) = x$ and $\beta(x, y) = 0$, the Melnikov function (10) becomes

$$M(\theta, t) = a(t)\sin 2\theta + b(t)\cos 2\theta, \tag{23}$$

where $a(t)$ and $b(t)$ are given by the absolutely convergent series

$$a(t) = \sum_{k\in\mathbb{Z}} \cos(2k\omega)\chi(t+kh), \qquad b(t) = \sum_{k\in\mathbb{Z}} \sin(2k\omega)\chi(t+kh).$$

We also introduce the complex-valued function

$$E(t) = E_\omega(t) = \sum_{k\in\mathbb{Z}} \mathrm{e}^{2k\omega\mathrm{i}}\chi(t+kh) = a(t) + b(t)\mathrm{i}, \tag{24}$$

which plays a crucial role in the digression because of the relation

$$\partial_\theta M(\theta,t)/2 + M(\theta,t)\mathrm{i} = E(t)\mathrm{e}^{2\theta\mathrm{i}}. \tag{25}$$

This relation has interesting consequences. For instance, if $(\theta_0, t_0) \in \mathbb{T}\times\mathbb{R}$ is a degenerate zero of the Melnikov function, $E(t_0)$ must be zero. In particular, 0 is a regular value of the Melnikov function when $E(t)$ has no real zeroes. Therefore, we are naturally led to the study of the sets

$$\Omega = \Omega_h = \{\omega\in\mathbb{T} : E_\omega(t) \text{ has some real zero}\}, \qquad h>0. \tag{26}$$

Their main properties are addressed in the following lemma, whose proof is deferred to Appendix A. The proof is based on some nice properties of quasi-elliptic functions that can be deduced from elementary facts of complex variable theory contained in any basic textbook, like, for instance, [34].

Lemma 14. *Given any $h>0$, the set (26) is finite, π-periodic, and symmetric: $\Omega = -\Omega$. If the function (24) has some real zero, all of them are simple, and the set of its real zeroes is either $h\mathbb{Z}$ or $h/2+h\mathbb{Z}$, so Ω is the disjoint union of the sets*

$$\Omega^0 = \{\omega\in\mathbb{T} : E_\omega(0)=0\}, \qquad \Omega^1 = \{\omega\in\mathbb{T} : E_\omega(h/2)=0\}.$$

Further, $\pm\pi/2\in\Omega^1$, $0\notin\Omega$, and $\pi\notin\Omega$. Finally, $\Omega^1 = \{\pm\pi/2\}$ for $h\ge h_1 := 2\log\frac{20}{9}\approx 1.60$ and $\Omega^0=\emptyset$ for $h\ge h_0 := \log 16 - \log(\sqrt{113}-9)\approx 2.28$.

Conjecture 15. *$\Omega = \Omega^1 = \{\pm\pi/2\}$ and $\Omega^0=\emptyset$ for all $h>0$.*

We present in Appendix B strong numerical evidence for this conjecture.

Lemma 16. *Let $E:\mathbb{R}\to\mathbb{C}$ be an analytic function such that $E(-t)=\overline{E(t)}$.*

(i) *If $E(t)$ has no real zeroes, then there exists a unique odd analytic function $\varphi:\mathbb{R}\to\mathbb{R}$ and an integer $n\in\{0,1\}$ such that $E(t) = |E(t)|\,\mathrm{e}^{(\varphi(t)+\pi n)\mathrm{i}}$ for all $t\in\mathbb{R}$.*

(ii) *If $E(t)$ has no real multiple zeroes, then there exists a unique odd analytic function $\varphi:\mathbb{R}\to\mathbb{R}$ and a function $n:\mathbb{R}\to\{0,1\}$ such that $E(t) = |E(t)|\,\mathrm{e}^{(\varphi(t)+\pi n(t))\mathrm{i}}$ for all $t\in\mathbb{R}$. The function $n(t)$ is constant, but at the zeroes of $E(t)$.*

Proof. (i) If a function is analytic and never zero on a convex subset of the complex plane, then it has an analytic argument on that convex subset. This is an elementary result in complex variable theory; see [4, section 2.1]. Let $\varphi(t)$ be an analytic argument of $E(t)/E(0)$; that is, any analytic function $\varphi:\mathbb{R}\to\mathbb{R}$ such that

$$E(t) = E(0)\,|E(t)/E(0)|\,\mathrm{e}^{\varphi(t)\mathrm{i}} = |E(t)|\,\mathrm{e}^{(\varphi(t)+\pi n)\mathrm{i}}.$$

Obviously, $n = 0$ if $E(0) > 0$ and $n = 1$ if $E(0) < 0$. The argument is not unique, but it is determined up to a multiple of 2π; that is, it is determined once we choose the value of $\varphi(0)$ from the set $2\pi\mathbb{Z}$. The condition $E(-t) = \overline{E(t)}$ implies that $\varphi(-t) + \varphi(t) = 2\varphi(0)$ for all real t. If we want an odd argument, $\varphi(0) = 0$ is the only possible choice.

(ii) It suffices to realize that, at any simple zero, the argument undergoes a jump by a multiple of π. When these jumps are stored in the discrete-valued function $n(t)$, the function $\varphi(t)$ remains analytic. ∎

These two lemmas are the basis for the next theorem, in which the shape and bifurcations of the zero-level set $Z = M^{-1}(0) \subset \mathbb{T} \times \mathbb{R}$ are described.

Theorem 17. *Let Z be the zero-level set of the Melnikov function (23). Let $\Omega = \Omega^0 \cup \Omega^1$ be the decomposition of the set (26) given in Lemma 14. Let $\omega \in \mathbb{T}$. There exists a unique odd analytic function $\bar{\theta}_\omega : \mathbb{R} \to \mathbb{R}$ such that the following hold:*

(i) *If $\omega \notin \Omega$, then $Z = \{\theta = \bar{\theta}_\omega(t) \pmod{\pi/2}\}$ and ω is a regular frequency.*

(ii) *If $\omega \in \Omega^j$, then $Z = \{t = jh/2 \pmod{h}\} \cup \{\theta = \bar{\theta}_\omega(t) \pmod{\pi/2}\}$ and ω is a singular frequency. The degenerate zeroes of the Melnikov function are just the points in the intersections between the horizontal lines and the vertical curves.*

(iii) *The function $\bar{\Theta}(t, \omega) := \bar{\theta}_\omega(t)$ is analytic on $\mathbb{R} \times (\mathbb{T} \setminus \Omega)$.*

(iv) *If $\omega = 0 \pmod{\pi/2}$, then $\bar{\theta}_\omega(t) \equiv 0$.*

(v) $\bar{\theta}_\omega(t + h) = \bar{\theta}_\omega(t) + \omega \pmod{\pi/2}$.

(vi) $\bar{\theta}_\omega(h/2 - t) + \bar{\theta}_\omega(h/2 + t) = \omega \pmod{\pi/2}$.

(vii) $\bar{\theta}_{-\omega}(t) = -\bar{\theta}_\omega(t)$ *and* $\bar{\theta}_{\omega+\pi}(t) = \bar{\theta}_\omega(t)$.

Proof. Sometimes, we do not write explicitly the dependence on the frequency. Using that $a(t)$ is even and $b(t)$ is odd, we see that the function (24) verifies the relation $E(-t) = \overline{E(t)}$. This is important, because it was a hypothesis in Lemma 16.

(i) If $\omega \notin \Omega$, then $E(t)$ has no real zeroes, and so ω is a regular frequency. It remains to prove that Z is composed of four vertical curves of the form $\{\theta = \bar{\theta}(t) \pmod{\pi/2}\}$ for some function $\bar{\theta}(t)$. Let $\bar{\theta} : \mathbb{R} \to \mathbb{R}$ be the odd analytic function $\bar{\theta}(t) = -\varphi(t)/2$, where $\varphi(t) = \arg(E(t)/E(0))$ is the argument introduced in Lemma 16. Let n be the integer mentioned in the same lemma. Using that $E(t)$ has no real zeroes jointly with relation (25), we have

$$\begin{aligned} Z = M^{-1}(0) &= \{(\theta, t) \in \mathbb{T} \times \mathbb{R} : E(t)\mathrm{e}^{2\theta \mathrm{i}} \in \mathbb{R}\} \\ &= \{(\theta, t) \in \mathbb{T} \times \mathbb{R} : \sin(\varphi(t) + \pi n + 2\theta) = 0\} \\ &= \{(\theta, t) \in \mathbb{T} \times \mathbb{R} : \theta = \bar{\theta}(t) \pmod{\pi/2}\}. \end{aligned}$$

(ii) We know that $E(t)$ has no real multiple zeroes. Let $\varphi(t)$ and $n(t)$ be the functions given in Lemma 16. Let $\bar{\theta}(t) = -\varphi(t)/2$. Then

$$\begin{aligned} Z &= \{(\theta, t) \in \mathbb{T} \times \mathbb{R} : E(t)\mathrm{e}^{2\theta \mathrm{i}} \in \mathbb{R}\} \\ &= \{(\theta, t) : E(t) = 0\} \cup \{(\theta, t) : \sin(\varphi(t) + \pi n(t) + 2\theta) = 0\} \\ &= \{t = jh/2 \pmod{h}\} \cup \{\theta = \bar{\theta}(t) \pmod{\pi/2}\}. \end{aligned}$$

Therefore, $Z = M^{-1}(0)$ contains four vertical curves that intersect infinitely many horizontal straight lines. Obviously, these intersections are degenerate zeroes of the Melnikov function. Next, we shall prove that the other zeroes are nondegenerate.

Let (θ_0, t_0) be a zero of the Melnikov function not contained in any horizontal line: $M(\theta_0, t_0) = 0$ and $E(t_0) \neq 0$. Then $\partial_\theta M(\theta_0, t_0) = 2E(t_0)\mathrm{e}^{2\theta_0 \mathrm{i}} \neq 0$; see (25).

On the other hand, let (θ, t_1) be a point contained in some horizontal line: $M(\theta, t_1) = 0$, $E(t_1) = 0$, and $E'(t_1) \neq 0$. Again from relation (25), we get $\partial_\theta M(\theta, t_1) = 0$ and $\partial_t M(\theta, t_1) = \Im E'(t_1)\mathrm{e}^{2\theta \mathrm{i}}$, where $\Im$ denotes imaginary part. Hence, the degenerate zeroes on the horizontal line $\{t = t_1\}$ are just those that verify the condition $\Im E'(t_1)\mathrm{e}^{2\theta \mathrm{i}} = 0$. But, since $E'(t_1) \neq 0$, there are exactly four of such angles $\theta \in \mathbb{T}$. These four angles are the ones corresponding to the four intersections of the horizontal line $\{t = t_1\}$ with the four vertical curves $\{\theta = \bar{\theta}(t) \pmod{\pi/2}\}$.

(iii) Level sets associated with regular values of analytic functions vary in an analytic way under analytic perturbations.

(iv) If $\omega = 0 \pmod{\pi/2}$, then $\sin(2k\omega) = 0$ for all k, and $b(t) = \Im E(t) \equiv 0$.

(v) This has to do with the fact that the zero-level set Z is (ω, h)-periodic. Given any $t \in \mathbb{R}$, we consider the slice $Z_t = \{\theta \in \mathbb{T} : (\theta, t) \in Z\}$. If $E(t) \neq 0$, then

$$Z_{t+h} = \{\theta \in \mathbb{T} : \theta = \bar{\theta}(t + h) \pmod{\pi/2}\},$$
$$Z_t + \omega = \{\theta \in \mathbb{T} : \theta = \bar{\theta}(t) + \omega \pmod{\pi/2}\}.$$

But these two sets coincide, due to the (ω, h)-periodicity of Z, and so we obtain that $\bar{\theta}(t+h) = \bar{\theta}(t) + \omega \pmod{\pi/2}$ for any real t such that $E(t) \neq 0$. Indeed, by analytic continuation, this equality holds for any real t.

(vi) It follows directly from the previous item and the odd character of $\bar{\theta}(t)$: $\bar{\theta}(h/2 - t) + \bar{\theta}(h/2 + t) = -\bar{\theta}(t - h/2) + \bar{\theta}(t - h/2) + \omega = \omega \pmod{\pi/2}$.

(vii) First, $\bar{\theta}_{-\omega}(t) = -\frac{1}{2}\arg E_{-\omega}(t) = -\frac{1}{2}\arg \overline{E_\omega(t)} = \frac{1}{2}\arg E_\omega(t) = -\bar{\theta}_\omega(t)$. Second, $\bar{\theta}_{\omega+\pi}(t) = -\frac{1}{2}\arg E_{\omega+\pi}(t) = -\frac{1}{2}\arg E_\omega(t) = \bar{\theta}_\omega(t)$. ∎

Remark 9. The numerical computations show that $\bar{\theta}_\omega(t + h) = \bar{\theta}_\omega(t) + \omega$ holds only in the range $-\pi/2 < \omega < \pi/2$; see Figure 4. This does not contradict item (v) in Theorem 17.

Remark 10. Similar results hold for the perturbation $\kappa(x, y, z) = (0, 0, y^2)$. In that case, it turns out that the Melnikov function has the form

$$M(\theta, t) = \hat{a}(t)\sin 2\theta + \hat{b}(t)\cos 2\theta + \hat{c}(t)$$

for some absolutely convergent series $\hat{a}(t)$, $\hat{b}(t)$, and $\hat{c}(t)$. The analytical study is harder because of the additional third term—compare with (23). We have numerically checked that the only bifurcations take place at the singular frequencies $\omega \in \{0, \pm\pi/2, \pi\}$, whereas the zero-level set still contains just four vertical curves for regular frequencies.

8. Conclusion and open problems.

In this paper, we have obtained several analytical results about the splitting of separatrices under perturbations of some integrable volume-preserving maps using a discrete version of the Melnikov method. The integrable maps have a two-dimensional heteroclinic connection of spherical shape between two fixed points of saddle-focus type. We have bounded the topological complexity of the primary heteroclinic set under some polynomial perturbations. We have also given a sufficient condition for the splitting of the separatrices under some entire perturbations. Finally, we have obtained a complete picture of the bifurcations that take place under a simple perturbation. Despite these results, many unsolved questions remain. We indicate four.

The first question is: How accurate are our first-order Melnikov estimates? Of course, it would be necessary to compute numerically the perturbed invariant manifolds and to compare the real distance between them with the distance predicted by using the Melnikov function. A related numerical experiment was performed in [9] for linear perturbations of a four-dimensional symplectic version of the McMillan map. This is a work in progress.

Second, we conjecture that the separatrix splitting studied in this paper is exponentially small in the characteristic exponent, although the role of the frequency is still unclear. Several examples of the effect that resonant frequencies can have in the dynamics of three-dimensional maps near Hopf-saddle-node bifurcations can be found in [11, 12], although not related to a problem about the splitting of separatrices. One could guess an asymptotic exponentially small formula for the splitting using a multiple-precision arithmetic, like in [31]. Such formulae for the splitting of one-dimensional heteroclinic connections between saddle-focus fixed points of volume-preserving systems have already been found in [2] (for maps) and [8] (for flows), but we do not know any similar formula for the two-dimensional case.

Another question is: What about Šil'nikov-like bifurcations in the discrete setting? The perturbation of a spheromak structure in three-dimensional flows is a classical setup for studying Šil'nikov bifurcations. Some results about the continuous case are contained in [10]. It is natural to consider the discrete version of this problem, although the problem seems qualitatively more complicated.

It would be also interesting to study some questions about transport. As a first step, we should compute the geometric flux through the perturbed separatrices. The $\mathrm{O}(\epsilon)$-term of this flux can be computed by integrating certain Melnikov two-forms over a suitable region; see [24]. Next, we could follow the ideas introduced in [26], although we must take into account that the scenario for maps is richer than the one for flows. For instance, we recall that equatorial and bubble-type heteroclinic curves cannot appear in autonomous flows.

Finally, we stress that only volume-preserving (conservative) perturbations have been studied in this paper, although the study of dissipative perturbations is also possible. See, for instance, the theories developed in [9, 7, 25].

Appendix A. Proof of Lemma 14. Here, we study the existence of real zeroes of the function (24). This function has many properties similar to those of elliptic functions, and so we shall study its zeroes using tools typical in the theory of elliptic functions.

We list in the next lemma some basic properties of the function $E(t)$, including that $E(t)$ is meromorphic, $2\pi\mathrm{i}$-periodic, and h-quasi-periodic, and so quasi-elliptic.

Lemma 18. *The function $E(t) = E_\omega(t) = \sum_{k\in\mathbb{Z}} \mathrm{e}^{2k\omega\mathrm{i}}\chi(t+kh)$ verifies the following:*

(i) *It is meromorphic in the complex plane and its poles are the points in the set $\mathcal{P} = \pi\mathrm{i} + h\mathbb{Z} + 2\pi\mathrm{i}\mathbb{Z}$ (double ones).*

(ii) *$E(t+2\pi\mathrm{i}) = E(t)$ and $E(t+h) = \mathrm{e}^{-2\omega\mathrm{i}}E(t)$ for all complex t.*

(iii) *$E(-\overline{t}) = \overline{E(t)}$ for all complex t.*

(iv) *If $\omega = \pi/2 \pmod{\pi}$, the points $t = h/2 \pmod{h}$ are the only real zeroes of $E(t)$, all of them being simple ones.*

(v) *If $\omega = 0 \pmod{\pi}$, then $E(t)$ has no real zeroes.*

(vi) *$E_{-\omega}(t) = \overline{E_\omega(\overline{t})}$ and $E_{\omega+\pi}(t) = E_\omega(t)$.*

Proof. (i) The function $\chi(t)$ is meromorphic in the complex plane, and its poles are the

points in $\pi\mathrm{i} + 2\pi\mathrm{i}\mathbb{Z}$ (double ones) and $\pi\mathrm{i} \pm h + 2\pi\mathrm{i}\mathbb{Z}$ (simple ones).

(ii) The function $E(t)$ is $2\pi\mathrm{i}$-periodic because so is $\chi(t)$. On the other hand,

$$E(t+h) = \sum_{k\in\mathbb{Z}} \mathrm{e}^{2k\omega\mathrm{i}}\chi(t+kh+h) = \sum_{k\in\mathbb{Z}} \mathrm{e}^{2(k-1)\omega\mathrm{i}}\chi(t+kh) = \mathrm{e}^{-2\omega\mathrm{i}}E(t).$$

(iii) We recall that $E(t) = a(t) + b(t)\mathrm{i}$, where $a(t)$ and $b(t)$ are real analytic functions such that $a(t)$ is even and $b(t)$ is odd. Hence, $E(-\overline{t}) = a(-\overline{t}) + b(-\overline{t})\mathrm{i} = a(\overline{t}) - b(\overline{t})\mathrm{i} = \overline{a(t)} - \overline{b(t)}\mathrm{i} = \overline{E(t)}$.

(iv) In this case, $\mathrm{e}^{2k\omega\mathrm{i}} = -1$, and so $E(t+h) = -E(t)$. Thus, $E(t)$ becomes an elliptic function with periods $2h$ and $2\pi\mathrm{i}$. Further, $E(t)$ has order four, because it has just four poles (counted with multiplicity) on any cell with periods $2h$ and $2\pi\mathrm{i}$; see (i).

Using that the elliptic function

$$E(t) = \sum_{k\in\mathbb{Z}} (-1)^k \chi(t+kh)$$

is even, h-antiperiodic, and $2\pi\mathrm{i}$-periodic, we get that $E(t)$ vanishes at the four points $h/2$, $3h/2$, $h/2 + \pi\mathrm{i}$, and $3h/2 + \pi\mathrm{i}$. For instance, $E(h/2) = E(-h/2) = -E(h/2)$, so $E(h/2) = 0$. But we know that $E(t)$ has exactly four zeroes (counted with multiplicity) on each cell with periods $2h$ and $2\pi\mathrm{i}$. Since the previous four zeroes belong to the same cell, they are the only ones (modulo periodicities), and they are simple.

(v) $\chi(t) > 0$ in $\mathbb{R}$. Thus, if $\mathrm{e}^{2\omega\mathrm{i}} = 1$, $E(t) = \sum_{k\in\mathbb{Z}} \chi(t+kh) > 0$ for any real t.

(vi) First, $E_{-\omega}(t) = \sum_{k\in\mathbb{Z}} \overline{\mathrm{e}^{2k\omega\mathrm{i}}\chi(t+kh)} = \overline{\sum_{k\in\mathbb{Z}} \mathrm{e}^{2k\omega\mathrm{i}}\chi(\overline{t}+kh)} = \overline{E_\omega(\overline{t})}$, because $\chi(t)$ is real analytic. The second property is trivial. ∎

Next, we gain some insight on the structure of the complex zeroes of the quasi-elliptic function $E(t)$. Roughly speaking, we state in the following lemma that $E(t)$ has order two, and its zeroes look like in Figure 5. The proof is adapted from similar proofs about elliptic functions.

Lemma 19. *The quasi-elliptic function $E(t)$ has order two; that is, it has two zeroes in any cell with periods h and $2\pi\mathrm{i}$. Let t_1 and t_2 be the zeroes in any cell. Then*

$$t_1 + t_2 \in 2\omega\mathrm{i} + h\mathbb{Z} + 2\pi\mathrm{i}\mathbb{Z}. \tag{27}$$

Additionally, the set

$$\mathcal{T} = \{t_1, t_2\} + h\mathbb{Z} + 2\pi\mathrm{i}\mathbb{Z}$$

formed by the complex zeroes of $E(t)$ is symmetric with regard to the vertical lines $\{\Re t = 0 \pmod h\}$ and $\{\Re t = h/2 \pmod h\}$.

Proof. We recall the following version of the argument principle [34, section 6.3]. Let C be a contour in the complex plane, let $f(t)$ be a function analytic inside and on C, let $g(t)$ be a meromorphic function without zeroes or poles on C, and let $t_1, \dots, t_J$ and $p_1, \dots, p_K$ be the zeroes and poles of $g(t)$ in the interior of C, repeated as many times as their multiplicities and orders, respectively. Then

$$\frac{1}{2\pi\mathrm{i}} \oint_C f(t)\frac{g'(t)}{g(t)}\mathrm{d}t = \sum_j f(t_j) - \sum_k f(p_k). \tag{28}$$

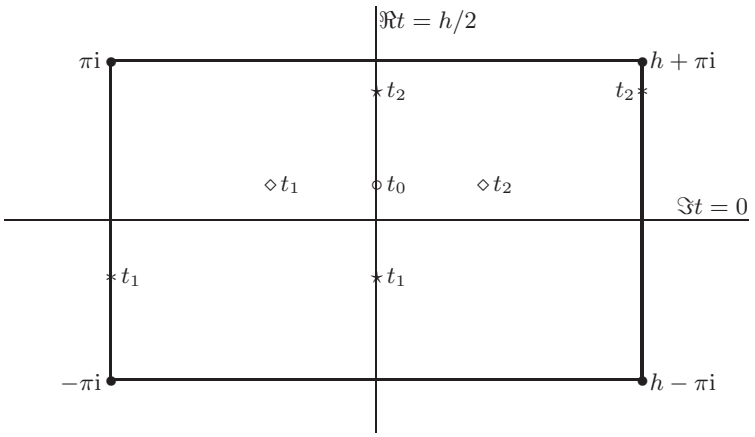


Figure 5. *The three scenarios for the set of zeroes of the quasi-elliptic function $E(t)$. First ($\star$): The zeroes are on the lines $\{\Re t = h/2 \pmod h\}$. Second ($\diamond$): The zeroes have the same imaginary part modulo $2\pi\mathrm{i}$. Third ($*$): The zeroes are on the lines $\{\Re t = 0 \pmod h\}$. The double poles are marked with the symbol $\bullet$. The middle point is $t_0 = h/2 + \omega\mathrm{i}$ in the three cases, because $t_1 + t_2 \in 2\omega\mathrm{i} + h\mathbb{Z} + 2\pi\mathrm{i}\mathbb{Z}$.*

This version of the principle assumes that the contour has no self-intersections, and that it is oriented counterclockwise.

If we choose any cell of periods h and $2\pi\mathrm{i}$ as the contour C, and set $f(t) = 1$, $g(t) = E(t)$ in (28), we get that $E(t)$ has $J = K = 2$ zeroes in the cell, because the integrals of the quotient $E'(t)/E(t)$ over opposite sides of the cell cancel out. (We recall that $E(t)$ has exactly one double pole on each cell.)

Let t_1 and t_2 be the zeroes and p be the double pole of $E(t)$ in a cell C. Let the corners of the cell be s, $s + h$, $s + h + 2\pi\mathrm{i}$, $s + 2\pi\mathrm{i}$. Now, if we keep the same contour, but take $f(t) = t$ and $g(t) = E(t)$, we get that

$$\begin{aligned} t_1 + t_2 - 2p &= \frac{1}{2\pi\mathrm{i}} \left(\int_s^{s+h} + \int_{s+h}^{s+h+2\pi\mathrm{i}} + \int_{s+h+2\pi\mathrm{i}}^{s+2\pi\mathrm{i}} + \int_{s+2\pi\mathrm{i}}^{s} \right) \frac{tE'(t)}{E(t)} \mathrm{d}t \\ &= \frac{1}{2\pi\mathrm{i}} \left(h \int_s^{s+2\pi\mathrm{i}} \frac{E'(t)}{E(t)} \mathrm{d}t - 2\pi\mathrm{i} \int_s^{s+h} \frac{E'(t)}{E(t)} \mathrm{d}t \right) \\ &= \frac{h}{2\pi\mathrm{i}} \log E(t)\big|_s^{s+2\pi\mathrm{i}} + \log E(t)\big|_{s+h}^{s} \end{aligned}$$

on making use of the quasi-periodic properties of $E(t)$.

Using again the quasi periodicities $E(s + 2\pi\mathrm{i}) = E(s)$ and $E(s + h) = \mathrm{e}^{-2\omega\mathrm{i}} E(s)$, we see that $\log E(t)\big]_s^{s+2\pi\mathrm{i}} \in 2\pi\mathrm{i}\mathbb{Z}$ and $\log E(t)\big]_{s+h}^{s} \in 2\omega\mathrm{i} + 2\pi\mathrm{i}\mathbb{Z}$. Therefore,

$$t_1 + t_2 \in 2\omega\mathrm{i} + 2p + h\mathbb{Z} + 2\pi\mathrm{i}\mathbb{Z}.$$

Now, relation (27) follows because we know that the double pole $p \in \pi\mathrm{i} + h\mathbb{Z} + 2\pi\mathrm{i}\mathbb{Z}$.

Finally, the specular symmetries with regard to the vertical lines are a direct consequence of the relations $E(-\overline{t}) = \overline{E(t)}$ and $E(t + h) = \mathrm{e}^{-2\omega\mathrm{i}} E(t)$. ■

Using this lemma, we realize that there are just three possible scenarios for the set of complex zeroes of the quasi-elliptic function $E(t)$, which are listed in the caption of Figure 5.

We have numerically checked that only the first scenario takes place, but we have not found a proof. Therefore, in the following lemma we can only deduce that the set of real zeroes of $E(t)$ is either $h\mathbb{Z}$ or $h/2+h\mathbb{Z}$, although we suspect that the case $h\mathbb{Z}$ is a mirage.

Lemma 20. *If $E(t)$ has some real zeroes, all of them are simple, and the set of its real zeroes is either $h\mathbb{Z}$ or $h/2+h\mathbb{Z}$.*

Proof. We note that $E(t)$ cannot have either a double real zero or two different real zeroes modulo h. On the contrary, we could take $t_1, t_2 \in \mathbb{R}$ in Lemma 19, so that $\mathbb{R} \ni t_1 + t_2 \in 2\omega\mathrm{i} + h\mathbb{Z} + 2\pi\mathrm{i}\mathbb{Z}$. But this would imply that $\omega = 0 \pmod{\pi}$, and then $E(t)$ has no real zeroes; see Lemma 18. Therefore, the set of real zeroes has the form $t_* + h\mathbb{Z}$ for some single real zero $t_* \in [0, h)$. But, since $t_* + h\mathbb{Z}$ must be symmetric with regard to the points 0 and $h/2$, there are only two possibilities: either $t_* = 0$ or $t_* = h/2$. ∎

As a by-product of this lemma, the set defined in (26) can also be defined as

$$\Omega = \Omega_h = \{\omega \in \mathbb{T} : E_\omega(0)E_\omega(h/2) = 0\}.$$

To prove Lemma 14, it suffices to check that (1) Ω is finite; (2) $E_\omega(0) \neq 0$ for all $h \geq h_0$ and all $\omega \in \mathbb{T}$; and (3) $E_\omega(h/2) \neq 0$ for all $h \geq h_1$ and all $\omega \neq \pm\pi/2$.

Lemma 21. *The set $\Omega = \{\omega \in \mathbb{T} : E_\omega(0)E_\omega(h/2) = 0\}$ is finite.*

Proof. The claim follows from the fact that, once any $h > 0$ is fixed, the function

$$\mathbb{T} \ni \omega \mapsto E_\omega(0)E_\omega(h/2) \in \mathbb{C}$$

is analytic, but not identically zero since the series $E_0(t) = \sum_{k\in\mathbb{Z}} \chi(t + kh)$ is positive for all real t. ∎

Lemma 22. *If $h \geq h_0 := \log 16 - \log(\sqrt{113} - 9)$, then $E_\omega(0) > 0$ for all $\omega \in \mathbb{T}$.*

Proof. We introduce the positive quantities

$$\chi_k = \chi_k(h) := \chi(kh) = \frac{4\cosh^2(h/2)\sinh^2(h/2)}{\cosh((k+1)h/2)\cosh^2(kh/2)\cosh((k-1)h/2)},$$

where $\chi(t)$ is the function given in (22). Our goal is to prove that

$$E_\omega(0) = \sum_{k\in\mathbb{Z}} \mathrm{e}^{2k\omega\mathrm{i}}\chi_k = \chi_0 + 2\sum_{k\geq 1} \cos(2k\omega)\chi_k > 0$$

for all $h \geq h_0$ and $\omega \in \mathbb{T}$. Here, we have used the symmetry $\chi_{-k} = \chi_k$. Since $\max_{\omega\in\mathbb{T}} |\cos(2k\omega)| = 1$, in order to prove the lemma it suffices to establish that

$$2\sum_{k\geq 1} \chi_k(h) < \chi_0(h) \qquad \forall h \geq h_0 := \log 16 - \log(\sqrt{113} - 9). \tag{29}$$

The rest of the proof is devoted to obtaining this bound. If we work with the multiplicative variable $x = \mathrm{e}^{-h} \in (0, 1)$, then $\chi_0 = \chi_0(x) = (1-x)^2/x$ and

$$\chi_k = \chi_k(x) = \frac{4(1-x^2)^2x^{2k-2}}{(1+x^{k+1})(1+x^k)^2(1+x^{k-1})} < 4(1-x^2)^2x^{2k-2}$$

for any $k \geq 1$ and $x \in (0,1)$. In particular,

$$\sum_{k\geq 1} \chi_k(x) < 4(1-x^2)^2 \sum_{k\geq 1} x^{2k-2} = 4(1+x)(1-x) \qquad \forall x \in (0,1).$$

Let $x_0 := (\sqrt{113}-9)/16 < 1$ and $h_0 := \log(1/x_0) > 0$. If $h \geq h_0$, then $x = \mathrm{e}^h \in (0, x_0]$ and $8x^2 + 9x - 1 \leq 0$. In particular, we conclude that the bound (29) holds. ■

Lemma 23. *If $h \geq h_1 := 2\log\frac{20}{9}$, then $E_\omega(h/2) \neq 0$ for all $\omega \neq \pm\pi/2$.*

Proof. This proof is similar to the previous one. We introduce the positive quantities

$$\tilde{\chi}_k = \tilde{\chi}_k(h) := \chi(kh + h/2) = \frac{4\cosh^2(h/2)\sinh^2(h/2)}{\cosh\big((\frac{k}{2}+\frac{3}{4})h\big)\cosh^2\big((\frac{k}{2}+\frac{1}{4})h\big)\cosh\big((\frac{k}{2}-\frac{1}{4})h\big)}.$$

Our goal is to prove that if $h \geq h_1$ and $\omega \neq \pm\pi/2$, then

$$\mathrm{e}^{\omega \mathrm{i}} E_\omega(h/2) = 2\sum_{k\geq 0} \cos((2k+1)\omega)\tilde{\chi}_k = 2\left(\tilde{\chi}_0 + \sum_{k\geq 1} a_k \tilde{\chi}_k\right)\cos\omega \neq 0.$$

Here, we have used the symmetry $\tilde{\chi}_{-(k+1)} = \tilde{\chi}_k$ and have introduced the notation

$$a_k = a_k(\omega) := \frac{\cos(2k+1)\omega}{\cos\omega}.$$

That is, $a_k(\omega) = T_{2k+1}(\cos\omega)/\cos\omega$, where $T_n(x)$ denotes the Chebyshev polynomial of first kind and degree n defined by relation $T_n(\cos\omega) = \cos n\omega$. Now, using some standard properties of Chebyshev polynomials contained in [1, entries 22.5.29 and 22.14.1], we realize that $\max_{\omega\in\mathbb{T}} |a_k(\omega)| = 2k+1$. Therefore, in order to prove the lemma it suffices to establish that

$$\sum_{k\geq 1} (2k+1)\tilde{\chi}_k(h) < \tilde{\chi}_0(h) \qquad \forall h \geq h_1 := 2\log(20/9). \tag{30}$$

The rest of the proof is devoted to proving this bound. If we work with the multiplicative variable $x = \mathrm{e}^{-h/2} \in (0,1)$, then $\tilde{\chi}_0 = \tilde{\chi}_0(x) = 4(1-x^4)^2/x(1+x^3)(1+x)^3$ and

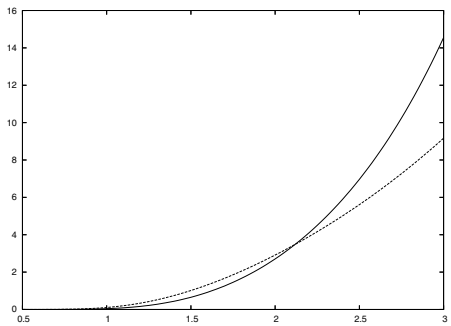
$$\tilde{\chi}_k = \tilde{\chi}_k(x) = \frac{4(1-x^4)^2 x^{4k-2}}{(1+x^{2k+3})(1+x^{2k+1})^2(1+x^{2k-1})} < 4(1-x^4)^2 x^{4k-2}$$

for any $k \geq 1$ and $x \in (0,1)$. In particular,

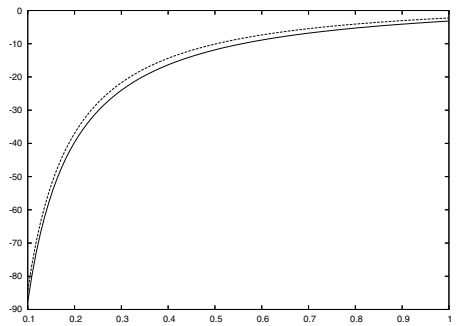
$$\sum_{k\geq 1} (2k+1)\tilde{\chi}_k(x) < 4(1-x^4)^2 \sum_{k\geq 1} (2k+1)x^{4k-2} = 12x^2(1-x^4/3)$$

for all $x \in (0,1)$. Hence, if there exists some $x_1 \in (0,1)$ such that

$$\frac{(1-x^4)^2}{1-x^4/3} =: f(x) \geq g(x) := 3x^3(1+x^3)(1+x)^3 \qquad \forall x \in (0, x_1],$$



(a) $m_0(h)$ and $m_1(h)$ vs $h \in (0.5, 3)$.



(b) $\log m_0(h)$ and $\log m_1(h)$ vs $h \in (0.1, 1)$.

Figure 6. *Graphs of the functions* $m_0(h) = \min\{M_0(\omega, h) : \omega \in \mathbb{T}\}$ *(full curves) and* $m_1(h) = \min\{M_1(\omega, h) : \omega \in \mathbb{T}\}$ *(broken curves) in normal (left) and logarithmic (right) vertical scales.*

then (30) holds for any $h \geq h_1 := 2\log(1/x_1)$. The function $f(x)$ is increasing in the interval $(0, 1)$, whereas $g(x)$ is decreasing in the same interval. On the other hand,

$$f(9/20) = \frac{23543526721}{25250080000} > \frac{465593887647}{512000000000} = g(9/20).$$

Therefore, we can take $x_1 := 9/20$. ∎

Appendix B. Numerical evidence for Conjecture 15. In the proofs of Lemmas 22 and 23, we have shown that the analytic functions $M_j : \mathbb{T} \times \mathbb{R}_+ \to \mathbb{R}$ defined by

$$M_0(\omega, h) = E_\omega(0), \qquad M_1(\omega, h) = \frac{\mathrm{e}^{\omega \mathrm{i}} E_\omega(h/2)}{2\cos\omega}$$

are positive when $h \geq h_0$ and $h \geq h_1$, respectively. We conjecture that, in fact, they are positive everywhere, which is equivalent to Conjecture 15.

Figure 6 provides strong numerical evidence for this conjecture. Concretely, we have numerically checked that the functions

$$m_j : \mathbb{R}_+ \to \mathbb{R}, \qquad m_j(h) = \min\{M_j(\omega, h) : \omega \in \mathbb{T}\}$$

are positive in the range $1/10 \leq h \leq 3$. Greater values of h are already covered by our analytical results. Smaller values of h represent a computational challenge, because the functions $m_j(h)$ are exponentially small in h as $h \to 0^+$; see subfigure 6(b). This is a typical behavior for splitting problems in weakly hyperbolic settings.

The computation of such exponentially small splittings requires the use of a multiple precision arithmetic to mitigate the strong cancellations that take place in such problems. For instance, to compute the functions $m_j(h)$ at $h = 1/10$ it is necessary to work with at least 50 digits.

Electrical Waves in a One-Dimensional Model of Cardiac Tissue*

Margaret Beck†, Christopher K. R. T. Jones‡, David Schaeffer§, and Martin Wechselberger¶

Abstract. The electrical dynamics in the heart is modeled by a two-component PDE. Using geometric singular perturbation theory, it is shown that a traveling pulse solution, which corresponds to a single heartbeat, exists. One key aspect of the proof involves tracking the solution near a point on the slow manifold that is not normally hyperbolic. This is achieved by desingularizing the vector field using a blow-up technique. This feature is relevant because it distinguishes cardiac impulses from, for example, nerve impulses. Stability of the pulse is also shown, by computing the zeros of the Evans function. Although the spectrum of one of the fast components is only marginally stable, due to essential spectrum that accumulates at the origin, it is shown that the spectrum of the full pulse consists of an isolated eigenvalue at zero and essential spectrum that is bounded away from the imaginary axis. Thus, this model provides an example in a biological application reminiscent of a previously observed mathematical phenomenon: that connecting an unstable—in this case marginally stable—front and back can produce a stable pulse. Finally, remarks are made regarding the existence and stability of spatially periodic pulses, corresponding to successive heartbeats, and their relationship with alternans, irregular action potentials that have been linked with arrhythmia.

Key words. geometric singular perturbation theory, Evans function, blow-up, cardiac model, arrhythmia, alternans

1. Introduction.

The first model of electrical activity in the cardiac membrane, an adaptation of the classic Hodgkin–Huxley model of neural dynamics, was introduced by Hutter and Noble [HN60] and Noble [Nob62] for the Purkinje fiber. Beeler and Reuter [BR77] introduced the first model for the dynamics of a ventricular myocyte, and more complicated models including additional and new experimental data (see, for example, Luo and Rudy [LR91, LR94]) followed. The main aim of all these models was to describe generic restitution properties of cardiac tissue, as well as to support spiral waves that break up spontaneously. (Restitution refers to the relation between the diastolic interval, the interval between the end of an action

potential and the beginning of the next action potential, and the duration of the next action potential pulse.) The length and shape of action potentials in myocardial cells are distinct from those of the Hodgkin–Huxley model. In particular, myocardial cells have substantially prolonged action potentials compared to neural action potentials, which facilitates muscular contraction. See Figure 1(a).

In order to focus on the qualitative aspects of the Hodgkin–Huxley model of membrane activity in the squid giant axon, a simplified version, known as the FitzHugh–Nagumo model, was developed. In the same spirit, Karma [Kar93, Kar94] extracted a model of minimal complexity that reproduces restitution properties of the above-mentioned cardiac cell models. Because these properties are absent in the standard FitzHugh–Nagumo model, it was necessary to introduce a different minimal model.

In this paper, we study a variant of Karma's model that was introduced by Mitchell and Schaeffer [MS03]. In addition, we allow for spatial variation and replace the step functions that appear in their model by smooth functions. The result is

$$\begin{aligned} v_t &= \kappa v_{xx} + I_{in}(v,h) + I_{out}(v) + I_{stim}(t), \\ h_t &= \frac{h_\infty(v) - h}{\tau_h(v)}, \end{aligned} \tag{1.1}$$

where

$$I_{in}(v,h) = \frac{1}{\tau_{in}} h v^2 (1-v), \quad I_{out}(v) = -\frac{1}{\tau_{out}} v,$$

$$h_\infty(v) = \begin{cases} 1 & \text{if } v < v_{crit} - \delta_v, \\ f^h(v) & \text{if } v_{crit} - \delta_v < v < v_{crit} + \delta_v, \\ 0 & \text{if } v_{crit} + \delta_v < v, \end{cases}$$

and

$$\tau_h(v) = \begin{cases} \tau_{open} & \text{if } v < v_{crit} - \delta_v, \\ f^\tau(v) & \text{if } v_{crit} - \delta_v < v < v_{crit} + \delta_v, \\ \tau_{close} & \text{if } v_{crit} + \delta_v < v, \end{cases}$$

where δ_v is sufficiently small, f^h and f^τ are smooth monotonic functions that give continuity of the functions h_∞ and τ_h, and $I_{stim}(t)$ is an external stimulus. In the above equations, $x \in \mathbb{R}$, $t > 0$, $v = v(x,t) \in \mathbb{R}$ corresponds to the membrane potential of myocardial tissue and $h = h(x,t) \in \mathbb{R}$ is a gating variable. Both are dimensionless quantities that can range between zero and one.

The change of membrane potential v is governed by diffusion, through the diffusion coefficient κ, and the ionic currents. The current $I_{in}(v,h)$ denotes a bulk inward current, a combination of all currents that raise the voltage across the membrane—primarily sodium and calcium current. This current is voltage dependent and includes the gating variable h—open when $h = 1$, closed when $h = 0$—that governs the inactivation of the bulk inward current. The current $I_{out}(v)$ denotes a bulk outward current, a combination of all currents that decreases the voltage across the membrane—primarily potassium current. This current is voltage dependent but ungated. The stimulus current I_{stim} is an external current usually applied in brief pulses, either by a pacemaker cell or an experimenter.

The parameters τ_{in} and τ_{out} govern the flow of ions into and out of the cell, respectively, and the parameters τ_{open} and τ_{close} govern the opening and closing rates of the gate h. Based upon physiological information, it is reasonable to assume that

$$\tau_{in},\ \tau_{out} \ll \tau_{open},\ \tau_{close}. \tag{1.2}$$

Therefore, changes in the voltage v occur much faster than changes in the gating variable h, the inactivation of the bulk inward current. We exclude the case where the speed τ_{out} of the bulk outward current is comparable to the speeds of the gating variable h. For a myocardial cell to be able to produce an action potential, it is a necessary to have $\tau_{out}/\tau_{in} =: R$ sufficiently large; i.e., activation must occur before deactivation—the inward current has to be sufficiently faster than the outward current. The exact minimum size for R is dependent on the specific model, and we will see below that for the model we investigate it is $R > 4$. Similar conditions on the gating speeds are not necessary for the existence of action potentials. We remark that, although R is large, it is not asymptotically large with respect to $1/\epsilon$, where ϵ is a small parameter that we define below.

Under these assumptions we will rescale space and time so that

$$\kappa = 1, \quad \tau_{out} = 1, \quad 1/\tau_{in} = R. \tag{1.3}$$

We remark that it is not necessary that $\tau_{open} = \tau_{close}$, but we assume this for convenience. Allowing them to differ, but remain of the same order, would only change the decay/growth rates on the slow manifold and would not qualitatively affect our results. Therefore, we define ϵ via

$$1/\tau_{open} = 1/\tau_{close} = \epsilon. \tag{1.4}$$

We note that similar scalings were used in [MS03]. For typical values of these parameters, see [CS06]. The relevance of different choices of R will be discussed further below. The voltage threshold v_{crit} determines when the gate switches from an opening to a closing state or vice versa, and it is reasonable to assume that $0 < v_{crit} < 1/2$ [MS03, CS06].

In this paper, we will be primarily interested in traveling pulse solutions, corresponding to a single heartbeat, stimulated in the distant past at $x = -\infty$. The reason for this is the following. One particularly interesting biological behavior, found in the ODE version of the model, is a bifurcation in the response to periodic external stimulation as the frequency is increased. For smaller frequencies, the model produces action potentials with constant maximum value in one-to-one correspondence with the stimulus. As the frequency increases, this behavior can destabilize, and alternans, action potentials with beat-to-beat variation in their restitution, can appear. This phenomenon has been linked with ventricular fibrillation and sudden cardiac death [CS06]. In order to eventually understand this phenomenon in spatially dependent models, we first seek to understand the dynamics of a single heartbeat, which is described by a traveling pulse solution to the above model without external stimulus. Therefore, in this paper we will set $I_{stim}(t) \equiv 0$.

Thus, the model we will study throughout is

$$\begin{aligned} v_t &= v_{xx} + Rhv^2(1-v) - v, \\ h_t &= \epsilon g(v,h), \end{aligned} \tag{1.5}$$

where

$$g(v,h) = \begin{cases} 1-h & \text{if } v < v_{crit} - \delta_v, \\ f^h(v) - h & \text{if } v_{crit} - \delta_v < v < v_{crit} + \delta_v, \\ -h & \text{if } v_{crit} + \delta_v < v, \end{cases} \tag{1.6}$$

and we have chosen $f^\tau(v) = 1/\epsilon = \tau_{open} = \tau_{close}$. Notice that $(v,h) \equiv (0,1)$ is a stationary solution of (1.5). We are interested in traveling pulses that are biasymptotic to this stationary solution. In order to study such solutions, we define the moving coordinate $\xi = x + ct$ and analyze the model in the (ξ, t) coordinates:

$$\begin{aligned} v_t &= v_{\xi\xi} - cv_\xi + Rhv^2(1-v) - v, \\ h_t &= -ch_\xi + \epsilon g(v,h). \end{aligned} \tag{1.7}$$

As mentioned above, this model has many similarities with the FitzHugh–Nagumo equation, which was analyzed in [JKL91] and [Jon84] using geometric singular perturbation theory [Fen71, Fen79, Jon94, Kap99]. The above model also contains a small parameter, ϵ, indicating the presence of two separated time-scales on which the dynamics occur, and so we will use similar techniques in our analysis. On the other hand, there are key structural differences manifested predominantly in the inward current term $Rhv^2(1-v)$, which will lead to properties of the associated traveling pulse solution that are distinct from those of the pulse solution to the FitzHugh–Nagumo model. We will point to these differences throughout the paper.

If we consider the ODE associated with spatially independent solutions,

$$\begin{aligned} v_t &= Rhv^2(1-v) - v, \\ h_t &= \epsilon g(v,h), \end{aligned}$$

we see that the v- and h-nullclines are given by the sets $\{v = 0\} \cup \{h = 1/(Rv(1-v))\}$ and $\{g(v,h) = 0\}$, respectively (see Figure 1(b)). This provides intuition for the stationary solutions that one can expect to exist for the PDE (1.7). For the construction of the pulse, the v-nullcline will correspond to the slow manifold. Thus, we expect that the pulse will consist of four pieces: a fast jump in $\{h = 1\}$ from $v = 0$ to $v = v^+$, on the right branch of the v-nullcline; a slow decay on the rightmost branch of the v-nullcline; a second fast jump in $\{h = 4/R\}$ from $v = 1/2$ to $v = 0$; and a slow growth along the leftmost branch of the v-nullcline, back to the point $(v,h) = (0,1)$. We will assume that $R > 4$, which is in accordance with our earlier comment on the size of the ratio τ_{out}/τ_{in} and their relative sizes in (1.3).

The key difference between this pulse and that of the FitzHugh–Nagumo model will be that the second "fast" jump, in the present case, occurs at the knee of the v-nullcline. This point is exactly where the slow manifold of the singularly perturbed system loses normal hyperbolicity. As a direct consequence, the repolarization period of the wave back is much longer than the fast depolarization period of the wave front. (This explains the quotes in *the second "fast" jump*, above.) This is one of the key features of membrane potentials in cardiac tissue.

The outline of the paper is as follows. Section 2 contains the proof of existence of traveling pulses. Section 3 is devoted to the stability analysis of such solutions. Finally, in section 4, we briefly discuss spatially periodic traveling pulses, corresponding to successive heartbeats.

2. Existence of the traveling pulse.

The main result of this section is Theorem 2.1, in which we prove that a traveling pulse, connecting $(v,h) = (0,1)$ at $\xi = \pm\infty$, exists for all $\epsilon \in (0, \epsilon_0)$, where ϵ_0 is sufficiently small.

2.1. Construction of the pulse: $\epsilon = 0$.

The traveling pulse is a stationary solution to the PDE (1.7) and also a solution to the ODE

$$\begin{aligned} v_\xi &= w, \\ w_\xi &= cw - Rhv^2(1-v) + v, \\ h_\xi &= \frac{\epsilon}{c} g(v,h). \end{aligned} \tag{2.1}$$

Notice that v and w are fast variables, while h is a slow variable. By setting $\epsilon = 0$ in the above system, we obtain the reduced fast system:

$$\begin{aligned} v_\xi &= w, \\ w_\xi &= cw - Rhv^2(1-v) + v, \\ h_\xi &= 0. \end{aligned} \tag{2.2}$$

By defining $y = \epsilon\xi$ in (2.1) and setting $\epsilon = 0$, we obtain the reduced slow system:

$$\begin{aligned} 0 &= w, \\ 0 &= cw - Rhv^2(1-v) + v, \\ h_y &= \frac{1}{c} g(v,h). \end{aligned} \tag{2.3}$$

First, consider the reduced slow equation (2.3). The associated leading order slow manifold is given by two pieces:

$$S_l = \{v = w = 0\} \quad \text{and} \quad \tilde{S}_r = \left\{ w = 0,\, h = \frac{1}{Rv(1-v)} \right\}.$$

We will be interested in S_l and the right branch of $\tilde{S}_r$, given by

$$S_r = \left\{ w = 0,\, h = \frac{1}{Rv(1-v)},\, v \geq \frac{1}{2} \right\}. \tag{2.4}$$

The slow dynamics on these manifolds is given by

$$\begin{aligned} h_y &= \frac{1}{c}(1-h) \quad \text{if} \quad (v,w) \in S_l, \\ h_y &= -\frac{1}{c}h \qquad \text{if} \quad (v,w) \in S_r. \end{aligned}$$

Next, consider system (2.2), where, due to the third equation, we may think of h as being a fixed parameter. For $1 \geq h > 4/R$, this equation has three fixed points: $(0,0)$, $(v^+(h),0)$, and $(v^-(h),0)$, where

$$v^{\pm}(h) = \frac{1}{2} \pm \frac{1}{2}\sqrt{1 - \frac{4}{Rh}}. \tag{2.5}$$

Note that $(0,0) \in S_l$ and $(v^+(h),0) \in S_r$. In addition, this system is equivalent to the traveling wave equation associated with the PDE

$$v_t = v_{\xi\xi} - cv_\xi - Rhv(v - v^+(h))(v - v^-(h)). \tag{2.6}$$

In other words, system (2.2) is the ODE satisfied by stationary solutions of (2.6). Using the change of coordinates $v \to v^+(h)v$, $\xi \to (1/v^+(h)\sqrt{Rh})\xi$, $c \to -(v^+(h)\sqrt{Rh})c$, and $t \to t/[(v^+(h))^2 Rh]$, we see that this equation is just the bistable equation

$$v_t = v_{\xi\xi} + cv_\xi + v(1-v)(v-\mu).$$

In the above equation, $\mu = v^-(h)/v^+(h)$. Traveling wave solutions to the bistable equation are relatively well understood. See, for example, [Xin00]. In particular, for $0 < \mu < 1/2$, there is an exact formula for the unique traveling wave connecting $v = 0$ at $\xi = -\infty$ to $v = 1$ at $\xi = +\infty$. Similarly, for $1/2 < \mu < 1$, there is an exact formula for the unique wave connecting $v = 1$ at $\xi = -\infty$ to $v = 0$ at $\xi = +\infty$. Translating back to the original variables, we obtain the following formulae for the traveling wave solutions of the reduced fast equation:

$$v(\xi) = \frac{v^+(h)}{1 + e^{-\sqrt{\frac{Rh}{2}}v^+(h)\xi}}; \quad c = \sqrt{2Rh}\left(\frac{1}{2}v^+(h) - v^-(h)\right) \quad \text{if} \quad \frac{1}{2}v^+(h) - v^-(h) > 0, \tag{2.7}$$

and

$$v(\xi) = \frac{v^+(h)}{1 + e^{\sqrt{\frac{Rh}{2}}v^+(h)\xi}}; \quad c = -\sqrt{2Rh}\left(\frac{1}{2}v^+(h) - v^-(h)\right) \quad \text{if} \quad \frac{1}{2}v^+(h) - v^-(h) < 0. \tag{2.8}$$

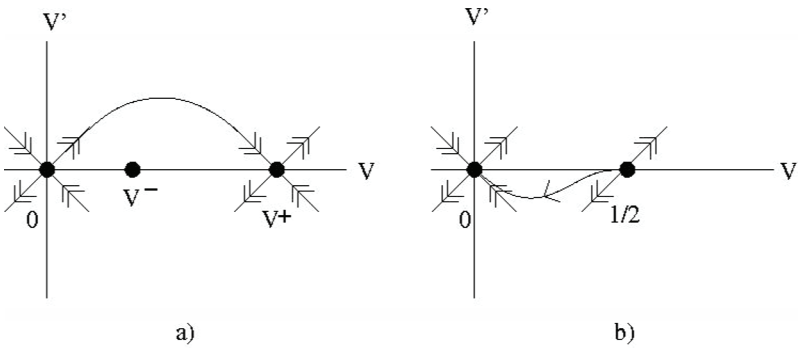

Figure 2. *A sketch of the phase planes for the leading order fast components of the pulse:* (a) *the traveling pulse of* (2.6)*, for* $\frac{1}{2}v^+ - v^- > 0$*;* (b) *the traveling pulse of* (2.9)*, for* $c > \sqrt{2}/2$*, which is asymptotic to the center manifold at* $-\infty$*.*

Notice this implies that, if $\frac{1}{2}v^+(h) - v^-(h) > 0$, then there is a unique heteroclinic connection between $v = 0$ at $-\infty$ and $v = v^+(h)$ at $+\infty$ (see Figure 2(a)). When $\frac{1}{2}v^+(h) - v^-(h) < 0$, then there is a unique connection going in the opposite direction. Using the formulae for $v^\pm(h)$, given in (2.5), one can see that the value of h for which $\frac{1}{2}v^+(h) - v^-(h) = 0$ is given by $\bar{h} = \frac{9}{2R}$.

It may be of interest to note the following. If one considers (2.6) with $c = 0$, then the associated ODE is Hamiltonian with $H(v, v') = (v')^2/2 - v^2/2 + Rhv^3/3 - Rhv^4/4$, where $v' = v_\xi$. For positive wavespeeds $c > 0$, $dH/d\xi = c(v')^2$. As h decreases through $\bar{h}$, the value of $H(v^+(h), 0)$ switches from being positive to negative. As a result, for $h > \bar{h}$, there is no way to have a connection going from $v = v^+(h)$ to $v = 0$, and, for $h < \bar{h}$, there is no way to go in the opposite direction.

The above reduced fast analysis was for $h \in (4/R, 1]$. If $h = 4/R$, however, we have $v^+(h) = v^-(h)$, and the structure of the reduced fast system changes. In that case, (2.2) becomes

$$\begin{aligned} v_\xi &= w, \\ w_\xi &= cw + v(2v-1)^2, \end{aligned}$$

which is equivalent to the traveling wave equation for the PDE

$$v_t = v_{\xi\xi} - cv_\xi - v(2v-1)^2. \tag{2.9}$$

Up to a change of variables, this PDE is exactly the generalized Fisher–KPP (Kolmogorov–Petrovskii–Piskunov) equation of order 2 [Xin00]. For each $c \geq \sqrt{2}/2$, equation (2.9) has a heteroclinic orbit connecting $(1/2, 0)$ at $-\infty$ with $(0, 0)$ at $+\infty$. If $c > \sqrt{2}/2$, then the orbit leaves $(1/2, 0)$ along a center manifold and approaches $(0, 0)$ along its stable manifold (see Figure 2(b)). If $c = \sqrt{2}/2$, known as the critical wavespeed, then the orbit leaves $(1/2, 0)$ along the unstable manifold and approaches $(0, 0)$ along its stable manifold. For more information on critical wavespeeds in this and other related equations, see, for example, [PK06].

Putting the information from the reduced slow and fast dynamics together, we expect that the leading order pulse will consist of four pieces as follows:

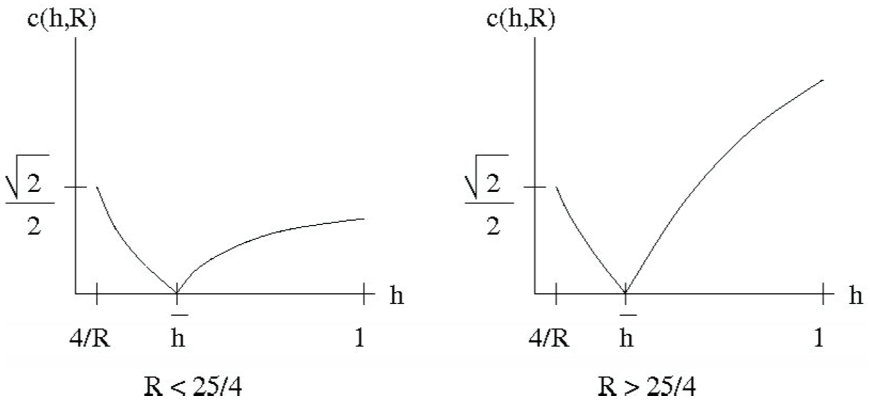

Figure 3. *A sketch of the function $c(R,h)$, as given in (2.7) and (2.8), for fixed R.*

1. a fast jump from $(0,0,1)$ to $(v^+(1),0,1)$, which is given explicitly in (2.7), with $c^* = c(R,1)$;
2. slow decay along S_r to a point $(v^+(h^*),0,h^*)$, where h^* will be determined by the third piece of the pulse;
3. a fast jump from $(v^+(h^*),0,h^*)$ to $(0,0,h^*)$, at the value of $h^* \in [4/R,1)$ such that $c^* = c^*(R,h^*)$; and
4. slow growth along S_l back to $(0,0,1)$.

Notice that the first piece will determine the wavespeed $c^* = c(R,1)$. The value of h^* at which the third piece occurs will be determined by the relation in (2.8) and will be the value of $h \in [4/R,1)$ such that $c(R,1) = c^* = c(R,h^*)$. A sketch of the function $c(R,h)$, for fixed R, is given in Figure 3.

If $4 < R < 25/4$, then there exists an $h^* \in (4/R,\bar{h})$ for which the reduced fast system (2.2) has a heteroclinic orbit of speed c^* connecting $(v+(h^*),0)$ at $-\infty$ with $(0,0)$ at $+\infty$. However, if $R > 25/4$, there is no such $h^* \in (4/R,\bar{h})$.

Recall that, based upon the relative sizes in (1.2), we expect R to be large. As a result, we are interested in the case where $R > 25/4$. Thus, the second fast jump must occur for $h = 4/R$, because for this value of h a connection exists for all $c \geq \sqrt{2}/2$. As a result, the complete, leading order pulse is given by a curve as sketched in Figure 4.

This situation corresponds to the pulse leaving the slow manifold at the knee, which is exactly the point where the manifold ceases to be normally hyperbolic. Therefore, it is not immediately clear what will happen to the pulse for $\epsilon > 0$. Furthermore, because $c(R,1) > \sqrt{2}/2$ (for $R > 25/4$), the second fast jump leaves the knee along the center, rather than the unstable, manifold. This will create a slow transition between the first slow and second fast piece of the pulse, due to the algebraic, rather than exponential, growth away from the slow manifold in the singular limit.

2.2. Persistence of the pulse: $1 \gg \epsilon > 0$. The above analysis tells us what the pulse looks like, to leading order. In order to show that a traveling pulse exists for $0 < \epsilon \ll 1$, we will track the leading order center-unstable manifold of $(0,0,1)$, which we will denote by W^{cu}, forward along the first fast jump, down the slow manifold, and along the second fast jump. In addition, we will track the leading order center-stable manifold of $(0,0,1)$, denoted by W^{cs},

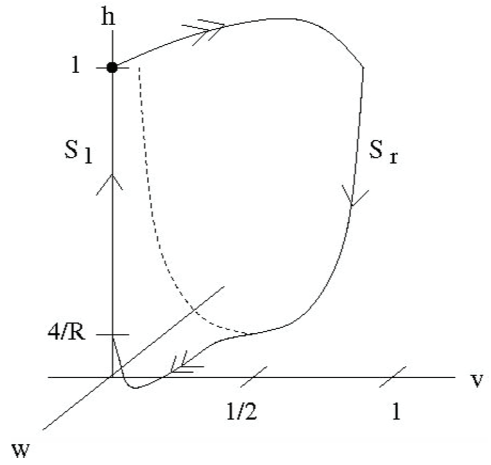

Figure 4. *A sketch of the leading order pulse, consisting of a fast jump from* $(0,0,1)$ *to* $(v^+(1),0,1)$*, slow decay along* S_r*, another fast jump connecting* $(1/2,0,4/R)$ *to* $(0,0,4/R)$ *and leaving at the knee, and slow growth along* S_l*.*

backward down along the leftmost piece of the slow manifold. We will show that, for $\epsilon = 0$, these manifolds intersect transversely, which proves that a traveling pulse must also exist for ϵ positive and sufficiently small.

There are two main difficulties in tracking the center-unstable manifold W^{cu} along the pulse. The first difficulty lies in following W^{cu} along the slow manifold S_r for large times. However, there is a tool, known as the exchange lemma and proved in [JK94], which will allow us to do this. Second, complications can arise due to the lack of normal hyperbolicity at the knee. Analysis in a neighborhood of the knee can be carried out using a geometric desingularization technique known as blow-up [KS01]. Using these techniques, we will prove the following theorem.

Theorem 2.1. *Let* ϕ_0 *denote the formal traveling pulse solution of* (1.5) *for* $\epsilon = 0$*, constructed in section 2.1. More specifically,* ϕ_0 *is defined by the union of the following curves in the* (v, v_ξ, h) *phase space. Define* $S_l = \{v = v_\xi = 0,\ h \in [4/R, 1]\}$*,* $S_r = \{v \in [1/2, v^+(1)],\ v_\xi = 0,\ h = \frac{1}{Rv(1-v)}\}$*,* $F_F = \{(v, v_\xi)$ *given by* (2.7) *for* $\xi \in \mathbb{R},\ h = 1\}$*, and* $F_B = \{(v, v_\xi)$ *the traveling wave solution of* (2.9) *when* $c = c^* > \sqrt{2}/2$ *for* $\xi \in \mathbb{R},\ h = 4/R\}$*. Then*

$$\phi_0 = F_F \cup S_r \cup F_B \cup S_l.$$

If $\epsilon_0 > 0$ *is sufficiently small, then for all* $\epsilon \in (0, \epsilon_0)$ *there exists a traveling pulse solution of* (1.5)*,* $\phi_\epsilon(\xi) = (V(\xi;\epsilon), V_\xi(\xi,\epsilon), H(\xi;\epsilon))$*, satisfying*

$$\lim_{\xi \to \pm\infty} (V(\xi;\epsilon), V_\xi(\xi,\epsilon), H(\xi;\epsilon)) = (0,0,1)$$

and lying as a curve within $\mathcal{O}(\epsilon^{2/3})$ *of the set* ϕ_0*.*

Remark 2.2. *In the statement of the above theorem, the perturbed pulse is parameterized by the spatial variable* ξ*. The leading order pulse,* ϕ_0*, cannot be parameterized in this way. This is because, for* $\epsilon = 0$*, it takes an infinite amount of "time" for the pulse to traverse each piece*

of the leading order orbit in the phase space. This is why the leading order pulse is defined geometrically, in terms of the sets F_F, S_r, F_B, S_l.

Proof. First, we remark that, along various pieces of the leading order pulse, different quantities (i.e., v, w, h, c, ϵ) will determine the key properties of the tracked manifold. Thus, we will consider only the relevant equations for v_ξ, w_ξ, h_ξ, c_ξ, or ϵ_ξ along each of the two fast and two slow components of the pulse. With a slight abuse of notation, we will still refer to the tracked manifold as the center-stable or center-unstable manifold along each piece and hope that it will be clear from the context exactly which variables we are keeping track of at the time.

We begin by tracking W^{cu} along the first fast jump. Consider the reduced fast system, equation (2.2). The plane $\{h = 1\}$ is invariant, and we want to determine how the unstable manifold of $(v, w) = (0, 0)$ intersects the stable manifold of $(v, w) = (v^+(1), 0)$ as we vary the wavespeed c. To do this, we fix $h = 1$ and append to (2.2) the equation $c_\xi = 0$:

$$\begin{aligned} v_\xi &= w, \\ w_\xi &= cw - Rv^2(1 - v) + v, \\ c_\xi &= 0. \end{aligned} \tag{2.10}$$

Based upon the analysis of the bistable equation mentioned above, there is a unique $c^* = c^*(R)$ for which a unique heteroclinic connection between the saddle $(0, 0)$ at $-\infty$ and the saddle $(v^+(1), 0)$ at $+\infty$ exists. We will show that the two-dimensional center-unstable manifold, which is a union of the unstable manifolds of $(v, w) = (0, 0)$ for values of c near c^* and denoted by $W^{cu}(0, 0)$, intersects the two-dimensional center-stable manifold of $(v^+(1), 0)$ (again defined as a union of the stable manifolds for c near c^*), denoted by $W^{cs}(v^+(1), 0)$, and that this intersection is transverse in the c direction. In other words, upon varying c along the fibers within the center-unstable and center-stable manifolds, there is an intersection for a unique value, $c = c^*$, and the manifolds intersect transversely at this point.

One way to track the evolution of two-dimensional manifolds is using two-forms, as in [JKL91]. This essentially allows one to track the evolution of their tangent planes. The vector of one-forms associated with (2.10) is (dv, dw, dc), and its evolution is given by

$$\begin{aligned} dv' &= dw, \\ dw' &= \left(1 - R2v(1 - v) + Rv^2\right) dv + cdw + wdc, \\ dc' &= 0, \end{aligned}$$

where $(\cdot)' = d/d\xi$. The associated two-forms are $P_{vw} = dv \wedge dw$, $P_{vc} = dv \wedge dc$, and $P_{wc} = dw \wedge dc$, with evolution equations

$$\begin{aligned} P'_{vw} &= cP_{vw} + wP_{vc}, \\ P'_{vc} &= P_{wc}, \\ P'_{wc} &= \left(1 - R2v(1 - v) + Rv^2\right) P_{vc} + cP_{wc}. \end{aligned}$$

These equations can be analyzed as in [JKL91], and we restate the details here for convenience. To be precise, we really should think of $\{P_{vw}, P_{vc}, P_{wc}\}$ as the basis for the space of two-forms

in vwc-space and write an arbitrary element as $f_1(v,w,c)P_{vw} + f_2(v,w,c)P_{vc} + f_3(v,w,c)P_{wc}$. It is really the coefficients f_i that we want to determine. The notation in the above system is therefore an abuse of notation: $P_{vw}(\xi)$ denotes the coefficient $f_1(v,w,c)(\xi)$, and so on. As this notation has become somewhat standard (for example, in system (2.1) we are in some sense thinking of $\{v,w,h\}$ as a basis for $\mathbb{R}^3$, particularly when we plot the phase diagram in Figure 4), we use it in the following.

Consider the equation for P_{vw}, and let $P_{vw}^{\pm}$ and $P_{vc}^{\pm}$ be the two forms associated with manifolds $W^{cu}(0,0)$ ($-$, coming from $-\infty$) and $W^{cs}(v^+(1),0)$ ($+$, coming from $+\infty$). We will show that P_{vc}^{+} and P_{vw}^{+} have the same sign, whereas P_{vc}^{-} and P_{vw}^{-} have the opposite sign. This implies that the vectors of two-forms associated with the manifolds, $(P_{vw}^{\pm}, P_{vc}^{\pm}, P_{wc}^{\pm})$, are linearly independent, and hence, that the manifolds intersect transversely.

The manifolds $W^{cu}(0,0)$ and $W^{cs}(v^+(1),0)$ both have the vector field, $(w, cw - Rv^2(1-v) + v, 0)$, as one tangent vector. Denote the other one by $(dv^{\pm}, dw^{\pm}, 1)$, respectively, where we can take $dc = 1$ since $dc' = 0$. This ensures that the two tangent vectors for each manifold are linearly independent. The two-forms for each tangent plane are, up to a positive normalization factor N, given by 2×2 subdeterminants of a 2×3 matrix, whose rows are exactly the above tangent vectors. Thus, we have

$$P_{vc}^{\pm} = N \det \begin{pmatrix} w & 0 \\ dv^{\pm} & 1 \end{pmatrix} = Nw.$$

As a result, the equation for P_{vw} is given by

$$P_{vw}' = cP_{vw} + Nw^2.$$

Since both $W^{cu}(0,0)$ and $W^{cs}(v^+(1),0)$ asymptotically contain a line of fixed points in the c-direction, we know that $P_{vw}^{+} \to 0$ as $\xi \to +\infty$, and $P_{vw}^{-} \to 0$ as $\xi \to -\infty$. Using the above equation, we can then see that $P_{vw}^{-} > 0$ and $P_{vw}^{+} < 0$ along the manifolds. Since $P_{vc}^{\pm} = Nw$ and w is positive along the first fast jump, $P_{vc}^{\pm} > 0$. Thus, the manifolds intersect transversely.

In order to continue tracking W^{cu} along the slow manifold S_r, we will need to use the exchange lemma [JK94]. This lemma tells us how information in the center direction, corresponding to the wavespeed c, at the top of S_r, is exchanged for information in the center direction, corresponding to h, at the bottom of S_r. More specifically, the lemma tells us that, since W^{cu} is transverse to $W^{cs}(v^+(1),0)$, when it leaves a neighborhood of S_r near any point with $1 > h > 4/R$, the tangent plane to W_{cu} will be C^1 $\mathcal{O}(\epsilon)$ close to the plane spanned by the tangent line to S_r in the plane $\{w = 0\}$ and the fast unstable fiber of the point $(v^+(h), 0, h)$. Thus, at a given value of h, the tangent plane to W^{cu} will be spanned, to leading order, by the vectors

$$\left(1, 0, \frac{2v^+(h) - 1}{2(v^+(h))^2(1 - v^+(h))^2}\right), \quad \left(1, \frac{c}{2} + \frac{\sqrt{c^2 + 4(Rhv^+(h) - 2)}}{2}, 0\right). \tag{2.11}$$

The exchange lemma tells us what W^{cu} looks like up to a neighborhood of the knee, when $h = 4/R$. At this point, the slow manifold S_r is not normally hyperbolic, and so we'll need to use blow-up to track the manifold around the knee.

2.2.1. Analysis of the knee. Consider the ODE for the pulse, (2.1), and append to it an equation for ϵ:

$$
\begin{aligned}
v_\xi &= w,\\
w_\xi &= cw - Rhv^2(1-v) + v,\\
h_\xi &= \frac{\epsilon}{c} g(v,h),\\
\epsilon_\xi &= 0.
\end{aligned}
\tag{2.12}
$$

Because the first fast jump selected the wavespeed $c = c(\epsilon)$, where $c(0) = c^*$, we now think of c as being fixed. (For notational convenience we do not explicitly write the epsilon dependence.) The relevant center directions, therefore, are now given by h and also by ϵ.

We are interested in the behavior of this equation near the knee, which corresponds to the fixed point $(1/2, 0, 4/R, 0)$. The Jacobian at this point is given by

$$
J = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & c & -R/8 & 0 \\ 0 & 0 & 0 & -4/(cR) \\ 0 & 0 & 0 & 0 \end{pmatrix}.
$$

This matrix has one positive eigenvalue, $\lambda = c$, with associated eigenvector $(1, c, 0, 0)$. In addition, $\lambda = 0$ is an eigenvalue with algebraic multiplicity three and geometric multiplicity one. The associated eigenvector is $(1, 0, 0, 0)$, and the generalized eigenvectors are $(0, 1, 8c/R, 0)$ and $(0, 0, -8/R, -2c^2)$. In order to do the blow-up, we will need to isolate the nonhyperbolic dynamics, which occur on a three-dimensional center manifold. In a neighborhood of the knee, this manifold can be represented by

$$
\begin{aligned}
w &= F\left((v-1/2), (h-4/R), \epsilon\right)\\
&= \alpha_0(h-4/R) + \alpha_1\epsilon + \beta_0(v-1/2)^2 + \beta_1(h-4/R)^2 + \beta_2\epsilon^2\\
&\quad + \gamma_0(v-1/2)(h-4/R) + \gamma_1(v-1/2)\epsilon + \gamma_2(h-4/R)\epsilon + \mathcal{O}(3),
\end{aligned}
\tag{2.13}
$$

where α_i, β_i, and γ_i are constants. We remark that the center manifold is not unique. However, the analysis that we carry out below is valid up to exponentially small terms, and thus is independent of the choice of the center manifold.

One can explicitly compute the above coefficients. As we will see below, the ones that will be relevant for the blow-up analysis are

$$
\alpha_0 = R/(8c), \quad \beta_0 = -2/c.
$$

Inserting these into (2.12), one sees that the dynamics on the center manifold are given by

$$
\begin{aligned}
v_\xi &= -\frac{2}{c}\left(v - \frac{1}{2}\right)^2 + \frac{R}{8c}\left(h - \frac{4}{R}\right)\\
&\quad + \mathcal{O}\left(\epsilon, \left(h-\frac{4}{R}\right)^2, \epsilon^2, \left(v-\frac{1}{2}\right)\left(h-\frac{4}{R}\right), \epsilon\left(h-\frac{4}{R}\right), \epsilon\left(v-\frac{1}{2}\right)\right),\\
h_\xi &= -\frac{4}{Rc}\epsilon + \mathcal{O}\left(\epsilon\left(h-\frac{4}{R}\right)\right),\\
\epsilon_\xi &= 0.
\end{aligned}
\tag{2.14}
$$

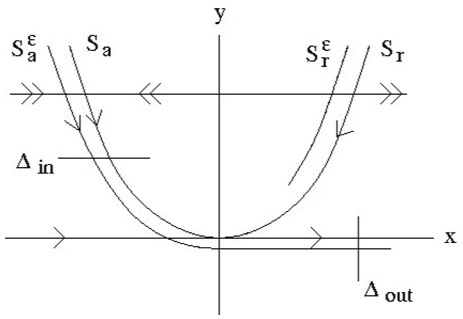

Figure 5. *A sketch of the slow manifolds and sections for the fold, as analyzed in* [KS01].

This system is essentially the normal form for a fold point, given in [KS01]. Their analysis explains why the terms of order $\mathcal{O}\left(\epsilon, (h-\frac{4}{R})^2, \epsilon^2, (v-\frac{1}{2})(h-\frac{4}{R}), \epsilon(h-\frac{4}{R}), \epsilon(v-\frac{1}{2})\right)$ are all indeed higher order. We now collect the results from [KS01] that are relevant for this paper.

In [KS01], the authors analyze systems of the form

$$\begin{aligned} x' &= -y + x^2 + \mathcal{O}(\epsilon, xy, y^2, x^3), \\ y' &= -\epsilon + \mathcal{O}(\epsilon x, \epsilon y, \epsilon^2). \end{aligned} \tag{2.15}$$

This system possesses a slow manifold that, for $\epsilon = 0$, is given by $S = \{(x, y) : y = x^2\}$. It can be divided into the attracting and repelling branches of the parabola, denoted by S_a and S_r, respectively. (To be consistent with the notation in [KS01], we use S_r to denote the repelling branch and hope that it will not be confused with the right branch of the slow manifold, given in (2.4).) Outside a neighborhood of the fold point, $(0, 0)$, these manifolds are normally hyperbolic and, therefore, perturb smoothly to locally invariant manifolds S_a^ϵ and S_r^ϵ, for ϵ positive and sufficiently small (see Figure 5).

The main result of [KS01] describes what happens in a neighborhood of $(0, 0)$ for $0 < \epsilon \ll 1$, and it can be explained as follows. Let $\Delta_{in} = \{(x, \rho^2),\ x \in I\}$ and $\Delta_{out} = \{(\rho, y),\ y \in \mathbb{R}\}$, where $I \subset \mathbb{R}$ is a suitable interval. Let $\pi : \Delta_{in} \to \Delta_{out}$ be the transition map associated with the flow of (2.15) (see Figure 5).

Proposition 2.3 (see [KS01]). *There exists an $\epsilon_0 > 0$ such that, for $\epsilon \in (0, \epsilon_0)$, the following hold:*

1. *The manifold S_a^ϵ passes through Δ_{out} at a point $(\rho, y(\epsilon))$, where $y(\epsilon) = \mathcal{O}(\epsilon^{2/3})$. In particular, $y(\epsilon) = -\Omega_0 \epsilon^{2/3} + o(\epsilon^{2/3})$, where $\Omega_0 > 0$ is known explicitly.*
2. *The transition map π is a contraction with contraction rate $\mathcal{O}(e^{-k/\epsilon})$, where k is a positive constant.*

The first item of this proposition tells us how to track the manifold W^{cu} around the knee. The second tells us that the resulting analysis will be independent of the choice of center manifold. We note the scaling $\epsilon^{2/3}$ is consistent with the higher order asymptotics of the restitution curve, computed in [MS03, CS06].

As mentioned above, for any $h \in (4/R, 1)$, the two-dimensional manifold W^{cu} is spanned by the one-dimensional fast unstable direction of the points $(v, w) = (v^+(h), 0)$ and the tangent line in the plane $\{w = 0\}$ to the one-dimensional slow manifold, given by $h = 1/(Rv(1-v))$.

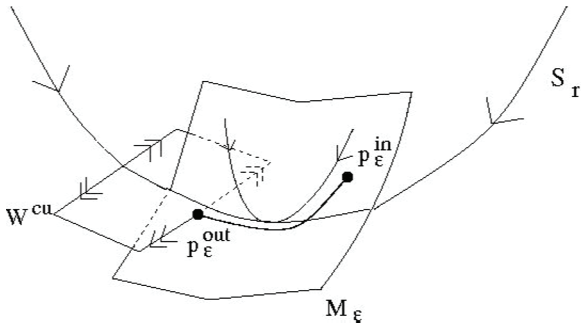

Figure 6. *A schematic diagram, in a neighborhood of the knee, of the tracked manifold W^{cu}. It is guided by the trajectory through the points p_ϵ^{in} and p_ϵ^{out}, which lies on the center manifold M_ϵ.*

As W^{cu} enters a neighborhood of the knee, it will intersect the center manifold of the knee, given in (2.13). We will denote this center manifold by $M_\epsilon = \{w = F(v, h, \epsilon)\}$ and its leading order version by $M_0 = \{w = F(v, h, 0)\}$.

In order to see how the dynamics on the center manifold at the knee will guide W^{cu}, define the following objects (with a slight abuse of notation, we will reuse the quantities $\Delta_{in,out}$ and ρ from the fold analysis):

$$\begin{aligned}
\Delta_{in} &= \left\{(v, w, h) : h = \frac{4}{R} + \rho^2\right\},\\
\Delta_{out} &= \left\{(v, w, h) : v = \frac{1}{2} - \rho\right\},\\
I^{u,in} &= W^{cu} \cap \Delta_{in},\\
p_\epsilon^{in} &= I^{u,in} \cap M_\epsilon,\\
I^{u,out} &= W^{cu} \cap \Delta_{out},\\
p_\epsilon^{out} &= I^{u,out} \cap M_\epsilon.
\end{aligned}$$

Both Δ_{in} and Δ_{out} are two-dimensional objects, as is W^{cu}. $I^{u,in}$ and $I^{u,out}$, however, are one-dimensional, and $p_\epsilon^{in,out}$ are points (at least for fixed ϵ, when M_ϵ is two-dimensional).

Because the point p_ϵ^{in} lies on the center manifold M_ϵ, its evolution will be governed by the dynamics of the fold. The trajectory through p_ϵ^{in} will follow the attracting critical manifold S_a^ϵ around the knee and exit the neighborhood of the knee on the section Δ_{out} at the point p_ϵ^{out}. Since p_ϵ^{in} is also in W^{cu}, the tracked manifold will follow its trajectory around the knee. Upon exiting a neighborhood of the knee, W^{cu} will be spanned by the one-dimensional direction of the flow at p_ϵ^{out} and the one-dimensional fast fibers of M_ϵ at p_ϵ^{out}. See Figure 6.

The important information to take away from the analysis at the knee is the following. When $\epsilon = 0$, the manifold W^{cu} is tangent at the knee to the plane spanned by the vectors $(1, 0, 0)$ and $(1, c, 0)$, which are obtained by setting $v = 1/2$ in (2.11), and has height $h = 4/R$. We need to know how this picture changes for ϵ positive and small. Based on the above analysis, we see that, on leaving a neighborhood of the knee, the tangent plane to W^{cu} is spanned by a vector tangent to the fast unstable fibers of M_ϵ and a vector in the direction of the flow. We know that the unstable fibers of the center manifold M_ϵ perturb smoothly, so their

h component will be $\mathcal{O}(\epsilon)$. The other tangent vector is given by the flow, whose h component is $\mathcal{O}(\epsilon)$. In addition, the height of the tangent plane to W^{cu} is given by $h = 4/R - \mathcal{O}(\epsilon^{2/3})$. Therefore, upon leaving a neighborhood of the knee, the perturbed manifold W^{cu} will be $\mathcal{C}^1$ $\mathcal{O}(\epsilon^{2/3})$ close to the unperturbed one. We remark that the C^1 aspect of the perturbation follows from the fact that the center manifold itself is normally hyperbolic, and therefore its unstable fibers perturb smoothly. It is these fibers that make up W^{cu}. Proposition 2.3 then ensures that the base points of these fibers can change by no more than $\mathcal{O}(\epsilon^{2/3})$.

2.2.2. Completion of the existence proof. We will now follow W^{cu} along the back and W^{cs} backward down the left branch of the slow manifold and show that they intersect transversely. This will complete the existence argument.

We have shown above that when W^{cu} leaves a neighborhood of the knee, its tangent plane is close to a plane that is parallel to the vw plane. One can see directly from (2.1) that, to leading order, any plane parallel to the vw plane is invariant. There is only a finite amount of time between when W^{cu} leaves a neighborhood of the knee and when it enters a neighborhood of the point $(0, 0, 4/R)$. Therefore, by choosing ϵ sufficiently small, we can make the tangent plane to W^{cu}, upon entering this neighborhood, as close to a plane parallel to the vw plane as we like.

The center stable manifold of $(0, 0, 1)$, W^{cs}, consists of the union of the stable manifolds of the saddle points $(0, 0)$ for $h \in [4/R, 1]$. As a result, it will transversely intersect any plane which is parallel to the vw plane. This implies that W^{cs} intersects W^{cu} transversely, which completes the proof. ■

3. Stability of the pulse. The goal of this section will be to prove the following theorem on the linear stability of the traveling pulse.

Theorem 3.1. *The traveling pulse solution, constructed in section 2, is spectrally stable. In other words, the operator obtained by linearizing around the wave (see (3.1)) has no spectrum in* $\{\mathrm{Re}(\lambda) \geq 0\}$ *except for an isolated eigenvalue at the origin of geometric and algebraic multiplicity one.*

We remark that linear stability of the wave follows from a spectral mapping theorem for the strongly continuous semigroup generated by the linear operator in (3.1). In addition, because the zero eigenvalue is isolated, standard arguments, such as invariant manifold theory, can be used to show that the traveling pulse is nonlinearly stable as well [BJ89].

The outline of the proof is as follows. First, we will show that the essential spectrum is bounded to the left of the imaginary axis, although the bound will be dependent on ϵ. We will then construct the Evans function [Eva73, AGJ90] associated with the full problem, for $\epsilon > 0$, followed by the Evans functions associated with the reduced fast pieces along the front and back of the pulse. This will be done in section 3.1. We will then show that eigenvalues of the full Evans function are determined by those of the reduced problems, and use information about the stability of the pulses in the bistable and generalized KPP equations to determine the stability of the pulse. This will be done in section 3.2.

There are two key elements of the argument. First, the spectrum of the reduced fast problem along the back, corresponding to the generalized KPP equation, contains essential spectrum that accumulates at the origin. Thus, one must be careful in analyzing the associated reduced Evans function. We will appeal to the results of [WXY06], in which the Evans function

for algebraically decaying solutions to such equations was analyzed. Second, the loss of normal hyperbolicity at the knee could potentially allow the zeros of the full Evans function to be different than those of the reduced problem. Using techniques similar to those of the existence argument above, we will see that this is not the case.

3.1. Essential spectrum and definition of the Evans function. We will denote the persistent traveling pulse solution to (1.7) by $(V(\xi), H(\xi))$. (Note that this solution is also dependent on the parameter ϵ, although we will suppress this in our notation.) In order to consider the stability of the pulse, assume that solutions to (1.7) have the form $(v,h)(\xi,t) = (V(\xi),H(\xi)) + (p,r)(\xi,t)$. The linearized flow for the new coordinates (p,r), which represent the perturbation of the wave, is then given by

$$\begin{aligned} p_t &= p_{\xi\xi} - cp_\xi + \left(2RHV(1-V) - RHV^2 - 1\right)p + RV^2(1-V)r, \\ r_t &= -cr_\xi + \epsilon g_v(V,H)p - \epsilon r. \end{aligned} \tag{3.1}$$

The associated eigenvalue problem, when written as a first order system, is given by

$$\begin{aligned} p_\xi &= q, \\ q_\xi &= \left(\lambda - 2RHV(1-V) + RHV^2 + 1\right)p + cq - RV^2(1-V)r, \\ r_\xi &= \epsilon\frac{g_v(V,H)}{c}p - \frac{(\lambda+\epsilon)}{c}r. \end{aligned} \tag{3.2}$$

We can write this eigenvalue problem using matrix notation

$$\frac{d}{d\xi}\begin{pmatrix} p \\ q \\ r \end{pmatrix} = A(\xi,\lambda)\begin{pmatrix} p \\ q \\ r \end{pmatrix}, \tag{3.3}$$

where

$$A(\xi,\lambda) = \begin{pmatrix} 0 & 1 & 0 \\ \lambda - 2RHV(1-V) + RHV^2 + 1 & c & -RV^2(1-V) \\ \epsilon\frac{g_v(V,H)}{c} & 0 & -\frac{(\lambda+\epsilon)}{c} \end{pmatrix} \tag{3.4}$$

and the ξ dependence is through the underlying wave, $(V,H) = (V(\xi),H(\xi))$.

3.1.1. Location of the essential spectrum. The essential spectrum is determined by the asymptotic limits of the matrix A, defined in (3.4), which are given by

$$\begin{aligned} A^\infty(\lambda) &= \lim_{\xi\to\pm\infty} A(\xi,\lambda) \\ &= \begin{pmatrix} 0 & 1 & 0 \\ \lambda+1 & c & 0 \\ 0 & 0 & -\frac{(\lambda+\epsilon)}{c} \end{pmatrix}. \end{aligned} \tag{3.5}$$

The boundary of the essential spectrum is given by all values of λ for which this matrix has purely imaginary eigenvalues [Hen81]. This set is given by

$$\{-\epsilon - ick : k \in \mathbb{R}\} \cup \{-k^2 - ick - 1 : k \in \mathbb{R}\}.$$

In addition, by [Hen81], the essential spectrum lies to the left of the above boundary: $\sigma_{ess} \subset \{\lambda \in \mathbb{R} : \mathrm{Re}(\lambda) \leq -\epsilon\}$. In the limit $\epsilon \to 0$, the essential spectrum will approach the imaginary axis. However, this will not affect the definition of the Evans function, as given below. We define $\Omega = \Omega(\epsilon)$ to be the open region in the complex plane that lies to the right of the essential spectrum, containing the right half plane.

3.1.2. Definition of the Evans function. The eigenvalues of the asymptotic matrix $A^{\infty}(\lambda)$, defined in (3.5), are given by

$$\nu_0 = -\frac{(\lambda+\epsilon)}{c}, \quad \nu^{\pm} = \frac{c}{2} \pm \frac{1}{2}\sqrt{c^2 + 4(\lambda+1)}.$$

For $\lambda \in \Omega$, $\nu^+(\lambda)$ is the unique eigenvalue with positive real part. One can check that there exists a b, independent of ϵ, such that, for all ϵ sufficiently small and all $\lambda \in \tilde{\Omega} := \{\lambda : \mathrm{Re}(\lambda) > -b\}$, $\nu^+(\lambda)$ remains the unique eigenvalue with largest real part. (Note that $\tilde{\Omega}$ is slightly larger than, but contains, Ω, for ϵ sufficiently small.) This remains true even when the real part of ν_0 changes sign. The eigenvector associated with ν^+ is given by $X^+ = (1, \nu^+, 0)^t$. As a result, there exists a unique solution to (3.3), $\zeta(\xi, \lambda)$, such that

$$\lim_{\xi \to -\infty} \zeta(\xi, \lambda) e^{-\nu^+(\lambda)\xi} = X^+(\lambda). \tag{3.6}$$

Consider now the associated adjoint problem,

$$\frac{d}{d\xi} Z = -\bar{A}^T(\lambda, \xi) Z. \tag{3.7}$$

Similarly, for $\lambda \in \tilde{\Omega}$, there is a unique eigenvalue of the associated asymptotic matrix with smallest real part. This eigenvalue is given by $\mu^-(\lambda) = -\bar{\nu}^+(\lambda)$, and its associated eigenvector is $Y^- = (\mu^- - c, 1, 0)^t$. For $\lambda \in \tilde{\Omega}$, we have that $\mathrm{Re}(\mu^-) < 0$. There exists a unique solution to (3.7), $\eta(\xi, \lambda)$, such that

$$\lim_{\xi \to +\infty} \eta(\xi, \lambda) e^{-\mu^-(\lambda)\xi} = Y^-(\lambda). \tag{3.8}$$

The Evans function [AGJ90] is then defined by

$$D(\lambda) = \zeta(\xi, \lambda) \cdot \eta(\xi, \lambda). \tag{3.9}$$

As in [Jon84], $D(\lambda)$ can be shown to be analytic on $\tilde{\Omega}$. This is because ν^+ and μ^- are the unique eigenvalues with largest and smallest real part, respectively, in $\tilde{\Omega}$, uniformly in ϵ, even as λ crosses into the essential spectrum. (For additional information on the extension of the Evans function into the essential spectrum, see, for example, [KS98, GZ98].) For $\lambda \in \Omega$, the zeros of $D(\lambda)$, along with their multiplicities, correspond to the eigenfunctions of the linear operator in (3.1). For $\lambda \in \tilde{\Omega}$, however, this relationship does not necessarily hold. Technically, the actual Evans function, $D(\lambda)$, is defined only on Ω, and the Evans function we consider is an analytic extension of it (sometimes denoted by $\tilde{D}(\lambda)$) into $\tilde{\Omega}$. We will not emphasize this distinction here.

3.2. Locating zeros of $D(\lambda)$ in the right half plane. The goal of this section is to show that the only zero of $D(\lambda)$ with $\mathrm{Re}(\lambda) \geq 0$ is $\lambda = 0$, and that its geometric and algebraic multiplicity is one. The argument will be similar to that in [Jon84], although we will have to do a bit of extra work to account for the loss of hyperbolicity in the knee of the existence construction.

The outline of the argument is as follows. First, we will construct the reduced Evans functions associated with the fast flow along the front and back of the pulse and show that the only zero in the closed right half plane is at the origin and associated with the front. The back does not contribute a zero there because of its algebraic decay at $-\infty$. This is a key difference between this problem and the stability of the pulse in the FitzHugh–Nagumo system. Next, it will be shown that any zeros of the full Evans function must be close to zeros of the reduced Evans functions. Thus, because there exists a unique zero of the reduced Evans functions in the right half plane, and we know it remains at zero for the full system due to translation invariance of the underlying wave, the wave must be spectrally stable. Note that it is not necessary to compute the derivative of the Evans function at the origin, as it was for the FitzHugh–Nagumo model, since there is no second zero to locate.

3.2.1. The reduced Evans functions. In this section, we consider the reduced Evans functions for the fast equation along the front and back of the pulse. We will show that both reduced Evans functions have no zeros with $\{\mathrm{Re}(\lambda) \geq 0\} \setminus \{0\}$, and that there is only one zero at $\lambda = 0$, associated with the front.

Recall that, along the front, to leading order we have $h \equiv 1$. As a result, the reduced, fast PDE that governs the dynamics of the front is given by

$$v_t = v_{\xi\xi} - cv_\xi + Rv^2(1-v) - v. \tag{3.10}$$

As mentioned above, this is just the bistable equation, and the front is the heteroclinic connection between 0 at $-\infty$ and $v^+(1)$ at $+\infty$. Up to rescaling, this is also the equation that governs the dynamics of the front of the pulse for the FitzHugh–Nagumo equation. Its Evans function was analyzed in detail in [Jon84], and we summarize those results in the following proposition.

Proposition 3.2 (see [Jon84]). *Let $D_F(\lambda)$ denote the reduced Evans function that one obtains from the stability analysis of the heteroclinic front of (3.10). Then D_F is analytic in $\tilde{\Omega}$ and*

1. $D_F(0) = 0$,
2. $D_F(\lambda) \neq 0$ *for all* $\lambda \in \tilde{\Omega} \setminus \{0\}$.

In [Jon84], it was also shown that $\frac{d}{d\lambda} D_F(\lambda)|_{\lambda=0} > 0$, although we will not need that fact here. However, we do need that the derivative of the Evans function at 0 is nonzero, for simplicity of the eigenvalue. We remark that the b in the definition of $\tilde{\Omega}$ may need to be chosen slightly smaller than above in order for this proposition to hold.

Next, consider the reduced PDE for the back,

$$v_t = v_{\xi\xi} - cv_\xi - v(2v-1)^2, \tag{3.11}$$

where c is the wavespeed that was selected in the analysis of the front (see (2.7) for $h = 1$). As mentioned above, this is the generalized Fisher–KPP equation of order 2. The back is a

heteroclinic connection between $1/2$ at $-\infty$ and 0 at $+\infty$. It is asymptotic to a stable manifold at $+\infty$, but a center manifold at $-\infty$, where it decays only algebraically. In addition, the essential spectrum of the associated linearized operator is contained in a parabolic region of the left half plane that touches the imaginary axis at the origin. As a result, the stability analysis of the back and construction of the associated reduced Evans function is a bit more subtle. However, this analysis has been carried out in [WXY06], and we collect the relevant results.

Proposition 3.3 (see [WXY06]). *Let $D_B(\lambda)$ denote the reduced Evans function that one obtains from the stability analysis of the heteroclinic solution of* (3.11). *Then*

1. *D_B is analytic in $\tilde{\Omega}$,*
2. *$D_B(\lambda) \neq 0$ for all $\lambda \in \tilde{\Omega}$.*

Again, it may be necessary to take b in the definition of $\tilde{\Omega}$ to be slightly smaller than above.

It may be surprising that the derivative of the heteroclinic solution does not lead to a zero of the reduced Evans function at the origin. This is because the Evans function in [WXY06] is constructed using the strong unstable eigenvalue at $-\infty$. Since the wave decays only algebraically there, it is asymptotic to the weak unstable direction and, therefore, does not contribute a zero. See Theorem 2.1 and Lemma 4.1 of [WXY06] for more details.

3.2.2. Approximation of eigenvalues. We now show that any zero of the Evans function $D(\lambda)$ in $\tilde{\Omega}$ must be near the unique zero of $D_F(\lambda)$ and $D_B(\lambda)$ in that region, $\lambda = 0$. Let B_δ denote the ball of radius δ at 0, where δ is chosen sufficiently small so that $B_\delta \subset \tilde{\Omega}$, and let $G = \tilde{\Omega} \setminus B_\delta$.

Lemma 3.4. *$D(\lambda) \neq 0$ for all $\lambda \in G$.*

Proof. First, we note that we need only consider a bounded region within G, say $\hat{G} = \{\lambda \in G : |\lambda| < M\}$ for some fixed M that is independent of ϵ. This can be shown using a scaling argument [San02].

Fix $\lambda \in \hat{G}$ and consider $\zeta(\xi, \lambda)$ and $\eta(\xi, \lambda)$, defined in (3.6) and (3.8). We will track ζ around the pulse until ξ is sufficiently large and then show that it cannot be orthogonal to η.

The main idea is to show that, in the absence of an eigenfunction for the reduced fast flows, the strong unstable direction is always an attractor for the evolution of ζ. As a result, if $\lambda \in \hat{G}$, then the unstable direction completely determines the evolution of ζ, and we can use it to track the evolution around the pulse and show it cannot be orthogonal to η. This argument will be similar to that of [Jon84], and so some details will be omitted.

In order to follow $\zeta(\xi, \lambda)$ around the pulse, we must track its evolution according to (3.2). To make this more precise, one must couple the traveling wave system (2.1) to (3.2) and track the combined solution $((V(\xi), W(\xi), H(\xi)), (p(\xi), q(\xi), r(\xi)))$. However, for our purposes it is sufficient to refer only to system (3.2). In addition, in [Jon84] the wave was parameterized by $\theta \in S^1$, but we will not discuss this further here.

First, we track ζ along the fast front. If $v_F(\xi)$ and $w_F(\xi)$ denote the leading order fast pulse along the front, then the eigenvalue problem associated with (3.10) is

$$\begin{aligned} v_\xi &= w, \\ w_\xi &= [\lambda - 2Rv_F(1 - v_F) + Rv_F^2 + 1]v + cw. \end{aligned} \tag{3.12}$$

The reduced Evans function along the front is defined by $D_F(\lambda) = \zeta_F(\xi, \lambda) \cdot \eta_F(\xi, \lambda)$, where ζ and η are defined analogously to (3.6) and (3.8).

To leading order, $\zeta(\xi, \lambda) = (\zeta_F(\xi, \lambda), 0)$ and $\eta(\xi, \lambda) = (\eta_F(\xi, \lambda), 0)$. In other words, the components of the full Evans function are just the inclusions in $\mathbb{R}^3$ of their reduced counterparts. Therefore, to leading order, the reduced equation can be used to track the evolution of ζ along the front of the wave.

We are really only interested in the direction of the vector $\zeta(\xi, \lambda)$, which can be studied using the projectivized version of (3.2). To that end, define $(a, b) := \pi(p, q, r) = (q/p, r/p)$. Thus, $\pi : \{(p, q, r) \in \mathbb{C}^3 : p \neq 0\} \to \mathbb{CP}^2$. The evolution of (a, b) is governed, to leading order, by

$$\begin{aligned} a' &= [\lambda - 2RHV(1 - V) + RHV^2 + 1] + ca - RV^2(1 - V)b - a^2, \\ b' &= -\frac{\lambda}{c}b - ab. \end{aligned} \tag{3.13}$$

The eigenvector associated with the unique largest eigenvalue of an ODE always corresponds to a stable fixed point of the corresponding projectivized system. If we fix λ and consider the "frozen" version of (3.13), where ξ is fixed on the right-hand side, then the projectivized version of that eigenvector is an attractor for the system. Taking a union over all ξ in some interval, for example, we would obtain an attractor for the evolution of (3.13) in that interval. (Note: this fact relies on the compactness of $\hat{G}$.) If we then let $\hat{\zeta}$ denote the projectivized version of ζ, that attractor would govern the evolution of $\hat{\zeta}$ along that interval.

We could similarly construct the projectivized version of the reduced equation (3.12). The unstable direction is an attractor for $\hat{\zeta}_F$ as it follows the front. For $\lambda \in \hat{G}$, we know that the reduced system does not have an eigenvalue, and so $\hat{\zeta}_F$ will approach the unstable direction as $\xi \to +\infty$. Thus, when the pulse enters a neighborhood of the invariant slow manifold, $\hat{\zeta}(\xi, \lambda)$ will be equal, to leading order, to the direction of the unstable fast fiber of the manifold.

Next, we need to track $\hat{\zeta}$ down along the slow manifold until the pulse enters a neighborhood of the knee. Using the projectivized equations associated with the fast flow for any fixed $h \in (4/R, 1]$, one sees that the union of the unstable eigenvectors associated with the fixed points $(v^+(h), 0)$ of (2.2) is an attractor. As a result, as $\hat{\zeta}$ follows the first slow piece of the pulse, it will remain close to the direction of the unstable fibers of the slow manifold, until it enters a neighborhood of the knee.

Now we must track $\hat{\zeta}$ around the knee. For $\lambda \in \hat{G}$, the presence of the knee does not pose any additional complications, and the analysis follows as in [Jon84]. This is because, when $(V, H) \sim (1/2, 4/R)$ at the knee, (3.2) is hyperbolic for $\lambda \neq 0$. There is still a unique largest eigenvalue, and $\hat{\zeta}$ will be attracted to the direction of its corresponding eigenvector.

The analysis of the evolution of $\hat{\zeta}$ along the back is similar to that of the front, above. The key fact is that, when $\hat{\zeta}$ emerges from a neighborhood of the knee, it will be close to the strong unstable direction. Since this direction corresponds to the unstable fiber of the (normally hyperbolic) center manifold, it will perturb smoothly. In other words, it is a tangent vector living in the tangent space of the traveling wave (which is $\mathcal{O}(\epsilon^{2/3})$ close to the leading order wave), and its direction is C^1 $\mathcal{O}(\epsilon)$ close to the leading order strong unstable direction. Since it is this direction that is used to construct the Evans function in [WXY06], we can

then use those results to conclude that any zero of the full Evans must be near a zero of the reduced Evans function.

Because the reduced equation, the linearization of the generalized KPP equation, does not have a eigenvalue in $\hat{G}$, $\hat{\zeta}$ must be $\mathcal{O}(\epsilon)$ close to the direction of the unstable fibers as the pulse enters a neighborhood of the slow invariant manifold. Thus, we can follow it up along the slow manifold S_l and conclude that it is not orthogonal to $\hat{\eta}(\xi,\lambda)$ when the pulse enters a neighborhood of the fixed point $(0,0,1)$. Because the $\hat{\zeta}$ and $\hat{\eta}$ determine the directions of the vectors ζ and η, this proves that ζ and η are not orthogonal, as well. ■

3.2.3. Winding number calculation. We know from the previous section that any potential unstable eigenvalues must lie in B_δ, the ball of radius δ at the origin. Let $K = \partial B_\delta$ denote the boundary of that ball, and choose δ sufficiently small that zero is the only eigenvalue of either reduced fast system that is contained in B_δ. We will compute the winding number of $D(\lambda)$ along K and show that it is one. This will show that there is exactly one zero of the Evans function in $\tilde{\Omega}$, which implies that there is exactly one eigenvalue of geometric and algebraic multiplicity one in $\tilde{\Omega}$ [AGJ90]. Since we know there must exist an eigenvalue at $\lambda = 0$, it is the only one. This will complete the proof of Theorem 3.1. We remark that, again, this argument is similar to that of [Jon84], and so we do not include all of the details here. As above, we must check that the presence of the knee does not affect the winding number.

Note that an analytic extension of the Evans function is defined for all $\lambda \in B_\delta \cup K$, uniformly in ϵ, and that it is nonzero on K. Any zero inside B_δ necessarily corresponds to an eigenvalue only if it is in $\Omega \cup \{0\}$.

In the previous section, it was shown that the projectivized equations can be used to track $\hat{\zeta}$ around the pulse. If we take an element $(q/p, r/p) \in \mathbb{CP}^2$, then we can associate it with an element in $\mathbb{C}^3$ using $\pi^{-1}(q/p, r/p) = (1, q/p, r/p)$, which is just a normalized version of the vector (p,q,r). When computing the winding number we will need not only the direction of the vector, but its amplitude as well. One can directly check that, for any ξ such that $p(\xi,\lambda) \neq 0$,

$$\zeta(\xi,\lambda) = p(\xi,\lambda)[\pi^{-1}(\hat{\zeta})](\xi,\lambda).$$

The Evans function is independent of ξ, and so we can evaluate the expression on the right-hand side of (3.9) at any value of ξ we choose. It is convenient to pick some sufficiently large value of ξ, denoted by T_4. One can then show that $W(D(K)) = W(p(T_4, K))$. The proof of this fact follows closely that in [Jon84], and so we do not repeat it here.

Let T_0 be the value of ξ for which the underlying wave exits a neighborhood of $(0,1)$, T_1 be the value at which it enters a neighborhood of $(v^+(1),1)$, T_2 be the value at which it exits a neighborhood of $(1/2, 4/R)$, and T_3 be the value at which it enters a neighborhood of $(0, 4/R)$. Similar to the previous section, we will track the evolution of $p(\xi,\lambda)$ around the underlying pulse and evaluate the winding numbers $W(p(T_i, K))$ for $i = 0, \ldots, 4$, showing

1. $W(p(T_0, K)) = 0$,
2. $W(p(T_1, K)) = 1$,
3. $W(p(T_2, K)) = 1$,
4. $W(p(T_3, K)) = 1$,
5. $W(p(T_4, K)) = 1$.

Note that, in [Jon84], it was shown $p(T_i, K) \neq 0$ for $i = 0, 4$. In other words, as p moves along the pulse, the corresponding winding number increases by one only as it moves along the front, due to the eigenvalue of the reduced system there. Along the rest of the wave, it remains constant.

The proof essentially follows from the results in [Jon84]. The only thing one needs to check, due to the presence of the knee, is that $W(p(T_2, K)) = 1$. This would follow if $p(\xi, \lambda) \neq 0$ for all $\xi \in [T_1, T_2]$, uniformly for λ near zero. This is because one could then construct a homotopy between $p(T_1, K)$ and $p(T_2, K)$ to show that their winding numbers are equal.

Consider the projectivized system (3.13) near the knee, i.e., for $(V, H) \sim (1/2, 4/R)$,

$$a' = \lambda + ca - \frac{R}{8}b - a^2,$$
$$b' = -\frac{\lambda}{c}b - ab.$$

The three fixed points of this system are $(a^+(\lambda), 0)$, $(a^-(\lambda), 0)$, and $(-\lambda/c, -8\lambda^2/Rc)$, where $a^\pm = (c \pm \sqrt{c^2 + 4\lambda})/2$. These correspond to the unstable, stable, and center directions of the slow manifold, respectively. As $\lambda \to 0$, $(a^-, 0)$ and $(-\lambda/c, -8\lambda^2/Rc)$ coincide, but the remaining fixed point remains separate, uniformly in λ. It is this direction that defines the attractor that $\hat{\zeta}$ follows as it moves along the wave. Since these fast unstable directions always point along vectors with nonzero p component, this shows that $p(\xi, \lambda) \neq 0$ for all $\xi \in [T_1, T_2]$, uniformly for λ near zero, just as in [Jon84].

In other words, the evolution of $\hat{\zeta}$, and hence the winding number, is determined primarily by the behavior of the strong unstable direction to which it is attracted. Since we have shown that this direction remains unique despite the nonhyperbolicity at the knee, the winding number calculation in essentially the same as in [Jon84].

By continuing to follow ζ along the pulse, we arrive at $W(p(T_4, K)) = W(D(K)) = 1$. This proves that there is only one zero of the Evans function in $\tilde{\Omega}$, and since we know there exists a zero at the origin, it must be the only one. This concludes the proof of the spectral stability of the wave.

4. Spatially periodic waves. We now briefly remark on the existence and biological relevance of spatially periodic waves, which will be the subject of future work.

Recall from (2.7) and (2.8) that the fast jumps exist for explicitly computable values of the wavespeed. If we can find a c_{per} and an $h_{per} \in (4/R, 1)$ such that a fast jump exists at h_{per} from $v = 0$ at $\xi = -\infty$ to $v = v^+(h_{per})$ at $\xi = +\infty$, and $c_{per} = c(h_{per}, R) > \sqrt{2}/2$, then we would be able to construct a leading order periodic solution consisting of the following four pieces:

1. a fast jump from $(0, 0, h_{per})$ to $(v^+(h_{per}), 0, v^+(h_{per}))$, which is given explicitly in (2.7), with $c_{per} = c(R, h_{per})$,
2. slow decay along S_r,
3. a fast jump from $(1/2, 0, 4/R)$ to $(0, 0, 4/R)$, with $c_{per} = c(R, h_{per})$,
4. slow growth along S_l back to $(0, 0, h_{per})$.

Note we require that $c_{per} > \sqrt{2}/2$, so that the second fast jump must occur at the knee along the center manifold. If $c_{per} \leq \sqrt{2}/2$, then the second fast jump would leave the slow manifold

along an unstable manifold, which is not what happens in cardiac dynamics, as discussed in section 1.

In Figure 3, we see that such an orbit is possible only if $R > 25/4$. Otherwise, the first fast jump will necessarily occur for a value of the wavespeed less than $\sqrt{2}/2$. If $R > 25/4$, then a first fast jump with sufficiently large wavespeed exists for $h > 25/4R$. As a result, there exists at leading order a family of periodic orbits, one for each $h_{per} \in (25/4R, 1)$.

Regarding the investigation of the persistence of this family, for $\epsilon > 0$, we expect that a combination of the techniques used to prove the existence of a family of spatially periodic solutions to the FitzHugh–Nagumo equation [Car77] and the blow-up, used in this paper, will be applicable. To investigate stability, it is possible that the theory developed in [Gar97, SS01] will apply. In those papers, the authors investigated the linear stability of families of periodic waves of reaction diffusion equations that are close to a homoclinic orbit—at least for sufficiently large period—and, in particular, applied their results to the family of periodic solutions of the FitzHugh–Nagumo equation.

Periodic solutions are of biological interest because they represent a beating heart. In cardiac models, the stability of these periodic waves cannot persist indefinitely as the period is shortened. Even the ODE model suffers a period-doubling bifurcation as the pacing period is shortened. The bifurcation in the PDE context is more complicated than simple period doubling—see, for example, [EK02, EK06]. We plan to study this bifurcation in a subsequent publication.

Canard Induced Mixed-Mode Oscillations in a Medial Entorhinal Cortex Layer II Stellate Cell Model*

Horacio G. Rotstein†, Martin Wechselberger‡, and Nancy Kopell§

Abstract. Stellate cells (SCs) of the medial entorhinal cortex (layer II) display mixed-mode oscillatory activity, subthreshold oscillations (small-amplitude) interspersed with spikes (large amplitude), at theta frequencies (8–12 Hz). In this paper we study the mechanism of generation of such patterns in an SC biophysical (conductance-based) model. In particular, we show that the mechanism is based on the three-dimensional canard phenomenon and that the subthreshold oscillatory phenomenon is intrinsically nonlinear, involving the participation of both components (fast and slow) of a hyperpolarization-activated current in addition to the voltage and a persistent sodium current. We discuss some consequences of this mechanism for the SC intrinsic dynamics as well as for the interaction between SCs and external inhibitory inputs.

Key words. theto rhythm, reduction-of-dimensions, mixed-mode oscillations, canards, folded node

1. Introduction.

The entorhinal cortex (EC) is the interface between the neocortex and the hippocampus [1], and it plays a very important role in orchestrating the flow of information between these two areas of the brain. Neocortical information flows to the hippocampus, to be processed, through the superficial layers (II and III) of the EC. The spiny stellate cells (SCs) are the most abundant principal cell type in layer II of the medial EC [1, 2]. These cells give rise to the main afferent fiber system to the hippocampus. In addition, in layer II of the EC grid cells are putative SCs [3] (and see references therein). Grid cells are principal neurons that exhibit multiple phase fields arranged in hexagonal patterns [4, 5, 6]. Their recent discovery implies that the EC contains a neural map of the spatial environment which is then transmitted to the hippocampus.

In vitro electrophysiological investigations have shown that, when depolarized, SCs develop small-amplitude rhythmic subthreshold membrane potential oscillations (STOs) at theta frequencies (8–12 Hz). If the membrane potential is depolarized further, then SCs fire action potentials at the peak of the STOs but not necessarily at every STO's cycle [7]. The amplitudes of STOs and spikes differ roughly in an order of magnitude. We refer to the resulting temporal patterns (combination of STOs and spikes) as mixed-mode oscillations (MMOs).

These are a distinctive property of SCs in layer II of the medial EC [8, 9, 10], and they can also be found in in vivo electrophysiological studies [11].

Theta frequency STOs and MMOs in SCs are intrinsic single-cell phenomena [8] and have been shown to result from the interaction between two currents: a persistent sodium current (I_p) and a hyperpolarization activated current (I_h) [9]. Mathematical (conductance-based) models, incorporating I_p and I_h in addition to the spiking currents (transient sodium, delayed rectifier potassium, and leak), have been used to reproduce, via simulations, several aspects of the SC dynamics [12, 13, 14]. However, the mechanistic aspects of the generation of STOs and MMOs are still not fully understood.

The goal of this paper is to uncover the mechanism of generation of STOs and MMOs in the biophysical SC model proposed in [12], and to identify the key parameters controlling the transition among the various types of MMO patterns. We use analytical and computational techniques to show that, as hypothesized in [10], the generation of STOs and the onset of spikes in this model is governed by the three-dimensional canard phenomenon [15, 16, 17]. Qualitatively different mechanisms have been proposed to explain the generation of MMOs in other models. These are break-up of an invariant torus [18], break-up (loss) of stability of a Shilnikov homoclinic orbit [19, 20], and subcritical Hopf-homoclinic bifurcation [21, 22]. See also [17, 23] and other articles in the focus issue on MMOs introduced in [24] for a detailed discussion.

In section 2 we provide some biophysical and mathematical background related to the generation of MMOs in SCs. We briefly describe the key experimental findings and the biophysical SC model that we use in this paper. This model is a three-dimensional (3D) reduction [10] of the 7D model presented in [12]. The former, which we will refer to as the SC model, is a good approximation to the latter in the subthreshold regime where STOs and the onset of spikes are observed [10], thus allowing the investigation of the mechanisms of generation of STOs and MMOs. In addition, we explain some basic aspects on the canard phenomenon.

In section 3 we describe the (dimensional) SC model and nondimensionalize it to uncover the multiple time-scale nature of the model. In particular, we show that the membrane potential evolves on a much faster time scale than the h-current gating variables (r_f and r_s). Although the former is faster than the latter, there is no significant time scale separation between the two gates compared with the time scale separation introduced by the fast voltage dynamics. Therefore both gating dynamics of the h-current are considered as slow. For the remainder of this paper we use this dimensionless SC model. However, the results will be presented in terms of both the dimensional and dimensionless values of the relevant parameters. We also present the result of our simulations using this SC model showing MMO patterns and their corresponding phase-space diagrams.

In section 4 we analyze the mechanism of generation of MMOs in the SC model using numerical and analytical techniques. We show that for the relevant (biophysically plausible) parameters the SC model can be put into the analytic and geometric 3D canard framework described in [16] for the generation of small-amplitude oscillations (see also [17]). We describe this framework using notation tailored to the model. In addition, we describe the return mechanism necessary to bring trajectories back to the subthreshold regime after they escape it towards the spiking one.

Our approach provides a geometric framework to qualitatively understand and predict the dynamic properties of the resulting MMO patterns. In particular, it allows us to study the dependence of these patterns on the relevant parameters: the I_h and I_p maximal conductances, the applied DC (constant) current, and the initial conditions of the participating variables in the subthreshold regime. These initial conditions reflect the reset properties of I_h after a spike has occurred. In addition, following the "canard approach," we explain how inhibitory pulses applied at different times after a spike has occurred may suppress some of the STOs of the unperturbed cell and advance the timing of the next spike. This type of calculation is the first step in the computation of spike-time response curves [12, 25, 26], which are used in the study of synchronization properties of small neural networks. We discuss our results and their implications for the understanding of SC dynamics in section 5.

2. Background.

2.1. Biophysics of subthreshold and mixed-mode oscillations in stellate cells. Voltage changes in single (isolated) neurons are the result of the flow of ionic currents into and out of the cells. Typically, three currents are involved in the generation of spikes: a transient sodium current (I_{Na}), a delayed-rectifier potassium current (I_K), and a leak current (I_L) [27]. We refer to them as the standard spiking currents. Spikes are usually initiated by the activation of I_{Na} and terminated by its inactivation followed by the activation of I_K. Additional (nonstandard or nonspiking) currents may be present and play various different roles in neural dynamics. Two nonstandard currents have been implicated in the pacemaking of single-cell rhythmicity at theta frequencies: a persistent sodium current (I_p) and an h-current (I_h) [7, 8, 9, 13, 28, 29, 30, 31, 32] (see also references therein). The former constitutes a depolarization-activated fast inward current that precisely tracks voltage changes and provides the main drive for the depolarizing phase of the STOs. The latter is a hyperpolarization-activated (noninactivating) current with slow activation kinetics, and it provides a delayed feedback effect that promotes resonance [33].

2.2. MMOs in a biophysically plausible SC model. In recent work, Rotstein et al. [10] showed that the biophysical (conductance-based) SC model presented in [12] displays STOs and MMOs, and they initiated a mechanistic study of these phenomena using computational tools and dynamical systems ideas. In [10], reduction-of-dimension techniques were used to reveal a three-dimensional reduced model that is a good approximation to the "full" seven-dimensional SC model in the subthreshold regime where STOs and the onset of spikes occur. This reduced model describes the evolution of the membrane potential V (mV) and the two (fast and slow) h-current gating variables r_f and r_s (dimensionless). The latter describe the opening/closing of the h-current ion channels. In [10] it was found that both I_{Na} and I_K can be neglected in the subthreshold regime where STOs and MMOs are generated, and that the persistent sodium gating variable p has fast dynamics, so the adiabatic approximation can be made; i.e., p can be well approximated by its corresponding voltage-dependent activation curve (see section 3). The resulting equations are presented in section 3, in formulas (1)–(3). As mentioned above, these equations describe the generation of STOs and the onset of spikes, which occurs in the subthreshold regime, but they do not describe the spike dynamics and the early recovery from spiking, which belong to a different regime (where I_{Na} and I_K are the

main active currents) [10]. If one is not interested in the spike details, the dynamics of the SC can be approximately described by (1)–(3) supplemented with an "artificial spike," operating in a much shorter time scale and reaching a peak of about 50 mV. This model has been called the nonlinear artificially spiking (NAS) SC model [10], a class of models that includes the generalized integrate-and-fire models (see [10, 34, 35] for details). For simplicity, in the remainder of this paper we will refer to it as the SC model. When working with this (NAS) SC model, one has to give appropriate threshold (V_{th}) and reset (V_{rst}) values. The former indicates that the trajectory has reached the spiking regime. The latter is the voltage value after a spike has occurred and represents the initial condition in the subthreshold regime. Note that, differently from other types of NAS models, V_{th} is not part of the mechanism of generation of action potentials which, as shown here and in [10], result from the dynamics of the so-called canard structure.

2.3. The canard phenomenon. Canards [36] were first studied in two-dimensional (2D) relaxation oscillators [37, 38, 39, 40], particularly in the van der Pol oscillator. There, the nature of the classical canard phenomenon is the transition from a small-amplitude oscillatory state created in a Hopf bifurcation to a large-amplitude relaxation oscillatory state within an exponentially small range of a control parameter. This transition, also called canard explosion, occurs through a sequence of canard cycles which can be asymptotically stable and is hard to observe in an experiment because of sensitivity to the control parameter. This is well known in the chemical literature, where a canard explosion is classified as a hard transition [41, 42]. Therefore, 2D slow-fast systems display either STOs or large-amplitude oscillations but no MMOs. However, MMOs are possible by the addition of noise [43, 44].

Deterministic 3D slow-fast systems with one fast and two slow variables can produce MMOs [10, 16, 17, 23, 45, 46, 47, 48, 49] (see also the articles in the focus issue on MMOs introduced in [24]). One way to explain these patterns is based on a generalized canard phenomenon, because a special class of canards in three dimensions called canards of folded node (or folded saddle-node) type can be responsible for small-amplitude oscillations [16, 46]. A good intuition for MMOs is that a system moves dynamically from a small-amplitude oscillatory state to a relaxation oscillatory state, and the feature of the large relaxation oscillation is to bring the system back to the basin of attraction of the small-amplitude oscillatory state. A detailed explanation of this generalized canard phenomenon is given in section 4.

3. The model.

3.1. Dimensional formulation. The dimensional equations are

$$C\frac{dV}{dt} = I_{app} - G_L\,(V - E_L) - G_p\,p_\infty(V)\,(V - E_{Na}) - G_h\,(c_f\,r_f + c_s\,r_s)\,(V - E_h), \tag{1}$$

$$\frac{dr_f}{dt} = \frac{r_{f,\infty}(V) - r_f}{\tau_{r_f}(V)}, \tag{2}$$

$$\frac{dr_s}{dt} = \frac{r_{s,\infty}(V) - r_s}{\tau_{r_s}(V)}, \tag{3}$$

where V is the membrane potential (mV), C is the membrane capacitance (μF/cm^2), I_{app} is the applied bias (DC) current (μA/cm^2), $I_L = G_L\,(V - E_L)$, $I_p = G_p\,p_\infty(V)\,(V - E_{Na})$, and

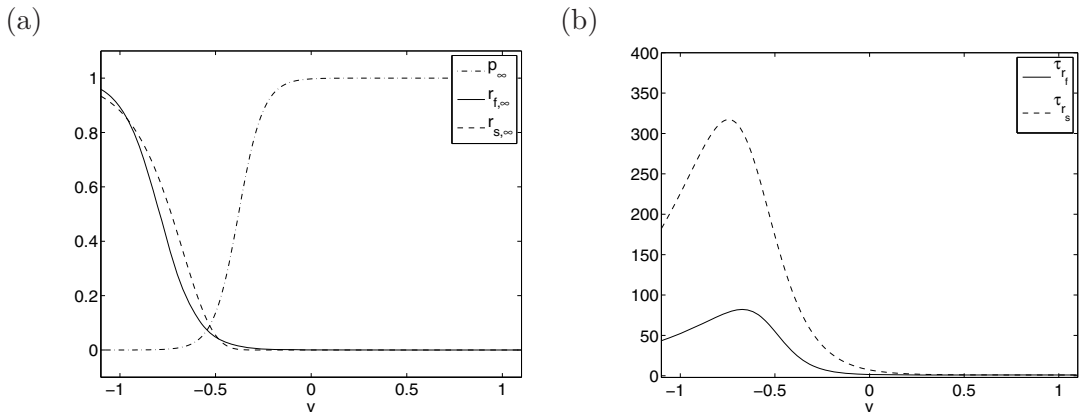

Figure 1. *SC model (1)–(3). (a) Activation/inactivation curves: $p_\infty(v)$, $r_{f,\infty}(v)$, and $r_{s,\infty}(v)$. (b) Voltage-dependent time scales: $\tau_{r_f}(v)$ and $\tau_{r_s}(v)$. The dimensionless voltage v is the result of the rescaling $v = V/K_v$ with $K_v = 100\,mV$.*

$I_h = G_h\,(\,c_f\,r_f + c_s\,r_s\,)\,(\,V - E_h\,)$ [10]. The parameters G_X and E_X $(X = L, p, Na, h)$ are the maximal conductances ($\mathrm{mS/cm^2}$) and reversal potentials (mV), respectively. The units of time are ms. The variables r_f and r_s are the h-current fast and slow gating variables, and the parameters c_f and c_s represent the fraction of the total h-current corresponding to its fast and slow components, respectively. Unless stated otherwise, we will use the following values for the parameters [10, 12]: $E_{Na} = 55$, $E_L = -65$, $E_h = -20$, $G_L = 0.5$, $G_p = 0.5$, $C = 1$, $c_f = 0.65$, and $c_s = 0.35$. The functions $r_{f,\infty}(V)$, $r_{s,\infty}(V)$, and $p_\infty(V)$ are the voltage-dependent activation/inactivation curves, and the functions $\tau_{r_f}(V)$ and $\tau_{r_s}(V)$ are the voltage-dependent time scales. They are given by $r_{f,\infty}(V) = 1/(1 + e^{(V+79.2)/9.78})$, $r_{s,\infty}(V) = 1/(1 + e^{(V+2.83)/15.9})^{58}$, $p_\infty(V) = 1/(1 + e^{-(V+38)/6.5})$, $\tau_{r_f}(V) = 0.51/(e^{(V-1.7)/10} + e^{-(V+340)/52}) + 1$, and $\tau_{r_s}(V) = 5.6/(e^{(V-1.7)/14} + e^{-(V+260)/43}) + 1$. The graphs of these functions are shown in Figure 1.

3.2. Initial and threshold conditions in the subthreshold regime. The initial conditions in the subthreshold regime are given by the reset values of the participating variables after a spike has occurred. For r_f and r_s these reset values can be derived from the 7D SC model [10]. More specifically, during a spike, V increases above zero to a value $V \sim 50\,\mathrm{mV}$. For these values of V, $r_{f,\infty}(V) \sim 0$ and $r_{s,\infty}(V) \sim 0$ (see Figure 1(a)). In addition, for these high values of V, both $\tau_{r_f}(V)$ and $\tau_{r_s}(V)$ are very small (see Figure 1(b)). Therefore, both r_f and r_s quickly decrease to values close to $r_f \sim r_s \sim 0$. The reset value of $V \sim -80\,\mathrm{mV}$ is estimated from numerical simulations of the 7D SC model [10]. Unless stated otherwise, we take $(V, r_f, r_s) = (-80, 0, 0)$ as the initial conditions of system (1)–(3), and we reset the trajectory to these values after each spike has occurred.

Since action potentials in this model are initiated at $V \sim -50\,\mathrm{mV}$ (see, e.g., Figure 2) we may set the voltage threshold value V_{th} for this event to any value $V > -50\,\mathrm{mV}$. Here we choose a value $V_{th} = -40\,\mathrm{mV}$, which is well above the initiation value. We emphasize that the spike results from the dynamics of the SC model, and, consequently, V_{th} only indicates that a spike has occurred and is not a component of the mechanism of spike generation [10].

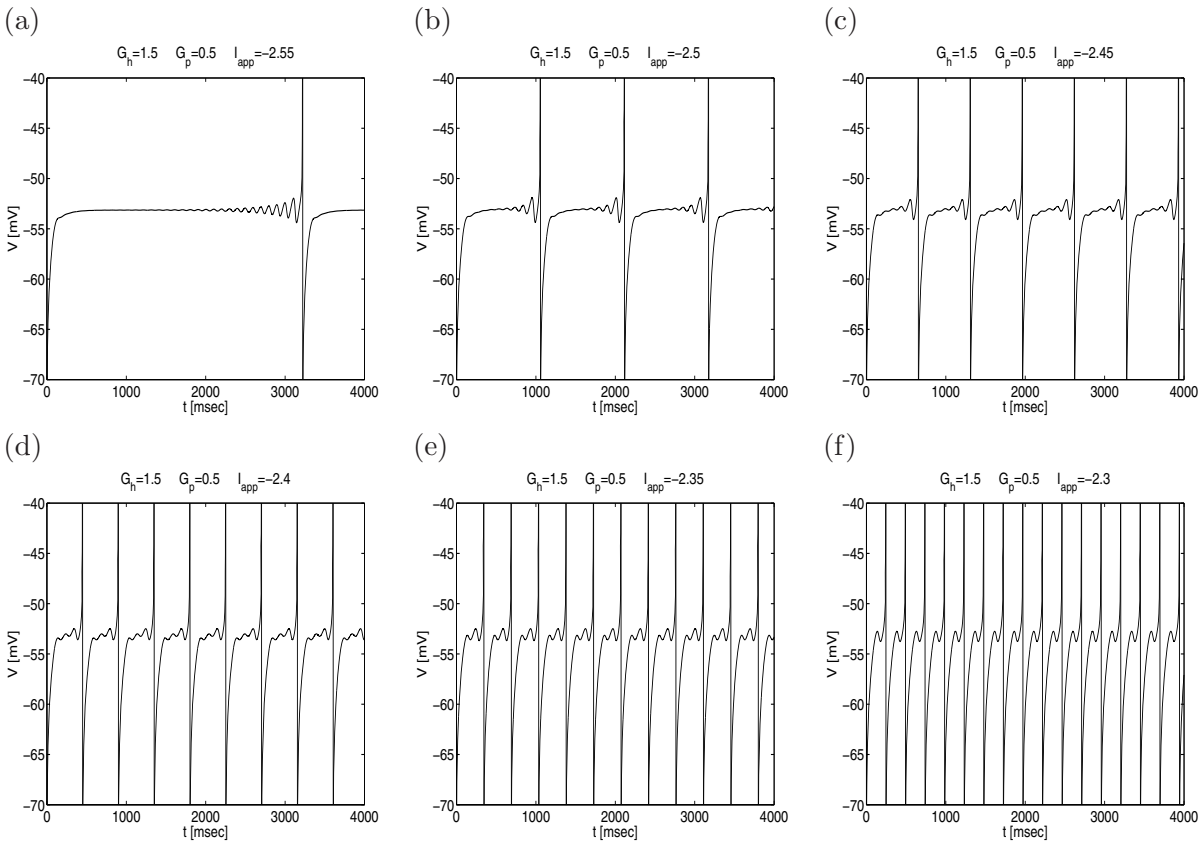

Figure 2. *MMO patterns for the dimensional SC model (1)–(3) with $V_{th} = -40\,mV$ and $V_{rst} = -80\,mV$. The number of subthreshold oscillations per spike decreases with increasing values of I_{app}. Note that V_{th} only indicates that a spike occurs and is not part of the mechanism of spike generation.*

3.3. MMOs in the dimensional model. In Figure 2 we illustrate various MMO patterns generated by the SC model. The voltage traces correspond to $G_h = 1.5$, $G_p = 0.5$, and a sequence of increasing values of I_{app}. We observe that the ratio of subthreshold oscillations to spikes decreases for increasing values of I_{app}. For values of I_{app} below and above these corresponding to Figures 2(a) and (e), the SC becomes silent and fully spiking, respectively (no MMOs). We will use the notation 1^s to indicate that an MMO pattern has a number s of STOs per spike.

Figure 3 shows the 3D phase space corresponding to the voltage traces presented in Figure 2(d) and (b). The V-nullsurface of the SC model is shown as well as the corresponding trajectories of MMO patterns. The trajectories move rapidly from their initial points towards the lower branch of the V-nullsurface and then along it towards the fold-curve (curve of knees of the V-nullsurface). Once the trajectories reach the vicinity of the fold-curve, they start to move almost parallel to the fold-curve and rotate, generating STOs. Finally, the trajectories move rapidly in the direction of increasing values of V, eventually initiating a spike by activating I_{Na}. (The spiking dynamics belongs in a different regime and is not described by this reduced SC model.)

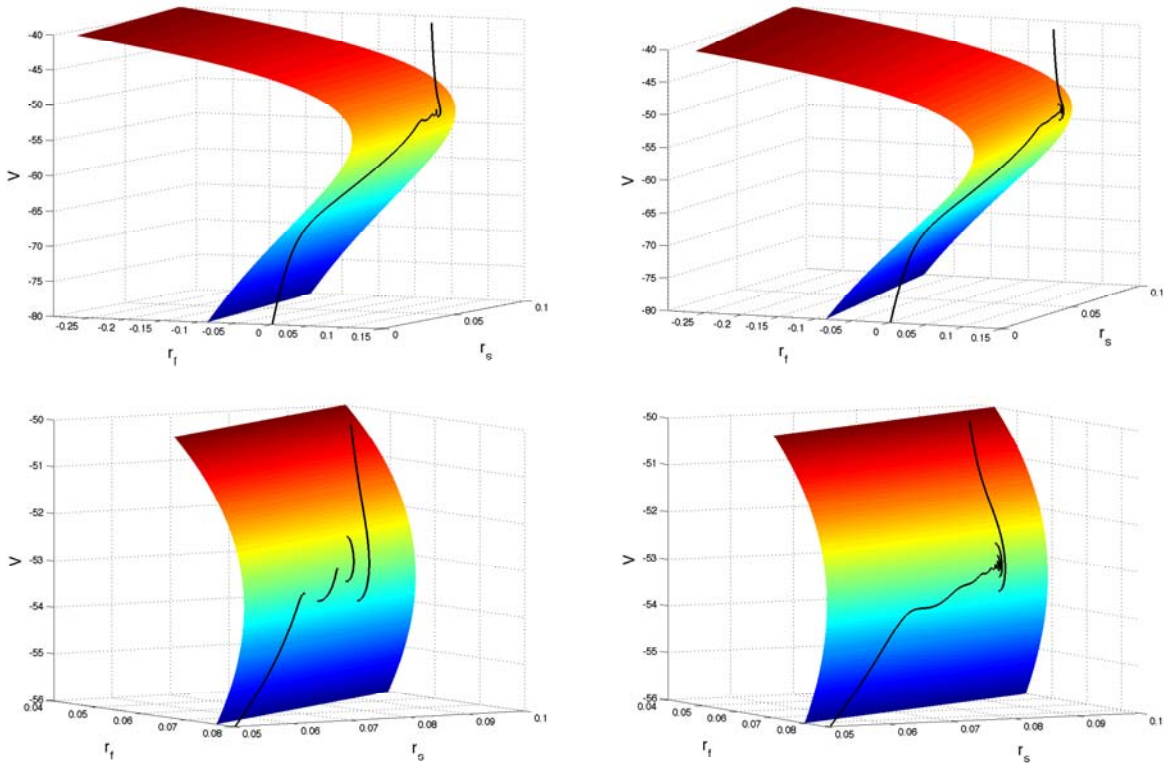

Figure 3. *Phase-space diagrams for the dimensional SC model (1)–(3); $I_{app} = -2.4$ (left) and $I_{app} = -2.5$ (right). The folded V-nullsurface is shown as well as the trajectories corresponding to the time traces shown in Figure 2(d) and (b). Note that the trajectories evolve approximately along the V-nullsurface towards the fold-curve, where they start to create subthreshold oscillations before they escape this regime to fire an action potential.*

3.4. Dimensionless formulation. Here we bring system (1)–(3) to a dimensionless form in order to uncover the different time scales in which the system operates. We first choose appropriate voltage and time scales, K_V and K_t, respectively, and define

$$v = \frac{V}{K_V}, \qquad \bar{t} = \frac{t}{K_t}. \tag{4}$$

From a dimensional analysis point of view one would choose K_V as a combination of the model parameters. A more standard choice would be $K_V = |E_K| = 90\,\mathrm{mV}$, which is the maximum, in absolute value, reversal potential for the full SC model [10], and an upper bound for V. Here we choose $K_V = 100\,\mathrm{mV}$, which is a typical voltage scale for neuronal models, for easier comparison with the original full model as well as with the dimensional reduced model. The dimensionless voltage threshold and reset values are then given by $v_{rst} = -80/K_V = -0.8$ and $v_{th} = -40/K_V = -0.4$. The relevant voltage range for our model in terms of the dimensionless variable v is therefore $[-0.8 : -0.4]$. We define

$$T_f = \min_{v\in[-0.8:-0.4]} \tau_{r_f}(K_V\, v), \qquad T_s = \min_{v\in[-0.8:-0.4]} \tau_{r_s}(K_V\, v), \tag{5}$$

and we choose $K_T = T_f \sim 30\,\text{ms}$ as a typical (slow) time scale (see Figure 1(b)).

We also define a reference maximal conductance $K_G = 1.5\,\text{mS/cm}^2$, which is at the top of the physiologically plausible scale for maximal conductances. This is the value of G_h that we used in the simulations presented in Figures 2 and 3. We define the following dimensionless variables, parameters, and functions:

$$\bar{E}_L = \frac{E_L}{K_V}, \qquad \bar{E}_{Na} = \frac{E_{Na}}{K_V}, \qquad \bar{E}_h = \frac{E_h}{K_V}, \tag{6}$$

$$\bar{G}_p = \frac{G_p}{K_G}, \qquad \bar{G}_h = \frac{G_h}{K_G}, \qquad \bar{G}_L = \frac{G_L}{K_G}, \qquad \bar{I}_{app} = \frac{I_{app}}{K_G\,K_V}, \tag{7}$$

$$\epsilon = \frac{C}{K_T\,K_G} = \frac{C}{T_f\,K_G} \sim 0.023 \ll 1, \qquad \eta = \frac{K_T}{T_s} = \frac{T_f}{T_s} \sim 0.286, \tag{8}$$

$$\bar{r}_{f,\infty}(v) = r_{f,\infty}(K_V\,v), \qquad \bar{r}_{s,\infty}(v) = r_{s,\infty}(K_V\,v), \qquad \bar{p}_\infty(v) = p_\infty(K_V\,v), \tag{9}$$

$$\bar{\tau}_{r_f}(v) = \frac{\tau_{r_f}(K_V\,v)}{T_f}, \qquad \bar{\tau}_{r_s}(v) = \frac{\tau_{r_s}(K_V\,v)}{T_s}. \tag{10}$$

Substituting (4)–(10) into (1)–(3) and deleting the "bar" sign, one gets

$$\epsilon\,\frac{dv}{dt} = I_{app} - G_L\,(v - E_L) - G_p\,p_\infty(v)\,(v - E_{Na}) - G_h\,(c_f\,r_f + c_s\,r_s)\,(v - E_h), \tag{11}$$

$$\frac{dr_f}{dt} = \frac{r_{f,\infty}(v) - r_f}{\tau_{r_f}(v)}, \tag{12}$$

$$\frac{dr_s}{dt} = \eta\,\frac{r_{s,\infty}(v) - r_s}{\tau_{r_s}(v)}. \tag{13}$$

System (11)–(13) is a slow-fast system with v evolving on the fast time scale and both r_f and r_s evolving on a slow scale. These two variables evolve on a similar slow time scale, as becomes apparent by comparing the values of ϵ and η ($\epsilon \ll \eta$).

4. The mechanism of generation of MMOs. MMOs consist of STOs interspersed with spikes (large-amplitude oscillations occurring on a faster time scale). In this section we show that the generation of MMOs in the SC model (11)–(13) is governed by the canard phenomenon. In our explanation we will follow [16, 17]. We use notation tailored to the model. For simplicity we call

$$f(v, r_f, r_s) = I_{app} - G_L\,(v - E_L) - G_p\,p_\infty(v)\,(v - E_{Na}) - G_h\,(c_f\,r_f + c_s\,r_s)\,(v - E_h), \tag{14}$$

$$g(v, r_f) = \frac{r_{f,\infty}(v) - r_f}{\tau_{r_f}(v)}, \tag{15}$$

$$h(v, r_s) = \eta\,\frac{r_{s,\infty}(v) - r_s}{\tau_{r_s}(v)}. \tag{16}$$

As we show below, the existence of MMOs for the SC model (11)–(13) is guaranteed by Theorem 4.1 or Theorem 4.2 in [17]. These theorems require that the v-nullsurface (which we will refer to as S) be folded (parabolic cylinder shape). STOs occur in the vicinity of the fold-curve L (the curve of knees of S), defined as the set of points $\{p \in S : f_v(p) = 0,\ f_{vv}(p) < 0\}$. The lower ($S_a$) and upper ($S_r$) branches of the folded manifold S are attracting ($f_v < 0$) and repelling ($f_v > 0$), respectively. After a finite number of STOs the trajectory moves away from S and escapes the subthreshold regime towards the spiking one, as we explain in section 4.2. For MMOs to occur, the trajectory should be able to come back to the subthreshold regime; i.e., a suitable return mechanism should bring the trajectory back to a region of S where it can evolve towards its curve of knees L (setting the initial conditions in the subthreshold regime). Different models may have different return mechanisms. The one corresponding to this model was described in section 3.2. In the following sections we describe the mechanism of generation of STOs and the onset of spikes for system (11)–(13), and we show their dependence on some of the parameters of the model.

We are mainly interested in understanding the contribution of I_h to the observed mixed-mode oscillatory patterns, since I_h is known to change with development and neuromodulators [50]. Changes in the amounts of I_h are reflected in changes in the maximal conductances G_h. Other effects include changes to the activation curves ($r_{f,\infty}(V)$ and $r_{s,\infty}(V)$) and the voltage-dependent time scales through the values of ϵ and η or the reset properties of I_h (initial conditions in the subthreshold regime). Changes in these values may affect the relative number of STOs, as well as the oscillatory frequency and the amplitude of the STOs.

4.1. A geometric singular perturbation theory approach. The SC model (11)–(13) is a singularly perturbed system with one fast (v) and two slow (r_f, r_s) variables. This system evolves on a slow time scale $t = \varepsilon\tau$. The limiting problem $\varepsilon \to 0$ on this slow time scale t is called the *reduced problem* and describes the evolution of the slow variables (r_f, r_s). The phase space of the reduced problem is the critical manifold S defined by $S := \{(v, r_f, r_s) \in \mathbb{R}^3 : f(v, r_f, r_s) = 0\}$; i.e., S is the v-nullsurface. We represent it by

$$r_f = \phi(v, r_s) = \frac{I_{app} - G_L\,(v - E_L) - G_p\,p_\infty(v)\,(v - E_{Na})}{c_f\ G_h\,(v - E_h)} - \frac{c_s}{c_f}\,r_s. \tag{17}$$

Figure 4 illustrates S for two values of I_{app} and other physiologically plausible parameters.

The second limiting problem is called the layer problem, and it is obtained by rescaling time ($\tau = t/\epsilon$) in system (11)–(13) and setting $\varepsilon \to 0$. The layer problem describes the evolution of v on the fast time scale for fixed values of the gating variables (r_f, r_s); i.e., the slow variables are considered as parameters in this singular limit. Note that the manifold S is a manifold of equilibria for the layer problem.

These two limiting problems, the reduced problem (2D) and layer problem (1D), are lower-dimensional than the full problem (3D) and are therefore more amenable to analysis. Geometric singular perturbation theory [17, 51, 52] provides a way to piece together the information obtained from these lower-dimensional problems in order to provide a unified global description of the observed MMOs in the full 3D system.

4.2. Layer problem. By rescaling time ($\tau = t/\epsilon$) in (11)–(13) and setting $\epsilon = 0$, one obtains the layer problem which describes the fast dynamics away from the critical manifold

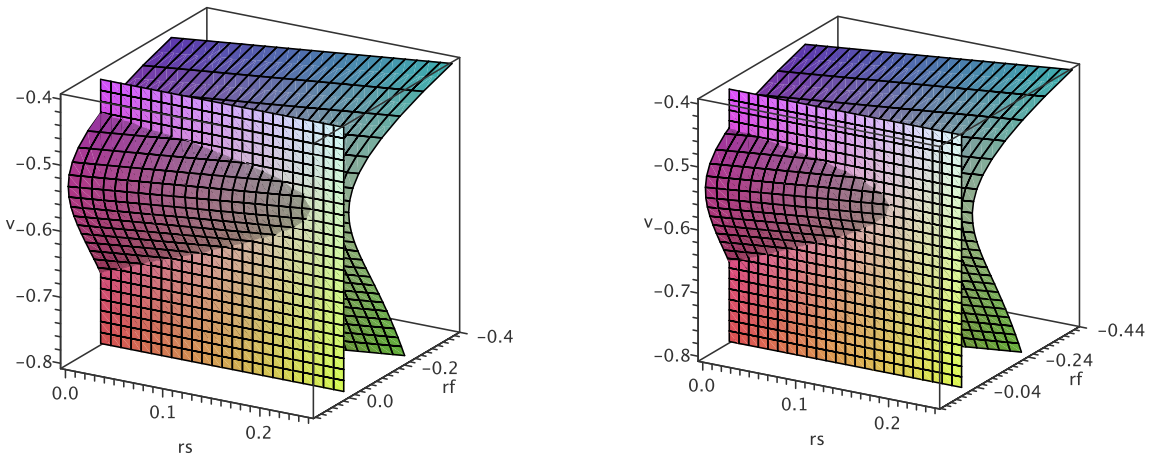

Figure 4. *Domains of possible initial conditions on the critical manifolds S for trajectories starting at the SC reset values. The left and right panels correspond to $I_{app} = -2.64$ (-0.0176) and $I_{app} = -1.86$ (-0.0124), respectively. The dimensionless values of the parameters are given in parentheses. All panels correspond to $G_h = 1.5$ (1.0). This figure illustrates the facts that I_{app} does not change the geometry of the critical manifold significantly and that I_{app} has also no significant influence on the domain of (biologically relevant) initial conditions.*

S, represented by (17):

$$\frac{dv}{d\tau} = f(v, r_f, r_s), \tag{18}$$

$$\frac{dr_f}{d\tau} = 0, \tag{19}$$

$$\frac{dr_s}{d\tau} = 0. \tag{20}$$

Trajectories of the layer problem starting at an initial point $(v_0, r_{s,0}, r_{f,0})$ evolve along 1D sets $(v, r_{s,0}, r_{f,0})$, called fast fibers, near the critical manifold. The critical manifold S is a manifold of equilibria for the layer problem; i.e., the intersection points between S and vertical lines containing the fast fibers define the fixed point corresponding to each trajectory. By linearizing the layer problem at S, one obtains information about the transient behavior of the solutions along the fast fibers. As we illustrate in Figure 4, the critical manifold S is folded. This remains true for parameter variations in the physiologically plausible regime (data not shown). The lower (S_a) and upper (S_r) branches of the folded manifold S are attracting $(f_v < 0)$ and repelling $(f_v > 0)$, respectively. Figure 4 also illustrates that changes in the key parameters of the model (e.g., I_{app}) do not affect the shape of the folded slow manifold S significantly.

4.3. Initial conditions of the reduced problem on the critical manifold. The relevant trajectory in the subthreshold regime starts at $(v, r_f, r_s) = (-0.8, 0, 0)$ (see sections 1 and 3.4).

This trajectory is projected on S_a along the corresponding fast fiber to the equilibrium point $(v_0, r_{f,0} = 0, r_{s,0} = 0)$ of the layer problem. This point on the critical manifold is then used as the initial condition of the reduced flow corresponding to the initial condition $(v, r_f, r_s) = (-0.8, 0, 0)$. Note that we use the same notation for initial conditions on the critical manifold S as for the initial conditions for problem (11)–(13). Figure 4(b) shows the critical manifold intersected with the plane $r_s = 0$. For $r_f = r_s = 0$ as initial conditions (reset values) this figure shows that $V \sim -70\,\mathrm{mV}$ ($v \sim -0.7$) corresponds to the intersection of the fast fiber through $r_f = r_s = 0$ with the critical manifold. Therefore we will take $v_0 \sim -0.7$ as initial condition for the reduced problem. The exact initial condition on the critical manifold depends on the parameters of the model. We make the appropriate calculations for each parameter set.

4.4. The reduced flow. The reduced flow is obtained by setting $\epsilon = 0$ in (11). System (11)–(13) becomes

$$0 = f(v, r_f, r_s), \tag{21}$$

$$\frac{dr_f}{dt} = g(v, r_f), \tag{22}$$

$$\frac{dr_s}{dt} = h(v, r_s). \tag{23}$$

These equations describe the evolution of r_f and r_s on the critical manifold S defined by (17).

Trajectories evolve on the slow manifold S (actually on S_a), from their initial conditions $(v_0, r_{f,0}, r_{s,0})$ towards the fold-curve L. Since S is given as a graph $\phi(v, r_s)$ we project the reduced system (21)–(23) onto the (v, r_s)-plane. By implicitly differentiating the function $f(v, r_f, r_s) = 0$, we obtain the reduced system

$$\begin{pmatrix} -f_v\, v' \\ r_s' \end{pmatrix} = \begin{pmatrix} f_{r_f}\, g + f_{r_s}\, h \\ h \end{pmatrix}_{r_f = \phi(v, r_s)}. \tag{24}$$

This system is singular along the fold-curve L ($f_v = 0$). Therefore we rescale time by a factor $-f_v$ to obtain the desingularized system

$$\begin{pmatrix} \dot{v} \\ \dot{r}_s \end{pmatrix} = \begin{pmatrix} f_{r_f}\, g + f_{r_s}\, h \\ -f_v\, h \end{pmatrix}_{r_f = \phi(v, r_s)}, \tag{25}$$

where the overdot represents differentiation with respect to this new time. Note that system (25) has the same phase portrait as system (24), but the orientation of the flow on S_r (unstable slow manifold) has to be reversed due to the rescaling of time.

There are two types of singularities in system (25): regular and folded singularities. Regular singularities are given by $h = 0$ and $g = 0$ and are therefore also equilibria of the reduced flow (24). These singularities will (generically) persist under small perturbations in system (11)–(13) with $\epsilon \ll 1$. On the other hand, folded singularities are given by $f_v = 0$, which defines the fold-curve L, and $f_{r_f}\, g + f_{r_s}\, h = 0$ (for points $\bar{p}$ on L). Each folded singularity is classified as a folded saddle, folded node, or folded saddle-node based on its classification as a saddle, node, or saddle-node as an equilibrium of (25). Folded singularities are not equilibria

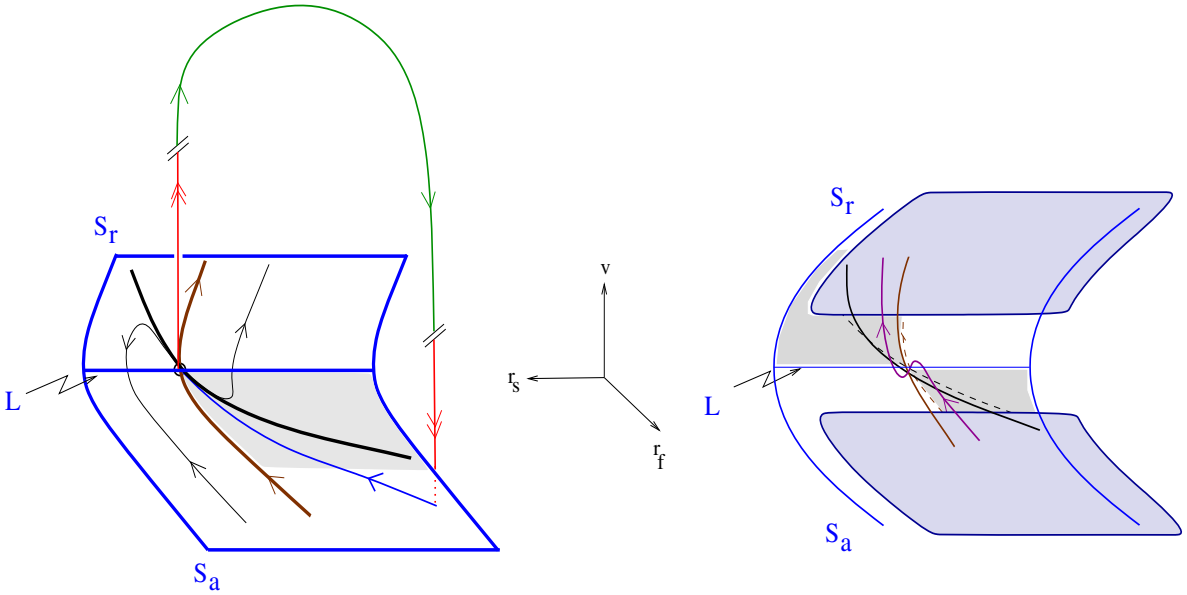

Figure 5. *Schematic representation of the canard mechanism generating MMOs in the SC and related models: A folded node singularity, located on the fold-curve L, forms a singular funnel. A singular periodic orbit consists of a segment on the attracting manifold S_a (blue) within the funnel with the folded node singularity as an endpoint. Then it follows a fast fiber of the layer problem (red), and a global return mechanism (green) projects the singular orbit back into the singular funnel. The return mechanism for the SC model is based on the reset properties of the h-current after a spike has occurred. The right panel shows a schematic representation of a trajectory rotating around the weak canard within the singular funnel.*

of the reduced system (24). However, as shown in [15, 17], their presence gives the opportunity for the reduced flow to cross from S_a to S_r through L in finite time. If there are no folded singularities, then trajectories of the reduced flow which arrive at the fold-curve subsequently jump along the fast fibers and escape the subthreshold regime without generating any STO.

As we show in section 4.6, the singularities found in the SC model, for the relevant biophysically plausible parameters, are folded nodes (or folded saddle-nodes). For more details about folded singularities we refer to [15, 16, 17, 45]. Associated with a folded node there exists a whole sector of trajectories, called singular canards, that are able to pass from S_a to S_r through the folded node. This sector is called the singular funnel. Two singular canards are related to the eigendirections of the folded node. They are the weak and strong canards. They correspond to the smallest and largest (in absolute value) eigenvalues, respectively. The singular funnel is bounded by the fold-curve L and the strong canard. The latter is the strong stable invariant manifold of the folded node. The canards and funnel existing from $\epsilon > 0$ (sufficiently small) arise as perturbation of their singular counterparts. Only trajectories entering the funnel are able to rotate around the weak canard (see Figure 5). For a geometric description of this phenomenon, we refer the reader to [16, 17].

4.5. Existence of MMOs. Based on the singular limit behavior of solutions in both the reduced and the layer problem, Brøns, Krupa, and Wechselberger [17] provided a theorem that guarantees the existence of MMOs for system (11)–(13) with a sufficiently small $0 < \epsilon \ll 1$.

This theorem is based on the following assumptions.

Assumption 1. The singularly perturbed system is (locally) a folded surface, as in system (11)–(13) for parameter sets in the physiologically plausible range. This was shown in section 4.2.

Assumption 2. The problem possesses a folded node singularity. In section 4.6 we will determine parameter ranges (in the physiologically plausible regime) for which folded nodes exist.

Assumption 3. There exists a singular periodic orbit (see Figure 5) which consists of a segment on S_a (blue) within the singular funnel (shadowed region) with the folded node singularity (black circle) as an endpoint, fast fibers (red) of the layer problem, and a global return mechanism (green). The global return mechanism for the SC model was described in sections 3.2 and 4.3.

If Assumptions 1–3 are fulfilled, then Theorem 4.1 in [17] predicts maximal 1^s MMO patterns (for sufficiently small ϵ). There are two limiting cases of the theory related to Assumptions 2 and 3. In Assumption 3, if the global return mechanism is on the border of the singular funnel (the brown trajectory in Figure 5), then Theorem 4.2 in [17] predicts submaximal MMO patterns. In the folded saddle-node limit, Assumption 2 is violated, but we still expect the existence of MMOs (with a large number of STOs). The theory for this limiting case has still to be developed, but we can use the folded node theory to make qualitative predictions of MMOs. We will discuss both limiting cases in section 4.8.

4.6. The folded node singularity and the canard phenomenon. In order to look for parameter ranges in which system (11)–(13) possesses a folded node singularity, we numerically calculated the desingularized reduced flow corresponding to (25) for various values of G_h and I_{app}. We used XPPAUT [53] for these computations and a Runge–Kutta method of order II [54] for the numerical simulations of the 3D system (11)–(13). The results are given in terms of the dimensional values of the parameters. Their corresponding dimensionless values are given in parentheses. We will first consider the case $G_h = 1.5$ (1.0) for which we found the existence of the following:

- a regular node singularity on S_a, a folded saddle singularity, and a regular node singularity on S_r for $I_{app} < -2.64$ (-0.0176);
- a folded saddle-node singularity and a regular node singularity on S_r for $I_{app} \approx -2.64$;
- a regular saddle singularity on S_r, a regular node singularity on S_r, and a folded node singularity for $-2.64 < I_{app} < -1.92$ (-0.0128);
- a saddle-node singularity on S_r and a folded node singularity for $I_{app} \approx -1.92$ (-0.0128);
- a folded node singularity for $-1.92 < I_{app} < -1.86$ (-0.0124);
- a folded focus singularity for $I_{app} > -1.86$.

Therefore a folded node singularity exists for values of $I_{app} \in (-2.64, -1.86)$. To each folded node corresponds a singular funnel which is bounded by the strong canard and the fold-curve. The strong canard is an invariant manifold of the folded node; it is a separatrix of the flow on the reduced phase space S and therefore a borderline for qualitatively different behaviors. Note that the strong canard is related to the strong eigendirection of the folded node and is therefore unique.

Figure 6 shows the folded node, the singular strong canard, the fold-curve, and the singular funnel for three values of I_{app} and the same values of both G_h and the initial conditions on S_a. In Figure 6(a), an initial condition within the singular funnel will be "funneled" into the folded singularity and gives the possibility of STOs [16] for $\epsilon > 0$. The corresponding voltage trace showing STOs is given in Figure 7(a). If an initial condition is outside the funnel (Figure 6(c)), then the reduced flow will reach the fold-curve at an (ordinary) *jump point* where solutions jump off the fold and follow a fast fiber, which leads to the spiking regime without displaying STOs. The corresponding voltage trace showing only spiking activity is given in Figure 7(c). Figures 6(b) and 7(b) correspond to a trajectory within the funnel but very close to its boundary. The voltage trace shows only one STO per spike. From Figure 6 and the voltage traces showed in Figure 7 we observe that as we increase I_{app} the folded node moves to the left and, accordingly, the strong canards (separatrices) intersect the v-axis at higher values. As this occur, trajectories starting at approximately the same initial values on the critical manifold, $v \in (-0.69, -0.68)$, evolve closer to the strong canard, decreasing their number of STOs (per spike), and, for higher values of I_{app}, they are left outside the funnel and generate only spiking activity.

Figure 8 shows the folded nodes and corresponding strong canards for various values of I_{app}. The range of values of v_0 whose corresponding trajectories will be attracted to the funnel shrinks as I_{app} increases. For example, the singular limit analysis predicts that trajectories on the slow manifold with initial conditions $(r_f(0), r_s(0)) = (0, 0)$ and the corresponding values of v_0 will not display STOs for $I_{app} > -2.25$ and for $I_{app} < -2.64$ (corresponding to a lower bound where a folded node singularity exists). Our simulations of the SC model (11)–(13) show the existence of MMOs for $-2.57 < I_{app} < -2.27$; i.e., both the onset of MMOs and the change from MMOs to relaxation oscillations occur for slightly higher values than theoretically predicted. However, in both cases these values are within the order of the singular perturbation parameter ϵ and therefore justify the singular prediction made above.

The observed MMO parameter window $-2.57 < I_{app} < -2.27$ for the SC model is also in good agreement with the MMO parameter window $-2.7 < I_{app} < -2.4$ of the full 7D model. The (small) shift to more depolarized values in the SC model (11)–(13) is basically explained by the lack of the depolarized current I_{Na} given by the full 7D model. A more detailed comparison of the two models can be found in [55].

4.7. Transition between subthreshold oscillatory regimes as a consequence of changes in the h-current reset properties. Changes in the h-current reset properties are reflected in changes in the initial values of its gating variables r_f and r_s in the subthreshold regime, and particularly on the slow manifold. Here we show how this affects the subthreshold oscillatory properties of the MMO 1^s patterns, particularly the number of subthreshold oscillations per spike. This number s depends on the ratio $\mu = \lambda_1 / \lambda_2 < 1$ between the eigenvalues corresponding to the weak and strong eigendirections of the folded node in system (25). In the case $\mu < 1/3$, it was shown in [16] that singularly perturbed systems like (11)–(13) possess $[(1-\mu)/(2\mu)]$ *secondary canards* besides the two primary (weak and strong) canards, where $[(1-\mu)/(2\mu)]$ denotes the greatest integer less than or equal to $(1-\mu)/(2\mu)$.

These secondary canards divide the singular funnel into subsectors (see Figure 9). Each of them is associated with a specific value of s in the MMO 1^s patterns; i.e., trajectories entering

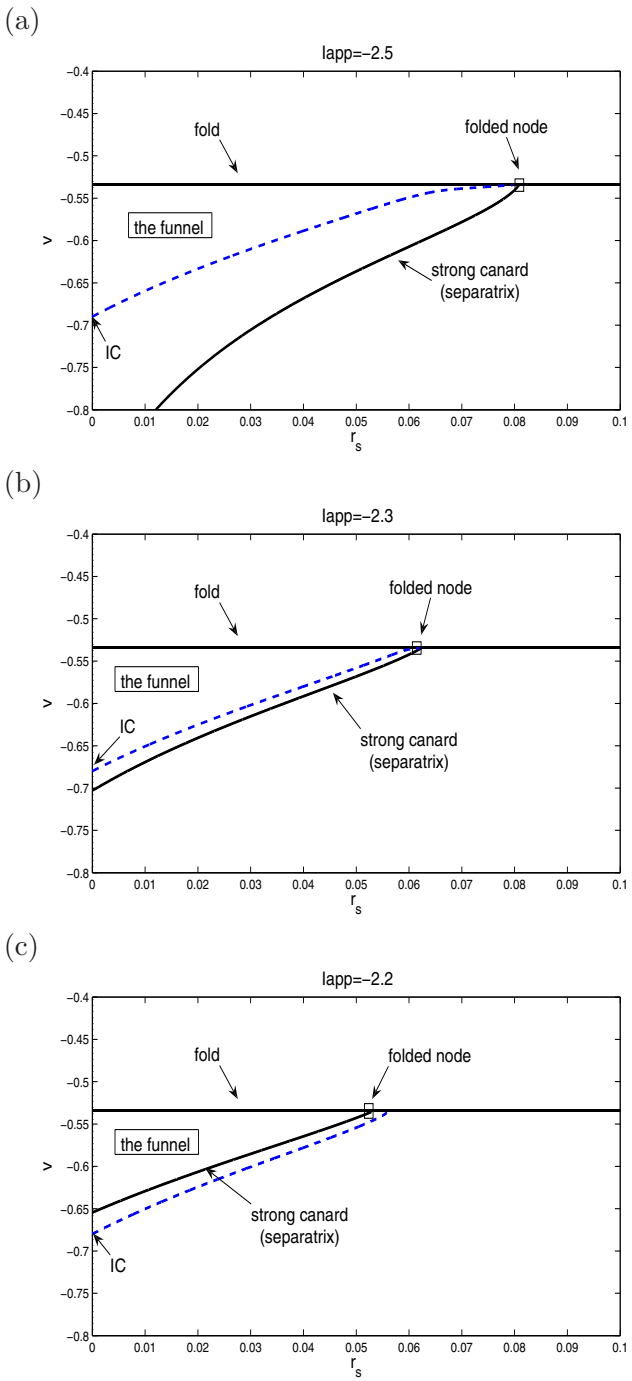

Figure 6. *Schematic representations of the singular funnel for various values of I_{app} and for $G_h = 1.5$ (1.0) and $G_p = 0.5$ (0.3333). The dimensionless values of the parameters are given in parentheses. The singular funnel is bounded by the fold (horizontal) line and the strong canard. The funnel is located on the attracting part of the slow manifold S_a (below the fold). Trajectories (dashed lines) start at their initial conditions (IC) on the slow manifold and evolve towards the folded node.*

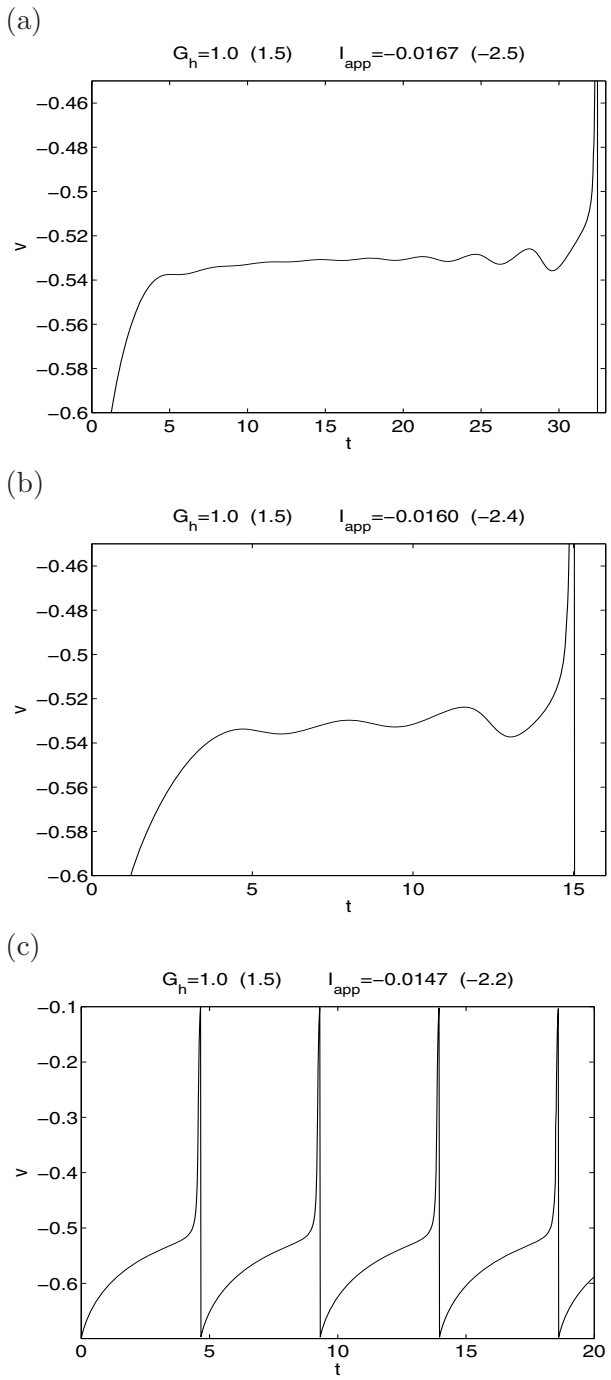

Figure 7. *Voltage traces for the (dimensionless) SC model (11)–(13). $G_h = 0.5$ (0.3333). The dimensional values of G_h and I_{app} are given in parentheses. The initial conditions are located on the slow manifold S. The number of subthreshold oscillations per spike increases with decreasing values of I_{app}.*

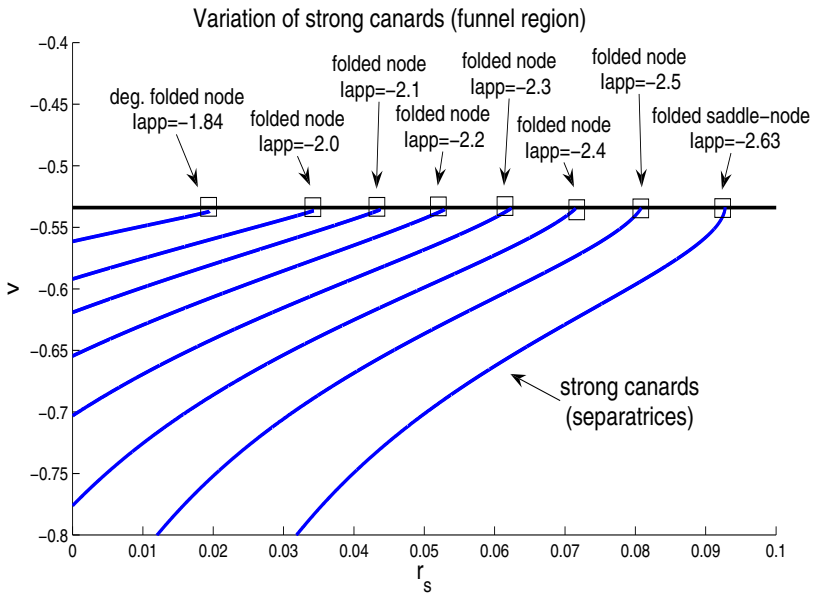

Figure 8. *Schematic representations of the singular funnel for various values of I_{app} and for $G_h = 1.5$ (1.0) and $G_p = 0.5$ (0.3333). The dimensionless values of the parameters are given in parentheses. Each singular funnel is bounded by the fold (horizontal) line and the corresponding strong canard. The funnels are located on the attracting part of the slow manifold S_a (below the fold).*

Table 1

Singular limit predictions of number of secondary canards and maximum number s^* of STOs for $G_h = 1.5$ (1.0) under the variation of I_{app}.

I_{app}	μ	$(1-\mu)/(2\mu)$	s^*
-2.6	0.0097	51	52
-2.5	0.0480	9	10
-2.4	0.0917	4	5
-2.3	0.1430	2	3
-2.25	0.1725	2	3
-2.1	0.2842	1	2
-2.0	0.3940	0	1

different sectors display a different number of STOs per spike. This number increases from the sector bounded by the strong canard to the sector bounded by the fold-curve. The maximum number of STOs is defined by $s^* := (1+\mu)/(2\mu)$, which is a singular limit prediction. Table 1 shows the number of secondary canards and maximum number s^* STOs for $G_h = 1.5$ (1.0) under the variation of I_{app}.

As a consequence of an increase in the initial values of r_f and r_s, the initial voltage on S also changes, and trajectories may enter a sector corresponding to a higher or lower number of STOs. We illustrate this in Figures 9 to 11. We first vary $r_s(0)$ and keep $r_f(0) = 0$ unchanged for $I_{app} = -2.4$ (dimensionless value: $I_{app} = -0.0160$). We illustrate this schematically in Figure 9(a). The voltage traces are presented in Figure 10. The initial conditions on the slow manifold S approximate a line passing through the points $(v_0, r_{f,0}, r_{s,0}) = (-0.69, 0, 0)$

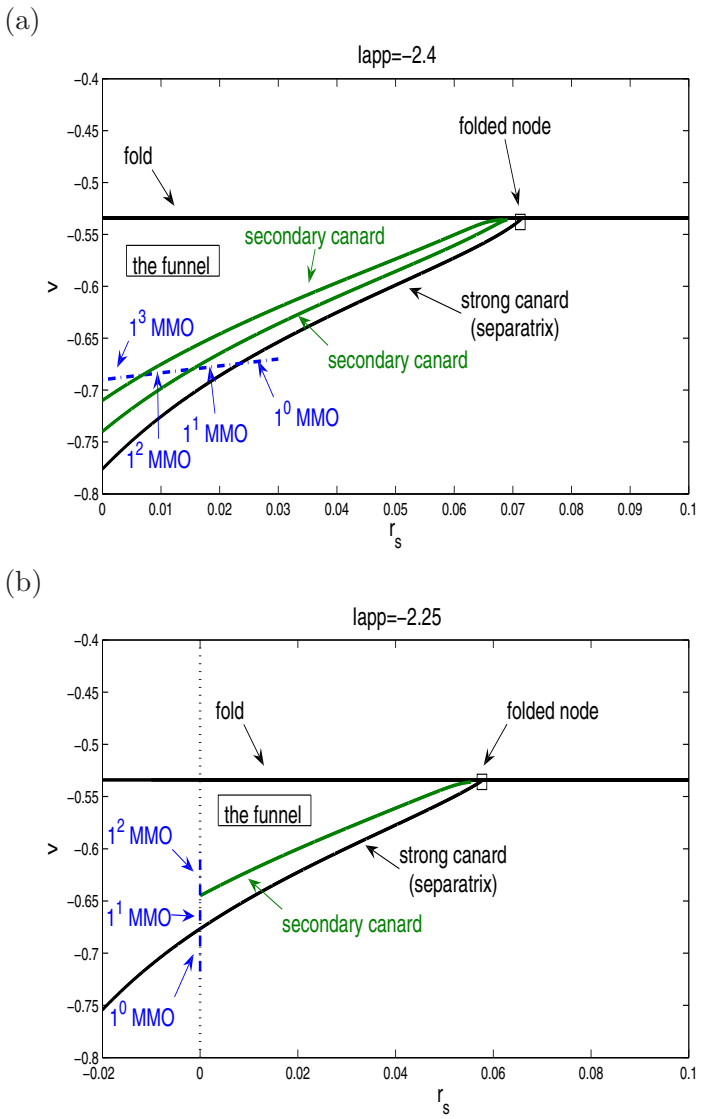

Figure 9. *Schematic illustration of the effect of changes in the initial values of the h-current gating variables r_s and r_f on the mixed-mode oscillatory patterns for $G_h = 1.5$ (1.0), $G_p = 0.5$ (0.3333), and* (a) $I_{app} = -2.4$ (-0.0160) *or* (b) $I_{app} = -2.25$ (-0.0150). *Each singular funnel is bounded by the "fold" line and the strong canard. The funnel is located on the attracting part of the slow manifold S_a (the repelling manifolds S_r are not shown). The secondary canards divide the funnel into sectors. Each sector corresponds to a 1^s mixed-mode oscillatory pattern. Trajectories starting in a given sector display s subthreshold oscillations per spike. Panel* (a) *corresponds to changes in $r_s(0)$ for fixed values of $v(0)$ and $r_f(0)$. The number of subthreshold oscillations per spike, s, decreases from left to right. The corresponding voltage traces are shown in Figure 10. Panel* (b) *corresponds to changes in $r_f(0)$ for fixed values of $v(0)$ and $r_s(0)$. The number of subthreshold oscillations per spike, s, decreases from top to bottom. The corresponding voltage traces are shown in Figure 11.*

and $(v_0, r_{f,0}, r_{s,0}) = (-0.67, 0, 0.03)$ (dashed segment in Figure 9(a)). We observe that the transition from MMO to only spiking patterns occurs for a value of $r_s(0)$ slightly higher than 0.02, and the number s of STOs per spike decreases as we increase $r_s(0)$. The results of

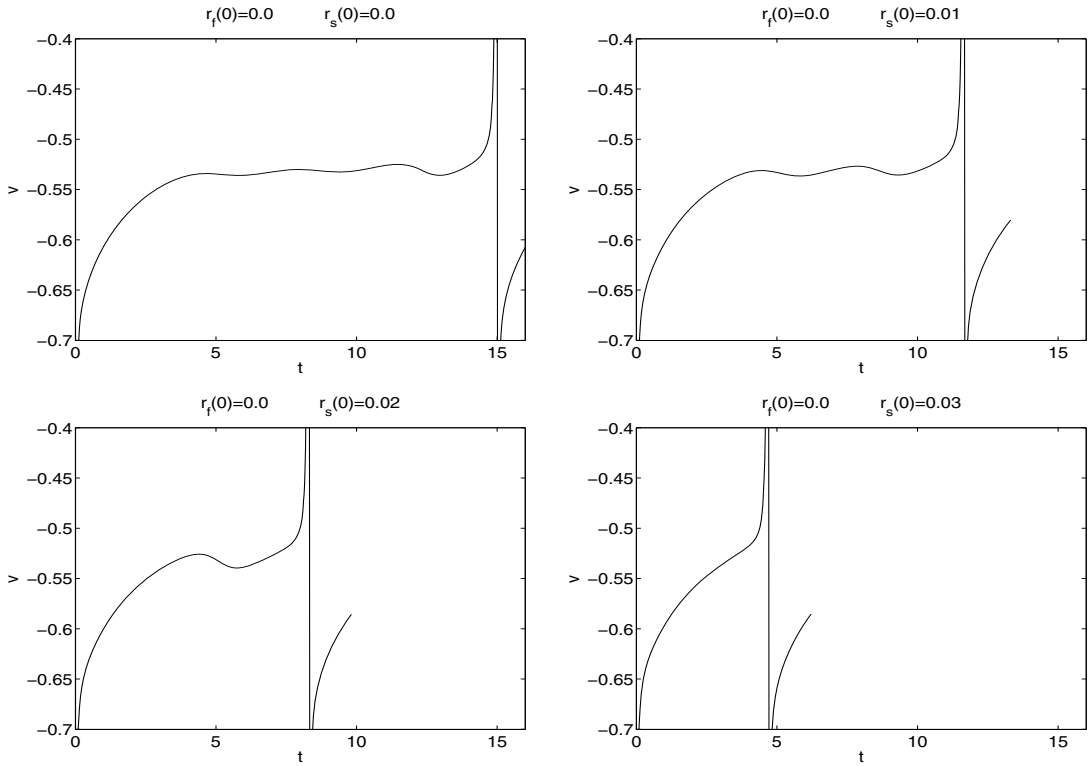

Figure 10. *Voltage traces showing the effect of changes in the initial values of r_s on the mixed-mode oscillatory patterns corresponding to trajectories starting in a vicinity of the slow manifold for fixed initial values of r_f. The dimensionless values of the parameters are given in parentheses: $G_h = 1.5$ (1.0), $G_p = 0.5$ (0.3333), $I_{app} = -2.4$ (−0.0160). The schematic representation of the corresponding singular funnel is given in Figure 9(a).*

our simulations (Figure 10) are in agreement with this prediction. In Figures 9(b) and 11 we vary $r_f(0)$ and keep $r_s(0) = 0$ unchanged for $I_{app} = -2.25$ (dimensionless value: $I_{app} = -0.0150$). The initial conditions on S are located on the v-axis at the points $(-0.69, 0, 0)$, $(-0.66, 0.025, 0)$, and $(-0.63, 0.05, 0)$ (dashed vertical segment in Figure 9(b)). This dashed vertical segment crosses the strong canard at $v \sim -0.675$. According to this, the transition from 1^1 to 1^0 (spikes only) MMO patterns occurs for r_s lower than 0.025. The results of our simulations (Figure 11) are in agreement with this prediction.

4.8. MMO theory and the dependence on the singular perturbation parameter. The existence results on MMOs presented here are based on singular perturbation theory and hold for sufficiently small singular perturbation parameter $0 < \epsilon \ll 1$ [16, 17]. In particular, Theorem 4.1 in [17] states that if Assumptions 1–3 are fulfilled, then maximal 1^{s^*} MMOs are expected for sufficiently small ϵ. Sufficiently small ϵ means here that $\mu \gg \sqrt{\epsilon}$ for the eigenvalue ratio of the folded node, as well as that $\delta \gg \sqrt{\epsilon}$, where δ defines the distance of the initial condition on S_a from the strong canard (relative position of the global return within the funnel). The $\sqrt{\epsilon}$-dependence follows from the canard theory (see, e.g., [16, 17, 55]). If one of these estimates is violated, then we still expect to observe an MMO pattern, but we

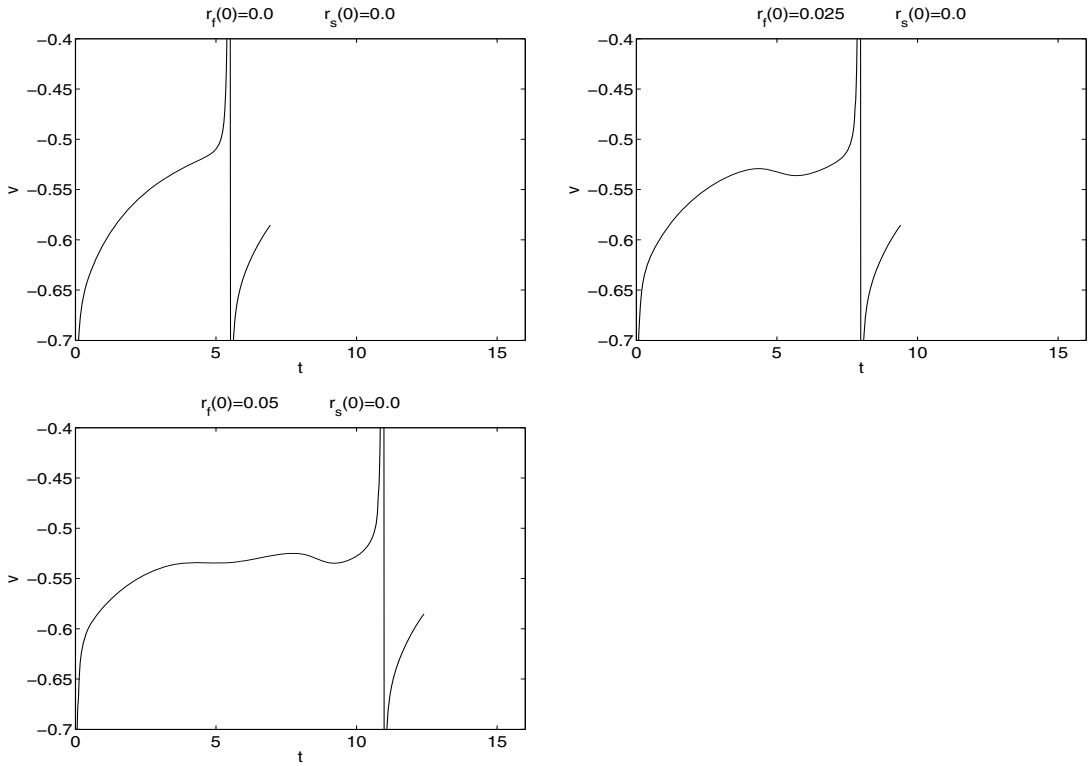

Figure 11. *Voltage traces showing the effect of changes in the initial values of r_f on the mixed-mode oscillatory patterns corresponding to trajectories starting in a vicinity of the slow manifold for fixed initial values of r_s. The dimensionless values of the parameters are given in parentheses: $G_h = 1.5$ (1.0), $G_p = 0.5$ (0.3333), $I_{app} = -2.25$ (−0.0150). The schematic representation of the corresponding singular funnel is given in Figure 9*(b).

cannot predict the exact MMO pattern. Theorem 4.2 in [17] covers the case where δ violates this condition.

For example, Table 1 predicts for $I_{app} = -2.4$ four secondary canards and therefore a maximal number $s^* = 5$ of STOs. If we compare the prediction with Figure 2(d), then we see that a 1^3 MMO pattern is realized with that particular choice of initial conditions. Therefore, Assumption 2 and/or 3 is violated; i.e., μ and/or δ are of order $O(\sqrt{\epsilon})$, where $\sqrt{\epsilon} \sim 0.15$. For $I_{app} = -2.4$, Table 1 shows that $\mu \sim 0.1$, and we estimate from Figure 9(a) that $\delta \sim 0.02$. Hence, both parameters are within the order $O(\sqrt{\epsilon})$, which explains why we do not find the maximal MMO pattern predicted by the singular perturbation theory. Nonetheless, we can explain certain trends. For instance, if we increase δ, i.e., if we decrease the initial conditions on S_a (to physiologically irrelevant negative values), then we observe an increase in STOs until we reach a maximum value of STOs. In the case $I_{app} = -2.4$, 1^8 MMO is the maximum pattern which is observed for initial conditions $r_s < -0.12$ (data not shown). Clearly, the maximum number of STOs, although larger than predicted, is still finite and therefore reflects the characteristics of a folded node induced MMO pattern. The perturbation ϵ is simply too large to give precise estimates on STOs. On the other hand, if we sufficiently decrease ϵ, then

we should observe the maximal 1^5 pattern as predicted. In this case, any $\epsilon < 10^{-5}$ gives this predicted result (data not shown).

Note that in the folded saddle-node limit $\mu \to 0$ an unbounded growth of STOs is expected. Folded saddle-nodes are related to the transition from an excitable to an oscillatory state, and we observe a large number of STOs in our simulations, e.g., for $I_{app} = 2.55$ in Figure 2(a). The MMO theory for this limiting case still has to be developed. So far, MMOs related to folded saddle-node singularities have been studied in [47] for a 3D autocatalator problem and in [23] for a dopaminergic neuron model.

4.9. Dependence of the subthreshold oscillatory frequency on the amount of the h-current. The dynamic picture described in section 4.6 is qualitatively affected by changes in the amount of the h-current, measured by the parameter G_h. We now consider values of G_h lower than the one considered in section 4.6. Table 2 shows that the ranges of values of I_{app} for which the system (11)–(13) has a folded node shrink with increasing values of G_h and $G_p = 0.5$ (dimensionless value: $G_p = 0.3333$). Note that the decrease in the amount of I_h results in an increase of the amount of I_{app}.

Table 2
Folded node regimes for different G_h values.

Dimensional			Dimensionless		
G_h	Folded nodes for	Interval size	G_h	Folded nodes for	Interval size
1.5	$-2.64 < I_{app} < -1.86$	0.78	1.0	$-0.0176 < I_{app} < -0.0124$	0.0052
1.4	$-2.43 < I_{app} < -1.72$	0.71	0.933	$-0.0162 < I_{app} < -0.0115$	0.0047
1.3	$-2.21 < I_{app} < -1.58$	0.63	0.866	$-0.0147 < I_{app} < -0.0105$	0.0042
1.2	$-1.98 < I_{app} < -1.43$	0.55	0.8	$-0.0132 < I_{app} < -0.0095$	0.0037
1.0	$-1.51 < I_{app} < -1.12$	0.39	0.666	$-0.0101 < I_{app} < -0.0075$	0.0026
0.5	$-0.24 < I_{app} < -0.11$	0.13	0.333	$-0.0016 < I_{app} < -0.0007$	0.0009

Figure 12 illustrates the effect that "balanced" changes in the values of G_h and I_{app} have on the MMO patterns for a constant value of G_p. To compensate for the decrease in the amount of I_h (decrease in G_h) we increased I_{app} so that the number of STOs per spike is kept constant, and for a fixed value of G_h, a lower value of I_{app} would produce one less STO per spike. We observe that as we decrease G_h, the STO frequency slightly decreases.

A decrease in the amount of I_h can be also compensated by an increase in the amount of I_p. In Figures 13(a) and (b) the values of I_{app} are kept constant and the values of G_h and G_p were chosen following the principle described in the previous paragraph. Similarly to the previous case, as we decrease G_h, the STO frequency slightly decreases.

4.10. Inhibitory pulses decrease the number of STOs per spike and increase the SC firing frequency. Inhibitory pulses typically delay firing in the postsynaptic cell. However, this is partially reversed when the postsynaptic cell has an h-current [26, 56]. Heuristically, we expect a pulse of inhibition applied at different times t_{pert} to have a differential effect on the postsynaptic spike-time. When the pulse of inhibition is applied to an SC whose trajectory is still far away from the "rotational region," it will have little effect, since the trajectory will have enough time to recover before starting to rotate. In contrast, a pulse of inhibition of the same magnitude applied to an SC that is already rotating may cause it to move from one

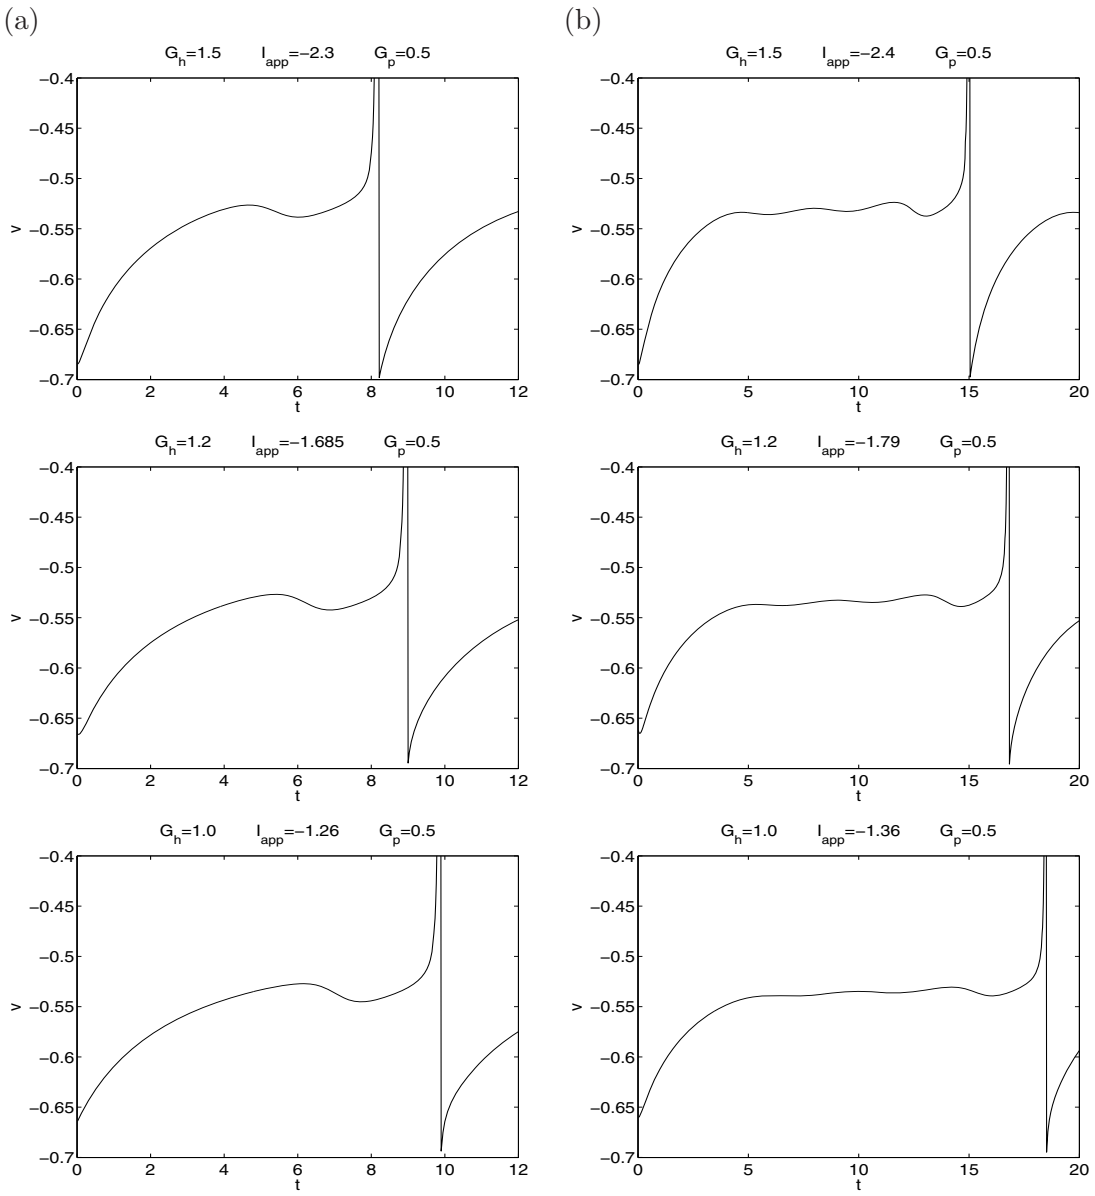

Figure 12. *Voltage traces showing the effect of changes in the values of G_h and I_{app} on the mixed-mode oscillatory patterns corresponding to trajectories starting in a vicinity of the slow manifold. Bottom: $G_h = 1.0$ (0.6667) and* (a) *$I_{app} = -1.26$ (-0.0084),* (b) *$I_{app} = -1.36$ (-0.0091).*

rotational sector to another with a lower number of STOs or no STOs at all. As a consequence, the spike-time of the perturbed SC will be considerably advanced with respect to that of the unperturbed cell. We illustrate this in Figures 14 and 15 for two different values of I_{app}. In Figure 14, the unperturbed SC displays one STO per spike. The pulses of inhibition applied

at $t_{pert} = 2.66$ and $t_{pert} = 2.83$ move the trajectory outside the funnel and cause the SC to spike with no STOs. In Figure 15, the unperturbed SC has three STOs per spike. Pulses of inhibition applied at $t_{pert} = 3.33$ and $t_{pert} = 5.0$ move the trajectory to sectors corresponding to two and one STO per spike, respectively, and a pulse of inhibition applied at $t_{pert} = 5.83$ moves the trajectory outside the funnel and causes the SC to spike with no STOs.

5. Discussion. Stellate cells (SCs) of the medial entorhinal cortex (MEC) display subthreshold oscillations (STOs) and mixed-mode oscillations (MMOs) at theta frequencies [8, 9]. In these MMO patterns, spikes occur at the peak of STOs, though not at every cycle. STOs found in single SCs are the result of the interaction between I_h and I_p [7, 8, 9]. It was recently found that their frequency varies along the dorsal-to-ventral axis of the MEC, scaling with the MEC grid-cells [3] that are believed to contain a neural map of the spatial environment [4, 5, 6].

Previous theoretical work has focused on various aspects of SC dynamics using biophysical (conductance-based) models: reproducing, via simulations, STOs, MMOs, and fully spiking patterns [10, 12, 13, 14, 30], the computational study of resonant properties of SCs [14, 57] and

the computational study of synchronization properties of networks including SCs [12, 10, 26].

In [10] we initiated a more detailed mechanistic study of the generation of STOs and MMOs in the 7D SC model proposed in [12]. We considered there a rather restricted set of parameters. Using reduction-of-dimensions techniques, we argued that this model can

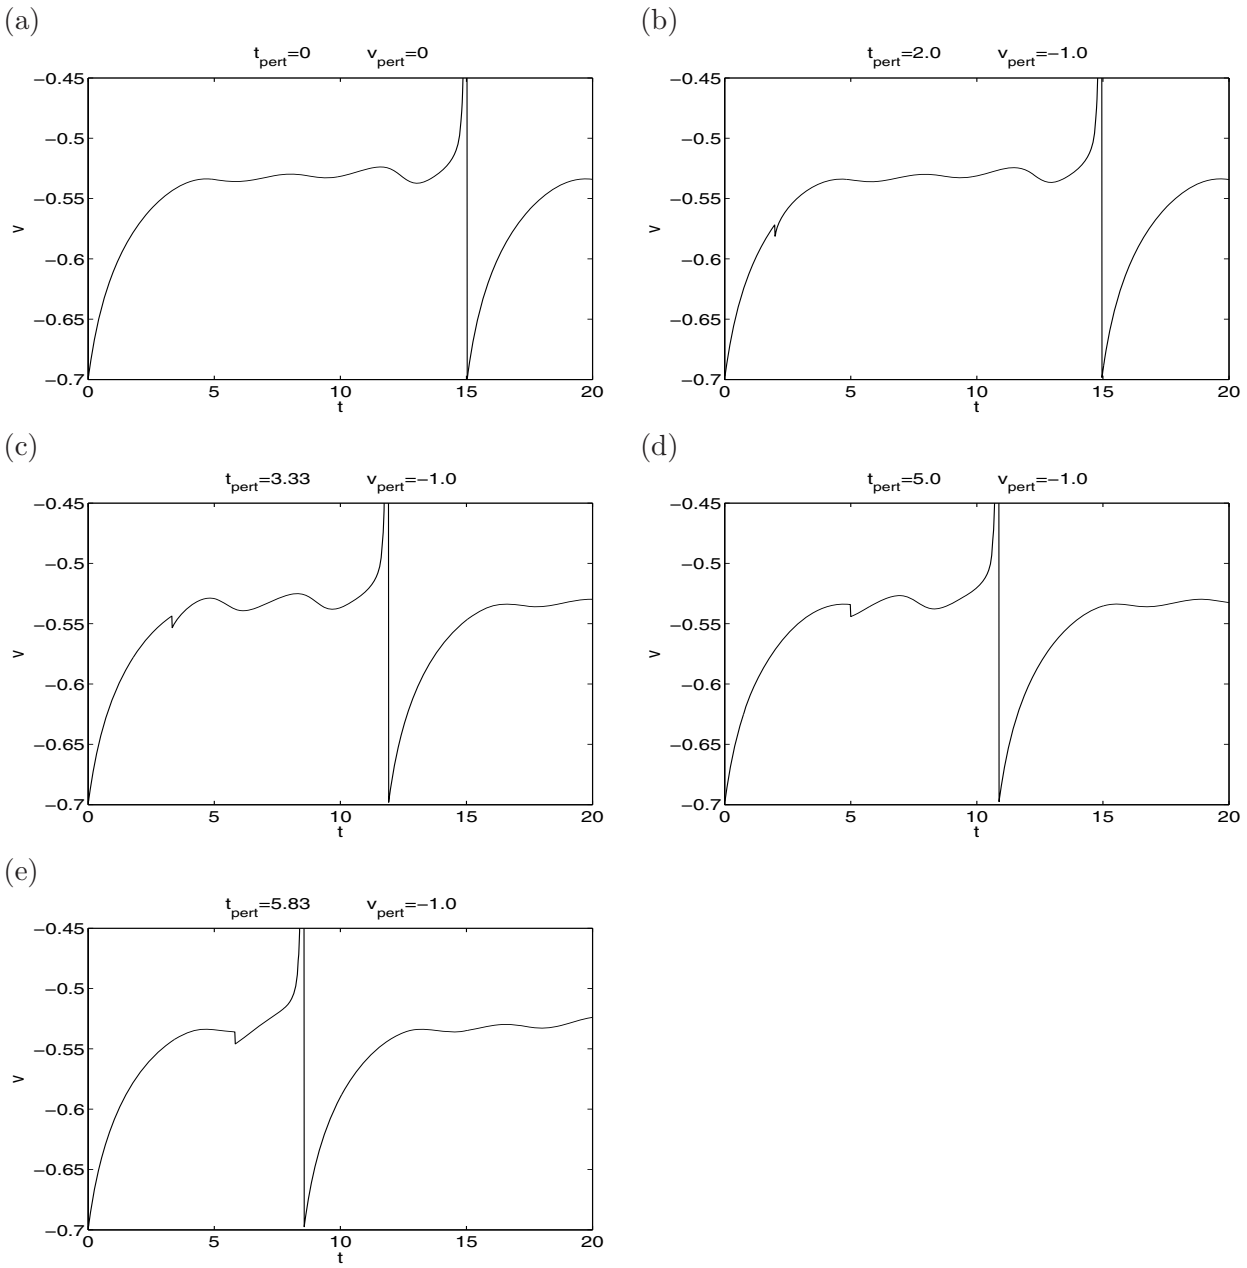

Figure 15. *Voltage traces showing the effect of inhibitory perturbations at various times t_{pert} on the mixed-mode oscillatory patterns corresponding to trajectories starting in a vicinity of the slow manifold for $G_h = 1.5$ (1.0), $I_{app} = -2.4$ (-0.0160). be approximated in the subthreshold regime by the 3D slow-fast system (1)–(3) studied in this paper (the dimensional SC model), which accounts for the interactions between I_p and I_h. Using computational techniques and dynamical systems ideas, we hypothesized that this interaction is intrinsically nonlinear and that the generation of STOs and MMOs is governed

by the 3D canard phenomenon.

In this paper we used analytical and computational tools to show that the 3D canard phenomenon is the main player in the mechanism of generation of STOs in the SC model (1)–(3) for a broad range of biophysically plausible parameter values that include those considered in [10]. The underlying dynamic structure also describes the onset of spikes but not the spike dynamics. Once the oscillating trajectory escapes the subthreshold regime to the spiking one, the reset properties of the h-current provide the additional mechanism needed for the trajectory to return to the subthreshold regime and produce MMOs.

From the mathematical point of view, our results show that the SC model (1)–(3) satisfies the conditions required by the theorems proposed in [17] (see section 4.4) to guarantee the existence of MMOs. Thus, the SC model becomes a biologically plausible example of the theory developed in [17]. Care has to be taken in the limiting case of a folded saddle-node ($\mu \to 0$), since the corresponding theory has still to be developed. Nonetheless, trends can be deduced from the folded node analysis and by sufficiently decreasing the singular perturbation parameter as shown in section 4.8. Examples related to other phenomena include those studied in [16, 45].

From the mechanistic point of view, our results provide an analytical and geometric framework to study various dynamic aspects of SCs: the role that the participating currents and their interaction play in shaping the observed MMO patterns, some of the consequences of these interactions when SCs receive external inputs (sinusoidal or synaptic-like), and the prediction of the effect that different amounts of the participating currents may have on the observed MMO patterns. These differences could be due to a heterogeneous distribution of channels in the EC, to the effect of neuromodulators, or to changes due to development.

A very important component of the framework we refer to above is the singular funnel. By calculating the strong canard it is possible to make qualitative predictions about whether STOs are expected within the spiking pattern or not, i.e., which initial conditions in the subthreshold regime lead to MMOs and which lead to fully spiking patterns. One can be more explicit about the precise number of STOs by further calculating the secondary canards. Changes in the parameters of the model are reflected in the singular funnel via changes in the strong canard, changes in the secondary canards, or changes in the initial conditions in the subthreshold regime due to variations in the trajectory reset values. So, for example, the trajectory corresponding to a specific initial condition and a certain set of parameters may enter the funnel while the trajectory corresponding to the same initial conditions and a different set of parameters may be left outside. The tools required to make more accurate quantitative predictions call for further research.

The results of this paper support our previous hypothesis [10] of the existence of a canard geometric/dynamic structure as the main player in the mechanism of generation of STOs in SCs. This canard structure is generated by the (nonlinear) nullsurfaces and the time scale separation between the participating variables, and it has the potential of producing the canard phenomenon. More specifically, STOs in SCs have been proposed to be sustained by a "push-pull" interplay between I_p and I_h [7, 8]. In particular, I_h has been proposed to play a major pacemaker role in the generation of STOs, providing a delayed feedback mechanism to the voltage changes led by I_p. This mechanism depends on the dynamic (kinetic) properties of I_h. There are various players in this interaction: the amount of I_h and I_p (expressed by the

maximal conductances G_h and G_p), the relative speeds of the voltage and gating variables, and the nonlinearities associated with the dynamic equations. Our results show that these are encoded in the canard structure. Different sets of parameters lead to similar canard structures which produce similar voltage traces: In our model, a decrease in G_h (reflecting a decrease in the amount of I_h) leads to an increase in the "height" of the V-nullsurface. Since the other nullsurfaces do not depend on the parameter of the model, for fixed values of I_{app} and low enough values of G_h, folded nodes no longer exist and trajectories will be attracted to a stable fixed point (see Table 2). However, this can be reversed by increasing the value of I_{app}, which lowers the V-nullsurface. The fact that MMOs with the same number of STOs per spike with roughly the same amplitude are obtained for different pairs of (G_h, I_{app}) and (G_h, G_p) (see Figures 12 and 13) shows that it is not a specific property of I_h and I_p that creates the STOs but rather a property of the various appropriate balances these currents can create, which are reflected in the generation of similar or "equivalent" canard structures. This raises the question of whether internal homeostatic mechanisms exist that keep the number of STOs per spike unchanged. On the other hand, as we mentioned earlier, the fact that the STO frequency changes with I_h shows a way in which the canard mechanism can account for the difference in frequencies experimentally observed in SCs along the ventral-to-dorsal axis of the EC [3].

Spike-time response curve (STRC) techniques have been used to study the synchronization properties of small networks including SCs [12, 25, 26], particularly to investigate how synchronization depends on key ionic currents known to be important to the theta rhythm. STRCs are functions that measure the effect of a spike of a presynaptic cell on the timing of the next spike of the postsynaptic cell. (STRCs are essentially the same as phase response curves [58, 59].) Our results also support the hypothesis that the canard structure is an important component in the mechanism of synchronization in networks including SCs and other excitatory and inhibitory neurons.

There has been some controversy in the literature about whether the observed subthreshold oscillations in SCs are intrinsically linear or nonlinear phenomena [14, 57]. As predicted in [10], our results show that the latter is the most plausible case. Our results also show that the interaction between I_p and I_h responsible for the generation of STOs involves both components of I_h, not only the fast one; i.e., the slow component of I_h does not simply play a modulatory role in the generation of STOs, but rather a dynamic one.

As occurs for many conductance-based models, the concept of a spiking threshold is not well defined in the SC model we study here (see [60] for a discussion on the topic). There are two ways in which spikes are generated in the SC model, leading to patterns whose interspike intervals differ by roughly an order of magnitude. The first type corresponds to initial conditions such that the trajectory is "captured" by the slow manifold S. The spiking period between two such spikes is determined by the time it takes the trajectory to move along the slow manifold. These trajectories may or may not enter the funnel. In either case, the onset of spikes occurs when the trajectory moves away from the slow manifold along a fast fiber towards the spiking regime. Once this occurs, spiking is unavoidable; i.e., the trajectory does not have to cross any voltage threshold value to spike. In the nonlinear artificially spiking model, the value of V_{th} only indicates that a spike has occurred so that it can be (artificially) added to the voltage trace. The second type of spike corresponds to initial conditions such

that the trajectory is never "captured" by the slow manifold S. These initial conditions are above the fold-curve. The period between two such spikes is determined by the time it takes the trajectory to move along a fast fiber (vertical direction); i.e., its order of magnitude is ϵ. As for the first type, once the trajectory enters the subthreshold regime a spike will occur without the need of a voltage threshold value. Spontaneous spikes of the second type are expected to be rare, since reset voltage values are typically lower than that corresponding to the fold-curve. However, trajectories may be forced to change from one spiking regime to the other by external inputs. This may have consequences for network dynamics in the EC.

There are several aspects of the SC dynamics not studied in this paper. One of them is how noise affects the MMO patterns. One important source of noise is the set of persistent sodium channels [13, 61]. In [10] we showed that STOs are less regular and more robust when persistent sodium channel noise is added to the SC model studied here. A second aspect is spike clustering, where two or more spikes occur without interspersed STOs. Noisy MMOs and clustering have been reproduced via simulations in the biophysical (conductance-based) model presented in [13]. Whether or not this model has an underlying canard structure qualitatively similar to the one we uncovered in this paper is still an open question.

Acknowledgments. We thank Tasso Kaper for his useful comments on an earlier draft of this manuscript, and Amit Bose, Morten Brøns, Martin Krupa, and John White for useful discussions.
