where F is the Faraday constant. The corresponding expression for water is then taken to be

$$\langle \mathbf{n}_{H_2O}.\mathbf{n} \rangle = \frac{M_{H_2O}(1+2\alpha)I}{2F}, \tag{2.35}$$

where α is a parameter accounting for the water transport by electro-osmosis in the membrane; typical values encountered in the literature are $\alpha = 0.3$ [41] and $0.5 \leq \alpha \leq 1.7$ [30, 44, 45]. Furthermore, since nitrogen does not participate in the reaction at the catalyst layer,

$$\langle \mathbf{n}_{N_2}.\mathbf{n} \rangle = 0. \tag{2.36}$$

This leads to the following boundary conditions for $\langle v \rangle$, $\langle x_{O_2} \rangle^{(\mathrm{g})}$, and $\langle x_{H_2O} \rangle^{(\mathrm{g})}$:

$$\langle \rho \rangle^{(\mathrm{g})} \langle v \rangle = \frac{I}{4F} \left(2(1+2\alpha) M_{H_2O} - M_{O_2} \right) \tag{2.37}$$

and

$$\frac{\langle \rho \rangle^{(\mathrm{g})} \langle v \rangle}{\langle M \rangle^{(\mathrm{g})}} \begin{bmatrix} \langle x_{O_2} \rangle^{(\mathrm{g})} \\ \langle x_{H_2O} \rangle^{(\mathrm{g})} \end{bmatrix} - \frac{\gamma^{\frac{3}{2}} \langle \rho \rangle^{(\mathrm{g})}}{\left(\langle M \rangle^{(\mathrm{g})} \right)^2} \bar{\mathbf{M}} \frac{\partial}{\partial y} \begin{bmatrix} \langle x_{O_2} \rangle^{(\mathrm{g})} \\ \langle x_{H_2O} \rangle^{(\mathrm{g})} \end{bmatrix} = \frac{I}{4F} \begin{bmatrix} -1 \\ 2(1+2\alpha) \end{bmatrix}.$$

3. Analysis.

3.1. Nondimensionalization.

Writing

$$\tilde{x} = \frac{x}{L}, \quad \tilde{y} = \frac{y}{L}, \quad \tilde{\mathbf{v}} = \frac{\mathbf{v}}{U^{in}}, \quad \langle \tilde{\mathbf{v}} \rangle = \frac{\langle \mathbf{v} \rangle}{U^{in}}, \; \tilde{\rho} = \frac{\rho}{[\rho]}, \; \langle \tilde{\rho} \rangle^{(\mathrm{g})} = \frac{\langle \rho \rangle^{(\mathrm{g})}}{[\rho]},$$

$$\tilde{p} = \frac{p - p^{out}}{[\rho] \left(U^{in} \right)^2}, \; \langle \tilde{p} \rangle^{(\mathrm{g})} = \frac{\langle p \rangle^{(\mathrm{g})} - p^{out}}{[\rho] \left(U^{in} \right)^2}, \; \tilde{p}' = \frac{p' - p^{out}}{[\rho] \left(U^{in} \right)^2}, \; \langle \tilde{p}' \rangle^{(\mathrm{g})} = \frac{\langle p' \rangle^{(\mathrm{g})} - p^{out}}{[\rho] \left(U^{in} \right)^2},$$

$$\widetilde{I} = \frac{I}{[I]}, \quad \mathcal{M} = \frac{M}{[M]}, \; \langle \mathcal{M} \rangle^{(\mathrm{g})} = \frac{\langle M \rangle^{(\mathrm{g})}}{[M]}, \quad \tilde{c} = \frac{c}{[\rho] / [M]},$$

$$\mathcal{M}_i = \frac{M_i}{[M]}, \; i = 1, \ldots, 3, \quad \tilde{D}_{ij} = \frac{D_{ij}}{[D]}, \; i, j = 1, \ldots, 3, \quad \tilde{D}_{ij}^{eff} = \frac{D_{ij}^{eff}}{[D]}, \; i, j = 1, \ldots, 3,$$

$$Re = \frac{[\rho] U^{in} L}{\mu}, \quad Sc = \frac{\mu}{[\rho] [D]}, \quad Da = \frac{\kappa}{L^2}, \quad Fr = \frac{U^2}{gL},$$

$$\tilde{\mathbf{M}} = \frac{\mathbf{M}}{[M] [D]}, \; \left\langle \tilde{\mathbf{M}} \right\rangle^{(\mathrm{g})} = \frac{\langle \mathbf{M} \rangle^{(\mathrm{g})}}{[M] [D]},$$

where $[\rho]$ is a density scale, $[D]$ is a diffusion scale, $[I]$ is a current density scale, and $[M]$ is a molecular weight scale (all to be either determined or specified shortly) and Re, Sc, Da, and Fr are the Reynolds, Schmidt, Darcy, and Froude numbers,

respectively, we drop the tildes and arrive at the following nondimensionalized forms. For the channel ($0 \le x \le 1$, $0 \le y \le 1$),

$$\nabla.(\rho \mathbf{v}) = 0, \tag{3.1}$$

$$\nabla.(\rho \mathbf{v} \otimes \mathbf{v}) = -\nabla\left(p + \frac{2\delta^2}{3}\nabla.\mathbf{v}\right) + \delta^2\nabla^2\mathbf{v} - Fr^{-1}\rho\mathbf{j}, \tag{3.2}$$

$$\nabla.\left(\frac{\rho\mathbf{v}}{\mathcal{M}}\begin{bmatrix} x_{O_2} \\ x_{H_2O}\end{bmatrix}\right) = \frac{\delta^2}{Sc}\nabla.\left(\frac{\rho}{\mathcal{M}^2}\mathbf{M}\begin{bmatrix}\nabla x_{O_2} \\ \nabla x_{H_2O}\end{bmatrix}\right), \tag{3.3}$$

where $\delta^2 = Re^{-1}$, and for the porous medium ($0 \le x \le 1$, $-h_p/L \le y \le 0$),

$$\nabla.\left(\langle\rho\rangle^{(g)}\langle\mathbf{v}\rangle\right) = 0, \tag{3.4}$$

$$\frac{\delta^2}{\epsilon^2}\langle\mathbf{v}\rangle = -\nabla\langle p'\rangle^{(g)} + \delta^2\nabla^2\left(\frac{\langle\mathbf{v}\rangle}{\gamma}\right) - Fr^{-1}\langle\rho\rangle^{(g)}\mathbf{j},$$

$$\nabla.\left(\frac{\langle\rho\rangle^{(g)}\langle\mathbf{v}\rangle}{\langle\mathcal{M}\rangle^{(g)}}\begin{bmatrix}\langle x_{O_2}\rangle^{(g)} \\ \langle x_{H_2O}\rangle^{(g)}\end{bmatrix}\right) = \frac{\delta^2}{Sc}\nabla.\left(\gamma^{\frac{3}{2}}\frac{\langle\rho\rangle^{(g)}}{\left(\langle\mathcal{M}\rangle^{(g)}\right)^2}\langle\mathbf{M}\rangle^{(g)}\begin{bmatrix}\nabla\langle x_{O_2}\rangle^{(g)} \\ \nabla\langle x_{H_2O}\rangle^{(g)}\end{bmatrix}\right), \tag{3.5}$$

where $\epsilon^2 = Da$. The boundary conditions are now

$$u = 1, \quad v = 0, \quad x_{O_2} = x_{O_2}^{in}, \quad x_{H_2O} = x_{H_2O}^{in} \quad \text{at} \quad x = 0, \quad 0 \le y \le h_f/L; \tag{3.6}$$

$$u = v = \frac{\partial x_{O_2}}{\partial y} = \frac{\partial x_{H_2O}}{\partial y} = 0 \quad \text{at} \quad 0 \le x \le 1, \quad y = h_f/L; \tag{3.7}$$

$$p = 0, \quad \frac{\partial v}{\partial x} = \frac{\partial x_{O_2}}{\partial x} = \frac{\partial x_{H_2O}}{\partial x} = 0 \quad \text{at} \quad x = 1, \quad 0 \le y \le h_f/L; \tag{3.8}$$

$$\langle u\rangle = \frac{\partial\langle v\rangle}{\partial x} = \frac{\partial\langle x_{O_2}\rangle^{(g)}}{\partial x} = \frac{\partial\langle x_{H_2O}\rangle^{(g)}}{\partial x} = 0 \quad \text{at} \quad x = 0, 1, \quad -h_p/L \le y \le 0. \tag{3.9}$$

The boundary conditions for $0 \le x \le 1$, $y = -h_p/L$ are now

$$\langle u\rangle = 0, \quad \langle\rho\rangle^{(g)}\langle v\rangle = \Lambda\left\{\frac{I}{4}\left(2(1+2\alpha)\mathcal{M}_{H_2O} - \mathcal{M}_{O_2}\right)\right\}, \tag{3.10}$$

$$\frac{\langle\rho\rangle^{(g)}\langle\mathbf{v}\rangle}{\langle\mathcal{M}\rangle^{(g)}}\begin{bmatrix}\langle x_{O_2}\rangle^{(g)} \\ \langle x_{H_2O}\rangle^{(g)}\end{bmatrix} - \frac{\delta^2\gamma^{\frac{3}{2}}\langle\rho\rangle^{(g)}}{Sc\left(\langle\mathcal{M}\rangle^{(g)}\right)^2}\langle\mathbf{M}\rangle^{(g)}\frac{\partial}{\partial y}\begin{bmatrix}\langle x_{O_2}\rangle^{(g)} \\ \langle x_{H_2O}\rangle^{(g)}\end{bmatrix} \tag{3.11}$$

$$= \frac{\Lambda I}{4}\begin{pmatrix}-1 \\ 2(1+2\alpha)\end{pmatrix},$$

TABLE 1
Scales for nondimensionalization.

$[\rho]$	1 kgm^{-3}
$[M]$	$[\rho]\, RT/p^{out}$
$[I]$	10^4 Am^{-2}

where $\Lambda = [I]\,[M]\,/FU^{in}\,[\rho]$. Finally, the boundary conditions along the fluid-porous interface on $y = 0$ reduce to

$$v = \langle v \rangle\,, \tag{3.12}$$

$$p - \delta^2 \frac{\partial v}{\partial y} = \langle p \rangle^{(\mathrm{g})} - \delta^2 \frac{\partial \langle v \rangle}{\partial y}, \tag{3.13}$$

$$u = \langle u \rangle\,, \tag{3.14}$$

$$\frac{1}{\gamma}\frac{\partial \langle u \rangle}{\partial y} - \frac{\partial u}{\partial y} = \left(\frac{\beta_1}{\varepsilon}\right) u + \left(\frac{\beta_2}{\delta^2}\right) \rho u^2 \tag{3.15}$$

and

$$\langle x_{O_2} \rangle^{(\mathrm{g})} = x_{O_2}, \quad \langle x_{H_2O} \rangle^{(\mathrm{g})} = x_{H_2O}, \tag{3.16}$$

$$\gamma^{\frac{3}{2}} \frac{\partial}{\partial y} \begin{bmatrix} \langle x_{O_2} \rangle^{(\mathrm{g})} \\ \langle x_{H_2O} \rangle^{(\mathrm{g})} \end{bmatrix} = \frac{\partial}{\partial y} \begin{bmatrix} x_{O_2} \\ x_{H_2O} \end{bmatrix}. \tag{3.17}$$

3.2. Parameters. Typically, $U^{in} \sim 1$ ms^{-1}, $h_f \sim 10^{-3}$ m, $h_p \sim 3 \times 10^{-4}$ m, $L \geq 10^{-2}$ m, $[I] \sim 10^4$ Am^{-2}, $p^{out} \sim 1$ atm $\sim 10^5$kgm^{-1}s^{-2}, $T \sim 300$–350 K, $0.1 \leq \gamma \leq 0.5$, $0.3 \leq \alpha \leq 1.7$, $\mu \sim O(10^{-5})$ kgm$^{-1}s^{-1}$. In addition, $M_{O_2} = 0.032$ kgmol^{-1}, $M_{H_2O} = 0.018$ kgmol^{-1}, $M_{N_2} = 0.028$ kgmol^{-1}, $F = 96487$ Asmol^{-1}, from which we note that $M_{min} \leq M \leq M_{max}$, where

$$M_{min} = M|_{x_{H_2O}=1, x_{O_2}=0} = 0.018 \text{ kgmol}^{-1},$$
$$M_{max} = M|_{x_{H_2O}=0, x_{O_2}=1} = 0.032 \text{ kgmol}^{-1}.$$

Further, we use the constitutive relation for an ideal gas in order to obtain the density scale $[\rho]$; with $p \sim p^{out}$, we have $\rho \sim 1$ kgm^{-3}, so that $[\rho] \sim 1$ kgm^{-3} seems appropriate. For $[D]$, we take $O\left(10^{-5}\right)$ m^{2}s^{-1} from available literature, e.g., [5, 6]. Note also that the relation (2.17) is satisfied, since the smallest length on the macroscale in the porous backing, h_p, is still much larger than the scale for l_γ, 10^{-5}–10^{-6}m, suggested by the electrochemical literature [16, 40]. The scales used for nondimensionalisation and the physical parameters are summarized in Tables 1 and 2, respectively.

Thence, for the nondimensional parameters Re, Sc, Da, Fr, Λ, we arrive at

$$Re \sim 10^4, \quad Sc \sim 1, \quad Da \leq 10^{-6}, \quad Fr \sim 1, \quad \Lambda \leq 10^{-2},$$

so that $\delta \sim 10^{-2}$ and $\epsilon \leq 10^{-3}$. We note here that some of these parameters have been encountered before in conjunction with the modeling of flow in SOFC [7, 11], in particular, the Reynolds number, Re, which represents the ratio of inertial to viscous forces and the product Schmidt $ReSc$, which is the ratio of gas flow rate to the rate of diffusion. (In fact $ReSc$ in our formulation corresponds to the parameter Q in [7, 11,

TABLE 2
Physical parameters.

M_{O_2}	0.032 kgmol^{-1}
M_{H_2O}	0.018 kgmol^{-1}
M_{N_2}	0.028 kgmol^{-1}
$\mathcal{D}_{O_2,H_2O}$	$3.749[M]/RT$
$\mathcal{D}_{O_2,N_2}$	$2.827[M]/RT$
$\mathcal{D}_{H_2O,N_2}$	$3.923[M]/RT$

26].) Furthermore, the parameter Λ is a measure of the ratio of the electrochemical flux of oxygen to the gas flow rate and thus corresponds to the combination E/Q in [7, 11, 26]. For completeness, we mention that the Froude number, *Fr*, is the ratio of inertial to gravitational forces, whereas the Darcy number, *Da*, is the ratio of the porous medium permeability to the square of the length scale of the entire geometry.

3.3. Narrow-gap approximation. Typically, $h_f/L, h_p/L \ll 1$, which leads us to further rescaling as follows. Writing

$$X = x, \quad Y = \frac{y}{\sigma}, \quad U = u, \; V = \frac{v}{\sigma}, \quad \langle U \rangle = \langle u \rangle, \quad \langle V \rangle = \frac{\langle v \rangle}{\sigma},$$
$$P = p, \; P' = p', \quad \langle P \rangle = \langle p \rangle, \quad \langle P' \rangle = \langle p' \rangle,$$

where $\sigma = h_f/L$, we simplify further by neglecting terms in $O(\sigma)$ or lower, although we retain for the time being terms which contain multiples of σ and the other dimensionless parameters. We introduce the dimensionless parameters Δ, Σ, and Ω, given by

$$\Delta = \delta^2/\sigma^2, \; \Sigma = \sigma^2/\varepsilon, \; \Omega = \Lambda/\sigma,$$

and that an alternative expression for Δ is $\Delta = \left(Re\sigma^2\right)^{-1}$, i.e., the reciprocal of the reduced Reynolds number. We have now, for the channel,

$$\frac{\partial}{\partial X}(\rho U) + \frac{\partial}{\partial Y}(\rho V) = 0, \tag{3.18}$$

$$\rho\left(U\frac{\partial U}{\partial X} + V\frac{\partial U}{\partial Y}\right) = -\frac{\partial P'}{\partial X} + \Delta\frac{\partial^2 U}{\partial Y^2}, \tag{3.19}$$

$$0 = -\frac{\partial P'}{\partial Y}, \tag{3.20}$$

$$\left(\rho U\frac{\partial}{\partial X} + \rho V\frac{\partial}{\partial Y}\right)\begin{bmatrix} 1 & x_{O_2} \\ \mathcal{M} & x_{H_2O} \end{bmatrix} = \frac{\Delta}{Sc}\frac{\partial}{\partial Y}\left(\frac{\rho}{\mathcal{M}^2}\mathbf{M}\frac{\partial}{\partial Y}\begin{bmatrix} x_{O_2} \\ x_{H_2O} \end{bmatrix}\right) \tag{3.21}$$

and for the porous medium,

$$0 = \frac{\partial}{\partial X}\left(\langle\rho\rangle^{(\mathrm{g})}\langle U\rangle\right) + \frac{\partial}{\partial Y}\left(\langle\rho\rangle^{(\mathrm{g})}\langle V\rangle\right), \tag{3.22}$$

$$\langle U\rangle = -\frac{\epsilon}{\Delta\Sigma}\frac{\partial\langle P'\rangle^{(\mathrm{g})}}{\partial X} + \frac{\varepsilon}{\Sigma\gamma}\frac{\partial^2\langle U\rangle}{\partial Y^2}, \tag{3.23}$$

$$\langle V\rangle = -\frac{1}{\Delta\Sigma^2}\frac{\partial\langle P'\rangle^{(\mathrm{g})}}{\partial Y} + \frac{\varepsilon}{\Sigma\gamma}\frac{\partial^2\langle V\rangle}{\partial Y^2}, \tag{3.24}$$

$$\begin{aligned}\left(\langle\rho\rangle^{(\mathrm{g})}\langle U\rangle\frac{\partial}{\partial X} + \langle\rho\rangle^{(\mathrm{g})}\langle V\rangle\frac{\partial}{\partial Y}\right)\left(\frac{1}{\langle\mathcal{M}\rangle^{(\mathrm{g})}}\begin{bmatrix}\langle x_{O_2}\rangle^{(\mathrm{g})}\\ \langle x_{H_2O}\rangle^{(\mathrm{g})}\end{bmatrix}\right)\\ = \frac{\Delta}{Sc}\frac{\partial}{\partial Y}\left(\frac{\gamma^{\frac{3}{2}}\langle\rho\rangle^{(\mathrm{g})}}{\left(\langle\mathcal{M}\rangle^{(\mathrm{g})}\right)^2}\langle\mathbf{M}\rangle^{(\mathrm{g})}\frac{\partial}{\partial Y}\begin{bmatrix}\langle x_{O_2}\rangle^{(\mathrm{g})}\\ \langle x_{H_2O}\rangle^{(\mathrm{g})}\end{bmatrix}\right).\end{aligned} \tag{3.25}$$

Note also that

$$P' = P + O\left(\delta^2\right), \quad \langle P'\rangle^{(\mathrm{g})} = \langle P\rangle^{(\mathrm{g})} + O\left(\delta^2\right),$$

and since $\delta^2 \ll 1$, henceforth, we use the actual pressure rather than the modified pressure. In addition, the gravitational terms in (3.20) and (3.24) are $O\left(Fr^{-1}\sigma\right)$ and have therefore been dropped. The boundary conditions are, for $0 \le X \le 1, Y = 1$,

$$U = V = \frac{\partial x_{O_2}}{\partial Y} = \frac{\partial x_{H_2O}}{\partial Y} = 0; \tag{3.26}$$

for $0 \le X \le 1, Y = 0$,

$$V = \langle V\rangle, \tag{3.27}$$

$$P = \langle P\rangle^{(\mathrm{g})}, \tag{3.28}$$

$$U = \langle U\rangle, \tag{3.29}$$

$$\frac{1}{\gamma}\frac{\partial\langle U\rangle}{\partial Y} - \frac{\partial U}{\partial Y} = \left(\frac{\beta_1\sigma}{\varepsilon}\right)U + \left(\frac{\beta_2\sigma}{\delta^2}\right)\rho U^2, \tag{3.30}$$

$$\langle x_{O_2}\rangle^{(\mathrm{g})} = x_{O_2}, \quad \langle x_{H_2O}\rangle^{(\mathrm{g})} = x_{H_2O}, \tag{3.31}$$

$$\gamma^{\frac{3}{2}}\frac{\partial}{\partial Y}\begin{bmatrix}\langle x_{O_2}\rangle^{(\mathrm{g})}\\ \langle x_{H_2O}\rangle^{(\mathrm{g})}\end{bmatrix} = \frac{\partial}{\partial Y}\begin{bmatrix}x_{O_2}\\ x_{H_2O}\end{bmatrix}; \tag{3.32}$$

for $0 \le X \le 1, Y = -\mathcal{H}\,(= h_p/h_f)$,

$$\langle U\rangle = 0, \quad \langle\rho\rangle^{(\mathrm{g})}\langle V\rangle = \Omega\left\{\frac{I}{4}\left(2(1+2\alpha)\mathcal{M}_{H_2O} - \mathcal{M}_{O_2}\right)\right\}, \tag{3.33}$$

$$\begin{aligned}&\frac{\langle\rho\rangle^{(\mathrm{g})}\langle V\rangle}{\langle\mathcal{M}\rangle^{(\mathrm{g})}}\begin{bmatrix}\langle x_{O_2}\rangle^{(\mathrm{g})}\\ \langle x_{H_2O}\rangle^{(\mathrm{g})}\end{bmatrix} - \frac{\Delta\gamma^{\frac{3}{2}}\langle\rho\rangle^{(\mathrm{g})}}{Sc\left(\langle\mathcal{M}\rangle^{(\mathrm{g})}\right)^2}\langle\mathbf{M}\rangle^{(\mathrm{g})}\frac{\partial}{\partial Y}\begin{bmatrix}\langle x_{O_2}\rangle^{(\mathrm{g})}\\ \langle x_{H_2O}\rangle^{(\mathrm{g})}\end{bmatrix}\\ &= \frac{\Omega I}{4}\begin{bmatrix}-1\\ 2(1+2\alpha)\end{bmatrix}.\end{aligned} \tag{3.34}$$

The neglect of streamwise diffusion terms will of course imply that not all of the original boundary conditions at $X = 0$ and 1 in this reduced formulation can be satisfied, and those terms would need to be reinstated for $X \sim O(\sigma)$ and $1 - X \sim O(\sigma)$. This is beyond the scope of interest here, and for a consistent formulation we simply retain

$$U = 1, \quad x_{O_2} = x_{O_2}^{in}, \quad x_{H_2O} = x_{H_2O}^{in} \quad \text{at} \quad X = 0, \quad 0 \le Y \le 1, \tag{3.35}$$

$$\langle U \rangle = \frac{\partial \langle x_{O_2} \rangle^{(g)}}{\partial X} = \frac{\partial \langle x_{H_2O} \rangle^{(g)}}{\partial X} = 0 \quad \text{at} \quad X = 0, \quad -\mathcal{H} \le Y \le 0. \tag{3.36}$$

For the initial discussion, we proceed under the assumption that $\Sigma, \Delta, \Omega \sim O(1)$; later, we will also require $\Omega \gg 1$. Further simplification is now possible by noting from (3.23) that $\langle U \rangle = 0$ to leading order, which reduces (3.22), (3.24), and (3.25) still further. Turning to the porous region near $Y = 0_-$, there is no reason a priori to suppose that the porous core flow should satisfy (3.27)–(3.30); if it did, we would arrive at $U = \frac{\partial U}{\partial Y} = 0$ at $Y = 0$, and there would be too many boundary conditions for (U, V, P) in the channel. Instead, we require a porous boundary layer for which $Y \sim \varepsilon^{\frac{1}{2}}$, $\langle U \rangle \sim \varepsilon^{\frac{1}{2}}$. Writing

$$Y = \varepsilon^{\frac{1}{2}} \widetilde{Y}, \quad \langle U \rangle = \varepsilon^{\frac{1}{2}} \left\langle \widetilde{U} \right\rangle, \quad \langle P \rangle^{(g)} = \left\langle \widetilde{P} \right\rangle^{(g)}, \quad \langle V \rangle = \left\langle \widetilde{V} \right\rangle,$$

we have, to leading order, in this layer

$$\frac{\partial}{\partial \widetilde{Y}} \left(\langle \rho \rangle^{(g)} \left\langle \widetilde{V} \right\rangle \right) = 0, \tag{3.37}$$

$$\left\langle \widetilde{U} \right\rangle = \frac{\partial^2}{\partial \widetilde{Y}^2} \left(\frac{\left\langle \widetilde{U} \right\rangle}{\gamma} \right), \tag{3.38}$$

$$0 = -\frac{\partial \left\langle \widetilde{P} \right\rangle^{(g)}}{\partial \widetilde{Y}} \tag{3.39}$$

subject to the matching conditions as $\widetilde{Y} \longrightarrow -\infty$

$$\left\langle \widetilde{V} \right\rangle \longrightarrow \langle V \rangle (X, 0), \quad \left\langle \widetilde{U} \right\rangle \longrightarrow 0, \quad \left\langle \widetilde{P} \right\rangle^{(g)} \longrightarrow \langle P \rangle^{(g)} (X, 0),$$

where

$$\langle V \rangle (X, 0) = \lim_{Y \to 0_-} \langle V \rangle, \quad \langle P \rangle^{(g)} (X, 0) = \lim_{Y \to 0_-} \langle P \rangle^{(g)}.$$

At $Y = \widetilde{Y} = 0$, we have

$$V = \left\langle \widetilde{V} \right\rangle, \tag{3.40}$$

$$P = \langle P \rangle^{(g)}, \tag{3.41}$$

$$U = \varepsilon^{\frac{1}{2}} \left\langle \widetilde{U} \right\rangle, \tag{3.42}$$

$$\frac{1}{\gamma} \frac{\partial \left\langle \widetilde{U} \right\rangle}{\partial \widetilde{Y}} - \frac{\partial U}{\partial Y} = \left(\frac{\beta_1 \sigma}{\varepsilon} \right) U + \left(\frac{\beta_2 \sigma}{\delta^2} \right) \rho U^2. \tag{3.43}$$

These equations are then used in the following order. First, the channel flow is determined with boundary conditions, to leading order,

$$U = 0,\ V = \left\langle \widetilde{V} \right\rangle.$$

This gives $P(X)$ which serves a boundary condition for $\langle P \rangle^{(\mathrm{g})}$, and finally $\langle \widetilde{U} \rangle$ can be computed, the boundary condition for this being, at leading order, simply

$$\frac{\partial \left\langle \widetilde{U} \right\rangle}{\partial \widetilde{Y}} = \gamma \left(\frac{\partial U}{\partial Y} \right)_{Y=0} \text{ at } \widetilde{Y} = 0.$$

As for the species equations, no such boundary layer in ε is necessary, with (3.25) being valid all the way up to $Y = 0_-$. In addition, we note that the leading order equations are independent of β_1 and β_2.

3.4. Further simplifications and observations. We invoke the constitutive relation for an ideal gas in dimensionless variables, with

$$\rho = \mathcal{M} + \left(\frac{[\rho] \left(U^{in} \right)^2}{p^{out}} \right) P, \quad \langle \rho \rangle^{(\mathrm{g})} = \langle \mathcal{M} \rangle^{(\mathrm{g})} + \left(\frac{[\rho] \left(U^{in} \right)^2}{p^{out}} \right) \langle P \rangle^{(\mathrm{g})} \tag{3.44}$$

for the channel and porous medium, respectively, which can be reduced to just $\rho = \mathcal{M}$, $\langle \rho \rangle^{(\mathrm{g})} = \langle \mathcal{M} \rangle^{(\mathrm{g})}$, respectively, for the pressures and velocities being considered here. The reduced system of equations is now, for $0 \leq X \leq 1$, $0 \leq Y \leq 1$,

$$\frac{\partial}{\partial X}(\rho U) + \frac{\partial}{\partial Y}(\rho V) = 0, \tag{3.45}$$

$$\rho \left(U \frac{\partial U}{\partial X} + V \frac{\partial U}{\partial Y} \right) = -\frac{dP}{dX} + \Delta \frac{\partial^2 U}{\partial Y^2}, \tag{3.46}$$

$$\frac{\partial}{\partial X} \left(U \begin{bmatrix} x_{O_2} \\ x_{H_2O} \end{bmatrix} \right) + \frac{\partial}{\partial Y} \left(V \begin{bmatrix} x_{O_2} \\ x_{H_2O} \end{bmatrix} \right) = \frac{\Delta}{Sc} \frac{\partial}{\partial Y} \left(\frac{\mathbf{M}}{\mathcal{M}} \frac{\partial}{\partial Y} \begin{bmatrix} x_{O_2} \\ x_{H_2O} \end{bmatrix} \right); \tag{3.47}$$

for $0 \leq X \leq 1$, $-\mathcal{H} \leq Y \leq 0$,

$$\langle \rho \rangle^{(\mathrm{g})} \langle V \rangle = \Omega \left\{ \frac{I}{4} \left(2(1+2\alpha) \mathcal{M}_{H_2O} - \mathcal{M}_{O_2} \right) \right\}, \tag{3.48}$$

$$\langle V \rangle = -\frac{1}{\Delta \Sigma^2} \frac{\partial \langle P \rangle^{(\mathrm{g})}}{\partial Y}, \tag{3.49}$$

$$\langle V \rangle \begin{bmatrix} \langle x_{O_2} \rangle^{(\mathrm{g})} \\ \langle x_{H_2O} \rangle^{(\mathrm{g})} \end{bmatrix} - \frac{\Delta \gamma^{\frac{3}{2}}}{Sc \langle \mathcal{M} \rangle^{(\mathrm{g})}} \langle \mathbf{M} \rangle^{(\mathrm{g})} \frac{\partial}{\partial Y} \begin{bmatrix} \langle x_{O_2} \rangle^{(\mathrm{g})} \\ \langle x_{H_2O} \rangle^{(\mathrm{g})} \end{bmatrix} = \frac{\Omega I}{4} \begin{bmatrix} -1 \\ 2(1+2\alpha) \end{bmatrix}. \tag{3.50}$$

Note here that (3.48), as well a consideration of the physical parameters, now helps to justify neglecting inertia terms between (2.12) and (2.22), as well as dispersion terms in (2.18) and (2.19). First, the Forchheimer correction term (see Whitaker [42]) will be of the order of magnitude of the Reynolds number, Re_γ, based on l_γ, loosely defined by

$$Re_\gamma = \frac{\langle \rho \rangle^{(\mathrm{g})} \langle v \rangle^{(\mathrm{g})} l_\gamma}{\mu}; \tag{3.51}$$

use of $\langle v\rangle^{(\mathrm{g})}$ for the velocity scale is justified since the foregoing analysis indicates that flow in the porous backing will be unidirectional. Consequently, using (2.37),

$$Re_\gamma \sim \frac{I}{4F\mu}\left(2(1+2\alpha)M_{H_2O} - M_{O_2}\right) l_\gamma \ll 1$$

as required. In addition, considerations based on this length scale provide some justification for neglecting dispersion effects in the porous backing, as compared to molecular diffusion. Experimental results for 1D flows (e.g., [2, pp. 606–609]) indicate that dispersion will be negligible if the Peclet number of molecular diffusion, Pe_γ, in the porous medium, defined here by

$$Pe_\gamma = \frac{\langle v\rangle^{(\mathrm{g})}\, l_\gamma}{[D]},$$

is much smaller than one; using the parameters given in section 3.2, this indeed turns out to be the case.

The boundary conditions are, for $0 \le X \le 1, Y = 1$,

$$U = V = \frac{\partial x_{O_2}}{\partial Y} = \frac{\partial x_{H_2O}}{\partial Y} = 0, \tag{3.52}$$

and for $X = 0,\ 0 \le Y \le 1$,

$$U = 1, \quad x_{O_2} = x_{O_2}^{in}, \quad x_{H_2O} = x_{H_2O}^{in} \quad \text{at} \quad X = 0, \quad 0 \le Y \le 1; \tag{3.53}$$

no boundary conditions as such prove to be necessary for $X = 0, -\mathcal{H} \le Y \le 0$ since only ordinary differential equations are solved for $-\mathcal{H} \le Y \le 0$. At $Y = 0$ for $0 \le X \le 1$, porous and fluid quantities are matched through

$$U = 0, \quad V = \langle V\rangle, \quad P = \langle P\rangle, \tag{3.54}$$

$$\langle x_{O_2}\rangle^{(\mathrm{g})} = x_{O_2}, \quad \langle x_{H_2O}\rangle^{(\mathrm{g})} = x_{H_2O}, \tag{3.55}$$

$$\gamma^{\frac{3}{2}} \frac{\partial}{\partial Y}\begin{bmatrix} \langle x_{O_2}\rangle^{(\mathrm{g})} \\ \langle x_{H_2O}\rangle^{(\mathrm{g})} \end{bmatrix} = \frac{\partial}{\partial Y}\begin{bmatrix} x_{O_2} \\ x_{H_2O} \end{bmatrix}. \tag{3.56}$$

In general, I will not be constant; even more generally, it cannot be described a priori but is determined by considering the transport of species in the catalyst, membrane, and the anode side also. However, a common practice in studies which emphasize the investigation of flow in the porous backing and the gas channel is simply to prescribe a current density as a function of mole fraction. For example, if we use the dimensional form of the Tafel law given by He, Yi, and Nguyen [22],

$$I = \frac{a\rho}{M}\exp\left(\frac{\alpha_c F\eta}{RT}\right),$$

where α_c $(= 2)$ is the transfer coefficient of the oxygen reduction reaction (1.2), η is the overpotential for the oxygen reaction, and a $\left(= 10^{-6}\ \mathrm{Am\ mol^{-1}}\right)$ is a constant

TABLE 3
Geometry and operating parameters for the base case.

$x_{O_2}^{in}$	0.21
$x_{H_2O}^{in}$	0
h_f	10^{-3}m
h_p	3×10^{-4}m
L	0.1 m
κ	10^{-12} m^2
γ	0.3
U^{in}	1 ms^{-1}
p^{out}	1 atm
T	353 K
μ	10^{-5}kgm^{-1}s^{-1}

related to the exchange current density and oxygen reference concentration for the oxygen reaction, we obtain the appropriate scale for $[I]$ as

$$[I] = \frac{a\,[\rho]}{[M]} \exp\left(\frac{\alpha_c F \eta}{RT}\right); \tag{3.57}$$

consequently, in dimensionless form,

$$I\left(\langle\rho\rangle^{(\mathrm{g})}, \langle x_{O_2}\rangle^{(\mathrm{g})}, \langle x_{H_2O}\rangle^{(\mathrm{g})}\right) = \frac{\langle\rho\rangle^{(\mathrm{g})}\,\langle x_{O_2}\rangle^{(\mathrm{g})}}{\langle\mathcal{M}\rangle^{(\mathrm{g})}} = \langle x_{O_2}\rangle^{(\mathrm{g})}. \tag{3.58}$$

A dimensional quantity of importance for the determination of polarization curves is the average current density, I_{av}, which is then given by

$$I_{av} = [I]\int_0^1 I dX.$$

This completes the formulation and necessary definitions. As a next step, we consider the possibility of finding an analytical solution in certain parameter ranges; an obvious choice, in view of the geometry, would be the lubrication theory limit $\left(\Delta^{-1} \ll 1\right)$. The data given in Table 3 for the base case physical parameters indicates that $\Delta^{-1} \sim O(1)$. Obviously, taking channels with a smaller aspect ratio or operating the fuel cell at lower inlet gas velocity would reduce Δ^{-1}, motivating us to then consider the lubrication theory limit, since it provides qualitatively useful analytical solutions, as well as a quantitative comparison with our numerical method (see section 6).

4. Asymptotics for $\frac{[\rho]\left(U^{in}\right)^2}{p^{out}} \ll \Delta^{-1} \ll 1$. Assume $\frac{[\rho]\left(U^{in}\right)^2}{p^{out}} \ll \Delta^{-1} \ll 1$, and rescale according to

$$\langle P\rangle^{(\mathrm{g})} = \Delta\,\langle P\rangle^{(\mathrm{g})},\ P = \Delta P;$$

note here that we require a lower restriction on Δ^{-1} for the following development to hold; otherwise the simplifications following (3.44) will not apply and ρ will depend

on P; in practice, the restriction is not unreasonable. Introducing the asymptotic series

$$\begin{aligned}
\chi &= \chi_0 + \Delta^{-1}\chi_1 + O\left(\Delta^{-2}\right), \quad \text{where } \chi = (U, V, P, \rho), \\
\langle\chi\rangle &= \langle\chi_0\rangle + \Delta^{-1}\langle\chi_1\rangle + O\left(\Delta^{-2}\right), \text{ where } \chi = (V, P), \\
\chi &= \chi^{(0)} + \Delta^{-1}\chi^{(1)} + O\left(\Delta^{-2}\right), \text{ where } \chi = (x_{O_2}, x_{H_2O}, \mathbf{M}), \\
\langle\chi\rangle^{(\mathrm{g})} &= \langle\chi_0\rangle^{(g)} + \Delta^{-1}\langle\chi_1\rangle^{(g)} + O\left(\Delta^{-2}\right), \text{ where } \chi = (\rho), \\
\langle\chi\rangle^{(\mathrm{g})} &= \left\langle\chi^{(0)}\right\rangle^{(\mathrm{g})} + \Delta^{-1}\left\langle\chi^{(1)}\right\rangle^{(\mathrm{g})} + O\left(\Delta^{-2}\right), \text{ where } \chi = (x_{O_2}, x_{H_2O}, \mathbf{M}),
\end{aligned}$$

we observe that, at leading order, the governing equations permit a solution of the form

$$\begin{aligned}
x_{O_2}^{(0)} &= \left\langle x_{O_2}^{(0)}\right\rangle^{(\mathrm{g})} = F_{O_2}(X), \\
x_{H_2O}^{(0)} &= \left\langle x_{H_2O}^{(0)}\right\rangle^{(\mathrm{g})} = F_{H_2O}(X),
\end{aligned}$$

with $F_{O_2}(0) = x_{O_2}^{in}$, $F_{H_2O}(0) = x_{H_2O}^{in}$. Then

$$U_0(X, Y) = \frac{1}{2}\frac{dP_0}{dX}\left(Y^2 - Y\right),$$

whereupon, writing $\Phi = (2(1+2\alpha)\mathcal{M}_{H_2O} - \mathcal{M}_{O_2})$ (note that $\Phi > 0$) and using

$$\frac{d}{dX}\left(\int_0^1 \rho_0 U_0 dY\right) = \frac{\Omega\Phi I\left(F_{O_2}(X)\right)}{4},$$

where

$$\rho_0(X) = \mathcal{M}_{N_2} + \left(\mathcal{M}_{O_2} - \mathcal{M}_{N_2}\right)F_{O_2}(X) + \left(\mathcal{M}_{H_2O} - \mathcal{M}_{N_2}\right)F_{H_2O}(X),$$

we have

$$\int_0^1 \rho_0 U_0 dY = \frac{\Omega\Phi}{4}J(X) + \rho_0(0),$$

where

$$J(X) = \int_0^X I\left(F_{O_2}(X')\right)dX'.$$

Hence

$$\frac{dP_0}{dX} = -\frac{12}{\rho_0(X)}\left[\frac{\Omega\Phi}{4}J(X) + \rho_0(0)\right],$$

and so

$$\begin{aligned}
U_0(X, Y) &= \frac{6}{\rho_0(X)}\left[\frac{\Omega\Phi}{4}J(X) + \rho_0(0)\right]\left(Y - Y^2\right), \\
V_0(X, Y) &= -\frac{3\Omega\Phi}{2}\frac{I\left(F_{O_2}(X)\right)}{\rho_0(X)}\left(\frac{Y^2}{2} - \frac{Y^3}{3} - \frac{1}{6}\right), \\
\langle V_0(X)\rangle &= \Omega\Phi\frac{I\left(F_{O_2}(X)\right)}{4\langle\rho_0(X)\rangle}, \\
\langle P_0(X, Y)\rangle &= -\Sigma^2\Omega\left\{\frac{\Phi I\left(F_{O_2}(X)\right)}{4\langle\rho_0(X)\rangle}\right\}Y - 12\left[\frac{\Omega\Phi J(X)}{\langle\rho_0(X)\rangle} + X\right].
\end{aligned}$$

At this stage, $F_{O_2}(X)$ and $F_{H_2O}(X)$ (and hence $U_0, V_0, \langle V_0\rangle, \langle P_0\rangle, \rho_0$) remain undetermined, indicating that the problem at $O(1)$ is degenerate; this appears to be because the boundary conditions for x_{O_2} and x_{H_2O} at $Y = -\mathcal{H}, 1$ at this order are both of Neumann type. This indeterminacy is remedied, however, at $O\left(\Delta^{-1}\right)$ as follows.

At $O\left(\Delta^{-1}\right)$, (3.47) gives

$$\frac{\partial}{\partial X}\left(U_0\begin{bmatrix} F_{O_2}(X) \\ F_{H_2O}(X)\end{bmatrix}\right)+\frac{\partial}{\partial Y}\left(V_0\begin{bmatrix} F_{O_2}(X) \\ F_{H_2O}(X)\end{bmatrix}\right) \tag{4.1}$$

$$=\frac{1}{Sc}\frac{\partial}{\partial Y}\left(\frac{\mathbf{M}^{(0)}}{\rho_0(X)}\frac{\partial}{\partial Y}\begin{bmatrix} x_{O_2}^{(1)} \\ x_{H_2O}^{(1)}\end{bmatrix}\right);$$

for $0 \le X \le 1$, $-\mathcal{H} \le Y \le 0$,

$$\frac{\Omega\Phi I(F_{O_2}(X))}{4\langle\rho_0(X)\rangle}\begin{bmatrix} F_{O_2}(X) \\ F_{H_2O}(X)\end{bmatrix}-\frac{\gamma^{\frac{3}{2}}}{Sc}\frac{\langle\mathbf{M}^{(0)}\rangle^{(\mathrm{g})}}{\langle\rho_0(X)\rangle}\frac{\partial}{\partial Y}\begin{bmatrix} \left\langle x_{O_2}^{(1)}\right\rangle^{(\mathrm{g})} \\ \left\langle x_{H_2O}^{(1)}\right\rangle^{(\mathrm{g})}\end{bmatrix} \tag{4.2}$$

$$=\frac{\Omega I(F_{O_2}(X))}{4}\begin{bmatrix} -1 \\ 2(1+2\alpha)\end{bmatrix}.$$

Equation (4.1) can be rewritten as

$$U_0\begin{bmatrix} F'_{O_2}(X) \\ F'_{H_2O}(X)\end{bmatrix}+\left(\frac{\partial U_0}{\partial X}+\frac{\partial V_0}{\partial Y}\right)\begin{bmatrix} F_{O_2}(X) \\ F_{H_2O}(X)\end{bmatrix}=\frac{1}{Sc}\frac{\mathbf{M}^{(0)}}{\rho_0(X)}\frac{\partial^2}{\partial Y^2}\begin{bmatrix} x_{O_2}^{(1)} \\ x_{H_2O}^{(1)}\end{bmatrix},$$

and then, on using

$$\frac{\partial}{\partial X}(\rho_0 U_0)+\frac{\partial}{\partial Y}(\rho_0 V_0)=0,$$

we have

$$U_0\left\{\begin{bmatrix} F'_{O_2}(X) \\ F'_{H_2O}(X)\end{bmatrix}-\frac{1}{\rho_0(X)}\frac{\partial\rho_0}{\partial X}\begin{bmatrix} F_{O_2}(X) \\ F_{H_2O}(X)\end{bmatrix}\right\}=\frac{1}{Sc}\frac{\mathbf{M}^{(0)}}{\rho_0(X)}\frac{\partial^2}{\partial Y^2}\begin{bmatrix} x_{O_2}^{(1)} \\ x_{H_2O}^{(1)}\end{bmatrix}.$$

Integrating once with respect to Y, we have

$$\lambda_0(X)\left\{\begin{bmatrix} F'_{O_2}(X) \\ F'_{H_2O}(X)\end{bmatrix}-\frac{1}{\rho_0(X)}\frac{\partial\rho_0}{\partial X}\begin{bmatrix} F_{O_2}(X) \\ F_{H_2O}(X)\end{bmatrix}\right\}\left(\frac{Y^2}{2}-\frac{Y^3}{3}-\frac{1}{6}\right) \tag{4.3}$$
$$=\frac{1}{Sc}\frac{\mathbf{M}^{(0)}}{\rho_0(X)}\frac{\partial}{\partial Y}\begin{bmatrix} x_{O_2}^{(1)} \\ x_{H_2O}^{(1)}\end{bmatrix},$$

where we have written $U_0 = \frac{\lambda_0(X)}{\rho_0(X)}\left(Y - Y^2\right)$, with

$$\lambda_0(X) = 6\left[\frac{\Omega\Phi}{4}J(X)+\rho_0(0)\right],$$

and have already implemented (3.52) at $O\left(\Delta^{-1}\right)$. Requiring now, at $Y=0$,

$$\gamma^{\frac{3}{2}}\frac{\partial}{\partial Y}\begin{bmatrix}\left\langle x_{O_2}^{(1)}\right\rangle^{(\mathrm{g})}\\ \left\langle x_{H_2O}^{(1)}\right\rangle^{(\mathrm{g})}\end{bmatrix}=\frac{\partial}{\partial Y}\begin{bmatrix}x_{O_2}^{(1)}\\ x_{H_2O}^{(1)}\end{bmatrix},$$

we combine (4.2) and (4.3) to give

$$-\frac{2\lambda_0(X)}{3\Omega\rho_0(X)I\left(F'_{O_2}(X)\right)}\left\{\begin{bmatrix}F'_{O_2}(X)\\ F'_{H_2O}(X)\end{bmatrix}-\frac{1}{\rho_0(X)}\frac{\partial\rho_0}{\partial X}\begin{bmatrix}F_{O_2}(X)\\ F_{H_2O}(X)\end{bmatrix}\right\}$$
$$=\frac{\Phi}{\rho_0(X)}\begin{bmatrix}F_{O_2}(X)\\ F_{H_2O}(X)\end{bmatrix}-\begin{bmatrix}-1\\ 2(1+2\alpha)\end{bmatrix}.$$

Note that this has led to the elimination of $x_{O_2}^{(1)}$ and $x_{H_2O}^{(1)}$ and has instead led to a pair of nonlinear ordinary differential equations for $F_{O_2}(X)$ and $F_{H_2O}(X)$.

Next, defining

$$\zeta_{O_2}(X)=F_{O_2}(X)/\rho_0(X),\ \zeta_{H_2O}(X)=F_{H_2O}(X)/\rho_0(X),$$

we simplify to

$$\frac{-4}{\Omega I\left(F_{O_2}(X)\right)}\left[\frac{\Omega\Phi}{4}J(X)+\rho_0(0)\right]\frac{\partial}{\partial X}\begin{bmatrix}\zeta_{O_2}(X)\\ \zeta_{H_2O}(X)\end{bmatrix}$$

$$=\Phi\begin{bmatrix}\zeta_{O_2}(X)\\ \zeta_{H_2O}(X)\end{bmatrix}-\begin{bmatrix}-1\\ 2(1+2\alpha)\end{bmatrix},$$

with initial conditions

$$\zeta_{O_2}(0)=\frac{x_{O_2}^{in}}{\mathcal{M}_{N_2}+\left(\mathcal{M}_{O_2}-\mathcal{M}_{N_2}\right)x_{O_2}^{in}+\left(\mathcal{M}_{H_2O}-\mathcal{M}_{N_2}\right)x_{H_2O}^{in}},$$
$$\zeta_{H_2O}(0)=\frac{x_{H_2O}^{in}}{\mathcal{M}_{N_2}+\left(\mathcal{M}_{O_2}-\mathcal{M}_{N_2}\right)x_{O_2}^{in}+\left(\mathcal{M}_{H_2O}-\mathcal{M}_{N_2}\right)x_{H_2O}^{in}}.$$

Replacing the partial derivative, we can simplify to

$$\frac{d\zeta_{O_2}}{d\zeta_{H_2O}}=\frac{\Phi\zeta_{O_2}+1}{\Phi\zeta_{H_2O}-2(1+2\alpha)},$$

whence, on applying the inlet conditions,

$$\left[\Phi\zeta_{O_2}(0)+1\right]\zeta_{H_2O}(X)-\left[\Phi\zeta_{H_2O}(0)-2(1+2\alpha)\right]\zeta_{O_2}(X)$$
$$=2(1+2\alpha)\zeta_{O_2}(0)+\zeta_{H_2O}(0). \tag{4.4}$$

Note, in addition, that this result holds regardless of the expression used for the current density.

Returning now to

$$\frac{-4}{\Omega I\left(F_{O_2}(X)\right)}\left[\frac{\Omega}{4}\Phi J(X)+\rho_0(0)\right]\frac{d\zeta_{O_2}}{dX}=\Phi\zeta_{O_2}+1,$$

this too can be integrated regardless of the form of I. We have, since $J(0) = 0$ for any current density we care to choose,

$$\zeta_{O_2}(X) = \frac{1}{\Phi}\left\{\left(\Phi\zeta_{O_2}(0)+1\right)\left(\frac{4\rho_0(0)}{4\rho_0(0)+\Omega\Phi J(X)}\right)-1\right\}, \tag{4.5}$$

which is effectively an integral equation for $\zeta_{O_2}(X)$. More convenient is a first order ordinary differential equation for $\zeta_{O_2}(X)$, which is obtained after rearranging and differentiating, as

$$I\left(\frac{\mathcal{M}_{N_2}\zeta_{O_2}(X)}{1-\left(\mathcal{M}_{O_2}-\mathcal{M}_{N_2}\right)\zeta_{O_2}(X)-\left(\mathcal{M}_{H_2O}-\mathcal{M}_{N_2}\right)\zeta_{H_2O}(X)}\right)$$

$$= -\frac{4\rho_0(0)}{\Omega}\frac{\left(\Phi\zeta_{O_2}(0)+1\right)}{\left(\Phi\zeta_{O_2}(X)+1\right)^2}\frac{d\zeta_{O_2}}{dX},$$

and then

$$I\left(\frac{\zeta_{O_2}(X)}{\mathcal{A}+\mathcal{B}\zeta_{O_2}(X)}\right) = -\frac{4\rho_0(0)}{\Omega}\frac{\left(\Phi\zeta_{O_2}(0)+1\right)}{\left(\Phi\zeta_{O_2}(X)+1\right)^2}\frac{d\zeta_{O_2}}{dX}, \tag{4.6}$$

where

$$\mathcal{A} = \frac{1}{\mathcal{M}_{N_2}}\left(\left(\mathcal{M}_{H_2O}-\mathcal{M}_{N_2}\right)\left(\frac{2(1+2\alpha)\zeta_{O_2}(0)+\zeta_{H_2O}(0)}{\left[\Phi\zeta_{O_2}(0)+1\right]}\right)-1\right),$$

$$\mathcal{B} = \frac{1}{\mathcal{M}_{N_2}}\left(\left(\mathcal{M}_{O_2}-\mathcal{M}_{N_2}\right)+\left(\mathcal{M}_{H_2O}-\mathcal{M}_{N_2}\right)\frac{\left[\Phi\zeta_{H_2O}(0)-2(1+2\alpha)\right]}{\left[\Phi\zeta_{O_2}(0)+1\right]}\right).$$

Note that (4.6) implies that if oxygen is fully depleted, at which point (say $X = X_0$) $\zeta_{O_2} = I = 0$, then we will necessarily have $\frac{d\zeta_{O_2}}{dX} = 0$ there also.

As an example, and for later use, we note a closed-form solution when $I \equiv \langle x_{O_2}\rangle^{(g)}$; in this case,

$$\frac{\zeta_{O_2}(X)}{\mathcal{A}+\mathcal{B}\zeta_{O_2}(X)} = -\frac{4\rho_0(0)}{\Omega}\frac{\left(\Phi\zeta_{O_2}(0)+1\right)}{\left(\Phi\zeta_{O_2}(X)+1\right)^2}\frac{d\zeta_{O_2}}{dX},$$

which can be integrated exactly to give

$$\mathcal{A}\log\left(\frac{\zeta_{O_2}(X)\left(\Phi\zeta_{O_2}(0)+1\right)}{\zeta_{O_2}(0)\left(\Phi\zeta_{O_2}(X)+1\right)}\right)-(\mathcal{A}\Phi-\mathcal{B})\left(\frac{\zeta_{O_2}(X)-\zeta_{O_2}(0)}{\left(\Phi\zeta_{O_2}(X)+1\right)\left(\Phi\zeta_{O_2}(0)+1\right)}\right)$$

$$= \frac{\Omega X}{4\rho_0(0)\left(\Phi\zeta_{O_2}(0)+1\right)}. \tag{4.7}$$

This formula suggests that for $\Omega \sim O(1)$ there is no possibility for oxygen depletion $\left(\zeta_{O_2} = 0\right)$, since the first term on the left-hand side of (4.7) could not then be balanced by either of the other two terms. In addition, for $\Omega \gg 1$ (and noting that $\mathcal{A} < 0$),

$$\mathcal{A}\log\left(\frac{\zeta_{O_2}(X)\left(\Phi\zeta_{O_2}(0)+1\right)}{\zeta_{O_2}(0)\left(\Phi\zeta_{O_2}(X)+1\right)}\right) \sim \frac{\Omega X}{4\rho_0(0)\left(\Phi\zeta_{O_2}(0)+1\right)},$$

whence

$$\frac{\zeta_{O_2}(X)}{\left(\Phi\zeta_{O_2}(X)+1\right)} \sim \frac{\zeta_{O_2}(0)}{\left(\Phi\zeta_{O_2}(0)+1\right)} \exp\left(\frac{\Omega X}{4\mathcal{A}\rho_0(0)\left(\Phi\zeta_{O_2}(0)+1\right)}\right),$$

and thus

$$\zeta_{O_2}(X) \sim \frac{1}{\left(\Phi+\frac{1}{\zeta_{O_2}(0)}\right)\exp\left(\frac{-\Omega X}{4\mathcal{A}\rho_0(0)\left(\Phi\zeta_{O_2}(0)+1\right)}\right)-\Phi};$$

in this regime, we also have

$$\zeta_{H_2O}(X) \sim \frac{2}{\Phi}(1+2\alpha) + \frac{\zeta_{H_2O}(0)-\frac{2}{\Phi}(1+2\alpha)}{\left(\Phi\zeta_{O_2}(0)+1\right)-\Phi\zeta_{O_2}(0)\exp\left(\frac{\Omega X}{4\mathcal{A}\rho_0(0)\left(\Phi\zeta_{O_2}(0)+1\right)}\right)}.$$

Note also that, thus far, the results are independent of whether or not crossed diffusion is assumed or if nonlinear diffusion coefficients are used or not.

As a corollary, we observe that the solution at $O\left(\Delta^{-1}\right)$, i.e., for $x_{O_2}^{(1)}$, $x_{H_2O}^{(1)}$, $\langle x_{O_2}^{(1)}\rangle^{(\mathrm{g})}$, $\langle x_{H_2O}^{(1)}\rangle^{(\mathrm{g})}$ still remains undetermined, since consideration of the field equations and boundary conditions at $O\left(\Delta^{-1}\right)$ merely leads to the solution being fully determined at $O(1)$. By analogy, to determine the solutions at $O\left(\Delta^{-1}\right)$ completely, we would need to consider the field equations and boundary conditions at $O\left(\Delta^{-2}\right)$; by this stage, however, the algebra becomes lengthy and in the interest of brevity we omit further discussion. In fact, one does not really gain so much by finding these solutions anyway, since there is no compact solution as there is at $O(1)$, and we proceed instead to a numerical solution for the general case when $\Delta^{-1} \sim O(1)$.

5. Numerical method and results. To complement the asymptotics for $\Delta^{-1} \ll 1$, so as to account for regimes when $\Delta^{-1} \sim O(1)$, the simplified parabolized equations were solved numerically using the Keller–Box discretization scheme and Newton iteration (see, for example, Cebeci and Bradshaw [10]). The system of partial differential equations to be solved in the channel is of 8th order, and this is coupled to a 6th order system of ordinary differential equations in the porous region. As is well known, the scheme is second order accurate in both time-like and space-like variables, and we omit any further details here. As an indication of the speed of the computations, we note that a typical run with 500 points across, and 200 points along, the channel required around 100 CPU seconds on a 500 MHz Compaq Alphaserver with 3GB RAM.

Results are presented for the Tafel law given in dimensionless form by (3.58) and used previously for PEFC studies by [22, 25, 30, 45]. Throughout, we keep $\gamma = 0.3, T = 353$ K, and concentrate more on the effect of changes in channel height and length, porous backing thickness and permeability, pressure, inlet speed, and composition. Physically realistic and implementable changes in any of these will result in, at most, an order of magnitude change in the relevant dimensionless parameter. The most sensitive parameter is Ω, which varies over several orders of magnitude as the cell voltage E_{cell} decreases; note here that we revert to using the cell voltage rather than the overpotential, η, with the two being related by

$$E_{cell} = E_0 - \eta,$$

where $E_0 (= 1.1$ V) is termed the open circuit voltage of the fuel cell.

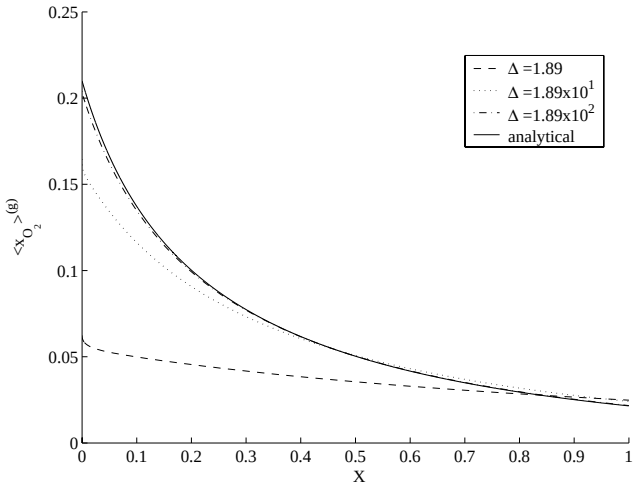

FIG. 3. *Comparison of analytical solution for* $\langle x_{O_2} \rangle^{(g)}$ *at* $Y = -\mathcal{H}$ *with numerical solutions for* $\Delta = 1.89, 1.89 \times 10^1, 1.89 \times 10^2$ ($E_{cell} = 0.75$ V).

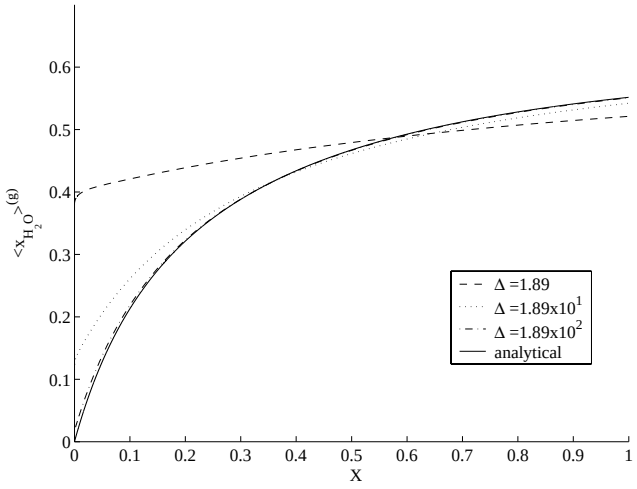

FIG. 4. *Comparison of analytical solution for* $\langle x_{H_2O} \rangle^{(g)}$ *at* $Y = -\mathcal{H}$ *with numerical solutions for* $\Delta = 1.89, 1.89 \times 10^1, 1.89 \times 10^2$ ($E_{cell} = 0.75$ V).

5.1. Effect of Δ and Ω. We show first results for $E_{cell} = 0.75$ V, corresponding to $\Omega = 10.2$, ranging over several orders of magnitude in Δ and compare these with the analytical results in the lubrication theory limit. Figures 3 and 4 are for intrinsic oxygen and water mole fraction at $Y = -\mathcal{H}$, respectively, and demonstrate that the lubrication solution works well for Δ^{-1} as high as $O\left(10^{-2}\right)$.

On the other hand, the base case physical values given in Table 3 correspond to $\Delta = 1.89$. Figure 5 shows the streamwise velocity U at $Y = \frac{1}{2}$ and illustrates the extent of deviation from the classical value $\frac{3}{2}$. An interesting limit occurs as E_{cell} is decreased. In this case, Ω increases although the quantity $\Omega \langle x_{O_2} \rangle^{(g)}$ at $Y = -\mathcal{H}$ remains $O(1)$; this corresponds to the attainment of the limiting current, and the

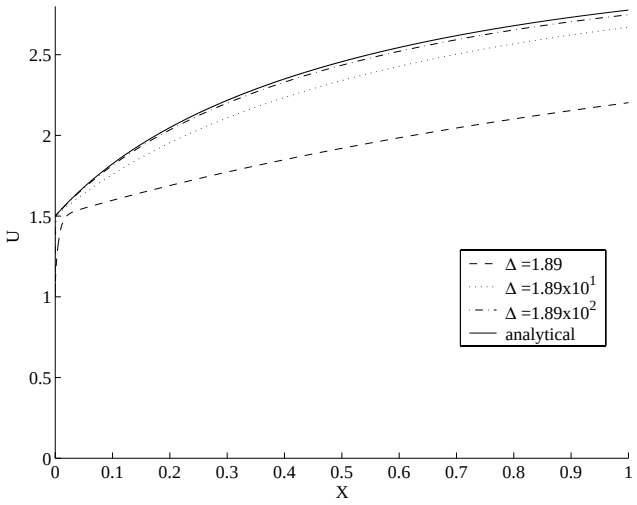

FIG. 5. *Comparison of analytical solution for* U *at* $Y = \frac{1}{2}$ *with numerical solutions for* $\Delta = 1.89, 1.89 \times 10^1, 1.89 \times 10^2$ ($E_{cell} = 0.75$ V).

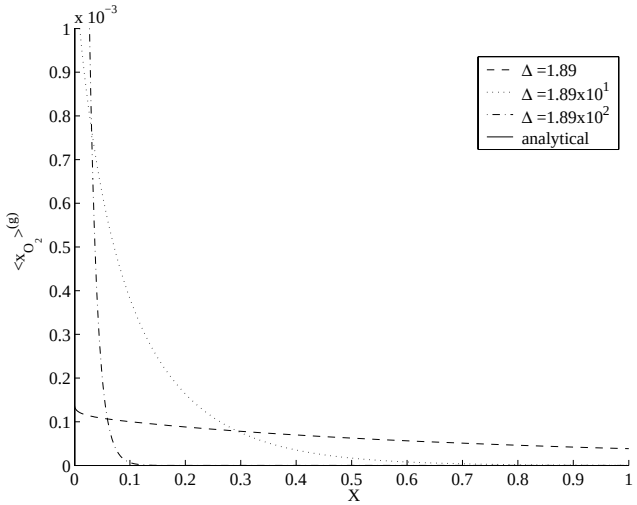

FIG. 6. *Comparison of analytical solution for* $\langle x_{O_2} \rangle^{(g)}$ *at* $Y = -\mathcal{H}$ *with numerical solutions for* $\Delta = 1.89, 1.89 \times 10^1, 1.89 \times 10^2$ ($E_{cell} = 0.65$ V).

corresponding plots are given in Figures 6, 7, and 8; observe that in Figures 6 and 7 the limiting values for intrinsic oxygen and water mole fraction for the analytical solution are reached very rapidly, so that in Figure 6 the curve for $\langle x_{O_2} \rangle^{(g)}$ effectively lies on the X-axis.

With regard to the numerics, it was found that considerably more outer loop iterations for the density were required as Ω was increased. For instance, whereas 4 iterations sufficed for $E_{cell} = 0.75$ V, it was common for 20–30 to be necessary for $E_{cell} = 0.65$ V. In addition, there were difficulties in initiating the marching scheme at $X = 0$ for higher values of Ω; we surmise this to be due to the increased nonlinearity of the equation system. Whilst setting the channel inlet values as an initial guess for

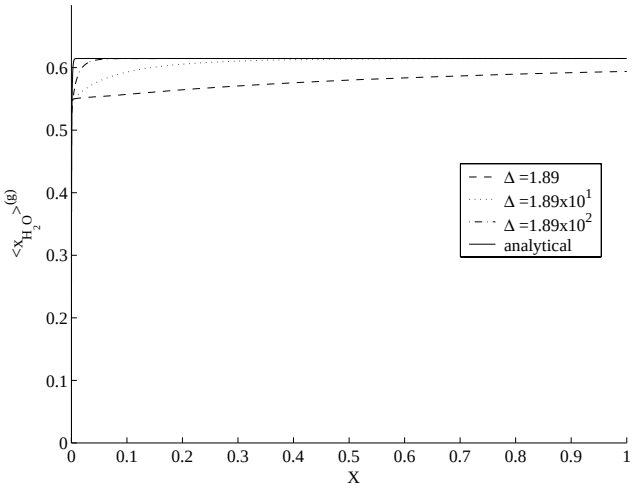

FIG. 7. *Comparison of analytical solution for* $\langle x_{H_2O} \rangle^{(g)}$ *at* $Y = -\mathcal{H}$ *with numerical solutions for* $\Delta = 1.89, 1.89 \times 10^1, 1.89 \times 10^2$ $(E_{cell} = 0.65 \text{ V})$.

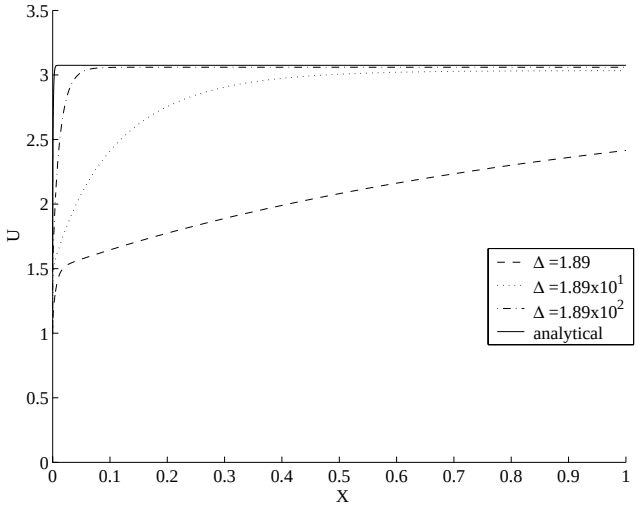

FIG. 8. *Comparison of analytical solution for* U *at* $Y = \frac{1}{2}$ *with numerical solutions for* $\Delta = 1.89, 1.89 \times 10^1, 1.89 \times 10^2$ $(E_{cell} = 0.65 \text{ V})$.

the first step along the channel was adequate for lower values of Ω, this was found to be not sufficient for E_{cell} lower than 0.71 V; for those cases, the first-step solution for $E_{cell} = 0.71$ V had to be used instead, then enabling numerical solutions to be obtained for higher and higher values of Ω until the limiting current was reached.

5.2. "Polarization surfaces". It is customary for fuel cell performance to be given in terms of a polarization curve where the cell potential, E_{cell}, is given as function of the average current density, I_{av}. Generally speaking, if the analysis is done dimensionally, this leads to a vast number of graphs for each alteration made in one of the physical parameters. However, a major benefit of the nondimensional analysis

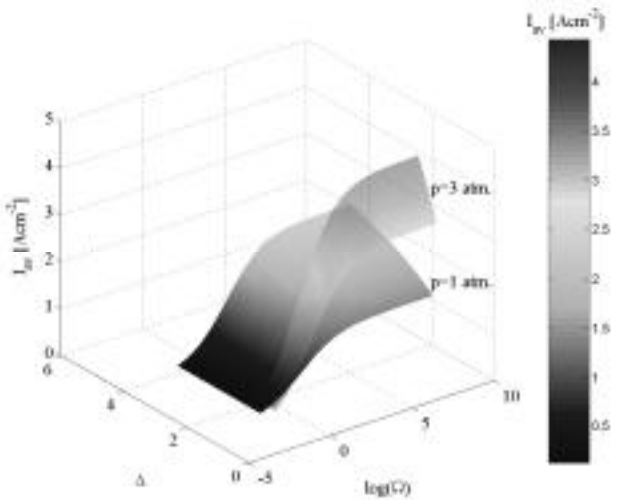

FIG. 9. *Polarization surfaces for* $p^{out} = 1, 3$ *atm* ($\mathcal{H} = 0.3$).

carried out here is that the results can be expressed considerably more compactly by plotting polarization "surfaces"; individual polarization curves will therefore be curves lying on those surfaces. We explain this as follows. From the nondimensionalization given above, the emergent nondimensional parameters were Δ, Σ, Ω, and Sc. In addition, there is γ, which we hold fixed in this study, and $x^{in}_{O_2}$,$x^{in}_{H_2O}$, and $\mathcal{H}$, whose effect on fuel cell performance one would like to explore. First, we observe that, in the parameter range of interest, Σ has no effect on I_{av}, since the dimensionless density is independent of pressure and the pressure in the channel serves as a boundary condition for the pressure in the porous medium. In addition, a change in Sc can be effected only by changes in $[\rho]$, which occurs only if the cathode is run at a different pressure. Consequently, a tidy representation of I_{av} is to plot it as a function of Δ and Ω, for fixed $Sc, x^{in}_{O_2}$,$x^{in}_{O_2}$, and $\mathcal{H}$, the benefit of this being that the effect of four parameters, h_f, L, U^{in}, and E_{cell}, are displayed on one graph; since Ω can vary over several orders of magnitude, it proves more convenient to use $\log(\Omega)$ as a variable. Examples of this are given below.

Figure 9 gives polarization surfaces for $\mathcal{H} = 0.3$, with the pressure at 1 and 3 atmospheres. The limiting current phenomenon is observed as Ω increases, and its value is observed to increase moderately with increasing Δ but strongly with increasing pressure. Figure 10 shows a similar plot, except with computations now for $p^{out} = 1$ atm, for $\mathcal{H} = 0.15$ and $\mathcal{H} = 0.6$. Average current densities are found to be higher for the thinner porous backing, and in both cases a limiting value is evident as Ω is increased. Figure 11 compares the base case for $p^{out} = 1$ atm and $x^{in}_{O_2} = 0.21$ with two other cases at 1 atm which have differing inlet compositions: dry oxygen $\left(x^{in}_{O_2} = 1\right)$ and partially humidified air, for which $x^{in}_{O_2} = 0.13$ and $x^{in}_{H_2O} = 0.36$ (corresponding to 76% relative humidity) [14, 17, 35]. As is evident, increased oxygen content at the inlet raises the average current density; for $x^{in}_{O_2} = 1$, convergence difficulties were experienced for quite low values of Ω, which explains the rather narrow range of values presented for this case, but nonetheless the average current density is much higher than that for the other two cases.

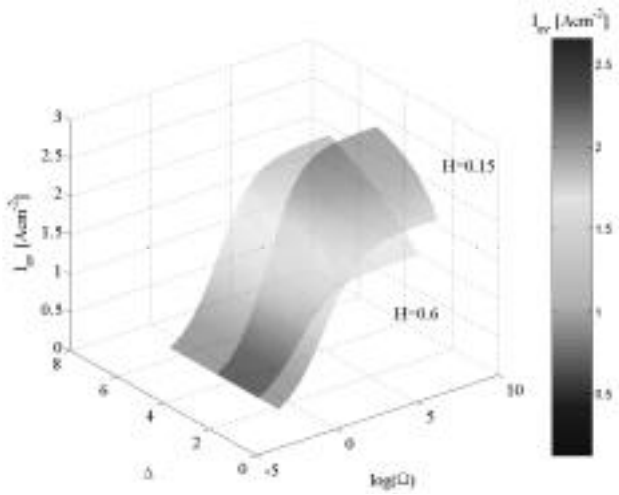

FIG. 10. *Polarization surfaces for* $\mathcal{H} = 0.3, 0.6$ $\left(p^{out} = 1\ atm\right)$.

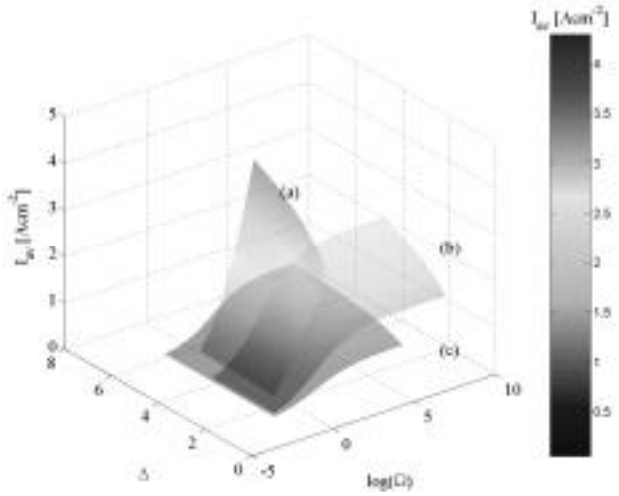

FIG. 11. *Polarization surfaces for* $p^{out} = 1$ *atm with* (a) $x^{in}_{O_2} = 1$, $x^{in}_{H_2O} = 0$; (b) $x^{in}_{O_2} = 0.21$, $x^{in}_{H_2O} = 0$; (c) $x^{in}_{O_2} = 0.13$, $x^{in}_{H_2O} = 0.36$.

6. Conclusions. In this paper, we have considered a 2D model for three-component gaseous flow in the cathode of a PEFC. Assuming a slender geometry, we have derived analytical solutions where possible and complemented these with a numerical study. By choosing to perform the study nondimensionally, we have identified several features that are not evident from earlier work done dimensionally. In summary, we identify four main dimensionless parameters ($\Delta, \Omega, \Sigma, Sc$; see sections 2 and 3 for definitions); other parameters that are present in this model are the porous backing porosity, γ (held fixed at 0.3 in this study), the temperature T (held fixed at 353 K), the ratio of channel and porous backing heights ($\mathcal{H}$), the inlet oxygen and water content ($x^{in}_{O_2}$ and $x^{in}_{H_2O}$, respectively), and the number of water molecules affiliated to each proton that passes across the membrane to the cathode (α). We find that

the flow in the porous backing is essentially unidirectional, although it interacts with a fully 2D flow in the gas channel. Furthermore, Σ is found to play a secondary role, having next to no effect on the gas mole fraction distribution in the porous backing; physically, this implies an insensitivity to porous backing permeability. The fact that the cathode is more or less isobaric gives that the density is a multiple of the molecular weight. In addition, the Schmidt number, Sc, can be affected only by variations in the operating pressure, and we find that a convenient and compact way to understand fuel cell performance is to plot average current density as a function of Δ and Ω for different values of Sc and $\mathcal{H}$; this gives a surface which implicitly contains an infinite family of polarization curves, which is the customary way to assess cell performance. These surfaces have been generated numerically, and in comparatively rapid fashion, using the Keller–Box scheme for systems of parabolic partial differential equations, to provide a rather comprehensive parameter study.

The present work was, needless to say, limited in several respects. To begin with, as has often been stated before, at higher current densities two-phase flow can be expected as water droplets form at the catalytic layer; this will be the starting point for future work. Also, we limited ourselves here to prescribing an often-used Tafel law for the current density relation at the catalytic layer, for one temperature value and one value of porosity; in addition, α was assumed to be constant along the length of the cell. Naturally, the question arises as to whether more sophisticated modeling would lead to a qualitative change in the results. Essentially, such an approach would involve attempting to represent the catalytic layer more faithfully, e.g., as has been attempted for MCFC [34]. A characteristic of this approach would be that a Tafel law is used for reactions across this layer, which would be treated as consisting of the material of which the gas-diffusion electrode as well as polymer electrolyte. Combined with the fact that this layer is much thinner than the gas-diffusion electrode, it is likely that the functional form for the current density would not be much different from what we have used here. On the other hand, if the overpotential and/or temperature are no longer treated as constant, then the exponential term involving these quantities in the expression for the current density could indeed affect the results significantly. Needless to say, this also is the subject of future work.

A final comment concerns the use of nondimensional analysis in fuel cell modeling. The way that the analysis presented here panned out was a function of the magnitudes of the relevant parameters for the PEFC. Subsequent work carried out by us on the anode of a direct methanol fuel cell [9] indicates that the dimensionless parameter Ω there will actually be much smaller than unity, leading to a different treatment of the subsequent equations. This emphasizes the point that the treatment presented here is more far-reaching than just the PEFC.

LARGE SOLUTIONS TO THE INITIAL-BOUNDARY VALUE PROBLEM FOR PLANAR MAGNETOHYDRODYNAMICS*

DEHUA WANG†

Abstract. An initial-boundary value problem for nonlinear magnetohydrodynamics (MHD) in one space dimension with general large initial data is investigated. The equations of state have nonlinear dependence on temperature as well as on density. For technical reasons the viscosity coefficients and magnetic diffusivity are assumed to depend only on density. The heat conductivity is a function of both density and temperature, with a certain growth rate on temperature. The existence, uniqueness, and regularity of global solutions are established with large initial data in H^1. It is shown that no shock wave, vacuum, or mass or heat concentration will be developed in a finite time, although the motion of the flow has large oscillations and there is a complex interaction between the hydrodynamic and magnetodynamic effects.

Key words. magnetohydrodynamics (MHD), global solutions, global a priori estimates

1. Introduction.

In this paper we are concerned with the initial-boundary value problem and large-time behavior of solutions for plane magnetohydrodynamic flows. Magnetohydrodynamics (MHD) concerns the motion of conducting fluids in an electromagnetic field with a very broad range of applications. The dynamic motion of the fluids and the magnetic field interact strongly with each other. The hydrodynamic and electrodynamic effects are coupled. The equations of three-dimensional magnetohydrodynamic flows have the following form [4, 16, 18]:

$$
\begin{aligned}
&\rho_t + \operatorname{div}(\rho\mathbf{u}) = 0, \qquad (1.1)\\
&(\rho\mathbf{u})_t + \operatorname{div}(\rho\mathbf{u}\otimes\mathbf{u}) + \nabla p = (\nabla\times\mathbf{H})\times\mathbf{H} + \operatorname{div}\mathbf{\Psi},\\
&\mathcal{E}_t + \operatorname{div}(\mathbf{u}(\mathcal{E}+p)) = \operatorname{div}\left((\mathbf{u}\times\mathbf{H})\times\mathbf{H} + \nu\mathbf{H}\times(\nabla\times\mathbf{H}) + \mathbf{u}\mathbf{\Psi} + \kappa\nabla\theta\right),\\
&\mathbf{H}_t - \nabla\times(\mathbf{u}\times\mathbf{H}) = -\nabla\times(\nu\nabla\times\mathbf{H}), \qquad \operatorname{div}\mathbf{H} = 0,
\end{aligned}
$$

where $\mathbf{\Psi} = \lambda'(\operatorname{div}\mathbf{u})\mathbf{I} + \mu(\nabla\mathbf{u} + (\nabla\mathbf{u})^\top)$; ρ denotes the density, $\mathbf{u}\in\mathbb{R}^3$ the velocity, $\mathbf{H}\in\mathbb{R}^3$ the magnetic field, and θ the temperature; $\mathcal{E}$ is the total energy given by

$$
\mathcal{E} = \rho\left(e + \frac{1}{2}|\mathbf{u}|^2\right) + \frac{1}{2}|\mathbf{H}|^2, \qquad (1.2)
$$

with e the internal energy, $\frac{1}{2}|\mathbf{u}|^2$ the kinetic energy, and $\frac{1}{2}|\mathbf{H}|^2$ the magnetic energy; the equations of state $p = p(\rho,\theta)$, $e = e(\rho,\theta)$ relate the pressure p and the internal energy e to the density and temperature of the flow; $\mathbf{I}$ is the 3×3 identity matrix, and $(\nabla\mathbf{u})^\top$ is the transpose of the matrix $\nabla\mathbf{u}$; $\lambda' = \lambda'(\rho,\theta)$ and $\mu = \mu(\rho,\theta)$ are the viscosity coefficients of the flow satisfying $\lambda' + 2\mu > 0$, $\nu = \nu(\rho,\theta)$ is the magnetic diffusivity (see [1]) acting as a magnetic diffusion coefficient of the magnetic field, $\kappa = \kappa(\rho,\theta)$ is the heat conductivity, and all these kinetic coefficients and the magnetic

diffusivity are independent of the magnitude and direction of the magnetic field (see [18]). The magnetic permeability differs only slightly from unity and therefore is taken to be 1, which does not appear in the equations. The viscosity and heat conduction terms describe the dissipative processes in MHD.

It is well known that the electromagnetic fields are governed by Maxwell's equations. In MHD, the displacement current can be neglected [16, 18]. As a consequence, the last equation in (1.1) is called the induction equation, and the electric field can be written in terms of the magnetic field $\mathbf{H}$ and the velocity $\mathbf{u}$:

$$\mathbf{E} = \nu \nabla \times \mathbf{H} - \mathbf{u} \times \mathbf{H}. \tag{1.3}$$

Although the electric field $\mathbf{E}$ does not appear in (1.1), it is indeed induced according to (1.3) by the moving conductive flow in the magnetic field.

Consider a three-dimensional MHD flow with spatial variables $\mathbf{x} = (x, x_2, x_3)$, which is moving in the x direction and uniform in the transverse direction (x_2, x_3):

$$\begin{aligned} &\rho = \rho(x,t), \qquad \theta = \theta(x,t), \\ &\mathbf{u} = (u, \mathbf{w})(x,t), \quad \mathbf{w} = (u_2, u_3), \\ &\mathbf{H} = (b_1, \mathbf{b})(x,t), \quad \mathbf{b} = (b_2, b_3), \end{aligned} \tag{1.4}$$

where u and b_1 are the longitudinal velocity and longitudinal magnetic field, respectively, and $\mathbf{w}$ and $\mathbf{b}$ are the transverse velocity and transverse magnetic field, respectively. See Figure 1(a) and (b).

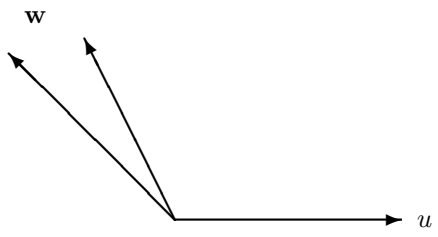

FIG. 1(a): *velocity* $(u, \mathbf{w})$.

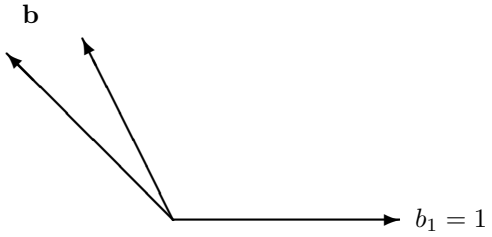

FIG. 1(b): *magnetic field* $(b_1, \mathbf{b})$.

With this special structure (1.4), equations (1.1) are reduced to the following system for the plane magnetohydrodynamic flows with constant longitudinal magnetic field $b_1 = 1$ (without loss of generality) and $\lambda = \lambda' + 2\mu > 0$:

$$\begin{aligned} \rho_t + (\rho u)_x &= 0, \\ (\rho u)_t + \left(\rho u^2 + P\right)_x &= (\lambda u_x)_x, \\ (\rho \mathbf{w})_t + (\rho u \mathbf{w} - \mathbf{b})_x &= (\mu \mathbf{w}_x)_x, \\ \mathbf{b}_t + (u\mathbf{b} - \mathbf{w})_x &= (\nu \mathbf{b}_x)_x, \\ \mathcal{E}_t + \left(u\left(\mathcal{E} + P\right) - \mathbf{w} \cdot \mathbf{b}\right)_x &= (\lambda u u_x + \mu \mathbf{w} \cdot \mathbf{w}_x + \nu \mathbf{b} \cdot \mathbf{b}_x + \kappa \theta_x)_x, \end{aligned} \tag{1.5}$$

where, again as in (1.1), $x \in \mathbb{R}$ is the spatial variable, $t > 0$ is the time variable; ρ denotes the density of the flow, $u \in \mathbb{R}$ the longitudinal velocity, $\mathbf{w} \in \mathbb{R}^2$ the transverse velocity, $\mathbf{b} \in \mathbb{R}^2$ the transverse magnetic field, and θ the temperature; the total energy of the plane magnetohydrodynamic flow is

$$\mathcal{E} = \rho\left(e + \frac{1}{2}(u^2 + |\mathbf{w}|^2)\right) + \frac{1}{2}|\mathbf{b}|^2,$$

with the internal energy e, and

$$P = p + \frac{1}{2}|\mathbf{b}|^2 \tag{1.6}$$

is the full pressure with p the pressure of fluid. The term $\frac{1}{2}|\mathbf{b}|^2$ appears here because of this equality: $(\nabla \times \mathbf{H}) \times \mathbf{H} = (-\frac{1}{2}|\mathbf{b}|^2, \mathbf{b})_x$; both the pressure p and the internal energy e are related to the density and temperature of the flow according to the equations of state:

$$p = p(\rho, \theta), \qquad e = e(\rho, \theta); \tag{1.7}$$

$\lambda = \lambda(\rho, \theta)$ and $\mu = \mu(\rho, \theta)$ are the viscosity coefficients of the flow, $\nu = \nu(\rho, \theta)$ is the magnetic diffusivity, and $\kappa = \kappa(\rho, \theta)$ is the heat conductivity. All these dissipation coefficients depend on both ρ and θ generally.

We consider the initial-boundary value problem of (1.5) in a bounded spatial domain $\Omega = (0, 1)$ (without loss of generality) with the following initial condition and impermeable, thermally insulated boundaries:

$$\begin{aligned} &(\rho, u, \mathbf{w}, \mathbf{b}, \theta)|_{t=0} = (\rho_0, u_0, \mathbf{w}_0, \mathbf{b}_0, \theta_0)(x), \quad x \in \Omega, \\ &(u, \mathbf{w}, \mathbf{b}, \theta_x)|_{\partial\Omega} = 0, \end{aligned} \tag{1.8}$$

where the initial data satisfy certain compatibility conditions as usual. In this paper, we are interested in the well-posedness and regularity of global solutions to this initial-boundary value problem (1.5) and (1.8), as well as the following issue: whether shock waves, vacuum, and mass and heat concentration are developed in the solutions in a finite time, provided that the initial data are bounded, smooth, and do not contain a vacuum. There have been a lot of studies on MHD by physicists and mathematicians because of its physical importance, complexity, rich phenomena, and mathematical challenges; see [1, 3, 4, 6, 8, 12, 13, 16, 18, 19, 20, 23, 24] and the references cited therein. The above initial-boundary value problem is fundamental for the MHD system. We investigate such an important problem for the magnetohydrodynamic fluid flow with the pressure, internal energy, and heat conductivity satisfying certain physical growth conditions on the temperature. These growth conditions are motivated by the physical facts for certain important physical regimes where the temperature is high and experiences rapid change [25]. In particular, the case of perfect gases with $p = R\rho\theta$, $e = c_v\theta$ is included in the class of fluids investigated in this paper, where R is the gas constant, $c_v = R/(\gamma - 1)$ is the heat capacity of the gas at constant volume, and γ is the adiabatic exponent. For perfect gases with small smooth initial data, the existence of global solutions was proved in [12], and the large-time behavior was studied in [20]. For large initial data, these problems have additional difficulties because of the presence of the magnetic field and its interaction with the hydrodynamic motion of the flow of large oscillation. A free boundary value problem on real MHD flow was studied in [5].

The main goal of this paper is to establish the existence and uniqueness of a global solution to the initial-boundary value problem with general large initial data in H^1 and to show that neither shock waves nor vacuum and concentration are developed in a finite time. There have been some similar fundamental results on nonlinear thermoviscoelasticity [7] and on viscous heat-conductive real gases [14]. We consider the real magnetohydrodynamic flows with general pressure and internal energy, and permit the generation of heat by the magnetic field as well as its interaction with

the fluid motion. We remark that the fundamental idea in [15] for the Navier–Stokes equations of perfect compressible viscous flows does not apply to the problem under consideration for the magnetohydrodynamic flows with general equations of state (1.7). Our approach is then based on the methods in [7, 14]. We introduce the Lagrangian variable and transform the initial-boundary value problem (1.5)–(1.8) into a corresponding problem in Lagrangian coordinates. The existence and uniqueness of local solutions can be obtained by using the Banach theorem and the contractivity of the operator defined by the linearization of the problem on a small time interval (see [21]). The existence of global solutions is proved by extending the local solutions globally in time based on the global a priori estimates of solutions. We first obtain an entropy-type energy estimate involving the dissipative effects of viscosity, magnetic diffusion, and heat diffusion, which is essential for deducing the lower and upper bounds of the density. Some new techniques are developed to achieve these bounds. With these bounds, all the required a priori estimates are obtained subsequently by our careful analysis and techniques. In particular, the estimates of the temperature θ are complicated because of the complexity of the system for the general flow and will be achieved by developing some detailed analysis of the energy equation. The boundedness of the temperature will be proved by a maximum principle. We remark that for technical reasons the viscosity coefficients and magnetic diffusion coefficient are assumed to depend on the density only, and the heat conductivity cannot be a constant even in the case of perfect flows. It is an open problem to develop more effective techniques to remove these restrictions.

We reformulate the problem and state the main results in section 2, prove the existence of global solutions with initial data in H^1 by establishing the a priori estimates on the density in section 3, on the velocity and magnetic field in section 4, and on the temperature in section 5.

2. Reformulation of the initial-boundary value problem and main results. Consider the initial-boundary value problem (1.5)–(1.8) with positive lower and upper bounds of the initial density and temperature: $C_0^{-1} \le \rho_0, \theta_0 \le C_0$, for some constant $C_0 > 0$. Without loss of generality, we take $\int_0^1 \rho_0(x)dx = 1$. We first assume that $\rho, \theta > 0$, and then will prove their positive lower bounds later. We introduce the Lagrangian variable:

$$y = y(x,t) = \int_0^x \rho(\xi,t)d\xi. \tag{2.1}$$

We have $0 \le y \le 1$ since y is increasing in x and

$$\int_0^1 \rho(x,t)dx = \int_0^1 \rho_0(x)dx = 1.$$

We translate problem (1.5)–(1.8) in Eulerian coordinates into the following initial-boundary value problem in Lagrangian coordinates (y,t), $y \in \Omega = (0,1)$, a moving coordinate along the particle path:

$$v_t - u_y = 0, \tag{2.2a}$$

$$u_t + P_y = (\lambda\rho u_y)_y, \tag{2.2b}$$

$$\mathbf{w}_t - \mathbf{b}_y = (\mu\rho\mathbf{w}_y)_y, \tag{2.2c}$$

$$(v\mathbf{b})_t - \mathbf{w}_y = (\nu\rho\mathbf{b}_y)_y, \tag{2.2d}$$

$$E_t + (uP - \mathbf{w}\cdot\mathbf{b})_y = (\rho(\lambda u u_y + \mu\mathbf{w}\cdot\mathbf{w}_y + \nu\mathbf{b}\cdot\mathbf{b}_y + \kappa\theta_y))_y, \tag{2.2e}$$

with the initial-boundary conditions

$$(v,u,\mathbf{w},\mathbf{b},\theta)|_{t=0}=(v_0,u_0,\mathbf{w}_0,\mathbf{b}_0,\theta_0)(y),\quad y\in\Omega,$$
$$(u,\mathbf{w},\mathbf{b},\theta_y)|_{\partial\Omega}=0, \tag{2.3}$$

where $v=1/\rho$ is the specific volume, $p=p(v,\theta)$, $e=e(v,\theta)$, and

$$P=p+\frac{1}{2}|\mathbf{b}|^2,\qquad E=e+\frac{1}{2}(u^2+|\mathbf{w}|^2)+\frac{1}{2}v|\mathbf{b}|^2. \tag{2.4}$$

The second law of thermodynamics states the relation between p and e:

$$e_v(v,\theta)+p(v,\theta)=\theta p_\theta(v,\theta). \tag{2.5}$$

Problem (1.5)–(1.8) and problem (2.2)–(2.3) are equivalent for the solutions under consideration. Our main interest is to study the behavior of solutions of this problem with physical equations of state and various physical viscosity coefficients λ, μ, magnetic diffusivity ν, and heat conductivity κ. We assume that p and e are continuously differentiable and κ is twice continuously differentiable in $v>0$ and $\theta\ge 0$. For technical reasons we assume that the viscosity coefficients λ, μ, and ν depend only on v, with continuous first derivatives in $v>0$ such that $\lambda_1\le\lambda\le\lambda_2$, $\mu_1\le\mu\le\mu_2$, $\nu_1\le\nu\le\nu_2$ for $v>0$ and for some positive constants λ_i,μ_i,ν_i $(i=1,2)$. It is an open problem to handle the case where these viscosity coefficients depend also on temperature. We also assume the growth conditions with exponents $r\in[0,1]$ and $q\ge 2+2r$ such that

(1) there exists a constant $e_0>0$ so that, for $v>0$ and $\theta\ge 0$,

$$p_v(v,\theta)\le 0,\quad e(v,\theta)\ge e_0(1+\theta^{1+r}); \tag{2.6}$$

(2) for any given $v_1>0$, there exist positive constants $\kappa_0=\kappa_0(v_1)$, $p_0=p_0(v_1)$, $e_1=e_1(v_1)$ such that, for $v\ge v_1$, $\theta\ge 0$,

$$0\le vp(v,\theta)\le p_0\left(1+\theta^{1+r}\right),\quad \kappa(v,\theta)\ge\kappa_0(1+\theta^q),\quad e_\theta(v,\theta)\ge e_1(1+\theta^r); \tag{2.7}$$

(3) for any given $v_2>v_1>0$, there exist positive constants $p_i=p_i(v_1,v_2)$ $(i=1,2,3)$, $e_j=e_j(v_1,v_2)$ $(j=2,3)$, and $\kappa_1=\kappa_1(v_1,v_2)$ so that, for any $v\in[v_1,v_2]$, $\theta\ge 0$,

$$|vp_\theta(v,\theta)|\le p_1\left(1+\theta^r\right),\qquad -p_3\left(1+\theta^{1+r}\right)\le v^2p_v(v,\theta)\le -p_2\left(1+\theta^{1+r}\right), \tag{2.8}$$
$$|e_v(v,\theta)|\le e_2(1+\theta^{1+r}),\qquad e_\theta(v,\theta)\le e_3(1+\theta^r), \tag{2.9}$$
$$\kappa(v,\theta)+|\kappa_v(v,\theta)|+|\kappa_{vv}(v,\theta)|\le\kappa_1(1+\theta^q). \tag{2.10}$$

These growth conditions are motivated by the physical facts: $e\propto\theta^{1+r}$ with $r\approx 0.5$ and $\kappa\propto\theta^{5/2}$ for important physical regimes where the temperature is high and changes rapidly; see [2, 6, 23, 25]. The perfect gases are included that correspond to the special case $r=0$. We remark that, if $r=0$, we still need the dependence of the heat conductivity on temperature, and new analysis is required to deal with the constant heat conductivity. For the initial-boundary value problem (2.2), (2.3), we will see that, if the initial data is in H^1, then the solution will be at least in H^1, and neither shock waves nor vacuum and concentration are developed in a finite time. Precisely, we have the following results.

MAIN THEOREM. *If for some constant $C_0 > 0$,*

$$C_0^{-1} \le v_0,\, \theta_0 \le C_0, \quad \|(u_0, \mathbf{w}_0, \mathbf{b}_0)\|_{L^4} + \|\theta_0\|_{L^2} \le C_0,$$
$$\|(v_0, u_0, \mathbf{w}_0, \mathbf{b}_0, \theta_0)\|_{H^1} \le C_0,$$

and $v_0 \in W^{1,\infty}(\Omega)$, then the initial-boundary value problem (2.2), (2.3) *has a unique global solution $(v, u, \mathbf{w}, \mathbf{b}, \theta)(y,t)$ such that, for any fixed $T > 0$,*

$$v \in L^\infty(0,T; H^1 \cap W^{1,\infty}(\Omega)), \qquad (u, \mathbf{w}, \mathbf{b}, \theta) \in L^\infty(0,T; H^1(\Omega)),$$

and, for each $(y,t) \in \Omega \times [0,T]$,

$$\begin{aligned} &C^{-1} \le v(y,t),\, \theta(y,t) \le C,\\ &\|(u, \mathbf{w}, \mathbf{b})\|_{L^2(0,T;L^4\cap H^1)} + \|\theta\|_{L^2(0,T;L^2\cap H^1)} \le C,\\ &\|(v, u, \mathbf{w}, \mathbf{b}, \theta)\|^2_{H^1}(t) + \int_0^t \|(v_{yt}, u_{yy}, \mathbf{w}_{yy}, \mathbf{b}_{yy}, \theta_{yy})\|^2_{L^2}(s)ds \le C, \end{aligned} \tag{2.11}$$

where $C > 0$ is some constant.

The results for the initial-boundary value problem (2.2), (2.3) in the main theorem in Lagrangian coordinates can easily be converted to equivalent statements for the corresponding results for the initial-boundary value problem (1.5), (1.8) in Eulerian coordinates. The details are omitted.

The existence and uniqueness of the local solution to the initial-boundary value problem (2.2), (2.3) is known from the standard method based on the Banach theorem and the contractivity of the operator defined by the linearization of the problem on a small time interval [21]. The global existence of a solution can be obtained by combining the local existence and the global a priori estimates (2.11) using a standard argument (see [9], for example). The uniqueness of the global solution follows from the uniqueness of the local solution. Therefore the remaining task is to establish the global a priori estimates (2.11).

3. A priori estimates on density. We will use the following notation: $U = (u, \mathbf{w}, \mathbf{b})$, $\Pi_t = (0,1) \times (0,t)$, and $\vartheta = 1/\theta$. Denote the L^1-norm on $\Omega \subset \mathbb{R}$ by $\|\cdot\| = \int_\Omega |\cdot| dy$, and the L^1-norm on $\Pi_t \subset \mathbb{R}^2$ by $|||\cdot||| = \iint_{\Pi_t} |\cdot|\, dy\, ds$. For $s > 1$, denote the L^s-norm on $\Omega \subset \mathbb{R}$ by $\|\cdot\|_s$, and the L^s-norm on $\Pi_t \subset \mathbb{R}^2$ by $|||\cdot|||_s$. In the rest of this paper, we will establish the a priori estimates of the solutions for $x \in \Omega$ and $t \in (0,T)$ with any T fixed.

In this section we prove the following estimates.

LEMMA 3.1.

$$C^{-1} \le v \le C, \quad \big\|v + \theta + \theta^{1+r} + |U|^2 + e\big\| + \big|\!\big|\!\big| K + |U_y|^2 + \theta_y^2 \big|\!\big|\!\big| \le C,$$

where

$$K = \rho\vartheta\left(\kappa\vartheta\theta_y^2 + \lambda u_y^2 + \mu|\mathbf{w}_y|^2 + \nu|\mathbf{b}_y|^2\right).$$

Proof. We have first from (2.2a), by integration, $\|v\| = \|v_0\| = 1$ without loss of generality. Integrating the energy equation (2.2e) and using (2.6) and the Cauchy–Schwarz inequality yields

$$\|e + u^2 + |\mathbf{w}|^2 + v|\mathbf{b}|^2 + \theta + \theta^{1+r}\| \le C.$$

Set $\psi(v,\theta) \equiv e(v,\theta) - \theta\eta(v,\theta)$, where $\eta(v,\theta)$ is defined by the relations $e_\theta = \theta\eta_\theta$, $\eta_v = p_\theta$. Then $e_\theta = -\theta\psi_{\theta\theta}$ and $\psi_v = -p$. Take $\Phi_1 \equiv 2(\psi(v,\theta) - \psi(v,1) - \psi_\theta(v,\theta)(\theta - 1))$ and $\Phi_2 \equiv 2(\psi(v,1) - \psi(1,1) - \psi_v(1,1)(v-1))$. Then

$$\begin{aligned}&\frac{1}{2}\left(\Phi_1 + \Phi_2 + u^2 + |\mathbf{w}|^2 + v|\mathbf{b}|^2\right)_t + K\\ &\quad = \left(\rho(\lambda u u_y + \mu \mathbf{w}\cdot\mathbf{w}_y + \nu\mathbf{b}\cdot\mathbf{b}_y + \kappa\theta_y) + p(1,1)u - uP + \mathbf{w}\cdot\mathbf{b} - \kappa\rho\vartheta\theta_y\right)_y,\end{aligned}$$

where $p(1,1)$ is the value of $p(v,\theta)$ at $v = \theta = 1$. Integrating the above equation over Π_t yields

$$\frac{1}{2}\int_\Omega (\Phi_1 + \Phi_2)dy + \frac{1}{2}\left\|u^2 + |\mathbf{w}|^2 + v|\mathbf{b}|^2\right\| + \|\!|K|\!\| \le C.$$

By (2.6),

$$\Phi_1 \ge 2(\theta-1)^2 \int_0^1 \frac{e_\theta(v, 1 + s(\theta-1))}{1 + s(\theta-1)}\, s\, ds \ge 0,$$

and $\Phi_2 = -p_v(\xi,1)(v-1)^2 \ge 0$ for some ξ using Taylor's expansion; therefore

$$\|\!|K|\!\| \le C. \tag{3.1}$$

Set

$$w(y,t) \equiv \int_0^t (\lambda\rho u_y - P)(y,s)ds + \int_0^y u_0(\xi)d\xi;$$

then $w_y = u$ from (2.2b), and thus

$$w(y,t) = w(a(t),t) + \int_{a(t)}^y u(\xi,t)d\xi,$$

where $a(t) \in [0,1]$ will be determined later. On the other hand,

$$w(y,t) = \int_0^t (V_t - P)ds + \int_0^y u_0(\xi)d\xi,$$

where $V(v) \equiv \int_1^v \lambda(\xi)\xi^{-1}d\xi$ is increasing in v and $\lambda_1 \ln v \le V(v) \le \lambda_2 \ln v$; then

$$\begin{aligned}V(y,t) &= V(y,0) + w(y,t) + \int_0^t P ds - \int_0^y u_0(\xi)d\xi\\ &= V(y,0) + w(a(t),t) + \int_0^t P ds + \int_{a(t)}^y u(\xi,t)d\xi - \int_0^y u_0(\xi)d\xi.\end{aligned} \tag{3.2}$$

From the definition of w, we have $w_t = \lambda\rho u_y - P$; then

$$(vw)_t = (uw)_y - u^2 - vP + \lambda u_y,$$

and by integration,

$$\int_\Omega vw dy = \int_\Omega v_0 w_0 dy - \iint_{\Pi_t} \left(u^2 + vP\right) dy\, ds + \iint_{\Pi_t} \lambda u_y\, dy\, ds.$$

There exists a function $a(t) \in [0,1]$ for any $t > 0$ such that

$$\int_\Omega vwdy = w(a(t),t)\int_\Omega vdy = w(a(t),t).$$

Therefore

$$\begin{aligned} V(y,t) = V(y,0) &+ \int_\Omega v_0(y)\int_0^y u_0(\xi)d\xi dy + \int_0^t P(y,s)ds - \iint_{\Pi_t}\left(u^2+vP\right)\,dy\,ds \\ &+ \int_{a(t)}^y u(\xi,t)d\xi - \int_0^y u_0(\xi)d\xi + \iint_{\Pi_t}\lambda u_y\,dy\,ds. \end{aligned} \tag{3.3}$$

Notice that, from (3.1),

$$\begin{aligned} \|\lambda u_y\| &\le \left\|\lambda\rho\vartheta u_y^2\right\| + C\int_0^t \max_y\theta\,\|v\|\,ds \\ &\le C + C\,\|\theta+\theta_y\| \le C + C\int_0^t \left\|\kappa\rho\vartheta^2\theta_y^2\right\|\,\|v\|\,ds \le C + C\,\|K\| \le C, \end{aligned} \tag{3.4}$$

and from (2.7),

$$\|u^2 + vP\| \le C\|u^2 + 1 + \theta^{1+r} + |\mathbf{b}|^2\| \le C.$$

Then $V(y,t) \ge -C$ since $P \ge 0$. Thus $v \ge C^{-1}$ and $\rho \le C$.

From (2.2), we have

$$e_t + pu_y = (\kappa\rho\theta_y)_y + \rho\left(\lambda u_y^2 + \mu|\mathbf{w}_y|^2 + \nu|\mathbf{b}_y|^2\right). \tag{3.5}$$

Integrating (3.5) and using (2.7), we obtain

$$\begin{aligned} &\iint_{\Pi_t}\rho\left(\lambda u_y^2 + \mu|\mathbf{w}_y|^2 + \nu|\mathbf{b}_y|^2\right)\,dy\,ds \\ &\quad\le C + \frac{1}{2}\iint_{\Pi_t}\lambda\rho u_y^2\,dy\,ds + C\iint_{\Pi_t}\rho\left(1+\theta^{2+2r}\right)\,dy\,ds, \end{aligned}$$

and then, from (2.7) and (3.1),

$$\begin{aligned} \frac{1}{2}\left\|\rho\left(\lambda u_y^2 + \mu|\mathbf{w}_y|^2 + \nu|\mathbf{b}_y|^2\right)\right\| &\le C + C\iint_{\Pi_t}\left(\|\theta^{1+r}\| + \|\theta^r\theta_y\|\right)^2\,dy\,ds \\ &\le C + C\int_0^t \|\kappa\rho\vartheta^2\theta_y^2\|\,\|v\|\,ds \le C + C\,\|K\| \le C. \end{aligned}$$

Thus, from the boundary condition (2.3) on $\mathbf{b}$ and the estimates above,

$$\int_0^t \frac{1}{2}|\mathbf{b}|^2 ds = \int_0^t\int_0^y \mathbf{b}\cdot\mathbf{b}_y ds \le \|v|\mathbf{b}|^2\| + C\|\nu\rho|\mathbf{b}_y|^2\| \le C.$$

Then

$$\begin{aligned} V(y,t) &\le C + C\int_0^t \theta^{1+r}ds + \int_0^t \frac{1}{2}|\mathbf{b}|^2 ds \le C + C\|\theta^{1+r} + \theta^r\theta_y\| \\ &\le C + C\|\kappa\rho\vartheta^2\theta_y^2\| + C\,\|v\| \le C, \end{aligned}$$

that is, $v \le C$ and $\rho \ge C^{-1}$. This completes the proof of Lemma 3.1. ∎

4. A priori estimates on velocity and the magnetic field. We now establish the following estimates on $U = (u, \mathbf{w}, \mathbf{b})$.

LEMMA 4.1.

$$\|(v_y, U_y)\|_2^2 + \|\!|U_{yy}|\!\|_2^2 + \|\!|U_y|\!\|_4^4 + |U|^2 \le C.$$

Proof. Rewrite (2.2b) as $(V_y - u)_t = P_y$, multiply it by $V_y - u$, and integrate it to obtain

$$\frac{1}{2}\|V_y - u\|_2^2 \le C + \iint_{\Pi_t} (p_v v_y + p_\theta \theta_y + \mathbf{b}\cdot\mathbf{b}_y)(V_y - u)\, dy\, ds.$$

From (2.7) we observe that

$$\begin{aligned} &\int_0^t \max_{y\in\Omega}\left(1+\theta^{1+r}\right) ds + \int_0^t \max_{y\in\Omega}\left(1+\theta^{2+2r}\right) ds + \int_0^t \max_{y\in\Omega}\left(1+\theta^{1+r}\right)^2 ds \\ &\le C\int_0^t \max_{y\in\Omega}\left(1+\theta^{1+r}\right)^2 ds \le C\int_0^t \left(1+\|\theta^{1+r}\| + \|\theta^r\theta_y\|\right)^2 ds \\ &\le C + C\|\!|\kappa\vartheta^2\theta_y^2|\!\| \le C; \end{aligned} \tag{4.1}$$

then, using (2.8) and $V_y = \lambda\rho v_y$, we obtain that there exists some constant $C_1 > 0$ such that

$$\begin{aligned} \frac{1}{2}\|V_y - u\|_2^2 &\le C - C_1\|\!|\left(1+\theta^{1+r}\right)v_y^2|\!\| + C\|\!|\left(1+\theta^{1+r}\right)v_y u|\!\| \\ &\quad + C\|\!|(1+\theta^r)\,\theta_y\,(V_y+u)|\!\| + \iint_{\Pi_t}\mathbf{b}\cdot\mathbf{b}_y\,(V_y-u)\,dy\,ds \\ &\le C - \frac{C_1}{2}\|\!|\left(1+\theta^{1+r}\right)v_y^2|\!\| + C\int_0^t \max_{y\in\Omega}\left(1+\theta^{1+r}\right)\|u^2\| ds \\ &\quad + C\|\!|\kappa\vartheta^2\theta_y^2|\!\| + C\,\|\!|(\mathbf{b}\cdot\mathbf{b}_y, u)|\!\|_2^2 \\ &\le C - \frac{C_1}{2}\|\!|\left(1+\theta^{1+r}\right)v_y^2|\!\| + C\,\|\!|\mathbf{b}\cdot\mathbf{b}_y|\!\|_2^2. \end{aligned}$$

Then

$$\|V_y - u\|_2^2 + \|\!|\left(1+\theta^{1+r}\right)v_y^2|\!\| \le C + C\,\|\!|\mathbf{b}\cdot\mathbf{b}_y|\!\|_2^2$$

and

$$\begin{aligned} \|v_y\|_2^2 &\le C\,\|V_y\|_2^2 \le C\,\|V_y - u\|_2^2 + C\,\|u\|_2^2 \\ &\le C + C\,\|\!|\mathbf{b}\cdot\mathbf{b}_y|\!\|_2^2. \end{aligned} \tag{4.2}$$

Multiplying (2.2e) by $K_1 E$ and (2.2b) by $K_2 u^3$, taking the inner product of (2.2c) with $K_3|\mathbf{w}|^2\mathbf{w}$ and (2.2d) with $K_4|v\mathbf{b}|^2 v\mathbf{b}$, multiplying (4.2) by K_5, respectively, for proper positive constants $K_j, 1 \le j \le 5$, integrating them over $[0,1]\times[0,t]$, adding them all together, and using Gronwall's inequality, we have $\|v_y\|_2^2 + \|\!|\mathbf{b}\cdot\mathbf{b}_y|\!\|_2^2 \le C$ by tedious calculations. Multiply (2.2b) by u_{yy} and integrate on $[0,1]\times[0,t]$ to obtain, using the interpolation inequality on u_y,

$$|u_y|^2 \le C(1+\delta^{-1})\,\|u_y\|_2^2 + \delta\|\lambda\rho u_{yy}^2\| \tag{4.3}$$

for any $\delta > 0$, and from (4.1),

$$\begin{aligned}
&\frac{1}{2}\|u_y\|_2^2 \le \frac{1}{2}\|u_{0y}\|_2^2 - \iint_{\Pi_t} \left(\lambda\rho u_{yy} + (\lambda\rho)_v v_y u_y - p_v v_y - p_\theta \theta_y - \mathbf{b}\cdot\mathbf{b}_y\right) u_{yy}\, dy\, ds \\
&\le C - \frac{1}{2}\left\|\!\left|\lambda\rho u_{yy}^2\right|\!\right\| + C\int_0^t \max_y \left(u_y^2 + \theta^{2+2r}\right)\left\|v_y^2\right\| ds + C\left\|\!\left|\kappa\vartheta^2\theta_y^2 + |\mathbf{b}\cdot\mathbf{b}_y|^2\right|\!\right\| \\
&\le C - \frac{1}{4}\left\|\!\left|\lambda\rho u_{yy}^2\right|\!\right\| + C\left\|u_y\right\|_2^2 \le C - \frac{1}{4}\left\|\!\left|\lambda\rho u_{yy}^2\right|\!\right\|;
\end{aligned}$$

then

$$\|u_y\|_2^2 + \left\|u_{yy}\right\|_2^2 \le C$$

and

$$\left\|u_y\right\|_4^4 = \int_0^t \max_y u_y^2 \|u_y\|_2^2\, ds \le C\left\|(u_y, u_{yy})\right\|_2^2 \le C.$$

Multiplying (2.2c) by $\mathbf{w}_{yy}$ and then integrating, and using the interpolation inequality on $\mathbf{w}_y$ similar to (4.3), we have

$$\begin{aligned}
\frac{1}{2}\|\mathbf{w}_y\|_2^2 &= \frac{1}{2}\|\mathbf{w}_y(y,0)\|_2^2 - \iint_{\Pi_t}\left(\mathbf{b} + \frac{\mu\mathbf{w}_y}{v}\right)_y \cdot \mathbf{w}_{yy}\, dy\, ds \\
&\le C - C_2\left\|\mathbf{w}_{yy}\right\|_2^2 + C\left\|(|\mathbf{b}_y| + |v_y||\mathbf{w}_y|)\,\mathbf{w}_{yy}\right\| \\
&\le C - \frac{3C_2}{4}\left\|\mathbf{w}_{yy}\right\|_2^2 + C\left\|\mathbf{b}_y\right\|_2^2 + C\int_0^t \max_{y\in\Omega}|\mathbf{w}_y|^2\,\|v_y\|_2^2\, ds \\
&\le C - \frac{C_2}{2}\left\|\mathbf{w}_{yy}\right\|_2^2 + C\left\|\mathbf{w}_y\right\|_2^2 \le C - \frac{C_2}{2}\left\|\mathbf{w}_{yy}\right\|_2^2,
\end{aligned}$$

and then

$$\|\mathbf{w}_y\|_2^2 + \left\|\mathbf{w}_{yy}\right\|_2^2 \le C.$$

As a consequence,

$$\left\|\mathbf{w}_y\right\|_4^4 \le \int_0^t \max_{y\in\Omega}|\mathbf{w}_y|^2\,\|\mathbf{w}_y\|_2^2\, ds \le C\left\|(\mathbf{w}_y, \mathbf{w}_{yy})\right\|_2^2 \le C.$$

Using $v_t = u_y$, we rewrite (2.2d) as

$$\mathbf{b}_t = \frac{u_y}{v}\mathbf{b} + \frac{1}{v}\left(\mathbf{w} + \frac{\nu\mathbf{b}_y}{v}\right)_y. \tag{4.4}$$

Multiplying the above equation by $\mathbf{b}_{yy}$, integrating it, and using Lemma 3.1 and the similar interpolation inequalities on $\mathbf{b}$ and $\mathbf{b}_y$ to (4.3) yields

$$\begin{aligned}
\frac{1}{2}\|\mathbf{b}_y\|_2^2 &\le C - C_3\left\|\mathbf{b}_{yy}\right\|_2^2 + C\left\|(|u_y||\mathbf{b}| + |\mathbf{w}_y| + |v_y||\mathbf{b}_y|)\,\mathbf{b}_{yy}\right\| \\
&\le C - \frac{3C_3}{4}\left\|\mathbf{b}_{yy}\right\|_2^2 + C\max_{y,t}|\mathbf{b}|^2\left\|u_y\right\|_2^2 + C\int_0^t \max_{y\in\Omega}|\mathbf{b}_y|^2\,\|v_y\|_2^2\, ds \\
&\le C - \frac{C_3}{2}\left\|\mathbf{b}_{yy}\right\|_2^2 + C\|\mathbf{b}\|_2^2 + \frac{1}{4}\|\mathbf{b}_y\|_2^2 + C\left\|\mathbf{b}_y\right\|_2^2 \\
&\le C - \frac{C_3}{2}\left\|\mathbf{b}_{yy}\right\|_2^2 + \frac{1}{4}\|\mathbf{b}_y\|_2^2.
\end{aligned}$$

Then

$$\|\mathbf{b}_y\|_2^2 + \|\mathbf{b}_{yy}\|_2^2 \le C.$$

Thus

$$\|\mathbf{b}_y\|_4^4 \le \int_0^t \max_{y\in\Omega} |\mathbf{b}_y|^2 \, \|\mathbf{b}_y\|_2^2 \, ds \le C \, \|(\mathbf{b}_y, \mathbf{b}_{yy})\|_2^2 \le C.$$

Using Lemma 3.1 and the above estimates, one obtains the following:

$$|U|^2 \le C \, \|U\|_2^2 + C \, \|U_y\|_2^2 \le C.$$

The proof of Lemma 4.1 is complete. □

5. A priori estimates on temperature. We now make estimates on the temperature θ. Due to the complicated structures of the pressure, internal energy, and heat conductivity, as well as the strong coupling of the equations, the estimates on the temperature θ are quite complex.

LEMMA 5.1.

$$\|(\theta_y, U_t, U_{yy})\|_2^2 + \|(\theta_t, U_t)\|_2^2 + |(v_y, U_y)|^2 \le C, \quad C^{-1} \le \theta \le C. \tag{5.1}$$

Proof. To make the estimates on θ, we first define the following:

$$\Theta = \max_{\Pi_T} \theta(y,t),$$
$$X = \left\| \left(1+\theta^{q+r}\right)\theta_t^2 \right\|, \quad Y = \max_{t\in[0,T]} \left\| \left(1+\theta^{2q}\right)\theta_y^2 \right\|, \quad Z = \max_{t\in[0,T]} \|u_{yy}\|_2^2.$$

We will show that Θ, X, and Y can be controlled by Z, and then we will derive an inequality on Z which yields the upper bound of Z and thus the upper bounds of Θ, X, and Y.

From Lemma 4.1, one has

$$u_y^2 \le \|u_y\|_2^2 + 2 \, \|u_y\|_2 \, \|u_{yy}\|_2 \le C + CZ^{1/2},$$

which implies

$$|u_y| \le C + CZ^{1/4}. \tag{5.2}$$

Define $y(t) \in [0,1]$ such that $\theta(y(t),t) = \int_0^1 \theta(y,t)dy \le C$. From Lemma 3.1, we have

$$\begin{aligned}\theta^{(2q+3+r)/2}(y,t) &= \|\theta\|^{(2q+3+r)/2} + \frac{2q+3+r}{2} \int_{y(t)}^{y} \theta^{(2q+1+r)/2}\theta_y d\xi \\ &\le C + C\left(\int_0^1 \theta^{2q}\theta_y^2 dy\right)^{1/2}\left(\int_0^1 \theta^{1+r} dy\right)^{1/2} \le C + CY^{1/2},\end{aligned}$$

and thus

$$\Theta \le C + CY^{\beta_1}, \tag{5.3}$$

where $\beta_1 = 1/(2q+3+r)$. The rest of the proof can be divided into four steps.

Step 1. We now show that X and Y can be controlled by Z. Use (2.5) and rewrite (3.5) as

$$e_\theta\theta_t+\theta p_\theta u_y=\left(\frac{\kappa\theta_y}{v}\right)_y+\frac{\lambda u_y^2}{v}+\frac{\mu|\mathbf{w}_y|^2}{v}+\frac{\nu|\mathbf{b}_y|^2}{v}. \tag{5.4}$$

Set $H(v,\theta)=v^{-1}\int_0^\theta \kappa(v,\xi)\,d\xi$. Multiplying (5.4) by H_t, using integration by parts and the boundary condition (2.3), we have

$$\iint_{\Pi_t}\left(e_\theta\theta_t+\theta p_\theta u_y-\frac{\lambda}{v}u_y^2-\frac{\mu}{v}|\mathbf{w}_y|^2-\frac{\nu}{v}|\mathbf{b}_y|^2\right)H_t\,dy\,ds+\iint_{\Pi_t}\frac{\kappa}{v}\theta_y H_{ty}\,dy\,ds=0, \tag{5.5}$$

where

$$H_t=H_v u_y+\frac{\kappa}{v}\theta_t,\qquad H_{ty}=H_v u_{yy}+H_{vv}u_y v_y+\left(\frac{\kappa}{v}\right)_v\theta_t v_y+\left(\frac{\kappa}{v}\theta_y\right)_t.$$

We now estimate all the terms in the above equality. First we have, from (2.6) and (2.7),

$$\iint_{\Pi_t} e_\theta\theta_t\frac{\kappa}{v}\theta_t\,dy\,ds\ge C_4X,\quad \int_0^T\int_0^1\frac{\kappa}{v}\theta_y\left(\frac{\kappa}{v}\theta_y\right)_t\,dy\,ds\ge C_5Y-C,$$

for some positive constants C_4 and C_5. From (2.10),

$$|H_v|+|H_{vv}|\le C\int_0^\theta\left(|\kappa|+|\kappa_v|+|\kappa_{vv}|\right)d\xi\le C\left(1+\theta^{q+1}\right).$$

Using (2.8), (2.9), (5.2), (5.3), Lemmas 3.1 and 4.1, and Young's inequality, we have

$$\begin{aligned}&\iint_{\Pi_t} e_\theta\theta_t H_v u_y\,dy\,ds\le C\left\|\left(1+\theta^{q+r+1}\right)\theta_t u_y\right\|\\&\le\frac{C_4}{8}X+C\left(1+\Theta^{q+2+r}\right)\left\|u_y^2\right\|\le\frac{C_4}{8}X+CY^{(q+2+r)\beta_1}+C\\&\le\frac{C_4}{8}X+\frac{C_5}{8}Y+C\end{aligned}$$

and

$$\begin{aligned}&\iint_{\Pi_t}\left(\theta p_\theta u_y-\frac{\lambda}{v}u_y^2-\frac{\mu}{v}|\mathbf{w}_y|^2-\frac{\nu}{v}|\mathbf{b}_y|^2\right)H_v u_y\,dy\,ds\\&\le C\left(1+\Theta^{q+1}\right)\max_{y,t}|u_y|\left\|\left(1+\theta^{1+r}\right)|u_y|+u_y^2+|\mathbf{w}_y|^2+|\mathbf{b}_y|^2\right\|\\&\le C\left(1+\Theta^{q+1}\right)\left(1+Z^{1/4}\right)\left\|\left(1+\theta^{1+r}\right)^2+u_y^2+|\mathbf{w}_y|^2+|\mathbf{b}_y|^2\right\|\\&\le C+\frac{C_5}{8}Y+CZ^{\beta_2},\end{aligned}$$

with $\beta_2=(2q+3+r)/(4(q+1+r))$ and

$$\begin{aligned}&\iint_{\Pi_t}\left(\theta p_\theta u_y-\frac{\lambda}{v}u_y^2-\frac{\mu}{v}|\mathbf{w}_y|^2-\frac{\nu}{v}|\mathbf{b}_y|^2\right)\frac{\kappa}{v}\theta_t\,dy\,ds\\&\le C\left\|\left(\left(1+\theta^{1+r}\right)|u_y|+u_y^2+|\mathbf{w}_y|^2+|\mathbf{b}_y|^2\right)\left(1+\theta^q\right)\theta_t\right\|\\&\le\frac{C_4}{8}X+C\left(1+\Theta^{q+2+r}\right)\|u_y\|_2^2+C\left(1+\Theta^{q-r}\right)\|(u_y,\mathbf{w}_y,\mathbf{b}_y)\|_4^4\\&\le\frac{C_4}{8}X+C\Theta^{q+2+r}+C\le\frac{C_4}{8}X+\frac{C_5}{8}Y+C.\end{aligned}$$

Since $\theta^q(y,t) = \|\theta\|^q + \int_{y(t)}^{y} q\theta^{q-1}\theta_y d\xi$, we use Lemma 3.1 and Young's inequality to obtain

$$\begin{aligned}
&\int_0^t \max_{y\in\Omega}\theta^q ds \le C + C\left\|\!\left|\theta^{q-1}\theta_y\right|\!\right\| \le C + \int_0^t \max_{y\in\Omega}\theta^{q-1}\,\|\theta\|\,ds + C\left\|\!\left|\kappa\vartheta^2\theta_y^2\right|\!\right\| \\
&\le C + \int_0^t \max_{y\in\Omega}\theta^{q-1} ds \le C + \frac{1}{2}\int_0^t \max_{y\in\Omega}\theta^q ds,
\end{aligned}$$

and then

$$\int_0^t \max_{y\in\Omega}\theta^q ds \le C. \tag{5.6}$$

From (2.6)–(2.10), (5.2), (5.3), (5.6), Lemmas 3.1 and 4.1, and Young's inequality, we have

$$\begin{aligned}
&\iint_{\Pi_t} \frac{\kappa}{v}\theta_y H_{vv} u_y v_y\, dy\, ds \le C\left(1+\Theta^{q+1}\right)\max_{y,t}|u_y|\,\|\!|\kappa\theta_y v_y|\!\| \\
&\le C\left(1+\Theta^{q+2}\right)\max_{y,t}|u_y|\left(\int_0^t \max_y\left(1+\theta^q\right)\left\|v_y^2\right\| ds\right)^{1/2}\left\|\!\left|\kappa\vartheta^2\theta_y^2\right|\!\right\|^{1/2} \\
&\le C(1+Z^{1/4})(1+Y^{(q+2)\beta_1}) \le \frac{C_6}{8}Y + CZ^{\beta_2} + C.
\end{aligned}$$

Using (2.10), (5.3), Lemma 4.1, and Young's inequality yields

$$\begin{aligned}
&\iint_{\Pi_t} \frac{\kappa}{v}\theta_y\left(\frac{\kappa}{v}\right)_v \theta_t v_y\, dy\, ds \le C\,\|\!|\left(1+\theta^q\right)\theta_t\left(\kappa\rho\theta_y\right)v_y|\!\| \\
&\le \frac{C_5}{16}X + C\left(1+\Theta^{q-r}\right)\int_0^t \max_y\left|\kappa\rho\theta_y\right|^2\|v_y\|_2^2\, ds \\
&\le \frac{C_5}{16}X + C\left(1+\Theta^{q-r}\right)\int_0^t\left(\|\kappa\rho\theta_y\|_2^2 + 2\|\kappa\rho\theta_y\left(\kappa\rho\theta_y\right)_y\|\right) ds \\
&\le \frac{C_5}{16}X + M\left(1+\Theta^{2q+2-r}\right)\left\|\!\left|\kappa\vartheta^2\theta_y^2\right|\!\right\| + C\left(1+\Theta^{q-r}\right)\|\!|\kappa\rho\theta_y\left(\kappa\rho\theta_y\right)_y|\!\| \\
&\le \frac{C_5}{16}X + C + CY^{(2q+2-r)\beta_1} + C\left(1+\Theta^{q+1-r}\right)\|\!|\kappa\left(\kappa\rho\theta_y\right)_y^2|\!\|^{1/2}\left\|\!\left|\kappa\vartheta^2\theta_y^2\right|\!\right\|^{1/2}.
\end{aligned}$$

Using (5.4), we continue to have

$$\begin{aligned}
&\iint_{\Pi_t} \frac{\kappa}{v}\theta_y\left(\frac{\kappa}{v}\right)_v \theta_t v_y\, dy\, ds \\
&\le \frac{C_5}{16}X + \frac{C_6}{16}Y + C + C\left(1+\Theta^{q+1-r}\right)\left\|\!\left|\kappa\left(e_\theta^2\theta_t^2 + \theta^2 p_\theta^2 u_y^2 + |U_y|^4\right)\right|\!\right\|^{1/2} \\
&\le \frac{C_5}{16}X + \frac{C_6}{16}Y + C + C(1+\Theta^{(2q+2-r)/2})X^{1/2} + C(1+\Theta^{(3q+4)/2})\,\|\!|u_y|\!\|_2 \\
&\quad + M(1+\Theta^{(3q+2-2r)/2})\,\|\!|U_y|\!\|_4^2 \\
&\le \frac{C_5}{16}X + \frac{C_6}{16}Y + C + C(1+\Theta^{(2q+2-r)/2})X^{1/2} + C\Theta^{(3q+4)/2} + C \\
&\le \frac{C_5}{8}X + \frac{C_6}{16}Y + C\Theta^{2q+2-r} + C \le \frac{C_5}{8}X + \frac{C_6}{8}Y + C.
\end{aligned}$$

From (2.6), (2.10), (5.2), (5.3), (5.6), Lemma 3.1, and Young's inequality, we have

$$\begin{aligned}
&\iint_{\Pi_t} \frac{\kappa}{v}\theta_y H_v u_{yy}\,dy\,ds \le C\left\|\left(1+\theta^{q+1}\right)\kappa\theta_y u_{yy}\right\| \\
&\le C(1+\Theta^{(4q+5)/4})\left\|\kappa\vartheta^2\theta_y^2\right\|^{1/2}\left(Z\int_0^t\left(1+\max_y\theta^{(2q+3)/2}\right)ds\right)^{1/2} \\
&\le C(1+Y^{\beta_1(4q+5)/4})Z^{1/2} \le \frac{C_6}{8}Y + CZ^{\beta_3} + C,
\end{aligned}$$

where $\beta_3 = 2(2q+3+r)/(4q+7+4r) \in (0,1)$ and the following estimate is employed:

$$\int_0^t \max_y \theta^{(2q+3)/2} ds \le C, \tag{5.7}$$

which will be shown in the next step. Assuming the estimate (5.7), we conclude, from (5.5), that

$$X + Y \le C + CZ^{\beta_4}, \tag{5.8}$$

where $0 < \beta_4 = \max\{\beta_2, \beta_3\} < 1$.

Step 2. The proof of (5.7) is as follows. For some small δ, from Lemma 3.1,

$$\begin{aligned}
\int_0^t \max_y \theta^{(2q+3)/2} ds &\le \int_0^t \left(\|\theta\|^{(2q+3)/2} + \|\theta^{(2q+1)/2}\theta_y\|\right) ds \\
&\le C + \delta\int_0^t \max_y \theta^{(2q+3)/2}\|\theta^{1+r}\| ds + C\|\theta^{(2q-3-2r)/2}\theta_y^2\| \\
&\le C + \frac{1}{2}\int_0^t \max_y \theta^{(2q+3)/2} ds + C\|\theta^{(2q-3-2r)/2}\theta_y^2\|,
\end{aligned}$$

and then

$$\int_0^t \max_y \theta^{(2q+3)/2} ds \le C + C\|\theta^{(2q-3-2r)/2}\theta_y^2\|.$$

For $r = 1$, using Lemma 3.1, we obtain (5.7) since

$$\int_0^t \max_y \theta^{(2q+3)/2} ds \le C + C\|\theta^{(2q-5)/2}\theta_y^2\| \le C + C\left\|\kappa\vartheta^2\theta_y^2\right\| \le C.$$

For $0 < r < 1$, define $G(v,\theta) = \int_0^\theta \xi^{-r} e_\theta(v,\xi)d\xi$. Then, from (2.6)–(2.10), Lemma 3.1, and (3.5),

$$\|G\| \le C\|\theta + \theta^{1-r}\| \le C\,\|\theta + 1\| \le C$$

and

$$G_t + (1-r)u_y\int_0^\theta \xi^{-r} p_\theta(v,\xi)d\xi = \frac{\lambda u_y^2 + \mu|\mathbf{w}_y|^2 + \nu|\mathbf{b}_y|^2}{v\theta^r} + \frac{r\kappa\theta_y^2}{v\theta^{r+1}} + \left(\frac{\kappa\theta_y}{v\theta^r}\right)_y.$$

Integrating the above equation and using (2.6)–(2.10) and Lemma 3.1, we have

$$\begin{aligned}
&\left\|\rho\vartheta^r\left(\lambda u_y^2 + \mu|\mathbf{w}_y|^2 + \nu|\mathbf{b}_y|^2\right) + r\kappa\rho\theta_y^2\vartheta^{r+1}\right\| \\
&\quad\le C + C\left\|u_y^2 + (1+\theta)^2\right\| \le C + C\left\|\kappa\vartheta^2\theta_y^2\right\| \le C.
\end{aligned}$$

Then, from the above estimate, we have

$$\int_0^t \max_y \theta^{(2q+3)/2} ds \le C + C\|\theta^{(2q-3-2r)/2}\theta_y^2\| \le C + C\left\|\kappa\theta_y^2\vartheta^{1+r}\right\| \le C.$$

If $r = 0$, replace the above definition of G by $G(v,\theta) = \int_0^\theta \xi^{-1/2} e_\theta(v,\xi)d\xi$ and follow the same procedure to obtain

$$\|2\rho\vartheta^{1/2}\left(\lambda u_y^2 + \mu|\mathbf{w}_y|^2 + \nu|\mathbf{b}_y|^2\right) + \kappa\rho\theta_y^2\vartheta^{3/2}\| \le C.$$

Then

$$\int_0^t \max_y \theta^{(2q+3)/2} ds \le C + C\|\theta^{(2q-3)/2}\theta_y^2\| \le C + C\|\kappa\theta_y^2\vartheta^{3/2}\| \le C.$$

Step 3. Now we estimate Z. Differentiate (2.2b) with respect to t, multiply it by u_t, and then integrate to obtain

$$\frac{1}{2}\left\|u_t^2\right\| + \iint_{\Pi_t}\left(\frac{\lambda}{v}u_{yt} + \left(\frac{\lambda}{v}\right)_v u_y^2 - p_t - \mathbf{b}\cdot\mathbf{b}_t\right)u_{yt}\,dy\,ds \le C,$$

from integration by parts and the initial-boundary condition (2.3). Using Lemmas 3.1 and 4.1 and (5.3), one has the following estimates:

$$\iint_{\Pi_t}\frac{\lambda}{v}u_{yt}^2\,dy\,ds \ge C_7\left\|u_{yt}\right\|_2^2,$$

$$\iint_{\Pi_t}\left(\frac{\lambda}{v}\right)_v u_y^2 u_{yt}\,dy\,ds \le \frac{C_7}{8}\left\|u_{yt}\right\|_2^2 + C\left\|u_y\right\|_4^4 \le \frac{C_7}{8}\left\|u_{yt}\right\|_2^2 + C,$$

and

$$\begin{aligned}
&\iint_{\Pi_t} p_t u_{yt}\,dy\,ds \le \left\|\left(p_v u_y + p_\theta\theta_t\right)u_{yt}\right\| \\
&\le \frac{C_7}{8}\left\|u_{yt}\right\|_2^2 + C\left(1+\Theta^{2+2r}\right)\left\|u_y\right\|_2^2 + C\left\|\left(1+\theta^{2r}\right)\theta_t^2\right\| \\
&\le \frac{C_7}{8}\left\|u_{yt}\right\|_2^2 + C(X+Y+1) \le \frac{C_7}{8}\left\|u_{yt}\right\|_2^2 + C + CZ^{\beta_4}.
\end{aligned}$$

From (4.4),

$$|\mathbf{b}_t|^2 \le M\left(|\mathbf{b}|^2 u_y^2 + |\mathbf{w}_y|^2 + |\mathbf{b}_{yy}|^2 + |\mathbf{b}_y|^2 v_y^2\right),$$

and then, by Lemmas 3.1 and 4.1,

$$\begin{aligned}
\left\|\mathbf{b}_t\right\|_2^2 &\le C\left\||\mathbf{b}|^2 u_y^2 + |\mathbf{w}_y|^2 + |\mathbf{b}_{yy}|^2 + |\mathbf{b}_y|^2 v_y^2\right\| \\
&\le C\max_t\left\|\mathbf{b}_y\right\|_2^2\left\|u_y\right\|_2^2 + C\left\|(\mathbf{w}_y,\mathbf{b}_{yy})\right\|_2^2 + C\int_0^t \max_y|\mathbf{b}_y|^2\left\|v_y\right\|_2^2 ds \qquad (5.9)\\
&\le C + C\left\|(\mathbf{b}_y,\mathbf{b}_{yy})\right\|_2^2 \le C.
\end{aligned}$$

Thus, we have

$$\iint_{\Pi_t} u_{yt}\mathbf{b}\cdot\mathbf{b}_t\,dy\,ds \le \frac{C_7}{8}\left\|u_{yt}\right\|_2^2 + C\left\|\mathbf{b}_t\right\|_2^2 \le \frac{C_7}{8}\left\|u_{yt}\right\|_2^2 + C,$$

and then

$$\|u_t\|_2^2 + \|\!|u_{yt}|\!\|_2^2 \le C + CZ^{\beta_4}.$$

From (2.2b),

$$u_{yy} = \frac{v}{\lambda}\left(u_t - p_y - \mathbf{b}\cdot\mathbf{b}_y - \left(\frac{\lambda}{v}\right)_v v_y u_y\right),$$

and then, by Lemma 4.1 and (5.2),

$$\begin{aligned}\|u_{yy}\|_2^2 &\le \left\|u_t^2 + p_v^2 v_y^2 + p_\theta^2\theta_y^2 + |\mathbf{b}|^2 + |\mathbf{b}_y|^2 + v_y^2 u_y^2\right\| \\ &\le C + CZ^{\beta_4} + C\Theta^{2+2r}\|v_y\|_2^2 + CY + C\max_{y,t} u_y^2 \|v_y\|_2^2 \le C + CZ^{1/2} + CZ^{\beta_4},\end{aligned}$$

that is, $Z \le C + CZ^{1/2} + CZ^{\beta_4}$. Therefore $Z \le C$ since the exponents of Z on the right-hand side of the above inequality are both less than one. Then (5.8) implies $X + Y \le C$.

Step 4. We now prove the positive lower bound of the temperature with the aid of a maximum principle. It follows from (5.2) that $|u_y| \le C$. Differentiate (2.2c) with respect to t and then multiply by $\mathbf{w}_t$ and integrate it to obtain

$$\begin{aligned}\frac{1}{2}\|\mathbf{w}_t\|_2^2 + \|\!|\mu\rho|\mathbf{w}_{yt}|^2|\!\| &\le C - \iint_{\Pi_t}\left(\frac{\mu}{v}\right)_v v_t \mathbf{w}_y\cdot\mathbf{w}_{yt}\,dy\,ds - \iint_{\Pi_t}\mathbf{b}_t\cdot\mathbf{w}_{yt}\,dy\,ds \\ &\le \frac{1}{2}\|\!|\mu\rho|\mathbf{w}_{yt}|^2|\!\| + C\|\!|u_y^4 + |\mathbf{w}_y|^4 + |\mathbf{b}_t|^2|\!\| \le \frac{1}{2}\|\!|\mu\rho|\mathbf{w}_{yt}|^2|\!\| + C,\end{aligned}$$

from integration by parts, the initial-boundary condition (2.3), Lemma 4.1, and (5.9). Then

$$\|\mathbf{w}_t\|_2^2 + \|\!|\mu\rho|\mathbf{w}_{yt}|^2|\!\| \le C.$$

From (2.2c),

$$\mathbf{w}_{yy} = \frac{v}{\mu}\left(\mathbf{w}_t - \mathbf{b}_y - \left(\frac{\mu}{v}\right)_v v_y \mathbf{w}_y\right),$$

and then

$$\begin{aligned}\|\mathbf{w}_{yy}\|_2^2 &\le C\left\||\mathbf{w}_t|^2 + |\mathbf{b}_y|^2 + v_y^2|\mathbf{w}_y|^2\right\| \le C + C\max_y|\mathbf{w}_y|^2\|v_y\|_2^2 \\ &\le C + C\|\mathbf{w}_y\|_2^2 + \frac{1}{2}\|\mathbf{w}_{yy}\|_2^2,\end{aligned}$$

which implies that

$$\|\mathbf{w}_{yy}\|_2^2 \le C + C\|\mathbf{w}_y\|_2^2 \le C$$

and

$$|\mathbf{w}_y|^2 \le C\|\mathbf{w}_y\|_2^2 + C\|\mathbf{w}_{yy}\|_2^2 \le C.$$

Rewrite (5.4) as

$$e_\theta\theta_t + \theta p_\theta u_y - \frac{\lambda}{v}u_y^2 - \frac{\mu}{v}|\mathbf{w}_y|^2 - \frac{\nu}{v}|\mathbf{b}_y|^2 = \left(\frac{\kappa}{v}\right)_v v_y\theta_y + \frac{\kappa_\theta}{v}\theta_y^2 + \frac{\kappa}{v}\theta_{yy}.$$

Then, by Lemma 4.1, the above estimates, and an interpolation inequality on θ_y^2,

$$\begin{aligned}\|\kappa\rho\theta_{yy}\|_2^2 &\le C\left\|\theta_t^2+u_y^2+u_y^4+|\mathbf{w}_y|^4+|\mathbf{b}_y|^4+v_y^2\theta_y^2+\theta_y^4\right\| \\ &\le C+C\int_0^t \max_y \theta_y^2\left\|v_y^2+\theta_y^2\right\| ds \le C+C\|\theta_y\|_2^2+\frac{1}{2}\|\kappa\rho\theta_{yy}\|_2^2,\end{aligned}$$

which implies

$$\|\kappa\rho\theta_{yy}\|_2^2 \le C+C\|\theta_y\|_2^2 \le C. \tag{5.10}$$

From (3.3),

$$V(v(y,t))_y = V(v(y,0))_y + u(y,t) - u_0(y) + \int_0^t (p_y + \mathbf{b}\cdot\mathbf{b}_y)dy.$$

Then, using the interpolation inequalities on $|\mathbf{b}_y|^2$ and θ_y^2, Lemmas 3.1 and 4.1, and (5.10), we have

$$\begin{aligned}v_y^2 &\le C(V(v)_y)^2 \le C+C\int_0^t \left(|\mathbf{b}_y|^2+p_v^2v_y^2+p_\theta^2\theta_y^2\right) ds \\ &\le C+C\|(\mathbf{b}_y,\mathbf{b}_{yy},\theta_y,\theta_{yy})\|_2^2+C\int_0^t v_y^2 ds \le C+C\int_0^t v_y^2 ds,\end{aligned}$$

which yields, from Gronwall's inequality, $v_y^2 \le M$. Differentiate (2.2d) with respect to t and then multiply by $(v\mathbf{b})_t$ and integrate to obtain

$$\begin{aligned}\frac{1}{2}\|(v\mathbf{b})_t\|_2^2 &\le C-\frac{1}{2}\left\|\nu\mathbf{b}_{yt}^2\right\|+C\left\||\mathbf{w}_t|^2+u_y^2|\mathbf{b}_y|^2+u_{yy}^2+v_y^2|\mathbf{b}_t|^2\right\| \\ &\le C-\frac{1}{2}\left\|\nu\mathbf{b}_{yt}^2\right\|+C\int_0^t \max_y|\mathbf{b}_y|^2\|u_y\|_2^2\,ds+C\|\mathbf{b}_t\|_2^2 \\ &\le C-\frac{1}{2}\left\|\nu\mathbf{b}_{yt}^2\right\|+C\|(\mathbf{b}_y,\mathbf{b}_{yy})\|_2^2 \le C-\frac{1}{2}\left\|\nu\mathbf{b}_{yt}^2\right\|,\end{aligned}$$

which yields

$$\|(v\mathbf{b})_t\|_2^2+\left\|\nu\mathbf{b}_{yt}^2\right\| \le C.$$

From (2.2d),

$$\||\mathbf{b}_{yy}|\|_2^2 \le C\left\|(v\mathbf{b})_t^2+|\mathbf{w}_y|^2+v_y^2|\mathbf{b}_y|^2\right\| \le C+C\|\mathbf{b}_y\|_2^2 \le C,$$

and then

$$|\mathbf{b}_y|^2 \le C\|(\mathbf{b}_y,\mathbf{b}_{yy})\|_2^2 \le C.$$

As a consequence, we have $C^{-1} \le \theta \le C$ from the maximum principle (see [22]) applied to (5.4) and the boundedness of $(v_y, u_y, \mathbf{w}_y, \mathbf{b}_y)$, $0<\theta\le C$ (from (5.3)), and the positive lower bound of θ_0.

This completes the proof of the main theorem. ∎

THE WIENER–HOPF TECHNIQUE FOR IMPENETRABLE WEDGES HAVING ARBITRARY APERTURE ANGLE*

V. G. DANIELE†

Abstract. Diffraction by impenetrable wedges having arbitrary aperture angle is studied by means of the Wiener–Hopf (W-H) technique. A system of functional equations called generalized Wiener–Hopf equations (GWHE) is obtained. Only for certain values of the aperture angle are these equations recognizable as standard or classical Wiener–Hopf equations (CWHE). However, in all cases a mapping is found that reduces the GWHE to CWHE. It means that the diffraction by an impenetrable wedge always reduces to a standard W-H factorization. The solution for the diffraction by a wedge with given face impedances (the Malyuzhinets problem) is obtained in closed form by an explicit factorization of the kernel.

Key words. Wiener–Hopf technique, diffraction, scattering, wedge, half-plane

1. Introduction.

The first rigorous studies of waves in the presence of geometric discontinuities are due to Poincaré [1] and Sommerfeld [2], who considered the presence of a half-plane in free space. The generalization of the half-plane problem led to the wedge problem, which constituted an important and challenging subject of applied mathematics in the last century. There are a vast number of papers that address the wedge problem. They concern many disciplines such as electromagnetism, acoustics, hydrodynamics, fracture mechanics, and so on. The impenetrable wedges arise from the introduction of approximate boundary conditions on the surfaces of the wedges. These conditions considerably simplify the study of wedge problems. In fact, the external problem (i.e., the evaluation of the fields outside the wedge) is decoupled from the internal problem (i.e., the evaluation of the fields inside the wedge). This article deals only with the impenetrable case.

There are many analytical methods for studying fields and waves in angular regions. Among them, the Malyuzhinets method [3] is particularly well known. This method is based on the use of the Sommerfeld integral. The Wiener–Hopf (W-H) technique is the most powerful method for solving field problems in the presence of geometrical discontinuities. However, concerning wedge problems there is the belief that this technique can be applied only for certain values of the aperture angle. We have never been satisfied with this limited use of the W-H technique for the wedge problems. The aim of this work is to show that the W-H technique can handle wedge problems also in the presence of arbitrary aperture angle. This proposed task is not easy. For instance, the W-H formulation of wedge problems yields functional equations (generalized W-H equations) that substantially differ from the well-known classical W-H equations studied in the literature [4]. However, in this paper it will be shown that, in a suitable complex plane, the generalized W-H equations (GWHE) always

reduce to classical W-H equations (CWHE). That means that the diffraction by an impenetrable wedge always reduces to a standard W-H factorization. For instance, the solution for the diffraction by a wedge with given face impedances (Malyuzhinets problem) is obtained in closed form in this paper by an explicit factorization of the matrix kernel. This yields a new solution of this important problem in a form completely different from, although equivalent to, the Malyuzhinets solution.

At present, important problems involving angular regions are concerned with either penetrable wedges or impenetrable wedges surrounded by media in which more types of waves propagate. In general, for these problems closed form solutions are not available. However, some recent progress has resulted in efficient approximate solutions of important cases [5, 6, 7, 8, 9, 10]. The techniques used in these works are substantially based on the regularization method for singular integral equations. The regularization method for singular integral equations is well known and used by many authors to obtain approximate solutions of singular integral equations when closed form solutions are not obtainable by other methods. The regularization method consists of reducing the singular integral equation to a Fredholm equation of the second kind. Such a technique is very convenient since Fredholm equations are amenable to efficient numerical integration schemes. Every year several papers are produced to reduce particular wedge problems to the solution of Fredholm equations. The most important of them differs only in the technique used to obtain the regularization of the kernels. For example, some works by Budaev [5] and Budaev and Bogy [6, 8] make use of the Sommerfeld–Malyuzhinets method. Conversely, in the work of Gautesen [10], the reduction of the singular equation to a Fredholm equation is obtained in part by using the W-H technique through a decomposition of functions. Even though the involved method is, of course, approximate, Gautesen's paper is very interesting since the kind of regularization performed produces very nice results, though on only one well-defined wedge problem.

It is worth noticing that the extension of the W-H technique reported in this paper to deal with wedge problems is not something that has been done merely for academic reasons, but could have important applications to obtaining the solution of yet-unsolved wedge problems by introducing approximate factorizations of the kernels [11], in contrast to methods based on the regularization of the operators.

This paper is organized as follows: Section 2 reports some important functional equations deduced in Appendix A. After indicating the geometry of the problem, the boundary conditions are considered in section 3. Their imposition yields the GWHE for impenetrable wedge problems. Section 4 describes some particular cases in which the GWHE are immediately recognizable as CWHE. Section 5 deals with the general case for which a fundamental mapping to a new complex plane is provided. This mapping reduces the GWHE to the CWHE. Section 6 concerns the diffraction by a perfectly electrical conducting (PEC) wedge; this problem involves scalar W-H equations. Section 7 describes the diffraction by a wedge with given face impedances (the Malyuzhinets problem). This problem involves vector W-H equations. Section 8 presents some physical aspects of the W-H solution.

2. Some functional equations occurring in angular regions. We consider only time-harmonic electromagnetic fields with a time dependence specified by the factor $e^{j\omega t}$, which is omitted. These electromagnetic fields will be studied in the angular region indicated in Figure 1 that is defined by the aperture angle γ_1, $(0 \leq \varphi \leq \gamma_1)$. This region is filled by an isotropic homogeneous medium having complex permittivity ε and complex permeability μ. Without loss of generality, we assume

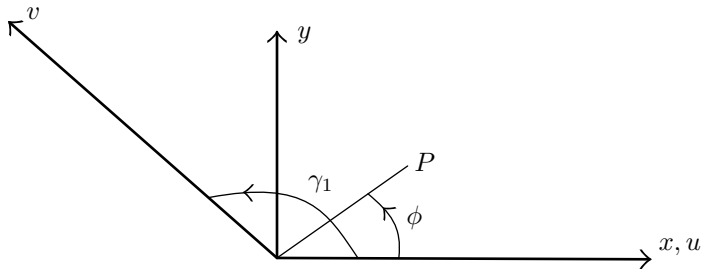

FIG. 1. *Angular region* $0 \le \phi \le \gamma_1$.

the z dependence of the electromagnetic field $\mathbf{E}$ and $\mathbf{H}$ specified by the factor $e^{-j\alpha_o z}$, which is omitted. According to the circumstances, Cartesian coordinates $\{x, y, z\}$, polar coordinates $\{\rho, \varphi, z\}$, or oblique coordinates $\{u, v, z\}$ will be used.

The W-H technique [4] for wedge problems is based on the introduction of the following Laplace transforms:

$$V_{z+}(\eta,\varphi) = \int_0^\infty E_z(\rho,\varphi)e^{j\eta\rho}d\rho, \qquad I_{z+}(\eta,\varphi) = \int_0^\infty H_z(\rho,\varphi)e^{j\eta\rho}d\rho, \tag{1}$$

$$V_{\rho+}(\eta,\varphi) = \int_0^\infty E_\rho(\rho,\varphi)e^{j\eta\rho}d\rho, \qquad I_{\rho+}(\eta,\varphi) = \int_0^\infty H_\rho(\rho,\varphi)e^{j\eta\rho}d\rho, \tag{2}$$

where the subscript + indicates plus functions, i.e., functions having regular half-planes of convergence that are upper half-planes in the η-plane.

Notice that even if E_ρ and H_ρ may be singular for vanishing values of ρ, there are no problems of existence of the Laplace transforms in physical problems. To avoid singular points on the real axis of the η-plane, we assume small losses also in the presence of no dissipative media. Consequently, the propagation constant (or wave number) defined by $k = \omega\sqrt{\mu\varepsilon}$ always has negative imaginary part $\mathrm{Im}[k] < 0$.

As will be shown in Appendix A, the following equations hold for $0 \le \gamma_1 \le \pi$:

$$\begin{aligned} &\xi V_{z+}(\eta,0) - \frac{\tau_o^2}{\omega\varepsilon} I_{\rho+}(\eta,0) - \frac{\alpha_o\eta}{\omega\varepsilon} I_{z+}(\eta,0) \\ &\qquad = -n_1 V_{z+}(-m_1,\gamma_1) - \frac{\tau_o^2}{\omega\varepsilon} I_{\rho+}(-m_1,\gamma_1) + \frac{\alpha_o m_1}{\omega\varepsilon} I_{z+}(-m_1,\gamma_1), \end{aligned} \tag{3}$$

$$\begin{aligned} &\xi I_{z+}(\eta,0) + \frac{\tau_o^2}{\omega\mu} V_{\rho+}(-\eta,0) + \frac{\alpha_o\eta}{\omega\mu} V_{z+}(\eta,0) \\ &\qquad = -n_1 I_{z+}(-m_1,\gamma_1) + \frac{\tau_o^2}{\omega\mu} V_{\rho+}(-m_1,\gamma_1) - \frac{\alpha_o m_1}{\omega\mu} V_{z+}(-m_1,\gamma_1), \end{aligned} \tag{4}$$

with $\tau_o = \sqrt{k^2 - \alpha_o^2}$, $\mathrm{Im}[\tau_o] \le 0$, $\xi = \xi(\eta) = \sqrt{\tau_o^2 - \eta^2}$ with the branch $\xi(0) = \tau_o$, and with m_1 and n_1 the functions $m = m(\eta)$ and $n = n(\eta)$ defined by $m = m(\eta) = -\eta\cos\gamma + \xi\sin\gamma$ and $n = n(\eta) = -\xi\cos\gamma - \eta\sin\gamma$ evaluated for $\gamma = \gamma_1$. These functional equations relate the Laplace transforms of the tangential components of $\mathbf{E}$ and $\mathbf{H}$ on the two boundaries $\varphi = 0$ and $\varphi = \gamma_1$ of the considered angular region. They are fundamental to deducing the W-H equations for wedge-shaped regions in the next section.

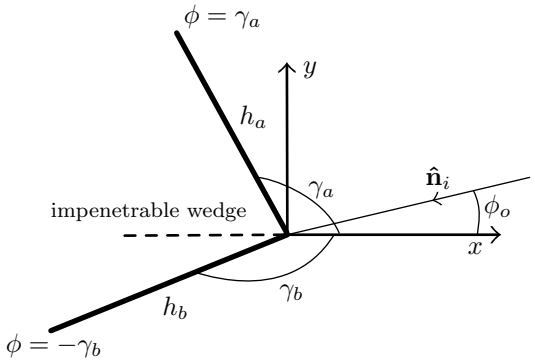

FIG. 2. *Scattering by an impenetrable wedge.*

When the angular region is defined for $-\gamma_2 \leq \varphi \leq 0$ ($0 \leq \gamma_2 \leq \pi$), a slight modification of the deduction reported in Appendix A yields similar equations:

$$\begin{aligned}(5)\quad & \xi V_{z+}(\eta,0) + \frac{\tau_o^2}{\omega\varepsilon} I_{\rho+}(\eta,0) + \frac{\alpha_o \eta}{\omega\varepsilon} I_{z+}(\eta,0) \\ & \quad = -n_2 V_{z+}(-m_2,-\gamma_2) + \frac{\tau_o^2}{\omega\varepsilon} I_{\rho+}(-m_2,-\gamma_2) - \frac{\alpha_o m_2}{\omega\varepsilon} I_{z+}(-m_2,-\gamma_2),\end{aligned}$$

$$\begin{aligned}(6)\quad & \xi I_{z+}(\eta,0) - \frac{\tau_o^2}{\omega\mu} V_{\rho+}(-\eta,0) - \frac{\alpha_o \eta}{\omega\mu} V_{z+}(\eta,0) \\ & \quad = -n_2 I_{z+}(-m_2,-\gamma_2) - \frac{\tau_o^2}{\omega\mu} V_{\rho+}(-m_2,-\gamma_2) + \frac{\alpha_o m_2}{\omega\mu} V_{z+}(-m_2,-\gamma_2),\end{aligned}$$

where m_2 and n_2 are the functions $m = m(\eta)$ and $n = n(\eta)$ defined by $m = m(\eta) = -\eta\cos\gamma + \xi\sin\gamma$ and $n = n(\eta) = -\xi\cos\gamma - \eta\sin\gamma$ evaluated for $\gamma = \gamma_2$. It is worth observing that (3)–(6) also hold in the presence of plane waves.

3. Generalized W-H equations for wedge-shaped regions. Figure 2 shows the problem that we will study. A plane wave with skew incidence $\hat{\mathbf{n}}_i$ excites an impenetrable wedge where linear conditions are defined on the boundaries $\varphi = \gamma_a$ and $\varphi = -\gamma_b$. The longitudinal field components of the plane wave are given by

$$(7)\qquad E_z^i = E_o e^{j\tau_o \rho\cos(\varphi-\varphi_o)} e^{-j\alpha_o z}, \qquad H_z^i = H_o e^{j\tau_o \rho\cos(\varphi-\varphi_o)} e^{-j\alpha_o z},$$

where E_o and H_o are known quantities, ϑ_o is the angle between the $\hat{\mathbf{n}}_i$ and $\hat{\mathbf{z}}$, $\alpha_o = k\cos\vartheta_o$, and $\tau_o = k\sin\vartheta_o$.

The Leontovich conditions on the boundaries of the wedge $\varphi = \gamma_a$ and $\varphi = -\gamma_b$ are expressed by

$$(8)\qquad \begin{bmatrix} E_z(\rho,\gamma_a) \\ H_z(\rho,\gamma_a) \end{bmatrix} = h_a \begin{bmatrix} H_\rho(\rho,\gamma_a) \\ -E_\rho(\rho,\gamma_a) \end{bmatrix}, \qquad \begin{bmatrix} E_z(\rho,-\gamma_b) \\ H_z(\rho,-\gamma_b) \end{bmatrix} = -h_b \begin{bmatrix} H_\rho(\rho,-\gamma_b) \\ -E_\rho(\rho,-\gamma_b) \end{bmatrix},$$

with the matrices

$$h_{a,b} = \begin{bmatrix} Z_e^{a,b} & T_e^{a,b} \\ T_h^{a,b} & Y_h^{a,b} \end{bmatrix}$$

depending on the wedge material.

The Maxwell equations provide the following relations between the radial components E_ρ and H_ρ and the longitudinal ones E_z and H_z:

$$\rho E_\rho = \frac{1}{j\tau_o^2}\left[\alpha_o\rho\frac{\partial E_z}{\partial\rho} + \omega\mu\frac{\partial H_z}{\partial\varphi}\right], \qquad \rho H_\rho = \frac{1}{j\tau_o^2}\left[\alpha_0\rho\frac{\partial H_z}{\partial\rho} - \omega\varepsilon\frac{\partial E_z}{\partial\varphi}\right]. \tag{9}$$

The mathematical problem to solve consists of finding the solutions E_z and H_z of the wave equations

$$\frac{\partial^2}{\partial x^2}E_z + \frac{\partial^2}{\partial y^2}E_z + \tau_o^2 E_z = 0, \qquad \frac{\partial^2}{\partial x^2}H_z + \frac{\partial^2}{\partial y^2}H_z + \tau_o^2 H_z = 0 \tag{10}$$

such that (9) and (8) hold on the boundaries $\varphi = \gamma_a$ and $\varphi = -\gamma_b$ of the wedge, and $E_z - E_z^i$ and $H_z - H_z^i$ satisfy the Sommerfeld radiation conditions in the angular region $-\gamma_b \le \varphi \le \gamma_a$. For physical problems the materials that constitute the wedge yield parameters of $h_{a,b}$ that ensure the existence and the uniqueness of the solution of this problem.

Equations (3)–(6) and the Leontovich conditions (8) written in the Laplace domain yield the following four equations:

$$\begin{aligned}\xi V_{z+}(\eta,0) - \frac{\tau_o^2}{\omega\varepsilon}I_{\rho+}(\eta,0) - \frac{\alpha_o\eta}{\omega\varepsilon}I_{z+}(\eta,0)\\ = (a_1\eta + b_1\xi + e_1)I_{\rho+}(-m_a,\gamma_a) + (c_1\eta + d_1\xi + f_1)V_{\rho+}(-m_a,\gamma_a),\end{aligned} \tag{11}$$

$$\begin{aligned}\xi V_{z+}(\eta,0) + \frac{\tau_o^2}{\omega\varepsilon}I_{\rho+}(\eta,0) + \frac{\alpha_o\eta}{\omega\varepsilon}I_{z+}(\eta,0)\\ = (a_2\eta + b_2\xi + e_2)I_{\rho+}(-m_b,-\gamma_b) + (c_2\eta + d_2\xi + f_2)V_{\rho+}(-m_b,-\gamma_b),\end{aligned} \tag{12}$$

$$\begin{aligned}\xi I_{z+}(\eta,0) + \frac{\tau_o^2}{\omega\mu}V_{\rho+}(-\eta,0) + \frac{\alpha_o\eta}{\omega\mu}V_{z+}(\eta,0)\\ = (a_3\eta + b_3\xi + e_3)I_{\rho+}(-m_a,\gamma_a) + (c_3\eta + d_3\xi + f_3)V_{\rho+}(-m_a,\gamma_a),\end{aligned} \tag{13}$$

$$\begin{aligned}\xi I_{z+}(\eta,0) - \frac{\tau_o^2}{\omega\mu}V_{\rho+}(-\eta,0) - \frac{\alpha_o\eta}{\omega\mu}V_{z+}(\eta,0)\\ = (a_4\eta + b_4\xi + e_4)I_{\rho+}(-m_b,-\gamma_b) + (c_4\eta + d_4\xi + f_4)V_{\rho+}(-m_b,-\gamma_b),\end{aligned} \tag{14}$$

with the constants a_i, b_i, c_i, d_i, e_i, f_i $(i = 1,2,3,4)$ depending on the geometrical and electromagnetic parameters involved in the problem being considered. They are not specified here.

Notice that, besides the four functions $V_{z+}(\eta,0)$, $I_{z+}(\eta,0)$, $V_{\rho+}(\eta,0)$, $I_{\rho+}(\eta,0)$ that are plus functions in the η-plane, there are four other functions which are regular in m_a-lower half-planes and in m_b-lower half-planes. Equations (11)–(14) will be called GWHE.

4. The cases involving classical W-H equations. In some important cases, (11)–(14) simplify considerably and constitute a vector system of classical W-H equations. These cases are indicated in Figure 3, and they will be discussed in some detail.

(a) *The problem of the half-plane.* The half-plane problem (Figure 3(a)) has been studied extensively in the past [12]. The most recent solution by means of the W-H technique [13] concerns the incidence of a skew plane wave on a wedge where the matrices h_a and h_b assume the form

$$h_{a,b} = \begin{bmatrix} Z^{a,b} & 0 \\ 0 & \dfrac{1}{Z^{a,b}} \end{bmatrix}. \tag{15}$$

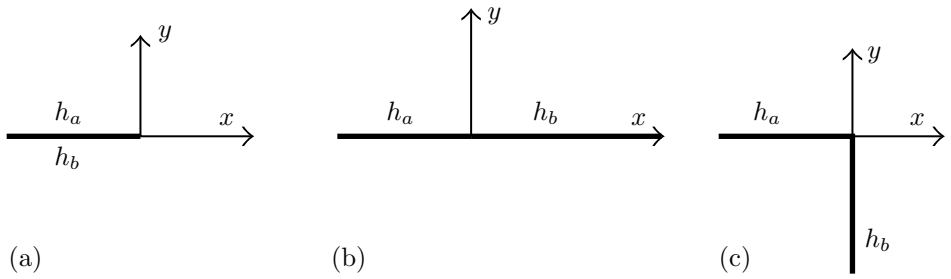

FIG. 3. (a) *Half-plane:* $\gamma_a = \gamma_b = \pi$; (b) *half-plane junction:* $\gamma_a = \pi$, $\gamma_b = 0$; (c) *right wedge:* $\gamma_a = \pi$, $\gamma_b = \pi/2$.

The problem of diffraction by an anisotropic impedance half-plane has been addressed by Hurd and Lüneburg [14] and by Senior and Legault [15].

In the case of the half-plane $\gamma_a = \gamma_b = \pi$, the functions m_a and m_b simplify considerably:

$$m_{a,b} = m_{a,b}(\eta) = -\eta \cos \gamma_{a,b} + \xi \sin \gamma_{a,b} = \eta. \tag{16}$$

After algebraic manipulation, the GWHEs (11)–(14) reduce to the classical W-H system

$$G_\pi(\eta) X_+(\eta) = Y_+(-\eta), \tag{17}$$

where

$$X_+(\eta) = \begin{bmatrix} V_{z+}(\eta, 0) \\ I_{\rho+}(\eta, 0) \\ I_{z+}(\eta, 0) \\ V_{\rho+}(\eta, 0) \end{bmatrix}, \qquad Y_+(-\eta) = \begin{bmatrix} I_{\rho+}(-\eta, \pi) \\ I_{\rho+}(-\eta, -\pi) \\ V_{\rho+}(-\eta, \pi) \\ V_{\rho+}(-\eta, -\pi) \end{bmatrix},$$

$$G_\pi(\eta) = R_0(\eta) + \xi R_1(\eta). \tag{18}$$

The function $Y_+(-\eta)$ is a minus function. These functions are regular in a lower half-plane in the η-plane. They will be denoted with the subscript $-$ as in $Y_+(-\eta) = X_-(\eta)$. Equation (18) defines the kernel matrix $G_\pi(\eta)$ through the two matrices $R_0(\eta)$ and $R_1(\eta)$. It should be observed that $R_0(\eta)$ and $R_1(\eta)$ are rational matrices of η. In general, they have complicated expressions that are not reported here.

The reason for the possibility of closed form solutions for the half-problem follows from the structure of the kernel $G_\pi(\eta) = G(\eta)$, which allows explicit factorizations. For instance, since we can explicitly factorize the rational matrix $R_0(\eta) = R_{0-}(\eta) R_{0+}(\eta)$, it is convenient to put $G(\eta)$ in the form

$$G(\eta) = R_{0-}(\eta) \Big[1 + \xi R_{0-}(\eta)^{-1} R_1(\eta) R_{0+}(\eta)^{-1} \Big] R_{0+}(\eta). \tag{19}$$

Taking into account that

$$R_{0-}(\eta)^{-1} R_1(\eta) R_{0+}(\eta)^{-1} = \frac{P(\eta)}{d(\eta)}, \tag{20}$$

where $P(\eta)$ and $d(\eta)$ are, respectively, matrix and scalar polynomial functions, we reduce the factorization of the matrix $G(\eta)$ to that of the matrix $1 + \frac{\sqrt{k^2-\eta^2}}{d(\eta)} P(\eta)$. This matrix does commute with the polynomial matrix $P(\eta)$ and can be explicitly factorized by using the procedure indicated in [16, 17, 20]. However, it must be observed that the more general cases are very cumbersome to deal with, and they still require considerable mathematical skill. This topic is beyond the scope of this work and will not be further pursued here.

(b) *The problem of the two half-plane junction.* The problem of the two half-plane junction (Figure 3(b)) has been studied extensively in the past [18]. To this author's knowledge, the more recent W-H solution is reported in [19]. For this problem, $\gamma_a = \pi \Rightarrow m = \eta$, and we can ignore (5) and (6). By imposing the boundary equation (8) on the two faces $\varphi = 0$ and $\varphi = \pi$ (Figure 3(b)), (3) and (4) yield a classical W-H equation of order two, where again the kernel has the form given in (18). Consequently, the same considerations as in the half-plane problem apply. It should be observed that, in presence of a skew incident plane wave, when h_a and h_b assume the form (15), the factorization of the kernel of order two can be obtained by slightly modifying the method indicated in [13].

(c) *The problem of the right wedge.* Even though it is well known that the right wedge (Figure 3(c)) involves classical W-H equations, these problems are usually approached with the Malyuzhinets method. The W-H formulation is based again on (11)–(14), where $\gamma_a = \pi$, $\gamma_b = \pi/2$. It yields $m_a = \eta$ and $m_b = \xi = \sqrt{k^2 - \eta^2}$. Changing η with $-\eta$ in (11)–(14) adds four independent equations that introduce the six new functions $V_{z+}(-\eta, 0)$, $I_{z+}(-\eta, 0)$, $V_{\rho+}(-\eta, 0)$, $I_{\rho+}(-\eta, 0)$, $I_{\rho+}(-\eta, \pi)$, $V_{\rho+}(-\eta, \pi)$. We now have eight equations that involve the fourteen unknowns $V_{z+}(\eta, 0)$, $I_{z+}(\eta, 0)$, $V_{\rho+}(\eta, 0)$, $I_{\rho+}(\eta, 0)$, $I_{\rho+}(\eta, \pi)$, $V_{\rho+}(\eta, \pi)$, $I_{\rho+}(-\xi, -\frac{\pi}{2})$, $V_{\rho+}(-\xi, -\frac{\pi}{2})$, $V_{z+}(-\eta, 0)$, $I_{z+}(-\eta, 0)$, $V_{\rho+}(-\eta, 0)$, $I_{\rho+}(-\eta, 0)$, $I_{\rho+}(-\eta, \pi)$, and $V_{\rho+}(-\eta, \pi)$. Two equations allow us to eliminate the two functions $I_{\rho+}(-\xi, -\frac{\pi}{2})$ and $V_{\rho+}(-\xi, -\frac{\pi}{2})$. Rearranging the other six yields a system of classical W-H equations that involve the six plus functions $V_{z+}(\eta, 0)$, $I_{z+}(\eta, 0)$, $V_{\rho+}(\eta, 0)$, $I_{\rho+}(\eta, 0)$, $I_{\rho+}(\eta, \pi)$, $V_{\rho+}(\eta, \pi)$ and the six minus functions $V_{z+}(-\eta, 0)$, $I_{z+}(-\eta, 0)$, $V_{\rho+}(-\eta, 0)$, $I_{\rho+}(-\eta, 0)$, $I_{\rho+}(-\eta, \pi)$, $V_{\rho+}(-\eta, \pi)$. Again the kernel matrix $G(\eta)$ of this system has the form (18). Consequently, the same considerations apply as in the half-plane problem.

5. The standard W-H equations of the wedge problem having arbitrary aperture angle. When the wedge has an arbitrary aperture angle, the GWHEs (11)–(14) constitute a closed mathematical problem that has been considered in [21]. By using the concept of generalized decomposition, these equations can be reduced to Fredholm systems. However, it is very remarkable that we can remain in the framework of CWHE by introducing a suitable mapping $\eta = \eta(\overline{\eta})$ that, by eliminating the m-plane, allows one to deal only with minus and plus functions of the $\overline{\eta}$-plane (see Appendix B). As will be seen later, in the $\overline{\eta}$-plane explicit W-H solutions will be provided for the problems solved by the Sommerfeld–Malyuzhinets method. In fact, for these problems the scalar decomposition can be accomplished with the classical Cauchy decomposition formula, and the matrices to factorize are of the Daniele–Khrapkov type.

With reference to Figure 4(a), equations (11)–(14) can be rearranged in the form

$$G_\Phi(\eta) X_+(\eta) = Y_+(-m), \tag{21}$$

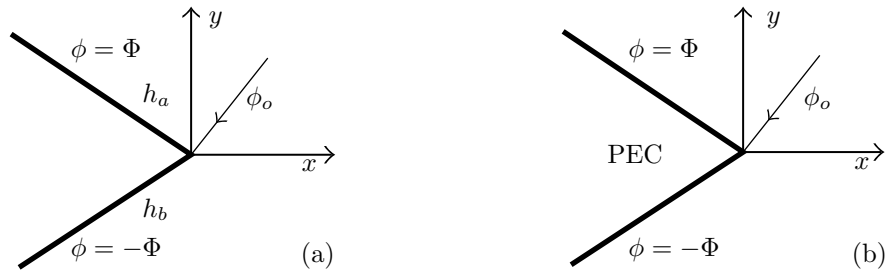

FIG. 4. (a) *An impenetrable wedge with arbitrary aperture angle* $\gamma_a = \gamma_b = \Phi$. (b) *PEC wedge with arbitrary aperture angle* $\gamma_a = \gamma_b = \Phi$.

where

$$X_+(\eta) = \begin{vmatrix} V_{z+}(\eta,0) \\ I_{z+}(\eta,0) \\ -\dfrac{\tau_o^2}{\omega\varepsilon} I_{\rho+}(\eta,0) - \dfrac{\alpha_o \eta}{\omega\varepsilon} I_{z+}(\eta,0) \\ \dfrac{\tau_o^2}{\omega\mu} V_{\rho+}(-\eta,0) + \dfrac{\alpha_o \eta}{\omega\mu} V_{z+}(\eta,0) \end{vmatrix},$$

$$Y_+(-m) = \begin{vmatrix} -\dfrac{\tau_o^2}{\omega\varepsilon} I_{\rho+}(-m,\Phi) + \dfrac{\alpha_o m}{\omega\varepsilon} I_{z+}(-m,\Phi) \\ \dfrac{\tau_o^2}{\omega\mu} V_{\rho+}(-m,\Phi) - \dfrac{\alpha_o m}{\omega\mu} V_{z+}(-m,\Phi) \\ \dfrac{\tau_o^2}{\omega\varepsilon} I_{\rho+}(-m,-\Phi) - \dfrac{\alpha_o m}{\omega\varepsilon} I_{z+}(-m,-\Phi) \\ -\dfrac{\tau_o^2}{\omega\mu} V_{\rho+}(-m,-\Phi) + \dfrac{\alpha_o m}{\omega\mu} V_{z+}(-m,-\Phi) \end{vmatrix}, \tag{22}$$

$$m = m(\eta) = -\eta\cos\Phi + \xi\sin\Phi, \qquad n = n(\eta) = -\xi\cos\Phi - \eta\sin\Phi.$$

In the general case, the matrix $G_\Phi(\eta)$ has a complicated expression that is not reported here.

The mapping to be used to obtain classical W-H equations in impenetrable wedge problems is (see Appendix B)

$$\eta = \eta(\overline{\eta}) = -\tau_o \cos\left[\frac{\Phi}{\pi}\arccos\left(-\frac{\overline{\eta}}{\tau_o}\right)\right]. \tag{23}$$

With this mapping, a generic plus function $F_+(\eta)$ in the η-plane is also a plus function $\overline{F}_+(\overline{\eta}) = F_+(\eta)$ in the $\overline{\eta}$-plane. Besides, since this mapping implies that $m = -\eta(-\overline{\eta})$, it follows that the minus function $Y_+(-m)$ in the m-plane becomes a minus function $\overline{Y}_+(-\overline{\eta}) = Y_+(-m)$ in the $\overline{\eta}$-plane. Consequently, the mapping reduces the equations (21) to the following W-H system in the $\overline{\eta}$-plane:

$$\overline{G}_\Phi(\overline{\eta})\overline{X}_+(\overline{\eta}) = \overline{Y}_+(-\overline{\eta}), \tag{24}$$

where $\overline{G}_\Phi(\overline{\eta}) = G_\Phi(\eta)$, $\overline{X}_+(\overline{\eta}) = X_+(\eta)$, $\overline{Y}_+(-\overline{\eta}) = Y_+(-m)$.

The solution of the classical W-H equation (24) requires the introduction of a source term. To this end we decompose the functions $Y_+(-m)$ in terms of the diffracted field (superscript d) and geometrical optical field (superscript g) as follows:

$$Y_+(-m) = Y_+^d(-m) + Y_+^g(-m). \tag{25}$$

The geometrical optical field is known. It depends on the direction of the plane wave φ_o and implies that the function $Y_+^g(-m)$ has a pole in $m_o = k\cos(\Phi - \varphi_o)$ with residue A_o. Taking into account that $m = -\eta(-\overline{\eta})$, it follows that $\overline{Y}_+^g(-\overline{\eta}) = Y_+^g(\eta(-\overline{\eta}))$ has a pole in $\overline{\eta}_o = -\tau_o \cos\frac{\pi}{\Phi}\varphi_o$, with residue R_o given by

$$R_o = A_o \left.\frac{d\overline{\eta}}{dm}\right|_{\overline{\eta}=\overline{\eta}_o} = A_o \frac{\pi}{\Phi}\frac{\sin\frac{\pi}{\Phi}\varphi_o}{\sin(\Phi - \varphi_o)}. \tag{26}$$

The standard factorization of $\overline{G}_\Phi(\overline{\eta}) = \overline{G}_{\Phi-}(\overline{\eta})\overline{G}_{\Phi+}(\overline{\eta})$ yields

$$\begin{aligned} &\overline{G}_{\Phi+}(\overline{\eta})\overline{X}_+(\overline{\eta}) - \overline{G}_{\Phi-}^{-1}(\overline{\eta}_o)\frac{R_o}{\overline{\eta} - \overline{\eta}_o} \\ &\qquad = \overline{G}_{\Phi-}^{-1}(\overline{\eta})[\overline{Y}_-^d(-\overline{\eta}) + \overline{Y}_+^g(-\overline{\eta})] - \overline{G}_{\Phi-}^{-1}(\overline{\eta}_o)\frac{R_o}{\overline{\eta} - \overline{\eta}_o} = w(\overline{\eta}). \end{aligned} \tag{27}$$

The member on the right-hand side of the first equality does not have the pole $\overline{\eta}_o = -\tau_o \cos\frac{\pi}{\Phi}\varphi_o$ and involves only minus functions that are regular for $\mathrm{Im}[\overline{\eta}] < \mathrm{Im}[-\tau_o]$; since the first member involves only plus functions, it follows that the function $w(\overline{\eta})$ is entire. Taking into account that $\eta \approx \overline{\eta}^{\Phi/\pi}$ as $\overline{\eta} \to \infty$, the presence of Laplace transforms, and the fact that standard factorized matrices have algebraic behavior as $\overline{\eta} \to \infty$ leads to the conclusion that $w(\overline{\eta})$ is vanishing. This provides the following solution of the W-H system (24):

$$\overline{X}_+(\overline{\eta}) = \overline{G}_{\Phi+}^{-1}(\overline{\eta})\overline{G}_{\Phi-}^{-1}(\overline{\eta}_o)\frac{R_o}{\overline{\eta} - \overline{\eta}_o}. \tag{28}$$

The W-H technique requires the decomposition in the $\overline{\eta}$-plane of arbitrary functions $\overline{X}(\overline{\eta})$:

$$X(\eta) = \overline{X}(\overline{\eta}) = X_+(\eta) + X_-(m) = \overline{X}_+(\overline{\eta}) + \overline{X}_-(\overline{\eta}). \tag{29}$$

An analytical manipulation of the Cauchy decomposition formula [4, p. 17] yields the following expression of the decomposed plus $\overline{X}_+(\overline{\eta}) = X_+(\eta)$:

$$\overline{X}_+(\overline{\eta}) = X_+(\eta) = -\frac{1}{\pi j}\int_{-\infty}^{\infty}[\hat{X}(-\pi + ju) - \hat{X}(-\pi - ju)]\frac{\sinh u}{\cosh u - \overline{\eta}/\tau_o}du - \sum_i \frac{R_i}{\overline{\eta} - \overline{\eta}_i}, \tag{30}$$

where $\hat{X}(\overline{w}) = \overline{X}(-\tau_o \cos\overline{w})$ and R_i represents the residue of $\overline{X}(\overline{\eta})$ in the poles $\overline{\eta}_i$ located in the half-plane $\mathrm{Im}[\overline{\eta}] < 0$.

To ascertain the validity of the solution (28), when possible we must verify that the results obtained with the W-H technique are equivalent to those obtained with other methods. We encountered some difficulties when, after considering specific problems, we compared the expressions obtained in this paper with the ones obtained by the Malyuzhinets method. In fact, the two approaches use two different spectral representations. These representations are the Laplace transform in the W-H technique and the Sommerfeld functions in the Malyuzhinets method. The difficulties were overcome only after we used expressions that relate the Sommerfeld function to the Laplace transform [3, 5, 22].

6. Solution of the CWHE in the scalar case. Let us consider the case of a PEC wedge excited by an E-polarized plane wave ($\partial/\partial z = 0, \tau_o = k$) (see Figure 4(b)). Even though simple, this case is significant since it shows all the difficulties involved in obtaining explicit W-H solutions in wedge problems having arbitrary aperture angles. For this problem, (4) and (6) may be ignored since the unknowns present in them are vanishing. Equations (3) and (5) simplify, becoming

$$\xi V_{z+}(\eta,0) - \omega\mu I_{\rho+}(\eta,0) = -\omega\mu I_{\rho+}(-m,\Phi), \tag{31}$$

$$\xi V_{z+}(\eta,0) + \omega\mu I_{\rho+}(\eta,0) = \omega\mu I_{\rho+}(-m,-\Phi), \tag{32}$$

where $\xi = \xi(\eta) = \sqrt{k^2-\eta^2}$ and $m = m(\eta) = -\eta\cos\Phi + \xi\sin\Phi$. Summing (31) and (32) yields the scalar generalized W-H equation

$$\xi X_+(\eta) = Y_+(-m), \tag{33}$$

with $X_+(\eta) = 2V_{z+}(\eta,0)$ and $Y_+(-m) = \omega\mu[I_{\rho+}(m,-\Phi) - I_{\rho+}(m,\Phi)]$. The mapping $\eta = \eta(\overline{\eta}) = -k\cos[\frac{\Phi}{\pi}\arccos(-\frac{\overline{\eta}}{k})]$ yields the following scalar CWHE equation in the $\overline{\eta}$-plane:

$$\overline{\xi}(\overline{\eta})\overline{X}_+(\overline{\eta}) = \overline{Y}_+(-\overline{\eta}) = \overline{X}_-(\overline{\eta}). \tag{34}$$

The key point for solving the CWHE is the factorization of the kernel $\overline{\xi}(\overline{\eta}) = \overline{\xi}_-(\overline{\eta})\overline{\xi}_+(\overline{\eta})$. Since we are dealing with scalar functions, this factorization can be accomplished by using well-known procedures. We obtain (see Appendix C)

$$\overline{\xi}_-(\overline{\eta}) = \sqrt{\frac{\tau_o+\overline{\eta}}{2}}, \qquad \overline{\xi}_+(\overline{\eta}) = \frac{\xi(\eta(\overline{\eta}))}{\overline{\xi}_-(\overline{\eta})}. \tag{35}$$

Taking the source into account, we consider, for illustrative purposes, the case (see Figure 4) in which the face $\varphi = -\Phi$ is in the shadow region: $I^g_{\rho+}(-m,-\Phi) = 0$. It yields

$$Y^g_+(-m) = \omega\mu[I^g_{\rho+}(-m,-\Phi) - I^g_{\rho+}(-m,\Phi)] = \frac{A_o}{[m - k\cos(\Phi-\varphi_o)]}, \tag{36}$$

with $A_o = 2jk\sin(\Phi-\varphi_o)E_o$. The residue R_o of $\overline{Y}^g_+(-\overline{\eta}) = Y^g_+(-m)$ in the simple pole $\overline{\eta}_o = -k\cos\frac{\pi}{\Phi}\varphi_o$ is given by (26) as follows:

$$R_o = A_o\left.\frac{d\overline{\eta}}{dm}\right|_{\overline{\eta}_o} = A_o\frac{\pi}{\Phi}\frac{\sin 2\frac{\varphi_o}{n}}{\sin(\Phi-\varphi_o)} = 4jkE_o\frac{\sin 2\frac{\varphi_o}{n_\Phi}}{n_\Phi},$$

with $n_\Phi = \frac{2\Phi}{\pi}$. Equation (28) provides the solution:

$$\overline{X}_+(\overline{\eta}) = \overline{\xi}^{-1}_+(\overline{\eta})\overline{\xi}^{-1}_-(\overline{\eta}_o)\frac{R_o}{\overline{\eta}-\overline{\eta}_o}. \tag{37}$$

To compare 37 to known solutions, we introduce the w-plane defined by $\eta = -k\cos w$ (see Appendix B). Algebraic manipulation on $V_{z+}(\eta,0) = \widetilde{X}_+(\overline{\eta})/2$ yields the well-known result

$$\begin{aligned} &V_{z+}(-k\cos w,0)\\ &\quad= \frac{jE_o\cos(\varphi_o/n_\Phi)}{n_\Phi k\sin w}\left(\frac{1}{\sin w/n_\Phi - \sin\varphi_o/n_\Phi} + \frac{1}{\sin w/n_\Phi + \sin\varphi_o/n_\Phi}\right). \end{aligned} \tag{38}$$

7. Solution of the CWHE in the vector case. In the wedge with two different face impedances excited by an E-polarized plane wave ($\partial/\partial z = 0, \tau_o = k$) (Malyuzhinets problem), (21) simplifies, and one obtains a vector generalized W-H equation of order two:

$$G_\Phi(\eta)F_+(\eta) = F_-(m), \tag{39}$$

where

$$F_+(\eta) = \begin{vmatrix} V_{z+}(\eta,0) \\ I_{\rho+}(\eta,0) \end{vmatrix}, \qquad F_-(m) = \begin{vmatrix} I_{\rho+}(-m,\Phi) \\ I_{\rho+}(-m,-\Phi) \end{vmatrix},$$

and the kernel $\overline{G}_\Phi(\overline{\eta})$ is the matrix given by

$$G_\Phi(\eta) = \begin{vmatrix} -\dfrac{\xi}{Z_a(n+n_a)} & \dfrac{\xi}{Z_a(n+n_a)}\dfrac{\omega\mu}{\xi} \\ \dfrac{\xi}{Z_b(n+n_b)} & \dfrac{\xi}{Z_b(n+n_b)}\dfrac{\omega\mu}{\xi} \end{vmatrix}, \tag{40}$$

where $n = -\xi\cos\Phi - \eta\sin\Phi$ and $n_{a,b} = \frac{\omega\mu}{Z_{a,b}}$.

In the $\overline{\eta}$-plane we will obtain an explicit factorization by reducing $\overline{G}_\Phi(\overline{\eta})$ to a Daniele–Khrapkov matrix. For this task an algebraic manipulation allows us to rewrite $\overline{G}_\Phi(\overline{\eta})$ in the form

$$\begin{aligned} &\overline{G}_\Phi(\overline{\eta}) \\ &= \frac{(Z_a - Z_b)\xi n}{2Z_aZ_b(n+n_a)(n+n_b)} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & \dfrac{\sqrt{\omega\mu}}{\overline{\xi}_-(\overline{\eta})} \end{bmatrix} \begin{bmatrix} 1 & a \\ b & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & \dfrac{\sqrt{\omega\mu}}{\overline{\xi}_+(\overline{\eta})} \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \end{aligned} \tag{41}$$

where

$$a = f(\eta)\frac{\sqrt{\omega\mu}}{\overline{\xi}_-(\overline{\eta})}, \quad b = f(\eta)\frac{\overline{\xi}_-(\overline{\eta})}{\sqrt{\omega\mu}}, \quad f(\eta) = 1 - \frac{2(n+n_a)Z_a}{n(Z_a - Z_b)}.$$

Equation (41) reduces the matrix factorization of $\overline{G}_\Phi(\overline{\eta})$ to the factorization of the scalar $\xi n/(n+n_a)(n+n_b)$ and the matrix factorization of the central matrix $\left[\begin{smallmatrix} 1 & a \\ b & 1 \end{smallmatrix}\right]$. The factorization of the scalar needs the factorization of ξ, n, and $\frac{n}{n+n_{a,b}}$ in the $\overline{\eta}$-plane. The factorization of ξ is reported in (35). Using the same procedure, we obtain the factorization of $\overline{n}(\overline{\eta}) = \overline{n}_-(\overline{\eta})\overline{n}_+(\overline{\eta}) : \overline{n}_+(\overline{\eta}) = \sqrt{\frac{k-\overline{\eta}}{2}}$, $\overline{n}_-(\overline{\eta}) = \frac{n(\eta(\overline{\eta}))}{\overline{n}_+(\overline{\eta})}$. For what concerns the factorization of $\frac{n}{n+n_{a,b}} = [\frac{n}{n+n_{a,b}}]_-[\frac{n}{n+n_{a,b}}]_+$, we can use the logarithmic decomposition. In the presence of inductive impedances $Z_{a,b}$, (30) yields

$$\left[\frac{n+n_{a,b}}{n}\right]_+ = d_\Phi(\overline{\eta}) = \exp\left[\frac{1}{\pi}\int_0^\infty \arctan\left[\frac{\sin\vartheta_{a,b}}{\sinh\left[\frac{\Phi}{\pi}u\right]}\right]\frac{\sinh u}{\cosh u - \overline{\eta}/k}du\right]. \tag{42}$$

We are left with the more difficult problem consisting of factorizing the central matrix. Since $\overline{\xi}^2_-(\overline{\eta}) = \frac{1}{2}(k+\overline{\eta})$, the ratio $\frac{a}{b} = \frac{\omega\mu}{\overline{\xi}^2_-(\overline{\eta})}$ is a rational function of $\overline{\eta}$. It follows that the matrix $\left[\begin{smallmatrix} 1 & a \\ b & 1 \end{smallmatrix}\right]$ is a Daniele–Khrapkov matrix. For these matrices there is a well-known method [20]. It yields $\left[\begin{smallmatrix} 1 & a \\ b & 1 \end{smallmatrix}\right] = \left[\begin{smallmatrix} 1 & a \\ b & 1 \end{smallmatrix}\right]_- \bullet \left[\begin{smallmatrix} 1 & a \\ b & 1 \end{smallmatrix}\right]_+$, where the minus and plus

factorized matrices are given by

$$\begin{bmatrix} 1 & a \\ b & 1 \end{bmatrix}_- = \sqrt{\overline{g}_-(\overline{\eta})} \begin{vmatrix} \cosh\left[\frac{1}{2}\log\left[\frac{-Z_b}{Z_a}\right]\right] & \frac{\sqrt{\omega\mu}}{\overline{\xi}_-(\overline{\eta})}\sinh\left[\frac{1}{2}\log\left[\frac{-Z_b}{Z_a}\right]\right] \\ \frac{\overline{\xi}_-(\overline{\eta})}{\sqrt{\omega\mu}}\sinh\left[\frac{1}{2}\log\left[\frac{-Z_b}{Z_a}\right]\right] & \cosh\left[\frac{1}{2}\log\left[\frac{-Z_b}{Z_a}\right]\right] \end{vmatrix}$$

$$\bullet \begin{vmatrix} \cosh\left[\frac{\sqrt{\omega\mu}}{2}\overline{t}_-(\overline{\eta})\overline{\xi}_-(\overline{\eta})\right] & \frac{\sqrt{\omega\mu}}{\overline{\xi}_-(\overline{\eta})}\sinh\left[\frac{\sqrt{\omega\mu}}{2}\overline{t}_-(\overline{\eta})\overline{\xi}_-(\overline{\eta})\right] \\ \frac{\overline{\xi}_-(\overline{\eta})}{\sqrt{\omega\mu}}\sinh\left[\frac{\sqrt{\omega\mu}}{2}\overline{t}_-(\overline{\eta})\overline{\xi}_-(\overline{\eta})\right] & \cosh\left[\frac{\sqrt{\omega\mu}}{2}\overline{t}_-(\overline{\eta})\overline{\xi}_-(\overline{\eta})\right] \end{vmatrix}, \tag{43}$$

$$\begin{bmatrix} 1 & a \\ b & 1 \end{bmatrix}_+ = \sqrt{\overline{g}_+(\overline{\eta})} \begin{vmatrix} \cosh\left[\frac{\sqrt{\omega\mu}}{2}\overline{t}_+(\overline{\eta})\overline{\xi}_-(\overline{\eta})\right] & \frac{\sqrt{\omega\mu}}{\overline{\xi}_-(\overline{\eta})}\sinh\left[\frac{\sqrt{\omega\mu}}{2}\overline{t}_+(\overline{\eta})\overline{\xi}_-(\overline{\eta})\right] \\ \frac{\overline{\xi}_-(\overline{\eta})}{\sqrt{\omega\mu}}\sinh\left[\frac{\sqrt{\omega\mu}}{2}\overline{t}_+(\overline{\eta})\overline{\xi}_-(\overline{\eta})\right] & \cosh\left[\frac{\sqrt{\omega\mu}}{2}\overline{t}_+(\overline{\eta})\overline{\xi}_-(\overline{\eta})\right] \end{vmatrix}.$$

The factorization of the scalar

$$g(\eta) = 1 - f^2(\eta) = -\frac{4Z_aZ_b}{(Z_a - Z_b)^2}\frac{n+n_a}{n}\frac{n+n_b}{n} = \overline{g}_-(\overline{\eta})\overline{g}_+(\overline{\eta})$$

and the decomposition of the scalar

$$\begin{aligned} t(\eta) &= \frac{1}{\sqrt{\omega\mu}\overline{\xi}(\overline{\eta})}\log\left[\frac{1+f(\eta)}{1-f(\eta)}\right] - \frac{1}{\sqrt{\omega\mu}\overline{\xi}(\overline{\eta})}\log\left[-\frac{Z_b}{Z_a}\right] \\ &= \frac{1}{\sqrt{\omega\mu}\overline{\xi}_-(\overline{\eta})}\log\left[\frac{n+n_b}{n+n_a}\right] = \overline{t}_-(\overline{\eta}) + \overline{t}_+(\overline{\eta}) \end{aligned}$$

can be accomplished without any difficulty through (30). For instance, in the presence of inductive impedances $Z_{a,b}$, we have

$$\begin{aligned} \overline{t}_+(\overline{\eta}) &= \left\{\frac{1}{\overline{\xi}_-(\overline{\eta})}\log\left[\frac{n+n_b}{n+n_a}\right]\right\}_+ \\ &= -\frac{2}{\pi}\int_0^\infty \left[\arctan\left[\frac{\sin\vartheta_b}{\sinh\left[\frac{\Phi}{\pi}u\right]}\right] - \arctan\left[\frac{\sin\vartheta_a}{\sinh\left[\frac{\Phi}{\pi}u\right]}\right]\right]\frac{\sinh\frac{u}{2}}{\cosh u - \frac{\overline{\eta}}{k}}du, \end{aligned} \tag{44}$$

with $n_{a,b} = k\sin\vartheta_{a,b}$. Notice that $\overline{g}_-(\overline{\eta})$ and $\overline{g}_+(\overline{\eta})$ behave as constants as $\overline{\eta}\to\infty$. In addition, taking into account that $\eta \approx \overline{\eta}^{\Phi/\pi}$, it follows that $\overline{t}_\pm(\overline{\eta}) = O[\frac{1}{\overline{\eta}^{1/2}\overline{\eta}^{\Phi/\pi}}]$. Since the argument of the hyperbolic functions in (43) is constant or vanishing as $\overline{\eta}\to\infty$, it yields an algebraic behavior of both the factorized matrices.

To complete the solution process, one needs to know the value of $\overline{\eta}_o$ and R_o in order to use (28); once again, one has $\overline{\eta}_o = -k\cos\frac{\pi}{\Phi}\varphi_o$. Furthermore, by taking into account (26) and the reflection coefficient on the face $\varphi = \Phi$, one obtains

$$A_o = \begin{vmatrix} -\frac{2j\sin(\Phi-\varphi_o)}{Z_o + Z_a\sin(\Phi-\varphi_o)}E_o \\ 0 \end{vmatrix}, \qquad R_o = \begin{vmatrix} -\frac{\pi}{\Phi}\frac{2j\sin\frac{\pi}{\Phi}\varphi_o}{Z_o + Z_a\sin(\Phi-\varphi_o)}E_o \\ 0 \end{vmatrix}.$$

Even though the integrals (42) and (44) may be evaluated numerically without any difficulty, it is worth observing that they involve the Malyuzhinets function $\Psi_\Phi(w)$. In fact, a cumbersome mathematical deduction not reported here shows that

(45)
$$\left[\frac{n+n_{a,b}}{\sqrt{k}}\right]_+\Bigg|_{\eta=-k\cos w} = d_\Phi(-k)\frac{\Psi_\Phi(w+\Phi+\widetilde{\vartheta}_{a,b})\Psi_\Phi(w+\Phi-\widetilde{\vartheta}_{a,b})\Psi_\Phi(w-\Phi+\widetilde{\vartheta}_{a,b})\Psi_\Phi(w-\Phi-\widetilde{\vartheta}_{a,b})}{\Psi_\Phi(\Phi+\widetilde{\vartheta}_{a,b})\Psi_\Phi(\Phi-\widetilde{\vartheta}_{a,b})\Psi_\Phi(-\Phi+\widetilde{\vartheta}_{a,b})\Psi_\Phi(-\Phi-\widetilde{\vartheta}_{a,b})},$$

(46)
$$\left\{\frac{\sqrt{k}}{\overline{\xi}_-(\overline{\eta})}\log\left[\frac{n+n_b}{n+n_a}\right]\right\}_+\Bigg|_{\eta=-k\cos w} = \frac{1}{\sin\left[\frac{\pi w}{2\Phi}\right]}\log\left[\frac{\Psi_\Phi(w-\Phi-\widetilde{\vartheta}_b)\Psi_\Phi(w-\Phi+\widetilde{\vartheta}_b)\Psi_\Phi(w+\Phi-\widetilde{\vartheta}_a)\Psi_\Phi(w+\Phi+\widetilde{\vartheta}_a)}{\Psi_\Phi(w+\Phi-\widetilde{\vartheta}_b)\Psi_\Phi(w+\Phi+\widetilde{\vartheta}_b)\Psi_\Phi(w-\Phi-\widetilde{\vartheta}_a)\Psi_\Phi(w-\Phi+\widetilde{\vartheta}_a)}\right],$$

with $\eta=-k\cos w$, $w=\frac{\Phi}{\pi}\overline{w}$, $\widetilde{\vartheta}_{a,b}=\frac{\pi}{2}-\vartheta_{a,b}$. These alternative expressions are very important since they allow one to verify that the W-H solution (28) agrees completely with the Malyuzhinets solution [3].

8. Physical considerations on the W-H technique applied to wedge problems. The W-H solution $X_+(\eta)=\overline{X}_+(\overline{\eta})$ of (28) provides the Laplace transforms of the electromagnetic field only in the direction $\varphi=0$. In order to obtain $E_z(\rho,\varphi)$ and $H_z(\rho,\varphi)$ for every value of φ, it can be shown [23] that the two functions $s_E(w)$ and $s_H(w)$ defined by

(47)
$$\begin{aligned} s_E(w) &= \frac{j}{2}\left[-\tau_o\sin w V_{z+}(-\tau_o\cos w,0)\right.\\ &\qquad \left.+\frac{\tau_o^2}{\omega\varepsilon}I_{\rho+}(-\tau_o\cos w,0)-\frac{\alpha_o\tau_o\cos w}{\omega\varepsilon}I_{z+}(-\tau_o\cos w,0)\right],\\ s_H(w) &= \frac{j}{2}\left[-\tau_o\sin w I_{z+}(-\tau_o\cos w,0)\right.\\ &\qquad \left.-\frac{\tau_o^2}{\omega\mu}V_{\rho+}(-\tau_o\cos w,0)+\frac{\alpha_o\tau_o\cos w}{\omega\mu}V_{z+}(-\tau_o\cos w,0)\right] \end{aligned}$$

are the Sommerfeld functions of the problem. It yields the following representation of the longitudinal components valid for every value of φ:

(48)
$$\begin{aligned} E_z(\rho,\varphi) &= \frac{1}{2\pi}\left[\int_{c_1+c_2}s_E[w+\varphi]e^{+j\tau_o\cos[w]\rho}dw\right],\\ H_z(\rho,\varphi) &= \frac{1}{2\pi}\left[\int_{c_1+c_2}s_H[w+\varphi]e^{+j\tau_o\cos[w]\rho}dw\right], \end{aligned}$$

where c_1+c_2 is the Sommerfeld contour. By using well-known techniques such as the saddle point integration method [24] and the Watson lemma, (47) and (48) permit us to gain a complete physical insight into the solution $X_+(\eta)=\overline{X}_+(\overline{\eta})$, as obtained from (28). For instance, these solutions provide the diffraction coefficients of the

geometrical theory of diffraction (GTD) [18, 24] as well as the field behaviors near the edge $\rho = 0$ (see [22]). From the engineering standpoint, applications of (28) also include well-known refinements such as the uniform theory of diffraction (UTD) and the uniform asymptotic theory (UAT) [18].

When studying diffraction problems where no exact solutions are possible, of course we must introduce approximate solutions. The basic technique in electromagnetic engineering is the physical optics approximation. The W-H solution immediately provides the physical optics solution by observing that the presence of the denominator $\overline{\eta} - \overline{\eta}_o$ in the solution (28) indicates that the dominant spectrum is for $\overline{\eta} \approx \overline{\eta}_o$. It suggests that setting $\overline{G}_{\Phi+}^{-1}(\overline{\eta}) \approx \overline{G}_{\Phi+}^{-1}(\overline{\eta}_o)$ yields

$$\overline{X}_+(\overline{\eta}) \approx \overline{G}_{\Phi+}^{-1}(\overline{\eta}_o)\overline{G}_{\Phi-}^{-1}(\overline{\eta}_o)\frac{R_o}{\overline{\eta} - \overline{\eta}_o} = \overline{G}_{\Phi}^{-1}(\overline{\eta}_o)\frac{R_o}{\overline{\eta} - \overline{\eta}_o}. \tag{49}$$

This approximation represents the physical optical solution. To improve this approximation we can introduce rational approximants for the kernels. They yield rational matrices that in general can be factorized in closed form. It has been ascertained that this procedure can be very efficient in obtaining accurate solutions of W-H equations [11, 25, 26].

9. Conclusions. This paper shows that the wedge problems solved with the Sommerfeld–Malyuzhinets method can be successfully solved also by the classical W-H technique. There are many differences between the two methods. For instance, the Sommerfeld–Malyuzhinets approach requires the solution of difference equations, whereas the W-H technique involves decomposition-factorization problems. Even though it seems that both of the methods have the same capability to solve wedge problems in closed form, it should be observed that, with the extension also to arbitrary angular regions, there is no doubt that the W-H technique constitutes the most general analytical method for solving field problems involving geometrical discontinuities.

Appendix A. Derivation of the functional equation (3) of section 2. For illustrative purposes, we consider only the reasoning behind (3) in the free source angular region indicated in Figure 1. In this region the field E_z must satisfy the wave equation

$$\frac{\partial^2}{\partial x^2}E_z + \frac{\partial^2}{\partial y^2}E_z + \tau_o^2 E_z = 0. \tag{A1}$$

Let us introduce the oblique Cartesian coordinates u and v to study this region ($\gamma = \gamma_1$):

$$u = x - y\cot\gamma, \quad v = \frac{y}{\sin\gamma} \quad \text{or} \quad x = u + v\cos\gamma, \quad y = v\sin\gamma. \tag{A2}$$

With these coordinates (see Figure 1), (1) assumes the form

$$\frac{\partial^2 E_z}{\partial u^2} + \frac{\partial^2 E_z}{\partial v^2} - 2\cos\gamma\frac{\partial^2 E_z}{\partial u \partial v} + \tau_0^2 \sin^2\gamma E_z = 0. \tag{A3}$$

Equation (A3) will be solved in the Laplace domain by introducing the Laplace transform

$$\widetilde{E}_z(\eta, v) = \mathrm{L}\left[E_z(u, v)\right] = \int_0^\infty E_z(u, v)e^{j\eta u}du. \tag{A4}$$

It follows that

$$\frac{d^2\widetilde{E}_z}{dv^2} + 2j\eta\cos\gamma\frac{d\widetilde{E}_z}{dv} + (\tau_0^2\cos^2\lambda - \eta^2)\widetilde{E}_z = f_\eta(v), \tag{A5}$$

where

$$f_\eta(v) = -2\cos\gamma\frac{dE_z(0_+,v)}{dv} - j\eta E_z(0_+,v) + \left.\frac{\partial E_z(u,v)}{\partial u}\right|_{u=0_+}. \tag{A6}$$

A standard procedure [24, p. 274] yields the solution of (A5) as follows:

$$\widetilde{E}_z(\eta,v) = A(\eta)e^{-j\vec{m}(\eta)v} - \int_0^\infty \frac{e^{j\eta(v-v_1)\cos\gamma}e^{-j\xi|v-v_1|\sin\gamma}}{2j\sin\gamma\xi} f_\eta(v_1)dv_1, \tag{A7}$$

where $A(\eta)$ is an unknown function and $\vec{m}(\eta)$ and $\overleftarrow{m}(\eta)$ are the two solutions of the characteristic equation $-m^2 + 2\eta\cos\gamma m + \tau_o^2\sin^2\gamma - \eta^2 = 0$ ($\frac{d}{dv} \Rightarrow -jm$):

$$\vec{m}(\eta) = \cos\gamma\eta + \sin\gamma\xi, \qquad \overleftarrow{m}(\eta) = \cos\gamma\eta - \sin\gamma\xi, \tag{A8}$$

with $\xi = \xi(\eta) = \sqrt{\tau_o^2 - \eta^2}$, $\xi(0) = \tau_o$ for $\eta = 0$. On the semiaxis $v = 0$, (A7) provides the equation

$$V_+(\eta,0) = \widetilde{E}_z(0,\eta) = A(\eta) - \int_0^\infty \frac{e^{-jm(\eta)v_1}}{2j\sin\gamma\xi} f_\eta(v_1)dv_1, \tag{A9}$$

where

$$m(\eta) = -\eta\cos\gamma + \sqrt{\tau_o^2 - \eta^2}\sin\gamma. \tag{A10}$$

The magnetic field H_x is obtained by the Maxwell equations

$$H_x = -\frac{j\omega\varepsilon}{\tau_o^2}\left(-\frac{\partial E_z}{\partial v}\frac{1}{\sin\gamma} + \frac{\partial E_z}{\partial u}\cot\gamma\right) + \frac{j\alpha_o}{\tau_o^2}\frac{\partial H_z}{\partial x}. \tag{A11}$$

Applying the Laplace transform $\widetilde{H}_x(\eta,v) = \mathrm{L}[H_y(u,v)] = \int_0^\infty H_x(u,v)e^{j\eta u}du$ and taking into account (A7) yields

$$\begin{aligned} I_{\rho+}(\eta,0) &= \widetilde{H}_x(0,\eta) \\ &= \frac{j\omega\varepsilon}{\tau_o^2}\left(\frac{1}{\sin\gamma}\left[j\vec{m}A(\eta) + \frac{jm}{2j\sin\gamma\xi}\int_0^\infty e^{-jm(\eta)v}f_\eta(v)dv\right.\right. \\ &\qquad \left.\left. - j\eta\cos\gamma\widetilde{E}_z(0,\eta) - E_z(0,0)\cos\gamma\right]\right) \\ &\quad + \frac{j\alpha_o}{\tau_0^2}[-j\eta I_{z+}(\eta,0) - H_z(0,0)]. \end{aligned} \tag{A12}$$

Algebraic manipulations on the Maxwell equations written in the coordinates u and v yield

$$\frac{\partial E_z}{\partial u} = -\frac{\sin\gamma}{\omega\varepsilon}\left(-\alpha_o\frac{\partial H_z}{\partial u} - j\tau_o^2 H_v - \omega\varepsilon\cot\gamma\frac{\partial E_z}{\partial v}\right). \tag{A13}$$

Substituting (A13) into (A6) leads to the following result:

$$\int_0^\infty e^{-jm(\eta)v} f_\eta(v)dv = -j\cos\gamma(mV_{\rho+}(-m,\gamma) - E_z(0,0)) - j\eta V_{\rho+}(-m,\gamma) + \frac{\sin\gamma}{\omega\varepsilon}(\alpha_o jmI_{z+}(-m,0) - \alpha_o H_z(0,0) - j\tau_o^2 I_{\rho+}(-m,\gamma)). \tag{A14}$$

Eliminating $A(\eta)$ in (A7) and (A12) and taking into account (A14) yields the final equation (3) of section 2.

Appendix B. The mapping $\eta = \overline{\eta}(\eta)$. In this appendix we will find a mapping $\eta = \eta(\overline{\eta})$ that will reduce the GWHE (21) in the η-plane to a system of classical W-H equations (24) in the $\overline{\eta}$-plane. For facilitating function-theoretic manipulations that may be obscure in the η-plane, we introduce also the angular complex variable w defined by

$$\eta = k\cos(w+\pi) = -k\cos w. \tag{B1}$$

We also will use the notation

$$f_+(\eta) = f_+(-k\cos w) = \widehat{f}_+(w). \tag{B2}$$

The key point is the observation that the plus functions $f_+(\eta)$ involved in wedge problems yield functions $f_+(-k\cos w) = \widehat{f}_+(w)$, whose analytical continuations are even functions of w in the w-plane, i.e., $\widehat{f}_+(-w) = \widehat{f}_+(w)$. In addition, the functions $\widehat{f}_+(w)$ are also regular in the point $w = 0$. In fact, from both mathematical and physical considerations, it is possible to ascertain that the function $f_+(\eta)$ has only one branch point that is located in $\eta = k$. It follows that $\widehat{f}_+(w)$ are meromorphic functions of w, i.e., $\widehat{f}_+(w) = \frac{n(w)}{d(w)}$ with $n(w)$ and $d(w)$ being entire functions. From (11)–(14) the functions $f_+(\eta)$ appear as functions of $\sqrt{\tau_o - \eta} = \sqrt{2\tau_o}\cos(\frac{w}{2})$ and $\eta = -\tau_o\cos w = \tau_o(1 - 2\cos^2\frac{w}{2})$. It means that near $\eta = \tau_o$, i.e., $w = -\pi$, we have

$$n(w) = a_0 + a_2w^2 + a_4w^4 + \cdots, \qquad d(w) = b_0 + b_2w^2 + b_4w^4 + \cdots \quad (w \approx -\pi). \tag{B3}$$

Since we are dealing with entire functions, (B3) holds for every w. It implies the evenness of $f_+(\eta) = n(w)/d(w)$ everywhere. Moreover, since the point $w = 0$ corresponds to the regular point $\eta = -\tau_o$, $f_+(-\tau_o\cos w)$ is regular in $w = 0$.

Conversely, the meromorphic functions $f(-\tau_o\cos w)$ that are even in the w-plane and regular in $w = 0$ do not involve the branch point $\eta = -\tau_o$ in the η-plane. In fact, a Taylor expansion near $w = 0$ involves only even powers of w:

$$f(-k\cos w) = c_0 + c_2w^2 + c_4w^4 + \cdots \quad (w \approx 0). \tag{B4}$$

Since $w = \sqrt{\tau_o^2 - \eta^2}s_+(\eta)$, where the plus function $s_+(\eta)$ is given by

$$s_+(\eta) = \frac{1}{j\pi\sqrt{\tau_o^2 - \eta^2}}\ln\frac{j\sqrt{\tau_o^2 - \eta^2} - \tau_o - \eta}{j\sqrt{\tau_o^2 - \eta^2} + \tau_o + \eta}, \tag{B5}$$

we can write

$$f(\eta) = c_0 + c_2(\tau_o^2 - \eta^2)(s_+(\eta))^2 + c_4(\tau_o^2 - \eta^2)^2(s_+(\eta))^4 + \cdots \quad (\eta \approx -\tau_o). \tag{B6}$$

It follows that $f(\eta)$ does not have a branch point in $\eta = -\tau_o$. We can also extend our discussion to minus functions $f_-(\eta)$ by relating them to plus function $g_+(\eta)$ through

$$f_-(\eta) = g_+(-\eta). \tag{B7}$$

In the proper sheet it must be

$$\xi = \sqrt{\tau_o^2 - \eta^2} = \sqrt{\tau_o^2 - (-\eta)^2} = -\tau_o \sin w. \tag{B8}$$

This equality holds only if $w(-\eta) = -w(\eta) - \pi$. Using the notation (B2), it follows that $g_+(-\eta) = \hat{g}_+(-w - \pi)$. This result also shows that a minus function does not change value when in the w-plane w is substituted by $-2\pi - w$.

In the w-plane we have $m = \tau_o \cos(w + \Phi)$, and the GWHE (21) assumes the form

$$\hat{G}_\Phi(w)\hat{X}_+(w) = \hat{Y}_+(w + \Phi). \tag{B9}$$

Now the mapping

$$w = \frac{\Phi}{\pi}\overline{w} \tag{B10}$$

yields

$$\widetilde{G}_\Phi(\overline{w})\widetilde{X}_+(\overline{w}) = \widetilde{Y}_+(\overline{w} + \pi), \tag{B11}$$

where the following notation has been used:

$$\widetilde{G}_\Phi(\overline{w}) = \hat{G}_\Phi(w) = \hat{G}_\Phi\left(\frac{\Phi}{\pi}\overline{w}\right). \tag{B12}$$

The mapping $w = \frac{\Phi}{\pi}\overline{w}$ ensures that $\widetilde{X}_+(\overline{w})$ and $\widetilde{Y}_+(\overline{w})$ are also even functions of $\overline{w}$. Consequently, in the plane $\overline{\eta}$ defined by $\overline{\eta} = -\tau_o \cos\overline{w} = -\tau_o \cos\frac{\pi}{\Phi}w$ or

$$\overline{\eta} = -\tau_o \cos\left[\frac{\pi}{\Phi}\arccos\left(-\frac{\eta}{\tau_o}\right)\right], \qquad \eta = \eta(\overline{\eta}) = -\tau_o \cos\left[\frac{\Phi}{\pi}\arccos\left(-\frac{\overline{\eta}}{\tau_o}\right)\right], \tag{B13}$$

these functions do not involve the branch point $\overline{\eta} = -\tau_o$. In addition, we have

$$m = -\eta(-\overline{\eta}), \tag{B14}$$

$$Y_+(-m) = \hat{Y}_+(-w - \Phi) = \widetilde{Y}_+(-\overline{w} - \pi) = \widetilde{Y}_+(\overline{w}(-\overline{\eta})) = \hat{Y}_+(w(-\overline{\eta})) = \overline{Y}_+(-\overline{\eta}). \tag{B15}$$

It means that $\overline{Y}_{\Phi+}(-\overline{\eta})$ do not involve the branch point $\overline{\eta} = \tau_o$ in the $\overline{\eta}$-plane.

The singularities involved in the $\overline{\eta}$-plane derive from the ones present in the η-plane. They consist of (a) a finite number of poles (structural surface waves), (b) branch points $\overline{\eta} = \pm\tau_o$, and (c) a limited number of poles that arise from the geometrical optic field. The limited number of the poles involved allows one to conclude that $\overline{X}_+(\overline{\eta})$ has a regular upper half-plane and that $\overline{X}_-(\overline{\eta}) = \overline{Y}_+(-\overline{\eta})$ has a regular lower half-plane. Consequently, (24) constitutes a classical system of W-H equations.

To facilitate the applications of the mapping $\eta = \overline{\eta}(\eta)$ defined in (B13), it is useful to remember that the variables w and $\overline{w}$ are defined by

$$\eta = -\tau_o \cos w, \quad \overline{\eta} = -\tau_o \cos \overline{w}, \quad w = \frac{\Phi}{\pi}\overline{w}. \tag{B16}$$

With these variables, we have $\xi = -\tau_o \sin w$, $m = \tau_o \cos(w+\Phi)$, and $n = \tau_o \sin(w+\Phi)$. As an example, the pole $m_o = \tau_o \cos(\Phi - \varphi_o) = \tau_o \cos(w_o + \Phi)$ implies $w_o = -\varphi_o$ or $\overline{w}_o = -\frac{\pi}{\Phi}\varphi_o$, which yields $\overline{\eta}_o = -\tau_o \cos \overline{w}_o = -\tau_o \cos \frac{\pi}{\Phi}\varphi_o$.

Appendix C. Factorization of the scalar ξ. There are many ways to obtain the factorization of ξ in the $\overline{\eta}$-plane (see [22]). In this appendix we will obtain this factorization by inspection, by observing that in the $\overline{w}$-plane

$$\xi = \sqrt{k^2 - \eta^2} = -k \sin w = \left(-\sqrt{k} \sin \frac{1}{2}\overline{w}\right) \frac{\sqrt{k} \sin \frac{\Phi}{\pi}\overline{w}}{\sin \frac{1}{2}\overline{w}}. \tag{C1}$$

The factorization is thus accomplished. In fact

$$-\frac{\sqrt{k} \sin \frac{\Phi}{\pi}\overline{w}}{\sin \frac{1}{2}\overline{w}}$$

is a plus function since it is even in $\overline{w}$ and regular in $\overline{w} = 0$. Here also $\sqrt{k} \sin \frac{1}{2}\overline{w}$ is a minus function since it does not change when $\overline{w}$ is substituted by $-2\pi - \overline{w}$. In the $\overline{\eta}$-plane we have

$$\overline{\xi}_-(\overline{\eta}) = \sqrt{k} \sin \frac{1}{2}\overline{w} = \sqrt{k \frac{1 - \cos \overline{w}}{2}} = \sqrt{\frac{k + \overline{\eta}}{2}}. \tag{C2}$$

MYRIAD RADIAL CAVITATING EQUILIBRIA IN NONLINEAR ELASTICITY*

JEYABAL SIVALOGANATHAN† AND SCOTT J. SPECTOR‡

For Donald E. Carlson on the occasion of his 65th birthday

Abstract. It is shown that every bounded strictly increasing smooth positive function of sufficiently slow growth is the Jacobian of a radial hole creating equilibrium deformation for an appropriately constructed compressible nonlinearly elastic energy.

Key words. cavitation, elastic, equilibrium, singular minimizers

AMS subject classifications. 74B20, 74G70, 35J55

PII. S0036139901397005

1. Introduction.

Explicit solutions of model equations can be useful in gaining insight concerning the qualitative behavior of solutions to more general problems. Unfortunately, the explicit construction of radial equilibrium deformations that create new holes in a compressible nonlinearly elastic body has proven to be unexpectedly complicated. Consequently, although cavitation is a common occurrence in rubbery polymers, explicit solutions that exhibit this phenomenon are rare. The only such solutions (modulo a radial null-Lagrangian; see Horgan [3] and Steigmann [15]) that appear in the literature are for an elastic fluid (see, e.g., [3, 6]); for the Blatz–Ko constitutive relation for foam rubbers, which was obtained, in two dimensions, by Horgan and Abeyaratne [4] and, in three dimensions, by Tian-hu [18]; for a compressible neo-Hookean material, which was obtained in [11] (see also [1, section 7.6]); and for the generalized Carroll material, which was obtained by Murphy and Biwa [7] (see also Shang and Cheng [12]).

The usual method of obtaining an explicit solution is to solve the differential equation for a postulated model problem. In this paper we take a different approach; we first posit deformations that, based upon prior results, have desired properties, and then construct differential equations that have these deformations as solutions. We show, in particular, that every function in a certain class of radial cavitating deformations will satisfy an equilibrium equation that is appropriately chosen for that particular function. The radial deformations we use are those for which the Jacobian is an increasing radial function. The appropriate stored energy is then constructed as the sum of two terms. The first is a homogeneous isotropic strongly elliptic stored-energy function, while the second is a function of the Jacobian of the chosen radial deformation. This second function is constructed so that the chosen deformation will automatically satisfy the radial equilibrium equation. Further information on radial cavitation is contained in the survey article by Horgan and Polignone [5].

2. The constitutive relation. Let $\Psi \in C^2((0,\infty)^n)$ be a symmetric function. We assume that the stored-energy function for the material is given by

$$W(\mathbf{F}) = \Phi(\nu_1, \nu_2, \dots, \nu_n) := \Psi(\nu_1, \nu_2, \dots, \nu_n) + h(\nu_1 \nu_2 \dots \nu_n) \tag{2.1}$$

for all $n \times n$ matrices $\mathbf{F}$ with positive determinant, where $\nu_1, \nu_2, \dots, \nu_n$ are the principal stretches, i.e., the eigenvalues of the square root of $\mathbf{F}\mathbf{F}^T$, and $h \in C^2((0,\infty))$ is a function to be determined.

The problem of interest is to determine stationary points of the energy

$$E(\mathbf{w}) = \int_{B_\mathrm{o}} W(\nabla \mathbf{w}(\mathbf{x}))\, d\mathbf{x} \tag{2.2}$$

among orientation-preserving injective $\mathbf{w}$ that satisfy the boundary condition $\mathbf{w}(\mathbf{x}) = \lambda \mathbf{x}$ for $\mathbf{x} \in \partial B_\mathrm{o}$, where $B_\mathrm{o} := B(\mathbf{0}, R_\mathrm{o}) \subset \mathbb{R}^n$ is the ball of radius R_o centered at the origin. For a radial deformation

$$\mathbf{w}(\mathbf{x}) = \frac{r(R)}{R}\mathbf{x}, \qquad R := |\mathbf{x}|,$$

$r : [0, R_\mathrm{o}] \to [0,\infty)$, the principal stretches at any point $\mathbf{x} \in B_\mathrm{o}$ are given by (see, e.g., [1]) $\nu_1(\mathbf{x}) = r'(R)$ and $\nu_i(\mathbf{x}) = r(R)/R$ for $i = 2, 3, \dots, n$. Thus (2.2) reduces to[1]

$$\overline{E}(r) = \int_0^{R_\mathrm{o}} \Phi\left(r'(R), \frac{r(R)}{R}, \frac{r(R)}{R}, \dots, \frac{r(R)}{R}\right) R^{n-1}\, dR \tag{2.3}$$

among those $r : [0, R_\mathrm{o}] \to [0,\infty)$ that satisfy $r' > 0$ a.e. and $r(R_\mathrm{o}) = \lambda R_\mathrm{o}$. A stationary point $\mathbf{w}$ of E corresponds to a solution r of the radial equilibrium equation

$$\frac{d}{dR}\left[R^{n-1}\Phi_{,1}\right] = (n-1)R^{n-2}\Phi_{,2}\,, \tag{2.4}$$

where

$$\Phi_{,i} = \Phi_{,i}\left(r'(R), \frac{r(R)}{R}, \frac{r(R)}{R}, \dots, \frac{r(R)}{R}\right)$$

and $\Phi_{,i}\,(v_1, v_2, \dots, v_n)$ denotes differentiation of Φ with respect to its ith argument (see [1, Theorem 7.3]). Also, if $r(0) > 0$, then the deformed ball contains a spherical cavity, and r must satisfy the natural boundary condition

$$T(R) := \left[\frac{R}{r(R)}\right]^{n-1} \Phi_{,1}\left(r'(R), \frac{r(R)}{R}, \frac{r(R)}{R}, \dots, \frac{r(R)}{R}\right) \to 0 \ \text{ as } R \to 0^+, \tag{2.5}$$

which corresponds to the radial component of the Cauchy stress vanishing on the cavity surface.

For energies of the form (2.1) the radial equilibrium equation (2.4) becomes

$$\frac{d}{dR}\left[R^{n-1}\Psi_{,1}\right] - (n-1)R^{n-2}\Psi_{,2} = -r(R)^{n-1}\frac{d}{dR}h'\left(r'(R)\left[\frac{r(R)}{R}\right]^{n-1}\right), \tag{2.6}$$

[1]The energy E is equal to $\overline{E}$ multiplied by the volume of the unit ball in $\mathbb{R}^n$.

and the natural boundary condition (2.5) reduces to

$$\lim_{R\to 0^+}\left[h'\left(r'(R)\left[\frac{r(R)}{R}\right]^{n-1}\right)+\left[\frac{R}{r(R)}\right]^{n-1}\Psi_{,1}\left(r'(R),\frac{r(R)}{R},\dots,\frac{r(R)}{R}\right)\right]=0. \tag{2.7}$$

The main idea in this paper is that, given Ψ and r, (2.6) can be used to define the function h. In order to accomplish this, we will need the following hypotheses on the energy:

(En1) for all $q>0$ and $t>0$

$$\Psi_{,11}(q,t,t,\dots,t)>0;$$

(En2) there exists $\lambda_*>0$ such that for every $\alpha\geq\lambda_*^n$

$$\lim_{t\to+\infty} t^{1-n}\Psi_{,1}(\alpha t^{1-n},t,t,\dots,t)=0;$$

(En3) for every $L>\lambda_*^n$ there are constants $\beta\in[0,n-1)$ and $K>0$ such that

$$\left|\Psi_{,2}(\kappa t^{1-n},t,t,\dots,t)\right|\leq Kt^{\beta}$$

for all $\lambda_*<t<\infty$ and $\lambda_*^n\leq\kappa\leq L$;

(En4) for $q\neq t$ define

$$\mathcal{R}(q,t):=\frac{q\Psi_{,1}(q,t,t,\dots,t)-t\Psi_{,2}(q,t,t,\dots,t)}{q-t}. \tag{2.8}$$

Then for every $\mu>\lambda_*$ we assume that there exists a $B_\mu>0$ such that

$$|\mathcal{R}(q,t)|\leq B_\mu$$

for all $\lambda_*<t<\mu$ and $0<q<t$.

Remark 2.1. Hypothesis (En1) is a consequence of the strong-ellipticity of the energy Ψ. Hypotheses (En2)–(En4) are satisfied by many examples of stored energies (see [1, 16, 17]). In particular, Stuart [16, 17] requires a more stringent growth hypothesis than (En4): $0\leq\mathcal{R}(q,t)\leq A+Bt^{\beta}$ for $0<q<t$.

3. The construction. Let $\lambda_{\rm crit}>\lambda_0>0$, and suppose that $J\in C^1([0,\infty))$ is a strictly monotone increasing function that satisfies

$$J(0)=\lambda_0^n,\qquad \lim_{R\to+\infty}J(R)=\lambda_{\rm crit}^n,\qquad \int_0^\infty J'(t)t^n\,dt\leq 1. \tag{3.1}$$

Define $\rho:[0,\infty)\to[1,\infty)$ by

$$\rho(R)^n:=1+n\int_0^R J(t)t^{n-1}\,dt \tag{3.2}$$

so that

$$\rho'(R)\left[\frac{\rho(R)}{R}\right]^{n-1}=J(R)\quad\text{for}\quad 0<R<\infty. \tag{3.3}$$

For future reference we note the following properties of ρ.

LEMMA 3.1. *The function ρ given by* (3.1) *and* (3.2) *satisfies*

(i) $0 < \rho'(R)$,

(ii) $\frac{d}{dR}[\frac{\rho(R)}{R}] < 0$,

(iii) $\rho'(R) < \frac{\rho(R)}{R}$,

(iv) $0 < \rho''(R)$,

(v) $\lim_{R\to+\infty} \frac{\rho(R)}{R} = \lim_{R\to+\infty} \rho'(R) = \lambda_{\text{crit}}$.

Remark 3.2. Properties (i)–(v) are standard properties of radial minimizers and radial equilibrium deformations (see, e.g., [1, 10, 16, 17]). Since our proof shows that $(3.1)_3$ is necessary and sufficient for (iii), it is now clear that $(3.1)_3$ is also a standard property of such deformations. Note also that by (3.2), $\rho(0) = 1$.

THEOREM 3.3. *Let Ψ satisfy* (En1)–(En4) *and let ρ be given by* (3.1) *and* (3.2), *where $\lambda_0 > \lambda_*$. Suppose that $h \in C^2((0,\infty);(0,\infty))$ and satisfies*

$$\begin{aligned} h'(J(R)) = &\int_0^R \frac{(n-1)s^{n-2}}{\rho(s)^{n-1}} \hat{\Psi}_2\left(\rho'(s), \frac{\rho(s)}{s}\right) ds \\ &- R^{n-1}\hat{\Psi}_1\left(\rho'(R), \frac{\rho(R)}{R}\right)\left[\frac{1}{\rho(R)}\right]^{n-1} \\ &+ \int_0^R s^{n-1}\hat{\Psi}_1\left(\rho'(s), \frac{\rho(s)}{s}\right) \frac{d}{ds}\left[\frac{1}{\rho(s)^{n-1}}\right] ds \end{aligned} \tag{3.4}$$

for $R \in (0,\infty)$, where $\hat{\Psi}_i(\rho'(s), \frac{\rho(s)}{s}) := \Psi_{,i}\,(\rho'(s), \frac{\rho(s)}{s}, \frac{\rho(s)}{s}, \ldots, \frac{\rho(s)}{s})$. Then ρ is a solution of the radial equilibrium equation (2.6) *on $(0,\infty)$ and satisfies the natural boundary condition* (2.7).

Remark 3.4. It follows from the proof of the above result (see (4.4)) that $h'(\lambda_0^n) = 0$.

Finally, we use ρ to construct a family of equilibrium deformations of B_{o}. For any $R_{\text{o}} > 0$ and $\delta > 0$

$$\mathbf{u}_\delta(\mathbf{x}) := \frac{r_\delta(|\mathbf{x}|)}{|\mathbf{x}|}\mathbf{x}, \qquad r_\delta(R) := \frac{\rho(\delta R)}{\delta} \tag{3.5}$$

is an orientation-preserving injective radial deformation of B_{o}, and, in view of (3.3), (4.1), and [1, Lemma 4.1], $J(\delta|\mathbf{x}|)$ is the Jacobian of $\mathbf{u}_\delta$ at any point $\mathbf{x} \neq \mathbf{0}$. Clearly, each $\mathbf{u}_\delta$ is a cavitating deformation that creates a new hole of radius $1/\delta$ at the center of the ball and satisfies the boundary condition

$$\mathbf{u}_\delta(\mathbf{x}) = \lambda\mathbf{x}, \qquad \lambda^n = \lambda(\delta, R_{\text{o}})^n := \frac{[1 + n\int_0^{\delta R_{\text{o}}} J(t)t^{n-1}\,dt]}{(\delta R_{\text{o}})^n} \tag{3.6}$$

for $\mathbf{x} \in \partial B_{\text{o}}$. Moreover, results in [1] show that each of these deformations is contained in the Sobolev space $W^{1,p}(B_{\text{o}};\mathbb{R}^n)$ for every $p \in [1,n)$, while Theorem 3.3 shows that $\mathbf{u}_\delta$ is a stationary point for the energy.

THEOREM 3.5. *Let W be given by* (2.1) *and satisfy* (En1)–(En4). *Let $\lambda > \lambda_{\text{crit}} > \lambda_0 > \lambda_*$. Then there exists a unique $\delta = \delta(\lambda)$ such that $\mathbf{u}_\delta$, given by* (3.1), (3.2), (3.5), *and* (3.6), *is a stationary point of the energy* (2.2) *and satisfies the boundary condition $\mathbf{u}_\delta(\mathbf{x}) = \lambda\mathbf{x}$ for $\mathbf{x} \in \partial B_{\text{o}}$.*

Proof. Let $\lambda > \lambda_{\text{crit}}$. Then since $\rho(0) = 1$, it is clear from Lemma 3.1(ii) and (v) that there exists a unique $R_\lambda > 0$ such that $\rho(R_\lambda) = \lambda R_\lambda$. Define $\delta = R_\lambda/R_{\text{o}}$. Then

by (3.5)

$$\mathbf{u}_\delta(\mathbf{x}) := \frac{\rho(\delta R_{\rm o})}{\delta R_{\rm o}}\mathbf{x} = \frac{\rho(R_\lambda)}{R_\lambda}\mathbf{x} = \lambda\mathbf{x} \quad \text{for} \quad |\mathbf{x}| = R_{\rm o}. \qquad \square$$

4. Proofs for the construction.

Proof of Lemma 3.1. We first note that (i) is clear from (3.2), (3.3), and the nonnegativity of J. Next, if we divide (3.2) by R^n and use the quotient rule to differentiate the result with respect to R, we find that

$$\begin{aligned}\left[\frac{\rho(R)}{R}\right]^{n-1}\frac{d}{dR}\left[\frac{\rho(R)}{R}\right] &= \frac{\left(nJ(R)R^{n-1}\right)R^n - nR^{n-1}(1+n\int_0^R J(t)t^{n-1}\,dt)}{nR^{2n}}\\ &= \frac{J(R)R^n - (1+n\int_0^R J(t)t^{n-1}\,dt)}{R^{n+1}}\\ &= \frac{-1+\int_0^R J'(t)t^n\,dt}{R^{n+1}},\end{aligned} \tag{4.1}$$

where an integration by parts has been used to deduce $(4.1)_3$ from $(4.1)_2$. It is now clear from (4.1) that $(3.1)_3$ is necessary and sufficient for (ii).

Next, if we differentiate $\rho(R)/R$ with respect to R, we see that

$$\frac{d}{dR}\left[\frac{\rho(R)}{R}\right] = \frac{1}{R}\left[\rho'(R) - \frac{\rho(R)}{R}\right], \tag{4.2}$$

and consequently (iii) is equivalent to (ii). Similarly, if we differentiate (3.3) with respect to R, we discover that

$$\rho''(R)\left[\frac{\rho(R)}{R}\right]^{n-1} = J'(R) - \rho'(R)(n-1)\left[\frac{\rho(R)}{R}\right]^{n-2}\frac{d}{dR}\left[\frac{\rho(R)}{R}\right], \tag{4.3}$$

and thus (iv) follows from (i), (ii), and the fact that J is increasing.

Finally, to obtain (v) we first note that (ii)–(iv) imply that both limits exist and are finite. Thus, if we divide (3.2) by R^n and take the limit as $R \to +\infty$, we find, using L'Hôpital's rule and $(3.1)_2$, that

$$\lim_{R\to+\infty}\left[\frac{\rho(R)}{R}\right]^n = \lim_{R\to+\infty} J(R) = \lambda_{\rm crit}^n,$$

which together with (3.3) yields (v). $\square$

Proof of Theorem 3.3. Assume for the moment that $s \mapsto s^{n-2}\hat{\Psi}_2(\rho'(s), \frac{\rho(s)}{s})$ and $s \mapsto s^{n-1}\hat{\Psi}_1(\rho'(s), \frac{\rho(s)}{s})$ are integrable on $(0,R)$, so that the right-hand side of (3.4) is well defined on $(0,\infty)$. Then, if we differentiate (3.4) with respect to R, it is clear that ρ satisfies the radial equilibrium equation (2.6) on $(0,\infty)$.

In order to show that $s \mapsto s^{n-2}\hat{\Psi}_2(\rho'(s), \frac{\rho(s)}{s})$ is integrable on $(0,R)$ we use (3.3), (En3), $\rho' \geq 0$, and the fact that $J(s) \in [\lambda_0^n, \lambda_{\rm crit}^n]$ for each s to conclude that

$$\begin{aligned}s^{n-2}\left|\hat{\Psi}_2\left(\rho'(s), \frac{\rho(s)}{s}\right)\right| &= \rho(s)^{n-2}\left[\frac{s}{\rho(s)}\right]^{n-2}\left|\hat{\Psi}_2\left(J(s)\left[\frac{\rho(s)}{s}\right]^{1-n}, \frac{\rho(s)}{s}\right)\right|\\ &\leq K\rho(s)^{n-2}\left[\frac{\rho(s)}{s}\right]^{\beta-n+2} \leq K\rho(R)^\beta s^{n-2-\beta},\end{aligned}$$

which is clearly integrable on $(0,R)$ since $\beta < n-1$.

In order to prove that $s \mapsto s^{n-1}\hat{\Psi}_1(\rho'(s), \frac{\rho(s)}{s})$ is integrable on $(0,R)$, we will show that

$$\lim_{s\to 0^+} s^{n-1}\hat{\Psi}_1\left(\rho'(s), \frac{\rho(s)}{s}\right) = 0. \tag{4.4}$$

Now, by (3.3),

$$s^{n-1}\hat{\Psi}_1\left(\rho'(s), \frac{\rho(s)}{s}\right) = \rho(s)^{n-1}\left[\frac{s}{\rho(s)}\right]^{n-1}\hat{\Psi}_1\left(J(s)\left[\frac{\rho(s)}{s}\right]^{1-n}, \frac{\rho(s)}{s}\right). \tag{4.5}$$

Moreover, since $\lambda_0^n \le J(s) \le \lambda_{\text{crit}}^n$, hypothesis (En1) implies

$$\hat{\Psi}_1\left(\lambda_0^n t^{1-n}, t\right) \le \hat{\Psi}_1\left(J(s)t^{1-n}, t\right) \le \hat{\Psi}_1\left(\lambda_{\text{crit}}^n t^{1-n}, t\right), \quad t := \frac{\rho(s)}{s}. \tag{4.6}$$

Since $\rho \to 1$ and $t \to +\infty$ as $s \to 0^+$, (4.4) now follows from (En2), (4.5), and (4.6). In addition, the natural boundary condition (2.7) follows from (3.4), (4.4), together with the integrability of $s \mapsto s^{n-2}\hat{\Psi}_2(\rho'(s), \frac{\rho(s)}{s})$ and $s \mapsto s^{n-1}\hat{\Psi}_1(\rho'(s), \frac{\rho(s)}{s})$ on $(0,R)$.

Finally, we need to show that the right-hand side of (3.4) is bounded as $R \to \infty$ in order that h can be extended smoothly as a real-valued function on $(\lambda_{\text{crit}}^n, \infty)$. Let $R_1 > 0$. Then by (3.4)

$$\begin{aligned} h'(J(R)) - h'(J(R_1)) \;=\; & \int_{R_1}^{R} \frac{(n-1)s^{n-2}}{\rho(s)^{n-1}}\hat{\Psi}_2\left(\rho'(s), \frac{\rho(s)}{s}\right) ds \\ & - R^{n-1}\hat{\Psi}_1\left(\rho'(R), \frac{\rho(R)}{R}\right)\rho(R)^{1-n} \\ & + {R_1}^{n-1}\hat{\Psi}_1\left(\rho'(R_1), \frac{\rho(R_1)}{R_1}\right)\rho(R_1)^{1-n} \\ & + \int_{R_1}^{R} s^{n-1}\hat{\Psi}_1\left(\rho'(s), \frac{\rho(s)}{s}\right)\frac{d}{ds}\left[\rho(s)^{1-n}\right] ds \end{aligned} \tag{4.7}$$

for $R \in (R_1, \infty)$. Now, it is clear from Lemma 3.1(v) that $(4.7)_2$ is bounded as $R \to \infty$. Next, the sum of the integrals on the right-hand side of $(4.7)_1$, $(4.7)_4$ is equal to

$$(n-1)\int_{R_1}^{R} s^{-1}\left[\frac{s}{\rho(s)}\right]^n \left[\frac{\rho(s)}{s}\hat{\Psi}_2\left(\rho'(s), \frac{\rho(s)}{s}\right) - \rho'(s)\hat{\Psi}_1\left(\rho'(s), \frac{\rho(s)}{s}\right)\right] ds. \tag{4.8}$$

However, by Lemma 3.1, $\lambda_{\text{crit}} < \frac{\rho(s)}{s} \le \frac{\rho(R_1)}{R_1} =: \mu$ for $R_1 \le s < \infty$ and hence, in view of (En4), the absolute value of (4.8) is bounded by a constant times

$$\begin{aligned} \int_{R_1}^{R} \frac{1}{s}\left[\frac{\rho(s)}{s} - \rho'(s)\right] ds &= \int_{R_1}^{R} -\frac{d}{ds}\left[\frac{\rho(s)}{s}\right] ds \\ &= \frac{\rho(R_1)}{R_1} - \frac{\rho(R)}{R}, \end{aligned}$$

which is bounded as $R \to \infty$. ∎

5. The energy: Uniqueness. In this section we note that, whenever the function h is convex, the cavitating radial equilibrium solution we have constructed is the unique global minimizer of the energy among radial deformations. The following three results can be found in Sivaloganathan [13] (see also [14]).

PROPOSITION 5.1. *Assume that*

$$\hat{\Phi}_{11}(q,t) > 0 \tag{5.1}$$

for all $q > 0$ and $t > 0$. Let $r_c \in C^1([0,\infty)) \cap C^2((0,\infty))$ be a cavitating equilibrium solution*; i.e., r_c satisfies* (2.4) *on $(0,\infty)$,* (2.5)*, $r_c(0) > 0$, and $r_c' > 0$ a.e. Suppose that $R_o > 0$, and define $\lambda = r_c(R_o)/R_o$. Let $r \in \mathcal{A}_\lambda$,*

$$\mathcal{A}_\lambda := \{r \in W^{1,1}((0,R_o)) : r(R_o) = \lambda R_o,\ r(0) \geq 0,\ r' > 0 \text{ a.e.}\}, \tag{5.2}$$

satisfy

$$0 < \limsup_{R\to 0^+} \left[\frac{r(R)}{R}\right]. \tag{5.3}$$

Then

$$\overline{E}(r_c) < \overline{E}(r)$$

unless $r \equiv r_c$, where $\overline{E}$ is given by (2.3)*.*

COROLLARY 5.2. *Let $\lambda > 0$ and $R_o > 0$. Then, under the hypotheses of the previous proposition, there exists at most one cavitating equilibrium solution $r_c \in C^1([0,\infty)) \cap C^2((0,\infty))$ that satisfies $r_c(R_o) = \lambda R_o$.*

Remarks. 1. The statement of Theorem 6.8 in [13] actually requires that (5.3) be satisfied with lim sup replaced by lim inf. However, the remark after the proof of [13, Theorem 6.9] notes that the result remains valid under this weaker hypothesis.

2. Theorems 6.8 and 6.9 in [13] also appear to require the weakened Baker–Ericksen inequality $\mathcal{R}(q,t) \geq 0$, where $\mathcal{R}$ is given by (2.8). However, an examination of the proofs in [13, 14] shows that this inequality is used only to extend a solution of the radial equilibrium equation from $(0,R_o)$ to $(0,\infty)$, a step not needed in our presentation.

Proof of Corollary 5.2. Let $\lambda > 0$ and $R_o > 0$. If r_c is any cavitating equilibrium solution that satisfies $r_c(R_o) = \lambda R_o$, then $r_c \in \mathcal{A}_\lambda$ and r_c satisfies (5.3). Thus, by the previous proposition, two distinct cavitating equilibrium solutions r_{c_1} and r_{c_2} would satisfy $\overline{E}(r_{c_2}) < \overline{E}(r_{c_1})$ and $\overline{E}(r_{c_1}) < \overline{E}(r_{c_2})$, which is a contradiction. □

COROLLARY 5.3. *Let $\lambda > 0$ and $R_o > 0$. Suppose that $r_c \in C^1([0,\infty)) \cap C^2((0,\infty))$ is a cavitating equilibrium solution that satisfies $r_c(R_o) = \lambda R_o$. Then, under the hypotheses of the previous proposition, $\overline{E}(r_c) < \overline{E}(r_h)$, where $r_h(R) := \lambda R$.*

Proof. For any $\lambda > 0$ and $R_o > 0$ the homogeneous deformation $r_h(R) := \lambda R$ satisfies $r_h \in \mathcal{A}_\lambda$ and (5.3). The result then follows from Proposition 5.1. □

In order to make use of Proposition 5.1 we will need the following additional hypothesis on the energy:

(En5) there exist $\phi, \psi : (0,\infty) \to \mathbb{R}$ and $\Psi^* \in C((0,\infty)^n; \mathbb{R})$, with $\phi > 0, \psi \geq 0$, and $\Psi \geq 0$, that satisfy

$$\Psi(\nu_1,\nu_2,\ldots,\nu_n) = \sum_{i=1}^{n} \phi(\nu_i) + \sum_{i\neq j} \psi(\nu_i\nu_j) + \Psi^*(\nu_1,\nu_2,\ldots,\nu_n),$$

where $t \mapsto \Psi^*(t,t,\dots,t)$ is bounded on $(0,\lambda^*]$ and $\psi \equiv 0$ if $n=2$.

We now use Proposition 5.1 to show that if our equilibrium solutions are supersolutions for the energy Ψ, then they are energy minimizers among the radial deformations.

THEOREM 5.4. *Let Ψ satisfy* (En1)–(En5) *and let ρ be given by* (3.1) *and* (3.2)*, where $\lambda_0 > \lambda_*$ and $J' > 0$ on $[0,\infty)$. Suppose that*

$$\frac{d}{dR}\left[R^{n-1}\hat{\Psi}_1\left(\rho'(R),\frac{\rho(R)}{R}\right)\right] < (n-1)R^{n-2}\hat{\Psi}_2\left(\rho'(R),\frac{\rho(R)}{R}\right). \tag{5.4}$$

Finally, suppose in addition that $h \in C^2((0,\infty);(0,\infty))$ satisfies (3.4) *and $h''(s) \geq 0$ for $s \in (0,\lambda_0^n) \cup [\lambda_{\text{crit}}^n,\infty)$. Then the radial cavitating deformation $r_{\delta(\lambda)}$ given by Theorem* 3.5 *satisfies*

$$\overline{E}(r_{\delta(\lambda)}) < \overline{E}(r)$$

for every $r \in \mathcal{A}_\lambda$ (see (5.2)*).*

Proof. We first show that h'' is nonnegative on its domain of definition. Let $s \in (0,\infty)$. If $s \notin [\lambda_0^n,\lambda_{\text{crit}}^n)$, then $h''(s) \geq 0$, by hypothesis. If $s \in [\lambda_0^n,\lambda_{\text{crit}}^n)$, then by (3.1) there exists an $R \in [0,\infty)$ such that $J(R) = s$. Therefore, by (3.3) and the radial equilibrium equation (2.6),

$$\frac{d}{dR}\left[R^{n-1}\Psi_{,1}\right] - (n-1)R^{n-2}\Psi_{,2} = -\rho(R)^{n-1}h''\left(J(R)\right)J'(R). \tag{5.5}$$

The desired result now follows from (5.4), (5.5), and the assumed positivity of ρ and J'.

Now let $\lambda > \lambda_{\text{crit}}$, $r \in \mathcal{A}_\lambda$, and suppose that

$$0 < \limsup_{R\to 0^+}\left[\frac{r(R)}{R}\right]. \tag{5.6}$$

Then, by Proposition 5.1, all we need show is that (5.1) is satisfied. If we differentiate (2.1) twice with respect to ν_1 and set $\nu_1 = q$ and $\nu_2 = \nu_3 = \cdots = \nu_n = t$, we find that

$$\hat{\Phi}_{11}(q,t) = \hat{\Psi}_{11}(q,t) + t^{2n-2}h''(qt^{n-1}).$$

Consequently, in view of (En1), a sufficient condition for (5.1) is that h'' be nonnegative on its domain of definition, which has previously been shown.

Before proceeding further we note that the convexity of h, together with $h'(\lambda_0^n) = 0$ (see the remark following Theorem 3.3), implies that h is bounded below by $h(\lambda_0^n)$ on $(0,\infty)$.

Next, suppose alternatively that (5.6) is not satisfied and therefore that

$$0 = \lim_{R\to 0^+}\left[\frac{r(R)}{R}\right].$$

Then, in particular, $r(0) = 0$, and hence

$$\int_0^{R_o} nr'r^{n-1}dR = \int_0^{R_o}\frac{d}{dR}\left[r^n\right]dR = r(R_o)^n = \lambda^n R_o^n = n\int_0^{R_o}\lambda^n R^{n-1}dR. \tag{5.7}$$

Now, in view of the convexity of h,

$$h\left(r'(R)\left[\frac{r(R)}{R}\right]^n\right) \geq h(\lambda^n) + \left(r'(R)\left[\frac{r(R)}{R}\right]^n - \lambda^n\right)h'(\lambda^n),$$

and consequently, by (5.7),

$$\int_0^{R_o} h\left(r'(R)\left[\frac{r(R)}{R}\right]^{n-1}\right)R^{n-1}dR \geq \int_0^{R_o} h(\lambda^n)R^{n-1}dR. \tag{5.8}$$

If $\overline{E}(r) = +\infty$, we are done. If instead $\overline{E}(r) < \infty$, then by (En5) and since h is bounded below,

$$R \mapsto R^{n-1}\phi\left(\frac{r(R)}{R}\right) \in L^1((0, R_o)), \tag{5.9}$$

$$R \mapsto R^{n-1}\psi\left(\left[\frac{r(R)}{R}\right]^2\right) \in L^1((0, R_o)). \tag{5.10}$$

We claim that

$$0 = \liminf_{R\to 0^+} R^n\hat{\Psi}\left(\frac{r(R)}{R}, \frac{r(R)}{R}\right). \tag{5.11}$$

Otherwise, $R^n\hat{\Psi}\big(\frac{r(R)}{R}, \frac{r(R)}{R}\big) \geq K > 0$ for small R, and thus

$$R^{n-1}\hat{\Psi}\left(\frac{r(R)}{R}, \frac{r(R)}{R}\right) \geq \frac{K}{R}.$$

This inequality, together with (En5), implies

$$nR^{n-1}\phi\left(\frac{r(R)}{R}\right) + \frac{1}{2}n(n-1)R^{n-1}\psi\left(\left[\frac{r(R)}{R}\right]^2\right) \geq \frac{K}{R} - \hat{\Psi}^*\left(\frac{r(R)}{R}, \frac{r(R)}{R}\right),$$

which, since $r(R)/R$ and hence Ψ^* are bounded, contradicts (5.9) or (5.10).

Next, $\Psi_{,11} > 0$. Therefore $\hat{\Psi}(q,t) \geq \hat{\Psi}(t,t) + (q-t)\hat{\Psi}_{,1}(t,t)$, and hence

$$\begin{aligned}\hat{\Psi}\left(r'(R), \frac{r(R)}{R}\right) &\geq \hat{\Psi}\left(\frac{r(R)}{R}, \frac{r(R)}{R}\right) + \left(r'(R) - \frac{r(R)}{R}\right)\hat{\Psi}_{,1}\left(\frac{r(R)}{R}, \frac{r(R)}{R}\right)\\ &= \frac{1}{n}R^{1-n}\frac{d}{dR}\left[R^n\hat{\Psi}\left(\frac{r(R)}{R}, \frac{r(R)}{R}\right)\right],\end{aligned}$$

which, when multiplied by nR^{n-1} and integrated over (R_k, R_o), yields

$$\int_{R_k}^{R_o} n\hat{\Psi}\left(r'(R), \frac{r(R)}{R}\right)R^{n-1}dR \geq \left[R_o^n\hat{\Psi}(\lambda,\lambda)\right] - \left[R_k^n\hat{\Psi}\left(\frac{r(R_k)}{R_k}, \frac{r(R_k)}{R_k}\right)\right]. \tag{5.12}$$

In particular, choose a sequence $R_k \to 0^+$ as $k \to \infty$ so that $R_k^n\hat{\Psi}\big(\frac{r(R_k)}{R_k}, \frac{r(R_k)}{R_k}\big)$ converges to its lim inf, which is zero by (5.11). Then, if we let $k \to \infty$ in (5.12) and apply the dominated convergence theorem, we find that

$$\int_0^{R_o} \hat{\Psi}\left(r'(R), \frac{r(R)}{R}\right)R^{n-1}dR \geq \int_0^{R_o} \hat{\Psi}(\lambda,\lambda)\,R^{n-1}dR,$$

which, together with (2.1) and (5.8), yields $\overline{E}(r) \geq \overline{E}(r_h)$. The desired result now follows from Corollary 5.3. ∎

6. Examples.

6.1. Ogden materials. In order to illustrate the form that hypotheses (En1)–(En5) take for a well-analyzed class of materials, we now restrict our attention to three dimensions and consider materials whose constitutive relation is of the form

$$\Psi(\lambda_1,\lambda_2,\lambda_3)=\phi(\lambda_1)+\phi(\lambda_2)+\phi(\lambda_3)+\psi(\lambda_1\lambda_2)+\psi(\lambda_2\lambda_3)+\psi(\lambda_1\lambda_3), \tag{6.1}$$

where $\phi,\psi\in C^2((0,\infty))$. (Such constitutive relations were used by Ogden [8] to match theory with experiments.)

For such materials we make the following assumptions (cf. [1, 16, 13, 14, 9] and especially [17, 10]):

(Og1) for all $s>0$

$$\phi''(s)>0,\qquad \psi''(s)\geq 0;$$

(Og2) there exist $\beta\in[1,2)$, $\gamma\in[0,1)$, and $B>0$ such that for every $s>0$

$$|\phi'(s)|\leq B\left[s^{-\gamma}+s^{\beta}\right],\qquad |\psi'(s)|\leq B[s^{-\gamma}+s^{(\beta-1)/2}].$$

We now show that (Og1) and (Og2) imply (En1)–(En5). First, it is clear that (En5) is satisfied with $\Psi^*\equiv 0$. Next, we differentiate (6.1) with respect to λ_1 and let $\lambda_1=q$ and $\lambda_2=\lambda_3=t$ to get

$$\begin{aligned}\hat{\Psi}_1(q,t)&=\phi'(q)+2t\psi'(qt),\\ \hat{\Psi}_{11}(q,t)&=\phi''(q)+2t^2\psi''(qt).\end{aligned} \tag{6.2}$$

Then (Og1) and $(6.2)_2$ yield (En1). If we differentiate (6.1) with respect to λ_2 and let $\lambda_1=q$ and $\lambda_2=\lambda_3=t$, we get

$$\hat{\Psi}_2(q,t)=\phi'(t)+q\psi'(qt)+t\psi'(t^2), \tag{6.3}$$

and hence, when $q=\kappa t^{-2}$, we find that

$$\hat{\Psi}_2(\kappa t^{-2},t)=\phi'(t)+\kappa t^{-2}\psi'(\kappa t^{-1})+t\psi'(t^2). \tag{6.4}$$

In order to obtain (En3) we take the absolute value of (6.4) and use the triangle inequality and (Og2) to conclude that

$$|\hat{\Psi}_2(\kappa t^{-2},t)|\leq B[(t^{-\gamma}+t^{\beta})+(\kappa^{1-\gamma}t^{\gamma-2}+\kappa^{(\beta+1)/2}t^{-(\beta+3)/2})+(t^{1-2\gamma}+t^{\beta})],$$

which implies (En3). Similarly, if we take $q=\alpha t^{-2}$ in $(6.2)_1$ and use the triangle inequality and (Og2), we obtain

$$|t^{-2}\hat{\Psi}_1(\alpha t^{-2},t)|\leq B[\alpha^{-\gamma}t^{2(\gamma-1)}+\alpha^{\beta}t^{-2(\beta+1)}+2\alpha^{-\gamma}t^{\gamma-1}+2\alpha^{(\beta-1)/2}t^{-(\beta+1)/2}],$$

which approaches zero as $t\to\infty$ since $\gamma<1$. This implies (En2).

In order to obtain (En4) we first use $(6.2)_1$ and (6.3) to get

$$\mathcal{R}(q,t)=\frac{t\phi'(t)-q\phi'(q)}{t-q}+\frac{t^2\psi'(t^2)-qt\psi'(qt)}{t-q}. \tag{6.5}$$

We then fix $\mu>\lambda_*$ and consider two cases: $\frac{1}{2}\lambda_*\leq q<t<\mu$ and $0<q<\frac{1}{2}\lambda_*<\lambda_*<t<\mu$.

Case I. $0 < q < \frac{1}{2}\lambda_* < \lambda_* < t < \mu$. Then $|t-q|^{-1} \leq 2/\lambda_*$, and hence (6.5) together with (Og2) and the triangle inequality yield

$$|\mathcal{R}(q,t)| \leq \frac{2B}{\lambda_*}[t^{1-\gamma} + t^{\beta+1} + q^{1-\gamma} + q^{\beta+1} + t^{2(1-\gamma)} + t^{\beta+1} + (qt)^{1-\gamma} + (qt)^{(\beta+1)/2}],$$

which is bounded for $0 < q < t < \mu$ since $\gamma < 1$. This implies (En4) for small q.

Case II. $\frac{1}{2}\lambda_* \leq q < t < \mu$. Then (6.5) together with the mean-value theorem applied to the functions $\tilde{\phi}(s) := s\phi'(s)$ and $\tilde{\psi}(s) := s\psi'(s)$ yield

$$\mathcal{R}(q,t) = \tilde{\phi}'(c^*) + t\tilde{\psi}'(\hat{c}) \tag{6.6}$$

for some $c^* \in (q,t)$ and $\hat{c} \in (qt, t^2)$. Thus, since ϕ and ψ are C^2, the function $|\mathcal{R}|$ is bounded when $\frac{1}{2}\lambda_* \leq q < t < \mu$. Therefore (En4) is also valid for larger q.

6.2. Deformations. It is easy to construct radial cavitating *deformations*: the specification of a strictly monotone increasing radial Jacobian $J(R)$ that satisfies (3.1) suffices. The content of Theorem 3.3 is that such a deformation will satisfy the radial equilibrium equation for *every* stored energy function of the form (6.1) that satisfies (Og1) and (Og2), *provided* h is defined by (3.4). The difficulty is then ensuring that this equilibrium deformation is the unique radial minimizer of the energy, i.e., that the combination of deformation and stored energy satisfies (5.4).

One method of obtaining a family of such deformations is to perturb from a known solution. We illustrate this idea when the initial solution is isochoric. The resulting deformations will be nearly incompressible, as is expected in many elastomers (see, e.g., [2] or [8]), since the resulting energy will heavily penalize even small changes in volume. First, let's restrict our attention to the energy

$$\Psi(\lambda_1, \lambda_2, \lambda_3) := \phi(\lambda_1) + \phi(\lambda_2) + \phi(\lambda_3), \tag{6.7}$$

where ϕ satisfies (Og1), (Og2) and ϕ' is a convex function. (For example, $\phi(t) = t^{\beta+1}$ with $\beta \in [1,2)$.) Then (5.4) reduces to

$$\frac{d}{dR}\left[R^2\phi'(\rho'(R))\right] < 2R\phi'\left(\frac{\rho(R)}{R}\right)$$

or, equivalently,

$$R\phi''(\rho'(R))\rho''(R) < 2\left[\phi'\left(\frac{\rho(R)}{R}\right) - \phi'(\rho'(R))\right]. \tag{6.8}$$

However, the mapping $t \mapsto \phi'(t)$ is convex:

$$\phi'\left(\frac{\rho(R)}{R}\right) \geq \phi'(\rho'(R)) + \phi''(\rho'(R))\left[\frac{\rho(R)}{R} - \rho'(R)\right],$$

and so, in view of (6.8), a sufficient condition for (5.4) is that the function ρ satisfies

$$R\rho''(R) < 2\left[\frac{\rho(R)}{R} - \rho'(R)\right] \tag{6.9}$$

(or, equivalently, $\frac{d}{dR}\mathrm{trace}(\mathbf{F}) > 0$).

Now, let $\lambda_0 > 0$, and suppose that $\theta : [0,1] \to [0,1]$ is continuous with $\theta > 0$ on $(0,1]$ and that

$$\theta(s) = o(s^6) \quad \text{as} \quad s \to 0^+. \tag{6.10}$$

Then for each $s \in [0,1]$ define

$$\rho(R,s)^3 := 1 + 3\int_0^R J(t,s)t^2\,dt, \tag{6.11}$$

$$J(R,s) := \lambda_0^3 + \theta(s)(1 - e^{-sR}) \tag{6.12}$$

and note that

$$J_R(R,s) = s\theta(s)e^{-sR}, \qquad s\theta(s)\int_0^\infty t^3 e^{-st}\,dt = \frac{6\theta(s)}{s^3}, \tag{6.13}$$

where the subscript R denotes the partial derivative with respect to R. (If $\lambda_0 = 1$, the deformation at $s = 0$ is isochoric.) By (6.13), for each $s > 0$, $R \mapsto J(R,s)$ is strictly monotone increasing and satisfies $(3.1)_3$, provided $0 < \theta(s) \le s^3/6$, which is a consequence of (6.10) for all sufficiently small s.

Next, by (4.2), (4.3), and $(6.13)_1$,

$$R\rho''(R)\left[\frac{\rho(R)}{R}\right]^2 = s\theta(s)Re^{-sR} - 2\rho'(R)\left[\frac{\rho(R)}{R}\right]\left[\rho'(R) - \frac{\rho(R)}{R}\right],$$

which shows that (6.9) is equivalent to

$$s\theta(s)Re^{-sR} < 2\left[\frac{\rho(R)}{R}\right]\left[\frac{\rho(R)}{R} - \rho'(R)\right]^2. \tag{6.14}$$

However, in view of (4.1), (4.2), and $(6.13)_1$,

$$R^6\left[\frac{\rho(R)}{R}\right]^4\left[\frac{\rho(R)}{R} - \rho'(R)\right]^2 = \left[1 - s\theta(s)\int_0^R t^3e^{-st}\,dt\right]^2,$$

so that (6.14) is the same as

$$s\theta(s)R^7\left[\frac{\rho(R)}{R}\right]^3 < 2e^{sR}\left[1 - s\theta(s)\int_0^R t^3e^{-st}\,dt\right]^2. \tag{6.15}$$

Finally, we note that in view of (6.10), $\theta(s) \le s^3/12$ for s sufficiently small, and consequently, by $(6.13)_2$,

$$s\theta(s)\int_0^R t^3e^{-st}\,dt \le \frac{1}{2} \tag{6.16}$$

for small s. In addition, $e^t \ge (1+t^7)/7!$ and hence, upon multiplying (6.15) by $(sR)^{-7}$ and making use of (6.16), it suffices to show

$$2\frac{\theta(s)}{s^6}\left[\frac{\rho(R)}{R}\right]^3 < \frac{1}{7!}\left[(sR)^{-7} + 1\right] \tag{6.17}$$

in order to obtain (6.15). However, for small s, (6.17) is a consequence of (6.10)–(6.12), which completes the example.

TIME REVERSAL AND REFOCUSING IN RANDOM MEDIA*

GUILLAUME BAL† AND LEONID RYZHIK‡

Abstract. In time reversal acoustics experiments, a signal is emitted from a localized source, recorded at an array of receivers, time reversed, and finally reemitted into the medium. A celebrated feature of time reversal experiments is that the refocusing of the reemitted signals at the location of the initial source is improved when the medium is heterogeneous. Contrary to intuition, multiple scattering enhances the spatial resolution of the refocused signal and allows one to beat the diffraction limit obtained in homogeneous media. This paper presents a quantitative explanation of time reversal and other more general refocusing phenomena for general classical waves in heterogeneous media. The theory is based on the asymptotic analysis of the Wigner transform of wave fields in the high frequency limit. Numerical experiments complement the theory.

Key words. waves in random media, time reversal, refocusing, radiative transfer equations, diffusion approximation

1. Introduction.

In time reversal experiments, acoustic waves are emitted from a localized source, recorded in time by an array of receiver-transducers, time reversed, and retransmitted into the medium, so that the signals recorded first are reemitted last and vice versa [7, 8, 13, 16, 18, 19]. The retransmitted signal refocuses at the location of the original source, with a modified shape that depends on the array of receivers. The salient feature of these time reversal experiments is that refocusing is much better when wave propagation occurs in complicated environments than in homogeneous media. Time reversal techniques with improved refocusing in heterogeneous media have found important applications in medicine, nondestructive testing, underwater acoustics, and wireless communications (see the above references). It has also been applied to imaging in weakly random media [4, 13].

A schematic depiction of the time reversal procedure is given in Figure 1.1. Early experiments in time reversal acoustics are described in [7]; see also the more recent papers [11, 12, 13]. A very qualitative explanation for the better refocusing observed in heterogeneous media is based on *multipathing*. Since waves can scatter off a larger number of heterogeneities, more paths coming from the source reach the recording array, thus more is known about the source by the transducers than in a homogeneous medium. The heterogeneous medium plays the role of a lens that widens the aperture through which the array of receivers sees the source. Refocusing is also qualitatively justified by ray theory (geometrical optics). The phase shift caused by multiple scattering is exactly compensated when the time reversed signal follows the same path back to the source location. This phase cancellation happens only at the source location. The phase shift along paths leading to other points in space is essentially

random. The interference of multiple paths will thus be constructive at the source location and destructive anywhere else. This explains why refocusing at the source location is improved when the number of scatterers is large.

As convincing as they are, the above explanations remain qualitative and do not allow us to quantify how the refocused signal is modified by the time reversal procedure. Quantitative justifications require more careful analysis of wave propagation. The first quantitative description of time reversal was obtained in [5] in the framework of randomly layered media (see also the recent work [10]). That paper provides the first mathematical explanation of two of the most prominent features of time reversal: heterogeneities improve refocusing, and refocusing occurs for almost every realization of the random medium. The first multidimensional quantitative description of time reversal was obtained in [3] for the parabolic approximation, i.e., for waves that propagate in a privileged direction with no backscattering (see also [23, 24] for further analysis of time reversal in this regime). That paper shows that the random medium indeed plays the role of a lens. The back-propagated signal behaves as if the initial array were replaced by another one with a much bigger effective aperture. In a slightly different context, a recent paper [2] analyzes time reversal in ergodic cavities. There, wave mixing is created by reflection at the boundary of a chaotic cavity, which plays a role similar to that of the heterogeneities in a heterogeneous medium.

This paper generalizes the results of [3] to the case of general classical waves propagating in weakly fluctuating random media. The main results are briefly sum-

marized as follows. We first show that refocusing in time reversal experiments may be understood in the following three-step more general framework:

(i) A signal propagating from a localized source is recorded at a single time $T > 0$ by an array of receivers.
(ii) The recorded signal is processed at the array location.
(iii) The processed signal is emitted from the array and propagates in the *same* medium for the same time duration T.

The first main result is that the resulting signal will refocus at the location of the original source for a large class of waves and a large class of processings. The experiments described above correspond to the specific processing of acoustic waves in which pressure is kept unchanged and the sign of the velocity field is reversed.

The second main result is a quantitative description of the repropagated signal at time T. We show that the repropagated signal $\mathbf{u}^B(\boldsymbol{\xi})$ at a point $\boldsymbol{\xi}$ near the source location can be written in the high frequency limit as the following convolution of the original source $\mathbf{S}$:

$$\mathbf{u}^B(\boldsymbol{\xi}) = (F * \mathbf{S})(\boldsymbol{\xi}). \tag{1.1}$$

The kernel F depends on the location of the recording array and on the signal processing. The quality of the refocusing depends on the spatial decay of F. It turns out that F can be expressed in terms of the Wigner transform [25] of two wave fields. The decay properties of F depend on the smoothness of the Wigner transform in the phase space. The Wigner transform in random media has been extensively studied [9, 25, 27], especially in the high frequency regime, when the wavelength of the initial signal is small compared to the distance of propagation. It satisfies a radiative transport equation, which is used to describe the evolution of the energy density of waves in random media [17, 25, 26, 27]. The transport equations possess a smoothing effect so that the Wigner distribution becomes less singular in random media, which implies a stronger decay of the convolution kernel F and a better refocusing. The diffusion approximation to the radiative transport equations provides simple reconstruction formulas that can be used to quantify the refocusing quality of the back-propagated signal. This construction applies to a large class of classical waves—acoustic, electromagnetic, elastic, and others—and allows for a large class of signal processings at the recording array.

Some results of this paper have been announced in [1]. The concept of single-time time reversal emerged during early discussions with Knut Solna. We also stress that the important property of self-averaging of the time reversed signal (the refocused signal is almost independent of the realization of the random medium) is not analyzed in this paper. A formal explanation is given in [3, 23, 24] in the parabolic approximation. Self-averaging for classical waves will be addressed elsewhere.

This paper is organized as follows. Section 2 recalls the classical setting of time reversal and introduces single-time time reversal. The retransmitted signal and its relation to the Wigner transform are analyzed in section 3. A quantitative description of acoustic wave refocusing in weakly fluctuating random media is obtained by asymptotic analysis; see (3.42) and (3.43) for an explicit expression in the diffusion approximation. Section 4 generalizes the results in two ways. First, a more general signal processing at the recording array is allowed, such as recording only the pressure field of acoustic waves and not the velocity field. Second, the retransmission scheme is applied to more general waves, and the role of polarization and mode coupling is explained.

2. Classical time reversal and single-time time reversal. Propagation of acoustic waves is described by a system of equations for the pressure $p(t,\mathbf{x})$ and acoustic velocity $\mathbf{v}(t,\mathbf{x})$:

$$\begin{aligned}\rho(\mathbf{x})\frac{\partial \mathbf{v}}{\partial t}+\nabla p=0,\\ \kappa(\mathbf{x})\frac{\partial p}{\partial t}+\nabla\cdot\mathbf{v}=0,\end{aligned} \tag{2.1}$$

with suitable initial conditions and where $\rho(\mathbf{x})$ and $\kappa(\mathbf{x})$ are density and compressibility of the underlying medium, respectively. These equations can be recast as the following linear hyperbolic system:

$$A(\mathbf{x})\frac{\partial \mathbf{u}}{\partial t}+D^j\frac{\partial \mathbf{u}}{\partial x^j}=0,\quad \mathbf{x}\in\mathbb{R}^3, \tag{2.2}$$

with the vector $\mathbf{u}=(\mathbf{v},p)\in\mathbb{C}^4$. The matrix $A=\mathrm{Diag}(\rho,\rho,\rho,\kappa)$ is positive definite. The 4×4 matrices D^j, $j=1,2,3$, are symmetric and given by $D^j_{mn}=\delta_{m4}\delta_{nj}+\delta_{n4}\delta_{mj}$. We use the Einstein convention of summation over repeated indices.

The time reversal experiments in [7] consist of two steps. First, the direct problem

$$\begin{aligned}&A(\mathbf{x})\frac{\partial \mathbf{u}}{\partial t}+D^j\frac{\partial \mathbf{u}}{\partial x^j}=0,\quad 0\le t\le T,\\ &\mathbf{u}(0,\mathbf{x})=\mathbf{S}(\mathbf{x}),\end{aligned} \tag{2.3}$$

with a localized source $\mathbf{S}$ centered at a point $\mathbf{x}_0$, is solved. The signal is recorded during the period of time $0\le t\le T$ by an array of receivers located at $\Omega\subset\mathbb{R}^3$. Second, the signal is time reversed and reemitted into the medium. Time reversal is described by multiplying $\mathbf{u}=(\mathbf{v},p)$ by the matrix $\Gamma=\mathrm{Diag}(-1,-1,-1,1)$. The back-propagated signal solves

$$\begin{aligned}&\frac{\partial \mathbf{u}}{\partial t}+A^{-1}(\mathbf{x})D^j\frac{\partial \mathbf{u}}{\partial x^j}=\frac{1}{T}\mathbf{R}(2T-t,\mathbf{x}),\quad T\le t\le 2T,\\ &\mathbf{u}(T,\mathbf{x})=0,\end{aligned} \tag{2.4}$$

with the source term

$$\mathbf{R}(t,\mathbf{x})=\Gamma\mathbf{u}(t,\mathbf{x})\chi(\mathbf{x}). \tag{2.5}$$

The function $\chi(\mathbf{x})$ is either the characteristic function of the set where the recording array is located, or some other function that allows for possibly space-dependent amplification of the retransmitted signal.

The back-propagated signal is then given by $\mathbf{u}(2T,\mathbf{x})$. We can decompose it as

$$\mathbf{u}(2T,\mathbf{x})=\frac{1}{T}\int_0^T ds\ \mathbf{w}(s,\mathbf{x};s), \tag{2.6}$$

where the vector-valued function $\mathbf{w}(t,\mathbf{x};s)$ solves the initial value problem

$$\begin{aligned}&A(\mathbf{x})\frac{\partial \mathbf{w}(t,\mathbf{x};s)}{\partial t}+D^j\frac{\partial \mathbf{w}(t,\mathbf{x};s)}{\partial x^j}=0,\quad 0\le t\le s,\\ &\mathbf{w}(0,\mathbf{x};s)=\mathbf{R}(s,\mathbf{x}).\end{aligned}$$

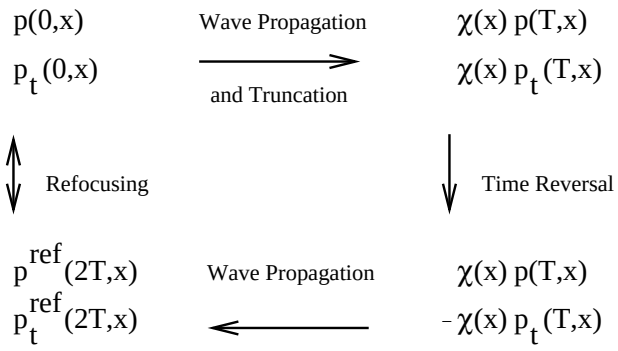

FIG. 2.1. *The single-time time reversal procedure. Here, p_t denotes $\frac{\partial p}{\partial t}$.*

We deduce from (2.6) that it is sufficient to analyze the refocusing properties of $\mathbf{w}(s,\mathbf{x};s)$ for $0 \le s \le T$ to obtain those of $\mathbf{u}(2T,\mathbf{x})$. For a fixed value of s, we call the construction of $\mathbf{w}(s,\mathbf{x};s)$ single-time time reversal.

We define single-time time reversal more generally as follows. The direct problem (2.3) is solved until time $t = T$ to yield $\mathbf{u}(T^-,\mathbf{x})$. At time T, the signal is recorded and processed. The processing is modeled by an amplification function $\chi(\mathbf{x})$, a blurring kernel $f(\mathbf{x})$, and a (possibly spatially varying) time reversal matrix Γ. After processing, we have

$$\mathbf{u}(T^+,\mathbf{x}) = \Gamma(f * (\chi\mathbf{u}))(T^-,\mathbf{x})\chi(\mathbf{x}). \tag{2.7}$$

The processed signal then propagates for the same time duration T:

$$\begin{aligned} &A(\mathbf{x})\frac{\partial \mathbf{u}}{\partial t} + D^j\frac{\partial \mathbf{u}}{\partial x^j} = 0, \quad T \le t \le 2T, \\ &\mathbf{u}(T^+,\mathbf{x}) = \Gamma(f * (\chi\mathbf{u}))(T^-,\mathbf{x})\chi(\mathbf{x}). \end{aligned} \tag{2.8}$$

The main questions are whether $\mathbf{u}(2T,\mathbf{x})$ refocuses at the location of the original source $\mathbf{S}(\mathbf{x})$ and how the original signal has been modified by the time reversal procedure. Notice that in the case of full ($\Omega = \mathbb{R}^3$) and exact ($f(\mathbf{x}) = \delta(\mathbf{x})$) measurements with $\Gamma = \mathrm{Diag}(-1,-1,-1,1)$, the time-reversibility of first-order hyperbolic systems implies that $\mathbf{u}(2T,\mathbf{x}) = \Gamma\mathbf{S}(\mathbf{x})$, which corresponds to exact refocusing. When only partial measurements are available, we shall see in the following sections that $\mathbf{u}(2T,\mathbf{x})$ is closer to $\Gamma\mathbf{S}(\mathbf{x})$ when propagation occurs in a heterogeneous medium than in a homogeneous medium.

The pressure field $p(t,\mathbf{x})$ satisfies the following scalar wave equation:

$$\frac{\partial^2 p}{\partial t^2} - \frac{1}{\kappa(\mathbf{x})}\nabla\cdot\left(\frac{1}{\rho(\mathbf{x})}\nabla p\right) = 0. \tag{2.9}$$

A schematic description of the single-time procedure for the wave equation is presented in Figure 2.1. This is the equation solved in the numerical experiments presented in this paper. The details of the numerical setting are described in the appendix. A numerical experiment for the single-time time reversal procedure is shown in Figure 2.2. In the numerical simulations, there is no blurring, $f(\mathbf{x}) = \delta(\mathbf{x})$, and the array of receivers is the domain $\Omega = (-1/6, 1/6)^2$. ($\chi(\mathbf{x})$ is the characteristic function of Ω.) Note that the truncated signal does not retain much information about the

ballistic part of the original wave (the part that propagates without scattering with the underlying medium). If we were in three space dimensions, the truncated signal in a homogeneous medium would even be identically zero, and no refocusing would be observed. The interesting aspect of time reversal is that a coherent signal emerges at time $2T$ out of a signal at time T^+ that seems to have no useful information.

3. Theory of time reversal in random media. Our objective now is to present a theory that explains in a quantitative manner the refocusing properties described in the preceding sections. We consider here the single-time time reversal for acoustic waves. Generalizations to other types of waves and more general processings in (2.8) are given in section 4.

3.1. Refocused signal. We recall that the single-time time reversal procedure consists of letting an initial pulse $\mathbf{S}(\mathbf{x})$ propagate according to (2.3) until time T,

$$\mathbf{u}(T^-,\mathbf{x}) = \int_{\mathbb{R}^3} G(T,\mathbf{x};\mathbf{z})\mathbf{S}(\mathbf{z})d\mathbf{z},$$

where $G(T,\mathbf{x};\mathbf{z})$ is the Green's matrix solution of

$$A(\mathbf{x})\frac{\partial G(t,\mathbf{x};\mathbf{y})}{\partial t}+D^j\frac{\partial G(t,\mathbf{x};\mathbf{y})}{\partial x^j}=0,\quad 0\le t\le T,\tag{3.1}$$
$$G(0,\mathbf{x};\mathbf{y})=I\delta(\mathbf{x}-\mathbf{y}).$$

At time T, the "intelligent" array reverses the signal. For acoustic pulses, this means keeping pressure unchanged and reversing the sign of the velocity field. The array of receivers is located in $\Omega\subset\mathbb{R}^3$. The amplification function $\chi(\mathbf{x})$ is an arbitrary bounded function supported in Ω, such as its characteristic function ($\chi(\mathbf{x})=1$ for $\mathbf{x}\in\Omega$ and $\chi(\mathbf{x})=0$ otherwise) when all transducers have the same amplification factor. We also allow for some blurring of the recorded data modeled by a convolution with a function $f(\mathbf{x})$. The case $f(\mathbf{x})=\delta(\mathbf{x})$ corresponds to exact measurements. Finally, the signal is time reversed, that is, the direction of the acoustic velocity is reversed. Here, the operator Γ in (2.7) is simply multiplication by the matrix

$$\Gamma=\mathrm{Diag}(-1,-1,-1,1).\tag{3.2}$$

The signal at time T^+ after time reversal then takes the form

$$\mathbf{u}(T^+,\mathbf{x})=\int_{\mathbb{R}^6}\Gamma G(T,\mathbf{y}';\mathbf{z})\chi(\mathbf{x})\chi(\mathbf{y}')f(\mathbf{x}-\mathbf{y}')\mathbf{S}(\mathbf{z})d\mathbf{z}d\mathbf{y}'.\tag{3.3}$$

The last step (2.8) consists of letting the time reversed field propagate through the random medium until time $2T$. To compare this signal with the initial pulse $\mathbf{S}$, we need to reverse the acoustic velocity once again and define

$$\mathbf{u}^B(\mathbf{x})=\Gamma\mathbf{u}(2T,\mathbf{x})=\int_{\mathbb{R}^9}\Gamma G(T,\mathbf{x};\mathbf{y})\Gamma G(T,\mathbf{y}';\mathbf{z})\chi(\mathbf{y})\chi(\mathbf{y}')f(\mathbf{y}-\mathbf{y}')\mathbf{S}(\mathbf{z})d\mathbf{y}d\mathbf{y}'d\mathbf{z}.\tag{3.4}$$

The time-reversibility of first-order hyperbolic systems implies that $\mathbf{u}^B(\mathbf{x})=\mathbf{S}(\mathbf{x})$ when $\Omega=\mathbb{R}^3$, $\chi\equiv 1$, and $f(\mathbf{x})=\delta(\mathbf{x})$, that is, when full and nondistorted measurements are available. It remains to understand which features of $\mathbf{S}$ are retained by $\mathbf{u}^B(\mathbf{x})$ when only partial measurement is available.

3.2. Localized source and scaling. We consider an asymptotic solution of the time reversal problem (2.3), (2.8) when the support λ of the initial pulse $\mathbf{S}(\mathbf{x})$ is much smaller than the distance L of propagation between the source and the recording array: $\varepsilon=\lambda/L\ll 1$. We also take the size a of the array comparable to L: $a/L=O(1)$. We assume that the time T between the emission of the original signal and recording is of order L/c_0, where c_0 is a typical speed of propagation of the acoustic wave. We consequently consider the initial pulse to be of the form

$$\mathbf{u}(0,\mathbf{x})=\mathbf{S}\left(\frac{\mathbf{x}-\mathbf{x}_0}{\varepsilon}\right)$$

in nondimensionalized variables $\mathbf{x}'=\mathbf{x}/L$ and $t'=t/(L/c_0)$. We drop primes to simplify notation. Here $\mathbf{x}_0$ is the location of the source. The transducers obviously have to be capable of capturing signals of frequency ε^{-1}, and blurring should happen on the scale of the source, so we replace $f(\mathbf{x})$ by $\varepsilon^{-3}f(\varepsilon^{-1}\mathbf{x})$. Finally, we are interested

in the refocusing properties of $\mathbf{u}^B(\mathbf{x})$ in the vicinity of $\mathbf{x}_0$. We therefore introduce the scaling $\mathbf{x} = \mathbf{x}_0 + \varepsilon\boldsymbol{\xi}$. With these changes of variables, expression (3.4) is recast as

$$\begin{aligned}\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0) &= \Gamma\mathbf{u}(2T,\mathbf{x}_0+\varepsilon\boldsymbol{\xi}) \\ &= \int_{\mathbb{R}^9} \Gamma G(T,\mathbf{x}_0+\varepsilon\boldsymbol{\xi};\mathbf{y})\Gamma G(T,\mathbf{y}';\mathbf{x}_0+\varepsilon\mathbf{z})\chi(\mathbf{y},\mathbf{y}')\mathbf{S}(\mathbf{z})d\mathbf{y}d\mathbf{y}'d\mathbf{z},\end{aligned} \tag{3.5}$$

where

$$\chi(\mathbf{y},\mathbf{y}') = \chi(\mathbf{y})\chi(\mathbf{y}')f\left(\frac{\mathbf{y}-\mathbf{y}'}{\varepsilon}\right). \tag{3.6}$$

In what follows we will also allow the medium to vary on a scale comparable to the source scale ε. Thus the Green's function G and the matrix A depend on ε. To simplify notation we do not make this dependence explicit. We are interested in the limit of $\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0)$ as $\varepsilon \to 0$. The scaling considered here is well adapted both to the physical experiments in [7] and the numerical experiments in Figure 2.2.

3.3. Adjoint Green's function. The analysis of the repropagated signal relies on the study of the two point correlation at nearby points of the Green's matrix in (3.5). There are two undesirable features in (3.5). First, the two nearby points $\mathbf{x}_0+\varepsilon\boldsymbol{\xi}$ and $\mathbf{x}_0+\varepsilon\mathbf{z}$ are terminal and initial points in their respective Green's matrices. Second, one would like to have the product of two Green's functions, with no matrix Γ in between. However, Γ and G do not commute. For these reasons, we introduce the *adjoint* Green's matrix, solution of

$$\begin{aligned}&\frac{\partial G_*(t,\mathbf{x};\mathbf{y})}{\partial t}A(\mathbf{x}) + \frac{\partial G_*(t,\mathbf{x};\mathbf{y})}{\partial x^j}D^j = 0, \\ &G_*(0,\mathbf{x};\mathbf{y}) = A^{-1}(\mathbf{x})\delta(\mathbf{x}-\mathbf{y}).\end{aligned} \tag{3.7}$$

We now prove that

$$G_*(t,\mathbf{x};\mathbf{y}) = \Gamma G(t,\mathbf{y};\mathbf{x})A^{-1}(\mathbf{x})\Gamma. \tag{3.8}$$

Note that for all initial data $\mathbf{S}(\mathbf{x})$, the solution $\mathbf{u}(t,\mathbf{x})$ of (2.3) satisfies

$$\mathbf{u}(t,\mathbf{x}) = \int_{\mathbb{R}^3} G(t-s,\mathbf{x};\mathbf{y})\mathbf{u}(s,\mathbf{y})d\mathbf{y}$$

for all $0 \le s \le t \le T$ since the coefficients in (2.3) are time-independent. Differentiating the above with respect to s and using (2.3) yields

$$0 = \int_{\mathbb{R}^3}\left(-\frac{\partial G(t-s,\mathbf{x};\mathbf{y})}{\partial t}\mathbf{u}(s,\mathbf{y}) - G(t-s,\mathbf{x};\mathbf{y})A^{-1}(\mathbf{y})D^j\frac{\partial\mathbf{u}(s,\mathbf{y})}{\partial y^j}\right)d\mathbf{y}.$$

Upon integrating by parts and letting $s=0$, we get

$$0 = \int_{\mathbb{R}^3}\left(-\frac{\partial G(t,\mathbf{x};\mathbf{y})}{\partial t} + \frac{\partial}{\partial y^j}\left[G(t,\mathbf{x};\mathbf{y})A^{-1}(\mathbf{y})D^j\right]\right)\mathbf{S}(\mathbf{y})d\mathbf{y}.$$

Since the above relation holds for all test functions $\mathbf{S}(\mathbf{y})$, we deduce that

$$\frac{\partial G(t,\mathbf{x};\mathbf{y})}{\partial t} - \frac{\partial}{\partial y^j}\left[G(t,\mathbf{x};\mathbf{y})A^{-1}(\mathbf{y})D^j\right] = 0. \tag{3.9}$$

Interchanging $\mathbf{x}$ and $\mathbf{y}$ in the above equation and multiplying it on the left and the right by Γ, we obtain that

$$\frac{\partial}{\partial t}\left[\Gamma G(t,\mathbf{y};\mathbf{x})A^{-1}(\mathbf{x})\right]A(\mathbf{x})\Gamma-\frac{\partial}{\partial x^j}\left[\Gamma G(t,\mathbf{y};\mathbf{x})A^{-1}(\mathbf{x})\right]D^j\Gamma=0. \tag{3.10}$$

We remark that with the choice of Γ in (3.2) we have

$$\Gamma D^j=-D^j\Gamma \qquad \text{and} \qquad \Gamma A(\mathbf{x})=A(\mathbf{x})\Gamma, \tag{3.11}$$

so that

$$\frac{\partial}{\partial t}\left[\Gamma G(t,\mathbf{y};\mathbf{x})A^{-1}(\mathbf{x})\Gamma\right]A(\mathbf{x})+\frac{\partial}{\partial x^j}\left[\Gamma G(t,\mathbf{y};\mathbf{x})A^{-1}(\mathbf{x})\Gamma\right]D^j=0$$

with $\Gamma G(0,\mathbf{y};\mathbf{x})A^{-1}(\mathbf{x})\Gamma=A^{-1}(\mathbf{x})\delta(\mathbf{x}-\mathbf{y})$. Thus (3.8) follows from the uniqueness of the solution to the above hyperbolic system with given initial conditions. We can now recast (3.5) as

$$\begin{aligned}\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0)\;=\;&\int_{\mathbb{R}^9}\Gamma G(T,\mathbf{x}_0+\varepsilon\boldsymbol{\xi};\mathbf{y})G_*(T,\mathbf{x}_0+\varepsilon\mathbf{z};\mathbf{y}')\Gamma\\&\times\chi(\mathbf{y})\chi(\mathbf{y}')f\left(\frac{\mathbf{y}-\mathbf{y}'}{\varepsilon}\right)A(\mathbf{x}_0+\varepsilon\mathbf{z})\mathbf{S}(\mathbf{z})d\mathbf{y}d\mathbf{y}'d\mathbf{z}.\end{aligned} \tag{3.12}$$

One further simplifies (3.12) with the help of the auxiliary matrix-valued functions $Q(t,\mathbf{x};\mathbf{q})$ and $Q_*(t,\mathbf{x},\mathbf{q})$ defined by

$$\begin{aligned}Q(T,\mathbf{x};\mathbf{q})&=\int_{\mathbb{R}^3}G(T,\mathbf{x};\mathbf{y})\chi(\mathbf{y})e^{i\mathbf{q}\cdot\mathbf{y}/\varepsilon}d\mathbf{y},\\Q_*(T,\mathbf{x};\mathbf{q})&=\int_{\mathbb{R}^3}G_*(T,\mathbf{x};\mathbf{y})\chi(\mathbf{y})e^{-i\mathbf{q}\cdot\mathbf{y}/\varepsilon}d\mathbf{y}.\end{aligned} \tag{3.13}$$

They solve the hyperbolic equations (2.3) and (3.7) with initial conditions given by $Q(0,\mathbf{x};\mathbf{q})=\chi(\mathbf{x})e^{i\mathbf{q}\cdot\mathbf{x}/\varepsilon}I$ and $Q_*(0,\mathbf{x};\mathbf{q})=A^{-1}(\mathbf{x})\chi(\mathbf{x})e^{-i\mathbf{q}\cdot\mathbf{x}/\varepsilon}$, respectively. Thus (3.12) becomes

$$\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0)=\int_{\mathbb{R}^6}\Gamma Q(T,\mathbf{x}_0+\varepsilon\boldsymbol{\xi};\mathbf{q})Q_*(T,\mathbf{x}_0+\varepsilon\mathbf{z};\mathbf{q})\Gamma A(\mathbf{x}_0+\varepsilon\mathbf{z})\mathbf{S}(\mathbf{z})\hat{f}(\mathbf{q})\frac{d\mathbf{q}d\mathbf{z}}{(2\pi)^3}, \tag{3.14}$$

where $\hat{f}(\mathbf{q})=\int_{\mathbb{R}^3}e^{-i\mathbf{q}\cdot\mathbf{x}}f(\mathbf{x})d\mathbf{x}$ is the Fourier transform of $f(\mathbf{x})$.

3.4. Wigner transform. The back-propagated signal in (3.14) now has the form suitable to be analyzed in the Wigner transform formalism [14, 25]. We define

$$W_\varepsilon(t,\mathbf{x},\mathbf{k})=\int_{\mathbb{R}^3}\hat{f}(\mathbf{q})U_\varepsilon(t,\mathbf{x},\mathbf{k};\mathbf{q})d\mathbf{q}, \tag{3.15}$$

where

$$U_\varepsilon(t,\mathbf{x},\mathbf{k};\mathbf{q})=\int_{\mathbb{R}^3}e^{i\mathbf{k}\cdot\mathbf{y}}Q\left(t,\mathbf{x}-\frac{\varepsilon\mathbf{y}}{2};\mathbf{q}\right)Q_*\left(t,\mathbf{x}+\frac{\varepsilon\mathbf{y}}{2};\mathbf{q}\right)\frac{d\mathbf{y}}{(2\pi)^3}. \tag{3.16}$$

Taking the inverse Fourier transform, we verify that

$$Q(t,\mathbf{x};\mathbf{q})Q_*(t,\mathbf{y};\mathbf{q})=\int_{\mathbb{R}^3}e^{-i\mathbf{k}\cdot(\mathbf{y}-\mathbf{x})/\varepsilon}U_\varepsilon\left(t,\frac{\mathbf{x}+\mathbf{y}}{2},\mathbf{k};\mathbf{q}\right)d\mathbf{k};$$

hence

$$\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0)=\int_{\mathbb{R}^6} e^{i\mathbf{k}\cdot(\boldsymbol{\xi}-\mathbf{z})}\Gamma W_\varepsilon\left(T,\mathbf{x}_0+\varepsilon\frac{\mathbf{z}+\boldsymbol{\xi}}{2},\mathbf{k}\right)\Gamma A(\mathbf{x}_0+\varepsilon\mathbf{z})\mathbf{S}(\mathbf{z})\frac{d\mathbf{z}d\mathbf{k}}{(2\pi)^3}. \tag{3.17}$$

We have thus reduced the analysis of $\mathbf{u}(\boldsymbol{\xi};\mathbf{x}_0)$ as $\varepsilon\to 0$ to that of the asymptotic properties of the Wigner transform W_ε. The Wigner transform has been used extensively in the study of wave propagation in random media, especially in the derivation of radiative transport equations modeling the propagation of high frequency waves. We refer to [14, 21, 25]. Note that in the usual definition of the Wigner transform, one has the adjoint matrix Q^* in place of Q_* in (3.16). This difference is not essential since Q_* and Q^* satisfy the same evolution equation, though with different initial data.

The main reason for using the Wigner transform in (3.17) is that W_ε has a weak limit W as $\varepsilon\to 0$. Its existence follows from simple a priori bounds for $W_\varepsilon(t,\mathbf{x},\mathbf{k})$. Let us introduce the space $\mathcal{A}$ of matrix-valued functions $\phi(\mathbf{x},\mathbf{k})$ bounded in the norm $\|\cdot\|_{\mathcal{A}}$ defined by

$$\|\phi\|_{\mathcal{A}}=\int_{\mathbb{R}^3}\sup_{\mathbf{x}}\|\tilde{\phi}(\mathbf{x},\mathbf{y})\|d\mathbf{y},\qquad\text{where}\quad\tilde{\phi}(\mathbf{x},\mathbf{y})=\int_{\mathbb{R}^3}e^{-i\mathbf{k}\cdot\mathbf{y}}\phi(\mathbf{x},\mathbf{k})d\mathbf{k}.$$

We denote by $\mathcal{A}'$ its dual space, which is a space of distributions large enough to contain matrix-valued bounded measures, for instance. We then have the following result.

LEMMA 3.1. *Let $\chi(\mathbf{x})\in L^2(\mathbb{R}^3)$ and $\hat{f}(\mathbf{q})\in L^1(\mathbb{R}^3)$. Then there is a constant $C>0$ independent of $\varepsilon>0$ and $t\in[0,\infty)$ such that for all $t\in[0,\infty)$ we have $\|W_\varepsilon(t,\mathbf{x},\mathbf{k})\|_{\mathcal{A}'}<C$.*

The proof of this lemma is essentially contained in [14, 21]; see also [1]. One may actually get L^2-bounds for W_ε in our setting because of the regularizing effect of $\hat{f}$ in (3.15), but this is not essential for the purposes of this paper. We therefore obtain the existence of a subsequence $\varepsilon_k\to 0$ such that W_{ε_k} converges weakly to a distribution $W\in\mathcal{A}'$. Moreover, an easy calculation shows that at time $t=0$ we have

$$W(0,\mathbf{x}_0,\mathbf{k})=|\chi(\mathbf{x}_0)|^2A_0^{-1}(\mathbf{x}_0)\hat{f}(\mathbf{k}). \tag{3.18}$$

Here, $A_0=A$ when A is independent of ε, and $A_0=\lim_{\varepsilon\to 0}A_\varepsilon$ if we assume that the family of diagonal matrices $A_\varepsilon(\mathbf{x})$ is uniformly positive definite, bounded, and continuous with limit A_0 in $\mathcal{C}(\mathbb{R}^d)$. These assumptions on A_ε are sufficient to deal with the radiative transport regime we will consider in section 3.7. Under the same assumptions on A_ε, we have the following result.

PROPOSITION 3.2. *The back-propagated signal $\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0)$ given by (3.17) converges weakly in $\mathcal{S}'(\mathbb{R}^3\times\mathbb{R}^3)$ as $\varepsilon\to 0$ to the limit*

$$\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0)=\int_{\mathbb{R}^6}e^{i\mathbf{k}\cdot(\boldsymbol{\xi}-\mathbf{z})}\Gamma W(T,\mathbf{x}_0,\mathbf{k})\Gamma A_0(\mathbf{x}_0)\mathbf{S}(\mathbf{z})\frac{d\mathbf{z}d\mathbf{k}}{(2\pi)^3}. \tag{3.19}$$

The proof of this proposition is based on taking the duality product of $\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0)$ with a vector-valued test function $\boldsymbol{\phi}(\boldsymbol{\xi};\mathbf{x}_0)$ in $\mathcal{S}(\mathbb{R}^3\times\mathbb{R}^3)$. After a change of variables we obtain $\langle\mathbf{u}^B,\boldsymbol{\phi}\rangle=\langle W_\varepsilon,Z_\varepsilon\rangle$. Here the duality product for matrices is given by the trace $\langle A,B\rangle=\sum_{i,k}\langle A_{ik},B_{ik}\rangle$, and

$$Z_\varepsilon(\mathbf{x}_0,\mathbf{k})=\int_{\mathbb{R}^6}e^{i\mathbf{k}\cdot(\mathbf{z}-\boldsymbol{\xi})}\Gamma\boldsymbol{\phi}\left(\boldsymbol{\xi},\mathbf{x}_0-\varepsilon\frac{\mathbf{z}+\boldsymbol{\xi}}{2}\right)\mathbf{S}^*(\mathbf{z})A_\varepsilon\left(\mathbf{x}_0+\varepsilon\frac{\mathbf{z}-\boldsymbol{\xi}}{2}\right)\Gamma\frac{d\mathbf{z}d\boldsymbol{\xi}}{(2\pi)^3}. \tag{3.20}$$

Defining Z as the limit of Z_ε as $\varepsilon \to 0$ by formally replacing ε by 0 in the above expression, (3.19) follows from showing that $\|Z_\varepsilon - Z\|_{\mathcal{A}} \to 0$ as $\varepsilon \to 0$. This is straightforward, and we omit the details.

The above proposition tells us how to reconstruct the back-propagated solution in the high frequency limit from the limit Wigner matrix W. Notice that we have made almost no assumptions on the medium described by the matrix $A_\varepsilon(\mathbf{x})$. At this level, the medium can be either homogeneous or heterogeneous. Without any further assumptions, we can also obtain some information about the matrix W. Let us define the dispersion matrix for the system (2.3) as (see [25])

$$L(\mathbf{x},\mathbf{k}) = A_0^{-1}(\mathbf{x})k_j D^j. \tag{3.21}$$

This is given explicitly by

$$L(\mathbf{x},\mathbf{k}) = \begin{pmatrix} 0 & 0 & 0 & k_1/\rho(\mathbf{x}) \\ 0 & 0 & 0 & k_2/\rho(\mathbf{x}) \\ 0 & 0 & 0 & k_3/\rho(\mathbf{x}) \\ k_1/\kappa(\mathbf{x}) & k_2/\kappa(\mathbf{x}) & k_3/\kappa(\mathbf{x}) & 0 \end{pmatrix}.$$

The matrix L has a double eigenvalue $\omega_0 = 0$ and two simple eigenvalues $\omega_\pm(\mathbf{x},\mathbf{k}) = \pm c(\mathbf{x})|\mathbf{k}|$, where $c(\mathbf{x}) = 1/\sqrt{\rho(\mathbf{x})\kappa(\mathbf{x})}$ is the speed of sound. The eigenvalues $\omega_\pm$ are associated with eigenvectors $\mathbf{b}_\pm(\mathbf{x},\mathbf{k})$, and the eigenvalue $\omega_0 = 0$ is associated with the eigenvectors $\mathbf{b}_j(\mathbf{x},\mathbf{k})$, $j = 1, 2$. The eigenvectors are given by

$$\mathbf{b}_\pm(\mathbf{x},\mathbf{k}) = \begin{pmatrix} \pm\dfrac{\hat{\mathbf{k}}}{\sqrt{2\rho(\mathbf{x})}} \\ \dfrac{1}{\sqrt{2\kappa(\mathbf{x})}} \end{pmatrix}, \qquad \mathbf{b}_j(\mathbf{x},\mathbf{k}) = \begin{pmatrix} \dfrac{\mathbf{z}^j(\mathbf{k})}{\sqrt{\rho(\mathbf{x})}} \\ 0 \end{pmatrix}, \tag{3.22}$$

where $\hat{\mathbf{k}} = \mathbf{k}/|\mathbf{k}|$ and $\mathbf{z}^1(\mathbf{k})$ and $\mathbf{z}^2(\mathbf{k})$ are chosen so that the triple $(\hat{\mathbf{k}}, \mathbf{z}^1(\mathbf{k}), \mathbf{z}^2(\mathbf{k}))$ forms an orthonormal basis. The eigenvectors are normalized so that

$$(A_0(\mathbf{x})\mathbf{b}_j(\mathbf{x},\mathbf{k}) \cdot \mathbf{b}_k(\mathbf{x},\mathbf{k})) = \delta_{jk} \tag{3.23}$$

for all $j, k \in J = \{+, -, 1, 2\}$. The space of 4×4 matrices is clearly spanned by the basis $\mathbf{b}_j \otimes \mathbf{b}_k$. We then have the following result.

PROPOSITION 3.3. *There exist scalar distributions $a_\pm$ and a_0^{mn}, $m, n = 1, 2$, so that the limit Wigner distribution matrix can be decomposed as*

$$\begin{aligned} W(t,\mathbf{x},\mathbf{k}) = &\sum_{j,m=1}^{2} a_0^{jm}(t,\mathbf{x},\mathbf{k})\mathbf{b}_j(\mathbf{x},\mathbf{k}) \otimes \mathbf{b}_m(\mathbf{x},\mathbf{k}) \\ &+ a_+(t,\mathbf{x},\mathbf{k})\mathbf{b}_+(\mathbf{x},\mathbf{k}) \otimes \mathbf{b}_+(\mathbf{x},\mathbf{k}) + a_-(t,\mathbf{x},\mathbf{k})\mathbf{b}_-(\mathbf{x},\mathbf{k}) \otimes \mathbf{b}_-(\mathbf{x},\mathbf{k}). \end{aligned} \tag{3.24}$$

The main result of this proposition is that the cross terms $\mathbf{b}_j \otimes \mathbf{b}_k$ with $\omega_j \neq \omega_k$ do not contribute to the limit W. The proof of this proposition can be found in [14] and a formal derivation in [25].

The initial conditions for the amplitudes a_j are calculated using the identity

$$A_0^{-1}(\mathbf{x}) = \sum_{j \in J} \mathbf{b}_j(\mathbf{x},\mathbf{k}) \otimes \mathbf{b}_j(\mathbf{x},\mathbf{k}).$$

Then (3.18) implies that $a_0^{12}(0,\mathbf{x},\mathbf{k}) = a_0^{21}(0,\mathbf{x},\mathbf{k}) = 0$ and

$$a_0^{jj}(0,\mathbf{x},\mathbf{k}) = a_\pm(0,\mathbf{x},\mathbf{k}) = |\chi(\mathbf{x})|^2 f(\mathbf{k}), \quad j = 1, 2. \tag{3.25}$$

3.5. Mode decomposition and refocusing. We can use the above result to recast (3.19) as

$$\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0) = (F(T,\cdot;\mathbf{x}_0) * \mathbf{S})(\boldsymbol{\xi}), \tag{3.26}$$

where

$$\begin{aligned} F(T,\boldsymbol{\xi};\mathbf{x}_0) = &\sum_{m,n=1}^{2} \int_{\mathbb{R}^3} e^{i\mathbf{k}\cdot\boldsymbol{\xi}} a_0^{mn}(T,\mathbf{x}_0;\mathbf{k}) \Gamma \mathbf{b}_m(\mathbf{x}_0,\mathbf{k}) \otimes \mathbf{b}_n(\mathbf{x}_0,\mathbf{k}) A_0(\mathbf{x}_0) \Gamma \frac{d\mathbf{k}}{(2\pi)^3} \\ &+ \int_{\mathbb{R}^3} e^{i\mathbf{k}\cdot\boldsymbol{\xi}} a_+(T,\mathbf{x}_0;\mathbf{k}) \Gamma \mathbf{b}_+(\mathbf{x}_0,\mathbf{k}) \otimes \mathbf{b}_+(\mathbf{x}_0,\mathbf{k}) A_0(\mathbf{x}_0) \Gamma \frac{d\mathbf{k}}{(2\pi)^3} \\ &+ \int_{\mathbb{R}^3} e^{i\mathbf{k}\cdot\boldsymbol{\xi}} a_-(T,\mathbf{x}_0;\mathbf{k}) \Gamma \mathbf{b}_-(\mathbf{x}_0,\mathbf{k}) \otimes \mathbf{b}_-(\mathbf{x}_0,\mathbf{k}) A_0(\mathbf{x}_0) \Gamma \frac{d\mathbf{k}}{(2\pi)^3}. \end{aligned} \tag{3.27}$$

This expression can be used to assess the quality of the refocusing. When $F(T,\boldsymbol{\xi};\mathbf{x}_0)$ has a narrow support in $\boldsymbol{\xi}$, refocusing is good. When its support in $\boldsymbol{\xi}$ grows larger, its quality degrades. The spatial decay of the kernel $F(t,\boldsymbol{\xi};\mathbf{x}_0)$ in $\boldsymbol{\xi}$ is directly related to the smoothness in $\mathbf{k}$ of its Fourier transform in $\boldsymbol{\xi}$:

$$\begin{aligned} \hat{F}(T,\mathbf{k};\mathbf{x}_0) = &\sum_{m,n=1}^{2} a_0^{mn}(T,\mathbf{x}_0;\mathbf{k}) \Gamma \mathbf{b}_m(\mathbf{x}_0,\mathbf{k}) \otimes \mathbf{b}_n(\mathbf{x}_0,\mathbf{k}) A_0(\mathbf{x}_0) \Gamma \frac{d\mathbf{k}}{(2\pi)^3} \\ &+ \Gamma \left[a_+(T,\mathbf{x}_0;\mathbf{k}) \mathbf{b}_+(\mathbf{x}_0,\mathbf{k}) \otimes \mathbf{b}_+(\mathbf{x}_0,\mathbf{k}) + a_-(T,\mathbf{x}_0;\mathbf{k}) \mathbf{b}_-(\mathbf{x}_0,\mathbf{k}) \otimes \mathbf{b}_-(\mathbf{x}_0,\mathbf{k}) \right] A_0(\mathbf{x}_0) \Gamma. \end{aligned}$$

Namely, for F to decay in $\boldsymbol{\xi}$, one needs $\hat{F}(\mathbf{k})$ to be smooth in $\mathbf{k}$. However, the eigenvectors $\mathbf{b}_j$ are singular at $\mathbf{k}=0$ as can be seen from the explicit expressions (3.22). Therefore, a priori $\hat{F}$ is not smooth at $\mathbf{k}=0$. This means that, in order to obtain good refocusing, one needs the original signal to have no low frequencies: $\hat{S}(\mathbf{k})=0$ near $\mathbf{k}=0$. Low frequencies in the initial data will not refocus well.

We can further simplify (3.26)–(3.27) if we assume that the initial condition is irrotational. Taking the Fourier transform of both sides in (3.26), we obtain that

$$\hat{\mathbf{u}}^B(\mathbf{k};\mathbf{x}_0) = \sum_{j,n\in J} a_j(T,\mathbf{x}_0,\mathbf{k}) \hat{S}_n(\mathbf{k}) (A_0(\mathbf{x}_0)\Gamma \mathbf{b}_n(\mathbf{x}_0,\mathbf{k}) \cdot \mathbf{b}_j(\mathbf{x}_0,\mathbf{k})) \Gamma \mathbf{b}_j(\mathbf{x}_0,\mathbf{k}), \tag{3.28}$$

where we have defined

$$\hat{\mathbf{S}}(\mathbf{k}) = \sum_{n\in J} \hat{S}_n(\mathbf{k}) \mathbf{b}_n(\mathbf{x}_0,\mathbf{k}). \tag{3.29}$$

Irrotationality of the initial condition means that $\hat{S}_1$ and $\hat{S}_2$ identically vanish, or equivalently that

$$\mathbf{S}(\mathbf{x}) = \begin{pmatrix} \nabla\phi(\mathbf{x}) \\ p(\mathbf{x}) \end{pmatrix} \tag{3.30}$$

for some pressure $p(\mathbf{x})$ and potential $\phi(\mathbf{x})$. Remarking that $\Gamma\mathbf{b}_\pm = -\mathbf{b}_\mp$ and by irrotationality that $(A_0(\mathbf{x}_0)\hat{\mathbf{S}}(\mathbf{k}) \cdot \mathbf{b}_{1,2}(\mathbf{k})) = 0$, we use (3.23) to recast (3.28) as

$$\hat{\mathbf{u}}^B(\mathbf{k};\mathbf{x}_0) = a_-(T,\mathbf{x}_0,\mathbf{k}) \hat{S}_+(\mathbf{k}) \mathbf{b}_+(\mathbf{x}_0,\mathbf{k}) + a_+(T,\mathbf{x}_0,\mathbf{k}) \hat{S}_-(\mathbf{k}) \mathbf{b}_-(\mathbf{x}_0,\mathbf{k}). \tag{3.31}$$

Decomposing the initial condition $\mathbf{S}(\mathbf{x})$ as

$$\mathbf{S}(\mathbf{x}) = \mathbf{S}_+(\mathbf{x}) + \mathbf{S}_-(\mathbf{x}) \qquad \text{such that} \quad \hat{\mathbf{S}}_\pm(\mathbf{k}) = \hat{S}_\pm(\mathbf{k})\mathbf{b}_\pm(\mathbf{x}_0, \mathbf{k}),$$

the back-propagated signal takes the form

$$\mathbf{u}^B(\boldsymbol{\xi}; \mathbf{x}_0) = (\hat{a}_-(T, \mathbf{x}_0, \cdot) * \mathbf{S}_+(\cdot))(\boldsymbol{\xi}) + (\hat{a}_+(T, \mathbf{x}_0, \cdot) * \mathbf{S}_-(\cdot))(\boldsymbol{\xi}), \tag{3.32}$$

where $\hat{a}_\pm$ is the Fourier transform of $a_\pm$ in $\mathbf{k}$. This form is much more tractable than (3.26)–(3.27). It is also almost as general. Indeed, rotational modes do not propagate in the high frequency regime. Therefore, they are exactly back-propagated when $\chi(\mathbf{x}_0) = 1$ and $f(\mathbf{x}) = \delta(\mathbf{x})$, and not back-propagated at all when $\chi(\mathbf{x}_0) = 0$. All the refocusing properties are thus captured by the amplitudes $a_\pm(T, \mathbf{x}_0, \mathbf{k})$. Their evolution equation characterizes how waves propagate in the medium and their initial conditions characterize the recording array.

3.6. Homogeneous media. In homogeneous media with $c(\mathbf{x}) = c_0$ the amplitudes $a_\pm(T, \mathbf{x}, \mathbf{k})$ satisfy the free transport equation [14, 25]

$$\frac{\partial a_\pm}{\partial t} \pm c_0 \hat{\mathbf{k}} \cdot \nabla_{\mathbf{x}} a_\pm = 0 \tag{3.33}$$

with initial data $a_\pm(0, \mathbf{x}, \mathbf{k}) = |\chi(\mathbf{x})|^2 f(\mathbf{k})$ as in (3.25). They are therefore given by

$$a_\pm(t, \mathbf{x}_0, \mathbf{k}) = |\chi(\mathbf{x}_0 \mp c_0 \hat{\mathbf{k}} t)|^2 \hat{f}(\mathbf{k}). \tag{3.34}$$

These amplitudes become more and more singular in $\mathbf{k}$ as time grows since their gradient in $\mathbf{k}$ grows linearly with time. The corresponding kernel F decays therefore more slowly in $\boldsymbol{\xi}$ as time grows. This implies that the quality of the refocusing degrades with time. For sufficiently large times, all the energy has left the domain Ω (assumed to be bounded), and the coefficients $a_\pm(t, \mathbf{x}_0, \mathbf{k})$ vanish. Therefore the back-propagated signal $\mathbf{u}^B(\boldsymbol{\xi}; \mathbf{x}_0)$ also vanishes, which means that there is no refocusing at all. The same conclusions could also be drawn by analyzing (3.4) directly in a homogeneous medium. This is the situation in the numerical experiment presented in Figure 2.2: in a homogeneous medium, the back-propagated signal would vanish.

3.7. Heterogeneous media and the radiative transport regime. The results of the preceding sections show how the back-propagated signal $\mathbf{u}^B(\boldsymbol{\xi}; \mathbf{x}_0)$ is related to the propagating modes $a_\pm(T, \mathbf{x}_0, \mathbf{k})$ of the Wigner matrix $W(T, \mathbf{x}_0, \mathbf{k})$. The form assumed by the modes $a_\pm(T, \mathbf{x}_0, \mathbf{k})$, and in particular their smoothness in $\mathbf{k}$, will depend on the hypotheses we make on the underlying medium, i.e., on the density $\rho(\mathbf{x})$ and compressibility $\kappa(\mathbf{x})$ that appear in the matrix $A(\mathbf{x})$. We have seen that partial measurements in homogeneous media yield poor refocusing properties. We now show that refocusing is much better in random media.

We consider here the radiative transport regime, also known as the weak coupling limit. There, the fluctuations in the physical parameters are weak and vary on a scale comparable to the scale of the initial condition. Density and compressibility assume the form

$$\rho(\mathbf{x}) = \rho_0 + \sqrt{\varepsilon}\rho_1\left(\frac{\mathbf{x}}{\varepsilon}\right) \qquad \text{and} \qquad \kappa(\mathbf{x}) = \kappa_0 + \sqrt{\varepsilon}\kappa_1\left(\frac{\mathbf{x}}{\varepsilon}\right). \tag{3.35}$$

The functions ρ_1 and κ_1 are assumed to be mean-zero spatially homogeneous processes. The average (with respect to realizations of the medium) of the propagating

amplitudes $a_\pm$, denoted by $\bar{a}_\pm$, satisfy in the high frequency limit $\varepsilon \to 0$ a radiative transfer equation (RTE), which is a linear Boltzmann equation of the form

$$\begin{aligned} &\frac{\partial \bar{a}_\pm}{\partial t} \pm c_0 \hat{\mathbf{k}} \cdot \nabla_{\mathbf{x}} \bar{a}_\pm = \int_{\mathbb{R}^3} \sigma(\mathbf{k},\mathbf{p})(\bar{a}_\pm(t,\mathbf{x},\mathbf{p}) - \bar{a}_\pm(t,\mathbf{x},\mathbf{k}))\delta(c_0(|\mathbf{k}|-|\mathbf{p}|))d\mathbf{p}, \\ &\bar{a}_\pm(0,\mathbf{x},\mathbf{k}) = |\chi(\mathbf{x})|^2 \hat{f}(\mathbf{k}). \end{aligned} \tag{3.36}$$

The scattering coefficient $\sigma(\mathbf{k},\mathbf{p})$ depends on the power spectra of ρ_1 and κ_1. We refer to [25] for the details of the derivation and explicit form of $\sigma(\mathbf{k},\mathbf{p})$. The above result remains formal for the wave equation and requires averaging over the realizations of the random medium, although this is not necessary in the physical and numerical time reversal experiments. A rigorous derivation of the linear Boltzmann equation (which also requires averaging over realizations) has been obtained only for the Schrödinger equation; see [9, 27]. Nevertheless, the above result formally characterizes the filter $F(T,\boldsymbol{\xi};\mathbf{x}_0)$ introduced in (3.27) and (3.32).

The transport equation (3.36) has a smoothing effect best seen in its integral formulation. Let us define the total scattering coefficient $\Sigma(\mathbf{k}) = \int_{\mathbb{R}^3} \sigma(\mathbf{k},\mathbf{p})\delta(c_0(|\mathbf{k}|-|\mathbf{p}|))d\mathbf{p}$. Then the transport equation (3.36) may be rewritten as

$$\begin{aligned} \bar{a}_\pm(t,\mathbf{x},\mathbf{k}) &= \bar{a}_\pm(0,\mathbf{x} \mp c_0\hat{\mathbf{k}}t,\mathbf{k})e^{-\Sigma(\mathbf{k})t} \\ &+ \frac{|\mathbf{k}|^2}{c_0}\int_0^t ds \int_{S^2} \sigma(\mathbf{k},|\mathbf{k}|\hat{\mathbf{p}})\bar{a}_\pm(s,\mathbf{x}\mp c_0(t-s)\hat{\mathbf{k}},|\mathbf{k}|\hat{\mathbf{p}})e^{-\Sigma(\mathbf{k})(t-s)}d\Omega(\hat{\mathbf{p}}). \end{aligned} \tag{3.37}$$

Here $\hat{\mathbf{p}} = \mathbf{p}/|\mathbf{p}|$ is the unit vector in the direction of $\mathbf{p}$, and $d\Omega(\hat{\mathbf{p}})$ is the surface element on the sphere S^2. The first term in (3.37) is the ballistic part that undergoes no scattering. It has no smoothing effect, and, moreover, if $a(0,\mathbf{x},\mathbf{k})$ is not smooth in $\mathbf{x}$, as may be the case for (3.25), the discontinuities in $\mathbf{x}$ translate into discontinuities in $\mathbf{k}$ at later times, as in (3.34) in a homogeneous medium. However, in contrast to the homogeneous medium case, the ballistic term decays exponentially in time and does not affect the refocused signal for sufficiently long times $t \gg 1/\Sigma$. The second term in (3.37) exhibits a smoothing effect. Namely, the operator $\mathcal{L}g$ defined by

$$\mathcal{L}g(t,\mathbf{x},\mathbf{k}) = \frac{|\mathbf{k}|^2}{c_0}\int_0^t ds \int_{S^2} \sigma(\mathbf{k},|\mathbf{k}|\hat{\mathbf{p}})g(s,\mathbf{x}\mp c_0(t-s)\hat{\mathbf{k}},|\mathbf{k}|\hat{\mathbf{p}})e^{-\Sigma(\mathbf{k})(t-s)}d\Omega(\hat{\mathbf{p}})$$

is regularizing, in the sense that the function $\tilde{g} = \mathcal{L}g$ has at least $1/2$ more derivatives than g (in the same space of a Sobolev scale). The precise formulation of this smoothing property is given by the averaging lemmas [15, 22] and will not be dwelt upon here. Iterating (3.37) n times, we obtain

$$\bar{a}_\pm(t,\mathbf{x},\mathbf{k}) = a^0_\pm(t,\mathbf{x},\mathbf{k}) + a^1_\pm(t,\mathbf{x},\mathbf{k}) + \cdots + a^n_\pm(t,\mathbf{x},\mathbf{k}) + \mathcal{L}^{n+1}\bar{a}_\pm(t,\mathbf{x},\mathbf{k}). \tag{3.38}$$

The terms $a^0_\pm, \ldots, a^n_\pm$ are given by

$$a^0_\pm(t,\mathbf{x},\mathbf{k}) = \bar{a}_\pm(0,\mathbf{x}\mp c_0\hat{\mathbf{k}}t,\mathbf{k})e^{-\Sigma(\mathbf{k})t}, \qquad a^j_\pm(t,\mathbf{x},\mathbf{k}) = \mathcal{L}a^{j-1}_\pm(t,\mathbf{x},\mathbf{k}).$$

They describe, respectively, the contributions from waves that do not scatter, scatter once, twice, ... It is straightforward to verify that all these terms decay exponentially in time and are negligible for times $t \gg 1/\Sigma$. The last term in (3.38) has at least $n/2$ more derivatives than the initial data a_0 or the solution (3.34) of the homogeneous transport equation. This leads to a faster decay in $\boldsymbol{\xi}$ of the Fourier transforms $\hat{a}_\pm(T,\mathbf{x}_0,\boldsymbol{\xi})$ of $\bar{a}_\pm(T,\mathbf{x}_0,\mathbf{k})$ in $\mathbf{k}$. This gives a qualitative explanation as to why refocusing is better in heterogeneous media than in homogeneous media. A more quantitative answer requires solving the transport equation (3.36).

3.8. Diffusion regime. It is known for times t much longer than the scattering mean free time $\tau_{sc} = 1/\Sigma$ and distances of propagation L very large compared to $l_{sc} = c_0\tau_{sc}$ that solutions to the radiative transport equation (3.36) can be approximated by solutions to a diffusion equation, provided that $c(\mathbf{x}) = c_0$ is independent of $\mathbf{x}$ [6, 20]. More precisely, we let $\delta = l_{sc}/L \ll 1$ be a small parameter and rescale time and space variables as $t \to t/\delta^2$ and $\mathbf{x} \to \mathbf{x}/\delta$. In this limit, the wave direction is completely randomized so that

$$\bar{a}_+(t,\mathbf{x},\mathbf{k}) \approx \bar{a}_-(t,\mathbf{x},\mathbf{k}) \approx a(t,\mathbf{x},|\mathbf{k}|),$$

where a solves

$$\begin{aligned} &\frac{\partial a(t,\mathbf{x},|\mathbf{k}|)}{\partial t} - D(|\mathbf{k}|)\Delta_{\mathbf{x}} a(t,\mathbf{x},|\mathbf{k}|) = 0, \\ &a(0,\mathbf{x},|\mathbf{k}|) = |\chi(\mathbf{x})|^2 \frac{1}{4\pi|\mathbf{k}|^2} \int_{\mathbb{R}^3} \hat{f}(\mathbf{q})\delta(|\mathbf{q}| - |\mathbf{k}|)d\mathbf{q}. \end{aligned} \tag{3.39}$$

The diffusion coefficient $D(|\mathbf{k}|)$ may be expressed explicitly in terms of the scattering coefficient $\sigma(\mathbf{k},\mathbf{p})$ and hence related to the power spectra of ρ_1 and κ_1. We refer to [25] for the details. For instance, let us assume for simplicity that the density is not fluctuating, $\rho_1 \equiv 0$, and that the compressibility fluctuations are delta-correlated, so that $\mathbb{E}\{\hat{\kappa}_1(\mathbf{p})\hat{\kappa}_1(\mathbf{q})\} = \kappa_0^2\hat{R}_0\delta(\mathbf{p}+\mathbf{q})$. Then we have

$$\sigma(\mathbf{k},\mathbf{p}) = \frac{\pi c_0^2|\mathbf{k}|^2\hat{R}_0}{2}, \qquad \Sigma(|\mathbf{k}|) = 2\pi^2 c_0|\mathbf{k}|^4\hat{R}_0 \tag{3.40}$$

and

$$D(|\mathbf{k}|) = \frac{c_0^2}{3\Sigma(|\mathbf{k}|)} = \frac{c_0}{6\pi^2|\mathbf{k}|^4\hat{R}_0}. \tag{3.41}$$

Let us assume that there are no initial rotational modes, so that the source $\mathbf{S}(\mathbf{x})$ is decomposed as in (3.30). Using (3.31), we obtain that

$$\hat{\mathbf{u}}^B(\mathbf{k};\mathbf{x}_0) = a(T,\mathbf{x}_0,|\mathbf{k}|)\hat{\mathbf{S}}(\mathbf{k}). \tag{3.42}$$

When $f(\mathbf{x})$ is isotropic so that $\hat{f}(\mathbf{k}) = \hat{f}(|\mathbf{k}|)$, and the diffusion coefficient is given by (3.41), the solution of (3.39) takes the form

(3.43)

$$a(T,\mathbf{x}_0,|\mathbf{k}|) = \hat{f}(|\mathbf{k}|)\left(\frac{3\pi|\mathbf{k}|^4\hat{R}_0}{2c_0T}\right)^{3/2}\int_{\mathbb{R}^3}\exp\left(-\frac{3\pi^2|\mathbf{k}|^4\hat{R}_0|\mathbf{x}_0-\mathbf{y}|^2}{2c_0T}\right)|\chi(\mathbf{y})|^2 d\mathbf{y}.$$

When $f(\mathbf{x}) = \delta(\mathbf{x})$, and $\Omega = \mathbb{R}^3$, so that $\chi(\mathbf{x}) \equiv 1$, we retrieve $a(T,\mathbf{x}_0,\mathbf{k}) \equiv 1$; hence the refocusing is perfect. When only partial measurement is available, the above formula indicates how the frequencies of the initial pulse are filtered by the single-time time reversal process. Notice that both the low and high frequencies are damped; the reason is that low frequencies scatter little from the underlying medium so that it takes a long time for them to be randomized. High frequencies strongly scatter with the underlying medium and consequently propagate little, so that the signal that reaches the recording array Ω is small unless recorders are also located at the source point: $\mathbf{x}_0 \in \Omega$. In the latter case they are very well measured and back-propagated, although this situation is not the most interesting physically. Expression (3.43) may be generalized to other power spectra of medium fluctuations in a straightforward manner using the formula for the diffusion coefficient in [25].

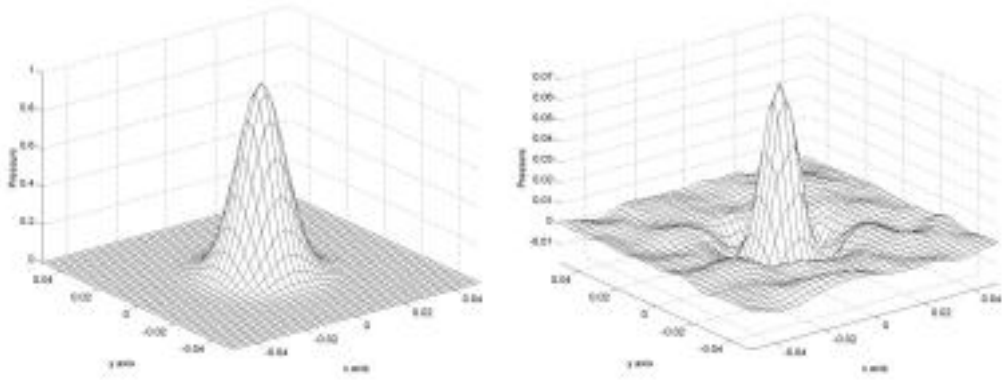

FIG. 3.1. *Zoom of the initial source and the refocused signal for the numerical experiment of Figure* 2.2.

3.9. Numerical results. The numerical results in Figure 2.2 show that some signal refocuses at the location of the initial source after the time reversal procedure. Based on the above theory, however, we do not expect the refocused signal to have exactly the same shape as the original one. Since the location of the initial source belongs to the recording array ($\chi(\mathbf{x}_0) = 1$) in our simulations, we expect from our theory that high frequencies will refocus well but that low frequencies will not. This is confirmed by the numerical results in Figure 3.1, where a zoom in the vicinity of $\mathbf{x}_0 = \mathbf{0}$ of the initial source and refocused signal are represented. Notice that the numerical simulations are presented here only to help in the understanding of the refocusing theory and do not aim at reproducing the theory in a quantitative manner. The random fluctuations are quite strong in our numerical simulations, and it is unlikely that the diffusive regime will be valid. The refocused signal in the right figure looks, however, like a high-pass filter of the signal in the left figure, as expected from theory.

4. Refocusing of classical waves. The theory presented in section 3 provides a quantitative explanation for the results observed in time reversal physical and numerical experiments. However, the time reversal procedure is by no means necessary to obtain refocusing. Time reversal is associated with the specific choice (3.2) for the matrix Γ in the preceding section, which reverses the direction of the acoustic velocity and keeps the pressure unchanged. Other choices for Γ are, however, possible. When nothing is done at time T, i.e., when we choose $\Gamma = I$, no refocusing occurs as one might expect. It turns out that $\Gamma = I$ is more or less the only choice of a matrix that prevents some sort of refocusing. Section 4.1 presents the theory of refocusing for acoustic waves, which is corroborated by numerical results presented in section 4.2. Sections 4.3 and 4.4 generalize the theory to other linear hyperbolic systems.

4.1. General refocusing of acoustic waves. In single-time time reversal, the action of the "intelligent" array is captured by the choice of the signal processing matrix Γ in (3.3). Time reversal is characterized by Γ given in (3.2). A passive array is characterized by $\Gamma = I$. This section analyzes the role of other choices for Γ, which we let depend on the receiver location so that each receiver may perform its own kind of signal processing.

The signal after time reversal is still given by (3.3), where $\Gamma(\mathbf{y}')$ is now arbitrary. At time $2T$, after back-propagation, we are free to multiply the signal by an arbitrary invertible matrix to analyze the signal. It is convenient to multiply the back-propagated signal by the matrix $\Gamma_0 = \mathrm{Diag}(-1,-1,-1,1)$ as in classical time reversal. The reconstruction formula (3.5) is then replaced by

$$\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0) = \int_{\mathbb{R}^9} \Gamma_0 G(T,\mathbf{x}_0+\varepsilon\boldsymbol{\xi};\mathbf{y})\Gamma(\mathbf{y}')G(T,\mathbf{y}';\mathbf{x}_0+\varepsilon\mathbf{z})\chi(\mathbf{y},\mathbf{y}')\mathbf{S}(\mathbf{z})d\mathbf{y}d\mathbf{y}'d\mathbf{z}, \tag{4.1}$$

with $\chi(\mathbf{y},\mathbf{y}')$ defined by (3.6). To generalize the results of section 3, we need to define an appropriate adjoint Green's matrix G_*. As before, this will allow us to remove the matrix Γ between the two Green's matrices in (4.1) and to interchange the order of points in the second Green's matrix. We define the new adjoint Green's function $G_*(t,\mathbf{x};\mathbf{y})$ as the solution to

$$\begin{aligned} &\frac{\partial G_*(t,\mathbf{x};\mathbf{y})}{\partial t}A(\mathbf{x}) + \frac{\partial G_*(t,\mathbf{x};\mathbf{y})}{\partial x^j}D^j = 0,\\ &G_*(0,\mathbf{x};\mathbf{y}) = \Gamma(\mathbf{x})\Gamma_0 A^{-1}(\mathbf{x})\delta(\mathbf{x}-\mathbf{y}). \end{aligned} \tag{4.2}$$

Following the steps of section 3.3, we show that

$$G_*(t,\mathbf{x},\mathbf{y}) = \Gamma(\mathbf{y})G(t,\mathbf{y};\mathbf{x})A^{-1}(\mathbf{x})\Gamma_0. \tag{4.3}$$

The only modification compared to the corresponding derivation of (3.8) is to multiply (3.9) on the left by $\Gamma(\mathbf{x})$ and on the right by Γ_0 so that $\Gamma(\mathbf{y})$ appears on the left in (3.10). The retransmitted signal may now be recast as

$$\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0) = \int_{\mathbb{R}^9} \Gamma_0 G(T,\mathbf{x}_0+\varepsilon\boldsymbol{\xi};\mathbf{y})G_*(T,\mathbf{x}_0+\varepsilon\mathbf{z};\mathbf{y}')\Gamma_0^{-1}A(\mathbf{x}_0+\varepsilon\mathbf{z})\chi(\mathbf{y},\mathbf{y}')\mathbf{S}(\mathbf{z})d\mathbf{y}d\mathbf{y}'d\mathbf{z}. \tag{4.4}$$

Therefore the only modification in the expression for the retransmitted signal compared to the time reversed signal (3.12) is in the initial data for (4.2), which is the only place where the matrix $\Gamma(\mathbf{x})$ appears.

The analysis in sections 3.3–3.7 requires only minor changes, which we now outline. The back-propagated signal may still be expressed in terms of the Wigner distribution (compare to (3.17))

$$\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0) = \int_{\mathbb{R}^6} e^{i\mathbf{k}\cdot(\boldsymbol{\xi}-\mathbf{z})}\Gamma_0 W_\varepsilon\left(T,\mathbf{x}_0+\varepsilon\frac{\mathbf{z}+\boldsymbol{\xi}}{2},\mathbf{k}\right)\Gamma_0 A(\mathbf{x}_0+\varepsilon\mathbf{z})\mathbf{S}(\mathbf{z})\frac{d\mathbf{z}d\mathbf{k}}{(2\pi)^3}. \tag{4.5}$$

The Wigner distribution is defined as before by (3.15) and (3.16). The function Q is defined as before as the solution of (2.3) with initial data $Q(0,x;\mathbf{q}) = \chi(\mathbf{x})e^{i\mathbf{q}\cdot\mathbf{x}/\varepsilon}I$, while Q_* solves (3.7) with the initial data $Q_*(0,\mathbf{x};\mathbf{q}) = \Gamma(\mathbf{x})\Gamma_0 A^{-1}(\mathbf{x})\chi(\mathbf{x})e^{-i\mathbf{q}\cdot\mathbf{x}/\varepsilon}$. The initial Wigner distribution is now given by

$$W(0,\mathbf{x},\mathbf{k}) = |\chi(\mathbf{x})|^2\Gamma(\mathbf{x})\Gamma_0 A^{-1}(\mathbf{x})\hat{f}(\mathbf{k}). \tag{4.6}$$

Lemma 3.1 and Proposition 3.2 also hold, and we obtain the analogue of (3.19):

$$\mathbf{u}(\boldsymbol{\xi};\mathbf{x}_0) = \int_{\mathbb{R}^6} e^{i\mathbf{k}\cdot(\boldsymbol{\xi}-\mathbf{z})}\Gamma_0 W(T,\mathbf{x}_0,\mathbf{k})\Gamma_0 A_0(\mathbf{x}_0)\mathbf{S}(\mathbf{z})d\mathbf{z}d\mathbf{k}. \tag{4.7}$$

The limit Wigner distribution $W(T, \mathbf{x}_0, \mathbf{k})$ admits the mode decomposition (3.24) as before. If we assume that the source $\mathbf{S}(\mathbf{x})$ has the form (3.30) so that no rotational modes are present initially, we recover the refocusing formula (3.31):

$$\hat{\mathbf{u}}^B(\mathbf{k}; \mathbf{x}_0) = a_-(T, \mathbf{x}_0, \mathbf{k})\hat{S}_+(\mathbf{k})\mathbf{b}_+(\mathbf{x}_0, \mathbf{k}) + a_+(T, \mathbf{x}_0, \mathbf{k})\hat{S}_-(\mathbf{k})\mathbf{b}_-(\mathbf{x}_0, \mathbf{k}). \tag{4.8}$$

The initial conditions for the amplitudes $a_\pm$ are replaced by

$$\begin{aligned} a_\pm(0, \mathbf{x}, \mathbf{k}) &= \mathrm{Tr}\left[A_0(\mathbf{x})W(0, \mathbf{x}, \mathbf{k})A_0(\mathbf{x})\mathbf{b}_\pm(\mathbf{x}_0, \mathbf{k})\mathbf{b}_\pm^*(\mathbf{x}_0, \mathbf{k})\right] \\ &= |\chi(\mathbf{x})|^2\hat{f}(\mathbf{k})(A_0(\mathbf{x})\Gamma(\mathbf{x})\mathbf{b}_\mp(\mathbf{x}, \mathbf{k}) \cdot \mathbf{b}_\pm(\mathbf{x}, \mathbf{k})). \end{aligned} \tag{4.9}$$

Observe that when $\Gamma(\mathbf{x}) = \Gamma_0$, we get back the results of section 3.7. When the signal is not changed at the array, so that $\Gamma = I$, the coefficients $a_\pm(0, \mathbf{x}, \mathbf{k}) \equiv 0$, by orthogonality (3.23) of the eigenvectors $\mathbf{b}_j$. Thus no refocusing occurs when the "intelligent" array is replaced by a passive array, as expected physically.

Another interesting example is when only pressure p is measured, so that the matrix $\Gamma = \mathrm{Diag}(0, 0, 0, 1)$. Then the initial data is

$$a_\pm(0, \mathbf{x}, \mathbf{k}) = \frac{1}{2}|\chi(\mathbf{x})|^2\hat{f}(\mathbf{k}),$$

which differs by a factor $1/2$ from the full time reversal case (3.25). Therefore the retransmitted signal $\mathbf{u}^B$ also differs by only a factor $1/2$ from the latter case, and the quality of refocusing as well as the shape of the repropagated signal are exactly the same. The same observation applies to the measurement and reversal of the acoustic velocity only, which corresponds to the matrix $\Gamma = \mathrm{Diag}(-1, -1, -1, 0)$. The factor $1/2$ comes from the fact that only the potential energy or the kinetic energy is measured in the first and second cases, respectively. For high frequency acoustic waves, the potential and kinetic energies are equal; hence the factor $1/2$. We can also verify that when only the first component of the velocity field is measured, so that $\Gamma = \mathrm{Diag}(-1, 0, 0, 0)$, the initial data is

$$a_\pm(0, \mathbf{x}, \mathbf{k}) = |\chi(\mathbf{x})|^2\hat{f}(\mathbf{k})\frac{k_1^2}{2|\mathbf{k}|^2}. \tag{4.10}$$

As in the time reversal setting of section 3, the quality of the refocusing is related to the smoothness of the amplitudes $a_\pm$ in $\mathbf{k}$. In a homogeneous medium they satisfy the free transport equation (3.33) and are given by

$$\begin{aligned} &a_\pm(t, \mathbf{x}, \mathbf{k}) \\ &\quad = |\chi(\mathbf{x} - c_0\hat{\mathbf{k}}t)|^2\hat{f}(\mathbf{k})(A_0(\mathbf{x} - c_0\hat{\mathbf{k}}t)\Gamma(\mathbf{x} - c_0\hat{\mathbf{k}}t)\mathbf{b}_\mp(\mathbf{x} - c_0\hat{\mathbf{k}}t, \mathbf{k}) \cdot \mathbf{b}_\pm(\mathbf{x} - c_0\hat{\mathbf{k}}t, \mathbf{k})). \end{aligned}$$

Once again we observe that, in a uniform medium, $a_\pm$ become less regular in $\mathbf{k}$ as time grows; thus refocusing is poor.

The considerations of section 3.7 show that in the radiative transport regime the amplitudes $a_\pm$ become smoother in $\mathbf{k}$ also with initial data given by (4.9). This leads to a better refocusing as explained in section 3.5. Let us assume that the diffusion regime of section 3.8 is valid and that the kernel f is isotropic $\hat{f}(\mathbf{k}) = \hat{f}(|\mathbf{k}|)$. This requires in particular that $A_0(\mathbf{x})$ be independent of $\mathbf{x}$. We obtain that $a_\pm(T, \mathbf{x}_0, \mathbf{k}) = \tilde{a}(T, \mathbf{x}_0, |\mathbf{k}|)$; thus the refocusing formula (4.8) reduces to

$$\hat{\mathbf{u}}^B(\mathbf{k}; \mathbf{x}_0) = \tilde{a}(T, \mathbf{x}_0, |\mathbf{k}|)\hat{\mathbf{S}}(\mathbf{k}). \tag{4.11}$$

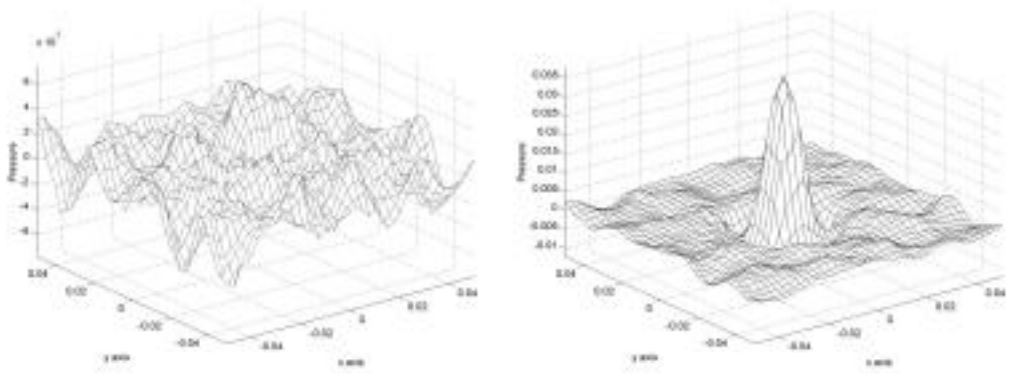

FIG. 4.1. *Zoom of the refocused signals for the numerical experiment of Figure* 2.2 *with processing* $\Gamma = I$ *(left), with a maximal amplitude of roughly* 4×10^{-3}, *and* $\Gamma = \mathrm{Diag}(0,0,0,1)$ *(right), with a maximal amplitude of roughly* 0.035.

The difference between this and the case treated in section 3.8 is that $\tilde{a}(T, \mathbf{x}, |\mathbf{k}|)$ solves the diffusion equation (3.39) with new initial conditions given by

$$\tilde{a}(0,\mathbf{x},|\mathbf{k}|) = \frac{|\chi(\mathbf{x})|^2}{4\pi|\mathbf{k}|^2}\int_{\mathbb{R}^3}\hat{f}(|\mathbf{q}|)(A_0\Gamma(\mathbf{x})\mathbf{b}_-(\mathbf{q})\cdot\mathbf{b}_+(\mathbf{q}))\delta(|\mathbf{q}|-|\mathbf{k}|)d\mathbf{q} \tag{4.12}$$
$$= \frac{|\chi(\mathbf{x})|^2}{4\pi|\mathbf{k}|^2}\int_{\mathbb{R}^3}\hat{f}(|\mathbf{q}|)(A_0\Gamma(\mathbf{x})\mathbf{b}_+(\mathbf{q})\cdot\mathbf{b}_-(\mathbf{q}))\delta(|\mathbf{q}|-|\mathbf{k}|)d\mathbf{q}.$$

When only the first component of the velocity field is measured, as in (4.10), the initial data for $\tilde{a}$ is

$$\tilde{a}(0,\mathbf{x},|\mathbf{k}|) = \frac{1}{6}|\chi(\mathbf{x})|^2\hat{f}(|\mathbf{k}|).$$

Therefore even time reversing only one component of the acoustic velocity field produces a repropagated signal that is equal to the full repropagated field up to a constant factor.

More generally, we deduce from (4.12) that a detector at $\mathbf{x}$ will contribute some refocusing for waves with wavenumber $|\mathbf{k}|$, provided that

$$\int_{S^2}\hat{f}(|\mathbf{k}|\hat{\mathbf{q}})(A_0\Gamma(\mathbf{x})\mathbf{b}_\mp(\hat{\mathbf{q}})\cdot\mathbf{b}_\pm(\hat{\mathbf{q}}))d\Omega(\hat{\mathbf{q}}) \neq 0.$$

When $f(\mathbf{x}) = f(|\mathbf{x}|)$ is radial, this property becomes independent of the wavenumber $|\mathbf{k}|$ and reduces to $\int_{S^2}(A_0\Gamma(\mathbf{x})\mathbf{b}_\mp(\hat{\mathbf{q}})\cdot\mathbf{b}_\pm(\hat{\mathbf{q}}))d\Omega(\hat{\mathbf{q}}) \neq 0$.

4.2. Numerical results. Let us come back to the numerical results presented in Figures 2.2 and 3.1. We now consider two different processings at the recording array. The first array is passive, corresponding to $\Gamma = I$, and the second array measures only pressure so that $\Gamma = \mathrm{Diag}(0,0,0,1)$. The zoom in the vicinity of $\mathbf{x}_0 = \mathbf{0}$ of the "refocused" signals is given in Figure 4.1. The left panel shows no refocusing, in accordance with physical intuition and theory. The right figure shows that refocusing indeed occurs when only pressure is recorded (and its time derivative is set to 0 in the solution of the wave equation presented in the appendix). Notice also that the

refocused signal is roughly one half the one obtained in Figure 3.1, as predicted by theory.

4.3. Refocusing of other classical waves. The preceding sections deal with the refocusing of acoustic waves. The theory can, however, be extended to more complicated linear hyperbolic systems of the form (2.3), with $A(\mathbf{x})$ a positive definite matrix, D^j symmetric matrices, and $\mathbf{u} \in \mathbb{C}^m$. These include electromagnetic and elastic waves. Their explicit representation in the form (2.3) and expressions for the matrices $A(\mathbf{x})$ and D^j in these cases may be found in [25]. For instance, the Maxwell equations

$$\frac{\partial \mathbf{E}}{\partial t} = \frac{1}{\epsilon(\mathbf{x})} \text{ curl } \mathbf{H},$$
$$\frac{\partial \mathbf{H}}{\partial t} = -\frac{1}{\mu(\mathbf{x})} \text{curl } \mathbf{E}$$

may be written in the form (2.3) with $\mathbf{u} = (\mathbf{E}, \mathbf{H}) \in \mathbb{C}^6$ and the matrix $A(\mathbf{x}) = \text{Diag}(\epsilon(\mathbf{x}), \epsilon(\mathbf{x}), \epsilon(\mathbf{x}), \mu(\mathbf{x}), \mu(\mathbf{x}), \mu(\mathbf{x}))$. Here $\epsilon(\mathbf{x})$ is the dielectric constant (not to be confused with the small parameter ε), and $\mu(\mathbf{x})$ is the magnetic permeability. The 6×6 dispersion matrix $L(\mathbf{x}, \mathbf{k})$ for the Maxwell equations is given by

$$L(\mathbf{x}, \mathbf{k}) = - \begin{pmatrix} 0 & 0 & 0 & 0 & -k_3/\epsilon(\mathbf{x}) & k_2/\epsilon(\mathbf{x}) \\ 0 & 0 & 0 & k_3/\epsilon(\mathbf{x}) & 0 & -k_1/\epsilon(\mathbf{x}) \\ 0 & 0 & 0 & -k_2/\epsilon(\mathbf{x}) & k_1/\epsilon(\mathbf{x}) & 0 \\ 0 & k_3/\mu(\mathbf{x}) & -k_2/\mu(\mathbf{x}) & 0 & 0 & 0 \\ -k_3/\mu(\mathbf{x}) & 0 & k_1/\mu(\mathbf{x}) & 0 & 0 & 0 \\ k_2/\mu(\mathbf{x}) & -k_1/\mu(\mathbf{x}) & 0 & 0 & 0 & 0 \end{pmatrix}.$$

Generalization of our results for acoustic waves to such general systems is quite straightforward, so we concentrate only on the modifications that need be made. The time reversal procedure is exactly the same as before: a signal propagates from a localized source, is recorded, processed as in (3.3) with a general matrix $\Gamma(\mathbf{y}')$, and re-emitted into the medium. The retransmitted signal is given by (4.1). Furthermore, the equation for the adjoint Green's matrix (4.2), the definition of the Wigner transform in section 3.4, and the expression (4.7) for the repropagated signal still hold.

The analysis of the repropagated signal is reduced to the study of the Wigner distribution, which is now modified. The mode decomposition must be generalized. We recall that

$$L(\mathbf{x}, \mathbf{k}) = A_0^{-1}(\mathbf{x}) k_j D^j$$

is the $m \times m$ dispersion matrix associated with the hyperbolic system (2.3). Since $L(\mathbf{x}, \mathbf{k})$ is symmetric with respect to the inner product $\langle \mathbf{u}, \mathbf{v} \rangle_{A_0} = (A_0 \mathbf{u} \cdot \mathbf{v})$, its eigenvalues are real and its eigenvectors form a basis. We assume the existence of a time reversal matrix Γ_0 such that (3.11) holds with $\Gamma = \Gamma_0$ and such that $\Gamma_0^2 = I$. For example, for electromagnetic waves $\Gamma_0 = \text{Diag}(1, 1, 1, -1, -1, -1)$. Then the spectrum of L is symmetric about zero and the eigenvalues $\pm\omega^\alpha$ have the same multiplicity. We assume in addition that L is isotropic so that its eigenvalues have the form $\omega_\pm^\alpha(\mathbf{x}, \mathbf{k}) = \pm c^\alpha(\mathbf{x})|\mathbf{k}|$, where $c_\alpha(\mathbf{x})$ is the speed of mode α. We denote by r_α their respective multiplicities, assumed to be independent of $\mathbf{x}$ and $\mathbf{k}$ for $\mathbf{k} \neq 0$. The matrix L has a basis of eigenvectors $\mathbf{b}_\pm^{\alpha,j}(\mathbf{x}, \mathbf{k})$ such that

$$L(\mathbf{x}, \mathbf{k}) \mathbf{b}_\pm^{\alpha,j}(\mathbf{x}, \mathbf{k}) = \pm\omega^\alpha(\mathbf{x}, \mathbf{k}) \mathbf{b}_\pm^{\alpha,j}(\mathbf{x}, \mathbf{k}), \quad j = 1, \ldots, r_\alpha,$$

and $\mathbf{b}_{\pm}^{\alpha,j}$ form an orthonormal set with respect to the inner product $\langle\,,\rangle_{A_0}$. The different ω_α's correspond to different types of waves (modes). Various indices $1 \le j \le r_\alpha$ refer to different polarizations of a given mode. The eigenvectors $\mathbf{b}_{+}^{\alpha,j}$ and $\mathbf{b}_{-}^{\alpha,j}$ are related by

$$\Gamma_0 \mathbf{b}_{+}^{\alpha,j}(\mathbf{x},\mathbf{k}) = \mathbf{b}_{-}^{\alpha,j}(\mathbf{x},\mathbf{k}), \qquad \Gamma_0 \mathbf{b}_{-}^{\alpha,j}(\mathbf{x},\mathbf{k}) = \mathbf{b}_{+}^{\alpha,j}(\mathbf{x},\mathbf{k}). \tag{4.13}$$

Proposition 3.3 is then generalized as follows (see [14, 25]).

PROPOSITION 4.1. *There exist scalar functions* $a_{\pm}^{\alpha,jm}(t,\mathbf{x},\mathbf{k})$ *such that*

$$W(t,\mathbf{x},\mathbf{k}) = \sum_{\pm,\alpha,j,m} a_{\pm}^{\alpha,jm}(t,\mathbf{x},\mathbf{k}) \mathbf{b}_{\pm}^{\alpha,j}(\mathbf{x},\mathbf{k}) \otimes \mathbf{b}_{\pm}^{\alpha,m}(\mathbf{x},\mathbf{k}). \tag{4.14}$$

Here the sum runs over all possible values of $\pm$, α, *and* $1 \le j,m \le r_\alpha$.

The main content of this proposition is again that the cross terms $\mathbf{b}_{\pm}^{\alpha,j}(\mathbf{x},\mathbf{k}) \otimes \mathbf{b}_{\mp}^{\beta,m}(\mathbf{x},\mathbf{k})$ do not contribute, and neither do the terms $\mathbf{b}_{\pm}^{\alpha,j}(\mathbf{x},\mathbf{k}) \otimes \mathbf{b}_{\pm}^{\alpha',m}(\mathbf{x},\mathbf{k})$ when $\alpha \neq \alpha'$. This is because modes propagating with different speeds do not interfere constructively in the high frequency limit.

We may now insert expression (4.14) into (4.7) and obtain the following generalization of (4.8):

$$\begin{aligned}\hat{\mathbf{u}}^B(\mathbf{k};\mathbf{x}_0) = \sum_{\alpha,j,m} \Big[& a_{-}^{\alpha,mj}(T,\mathbf{x}_0,\mathbf{k}) \hat{S}_{+}^{\alpha,j}(\mathbf{x}_0,\mathbf{k}) \mathbf{b}_{+}^{\alpha,m}(\mathbf{x}_0,\mathbf{k}) \\ & + a_{+}^{\alpha,mj}(T,\mathbf{x}_0,\mathbf{k}) \hat{S}_{-}^{\alpha,j}(\mathbf{x}_0,\mathbf{k}) \mathbf{b}_{-}^{\alpha,m}(\mathbf{x}_0,\mathbf{k}) \Big],\end{aligned} \tag{4.15}$$

where $\hat{S}_{\pm}^{\alpha,j}(\mathbf{k}) = (A(\mathbf{x}_0)\hat{\mathbf{S}}(\mathbf{k}) \cdot \mathbf{b}_{\pm}^{\alpha,j}(\mathbf{x}_0,\mathbf{k}))$. This formula tells us that only the modes that are present in the initial source ($\hat{S}_{\pm}^{\alpha,j}(\mathbf{k}) \neq 0$) will be present in the back-propagated signal but possibly with a different polarization, that is, $j \neq m$.

The initial conditions for the modes $a_{\pm}^{\alpha,jm}$ are given by

$$a_{\pm}^{\alpha,jm}(0,\mathbf{x},\mathbf{k}) = |\chi(\mathbf{x})|^2 \hat{f}(\mathbf{k}) (A(\mathbf{x})\Gamma(\mathbf{x}) \mathbf{b}_{\mp}^{\alpha,m}(\mathbf{x},\mathbf{k}) \cdot \mathbf{b}_{\pm}^{\alpha,j}(\mathbf{x},\mathbf{k})), \tag{4.16}$$

which generalizes (4.9). When $\Gamma(\mathbf{x}) \equiv I$, we again obtain that $a_{\pm}^{\alpha,jm}(0,\mathbf{x},\mathbf{k}) \equiv 0$, i.e., there is no refocusing as physically expected. When $\Gamma(\mathbf{x}) \equiv \Gamma_0$, we have for all α that

$$a_{\pm}^{\alpha,jm}(0,\mathbf{x},\mathbf{k}) = |\chi(\mathbf{x})|^2 \hat{f}(\mathbf{k}) \delta_{jm}.$$

In a uniform medium the amplitudes $a_{\pm}^{\alpha,jm}$ satisfy an uncoupled system of free transport equations (3.33),

$$\frac{\partial a_{\pm}^{\alpha,jm}}{\partial t} \pm c_\alpha \hat{\mathbf{k}} \cdot \nabla_{\mathbf{x}} a_{\pm}^{\alpha,jm} = 0, \tag{4.17}$$

which have no smoothing effect, and hence refocusing in a homogeneous medium is still poor. When $f(\mathbf{x}) = \delta(\mathbf{x})$ and $\Omega = \mathbb{R}^3$, so that $\chi(\mathbf{x}) \equiv 1$, we still have that $a_{\pm}^{\alpha,jm}(T,\mathbf{x}_0,\mathbf{k}) = \delta_{jm}$ and refocusing is again perfect, that is, $\mathbf{u}^B(\boldsymbol{\xi};\mathbf{x}_0) = \mathbf{S}(\boldsymbol{\xi})$, as may be seen from (4.15).

4.4. The diffusive regime. The radiative transport regime holds when the matrices $A(\mathbf{x})$ have the form

$$A(\mathbf{x}) = A_0(\mathbf{x}) + \sqrt{\varepsilon} A_1\left(\frac{\mathbf{x}}{\varepsilon}\right),$$

as in (3.35). Then the $r_\alpha \times r_\alpha$ coherence matrices $w^\alpha_\pm$ with entries $w^\alpha_{\pm,jm} = a^{\alpha,jm}_\pm$ satisfy a system of matrix-valued radiative transport equations (see [25] for the details) similar to (3.36). The matrix transport equations simplify considerably in the diffusive regime, such as the one considered in section 3.8 when waves propagate over large distances and long times. We assume for simplicity that $A_0 = A_0(\mathbf{x})$ and $\Gamma = \Gamma(\mathbf{x})$ are independent of $\mathbf{x}$. Polarization is lost in this regime; that is, $a^{\alpha,jm}(t,\mathbf{x},\mathbf{k}) = 0$ for $j \neq m$, and wave energy is equidistributed over all directions. This implies that

$$a^{\alpha,jj}_+(t,\mathbf{x},\mathbf{k}) = a^{\alpha,jj}_-(t,\mathbf{x},\mathbf{k}) = a_\alpha(t,\mathbf{x},|\mathbf{k}|)$$

so that $a^{\alpha,jj}$ is independent of $j = 1,\ldots,r_\alpha$ and of the direction $\hat{\mathbf{k}} = \mathbf{k}/|\mathbf{k}|$. Furthermore, because of multiple scattering, a universal equipartition regime takes place so that

$$a_\alpha(t,\mathbf{x}_0,|\mathbf{k}|) = \phi(t,\mathbf{x}_0,c_\alpha|\mathbf{k}|), \tag{4.18}$$

where $\phi(t,\mathbf{x},\omega)$ solves a diffusion equation in $\mathbf{x}$ like (3.39) (see [25]). The diffusion coefficient $D(\omega)$ may be expressed explicitly in terms of the power spectra of the medium fluctuations [25]. Using (4.16) and (4.18), we obtain when f is isotropic the following initial data for the function ϕ:

$$\phi(0,\mathbf{x},\omega) = \frac{1}{4\pi}|\chi(\mathbf{x})|^2 \int_{S^2} \frac{2}{|\alpha|} \sum_{j,\omega_\alpha>0} \hat{f}\left(\frac{\omega}{c_\alpha}\right) (A_0\Gamma \mathbf{b}^{\alpha,j}_-(\hat{\mathbf{k}}), \mathbf{b}^{\alpha,j}_+(\hat{\mathbf{k}}))d\Omega(\hat{\mathbf{k}}), \tag{4.19}$$

where $|\alpha|$ is the number of nonvanishing eigenvalues of $L(\mathbf{x},\mathbf{k})$, and $d\Omega(\hat{\mathbf{k}})$ is the Lebesgue measure on the unit sphere S^2.

Let us assume that nonpropagating modes are absent in the initial source $\mathbf{S}(\mathbf{x})$; that is, $\hat{S}^j_0(\mathbf{k}) = 0$, with the subscript zero referring to modes corresponding to $\omega_0 = 0$. Then (4.15) becomes

$$\hat{\mathbf{u}}(\mathbf{k};\mathbf{x}_0) = \sum_{\alpha,j} \phi(T,\mathbf{x}_0,c_\alpha|\mathbf{k}|)\left[\hat{S}^{\alpha,j}_+(\mathbf{k})\mathbf{b}^{\alpha,j}_+(\mathbf{x}_0,\mathbf{k}) + \hat{S}^{\alpha,j}_-(\mathbf{k})\mathbf{b}^{\alpha,j}_-(\mathbf{x}_0,\mathbf{k})\right]. \tag{4.20}$$

This is an explicit expression for the repropagated signal in the diffusive regime, where ϕ solves the diffusion equation (3.39) with initial conditions (4.19).

5. Conclusions. This paper presents a theory that quantitatively describes the refocusing phenomena in time reversal acoustics as well as for more general processings of acoustic and other classical waves. We show that the back-propagated signal may be expressed as the convolution (1.1) of the original source $\mathbf{S}$ with a filter F. The quality of the refocusing is therefore determined by the spatial decay of the kernel F. For acoustic waves, the explicit expression (3.27) relates F to the Wigner distribution of certain solutions of the wave equation. The decay of F is related to the smoothness in the phase space of the amplitudes $a_j(t,\mathbf{x},\mathbf{k})$ defined in Proposition 3.3. The latter satisfy free transport equations in homogeneous media, which sharpens the gradients

of a_j and leads to poor refocusing. In contrast, the amplitudes a_j satisfy the radiative transport equation (3.36) in heterogeneous media, which has a smoothing effect. This leads to a rapid spatial decay of the filter F and a better refocusing. For longer times, a_j satisfies a diffusion equation. This allows for an explicit expression (3.42)–(3.43) of the time reversed signal. The same theory holds for more general waves and more general processing procedures at the recording array, which allows us to describe the refocusing of electromagnetic waves when only one component of the electric field is measured, for instance.

Appendix. This appendix presents the details of the numerical simulation of (2.9). We assume that ρ is constant and that only $\kappa(\mathbf{x})$ fluctuates. We can therefore recast (2.9) as

$$\frac{\partial^2 p}{\partial t^2} - c^2(\mathbf{x})\Delta p = 0.$$

The above wave equation is discretized using a second-order scheme (three point stencil in every variable) both in time and space. The resolution in time is explicit and time reversible; i.e., the equation that yields $p(t_{n+1})$ from $p(t_{n-1})$ and $p(t_n)$ can be used to retrieve $p(t_{n-1})$ exactly from $p(t_n)$ and $p(t_{n+1})$. We write $c^2(\mathbf{x}) = c_0^2 + c_1^2(\mathbf{x})$. The average velocity is $c_0^2 = 1$. The random part c_1^2 has been constructed as follows. Let $2N \times 2N$ be the number of spatial grid points and $c^2_{1;n,m}$ be the value of c_1^2 at the grid point (n, m). The values $c^2_{1;2n,2m}$ have been chosen independently and uniformly on $(-r, r)$ with $r < 1/2$. The value of c_1^2 is then set constant on four adjacent pixels by enforcing that $c^2_{1;2n-1,2m} = c^2_{1;2n-1,2m-1} = c^2_{1;2n,2m-1} = c^2_{1;2n,2m}$ for $1 \le n, m \le N$. In all simulations, we have $N = 200$, which generates a grid of $400^2 = 1.6 \times 10^4$ points. The time step has been chosen so that the CFL condition $\delta t < \min_{\mathbf{x}} c(\mathbf{x})/(2N)$ is ensured. The fluctuations of the velocity field have been chosen larger than those in the weak-fluctuation regime analyzed in this paper. This is to ensure that sufficient mixing occurs on the limited 400×400 grid that fits on a personal computer. The domain of truncation has also been centered to maximize the mixing of the recorded signal. Off-centered domains of truncation give very similar results, albeit with a smaller signal-to-noise ratio.

Acknowledgments. We would like to thank Knut Solna for fruitful discussions during the preparation of this work. We are indebted to George Papanicolaou for his contributions to the analysis of time reversal, which lie at the core of this paper. This work would also not have been possible without the numerous exchanges we benefited from at the Stanford MGSS summer school.

HEAT-INDUCED STRETCHING OF A GLASS TUBE UNDER TENSION: APPLICATION TO GLASS MICROELECTRODES*

HUAXIONG HUANG†, ROBERT M. MIURA‡, WILLIAM P. IRELAND§, AND ERNEST PUIL¶

Abstract. Deformation of glass using heat occurs in many industrial and artistic applications, including the manufacturing of laboratory glass products, drawing of fiber optics, and hand-blown artistic creations. The formation of glass objects is an art, but the trial-and-error aspect of the procedures can be reduced by development of a systematic theory, especially when the objects are formed using mechanical means. Glass microelectrodes are ubiquitous in experimental studies of the electrophysiology of biological cells and their membranes, and the "pulling" of these electrodes is based on trial-and-error. To make this process more systematic, we derive a model for glass microelectrode formation using a coil heater with a gravity-forced electrode puller, assuming that the glass tube is an incompressible, viscous fluid. The model is one-dimensional, and the effects of thermal radiation from the coil heater are essential in the formation process. A breaking stress criterion is imposed to fracture the glass tube, forming the electrode tip. The difficulty with the moving free end is avoided by introducing a quasi-Lagrangian coordinate system. The model equations are solved using an adaptive moving grid to account for the local stretching of the glass. A number of examples using a double-pull paradigm have been computed to illustrate the dependence of the electrode shape and tip diameter on the heater temperature and the ratio between the inner and outer radii.

Key words. glass tube, microelectrodes, viscous incompressible fluid, radiation heat transfer, finite-difference method, adaptive grid

1. Introduction.

Glass objects are routinely produced in industry and in some technical arts. Such objects include laboratory products, fiber optics, and hand-blown glassware. In some applications, heat is applied to soften the glass during the formation of these glass objects, using trial-and-error procedures. However, when these procedures involve mechanical devices, the use of mathematical models provides a more systematic approach. For example, the pulling of glass fiber optics has been studied by Fitt et al. [1] and other researchers [4, 12]. Most of these studies focus on isothermal or prescribed temperature conditions and on given pulling velocities.

Glass microelectrodes have played an essential role in cell electrophysiology for decades and will continue to be an important tool in the future. These micropipettes are used to inject electric current and dyes into cells and to measure membrane potentials by insertion through cellular membranes or formation of a patch clamp of

the membrane. The data collected give information about membrane electrical properties in the presence of voltage-gated and receptor-gated ion channels and with the application of drugs. Laboratories using these microelectrodes usually make them on a daily basis, using commercially available glass tubes and electrode pullers that use coil heaters for softening the glass tubes during the stretching procedure.

There are four experimentally relevant parameters that can be measured on glass microelectrodes. They are tip length, tip diameter, electrode resistance, and electrode capacitance. Tip length is significant because this determines the physical strength of the electrode and how easily it will penetrate tissue and cells. A short tip with steep taper is robust but does not penetrate tissue easily. The converse is true of long, gently tapering tips.

Tip diameter is important because it determines whether the electrode is suitable for intracellular recording or for patch recording. Intracellular recordings are made with electrodes having very narrow tips (approximately 0.1 micron), which can be obtained using a single-pull electrode puller. Generally, patch clamping requires a larger tip diameter, of approximately 1 micron outside diameter and 0.5 micron inside diameter, obtained using a double-pull electrode puller. There is a correlation between tip length and distal tip diameter; for example, using a specific puller with varying heater widths and geometries, long tips were of narrower gauge at the ends than short tips [2].

Capacitance and resistance are properties of the electrode that determine its confounding effect on measurements taken from neurons. In order to get accurate data, one needs to measure these properties and compensate for them. These properties are functions of the physical form of the electrode, the properties of the glass used to make it, and the electrolyte used to fill it. Therefore, since the manufacturing process determines this physical form, the process should be understood so that it can be tailored to create electrodes fitting the experimentalist's needs.

Capacitance and electrode resistance as a function of the pulling parameters can be measured but not at the same time as precise measurement of tip diameter or shank geometry. The procedure for measuring tip size accurately involves using the scanning electron microscope (SEM), which is time-consuming and expensive. There are means to do this nondestructively [3]. Other methods have been explored, including measuring the rate of flow of a solution down the shank of an electrode and using a mathematical model to find tip size [9]. Mittman et al. [7] estimated tip diameter from the pressure needed to force bubbles from a microelectrode immersed in methanol. From knowledge of the tip diameter and length of the electrode's tapering shank, capacitance also has been computed using the approximation that the shank is a cone [11].

However, the exact relationship between the variables in the actual manufacturing process (heater geometry, rate of pulling the glass tube, length of first pull (for a patch electrode), rate of the second pull, etc.) and electrode properties is usually determined empirically by a method of trial-and-error. Though some work has been done on the influence of heater geometry and width on electrode form (see [2]), in general the process is not well determined. In this paper, our objective is to develop a basic mathematical model for the formation process of these glass microelectrodes and, through computer simulations, understand the complex interaction of variables in the manufacturing process with the properties of the resulting electrode. This has the advantages that many different types of pullers can be simulated, the effects of many parameters can be explored rapidly, and predictions to guide the formation of microelectrodes using existing pullers as well as future design of electrode pullers can

be made. There are several types of pullers in common use today. The differences among them include heater size and shape, method of application of the force (gravity, electromagnetic) to extend the glass tube, use of single and double pulls, and auxiliary cooling methods (e.g., puffs of air).

The main focus of this paper is on the pulling of glass microelectrodes. We will not analyze the rupture of the glass tube at the end of the pulling process. Instead, we will impose a breaking stress criterion to terminate the stretching of the glass tube when the viscous stress inside the glass tube exceeds the critical value of the stress, i.e., the breaking stress. However, the theory developed here can be generalized and applied to a broader class of problems. From the fluid dynamics point of view, the breaking of the glass tube may be due to the collapse of the glass wall. Furthermore, it also is possible that the inner radius of the glass tube shrinks to zero, resulting in failure of this production method to produce a functional electrode. Three major factors that determine these outcomes are the surface tension, viscous stress (tension), and pressure, which are all affected by the temperature of the glass. Previous studies of the stability of free surfaces of isothermal fluid jets as well as the effects of pressure and temperature may be used to predict the behavior of the surfaces in the stretched section of the glass tube. This will be the subject of a future paper.

The paper is organized as follows. In section 2, the assumptions for the model and derivation of the model equations are given. Details of the control-volume approach used in this derivation are specified in Appendix A. The effects of thermal radiation from the coil heater on the glass tube require the determination of the geometric factors from the coil and from the background to the glass; see Appendix B. Also described are the breaking stress criterion, which is used to terminate the numerical computations, and the glass properties used in the model. The added complication of a moving boundary due to the stretching of the glass tube is avoided by introducing a quasi-Lagrangian coordinate system. The actual length of the tube evolves according to a system of ordinary differential equations.

The finite-difference method is described in section 3 and is used to compute the solutions numerically in space and time. In section 4, several different cases of parameter values are given as examples for the numerical computations, and results for a double pull case are described. The paper closes with a discussion in section 5 on the limitation of the present model and future work for improving it.

2. A model for glass microelectrode formation.

2.1. Derivation of the model. In the model equations developed here for glass microelectrode formation, we account for certain types of electrode pullers which are capable of single and multiple pulls. The microelectrode starts off as a glass tube that is held vertically, being clamped at the top and with a weight hanging from the bottom; see Figure 2.1(a). The tube then is heated nonuniformly in the longitudinal direction by radiation from an axially symmetric heated wire coil, which surrounds the tube near the middle at the initial time. Also, there is radiation loss to the background, and we assume there is no radiant energy passing through the glass. The tube heats up to the softening point and begins to stretch due to the weight; see Figure 2.1(b). Examination of microelectrodes formed in this way shows that symmetrical radial contraction of the glass tube occurs as longitudinal stretching takes place. Although this is a two-dimensional formation process, we treat the problem in one space dimension along the tube length by averaging over the cross-sectional area. This is justified because of the small diameter of the tube compared with its length.

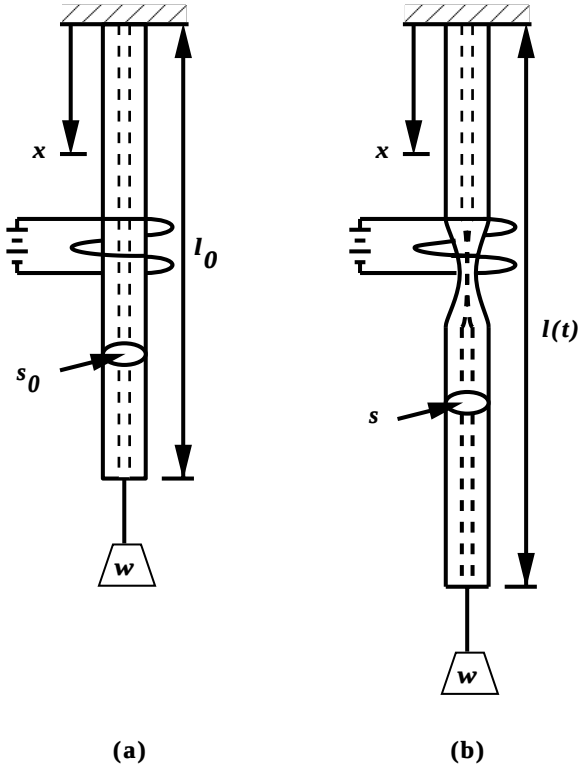

FIG. 2.1. *Schematics of the glass tube before* (a) *and during* (b) *the stretching.*

In developing a mathematical model to describe the heating of a glass tube to form a microelectrode, we initially will be working with an Eulerian coordinate system, with x and t as the spatial and temporal coordinates, respectively. The mass of the tube is small compared to the hanging weight w and will be ignored in the following derivation. At $t = 0$, we assume a uniform glass tube of length ℓ_0 with a circular annular cross section having constant outer radius R_0 and constant inner radius r_0. The resulting area of the annular cross section is denoted by $s_0 = \pi(R_0^2 - r_0^2)$, and the coordinate along the glass tube is given by $0 \le x \le \ell_0$.

We assume that the stretching glass tube maintains a circular annular cross section with outer radius $R(x,t)$ and inner radius $r(x,t)$ at a given location x and time t (thus, $R_0 = R(x,0)$ and $r_0 = r(x,0)$). The cross-sectional area of the glass tube is given by $s(x,t) = \pi(R^2 - r^2)$ (thus, $s_0 = s(x,0)$). The length of the tube at time t is denoted by $\ell(t)$ (thus, $\ell_0 = \ell(0)$), and we refer to the location $x = \ell(t)$ as the "free end." The velocity of the glass at x at time t is given by $u(x,t)$. Thus the extensional strain rate is given by $\partial u/\partial x$, which corresponds to the spatial variation of the glass velocity.

From experiments, the dependence of density changes on temperature is negligible. Therefore, to simplify the model equations, we assume that the glass is an incompressible fluid with constant density and that the stretching is axial with concomitant shrinking of the cross-sectional area, $s(x,t)$. Using a control-volume approach (cf. Appendix A), we have the continuity equation

$$\frac{\partial \gamma}{\partial t} + u\frac{\partial \gamma}{\partial x} + \gamma\frac{\partial u}{\partial x} = 0 \tag{2.1}$$

where $\gamma(x,t) = s(x,t)/s_0$.

The axial stress at each point in the glass tube is given by

$$\text{axial stress} = \frac{F}{s(x,t)} \tag{2.2}$$

where F is the axial force and is uniform over the length of the tube because we have neglected its mass.[1] To determine F, we use Newton's second law to describe the motion of the applied weight w,

$$w - F = \frac{wa}{g} \tag{2.3}$$

where the acceleration $a = d^2\ell/dt^2$ is measured at the end of the glass tube and g is the gravitational acceleration. Thus the glass satisfies the constitutive relation

$$\frac{w}{s(x,t)}\left(1 - \frac{a}{g}\right) = 3\mu\frac{\partial u}{\partial x} \tag{2.4}$$

where μ is the shear viscosity and 3μ is the coefficient of viscosity for axial tension. We have assumed that viscous stress is dominant over the inertia of the glass and the surface tension of the glass-air interface. Therefore, the Reynolds number, $Re = \rho\mathcal{U}\mathcal{L}/\bar{\mu}$, is small[2] where ρ is the glass density and $\mathcal{U}$, $\mathcal{L}$, and $\bar{\mu}$ are the characteristic velocity, length, and viscosity, respectively. Note that $\mu = \mu(\theta(x,t))$, where $\theta(x,t)$ is the temperature of the glass at (x,t). (The issue of surface tension is addressed briefly in section 5.) Combining (2.1) and (2.4) yields

$$\frac{\partial\gamma}{\partial t} + u\frac{\partial\gamma}{\partial x} = -\frac{\mathcal{P}}{\mu}\left(1 - \frac{a}{g}\right) \tag{2.5}$$

where $\mathcal{P} \equiv w/3s_0 = \text{constant}$.

The temperature distribution $\theta(x,t),\ 0 < x < \ell(t),\ t > 0$, is subject to the initial condition $\theta(x,0) = \theta_0(x),\ 0 \le x \le \ell(0)$. We apply a standard control-volume method for deriving the energy equation (see Appendix A), resulting in

$$\rho\left(\frac{\partial c_p\theta}{\partial t} + u\frac{\partial c_p\theta}{\partial x}\right) = \frac{1}{s}\frac{\partial}{\partial x}\left(s\kappa(\theta)\frac{\partial\theta}{\partial x}\right) + E_R \tag{2.6}$$

where c_p and κ are the specific heat and thermal conductivity of the glass, respectively, and E_R represents the transport of thermal energy to the glass tube by radiation. This radiation term is given by

$$\begin{aligned} E_R = 2k\sqrt{\frac{\pi}{s(1-\beta^2)}}\Bigg[&F_{hg}\frac{\varepsilon_h\alpha}{1-(1-\alpha)(1-\varepsilon_h)}\left(\theta_h^4 - \theta^4\right) \\ &+ F_{bg}\frac{\varepsilon_b\alpha}{1-(1-\alpha)(1-\varepsilon_b)}\left(\theta_b^4 - \theta^4\right)\Bigg] \end{aligned} \tag{2.7}$$

where k is the Boltzmann constant, α is the absorptivity of the glass to radiative thermal energy, ε_h and ε_b are the emissivities of the heater and background, respectively,

[1] We refer the reader to Appendix A for more details.

[2] This assumption will be justified in the next section.

and $\theta_h(x,t)$ and $\theta_b(x,t)$ are the temperatures of the heater and the background, respectively. The quantities F_{hg}, F_{bg}, and F_{bh} are geometric factors between the heater and the glass tube, the background and the glass tube, and the background and the heater, respectively. We note that $F_{gh} = F_{hg}$, and similarly for the other two geometric factors. (The derivation of the geometric factors is given in Appendix B.) Finally, $\beta = r/R$ is the ratio of the inner and outer radii; thus $s = \pi R^2(1-\beta^2)$. In general, β is a function of x and t and can be determined by treating the interfaces between the glass tube and the air as free boundaries. When the viscosity of the glass is small, i.e., the Reynolds number is large, it can be shown that β is approximately a constant, which is not the case for moderate and large values of the viscosity. Further discussion of these issues will be given in section 4.

The initial conditions are given by $\theta(x,0) = \theta_0$, $\gamma(x,0) = 1$, and $u(x,0) = 0$. At the boundaries $x = 0$ and $x = \ell(t)$, θ is fixed at θ_a, which is the ambient temperature. Since the boundary at $x = 0$ is fixed, the velocity $u(0,t) = 0$. At the moving boundary, $x = \ell(t)$, the velocity is given by $u(\ell(t),t) = d\ell(t)/dt$. In summary, the governing equations of our problem are the coupled equations, (2.5) and (2.6), with the specified initial and boundary conditions.

Finally, the criterion for determining when the glass tube breaks is the breaking stress for the glass. The maximal stress in the tube can be computed, and when it reaches the assumed breaking stress, the tube is considered broken. This procedure requires an accurate determination of the stress distribution in the tube both spatially and temporally because it varies rapidly as the tube thins down to small diameters. In the present study, we will find that, in some cases, the breaking stress is not achieved after the maximum allowed extension of the glass tube is reached, and this results in an extremely fine tip with a long shank, which is not usable in experiments. When the breaking stress is achieved, the glass tube will break into two pieces, and the resulting shapes of the two electrodes produced then are determined.

3. Numerical procedures. Since the governing equations are nonlinear, we seek the solution through numerical means. The main purpose of the numerical tests in this paper is to investigate the effects on the shape of the glass microelectrode tips obtained by changing the heater temperature θ_h. This parameter has been chosen since it is easy to adjust in the laboratory. We will simulate a typical two-pull electrode formation process used in the laboratory when the glass microelectrode is produced, which will be described briefly in the following.

3.1. Coordinate transformation. The moving boundary introduces an extra complication into the model even though the solution behavior is quite regular. To avoid this added complication in the numerical computations, we choose a quasi-Lagrangian coordinate system in which the moving boundary is fixed. However, this coordinate system does not follow the material motion as in true Lagrangian coordinates. This coordinate system can be obtained by a simple transformation from the Eulerian coordinates, which we now describe.

We derive the governing equations under the new coordinates (ξ,τ) defined by

$$\xi = \xi(x,t) \quad \text{or} \quad x = X(\xi,\tau), \tag{3.1}$$

$$\tau = t, \tag{3.2}$$

where $\xi(0,t) = 0$ and $\xi(\ell(t),t) = 1$, and with new dependent variables

$$u(x,t) = U(\xi,\tau), \quad \theta(x,t) = \Theta(\xi,\tau), \quad \ell(t) = L(\tau), \tag{3.3}$$

$$a(t) = A(\tau), \quad \gamma(x,t) = \Gamma(\xi,\tau), \quad \mu(x,t) = \nu(\xi,\tau). \tag{3.4}$$

The relationships between the derivatives in the new (ξ,τ) and the old (x,t) coordinates are

$$\frac{\partial}{\partial x} = G\frac{\partial}{\partial \xi}, \tag{3.5}$$

$$\begin{aligned}\frac{\partial}{\partial t} &= \frac{\partial}{\partial \tau} - V\frac{\partial}{\partial x} \\ &= \frac{\partial}{\partial \tau} - VG\frac{\partial}{\partial \xi}\end{aligned} \tag{3.6}$$

where $V = \partial X/\partial\tau$ is the "grid velocity," and $G = \partial\xi/\partial x$ is the "reciprocal grid stretching ratio," which is to be specified.

From (2.4), we have

$$\frac{\partial u}{\partial x} = \frac{\mathcal{P}}{\gamma\mu}\left(1 - \frac{a}{g}\right), \tag{3.7}$$

and in the new coordinates, this becomes

$$\frac{\partial U}{\partial \xi} = \frac{\mathcal{P}}{G\Gamma\nu}\left(1 - \frac{A}{g}\right) \tag{3.8}$$

where $\nu = \gamma\mu$. The constitutive equation for γ, (2.5), under the transformation can be written as

$$\frac{\partial \Gamma}{\partial \tau} + (U - V)G\frac{\partial \Gamma}{\partial \xi} = -\frac{\mathcal{P}}{\nu}\left(1 - \frac{A}{g}\right). \tag{3.9}$$

The energy equation, (2.6), now is written in the new coordinates as

$$\rho\left(\frac{\partial c_p\Theta}{\partial \tau} + G(U - V)\frac{\partial c_p\Theta}{\partial \xi}\right) = G\Gamma\frac{\partial}{\partial \xi}\left(\frac{\kappa(\Theta)G}{\Gamma}\frac{\partial \Theta}{\partial \xi}\right) + E_R. \tag{3.10}$$

In order to solve (3.8)–(3.9), we need to compute conditions at the free end, $L(\tau)$. Integrating (3.8) from $\xi = 0$ to $\xi = 1$ and using $W(\tau) = U(1,\tau) = dL/d\tau$ and $dW/d\tau = A(\tau) = d^2L/d\tau^2$, we obtain

$$\frac{dL}{d\tau} = \left(1 - \frac{1}{g}\frac{d^2L}{d\tau^2}\right)\int_0^1 \frac{\mathcal{P}}{G\Gamma\nu}d\xi. \tag{3.11}$$

The information for the moving boundary (the length $L(\tau)$ and velocity $W(\tau)$) is obtained by solving a system of ordinary differential equations derived from (3.11):

$$\frac{dW}{d\tau} = g - \frac{1}{\mathcal{I}}W, \tag{3.12}$$

$$\frac{dL}{d\tau} = W \tag{3.13}$$

where $\mathcal{I} = \int_0^1 \mathcal{P}/(\nu g G\Gamma)d\xi$.

3.2. Adaptive moving grid generation. A special feature of the problem being studied here is that the solutions (temperature, radius of the tube, etc.) vary rapidly in the region near the heater and much more slowly in regions away from the heater. A uniform grid results in grid points that are unnecessarily dense in some regions and not sufficiently dense in other regions. Therefore, an adaptive grid is desirable in the computation.

The approaches used in adaptive grid generation can be divided into two general categories. When the grid generation and the physical equations are dealt with separately, the approach is called *static regridding*. This approach is usually robust and relatively simple to use. If the grid is generated simultaneously with the solution of the physical equations, then the approach belongs to the *moving mesh* methods.

We use a simple moving mesh method by solving a partial differential equation for the coordinate transformation

$$\xi = \xi(x,t), \tag{3.14}$$

$$\tau = t \tag{3.15}$$

between the domain $\xi \in [0,1]$ and $x \in [0, L(\tau)]$. The differential equation, based on the equidistribution principle, can be written as

$$\frac{\partial X}{\partial \tau} = \frac{1}{\tau_r}\frac{\partial}{\partial \xi}\left(M\frac{\partial X}{d\xi}\right), \qquad 0 < \xi < 1. \tag{3.16}$$

Here τ_r is a (small) relaxation parameter and $M = \sqrt{(1+p\Gamma^{-2})/(1+\Gamma^{-2})}$ is the monitor function, which is chosen such that the grid is dense where Γ is small. The smoothing parameter p determines the ratio of finest and coarsest grid sizes and therefore prevents the distribution of too many points in the region when Γ is small. When solved numerically on a uniform grid $0 = \xi_0 < \xi_1 < \cdots < \xi_N = 1$, subject to the boundary conditions $X(0,\tau) = 0$ and $X_\tau(1,\tau) = U(1,\tau) = W(\tau)$ (or $X(1,\tau) = L(\tau)$), (3.16) generates a nonuniform grid $0 = x_0 < x_1 < \cdots < x_N = L(t)$.

We note that X must be a monotone function of ξ at any given time τ in order to be a coordinate transformation. This is guaranteed since (3.16) is a heat equation. Other equations and monitor functions can be used as well. For a detailed discussion, see [6] and references therein.

3.3. Finite-difference scheme. We solve the system (3.9)–(3.10) by a finite-difference method. We discretize (3.9) using a backward Euler scheme in time and an upwind difference in space, namely,

$$\begin{aligned}\Gamma_{i,n+1} - \Gamma_{i,n} = {} & -\delta\tau\frac{\mathcal{P}}{\nu_{i,n+1}}\left(1 - \frac{A_{n+1}}{g}\right) \\ & + \begin{cases} G_{i+1/2,n+1}(U_{i,n+1} - V_{i,n+1})(\Gamma_{i+1,n+1} - \Gamma_{i,n+1})\frac{\delta\tau}{\delta\xi} \\ \qquad \text{if} \quad U_{i,n+1} - V_{i,n+1} \le 0, \\ G_{i-1/2,n+1}(U_{i,n+1} - V_{i,n+1})(\Gamma_{i,n+1} - \Gamma_{i-1,n+1})\frac{\delta\tau}{\delta\xi} \\ \qquad \text{if} \quad U_{i,n+1} - V_{i,n+1} > 0 \end{cases}\end{aligned} \tag{3.17}$$

where $\delta\xi$ and $\delta\tau$ are the mesh and time step sizes, respectively, and i and n are the indices for the space coordinate and time level, respectively. For any grid function $f_{i,n}$, we define $f_{i+1/2,n} = (f_{i+1,n} + f_{i,n})/2$, $f_{i-1/2,n} = (f_{i-1,n} + f_{i,n})/2$. The reciprocal grid stretching ratio $G_{i,n}$ is computed using the standard central difference formula.

We now discretize (3.10) using a backward Euler scheme in time and central-differences in space; thus

$$\begin{aligned}\rho c_p\Theta_{i,n+1} = \rho c_p\Theta_{i,n} &- \frac{\rho c_p G_{i,n+1}\delta\tau}{2L_{n+1}\delta\xi}\left(U_{i,n+1}-V_{i,n+1}\right)\left(\Theta_{i+1,n+1}-\Theta_{i-1,n+1}\right)\\ &+ \frac{G_{i,n+1}\delta\tau}{\Gamma_{i,n+1}(L_{n+1})^2\delta\xi^2}\left[\kappa_{i+1/2,n+1}\Gamma_{i+1/2,n+1}\left(\Theta_{i+1,n+1}-\Theta_{i,n+1}\right)\right.\\ &\qquad\left.- \kappa_{i-1/2,n+1}\Gamma_{i-1/2,n+1}\left(\Theta_{i,n+1}-\Theta_{i-1,n+1}\right)\right]\\ &+ 2k\delta\tau\sqrt{\frac{\pi}{S_0\Gamma_{i,n+1}(1-\beta^2)}}\left[F_{hg}\frac{\varepsilon_h\alpha}{1-(1-\alpha)(1-\varepsilon_h)}\left(\Theta_h^4-\Theta_{i,n+1}^4\right)\right.\\ &\qquad\left.+ F_{bg}\frac{\varepsilon_b\alpha}{1-(1-\alpha)(1-\varepsilon_b)}\left(\Theta_b^4-\Theta_{i,n+1}^4\right)\right].\end{aligned} \tag{3.18}$$

The equations describing the tip motion, (3.12) and (3.13), are solved in a different fashion. First, (3.12) is integrated from time level n (τ) to $n+1$ ($\tau+\delta\tau$), assuming that $\mathcal{I}$ is a constant in that time interval, which yields

$$W_{n+1} = g\mathcal{I}_{n+1}\left[1-\exp\left(\frac{-\delta\tau}{\mathcal{I}_{n+1}}\right)\right] + W_n\exp\left(\frac{-\delta\tau}{\mathcal{I}_{n+1}}\right). \tag{3.19}$$

The acceleration then is obtained using (3.12) as

$$A_{n+1} = g - \frac{W_{n+1}}{\mathcal{I}_{n+1}}. \tag{3.20}$$

The tip length is obtained using a backward Euler method,

$$L_{n+1} = L_n + W_{n+1}\delta\tau. \tag{3.21}$$

The trapezoidal rule is used to evaluate the integral

$$\mathcal{I}_{n+1} = \delta\xi\sum_{i=1}^{N}\frac{\mathcal{P}}{2g}\left(\frac{1}{G_{i,n+1}\Gamma_{i,n+1}\nu_{i,n+1}}+\frac{1}{G_{i-1,n+1}\Gamma_{i-1,n+1}\nu_{i-1,n+1}}\right). \tag{3.22}$$

Finally, the velocity at each interior point is computed by discretizing (3.8) using the trapezoidal rule

$$\begin{aligned}U_{i,n+1} &= U_{i-1,n+1}\\ &+ \delta\xi\frac{\mathcal{P}}{2}\left(1-\frac{A_{n+1}}{g}\right)\left(\frac{1}{G_{i,n+1}\Gamma_{i,n+1}\nu_{i,n+1}}+\frac{1}{G_{i-1,n+1}\Gamma_{i-1,n+1}\nu_{i-1,n+1}}\right).\end{aligned} \tag{3.23}$$

The mesh adaptation also is done numerically. The finite-difference approximation of (3.16) is

$$\begin{aligned}X_{i,n+1} = X_{i,n} &+ \frac{\delta\tau}{\tau_r(\delta\xi)^2}\left[M_{i+1/2,n+1}(X_{i+1,n+1}-X_{i,n+1})\right.\\ &\qquad\left.- M_{i-1/2,n+1}(X_{i,n+1}-X_{i-1,n+1})\right].\end{aligned} \tag{3.24}$$

The boundary conditions for (3.24) are

$$X_{0,n+1} = 0, \qquad X_{N,n+1} = L_{n+1}.$$

3.4. Solution algorithm. For the initial conditions, we assume that the glass tube has uniform properties and constant temperature distribution with no motion. Since the equation for temperature is second-order in space, we need two boundary conditions, namely, the Dirichlet conditions that the temperature is held fixed at both ends. The equation for Γ is first-order in space, which means that normally one condition needs to be specified. However, $U-V=0$ at both ends, so the characteristic curve at each boundary point, $\xi=0$ and 1, is tangent to the boundary. Therefore, no explicit boundary conditions are needed for Γ. Furthermore, $U_{0,n+1}=0$, which is sufficient to solve for $U_{i,n+1}$.

We assume that the values of the variables at time level n are known, and we use an iterative procedure for solving the discrete equations for these variables at time level $n+1$ as follows:

1. the temperature Θ is computed using (3.18);
2. the value of $\mathcal{I}$ is calculated using (3.22);
3. then, W, A, and L are obtained from (3.19), (3.20), and (3.21), respectively;
4. the values of Γ are computed from (3.17);
5. the velocity U is determined from (3.23); and
6. after the physical equations are solved, we update the mesh by solving the mesh equation (3.24), and then move to the next time level.

Using these values of the variables, we update the coefficients, e.g., ν, etc., in the discrete equations, and repeat steps 1–6 until convergence is achieved. These computations are repeated until either the maximum extension length is reached or the breaking stress in the glass tube is exceeded.

We note that our numerical method is implicit and an iterative procedure is required due to the nonlinear nature of the physical and grid generation equations. In principle, a simpler explicit method also can be used to solve the set of equations listed above. However, such methods normally impose a severe constraint on the size of the time step even for linear problems. On the other hand, we can choose a relatively large step size by using the implicit method. The iterative procedure at each time step usually converges with only a few iterations.

Most of the results presented in the following section are obtained using 512 grid points, in the spatial discretization. We have experimented with more grid points, but the results are essentially the same. The size of the time step, which is allowed to vary in our computations, is chosen according to the velocity of the glass so that the free end of the glass moves less than 10^{-3} of the initial tube length ℓ_0.

4. Results. To illustrate the theory developed in this paper, we have carried out several representative computations of glass microelectrode formation. For patch-clamp experiments, appropriate strength in the shank of the electrode requires two separate pulls with different heater temperatures. Therefore, the first pull with heater temperature θ_h^1 is stopped when the glass tube is extended to a certain length and forms a "neck." The heater is switched off, and switched on again, usually at a lower temperature θ_h^2, after it has been moved to a location approximately at the smallest part of the neck and the glass tube has cooled down. The glass tube usually breaks during the second pull with the desired tip shape if the temperature of the heater is set properly. A maximum extension length, which is determined by the dimension of the puller, is set for the second pull. The adjustable parameters are the temperature, the location of the heater, and the force load on the end of the tube. The computations were carried out for two different values of θ_h^1 for the first pull, combined with various heater temperatures θ_h^2 for the second pull.

TABLE 4.1
List of the physical parameters used in the computations.

ρ g/cm^3	c_p Erg/Kg	κ cm^2/sec	k Erg/cm^{2}sec K^4	ε_h cm^2/g	ε_h cm^2/g	α cm^2/g
2.23	7.538×10^6	1.130×10^5	5.67×10^{-5}	1	1	0.4

Since the ratio of the inner and outer radii of the tube, $\beta = r/R$, is treated as an unknown function in our model, we considered two cases. The first set of computations were carried out assuming that β is a constant, which is valid when the viscosity is relatively small. For the second set of computations, we assumed that β is a linear function of the nondimensional area Γ,

$$\beta = \frac{1}{2} + \beta_0(\Gamma - 1) \tag{4.1}$$

where β_0 is a constant. We note that neither of these assumptions on β may be realistic. However, the computations based on these assumptions will provide useful information on the limitations and effects of β on the shape of the electrode when other parameters remain unchanged.

We carried out a number of numerical computations for the double-pull paradigm. The objective in the double-pull cases was to obtain tip diameters of approximately 1 micron. The important parameter was the heater temperature, which can be controlled in experiments and was varied in the computations. We first describe the properties of the glass tubes used in the numerical computations and then present the results of these computations for the glass shapes, temperature distributions, stress distributions, and their time evolutions.

4.1. Glass properties and geometrical parameters. We first describe the relevant physical and geometrical parameters. The nonlinear dependence on temperature of the coefficients in the governing equations is determined by experimental measurements. In order to follow the physical process as closely as possible, we estimate the parameter values from these data.

The most important parameter is the viscosity of the glass, μ. According to the measurements, the relationship between $\ln \mu$ and the temperature is piecewise linear. Therefore, we use power laws for the temperature dependence over certain intervals. A typical formula for the viscosity of the glass (in g/cm sec) is given by

$$\mu(\theta) = \begin{cases} 10^{9-c_1(\theta-293)}, & \theta \le 900, \\ 10^{3.612-c_2(\theta-900)}, & 900 \le \theta \le 1100, \\ 10^{3.38-c_3(\theta-1100)}, & 1100 \le \theta \le 1500. \end{cases} \tag{4.2}$$

Here $c_1 = 8.876 \times 10^{-3}$, $c_2 = 1.16 \times 10^{-3}$, and $c_3 = 7.355 \times 10^{-3}$, based on measurements for soda-lime [8]. The other physical parameters used in our computations also come from the experimental setup and are summarized in Table 4.1. The initial temperature of the glass tube is set to be the background temperature, or room temperature (assumed to be 20°C), i.e., $\theta_0 = \theta_b = 293$°K.

The geometrical parameters for the glass tube and heater are given in Table 4.2. The other two relevant parameters are ℓ_{p1} and ℓ_{p2}, which are the maximum lengths set for the first and second pulls, respectively. Due to the physical constraint of the puller, $\ell_{p1} + \ell_{p2}$ is usually fixed, while various combinations are allowed. In this

TABLE 4.2
List of the geometrical parameters used in the computations.

R_{min}^b (μm)	51.2	NB	NB	55.3	43.0	NB
r_{min}^b (μm)	25.6	NB	NB	27.6	21.5	NB

study, however, we have chosen $\ell_{p1} = 0.58$ cm and $\ell_{p2} = 4$ cm. The initial area is $s_0 = \pi(R_0^2 - r_0^2) = \pi R_0^2(1 - \beta_0^2) = 1.767 \times 10^{-2}$.

During the pulling processes, the glass tube usually breaks in the location where the stress exceeds the "breaking stress." The breaking stress is a material-dependent parameter that also depends on the temperature. For example, for the glass used in this study, the breaking stress (in dyn/cm^3) is given by the empirical formula (see Scholze [10, pp. 255–272])

$$\mathcal{S}_b = \frac{5.12 \times 10^{10}}{\sqrt{\theta}}, \tag{4.3}$$

which indicates that it becomes easier to break this type of glass as the temperature increases. For our first set of computations with a constant β, we choose not to impose the breaking stress. Instead, we use the maximum length $\ell_{p1} + \ell_{p2}$ as a stopping criterion. The breaking stress using (4.3) is computed as a reference value. The breaking stress criterion is imposed for the second set of computations when β is a function of Γ (4.1).

4.2. Numerical results for constant β. In Table 4.3, we summarize the computational results based on the constant area ratio $\beta = 1/2$.

The table lists the minimum radii (the values at the "neck" of the tube) and the maximum stress at the ends of the first and the second pulls, and when the stress in the glass tube exceeds the breaking stress computed using formula (4.3). The heater temperatures for the two pulls are chosen to be a combination of 900°K, 1100°K, and 1500°K, since these are the critical values for the glass viscosity shown in (4.2).

TABLE 4.4

NB stands for the cases in which the breaking stress criterion is not met; the superscript b denotes the values at which the maximum stress $\mathcal{S}^b_{max}$ first exceeds the breaking stress $\mathcal{S}_b$; R^b_{min} and r^b_{min} are the outer and inner radii, respectively, at the neck; t is the time from the start of the second pull; and x_{min} is the location of the neck from the clamped end of the glass.

θ^1_h (°K)	1100				1500			
θ^2_h (°K)	900	1042	1044	1046	1100	1190	1192	1194

x^b_{min} (cm)	4.59	4.92	4.99	NB	4.31	4.58	4.65	NB

The first observation one can make is that critical heater temperatures exist, i.e., temperatures beyond which the stress in the glass tube never reaches the breaking stress. It also can be seen that radii at the end of the second pull do not vary significantly. However, the value of maximum stress that exceeds the breaking stress, for some of the cases listed, is affected by the heater temperature. This suggests that if the breaking stress criterion is imposed, then the glass tube may break and the minimum radius (at the neck) of the tube may vary. This is confirmed by the values of the radii at which the stress first exceeds the breaking stress. In all the cases, the radii at the end of the second pull are comparable to the values for the glass electrodes pulled in the laboratory. However, the radii when the stress exceeds the breaking stress on the first pull are much larger than those at the end of the second pull.

To further investigate the dependence of the minimum radii on the heater temperature, we have done simulations with careful variations of the temperature. The results are given in Table 4.4.

With small variations of the heater temperature, we numerically identified the critical temperatures for the second pull. For $\theta^1_h = 1100°$K, this critical temperature is about $\theta^2_h = 1044°$K, whereas for $\theta^1_h = 1500°$K, this critical temperature is about $\theta^2_h = 1192°$K. In general, the neck radii are sensitive to the heater temperature. However, when the glass breaks (breaking stress is reached) at the critical heater temperatures during the second pull, the radii of the neck appear to be less sensitive to the heater temperature of the first pull.

The time history of the stress and breaking stress offers a clearer picture of what happens near the critical temperature, as plotted in Figure 4.1 for $\theta^1_h = 1500°$K. It can be seen that, during the second pull, the breaking stress decreases initially, reaches a minimum value, and then starts to increase again. This apparently corresponds to the fact that the temperature at the neck rises first, reaches a maximum, and then decays when the neck moves away from the center of the heater. In the cases shown in Figures 4.1(a)–(c), at a relatively low heater temperature ($\theta^2_h = 1100°$K), the stress at the neck of the glass tube increases monotonically with time and passes the breaking stress during the second pull. At a higher heater temperature ($\theta^2_h = 1500°$K), the maximum stress increases initially, reaches a maximum value, and then

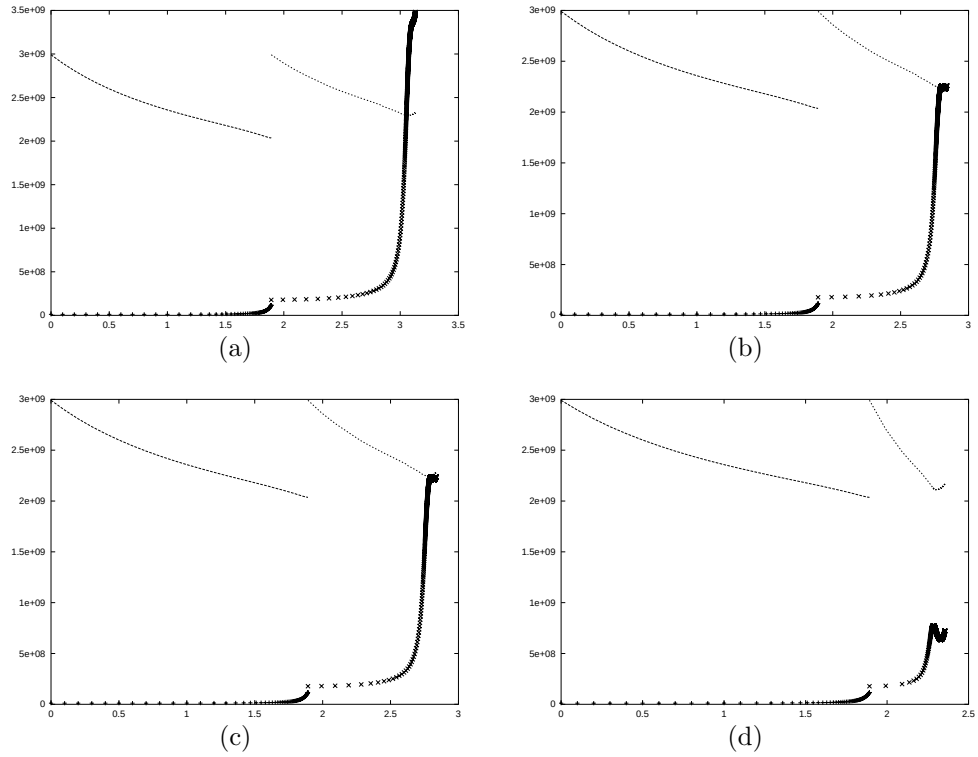

FIG. 4.1. *Stress and breaking stress (in dyn/cm^3) versus time with $\theta_h^1 = 1500°K$ and* (a) $\theta_h^2 = 1100°K$, (b) $\theta_h^2 = 1192°K$, (c) $\theta_h^2 = 1194°K$, (d) $\theta_h^2 = 1500°K$. *The dashed line denotes the breaking stress, and the symbols ($\times$ and $+$) are the maximum stresses.*

decreases. It never reaches the breaking stress (Figure 4.1(d)). Note that the peak of the maximum stress, just before breaking, decreases with increasing temperature during the second pull. Deceasing the heater temperature raises the maximum value of the stress (Figure 4.1(a)). As a result, the stress reaches and passes the breaking stress sooner for lower heater temperature during the second pull. Therefore, the neck radii are greater at lower heater temperature during the second pull when the breaking stress is met since there is insufficient time for the tube to stretch and reduce the neck radii. This is demonstrated in Figure 4.2, where the outer radius of the neck is plotted against time.

4.3. Numerical results for variable β. In order to gain some insight on the effect of β, the ratio of the inner and outer radii of the glass tube, we present some computations with $\theta_h^1 = 1500°$K and $\theta_h^2 = 1190°$K, with β given by (4.1) where β_0 varies from 0.3 to -0.2. The breaking stress criterion is imposed, and the glass breaks for every value of β_0. In Table 4.5, we have listed the outer and inner radii and the dimensionless area at the tip (neck) as well as the minimum value of β when the glass tube breaks. Note that γ is initially 1, so β is initially 0.5 for the first pull. However, the value of γ is negligible in determining β_{min} when the glass tube breaks; cf. (4.1) and Table 4.5. Clearly, the value of β_0 (therefore the value of β) has a visible effect

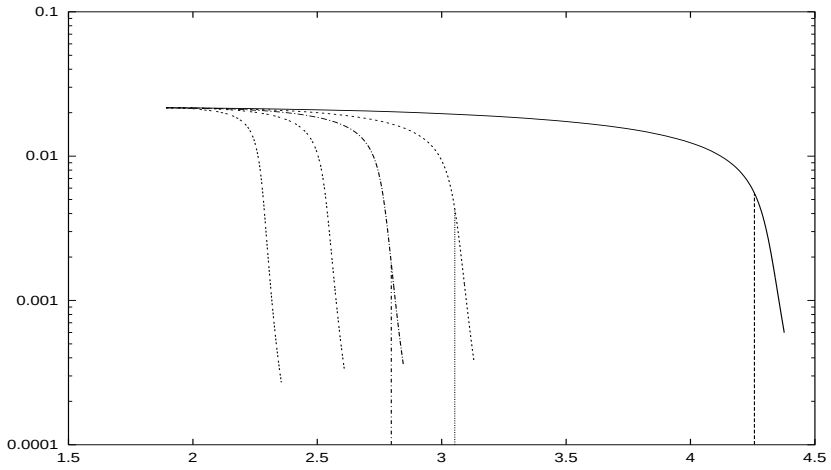

FIG. 4.2. *Neck outer radius (in cm) versus time (in sec) with the same heater temperature* $\Theta_H^1 = 1500^\circ K$ *for the first pull and* $\theta_h^2 = 900$, 1100, 1190, 1300, *and* $1500^\circ K$ *for the second pull, ordered from right to left. The times when the maximum stress exceeds the breaking stress and the corresponding values of the radii are marked. These times depend on the heater temperature during the second pull.*

–0.2	1.31×10^{-5}	3.80	2.66	0.70

on the values of the tip radii and area. It can be seen that the tip area decreases monotonically as β_0 decreases. However, the actual values of the tip outer and inner radii vary in a more complicated fashion. We note that the effect of β_0 (and β) is more effective in reducing R_{min} and r_{min} when $\beta_0 \leq 0$ ($\beta_{min} \geq 0.5$). There seems to exist a β_0 value between 0 and -0.2 (correspondingly $\beta_{\min}$ is between 0.5 and 0.7) for which both radii at the tip are reduced by about a factor of 3–4 (close to their respective local minima). This corresponds to the case in which the inner radius contracts more slowly than the outer radius, resulting in a smaller tip area. On the other hand, if the inner radius contracts more quickly than the outer one ($\beta < 0.5$), the effects of different β_0 (β) on the inner radius are clearly demonstrated, while the effects on the tip area and its outer radius are limited as β_0 increases (β_{min} decreases).

Finally in Figure 4.3, we plot the corresponding shape of the glass tube for three of the cases computed when the breaking stress is reached. It can be seen that smaller values of the tip radii, when $\beta_0 = -0.1$, are due mainly to the time available for the glass to stretch.

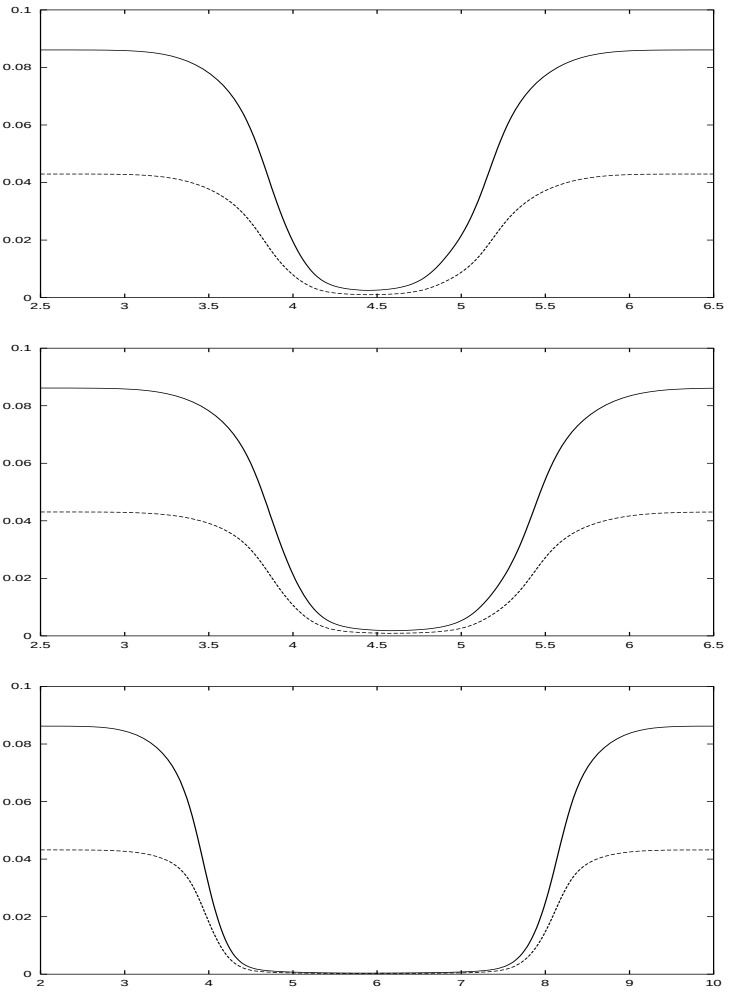

FIG. 4.3. *Shape (outer (solid) and inner (dashed) radii) of a glass tube when it breaks with* $\theta_h^1 = 1500°K$ *and* $\theta_h^2 = 1100°K$*: $\beta_0 = 0.1$ (top); $\beta_0 = 0$ (middle); $\beta_0 = -0.1$ (bottom).*

5. Concluding remarks. In this study, we present a mathematical model for the formation of glass microelectrodes using a double pull paradigm. The model is one-dimensional and is based on the assumption that the glass material is an incompressible viscous fluid. Numerical results indicate that the heater temperature plays a critical role in the formation process. In order to obtain glass electrodes with desirable tip shape and dimension, one needs a suitable combination of the heater temperature for the two pulls. Another important factor revealed by our model and the numerical simulations is the ratio of the inner and outer radii, β. Since our model does not take the free boundary into account, this ratio remains a free parameter. The effect of β is investigated by using a simple linear relationship between β and the dimensionless area γ, which can be viewed as the first-order approximation when γ is close to its initial value. It is shown that changing the value of β has little effect on the results when the inner radius contracts faster than the outer one. On the other hand, both

the inner and outer radii at the tip could be reduced by a factor of four or more if the inner radius contracts more slowly than the outer one. We also have investigated the effects of surface tension. It was found that under the physical conditions, surface tension is at least one order of magnitude smaller than the viscous stress. Therefore, excluding the effect of surface tension in the current model is justified.

Although our focus here has been on the specific manufacturing paradigm for glass microelectrodes in the laboratory, our mathematical model does allow us to investigate a variety of other possible changes in the parameters to obtain better shaped microelectrodes, e.g., the effects of changes in the weight, the ambient temperature, and different pulling strategies.

However, a more conclusive result only can be obtained from a more realistic model which takes the free boundary into account. Work is currently underway to incorporate the effects of surface tension and pressure changes due to temperature variations into the current model.

Appendix A. Derivation of the model. To derive both the continuity equation (2.1) and the energy equation (2.6) for the glass tube, we apply a control-volume approach. Figure A.1 is a schematic diagram of a typical infinitesimal section of the glass tube with length Δx. The control volume consists of four surfaces: two annuli with areas $s(x,t)$ on the left side and $s(x+\Delta x,t)$ on the right side, and outer and inner surfaces with areas given approximately by $s_{\text{out}} = 2\pi R(x,t)\Delta x$ and $s_{\text{in}} = 2\pi r(x,t)\Delta x$ where R and r are the radii of the outer and inner circles on the left side, respectively. We assume that the effect of the local slopes with respect to x of the outer and inner radii are negligible.

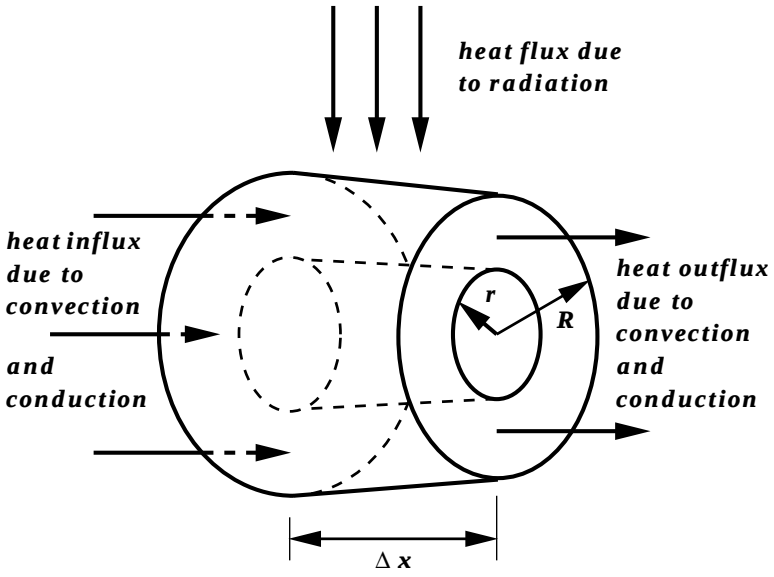

FIG. A.1. *Schematic of the control volume for the conservation of energy in the glass tube.*

The conservation of mass, i.e., the net change of the glass in the control volume due to the net flux of glass from the left and right sides, is given by the continuity equation

$$\frac{\partial(\rho s)}{\partial t} + \frac{\partial(\rho s u)}{\partial x} = 0 \tag{A.1}$$

where ρ is the glass density and u is the local velocity. With the incompressibility assumption, i.e., the material derivative of the density is $D\rho/Dt = \partial\rho/\partial t + u\partial\rho/\partial x = 0$, the continuity equation can be simplified to

$$\frac{\partial s}{\partial t} + \frac{\partial (su)}{\partial x} = 0. \tag{A.2}$$

Define $\gamma \equiv s/s_0$ where s_0 is the initial constant annular cross-sectional area of the tube. Then (A.2) becomes

$$\frac{\partial \gamma}{\partial t} + u\frac{\partial \gamma}{\partial x} + \gamma\frac{\partial u}{\partial x} = 0. \tag{A.3}$$

In order to write down the conservation law for the energy, we make the following observations:

1. On the left surface, the energy influx is due to convective flow of the glass and conduction of heat through the glass within a period Δt, which is given by

$$E^{\text{in}} = s\left(\rho c_p u\theta - \kappa\frac{\partial\theta}{\partial x}\right)\Delta t \tag{A.4}$$

where c_p, κ, and θ are the specific heat, thermal conductivity, and temperature of the glass, respectively. The first term on the right-hand side is the convection due to motion of the glass, and the second term is the heat conduction using Fourier's law.

2. On the right surface, the energy outflux can be written similarly as

$$E^{\text{out}} = -s\left(\rho c_p u\theta - \kappa\frac{\partial\theta}{\partial x}\right)\Delta t - \frac{\partial}{\partial x}\left[s\left(\rho c_p u\theta - \kappa\frac{\partial\theta}{\partial x}\right)\right]\Delta x\Delta t. \tag{A.5}$$

The minus signs reflect the fact that energy is being removed.

3. On the outer surface, the energy exchange mechanism is mainly radiation between the heater coil, glass pipette, and background. For a differential cross section of the tube, the radiative heat transfer absorbed at the surface is given by

$$E^{\text{rad}} = s_{\text{out}}\left[F_{hg}\frac{\varepsilon_h\alpha}{\varepsilon_h + \alpha - \varepsilon_h\alpha}(\theta_h^4 - \theta^4) + F_{bg}\frac{\varepsilon_b\alpha}{\varepsilon_b + \alpha - \varepsilon_b\alpha}(\theta_b^4 - \theta^4)\right], \tag{A.6}$$

where we have assumed the standard fourth-power law of surface-to-surface radiative heat transfer. The factors F_{hg} and F_{bg} are geometrical factors related to the relevant surfaces. In this case, they are the heater surface, the glass outer surface, and the background. Therefore, the subscripts hg and bg refer to the relationship between the heater and glass surfaces, and the background and glass surfaces, respectively. The detailed derivations of these factors are given in Appendix B. The parameters $\varepsilon_h, \varepsilon_b$, and α are the emissivities for the heater and the background, and the absorptivity of the glass, respectively. The first term is the amount of the net energy flux absorbed by the outer surface of the glass tube, due to the radiation from the heater, which is at the temperature $\theta_h \geq \theta$. The second term is the net energy radiated away from the glass tube towards the background, which is at the temperature $\theta_b \leq \theta$.

4. There is no net energy exchange through the inner surface of the glass.

5. The incremental change in the internal energy within the control volume of the glass tube is determined by the change of temperature during the time period Δt and is given by

$$E^{\text{int}} = [\rho c_p s(x, t+\Delta t)\theta(x, t+\Delta t) - \rho c_p s(x,t)\theta(x,t)]\Delta x. \tag{A.7}$$

With these assumptions, we can write down the equation for the temperature using the conservation of energy; i.e., the net increase in the internal energy is equal to the net flux of energy into the control volume, and thus (A.7) = (A.4) + (A.5) + (A.6). After rearranging the terms, we obtain

$$\begin{aligned}\frac{\partial \rho c_p s\theta}{\partial t} + \frac{\partial \rho c_p su\theta}{\partial x} &= \frac{1}{s}\frac{\partial}{\partial x}\left(s\kappa(\theta)\frac{\partial \theta}{\partial x}\right) \\ &\quad + 2\sqrt{\frac{\pi}{s(1-\beta^2)}}k\left[F_{hg}\frac{\varepsilon_h \alpha}{\varepsilon_h + \alpha - \varepsilon_h\alpha}(\theta_h^4 - \theta^4)\right. \\ &\quad \left. + F_{bg}\frac{\varepsilon_b \alpha}{\varepsilon_b + \alpha - \varepsilon_b\alpha}(\theta_b^4 - \theta^4)\right]. \end{aligned} \tag{A.8}$$

We have assumed that the ratio of the inner and outer radii, $\beta = r/R$, is a constant independent of t and x. Note that this equation is different from (2.6) used in our computations. Equation (A.8) is written in conservation form, while (2.6) is in nonconservative form. In (A.8), we can rewrite the two terms on the left-hand side as

$$\begin{aligned}\frac{\partial \rho c_p s\theta}{\partial t} + \frac{\partial \rho c_p su\theta}{\partial x} &= \rho s\left(\frac{\partial c_p\theta}{\partial t} + u\frac{\partial c_p\theta}{\partial x}\right) + c_p\theta\left(\frac{\partial(\rho s)}{\partial t} + \frac{\partial \rho su}{\partial x}\right) \\ &= \rho s\left(\frac{\partial c_p\theta}{\partial t} + u\frac{\partial c_p\theta}{\partial x}\right)\end{aligned}$$

where we have used the continuity equation (A.1). Therefore, the conservation form (A.8) and nonconservative form (2.6) of the energy equation are equivalent.

Appendix B. Derivation of geometric factors. The derivation of the equation for the transfer of thermal energy from the coil heater to the glass tube through radiation requires a detailed knowledge of the differential radiation from a differential area element on the inside surface of the heater to a differential area element on the outer surface of the glass tube. It is assumed that there is no radiation passing through the tube itself. The glass tube surface is assumed to have an absorptivity equal to α. Also, we take into account the variations of the inner and outer radii of the tube. However, we assume that the effects due to the local slope of the outer radius with respect to x are negligible. Also, we approximate the coil by a cylindrical surface with emissivity ε_h.

To account for the relative surface orientations of the heater and tube surfaces, we compute the geometric (or radiation configuration) factor needed to evaluate the thermal energy transfer to the tube (Howell [5]). The geometry of the heater and tube system and the notation are shown in Figure B.1. We evaluate the total radiative heat transfer from the heater to a differential cross section of the tube centered at x. The differential of the geometric factor for a differential area ds at x on the tube for a differential area ds_h on the heater is given by

$$dF_{hg} = \frac{\cos\phi \cos\phi_h ds ds_h}{\pi\sigma^2}$$

where ϕ and ϕ_h are the angles of the line (of length σ) connecting the differential area elements ds and ds_h with the outer normal of the glass tube and inner normal of the heater, respectively. The differential area element on the heater is

$$ds_h = R_h dy d\Phi$$

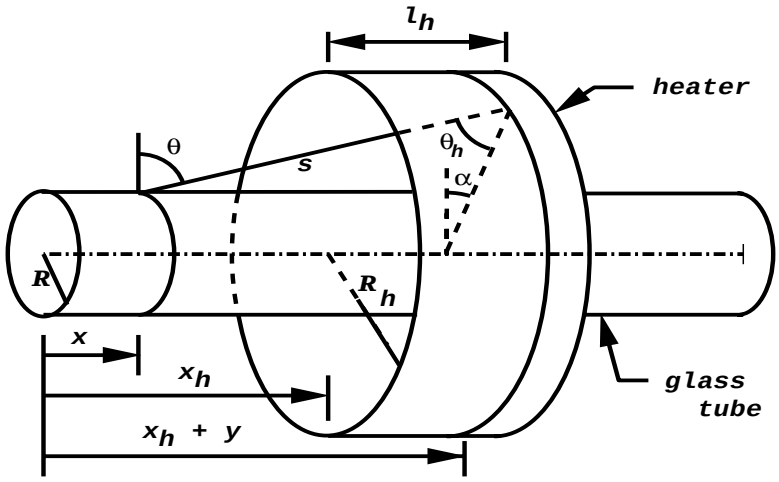

FIG. B.1. *Geometry for radiative heat transfer from the heater to the glass tube.*

where R_h is the heater radius, y is the axial distance between the differential area elements, and Φ is the angle between the two radial segments shown in Figure B.1. Thus the geometric factor from the heater to the area element ds is given by

$$\begin{aligned} F_{hg} &= \frac{1}{\pi}\iint \frac{\cos\phi\cos\phi_h}{\sigma^2}\,ds_h \\ &= \frac{1}{\pi}\int_{-\Phi_0}^{\Phi_0}\int_0^{\ell_h} \frac{\cos\phi\cos\phi_h}{\sigma^2} R_h\,dy\,d\Phi \end{aligned} \tag{B.1}$$

where

$$\begin{aligned} \cos\phi &= -\frac{R^2+\sigma^2-(\ell_h^2+R_h^2)}{2R\sigma}, \\ \cos\phi_h &= \frac{R_h^2+\sigma^2-(\ell_h^2+R_h^2)}{2R_h\sigma}, \\ \sigma^2 &= (y+x_h-x)^2 + R^2 + R_h^2 - 2RR_h\cos\Phi, \\ \Phi_0 &= \cos^{-1}\left(\frac{R}{R_h}\right). \end{aligned} \tag{B.2}$$

The double integral for the geometric factor (B.1) can be simplified to a single integral

$$\begin{aligned} F_{hg} = -\frac{1}{\pi}\int_0^{\Phi_0} & R_h(R_h - R\cos\Phi)(R - R_h\cos\Phi) \\ & \cdot\left[\frac{y+x_h-x}{\mathcal{R}^2[(y+x_h-x)^2+\mathcal{R}^2]} + \frac{\tan^{-1}\frac{y+x_h-x}{\mathcal{R}}}{\mathcal{R}^3}\right]_{y=0}^{y=\ell_h} d\Phi \end{aligned} \tag{B.3}$$

where

$$\mathcal{R}^2 = R^2 + R_h^2 - 2RR_h\cos\Phi.$$

The geometric factor between the glass tube and the background is equivalent to the geometric factor between the glass tube and an infinite cylindrical shell where the segment shielded by the heater is excluded. The formula for this geometric factor can be obtained more simply by replacing the cylinder with a spherical shell, again excluding the portion of the shell shielded by the heater. This formula is given by

$$F_{bg} = 1 - \frac{1}{2\pi}[2(\beta_2 - \beta_1) + \sin 2\beta_2 - \sin 2\beta_1] \tag{B.4}$$

where $\beta_1 = \arctan \frac{R_h}{x_h}$ and $\beta_2 = \arctan \frac{R_h}{x_h + \ell_h}$.

Acknowledgments. We wish to thank Dr. Hilton Ramsey for several useful discussions in the early part of this research. Also, we thank Ken Burkett and Bruce Walding of Corning Glass for supplying us with the thermal and mechanical properties of Corning glass.

PERIODIC TRAVELLING WAVE SELECTION BY DIRICHLET BOUNDARY CONDITIONS IN OSCILLATORY REACTION-DIFFUSION SYSTEMS*

JONATHAN A. SHERRATT†

Abstract. Periodic travelling waves are a fundamental solution form in oscillatory reaction-diffusion equations. Here I discuss the generation of periodic travelling waves in a reaction-diffusion system of the generic λ-ω form. I present numerical results suggesting that when this system is solved on a semi-infinite domain subject to Dirichlet boundary conditions in which the variables are fixed at zero, periodic travelling waves develop in the domain. The amplitude and speed of these waves are independent of the initial conditions, which I generate randomly in numerical simulations. Using a combination of numerical and analytical methods, I investigate the mechanism of periodic travelling wave selection. By looking for an appropriate similarity solution, I reduce the problem to an ODE system. Using this, I derive a formula for the selected speed and amplitude as a function of parameters. Finally, I discuss applications of this work to ecology.

1. Introduction.

Periodic travelling waves (PTWs) are a fundamental solution form in oscillatory reaction-diffusion equations, by which I mean reaction-diffusion systems whose kinetics have a stable limit cycle. PTWs are the one-dimensional analogue of spiral waves and target patterns, and underlie many observed behaviors in biology and chemistry (Bjørnstad, Ims, and Lambin (1999); Scott et al. (2000)). In 1973, Kopell and Howard published their seminal paper, which showed that a reaction-diffusion system develops a one-parameter family of PTWs as its kinetics pass through a Hopf bifurcation. Wave speed or amplitude are convenient parameters for this family, and an oscillatory reaction-diffusion equation has a PTW solution for any speed above a critical minimum value and for any amplitude below that of the limit cycle in the kinetics. Building on Kopell and Howard's work, periodic travelling waves were studied extensively in the 1970s and 1980s. This work focussed primarily on the existence and stability of the solutions. For instance, Maginu (1981) showed that PTWs of sufficiently high speed are stable in general systems, and Ermentrout (1981) demonstrated stable small amplitude waves in a particular reaction-diffusion system. More recent work includes nonlinear stability analysis (Kapitula (1994)), the application of symmetry methods (Romero, Gandarias, and Medina (2000)), and the generation of PTWs behind invasive fronts (Sherratt (1994a,b); Sneyd and Sherratt (1997); Ermentrout, Chen, and Chen (1997); Petrovskii and Malchow (1999), (2000); Ashwin et al. (2002)).

The simplest behavior of an oscillatory system is a spatially uniform oscillation. In many cases, this solution is stable on an infinite, spatially homogeneous domain: for instance, in reaction-diffusion systems, stability is guaranteed when the diffusion coefficients are sufficiently similar (Kopell and Howard (1973)). However, spatially

†Centre for Theoretical Modelling in Medicine, Department of Mathematics, Heriot-Watt University, Edinburgh EH14 4AS, UK (jas@ma.hw.ac.uk).

uniform oscillations are incompatible with spatial heterogeneities, which can arise via spatially varying parameter values or via conditions imposed on finite boundaries. Such situations provide a potential mechanism for the generation of PTWs in oscillatory chemical or biological systems. For instance, it is well known that in experiments with the oscillatory Belousov–Zhabotinskii chemical reaction, small impurities such as dust particles force target patterns or spiral waves rather than homogeneous oscillations (Nagashima (1991), Winfree (2001)). Mathematically, the effects of such heterogeneities have been studied most fully for systems of discrete coupled oscillators. In particular, the work of Ermentrout, Kopell, and colleagues gives a detailed account of the response of chains of weakly coupled oscillators to both boundary- and parameter-based heterogeneities (Ermentrout and Kopell (1984), (1986); Kopell, Ermentrout, and Williams (1991); Ren and Ermentrout (1998)). In oscillatory reaction-diffusion systems, there has been some study of periodic wave generation by spatial inhomogeneities in the domain (Hagan (1981a); Kopell (1981); Kay and Sherratt (2000)). However, heterogeneities imposed at the edges of a domain have received little attention, despite early work by Auchmuty and Nicolis (1976), who developed series solutions for the Brusselator model close to Hopf bifurcation on a finite domain with Neumann and Dirichlet end conditions.

In the present paper, I study the generation of PTWs by particular Dirichlet conditions at one edge of a semi-infinite domain. In section 2, I introduce this behavior with the results of numerical simulations. In section 3, I show that solutions of the observed form satisfy an ODE system with one free parameter, which corresponds to the temporal frequency of the oscillations. I then present a combination of analytical and numerical results suggesting that this ODE system has a solution satisfying appropriate end conditions for a countably infinite set of values of this parameter. In section 5, I discuss the hypothesis that in only one of these solutions does the amplitude vary monotonically in space, and that this determines the stability of the solutions. In section 6, I use a similarity solution to derive a formula for the speed and amplitude of the observed periodic wave. Finally, in section 7, I discuss extensions to two space dimensions and applications of the results.

2. Numerical simulations of PTW generation. All of the work in this paper involves the following oscillatory reaction-diffusion system:

$$\frac{\partial u}{\partial t} = \nabla^2 u + (1 - r^2)u - (\omega_0 - \omega_1 r^2)v, \tag{2.1a}$$

$$\frac{\partial v}{\partial t} = \nabla^2 v + (\omega_0 - \omega_1 r^2)u + (1 - r^2)v, \tag{2.1b}$$

where $r = \sqrt{u^2 + v^2}$. This belongs to the "λ-ω" class of equations introduced by Kopell and Howard (1973). The kinetics in (2.1) are the normal form of any oscillatory kinetics close to a supercritical Hopf bifurcation, and, as such, (2.1) is the natural system for studying generic behavior in systems in which each variable has the same diffusion coefficient. This system is often seen with $(1 - r^2)$ replaced by $(\lambda_0 - \lambda_1 r^2)$, but the coefficients λ_0 and λ_1 can easily be removed by rescaling. All of the work in sections 2–6 is in one space dimension; in section 7, two-dimensional behavior is discussed briefly.

The kinetics of (2.1) have an unstable equilibrium at $u = v = 0$ and a stable circular limit cycle centered at this equilibrium, of radius 1. Standard theory, due

originally to Kopell and Howard (1973), shows that the family of PTWs is given by

$$u = r^* \cos\left[\theta_0 \pm \sqrt{1-r^{*\,2}}x + \left(\omega_0 - \omega_1 r^{*\,2}\right)t\right], \tag{2.2a}$$

$$v = r^* \sin\left[\theta_0 \pm \sqrt{1-r^{*\,2}}x + \left(\omega_0 - \omega_1 r^{*\,2}\right)t\right], \tag{2.2b}$$

where r^* parameterizes the family and θ_0 is an arbitrary constant. The wave is stable as a solution of (2.1), provided that

$$r^* > r_{stab} \equiv \left(\frac{2+2\omega_1^2}{3+2\omega_1^2}\right)^{1/2} \tag{2.3}$$

(Kopell and Howard (1973)). In many situations, it is convenient to rewrite system (2.1) using r and $\theta = \tan^{-1}(v/u)$, which are polar coordinates in the u-v plane. In one space dimension, this gives

$$r_t = r_{xx} - r\theta_x^2 + r(1-r^2), \tag{2.4a}$$

$$\theta_t = \theta_{xx} + \frac{2r_x\theta_x}{r} + \omega_0 - \omega_1 r^2. \tag{2.4b}$$

Here and throughout the paper, the suffixes $_x$ and $_t$ denote derivatives. The PTW solutions (2.2) are of course given in terms of r and θ by

$$r = r^*, \qquad \theta = \theta_0 \pm \sqrt{1-r^{*\,2}}\,x + \left(\omega_0 - \omega_1 r^{*\,2}\right)t.$$

In fact, it is easy to show that any solution with r constant and < 1 is a PTW.

The starting point of my work is the following very simple situation. I consider (2.1) on a semi-infinite domain $x > 0$, say, with the boundary condition $u = v = 0$ at $x = 0$. Numerically this can be reproduced by solving on the finite domain $0 < x < X_\infty$, with X_∞ large and with $u_x = v_x = 0$ at $x = X_\infty$. I consider the solution that develops from random initial conditions, by which I mean that I use a random number generator to calculate u and v values, between ± 1, at points with an equal spacing of about $\Delta x = 5$ throughout the domain, and then join these random values by straight lines to give the initial condition.

For a wide range of values of the parameters ω_0 and ω_1, the numerical solutions of this problem show the same behavior (Figure 1). The solution changes rapidly from the random initial conditions to spatially uniform oscillations everywhere away from the $x = 0$ boundary. A transition wave then develops, which has homogeneous oscillations ahead of it and a PTW behind; this PTW is the long term solution form away from the $x = 0$ boundary. The development and persistence of PTWs in these solutions depends intrinsically on the boundary condition at $x = 0$. For example, if the boundary condition is switched to zero flux ($u_x = v_x = 0$ at $x = 0$), the PTWs disappear, to be replaced by spatially uniform oscillations (see Kay and Sherratt (1999)). Moreover, the speed/amplitude of the PTWs is independent of the seed in the random number generator used for the initial conditions. This suggests that the Dirichlet boundary condition robustly selects a particular member of the PTW family. The basic goal of the paper is to investigate the details of this selection process.

Before I begin analytical investigation of the solution shown in Figure 1, I mention one final and important result from the numerical simulations. The behavior illustrated in Figure 1 applies when $|\omega_1|$ is relatively small. For larger $|\omega_1|$, the long

term behavior consists not of PTWs, but of irregular spatiotemporal oscillations (Figure 2). Later in the paper, I will show that this behavior arises through the same basic mechanism and occurs when the PTW that is selected by the boundary conditions has an amplitude below r_{stab}, defined in (2.3), so that the selected PTW is unstable as a solution of the PDEs.

3. Reduction to an ODE system. The solutions shown in Figure 1 are illustrated more clearly by plotting r and θ_x rather than u and v (Figure 3). The solution changes rapidly from the initial conditions, until $r \approx 1$ and $\theta_x \approx 0$ everywhere away from the $x = 0$ boundary, corresponding to spatially homogeneous oscillations in u and v. A transition wave front in r and θ_x then develops, moving in the positive x-direction. Ahead of this front, $r \to 1$ and $\theta_x \to 0$; behind it, r and θ_x have constant values, r_{ptw} and ψ_{ptw} say, corresponding to the PTW. Numerical results indicate that this transition front moves with constant shape and speed, suggesting that one look

for solutions of (2.1) with the form

$$r(x,t) = \hat{r}(x - st) \quad \text{and} \quad \theta_x(x,t) = \hat{\psi}(x - st) \Rightarrow \theta(x,t) = \int^{z=x-st} \hat{\psi}(z)\, dz + f(t).$$

Here $s > 0$ is the front speed, and $f(t)$ is an arbitrary function of time that enters as a constant of integration. Substituting these solution forms into (2.4) gives

$$\hat{r}'' + s\hat{r}' + \hat{r}(1 - \hat{r}^2 - \hat{\psi}^2) = 0, \tag{3.1a}$$

$$\hat{\psi}' + s\hat{\psi} + \omega_0 - \omega_1\hat{r}^2 + 2\hat{\psi}\hat{r}'/\hat{r} = f'(t). \tag{3.1b}$$

Thus $f'(t)$ must be a constant, independent of t. Moreover, since $\hat{r} \to 1$ and $\hat{\psi} \to 0$ as $x - st \to \infty$, this constant value must be $\omega_0 - \omega_1$. Substituting $\hat{r} = r_{ptw}$ and $\hat{\psi} = \psi_{ptw}$ (values at $x - st = -\infty$) gives solutions for r_{ptw} and ψ_{ptw} in terms of s:

$$r_{ptw} = \sqrt{1 - \frac{s^2}{\omega_1^2}}, \qquad \psi_{ptw} = -\frac{s}{\omega_1}. \tag{3.2}$$

Unfortunately, these formulae cannot be used to obtain the values of r_{ptw} and ψ_{ptw}, since the front speed s is an unknown. However, they do provide one key piece of information: ψ_{ptw} has the sign opposite to that of ω_1, since s must be positive. This will be required in what follows.

Having established the sign of ψ_{ptw}, I now move on to consider the large time form of the solution for r and θ_x. Numerical simulations suggest that this is an equilibrium, which I denote by $r(x,t) = R(x)$ and $\theta_x(x,t) = \Psi(x)$. Hence $\theta = \int^x \Psi(\overline{x})\, d\overline{x} + g(t)$, where $g(t)$ is a constant of integration. Substituting these solution forms into (2.4) implies that $g'(t)$ must be a constant, which it is convenient to take as $\omega_0 - k$, where

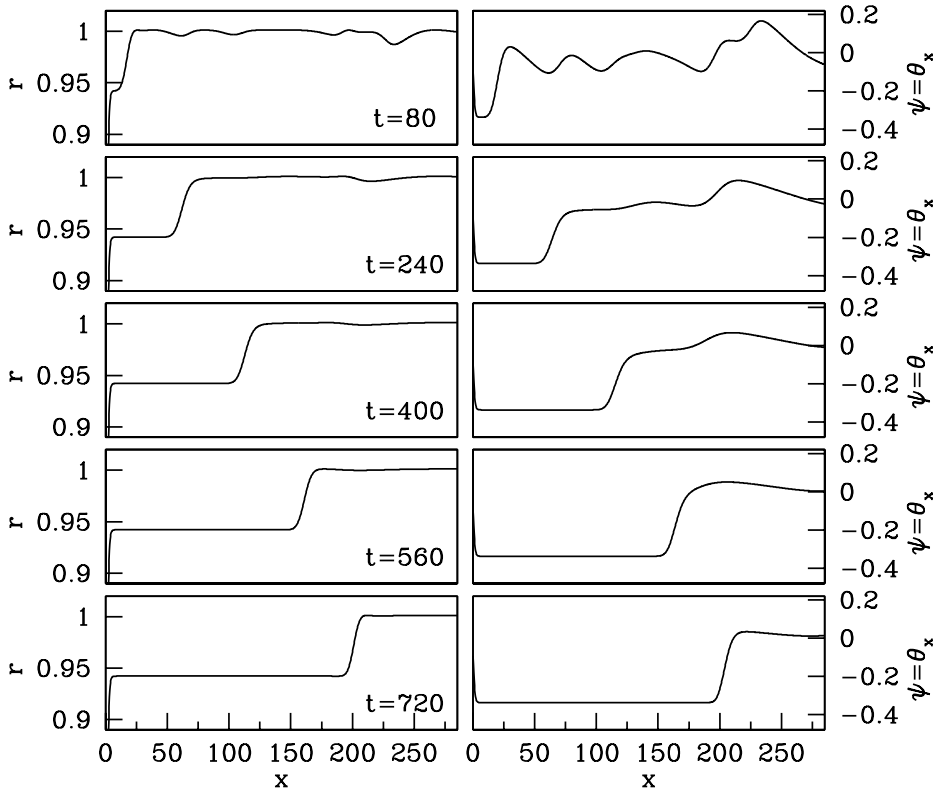

FIG. 3. *Time evolution of the solution of* (2.1) *subject to* $u = v = 0$ *at* $x = 0$. *I solve on* $0 < x < 400$ *with* $u_x = v_x = 0$ *at* $x = 400$, *to approximate a semi-infinite domain. The randomly generated initial condition rapidly evolves to* $u, v \approx 1$. *A transition wave front then develops, moving in the positive* x*-direction. Ahead of the front,* $r = 1$ *and* $\psi = 0$, *while behind it,* r *and* ψ *have values that are constants corresponding to a periodic travelling wave. The parameter values are* $\omega_0 = 0.3$ *and* $\omega_1 = 0.8$. *The equations were solved numerically using a semi-implicit Crank–Nicolson method.*

k is arbitrary and of either sign. The substitution also gives the following equations for R and Ψ:

$$R_{xx} + R(1 - R^2 - \Psi^2) = 0, \tag{3.3a}$$

$$\Psi_x + \frac{2\Psi R_x}{R} + k - \omega_1 R^2 = 0. \tag{3.3b}$$

The boundary condition $u = v = 0$ implies that $R = 0$ at $x = 0$, and I am looking for solutions for which R and Ψ tend to constant values, denoted r_{ptw} and ψ_{ptw}, as $x \to \infty$, with the sign of ψ_{ptw} opposite to that of ω_1. In a solution of this form, the values of r_{ptw} and ψ_{ptw} will be related to k and ω_1 by

$$r_{ptw} = \sqrt{\frac{k}{\omega_1}}, \qquad \psi_{ptw} = -\mathrm{sign}(\omega_1)\sqrt{1 - \frac{k}{\omega_1}}. \tag{3.4}$$

These are given simply by substituting the constant values into (3.3) and using the result that ψ_{ptw} and ω_1 have opposite signs; k is related to the speed s introduced above by $k = \omega_1 - s^2/\omega_1$. Note that k must have the same sign as ω_1.

It is convenient to rescale (3.3) as follows,

$$\phi = R\left(\frac{\omega_1}{k}\right)^{1/2}, \qquad w = R_x\left(\frac{\omega_1 - k}{k}\right)^{1/2} \cdot \frac{\text{sign}(\omega_1)}{k},$$

$$\Gamma = -\frac{\Psi}{R}\left(\frac{k}{\omega_1 - k}\right)^{1/2} \text{sign}(\omega_1), \qquad z = x\left(\frac{\omega_1}{\omega_1 - k}\right)^{1/2} \cdot k \cdot \text{sign}(\omega_1),$$

which gives

$$\phi_z = w, \tag{3.5a}$$

$$w_z = \frac{-\alpha}{k^2}\phi\left[1 - \phi^2 - \alpha\phi^2(\Gamma^2 - 1)\right], \tag{3.5b}$$

$$\Gamma_z = \frac{1 - 3w\Gamma - \phi^2}{\phi}, \tag{3.5c}$$

where $\alpha = 1 - k/\omega_1$, so that $0 \le \alpha \le 1$. In terms of these new variables, the required end conditions are

$$\phi = 0 \text{ at } z = 0 \quad \text{and} \quad \phi = 1,\ w = 0,\ \Gamma = 1 \text{ at } z = \infty. \tag{3.6}$$

Recall that the parameter k in (3.5) is an arbitrary constant of integration, and the initial question to be studied is for which values of k there are solutions of (3.5) satisfying these end conditions.

Numerical investigation of appropriate solutions to (3.5) is easiest if one integrates backwards in z from $(1, 0, 1)$. Straightforward calculation of the eigenvalues at this equilibrium shows that there is a unique stable eigenvector, and one can calculate numerically both trajectories corresponding to this eigenvector. For given values of k and ω_1, there is a solution of (3.5) of the required form if ϕ becomes zero along one of these trajectories. Numerical investigation indicates that this occurs at a large but discrete set of values of k. As illustrated in Figure 4, these values of k are widely separated when $|k|$ is just below $|\omega_1|$, and become closer together as $|k|$ approaches zero. (Recall that the sign of k is determined by that of ω_1.) Figure 5 illustrates how the critical values of k vary with ω_1.

4. Solution for small ω_1. I have been unable to calculate in general the values of k for which (3.5) has a solution of the required form. However for small $|\omega_1|$ the solutions, and thus the critical values of k, can be found using perturbation theory. Here I am exploiting the relative simplicity of (2.1) when $\omega_1 = 0$, a special case which has been used by a number of previous authors (for example, Kopell and Howard (1981)). Figure 6 illustrates the typical form of the solution for the largest few critical values of $|k|$ when $|\omega_1|$ is small. There is a characteristic solution form, with almost periodic oscillations in ϕ, w, and Γ. To calculate the solutions, it is enough to investigate one cycle of these oscillations.

Numerical solutions suggest that when $|\omega_1|$ is small, $|k|$ is also small, with the ratio $A \equiv \alpha/k^2$ being $O(1)$ as $|\omega_1| \to 0$. Then $\alpha^2/k^2 = A^2\omega_1^2 + O(\omega_1^4)$, and thus the equations (3.5) have the form

$$\phi_{zz} = -A\phi(1 - \phi^2) + \epsilon A^2\phi^3(\Gamma^2 - 1), \tag{4.1a}$$

$$\Gamma_z = \frac{1 - 3\phi_z\Gamma - \phi^2}{\phi}, \tag{4.1b}$$

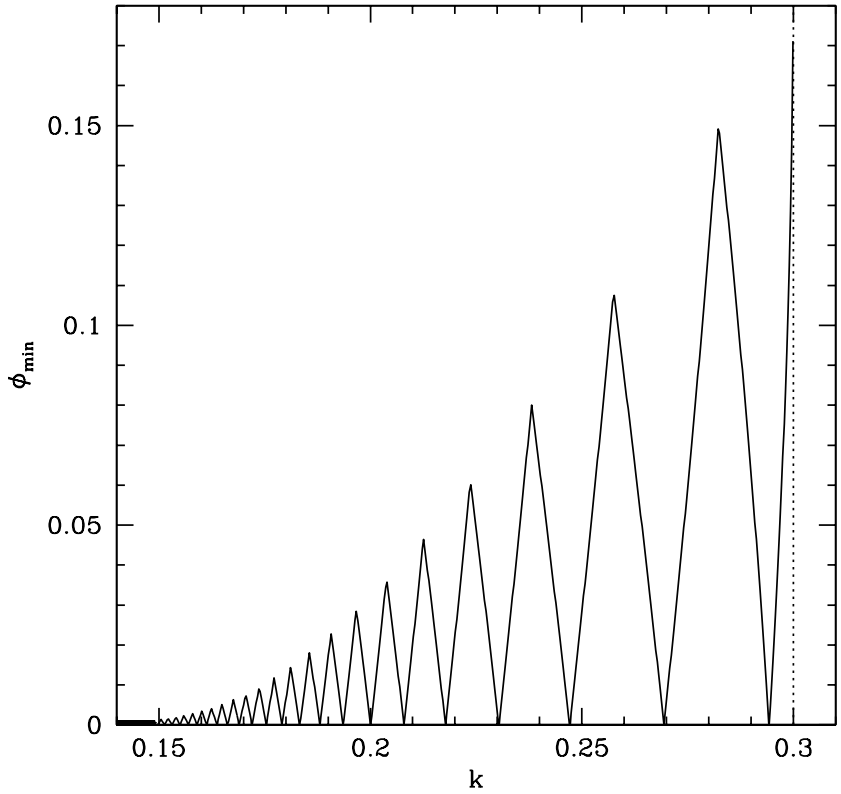

FIG. 4. *A typical plot of the variation with k of ϕ_{min}, the minimum value of ϕ along the two solution trajectories passing through the point $\phi = 1$, $w = 0$, $\Gamma = 1$. The variation has a "zig-zag" form, with ϕ_{min} approaching zero at a series of discrete values of k. The case shown is for $\omega_1 = 0.3$, and the dotted line is $k = \omega_1$; the constant k must lie between 0 and ω_1. The value of ϕ_{min} is calculated by solving* (3.5) *in the negative z-direction starting on the (unique) stable eigenvector at* $(1, 0, 1)$. *The solution is continued until $\phi > 1$, keeping track of the minimum value of ϕ. For each parameter set, this procedure must be followed twice, starting on either side of* $(1, 0, 1)$ *along the stable eigenvector.*

where $\epsilon = \omega_1^2$. The appropriate solution structure for these equations when $\epsilon \ll 1$ is illustrated in Figure 7. I consider one cycle of the solution in three separate regions a–c, with a fourth region a′ corresponding to region a in the next cycle. The boundary between regions a and b is the position at which ϕ has its local maximum, while region c is a thin layer centered on the local minimum of ϕ. No thin transition layer is required between regions a and b, but the location $z = z_1$ of the interface may depend on ϵ, as may the location $z = z_2$ of region c, and these dependencies must be found as part of the solution. The position $z = z_0$ to the left of region a is arbitrary.

In region a, there is no rescaling, and the leading order solutions ϕ_0^a, Γ_0^a satisfy (4.1) with ϵ set to zero. The two equations decouple, giving

$$\frac{d^2\phi_0^a}{dz^2} = -A\phi_0^a\left[1 - \phi_0^{a\,2}\right],$$
$$\frac{d\Gamma_0^a}{dz} = \frac{1 - 3\Gamma_0^a d\phi_0^a/dz - \phi_0^{a\,2}}{\phi_0^a}.$$

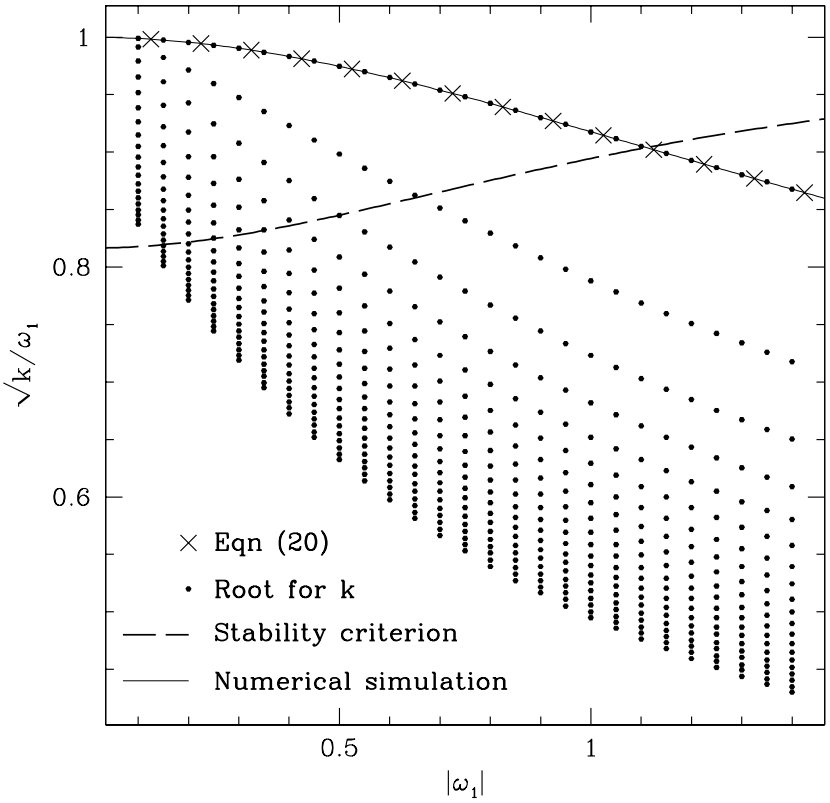

FIG. 5. *A plot of the amplitude* ($\sqrt{k/\omega_1}$) *of possible PTW solutions, corresponding to the critical values of* k *for which* (3.5) *has a solution of the required form. For a series of values of* ω_1, *I plot the amplitude corresponding to the largest* 20 *critical values of* k, *calculated numerically as discussed in the legend to Figure* 4. *Superimposed on the plot are the amplitude of PTWs predicted by numerical simulations of the PDEs* (2.1), *the theoretical prediction* (6.2) *of the PTW amplitude, and the curve determining PTW stability, which is given by* (2.3). *Note that this last curve does not refer to the stability of the solution of* (3.5), (3.6), *but simply to the PTW which this solution approaches as* $z \to \infty$. *Stability of this PTW is clearly a necessary but not sufficient condition for the stability of the solution of* (3.5), (3.6).

Thus

$$\left(\frac{d\phi_0^a}{dz}\right)^2 = \frac{1}{2}A({\phi_0^a}^2 - 1)^2 + C_1,$$

where C_1 is a constant of integration. Numerical solutions suggest that the local maxima in ϕ occur at $\phi = 1 + o(1)$ as $\epsilon \to 0$, and thus $C_1 = 0$. By construction, ϕ_0^a has positive slope, and thus further integration gives

$$\phi_0^a = \tanh\left[(z - z_0)\sqrt{\frac{A}{2}}\right], \tag{4.2a}$$

$$\Gamma_0^a = \sqrt{\frac{2}{9A}} + \frac{k_1}{\tanh^3[(z - z_0)\sqrt{A/2}\,]}. \tag{4.2b}$$

Here I am taking $\phi_0^a = 0$ at $z = z_0$, since numerical solutions suggest that the minima of ϕ are $o(1)$ as $\epsilon \to 0$; k_1 is a constant of integration.

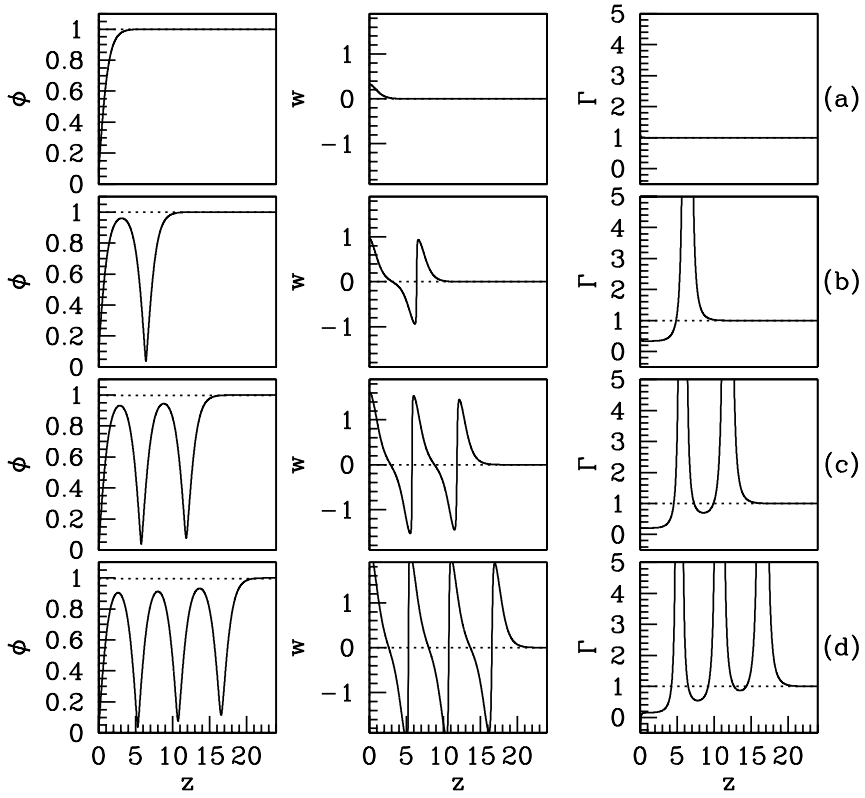

FIG. 6. *Typical solutions of* (3.5) *for small* $|\omega_1|$. *I show the solution for the largest three critical values of* $|k|$, *illustrating the typical form of the solution. For the largest value of* $|k|$, *the solution is monotonic in* ϕ, *and in successive solutions the variables cycle. The parameter values are* $\omega_1 = 0.03$ *and* (a) $k = 0.029994$, (b) $k = 0.029947$, (c) $k = 0.02986$, (d) $k = 0.02973$.

Similarly, in region b

$$\phi_0^b = -\tanh\left[(z - z_2)\sqrt{\frac{A}{2}}\right], \tag{4.3a}$$

$$\Gamma_0^b = -\sqrt{\frac{2}{9A}} + \frac{k_2}{\tanh^3[(z - z_2)\sqrt{A/2}\,]}, \tag{4.3b}$$

where k_2 is a constant of integration. The solutions in regions a and b are linked by conditions at $z = z_1$, namely, that $d\phi/dz = 0$ with ϕ and Γ continuous. Continuity of ϕ requires $z_1 - z_0 = z_2 - z_1 \equiv Z$, say, so that $z_1 = (z_0 + z_2)/2$. The zero derivative for ϕ then implies that $\operatorname{sech}^2\,[Z\sqrt{A/2}\,] = o(1)$, so that $Z \to \infty$ as $\epsilon \to 0$. Thus the widths of regions a and b become infinite as $\epsilon \to 0$. Further details of these widths are not determined at leading order, but higher order solutions (omitted for brevity) show that $Z = O_s(\log \epsilon)$ as $\epsilon \to 0$. Finally, continuity of Γ at $z = z_1$ gives a relationship between k_1 and k_2:

$$k_2 = k_1 + \sqrt{\frac{8}{9A}}\,;$$

here I use the fact that $\tanh(Z\sqrt{A/2}) = 1 + o(1)$ as $\epsilon \to 0$.

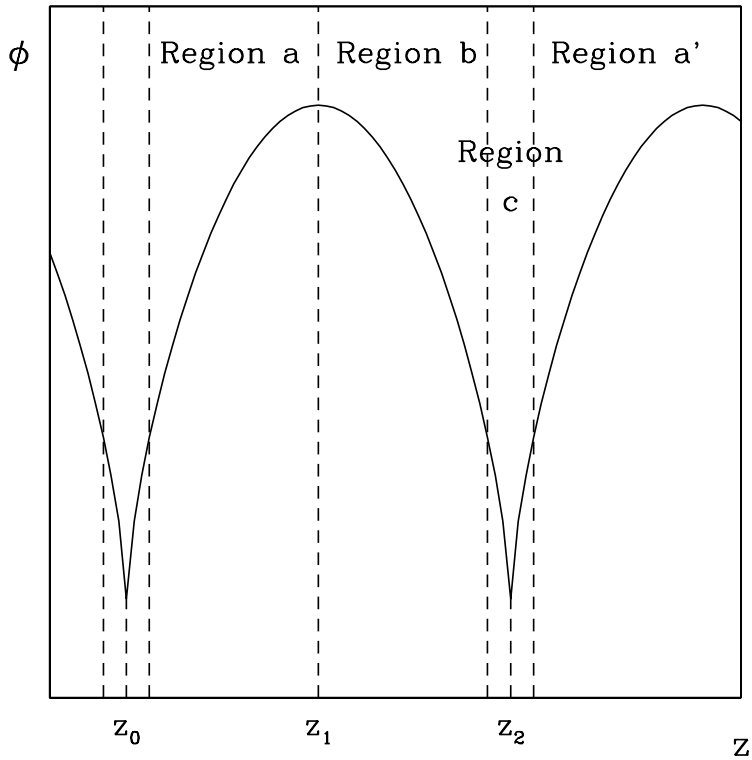

FIG. 7. *A schematic illustration of one cycle of the solution for* ϕ *of* (3.5) *when* ω_1 *is small, illustrating the different regions into which the solution is divided for the perturbation theory calculation.*

In region c, which is centered on the minimum of ϕ, a rescaling of the variables is required. Numerical solutions suggest that ϕ is small and Γ large in this region, with rapid changes in z. Therefore I substitute

$$\tilde{\phi} = \frac{\phi}{\nu_1}, \qquad \tilde{\Gamma} = \Gamma \cdot \nu_2, \qquad \zeta = \frac{z - z_2}{\nu_1}$$

into (3.5), where ν_1 and ν_2 are $o(1)$ as $\epsilon \to 0$; the rescaling of ϕ and z must be the same to allow matching of ϕ in regions b and c. This gives

$$\frac{d^2\tilde{\phi}}{d\zeta^2} = -\nu_1^2 A\tilde{\phi}(1 - \nu_1^2\tilde{\phi}^2) + \epsilon A^2\nu_1^4\tilde{\phi}^3\left(\frac{\tilde{\Gamma}^2}{\nu_2^2} - 1\right),$$
$$\frac{d\tilde{\Gamma}}{d\zeta} = \frac{\nu_2 - 3\tilde{\Gamma}d\tilde{\phi}/d\zeta - \nu_1^2\nu_2\tilde{\phi}^2}{\tilde{\phi}}.$$

Therefore the distinguished limit has $\epsilon^{1/2}\nu_1^2/\nu_2 = 1$, in which case the leading order solutions $\tilde{\phi}_0^c$ and $\tilde{\Gamma}_0^c$ satisfy

$$\frac{d^2\tilde{\phi}_0^c}{d\zeta^2} = A^2\tilde{\phi}_0^{c\,3}\tilde{\Gamma}_0^{c\,2},$$
$$\frac{d\tilde{\Gamma}_0^c}{d\zeta} = \frac{-3\tilde{\Gamma}_0^c d\tilde{\phi}_0^c/d\zeta}{\tilde{\phi}_0^c}.$$

Thus $\tilde{\Gamma}_0^c = k_3/\tilde{\phi}_0^{c\,3}$ and

$$\left(\frac{d\tilde{\phi}_0^c}{d\zeta}\right)^2 = k_4 - \frac{A^2 k_3^2}{\tilde{\phi}_0^{c\,2}}. \tag{4.4}$$

Here k_3 and k_4 are constants of integration, which are determined by matching the solution to that in region b. As $\zeta \to \pm\infty$, (4.4) implies that $\tilde{\phi}_0^c = \pm k_4^{1/2}\zeta + o(\zeta)$, so that $\tilde{\Gamma}_0^c = \pm k_3/(k_4^{3/2}\zeta^3) + o(\zeta^{-3})$. In comparison, as $z \to z_2^-$, $\phi_0^b \sim -(z - z_2)\sqrt{A/2}$ and $\Gamma_0^b \sim (2/A)^{3/2} k_2 (z - z_2)^{-3}$. Therefore, matching requires $k_4 = A/2$, $k_2 = k_3$, and $\nu_2 = \nu_1^3 \Rightarrow \nu_1 = \epsilon^{1/2}$, $\nu_2 = \epsilon^{3/2}$.

The final step in the leading order solution is to determine behavior in region a′. The solution here is the same as in region a, but with new constants of integration:

$$\phi_0^{a'} = \tanh\left[(z - z_0')\sqrt{\frac{A}{2}}\right], \tag{4.5a}$$

$$\Gamma_0^{a'} = \sqrt{\frac{2}{9A}} + \frac{k_1'}{\tanh^3[(z - z_0)\sqrt{A/2}\,]}. \tag{4.5b}$$

Matching this solution with that in region c is directly analogous to the matching of solutions in regions b and c, and requires $k_1' = k_3$. Hence $k_1' = k_1 + \sqrt{8/9A}$.

Consider now a solution of the form illustrated in Figure 6, and with N local maxima in ϕ before ϕ approaches 1 asymptotically. Let k_1^i be the constant of integration k_1 in the leading order solution in region a before the ith maximum ($i = 1, \dots, N-1$) or in the part of the solution in which ϕ approaches 1 asymptotically ($i = N$). Then I have shown that $k_1^i = k_1^{i-1} + \sqrt{8/9A}$. Now I require Γ finite at $z = 0$, and $\Gamma \to 1$ as $z \to \infty$. Thus $k_1^1 = 0$ and $\sqrt{2/9A} + k_1^N = 1 + O(\epsilon^{1/2})$; the correction is based on the next order term in the expansion for Γ in region a (omitted for brevity). Therefore $\sqrt{2/9A} + (N-1)\sqrt{8/9A} = 1$, which can be rearranged to give $A = \frac{8}{9}(N - \frac{1}{2})^2$.

This calculation shows that there are a discrete but infinite set of values of A for which (4.1) has a solution of the required form. These correspond to the values of k plotted in Figure 4. To make this correspondence precise, recall that $A = \alpha/k^2$, with $\alpha = 1 - k/\omega_1$ and $\omega_1 = \epsilon^{1/2}$, so that $k = \epsilon^{1/2} - A\epsilon^{3/2} + O(\epsilon^{5/2})$. Therefore, at least for sufficiently small ω_1, there are solutions of (3.5) for an infinite set of values of k, given by $k = \omega_1 - \frac{8}{9}(N - \frac{1}{2})^2\omega_1^3 + O(\omega_1^5)$ ($N = 1, 2, \dots$). The solution with index N has $N - 1$ local maxima and minima in ϕ. The values of ϕ at these extrema depend on ϵ: the minima have a height that is $O(\epsilon^{1/2}) = O(\omega_1)$, and the leading order correction to ϕ in regions a and b is $O(\epsilon)$, implying that the maxima have a height that is $1 - O(\epsilon) = 1 - O(\omega_1^2)$.

5. Solutions for general ω_1. In the plot of the critical values of k in Figure 4, I superimpose a plot of the amplitude of the PTW that develops in numerical solutions of (2.1) subject to $u = v = 0$ at $x = 0$ on $0 < x < \infty$. In every case, this corresponds to the critical value of k with largest absolute value. This is despite the fact that each of the other critical values of k corresponds to a possible long term solution of (2.1). In this section, I will discuss in more detail the structure of the ϕ-w-Γ phase plane, to give further insight into the equation forms at different critical values of k.

I begin by investigating the behavior of (3.5) near $\phi = 0$, which is a singularity. As $\phi \to 0$, simple inspection of (3.5c) shows that $|d\Gamma/dz| \to \infty$ away from the curve $w\Gamma = 1/3$. Behavior near this curve requires more careful investigation, and I look

for trajectories of the form $w = w_0 + \tilde{w}(\phi)$, $\Gamma = w_0/3 + \tilde{\Gamma}(\phi)$, where w_0 is an arbitrary constant and $\tilde{w}$ and $\tilde{\Gamma}$ are $o(1)$ as $\phi \to 0$. Substituting these solution forms into (3.5) shows that to leading order

$$\tilde{w}(\phi) = \frac{-\alpha}{2k^2 w_0}\phi^2, \qquad \tilde{\Gamma}(\phi) = \frac{1}{10w_0}\left(\frac{\alpha}{w_0^2 k^2} - 2\right)\phi^2. \tag{5.1}$$

Therefore, despite the singularity of (3.5) at $\phi = 0$, there is a family of nonsingular trajectories which cross the $\phi = 0$ plane through the curve $\Gamma w = 1/3$. Such a curve is sometimes known as a "hole in a singular barrier" (Perumpanani et al. (1999); Pettet, McElwain, and Norbury (2000)). Of the trajectories crossing $\phi = 0$ through this curve, only those crossing at positive values of w and Γ are of interest, and taken together, these make up a surface in ϕ-w-Γ phase space, which I denote by $\mathcal{S}(k)$. There is a trajectory of the required form for a given value of k if and only if this surface $\mathcal{S}(k)$ contains the point $\phi = 1$, $w = 0$, $\Gamma = 1$.

The surface $\mathcal{S}(k)$ has a very complex form, especially for small values of k, making visualization in three dimensions very difficult. I have found it most instructive to plot a cross section of the surface, and a natural cross section is the $w = 0$ plane, which is illustrated in Figure 8 for the largest three critical values of k when $\omega_1 = 1$. Note that, in each case, the intersection includes the point $\Gamma = \phi = 1$.

In Figure 8(a) the trajectories making up $\mathcal{S}(k)$ intersect the $w_z < 0$ portion of the $w = 0$ plane only once. This implies that the corresponding solution of (3.5), (3.6) is monotonic in ϕ, and numerical results suggest that this is also true for other ω_1, when k is at its largest critical value. Conversely, for the other critical values of k, numerical solutions suggest that the trajectory passing through $\phi = \Gamma = 1$, $w = 0$ does so only after previously crossing the $w = 0$ plane. Based on this, I hypothesize that for given ω_1 there is only one solution of (3.5), (3.6) that is monotonic in ϕ, namely, that corresponding to the largest initial value of k. Further, I hypothesize that any solutions of (3.5) with nonmonotonic ϕ are unstable as solutions of (2.1). A number of results of the form "nonmonotonicity implies instability" are known for scalar reaction-diffusion equations (Hagan (1981b), Henry (1981)), and numerical simulations using the solutions of (3.5), (3.6) with small perturbations as initial conditions for (2.1) suggest that a corresponding result applies in this case. Taken together, these hypotheses provide an explanation for the solution of (2.1) always corresponding to the solution of (3.5), (3.6) with the largest critical value of k.

Although I cannot prove these hypotheses, I will present a sketch proof of the first one. Proof that a solution that is monotonic in ϕ exists for some value of k is obtained by direct construction. Numerical solutions of (2.1) with $u = v = 0$ at $x = 0$ suggest that the ratio of Ψ and R is constant in the observed solution. Based on this, I look for a solution of (3.5) in which $\Gamma \equiv 1$. The equations (3.5) then give

$$\phi_z = w, \tag{5.2a}$$

$$w_z = -\left(\frac{\alpha}{k^2}\right)\phi(1 - \phi^2), \tag{5.2b}$$

$$3w + \phi^2 = 1. \tag{5.2c}$$

Combining (5.2a) and (5.2b), and requiring $\phi = 1$ when $w = 0$, gives

$$w^2 = \frac{\alpha}{2k^2}(1 - \phi^2)^2.$$

This is consistent with (5.2c) if and only if $k^2 = 9\alpha/2$. (Recall that the sign of k must

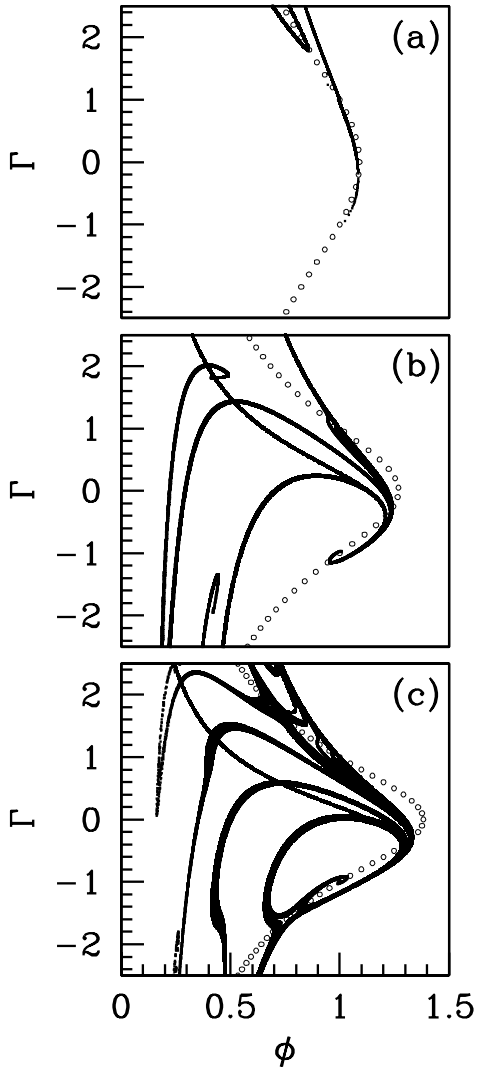

FIG. 8. *An illustration of the intersection between the surface $\mathcal{S}(k)$ and the $w = 0$ plane for the largest three critical values of k when $\omega_1 = 1$. The small circles represent the curve $\phi^2\left[1-\alpha+\alpha\Gamma^2\right] = 1$; to the right of this curve, $w_z > 0$, so that the trajectories are crossing from negative to positive w, and to the left of the curve, $w_z < 0$. I have solved* (3.5) *numerically for values of w_0 increasing from* 0.01 *in increments of 10^{-6}; initial conditions are $w = w_0 + \tilde{w}$, $\Gamma = \Gamma_0 + \tilde{\Gamma}$ with $\tilde{w}$ and $\tilde{\Gamma}$ given by* (5.1)*, and $\phi = 0.001$. In each of these solutions, I record and plot each point at which the $w = 0$ plane is crossed. The values of k are* (a) $k = 0.842$, (b) $k = 0.621$, (c) $k = 0.523$.

be the same as that of ω_1.) Recalling that $\alpha = 1 - k/\omega_1$, this implies

$$k = k^* \equiv \frac{-9 + \sqrt{81 + 72\omega_1^2}}{4\omega_1}.$$

Note that the solution trajectory corresponding to this value of k is monotonic in w as well as ϕ, and thus lies within $\hat{\mathcal{S}}(k)$, the subset of $\mathcal{S}(k)$ formed by the portion of the trajectories starting on $\phi = 0$, $w\Gamma = 1/3$, until they leave the region $\phi > 0$, $w > 0$, $\phi^2[1 + \alpha(\Gamma^2 - 1)] < 1$; this last condition is simply $w_z < 0$.

To study uniqueness, it is convenient to consider varying k with α, rather than ω_1, fixed. Suppose that there is a value of k, k_1 say, not equal to k^*, for which there is a trajectory that is monotonic in ϕ and connects $\phi = 0$, $w\Gamma = 1/3$ with $w = 0$, $\phi = \Gamma = 1$. To be specific, I assume that $k_1 < k^*$, though a corresponding argument is valid if $k_1 > k^*$. The solution trajectories for $k = k_1$ and k^* are contained in $\mathcal{S}(k_1)$ and $\hat{\mathcal{S}}(k^*)$, respectively; note that in general the trajectories for k^* and k_1 will cross $\phi = 0$ at different points along $w\Gamma = 1/3$. Straightforward examination of the eigenvalues and eigenvectors of (3.5) at $w = 0$, $\phi = \Gamma = 1$ implies that $\mathcal{S}(k_1)$ lies above $\hat{\mathcal{S}}(k^*)$ close to this point, in the sense that w is greater on $\mathcal{S}(k_1)$ than on $\hat{\mathcal{S}}(k^*)$. Moreover eliminating w_0 in (5.1) implies that $\hat{\mathcal{S}}(k^*)$ lies above $\mathcal{S}(k_1)$ for sufficiently small ϕ. This suggests that the surfaces $\mathcal{S}(k_1)$ and $\hat{\mathcal{S}}(k^*)$ intersect, which is impossible since (3.5b) implies that w_z increases with k in the region $\phi^2[1 + \alpha(\Gamma^2 - 1)] < 1$. It remains possible that $\mathcal{S}(k_1)$ and $\hat{\mathcal{S}}(k^*)$ wind around one another; I have been unable to rule this out, although numerical solutions suggest that it does not happen.

6. The form of the observed periodic travelling wave. The sketch proof in the previous section is constructive, in the sense that it explicitly determines a formula for k^*. The corresponding solution of (3.5) can easily be determined from (5.2c) as $\phi = \tanh(z/3)$. Converting back to the original variables gives

$$R(x) = r_{ptw} \tanh\left(\frac{x}{\sqrt{2}}\right), \qquad \Psi(x) = \psi_{ptw} \tanh\left(\frac{x}{\sqrt{2}}\right), \tag{6.1}$$

where

$$r_{ptw} = \left\{\frac{1}{2}\left[1 + \sqrt{1 + \frac{8}{9}\omega_1^2}\right]\right\}^{-1/2}, \qquad \psi_{ptw} = -\text{sign}(\omega_1)\left\{\frac{\sqrt{1 + \frac{8}{9}\omega_1^2} - 1}{\sqrt{1 + \frac{8}{9}\omega_1^2} + 1}\right\}^{1/2}. \tag{6.2}$$

The solution given by (6.1), (6.2) is an excellent match with the long term behavior predicted by numerical simulations of (2.1) subject to $u = v = 0$ at $x = 0$, as illustrated in Figure 4. Moreover, (6.2) enables direct determination of the properties of PTWs generated by Dirichlet boundary conditions. For example, substitution of (6.2) into (2.3) gives the condition for PTW stability as

$$8\omega_1^6 + 16\omega_1^4 - 10\omega_1^2 - 27 < 0 \quad \Longleftrightarrow \quad |\omega_1| < 1.110468\ldots. \tag{6.3}$$

A detailed numerical study shows that cases such as that shown in Figure 3, in which irregular oscillations develop, correspond exactly to values of ω_1 above this critical value. Similarly the direction of the PTWs can be determined—this depends on ω_0 as well as ω_1. The PTW solution for u and v, given in (2.2), moves in the positive x-direction if and only if $(\omega_0 - \omega_1 r^2)$ and θ_x have opposite signs. Therefore the PTW given by (6.2) moves in the positive x-direction if and only if

$$\psi_{ptw} \cdot (\omega_0 - \omega_1 r_{ptw}^2) < 0 \Leftrightarrow \omega_0 \text{ and } \omega_1 \text{ have the same sign} \tag{6.4a}$$

$$\text{and } |\omega_0| > \frac{2|\omega_1|}{1 + \sqrt{1 + \frac{8}{9}\omega_1^2}}. \tag{6.4b}$$

Conditions (6.3) and (6.4) are illustrated graphically in Figure 9.

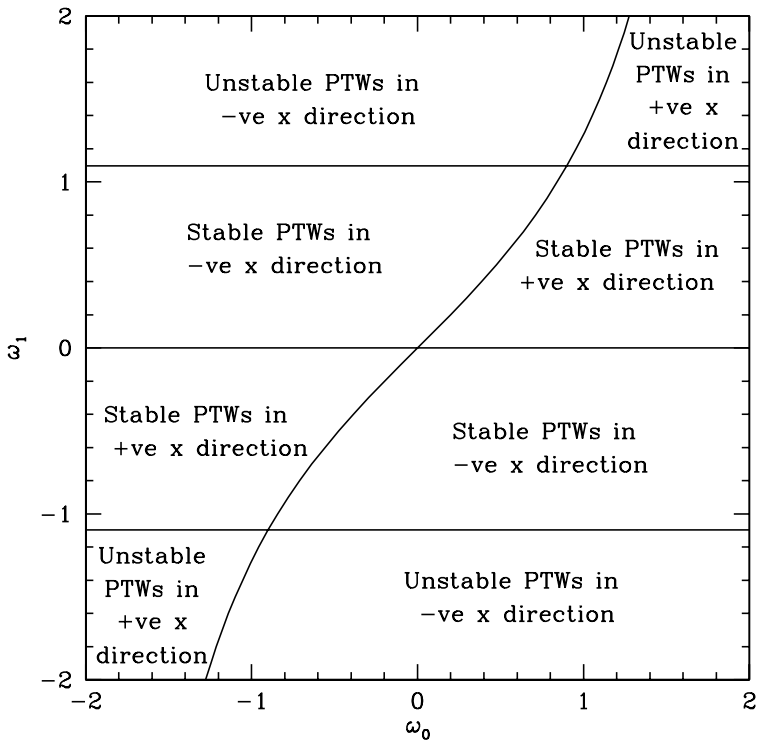

FIG. 9. *An illustration of conditions* (6.3) *and* (6.4) *for the stability and direction of the PTW solution generated in the region* $x > 0$ *by the boundary condition* $u = v = 0$ *at* $x = 0$.

7. Discussion. Using a combination of analysis and numerical simulation, I have shown that when the λ-ω system (2.1) is solved on a finite domain subject to zero Dirichlet boundary conditions, PTWs develop. I have shown that there is a discrete family of possible wave amplitudes for which solutions exist, but my results suggest that in only one of these cases does the amplitude vary monotonically in space. I hypothesize that this family is the only stable solution, implying that the boundary conditions select a unique PTW amplitude that is independent of initial conditions. A formula for this amplitude is given in (6.2).

An obvious extension of the work presented in this paper is to consider behavior in two spatial dimensions. I have done a limited program of numerical simulations of the λ-ω system (2.1) in two dimensions, and a typical result is illustrated in Figure 10. For this figure, equations (2.1) were solved on an approximately circular but irregular domain, with the boundary condition $u = v = 0$. A solution of "target pattern" form develops, moving inwards from the boundary; an animation of this solution can be seen at www.ma.hw.ac.uk/∼jas/supplements/dirichlet/. This solution is a natural two-dimensional extension of the one-dimensional results I have been discussing, in which planar PTW solutions are modulated by the curvature of the domain. A natural topic for future analytical work is the spatial scale over which the curvature of the wave fronts varies.

The mathematical study of PTWs has been given a significant boost recently by the identification by ecologists of PTWs in cyclic populations. This empirical work is slow, requiring spatiotemporal field data gathered over many years. (Pop-

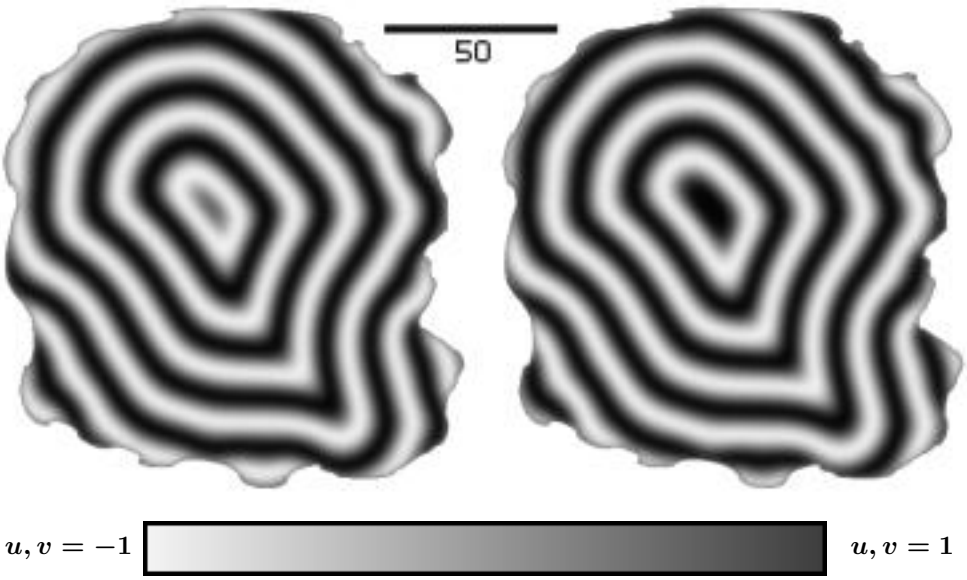

FIG. 10. *Numerical simulation of the λ-ω system* (2.1) *in two space dimensions on an irregular domain with boundary condition* $u = v = 0$ *on the perimeter. The solutions for* u *(left) and* v *(right) are shown at time* $t = 400$*; a "target pattern"-type solution moves inwards from the boundary towards the center of the domain. The initial conditions (at* $t = 0$*) are generated randomly, and the parameters are* $\omega_0 = \omega_1 = 1$*. The size of the spatial domain is indicated by the scale bar, which is* 50 *space units long. The equations were solved numerically using an alternating direction semi-implicit method.*

ulation cycles typically have a period of between 4 and 10 years.) The analysis of the data then depends on spatiotemporal statistical methods developed only recently (Bjørnstad, Ims, and Lambin (1999)). For these reasons, it is too early to assess how widespread PTWs are in real populations. However, there is now very strong evidence for the existence of a PTW in cyclic field vole populations in the Kielder forest, on the Scotland–England border (Lambin et al. (1998); MacKinnon et al. (2001)), and more limited evidence for PTWs in various other populations, including red grouse in Northeast Scotland (Moss, Elston, and Watson (2000)), water voles in Eastern France (Giraudoux et al. (1997)), and larch budmoths in the European Alps (Bjørnstad et al. (2002)). The major question raised by these ecological studies is, what are the cause(s) of the PTWs? One possibility is that the PTWs are generated by the invasion of a prey population by predators (Sherratt, Lewis, and Fowler (1995); Sherratt et al. (2000)). However, once a whole domain has been invaded, PDE models predict that the waves will gradually die out (with zero flux boundary conditions; see Kay and Sherratt (1999)). Thus this mechanism requires a recent invasion, which does not apply in most cases. In contrast, the mechanism studied in this paper is consistent with conditions found in many real ecological systems. A Dirichlet boundary condition (with population density equal to zero) is appropriate when the domain is surrounded by a region of different habitat in which the population cannot survive—for example, an area of woodland surrounded by open fields. In a companion paper (Sherratt et al. (2002)), coworkers and I show that numerical simulations of both PDE and spatially discrete predator-prey models predict the generation of periodic waves by Dirichlet

boundary conditions. Extension of the analytical results in the present paper to realistic predator-prey models is a major challenge for future work, which would enable systematic prediction of the occurrence of periodic waves in real populations.

Acknowledgments. This work arose from discussions with Tom Sherratt and Xavier Lambin, to whom I am very grateful. In particular, the original idea for periodic wave generation by Dirichlet boundary conditions in ecological systems is due to Tom Sherratt. I also thank Vadim Biktashev and Jack Carr for helpful discussions.

SOLITARY WAVES IN LAYERED NONLINEAR MEDIA*

RANDALL J. LEVEQUE† AND DARRYL H. YONG‡

Abstract. We study longitudinal elastic strain waves in a one-dimensional periodically layered medium, alternating between two materials with different densities and stress-strain relations. If the impedances are different, dispersive effects are seen due to reflection at the interfaces. When the stress-strain relations are nonlinear, the combination of dispersion and nonlinearity leads to the appearance of solitary waves that interact like solitons. We study the scaling properties of these solitary waves and derive a homogenized system of equations that includes dispersive terms. We show that pseudospectral solutions to these equations agree well with direct solutions of the hyperbolic conservation laws in the layered medium using a high-resolution finite volume method. For particular parameters we also show how the layered medium can be related to the Toda lattice, which has discrete soliton solutions.

1. Introduction.

Consider a heterogeneous medium composed of alternating layers of two different materials labeled A and B. The layers have widths $\delta_A = \alpha\delta$ and $\delta_B = (1-\alpha)\delta$, repeating periodically with period δ. The densities of the two materials are ρ_A and ρ_B, respectively, and their response to compression or expansion is characterized by the stress-strain relations $\sigma_A(\epsilon)$ and $\sigma_B(\epsilon)$. Then compressional waves propagating in the direction of layering are modeled by the one-dimensional hyperbolic system of conservation laws

$$\epsilon_t(x,t) - u_x(x,t) = 0, \tag{1.1a}$$

$$(\rho(x)u(x,t))_t - \sigma(\epsilon(x,t),x)_x = 0, \tag{1.1b}$$

where $\epsilon(x,t)$ is the strain and $u(x,t)$ the velocity. For the layered medium we have

$$(\rho(x),\sigma(\epsilon,x)) = \begin{cases} (\rho_A,\sigma_A(\epsilon)) & \text{if } j\delta < x < (j+\alpha)\delta \text{ for some integer } j, \\ (\rho_B,\sigma_B(\epsilon)) & \text{otherwise.} \end{cases} \tag{1.2}$$

For sufficiently small strains, the response can be modeled by linear constitutive relations

$$\sigma_A(\epsilon) = K_A\epsilon, \qquad \sigma_B(\epsilon) = K_B\epsilon, \tag{1.3}$$

where the bulk moduli K_A and K_B of both materials are constants. Waves having long wavelength relative to the layer width can be modeled by a homogenized linear PDE that has the form of a wave equation with small dispersive term. The effective wave speed and dispersion coefficient can be calculated from the above parameters describing the layered medium. This linear case is reviewed in section 2.

More interesting behavior is observed when the constitutive relations are nonlinear in each layer. In this case a long-wavelength pulse breaks up into a series of solitary waves that are each only a few layers wide. This is not a complete surprise since we expect that a nonlinear wave equation with a dispersive term (again arising from the layering) may give rise to soliton-like solutions, and the classic soliton equations such as the KdV equation also exhibit this type of behavior. However, the waves appearing in the layered medium are harder to characterize than classical solitary waves. The wave shape is constantly modulating as it passes through the layers, and thus it cannot be expressed in the form of a fixed-shape wave propagating at constant speed. These waves appear to interact as solitons, essentially passing through one another with at most a shift in phase, but it is not yet clear to what extent they are truly solitons in the technical sense.

To the best of our knowledge, these waves were first observed computationally in [4], where a high-resolution finite volume method is presented that calculates accurate approximations to these waves. This method is also described in [1]. Here we use this method to further explore the nature of these waves.

Solitary waves in nonlinear elastic bars have been observed and studied in the past; see, for example, [5] and the references therein. In this case the material is homogeneous but the finite cross-sectional area gives rise to reflections at the traction-free boundaries and hence dispersion.

In section 4 we show that a particular choice of the layered medium can be directly related to the Toda lattice. This may be significant since the Toda lattice is completely integrable and has discrete soliton solutions that can be compared directly to the solitary waves we observe in the corresponding layered medium.

In section 5 we present a homogenized set of equations for the nonlinear layered medium, and show that solutions to this system agree well with solutions to the layered medium equations. These equations contain dispersive terms and more complicated nonlinearities.

2. Waves in linear media. For a homogeneous linear medium with constant material parameters ρ and K, the governing equations (1.1) are simply

$$\epsilon_t - u_x = 0, \tag{2.1a}$$

$$\rho u_t - K\epsilon_x = 0 \tag{2.1b}$$

or $q_t + Aq_x = 0$, where

$$q = \begin{bmatrix} \epsilon \\ \rho u \end{bmatrix}, \qquad A = -\begin{bmatrix} 0 & 1/\rho \\ K & 0 \end{bmatrix}. \tag{2.2}$$

The eigenvalues of A are $\lambda^1 = -c$ and $\lambda^2 = +c$, where $c = \sqrt{K/\rho}$ is the speed of sound in the material. Purely leftgoing or rightgoing waves have $q(x,t)$ proportional to the corresponding eigenvector r^1 or r^2, respectively, given by

$$r^1 = \begin{bmatrix} 1 \\ Z \end{bmatrix} \quad \text{and} \quad r^2 = \begin{bmatrix} 1 \\ -Z \end{bmatrix}.$$

Here $Z = \rho c = \sqrt{K\rho}$ is the *impedance* of the material.

In a layered linear medium, wave propagation can be more complicated. If the layers are impedance-matched, $Z_A = Z_B$, then a rightgoing wave (for example) has the same characteristic form in both layers, and the wave simply has a different speed

in each layer. It will distort as it speeds up and slows down, but remains entirely rightgoing and moves with an effective velocity

$$\bar{c} = \left(\frac{\alpha}{c_A} + \frac{(1-\alpha)}{c_B} \right)^{-1}, \tag{2.3}$$

as is easily verified by computing the time required to cross two adjacent layers.

If $Z_A \neq Z_B$, on the other hand, then waves are partially reflected at each interface. It is impossible to have a purely rightgoing wave in such a composite material. However, a wave with long wavelength relative to the scale of the layers (i.e., wavelength $\gg \delta$) can appear to be essentially rightgoing, and propagates at an effective velocity of

$$\bar{c} = \sqrt{\hat{K}/\bar{\rho}}, \tag{2.4}$$

where

$$\bar{\rho} = \langle \rho \rangle = \alpha \rho_A + (1-\alpha)\rho_B \tag{2.5}$$

is the average density and

$$\hat{K} = \left\langle K^{-1} \right\rangle^{-1} = \left(\frac{\alpha}{K_A} + \frac{(1-\alpha)}{K_B} \right)^{-1} \tag{2.6}$$

is the harmonic average of the bulk moduli. The velocity (2.4) reduces to (2.3) if $Z_A = Z_B$, but more generally (2.3) does not hold. In particular, if $c_A = c_B \equiv c$ but $Z_A \neq Z_B$, then $\bar{c} < c$, so that even though all waves propagate with speed c, the effective velocity observed will be smaller. This is because the wave is constantly reflecting at each interface, and thus the energy propagates more slowly than the local wave speed.

The layered linear medium can be modeled by a homogenized equation with a dispersion relation of the form

$$\omega = \bar{c}\xi + d\xi^3 + \cdots, \tag{2.7}$$

where ξ is the spatial wavenumber and ω the temporal frequency. The effective speed $\bar{c}$ and the dispersion coefficient d were derived by Santosa and Symes [6] using Bloch wave expansions. These can also be determined from the more general homogenized equations derived in section 5 for the nonlinear case.

Figures 1 and 2 show a comparison of waves propagating in a homogeneous medium and two different layered media. In each case the initial data are $q(x,0) \equiv 0$ for $x \geq 0$, and a wave is generated by motion of the left boundary,

$$u(0,t) = \begin{cases} \bar{u}(1 + \cos(\pi(t-10)/10)) & \text{if } 0 \leq t \leq 20, \\ 0 & \text{if } t > 20. \end{cases} \tag{2.8}$$

The left edge is pulled outward for $0 < t < 20$, generating a strain wave that propagates to the right. Since the equations are linear, the magnitude of the disturbance scales out and we take $\bar{u} = 1$, but for the nonlinear case the magnitude will be important.

In the figures, the solution is shown at time $t = 40$, and four different quantities are displayed in each case: the strain $\epsilon(x,t)$, the corresponding stress $\sigma(\epsilon(x,t),x)$, the

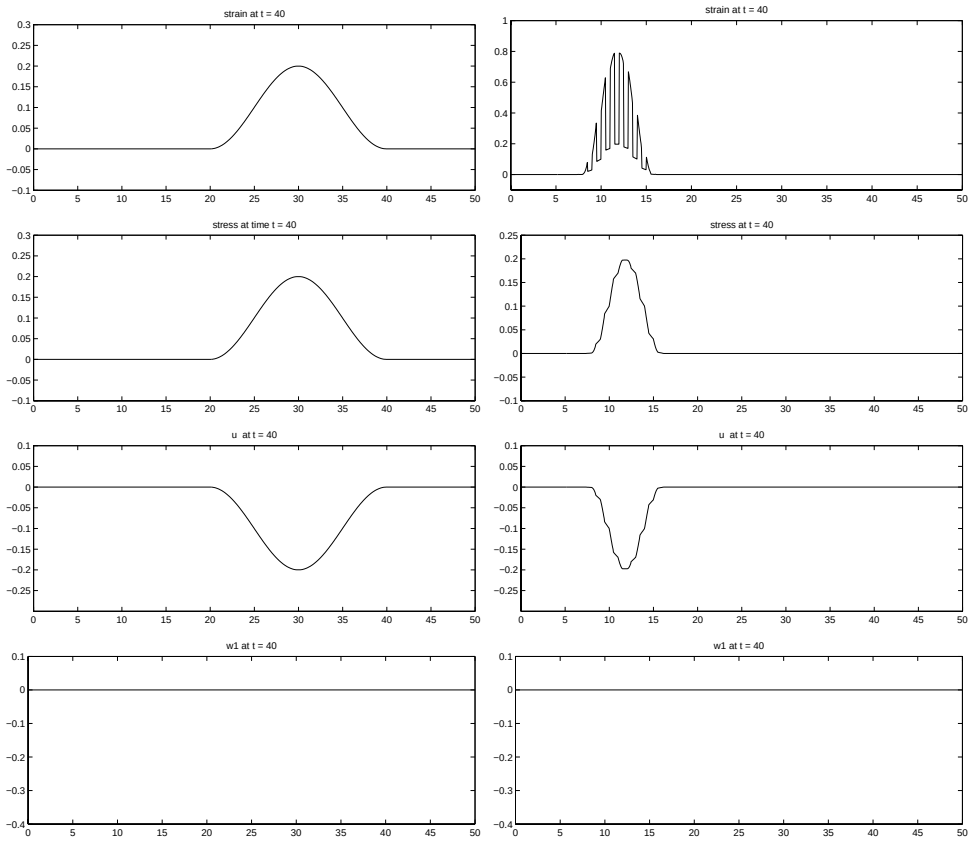

FIG. 1. *The left column shows a strain wave propagating in a homogeneous medium with wave speed $c = 1$. The right column shows a strain wave propagating in a layered medium with constant impedance. In each case four quantities are shown: strain, stress, velocity, and the characteristic variable $w^1(x,t)$, at time $t = 40$.*

velocity $u(x,t)$, and $w^1(x,t)$, where the characteristic variables w^1 and w^2 are defined by

$$w^1(x,t) = \frac{1}{2Z(x)}(Z(x)\epsilon(x,t) + \rho(x)u(x,t)), \tag{2.9a}$$

$$w^2(x,t) = \frac{1}{2Z(x)}(Z(x)\epsilon(x,t) - \rho(x)u(x,t)). \tag{2.9b}$$

These satisfy $w(x,t) = R^{-1}(x)q(x,t)$, where $R(x)$ is the matrix of right eigenvectors of the coefficient matrix $A(x)$ given in (2.2):

$$R(x) = \begin{bmatrix} 1 & 1 \\ Z(x) & -Z(x) \end{bmatrix}, \qquad R^{-1}(x) = \frac{1}{2Z(x)} \begin{bmatrix} 1 & Z(x) \\ 1 & -Z(x) \end{bmatrix}. \tag{2.10}$$

The quantities w^1 and w^2 give the magnitude of leftgoing and rightgoing waves, respectively.

The left column of Figure 1 shows results for a homogeneous medium with $\rho \equiv 1$, $K \equiv 1$. The wave moves at velocity $c = 1$ and so lies between $x = 20$ and $x = 40$ at

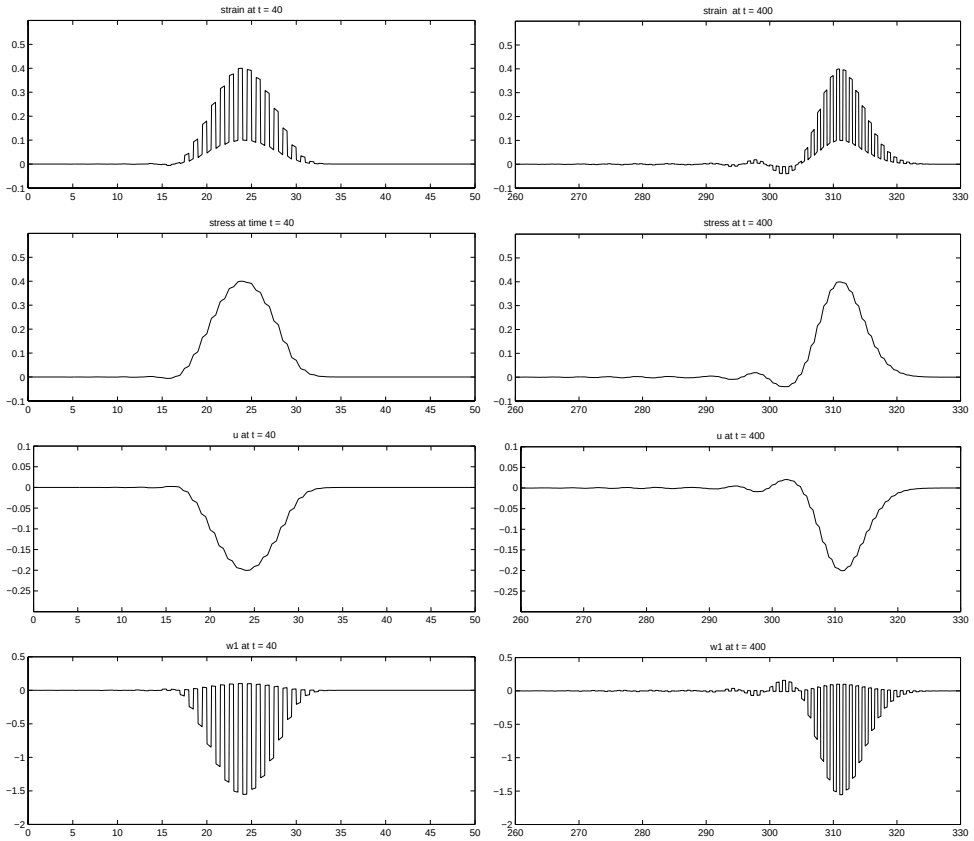

FIG. 2. *A strain wave propagating in a layered medium with impedance mismatch. The left column shows the solution at time $t = 40$, the right column at time $t = 400$. In each case four quantities are shown: strain, stress, velocity, and the characteristic variable $w^1(x,t)$.*

time $t = 40$, with peak at $x = 30$. Note that $w^1(x,t) \equiv 0$ since the wave is purely rightgoing.

The right column of Figure 1 shows a layered medium in which $\delta = 1$ and

$$\begin{array}{lllll} \delta_A = 0.5, & \rho_A = 4, & K_A = 0.25, & c_A = 0.25, & Z_A = 1, \\ \delta_B = 0.5, & \rho_B = 1, & K_B = 1, & c_B = 1, & Z_B = 1. \end{array} \tag{2.11}$$

In this case $Z_A = Z_B$, and so again the wave is purely rightgoing ($w^1(x,t) \equiv 0$) and propagates with velocity $\bar{c} = 2/5$ from (2.3). The peak of the disturbance is now observed at $x = 30\bar{c} = 12$. Note that in this case the strain $\epsilon(x,t)$ is discontinuous at each layer interface. The B layers are more easily stretched than the A layers since $K_B > K_A$. The stress $\sigma(\epsilon(x,t),x)$ must be continuous, however, since the force acting on each side of the interface must be equal. This condition can be used to find the jump conditions on ϵ. Similarly, the velocity $u(x,t)$ must be continuous everywhere, but the momentum $\rho(x)u(x,t)$ will be discontinuous at the interfaces where $\rho(x)$ has a jump discontinuity.

The left column of Figure 2 shows a layered medium in which

$$\begin{array}{lllll} \delta_A = 0.5, & \rho_A = 4, & K_A = 4, & c_A = 1, & Z_A = 4, \\ \delta_B = 0.5, & \rho_B = 1, & K_B = 1, & c_B = 1, & Z_B = 1. \end{array} \tag{2.12}$$

In this case $Z_A \neq Z_B$, and we have

$$\bar{\rho} = \frac{5}{2}, \qquad \hat{K} = \frac{8}{5}, \qquad \bar{c} = \sqrt{\frac{\hat{K}}{\bar{\rho}}} = \frac{4}{5}. \tag{2.13}$$

The peak of the disturbance is now located at $x = 30\bar{c} = 24$. Note that in this case $w^1(x,t)$ is not identically zero, showing that the wave has a significant leftgoing component, although the envelope of w^1 propagates to the right at the effective velocity $\bar{c}$.

The right column of Figure 2 shows this same wave at a much later time, $t = 400$, at which point the dispersive effect of the layered medium is apparent. The leading edge of the wave is still at approximately $\bar{c}t = 320$, as expected, but trailing oscillations have appeared behind the wave due to the dispersion.

3. Waves in nonlinear media. We now consider the case of a nonlinear stress-strain relation $\sigma(\epsilon, x)$. In particular, we consider the exponential relation

$$\sigma(\epsilon, x) = e^{K(x)\epsilon} - 1, \tag{3.1}$$

which will be related to the Toda lattice in section 4, and the simpler quadratic relation

$$\sigma(\epsilon, x) = K(x)\epsilon + \beta K^2(x)\epsilon^2, \tag{3.2}$$

which approximates the exponential relation if $\beta = 1/2$, and reduces to the linear case if $\beta = 0$. For both of these nonlinear constitutive relations $\sigma_\epsilon(\epsilon, x) = K(x) + O(\epsilon) \to K(x)$ as $\epsilon \to 0$, and so for very small amplitude waves the linear theory of the last section applies with bulk modulus $K(x)$.

The system of conservation laws (1.1) can now be written as

$$q_t + f(q, x)_x = 0 \tag{3.3}$$

or, for smooth solutions, as

$$q_t + f_q(q, x)q_x = -f_x(q, x). \tag{3.4}$$

Note that we distinguish between $f(q, x)_x$, the total derivative of $f(q(x,t), x)$ with respect to x, and $f_x(q, x)$, the partial derivative of $f(q, x)$ with respect to the second variable. The Jacobian matrix for the system (3.4) is

$$f_q(q, x) = \begin{bmatrix} 0 & 1/\rho(x) \\ \sigma_\epsilon(\epsilon, x) & 0 \end{bmatrix}, \tag{3.5}$$

with eigenvalues $\lambda^1 = -c$ and $\lambda^2 = +c$, where the sound speed c now depends on the strain as well as x,

$$c(\epsilon, x) = \sqrt{\frac{\sigma_\epsilon(\epsilon, x)}{\rho(x)}}.$$

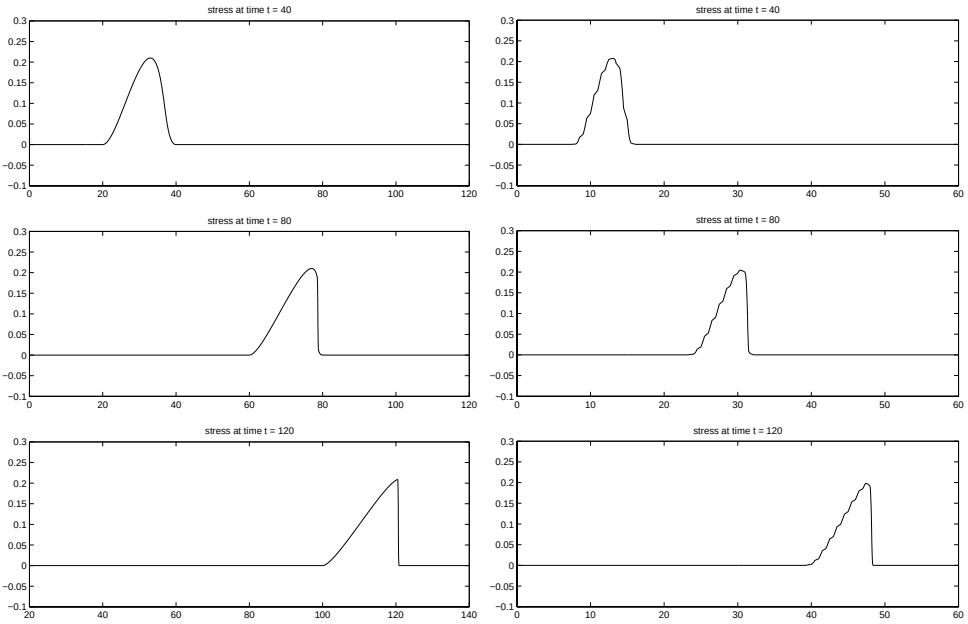

FIG. 3. *The left column shows a wave propagating in a homogeneous nonlinear medium. Only the stress is shown at three different times, illustrating shock formation. The right column shows propagation in a layered nonlinear medium with constant linearized impedance.*

The corresponding right eigenvectors of f_q are

$$r^1 = \begin{bmatrix} 1 \\ Z(\epsilon, x) \end{bmatrix}, \qquad r^2 = \begin{bmatrix} 1 \\ -Z(\epsilon, x) \end{bmatrix}, \tag{3.6}$$

where the impedance $Z(\epsilon, x) = \sqrt{\rho(x)\sigma_\epsilon(\epsilon, x)}$ now also depends on ϵ. For either constitutive model (3.1) or (3.2) we have $c(\epsilon, x) \to \sqrt{K(x)/\rho(x)}$ and $Z(\epsilon, x) \to \sqrt{\rho(x)K(x)}$ as $\epsilon \to 0$, which are the linearized sound speed and impedance.

Figures 3 and 4 show computed results for three cases analogous to those shown for the linear problem in the previous section, but now using the exponential relation (3.1) and $\bar{u} = 0.2$ in the boundary data (2.8). Here we display only one quantity, the stress $\sigma(\epsilon(x, t), x)$, but plot the solution at several different times to show the evolution.

The left column of Figure 3 shows nonlinear propagation in a homogeneous medium, with $\rho \equiv 1$, $K \equiv 1$. The cosine-shaped wave generated by the boundary condition (2.8) steepens into a shock followed by a rarefaction wave, as expected from standard nonlinear conservation law theory.

The right column of Figure 3 shows a layered medium with

$$\begin{aligned} \delta_A &= 0.5, \qquad \rho_A = 4, \qquad K_A = 0.25, \\ \delta_B &= 0.5, \qquad \rho_B = 1, \qquad K_B = 1. \end{aligned} \tag{3.7}$$

In this case the linearized impedances are matched since $\rho_A K_A = \rho_B K_B$, and again the rightgoing wave appears to steepen into a shock followed by a rarefaction wave. However, the full nonlinear impedance does not remain matched, and some reflection occurs at interfaces. This shock wave is not a sharp discontinuity but remains smeared

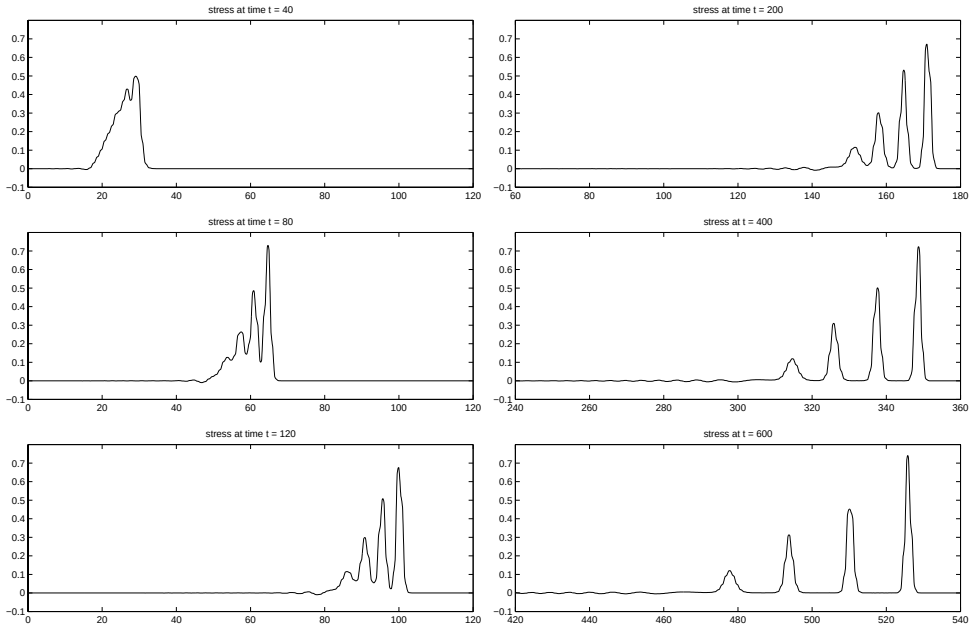

FIG. 4. *Propagation in a layered nonlinear medium with impedance mismatch at the interfaces. The left column shows the stress at three times, and the right column at three later times, illustrating breakup into a train of solitary waves.*

over a few layers. In this case the layering gives rise to an effective viscous equation. (In this case C_{13} is nonzero in (5.17) below, while the other C coefficients are all zero.)

Figure 4 shows a more interesting case that is the primary object of study in this paper. Here the material parameters are

$$\begin{aligned} \delta_A &= 0.5, \qquad \rho_A = 4, \qquad K_A = 4, \\ \delta_B &= 0.5, \qquad \rho_B = 1, \qquad K_B = 1. \end{aligned} \tag{3.8}$$

Now the linearized impedance is not matched, and large-scale reflections at each interface lead to dispersive behavior. This dispersion, coupled with the nonlinearity, results in the existence of solitary waves. In Figure 4 the same boundary motion (2.8) is applied as before. The resulting pulse, which is long compared to the layer width, initially starts to steepen as if a shock were forming. But then oscillations develop and the pulse ultimately breaks up into a train of solitary waves. Similar behavior is seen with nonlinear dispersive equations such as the KdV equation that are known to have soliton solutions.

Figure 5 shows both the stress and the strain in the first two solitary waves at time $t = 600$. Since it is not clear whether these solitary waves are formally solitons, we will refer to them as *stegotons* for shorthand, coming from the Greek root "stego-," meaning roof or ridge, and suggested by the rough resemblance of these strain waves in a layered medium to the back of a stegosaurus.

Note that each stegoton has a width of about ten layers, a fact that is independent of the periodicity δ used. If δ is made smaller, then the stegotons scale with δ but remain about ten layers wide. This is expected from the form of the equations. If $\tilde{q}(x,t)$ is a solution to (3.3) for $\delta = 1$, then $q(x,t) = \tilde{q}(x/\delta, t/\delta)$ is a solution for arbitrary δ (with α fixed). The width in layers does vary slightly with amplitude, as

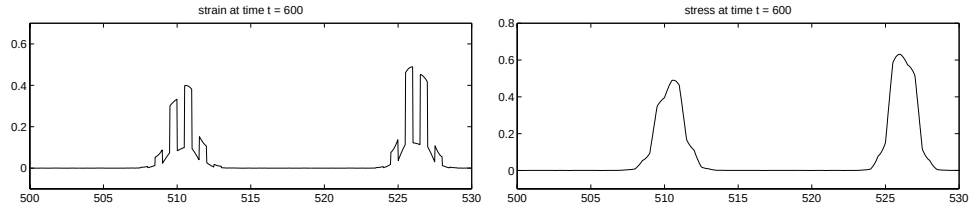

FIG. 5. *Close-up view of the first two solitary waves from Figure* 4 *at time* $t = 600$*, showing both the strain and the stress.*

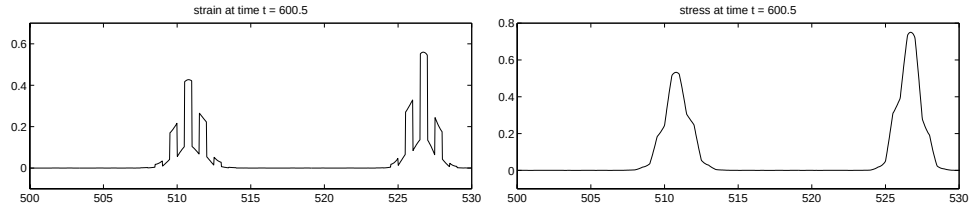

FIG. 6. *Close-up view of the two solitary waves from Figure* 5 *at a slightly later time* $t = 600.5$.

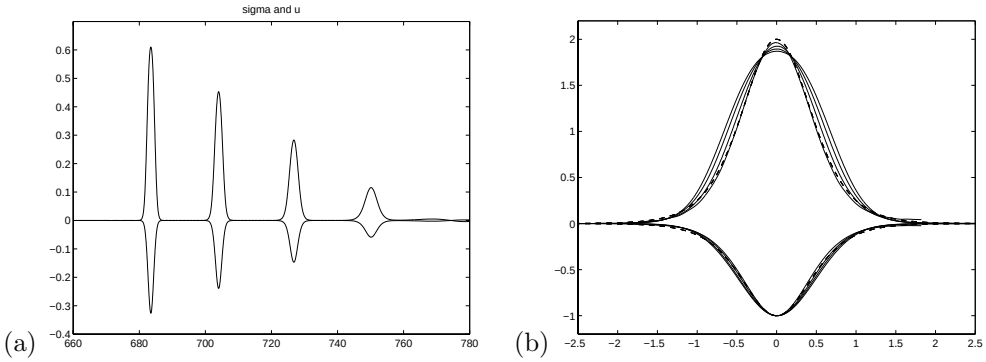

FIG. 7. (a) *A time trace of the stress* $\sigma(x_0, t) \geq 0$ *and velocity* $u(x_0, t) \leq 0$ *at a fixed point* x_0 *as four stegotons pass by.* (b) *The same four waves replotted as functions of* τ *with the scaling described in the text. The dashed lines are* $-\operatorname{sech}^2(b\tau)$ *and* $2\operatorname{sech}^2(b\tau)$.

does the speed of the solitary wave. The taller stegotons are thinner and travel faster than shorter ones, similar to the behavior of KdV solitons, for example.

Stegotons do not translate with a fixed wave shape, as illustrated in Figure 6, where the two stegotons from Figure 5 are shown at a slightly later time, $t = 600.5$. For this reason it is difficult to carefully investigate the scaling properties of stegotons by studying their appearance as functions of x for fixed t. On the other hand, if we pick a physical location x and observe the solution as a function of t as a stegoton passes by, then all components of the solution vary smoothly in time. By observing the waves in this manner it is easy to determine the scaling relation between amplitude, speed, and width. Figure 7(a) shows the stress $\sigma(x_0, t)$ as a function of t at $x_0 = 600.25$, a location that is in the center of an A-layer. This shows four distinct solitary waves passing by, followed by some trailing noise. Here we have also plotted the velocity $u(x_0, t)$, which is negative in each wave.

Figure 7(b) shows plots of the four leading solitary waves from Figure 7(a) after

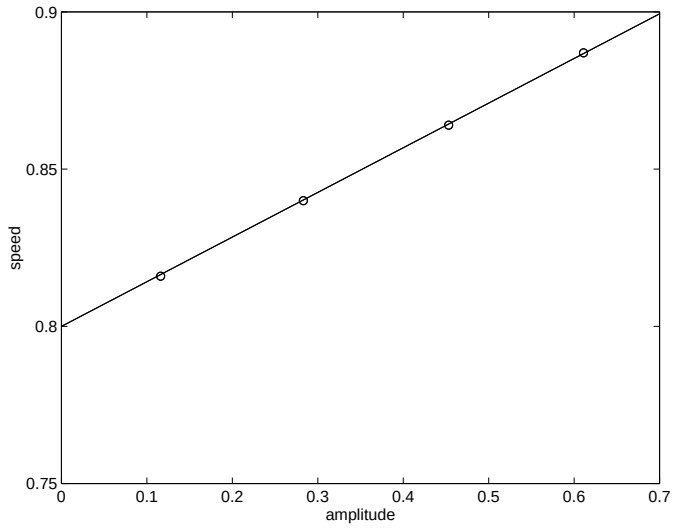

FIG. 8. *The observed speed of a solitary wave plotted as a function of amplitude, for the four waves shown in Figure* 7.

shifting them to a common location, rescaling each by its amplitude a as measured from the velocity, $a = \max|u|$, and rescaling the width by $\sqrt{a}$. Hence we plot

$$\frac{1}{a}\sigma(x_0,\tau) \qquad \text{and} \qquad \frac{1}{a}u(x_0,\tau) \tag{3.9}$$

as functions of τ, where $\tau = \sqrt{a}(t-t_m)$ and t_m is the time at which the velocity reaches its peak value $-a$. The velocity plots lie nearly on top of one another, suggesting that at $x = x_0$ a stegoton of amplitude a has velocity of the form

$$u(x_0,t) = a\,U\left(\sqrt{a}(t-t_m)\right) \tag{3.10}$$

for some function $U(\tau)$. The dashed lines in Figure 7(b) show the functions $-\operatorname{sech}^2(b\tau)$ and $2\operatorname{sech}^2(b\tau)$ for $b = 1.7$. This shows that the stegoton has roughly, though not exactly, the sech^2 shape seen for many solitons.

The stress does not scale quite as nicely as the velocity, and in particular the stress is not simply a scalar multiple of the velocity. It is nearly so, however, for the stress curve that appears tallest in Figure 7(b). This actually corresponds to the shortest stegoton in the original time trace of Figure 7(a). For this small amplitude wave we observe $\sigma \approx -2u$. This is consistent with the fact that a linearized homogeneous medium with impedance Z would have $\sigma = -Zu$, and the layered medium we are using has an effective impedance in the linearized case that is $(\hat{K}\bar{\rho})^{1/2} = 2$.

By observing when the peak appears in the time history at different points x (each in the center of an A-layer), we can estimate the velocity of each wave. The observed velocity is plotted against the amplitude in Figure 8 for each of these four stegotons. They lie almost exactly on the line

$$v = 0.8 + 0.142a. \tag{3.11}$$

Recall that $\bar{c} = 0.8$ is the effective velocity of the linearized medium from (2.13), which is the velocity we expect to observe for very small amplitude waves. The velocity appears to increase linearly with amplitude for nonlinear waves.

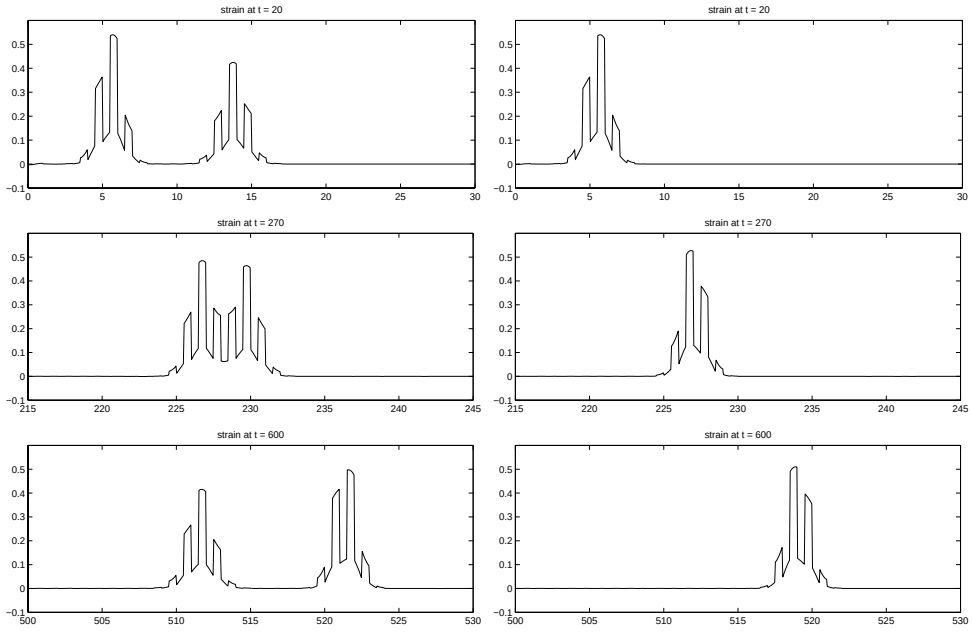

FIG. 9. *The collision of two stegotons at three different times is shown in the left column. For comparison, the right column shows results at the same times for a single stegoton.*

These results are for the case in which x_0 is in the center of an A-layer. If we fix x_0 at a different spot, then the scaling is the same but the amplitude a and wave shape $U(\tau)$ are different. Indeed, the amplitude varies significantly at different points, even within the same layer. A more complete characterization of these waves is still under development.

By recording $u(x_0, t)$ at a location x_0 that is at the left edge of an A-layer, and then selecting the part of this time history that captures a single wave passing by, we obtain data that can be used to replace (2.8) as boundary data for generating a single stegoton. By rescaling the amplitude and width of this data appropriately using the scaling determined above, we can also generate stegotons of arbitrary amplitude a. We have verified that these also propagate as solitary waves, at least if the amplitude is not too large.

We can also generate a short stegoton at the boundary followed by a taller stegoton that travels faster and eventually overtakes the first. The left column of Figure 9 shows the results of this experiment. We observe that the two waves interact in a manner analogous to classical solitons: the waves appear to exchange identity, and the wave in front grows and accelerates. After the waves separate, each again has the form of a solitary stegoton, though shifted in location from where they would be without interaction. For comparison, the right column of Figure 9 shows the propagation of the larger stegoton alone, without the presence of the smaller one.

4. Relation to the Toda lattice. The Toda lattice is a discrete lattice of particles having mass m connected by nonlinear springs with a restoring force that depends exponentially on the distance stretched. Let $X_j(t)$ be the location of the jth particle at time t, and assume that the unstretched configuration has $X_j = j\Delta x$. The velocity of this particle is denoted by $U_j(t)$. The spring connecting particle j to $j+1$

has strain

$$\epsilon_{j+1/2}(t) = \frac{X_{j+1}(t) - X_j(t)}{\Delta x} - 1 \tag{4.1}$$

and exerts a restoring force $\sigma(\epsilon_{j+1/2}(t))$, where

$$\sigma(\epsilon) = e^{K\epsilon} - 1.$$

Since $X_j'(t) = U_j(t)$, differentiating (4.1) yields

$$\epsilon'_{j+1/2}(t) = \frac{U_{j+1}(t) - U_j(t)}{\Delta x}. \tag{4.2}$$

The Toda lattice is modeled by a system of ODEs consisting of this equation along with the dynamic equation

$$mU_j'(t) = \sigma(\epsilon_{j+1/2}(t)) - \sigma(\epsilon_{j-1/2}(t)). \tag{4.3}$$

If we rewrite $m = \rho\Delta x$, then the system of equations becomes

$$\begin{aligned} \epsilon'_{j+1/2}(t) &= \frac{U_{j+1}(t) - U_j(t)}{\Delta x}, \\ \rho U_j'(t) &= \frac{\sigma(\epsilon_{j+1/2}(t)) - \sigma(\epsilon_{j-1/2}(t))}{\Delta x}. \end{aligned} \tag{4.4}$$

Note that this can be viewed as a finite-difference discretization of the elastic equation (1.1). Centered differences on a staggered grid are used to approximate each x-derivative in (1.1). The classical theory of finite-difference methods thus leads us to expect dispersive behavior, and a "modified equation" analysis of this system would show that the discrete equations can be approximated by a dispersive nonlinear system of PDEs. With this combination of nonlinearity and dispersion, solitary waves can arise. Toda showed that with exponential springs the discrete system is completely integrable and discrete soliton solutions exist; see [7], [8].

To relate the Toda lattice to a layered medium, it may be tempting to introduce two different types of springs with constitutive relations $\sigma_A(\epsilon)$ and $\sigma_B(\epsilon)$ and have these alternate in the discrete lattice. However, this would introduce a second form of dispersion and result in a doubly dispersive system.

Since the original Toda lattice already has soliton solutions, we wish to relate the layered medium directly to the lattice. This is easily done by realizing that the Toda lattice does in fact consist of alternating layers, since particles alternate with springs. The corresponding layered medium is one in which thin "particle layers" with finite mass and infinitesimal compressibility alternate with thicker "spring layers" having infinitesimal mass and finite compressibility, i.e.,

$$\begin{aligned} &\delta_A \ll 1, && \rho_A = O\left(\frac{1}{\delta_A}\right), && K_A \gg 1, \\ &\delta_B = 1 - \delta_A, && \rho_B \ll 1, && K_B = O(1). \end{aligned} \tag{4.5}$$

See Figure 10 for an illustration of this correspondence. (In fact, one observes close correspondence even when δ_A is not small relative to δ_B.)

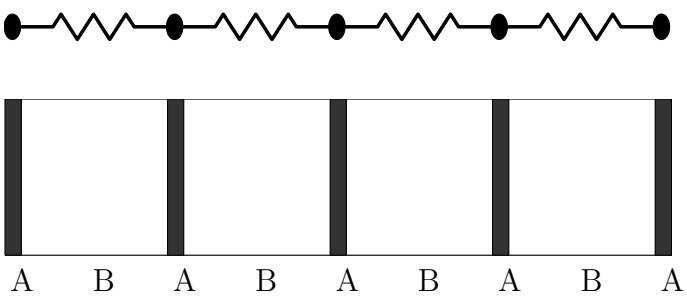

FIG. 10. *The Toda lattice and a roughly equivalent layered medium.*

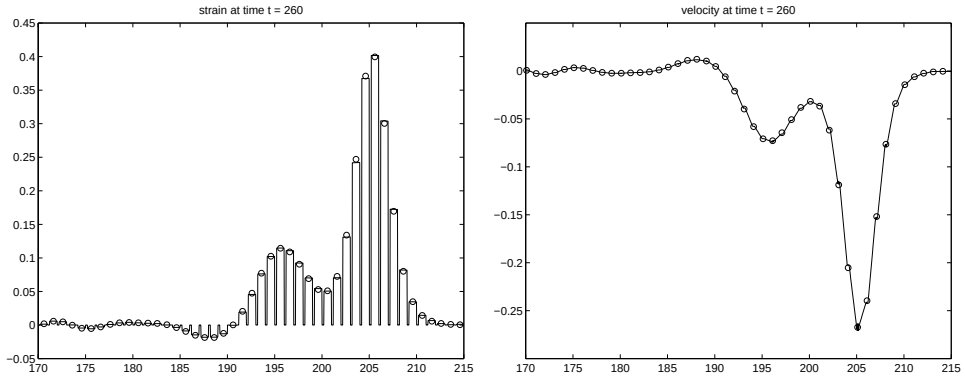

FIG. 11. *Comparison of the solution to the discrete Toda lattice (circles) with the finite-volume solution to the layered medium equations (solid line). The strain and velocity are shown.*

Figure 11 shows a sample calculation obtained by solving the layered media equations using

$$\begin{array}{lll} \delta_A = 0.2, & \rho_A = 5, & K_A = 2000, \\ \delta_B = 0.8, & \rho_B = 0.005, & K_B = 0.5. \end{array} \tag{4.6}$$

In the particle layers, which exhibit little strain, the constitutive relation is taken to be linear with $\sigma_A(\epsilon) = K_A\epsilon$. The wave speed is then constant in these layers, $c_A = 20$, which is convenient numerically since by taking $\Delta t = \Delta x/20$ (so the Courant number is exactly 1) an accurate solution is computed even when there are very few points in these thin layers. The spring layers have the exponential relation $\sigma_B(\epsilon) = e^{K_B\epsilon} - 1$, with a wave speed that approaches $c_B = \sqrt{K_B/\rho_B} = 10$ for small ϵ and remains below 20 so that the calculations are stable.

The parameters (4.6) lead to an effective wave speed for the linearized response (small ϵ) of

$$\bar{c} = \sqrt{\frac{\hat{K}}{\bar{\rho}}} = \sqrt{\frac{0.625}{1.004}} \approx 0.789, \tag{4.7}$$

and solitary waves move with a speed that is less than 1. To have a close connection with the Toda lattice, it is important that the wave speeds c_A and c_B are much larger than this homogenized wave speed. This means that small amplitude waves bounce

back and forth within each layer on a much faster time scale than the observed wave motion, leading to a local equilibration within each layer. As a result, the stress observed in Figure 11 at any time is roughly constant in each thick spring layer, and varies rapidly, but essentially linearly, in the thin particle layers. The velocity u, on the other hand, is roughly constant in each particle layer, since the particle moves as a rigid unit, and varies linearly across a spring layer. Only under these conditions can we hope to model the continuum material by a set of discrete springs and masses, where each spring has a single stress associated with it and is assumed to compress and expand uniformly.

Figure 11 shows that there is in fact good agreement between the layered medium and the Toda lattice in this case. The parameters for the Toda lattice used here are $m = 1.004$ for the particle mass and $K = 0.5$ in the stress-strain relation. The mass is the average density from the layered medium, while the value of K is taken to be K_B, the corresponding parameter from the spring layers. Note that, for the layered medium solution (solid line), the strain is nearly zero in each thin particle layer and nearly constant throughout each spring layer. The circles show the discrete solution computed by solving the ODEs of the Toda lattice. These results are shown at a time when the initial pulse is just breaking up into solitary waves. At later times both solutions break up into similar trains of solitary waves.

Because of the correspondence in Figure 10, it is not surprising that the layered medium exhibits solitary waves in this special case. What is more interesting is the fact that it continues to exhibit solitary wave behavior even for situations that are far from this limit, as was exhibited in section 3. In the next section we derive homogenized equations for the general case that may help to shed some light on this.

5. Homogenized equations. In this section we derive homogenized equations that describe the effective behavior of the layered media (both linear and nonlinear) studied in the previous sections. Since the strain and momentum have discontinuities at each interface and cannot be approximated directly by continuous functions, we start by rewriting the equations in terms of the stress and velocity, which are continuous. Equation (1.1b), $\rho(x)u_t - \sigma_x = 0$, is one equation of this system. We must use (1.1a) to derive an equation for σ_t. To do so, we use

$$\sigma_t = \sigma_\epsilon(\epsilon, x)\epsilon_t = \sigma_\epsilon(\epsilon, x)u_x$$

and will assume that the constitutive relation $\sigma(\epsilon, x)$ is such that we can solve for $\sigma_\epsilon(\epsilon, x)$ as a function of σ and x in the form

$$\sigma_\epsilon(\epsilon, x) = K(x)G(\sigma). \tag{5.1}$$

In particular, for the constitutive equations used in this paper we have

$$\begin{array}{lll} \sigma(\epsilon, x) = K(x)\epsilon & \Longrightarrow & G(\sigma) = 1, \\ \sigma(\epsilon, x) = \exp(K(x)\epsilon) - 1 & \Longrightarrow & G(\sigma) = 1 + \sigma, \\ \sigma(\epsilon, x) = K(x)\epsilon + \beta K^2(x)\epsilon^2 & \Longrightarrow & G(\sigma) = 1 + 2\beta\sigma - 2\beta^2\sigma^2 + O(\sigma^3). \end{array} \tag{5.2}$$

Then the system (1.1) can be rewritten as

$$\begin{aligned} \sigma_t - K(x)G(\sigma)u_x &= 0, \\ \rho(x)u_t - \sigma_x &= 0. \end{aligned} \tag{5.3}$$

This nonlinear system is not in conservation form but is still valid since we are not interested in shock waves. The leading order terms in the homogenized equation are

easy to derive by rewriting (5.3) as

$$\begin{aligned} K^{-1}(x)\sigma_t - G(\sigma)u_x &= 0, \\ \rho(x)u_t - \sigma_x &= 0. \end{aligned} \tag{5.4}$$

The functions $K(x)$ and $\rho(x)$ vary on a much faster scale than σ and u, and thus averaging these equations over a period leads to

$$\begin{aligned} \langle K^{-1}(x)\rangle\sigma_t - G(\sigma)u_x &\approx 0, \\ \langle \rho(x)\rangle u_t - \sigma_x &\approx 0. \end{aligned} \tag{5.5}$$

This gives a homogenized system that again has the form (5.3) but with $\rho(x)$ and $K(x)$ replaced by the average and harmonic average, respectively. This gives the expected effective velocity in the linear case, but is lacking the crucial dispersive terms needed to explain the solitary waves.

To obtain a more accurate description of the homogenized equations, we use a multiple scale homogenization technique, following [3]. We begin by defining a fast spatial variable $x^* = x/\delta$, where δ is the period of the medium, as before, and writing the bulk modulus and density as functions of x^*: $K = K(x^*)$ and $\rho = \rho(x^*)$. (This is a slight abuse of notation.) We now adopt the formalism that $\bar{x} = x$ and x^* are independent variables by assuming $\delta \ll 1$. As a result, spatial derivatives in (5.3) must be transformed according to

$$\frac{\partial}{\partial x} = \frac{\partial}{\partial \bar{x}} + \frac{1}{\delta}\frac{\partial}{\partial x^*}.$$

(We introduce $x = \bar{x}$ in this step to clearly delineate the original spatial scale x and the new multiple scales $\bar{x}$ and x^*, but we will simply use x from now on.) System (5.3) becomes

$$\begin{aligned} \sigma_t - K(x^*)G(\sigma)\left[u_x + \delta^{-1}u_{x^*}\right] &= 0, \\ \rho(x^*)u_t - \left[\sigma_x + \delta^{-1}\sigma_{x^*}\right] &= 0. \end{aligned} \tag{5.6}$$

Using the convention that all underlined quantities are independent of the fast variable x^*, we insert the asymptotic expansions

$$\begin{aligned} u(x,t;\delta) &= \underline{u}^{(0)}(x,t) + \delta u^{(1)}(x,x^*,t) + \delta^2 u^{(2)}(x,x^*,t) + O(\delta^3), \\ \sigma(x,t;\delta) &= \underline{\sigma}^{(0)}(x,t) + \delta\sigma^{(1)}(x,x^*,t) + \delta^2\sigma^{(2)}(x,x^*,t) + O(\delta^3) \end{aligned}$$

into (5.6) and collect terms by their powers of δ. During this process, the function $G(\sigma)$ must be expanded as

$$\begin{aligned} G(\sigma) &= G(\underline{\sigma}^{(0)} + \delta\sigma^{(1)} + \delta^2\sigma^{(2)} + \cdots) \\ &= G(\underline{\sigma}^{(0)}) + G'(\underline{\sigma}^{(0)})(\delta\sigma^{(1)} + \delta^2\sigma^{(2)} + \cdots) \\ &\qquad + \frac{1}{2}G''(\underline{\sigma}^{(0)})(\delta\sigma^{(1)} + \delta^2\sigma^{(2)} + \cdots)^2 + \cdots. \end{aligned}$$

Once the proper choices for scales and asymptotic expansions have been made, obtaining homogenized equations becomes a purely mechanical, although algebraically intensive, procedure. For the system of equations that is proportional to δ^n, we solve for $u_{x^*}^{(n+1)}$ and $\sigma_{x^*}^{(n+1)}$ and identify any terms that are independent of x^*. These terms

must be set to zero; otherwise, when $u^{(n+1)}_{x^*}$ and $\sigma^{(n+1)}_{x^*}$ are integrated with respect to x^*, secular terms will arise. The terms that are set to zero give rise to the homogenized equations.

To identify terms that are independent of x^*, we introduce the following linear operators:

$$\langle a(x^*)\rangle = \int_0^1 a(x^*)dx^*,$$
$$\{a\}(x^*) = a(x^*) - \langle a(x^*)\rangle,$$
$$[\![a]\!](x^*) = \int_s^{x^*} \{a\}(\xi)d\xi, \quad \text{where } s \text{ is chosen such that } \langle [\![a]\!](x^*)\rangle = 0.$$

When using the normal spatial scale, δ is the period of the medium, but when using the fast spatial scale $x^* = x/\delta$, the period of the functions $K(x^*)$ and $\rho(x^*)$ is 1. Therefore, the averaging operator $\langle K(x^*)\rangle$, defined above, gives the average value of $K(x^*)$. (A similar averaging operator can be defined for nonperiodic functions.) The $\{\cdot\}$ operator generates the fluctuating part of a function: the part of the function that has zero average. The $[\![\cdot]\!]$ operator gives the integral of the fluctuating part of a function, where the constant of integration is chosen such that the average of the integral of the fluctuating part is zero. As opposed to $\langle\cdot\rangle$, both $\{\cdot\}$ and $[\![\cdot]\!]$ return functions of x^*. Some useful properties of these operators are derived in [11].

In the case of piecewise constant functions (1.2), $\langle\rho(x^*)\rangle = \bar\rho = \alpha\rho_A + (1-\alpha)\rho_B$,

$$\{\rho\}(x^*) = \begin{cases} (1-\alpha)(\rho_A - \rho_B) & \text{if } j < x^* < (j+\alpha) \text{ for some integer } j, \\ \alpha(\rho_B - \rho_A) & \text{otherwise,} \end{cases}$$

and

$$[\![\rho]\!](x^*) = \begin{cases} (1-\alpha)(\rho_A - \rho_B)\left(x^* - \frac{\alpha}{2}\right) & \text{if } j < x^* < (j+\alpha) \text{ for some integer } j, \\ \alpha(\rho_B - \rho_A)\left(x^* - \frac{1+\alpha}{2}\right) & \text{otherwise.} \end{cases}$$

Now we illustrate how the first few terms of the homogenized equations are derived. The leading order equations are

$$\underline{\sigma}^{(0)}_t - K(x^*)G(\underline{\sigma}^{(0)})(\underline{u}^{(0)}_x + u^{(1)}_{x^*}) = 0, \tag{5.7a}$$
$$\rho(x^*)\underline{u}^{(0)}_t - \underline{\sigma}^{(0)}_x - \sigma^{(1)}_{x^*} = 0. \tag{5.7b}$$

We solve for $u^{(1)}_{x^*}$ and $\sigma^{(1)}_{x^*}$ to obtain

$$u^{(1)}_{x^*} = \frac{\underline{\sigma}^{(0)}_t}{K(x^*)G(\underline{\sigma}^{(0)})} - \underline{u}^{(0)}_x, \tag{5.8a}$$
$$\sigma^{(1)}_{x^*} = \rho(x^*)\underline{u}^{(0)}_t - \underline{\sigma}^{(0)}_x. \tag{5.8b}$$

Before integrating with respect to x^*, we must first remove x^*-independent terms from the right-hand sides of (5.8). To do this, we apply $\langle\cdot\rangle$ to the right-hand sides of (5.8) and set the result to zero:

$$0 = \left\langle K^{-1}\right\rangle \underline{\sigma}^{(0)}_t - G(\underline{\sigma}^{(0)})\underline{u}^{(0)}_x, \tag{5.9a}$$
$$0 = \langle\rho\rangle\, \underline{u}^{(0)}_t - \underline{\sigma}^{(0)}_x. \tag{5.9b}$$

We can then integrate the remaining terms in (5.8) to get

$$u^{(1)} = \left[\!\left[K^{-1}\right]\!\right] \frac{\underline{\sigma}_t^{(0)}}{G(\underline{\sigma}^{(0)})} + \underline{u}^{(1)}, \tag{5.10a}$$

$$\sigma^{(1)} = \left[\!\left[\rho\right]\!\right] \underline{u}_t^{(0)} + \underline{\sigma}^{(1)}, \tag{5.10b}$$

where $\underline{u}^{(1)}$ and $\underline{\sigma}^{(1)}$ are "constants" of integration in terms of x^* but vary with x and t.

The $O(\delta)$ equations are

$$\sigma_t^{(1)} - K(x^*)G(\underline{\sigma}^{(0)})(u_x^{(1)} + u_{x^*}^{(2)}) - K(x^*)G'(\underline{\sigma}^{(0)})\sigma^{(1)}(\underline{u}_x^{(0)} + u_{x^*}^{(1)}) = 0, \tag{5.11a}$$

$$\rho(x^*)u_t^{(1)} - \sigma_x^{(1)} - \sigma_{x^*}^{(2)} = 0. \tag{5.11b}$$

We substitute in (5.7a) and (5.10) and solve for $u_{x^*}^{(2)}$ and $\sigma_{x^*}^{(2)}$ to obtain

$$\begin{aligned} u_{x^*}^{(2)} = {} & \frac{\left[\!\left[\rho\right]\!\right] \underline{u}_{tt}^{(0)} + \underline{\sigma}_t^{(1)}}{K(x^*)G(\underline{\sigma}^{(0)})} - \left[\!\left[K^{-1}\right]\!\right] \frac{G(\underline{\sigma}^{(0)})\underline{\sigma}_{xt}^{(0)} - \underline{\sigma}_t^{(0)}\underline{\sigma}_x^{(0)}G'(\underline{\sigma}^{(0)})}{G(\underline{\sigma}^{(0)})^2} - \underline{u}_x^{(1)} \\ & - \frac{G'(\underline{\sigma}^{(0)})\underline{\sigma}_t^{(0)}}{K(x^*)G(\underline{\sigma}^{(0)})^2} \left[\left[\!\left[\rho\right]\!\right] \underline{u}_t^{(0)} + \underline{\sigma}^{(1)}\right], \end{aligned} \tag{5.12a}$$

$$\sigma_{x^*}^{(2)} = \rho(x^*) \left[\left[\!\left[K^{-1}\right]\!\right] \frac{G(\underline{\sigma}^{(0)})\underline{\sigma}_{tt}^{(0)} - (\underline{\sigma}_t^{(0)})^2 G'(\underline{\sigma}^{(0)})}{G(\underline{\sigma}^{(0)})^2} + \underline{u}_t^{(1)} \right] - \left[\!\left[\rho\right]\!\right] \underline{u}_{xt}^{(0)} - \underline{\sigma}_x^{(1)}. \tag{5.12b}$$

We remove x^*-independent terms by setting

$$\begin{aligned} 0 = {} & \left\langle \left[\!\left[\rho\right]\!\right] K^{-1} \right\rangle \underline{u}_{tt}^{(0)} + \left\langle K^{-1} \right\rangle \underline{\sigma}_t^{(1)} - G(\underline{\sigma}^{(0)})\underline{u}_x^{(1)} - \left\langle \left[\!\left[\rho\right]\!\right] K^{-1} \right\rangle \frac{\underline{u}_t^{(0)}\underline{\sigma}_t^{(0)}G'(\underline{\sigma}^{(0)})}{G(\underline{\sigma}^{(0)})} \\ & - \left\langle K^{-1} \right\rangle \frac{\underline{\sigma}^{(1)}\underline{\sigma}_t^{(0)}G'(\underline{\sigma}^{(0)})}{G(\underline{\sigma}^{(0)})}, \end{aligned} \tag{5.13a}$$

$$0 = \left\langle \rho \left[\!\left[K^{-1}\right]\!\right] \right\rangle \frac{G(\underline{\sigma}^{(0)})\underline{\sigma}_{tt}^{(0)} - (\underline{\sigma}_t^{(0)})^2 G'(\underline{\sigma}^{(0)})}{G(\underline{\sigma}^{(0)})^2} + \langle \rho \rangle \, \underline{u}_t^{(1)} - \underline{\sigma}_x^{(1)}. \tag{5.13b}$$

To save space, we will not perform the final step in the analysis of the $O(\delta)$ system of equations, which involves integrating remaining terms in (5.12).

The most important part of the analysis above is the removal of all terms that are independent of x^*, since these terms lead to the homogenized equations. To see this, let us define

$$\begin{aligned} \underline{u}(x,t) &= \langle u(x,x^*,t) \rangle = \underline{u}^{(0)}(x,t) + \delta \underline{u}^{(1)}(x,t) + O(\delta^2), \\ \underline{\sigma}(x,t) &= \langle \sigma(x,x^*,t) \rangle = \underline{\sigma}^{(0)}(x,t) + \delta \underline{\sigma}^{(1)}(x,t) + O(\delta^2) \end{aligned}$$

and add up the homogenized equations (5.9) and (5.13) to get

$$0 = \left\langle K^{-1} \right\rangle \underline{\sigma}_t - G(\underline{\sigma}^{(0)})\underline{u}_x + \delta \left\langle \left[\!\left[\rho\right]\!\right] K^{-1} \right\rangle \underline{u}_{tt} - \delta \left\langle \left[\!\left[\rho\right]\!\right] K^{-1} \right\rangle \frac{\underline{u}_t \underline{\sigma}_t G'(\underline{\sigma}^{(0)})}{G(\underline{\sigma}^{(0)})}$$

$$- \delta \left\langle K^{-1} \right\rangle \frac{\underline{\sigma}^{(1)} \underline{\sigma}_t G'(\underline{\sigma}^{(0)})}{G(\underline{\sigma}^{(0)})} + O(\delta^2), \tag{5.14a}$$

$$0 = \langle \rho \rangle \, \underline{u}_t - \underline{\sigma}_x + \delta \left\langle \rho \left[\!\left[K^{-1} \right]\!\right] \right\rangle \frac{G(\underline{\sigma}^{(0)})\underline{\sigma}^{(0)}_{tt} - (\underline{\sigma}^{(0)}_t)^2 G'(\underline{\sigma}^{(0)})}{G(\underline{\sigma}^{(0)})^2} + O(\delta^2). \tag{5.14b}$$

To make these equations look more like the original system of equations (3.3), we replace all t-derivatives (except for the first terms in (5.14)) with x-derivatives by substituting the equations into themselves. For example,

$$\begin{aligned} \frac{G(\underline{\sigma}^{(0)})\underline{\sigma}^{(0)}_{tt} - (\underline{\sigma}^{(0)}_t)^2 G'(\underline{\sigma}^{(0)})}{G(\underline{\sigma}^{(0)})^2} &= \frac{\partial}{\partial t}\left[\frac{\underline{\sigma}^{(0)}_t}{G(\underline{\sigma}^{(0)})}\right] = \frac{\partial}{\partial t}\left[\frac{\underline{u}^{(0)}_x}{\langle K^{-1} \rangle}\right] + O(\delta) \\ &= \frac{\underline{\sigma}^{(0)}_{xx}}{\langle \rho \rangle \langle K^{-1} \rangle} + O(\delta) = \frac{\underline{\sigma}_{xx}}{\langle \rho \rangle \langle K^{-1} \rangle} + O(\delta). \end{aligned}$$

Similar substitutions eventually produce

$$0 = \left\langle K^{-1} \right\rangle \underline{\sigma}_t - G(\underline{\sigma}^{(0)})\underline{u}_x - \delta \underline{\sigma}^{(1)} \underline{u}_x G'(\underline{\sigma}^{(0)}) + \delta \frac{\left\langle \left[\!\left[\rho\right]\!\right] K^{-1} \right\rangle}{\langle \rho \rangle \langle K^{-1} \rangle} G(\underline{\sigma}^{(0)}) \underline{u}_{xx} + O(\delta^2), \tag{5.15a}$$

$$0 = \langle \rho \rangle \, \underline{u}_t - \underline{\sigma}_x + \delta \frac{\left\langle \rho \left[\!\left[K^{-1} \right]\!\right] \right\rangle}{\langle \rho \rangle \langle K^{-1} \rangle} \underline{\sigma}_{xx} + O(\delta^2). \tag{5.15b}$$

Furthermore, we recognize the first few terms of the expansion of $G(\underline{\sigma})$ in (5.15a), and thus this can be simplified to

$$0 = \left\langle K^{-1} \right\rangle \underline{\sigma}_t - G(\underline{\sigma})\underline{u}_x + \delta \frac{\left\langle \left[\!\left[\rho\right]\!\right] K^{-1} \right\rangle}{\langle \rho \rangle \langle K^{-1} \rangle} G(\underline{\sigma}) \underline{u}_{xx} + O(\delta^2), \tag{5.16a}$$

$$0 = \langle \rho \rangle \, \underline{u}_t - \underline{\sigma}_x + \delta \frac{\left\langle \rho \left[\!\left[K^{-1} \right]\!\right] \right\rangle}{\langle \rho \rangle \langle K^{-1} \rangle} \underline{\sigma}_{xx} + O(\delta^2). \tag{5.16b}$$

The equations above represent the homogenized versions of (3.3), with terms up to $O(\delta)$ included. However, $\left\langle \rho \left[\!\left[K^{-1} \right]\!\right] \right\rangle = 0$ for piecewise constant functions $\rho(x)$ and $K(x)$, so we have to compute more terms of this equation to see any interesting behavior. Hence the terms involving second derivatives vanish in this case, and dispersive effects at the next order will dominate. (For other choices of $\rho(x)$ and $K(x)$ that are rapidly varying but not piecewise constant, the second-derivative terms may not drop out. Numerical experiments show different behavior in this case, but we have not yet investigated this in detail.)

As the algebra involved increases exponentially with each order of δ, we have employed Mathematica to perform the calculations. The homogenized equations in-

cluding $O(\delta^2)$ terms are found to be

$$0 = \left\langle K^{-1} \right\rangle \underline{\sigma}_t - G(\underline{\sigma})\underline{u}_x + \delta C_{11} G(\underline{\sigma})\underline{u}_{xx} + \delta^2 C_{12} G(\underline{\sigma})\underline{u}_{xxx} + \delta^2 C_{13}\left(G'(\underline{\sigma})\underline{\sigma}_x \underline{u}_{xx} + \frac{1}{2} G''(\underline{\sigma})\underline{\sigma}_x^2 \underline{u}_x \right) + O(\delta^3), \tag{5.17a}$$

$$0 = \langle \rho \rangle \, \underline{u}_t - \underline{\sigma}_x + \delta C_{21} \underline{\sigma}_{xx} + \delta^2 C_{22} \underline{\sigma}_{xxx} + O(\delta^3), \tag{5.17b}$$

where

$$\begin{aligned}
C_{11} &= \frac{\left\langle [\![\rho]\!] K^{-1} \right\rangle}{\langle \rho \rangle \left\langle K^{-1} \right\rangle}, \\
C_{21} &= \frac{\left\langle \rho [\![K^{-1}]\!] \right\rangle}{\langle \rho \rangle \left\langle K^{-1} \right\rangle}, \\
C_{12} &= \frac{\left\langle [\![K^{-1}]\!] [\![\rho]\!] \right\rangle}{\left\langle K^{-1} \right\rangle \langle \rho \rangle} - \frac{\left\langle K^{-1} [\![\rho]\!]^2 \right\rangle}{\left\langle K^{-1} \right\rangle \langle \rho \rangle^2}, \\
C_{22} &= \frac{\left\langle [\![K^{-1}]\!] [\![\rho]\!] \right\rangle}{\left\langle K^{-1} \right\rangle \langle \rho \rangle} - \frac{\left\langle [\![K^{-1}]\!]^2 \rho \right\rangle}{\left\langle K^{-1} \right\rangle^2 \langle \rho \rangle}, \\
C_{13} &= 2\frac{\left\langle [\![K^{-1}]\!] \rho \right\rangle^2}{\left\langle K^{-1} \right\rangle^2 \langle \rho \rangle^2} + 2\frac{\left\langle [\![K^{-1}]\!] [\![\rho]\!] \right\rangle}{\left\langle K^{-1} \right\rangle \langle \rho \rangle} - 2\frac{\left\langle [\![K^{-1}]\!]^2 \rho \right\rangle}{\left\langle K^{-1} \right\rangle^2 \langle \rho \rangle} - \frac{\left\langle K^{-1} [\![\rho]\!]^2 \right\rangle}{\left\langle K^{-1} \right\rangle \langle \rho \rangle^2}.
\end{aligned} \tag{5.18}$$

In general it can be shown that $C_{11} = -C_{12}$; see [11]. For the special case of piecewise constant material parameters considered in this paper, we find that

$$\begin{aligned}
C_{11} &= C_{21} = 0, \\
C_{12} &= -\frac{1}{12}\alpha^2(1-\alpha)^2 \frac{(\rho_A - \rho_B)(Z_A^2 - Z_B^2)}{K_A K_B \left\langle K^{-1} \right\rangle \langle \rho \rangle^2}, \\
C_{22} &= -\frac{1}{12}\alpha^2(1-\alpha)^2 \frac{(K_A - K_B)(Z_A^2 - Z_B^2)}{K_A^2 K_B^2 \left\langle K^{-1} \right\rangle^2 \langle \rho \rangle}, \\
C_{13} &= -\frac{1}{12}\alpha^2(1-\alpha)^2 \frac{\langle \rho \rangle^2 (K_A - K_B)^2 + (Z_A^2 - Z_B^2)}{K_A^2 K_B^2 \left\langle K^{-1} \right\rangle^2 \langle \rho \rangle^2}.
\end{aligned} \tag{5.19}$$

Here $Z_A = \sqrt{\rho_A K_A}$ and $Z_B = \sqrt{\rho_B K_B}$ are the linearized impedances. Note that if $Z_A = Z_B$, then $C_{12} = C_{22} = 0$. Also note that for the linear case $G(\sigma) = 1$, the factor multiplying C_{13} vanishes in the homogenized equations (5.17).

Additional terms in the homogenized equations are too complicated to present in their general form. For the specific case used in section 3 to produce Figures 4–9, we have calculated the homogenized equations including $O(\delta^4)$ terms. We take $\alpha = 1/2$ and use the exponential stress-strain relationship $G(\sigma) = \sigma + 1$ and the piecewise constant material parameters $\rho_A = k_A = 4$, $\rho_B = k_B = 1$. The homogenized

equations are then

$$u_t = \frac{2\sigma_x}{5} + \frac{3\delta^2\sigma_{xxx}}{500} + \delta^4\left(\frac{3\sigma_{xxx}\sigma_x^2}{15625(\sigma+1)^2} - \frac{72u_{xx}^2\sigma_x}{15625(\sigma+1)} - \frac{12\sigma_{xxxx}\sigma_x}{15625(\sigma+1)}\right.$$

(5.20a)

$$\left. - \frac{96u_{xx}u_{xxx}}{15625} - \frac{12\sigma_{xx}\sigma_{xxx}}{15625(\sigma+1)} - \frac{357\sigma_{xxxxx}}{1000000}\right) + O(\delta^6),$$

$$\sigma_t = \frac{8(\sigma+1)u_x}{5} + \delta^2\left(\frac{3(\sigma+1)u_{xxx}}{125} + \frac{3u_{xx}\sigma_x}{50}\right)$$

$$+ \delta^4\left(\frac{48u_xu_{xx}^2}{15625} - \frac{48\sigma_x\sigma_{xx}u_{xx}}{15625(\sigma+1)} - \frac{4761\sigma_{xxx}u_{xx}}{500000} - \frac{72u_{xxx}\sigma_x^2}{15625(\sigma+1)}\right.$$

(5.20b)

$$\left. - \frac{357(\sigma+1)u_{xxxxx}}{250000} - \frac{3543u_{xxxx}\sigma_x}{500000} - \frac{3891u_{xxx}\sigma_{xx}}{500000}\right) + O(\delta^6).$$

(The underlines have been dropped for clarity.) Note again that for this case the u_{xx} and σ_{xx} terms drop out, and we can see the appearance of dispersive terms like u_{xxx} and σ_{xxx} in δ^2 terms. Also notice that (5.20) has the property that it is invariant under the reflection $u(x,t) \to -u(-x,t)$ and $\sigma(x,t) \to \sigma(-x,t)$, a property inherited from the original equations (3.3).

Furthermore, we see that each term proportional to δ^n always has a total of $n+1$ spatial derivatives, which corroborates the observation made earlier that if $\tilde{u}(x,t)$ and $\tilde{\sigma}(x,t)$ are solutions to (5.20) for $\delta = 1$, then $u(x,t) = \tilde{u}(x/\delta, t/\delta)$ and $\sigma(x,t) = \tilde{\sigma}(x/\delta, t/\delta)$ are solutions for arbitrary δ. This property implies that the value of δ does not have to be small and that these homogenized equations are valid for any δ. This suggests that the "higher-order" terms can be dropped, not because δ is small, but because they involve small coefficients coming from higher-order averages of the rapidly varying coefficients, as is already apparent in (5.20).

In Figure 12 we compare the solution to the homogenized equations (5.20) with $\delta = 1$, dropping the $O(\delta^6)$ terms, with the numerical solution to the original equations (3.3). The homogenized equations were solved using a pseudospectral numerical method that computes these smooth solutions with high accuracy (using techniques discussed in [2] and [9] for similar equations). In this test we take initial data consisting of a nonzero strain in the middle of the computational domain, with zero velocity, which results in two outgoing pulses that each break up into a train of stegotons. At later times we show only the leftgoing wave train. We use this initial data with periodic boundary conditions for ease in using the pseudospectral method, and also because it is not clear how to impose appropriate boundary conditions of the type used earlier for the higher-order homogenized equations. The agreement is good, especially when one considers that the waves have traveled over 400 units by $t = 500$. If only the terms up to $O(\delta^3)$ are retained, solitary waves are still observed, but the agreement is not as good.

Solving the homogenized equations with boundary data corresponding directly to the layered medium tests done earlier would require the derivation of appropriate boundary conditions for these higher-order equations. An example of how this can be done in a weakly nonlinear case is shown in [10] and [11], but this has not yet been carried through for the homogenized equations presented here.

6. Conclusions. We have studied elastic waves in nonlinear layered media by computing numerical solutions to a first-order hyperbolic system of conservation laws

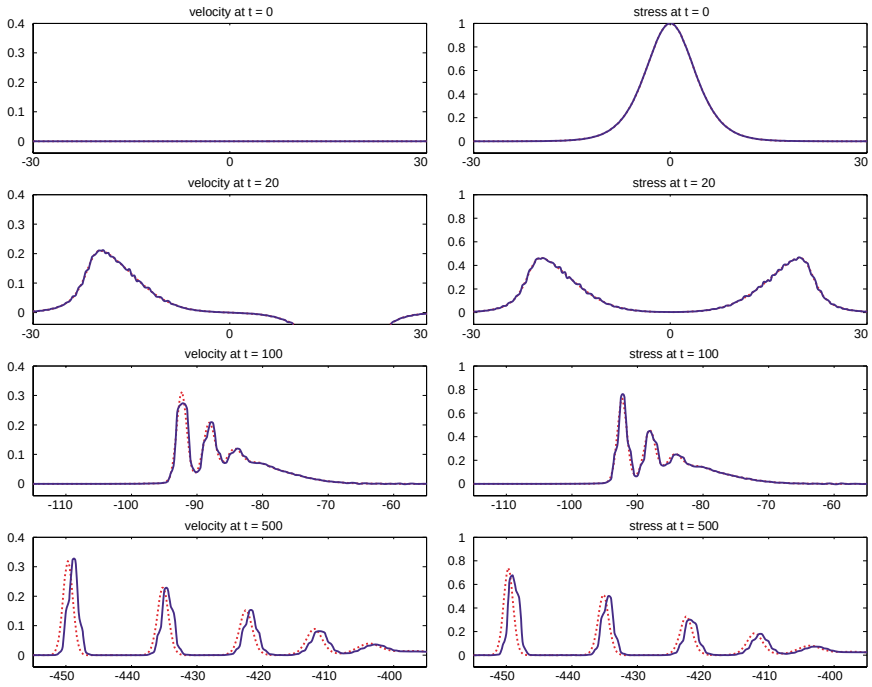

FIG. 12. *Comparison of a pseudospectral solution (dashed curve) to the homogenized equations* (5.20) *with the finite-volume solution (solid curve) to the layered medium equations* (3.3).

with a spatially varying flux function, using the method described in [1] and [4]. The layering leads to dispersive behavior if the layers are not impedance-matched, which in turn gives rise to the appearance of solitary waves that appear to interact in the manner of classical solitons. There is an approximate one-parameter family of such waves, whose velocity varies linearly with amplitude. By studying the solution as a function of time at a fixed point x_0, we obtain some indication of the scaling properties of these waves as the amplitude is varied.

We also showed that, for a special limiting choice of parameters, the layered medium can be modeled directly by the Toda lattice. Since the Toda lattice is known to have exact soliton solutions, it is not surprising that similar behavior is observed in the layered medium in this case. It is more surprising that solitary waves are observed in cases far from this limit.

A set of nonlinear homogenized equations has been derived that contains dispersive terms. Numerical solution of these equations yields results that agree well with the direct solution of the original hyperbolic system. We hope that further study of these equations may provide more insight into the nature of these solitary waves.

We have studied in detail only one particular choice of material parameters in the piecewise constant case with an exponential stress-strain relation. Preliminary experiments with different choices show a rich variety of other interesting behavior that should be explored further.

Acknowledgment. The authors would like to thank Arnold D. Kim for advice on pseudospectral numerical methods.

FORMAL ASYMPTOTIC MODELS OF VEHICULAR TRAFFIC. MODEL CLOSURES*

ALEXANDROS SOPASAKIS†

Abstract. Formal closed models for vehicular traffic flow are obtained based on the novel equilibrium solution of the Prigogine–Herman equation. To that effect, Hilbert and Chapman–Enskog asymptotic series expansions are employed, obtaining the Euler and Navier–Stokes equivalent equations for traffic flow.

Key words. traffic flow models, Chapman–Enskog, Hilbert asymptotic expansions, nonlinear kinetic equations

1. Introduction. We show that hydrodynamic (continuum) models of traffic can be obtained via asymptotic expansions about equilibrium solutions of the Prigogine–Herman kinetic equation. We therefore focus our efforts on the interval of vehicular concentrations c, which are less than or equal to the critical concentration c_{crit}. Here c_{crit} is the concentration for which the equilibrium solutions of the Prigogine–Herman equation bifurcate from a one-parameter family of solutions to a two-parameter family [25]. It is interesting to note that for many reasonable data (i.e., f_0, P, T) in the Prigogine–Herman equation the mathematical value of the critical concentration closely coincides with the value of the concentration at which traffic flow is observed to become "unstable" [7]. The term "unstable" is used by traffic engineers to describe the onset of traffic breakdown (flow is no longer smooth and is prone to sudden fluctuations). Mathematically this unstable regime is comprised of the concentrations c above some constant critical concentration defined via $c_{crit} = \frac{1}{Tw(1-P)}$, where w denotes the desired speed of drivers (T, P are as in (3.5), (3.6), respectively).

Macroscopic (continuum) models of traffic flow typically take the form of partial differential equations that have as their dependent variables quantities that can be identified with low-order polynomial moments (in speed) of the distribution function that is the dependent variable in a kinetic equation. One natural application of kinetic equations is therefore the rational development of continuum approximations for traffic flow. One possible approach is via asymptotic expansions, similar to those of Chapman and Enskog (e.g., Chapman and Cowling [6]) or Hilbert [12] in the kinetic theory of gases, about some underlying "equilibrium solution" as the low-order approximation. Because equilibrium solutions of nonlinear kinetic equations of vehicular traffic are not easy to obtain [9, 16], approaches other than asymptotic expansions of the type mentioned above have primarily been used to date. For example, Helbing [10] assumes a Gaussian type of equilibrium solution for the Paveri-Fontana [28] kinetic equation and expands asymptotically about it. Wegener and Klar [34] obtain macro-

scopic approximations in the classical manner of introducing *ad hoc* approximations to "close" the system of equations obtained from the first few polynomial moments of a particular kinetic equation.

Cercignani [4] uses an implementation of the method as proposed by Chapman [5] and Enskog [8] to obtain Chapman–Enskog approximations of different orders for the Boltzmann equation. Nelson and Sopasakis [26] have carried out similar calculations using Chapman–Enskog-type expansions, obtaining zeroth- and first-order model equations of traffic flow.

In this work we employ Hilbert expansions, obtaining zeroth- and first-order models for the low concentration regime. Further we obtain a higher-order "Burnett equivalent" model, which is valid for the low concentration regime, using Chapman–Enskog approximations up to second order.

We start by presenting in review the Prigogine–Herman equation and a brief overview of similar models in section 2. In section 3 we describe and explain how to obtain the equilibrium solutions for the Prigogine–Herman equation under different cases of the passing probability P and relaxation time T. Then in section 4 we show how to use those equilibrium solutions and expand asymptotically around them, thus obtaining traffic flow models. Expansions of Chapman–Enskog type are presented in subsection 4.1. Those include the zero-order or Euler-like expansion, the first-order or Navier–Stokes-like expansion, and the second-order or Burnett-like expansion. Equivalent expansions of Hilbert type are presented in subsection 4.3 for the zeroth and first orders only. Last, we briefly present a preliminary numerical simulation for only the zeroth- and first-order approximations and for a very simple traffic incident in section 5. For the complete numerical investigations, we refer to the sequel of this paper [32].

2. Nonlinear models of vehicular traffic. The kinetic model of Prigogine and Herman is

$$\frac{\partial f(x,v,t)}{\partial t} + v\frac{\partial f(x,v,t)}{\partial x} = -\frac{(f(x,v,t) - f_0(x,v,t))}{T} + c(x,t)(\bar{v}-v)(1-P)f(x,v,t). \tag{2.1}$$

Here the various symbols have the following meanings:

– The zeroth-order moment of $f(x,v,t)$, $c(x,t) = \int_0^\infty f(x,v,t)\,dv$ is vehicular *concentration* (or *density*);

– The first-order moment, $\bar{v}(x,t) = \frac{1}{c(x,t)}\int_0^\infty v f(x,v,t)\,dv$, is mean *speed*;

– P is the passing probability, which is assumed known (in this work depending explicitly on c);

– T is the relaxation time, which is assumed known (in this work depending explicitly on c);

– $f_0(x,v,t)$ is the density function for the desired speed of vehicles, which is assumed to be known a priori;

– $f(x,v,t)$ is the *distribution function* of vehicles in space and speed. Thus $f(x,v,t)\,dx\,dv$ is the expected number of vehicles at time t that have position between x and $x+dx$ and speed between v and $v+dv$. This is the unknown function, which presumably is determined by the Prigogine–Herman equation, along with suitable boundary and initial conditions.

In the text to follow, all notation will be suppressed (when understood) in regard to dependence on space (x), time (t), and velocity (v) variables, unless necessary for clarity. All distribution functions to be encountered depend on x, v, and t.

A vehicle, in practice, changes speed due to three types of vehicular interactions: "slowing down," "speeding up," and "passing." In the classical Prigogine–Herman kinetic model of vehicular traffic, the first of these types is treated by a fundamental quadratic interaction term of the Boltzmann type,

$$c(x,t)(\bar{v}-v)(1-P)f(x,v,t) \equiv (1-P)\left(f(v)\int_0^\infty f(v')v'\,dv' - f(v)v\int_0^\infty f(v')\,dv'\right),$$

based on the assumption that the speed of the vehicle slowing down is uncorrelated with that of the vehicle immediately ahead ("lead vehicle") that necessitates the slowing down. (This is reasonable since we assume a one-lane highway where passing is always possible and can occur without change in speed by use of another lane which is designated for passing alone.) By contrast, the other two types of interactions, for which this "zero correlation" assumption is not true, are treated through a phenomenological relaxation term,

$$-\frac{(f(x,v,t)-f_0(x,v,t))}{T}.$$

In keeping with the traditions of the Boltzmann equation of the kinetic theory of gases, both accelerations and decelerations are assumed to occur instantaneously. This imposes some limitations on the distance and time scales for validity of the resulting kinetic equation, and therefore also on any macroscopic (continuum) equation derived therefrom. Limitations of the latter type do not appear to have been extensively discussed in the traffic flow literature; they are discussed in the work of Nelson, Bui, and Sopasakis [27]. One should be very careful in using the Prigogine–Herman equation to attempt to resolve traffic phenomena on time scales comparable to or smaller than the time for a vehicle to accelerate. Also important in the derivation of the equation is the assumption that vehicles are treated as being "point particles," which means that they have zero length.

Paveri-Fontana adds [28] a new dimension to the Prigogine–Herman model by treating desired speeds of drivers as an additional independent variable w,

$$\begin{aligned}\left(\frac{\partial}{\partial t}+v\frac{\partial}{\partial x}\right)g(x,v,t;w)+\frac{\partial}{\partial v}\left(\frac{w-v}{T}g(x,v,t;w)\right)\\ = f(x,v,t)\int_v^\infty (1-P)(v'-v)g(x,v',t;w)\,dv'\\ -g(x,v,t;w)\int_0^v (1-P)(v-v')f(x,v',t)\,dv',\end{aligned}$$

where

$$f(x,v,t)=\int_0^\infty g(x,v,t;w)\,dw.$$

Here $g = g(x,v,w;t)$ is the density function, so that $g(x,v,w,t)\,dx\,dv\,dw$ is the expected number of vehicles at time t that have position between x and $x+dx$, speed between v and $v+dv$, and desired velocity between w and $w+dw$. P is probability of passing, T is relaxation time, and v is velocity. Recently Hoogendoorn and Bovy [13] generalize the Paveri-Fontana theory and develop a traffic model with multiple user classes and thus multiple desired speeds.

Nelson [24] attempts to treat both "slowing down" and "speeding up" interactions, as quadratic interaction terms of the Boltzmann type,

$$\frac{\partial f}{\partial t} + v\frac{\partial f}{\partial x} = \left(\frac{\delta f}{\delta t}\right)_+ + \left(\frac{\delta f}{\delta t}\right)_- .$$

Here $(\frac{\delta f}{\delta t})_+$ and $(\frac{\delta f}{\delta t})_-$ denote the rate of change of f due, respectively, to speeding up and slowing down interactions, and suitable expressions for these were obtained by introducing a certain "mechanical model" describing the behavior of drivers, and a certain correlation model approximating the passing distribution of vehicles in terms of f.

Klar and Wegener [16] built on the ideas of Nelson and derived a kinetic model of vehicular traffic which also takes into account vehicle length:

$$\frac{\partial f}{\partial t} + v\frac{\partial f}{\partial x} = \left(\frac{\delta f}{\delta t}\right)_g + \left(\frac{\delta f}{\delta t}\right)_l,$$

$$\text{where } \left(\frac{\delta f}{\delta t}\right)_g + \left(\frac{\delta f}{\delta t}\right)_l = \sum_{i=1}^{N}\left(\frac{\delta f}{\delta t}\right)_g^i + \sum_{i=1}^{N}\left(\frac{\delta f}{\delta t}\right)_l^i.$$

Here $(\frac{\delta f}{\delta t})_g$ and $(\frac{\delta f}{\delta t})_l$ denote the gain and loss terms, respectively, due to the ith threshold. A threshold here generates a change in velocity. Consider two cars, car 1 with position x_1 and speed v_1, and car 2 at position x_2 and speed v_2. Car 1 is assumed to change velocity only in response to its leading vehicle, car 2. If car 1 is faster than the leading vehicle, car 2, and the headway to car 2 becomes smaller than a certain threshold, the driver will either slow down or pass the leading vehicle. This use of thresholds allows cars to be considered as also having lengths.

3. Equilibrium solutions and behavior at high concentrations. This section will serve to introduce all the necessary background information regarding equilibrium solutions, as a prelude to the asymptotic expansions to follow in the next section. This leads to novel equilibrium solutions of the Prigogine–Herman kinetic equation (based on some mild assumptions to be found in [25]) that comprise a one-parameter family in the "stable" low-concentration regime, $0 < c < c_{crit}$ for a certain $c_{crit} > 0$, but a two-parameter family on the complementary unstable concentration range, $c_{crit} < c < c_{jam}$. Here c_{jam} is defined to be the concentration of vehicles for which the flow becomes zero.

We introduce the following notations:

$$v_0(c) = \frac{1}{Tc(1-P)}, \quad \zeta = \zeta(c) = \bar{v} - v_0(c). \tag{3.1}$$

The equilibrium solutions of (2.1) can then be expressed as

$$f_{eq} = f_{eq}(v) = \frac{v_0}{v-\zeta} f_0 + \alpha c \delta(v-\zeta), \tag{3.2}$$

where δ is the Dirac delta function, α a parameter to be determined later, and all dependence on x and t has been notationally suppressed.

We assume that the desired speed distribution function (f_0), the passing probability (P), and the relaxation time (T) are known a priori (with P and T even taken to depend on concentration (c)), according to the usual assumptions of the

Prigogine–Herman kinetic theory. Under these assumptions the equilibrium solution (3.2) depends upon three parameters, namely c, $\bar{v}$, and α. (For some of the following considerations it is convenient to replace one of these parameters, usually α, by ζ.) However, the basic definitions of the distribution function and the associated concentration requires satisfaction of the *normalization condition* (for the zeroth moment),

$$c = \int_0^\infty f_{eq}(v)\, dv, \tag{3.3}$$

and the *mean-speed condition* (for the first moment),

$$c\bar{v} = \int_0^\infty v f_{eq}(v)\, dv. \tag{3.4}$$

Upon substituting the expression (3.2) into these conditions, there results a system of two equations that must be satisfied by these three parameters. We will work with more realistic forms of passing probability and relaxation time, as also assumed in Chapter 4 of Prigogine and Herman [29],

$$P = 1 - \frac{c}{c_{jam}} \tag{3.5}$$

and

$$T = \tau \frac{c/c_{jam}}{1 - c/c_{jam}}. \tag{3.6}$$

We shall frequently find it convenient to work with the "reduced" desired speed distribution, $\varphi_0(v; c)$, as defined by $\int c\varphi_0(v; c)\, dv = \int f_0(v)\, dv$. The main result of this section can now be summarized by the following theorem.

THEOREM 3.1. *In terms of the reduced desired speed distribution, the possible equilibrium solutions* (3.2) *can be written as*

$$f_{eq}(v; c, \alpha) = cv_0(c)\frac{\varphi_0(v; c)}{v - \zeta} + c\alpha\delta(v - \zeta) \tag{3.7}$$

$$\text{for the cases of} \begin{cases} 0 < c \le c_{crit} & \text{and } \alpha = 0, \text{ or} \\ c_{crit} < c < c_{jam} & \text{and } \alpha_{min} \le \alpha \le \alpha_{max}, \end{cases} \tag{3.8}$$

where $\zeta = \bar{\zeta}(\alpha, c) = w - \frac{v_o(c)}{1-\alpha}$, c_{jam} *is the jam concentration of vehicles,* $v_0(c)$ *is defined in* (3.1), *and* c_{crit} *is the root of* $c := \frac{1}{T(1-P)} \int_{w_-}^{w^+} \frac{\varphi_0(v;c)}{v-\zeta}\, dv$. *Further,* $\alpha_{min} = \max\{0, 1 - v_0(c)F(w_-; c)\}$ *and* $\alpha_{max} = 1 - v_0(c)F(0; c)$, *where* $F(\zeta; c) = \int_{w-}^{w+} \frac{\varphi_0(v;c)}{v-\zeta}\, dv$.

(The exact same theorem will hold if we take constant values of P and T.) For the details regarding the proof of this theorem, we refer the reader to [25]. To obtain this result it is necessary to invoke the fact that the traffic-theoretic interpretation of $f_{eq}(v)$ requires that it have support on the interval 0 to w and assumes only nonnegative values there. The equilibrium solutions comprise a two-parameter family (e.g., c and α), for $c > c_{crit}$. The delta function component can be interpreted as "platoons" of vehicles traveling at some "synchronized" speed, but now the platoon speed can vary from $\bar{\zeta}(\alpha_{max}, c) = 0$ to $\bar{\zeta}(\alpha_{min}, c) > 0$, rather than being fixed at 0 as in the classical results of Prigogine and Herman [29, Chapter 4] and Prigogine, Herman, and Anderson [30].

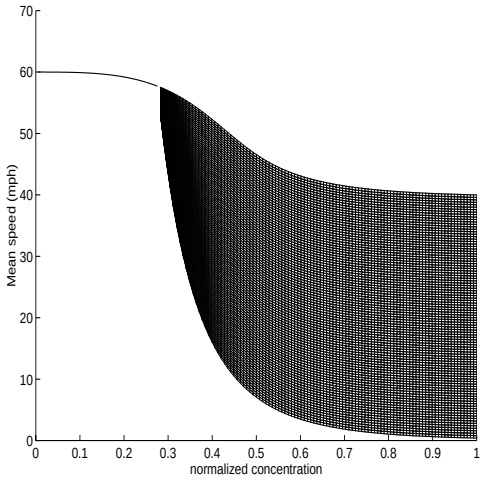

FIG. 1. *Dependence of the mean-speed curve/continuum on the concentration for a uniform desired speed distribution from* 45 *to* 90 *mph* ($c_{jam} = 225$ *vpm,* $\tau = .002$ *hours).*

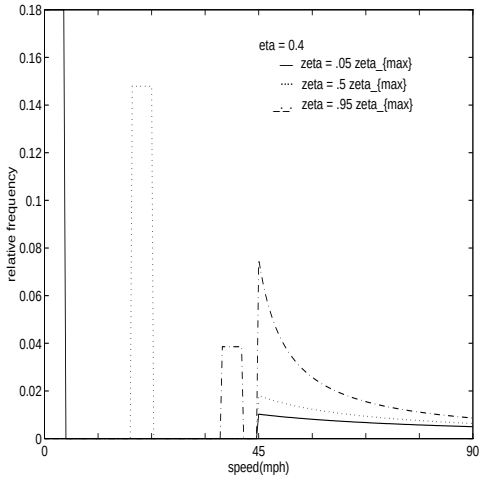

FIG. 2. *Variation of the equilibrium distribution with speed of the collective flow, for normalized concentration* = .4 *and a uniform desired speed distribution from* 45 *to* 90 *mph* ($c_{jam} = 225$ *vpm,* $\tau = .002$ *hours).*

Figure 1 shows the mean-speed curve/continuum as a function of concentration, for a hypothetical situation in which the distribution of desired speeds is uniform from 45 mph to 90 mph, $c_{jam} = 225$ vehicles per mile (vpm), and $\tau = .002$ hours. A graph of this distribution function can be found in Figure 2. (These values are reasonably representative of those obtained observationally by Edie, Herman, and Lam [7].) For this instance the bifurcation from a curve to a continuum occurs at slightly above $c_{jam}/3$ ($c_{crit} \approx 0.29 \cdot c_{jam} = 65$ vpm). This behavior of a two-parameter family of solutions for concentrations above c_{crit} is the reason that the Prigogine–Herman equation is so attractive and preferable to other alternative models of traffic flow. This model equation, which not only allows for an explicitly calculated equilibrium solution to be found, also predicts (see [33]) recently only experimentally observed

concepts such as "synchronized flow" (see Kerner [15]) and "stop and go" traffic.

4. Formal asymptotic solutions of the Prigogine–Herman kinetic equation. Here we use the equilibrium solutions previously obtained for the Prigogine–Herman kinetic equation and asymptotically expand them in a small parameter ϵ (using the Chapman–Enskog [5, 8] or Hilbert [12] method) to derive hydrodynamic equivalent equations for traffic flow for the stable ($0 < c < c_{crit}$) traffic regime. The purpose of these expansions will be to produce hydrodynamic equivalent approximations of traffic flow models.

4.1. The Chapman–Enskog asymptotic expansion. In this section the zeroth-, first-, and second-order Chapman–Enskog asymptotic expansions are obtained. Numerical results under appropriate conservation-preserving and entropy-satisfying methods follow in a sequel to this paper [32].

We find a formal asymptotic solution, for the Prigogine–Herman equation, of the form

$$f = \sum_{n=0}^{\infty} \epsilon^n f^{(n)}. \tag{4.1}$$

To accomplish this we rewrite the Prigogine–Herman equation with the addition of an artificial "small" parameter ϵ on the left-hand side,

$$\epsilon \left(\frac{\partial f}{\partial t} + v \frac{\partial f}{\partial x} \right) = Qf, \tag{4.2}$$

where the operator Qf is defined as

$$Qf = -\frac{f - \varphi_0(v) \int_0^{w^+} f(v')\, dv'}{T} + (1 - P) f(v) \int_0^{w^+} (v' - v) f(v')\, dv'. \tag{4.3}$$

The addition of the parameter ϵ concerns scaling issues of Qf. For the Chapman–Enskog expansion the time derivative is also expanded in powers of ϵ, as

$$\frac{\partial f}{\partial t} = \sum_{n=0}^{\infty} \epsilon^n \frac{\partial^{(n)} f}{\partial t} = \sum_{n=0}^{\infty} \epsilon^n \left(\sum_{k=0}^{n} \frac{\partial^{(k)} f^{(n-k)}}{\partial t} \right). \tag{4.4}$$

In the last equality the expression (4.1) has been used. The $\frac{\partial^{(k)} f^{(n-k)}}{\partial t}$ are assumed to be unknowns to be determined so that existence of terms of the solution (4.1) is ensured when (4.1) is substituted into (4.2).

Although f is expanded in powers of ϵ, the concentration c, according to the Chapman–Enskog method, is not. Thus it is required that all higher-order contributions to c be zero:

$$c^{(n)} = \int_0^{w^+} f^{(n)}\, dv \equiv 0, \quad n = 1, 2, \ldots, \quad \text{and} \tag{4.5}$$

$$c^{(0)} = \int_0^{w^+} f^{(0)}\, dv \equiv c(x, t), \tag{4.6}$$

$$\text{where} \qquad c = \sum_{n=0}^{\infty} \epsilon^n c^{(n)}. \tag{4.7}$$

Another important point which is a result of the previous remark is that even though T and P vary with c, c itself is *not* expanded in a power series in ϵ as will be the case for the Hilbert expansion in the next subsection. Therefore T and P are also *not* expanded in ϵ. This is a very important point and will be used later in the way we define operators and prove results. For a Chapman–Enskog expansion, T depends on $c(= c^{(0)})$ from

$$T(f^{(0)}) \equiv T(c; f^{(0)}) = \tau \frac{\int f^{(0)}(v)\, dv}{c_{jam} - \int f^{(0)}(v)\, dv}. \tag{4.8}$$

To prove the main result in this section we first define the following auxiliary operator,

$$\begin{aligned}\mathbf{L}(g)h(v) := &-\frac{h(v) - \varphi_0(v)\int_0^{w^+} h(v')\, dv'}{T(g)} + (1 - P(g))h(v)\int_0^{w^+} (v' - v)g(v')\, dv' \\ &+ (1 - P(g))g(v)\int_0^{w^+} (v' - v)h(v')dv',\end{aligned} \tag{4.9}$$

and prove the following simple lemma.

LEMMA 4.1. *The null space of* $\mathbf{L}^*(f^{(0)})$ *consists of the constants.*

Proof. The adjoint of $\mathbf{L}(f^{(0)})$ is

$$\begin{aligned}\mathbf{L}^*(f^{(0)})h(v) = &(1 - P)c^{(0)}(\zeta(c^{(0)}) - v)[h(v)(1 - \alpha) + \alpha(h(\zeta))] \\ &+ \frac{v - \zeta(c^{(0)})}{T}\int_0^{w^+} \frac{\varphi_0(v')}{v' - \zeta(c^{(0)})} h(v')\, dv',\end{aligned} \tag{4.10}$$

and we therefore need to solve $\mathbf{L}^*(f^{(0)})h(v) = 0$. So we find functions $h(v)$ such that

$$(1 - P)c^{(0)}T[h(v)(1 - \alpha) + \alpha(h(\zeta))] = \int_0^{w^+} \frac{\varphi_0(v)}{v - \zeta(c^{(0)})} h(v)\, dv, \tag{4.11}$$

implying that $h(v)$ is constant. ∎

LEMMA 4.2 (necessary and sufficient condition). *There exists a solution of* (4.2) *with* (4.1) *if and only if for every order of the expansion* n *the following equations hold:*

$$\frac{\partial^{(n-1)}}{\partial t} c = -\frac{\partial q^{(n-1)}}{\partial x} \qquad \text{for } n = 1, 2, \ldots. \tag{4.12}$$

Proof. We substitute expansions (4.1), (4.4), (4.7) into (4.2). By the Fredholm alternative, (4.2) will have a solution if and only if the integral over $0 < v < w^+$ of the right-hand side is zero, or otherwise, if

$$\int_0^{w^+} \sum_{k=0}^{n-1} \frac{\partial^{(k)} f^{(n-k-1)}}{\partial t} + v\frac{\partial f^{(n-1)}}{\partial x}\, dv = 0. \tag{4.13}$$

The result now follows from (4.5), (4.6), and the definition of

$$q^{(n)} = \int_0^{w^+} v f^{(n)}(v)\, dv \qquad \text{for } n = 0, 1, \ldots. \tag{4.14}$$

∎

Note that (4.12) is nothing more than the Lighthill–Whitham–Richards [22, 31] equations, which, according to this lemma, must hold at every level of the expansion n in order for the problem to have a solution.

THEOREM 4.3. *The Chapman–Enskog expansion for the Prigogine–Herman equation at any order of ϵ has the form*

$$\frac{\partial c}{\partial t} + \sum_{n=0}^{\infty} \epsilon^n \frac{\partial q^{(n)}}{\partial x} = 0, \tag{4.15}$$

where $q^{(n)}(x,t;c) = \int_0^{w^+} v f^{(n)}(x,v,t;c)\, dv$.

For the proof of this theorem, but also the two corollaries that follow, we direct the interested reader to [26].

COROLLARY 4.4. *The zeroth-order approximation (ϵ^0) is the Lighthill–Whitham–Richards (LWR) model,*

$$\frac{\partial c}{\partial t} + \frac{\partial q}{\partial x} = 0, \tag{4.16}$$

where

$$q = q^{(0)} = Q_0(c) := \frac{1}{T(1-P)} + c\zeta, \tag{4.17}$$

with $\zeta(c)$ the root of $F_0(\zeta) = Tc(1-P)(1-\alpha)$, where $F_0(\zeta) := \int_{w^-}^{w^+} \frac{\varphi_0}{v-\zeta}\, dv$.

COROLLARY 4.5. *The first-order Chapman–Enskog approximation is given by*

$$\begin{aligned} \frac{\partial c}{\partial t} + \frac{\partial q}{\partial x} &= \frac{\partial c}{\partial t} + \frac{\partial \left[q_{CE}^{(0)} + q_{CE}^{(1)} \right]}{\partial x} \\ &= \frac{\partial c}{\partial t} + Q_0'(c) \frac{\partial c}{\partial x} - \frac{\partial}{\partial x} \left(\mathcal{D}(c) \frac{\partial c}{\partial x} \right) = 0. \end{aligned} \tag{4.18}$$

Here $Q_0' = \frac{dQ_0}{dc}$, where Q_0 is as in Corollary 4.4, and the "diffusion coefficient" is defined by

$$\mathcal{D}(c) = \frac{T}{F_1(\zeta(c))} \left(cT(1-P) \frac{F_2(\zeta(c))}{F_1(\zeta(c))^2} - 1 \right) \geq 0, \tag{4.19}$$

where $F_n(\zeta(c)) \equiv \int_0^{w^+} \frac{\varphi_0(v)}{(v-\zeta)^{n+1}} dv$.

4.1.1. Second-order (or Burnett-like) expansion.

COROLLARY 4.6. *The Burnett (order 2) approximation to the Prigogine–Herman equation is given by*

$$\begin{aligned} \frac{\partial c}{\partial t} + \frac{\partial q}{\partial x} &= \frac{\partial c}{\partial t} + \frac{\partial \left[q_{CE}^{(0)} + q_{CE}^{(1)} + q_{CE}^{(2)} \right]}{\partial x} \\ &= \frac{\partial c}{\partial t} + Q_0'(c) \frac{\partial c}{\partial x} - \frac{\partial}{\partial c} \left(\mathcal{D}(c) \frac{\partial c}{\partial x} \right) \frac{\partial c}{\partial x} + \frac{\partial}{\partial c} \left(I(c) \left(\frac{\partial c}{\partial x} \right)^2 \right) \frac{\partial c}{\partial x} = 0, \end{aligned} \tag{4.20}$$

where Q_0 and $\mathcal{D}$ are as in (4.17) and (4.19), respectively, and

$$A(c) = \frac{T}{F_1^3} \left(\frac{3F_1' F_2}{F_1} - F_2' \right),$$

$$B(c) = \frac{T}{F_1^3}\left(\frac{F_0^{'}F_2}{F_1} + 2\frac{F_2^{'}F_0}{F_1} - 6\frac{F_0F_1^{'}F_2}{F_1^2} - F_1^{'} - 2\zeta^{'}F_2\right),$$
$$G(c) = \frac{T}{F_1^3}\left(2\frac{F_0}{F_1}(F_1^{'} + \zeta F_2) + 3\frac{F_0}{c}\right),$$
$$H(c) = -3\frac{TF_0}{cF_1^4},$$
$$I(c) = \frac{T}{F_1}(AF_1 + BF_2 + GF_3 + HF_4) - \frac{T\mathcal{D}(c)F_0}{cF_1^3}\left(F_3 - \frac{F_2^2}{F_1}\right),$$

where $F_n(\zeta) := \int_0^{w^+} \frac{\varphi_0(v)}{(v-\zeta)^{n+1}}\, dv$, *and all primes denote derivatives with respect to* c.

Proof. The left-hand side of the Prigogine–Herman equation expanded in powers of a small parameter ϵ has the form

$$\epsilon\left[\frac{\partial f}{\partial t} + v\cdot\frac{\partial f}{\partial x}\right] = \epsilon\Bigg[\left(\frac{\partial^{(0)}}{\partial t} + \epsilon\frac{\partial^{(1)}}{\partial t} + \epsilon^2\frac{\partial^{(2)}}{\partial t} + O(\epsilon^3)\right)(f^{(0)} + \epsilon f^{(1)} + \epsilon^2 f^{(2)} + O(\epsilon^3)) + v\cdot\frac{\partial}{\partial x}(f^{(0)} + \epsilon f^{(1)} + \epsilon^2 f^{(2)} + O(\epsilon^3))\Bigg].$$

Thus the ϵ^2 terms are $\frac{\partial^{(0)}}{\partial t}f^{(1)} + \frac{\partial^{(1)}}{\partial t}f^{(0)} + v\cdot\frac{\partial}{\partial x}f^{(1)}$. Applying Lemma 4.2, there exists a solution if and only if

$$\frac{\partial^{(1)}}{\partial t}c = -\frac{\partial}{\partial x}q^{(1)}. \tag{4.21}$$

This, together with

$$\frac{\partial^{(0)}}{\partial t}c = -\frac{\partial}{\partial x}q^{(0)}, \tag{4.22}$$

which can be similarly derived while showing Corollary 4.5, will be proven useful in the formulations to follow.

Using the conservation law (4.16), or in effect relationship (4.21) and (4.22), we obtain

$$\frac{\partial^{(0)}}{\partial t}f^{(1)} + \frac{\partial^{(1)}}{\partial t}f^{(0)} + v\cdot\frac{\partial}{\partial x}f^{(1)} = \left(v - \frac{\partial q^{(0)}}{\partial c}\right)\frac{\partial f^{(1)}}{\partial c}\frac{\partial c}{\partial x} - \frac{\partial q^{(1)}}{\partial c}\frac{\partial f^{(0)}}{\partial c}\frac{\partial c}{\partial x} := g_2\left(c, \frac{\partial c}{\partial x}\right)\frac{\partial c}{\partial x}.$$

Similarly, the Chapman–Enskog expansion of the right-hand side of the Prigogine–Herman equation at order ϵ^2 provides us with

$$-f^{(2)}(1-P)c(v-\zeta) + (1-P)[f^{(0)}q^{(2)} + f^{(1)}q^{(1)}] := \mathcal{L}(f^{(0)}, f^{(1)})f^{(2)}. \tag{4.23}$$

When we solve the full approximation,

$$g_2\left(c, \frac{\partial c}{\partial x}\right)\frac{\partial c}{\partial x} = \mathcal{L}(f^{(0)}, f^{(1)})f^{(2)} = -f^{(2)}(1-P)c(v-\zeta) + (1-P)(f^{(0)}q^{(2)} + f^{(1)}q^{(1)}),$$

for $f^{(2)}$ we obtain

$$f^{(2)} = \frac{1}{(1-P)c(v-\zeta)}\left((1-P)\left(f^{(0)}q^{(2)} + f^{(1)}q^{(1)}\right) - g_2\frac{\partial c}{\partial x}\right). \tag{4.24}$$

Integrating with respect to v, we obtain the contribution to the flow as

$$0 = \frac{q^{(2)}}{c}\int_0^{w^+}\frac{f^{(0)}}{v-\zeta}\,dv + \frac{q^{(1)}}{c}\int_0^{w^+}\frac{f^{(1)}}{v-\zeta}\,dv - \frac{T}{F_0}\int_0^{w^+}\frac{g_2}{v-\zeta}\,dv\frac{\partial c}{\partial x}. \tag{4.25}$$

Some of the expressions appearing above are now evaluated here. Particularly, we simplify the three terms $\int_0^{w^+}\frac{f^{(0)}}{v-\zeta}\,dv$, $\int_0^{w^+}\frac{f^{(1)}}{v-\zeta}\,dv$, and $\int_0^{w^+}\frac{g_2}{v-\zeta}\,dv$ below. First note that

$$\int_0^{w^+}\frac{f^{(0)}}{v-\zeta}\,dv = c\frac{F_1}{F_0}. \tag{4.26}$$

Similarly,

$$\int_0^{w^+}\frac{f^{(1)}}{v-\zeta}\,dv = \frac{T}{F_1^2}\left(F_3 - \frac{F_2^2}{F_1}\right)\frac{\partial c}{\partial x}. \tag{4.27}$$

Last we calculate

$$g_2(v) = \left(A\frac{\varphi(c)}{(v-\zeta)} + B\frac{\varphi(c)}{(v-\zeta)^2} + G\frac{\varphi(c)}{(v-\zeta)^3} + H\frac{\varphi(c)}{(v-\zeta)^4}\right)\frac{\partial c}{\partial x}, \tag{4.28}$$

where $A = A(c)$, $B = B(c)$, $G = G(c)$, and $H = H(c)$ are as in the statement of the theorem. As a result,

$$\int_0^{w^+}\frac{g_2(v)}{v-\zeta}\,dv = (AF_1 + BF_2 + GF_3 + HF_4)\frac{\partial c}{\partial x}. \tag{4.29}$$

Therefore the second approximation to the flow, $q^{(2)}$, can now be expressed from (4.25) through expressions (4.26), (4.27), and (4.29), as $q^{(2)} = I(c)(\frac{\partial c}{\partial x})^2$, where $I(c)$ is as in the theorem. Thus the second-order hydrodynamic approximation, given the flow $q = q^{(0)} + q^{(1)} + q^{(2)}$, becomes

$$\begin{aligned} 0 &= \frac{\partial c}{\partial t} + \frac{\partial q}{\partial x} \\ &= \frac{\partial c}{\partial t} + Q_0'(c)\frac{\partial c}{\partial x} - \frac{\partial}{\partial c}\left[\mathcal{D}(c)\frac{\partial c}{\partial x} - I(c)\left(\frac{\partial c}{\partial x}\right)^2\right]\frac{\partial c}{\partial x}. \end{aligned}$$ □

Some very simple nondimensional analysis reveals that we have obtained the correct form in this complicated-looking flux function. If we abbreviate quantities such as length (L) and time (t), we have that $\mathcal{D}(c)$ is represented in L^2/t, $\partial c/\partial x$ in $1/L^2$, and $I(c)$ in t^4/L^3. We therefore obtain the extra contribution to the flow $q^{(2)}$ in $1/t$ as expected.

4.2. Linear stability analysis. The question of stability for the Chapman–Enskog expansions just presented is natural, especially in light of the fact that Burnett level expansions for fluid dynamic problems are destabilizing [14]. We therefore now perform a linear stability analysis. A brief outline of this procedure is as follows: We start by linearizing (4.20). We then obtain $\nu_k(\omega)$ the Fourier–Laplace transform for plane (couette) flow of $\hat{c}(x,t)$. (The "hat" on the c represents small perturbations from equilibrium, c_{eq}, in space and time.) As a result, the inverse Laplace transform of $\nu_k(\omega)$ gives contributions in the form

$$Ae^{-i\omega(k)t}, \tag{4.30}$$

where A is the amplitude. Therefore our interest lies in identifying the sign of the imaginary part of ω. It is clear from (4.30) that a positive (negative) value of $\mathrm{Im}(\omega)$ implies instability (stability).

To linearize (4.20) we need to introduce some notation. We define the nonlinear differential operator by

$$F(c) = f(t,x,D^m c) = \frac{\partial c}{\partial t} + \frac{\partial}{\partial x}\left[Q_0(c) - \mathcal{D}(c)\frac{\partial c}{\partial x} + I(c)\left(\frac{\partial c}{\partial x}\right)^2\right]. \tag{4.31}$$

Suppose that $f(t,x,\xi)$ is smooth in its arguments $t \in R^+, x \in \Omega \subset R$, and $\xi = \{\xi_\alpha : |\alpha| \le m\}$, where c can take values on some vector space R and $F : C^\infty(\Omega) \to C^\infty(\Omega)$. We let the equilibrium solution $c_{eq} \in C^m(\omega)$. Then the linearization of F at c_{eq} is $LF(c_{eq}) : C^m(\Omega) \to C(\Omega)$,

$$LF(c_e q)\hat{c} = \frac{\partial}{\partial \epsilon}F(c_{eq} + \epsilon\hat{c})|_{\epsilon=0} = \sum_{|\beta|\le m}\frac{\partial f}{\partial \xi_\beta}(t,x,D^m c_{eq})D^\beta \hat{c}. \tag{4.32}$$

As a result, linearizing (4.20) gives

$$\frac{\partial \hat{c}}{\partial t} + P_1\hat{c} + P_2\frac{\partial \hat{c}}{\partial x} + P_3\frac{\partial^2 \hat{c}}{\partial x^2} = 0, \tag{4.33}$$

where

$$P_1 = Q_0^{''}\frac{\partial c_{eq}}{\partial x} - \mathcal{D}^{''}\left(\frac{\partial c_{eq}}{\partial x}\right)^2 - \mathcal{D}^{'}\frac{\partial^2 c_{eq}}{\partial x^2} + I^{''}\left(\frac{\partial c_{eq}}{\partial x}\right)^3 + 2I^{'}\frac{\partial c_{eq}}{\partial x}\frac{\partial^2 c_{eq}}{\partial x^2},$$

$$P_2 = Q_0^{'} - 2\mathcal{D}^{'}\frac{\partial c_{eq}}{\partial x} + 3I^{'}\left(\frac{\partial c_{eq}}{\partial x}\right)^2 + 2I\frac{\partial^2 c_{eq}}{\partial x^2}, \quad \text{and} \quad P_3 = -\mathcal{D} + 2I\frac{\partial c_{eq}}{\partial x},$$

where all primes denote derivatives with respect to ξ and all coefficients are evaluated at c_{eq}. We now introduce the Fourier–Laplace transform

$$\hat{c}(t;x) = \frac{1}{2\pi}\int_0^\infty e^{i\omega(k)t}\int_{-\infty}^\infty e^{ikx}\nu_k(v;\omega)\,dk\,d\omega. \tag{4.34}$$

Therefore (4.33) gives $\omega(k) = -P_1 i + P_2 k + P_3 k^2 i$, which implies that we must have

$$-P_1 + P_3 k^2 < 0 \quad \text{for stability.} \tag{4.35}$$

In Figure 3 we see, numerically, the contribution to stability due to the advective part alone. Note that in fact we have instability for this case (positive value) but no

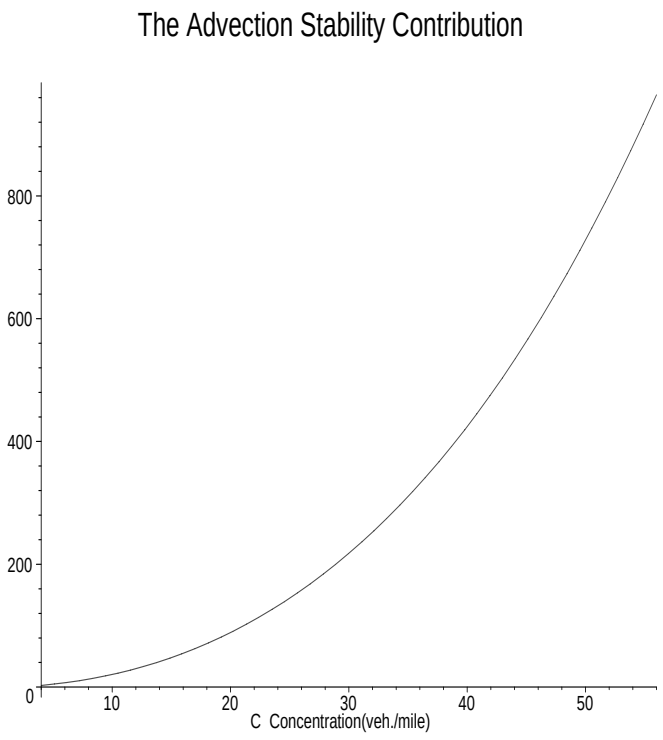

FIG. 3. *The stability contribution term* $-Q_0'' \frac{\partial c_{eq}}{\partial x}$ *due solely to advection, for representative values of* $\frac{\partial c_{eq}}{\partial x}$ *for our traffic release problem. Note that, even though the values are positive, they remain finite for all values of the concentration* c *up to* $c_{crit} \approx 56$*. Also note the exponential increase of instability with concentration.*

blow-up, and thus the amplitude A of (4.30) is finite and controlled for concentrations in the range $0 \leq c \leq c_{crit}$. Also note that, as the concentration increases, stability becomes exponentially difficult to maintain. Similarly, we plot in Figure 4 the stability due to advection and diffusion terms. Here we notice that, due to the inclusion of the diffusion part, we have stability (negative value), as would be expected. At the end of the concentration range we observe small positive (unstable) contributions but still no blow-up. Notice that stability remains, but instability grows logarithmically with concentration. Last, in Figure 5 we plot the (in)stability of the complete system $-P_1 + P_3 k^2$. Based on these three figures, it is clear that the instability is attributed to "Burnett" terms contributions. Therefore, once again we observe, similarly to fluid dynamics problems, that the Burnett expansion is actually destabilizing for all time! In fact we get a blow-up to stability immediately even for very low concentrations. That can also be seen numerically in Figure 6, where we try to show the blow-up in solutions even at times as small as $t = 10^{-13}$. (See section 5.3 regarding details on numerics.)

4.3. The Hilbert asymptotic expansion. The Hilbert [12] expansion of the Prigogine–Herman equation is very similar in form to the Chapman–Enskog expansion considered above.

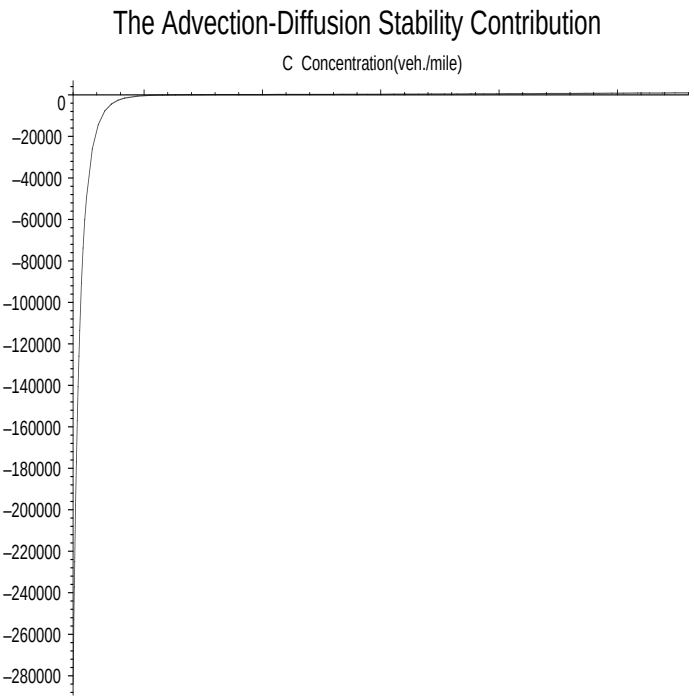

FIG. 4. *The stability contribution term* $-Q_0^{''}\frac{\partial c_{eq}}{\partial x}+\mathcal{D}^{''}(\frac{\partial c_{eq}}{\partial x})^2+\mathcal{D}^{'}\frac{\partial^2 c_{eq}}{\partial x^2}-\mathcal{D}$ *due to advection and diffusion for representative values of* $\frac{\partial c_{eq}}{\partial x}$ *for our traffic release problem. Note that it starts negative and therefore stable while logarithmically increasing but remains finite for all values of the concentration* c *up to* $c_{crit}\approx 56$.

THEOREM 4.7. *The Hilbert hydrodynamic approximation to the concentration* c *for the Prigogine–Herman equation has the form*

$$\frac{\partial c^{(m)}}{\partial t}+\frac{\partial q^{(m)}}{\partial x}=0, \qquad m=0,1,\dots,n, \tag{4.36}$$

where

$$q^{(m)}=Q_m^H(c^{(0)},c^{(1)},\dots,c^{(m)}) \tag{4.37}$$

is known at order n *of the expansion.*

We want to solve this system of $n+1$ partial differential equations for $n+1$ unknowns.

Proof. The proof is similar to the one given for the Chapman–Enskog expansion. However, a major difference is that the expansion of the concentration in powers of the artificially introduced small parameter ϵ will no longer be set to zero for $n\geq 1$. The flow $q^{(m)}$ will be, at least in principle, known in terms of $c^{(0)},c^{(1)},\dots,c^{(m)}$. The macroscopic form of the nth-order Hilbert approximation is the system for $m=0,1,\dots,n$. The corresponding approximation for the density and flow are, respectively, $c=c^{(0)}+c^{(1)}+\cdots+c^{(n)}$ and $q=q^{(0)}+q^{(1)}+\cdots+q^{(n)}$.

We substitute (4.1), (4.7) into (4.2), and for different powers of ϵ we obtain

$$Qf^{(0)}=0 \qquad \text{for } \epsilon^0, \tag{4.38}$$

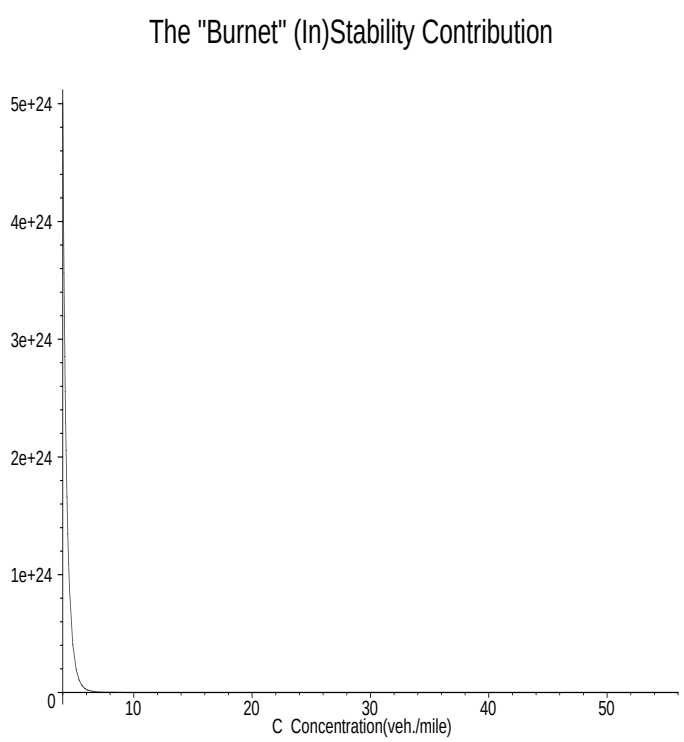

FIG. 5. *The total stability contribution,* $-P_1 + P_3$*, for representative values of* $\frac{\partial c_{eq}}{\partial x}$ *and* $\frac{\partial^2 c_{eq}}{\partial x^2}$ *for our traffic release problem. Note that it is positive and therefore* unstable *for all values of the concentration* c *up to* $c_{crit} \approx 56$*. It is clear from this that the extra "Burnett" approximation determines the stability and dominates the advection diffusion term contributions that we have observed thus far.*

$$\mathbf{L}(f^{(0)})f^{(n)} = \sum_{k=0}^{n-1} \frac{\partial^{(k)} f^{(n-k-1)}}{\partial t} + v\frac{\partial f^{(n-1)}}{\partial x} \quad \text{for } \epsilon^n, \quad \text{where } n = 1, 2, \ldots.$$

Again it is necessary that $\frac{\partial f^{(n-1)}}{\partial t} + v\frac{\partial f^{(n-1)}}{\partial x}$ be orthogonal to the null space of the adjoint, $\mathbf{L}(f^{(0)})^*$. We know that the null space of $\mathbf{L}(f^{(0)})^*$ consists of constants. Therefore the compatibility condition implies again that a solution $f^{(n)}$ exists if and only if $\int_0^{w^+} (\frac{\partial f^{(n-1)}}{\partial t} + v\frac{\partial f^{(n-1)}}{\partial x})\, dv = 0$. This provides the result since it implies the law of conservation of vehicles,

$$\frac{\partial c^{(n)}}{\partial t} + \frac{\partial q^{(n)}}{\partial x} = 0 \qquad \text{for } n = 0, 1, \ldots. \qquad \square \tag{4.39}$$

4.3.1. Zero-order Hilbert expansion.

COROLLARY 4.8. *The zero-order Hilbert asymptotic expansion of the Prigogine–Herman equation has the form*

$$\frac{\partial c^{(0)}}{\partial t} + \frac{\partial q^{(0)}}{\partial c^{(0)}}\frac{\partial c^{(0)}}{\partial x} = 0, \tag{4.40}$$

where

$$q^{(0)}(v) = \int_0^{w^+} v f^{(0)}(v)\, dv = \frac{1}{T(1-P)} + c^{(0)}\zeta(c^{(0)}), \tag{4.41}$$

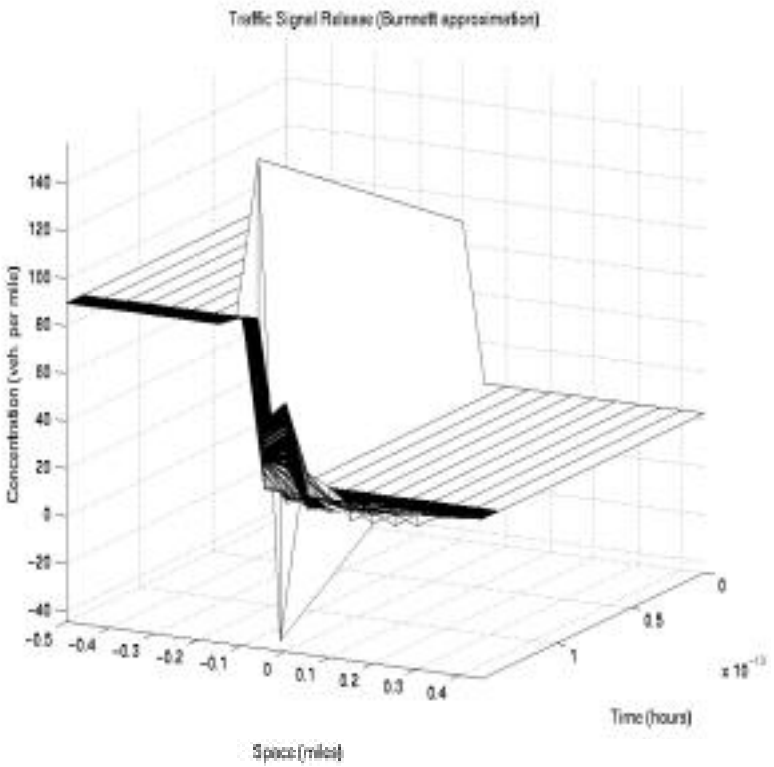

FIG. 6. *Chapman–Enskog solution using Godunov's method for the second-order approximation (Burnett equivalent) equation. The solution blows up (note the nonphysical negative concentrations) even for very small times.*

where T and P will be assumed constant here.

Proof. We solve the right-hand side of (2.1),

$$Q(f^{(0)}) = 0, \tag{4.42}$$

and obtain

$$f^{(0)}(v) = \frac{1}{T(1-P)} \frac{\varphi_0(v)}{v - \zeta(c^{(0)})}. \tag{4.43}$$

Thus,

$$c^{(0)} = \int_0^{w^+} f^{(0)}(v)\, dv = \frac{1}{T(1-P)} \int_0^{w^+} \frac{\varphi_0}{v - \zeta(c^{(0)})}\, dv, \tag{4.44}$$

which gives a simplifying relation we have used many times before in the Chapman–Enskog expansion, with the significant difference that now $c^{(0)} \neq c$,

$$\int_0^{w^+} \frac{\varphi_0}{v - \zeta(c^{(0)})}\, dv = T(1-P)c^{(0)} := F_0(\zeta(c^{(0)})). \tag{4.45}$$

As a result we can write

$$q^{(0)} = \frac{1}{T(1-P)} \int_0^{w^+} v \frac{\varphi_0(v)}{v - \zeta(c^{(0)})}\, dv = \frac{1}{T(1-P)} + c^{(0)}\zeta(c^{(0)}). \tag{4.46}$$

For $f^{(0)}$ to exist, it must satisfy the condition

$$\int_0^{w^+} \frac{\partial f^{(0)}}{\partial t} + v\frac{\partial f^{(0)}}{\partial x}\, dv = 0, \tag{4.47}$$

which gives the zero-order hydrodynamic approximation as

$$\frac{\partial c^{(0)}}{\partial t} + \frac{\partial q^{(0)}}{\partial x} = 0. \qquad \square \tag{4.48}$$

A crucial point that must be emphasized here is that not only will the zero-order Chapman–Enskog expansion and the zero-order Hilbert expansion both give an LWR model, but they give the *same* LWR model! This is not always so obvious in higher-order expansions, as we will soon see.

4.3.2. First-order Hilbert expansion. We now carry out the evaluation of f up to two terms, $f^{(0)}$ and $f^{(1)}$.

COROLLARY 4.9. *The first-order Hilbert approximation to the concentration is given by* (4.40) *and*

$$\frac{\partial c^{(1)}}{\partial t} + \frac{\partial q^{(1)}}{\partial c^{(1)}}\frac{\partial c^{(1)}}{\partial x} + \frac{\partial q^{(1)}}{\partial c^{(0)}}\frac{\partial c^{(0)}}{\partial x} = 0, \tag{4.49}$$

where

$$f^{(1)}(v) = \frac{c^{(1)}}{F_1(\zeta(c^{(0)}))}\frac{\varphi_0(v)}{v - \zeta(c^{(0)})^2}, \tag{4.50}$$

with $c^{(1)} = CF_1(\zeta(c^{(0)}))$ *for* C *an arbitrary constant and*

$$q^{(1)} = c^{(1)}\left\{\frac{F_0(\zeta(c^{(0)}))}{F_1(\zeta(c^{(0)}))} + \zeta(c^{(0)})\right\},$$

where T *and* P *will be assumed constant here.*

Proof. We look for a solution (at first order of the series expansion in ϵ) $f^{(1)}$ of (2.1) which has the form $f_p^{(1)} + f_h^{(1)}$, where $f_p^{(1)}$ is the particular solution and $f_h^{(1)}$ is the homogeneous solution of

$$\mathbf{L}(f^{(0)})f^{(1)} = \frac{\partial f^{(0)}}{\partial t} + v\frac{\partial f^{(0)}}{\partial x}, \tag{4.51}$$

where

$$\begin{aligned}\mathbf{L}(g)h(v) = &-\frac{h(v) - \varphi_0(v)\int_0^{w^+} h(v')\, dv'}{T} + (1-P)h(v)\int_0^{w^+}(v'-v)g(v')\, dv' \\ &+ (1-P)g(v)\int_0^{w^+}(v'-v)h(v')\, dv'.\end{aligned}$$

To obtain the homogeneous solution we start by simplifying:

$$
\begin{aligned}
\mathbf{L}(f^{(0)})f_h^{(1)}(v) = {} & \frac{-f_h^{(1)}}{T} + \frac{\varphi_0(v)}{T}\int_0^{w^+} f_h^{(1)}(v)\,dv + \frac{1}{T}f_h^{(1)}(v)\int_0^{w^+}\frac{v^{'}\varphi_0(v^{'})}{(v^{'}-\zeta(c^{(0)}))}\,dv^{'} \\
& - \frac{vf_h^{(1)}(v)}{T}\int_0^{w^+}\frac{\varphi_0(v^{'})}{(v^{'}-\zeta(c^{(0)}))}\,dv^{'} + \frac{1}{T}\frac{\varphi_0(v)}{(v-\zeta(c^{(0)}))}\int_0^{w^+} v^{'}f_h^{(1)}(v^{'})\,dv^{'} \\
& - \frac{1}{T}\frac{v\varphi_0(v)}{(v-\zeta(c^{(0)}))}\int_0^{w^+} f_h^{(1)}(v^{'})\,dv^{'} \\
= {} & \frac{\zeta(c^{(0)})}{(v-\zeta(c^{(0)}))}\frac{\varphi_0(v)}{T}\int_0^{w^+} f_h^{(1)}(v^{'})\,dv^{'} + \frac{f_h^{(1)}(v)}{T}(\zeta(c^{(0)})-v)Tc(1-P) \\
& + \frac{1}{T}\frac{\varphi_0(v)}{v-\zeta(c^{(0)}}\int_0^{w^+} v^{'}f_h^{(1)}(v^{'})\,dv^{'} \\
= {} & (1-P)c^{(0)}(\zeta(c^{(0)})-v)f_h^{(1)}(v) + \frac{\varphi_0(v)}{T}\int_0^{w^+}\frac{v^{'}-\zeta(c^{(0)})}{v-\zeta(c^{(0)})}f_h^{(1)}(v^{'})\,dv^{'}.
\end{aligned}
$$

We define $K := \int_0^{w^+}(v^{'}-\zeta(c^{(0)})f_h^{(1)}(v^{'})\,dv$, and we solve the equation above for $f_h^{(1)}$:

$$
f_h^{(1)} = \frac{K}{F_0(\zeta(c^{(0)}))}\frac{\varphi_0(v)}{(v-\zeta(c^{(0)}))^2}. \tag{4.52}
$$

A specific description of K can be obtained by simply enforcing the normalization condition (3.3). This gives $K = \frac{c^{(1)}F_0(\zeta(c^{(0)}))}{F_1(\zeta(c^{(0)}))}$. As a result,

$$
f_h^{(1)} = \frac{c^{(1)}}{F_1(\zeta(c^{(0)}))}\frac{\varphi_0(v)}{(v-\zeta(c^{(0)}))^2}. \tag{4.53}
$$

It is convenient to take $f_p^1(v)$ as the solution that satisfies $\int_0^{w^+} f_p^{(1)}(v)\,dv = 0$. That is, the concentration contribution comes only from the homogeneous solution of the equation. Therefore from $\int_0^{w^+}\frac{\partial f^{(0)}}{\partial t} + v\frac{\partial f^{(0)}}{\partial x}\,dv = 0$ we also get $\int_0^{w^+} vf_p^{(1)}(v)\,dv = 0$. Thus,

$$
f^{(1)}(v) = f_p^{(1)}(v) + \frac{c^{(1)}}{F_1(\zeta(c^{(0)}))}\frac{\varphi_0(v)}{(v-\zeta(c^{(0)}))^2}. \tag{4.54}
$$

Therefore the values of $c^{(1)}$ and $q^{(1)}$ are related by

$$
q^{(1)} = c^{(1)}\left\{\frac{F_0(\zeta(c^{(0)}))}{F_1(\zeta(c^{(0)}))} + \zeta(c^{(0)})\right\}, \tag{4.55}
$$

where it is clear here that $= q^{(1)}(c^{(0)}, c^{(1)})$. Thus we have

$$
\frac{\partial c^{(1)}}{\partial t} + \frac{\partial Q^{(1)}}{\partial x} = 0, \tag{4.56}
$$

where $Q^{(1)} = q^{(1)}(c^{(0)}, c^{(1)})$; in effect the first-order model is really a system of two equations in two unknowns. More specifically, it is a system of equations (4.40) and (4.49) with $c^{(0)}$ and $c^{(1)}$ as the unknowns. This is the central difference between the Hilbert and Chapman–Enskog expansions. The complete Hilbert first-order approximation for this order of the expansion is

$$
\begin{aligned}
c^{[1]} &= c^{(0)} + c^{(1)}, \\
q^{[1]} &= q^{(0)} + q^{(1)}. \qquad \square
\end{aligned}
$$

Similarly the nth-order model will be a system of n equations in n unknowns.

5. Brief simulations. We now give some preliminary numerical simulations of solutions to our model equations. We only do this here for the zeroth- and first-order Chapman–Enskog expansion approximations since this section is meant to give only a flavor of the type of solutions we can obtain. For a complete investigation, which will include the second-order approximation and analysis under different traffic situations and different numerical techniques, we refer to the sequel [32] to this paper, which is to follow. For the examples that follow here we will leave most of the numerical details to [32].

5.1. Entropy. It is necessary [21] for uniqueness models, such as the LWR model [22, 31], to require that their solutions satisfy more than just the conservation equation and associated initial/boundary conditions. Solutions must also satisfy [17, 23] the so-called entropy condition. (See Ansorge [1] for a traffic-theoretic interpretation of the entropy condition.) The entropy condition states [2] (in one of its many versions) that the shock speed s is restricted by

$$q^{'}(c_l,t) < s < q^{'}(c_r,t) \tag{5.1}$$

for $c_l > c_r$, where q is as usual, for traffic flow, a concave function. For the numerical methods that follow we use a numerical flux function q^*, which implements (5.1) as follows:

$$q^*(c_l,c_r) = \begin{cases} \min\limits_{c_l \le c \le c_r} q(c) \text{ for } c_l \le c_r, \\ \max\limits_{c_r \le c \le c_l} q(c) \text{ for } c_r < c_l. \end{cases} \tag{5.2}$$

5.2. Conditions. We construct a traffic flow example for the algorithms in this work. The value of the parameter $\tau := .003$ hours ≈ 11 seconds is used, as obtained from data [7]. The reduced desired speed distribution used, φ_0, corresponds to a uniform distribution of desired speeds from 40 to 80 mph and 0 elsewhere. The corresponding equilibrium solution from (3.7), in the stable regime, is

$$f_{eq}(v;c) = \begin{cases} cv_0(c)\frac{\varphi_0(v;c)}{v-\zeta} \text{ for 40 mph } \le v \le 80 \text{ mph}, \\ 0 \text{ otherwise}, \end{cases} \tag{5.3}$$

where c is the density in vehicles per mile per lane (vpmpl).

The problem considered here is defined by the parameters of the preceding paragraph and the following initial conditions:

$$c(x,0) = c(x,t)|_{t=0} = \begin{cases} 59(\approx c_{crit}) \text{ vpmpl}, & x \le 0, \\ 4 \text{ vpmpl}, & x > 0. \end{cases}$$

This corresponds to release into a relatively vacant region at $t = 0$ of a semi-infinite "platoon" of vehicles extending indefinitely to the left from $x = 0$, and initially at the critical concentration. In that respect, Dirichlet-type boundary conditions are implemented in the schemes at the ends of the spatial interval. In fact, the spatial interval has been chosen so that under the given time of consideration of the development of the wave fronts there will be no interaction with the boundaries. The resulting solution should have the form of an "acceleration wave," which is analogous to a rarefaction wave in gas dynamics [21]. Such flows are often termed "queue discharge" in traffic engineering.

The corresponding exact solution to the LWR model (4.16) is a traveling wave, moving to the left, with density $c_\ell = 59$ vpmpl on the left, and density $c_r = 4$ vpmpl on the right. The wave thus propagates to the right (downstream) at a speed s (also called propagation speed) $(q^{(0)}(c_r) - q^{(0)}(c_\ell))/(c_r - c_\ell) = 57.7$ mph initially, and varies accordingly as the concentration changes after each subsequent approximation.

5.3. Godunov's method for the stable flow. Godunov's scheme is the preferred method [18, 19, 21, 2] for solving hyperbolic conservation laws such as (4.16). Originally the method was devised to solve inviscid Euler equations in one dimension. However, here we also implement Godunov's method [21] for solving the higher-order hydrodynamic approximation equations (as produced by the Chapman–Enskog first-order expansion), even though the method is used mostly for hyperbolic problems. This is feasible, since, for instance, we can reformulate the first-order model (4.18) as

$$\frac{\partial c}{\partial t} + \frac{\partial \left(Q_0(c) - \mathcal{D}(c)\frac{dc}{dx}\right)}{\partial x} = 0, \tag{5.4}$$

where now the flux function is $q = Q_0(c) - \mathcal{D}(c)\frac{dc}{dx}$. We apply Godunov's method to this (5.4) form of the advection-diffusion equation with this more elaborate flux function. Note that, numerically, $q = Q(c_i^n, c_{i+1}^n)$, as seen immediately below. This gives a natural way to define $\frac{dc}{dx} = \frac{c_{i+1}^n - c_i^n}{x_{i+1} - x_i}$ for each time step n.

The Godunov scheme in general is implemented through

$$c_i^{n+1} = c_i^n - \frac{\Delta t_n}{h_i}\left(Q(c_i^n, c_{i+1}^n) - Q(c_{i-1}^n, c_i^n)\right), \tag{5.5}$$

where the c_i^n's are approximations to the concentration c at different spatial (i) and time (n) intervals. Any numerical approximation of the form (5.5) is said to be *conservative*. Here $h_i = x_{i+1/2} - x_{i-1/2}$, and Q is a numerical approximation to the average flow q past the section boundary $x_{i+1/2}$ during the time interval $[t_n, t_{n+1}]$,

$$Q(c_i^n, c_{i+1}^n) \approx \frac{1}{\Delta t_n}\int_{t_n}^{t_{n+1}} q(c(x_{i+1/2}, t))\, dt. \tag{5.6}$$

We use relation (5.2) in evaluating the integral above (see [21, 2]). The Courant, Friedrichs, and Lewy (CFL) condition is used as a way to ensure that solutions do not blow up.

We plot the solution of the zero-order (LWR) model in Figure 7. The results of this diffusive equation, as can be seen in Figure 8, show the expected behavior for the concentration. The diffusive action can be seen in the way that the wave front widens in the space dimension as time advances. This diffusive effect is even more evident in Figure 9, where we plot the final solution of the front wave for the Godunov scheme for the advection-diffusion equation together with the corresponding final solution of the approximate and initial solutions for the LWR equation. For this figure the computational parameters used are $\Delta x = .016$ miles, while Δt varies as specified from the CFL condition.

Godunov's method, which was originally designed to solve hyperbolic problems, seems to produce a solution which looks meaningful (and stays bounded) even though we use it on an advection-dominated diffusion equation. The effect on the time step from the contribution due to the diffusion coefficient D is seen through the CFL condition:

$$\Delta t \le \frac{\Delta x}{\frac{\partial Q_0}{\partial c} - \frac{\partial \mathcal{D}}{\partial c}\frac{dc}{dx}}. \tag{5.7}$$

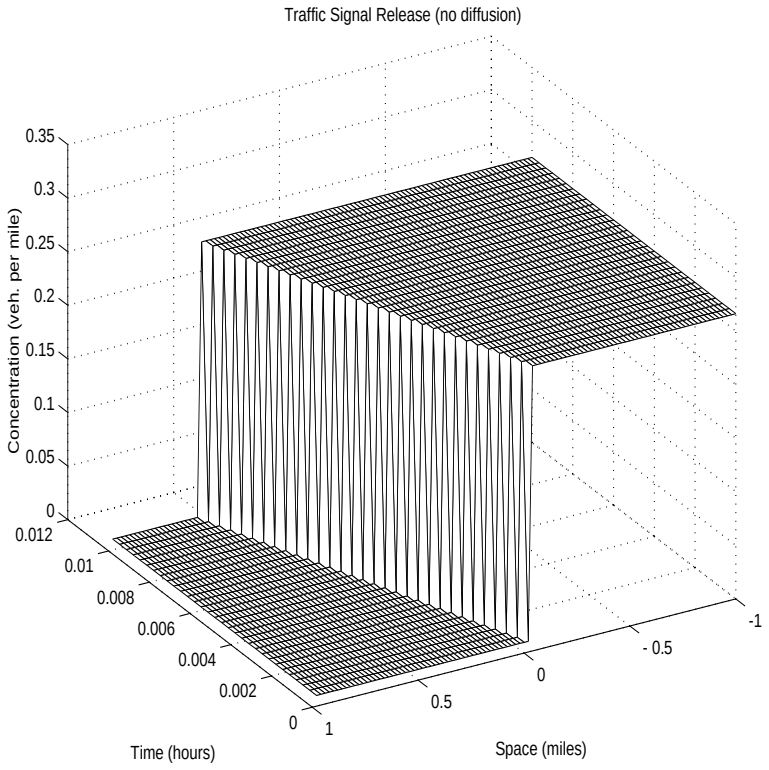

FIG. 7. *Solution using Godunov's method for the advection equation. (Concentration is normalized.)*

Note that the denominator of the quantity above stays positive, since $\frac{dc}{dx} \leq 0$, with a minimum value of $\frac{\partial Q_0}{\partial c}$ for cases in which the concentration is unchanged. In fact, the contributions to the time step due to $\mathcal{D}$ are minimal since, for the traffic parameters involved in the implementation of this example, $0 \leq \frac{\partial \mathcal{D}}{\partial c} < .003$ for the stable concentration regime, and the denominator is therefore dominated by $50 < \frac{\partial Q_0}{\partial c} < 60$. For the extreme cases of $\frac{dc}{dx} = \frac{c_{min} - c_{crit}}{\Delta x}$ the time step suffers a temporary setback, which, however, will be quickly remedied in the next time step from the diffusion of the concentration.

We expect to see that the original shock concentration will eventually "diffuse" and spread in front of and behind the shock formation, so that the concentration in the front of the shock will increase and the concentration behind it will decrease. The solution produced by our method exhibits this type of behavior. Also the scheme seems to behave well in not producing any erroneous results such as infinite or negative concentrations.

6. Conclusions. We have seen how traffic flow models can be obtained from the equilibrium solution of the Prigogine–Herman nonlinear kinetic equation. We rely on a *deterministic* equilibrium solution of the form (3.7), which is suitable for expansion calculations (but also predicts traffic flow for the complete range of possible traffic concentrations, unlike most other such kinetic equations [25, 33]). As a result, we obtain here a number of different models of flow, depending on the order of

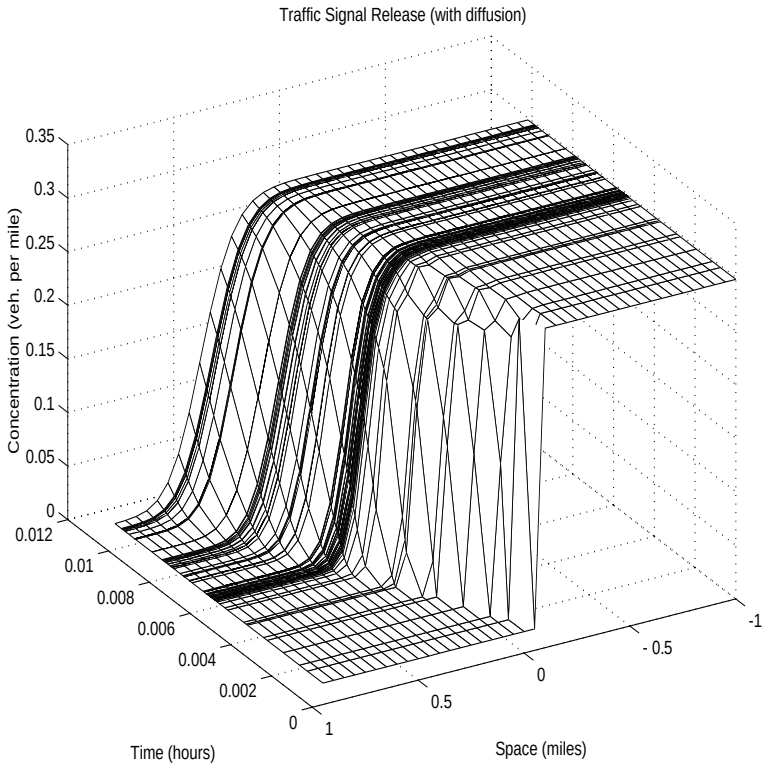

FIG. 8. *Solution using Godunov's method for the advection-diffusion equation. (Concentration is normalized.)*

series expansion carried out. This derivation is based solely on (formal) mathematical principles, which close our equations without any need for ad hoc assumptions.

Chapman–Enskog and Hilbert expansions are presented for zeroth- and first-order approximations. It is rewarding that at the lowest possible approximation level (zeroth) we obtain the well-known LWR model under either type of expansion. For the first-order model we obtain two seemingly different looking equations. In theory, however, the Chapman–Enskog and Hilbert expansions are supposed to produce models which can be shown to be the same. Since numerical results are forthcoming in a sequel to this paper [32], we will leave this question to be partially resolved there. Finally, the second-order Chapman–Enskog expansion is carried out to produce a Burnett equivalent model for traffic flow. Note, however, that, given the stability analysis results of section 4.2, this level of the expansion will not produce a useful model. It is possible that techniques similar to those implemented in [14] will be useful in that respect. The formal mathematical derivation obtained here becomes even more interesting in light of recent work [3] of such higher-order models. In [3] the correlation between car-following models such as [11] and [20] and the Kortweg–de Vries equation is established, and it is shown that the well-known "stop and go" traffic effect can be triggered by a car following equation that has the form of our second-order "Burnett-like" model or its possible successor based on techniques from [14]. In this paper we therefore hint at a mathematical link between empirical models (such as [3, 20]), which shows the relationship of model parameters to physically meaningful variables.

A PERIODICALLY FORCED WILSON–COWAN SYSTEM*

V. W. NOONBURG†, D. BENARDETE†, AND B. POLLINA†

Abstract. A Wilson–Cowan system, which models the interaction between subpopulations of excitatory and inhibitory neurons, is studied for the case in which the inhibitory neurons are receiving external periodic input. If the feedback within the excitatory population is large enough, the response of the system to large amplitude, low frequency input is determined by the relative values of the excitatory threshold θ_x and the inhibitory-to-excitatory feedback parameter b. Feedback to the inhibitory cells is assumed to be relatively small. In the parameter range considered, the system has two periodic attractors: a high activity state and a low activity state. It is shown that, depending on the parameter values, periodic input can produce two completely different effects; it can either initiate the high activity state or switch it off. If it is assumed that the threshold θ_x increases with increased excitatory activity, there exists a range of b for which periodic input can cause bursting activity in the system.

Key words. Wilson–Cowan system, periodic forcing, bursting, structural stability

1. Introduction.

A Wilson–Cowan system is a system of two first-order differential equations that model the activity in a localized population of neurons. The population is assumed to consist of two homogeneous subpopulations, one containing only excitatory cells and the other only inhibitory cells. The original derivation of the Wilson–Cowan equations appeared in a 1972 paper [14]. As pointed out recently in a book by Whittle [13, p. 122], the approximations used in the derivation are "Draconian in the extreme"; however, as shown by Hoppensteadt and Izhikevich [5, pp. 45–48], the behavior of an autonomous Wilson–Cowan system can be complex and interesting. A recent paper by Eggert and van Hemmen [1] shows that it is possible to design a macroscopic model of neural activity, such as the Wilson–Cowan model, so it will reproduce in a quantitatively exact manner the joint activity of large groups of "integrate-and-fire" neurons. This suggests that new results for the Wilson–Cowan system may apply directly to current models for large populations of single neurons.

In a 1997 paper [12], Tsodyks et al. use a Wilson–Cowan model with biologically derived coefficients to explain paradoxical behavior in the rat hippocampus, where the inhibitory cells (interneurons) are assumed to be receiving external periodic input. The authors of that paper make the assumption that the time-dependent input changes slowly enough so that the system returns to equilibrium at each moment of time. In this paper, we will analytically examine the time-dependent behavior of a Wilson–Cowan system with periodic forcing to the inhibitory cells. Our aim is to determine conditions on the parameters under which periodic forcing of low frequency can significantly alter the behavior of the system. Such results occur when the autonomous system is bistable. In [12] it is assumed that the autonomous system has a single attractor in the interior of the unit square; therefore, most of our results

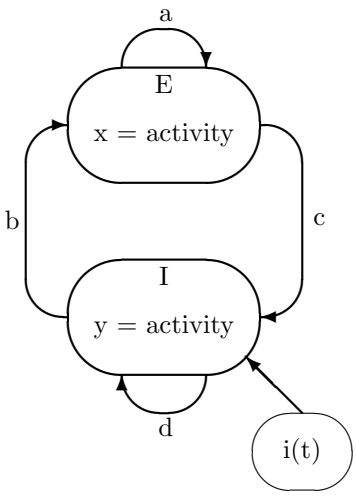

FIG. 1.1. *Feedback in the neural population.*

are complementary to those in [12]. However, in section 3 we point out one region of parameter space where our results do overlap and confirm experimental results described in [12].

The functions $x(t)$ and $y(t)$ in the Wilson–Cowan equations represent, respectively, the fraction of cells in the excitatory subpopulation E and the inhibitory subpopulation I that are active at time t. There are four positive feedback parameters a, b, c, and d which are used to specify the connection strengths both between and within the two subpopulations (see Figure 1.1). For example, the net feedback to E at time t is $ax(t) - by(t)$, and the effect of this on cells in E is determined by a *sigmoidal response function* $\mathbf{S}$.

In our analysis, it is not necessary to know the exact form of the function $\mathbf{S}$ in order to determine the behavior of the system. We require only that $\mathbf{S}$ be a "soft threshold function," as defined in [13, p. 21], that is, have the following properties:

1. $\mathbf{S}(z)$ is at least twice continuously differentiable on $(-\infty, \infty)$.
2. $\mathbf{S}(z)$ increases monotonically from 0 to 1 on $(-\infty, \infty)$.
3. $\mathbf{S}(z)$ has a single point of inflection at $z = 0$.

The third property implies that $\mathbf{S}'(z)$ increases monotonically on $(-\infty, 0)$ and decreases monotonically on $(0, \infty)$.

The Wilson–Cowan system to be studied can then be written in the form

$$\left\{ \begin{array}{rcl} \tau_x x'(t) & = & -x(t) + \mathbf{S}(ax(t) - by(t) - \theta_x), \\ \tau_y y'(t) & = & -y(t) + \mathbf{S}(cx(t) - dy(t) - \theta_y + i(t)), \end{array} \right. \tag{1.1}$$

where $i(t) = \alpha \sin(\omega t)$ is the external periodic input to the inhibitory cells and θ_x and θ_y are the thresholds for the excitatory and inhibitory cells, respectively. Tsodyks et al. [12] define the constants τ_x and τ_y as the time required to bring neurons in the respective populations to firing, as they receive subthreshold excitation. In the original derivation of the equations (see [14]), the time constant τ_x, for example, was introduced by setting $x(t+\tau_x)$ equal to the proportion of cells in E which were sensitive (that is, not in their refractory period) and also receiving threshold excitation at time

t. In our analysis, we assume that the two time constants are equal, and we therefore take $\tau_x = \tau_y = 1$. However, due to the structural stability of the system in the regions of parameter space being considered, it will be made clear, in section 4, that our results can be extended to cases in which these two time constants are not the same.

For the system (1.1) we are able to show, under certain conditions on the parameters, that low frequency periodic input $i(t) = \alpha \sin(\omega t)$, with large enough amplitude α, can be used to *switch* the activity in the network from a high activity state to a low activity state. If the parameters are altered slightly, the input can have the opposite effect; that is, it can force the system into its high activity state. Furthermore, if it is assumed that θ_x increases slightly as the activity level x increases, the input can produce a "bursting" response. The two parameters that are the major determinants of which type of behavior occurs are the excitatory threshold θ_x and the feedback parameter b from $I \Rightarrow E$. In the next two sections the reason for requiring *low frequency* input will be made clear.

2. Reduction to a first-order equation. In this section it will be shown that by placing a single restriction on the four feedback parameters a, b, c, and d, the study of the behavior of the forced Wilson–Cowan system can be reduced to the study of a single periodic differential equation of first order. Some known properties of periodic first-order differential equations are stated in the appendix; and these are referred to, when needed, in this section and in section 3.

We define a new parameter $\lambda \equiv c/a$; that is, λ is the ratio of the $E \Rightarrow I$ feedback parameter c to the recurrent excitatory $E \Rightarrow E$ feedback parameter a. We then make the assumption that the inhibitory feedback parameters are similarly related; that is, we assume that $d/b = \lambda$. This choice of parameter values was motivated by the experimental data used in the examples in [12]. By proving the structural stability of the system, the results obtained under this restriction will subsequently be shown to hold for all d/b sufficiently close to λ. In the numerical simulations in section 5 the meaning of "sufficiently close" will be quantified for a set of representative systems.

Assume $\tau_x = \tau_y = 1$ and $d = b\lambda$. Then the system (1.1) becomes

$$\begin{aligned} x' &= -x + \mathbf{S}(ax - by - \theta_x), \\ y' &= -y + \mathbf{S}(\lambda ax - \lambda by - \theta_y + i(t)). \end{aligned} \tag{2.1}$$

We now make a linear change of variables, where (t, x, y) maps to (t, u, x), with $u = ax - by$. This linear map induces a topological conjugacy between system (2.1) and the system

$$\begin{aligned} u' &= ax' - by' \\ &= f(t, u) = -u + a\mathbf{S}(u - \theta_x) - b\mathbf{S}(\lambda u - \theta_y + i(t)), \\ x' &= k(t, u, x) = -x + \mathbf{S}(u - \theta_x). \end{aligned} \tag{2.2}$$

Let $P = 2\pi/\omega$ be the period of $i(t)$. Since the linear conjugacy of (2.1) with (2.2) respects the identification of (t, x, y) with $(t + P, x, y)$ and (t, u, x) with $(t + P, u, x)$, it follows that it passes to a linear conjugacy of the induced flows on the quotient spaces $S^1 \times \mathbf{R}^2$. Therefore there is a one-to-one correspondence between periodic orbits of (2.1) and periodic orbits of (2.2). Moreover, this correspondence respects the type (attractor, repeller, saddle) of the periodic orbit.

Consider now system (2.2) on $S^1 \times \mathbf{R}^2$, and the single differential equation

$$u' = f(t, u) \tag{2.3}$$

on $S^1 \times \mathbf{R}$. There is a one-to-one correspondence of periodic solutions of (2.2) and (2.3) which takes attractors of (2.2) to attractors of (2.3) and saddles of (2.2) to repellers of (2.3). Periodic orbits of (2.2) induce periodic orbits of (2.3) simply by projecting on the u variable. Going the other way, assume that $\hat{u}(t)$ is a periodic solution of (2.3). Since the response function $\mathbf{S}$ is bounded, it follows that there exist constants $r < 0 < s$ such that the slope function k is positive on the line $x = r$ and negative on the line $x = s$. Furthermore, the derivative k_x is -1. The region $\{(t, x) | r \leq x \leq s\}$ is a forward invariant contracting region for the equation $x' = k(t, \hat{u}, x)$ and therefore contains a unique periodic attractor for the equation (see Lemma A.4 in the appendix). It is clear that $x' = k(t, \hat{u}, x)$ has no periodic solution outside this invariant region. So we have shown how a periodic solution of (2.3) corresponds to a periodic solution of system (2.2).

To simplify the analysis of (2.3) we define a new time variable $\tau = \omega t/(2\pi)$. In terms of τ, (2.3) becomes

$$\begin{aligned} \frac{du}{d\tau} &= \frac{2\pi}{\omega} f(\tau, u) \\ &= \frac{2\pi}{\omega} [-u + a\mathbf{S}(u - \theta_x) - b\mathbf{S}(\lambda u - \theta_y + \alpha \sin(2\pi\tau))]. \end{aligned} \tag{2.4}$$

Equation (2.4) is periodic of period 1 in τ, and the period in t, $P = 2\pi/\omega$, acts as a multiplier of the slopes. This is the reason why low frequency input has a large effect on the system behavior, whereas high frequency input does not. Using the fact that $\mathbf{S}$ takes values only between 0 and 1, it can be seen that $f(\tau, u) < 0$ whenever $u \geq a$, and $f(\tau, u) > 0$ whenever $u \leq -b$. This implies that, as $\tau \to \infty$, all solutions of (2.4) ultimately end up inside the region $-b \leq u \leq a$. In the next section we will examine the slope field for (2.4), restricted to the invariant cylinder $\mathcal{H} = \{0 \leq \tau < 1 \pmod 1, -b \leq u \leq a\} \subset S^1 \times \mathbf{R}$, and determine the behavior of solutions under various conditions on the parameters.

3. Periodic solutions of the equation in u. In this section it will be shown that there are three distinct regions of parameter space in which periodic forcing to the inhibitory cells can significantly alter the behavior of solutions of (2.4), and consequently the behavior of solutions of the Wilson–Cowan system (2.1).

In order to determine the number and position of periodic solutions of (2.4), we need to examine the nullclines $f(\tau, u) = 0$, and also the curves $f_u(\tau, u) = 0$. The former divide the region $\mathcal{H}$ into subregions of positive or negative slopes, and the latter determine where trajectories are getting closer together or further apart.

The function $f_u(\tau, u) = -1 + a\mathbf{S}'(u - \theta_x) - b\lambda\mathbf{S}'(\lambda u - \theta_y + \alpha \sin(2\pi\tau))$. Since $\mathbf{S}'(z)$ is everywhere positive and assumes its maximum value at $z = 0$, if $a < 1/\mathbf{S}'(0)$, $f_u(\tau, u)$ is negative for all τ and u, and the cylinder $\mathcal{H}$ is an invariant contracting region. In this case, (2.4) has a single periodic attractor (see Lemma A.4 in the appendix). The more interesting behavior occurs when $a > 1/\mathbf{S}'(0)$, and it will be assumed that this is the case in what follows.

It should be noted that all of the graphs in this section were produced by MAPLE. The $\mathbf{S}$-function used in drawing these graphs is $\mathbf{S}(z) = 1/(1 + e^{-z})$; however, the conclusions reached require only that $\mathbf{S}$ satisfy the three properties for a generic $\mathbf{S}$-function, which were given in section 1.

Consider the function f as the difference between two functions $g(u) = -u + a\mathbf{S}(u - \theta_x)$ and the sigmoidally shaped time-dependent function $h(\tau, u) = b\mathbf{S}(\lambda u -$

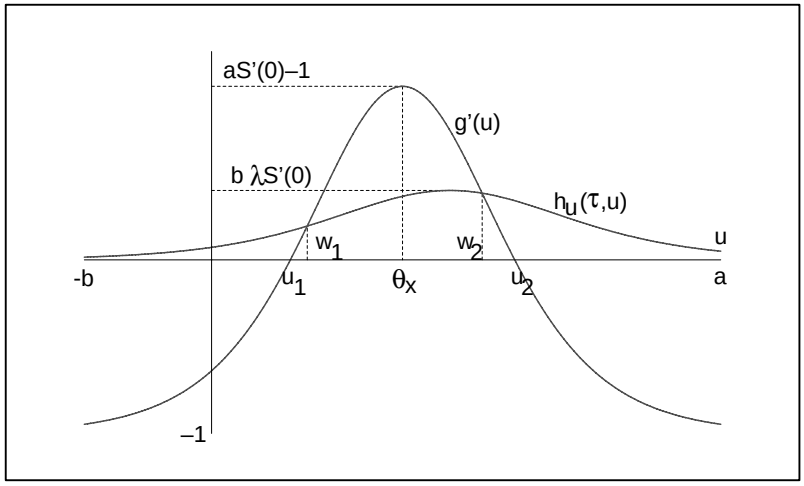

FIG. 3.1. *Zeros of* $f_u(\tau,u) = g'(u) - h_u(\tau,u)$.

$\theta_y + \alpha\sin(2\pi\tau)$). The function $f(\tau,u)$ is zero wherever $g(u)$ and $h(\tau,u)$ are equal; similarly, the function $f_u(\tau,u)$ is zero where $g'(u)$ and $h_u(\tau,u)$ are equal.

We look first for the zeros of $f_u(\tau,u)$. Again, using the fact that $\mathbf{S}'(z)$ has its maximum at $z=0$ and is strictly monotonic on $(-\infty,0)$ and $(0,\infty)$, it can be seen in Figure 3.1 that the function $g'(u) = -1 + a\mathbf{S}'(u-\theta_x)$ always has exactly two zeros when $a > 1/\mathbf{S}'(0)$. We define u_1 and u_2 to be the values of u at which $g'(u) = 0$; that is,

$$u_1 < u_2 \text{ are the two solutions of } \mathbf{S}'(u-\theta_x) = \frac{1}{a}. \tag{3.1}$$

As τ varies between 0 and 1, the graph of g' remains fixed, while the graph of $h_u(\tau,u) = b\lambda\mathbf{S}'(\lambda u - \theta_y + \alpha\sin(2\pi\tau))$ moves left and right (see Figure 3.1); and if $b\lambda\mathbf{S}'(0) < a\mathbf{S}'(0) - 1$, the graph of $h_u(\tau,u)$ must intersect the graph of $g'(u)$ at least twice, but always between u_1 and u_2.

Assume that $\lambda < \frac{a\mathbf{S}'(0)-1}{b\mathbf{S}'(0)} \equiv \lambda_b$. Notice that for large a the condition $\lambda < \lambda_b$ is essentially the condition $c/a < a/b$, which requires the product of the two external feedback parameters to be small relative to the recurrent excitation. With this restriction on λ, there will be *exactly* two intersections if we can show that the slope of $g'(u)$ is always steeper than the slope of $h_u(\tau,u)$ at a point of intersection, that is, if $|g''(u)| > |h_{uu}|$. Consider the closed u-intervals $I_1 = \{u | 0 \le g'(u) \le b\lambda\mathbf{S}'(0), u < \theta_x\}$ and $I_2 = \{u | 0 \le g'(u) \le b\lambda\mathbf{S}'(0), u > \theta_x\}$. The continuous function $\mathbf{S}''(z)$ is zero only at $z=0$, and therefore $|\mathbf{S}''(u-\theta_x)|$ has strictly positive minimum values m_1 on I_1, and m_2 on I_2. Thus $g'(u)$ has slope $a\mathbf{S}''(u-\theta_x) \ge am_1$ in I_1 and $\le -am_2$ in I_2. For any fixed value of τ, the slope of $h_u(\tau,u)$ is $h_{uu}(\tau,u) = b\lambda^2\mathbf{S}''(\lambda u - \theta_y + \alpha\sin(2\pi\tau))$; therefore, for any u in the closed interval $[-b,a]$, $|h_{uu}(\tau,u)|$ is less than or equal to $b\lambda^2 M$, where M is the maximum of $|\mathbf{S}''(z)|$ on the interval $-b\lambda - \theta_y - \alpha \le z \le a\lambda - \theta_y + \alpha$. Therefore, if $b\lambda^2 M < am$, where $m = \min(m_1, m_2)$, at any point of intersection of the curves g' and h_u we have $|g''(u)| > |h_{uu}(u)|$.

Now consider the region bounded by the curve $g'(u)$ and the interval $u_1 \le u \le u_2$ on the u-axis. This region is divided by the vertical line through θ_x into a left subregion L and a right subregion R. Orienting h_u in the direction of increasing u, the result

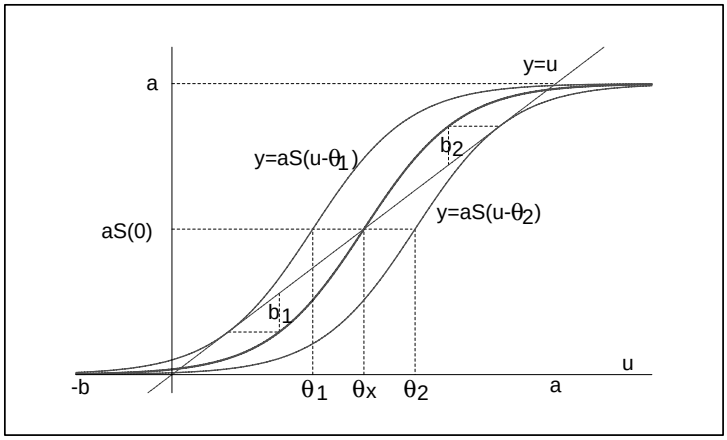

FIG. 3.2. *Values of θ_x for which $a\mathbf{S}(u-\theta_x)$ is tangent to $y=u$.*

$|g''(u)| > |h_{uu}(u)|$ implies that any intersection of h_u with the left boundary of L is an entrance to L. There is a unique exit from L at the point where h_u crosses the vertical line through θ_x. Since the number of entrances to L must equal the number of exits from L, it follows that there is only one intersection of h_u with the left boundary of L. Similarly there is only one intersection of h_u with the right boundary of R. These two intersections are the unique intersections of g' with h_u.

We have therefore shown that if $\lambda < \min(\lambda_b, \sqrt{\frac{am}{bM}}) \equiv \Lambda$, the function $f_u(\tau, u)$ will have exactly two zeros $w_1(\tau)$ and $w_2(\tau)$, lying between u_1 and u_2 for each value of τ. Note that this also implies that the function $f(\tau, u)$ has at most three zeros. Furthermore, since w_1 and w_2 are solutions of $f_u(\tau, u) = 0$, by implicit differentiation they are seen to be differentiable functions of τ, with $dw_i/d\tau = -f_{u\tau}/f_{uu}$. The second partial derivative $f_{uu}(\tau, u)$ is never zero at the points $w_1(\tau)$ or $w_2(\tau)$, since it is equal to the *difference* of the slopes of $g'(u)$ and $h_u(\tau, u)$ at those points.

The condition $\lambda < \sqrt{\frac{am}{bM}}$ appears to be more restrictive than the condition $\lambda < \lambda_b$. The ratio m/M is less than 1 and approaches 1 as the derivative $\mathbf{S}'$ approaches a piecewise linear tent function with its peak at 0. However, our proof of the structural stability of the Wilson–Cowan system in section 4 shows that "sufficiently small" perturbations of the **S**-function can be made without altering the general behavior of the system. Therefore, in biological terms, the condition $\lambda < \Lambda$ simply requires that the external feedback between the two populations be small enough relative to the recurrent excitation in E.

Next consider the curves where $f(\tau, u) = 0$. With $a > 1/\mathbf{S}'(0)$, the graph of $y = a\mathbf{S}(u-\theta_x)$ has its maximum slope, greater than 1, at $u = \theta_x$ and intersects the line $y = u$ in $1, 2$, or 3 points depending on the value of θ_x. Define θ_1 and θ_2 to be the lower and upper values of θ_x for which the curve $y = a\mathbf{S}(u-\theta_x)$ is tangent to the line $y = u$ (see Figure 3.2); that is, $\theta_1 < \theta_2$ are the solutions θ of the simultaneous equations

$$\begin{cases} a\mathbf{S}(u-\theta) = u, \\ a\mathbf{S}'(u-\theta) = 1. \end{cases} \tag{3.2}$$

Then if $\theta_1 < \theta_x < \theta_2$, $g(u) = -u + a\mathbf{S}(u-\theta_x)$ has exactly three zeros, and if $\theta_x < \theta_1$ or $\theta_x > \theta_2$, $g(u)$ has only one zero.

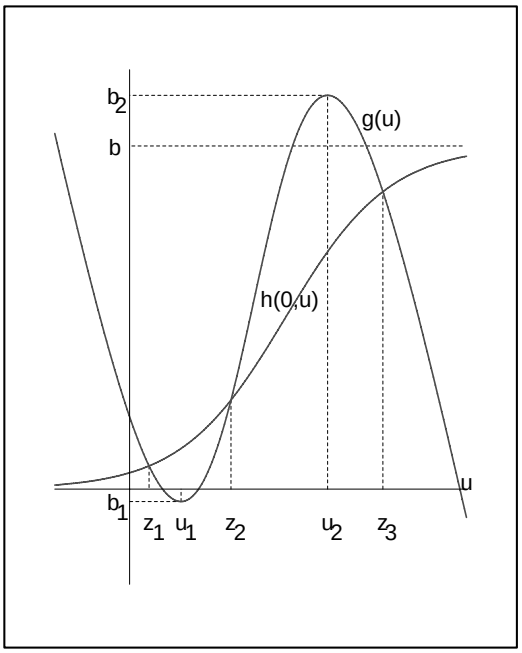

FIG. 3.3. *Zeros of the function* $f(0,u) = g(u) - h(0,u)$, $\theta_1 < \theta_x < \theta_2$, $b < b_2$.

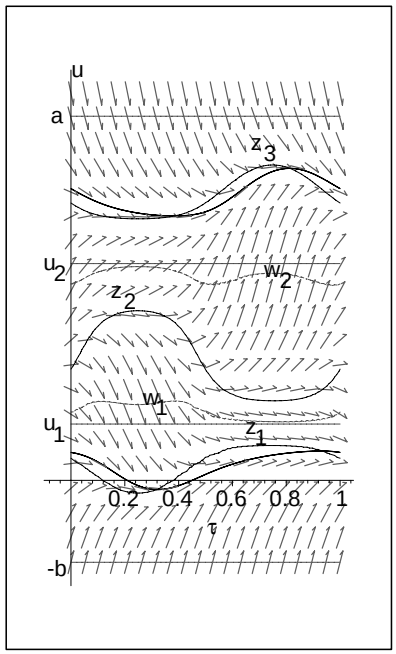

FIG. 3.4. *Slope field in* $\mathcal{H}$, *with* $\theta_1 < \theta_x < \theta_2$, $b < b_2$.

We consider first the case of $\theta_1 < \theta_x < \theta_2$. In Figure 3.3, graphs of $g(u)$ and $h(0,u)$ are drawn. From our discussion of the function $g'(u)$, we know that a local minimum and a local maximum of g occur at u_1 and u_2, respectively. Define $b_2 = g(u_2)$ to be the local maximum of g, and $b_1 = g(u_1)$ to be the local minimum. Notice that $b_2 = 0$ when $\theta_x = \theta_2$. As θ_x moves to the left or right of θ_2 on the u-axis, the position of the maximum of $g(u)$, and its magnitude, both change by the same amount $\theta_2 - \theta_x$ (see Figure 3.2); therefore, $b_2 = \theta_2 - \theta_x$. Similarly, it can be seen that the minimum $b_1 = g(u_1) = \theta_1 - \theta_x$.

If $b < b_2$, as the curve $h(\tau,u)$ moves left and right with τ, for any τ between 0 and 1, it always intersects the curve $g(u)$ in exactly three points $z_i(\tau)$. It can be seen from Figure 3.3 that for all τ these intersection points satisfy $z_1(\tau) < u_1 < z_2(\tau) < u_2 < z_3(\tau)$. From our previous analysis of the function f_u, we know that the curve $z_2(\tau)$ lies in the region between the curves $w_1(\tau)$ and $w_2(\tau)$.

For a representative set of parameter values $a > 1/\mathbf{S}'(0), \theta_1 < \theta_x < \theta_2$, $b < b_2$, and $\lambda < \Lambda$, the position of these curves in $\mathcal{H}$ is shown in Figure 3.4. Since f_u is negative for $u < u_1$ and $u > u_2$, and $f(\tau,u_1) < 0, f(\tau,u_2) > 0$ for any τ, the subregions $\mathcal{H}_1 = \{0 \le \tau < 1 \pmod 1, -b \le u \le u_1\}$ and $\mathcal{H}_2 = \{0 \le \tau < 1 \pmod 1, u_2 \le u \le a\}$ are invariant *contracting* regions for (2.4), so that Lemma A.4 (appendix) shows that there always exists a unique attracting period-1 solution $u^-(\tau)$ in $\mathcal{H}_1$ and $u^+(\tau)$ in $\mathcal{H}_2$. These are the two darker curves seen in Figure 3.4.

By making the input frequency ω small enough, the absolute value of the slope function $(2\pi/\omega)f(\tau,u)$ can be made larger than the absolute value of the derivative of both w_1 and w_2 at every value of τ. Under these conditions, the region $w_1(\tau) < u < w_2(\tau)$ is a repelling region for $u(\tau)$; that is, it is a contracting forward invariant

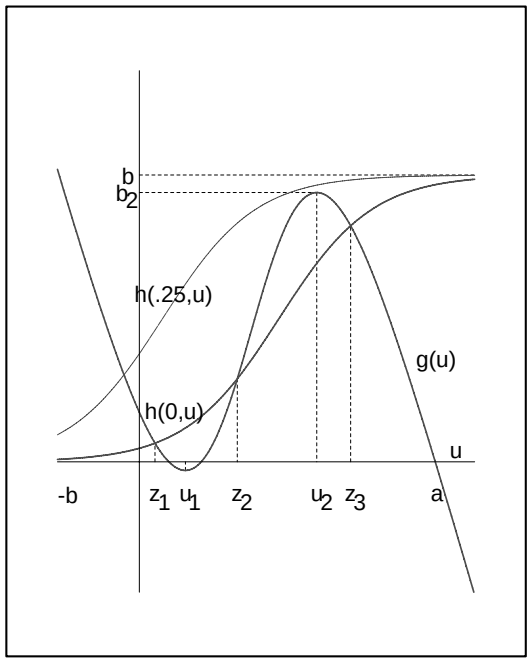

FIG. 3.5. *Zeros of the function* $f(\tau,u) = g(u) - h(\tau,u)$, $\theta_1 < \theta_x < \theta_2$, $b > b_2$.

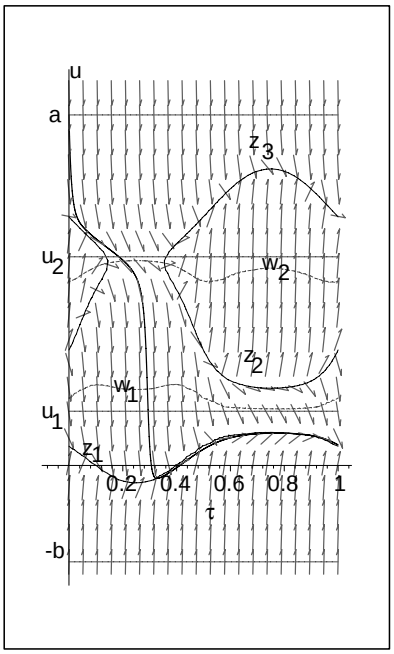

FIG. 3.6. *Slope field in* $\mathcal{H}$, *with* $\theta_1 < \theta_x < \theta_2$, $b > b_2$.

region when τ is replaced by $-\tau$. In this case there is a unique period-1 repeller in the interior of this subregion of $\mathcal{H}$ (see the appendix). All of the other solutions are attracted to either u^- or u^+. The above analysis allows us to state the following theorem.

THEOREM 3.1. *If* $a > 1/\mathbf{S}'(0)$, $\theta_1 < \theta_x < \theta_2$, $b < b_2 = \theta_2 - \theta_x$, *and* $\lambda < \Lambda$, *then, for all* ω *small enough, for any value of the amplitude* α *the equation* $u' = (2\pi/\omega)f(\tau,u)$ *has exactly three period-*1 *solutions; attractors* $u^-(\tau)$ *and* $u^+(\tau)$ *and repeller* $u^0(\tau)$ *satisfying* $u^-(\tau) < u_1 < u^0(\tau) < u_2 < u^+(\tau)$ *for all* τ. *The corresponding Wilson–Cowan system* (1.1), *with* $d = \lambda b$, $\tau_x = \tau_y = 1$, *has a low activity attracting state* $(x^-(t), y^-(t))$ *corresponding to* $u^-(\tau)$ *and a high activity attracting state* $(x^+(t), y^+(t))$ *corresponding to* $u^+(\tau)$. *Every solution with initial values* $(x(0), y(0))$ *satisfying* $ax(0) - by(0) > u^0(0)$ *is attracted to* (x^+, y^+), *and solutions with* $(x(0), y(0))$ *satisfying* $ax(0) - by(0) < u^0(0)$ *are attracted to* (x^-, y^-). *The period of oscillation, in* t, *of each of these attracting solutions is* $2\pi/\omega$.

With the parameter values a, b, θ_x, and λ as hypothesized in Theorem 3.1, low frequency external input $\alpha \sin(\omega t)$ to the inhibitory cells cannot significantly change the behavior of the system. In order for the input to cause one of the two attractors to lose stability, and hence *switch* the system from one attracting state to the other, it is necessary that either (1) the feedback parameter b from $I \Rightarrow E$ be increased to a value greater than the bifurcation value b_2, or (2) the excitatory threshold θ_x be decreased to a value less than θ_1. If $\theta_x > \theta_2$, the local maximum of the function $f(\tau,u)$ is negative for all values of τ, so that only the lower attractor $u^-(\tau)$ exists for any input.

Consider now the case in which $\theta_1 < \theta_x < \theta_2$ and $b > b_2$. In this case it can be seen in Figure 3.5 that there exists an α^* such that for all $\alpha > \alpha^*$ the curve $h(\tau,u)$

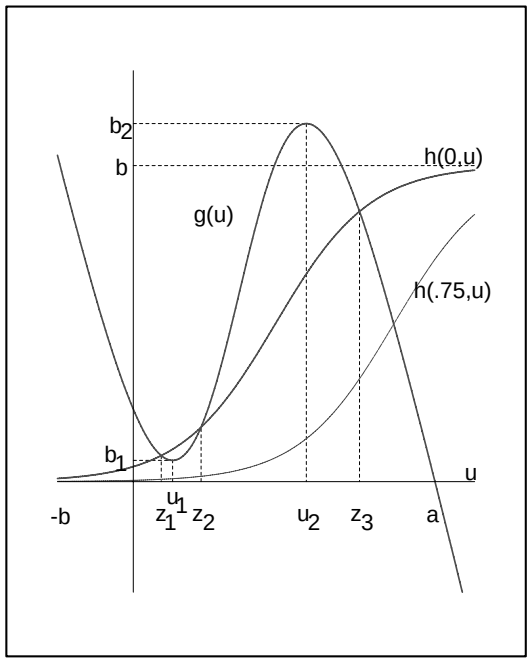

FIG. 3.7. *Zeros of the function* $f(\tau, u) = g(u) - h(\tau, u)$, $\theta_x < \theta_1$, $b_1 < b < b_2$.

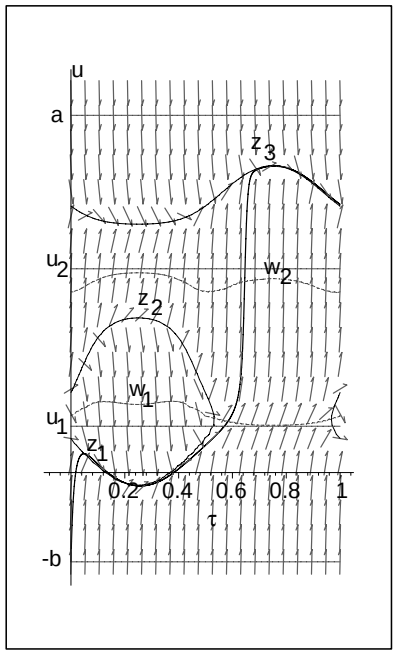

FIG. 3.8. *Slope field in* $\mathcal{H}$, *with* $\theta_x < \theta_1$, $b_1 < b < b_2$.

moves far enough to the left so that there will be an interval of τ (around $\tau = 0.25$) in which the intersections $z_2(\tau)$ and $z_3(\tau)$ no longer exist. Figure 3.6 shows the corresponding arrangement of the curves $z_i(\tau)$ in $\mathcal{H}$. The lower invariant contracting region $\mathcal{H}_1$ still exists, but by making the input frequency ω small enough, the solution $u(\tau)$ of (2.4) with $u(0) = a$ can be made to decrease below the minimum u-value on the curve $z_2(\tau)$, and $u(\tau)$ will therefore be attracted to the lower period-1 solution $u^-(\tau)$. Using the uniqueness of the solutions, it can be seen that all solutions of (2.4) are then attracted to $u^-(\tau)$ as $\tau \to \infty$. The solution starting at $u(0) = a$ is seen as the darker curve in Figure 3.6.

THEOREM 3.2. *If* $a > 1/\mathbf{S}'(0), \theta_1 < \theta_x < \theta_2, b > b_2$, *and* $\lambda < \Lambda$, *there exist positive constants* α^*, *and* ω^* *depending on* α, *such that for all* $\alpha > \alpha^*$ *and* $\omega < \omega^*(\alpha)$ *all solutions of* (2.4) *tend to the period*-1 *solution* $u^-(\tau)$, *with* $-b < u^-(\tau) < u_1$. *For these values of the parameters, external input* $i(t) = \alpha \sin(\omega t)$ *to the inhibitory cells forces all solutions of the Wilson–Cowan system* (2.1) *to the low activity state* $(x^-(t), y^-(t))$, *which is periodic with period* $2\pi/\omega$.

If $\theta_x < \theta_1$, the external input can produce two different types of behavior. If b is less than the value of the local minimum $b_1 = g(u_1) = \theta_1 - \theta_x$, which is now positive, then only the upper period-1 solution $u^+(\tau)$ exists for any input $\alpha \sin(\omega t)$; but if $b_1 < b < b_2$, then for all α large enough there will be an interval of τ around $\tau = 0.75$ for which $z_3(\tau)$ is the only solution of $f(\tau, u) = 0$ (see Figure 3.7). In this case, only the upper invariant contracting region $\mathcal{H}_2$ exists, and the input $\alpha \sin(\omega t)$ can be used to drive all solutions to the upper attractor $u^+(\tau)$ if $\alpha > \alpha^*$ and $\omega < \omega^*(\alpha)$. Such a solution can be seen in the slope field in Figure 3.8, where we have used the initial value $u(0) = -b$.

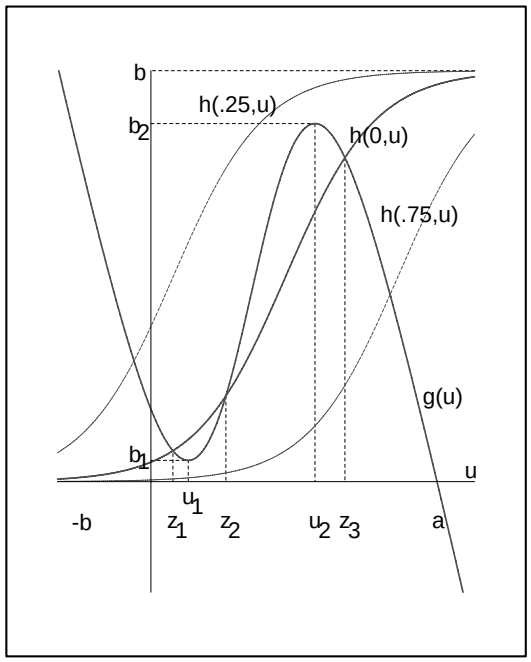

FIG. 3.9. *Zeros of the function* $f(\tau, u) = g(u) - h(\tau, u)$, $\theta_x < \theta_1$, $b > b_2$.

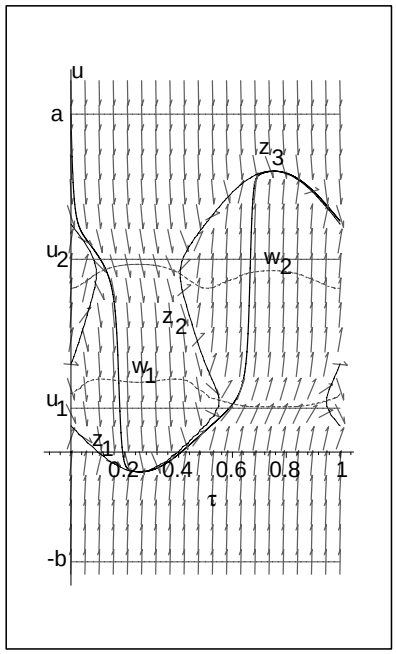

FIG. 3.10. *Slope field in* $\mathcal{H}$, *with* $\theta_x < \theta_1$, $b > b_2$.

THEOREM 3.3. *If* $a > 1/\mathbf{S}'(0), \theta_x < \theta_1, b_1 < b < b_2$, *and* $\lambda < \Lambda$, *there exist positive constants* α^*, *and* ω^* *depending on* α, *such that for all* $\alpha > \alpha^*$ *and* $\omega < \omega^*(\alpha)$ *all solutions of* (2.4) *tend to the period-*1 *solution* $u^+(\tau)$, *with* $u_2 < u^+(\tau) < a$. *For these values of the parameters, external input* $i(t) = \alpha \sin(\omega t)$ *to the inhibitory cells drives all solutions of the Wilson–Cowan system* (2.1) *to the high activity state* $(x^+(t), y^+(t))$, *which is periodic with period* $2\pi/\omega$ *in* t.

It can be seen in Figure 3.9, however, that if $\theta_x < \theta_1$ and $b > b_2$, then for large enough α there can be intervals of τ where z_3 is the only solution of $f(\tau, u) = 0$, as well as intervals of τ where z_1 is the only solution. In this case, with large amplitude, low frequency input $\alpha \sin(\omega t)$, both the upper and lower attractors can lose stability, and the solutions of (2.4) can be made to converge to an attracting periodic solution which oscillates alternately between the high and low activity states. Such a solution is shown in the slope field in Figure 3.10. With b large enough, our results in this region of parameter space resemble those in [12]. As hypothesized in [12], $x(t)$ and $y(t)$ appear to oscillate *in phase* in this region. This can be seen in the graph of the numerical solution pictured in Figure 5.4 in section 5.

The above theorems describe the behavior of the system in three distinct regions of parameter space. In each of these regions, the system has only hyperbolic periodic solutions, and in section 4 it will be shown to be a structurally stable system. This in turn implies that the behavior of the system in each of these regions remains similar for small perturbations of the parameters d, τ_x, and τ_y and also for small perturbations of the **S**-function and the input $i(t)$. In all of the systems we have simulated numerically, the value of d can be varied by a large percentage before any system bifurcation occurs. Note that the parameter d determines the magnitude of

the feedback among the cells in the inhibitory subpopulation, and the systems seem not to be very sensitive to this particular parameter in the regions of parameter space under consideration.

4. Structural stability of the periodically forced Wilson–Cowan system. In this section we show that in each of the three regions of parameter space described in Theorems 3.1, 3.2, and 3.3 the periodic Wilson–Cowan system (1.1) is structurally stable. This allows us to conclude that the results for the constrained system, with $d/b = c/a$ and $\tau_x = \tau_y$, can be extended to systems where the values of these parameters lie in sufficiently small neighborhoods of the constrained values, but in which the constraints are relaxed. In section 5, numerical simulations will be used to show what this means quantitatively.

We first give the definition of a structurally stable system and state the classical theorem which applies to three-dimensional autonomous systems on compact manifolds [8], [9], [11]. We then prove in Theorem 4.2 that, under certain conditions, the Wilson–Cowan system (1.1) satisfies the Morse–Smale conditions for structural stability. The corollary of Theorem 4.2 below shows that in each of the regions described in Theorems 3.1, 3.2, and 3.3, system (1.1) satisfies all of the hypotheses of Theorem 4.2.

DEFINITION 4.1. *A system of differential equations $x' = F(x)$ on a smooth manifold M (with or without boundary) is C^r* structurally stable *if, for all sufficiently small perturbations of the vector field F and its partial derivatives of order $\leq r$, the unperturbed and perturbed systems are topologically equivalent; that is, there exists a homeomorphism $h : M \to M$ which takes trajectories of the unperturbed system to trajectories of the perturbed system, preserving the time orientation but not necessarily the parameterization.*

Starting with the periodically forced Wilson–Cowan system (1.1) on $\mathbf{R}^2$, we add a new variable s and a new equation to form a related autonomous system on $\mathbf{R} \times \mathbf{R}^2$. We then identify the point (s, x, y) with the point $(s+P, x, y)$ to induce on the manifold $S^1 \times \mathbf{R}^2$ the system

$$\left\{ \begin{array}{rl} s'(t) & = 1, \\ \tau_x x'(t) & = -x(t) + \mathbf{S}(ax(t) - by(t) - \theta_x), \\ \tau_y y'(t) & = -y(t) + \mathbf{S}(cx(t) - dy(t) - \theta_y + i(s)). \end{array} \right. \tag{4.1}$$

THEOREM 4.2. *Suppose that system* (4.1) *has finitely many periodic orbits on the manifold $S^1 \times \mathbf{R}^2$, all of which are hyperbolic, and that every point approaches a periodic orbit in forward time, while in backward time every point approaches a periodic orbit or escapes to infinity, but no nonperiodic point approaches a saddle orbit in forward time and a saddle orbit in backward time. Further, suppose that from the Wilson–Cowan system a sufficiently small perturbation is made of the positive constants $\tau_x, \tau_y, a, b, c, d, \theta_x$, and θ_y; a C^1 sufficiently small perturbation is made of $i(t)$, preserving the period P; and a C^1 sufficiently small perturbation is made of the function $\mathbf{S}$. Then there exists a closed disk $D \subseteq \mathbf{R}^2$ such that any trajectory of the original or perturbed system either lies entirely in the interior of the manifold with boundary $M = S^1 \times D$ or else enters M and never leaves. In particular, all periodic orbits of the perturbed and unperturbed system are contained in the interior of M. The perturbed system is topologically equivalent on M to the unperturbed system, and the topological equivalence $h : M \to M$ approaches the identity as the perturbation and its first-order partial derivatives approach the unperturbed system and its corresponding partial derivatives. In particular, the perturbed system has no equilibria, all the*

periodic orbits of the perturbed system are hyperbolic, the number of periodic orbits in the unperturbed and perturbed systems is the same, and corresponding periodic orbits in the two systems have the same period and type (i.e., attractor, repeller, saddle).

This theorem will be proved by invoking a theorem of Palis, which requires the following definition.

DEFINITION 4.3 (see [10, pp. 319, 322]). *On a compact manifold M (with or without boundary), we call a differential equation* Morse–Smale *if*

(a) *the vector field of the differential equation is nowhere zero on the boundary and nowhere tangent to the boundary;*

(b) *there are finitely many equilibria and periodic orbits;*

(c) *all equilibria and periodic orbits are hyperbolic;*

(d) *all stable and unstable manifolds intersect transversally;*

(e) *the nonwandering set coincides with the set of equilibria and periodic orbits.*

The following theorem is usually stated for a compact manifold without boundary, but the proof carries over for a compact manifold with boundary, provided that one stipulates the tangency condition (a) given in the above definition.

THEOREM 4.4 (see [7]). *On a compact manifold M (with or without boundary), a Morse–Smale differential equation is C^1 structurally stable, and the equivalence $h : M \to M$ approaches the identity as the perturbation and its first partial derivatives approach the unperturbed system and its first partial derivatives.*

Proof of Theorem 4.2. Let us first rewrite system (1.1) in the form

$$x' = F_1(t,x,y) = -mx + m\mathbf{S}(f_1(t,x,y)),$$
$$y' = F_2(t,x,y) = -ny + n\mathbf{S}(f_2(t,x,y)),$$

where $m = 1/\tau_x, n = 1/\tau_y, f_1(t,x,y) = ax - by - \theta_x$, and $f_2(t,x,y) = cx - dy - \theta_y + i(t)$. The same differential equation can also be written in vector form as $(x,y)' = F(t,x,y)$, where the nonautonomous vector field $F(t,x,y) = (F_1(t,x,y), F_2(t,x,y))$.

As was shown previously, the nonautonomous system (1.1) on $\mathbf{R} \times \mathbf{R}^2$ can be rewritten as an autonomous system (4.1) on $S^1 \times \mathbf{R}^2$, which in vector form can be denoted by $(s,x,y)' = F^{\#}(s,x,y)$.

Choose $r > (m+n)/\min(m,n)$, and let D be a disk in the (x,y) plane of radius r, centered at the origin. The vector $\nu = (x,y)$ is an outward-pointing normal vector to the boundary circle of D. For any fixed t, the dot product $F \bullet \nu = -mx^2 - ny^2 + mx\mathbf{S}(f_1(t,x,y)) + ny\mathbf{S}(f_2(t,x,y)) \le -\min(m,n)r^2 + (m+n)r$. Our choice of r implies that $F \bullet \nu < 0$, which shows that for any fixed t, the vector field F points into the disk D. As a consequence, the vector field $F^{\#}$ for the system (4.1) on the manifold $S^1 \times \mathbf{R}^2$ points into the manifold with boundary $M = S^1 \times D$. The same is true for any vector field $G^{\#}$ on M that is a sufficiently small C^0 perturbation of $F^{\#}$.

Since the first equation in system (4.1) is $s'(t) = 1$, it follows that the system has no equilibria. By hypothesis, it has only finitely many periodic orbits, all of which are hyperbolic.

The condition of Theorem 4.2 that no nonperiodic point is both backward and forward asymptotic to a saddle implies that the only possible intersection of stable and unstable manifolds occurs on a periodic orbit. But by the hyperbolicity of periodic orbits, an intersection of stable and unstable manifolds along a periodic orbit is transverse. Therefore all intersections of stable and unstable manifolds are transverse.

If a point does not escape to infinity in backward time, it approaches a repeller in backward time or an attractor in forward time. Therefore no nonperiodic point

can be nonwandering. It follows that the nonwandering set coincides with the set of periodic orbits.

We have shown above that the conditions of Theorem 4.4 are satisfied. It follows that system (4.1) on M is C^1 structurally stable. Let $G^{\#}$ be a sufficiently small C^1 perturbation of the unperturbed vector field $F^{\#}$. Then the systems determined by $F^{\#}$ and $G^{\#}$ are topologically equivalent on M; that is, both systems have the same number of periodic orbits, and corresponding orbits have the same type. □

COROLLARY OF THEOREM 4.2. Consider any set of parameters $\tau_x = \tau_y = 1$, $a, b, c, \lambda, d = \lambda b, \theta_x, \theta_y, \alpha$, and ω, with $i(t) = \alpha \sin(\omega t)$ such that the resulting Wilson–Cowan system satisfies the conditions for Theorem 3.1, Theorem 3.2, or Theorem 3.3. Suppose a sufficiently small perturbation is made of the parameters $\tau_x, \tau_y, a, b, c, d, \theta_x$, and θ_y, together with a C^1 sufficiently small perturbation of $i(t)$ preserving the period $P = 2\pi/\omega$, and a C^1 sufficiently small perturbation of the function $\mathbf{S}$. It follows that the perturbed system has the same properties as the properties demonstrated for the unperturbed system in Theorems 3.1, 3.2, and 3.3.

Proof of the corollary. Given a case of the Wilson–Cowan system whose properties are demonstrated in Theorem 3.1, 3.2, or 3.3, we need to show that this unperturbed system satisfies the conditions needed to apply Theorem 4.2.

In the ensuing argument we will need to refer to system (4.1), to the linearly equivalent system

$$s' = 1, \quad u' = f(s,u), \quad x' = k(s,u,x), \tag{4.2}$$

and to system

$$s' = 1, \quad u' = f(s,u). \tag{4.3}$$

The latter are autonomous systems corresponding to systems (2.2) and (2.3) in section 2, with $u = ax - by$.

The system of Theorem 3.1 has three periodic orbits, and the systems of Theorem 3.2 and Theorem 3.3 have one periodic orbit. Therefore each one has at most finitely many periodic orbits. We first show that each of these periodic orbits is hyperbolic. In system (4.2), because u' depends only on s and u, it follows that a Poincaré map $H : \mathbf{R}^2 \to \mathbf{R}^2$ has the form $H(u_0, x_0) = (H_1(u_0), H_2(u_0, x_0))$. The Jacobian matrix of this map has the form

$$\begin{pmatrix} dH_1/du_0 & 0 \\ \partial H_2/\partial u_0 & \partial H_2/\partial x_0 \end{pmatrix}.$$

Therefore the eigenvalues of the Jacobian map are $\lambda_1 = dH_1/du_0$ and $\lambda_2 = \partial H_2/\partial x_0$. We now compute those eigenvalues.

A Poincaré map H of a periodic differential equation maps the initial value of each trajectory into its value one period later. We will use the Poincaré map with initial value at $t = 0$. It is known [3, pp. 129–130] that the derivative $H_1'(u_0) = \exp[\int_0^1 f_u(t, u(t))dt]$, where $u(t)$ is the solution of the differential equation $u' = f(t,u)$, with $u(0) = u_0$. Since the periodic orbits determined by Theorems 3.1, 3.2, and 3.3 lie entirely in invariant regions where f_u has constant sign, it follows that $0 < \lambda_1 = H_1'(u_0) \neq 1$ for any u_0 which is the initial point of a periodic orbit. In particular, for an attracting periodic orbit of the equation $u' = f(t,u)$ we have $0 < \lambda_1 < 1$, and for a repelling periodic orbit we have $\lambda_1 > 1$. For a fixed u_0, the equation $x' = -x + S(u -$

θ_x) is a first-order linear equation with solution $x(t) = e^{-t}\int_0^t e^s S(u(s)-\theta_x)ds + e^{-t}x_0$, and therefore, $\lambda_2 = \partial H_2/\partial x_0 = 1/e$.

It follows that corresponding to an attracting periodic orbit for system (4.3) we have lying above it an attractor in system (4.2), and this attractor has eigenvalues $0 < \lambda_1 < 1$ and $\lambda_2 = 1/e$. Corresponding to a repelling periodic orbit for system (4.3), we have lying above it a saddle in system (4.2), and this saddle has eigenvalues $\lambda_1 > 1$ and $\lambda_2 = 1/e$. Since the eigenvalues are preserved under the linear change of variables going from system (4.1) to system (4.2), it follows that the periodic orbits shown to exist in Theorems 3.1, 3.2, and 3.3 are in fact hyperbolic.

Every initial point (s_0, u_0, x_0) in system (4.2) approaches a periodic orbit in forward time. In backward time it either approaches a periodic orbit or escapes to infinity.

In the cases of Theorems 3.2 and 3.3, there is no saddle orbit. In the case of Theorem 3.1, there is a unique saddle orbit α for (4.2) which projects to the repeller α^* of (4.3). The points attracted to α in forward time are precisely the points which project to α^*. However, for such a point which is not on α, in backwards time, the x value of the trajectory goes to $\pm\infty$. Therefore, there is no nonperiodic point of (4.2) which in both backwards and forwards time is attracted to a saddle orbit.

We have thus shown that any system satisfying the conditions for Theorem 3.1, 3.2, or 3.3 also satisfies the conditions for Theorem 4.2 on structural stability. Therefore these systems are structurally stable in the sense of Theorem 4.2. In particular, all the properties demonstrated for the systems in Theorems 3.1, 3.2, or 3.3 also hold under a sufficiently small C^1 perturbation of the type referred to in the corollary. □

5. Examples. This section contains numerical solutions of the Wilson–Cowan system (2.1) for some suitably chosen parameter values, to demonstrate the types of behavior described in section 3. The examples are specifically chosen to illustrate the behavior in four different regions of the bifurcation diagram pictured in section 6, and are labelled according to the region in which they lie. In each of these examples we are assuming that $d/b = c/a = \lambda$. For simplicity we use the sigmoidal response function $\mathbf{S}(z) = \frac{1}{(1+e^{-z})}$. For this particular $\mathbf{S}$-function, the derivative $\mathbf{S}'(z) = \mathbf{S}(z)(1-\mathbf{S}(z))$, and $\mathbf{S}'(0) = 1/4$. The excitatory feedback parameter a needs only to satisfy $a > 1/\mathbf{S}'(0) = 4$, and we will arbitrarily choose $a = 8$. For the chosen $\mathbf{S}$-function the values of θ_1 and θ_2, which depend only on $\mathbf{S}$ and a, can be found from (3.2) by using the inverse function $\mathbf{S}^{-1}(z) = \ln(z/(1-z))$:

$$\theta_1 = \frac{a}{2} - \left[\left(\frac{a}{2}\right)\sqrt{1-\frac{4}{a}} + \ln\left(\frac{1-\sqrt{1-4/a}}{1+\sqrt{1-4/a}}\right)\right] \approx 2.9343, \tag{5.1}$$

$$\theta_2 = \frac{a}{2} + \left[\left(\frac{a}{2}\right)\sqrt{1-\frac{4}{a}} + \ln\left(\frac{1-\sqrt{1-4/a}}{1+\sqrt{1-4/a}}\right)\right] \approx 5.0657.$$

We first consider a system with $\theta_1 < \theta_x < \theta_2$, by letting $\theta_x = 3$. The bifurcation value $b_2 = \theta_2 - \theta_x$ is approximately equal to 2.0657. The parameter λ is required to be less than $(a\mathbf{S}'(0)-1)/(b\mathbf{S}'(0)) = 4/b$, and we will arbitrarily choose $\lambda = 0.8$, which is well within the required limit when b is close to b_2. This value of λ can also be shown to satisfy the condition $\lambda < \sqrt{\frac{am}{bM}}$ for this particular $\mathbf{S}$-function and the values of b being considered. The inhibitory threshold θ_y is arbitrary, but both θ_y and λ will affect the bifurcation value α^*, since they each affect where the function $h(\tau, u)$ has

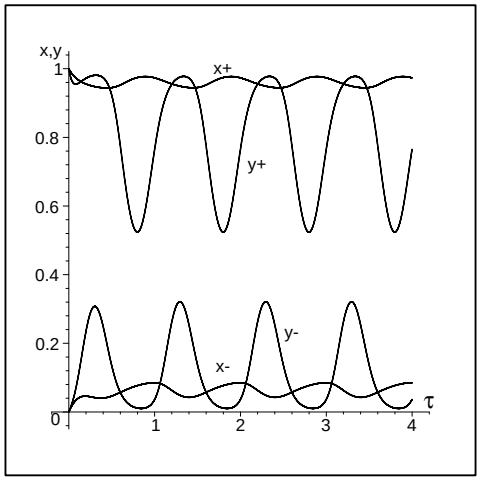

FIG. 5.1. *Solutions* (x, y) *in Region* 1*:* $\theta_x = 3$*,* $b = 1.8$.

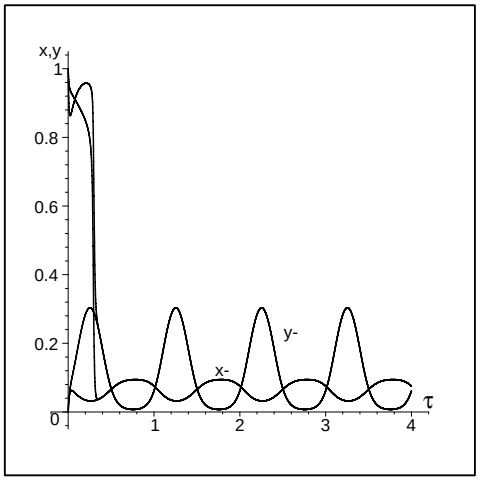

FIG. 5.2. *Solutions* (x, y) *in Region* 2*:* $\theta_x = 3$*,* $b = 2.2$.

its point of inflection. We arbitrarily set $\theta_y = 3$. The resulting Wilson–Cowan system is

$$\begin{cases} x' &= -x + \mathbf{S}(8x - by - \theta_x), \\ y' &= -y + \mathbf{S}(0.8(8x - by) - 3 + \alpha \sin(\omega t)). \end{cases} \tag{5.2}$$

Region 1. With $\theta_x = 3$ and $b = 1.8 < b_2$, we know from Theorem 3.1 that for *any* input $\alpha \sin(\omega t)$, with small enough frequency ω, almost every solution $(x(t), y(t))$ will approach one of the two attracting states $(x^-, y^-), (x^+, y^+)$, depending only on the values of $x(0)$ and $y(0)$. Figure 5.1 shows solutions of (5.2) with $b = 1.8$ and $i(t) = 2.5 \sin(0.5t)$. Two initial conditions, $(x(0), y(0)) = (0, 0)$ and $(x(0), y(0)) = (1, 1)$, are used, and the corresponding solutions are attracted, respectively, to the lower and upper periodic solutions. In this case, simulation shows that, except for the change in period, the periodic solutions are very similar for *all* values of ω.

Region 2. For the same threshold value $\theta_x = 3$, with $b = 2.2 > b_2$ and $i(t) = 2.5 \sin(0.05t)$, the same two sets of initial conditions were used. It can be seen in Figure 5.2 that, with $\alpha = 2.5$, the frequency $\omega = 0.05$ is small enough to drive *all* solutions to the lower attractor (x^-, y^-); that is, $2.5 > \alpha^*$ and $0.05 < \omega^*(2.5)$.

The parameter values used in the examples described here are of the same order of magnitude as those used by Tsodyks et al. [12]; therefore, assuming that the unit of time is milliseconds, the frequency $\omega = 0.05$ corresponds to a periodic input of approximately 8 Hertz, whereas $\omega = 0.5$ corresponds to an input of 80 Hertz. In the case in which $\theta_x = 3$ and $b = 2.2$, further simulations were done to find the bifurcation value of ω when α was equal to 2.5. The upper periodic solution lost stability at $\omega \approx 0.085$. This means that the periodic input must cycle at approximately 13 Hertz or less to cause all of the solutions to tend to the lower attractor (x^-, y^-), that is, to turn off the excitation.

Region 3. When $\theta_x = 2.8 < \theta_1$, the corresponding value of $b_2 = \theta_2 - \theta_x \approx 2.2657$. Now the value $b = 2.1$ is less than b_2 and greater than $b_1 = \theta_1 - \theta_x \approx 0.0134$. With initial conditions as before, and $i(t)$ again taken to be equal to $2.5 \sin(0.05t)$, Figure 5.3 shows both solutions being driven to the upper attractor (x^+, y^+). By simulation,

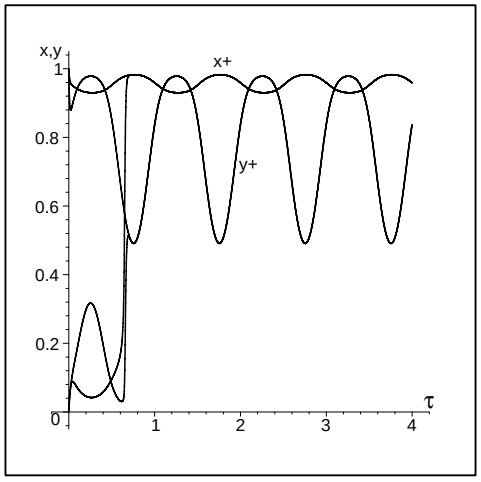

FIG. 5.3. *Solutions* (x, y) *in Region* 3*:* $\theta_x = 2.8$*,* $b = 2.1$.

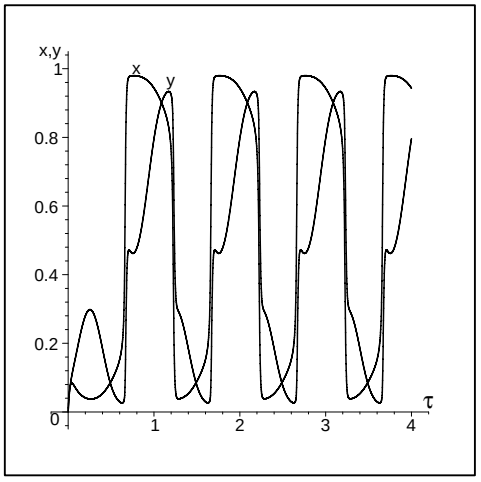

FIG. 5.4. *Wide oscillation in Region* 4*:* $\theta_x = 2.8$*,* $b = 2.5$.

the bifurcation value in this case was found to be $\omega^*(2.5) \approx 0.247$. This corresponds to an input of about 25 Hertz.

Region 4. In Figure 5.4, $\theta_x = 2.8$ and $b = 2.5 > b_2$, and with the same input $i(t)$ one sees large oscillations; that is, the solutions oscillate alternately between the high and low activity states. It can be seen in Figure 5.4 that $x(t)$ and $y(t)$ are oscillating *in phase* in this region, whereas in the other three regions they can be seen to oscillate nearly 180 degrees out of phase. This tends to reinforce the paradoxical behavior observed by Tsodyks et al. [12]. For this set of parameter values, additional simulations show that the lower solution loses stability at $\omega \approx 0.223$, and then the upper solution loses stability at $\omega \approx 0.156$. For any $\omega < 0.156$, the system has the oscillatory behavior shown in Figure 5.4.

A sensitivity analysis was done in each of the four regions by varying d above and below the value λb. Decreasing d all the way to zero has no significant effect on the behavior of the system in any of the regions. However, when d is increased, there is a reduction in the general level of activity in I. This causes the upper solution to regain stability in Region 2 after a 20 percent increase in d, and in Region 4 after an increase of 35 percent in d. An increase in d produces no significant change in Regions 1 and 3.

It is interesting to note from the above results that if b is approximately equal to $\theta_2 - \theta_1$, periodic forcing of low frequency to the inhibitory cells can be used to drive the system to *either* its high or low activity state, depending only on whether the excitatory threshold θ_x is above or below θ_1. If one assumes that, after a period of high excitation, θ_x increases (for example, if we had included a refractory period for the excitatory cells, it might have had this effect), then it can be shown that, in the range of parameter space where $b \approx \theta_2 - \theta_1$, the system can be forced to produce "bursting" activity. To demonstrate this by simulation, the system (5.2) with $b = 2.1$, $i(t) = 2.5\sin(0.05t)$, and a third differential equation for θ_x of the form

$$\frac{d\theta_x}{dt} = K_1(2.7 - \theta_x(t)) + \delta(x(t) - 0.5)[K_2(3.2 - \theta_x(t)) - K_1(2.7 - \theta_x(t))]$$

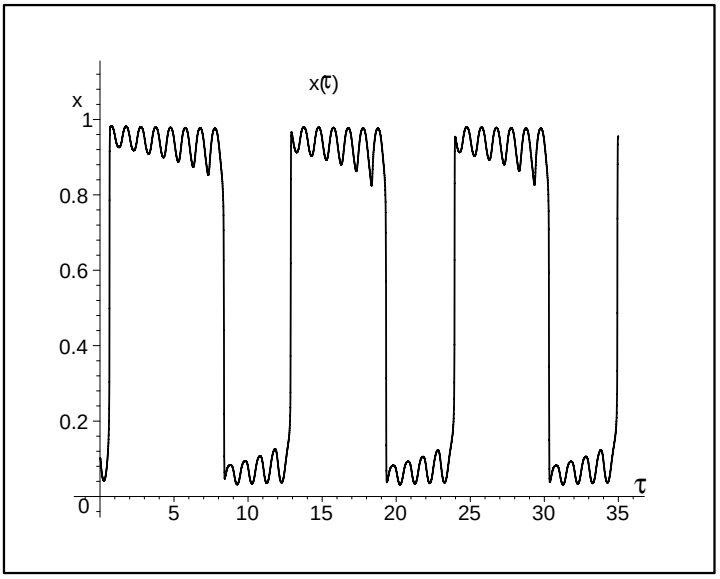

FIG. 5.5. *Bursting response to input, with variable* θ_x.

was solved numerically using MAPLE. The delta function used in the calculation is $\delta(z) = 1/(1 + \exp(-50z))$, and K_1 and K_2 were arbitrarily chosen to be 0.15. The value of θ_x was initialized to 2.8. While the excitatory activity x is greater than 50 percent, θ_x increases toward 3.2, but it then decreases again when the activity becomes less than 50 percent. A solution of this system is shown in Figure 5.5. Further simulations also showed that if d is varied about the value $\lambda b = 1.68$, the bursting activity persists, but the length of the bursts increases as d increases. In contrast, increasing the amplitude α of the forcing function shortened the length of the bursts.

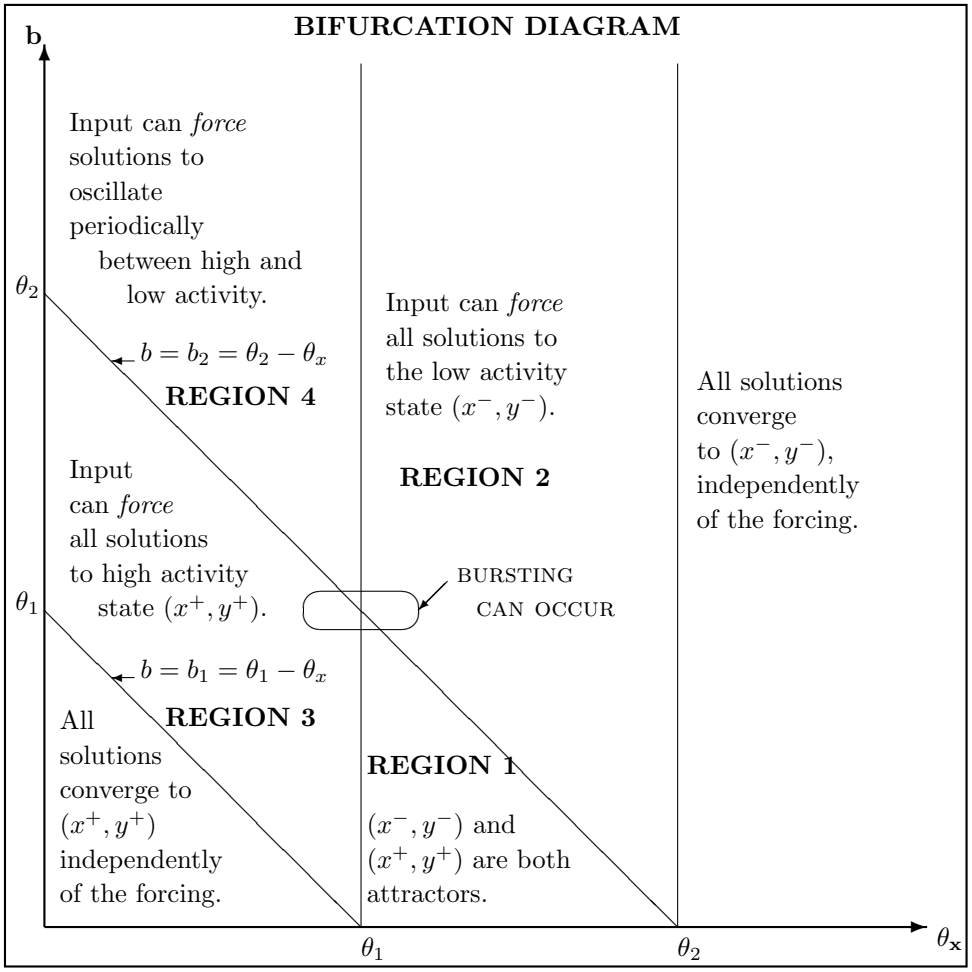
6. Summary. By reducing the Wilson–Cowan system to a single first-order differential equation, one is able to bring several known results for periodic first-order differential equations to bear on the problem of the behavior of the forced two-dimensional system.

Our results can be summarized in the bifurcation diagram below, using b and θ_x as the two bifurcation parameters. In all cases it is assumed that $a > 1/\mathbf{S}'(0)$, $\lambda \equiv c/a < \Lambda$, $d/b \approx c/a$, and the system is being forced with *low* frequency periodic input.

Note that in only three of the six regions of parameter space is it possible to use periodic input to the inhibitory cells to force the system to alter its behavior significantly, and then only if the frequency of the input is low and its amplitude is large enough. The bursting behavior, noted in the bifurcation diagram, appears to be a new result for a system of this type.

It seems clear that our results hold not only for the input function $i(t) = \alpha \sin(\omega t)$ but also for any P-periodic function which has a single maximum and single minimum between 0 and P. This will be an area of further study, to determine just exactly what type of periodic input functions produce the effects noted in this paper.

Another problem for further study involves the question of whether or not the first-order periodic equation (2.4), with parameters in our parameter range, can *ever*



have more than three periodic solutions for *any* values of ω. In the slope field region between the two invariant subregions $\mathcal{H}_1$ and $\mathcal{H}_2$ it seems to be the case, from simulations, that only the single periodic repeller exists. This is definitely true if λ is small enough, and it can be proved to be true in general for small ω and also for large ω, but in a middle region both proofs break down. For a slope function $f(\tau, u)$ which is a cubic in u, with coefficient of u^3 negative for all τ, there is a theorem (see [2], [6]) which shows that the differential equation can have *at most* three periodic solutions. Our slope function is similar to a cubic, for $-b < u < a$, in the sense that it has two turning points, a local minimum and then a local maximum. There may be a way to extend the theorem to such functions, but this has so far proved difficult to do.

Appendix. Properties of solutions of $y' = f(t, y)$. This section contains statements of some well-known properties (see, for example, [3], [4]) of solutions of the first-order differential equation

$$\frac{dy}{dt} = f(t, y). \tag{A.1}$$

A solution of an initial-value problem for (A.1) will be denoted by $\phi \equiv \phi(t, t_0, y_0)$, where $\phi(t_0, t_0, y_0) = y_0$ and $d\phi/dt \equiv f(t, \phi(t, t_0, y_0))$ for $t \geq t_0$. We will assume that

the slope function $f(t, y)$ is continuous and continuously differentiable in y; therefore, for any initial value the solution of (A.1) is unique. Furthermore, if $y_2 > y_1$, then the uniqueness and existence theorem for first-order differential equations implies that $\phi(t, t_0, y_2) > \phi(t, t_0, y_1)$ for all $t > t_0$.

DEFINITION A.1. *A* forward invariant region *for* (A.1), *in the* (t, y)*-plane, is a region* $V = \{t_0 \le t < \infty, v_1(t) < y < v_2(t)\}$, *where* v_1 *and* v_2 *are continuously differentiable curves such that* $f(t, v_1(t)) > v_1'(t)$ *and* $f(t, v_2(t)) < v_2'(t)$ *for all* $t \ge t_0$. *This implies that the vector field* f *is entering the region* V *everywhere along the curves* v_1 *and* v_2.

Once a solution of (A.1) enters a forward invariant region V, it can never cross the curves v_1 or v_2, and therefore it must remain in V for all $t > t_0$.

DEFINITION A.2. *A forward invariant region* V *for* (A.1) *is called* contracting *if* $f_y(t, y) \le -\delta < 0$, *for some positive constant* δ, *for all* $(t, y) \in V$.

DEFINITION A.3. *The slope function* $f(t, y)$ *is called* periodic of period P *if* $f(t + P, y) = f(t, y)$ *for all* t.

LEMMA A.4. *If the slope function* $f(t, y)$ *in* (A.1) *is periodic of period* P *and* V *is a contracting forward invariant region for* (A.1), *then there exists a unique period-*P *attractor* $\hat{\phi}$ *in* V, *and all solutions of* (A.1) *that enter* V *are attracted to* $\hat{\phi}$ *as* $t \to \infty$.

For a nice proof of this lemma, see p. 115 in [3].

If W is a contracting forward invariant region for (A.1) when the independent variable t is replaced by $-t$, a similar proof can be used to show that there exists a unique *repelling* solution for (A.1) in W.

OSCILLATORY FLOW NEAR A STAGNATION POINT*

M. G. BLYTH† AND P. HALL‡

Abstract. The classical Hiemenz solution describes incompressible two-dimensional stagnation point flow at a solid wall. We consider an unsteady version of this problem, examining particularly the response close to the wall when the solution at infinity is modulated in time by a periodic factor of specified amplitude and frequency. While this problem has already been tackled in the literature for general frequency in cases when the amplitude of the time-periodic factor is either large or small, we compute the flow for arbitrary values of both these parameters. For any given amplitude, we find that there exists a threshold frequency above which the flow is regular and periodic, with the same period as the modulation factor, and beneath which the solution terminates in a finite time singularity. The dividing line in parameter space between these two possibilities is identified and favorably compared with the predictions of asymptotic analyses in the small and large frequency limits.

Key words. stagnation point, boundary layer, steady streaming

AMS subject classification. 76D10

1. Introduction.

The classical Hiemenz solution describes the flow near a stagnation point on a plane wall and may be found in Batchelor [1]. When this flow is modulated in time by a periodic multiplicative factor on the streamfunction at infinity, the resulting solution can be used to describe the local dynamics around a stagnation point on an oscillating body. Equally, the body may be thought of as fixed, with the flow out in the far field varying periodically in time. The steady streaming motion established by the Reynolds stresses associated with the oscillatory motion (Stuart [2]) is an important feature of such time-periodic flows. This effect occurs, for example, around a transversely oscillating circular cylinder (Schlichting [3]). When the amplitude of the far field fluctuation is small, modified Hiemenz flow can be used to model the local effects of disturbances such as acoustic noise impinging on the boundary layer around a translating bluff body. More generally, such problems fall within the purview of receptivity theory (e.g., Erturk and Corke [4], Morkovin [5]). We are concerned with the behavior in the vicinity of the stagnation point, where the body surface may be considered to be locally flat. In this context we allow for fluctuations of arbitrary amplitude and frequency.

Other studies pertinent to this modified Hiemenz problem include those by Grosch and Salwen [6] and Merchant and Davis [7]; among earlier investigations, we mention those by Matunobu [8], Pedley [9], and Ishigaki [10]; see also Lighthill [11]. Grosch and Salwen, while confining their attention to small free stream fluctuations, examined the flow when the frequency of these disturbances is either small or large. Expanding in power series in the disturbance amplitude and Fourier series in time, they showed that to leading order the low frequency case is merely a quasi-steady version of the classical Hiemenz solution, while the high frequency case exhibits a double boundary layer structure similar to that first discussed by Riley [12] and Stuart [2] for oscillating

flows. Merchant and Davis tackled the same unsteady Hiemenz problem, but also examined the flow structure when the mean component of the free stream is very much smaller than the oscillatory part. In this case a double boundary layer structure is once again revealed, although the authors showed that no solutions exist when the mean component of the free stream drops below a certain cut-off point. This is not to say that solutions with a different asymptotic form do not exist at smaller values of the free stream mean. We address this point in the current work.

Our interest in the problem was prompted by Hall and Papageorgiou's [13] recent study of unsteady incompressible flow induced in an infinite channel when the walls pulsate uniformly in space and periodically in time. Assuming a stagnation point structure for this flow, they demonstrated numerically the existence of purely periodic, quasi-periodic, and even chaotic flow solutions, depending on the frequency and amplitude of the wall motion. Our aim was to investigate the possibility of such varied dynamics for a periodically forced stagnation point flow in a semi-infinite domain. In fact, numerical solution of the unsteady Hiemenz problem shows that for many parameter values a singularity is encountered at a finite time. This eventuality is perhaps unsurprising in light of previous studies of colliding boundary layers or those in which the external flow reverses direction, where such singularities may also be found. One example is the flow over a rotating disk in a counter-rotating fluid, whose near-singularity structure was described by [14]. Another study of particular relevance to the current work is that by Riley and Vasantha [15], who considered the same problem as ours but with a purely oscillatory (zero mean) free stream. In this case the equations break down in finite time for any value of the forcing frequency. The breakdown was interpreted by Riley and Vasantha as the result of drifting fluid particles in the steady streaming layer accumulating at the stagnation point and ultimately causing an eruption of fluid from the boundary layer. The nature of the finite time singularity was found to have the same form as that occurring near the equator of an impulsively started sphere, as studied by Banks and Zaturska [16]. When the flow in the far field has nonzero mean, as is to be discussed here, the near-singularity structure is also described by Banks and Zaturska's analysis. The blow-up is not localized in space but occurs over the entire flow domain.

That the flow can break down when the mean component of the free stream is nonzero is not mentioned by either Grosch and Salwen or Merchant and Davis. However, the former authors demonstrate that the inclusion of a nonzero mean component in the free stream can allow the solution to be continued indefinitely without breakdown. We have found that this is true, provided that a condition between the fluctuation amplitude and frequency is not violated. The condition amounts to a threshold frequency, at any given amplitude, below which blow-up will occur but above which the solution remains regular. It is still conceivable that aperiodic or even chaotic solutions might exist in the large frequency limit, so long as this condition is satisfied. However, we have not been able to identify any such solutions despite extensive numerical searches. At all candidate parameter values tested, the solutions remain periodic with frequency equal to that of the free stream fluctuation. Nevertheless, the nature of the condition under which breakdown occurs is of interest, and in this sense our work constitutes a worthwhile extension of the previous studies.

We begin with a problem description, followed by a brief discussion of the numerical methods utilized to solve the governing equations. Results are then presented together with asymptotic analyses in the small and large frequency limits, and comparison is made between the two. We conclude with a short note on the axisymmetric version of the problem.

2. Problem statement and numerical method. The problem under consideration is that of two-dimensional unsteady Hiemenz flow approaching a flat plate. Referring to a set of Cartesian axes (x, y), the flat plate occupies $-\infty < x < \infty$, $y = 0$. We define velocity components $U_\infty u(x, y, t)$, $U_\infty v(x, y, t)$ in the x, y directions, respectively, where U_∞ is the typical flow speed in the far field. In this region the flow is potential, with $u = (x/l)U(t)$, $v = -(y/l)U(t)$, where

$$U(t) = 1 + \Delta \cos(\omega t) \tag{2.1}$$

for a chosen amplitude Δ and frequency ω. The remaining parameters are the kinematic viscosity ν and an arbitrarily chosen length scale l.

As in the steady case, it is reasonable to assume that the same simple velocity dependence on the x coordinate also applies in the viscous layer close to the plate. In this region we introduce the new coordinate $\eta = (y/l)R^{1/2}$ and set

$$u = \left(\frac{x}{l}\right) F_\eta(\eta, \tau), \qquad v = -R^{-1/2} F(\eta, \tau)$$

defining the Reynolds number to be $R = U_\infty l/\nu$ and introducing the new time variable $\tau = \omega t$. Note that we do not require R to be large. Finally, defining the Strouhal number

$$\sigma = \frac{\omega l}{U_\infty}$$

and setting $a(\tau) = 1 + \Delta \cos \tau$, we may express the wall layer system as

$$\sigma F_{\eta\tau} + F_\eta^2 - F F_{\eta\eta} = \sigma a_\tau + a^2 + F_{\eta\eta\eta}, \tag{2.2}$$

with

$$F(0, \tau) = F_\eta(0, \tau) = 0, \qquad F_\eta \to a(\tau) \quad \text{as} \quad \eta \to \infty, \tag{2.3}$$

to satisfy the solid wall boundary conditions and to match to the outer potential solution. When $\Delta = 0$, the problem reduces to that of classical steady Hiemenz flow. The temporally periodic part of (2.1) represents a superimposed disturbance on the steady far field solution. The response to this disturbance close to the plate is quantified by solving (2.2) and (2.3) for different values of the fluctuation amplitude Δ and the Strouhal number σ. We emphasize that Δ is not restricted to being small.

At this stage we note that functions satisfying (2.2) and (2.3) represent exact solutions of the Navier–Stokes equations since no approximations have been made. In addition, while the Reynolds number is not required to be large in this analysis, for ease of description we shall refer to the main flow governed by (2.2) as the Hiemenz boundary layer, even though no conventional boundary layer approximation is necessary.

Asymptotic solutions are possible in the limits of small and large frequency, and these will be discussed in a later section. For general values of the parameters (Δ, σ) numerical methods must be used to solve the wall layer equations. To expedite the numerical solution, we introduce the function $G = F_\eta$ and write the equations in the form

$$\sigma G_\tau + G^2 - F G_\eta = \sigma a_\tau + a^2 + G_{\eta\eta}, \tag{2.4a}$$

$$G = F_\eta, \tag{2.4b}$$

with

$$F(0,\tau) = G(0,\tau) = 0, \qquad G \to a(\tau) \quad \text{as} \quad \eta \to \infty. \tag{2.5}$$

We found that calculations should be started at $\tau = \pi/2$ rather than $\tau = 0$; otherwise, when $\Delta \gg 1$, the forcing is too large when the integration is initiated and the numerical solution blows up instantaneously. In practice, the initial profile makes negligible difference to the computation of the singular time, and calculations were always begun with $F = G = 0$. To march forwards in time we used either the second order accurate Crank–Nicholson method or the fourth order accurate Runge–Kutta integration, both with a second order accurate spatial discretization. Thus some independent numerical check on our results was available. Most of the results presented in this paper were computed using the latter of the two schemes. However, at various stages the computations were repeated using the Crank–Nicholson method, and these always provided good agreement. For large σ, we found it useful to introduce a stretched grid in order to insert many more points in the Stokes shear-wave layer next to the wall, where the most significant changes in the flow are concentrated. We present some of our results in the next section.

3. Analytical discussion and results. Grosch and Salwen [6] show that, for sufficiently small amplitude and in the limit of vanishing Strouhal number, the quasi-steady Hiemenz solution describes the flow to leading order. Specifically, to $O(\sigma)$, the solution may be written as $F = a(\tau)^{1/2} f(a^{1/2}\eta)$, where f satisfies the usual steady Hiemenz equation and boundary conditions. When $\sigma \to \infty$, again for small enough Δ, the solution adopts a double boundary layer structure, similar to that analyzed by Riley [12] and Stuart [2]. In this case the boundary layer splits into two regions. In the lower region, the Stokes layer, the solution is periodic to leading order. The nonlinear terms in the equations generate a small steady component, which persists to the upper reaches of the Stokes layer and acts to drive a steady streaming flow in the outer part of the Hiemenz boundary layer. For both small and large σ, Grosch and Salwen expanded in Taylor series in the amplitude Δ and Fourier series in time. While they were not able to determine the radius of convergence of their series exactly, they estimated that for large σ the series should converge when $\Delta < \sigma$. Later Merchant and Davis [7] showed that if both the amplitude and the Strouhal number are large, and if the thickness of the main boundary layer and the induced steady-streaming layer are chosen to coincide, then no solutions exist in our notation when $\Delta > 1.289\,\sigma^{1/2}$. This derives from the fact that the leading order steady-streaming equation has no solution when the amplitude exceeds this bound. However, this does not deny the existence of other solutions with a different boundary layer structure in these limits. In the Merchant and Davis flow structure the Stokes layer is linear to leading order. If instead we hypothesize that solutions exist wherein the nonlinear terms are of the same order of magnitude as the unsteady terms, corresponding to the scaling $\Delta \sim \sigma$ as $\sigma \to \infty$, we find that the equations for the leading order Stokes layer problem, with the appropriate matching condition at infinity, are the same as those studied by Riley and Vasantha [15]. These correspond to (2.2) and (2.3) with $a(\tau) = \cos\tau$. Riley and Vasantha's results show that these slightly reduced equations terminate in a singularity at a finite time for all values of σ. In due course we shall present numerical evidence that no regular solutions exist above the limit laid down by Merchant and Davis.

As a preliminary test of our codes, we computed small amplitude solutions and obtained results in excellent agreement with those of Grosch and Salwen. For large σ,

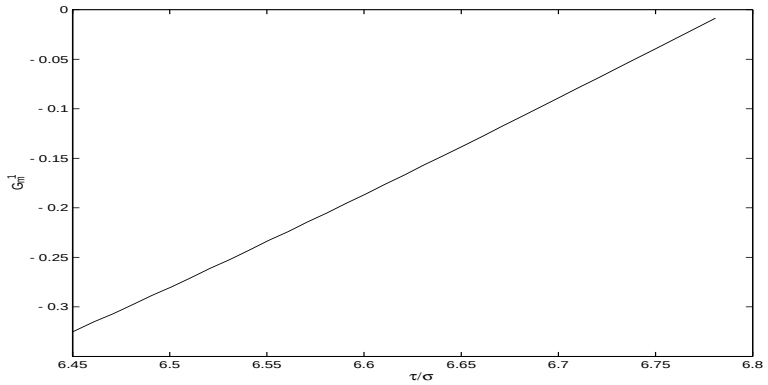

FIG. 3.1. $\Delta = 2.0$, $\sigma = 0.5$: *The locus of* $G_m^{-1} = 1/\min_\eta\{G\}$ *in time,* τ*, close to the singularity at* $\tau_s = 3.39$.

and for Δ of typical size $O(\sigma^{1/2})$, we compared our results with the first two terms in the asymptotic expansion of Merchant and Davis and again found that our numerics were in excellent agreement with the theory. For a fixed σ, however, we discovered that when the value of Δ exceeds a certain limit, the integration blows up at a finite time singularity. We shall henceforth label the singular time τ_s. The flow structure in the vicinity of τ_s is the same as that arising near the equator of an impulsively started sphere, a problem analyzed by Banks and Zaturska [16]. As the singularity is approached in that situation, the most important terms in the near-equator equations over the main part of the flow combine to mimic those of our own equation. Close to the singular time the flow acquires a three-tiered structure, with viscous zones at the wall and infinity sandwiching an inviscid core region. In this sense the flow is similar to that attained just prior to the breakdown which occurs a short time after the direction of a rotating disk is suddenly reversed. The near-singularity structure for this flow has been examined by Stewartson and Bodonyi [17] and corrected by Stewartson, Simpson, and Bodonyi [14]. (See also Ockendon [18] for a discussion of a steady rotating disk flow with a similar three-zone structure.) While Banks and Zaturska do not give the details of the flow in the upper and lower viscous regions, we have confirmed that the arguments of Stewartson, Simpson, and Bodonyi may be adapted accordingly. Further discussion of the viscous zones is suppressed. Instead we demonstrate that the flow behavior in the middle region is consistent with that of Banks and Zaturska. By comparison with their theory, in the main part of the flow we expect η to scale like $(\tau_s - \tau)^{-1/2}$, and thus we write $\widehat{\eta} = \eta(\tau_s - \tau)^{1/2}$. From their predictions we anticipate that $F \propto (\tau_s - \tau)^{-3/2}\phi(\widehat{\eta})$, and thus $G \propto (\tau_s - \tau)^{-1}$ as $\tau \to \tau_s^-$. As time progresses we observe that, at a given τ, the $G(\eta, \tau)$ profile has at most one local minimum G_m at $\eta = \eta_m$. Tracking the inverse of this minimum value up to the singular time for the case $\Delta = 2.0$, $\sigma = 0.5$, we plot the graph shown in Figure 3.1. The relationship between G_m^{-1} and τ appears convincingly linear. Assuming this to be the case, a more accurate value for τ_s may be predicted by means of linear interpolation. Similarly, plotting η_m^{-2} against τ close to the singular time reveals an apparent linear dependence which is equally compelling. The critical point dividing singular and periodic solutions at this frequency is $\Delta \approx 1.537$. As the amplitude approaches this value from above, we find that the singular time τ_s increases without bound.

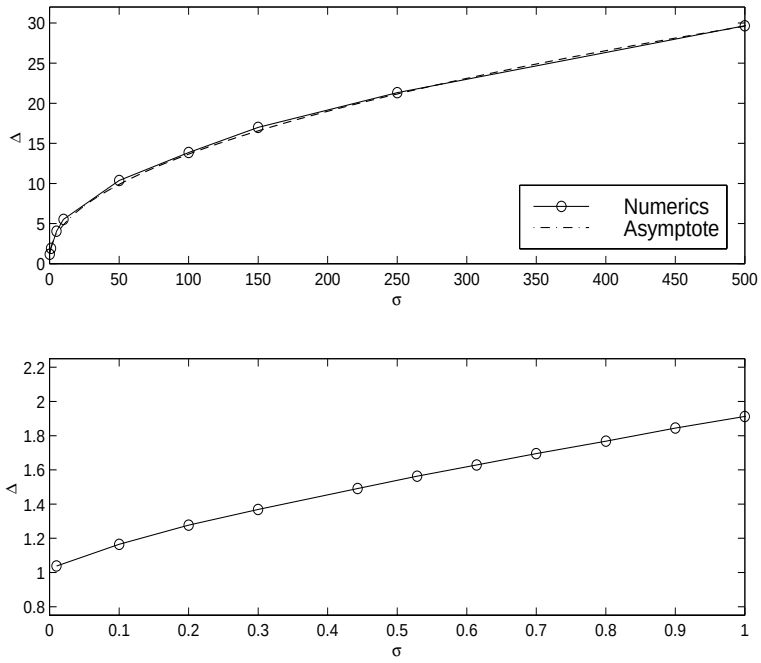

FIG. 3.2. *The barrier in* (Δ, σ) *parameter space between regular periodic solutions (below the line) and those which blow up in finite time (above the line). The lower graph shows the barrier close to* $\sigma = 0$. *The upper graph includes the asymptotic approximation* $\Delta \sim 1.289\sigma^{1/2} + 0.76$ *for large* σ *(see section* 3.1*).*

We now turn to the general picture in (Δ, σ) parameter space. Using the numerical procedure described above, we have identified the parametric regions in which the solutions either remain regular and periodic or else become singular in finite time. The parameter space is divided neatly into two regions by the curve depicted in Figure 3.2. We believe that points on this curve have been calculated accurately to within 0.1%. Flows corresponding to points (Δ, σ) lying below the curve are periodic, while those lying above eventually reach a singularity. We have calculated solutions up to and including $\sigma = 1000$ and, for the regular solutions, have encountered no bifurcations leading to aperiodic flows. Rather, the solutions remain periodic with the same period as that of the far field disturbance.

Also shown in Figure 3.2 is the asymptotic approximation valid for large values of σ, to be discussed shortly. Magnifying the curve in the region of zero frequency shows that it approaches unity as $\sigma \to 0$, suggesting that, for temporally slowly varying flows of this kind, only a small amount of flow reversal can be tolerated if the solution is to remain regular. This limit is discussed in due course.

When the disturbance frequency is large, the boundary layer supports a small steady flow component, driven by a residual slip velocity from a Stokes layer beneath. The analysis of Merchant and Davis suggests that no regular solutions exist when the amplitude is also large, specifically when $\Delta > 1.289\sigma^{1/2}$, since then the system governing the steady streaming component has no solution. In order to provide the best agreement between our numerical calculations and the large amplitude theory, we have found it worthwhile to compute the next term in this asymptotic expansion.

In what follows, we therefore supply a brief description of the asymptotic flow at large frequencies.

3.1. Large amplitude and frequency. It is convenient at this stage to rescale (2.2), (2.3) by writing $\eta = \Delta^{-1/2}\widehat{\eta}$, $F = \Delta^{-1/2}\widehat{F}$, $\sigma = \Delta\Omega$ and introducing the small parameter $\varepsilon = 1/\Delta$. This leads to the equivalent system:

$$\Omega\widehat{F}_{\widehat{\eta}\tau} + \widehat{F}_{\widehat{\eta}}^2 - \widehat{F}\widehat{F}_{\widehat{\eta}\widehat{\eta}} = -\Omega\sin\tau + (\varepsilon + \cos\tau)^2 + \widehat{F}_{\widehat{\eta}\widehat{\eta}\widehat{\eta}}, \tag{3.1}$$

with

$$\widehat{F}(0,\tau) = \widehat{F}_{\widehat{\eta}}(0,\tau) = 0, \quad \widehat{F}_{\widehat{\eta}} \to \varepsilon + \cos\tau \quad \text{as} \quad \widehat{\eta} \to \infty. \tag{3.2}$$

Now, when ε is small and Ω is large, we look for solutions with $\varepsilon = a_0\Omega^{-1} + a_1\Omega^{-2} + \cdots$. In the Stokes layer, of thickness $O(\Omega^{-1/2})$, the expansion proceeds as

$$\widehat{F} = \Omega^{-1/2}\phi_0(\xi,\tau) + \Omega^{-3/2}\phi_1(\xi,\tau) + \cdots, \tag{3.3}$$

where $\xi = \Omega^{1/2}\widehat{\eta}$ is a scaled coordinate normal to the wall. The first order solution is given by

$$\phi_0(\xi,\tau) = \xi\cos\tau - \cos\left(\tau - \frac{\pi}{4}\right) + \mathrm{e}^{-\xi/\sqrt{2}}\cos\left(\tau - \frac{\xi}{\sqrt{2}} - \frac{\pi}{4}\right). \tag{3.4}$$

At second order, the solution may be written as $\phi_1(\xi,\tau) = \frac{1}{2}\phi_M(\xi,\tau)$, where ϕ_M is a somewhat lengthy expression appearing as formula (3.20c) of Merchant and Davis's paper. As pointed out by Stuart [2], it is not possible to satisfy the infinity condition at this order; rather a steady slip velocity persists at the top of the Stokes layer, driving a steady streaming motion above. Therefore we simply note at this stage that $\phi_{1\xi}(\infty,\tau) = -3/4$.

With the current choice of scaling, the streaming layer has the same thickness as the Hiemenz boundary layer (of order $\Omega^{1/2}$ in this notation). Introducing the new coordinate $\zeta = \Omega^{-1/2}\widehat{\eta}$, the relevant expansion is

$$\widehat{G} = \Omega^{-1/2}\{\psi_0(\zeta,\tau) + f_0(\zeta)\} + \Omega^{-3/2}\{\psi_1(\zeta,\tau) + f_1(\zeta)\} + \cdots, \tag{3.5}$$

where $\widehat{G} = \widehat{F} - \Omega^{1/2}\zeta\cos(\tau) - \Omega^{-1/2}\cos(\tau - \pi/4)$. The functions ψ_i equal zero when averaged over a single time period. In fact $\psi_0 \equiv 0$, and the first order streaming problem is given by

$$f_0''' + f_0 f_0'' - f_0'^2 + a_0^2 = 0, \tag{3.6}$$

with

$$f_0(0) = 0, \quad f_0'(0) = \frac{-3}{4}, \quad f_0'(\infty) = a_0. \tag{3.7}$$

A numerical treatment of this problem by both Merchant and Davis and also by Riley and Weidman [19] indicates that a unique solution exists when $0 < a_0 < 3/4$, two solutions exist when $3/4 < a_0 < a_{0c}$, and no solutions exist when $a_0 > a_{0c}$, where $a_{0c} \approx 0.602$. Continuing, we derive the second order streaming problem:

$$f_1''' + f_0 f_1'' - 2f_0' f_1' + f_0'' f_1 = \frac{1}{2\sqrt{2}}f_0'' - 2a_0 a_1, \tag{3.8}$$

with

$$f_1(0) = \frac{13}{4\sqrt{2}}, \quad f_1'(0) = 0, \quad f_1'(\infty) = a_1. \tag{3.9}$$

Taking $a_1 = 0$ should reduce the problem to the corresponding equation of Merchant and Davis. However, we remark that this leaves a right-hand side proportional to f_0'', which is absent in that paper and which we believe should be included.

Our concern now is to calculate a_1 when $a_0 = a_{0c}$. Numerical trials suggest that a solution exists for the value $a_1 = -0.55$ and is unique. Reverting to our original notation, the asymptotic approximation for the critical amplitude proceeds as

$$\Delta = 1.29\sigma^{1/2} + 0.76 + O(\sigma^{-1/2}) \qquad \text{as} \quad \sigma \to \infty.$$

This is plotted in Figure 3.2 along with our full numerical results. It provides strong evidence that it is this asymptote which defines the barrier between large frequency solutions remaining regular and periodic and those encountering a finite time singularity.

3.2. Small frequency. We now focus our attention on small frequency solutions. The numerical calculations suggest that the barrier between regular and singular solutions approaches $\Delta = 1$ as $\sigma \to 0$ (see Figure 3.2). Naturally, when $\sigma = 0$ we obtain classical Hiemenz flow and therefore expect steady solutions at any amplitude. In this sense we expect $\sigma \to 0$ to be a singular limit. While considering a similar flow but with zero mean at infinity, Riley and Vasantha [15] showed that the singular time grows without bound as the fluctuation frequency tends to zero. Paralleling their analysis, we now examine the solution close to $\sigma = 0$.

When both the frequency and amplitude are small, the flow follows the quasi-steady solution given by Grosch and Salwen [6] and mentioned above in section 3. However, if the amplitude equals or exceeds unity, $a(\tau)$ has a zero at $\tau = \tau_0$, where $\tau_0 = \pi - \cos^{-1}(1/\Delta)$. In what follows, $\Delta - 1$ is assumed to be nonnegative (but not necessarily small) so that $a(\tau)$ has such a zero. The quasi-steady approximation will break down when τ approaches τ_0, as the unsteady terms, which were hitherto small, grow to become comparable in size with the others. A consideration of the relative magnitudes of terms in (2.2) suggests that the quasi-steady approximation will become invalid when $a(\tau) = O(\sigma^{1/2})$.

In the vicinity of $\tau = \tau_0$, a balance of the terms in (2.2) suggests the scalings

$$(\tau_0 - \tau) = \sigma^{1/2}T, \quad \eta = \sigma^{-1/4}Y, \quad F = \sigma^{1/4}\widetilde{F}(Y,T)$$

for new order one variables T, Y, $\widetilde{F}$. Neglecting terms of order $o(\sigma^{4/3})$, the governing system reduces to

$$-\widetilde{F}_{YT} + \widetilde{F}_Y^2 - \widetilde{F}\widetilde{F}_{YY} = -\mu + \mu^2 T^2 + \widetilde{F}_{YYY}, \tag{3.10a}$$

$$\widetilde{F}(0,T) = \widetilde{F}_Y(0,T) = 0, \quad \widetilde{F}_Y \to \mu T \quad \text{as} \quad Y \to \infty, \tag{3.10b}$$

where $\mu = (\Delta - 1)^{1/2}$. As $T \to \infty$, $\widetilde{F}$ must match to the quasi-steady Hiemenz solution. We initiate the calculation at $T = T_\infty$, where T_∞ is sufficiently large, with the profile

$$\widetilde{F} = \left(\frac{\mu T}{T_\infty}\right)^{1/2} f(x), \quad \text{with} \quad x = \left(\frac{\mu T}{T_\infty}\right)^{1/2} Y,$$

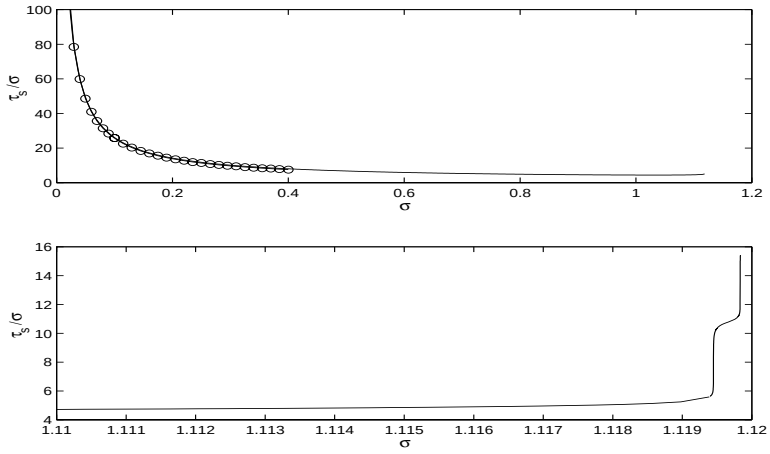

FIG. 3.3. *Variation of τ_s with σ when $\Delta = 2.0$. Top: τ_s in the singular window $\sigma \in (0, 1.12)$, plotted with the approximation $\tau_s/\sigma = 2\pi/3\sigma + 1.51/\sigma^{1/2}$ valid as $\sigma \to 0$ (shown as circles). Bottom: Magnification of the curve close to $\sigma = 1.12$.*

where $f(x)$ satisfies a scaled version of the steady Hiemenz equations. The system (3.10) is then integrated backwards in time T, using a Crank–Nicholson method. For all cases considered, the integration terminates at a singularity after a finite time. The singular time T_s is computed using an interpolation procedure similar to that mentioned above for the full numerics.

For the particular case $\Delta = 2.0$, we have computed $T_s = -1.51$. Thus we predict that

$$\frac{\tau_s}{\sigma} = \frac{2\pi}{3\sigma} + \frac{1.51}{\sigma^{1/2}} + \cdots \quad \text{as} \quad \sigma \to 0. \tag{3.11}$$

In Figure 3.3 we show how this estimate compares with the calculated values of τ_s at small frequency obtained by solving the full system (2.2), (2.3). The agreement is very satisfactory. The flow becomes singular for all frequencies in the window $\sigma \in (0, 1.12)$, beyond which we cross the barrier in Figure 3.2 and the solutions become periodic. It is interesting to note that as $\sigma \to 1.12^-$, the curve begins to wiggle, a behavior reminiscent of that seen in Riley and Vasantha's problem.

In summary of this short section, we remark that low frequency solutions can become singular as long as $\Delta \geq 1$. When $\Delta < 1$, this is not possible, and the flow is quasi-steady and periodic. These conclusions are in agreement with the picture presented in Figure 3.2, where the barrier between regular and irregular solutions approaches unit fluctuation amplitude as the frequency tends to zero.

4. Axisymmetric stagnation point. As a final note, we remark that behavior similar to that described in the previous sections is encountered at an axisymmetric stagnation point. In this case we envisage flow hitting a flat surface and spreading out radially from the stagnation point in the middle. An exact similarity solution with linear dependence in the radial coordinate may then be sought. If we confine our attention to the case in which there is no azimuthal variation, we find that the governing equation and boundary conditions for this flow are almost exactly the same as those for the two-dimensional case, the only difference arising in the nonlinear term,

where $-2FF_{\eta\eta}$ appears instead of $-FF_{\eta\eta}$. By analogy with our preceding work, an amplitude Δ and Strouhal number σ may be defined. Riley [20] has studied this flow in detail when the infinity condition has zero mean, and his results suggest that, in common with the two-dimensional stagnation point looked at by Riley and Vasantha, finite time breakdown occurs for all values of the frequency parameter σ. The flow with nonzero mean at infinity may also be studied and, as in the two-dimensional case, we find that the flow breaks down at a fixed σ as soon as a critical value of Δ is exceeded. A steady-streaming analysis analogous to that performed above again agrees well with the numerically computed results. Unfortunately we once more find no evidence of aperiodic solutions as σ is increased (with Δ remaining below the critical curve for regular solutions).

5. Concluding remarks. We have investigated unsteady stagnation point flow of a modified Hiemenz type. Previously Grosch and Salwen [6] investigated this problem for small fluctuation amplitudes in the low and high frequency limits. Merchant and Davis [7] also considered the large amplitude, high frequency limits, establishing an asymptotic structure in which the streaming region above the Stokes layer is the same thickness as the Hiemenz boundary layer. We have studied the same flow and, for general parameter values, provided numerical evidence that for all frequencies there exists a threshold value of the amplitude beyond which the flow will break down in finite time. The flow structure in the vicinity of the singularity is the same as that arising near the equator of an impulsively started sphere, reported by Banks and Zaturska [16]. Below the threshold value, the solutions are regular and periodic, with period equal to that of the free stream disturbance; in the limit of small frequency, they correspond to the solutions presented by Grosch and Salwen. We have also conducted asymptotic analyses at small and large frequency to predict the dividing line between singular and periodic solutions in these limits. Both have been successfully compared with the results of numerical simulations.

In an earlier study, Riley and Vasantha [15] showed that the same problem with zero mean flow in the free stream breaks down for all possible frequencies. However, when there exists a small mean flow in the free stream, corresponding to the limit of large disturbance amplitude in our problem, our work shows that the solution becomes singular in finite time only when the frequency is smaller than a given value proportional to the square of the amplitude. All frequencies exceeding this value lead to regular, periodic solutions.

SYSTEM OF PHASE OSCILLATORS WITH DIAGONALIZABLE INTERACTION*

TAKASHI NISHIKAWA† AND FRANK C. HOPPENSTEADT†

Abstract. We consider a system of N phase oscillators having randomly distributed natural frequencies and diagonalizable interactions among the oscillators. We show that, in the limit of $N \to \infty$, all solutions of such a system are incoherent with probability one for any strength of coupling, which implies that there is no sharp transition from incoherence to coherence as the coupling strength is increased, in striking contrast to Kuramoto's (special) oscillator system.

Key words. network of phase oscillators, Kuramoto model

DOI. 10.1137/S0036139902411132

1. Introduction.

Synchronization of coupled oscillators is a ubiquitous phenomenon in natural and artificial systems. Examples include synchronization of pacemaker cells of the heart [11, 12], rhythmic activities in the brain [4, 13], synchronous flashing of fireflies [1, 2], arrays of lasers [8, 9], and superconducting Josephson junctions [18, 19]. Characterization of the phenomenon using mathematical models has been a topic of great interest for researchers in various scientific and engineering disciplines.

Wiener [16, 17], who recognized the ubiquity of synchronization phenomena in the real world, made a first attempt at characterization using the Fourier integrals. A more successful approach was taken by Winfree [20], who used a population of interacting limit-cycle oscillators to describe synchronization properties. He realized that if the interactions among the oscillators are weak and the oscillators are nearly identical, the separation of fast and slow timescales leads to a reduced model that can be expressed in terms solely of the phase of each oscillator. Kuramoto [10] put this idea on a firmer foundation by employing a perturbation method to show that the reduced equation has a universal form. His analysis of this model in the case of mean-field coupling kicked off an avalanche of theoretical investigations of his model and its generalizations.

More generally and rigorously, if each oscillator has an exponentially stable limit-cycle and interactions among them are weak, the reduced phase equation can be shown (see [6, Theorem 9.1, p. 253]) to have the form

$$\dot{\theta} = \omega + \varepsilon f(\theta), \qquad \theta \in \mathbb{T}^N, \tag{1.1}$$

where $\omega \in \mathbb{R}^N$ is the vector of natural frequencies of the oscillators that are coupled to one another through the interaction function $f : \mathbb{T}^N \to \mathbb{R}^N$, and $\varepsilon > 0$ represents the overall strength of the coupling. The universal form of the interaction function, derived by Kuramoto [10] under the additional assumption that the oscillators are

almost identical, corresponds to the choice

$$f_i(\theta) = \sum_{j=1}^{N} h_{ij}(\theta_j - \theta_i), \qquad i = 1, \dots, N, \tag{1.2}$$

where $f(\theta) = (f_1(\theta), \dots, f_N(\theta))^T$. The mean-field model that he studied results when $h_{ij}(x) = \sin(x)/N$ for all i, j.

Let $\theta(t)$ be a solution of (1.1). The oscillators i and j are said to be *locked* if $\lim_{t\to\infty} \theta_i(t)/\theta_j(t) = 1$. The solution is said to be *coherent* if all pairs of oscillators are locked. If none of the oscillator pairs are locked, the solution is *incoherent*. A solution that is neither coherent nor incoherent is called *partially coherent*. The main conclusion of Kuramoto's work [10] on his mean-field model is that in the limit of $N \to \infty$ there exists a critical coupling strength ε_c such that for $\varepsilon < \varepsilon_c$ the solution is incoherent, but for $\varepsilon > \varepsilon_c$ partially coherent solutions appear, for which the fraction of locked oscillator pairs is nonzero. Although his result was important, since this behavior closely resembles the phase transition phenomena widely observed in statistical physics, his analysis is heuristic and makes assumptions about the symmetry of the distribution of natural frequencies, which might not be necessary for the results [14].

In this paper, we consider a class of *diagonalizable* interaction functions, in which separation of variables is possible after an appropriate coordinate transformation. This allows us to prove rigorously that for the system (1.1) with a generic diagonalizable interaction function, if the solution is partially coherent, then it is almost surely coherent. This, together with the fact that the probability of having a coherent solution goes to zero in the limit of $N \to \infty$, leads to our main conclusion. Namely, for any $\varepsilon > 0$, the solution is almost surely incoherent in the limit of $N \to \infty$. Our result shows that a diagonalizable system of phase oscillators cannot exhibit a sudden transition from incoherence to coherence, in sharp contrast to the mean-field model of Kuramoto. This implies that for the system (1.1) to exhibit a phase transition, the interaction function f cannot be diagonalized.

There is an alternative rigorous approach to Kuramoto's mean-field model, in which the partial differential equation for the density of oscillators with certain frequency, which is obtained by taking the continuum limit $N \to \infty$, is studied to analyze the stability of the solutions. See [15] for an excellent review in this direction.

The approach taken here is similar to that in [5, p. 80]. However, some conclusions made there might be misleading or lack detailed analysis. This paper is intended to correct and clarify those points.

The rest of the paper is organized as follows. In section 2, we introduce an appropriate change of variables to separate a time-like variable from the rest of the system. In section 3, we define diagonalizable interaction and show how complete separation of variables can be achieved. We also establish some properties of diagonalizable systems. Then, in section 4, we introduce randomness of the natural frequencies of the oscillators and state our main results. Finally, we discuss some approximate behavior of the system for large N in section 6, and section 7 is reserved for concluding remarks.

2. Separation of the time-like variable. In this and the following sections, we consider the system (1.1) of N phase oscillators, where the natural frequency vector ω and the coupling strength ε are fixed (nonrandom) constants. We will consider ω to be a random vector in section 4 in order to make probabilistic statements about the system.

Let us suppose that the interaction function f satisfies two conditions,

(C1) $\mathbf{1}^T f(\theta) = \mathbf{0}$ for all $\theta \in \mathbb{T}^N$ and
(C2) $f(v\mathbf{1} + \theta) = f(\theta)$ for all $\theta \in \mathbb{T}^N$,
where $\mathbf{1} = (1/\sqrt{N}, \dots, 1/\sqrt{N})^T$. The condition (C1) says that the interaction function is orthogonal to the vector $\mathbf{1}$. The second condition (C2) expresses the translation invariance of f along the direction of $\mathbf{1}$. If, for example, the interaction function has the form (1.2), these conditions are satisfied if the functions h_{ij} are odd. In particular, the mean-field model of Kuramoto does satisfy these conditions.

Under conditions (C1) and (C2), the system (1.1) can be separated into two independent systems—one for the time-like variable and the other for the phase deviations.

Let W be an $N \times (N-1)$ matrix whose columns, denoted by W_j, $j = 1, \dots, N-1$, form an orthonormal basis of the subspace $\mathbf{1}^\perp \equiv \{x \in \mathbb{R}^N : \mathbf{1}^T x = 0\}$. In other words, W is an $N \times (N-1)$ matrix that satisfies $\mathbf{1}^T W = \mathbf{0}$ and $W^T W = I_{N-1}$, where I_{N-1} is the $(N-1) \times (N-1)$ identity matrix. Then, the change of variable

$$\theta = v\mathbf{1} + Wu \tag{2.1}$$

converts the system (1.1) into two systems,

$$\dot{v} = \mathbf{1}^T \omega, \tag{2.2}$$

$$\dot{u} = W^T \omega + \varepsilon W^T f(Wu), \tag{2.3}$$

which can be solved separately.

Systems satisfying the conditions (C1) and (C2) arise in mathematical neuroscience [5, 6], in which θ often takes the form $\omega t + \phi$ in the limit $t \to \infty$, where ω is the vector of carrier frequencies and ϕ is the vector of phase deviations. The equation (2.3), in some sense, governs the behavior of the phase deviations.

The solution to (2.2) is $v(t) = v(0) + (\mathbf{1}^T \omega)t$, and hence the variable v is time-like if $\mathbf{1}^T \omega \neq 0$ or, equivalently, if the average natural frequency $\sum_i \omega_i / N$ is nonzero. Thus, the behavior of the solution of (1.1) is essentially determined by (2.3).

Recall that the solution is called coherent if $\lim_{t\to\infty} \theta_i(t)/\theta_j(t) = 1$. This can be rephrased in terms of the vector $\mu \equiv \lim_{t\to\infty} u(t)/t$ of output frequencies of the u-equation (2.3), if it exists.

LEMMA 2.1. *Let $u(t)$ be a solution of (2.3), and suppose that $\mu \equiv \lim_{t\to\infty} u(t)/t$ exists. Then, the solution of (1.1) is coherent if and only if $\mu = 0$.*

Proof. Let $\Omega = \lim_{t\to\infty} \theta(t)/t = (\mathbf{1}^T \omega)\mathbf{1} + W\mu$. Then $\mu = 0$ implies that $\Omega = (\mathbf{1}^T \omega)\mathbf{1}$, which in turn implies that $\lim_{t\to\infty} \theta_i(t)/\theta_j(t) = 1$.

Conversely, if $\lim_{t\to\infty} \theta_i(t)/\theta_j(t) = 1$, Ω must be a multiple of $\mathbf{1}$. Since W is orthogonal to $\mathbf{1}$, this implies that $W\mu = 0$. Since W is invertible, it follows that $\mu = 0$. ∎

As an immediate consequence of Lemma 2.1, if the solution of (2.3) tends to an equilibrium, then the corresponding solution of (1.1) is coherent. For example, if the interaction function f that satisfies (C1) and (C2) is a gradient vector field, i.e., $f(\theta) = -\nabla V_0(\theta)$ for some potential function $V_0 : \mathbb{T}^N \to \mathbb{R}$, then the u-equation (2.3) is also a gradient system:

$$\dot{u} = -\nabla \left[-\omega^T W u + \varepsilon V(u) \right], \tag{2.4}$$

where $V(u) = V_0(Wu)$. A minimum u^* of the potential function $-\omega^T W u + \varepsilon V(u)$ then corresponds to the vector of phase deviations for a coherent solution of the original oscillator system (1.1). As in the proof of Lemma 2.1, we have $\Omega = (\mathbf{1}^T \omega)\mathbf{1}$ in this case, meaning that the output frequency of every oscillator tends to the mean natural

frequency $\bar{\omega} \equiv \sum_i \omega_i/N$ of the oscillators. For the interaction of the form (1.2), the potential function takes the form

$$V(u) = -\frac{1}{2N}\sum_{i=1}^{N}\sum_{j=1}^{N} H_{ij}(\theta_i - \theta_j) = -\frac{1}{2N}\sum_{i=1}^{N}\sum_{j=1}^{N} H_{ij}\left(\sum_{k=1}^{N-1}[W_{ik} - W_{jk}]u_k\right),$$

where $H_{ij}(x) \equiv \int_0^x h_{ij}(y)dy$.

3. Diagonalizable interaction. Assuming that the interactions among the oscillators are diagonalizable enables us to carry out a rigorous analysis of the system.

DEFINITION 3.1. *We say that the system* (1.1) *(or the interaction function f) is* diagonalizable *if there exist an $N \times (N-1)$ matrix W and real, continuous, periodic functions p_j such that*

(i) $\mathbf{1}^T W = \mathbf{0}$,
(ii) $W^T W = I_{N-1}$, *and*
(iii) $f(Wu) = Wp(u)$ *with* $p(u) = (p_1(u_1), \dots, p_{N-1}(u_{N-1}))^T$.

For example, $W = W^{(N)}$ defined by

$$\begin{aligned} W_{jk}^{(N)} &= \frac{1}{\sqrt{N}}\left(\sin\frac{2\pi jk}{N} + \cos\frac{2\pi jk}{N}\right) \\ &= \frac{2}{\sqrt{N}}\sin\left(\frac{2\pi jk}{N} + \frac{\pi}{4}\right) \end{aligned} \tag{3.1}$$

satisfies these conditions.

When the system (1.1) is diagonalizable, the equations for the components of u become independent of other components:

$$\dot{u_j} = a_j + \varepsilon p_j(u_j), \qquad j = 1, \dots, N-1, \tag{3.2}$$

where we set $a_j = W_j^T \omega$. Thus, the problem is reduced to solving a scalar differential equation for each j. The following lemma applies to each equation in (3.2).

LEMMA 3.2. *Let $\varepsilon > 0$, and let a be a real number. Let $p(u)$ be a real, continuous, periodic function with period $L > 0$. Define $m = \min_{0\le u<L} p(u)$, $M = \max_{0\le u<L} p(u)$. For any solution $u(t)$ of $\dot{u} = a + \varepsilon p(u)$, the limit $\mu_p(a,\varepsilon) \equiv \lim_{t\to\infty} u(t)/t$ exists and*

$$\mu_p(a,\varepsilon) = \begin{cases} L/T(a,\varepsilon), & a < -\varepsilon M,\ a > -\varepsilon m, \\ 0, & -\varepsilon M \le a \le -\varepsilon m, \end{cases} \tag{3.3}$$

where

$$T(a,\varepsilon) \equiv \int_0^L \frac{du}{a + \varepsilon p(u)}$$

is the "period" of the solution in the case of $a < -\varepsilon M$ or $a > -\varepsilon m$, in the sense that $u(t + T(a,\varepsilon)) = u(t) + L$.

Proof. If $-\varepsilon M \le a \le -\varepsilon m$, then any solution $u(t)$ tends to a zero of the function $a + \varepsilon p(u)$. Hence, $\mu_p(a,\varepsilon) = 0$.

For notational simplicity, let us drop the dependence of $T(a,\varepsilon)$ on a and ε below. Suppose $a > -\varepsilon m$, so that $a + \varepsilon p(u) > 0$ for all u. It is straightforward to show that the function $u(t)$ defined implicitly by the formula

$$\int_{u_0}^{u(t)} \frac{du}{a + \varepsilon p(u)} = t$$

is the unique solution of $\dot{u} = a + \varepsilon p(u)$ with the initial condition $u(0) = u_0$, and that it satisfies $u(t+T) = u(t) + L$. We have

$$\begin{aligned}\mu_p(a,\varepsilon) &= \lim_{t\to\infty} \frac{u(t)}{t} \\ &= \lim_{t\to\infty} \frac{1}{t}\left(u_0 + \int_0^t [a + \varepsilon p(u(s))]ds\right) \\ &= a + \varepsilon \lim_{t\to\infty} \frac{1}{t}\int_0^t p(u(s))ds.\end{aligned}$$

Let n be the largest integer for which $nT \le t$. Then, by changing the variables in each integral using the translation by multiples of T, we see that

$$\begin{aligned}\int_0^t p(u(s))ds &= \sum_{k=1}^{n} \int_{(k-1)T}^{kT} p(u(s))ds + \int_{nT}^{t} p(u(s))ds \\ &= n\int_0^T p(u(s))ds + \int_0^{t-nT} p(u(s))ds.\end{aligned}$$

Consequently,

$$\begin{aligned}\left|\frac{1}{t}\int_0^t p(u(s))ds - \frac{1}{T}\int_0^T p(u(s))ds\right| &= \left|\left(\frac{n}{t} - \frac{1}{T}\right)\int_0^T p(u(s))ds + \frac{1}{t}\int_0^{t-nT} p(u(s))ds\right| \\ &\le \frac{|nT-t|}{tT}\int_0^T |p(u(s))|ds + \frac{1}{t}\int_0^{t-nT} |p(u(s))|ds \\ &\le \frac{T}{tT}\, T\max\{|m|,|M|\} + \frac{1}{t}\, T\max\{|m|,|M|\} \\ &\to 0\end{aligned}$$

as $t \to \infty$, showing that the limit $\lim_{t\to\infty} \frac{1}{t}\int_0^t p(u(s))ds$ exists and is equal to $\frac{1}{T}\int_0^T p(u(s))ds$. Thus, by changing variables from s to u and translating by u_0, we see that $\mu_p(a,\varepsilon)$ exists and

$$\begin{aligned}\mu_p(a,\varepsilon) &= a + \frac{\varepsilon}{T}\int_0^T p(u(s))ds \\ &= a + \frac{\varepsilon}{T}\int_0^L \frac{p(u)du}{a + \varepsilon p(u)} \\ &= \frac{L}{T}.\end{aligned}$$

If $a < -\varepsilon M$, then, by replacing u with $-u$, a with $-a$, ε with $-\varepsilon$, and m with M, the problem reduces to the previous case. The lemma is proved. □

The function $\mu_p(\cdot,\varepsilon)$ in Lemma 3.2, which can easily be shown to be differentiable with positive derivative outside the interval $[-\varepsilon M, \varepsilon M]$, determines the relationship between the input frequency a and the output frequency $\mu_p(a,\varepsilon)$. If we take $p(u) = \sin(u)$, for example, the integration in the expression of μ_p can be carried out, and we get

$$\mu_p(a,\varepsilon) = \begin{cases} -\sqrt{a^2-\varepsilon^2}, & a < -\varepsilon, \\ 0, & -\varepsilon \le a < \varepsilon, \\ \sqrt{a^2-\varepsilon^2}, & a \ge \varepsilon, \end{cases}$$

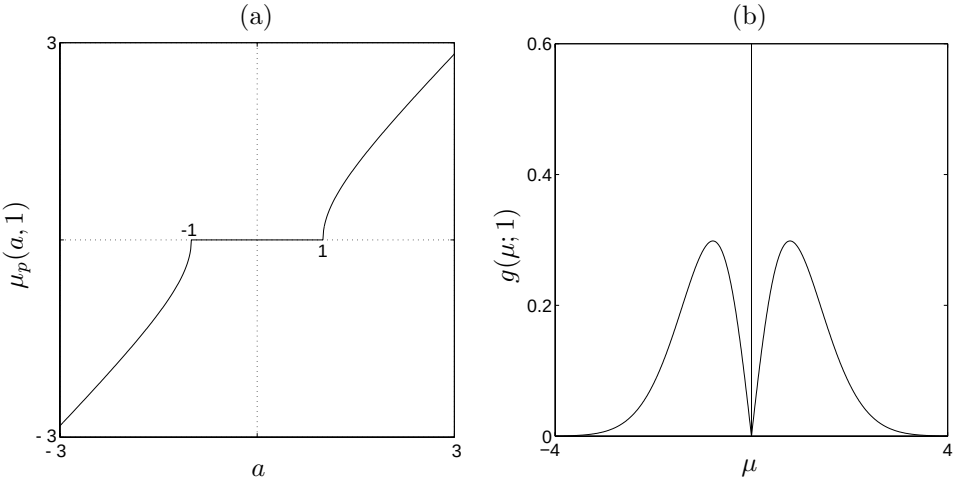

FIG. 3.1. (a) *The graph of the input-output frequency function* $\mu_p(a,\varepsilon)$ *versus* a *for* $\varepsilon = 1$ *and* $p(u) = \sin(u)$. (b) *The corresponding density* $g(\mu;1)$ *when* a *is the standard Gaussian random variable.*

the graph of which is given in Figure 3.1(a) for $\varepsilon = 1$. With this function, the output frequency vector μ of the u-equation (2.3) can be written as

$$\mu = \mu(a) = (\mu_{p_1}(a_1,\varepsilon), \dots, \mu_{p_{N-1}}(a_{N-1},\varepsilon))^T.$$

It is important to note here that μ does *not* depend on the initial condition $u(0) = u_0$, which implies that it is also independent of the initial condition for θ. In other words, the initial condition for the system (1.1) does not affect the behavior of its solution, as far as its coherence properties are concerned. Therefore, in this sense, coherence, partial coherence, and incoherence are properties of the system rather than of individual solutions for a diagonalizable system.

4. Randomly distributed frequencies. In this section we consider ω to be a random vector in $\mathbb{R}^N$. We take the components $\omega_1, \dots, \omega_N$ of ω to be independent and identically distributed (i.i.d.) random variables with mean 0 and variance $\sigma^2 > 0$. In the general case of mean $\omega_0 \neq 0$, the problem can always be reduced to the zero-mean case by the translation of θ by $-\omega_0 t$.

Since ω is random, the vectors a and μ are also random vectors in $\mathbb{R}^{N-1}$. Lemma 3.2 along with the relation $a = W^T\omega$ can be used to determine the distribution of μ from the distribution of ω. For example, if each ω_j is standard Gaussian, then so is each a_j, in which case the density $g(\mu;\varepsilon)$ for the random variable $\mu_p(a_j,1)$ when $p(u) = \sin(u)$ can be computed. The result is

$$g(\mu;\varepsilon) = \frac{|\mu| e^{-(\mu^2+\varepsilon^2)/2}}{\sqrt{2\pi(\mu^2+\varepsilon^2)}} + \delta(\mu)\,\mathrm{erf}\left(\frac{\varepsilon}{\sqrt{2}}\right),$$

where $\delta(\mu)$ is Dirac's delta function. The graph of this density is shown in Figure 3.1 for $\varepsilon = 1$.

Our main goal is this section is to compute the probabilities that the system (1.1) is coherent, partially coherent, or incoherent. The following theorem reveals a curious property of a generic diagonalizable system of phase oscillators.

THEOREM 4.1. *Let the natural frequency vector ω be a random vector in $\mathbb{R}^N$, whose components are i.i.d. with a common continuous distribution. Suppose that* (1.1) *is a diagonalizable system of N phase oscillators such that W satisfies the condition that $W_{ki} \neq W_{kj}$ for all $k = 1, 2, \dots, N$ and for all $i, j = 1, 2, \dots, N-1$ such that $i \neq j$. Then, the partial coherence of the system almost surely implies coherence; i.e., given that the system is partially coherent, the probability that it is coherent is one.*

Proof. Once again, let $\Omega(\omega) = \lim_{t\to\infty} \theta(t)/t = (\mathbf{1}^T\omega)\mathbf{1} + W\mu(\omega)$. Let S_c be the set of ω in $\mathbb{R}^N$ that corresponds to coherent systems, i.e., $S_c = \{\omega \in R^N : \Omega(\omega) = \mathbf{0}\}$. By Lemma 2.1, we may also write $S_c = \{\omega \in R^N : \mu(\omega) = \mathbf{0}\}$. Let S_{pc} be the set corresponding to partially coherent systems, that is, $S_{pc} = \{\omega \in R^N : \Omega_i(\omega) = \Omega_j(\omega)$ for some $i \neq j\}$. It is easy to see that we can also rewrite this in terms of μ as

$$\begin{aligned} S_{pc} &= \left\{ \omega \in R^N : \text{ There are } i \neq j \text{ s.t. } \sum_{k=1}^{N-1} (W_{ki} - W_{kj})\mu_k(\omega) = 0 \right\} \\ &= \bigcup_{i\neq j} \left\{ \omega \in R^N : \sum_{k=1}^{N-1} (W_{ki} - W_{kj})\mu_k(\omega) = 0 \right\} \equiv \bigcup_{i\neq j} S_{pc}^{(i,j)}. \end{aligned}$$

The probability that the system is coherent, given that the system is partially coherent, is $P(S_c)/P(S_{pc})$ since $S_c \subset S_{pc}$. This probability is one if and only if $P(S_{pc} \setminus S_c) = 0$, which would be satisfied if $P(S_{pc}^{(i,j)} \setminus S_c) = 0$ for every pair $i \neq j$. We shall show this next.

Let us fix i and j. For any $A \subset \{1, 2, \dots, N-1\}$, denote by Z_k the subspace $\{\mu \in \mathbb{R}^{N-1} : \mu_k = 0\}$, and let $Z_A = \bigcup_{k\in A} Z_k$ and $Z'_A = \bigcap_{k\notin A} Z_k$. Let R_A denote the subspace $\{\mu \in \mathbb{R}^{N-1} : \sum_{k\in A}(W_{ki} - W_{kj})\mu_k = 0\}$. Define $Q_A = R_A \cap Z'_A \setminus \{\mathbf{0}\}$. We will show that $P(Q_A) = 0$ for any choice of A. $P(S_{pc}^{(i,j)} \setminus S_c) = 0$ follows from this by taking $A = \{1, 2, \dots, N-1\}$.

We shall prove $P(Q_A) = 0$ by induction on $n = |A|$, the cardinality of A. Suppose first that $n = 1$ and, say, $A = \{1\}$. Since $W_{1i} - W_{1j} \neq 0$, we have $R_A = \{\mu \in \mathbb{R}^{N-1} : \mu_1 = 0\} = Z_1$ and $Z'_A = \bigcap_{k=2}^{N-1} Z_k$. Thus, $Q_A = \bigcap_{k=1}^{N-1} Z_k \setminus \{\mathbf{0}\} = \varnothing$, which implies $P(Q_A) = 0$. The same holds for any other A with $|A| = 1$.

Suppose that $P(Q_A) = 0$ for any A with $|A| = n-1$, and consider the case $|A| = n$. We have

$$\begin{aligned} P(Q_A) &= P(Q_A \cap Z_A) + P(Q_A \setminus Z_A) \\ &= P\left(\bigcup_{k\in A} Q_A \cap Z_k \right) + P(Q_A \setminus Z_A) \\ &\leq \sum_{k\in A} P(Q_A \cap Z_k) + P(Q_A \setminus Z_A). \end{aligned}$$

We see that $P(Q_A \cap Z_k) = 0$ for each $k \in A$, by the induction hypothesis, since we can write $Q_A \cap Z_k = R_A \cap Z'_A \cap Z_k \setminus \{\mathbf{0}\} = R_{A_k} \cap Z'_{A_k} \setminus \{\mathbf{0}\} = Q_{A_k}$ with $A_k = A \setminus \{k\}$, for which we have $|A_k| = n - 1$. Thus, if we can show $P(Q_A \setminus Z_A) = 0$, then we are done.

We show $P(Q_A \setminus Z_A) = 0$ in three steps. First, since Z'_A is an n-dimensional subspace and $Q_A \subset R_A \cap Z'_A$ is an $(n-1)$-dimensional subspace, the n-dimensional Lebesgue measure of Q_A in Z'_A must be zero.

Next, note that the conditional probability distribution of μ, given $\mu \in Z'_A$, is continuous with respect to the Lebesgue measure outside the set Z_A. This can be seen by noting the following: (1) each component can be written as $\mu_j = \mu_{p_j}(a_j)$ by Lemma 3.2, (2) $\mu_{p_j}^{-1}$ exists and is differentiable except at the origin, again by Lemma 3.2, and (3) the conditional distribution of $a_j = \sum_k W_{kj}\omega_k$, given that $\mu(\omega) \in Z'_A$ (which is equivalent to $-\varepsilon M_k \le \sum_l W_{lk}\omega_l \le -\varepsilon m_k$ for all $k \notin A$), is continuous everywhere.

Finally, combining these two observations, we see that $P(Q_A \setminus Z_A \mid Z'_A) = 0$, which implies that $P(Q_A \setminus Z_A) = P(Z'_A)P(Q_A \setminus Z_A \mid Z'_A) = 0$. This completes the proof of the theorem. □

We next describe the behavior of a generic diagonalizable system in the limit of $N \to \infty$. In order to formalize the process of taking the limit, we need to choose a sequence of systems of the form (1.1). Such a sequence can be characterized by the following:

1. Consider a sequence $\{W^{(N)}\}_{N=1,2,\dots}$ of matrices with the following properties:
   (a) Each $W^{(N)}$ is an $N \times (N-1)$ matrix with orthonormal columns.
   (b) $\mathbf{1}_N^T W^{(N)} = \mathbf{0}$ for all N.
   (c) Each $W^{(N)}$ satisfies the condition for W in Theorem 4.1.
   (d) $||W^{(N)}||_\infty \to 0$ as $N \to \infty$. (Here $||\cdot||_\infty$ denotes the maximum matrix norm defined by $||A||_\infty = \max|A_{ij}|$, where the maximum is taken over all elements of A.) This is like a mixing condition that will be necessary later in order to apply Proposition 4.3.
2. Consider a sequence $\{p_j\}_{j=1,2,\dots}$ of real, continuous, periodic functions such that the corresponding sequence of norms $||p_j|| \equiv \max_j |p_j(u)|$ is bounded.
3. Consider a sequence $\{\omega_j\}_{j=1,2,\dots}$ of i.i.d. random variables with mean ω_0 and variance σ^2.

The sequence of matrices $W^{(N)}$ defined by (3.1) satisfies the conditions above. Given such sequences, for each $\varepsilon > 0$ and N, we define $\mathcal{S}_{N,\varepsilon}$ to be the diagonalizable system (1.1) of phase oscillators using the natural frequency vector $\omega = (\omega_1, \dots, \omega_N)^T$, the functions $\{p_1, \dots, p_{N-1}\}$, and the matrix $W^{(N)}$. We are now ready to state and prove our main theorem.

THEOREM 4.2. *Let $\mathcal{S}_{N,\varepsilon}$ be defined as above. Then, for any fixed $\varepsilon > 0$, $\mathcal{S}_{N,\varepsilon}$ is almost surely incoherent as $N \to \infty$; i.e., the probability that $\mathcal{S}_{N,\varepsilon}$ is incoherent tends to one in the limit of $N \to \infty$.*

Proof. As mentioned before, we may assume $\omega_0 = 0$ without loss of generality, since the $\omega_0 \neq 0$ case can always be reduced to the $\omega_0 = 0$ case.

From Theorem 4.1, we know that the probability that $\mathcal{S}_{N,\varepsilon}$ is *not* incoherent is equal to the probability q_c that it is coherent. We need to show that $q_c \to 0$ as $N \to \infty$.

Let $N_0 < N$ be fixed. From Lemma 2.1, it follows that $q_c = P(\mu = \mathbf{0})$. Since the sequence $\{||p_j||\}_{j=1,2,\dots}$ is bounded, we can define $M = \sup M_j$ and $m = \inf m_j$, where $m_j = \min_{0\le u<L} p_j(u)$, $M_j = \max_{0\le u<L} p_j(u)$ for each j. Then, Lemma 3.2 implies

$$\begin{aligned} q_c &= P(\mu = \mathbf{0}) \\ &= P(-\varepsilon M_j \le a_j^{(N)} \le -\varepsilon m_j,\ j = 1, \dots, N-1) \\ &\le P(-\varepsilon M \le a_j^{(N)} \le -\varepsilon m,\ j = 1, \dots, N_0), \end{aligned}$$

where $a_j^{(N)} = (W_j^{(N)})^T \omega$.

The following Proposition shows that for each j, $a_j^{(N)}$ converges to a Gaussian random variable with mean 0 and variance σ^2.

PROPOSITION 4.3. *Let $X_1, X_2, \dots$ be a sequence of i.i.d. random variables with $EX_j = 0$ and $Var(X_j) = E(X_j^2) = \sigma^2$. Suppose that, for each N, real numbers $b_{N,1}, \dots, b_{N,N}$ satisfy $\sum_{j=1}^N b_{N,j}^2 = 1$. Also, suppose that*

$$\lim_{N\to\infty} \max_{1\le j\le N} |b_{N,j}| = 0.$$

Then we have

$$S_N = \sum_{j=1}^N b_{N,j} X_j \xrightarrow{d} \mathcal{N}(0, \sigma^2)$$

as $N \to \infty$.

Proof. Let $Y_{N,j} = b_{N,j} X_j$. We will apply the Lindeberg–Feller central limit theorem (see, for example, [3, p. 98]) to $Y_{N,j}$. For this we need to check three conditions. The first is $EY_{N,j} = b_{N,j} EX_j = 0$. The second condition is satisfied because $\sum_{j=1}^N EY_{N,j}^2 = \sum_{j=1}^N b_{N,j}^2 EX_j^2 = \sigma^2 > 0$. To show that the third condition is satisfied, let $\varepsilon > 0$ be fixed. We have

$$\sum_{j=1}^N E\Big(|Y_{N,j}|^2 \,\Big|\, |Y_{N,j}| > \varepsilon\Big) = \sum_{j=1}^N b_{N,j}^2 E\left(|X_j|^2 \,\middle|\, |X_j| > \frac{\varepsilon}{|b_{N,j}|}\right),$$

where $E(X|A)$ denotes the conditional expectation of X, given A. Let j be fixed. For each N, set $Z_N = |X_j|^2$ if $|X_j| > \varepsilon/|b_{N,j}|$, and 0 otherwise. Since $|b_{N,j}| \to 0$, $Z_N \le |X_j|^2$ for each N, and $Z_N \to 0$ almost surely, we may use the dominated convergence theorem to show that for each $j = 1, 2, \dots$, $EZ_N = E\big(|X_j|^2 \mid |X_j| > \varepsilon/|b_{N,j}|\big) \to 0$ as $N \to \infty$. Thus, the third condition $\sum_{j=1}^N E\big(|Y_{N,j}|^2 \mid |Y_{N,j}| > \varepsilon\big) \to 0$ is satisfied. The conclusion now follows directly from application of the Lindeberg–Feller theorem. ∎

For each $j = 1, \dots, N-1$, we take $b_{N,i} = W_{ij}^{(N)}$ and $X_i = \omega_i$ in Proposition 4.3, and we see that $a_j^{(N)}$ converges in distribution to $a_j^{(\infty)}$ as $N \to \infty$, where $a_j^{(\infty)}$ is a Gaussian random variable. Moreover, due to the orthogonality of $W^{(N)}$, $a_1^{(N)}, \dots, a_{N-1}^{(N)}$, in some sense, become independent in the limit.

LEMMA 4.4. *The random variables $a_1^{(\infty)}, a_2^{(\infty)}, \dots$ are independent.*

Proof. We need to show that for any finite $A \subset \mathbb{N}$, the collection $\{a_k^{(\infty)}\}_{k\in A}$ is a set of independent random variables. For simplicity, we prove this only for $A = \{1, 2\}$, but a similar argument works for a general case.

Let t_1 and t_2 be given. Set

$$b_{N,j} = \frac{t_1 W_{1j}^{(N)} + t_2 W_{2j}^{(N)}}{\sqrt{t_1^2 + t_2^2}}.$$

Then, as $N \to \infty$, $\max_j |b_{N,j}|$ approaches zero because $\max_j |W_{1j}|$ and $\max_j |W_{2j}|$ go to zero. Also, it is easy to check that $\sum_{j=1}^N b_{N,j}^2 = 1$ for all N. Applying Proposition 4.3, we see that

$$\frac{t_1 a_1^{(N)} + t_2 a_2^{(N)}}{\sqrt{t_1^2 + t_2^2}} = \sum_{j=1}^N b_{N,j}\omega_j \xrightarrow{d} \mathcal{N}(0, \sigma^2),$$

which implies that $t_1 a_1^{(N)} + t_2 a_2^{(N)} \xrightarrow{d} \mathcal{N}(0, \sigma^2(t_1^2+t_2^2))$, which in turn implies the convergence of the joint characteristic function of $a_1^{(N)}$ and $a_2^{(N)}$ as $N \to \infty$. Specifically,

$$Ee^{it_1 a_1^{(\infty)} + it_2 a_2^{(\infty)}} = \lim_{N\to\infty} Ee^{i(t_1 a_1^{(N)} + t_2 a_2^{(N)})} = e^{-\sigma^2(t_1^2+t_2^2)/2} = e^{-\sigma^2 t_1^2/2}\, e^{-\sigma^2 t_2^2/2}.$$

Therefore, $a_1^{(\infty)}$ and $a_2^{(\infty)}$ are independent. □

Let us come back to the proof of Theorem 4.2. As a consequence of $a_1^{(\infty)}, a_2^{(\infty)}, \ldots$ being independent Gaussian random variables, we have

$$\begin{aligned} q_c &\le P(\{-\varepsilon M \le a_j^{(N)} \le -\varepsilon m,\ j = 1, \ldots, N_0\}) \\ &\to \left[\frac{1}{\sqrt{2\pi\sigma^2}} \int_{-\varepsilon M}^{-\varepsilon m} e^{-x^2/2\sigma^2} dx\right]^{N_0} \end{aligned}$$

as $N \to \infty$. Since this holds for any fixed N_0, and since the right-hand side goes to zero as $N_0 \to \infty$, we conclude that $q_c \to 0$. This completes the proof of Theorem 4.2. □

5. Example. A network of voltage-controlled oscillator (VCO) devices can be built as an example of systems with diagonalizable interaction. The behavior of the jth VCO in the network is described by its phase variable θ_j, which satisfies [5, 7]:

$$\dot{\theta_j} = \omega_j + I_j(t),$$

where ω_j is the center frequency and $I_j(t)$ is the input signal from other VCOs. The system is diagonalizable if, for example, $I_j(t)$ has the form

$$I_j(t) = \varepsilon \sum_{k=1}^{N-1} W_{jk}^{(N)} \sin\left(\sum_{\ell=1}^{N} W_{\ell k}^{(N)} \theta_\ell\right),$$

with $W^{(N)}$ defined by (3.1).

This type of interaction can be implemented using commercially available circuit elements, as follows. The sine terms on the right-hand side can be constructed as sums and products of output voltages:

$$\sin\left(\sum_{\ell=1}^{N} W_{\ell k}^{(N)} \theta_\ell\right) = \sum_b \prod_{\ell=1}^{N} \cos\left(W_{\ell k}^{(N)} \theta_\ell - \frac{b_\ell \pi}{2}\right),$$

where the sum is taken over all (ordered) binary N-tuples $b = (b_1, \ldots, b_N)$, $b_\ell = 0, 1$, such that $\sum_\ell b_\ell$ is odd. This means that $I_j(t)$ is a sum of terms that are products of $\sin(W_{\ell k}^{(N)} \theta_\ell)$ and $\cos(W_{\ell k}^{(N)} \theta_\ell)$. Signals of the form $\sin(W_{\ell k}^{(N)} \theta_\ell)$ can be obtained by using the amplified version of the input $W_{\ell k}^{(N)} I_\ell(t)$ as the controlling voltage in a separate VCO with center frequency $W_{\ell k}^{(N)} \omega_\ell$. From these we can get $\cos(W_{\ell k}^{(N)} \theta_\ell)$ by the phase shift of $\pi/2$. Finally, $I_j(t)$ is obtained by putting these signals through multipliers and adding the outputs.

6. Discussion. In order to gain additional insights, let us consider the case when the functions $p_j = p$ have the range $[-1, 1]$ and do not depend on j. The arguments in the proof of Theorem 4.2 suggest that for a diagonalizable system (1.1) with large N, the probability q_c that it is coherent is approximately

$$q_c \approx \left[\frac{1}{\sqrt{2\pi\sigma^2}} \int_{-\varepsilon}^{\varepsilon} e^{-x^2/2\sigma^2} dx\right]^{N-1} = \left[\operatorname{erf}\left(\frac{\varepsilon}{\sigma\sqrt{2}}\right)\right]^{N-1} \equiv \tilde{q}_c(\varepsilon; N),$$

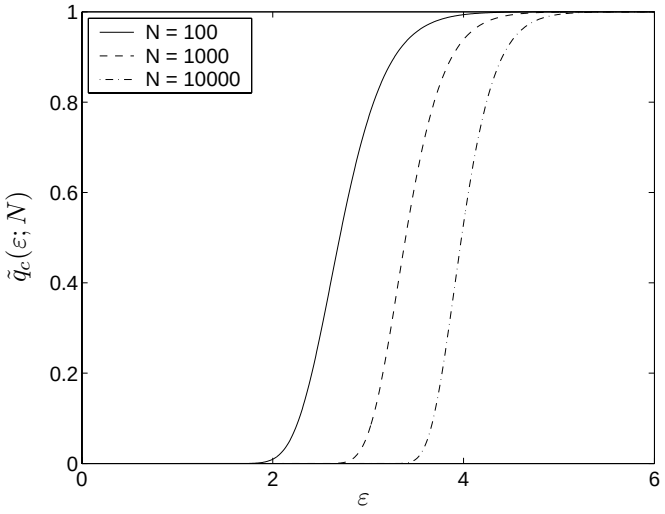

FIG. 6.1. *Probability of coherence* $\tilde{q}_c(\varepsilon; N)$ *as a function of* ε *for* $\sigma = 1$ *and* $N = 100, 1000, 10000$.

where $\mathrm{erf}(x)$ is the error function. Typical graphs of $\tilde{q}_c(\varepsilon; N)$ are plotted in Figure 6.1. One can see that for any finite value of N, there seems to be a sharp transition point through which $\tilde{q}_c(\varepsilon; N)$ changes from 0 to 1. However, unlike the mean-field model of Kuramoto, this point keeps shifting to the right as N increases, and tends to ∞ in the limit of $N \to \infty$, although it can be shown that this increase is at most $O(\sqrt{\ln N})$.

LEMMA 6.1. *Let* $\sigma > 0$ *and* $0 < q < 1$ *be fixed. Define* $\varepsilon_{q,\sigma}(N)$ *implicitly by* $q = \tilde{q}_c(\varepsilon_{q,\sigma}(N); N)$. *Then* $\varepsilon_{q,\sigma}(N) = O(\sqrt{\ln N})$ *as* $N \to \infty$*; i.e.,* $\varepsilon_{q,\sigma}(N)/\sqrt{\ln N}$ *is bounded as* $N \to \infty$.

Proof. Let $x = (\sigma\sqrt{2})^{-1}\varepsilon_{q,\sigma}(N)$. Then, using a known estimate for the error function, we have for $x \geq 1$

$$\mathrm{erf}(x) \geq 1 - \frac{2e^{-x^2}}{\sqrt{\pi}x + \sqrt{\pi x^2 + 4}} \geq 1 - \frac{2e^{-x^2}}{\sqrt{\pi} + \sqrt{\pi + 4}}.$$

Hence, we have the estimate

$$q \geq (1 - C_0 e^{-x^2})^{N-1} \geq 1 - (N-1)C_0 e^{-x^2},$$

where

$$C_0 = \frac{2}{\sqrt{\pi} + \sqrt{\pi + 4}}.$$

Here we used the relation $(1-x)^n \geq 1 - nx$, which is valid for $n \geq 0$ and $0 \leq x \leq 1$. The estimate for $\varepsilon_{q,\sigma}(N)$ can be obtained by rearranging:

$$\varepsilon_{q,\sigma}(N) \leq \sigma\sqrt{C_1 + 2\ln(N-1)},$$

where $C_1 = 2\ln C_0 - \ln(1-q)$. This implies $\varepsilon_{q,\sigma}(N) = O(\sqrt{\ln N})$. ∎

7. Conclusions. In this paper, we have defined a class of systems of phase oscillators characterized by having diagonalizable interactions. For a system in this class, complete separation of variables through appropriate changes of variable is possible, which enables us to draw rigorous conclusions about the probabilistic properties of the system. In particular, we have shown that partial coherence of the system almost surely implies coherence and, in the limit of large system size, the system is almost surely incoherent. A major implication of our result is that, unlike the mean-field model of Kuramoto, diagonalizable systems cannot exhibit a sharp transition from incoherence to coherence. This provides some insight into what is necessary to see such a transition in a system of phase oscillators.

NONLINEAR COUPLING NEAR A DEGENERATE HOPF (BAUTIN) BIFURCATION*

JONATHAN D. DROVER† AND BARD ERMENTROUT†

Abstract. A nonlinearly coupled system of bistable (fixed point and limit cycle) differential equations is analyzed. The nonlinear equations arise from the first several terms in the normal form expansion near a Bautin bifurcation. Existence and stability of in-phase and out-of-phase periodic solutions to a pair of identical systems are explored. Existence, uniqueness, and stability of traveling wave solutions from a stable rest state to a stable periodic solution are proved for the associated evolution/convolution equation. Numerical simulations suggest some interesting patterns in regimes where waves no longer exist. The results are shown to hold for a nonreduced conductance-based model.

Key words. Bautin bifurcation, subcritical Hopf bifurcation, bistability, traveling waves, localized pulses

1. Introduction.

The analysis of the behavior of coupled neuronal oscillators and "near" oscillators (i.e., excitable cells) has been the subject of many recent papers [2, 13, 15, 14]. Intrinsic neuronal oscillations arise primarily via two distinct mechanisms [21, 15]: (i) a saddle-node on a limit cycle bifurcation or (ii) a subcritical or supercritical Hopf bifurcation. In the saddle-node bifurcation, the oscillations that arise are large-amplitude, and so it is possible to study the effects of coupling between them by looking at certain normal forms that arise [14, 8]. Coupled systems near a supercritical Hopf bifurcation have been the subject of numerous studies (e.g., Aronson, Ermentrout, and Kopell [1]), most recently by Hoppensteadt and Izhikevich [13]. The problem with such analysis is that the coupling that has been analyzed is linear. This means that the coupling itself can determine whether or not the system is at rest or oscillates. Chemical synaptic coupling is inherently nonlinear, unlike coupling via diffusive-like interactions. This is because subthreshold oscillations and perturbations from rest are insufficient to excite the channels which release the chemical transmitters necessary for communication between neurons. Because synaptic coupling between neurons is nonlinear, the presence of coupling does not alter the stability of the resting state of such a neuron. This contrasts with diffusive or gap junctional coupling, which is linear and can therefore affect the stability of the resting state [7, 10, 19].

The oscillations emerging from a *subcritical* Hopf bifurcation generally "turn around" for neuronal models to become large-amplitude stable oscillations. Thus, like the saddle-node case, these large-amplitude oscillations are sufficient to excite chemical synapses. Furthermore, unlike a supercritical Hopf bifurcation, there is a range of parameters for which the system is intrinsically bistable: there is a stable equilibrium point and a stable oscillation. The goal of this paper is to study a reduced model (normal form) that nonlinearly couples systems with a subcritical Hopf bifurcation.

We model the bistable subcritical Hopf bifurcation by considering a degenerate form of the Hopf bifurcation, which arises at the transition between sub- and supercritical bifurcations. This is called the Bautin bifurcation, and the normal form for such a bifurcation is

$$z' = z(\lambda + b|z|^2 + f|z|^4) \equiv N(z), \tag{1.1}$$

where b, f are complex numbers and λ is the bifurcation parameter. The usual Hopf bifurcation does not involve the parameter f and is sub- or supercritical according to whether the real part of b is, respectively, positive or negative. In the Bautin bifurcation, the real part of the coefficient b vanishes. Thus, the degeneracy in the normal form arises from the nonlinear terms in the system. The advantage of the Bautin normal form is that it captures the bistability of the medium as well as the fact that the stable oscillation is bounded away from the rest state. Equation (1.1) can be derived from any nonlinear system near a degenerate Hopf bifurcation [17].

Consider, now, a pair of synaptically coupled neurons near this bifurcation. In the absence of coupling, they can be described in terms of the complex amplitudes z_1, z_2, where each z_j satisfies (1.1). Coupling alters the normal form by adding new terms, whose form can be deduced by using standard symmetry arguments [12] or by direct (albeit tedious) calculation. The coupled system has the form

$$\begin{aligned} z_1' = {} & N(z_1) + L_1 z_1 + L_2 z_2 + C_1 z_1|z_2|^2 + C_2 z_2|z_2|^2 \\ & + C_3 z_1^2 \bar{z}_2 + C_4 z_2^2 \bar{z}_1 + C_5 z_2|z_1|^2 + C_6 z_1|z_1|^2, \end{aligned} \tag{1.2}$$

with an analogous equation for z_2'. If the coupling between oscillators is through diffusion (e.g., gap junctions) then $L_1 = -L_2$. In [1, 13] only the linear coupling terms are kept. [16] studied (1.1) in the context of synchronization between bursters with linear coupling. We have also included nonlinear coupling terms up to order 3 in (1.2). The motivation for this is as follows. Consider the stability of the origin $z_j = 0$. The linearized equations have the form

$$\begin{aligned} z_1' &= (\lambda + L_1) z_1 + L_2 z_2, \\ z_2' &= (\lambda + L_1) z_2 + L_2 z_1, \end{aligned}$$

with eigenvalues $\lambda + L_1 \pm L_2$. Thus, linear coupling can alter the stability of the origin. This cannot happen in a system of synaptically coupled neurons except in very unusual circumstances. That is, the threshold for synaptic interactions would have to be nearly identical to the resting state of the neuron. For this reason, we will assume that the coupling between the two normal forms should not be linear. Thus, in this paper, we set $L_1 = L_2 = 0$.

We turn to the nonlinear coupling terms, of which there are six. Consider two neurons which are stably at rest ($z_j = 0$). Suppose that we excite one of them past threshold so that it begins to fire. Then if the neurons are coupled sufficiently strongly, this should induce the other neuron to begin firing. Of the six coupling terms in (1.2), only one term can cause this. Since $z_j = 0$ is the rest state, then any coupling term which includes z_j cannot contribute to pushing z_j away from rest. For example, if z_2 is oscillating, then the only term which can influence a *resting* z_1 is the second term:

$$z_2|z_2|^2.$$

While all terms are important once the neurons are both oscillating, the onset of oscillations is effected only through the second term. Thus, we will restrict the analysis

of coupled systems to nonlinear coupling with $C_n = 0$ except for C_2. If there is linear coupling and we are very close to the bifurcation, then the nonlinear coupling can be scaled out. Thus, one should regard our analysis, which includes nonlinear coupling terms, to hold for systems that are a small distance from the actual bifurcation. As the magnitude of the linear terms decreases (and for synaptic coupling, this is very small), the nonlinear terms have a stronger effect on the behavior, and thus in principle, we need not be very far from the critical bifurcation at all.

In the first part of the paper, we describe the bifurcations that occur in

$$\begin{aligned} z_1' &= z_1(\lambda + (iq)|z_1|^2 - |z_1|^4) + (c_1 + ic_2)z_2^2\bar{z}_2, \\ z_2' &= z_2(\lambda + (iq)|z_2|^2 - |z_2|^4) + (c_1 + ic_2)z_1^2\bar{z}_1, \end{aligned} \tag{1.3}$$

where $b = iq$ (at the Bautin bifurcation) and all parameters are real. We restrict our attention to the case in which the coefficient f in (1.1) is real and negative since we want the resulting large-amplitude oscillations to be stable. We set $f = -1$ with no loss in generality. We establish the existence and stability of in- and out-of-phase oscillations in preparation for section 3 in which we look at spatially distributed networks.

Spatially distributed neurons and waves have been the object of much recent analysis. Coupling between neurons is not restricted to nearest neighbors but instead can involve long spatial scales. Typically, when modeled as a continuum, interactions take the form of convolutions. The coupled pair of Bautin oscillators can be easily generalized to a continuous spatial model with convolution coupling:

$$z_t = z(\lambda + (iq)|z|^2 - |z|^4) + (c_1 + ic_2)\int_{-\infty}^{\infty} J(x-y)z^2(y)\bar{z}(y)dy. \tag{1.4}$$

In the second part of the paper, we will describe the existence of traveling wavefronts, which join the stable resting state to an oscillatory solution. The resulting waves are similar in structure to those found in [9] when coupling was diffusive. We analyze the existence and stability of plane waves for (1.4) as well. We use numerical simulations to find spatially localized patterns which may be analogous to patterns of activity used to model working memory. Finally, we close the paper with simulations of a simple biophysically based model in order to demonstrate that the behavior of the normal-form-based model holds in more "realistic" neural models.

2. Two coupled equations. In this section we determine under what conditions the symmetric and asymmetric solutions exist and are stable. For this analysis, it is easiest to put the equations into polar form. We let

$$z_j = r_j e^{i\theta_j}$$

and let $\phi = \theta_1 - \theta_2$. Then, substituting into (1.3), we obtain the equations

$$\begin{aligned} r_1' &= \lambda r_1 - r_1^5 + c_1 r_2^3\cos(\phi) + c_2 r_2^3\sin(\phi), \\ r_2' &= \lambda r_2 - r_2^5 + c_1 r_1^3\cos(\phi) - c_2 r_1^3\sin(\phi), \\ \phi' &= q(r_1^2 - r_2^2) - c_1\left(\frac{r_1^3}{r_2} + \frac{r_2^3}{r_1}\right)\sin(\phi) + c_2\left(\frac{r_2^3}{r_1} - \frac{r_1^3}{r_2}\right)\cos(\phi). \end{aligned} \tag{2.1}$$

Phase-locked solutions with constant r_1, r_2 to the coupled system of oscillators are fixed points of (2.1). The existence and stability of periodic solutions is readily obtained. We remark that $z_j = 0$ is an asymptotically stable solution to (1.3) if and only

if $\lambda < 0$. In this section, we will look for limit-cycle solutions to (1.3) with amplitudes r_j bounded away from zero so that the denominators in the equation for ϕ cause no problems.

2.1. Symmetric in-phase solutions. We look for solutions of the form $\rho = r_1 = r_2$ (symmetric) and $\phi = 0$. When $\phi = 0$, the sine terms in (2.1) vanish. Inserting the solution $\phi = 0$, (2.1) is reduced to the first order ODE

$$\rho' = \lambda\rho + c_1\rho^3 - \rho^5. \tag{2.2}$$

The positive roots are given by

$$\frac{1}{2}\sqrt{2c_1 \pm 2\sqrt{c_1^2 + 4\lambda}}. \tag{2.3}$$

First, we will establish when these solutions exist.

2.1.1. Existence. We want to determine under what conditions on the parameters the solutions (2.3) are real. Thus we want to know when the polynomial $f(x) = \lambda + c_1x^2 - x^4$ has two positive, real roots. For $\lambda > 0$ this polynomial will always have one positive root; thus the upper branch of solutions (2.3) will be real. Now, because this polynomial is symmetric about the y-axis, in order for two real, positive roots to exist it must be true that $f(0) < 0$, implying $\lambda < 0$. Also, there must be a relative maximum at a point $x = a$ so that $f(a) > 0$. This maximum occurs at $x = \sqrt{c_1/2}$. Thus, the polynomial $f(x)$ will have two positive, real roots if $c_1 > \sqrt{-2\lambda}$.

One of the goals of this paper is to prove the existence of traveling waves connecting a stable rest state to a stable plane wave. Thus, we must choose parameters so that equations lie in a bistable regime. For this reason, we will only consider parameter values that allow two stable states. Thus, we must have two nonzero solutions to separate stable regions. We will consider only $\lambda < 0$. The only requirement that follows is that $c_1 > \sqrt{-2\lambda}$ must hold.

2.1.2. Stability. The Jacobian for the polar coordinate system is

$$\begin{pmatrix} \alpha(r) & \beta(r) & \gamma(r) \\ \beta(r) & \alpha(r) & -\gamma(r) \\ a(r) & -a(r) & b(r) \end{pmatrix}, \tag{2.4}$$

where $\alpha(r) = \lambda - 5r^4$, $\beta(r) = 3c_1r^2$, $\gamma(r) = c_2r^2$, $a(r) = 2qr - 4c_2r$, and $b(r) = -2c_1r^2$.

The characteristic polynomial for (2.4) is

$$(x - \alpha - \beta)(x^2 + (\beta - b - \alpha) + \alpha b - \beta b - 2\gamma a).$$

Thus, a symmetric in-phase solution is stable if the following three conditions hold at the equilibrium:

$$\alpha + \beta < 0, \tag{2.5}$$

$$\beta - b - \alpha > 0, \tag{2.6}$$

$$\alpha b - \beta b - 2\gamma a > 0. \tag{2.7}$$

The lower branch of solutions is always unstable. Substituting the value of the lower branch solution into $\alpha + \beta$ gives

$$-4\lambda - c_1^2 + c_1\sqrt{c_1^2 + 4\lambda}.$$

By the requirement for existence, we have that $c_1 > \sqrt{-2\lambda}$, and so the above quantity is real. It is easily seen that the expression is the same as

$$\sqrt{c_1^2 + 4\lambda}\left[c_1 - \sqrt{c_1^2 + 4\lambda}\right] > 0,$$

and so the value (2.5) is positive. Thus this periodic solution to (2.2) is unstable and will act as the desired separatrix between the stable fixed point and the upper periodic branch. A similar proof is used to show that this eigenvalue is always negative for the upper branch of solutions; thus it will not prevent stability.

We turn now to the other two conditions. First, consider condition (2.6). Using the definitions of the various parameters, this condition becomes

$$5c_1^2 + 4\lambda + 5c_1 R > 0,$$

where $R = \sqrt{(c_1^2 + 4\lambda)} > 0$. Since $c_1^2 + 4\lambda > 0$, this expression is clearly positive, and thus the condition (2.6) holds on the upper branch. The last condition, (2.7), will not hold for all parameters, and in fact, as we will show, the left-hand side can become negative if the parameters c_2, q are sufficiently large. We can rewrite condition (2.7) as

$$F(c_2) \equiv Ac_2^2 + Bc_2 + C > 0,$$

where

$$\begin{aligned} A &= 4c_1^2 + 8\lambda + 4c_1 R, \\ B &= -q(c_1^2 + 4\lambda + c_1^2 + c_1 R) \equiv -qD, \\ C &= 4c_1 R(\lambda + 2c_1^2) + 4c_1^2(5\lambda + 2c_1^2). \end{aligned}$$

We note that since $c_1^2 + 4\lambda > 0$, $\lambda < 0$, and $c_1 > 0$, A, D, C are all positive. In particular, if $c_2 = 0$, then condition (2.7) holds and the upper branch is asymptotically stable. Suppose that c_2 is nonzero. The parameter q appears only in the coefficient B. Furthermore, $D > 0$ so that for fixed c_2 we can always find a sufficiently large value of $|q|$ so that $F(c_2) < 0$ and the upper branch is destabilized. We should choose c_2, q to have the same sign. The critical value of q leads to a zero eigenvalue for the stability matrix. Since the synchronous solution cannot disappear (its existence is independent of both c_2, q), the bifurcation occurring must be either a transcritical or a pitchfork. However, due to symmetry, the transcritical cannot occur, and the resulting bifurcation must be a pitchfork [23]. The critical value of q is readily found to be

$$q^* = \frac{Ac_2^2 + C}{Dc_2}.$$

Using AUTO [6], we have tracked the solution through this instability and verified that it is indeed a pitchfork bifurcation. For $\lambda = -1/5$, $c_1 = c_2 = 1$, we find that the synchronous state becomes unstable at $q^* = 5.4473$, in agreement with the above formula. Furthermore, the bifurcation is subcritical. Thus, once the critical value of q is exceeded, we find that the only stable state is the resting value, $r_1 = r_2 = 0$.

2.2. Symmetric out-of-phase solutions. In order for the out-of-phase solutions to exist we must have that $c_1 < 0$. In this paper we will assume that $c_1 > \sqrt{-2\lambda}$ and $\lambda < 0$, so these solutions are of little interest here.

2.3. Two-equation summary. For $\lambda < 0$ and $c_1 > \sqrt{-2\lambda}$ there are two in-phase symmetric periodic solutions. The top branch of solutions is stable as long as q is sufficiently small. The lower branch is unstable. These solutions, and the zero solution which is linearly stable, provide a bistable region. For the two-equation system this is of little consequence in the existence and stability of phase-locked periodic solutions; however, when modeled in continuum, the bistability leads to traveling waves and pulsing behaviors that connect the stable origin to the stable periodic solutions, as we shall see in the subsequent sections.

3. The convolution equation. As stated in the introduction, we will consider the equation

$$z_t = z[\lambda + (b_1 + iq)|z|^2 - |z|^4] + (c_1 + ic_2)\int_{-\infty}^{\infty} J(x-y)z^2(y)\overline{z}(y)dy,$$

where $\int_{-\infty}^{\infty} J(x)dx = 1$, $J(x) \geq 0$, and $||J||_\infty < \infty$. We remark that if $c_2 = 0$, then, no matter what the value of q, the synchronous periodic state $z(x,t) = \rho \exp(i\Omega t)$ is always stable when it exists. We will also assume that $b_1 \geq 0$ since we want the local Hopf bifurcation to be subcritical (and, in fact, throughout most of the paper, we assume $b_1 = 0$). We will first study the existence and stability of plane wave solutions to this system. We then turn to the existence of traveling fronts, which join the stable equilibrium point, $z = 0$, to a plane wave. Finally, we look at the behavior of these fronts as q increases. We present numerical evidence for the existence of localized regions of periodic activity surrounded by the near absence of activity.

3.1. Relationship of the normal form to a kinetic model. The relationship between the coupling in an actual kinetic model and the normal form given in (1.4) is derived here. Consider the following system consisting of two synaptically coupled neurons:

$$\begin{aligned}
\frac{dV_1}{dt} &= f(V_1) - gs_2(V_1 - V_{syn}),\\
\frac{ds_1}{dt} &= \alpha(V_1)(1-s_1) - \beta s_1,\\
\frac{dV_2}{dt} &= f(V_2) - gs_1(V_2 - V_{syn}),\\
\frac{ds_2}{dt} &= \alpha(V_2)(1-s_2) - \beta s_2.
\end{aligned}$$

Assume that $f(V_{rest}) = 0$ and that $\frac{\partial f}{\partial V}(V_{rest}) < 0$. Then the uncoupled system has a stable rest state at $V = V_{rest}$. Suppose that $\alpha(V) = \alpha'(V) = 0$ for V less than some critical value, which itself is greater than V_{rest}. Then V_{rest} will remain a stable equilibrium point for the coupled system. Hence, the coupling will not affect the existence or stability of the rest state. If we consider N neurons coupled similarly, we get a system

$$\begin{aligned}
\frac{dV_i}{dt} &= f(V_i) - g(V_i - V_{syn})\sum_j w_{i-j}s_j,\\
\frac{ds_i}{dt} &= \alpha(V_i)(1-s_i) - \beta s_i.
\end{aligned}$$

We may slave the coupling directly to the presynaptic potentials. Because we have that $\alpha(V_{rest}) = \alpha'(V_{rest}) = 0$, the expression must be at least second order, and we

get that

$$\frac{dV_i}{dt} = f(V_i) - g(V_i - V_{syn}) \sum_j w_{i-j} R(V_j - V_{rest}),$$

where R is a function with no linear component. Because we are allowing only terms that contribute to excitation away from rest, we may simplify even further:

$$\frac{dV_i}{dt} = f(V_i) - g(V_{rest} - V_{syn}) \sum_j w_{i-j} R(V_j - V_{rest}).$$

And finally, if modeled in continuum, we get that

$$V_t(x,t) = f(V(x,t)) - \hat{g} \int_{\infty}^{\infty} J(x-y) R(V(y,t) - V_{rest}) dy,$$

as desired. (Note that $\hat{g} = g(V_{rest} - V_{syn})$.)

3.2. Plane wave solutions. Consider solutions of (1.4) of the form $\rho e^{i(\Omega t - kx)}$. Substituting this in yields

$$\begin{aligned} i\rho\Omega e^{i(\Omega t-kx)} &= \rho e^{i(\Omega t-kx)}(\lambda + (b_1 + iq)\rho^2 - \rho^4) \\ &\quad + (c_1 + ic_2)\int_{-\infty}^{\infty} J(x-y)\rho^3 e^{i(\Omega t - ky)} dy, \end{aligned}$$

which implies

$$i\Omega = \lambda + (b_1 + iq)\rho^2 - \rho^4 + \rho^2(c_1 + ic_2)\int_{-\infty}^{\infty} J(x-y)e^{ik(x-y)} dy$$

and finally

$$i\Omega = \lambda + (b_1 + iq)\rho^2 - \rho^4 + \rho^2(c_1 + ic_1)\hat{J}(k), \tag{3.1}$$

where $\hat{J}(k) = \int_{-\infty}^{\infty} J(s)e^{iks} ds$. Taking the imaginary part of the right-hand side of (3.1), we find that

$$\Omega = q\rho^2 + c_1\rho^2 \mathrm{Im}(\hat{J}(k)) + c_2\rho^2 \mathrm{Re}(\hat{J}(k)), \tag{3.2}$$

with ρ determined so that

$$\lambda + b_1\rho^2 - \rho^4 + c_1\rho^2 \mathrm{Re}(\hat{J}(k)) - c_2\rho^2 \mathrm{Im}(\hat{J}(k)) = 0. \tag{3.3}$$

For the remainder of the paper, we will assume that $c_2 = 0$ and that $J(x)$ is a symmetric kernel; thus (3.2) and (3.3) become, respectively,

$$\Omega = q\rho^2 \tag{3.4}$$

and

$$\lambda - \rho^4 + c_1\rho^2 \hat{J}(k) = 0. \tag{3.5}$$

In the next subsection, we prove the asymptotic stability of these plane waves so that we can then show the existence of traveling wavefronts connecting the stable rest state to these oscillations. We remark that setting $c_2 = 0$ is a major simplification. It is well known that if $c_2 q$ is large enough, then the corresponding Ginzburg–Landau model has spatiotemporal chaos. (See, for example, [20], where spatiotemporal chaos is explored for $z_t = z(a + bz\bar{z}) + dz_{xx}$. See also section 3.4.3, where such a solution is exhibited for the present model.)

3.3. Plane wave stability. We claim that the plane wave solutions defined by (3.5), (3.4) are asymptotically stable for sufficiently small k. We will show this using a symmetric kernel $J(x)$ such that $\frac{dJ}{dx}(0) = 0$ and $\int_{-\infty}^{\infty} J(x)dx = 1$. The kernel we use is $(1/\sqrt{\pi})e^{-x^2}$, and the results can be generalized to any function satisfying the above requirements.

The plane wave has the form $z(x,t) = \rho e^{i(\Omega t - kx)}$, with ρ and Ω defined as in (3.5) and (3.4). We now examine the stability of the plane waves by linearizing about a solution. Let

$$z(x,t) = \rho e^{i(\Omega t - kx)} + w(x,t). \tag{3.6}$$

Substituting (3.6) into (1.4) and taking terms linear in w, we obtain

$$w_t = f(w) + c_1\rho^2 \int_{-\infty}^{\infty} J(x-y)\left[e^{2i(\Omega t - kx)}\bar{w} + 2w\right] dy, \tag{3.7}$$

where

$$f(w) = \lambda w + iq\rho^2\left[2w + e^{2i(\Omega t - kx)}\bar{w}\right] - \rho^4\left[3w + 2e^{2i(\Omega t - kx)}\bar{w}\right]. \tag{3.8}$$

Now, let $w = e^{i(\Omega t - kx)}v$ and $v = v_1 + iv_2$ and substitute into (3.7). This gives the equation

$$\begin{aligned} i\Omega(v_1 + iv_2) + (v_1 + iv_2)_t \\ = g(v_1, v_2) + c_1\rho^2 \int_{-\infty}^{\infty} J(s)e^{iks}\left[3v_1(x-s) + iv_2(x-s)\right] ds, \end{aligned} \tag{3.9}$$

where

$$g(v) = \lambda(v_1 + iv_2) + 2iq\rho^2(v_1 + iv_2) + iq\rho^2(v_1 - iv_2) - 3\rho^4(v_1 + iv_2) - 2\rho^4(v_1 - iv_2).$$

Expanding the integrand in (3.9) and separating the real and imaginary parts gives

$$c_1\rho^2 \int_{-\infty}^{\infty} J(s)\left[3\cos(ks)v_1(x-s) - \sin(ks)v_2(x-s)\right] ds \tag{3.10}$$

and

$$c_1\rho^2 \int_{-\infty}^{\infty} J(s)\left[\cos(ks)v_2(x-s) + 3\sin(ks)v_1(x-s)\right] ds. \tag{3.11}$$

Let $g = g_1 + ig_2$. Then these are

$$g_1(v) = \lambda v_1 - q\rho^2 v_2 - 5\rho^4 v_1 \tag{3.12}$$

and

$$g_2(v) = \lambda v_2 + 3q\rho^2 v_1 - \rho^4 v_2. \tag{3.13}$$

Because $\Omega = q\rho^2$, we can subtract this from both sides of (3.9). We define

$$h_1(v) = g_1(v) + q\rho^2 v_2 = \lambda v_1 - 5\rho^4 v_1, \tag{3.14}$$

$$h_2(v) = g_2(v) - q\rho^2 v_1 = \lambda v_2 + 2q\rho^2 v_1 - \rho^4 v_2. \tag{3.15}$$

Now, let $v_1 = e^{\alpha t}e^{ilx}u_1$ and $v_2 = e^{\alpha t}e^{ilx}u_2$. Then (3.10) becomes

$$c_1\rho^2 e^{\alpha t}e^{ilx}\int_{-\infty}^{\infty} J(s)\left[3\cos(ks)e^{-ils}u_1 - \sin(ks)e^{-ils}u_2\right]ds,$$

which, because J is assumed to be even, simplifies to

$$c_1\rho^2 e^{\alpha t}e^{ilx}\left[3\int_{-\infty}^{\infty} J(s)\cos(ks)\cos(ls)u_1 ds + \int_{-\infty}^{\infty} J(s)\sin(ks)\sin(ls)u_2 ds\right]. \tag{3.16}$$

Similarly, (3.11) becomes

$$c_1\rho^2 e^{\alpha t}e^{ilx}\left[\int_{-\infty}^{\infty} J(s)\cos(ks)\cos(ls)u_2 ds - 3\int_{-\infty}^{\infty} J(s)\sin(ks)\sin(ls)u_1 ds\right]. \tag{3.17}$$

Thus, (3.9) becomes

$$\alpha u_1 = \left[\lambda - 5\rho^4 + 3c_1\rho^2 J_{cc}\right]u_1 + iJ_{ss}u_2, \tag{3.18}$$

$$\alpha u_2 = \left[\lambda - \rho^4 + c_1\rho^2 J_{cc}\right]u_2 + \left[2q\rho^2 - iJ_{ss}\right]u_2, \tag{3.19}$$

where

$$J_{ss} = \int_{-\infty}^{\infty} J(s)\sin(ks)\sin(ls)ds$$

and

$$J_{cc} = \int_{-\infty}^{\infty} J(s)\cos(ks)\cos(ls)ds.$$

These can be expressed in terms of the Fourier transform $\hat{J}(k)$ of the kernel

$$J_{cc} = \frac{1}{2}\hat{J}(k+l) + \frac{1}{2}\hat{J}(k-l)$$

and

$$J_{ss} = -\frac{1}{2}\hat{J}(k+l) + \frac{1}{2}\hat{J}(k-l).$$

For the kernel J chosen, we have the transform $\hat{J}(k) = e^{-\frac{1}{4}k^2}$. The top panel of Figure 1 shows that, for $k = 0$, the real part of the greatest eigenvalue is negative for all $l \neq 0$. The middle panel shows that when $k = 1$, the plane wave solution is unstable, with the real part of the greatest eigenvalue positive. The bottom panel shows that there is a $k > 0$ such that the corresponding plane wave is stable. Thus there is an interval surrounding $k = 0$ such that the perturbation goes to zero, and hence the plane wave is stable.

This result is generalizable to any symmetric, nonnegative, integrable kernel qualitatively like a Gaussian. We need only that $\hat{J}$ decreases as $|k|$ gets farther from 0.

3.4. Traveling wavefronts. We will show that, under certain restrictions on the parameters, there exists a traveling wavefront that takes the system from the stable equilibrium point $z = 0$ to the plane wave solutions defined by (3.4), (3.5).

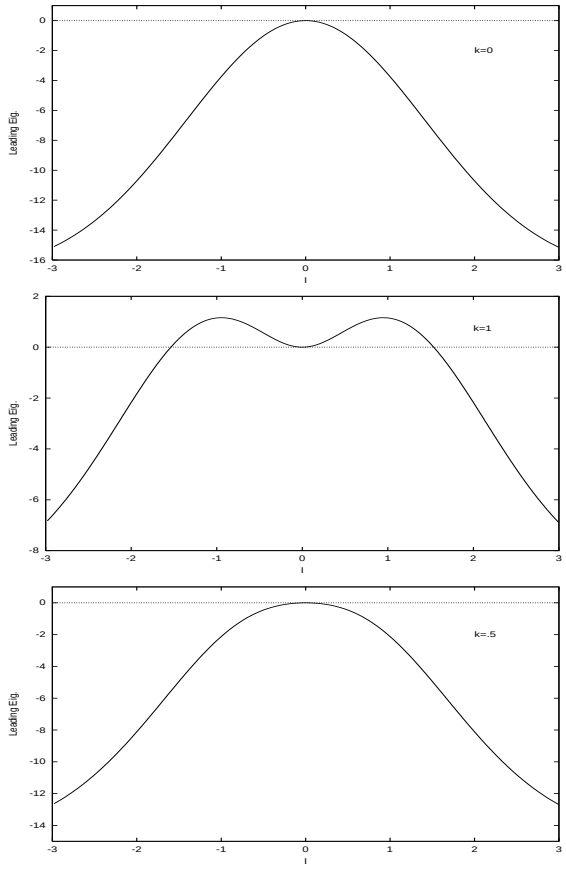

FIG. 1. *The real part of the leading eigenvalue for $k = 0$, $k = 1$, and $k = .5$. The horizontal axis is l, and the vertical axis is the value of the real part of the eigenvalue.*

Let $Z(k; x, t) = \rho(k) \exp(i[\Omega(k)t - kx])$ be a plane wave as constructed above. For $k = k^*(q)$ we seek traveling waves connecting $z(x, t) = 0$ to $Z(k^*; x, t)$. That is, there exists a real valued function $h(\xi)$ and a real c such that

$$z(x, t) = h(x - ct)Z(k^*; x, t),$$

where $h(-\infty) = 0$ and $h(\infty) = 1$. In this paper, we prove only the $q = 0$ case.

We put the system (1.4) into polar coordinates, making the substitution $z = re^{i\theta}$:

$$r_t = \lambda r + b_1 r - r^5 + c_1 G_1(x, t) + c_2 G_2(x, t), \tag{3.20}$$

$$r\theta_t = qr^3 + c_1 G_2(x, t) + c_2 G_1(x, t), \tag{3.21}$$

where

$$G_1(x, t) = \int_{-\infty}^{\infty} J(x - y)r^3(y)\cos(\theta(x) - \theta(y))dy, \tag{3.22}$$

$$G_2(x, t) = \int_{-\infty}^{\infty} J(x - y)r^3(y)\sin(\theta(x) - \theta(y))dy.$$

First, suppose that $b_1 = q = c_2 = 0$. Then $\theta = 0$ satisfies (3.21). This makes (3.20)

$$\rho' = \lambda\rho + b_1\rho^3 - \rho^5 + c_1 \int_{-\infty}^{\infty} J(x-y)\rho^3(y)dy. \tag{3.23}$$

3.4.1. Existence, uniqueness, asymptotic stability. Proving the existence, uniqueness, and asymptotic stability of a traveling wave connecting the stable equilibrium at $z = 0$ with a stable periodic orbit is done by appealing to the following theorem.

THEOREM 3.1 (see Chen [4]). *Consider the evolution equation*

$$u_t = Du_{xx} + G(u, J_1 * S_1(u), \ldots, J_n * S_n(u)), \tag{3.24}$$

where $J*S(u)$ stands for the convolution $\int_R J(x-y)S(u(y))dy$. Assume the following:

1. *For some $a \in (0,1)$, the function $f(u) = G(u, S_1(u), \ldots, S_n(u))$ satisfies $f > 0$ in $(-1,0) \cup (a,1)$, $f < 0$ in $(0,a) \cup (1,2)$, and $f'(0) < 0$, $f'(a) > 0$, and $f'(1) < 0$.*

2. *For each $i = 1, \ldots, n$, the kernel J_i is C^1 and satisfies $J_i(.) \geq 0$, $\int_R J_i(y)dy = 1$, and $\int_R |J_i(y)|dy < \infty$.*

3. *The functions $G(u,p)$ ($p = (p_1, \ldots, p_n)$) and $S_1(u), \ldots, S_n(u)$ are smooth functions satisfying for all $u \in [-1,2]$, $p \in [-1,2]^n$, $i = 1, \ldots, n$, $G_{p_i}(u,p) \geq 0$, $S_{u_i}(u) \geq 0$.*

4. *Either $D > 0$ or $G_u(u,p) < 0$ and $G_{p_1}(u,p)S_{u_1}(u) > 0$ on $[-1,2]^{n+1}$.*

If conditions 1–4 hold, there exists a unique (up to a translation) asymptotically stable, monotone traveling wave connecting 0 to 1.

Remark. In our system, the fixed point $\rho = 0$ corresponds to the zero fixed point of (1.4), and the fixed point $\rho > 0$ corresponds to the synchronous periodic solution to (1.4). Here $k^*(0) = 0$.

We now show that the following assumptions hold for (3.23).

1. The function $f(x) = \lambda x + b_1x^3 - x^5 + c_1x^3$ must satisfy a number of conditions regarding stability. This is to ensure that there is both a stable equilibrium and a stable periodic solution with an unstable periodic solution between the two acting as a separatrix. The first condition is $f(0) = 0$, $f(a) = 0$, and $f(b) = 0$, where b is the amplitude of the stable periodic orbit and a is the amplitude of the unstable separatrix. These values can be scaled so that $b = 1$; however, that is not necessary to satisfy the assumption. The requirements that $f'(0) < 0$ and $f'(b) < 0$ are simply to ensure that both the rest state and periodic solution are stable solutions. $f(x)$ does satisfy these conditions, as shown in section 1.2, so the first assumption in Chen's theorem is satisfied.

2. $\int_{-\infty}^{\infty} J(x-y)dy = 1$, $J(x) \geq 0$, and $J(x)$ is bounded for all x. We defined J in this way, so this assumption is satisfied.

3. $G_p(u,p) > 0$. For our purposes, this quantity is just c_1, so we will assume $c_1 > 0$. This is necessary for the existence of a nonzero root for f.

4. $G_u(u,p) < 0$ and $S_u(u) > 0$. The first of these is true for sufficiently small b_1. Because we have assumed that $b_1 = 0$, this condition is satisfied. The second quantity, $3c_1u^2$, is slightly problematic because it vanishes at $u = 0$; however, because it holds for all $u \neq 0$, the inequality that this condition is used to satisfy is still satisfied for our purposes (see the proof of Chen's theorem). Hence, this assumption is satisfied.

Because all four of the assumptions are valid for the scalar equation, there exists a unique and asymptotically stable traveling wave connecting the stable fixed point at $z = 0$ and the stable periodic solution of (3.23).

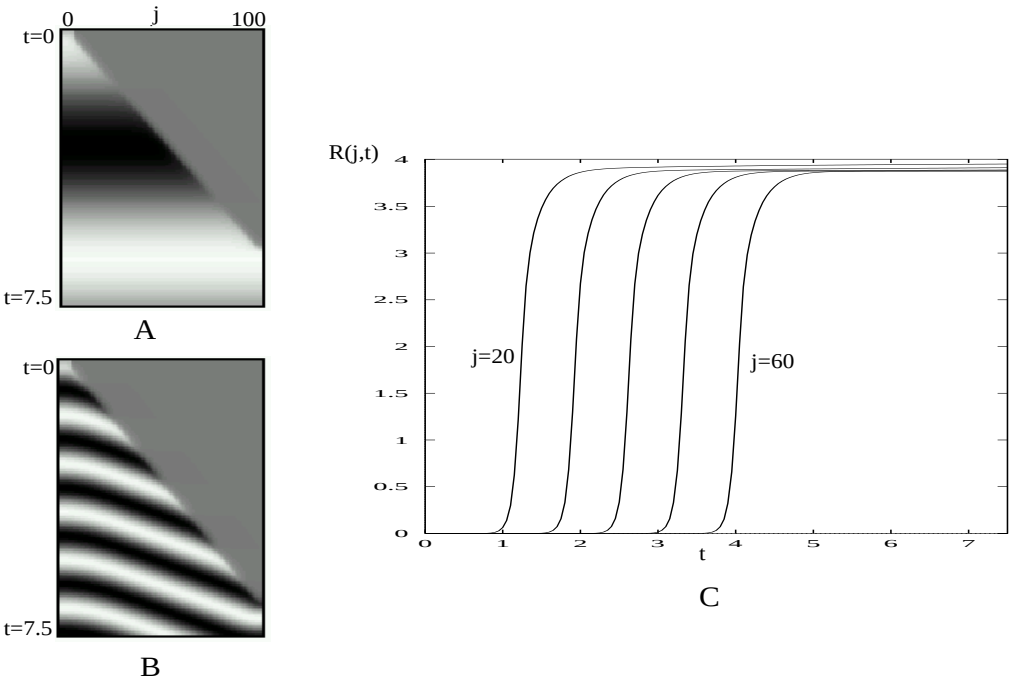

FIG. 2. *Traveling wave solution.* (A) $q = 0.0$, $\lambda = -0.2$, $c_1 = 1$. *This shows* $u(j,t)$ *with* j *horizontal and* t *vertical. Lightest color is* $u = 2$*, and darkest,* $u = -2$. (B) *Same as* (A) *but* $q = 1.0$. (C) *Amplitude* $R = u^2 + v^2$ *as a function of* t *for* $j = 20, 30, 40, 50, 60$*, for* $q = 1.0$.

Since $\theta = 0$, the imaginary part of z is never excited; hence the wave propagated will be from the stable solution $z(x) = 0$ for all $x > x_0$ (without loss of generality we may assume that the wave propagates from left to right) to the stable (parameter dependent) periodic $z(x) = \rho_0$ with zero imaginary part, as shown in Figure 2(A). There is no phase-gradient; all of the oscillators are perfectly synchronized after the wave passes. Because there is no imaginary component of the wave, it has wave number 0. Although we have no proof of existence of the wave for nonzero q, we expect that waves continue to exist at least for some finite range of q around 0. Figure 2(B,C) shows a simulation of the equations for $q = 1.0$. The magnitude, $R = u^2 + v^2$, travels as a front, but there is a clear phase-gradient in the wake of the wave. The frequency of the oscillations is also higher. More properties of the case $q \neq 0$ are considered in the next section.

3.5. The parameter q.

3.5.1. Small q. Assume that $b_1 = c_2 = 0$ and that q is sufficiently small. (Here, small depends on the parameters λ and c_1.) For nonzero q, we cannot assume that $\theta = 0$, so that a phase-gradient will appear (see Figure 2(B)). This, in turn, lowers the effective coupling strength between the oscillators since the coupling includes the term $\cos(\theta(y) - \theta(x))$, and for a large enough gradient, this can be quite small. Thus, one effect of increasing q is the appearance of a phase-gradient which, in turn, weakens the effective coupling strength and thus should slow the wave down.

Figure 3 shows some properties of the wavefront as a function of the magnitude q for $\lambda = -0.2, c_1 = 1$ fixed. As expected from the above discussion, the parameter q

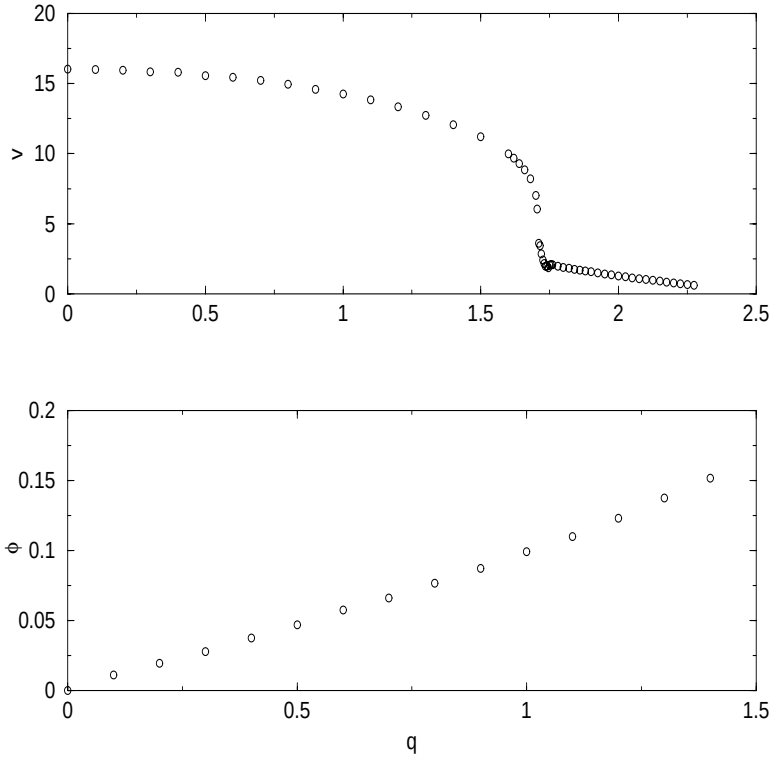

FIG. 3. *Dependence of the wave properties on the parameter q. Upper panel shows the velocity of the front for* $\lambda = -0.2$ *and* $c_1 = 1$. *Lower panel shows the phase-gradient. Note the different horizontal scales. The simulation consists of* 100 *cells coupled to* 20 *nearest neighbors with coupling strength* $\exp(-|j|/2)$. *Front velocity is measured as follows. Let* T_j *denote the time at which* $r_j = 1$. *Then the plotted velocity is just* $10/(T_{70} - T_{60})$, *that is,* $\Delta x/\Delta t$. *The phase-gradient is measured as follows. Let* $\theta_j = \arctan(v_j/u_j)$. *The quantity* $D(t) = (\theta_{60} - \theta_{40})/20 \approx \theta_x$ *is plotted, and the value after the second oscillation is taken to be an approximation of the phase gradient. In a finite domain,* $D(t)$ *always goes to zero since the network synchronizes.*

slows the wave down. For low values of q, this is a gradual decrease in speed. However, at $q \approx 1.75$ there is a precipitous drop in the velocity. For q larger than about 2.25, the wave ceases to exist and is replaced by a stable localized pulse (see below). The critical value of q depends on both the coupling strength c_1 and λ. The closer λ is to zero, the less excitation is required to cause propagation, due to the location of the unstable periodic orbit separating the rest state from the stable oscillation. Thus, for λ close to zero, wave propagation can occur for higher values of q. As λ gets larger in magnitude, the separatrix is farther from the stable rest state, and propagation of a wavefront requires more from the coupling, which large q prevents. This means that if q is fixed, we can achieve a similar slowing by altering the parameter λ. Indeed, we will exploit this in the next section, where we show similar phenomena for a conductance-based neural model. In addition to the drop in the velocity, the phase-gradient increases with q in an almost linear fashion. We compute the phase-gradient only up to about $q = 1.4$, as beyond that, the wave velocity becomes nearly zero, and whether or not there is a traveling front becomes ambiguous. The nearly linear dependence on q leads to a simplification for analyzing the effects of q on the wave velocity. Assume that the oscillations behind the front are quickly drawn to the plane

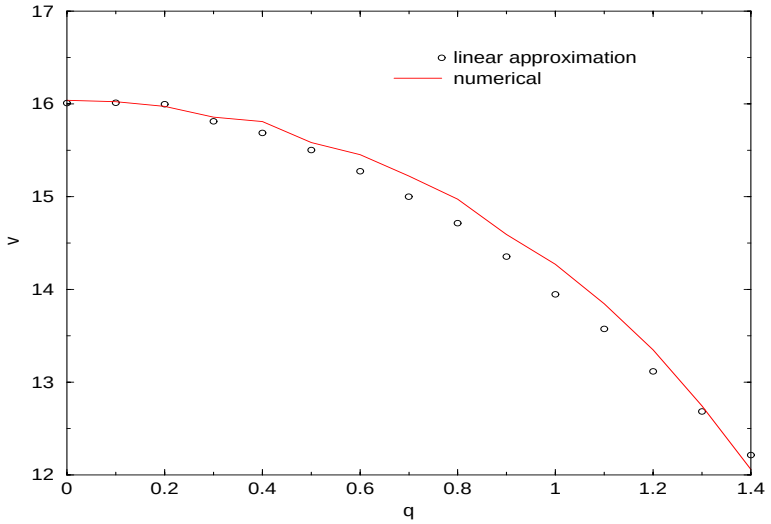

FIG. 4. *Velocity of the full equations (Figure* 3*, top) as* q *varies compared to the velocity computed from the approximate equation* (3.25) *using* $k(q) = q/10$*, which approximates the slope of the lower curve in Figure* 3.

wave and thus $\theta(x,t) = \Omega t + k(q)x$. Here $k(q) \approx mq$ is the asymptotic wave number, and m is the slope of the dependence. Then the amplitude evolves according to the equation

$$r_t = r(\lambda + b_1 r^2 - r^4) + c_1 \int_{-\infty}^{\infty} \tilde{J}(x-y) r^3(y)\, dy, \tag{3.25}$$

where $\tilde{J}(x) = J(x)\cos(k(q)x)$. This is identical (up to normalization) to the zero q model, for which we have proved the existence of a front. Thus, we expect that there will continue to be traveling fronts for q small enough. However, the new convolution kernel $\tilde{J}$ is narrower than the original, and thus we expect the velocity to decrease. Figure 4 shows a comparison of the front velocity for the approximation and the full equations. For values up to $q \approx 1.4$ the approximation is very good. (Recall that the computation of the phase became difficult beyond $q = 1.4$.) For larger values of q, the approximation was not very good.

3.5.2. Larger q and pulse formation. We saw above that the velocity of the front seems to go to zero as q approaches some fixed finite value. We can ask what happens for q beyond this point. One possibility is that the wave will not propagate at all and all initial data will return to the rest state, $z = 0$. However, numerical simulations indicate that rather than decay to rest, the medium remains excited locally and forms localized pulses. Because this excitation is necessary to get the θ variable excited, q large will prohibit excitation. The parameters are selected to lie in a bistable region, and thus the solution $z(t,x) = 0$ is stable. If there is not sufficient coupling, the wave will not propagate, and under sufficiently large initial conditions this can result in bumps or pulse solutions (see Figure 5). This figure shows the real part $u(x,t)$ in a simulation for $q = 3.25$, which is past the regime of existence of traveling fronts. The envelope $R = u^2 + v^2 = |z|^2$ of a pulse appears to be stationary (inset, Figure 5(B)), while the imaginary part appears to be periodic.

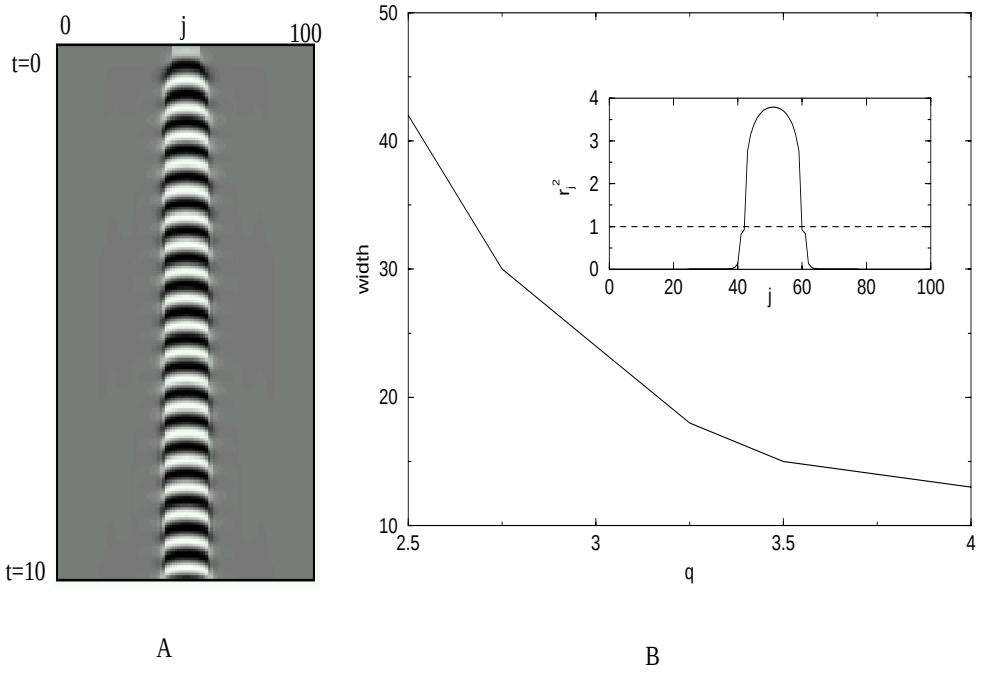

FIG. 5. (A) *Stable localized pulse with* $q = 3.25$, $\lambda = -.2$, $c_1 = 1$. *Grey scale indicates magnitude of* $u_j(t)$. *Index is horizontal, and time runs vertically from* 0 *to* 10. (B) *Pulse width versus* q. *Inset shows* r_j^2, *which appears to be stationary. The horizontal line at* 1 *shows the points at which the width is measured.*

This makes the pulses here quite different from those described in models for working memory (see the discussion and the next section), which have aperiodic behavior. As the parameter q decreases, the width of the pulses gets larger (Figure 5(B)). We conjecture that the width goes to infinity as $|q|$ decreases to q_∞. Figure 3 indicates that the velocity of the fronts goes to zero as q goes to a critical value, q_0. We conjecture that $q_\infty = q_0$, and for the present system that this critical value of q is around 2.5. The reason for this is as follows. Suppose that $q < q_\infty$. Then there are no finite-width pulses. That is, an initial stimulus in the middle of the medium will expand without bound. This is just a pair of wavefronts propagating outward. Similarly, if $q > q_0$, then there are no waves with a positive velocity; we expect that localized sufficiently large initial data will persist and not propagate.

3.5.3. Interactions of pulses. It is possible to initiate multiple pulses in the same medium; however, the behavior is quite dependent on the initial distance as well as the relative phases of the two initial conditions. For example, it is possible for two pulses to merge and form a single pulse, or they can merge and then expand to fill the medium. In the following simulations, the medium is started at rest except for two local regions in which u_j is either 1 or -1. When $u_j = 1$ for both regions, we call this an "in-phase" initial condition, and when $u_j = -1$ we call it "out-of-phase." Figure 6 shows some examples. In (A), a pair of in-phase initial data merge and then chaotically fill the medium. This suggests that the appearance of pulses and the steady-state behavior could depend on the amount of medium initially excited. Indeed, if we excite successively larger parts of the medium, there is a transition from

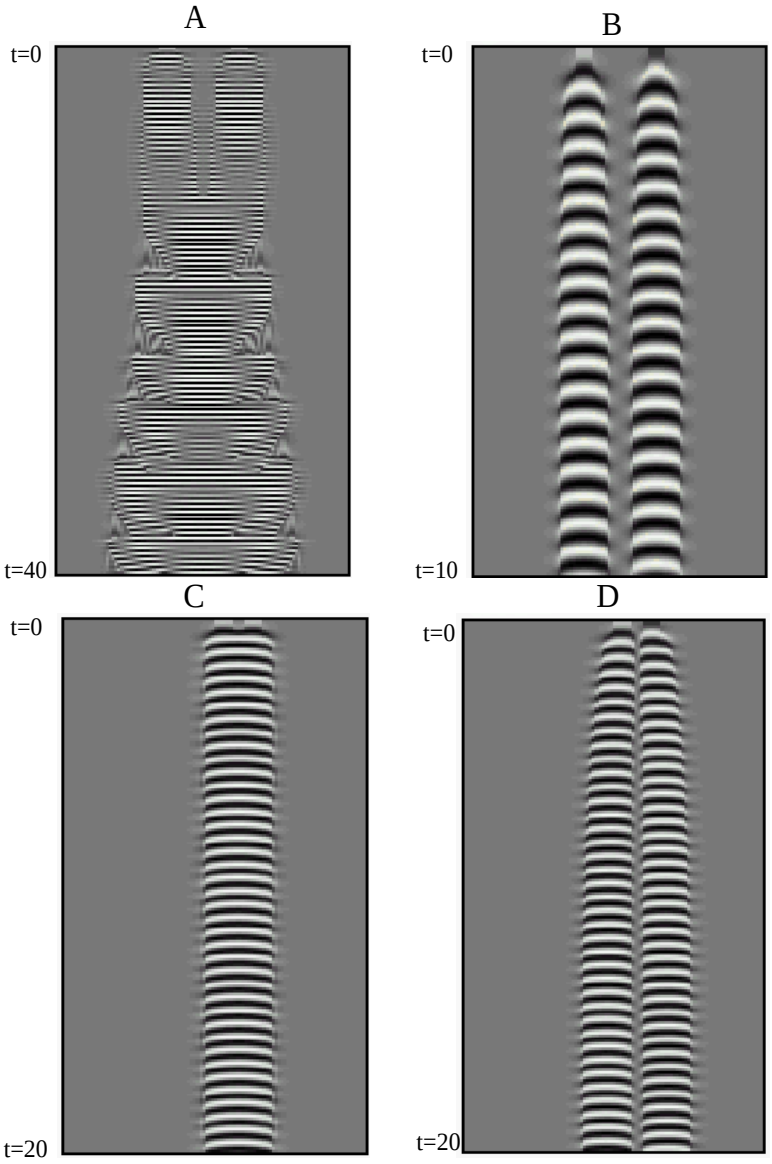

FIG. 6. *Interactions between pulses.* (A) *Two initiated in-phase lead to chaotic behavior;* (B) *same as* (A) *but initially out of phase;* (C) *same as* (A) *but started closer together, leading to merging;* (D) *two out-of-phase pulses split apart. All figures have* $q = 3.25, c_1 = 1, \lambda = -0.2$.

spatially localized behavior to chaotically expanding behavior. In Figure 6(B), the same initial data are given as in A, but the two are out of phase. This results in a pair of local pulses oscillating exactly a half-cycle out of phase. In Figure 6(C), an in-phase pair is started close to each other, leading to simple merging to a single pulse. Finally in (D), the same initial data as in (C) but in antiphase results in a splitting apart of the two pulses rather than a merging. There are many other aspects of interaction which remain to be explored. In particular, the transition between localized pulses and slow chaotic spreading is an intriguing problem.

4. Conductance-based models. The results described in the previous section apply to a very special system of equations, namely, the normal form for a Hopf bifurcation. Thus, a natural question to ask is whether a system away from the bifurcation can have the same behavior. In this section, we consider the behavior of a simple biophysical model with synaptic coupling. The Morris–Lecar (ML) model [21] is a membrane model with leak, calcium, and potassium currents. With the right choice of parameters, the isolated model undergoes a subcritical Hopf bifurcation and has a small regime of bistability between a resting state and a periodic solution. Thus, we will synaptically couple an array of ML neurons and, by altering the applied current, show that the network is able to produce both traveling fronts joining a fixed point to a periodic orbit and localized regions of activity. The equations for each cell are

$$\begin{aligned} C\frac{dV}{dt} &= I - g_l(V - E_l) - g_{Ca}m_\infty(V)(V - E_{Ca}) - g_K n(V - E_K) - I_{syn}, \\ \frac{dn}{dt} &= \frac{n_\infty(V) - n}{\tau_n(V)}, \\ \frac{ds}{dt} &= \alpha(V)(1 - s) - \frac{s}{\tau}, \end{aligned} \tag{4.1}$$

where I_{syn} is the total synaptic current applied to the ith neuron:

$$I_{syn,i} = \left(\sum_j W(i-j)s_j \right) (V_i - E_{syn}).$$

The functions and parameters used are in the appendix. Basically the g's are maximal conductances, the E's are reversal potentials, and $W(j)$ is the coupling strength between neurons and decays with distance. In the normal form, we are able to alter certain abstract parameters such as the imaginary part of the coupling and the nonlinear frequency parameter q. In the actual model, there is no direct analogue of these parameters. However, we can instead alter the applied current I to take the system into and out of the regime of bistability. In Figure 7, we choose I so that the network is near the onset of spontaneous periodicity but remains bistable. A shock at the left of the medium results in a propagating wave shown on the left. Decreasing the current (and making the network less excitable) results in a pulse.

Unlike in the simplified model, the pulse does not seem to be periodic. Rather, it is aperiodic, as is often the case for conductance-based models (see, e.g., [18]).

5. Discussion. We have used a simple canonical model of a bistable oscillatory system to study the propagation of periodic waves and the loss of these waves as either the threshold (λ) changes or the "twist"(q) varies. We have also studied the stability of plane waves in this system. In previous work, we have shown that diffusive coupling in a bistable (oscillatory and fixed point) system leads to a unique traveling front [9]. We also showed that as the threshold changed, the waves disappeared, leaving in their wake spatial patterns. Similar behavior is found in the present model. Unlike the results in [9], we have no closed form for the traveling waves. The existence of wavefronts for sufficiently small values of q remains an open problem; we have proved it only for $q = 0$.

The physiological motivation for this work comes from the behavior of disinhibited slices of cortical tissue [11, 5]. Shocking the tissue results in the propagation of a front

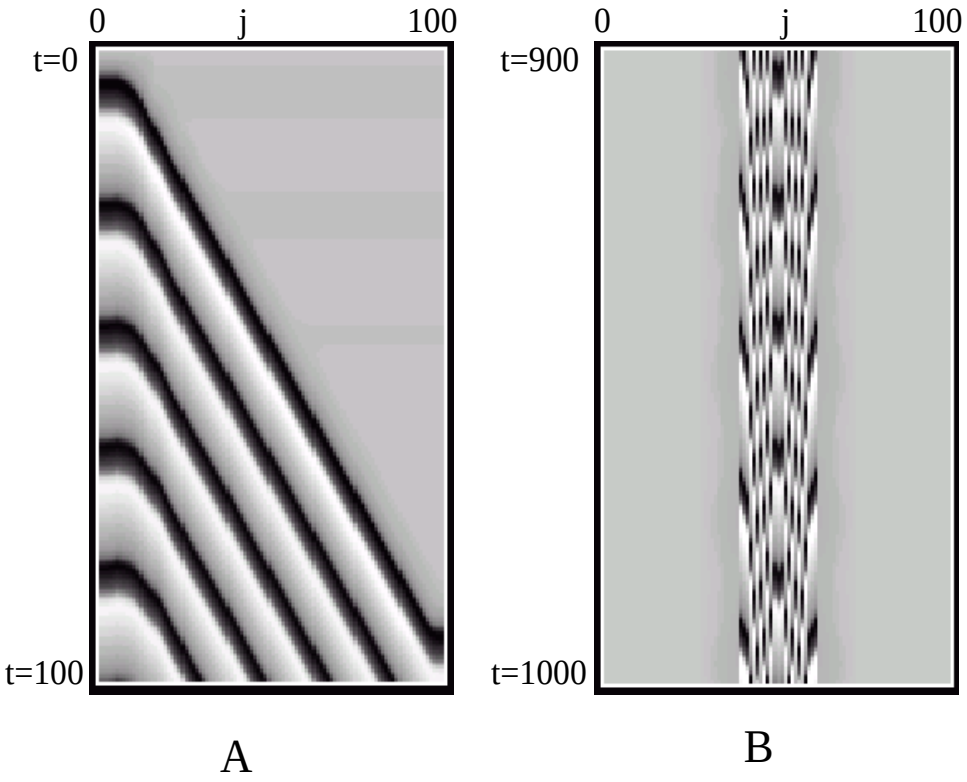

FIG. 7. *Evolution of the voltage for a network of* 100 *ML neurons. The horizontal axis is cell number, and the vertical axis is time in milliseconds. White is a potential of* -45 *mV, and black is a potential of* 20 *mV.* (A) *Traveling wave for* $I = 88$. (B) *Localized pulse for* $I = 82$.

of activity. In experiments the activity eventually terminates due to additional slow processes so that, rather than a front, one obtains a traveling pulse with a finite number of oscillations within the envelope. The present model can be augmented by the addition of a slow negative feedback term, which will terminate the activity, resulting in a spatially confined propagating pulse.

Stationary patterns of localized activity in networks of spiking models have been suggested as models for locally persistent neural activity known as working memory [18, 22]. In these models, the mechanism depends on recurrent excitation of the neurons coupled with *lateral inhibition*. In the context of these models, lateral inhibition means that the connection function $J(x)$ is positive for small $|x|$ and negative for $|x|$ sufficiently large. The present model provides another mechanism which does not depend on lateral inhibition. Rather it depends on bistability between an oscillatory and a rest state. [3] utilized bistability in a firing rate model to obtain localized structures, but, as in the above-mentioned models, they require lateral inhibition. The reason for this can be clarified by looking at our model without the oscillatory component:

$$r_t = r(\lambda + br^2 - r^4) + c\int_{-\infty}^{\infty} J(x-y)r^3(y,t)\ dy.$$

The results of [4], while not precluding localized structures, indicate that in the bistable case, the main type of behavior observed will be stable traveling fronts.

Thus, even though the system is bistable, localized pulses cannot be found with positive $J(x)$. However, the presence of oscillations enables local phase gradients to develop, which can prevent the expansion of the wavefronts beyond a certain range. The mechanism applies to whole classes of voltage-dependent models in which there is a subcritical Hopf bifurcation as current is applied to the system (so-called Type II excitability; see [21]).

It still remains to rigorously prove the existence of these stationary solutions. These satisfy

$$0 = R(\lambda + b_1 R^2 - R^4) + c_1 \int_{-\infty}^{\infty} J(x-y) R^3(y) \cos[\Theta(y) - \Theta(x)]\ dy,$$
$$R(x)\Omega = qR^3(x) + c_1 \int_{-\infty}^{\infty} J(x-y) R^3(y) \sin[\Theta(y) - \Theta(x)]\ dy,$$

where Ω is an unknown parameter, $R(\pm\infty) \to 0$, and $\Theta(0) = 0$. In the case in which $J(x) = \exp(-|x|)/2$, one can then convert the integral equations to a set of differential algebraic equations as follows. Let

$$C(x) = \int_{-\infty}^{\infty} J(x-y) R^3(y) \cos(\Theta(y))\ dy,$$
$$S(x) = \int_{-\infty}^{\infty} J(x-y) R^3(y) \sin(\Theta(y))\ dy,$$

so that we must solve

$$C - C_{xx} = R^3(x) \cos\Theta(x), \qquad S - S_{xx} = R^3(x) \sin\Theta(x),$$

with the constraints

$$0 = R(\lambda + b_1 R^2 - R^4) + c_1 \left(\cos\Theta(x) C(x) + \sin\Theta(x) S(x)\right),$$
$$R\Omega = qR^3 + c_1 \left(\cos\Theta(x) S(x) - \sin\Theta(x) C(x)\right).$$

We have made little progress on this open problem.

Appendix. In the ML equations (4.1), V denotes membrane potential, C is membrane capacitance, and m and h are gating variables. The g's and E_j's are the maximal conductances and reversal potentials, respectively, for calcium, potassium, and leak currents. The gating functions are as follows:

$$n_\infty(v) = .5\left(1 + \tanh\left(\frac{v - v_3}{v_4}\right)\right),$$

$$m_\infty(v) = .5\left(1 + \tanh\left(\frac{v - v_1}{v_2}\right)\right),$$

$$k(v) = \frac{1}{1 + \exp\left(-\dfrac{v - v_t}{v_s}\right)},$$

$$\tau_n(v) = \frac{1}{\cosh\left(\dfrac{v - v_3}{2v_4}\right)},$$

where $v_t = 10$, $v_s = 5$, $v_1 = -1.2$, $v_2 = 18$, $v_3 = 2$, and $v_4 = 30$.

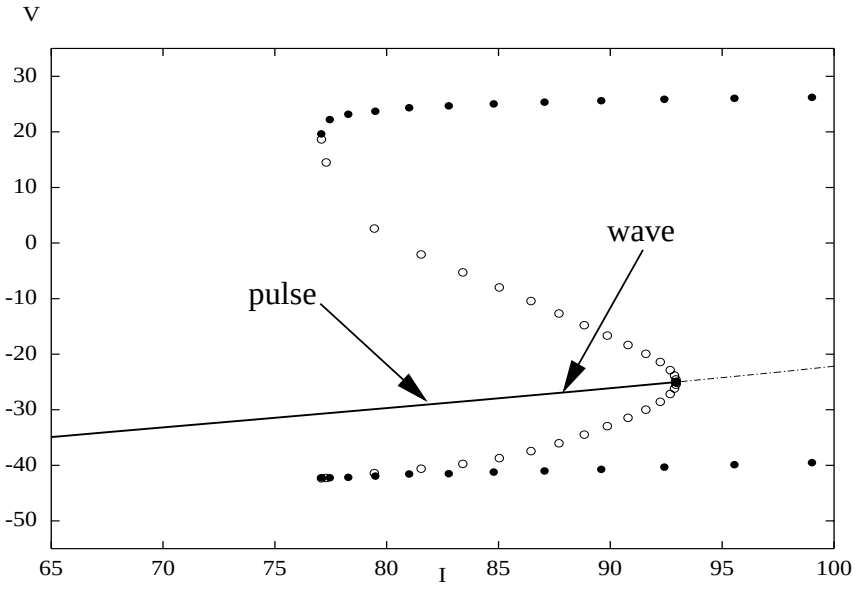

FIG. 8. *Bifurcation diagram obtained by varying I. Arrows denote the values of the current used for the wave and pulse shown in Figure 7.*

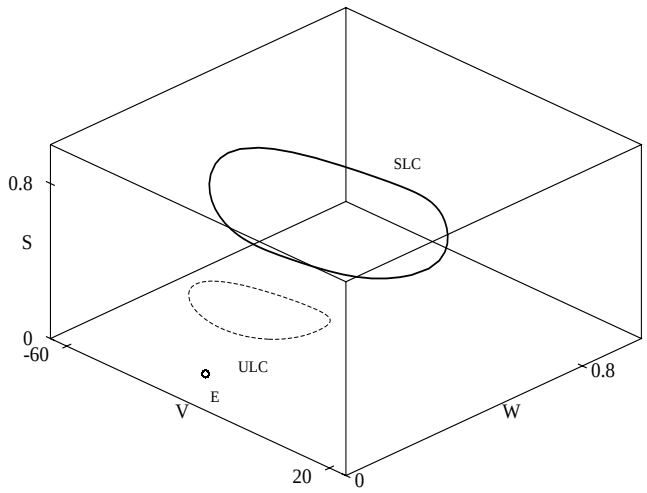

FIG. 9. *In this figure, ULC is the unstable periodic orbit separating the stable fixed point (E) and the stable periodic solution (SLC) in three dimensions (V, w, s) for the ML model.*

The parameters for the ML equations (4.1) for Figure 7 are $\phi = .16$, $g_l = 2$, $g_{ca} = 4.4$, $g_k = 8$, $E_K = -84$, $E_L = -60$, $E_{Ca} = 120$, $E_{syn} = 0$, $\tau_{syn} = 50$, $\alpha = 1$, $g_{syn} = 0.3$, and $C = 5$. With these parameters, the Hopf bifurcation that causes the bistability occurs slightly to the right of $I = 93$. The current used for the traveling waves is $I = 88$ and for the pulses, $I = 82$. These are indicated in the bifurcation diagram. From the bifurcation diagram in Figure 8, at the chosen values for I there

is a stable rest state and a stable periodic, separated by an unstable separatrix. A picture of these orbits is shown in Figure 9. It is not easy in three dimensions to delineate the basins of attraction for the two stable orbits; however, we have found that low values of s and (V, w) near the fixed point are pulled into the rest state, while all other initial data are attracted to the limit cycle.

From the bifurcation diagram, it is possible to estimate the parameters $\lambda = 11.07$, $b = 0.56$, $q = 2.47$ for the model. (Note that we have converted the timescale from milliseconds to seconds, since frequencies are typically measured in Hz.)

SINGULAR PERTURBATIONS IN OPTION PRICING*

J.-P. FOUQUE†, G. PAPANICOLAOU‡, R. SIRCAR§, AND K. SOLNA¶

Abstract. After the celebrated Black–Scholes formula for pricing call options under constant volatility, the need for more general nonconstant volatility models in financial mathematics motivated numerous works during the 1980s and 1990s. In particular, a lot of attention has been paid to stochastic volatility models in which the volatility is randomly fluctuating driven by an additional Brownian motion. We have shown in [*Derivatives in Financial Markets with Stochastic Volatility*, Cambridge University Press, Cambridge, UK, 2000; *Internat. J. Theoret. Appl. Finance*, 13 (2000), pp. 101–142] that, in the presence of a separation of time scales between the main observed process and the volatility driving process, asymptotic methods are very efficient in capturing the effects of random volatility in simple robust corrections to constant volatility formulas. From the point of view of PDEs, this method corresponds to a singular perturbation analysis. The aim of this paper is to deal with the nonsmoothness of the payoff function inherent to option pricing. We present the case of call options for which the payoff function forms an angle at the strike price. This case is important since these are the typical instruments used in the calibration of pricing models. We establish the pointwise accuracy of the corrected Black–Scholes price by using an appropriate payoff regularization which is removed simultaneously as the asymptotics is performed.

Key words. mathematical finance, option pricing, stochastic volatility, singular perturbations

1. Introduction.

Stochastic volatility models in financial mathematics can be thought of as a Brownian-type particle (the stock price) moving in an environment where the diffusion coefficient is randomly fluctuating in time according to some ergodic (mean-reverting) diffusion process. We then have two Brownian motions, one driving the motion of the particle and the other driving the fluctuations of the medium. In the context of physics there is no natural correlation between these two Brownian motions since they do not "live" in the same space. In the context of finance they jointly define the dynamics of the stock price under its physical probability measure or an equivalent risk-neutral martingale measure. Correlation between them is perfectly natural. There are economic arguments for a negative correlation or *leverage effect* between stock price and volatility shocks, and from common experience and empirical studies we know that asset prices tend to go down when volatility goes up. The diffusion equation appears as a contingent claim pricing equation, its terminal condition being the payoff of the claim. We refer to [5] or [6] for surveys on stochastic volatility. When volatility is fast mean-reverting, on a timescale smaller than typical maturities, one can perform a singular perturbation analysis of the pricing PDE. As we have shown in [2], this expansion reveals a first correction made of two terms: one is directly associated with the market price of volatility risk, and the other is propor-

tional to the correlation coefficient between the two Brownian motions involved. We refer to [2] for a detailed account of evidence of a fast scale in volatility and the use of this asymptotics to parametrize the evolution of the *skew* or the implied volatility surface. We also refer to [4] for a different type of application, namely, variance reduction in Monte Carlo methods.

The present paper deals with the accuracy of such an expansion in the presence of another essential characteristic feature in option pricing, namely, the nonsmoothness of payoff functions. We present the case of call options since these are the liquid instruments used in the calibration of pricing models. By inverting the Black–Scholes formula, the price of a call option is given in terms of its implied volatility, which depends on the strike and the maturity of the option. This set of implied volatilities form the *term structure of implied volatility*. For fixed maturity and across strikes it is known as the *smile* or the *skew* due to the observed asymmetry. These objects and their dynamics are what volatility models are trying to reproduce in order to price and hedge other instruments.

In [2] we have performed an expansion of the price in powers of the characteristic mean-reversion time of volatility, and we have shown that the leading order term corresponds to a Black–Scholes price computed under a constant effective volatility. The first correction involves derivatives of this constant volatility price. When the payoff is smooth, we have shown that the corrected price, leading order term plus first correction, has the expected accuracy; namely, the remainder of the expansion is of the next order. The nonsmoothness of a call payoff which forms an angle at the strike price creates a singularity at the maturity time near the strike price of the option.

This paper is devoted to the proof of the accuracy of the approximation in that case. It is important because this is a natural situation in financial mathematics that one has to deal with. The proof given here relies on a payoff smoothing argument, which can certainly be useful in other contexts.

In section 2 we introduce the class of stochastic volatility models which we consider. They are written directly under the pricing equivalent martingale measure and with a small parameter representing the short timescale of volatility. We recall how option prices are given as expected values of discounted payoffs or as solutions of pricing backward parabolic PDEs with terminal conditions at maturity times. In section 3 we recall the formal asymptotic expansion presented in [2]. In section 4 we introduce the regularization of the payoff and decompose the main result, accuracy of the price approximation, into three lemmas. Section 5 is devoted to the proof of these lemmas. Detailed computations involving derivatives of Black–Scholes prices up to order seven are given in the appendices, where we also recall the properties of the solutions of Poisson equations associated with the infinitesimal generator of the Ornstein-Uhlenbeck process driving the volatility.

2. Class of models and pricing equations. The family of Ornstein–Uhlenbeck (OU) driven stochastic volatility models $(S_t^\varepsilon, Y_t^\varepsilon)$ that we consider can be written, under a risk-neutral probability $\mathbb{P}^\star$, in terms of the small parameter ε,

$$\begin{aligned} dS_t^\varepsilon &= rS_t^\varepsilon dt + f(Y_t^\varepsilon) S_t^\varepsilon dW_t^\star, \\ dY_t^\varepsilon &= \left[\frac{1}{\varepsilon}(m - Y_t^\varepsilon) - \frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}\Lambda(Y_t^\varepsilon)\right] dt + \frac{\nu\sqrt{2}}{\sqrt{\varepsilon}} d\hat{Z}_t^\star, \end{aligned}$$

where the Brownian motions $(W_t^\star, \hat{Z}_t^\star)$ have instantaneous correlation $\rho \in (-1, 1)$,

$$d\langle W^\star, \hat{Z}^\star\rangle_t = \mathbb{E}^\star\{dW_t^\star \, d\hat{Z}_t^\star\} = \rho \, dt$$

and

$$\Lambda(y) = \frac{\rho(\mu - r)}{f(y)} + \gamma(y)\sqrt{1-\rho^2}$$

is a combined market price of risk. It describes the relationship between the physical measure under which the stock price is observed and the risk-neutral measure under which the market prices derivative securities; see [2], for example. The price of the underlying stock is S_t^ε, and the volatility is a function f of the process Y_t^ε. At the leading order $1/\varepsilon$, that is, omitting the Λ-term, Y_t^ε is an OU process that is fast mean-reverting with a normal invariant distribution $\mathcal{N}(m, \nu^2)$. Notice that in this framework the volatility driving process (Y_t^ε) is autonomous in the sense that the coefficients in its defining SDE do not depend on the stock price S_t^ε.

In this *fast mean-reverting* stochastic volatility scenario, the volatility level fluctuates randomly around its mean level, and the epochs of high/low volatility are relatively short. This is the regime that we consider and under which we analyze the price of European derivatives. A derivative is defined by its nonnegative payoff function $H(S)$, which prescribes the value of the contract at its maturity time T when the stock price is S. The payoff function must in general satisfy the integrability condition

$$\mathbb{E}^\star\{H(S_T)^2\} < \infty,$$

with $\mathbb{E}^\star$ denoting expectation with respect to $\mathbb{P}^\star$. Moreover, we *assume* the following:

1. The volatility is positive and bounded: there are constants m_1 and m_2 such that

$$0 < m_1 \le f(y) \le m_2 < \infty \qquad \forall y \in \mathcal{R}.$$

2. The volatility risk-premium is bounded:

$$|\gamma(y)| < l < \infty \qquad \forall y \in \mathcal{R}$$

for some constant l.

It is convenient at this stage to make the change of variable

$$X_t^\varepsilon = \log S_t^\varepsilon, \qquad t \ge 0,$$

and write the problem in terms of the processes $(X_t^\varepsilon, Y_t^\varepsilon)$, which satisfy, by Itô's formula, the stochastic differential equations

$$dX_t^\varepsilon = \left(r - \frac{1}{2} f(Y_t^\varepsilon)^2\right) dt + f(Y_t^\varepsilon)\, dW_t^\star, \tag{2.1}$$

$$dY_t^\varepsilon = \left[\frac{1}{\varepsilon}(m - Y_t^\varepsilon) - \frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}\Lambda(Y_t^\varepsilon)\right] dt + \frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}\, d\hat{Z}_t^\star. \tag{2.2}$$

We also define the payoff function h in terms of the log stock price via

$$H(e^x) = h(x), \qquad x \in \mathcal{R}.$$

The price at time $t < T$ of this derivative is a function of the present value of the stock price, or equivalently the log stock price, $X_t^\varepsilon = x$ and the present value $Y_t^\varepsilon = y$ of the process driving the volatility. We denote this price by $P^\varepsilon(t, x, y)$. It is standard

in finance to assume that the price is given by (2.3), which is the expected discounted payoff under the risk-neutral probability measure $\mathbb{P}^\star$. See [1], for example.

$$P^\varepsilon(t,x,y) = \mathbb{E}^\star\left\{e^{-r(T-t)}h(X_T^\varepsilon)|X_t^\varepsilon = x, Y_t^\varepsilon = y\right\}. \tag{2.3}$$

We shall also write these conditional expectations more compactly as

$$P^\varepsilon(t,x,y) = \mathbb{E}^\star{}_{t,x,y}\left\{e^{-r(T-t)}h(X_T^\varepsilon)\right\}.$$

Under the assumptions on the models considered and the payoff, $P^\varepsilon(t,x,y)$ is the unique classical solution to the associated backward Kolmogorov PDE problem

$$\begin{aligned}\mathcal{L}^\varepsilon P^\varepsilon &= 0,\\ P^\varepsilon(T,x,y) &= h(x)\end{aligned} \tag{2.4}$$

in $t<T$, $x,y\in\mathcal{R}$, where we have defined the operators

$$\mathcal{L}^\varepsilon = \frac{1}{\varepsilon}\mathcal{L}_0 + \frac{1}{\sqrt{\varepsilon}}\mathcal{L}_1 + \mathcal{L}_2,$$

$$\mathcal{L}_0 = \nu^2\frac{\partial^2}{\partial y^2} + (m-y)\frac{\partial}{\partial y}, \tag{2.5}$$

$$\mathcal{L}_1 = \sqrt{2}\rho\nu f(y)\frac{\partial^2}{\partial x\partial y} - \sqrt{2}\nu\Lambda(y)\frac{\partial}{\partial y}, \tag{2.6}$$

$$\mathcal{L}_2 = \frac{\partial}{\partial t} + \frac{1}{2}f(y)^2\frac{\partial^2}{\partial x^2} + \left(r - \frac{1}{2}f(y)^2\right)\frac{\partial}{\partial x} - r\cdot. \tag{2.7}$$

The operator $\mathcal{L}_0$ is the infinitesimal generator of the OU process (Y_t) defined by

$$dY_t = (m - Y_t)\,dt + \nu\sqrt{2}\,d\hat{Z}_t^\star; \tag{2.8}$$

$\mathcal{L}_1$ contains the mixed partial derivative due to the correlation and the derivative due to the market price of risk, and $\mathcal{L}_2$, also denoted by $\mathcal{L}_{BS}(f(y))$, is the Black–Scholes operator in the log variable and with volatility $f(y)$.

3. Price approximation. We present here the formal asymptotic expansion computed as in [2, 3], which leads to a (first-order in $\sqrt{\varepsilon}$) approximation $P^\varepsilon(t,x,y)\approx Q^\varepsilon(t,x)$. In the next section we prove the convergence and accuracy as $\varepsilon\downarrow 0$ of this approximation, which consists of the first two terms of the asymptotic price expansion:

$$Q^\varepsilon(t,x) = P_0(t,x) + \sqrt{\varepsilon}P_1(t,x),$$

which do not depend on y and are derived as follows. We start by writing

$$P^\varepsilon = Q^\varepsilon + \varepsilon Q_2 + \varepsilon^{3/2}Q_3 + \cdots = P_0 + \sqrt{\varepsilon}P_1 + \varepsilon Q_2 + \varepsilon^{3/2}Q_3 + \cdots. \tag{3.1}$$

Substituting (3.1) into (2.4) leads to

$$\begin{aligned}&\frac{1}{\varepsilon}\mathcal{L}_0P_0 + \frac{1}{\sqrt{\varepsilon}}\left(\mathcal{L}_0P_1 + \mathcal{L}_1P_0\right)\\ &+ \left(\mathcal{L}_0Q_2 + \mathcal{L}_1P_1 + \mathcal{L}_2P_0\right) + \sqrt{\varepsilon}\left(\mathcal{L}_0Q_3 + \mathcal{L}_1Q_2 + \mathcal{L}_2P_1\right) + \cdots \;=\; 0.\end{aligned} \tag{3.2}$$

We shall next obtain expressions for P_0 and P_1 by successively equating the four leading order terms in (3.2) to zero. We let $\langle\cdot\rangle$ denote the averaging with respect to the invariant distribution $\mathcal{N}(m,\nu^2)$ of the OU process Y introduced in (2.8):

$$\langle g\rangle = \frac{1}{\nu\sqrt{2\pi}}\int_{\mathcal{R}} g(y)e^{-(m-y)^2/2\nu^2}dy. \tag{3.3}$$

Notice that this averaged quantity does not depend on ε.

Below, we will need to solve the *Poisson equation* associated with $\mathcal{L}_0$,

$$\mathcal{L}_0\chi + g = 0, \tag{3.4}$$

which requires the solvability condition

$$\langle g\rangle = 0 \tag{3.5}$$

in order to admit solutions with reasonable growth at infinity. Properties of this equation and its solutions are recalled in Appendix C.

Consider first the leading order term

$$\mathcal{L}_0 P_0 = 0.$$

Since $\mathcal{L}_0$ takes derivatives with respect to y, any function independent of y satisfies this equation. On the other hand y-dependent solutions exhibit the unreasonable growth $\exp(y^2/2\nu^2)$ at infinity. Therefore we seek solutions which are independent of y: $P_0 = P_0(t,x)$ with the terminal condition $P_0(T,x) = h(x)$.

Consider next

$$\mathcal{L}_0 P_1 + \mathcal{L}_1 P_0 = 0,$$

which corresponds to the second term in (3.2). Since $\mathcal{L}_1$ contains only terms with derivatives in y, it reduces to $\mathcal{L}_0 P_1 = 0$ and, as for P_0, we seek again a function $P_1 = P_1(t,x)$, independent of y, with a zero terminal condition $P_1(T,x) = 0$. Hence, $Q^\varepsilon = P_0 + \sqrt{\varepsilon}P_1$, the leading order approximation, does not depend on the current value of the volatility level.

The next equation

$$\mathcal{L}_0 Q_2 + \mathcal{L}_1 P_1 + \mathcal{L}_2 P_0 = 0,$$

which corresponds to the third term in (3.2), reduces to the Poisson equation

$$\mathcal{L}_0 Q_2 + \mathcal{L}_2 P_0 = 0, \tag{3.6}$$

since $\mathcal{L}_1 P_1 = 0$. Its solvability condition

$$\langle \mathcal{L}_2 P_0\rangle = \langle \mathcal{L}_2\rangle P_0 = 0,$$

is the Black–Scholes PDE (in the log variable) with constant square volatility $\langle f^2\rangle$:

$$\langle \mathcal{L}_2\rangle P_0 = \mathcal{L}_{BS}(\bar\sigma)P_0 = \frac{\partial P_0}{\partial t} + \frac{1}{2}\bar\sigma^2\frac{\partial^2 P_0}{\partial x^2} + \left(r - \frac{1}{2}\bar\sigma^2\right)\frac{\partial P_0}{\partial x} - rP_0 = 0, \tag{3.7}$$

where we define the *effective constant volatility* $\bar\sigma$ by

$$\bar\sigma^2 = \langle f^2\rangle.$$

We choose $P_0(t,x)$ to be the classical Black–Scholes price, solution of (3.7) with the terminal condition $P_0(T,x) = h(x)$.

Observe that $Q_2 = -\mathcal{L}_0^{-1}(\mathcal{L}_2 - \langle\mathcal{L}_2\rangle)P_0$ as a solution of the Poisson equation (3.6). This notation includes an additive constant in y, which will disappear when hit by the operator $\mathcal{L}_1$ below. The fourth term in (3.2) gives the equation

$$\mathcal{L}_0 Q_3 + \mathcal{L}_1 Q_2 + \mathcal{L}_2 P_1 = 0. \tag{3.8}$$

This is a Poisson equation in Q_3, and its solvability condition gives

$$\langle\mathcal{L}_2\rangle P_1 = -\langle\mathcal{L}_1 Q_2\rangle = \langle\mathcal{L}_1\mathcal{L}_0^{-1}(\mathcal{L}_2 - \langle\mathcal{L}_2\rangle)\rangle P_0,$$

which, with its zero terminal condition, determines P_1 as a solution of a Black–Scholes equation with constant square volatility $\langle f^2\rangle$ and a source term. Using the expressions for $\mathcal{L}_i$, one can rewrite the source as

$$\begin{aligned}\langle\mathcal{L}_1\mathcal{L}_0^{-1}(\mathcal{L}_2 - \langle\mathcal{L}_2\rangle)\rangle P_0 &= \left\langle\mathcal{L}_1\mathcal{L}_0^{-1}\left(f(y)^2 - \langle f^2\rangle\right)\right\rangle \frac{1}{2}\left(\frac{\partial^2}{\partial x^2} - \frac{\partial}{\partial x}\right)P_0 \\ &= \left(v_3\frac{\partial^3}{\partial x^3} + (v_2 - 3v_3)\frac{\partial^2}{\partial x^2} + (2v_3 - v_2)\frac{\partial}{\partial x}\right)P_0, \end{aligned} \tag{3.9}$$

where

$$\begin{aligned} v_2 &= \frac{\nu}{\sqrt{2}}(2\rho\langle f\phi'\rangle - \langle\Lambda\phi'\rangle), \\ v_3 &= \frac{\rho\nu}{\sqrt{2}}\langle f\phi'\rangle, \end{aligned} \tag{3.10}$$

and ϕ is a solution of the Poisson equation

$$\mathcal{L}_0\phi(y) = f(y)^2 - \langle f^2\rangle. \tag{3.11}$$

We can therefore conclude the following:

a. The first term P_0 is chosen to be the solution of the "homogenized" PDE problem (3.7). In other words, P_0 is simply the Black–Scholes price of the derivative computed with the effective volatility $\bar\sigma$.

b. The second term, or correction to the Black–Scholes price, is given explicitly as a linear combination of the first three derivatives of P_0, by

$$\sqrt{\varepsilon}\,P_1 = -(T-t)\left(V_3^\varepsilon\frac{\partial^3}{\partial x^3} + (V_2^\varepsilon - 3V_3^\varepsilon)\frac{\partial^2}{\partial x^2} + (2V_3^\varepsilon - V_2^\varepsilon)\frac{\partial}{\partial x}\right)P_0, \tag{3.12}$$

with

$$V_{2,3}^\varepsilon = \sqrt{\varepsilon}\,v_{2,3}, \tag{3.13}$$

since it is easily seen, by using $\langle\mathcal{L}_2\rangle P_0 = 0$, that (3.9) is satisfied and that, on the other hand, the terminal condition $P_1(T,x) = 0$ is satisfied when $\lim_{t\to T}(T-t)\frac{\partial^i P_0}{\partial x^i} = 0$ for $i = 1,2,3$.

Essential instruments in financial markets are put and call options for which the payoff function $H(S)$ is piecewise linear. We shall focus on call options:

$$H(S) = (S-K)^+ \qquad \Rightarrow \qquad h(x) = (e^x - K)^+$$

for some given strike price $K > 0$. Notice that h is only $\mathcal{C}^0$ smooth with a discontinuous first derivative at the kink $x = \log K$ ("at the money" in financial terms). Nonetheless, at $t < T$, the Black–Scholes pricing function $P_0(t, x)$ is smooth and $P_1(t, x)$ is well defined, but second and higher derivatives of P_0 with respect to x blow up as $t \to T$ (at the money).

Our main result on the accuracy of the approximation $Q^\varepsilon = P_0 + \sqrt{\varepsilon}\, P_1$ is as follows.

THEOREM 3.1. *Under the assumptions* 1 *and* 2 *above, at a fixed point* $t < T$, $x, y \in \mathcal{R}$, *the accuracy of the approximation of call prices is given by*

$$\lim_{\varepsilon \downarrow 0} \frac{|P^\varepsilon(t, x, y) - Q^\varepsilon(t, x)|}{\varepsilon |\log \varepsilon|^{1+p}} = 0$$

for any $p > 0$.

Observe that this pointwise approximation is the sense of accuracy needed in finance applications since option prices are computed at given values of (t, x, y).

Before giving in the next section the proof of Theorem 3.1, we comment on the interpretation of the approximation and on the validity of the result for more general payoffs.

Financial interpretation of the approximation. In order to give a meaningful interpretation to the leading order term and the correction in our price approximation it is convenient to return to the variable S, the underlying price. With a slight abuse of notation we denote the call option price approximation by $P_0(t, S) + \sqrt{\varepsilon} P_1(t, S)$. Indeed, the leading order term $P_0(t, S)$ is the standard Black–Scholes price of the call option computed at the effective constant volatility $\bar{\sigma}$. From (3.12), one can easily deduce that

$$\sqrt{\varepsilon}\, P_1(t, S) = -(T - t) \left(V_2^\varepsilon S^2 \frac{\partial^2 P_0}{\partial S^2} + V_3^\varepsilon S^3 \frac{\partial^3 P_0}{\partial S^3} \right), \tag{3.14}$$

which shows that the correction is a combination of the two variables *gamma* and *epsilon*, as introduced in [2]. This correction can alternatively be written in the form

$$\sqrt{\varepsilon}\, P_1(t, S) = -(T - t) \left((V_2^\varepsilon - 2V_3^\varepsilon) S^2 \frac{\partial^2 P_0}{\partial S^2} + V_3^\varepsilon S \frac{\partial}{\partial S} \left(S^2 \frac{\partial^2 P_0}{\partial S^2} \right) \right). \tag{3.15}$$

Using the classical relation between *gamma* and *vega* for Black–Scholes prices of European derivatives

$$\frac{\partial P_0}{\partial \sigma} = (T - t) \sigma S^2 \frac{\partial^2 P_0}{\partial S^2},$$

which is easily obtained by differentiating the Black–Scholes PDE with respect to σ, one can rewrite the correction as

$$\sqrt{\varepsilon}\, P_1(t, S) = -\frac{1}{\bar{\sigma}} \left((V_2^\varepsilon - 2V_3^\varepsilon) \frac{\partial P_0}{\partial \sigma} + V_3^\varepsilon S \frac{\partial}{\partial S} \left(\frac{\partial P_0}{\partial \sigma} \right) \right). \tag{3.16}$$

Therefore the price correction is a combination of the *vega* and the *delta-vega* of the Black–Scholes price. The *vega* term corresponds simply to a volatility level correction. The *delta-vega* term is proportional to the correlation coefficient ρ and captures the main effect of skewness in implied volatility as discussed in detail in [2].

Other payoff functions. The main idea of the proof presented in the next section is a regularization of the payoff, which does not rely on the particular choice of a call option. The only place where we use the explicit Black–Scholes formula for a call option is in the computation (B.1) of the successive derivatives $\partial_x^n P_0^\delta$ carried out in Appendix B. Note that if we had started with a payoff function h which was continuous and piecewise smooth (a call option being a particular case), then P_0^δ, the solution of the parabolic PDE (3.7), would be an integral of the payoff function with respect to a normal density, as in the case of a call option. The first derivative with respect to x can be taken on the payoff function, and the higher-order derivatives can then be taken on the normal density, as detailed in Appendix B for a call option. Therefore Theorem 3.1 remains valid for general European claims with continuous payoffs that have singular behavior in their derivatives.

Numerical illustration. To illustrate the asymptotic approximation, we compare the approximation

$$Q^\varepsilon = P_0 + \sqrt{\varepsilon}\, P_1$$

with a numerical solution of the PDE (2.4) for a particular stochastic volatility model and a call option with strike price $K = 100$ and three months before expiration. (In practice, the asymptotic approximation is not used in this manner because of the difficulties of estimating the volatility parameters precisely; instead the parameters of the approximation V_2^ε and V_3^ε are estimated directly from observed options prices, as described in [2].)

We choose $f(y) = e^y$, where this is understood to stand for a cutoff version of the exponential function, with the cutoffs (above and below) sufficiently large and small, respectively, so as not to affect the calculations within the accuracy of our comparisons. We use the parameter values

$$\varepsilon = \frac{1}{200}, \qquad m = \log 0.1, \qquad \nu = \frac{1}{\sqrt{2}}, \qquad \rho = -0.2,$$

$$\mu = 0.2, \qquad r = 0.04$$

and choose the volatility risk premium $\gamma \equiv 0$. It follows from explicit calculations that the parameters for the asymptotic approximation, are

$$\bar\sigma = 0.165, \qquad V_2^\varepsilon = -3.30 \times 10^{-4}, \qquad V_3^\varepsilon = 8.48 \times 10^{-5}.$$

Figure 1 shows the numerical solution from an implicit finite-difference approximation at two levels of the current volatility e^y, one at the long-run mean-level $\bar\sigma$, and one far above it (0.607). These are compared to the asymptotic approximation, which does not depend on the current volatility level. In the range $0.95 \le K/S \le 1.04$ shown in the graph on the right, the maximum deviation of the asymptotic approximation from the price with the higher volatility is 9% of the latter price, and the maximum deviation of the asymptotic approximation from the price with the lower volatility is 2.1% of this price.

4. Derivation of the accuracy of the price approximation. In order to prove Theorem 3.1, we introduce in the next section the regularized price $P^{\varepsilon,\delta}$, the price of a slightly smoothed call option, with δ being the (small) smoothing parameter. We denote the associated price approximation by $Q^{\varepsilon,\delta}$. The proof then involves showing that (i) $P^\varepsilon \approx P^{\varepsilon,\delta}$, (ii) $Q^{\varepsilon,\delta} \approx Q^\varepsilon$, (iii) $P^{\varepsilon,\delta} \approx Q^{\varepsilon,\delta}$ and controlling the accuracy in these approximations by choosing δ appropriately.

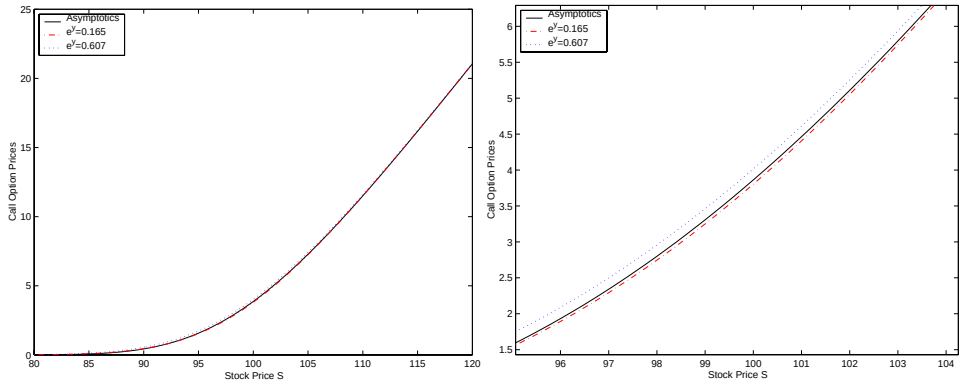

FIG. 1. *Call option prices three months from maturity as a function of the current stock price S. The strike price is $K = 100$, and the graph on the right focuses on the region "around the money."*

4.1. Regularization. We begin by regularizing the payoff, which is a *call option*, by replacing it with the Black–Scholes price of a call with volatility $\bar{\sigma}$ and time to maturity δ. We define

$$h^\delta(x) := C_{BS}(T-\delta, x; K, T; \bar{\sigma}),$$

where $C_{BS}(t, x; K, T; \bar{\sigma})$ denotes the Black–Scholes call option price as a function of current time t, log stock price x, strike price K, expiration date T, and volatility $\bar{\sigma}$. It is given by

$$\begin{aligned} C_{BS}(t,x;K,T;\bar{\sigma}) = P_0(t,x;K,T;\bar{\sigma}) &= e^x N(d_1) - K e^{-r\frac{\tau^2}{\bar{\sigma}^2}} N(d_2), \\ N(x) &= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-y^2/2}\, dy, \\ d_1 &= \frac{x - \log K}{\tau} + b\tau, \\ d_2 &= d_1 - \tau, \end{aligned} \tag{4.1}$$

where we define

$$\tau = \bar{\sigma}\sqrt{T-t}, \qquad b = \frac{r}{\bar{\sigma}^2} + \frac{1}{2}.$$

For $\delta > 0$, this new payoff is $\mathcal{C}^\infty$. The price $P^{\varepsilon,\delta}(t,x,y)$ of the option with the regularized payoff solves

$$\begin{aligned} \mathcal{L}^\varepsilon P^{\varepsilon,\delta} &= 0, \\ P^{\varepsilon,\delta}(T,x,y) &= h^\delta(x). \end{aligned}$$

4.2. Main convergence result. Let $Q^{\varepsilon,\delta}(t,x)$ denote the first-order approximation to the regularized option price:

$$P^{\varepsilon,\delta} \approx Q^{\varepsilon,\delta} \equiv P_0^\delta + \sqrt{\varepsilon} P_1^\delta,$$

where

$$P_0^\delta(t,x) = C_{BS}(t-\delta, x; K, T; \bar{\sigma}), \tag{4.2}$$

$$\sqrt{\varepsilon} P_1^\delta = -(T-t)\left(V_3^\varepsilon \frac{\partial^3}{\partial x^3} + (V_2^\varepsilon - 3V_3^\varepsilon)\frac{\partial^2}{\partial x^2} + (2V_3^\varepsilon - V_2^\varepsilon)\frac{\partial}{\partial x} \right) P_0^\delta. \tag{4.3}$$

We establish the following pathway to proving Theorem 3.1, where constants may depend on (t, T, x, y) but not on (ε, δ).

LEMMA 4.1. *Fix the point (t, x, y), where $t < T$. There exist constants $\bar{\delta}_1 > 0$, $\bar{\varepsilon}_1 > 0$, and $c_1 > 0$ such that*

$$|P^{\varepsilon}(t, x, y) - P^{\varepsilon,\delta}(t, x, y)| \leq c_1 \delta$$

for all $0 < \delta < \bar{\delta}_1$ and $0 < \varepsilon < \bar{\varepsilon}_1$.

This establishes that the solutions to the regularized and unregularized problems are close.

LEMMA 4.2. *Fix the point (t, x, y), where $t < T$. There exist constants $\bar{\delta}_2 > 0$, $\bar{\varepsilon}_2 > 0$, and $c_2 > 0$ such that*

$$|Q^{\varepsilon}(t, x) - Q^{\varepsilon,\delta}(t, x)| \leq c_2 \delta$$

for all $0 < \delta < \bar{\delta}_2$ and $0 < \varepsilon < \bar{\varepsilon}_2$.

This establishes that the first-order asymptotic approximations to the regularized and unregularized problems are close.

LEMMA 4.3. *Fix the point (t, x, y), where $t < T$. There exist constants $\bar{\delta}_3 > 0$, $\bar{\varepsilon}_3 > 0$, and $c_3 > 0$ such that*

$$|P^{\varepsilon,\delta}(t, x, y) - Q^{\varepsilon,\delta}(t, x)| \leq c_3 \left(\varepsilon |\log \delta| + \varepsilon \sqrt{\frac{\varepsilon}{\delta}} + \varepsilon \right)$$

for all $0 < \delta < \bar{\delta}_3$ and $0 < \varepsilon < \bar{\varepsilon}_3$.

This establishes that for fixed δ the approximation to the regularized problem converges to the regularized price as $\varepsilon \downarrow 0$.

The convergence result proceeds from these lemmas as follows.

Proof of Theorem 3.1. Take $\bar{\delta} = \min(\bar{\delta}_1, \bar{\delta}_2, \bar{\delta}_3)$ and $\bar{\varepsilon} = \min(\bar{\varepsilon}_1, \bar{\varepsilon}_2, \bar{\varepsilon}_3)$. Then using Lemmas 4.1, 4.2, and 4.3, we obtain

$$\begin{aligned} |P^{\varepsilon} - Q^{\varepsilon}| &\leq |P^{\varepsilon} - P^{\varepsilon,\delta}| + |P^{\varepsilon,\delta} - Q^{\varepsilon,\delta}| + |Q^{\varepsilon,\delta} - Q^{\varepsilon}| \\ &\leq 2 \max(c_1, c_2) \delta + c_3 \left(\varepsilon |\log \delta| + \varepsilon \sqrt{\frac{\varepsilon}{\delta}} + \varepsilon \right) \end{aligned}$$

for $0 < \delta < \bar{\delta}$ and $0 < \varepsilon < \bar{\varepsilon}$, where the functions are evaluated at the fixed (t, x, y). Taking $\delta = \varepsilon$, we have

$$|P^{\varepsilon} - Q^{\varepsilon}| \leq c_5 (\varepsilon + \varepsilon |\log \varepsilon|)$$

for some fixed $c_5 > 0$, and Theorem 3.1 follows.

A general conclusion to our work is given in section 6 after the proofs of Lemmas 4.1, 4.2, and 4.3 given in the following section.

5. Proof of lemmas.

5.1. Proof of Lemma 4.1. We use the probabilistic representation of the price given as the expected discounted payoff with respect to the risk-neutral pricing equivalent martingale measure $\mathbb{P}^{\star}$:

$$P^{\varepsilon,\delta}(t, x, y) = \mathbb{E}^{\star}{}_{t,x,y} \left\{ e^{-r(T-t)} h^{\delta}(X_T^{\varepsilon}) \right\}.$$

We define the new process $(\tilde{X}_t^\varepsilon)$ by

$$d\tilde{X}_t^\varepsilon = \left(r - \frac{1}{2}\tilde{f}(t, Y_t^\varepsilon)^2\right) dt + \tilde{f}(t, Y_t^\varepsilon)\left(\sqrt{1-\rho^2}\, d\hat{W}_t^\star + \rho\, d\hat{Z}_t^\star\right),$$

where $(\hat{W}_t^\star)$ is a Brownian motion independent of $(\hat{Z}_t^\star)$, (Y_t^ε) is still a solution of (2.2), and

$$\tilde{f}(t,y) = \begin{cases} f(y) & \text{for } t \le T, \\ \bar{\sigma} & \text{for } t > T. \end{cases}$$

Then we can write

$$P^{\varepsilon,\delta}(t,x,y) = \mathbb{E}^\star{}_{t,x,y}\left\{e^{-r(T-t+\delta)} h(\tilde{X}^\varepsilon_{T+\delta})\right\}$$

and

$$P^{\varepsilon}(t,x,y) = \mathbb{E}^\star{}_{t,x,y}\left\{e^{-r(T-t)} h(\tilde{X}^\varepsilon_{T})\right\}.$$

Next we use the iterated expectations formula

$$\begin{aligned} &P^{\varepsilon,\delta}(t,x,y) - P^{\varepsilon}(t,x,y) \\ &\quad = \mathbb{E}^\star{}_{t,x,y}\big\{\mathbb{E}^\star\big\{e^{-r(T-t+\delta)} h(\tilde{X}^\varepsilon_{T+\delta}) - e^{-r(T-t)} h(\tilde{X}^\varepsilon_{T}) \mid (\hat{Z}^\star_s)_{t\le s\le T}\big\}\big\} \end{aligned}$$

to obtain a representation of this price difference in terms of the Black–Scholes function P_0, which is smooth away from the terminal date T. In the uncorrelated case it corresponds to the Hull–White formula [7]. In the correlated case, as considered here, this formula is in [8], and can be found in [2, (2.8.3)]. It is simple to compute explicitly the conditional distribution $\mathcal{D}(\tilde{X}^\varepsilon_T | (\hat{Z}^\star_s)_{t\le s\le T}, \tilde{X}^\varepsilon_t)$ of $\tilde{X}^\varepsilon_T$, given the path of the second Brownian motion $(\hat{Z}^\star_s)_{t\le s\le T}$. One obtains

$$\mathcal{D}(\tilde{X}^\varepsilon_T | (\hat{Z}^\star_s)_{t\le s\le T}, \tilde{X}^\varepsilon_t = x) = \mathcal{N}(m_1^\varepsilon, v_1^\varepsilon),$$

where the mean and variance are given by

$$\begin{aligned} m_1^\varepsilon &= x + \xi_{t,T} + \left(r - \frac{1}{2}\bar{\sigma}_\rho^2\right)(T-t), \\ v_1^\varepsilon &= \bar{\sigma}_\rho^2 (T-t) \end{aligned}$$

and we define

$$\begin{aligned} \xi_{t,T} &= \rho \int_t^T \tilde{f}(s, Y_s^\varepsilon)\, d\hat{Z}_s^\star - \frac{1}{2}\rho^2 \int_t^T \tilde{f}(s, Y_s^\varepsilon)^2 ds, \\ \bar{\sigma}_\rho^2 &= \frac{1-\rho^2}{T-t} \int_t^T \tilde{f}(s, Y_s^\varepsilon)^2 ds. \end{aligned} \tag{5.1}$$

It follows from the calculation that leads to the Black–Scholes formula that

$$\mathbb{E}^\star{}_{t,x,y}\{e^{-r(T-t)} h(\tilde{X}^\varepsilon_T) \mid (\hat{Z}^\star_s)_{t\le s\le T}\} = P_0(t, \tilde{X}^\varepsilon_t + \xi_{t,T}; K, T; \bar{\sigma}_\rho).$$

Similarly, we compute

$$\mathcal{D}(\tilde{X}^\varepsilon_{T+\delta} \mid (\hat{Z}^\star_s)_{t\le s\le T}, \tilde{X}^\varepsilon_t = x) = \mathcal{N}(m_2^\varepsilon, v_2^\varepsilon),$$

where the mean and variance are given by

$$m_2^\varepsilon = x + \xi_{t,T} + r\delta + \left(r - \frac{1}{2}\tilde{\sigma}^2_{\rho,\delta}\right)(T-t),$$
$$v_2^\varepsilon = \tilde{\sigma}^2_{\rho,\delta}(T-t)$$

and we define

$$\tilde{\sigma}^2_{\rho,\delta} = \bar{\sigma}^2_\rho + \frac{\delta\bar{\sigma}^2}{T-t}.$$

Therefore

$$\mathbb{E}^\star{}_{t,x,y}\{e^{-r(T-t+\delta)}h(\tilde{X}^\varepsilon_{T+\delta}) \mid (\hat{Z}^\star_s)_{t\le s\le T}\} = P_0(t, \tilde{X}^\varepsilon_t + \xi_{t,T} + r\delta; K, T; \tilde{\sigma}_{\rho,\delta}),$$

and we can write

$$\begin{aligned} &P^{\varepsilon,\delta}(t,x,y) - P^\varepsilon(t,x,y) \\ &\quad = \mathbb{E}^\star{}_{t,x,y}\left\{P_0(t, x + \xi_{t,T} + r\delta; K, T; \tilde{\sigma}_{\rho,\delta}) - P_0(t, x + \xi_{t,T}; K, T; \bar{\sigma}_\rho)\right\}. \end{aligned}$$

Using the explicit representation (4.1) and that $\bar{\sigma}_\rho$ is bounded above and below as $f(y)$ is, we find

$$|P_0(t, x + \xi_{t,T} + r\delta; K, T; \tilde{\sigma}_{\rho,\delta}) - P_0(t, x + \xi_{t,T}; K, T; \bar{\sigma}_\rho)| \le \delta c_1(e^{\xi_{t,T}}\left[|\xi_{t,T}| + 1\right] + 1)$$

for some c_1 and for δ small enough. Using the definition (5.1) of $\xi_{t,T}$ and the existence of its exponential moments, we thus find that

$$|P^\varepsilon(t,x,y) - P^{\varepsilon,\delta}(t,x,y)| \le c_2\delta$$

for some c_2 and for δ small enough.

5.2. Proof of Lemma 4.2. From the definition (3.12) of the correction $\sqrt{\varepsilon}P_1$ and the corresponding definition (4.3) of the correction $\sqrt{\varepsilon}P_1^\delta$ we deduce

$$Q^{\varepsilon,\delta} - Q^\varepsilon = \left(1 - (T-t)\left(V_3^\varepsilon\frac{\partial^3}{\partial x^3} + (V_2^\varepsilon - 3V_3^\varepsilon)\frac{\partial^2}{\partial x^2} + (2V_3^\varepsilon - V_2^\varepsilon)\frac{\partial}{\partial x}\right)\right)(P_0^\delta - P_0).$$

From the definition (3.10) of the v_i's, the definition (3.13) of the V_i's, and the bounds on the solution of the Poisson equation (3.11) given in Appendix C, it follows that

$$\max(|V_2^\varepsilon|, |V_3^\varepsilon|) \le c_1\sqrt{\varepsilon}$$

for some constant $c_1 > 0$. Notice that we can write

$$P_0^\delta(t,x) = P_0(t-\delta, x).$$

Using the explicit formula (4.1), it is easily seen that P_0 and its successive derivatives with respect to x are differentiable in t at any $t < T$. Therefore we conclude that for (t,x,y) fixed with $t < T$

$$|Q^\varepsilon(t,x) - Q^{\varepsilon,\delta}(t,x)| \le c_2\delta$$

for some $c_2 > 0$ and δ small enough.

5.3. Proof of Lemma 4.3. We first introduce some additional notation. Define the error $Z^{\varepsilon,\delta}$ in the approximation for the regularized problem by

$$P^{\varepsilon,\delta} = P_0^\delta + \sqrt{\varepsilon} P_1^\delta + \varepsilon Q_2^\delta + \varepsilon^{3/2} Q_3^\delta - Z^{\varepsilon,\delta}$$

for Q_2^δ and Q_3^δ stated below in (5.3) and (5.4). Setting

$$\mathcal{L}^\varepsilon = \frac{1}{\varepsilon}\mathcal{L}_0 + \frac{1}{\sqrt{\varepsilon}}\mathcal{L}_1 + \mathcal{L}_2,$$

one can write

$$\begin{aligned}
\mathcal{L}^\varepsilon Z^{\varepsilon,\delta} &= \mathcal{L}^\varepsilon \left(P_0^\delta + \sqrt{\varepsilon} P_1^\delta + \varepsilon Q_2^\delta + \varepsilon^{3/2} Q_3^\delta - P^{\varepsilon,\delta}\right) \\
&= \frac{1}{\varepsilon}\mathcal{L}_0 P_0^\delta + \frac{1}{\sqrt{\varepsilon}}(\mathcal{L}_0 P_1^\delta + \mathcal{L}_1 P_0^\delta) \\
&\quad + (\mathcal{L}_0 Q_2^\delta + \mathcal{L}_1 P_1^\delta + \mathcal{L}_2 P_0^\delta) + \sqrt{\varepsilon}\left(\mathcal{L}_0 Q_3^\delta + \mathcal{L}_1 Q_2^\delta + \mathcal{L}_2 P_1^\delta\right) \\
&\quad + \varepsilon\left(\mathcal{L}_1 Q_3^\delta + \mathcal{L}_2 Q_2^\delta + \sqrt{\varepsilon}\mathcal{L}_2 Q_3^\delta\right) \\
&= \varepsilon\left(\mathcal{L}_1 Q_3^\delta + \mathcal{L}_2 Q_2^\delta\right) + \varepsilon^{3/2}\mathcal{L}_2 Q_3^\delta \equiv G^{\varepsilon,\delta}
\end{aligned} \tag{5.2}$$

because $P^{\varepsilon,\delta}$ solves the original equation $\mathcal{L}^\varepsilon P^{\varepsilon,\delta} = 0$, and we choose P_0^δ, P_1^δ, Q_2^δ, and Q_3^δ to cancel the first four terms. In particular, we choose

$$Q_2^\delta(t,x,y) = -\frac{1}{2}\phi(y)\left(\frac{\partial^2 P_0^\delta}{\partial x^2} - \frac{\partial P_0^\delta}{\partial x}\right), \tag{5.3}$$

so that

$$\mathcal{L}_0 Q_2^\delta = -\mathcal{L}_2 P_0^\delta$$

(with an "integration constant" arbitrarily set to zero), whereas Q_3^δ is a solution of the Poisson equation

$$\mathcal{L}_0 Q_3^\delta = -(\mathcal{L}_1 Q_2^\delta + \mathcal{L}_2 P_1^\delta), \tag{5.4}$$

where the centering condition is ensured by our choice of P_1^δ.
At the terminal time T we have

$$Z^{\varepsilon,\delta}(T,x,y) = \varepsilon\left(Q_2^\delta(T,x,y) + \sqrt{\varepsilon} Q_3^\delta(T,x,y)\right) \equiv H^{\varepsilon,\delta}(x,y), \tag{5.5}$$

where we have used the terminal conditions $P^{\varepsilon,\delta}(T,x,y) = P_0^\delta(T,x) = h^\delta(x)$ and $P_1^\delta(T,x) = 0$. This assumes smooth derivatives of P_0^δ in the domain $t \le T$, which is the case because h^δ is smooth. It is shown in Appendix A that the source term $G^{\varepsilon,\delta}(t,x,y)$ on the right-hand side of (5.2) can be written in the form

$$\begin{aligned}
G^{\varepsilon,\delta} &= \varepsilon\left(\sum_{i=1}^4 g_i^{(1)}(y)\frac{\partial^i}{\partial x^i}P_0^\delta + (T-t)\sum_{i=1}^6 g_i^{(2)}(y)\frac{\partial^i}{\partial x^i}P_0^\delta\right) \\
&\quad + \varepsilon^{3/2}\left(\sum_{i=1}^5 g_i^{(3)}(y)\frac{\partial^i}{\partial x^i}P_0^\delta + (T-t)\sum_{i=1}^7 g_i^{(4)}(y)\frac{\partial^i}{\partial x^i}P_0^\delta\right).
\end{aligned} \tag{5.6}$$

In Appendix A we also show that the terminal condition $H^{\varepsilon,\delta}(x,y)$ in (5.5) can be written

$$H^{\varepsilon,\delta}(x,y) = \varepsilon\left(\sum_{i=1}^{2} h_i^{(1)}(y)\frac{\partial^i}{\partial x^i}P_0^\delta(T,x)\right) + \varepsilon^{3/2}\left(\sum_{i=1}^{3} h_i^{(2)}(y)\frac{\partial^i}{\partial x^i}P_0^\delta(T,x)\right). \tag{5.7}$$

To bound the contributions from the source term and terminal conditions we need the following two lemmas, which are derived in Appendices C and B, respectively.

LEMMA 5.1. *Let $\chi = g_i^{(j)}$ or $\chi = h_i^{(j)}$ with the functions $g_i^{(j)}$ and $h_i^{(j)}$ being defined in* (5.6) *and* (5.7). *Then there exists a constant $c > 0$ (which may depend on y) such that $\mathbb{E}^\star\{|\chi(Y_s^\varepsilon)|Y_t^\varepsilon = y\} \le c < \infty$ for $t \le s \le T$.*

LEMMA 5.2. *Assume $T - t > \Delta > 0$ and $\mathbb{E}^\star\{|\chi(Y_s^\varepsilon)|Y_t^\varepsilon = y\} \le c_1 < \infty$ for some constant c_1; then there exist constants $c_2 > 0$ and $\bar\delta > 0$ such that for $\delta < \bar\delta$ and $t \le s \le T$*

$$\left|\mathbb{E}^\star{}_{t,x,y}\left\{\sum_{i=1}^{n}\chi(Y_s^\varepsilon)\frac{\partial^i}{\partial x^i}P_0^\delta(s,X_s^\varepsilon)\right\}\right| \le c_2[T+\delta-s]^{\min[0,1-n/2]}, \tag{5.8}$$

and consequently

$$\begin{aligned}&\left|\mathbb{E}^\star{}_{t,x,y}\left\{\int_t^T (T-s)^p\sum_{i=1}^{n} e^{-r(s-t)}\chi(Y_s^\varepsilon)\frac{\partial^i}{\partial x^i}P_0^\delta(s,X_s^\varepsilon)\ ds\right\}\right| \\ &\le \begin{cases} c_2\ |\log(\delta)| & \text{for } n = 4+2p, \\ c_2\ \delta^{\min[0,p+(4-n)/2]} & \text{otherwise.}\end{cases}\end{aligned} \tag{5.9}$$

Proof of Lemma 4.3. We use the probabilistic representation of (5.2), $\mathcal{L}^\varepsilon Z^{\varepsilon,\delta} = G^{\varepsilon,\delta}$ with terminal condition $H^{\varepsilon,\delta}$:

$$Z^{\varepsilon,\delta}(t,x,y) = \mathbb{E}^\star{}_{t,x,y}\left\{e^{-r(T-t)}H^{\varepsilon,\delta}(X_T^\varepsilon,Y_T^\varepsilon) - \int_t^T e^{-r(s-t)}G^{\varepsilon,\delta}(s,X_s^\varepsilon,Y_s^\varepsilon)ds\right\}.$$

From Lemma 5.2 it follows that there exists a constant $c > 0$ such that

$$\left|\mathbb{E}^\star{}_{t,x,y}\left\{\int_t^T e^{-r(s-t)}G^{\varepsilon,\delta}(X_s^\varepsilon,Y_s^\varepsilon)ds\right\}\right| \le c\left\{\varepsilon + \varepsilon|\log(\delta)| + \varepsilon\sqrt{\varepsilon/\delta}\right\}, \tag{5.10}$$

$$|\mathbb{E}^\star{}_{t,x,y}\left\{H^{\varepsilon,\delta}(X_T^\varepsilon,Y_T^\varepsilon)\right\}| \le c\left\{\varepsilon + \varepsilon\sqrt{\varepsilon/\delta}\right\}, \tag{5.11}$$

and therefore also for (t,x,y) fixed with $t < T$

$$\begin{aligned}|P^{\varepsilon,\delta} - Q^{\varepsilon,\delta}| &= |\varepsilon Q_2^\delta + \varepsilon^{3/2}Q_3^\delta - Z^{\varepsilon,\delta}| \\ &\le c\left\{\varepsilon + \varepsilon|\log(\delta)| + \varepsilon\sqrt{\varepsilon/\delta}\right\},\end{aligned} \tag{5.12}$$

since Q_2^δ and Q_3^δ evaluated for $t < T$ can also be bounded using (5.3) and (A.5).

6. Conclusion. We have shown that the singular perturbation analysis of fast mean-reverting stochastic volatility pricing PDEs can be rigorously carried out for call options. We found that the leading order term and the first correction in the formal expansion are correct. The accuracy is pointwise in time, stock price, and volatility

level. It is precisely given in Theorem 3.1. The first correction involves higher-order derivatives of the Black–Scholes price, which blow up at maturity time and at the strike price. To overcome this difficulty we have used a payoff smoothing method, and we have exploited the fact that the perturbation is around the Black–Scholes price, for which there is an explicit formula. The case of call options is particularly important, since the calibration of models is based on these instruments. The case of other types of singularities is open. With some work one can certainly generalize the method presented here to other European derivatives such as binary options. The case of path-dependent derivatives such as barrier options is more difficult due to the lack of an explicit formula for the correction. The situation with American contracts such as the simplest one, the American put, is much more involved due to the singularities at the exercise boundary.

Appendix A. Expressions for source term and terminal condition. From (5.2), the source term in the equation for the error $Z^{\varepsilon,\delta}$ is

$$G^{\varepsilon,\delta} = \varepsilon\left(\mathcal{L}_1 Q_3^\delta + \mathcal{L}_2 Q_2^\delta\right) + \varepsilon^{3/2}\mathcal{L}_2 Q_3^\delta. \tag{A.1}$$

To obtain an explicit form for this source term, we consider the three terms separately. We first introduce the convenient notation

$$\mathcal{D} \equiv \frac{\partial}{\partial x},$$
$$\mathcal{D}_2 \equiv \frac{\partial^2}{\partial x^2} - \frac{\partial}{\partial x}.$$

Consider the term $\mathcal{L}_2 Q_2^\delta$ in (A.1). Using that

$$\mathcal{L}_2 = \mathcal{L}_{BS}(f(y)) = \mathcal{L}_{BS}(\bar\sigma) + \frac{1}{2}\left(f(y)^2 - \bar\sigma^2\right)\mathcal{D}_2, \tag{A.2}$$
$$\mathcal{L}_{BS}(\bar\sigma)\mathcal{D}_2 P_0^\delta = 0,$$

and (5.3), one deduces

$$\mathcal{L}_2 Q_2^\delta = -\frac{1}{4}\left(f(y)^2 - \bar\sigma^2\right)\phi(y)\mathcal{D}_2\mathcal{D}_2 P_0^\delta.$$

Consider next the term $\mathcal{L}_1 Q_3^\delta$ in (A.1). Using (3.8), we have

$$\begin{aligned} Q_3^\delta &= -\mathcal{L}_0^{-1}\left(\mathcal{L}_1 Q_2^\delta + \mathcal{L}_2 P_1^\delta - \langle \mathcal{L}_1 Q_2^\delta + \mathcal{L}_2 P_1^\delta\rangle\right) \\ &= -\mathcal{L}_0^{-1}\left(\mathcal{L}_1 Q_2^\delta - \langle \mathcal{L}_1 Q_2^\delta\rangle + \left(\mathcal{L}_2 - \langle\mathcal{L}_2\rangle\right)P_1^\delta\right). \end{aligned} \tag{A.3}$$

It follows from (5.3) that

$$\begin{aligned} \mathcal{L}_1 Q_2^\delta &= \left(\sqrt{2}\nu\rho f(y)\frac{\partial^2}{\partial x\partial y} - \sqrt{2}\nu\Lambda(y)\frac{\partial}{\partial y}\right)\left(-\frac{1}{2}\phi(y)\mathcal{D}_2 P_0^\delta\right) \\ &= -\frac{1}{\sqrt{2}}\nu\rho f(y)\phi'(y)\mathcal{D}\mathcal{D}_2 P_0^\delta + \frac{1}{\sqrt{2}}\nu\Lambda(y)\phi'(y)\mathcal{D}_2 P_0^\delta. \end{aligned}$$

Now let ψ_1 and ψ_2 be solutions of

$$\begin{aligned} \mathcal{L}_0\psi_1 &= f(y)\phi'(y) - \langle f\phi'\rangle, \\ \mathcal{L}_0\psi_2 &= \Lambda(y)\phi'(y) - \langle\Lambda\phi'\rangle; \end{aligned} \tag{A.4}$$

then we find, using (3.11) and (A.2), that Q_3^δ can be written

$$Q_3^\delta = \left(\frac{\nu\rho}{\sqrt{2}}\psi_1(y)\mathcal{D}\mathcal{D}_2P_0^\delta - \frac{\nu}{\sqrt{2}}\psi_2(y)\mathcal{D}_2P_0^\delta\right) - \frac{1}{2}\left(\phi(y)\mathcal{D}_2P_1^\delta\right). \tag{A.5}$$

Substituting for $\mathcal{L}_1$ and expanding gives

$$\begin{aligned}\mathcal{L}_1Q_3^\delta = {}& \nu^2\rho^2 f(y)\psi_1'(y)\mathcal{D}\mathcal{D}\mathcal{D}_2P_0^\delta - \nu^2\rho f(y)\psi_2'(y)\mathcal{D}\mathcal{D}_2P_0^\delta\\ & - \nu^2\rho\Lambda(y)\psi_1'(y)\mathcal{D}\mathcal{D}_2P_0^\delta + \nu^2\Lambda(y)\psi_2'(y)\mathcal{D}_2P_0^\delta\\ & - \frac{\nu}{\sqrt{2}}\left(\rho f(y)\phi'(y)\mathcal{D}\mathcal{D}_2P_1^\delta - \Lambda(y)\phi'(y)\mathcal{D}_2P_1^\delta\right).\end{aligned}$$

Consider finally the term $\mathcal{L}_2Q_3^\delta$ in (A.1); we find, using (A.2) and (A.5),

$$\begin{aligned}\mathcal{L}_2Q_3^\delta = {}& \frac{1}{2}(f(y)^2-\bar\sigma^2)\left[\frac{\rho\nu}{\sqrt{2}}\psi_1(y)\mathcal{D}_2\mathcal{D}\mathcal{D}_2P_0^\delta - \frac{\nu}{\sqrt{2}}\psi_2(y)\mathcal{D}_2\mathcal{D}_2P_0^\delta - \frac{1}{2}\phi(y)\mathcal{D}_2\mathcal{D}_2P_1^\delta\right]\\ & - \frac{1}{2}\phi(y)\mathcal{D}_2\left(v_3\mathcal{D}_3P_0^\delta + v_2\mathcal{D}_2P_0^\delta\right),\end{aligned}$$

with

$$\mathcal{D}_3 = \frac{\partial^3}{\partial x^3} - 3\frac{\partial^2}{\partial x^2} + 2\frac{\partial}{\partial x}$$

and $v_{2,3}$ defined in (3.10).

To summarize, the source term is given by

$$\begin{aligned}G^{\varepsilon,\delta} = {}& \varepsilon\left\{\nu^2\rho^2 f(y)\psi_1'(y)\mathcal{D}\mathcal{D}\mathcal{D}_2P_0^\delta - \nu^2\rho f(y)\psi_2'(y)\mathcal{D}\mathcal{D}_2P_0^\delta\right.\\ & - \nu^2\rho\Lambda(y)\psi_1'(y)\mathcal{D}\mathcal{D}_2P_0^\delta + \nu^2\Lambda(y)\psi_2'(y)\mathcal{D}_2P_0^\delta\\ & - \frac{\nu}{\sqrt{2}}\left(\rho f(y)\phi'(y)\mathcal{D}\mathcal{D}_2P_1^\delta - \Lambda(y)\phi'(y)\mathcal{D}_2P_1^\delta\right)\\ & \left. - \frac{1}{4}\left(f(y)^2-\bar\sigma^2\right)\phi(y)\mathcal{D}_2\mathcal{D}_2P_0^\delta\right\}\\ & + \varepsilon^{3/2}\left\{\frac{1}{2}(f(y)^2-\bar\sigma^2)\left[\frac{\rho\nu}{\sqrt{2}}\psi_1(y)\mathcal{D}_2\mathcal{D}\mathcal{D}_2P_0^\delta - \frac{\nu}{\sqrt{2}}\psi_2(y)\mathcal{D}_2\mathcal{D}_2P_0^\delta - \frac{1}{2}\phi(y)\mathcal{D}_2\mathcal{D}_2P_1^\delta\right]\right.\\ & \left. - \frac{1}{2}\phi(y)\mathcal{D}_2(v_3\mathcal{D}_3P_0^\delta + v_2\mathcal{D}_2P_0^\delta)\right\}.\end{aligned}$$

By inspection, this can be written in the form (5.6).

From (5.3) and (A.5) we can also see that the terminal condition $H^{\varepsilon,\delta}$ in (5.5) can be written in the form (5.7).

Appendix B. Proof of Lemma 5.2. To prove Lemma 5.2 notice first that a calculation based on the analytic expression for the Black–Scholes price in the standard constant volatility case gives

$$\partial_x^n P_0^\delta(s,x) = \begin{cases} e^x N(u/\tau + b\tau) & \text{for } n=1,\\ e^x N(u/\tau + b\tau) + \sum_{i=0}^{n-2}\frac{b_i^{(n)}}{\tau}e^u\partial_u^i e^{-(u/\tau+b\tau)^2/2} & \text{for } n\geq 2\end{cases} \tag{B.1}$$

for some constants b_i and with

$$\tau \equiv \bar{\sigma}\sqrt{T+\delta-s},$$
$$u \equiv x - \log(K),$$
$$b \equiv \left(\frac{r}{\bar{\sigma}^2} + \frac{1}{2}\right).$$

Assume first that $T - s \geq (T-t)/2 > 0$, so that $\tau \geq \bar{\sigma}\sqrt{(T-t)/2}$. Since $\partial_x^i P_0^\delta(s,x)$ is uniformly bounded in δ, it follows that

$$|\mathbb{E}^\star{}_{t,x,y}\left\{\chi(Y_s^\varepsilon)\partial_x^i P_0^\delta(s,X_s^\varepsilon)\right\}| \leq c\mathbb{E}^\star{}_{t,x,y}\left\{|\chi(Y_s^\varepsilon)|\right\} \tag{B.2}$$

for some constant c that may depend on x.

Consider next the case $0 < T - s < (T-t)/2$; then

$$\left|\mathbb{E}^\star{}_{t,x,y}\left\{\chi(Y_s^\varepsilon)\partial_x^i P_0^\delta(s,X_s^\varepsilon)\right\}\right| = \left|\mathbb{E}^\star{}_{t,x,y}\left\{\chi(Y_s^\varepsilon)\mathbb{E}^\star{}_{t,x,y}\left\{\partial_x^i P_0^\delta(s,X_s^\varepsilon) \mid \hat{Z}_v^\star; t \leq v \leq s\right\}\right\}\right|$$

and

$$\begin{aligned}
&\left|\mathbb{E}^\star{}_{t,x,y}\left\{\frac{1}{\tau}e^u\partial_u^i e^{-(u/\tau+b\tau)^2/2} \;\middle|\; \hat{Z}_v^\star; t \leq v \leq s\right\}\right| \\
&= \frac{1}{\tau}\left|\int e^u \partial_u^i e^{-(u/\tau+b\tau)^2/2} p(u)du\right| \\
&= \frac{1}{\tau^i}\left|\int e^{\tau u}\partial_u^i e^{-(u+b\tau)^2/2}p(\tau u)du\right| \;\leq\; \frac{c}{\tau^i},
\end{aligned} \tag{B.3}$$

where p is the conditional distribution of $u \equiv X_s^\varepsilon - \log(K)$, which is the Gaussian distribution with variance at least $(T-t)(1-\rho^2)m_1^2/2$. The bound (5.8) follows readily from (B.1), (B.2), and (B.3). The bound (5.9) is a direct consequence of (5.8), and Lemma 5.2 is established.

Appendix C. On the solution of the Poisson equation. Let χ solve

$$\mathcal{L}_0\chi + g = 0,$$

with $\mathcal{L}_0$ defined as in (2.5) and with g satisfying the centering condition

$$\langle g \rangle = 0,$$

where the averaging is done with respect to the invariant distribution associated with the infinitesimal generator $\mathcal{L}_0$ (see (3.3) for an explicit formula). Using the explicit form of the differential operator $\mathcal{L}_0$, one can easily deduce that

$$\Phi(y)\chi'(y) = \frac{-1}{\nu^2}\int_{-\infty}^{y} g(z)\Phi(z)\,dz = \frac{1}{\nu^2}\int_{y}^{\infty} g(z)\Phi(z)\,dz,$$

with Φ being the probability density of the invariant distribution $\mathcal{N}(m,\nu^2)$ associated with $\mathcal{L}_0$. From this it follows that if g is bounded,

$$|\chi'(y)| \leq c_1,$$
$$|\chi(y)| \leq c_2(1 + \log(1+|y|)).$$

Notice that χ in Lemma 5.1 satisfies

$$|\chi(y)| \leq c \max(|\phi(y)|, |\phi'(y)|, |\psi_{1,2}(y)|, |\psi'_{1,2}(y)|)$$

for some constant c and with ϕ and $\psi_{1,2}$ defined in (3.11) and (A.4), respectively. These functions are solutions of Poisson equations with $g = f^2 - \langle f^2 \rangle$ or $g = f\phi' - \langle f\phi' \rangle$ or $g = \Lambda\phi' - \langle \Lambda\phi' \rangle$, which are bounded. Therefore $\chi(y)$ is at most logarithmically growing at infinity. The bound in Lemma 5.1 now follows from classical a priori estimates on the moments of the process Y_t^ε, which are uniform in ε. In the case $\Lambda = 0$ this can easily be seen by a simple time change $t = \varepsilon t'$ in (2.2). The case $\Lambda \neq 0$ follows by a Girsanov change of measure argument.

CHEMOTACTIC CELLULAR MIGRATION: SMOOTH AND DISCONTINUOUS TRAVELLING WAVE SOLUTIONS*

K. A. LANDMAN†, G. J. PETTET‡, AND D. F. NEWGREEN§

Abstract. A simple model of chemotactic cell migration gives rise to travelling wave solutions. By varying the cellular growth rate and chemoattractant production rate, travelling waves with both smooth and discontinuous fronts are found using phase plane analysis. The phase plane exhibits a curve of singularities whose position relative to the equilibrium points in the phase plane determines the nature of the heteroclinic orbits, where they exist. Smooth solutions have trajectories connecting the steady states lying to one side of the singular curve. Travelling shock waves arise by connecting trajectories passing through a special point in the singular curve and recrossing the singular curve, by way of a discontinuity. Hyperbolic partial differential equation theory gives the necessary shock condition. Conditions on the parameter values determine when the solutions are smooth travelling waves versus discontinuous travelling wave solutions. These conditions provide bounds on the travelling wave speeds, corresponding to bounds on the chemotactic velocity or bounds on cellular growth rate. This analysis gives rise to the possibility of representing sharp fronts to waves of invading cells through a simple chemotactic term, without introducing a nonlinear diffusion term. This is more appropriate when cell populations are sufficiently dense.

Key words. migration, chemotaxis, travelling wave, phase plane, shock

1. Introduction.

The active migration of cells is a significant feature of numerous biological phenomena ranging from wound healing, scar tissue formation, and tumor invasion to embryo implantation and organogenesis.

Despite having been the focus of much research, a comprehensive understanding of the processes of receptor activation, cell-cell signalling, and intracellular organization associated with cell migration in various contexts eludes us. In part this is due to the numerous and complicated mechanisms that are involved and, perhaps more importantly, to the cooperative or antagonistic interactions between such processes.

Mathematical modelling of biological phenomena provides a timely and efficient theoretical tool for considering the interaction of various cell migration mechanisms, and the emergent behavior that arises from these interactions. To date, much of the mathematical modelling of cell migration has been predicated on the phenomena of diffusion, chemotaxis, and haptotaxis, either singly or in combination. Such models typically support travelling wave solutions, which are taken to represent the invading fronts of populations of migrating cells. An exemplar of such a model based on the process of diffusion is Fisher's equation on a one-dimensional spatial domain [15]. Chemotaxis-based models employ a gradient of a diffusible signaling chemical to determine the velocity of cell migration [1], [14], [18], whilst haptotaxis-based models

employ a gradient of extracellular matrix or ligand density [17] to this end.

The extensive literature developed over the last few decades concerning the theoretical modelling of chemotaxis is testament to the perceived importance of the role it plays in cell migration. Many of these mathematical models can identify their origins in the work of Keller and Segel [9] describing the motion of bacteria as a chemotactic response. Significant contributions to this body of knowledge include those by Tranquillo [22], Tranquillo and Alt [23], Hillen [8], and Othmer and Stevens [16], while others may be identified in a recent review by Ford and Cummings [6].

The analysis of such models can lead to an understanding of the relative contributions by the mechanisms modelled to the speed of the invading front of cells, and, by implication, potential strategies for effecting changes to the speed of the invading front can be hypothesized and investigated.

Typically, invasive phenomena in the context of migrating populations of cells are characterized by a well-defined boundary. This feature is difficult to reproduce when using a diffusive flux to represent the migration process. Mathematical models involving a linear diffusive flux give rise to smooth-fronted solutions, with the solution being nonzero everywhere (albeit small). A nonlinear diffusive flux, where the diffusivity is density dependent (and equal to zero when the density is zero), gives rise to solutions with distinct interfaces beyond which the density equals zero. Such models have been explored in describing population pressures and moisture infiltration [5], [7], [15], [20], [24], [25]. Even though such solutions have compact support, they are smooth when the density is positive and do not exhibit shocks. Solutions with shocks are not realizable with a diffusive mechanism.

For a limited number of specific and very simple models based on chemotaxis, recent research by Pettet, McElwain, and Norbury [19] and others [17], [12] has shown the potential for chemotaxis-based models to exhibit travelling wave solutions with shock fronts. Such sharp-fronted solutions may be viewed as being more indicative of invading cell populations with a well-defined front or margin than those described above.

In this article we consider a simple model of chemotactic cell migration, where there is no contribution to the cell velocity from a diffusion-like term. We explore this theoretical model of cell migration numerically and analytically to show that, for various parameter regimes, smooth-fronted or shock-fronted travelling wave solutions can be supported.

A coupled system of partial differential equations for cell density and chemoattractant concentration is considered. We introduce a travelling wave coordinate system with an unknown wave speed to convert the system into a coupled system of ordinary differential equations. This is explored using phase plane analysis, giving rise to a rich variety of possible solutions. Consideration of the original system as a hyperbolic system allows shock conditions to be specified uniquely. Some asymptotic analysis for large wave speed is also examined.

2. Chemotactic cell migration in a fixed spatial domain of one dimension. We begin by describing a simple system of equations designed to describe the chemotactic migration of cells in a fixed domain. We use a coordinate x fixed in space (i.e., a Eulerian system). The cell density per unit length and the chemoattractant concentration are denoted by $n(x,t)$ and $g(x,t)$, respectively. The usual conservation-of-mass argument for a generic chemotaxis problem gives

$$\frac{\partial n}{\partial t} = -\chi \frac{\partial}{\partial x}\left(n\frac{\partial g}{\partial x}\right) + f(n,g), \tag{2.1}$$

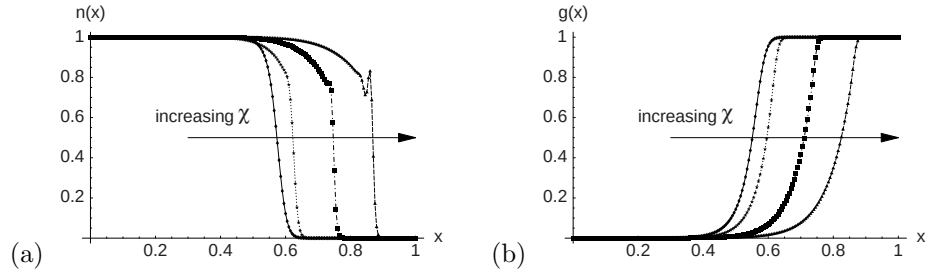

FIG. 2.1. *Chemotactic cell migration at different wave speeds. Numerical solutions of equations* (2.1)–(2.4) *on* $[0,1]$ *with the inclusion of Fickian diffusion* ($D_n \frac{\partial^2 n}{\partial x^2}$) *in* (2.1). *Here* $D_n = 0.00001$, $\lambda_1 = 2$, $k_1 = 1$, $\lambda_2 = 0.25$, $\lambda_3 = 1$, $k_2 = 1$ *and* $\chi = 0.0001, 0.001, 0.002$ *and* 0.003. *Initial conditions are* $n(x,0) = e^{-500x^2}$ *and* $g(x,0) = 1$ *with zero flux boundary conditions at* $x = 0, 1$. (a) *Advancing front (moving left to right) of migrating cells at dimensioned time* $t = 17.5$. (b) *Retreating front (moving left to right) of chemoattractant at dimensioned time* $t = 17.5$.

$$\frac{\partial g}{\partial t} = h(n,g), \tag{2.2}$$

where the chemotactic factor χ is assumed to be a constant and f and h represent the kinetic terms. This type of model system, where only chemotaxis contributes to the cell migration, has been studied by several authors [2], [19], [11]. For this reason we have excluded diffusivity from the model equations (2.1)–(2.2).

Our problem concerns cells n, which proliferate by mitosis and may die or differentiate into another cell type. These two effects can be incorporated into a logistic-type term for f. The chemoattractant g is produced uniformly throughout the domain and has a maximum value. Furthermore, the cells consume the chemoattractant, which creates a gradient of g and produces a migration velocity. These effects are reflected in our choice of f and h as

$$f = \lambda_1 n(k_1 - n), \tag{2.3}$$

$$h = \lambda_2 g(k_2 - g) - \lambda_3 ng. \tag{2.4}$$

Numerical solutions to such a system on a finite domain exhibit travelling wave solutions, as illustrated in Figure 2.1. Here we have included a small amount of diffusion in n in order to stabilize the system, allowing the use of the Numerical Algorithms Group (NAG) parabolic partial differential equations package DO3PCF. In Landman, Pettet, and Newgreen [10] we explicitly introduce two migration mechanisms, namely, chemotaxis and diffusion. We look at the effect of decreasing diffusivity, when the diffusion coefficient is small in comparison to the chemotactic sensitivity coefficient, and show that the solutions look almost identical as the diffusion coefficient is reduced by several orders of magnitude. Since our interest is in systems of invasion, for which chemotaxis is the dominant cell migration mechanism, the arguments considered in [10] allow us to neglect any effect attributable to the small diffusivity introduced for these numerical results.

We observe that the front of n steepens as the chemoattractant coefficient χ increases. If the parameter is pushed too far, the solution appears to develop a numerical instability which may be interpreted as the evolution of a jump discontinuity. These numerical simulations initiate questions about the nature of such solutions and whether or not smooth and discontinuous travelling wave solutions can be determined analytically.

An appropriate dimensionalization is carried out with the following transformation, where we introduce a length scale L and scaled parameters a and b as shown:

$$n = k_1 n^*, \qquad g = k_2 g^*, \qquad t = Tt^*, \qquad x = Lx^*, \tag{2.5}$$

$$T = \frac{1}{\lambda_3 k_1}, \qquad L^2 = \frac{\chi k_2}{\lambda_3 k_1}, \qquad a = \frac{\lambda_1}{\lambda_3}, \qquad b = \frac{\lambda_2 k_2}{\lambda_3 k_1}. \tag{2.6}$$

Omitting the asterisk notation, the dimensionless system is

$$\frac{\partial n}{\partial t} = -\frac{\partial}{\partial x}\left(n\frac{\partial g}{\partial x}\right) + an(1-n), \tag{2.7}$$

$$\frac{\partial g}{\partial t} = bg(1-g) - ng. \tag{2.8}$$

There are many scalings we could have chosen. This scaling focuses on the two most important terms in the problem, namely, chemotactic migration and the interaction terms between n and g.

Now, making the traveling wave coordinate transformation $z = x - ct$, we obtain

$$\frac{dn}{dz} = \frac{1}{c}\frac{d}{dz}\left(n\frac{dg}{dz}\right) - \frac{an}{c}(1-n), \tag{2.9}$$

$$\frac{dg}{dz} = -\frac{1}{c}\left[bg(1-g) - ng\right], \tag{2.10}$$

which, after appropriate substitutions from (2.10) into (2.9), may be written as

$$\left[1 + \frac{g}{c^2}(b(1-g) - 2n)\right]\frac{dn}{dz} = \frac{ng}{c^3}\left[b(1-2g) - n\right]\left[b(1-g) - n\right] - \frac{an}{c}(1-n), \tag{2.11}$$

$$\frac{dg}{dz} = -\frac{1}{c}\left[bg(1-g) - ng\right]. \tag{2.12}$$

We will be considering (2.11)–(2.12) in the phase plane, and we will plot trajectories in the (g, n) plane. For $b > 0$, the steady states of the system are $(g, n) = (0,0), (1,0), (0,1)$ and $(1-\frac{1}{b}, 1)$. Since we are interested only in solutions where n and g are nonnegative, the last state exists only for $b > 1$. When $b = 0$, the steady state $(0,0)$ is replaced by a continuum of steady states $(\bar{g}, 0)$. In this paper, we concentrate on the case $b > 0$ and briefly comment on the degenerate case $b = 0$ in section 5.3.

We seek traveling wave solutions connecting $(0,1)$ or $(1-\frac{1}{b}, 1)$ and $(1,0)$. Linearization about the steady states yields the nature of these states. This information, together with the eigenvalues and eigenvectors, is listed in Table 1.

3. Phase plane analysis. We will investigate the positive quadrant of the (g, n) phase plane; this is made interesting by the position of the curve, where the function premultiplying $\frac{dn}{dz}$ in (2.11) is identically equal to zero. Pettet, McElwain, and Norbury [19] defined such a curve as a "wall-of-singularities." Here the wall-of-singularities can be written as

$$n = \frac{1}{2}\left(\frac{c^2}{g} + b(1-g)\right). \tag{3.1}$$

This wall is asymptotic to the n-axis, cutting the positive g-axis at

$$g = \frac{1}{2}\left(1 + \sqrt{1 + \frac{4c^2}{b}}\right),$$

TABLE 1
Nature of equilibrium points.

(g, n)	Type	Eigenvalues	Corresponding eigenvectors (g, n)
$(0, 0)$	Stable node	$-\frac{a}{c}, -\frac{b}{c}$	$(0, 1)$, $(1, 0)$
$(1, 0)$	Saddle	$-\frac{a}{c}, \frac{b}{c}$	$(1, -a - b)$, $(1, 0)$
$(0, 1)$	$b < 1$ Unstable node $b > 1$ Saddle	$\frac{a}{c}, \frac{1-b}{c}$	$(0, 1)$, $\left(1, -\frac{(b-1)^2}{c^2(a+b-1)}\right)$
$(1 - \frac{1}{b}, 1)$ for $b > 1$	$c^2 > 1 - \frac{1}{b}$ Unstable node $c^2 < 1 - \frac{1}{b}$ Saddle	$\frac{(a+b-1)c \pm \sqrt{\beta+\gamma^2}}{2(c^2-1+\frac{1}{b})}$, where $\beta = \frac{4a(b-1)^2}{b}$, $\gamma = (a - b + 1)c$	Complicated form

to the right of the steady state $(1, 0)$. Hence all the steady states are to the left of the wall when $0 < b < 1$. If $b > 1$, the new steady state $(1 - \frac{1}{b}, 1)$ is below (above) the wall if $c^2 > 1 - \frac{1}{b}$ ($c^2 < 1 - \frac{1}{b}$). From Table 1, we can see that the nature of this steady state changes according to the same inequality. The wall gets closer to the origin as c decreases.

Pettet, McElwain, and Norbury [19] showed that solutions approaching a wall-of-singularities could not cross the wall unless it passed through special points called gates or holes in the wall. These points are defined by both the function premultiplying $\frac{dn}{dz}$ and the right-hand side in (2.11) being equal to zero simultaneously. Thus, travelling wave solutions joining two steady states (one unstable and the other stable) on the same side of the wall-of-singularities could under some circumstance be shown not to exist when the wall-of-singularities interfered with the trajectory emanating from the unstable steady state.

Pettet, McElwain, and Norbury concerned themselves only with smooth-fronted travelling waves. They presumed that any trajectory exiting the unstable steady state of interest that passed through a hole in the wall could then not recross the wall in order to connect with the stable steady state. However, Marchant, Norbury, and Perumpanani [12] showed that for a very simple system of equations (in the class of (2.1)–(2.2)) a trajectory in the phase plane could indeed follow such a path, recrossing the wall by way of a jump discontinuity.

In the system we describe here, there is always a hole at the intersection of the wall with the g-axis. However, it is necessary for the holes to lie within the positive (g, n) quadrant if any trajectory passing through the hole is to remain in that quadrant. Depending on the parameter values, for our system there can be no, one, or two holes contained within the positive quadrant.

The interaction of the trajectories and the wall-of-singularities is extremely interesting. We start by giving some examples.

Consider first the case $0 < b < 1$. We seek a trajectory connecting the unstable node $(0, 1)$ to the saddle $(1, 0)$. By considering the vector field associated with (2.11) and (2.12), it can be shown that such a trajectory certainly exists if the wall is sufficiently far from the axes. For example, we fix the wall position (fix b and c) and vary a, the effective cellular growth rate or mitotic index of n, as illustrated in Figure 3.1. For sufficiently small values of a there is a unique trajectory to the left of the

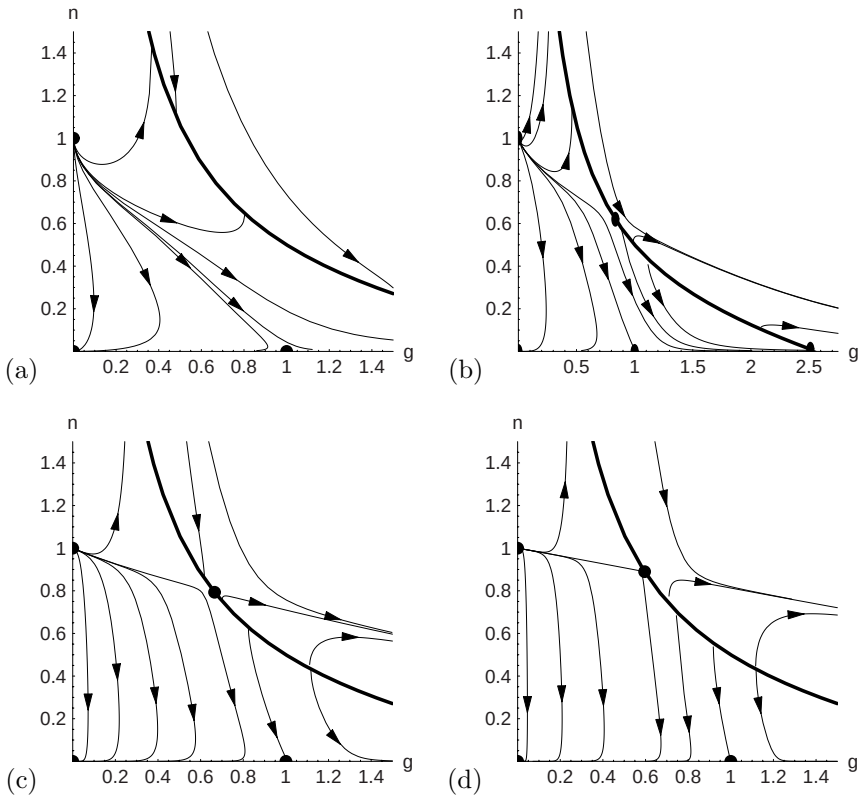

FIG. 3.1. *Phase plane for (g, n) for increasing values of cellular growth rate a. Here $b = 0.25, c = 1$. The wall is indicated with a dark line; the holes in the wall and the steady states are marked with a* ●. (a) $a = 0.5$, *no holes.* (b) $a = 1.0$, *two holes (both with $g > 0$).* (c) $a = 2.0$, *one hole.* (d) $a = 4.0$, *one hole.*

wall, connecting the two states (shown here with $a = 0.5$ and 1); this gives a smooth travelling wave. However, for large enough values of a, no such trajectory can be found below the wall, as shown here with $a = 2$ and 4. In fact, there appears to be a trajectory from $(0, 1)$ travelling towards the hole in the wall.

Alternatively, we can consider the effect of fixing the two rates a and b and decreasing the wave speed c. This translates the wall closer to the axes, as shown in Figure 3.2. When $c = 1.5$, there is a trajectory lying below the wall joining the steady states. However, for $c = 1$ and 0.5, no such trajectory exists, but again there is one trajectory from $(0, 1)$ heading towards the hole in the wall.

Since trajectories cannot cross each other, or cross the wall at any point other than a hole in the wall, we must determine how it is possible for a trajectory passing through a hole to recross the wall and connect to the other steady state. Marchant [11] investigated this scenario for his system, and his arguments apply equally to our system of equations. No smooth connection between the two states can be made; however, there is the possibility for the solution to be nonsmooth, by containing a jump discontinuity.

It is appropriate to apply Marchant's approach here to our system. We do this now, and then return to the phase plane analysis in section 5.

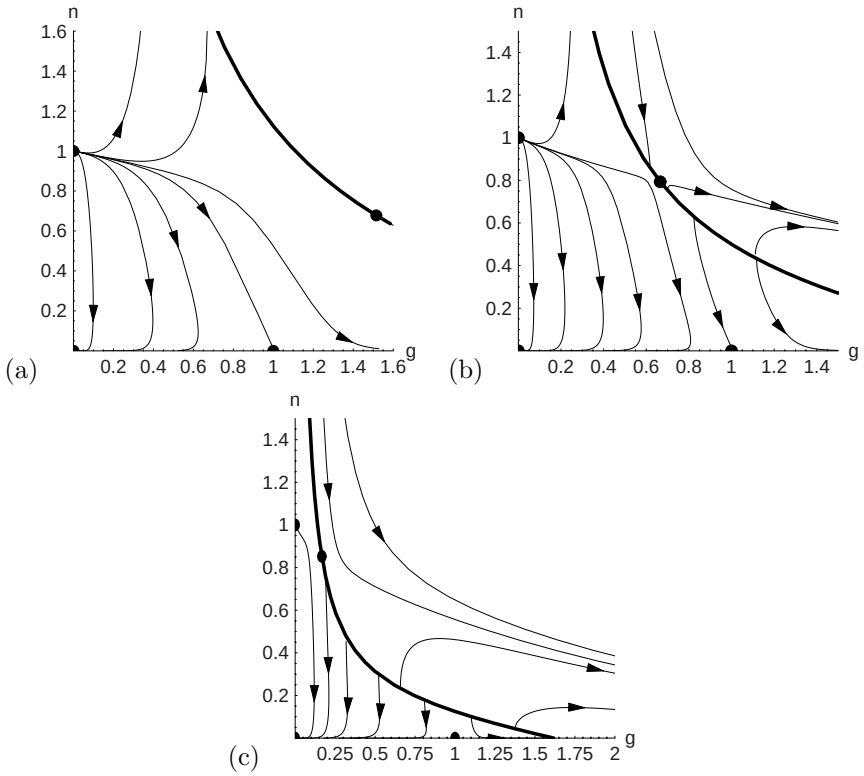

FIG. 3.2. *Phase plane for (g, n) for decreasing values of wave speed c. Here $a = 2.0$, $b = 0.25$. Wall, holes, and steady states marked as indicated previously. Each example has one hole in the positive quadrant.* (a) $c = 1.5$. (b) $c = 1.0$. (c) $c = 0.5$.

4. Hyperbolic PDE theory: Shocks and discontinuities. Introducing a third variable $u = \frac{\partial g}{\partial x}$, consider the scaled generic chemotaxis problem (2.7) and (2.8) as a hyperbolic system, namely,

$$\frac{\partial n}{\partial t} = -\frac{\partial}{\partial x}(nu) + f(n,g) = -u\frac{\partial n}{\partial x} - n\frac{\partial u}{\partial x} + f(n,g), \tag{4.1}$$

$$\frac{\partial u}{\partial t} = h_n\frac{\partial n}{\partial x} + h_g\frac{\partial g}{\partial x}, \tag{4.2}$$

$$\frac{\partial g}{\partial t} = h(n,g), \tag{4.3}$$

which in matrix form becomes

$$\frac{\partial}{\partial t}\begin{bmatrix} n \\ u \\ g \end{bmatrix} + \begin{bmatrix} u & n & 0 \\ -h_n & 0 & -h_g \\ 0 & 0 & 0 \end{bmatrix}\frac{\partial}{\partial x}\begin{bmatrix} n \\ u \\ g \end{bmatrix} = \begin{bmatrix} f \\ 0 \\ h \end{bmatrix}. \tag{4.4}$$

The characteristic slopes are determined from the eigenvalues of the 3×3 matrix in (4.4). These are solutions of

$$\lambda\left[(u-\lambda)(\lambda) - nh_n\right] = 0. \tag{4.5}$$

There are three distinct solutions for $h_n < 0$ and $n > 0$. This confirms that the

system is strictly hyperbolic [21] with

$$\lambda_1 = \frac{1}{2}\left[u - \sqrt{u^2 - 4nh_n}\right] \le \lambda_2 = 0 \le \lambda_3 = \frac{1}{2}\left[u + \sqrt{u^2 - 4nh_n}\right]. \tag{4.6}$$

The characteristics have gradient $dx/dt = \lambda_i$, which is never infinite, so the line $t = 0$ is nowhere tangent to a characteristic. Hence if initial data for n, u, g is given along the line $t = 0$, the resulting Cauchy problem is well posed. By considering the matrix of right eigenvectors, which correspond to each λ_i, the λ_2 field is always linearly degenerate, and the λ_1 and λ_3 fields are genuinely nonlinear characteristic fields for (n, u, g) in the positive quadrant.

A shock (i.e., a curve separating intersecting characteristics defining a discontinuity in at least one of the variables on either side of the curve) may exist in either of the two genuinely nonlinear fields. We are looking for a shock that propagates with the travelling wave speed c, since *all* the information on a travelling wave moves with this speed. Following Marchant [11], [12], the Lax entropy condition ensures that the shocks are physically relevant [4]; hence, since the wave speed $c > 0$, only the λ_3 field is relevant.

4.1. Shock conditions. We write the system (4.4) in conservation form,

$$\frac{\partial P}{\partial t} + \frac{\partial Q}{\partial x} = S, \tag{4.7}$$

where

$$P = \begin{bmatrix} n \\ u \\ g \end{bmatrix}, \quad Q = \begin{bmatrix} nu \\ -h \\ 0 \end{bmatrix}, \quad S = \begin{bmatrix} f \\ 0 \\ h \end{bmatrix}. \tag{4.8}$$

The Rankine–Hugoniot jump condition [4] defining the shock moving with velocity c in the third field is

$$[P]\, c = [Q]\,, \tag{4.9}$$

where $[q]$ denotes the jump in the quantity q. For our system this gives

$$[n]\, c = [nu]\,, \tag{4.10}$$

$$[u]\, c = [-h]\,, \tag{4.11}$$

$$[g]\, c = 0. \tag{4.12}$$

Since $u = \frac{\partial g}{\partial x} = -\frac{1}{c}h$, the second equation always holds, while the third equation says that there is no discontinuity in g. Using the definition of u and our particular choice of (dimensionless) kinetic term $h = bg(1-g) - ng$, the first equation gives

$$\begin{aligned} [n]\, c = [nu] &= \left[-\frac{1}{c}nh\right] \\ &= -\frac{1}{c}[bng(1-g) - n^2 g] \\ &= -\frac{1}{c}bg(1-g)[n] + \frac{1}{c}g[n^2]. \end{aligned} \tag{4.13}$$

This simplifies to

$$\left(c^2 + bg(1-g)\right)[n] = g\left[n^2\right]. \tag{4.14}$$

Using the definition $[n] = n_L - n_R$, where n_L and n_R are the values of n on either side of the shock, (4.14) and (4.12) reduce to

$$n_L + n_R = \frac{1}{g}\left(c^2 + bg(1-g)\right), \quad g_L = g_R. \tag{4.15}$$

Recall that the wall-of-singularities satisfies (3.1). Hence, the geometric center of the jump $\frac{1}{2}(n_L + n_R)$ lies exactly on the wall-of-singularities, and therefore any jump takes the trajectory to the other side of the wall. Of course, a jump is only allowable if $n_R > 0$. Note that the Lax entropy condition [4] for the λ_3 field is satisfied only if $n_L > n_R$.

4.2. Power series. The trajectories needed to construct a travelling shock wave can be determined by power series solutions. Equations (2.11) and (2.12) can be written in the form

$$\frac{dn}{dg} = -\frac{\frac{ng}{c^2}\left[b(1-2g)-n\right]\left[b(1-g)-n\right] - an(1-n)}{\left[1+\frac{g}{c^2}(b(1-g)-2n)\right]\left[bg(1-g)-ng\right]}. \tag{4.16}$$

Solutions $n(g)$ can be found by expanding in powers about special points. Such points are steady-state solutions to the system and holes in the wall. Let (g_s, n_s) be such a point, and then write

$$g = g_s + f, \tag{4.17}$$

$$n(g) = n_s + \alpha_1 f + \alpha_2 f^2 + \alpha_3 f^3 + \cdots. \tag{4.18}$$

The coefficients α_i are determined sequentially by substituting into (4.16) and then matching powers of f. The resulting power series has a radius of convergence defined by the analyticity of the right-hand side of (4.16). This term is not analytic along the wall, and the lines $g = 0$ and $n = bg(1-g)$. Below we will be generating a power series about a hole in the wall and around (1, 0).

5. Phase plane revisited.

5.1. Production rate of g satisfies $0 < b < 1$. We now show how to construct a travelling shock wave to the example in Figure 3.1(c), where there is one hole in the wall in the positive quadrant. This is illustrated in Figure 5.1(a). We first determine the power series about this hole and find that there are two possible values of α_1. Each of these values provides unique values of the other α_i; hence we obtain two trajectories through the hole in the wall. One of these passes through the n-axis at $n = 1$, and this is the one of interest. Points on this curve, to the right of the hole, are possible values of n_L. We next determine the power series through $(1, 0)$ and determine its intersection with the wall (the limit of its convergence). To the right of this, we determine the curve which lies below the wall, which marks the outer envelope of the possible points for n_R, such that the midpoint of the shock lies on the wall. There is a unique value of g that satisfies the jump conditions (4.15). Hence we obtain two trajectories, one allowing passage through the hole, and, by recrossing the wall with a jump discontinuity, the other connecting to the steady state on the g-axis. The corresponding $n(z)$ and $g(z)$ are shown in Figure 5.1(b) (where we have arbitrarily placed the shock at $z = 0$).

This example illustrates two interesting facts about the solutions for n. For wave speed sufficiently large, a unique smooth travelling solution exists between the steady states $(0, 1)$ and $(1, 0)$. Furthermore, there exists a sufficiently large cellular growth

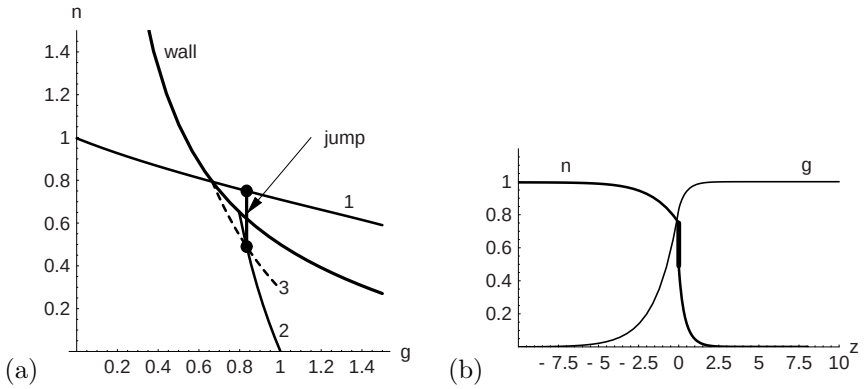

FIG. 5.1. *Travelling shock wave. Here* $a = 2.0$, $b = 0.25$, $c = 1.0$. (a) *Construction of the shock solution. Curve* 1 *is the power series solution around the hole in the wall;* n_L *must lie on this curve to the right of the hole. Curve* 2 *is the power series solution around* $(1, 0)$. *Curve* 3 *is equidistant below the wall as curve* 1 *is above the wall, defined to the right of the hole. rate such that smooth solutions no longer exist and a travelling wave with a shock exists. Alternatively, for fixed a and b, there is a minimum wave speed such that smooth travelling wave solutions exist for $c > c_{crit}$. We have also found that if c is decreased further, travelling shock wave solutions exist for $c_{min} < c < c_{crit}$. The c_{min} is the value which determines the trajectory which jumps directly to the steady state $(1, 0)$. For $0 < c < c_{min}$, no smooth or nonsmooth trajectories exist, since to the right of the hole the distance between the wall and the trajectory through the hole is greater than the distance between the wall and the g-axis.

5.2. Production rate of g satisfies $b > 1$. We now turn to increasing b. Within the range $0 < b < 1$, the qualitative behavior of the phase plane is the same as outlined here with $b = 0.25$. It remains qualitatively similar when $b = 1$, although now all trajectories (except the one along the n-axis) leave the point $(0, 1)$ horizontally. In Figure 5.2(a) there is a smooth trajectory corresponding to a travelling wave, and in Figure 5.2(b) there will be a trajectory with a jump corresponding to a travelling shock wave. However, as b increases through unity, the steady state $(0, 1)$ changes from an unstable node to a saddle. The only outgoing trajectory emanating from this point is along the n-axis; hence there is no trajectory joining this point to $(1, 0)$. However, at the same time a new steady state moves into the positive quadrant, namely $(1 - \frac{1}{b}, 1)$, which is an unstable node if it lies below the wall (i.e., if $c^2 > 1 - \frac{1}{b}$), and is a saddle if it lies above the wall (i.e., if $c^2 < 1 - \frac{1}{b}$). We wish to determine whether a trajectory joining $(1 - \frac{1}{b}, 1)$ and $(1, 0)$ exists and whether it corresponds to smooth travelling wave solutions.

5.2.1. Sufficiently large wave speed: $c^2 > 1 - \frac{1}{b}$. In this case, both steady states are below the wall. Figure 5.3(a) shows that there is a trajectory connecting these two states. Again, when a is increased as illustrated in Figure 5.3(b), these two states can be connected by a trajectory passing through a hole in the wall, allowing a jump discontinuity in n with the wall lying at the midpoint of the jump. Hence again there is a transition from smooth travelling solutions to travelling solutions with a discontinuity.

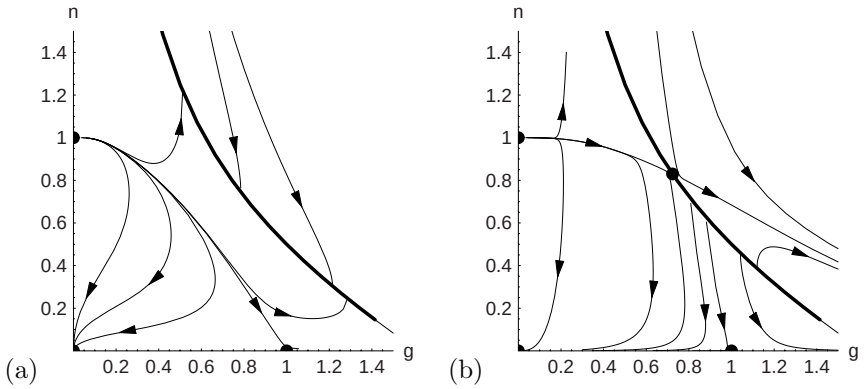

FIG. 5.2. *Phase plane for* (g, n) *for increasing values of cellular growth rate* a*. Here* $b = 1.0$*,* $c = 1.0$*. Wall, holes, and steady states marked as indicated previously.* (a) $a = 0.5$*, no holes.* (b) $a = 3.0$*, one hole.*

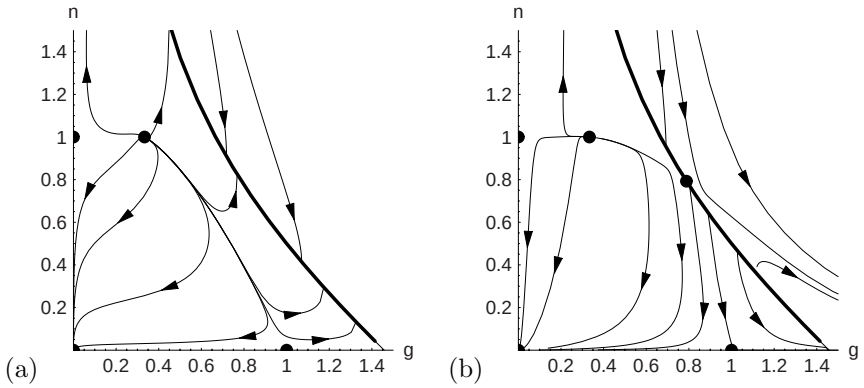

FIG. 5.3. *Phase plane for* (g, n) *for sufficiently large wave speed and increasing values of cellular growth rate* a*. Here* $b = 1.5$*,* $c = 1.0$*, and so* $c^2 > 1 - \frac{1}{b}$*. Wall, holes, and steady states marked as indicated previously.* (a) $a = 0.5$*, no holes.* (b) $a = 3.0$*, one hole.*

5.2.2. Sufficiently small wave speed: $c^2 < 1 - \frac{1}{b}$. In this case, both steady states are separated by the wall. The only possible way to connect them would be with a trajectory passing through a hole in the wall. In the two examples shown in Figure 5.4 (and in others we have tried), there appears to be no connection between these states. To understand the phase plane figures, it is useful to use a coordinate transformation similar to that employed by Pettet, McElwain, and Norbury [19], namely,

$$\frac{d}{dZ} = \left[1 + \frac{g}{c^2}(b(1-g) - 2n)\right] \frac{d}{dz}$$

when $[1 + \frac{g}{c^2}(b(1-g) - 2n)] \neq 0$. Now the holes in the wall become new steady states, and the wall becomes a g-nullcline. Figure 5.5 gives the transformed phase plane corresponding to the examples in Figure 5.4. In Figure 5.5(a), the hole becomes a stable spiral, and the one on the g-axis is a stable node. It appears that there is a limit cycle in this example. Since there is no physical or biological interpretation of Z, unlike $z = x - ct$, it is not fruitful to pursue the limit cycle analysis here. In

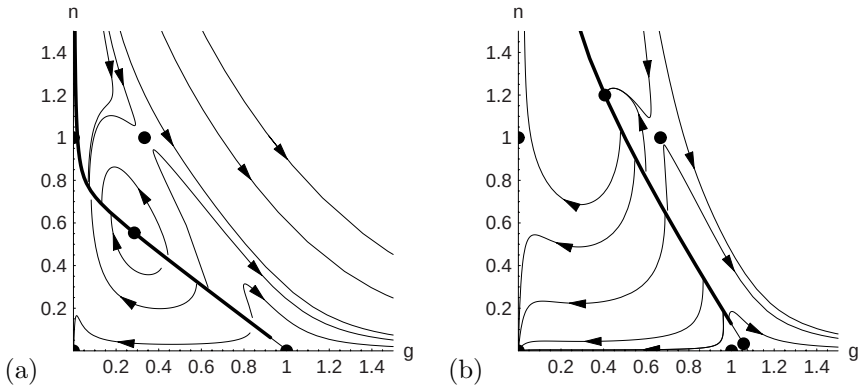

FIG. 5.4. *Phase plane for (g, n) for sufficiently small wave speed and $b > 1$. Here $a = 3.0$, and both examples satisfy $c^2 < 1 - \frac{1}{b}$. Wall, holes, and steady states marked as indicated previously.* (a) *$b = 1.5$, $c = 0.1$, one hole.* (b) *$b = 3.0$, $c = 0.5$, two holes.*

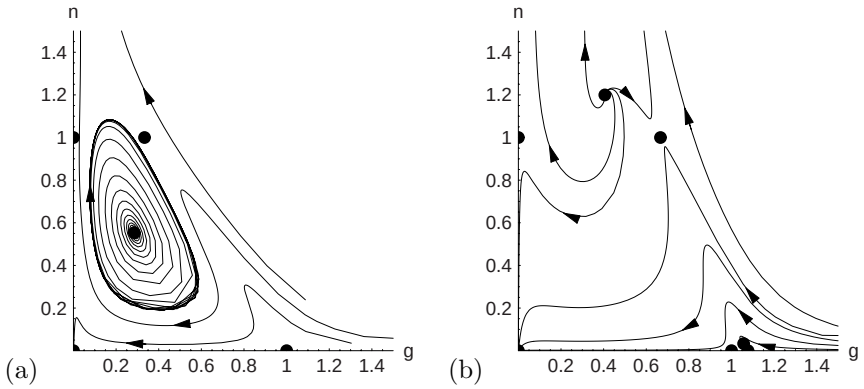

FIG. 5.5. *Z phase plane for (g, n) for sufficiently small wave speed and $b > 1$. Here $a = 3.0$, and both examples satisfy $c^2 < 1 - \frac{1}{b}$. Steady states marked as indicated previously. The parameter values are as for Figure* 5.4. (a) *$b = 1.5$, $c = 0.1$.* (b) *$b = 3.0$, $c = 0.5$.*

Figure 5.5(b), one hole becomes an unstable spiral and the other a stable node, while the one on the g-axis is a saddle.

5.3. Production rate of g satisfies $b = 0$. In this case, the chemoattractant has no production term. Since this degenerate case is similar to other recent work [11], [12], [17], we just summarize the results. When $b = 0$, the steady state $(0, 0)$ is replaced by a continuum of steady states $(\bar{g}, 0)$. Smooth travelling waves exist between $(0, 1)$ and $(\bar{g}, 0)$ for $\bar{g} < \bar{g}_{crit}$, as shown in Figure 5.6. Using the power series method about the hole, we find that there are two values of α_1, resulting in two trajectories through the hole in the wall. One of these passes through the n-axis at $n = 1$, and the other passes through the g-axis at $g = \bar{g}$, thus defining $\bar{g}_{crit}$. For $\bar{g}_{crit} < \bar{g} < \bar{g}_{max}$, the connecting trajectory passes through a hole in the wall and has a jump in it, satisfying the jump condition. The maximum value $\bar{g}_{max}$ is defined as the value of g when the trajectory through the hole jumps directly to a point on the g-axis, that is, $n_R = 0$.

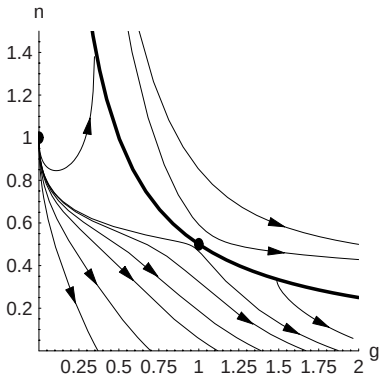

FIG. 5.6. *Phase plane for* (g, n) *for degenerate case* $b = 0$. *Here* $a = 0.5$ *and* $c = 1$. *Wall, holes, and steady states marked as indicated previously.*

6. Asymptotic analysis for large wave speed *c*. We have demonstrated that there is a minimum wave speed for a smooth travelling wave to exist. The phase plane analysis does not actually allow for a calculation of the actual solution. It can be found numerically on a finite domain, but the numerical solution will always tend to the *minimum* wave speed (see Figure 2.1). Here we investigate the analytic form of the solution for large wave speed c, following Canosa [3]. We introduce a new space variable as $z = c\xi$ and $\epsilon = \frac{1}{c^2}$ into (2.11)–(2.12) and obtain

$$[1 + \epsilon g(b(1-g) - 2n)] \frac{dn}{d\xi} = \epsilon n g \left[b(1-2g) - n\right] \left[b(1-g) - n\right] - an(1-n), \tag{6.1}$$

$$\frac{dg}{d\xi} = -(bg(1-g) - ng). \tag{6.2}$$

For small ϵ we look for an asymptotic expansion of the solution in terms of ϵ as

$$n = n_0 + \epsilon n_1 + \epsilon^2 n_2 + \cdots, \tag{6.3}$$

$$g = g_0 + \epsilon g_1 + \epsilon^2 g_2 + \cdots. \tag{6.4}$$

Here we investigate the lowest order terms n_0 and g_0 of the solution. These satisfy

$$\frac{dn_0}{d\xi} = -an_0(1 - n_0), \tag{6.5}$$

$$\frac{dg_0}{d\xi} = -bg_0(1 - g_0) + n_0 g_0. \tag{6.6}$$

The n_0 equation is decoupled and can be solved as

$$n_0 = (1 + e^{a\xi})^{-1}, \tag{6.7}$$

where the integration constant has been chosen without any loss of generality so that $n_0(0) = \frac{1}{2}$. Equation (6.6) can be solved analytically, but it is in terms of hypergeometric functions, which is not very helpful. For $b = 0$, the solution is simply

$$g_0 = (1 + e^{-a\xi})^{-1/a}, \tag{6.8}$$

so that $n_0 = 1 - g_0^a$. We see in Figure 6.1 that the numerical solution for g_0 when $0 < b < 1$ differs only slightly from the solution when $b = 0$, and all solutions for

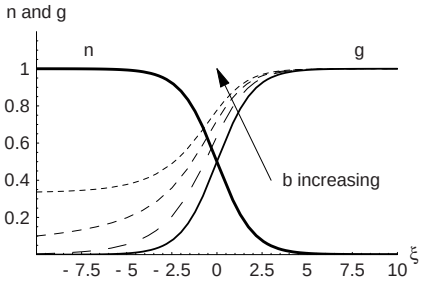

FIG. 6.1. *The lowest order solution profiles for n and g versus $\xi = z/c$ for large wave speed c. Here $a = 1.0$. The g curves depend on its production rate b; here $b = 0, 0.5, 1.0,$ and 1.5.*

g_0 tend to zero as $\xi \to -\infty$. For $b > 1$, g_0 tends to $1 - \frac{1}{b}$. Increasing the cellular growth rate a steepens the gradient of the front for n_0, as expected from our previous analysis. In particular, the slope $-\frac{\partial n}{\partial \xi}(0) = a$, and so it increases linearly with a and is independent of b to lowest order.

7. Conclusions. In this article we have considered a simple mathematical model of cell migration, where the dominant mechanism driving the migration is the phenomenon of chemotaxis. Such models have been explored in a number of contexts, generally with the view to seeking travelling wave solutions that may in some way characterize the front of invasion.

We have explored the possibility of the existence of both smooth-fronted and shock-fronted travelling wave solutions to a general model of chemotactic cell migration. Not surprisingly the mathematical model supports a rich variety of solutions exhibiting a family of identifiable characteristic behaviors such as shock-fronted travelling wave solutions with lower wave speeds than the smooth-fronted waves.

We have shown that for the model of chemotactic migration considered, for fixed a and $0 < b < 1$, there is a minimum wave speed such that smooth travelling wave solutions exist between the steady states $(0, 1)$ and $(1, 0)$ for $c > c_{crit}$. We have also found that if c is decreased further, travelling shock wave solutions exist for $c_{min} < c < c_{crit}$. The c_{min} is the value which gives the trajectory that jumps directly to the steady state $(1, 0)$. For $0 < c < c_{min}$, no smooth or nonsmooth trajectories exist, since to the right of the hole in the wall, the distance between the wall and the trajectory through the hole is greater than the distance between the wall and the g-axis. A similar argument holds for the case of a sufficiently large wave speed c, such that for fixed b and c it is possible to increase the cellular growth rate a through a critical value so that there is a transition from the existence of a smooth-fronted to a sharp-fronted travelling wave.

When $b > 1$, similar critical wave speeds can be found defining smooth and discontinuous travelling wave solutions between the steady states $(1 - \frac{1}{b}, 1)$ and $(1, 0)$, but only if the steady states are both on the same side of the wall. If the wall separates these two steady states, then no travelling wave solutions appear to exist.

The wave speeds described above are dimensionless. In terms of dimensioned variables they correspond to $\frac{Tv}{L} = \frac{v}{\sqrt{\chi \lambda_3 k_1 k_2}}$, using (2.5)–(2.6) and where v is dimensioned wave speed. Hence, converting bounds on c to bounds on χ, smooth travelling wave solutions exist for $0 < \chi < \chi_{crit}$, and travelling shock solutions exist for $\chi_{crit} < \chi < \chi_{max}$. For $\chi > \chi_{max}$, no smooth or nonsmooth trajectories exist.

These results have been obtained by considering a phase plane analysis for a coupled system of equations (2.11)–(2.12), along with power series solutions around some special points. It should be noted that, near the wall, this system is a singularly perturbed system, since then the coefficient multiplying the derivative in (2.11) is small and vanishes identically on the wall. Hence at the wall the system reduces to a differential-algebraic system. The dynamics near the wall could be decomposed into fast and slow times. Solutions consist of outer segments away from the wall and inner segments near the wall; matching occurs at holes in the wall. Such an approach could be used to establish our results theoretically. This is beyond the scope of this current paper, which is concerned with establishing the possibility of both smooth-fronted and shock-fronted travelling wave solutions to a general model of chemotactic cell migration.

Typically, migrating cell populations in invasive phenomena are characterized by a well-defined boundary. A nonlinear diffusive flux can capture this feature, but does not allow for shock solutions. Of particular interest here, though, is the possibility of representing sharp fronts to waves of invading cells by the simple chemotactic term, without the need for nonlinear diffusion. As presented here, the chemotactic cell migration model (2.1)–(2.2) supports jump discontinuities when $c_{min} < c < c_{crit}$. However, solutions with compact support exist only for $c = c_{min}$, whereas for $c_{min} < c < c_{crit}$ there is a smooth leading segment of the front ahead of the discontinuity. We anticipate that the minimum invasion speed solution (with c_{min}) will evolve as the stable solution, using a hyperbolic numerical solver, as indicated by Marchant and Norbury [13]. Furthermore, the numerical solutions in Figure 2.1 suggest that this may be the case, since as χ increases, corresponding to c decreasing, the leading edge contracts. We are presently tackling these issues.

When cell population numbers are sufficiently dense to imply frequent and significant cell-cell interactions, the suitability of a diffusive flux term comes into question. In such circumstances, mathematical models of cell migration in which a chemotactic flux dominates over the diffusive flux are more appropriate. Being essentially hyperbolic in nature, these models have the potential to support shock-fronted solutions, which may be seen as a new paradigm for the representation of cell migration.

Acknowledgments. We would like to thank Dr. Mark McGuinness, at Victoria University of Wellington, for initial discussions on the model. We also thank the reviewers for their helpful comments and suggestions.

FORMAL ASYMPTOTICS OF BUBBLING IN THE HARMONIC MAP HEAT FLOW*

JAN BOUWE VAN DEN BERG†, JOSEPHUS HULSHOF†, AND JOHN R. KING‡

Abstract. The harmonic map heat flow is a model for nematic liquid crystals and also has origins in geometry. We present an analysis of the asymptotic behavior of singularities arising in this flow for a special class of solutions which generalizes a known (radially symmetric) reduction. Specifically, the rate at which blowup occurs is investigated in settings with certain symmetries, using the method of matched asymptotic expansions. We identify a range of blowup scenarios in both finite and infinite time, including degenerate cases.

Key words. harmonic maps, blowup, bubbling, matched asymptotics, nematic liquid crystal

1. Introduction.

We consider the equation

$$\theta_t = \theta_{rr} + \frac{1}{r}\theta_r - \frac{\sin 2\theta}{2r^2}, \qquad 0 < r < 1, \tag{1.1}$$

with boundary conditions $\theta(t,0) \in \pi\mathbb{Z}$ and $\theta(t,1) = \theta_1 \in \mathbb{R}$; the reason for this type of boundary condition at $r = 0$ will become clear shortly. Solutions of (1.1) may develop a singularity. In this paper we analyze this blowup behavior using formal matched asymptotics.

Equation (1.1) is a special case of the harmonic map heat flow

$$\frac{\partial u}{\partial t} = \Delta u + |\nabla u|^2 u, \tag{1.2}$$

where $u(t,\cdot) : \Omega \to S^2$; i.e., $u(t,x)$ denotes a unit vector in $\mathbb{R}^3$, $\Omega \subset \mathbb{R}^N$ (in most physical models $N = 3$), and $|\nabla u|^2 = \sum_{j=1}^{N} \sum_{i=1}^{3} (\frac{\partial u_i}{\partial x_j})^2$. Stationary solutions of (1.2) are harmonic maps from Ω to S^2.

Observe that we are dealing with blowup of the derivative ∇u while u remains bounded (in fact, $|u(t,x)| = 1$ for all t and x), and similarly θ_r blows up while θ remains bounded. (As we shall see, θ can make finite jumps.) This stands in contrast to many widely studied blowup problems, such as the reaction-diffusion equation $u_t = \Delta u + u^p$ with $p > 1$, where u itself blows up (see, e.g., [8] and references therein).

Equation (1.2) may be reduced to (1.1) if Ω is a disk in $\mathbb{R}^2$: assuming the solution to be radially symmetric and using polar coordinates (r,ϕ) on the unit disk, a special type of solution of (1.2) is given by

$$u(t,\cdot) : (r,\phi) \to \begin{pmatrix} \cos\phi \, \sin\theta(t,r) \\ \sin\phi \, \sin\theta(t,r) \\ \cos\theta(t,r) \end{pmatrix}, \tag{1.3}$$

where $\theta(t,r)$ satisfies (1.1). Similarly, when Ω is a cylinder, then the problem of finding solutions of (1.2) that are both radially symmetric and uniform in the axial direction may be reduced to (1.1). This is the configuration studied in [11] as a model for aligned nematic liquid crystals, with the motivation coming from applications in fiber spinning. Beside the context of liquid crystals (see, e.g., [14]), another application in which (1.2) appears is the theory of ferromagnetic materials (e.g., [6, 3]). In geometry, (1.2) is studied in the construction of harmonic maps of certain homotopy types (see, e.g., [15]), where Ω is generally (a subset of) an N-manifold. (The target manifold may also differ from S^2, but if it is not a sphere, (1.2) is altered.) The formation of singularities in the flow of (1.2) has been extensively studied; we refer to [15, 16, 9]. Singularities occur due to topological obstructions, a situation which is comparable to closely related problems in the Ginzburg–Landau equation (see, e.g., [4]). In the present context, the issue is that while all solutions eventually converge to equilibria, we can choose initial data in a topological class that does not contain any equilibria. The solution must then "jump" to another topological class. The different topological classes are (for fixed $\theta(t,1)=\theta_1$) characterized by the value of θ at the origin, which has to be a multiple of π for the solution to have finite energy (see below).

We recall some important results, where in view of (1.1) we concentrate on domains $\Omega \subset \mathbb{R}^2$. Equation (1.2) is the gradient flow associated with the energy $\mathcal{E} = \frac{1}{2}\int_\Omega |\nabla u|^2\,dx$. It is well known that a weak solution of (1.2) exists globally. There may be many weak solutions, but there is a unique one in the class of energy-decreasing solutions; see [7, 15]. Weak solutions are in $H^1(\Omega, S^2)$ for almost all $t>0$, and, when the initial data are smooth, the solution is locally a classical solution. In fact, the solution is smooth everywhere except for at most a finite number of space-time points [15]. Moreover, there are smooth initial conditions for which a singularity occurs in finite time [5, 2]. As $t\to\infty$ the solution converges weakly to a stationary solution and does so smoothly away from at most a finite number of points. At a singularity, either in finite time or at $t=\infty$, a sphere is said to bubble off: an appropriate blowup near the singularity converges to a harmonic map on the sphere $S^2 \cong \overline{\mathbb{R}^2}$ (see [15]). In this paper we investigate the rate at which these spheres bubble off in the symmetric setting of (1.1). In the context of liquid crystals this bubbling means that quanta of energy (i.e., a multiple of 4π) are stored in a singularity (a region smaller than that captured by the model).

Let us now concentrate on the implications for (1.1). The (weak) solution $\theta(t,\cdot)$ is continuous on $[0,1]$ and $\theta(t,0)\in\pi\mathbb{Z}$ for all $t>0$. The requirement that $\theta(t,0)\in\pi\mathbb{Z}$ is necessary for solutions to have finite energy. Singularities can develop only at the origin. At a singularity the energy

$$\mathcal{E}(t) = \pi\int_0^1 \left(r\,\theta_r^2 + \frac{\sin^2\theta}{r}\right) dr \tag{1.4}$$

decreases (jumps) by 4π or a multiple thereof. (Of course, away from such singularities, the energy $\mathcal{E}(t)$ decreases continuously throughout the evolution, since (1.1) is the gradient flow associated with (1.4).) Notice that the stationary solutions of (1.1) with finite energy $\mathcal{E}$ are given by

$$\theta(r) = m\pi + 2\arctan qr \qquad \text{for any } q\in\mathbb{R} \text{ and } m\in\mathbb{Z},$$

and their energy tends to 4π as $q\to\infty$. The solutions $\theta(r)=(m+\frac{1}{2})\pi$, $m\in\mathbb{Z}$, have infinite energy and can be disregarded.

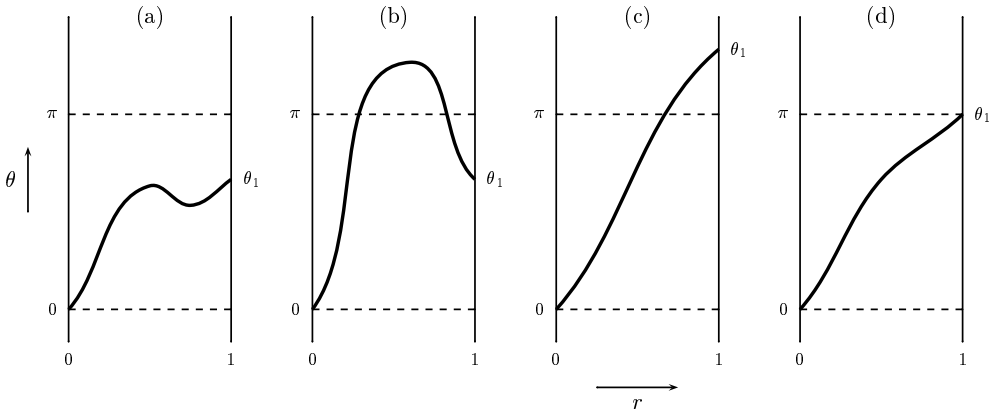

FIG. 1.1. *Several initial conditions* $\theta(0,r)$*:* (a) *no blowup will occur;* (b) *blowup may occur;* (c) *blowup must occur;* (d) *the degenerate case* $\theta_1 = \pi$*, which leads to infinite time blowup, as opposed to finite time blowup for* $\theta_1 > \pi$*.*

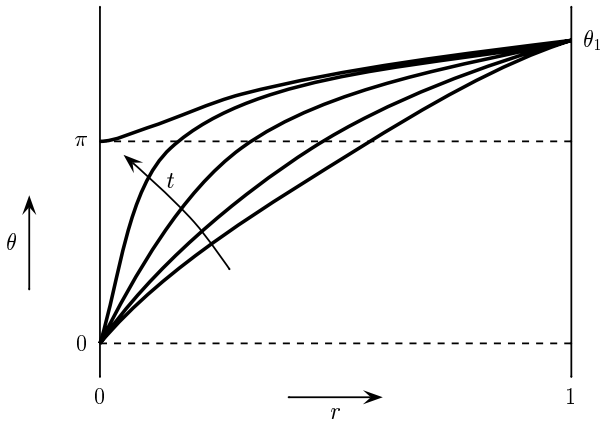

FIG. 1.2. *The profile at several times leading up to blowup at* $t = T$*. The slope* $\theta_r(0)$ *goes to infinity, and the solution jumps from* 0 *to* π *at the origin.*

Whether or not singularities occur will depend on the initial and boundary data (see also Figure 1.1). Consider initial conditions such that $|\theta(0,0)-\theta_1| < \pi$. Then the solution may converge to one of the stationary states as $t \to \infty$ without forming a singularity. This is indeed what happens when $\theta(0,r) \in C^1$ and $\|\theta(0,r) - \theta(0,0)\|_\infty \leq \pi$. On the other hand, it has been proved in [2] that blowup may occur for initial data with $|\theta(0,0) - \theta_1| < \pi$ but $|\theta(0,0) - \theta(0,r)| > \pi$ for some $r \in (0,1)$. A more dramatic situation occurs when $|\theta(0,0) - \theta_1| \geq \pi$: no stationary solution is available that obeys both boundary conditions (i.e., $\theta(0) = \theta(0,0)$ and $\theta(1) = \theta_1$). Therefore, for the solution to approach any of the stationary solutions a jump at the origin must necessarily occur. This is depicted in Figure 1.2. We focus on this case, and after shifting θ by a multiple of π, we may restrict our attention to initial/boundary data $\theta(0,0) = 0$ and $\theta(t,1) = \theta_1 \geq \pi$. Without loss of generality we will analyze the first instance of blowup.

As mentioned before, when blowup occurs, appropriately zooming in on the singularity will reveal a harmonic map, i.e., one of the stationary solutions. We first focus on boundary data $\theta_1 > \pi$ and consider the special case $\theta_1 = \pi$ later. Assuming the jump of $\theta(t,0)$ to be upwards (without loss of generality), we select a zooming function $R(t) > 0$ by requiring that

$$R(t)\theta_r(t,0) = 2 \qquad \text{for all } t \text{ up to the blowup time } T \in (0,\infty].$$

We choose the constant in the right-hand side to be 2 in order to keep the subsequent algebra as simple as possible. When blowup occurs at $t = T$, we will thus have

$$\lim_{t\uparrow T} \theta(t, \rho R(t)) = 2\arctan\rho \qquad \text{for all fixed } \rho > 0.$$

The main objective of this paper is to determine the asymptotic form of $R(t)$.

At first sight one might think that the blowup rate simply corresponds to self-similar variables, i.e., $R(t) \sim \kappa\sqrt{T-t}$. However, no suitable self-similar solution exists. (We postpone justification of this statement until the end of this section.) Indeed, we find that the blowup rate is not the self-similar one. Using formal asymptotics, we match an inner layer near $r = 0$ to an outer region near $\theta = \pi$ (where the solution is approximately self-similar), which in turn matches into the remote region where $r = O(1)$. We find that generically

$$R(t) \sim \kappa \frac{T-t}{|\ln(T-t)|^2} \qquad \text{as } t \uparrow T \tag{1.5}$$

for some blowup time $T > 0$ and some constant $\kappa > 0$. That there is an unknown constant κ is a consequence of the fact that the profile in the remote region plays a subdued role. Therefore, in spite of the finiteness of the domain, the scaling invariance $(t,r) \mapsto (\mu^2 t, \mu r)$ with $\mu > 0$ of (1.1) causes an indeterminacy.

The point $S(t)$, the smallest intersection of $\theta(t,r)$ with π, behaves as

$$S(t) \sim 2\sqrt{\frac{T-t}{|\ln(T-t)|}} \qquad \text{as } t \uparrow T.$$

In particular, in this scenario the solution always intersects π close to blowup. There is no undetermined constant in this asymptotic expression for $S(t)$ because it is (to leading order) invariant under the scaling invariance. The limit profile at $t = T$ for small r becomes

$$\theta(T,r) \sim \pi + \frac{1}{4}\kappa \frac{r}{|\ln r|} \qquad \text{for small } r,$$

with the same constant $\kappa > 0$ as in (1.5). We remark that there may be additional blowup times $T' > T$, for example when $|\theta(0,0) - \theta_1| > 2\pi$, and that $\theta(t,0)$ can jump only by $\pm\pi$ at a time (and thus the energy by 4π); see [12].

A nongeneric case arises when $\theta_1 = \pi$ and, for example, $-\pi < \theta(0,r) < \pi$ for $r \in (0,1)$. In that case the asymptotics indicate blowup in infinite time:

$$R(t) \sim e^{-2\sqrt{t}-5/4} \qquad \text{as } t \to \infty.$$

Notice that the blowup is now in infinite time as opposed to finite time for $\theta_1 > \pi$. Besides, there is no undetermined constant in the leading order term for $R(t)$; the

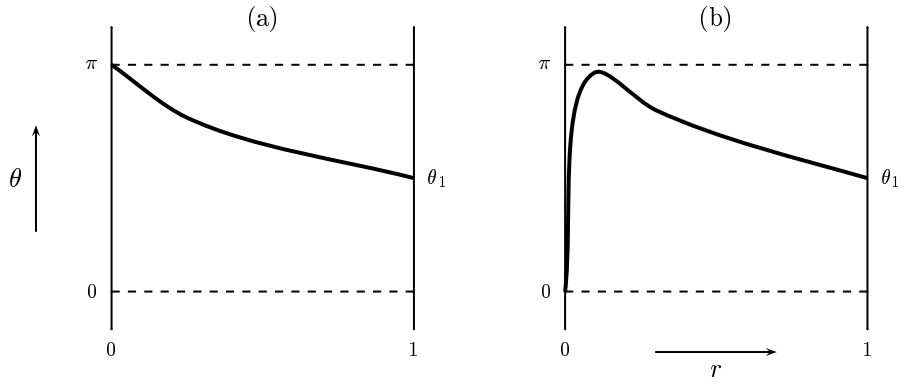

FIG. 1.3. *In a reverse jump the energy of the solution increases:* (a) *just before* t_0, (b) *just after* t_0.

length of the interval has a direct bearing on the analysis so that the scaling invariance is lifted. We remark that when $\theta(0,r) > \pi$ for some $r \in (0,1)$, then it can (but does not necessarily) happen that blowup occurs in finite time via the scenario described before. In that case the solution intersects π just before blowup. On the other hand, for initial profiles with $-\pi < \theta(0,r) < \pi$ a comparison argument shows that this is not possible.

A different situation in which we can easily see that nongeneric behavior must occur is when $\theta_1 < \pi$, and the initial data are roughly as depicted in Figure 1.1(b). When the initial profile has a sufficiently large bump above π, the solution will blow up in finite time via the scenario described above. On the other hand, when the bump is small (e.g., stays below π), no blowup occurs. In between these generic (codimension 0) possibilities there needs to be at least one borderline (nongeneric) scenario, and such degenerate cases are also discussed below. Regarding the large time behavior of these solutions, in the latter generic case (when no blowup occurs) the limit profile as $t \to \infty$ is $\theta_\infty(r) = 2\arctan\bigl(r\tan\frac{\theta_1}{2}\bigr)$, while in the former case the stationary state $\theta_\infty(r) = \pi - 2\arctan\bigl(r\tan\frac{\pi-\theta_1}{2}\bigr)$ is selected (provided that no additional jump back to 0 occurs), and it turns out this last stationary state is also the limit profile in the degenerate scenario (if no additional jumps occur).

There is another issue related to these singularities. As explained in [2, 18, 5], weak solutions have the possibility of releasing the energy formerly lost in a singularity, thereby causing a sudden *increase* in the energy $\mathcal{E}(t)$. The physical interpretation is that this released energy was stored in a region of smaller scale than that captured by the model. We consider the situation where θ makes such a "reverse" jump at $t = t_0$; see also Figure 1.3. When θ jumps from π to 0 at $t = t_0$, we define as before $R(t) = \frac{2}{\theta_r(t,0)}$ for $t > t_0$. One finds that generically

$$R(t) \sim \kappa \frac{t - t_0}{|\ln(t - t_0)|} \qquad \text{as } t \downarrow t_0$$

for some arbitrary constant $\kappa > 0$. Notice the slight difference with (1.5).

Reexamining the reduction of (1.2) to (1.1), the physical meaning of the ansatz (1.3) is that the direction field $u(t,\cdot)$ at the boundary of the cylinder is axisymmetric and the in-plane component points in the radial direction. In fact, the solution class

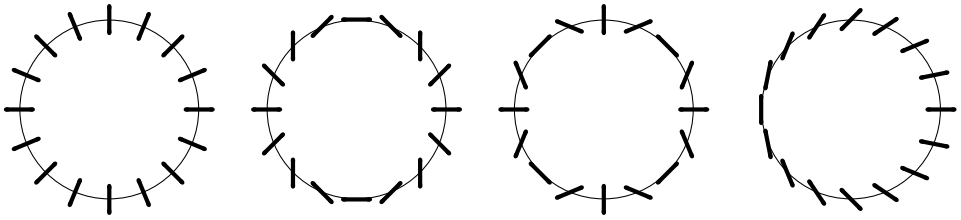

FIG. 1.4. *Top view of the behavior of the vector u at the boundary of the domain for $n = 1$, $n = 2$, $n = 3$, and $n = \frac{1}{2}$, the last one necessarily leading to configurations with infinite energy.*

defined by (1.3) belongs to a family of solution classes given by

$$u(t,\cdot) : (r,\phi) \to \begin{pmatrix} \cos n\phi \, \sin\theta(t,r) \\ \sin n\phi \, \sin\theta(t,r) \\ \cos\theta(t,r) \end{pmatrix}. \tag{1.6}$$

The equation for θ now becomes

$$\theta_t = \theta_{rr} + \frac{1}{r}\theta_r - n^2 \frac{\sin 2\theta}{2r^2}, \qquad 0 \le r \le 1. \tag{1.7}$$

From a mathematical point of view the constant $n > 0$ (ignoring the trivial case $n = 0$ throughout) can be considered as a continuous parameter in (1.7), and it can be used to unravel the delicate analysis of blowup for $n = 1$ (which is a borderline case, so that the asymptotic analysis is particularly delicate). From a physical point of view, only the values $n = 1, 2, 3, \ldots$ make sense. In Figure 1.4 the configurations for $n = 1$, 2, and 3 are depicted. We note that for $n = \frac{1}{2}$ (and odd multiples of $\frac{1}{2}$) the view from the top (see Figure 1.4) gives the impression of smoothness (because the molecules in a nematic liquid crystal are invariant under inversion, or in other words, because in (1.2) the function $u(t,\cdot)$ maps from Ω to the projective plane instead of to the sphere). However, on closer inspection, one observes that in fact a line singularity with infinite energy is unavoidable, and hence such cases fall outside the scope of the present paper.

The stationary solutions of (1.7) with finite energy are

$$\theta(r) = m\pi + 2\arctan(qr^n), \qquad m \in \mathbb{Z},\ q \in \mathbb{R}.$$

We define $R(t)$ such that

$$R(t)^n \theta(t,r) \sim 2r^n \quad \text{as } r \downarrow 0 \qquad \text{for all } t \text{ up to the blowup time.}$$

After rescaling with this blowup rate, the profile tends to a harmonic map (a stationary state) as t approaches the blowup time T:

$$\lim_{t \uparrow T} \theta(t, \rho R(t)) = 2\arctan\rho^n \qquad \text{for all fixed } \rho > 0.$$

The results of our asymptotic analysis for $R(t)$ give the following as the generic blowup

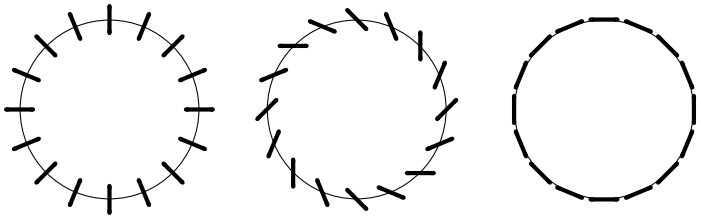

FIG. 1.5. *Top view of the behavior of the vector u at the boundary of the domain for $n = 1$ with $\phi_0 = 0$, $\phi_0 = \frac{\pi}{4}$, and $\phi_0 = \frac{\pi}{2}$.*

behavior:

$$\begin{aligned}
n < 1: &\qquad R \sim \kappa\,(T-t)^{1/n} &&\text{as } t \uparrow T,\\
n = 1: &\qquad R \sim \kappa\,\frac{T-t}{|\ln(T-t)|^2} &&\text{as } t \uparrow T,\\
1 < n < 2: &\qquad R \sim \kappa\,(T-t)^{1/(2-n)} &&\text{as } t \uparrow T,\\
n = 2: &\qquad R \sim \kappa\, e^{-\frac{\alpha_0}{E_2}t} &&\text{as } t \to \infty,\\
n > 2: &\qquad R \sim \left(\tfrac{(n-2)\alpha_0}{E_n}t\right)^{-1/(n-2)} &&\text{as } t \to \infty.
\end{aligned}$$

Here $\kappa > 0$ is an arbitrary constant, $E_n = \frac{\pi}{2n^2 \sin(\frac{\pi}{n})}$, and $\alpha_0 = \tan(\frac{\theta_1 - \pi}{2})$ for $\theta_1 \in (\pi, 2\pi)$. The above represent the generic behavior (e.g., $\theta_1 = \pi$ needs to be considered separately), and for $n \geq 2$ it does not apply to boundary conditions with $\theta_1 \geq 2\pi$; the analysis is more involved in that case (see section 3.6). Notice that the blowup is in finite time for $n < 2$, versus infinite time blowup for $n \geq 2$. Furthermore, it is remarkable that the borderline case $n = 1$ has the fastest blowup rate. Finally, there is no unknown constant for $n > 2$ since the boundary condition on the right has direct influence on the asymptotics (and thus there is no scaling invariance). This is equally true for $n = 2$, and the translation invariance in time rather than the scaling invariance can be considered responsible for the indeterminacy here. On the other hand, $n = 2$ marks the transition from finite to infinite time blowup, and subtle behavior can be expected at such a critical value.

There is an additional symmetry which needs to be noted. In the right-hand side of (1.6) one may replace ϕ by $\phi + \phi_0$, which again leads to (1.7). For $n = 1$ this presents us with a family of geometrically different solutions, while for $n \neq 1$ all these solutions are equivalent by rotation of the domain. In Figure 1.5 we have depicted the situation occurring for $\phi_0 = \frac{\pi}{4}$ and $\phi_0 = \frac{\pi}{2}$ (and $n = 1$), which may be compared to $\phi_0 = 0$ to see the difference in geometry. All these cases are covered by (1.7).

In order to prevent cumbersome bookkeeping and to be able to clarify the crucial points, we will first analyze the special case $n = 1$ in section 2. Degenerate cases, including the special boundary condition $\theta_1 = \pi$, and reverse jumps are treated in sections 2.5 to 2.7. In section 3 we analyze the general case (1.7), and the special role of $n = 1$ will become apparent. We also discuss in section 3.6 the multiscale blowup associated with boundary conditions $\theta_1 \geq 2\pi$ for $n \geq 2$; in section 3.8 we deal with the case of an unbounded domain. Finally, we present an overview of our results and draw conclusions in section 4.

It remains a challenge to find proofs for the formal asymptotic results in this paper. We refer to [1] for some tentative results in which the comparison principle and

lap number theorem for parabolic equations are exploited. These methods circumvent nondegeneracy conditions so that, while avoiding the problems associated with degenerate cases, they fail to uncover the full range of the generic behavior. Another open problem is what happens in a nonsymmetric situation, both in two and three dimensions, and what role is played by symmetric solutions in that context. The fact that $n = 1$ is such an exceptional case may suggest that it plays a special role.

To finish this section we show why blowup is not governed by self-similar variables. (This was also observed in [1].) A self-similar solution for finite time blowup is of the form $\theta(t, r) = \Theta(r/\sqrt{T-t})$. For the function $\Theta(y)$ one obtains the equation

$$\Theta_{yy} + \left(\frac{1}{y} - \frac{y}{2}\right)\Theta_y - n^2\frac{\sin 2\Theta}{2y^2} = 0.$$

Since $\theta(t, 0)$ jumps from 0 to π, the boundary conditions are $\Theta(0) = 0$, and at infinity $\lim_{y\to\infty}\Theta(y) = \pi$. We now change coordinates to $z = \ln y$ and obtain for $\tilde{\Theta}(z) = \Theta(y)$

$$\tilde{\Theta}_{zz} - \frac{1}{2}e^{2z}\tilde{\Theta}_z - \frac{n^2}{2}\sin 2\tilde{\Theta} = 0, \tag{1.8}$$

with boundary conditions $\lim_{z\to-\infty}\tilde{\Theta}(z) = 0$ and $\lim_{z\to\infty}\tilde{\Theta}(z) = \pi$. There is no solution to this problem since, on the one hand, $G(z) \stackrel{\text{def}}{=} \frac{1}{8}\tilde{\Theta}_z^2 + n^2\cos 2\tilde{\Theta}$ is monotonically increasing, while, on the other hand, $\lim_{z\to-\infty}G(z) = \lim_{z\to+\infty}G(z) = n^2$. This contradiction shows that there is no such solution, and hence this self-similar scenario for blowup cannot occur. In fact, $\tilde{\Theta} = \pi$ is the only solution satisfying the condition as $z \to \infty$; this in part explains why $\theta \sim \pi$ necessarily holds in the outer region described below. In this argument it is crucial that $\int_0^\pi \sin 2\theta\, d\theta = 0$. For nonlinearities that do not have zero average, a self-similar blowup rate may be expected. It could thus be interesting to study a problem in which the average of the nonlinearity approaches zero as a parameter is varied.

2. The case $n = 1$.

2.1. Preamble. There will be three scales: the inner, the outer, and the remote region (see Figure 2.1). The inner is a small region near the origin in which the blowup is concentrated. It is of order $r = O(R(t))$, where $R(t)$ is an unknown function (in fact, the main goal is to determine the asymptotic behavior of $R(t)$), and in this region the profile near blowup is $2\arctan(r/R(t))$. The outer region is a region with θ near π in which the equation can be linearized. The typical scale in this region is $r = O(\sqrt{T-t})$, where T is the blowup time. An obvious requirement for self-consistency is that $R(t) \ll \sqrt{T-t}$. The remote region is the region where $r = O(1)$, and at the time of blowup the profile in this region is unknown, but the limit profile as the origin is approached will come out of the matching procedure.

Throughout the paper the constants C, $\tilde{C}$, and C_i ($i \in \mathbb{N}$) will vary from subsection to subsection.

2.2. The inner approximation. We analyze the boundary layer near $r = 0$. As explained in section 1, it is known on general grounds that, when we zoom in appropriately, we should see $2\arctan(r/R(t))$, with $R(t) \to 0$ as $t \uparrow T$. Recall that the definition of R is $R(t) = \frac{2}{\theta_r(t,0)}$. We introduce a new variable $\xi = r/R(t)$ and obtain for $v(t, \xi) = \theta(t, r)$

$$R^2 v_t - R'R\,\xi v_\xi = v_{\xi\xi} + \frac{1}{\xi}v_\xi - \frac{\sin 2v}{2\xi^2}.$$

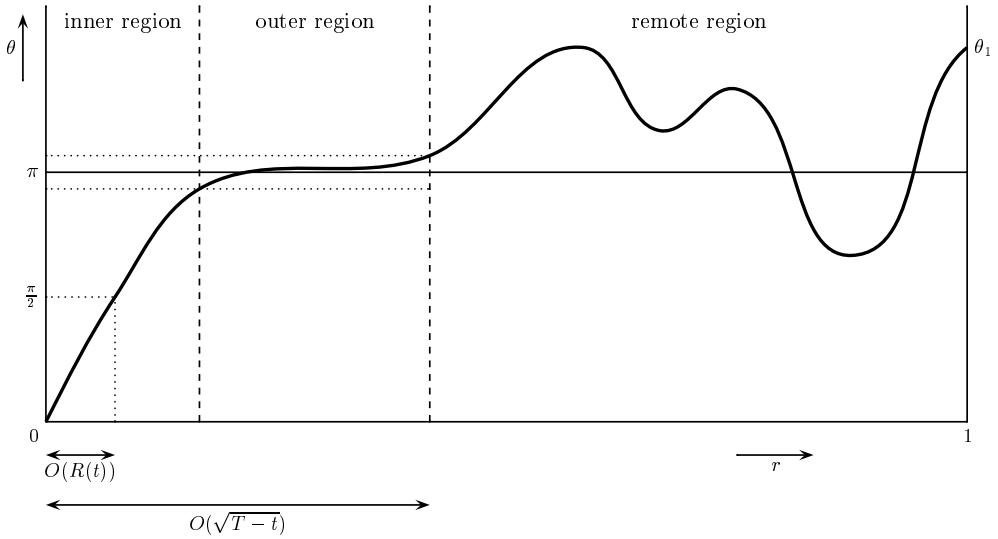

FIG. 2.1. *The three different scales.*

Since $R(t)$ becomes small for t close to blowup, we formally expand the solution in powers of $R'R$:

$$v(t,\xi) \sim \Phi_0(\xi) + R'(t)R(t)\Phi_1(\xi) + (R'(t)R(t))^2\Phi_2(\xi). \tag{2.1}$$

A motivation for this expansion is that we anticipate that $R \ll R'$ as $t \to T$. To these orders, $R^2 v_t$ does not contribute, since the rescaling is chosen such that the leading order solution is stationary. Of course we need that $R'R \to 0$ as $t \to T$.

One finds that

$$\Phi_0(\xi) = 2\arctan\xi,$$

and $\Phi_1(\xi)$ satisfies

$$\Phi_{1\xi\xi} + \frac{1}{\xi}\Phi_{1\xi} - \frac{\cos 2\Phi_0}{\xi^2}\Phi_1 = -\xi\Phi_{0\xi}.$$

It turns out that Φ_1 is already the interesting term, so that we could have restricted our analysis to linearizing around Φ_0. The equation for Φ_2 is

$$\Phi_{2\xi\xi} + \frac{1}{\xi}\Phi_{2\xi} - \frac{\cos 4\arctan\xi}{\xi^2}\Phi_2 = \big(1+K\big)\Phi_1 - \xi\Phi_{1\xi} - \frac{\sin(4\arctan\xi)}{\xi^2}\Phi_1^2, \tag{2.2}$$

where $K = \lim_{t\to T}\frac{R''R}{R'^2}$. Here we see that we need $R''R = O(R'^2)$ as $t \to T$ in order for (2.1)–(2.2) to be self-consistent. (It includes, for example, $R \sim (T-t)^a$ and $R \sim t^{-a}$ when $T = \infty$ for any $a > 0$.) This will turn out to be the case with $K = 0$.

The nonuniqueness of Φ_i is resolved by requiring Φ_i to be regular near $\xi = 0$, i.e., $\Phi_i(0) = 0$, and $\Phi_i'(0) = 0$ in view of the definition of $R(t)$. One finds

$$\Phi_1 = \frac{\xi}{1+\xi^2}\int_0^\xi \frac{s(s^4+4s^2\ln s - 1)}{(1+s^2)^2}ds - \frac{\xi^4+4\xi^2\ln\xi - 1}{\xi(1+\xi^2)}\int_0^\xi \frac{s^3}{(1+s^2)^2}ds,$$

which, after a quite tedious calculation, can be rewritten as

$$\Phi_1 = \frac{(1-\xi^4)\ln(1+\xi^2) + 2\xi^4 - \xi^2 - 4\xi^2 \int_0^\xi \frac{\ln(1+s^2)}{s} ds}{2\xi(1+\xi^2)}.$$

For large ξ the inner approximation thus satisfies

$$v(t,\xi) \sim \pi - 2\,\xi^{-1} + R'(t)R(t)(-\xi \ln \xi + \xi) \qquad \text{for } t \text{ close to } T \text{ and large } \xi. \tag{2.3}$$

Here, and in other asymptotic expansions to come, we include all those terms which might be necessary for performing the matching analysis. (It is not a priori clear whether all of them will be needed.) Let us briefly comment on the inclusion of the term $R'(t)R(t)\xi$ in this expansion. Although it is dominated by $R'(t)R(t)\xi \ln \xi$, it is well known that terms that differ only by orders of $\ln \xi$ can play a role in the matching. We remark that the leading order approximation $v \sim \pi - 2\xi^{-1} - R'(t)R(t)\xi \ln \xi$ is valid if $\xi^4 \gg \frac{1}{|R'R|}$ and $\xi^2 \ll \frac{1}{|R'R|}$, because the next terms are of order $O(\xi^{-3})$ and $O(R'^2R^2\xi^3 \ln \xi)$; this last term comes from the large ξ behavior for the solution of (2.2).

We remark that we could for most purposes have restricted our attention to the asymptotic equation for Φ_1,

$$\Phi_{1\xi\xi} + \frac{1}{\xi}\Phi_{1\xi} - \frac{1}{\xi^2}\Phi_1 \sim -\frac{2}{\xi},$$

from which we obtain $\Phi_1 \sim -\xi \ln \xi + C\xi$ for large ξ. The value of C can be determined only by solving the full problem for Φ_1 (with boundary conditions at $\xi = 0$) as performed above (i.e., $C = 1$).

2.3. The outer solution. To analyze the outer solution we convert to self-similar coordinates

$$\tau = \ln(T-t)^{-1}, \qquad y = e^{\tau/2} r,$$

where T is the time of blowup. When we set $\zeta(\tau, y) = \theta(t, r)$, ζ satisfies the equation

$$\zeta_\tau = \zeta_{yy} + \left(\frac{1}{y} - \frac{y}{2}\right)\zeta_y - \frac{\sin 2\zeta}{2y^2}.$$

Linearizing around $\zeta = \pi$, one obtains the linear equation

$$\eta_\tau = \mathcal{L}_0 \eta \stackrel{\text{def}}{=} \eta_{yy} + \left(\frac{1}{y} - \frac{y}{2}\right)\eta_y - \frac{1}{y^2}\eta. \tag{2.4}$$

We require that $\eta(\tau, y)$ grow less than exponentially for large y, since otherwise it is impossible to match the outer to the remote region. As a boundary condition for small y we take $\eta(\tau, 0) = 0$, at least to leading order. The reason for this choice is not transparent at the moment since it is actually part of the matching process. We will clarify this point in the next section. For now we just stress that this boundary condition is not forced by regularity requirements but turns out to be required to get consistent matching.

We look for separable solutions of (2.4) obeying these two "boundary" conditions (one boundary condition and one growth condition, really). The solution of this type that decays most slowly with τ is $\eta = e^{-\tau/2} y$. From a different perspective this means

that, under the above boundary conditions, $\lambda = -\frac{1}{2}$ is the smallest eigenvalue of $\mathcal{L}_0$. (By standard arguments the eigenfunctions are polynomials.) Hence one expects η to approach π essentially at rate $e^{-\tau/2}$, and thus we set

$$\eta \sim \sigma(\tau) e^{-\tau/2}\, y.$$

Since we still have to match to the inner solution (i.e., the true boundary condition is not $\eta(\tau, 0) = 0$), we need to let the coefficient σ depend on τ, but in such a way that σ is not exponential in τ. We thus use "almost" separable solutions or, in the original variables, "almost" self-similar solutions. For the solution of (2.4) we now put forward the ansatz

$$\eta \sim e^{-\tau/2} \sum_{i=0}^{\infty} \frac{d^i \sigma(\tau)}{d\tau^i} \Omega_i(y), \tag{2.5}$$

where we anticipate σ to be algebraically decaying. When (with the linear operator $\mathcal{L}_0$ defined in (2.4))

$$\left(\mathcal{L}_0 + \tfrac{1}{2}\right) \Omega_0 = 0 \qquad \text{and} \qquad \left(\mathcal{L}_0 + \tfrac{1}{2}\right) \Omega_i = \Omega_{i-1}, \qquad i = 1, 2, \ldots,$$

then (2.5) is formally a solution of (2.4) for arbitrary $\sigma(\tau)$. In some sense the sequence Ω_i forms a Jordan sequence of the linear operator $\mathcal{L}_0$ at eigenvalue $-\frac{1}{2}$, except that the left boundary condition need no longer be satisfied. (In fact, since $-\frac{1}{2}$ is a simple eigenvalue, the left boundary condition cannot be satisfied.) This shortage of boundary conditions causes nonuniqueness for Ω_i, but this is not an issue. The left boundary condition was not a true boundary condition anyway, but merely induced by matching requirements. One obtains

$$\begin{aligned} \Omega_0 &= C_0 y, \\ \Omega_1 &= C_0(4y^{-1} - 2y \ln y) + C_1 y, \end{aligned}$$

where the values of the constants are of no significance because they can be absorbed in σ, and without loss of information we set $C_0 = 1$ and $C_1 = 0$. Thus for large τ the outer approximation is

$$\zeta(\tau, y) \sim \pi + e^{-\tau/2}\left[\sigma(\tau) y + \sigma'(\tau)(4y^{-1} - 2y \ln y)\right] \qquad \text{for large } \tau. \tag{2.6}$$

The function $\sigma(\tau)$ will have to be determined by matching to the inner solution. The outer approximation is valid, provided that $y^2 (\ln y)^2 \ll |\frac{\sigma'}{\sigma''}|$ and $y^2 |\ln y| \gg |\frac{\sigma''}{\sigma'}|$ on the side of large and small y, respectively, because the next terms are of order $O(\sigma'' y (\ln y)^2)$ for large y and $O(\sigma'' y^{-1})$ for small y. Here we should keep in mind that σ will turn out to be algebraically decaying (in which case $|\frac{\sigma''}{\sigma'}| = O(\tau^{-1})$).

2.4. Matching. To match the outer to the inner solution we rewrite (2.3) in terms of the self-similar variables:

$$v(t, \xi) = \tilde{v}(\tau, y) \sim \pi - 2e^{\tau/2} \tilde{R}\, y^{-1} + e^{\tau/2} \tilde{R}'\, y \left(-\ln y + \ln \tilde{R} + \frac{\tau}{2} + 1\right),$$

where $\tilde{R}(\tau) = R(t)$ and hence $R'(t) = e^{\tau} \tilde{R}'(\tau)$. Comparing this to (2.6), we obtain

$$O(y^{-1}): \qquad 4e^{-\tau/2}\sigma' \sim -2\tilde{R} e^{\tau/2}, \tag{2.7}$$

$$O(y \ln y): \qquad -2e^{-\tau/2}\sigma' \sim -\tilde{R}' e^{\tau/2}, \tag{2.8}$$

$$O(y): \qquad e^{-\tau/2}\sigma \sim \tilde{R}' e^{\tau/2} \left(\ln \tilde{R} + \frac{\tau}{2} + 1\right). \tag{2.9}$$

Equations (2.7) and (2.8) suggest that $\tilde{R}(\tau) = e^{-\tau}\rho(\tau)$, where $\rho(\tau)$ is algebraic for large τ. Substituting this into (2.7) and (2.9), we obtain the following relations for ρ and σ,

$$\rho \sim -2\sigma' \quad \text{and} \quad \frac{\tau}{2}\rho \sim \sigma \qquad \text{as } \tau \to \infty,$$

from which we conclude that

$$\sigma(\tau) \sim \frac{\kappa}{2\tau} \quad \text{and} \quad \rho(\tau) \sim \frac{\kappa}{\tau^2} \qquad \text{as } \tau \to \infty$$

for some $\kappa > 0$. We thus find

$$R(t) \sim \kappa \frac{T-t}{|\ln(T-t)|^2} \qquad \text{as } t \uparrow T. \tag{2.10}$$

We emphasize that this asymptotic behavior of $R(t)$ is clearly completely different from the self-similar rate $(T-t)^{1/2}$. It is now possible to check that the regions of validity for the inner and outer approximations do indeed overlap: the region of overlap is $(\tau \ln \tau)^{-1/2} \ll y \ll 1$. We note that the matching conditions (2.7) and (2.8) convey the same information, so that (2.8) is in some sense redundant, though it provides additional confidence in the matching.

The smallest intersection of $\theta(t,r)$ with π, denoted by $r = S(t)$, can be calculated from (2.6) using the asymptotic form of σ, which leads to

$$S(t) \sim 2\sqrt{\frac{T-t}{|\ln(T-t)|}} \qquad \text{as } t \uparrow T.$$

Notice that there is no undetermined constant in this leading order formula.

The asymptotic behavior for small r of the limit profile at $t = T$ is computed by matching the outer approximation to the remote solution

$$\theta(t,r) \sim \Theta(r) + (t-T)\left[\Theta_{rr} + \frac{1}{r}\Theta_r - \frac{\sin 2\Theta}{2r^2}\right] \qquad \text{as } t \to T,$$

with $\Theta(r)$ being the limit profile $\theta(T,r)$. This approximation in the remote region is valid for $r \gg (T-t)^{1/2}$ (at the least). The regions of validity of the outer and remote approximation overlap. Matching the remote solution to (2.6), we find

$$\theta(T,r) \sim \pi + \frac{1}{4}\kappa \frac{r}{|\ln r|} \qquad \text{for small } r, \tag{2.11}$$

with the same constant $\kappa > 0$ as in (2.10). Notice that $\theta(T,r) > \pi$ for small r. A quick way to obtain this behavior from (2.6) is by letting τ tend to infinity for fixed y.

We remark that immediately after blowup a different type of inner layer near $r = 0$ appears, which describes how analyticity is recovered. In this layer almost self-similar behavior occurs of the form

$$\theta(t,r) \sim \pi + \frac{\sqrt{t-T}}{|\ln(t-T)|} f_1\left(\frac{r}{\sqrt{t-T}}\right) + \frac{\sqrt{t-T}}{|\ln(t-T)|^2} f_2\left(\frac{r}{\sqrt{t-T}}\right)$$

as $t \downarrow T$ for small r. Substituting this into the equation for θ, one finds that $f_1(z) = Dz$ for some $D \in \mathbb{R}$ to be determined, and $f_2(z)$ is a solution of

$$f_2'' + \left(\frac{1}{z} + \frac{z}{2}\right) f_2' - \left(\frac{1}{z^2} + \frac{1}{2}\right) f_2 = f_1,$$

with the property that $f_2(z) = O(z)$ as $z \to 0$. One may solve for f_2 by reduction of order, but it is sufficient to remark that it follows from the limiting equation for large z that $f_2(z) \sim 2Dz \ln z$ as $z \to \infty$. Matching this with (2.11) implies that $D = \frac{1}{8}\kappa$, so that the result is

$$\theta(t,r) \sim \pi + \frac{1}{8}\kappa \frac{r}{|\ln(t-T)|} + \frac{\sqrt{t-T}}{|\ln(t-T)|^2} f_2\left(\frac{r}{\sqrt{t-T}}\right) \qquad \text{as } t \downarrow T \text{ for small } r.$$

Let us now come back to the point of choosing the boundary condition for the outer solution. In section 2.3 it was put forward that the left boundary condition for the outer solution is $\eta(\tau, 0) = 0$ but that this is in fact already part of the matching. Here we explain the reasoning behind this. There is a family of separable solutions to (2.4):

$$\eta = e^{\lambda\tau} f_\lambda(y),$$

where $f = f_\lambda$ obeys

$$\lambda f = \mathcal{L}_0 f \stackrel{\text{def}}{=} f_{yy} + \left(\frac{1}{y} - \frac{y}{2}\right) f_y - \frac{1}{y^2} f. \tag{2.12}$$

Since we are looking for solutions that do not blow up as $\tau \to \infty$, we restrict ourselves to $\lambda \leq 0$. (On the other hand, this restriction will also be a consequence of what follows.)

Now suppose that λ is not in the set $\{-\frac{1}{2}, -\frac{3}{2}, -\frac{5}{2}, \dots\}$. We will show that this leads to inconsistent matching conditions. We find two linearly independent solutions $g(y)$ and $h(y)$ of (2.12) with the following properties. The asymptotic behavior of $g(y)$ is $g(y) \sim y$ as $y \downarrow 0$, and it grows faster than exponentially as $y \to \infty$; it can therefore be ruled out. The other, linearly independent, solution $h(y)$ grows less than exponentially as $y \to \infty$, and for small y it behaves as

$$h(y) \sim y^{-1} + \frac{2\lambda - 1}{4} y \ln y + C_\lambda y$$

for some constant $C_\lambda \in \mathbb{R}$, the value of which is not relevant except for $\lambda = 0$: $C_0 = \frac{1}{8}(4\ln 2 + 1 - \gamma)$, where γ is Euler's constant. We note that $h(y)$ is closely related to a Kummer-U function.

Still assuming that $\lambda \notin \{-\frac{1}{2}, -\frac{3}{2}, -\frac{5}{2}, \dots\}$, we are lead to matching conditions of the form (assuming throughout that $\sigma' \ll \sigma$)

$$\begin{aligned} O(y^{-1}): &\qquad e^{\lambda\tau}\sigma \sim -2\tilde{R}e^{\tau/2}, \\ O(y\ln y): &\quad \frac{2\lambda-1}{4} e^{\lambda\tau}\sigma \sim -\tilde{R}' e^{\tau/2}, \\ O(y): &\qquad C_\lambda e^{\lambda\tau}\sigma \sim \tilde{R}' e^{\tau/2}\left(\ln\tilde{R} + \frac{\tau}{2} + 1\right). \end{aligned}$$

Now $\tilde{R} = e^{(\lambda - 1/2)\tau}\rho(\tau)$, where $\rho(\tau)$ is not exponential in τ. Since we require that $R \ll (T-t)^{1/2} = e^{-\tau/2}$ for self-consistency, we find that $\lambda \leq 0$. For $\rho(\tau)$ one obtains the relations (if $\lambda < 0$)

$$\sigma(\tau) \sim -2\rho(\tau) \qquad \text{and} \qquad C_\lambda \sigma(\tau) \sim \lambda\left(\lambda - \frac{1}{2}\right)\tau\rho(\tau),$$

which immediately leads to a contradiction. When $\lambda = 0$ (which would correspond to an almost self-similar blowup rate) we obtain

$$\sigma(\tau) \sim -2\rho(\tau) \qquad \text{and} \qquad C_0\sigma(\tau) \sim -\frac{1}{2}\rho(\tau),$$

and since $C_0 \neq \frac{1}{4}$, this leads to a contradiction as well. A more intuitive explanation for the matching failure is that it is impossible to match a leading order term y^{-1} from the outer expansion with a correction term from the inner one.

If $\lambda \in \{-\frac{1}{2}, -\frac{3}{2}, -\frac{5}{2}, \dots\}$, then the solution obeying the growth condition on the right is regular near $y = 0$; i.e., there are no terms of order y^{-1} (or $y \ln y$). The set $\{-\frac{1}{2}, -\frac{3}{2}, -\frac{5}{2}, \dots\}$ thus consists of the eigenvalues of problem (2.12) with boundary condition $f(0) = 0$ and the growth condition for $y \to \infty$. This explains the choice of boundary conditions in section 2.3. The case $\lambda = -\frac{1}{2}$ was dealt with in the previous sections. In the next section we consider the remaining possibilities.

2.5. Degenerate (nongeneric) cases. There is a whole family of separable solutions of (2.4) which obey the growth condition (less than exponential) on the right and the boundary condition on the left (regular near $y = 0$). The solution $\eta = e^{-\tau/2}y$ is the first one, i.e., the least rapidly decaying one. In degenerate cases it may, however, happen that the coefficient σ in front of this term in (2.6) vanishes. In that case a degenerate situation occurs with codimension 1. The outer solution in that case becomes

$$\zeta \sim \pi + e^{-3\tau/2}\sigma(\tau)\left(y - \frac{1}{8}y^3\right),$$

since $\lambda = -\frac{3}{2}$ is the second smallest eigenvalue of $\mathcal{L}_0$, with eigenfunction $y - \frac{1}{8}y^3$. Following the calculation in section 2.3, the outer approximation now becomes

(2.13)
$$\zeta \sim \pi + e^{-3\tau/2}\left[\sigma(\tau)\left(y - \frac{1}{8}y^3\right) + \sigma'(\tau)\left(2y^{-1} - 2y\ln y + \frac{1}{4}y^3\ln y - \frac{3}{2}y\right)\right].$$

Notice that the profile is nonmonotone for times close to blowup. The matching conditions become

$$\begin{aligned} O(y^{-1}): &\quad 2e^{-3\tau/2}\sigma' \sim -2\tilde{R}e^{\tau/2}, \\ O(y\ln y): &\quad -2e^{-3\tau/2}\sigma' \sim -\tilde{R}'e^{\tau/2}, \\ O(y): &\quad e^{-3\tau/2}\sigma \sim \tilde{R}'e^{\tau/2}\left(\ln\tilde{R} + \frac{\tau}{2} + 1\right), \end{aligned}$$

so that $\tilde{R}(\tau) = e^{-2\tau}\rho(\tau)$ and $\rho(\tau) \sim C\tau^{-4/3}$; hence

$$R(t) \sim \kappa\frac{(T-t)^2}{|\ln(T-t)|^{4/3}} \qquad \text{as } t \uparrow T$$

for some $\kappa > 0$.

To calculate the limit profile we have to match the outer solution into the remote solution $\theta(t, r) \sim \Theta(r) = \theta(T, r)$. To match (2.13) to the remote region, one needs to take into account the highest order terms in τ and y only. For the limit profile one finds

$$\theta(T, r) \sim \pi - \frac{3}{8}\kappa\frac{r^3}{|2\ln r|^{1/3}} \qquad \text{for small } r,$$

with the same constant $\kappa > 0$ as above. Notice that $\theta(T, r) < \pi$ for small r (in contrast to the nondegenerate case). The first two intersections of $\theta(t, r)$ with π, denoted by $S_1(t)$ and $S_2(t)$, behave asymptotically as

$$S_1 \sim \sqrt{\frac{2}{3}\frac{T-t}{|\ln(T-t)|}} \qquad \text{and} \qquad S_2 \sim \sqrt{8(T-t)}\,.$$

The first intersection comes from the balance between Ω_0 and Ω_1 (i.e., occurs for small y), while the second intersection depends only on Ω_0 (having $y = O(1)$).

In a similar vein, for degenerate cases occurring with codimension k (with $k = 0, 1, 2, \ldots$; the generic case is embedded in this), the $(k+1)$th eigenvalue of $\mathcal{L}_0$ is $\lambda = -k - \frac{1}{2}$, with as eigenfunction a $(2k+1)$th order polynomial with only odd terms, say $\Omega_0^k(y)$, which we normalize so that $\Omega_0^k(y) \sim y$ as $y \to 0$. We note that $\Omega_0^k(y)$ can be expressed in terms of a generalized Laguerre polynomial. Then

$$\Omega_0^k(y) = \sum_{i=0}^{k} a_i y^{2i+1} \quad \text{with} \quad a_i = (-1)^i \frac{k!}{2^{2i}(k-i)!(i+1)!i!} \quad \text{for } i = 0, 1, \ldots, k.$$

To calculate the next term in the expansion Ω_1^k we have to solve

$$\left(\mathcal{L}_0 + k + \frac{1}{2}\right)\Omega_1^k = \Omega_0^k.$$

After a bit of calculation one finds that

$$\Omega_1^k(y) = \frac{4}{k+1} y^{-1} - 2\Omega_0^k(y)\ln y + h_k(y),$$

where h_k is some odd polynomial of degree $2k-1$. The outer approximation becomes

$$\zeta \sim \pi + e^{-(k+1/2)\tau}[\sigma(\tau)\Omega_0^k(y) + \sigma'(\tau)\Omega_1^k(y)],$$

and thus for small y

$$\zeta \sim \pi + e^{-(k+1/2)\tau}\left[\sigma(\tau)\, y + \sigma'(\tau)\,\left(\frac{4}{k+1} y^{-1} - 2y\ln y\right)\right].$$

The matching condition for the codimension k degeneracy become

$$\begin{aligned} O(y^{-1}): &\quad \frac{4}{k+1} e^{-(k+1/2)\tau}\sigma' \sim -2\tilde{R}e^{\tau/2}, \\ O(y\ln y): &\quad -2e^{-(k+1/2)\tau}\sigma' \sim -\tilde{R}'e^{\tau/2}, \\ O(y): &\quad e^{-(k+1/2)\tau}\sigma \sim \tilde{R}'e^{\tau/2}\left(\ln\tilde{R} + \frac{\tau}{2} + 1\right). \end{aligned}$$

Hence $\tilde{R} \sim \kappa e^{-(k+1)\tau}\tau^{-(2k+2)/(2k+1)}$, or in the original variables,

$$R(t) \sim \kappa \frac{(T-t)^{k+1}}{|\ln(T-t)|^{(2k+2)/(2k+1)}} \qquad \text{as } t \uparrow T$$

for some $\kappa > 0$. Since $\Omega_0^k \sim a_k y^{2k+1}$ as $y \to \infty$, the limit profile is

$$\theta(T, r) \sim \pi + (-1)^k \kappa \frac{2k+1}{2^{2k+1}k!} \frac{r^{2k+1}}{|2\ln r|^{1/(2k+1)}} \qquad \text{as } t \uparrow T.$$

This limit profile is again obtained by matching to the outer solution or, alternatively, by taking the limit $\tau \to \infty$ for fixed y and subsequently $y \to \infty$. One can analyze the short time behavior just after blowup in a similar way to that in section 2.4. Finally, the asymptotic behavior of the first intersection of $\theta(t,r)$ with π, denoted by $S_1(t)$, is

$$S_1(t) \sim 2\sqrt{\frac{1}{(k+1)(2k+1)}\frac{T-t}{|\ln(T-t)|}} \qquad \text{as } t \uparrow T.$$

We have thus found a countable family of nongeneric blowup scenarios. The codimension 1 situation, for example, occurs at the borderline between the generic blowup scenario and the case of no blowup (as explained in section 1); it is characterized by the fact that *two* intersections of $\theta(t,r)$ with π approach the origin simultaneously as $t \uparrow T$ (though at different rates). More generally, in the codimension k scenario the profile $\theta(t,r)$ just before blowup has $k+1$ intersections with π that approach the origin as $t \uparrow T$; in other words, it corresponds to a nongeneric scenario in which the disappearance of sign changes in $\theta - \pi$ coincides with the blowup time (cf. [13] for a detailed discussion of sign change solutions in a different second order parabolic problem). The appearance of degenerate cases indicates that it might be hard to obtain a proof of the formal result that near blowup $R(t) \sim \kappa \frac{T-t}{|\ln(T-t)|^2}$ holds *generically*. Restricting our analysis to certain classes of monotone initial data excludes the degenerate possibilities, because one can show that the solution then has to remain monotone for all $t > 0$ (see [1]), and all the degenerate blowup scenarios have nonmonotone profiles just before blowup. Our analysis strongly suggests, however, that even without such restrictions on the initial data, the generic blowup rate is $R(t) \sim \kappa \frac{T-t}{|\ln(T-t)|^2}$.

2.6. Boundary condition $\theta_1 = \pi$. When the boundary condition is $\theta(t,1) = \pi$, there is, besides the finite time blowup scenarios described above, an additional possibility, namely that blowup occurs in infinite time. This infinite time blowup is a codimension 0 scenario (we analyze degenerate cases as well). In this case there is no urge to change to self-similar coordinates. Close to blowup the profile is assumed to be near π in the whole of the remote region (and the limit profile is identically equal to π). The linearized equation around π is

$$w_t = \mathcal{L}_1 w \stackrel{\text{def}}{=} w_{rr} + \frac{1}{r} w_r - \frac{1}{r^2} w. \tag{2.14}$$

We substitute a formal series

$$w \sim \pi + \sum_{i=0}^{\infty} \frac{d^i s(t)}{dt^i} W_i(r), \tag{2.15}$$

where $s(t)$ is an arbitrary function and

$$\mathcal{L}_1 W_0 = 0 \qquad \text{and} \qquad \mathcal{L}_1 W_i = W_{i-1}, \qquad i = 1, 2, \ldots.$$

Now (2.15) is again a formal solution of the linearized differential equation for any $s(t)$, and when we require that $W_i(1) = 0$, then the right boundary condition is satisfied. There is no a priori left boundary condition. We obtain

$$\begin{aligned} W_0 &= C_0(r^{-1} - r), \\ W_1 &= C_0\left(\frac{1}{2} r \ln r + \frac{1}{8} r - \frac{1}{8} r^3\right) + C_1(r^{-1} - r), \end{aligned}$$

where we may again set $C_0 = 1$ and $C_1 = 0$ without loss of generality. Hence for the remote region we obtain for small r

$$\theta \sim \pi + s(t)(r^{-1} - r) + s'(t)\left(\frac{1}{2} r \ln r + \frac{1}{8} r\right).$$

Matching in a way similar to that of section 2.4 to the inner solution (2.3), we find that

$$\begin{aligned} O(r^{-1}): &\qquad s \sim -2R, \\ O(r \ln r): &\qquad \frac{1}{2} s' \sim -R', \\ O(r): &\quad -s + \frac{1}{8} s' \sim R'(\ln R + 1). \end{aligned}$$

Hence for large t

$$R(t) \sim e^{-2\sqrt{t} - 5/4} \qquad \text{as } t \to \infty.$$

We note that this is the one instance where the term $R'R\xi = R'r$ in the inner approximation has an influence on the leading order result. (It is needed to calculate the multiplicative constant $e^{-5/4}$.) The most striking difference between this result and the situation in section 2.4 is that blowup now occurs in infinite time. We remark that, for suitable initial data, blowup may happen in finite time via the scenario in the previous sections, after which $\theta \to \pi$ uniformly as $t \to \infty$ (generically at rate $e^{-\lambda_1^2 t}$, where λ_1 is the first zero of the Bessel function J_1; see also below). However, this cannot happen for initial profiles $|\theta(0, r)| \le \pi$ for all $r \in [0, 1]$, since then $|\theta(t, r)| \le \pi$ for all $t > 0$ (by the comparison principle) and blowup is postponed until $t = \infty$.

As in the previous section, there is a hierarchy of degenerate cases. Looking for almost separable solutions, one tries, with $\lambda > 0$,

$$w \sim \pi + e^{-\lambda^2 t} \sum_{i=0}^{\infty} \frac{d^i s(t)}{dt^i} W_i(r).$$

Now

$$W_0 = J_1(\lambda r) - \frac{J_1(\lambda)}{Y_1(\lambda)} Y_1(\lambda r),$$

where J_i and Y_i are the Bessel functions of order i (take $W_0 = Y_1(\lambda r)$ if $Y_1(\lambda) = 0$). Analogous to section 2.4, this does not lead to self-consistent matching unless W_0 is regular at $r = 0$. Therefore we require that $J_1(\lambda) = 0$, and we obtain a nice eigenvalue problem with Dirichlet boundary conditions.

Let $\lambda_k > 0$ be the kth zero of J_1 and $W_0(r) = J_1(\lambda_k r)$. Then one finds that

$$\begin{aligned} W_1 = \frac{\pi}{8} \big[& J_1(\lambda_k r) J_2(\lambda_k r) Y_0(\lambda_k r) r^2 + J_1(\lambda_k r) J_0(\lambda_k r) Y_2(\lambda_k r) r^2 \\ & - 2 J_0(\lambda_k r) J_2(\lambda_k r) Y_1(\lambda_k r) r^2 + D_k Y_1(\lambda_k r) \big], \end{aligned}$$

where

$$D_k \stackrel{\text{def}}{=} 2 J_0(\lambda_k) J_2(\lambda_k) < 0.$$

The matching conditions become

$$\begin{aligned} O(r^{-1}): &\quad -e^{-\lambda_k^2 t}\frac{D_k}{4\lambda_k}s' \sim -2R, \\ O(r\ln r): &\quad e^{-\lambda_k^2 t}\frac{D_k\lambda_k}{8}s' \sim -R', \\ O(r): &\quad e^{-\lambda_k^2 t}\frac{1}{2}\lambda_k s \sim R'(\ln R + 1). \end{aligned}$$

We infer that, with codimension $k > 0$,

$$R(t) \sim \kappa\, t^{-1+4/D_k\lambda_k^2}\, e^{-\lambda_k^2 t} \qquad \text{as } t \to \infty$$

for some $\kappa > 0$.

We stress that the generic case (discussed at the beginning of this subsection) does not obey the boundary condition $W_0(0) = 0$ but nevertheless leads to consistent matching. This is, however, the only consistent case that has a spatial singularity near the origin in the remote region. (The solution is, of course, not singular in the inner variable.) This may be somewhat surprising. Let us clarify the role of the generic and nongeneric scenarios.

Notice that for any $\lambda > 0$ the associated eigenfunction $W_0(r)$ has sign changes on $(0, 1)$, leading to intersections of the solution with π close to blowup. Consider initial profiles that lie entirely below π, i.e., $-\pi < \theta(0, r) < \pi$ for $r \in (0, 1)$. A comparison argument shows that for such initial data these blowup profiles are excluded. This indicates that a generic scenario is associated with $\lambda = 0$ (even though the "eigenfunction" (which obeys the boundary condition at $r = 1$) for $\lambda = 0$ is singular).

The degenerate cases act as borderline cases between finite time blowup and infinite time blowup. For example, when the initial data have a sufficiently large bump above π, the solution will blowup in finite time, whereas solutions starting from initial data below π blow up in infinite time. The codimension 1 scenario found in this subsection acts as the borderline between generic infinite and generic finite time blowup. This is most easily understood for initial conditions which have only one crossing with π, since for such initial data the finite time codimension 1 scenario plays no role (because it has two crossings with π close to blowup). As we have seen in this section, the infinite time blowup phenomenon for $\theta_1 = \pi$ is essentially driven by the linear equation (2.14), and for such an equation the presence of high codimension cases with many sign changes (of $\theta - \pi$) is not unexpected.

2.7. Reverse jumps. As explained in section 1, weak solutions have the possibility to make a jump in which they *increase* their energy $\mathcal{E}(t)$; see [5, 2]. We consider the situation where $\theta(t, 0)$ jumps from π to 0 ("jumping back") at $t = t_0$. In these jumps the energy $\mathcal{E}$ necessarily increases by 4π at $t = t_0$.

The inner approximation is the same as in section 2.2, although now $R(t) \to 0$ as $t \downarrow t_0$. Concerning the outer approximation, we argue as follows. As in section 2.3, we turn to self-similar variables ($t > t_0$),

$$\tau = \ln(t - t_0), \qquad y = e^{-\tau/2}r,$$

and obtain for $\zeta(\tau, y) = \theta(t, r)$

$$\zeta_\tau = \zeta_{yy} + \left(\frac{1}{y} + \frac{y}{2}\right)\zeta_y - \frac{\sin 2\zeta}{2y^2}.$$

Since a reverse jump can occur at any moment, one generically has $\theta_r(t_0, 0) = C \neq 0$, i.e., the dominant term in the local expansion is $Cr = Ce^{\tau/2}y$. This being a separable solution of the linearized equation, one proposes a solution of the form $e^{\tau/2}\eta(y)$ (cf. section 2.3), where η satisfies

$$\eta_{yy} + \left(\frac{1}{y} + \frac{y}{2}\right)\eta_y - \left(\frac{1}{y^2} + \frac{1}{2}\right)\eta = 0.$$

The general solution is

$$\eta = C_0 y + C_1 y \int_y^\infty \frac{e^{-s^2/4}}{s^3} ds,$$

with arbitrary constants C_0, $C_1 \in \mathbb{R}$ and $y_0 > 0$. We see that, as opposed to the situation in section 2.3, the second independent solution has reasonable growth. In fact, it tends to 0 as $y \to \infty$ and behaves as $y^{-1} + \frac{1}{2}y \ln y$ for small y. Therefore the outer approximation becomes

$$\zeta \sim \pi + e^{\tau/2}\left[\alpha(\tau)y + \beta(\tau)(4y^{-1} + 2y \ln y)\right] \qquad \text{for small } y \text{ and } -\tau \gg 1.$$

As matching conditions for $\tau \to -\infty$ we find (writing $\tilde{R}(\tau) = R(t)$)

$$\begin{aligned} O(y^{-1}): &\quad 4\beta e^{\tau/2} \sim -2\tilde{R}e^{-\tau/2}, \\ O(y \ln y): &\quad 2\beta e^{\tau/2} \sim -\tilde{R}' e^{-\tau/2}, \\ O(y): &\quad \alpha e^{\tau/2} \sim \tilde{R}' e^{-\tau/2}\left(\ln \tilde{R} - \frac{\tau}{2} + 1\right). \end{aligned}$$

We infer that $\tilde{R} \sim e^\tau \rho(\tau)$ with $\rho(\tau) \sim -\frac{2\ell}{\tau}$ for some $\ell = -\alpha(-\infty) > 0$, and $\beta \sim \frac{\ell}{\tau}$, so that $|\beta(\tau)| \ll |\alpha(\tau)|$ as $\tau \to -\infty$. Hence

$$R(t) \sim 2\ell \frac{t - t_0}{|\ln(t - t_0)|} \qquad \text{as } t \downarrow t_0$$

for some $\ell > 0$. The limit profile is

$$\theta(t_0, r) \sim \pi - \ell r \quad \text{for small } r,$$

which is consistent with the assumption at the start, so that $\ell = -C$. Notice that, when the jump is downwards from π to 0, then the profile at $t = t_0$ has to be decreasing for small r.

A whole hierarchy of degenerate cases in which $\theta_r(0, 0) = 0$ can be calculated as well. At some $t_0 > 0$ (i.e., after the solution has started to evolve) it happens with codimension k that $\theta(t_0, r) \sim \pi - \tilde{C}r^{2k+1}$ as $r \downarrow 0$ for some $\tilde{C} \neq 0$. Reverse jumps at such nongeneric instances can be analyzed via the method presented above. The jump (of $\theta(t, 0)$) is downwards when $\tilde{C} > 0$ and upwards when $\tilde{C} < 0$. For example, for the codimension 1 scenario one finds

$$R \sim \frac{8}{3}\ell \frac{(t - t_0)^2}{|\ln(t - t_0)|} \qquad \text{as } t \downarrow t_0 \tag{2.16}$$

for some $\ell > 0$, with $\theta(t_0, r) \sim \pi - \ell r^3$ as $r \to 0$. Reverse jumps can also happen at the moment of a forward jump (i.e., $t_0 = T$); see also [18, section 5]. Then at

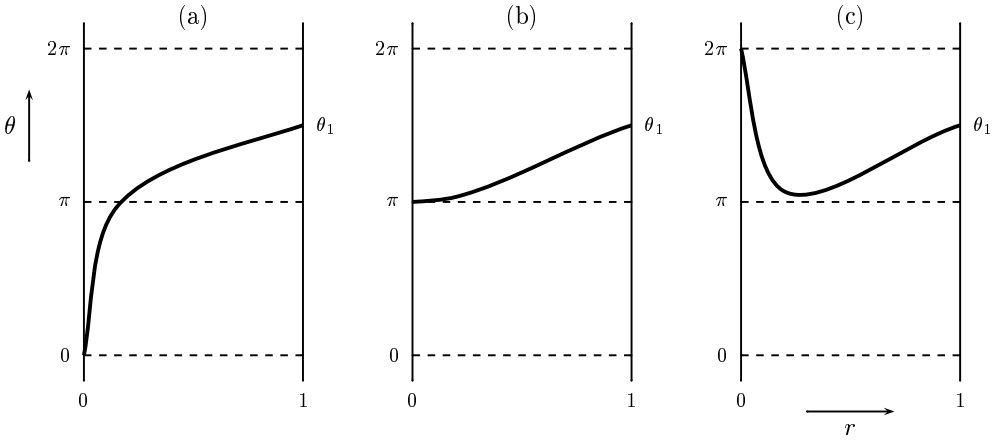

FIG. 2.2. *Picture of the situation when $t_0 = T$; i.e., a reverse jump happens at the moment of a forward jump:* (a) *a time just before $t = T$,* (b) $t = T = t_0$, (c) *a time just after $t = t_0$.*

the self-similar scale a logarithmic correction needs to be applied (cf. the recovery of analyticity in section 2.4). We note that if $t_0 = T$ and if the forward jump from 0 to π behaves according to the generic scenario, then the reverse jump must be from π to 2π. (This follows from a comparison of the limiting profiles as $t \uparrow T$ and $t \downarrow t_0$.) A schematic picture of the situation is given in Figure 2.2. We leave the details to the reader and just state the result:

$$R(t) \sim \kappa \frac{t - t_0}{|\ln(t - t_0)|^2} \qquad \text{as } t \downarrow t_0, \tag{2.17}$$

where $\kappa > 0$ is the same constant as in the forward jump (see (2.10)). For $t_0 = 0$ one may choose, for example, initial data with $\theta(0, r) \sim \pi - \hat{C} r^a$ as $r \downarrow 0$ for any $a > 0$ and some $\hat{C} \neq 0$, and a reverse jump can then happen instantaneously. The analysis is again along the same lines.

Finally, our analysis suggests that, given a jump time t_0, the asymptotic profile of $\theta(t_0, r)$ as $r \downarrow 0$ completely determines the blowup rate $R(t)$. In [2] it is conjectured that from a physical perspective it is most likely that if the solution has first made a forward jump from 0 to π, the reverse jump happens at the first instance at which $\theta(t_0, r) < 0$ close to the origin. This corresponds to the system selecting an otherwise degenerate scenario, whereby $\theta(t_0, r) \sim \pi - \ell r^3$ as $r \to 0$ for some $\ell > 0$, and the blowup rate is then given by (2.16). More degenerate scenarios can of course occur with higher codimension. We note that our scenario is subtly different from the one studied in [2], which requires linear behavior of θ at the origin.

3. The general case.

3.1. Preamble.

We now analyze the generalization

$$\theta_t = \theta_{rr} + \frac{1}{r}\theta_r - n^2 \frac{\sin 2\theta}{2r^2}, \qquad 0 \leq r \leq 1. \tag{3.1}$$

Apart from the fact that the equation yields physically relevant solutions for $n = 1, 2, 3, \ldots$ as explained in section 1, analyzing the dependence of the blowup behavior on n also enhances the understanding of the special case $n = 1$.

We deal with the inner approximation in section 3.2 and then have a first attempt at matching without using self-similar coordinates to get the general idea in section 3.3. In section 3.4 we deal with $n < 2$, while section 3.5 deals with $n \geq 2$. In section 3.6 we discuss simultaneous blowup at several scales. The special boundary condition $\theta(t,1) = \pi$ is dealt with in section 3.7. We remark on the case of an infinite domain in section 3.8, and section 3.9 is devoted to reverse jumps.

3.2. The inner approximation. The stationary solutions of (3.1) are

$$\theta(r) = m\pi + 2\arctan(qr^n), \qquad m \in \mathbb{Z},\ q \in \mathbb{R}.$$

Choosing the scaling $\xi = r/R(t)$ so that

$$R(t)^n\theta(t,r) \sim 2r^n \quad \text{as } r \downarrow 0 \qquad \text{for all } t \text{ up to the blowup time,}$$

the outer limit of the inner approximation $v(t,\xi) = \theta(t,r)$ (cf. section 2.2) becomes for $n > \frac{1}{2}$, $n \neq 1$,

$$v \sim \pi - 2\,\xi^{-n} + R'R\left(\frac{n}{2n-2}\xi^{-n+2} - E_n\xi^n\right). \tag{3.2}$$

The coefficient of the term ξ^{-n+2} can be obtained from the asymptotic equation for Φ_1 at large ξ, as explained at the end of section 2.2. The coefficient E_n of the term ξ^n can be obtained only by solving the full problem for Φ_1 (borrowing the notation from section 2.2):

$$\Phi_{1\xi\xi} + \frac{1}{\xi}\Phi_{1\xi} - n^2\frac{\cos(4\arctan\xi^n)}{\xi^2}\Phi_1 = -\frac{2n\xi^n}{1+\xi^{2n}},$$

with boundary condition $\lim_{\xi\downarrow 0}\frac{\Phi_1(\xi)}{\xi^n} = 0$. We rewrite

$$\cos(4\arctan\xi^n) = \frac{-6\xi^{2n}+1+\xi^{4n}}{(1+\xi^{2n})^2}$$

and note that

$$\frac{d(2\arctan q\xi^n)}{dq}\Big|_{q=1} = \frac{2n\xi^n}{1+\xi^{2n}}$$

is a solution of the homogeneous equation. Using variation of constants, one finds that the solution we are looking for is

$$\Phi_1 = \frac{(1-\xi^{4n}-4n\xi^{2n}\ln\xi)\int_0^\xi \frac{s^{2n+1}}{(1+s^{2n})^2}ds + \xi^{2n}\int_0^\xi \frac{s(s^{4n}-1+4ns^{2n}\ln s)}{(1+s^{2n})^2}ds}{\xi^n(1+\xi^{2n})}.$$

This gives for $n > 1$

$$E_n = \int_0^\infty \frac{s^{2n+1}}{(1+s^{2n})^2}ds = \frac{\pi}{2n^2\sin(\frac{\pi}{n})}.$$

For $n < 1$ the value of E_n is somewhat irrelevant, since the term ξ^n in (3.2) is non-dominant in that case. Nevertheless, for $\frac{1}{2} < n < 1$,

$$E_n = \int_0^1 \frac{s^{2n+1}-2s^{4n-3}-s^{6n-3}}{(1+s^{2n})^2}ds - 1.$$

For $n = \frac{1}{2}$ the outer limit of the inner approximation is

$$v \sim \pi - 2\xi^{-1/2} + R'R\left(-\frac{1}{2}\xi^{3/2} + \left(-\frac{9}{2} + 2\ln\xi\right)\xi^{1/2}\right),$$

and for $n < \frac{1}{2}$ it becomes

$$v \sim \pi - 2\xi^{-n} + R'R\left(\frac{n}{2n-2}\xi^{2-n} + \frac{n(2n^2-n+1)}{4(1-n)^2(\frac{1}{2}-n)}\xi^{2-3n}\right).$$

3.3. A first try. To get a preliminary idea, let us first attempt to match without going to self-similar coordinates. (This turns out to produce the correct generic rate for $n \neq 1$; nongeneric cases have to be analyzed in self-similar coordinates.) Near $\theta = \pi$ the equation can be linearized to

$$w_t = \mathcal{L}_2 w \stackrel{\text{def}}{=} w_{rr} + \frac{1}{r}w_r - \frac{n^2}{r^2}w. \tag{3.3}$$

The stationary solution is $w = C_0 r^n + C_1 r^{-n}$, with C_0, $C_1 \in \mathbb{R}$, and this forms the inspiration for the formal solution

$$w = \sum_{i=0}^{\infty} \frac{d^i\alpha}{dt^i}\psi_i(r) + \sum_{i=0}^{\infty} \frac{d^i\beta}{dt^i}\chi_i(r),$$

for some functions $\alpha(t)$ and $\beta(t)$, and

$$\begin{aligned} &\psi_0 = r^n, && \mathcal{L}_2\psi_i = \psi_{i-1}, \quad i = 1, 2, \ldots, \\ &\chi_0 = r^{-n}, && \mathcal{L}_2\chi_i = \chi_{i-1}, \quad i = 1, 2, \ldots. \end{aligned}$$

The outer approximation becomes

$$\theta \sim \pi + \alpha(t)r^n + \beta(t)r^{-n} + \beta'(t)\frac{1}{4(1-n)}r^{-n+2}.$$

Matching yields (for $n > \frac{1}{2}$)

$$\begin{aligned} O(r^{-n}): &\qquad \beta \sim -2R^n, \\ O(r^{-n+2}): &\quad \beta'\frac{1}{4(1-n)} \sim \frac{n}{2n-2}R'R^{n-1}, \\ O(r^n): &\qquad \alpha \sim -E_n R'R^{1-n}, \end{aligned}$$

from which we conclude that

$$\begin{aligned} &R \sim \left[\frac{\beta_0}{2}(T-t)\right]^{1/n}, && n < 1, && \text{as } t \uparrow T, \\ &R \sim \left[\frac{(2-n)\alpha_0}{E_n}(T-t)\right]^{1/(2-n)}, && 1 < n < 2, && \text{as } t \uparrow T, \\ &R \sim \kappa e^{-\frac{\alpha_0}{E_2}t}, && n = 2, && \text{as } t \to \infty, \\ &R \sim \left(\frac{(n-2)\alpha_0}{E_n}t\right)^{-1/(n-2)}, && n > 2, && \text{as } t \to \infty, \end{aligned}$$

for some $\kappa > 0$ and $\alpha_0 = \alpha(T) > 0$ and $\beta_0 = \beta'(T) > 0$ (i.e., $\beta(t) \sim \beta_0(t-T)$). For $n < 1$ we have to separately consider the three cases ($n < \frac{1}{2}$, $n = \frac{1}{2}$, $n > \frac{1}{2}$) with different asymptotic behavior for the inner solutions; they all lead to results of the same form.

Notice that when we perform the same analysis for $n = 1$ we obtain

$$\begin{aligned} O(r^{-1}): &\quad \beta \sim -2R, \\ O(r\ln r): &\quad \frac{1}{2}\beta' \sim -R', \\ O(r): &\quad \alpha \sim R'(\ln R + 1). \end{aligned}$$

One deduces that $R \sim \alpha_0 \frac{(T-t)}{|\ln(T-t)|}$, which is the wrong asymptotic behavior (although it is almost right); see section 2. The artefact is caused by the fact that one a priori assumes the limit profile to be $\theta(T,r) \sim \pi + Cr$ for some $C \neq 0$, whereas this cannot be fixed a priori but should be determined by matching with the region in which θ is near π; for this one needs to analyze what happens at an intermediate scale, the self-similar one. When one performs the matching at the self-similar scale (with variable $y = r/(T-t)^{1/2}$), as will be done in section 3.4, it turns out that in the generic (codimension 0) case the solution is y^n ($1 < n < 2$) or y^{-n} ($n < 1$); hence the self-similar scale seems to have no influence. However, this region is crucial since it introduces a selection mechanism (the requirement that the solution does not grow exponentially for large y). Therefore, the analysis of the self-similar region does not appear to influence the result for $n \neq 1$ (in the generic scenario), but for $n = 1$ it corrects the result from the above naive approach.

Finally, it is important to note that our analysis thus far suggests that blowup occurs in infinite time for $n \geq 2$ and in finite time for $n < 2$. This difference causes us to investigate these cases separately.

3.4. The case $n < 2$: Finite time blowup. The analysis goes along the same lines as for $n = 1$. The inner approximation has been obtained in section 3.2. Let us here pay some extra attention to the outer solution. One could formulate this analysis in the same terms as used in section 2.3 for $n = 1$. The matching for $n \neq 1$ is easier because it turns out that only the dominant term needs to be taken into account. We can therefore use a slightly more straightforward approach.

We look for a self-similar solution to (3.3) of the form

$$w = (T-t)^{\gamma}\phi\left(\frac{r}{\sqrt{T-t}}\right), \tag{3.4}$$

where γ is not known a priori but has to be determined as part of the process. As the first boundary conditions we require that $\phi(y)$ does not grow exponentially for $y \to \infty$. The second boundary condition is different for $n > 1$ and $n < 1$. For $n > 1$ we require that $\phi(0) = 0$, while for $n < 1$ we require that $\phi = Cy^{-n} + o(y^n)$ for some $C \neq 0$. These boundary conditions are suggested by our preliminary results in section 3.3: the terms of order y^n and y^{-n} are dominant for $n > 1$ and $n < 1$, respectively. Another, equivalent, point of view is that this boundary condition is in fact a matching condition, as explained in section 2.4. For both $n > 1$ and $n < 1$ there is a sequence of self-similar solutions of the boundary value problem.

For $n > 1$ the first one is $\gamma = n/2$ and $\phi_0 = C_0 y^n$ with $C_0 \neq 0$; the second one is $\gamma = n/2 + 1$ and $\phi_1 = C_1 y^n(1 - \frac{1}{4n+4}y^2)$. In general, there is a family of solutions $\gamma = n/2 + k$ and $\phi_k = C_k y^n f_{k,n}(y^2)$ for $k = 0, 1, 2, \ldots$, where $f_{k,n}$ is a polynomial

of degree k and $f_{k,n}(0) = 1$. (We note that $f_{k,n}$ can be expressed in terms of a generalized Laguerre polynomial.) Since the inner approximation (3.2) thus needs to match into $C_0(T-t)^k r^n$ for some $C_0 \neq 0$, one obtains the matching condition

$$O(r^n): \quad C_0(T-t)^k \sim -E_n R'(t) R(t)^{1-n}.$$

We only use this one term since we have already seen in section 3.3 that it is the dominant one. Hence with codimension $k = 0, 1, 2, \ldots$ (and $1 < n < 2$)

$$R(t) = \kappa(T-t)^{(k+1)/(2-n)} \qquad \text{as } t \uparrow T$$

for some $\kappa > 0$, with limit profile

$$\theta(T, r) \sim \pi + A_{k,n}\kappa^{2-n} r^{n+2k} \qquad \text{as } r \downarrow 0$$

for some constant $A_{k,n}$, which can be calculated from the coefficient of the highest order term in the polynomial $f_{k,n}$ (e.g., $A_{0,n} = \frac{E_n}{4(n+1)(2-n)}$).

For $n < 1$ the first possibly relevant self-similar solution of the form (3.4) is $(T-t)^{-n/2} y^{-n}$, but this is simply r^{-n} and does not tend to 0 as $t \to T$, and hence it is not suitable (it does not correspond to blowup at $t = T$). The next is $\gamma = -n/2 + 1$ and $\phi_0 = \tilde{C}_0 y^{-n}(1 - \frac{1}{4(1-n)} y^2)$ with $\tilde{C}_0 \neq 0$. There is again a family of solutions $\gamma = -n/2 + k + 1$ and $\phi_k = \tilde{C}_k y^{-n} \tilde{f}_{k,n}(y^2)$, where $\tilde{f}_{k,n}$ is a polynomial of degree $k+1$ and $\tilde{f}_{k,n}(0) = 1$. (Again $f_{k,n}$ can be expressed in terms of a generalized Laguerre polynomial.) Because (3.2) thus needs to match into $\tilde{C}_0(T-t)^{k+1} r^{-n}$ for some $\tilde{C}_0 \neq 0$, one obtains the matching condition

$$O(r^{-n}): \quad \tilde{C}_0(T-t)^{k+1} \sim -2R^n,$$

and hence with codimension $k = 0, 1, 2, \ldots$ (and $0 < n < 1$)

$$R(t) \sim \kappa(T-t)^{(k+1)/n} \qquad \text{as } t \uparrow T$$

for some $\kappa > 0$, and the limit profile is

$$\theta(T, r) \sim \pi + A_{k,n}\kappa^n r^{2-n+2k} \qquad \text{as } r \downarrow 0$$

for some constant $A_{k,n}$, which can be calculated from the coefficient of the highest order term in the polynomial $\tilde{f}_{k,n}$ (e.g., $A_{0,n} = \frac{1}{2(1-n)}$).

Immediately after blowup, an inner layer near $r = 0$ appears. For $n < 1$ the leading order behavior in this layer is simpler than for $n = 1$, being exactly self-similar. In the generic case ($k = 0$) one finds

$$\theta(t, r) \sim \pi + d_n \kappa^n (t-T)^{(2-n)/2} g_n\left(\frac{r}{\sqrt{t-T}}\right) \qquad \text{as } t \downarrow T \text{ for small } r$$

for some $d_n > 0$ to be determined. Here

$$g_n(z) = \left(8n(1-n)z^{2-n} + 32n(1-n)^2 z^{-n}\right) \int_0^z \frac{s^{2n-1} e^{-s^2/4}}{(4(1-n) + s^2)^2}\, ds$$

is the solution of the linearized equation in self-similar coordinates with the property that $g_n(z) \sim z^n$ as $z \to 0$. It follows that $g_n(z) \sim 4^{n-1}\Gamma(n+1) z^{2-n}$ as $z \to \infty$. Matching with the limit profile at $t = T$ yields $d_n = \left[2^{2n-1}(1-n)\Gamma(n+1)\right]^{-1}$. Notice that for $1 < n < 2$ special treatment of the short time behavior after blowup is not necessary. (One would just find that $\theta(t, r) \sim \pi + (t-T)^{n/2} g_n(r/\sqrt{t-T})$, with $g_n(z) = \frac{E_n}{4(n+1)(2-n)} z^n$.)

3.5. The case $n \geq 2$: Infinite time blowup. For $n \geq 2$ blowup occurs in infinite time, and there are only two scales: an inner and a remote region. In the remote region the limit profile is now known. Namely, for boundary condition $\theta(t,1) = \theta_1 \in (\pi, 2\pi)$ the limit profile is

$$\lim_{t\to\infty} \theta(t,r) \sim \pi + 2\arctan\left(\tan\left(\frac{\theta_1 - \pi}{2}\right) r^n\right). \tag{3.5}$$

The special case $\theta_1 = \pi$ is dealt with in section 3.7, and $\theta_1 > 2\pi$ is discussed in section 3.6. For small r the limit profile (3.5) behaves as $\pi + 2\tan(\frac{\theta_1-\pi}{2})r^n$. For $\theta_1 \in (\pi, 2\pi)$ we define $\alpha_0 \stackrel{\text{def}}{=} 2\tan(\frac{\theta_1-\pi}{2})$.

Now the inner approximation (3.2) has to match into $\alpha_0 r$, and hence

$$O(r^n): \quad \alpha_0 \sim -E_n R'(t) R(t)^{1-n}.$$

One obtains

$$R \sim \begin{cases} \kappa e^{-\frac{\alpha_0}{E_2}t}, & n = 2, \\ \left(\frac{(n-2)\alpha_0}{E_n} t\right)^{-1/(n-2)}, & n > 2, \end{cases} \qquad \text{as } t \to \infty \tag{3.6}$$

for some $\kappa > 0$. Because the limit profile is known a priori (as opposed to $n < 2$), the unknown constant appears to leading order only when $n = 2$, where it is required due to translation invariance in time. Furthermore, we note that there are no degenerate cases; since blowup occurs as $t \to \infty$, it can be determined a priori which of the stationary states will be the final profile. This depends only on the value of θ_1 and $\theta(0,0)$, and since $\theta(0,0) \in \pi\mathbb{Z}$ is not a continuous parameter, degenerate (borderline) cases are not needed.

3.6. Multiple blowup. In certain situations it may happen that blowup occurs at several scales simultaneously (a so-called bubble tree; see also [17]), for example, when $\theta_1 \geq 2\pi$. For $n < 2$, i.e., finite time blowup, double (or multiple) blowup does not need to happen since the necessary jumps can occur at different instances, and simultaneous blowup is indeed not possible, at least for $n = 1$; see [12] (and our analysis reveals no possible finite time bubble tree). On the other hand, for $n \geq 2$ multiscale blowup necessarily happens if $\theta_1 \geq 2\pi$, since all blowup occurs as $t \to \infty$.

Let us take $\theta_1 \in (2\pi, 3\pi)$ as an example. The limit profile is now

$$\lim_{t\to\infty} \theta(t,r) = 2\pi + 2\arctan\left(\tan\left(\frac{\theta_1}{2}\right) r^n\right).$$

Define $\alpha_1 = 2\tan(\frac{\theta_1}{2})$ for $\theta_1 \in (2\pi, 3\pi)$. The two blowup rates are $R_1(t)$ and $R_2(t)$ for the jumps from 0 to π and from π to 2π, respectively, with $R_1 \ll R_2 \ll 1$. The first blowup rate $R_1(t)$ is defined as before, namely, so that $R_1(t)^n \theta(t,r) \sim 2r^n$ as $r \downarrow 0$ for all $t > 0$. The second blowup rate $R_2(t)$ cannot be defined in the same way, and instead we set

$$\theta(t, R_2(t)) = \frac{3\pi}{2} \qquad \text{for all } t \text{ close to blowup,}$$

so that in the limit we have for all $\rho > 0$

$$\lim_{t\to\infty} \theta(t, \rho R_2(t)) = \pi + 2\arctan\rho^n \qquad \text{and} \qquad \lim_{t\to\infty} \theta(t, \rho R_1(t)) = 2\arctan\rho^n.$$

The inner-inner region, $r = O(R_1(t))$, is as analyzed in section 3.2. The analysis of the inner region, $r = O(R_2(t))$, is the same except for the boundary condition on the left. Let $x = r/R_2(t)$; then $v(t,x) = u(t,r)$ behaves for large t as

$$v \sim \pi + 2\arctan x^n + R_2' R_2 \Psi,$$

where Ψ obeys

$$\Psi_{xx} + \frac{1}{x}\Psi_x - n^2 \frac{\cos(4\arctan x^n)}{x^2}\Psi = -\frac{2nx^n}{1+x^{2n}},$$

with "boundary" condition $\Psi(1) = 0$. The solution is

$$\Psi = \frac{(1 - x^{4n} - 4nx^{2n}\ln x)(A + \int_1^x \frac{s^{2n+1}}{(1+s^{2n})^2} ds) + x^{2n}\int_1^x \frac{s(s^{4n}-1+4ns^{2n}\ln s)}{(1+s^{2n})^2} ds}{x^n(1+x^{2n})}$$

with arbitrary $A \in \mathbb{R}$. For convenience we define

$$B_n = \int_0^1 \frac{s^{2n+1}}{(1+s^{2n})^2} ds.$$

One infers that

$$\begin{aligned} &\Psi \sim (A - B_n)x^{-n} && \text{for small } x, \\ &\Psi \sim \left(-\int_1^\infty \frac{s^{2n+1}}{(1+s^{2n})^2} ds - A\right) x^n + \frac{n}{2n-2} x^{-n+2} && \text{for large } x. \end{aligned}$$

Matching with the remote solution gives (recalling that $E_n = \int_0^\infty \frac{s^{2n+1}}{(1+s^{2n})^2} ds$)

$$O(r^n): \quad \alpha_1 \sim (B_n - E_n - A) R_2' R_2^{1-n};$$

hence

$$R_2 \sim \begin{cases} c_0 e^{-\frac{\alpha_1}{E_2 - B_2 + A} t}, & n = 2, \\ \left(\frac{(n-2)\alpha_1}{E_n - B_n + A} t\right)^{-1/(n-2)}, & n > 2, \end{cases} \tag{3.7}$$

for an arbitrary constant $c_0 > 0$.

Matching the inner-inner with the inner gives

$$O(r^{-n}): \qquad -2R_1^n \sim (A - B_n) R_2' R_2^{1+n}, \tag{3.8}$$

$$O(r^n): \qquad -E_n R_1' R_1^{1-n} \sim 2R_2^{-n}. \tag{3.9}$$

From (3.7) and (3.9) we deduce that

$$R_1 \sim \begin{cases} c_2 e^{-c_1 e^{\frac{2\alpha_1}{E_2 - B_2 + A} t}}, & n = 2, \\ \left(\frac{(n-2)(E_n - B_n + A)}{E_n \alpha_1 (n-1)}\right)^{-1/(n-2)} \left(\frac{(n-2)\alpha_1}{E_n - B_n + A} t\right)^{-(2n-2)/(n-2)^2}, & n > 2, \end{cases}$$

for arbitrary constants c_1, $c_2 > 0$ ($c_1 = \frac{2}{E_2} c_0$). From (3.8) we then conclude that $A = B_n$, and hence

$$R_1 \sim \begin{cases} c_2 e^{-c_1 e^{\frac{2\alpha_1}{E_2} t}}, & n = 2, \\ \left(\frac{n-2}{\alpha_1 (n-1)}\right)^{-1/(n-2)} \left(\frac{(n-2)\alpha_1}{E_n} t\right)^{-(2n-2)/(n-2)^2}, & n > 2, \end{cases}$$

for arbitrary constants c_1, $c_2 > 0$ (which only appear for $n = 2$), and $\alpha_1 = 2\tan(\frac{\theta_1}{2})$, $E_n = \frac{\pi}{2n^2 \sin(\frac{\pi}{n})}$. Notice the doubly exponential decay for $n = 2$; there are two unknown constants c_1 and c_2 in the leading order asymptotic expression because at both blowup scales there is a scaling invariance. While the first one could be attributed to translation invariance in time, the criticality of the case $n = 2$ is apparent in the appearance of a second unknown constant; for $n > 2$ there are no free constants in the leading order expression. One could generalize this to triple and higher multijumps, but we leave this to the puzzle-minded reader.

When one tries to perform the above analysis for $n < 2$, one readily encounters matching conditions which cannot be fulfilled. We therefore conjecture that there exist no bubble trees for $n < 2$; in particular, there are no finite time bubble trees.

3.7. Boundary condition $\theta_1 = \pi$. In the case of the special boundary condition $\theta(t, 1) = \pi$ we follow the argument of section 2.6. The remote solution w behaves as

$$w \sim \pi + s(t)(r^n - r^{-n}) + s'(t)\frac{1}{4}\left(\frac{1}{n-1}r^{2-n} + \frac{1}{n+1}r^{2+n} - \frac{2n}{n^2-1}r^n\right).$$

Matching this with the inner solution, we find

$$\begin{aligned} O(r^{-n}): &\qquad -s \sim -2R^n, \\ O(r^{-n+2}): &\quad \frac{1}{4(n-1)}s' \sim \frac{n}{2(n-1)}R'R^{n-1}, \\ O(r^n): &\qquad s \sim -E_n R' R^{1-n}. \end{aligned}$$

We obtain

$$R(t) \sim \left(\frac{4(n-1)}{E_n}t\right)^{-1/(2n-2)} \qquad \text{as } t \to \infty \qquad \text{for } n > 1.$$

For $n < 1$ matching suggests $R(t) \sim \left(\frac{4(1-n)}{E_n}(T-t)\right)^{1/(2-2n)}$. However, this does not provide consistent matching since it implies that $s' \gg s$. This suggests that we need a left boundary condition on the remote region of the form $w \sim Cr^{-n} + o(r^n)$ as $r \to 0$ for some $C \neq 0$. Hence we need to consider solutions of the form (compare to the degenerate case in section 2.6)

$$w \sim \pi + C_0 e^{-\nu_n^2 t} r^{-n}$$

for some $C_0 \neq 0$. Here ν_n is the first zero of the nth order singular Bessel function $\tilde{Y}_n$, which (for the occasion) is defined with the choice that $\tilde{Y}_n(r) \sim \tilde{C}r^{-n} + o(r^n)$, with $\tilde{C} \neq 0$ arbitrary. We remark that $\nu_n \to 0$ as $n \uparrow 1$. Matching now yields

$$O(r^{-n}): \quad C_0 e^{-\nu_n^2 t} \sim -2R^n,$$

and hence

$$R(t) \sim \kappa e^{-\frac{\nu_n^2}{n}t} \qquad \text{for } n < 1$$

for some $\kappa > 0$. To summarize, one finds that for $\theta_1 = \pi$ generically

$$R(t) \sim \begin{cases} \kappa e^{-\nu_n^2 t/n}, & n < 1, \\ e^{-2\sqrt{t}-5/4}, & n = 1, \\ \left(\frac{4(n-1)}{E_n}t\right)^{-1/(2n-2)}, & n > 1, \end{cases}$$

provided that no finite time blowup occurs (for $n < 2$), for example, when one takes initial data which lie entirely between 0 and π.

For $n < 2$ there is again a family of degenerate cases (cf. section 2.6); the blowup is at an exponential rate determined by the zeros of the Bessel functions $\tilde{Y}_n$ for $n < 1$ and J_n for $1 < n < 2$. For $n \geq 2$ degenerate scenarios do not exist. We leave the details to the diligent reader. For $n \geq 2$ the cases $\theta_1 = m\pi$, $m = 2, 3, \ldots$, involve multiple blowup, and the technique from the previous section may be used.

3.8. The infinite domain. We will now discuss how the results obtained so far have to be adapted when we consider an infinite domain, i.e., $r \in (0, \infty)$, instead of a finite one. In order to have a solution with finite energy $\mathcal{E}(t) = \pi \int_0^\infty \left(r\theta_r^2 + n^2 \frac{\sin^2\theta}{r}\right) dr$ the profile has to approach a multiple of π at a reasonably fast rate as $r \to \infty$; we denote this "boundary" condition by $\lim_{r\to\infty} \theta(t, r) = \tilde{\theta}_1 \in \pi\mathbb{Z}$. We focus on initial data which have compact support in the sense that $\theta(0, r) = m\pi$ for all sufficiently large r or, more generally, data which decay to $m\pi$ exponentially (thus, in particular, excluding algebraic decay).

Let us first discuss the case $\tilde{\theta}_1 = \pi$. There are several possibilities, depending on the initial data. For $n < 2$ a generic possibility is finite time blowup (see section 3.4). A priori, another possibility is that there is no blowup and that for large time the solution converges to one of the equilibria $\theta(r) = 2\arctan qr^n$ for some $q > 0$. For $n \geq 2$ this is in fact the only feasible scenario, and no blowup turns out to be a generic scenario for $1 < n < 2$; on the other hand, for $n \leq 1$ blowup always occurs (as is explained below). Regarding nongeneric possibilities, consider, for example, the parameter range $1 < n < 2$ and initial data which have one crossing with π (so that the finite time codimension 1 blowup scenario is not possible). We deduce that there should be at least one nongeneric infinite time blowup scenario which acts as the borderline between the two generic possibilities.

The large time behavior away from the origin is described in terms of self-similar variables $\tau = \ln t$ and $y = r/\sqrt{t} = e^{-\tau/2} r$, which leads to the linearized equation

$$\eta_\tau = \eta_{yy} + \left(\frac{1}{y} + \frac{y}{2}\right)\eta_y - \frac{n^2}{y^2}\,\eta.$$

We now analyze the codimension 0 and 1 scenarios for various ranges of n. (Higher codimension cases can be analyzed in a similar manner.)

For $n > 1$ the generic behavior is described by the solution

$$\eta = C_0 e^{-n\tau/2}\, y^{-n} \int_y^\infty s^{2n-1} e^{-s^2/4}\, ds \tag{3.10}$$

for some $C_0 \neq 0$; it decays faster than exponentially as $y \to \infty$, and as $y \to 0$ it asymptotically satisfies $\eta \sim C_0 2^{2n-1}\Gamma(n) e^{-n\tau/2} y^{-n} = C_0 2^{2n-1}\Gamma(n) r^{-n}$. Since matching into the inner solution (3.2) leads to $R(t) \to \kappa$ as $t \to \infty$ for some $\kappa > 0$ with limit profile $\theta_\infty(r) = 2\arctan(r/\kappa)^n$, the generic scenario corresponds to no blowup. To be more precise, for $n > 1$ the matching conditions are

$$\begin{aligned} O(r^{-n}): &\qquad C_0 2^{2n-1}\Gamma(n) \sim -2R^n, \\ O(r^n): &\qquad -\tfrac{1}{2n} C_0 t^{-n} \sim -E_n R' R^{1-n}. \end{aligned}$$

Hence $R(t) \sim \kappa + Q_{q,n} t^{1-n}$ as $t \to \infty$, where

$$Q_{q,n} = \left[2^{2n-1}\kappa^{1-2n}(n-1)\Gamma(n+1)E_n\right]^{-1} > 0.$$

In between the generic possibilities of no blowup and finite time blowup there is a degenerate infinite time blowup scenario. For this codimension 1 case we find the outer approximation (writing $\zeta(\tau, y) = \theta(t, r)$)

$$\zeta(\tau, y) \sim \pi + C_1 e^{-(2+n)\tau/2}\, y^n\, e^{-y^2/4} \qquad \text{as } \tau \to \infty$$

for some $C_1 \neq 0$. Matching this with the inner solution, we infer that for $1 < n < 2$ the codimension 1 blowup rate is

$$R(t) \sim \kappa t^{-n/(2-n)} \qquad \text{as } t \to \infty \qquad \text{for } 1 < n < 2 \tag{3.11}$$

for some $\kappa > 0$. Away from the origin the decay towards π is at algebraic rate $O(t^{-1-n})$. For $n \geq 2$ matching in the nongeneric case is impossible (looking at (3.11), one could anticipate this), implying that for $\tilde{\theta}_1 = \pi$ there is never blowup when $n \geq 2$.

The case $n = 1$ is again a borderline one; we find that (3.10) again describes the generic behavior in the outer region, but we need C_0 to depend on τ in a nonexponential manner. Matching this with the inner solution (2.3) gives matching conditions (with $\tilde{R}(\tau) = R(t)$)

$$\begin{aligned} O(y^{-1}): &\qquad 2C_0(\tau)e^{-\tau/2} \sim -2e^{-\tau/2}\tilde{R}, \\ O(y \ln y): &\qquad C_0'(\tau)e^{-\tau/2} \sim -e^{-\tau/2}\tilde{R}', \\ O(y): &\qquad -\frac{1}{2}C_0(\tau)e^{-\tau/2} \sim e^{-\tau/2}\tilde{R}'\left(\ln \tilde{R} - \frac{\tau}{2} + 1\right). \end{aligned}$$

This generic scenario thus describes blowup at rate

$$R(t) \sim \frac{\kappa}{\ln t} \qquad \text{as } t \to \infty \qquad \text{for } n = 1$$

for some $\kappa > 0$. (Since the problem on the infinite domain is scaling invariant, a multiplicative constant, whose value depends on the initial data, must again be present.) For $r = O(1)$ the solution approaches π at rate $O(1/\ln t)$ as $t \to \infty$. The outer approximation in the codimension 1 case is

$$\zeta(\tau, y) \sim \pi + e^{-3\tau/2} e^{-y^2/4}\big[\sigma(\tau)y + \sigma'(\tau)(4y^{-1} - 2y \ln y)\big] \qquad \text{as } \tau \to \infty$$

for some $\sigma(\tau)$, and matching gives the blowup rate $R \sim \kappa t^{-1}(\ln t)^{-4/3}$ as $t \to \infty$ (i.e., a logarithmically corrected version of (3.11) with $n = 1$), where $\kappa > 0$ is arbitrary. Away from the origin the rate of decay towards π is of order $O(t^{-1}(\ln t)^{-4/3})$.

For $n < 1$ the outer approximation described by (3.10) does not lead to consistent matching; we have seen previously that for $n < 1$ the outer solution should behave as $\tilde{C}y^{-n} + o(y^n)$ for small y with $\tilde{C} \neq 0$, which is not satisfied by (3.10). Therefore, for $n < 1$ the outer approximation in the generic case is

$$\zeta(\tau, y) \sim \pi + C_2 e^{-(2-n)\tau/2}\, y^{-n}\, e^{-y^2/4} \qquad \text{as } \tau \to \infty$$

for some $C_2 \neq 0$. Matching with the inner solution, we find that generically

$$R(t) \sim \kappa t^{-(1-n)/n} \qquad \text{as } t \to \infty \qquad \text{for } n < 1$$

for some $\kappa > 0$. Away from the origin the decay towards π as $t \to \infty$ is at algebraic rate $O(t^{-1})$. For the codimension 1 scenario we find $R \sim \kappa t^{-(2-n)/n}$ as $t \to \infty$ for some $\kappa > 0$.

We note that, although the infinite domain allows scaling invariance, spreading of the form $\theta(t,r) = \Theta(r/\sqrt{t})$ is seen to be impossible by an argument analogous to that given at the end of section 1. On the other hand, taking initial data with $\theta(t_0,r) \sim \hat{C}r^{-a}$ as $r \to \infty$ for some $\hat{C} \neq 0$, where $0 < a < n$, spreading at a rate slower than the self-similar one will occur as $t \to \infty$. The matching conditions in that case imply that the term of order r^{-n} is dominant for all $n > 0$, which yields $R(t) \sim \kappa t^{(n-a)/2n}$ as $t \to \infty$ for some $\kappa > 0$ and any $0 < a < n$; notice that $\frac{n-a}{2n} < \frac{1}{2}$ so that the self-consistency condition $R'R \to 0$ as $t \to \infty$ holds. For $a = n$ (i.e., $\theta(t_0,r) \sim \hat{C}r^{-n}$ as $r \to \infty$, which is the same rate as a stationary solution) no blowup occurs, while for $a > n$ there is either blowup (for $n \leq 1$) or no blowup (for $n > 1$), but we will not pursue the issue of algebraically decaying initial data any further.

The analysis is similar for $\lim_{r\to\infty} \theta(t,r) = \tilde{\theta}_1 = m\pi$, $m = 2,3,\ldots$. For $n < 2$ a (finite) number of finite time jumps essentially reduces the situation to the case $\tilde{\theta}_1 = \pi$. For $n \geq 2$ and boundary value $\tilde{\theta}_1 = 2\pi$, blowup will happen as $t \to \infty$ and one of the stationary states $\theta_\infty(r) = \pi + 2\arctan qr^n$ for some $q > 0$ is selected. The analysis is completely analogous to the finite domain case $\theta_1 \in (\pi, 2\pi)$ discussed in section 3.5 (notice that it thus differs from the finite domain with $\theta_1 = 2\pi$). The result is the same as in section 3.5 except that the constant $q = \alpha_0$ cannot be determined a priori in the case of an infinite domain (and it should not be since the equation has a scaling invariance). Hence, the asymptotic blowup rate is given by (3.6), the only alteration being that, in the case of an infinite domain, $\alpha_0 > 0$ is an arbitrary constant whose value depends on the initial data. For $\tilde{\theta}_1 = m\pi$ with $m = 3,4,\ldots$ (and $n \geq 2$) multiscale blowup occurs (see section 3.6), and the analysis of the infinite domain is analogous to that of the finite domain with $\theta_1 \in ((m-1)\pi, m\pi)$.

3.9. Jumping back. Finally, we analyze the possibility of reverse jumps for (3.1). Analogous to section 2.7, the profile at any time generically behaves as Cr^n for small r with $C \neq 0$. Hence in the outer region, in self-similar coordinates $\tau = \ln(t-t_0)$ and $y = e^{-\tau/2}r$, we look for a solution of the form $e^{n\tau/2}\psi(y)$. The linear equation for ψ has as solution

$$\psi = C_0 y^n + C_1 y^n \int_y^\infty e^{-s^2/4} s^{-2n-1} ds,$$

with arbitrary constants C_0, $C_1 \in \mathbb{R}$, and $y_0 > 0$. The inner limit of the outer approximation thus becomes

$$\zeta \sim \pi + e^{n\tau/2}\left[\alpha(\tau)y^n + \beta(\tau)\left(\frac{1}{2n}y^{-n} - \frac{1}{8(n-1)}y^{2-n}\right)\right] \qquad \text{for small } y \text{ and } -\tau \gg 1.$$

Matching with the inner solution gives (writing $\tilde{R}(\tau) = R(t)$)

$$\begin{aligned} O(y^{-n}): &\qquad \frac{1}{2n}\beta e^{n\tau/2} \sim -2\tilde{R}^n e^{-n\tau/2}, \\ O(y^{2-n}): &\quad -\frac{1}{8(n-1)}\beta e^{n\tau/2} \sim \frac{n}{2(n-1)}\tilde{R}'\tilde{R}^{n-1}e^{-n\tau/2}, \\ O(y^n): &\qquad \alpha e^{n\tau/2} \sim -E_n \tilde{R}'\tilde{R}^{1-n}e^{(-1+n/2)\tau}. \end{aligned}$$

One concludes that for $n > 1$ the term of order y^n is dominant, and hence as $t \downarrow t_0$

$$R \sim \left[\frac{\ell(2-n)}{E_n}(t-t_0)\right]^{1/(2-n)} \qquad \text{for } 1 < n < 2$$

for some $\ell > 0$, the limit profile being $\theta(t_0, r) \sim \pi - \ell r^n$. Considerations about nongeneric cases are analogous to those in section 2.7; for the codimension 1 case one finds that

$$R \sim \left[\frac{2\ell(n+1)(2-n)}{E_n}\right]^{1/(2-n)} (t-t_0)^{2/(2-n)} \qquad \text{as } t \downarrow t_0$$

for some $\ell > 0$ with $\theta(t_0, r) \sim \pi - \ell r^{2+n}$ as $r \to 0$. For $n \geq 2$ no consistent matching is found, implying the rather strong result that reverse jumps do not seem possible. Notice that these conclusions are in line with what one could expect from section 3.3.

For $n < 1$ the term of order y^{-n} is dominant; hence the matching conditions give $R \sim \omega_n(t - t_0)$ as $t \downarrow t_0$ for some $\omega_n > 0$, which can be determined using the limit profile $\theta(t_0, r) \sim \pi - \ell r^n$ as $r \to 0$. Since the inner limit of the outer approximation behaves as $(\zeta - \pi)e^{-n\tau/2} \sim -4n\omega_n^n y^{-n} + o(y^n)$ as $y \to 0$, the outer limit of the outer approximation becomes

$$\zeta \sim \pi - 4n\omega_n^n e^{n\tau/2} y^n \left[-2^{-2n-1}\Gamma(-n) + \int_y^\infty e^{-s^2/4} s^{-2n-1} ds\right].$$

Hence as $t \downarrow t_0$

$$R \sim \left(\frac{\ell\, 2^{2n-1}}{\Gamma(1-n)}\right)^{1/n} (t - t_0) \qquad \text{for } n < 1$$

for some ℓ with $\theta(t_0, r) \sim \pi - \ell r^n$ as $r \downarrow 0$. Nongeneric cases can also be considered; for example, for the codimension 1 scenario one finds

$$R \sim \left(\frac{\ell\, 2^{2n+1}}{\Gamma(1-n)}\right)^{1/n} (t - t_0)^{(n+1)/n} \qquad \text{as } t \downarrow t_0$$

for some ℓ with $\theta(t_0, r) \sim \pi - \ell r^{n+2}$ as $r \downarrow 0$.

Finally, we do not find any self-consistent scenarios for reverse jumps which increase the energy by more than 4π, i.e., no reverse bubble trees for any n. (This is analogous to the conclusion in section 3.6 that there are no normal (energy-decreasing) bubble trees for $n < 2$; for $n \geq 2$ there are normal bubble trees but they are of the infinite time blowup type.)

4. Conclusion. We have analyzed the blowup rate in the harmonic map heat flow in a family of symmetric settings, leading to a parabolic problem in one space dimension:

$$\theta_t = \theta_{rr} + \frac{1}{r}\theta_r - n^2 \frac{\sin 2\theta}{2r^2}, \qquad 0 < r < 1, \tag{4.1}$$

with boundary conditions $\theta(t, 0) \in \pi\mathbb{Z}$ and $\theta(1, t) = \theta_1$. Here $n > 0$ is a parameter, and it corresponds to a well-defined physical situation (e.g., in the context of aligned nematic liquid crystals) when $n = 1, 2, 3, \ldots$. The initial value problem has a unique energy-decreasing solution, the energy being $\mathcal{E}(t) = \pi \int_0^1 (\theta_r^2 + r^{-2} n^2 \sin^2\theta) r dr$. Equation (4.1) is the gradient flow associated with this energy.

Without loss of generality we may assume that $\theta(0, 0) = 0$. During the evolution of a solution the value of θ at the origin may jump at some time(s) $t = T \in (0, \infty]$.

As the time approaches T the quantity $\lim_{r\downarrow 0} r^{-n}\theta(t,r)$ blows up. In this paper we have determined the asymptotic behavior of the blowup rate $R(t)$, defined by

$$R(t)^n\theta(t,r) \sim 2r^n \quad \text{as } r \downarrow 0 \qquad \text{for all } t \text{ up to the blowup time,}$$

using formal matched asymptotic expansions. After rescaling with this blowup rate, the profile approaches a harmonic map (a stationary state):

$$\lim_{t\uparrow T} \theta(t, \xi R(t)) = 2\arctan \xi^n \qquad \text{for all fixed } \xi > 0.$$

Since our results suggest important differences between $n < 2$ and $n \geq 2$, let us first summarize the behavior for $n < 2$. The generic behavior for $\theta_1 > \pi$ is

$$\begin{aligned} n < 1: &\qquad R \sim \kappa\,(T-t)^{1/n} && \text{as } t \uparrow T,\\ n = 1: &\qquad R \sim \kappa\,\frac{T-t}{|\ln(T-t)|^2} && \text{as } t \uparrow T,\\ 1 < n < 2: &\qquad R \sim \kappa\,(T-t)^{1/(2-n)} && \text{as } t \uparrow T, \end{aligned}$$

where $\kappa > 0$ is an arbitrary constant and $T < \infty$ is the time of blowup. There is also a countable family of degenerate cases. We find that with codimension k $(k = 0, 1, 2, \dots)$

$$\begin{aligned} n < 1: &\qquad R \sim \kappa\,(T-t)^{(k+1)/n} && \text{as } t \uparrow T,\\ n = 1: &\qquad R \sim \kappa\,\frac{(T-t)^{k+1}}{|\ln(T-t)|^{(2k+2)/(2k+1)}} && \text{as } t \uparrow T,\\ 1 < n < 2: &\qquad R \sim \kappa\,(T-t)^{(k+1)/(2-n)} && \text{as } t \uparrow T, \end{aligned}$$

where $\kappa > 0$ is again an arbitrary constant. In the codimension k scenario the profile $\theta(t,r)$ just before blowup has $k+1$ intersections with π, which approach the origin as $t \uparrow T$. Countable families of nongeneric blowup rates are encountered in a wide variety of problems; see [10] for an illustrative example.

For boundary data $\theta_1 = \pi$, blowup can occur (in finite time) via the scenario described above, but there is another generic blowup behavior (in infinite time) of the form

$$\begin{aligned} n < 1: &\qquad R \sim \kappa\, e^{-\frac{\nu_n^2}{n}t} && \text{as } t \to \infty,\\ n = 1: &\qquad R \sim e^{-2\sqrt{t}-5/4} && \text{as } t \to \infty,\\ 1 < n < 2: &\qquad R \sim \left(\frac{4(n-1)}{E_n}t\right)^{-1/(2n-2)} && \text{as } t \to \infty, \end{aligned}$$

with arbitrary constant $\kappa > 0$. Here $E_n = \frac{\pi}{2n^2\sin(\frac{\pi}{n})}$ and ν_n is the first zero of the Bessel function $\tilde{Y}_n$ (see section 3.7 for details). There is also a family of nongeneric infinite time blowup possibilities.

For $n \geq 2$ all blowup occurs as $t \to \infty$, and there is always a unique blowup scenario. For $\theta_1 \in (0, \pi)$ blowup never occurs (whereas for $n < 2$ this depends on the initial profile). For $\theta_1 \in (\pi, 2\pi)$ one finds

$$\begin{aligned} n = 2: &\qquad R \sim \kappa\, e^{-\frac{\alpha_0}{E_2}t} && \text{as } t \to \infty,\\ n > 2: &\qquad R \sim \left(\frac{(n-2)\alpha_0}{E_n}t\right)^{-1/(n-2)} && \text{as } t \to \infty, \end{aligned}$$

where $\kappa > 0$ is arbitrary, $E_n = \frac{\pi}{2n^2 \sin(\frac{\pi}{n})}$, and $\alpha_0 = \tan(\frac{\theta_1 - \pi}{2})$. No other (nongeneric) scenarios are found. In the case of boundary data $\theta_1 = \pi$ the result is

$$n \geq 2: \qquad R \sim \left(\frac{4(n-1)}{E_n} t \right)^{-1/(2n-2)} \qquad \text{as } t \to \infty,$$

which is the same expression as for $1 < n < 2$.

For $\theta_1 \geq 2\pi$ there is blowup over two or more scales (the number being known a priori from the value of θ_1). For $2\pi \leq \theta < 3\pi$ there is blowup over two scales; these are the simplest examples of so-called bubble trees. For $\theta_1 = 2\pi$ the blowup rate in the innermost region is

$$\begin{aligned} n = 2: &\qquad R \sim \kappa\, e^{-4E_2^{-2} t^2} && \text{as } t \to \infty, \\ n > 2: &\qquad R \sim \left(\frac{n-2}{3n-2} \right)^{-1/(n-2)} \left(\frac{4(n-1)}{E_n} t \right)^{-(3n-2)/(2(n-1)(n-2))} && \text{as } t \to \infty, \end{aligned}$$

where $\kappa > 0$ is arbitrary. For $\theta_1 \in (2\pi, 3\pi)$ we obtain (for the innermost blowup)

$$\begin{aligned} n = 2: &\qquad R \sim \kappa_2\, e^{-\kappa_1 e^{\frac{2\alpha_1}{E_2} t}} && \text{as } t \to \infty, \\ n > 2: &\qquad R \sim \left(\frac{n-2}{\alpha_1 (n-1)} \right)^{-1/(n-2)} \left(\frac{(n-2)\alpha_1}{E_n} t \right)^{-(2n-2)/(n-2)^2} && \text{as } t \to \infty, \end{aligned}$$

where $\kappa_1, \kappa_2 > 0$ are arbitrary and $\alpha_1 = 2\tan(\frac{\theta_1}{2})$. Analogous results hold for other values of $\theta_1 \geq 3\pi$.

We now describe the global picture suggested by these formal results. Since the equation is invariant under the discrete symmetries $\theta \mapsto -\theta$ and $\theta \mapsto \theta + \pi$, we may without loss of generality assume that $\theta(0,0) = 0$ and $\theta_1 \geq 0$. For convenience of notation, let the stationary solution $2\arctan(r^n \tan\frac{\theta_1}{2})$ be denoted by $\vartheta_{\theta_1}(r)$. We make a subdivision depending on the value of the boundary data θ_1.

Case 1: $0 \leq \theta_1 < \pi$. No blowup occurs for $n \geq 2$ and the limit profile $\lim_{t\to\infty} \theta(t,r) = \theta_\infty(r) = \vartheta_{\theta_1}(r)$ for all fixed $r > 0$. For $n < 2$ there is, depending on the initial data, either no blowup or blowup at a finite set of finite time moments $\{T_i\}_{i=1}^K$ for some integer K; if $\theta_1 = 0$, then K must be even. At each blowup time T_i the value of θ at the origin jumps by $\pm\pi$, and an amount $\mathcal{E}(T_i) - \lim_{t\uparrow T_i} = 4\pi n$ of energy is lost (a sphere bubbles off). This may happen via either a generic or a nongeneric scenario. The blowup instances T_i are all different, and there is no blowup as $T \to \infty$. If K is even, then the limit profile is $\theta_\infty(r) = \vartheta_{\theta_1}(r)$, while if K is odd, it is $\theta_\infty(r) = \pi - \vartheta_{\pi-\theta_1}(r)$. The number of jumps K is a priori bounded from above by $\frac{1}{4\pi n} \max\{\mathcal{E}(0) - \mathcal{E}_{\theta_1}, \mathcal{E}(0) - \mathcal{E}_{\pi-\theta_1}\}$, where $\mathcal{E}(0)$ is the energy of the initial data and $\mathcal{E}_{\theta_1}$ is the energy of the stationary state ϑ_{θ_1}; if $\mathcal{E}(0) < \mathcal{E}_{\pi-\theta_1} + 4\pi n$, then no jump can occur.

Case 2: $\theta_1 = \pi$. For any $n > 0$ the limit profile is $\theta_\infty(r) \equiv \pi$, and blowup has to occur at at least one time $T \in (0, \infty]$. For $n \geq 2$ blowup occurs only as $t \to \infty$, and an energy loss of $4\pi n$ occurs in this limit (i.e., $\lim_{t\to\infty} \mathcal{E}(t) = 4\pi n$, while $\mathcal{E}(\theta_\infty) = 0$). There is only one possible blowup rate. For $n < 2$ there is a finite set of time moments $\{T_i\}_{i=1}^K$ for some integer K with the same properties as for $\theta_1 < \pi$, except that K is odd (and thus $K \geq 1$) and one of the T_i may be equal to ∞, in which case the energy

jump at infinity is $4\pi n$ (i.e., the same as for a finite time jump). Both the finite time and the infinite time blowup can happen via a generic or nongeneric scenario.

Case 3: $\pi < \theta_1 < 2\pi$. Blowup has to occur at at least one time $T \in (0, \infty]$. For $n \geq 2$ there is blowup only as $t \to \infty$, and the limit profile is $\theta_\infty(r) = \pi + \vartheta_{\theta_1 - \pi}(r)$. The energy loss at infinity is $4\pi n$, and there is only one possible blowup rate. For $n < 2$ the scenario is the same as for $\theta < \pi$ (in particular, there is no infinite time blowup), with the adaptation that $K \geq 1$. If K is odd, then the limit profile is $\theta_\infty(r) = \pi + \vartheta_{\theta_1 - \pi}(r)$, while if K is even, it is $\theta_\infty(r) = 2\pi - \vartheta_{2\pi - \theta_1}(r)$.

Case 4: $\theta_1 = m\pi$, $m = 2, 3, \ldots$. For any $n > 0$ the limit profile is $\theta_\infty(r) \equiv k\pi$, and blowup has to occur at at least one time moment $T \in (0, \infty]$. For $n \geq 2$ blowup occurs only as $t \to \infty$, and an energy loss of $4\pi nm$ occurs in this limit. There is only one possible blowup rate, and blowup occurs over m different scales (a so-called bubble tree, the current analysis furnishing simple concrete examples of how such behavior can occur); there is a unique blowup scenario. For $n < 2$ there is a finite set of time moments $\{T_i\}_{i=1}^K$ for some integer K with the same properties as for $\theta_1 = \pi$ (one of the T_i can be equal to ∞), except that the number of blowup times $K \geq m$ and $K - m$ is always even. There is no bubble tree, and the energy loss at each T_i is $4\pi n$.

Case 5: $\theta_1 > 2\pi$, $\theta_1 \notin \pi\mathbb{Z}$. Blowup has to occur at at least one time $T \in (0, \infty]$. For $n \geq 2$ there is blowup only as $t \to \infty$, and the limit profile is $\theta_\infty(r) = M\pi + \vartheta_{\theta_1 - M\pi}(r)$, where M is the largest integer smaller than θ_1. There is blowup over M different scales, and the energy loss at infinity is $4\pi nM$ (i.e., a bubble tree). There is just one possible scenario. For $n < 2$ the scenario is the same as for $\pi < \theta < 2\pi$, with the adaptation that $K \geq M$. If $K - M$ is even, then the limit profile is $\theta_\infty(r) = M\pi + \vartheta_{\theta_1 - M\pi}(r)$, while if K is even, it is $\theta_\infty(r) = (M+1)\pi - \vartheta_{(M+1)\pi - \theta_1}(r)$. Again, at each blowup time one quantum of energy (i.e., $4\pi n$) is lost.

In the case of an infinite domain $r \in (0, \infty)$ and boundary conditions at infinity $\lim_{r \to \infty} \theta(t, r) = \tilde{\theta}_1 = m\pi$, $m = 0, 1, 2, \ldots$ (in order for profiles to have finite energy), we restrict our attention to initial data that approach $\tilde{\theta}_1$ sufficiently fast as $r \to \infty$. We again describe the results for $n \geq 2$ and $n < 2$ separately.

For $n \geq 2$ and $\tilde{\theta}_1 = m\pi$, $m = 1, 2, \ldots$, the situation is very similar to that of a finite domain with $\theta_1 \in ((m-1)\pi, m\pi)$. (For $m = 0$ there is no blowup, and the solution converges to 0 uniformly as $t \to \infty$.) Blowup occurs over $m - 1$ scales, and the limit profile is a stationary state $\theta_\infty(r) = (m-1)\pi + 2\arctan qr^n$ for some $q > 0$ (which depends on the initial data). The blowup rate is the same as for the finite domain described previously (with q replacing the constants α_0 and α_1). There are no nongeneric scenarios.

For $n < 2$ the solution has $K \geq m$ blowup times (cf. the finite domain case), one of which may be infinity. If $K - m$ is odd, then the limit profile is $\theta_\infty(r) = (m \pm 1)\pi \mp 2\arctan qr^n$ for some $q > 0$, while if $K - m$ is even, then $\theta_\infty(r) = m\pi$. The finite time blowup rates are the same as for the finite domain (including the possibility of nongeneric finite time blowup). Whereas for $1 < n < 2$ the blowup times are all generically finite (and there is thus no generic blowup as $t \to \infty$), for $n \leq 1$ infinite time blowup is generic and the rate is

$$\begin{aligned} n < 1: &\qquad R \sim \kappa\, t^{-(1-n)/n} &&\text{as } t \to \infty, \\ n = 1: &\qquad R \sim \kappa\, (\ln t)^{-1} &&\text{as } t \to \infty, \end{aligned}$$

with $\kappa > 0$ arbitrary. For $1 < n < 2$ infinite time blowup can occur with codimen-

sion 1; the corresponding blowup rate is

$$\begin{aligned} n<1: &\qquad R\sim \kappa\, t^{-(2-n)/n} &&\text{as } t\to\infty,\\ n=1: &\qquad R\sim \kappa\, t^{-1}(\ln t)^{-4/3} &&\text{as } t\to\infty,\\ 1<n<2: &\qquad R\sim \kappa\, t^{-n/(2-n)} &&\text{as } t\to\infty \end{aligned}$$

for arbitrary $\kappa>0$. There is again a countable family of infinite time blowup scenarios with higher codimension.

Finally, when one allows for solutions that do not necessarily have decreasing energy (thereby introducing nonuniqueness), then, depending on n, jumps can occur in which the energy increases. The physical interpretation is that the energy stored in the origin at a forward (energy-decreasing) jump is released.

For $n<2$ reverse jumps can happen at any time. In the nominally generic (codimension 0) case we have

$$\begin{aligned} n<1: &\qquad R\sim \left(\frac{\ell\, 2^{2n-1}}{\Gamma(1-n)}\right)^{1/n}(t-t_0) &&\text{as } t\downarrow t_0,\\ n=1: &\qquad R\sim 2\ell\,\frac{t-t_0}{|\ln(t-t_0)|} &&\text{as } t\downarrow t_0,\\ 1<n<2: &\qquad R\sim \left[\frac{\ell(2-n)}{E_n}(t-t_0)\right]^{1/(2-n)} &&\text{as } t\downarrow t_0, \end{aligned}$$

where $\ell>0$ with $\theta(t_0,r)\sim\pi-\ell r^n$. For the codimension 1 scenario one finds

$$\begin{aligned} n<1: &\qquad R\sim \left(\frac{\ell\, 2^{2n+1}}{\Gamma(1-n)}\right)^{1/n}(t-t_0)^{(n+1)/n} &&\text{as } t\downarrow t_0,\\ n=1: &\qquad R\sim \frac{8}{3}\ell\,\frac{(t-t_0)^2}{|\ln(t-t_0)|} &&\text{as } t\downarrow t_0,\\ 1<n<2: &\qquad R\sim \left(\frac{2\ell(n+1)(2-n)}{E_n}\right)^{1/(2-n)}(t-t_0)^{2/(2-n)} &&\text{as } t\downarrow t_0, \end{aligned}$$

where $\ell>0$ with $\theta(t_0,r)\sim\pi-\ell r^{n+2}$. It is conjectured in [2] that a physical system selects the codimension 1 scenario to release the energy stored in the origin. When a forward and a reverse jump occur at the same instant (cf. [18]), the rate is given by (2.17).

For $n\geq 2$ no reverse jumps are possible; this is not surprising since energy can be stored in the origin only as $t\to\infty$, and thus none is available for release.

Acknowledgments. We would like to thank Sigurd Angenent, Marek Fila, Rein van der Hout, and Giles Richardson for a series of pleasant and enlightening discussions.

BACKSCATTERING AND NONPARAXIALITY ARREST COLLAPSE OF DAMPED NONLINEAR WAVES*

G. FIBICH†, B. ILAN†, AND S. TSYNKOV‡

Abstract. The critical nonlinear Schrödinger equation (NLS) models the propagation of intense laser light in Kerr media. This equation is derived from the more comprehensive nonlinear Helmholtz equation (NLH) by employing the paraxial approximation and neglecting the backscattered waves. It is known that if the input power of the laser beam (i.e., L_2 norm of the initial solution) is sufficiently high, then the NLS model predicts that the beam will self-focus to a point (i.e., collapse) at a finite propagation distance. Mathematically, this behavior corresponds to the formation of a singularity in the solution of the NLS. A key question which has been open for many years is whether the solution to the NLH, i.e., the "parent" equation, may nonetheless exist and remain regular everywhere, particularly for those initial conditions (input powers) that lead to blowup in the NLS. In the current study we address this question by introducing linear damping into both models and subsequently comparing the numerical solutions of the damped NLH (boundary-value problem) with the corresponding solutions of the damped NLS (initial-value problem) for the case of one transverse dimension. Linear damping is introduced in much the same way as is done when analyzing the classical constant-coefficient Helmholtz equation using the limiting absorption principle. Numerically, we have found that it provides a very efficient tool for controlling the solutions of both the NLH and NLS. In particular, we have been able to identify initial conditions for which the NLS solution does become singular, while the NLH solution still remains regular everywhere. We believe that our finding of a larger domain of existence for the NLH than for the NLS is accounted for by precisely those mechanisms that have been neglected when deriving the NLS from the NLH, i.e., nonparaxiality and backscattering.

Key words. Kerr medium, nonlinear wave propagation, self-focusing, singularity formation, linear damping, limiting absorption, two-way ABCs

1. Introduction.

The focusing critical nonlinear Schrödinger equation (NLS)

$$i\psi_z(z,\boldsymbol{x}) + \Delta_\perp \psi + |\psi|^{4/d}\psi = 0, \qquad \psi(0,\boldsymbol{x}) = \psi_0(\boldsymbol{x}), \tag{1.1}$$

where $\boldsymbol{x} \in \mathbb{R}^d$ and $\Delta_\perp = \partial_{x_1 x_1} + \cdots + \partial_{x_d x_d}$, arises in a variety of physical contexts. Of foremost interest is the case $d = 2$, which corresponds to the propagation of intense laser beams in Kerr media. In this case, z is the axial coordinate in the direction of propagation, $\boldsymbol{x} = (x, y)$ are the spatial coordinates in the transverse plane, $\Delta_\perp = \partial_{xx} + \partial_{yy}$ is the diffraction term (transverse Laplacian), and $|\psi|^2\psi$ describes the nonlinear polarization of the Kerr medium. It is well known that solutions to the critical NLS (1.1) can self-focus and eventually collapse, i.e., become singular, at a finite propagation distance, provided that their *initial power* $N(0) = \int |\psi_0|^2 \, d\boldsymbol{x}$ exceeds a threshold power $N_{\rm c}$, whose value depends only on the dimension d (see [7,28]). Since,

however, physical quantities do not become infinite, and since in experiments laser beams continue to propagate beyond the NLS blowup point, the question arises as to what specific physical mechanism(s), among those that have been neglected when deriving the NLS from the Maxwell's equations, actually arrest(s) the collapse. We recall that the final stage in the derivation of the NLS is to disregard the backscattering and apply the paraxial approximation (see section 2.2) to the critical nonlinear Helmholtz equation (NLH)

$$\Delta E(z,\boldsymbol{x}) + k_0^2(1+\epsilon|E|^{4/d})E = 0, \qquad \Delta \equiv \partial_{zz} + \Delta_\perp, \tag{1.2}$$

where k_0 is the linear wavenumber and the extent of nonlinearity is measured by the quantity $\epsilon = 4\epsilon_0 c n_2$, where n_2 is the Kerr coefficient; see, e.g., [3, 19]. Therefore, it is natural to ask whether going back from the NLS to the NLH, i.e., adding nonparaxiality and backscattering, is sufficient to guarantee existence of the solution with no singularities. In other words, for a given initial condition that leads to blowup in the critical NLS, does the NLH (always) have a solution that remains regular everywhere?

The foregoing question has been open for many years. In his celebrated 1965 paper [15], which was the first paper in the literature to predict that the solutions to the critical NLS could become singular, Kelley was careful to note that the paraxial approximation, and hence the entire NLS model, breaks down near the singularity. Feit and Fleck [4] were the first to demonstrate that nonparaxiality of the beam can arrest the blowup, by showing numerically that the initial conditions that lead to singularity formation in the NLS result in focusing-defocusing oscillations in the NLH. In these simulations, however, they did not solve a true boundary-value problem for the NLH. Instead, they solved an initial-value problem for a "modified" NLH that only describes the right-propagating wave (while introducing several additional assumptions along the way). Akhmediev and collaborators [1, 2] analyzed an initial-value problem for a different "modified" NLH; their numerical simulations also suggested that nonparaxiality arrests the singularity formation. Neither numerical approach [4] nor [1, 2], however, accounted for the effect of backscattering. Fibich [5] applied asymptotic analysis to derive an ODE in z for self-focusing in the presence of small nonparaxiality. His analysis suggests that nonparaxiality indeed arrests the singularity formation, resulting instead in decaying focusing-defocusing oscillations. However, backscattering effects were neglected in this asymptotic analysis.

The aforementioned studies [1,2,4,5,15] have prompted a general belief that nonparaxiality arrests the collapse. However, no rigorous proof of global existence for the NLH has ever been provided. Moreover, all the simulations in the above studies neglected the backscattering and considered only the forward-propagating field. The first numerical solutions of the NLH as a true boundary-value problem, with backscattering effects fully included, have been obtained by Fibich and Tsynkov in [12], using a high-order discretization supplemented by a new two-way artificial boundary condition (ABC). In that study only the case of one transverse dimension was considered, in order to keep the computational costs low. The simulations in [12] were performed for the values of the input power of up to 90% of the threshold N_c, and they have captured the mild self-focusing of the corresponding solutions. In a subsequent paper [10], we have corroborated experimentally the prediction of the asymptotic analysis that the magnitude of the backscattered signal scales quadratically with the nonparaxiality parameter f (see section 2.2), and that the computed NLH solutions converge to the corresponding NLS solutions as f goes to zero.

The numerical methodology of [12] was obviously not free of limitations of its own. Foremost, we could not obtain converging solutions for initial powers equal

to or higher than the critical value N_c. In [12], we considered initial powers only up to 90% of N_c; in the current paper we computed the NLH solutions for up to $N(0) = 0.99N_c$; see section 4. In the course of these simulations we have noticed that, as $N(0)$ approaches the critical power from below, the convergence rate of the iterations slows down noticeably. This makes the simulations for higher subcritical values of $N(0)$ ($0.99N_c < N(0) < N_c$) difficult to conduct, although it is reasonable to assume that the NLH solution will converge for input powers all the way up to N_c. However, for the input power $N(0)$ exactly equal to N_c the convergence of nonlinear iterations of [12] is lost; see section 4.

The aforementioned slowdown of convergence for input powers slightly below N_c should be attributed either to deficiencies of the method itself, or to the limits that insufficient computer resources may impose on the parameters that control the quality of the discrete approximation, or to both. As concerns the iteration method of [12], it is the most straightforward approach based on simply freezing the nonlinearity; most likely, it can be improved or replaced by a more advanced technique, and we plan on looking into this issue in the future. As for the computer resource requirements, they are determined by the size of the computational domain, which should be sufficiently large so as to meet the condition of near-linear propagation in the far field (see [12]), and by the grid size, which should be sufficiently fine to resolve a given wavelength and the sharp near-blowup profile. These requirements become more stringent for higher input powers, which decay at larger distances and/or undergo stronger focusing. In other words, the higher the input power, the larger the domain and/or the finer the grid that one needs to use in order to maintain the same solution quality and/or convergence rate. In our previous simulations we have, indeed, seen examples of diverging NLH solutions with subcritical input powers which converged on a larger computational domain and/or at a finer resolution. It is still unclear, however, whether having more computer resources and/or a better nonlinear iteration scheme will allow one to solve the NLH for initial conditions that lead to collapse in the NLS, or whether the convergence breakdown at $N(0) > N_c$ is an indication of the loss of solvability of the NLH or loss of regularity of the solution.

As such, in the current paper we explore *an alternative approach* to the issue of solving the NLH in the blowup regime of the NLS, by considering *the linearly damped NLH* and the corresponding *linearly damped NLS*. The addition of linear damping is not an ad hoc procedure. Indeed, an electromagnetic wave is always partially absorbed by the medium through which it propagates, an effect neglected in the original undamped NLH and NLS, both of which model the propagation under "ideal transparency." A mathematical motivation to add linear damping comes from the so-called *limiting absorption principle* that is used for identifying the unique solutions of the linear Helmholtz equation; see, e.g., [27]. It is known that the classical constant-coefficient homogeneous Helmholtz equation

$$\Delta E + k_0^2 E = 0 \tag{1.3a}$$

has nontrivial solutions on the entire space even in the class of functions that vanish at infinity, which obviously amounts to nonuniqueness. To fix the problem, the additional Sommerfeld boundary conditions need to be introduced at infinity that basically distinguish between the incoming and outgoing waves. On the other hand, when a complex absorption coefficient is added, the new damped equation

$$\Delta E + k_0^2(1 + i\delta)E = 0 \tag{1.3b}$$

has only trivial solution. Consequently, its inhomogeneous counterpart will be uniquely solvable for any compactly supported right-hand side in rather wide classes of functions, such as tempered distributions; see [27]. Moreover, when $\delta \longrightarrow \pm 0$, the unique solution of the inhomogeneous damped equation will *converge uniformly on the entire space* to the solution of the respective undamped equation that corresponds to either the radiation of waves toward infinity (outgoing waves) or, conversely, the incidence of waves from infinity (incoming waves), where the distinction is rendered by the sign of δ. This, in particular, implies that if we decide to keep a small but finite damping in the equation, we may expect its solution to be uniformly close to the solution of the undamped equation that is driven by the same source terms and is composed of either only outgoing or only incoming waves in the far field. The latter consideration is especially important in the context of our iteration algorithm (see section 3 and [12] for detail), which basically reduces to a repeated solution of the constant-coefficient Helmholtz equation driven by a variety of compactly supported right-hand sides and subject to the radiation boundary conditions in the far field.

Solving the damped NLH numerically as a true boundary-value problem required only minor changes in the algorithm of [12] for the undamped NLH, which are described in section 3. At the same time, *the addition of damping allows us to better control the solution.* In particular, damping decreases the solution magnitude in the far field, which is a key requirement for the validity of the ABCs of [12]. As a result, *we have been able to consider initial conditions with powers well above* N_{c}.

Let us recall that, for a given initial condition that leads to the blowup in the undamped critical NLS, there is a threshold value $\delta_{\mathrm{th}}^{\mathrm{S}}$ of the damping parameter δ such that if $\delta > \delta_{\mathrm{th}}^{\mathrm{S}}$, then linear damping arrests the collapse, whereas when $\delta < \delta_{\mathrm{th}}^{\mathrm{S}}$, the solution of the NLS blows up; see [6].[1] In the numerical simulations of the damped NLH reported hereafter we found a similar threshold value $\delta_{\mathrm{th}}^{\mathrm{H}}$ such that for $\delta > \delta_{\mathrm{th}}^{\mathrm{H}}$ the solution exists and is regular everywhere, whereas when $\delta < \delta_{\mathrm{th}}^{\mathrm{H}}$ the iteration scheme diverges. As has been mentioned, in the latter case it is not clear whether the divergence indicates that there is no solution to the NLH or that our computational resources are insufficient (or the iteration scheme is suboptimal) to calculate the solution. Therefore, we can conclude that the actual (analytical) threshold value $\hat{\delta}_{\mathrm{th}}^{\mathrm{H}}$, such that regular solutions to the NLH exist for all $\delta > \hat{\delta}_{\mathrm{th}}^{\mathrm{H}}$, is *less than or equal to* the computed threshold $\delta_{\mathrm{th}}^{\mathrm{H}}$, which is determined from the simulations, i.e., that $0 \le \hat{\delta}_{\mathrm{th}}^{\mathrm{H}} \le \delta_{\mathrm{th}}^{\mathrm{H}}$.

The main result of the current study is that

$$\delta_{\mathrm{th}}^{\mathrm{H}} < \delta_{\mathrm{th}}^{\mathrm{S}}.$$

In other words, for a given initial condition that leads to the blowup in the undamped NLS, there is an entire range of values for the damping coefficient, $\delta_{\mathrm{th}}^{\mathrm{H}} < \delta < \delta_{\mathrm{th}}^{\mathrm{S}}$, for which the damped NLS solution will blow up, but the NLH solution will be regular everywhere. Therefore, we can conclude that nonparaxiality and backscattering arrest the collapse when the damping parameter is in the range $\delta_{\mathrm{th}}^{\mathrm{H}} < \delta < \delta_{\mathrm{th}}^{\mathrm{S}}$. Whether NLH solutions exist for infinitely small linear damping as well, i.e., in the limit $\delta \longrightarrow 0$, is a question that yet remains to be answered. We believe, however, that this question

[1] Self-focusing in the critical NLS is highly sensitive to the effect of small perturbations. Some perturbations can arrest the collapse even if they are initially infinitesimally small [11]. In contrast, an infinitesimally small linear damping does not arrest the collapse, and a sufficient amount of damping must be present to regularize the solution.

should be considerably easier to address, both numerically and analytically, than the question of solvability of the original undamped NLH.

2. Formulation of the problem.

2.1. The nonlinear Helmholtz equation. A typical setup for the propagation of electromagnetic waves in a Kerr medium is shown in Figure 2.1. An incoming laser beam with known characteristics impinges normally on the planar interface $z = 0$ between the linear and the nonlinear medium. The electric field $E = E(z, \boldsymbol{x})$ is governed by the NLH (1.2). For simplicity, we consider the cylindrically symmetric case,[2] where $E = E(z, r)$ and $r = \sqrt{x_1^2 + \cdots + x_d^2}$. The nonlinear medium occupies the semispace $z \geq 0$ (see Figure 2.1). Consequently, the NLH (1.2) has to be supplemented by boundary conditions at $z = 0$ and $z \longrightarrow +\infty$. We require that as $z \longrightarrow +\infty$, E have no left-traveling components and that the propagation be diffraction-dominated, with the field amplitude decaying to zero, i.e., $\lim_{z\to\infty} \max_{0\leq r<\infty} |E(z, r)| = 0$, which also means that the nonlinear wavenumber $k^2 \equiv k_0^2(1 + \epsilon|E|^{4/d})$ approaches its linear limit: $\lim_{z\to+\infty} k^2 = k_0^2$. In other words, at large z's the solution should be a linear superposition of right-traveling waves. Since the actual numerical simulation is carried out on a truncated domain $0 \leq z \leq z_{\max}$ (Figure 2.1), the desired behavior of the solution as $z \longrightarrow +\infty$ has to be captured by a far-field ABC at the artificial boundary $z = z_{\max}$. This boundary condition should guarantee a reflectionless propagation of all the waves traveling towards $z = +\infty$. Often, boundary conditions designed to ensure the transparency of the outer boundary to the outgoing waves are called *radiation boundary conditions* [24].

The situation is more complex at the interface $z = 0$, where the total field $E(0, r)$ is composed of a given incoming (right-traveling) component $E_{\text{inc}}(0, r)$ and an unknown backscattered (left-traveling) component $E_{\text{scat}}(0, r)$, i.e.,

$$E(0, r) = E_{\text{inc}}(0, r) + E_{\text{scat}}(0, r).$$

As such, the boundary condition at $z = 0$ has to guarantee the reflectionless propagation of any left-traveling wave through the interface and at the same time be able

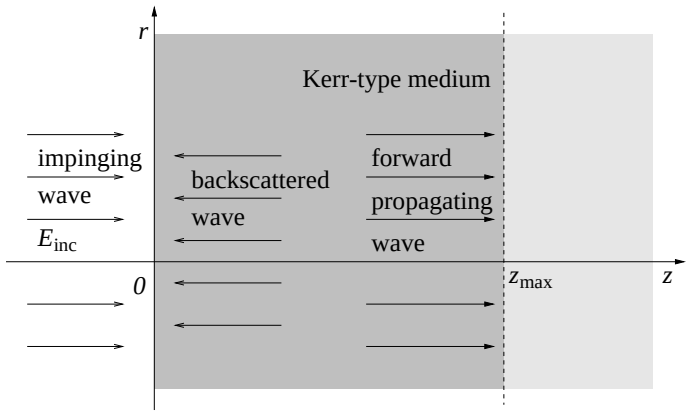

FIG. 2.1. *Schematic of propagation of waves in Kerr media.*

[2]This assumption is quite reasonable, since even when the initial conditions of the NLS are not cylindrically symmetric, near the singularity the solution becomes cylindrically symmetric [8].

to correctly prescribe the incoming signal. Implementation of such a *two-way ABC* was first carried out in [12] for the undamped NLS, and is extended to the damped case in section 3.3.

Finally, the electric field vanishes as $r \longrightarrow +\infty$. In practice, we truncate the domain at some large but finite $r_{\max}$ and require that $E(z, r_{\max}) = 0$. Similar approaches to the treatment of remote transverse artificial boundaries have been introduced and tested previously; see the discussion in the end of section 3.2. In order to avoid possible problems with reflections from the boundary $r = r_{\max}$, the computations of section 4 were conducted with $r_{\max}$ being 40 times larger than the radius of the impinging beam.

2.2. Paraxial approximation and the NLS. We first introduce the dimensionless quantities $\tilde{r}$, $\tilde{z}$, and ψ as

$$\tilde{r} = \frac{r}{r_0}, \quad \tilde{z} = \frac{z}{2L_{DF}}, \quad E = e^{ik_0 z}(\epsilon r_0^2 k_0^2)^{-d/4}\psi(z, r), \tag{2.1}$$

where r_0 is the transverse width of the input beam and $L_{DF} = k_0 r_0^2$ is the *diffraction length*. Then, by substituting the quantities (2.1) into the NLH (1.2) and dropping the tildes, we obtain

$$i\psi_z + \Delta_\perp \psi + |\psi|^{4/d}\psi = -4f^2\psi_{zz}, \tag{2.2}$$

where $f = 1/r_0 k_0 = \lambda/2\pi r_0$ is the *nonparaxiality parameter*.

The standard derivation of the NLS is motivated by the observation that $f \ll 1$, since typically $\lambda \ll r_0$. This suggests that one can neglect the ψ_{zz} term, i.e., apply the *paraxial approximation*, and obtain the NLS

$$i\psi_z(z, r) + \Delta_\perp \psi + |\psi|^{4/d}\psi = 0, \tag{2.3}$$

which is the same as the previously introduced (1.1), except that in (2.3) we use r instead of $\boldsymbol{x}$ for simplicity. The NLS (2.3) is supplemented by the initial condition at $z = 0$:

$$\psi(0, r) = (\epsilon r_0^2 k_0^2)^{d/4} E_{\text{inc}}(0, r).$$

Subsequently, it needs to be integrated by a "time"-marching algorithm, where the direction of propagation z plays the role of time. We reemphasize that *backscattering effects are not taken into account by the NLS* (2.3). Indeed, once (2.3) is solved, the overall solution, according to (2.1), is the slowly varying amplitude ψ times the forward-propagating oscillatory component $e^{ik_0 z}$.

2.3. Linear damping. When damping, i.e., linear absorption, is included, the NLH (1.2) becomes

$$\Delta E(z, \boldsymbol{x}) + k_0^2(1 + i\delta + \epsilon|E|^{4/d})E = 0, \tag{2.4}$$

where k_0 is the (real part of the) wavenumber,

$$\delta = \frac{\text{Im}(n_0^2)}{\text{Re}(n_0^2)},$$

and n_0 is the linear index of refraction of the medium. The corresponding NLS (2.3) becomes (see (2.1))

$$i\psi_z + \Delta_\perp \psi + |\psi|^{4/d}\psi + ir_0^2 k_0^2 \delta\psi = 0. \tag{2.5}$$

By definition, optical transparency of the medium means that the damping is small. For example, for water in the visible regime [14],

$$\frac{\mathrm{Im}(n_0^2)}{\mathrm{Re}(n_0^2)} \sim 10^{-7}.$$

Having small physical values of damping also agrees well with the mathematical reasoning behind the limiting absorption principle. As indicated in section 1 (see, e.g., [27] for detail), for a classical constant-coefficient Helmholtz operator of (1.3a), the introduction of a small complex absorption coefficient of the appropriate sign [as in (1.3b)] implies that there will be a unique solution for any compactly supported excitation, and that this solution will be uniformly close in the entire space $\mathbb{R}^{d+1}$ to the solution of the corresponding undamped linear Helmholtz equation driven by the same sources and subject to the radiation boundary conditions in the far field. In the following section 3, we show that for the formulation analyzed in this paper the proper sign of δ is positive.

As we have noted before, the physical case that corresponds to the propagation of laser beams in bulk Kerr media is $d = 2$. However, in order to reduce the complexity of the computations we rather consider a simpler case $d = 1$, as was previously done in [12]. Thus, the damped NLH for $E = E(z, r)$ and the damped NLS for $\psi = \psi(z, r)$ that are solved numerically in this study are

$$E_{zz}(z,r) + E_{rr} + k_0^2(1 + i\delta + \epsilon|E|^4)E = 0 \tag{2.6}$$

and

$$i\psi_z(z,r) + \psi_{rr} + ir_0^2k_0^2\delta\psi + |\psi|^4\psi = 0, \tag{2.7}$$

respectively.

3. Numerical methods. The damped NLH (2.6) is solved using fourth-order finite differences. The methodology of solution is outlined below in section 3.1; it is similar to the one that we have introduced in our previous work [12] for solving the undamped NLH. The choice of a higher-order method is motivated primarily by the necessity to resolve a small-scale phenomenon of backscattering at the background of the forward-propagating waves. Indeed, it is generally known that higher-order methods provide for a better resolution of waves. The damped NLS (2.7) is also solved using a fourth-order approximation in all coordinate directions. Since the Schödinger equation models the evolution of the slowly varying envelope, one can expect the magnitudes of the corresponding higher-order derivatives involved in the truncation error terms to be smaller for the NLS than for the NLH. This implies that on a grid of comparable size the accuracy of the numerical approximation for the NLS should be better than of those for the NLH. Moreover, in our simulations we typically employ finer grids for the NLS than those that we use for the NLH, thus obtaining an accurate numerical solution for the simpler model. It then serves as a natural reference point for the more "elaborate" NLH solution to be compared against.

3.1. Discretization of the NLH and solution methodology. We use a conventional fourth-order central-difference discretization for the Laplacian $\Delta = \partial_{zz} + \partial_{rr}$ of (2.6); thus the stencil is five nodes wide in each coordinate direction. As the equation is nonlinear, we implement a nested iteration scheme. On the outer loop, we freeze the nonlinearity, i.e., consider the coefficient $k^2 \equiv k_0^2(1 + i\delta + \epsilon|E|^4)$ as a given

function of the coordinates z and r, which is actually obtained by taking the quantity $|E|^4$ from the previous iteration; see (2.6). This way we arrive at a linear equation with variable coefficients. The latter is also solved by iterations on the inner loop of the nested scheme. Here, we leave the entire varying part of the equation, which is proportional to ϵ, on the lower level, and on the upper level need to invert only *the constant-coefficient linear damped Helmholtz operator* $\Delta + k_0^2(1+i\delta)\boldsymbol{I}$ (cf. (1.3b)).

Formally, our iteration scheme resembles the fixed-point approach; however, no rigorous convergence theory is available yet, and the convergence is assessed experimentally. The advantages of using these nested iterations are twofold. First, the method eventually reduces to the repeated solution of one and the same linear constant-coefficient equation driven by different source terms, which can be done efficiently at the discrete level. Second, the radiation boundary conditions at $z = z_{\max}$ and the two-way ABCs at $z = 0$ (see Figure 2.1) are most convenient to set on the upper time level of the iteration scheme already for the linear constant-coefficient operator.

To solve the linear constant-coefficient damped discrete Helmholtz equation

$$\Delta^{(h)}E + k_0^2(1+i\delta)E = g, \tag{3.1}$$

where g is the right-hand side generated on the previous iteration, we first separate the variables by implementing the discrete Fourier transform in the transverse direction r; the boundary conditions are symmetry at $r = 0$ and zero Dirichlet at $r = r_{\max}$ (see section 2.1). This yields a collection of fourth-order one-dimensional finite-difference equations (grid index n corresponds to the continuous variable z):

$$\frac{-\hat{E}_{n-2} + 16\hat{E}_{n-1} - 30\hat{E}_n + 16\hat{E}_{n+1} - \hat{E}_{n+2}}{12h_z^2} + (k_0^2(1+i\delta) - \lambda_m)\hat{E}_n = \hat{g}_n \tag{3.2}$$

parameterized by the dual Fourier variable λ_m; the latter is defined by formula (29) of [12]. Each equation (3.2) needs to be solved independently.[3] The two-way and radiation ABCs at $z = 0$ and $z = z_{\max}$, respectively, for the discrete equation (3.1) are set in the Fourier space, i.e., individually for each one-dimensional equation (3.2). This is done by first identifying the linearly independent eigenmodes for the homogeneous version of this equation. It is important to note that, even though the original differential equation is of the second order, we are using its fourth-order approximation, and thus each homogeneous discrete one-dimensional equation of type (3.2) has *four linearly independent solutions.* These solutions are q_1^n, q_1^{-n}, q_2^n, and q_2^{-n} (see [12]), where q_1, $1/q_1$, q_2, and $1/q_2$ are roots of the characteristic algebraic equation

$$-1 + 16q + (12h_z^2(k_0^2(1+i\delta) - \lambda_m) - 30)q^2 + 16q^3 - q^4 = 0. \tag{3.3}$$

3.2. Roots of the characteristic equation. It is indeed easy to see that (3.3) has two pairs of mutually inverse roots. We first notice that this equation originates from a central-difference, i.e., symmetric, discretization (3.2). Given that, if q is a root, then q^{-1} is obviously a root as well, which can be verified by direct substitution. Then, to actually find the roots we rewrite the polynomial on the left-hand side of (3.3) as

$$\begin{aligned}&(q-q_1)(q-q_1^{-1})(q-q_2)(q-q_2^{-1})\\ \equiv&-1 + (d_1+d_2)q - (2+d_1d_2)q^2 + (d_1+d_2)q^3 - q^4,\end{aligned}$$

[3]Note that the discrete equations (3.1) and (3.2) are very similar to the corresponding discrete equations studied in [12], except that previously we had no damping.

where

$$d_1 = q_1 + q_1^{-1}, \qquad d_2 = q_2 + q_2^{-1},$$

and match the coefficients. In so doing, we obtain

$$d_1 + d_2 = 16, \qquad -2 - d_1 d_2 = 12h_z^2(k_0^2(1+i\delta) - \lambda_m) - 30, \tag{3.4}$$

so that each pair of roots, q_1, q_1^{-1} and q_2, q_2^{-1}, can be found by solving the corresponding quadratic equation,

$$q^2 - d_1 q + 1 = 0 \tag{3.5a}$$

or

$$q^2 - d_2 q + 1 = 0, \tag{3.5b}$$

while the coefficients d_1 and d_2 are, in turn, determined by solving quadratic equations (3.4).

At this stage, the key difference between the current analysis for the damped equation and the previous analysis for the undamped equation of [12] needs to be emphasized. As shown in [12], when $\delta = 0$, the first pair of solutions of the homogeneous equation (3.2), q_1^n and q_1^{-n}, approximates the genuine "longitudinal," i.e., z-aligned, modes of the *undamped* homogeneous differential equation (1.3a):

$$\hat{E}_1 = e^{ik_c z} \quad \text{and} \quad \hat{E}_2 = e^{-ik_c z}, \tag{3.6}$$

respectively. The functions $\hat{E}_1 = \hat{E}_1(z)$ and $\hat{E}_2 = \hat{E}_2(z)$ are two linearly independent solutions of the ODE

$$\hat{E}_{zz} + (k_0^2 - \lambda)\hat{E} = 0 \tag{3.7}$$

obtained by Fourier transforming (1.3a) with respect to r; λ is the dual variable. In formulae (3.6), we have denoted $k_c = \sqrt{k_0^2 - \lambda}$, and a particular branch of the square root that we always take is $\sqrt{\rho e^{i\theta}} = \rho^{1/2} e^{i\theta/2}$. The two continuous modes (3.6) may be either traveling or evanescent waves, depending on whether the real quantity $k_c^2 = (k_0^2 - \lambda)$ is positive or negative, or in other words, whether the dual Fourier variable λ is less or greater than k_0^2. To demonstrate the aforementioned approximation property for the undamped ($\delta = 0$) discretization (3.2), we redefine $k_c = \sqrt{k_0^2 - \lambda_m}$, introduce $\alpha = h_z^2 k_c^2$, and show in [12] that if $\alpha > 0$, then q_1 and q_1^{-1} are complex conjugate roots of the characteristic equation (3.3). Both these roots have unit magnitude $|q_1| = |q_1^{-1}| = 1$, which indicates that q_1^n and q_1^{-n} are pure discrete traveling waves. Moreover, if $\alpha \ll 1$, then (see [12])

$$q_1 = e^{ik_c h_z} + \mathcal{O}((k_c h_z)^5), \qquad q_1^{-1} = e^{-ik_c h_z} + \mathcal{O}((k_c h_z)^5). \tag{3.8}$$

Equalities (3.8) imply that in the undamped case $\delta = 0$, q_1^n is a discrete counterpart of the right-traveling wave $\hat{E}_1$, and q_1^{-n} is a discrete counterpart of the left-traveling wave $\hat{E}_2$; the approximation is obviously fourth-order accurate because on the grid $z_n = h_z n$. If $\alpha < 0$ and still $\delta = 0$, then we again show in [12] that $|q_1| < 1$ and $|q_1^{-1}| > 1$, which indicates that q_1^n is a right-evanescent wave and q_1^{-n} is a left-evanescent wave.

The situation changes drastically with the introduction of damping. In contradistinction to the undamped case, when $\delta \neq 0$ the homogeneous differential equation no longer has pure propagating, i.e., constant-amplitude, longitudinal modes. Indeed, by Fourier transforming equation (1.3b) in the r direction, we arrive at the family of ODEs

$$\hat{E}_{zz} + (k_0^2(1+i\delta) - \lambda)\hat{E} = 0 \tag{3.9}$$

parameterized by the dual variable λ. Each of the equations (3.9) has two linearly independent solutions:

$$\begin{aligned} \hat{E}_1 &= e^{iz\sqrt{k_c^2+ik_0^2\delta}} = e^{ik_cz\sqrt{1+i\frac{k_0^2}{k_c^2}\delta}}, \\ \hat{E}_2 &= e^{-iz\sqrt{k_c^2+ik_0^2\delta}} = e^{-ik_cz\sqrt{1+i\frac{k_0^2}{k_c^2}\delta}}. \end{aligned} \tag{3.10}$$

Clearly, the second equality in each formula (3.10) is valid only if $k_c \neq 0$. Formulae (3.10) show that, as long as $\delta \neq 0$, there will always be a nontrivial real part in each exponent. Consequently, the amplitudes of the waves (3.10) *will always decrease or increase exponentially* for $z \longrightarrow \pm\infty$. In particular, if we analyze the traveling waves regime of the undamped equation, i.e., the case of small λ: $k_0^2 - \lambda > 0$, and additionally assume that $|\delta| \ll 1$, then formulae (3.10) yield (cf. formulae (3.6))

$$\begin{aligned} \hat{E}_1^{(\text{damped})} &\approx e^{ik_cz\left(1+i\frac{1}{2}\frac{k_0^2}{k_c^2}\delta\right)} = e^{ik_cz-\frac{1}{2}\frac{k_0^2}{k_c}\delta z} = \hat{E}_1^{(\text{undamped})} \cdot e^{-\frac{1}{2}\frac{k_0^2}{k_c}\delta z}, \\ \hat{E}_2^{(\text{damped})} &\approx e^{-ik_cz\left(1+i\frac{1}{2}\frac{k_0^2}{k_c^2}\delta\right)} = e^{-ik_cz+\frac{1}{2}\frac{k_0^2}{k_c}\delta z} = \hat{E}_2^{(\text{undamped})} \cdot e^{\frac{1}{2}\frac{k_0^2}{k_c}\delta z}. \end{aligned} \tag{3.11}$$

Since we identify $\hat{E}_1^{(\text{undamped})} = e^{ik_cz}$ of (3.6) as the right-traveling wave, and $\hat{E}_2^{(\text{undamped})} = e^{-ik_cz}$ of (3.6) as the left traveling wave, we can conclude that to have the propagation toward infinity (i.e., the radiation of waves) accompanied by *the decay of the amplitude* (as opposed to growth with no bound), we have to take *positive values of the damping factor* $\delta > 0$ (cf. section 1). In this case, the amplitude of $\hat{E}_1^{(\text{damped})}$ will decay exponentially for $z \longrightarrow +\infty$ (propagation to the right), and the amplitude of $\hat{E}_2^{(\text{damped})}$ will decay exponentially for $z \longrightarrow -\infty$ (propagation to the left). As one can easily see from (3.11), the rate of decay is controlled by the value of δ.

In connection to the aforementioned exponential behavior of the longitudinal modes, a more general fact is also worth mentioning. The full Fourier symbol of the undamped operator of (1.3a) obviously has real roots on the dual plane; these roots occupy the entire circle of radius k_0 centered at the origin. In contradistinction to that, the symbol of the damped operator of (1.3b) *does not have real roots* on the dual plane. As shown in [20], the damped operator will therefore have an exponentially decaying fundamental solution. In practical terms it means that the outgoing waves governed by the damped Helmholtz equation will decay exponentially toward infinity in all directions. For comparison we recall that the fundamental solution of the undamped operator is given by a zero-order Hankel function, which only decays at infinity as the inverse square root of the distance from the origin.

To establish the properties of the propagating modes for the discretization (3.2) in the presence of damping, and to demonstrate similarities to the continuous damped case, we first introduce and prove the following result.

PROPOSITION 3.1. *The characteristic equation* (3.3) *for* $\delta \neq 0$ *does not have roots with unit magnitude.*

Proof. Let us assume the opposite: There exists a unit magnitude root $q = e^{i\theta}$ to the algebraic characteristic equation (3.3). Then,

$$\begin{aligned} -1 + 16e^{i\theta} + (12h_z^2(k_0^2(1+i\delta) - \lambda_m) - 30)e^{2i\theta} + 16e^{3i\theta} - e^{4i\theta} \\ = \left[-e^{-2i\theta} + 16e^{-i\theta} + (12h_z^2(k_0^2(1+i\delta) - \lambda_m) - 30) + 16e^{i\theta} - e^{2i\theta}\right] \cdot e^{2i\theta} \\ = \left[-2\cos(2\theta) + 32\cos\theta + (12h_z^2(k_0^2(1+i\delta) - \lambda_m) - 30)\right] \cdot e^{2i\theta} = 0. \end{aligned}$$

As $e^{2i\theta} \neq 0$, the expression in rectangular brackets has to be equal to zero. Since the only imaginary contribution to this expression is proportional to δ, we conclude that it is only possible when $\delta = 0$. ∎

Proposition 3.1 implies that, similarly to the continuous case, there will be no constant-amplitude solutions to the homogeneous counterpart of the discrete equation (3.2). Each of the four corresponding modes, q_1^n, q_1^{-n}, q_2^n, and q_2^{-n}, will exponentially decrease in one direction and exponentially increase in the opposite direction. In particular, if we assume as before that $\alpha \ll 1$ in the undamped traveling waves regime,[4] and if we in addition let $\delta \ll 1$, then, solving (3.4) for d_1 first, then (3.5a) for q_1 and q_1^{-1}, and finally using the Taylor expansion, we obtain (cf. (3.8))

$$\begin{aligned} q_1 &= e^{ik_c h_z - \frac{1}{2}\frac{k_0^2}{k_c}\delta h_z} + \mathcal{O}\left(\left[k_c h_z\left(1 + i\frac{1}{2}\frac{k_0^2}{k_c^2}\delta\right)\right]^5\right), \\ q_1^{-1} &= e^{-ik_c h_z + \frac{1}{2}\frac{k_0^2}{k_c}\delta h_z} + \mathcal{O}\left(\left[k_c h_z\left(1 + i\frac{1}{2}\frac{k_0^2}{k_c^2}\delta\right)\right]^5\right). \end{aligned} \tag{3.12}$$

Equalities (3.12) mean that the damped discrete traveling waves q_1^n and q_1^{-n} approximate the damped continuous waves (3.11) with the fourth order of accuracy. This result is obviously similar to the one obtained in the undamped case; see formulae (3.8).

Thus far, our discussion has focused on the first pair of roots q_1 and q_1^{-1} of the characteristic equation (3.3), because these roots correspond to the genuine modes of the original differential equation. The second pair of roots q_2 and q_2^{-1} is obtained by solving (3.4) for d_2 and subsequently solving (3.5b). The corresponding pair of solutions q_2^n and q_2^{-n} is, of course, a pure numerical artifact. In [12] we have shown that for $\delta = 0$ the roots q_1 and q_1^{-1} cannot have unit magnitude: $|q_2| < 1$ and $|q_2^{-1}| > 1$, which means that the waves q_2^n and q_2^{-n} are always evanescent. In the damped case, Proposition 3.1 implies that these waves will remain evanescent as well. The presence of the second pair of waves, however, implies that the discrete equation requires two more boundary conditions compared to the original differential equation.

In section 1, we have outlined a general two-fold motivation behind the introduction of damping into the Helmholtz equation. One part was coming from physics because absorption by the medium always accompanies the propagation of electromagnetic waves in real-life settings. Moreover, from the standpoint of mathematics the introduction of damping helps select a unique solution using the limiting absorption principle. Besides these two key reasons, the presence of damping in the equation also positively affects the properties of the numerical algorithm.

[4] This would also imply $\frac{k_0^2}{k_c}h_z \ll 1$ because λ_m is small and $k_c \sim k_0$.

First, *having no roots of unit magnitude presents a significant advantage from the viewpoint of numerical stability.* In this case, every discrete system (3.2), supplemented by the boundary conditions that are discussed below in section 3.3, will be well posed in the classical sense of [13, 21]. In contrast to that, in the original undamped case existence of the roots with unit magnitude may, generally speaking, cause a weak polynomial growth of the error when the grid size is refined, although no major exponential instability will be possible.

We recall that the original formulation of the problem requires that $E(z, r)$ vanish as $|r| \longrightarrow \infty$. Instead, when solving the problem numerically, we set $E(z, r) = 0$ at a large but still finite distance $r = r_{\max}$. Of course, we expect that on some fixed bounded region of interest located next to the axis of the propagating beam our solution will converge to the original infinite-domain solution with the increase of $r_{\max}$. A general methodology for solving infinite-domain problems based on a similar idea was first introduced and studied in [22, 23, 25, 26] in the context of fluid flow. It was shown, in particular, that one may obtain the convergence rate inversely proportional to the square of the domain size (i.e., $\sim 1/r_{\max}^2$ using our particular notations). Besides, for a specific example that involves the Laplace equation that transforms into a Yukawa equation by introducing small "dissipation," Mishkov and Ryaben'kii have shown in [18] that one may expect a much faster convergence of the damped solution to the undamped one on a fixed-size domain rather than on the original unbounded domain. Even though the formulation of the problem in [18] is not quite the same as the one analyzed here, there are still similarities that allow us to consider the results of [18] as another argument for using the damped equation.

3.3. Boundary conditions. Apart from the foregoing key difference in the properties of the roots of (3.3) in the undamped and damped case (see section 3.2), the algorithm for solving the damped NLH remains basically the same as the undamped algorithm of [12]. Each equation (3.2) needs to be supplemented by the radiation boundary conditions at $z = z_{\max}$ and two-way ABCs at $z = 0$.

The *radiation boundary conditions* are constructed by requiring that on the right boundary $z = z_{\max}$ the solution of (3.2) be composed of only the waves that propagate/decay to the right, i.e., $\hat{E}_n = c_1 q_1^n + c_2 q_2^n$. The selection is rendered by the so-called one-way discrete Helmholtz equation [12], which is a linear homogeneous relation that defines the span of all the appropriate modes. Specifically, let us consider (3.2) on the grid $n = 0, 1, \ldots, N-1, N$, and assume that the right-hand side $\hat{g}_n$ is small and can therefore be neglected near the right boundary $n = N$, i.e., that *the propagation is almost linear in the far field.* Then, we require that the vector $[\hat{E}_{N-3}, \hat{E}_{N-2}, \hat{E}_{N-1}, \hat{E}_N]^T$ be a linear combination of the two vectors $[q_1^{N-3}, q_1^{N-2}, q_1^{N-1}, q_1^N]^T$ and $[q_2^{N-3}, q_2^{N-2}, q_2^{N-1}, q_2^N]^T$, which obviously translates into

$$\text{Rank} \begin{bmatrix} \hat{E}_{N-3} & \hat{E}_{N-2} & \hat{E}_{N-1} & \hat{E}_N \\ 1 & q_1 & q_1^2 & q_1^3 \\ 1 & q_2 & q_2^2 & q_2^3 \end{bmatrix} = 2. \tag{3.13}$$

Relation (3.13) is, in turn, equivalent to the two scalar equalities

$$q_1 q_2 \hat{E}_{N-3} - (q_1 + q_2)\hat{E}_{N-2} + \hat{E}_{N-1} = 0, \tag{3.14a}$$

$$q_1 q_2 \hat{E}_{N-2} - (q_1 + q_2)\hat{E}_{N-1} + \hat{E}_N = 0, \tag{3.14b}$$

which constitute *the one-way-to-the-right discrete Helmholtz equation.* Relations (3.14a) and (3.14b) supplement the scheme (3.2) at $n = N - 1$ and $n = N$, respec-

tively, i.e., at the two near-edge nodes of the grid where the regular five-point-wide stencil of (3.2) cannot be applied.

The *two-way ABC* at $z = 0$ also has to possess the capability of radiation boundary conditions, i.e., it has guarantee the transparency of the interface for all the waves that propagate/decay to the left. In other words, we require that at the left boundary the outgoing, i.e., scattered, waves be given by $\hat{E}_n^{(\mathrm{scat})} = c_1 q_1^{-n} + c_2 q_2^{-n}$. Assuming for a second the homogeneity $\hat{g}_n = 0$ near $n = 0$, we could obtain, similarly to (3.13),

$$\mathrm{Rank} \begin{bmatrix} \hat{E}_0^{(\mathrm{scat})} & \hat{E}_1^{(\mathrm{scat})} & \hat{E}_2^{(\mathrm{scat})} & \hat{E}_3^{(\mathrm{scat})} \\ 1 & q_1^{-1} & q_1^{-2} & q_1^{-3} \\ 1 & q_2^{-1} & q_2^{-2} & q_2^{-3} \end{bmatrix} = 2. \tag{3.15}$$

Relation (3.15), again, is equivalent to *the one-way-to-the-left discrete Helmholtz equation:*

$$\hat{E}_0^{(\mathrm{scat})} - (q_1 + q_2)\hat{E}_1^{(\mathrm{scat})} + q_1 q_2 \hat{E}_2^{(\mathrm{scat})} = 0, \tag{3.16a}$$

$$\hat{E}_1^{(\mathrm{scat})} - (q_1 + q_2)\hat{E}_2^{(\mathrm{scat})} + q_1 q_2 \hat{E}_3^{(\mathrm{scat})} = 0. \tag{3.16b}$$

Equations (3.16a), (3.16b), however, cannot be immediately used as the ABC at $z = 0$ because the foregoing assumption of homogeneity near the interface is, generally speaking, not correct, and moreover, (3.16a), (3.16b) do not account for the incoming wave at $z = 0$ (see section 2.1), i.e., do not have the important two-way capability. The analysis of [12] shows that to accurately address both issues, i.e., the inhomogeneity that comes from the previous iteration and the presence of the incoming wave, it is sufficient to introduce particular modifications to the right-hand side g_n at only two nodes: $n = 0$ and $n = 1$. The corresponding modification due to the incoming signal is obtained by simply substituting the right-traveling incoming wave $\hat{E}_0^{(\mathrm{inc})} q_1^n$ into the one-way-to-the-left Helmholtz equation (3.16a), (3.16b). Altogether, the two-way ABCs at $z = 0$ are given by (cf. formulae (3.16a), (3.16b))

$$\hat{E}_0 - (q_1 + q_2)\hat{E}_1 + q_1 q_2 \hat{E}_2 = \hat{g}_0', \tag{3.17a}$$

$$\hat{E}_1 - (q_1 + q_2)\hat{E}_2 + q_1 q_2 \hat{E}_3 = \hat{g}_1', \tag{3.17b}$$

where a prime denotes the aforementioned modification of the right-hand side; see [12]. Again, relations (3.17a) and (3.17b) supplement the scheme (3.2) at the near-edge nodes $n = 0$ and $n = 1$, respectively, where the regular five-point stencil cannot be applied. Straightforward considerations based on the linear superposition principle and uniqueness (see [12]) guarantee that inhomogeneous relations (3.17a), (3.17b) correctly specify the incoming signal at $z = 0$ and still ensure the reflectionless propagation of all the outgoing waves through $z = 0$ toward $z = -\infty$.

3.4. Computational complexity. The computational complexity of one solution of (3.1) is $\mathcal{O}(N_z N_r \ln N_r)$ operations, where N_z and N_r are the corresponding grid dimensions. Indeed, the cost of solving each of the N_r one-dimensional systems (3.2) is linear with respect to N_z, because each of these systems needs to be solved repeatedly for multiple right-hand sides. As such, the sparse LU decomposition can be performed only once ahead of time, and the cost of backward substitution is linear. Therefore, the overall complexity is dominated by the cost of N_z direct and inverse FFTs of length N_r, which is $\mathcal{O}(N_z N_r \ln N_r)$.

For the specific discretization parameters provided in section 4, the numbers of iterations could vary significantly. The borderline cases, i.e., those with the minimal damping necessary to allow the algorithm to converge, could take as many as a thousand iterations to reduce the initial relative difference between two successive iterations by three to four orders of magnitude. In contrast, the cases that involved damping substantially larger than the required minimum could converge to machine zero (fifteen orders of magnitude reduction) in as little as two hundred iterations.

4. Results. In this section we present simulation results for the Gaussian initial conditions $E^0_{\rm inc} = \exp(-r^2)$ and $\psi_0 = (\epsilon r_0^2 k_0^2)^{1/4} \exp(-r^2/r_0^2)$ for the NLH and NLS, respectively. Denoting, as before, the input power of the incoming wave by $N(0)$, we define *the fractional input power* as

$$p = \frac{N(0)}{N_{\rm c}}, \tag{4.1}$$

i.e., $p = 1$ when the input power is equal to the NLS critical power $N_{\rm c}$. For the Gaussian initial conditions used in our simulations, $p = k_0\sqrt{2\epsilon/3\pi}$ (see [12]). In all simulations we set $k_0 = 8$ and $r_0 = 1$.

In Table 4.1 we show the calculated threshold values $\delta^{\rm H}_{\rm th}$ and $\delta^{\rm S}_{\rm th}$. The quantity $\delta^{\rm H}_{\rm th}$ in Table 4.1 represents the smallest nonnegative value of δ for which we obtain a global solution of the NLH. By this we mean that the nonlinear iterations converge in the sense that the value of $\max_{z,r}(E^{(n+1)} - E^{(n)})/\max_{z,r} E^{(n+1)}$ drops by at least a factor of 10^{-6} in the course of iterations on the computational domain $0 \le z \le 40$ and $0 \le r \le 40$, with grid sizes $h_z = \lambda/20$ and $h_r = \lambda/8$, where $\lambda = 2\pi/k_0$. The particular choice of the domain size and grid resolution is "inherited" from our previous numerical experiments; see [10,12]. The values of $\delta^{\rm H}_{\rm th}$ in Table 4.1 are obtained with at least two significant digits by repeatedly running the code for a given ϵ and varying δ, which allows one to "close in" on the threshold. However, as discussed in section 1, with a larger computational domain and/or a finer grid it may be possible to obtain regular solutions for smaller values of δ, hence, to obtain a lower value of the threshold $\delta^{\rm H}_{\rm th}$. For example, using the same computational domain and twice as fine a grid, $h_z = \lambda/40$ and $h_r = \lambda/16$, we could obtain $\delta^{\rm H}_{\rm th} = 0.0133$ instead

TABLE 4.1
Threshold values of linear damping δ.

13	0.5	261%	0.058	0.065

of $\delta_{\rm th}^{\rm H} = 0.0145$ for the data in row 10 of Table 4.1 ($\epsilon = 0.2$). Likewise, using the original grid resolution $h_z = \lambda/20$ and $h_r = \lambda/8$ and a computational domain that was twice as large, $z_{\max} = 80$ and $r_{\max} = 80$, we could obtain $\delta_{\rm th}^{\rm H} = 0.0022$ instead of $\delta_{\rm th}^{\rm H} = 0.0027$ for the data in row 7 of Table 4.1 ($\epsilon = 0.1$). In other words, the values of $\delta_{\rm th}^{\rm H}$ from Table 4.1 should be considered *upper bounds* for the actual thresholds. However, the quantitative limits of pursuing this venue are still unexplored, i.e., it is not known how far down in $\delta_{\rm th}^{\rm H}$ one can go by increasing the domain size and/or grid resolution. Our ability to answer this question is obviously limited by computer resources, and as of yet *the question remains open.* In particular, it is unclear whether we can achieve $\delta_{\rm th}^{\rm H} = 0$ by choosing a sufficiently large domain and/or fine grid.

Similarly, the quantity $\delta_{\rm th}^{\rm S}$ in Table 4.1 represents the smallest nonnegative value of damping δ for which the NLS solution does not blow up. In our NLS simulations we use standard fourth-order finite-difference schemes for the spatial derivatives and explicit fourth-order Runge–Kutta for marching in z. As has recently been shown in [9], in finite-difference simulations of NLS solutions that are known analytically to become singular, the computed solution still remains bounded. Therefore, there is always an element of arbitrariness in selecting a numerical criterion for blowup in NLS simulations. In our NLH simulations the largest relative increase in amplitude due to self-focusing has never exceeded a factor of two. In order to make the blowup criteria in NLH and NLS simulations as close to one another as possible, we define the computed NLS solution as becoming singular once its amplitude increases by a factor of two. We checked that altering this NLS blowup criterion leads to only minor changes in the results for $\delta_{\rm th}^{\rm S}$. For example, using the blowup criterion of relative focusing by a factor of 4, rather than 2, for $\epsilon = 0.08$ (row 6 of Table 4.1) gives $\delta_{\rm th}^{\rm S} = 0.00021$ instead of $\delta_{\rm th}^{\rm S} = 0.00025$; and using this new criterion for $\epsilon = 0.15$ (row 9 of Table 4.1) yields $\delta_{\rm th}^{\rm S} = 0.0089$ instead of $\delta_{\rm th}^{\rm S} = 0.010$. In particular, this change does not affect our main finding of initial conditions for which $\delta_{\rm th}^{\rm H} < \delta_{\rm th}^{\rm S}$.

As expected, for both the NLS and the NLH the threshold values of δ increase with ϵ (i.e., a larger amount of damping is needed to arrest collapse of beams with higher input power). For $\epsilon = 0.06$ and $\epsilon = 0.07$ the input power is below critical. Therefore, both the NLS and the NLH have global solutions for $\delta = 0$. This behavior for the NLH holds (at least) until $\epsilon = 0.072165819$, which corresponds to the last subcritical value[5] that we have checked, $N(0)$ being equal to 99% of $N_{\rm c}$.

Starting from $\epsilon = 3\pi/2k_0^2 \approx 0.073631077$, which corresponds exactly to $N(0) = N_{\rm c}$, the NLH requires a certain positive amount of damping δ to maintain the regularity of the solution. For the NLS, the solution with no damping remains regular until $\epsilon = 0.75$, which corresponds to $p = N(0)/N_{\rm c} = 1.009$. Indeed, it is known that $N_{\rm c}$ is only a *lower bound* for the threshold power for NLS collapse, and that any initial condition which does blow up, and whose amplitude $|\psi_0|$ is not equal to the ground state profile $3^{1/4}\sqrt{\mathrm{sech}(2r)}$, has power strictly above $N_{\rm c}$ (see [7, 16, 17]). In our simulations we have discovered that for $\epsilon = 3\pi/2k_0^2$, which is the critical value for the NLH, as well as for the moderately supercritical values $\epsilon = 0.075$, $\epsilon = 0.08$, and $\epsilon = 0.1$, when the input power $N(0)$ is only slightly above $N_{\rm c}$, the threshold damping for the NLH is larger[6] than that for the NLS: $\delta_{\rm th}^{\rm H} > \delta_{\rm th}^{\rm S}$. However, for input powers that are equal to or higher than $1.30N_{\rm c}$ (which corresponds to $\epsilon = 0.125$) this trend

[5] As mentioned in section 1, for larger subcritical values of $N(0)$ the convergence of nonlinear iterations becomes prohibitively slow.

[6] We recall that the values of $\delta_{\rm th}^{\rm H}$ in Table 4.1 are only upper bounds for the threshold; lower values may be obtained by refining the grid and/or enlarging the computational domain.

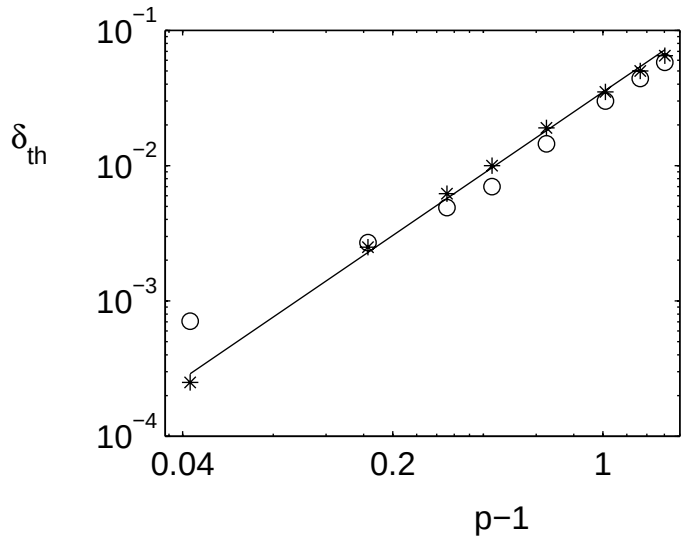

FIG. 4.1. *Threshold values* $\delta_{\rm th}^{\rm H}$ *(open circles "∘") and* $\delta_{\rm th}^{\rm S}$ *(asterisks "∗") as a function of* $(p-1)$ *for the data in Table* 4.1. *The solid line* $0.035(p-1)^{1.517}$ *is the best fit to the values of* $\delta_{\rm th}^{\rm S}$.

reverses (see Table 4.1), and we obtain $\delta_{\rm th}^{\rm H} < \delta_{\rm th}^{\rm S}$. Thus, for $N(0) \geq 1.30N_{\rm c}$,[7] there must be other mechanisms in the NLH not present in the NLS that help suppress the formation of singularity in the solution. Therefore, we may conclude that in this regime *nonparaxiality and backscattering help arrest collapse of nonlinear waves.*[8]

In [6] Fibich has used asymptotic analysis to show that

$$\delta_{\rm th}^{\rm S} \sim c(p-1)^{3/2}, \tag{4.2}$$

where p is the fractional critical power (4.1). In Figure 4.1 we put this theoretical prediction to a test by plotting the values of $\delta_{\rm th}^{\rm S}$ and $\delta_{\rm th}^{\rm H}$ as a function of $(p-1)$. When we computed the best fit of the values of $\delta_{\rm th}^{\rm S}$ with the two-parameter family of curves $\delta_{\rm th} = c(p-1)^{\alpha}$, we obtained $\alpha = 1.517$, which is in excellent agreement with formula (4.2). Relation (4.2) also provides a good approximation to the data points $\delta_{\rm th}^{\rm H}$; see Figure 4.1. The only exception is the lowest-power NLH data point in Figure 4.1 that corresponds to $\epsilon = 0.08$ (row 6 in Table 4.1), for which the value of $\delta_{\rm th}^{\rm H}$ has most likely been overpredicted numerically because of the computational constraints discussed previously.

In Figure 4.2 we plot the on-axis ($r = 0$) amplitudes of the NLH and NLS solutions for $\epsilon = 0.2$ and various values of δ. The on-axis behavior is most representative of the physical processes that we are studying, because for symmetric beams this is the location of the peak intensity. When $\delta = \delta_{\rm th}^{\rm H} = 0.0145$, the NLH solution exists globally, but the NLS solution becomes singular at a finite propagation distance. As the value of damping increases, both the NLS and the NLH solutions undergo less

[7] More precisely, $N(0)$ higher than some value between $1.16N_{\rm c}$ and $1.30N_{\rm c}$.

[8] The fact that for the input values just above the critical power we do not observe nonparaxiality and backscattering helping arrest the collapse is apparently the "continuation" of the fact that we have been unable yet to solve the undamped NLH for $N(0) \geq N_{\rm c}$, even though the NLS solution exists globally for $N(0) \leq 1.009N_{\rm c}$. The reasons are probably the same in both cases; those for the latter have already been discussed in the section 1.

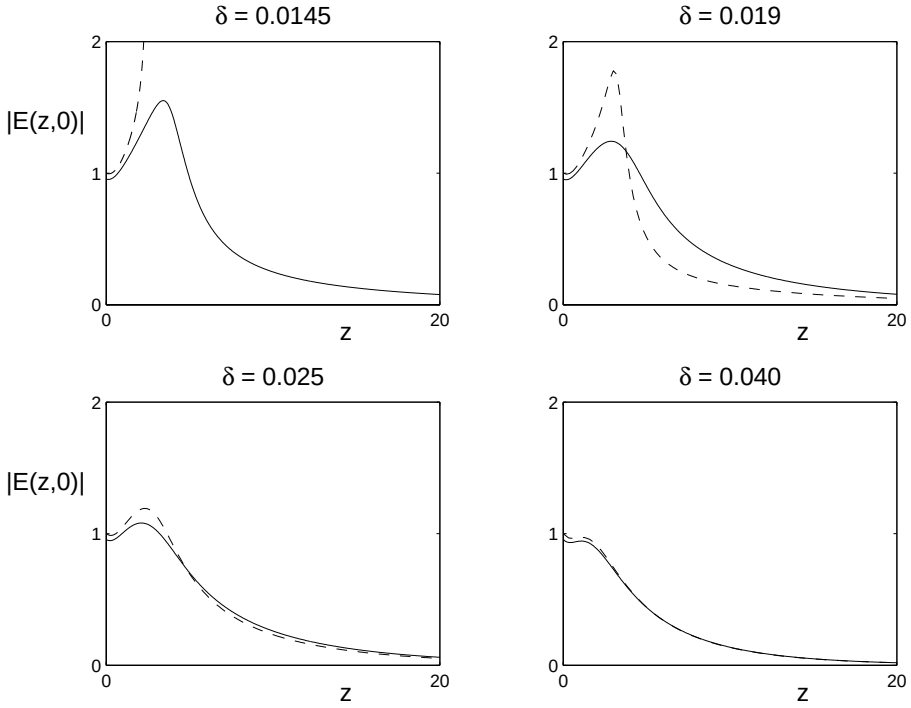

FIG. 4.2. *On-axis amplitude of NLH (solid) and NLS (dashes) solutions for* $\epsilon = 0.2$ *and various values of* δ.

focusing. For all the cases for which both solutions remain regular, the NLS solution curve is higher than the NLH one from $z = 0$ until its maximum, i.e., the point of the arrest of collapse. This provides additional support to the foregoing conclusion that nonparaxiality and backscattering arrest collapse of nonlinear waves. Note that after the collapse has been arrested, the NLS solution becomes lower than that of the NLH. One possible explanation for this is that the NLS solution is undergoing higher focusing, and hence it loses more power due to damping.

We emphasize that at $z = 0$ the NLH solution is not equal to $E^0_{\rm inc}$; see Figure 4.2. The difference between the two is due to backscattering and can be used to quantify the level of backscattering for a particular setting; see [10, 12].[9] In Table 4.2 we provide the values of maximum self-focusing and maximum backscattering in the NLH, defined as $\max_{r,z} |E(z,r)|$ and $\max_r |E(0,r) - E^0_{\rm inc}(r)|$, respectively, for various values of ϵ and δ. The dash "—" in a particular cell of Table 4.2 means that the level of damping was insufficient to guarantee the convergence of the numerical algorithm. As expected, for a given level of damping δ, the NLH solution undergoes stronger self-focusing as the nonlinearity coefficient ϵ increases. The level of backscattering also increases with the increase of ϵ. As also expected, for a given input power ϵ, when the damping δ increases, the NLH solution undergoes weaker self-focusing (see Figure 4.2).

[9] There are, in fact, two phenomena that account for the discrepancy between the NLH and NLS curves: nonparaxiality of the forward propagating wave and backscattering. Because the problem is nonlinear, these two mechanisms cannot be easily and explicitly told apart inside the domain. The only location where we can clearly say that the difference is purely due to backscattering is the "inflow" interface $z = 0$; see [10].

TABLE 4.2
Maximum absolute levels of self-focusing and backscattering in the NLH for a variety of ϵ and δ.

	Maximum self-focusing			Maximum backscattering		
	$\delta = 0.0145$	$\delta = 0.0175$	$\delta = 0.0210$	$\delta = 0.0145$	$\delta = 0.0175$	$\delta = 0.0210$

$\epsilon = 0.225$	—	—	1.3242	—	—	0.0509

TABLE 4.3
Maximum absolute levels of self-focusing and backscattering in the NLH for $\epsilon = 0.2$.

Case No.	Damping δ	Max. self-focusing	Max. backscattering
1	0.0145	1.5515	0.0465
2	0.0147	1.5296	0.0465
3	0.0150	1.4992	0.0465
4	0.0155	1.4538	0.0465
5	0.0160	1.4135	0.0466
6	0.0165	1.3776	0.0466
7	0.0170	1.3451	0.0466
8	0.0175	1.3158	0.0466
9	0.0180	1.2892	0.0466
10	0.0190	1.2428	0.0466
11	0.0200	1.2041	0.0466
12	0.0210	1.1716	0.0467

Surprisingly, however, *changing the value of damping δ has very little or no effect on the level of backscattering.* To further corroborate this observation, we picked a particular value of the nonlinearity coefficient, $\epsilon = 0.2$, and ran an additional series of numerical tests with a substantially finer sampling for δ. These results, which are presented in Table 4.3, confirm that backscattering is not affected by linear damping. This phenomenon certainly cannot be explained by saying that linear damping has an overall negligible effect, since its effect on the focusing dynamics can be clearly seen through the changing values of the maximum focusing both in Table 4.2 and in Figure 4.2. At present, we have no good explanation for this surprising observation.

5. Concluding remarks. The question of whether nonparaxiality and backscattering may arrest collapse of nonlinear waves has been open for many years. While the answer to this question is probably positive, no conclusive argument toward it, whether analytical or numerical, has been previously available in the literature. In this study we addressed this question within the framework of the linearly damped NLH and NLS. As has been mentioned, the addition of linear damping is not ad hoc, because it has both physical and mathematical motivation. Methodologically, linear damping provides a very useful "extra dimension" that allows us to efficiently control the solutions of the NLH and NLS. Specifically, the variation along this extra dimension has helped us to numerically identify the regimes for which the NLS solution blows up, while the NLH solution remains regular. In other words, our results furnish the first ever definite numerical evidence that *nonparaxiality and backscattering can arrest collapse.* The question of whether regular solutions to the NLH still exist in the absence of damping remains open. However, we hope that the arguments based on linear damping and the limiting absorption principle may be useful for proving global existence and uniqueness, both for the damped NLH and for the undamped NLH.

THE RADIO-FREQUENCY DRIVEN PLASMA SHEATH: ASYMPTOTICS AND ANALYSIS*

M. SLEMROD†

Abstract. This paper considers the dynamics of a radio-frequency driven plasma consisting of ions and electrons. The method of matched asymptotic expansions is used to derive the dynamics in bulk quasi-neutral plasma, transition, and sheath regions. Furthermore, a constructive existence theorem is presented for solutions of the system governing sheath dynamics.

Key words. plasma, sheath

DOI. 10.1137/S0036139902411831

1. Introduction. The purpose of this paper is to provide a unified discussion of the dynamics of a bounded plasma consisting of ions and electrons sustained by a radio-frequency (rf) current. Such configurations occur naturally in reactive ion etching [1]. Various models have been introduced to describe the plasma behavior [2], [3], [4]; a rather complete discussion is found in [1]. In fact the main interest, both physical and mathematical, for the rf driven plasma is the formation of a space charge sheath boundary layer near the bounding wall. In this boundary layer the plasma exhibits time periodic motion, with the same period as the driving current and with an electric potential $\varphi(\xi,\tau)$ satisfying to leading order in a small parameter the nonlocal (in time τ)-local (in space ξ) system

$$\begin{aligned} &\frac{\partial^2\varphi}{\partial\xi^2} = (1+2\overline{\varphi})^{-1/2} - e^{-\varphi}, \quad -\infty<\xi<0,\ 0\le\tau\le 1,\\ &\frac{\partial\varphi}{\partial\xi} = F(\tau) \quad \text{at } \xi=0,\\ &\varphi\to 0,\ \frac{\partial\varphi}{\partial\xi}\to 0 \quad \text{as } \xi\to-\infty, \end{aligned} \tag{1.1}$$

where $\overline{\varphi}(\xi)=\int_0^1\varphi(\xi,\tau)d\tau$, and $F(\tau)>0$ is continuously differentiable with period 1.

System (1.1) is rather intriguing. It possesses no time τ derivatives, yet temporal behavior is nontrivial due to the appearance of the time average $\overline{\varphi}$ in the differential equation for φ. Hence two questions come immediately to mind:

i. Where does the nonlocal system (1.1) come from?

ii. Does (1.1) have a solution, and how do we find it?

This paper answers both questions. It is shown that the nonlocal system arises from the method of matched asymptotic expansions applied to the classical two fluid model for a collisional plasma undergoing ionization.

Modulo the matching, the physics is well understood and can be found in references [2], [3], [4], and the matching itself without details has been suggested in [4]

and is similar to that given in the paper of Franklin and Ockendon [5], where the plasma was undriven. Nevertheless, the matching is provided so that the uninitiated reader will have a straightforward self-contained derivation of (1.1). (While this paper considers the case of an essentially collisionless sheath, the interested reader can also consult the paper of Gegick and Young [6], which considers the opposite limit of a collisional sheath.)

As to solvability of (1.1), the answer is that (1.1) does indeed possess a time periodic solution. More valuable, however, is that the proof of existence is constructive. Simply put, the proof is done in two stages as follows.

Step 1. *Regularization.* The problem (1.1) is regularized in the form

$$\begin{aligned} &\frac{\partial^2\varphi}{\partial\xi^2} = (1+2\overline{\varphi})^{-1/2} - e^{-\varphi} + \mu\varphi, \qquad -\frac{1}{\mu} < \xi < 0,\ 0 \le \tau \le 1, \\ &\frac{\partial\varphi}{\partial\xi} = F(\tau) \quad \text{at } \xi = 0, \\ &\varphi = 0 \quad \text{at } \xi = -\frac{1}{\mu}. \end{aligned} \tag{1.2}$$

Here $\mu > 0$ represents a small parameter.

Of course (1.2) is still a nonlocal problem, but it admits a *variational principle*. If

$$J(\varphi) \stackrel{\text{def}}{=} \int_0^1 \int_{-\frac{1}{\mu}}^0 \frac{1}{2}\left(\frac{\partial\varphi}{\partial\xi}\right)^2 + (1+2\overline{\varphi})^{1/2} + e^{-\varphi} + \mu\frac{\varphi^2}{2} - F(\tau)\frac{\partial\varphi}{\partial\xi}\,d\xi\,d\tau,$$

then the Euler–Lagrange equations corresponding to minimizing $J(\varphi)$ over a suitable class of functions φ, vanishing at $\xi = -\frac{1}{\mu}$, are precisely (1.2). Hence the existence of solutions of (1.2) and their explicit computation in practice can be accomplished by minimizing $J(\varphi)$.

Step 2. *Passage to the limit* $\mu \to 0$. In fact, it is this process that is the most delicate. As in all such limiting arguments, precompactness of a sequence of solutions to (1.2) must be established; this is accomplished with straightforward arguments based on the behavior of solutions of (1.2) as functions of ξ for fixed τ values.

In practice, of course, one cannot numerically resolve either Step 1 or Step 2 directly. However, it seems that finite-dimensional minimization problems approximating Step 1 implemented on larger and larger spatial ξ domains would generate a sequence of approximations. The results given here guarantee a convergent subsequence.

The paper is divided into two sections after this Introduction. Section 2 uses the method of matched asymptotic expansions, similar in spirit to [5], to derive the dynamics of the plasma in (A) the bulk quasi-neutral plasma regime, (B) a transition regime between bulk plasma and the space charge sheath, and (C) the sheath itself. In subsection (D) a short discussion of higher order matching and the need for the transition layer (B) is provided. Section 3 is devoted to analysis of (1.1). Steps 1 and 2 as outlined above are carried out, and existence of a periodic-in-τ solution of (1.1) is proven.

2. Derivation of the basic equations. Let n_i denote ion density, n_e electron density, Φ electric potential, n_{ch} characteristic charged particle density, u_i ion velocity, u_e electron velocity, θ_e electron temperature. We consider a one-dimensional spatial

domain $-R < X < X_w$, where X_w is the location of the wall. T denotes time. For small electron mass, we assume the Boltzmann relation

$$n_e = n_{ch} \exp\left(\frac{e\Phi}{k\theta_e}\right),$$

where e is the electron charge and k is Boltzmann's constant. Denote by m_i the mass of the ions. Then the conservation laws of mass for the ions and electrons and of momentum for the ions are

$$\begin{aligned}
\frac{\partial n_i}{\partial T} + \frac{\partial}{\partial X}(n_i u_i) &= Z n_e, \\
\frac{\partial n_e}{\partial T} + \frac{\partial}{\partial X}(n_e u_e) &= Z n_e, \\
m_i \frac{\partial (n_i u_i)}{\partial T} + m_i \frac{\partial}{\partial X}(n_i u_i^2) &= -e n_i \frac{\partial \Phi}{\partial X} - \nu(u_i) m_i u_i n_i,
\end{aligned}$$

where ν is the ion friction coefficient and Z is rate of ionization. (We assume cold ions and hence the ion pressure is zero.) For simplicity we take $\nu(u_i) = \frac{|u_i|}{\lambda}$; $\lambda > 0$ is the constant ion collision mean free path. In addition, Φ satisfies Poisson's equation

$$-\frac{\epsilon_0}{e}\frac{\partial^2 \Phi}{\partial X^2} = n_i - n_e,$$

where ϵ_0 is the permittivity of free space.

The above equations for n_i, n_e, u_i, Φ may be simplified if we introduce the quantities

$$c_s = \sqrt{\frac{k\theta_e}{m_i}}, \qquad \lambda_D = \sqrt{\frac{\epsilon_0 k \theta_e}{n_{cn} e^2}}$$

representing ion sound velocity and Debye length,

$$\begin{aligned}
&t = \frac{T c_s}{\lambda},\ x = \frac{X}{\lambda},\ \varphi = \frac{-e\Phi}{k\theta_e},\ n_+ = \frac{n_i}{n_{ch}},\ n_- = \frac{n_e}{n_{ch}}, \\
&u_+ = \frac{u_i}{c_s},\ u_- = \frac{u_e}{c_s},\ \epsilon = \frac{\lambda_D}{\lambda},\ z = \frac{Z\lambda}{c_s},
\end{aligned}$$

and set $n_- = e^{-\varphi}$ by adjusting the zero point of the potential Φ.

In the new dependent variables $n_+, n_-, u_+, u_-, \varphi$ the balance laws are now

$$\frac{\partial n_+}{\partial t} + \frac{\partial}{\partial x}(n_+ u_+) = z n_-, \tag{2.1}$$

$$\frac{\partial n_-}{\partial t} + \frac{\partial}{\partial x}(n_- u_-) = z n_-, \tag{2.2}$$

$$\frac{\partial u_+}{\partial t} + u_+ \frac{\partial u_+}{\partial x} = \frac{\partial \varphi}{\partial x} - |u_+| u_+ - z u_+ \left(\frac{n_-}{n_+}\right), \tag{2.3}$$

$$\epsilon^2 \frac{\partial^2 \varphi}{\partial x^2} = n_+ - n_-, \tag{2.4}$$

$$n_- = e^{-\varphi}. \tag{2.5}$$

The system is now considered on a bounded domain $-L < x < x_w$, and at $x = -L$ ($L = \frac{R}{\lambda}, x_w = \frac{X_w}{\lambda}$) we impose boundary conditions

$$\varphi = \varphi_L, \quad u_+ = u_L, \quad u_- = u_L^e\left(\frac{t}{\epsilon^2 p}\right), \quad n_+ = u_L^{-1}, \quad n_- = u_L^{-1}, \tag{2.6}$$

where $u_L = e^{\varphi_L}$ and $\varphi_L \ll 0$ so that $0 < u_L \ll 1$. The boundary value u_L^e will be determined in subsection A to follow. At the wall $x = x_w$ we impose the electron velocity

$$u_- = u_{-_{\text{wall}}}, \tag{2.7}$$

where $u_{-_{\text{wall}}}$ is independent of ϵ.

One of the delicate points in this asymptotic derivation is that the wall position x_w is itself to be determined. This is done in subsection C.

Differentiation of the Poisson equation (2.4) with respect to t yields

$$\frac{\epsilon^2 \partial^3 \varphi}{\partial t \partial x^2} = \frac{\partial n_+}{\partial t} - \frac{\partial n}{\partial t} = -\frac{\partial}{\partial x}(n_+ u_+) + \frac{\partial}{\partial x}(n_- u_-),$$

and hence

$$\epsilon^2 \frac{\partial^2 \varphi}{\partial x \partial t} + n_+ u_+ - n_- u_- = \frac{f_1(t)}{\epsilon} \tag{2.8}$$

for all x. Here $\frac{f_1(t)}{\epsilon}$ is the prescribed rf current. We take $f_1(t)$ to be a periodic function in t with period $\epsilon^2 p$, $\int_0^{\epsilon^2 p} f_1(t)dt = 0$. Set $t = \epsilon^2 \tau p$, $f(\tau) \overset{\text{def}}{=} f_1(\epsilon^2 \tau p)$ so that $f(\tau)$ is periodic with period 1.

In the new $\tau = t/\epsilon^2 p$ time variable, the Euler–Poisson equations become

$$\frac{1}{\epsilon^2 p}\frac{\partial n_+}{\partial \tau} + \frac{\partial}{\partial x}(n_+ u_+) = z n_-, \tag{2.9}$$

$$\frac{1}{\epsilon^2 p}\frac{\partial u_+}{\partial \tau} + u_+ \frac{\partial u_+}{\partial x} = \frac{\partial \varphi}{\partial x} - |u_+| u_+ - z u_+ \left(\frac{n_-}{n_+}\right), \tag{2.10}$$

$$\epsilon^2 \frac{\partial^2 \varphi}{\partial x^2} = n_+ - n_-, \tag{2.11}$$

$$\frac{1}{p}\frac{\partial^2 \varphi}{\partial x \partial \tau} + n_+ u_+ - n_- u_- = \frac{f(\tau)}{\epsilon}, \tag{2.12}$$

$$n_- = e^{-\varphi}. \tag{2.13}$$

Notice that the current equation (2.12) is now used instead of (2.2) since (2.9), (2.11), (2.12) imply (2.2).

A. Bulk plasma outer solution. First consider a region away from the wall. Write $n_+(x, \tau)$, etc., as asymptotic expansions in ϵ:

$$\begin{aligned} n_+ &= n_0 + \epsilon n_1 + \cdots, \\ u_+ &= u_0 + \epsilon u_1 + \cdots, \\ \varphi &= \varphi_0 + \epsilon \varphi_1 + \cdots, \\ u_- &= \frac{u_0^-}{\epsilon} + u_1^- + \epsilon u_2^-, \end{aligned} \tag{2.14}$$

where periodicity in τ is assumed.

Substitution of (2.14) into the rescaled Euler–Poisson system (2.9)–(2.12) and balancing powers of ϵ yields

$$\frac{\partial n_0}{\partial \tau} = \frac{\partial n_1}{\partial \tau} = \frac{\partial u_0}{\partial \tau} = \frac{\partial u_1}{\partial \tau} = 0,$$

and hence n_0, n_1, u_0, u_1 are independent of τ and depend only on x. Furthermore, (2.9) implies

$$\frac{1}{p}\frac{\partial n_2}{\partial \tau} + \frac{\partial}{\partial x}(n_0 u_0) = z e^{-\varphi}. \tag{2.15}$$

The Poisson equation (2.11) implies $n_0 = e^{-\varphi_0}$, and φ_0 is also independent of τ. Additionally, integration of (2.15) from $\tau = 0$ to $\tau = 1$ and the periodicity of n_2 in τ imply

$$\frac{d}{dx}(n_0 u_0) = z n_0, \tag{2.16}$$

which combined with (2.10) and $n_0 = e^{-\varphi_0}$ yields

$$\frac{du_0}{dx} = \frac{z(1+u_0^2) + u_0^3}{1 - u_0^2}. \tag{2.17}$$

Hence u_0 is monotone increasing in x and

$$\frac{du_0}{dx} \to \infty \quad \text{as} \quad u_0 \to 1. \tag{2.18}$$

Let x_B (the Bohm point) denote that value of x for which $\lim_{x \to x_B} u_0(x) = 1$.

From (2.16), once $u_0(x)$ is determined, n_0 and hence φ_0 are determined as well on $(-L, x_B)$. The current equation (2.12) determines

$$u_0^- = -e^{\varphi_0} f(\tau). \tag{2.19}$$

Returning to boundary condition (2.6), we see that (2.19) implies $u_L^e(\tau) = e^{\varphi_L} f(\tau)$. *Thus in fact the current f is determined by the boundary condition or vice versa.*

To determine the nature of the singularity at x_B, set $u_0 = 1 + U$ and substitute into (2.17). Then to leading order in U we find

$$\frac{d}{dx} U^2 = -(2z+1),$$

and, setting $U(x_B) = 0$, we see

$$U(x) = -((2z+1)(x_B - x))^{1/2}$$

and

$$u_0(x) \sim 1 - ((2z+1)(x_B - x))^{1/2} \quad \text{as} \quad x \to x_B. \tag{2.20}$$

From (2.16) we then see

$$\frac{dn_0}{dx} \sim -\frac{n_0}{2}(2z+1)^{-1/2} \quad \text{as} \quad x \nearrow x_B,$$

and since $\frac{d\varphi_0}{dx} = -\frac{1}{n_0}\frac{dn_0}{dx}$ we see

$$\frac{d\varphi_0}{dx} \sim \frac{(2z+1)^{-1/2}}{2}(x_B - x)^{1/2} \quad \text{as} \quad x \nearrow x_B.$$

Hence

$$\varphi_0(x) \sim \varphi_0(x_B) - (2z+1)^{1/2}(x_B - x)^{1/2} \quad \text{as} \quad x \nearrow x_B, \tag{2.21}$$

where $\varphi_B = \varphi_0(x_B) = -\ln n_0(x_B)$ and $n_B \doteq n_0(x_B)$ are determined by solving (2.16) subject to the boundary conditions (2.6).

Let us employ the normalization

$$\varphi_B = 0, \qquad n_B = 1,$$

which will provide a simplification of the algebraic computation to follow. Of course this will shift the value of φ and hence φ_L by a constant.

B. Transition layer. Introduce a new space variable $\zeta = \frac{x - x_B}{\delta}, \delta = \epsilon^{4/5}, \zeta < 0$, so that the Euler–Poisson system (2.9)–(2.12) becomes

$$\frac{1}{\delta^{3/2}p}\frac{\partial n_+}{\partial \tau} + \frac{\partial}{\partial \zeta}(n_+ u_+) = \delta z e^{-\varphi}, \tag{2.22}$$

$$\frac{1}{\delta^{3/2}p}\frac{\partial u_+}{\partial \tau} + u_+\frac{\partial u_+}{\partial \zeta} = \frac{\partial \varphi}{\partial \zeta} - \delta |u_+| u_+ - \delta z \frac{u_+ e^{-\varphi}}{n_+}, \tag{2.23}$$

$$\delta^{1/2}\frac{\partial^2 \varphi}{\partial \zeta^2} = n_+ - e^{-\varphi}, \tag{2.24}$$

$$\frac{1}{\delta p}\frac{\partial^2 \varphi}{\partial \zeta \partial \tau} + n_+ u_+ - n_- u_- = \frac{f(\tau)}{\epsilon}. \tag{2.25}$$

Again expand

$$\begin{aligned} n_+ &= 1 + \delta^{1/2} n_1 + \cdots, \\ u_+ &= 1 + \delta^{1/2} u_1 + \cdots, \\ \varphi &= \delta^{1/2}\varphi_1 + \cdots, \\ u_- &= \frac{u_0^-}{\delta^{5/4}} + \frac{u_1^-}{\delta} + \cdots, \\ x_w &= x_B + \delta x_{w_1} + \cdots, \end{aligned}$$

where all the indicated terms except those for x_w are now functions of ζ, τ and are periodic in τ with period 1. The expansion of the wall location x_w will become crucial in subsection C.

Substitute the expansions into (2.22)–(2.25). We then see, equating powers of δ, that

$$\frac{\partial n_1}{\partial \tau} = \frac{\partial n_2}{\partial \tau} = \frac{\partial n_3}{\partial \tau} = \frac{\partial u_1}{\partial \tau} = \frac{\partial u_2}{\partial \tau} = \frac{\partial u_3}{\partial \tau} = 0$$

and $n_1, n_2, n_3, u_1, u_2, u_3$ are independent of τ. Also (2.22) and the periodicity of n_4, n_5 in τ imply

$$\frac{\partial}{\partial \zeta}(n_1 + u_1) = 0, \qquad \frac{\partial}{\partial \zeta}(n_1 u_1 + n_2 + u_2) = z, \tag{2.26}$$

whereas (2.23) and the periodicity of u_4, u_5 in τ imply

$$\frac{\partial}{\partial \zeta}(u_1 - \overline{\varphi}_1) = 0, \qquad \frac{\partial u_2}{\partial \zeta} + u_1\frac{\partial u_1}{\partial \zeta} = \frac{\partial \overline{\varphi}_2}{\partial \zeta} - 1 - z. \tag{2.27}$$

Equating order $\delta^{1/2}$ and δ terms in the Poisson equation (2.24) yields

$$n_1 + \varphi_1 = 0, \qquad n_2 + \varphi_2 - \frac{\varphi_1^2}{2} = \frac{\partial^2 \varphi_1}{\partial \zeta^2}. \tag{2.28}$$

Hence φ_1, φ_2 are independent of τ as well, and $\overline{\varphi}_2 = \varphi_2$ in (2.27).

For x in a transition matching regime (say, $x - x_B = -\epsilon^\alpha, 0 < \alpha < 4/5$) we have $x \to x_B-$ and $\zeta \to -\infty$ as $\epsilon \to 0$. Hence the matching condition

$$\lim_{\zeta \to -\infty} n_+ u_+ = 1$$

is inherited from the bulk plasma solution of subsection A. Since $n_+ = 1 + \delta^{1/2} n_1 + \cdots$, $u_+ = 1 + \delta^{1/2} u_1 + \cdots$, in this middle transition layer we see

$$\lim_{\zeta \to -\infty} n_1 + u_1 = 0;$$

however, (2.26) tells us that $n_1 + u_1 = \text{const}$, and hence

$$n_1 + u_1 = 0. \tag{2.29}$$

Also from (2.27), (2.28), $u_1 - \overline{\varphi}_1 = \text{const}$, $n_1 = -\varphi_1$, and since $\varphi_1 = \overline{\varphi}_1$ we have

$$u_1 = \varphi_1 = -n_1. \tag{2.30}$$

Next differentiate (2.28) with respect to ζ, and to the resulting expression add (2.27). This yields

$$\frac{\partial}{\partial \zeta}(u_2 + n_2) - \frac{\partial^3 \varphi_1}{\partial \zeta^3} + u_1 \frac{\partial u_1}{\partial \zeta} = -1 - z + \varphi_1 \frac{\partial \varphi_1}{\partial \zeta}.$$

However, from (2.26), $\frac{\partial}{\partial \zeta}(u_2 + n_2) = z - \frac{\partial}{\partial \zeta}(n_1 u_1)$, and so

$$2z - \frac{\partial}{\partial \zeta}(u_1 u_1) - \frac{\partial^3 \varphi_1}{\partial \zeta^3} + u_1 \frac{\partial u_1}{\partial \zeta} = -1 + \varphi_1 \frac{\partial \varphi_1}{\partial \zeta}.$$

Finally, use (2.30) to obtain

$$\frac{d^3 \varphi_1}{d\zeta^3} = \frac{d}{d\zeta}(\varphi_1^2) + 1 + 2z. \tag{2.31}$$

Recall that in subsection A we have shown for the bulk plasma potential $\varphi(x) \sim -(2z+1)^{1/2}(x_B - x)^{1/2}$ as $x \to x_B-$. Hence the matching condition for $\varphi(\zeta) = \delta^{1/2}\varphi_1(\zeta) + \cdots$ as $\zeta \to -\infty$ is

$$\varphi_1(\zeta) \to -(2z+1)^{1/2}(-\zeta)^{1/2} \quad \text{as} \quad \zeta \to -\infty. \tag{2.32}$$

The integration of (2.31) and use of (2.32) yield the Painlevé 1 equation

$$\frac{d^2 \varphi_1}{d\zeta^2} = \varphi_1^2 + (1 + 2z)\zeta \quad \text{for} \quad -\infty < \zeta < 0. \tag{2.33}$$

If in addition we wish to match the electric field $\frac{\partial \varphi}{\partial x}$ of bulk plasma of subsection A with the transition layer solution of this section, we need to match the additional condition

$$\frac{\partial \varphi}{\partial x}(x) - \left(\frac{(2z+1)^{1/2}}{2}\right)(x - x_B)^{-1/2} \to 0 \quad \text{as} \quad x \to x_B,$$

which implies

$$\varphi_1'(\zeta) - \frac{(2z+1)^{1/2}}{2}(-\zeta)^{-1/2} \to 0 \quad \text{as} \quad \zeta \to -\infty. \tag{2.34}$$

In [7], [8] it is shown there is only one solution of (2.33) that satisfies (2.31) and (2.34), i.e., the unique monotone increasing solution of the Painlevé 1 equation.

Hence $\varphi_1 = u_1 = -n_1$, where φ_1 is the unique monotone increasing solution of the Painlevé 1 equation (2.33). Finally, a simple substitution of our asymptotic expansions into (2.25) yields $u_0^- = f(\tau)$.

C. Sheath layer. For the study of the sheath boundary layer near $x = x_w$ we introduce yet another space variable $\xi = \frac{x-x_w}{\epsilon}, \xi \le 0$. In this scaling, (2.9)–(2.12) become

$$\frac{1}{\epsilon p}\frac{\partial n_+}{\partial \tau} + \frac{\partial}{\partial \xi}(n_+ u_+) = \epsilon z e^{-\varphi}, \tag{2.35}$$

$$\frac{1}{\epsilon p}\frac{\partial u_+}{\partial \tau} + u_+\frac{\partial u_+}{\partial \xi} = \frac{\partial \varphi}{\partial \xi} - \epsilon |u_+| u_+ - \epsilon u_+ \frac{e^{-\varphi}}{n_+}, \tag{2.36}$$

$$\frac{\partial^2 \varphi}{\partial \xi^2} = n_+ - e^{-\varphi}, \tag{2.37}$$

$$\frac{1}{\epsilon p}\frac{\partial^2 \varphi}{\partial \xi \partial \tau} + n_+ u_+ - n_- u_- = \frac{f(\tau)}{\epsilon}. \tag{2.38}$$

Again we expand the dependent variables in asymptotic expansions:

$$\begin{aligned} n_+ &= n_0 + \epsilon n_1 + \cdots, \\ u_+ &= u_0 + \epsilon u_1 + \cdots, \\ \varphi &= \varphi_0 + \epsilon \varphi_1 + \cdots, \\ u_- &= \frac{u_0^-}{\epsilon} + u_1^- + \cdots. \end{aligned} \tag{2.39}$$

Again all terms depend on τ, ξ, where periodicity in τ with period 1 is assumed.

Substituting (2.39) into (2.35)–(2.38) and equating powers of ϵ, we find

$$\frac{\partial n_0}{\partial \tau} = \frac{\partial u_0}{\partial \tau} = 0,$$

and hence u_0, n_0 are independent of τ. Also balancing terms of order one in (2.36) gives

$$\frac{1}{p}\frac{\partial n_1}{\partial \tau} + \frac{\partial}{\partial \xi}(n_0 u_0) = 0,$$

and integration in τ from 0 to 1 and the periodicity of n_1 imply

$$\frac{d}{d\xi}(n_0 u_0) = 0.$$

In fact we also see that n_1 is independent of τ.

Recall that the middle region is defined by $\zeta = \frac{x-x_B}{\delta}$ and the sheath region by $\xi = \frac{x-x_w}{\epsilon}$. Hence in a matching regime, e.g., $x - x_w = -\epsilon^\alpha, \frac{4}{5} < \alpha < 1$, we have $\zeta = -\epsilon^{\alpha-4/5} + x_{w_1}$, $\xi = -\epsilon^{\alpha-1}$, and $\zeta \to x_{w_1}$, $\xi \to -\infty$ as $\epsilon \to 0$.

Substitution into (2.36) of our asymptotic expansions also yields

$$\frac{1}{p}\frac{\partial u_1}{\partial \tau} + u_0\frac{\partial u_0}{\partial \xi} = \frac{\partial \varphi_0}{\partial \xi}, \tag{2.40}$$

and again, since u_1 is periodic in τ with period one, we see

$$u_0\frac{du_0}{d\xi} = \frac{d}{d\xi}\overline{\varphi}_0$$

and hence

$$\frac{u_0^2}{2} - \overline{\varphi}_0 = \text{ const.}$$

Recall in the middle region (subsection B)

$$\varphi(\zeta,\tau) = 1 + \delta^{1/2}\varphi_1 + \cdots,$$
$$u_+(\zeta,\tau) = 1 + \delta^{1/2}u_1 + \cdots;$$

with $x - x_w = O(\epsilon^\alpha)(\frac{4}{5} < \alpha < 1)$ we know $\zeta \to x_{w_1}$, $\xi \to -\infty$.

Thus matching the middle and sheath regions must be done as $\zeta \to x_{w_1}$ from the middle region and $\xi \to -\infty$ from the sheath region.

Since $n_+u_+ = 1$ in the middle region trivially, we see that matching requires $n_0u_0 = 1$ for all ξ in the sheath region.

Matching the ion velocity u_0 and potential φ_0 to the middle region requires

$$u_0 \to 1,\ \varphi_0 \to 0 \quad \text{as} \quad \xi \to -\infty,$$

and hence the above const. $= \frac{1}{2}$ and we have

$$\frac{u_0^2}{2} - \overline{\varphi}_0 = \frac{1}{2}.$$

But since $n_0u_0 = 1$, we have trivially

$$n_0 = (1 + 2\overline{\varphi}_0)^{-1/2}. \tag{2.41}$$

Substitution of the asymptotic expansions into the Poisson equation (2.37) gives

$$\frac{\partial^2 \varphi_0}{\partial \xi^2} = n_0 - e^{-\varphi_0},$$

and use of the relation (2.41) then gives

$$\frac{\partial^2 \varphi_0}{\partial \xi^2} = (1 + 2\overline{\varphi}_0)^{-1/2} - e^{-\varphi_0}. \tag{2.42}$$

Next substitute the asymptotic expansion into the current equation (2.38) to obtain

$$\frac{1}{p}\frac{\partial^2 \varphi_0}{\partial \xi \partial \tau} - e^{-\varphi_0}u_0^- = f(\tau). \tag{2.43}$$

But recall

$$u_- = \frac{u_0^-}{\epsilon} + u_1^- + \cdots,$$

and u_- at $x = x_w$ is prescribed independent of ϵ. Hence at the boundary $x = x_w$, i.e., $\xi = 0$, we must have $u_0^-(0,\tau) = 0$, and thus at the boundary $\xi = 0$ we have

$$\frac{1}{p}\frac{\partial^2\varphi_0}{\partial\xi\partial\tau} = f(\tau).$$

Integrating with respect to τ, we find

$$\frac{\partial\varphi_0}{\partial\xi} = F(\tau) \quad \text{at} \quad \xi = 0, \tag{2.44}$$

where

$$F(\tau) = p\int_0^\tau f(\tau)d\tau + \frac{\partial\varphi_0}{\partial\xi}(0,0).$$

(Notice that $\frac{\partial\varphi_0}{\partial\xi}(0,0)$ is the prescribed initial (rescaled) electric field evaluated at the boundary $\xi = 0$.) *We will assume* $F(\tau) > 0$ *on* $[0,1]$.

As noted above, matching the potential in the sheath with the potential determined by the middle region requires

$$\varphi_0 \to 0 \quad \text{as} \quad \xi \to -\infty. \tag{2.45}$$

Matching $\frac{\partial\varphi}{\partial\xi}$ requires revisiting the expansion for the potential φ in the middle region.

Recall in the middle region

$$\varphi(\xi,\tau) = \delta^{1/2}\varphi_1(\zeta) + \cdots.$$

Hence

$$\frac{\partial\varphi}{\partial\xi}(\xi,\tau) = \delta^{1/2}\frac{d\varphi_1}{d\zeta}(\xi)\frac{d\zeta}{d\xi} + \cdots,$$

and since $\zeta = \epsilon^{1/5}\xi + \epsilon^{-4/5}x_w$, $\frac{d\zeta}{d\xi} = \epsilon^{1/5}$ and

$$\frac{\partial\varphi}{\partial\xi}(\xi,\tau) = \epsilon^{3/5}\frac{d\varphi_1}{d\zeta}(\zeta) + \cdots.$$

Hence again for a typical transition layer (say, $x = -\epsilon^\alpha$, $\frac{4}{5} < \alpha < 1$), $\xi \to -\infty$, $\zeta \to x_{w_1}$ as $\epsilon \to 0$, and

$$\frac{\partial\varphi}{\partial\xi} \to 0 \quad \text{as} \quad \zeta \to x_{w_1}.$$

Thus the matching condition for $\frac{\partial\varphi_0}{\partial\xi}$ is

$$\frac{\partial\varphi_0}{\partial\xi} \to 0 \quad \text{as} \quad \xi \to -\infty. \tag{2.46}$$

In summary, $\varphi_0(\xi,\tau)$ will satisfy

$$\frac{\partial^2\varphi_0}{\partial\xi^2} = (1 + 2\overline{\varphi}_0)^{-1/2} - e^{-\varphi_0}, \quad -\infty < \xi < 0, \tag{2.47}$$

$$\frac{\partial\varphi_0}{\partial\xi} = F(\tau) \quad \text{at} \quad \xi = 0, \tag{2.48}$$

$$\varphi_0, \frac{\partial\varphi_0}{\partial\xi} \to 0, 0 \quad \text{as} \quad \xi \to -\infty. \tag{2.49}$$

There is still one more step in matching the middle and sheath regions, i.e., the determination of x_{w_1}. Recall that from the middle region

$$\varphi(\zeta) = \epsilon^{2/5}\varphi_1(\zeta) + \cdots,$$

where φ_1 satisfies the Painlevé 1 equation (2.33), which classically [9] satisfies the formula

$$\varphi_1(\zeta) = \frac{6}{(\zeta - \zeta_0)^2}(1 + \text{h.o.t.} \quad \text{in} \ \ (\zeta - \zeta_0))$$

near ζ_0. Here $\zeta_0 > 0$ is the left-most pole of the unique monotone increasing first Painlevé transient. On the other hand, the sheath solution satisfies (2.47). As we shall see in subsection D, $\varphi_0 - \overline{\varphi}_0 \to 0$ exponentially as $\xi \to -\infty$, and hence (2.47) implies

$$\frac{d^2\varphi_0}{d\xi^2} \sim \varphi_0^2 \quad \text{as} \quad \xi \to -\infty$$

and hence

$$\varphi_0(\xi) \sim \frac{6}{\xi^2} \quad \text{as} \quad \xi \to -\infty.$$

Thus in a matching region, φ has representations $\varphi(\zeta) \sim \frac{6\epsilon^{2/5}}{(\zeta-\zeta_0)^2}$ from the middle region, $\varphi(\xi) \sim \frac{6}{\xi^2}$ from the sheath region. However, since $\zeta = \frac{x-x_B}{\epsilon^{4/5}}, \xi = \frac{x-x_w}{\epsilon}$, we see $\zeta = \epsilon^{-4/5}(x_w - x_B) + \epsilon^{1/5}\xi$, and substitution into the above expression for φ in the middle region shows that equality of the two representations of φ occurs when

$$x_w = x_B + \epsilon^{4/5}\zeta_0 + \cdots, \quad \text{i.e.,} \quad x_{w_1} = \zeta_0.$$

D. Higher order sheath asymptotics. From subsection C we know that n_0, u_0, n_1 are independent of τ, and balancing terms of order ϵ yields

$$\frac{d}{d\xi}(n_1u_0 + n_0\overline{u}_1) = \overline{ze^{-\varphi_0}}, \tag{2.50}$$

$$\frac{d}{d\xi}(u_0\overline{u}_1) = \frac{d\overline{\varphi}_1}{d\xi} - u_0^2 - \frac{zu_0}{n_0}\overline{e^{-\varphi_0}}, \tag{2.51}$$

$$\frac{\partial^2\varphi_1}{\partial\xi^2} = n_1 + e^{-\varphi_0}\varphi_1. \tag{2.52}$$

It is possible to eliminate $n_1, \overline{u}_1$ from (2.50)–(2.52) to find a single higher order equation for φ_1. However, the goal here to compute an asymptotic relation for φ_1 as $\xi \to -\infty$. The computation is in fact elementary.

Equation (2.50) implies

$$n_1u_0 + n_0\overline{u}_1 \sim z\xi + c_1(\tau) \quad \text{as} \quad \xi \to -\infty. \tag{2.53}$$

Equation (2.51) implies

$$u_0\overline{u}_1 - \overline{\varphi}_1 \sim -(1+z)\xi + c_2 \quad \text{as} \quad \xi \to -\infty. \tag{2.54}$$

Thus if we multiply (2.53) by u_0, (2.54) by n_0, and subtract the resultant equations, we find

$$n_1 u_0^2 + n_0 \overline{\varphi}_1 \sim u_0(z\xi + c_1(\tau)) + n_0((1+z)\xi - c_2) \quad \text{as} \quad \xi \to -\infty, \tag{2.55}$$

and hence

$$n_1 \sim -\frac{n_0}{u_0^2}\overline{\varphi}_1 + \frac{1}{u_0}(z\xi + c_1(\tau)) + \frac{n_0}{u_0^2}((1+z)\xi - c_2) \quad \text{as} \quad \xi \to -\infty. \tag{2.56}$$

Since $n_0 u_0 = 1$, $u_0^2 = 1 + 2\overline{\varphi}_0$, and $n_0(\xi) \to 1$, $u_0(\xi) \to 1$ as $\xi \to -\infty$, (2.56) can be simplified by writing

$$n_1 \sim -(1 + 2\overline{\varphi}_0)^{-3/2}\overline{\varphi}_1 + (2z+1)\xi \quad \text{as} \quad \xi \to -\infty. \tag{2.57}$$

Inserting (2.57) into (2.52), we see

$$\frac{\partial^2 \varphi_1}{\partial \xi^2} \sim (e^{-\varphi_0} - (1 + 2\overline{\varphi}_0)^{-3/2})\overline{\varphi}_1 + (2z+1)\xi \quad \text{as} \quad \xi \to -\infty. \tag{2.58}$$

Now average (2.58) to see that $\overline{\varphi}_1$ will have asymptotic behavior as $\xi \to -\infty$ given by solutions $y(\xi)$ of the equation

$$\frac{d^2 y}{d\xi^2} = \big(\overline{e^{-\varphi_0}} - (1 + 2\overline{\varphi}_0)^{-3/2}\big)y + (2z+1)\xi. \tag{2.59}$$

Next note that $\varphi_0 - \overline{\varphi}_0$ satisfies the equation

$$\frac{\partial^2}{\partial \xi^2}(\varphi_0 - \overline{\varphi}_0) = -e^{-\varphi_0} + \overline{e^{-\varphi_0}} = (\varphi_0 - \overline{\varphi}_0) + \cdots,$$

and hence

$$\varphi_0 - \overline{\varphi}_0 \sim a_1 e^{\xi} + a_2 e^{-\xi} \quad \text{as} \quad \xi \to -\infty.$$

Since $\varphi_0, \overline{\varphi}_0$ are bounded as $\xi \to -\infty$, we must have $a_1 = 0$, $\overline{\varphi}_0 = \varphi_0$ plus exponentially small terms as $\xi \to -\infty$. Hence in (2.47) we may replace $\overline{\varphi}_0$ by φ_0 as $\xi \to -\infty$ to see

$$\frac{\partial^2 \varphi_0}{\partial \xi^2} \sim (1 + 2\varphi_0)^{-1/2} - e^{-\varphi_0} \sim \varphi_0^2 \quad \text{as} \quad \xi \to -\infty$$

and hence

$$\varphi_0 \sim \frac{6}{\xi^2} \quad \text{as} \quad \xi \to -\infty. \tag{2.60}$$

Substitution of (2.60) into (2.59) shows that (2.59) is asymptotically equivalent to

$$\frac{d^2 y}{d\xi^2} = \frac{12}{\xi^2} y + (2z+1)\xi, \tag{2.61}$$

which has the explicit solution

$$y(\xi) = b_1 \xi^4 + b_2 \xi^{-3} - \frac{(2z+1)}{6}\xi^3.$$

We enforce minimal growth as $\xi \to -\infty$ and set $b_1 = 0$ so that

$$\overline{\varphi}_1 \sim \frac{2z+1}{6}\xi^3 \quad \text{as} \quad \xi \to -\infty.$$

Recall that our expansion for the potential φ in the sheath was written as

$$\varphi(\xi,\tau) = \varphi_0(\xi,\tau) + \epsilon\varphi_1(\xi,\tau) + \cdots,$$

and hence

$$\overline{\varphi}(\xi) = \overline{\varphi_0(\xi)} + \epsilon\overline{\varphi_1(\xi)} + \cdots.$$

Thus on a matching overlap domain between the middle region and the sheath domain, say,

$$x - x_w = -\epsilon^\beta,$$

$\frac{4}{5} < \beta < 1$, we see $\xi = \frac{x-x_w}{\epsilon} = -\epsilon^{(\beta-1)}$ and

$$\overline{\varphi}_0(\xi) + \epsilon\overline{\varphi}_1(\xi) \sim -\frac{(2z+1)}{6}\epsilon^{3\beta-2} \quad \text{as} \quad \epsilon \to 0$$
$$\to 0 \quad \text{since} \quad 3\beta - 2 > \frac{2}{5}.$$

Analysis of (2.52) shows that

$$\frac{\partial^2}{\partial\xi}(\varphi_1 - \overline{\varphi}_1) \sim (\varphi_1 - \overline{\varphi}_1),$$

and hence φ_1 and $\overline{\varphi}_1$ are exponentially close as $\xi \to -\infty$. Thus on a matching regime $\varphi_0 + \epsilon\varphi_1$ may be matched to the middle solution.

On the other hand, in the absence of a middle regime, an attempt to directly match plasma and sheath fails. For example, if $x - x_w = -\epsilon^\beta$, $0 < \beta < \frac{2}{3}$, we have

$$\overline{\varphi_0(\xi)} + \epsilon\overline{\varphi_1(\xi)} \sim -\frac{(2z+1)}{6}\epsilon^{3\beta-2} \to -\infty \quad \text{as} \quad \epsilon \to 0,$$

which does not match the limit from the quasi-neutral plasma

$$\lim_{x \to x_{B^-}} \varphi(x) \sim \lim_{x \to x_B^-} -(x - x_B)^{1/2} = 0.$$

We note that a similar argument is given in the paper of Franklin and Ockendon [5] in the case when the rf-current and friction are not considered.

3. Existence of solutions for the "exact" sheath system. In this section we will prove existence of solutions to the exact sheath system (1.1) ((2.47)–(2.49) of subsection C). It is rewritten here with the subscript zero deleted, i.e., as

$$\frac{\partial^2\varphi}{\partial\xi^2} = (1 + 2\overline{\varphi})^{-1/2} - e^{-\varphi}, \quad -\infty < \xi < 0, \tag{3.1}$$

$$\frac{\partial\varphi}{\partial\xi} = F(\tau) \quad \text{at} \quad \xi = 0, \tag{3.2}$$

$$\varphi, \frac{\partial\varphi}{\partial\xi} \to 0, 0 \quad \text{as} \quad \xi \to -\infty. \tag{3.3}$$

Again recall that F is a given positive C^1 periodic function of τ with period 1, and the overbar denotes the τ average over interval $0 \le \tau \le 1$.

Step 1. *Regularization.* Define

$$g(\varphi) = \begin{cases} e^{-\varphi}, & \varphi \ge 0, \\ 1 - \varphi, & \varphi \le 0, \end{cases}$$

so that $g(\varphi)$ is $C^1(\mathbb{R})$, convex, and $|g'(\varphi)| \le 1$. It is the boundedness of $g'(\varphi)$ that proves useful.

We now consider the regularized problem

$$\frac{\partial^2 \varphi}{\partial \xi^2} = (1 + 2\overline{\varphi})^{-1/2} + g'(\varphi) + \mu\varphi, \quad -L < \xi < 0, \tag{3.4}$$

$$\frac{\partial \varphi}{\partial \xi} = F(\tau) \quad \text{at} \quad \xi = 0, \quad 0 \le \tau \le 1, \tag{3.5}$$

$$\varphi = 0 \quad \text{at} \quad \xi = -L, \quad 0 \le \tau \le 1, \tag{3.6}$$

where $L = \mu^{-1}, 0 < \mu \le 1$.

We shall prove existence of solutions to (3.4)–(3.6) via the direct method of the calculus of variations [10].

Set

$$J(\varphi) = \int_0^1 \int_{-L}^0 \left\{ \frac{1}{2} \left(\frac{\partial \varphi}{\partial \xi} \right)^2 - \frac{\partial \varphi}{\partial \xi} F(\tau) + (1 + 2\overline{\varphi})^{1/2} + g(\varphi) + \frac{\mu \varphi^2}{2} \right\} d\xi d\tau. \tag{3.7}$$

Let

$$\tilde{H}^1(-L, 0) = \{\varphi \in H^1(-L, 0); \ \varphi = 0 \quad \text{at} \quad \xi = -L\},$$

where $H^1(-L, 0) \subset C[-L, 0]$ denotes the usual Sobolev space of square integrable functions with square integrable generalized derivatives on $(-L, 0)$ endowed with inner product

$$(\varphi, \psi)_{H^1(-L,0)} = \int_{-L}^0 \{\varphi\psi + \varphi_\xi \psi_\xi\} d\xi.$$

Of course $\tilde{H}^1$ inherits the H^1 inner product. Let $\mathbb{H} = L^2((0, 1); \tilde{H}^1(-L, 0))$ so that $\mathbb{H}$ is a Hilbert space endowed with inner product

$$(\varphi, \psi)_{\mathbb{H}} = \int_0^1 \int_{-L}^0 \{\varphi\psi + \varphi_\xi \psi_\xi\} d\xi d\tau.$$

For convenience we recall Jensen's inequality [10] within the context we will use here: Let $f : \mathbb{R} \to \mathbb{R}$ be convex and $u : [0, 1] \to \mathbb{R}$ be summable; then

$$f(\overline{u}) \le \overline{f(u)}. \tag{3.8}$$

Notice that Jensen's inequality implies

$$\|\varphi\|_{\mathbb{H}} \ge \|\overline{\varphi}\|_{\tilde{H}^1}, \tag{3.9}$$

and hence $\varphi \in \mathbb{H}$ implies $\overline{\varphi} \in C$ via the usual Sobolev embedding theorem [10]. Hence the admissible set

$$A \stackrel{\text{def}}{=} \{\varphi \in \mathbb{H}; \overline{\varphi} \ge 0 \quad \text{on} \quad [-L, 0]\} \tag{3.10}$$

is a well defined closed subset of $\mathbb{H}$.

Application of the direct method requires three basic estimates [10]:

(i) The functional to be minimized is bounded from below in the class of admissible functions, so that the infimum and therefore a minimizing sequence exists.

(ii) The functional is weakly lower semicontinuous with respect to weak convergence in the class of admissible functions.

(iii) The minimizing sequence possesses a weakly convergent subsequence, which converges to an admissible function.

If these estimates can be satisfied, existence of a minimizer can be ascertained.

We will now check (i)–(iii) for our functional $J(\varphi)$ given by (3.7). For $\varphi \in A$ note

$$J(\varphi) \geq \frac{\mu}{2}\|\varphi\|_{\mathbb{H}}^2 - \max|F(\tau)|\mu^{-1/2}\|\varphi\|_{\mathbb{H}},$$

and hence $J(\varphi)$ is bounded from below for $\varphi \in \mathbb{H}$. Thus a minimizing sequence $\{\varphi^{(n)}\}$ exists so that $m = \inf_{\varphi\in A} J(\varphi)$, $J(\varphi^{(n)}) \to m$ as $n \to \infty$, and $\|\varphi^{(n)}\|_{\mathbb{H}}$ is bounded for all $n \geq 1$. Furthermore, by (3.9), const. $\geq \|\overline{\varphi}^{(n)}\|_{\tilde{H}^1}$ for all n. Hence there is a subsequence of $\{\varphi^{(n)}\}$ also denoted by $\{\varphi^{(n)}\}$ and $\varphi \in \mathbb{H}$ so that $\varphi^{(n)} \to \varphi$ weakly in $\mathbb{H}$ and $\overline{\varphi}^{(n)} \to w$ strongly in $L^2(-L,0)$. In fact $w = \overline{\varphi}$. To see this, let $\theta \in L^2(-L,0)$. By weak convergence of $\{\varphi^{(n)}\}$ in $\mathbb{H}$,

$$\int_{-L}^{0} \theta(\xi) \int_0^1 (\varphi^{(n)} - \varphi) d\tau d\xi \to 0 \quad \text{as} \quad n \to \infty,$$

and hence

$$\int_{-L}^{0} \theta(\xi)(\overline{\varphi}^{(n)} - \overline{\varphi}) d\xi \to 0 \quad \text{as} \quad n \to \infty,$$

and so $w = \overline{\varphi}$.

Finally, by the usual Sobolev embedding theorem, $\overline{\varphi}^{(n)} \to \overline{\varphi}$ uniformly on $[-L,0]$, $\overline{\varphi}(-L) = 0$, $\overline{\varphi}$ is continuous in $[-L,0]$, $\overline{\varphi} \geq 0$. We summarize the above information in the following lemma.

LEMMA 3.1. *$J(\cdot)$ has a minimizing sequence $\{\varphi^{(n)}\} \subset \mathbb{H}$, $\varphi^{(n)} \to \varphi$ weakly in $\mathbb{H}$, $\overline{\varphi}^{(n)} \to \overline{\varphi}$ strongly in $L^2(-L,0)$ and uniformly on $[-L,0]$, $\overline{\varphi}$ is continuous nonnegative with $\overline{\varphi}(-L) = 0$ and $\varphi \in A$.*

The first and third estimates (i), (iii) in our agenda for applying the direct method are now complete, and we move on to (ii), i.e., lower semicontinuity.

LEMMA 3.2. *Let $\{\varphi^{(n)}\}$ be the convergent minimizing sequence of $J(\cdot)$ given in Lemma* 3.1. *Then*

$$\liminf_{n\to\infty} J(\varphi^{(n)}) \geq J(\varphi).$$

Proof. We will examine pieces of $J(\varphi^{(n)})$ separately. First note that the uniform convergence of $\{\overline{\varphi}^{(n)}\}$ on $[-L,0]$ implies

$$\int_{-L}^{\infty} (1 + 2\overline{\varphi}^{(n)})^{1/2} d\xi \to \int_{-L}^{0} (1 + 2\overline{\varphi})^{1/2} d\xi \quad \text{as} \quad n \to \infty.$$

Next note that since g is convex $\int_0^1 \int_{-L}^0 g(\varphi_n) - g(\varphi) d\xi d\tau \geq \int_0^1 \int_{-L}^0 g'(\varphi)(\varphi_n - \varphi) d\xi d\tau$. Since $|g'(\varphi)| \leq 1$ we have $g' \in L^2((-L,0)\times(0,1))$, and via weak convergence $\lim_{n\to\infty} \int_0^1 \int_{-L}^0 g(\varphi_n) d\xi d\tau \geq \int_0^1 \int_{-L}^0 g(\varphi) d\xi d\tau$. Thus

$$\int_0^1 \int_{-L}^0 \left\{ \frac{1}{2}\left(\frac{\partial\varphi}{\partial\xi}\right)^2 + \frac{\mu}{2}\varphi^2 + g(\varphi) - \frac{\partial\varphi}{\partial\xi} F(\tau) \right\} d\xi d\tau$$

is weakly lower semicontinuous on $\mathbb{H}$. Now put the two pieces of $J(\cdot)$ together, and the lemma is proven. (Notice that if we had used the original function $e^{-\varphi}$ and not g we would not know a priori that $e^{-\varphi}$ was in $L^2((-L,0)\times(0,1))$.) □

Now all three elements of the application of the direct method have been satisfied, and we can assert the following theorem.

THEOREM 3.3. *$J(\cdot)$ has a minimizer $\varphi \in A$, and φ satisfies the weak form of the Euler–Lagrange equation*

$$\int_0^1 \int_{-L}^0 \left\{ \frac{\partial \varphi}{\partial \xi}\frac{\partial \psi}{\partial \xi} - \frac{\partial \psi}{\partial \xi} F(\tau) + (1+2\overline{\varphi})^{-1/2}\overline{\psi} + g'(\varphi)\psi - \mu\varphi\psi \right\} d\xi d\tau = 0 \tag{3.11}$$

for all $\psi \in A$.

Proof. We know that $m \geq J(\varphi)$, and hence $J(\varphi) = m$ and φ is a minimizer. The derivation of the weak form of the Euler–Lagrange equation is classical.

Now set $\psi(s,\xi) = \chi_{[0,\tau]}\psi_1(\xi)$ in (3.11), where

$$\chi_{[0,\tau]}(s) = \begin{cases} 1, & 0 \leq s \leq \tau, \\ 0, & \tau < s < 1, \end{cases}$$

and $\psi_1 \in \tilde{H}^1(-L,0), \psi_1 \geq 0$. Then $\psi \in A$, and the weak form of the Euler–Lagrange equation can be written

$$\int_0^\tau h(\tau)d\tau = 0, \quad 0 \leq \tau \leq 1, \tag{3.12}$$

where

$$h(\tau) \stackrel{\text{def}}{=} \int_{-L}^0 \left(\frac{\partial \varphi}{\partial \xi} - F(\tau) \right) \psi_1'(\xi) + ((1+2\overline{\varphi})^{-1/2} + g'(\varphi) + \mu\varphi)\psi_1(\xi)d\xi.$$

It is a straightforward application of the Cauchy–Schwarz inequality to see

$$|h(\tau)| \leq \text{ const.} \left(\left\| \frac{\partial \varphi}{\partial \xi} \right\|_{L^2(-L,0)} + \mu^{-1}|F(\tau)| + 2\mu^{-1} + \mu\|\varphi\|_{L^2(-L,0)} \right)$$

and hence $h \in L^1(0,1)$. Thus (3.12) holds for all $\tau \in [0,1]$ and $h \in L^1(0,1)$, so $h(\tau) = 0$ a.e. in $[0,1]$. □

We summarize in the following lemma.

LEMMA 3.4.

$$\int_{-L}^0 \left\{ \left(\frac{\partial \varphi}{\partial \xi} - F(\tau) \right) \psi_1'(\xi) + ((1+2\overline{\varphi})^{-1/2} + g'(\varphi) + \mu\varphi)\psi_1(\xi) \right\} d\xi = 0 \tag{3.13}$$

for all $\psi_1 \in \tilde{H}^1(-L,0), \psi_1 \geq 0$, for all $\tau \in S \subseteq [0,1]$, meas $S = 1$; i.e., φ is a weak solution of our regularized problem (3.4)–(3.6) *for τ a.e. in* $[0,1]$.

LEMMA 3.5. *There is a set $S_1 \subset S$, meas $S_1 = 1$, so that φ is a classical $C^2[-L,0]$ solution of* (3.4)–(3.6) *for all $\tau \in S_1$.*

Proof. First $\varphi(\tau,\cdot) \in \tilde{H}^1(-L,0)$ for $\tau \in S_1 \subset S$, where meas $S_1 = 1$. For if meas $S_1 < 1$, then set $S_2 = [0,1]/S_1$, where meas $S_2 > 0$, and the inequality

$$\int_{S_2} \|\varphi(\tau,\cdot)\|^2_{\tilde{H}^1(-L,0)} d\tau \leq \int_0^1 \|\varphi(\tau,\cdot)\|^2_{\tilde{H}^1(-L,0)} = \|\varphi\|^2_{\mathbb{H}}$$

will be violated. Thus $\varphi(\tau,\xi)$ is both a weak solution for (3.4)–(3.6) and a continuous function of ξ on $[-L,0]$ for all $\tau \in S_1$, $S_1 \subset [0,1]$, meas $S_1 = 1$. Of course $\overline{\varphi} \in \tilde{H}^1(-L,0)$. Hence the right-hand side of (3.4) is continuous in ξ for $\tau \in S_1$, and hence φ must be in $C^2[-L,0]$, and φ is a classical $C^2[-L,0]$ solution of (3.4)–(3.6) for $\tau \in S_1$. ∎

LEMMA 3.6. *Assume $F(\tau) > 0$ for all $\tau \in [0,1]$; then $\varphi \geq 0$ for $-L \leq \xi \leq 0$ and almost all $\tau \in [0,1]$.*

Proof. Since φ is a classical solution of (3.4)–(3.6) for $\tau_1 \in S_1$, if $\varphi < 0$ at some $\xi \in (-L,0]$, then boundary conditions $\varphi(-L,\tau) = 0$, $\frac{\partial\varphi}{\partial\xi}(0,\tau) > 0$, imply that φ must have a negative minimum at ξ^* for this value of τ_1. Hence $\overline{\varphi}(\xi^*) > 0$, $\frac{\partial^2\varphi}{\partial\xi^2}(\xi^*,\tau_1) \geq 0$, and (3.4) implies

$$0 \leq (1 + 2\overline{\varphi}(\xi^*))^{-1/2} + g'(\varphi(\xi^*,\tau_1)) + \mu\varphi(\xi^*,\tau_1).$$

But $g(\varphi) = 1 - \varphi$ when $\varphi < 0$, and hence $g'(\varphi(\xi^*,\tau_1)) = -1$ and

$$0 \leq (1 + 2\overline{\varphi}(\xi^*))^{-1/2} - 1 + \mu\varphi(\xi^*,\tau_1) \leq \mu\varphi(\xi^*,\tau_1),$$

which is a contradiction. ∎

THEOREM 3.7. *Assume $F(\tau) > 0$ for all $\tau \in [0,1]$. There is a classical nonnegative solution φ of the regularized system*

$$\frac{\partial^2\varphi}{\partial\xi^2} = (1 + 2\overline{\varphi})^{-1/2} - e^{-\varphi} + \mu\varphi, \tag{3.14}$$

$$\frac{\partial\varphi}{\partial\xi} = F(\tau) \quad at \quad \xi = 0, \tag{3.15}$$

$$\varphi = 0 \quad at \quad \xi = -L, \tag{3.16}$$

which is continuous in τ and twice continuously differentiable in ξ on $[0,1]\times[-L,0]$.

Proof. By Lemma 3.6 we know $\varphi \geq 0$ and hence $g'(\varphi) = -e^{-\varphi}$. Hence all that remains to be shown is continuity in τ. Let $\tau_1, \tau_2 \in S_1$ so that we know that $\varphi(\cdot,\tau_1), \varphi(\cdot,\tau_2)$ are solutions of (3.14)–(3.16). Set $w(\xi) = \varphi(\xi,\tau_1) - \varphi(\xi,\tau_2)$. Then from (3.14) we know

$$w''(\xi) = -e^{-\varphi(\xi,\tau_1)} + e^{-\varphi(\xi,\tau_2)} + \mu w(\xi),$$

and, by the mean-value theorem,

$$w''(\xi) = e^{\hat{\varphi}(\xi)} w(\xi) + \mu w(\xi), \tag{3.17}$$

where $0 < \varphi(\xi,\tau_1) \leq \hat{\varphi}(\xi) \leq \varphi(\xi,\tau_2)$ (or vice versa with τ_1, τ_2 interchanged). Thus, by integration by parts,

$$\begin{aligned}\int_{-L}^{0} w(\xi)w''(\xi)d\xi &= w(\xi)w'(\xi)\,|_{\xi=-L}^{\xi=0} - \int_{-L}^{0} w'(\xi)^2 d\xi \\ &= w(0)(F(\tau_1) - F(\tau_2)) - \int_{-L}^{0} w'(\xi)^2 d\xi, \end{aligned} \tag{3.18}$$

and by (3.17),

$$\int_{-L}^{0} (w'(\xi)^2 + e^{\hat{\varphi}(\xi)} w^2(\xi) + \mu^2 w^2(\xi))d\xi \leq |w(0)||F(\tau_1) - F(\tau_2)|.$$

By the embedding of the Sobolev space $H^1(-L,0)$ into $C[-L,0]$, we have

$$\sup_{0\le\xi\le L}|w(\xi)|^2 \le \text{ const. } \sup_{0\le\xi\le L}|w(\xi)||F(\tau_1)-F(\tau_2)|$$

and

$$\sup_{\xi}|w(\xi)| \le |F(\tau_1)-F(\tau_2)|. \tag{3.19}$$

Hence for $\tau \notin S_1$ let $\{\tau_n\} \subset S_1$, $\tau_n \to \tau$. Then by (3.19)

$$\sup_{\xi}|\varphi(\xi,\tau_n)-\varphi(\xi,\tau_m)| \le |F(\tau_n)-F(\tau_m)| \to 0 \quad \text{as} \quad m,n\to\infty.$$

Thus $\varphi(\cdot,\tau_n)$ is a Cauchy sequence in $C[-L,0]$ and converges to an element of $C[-L,0]$ which we call $\varphi(\xi,\tau)$. By construction, $\varphi(\xi,\cdot)$ is continuous at τ. Finally, represent the solution of (3.14) as integrals (simply by integrating (3.14) with respect to ξ twice); then passing to the same limit shows that $\varphi(\xi,\tau)$ is a classical solution to (3.14)–(3.16). □

Thus Step 1 is completed: A classical solution of the regularized problem (3.14)–(3.16) has been obtained. We now proceed to Step 2, passage to the limit as $\mu \to 0+$ to obtain a classical solution of (3.1)–(3.3).

Step 2. *Passage to the limit as* $\mu \to 0$.

LEMMA 3.8. *If* $\varphi(\cdot,\tau)$ *has a local maximum at* $\xi^* \in (-L,0)$, *then* $\overline{\varphi}(\xi^*) \ge \varphi(\xi^*,\tau)$.

Proof. If φ has a local maximum at ξ^*, then $\frac{\partial^2\varphi}{\partial\xi^2}(\xi^*,\tau) \le 0$ and, from (3.14), $0 \ge (1+2\overline{\varphi}(\xi^*))^{-1/2} - e^{-\varphi(\xi^*,\tau)} + \mu\varphi(\xi^*,\tau)$. Since φ is nonnegative, $e^{-\varphi(\xi^*,\tau)} \ge (1+2\overline{\varphi}(\xi^*))^{-1/2}$, and hence $1+2\overline{\varphi}(\xi^*) \ge e^{2\varphi(\xi^*,\tau)} = 1+2\varphi(\xi^*,\tau) + \text{positive terms}$, and the lemma is proven. □

LEMMA 3.9. *Define* $v(\xi,\tau) = \varphi(\xi,\tau) - \overline{\varphi}(\xi)$. *If* $v(\cdot,\tau)$ *has a local maximum at* $\xi^* \in (-L,0)$, *then* $v(\xi^*,\tau) \le 0$, *i.e.,* $\varphi(\xi^*,\tau) \le \overline{\varphi}(\xi^*)$.

Proof. From (3.14),

$$\frac{\partial^2\varphi}{\partial\xi^2} = (1+2\overline{\varphi})^{-1/2} - e^{-\varphi} + \mu\varphi, \qquad \frac{\partial^2\overline{\varphi}}{\partial\xi^2} = (1+2\overline{\varphi})^{-1/2} - \overline{e^{-\varphi}} + \mu\overline{\varphi},$$

and hence by Jensen's inequality

$$\frac{\partial^2 v}{\partial\xi^2} = -e^{-\varphi} + \overline{e^{-\varphi}} + \mu v \ge -e^{-\varphi} + e^{-\overline{\varphi}} + \mu v.$$

This in turn implies

$$\frac{\partial^2 v}{\partial\xi^2} \ge e^{-\overline{\varphi}}(1-e^{-v}) + \mu v.$$

Now if v has a local maximum at $\xi^* \in (-L,0)$, then $\frac{\partial^2 v}{\partial\xi^2}(\xi^*,\tau) \le 0$ and $0 \ge e^{-\overline{\varphi}}(1-e^{-v}) + \mu v$. Since $v(\xi^*,\tau) > 0$ would yield a contradiction, we must have $v(\xi^*,\tau) \le 0$. □

LEMMA 3.10. (i) *If* $\varphi(0,\tau) - \overline{\varphi}(0) > 0$, *then the graph of* $\varphi(\cdot,\tau)$ *can intersect the graph of* $\overline{\varphi}$ *at most once on* $(-L,0)$.

(ii) *If* $\varphi(0,\tau) - \overline{\varphi}(0) \le 0$, *then the graph of* $\varphi(\cdot,\tau)$ *can never intersect the graph of* $\overline{\varphi}$ *on* $(-L,0)$.

Proof. (i) In this case, $v(0,\tau) = \varphi(0,\tau) - \overline{\varphi}(0) > 0$, $v(-L,\tau) = \varphi(-L,\tau) - \overline{\varphi}(-L) = 0$. If $\varphi(\cdot,\tau)$ intersects $\overline{\varphi}$ twice on $(-L,0)$, then $v(\cdot,\tau)$ has a positive local maximum in $(-L,0)$, which contradicts Lemma 3.9.

(ii) In this case, $v(0,\tau) = \varphi(0,\tau) - \overline{\varphi}(0) \le 0$, $v(-L,\tau) = 0$, and again if $\varphi(\cdot,\tau)$ intersects $\overline{\varphi}$, then $v(\cdot,\tau)$ has a positive local maximum in $(-L,0)$, which again contradicts Lemma 3.9. ∎

From Lemma 3.10 we see that there are three possible cases for behavior of the graph $\varphi(\cdot,\tau)$:

(a) $\varphi(0,\tau) > \overline{\varphi}(0)$, and the graph of $\varphi(\cdot,\tau)$ is always above the graph of $\overline{\varphi}$ on $(-L,0)$.

(b) $\varphi(0,\tau) > \overline{\varphi}(0)$, and the graph of $\varphi(\cdot,\tau)$ intersects the graph of $\overline{\varphi}$ once on $(-L,0)$.

(c) $\varphi(0,\tau) \le \overline{\varphi}(0)$, and the graph of $\varphi(\cdot,\tau)$ is always below the graph of $\overline{\varphi}$ on $(-L,0)$.

LEMMA 3.11. *In case* (a), $\varphi(\cdot,\tau)$ *is monotone increasing in* $[-L,0]$.

Proof. Since $\frac{\partial\varphi}{\partial\xi}(0,\tau) = F(\tau) > 0$, φ is monotone increasing near $\xi = 0$. Thus for φ to lose monotonicity it would have to possess a local minimum, say at $\xi_1 < 0$, where $\varphi(\xi_1,\tau) > 0$. Since $\varphi(-L,\tau) = 0$, there would have been a local maximum of $\xi_2 \in (-L,\xi_1)$. By Lemma 3.8, $\overline{\varphi}(\xi_2) \ge \varphi(\xi_2,\tau)$, which is a contradiction, and the lemma is proven. ∎

LEMMA 3.12. φ *is bounded on* $[-L,0]\times[0,1]$, $L = \mu^{-1}$, *uniformly in* τ,ξ, *and* μ.

Proof. If case (a) occurs for some value of $\tau \in [0,\tau]$, then $\varphi(\xi,\tau) > \overline{\varphi}(\xi)$ on $(-L,0)$, and hence $(1+2\overline{\varphi}(\xi))^{-1/2} > (1+2\varphi(\xi,\tau))^{-1/2}$. Hence (3.14) implies

$$\frac{\partial^2\varphi}{\partial\xi^2} > (1+2\varphi)^{-1/2} - e^{-\varphi} + \mu\varphi.$$

Multiplication by $\frac{\partial\varphi}{\partial\xi}$ (which is nonnegative, by Lemma 3.11) and integration from $\xi = -L$ to $\xi = 0$ yields

$$\left[\frac{1}{2}\left(\frac{\partial\varphi}{\partial\xi}\right)^2 - (1+2\varphi)^{1/2} - e^{-\varphi} - \frac{\mu\varphi^2}{2}\right]_{\xi=-L}^{\xi=0} \ge 0.$$

Evaluation of φ at $\xi = 0$, $\xi = -L$ and use of (3.15) imply

$$\frac{F^2(\tau)}{2} \ge (1+2\varphi(0,\tau))^{1/2} + e^{-\varphi(0,\tau)} + \mu\frac{\varphi^2}{2}(0,\tau) - 2,$$

which gives

$$2 + \frac{F^2(\tau)}{2} > (1+2\varphi(0,\tau))^{1/2}.$$

Thus in case (a), $\varphi(0,\tau)$ is bounded independently of μ, and by monotonicity of $\varphi(\xi,\tau)$ in ξ, so is $\varphi(\cdot,\tau)$. Moreover, if case (a) occurs for all $\tau \in [0,1]$, the above inequality shows that φ is bounded on $[-L,0], L = \mu^{-1}$, uniformly in τ and μ.

Now note that case (a) must occur for some value of $\tau \in [0,1]$. (If not, then we would have only cases (b), (c) and hence a value of ξ where the τ average of φ is less

than $\overline{\varphi}(\xi)$, which is of course impossible.) Hence, since φ is above $\overline{\varphi}$ in case (a), we have $\overline{\varphi}$ bounded independently of μ, and hence trivially case (c) is now covered; i.e., φ is bounded independently of μ in case (c).

Thus we need consider only case (b). In case (b) denote by ξ_* the crossing value of ξ, i.e., $\varphi(\xi_*,\tau)=\overline{\varphi}(\xi_*)$. (Of course ξ_* will in general depend on τ.) Hence $\varphi(\xi,\tau)>\overline{\varphi}(\xi)$ on $(\xi_*,0]$, $0<\varphi(\xi,\tau)<\overline{\varphi}(\xi)$ on $(-L,\xi_*)$. Thus we need consider only the interval $(\xi_*,0)$ since the boundedness of $\overline{\varphi}$ implies boundedness of $\varphi(\cdot,\tau)$ on $(-L,\xi_*]$.

By Lemma 3.8, $\varphi(\cdot,\tau)$ cannot have a local maximum on $(\xi_*,0)$. Hence $\varphi(\cdot,\tau)$ can be monotone increasing, be monotone decreasing, or have a local minimum. If $\varphi(\cdot,\tau)$ is monotone decreasing, we trivially have an upper bound, i.e., $\overline{\varphi}(\xi_*)$. On the other hand, if $\varphi(\cdot,\tau)$ is monotone increasing in $(\xi_*,0)$, then again

$$\frac{\partial^2\varphi}{\partial\xi^2}>(1+2\varphi)^{-1/2}-e^{-\varphi}+\mu\varphi,$$

and multiplication by $\frac{\partial\varphi}{\partial\xi}>0$ and integration from ξ_* to 0 yields

$$\begin{aligned}\frac{F^2(\tau)}{2}+(1+2\overline{\varphi}(\xi_*))^{1/2}+e^{-\overline{\varphi}(\xi_*)}+\frac{\mu\overline{\varphi}^2(\xi_*)}{2}&\\ >(1+2\varphi(0,\tau))^{1/2}+e^{-\varphi(0,\tau)}+\frac{\mu\varphi(0,\tau)^2}{2}&\\ >(1+2\varphi(0,\tau))^{1/2}.&\end{aligned}$$

Since $\overline{\varphi}$ is bounded independently of μ, we see that $\varphi(0,\tau)$ is bounded independently of μ for all $\tau\in[0,1]$. Thus the monotonicity of φ on $(\xi_*,0)$ yields φ bounded independently of μ on $(\xi_*,0)$ as well as $(-L,\xi_*]$.

Finally, if φ has a minimum on $(\xi_*,0)$, then φ is monotone decreasing on (ξ_*,ξ_{**}) and monotone increasing on $(\xi_{**},0)$, where ξ_{**} is the point of local minimum. On (ξ_*,ξ_{**}), φ is trivially less than $\overline{\varphi}(\xi_*)$, whereas on $(\xi_{**},0)$, φ is monotone increasing, and the same argument given above when φ was monotone increasing on $(\xi_*,0)$ applies. Hence φ is bounded on $(-L,0)$ uniformly in ξ,τ,μ. ∎

LEMMA 3.13. *In case* (b), $0\le\frac{\partial\varphi}{\partial\xi}(\xi,\tau)\le F(\tau)$, $-L\le\xi\le 0$, *and* $\frac{\partial\varphi}{\partial\xi}$ *is bounded uniformly in* ξ,τ,μ.

Proof. In case (b), we know from Lemma 3.11 that $\varphi(\cdot,\tau)$ is monotone, $\varphi>\overline{\varphi}$. Hence

$$\frac{\partial^2\varphi}{\partial\xi^2}=(1+2\overline{\varphi})^{-1/2}-e^{-\varphi}+\mu\varphi\ge(1+2\varphi)^{-1/2}-e^{-\varphi}+\mu\varphi\ge\mu\varphi>0$$

on $(-L,0)$. Hence $\frac{\partial\varphi}{\partial\xi}(\xi,\tau)$ is monotone increasing in ξ, and hence $\frac{\partial\varphi}{\partial\xi}(-L,\tau)\le\frac{\partial\varphi}{\partial\xi}(\xi,\tau)\le F(\tau)$. But $\frac{\partial\varphi}{\partial\xi}(-L,\tau)\ge 0$ since if $\frac{\partial\varphi}{\partial\xi}(-L,\tau)<0$, then the fact that $\varphi(-L,\tau)=0$ implies that φ would take on negative values for $\xi>-L$, which is impossible. Hence $0\le\frac{\partial\varphi}{\partial\xi}(\xi,\tau)\le F(\tau)$ in case (a). ∎

LEMMA 3.14. *In case* (c), $\frac{\partial\varphi}{\partial\xi}$ *is bounded uniformly in* ξ,τ,μ.

Proof. Let τ_1,τ_3 be values of τ so that $\varphi(\tau_1,\xi)$ is in case (a) and $\varphi(\tau_3,\xi)$ is case (c). Let $\psi(\xi)=\varphi(\xi,\tau_1)-\varphi(\xi,\tau_3)$. Then

$$\psi''(\xi)=-e^{-\varphi(\xi,\tau_1)}+e^{-\varphi(\xi,\tau_3)}+\mu(\varphi(\xi,\tau_1)-\varphi(\xi,\tau_3))\ge 0\quad\text{on}\quad(-L,0)$$

since $\varphi(\xi,\tau_1) > \overline{\varphi}(\xi) > \varphi(\xi,\tau_3)$ on $(-L,0)$. Furthermore, $\psi'(-L) \geq 0$ since $\varphi(\xi,\tau_1) \to 0$ as $\xi \to -L$ from values above $\overline{\varphi}$, while $\varphi(\xi,\tau_3) \to 0$ as $\xi \to -L$ from values below $\overline{\varphi}$. Hence $\psi'(\xi) \geq 0$ on $[-L,0]$ and $\frac{\partial\varphi}{\partial\xi}(\xi,\tau_1) \geq \frac{\partial\varphi}{\partial\xi}(\xi,\tau_3)$ on $[-L,0]$, and from Lemma 3.13, $F(\tau_1) \geq \frac{\partial\varphi}{\partial\xi}(\xi,\tau_3)$. Finally, integrate the inequality $\psi''(\xi) \geq 0$ from ξ to 0 to see $\psi'(0) \geq \psi'(\xi)$ and hence $F(\tau_1) - F(\tau_3) \geq \frac{\partial\varphi}{\partial\xi}(\xi,\tau_1) - \frac{\partial\varphi}{\partial\xi}(\xi,\tau_3)$. Since $\frac{\partial\varphi}{\partial\xi}(\xi,\tau_1) \geq 0$, we conclude $F(\tau_1) \geq \frac{\partial\varphi}{\partial\xi}(\xi,\tau_3) \geq F(\tau_3) - F(\tau_1)$ on $[-L,0]$, and the lemma is proven. ∎

LEMMA 3.15. *$\overline{\varphi}'$ is bounded uniformly in μ,ξ.*

Proof. From (3.14) we have

$$\frac{\partial^2\varphi}{\partial\xi^2} = (1+2\overline{\varphi})^{-1/2} + e^{-\varphi} + \mu\varphi \quad \text{on} \quad (-L,0).$$

Multiply by $\frac{\partial\varphi}{\partial\xi}$ and integrate in τ from 0 to 1 to obtain

$$\frac{1}{2}\frac{\partial}{\partial\xi}\overline{\left(\left(\frac{\partial\varphi}{\partial\xi}\right)^2\right)} = (1+2\overline{\varphi})^{-1/2}\overline{\varphi}'(\xi) + \frac{\partial}{\partial\xi}\overline{\left(e^{-\varphi} + \frac{\mu\varphi^2}{2}\right)}.$$

Now integrate from $-L$ to ξ and we see

$$\frac{1}{2}\overline{\left(\frac{\partial\varphi}{\partial\xi}\right)^2}\Bigg|_{-L}^{\xi} = (1+2\overline{\varphi})^{1/2} + \overline{e^{-\varphi} + \frac{\mu\varphi^2}{2}}\Bigg|_{-L}^{\xi}. \tag{3.20}$$

From Lemma 3.12 the right-hand side of (3.20) is bounded uniformly in μ,ξ. Hence by Jensen's inequality

$$\left(\frac{\partial\overline{\varphi}}{\partial\xi}(\xi)\right)^2 \leq \overline{\left(\frac{\partial\varphi}{\partial\xi}(\cdot,-L)\right)^2} + \text{ const.} \tag{3.21}$$

Since $\frac{\partial\varphi}{\partial\xi}(\tau,-L) \geq 0$, the greatest value of $\frac{\partial\varphi}{\partial\xi}(\tau,-L)$ must occur in case (a) when $\varphi \to 0$ as $\xi \to -L$ from above $\overline{\varphi}$. But in case (a) we already know from Lemma 3.13 that $\frac{\partial\varphi}{\partial\xi}$ is bounded uniformly in ξ,τ,μ. Therefore (3.21) implies the statement of the lemma. ∎

LEMMA 3.16. *In case* (b), *$\frac{\partial\varphi}{\partial\xi}$ is bounded uniformly in ξ,τ,μ.*

Proof. We use the same solution as in the proof of Lemma 3.12 and let ξ_* denote the point where $\varphi(\xi_*,\tau) = \overline{\varphi}(\xi_*)$ (where of course ξ_* will generally depend on τ). Recall that on $(-L,\xi_*)$, $\varphi(\xi,\tau)$ is below $\overline{\varphi}$, and on $(\xi_*,0]$, $\varphi(\xi,\tau)$ is above $\overline{\varphi}$.

We first consider $(-L,\xi_*)$ and let τ_1,τ_2 be values of τ for which cases (a) and (b) occur. (Recall that case (a) must occur since otherwise we would have $\overline{\varphi} < 0$ at some values of ξ on $(-L,0)$.) Hence $\varphi(\xi,\tau_2) < \overline{\varphi}(\xi) < \varphi(\xi,\tau_1)$ on $(-L,\xi_*(\tau_2))$. Set $\psi(\xi) = \varphi(\xi,\tau_1) - \varphi(\xi,\tau_2)$. Then

$$\frac{\partial^2\psi}{\partial\xi^2} = e^{-\varphi(\xi,\tau_2)} - e^{-\varphi(\xi,\tau_1)} + \mu(\varphi(\xi,\tau_1) - \varphi(\xi_2,\tau_2)) \geq 0$$

on $(-L,\xi_*(\tau_2))$. Since $\varphi(\xi,\tau_1)$ approaches 0 as $\xi \to -L$ from above $\overline{\varphi}$, while $\varphi(\xi,\tau_2)$ approaches 0 as $\xi \to -L$ from below $\overline{\varphi}$, we have $\psi'(-L) \geq 0$ and hence $\psi'(\xi) \geq 0$ on $[-L,\xi_*(\tau_2)]$. Thus $\frac{\partial\varphi}{\partial\xi}(\xi,\tau_1) > \frac{\partial\varphi}{\partial\xi}(\xi,\tau_2)$ on $[-L,\xi_*(\tau_2)]$, and by Lemma 3.13, $F(\tau_1) \geq \frac{\partial\varphi}{\partial\xi}(\xi,\tau_2)$.

Thus on $(-L, \xi_*(\tau_2)]$ we have $\frac{\partial\varphi}{\partial\xi}$ bounded from above uniformly in ξ, τ, μ. When $\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2) \geq 0$, then the bound from below is trivial. Otherwise, a bound from below can be obtained by considering two cases.

Case 1. $\frac{\partial\varphi}{\partial\xi}(\xi_*(\tau_2), \tau_2) \geq 0$. In this case, $\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2)$ can be negative but only on subintervals, say (ξ_1, ξ_2), for which $\frac{\partial\varphi}{\partial\xi}(\xi_1, \tau_2) = \frac{\partial\varphi}{\partial\xi}(\xi_2, \tau_2) = 0$. This is because at the end points of the region $(-L, \xi_*(\tau_2))$ we have $\frac{\partial\varphi}{\partial\xi}(-L, \tau_2) \geq 0$ and $\frac{\partial\varphi}{\partial\xi}(\xi_*(\tau_2), \tau_2) \geq 0$. Thus on a region (ξ_1, ξ_2), for which $\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2) < 0$, we have

$$\frac{\partial^2\varphi}{\partial\xi^2} \leq (1 + 2\varphi)^{-1/2} - e^{-\varphi} + \mu\varphi$$

(since $\varphi < \overline{\varphi}$), and multiplication by $\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2)$ and integration from ξ to ξ_2 yields

$$\frac{1}{2}\left(\frac{\partial\varphi}{\partial\xi}\right)^2\Bigg|_{\xi}^{\xi_2} \geq \left[(1 + 2\varphi)^{1/2} + e^{-\varphi} + \frac{\mu\varphi^2}{2}\right]\Bigg|_{\xi}^{\xi_2}$$

and hence

$$\sup_{\xi}\left\{(1 + 2\varphi)^{1/2} + e^{-\varphi} + \frac{\mu\varphi^2}{2}\right\} \geq \frac{1}{2}\left(\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2)\right)^2. \tag{3.22}$$

Since Lemma 3.12 implies that the left-hand side of (3.21) is bounded uniformly in μ, τ, we have $\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2)$ uniformly bounded in ξ, μ, τ when $\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2) < 0$ and $-L \leq \xi \leq \xi_*(\tau_2)$.

Case 2. $\frac{\partial\varphi}{\partial\xi}(\xi_*(\tau_2), \tau_2) < 0$. In this case, since $\varphi < \overline{\varphi}$ on $(-L, \xi_*(\tau_2))$ and $\varphi > \overline{\varphi}$ on $(\xi_*(\tau_2), 0)$, we must have

$$\overline{\varphi}'(\xi_*(\tau_2)) < \frac{\partial\varphi}{\partial\xi}(\xi_*(\tau_2), \tau_2) < 0. \tag{3.23}$$

Thus on an interval $(\xi_3, \xi_*(\tau_2))$, where

$$\frac{\partial\varphi}{\partial\xi}(\xi_3, \tau_2) = 0, \qquad \frac{\partial\varphi}{\partial\xi}(\xi_*(\tau_2), \tau_2) < 0,$$

and $\frac{\partial\varphi}{\partial\xi}(\xi, \tau) < 0$ on $(\xi_3, \xi_*(\tau_2))$, we have again have from (3.14)

$$\frac{\partial^2\varphi}{\partial\xi^2} \leq (1 + 2\varphi)^{-1/2} - e^{-\varphi} + \mu\varphi,$$

and multiplication by $\frac{\partial\varphi}{\partial\xi} < 0$ and integration from ξ to $\xi_*(\tau_2)$ yields

$$\frac{1}{2}\left(\frac{\partial\varphi}{\partial\xi}\right)^2\Bigg|_{\xi}^{\xi_*(\tau_2)} \geq \left[(1 + 2\varphi)^{1/2} + e^{-\varphi} + \frac{\mu\varphi^2}{2}\right]\Bigg|_{\xi}^{\xi_*(\tau_2)}$$

and

$$\frac{1}{2}\left(\frac{\partial\varphi}{\partial\xi}(\xi_*(\tau_2), \tau_2)\right)^2 + \sup_{\xi}\left((1 + 2\varphi)^{1/2} + e^{-\varphi} + \frac{\mu\varphi^2}{2}\right) \geq \frac{1}{2}\left(\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2)\right)^2. \tag{3.24}$$

Lemma 2.12 shows that the second term on the left-hand side of (3.24) is bounded uniformly in μ, τ, while inequality (3.23) and Lemma 3.15 cover the first term, and Case 2 is complete.

To complete the proof of the lemma we must consider the interval $(\xi_*(\tau_2), 0]$. Now define $\Gamma(\xi) = \varphi(\xi, \tau_2) - \varphi(\xi, \tau_3)$, where τ_2, τ_3 are values for which cases (b), (c) occur, respectively. Again note that if the case (b) occurs, where $\varphi > \overline{\varphi}$ on $(\xi_*(\tau_2), 0]$ since case (a) must occur, then case (c) must also occur. Otherwise, φ would be greater than $\overline{\varphi}$ on some ξ interval for all $\tau \in [0, 1]$. Thus $\Gamma(\xi)$ is well defined and $\Gamma(\xi) > 0$. From (3.14)

$$\Gamma''(\xi) = -e^{-\varphi(\xi,\tau_2)} + e^{-\varphi(\xi,\tau_3)} + \mu\Gamma(\xi) > 0 \tag{3.25}$$

since $\varphi(\xi, \tau_2) > \overline{\varphi} > \varphi(\xi, \tau_3)$ on $(\xi_*(\tau_2), 0]$. Integrate (3.25) from ξ to 0. We obtain

$$\Gamma'(\xi) < \Gamma'(0) = \frac{\partial\varphi}{\partial\xi}(0, \tau_2) - \frac{\partial\varphi}{\partial\xi}(0, \tau_3) = F(\tau_2) - F(\tau_3)$$

and hence

$$\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2) < \frac{\partial\varphi}{\partial\xi}(\xi, \tau_3) + F(\tau_2) - F(\tau_3). \tag{3.26}$$

Now on $(\xi_*(\tau_2), 0)$ we have $\varphi(\xi, \tau_2) > \overline{\varphi}(\xi)$, and hence by (3.14)

$$\frac{\partial^2\varphi}{\partial\xi^2} > (1 + 2\varphi)^{-1/2} - e^{-\varphi} + \mu\varphi > 0. \tag{3.27}$$

Hence $\varphi(\xi, \tau_2)$ can have a local minimum but no local maximum. Hence either $\varphi(\xi, \tau_2)$ is monotone increasing or $\varphi(\xi, \tau_2)$ has a local minimum at $\xi_{**}(\tau_2), \xi_*(\tau_2) < \xi_{**}(\tau_2) < 0$. If $\varphi(\xi, \tau_2)$ is monotone increasing, then (3.26) and Lemma 3.14 imply that $\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2)$ is bounded uniformly in ξ, μ, τ, and we are finished. If $\varphi(\xi, \tau_2)$ has a local minimum at $\xi_{**}(\tau_2)$, then on $(\xi_{**}(\tau_2), 0)$, $\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2) \geq 0$, and again (3.26) yields the uniform bound. Finally on $(\xi_*(\tau_2), \xi_{**}(\tau_2))$ we have $\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2) < 0$. Multiply (3.27) by $\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2) < 0$. Then integration from $\xi_*(\tau_2)$ to ξ yields

$$\frac{1}{2}\left(\frac{\partial\varphi}{\partial\xi}\right)^2 \Bigg|_{\xi_*(\tau_2)}^{\xi} < \left[(1 + 2\varphi)^{1/2} + e^{-\varphi} + \frac{\mu\varphi^2}{2}\right] \Bigg|_{\xi_*(\tau_2)}^{\xi}. \tag{3.28}$$

The right-hand side of (3.28) is bounded uniformly in ξ, μ, τ by Lemma 3.12, and $\frac{\partial\varphi}{\partial\xi}(\xi_*(\tau_2), \tau_2)$ is also bounded uniformly in ξ, μ, τ by Cases 1 and 2 above. Hence $\frac{\partial\varphi}{\partial\xi}(\xi, \tau_2)$ is uniformly bounded as well, and the lemma is proven. ∎

LEMMA 3.17. *Let $\tau, \sigma \in [0, 1]$. Then*

$$\sup_{\xi} |\varphi(\tau, \xi) - \varphi(\sigma, \xi)| \leq \text{ const.} |F(\tau) - F(\sigma)|,$$

where the const. is independent of τ, σ, μ.

Proof. Set $w(\xi) = \varphi(\tau, \xi) - \varphi(\sigma, \xi)$. Then from (3.14)

$$w''(\xi) = -e^{-\varphi(\tau,\xi)} + e^{-\varphi(\sigma,\xi)} + \mu w,$$

and by the mean value theorem

$$e^{-\varphi(\sigma,\xi)} - e^{-\varphi(\tau,\xi)} = -e^{-\gamma(\xi,\sigma,\tau)}(\varphi(\sigma, \xi) - \varphi(\tau, \xi)) = e^{-\gamma(\xi,\sigma,\tau)} w(\xi),$$

where either

$$0 < \varphi(\sigma,\xi) < \gamma(\xi,\sigma,\tau) < \varphi(\tau,\xi) \quad \text{or} \quad 0 < \varphi(\tau,\xi) < \gamma(\xi,\sigma,\tau) < \varphi(\sigma,\xi). \tag{3.29}$$

Hence we see

$$w''(\xi) = e^{-\gamma(\xi,\sigma,\tau)} w(\xi) + \mu w(\xi), \tag{3.30}$$

and multiplying (3.30) by $w(\xi)$ and integrating from $-L$ to ξ we find

$$-\int_{-L}^{0} w'(\xi)^2 d\xi + w(\xi)w'(\xi)\,|_{-L}^{0} = \int_{-L}^{0} e^{-\gamma(\xi,\sigma,\tau)} w^2(\xi) + \mu w^2(\xi) d\xi. \tag{3.31}$$

Since $w(-L) = 0, w'(0) = F(\tau) - F(\sigma)$, γ is nonnegative, and by Lemma 3.12 the function γ is uniformly bounded in τ, σ, μ, ξ, we see

$$\begin{aligned} -\int_{-L}^{0} w'(\xi)^2 d\xi + w(0)(F(\tau) - F(\sigma)) \\ \geq \text{const}_1 \int_{-L}^{0} w^2(\xi) d\xi, \end{aligned} \tag{3.32}$$

where

$$e^{-\gamma(\xi,\sigma,\tau)} \geq \text{const}_1 > 0$$

and the const_1 is independent of μ, ξ, τ. From (3.32) we easily see

$$\begin{aligned} \sup_{\xi} |w(\xi)||F(\tau) - F(\sigma)| &\geq \text{const}_1 \int_{-L}^{0} w'(\xi)^2 + \int_{-L}^{0} w(\xi)^2 d\xi \\ &\geq \text{const}_2 \left(\sup_{\xi} |w(\xi)| \right)^2, \end{aligned}$$

where const_2 is independent of μ, ξ, τ. The lemma is proven. ∎

Now define the extended function φ_e:

$$\varphi_e(\xi,\tau;\mu) \stackrel{\text{def}}{=} \begin{cases} \varphi(\xi,\tau), & -L \leq \xi \leq 0, \\ 0, & \xi < -L. \end{cases}$$

LEMMA 3.18. *$\{\varphi_e(\cdot,\cdot;\mu)\}$ is uniformly bounded and equicontinuous on $(-\infty, 0] \times [0,1]$. Furthermore, $\{\varphi_e(\cdot,\cdot;\mu)\}$ has a subsequence which converges as $\mu \to 0$ uniformly on compact subsets of $(-\infty, 0] \times [0,1]$ to a function $\varphi_\#$. The function $\varphi_\#(\xi,\tau)$ is periodic in τ with period 1.*

Proof. Lemmas 3.12, 3.13, 3.14, 3.16, 3.17 prove the uniform boundedness and equicontinuity. Existence of a convergent subsequence on compact subsets of $(-\infty, 0] \times [0,1]$ follows from the Ascoli–Arzela theorem. Finally, the limit function $\varphi_\#$ inherits the inequality of Lemma 3.17, and hence $\varphi_\#$ is periodic in τ with period 1. ∎

LEMMA 3.19. *The limit function $\varphi_\#(\cdot,\tau)$ is nonnegative on $(-\infty, 0]$ and satisfies (3.1), (3.2) for every $\tau \in [0,1]$.*

Proof. Since $\varphi(\cdot,\cdot;\mu)$ is a smooth solution of (3.14)–(3.16), it solves the weak form of the equations (3.14)–(3.16):

$$\int_{-L}^{0} \left(\frac{\partial \varphi}{\partial \xi} - F(\tau) \right) \psi'(\xi) + ((1 + 2\overline{\varphi})^{-1/2} + e^{-\varphi} + \mu\varphi)\psi(\xi) d\xi = 0,$$

$0 \le \tau \le 1$, and all $\psi \in C_0^\infty(-\infty, 0]$. Integration by parts and use of the definition of φ_e imply

$$\int_{-\infty}^{0} -\varphi_e \psi''(\xi) + ((1 + 2\overline{\varphi}_e)^{-1/2} + e^{-\varphi_e} + \mu\varphi_e)\psi(\xi) d\xi + (\varphi_e(0,\tau) - F(\tau))\psi'(0) = 0. \tag{3.33}$$

Now let $\mu \to 0$. By Lemma 3.18, $\{\varphi_e(\cdot,\cdot,\mu)\}$ has a convergent subsequence which approaches $\varphi_\#$ uniformly on compact subsets of $(-\infty, 0] \times [0, 1]$. By the uniform convergence of φ_e to $\varphi_\#$, the limit function $\varphi_\#$ satisfies (3.33) and is a weak solution of (3.1), (3.2). Since the right-hand side of (3.1) is continuous in ξ, we see that $\varphi_\#$ is C^2 in ξ, and $\varphi_\#$ is a classical solution of (3.1), (3.2), twice continuously differentiable in ξ and continuous in τ. The nonnegativity of $\varphi_\#$ follows from the nonnegativity of φ_e. ∎

THEOREM 3.20. *Assume that* $F(\tau) = p\int_0^t f(\tau)d\tau + \frac{\partial\varphi_0}{\partial\xi}(0,0) > 0$ *is given, continuously differentiable, and periodic with period* 1. *Then the limit function* $\varphi_\#$ *is a classical solution of* (3.1)–(3.3)*, twice continuously differentiable in* ξ*, continuous in* τ*, on* $(-\infty, 0] \times [0, 1]$*, and periodic in* τ *with period* 1.

Proof. From Lemma 3.19 we know that $\varphi_\#$ satisfies (3.1)–(3.2). Thus we need only verify the boundary condition (3.3). Since $\varphi(\cdot,\cdot,\mu)$ satisfied cases (a), (b), (c), we see that $\varphi_e(\cdot,\cdot,\mu)$ satisfies the following cases:

(a_e). $\varphi_e(0,\tau;\mu) > \overline{\varphi}_e(0;\mu)$, and the graph of φ_e is always above the graph of $\overline{\varphi}_e$ on $(-L, 0)$ and $\varphi_e(\xi,\tau;\mu) = \overline{\varphi}_e(\xi,\mu) = 0$ on $(-\infty, -L)$.

(b_e). $\varphi_e(0,\tau;\mu) > \overline{\varphi}_e(0;\mu)$, and the graph of φ_e intersects the graph of $\overline{\varphi}_e$ once on $(-L, 0)$ and $\varphi_e(\xi,\tau;\mu) = \overline{\varphi}_e(\xi,\mu) = 0$ on $(-\infty, -L)$.

(c_e). $\varphi_e(0,\tau;\mu) \le \overline{\varphi}_e(0;\mu)$, and the graph of φ_e is always below the graph of $\overline{\varphi}_e$ on $(-L, 0)$ and $\varphi_e(\xi,\tau;\mu) = \overline{\varphi}_e(\xi,\mu) = 0$ on $(-\infty, -L)$.

Since $\varphi_e(\cdot,\tau;\mu_k) \to \varphi_\#(\cdot,\tau)$ uniformly on compact subsets of $(-\infty, 0]$ for some sequence $\mu_k \to 0$ as $k \to \infty$, the inequalities $\varphi_e \ge \overline{\varphi}_e$ and $\varphi_e \le \overline{\varphi}_e$ of cases (a_e), (c_e) are preserved in the limit.

Case (b_e) has $\varphi_e > \overline{\varphi}_e$ on $(\xi_*(\mu), 0]$, $\varphi_e < \overline{\varphi}_e$ on $(-L, \xi_*(\mu))$, $\varphi_e = \overline{\varphi}_e$ on $(-\infty, -L]$. Consider the sequence $\{\xi_*(\mu_k)\}$. If $\xi_*(\mu_k) \to \infty$ as $\mu_k \to 0$, then the limit function $\varphi_\#$ satisfies $\varphi_\# \ge \overline{\varphi}_\#$ on $(-\infty, 0]$. On the other hand, if $\{\xi_*(\mu_k)\}$ is bounded as $\mu_k \to 0$, then, possibly extracting a convergent subsequence if necessary, we have $\xi_*(\mu_k) \to \xi_0 \le 0$ and, by uniform convergence, $\varphi_\# \ge \overline{\varphi}_\#$ on $(\xi_0, 0]$, $\varphi_\# \le \overline{\varphi}_\#$ on $(-\infty, \xi_0]$. Hence the limit function $\varphi_\#$ satisfies

($a_\#$). $\varphi_\#(0,\tau) \ge \overline{\varphi}_\#(0)$, and the graph of $\varphi_\#$ is above or touching the graph of $\overline{\varphi}_\#$ on $(-\infty, 0]$.

($b_\#$). $\varphi_\#(0,\tau) \ge \overline{\varphi}_\#(0)$, and the graph of $\varphi_\#$ intersects the graph of $\varphi_\#$ once on $(-\infty, 0]$.

($c_\#$). $\varphi_\#(0,\tau) \le \overline{\varphi}_\#(0)$, and the graph of $\varphi_\#$ is below or touching the graph of $\overline{\varphi}_\#$ on $(-\infty, 0]$.

In case ($a_\#$), $\varphi_\#$ is obtained as the uniform limit of monotone increasing functions (via Lemma 3.13). Hence $\varphi_\#$ is nondecreasing in ξ, and $\frac{\partial\varphi_\#}{\partial\xi} \ge 0$ on $(-\infty, 0)$. Also since $\overline{\varphi}_\# \ge \varphi_\#$, (3.1) implies

$$\frac{\partial^2\varphi_\#}{\partial\xi^2} \ge (1 + 2\varphi_\#)^{-1/2} - e^{-\varphi_\#} \ge 0, \tag{3.34}$$

and hence both $\varphi_\#$ and $\frac{\partial\varphi_\#}{\partial\xi}$ are nondecreasing and bounded from below on $(-\infty, 0]$. Hence $\lim_{\xi\to-\infty}\varphi_\#(\xi,\tau)$ and $\lim_{\xi\to-\infty}\frac{\partial\varphi_\#}{\partial\xi}(\xi,\tau)$ exist.

Now integrate (3.34) from $-\infty$ to 0 in ξ. We see

$$F(\tau) - \frac{\partial\varphi_\#}{\partial\xi}(-\infty,\tau) > \int_{-\infty}^{0}((1+2\varphi_\#)^{-1/2} - e^{-\varphi_\#})d\xi. \tag{3.35}$$

Since the integrand in (3.35) is nonnegative and $\lim_{\xi\to\infty}\varphi_\#$ exists, (3.35) implies that the limit is zero. Similarly we have

$$\varphi_\#(0,\tau) - \varphi_\#(-\infty,\tau) = \int_{-\infty}^{0}\frac{\partial\varphi_\#}{\partial\xi}(\xi,\tau)d\xi. \tag{3.36}$$

Again the left-hand side of (3.36) is bounded and the integrand is nonnegative; hence $\lim_{\xi\to-\infty}\frac{\partial\varphi_\#}{\partial\xi}(\xi,\tau) = 0$.

Cases ($b_\#$) and ($c_\#$): Since case ($a_\#$) must always occur, and since for ξ sufficiently negative the graphs of $\varphi_\#$ in cases ($b_\#$) and ($c_\#$) lie below the graph $\varphi_\#$ of case ($a_\#$), we have $\lim_{\xi\to\infty}\varphi_\#(\xi,\tau) = 0$ in cases ($b_\#$) and ($c_\#$) as well.

Now set $w(\xi) = \varphi_\#(\tau_1,\xi) - \varphi_\#(\tau_2,\xi)$, where $\varphi_\#(\tau_1,\xi)$ is as in case ($a_\#$) and $\varphi(\tau_2,\xi)$ is as in case ($b_\#$). Then since $\varphi_\#(\tau_1,\xi) > \varphi_\#(\tau_2,\xi)$ for ξ sufficiently negative, say, $-\infty < \xi < \xi_1 < 0$, we have

$$w(\xi) > 0, \tag{3.37}$$

$$w''(\xi) = -e^{-\varphi_\#(\tau_1,\xi)} + e^{-\varphi_\#(\tau_2,\xi)} > 0 \tag{3.38}$$

on $(-\infty,\xi_1)$.

If $w'(\xi_1) < 0$, then $w'(\xi) < 0$ on $(-\infty,\xi_1)$ by (3.38). Since $w(\xi)\to 0$ as $\xi\to-\infty$, we have

$$0 > \int_{-\infty}^{\xi_1} w'(\xi)d\xi = w(\xi_1),$$

which is impossible. Hence the only possibility is $w'(\xi_1)\geq 0$. We must have $w'(\xi)\geq 0$ on $(-\infty,\xi_1)$ since if $w'(\xi_2) < 0$ for some $-\infty < \xi_2 < \xi_1$, then the preceding argument with ξ_1 replaced by ξ_2 would show $w(\xi_2) < 0$, a contradiction. Thus for decreasing ξ, $w'(\xi)$ is monotone decreasing and bounded from below by zero. Hence $\lim_{\xi\to-\infty}w'(\xi)$ exists. Since

$$w(\xi) = \int_{-\infty}^{\xi} w'(\xi)d\xi$$

and the left-hand side is bounded and the integrand is nonnegative, $\lim_{\xi\to-\infty}w'(\xi) = 0$. Hence

$$\lim_{\xi\to-\infty}\frac{\partial\varphi_\#}{\partial\xi}(\tau_2,\xi) = \lim_{\xi\to-\infty}\left(\frac{\partial\varphi_\#}{\partial\xi}(\tau_1,\xi) - w'(\xi)\right) = 0,$$

and case ($b_\#$) is complete. Fortunately the same argument that was used for case ($b_\#$) applies to case ($c_\#$), and the theorem is proven. □

ACOUSTIC PULSE SPREADING IN A RANDOM FRACTAL*

KNUT SØLNA†

Abstract. Fractal medium models are used to model, for instance, the heterogeneous earth and the turbulent atmosphere. A wave pulse propagating through such a medium will be affected by multiscale medium fluctuations. For a class of one-dimensional fractal random media defined in terms of fractional Brownian motion we show how the wave interacts with the medium fluctuations. The modification in the pulse shape depends on the roughness of the medium and can be described in a *deterministic* way when the pulse is observed at its *random* arrival time. For very rough media the coherent wave is confined to a surface layer.

Key words. wave propagation, random medium, fractional Brownian motion, homogenization, anomalous diffusion

1. Introduction.

Propagation of wave pulses in a *smooth* medium is well understood, but propagation in a *rough* or *multiscale* medium is not as well understood. We will look at how a propagating pulse interacts with rough variations in the medium.

Given the importance and long history of wave propagation and scattering problems, a multitude of approaches have been developed to analyze them. In the homogenization or effective media regime, rapidly varying properties of the medium average out when the width of the propagating pulse is large compared to the scale of the medium fluctuations. However, over long propagation distances the accumulated effect of the scattering, associated with the medium microstructure, gradually changes the pulse *beyond* the geometrical effects of the high frequency analysis in the smooth homogenized medium. In the 1960s and early 1970s, *mean* pulse propagation over long distances was analyzed. More recently a mathematical theory has been developed that gives a more precise description [1, 8, 16] of pulse propagation. It deals with pulses in a particular realization of the random medium and explains why in many cases the evolution of the *pulse shape* is to leading order *deterministic*. We refer to this phenomenon as pulse *stabilization*. So far, two salient features of this "pulse shaping" theory have been that it assumes a one-dimensional medium and a separation of scales for the medium heterogeneities; that is, the medium has features on microscales which are well separated from the macroscale. However, several studies [9, 13, 14, 21] suggest that, for instance, the earth's crust should be modeled as containing fluctuations on a continuum of length scales. Multiscale medium models are also used for the turbulent atmosphere [20] and, moreover, to model the transition zone between different parts of tissues or the zone between different parts of certain devices, for instance, the zone associated with a large change in the dielectric permittivity. Burridge, Papanicolaou, and White give a nice derivation of pulse shaping in periodic and stationary random media in [6]. Here, we generalize the pulse shaping theory for a two scale medium, as presented in [6], to the multiscale case.

The stabilization phenomenon has been shown to hold true also for waves propagating in three spatial dimensions in the case with layered media. This problem has been analyzed in detail in [7] and more recently also in [12], where it is discussed in the context of time-reversal of waves. Stabilization and pulse shaping in the case with slow lateral variations in the medium have been analyzed in [15] and [25].

The analysis of the interaction of a wave pulse with a medium varying on many length scales is an interesting but largely open question from a mathematical viewpoint, despite its importance in applications. We analyze this problem for acoustic waves propagating in a one-dimensional discrete medium, modeled in terms of fractional Brownian motion. Fractional Brownian motion is a Gaussian (self-similar) stochastic process and is often used as a model for processes containing fluctuations on a continuum of length scales, for instance, for modeling of turbulent environments. The discretization assumes that the medium has a smallest scale. In turbulence theory this is the *inner* scale. Below, we refer to media defined in terms of fractional Brownian motion as "fractal" media. The Hurst exponent H characterizes the roughness of the fractional Brownian motion, and the value $H = 1/2$ gives standard Brownian motion. In the simplest case with $H = 1/2$ the medium model that we consider satisfies a separation of scales assumption. For $H \neq 1/2$ the medium contains long-range interactions and variations on many scales. We show that in the limit of small inner scale relative to the travel distance the transformation of the pulse shape becomes *deterministic*; thus the classic pulse shaping theory for media satisfying a separation of scales assumption generalizes in this sense. However, now the *scale* on which the spreading of the pulse happens depends on the roughness of the medium and does *not* in general correspond to the inner scale as in the classic theory. In fact, a pulse supported on the inner scale is trapped in a surface layer if the medium is rougher than the standard model. If the medium is smoother than the standard model, i.e., $H > 1/2$, the shape of such a pulse is *not* affected by the random medium fluctuations.

Most previous work on wave interaction with a fractal object deals with scattering caused by fractal interfaces. However, some authors have explored wave-interaction with deterministic fractal media using numerical simulations [4, 17, 26]. Reflections from a random fractal and how they depend on the fractal exponent is explored by numerical experiments in [4]. In [17], Konotop, Fei, and Vazquez examine the wave reflections from a fractal devil's staircase and introduce a heuristic scheme for computing effective parameters of such a medium. Sun and Jaggard [26] numerically explore wave propagation in a similar medium and observe strong resonance effects. Here, we analyze acoustic pulse transmission through a random fractal and illustrate our theoretical results with numerical simulations.

In section 2 we state the governing equations for the acoustic pulse and in section 3 the models for the fractal media that we consider. We summarize how the pulse shaping theory generalizes to these media in section 4. In section 5 we derive the general averaging result that can be used for fractal media. Finally, in section 6 we apply this averaging result to the fractal media that we consider and also illustrate our theoretical results with numerical simulations.

2. Governing equations. We follow the notation set forth in [3] and [6]. The governing equations for the continuum are the Euler equations giving conservation of momentum and mass:

$$\begin{aligned} \rho\, u_t + p_z &= 0, \\ K^{-1} p_t + u_z &= 0, \end{aligned} \tag{1}$$

with t being time and z measuring depth into the medium. The dependent variables are the pressure p and the (z-component) of the particle velocity u. The medium parameters are the density ρ and the bulk-modulus K, which is the reciprocal of the compressibility. We next make a change of variables from depth z to the first arrival time from the surface to this depth:

$$x = x(z) \;=\; \int_0^z \frac{1}{c(s)}\, ds, \tag{2}$$

with the local speed of sound being $c \;=\; \sqrt{K/\rho}$. The first arrival time gives the travel time for the first arriving disturbances. An important aspect of the propagating pulse is the travel time of its *coherent* part and this differs in general from the first arrival time. In travel time coordinates (1) transforms into

$$\begin{aligned} \zeta u_t + p_x &= 0, \\ p_t + \zeta u_x &= 0. \end{aligned} \tag{3}$$

The characteristic impedance ζ is

$$\zeta = \zeta(x) \;=\; \sqrt{\rho(z(x))\; K(z(x))} \;=\; \rho(z(x))\; c(z(x)), \tag{4}$$

where $z(x)$ is the inverse of the map defined in (2).

We model ζ as being piecewise constant; thus, within each medium section the wave propagation can be described as a pure translation of "up"- and "down"-propagating wave components. We decompose the wavefield in terms of up- and down-propagating wave components as

$$\begin{aligned} u &= \frac{1}{\sqrt{\zeta}}\; (D - U), \\ p &= \sqrt{\zeta}\; (D + U). \end{aligned} \tag{5}$$

The positive x direction defines the downward direction, and D is the wave propagating in this direction. Our objective is to describe a down-propagating pressure pulse somewhere deep into the medium and examine how the multiscale random fluctuations in ζ affect this pulse. In section 3 we give the particular models that we consider for the medium fluctuations and in section 4 discuss their impact on the transmitted pulse.

3. Modeling of the medium. The discrete medium is defined by a *uniform* discretization in the travel time coordinate x as

$$\zeta = \begin{cases} 1 & \text{for } \; x < h, \\ \zeta_k^h & \text{for } \; (k-1)\; h \le x < k\; h, \end{cases} \tag{6}$$

with $k \in \{1, 2, \ldots\}$. Therefore, the time it takes a pulse to traverse a medium section is constant and equal to h. Such a medium is sometimes referred to as a Goupillaud medium; it has been discussed in, for instance, [6, 22, 24]. Here, we consider finely layered media, and h is the small parameter in our modeling. In the next section we describe our choices for the impedance sequence ζ_k^h, the sequence that defines the medium.

3.1. A standard one-scale medium model. We first consider a medium model where the fluctuations form a stationary process, with the impedances in the different medium sections being independent and identically distributed. Such a medium model is used in [5, 6, 16]. Let the discrete impedance sequence be given by

$$\zeta_k^h = 1 + Z_k^h, \tag{7}$$

with Z_k^h a sequence of independent mean zero Gaussian random variables with variance $\mathcal{O}(h)$. The medium fluctuations are therefore relatively weak. Note that in practice we truncate the fluctuations in the above model such that the impedance is positive and bounded. If β denotes standard Brownian motion, then a version of (7) can be constructed as

$$\zeta_k^h = 1 + \beta(kh) - \beta((k-1)h). \tag{8}$$

This formulation serves to motivate the medium model we introduce next, a model that incorporates fluctuations on many scales.

3.2. Multiscale medium from fractional Brownian noise. We aim to formulate a simple medium model that incorporates long range interactions or correlations, that is, a model that is not limited to one intrinsic scale as is the one in (8). A standard stochastic model process that incorporates long-range interactions and variations on a continuum of length scales is fractional Brownian motion (fBm), $\{\beta_H(x); x \geq 0\}$. This process was introduced by Mandelbrot and Van Ness in [18]. We define the medium model in terms of this process.

First, consider the following generalization of (8):

$$\zeta_k^h = 1 + \beta_H(kh) - \beta_H((k-1)h), \tag{9}$$

with β_H being fBm with Hurst exponent H. Thus, the fluctuations in the impedance form a fBm *noise* sequence. Note that $\beta_{1/2}$ is standard Brownian motion, and then the models (8) and (9) coincide. In general, fBm is a Gaussian process with mean zero, stationary increments, and with covariance and structure functions

$$E[\beta_H(x)\beta_H(y)] = \frac{\sigma^2}{2}(|x|^{2H} + |y|^{2H} - |x-y|^{2H}), \tag{10}$$

$$E[(\beta_H(x) - \beta_H(x-\Delta x))^2] = \sigma^2|\Delta x|^{2H}, \tag{11}$$

where $0 < H < 1$, σ is a scaling parameter, and $\beta_H(0) = 0$. The Hurst exponent H determines the correlation of the increments. The covariance of a future increment with the past increment is

$$E[(\beta_H(x) - \beta_H(x-\Delta x))(\beta_H(x+\Delta x) - \beta_H(x))] = \sigma^2(2^{2H-1} - 1)|\Delta x|^{2H}$$

and is independent of the location index x. When $H > 1/2$ this quantity is positive, so if the past increment is positive, then on average the future increment will be positive. Feder [10] calls this persistence. When $H < 1/2$ we have an antipersistent process, with a positive increment in the past making a positive increment in the future less likely. The paths of fBm in the persistent case will be associated with larger excursions, but will be "smoother" than the paths in the antipersistent case. The quadratic variation of the process in the persistent case is almost surely zero,

whereas it is almost surely infinite in the antipersistent case [23]. Below we show how this entails that wave propagation through a medium defined in terms of antipersistent fBm be qualitatively very different from wave propagation in the persistent case.

In the model (8) the impedance is piecewise constant and ζ_k^h are uncorrelated with ζ_{k+m}^h unless $m = 0$. We refer to this model as a one-scale model whose scale of variation corresponds to the discretization scale.

In this section we consider a model for the impedance that has long-range correlations; the covariance is now

$$C_\zeta(m; h, H, \sigma) := Cov[\zeta_k^h, \zeta_{k+m}^h] \ \sim \ \frac{\sigma^2 h^{2H} H(2H-1)}{m^{2(1-H)}} \quad \text{as } m \ \to \ \infty,$$

and the medium therefore exhibits correlations also over long scales. Note that if we observe the medium on a coarser scale, then we see the same decay of correlations for $a > 0$:

$$C_\zeta(am; h, H, \sigma) \sim a^{-2(1-H)} C_\zeta(m; h, H, \sigma) \quad \text{as } m \ \to \ \infty.$$

Since the medium has similar and nontrivial correlation structure over many scales, we refer to it as a multiscale model.

In fact, fBm itself is self-similar since $\beta_H(x)$ and $a^H \beta_H(x/a)$ have the same finite-dimensional distributions for all $a > 0$. This property illustrates how this process incorporates variations on all scales.

3.3. A fractal medium model. The model (9) is defined in terms of fractional Gaussian noise, and the medium fluctuations are therefore stationary. Next, we define a medium model where the fluctuations are defined by the fBM process itself. In this case the fluctuations are nonstationary; moreover, they are strong $\mathcal{O}(1)$ and not weak as in the above two models. We consider the medium model

$$\zeta_k^h = \exp(\beta_H(kh)). \tag{12}$$

The value $H = 1/3$ is of particular interest since the fBm process then corresponds to Kolmogorov turbulence, a standard medium model in the context of wave propagation in the turbulent atmosphere. We will see below that the same theorem, Theorem 5.1, that characterizes the transformation of the pulse shape for the models in the previous two subsections with weak or small medium fluctuations applies in this case with relatively strong medium fluctuations. Below, in (16), we introduce the interface reflection coefficients associated with the sequence ζ_k^h. The theorem characterizes the way in which the decay of the correlations in these interface reflection coefficients determines how the medium affects the shape of the propagating wave pulse. The important parameter that determines this decay is the Hurst exponent H, and the pulse shaping thus depends sensitively on the value of this. We give the decay of correlations for the interface reflection coefficients in (41). Note that even though the fluctuations of the impedance in (12) are large, the magnitude of the fluctuations of the interface reflection coefficients are actually small.

Observe finally that the analysis we present below holds for more general media models than those discussed above.

4. Summary of results. In this section we characterize the wave pulse that has propagated through the multiscale medium. We assume the model (9) and in addition that the density ρ in (4) is constant. This allows us to characterize the travel time to a given depth. The general case is considered in (5.1). We give a more detailed account of the results and how they are derived in sections 5 and 6.

The pulse impinging on the half-space $z > 0$ has shape p_0, a compactly supported function. In the *random* medium the transmitted pulse at depth L can be characterized in terms of (i) $\chi_h(L)$, a *random* travel time correction, and (ii) $\mathcal{G}$, a *deterministic* pulse shaping function. The support of $\mathcal{G}$ is $\mathcal{O}(\sqrt{L})$. Let $\tau(L)$ be the travel time to depth $z = L$ in the deterministic (homogenized) medium; then we have the following result for the transmitted pulse.

LEMMA 4.1. *Let $1/4 < H \leq 1/2$ and $p(0,t) = p_0(t/h^{H+1/2})$ be the impinging pulse at the surface. Then for every $\varepsilon > 0$ and $M > 0$,*

$$\mathbb{P}\left(\sup_{|s|<M}\left|p(L,\tau(L)+\chi_h(L)+h^{H+1/2}s) - \int p_0(s-u)\mathcal{G}(u;L)\,du\right| > \varepsilon\right) \to 0 \quad \text{as} \quad h \to 0. \tag{13}$$

The random variable χ_h is a Gaussian random variable with magnitude $\mathcal{O}(h)$. Thus, when we observe the transmitted pulse in a randomly corrected time frame, we see a deterministic pulse in the small h limit. This is what we refer to as *stabilization*. If $H = 1/2$, then β_H is standard Brownian motion that has independent increments, corresponding to independent medium fluctuations. In this case the spreading of the pulse happens on the diffusion scale h, which is a measure of the correlation length of the medium fluctuations. Spreading on this scale corresponds to that discussed by O'Doherty and Anstey in [19]. If $H < 1/2$, the increments of β_H are *negatively* correlated and the medium fluctuations are rougher than in the standard Brownian case. In this case the pulse shaping is stronger and happens on the anomalous diffusion scale $h^{H+1/2}$.

Consider next the case of $H > 1/2$; now the increments of β_H are *positively* correlated and the medium fluctuations are smoother than in the standard Brownian case. The next result shows that in this case there is no change in pulse shape on the discretization scale in the small h limit.

LEMMA 4.2. *Let $H > 1/2$ and $p(0,t) = p_0(t/h)$ be the impinging pulse at the surface. Then for every $\varepsilon > 0$ and $M > 0$,*

$$\mathbb{P}\left(\sup_{|s|<M}|p(L,\tau(L)+\chi_h(L)+hs) - p_0(s)| > \varepsilon\right) \to 0 \quad \text{as} \quad h \to 0. \tag{14}$$

The travel time correction χ_h is characterized as in Lemma 4.1.

Assume that the source pulse is supported on the inner scale: $p_0 = p_0(t/h)$. In the Brownian case with $H = 1/2$ it follows from Lemma 4.1 that on the standard diffusion scale h we observe stabilization to a *fixed* pulse shape at the *fixed* depth L. If $H < 1/2$ with a stronger pulse shaping, this result generalizes in that we see stabilization on the scale h to a fixed pulse, but for a travel distance that *decreases* with h. Analogously, for $H > 1/2$, with a weaker pulse shaping, we observe stabilization on the scale h for a travel distance that *increases* with decreasing h. This follows from the next result.

LEMMA 4.3. *Let $1/4 < H < 3/4$ and $p(0,t) = p_0(t/h)$ be the impinging pulse at the surface. Then for every $\varepsilon > 0$ and $M > 0$,*

$$\mathbb{P}\left(\sup_{|s|<M}\left|p(Lh^{1-2H},\tau(Lh^{1-2H})+\chi_h(L)+hs) - \int p_0(s-u)\mathcal{G}(u;L)\,du\right| > \varepsilon\right) \to 0 \text{ as } h \to 0. \tag{15}$$

Thus, the coherent pulse front will be confined to an $\mathcal{O}(Lh^{1-2H})$ neighborhood of the surface. The random variable χ_h is a Gaussian random variable, now with magnitude $\mathcal{O}(h^{1+H(1-2H)})$.

5. Derivation of pulse shaping.

5.1. Dynamic equations for the pulse front. In order to derive the above results we need to characterize the evolution of the pulse front and how this relates to the fluctuations in the impedance ζ. Wave propagation in the discrete medium is determined by the interface reflection coefficients r_k^h and the transmission coefficients τ_k^h. These are defined by

$$r_k^h = \frac{\zeta_{k+1}^h - \zeta_k^h}{\zeta_{k+1}^h + \zeta_k^h}, \tag{16}$$

$$\tau_k^h = \sqrt{1 - |r_k^h|^2}. \tag{17}$$

Let $D^{\pm}$ and $U^{\pm}$ be the wave components in (5) evaluated immediately to the right and left of interface k at location $x_k = kh$. The interface corresponds to a jump in the characteristic impedance ζ, and the continuity of p and u gives the appropriate interface conditions that determine the associated jumps in D and U. These jumps correspond to some of the down-propagating energy being converted to the up-propagating mode and vice-versa. The interface conditions give (see [6])

$$\begin{bmatrix} D^+ \\ U^- \end{bmatrix} = \begin{bmatrix} \tau_k^h & -r_k^h \\ r_k^h & \tau_k^h \end{bmatrix} \begin{bmatrix} D^- \\ U^+ \end{bmatrix}. \tag{18}$$

We are interested in the impulse response of the medium, that is, how a down-propagating impulse at the surface is being transformed as it propagates. The impulse response is an analogue of the Green's function for the medium. The transmitted pulse when we probe the medium with a general *down*-propagating wave is easily found by convolution of the source wave with this impulse response. At the initial time we assume that the medium is at rest and that we probe it with a down-propagating impulse:

$$\begin{aligned} D_{t=0} &= \delta(x^+), \\ U_{t=0} &= 0. \end{aligned} \tag{19}$$

Wave reflections at the interfaces in the discrete medium lead to a set of down- and up-propagating impulses. At the time instances $t = ih$, with i integer, these impulses are located at the interfaces. The down-propagating pulses are separated by integer multiples of h in the time coordinate t, and also in the travel time coordinated, x, as are the up-propagating impulses. We find it convenient to represent these "impulse-trains" by the magnitude of the impulses indexed as D_j^i and U_j^i, with i being the time index and corresponding to times $t = ih$. The index j gives the distance from the front in the x dimension, measured in units of h. Thus, D_0^i is the magnitude of the first impulse in the down-propagating pulse-train at time $t = ih$. The initial condition (19) gives

$$\begin{aligned} D_j^0 &= \delta_0(j), \\ U_j^0 &= 0. \end{aligned} \tag{20}$$

In Figure 1 we illustrate the propagation of the impulses by a sequence of "snapshots" taken at times $t = 0, h$, and $2h$. The figure makes it clear that at time instances $t = ih$ only every second interface is associated with nonzero impulses and that the support of the pulse-trains increases with increasing time, giving pulse spreading. An important aspect of the parameterization is that a finite section of the wave front evolves autonomously and can be described independently of the tail part of the wave. We make use of this fact for the analysis of the problem and also for numerical simulation of the evolution of the wave front. Consider D_2^2 in the example given in Figure 1, that is, the magnitude of the second down-propagating impulse at time $2h$. It trails the leading impulse by two sections and is determined by a double scattering event associated with the initial impulse D_0^0. Part of the initial impulse is first reflected to an up-propagating mode and then aligned with D_2^2 through a second scattering event. The change in D_{2j}^i from one time step to the next can in general be expressed *exactly* in terms of double scattering events associated with down-propagating impulses "ahead" of it when these are evaluated at previous times. We next show how by unraveling the evolution seen in Figure 1.

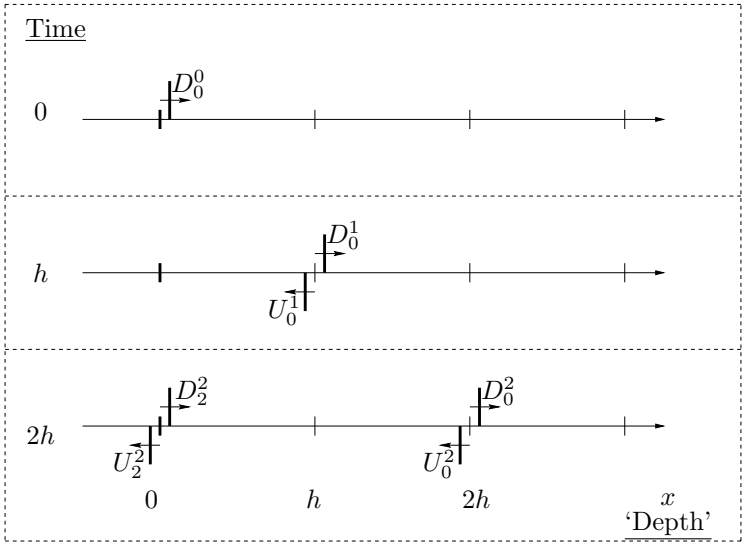

FIG. 1. *The generation of multiple reflections in the discrete medium.*

From (18) we find

$$\begin{bmatrix} D_j^{i+1} \\ U_j^{i+1} \end{bmatrix} = \begin{bmatrix} \tau_k^h & -r_k^h \\ r_k^h & \tau_k^h \end{bmatrix} \begin{bmatrix} D_j^i \\ U_{j-2}^i \end{bmatrix}, \tag{21}$$

with $k = i + 1 - j$. Define

$$d_j^i = \prod_{k=0}^{i-j} \tau_k^h \; D_j^i, \tag{22}$$

$$u_j^i = \prod_{k=0}^{i-j-1} \tau_k^h \; U_j^i,$$

with $\tau_k^h = 1$ for $k < 0$. This gives, using (18), that

$$d_j^{i+1} = d_j^i - r_k^h u_j^{i+1},$$
$$u_j^{i+1} = u_{j-2}^i + r_k^h d_j^i,$$

with $k = i + 1 - j$. Then, upon elimination of u_j^i, it follows in view of (20) that

$$\mathbf{d}^{i+1} = \mathbf{d}^i - \mathbf{A}_i^h \mathbf{d}^i, \tag{23}$$

with the vector $\mathbf{d}^i$ corresponding to the front part of the wave:

$$\mathbf{d}^i = [d_0^i, d_2^{i+1}, d_4^{i+2}, \ldots]'.$$

The matrix $\mathbf{A}_i^h = \{a_{k,l}^i\}$ is *lower triangular* with

$$a_{k,l}^i = r_{i-k+2}^h \; r_{i-l+2}^h \tag{24}$$

for $k \geq l$. In the next section we use (23) to obtain a characterization of the transmitted pulse. Note that (23) articulates how the change in a down-propagating impulse at a given time can be expressed exactly in terms of double scattering events associated with impulses ahead of it when these are evaluated at previous times. Thus, the statistics of products of reflection coefficients, corresponding to these double scattering events, will determine the evolution of the pulse shape.

5.2. Stabilization from averaging. We state the conditions and the result that describe the fascinating stabilization property of the down-propagating pulse when this is observed in a travel-time frame. With stabilization we mean that the transmitted pulse becomes essentially deterministic in the small h limit due to averaging in (23). Averaging in (23) means that we can replace $\mathbf{A}_i^h$ by its mean value, which is a lower triangular Toeplitz matrix with the entries on the ith subdiagonal being $E[r_m^h r_{m+i}^h]$, assuming here that the interface reflection coefficients form a stationary sequence. The following theorem generalizes and makes this precise.

Let $[\cdot]$ denote rounding to integer value, and define

$$\frac{d\mathcal{D}}{ds}(s,h) = -\bar{\mathbf{A}}(s,h)\; \mathcal{D}(s,h),$$
$$\mathcal{D}(0,h) = \mathbf{e}_1, \tag{25}$$

with $\bar{\mathbf{A}}(s,h)$ being a lower triangular Toeplitz matrix whose first column is

$$[a(0, s/g(h), h)/2, a(1, s/g(h), h), \ldots, a(K, s/g(h), h)]'$$

for some function a, and $\mathbf{e}_1$ a vector with one in the first entry and zero else; moreover,

$$\mathbf{D}(x,h) = [D_0^{[x/h]}, D_2^{[x/h]}, \ldots, D_{2K}^{[x/h]}]',$$
$$\mathbf{U}(x,h) = [U_0^{[x/h]}, U_2^{[x/h]}, \ldots, U_{2K}^{[x/h]}]', \tag{26}$$

with D_j^i and U_j^i as defined above. Then we have the following.

THEOREM 5.1. *If for all $\epsilon > 0$ and $\Delta \in \{0, 1, 2, \ldots\}$*

$$\lim_{h \to 0} \mathbb{P}\left[\sup_{0<s<L} \left| \sum_{m=1}^{[s/(g(h)h)]} r_m^h r_{m+\Delta}^h - \int_0^s a(\Delta, v/g(h), h)\; dv \right| > \epsilon \right] = 0, \tag{27}$$

where $0 < g(h)h = o(1)$ *and* $|a| < c$ *for some constant* c*, then for all* $\epsilon > 0$

$$\lim_{h\to 0} \mathbb{P}\left[\sup_{0<s<L} ||\mathbf{D}(s/g(h), h) - \mathcal{D}(s, h)|| > \epsilon\right] = 0, \tag{28}$$

$$\lim_{h\to 0} \mathbb{P}\left[\sup_{0<s<L} ||\mathbf{U}(s/g(h), h)|| > \epsilon\right] = 0. \tag{29}$$

The proof of this result is given in Appendix C. The formulation (25) follows from replacing $\mathbf{A}_i^h$ in (23) and the factor $\prod_{k=1}^m \tau_k^h$ in (22) by their corresponding averaged values. We apply the above result to fractal media in section 6.

The following lemma shows that the condition (27) entails that the interface reflection coefficients are small. Note, however, that this does not mean that the medium fluctuations themselves are relatively small.

LEMMA 5.2. *If for all* $\epsilon > 0$ *and* $\Delta \in \{0, 1, 2, \ldots\}$

$$\lim_{h\to 0} \mathbb{P}\left[\sup_{0<s<L} \left| \sum_{m=1}^{[s/(g(h)h)]} r_m^h r_{m+\Delta}^h - \int_0^s a(\Delta, v/g(h), h)\, dv \right| > \epsilon\right] = 0, \tag{30}$$

where $0 < g(h)h = o(1)$ *and* $|a| < c$ *for some constant* c*, then for all* $\epsilon > 0$

$$\lim_{h\to 0} \mathbb{P}\left[\sup_{1\le i\le [L/(g(h)h)]} |r_i^h| > \epsilon\right] = 0. \tag{31}$$

We prove this lemma in Appendix A.

For a given random medium model the following lemma gives a convenient way to check that the condition (27) is satisfied. Define

$$S^h(s, \Delta) = \sum_{m=1}^{[s/(g(h)h)]} r_m^h r_{m+\Delta}^h - \int_0^s a(\Delta, v/g(h), h)\, dv; \tag{32}$$

then we have the following.

LEMMA 5.3. *With* a *and* g *defined as in* (27)*, if there is an* $\alpha > 0$ *and a* $C > 0$ *such that for* $h < h_0$

$$\sup_{0<s<t<L} E[|S^h(t, \Delta) - S^h(s, \Delta)|^\alpha] \le g(h)h|t - s|C, \tag{33}$$

then the condition (27) *is satisfied.*

The proof of this lemma can be found in Appendix B.

Theorem 5.1 shows how the shape of the transmitted pulse is affected by the medium fluctuations. In the next section we give an interpretation of this modification and show that for an important class of random media models the spreading of the pulse in the random medium can be described as a convolution with a deterministic Gaussian pulse shape.

5.3. Pulse shape from the central limit theorem. Assume first that the interface reflection coefficients are stationary and that

$$E[r_i^h\ r_{i+\Delta}^h] = ha(\Delta).$$

It then follows from Theorem 5.1 that in probability $\lim_{h\to 0}\mathbf{D}(L,h)=\mathcal{D}(L)$ with

$$\mathcal{D}(L)=\exp(-L\bar{\mathbf{A}})\ \mathbf{e}_1=\exp(-La(0)/2)\exp(La(0)\mathcal{Q}/2)\ \mathbf{e}_1,$$

where $\bar{\mathbf{A}}$ and $\mathcal{Q}$ are lower triangular Toeplitz matrices whose first columns are

$$\mathbf{a}=[a(0)/2,\ a(1),\ a(2),\ldots]',$$
$$\mathbf{q}=-[0,\ 2a(1)/a(0),\ 2a(2)/a(0),\ldots]',$$

respectively. Note that multiplication with $\mathcal{Q}$ corresponds to a discrete convolution with its first column. Therefore

$$\mathcal{D}(L)=\sum_{n=0}^{\infty}p_n\mathbf{q}^{n*}\qquad\text{as}\ \ h\downarrow 0, \tag{34}$$

where $\mathbf{q}^{n*}$ denote n-fold convolution, $\mathbf{q}^0=e_1$, and where

$$p_n=\exp(-La(0)/2)(La(0)/2)^n/n!$$

is a discrete Poisson distribution. For typical media models, for instance, when ζ_k^h form a Markov process, the first column of $\mathcal{Q}$ defines a discrete probability distribution. Then $\mathcal{D}$ is the distribution of a *random sum*. A central limit theorem argument then gives that $\mathcal{D}$ is approximately a Gaussian pulse shape with standard deviation $\mathcal{O}(\sqrt{L})$ for L large. We show this in Appendix F, where we consider media with slowly varying media statistics.

6. Application to a fractal environment. In this section we consider the multiscale medium models introduced in sections 3.2 and 3.3. We show how Theorem 5.1 applies to these media and give the medium statistics that define the deterministic transformation in the shape of the propagating pulse. The results presented in section 4 follow via a transformation from the travel time coordinate to physical depth.

6.1. Fractional Brownian noise medium. We consider the medium model (9). A calculation involving the algebra of the moments of Gaussian random variables gives Lemma 6.1 below.

LEMMA 6.1. *Let ζ_k^h be defined by* (9) *and $1/4<H<3/4$; then there exists $h_0>0$ such that*

$$\lim_{h\to 0}E\left[\sum_{m=1}^{[s/g(h)h]}r_m^h r_{m+\Delta}^h\right]=sa(\Delta), \tag{35}$$

$$Var\left[\sum_{m=1}^{[s/g(h)h]}r_m^h r_{m+\Delta}^h\right]\le g(h)hs\sigma^4C(H)\quad \textit{for}\ \ h\le h_0, \tag{36}$$

with $g(h)=h^{2H-1}$ and for $\Delta\ge 1$

$$\begin{aligned}a(\Delta)&=-\Delta^{2H-4}\ (\sigma^2/8)\ \delta^4_{1/\Delta}[x^{2H}]_{x=1}\\ &\sim-\Delta^{2H-4}\ \sigma^2\ H(H-1/2)(H-1)(2H-3)\ \ \textit{as}\ \ \Delta\to\infty.\end{aligned} \tag{37}$$

In (37) we used the fourth order discrete central difference operator δ^4_Δ defined by

$$\delta_\epsilon[f(x)]=\frac{f(x+\epsilon/2)-f(x-\epsilon/2)}{\epsilon}.$$

Thus, the coefficients $a(\cdot)$ can be expressed in terms of a fourth order difference operator of the power law of the underlying fBm. This is related to the fact that these coefficients are means of products of interface reflection coefficients that themselves are obtained essentially by discrete differentiation of the impedance sequence. Lemmas 5.3 and 6.1 entail that the condition (27) in Theorem 5.1 is satisfied for the model (9) with $g(h) = h^{2H-1}$. Thus, in probability, the transmitted impulse response when evaluated at depth $\tilde{L} = Lh^{1-2H}$ satisfies

$$\lim_{h\to 0} \mathbf{D}(\tilde{L}/h, h) = \exp(-L\bar{\mathbf{A}})\ \mathbf{e}_1, \tag{38}$$
$$\lim_{h\to 0} ||\mathbf{U}(\tilde{L}/h, h)|| = 0,$$

where $\bar{\mathbf{A}}$ is a lower triangular Toeplitz matrix whose first column is

$$[a(0)/2,\ a(1),\ a(2), \ldots]$$

and $\mathbf{U}$ and $\mathbf{D}$ are defined in (26). Thus, when we probe the medium with a unit downgoing impulse at the surface, we observe the pulse shape defined by (38) at depth $\tilde{L}$. By a transformation of the independent variable to physical depth this entails that Lemmas 4.2 and 4.3 in section 4 are valid when the fractal medium is defined by (9). That Lemma 4.1 holds follows from Lemmas 5.3 and 6.1 and from Theorem 5.1 upon a transformation of the travel-time argument.

We next illustrate these results regarding the model (9) with numerical simulations. In the numerical simulations we use the initial condition (19) and propagate the pulse essentially according to (23). In practice we reformulate (23) to obtain an orthogonal propagation operator. In the figures we plot the down-propagating pulse $\mathbf{D}$ at the considered depth. Note that the origin in the plotted coordinate system corresponds to the front of the pulse, that is D_0^N, with N the total number of sections in the discrete medium. Thus, in the absence of random medium fluctuations we will see a unit impulse only at the origin. The random medium variations cause a spreading of the impulse.

First, we illustrate Lemma 4.3 using the medium model (9). In Figure 2 we use $\sigma = 5$, and the solid, dashed, and dotted lines correspond to $h_0 = 2^{-12}$, $h_1 = 2^{-14}$, and $h_2 = 2^{-16}$, respectively. The pulses are plotted at the scaled depth

$$\bar{x}(h_i) = \left(\frac{h_i}{h_0}\right)^{1-2H}.$$

The crosses give the stabilized pulse shape defined by (34). In the top plot we use $H = 0.4$, whereas in the bottom plot we use $H = 0.6$. As expected, we see stabilization to the theoretical pulse in both cases. Note that the horizontal axis is scaled by h. The pulse shaping is stronger in the antipersistent case with a rougher medium (top plot). The limiting pulse shape is close to the Gaussian pulse shape. This can be explained by the representation (34) of the impulse response. Recall that if the vector $\mathbf{q}$, the first column of $\mathcal{Q}$, is nonnegative, then (34) can be interpreted as the distribution of a random sum, and the impulse response will be close to the Gaussian pulse shape. The vector $\mathbf{q}$ is nonnegative for $H \geq 1/2$, giving in the small h limit a Gaussian pulse, as in the bottom plot. For $H < 1/2$ the sequence $\mathbf{q}$ is partly negative. In the top plot we used a value for the Hurst exponent that is slightly smaller than the Brownian case, $H = 0.4$, and the pulse shape is close to the Gaussian shape. Note that, since the pulses are plotted at depth $\propto h^{1-2H}$, we have to go shallower and shallower in the

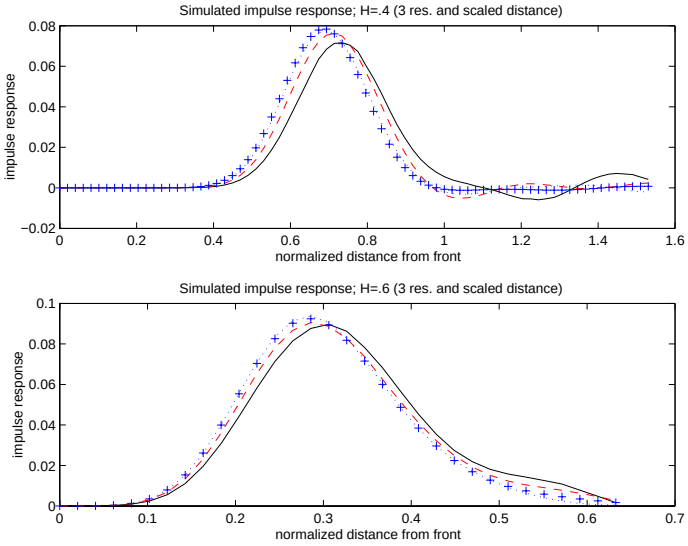

FIG. 2. *The impulse response of the fractal medium plotted at a depth that* scales *with the inner scale* h *as* h^{1-2H}. *The horizontal axis is scaled by* h. *In this frame we see stabilization to a fixed pulse in the small* h *limit. This limit is approximately a Gaussian pulse shape. In the top plot* $H = .4$, *and in the bottom* $H = .6$. *The medium model is the one defined in* (9). *The solid, dashed, and dotted lines correspond to* $h_0 = 2^{-12}$, $h_1 = 2^{-14}$, *and* $h_2 = 2^{-16}$, *respectively. The crosses give the theoretical pulse shapes.*

case $H < 1/2$ to see the stabilized pulse. This corresponds to an antipersistent fBm and to rough medium variations. In the persistent case with $H > 1/2$ and a smoother medium we have to go deeper and deeper into the medium to see the stabilized pulse. Only in the pure Brownian case with $H = 1/2$ do we observe the pulse stabilization at a *fixed* depth.

Next, we illustrate Lemmas 4.1 and 4.2 using the medium model (9). In Figure 3 we plot the same impulse responses as in Figure 2, only evaluated at the fixed depth $L = 1$. As expected, in the small h limit the impulse response in the case $H = .4 < 1/2$ (top plot) approaches a stabilized Gaussian pulse shape. Note that the impulse responses are plotted relative to the scale $h^{2H} = h^{.8}$. This is the scale at which the pulse shape stabilizes in the small h limit. The crosses give the limiting pulse shape and conform closely with the numerical simulations. The bottom plot shows the transmitted impulses when $H = .6 > 1/2$. Then the impulse response becomes close to a unit impulse for small h. The figure shows that the numerical impulse responses approach, albeit slowly, the unit impulse as h is reduced.

In Figure 4 we show how the impulse response depends rather sensitively on the value of the Hurst exponent H that gives the roughness of the medium. We use $h = 2^{-16}$, $L = 1$, $\sigma = 1$, and the model defined in (9). The solid curve corresponds to the Kolmogorov scaling law with $H = 1/3$. The dotted and dashed lines correspond, respectively, to a 20% increase/decrease in the Hurst exponent, giving less (respectively, more) spreading of the pulse.

6.2. The fractal case. Next, we let ζ_k^h be defined by the medium model in (12). Observe therefore that the medium fluctuations are strong and $\mathcal{O}(1)$, in contrast to the models considered above, where they were small. However, we will find that the interaction with the medium fluctuations can be characterized in a way similar to

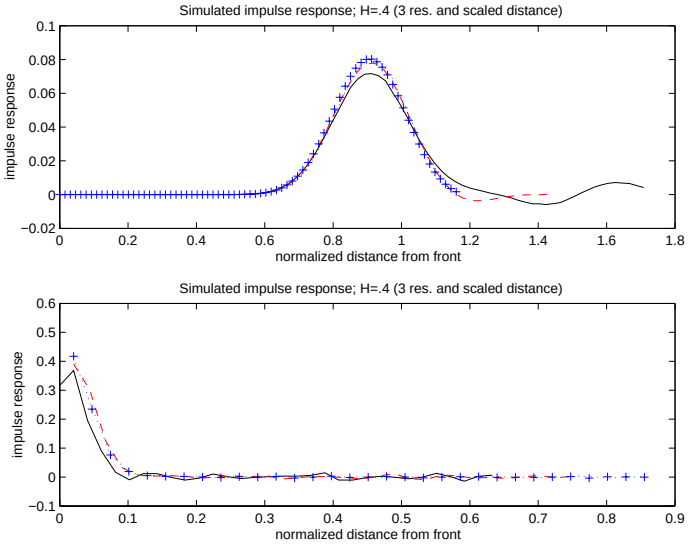

FIG. 3. *The impulse response of the fractal medium plotted at a* fixed *depth. The horizontal axis is scaled by* h^{2H}. *The top plot illustrates stabilization to a Gaussian pulse on the relative scale* $h^{2H} = h^{.8}$, *the bottom stabilization to the unit impulse. As above, in the top plot* $H = .4$, *and in the bottom* $H = .6$. *The medium model is the one defined in* (9). *The solid, dashed, and dotted lines correspond to* $h_0 = 2^{-12}$, $h_1 = 2^{-14}$, *and* $h_2 = 2^{-16}$, *respectively. The crosses give the theoretical pulse shapes corresponding to the smallest h value.*

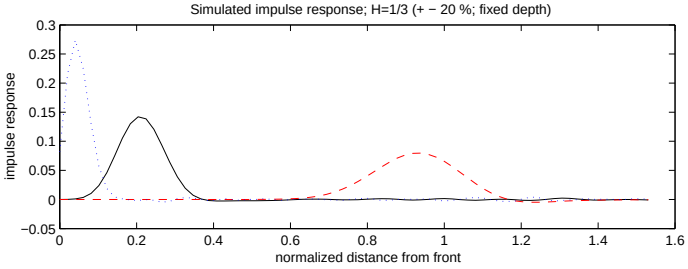

FIG. 4. *The impulse response of the fractal medium plotted at a* fixed *depth. It illustrates how the pulse shaping depends on the value of the Hurst exponent H that gives the roughness of the medium. The solid line corresponds to* $H = 1/3$, *and the dotted and dashed lines to a* 20% *increase (respectively, decrease). The medium model is the one defined in* (9).

that above. The following lemma can be shown by a generalization of the analysis that leads to Lemma 6.1.

LEMMA 6.2. *Let* ζ_k^h *be defined by* (12) *and* $1/4 < H < 3/4$; *then*

$$\lim_{h\to 0} E\left[\sum_{m=1}^{[s/g(h)h]} r_m^h r_{m+\Delta}^h\right] = sa(\Delta), \tag{39}$$

$$Var\left[\sum_{m=1}^{[s/g(h)h]} r_m^h r_{m+\Delta}^h\right] \le g(h)hs\sigma^4 C(H) \quad for \quad h \le h_0, \tag{40}$$

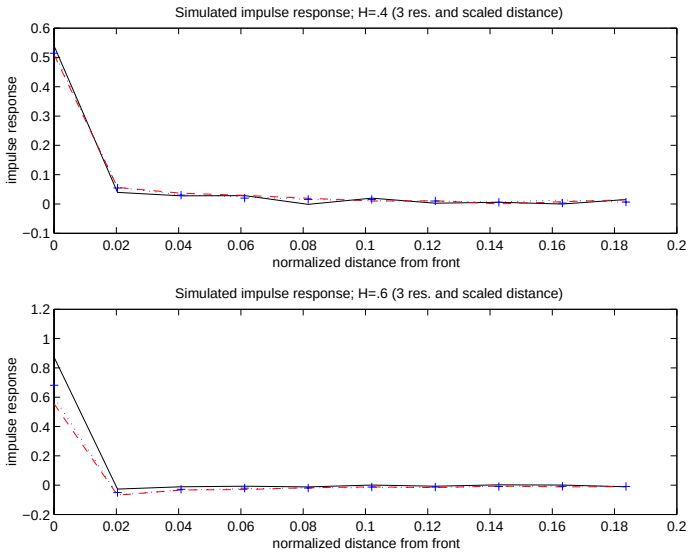

FIG. 5. *The figure corresponds to Figure* 2 *except that medium model* (12) *rather than* (9) *is used. The figure shows the impulse response of the fractal medium plotted at a depth that* scales *with the inner scale* h *as* h^{1-2H}*, and the horizontal axis is scaled by* h*. In this frame we see stabilization to a fixed pulse in the small* h *limit. In the top plot* $H = .4$*, and in the bottom* $H = .6$*. The solid, dashed, and dotted lines correspond to* $h_0 = 2^{-12}$*,* $h_1 = 2^{-14}$*, and* $h_2 = 2^{-16}$*, respectively.*

with $g(h) = h^{2H-1}$ *and for* $\Delta \geq 1$

$$a(\Delta) = \sigma^2 \Delta^{2H-2}\ \delta^2_{1/\Delta}[x^{2H}]_{x=1}/8 \sim \Delta^{2H-2}\ \sigma^2 H(H-1/2)/2 \qquad as \quad \Delta \to \infty. \tag{41}$$

Note that now the impedance is defined in terms of the fBm process itself rather than fBm noise, and that the $a(\cdot)$ coefficients thus are defined in terms of a second rather than fourth order difference operator. We show below that this has a strong effect on the impulse response. Lemma 6.2 entails that the condition (27) in Theorem 5.1 again is satisfied with $g(h) = h^{2H-1}$. Thus, in probability, the transmitted impulse response when evaluated at depth $\tilde{L} = Lh^{1-2H}$ satisfies (38), where $\bar{\mathbf{A}}$ is a lower triangular Toeplitz matrix whose first column is $\mathbf{a}' = [a(0)/2,\ a(1),\ a(2), \ldots]$, with $a(\cdot)$ now defined by (41).

Figure 5 corresponds to Figure 2 except that we used the model (12) with $\sigma = 1$. The impulse response is again plotted relative to the scale h and at depth

$$\bar{x}(h_i) = \left(\frac{h_i}{h_0}\right)^{1-2H}.$$

Again we observe stabilization in this frame. The solid, dashed, and dotted lines correspond to $h_0 = 2^{-12}$, $h_1 = 2^{-14}$, and $h_2 = 2^{-16}$, respectively. In the top plot $H = .4$, and in the bottom plot $H = .6$. The transformation of the pulse shape is weaker than above due to the smoother medium fluctuations. The crosses give the theoretical pulse shapes, and these conform closely with the numerical simulations for small h. In this case with a fractal medium the correlations decay more slowly than for the medium discussed in the previous section, as can be seen from (37) and

(41). The second moment associated with the discrete distribution $\mathbf{q}$, defined as the first column of $\mathcal{Q}$ in (34), is now unbounded, and the central limit theorem is not valid for this distribution. Thus, the pulse shape does not approach the Gaussian shape as it did above. Due to the long-range interactions in the medium fluctuations, the scattered wave energy is now spread far out and the coherent part of the pulse reduced in amplitude but not much in its shape.

Appendix A. Magnitude of medium fluctuations. We prove Lemma 5.2 stated in section 5. This lemma shows that the condition (27) entails that in the small h limit the interface reflection coefficients are small.

First, observe that the condition (27) allows us, for any given $\epsilon > 0$, to choose h_0 so small that for $h < h_0$

$$\mathbb{P}\left[\sup_{0<s<L}\left|\sum_{m=1}^{[s/(g(h)h)]}|r_m^h(\omega)|^2 - \int_0^s a(0,v/g(h),h)\ dv\right| > \epsilon^2/4\right] < \frac{\epsilon}{2}. \tag{42}$$

Now let $\{h^j\}$ be a sequence such that $\lim_{j\to\infty} h^j = 0$. Denote the associated array of interface reflection coefficients $r_i^{h^j}(\omega),\ 1 < i < N^j$, with

$$N^j = [L/(g(h^j)h^j)].$$

Assume that Lemma 5.2 is *false*. Then there is a subsequence $\{h^j\}$ of the above kind, a fixed $\epsilon > 0$, and a sequence of collections of disjoint sets $\{\mathcal{F}_i^j\}_{i=1}^{N_j}$ so that

$$\mathbb{P}\left[\bigcup_i \mathcal{F}_i^j\right] = \sum_{i=1}^{N_j}\mathbb{P}[\mathcal{F}_i^j] \ > \ \epsilon,$$

with

$$|r_i^{h^j}(\omega)| > \epsilon \ \text{ for } \ \omega \in \mathcal{F}_i^j. \tag{43}$$

We next show that this leads to a contradiction. Define

$$f(s;j) := S^{h_j}(s,0) = \sum_{m=1}^{[s/(g(h^j)h^j)]}|r_m^{h^j}(\omega)|^2 - \int_0^s a(0,v/g(h^j),h^j)\ dv.$$

Note that $f(s;j)$ has a jump discontinuity at

$$s_{(i;j)} := ig(h^j)h^j,$$

that is,

$$f(s^+_{(i;j)};j) - f(s^-_{(i;j)};j) = |r_i^{h^j}(\omega)|^2.$$

For $1 \le i \le N^j$ we therefore find

$$\sup_{0<s<L}\left|\sum_{m=1}^{[s/g(h^j)h^j]}|r_m^{h^j}(\omega)|^2 - \int_0^s a(0,v/g(h^j),h^j)\ dv\right| \ = \ \sup_{0<s<L}|f(s;j)|$$
$$\ge \ \frac{|f(s^+_{(i;j)};j) - f(s^-_{(i;j)};j)|}{2} \ = \ \frac{|r_i^{h^j}(\omega)|^2}{2},$$

and for $\omega \in \mathcal{F}_i^j$ it follows that

$$\sup_{0<s<L} \left| \sum_{m=1}^{[s/g(h^j)h^j]} |r_m^{h^j}(\omega)|^2 - \int_0^s a(0, v/g(h^j), h^j)\ dv \right| \ > \ \frac{\epsilon^2}{2}. \tag{44}$$

We can thus conclude that

$$\mathbb{P}\left[\sup_{0<s<L} \left| \sum_{m=1}^{[s/g(h^j)h^j]} |r_m^{h^j}|^2 - \int_0^s a(0, v/g(h^j), h^j)\ dv \right| > \frac{\epsilon^2}{4} \right] \geq \sum_{i=1}^{N_j} \mathbb{P}[\mathcal{F}_i^j] \ > \ \epsilon,$$

contradicting (42).

Appendix B. A stabilization criterion. In this appendix we prove Lemma 5.3 stated in section 5. To prove Lemma 5.3 we need to show that (33) implies that for $\epsilon > 0$ and $\delta > 0$ there is an h_0 such that for $h < h_0$

$$\mathbb{P}\left[\sup_{0<s<L} |S^h(s, \Delta)| \geq \epsilon \right] \leq \delta, \tag{45}$$

with S^h defined by (32):

$$S^h(s, \Delta) = \sum_{m=1}^{[s/(g(h)h)]} r_m^h r_{m+\Delta}^h - \int_0^s a(\Delta, v/g(h), h)\ dv. \tag{46}$$

Observe first that we can choose $\bar{h}$ so small that for $h < \bar{h}$

$$g(h)h \sup_{(\Delta, v, h)} a(\Delta, v, h) < \frac{\epsilon}{2} \tag{47}$$

since $|a|$ is bounded and $g(h)h = o(1)$. From (46) it follows that for $h < \bar{h}$ and i integer

$$\mathbb{P}\left[\sup_{0<s<L} |S^h(s, \Delta)| \geq \epsilon \right] \leq \mathbb{P}\left[\sup_{0 \leq i \leq [L/(g(h)h)]} |S^h(ig(h)h, \Delta)| \geq \frac{\epsilon}{2} \right].$$

Therefore, to show (45) we need to show that for h small enough:

$$\mathbb{P}\left[\sup_{0 \leq i \leq [L/(g(h)h)]} |S^h(ig(h)h, \Delta)| \geq \frac{\epsilon}{2} \right] \leq \delta. \tag{48}$$

In the rest of this section we suppress the dependence on Δ.

The result (48) follows from two bounds that we will derive below from (33). For i and j integers we have the following two bounds. First,

$$\frac{2L}{\bar{\Delta}} \sup_{0 \leq i \leq [L/\bar{\Delta}]} \mathbb{P}\left[\sup_{0 \leq j \leq [\bar{\Delta}/(g(h)h)]} |S^h(i\bar{\Delta} + jg(h)h) - S^h(i\bar{\Delta})| \geq \frac{\epsilon}{4} \right] \leq \frac{\delta}{2} \tag{49}$$

for

$$\bar{\Delta} = \min\left[\frac{(\delta/2)(\epsilon/4)^\alpha}{2LC}, L \right], \tag{50}$$

with the quantities involved being defined as in Lemma 5.3. Second,

$$\mathbb{P}\left[\sup_{0\le i\le[L/\bar{\Delta}]}|S^h(i\bar{\Delta})|\ge\frac{\epsilon}{4}\right]\le\frac{\delta}{2} \tag{51}$$

for

$$h\le\mathcal{H}\left[\frac{\bar{\Delta}(\delta/2)(\epsilon/4)^\alpha}{L(L+\bar{\Delta})C}\right], \tag{52}$$

with

$$\mathcal{H}(v)=\begin{cases}\infty & \text{if } \sup_h(g(h)h) < v,\\ \inf_h \mid [g(h)h>v] & \text{else.}\end{cases}$$

From (49) and (51) we can conclude that (48) is indeed satisfied for ϵ small if

$$h\le\mathcal{H}\left[\frac{(\delta/2)^2(\epsilon/4)^{2\alpha}}{4L^3C^2}\right],$$

and $\bar{\Delta}$ is chosen as in (50) because then

$$\begin{aligned}&\mathbb{P}\left[\sup_{0\le i\le[L/(g(h)h)]}|S^h(ig(h)h)|\ge\frac{\epsilon}{2}\right]\\ &\le\sum_{i=0}^{[L/\bar{\Delta}]}\mathbb{P}\left[\sup_{0\le j\le[\bar{\Delta}/(g(h)h)]}|S^h(i\bar{\Delta}+jg(h)h)-S^h(i\bar{\Delta})|\ge\frac{\epsilon}{4}\right]\\ &\quad+\mathbb{P}\left[\sup_{0\le i\le[L/\bar{\Delta}]}|S^h(i\bar{\Delta})|\ge\frac{\epsilon}{4}\right]\\ &\le\frac{2L}{\bar{\Delta}}\sup_{0\le i\le[L/\bar{\Delta}]}\mathbb{P}\left[\sup_{0\le j\le[\bar{\Delta}/(g(h)h)]}|S^h(i\bar{\Delta}+jg(h)h)-S^h(i\bar{\Delta})|\ge\frac{\epsilon}{4}\right]+\frac{\delta}{2}\ \le\ \delta.\end{aligned}$$

We now show (49). Define first the event

$$A(j;i)=\left[|S^h(i\bar{\Delta}+jg(h)h)-S^h(i\bar{\Delta})|\ge\frac{\epsilon}{4}\right].$$

Observe that then

$$\begin{aligned}&\mathbb{P}\left[\sup_{0\le j\le[\bar{\Delta}/(g(h)h)]}|S^h(i\bar{\Delta}+jg(h)h)-S^h(i\bar{\Delta})|\ge\frac{\epsilon}{4}\right]\\ &=\mathbb{P}\left[\bigcup_{j=1}^{[\bar{\Delta}/(g(h)h)]}A(j;i)\right]\ \le\ \sum_{j=1}^{[\bar{\Delta}/(g(h)h)]}\mathbb{P}[A(j;i)].\end{aligned}$$

Using Chebyshev's inequality and (33), we find

$$\mathbb{P}[A(j;i)]\le\frac{E[|S^h(i\bar{\Delta}+jg(h)h)-S^h(i\bar{\Delta})|^\alpha]}{(\epsilon/4)^\alpha}\ \le\ \frac{Cj(g(h)h)^2}{(\epsilon/4)^\alpha}.$$

Therefore, we can conclude

$$\mathbb{P}\left[\sup_{0\le j\le[\bar\Delta/(g(h)h)]}|S^h(i\bar\Delta+jg(h)h)-S^h(i\bar\Delta)|\ge\frac{\epsilon}{4}\right]$$
$$\le\frac{\bar\Delta}{g(h)h}\sup_{1\le j\le[\bar\Delta/(g(h)h)]}\mathbb{P}[A(j;i)]\ \le\ \frac{\bar\Delta}{g(h)h}\,\frac{C\bar\Delta g(h)h}{(\epsilon/4)^\alpha}\ =\ \frac{C\bar\Delta^2}{(\epsilon/4)^\alpha}.$$

Thus, (49) is satisfied for $\bar\Delta$ given as in (50).

Consider next showing (51). Note that

$$\mathbb{P}\left[\sup_{0\le i\le[L/\bar\Delta]}|S^h(i\bar\Delta)|\ge\frac{\epsilon}{4}\right]\le\left[\frac{L}{\bar\Delta}+1\right]\sup_{0\le i\le[L/\bar\Delta]}\frac{E[|S^h(i\bar\Delta)|^\alpha]}{(\epsilon/4)^\alpha}\le\left[\frac{L}{\bar\Delta}+1\right]\frac{CLg(h)h}{(\epsilon/4)^\alpha}.$$

Thus, (51) is satisfied if

$$\frac{(L+\bar\Delta)LCg(h)h}{\bar\Delta(\epsilon/4)^\alpha}\le\frac{\delta}{2}$$

or

$$g(h)h\le\left[\frac{\bar\Delta(\delta/2)(\epsilon/4)^\alpha}{L(L+\bar\Delta)C}\right],$$

which gives (52).

Appendix C. Stabilization. We prove Theorem 5.1 given in section 5. Let $\mathbf{X}_i^h$ satisfy

$$\begin{aligned}\mathbf{X}_{i+1}^h&=(\mathbf{I}-\mathbf{A}_i^h)\ \mathbf{X}_i^h,\\ \mathbf{X}_0^h&=\mathbf{I},\end{aligned}\tag{53}$$

with $\mathbf{A}_i^h$ defined in (23) and $\mathbf{X}\ \in\ \mathbb{R}^{[K]\times[K]}$. We show for all $\epsilon>0$

$$\lim_{h\to0}\mathbb{P}\left[\sup_{0<s<L}||\mathbf{X}^h_{[s/(g(h)h)]}-\mathbf{X}(s)||>\epsilon\right]=0,\tag{54}$$

where

$$\begin{aligned}\frac{d\mathbf{X}(s)}{ds}&=-\mathcal{A}(s,h)\ \mathbf{X}(s),\\ \mathbf{X}(0)&=\mathbf{I},\end{aligned}\tag{55}$$

and $\mathcal{A}$ is a lower triangular Toeplitz matrix whose first column is

$$[a(0,s/g(h),h),a(1,s/g(h),h),\dots,a(K,s/g(h),h)]'$$

and with the function a being defined as in (25).

In order to show (54) we introduce a continuous version of $\mathbf{X}_i^h$. Let $\mathbf{X}^h(s)$ satisfy

$$\begin{aligned}\frac{d\mathbf{X}^h(s)}{ds}&=-\mathcal{A}^h(s)\ \mathbf{X}^h(s),\\ \mathbf{X}^h(0)&=\mathbf{I},\end{aligned}$$

with

$$\mathcal{A}^h(s) = -\frac{1}{g(h)h}\ln(\mathbf{I} - \mathbf{A}_i^h) \quad \text{for} \quad (i-1)g(h)h \ \le \ s \ \le \ ig(h)h;$$

then $\mathbf{X}^h(ig(h)h) = \mathbf{X}_i^h$. (Note that, in view of Lemma 5.2, we can truncate the elements of $\mathbf{A}$.)

Next, define the residual

$$\tilde{\mathbf{X}}^h(s) = \mathbf{X}^h(s) - \mathbf{X}(s).$$

Making use of an integrating factor and that

$$\begin{aligned} \frac{d\mathbf{X}^{-1}(s)}{ds} &= \mathbf{X}^{-1}(s)\mathcal{A}(s,h), \\ \mathbf{X}^{-1}(0) &= \mathbf{I}, \end{aligned} \tag{56}$$

we find

$$\begin{aligned} \tilde{\mathbf{X}}^h(s) = &-\int_0^s \tilde{\mathcal{A}}^h(v)\ dv\ \mathbf{X}^h(s) - \int_0^s \mathbf{X}(s)\ \mathbf{X}^{-1}(v) \int_0^v \tilde{\mathcal{A}}^h(v')\ dv'\ \mathcal{A}^h(v)\ \mathbf{X}^h(v)\ dv \\ &+ \int_0^s \mathbf{X}(s)\ \mathbf{X}^{-1}(v)\ \mathcal{A}(v,h)\ \int_0^v \tilde{\mathcal{A}}^h(v')\ dv'\ \mathbf{X}^h(v)\ dv \end{aligned} \tag{57}$$

with

$$\tilde{\mathcal{A}}^h(v) = \mathcal{A}^h(v) - \mathcal{A}(v,h).$$

From (31) it follows that for all $\epsilon > 0$

$$\lim_{h\to 0} \mathbb{P}\left[\sup_{1\le i\le [L/(g(h)h)]} ||\mathbf{A}_i^h|| > \epsilon\right] = 0. \tag{58}$$

Moreover, from (27) it follows that for all $\epsilon > 0$

$$\lim_{h\to 0} \mathbb{P}\left[\sum_{i=1}^{[s/(g(h)h)]} |\mathbf{A}_i^h(k,l)| - 2\int_0^s a(0, s/g(h), h)ds > \epsilon\right] = 0, \tag{59}$$

with $\mathbf{A}_i^h(k,l)$ being the elements of the matrix $\mathbf{A}_i^h$. Given a $c_1 > 0$, we find using (58) that there exists $c_2 > 0$ such that for all $\delta > 0$ there exists $h_0 > 0$ so that

$$\mathbb{P}\left[\int_0^s ||\mathcal{A}^h(v)||dv > c_1\right] \le \mathbb{P}\left[\sum_{i=1}^{[s/(g(h)h)]} ||\mathbf{A}_i^h|| + c_2 \sup_j ||\mathbf{A}_j^h||||\mathbf{A}_i^h|| > c_1\right] + \delta$$

for $h \le h_0$. Therefore, using (58), we find that there exists $c_1 > 0$ such that

$$\lim_{h\to 0} \mathbb{P}\left[\int_0^s ||\mathcal{A}^h(v)||dv > c_1\right] = 0. \tag{60}$$

Note also that for some $c_3 > 0$

$$\int_0^s ||\mathcal{A}(v,h)||dv < c_3 \tag{61}$$

since the coefficients a are bounded. In view of (55), (56), and (61), we find $c_4 > 0$ such that

$$\max\{||\mathbf{X}^{-1}||, ||\mathbf{X}||\} < c_4, \tag{62}$$

and from (60) that there exists $c_5 > 0$ so that

$$\lim_{h\to 0} \mathbb{P}\left[\sup_{0\le s\le t} ||\mathbf{X}^h(s)|| > c_5\right] = 0. \tag{63}$$

We find using (58) that there exists $c_6 > 0$ such that for all $\delta > 0$ there exists $h_2 > 0$ so that

$$\begin{aligned}&\mathbb{P}\left[\sup_{0\le s\le L}\left\|\int_0^s \mathcal{A}^h(v) - \mathcal{A}(v,h)dv\right\| > \epsilon\right]\\ &\le \mathbb{P}\left[\sup_{0\le s\le L}\left\|\sum_{i=1}^{[s/(g(h)h)]} \mathbf{A}_i^h + \mathbf{B}\sup_{1\le i\le [L/(g(h)h)]}||\mathbf{A}_i^h|| - \int_0^s \mathcal{A}(v,h)dv\right\| > \epsilon\right] + \delta\end{aligned}$$

for $h \le h_2$ with $||\mathbf{B}|| < c_6$. The bound in (27) then gives

$$\lim_{h\to 0} \mathbb{P}\left[\sup_{0\le s\le L}\left\|\int_0^s \mathcal{A}^h(v) - \mathcal{A}(v,h)dv\right\| > \epsilon\right] = 0. \tag{64}$$

From (57) and the above it then follows that

$$\lim_{h\to 0} \mathbb{P}\left[\sup_{0\le s\le L} ||\tilde{\mathbf{X}}^h(s)|| > \epsilon\right] = 0,$$

and we have shown (54). Recall that

$$d_k^{N_s+k} = D_k^{N_s+k}\ \Pi_s^h$$

with $N_s = [s/(g(h)h)]$ and

$$\Pi_s^h = \prod_{m=1}^{[s/(g(h)h)]} \tau_m^h.$$

Finally, by using Lemma E.1, which gives the magnitude of Π_s^h, and the result of section D, which bounds the relative magnitude of the reflected mode, we obtain Theorem 5.1.

Appendix D. The reflected mode. In (5) we decompose the wavefield in terms of up- and a down-propagating wave components. Note that if the wave enters a homogeneous section with $\zeta(x) = \bar{\zeta}$ for $x > L$, then trivially the reflected wave component U vanishes for $x > L$, and the wave field is given in terms of the down-propagating wave component only. As we now show, the reflected wave component will be small in general.

Note first that from (21) it follows

$$U_{2j}^{i+1} = \sum_{n=0}^{j} r_{i+1-2(j-n)}^h \prod_{k=1}^{n} \tau_{i-1-2(j-k)}^h\ D_{2(j-n)}^{i-n}, \tag{65}$$

where

$$\prod_{k=1}^{0} := 1.$$

We parameterize the vector of wave components at the front by

$$\tilde{\mathbf{D}}_j^i = [D_0^{i-j}, D_2^{i-j+1}, \ldots, D_{2j}^i]'.$$

Observe that

$$\prod_{k=1}^{n} \tau_{i-1-2(j-k)}^h \leq 1.$$

Let $i \in \{0, \ldots, [L/(g(h)h)]\}$; then we find

$$U_{2j}^{i+1} \leq \left\{ \sup_{i+1-2j \leq k \leq i+1} |r_k^h| \right\} \, ||\tilde{\mathbf{D}}_j^i||.$$

From (19) and (21) we get the uniform bound

$$|D_j^i| \leq 1. \tag{66}$$

Thus, in view of (31), we find that for all $\epsilon > 0$ and $j \in \{0, \ldots, K\}$

$$\lim_{h \to 0} \mathbb{P} \left[\sup_{1 \leq i \leq [L/(g(h)h)]} |U_{2j}^i| > \epsilon \right] = 0$$

and that (29) is satisfied.

Appendix E. A bound on transmission. We show how the magnitude of the solution of (23) can be bounded. Recall that

$$d_k^{N_s+k} = D_k^{N_s+k} \, \Pi_s^h,$$

with $N_s = [s/(g(h)h)]$. Thus, in view of (66), we need to characterize the magnitude of Π_s^h.

LEMMA E.1. *The condition* (27) *implies that for all* $\epsilon > 0$

$$\lim_{h \to 0} \mathbb{P} \left[\sup_{0 < s < L} \left| \ln(\Pi_s^h) + \int_0^s a(0, v/g(h), h) \, dv/2 \right| > \epsilon \right] = 0, \tag{67}$$

with

$$\Pi_s^h = \prod_{m=1}^{[s/(g(h)h)]} \tau_m^h = \prod_{m=1}^{[s/(g(h)h)]} \sqrt{1 - |r_m^h|^2}. \tag{68}$$

Proof. Note first that we can write

$$\ln \sqrt{1 - |r_m^h|^2} = -\frac{|r_m^h|^2 (1 + v_m^h)}{2},$$

with

$$|v_m^h| \le |r_m^h|^2 \tag{69}$$

if $r_m^h < 1/2$. Observe next

$$\begin{aligned}
&\mathbb{P}\left[\sup_{0<s<L}\left|\ln(\Pi_s^h) + \int_0^s a(0, v/g(h), h)\ dv/2\right| > \epsilon\right] \\
&\le \mathbb{P}\left[\sup_{0<s<L}\frac{1}{2}\left|\sum_{m=1}^{[s/(g(h)h)]} |r_m^h|^2 - \int_0^s a(0, v/g(h), h)\ dv\right| + \frac{1}{2}\sup_m |v_m^h| \sum_{m=1}^{[s/(g(h)h)]} |r_m^h|^2 > \epsilon\right].
\end{aligned}$$

Let $\delta > 0$ be given; then from (27), (31), and (69) it follows that we can choose $h_0 > 0$ such that for $h \le h_0$

$$\mathbb{P}\left[\sup_{0<s<L}\frac{1}{2}\left\{\sup_m |v_m^h| \sum_{m=1}^{[s/(g(h)h)]} |r_m^h|^2\right\} > \frac{\epsilon}{2}\right] < \frac{\delta}{2}.$$

Therefore, for $h \le h_0$

$$\begin{aligned}
&\mathbb{P}\left[\sup_{0<s<L}\left|\ln(\Pi_s^h) + \int_0^s a(0, v/g(h), h)\ dv/2\right| > \epsilon\right] \\
&\le \frac{\delta}{2} + \mathbb{P}\left[\sup_{0<s<L}\frac{1}{2}\left|\sum_{m=1}^{[s/(g(h)h)]} |r_m^h|^2 - \int_0^s a(0, v/g(h), h)\ dv\right| > \frac{\epsilon}{2}\right].
\end{aligned}$$

The result (67) then follows from (27). □

Appendix F. Limiting pulse shape and the central limit theorem. Recall that in the small h limit the impulse response of the random medium is characterized by the solution of (25). The matrix $\bar{\mathbf{A}}$ in (25) is lower triangular and Toeplitz, and we find

$$\begin{aligned}
\mathcal{D}(T, h) &= \exp\left(-\int_0^T \bar{\mathbf{A}}(s, h)\ ds\right)\ \mathbf{e}_1 \\
&= \exp(-\lambda(T, h)) \exp(\lambda(T, h)\mathcal{Q}(T, h))\ \mathbf{e}_1
\end{aligned}$$

using a parameterization analogous to the one in section 5.3. Note that $\mathcal{Q}$ is a strictly lower triangular Toeplitz matrix and $\lambda(T, h) = \int_0^T \bar{\mathbf{A}}(s, h)_{(1,1)}\ ds$, where $\bar{\mathbf{A}}(s, h)_{(1,1)}$ is the main diagonal entry of the matrix $\bar{\mathbf{A}}(s, h)$. For some important random media models the first column of the matrix $\mathcal{Q}$ (denote it $\mathbf{q}$) has nonnegative entries and defines a discrete density supported on the nonnegative integers. This is the case if, for instance, the random medium is Markovian. We want to characterize $\mathcal{D}$:

$$\mathcal{D} = \mathcal{D}(\lambda) \ = \ \exp(-\lambda)\exp(\lambda\mathcal{Q}(\lambda))\ \mathbf{e}_1 \ = \ \sum_{k=0}^{\infty} \exp(-\lambda)\ \frac{\lambda^k}{k!}\ \mathbf{q}_\lambda^{k*} \tag{70}$$

in the limit of large $\lambda = \lambda(T, h) = \int_0^T \mathcal{A}(s, h)_{(1,1)}\ ds$, corresponding to large travel time depths. Note that in (70) we made use of the fact that multiplication with $\mathcal{Q}$ corresponds to a discrete convolution. This formulation shows that if indeed $\mathbf{q}_\lambda$

defines a discrete distribution, then we can regard $\mathcal{D}$ as the distribution of a random sum supported on the nonnegative integers. It follows that the pulse has constant area as it travels. By the formulas for the moments of a random sum (see [11]), we find that then the mean of $\mathcal{D}$ is $\lambda m(\lambda)$ and the variance $\lambda(v(\lambda)+m(\lambda)^2)$ when $m(\lambda)$ and $v(\lambda)$ are respectively the mean and variance associated with $\mathbf{q}_\lambda$. The next theorem shows that the normalized random sum converges in distribution to the standard normal; hence, the wave pulse attains the Gaussian shape as it penetrates deep into the medium.

LEMMA F.1. *Let $\mathbf{q}_\lambda$ define a discrete distribution with mean $m(\lambda) \le \overline{m}$ and variance $0 < \underline{v} \le v(\lambda) \le \overline{v}$, and let S_λ be distributed as a random sum according to*

$$\sum_{k=0}^{\infty} p_k^\lambda \mathbf{q}_\lambda^{k*},$$

with $p_k^\lambda = \exp(-\lambda)\lambda^k/k!$. Then, in the large λ limit,

$$X_\lambda = \frac{S_\lambda - \lambda m(\lambda)}{\sqrt{\lambda(v(\lambda)+m(\lambda)^2)}} \tag{71}$$

converges in distribution to a standardized zero mean normal random variable.

Proof. Let

$$\exp(im(\lambda)t)\phi_\lambda(t)$$

be the characteristic function of $\mathbf{q}_\lambda$. The characteristic function of $S_\lambda/\sqrt{\lambda}$ is then

$$\begin{aligned}&\exp\{-\lambda+\lambda[\exp(im(\lambda)t/\sqrt{\lambda})\ \phi_\lambda(t/\sqrt{\lambda})]\}\\ &= \exp\left\{-\lambda+\lambda\left[1+i\frac{m(\lambda)t}{\sqrt{\lambda}}-\frac{v(\lambda)t^2}{2\lambda}-\frac{m(\lambda)^2t^2}{2\lambda}\right]+o(1)\right\}\end{aligned}$$

for λ large. Thus, the characteristic function associated with X_λ defined in (71) is

$$\exp\left(\frac{-t^2}{2}+o(1)\right)$$

in the λ large limit. Hence, Lemma F.1 follows in view of Theorem 26.3 in [2]. ∎

Note also that the distribution of $S_\lambda/\sqrt{\lambda}$ can be approximated by the distribution of a random sum of Gaussian random variables. The following lemma gives this characterization of S_λ.

LEMMA F.2. *Let p_k^λ, $\mathbf{q}_\lambda$, and S_λ be defined as in Lemma* F.1. *Let E_X denote expectation with respect to the distribution of $X_\lambda = S_\lambda/\sqrt{\lambda}$, and E_g denote expectation with respect to the distribution defined by*

$$g_\lambda(x) = \sum_{k=0}^{\infty} p_k^\lambda\ \frac{\eta((x-\mu_k)/\sigma_k)}{\sigma_k}, \tag{72}$$

where $\eta(\cdot)$ is the standard normal distribution, $\mu_k = km(\lambda)/\sqrt{\lambda}$, $\sigma_k^2 = kv(\lambda)/\lambda$, and $m(\lambda)$ and $v(\lambda)$ are defined as in Theorem F.1. *Then*

$$\lim_{\lambda\to\infty}(E_g[u]-E_X[u]) = 0 \tag{73}$$

for every bounded continuous function u.

ORTHONORMAL POLYNOMIAL WAVELETS ON THE INTERVAL AND APPLICATIONS TO THE ANALYSIS OF TURBULENT FLOW FIELDS*

J. FRÖHLICH† AND M. UHLMANN‡

Abstract. The paper presents an orthogonal wavelet basis for the interval using a linear combination of Legendre polynomials. Expansion coefficients are taken as appropriate roots of the Chebyshev polynomials of the second kind. The new transform is first applied to analytical data, and appropriate definitions of a scalogram are presented. The transform is then extended to the multidimensional case, finding the tensor-product construction more appropriate than the multiresolution. The new method offers the possibility to determine meaningful spectra for signals on bounded domains which are constructed in a global and in a local fashion. Analyses of one- and two-dimensional data from a direct numerical simulation of turbulent channel flow are presented and demonstrate the potential of the method.

Key words. wavelets, Legendre polynomials, bounded domains, turbulence, turbulent channel flow

1. Introduction.

Since their advent in the 1980s, wavelets have been put to use in many different scientific areas. Applications to turbulent flows have been amongst the first and are comprehensively reviewed in [10]. Recent activity in this area includes analysis of the flow field in space by means of either continuous or discrete transforms [3, 26], data compression using orthogonal schemes [28], and the discretization of the governing Navier–Stokes equations in terms of wavelet functions [13]. Here, we are concerned with the first of these tasks: data analysis. This is motivated by the need for an improved understanding of local nonlinear transfer of turbulent kinetic energy in scale space.

While wavelet analysis has proven to be a valuable tool for investigating spatially homogeneous configurations, i.e., flow in periodic domains [3, 26, 7, 22], there are only very few publications dealing with bounded flows. One such example is reference [9], where, however, only planes parallel to the nonhomogeneous spatial direction are investigated. We believe that this situation is at least partially due to the lack of wavelet functions specifically designed for use on bounded intervals which are fully appropriate for the analysis. A proposal for such a construction is made in the present paper.

Fischer and Prestin [11] have developed a general method for constructing wavelet bases on the interval, starting from a set of orthogonal polynomials and making use

of their reproducing kernel property. However, these authors present only one specific basis—constructed from Chebyshev polynomials of the second kind—which is orthogonal. These wavelets are related to a scalar product weighted by the function $w(x) = (1-x^2)^{1/2}$, and orthogonality is obtained with respect to this weighted product. For the purpose of data analysis, any weight other than unity is undesirable since the interpretation of coefficient values with respect to their energy contribution turns out to be nonintuitive. Prestin (in a private communication) proposed a modification to the original construction in which a "hybrid" basis would instead be built from a combination of Chebyshev and Legendre polynomials, thereby carrying over the orthogonality of the original pure Chebyshev basis to a weight function of unity.

In the present paper we first discuss the specific requirements a wavelet basis should fulfill in order to be useful for the purpose of analysis of turbulent flows. This is followed by a concise overview of related constructions developed in the literature. The new construction is presented in section 3 and applied to different types of analytical signals. This leads to important issues, such as the visual presentation of the coefficients (scalogram) and the study of the local power spectral density, for which we propose appropriate definitions in section 4. In a further step, the construction is extended to the multidimensional case (section 5). Applications of the method to data from turbulent plane channel flow in section 6 give an impression of its potential for the analysis of nonperiodic turbulent data.

2. Requirements and previous constructions.

2.1. Requirements. The term wavelet is often used in a very broad sense and can designate functions used in quite different multiscale methods. Features of such schemes are (i) a certain number of vanishing moments reflected by an oscillatory nature of the functions; (ii) localization in space; (iii) translational invariance; (iv) localization in frequency; (v) a rescaling mechanism. In practice, some of these properties are often watered down due to practical constraints. Since compromises need to be made it is important to fix desired properties a priori according to the needs of a target application. This issue is briefly discussed in the following, considering for notational ease the one-dimensional case. The term *frequency* will be used when referring to a Fourier basis while the term *scale* is employed in a more general sense.

Two- and three-dimensional data sets from turbulent flows tend to be extremely large. A redundant representation of these data can increase their size considerably and pose problems of computation time and storage requirements. A discrete, nonredundant representation therefore seems indispensable [26], and the continuous transform will not be considered in the present context.

The long-range goal of our research is the investigation of energy transfer mechanisms in turbulent flows. One approach to perform this is to represent a turbulent signal $f(x) \in L_2(\Omega)$, where Ω is the spatial domain, through an orthonormal set of basis functions $\beta_\lambda(x) \in L_2(\Omega)$, viz.

$$f(x) = \sum_\lambda a_\lambda \, \beta_\lambda(x). \tag{1}$$

The orthonormality property then allows us to decompose the energy E into contributions related to each basis function as

$$E = \frac{1}{|\,\Omega\,|} \int_\Omega f^2(x)\, dx \; = \; \sum_\lambda a_\lambda^2. \tag{2}$$

In mathematical terms, the L^2 norm of f is represented by the expansion coefficients with respect to the basis β_λ, according to the Plancherel identity. The scalar product generating this norm is denoted $\langle \cdot, \cdot \rangle$. In the next step, the representation (1) can be inserted into the governing Navier–Stokes equations to obtain equations for the evolution of the coefficients a_λ and hence equations for the energy transfer [26].

Turbulent flows exhibit motions over a wide range of scales. If the basis functions β_λ are not very smooth, they contain high-frequency contributions and are not well localized in the upper frequency range. On the other end of the spectrum, the number of vanishing moments determines the localization in the low-frequency range. If the number of these vanishing moments is insufficient, this can yield a decay of the wavelet spectrum which differs significantly from that of the analogous Fourier spectrum, which is an undesirable feature [30].

For the physical interpretation of the transform (1) and quantities derived from it, a pronounced asymmetry of the basis functions also is undesirable. Daubechies' wavelets, e.g., which have compact support, exhibit such an asymmetry. It can be alleviated to some extent, but compact support and symmetry exclude each other if orthogonality is required [5], except for the Haar basis, which is not smooth.

To sum up, we require vanishing moments, orthonormality, smoothness, and some sort of translational invariance and symmetry for the wavelets to be employed. The last two notions have to be relaxed for a basis on the interval as discussed below. Multiresolution algorithms often yield fast numerical schemes due to recursions over the refinement level. This last issue will be disregarded in the present paper and postponed to later work.

Finally, it should be stressed that a nonperiodic transform of turbulent data is important for signals in space rather than in time. The latter can always be made very long—provided the flow is statistically stationary—such that end effects are removed by an appropriate windowing. Signals in space, on the other hand, are often limited by the geometry of the flow. Moreover, physically interesting features frequently develop in direct proximity of the boundaries. A prototype case is the turbulent plane channel considered below.

2.2. Real line and periodic case. For later reference we recall some constructions for the real line. Here, it is convenient to work in Fourier space defined by the Fourier transform

$$\widehat{f}(\omega) = \int f(x)\, e^{-2\pi i x \omega} dx. \tag{3}$$

The trigonometric functions are not localized in space and are maximally localized in frequency. In order to design basis functions with localization in space, as well as frequency, localization in frequency is sacrificed to some extent by lumping together basis functions with neighboring frequencies. In the following we denote a wavelet by ψ and a scaling function by φ, using j and i as scale and shift indices, respectively. In the classical case this leads to a dyadic set of wavelet functions with

$$\psi_{ji} = 2^{j/2}\, \psi(2^j x - i), \tag{4}$$

and analogously for φ_{ji}. The Shannon wavelet, also termed the Littlewood–Paley basis, [5] is obtained by selecting only frequencies in the band $\omega \in [1/2, 1]$:

$$\widehat{\psi}^S(\omega) = \begin{cases} 1 & \text{if} \quad \mid \omega \mid \in [\frac{1}{2}, 1], \\ 0 & \text{else.} \end{cases} \tag{5}$$

Fourier theory immediately yields the asymptotic decay rate of $\psi \propto 1/x$ in space. Better decay is possible only with higher smoothness in frequency space. Meyer wavelets are constructed by an ingenious incorporation of neighboring decades using a blending function

$$\widehat{\psi}^M(\omega) = \begin{cases} e^{-i\omega x}\, S(3 \mid \omega \mid -1) & \text{if} \quad \mid \omega \mid \in [\frac{1}{3}, \frac{2}{3}], \\ e^{-i\omega x}\, S(2 - \frac{3}{2} \mid \omega \mid) & \text{if} \quad \mid \omega \mid \in [\frac{2}{3}, \frac{4}{3}], \\ 0 & \text{else}, \end{cases} \tag{6}$$

where S is a cosine-based smooth function with $S(0) = 0, S(1) = 1$, and $S^2(t)+S^2(1-t) = 1$ for $t \in [0;1]$ [5]. The smoother the blending function, the faster the asymptotic decay of the wavelets in space. It is polynomial for this family if S is not in C^∞. Other constructions such as spline wavelets have noncompact support in frequency space and decay exponentially in physical space. Wavelets on different scales are obtained by multiplying ω by a power of two, introducing a logarithmic decomposition of the frequency axis. But whether it is decomposed into logarithmic segments or some other intervals, the asymptotic decay rate in physical space is unaltered if the regularity in Fourier space is maintained.

A periodic basis, i.e., a basis on the circle $\mathbb{T} = [0, 1]$, can be obtained from a wavelet basis on the real line by restricting the frequency to integer values $\widehat{f}_k = \widehat{f}(\omega = k), k \in \mathbb{Z}$. This introduces a coarsest scale represented by $\widehat{f}_0$, i.e., the constant function. When considering the periodic case, asymptotic decay in space refers to the behavior in the limit $j \to \infty$.

2.3. Orthogonal wavelets on the interval. By functions on the interval (here $I = [-1, 1]$ for later convenience) we understand that in contrast to the circle $\mathbb{T}$ no periodicity is imposed.

Embedding the interval in a larger periodic domain or the real line by padding with zero and using standard transforms on the larger domains usually creates artifacts at the boundaries of the interval due to the generation of a strong singularity. This is very inconvenient for the analysis.

On the interval, translational invariance therefore has to be relaxed in some way. In addition to the length scale introduced by the scale index j of the wavelet, the distance to the nearest boundary unavoidably appears as a second length scale contradicting complete shift invariance. This fact has to be reflected to some extent by the construction, and translational invariance can therefore be realized only in some relaxed sense. For the Daubechies wavelets adapted to the interval [4] this is performed through modification of those translates touching the boundaries. Due to the orthogonalization procedure, the modified functions tend to take a quite irregular shape. Furthermore, a minimal refinement level is required to separate the regions of modification close to both boundaries. According to the above requirements we therefore do not use this construction for the present application.

2.4. Using the Chebyshev transform. A very elegant method to turn a periodic wavelet basis into a basis on the interval I is the mapping

$$x = \cos\theta, \qquad \theta \in [0, \pi]. \tag{7}$$

This is the mapping relating cosines and Chebyshev polynomials through $T_n(x) = cos(n\theta)$. In fact, if $\beta_\lambda^{\mathbb{T}}$ is a basis of periodic functions on $\mathbb{T}$, orthogonal with respect

to the scalar product

$$\langle \cdot, \cdot \rangle_{\mathbb{T}} = \int_0^1 \cdot \; \cdot \, dx, \tag{8}$$

the functions

$$\beta_\lambda^I(\theta) = \beta_\lambda^{\mathbb{T}}(\theta) + \beta_\lambda^{\mathbb{T}}(1-\theta) \tag{9}$$

constitute an orthogonal basis for the weighted scalar product

$$\langle \cdot, \cdot \rangle_w = \int_{-1}^1 \cdot \; \cdot \, w(x)\, dx \tag{10}$$

with the Chebyshev weight $w(x) = 1/\sqrt{1-x^2}$ [19, 31]. In fact, this was already announced and used in [24], where unfortunately the second entry of the sum in (9) was overlooked. The transform (7), (9) allows us to map an arbitrary periodic basis onto a basis for the interval I. Computations can then be done with the classical algorithms (employing fast convolution by FFT for long filters) requiring only a rescaling of the abscissa. The price, however, is the introduction of the Chebyshev weight.

For the reasons mentioned above we require a basis which is orthonormal with respect to the unweighted scalar product. A naive way of achieving this is to incorporate the weight into the basis by defining

$$\tilde{\beta}_\lambda^I = \sqrt{w(x)}\beta_\lambda^I \tag{11}$$

and using $\tilde{\beta}_\lambda^I$ instead of $\beta_\lambda^{\mathbb{T}}$ in (1). Approximations of square-integrable functions on I using this basis with finer and finer scale converge in an integral sense. Pointwise convergence at the interval boundaries, however, is destroyed by the singularities of the weight at ± 1 which are introduced into the basis. This is illustrated in Figure 1, where a very smooth function is approximated by a truncated series of such wavelets based on periodic spline wavelets. Hence, this approach is not useful for the present purpose.

2.5. Wavelets based on Jacobi polynomials. In [11] the authors have constructed wavelets based on orthogonal polynomials P_n by means of the reproducing kernel polynomials. The construction is possible for general orthogonal polynomials, but in the present context we take P_n to be the Jacobi polynomial of degree n defined on the interval $I = [-1, 1]$ and orthogonal with respect to the weighted scalar product (10) with $w(x) = w^{\alpha,\beta}(x) = (1-x)^\alpha(1+x)^\beta$. (The indices α, β are dropped from now on for convenience.) The reproducing kernel polynomial is

$$K_n(x, y) = \sum_{k=0}^n P_k(x)\, P_k(y). \tag{12}$$

Scaling functions are defined as

$$\varphi_{n,i} = K_n(x, y_i^{(n+1)}), \qquad i = 0, \ldots, n, \tag{13}$$

with a suitable set of points $y_i^{(n+1)}$, e.g., the zeros of the polynomial P_{n+1}. Wavelets are constructed as

$$\psi_{n,i} = K_{2n}(x, y_i^{(n)}) - K_n(x, y_i^{(n)}), \qquad i = 0, \ldots, n-1. \tag{14}$$

Based on this approach a multiresolution analysis (MRA) [25] of nested subspaces $V_j \subset V_{j+1}$ with difference spaces W_j can be generated. Orthogonality of all transla-

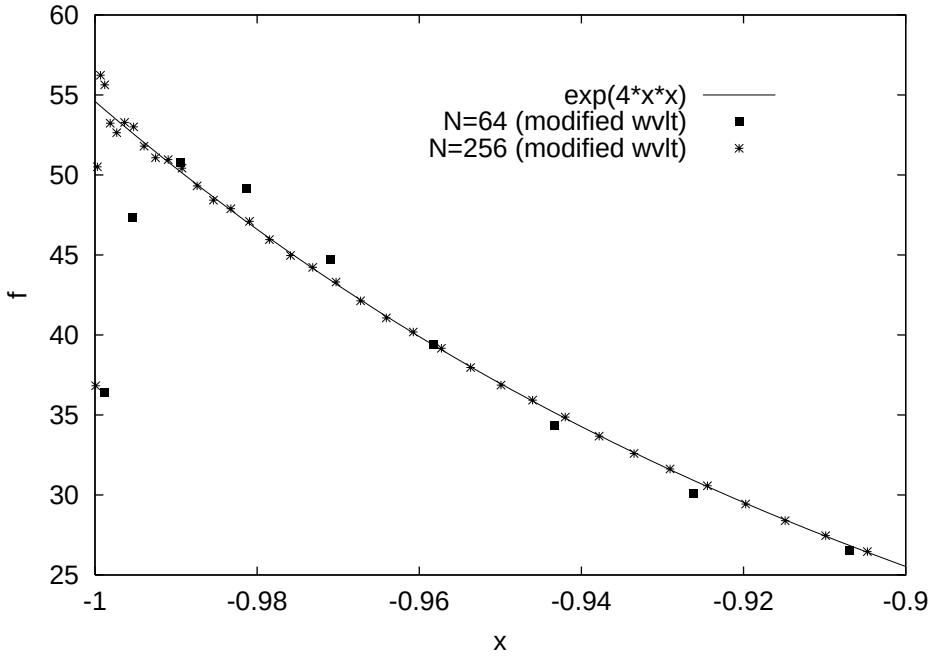

FIG. 1. *The reconstructed signal when approximating the function* $u(x) = \exp(-4x^2)$ *with the modified wavelets* $\tilde{\beta}$ *defined in* (11). *Two different resolutions are used. tions with respect to the related scalar product (including the Jacobi weight) is not necessarily obtained but can be investigated as described in [11]. In this reference one example of an orthogonal basis is presented using the Chebyshev polynomials of the second kind U_n. The same construction, when applied directly to Legendre polynomials L_n, however, does not yield an orthogonal basis.

3. New construction.

3.1. The general setting. In [11] linear combinations of orthogonal polynomials $P_k(x)$ are used for constructing scaling functions and wavelets by regrouping low-order and high-order polynomials via

$$\varphi_{ji}(x) = \sum_{k=0}^{2^j} a_{jik}\, P_k(x)\,, \tag{15a}$$

$$\psi_{ji}(x) = \sum_{k=2^j+1}^{2^{j+1}} b_{jik}\, P_k(x)\,. \tag{15b}$$

For wavelets and scaling functions spanning an orthonormal basis of an MRA, these need to fulfill the following orthogonality conditions:

$$\langle \varphi_{ji}, \varphi_{jl} \rangle_w = \delta_{il}\,, \tag{16a}$$

$$\langle \psi_{ji}, \psi_{ml} \rangle_w = \delta_{il}\, \delta_{jm}\,, \tag{16b}$$

$$\langle \varphi_{ji}, \psi_{ml} \rangle_w = 0 \qquad (m \geq j)\,. \tag{16c}$$

Introducing the ansatz (15), we obtain

$$\langle \varphi_{ji}, \varphi_{jl} \rangle_w = \sum_{k=0}^{2^j} \sum_{n=0}^{2^j} a_{jik} a_{mln} \langle P_k, P_n \rangle_w \,, \tag{17a}$$

$$\langle \psi_{ji}, \psi_{ml} \rangle_w = \sum_{k=2^j+1}^{2^{j+1}} \sum_{n=2^m+1}^{2^{m+1}} b_{jik} b_{mln} \langle P_k, P_n \rangle_w \,, \tag{17b}$$

$$\langle \varphi_{ji}, \psi_{ml} \rangle_w = \sum_{k=0}^{2^j} \sum_{n=2^m+1}^{2^{m+1}} a_{jik} b_{mln} \langle P_k, P_n \rangle_w \,. \tag{17c}$$

It is clear that due to the orthogonality of the polynomials (i.e., $\langle P_k, P_n \rangle_w = \delta_{kn}$) the choice of the coefficients a, b alone determines the orthogonality properties of the basis. Therefore, we find

$$\langle \varphi_{ji}, \varphi_{jl} \rangle_w = \sum_{k=0}^{2^j} a_{jik}\, a_{jlk} \,, \tag{18a}$$

$$\langle \psi_{ji}, \psi_{ml} \rangle_w = \delta_{jm} \sum_{k=2^j+1}^{2^{j+1}} b_{jik}\, b_{jlk} \,, \tag{18b}$$

$$\langle \varphi_{ji}, \psi_{ml} \rangle_w = 0 \qquad\qquad (m \geq j) \,. \tag{18c}$$

(The factor δ_{jm} in relation (18b) follows from the fact that the bounds of the two sums in (17b) need to be equal if the scalar product is to be nonzero.) As a consequence it is possible to interchange freely the particular type of polynomial—amongst the class of orthogonal ones—without changing the above properties. Therefore, we can go about and modify a given basis whose a's and b's are such that (16) is verified and replace the functions $P_k(x)$ and the weight w with any other orthogonal function and associated weight, in particular with Legendre polynomials related to the weight $w(x) = 1$. The construction will now be described in detail.

3.2. Definition of the basis functions. We define wavelets and scaling functions based upon Legendre polynomials $L_k(x)$ and coefficients related to the Chebyshev polynomials of the second kind $U_k(x)$ as follows:

$$\varphi_{ji}(x) = C_{ji}^{\varphi} \sum_{k=0}^{2^j} U_k(y_i^{(2^j+1)}) \sqrt{k+1/2}\, L_k(x) \,, \qquad j = 0, 1, \ldots, i = 0 \ldots 2^j \,, \tag{19a}$$

$$\psi_{ji}(x) = C_{ji}^{\psi} \sum_{k=2^j+1}^{2^{j+1}} U_k(y_i^{(2^j)}) \sqrt{k+1/2}\, L_k(x) \,, \qquad j = 0, 1, \ldots, i = 0 \ldots 2^j - 1 \,. \tag{19b}$$

With the above index bounds these functions span the scale spaces V_j and the difference spaces W_j of an MRA. This MRA fulfills the classical requirements of [25]. The

polynomials $L_k(x)$ and $U_k(x)$ on the interval $x \in [-1,1]$ can be defined by [1]:

$$L_k(x) = \frac{1}{2^k} \sum_{l=0}^{\mathrm{int}(k/2)} (-1)^l \begin{pmatrix} k \\ l \end{pmatrix} \begin{pmatrix} 2k-2l \\ k \end{pmatrix} x^{k-2l}\,, \tag{20a}$$

$$U_k(x) = \frac{\sin((k+1)\,\arccos(x))}{\sin(\arccos(x))}\,, \tag{20b}$$

(where $\mathrm{int}(r)$ is the largest integer less or equal r). For an efficient computation their three-term recursion formulae

$$L_{k+1}(x) = \frac{2k+1}{k+1} x\, L_k(x) - \frac{k}{k+1}\, L_{k-1}(x)\,, \qquad L_0(x) = 1\,, \quad L_1(x) = x\,, \tag{21a}$$

$$U_{k+1}(x) = 2x\, U_k(x) - U_{k-1}(x)\,, \qquad U_0(x) = 1\,, \quad U_1(x) = 2x \tag{21b}$$

are used. The parameters $y_i^{(n)}$ in equations (19) are the zeros of the nth-order Chebyshev polynomial of the second kind, i.e.,

$$y_i^{(n)} = -\cos\left(\frac{(i+1)\,\pi}{n+1}\right)\,, \qquad i = 0 \ldots n-1. \tag{22}$$

For convenience, the present numbering is different from the standard numbering in that we have $y_i^{(n)} < y_{i+1}^{(n)}$. Equations (19) define the coefficients a_{ijk} and b_{ijk} in (15). In [11] the orthogonality of the resulting basis with $P_k = U_k$ in (15) is proved. As discussed above, this property carries over to the functions defined by (19). The factors

$$C_{ji}^{\varphi} = \sqrt{\frac{2}{2^j+2}}\, \sin\left(\pi \frac{i+1}{2^j+2}\right)\,, \tag{23a}$$

$$C_{ji}^{\psi} = \sqrt{\frac{2}{2^j+1}}\, \sin\left(\pi \frac{i+1}{2^j+1}\right) \tag{23b}$$

have been introduced here for the purpose of normalization in order to fulfill equations (16) without further constants. The derivation makes use of a trigonometric identity given in [15, p. 14].

From the presentation it is obvious that the linear approximation properties of the wavelet functions ψ_{ji} are those of the spaces V_j spanned by the Legendre polynomials up to degree 2^j. In particular, these polynomials constitute an unconditional basis of $L_2([-1,1])$ so that any square-integrable function $u(x)$, $x \in [-1,1]$, can be decomposed as

$$u(x) = c_{00}\, \varphi_{00}(x) + c_{01}\, \varphi_{01}(x) + \sum_{j=0}^{\infty} \sum_{i=0}^{2^j-1} d_{ji} \psi_{ji}(x), \tag{24}$$

where, by orthonormality, the coefficients are obtained from

$$d_{ji} = \int_{-1}^{1} u(x) \psi_{ji}(x)\, \mathrm{d}x\,, \tag{25a}$$

$$c_{ji} = \int_{-1}^{1} u(x) \varphi_{ji}(x)\, \mathrm{d}x. \tag{25b}$$

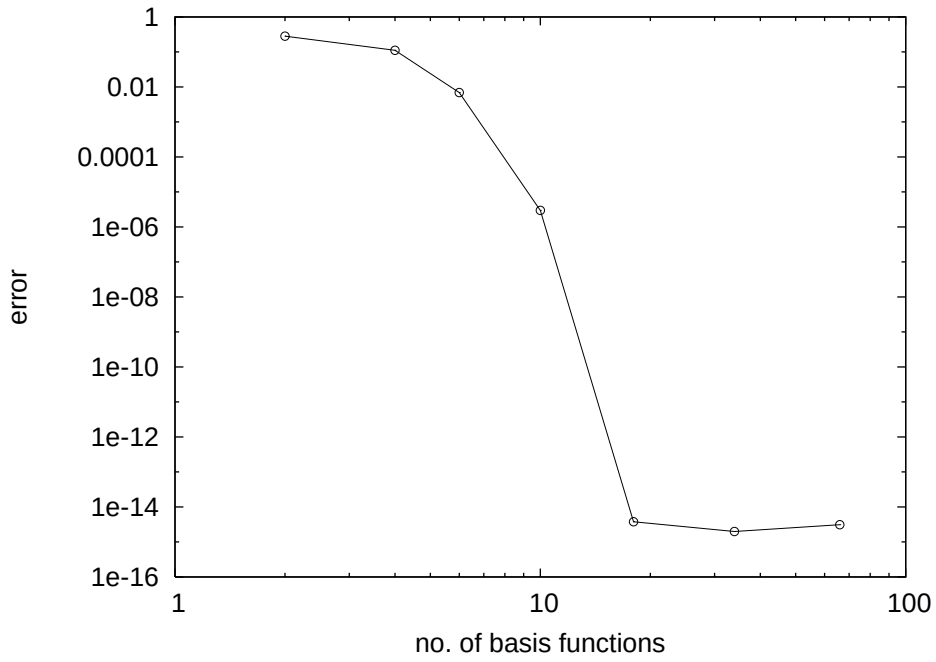

FIG. 2. *Convergence of the approximation when analyzing the function* $u(x) = \exp(-4x^2)$ *for* $x \in [-1; 1]$. *The curve shows the maximum relative error as a function of the number of basis functions used in the reconstruction. The r.m.s. error (not shown) has a similar behavior.*

Again due to orthonormality the decomposition (24) yields a corresponding decomposition of the "energy" of the signal in terms of the coefficients

$$\int_{-1}^{1} u(x)^2 \mathrm{d}x = c_{00}^2 + c_{01}^2 + \sum_{j,i} d_{ji}^2. \tag{26}$$

4. Properties and definition of secondary quantities.

4.1. Implementation and convergence of the approximation. We illustrate the global convergence of the approximation of a function by its wavelet expansion through numerical tests with analytical signals. For this purpose, a partial reconstruction according to (24) with $j \leq J < \infty$ is performed. As a representative example, Figure 2 shows the variation of the maximum error for the signal $u(x) = \exp(-4x^2)$ when the truncation index J is increased. Spectral convergence is observed as expected. The equivalent to Figure 1 is not shown here since at these resolutions no difference between the exact and the approximated data can be discerned. We also note that each function ψ_{ji} has at least 2^j vanishing moments, a fact resulting from the bounds of the sum in (19) and the orthogonality of the Legendre polynomials.

At present, the scalar products (25) are evaluated by a Gauss–Lobatto quadrature, i.e., first performing a Legendre transform of the data—sampled on a Gauss–Lobatto grid—and then computing the linear combination of Legendre coefficients, which leads to the respective wavelet coefficients. If data are given in terms of coefficients of orthogonal polynomials of a different type, like Chebyshev polynomials of the first kind

as, e.g., used in a spectral simulation, explicit conversion formulas [2] might be used. Another means for such a conversion is spectral interpolation onto the Legendre grid as applied in section 4.5 below. The construction of a fast recursive implementation of the present algorithm using classical relations for orthogonal polynomials is left as a future extension.

4.2. Localization properties. Figure 3 shows sample wavelet functions of scale $j = 5$. It can be observed that they are almost translationally invariant near the center of the interval, while they visibly increase their amplitude and frequency near the boundary. This effect of varying shape is more vividly illustrated in Figure 4, where the envelope of the square of several wavelet functions is shown. Particularly, the existence of a second local maximum of the amplitude at the nearest boundary can be observed. From the semilogarithmic plots in Figure 5 the spatial decay of the functions around their center location can be judged. The envelopes approximately decay like $\mathcal{O}(x^{-2})$ (cf. Figure 6) which means that the wavelets themselves decay at a rate of $1/x$. This can be understood by referring to the Littlewood–Paley basis recalled above in section 2.2. In fact, for increasing degree, the zeros of the orthogonal polynomials become more and more uniformly spaced in the center of the interval so that in this region the analysis locally resembles a Fourier analysis. For functions φ_{ji} and ψ_{ji} defined by (15) this amounts to approaching Shannon wavelets due to the employed summation bounds. We can therefore conjecture that with nonoverlapping summation bounds in (15) it will not be possible to improve the decay rate of these functions. Overlapping bounds, however, would add an additional level of complexity to the construction as this destroys the automatic interscale orthogonality which is readily obtained with (15) due to the orthogonality of the underlying polynomials.

The decay, however, is only local. Close to the boundaries the wavelet functions have a tendency to increase and to exhibit the "tails" mentioned above. Table 1 gives the contribution of these tails to the energy of the wavelet, i.e., the integral $\int_{x_{tail}}^{+1} \psi_{ji}^2 \mathrm{d}x$ with x_{tail} being the location where the slope of the envelope reverses. This quantity is below one percent for centrally located wavelets. For comparison, Figure 7 shows the corresponding decay of the wavelets of Fischer and Prestin [11], which are based upon Chebyshev polynomials of the second kind (U_k instead of L_k in (19)). In the latter case the tails are similar and even more pronounced. This is also reflected in the values of Table 1.

We recall that both families of wavelets are related through the basic equation (15) inasmuch as they have common coefficients a_{ijk}, b_{ijk} and differ only in the definition of the associated polynomial function $P_k(x)$. These coefficients a_{ijk} are plotted in Figure 8, where the same indices i, j as in the previous graphs have been chosen. At the same time, the coefficients represent the Legendre spectrum of the present wavelets. It is evident from the graphs that the exact spectral distribution of the basis functions varies with the position index. Furthermore, the low-pass nature of the scaling functions and the band-pass property of the wavelets is obvious.

One question which arises naturally with respect to the usefulness of the current basis is its ability to pick up existing features of a given signal without creating artifacts due to the particular shape of the wavelet functions near the boundary. We will address this point in section 4.4.

4.3. Definition of a scale number. From the definition of the wavelets and from the plots in Figure 3 it is obvious that the period of oscillation of wavelets with

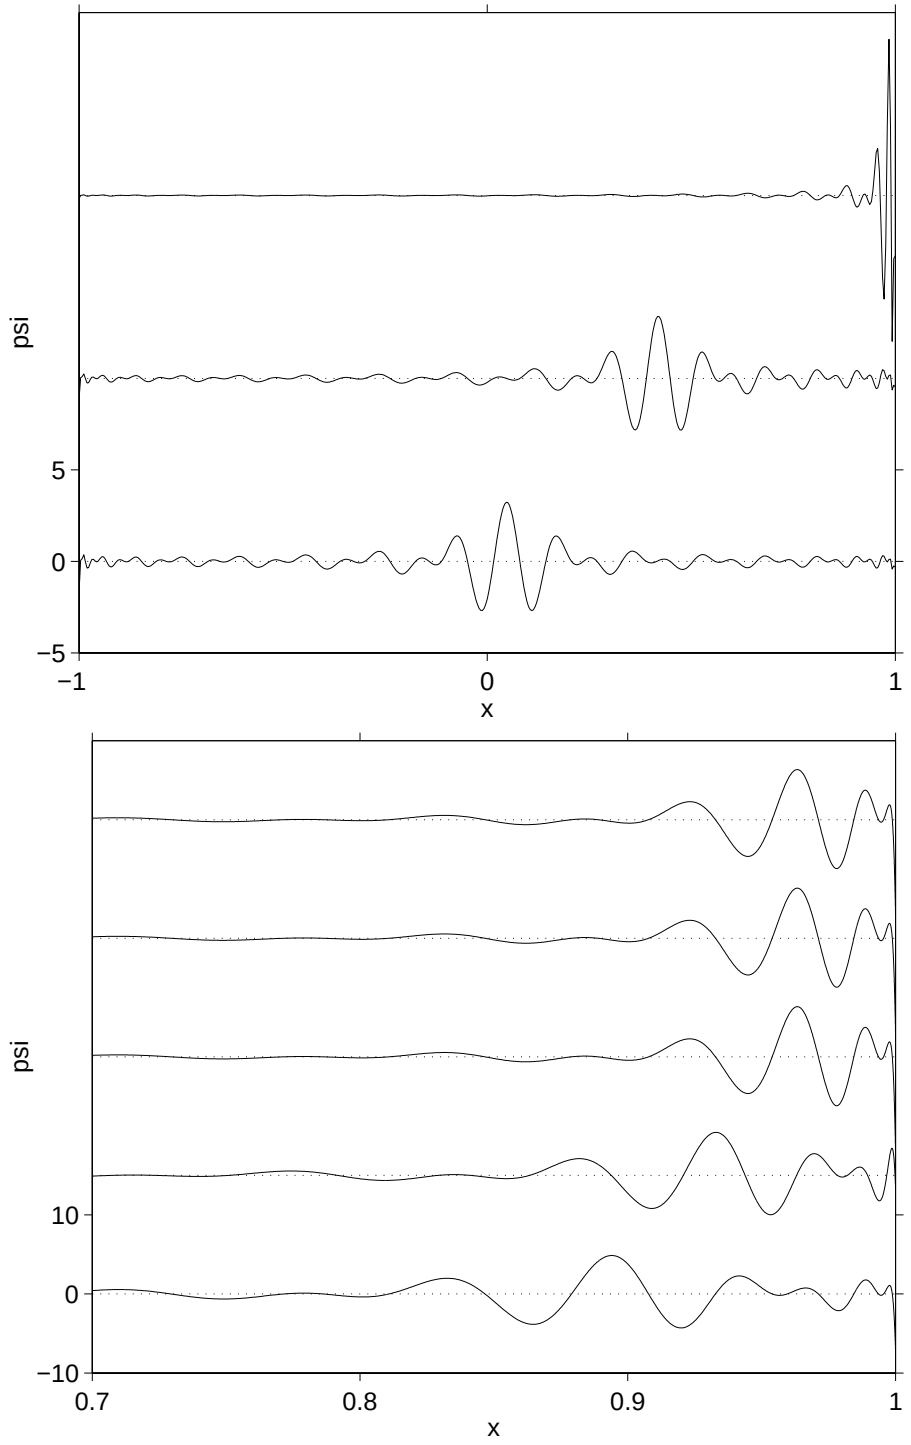

FIG. 3. *Wavelet functions of scale index $j = 5$ computed on a grid with $N = 4096$ points. Position indices are $i = 16, 19, 29$ (top) and $i = 26, 27, 28, 29, 30$ (bottom). Observe that the abscissa of the lower plot is zoomed.*

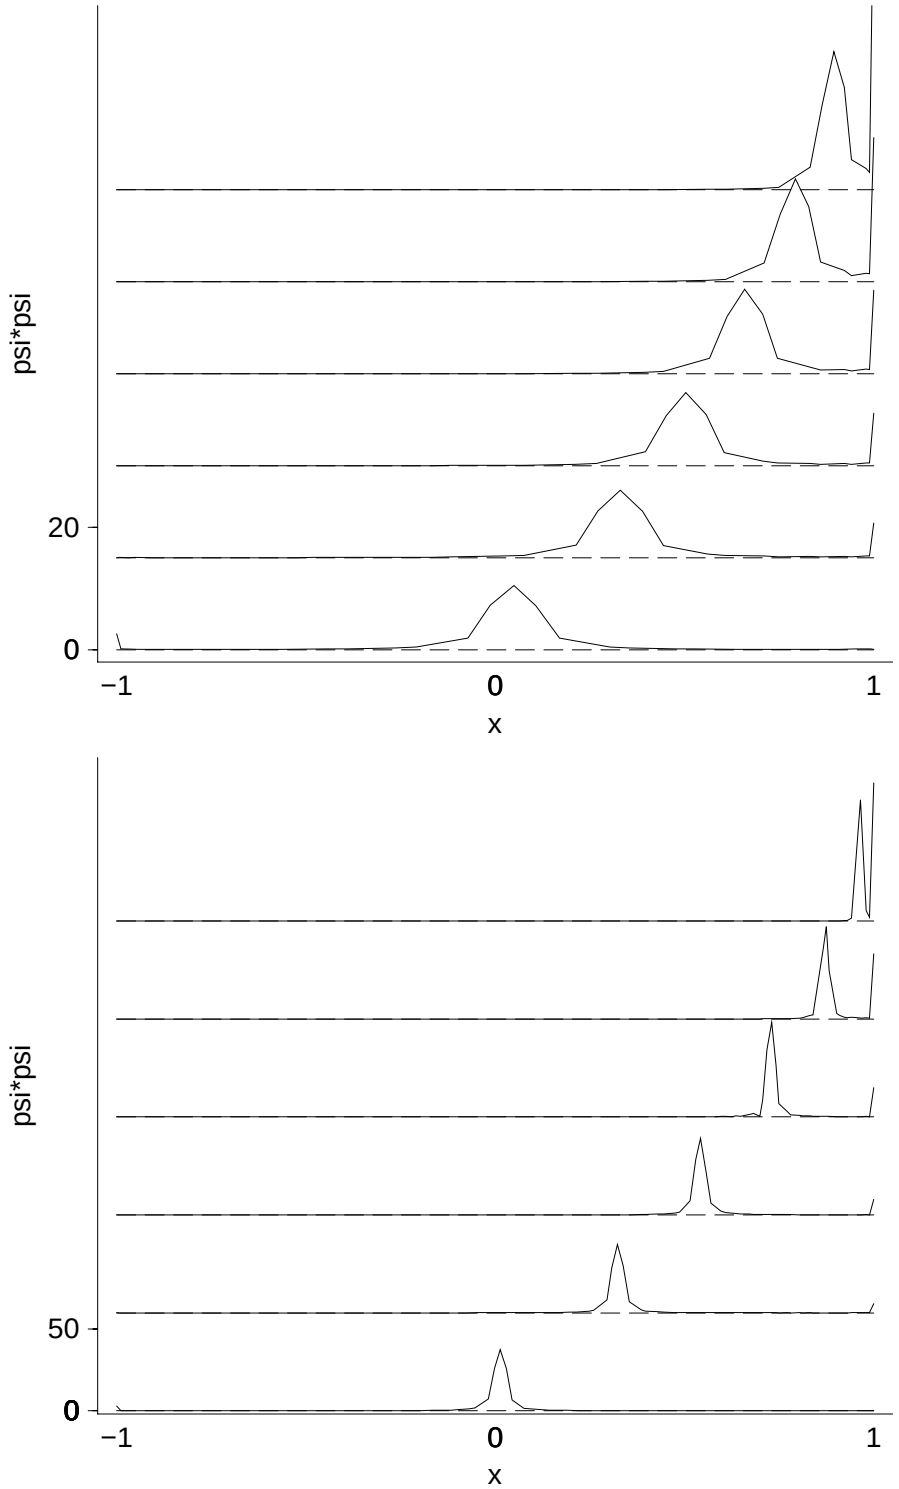

FIG. 4. *Envelope of the square of wavelet functions with scale index $j = 5$ (top) and $j = 7$ (bottom) for different center locations, i.e., computed on a grid with $N = 512$ points.*

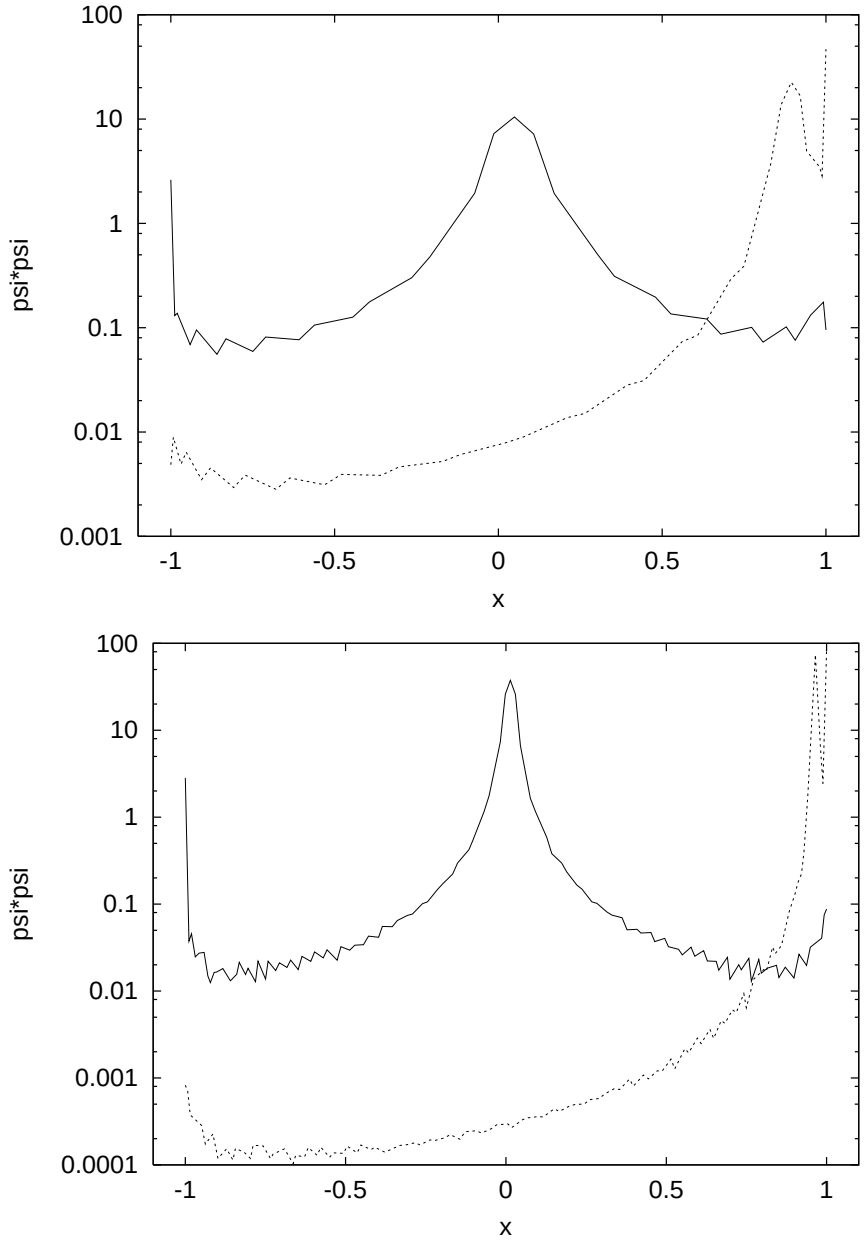

FIG. 5. *Semilogarithmic plot of the envelope of the square of wavelet functions with scale index $j = 5$ (top) and $j = 7$ (bottom) in the center of the interval and close to the boundary, i.e., $i = 15 = 6, 27$ (top) and $i = 64, 117$ (bottom) computed on a grid with $N = 512$ points.*

the same scale index j varies over the interval. Hence, it is important to distinguish between the scale index j and the "physical scale." We therefore attribute a scale number s_{ji} to each wavelet which, at constant j, changes with the position index i. Defining a "scale" and drawing a scalogram hence becomes a nontrivial issue. Here we use the centers of the wavelet functions for this purpose as described in the following.

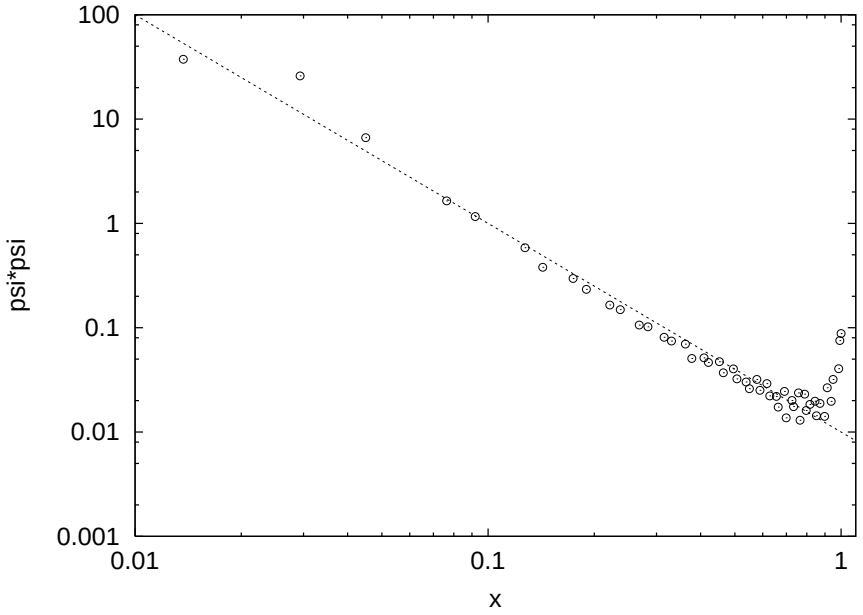

FIG. 6. *Double-logarithmic plot of the decay of the square of the wavelet functions with scale index $j = 7$ and with center location in the middle of the interval. The straight line has a slope of -2.*

TABLE 1

Energy contained in the tails of the wavelet functions at two different levels j and various positions i (cf. Figures 4 and 5). The "tail-location" x_{tail} corresponds to the local minimum of the envelope and has been determined visually using a grid with $N = 1024$ points. The integral has been evaluated by a low-order quadrature. For comparison, the last two columns show the corresponding quantities computed for the wavelets of Fischer and Prestin [11] based upon Chebyshev polynomials of the second kind.

		Legendre wavelets		Chebyshev wavelets	
j	i	x_{tail}	$\int_{x_{tail}}^{+1} \psi_{ji}^2 \mathrm{d}x$	x_{tail}	$\int_{x_{tail}}^{+1} \psi_{ji}^2 \mathrm{d}x$
5	15	0.879	6.17e-3	0.933	4.40e-2
	12	0.850	1.46e-2	0.933	1.17e-1
	10	0.922	1.67e-2	0.933	1.59e-1
	8	0.922	2.80e-2	0.962	2.03e-1

	4	0.957	7.87e-2	0.996	3.31e-1
7	63	0.844	1.79e-3	0.953	1.12e-2
	50	0.932	2.15e-3	0.992	2.29e-2
	40	0.932	3.79e-3	0.992	3.47e-2
	30	0.932	7.64e-3	0.992	5.29e-2
	20	0.975	1.04e-2	0.992	8.66e-1

Recall that the zeros of the Legendre polynomials are not available in closed form. As a consequence, the locations of the "centers" of the wavelets and scaling functions defined here are not available in closed form but need to be determined numerically. To be specific, by "centers" z_{ji}^{φ}, z_{ji}^{ψ} we mean the position of the largest positive local maximum values, excluding the boundaries of the interval, which can be obtained, e.g.,

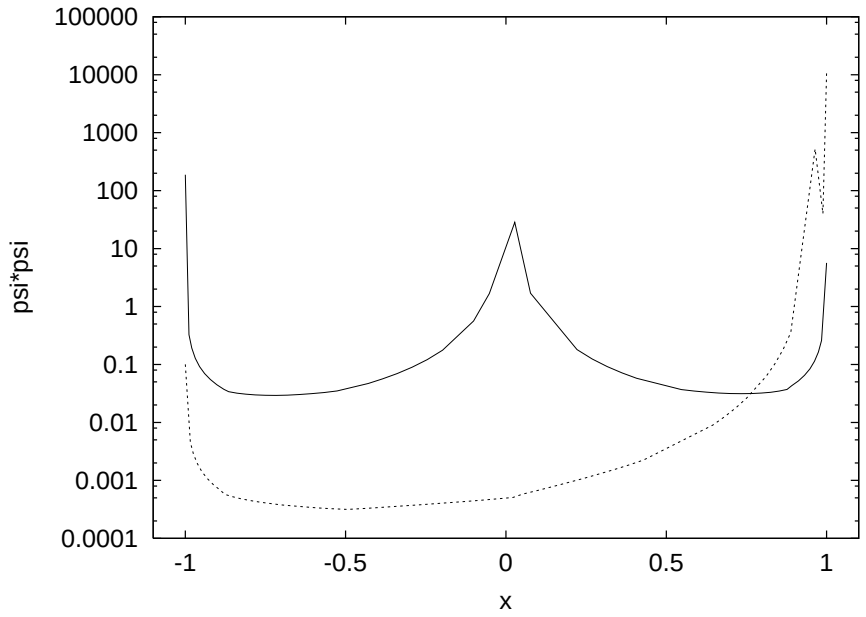

FIG. 7. *As the second plot of Figure* 5*, but for the wavelet functions of* [11]*, being based upon Chebyshev polynomials of the second kind instead of the present Legendre polynomials.*

by a fixed point iteration of the first derivative of (19). In practice, this procedure is, however, very cumbersome and an analytic expression, even approximate, would be preferable, particularly in view of the way of presenting information with respect to scale as discussed below. Therefore, we propose—solely for the definition of the "scale" of a wavelet function—to work with the roots of the Chebyshev polynomials of the second kind. Instead of the centers z_{ji}^{φ}, z_{ji}^{ψ} defined above we therefore use the approximations

$$\hat{z}_{ji}^{\varphi} = y_i^{(2^j+1)}\,, \tag{27a}$$

$$\hat{z}_{ji}^{\psi} = y_i^{(2^j)}\,, \tag{27b}$$

with $y_i^{(n)}$ given in (22). Figure 9 shows the relative difference between the two definitions z_{ji}^{ψ} and $\hat{z}_{ji}^{\psi}$. It exhibits a minimum in the center of the interval and near the boundaries.

For the purpose of data analysis, we associate a "physical scale" with each wavelet function. In the classical MRA, where wavelets are translationally invariant, the scale is simply $s_j = 2^{-j} L_x$, with L_x being the size of the domain. Here we define the scale number s_{ji} for the nonperiodic wavelets as follows:

$$s_{ji} = \frac{L_x}{2} \begin{cases} \dfrac{z_{ji+1}^{\psi} + z_{ji}^{\psi}}{2} + 1 & \text{if} \qquad i = 0\,, \\ 1 - \dfrac{z_{ji}^{\psi} + z_{ji-1}^{\psi}}{2} & \text{if} \qquad i = 2^j - 1\,, \\ \dfrac{z_{ji+1}^{\psi} - z_{ji-1}^{\psi}}{2} & \text{otherwise}\,. \end{cases} \tag{28}$$

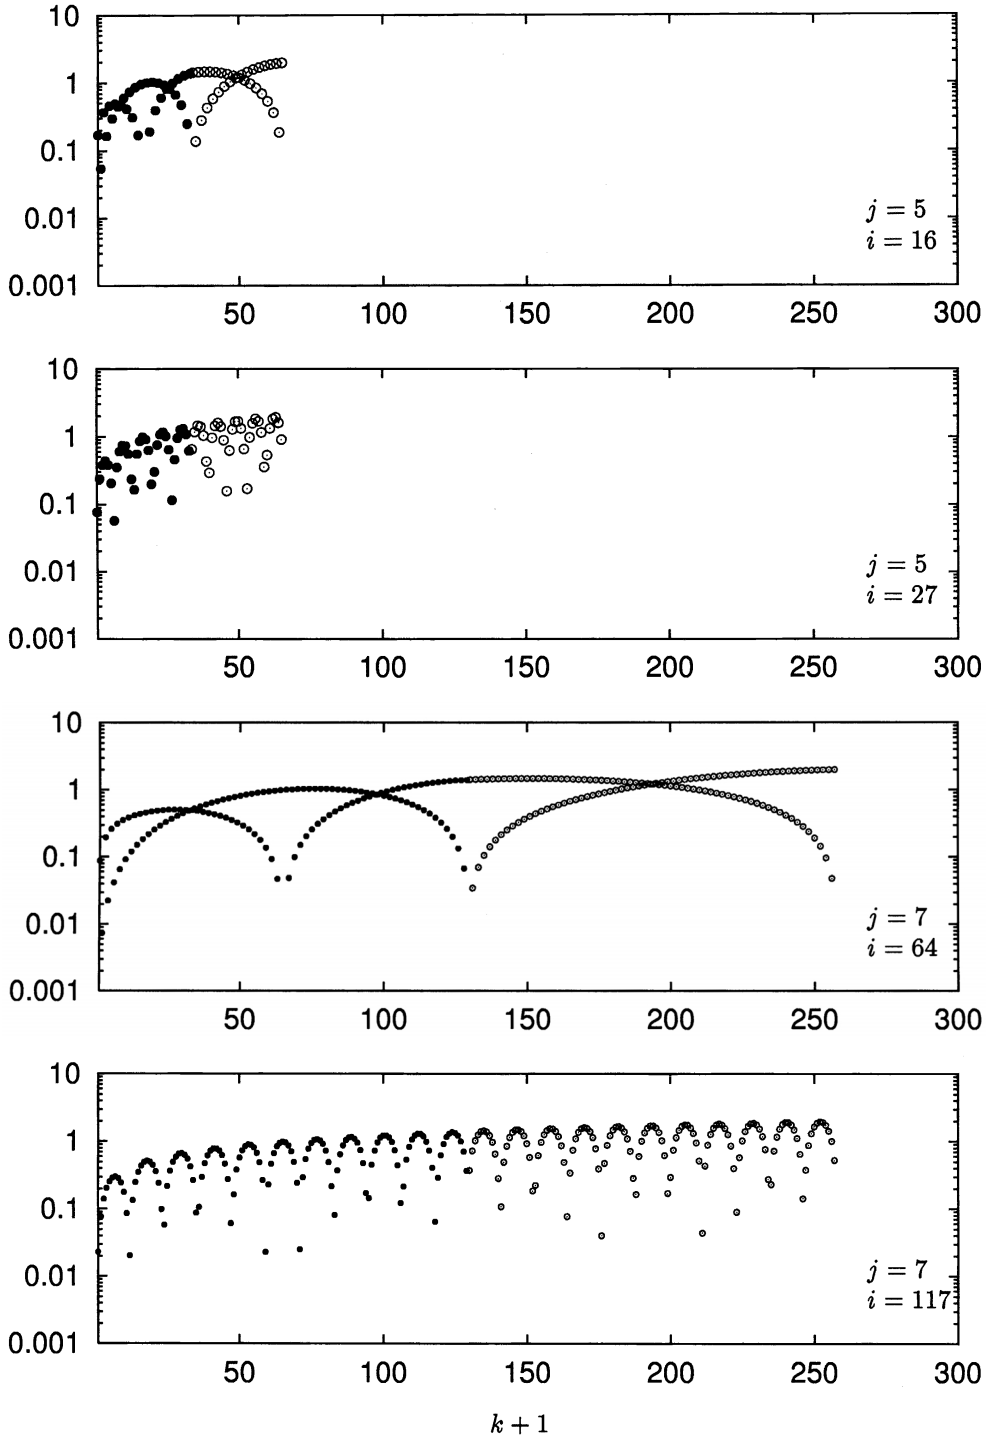

FIG. 8. *Semilogarithmic plot of the absolute value of the Legendre spectral coefficients (as a function of the wavenumber k) of wavelet functions (open symbols) and scaling functions (full symbols). Plots are displayed for scale index* $j = 5$ *and* $i = 4$ *(top),* $i = 15$ *(second), as well as for* $j = 7$ *with* $i = 64$ *(third) and* $i = 117$ *(bottom), respectively.*

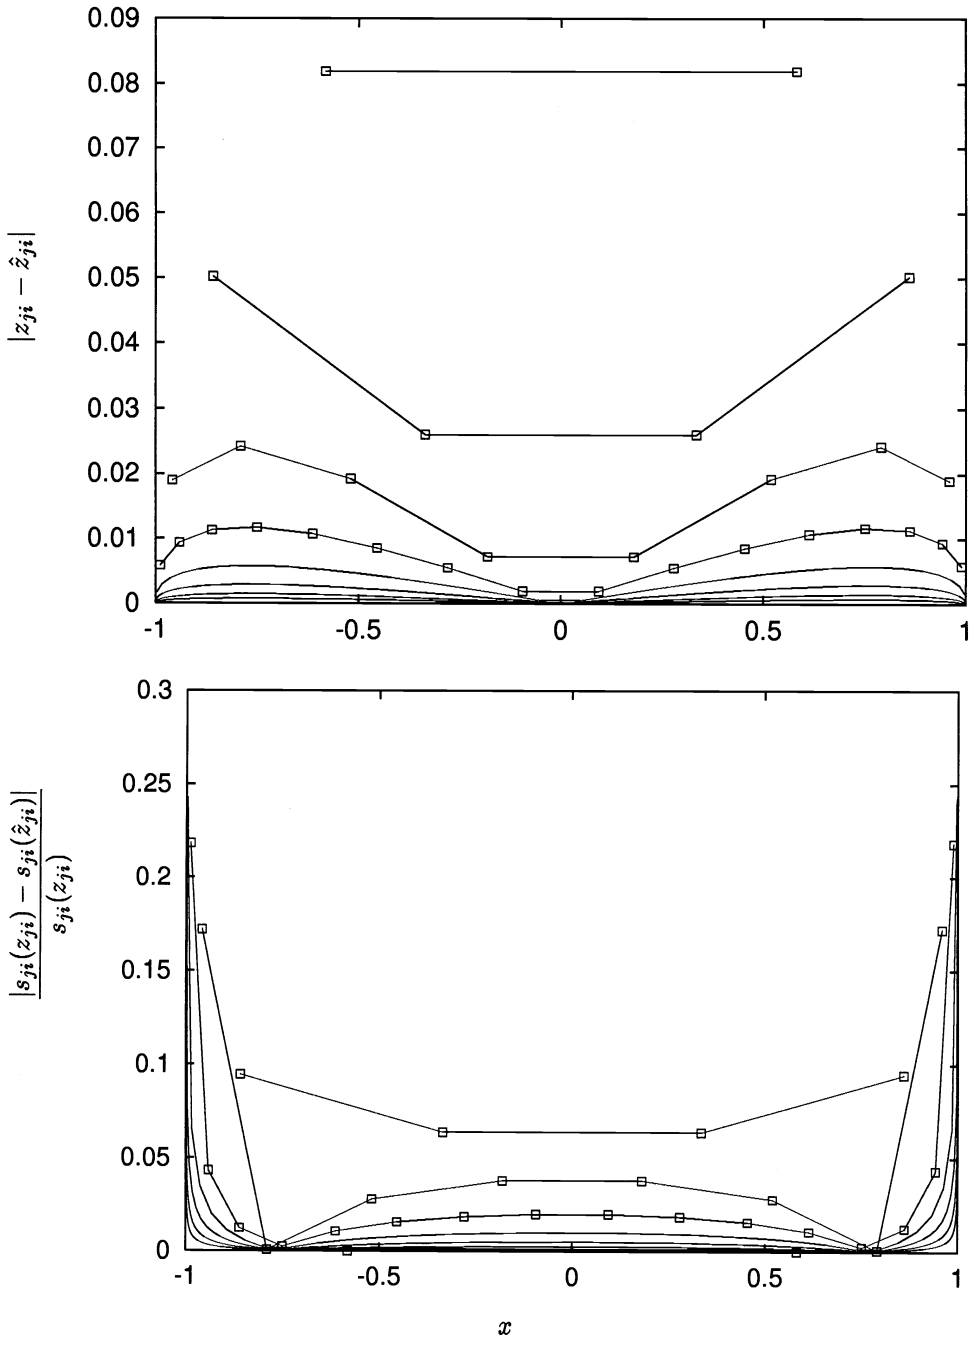

FIG. 9. *The difference in the definition of the center locations (top) and the scale number (bottom) corresponding to each wavelet ψ_{ji} of the present Legendre basis: $s_{ij}(\hat{z}_{ji})$ is the scale defined by the spatial variation of the Chebyshev roots $\hat{z}_{ji}$ given in* (28)*; $s_{ji}(z_{ji})$ is the value obtained by numerically computing the distance between neighboring centers z_{ji} of wavelets.*

This results from partitioning the interval into subintervals bounded by the midpoints between neighboring center locations. Consequently, it implies that $\sum_i s_{ji} = L_x$ and in particular that $s_{00} = L_x$. As discussed above, the quantity s_{ji} cannot be determined analytically if the exact centers z^ψ_{ji} are used. As a remedy we propose using, instead of z^ψ_{ji}, the roots of the Chebyshev polynomials $\hat{z}^\psi_{ji}$ in (28) which upon substitution of (22) yield

(29)
$$s_{ji}(\hat{z}^\psi_{ji}) = \frac{L_x}{2} \begin{cases} \cos\left(\dfrac{(2^j - 1/2)\pi}{2^j + 1}\right) \cos\left(\dfrac{\pi/2}{2^j + 1}\right) + 1 & \text{if} \quad i = 0\,, \\ 1 - \cos\left(\dfrac{3/2\pi}{2^j + 1}\right) \cos\left(\dfrac{\pi/2}{2^j + 1}\right) & \text{if} \quad i = 2^j - 1\,, \\ \sin\left(\dfrac{(i+1)\pi}{2^j + 1}\right) \sin\left(\dfrac{\pi}{2^j + 1}\right) & \text{otherwise}\,. \end{cases}$$

Figure 9 shows the resulting relative difference in scale between the definition of s_{ji} with the exact and with the approximated centers. These differences are only appreciable near the boundary, where they reach a very localized maximum of 25 percent. In the present situation the definition of a "scale" associated with a wavelet necessarily has to be somewhat arbitrary, in particular close to the boundaries. We therefore feel that the definition (29) suits the purpose of data analysis and visualization. This is backed by the examples below.

Based on the two definitions of the scale parameter s_{ji} two ways of presenting the coefficients of the present transform can be constructed. They will be detailed and illustrated by means of analytical signals in the following paragraph. In what follows, we will then adopt definition (29).

4.4. Transform of analytical signals and coefficient scheme. Before application to real-life signals it is instructive to study the transform itself by means of analytical signals. We consider as a first case the transform of a periodic signal, $u(x) = \sin(2\pi\, x\, a)$, with various frequencies a. This is a particular case of a signal which can be analyzed with the present new algorithm as well as with a standard method for periodic signals.

Let us now discuss the representation of the wavelet coefficients. In Figures 10 and 11 we compare two different ways of drawing scalograms for the same coefficient values. In the first method, used in Figure 10, the "exact"—i.e., iteratively determined—center locations z^ψ_{ji} and resulting scales $s_{ji}(z_{ji})$ are used to define rectangular cells Ω_{ji} in the following way:

(a1) The center of Ω_{ji} is defined by the coordinate pair $(z^\psi_{ji}, -\log_2(s_{ji}))$.
(a2) The width of Ω_{ji} is equal to the scale s_{ji}.
(a3) The height of Ω_{ji} is set to an arbitrary constant value.

The plot is then obtained by drawing each cell colored according to the absolute value of the corresponding wavelet coefficient. Note that due to some overlapping of the rectangles they seem to have the shape of more irregular polygons. In Figure 10 as well as the subsequent scalograms below, 8 wavelet levels $j = 0, \ldots, 7$ have been computed and plotted. The coefficients of the finest scales are often not visible since their amplitude is below the threshold for the grayscale.

The second type of visual presentation is displayed in Figure 11. It is based on the approximate center points and scales via the roots of the Chebyshev polynomials of the second kind. Introducing the parameter $\theta_{ji} = \pi(i+1)/(2^j + 1)$, we can rewrite

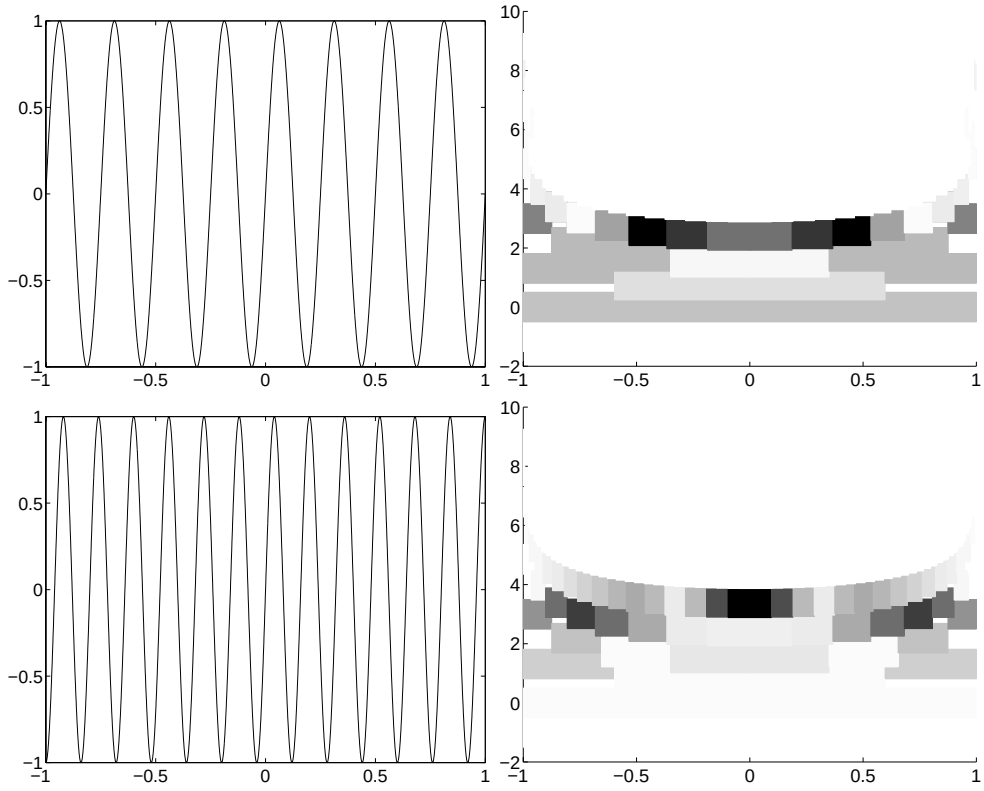

FIG. 10. *Wavelet transform of a periodic signal:* $u(x) = \sin(2\pi\, x\, a)$ *with* $a = 4$ *(top) and* $a = 6.25$ *(bottom). Note that the second signal is not periodic on the present interval* $[-1, 1]$. *In the scalogram on the right the abscissa relates to the position in the domain* $x \in [-1, 1]$ *while the ordinate gives the inverse of the scale number in logarithmic scale, i.e.,* $-\log_2(s_{ji})$. *Darker shading indicates higher (absolute) coefficient values on a linear scale. The total number of modes is* $N + 1 = 257$. *The scale is defined by means of the "exact," numerically determined centers* z^{ψ}_{ji} *of the wavelets. Therefore, the visualization features "cells" which have a seemingly polygonal shape through overlapping and are filled with the grayscale value according to the coefficients.*

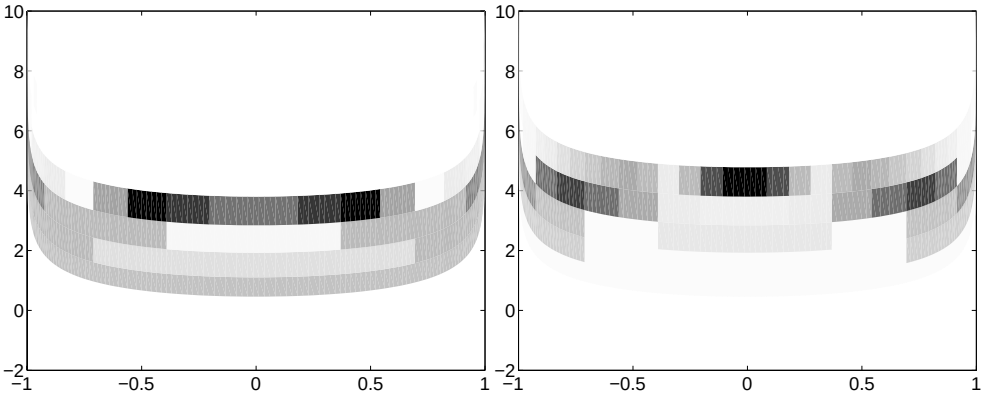

FIG. 11. *Coefficient scalograms as in Figure* 10, *but with the scale defined by means of the approximate centers* $\hat{z}^{\psi}_{ji}$ *of the wavelets and with the related transform used to determine the shape of the cells representing the coefficients.*

the definitions (27), (29) as

$$\hat{z}_{ji}^{\psi} = \cos(\theta_{ji})\,, \tag{30a}$$

$$s_{ji}(\hat{z}_{ji}^{\psi}) = \frac{L_x}{2}\,\sin(\theta_{ji})\sin\left(\frac{\pi}{2^j+1}\right), \qquad 0 < i < 2^j - 1\,. \tag{30b}$$

These relations represent a discrete mapping from dyadic θ_{ji} to $\hat{z}_{ji}$ and s_{ji}, respectively, which can be extended to the continuous case by replacing θ_{ji} with $\theta \in]0, \pi[$. In this fashion, a scalogram is constructed with cell boundaries progressively deformed such as to indicate a spatial change of scale at fixed scale index j. In practice, we proceed as follows:

(b1) We define a classical scalogram with rectangular cells centered at $(\theta_{ji}, -\log_2(s_{ji}(\hat{z}_{j,i=2^j/2}))$, i.e., using the scale of the centrally located wavelets given in (29), and we separate the cells at the midpoints between neighbors.

(b2) We transform the coordinate locations of the cell boundaries by the maps $x = \cos(\theta)$, $y = -\log_2(\sin(\theta))$.

The result is a pattern with strips of coefficients of common scale index j which are bent upwards near the boundaries. By this method, the coefficient values corresponding to small-scale indices j appear at different physical scales along their horizontal extent, which in a way is a visual representation of the fact that a single wavelet undergoes a similar variation in frequency along the interval. As Figures 11 and 10 demonstrate, both methods of visualization are of fairly similar quality with respect to the readability of frequency content and position of the signal. For its smoothness and because it allows for a natural partitioning of the ordinate without gaps we will henceforth retain the second type of scalogram.

It can be seen in Figure 11 that the present basis correctly shows a response at approximately constant scale across the interval. Recall that the use of a real-valued wavelet always tends to yield small-scale oscillations of the coefficients due to cancellations between the signal and the wavelet itself [8]. Therefore, a pure sine wave does not show up as a solid line in the scalogram but rather as a horizontal band with alternating values. It is particularly noteworthy that in the coefficient plots no artifacts are generated at the ends of the interval. Although the signal is periodic in the upper plot, the analysis is entirely independent of this fact. No relation between both boundaries is imposed or assumed. In the lower graph of Figures 10 and the right-hand graph of Figure 11 the period length of the sine was chosen to be incommensurate with the length of the interval—a configuration which is not compatible with a periodic analysis. In the present case, however, the plots of the coefficients remain similar, even if the values $u(x = 1)$ and $u(x = -1)$ are different and not zero.

Next, let us turn to the transform of a Gaussian bump, $u(x) = \exp(-(x - x_c)/(2\sigma^2))$, with different standard deviations σ and center locations x_c. Here, the question is whether the position of the peak can be correctly determined from the scalogram and if information on the characteristic scale can be extracted in this fashion. Figures 12 to 13 show that this indeed is the case. The maximum amplitudes of the coefficients are not exactly pyramid-shaped when x_c is off-center—an effect common to all wavelet transforms with downsampling between different levels—but they do point to the x_c-locations. Furthermore, the scale of the cusp (i.e., the smallest scale where a large amplitude is recorded) corresponds to the scale of the signal. The observed difference between the cusps of the scalograms in Figures 12 and 13 is of

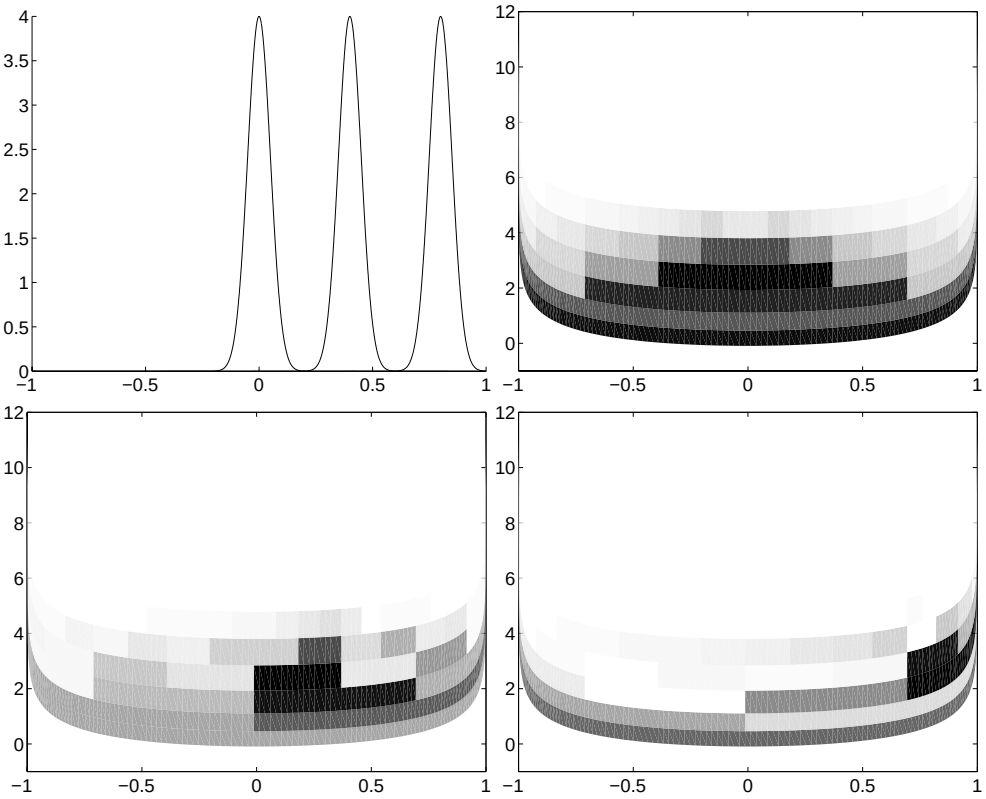

FIG. 12. *Wavelet transform of a single Gaussian bump:* $u(x) = \exp(-((x - x_c)/(2\sigma))^2)$ *with* $\sigma = 0.05$ *and the locations* $x_c = 0.0, 0.4, 0.8$ *from top to bottom and from left to right. Darker shading indicates higher (absolute) coefficient values on a linear scale. The abscissa relates to the position in the domain* $x \in [-1, 1]$ *while the ordinate gives the inverse of the scale number in logarithmic scale, i.e.,* $-\log_2(s_{ji})$*. The total number of modes is* $N + 1 = 257$*.*

roughly two octaves, i.e., a factor of 4, while the standard deviation of the data varies fivefold.

4.5. Definition of wavelet spectra. Let us now introduce a pseudowavenumber as the inverse of the scale parameter, $k_{ji} = 1/s_{ji}$. As a *global* power-spectral density per unit wavenumber we then define

$$E(k_m) = \frac{1}{\Delta k_m} \sum_{j,i \,/\, k_L^m \le k_{ji} \le k_R^m} d_{ji}^2. \tag{31}$$

The index pairs (j, i) in the sum are selected such that the pseudowavenumber of the corresponding wavelet falls into the interval $[k_L^m, k_R^m]$, where the whole wavenumber range considered is partitioned into M such bins, $1 \le m \le M$. In the present work, the bins are spaced logarithmically. The function (31) is normalized by the wavenumber increment Δk_m so that the following identity holds for the total energy:

$$E_{tot} = \int_{-1}^{+1} u(x)^2 \, \mathrm{d}x = \sum_{i=0}^{1} c_{0i}^2 + \sum_{j=0}^{J} \sum_{i=0}^{2^j-1} d_{ji}^2 = \sum_{i=0}^{1} c_{0i}^2 + \sum_{m=1}^{M} E(k_m) \, \Delta k_m. \tag{32}$$

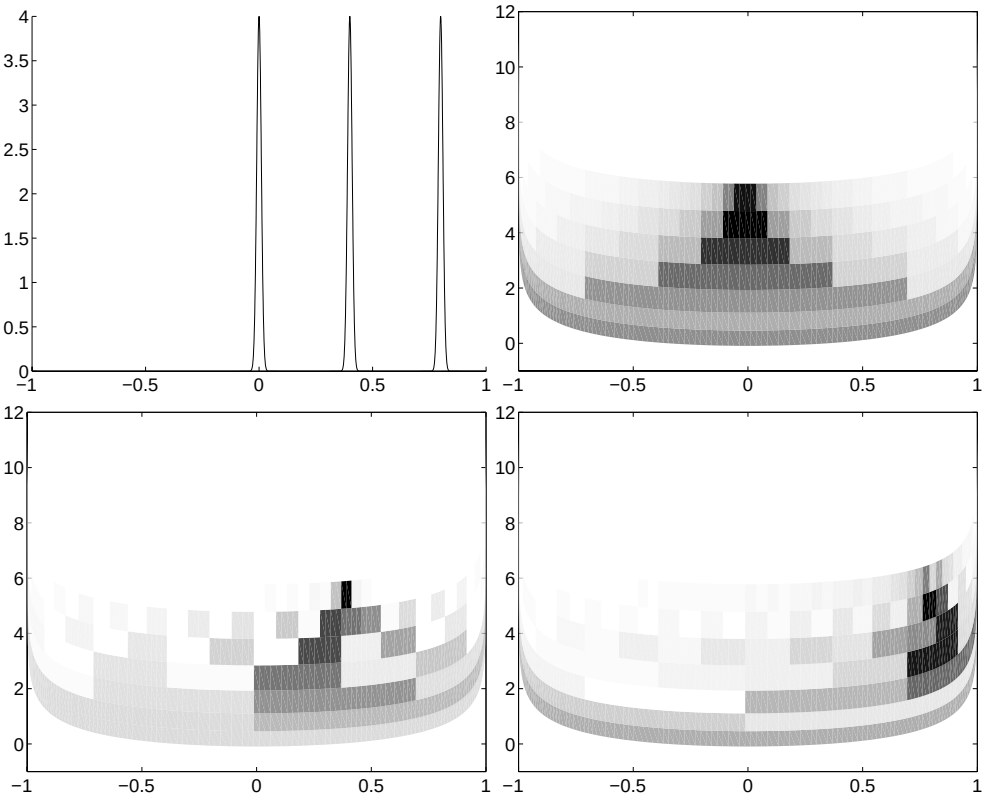

FIG. 13. *As Figure* 12*, but the signal is a narrower bump with* $\sigma = 0.01$.

Next, we define a *local* power-spectral density per unit wavenumber

$$E(k_j, x) = 2^j \frac{d_{ji^*}^2}{\Delta k_j}, \tag{33}$$

where the position index $i^* = i^*(x)$ corresponds to the wavelet at scale index j whose center $\hat{z}_{ji}^{\psi}$ lies closest to the location x. In other words, the function $E(k_j, x)$ represents a cut through the scalogram at the abscissa x. Therefore, there are exactly $J + 1$ such spectral values at each location and the largest scales are obviously redundantly reproduced in spectra evaluated at small distances from each other. In particular, the $j = 0$-coefficient will enter all local spectra. In contrast to the fixed wavenumber increment Δk_m in (31), the increment Δk_j is based on $k_{j,i^*} = 1/s_{j,i^*}$, i.e., on the scale parameters of the coefficients actually selected. The factor 2^j in (33) is introduced for compatibility with the global spectrum (cf. [7]). Applications of spectral analysis using the present wavelet basis are given in section 6.

5. Multidimensional basis. The construction of a wavelet basis in more than one dimension typically proceeds along either one of the following lines [5, p. 313]:

A Performing a tensor product of one-dimensional bases in each coordinate direction. With this procedure two separate scale indices j_x, j_y are introduced and the mechanism of rescaling is not directionally invariant. Therefore, this method is sometimes called *rectangular transform* [16].

B Performing a tensor product of one-dimensional MRAs with a "global" scale index j (*square transform*) and different wavelets for picking up the various directional features.

C Design of genuinely multidimensional wavelet/scaling functions with the desired orthonormality and angular selectivity properties.

Due to its additional complexity, a construction of type **C** is beyond the scope of the present paper. On the other hand, both constructions **A** and **B** are straightforward once a suitable one-dimensional basis has been found. Regarding their use as a tool for data analysis, these two options differ in various respects. We have found method **A** more useful in the present context and will retain it for subsequent applications. The reasons for this choice will become obvious during the following presentation of both methods. The discussion is performed for two space dimensions; for higher dimensions the situation is analogous.

5.1. Method A: Tensor product of one-dimensional wavelet functions. The two-dimensional basis according to procedure **A** consists of the following functions:

$$\text{(34a)}\quad \varphi^{0,j_y}_{i_x,i_y}(x,y) = \varphi_{0,i_x}(x)\,\psi_{j_y,i_y}(y), \qquad i_x = 0\dots 1, \qquad i_y = 0\dots 2^{j_y}-1,$$

$$\text{(34b)}\quad \varphi^{j_x,0}_{i_x,i_y}(x,y) = \psi_{j_x,i_x}(x)\,\varphi_{0,i_y}(y), \qquad i_x = 0\dots 2^{j_x}-1, \quad i_y = 0\dots 1,$$

$$\text{(34c)}\quad \psi^{j_x,j_y}_{i_x,i_y}(x,y) = \psi_{j_x,i_x}(x)\,\psi_{j_y,i_y}(y), \qquad i_x = 0\dots 2^{j_x}-1, \quad i_y = 0\dots 2^{j_y}-1,$$

where $j_x, j_y = 0, 1, \dots$ and the one-dimensional functions $\psi_{j,i}$ and $\phi_{j,i}$ are defined in (19).

Below we wish to analyze two-dimensional data from a turbulent plane channel flow computation which possesses one periodic (x) and one bounded (y) coordinate direction, i.e., we consider the space $L^2(\mathbb{R}/\mathbb{Z}\times[-1,1])$. For this task we propose a hybrid construction composed of a periodic wavelet basis and the Legendre wavelet basis of section 3.2. The two-dimensional scaling functions and the wavelet functions are then defined as follows:

$$\text{(35a)}\quad \varphi^{0,j_y}_{i_x,i_y}(x,y) = \widetilde{\varphi}_{0,i_x}(x)\,\psi_{j_y,i_y}(y), \qquad i_x = 0, \qquad i_y = 0\dots 2^{j_y}-1,$$

$$\text{(35b)}\quad \varphi^{j_x,0}_{i_x,i_y}(x,y) = \widetilde{\psi}_{j_x,i_x}(x)\,\varphi_{0,i_y}(y), \qquad i_x = 0\dots 2^{j_x}-1, \quad i_y = 0\dots 1,$$

$$\text{(35c)}\quad \psi^{j_x,j_y}_{i_x,i_y}(x,y) = \widetilde{\psi}_{j_x,i_x}(x)\,\psi_{j_y,i_y}(y), \qquad i_x = 0\dots 2^{j_x}-1, \quad i_y = 0\dots 2^{j_y}-1.$$

The functions $\varphi(y)$, $\psi(y)$ are defined in (19). The periodic functions $\widetilde{\varphi}(x)$, $\widetilde{\psi}(x)$ employed here are spline wavelets of order 4 and can be found in detail in references [29, 12]. With the basis (35), the approximation of a two-dimensional function up to a scale J reads as follows:

$$\begin{aligned} u(x,y) = &\sum_{j_y=0}^{J}\sum_{i_y=0}^{2^{j_y}-1} c^{0,j_y}_{0,i_y}\,\varphi^{0,j_y}_{0,i_y}(x,y) + \sum_{j_x=0}^{J}\sum_{i_x=0}^{2^{j_y}-1}\sum_{i_y=0}^{1} c^{j_x,0}_{i_x,i_y}\,\varphi^{j_x,0}_{i_x,i_y}(x,y) \\ &+ \sum_{j_x=0}^{J}\sum_{i_x=0}^{2^{j_x}-1}\sum_{j_y=0}^{J}\sum_{i_y=0}^{2^{j_y}-1} d^{j_x,j_y}_{i_x,i_y}\,\psi^{j_x,j_y}_{i_x,i_y}, \end{aligned} \tag{36}$$

which leads to a total number of $N(N+1)$ coefficients, where $N = 2^{J+1}$. Due to

orthogonality, the coefficients are obtained from the following scalar products:

$$d_{i_x,i_y}^{j_x,j_y} = \int_x \int_y u(x,y)\, \psi_{i_x,i_y}^{j_x,j_y}(x,y)\, \mathrm{d}y\mathrm{d}x\,, \tag{37a}$$

$$c_{i_x,i_y}^{j_x,j_y} = \int_x \int_y u(x,y)\, \varphi_{i_x,i_y}^{j_x,j_y}(x,y)\, \mathrm{d}y\mathrm{d}x\,. \tag{37b}$$

These integrals can be factorized during the computation due to the tensorial nature of the wavelets and the scaling functions. Therefore, we can first apply the standard Mallat algorithm to each "row" of data at constant y and then proceed column-wise by computing the remaining integration in the y-direction by the new scheme of section 4.1.

Figure 14 shows the shape of the wavelets $\psi_{i_x,i_y}^{j_x,j_y}(x,y)$, for the scale indices being combinations of 2 and 5 and at two locations, in the center of the domain and close to the boundary $y = 1$. The localization properties are quite different in the two coordinate directions. Spline wavelets have an exponential decay while the Legendre wavelets decay roughly as x^{-1} and exhibit the characteristic tails near the boundaries as discussed above.

For visual presentation, the coefficients can be arranged in matrix fashion, i.e., collocated blockwise according to the values of the index pair (j_x, j_y) (cf. Figure 15). Each coefficient within a block is represented by a rectangle colored according to the coefficient's absolute value. The size of this rectangle is determined according to the wavelet centers, i.e., uniform in the x-direction and using the approximate center locations of the Legendre wavelets (27) in the y-direction. This leads to flattened cells near the boundaries $y = \pm 1$, reflecting the two length scales by their aspect ratio s_x/s_y. Examples are provided below.

5.2. Method B: Multidimensional MRA. Following Mallat [25] we define the following two-dimensional scaling functions and a set of three different types of wavelet functions:

$$\varphi_{i_x,i_y}^{j}(x,y) = \widetilde{\varphi}_{j,i_x}(x)\, \varphi_{j,i_y}(y), \qquad i_x = 0 \ldots 2^j - 1, \qquad i_y = 0 \ldots 2^j, \tag{38a}$$

$$\psi_{i_x,i_y}^{j,1}(x,y) = \widetilde{\varphi}_{j,i_x}(x)\, \psi_{j,i_y}(y), \qquad i_x = 0 \ldots 2^j - 1, \qquad i_y = 0 \ldots 2^j - 1, \tag{38b}$$

$$\psi_{i_x,i_y}^{j,2}(x,y) = \widetilde{\psi}_{j,i_x}(x)\, \varphi_{j,i_y}(y), \qquad i_x = 0 \ldots 2^j - 1, \qquad i_y = 0 \ldots 2^j, \tag{38c}$$

$$\psi_{i_x,i_y}^{j,3}(x,y) = \widetilde{\psi}_{j,i_x}(x)\, \psi_{j,i_y}(y), \qquad i_x = 0 \ldots 2^j - 1, \qquad i_y = 0 \ldots 2^j - 1, \tag{38d}$$

where $j = 0, 1, \ldots$. Similar to the one-dimensional case this defines a multidimensional MRA of $L^2(\mathbb{R}/\mathbb{Z}\times[-1,1])$. Removing the tilde and adjusting the indices in x-direction provides the analogous basis for the fully nonperiodic case. Observe that the two-dimensional scaling function φ_{i_x,i_y}^{j} represents the smooth content of the signal in both directions at scale index j while the wavelets $\psi_{i_x,i_y}^{j,1}$, $\psi_{i_x,i_y}^{j,2}$, $\psi_{i_x,i_y}^{j,3}$ pick up the detailed information with respect to vertical (y), horizontal (x), and diagonal variations of the signal, respectively. Figure 16 shows the shape of the three types of wavelets $\psi_{i_x,i_y}^{j,q}(x,y)$, $q = 1, 2, 3$, for the scale index $j = 5$ at two locations: in the center of the domain and close to the boundary $y = 1$.

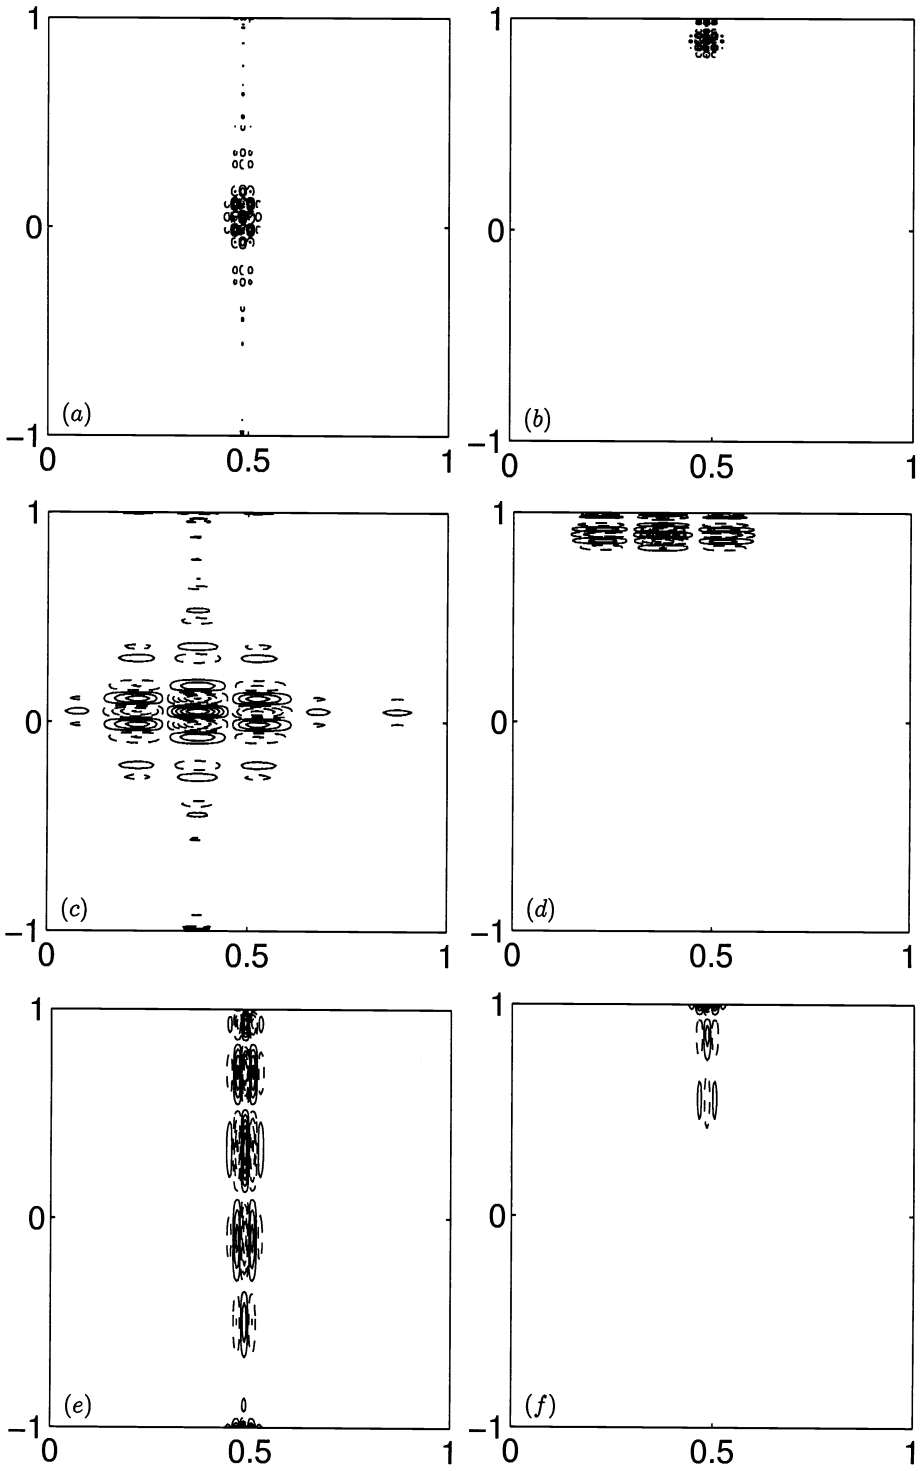

FIG. 14. *Illustration of the basis functions of the tensor-product construction according to method* **A** *sampled on a grid with* 256^2 *points. The values for the quadruplet of indices* j_x, j_y, i_x, i_y *are* (a) $5, 5, 16, 16$*;* (b) $5, 5, 16, 27$*;* (c) $2, 5, 2, 16$*;* (d) $2, 5, 2, 27$*;* (e) $5, 2, 16, 2$*;* (f) $5, 2, 16, 3$.

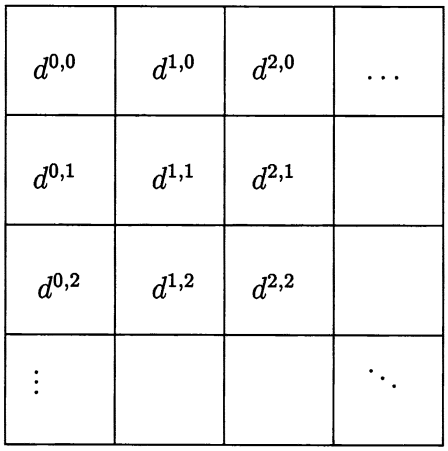

FIG. 15. *The graphical representation of the wavelet coefficients* $d^{j_x,j_y}_{i_x,i_y}$ *of the two-dimensional tensor-product basis (method* **A***) defined by* (35).

With (38), the approximation of a two-dimensional function up to a scale J reads

$$u(x,y) = c^0_{0,0}\,\varphi^0_{0,0}(x,y) + c^0_{0,1}\,\varphi^0_{0,1}(x,y) + \sum_{j=0}^{J}\sum_{i_x=0}^{2^j-1}\left[\sum_{i_y=0}^{2^j} d^{j,2}_{i_x,i_y}\,\psi^{j,2}_{i_x,i_y}(x,y) + \sum_{q=\{1,3\}}\sum_{i_y=0}^{2^j-1} d^{j,q}_{i_x,i_y}\,\psi^{j,q}_{i_x,i_y}(x,y)\right], \tag{39}$$

which leads to a total number of $2+\sum_{j=0}^{J}\{2^j\,(2^j+1)+2\cdot 2^{2j}\} = N(N+1)$ coefficients. Splitting the inner sum results from the different number of scaling functions and wavelets in the Legendre construction, as already reflected by the index bounds in (38). When representing the coefficients obtained from a "classical" two-dimensional MRA graphically, one customarily uses a block diagram where at each level j the rectangular domain is divided into quarters. Three of them are used for representing the coefficients of level j, while the fourth is subdivided again for the following level $j-1$ and so on [25]. We locate the coefficients $d^{j,1}_{i_x,i_y}$ in the lower left quadrant, $d^{j,3}_{i_x,i_y}$ in the lower right, and $d^{j,2}_{i_x,i_y}$ in the upper right (cf. the schematic in Figure 17), an arrangement differing from the one of Mallat [25, 5]. Its advantage is that in the one-dimensional limit $u(x,y) = u_1(x)$ the coefficients in the scheme located on the uppermost horizontal line yield the coefficients of the one-dimensional analysis of $u_1(x)$, while analogously those on the leftmost vertical line reproduce the one-dimensional analysis of $u(x,y) = u_2(y)$.

5.3. Transform of a two-dimensional test function. In what follows, the domain has been mapped to $\Omega = \pi\mathbb{T} \times [-1,1]$, which corresponds to the domain of the turbulence data we wish to analyze below in section 6.3. As an analytical test we consider a two-dimensional Gaussian bump,

$$\begin{aligned} u(x,y) &= g\,(\,(y-y_c)\sin(\alpha) + (x-x_c)\cos(\alpha)\,,\\ &\qquad (y-y_c)\cos(\alpha) - (x-x_c)\sin(\alpha)\,)\,,\\ g(x,y) &= \exp\left(-\frac{1}{2}\left(\frac{x}{\sigma_x}\right)^2 - \frac{1}{2}\left(\frac{y}{\sigma_y}\right)^2\right), \end{aligned} \tag{40}$$

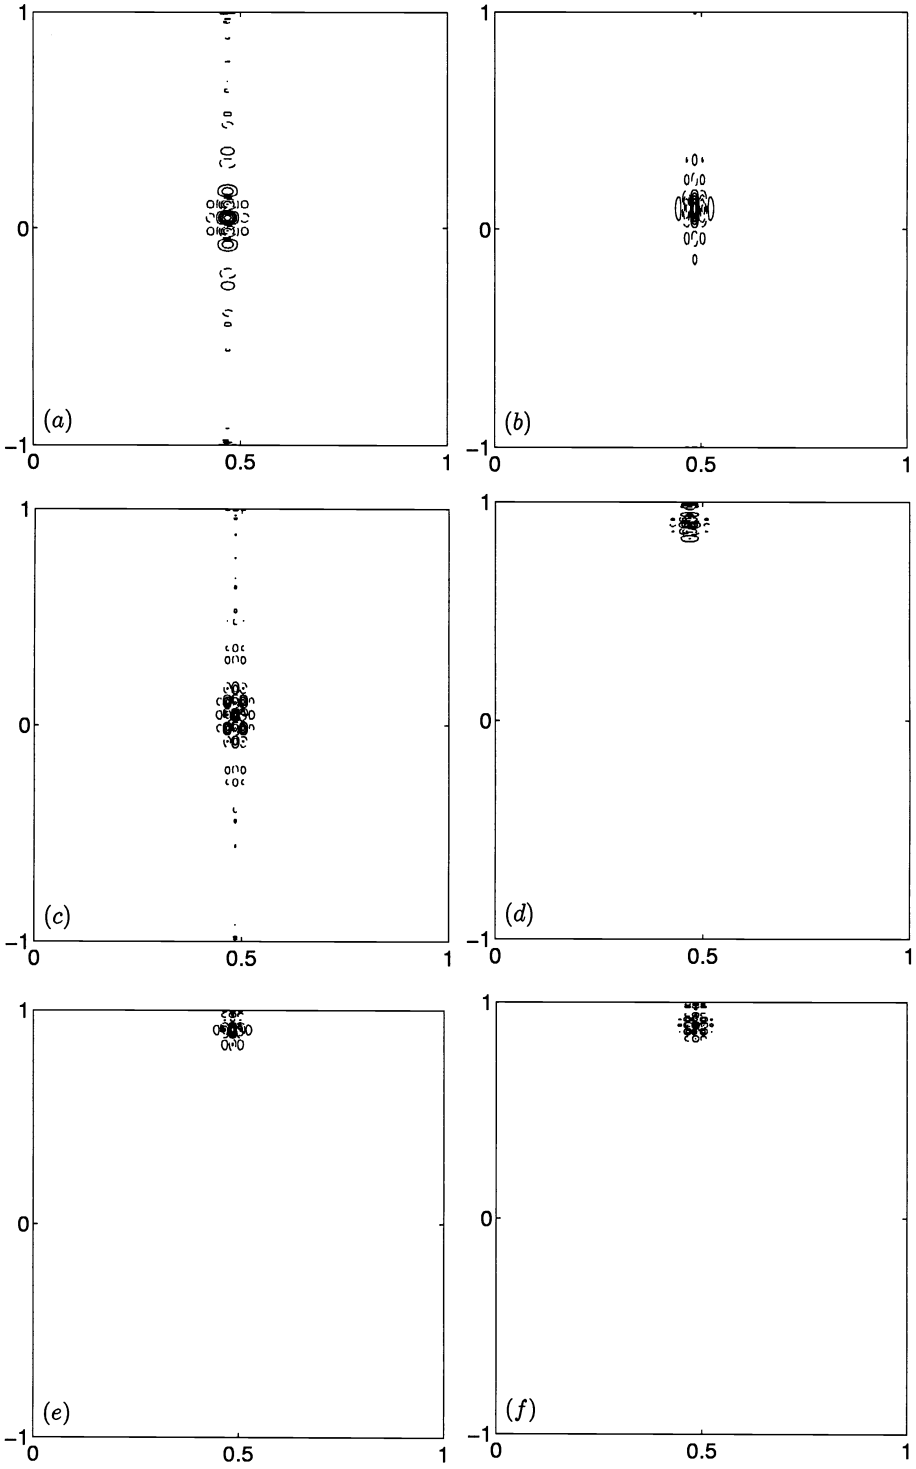

FIG. 16. *Illustration of the basis functions of the two-dimensional MRA (method* **B***) at scale number* $j = 5$*, sampled on a grid with* 256^2 *points.* (a) $q=1$, $i_y=16$, (b) $q=2$, $i_y=16$, (c) $q=3$, $i_y=16$, (d) $q=1$, $i_y=27$, (e) $q=2$, $i_y=27$, (f) $q=3$, $i_y=27$.

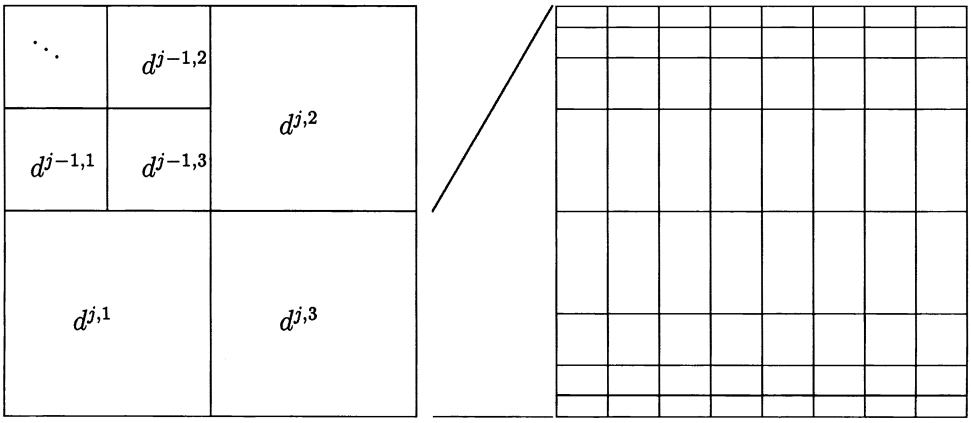

FIG. 17. *Graphical representation of the wavelet coefficients* $d^{j,q}_{i_x,i_y}$ *of the two-dimensional MRA (method* **B***) given in* (38)*. The enlargement on the right shows that the individual colored cells of each block of data (coefficients which have common* j *and* q *indices) are uniformly spaced in the horizontal direction and spaced according to the approximate definition of the Legendre wavelet centers in* (29) *in the vertical direction. Note that the position of* $d^{j,2}$ *and* $d^{j,1}$ *is interchanged with respect to* [25, 5].

centered around the position (x_c, y_c), having the two characteristic length scales σ_x and σ_y and possibly a rotation by an angle α.

The coefficient diagrams of the transforms for various values of the parameters y_c, σ_x, σ_y, α (Figures 18 to 21) demonstrate several characteristics of the present hybrid MRA which are common to methods **A** and **B**:

(i) In both cases **A** and **B**, the position of the bump can be correctly determined from the location with the largest scale index (or scale index pair) at which a significant response is obtained.

(ii) Due to the different localization properties of $\tilde{\psi}(x)$ and $\psi(y)$, the response appears more smeared out in the vertical direction than in the horizontal direction, especially when the bump is centered near the boundary of the interval.

(iii) Since the characteristic vertical scale s_y of the Legendre wavelets varies with the position index i_y, the response appears at lower values of j_x (respectively, at lower j for $q = 1$ with method **B**) when the bump is located closer to the boundary. Locally, however, both variants of our hybrid base still bear the strict hierarchical feature of the original MRA in the sense that at a fixed location the scale varies exponentially with the scale indices j_x, j_y (or j, respectively).

With method **A**, directional information is solely represented by the aspect ratio s_x/s_y of the basis functions. We define a global index I_s for the aspect ratio:

$$I_s = \frac{\sum_{j_x,j_y,i_x,i_y} (d^{j_x,j_y}_{i_x,i_y})^2 \, \dfrac{s_x(j_x)}{s_y(j_y,i_y)}}{\sum_{j_x,j_y,i_x,i_y} (d^{j_x,j_y}_{i_x,i_y})^2}. \tag{41}$$

The values obtained for various choices of the parameters in the example (40) are shown in Table 2. The fact that I_s takes a value significantly higher than unity

				Method **A**	Method **B**
y_c	σ_x	σ_y	α	I_s	I_q
0.0	0.01	0.01	0	3.43	1.14
0.95	0.01	0.01	0	3.25	5.4
0.0	0.01	0.1	0	0.41	21.0
0.95	0.01	0.1	0	0.23	57.5
0.0	0.1	0.01	0	19.45	0.06
0.95	0.1	0.01	0	18.45	0.23
0.0	0.1	0.01	$-45°$	1.36	1.24
0.95	0.1	0.01	$-45°$	0.88	26.0

although $\sigma_x/\sigma_y = 1$ again is a consequence of the different localization properties of the underlying one-dimensional wavelet bases used for the two coordinate directions. Important, however, is here that this index is approximately invariant with respect to a vertical shift of the center of the bump (except when $\sigma_x/\sigma_y = 1/10$ in which case a large part of the bump lies outside the upper boundary when $y_c = 0.95$). This quantity hence provides a useful characterization of the anisotropy of a signal. It can also be extended to a local coefficient or a scalewise coefficient by an appropriate restriction of the summation bounds in (41).

Turning now to method **B**, we remark that the angular selectivity (i.e., the index q) and the aspect ratio s_x/s_y are not independent but jointly represent the signal's directional properties. We therefore define the index

$$I_q = \frac{\sum_{j,i_x,i_y} (d^{j,1}_{i_x,i_y})^2}{\sum_{j,i_x,i_y} (d^{j,2}_{i_x,i_y})^2} \tag{42}$$

reflecting the ratio of the energies of coefficients with $q = 1$ and $q = 2$. Table 2 shows that, in contrast to I_s, the latter coefficient changes considerably when the signal is shifted vertically. Hence, changing y_c not only provokes a shift of the index j_y, but also causes the response to shift between the three wavelet types $q = 1, 2, 3$. Attempts to construct a robust joint directional index for method **B** failed, mainly due to the problem of attributing a meaningful physical scale to the scaling functions. Similar effects have to be expected for the doubly nonperiodic case. Because of the apparent difficulties in interpreting the coefficients from transform **B** in terms of orientation, we decided to work with method **A** from here on.

As discussed in section 4.5, interesting quantitative information can be extracted from the transformation by means of local spectra. For method **A** we therefore define the two-dimensional equivalent of the local power-spectral density (33) as

$$E(k_{j_x}, k_{j_y}, x, y) = 2^{j_x} 2^{j_y} \frac{\left(d^{j_x,j_y}_{i_{x^*},i_{y^*}}\right)^2}{\Delta k_{j_x}\, \Delta k_{j_y}}, \tag{43}$$

with, again, the indices i_{x^*}, i_{y^*} determined from the wavelet center nearest to the point (x, y).

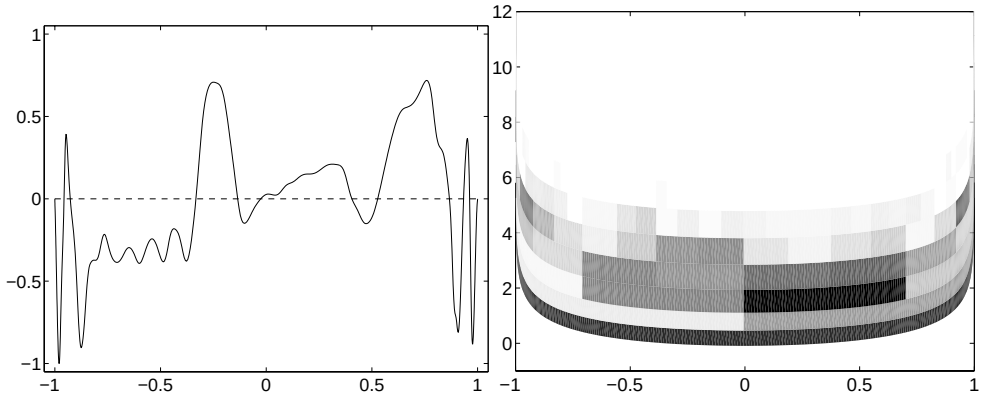

FIG. 22. *Signal and wavelet coefficient diagram of an instantaneous cut along a wall-normal line in a turbulent channel flow at friction velocity Reynolds number* $Re_\tau = 590$. *The signal is the fluctuation of the streamwise velocity component, normalized such that its maximum absolute value is unity.*

6. An application: Local scales in turbulent plane channel flow.

6.1. Flow configuration. We consider the fully developed turbulent flow in a doubly periodic box between two parallel walls which are spaced apart by $2h$. Here, x is the streamwise, y the wall-normal, and z the spanwise coordinate with u, v, w being the corresponding velocity components. Fluctuations with respect to the time-averaged signal are denoted by a prime. The characteristic Reynolds number $Re_\tau \equiv u_\tau h/\nu$ is based upon the wall-friction velocity $u_\tau = \sqrt{\nu|\overline{\partial u/\partial y}|_{y=\pm h}}$ (averaged over the channel walls and in time), the channel half-width h, and the kinematic viscosity ν. The same reference quantities are used to form a nondimensional length scale $l^+ = lu_\tau/\nu$, the so-called wall-scaling or wall units, which is the analogue to Kolmogorov scaling in homogeneous-isotropic turbulence and indicates the size of the smallest features in the flow close to the wall. The superscript + added when numerical values are given refers to quantities normalized by l^+.

We use flow data from a pseudospectral direct numerical simulation of the second author, performed at $Re_\tau = 590$ in a computational domain of size $\Omega_{DNS} = 2\pi h\mathbb{T} \times [-h, h] \times \pi h\mathbb{T}$ using $600 \times 385 \times 600$ discrete Fourier/Chebyshev modes, respectively. This case is similar to the highest Reynolds number case studied in [27], except that the spatial resolution has been increased substantially.

6.2. Local one-dimensional spectra. We extract instantaneous wall-normal profiles of velocity fluctuations and interpolate them spectrally to a $N = 256$ Legendre–Gauss–Lobatto grid before performing the wavelet transform given by (25).

In turbulent channel flow, high gradients and small structures are generated close to the solid surfaces. In the one-dimensional cuts these are hence located close to the extrema of the interval. Figure 22 displays such a snapshot, where the fluctuations of the streamwise velocity component u' show such features near $y=-1$ and $y=1$, both of which are not unlike the narrow Gaussian bumps considered in section 4.4. The wavelet coefficient scalogram again allows a localization of these peaks as well as an approximate determination of their relative scales. Several coarser undulations of u' towards the center of the interval produce responses at larger scales.

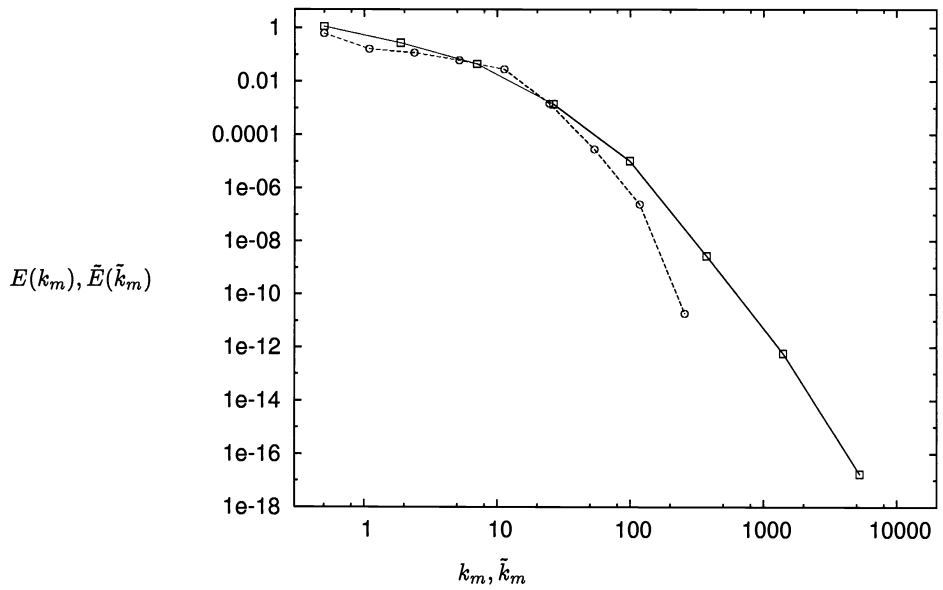

FIG. 23. *The global wavelet spectrum $E(k_m)$ as a function of the inverse of the scale number $k_m = 1/s_{ij}$ (solid line) corresponding to the transform of the data in Figure 22. The dashed line shows the Legendre coefficient spectrum $\tilde{E}(\tilde{k}_m)$. In both cases, the values of the spectrum are accumulated over logarithmically spaced bins and normalized such that their integral amounts to unity.*

Figure 23 shows the global wavelet energy spectrum for the signal reported in Figure 22. Also included is the corresponding Legendre coefficient spectrum. Both curves are normalized by the respective total energy E_{tot}. A very close comparison is delicate due to the different meaning of "scale" in both cases. The wavenumber associated with a Legendre polynomial is naturally defined by its degree n as $\tilde{k}_n = n/L_x$. The spacing of zeros and extrema, however, varies over the interval. Since these functions do not have local character, physical information from features of different size is summed up over the whole interval. The physical significance of this averaging over the nonhomogeneous flow direction is unclear and motivates the present approach for defining a global spectrum by means of wavelets. Here, it is assumed that only contributions from the same physical scale are accounted for in $E(k_m)$ (see (31)).

Figure 24 shows the local energy spectra of the streamwise velocity data from Figure 22, evaluated at different locations. Not surprisingly, close to the center the largest scales dominate the flow. About halfway towards the lower wall ($x = -0.6$) a distinct medium-scale peak is observed, while at $x = -0.94$ the maximum energy is recorded for even smaller scales. There are of course strong temporal variations and any significant statement about turbulent flow structures requires a statistical approach. This will be done in section 6.4 below.

6.3. Local two-dimensional spectra. Data in planes (containing the wall-normal and either the streamwise or the spanwise direction) extracted from the raw three-dimensional fields have been transformed to wavelet space by method **A**. To this end, we have first spectrally interpolated the data on a grid comprised of $N_1 = 512$ uniformly spaced points times $N_2 = 512$ Legendre–Gauss–Lobatto points before evaluating the scalar products in (37).

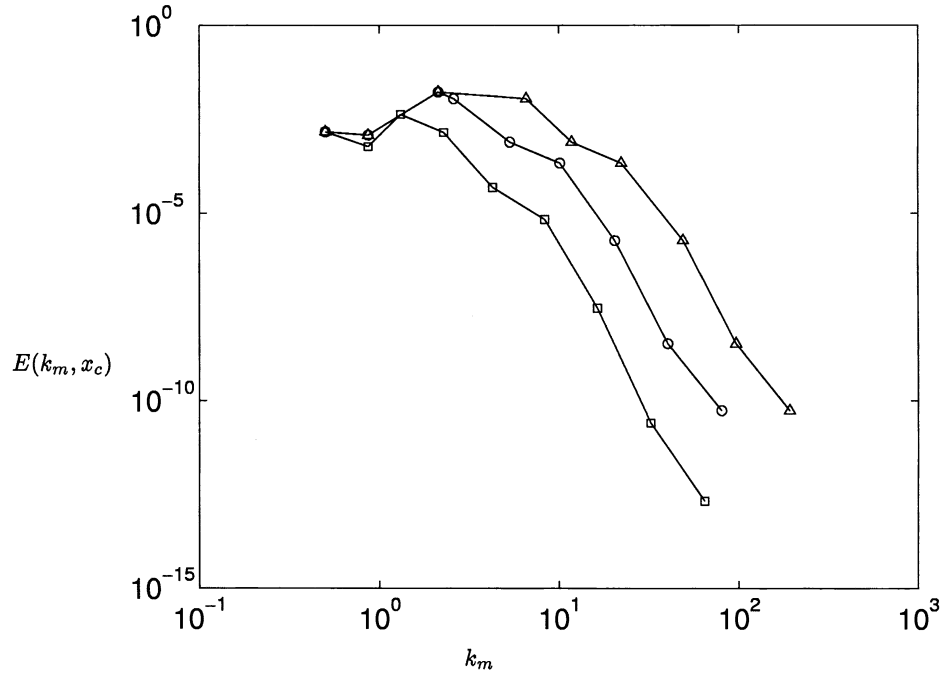

FIG. 24. *Local wavelet spectra $E(k_m, x_c)$ as a function of the inverse of the scale number $k_m = 1/s_{ij}$ corresponding to the data of Figure 22 and taken at the following positions within the interval $x \in [-1, 1]$: □, $x_c = 0.1$; ○, $x_c = -0.6$; △, $x_c = -0.94$.*

Figure 25 shows a snapshot of the streamwise velocity fluctuation in a spanwise/wall-normal plane. The signal bears a vast number of features and one clearly needs a formalism which helps to extract the desired information. Figure 26 displays the wavelet representation of this signal by means of the two-dimensional periodic/non-periodic transform defined above. Inspecting these coefficients, we see that the well-known small-scale intermittency [18] is apparent. For this purpose, the small-scale coefficients have been overexposed by multiplying all coefficient values with a factor of $2^{\max(j_x, j_y)}$ in the lower graph. This reveals that the high intensity regions become increasingly localized, i.e., less space-filling, with increasing values of $\max(j_x, j_y)$.

In the following we consider two locations in the near-wall region, i.e., at a wall-distance of $y^+ = 89$, one of which is located in what seems a lifted low-speed streak (marked "B" in Figure 25), the other (marked "A") well away from such events. The third location, marked "C," is situated on the centerline of the channel. Figures 27 and 28 show the two-dimensional power-spectral density evaluated at these locations and plotted for each value of the horizontal scale number k_{j_x} as a function of k_{j_y}. For clarity, only the higher horizontal scale numbers $k^+_{j_x} \geq 4.3 \cdot 10^{-3}$ are included.

Comparing the center to the wall region ("C" vs. "A"), it is visible that for all horizontal scale numbers k_{j_x} the decay of the signal's energy with increasing k_{j_y} is much faster in the center of the channel, especially at vertical scale numbers around $k^+_{j_y} = 10^{-2}$. This is an indication that smaller vertical scales of motion are active at point "A" while the horizontal scales are comparable to those at "C."

Comparing locations "A" and "B," more fine-scale contributions are observed at point "B" in vertical as well as horizontal direction. While at "A" a smooth and

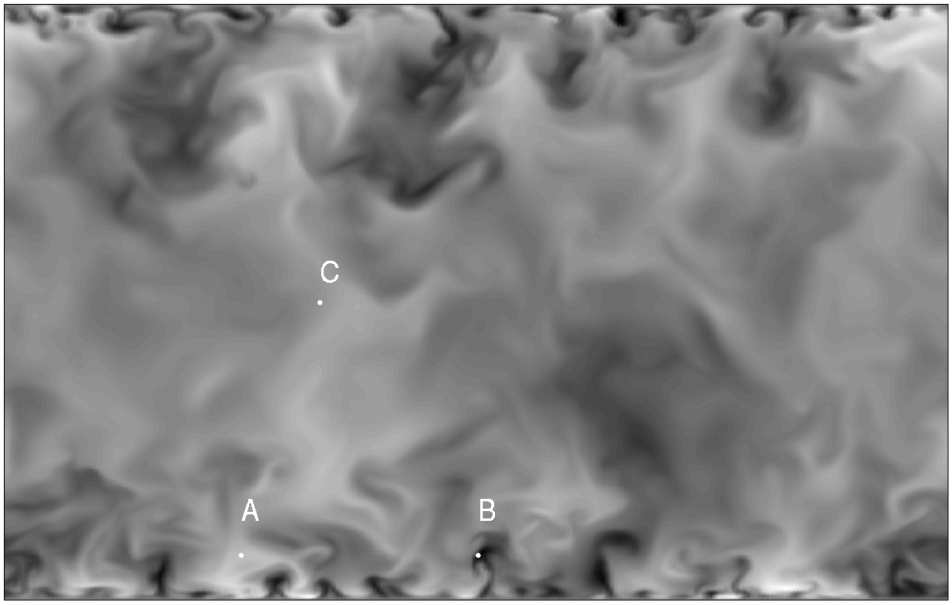

FIG. 25. *Streamwise velocity fluctuations of a snapshot from a turbulent channel flow at friction velocity Reynolds number $Re_\tau = 590$. The plane is spanwise/wall-normal, i.e., the mean flow is perpendicular to the plane. The aspect ratio reflects the physical size of the domain. The locations marked "A," "B," and "C" are used in subsequent graphs.*

continuous decay of the vertical coefficients is detected for all horizontal wavenumbers, the spectrum forms a plateau at "B," in particular for larger k_{j_x}. Furthermore, for $k^+_{j_x} = 8.6 \cdot 10^{-3} \ldots 3.5 \cdot 10^{-2}$ a local maximum is observed around $k^+_{j_y} = 1.5 \cdot 10^{-2}$. This corresponds to features in the flow having a size about the distance of this point from the wall which indeed is the case for such a low-speed streak. Towards higher wavenumbers k_{j_y} a regular decay of the energy is observed. Its rate at point "B" is only half of the one at point "A." Furthermore, the same values are observed for different k_{j_x} in the former case, which means that saturation is attained in the streamwise direction.

6.4. Statistical results for wall-normal scales. In the past, the wall-normal scales of turbulent flow have basically been characterized by two methods: inspection of two-point autocorrelations (e.g., [20]) or analysis of the most energetic modes from proper orthogonal decomposition (e.g., [23]). In neither case, a clear correspondence between an a priori defined length scale and its energy is available. The present wavelet basis for the interval provides just these two ingredients and thus allows for a quantitative description of the energy content of wall-normal scales and their position.

For the generation of statistical data we have used a total of $n_{stat} = 150$ streamwise/wall-normal planes from 5 flow fields covering a time span equivalent to one flow-through time of the computational domain. The quantities considered are the three velocity components u_α ($\alpha = 1 \ldots 3$) with their transform coefficients denoted as $d^{j_x,j_y}_{i_x,i_y}(u_\alpha)$. Furthermore, we focus on the distribution of the wall-normal scales and therefore sum over the indices j_x and i_x of the statistically homogeneous direction. This leads us to the following definition of the ensemble-averaged one-dimensional

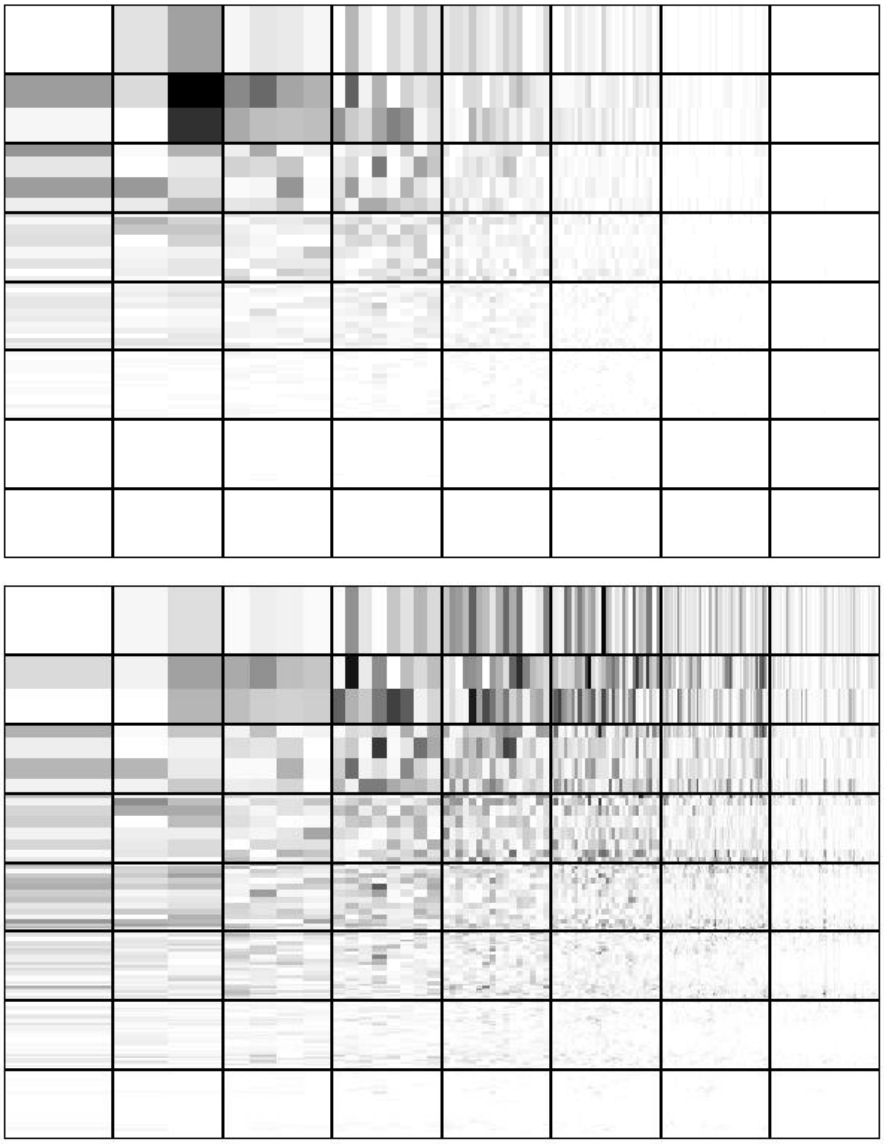

FIG. 26. *The absolute value of the wavelet coefficients of the transform of streamwise velocity fluctuations in a turbulent channel flow at friction velocity Reynolds number* $Re_\tau = 590$. *The plane is spanwise/wall-normal. The numerical grid has a dimension of* $N = 2^9$. *The grayscale coloring is chosen such that white corresponds to zero intensity and black to maximum intensity. Both graphs originate from the same data. In the lower graph, the small-scale coefficients are overexposed by a factor of* $2^{\max(j_x,j_y)}$.

power-spectral density as a function of wall-normal position y and wavenumber k_{j_y}:

$$E_{\alpha\alpha}(k_{j_y}, y) = 2^{j_y} \sum_{j_x,i_x} \frac{\left\langle \left(d^{j_x,j_y}_{i_{x_c},i_y}(u_\alpha) \right)^2 \right\rangle_{n_{stat}}}{\Delta k_{j_y}}, \tag{44}$$

where $\langle\cdot\rangle_{n_{stat}}$ denotes an average over the available samples.

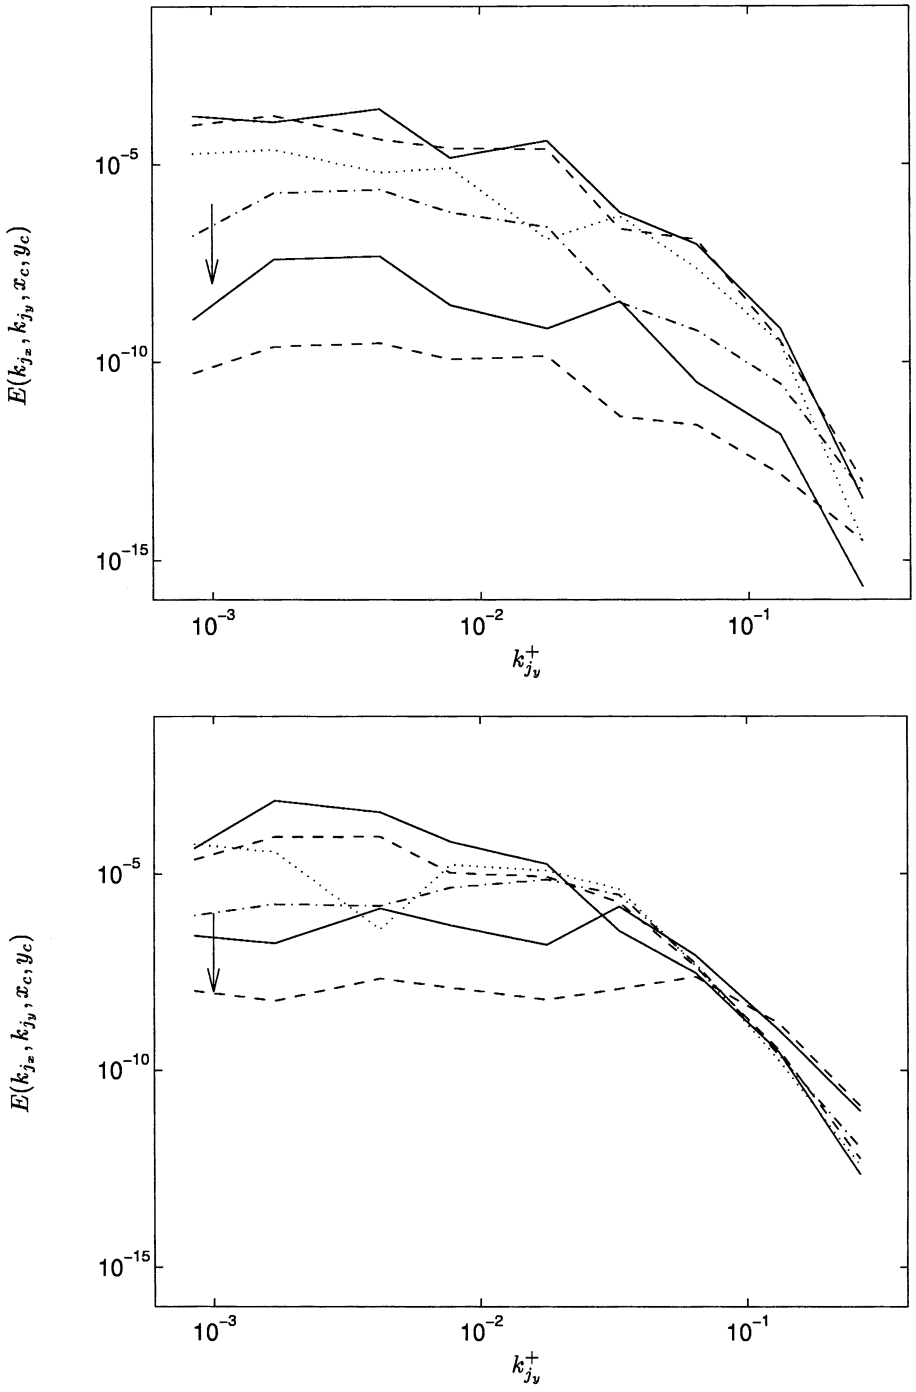

FIG. 27. *Local spectral energy density of the streamwise velocity fluctuations, determined by the two-dimensional wavelet analysis. The results presented refer locations "A" (top) and "B" (bottom), indicated in Figure* 25*, both at a wall-distance of* $y^+ = 89$*. The various lines correspond to different values of the spanwise (i.e., horizontal) scale number, stepping through* $k^+_{j_x} = 4.3 \cdot 10^{-3}$ *(solid),* $8.6 \cdot 10^{-3}$ *(dashed),* $1.7 \cdot 10^{-2}$ *(dotted),* $3.5 \cdot 10^{-2}$ *(dash-dotted),* $6.9 \cdot 10^{-2}$ *(solid),* 0.14 *(dashed) in the direction indicated by the arrow.*

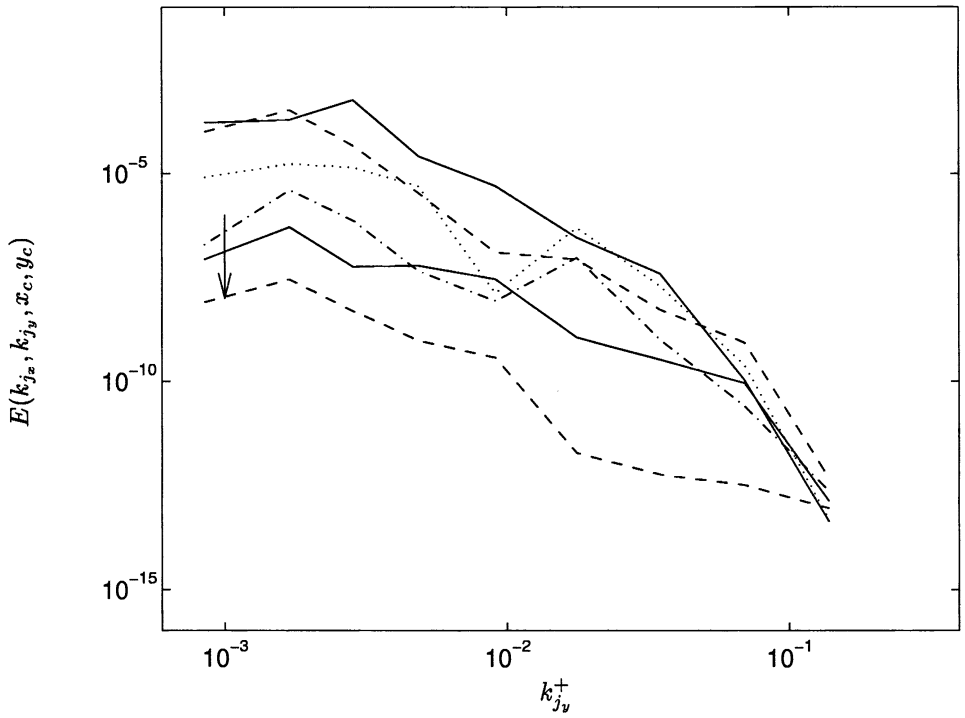

FIG. 28. *As Figure* 27*, but for location "C" on the centerline of the channel.*

Figure 29 shows the premultiplied spectra $k_{j_y} E_{\alpha\alpha}(k_{j_y}, y)$ for the streamwise ($\alpha = 1$) and the wall-normal component ($\alpha = 2$) of velocity, evaluated at different wall-distances across the channel. This representation allows for a direct comparison with results for the corresponding streamwise and spanwise spectra available through Fourier analysis. (For a compilation of experimental and numerical data cf. [17].) Here we observe a very distinct behavior of the velocity components. The wall-normal velocity has the maximum energy contained in scales which increase with the wall-distance, from a peak scale of 15 wall units at $y^+ = 5$ to the largest scale (i.e., the full channel width) at the centerline. Contrarily, the scale of the energy peak is *always* the largest scale in the case of the streamwise velocity fluctuations. These observations imply that the energetic scales of the wall-normal velocity are strongly constrained near the wall, while those of the streamwise velocity are affected only to a much lesser extent. It has long been recognized (e.g., [32, p. 150]) that wall-impermeability has a strong direct effect upon the wall-normal velocity in turbulent shear flow while not restricting the motion in planes parallel to the wall. With the present analytical tools it is finally possible to describe the above effect quantitatively. We believe that the local wall-normal spectrum could play a particularly important role during the analysis of new data from ongoing efforts to capture the dynamics of the very large scales of the logarithmic layer [6].

7. Conclusions. Starting from [11] we have constructed an orthonormal wavelet basis for the interval by an appropriate recombination of Legendre polynomials. These functions have been implemented together with routines to perform the corresponding

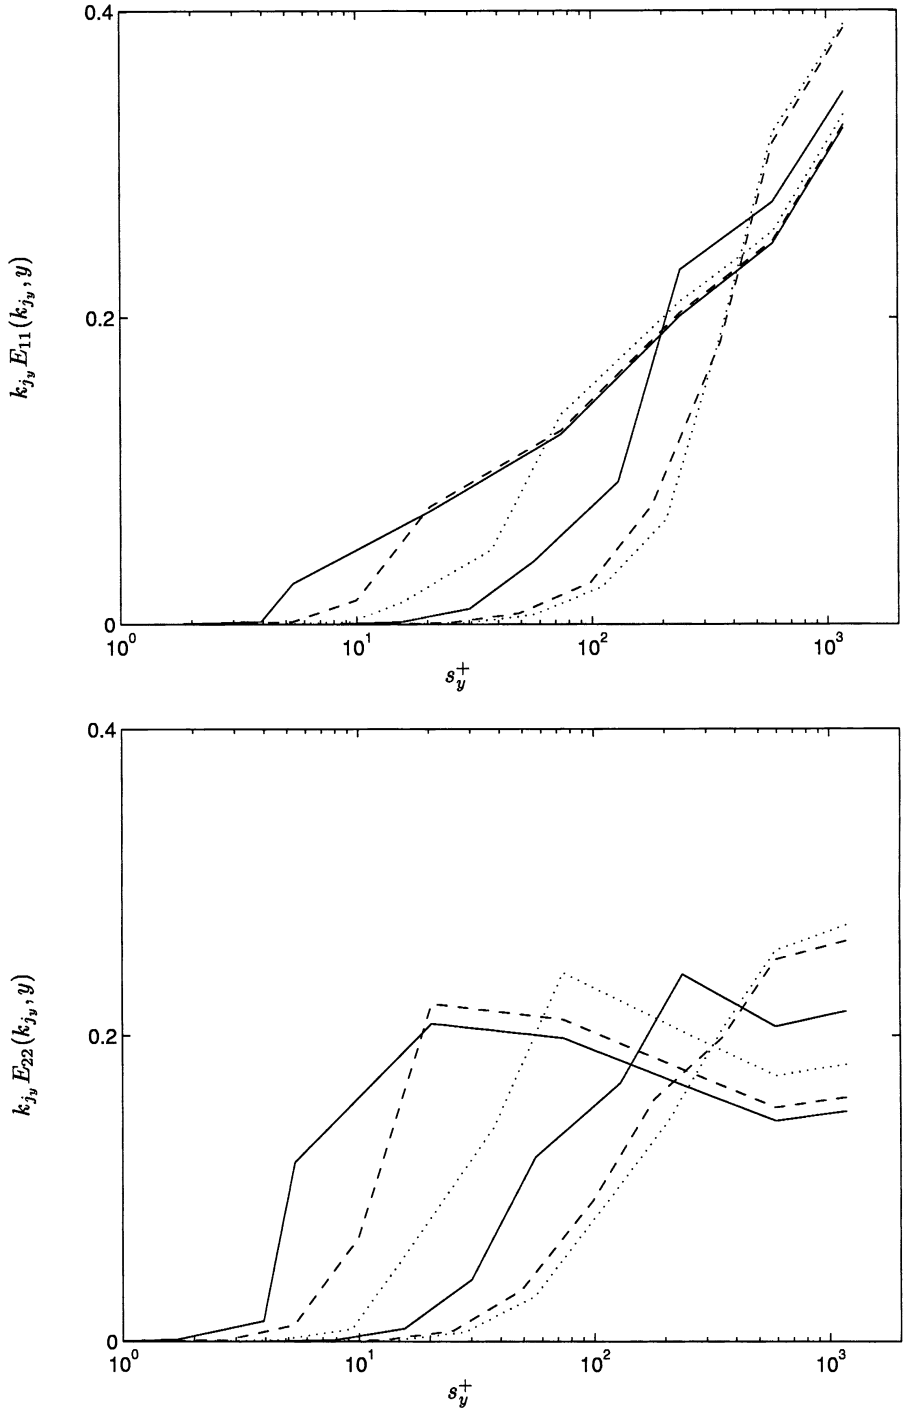

FIG. 29. *Premultiplied, ensemble-averaged, wall-normal power spectra* $k_{j_y} E_{\alpha\alpha}(k_{j_y}, y)$ *as a function of scale* s_y^+ *in plane channel flow at* $Re_\tau = 590$ *for streamwise* ($\alpha = 1$) *and wall-normal* ($\alpha = 2$) *velocity components. The different lines correspond to different wall distances* $y^+ = \{5, 10, 30, 100, 300, 500\}$*; in both graphs, increasing* y^+ *results in a shift towards larger scales while line styles rotate through solid, dashed, dotted. forward and backward transform. As a consequence of the inhomogeneity, the spatial scale of the wavelets depends to some extent not only on the scale index but also on the translation index. We have devised a suitable definition of the scale number and developed a scheme for the representation and analysis of the coefficients. The usefulness of the present basis for data analysis is demonstrated by studying the transforms of analytical functions as well as data from turbulent flow simulations. We have defined local power-spectral density functions and find that they constitute an important tool for the analyst. We have argued that with the present lumping of blocks of polynomials no decay better than $\propto 1/x$ is possible. While the rate of decay cannot be changed, the actual values and the properties of the tails might be improved. Another route is to modify the lumping by using a smoother selection of polynomial coefficients as employed in [14]. This work is currently under way.[1]

In a second part of the paper two variants of a hybrid two-dimensional MRA have been proposed and implemented. Method **A** is constructed from a tensor product between periodic spline wavelets in the first direction and the present Legendre wavelets in the second direction. Method **B** uses the more widespread procedure of a tensor product of the two corresponding one-dimensional MRAs, leading to three types of wavelets with different directional properties. In both cases, the implementation of two nonperiodic directions can be accomplished analogously by using Legendre wavelets in both directions. Higher dimensions are also straightforward.

The graphical representation of a two-dimensional wavelet analysis is genuinely more difficult than in the one-dimensional case. We have discussed the implications of a spatially varying scale parameter and performed visualizations with an adaptation of the classical scheme combining coefficients with the same scale and, in the case of method **B**, direction indices in blocks. It was found that due to the interaction between directional properties and varying scale ratio s_x/s_y, method **B** is less useful for the purpose of data analysis.

Finally, we have applied the new transform (method **A**) to the analysis of data from direct numerical simulation of turbulent plane channel flow. The qualitative analysis of intermittency of a plane extracted from a snapshot showed velocity fluctuations which are more intermittent at small scales than at large scales—an observation which is consistent with previous wavelet analyses of spatially homogeneous flows [26, 3, 21]. We then performed ensemble-averaging and reduced the data to the form of local wall-normal power spectra. It was found that near the wall, the most energetic scales of the wall-normal velocity are much smaller than those of the streamwise velocity, probably due to the constraining effect of wall-impermeability.

The constructions presented in this paper offer numerous perspectives for future extensions. One direction is the construction itself in the one-dimensional and multidimensional cases, such as a variant for semi-infinite intervals, and its optimized implementation. A second direction is the application to signals of various other areas and the definition of further secondary quantities based on the wavelet coefficients.

Acknowledgments. The authors like to thank J. Prestin for pointing them to the possibility of replacing the Chebyshev polynomials by Legendre polynomials in the wavelet construction.

[1] This construction has been completed in the meantime. A copy of the manuscript can be obtained from the authors upon request.

INITIATION OF FREE-RADICAL POLYMERIZATION WAVES*

L. R. RITTER†, W. E. OLMSTEAD†, AND V. A. VOLPERT†

Abstract. Frontal polymerization is a process of converting a monomer into a polymer by means of a self-propagating thermal reaction wave. We study initiation of polymerization waves by a high temperature heat source. A five species reaction model is considered with a focus on the evolution of two of these species and the temperature of the mixture. The temperature is tracked from the inert heating to the transition stage. Through an asymptotic analysis, the first correction to the temperature in transition is found as the solution to an integral equation. Two parameters govern the qualitative behavior of the solution to the integral equation. Depending on the magnitude of these parameters, the solution exhibits either bounded or unbounded behavior indicating the onset or inhibition of propagation of a polymerization wave.

1. Introduction.

Frontal polymerization is the process of converting a monomer into a polymer by means of a self-propagating high temperature reaction wave. The chemical process involves two species: a monomer and an initiator, which is needed to start the growth of polymer chains. In a typical experiment, the species are placed into a test tube, and the temperature at the end of the tube is increased by applying a heat source. The increase in temperature induces decomposition of the initiator, which produces active radicals, and the highly exothermic propagation process begins. The resulting heat release promotes initiator decomposition ahead of the front, and a self-sustained reaction wave travels through the mixture leaving polymer in its wake.

Experimental and theoretical studies of frontal polymerization began in the 1970s (see references 1–4 in [5]). In [5] and [6], a mathematical model for the five species reaction is presented, and traveling wave solutions are sought. In these theoretical examinations of the process, the focus has been on the propagation of the thermal front and its velocity, the spatial profiles of the species involved, the degree of conversion of monomer, and the final temperature of the mixture. Initiation of a polymerization front is presumed. From experimental work, however, it is found that initiation of the front does not always occur. It is desirable to determine the dependence of initiation on the amount of reactants at the onset of the experiment, the initial temperature, the heat control imposed at the end of the test tube, and the properties of the initiator.

The purpose of this paper is to examine the initiation process necessary for propagation. In this respect, the current study is similar to ignition considerations in solid phase combustion problems. Unlike the combustion problem with a single reactant, the frontal polymerization process involves several chemical reaction steps with different reaction rates and activation energies. However, the reaction mechanism in both types of problem is assumed to be Arrhenius, and, upon nondimensionalization of the kinetic equations governing frontal polymerization, we can obtain a system of partial

differential equations of a form similar to those arising in solid phase combustion. For this reason, the techniques applied in the current analysis are similar to those employed in [1, 2, 3, 4] in the examination of ignition of a combustible half-space. Lasseigne and Olmstead [4] consider the effects of reactant consumption, and they derive an integral equation governing the temperature at the ignition site. In this paper, we show that the mechanism governing initiation of the polymerization front gives rise to a similar two parameter integral equation governing the temperature in the transitional heating stage. In fact, under certain limiting conditions, the integral equation in [4] for a first order Arrhenius reaction appears as a special case of the integral equation presented in the current work. An asymptotic analysis of this integral equation is given, and numerical results are presented.

2. The mathematical model. The typical experiment in free radical frontal polymerization involves placing a mixture of initiator and monomer into a test tube. Assuming that the cross-sectional area of the tube is small relative to its length, we can model the tube as a thin semi-infinite channel $\hat{x} \geq 0$. A boundary condition on the heat flux will be prescribed at the end ($\hat{x} = 0$). The evolution of the reactants and the temperature can then be tracked. A mathematical model for a five species reaction is derived in [5] and [6], and the following system of equations governing the kinetics at time $\hat{t}$ in dimensional coordinates is given:

$$\frac{dI}{d\hat{t}} = -k_d I, \tag{2.1}$$

$$\frac{dR}{d\hat{t}} = 2fk_d I - k_i RM - k_e RR_p, \tag{2.2}$$

$$\frac{dM}{d\hat{t}} = -k_i RM - k_p MR_p, \tag{2.3}$$

$$\frac{dR_p}{d\hat{t}} = k_i RM - k_e RR_p - 2k_t R_p^2, \tag{2.4}$$

$$\frac{dP}{d\hat{t}} = k_e RR_p + k_t R_p^2. \tag{2.5}$$

The five species are the initiator, free radicals, monomer, polymer radicals, and the final polymer, denoted by I, R, M, R_p, and P, respectively. The parameter f appearing in the second equation is the ratio of primary radicals in the polymer to the primary radicals formed by the initiator. In practice, its value is taken to be $1/2$ (see [5]). The quantities, written above as k with a subscript, are assumed to have an Arrhenius dependence on the temperature T of the system. Thus, they can be expressed as

$$k_\alpha(T) = k_\alpha^0 \exp\left(\frac{-E_\alpha}{R_g T}\right) \quad \text{for} \quad \alpha = d, i, p, e, t.$$

Here, k_α^0 is the frequency factor, E_α is the activation energy for the corresponding reaction, and R_g is the universal gas constant. The subscripts correspond to the five reaction steps—initiator decomposition d, polymer chain initiation i, chain propagation p, free radical termination e, and polymer radical termination t.

To formulate the heat balance in the system, we note that the decomposition step is slightly endothermic but that each of the four subsequent reactions is exothermic. However, the most significant heat release occurs in the propagation step [9]. Thus, only this contribution to the net energy of the system will be considered here. Letting

$T(\hat{t},\hat{x})$ denote the temperature of the mixture at time $\hat{t}$ and at the point $\hat{x}$, $\kappa > 0$ the thermal diffusivity of the mixture, and $q > 0$ the increase in temperature induced per unit reacted monomer, we can write the following reaction diffusion equation governing the temperature:

$$\frac{\partial T}{\partial \hat{t}} = \kappa \frac{\partial^2 T}{\partial \hat{x}^2} - q\frac{\partial M}{\partial \hat{t}}. \tag{2.6}$$

Equations (2.1)–(2.6), together with appropriate initial and boundary conditions, completely describe the state of the mixture. Because we are interested in initiation of a polymerization front, we will consider a reduced system obtained by imposing the quasi-steady-state assumption (QSSA) [6], reducing the number of unknowns as in [5] and [6], and considering only the evolution of the initiator, the monomer, and the temperature. The QSSA states that the level of free and polymer radicals in the mixture is nearly constant. Hence, we set $(d/d\hat{t})(R + R_p) = 0$. In addition, we make the following simplifying assumptions as justified in [6]:

$$k_i = k_p,\ k_e = k_t, \quad \text{and} \quad R_p \gg R.$$

Summing (2.2) and (2.4) and making the aforementioned assumptions yields

$$R + R_p \approx \sqrt{\frac{2fk_d}{k_t}}\sqrt{I}.$$

Then (2.3) becomes

$$\frac{dM}{d\hat{t}} = -k_p\sqrt{\frac{2fk_d}{k_t}}M\sqrt{I}.$$

Noting that the coefficient in front of M in the above equation is an Arrhenius exponential motivates the following convenient notation for the effective reaction rate:

$$k_{eff} = k_p\sqrt{\frac{2fk_d}{k_t}}, \quad k^0_{eff} = k^0_p\sqrt{\frac{2fk^0_d}{k^0_t}}, \quad \text{and} \quad E_{eff} = \frac{1}{2}(E_d - E_t) + E_p.$$

The initial amounts of monomer and initiator present are known and will be denoted by M_0 and I_0. Similarly, the initial temperature of the system is given as T_0. In the current work, we will assume that the boundary condition on the temperature at $\hat{x} = 0$ will be a Neumann condition. That is, the heat flux is prescribed as

$$\frac{\partial T}{\partial \hat{x}} = -\hat{h}(\hat{t}) \quad \text{for} \quad \hat{x} = 0,\ \hat{t} > 0.$$

Further, we assume that $\hat{h}(\hat{t}) > 0$ for all $\hat{t}$. This restriction implies an energy input at the end of the test tube. Finally, the temperature far from the end is assumed to be equal to the initial temperature. The reduced, dimensional form of the system to be studied can then be written as

$$\frac{\partial I}{\partial \hat{t}} = -k_d(T)I, \quad I(0) = I_0, \tag{2.7}$$

$$\frac{\partial M}{\partial \hat{t}} = -k_{eff}(T)M\sqrt{I}, \quad M(0) = M_0, \tag{2.8}$$

$$\frac{\partial T}{\partial \hat{t}} = \kappa\frac{\partial^2 T}{\partial \hat{x}^2} + qk_{eff}(T)M\sqrt{I}, \quad T(0,\hat{x}) = T_0, \quad \hat{x} \geq 0, \tag{2.9}$$

$$\frac{\partial T(\hat{t},0)}{\partial \hat{x}} = -\hat{h}(\hat{t}), \quad \text{and} \quad T \to T_0 \quad \text{as} \quad \hat{x} \to \infty. \tag{2.10}$$

3. Scaling and nondimensionalization. Because the activation energies are relatively large, the Arrhenius reaction terms are insignificant, provided that the temperature is relatively small. Thus, we will consider a critical value of the temperature T_c at which the reaction terms become appreciable. The value of T_c will be made more precise later. Further, the largeness of the activation energies facilitates a perturbation scheme in solving for the temperature. Hence, we introduce the small parameter

$$\epsilon = \frac{R_g T_c}{E_{eff}}$$

and define the quantities

$$r = \frac{E_d}{E_{eff}}, \qquad \tilde{k}_d^0 = k_d^0 e^{-r/\epsilon}, \qquad \tilde{k}_{eff}^0 = k_{eff}^0 e^{-1/\epsilon},$$

$$t_* = (\tilde{k}_{eff}^0 \sqrt{I_0}\,)^{-1}, \qquad x_* = \sqrt{\kappa t_*}.$$

We also introduce the nondimensional variables

$$\phi = \frac{I}{I_0}, \quad \psi = \frac{M}{M_0}, \quad \theta = \frac{T}{T_c}, \quad \theta_0 = \frac{T_0}{T_c},$$
$$h(t) = \frac{x^*}{T_c}\hat{h}(\hat{t}), \quad t = \frac{\hat{t}}{t_*}, \quad \text{and} \quad x = \frac{\hat{x}}{x_*}.$$

From (2.7)–(2.9), we obtain the corresponding nondimensional system:

$$\frac{\partial \phi}{\partial t} = -A\phi \exp\left\{\frac{r}{\epsilon}\left(1 - \frac{1}{\theta}\right)\right\}, \quad \phi(0) = 1, \tag{3.1}$$

$$\frac{\partial \psi}{\partial t} = -\psi\sqrt{\phi} \exp\left\{\frac{1}{\epsilon}\left(1 - \frac{1}{\theta}\right)\right\}, \quad \psi(0) = 1, \tag{3.2}$$

$$\frac{\partial \theta}{\partial t} = \frac{\partial^2 \theta}{\partial x^2} + B\psi\sqrt{\phi} \exp\left\{\frac{1}{\epsilon}\left(1 - \frac{1}{\theta}\right)\right\}, \quad \theta(0, x) = \theta_0, \tag{3.3}$$

$$\frac{\partial \theta(t,0)}{\partial x} = -h(t), \quad \text{and} \quad \theta \to \theta_0 \quad \text{as} \quad x \to \infty. \tag{3.4}$$

The additional nondimensional parameters A and B appearing in (3.1) and (3.3) are defined by

$$A = \frac{\tilde{k}_d^0}{\tilde{k}_{eff}^0 \sqrt{I_0}} \quad \text{and} \quad B = \frac{M_0 q}{T_c}.$$

The role of initiator consumption in the possible inhibition of initiation is inherent in the scaling of these two parameters. If A is large, for example, we can expect that the amount of initiator will rapidly decay. This rapid decay or an insufficient quantity of initiator at the onset of the experiment will cause the reaction to stop before a thermal front can develop. Similarly, if B is small, the effect of the reaction term in (3.3) is decreased. This can result in insufficient heat to initiate and maintain propagation of the polymer chain. In the present analysis, the following scaling will be assumed:

$$A = A_0 \epsilon^{-1} \quad \text{and} \quad B = B_0 \epsilon^{-\frac{1}{2}},$$

with $A_0 = O(1)$ and $B_0 = O(1)$ with respect to ϵ. The numerical values of A, B, and ϵ depend on the choice of reactants, their kinetic properties, and the conditions of the

experiment (e.g., pressure and ambient temperature). Extensive tabulated values of activation energies, preexponential factors, and other kinetic parameters for various initiators and monomers can be found in [10]. For typical values of the physical parameters appearing in (2.7)–(2.10), the value of ϵ is expected to be in the range of 10^{-4} to 10^{-3}. Moreover, at room temperature the values of A_0 and B_0 can range between 0.01 and 10. Given the typical range of values for ϵ, this is consistent with the assumption that A_0 and B_0 are $O(1)$ with respect to ϵ.

For fixed A_0, the quantity T_c is defined by the relation

$$A = \frac{k_d(T_c)}{k_{eff}(T_c)\sqrt{I_0}}. \tag{3.5}$$

Equations (3.1) and (3.2) are separable and can be solved explicitly. We have

$$\phi(t) = \exp\left(-A\int_0^t e^{\frac{r}{\epsilon}\left(1-\frac{1}{\theta}\right)}\,ds\right),$$
$$\psi(t) = \exp\left(-\int_0^t e^{\frac{1}{\epsilon}\left(1-\frac{1}{\theta}\right)} \times e^{-\frac{A}{2}\int_0^s e^{\frac{r}{\epsilon}\left(1-\frac{1}{\theta}\right)}\,dq}\,ds\right).$$

Upon substitution of the above into the boundary value problem (3.3)–(3.4), the system reduces to one involving only a single dependent variable. In the next section, an asymptotic solution to (3.3)–(3.4) will be derived.

4. Solving for the temperature. As stated, we consider the initial temperature to be small so that the reaction terms are negligible at the onset of the experiment—during the inert heating stage. In the formulation above, this means that we take $\theta_0 < 1$ and $1 - \theta_0 = O(1)$ with respect to ϵ. This allows us to initially ignore the Arrhenius term, which is mathematically equivalent to taking the limit $\epsilon \to 0$ in (3.1)–(3.3). Let θ_I be given by

$$\theta_I(t,x) = \theta_0 + \int_0^t h(\tau)\frac{e^{\frac{-x^2}{4(t-\tau)}}}{\sqrt{\pi(t-\tau)}}\,d\tau.$$

Then θ_I solves the problem (3.3)–(3.4) in the limit $\epsilon \to 0$; we will call this the inert solution. From $0 < 1 - \theta_0$ and $1 - \theta_0 = O(1)$, it follows that initially

$$\theta = \theta_I + \text{e.s.t.},$$

where e.s.t. represents terms that are exponentially small with respect to ϵ. However, this remains valid only until such time as $\theta_I \approx 1$. In order to continue the analysis, let us define the critical time t_c to be the smallest value such that

$$1 = \theta_I(t_c, 0) = \theta_0 + \int_0^{t_c} \frac{h(\tau)}{\sqrt{\pi(t_c-\tau)}}\,d\tau.$$

For arbitrary $h(t)$, such a critical time need not exist. This suggests a restriction on the class of boundary conditions that can lead to initiation. We will assume that the imposed flux $h(t)$ given is such that this critical time does exist. Also note that the above is evaluated at $x = 0$ because θ_I attains its maximum at the end $x = 0$. The inert stage of the reaction ends in the neighborhood of $(t_c, 0)$, and the system enters a transition stage where the reaction terms first become appreciable. To further

our investigation, we perturb about this point and introduce the new independent variables

$$\xi = \frac{x}{\epsilon}, \qquad \tau = \frac{t - t_c}{\epsilon}.$$

In these inner variables, (3.1)–(3.3) become

$$\phi_\tau = -A_0 \phi \exp\left\{\frac{r}{\epsilon}\left(1 - \frac{1}{\theta}\right)\right\}, \quad \phi \to 1 \quad \text{as} \quad \tau \to -\infty, \tag{4.1}$$

$$\psi_\tau = -\epsilon \psi \sqrt{\phi} \exp\left\{\frac{1}{\epsilon}\left(1 - \frac{1}{\theta}\right)\right\}, \quad \psi \to 1 \quad \text{as} \quad \tau \to -\infty, \tag{4.2}$$

$$\epsilon\theta_\tau = \theta_{\xi\xi} + \epsilon^{3/2} B_0 \psi \sqrt{\phi} \exp\left\{\frac{1}{\epsilon}\left(1 - \frac{1}{\theta}\right)\right\}, \quad \theta \to \theta_0 \quad \text{as} \quad \tau \to -\infty, \tag{4.3}$$

$$\theta_\xi = O(\epsilon) \quad \text{for} \quad \xi = 0 \quad \text{and} \quad \tau > -\infty. \tag{4.4}$$

We note here that the conditions at $t = 0$ in the outer variables correspond asymptotically to conditions in the inner variables as $\tau \to -\infty$. The first two equations can again be solved to obtain

$$\phi(\tau) = \exp\left(-A_0 \int_{-\infty}^{\tau} e^{\frac{r}{\epsilon}\left(1 - \frac{1}{\theta}\right)}\, ds\right), \tag{4.5}$$

$$\psi(\tau) = \exp\left(-\epsilon \int_{-\infty}^{\tau} e^{\frac{1}{\epsilon}\left(1 - \frac{1}{\theta}\right)} \times e^{-\frac{A_0}{2}\int_{-\infty}^{s} e^{\frac{r}{\epsilon}\left(1 - \frac{1}{\theta}\right)}\, dq}\, ds\right). \tag{4.6}$$

Substitution of these integrals into (4.3)–(4.4) yields a single problem in the variable θ.

4.1. An asymptotic expansion. We seek an asymptotic expansion for θ of the form

$$\theta = \theta_I + \epsilon\theta^0 + \epsilon^{3/2}\theta^1 + \cdots.$$

Then we can expand θ_I about $(t_c, 0)$ and write

$$\theta_I = 1 + \epsilon a\tau - \epsilon b\xi + o(\epsilon), \tag{4.7}$$

where

$$a = \lim_{t \to t_c} \frac{\partial \theta_I}{\partial t}, \qquad b = -\lim_{x \to 0} \frac{\partial \theta_I}{\partial x}.$$

For the continued analysis, we must assume that these limits exist and that $a > 0$ and $b > 0$. The latter condition follows from requiring that h be a nonnegative function for all times corresponding to an influx of energy at the end of the test tube. The condition $a > 0$ implies that the temperature is increasing at the onset of the transition phase. Both of these are consistent with the potential for initiation.

Substitution of (4.7) into the expansion of θ yields

$$\theta = 1 + \epsilon(a\tau - b\xi + \theta^0) + \epsilon^{3/2}\theta^1 + o(\epsilon^{3/2}),$$

so that

$$\frac{1}{\epsilon}\left(1 - \frac{1}{\theta}\right) = (a\tau - b\xi + \theta^0) + o(1).$$

Combining this result with (4.5) and (4.6) and substituting into the boundary value problem (4.3)–(4.4), we arrive at the equations governing θ^0 and θ^1:

$$O(\epsilon): \quad \begin{aligned} &\theta^0_{\xi\xi} = 0, \\ &\theta^0(-\infty,\xi) = 0, \quad \theta^0_\xi(\tau,0) = 0, \end{aligned} \tag{4.8}$$

$$O(\epsilon^{3/2}): \quad \begin{aligned} &\theta^1_{\xi\xi} = -B_0 e^{a\tau - b\xi + \theta^0} \exp\left(\tfrac{-A_0}{2}\int_{-\infty}^{\tau} e^{r(as - b\xi + \theta_0)}\, ds\right), \\ &\theta^1(-\infty,\xi) = 0, \quad \theta^1_\xi(\tau,0) = 0. \end{aligned} \tag{4.9}$$

Equation (4.8) has solution

$$\theta^0(\tau,\xi) = f_0(\tau), \quad \text{where} \quad f_0(\tau) \to 0 \text{ as } \tau \to -\infty.$$

This is substituted into (4.9) to obtain

$$\theta^1(\tau,\xi) = -B_0 e^{a\tau + f_0(\tau)} \int_0^\xi \int_0^z e^{-b\hat{z}} \exp\left(\frac{-A_0}{2} e^{-rb\hat{z}} \int_{-\infty}^{\tau} e^{r(as + f_0(s))}\, ds\right) d\hat{z}\, dz + f_1(\tau),$$

with $f_1(\tau) \to 0$ as $\tau \to -\infty$.

The function $f_0(\tau)$ governs the first order correction to the inert solution in the transition stage.

4.2. The transition stage solution. In order to determine the nature of f_0 we need a matching condition for large ξ. To this end, we consider the stretched space variable

$$X = \sqrt{\epsilon}\xi.$$

Let $\hat{\Theta}$ represent the solution in the boundary layer. From (4.3) we have

$$\hat{\Theta}_\tau = \hat{\Theta}_{XX} + O(\epsilon^{1/2}).$$

Assuming that θ has the following form in the boundary layer,

$$\theta = \theta_I + \epsilon\hat{\Theta}^0 + \epsilon^{3/2}\hat{\Theta}^1 + \cdots,$$

the $O(\epsilon)$ problem is

$$\hat{\Theta}^0_\tau = \hat{\Theta}^0_{XX}, \quad \hat{\Theta}^0 \to 0 \text{ as } \tau \to -\infty.$$

Additional conditions at $X = 0$ are needed and are determined by matching to the outer solution. Observe that as $X \to 0$ and $\xi \to \infty$,

$$\epsilon\hat{\Theta}^0 + \epsilon^{3/2}\hat{\Theta}^1 + \cdots = \epsilon\theta^0 + \epsilon^{3/2}\theta^1 + \cdots, \tag{4.10}$$

$$\begin{aligned} \epsilon\hat{\Theta}^0_X + \epsilon^{3/2}\hat{\Theta}^1_X + \cdots &= 0 + \epsilon^{3/2}\theta^1_X + \cdots \\ &= 0 + \epsilon^{3/2}(\epsilon^{-1/2}\theta^1_\xi) + \cdots. \end{aligned} \tag{4.11}$$

Equating by powers in ϵ, the above implies that

$$\lim_{X\to 0} \hat{\Theta}^0(\tau,X) = \lim_{\xi\to\infty} \theta^0(\tau,\xi), \qquad \lim_{X\to 0} \hat{\Theta}_X(\tau,X) = \lim_{\xi\to\infty} \theta^1_\xi(\tau,\xi).$$

The equation that $\hat{\Theta}^0$ satisfies is

$$\begin{aligned} \hat{\Theta}^0_\tau &= \hat{\Theta}^0_{XX}, \\ \hat{\Theta}^0_X(\tau,0) &= -B_0 e^{a\tau+f_0(\tau)} \int_0^\infty e^{-bz} e^{\frac{-A_0}{2} e^{-rbz} \int_{-\infty}^{\tau} e^{r(as+f_0(s))}\, ds}\, dz \\ &\equiv J(\tau), \\ \hat{\Theta}^0 &\to 0 \text{ as } \tau \to -\infty. \end{aligned} \tag{4.12}$$

The additional condition

$$\hat{\Theta}^0(\tau,0) = f_0(\tau)$$

determines the unknown function f_0. The solution of (4.12) can be expressed in terms of the Green's function

$$\hat{\Theta}^0(X,\tau) = -\int_{-\infty}^{\tau} J(\sigma) G(X,\tau;0,\sigma)\, d\sigma,$$

where

$$G(X,\tau;0,\sigma) = \frac{1}{\sqrt{\pi(\tau-\sigma)}} e^{\frac{-X^2}{4(\tau-\sigma)}}.$$

Finally, applying the condition on $\hat{\Theta}^0$ at $X = 0$, we arrive at the nonlinear integral equation governing the temperature in the transition stage:

$$f_0(\tau) = -\int_{-\infty}^{\tau} \frac{J(\sigma)}{\sqrt{\pi(\tau-\sigma)}}\, d\sigma = \frac{B_0}{b} \int_{-\infty}^{\tau} \frac{e^{f_0(\sigma)+a\sigma}}{\sqrt{\pi(\tau-\sigma)}} Q(\sigma)\, d\sigma, \tag{4.13}$$

where

$$Q(\sigma) = \int_0^\infty b e^{-bz} \exp\left(-e^{-rbz} \frac{A_0}{2} \int_{-\infty}^{\sigma} e^{r(f_0(s)+as)}\, ds \right) dz.$$

In the next section, we will examine the integral equation (4.13). We will perform a coordinate change resulting in the appearance of an additional parameter governing the qualitative behavior of the solution. Existence considerations will be addressed, and both analytical and numerical results presented.

5. Analysis of the integral equation. The parameter r was defined as the ratio of the decomposition activation energy to the effective activation energy obtained by applying the QSSA. Typical experimental values of the activation energy for decomposition, propagation, and termination are such that $E_d \gg E_p \gg E_t$. It follows that the ratio r is roughly 2. We will consider only values of r such that $1 < r \leq 2$, with special attention given to the case $r = 2$.

The integral Q appearing in (4.13) can be expressed in terms of gamma functions. Note that

$$\int_0^\infty b e^{-bz} \exp\left(-e^{-rbz} \frac{A_0}{2} \int_{-\infty}^{\sigma} e^{r(f_0(s)+as)}\, ds \right) dz = \frac{\Gamma\left(\frac{1}{r}\right)}{r} \gamma\left(\frac{1}{r}, q(\sigma) \right),$$

where

$$q(\sigma) = \frac{A_0}{2} \int_{-\infty}^{\sigma} e^{r(f_0(s)+as)}\, ds,$$

Γ is the gamma function, and γ is the incomplete gamma function defined by

$$\gamma(\alpha, z) = \frac{z^{-\alpha}}{\Gamma(\alpha)} \int_0^z e^{-t} t^{\alpha-1}\, dt.$$

To facilitate the analysis of the integral equation, let us introduce the change of variables

$$\eta = a\tau + \log\left(\frac{B_0}{b\sqrt{a}}\right) \quad \text{and} \quad u(\eta) = f_0(\tau).$$

In these new coordinates, (4.13) takes the form

$$u(\eta) = \int_{-\infty}^{\eta} \frac{e^{u(\sigma)+\sigma}}{\sqrt{\pi(\eta-\sigma)}} F_r\left(\lambda_r \int_{-\infty}^{\sigma} e^{r(u(s)+s)}\, ds\right) d\sigma. \tag{5.1}$$

The function F_r appearing above is defined by

$$F_r(x) = \frac{\Gamma\left(\frac{1}{r}\right)}{r}\, \gamma\left(\frac{1}{r}, x\right) \quad \text{for} \quad x > 0, \quad \text{with} \quad F_r(0) = 1,$$

and the parameter λ_r is the ratio

$$\lambda_r = a^{r/2-1} \frac{A_0 b^r}{2B_0^r} \geq 0.$$

Note that in the limiting case $r = 2$,

$$F_2(x) = \frac{\sqrt{\pi}}{2} \frac{\operatorname{erf}(\sqrt{x})}{\sqrt{x}}$$

and

$$\lambda_2 = \frac{A_0 b^2}{2B_0^2}.$$

A number of observations should be made about the parameter λ_r and the function F_r defined above. First, in the limiting case, $\lambda = 0$ ($F_r \equiv 1$), equation (5.1) reduces to the integral equation derived by Liñàn and Williams [1], Kapila [2], and Olmstead [3]. It is known that this equation has a solution u that is positive and monotonically increasing, with the asymptotic behavior

$$u \sim e^{\eta} + \frac{1}{\sqrt{2}} e^{2\eta} + \cdots \quad \text{as} \quad \eta \to -\infty,$$
$$u \sim -\frac{1}{2} \log(\eta^* - \eta) + \cdots \quad \text{as} \quad \eta \to \eta^*,$$

with $\eta^* \approx -0.431$ determined numerically. Also, for every value of r, F_r is positive monotonically decreasing, with $F_r \to 0$ as its argument tends to infinity. If $r = 1$, then (5.1) is exactly that obtained by Lasseigne and Olmstead [4] governing ignition of a solid half-space with first order Arrhenius reaction and accounting for reactant consumption. They found that there is a critical value of the parameter λ_1 such that, for values less than this critical value, the solution u becomes unbounded in finite time—it is this unbounded behavior that is taken to signal the onset of ignition.

For values of λ_1 larger than this critical value, the solution remains bounded for all finite time. It is the decaying nature of F_r that serves to inhibit initiation of a polymerization front. This is the case for all r on $1 < r \leq 2$. However, for fixed x note that $(d/dr)\, F_r(x) > 0$. Hence, as r increases, F_r decays less rapidly. As will be shown in section 5.3, $r = 2$ appears to be an upper limit for the possible existence of solutions exhibiting the type of logarithmic singularity analogous to those discussed in [3] and [4].

5.1. Existence of solutions to the integral equation. We continue the analysis by establishing the existence of solutions to (5.1). This is useful because it will establish a lower bound on the time of initiation. To that end, let us consider the class of bounded functions

$$S = \{u : (-\infty, \tilde{\eta}] \to [0, N]\},$$

where $\tilde{\eta} > -\infty$ and $0 < N < \infty$. Additionally, let the integral operator T be given by

$$Tu \longmapsto \int_{-\infty}^{\eta} \frac{e^{u(\sigma)+\sigma}}{\sqrt{\pi(\eta-\sigma)}} F_r\left(\lambda_r \int_{-\infty}^{\sigma} e^{r(u(s)+s)}\, ds\right) d\sigma \quad \text{for} \quad \eta \leq \tilde{\eta},\ u \in S.$$

Conditions on $\tilde{\eta}$ and N are sought to ensure that T is a contraction on S. First, observe that, for $u \in S$,

$$Tu \leq e^N I_0(\eta; r, \lambda_r),$$

where

$$I_0(\eta; r, \lambda_r) = \int_{-\infty}^{\eta} \frac{e^{\sigma}}{\sqrt{\pi(\eta-\sigma)}} F_r\left(\frac{\lambda_r}{r} e^{r\sigma}\right) d\sigma.$$

Second, let u_1 and u_2 be elements of S. Then

$$|Tu_1 - Tu_2| \leq \sup_{u_1, u_2 \in S} |u_1 - u_2| \left\{ e^N I_0(\eta; r, \lambda_r) + e^{(r+1)N} I_1(\eta; r, \lambda_r) \right\},$$

where

$$I_1(\eta; r, \lambda_r) = \lambda_r \int_{-\infty}^{\eta} \frac{e^{(r+1)\sigma}}{\sqrt{\pi(\eta-\sigma)}} \left| F_r'\left(\frac{\lambda_r}{r} e^{r\sigma}\right) \right| d\sigma.$$

Since I_0 and I_1 are monotonic increasing in η, we can conclude that T is a contraction on S, provided

$$I_0(\tilde{\eta}; r, \lambda_r) \leq N e^{-N} \tag{5.2}$$

and

$$e^N I_0(\tilde{\eta}; r, \lambda_r) + e^{(r+1)N} I_1(\tilde{\eta}; r, \lambda_r) < 1. \tag{5.3}$$

For given λ_r, there exists a unique pair $\hat{N} < 1,\ \hat{\eta} > -\infty$ such that (5.2) and (5.3) are satisfied as equalities. That is,

$$e^{\hat{N}} I_0(\hat{\eta}; r, \lambda_r) = \hat{N},$$
$$e^{\hat{N}} I_0(\hat{\eta}; r, \lambda_r) + e^{(r+1)\hat{N}} I_1(\hat{\eta}; r, \lambda_r) = 1.$$

Inequalities (5.2) and (5.3) are satisfied for $N = \hat{N}$ and any choice of $\tilde{\eta} < \hat{\eta}$. We note that the value of $\hat{\eta}(\lambda_r)$ provides a lower bound on the time of initiation for given λ_r. Moreover, $\hat{N}$ and $\hat{\eta}$ have the following asymptotic expansions for $\lambda_r \ll 1$ and $\lambda_r \to \infty$:

$$\hat{N} \sim 1 - \frac{\lambda_r}{(r+1)^{3/2}} + \cdots,$$
$$\hat{\eta} \sim -1 + \frac{\lambda_r}{re^r(r+1)^{3/2}} + \cdots \quad \text{as} \quad \lambda \to 0$$

and

$$\hat{N} \sim \hat{N}_\infty + \cdots,$$
$$\hat{\eta} \sim \lambda_r^{2/r}\left(\frac{\pi}{4\Gamma^2(\frac{1}{r})} r^{2-2/r}\right)\hat{N}_\infty^2 e^{-2\hat{N}_\infty} + \cdots \quad \text{as} \quad \lambda \to \infty.$$

The value $\hat{N}_\infty$ is the solution to the transcendental equation $\hat{N}_\infty = (1 - \hat{N}_\infty)e^{-r\hat{N}_\infty}$. For $1 < r \le 2$, the value of $\hat{N}_\infty$ is such that $0.33 \le \hat{N}_\infty < 0.41$. Also, $r \le 2$ and $\hat{\eta} = O(\lambda_r^{2/r})$ as $\lambda_r \to \infty$ suggests that the onset of initiation can be delayed as long as desired by taking λ_r sufficiently large.

We anticipate two qualitatively different types of solutions to (5.1), depending on the value of λ_r. Self-consistent analyses for solutions that remain bounded in finite time and those that exhibit an unbounded singularity at a finite time are sought. Such solutions are interpreted as indicating noninitiation and initiation of a front, respectively. Moreover, for a given r, there is a critical value λ_r^c separating the initiation and noninitiation regimes.

5.2. Noninitiation solutions. First, we consider the existence of solutions bounded for all finite η. To this end, assume that the solution u has the following form:

$$u \sim C\eta^d \quad \text{as} \quad \eta \to \infty, \tag{5.4}$$

where C and d are constants to be determined. If $\lambda_r > 0$ and $d < 1$, then (5.4) implies

$$e^{u+\eta}F_r\left(\lambda_r \int_{-\infty}^{\eta} e^{r(u+s)}\, ds\right) \sim \frac{\Gamma(\frac{1}{r})}{r}\left(\frac{r}{\lambda_r}\right)^{1/r} \quad \text{as} \quad \eta \to \infty.$$

For each $\eta \gg 1$, we can write

$$u(\eta) = C_0 + J(\eta),$$

where J is defined as

$$J(\eta) = \frac{1}{\sqrt{\pi}} \int_0^{\eta} \frac{e^{u+\eta}}{\sqrt{\eta - \sigma}} F_r\left(\lambda_r \int_{-\infty}^{\sigma} e^{r(u+s)}\, ds\right) d\sigma.$$

Employing the asymptotic techniques given in [7], we find that, as $\eta \to \infty$,

$$J(\eta) \sim \frac{2\Gamma(\frac{1}{r})}{r\sqrt{\pi}}\left(\frac{r}{\lambda_r}\right)^{1/r} \eta^{1/2} + \cdots.$$

Hence, u has the form given in (5.4), with the constants determined as

$$C = \frac{2\Gamma(\frac{1}{r})}{r\sqrt{\pi}}\left(\frac{r}{\lambda_r}\right)^{1/r} \quad \text{and} \quad d = \frac{1}{2}.$$

Note that $d < 1$, which is consistent with our initial requirement. If λ_r is large enough so as to advance the damping effect of F_r appearing in the integrand of (5.1), the leading order behavior of the solution is expected to be square root growth. In section 5.4, numerical confirmation of this is presented.

5.3. Initiation solutions. Next, we look for solutions of (5.1) that become unbounded at some finite time value η^*. In the case $\lambda_r = 0$, we know that the solution of (5.1) has a logarithmic singularity as previously discussed. This motivates looking for behavior of the form

$$u \sim -\beta \log(\eta^* - \eta) + \cdots \quad \text{as} \quad \eta \to \eta^*, \tag{5.5}$$

where $\beta = \beta(\lambda_r)$ and $\eta^* = \eta^*(\lambda_r) < \infty$. The analysis is facilitated by translating the singularity to the point at infinity. The techniques given in [7] and [8] can then be used. In the coordinates

$$\rho = (\eta^* - \eta)^{-1}, \qquad v(\rho) = u(\eta),$$

equation (5.1) becomes

$$v(\rho) = \sqrt{\rho}\, e^{\eta^*} \int_0^\rho \frac{e^{v - s^{-1}}}{\sqrt{\pi(\rho - s)}} s^{-3/2} F_r\left(\lambda_r e^{r\eta^*} \int_0^s t^{-2} e^{rv - rt^{-1}}\, dt\right) ds, \tag{5.6}$$

and the asymptotic behavior of v is sought as ρ tends to infinity. The cases $1 < r < 2$ and $r = 2$ must be considered separately as they give rise to different matching requirements.

Suppose $1 < r < 2$ and

$$v \sim \log(\rho^{1/2}) + \log(P) + \log(1 + o(\rho^{1/2})) \quad \text{as} \quad \rho \to \infty, \tag{5.7}$$

where P is constant. Then, as $\rho \to \infty$,

$$\frac{e^{v - 1/\rho}}{\rho^{3/2}} F_r\left(\lambda_r e^{r\eta^*} \int_0^\rho t^{-2} e^{rv - rt^{-1}}\, dt\right) \sim P\rho^{-1} F_r(\lambda_r e^{r\eta^*} I_r(\infty)) + o(\rho^{-1}),$$

where

$$I_r(\infty) = \int_0^\infty \frac{e^{rv - r/t}}{t^2}\, dt < \infty.$$

By the results in [7] and [8], it follows that

$$\int_0^\rho \frac{e^{v - 1/s}}{s^{3/2}} F_r(\lambda_r e^{r\eta^*} I_r(s)) \frac{ds}{\sqrt{\pi(\rho - s)}} \sim \frac{P}{\sqrt{\pi}} F_r(\lambda_r e^{r\eta^*} I_r(\infty)) \rho^{-1/2} \log(\rho) \tag{5.8}$$

as $\rho \to \infty$. Comparison of (5.7) and (5.8) yields

$$P = \frac{\sqrt{\pi} e^{-\eta^*}}{2F_r(\lambda_r e^{r\eta^*} I_r(\infty))}.$$

Hence,

$$v \sim \frac{1}{2} \log(\rho) + O(1) \quad \text{as} \quad \rho \to \infty,$$

and, returning to the previous coordinates, we have

$$u \sim \frac{-1}{2}\log(\eta^* - \eta) + O(1) \quad \text{as} \quad \eta \to \eta^*.$$

Different initial assumptions are needed when $r = 2$. In this case, we look for the solution of (5.6) to have the asymptotic form

$$v \sim \log(\rho^\beta) + \log(1 + o(\rho^\beta)) \quad \text{as} \quad \rho \to \infty. \tag{5.9}$$

Under the assumption (5.9), observe that the integral in the argument of F_2 appearing in (5.6) is finite only if $\beta > 1/2$. That is, matching can occur only if we restrict $\beta > 1/2$; this becomes a consistency condition on the analysis. Supposing that this is the case and that (5.9) holds, we find that

$$\frac{e^{v-\rho^{-1}}}{\rho^{3/2}} F_2\left(\lambda_2 e^{2\eta^*} \int_0^\rho \frac{e^{2v-2t^{-1}}}{t^2}\, dt\right) \sim \frac{\sqrt{\pi}}{2} e^{-\eta^*} \lambda^{-1/2} \rho^{-1} \sqrt{2\beta - 1} + o(\rho^{-1})$$

as $\rho \to \infty$. Then, employing the results in [7] and [8],

$$\rho^{-1/2} e^{-\eta^*} v(\rho) \sim \frac{\lambda_2^{-1/2}}{2} e^{-\eta^*} \sqrt{2\beta - 1}\, \rho^{-1/2} \log(\rho) \quad \text{as} \quad \rho \to \infty. \tag{5.10}$$

Comparing the left- and right-hand sides of this relation and using (5.9), we arrive at the equation for β:

$$\beta(\lambda_2) = \frac{1}{4\lambda_2}\left(1 - \sqrt{1 - 4\lambda_2}\right). \tag{5.11}$$

The following observations should be made about this result. First, note that $\beta > 1/2$, as was required for the derivation. Also, we see that this result makes sense—insofar as β is real—only for values of λ_2 between 0 and 0.25. This seems to suggest an upper bound of 0.25 on the critical value of λ_2. In fact, the numerical analysis confirms this where we find that $\lambda_2^c = 0.11998$. Finally, we note that $\beta \to 1/2$ as $\lambda_2 \to 0$, which is consistent with the results for $r < 2$ and those in [1] and [3] for the $\lambda = 0$ case. In terms of the variables u and η, the asymptotic results for the initiation case are summarized:

$$u \sim -\frac{1}{2}\log(\eta^* - \eta) + \cdots \quad \text{as} \quad \eta \to \eta^*(\lambda_r)$$

for $1 < r < 2$, and

$$u(\eta) \sim -\beta(\lambda_2)\log(\eta^*(\lambda_2) - \eta) + \cdots \quad \text{as} \quad \eta \to \eta^*(\lambda_2)$$

for $r = 2$ with β given by (5.11). In both cases, the value of η^* is to be determined numerically.

5.4. Numerical analysis. Equation (5.1) was solved numerically for several values of r and λ_r. Because the lower bound of the integral is infinite, the asymptotic form of the solution u as $\eta \to -\infty$ is useful. Using the properties of the incomplete

gamma function and the identity

$$\int_{-\infty}^{\eta} \frac{e^{\alpha\sigma}}{\sqrt{\pi(\eta-\sigma)}}\,d\sigma = \frac{e^{\alpha\eta}}{\sqrt{\alpha}} \quad \text{for all} \quad \alpha > 0,$$

we have

$$u \sim e^{\eta} + \frac{1}{\sqrt{2}}e^{2\eta} + \cdots \quad \text{as} \quad \eta \to -\infty, \tag{5.12}$$

$$\int_{-\infty}^{\sigma} e^{r(u+s)}\,ds \sim \frac{1}{r}e^{r\sigma} + \frac{r}{r+1}e^{(r+1)\sigma} + \cdots \quad \text{as} \quad \sigma \to -\infty. \tag{5.13}$$

We then fix $\eta_0 > -\infty$ and assume that for all $\eta, \sigma < \eta_0$ the relations (5.12) and (5.13) hold. Substituting (5.12) and (5.13) into (5.1), we arrive at the following equation, which is solved numerically:

$$u(\eta) = e^{\eta}\text{erfc}\sqrt{\eta-\eta_0} + \frac{1}{\sqrt{2}}e^{2\eta}\text{erfc}\sqrt{2(\eta-\eta_0)} + \int_{\eta_0}^{\eta} \frac{e^{u+\sigma}}{\sqrt{\pi(\eta-\sigma)}} F_r\left(\lambda_r I_r(\sigma)\right)\,d\sigma,$$

where

$$I_r(\sigma) = \frac{1}{r}e^{r\eta_0} + \frac{r}{r+1}e^{(r+1)\eta_0} + \int_{\eta_0}^{\sigma} e^{r(u+s)}\,ds.$$

This approach is similar to that applied by Lasseigne and Olmstead [4]. Moreover, if $r = 1$, the above reduces to the integral equation considered in [4] for a first order reaction term. The accuracy of the numerical methods employed in the current work was tested by comparing the results obtained for $r = 1$ with those in [4]. The value $\eta_0 = -10$ was found to be sufficient to produce reliable results, and this was used for all numerical trials given in this paper.

6. Results and discussion. For convenience, we restate the definition of the parameter λ_r here,

$$\lambda_r = a^{r/2-1}\frac{A_0 b^r}{2B_0^r},$$

and recall that A_0 and B_0 are measures of the consumption rate of initiator and heat release due to conversion of monomer, respectively; r $(1 < r \leq 2)$ is the ratio of activation energies associated with decomposition of initiator and polymer chain propagation. We see that λ_r is small, provided that A_0 is relatively small and B_0 relatively large. Hence, we can consider large values of λ_r to indicate an inadequate amount of initiator (i.e., initiator is consumed too rapidly) or that heat release is insufficient to sustain further reaction. Conversely, small values of λ_r represent a sufficiently exothermic reaction, in which the consumption rate of initiator is small relative to the amount of initiator present in the mixture. Small λ_r values are therefore expected to lead to initiation, while large values of λ_r are not. The appearance of a and b in the ratio is the effect of the inert heating, and the values of these parameters are controlled by the choice of heat source applied. As suggested by the results in [4] and the self-consistent analyses in sections 5.2 and 5.3 of this paper, there exists a critical value of λ_r separating the initiation and noninitiation regimes.

TABLE 6.1
The critical parameter value, λ_r^c, as a function of r.

r	1.5	1.8	1.9	2
λ_r^c	0.6645	0.31086	0.21058	0.11998

TABLE 6.2
Initiation time η^* for selected values of λ_2.

λ_2	0	0.01	0.1	0.117	0.11997
η^*	-0.4310	-0.4287	-0.4088	-0.4048	-0.4037

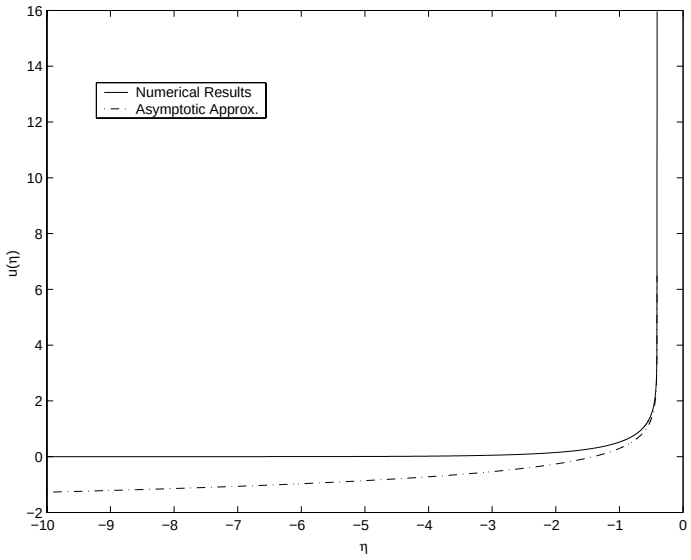

FIG. 6.1. *Initiation solution of the integral equation for $r = 2$ and $\lambda_2 = 0.1$ The solution approaches the asymptotic approximation $U = -\beta(0.1)\log(\eta^* - \eta)$ as $\eta \to \eta^* \approx -0.4088$.*

The critical parameter value, λ_r^c, was determined numerically for different r values. The results are given in Table 6.1. If $\lambda_r < \lambda_r^c$, then the solution exhibits a logarithmic singularity, with the asymptotic behavior described in section 5.3. For values of λ_r larger than λ_r^c, the solution to (5.1) exists and is finite for all η. When λ_r is only slightly larger than the critical value, the solution exhibits behavior on two time scales (see Figure 6.3). The temperature grows slowly while oscillating on a short time scale. This results from the competing effects of the exponential term appearing in (5.1) and the decaying function F_r. If λ_r is increased further, the solution has the leading form described in section 5.2.

The time at which initiation occurs for the case $r = 2$ is given in Table 6.2 for various λ_2, with the critical value found to be 0.11998. Solutions of the types described above for $r = 2$ are shown in Figures 6.1–6.4. In Figure 6.1, λ_2 is less than the critical value. The solution becomes unbounded at $\eta = -0.4088$. The asymptotic results are shown as a dashed curve for comparison. Similarly, Figure 6.2 shows the initiation solution for $\lambda_2 = 0.11997$, just slightly less than the critical value. In both cases, the singular behavior indicates that the temperature progresses beyond the transition stage, and a polymerization front is formed. In contrast, Figures 6.3 and 6.4 show the solution when λ_2 is above the critical value. In Figure 6.3, $\lambda_2 = 0.4$ and the

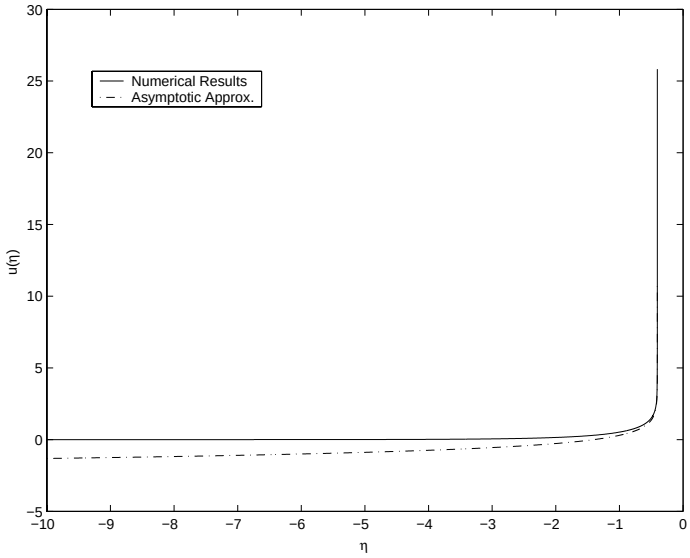

FIG. 6.2. *Initiation solution of the integral equation for* $r = 2$ *and* $\lambda_2 = 0.11997$*, just below the critical value of* 0.11998*. The solution approaches the asymptotic approximation* $U = -\beta(0.11997)\log(\eta^* - \eta)$ *as* $\eta \to \eta^* \approx -0.4037$*.*

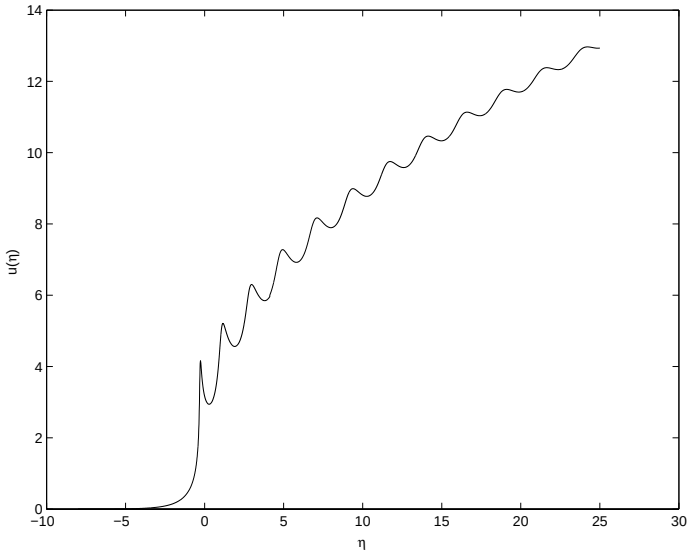

FIG. 6.3. *The noninitiation solution showing oscillation for* $r = 2$ *and* $\lambda_2 = 0.4$*.*

temperature oscillations described can be seen. However, the large scale behavior is slow growth with the oscillations damping as η increases. Figure 6.4 is a plot of the solution when $\lambda_2 = 1$. Here, the solution is monotonic with a change of concavity occurring in a neighborhood of $\eta = 0$. The temperature remains bounded, indicating that a reaction front does not form.

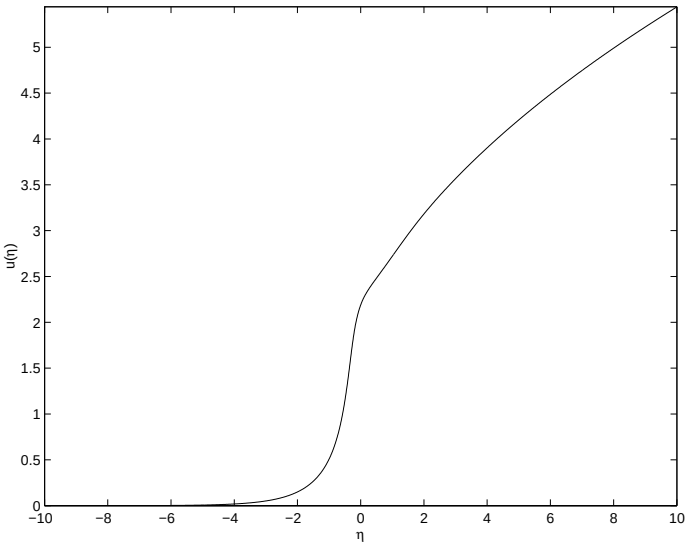

FIG. 6.4. *The noninitiation solution for* $r = 2$ *and* $\lambda_2 = 1$.

7. Summary and conclusion. A reduced system governing a five species reaction model of free radical frontal polymerization was considered, and the temperature was tracked from the inert heating to the transition stage. Through an asymptotic analysis, the integral equation (4.13) arose as the first correction to the inert solution. This integral equation was then rewritten by a change of variables as (5.1), where there appears the parameter λ_r which governs the qualitative behavior of the solution. For a fixed ratio of the activation energies, there is a critical value of the parameter λ_r^c such that the solution of (5.1) has an infinite singularity in finite time if $\lambda_r < \lambda_r^c$ but remains bounded for all time if $\lambda_r > \lambda_r^c$.

The unbounded and bounded types of solutions are taken to indicate initiation and noninitiation in the underlying system, initiation being the formation and onset of propagation of a polymerization front. In the noninitiation case, but for values of λ_r close to the critical value, an oscillatory type of solution was found numerically. The solution remains bounded in this case, and it appears that the oscillations dampen with the growth of the independent variable.

The experimental parameters can be chosen so as to ensure the onset of a thermal front. The critical temperature T_c used in the scaling can be determined by taking $A_0 = 1$ in the relation (3.5). This results in a transcendental equation for T_c,

$$\frac{E_{eff}}{R_g T_c} = \frac{k_d(T_c)}{k_{eff}(T_c)\sqrt{I_0}}.$$

Then, B_0 can be found in terms of the initial amount of monomer and the heat release parameter q, and the values a and b are given in terms of the known flux condition.

Some additional comments regarding the relationship of the integral equation (5.1) to the original system (3.1)–(3.4) and the limitations of the results are in order. First, we have shown that, under certain conditions, the solution to the integral equation (5.1) exhibits an infinite singularity at a finite time. This singular behavior is interpreted as thermal runaway and hence initiation of a polymerization front. This

does not, however, correspond to blow-up of the solution of the original system (3.1)–(3.4) of interest in this study. For the system (3.1)–(3.4), there exists a unique, global solution as indicated by the classical theory of parabolic equations. However, the Arrhenius reaction term produces a large temperature gradient at the site of initiation so that the temperature profile at the end of the tube exhibits a steep increase to the maximum temperature in a thin reaction zone. It is this sharp increase in temperature that is modeled asymptotically by the thermal runaway phenomenon of the integral equation (5.1).

Second, we note that even in the case when thermal runaway occurs in (5.1)—i.e., when the parameter values are such that $\lambda_r < \lambda_r^c$—the front formed requires a sufficiently large amount of initiator present in the mixture for propagation throughout the tube. While it is possible to induce runaway by imposing a sufficiently high level of external energy input at $x = 0$, this case is not of interest since the reaction will die off and the polymer will not be produced. Hence, for the results obtained in this paper to be of practical use, the values of a and b must be assumed to be $O(1)$ and fixed as prescribed by the externally imposed heat flux. Then, the variation in the magnitude of λ_r can be viewed as due to changes in the values of A_0 and B_0, which correspond to the physical and chemical properties of any particular mixture.

EFFECTIVE EQUATIONS FOR SOUND AND VOID WAVE PROPAGATION IN BUBBLY FLUIDS*

NIANQING WANG† AND PETER SMEREKA‡

Abstract. Effective equations that describe both sound wave and void wave propagation for bubbly flows at high Reynolds numbers are derived in this paper. First ideal bubble flows are considered, and a new method for solving Laplace's equation for the velocity potential is presented. This approach is based on a generalization of the method of images and also yields a precise definition of the ambient field experienced by a bubble. With the velocity potential known, the Lagrangian is then computed, and equations of motion for a finite number of bubbles using the Euler–Lagrange equations are derived. The continuum limit is then used to obtain our effective equations. Our expressions for the sound wave and void wave speeds agree well with previous investigations. The effects of gravity and viscosity on void waves are considered. Viscous effects are incorporated using a dissipation function. The steady rise speed and void wave speed for a column of rising bubbles are computed and found to agree well with experiments.

1. Introduction.

In this paper, we derive effective equations for sound and void wave propagation in bubbly fluids. Sound propagation was studied by Carstensen and Foldy [11], who derived the speed of sound using a linear scattering theory developed by Foldy [13]. Iordanskii [21] and van Wijngaarden [48] derived effective equations including nonlinear effects. For review of the literature on acoustic waves in bubbly liquids the reader is referred to the article by van Wijngaarden [49]. Later, Caflisch et al. [9] provided an alternate derivation that clarified the range of validity of the effective equations derived by Iordanskii and van Wijngaarden. These equations are valid when the volume fraction of bubbles is very small. This is, in part, because in these investigations it was assumed that bubbles would undergo only radial motion. In order to develop equations valid at higher volume fraction, one must include the effects of bubble translation. This has been investigated by Crespo [12], Noordzij and van Wijngaarden [32], Caflisch et al. [10], and Sangani [38], among others. Crespo used volume averaged equations of motion, which are valid for low frequency perturbations. He then linearized these equations of motion and computed the speed of sound waves, the results of which were found to be in good agreement with experiments. Caflisch et al. [10] linearized the equations of motion and used a multiple-scale method. Their computation of the wave speed is valid only for small frequencies and was in agreement with the results of Crespo. Sangani also linearized the equations of motion and then performed ensemble averaging. He also computed the wave speed, and his expression was valid over a wide range of wave frequencies. Sangani's results compare well to the experimental results of Silberman [40]. In this work we shall derive equations of motion that are fully nonlinear and valid over a wide range of frequencies. Our

calculation of the sound speed agrees with those of previous investigators.

There has been considerable work on void wave propagation for ideal bubbly flows where the bubbles are considered to be rigid spheres surrounded by an incompressible, inviscid, irrotational fluid. For example, Biesheuvel and van Wijngaarden [8], Geurst [17, 18], Biesheuvel and Gorissen [6], Wallis [47], Pauchon and Smereka [34], Zhang and Prosperetti [56], and Park, Drew, and Lahey [33], among others, have derived effective equations using various types of averaging. The motion of individual bubbles was studied numerically by Sangani and Didwania [39] and Smereka [42]. Smereka used the point bubble approximation combined with Euler–Lagrange equations to obtain explicit equations of motion which were integrated numerically. Sangani and Didwania used a multipole method together with Newton's law to simulate bubble motion. Both investigations observed that in many situations a spatially uniform mixture of bubbles moving with approximately the same velocity was unstable and the bubbles would form clusters. In should also be mentioned that van Wijngaarden [53] predicted that bubbly flows would have a tendency to cluster. We speculate that the instability of the spatially uniform mixture of bubbles is consistent with the ill-posed effective equations found by Geurst [17], Wallis [47], and Pauchon and Smereka [34] for dilute bubbly flows.

It was also found by Sangani and Didwania [39] and Smereka [42] that, if gravity and viscosity were included, the clustering was much more pronounced. Smereka constructed a Lyapunov function and showed that bubbles have a strong tendency to maximize their virtual mass in the direction of motion. This means that the bubbles will form pancake-shaped clusters. The dynamics of clustering has been studied in more detail by Yurkovetsky and Brady [55] and Galper and Miloh [16]. Many aspects of bubbly flows with potential flow interaction have also been discussed in the review article by Koch and Hill [24].

In an effort to understand the numerical simulations of Sangani and Didwania and Smereka, Russo and Smereka [37] wrote the equations of motion for individual bubbles in Hamiltonian form (using the point bubble approximation) and then deduced a kinetic equation for the probability density of the bubbles in phase space. They proved that the spatially uniform case was unstable, provided that the variance of the bubble's velocity was sufficiently small. On the other hand, they proved that, if the variance of the bubble's velocity was sufficiently large, the spatially uniform bubbly fluid was stable. Similar results were obtained by Spelt and Sangani [45]. Herrero, Lucquin-Desreux, and Perthame [20] were able to provide a more rigorous derivation of the equations derived by Russo and Smereka and remove an important assumption.

The effects of liquid viscosity have also been considered by van Wijngaarden and Kapteyn [52] and van Wijngaarden [53]. Van Wijngaarden and Kaptyen computed the drag force on a pair of bubbles using an energy dissipation argument. They then computed averaged equations using ensemble averages over pairs of bubbles. The results were used to compute the profile of a wave of steady shape. Van Wijngaarden used the results of van Wijngaarden and Kapteyn to compute the rise speed of a mixture of bubbles. The result is in good agreement with experimental data.

More recently, Lammers and Biesheuvel [26] studied void waves in bubbly flows using a theory of Batchelor [4]. They find that the speed c of void waves is given by

$$c = U_0(\beta) + \beta U_0'(\beta), \tag{1}$$

where U_0 is the rise speed of the bubbles and β is the void fraction. They measure both c and U_0 and find that they agree well with (1). In the current work we also

obtain (1) by a different approach. In addition, we calculate U_0 and find that it agrees closely with the experimental results of Lammers and Biesheuvel.

2. Outline. We shall derive effective equations by first computing the equations of motion of N bubbles surrounded by an ideal liquid of infinite extent. We assume that the bubbles are spherical but may change their radius. To fix ideas let us first consider a single spherical gas bubble in a liquid which is at rest at infinity. The equations of motion are well known; they are

$$R\ddot{R} + \frac{3}{2}\dot{R}^2 - \frac{1}{4}|\mathbf{U}|^2 + \frac{p_\infty - P}{\rho_\ell} = 0, \tag{2}$$

$$\frac{1}{3}\dot{\mathbf{U}} + \frac{\dot{R}}{R}\mathbf{U} = 0, \tag{3}$$

where $R(t)$ is the bubble radius, $\mathbf{U}(t)$ is the bubble velocity, ρ_ℓ is the density of the liquid, p_∞ is the pressure at infinity, and P is the pressure inside the bubble. Surface tension is neglected for the purpose of simplicity. Equation (2) with $\mathbf{U} = 0$ can be found in Lamb [25], for example. The inclusion of (3) can be found in Hermans [19], for example.

Next we consider the situation in which the surrounding liquid is uniformly accelerated. The equations of motion are

$$R\ddot{R} + \frac{3}{2}\dot{R}^2 - \frac{1}{4}|\mathbf{U} - \mathbf{v}|^2 + \frac{p_\infty - p_g}{\rho_\ell} = 0, \tag{4}$$

$$\frac{1}{3}\dot{\mathbf{U}} - \dot{\mathbf{v}} + \frac{\dot{R}}{R}(\mathbf{U} - \mathbf{v}) = 0, \tag{5}$$

where $\mathbf{v}$ is the velocity of the liquid at infinity. The equations of motion in this case are derived by first obtaining the pressure at the bubble surface from Bernoulli's law and then demanding that the average pressure on the surface be equal to the pressure inside the bubble and that total force on the bubble be zero. Equation (5) can be found in Batchelor [3, p. 455].

Let us consider the situation with N bubbles surrounded by a fluid of infinite extent initially at rest. The bubbles are then set into motion. It is plausible to think that each bubble moves only according to certain "ambient" fields. Therefore we write the equations of motion, heuristically, for the kth bubble as

$$R_k\ddot{R}_k + \frac{3}{2}\dot{R}^2 - \frac{1}{4}|\mathbf{U}_k - \mathbf{v}_A(k)|^2 + \frac{p_A(k) - P_k}{\rho_\ell} = 0, \tag{6}$$

$$\frac{1}{3}\dot{\mathbf{U}}_k - \frac{D_?}{Dt}\mathbf{v}_A(k) + \frac{\dot{R}_k}{R_k}(\mathbf{U}_k - \mathbf{v}_A(k)) = 0, \tag{7}$$

where $\mathbf{v}_A(k)$ and $p_A(k)$ are the ambient liquid velocity and the ambient pressure of the kth bubble, which must be determined. $\frac{D_?}{Dt}$ denotes a material derivative associated to a velocity field yet to be determined. One of the key results of this paper is a systematic way to determine these ambient fields.

2.1. Summary and approach. Our approach is as follows. First consider a finite number of bubbles in an infinite expanse of fluid. We assume that the fluid motion is irrotational, inviscid, incompressible, and at rest at infinity. We also assume that the bubbles are spherical. We then derive equations of motion for this finite collection of bubbles using Lagrange's variational principal as outlined in Lamb [25]

or Milne-Thompson [30], for example. This requires one to compute the velocity potential. We develop a new method to solve for the velocity potential. The method is an extension of the method of images for two bubbles (e.g., Lamb [25]) to multiple bubbles. We prove that this method is convergent.

With the velocity potential known, we can calculate the Lagrangian for a finite number of bubbles. In principle we could calculate the exact equations of motion; however, they would be extremely complex. Instead we truncate our equations of motion and include only terms involving monopoles and dipoles. In addition, we are able to systematically deduce the ambient fields. We then take the continuum limit of our discrete equations of motion and find the following effective equations:

$$R\frac{d^2R}{dt^2} + \frac{3}{2}\left(\frac{dR}{dt}\right)^2 - \frac{1}{4}|\mathbf{U}-\mathbf{v}|^2 + \frac{p-p_g(R)}{\rho_\ell} = 0, \tag{8}$$

$$\frac{1}{3}\frac{d\mathbf{U}}{dt} - \frac{D\mathbf{v}}{Dt} + \frac{1}{R}\frac{dR}{dt}(\mathbf{U}-\mathbf{v}) + (\mathbf{U}-\mathbf{v})\times(\nabla\times\mathbf{v}) = 0, \tag{9}$$

where $\frac{d}{dt} = \partial_t + \mathbf{U}\cdot\nabla$ and $\frac{D}{Dt} = \partial_t + \mathbf{v}\cdot\nabla$. The dependent variables are now functions of space and time (e.g., $R = R(\mathbf{x}, t)$). The ambient pressure p and ambient liquid velocity $\mathbf{v}$ are related as follows:

$$\mathbf{v} = \nabla\psi \quad \text{and} \quad p = p_\infty - \frac{\partial\psi}{\partial t} - \frac{1}{2}|\mathbf{v}|^2,$$

where p_∞ is the pressure at infinity and ψ is the ambient velocity potential. An explicit expression for ψ is given by (42). We also establish that, to leading order, $\mathbf{v}$ is the volume averaged liquid velocity.

We also consider the effects of gravity and liquid viscosity. We include the viscous effects by using the energy dissipation method. Our approach is similar to that of van Wijngaarden and Kapteyn [52] and van Wijngaarden [53] except that we do not use the assumption of pairwise interaction. When we pass to the continuum limit we find that, to leading order, the drag force on a bubble, in the case of zero volume flux, is

$$12\pi\mu R(\mathbf{U} - 2\mathbf{v} - \mathbf{w}).$$

The expression for $\mathbf{w}$ is given by (79) in section 5. The above formula in one space dimension can be written as

$$12\pi\mu R(1 + \beta + \beta^2)(U - v).$$

This formula is also valid for all cases when the volume flux is constant in time.

We include this formula in our model along with effects of gravity to study the propagation of void waves in bubbly flow. Work of Sangani and Didwania [39] and Smereka [42] suggest that the potential flow approximation cannot be used for void wave propagation in bubbly flows since it predicts strong clustering of the bubbles, which is something not observed in experiments. Recent experiments of Zenit, Koch, and Sangani [58] show that there is some clustering but not to the extent predicted in [39, 42].

We show that our model has a steady solution which corresponds to a spatially homogeneous bubble mixture; the computed velocity is in good agreement with experiments. Furthermore, we demonstrate that this steady solution is unstable, which is in agreement with [39, 42]. We then argue that for naturally occurring perturbations the instability is rather weak. The propagation of these perturbations corresponds to void waves. We calculate the speed of these waves and find that our calculations agree closely with experimental results.

3. Equations of motion. We neglect liquid viscosity and gravity in this chapter. The total energy, the sum of the kinetic energy of the liquid and potential energy stored in the bubbles, is conserved. The Lagrangian is calculated, and the Euler–Lagrange equations give the equations of motion. The velocity potential, given as a convergent series, and its combinatorial properties play an important role in the derivation.

3.1. Velocity potential. For a flow with N disjoint spherical bubbles, we want to find the velocity potential satisfying

$$\triangle\phi = 0 \quad \text{outside the bubbles,} \tag{10}$$

$$\frac{\partial\phi}{\partial n} = \mathbf{U}_i \cdot \mathbf{n} + \dot{R}_i \quad \text{on the surface of bubble } i,\ i = 1, \dots, N, \tag{11}$$

$$\nabla\phi = 0 \quad \text{at infinity,} \tag{12}$$

where $\dot{R}_i$, $\mathbf{U}_i$ are radial and translational velocities of bubble i, $\mathbf{n}$ is the unit normal vector pointing toward the liquid phase on the surface, and

$$\frac{\partial\phi}{\partial n} = \mathbf{n} \cdot \nabla\phi$$

is the directional derivative along $\mathbf{n}$. We have the following result concerning the solution of (10)–(12).

THEOREM 3.1. *Let*

$$\phi_i(\mathbf{r}) = -\frac{R_i^2 \dot{R}_i}{|\mathbf{r} - \mathbf{x}_i|} + \frac{1}{2} R_i^3 \nabla_r \left(\frac{1}{|\mathbf{r} - \mathbf{x}_i|} \right) \cdot \mathbf{U}_i. \tag{13}$$

Here ϕ_i is the solution if only the ith bubble is present. The solution of (10)–(12) *can be written as the uniformly convergent series in the liquid,*

$$\phi = \sum_{i_1=1}^{N} \phi_{i_1} + \sum_{\substack{i_1, i_2 = 1 \\ i_1 \neq i_2}}^{N} I_{i_1} \phi_{i_2} + \cdots + \sum_{\substack{i_1, \dots, i_k = 1 \\ i_\ell \neq i_{\ell+1}}}^{N} I_{i_1} I_{i_2} \cdots I_{i_{k-1}} \phi_{i_k} + \cdots, \tag{14}$$

where I_i refers to the image potential operator with respect to bubble i. I_i is defined as follows: let $f(\mathbf{x})$ be a harmonic function inside the ith bubble and let $g(\mathbf{x})$ be a harmonic function outside the ith bubble such that

$$\frac{\partial f}{\partial n} = -\frac{\partial g}{\partial n} \tag{15}$$

on the surface of the ith bubble; then g is called the image potential of f with respect to bubble i with the notation $g = I_i f$.

We note that this is a generalization of the method of images used to solve the motion of two spheres as outlined in Lamb [25].

Next we define the ambient velocity potential experienced by the jth bubble to be

$$\psi_j = \sum_{i_1 \neq j}^{N} \phi_{i_1} + \sum_{\substack{i_1, i_2 = 1 \\ i_1 \neq j, i_1 \neq i_2}}^{N} I_{i_1} \phi_{i_2} + \cdots + \sum_{\substack{i_1, \dots, i_k = 1 \\ i_1 \neq j, i_\ell \neq i_{\ell+1}}}^{N} I_{i_1} I_{i_2} \cdots I_{i_{k-1}} \phi_{i_k} + \cdots. \tag{16}$$

The ambient liquid velocity experienced by bubble j is defined as $\mathbf{v}_j = \nabla\psi_j$. In the expression for ψ_j we see that the final image reflection of each term is not with respect to bubble j. This means that ψ_j is harmonic inside bubble j and $I_j\psi_j$ is well defined.

It is easy to derive two useful expressions,

$$\phi = \phi_j + \psi_j + I_j\psi_j \tag{17}$$

and

$$\psi_j = \sum_{j\neq k} \left(\phi_k + I_k\psi_k\right). \tag{18}$$

Most of the proof of Theorem 3.1 will be in Appendix A. Here we only outline the proof of convergence and show that ϕ satisfies the boundary condition (11). To prove the latter, we first notice that

$$\frac{\partial\phi_i}{\partial n} = \mathbf{U}_i \cdot \mathbf{n} + \dot{R}_i$$

on the surface of bubble i. Thus ϕ_i is the exact solution of (10)–(12) for one bubble. In the case of multiple bubbles, it follows from (17) that

$$\frac{\partial\phi}{\partial n} = \frac{\partial\phi_i}{\partial n} + \frac{\partial\psi_i}{\partial n} + \frac{\partial I_i\psi_i}{\partial n}.$$

From the definition of the operator I, we have

$$\frac{\partial\psi_i}{\partial n} = -\frac{\partial I_i\psi_i}{\partial n}$$

at the surface of the bubble i. Hence we find

$$\frac{\partial\phi}{\partial n} = \frac{\partial\phi_i}{\partial n} = \mathbf{U}_i \cdot \mathbf{n} + \dot{R}_i.$$

To prove convergence we first separate the series into N subseries (one for each bubble), each of which is harmonic in the region exterior to the corresponding bubble. We then prove that this series converges in the energy norm. This allows us to prove that the velocity potential converges on the surface of the corresponding bubble. This enables us to find the velocity potential on the bubble surface. The Poisson kernel for the exterior Dirichlet problem is used to prove that the series converges at each point in the liquid to a solution of Laplace's equation. The details can be found in Appendix A.

3.1.1. Example. To understand some of the preceding formulas more easily it is useful to write them explicitly for the case $N = 2$. We begin with

$$\phi = \phi_1 + \phi_2 + I_1\phi_2 + I_2\phi_1 + I_2I_1\phi_2 + I_1I_2\phi_1 + I_2I_1I_2\phi_1 + I_1I_2I_1\phi_2 + \cdots.$$

The ambient velocity potential for the first bubble is

$$\psi_1 = \phi_2 + I_2\phi_1 + I_2I_1\phi_2 + I_2I_1I_2\phi_1 + \cdots.$$

3.1.2. The image operator. The following theorem provides an explicit formula for the image potential with respect to a bubble centered at $\mathbf{x} = \mathbf{p}$ with radius R (denoted B).

THEOREM 3.2. *If $f(\mathbf{x})$ is harmonic inside a bubble centered at $\mathbf{p}$ with radius R, then*

$$I_B f(\mathbf{x}) = \sum_{n=1}^{\infty} \frac{(-1)^n R^{2n+1} \nabla^n f(\mathbf{p}) \cdot \nabla_{\mathbf{x}}^n (\frac{1}{|\mathbf{x}-\mathbf{p}|})}{(n-1)!(n+1)(2n-1)!!}$$
$$= -\frac{1}{2} R^3 \nabla f(\mathbf{p}) \cdot \nabla_{\mathbf{x}} \left(\frac{1}{|\mathbf{x}-\mathbf{p}|} \right) + \textit{(higher order harmonics)}.$$

The proof is given in Appendix B.

This theorem expresses the image potential as an expansion of spherical harmonics centered at $\mathbf{p}$. With this theorem, (14) can be written as a multipole series, and it becomes a natural extension of the twin spherical expansion method, which is commonly used when solving Laplace's equation outside two spheres (e.g., Ross [36] or Jeffrey [22]). ∇^n is the nth order matrix of partial derivatives, i.e.,

$$\nabla^n = \frac{\partial^n}{\partial x_{k_1} \partial x_{k_2} \cdots \partial x_{k_n}},$$

where $k_j = 1, 2$, or 3, with $j = 1, \ldots, n$. $\nabla^n f \cdot \nabla^n g$ denotes the scalar product of two nth order matrices.

3.2. Kinetic energy and potential energy. The kinetic energy of the liquid is

$$K = \frac{1}{2}\rho_\ell \int_{V_\ell} |\nabla\phi|^2 dv = \frac{1}{2}\rho_\ell \int_{V_\ell} \nabla \cdot (\phi \nabla\phi) dv = -\frac{1}{2}\rho_\ell \sum_{j=1}^{N} \int_{S_j} \phi \frac{\partial \phi}{\partial n} ds, \tag{19}$$

where ρ_ℓ is the density of the liquid, V_ℓ is the volume occupied by the liquid, and S_i is the surface of the ith bubble. From (17), we have

$$K = -\frac{1}{2}\rho_\ell \sum_{j=1}^{N} \int_{S_j} (\phi_j + \psi_j + I_j\psi_j)(\dot{R}_j + \mathbf{U}_j \cdot n) ds.$$

Substituting (13) into the above expression, we obtain

$$K = -\frac{1}{2}\rho_\ell \sum_{j=1}^{N} \int_{S_j} \left(-R_j \dot{R}_j - \frac{1}{2} R_j \mathbf{U}_j \cdot \mathbf{n} + \psi_j + I_j\psi_j \right) \cdot (R_j + \mathbf{U}_j \cdot \mathbf{n}) ds.$$

Next, we use the expressions in Appendix C, and the kinetic energy of the liquid becomes

$$K = 2\pi\rho_\ell \sum_{i=1}^{N} \left(R_i^3 \dot{R}^2 + \frac{1}{6} R_i^3 \mathbf{U}_i^2 - R_i^2 \dot{R}_i \psi_i(\mathbf{x}_i) - \frac{1}{2} R_i^3 \mathbf{U}_i \cdot \mathbf{v}_i(\mathbf{x}_i) \right). \tag{20}$$

The first two terms in the parentheses correspond to the energy generated by the motion of each individual bubble, as if no other bubbles exist. The last two terms are caused by the interactions between the bubbles through the ambient fields ψ_i and $\mathbf{v}_i$.

We assume that there is no heat transfer involved in the radial oscillation of the bubbles and that the adiabatic constant for the gas is γ. Therefore the pressure inside the bubble is

$$p_g(R) = p_\infty \left(\frac{\rho_0}{\rho}\right)^\gamma = p_\infty \left(\frac{R_0}{R}\right)^{3\gamma}.$$

Therefore the potential energy for a single bubble is

$$\begin{aligned} -\int_{R_0}^{R} 4\pi R^2 (p_g(R) - p_\infty) dR &= -\int_{R_0}^{R} 4\pi R^2 p_\infty \left(\left(\frac{R_0}{R}\right)^{3\gamma} - 1\right) dR \\ &= 4\pi p_\infty \left(\frac{R_0^{3\gamma} R^{-3\gamma+3}}{3\gamma - 3} + \frac{1}{3}R^3 - \frac{R_0^3}{3\gamma-3} - \frac{1}{3}R_0^3\right). \end{aligned}$$

The total potential energy of the bubbles is

$$\mathcal{U}_g = 4\pi p_\infty \sum_{i=1}^{N} \left(\frac{R_0^{3\gamma} R_i^{-3\gamma+3}}{3\gamma - 3} + \frac{1}{3}R_i^3 - \frac{R_0^3}{3\gamma-3} - \frac{1}{3}R_0^3\right). \tag{21}$$

We remark that the assumption that the bubbles behave adiabatically can be removed by using the approach outlined by Smereka [44].

3.3. Euler–Lagrange equations. With the kinetic and potential energy obtained in the last two sections, we can write the Lagrangian of the system as

$$\mathcal{L} = \mathcal{K} - \mathcal{U}_g.$$

The Euler–Lagrange equations are

$$\begin{aligned} \frac{d}{dt}\frac{\partial \mathcal{L}}{\partial \dot{R}_i} - \frac{\partial \mathcal{L}}{\partial R_i} &= 0, \\ \frac{d}{dt}\frac{\partial \mathcal{L}}{\partial \mathbf{U}_i} - \frac{\partial \mathcal{L}}{\partial \mathbf{x}_i} &= 0. \end{aligned}$$

To simplify notation, $\psi_i, \mathbf{v}_i, \nabla\psi_i$, etc. will be used to refer to their function values at $\mathbf{x}_i$ in the subsequent equations of this section. The following formulas are derived in Appendix D:

$$\frac{\partial K}{\partial \dot{R}_i} = 2\pi\rho_\ell (2R_i^3\dot{R} - 2R_i^2\psi_i), \tag{22}$$

$$\frac{\partial K}{\partial \mathbf{U}_i} = 2\pi\rho_\ell \left(\frac{1}{3}R_i^3\mathbf{U}_i - R_i^3\mathbf{v}_i\right), \tag{23}$$

$$\frac{\partial K}{\partial R_i} = 2\pi\rho_\ell \left(3R_i^2\dot{R}_i^2 + \frac{1}{2}R_i^2|\mathbf{U}_i|^2 - 4R_i\dot{R}_i\psi_i - 3R_i^3\mathbf{U}_i\cdot\mathbf{v}_i + \frac{3}{2}R_i^2|\mathbf{v}_i|^2 + F\right), \tag{24}$$

$$\frac{\partial K}{\partial \mathbf{x}_i} = 2\pi\rho_\ell (-2R_i^2\dot{R}_i\mathbf{v}_i + R_i^3 (\nabla\mathbf{v}_i)^T \cdot (\mathbf{v}_i - \mathbf{U}_i) + G), \tag{25}$$

where F and G involve only $\nabla^2\psi_i, \nabla^3\psi_i, \ldots$, which correspond to spherical harmonics of higher order than a dipole. From the above formulas, we obtain the equations of motion

$$\frac{d}{dt}\left(2R_i^3\dot{R}_i - 2R_i^2\psi_i\right) - \left(3R_i^2\dot{R}_i^2 + \frac{1}{2}R_i^2|\mathbf{U}_i|^2 - 4R_i\dot{R}_i\psi_i - 3R_i^3\mathbf{U}_i\cdot\mathbf{v}_i + \frac{3}{2}R_i^2|\mathbf{v}_i|^2 + F\right) + 2\frac{p_\infty}{\rho_\ell}\left(-R_0^{3\gamma}R_i^{-3\gamma+2} + R_i^2\right) = 0, \tag{26}$$

$$\frac{d}{dt}\left(\frac{1}{3}R_i^3\mathbf{U}_i - R_i^3\mathbf{v}_i\right) - \left(-2R_i^2\dot{R}_i\mathbf{v}_i + R_i^3\left(\nabla\mathbf{v}_i\right)^T\cdot(\mathbf{v}_i - \mathbf{U}_i) + G\right) = 0, \tag{27}$$

$$\psi_i = \sum_{i\neq k}\left(\phi_k(\mathbf{x}_i) + I_k\psi_k(\mathbf{x}_i)\right), \tag{28}$$

$$\mathbf{v}_i = \nabla\psi_i. \tag{29}$$

As it stands, the above system is rather intractable for analysis. To proceed further we must make a simplifying approximation, which will be to keep only terms that arise from monopoles and dipoles. Therefore, the F and G terms in (26) and (27) will be ignored. We will also use this approximation to simplify (28) and (29) as follows: from Theorem 3.2 we have

$$I_k\psi_k(\mathbf{x}_i) = -\frac{1}{2}R_k^3\nabla\psi_k(\mathbf{x}_k)\cdot\nabla_{\mathbf{x}_k}\left(\frac{1}{|\mathbf{x}_i - \mathbf{x}_k|}\right) + (\text{higher order harmonics}),$$

which when used with (29) gives

$$I_k\psi_k(\mathbf{x}_i) = -\frac{1}{2}R_k^3\mathbf{v}_k\cdot\nabla_{\mathbf{x}_k}\left(\frac{1}{|\mathbf{x}_i - \mathbf{x}_k|}\right) + (\text{higher order harmonics}).$$

Next, we combine the above formula with (28) to obtain

$$\psi_i = \sum_{k\neq i}\left[-\frac{R_k^2\dot{R}_k}{|\mathbf{x}_i - \mathbf{x}_k|} + \frac{1}{2}R_k^3\nabla_{\mathbf{x}_i}\left(\frac{1}{|\mathbf{x}_i - \mathbf{x}_k|}\right)\cdot(\mathbf{U}_k - \mathbf{v}_k)\right] + (\text{higher order harmonics}).$$

Thus by ignoring the terms caused by spherical harmonics of orders higher than dipole, (26)–(29) simplify to

$$\frac{d}{dt}(R_i^3\dot{R}_i - R_i^2\psi_i) - \left(\frac{3}{2}R_i^2\dot{R}_i^2 + \frac{1}{4}R_i^2|\mathbf{U}_i|^2 - 2R_i\dot{R}_i\psi_i - \frac{3}{2}R_i^3\mathbf{U}_i\cdot\mathbf{v}_i + \frac{3}{4}R_i^2|\mathbf{v}_i|^2\right) + \frac{p_\infty}{\rho_\ell}(-R_0^{3\gamma}R_i^{-3\gamma+2} + R_i^2) = 0, \tag{30}$$

$$\frac{d}{dt}\left(\frac{1}{3}R_i^3\mathbf{U}_i - R_i^3\mathbf{v}_i\right) - \left(-2R_i^2\dot{R}_i\mathbf{v}_i + R_i^3\left(\nabla\mathbf{v}_i\right)^T\cdot(\mathbf{v}_i - \mathbf{U}_i)\right) = 0, \tag{31}$$

$$\psi_i = \sum_{k\neq i} -\frac{R_k^2\dot{R}_k}{|\mathbf{x}_i - \mathbf{x}_k|} + \frac{1}{2}R_k^3\nabla_{\mathbf{x}_i}\left(\frac{1}{|\mathbf{x}_i - \mathbf{x}_k|}\right)\cdot(\mathbf{U}_k - \mathbf{v}_k), \tag{32}$$

$$\mathbf{v}_i = \nabla_{\mathbf{x}_i}\psi_i = \sum_{k\neq i}\nabla_{\mathbf{x}_i}\left(-\frac{R_k^2\dot{R}_k}{|\mathbf{x}_i - \mathbf{x}_k|} + \frac{1}{2}R_k^3\nabla_{\mathbf{x}_i}\left(\frac{1}{|\mathbf{x}_i - \mathbf{x}_k|}\right)\cdot(\mathbf{U}_k - \mathbf{v}_k)\right). \tag{33}$$

These equations simplify greatly if we define the following ambient pressure motivated using Bernoulli's law. The ambient pressure associated with the ith bubble is defined as

$$\frac{p_i}{\rho_\ell} = \frac{p_\infty}{\rho_l} - \frac{\partial \psi_i}{\partial t} - \frac{1}{2}|\mathbf{v}_i|^2. \tag{34}$$

Then (30) and (31) can be written as

$$R_i\ddot{R}_i + \frac{3}{2}\dot{R}_i^2 - \frac{1}{4}|\mathbf{U}_i - \mathbf{v}_i|^2 + \frac{1}{\rho_\ell}(p_i - p_{g,i}) = 0, \tag{35}$$

$$\frac{1}{3}\dot{\mathbf{U}}_i - \frac{D\mathbf{v}_i}{Dt} + \frac{\dot{R}_i}{R_i}(\mathbf{U}_i - \mathbf{v}_i) = (\mathbf{v}_i - \mathbf{U}_i) \times (\nabla \times \mathbf{v}_i), \tag{36}$$

where

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + \mathbf{v}_i \cdot \nabla \quad \text{and} \quad p_{g,i} = p_\infty \left(\frac{R_0}{R_i}\right)^{3\gamma}.$$

In arriving at (36) we have used the identity

$$-(\mathbf{u} \cdot \nabla)\mathbf{v} + (\nabla \mathbf{v})^T \cdot \mathbf{u} = \mathbf{u} \times (\nabla \times \mathbf{v}).$$

In deriving these equations of motion we have not assumed that $\nabla \times \mathbf{v}_i = 0$; however, it is apparent from (33) that $\nabla \times \mathbf{v}_i = 0$ since $\mathbf{v}_i = \nabla \psi_i$. This means the right-hand side of (36) is zero. Nevertheless, we shall leave (36) in the form we have written since, as we shall see later, the continuum limit of $\mathbf{v}_i$ is not necessarily curl free.

3.3.1. Bubble motion in nonuniform flows. The motion of a bubble in a nonuniform potential flow has been the subject of much interest. If we consider a massless rigid spherical bubble with velocity $\mathbf{U}$ moving in liquid with an ambient velocity $\mathbf{v}$, then the equation of motion is

$$\frac{1}{2}\dot{U} = \frac{3}{2}\left(\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v}\right), \tag{37}$$

where $\mathbf{v}$ is derived from a potential flow, thus $\nabla \times \mathbf{v} = 0$. This equation has been derived by Voinov, Voinov, and Petrov [54], Landweber and Miloh [27], van Wijngaarden [51], and Galper and Miloh [14]. Galper and Miloh [14, 15] also derive extensions of this formula for more complex problems. If $\dot{R}_i = 0$, then we see that (36) reduces to (37), where we have used $\nabla \times \mathbf{v}_i = 0$.

Therefore we see that our computation is in agreement with well-known results. The main contribution of our work is in finding a self-consistent expression for the ambient liquid velocity produced by the motion of the other bubbles.

4. Continuum limit. In the previous section, we derived the equations of motion for a finite number of bubbles. In this section, we will take the continuum limit to obtain our effective equations. This approach is similar to that used by solid state physics to obtain effective equations; see, for example, Batteh and Powell [5] or Rosenau [35]. It also very close to the approach used by Caflisch et al. [9]. This approach is expected to give a faithful approximation, provided that the wavelength of interest is considerably longer than the distance between particles. One of the important parts of this section is taking the continuum limit of (32). This is obtained by approximating the summation by an integration. Let us explain this with the following example.

4.0.1. Example. Consider the situation with N point charges located at $\mathbf{x}_j$ with charge q_j, where $j = 1, \ldots, N$. The ambient electric potential at $\mathbf{x}_i$ is

$$\psi_i(\mathbf{x}_i) = \sum_{i \neq j}^{N} \frac{q_j}{|\mathbf{x}_i - \mathbf{x}_j|}. \tag{38}$$

We suppose that there exists a smooth function $q(\mathbf{x})$ such that $q_j = q(\mathbf{x}_j)$; then this summation can be approximated as

$$\psi(\mathbf{x}) = \int \frac{\rho(\mathbf{y})q(\mathbf{y})}{|\mathbf{x} - \mathbf{y}|} d\mathbf{y}, \tag{39}$$

where $\rho(\mathbf{x})$ is the number of particles per unit volume. Since $-(4\pi|\mathbf{x}|)^{-1}$ is the fundamental solution of Laplace's equation in three space dimensions, then it follows that (39) is equivalent to

$$\triangle \psi = -4\pi q(\mathbf{x})\rho(\mathbf{x}). \tag{40}$$

4.1. Effective equations for bubbly flows. Our equations of motion for a finite number of bubbles are given by (35) and (36), with the ambient field determined from (32), (33), and (34). When passing to the continuum limit, we first assume that there exist functions $R(\mathbf{x}, t)$ and $\mathbf{U}(\mathbf{x}, t)$ such that $R_k(t) = R(\mathbf{x}_k, t)$ and $\mathbf{U}_k(t) = \mathbf{U}(\mathbf{x}_k, t)$. We note that this assumption indicates that we assume that, on length scales less than the wavelength of interest, the bubbles are all "doing the same thing." This assumption implies that neighboring bubbles are oscillating coherently and moving with the same velocity. If we assume that nearby bubbles have the same velocity, then this means that we are studying "cold" bubbly flows; in other words, we are ignoring effects of the fluctuation of the bubbles' velocity. These effects have been studied in simpler models of bubbly flows by Russo and Smereka [37] and Herrero, Lucquin-Desreux, and Perthame [20]. The effects of incoherent bubble oscillations have been considered by, for example, Carstensen and Foldy [11] and Smereka [44] for models that ignore the effects of bubble translation. We also point out that this same assumption was used by Zhang and Prosperetti [57] in what they call sharply peaked probability distributions. As pointed out in [44], this same assumption was used by van Wijngaarden [48] and Caflisch et al. [10].

Now we take the continuum limit of (32), following the approach outlined in the example above, and we find

$$\psi(\mathbf{x}, t) = \int \rho \left(-\frac{R^2(\mathbf{y}, t)\dot{R}(\mathbf{y}, t)}{|\mathbf{x} - \mathbf{y}|} + \frac{1}{2} R^3(\mathbf{y}, t) \nabla_{\mathbf{x}} \left(\frac{1}{|\mathbf{x} - \mathbf{y}|} \right) \cdot (\mathbf{U}(\mathbf{y}, t) - \mathbf{v}(\mathbf{y}, t)) \right) d\mathbf{y},$$

where $\dot{}$ denotes $\frac{d}{dt} = \partial_t + \mathbf{U} \cdot \nabla$ and $\rho = \rho(\mathbf{y}, t)$ is the number of bubbles per unit volume. ρ satisfies the following conservation equation,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{U}) = 0, \tag{41}$$

and is a statement of particle conservation.

Using integration by parts on our expression for ψ, we have

$$\psi(\mathbf{x}, t) = \int \left(-\frac{\rho R^2 \dot{R}}{|\mathbf{x} - \mathbf{y}|} + \frac{1}{2} \frac{\nabla \cdot \left(\rho R^3 (\mathbf{U} - \mathbf{v}) \right)}{|\mathbf{x} - \mathbf{y}|} \right) d\mathbf{y},$$

which is equivalent to

$$\triangle\psi = -4\pi\left(-\rho R^2\dot{R} + \frac{1}{2}\nabla\cdot\left(\rho R^3(\mathbf{U}-\mathbf{v})\right)\right).$$

If we use the void fraction $\beta = \frac{4}{3}\pi R^3\rho$ instead of ρ, the above equation becomes

$$\triangle\psi = \frac{3\beta}{R}\dot{R} - \frac{3}{2}\nabla\left(\cdot\beta(\mathbf{U}-\mathbf{v})\right). \tag{42}$$

In a similar way we see that the continuum limit of (33) is

$$\mathbf{v} = \int\left(-R^2\dot{R}\nabla_{\mathbf{x}}\left(\frac{1}{|\mathbf{x}-\mathbf{y}|}\right) + \frac{1}{2}R^3\nabla^2_{\mathbf{x}}\left(\frac{1}{|\mathbf{x}-\mathbf{y}|}\right)\cdot(\mathbf{U}-\mathbf{v})d\mathbf{y}\right). \tag{43}$$

Caution has to be taken in evaluating the second part of the above integral, as

$$\int\nabla^2_{\mathbf{x}}\left(\frac{1}{|\mathbf{x}-\mathbf{y}|}\right)\cdot\mathbf{p}d\mathbf{y}$$

is singular and the integrand is not integrable. We take the principal value, which is defined. This is justified because bubble i is not in the original sum of (33). From Smereka [43, (27)] we have

$$⨍\nabla^2_{\mathbf{x}}\left(\frac{1}{|\mathbf{x}-\mathbf{y}|}\right)\cdot\mathbf{p}(\mathbf{y})d\mathbf{y} = \frac{4\pi}{3}\mathbf{p}(x) + \nabla_{\mathbf{x}}\int_V\nabla_{\mathbf{x}}\left(\frac{1}{|\mathbf{x}-\mathbf{y}|}\right)\cdot\mathbf{p}(\mathbf{y})d\mathbf{y}, \tag{44}$$

where $⨍$ is the principal value integral. Using the above formula in (43), we obtain

$$\mathbf{v} = \nabla\psi + \frac{\beta}{2}(\mathbf{U}-\mathbf{v}). \tag{45}$$

To obtain an expression for β we start with (41) and use $\beta = \frac{4}{3}\pi R^3\rho$ to obtain

$$\frac{d}{dt}\left(\frac{3\beta}{4\pi R^3}\right) + \left(\frac{3\beta}{4\pi R^3}\right)\nabla\cdot U = 0,$$

which can be simplified to

$$\frac{d\beta}{dt} - \frac{3\beta}{R}\frac{dR}{dt} + \beta\nabla\cdot\mathbf{U} = 0. \tag{46}$$

This is the conservation of volume for the gas phase. If we take the gradient of (45) and substitute it into (42), we find

$$\nabla\cdot(\beta\mathbf{U} + (1-\beta)\mathbf{v}) - \frac{3\beta}{R}\frac{dR}{dt} = 0. \tag{47}$$

This is exactly the conservation of total volume. This indicates that, to the level of our approximation, $\mathbf{v}$ is also the volume averaged liquid velocity. We can make this point even more transparent by subtracting (46) from (47), to obtain

$$\frac{\partial(1-\beta)}{\partial t} + \nabla\cdot((1-\beta)\mathbf{v}) = 0. \tag{48}$$

This is a statement of conservation of liquid volume.

The continuum limit of (35) and (36) are obtained by realizing that $\frac{d}{dt}$ is the material derivative. Collecting our results, we find the following set of effective equations:

$$R\frac{d^2R}{dt^2} + \frac{3}{2}\left(\frac{dR}{dt}\right)^2 - \frac{1}{4}|\mathbf{U}-\mathbf{v}|^2 + \frac{p-p_g}{\rho_\ell} = 0, \tag{49}$$

$$\frac{1}{3}\frac{d\mathbf{U}}{dt} - \frac{D\mathbf{v}}{Dt} + \frac{1}{R}\frac{dR}{dt}(\mathbf{U}-\mathbf{v}) + (\mathbf{U}-\mathbf{v})\times(\nabla\times\mathbf{v}) = 0, \tag{50}$$

$$\triangle\psi - \frac{3\beta}{R}\frac{dR}{dt} + \frac{3}{2}\nabla\cdot(\beta(\mathbf{U}-\mathbf{v})) = 0, \tag{51}$$

$$\mathbf{v} - \nabla\psi - \frac{\beta}{2}(\mathbf{U}-\mathbf{v}) = 0, \tag{52}$$

$$\frac{1}{2}\mathbf{v}^2 + \frac{\partial\psi}{\partial t} + \frac{p-p_\infty}{\rho_\ell} = 0, \tag{53}$$

$$\frac{\partial\beta}{\partial t} + \nabla\cdot(\beta\mathbf{U}) - \frac{3\beta}{R}\frac{dR}{dt} = 0, \tag{54}$$

$$p_g - p_\infty\left(\frac{R_0}{R}\right)^{3\gamma} = 0, \tag{55}$$

where

$$\frac{d}{dt} = \frac{\partial}{\partial t} + \mathbf{U}\cdot\nabla \quad \text{and} \quad \frac{D}{Dt} = \frac{\partial}{\partial t} + \mathbf{v}\cdot\nabla.$$

To summarize, in the above set of effective equations, (49) and (50) are the continuum versions of (35) and (36). Equations (51), (52), and (53) are the continuum versions of (32), (33), and (34), respectively. Finally, (54) is a statement of bubble number conservation (equivalently, conservation of liquid volume), and (55) is the equation of state for the gas contained in the bubbles. The equation for the conservation of liquid volume, (48), shows that the ambient velocity is well approximated by the average liquid velocity.

We observe from (52) that

$$\nabla\times\mathbf{v} = \nabla\psi\times\nabla\left(\frac{2}{2+\beta}\right) + \nabla\times(\beta\mathbf{U}),$$

which is not necessarily zero. This may seem strange since it appears from (33) that $\mathbf{v}_i$ is curl free. However, it is important to note that $\mathbf{v}_i(\mathbf{x})$ has singularities when $\mathbf{x} = \mathbf{x}_k$. In the discrete case these singularities are not important, as is clear from (33). However, when we pass to the continuum limit, these singularities become source terms which cause the continuum limit to have a nonzero curl.

A simple example of this behavior can be understood using the example given in subsection 4.01. It is clear that (38) is a harmonic function of $\mathbf{x}_i$ ($\triangle_{\mathbf{x}_i}\psi_i = 0$) except when $\mathbf{x}_i = \mathbf{x}_k$. The expression for (38) is singular at $\mathbf{x}_i = \mathbf{x}_k$, corresponding to the location of the charges. It is evident from (40) that the continuum limit, (39), of (38) is not harmonic due the presence of the charges.

In a similar way, it follows that while the discrete ambient velocity field $\mathbf{v}_i$ is curl free, the same is not true of the continuum limit. This behavior is not uncommon; for example, in the theory of dielectrics the local electric field is curl free, whereas the ambient field of a continuum of dipoles is not curl free (see, for example Lorrain

and Corson [29]). We are not claiming that this flow has vorticity. The ambient liquid velocity has a nonzero curl, whereas the local liquid velocity is curl free. This may sound contradictory, but it is not; the ambient liquid velocity does not satisfy the Euler equation. Another way to look at this term is that it reflects the vorticity present on the surface of each bubble, and the ambient liquid velocity is a homogenized liquid velocity that accounts for the bubbles. In fact, the net vorticity produced by a single bubble is zero. Therefore if we had a homogeneous suspension of bubbles all moving with same velocity, then $\mathbf{v}$ would be constant in space and $\nabla \times \mathbf{v} = 0$.

It is interesting to compare (50) with work of Auton, Hunt, and Prud'homme [1]. In this work the authors compute the force on a bubble in a nonuniform flow with vorticity. From their work it follows that the equation of motion of the bubble (in our notation) is given by

$$C_M \left(\frac{\partial \mathbf{U}}{\partial t} + \mathbf{U} \cdot \nabla \mathbf{U} \right) = (1 + C_M) \left(\frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} \right) - C_L (\mathbf{U} - \mathbf{v}) \times \boldsymbol{\omega}, \tag{56}$$

where C_M is the added mass coefficient, C_L is the rotational lift coefficient, and $\boldsymbol{\omega}$ is the liquid vorticity. If we choose $C_M = \frac{1}{2}$ and $C_L = \frac{3}{2}$, then we see that our result is the same as theirs (using $\dot{R} = 0$). A priori we should not expect any close relation between (56) and (50), since in (50), $\nabla \times \mathbf{v}$ is not the vorticity of the liquid. In fact, Auton, Hunt, and Prud'homme argue for a spherical bubble that $C_L = \frac{1}{2}$, whereas we find $C_L = \frac{3}{2}$.

4.2. Sound speed. We now study sound propagation for one dimensional flows, and therefore we assume that our dependent variables depend on only one space coordinate, which we take to be x. We linearize (49) through (55) around the equilibrium

$$R = R_0, \quad U = v = \psi = 0, \quad \beta = \beta_0,$$

and obtain the linearized equations

$$\begin{aligned}
&\frac{\partial^2 R}{\partial t^2} + \omega_0^2 R - \frac{1}{R_0} \frac{\partial \psi}{\partial t} = 0, \\
&\frac{\partial U}{\partial t} - 3 \frac{\partial v}{\partial t} = 0, \\
&\frac{\partial^2 \psi}{\partial x^2} = \frac{3\beta_0}{R_0} \frac{\partial R}{\partial t} - \frac{3}{2} \beta_0 \frac{\partial (U - v)}{\partial x}, \\
&v = \frac{\partial \psi}{\partial x} + \frac{\beta_0}{2} (U - v), \\
&\frac{\partial \beta}{\partial t} - \frac{3\beta_0}{R_0} \frac{\partial R}{\partial t} + \beta_0 \frac{\partial U}{\partial x} = 0,
\end{aligned}$$

where the unsubscripted variables represent perturbations from equilibrium and

$$\omega_0 = \sqrt{\frac{3\gamma P_\infty}{\rho_\ell R_0^2}}$$

is the natural frequency of a single bubble in an unbounded fluid.

We let $(R, U, v, \psi, \beta) = (A, B, C, D, E)e^{i(\omega t - kx)}$ and find

$$\begin{pmatrix} -\omega^2+\omega_0^2 & 0 & 0 & -\frac{i\omega}{R_0} & 0 \\ 0 & i\omega & -3i\omega & 0 & 0 \\ -\frac{3i\omega\beta_0}{R_0} & -\frac{3ik\beta_0}{2} & \frac{3ik\beta_0}{2} & -k^2 & 0 \\ 0 & -\frac{\beta_0}{2} & 1+\frac{\beta_0}{2} & ik & 0 \\ -\frac{3\beta_0 i\omega}{R_0} & -ik\beta_0 & 0 & 0 & i\omega \end{pmatrix} \begin{pmatrix} A \\ B \\ C \\ D \\ E \end{pmatrix} = 0.$$

The above equations will have nontrivial solutions when the determinant is zero. Thus, we obtain the dispersion relation

$$3\omega^2\beta_0(1-\beta_0) = k^2R_0^2(1+2\beta_0)(\omega_0^2-\omega^2).$$

The effective sound speed is $c = \frac{\omega}{k}$ and

$$c^2 = \frac{R_0^2(1+2\beta_0)(\omega_0^2-\omega^2)}{3\beta_0(1-\beta_0)}. \tag{57}$$

If we let $\omega \to 0$, we have

$$c_0^2 = \frac{R_0^2(1+2\beta_0)\omega_0^2}{3\beta_0(1-\beta_0)},$$

which is the same as the expression given by Crespo [12] and Caflisch et al. [10]. The sound speed in (57) is also in agreement with Sangani [38]. We note that we have assumed that the liquid is incompressible; therefore to compare with other investigations one must consider the case $C_\ell \to \infty$, where C_ℓ is the speed of sound in the liquid region.

4.3. Void waves. Void waves have been observed, and various properties such as wave speed have been measured. Typically void waves travel at speeds much slower than sound waves. This means that void waves and sound waves interact weakly, and we will not make any significant error if we assume the bubble radius is fixed. In this case our system of equations becomes

$$\frac{1}{3}\frac{d\mathbf{U}}{dt} - \frac{D\mathbf{v}}{Dt} + (\mathbf{U}-\mathbf{v}) \times (\nabla \times \mathbf{v}) = 0, \tag{58}$$

$$\triangle\psi + \frac{3}{2}\nabla \cdot (\beta(\mathbf{U}-\mathbf{v})) = 0, \tag{59}$$

$$\mathbf{v} - \nabla\psi - \frac{\beta}{2}(\mathbf{U}-\mathbf{v}) = 0, \tag{60}$$

$$\frac{\partial\beta}{\partial t} + \nabla \cdot (\beta\mathbf{U}) = 0. \tag{61}$$

These equations simplify greatly if we consider flows in one spatial dimension. In this situation (59) and (60) become

$$\frac{\partial^2\psi}{\partial x^2} + \frac{3}{2}\frac{\partial}{\partial x}(\beta(U-v)) = 0 \quad \text{and} \quad v - \frac{\partial\psi}{\partial x} - \frac{\beta}{2}(U-v) = 0.$$

We eliminate ψ to obtain

$$\frac{\partial}{\partial x}\left((1-\beta)v + \beta U\right) = 0.$$

Since we are in the situation where the volume flux is zero, the above equation indicates that

$$v = \frac{-\beta U}{(1-\beta)}. \tag{62}$$

In the one dimensional case, (58) and (61) become

$$\frac{1}{3}\left(\frac{\partial U}{\partial t} + U\frac{\partial U}{\partial x}\right) - \left(\frac{\partial v}{\partial t} + v\frac{\partial v}{\partial x}\right) = 0, \tag{63}$$

$$\frac{\partial \beta}{\partial t} + \frac{\partial}{\partial x}(\beta U) = 0. \tag{64}$$

If we multiply (63) by 3/2 and use (62), we find

$$\frac{\partial}{\partial t}\left(\frac{(1+2\beta)}{2(1-\beta)}U\right) + \frac{\partial}{\partial x}\left(\frac{(1-2\beta-2\beta^2)}{4(1-\beta)^2}U^2\right) = 0. \tag{65}$$

Next we consider a new variable

$$M = \frac{\beta U}{h(\beta)}, \quad \text{where} \quad h(\beta) = \frac{2\beta(1-\beta)}{1+2\beta}; \tag{66}$$

then (64) and (65) can be written as the following system:

$$\begin{aligned} &\frac{\partial \beta}{\partial t} + \frac{\partial}{\partial x}(h(\beta)M) = 0, \\ &\frac{\partial M}{\partial t} + \frac{\partial}{\partial x}\left(\frac{1}{2}h'(\beta)M^2\right) = 0. \end{aligned} \tag{67}$$

This set of conservation laws can be written as

$$\frac{\partial}{\partial t}\begin{pmatrix} \beta \\ M \end{pmatrix} + \mathsf{A}\frac{\partial}{\partial x}\begin{pmatrix} \beta \\ M \end{pmatrix} = 0, \quad \text{where} \quad \mathsf{A} = \begin{pmatrix} h'(\beta)M & h(\beta) \\ \frac{1}{2}h''(\beta)M^2 & h'(\beta)M \end{pmatrix}. \tag{68}$$

The eigenvalues of A are

$$\lambda = M\left(h'(\beta) \pm \sqrt{\frac{1}{2}h(\beta)h''(\beta)}\right).$$

Upon substituting the expression for $h(\beta)$, we find

$$\lambda = \frac{2M}{(1+2\beta)^2}\left(1-2\beta-2\beta^2 \pm i\sqrt{3\beta(1-\beta)}\right). \tag{69}$$

This dispersion relation shows that the Fourier modes will increase in magnitude at a rate proportional to wave number. This indicates that a spatially uniform bubbly flow is unstable to all perturbations. In fact, the initial value problem for (68) is ill-posed. This is consistent with the bubble clustering observed in the numerical simulations done by Sangani and Didwania [39] and Smereka [42]. In the next section, we will compute the dispersion relation when viscosity and gravity are considered. We will also offer an explanation of the discrepancy between experiments and numerical simulations.

4.4. Comparison with previous work. Geurst [17, 18] derived a set of equations for two-phase flow using a variational method. The same set of equations were derived by Wallis [47] and Pauchon and Smereka [34] using different approaches. The equations contained one phenomenological relation, denoted $m_G(\beta)$, which Wallis calls the exteria. Pauchon and Smereka showed that Geurst's equations simplify greatly in the frame of reference where the volume flux is zero. If we use $m_G(\beta) = \beta/2$ in Guerst's equations (as written by Pauchon and Smereka), we find that they are identical to (67). (Note, however, that Pauchon and Smereka use $\Gamma(\beta)$, which is $1/h(\beta)$). It should also be noted that from the work of Smereka and Milton [41] one can show that the exteria, $m_G(\beta)$, is related to the virtual mass in the zero volume flux frame $m(\beta)$, as follows:

$$m_G(\beta) = \frac{m(\beta)}{\rho_\ell}(1-\beta) - \beta^2. \tag{70}$$

The virtual mass in the zero volume flux frame has been calculated by Zuber [59], van Wijngaarden [50], Biesheuvel and Spolestra [7], Wallis [47], and Smereka and Milton [41]. Zuber's result was

$$m(\beta) = \rho_\ell \frac{\beta}{2}\left(\frac{1+2\beta}{1-\beta}\right).$$

The results of the other investigators were similar. Smereka and Milton showed that Zuber's result was exact for a certain type of bubbly flow. If we substitute Zuber's result into (70), then we find $m_G(\beta) = \beta/2$. Thus we conclude that (67) is the same as that derived by Geurst when Zuber's expression for the virtual mass is used.

5. Effects of liquid viscosity and gravity. In this section, we consider the effects of liquid viscosity and gravity in an effort to understand the dynamics of void waves. We shall assume that the bubble radii are unchanging and of identical sizes.

The effective equations are derived, and the void wave speed obtained is in good agreement with experimental data. We also offer an explanation of why bubble clustering is not observed in experiments.

5.1. Equations of motion. We shall proceed in a fashion similar to that in section 3. The Lagrangian is given by

$$\mathcal{L} = \mathcal{K} - \mathcal{U},$$

where $\mathcal{K}$ is given by (20). The potential energy is modified by gravity as follows:

$$\mathcal{U} = \mathcal{U}_g + \rho_\ell g \sum_{k=1}^{N} \frac{4}{3}\pi R_k^3 z_k,$$

where z_k is the z coordinate of the kth bubble and $\mathcal{U}_g$ is given by (21). We shall include effects of liquid viscosity by using a dissipation function denoted as $\mathcal{D}$. The equations of motion are now

$$\frac{d}{dt}\frac{\partial \mathcal{L}}{\partial \mathbf{U}_i} - \frac{\partial \mathcal{L}}{\partial \mathbf{x}_i} = \frac{1}{2}\frac{\partial \mathcal{D}}{\partial \mathbf{U}_i}. \tag{71}$$

The amount of energy dissipated is given by

$$\mathcal{D} = \int_{V_\ell} D d\mathbf{x}, \qquad \text{where} \quad D = 2\mu \varepsilon_{ij} \cdot \varepsilon_{ij},$$

where ε_{ij} is the rate-of-strain tensor.

We shall assume that the Reynolds number is high, so the flow is close to potential flow except in the thin boundary layer wrapped around each bubble. We shall further assume that no significant amount of energy dissipates in the boundary layer. The verification of this assumption for one bubble can be found in Moore [31]. With this assumption one finds that

$$\varepsilon_{ij} = \frac{\partial^2 \phi}{\partial x_i \partial x_j}.$$

We can check that

$$D = \mu \Delta E, \qquad \text{where} \quad E = \nabla\phi \cdot \nabla\phi.$$

Using Green's theorem, we have

$$\mathcal{D} = \int_{V_\ell} \mu \Delta E dv = -\mu \int_S \nabla E \cdot \mathbf{n} ds = -\mu \int_S \frac{\partial E}{\partial n} ds = -\mu \int_S \frac{\partial (\nabla\phi \cdot \nabla\phi)}{\partial n} ds, \tag{72}$$

where the integral is taken on the surface of the bubbles, and $\mathbf{n}$ is an outward normal vector.

5.2. Calculation of drag. In this section we calculate the drag force of a bubble in the presence of a finite number of bubbles. We begin with the case of a single bubble.

5.2.1. Single bubble. We consider a single bubble, moving with a fixed radius and a translational velocity $\mathbf{U}$, in a fluid with a constant ambient velocity $\mathbf{v}_\infty$. The velocity potential in this case is

$$\phi = \frac{1}{2} R^3 \nabla_r \left(\frac{1}{|\mathbf{r} - \mathbf{x}|} \right) \cdot (\mathbf{U} - \mathbf{v}_\infty) + \mathbf{v}_\infty \cdot \mathbf{r}.$$

The energy dissipation is computed using (72) and found to be

$$\mathcal{D} = 12\pi\mu R |\mathbf{U} - \mathbf{v}_\infty|^2. \tag{73}$$

The drag on the bubble is then given by

$$\mathbf{F} = \frac{1}{2} \frac{\partial \mathcal{D}}{\partial \mathbf{U}} = 12\pi\mu R (\mathbf{U} - \mathbf{v}_\infty). \tag{74}$$

Levich [28] derived (74) using the method outlined here. Moore [31] determined the drag force by computing the pressure distribution around the bubble. Kang and Leal [23] and Stone [46] provide alternate derivations.

5.2.2. Two bubbles. For the case of two bubbles in an infinite liquid, van Wijngaarden and Kapteyn [52], using the energy dissipation argument, derived

$$\mathbf{F} = -12\pi\mu R (\mathbf{U} - 2\mathbf{v}_{ind}), \tag{75}$$

where $\mathbf{v}_{ind}$ is the velocity generated by the other bubble.

5.2.3. N bubbles. With the expression of the velocity potential (14), we calculate $\mathcal{D}$ in Appendix E. After neglecting terms caused by spherical harmonics of orders higher than dipole, we have

$$\mathcal{D} = 12\pi\mu R \sum_{i=1}^{N} |\mathbf{U}_i - \mathbf{v}_i(\mathbf{x}_i)|^2. \tag{76}$$

From this equation we see that the dissipation due to the ith bubble is

$$12\pi\mu R|\mathbf{U}_i - \mathbf{v}_i(\mathbf{x}_i)|^2.$$

This compares closely with (73), with $\mathbf{v}_\infty$ replaced by the ambient field of the ith bubble ($\mathbf{v}_i$). Nevertheless, the drag force will be different from (74) since the ambient velocity of the ith bubble will depend on the velocities of all of the bubbles. In Appendix E we compute the drag force and find

$$\frac{1}{2}\frac{\partial \mathcal{D}}{\partial \mathbf{U}_i} = 12\pi\mu R(\mathbf{U}_i - 2\mathbf{v}_i(\mathbf{x}_i) - \mathbf{w}_i(\mathbf{x}_i)), \tag{77}$$

where

$$\mathbf{w}_i(\mathbf{r}) = -\sum_{j\neq i} \frac{1}{2}R^3\nabla^2\left(\frac{1}{|\mathbf{r}-\mathbf{x}_j|}\right)\cdot\mathbf{v}_j.$$

This compares closely with the result by van Wijngaarden and Kapteyn [52].

The continuum limit of (77) is

$$12\pi\mu R(\mathbf{U} - 2\mathbf{v} - \mathbf{w}),$$

where $\mathbf{v}$ is given by (59) and (60); $\mathbf{w}$ is determined from

$$\triangle\chi - \frac{3}{2}\nabla\cdot(\beta\mathbf{v}) = 0, \tag{78}$$

$$\mathbf{w} - \nabla\chi + \frac{\beta\mathbf{v}}{2} = 0. \tag{79}$$

In one space dimension, (78) and (79) simplify to

$$\frac{\partial^2\chi}{\partial x^2} = \frac{3}{2}\frac{\partial\beta v}{\partial x} \quad \text{and} \quad w = \frac{\partial\chi}{\partial x} - \frac{1}{2}\beta v,$$

from which it follows that

$$\frac{\partial w}{\partial x} - \frac{\partial(\beta v)}{\partial x} = 0.$$

Since w must vanish if v vanishes, then we find

$$w = \beta v.$$

Therefore the drag force is

$$12\pi\mu R(U - (2+\beta)v). \tag{80}$$

Using the expression for v given by (62), we find that the drag force is

$$12\pi\mu RU\frac{1+\beta+\beta^2}{1-\beta}. \tag{81}$$

We can write this formula in a different form by noticing that the bubble's velocity relative to the ambient liquid velocity is

$$U - v = \frac{U}{1-\beta}.$$

Therefore we can rewrite the drag force as

$$12\pi\mu R(1+\beta+\beta^2)(U-v).$$

We have shown, by following a procedure similar to that outlined in Appendix E, that the formula above is valid for any value of the volume flux.

5.3. Void waves. With the drag force computed, we can now modify our model for void waves to include gravity and liquid viscosity. Following the approach previously outlined, we find that (71) becomes, in the continuum limit,

$$\frac{1}{3}\left(\frac{\partial U}{\partial t}+U\frac{\partial U}{\partial x}\right)-\left(\frac{\partial v}{\partial t}+v\frac{\partial v}{\partial x}\right)=\frac{2}{3}g\left(1-\frac{U}{U_\infty}\frac{1+\beta+\beta^2}{1-\beta}\right), \tag{82}$$

$$\frac{\partial \beta}{\partial t}+\frac{\partial\left(\beta U\right)}{\partial x}=0, \tag{83}$$

where v is given by (62) and

$$U_\infty=\frac{R^2\rho_\ell g}{9\mu}$$

is the steady speed of a single bubble rising in an infinite fluid under the force of gravity. Next we multiply (82) by 3/2, use the expression for v, and rewrite (82) as

$$\frac{\partial}{\partial t}\left(\frac{(1+2\beta)}{2(1-\beta)}U\right)+\frac{\partial}{\partial x}\left(\frac{(1-2\beta-2\beta^2)}{4(1-\beta)^2}U^2\right)=g-\frac{gU}{U_\infty}\left(\frac{(1+\beta+\beta^2)}{1-\beta}\right). \tag{84}$$

Our model for void wave propagation including dissipation is then given by (83) and (84).

It is easy to verify that (83) and (84) have the equilibrium solution $\beta=\beta_0$ and $U=U_0$, where

$$U_0=\frac{1-\beta_0}{1+\beta_0+\beta_0^2}U_\infty. \tag{85}$$

This corresponds to a spatially uniform mixture of bubbles rising due to gravity in the zero volume flux frame of reference. The rise speed of the bubbles is given by (85). The prediction of (85) is in good agreement with the experimental data reported by Lammers and Biesheuvel [26] as shown in Figure 1 below. This result seems somewhat paradoxical; it has been shown by Sangani and Didwania [39], Smereka [42], and van Wijngaarden [53] that, in the context of potential theory, there is not a stable steady homogeneous distribution of rising bubbles; the key word here is stable. We shall now show that this steady solution that we have calculated is in fact unstable, in agreement with [39, 42, 53]. In fact we conjecture that this steady state is only weakly unstable, which is why (85) is in good agreement with experimental data.

Next we wish to examine the stability of this equilibrium solution. For this purpose it is useful to use the change of variables described in section 3. That is, we consider $M=\beta U/h(\beta)$; then (83) and (84) can be written as the following system:

$$\begin{aligned}&\frac{\partial \beta}{\partial t}+\frac{\partial}{\partial x}\left(h(\beta)M\right)=0,\\ &\frac{\partial M}{\partial t}+\frac{\partial}{\partial x}\left(\frac{1}{2}h'(\beta)M^2\right)=g\left(1-\frac{M}{M_0(\beta)}\right),\end{aligned} \tag{86}$$

where $h(\beta)$ is given by (66) and

$$M_0(\beta)=U_\infty\frac{1+2\beta}{2(1+\beta+\beta^2)}.$$

In these variables the equilibrium solution is $(\beta, M) = (\beta_0, M_0(\beta_0))$. If we linearize (86) about the equilibrium solution, we obtain the following linear system, with M and β now being the linearized variables:

$$\frac{\partial}{\partial t}\begin{pmatrix} \beta \\ M \end{pmatrix} + \mathsf{A}_0 \frac{\partial}{\partial x}\begin{pmatrix} \beta \\ M \end{pmatrix} = \mathsf{R}\begin{pmatrix} \beta \\ M \end{pmatrix}, \tag{87}$$

where

$$\mathsf{A}_0 = \begin{pmatrix} h'(\beta_0)M_0 & h(\beta_0) \\ \frac{1}{2}h''(\beta_0)M_0^2 & h'(\beta_0)M_0 \end{pmatrix} \quad \text{and} \quad \mathsf{R} = \frac{g}{M_0(\beta_0)}\begin{pmatrix} 0 & 0 \\ M_0'(\beta_0) & -1 \end{pmatrix}.$$

Next we look for solutions of the form $(\beta, M) = (A, B)e^{i(\omega t - kx)}$. We find that there will be solutions of this form, provided that the following dispersion relationship is satisfied:

$$z^2 + \frac{g}{ikM_0(\beta_0)}z - h(\beta_0)\left(\frac{1}{2}h''(\beta_0)M_0^2(\beta_0) + \frac{gM_0'(\beta_0)}{ikM_0(\beta_0)}\right) = 0, \tag{88}$$

with $z = c - h'(\beta_0)M_0(\beta_0)$, where $c = \frac{\omega}{k}$ is the phase speed. Solving the above equation for z reveals that z always has complex roots, indicating that the initial value problem for (87) is ill-posed. Hence, the growth rate of a Fourier mode is proporational to its wave number. This seems consistent with numerical simulations of bubble clustering. In these simulations a spatially uniform distribution of bubbles quickly assembles into horizontal clusters of bubbles (see Sangani and Didwania [39] and Smereka [42]). However, in experiments such behavior is not observed and is inconsistent with experimental observations of void wave propagation. Nevertheless, we shall see below that our model can predict some phenomena seen in experiments. To this end, let us then consider situations where the wavelengths tend to be large and therefore k is small. For small k the dispersion relationship has the two solutions

$$c_1 = \frac{ig}{M_0(\beta)k} + h'(\beta_0)M_0(\beta_0) - h(\beta_0)M_0'(\beta_0) + ic_I + O(k^2),$$

$$c_2 = (h(\beta_0)M_0(\beta_0))' - ic_I + O(k^2),$$

where

$$c_I = \frac{kh(\beta_0)M_0(\beta_0)}{2g}\left(2h(\beta_0)(M_0'(\beta_0))^2 - M_0^2(\beta_0)h''(\beta_0)\right).$$

Substituting in our expressions for h and M_0, these become

$$c_1 = i\frac{2g}{kU_\infty}\frac{1+\beta_0+\beta_0^2}{1+2\beta_0} + U_\infty(1 - 6\beta_0 + O(\beta_0^2)) + ic_I,$$

$$c_2 = c_R - ic_I,$$

where

$$c_R = \frac{1 - 2\beta_0 - 2\beta_0^2}{(1+\beta_0+\beta_0^2)^2}U_\infty \tag{89}$$

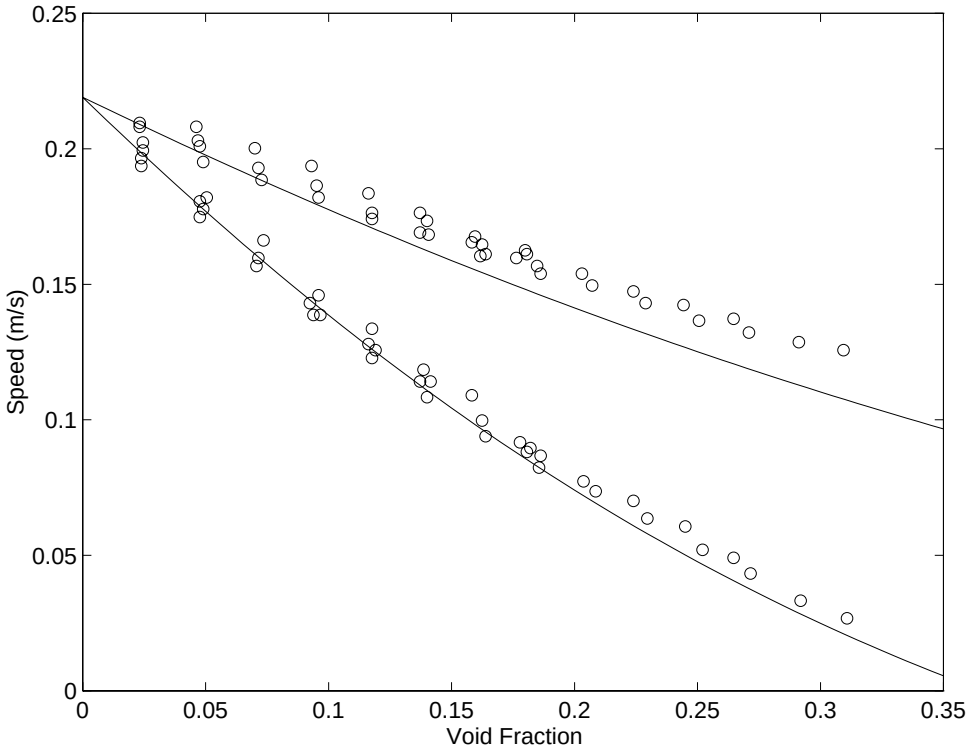

FIG. 1. *The upper curve shows a plot of the predicted bubble rise speed using* (85), *and the lower curve shows the predicted void wave speed using* (89). *We have used* $U_\infty = .219$ *m/sec. The circles are the experimental findings of Lammers and Biesheuvel* [26], *as is the value for* U_∞.

and

$$c_I = \frac{U_\infty^3 k}{2g}(3\beta_0 + O(\beta_0^2)). \tag{90}$$

In the expression for c_1 we observe that its imaginary part is positive. This indicates that this mode decays. This corresponds to the relaxation of the bubble's speed to the equilibrium speed. The second mode corresponds to void waves. It predicts that the void waves will move with speed c_R and will grow with a rate given by $c_I k$. Figure 1 shows a plot of c_R as function of the volume fraction along with experimental data. The agreement is good.

In the experiments of Lammers and Biesheuvel [26] the rise speed of a single bubble was approximately 25 cm/sec, the void fraction was in the range 0 to 0.4, and the frequency of naturally occurring void waves was approximately 1 Hz (see Biesheuvel and Gorissen [6]). Using our expression for the real part of the wave speed, we can estimate that this corresponds to disturbances with a wavelength of approximately 27 cm ($k \approx .2$). The growth rate of these disturbances (using (90)) is

$$c_I k \approx \frac{3\beta_0 U_\infty^3 k^2}{2g}.$$

If we use the experimental parameters given above, we find that the growth rate is approximately β_0. This suggests that the void waves do not have time to grow

significantly in normal experimental settings. Therefore our model predicts that the observed void waves should grow slightly and travel with a phase speed given by c_R. Recent experiments of Zenit, Koch, and Sangani [58] demonstrate a small amount of clustering.

Therefore, it appears that our model provides an accurate description of long wavelength disturbances. It is possible that the model breaks down for small wavelength disturbances and that there are regularizing effects which, when included in our model, will result in a well-posed model. Another possibility is that Sangani and Didwania [39] and Smereka [42] overestimate the amount of cluster formation observed in experiments. This could be because in these numerical simulations the computational domain was a cube with a size of only a few centimeters. Thus they were exciting modes of a much smaller wavelength than those observed in experiments, due to the periodic boundary conditions.

Finally, we remark that, if we assume the wave frequencies and wave numbers are small, then it follows from (84) that

$$g - \frac{gU}{U_\infty}\left(\frac{(1+\beta+\beta^2)}{1-\beta}\right) \approx 0,$$

which implies that

$$U \approx U_0(\beta),$$

where U_0 is given by (85). We can rewrite (83) using the above expression as

$$\frac{\partial \beta}{\partial t} + (U_0(\beta) + \beta U_0'(\beta))\frac{\partial \beta}{\partial x} \approx 0.$$

This equation was obtained by Lammers and Biesheuvel [26]. Using (85), we note that the above equation can be written as

$$\frac{\partial \beta}{\partial t} + c_R \frac{\partial \beta}{\partial x} \approx 0,$$

where c_R is given by (89). Thus we see, again, that when the frequency and wavenumber of the waves are small, the void wave should travel with a speed given by c_R.

6. Summary and conclusions. In this paper we have developed a new method for solving Laplace's equation for the velocity potential in a liquid with a finite number of bubbles. This method is a generalization of the method of images. Our approach also allows us to define the ambient velocity and ambient pressure associated with a particular bubble. The velocity potential is then used to calculate the total kinetic energy of the liquid. We then use the Euler–Lagrange equation to compute exact equations of motion for a finite collection of bubbles, which are a set of ordinary differential equations. We then make a simplifying approximation, which is to keep only terms arising from monopoles and dipoles. We then take the continuum limit of the equations of motion to obtain a set of partial differential equations that represent our effective equations for ideal bubbly fluids. Our model includes both sound and void wave propagation, includes nonlinear effects, and is valid over a wide range of wave numbers. We show that our model captures the results for the speed of sound waves from Caflisch et al. [10], Crespo [12], and Sangani [38]. We also show that our model reduces to Geurst's model [17, 18] when we consider void wave propagation.

We then consider the effects of liquid viscosity and gravity on void wave propagation. The effects of liquid viscosity are incorporated by using an energy dissipation function. We apply this technique for finite collection of bubbles, thus extending the work of van Wijngaarden and Kapteyn [52] for the two-bubble problem. We then compute the drag force. The continuum limit of the drag force is found, and our effective equations for void waves including gravity and liquid viscosity are formulated. We then observe that our model has a steady-state solution which corresponds to a mixture of bubbles rising with a steady speed. The calculated bubble rise speed is in good agreement with experimental values. We also compute the speed of void waves and find good agreement with experimental results. Our computations show that these waves are unstable, but, using the experimental parameters, we find that the instability can be small.

Appendix A. Proof of Theorem 3.1. Theorem 3.1 states that the method of images, when generalized to N spheres, results in a converging sequence which is the solution to Laplace's equation with the correct boundary conditions.

We begin our proof with some definitions. Let $B = B(\mathbf{p}, R)$ be a ball of radius R centered at the point $\mathbf{p}$. We define the energy norms:

$$||f||_B = \int_B |\nabla f|^2 d\mathbf{x} \quad \text{and} \quad ||f||_{\overline{B}} = \int_{\overline{B}} |\nabla f|^2 d\mathbf{x},$$

where $\overline{B}$ is the region exterior to B. We will also use the L_2 norm on the surface of B (∂B):

$$||f||_{\partial B} = \left(\int_{\partial B} f^2 ds \right)^{\frac{1}{2}}.$$

We shall make use of Weiss' sphere theorem, which, in the notation of our paper, is the following: *If $f(\mathbf{x})$ is harmonic inside $B = B(\mathbf{p}, R)$, then the image operator with respect to B is*

$$I_B f(r, \theta, \psi) = \frac{1}{R} \int_0^{\frac{R^2}{r}} w \frac{\partial f}{\partial w}(w, \theta, \psi) dw.$$

This can be found, for example, in Milne-Thompson [30, p. 520].

Remark. If the closest singularity of f has distance d from $\mathbf{p}$, then $I_B f$ is harmonic for all points outside of $B^*(\mathbf{p}, \frac{R^2}{d})$, which is a sphere smaller than $B(\mathbf{p}, R)$.

Our proof begins with the following three lemmas.

LEMMA A.1. *$B^m = B^m(\mathbf{p}, mR)$, $B = B(\mathbf{p}, R)$, and $B^M = B^M(\mathbf{p}, MR)$ are three concentric spheres with*

$$m < 1 < M, \quad c < 1, \quad 1 < cMm;$$

f is a harmonic function inside B^M; and $I_B f$ is harmonic exterior to B^m. Then we have

$$||I_B f||_{\overline{B^m}} < c||f||_{B^M},$$

where $\overline{B^m}$ is the region exterior to B^m.

Proof. Assume that $\mathbf{p}$ is at the origin. We can write f in terms of spherical harmonics:

$$f(r,\theta,\psi) = f(0) + \sum_{k=1}^{\infty}\sum_{j=1}^{2k+1} c_{k,j}h_{k,j}(\theta,\psi)r^k,$$

where $c_{k,j}$ are constants and $h_{k,j}$ is a set of spherical harmonics which satisfy the orthogonality condition

$$\int_{\text{unit ball}} h_{k,j}h_{m,i}dS = \delta_{km}\delta_{ij}.$$

From Weiss' sphere theorem, we have

$$\begin{aligned} I_B f &= \frac{1}{R}\int_0^{\frac{R^2}{r}} w\frac{\partial f}{\partial w}(w,\theta,\psi)dw \\ &= \frac{1}{R}\sum_{k=1}^{\infty}\sum_{j=1}^{2k+1}\frac{k}{k+1}c_{k,j}h_{k,j}R^{k+1}\Big|_0^{\frac{R^2}{r}} \\ &= \sum_{k=1}^{\infty}\sum_{j=1}^{2k+1}\frac{kR^{2k+1}}{(k+1)r^{k+1}}c_{k,j}h_{k,j}. \end{aligned}$$

We can use the divergence theorem and the expansion of f in spherical harmonics to obtain

$$||f||_{B^M} = \int_{\partial B^M} f\frac{\partial f}{\partial n}ds = \sum_{k=1}^{\infty}\sum_{j=1}^{2k+1} z_{k,j}^{(1)} \tag{91}$$

with

$$z_{k,j}^{(1)} = k(MR)^{2k+1}c_{k,j}^2.$$

In a similar fashion,

$$||I_B f||_{\overline{B^m}} = -\int_{\partial B^m} I_B f\frac{\partial I_B f}{\partial n}ds = \sum_{k=1}^{\infty}\sum_{j=1}^{2k+1} z_{k,j}^{(2)}, \tag{92}$$

where

$$z_{k,j}^{(2)} = \frac{k^2R^{4k+2}}{(k+1)(mR)^{2k+1}}c_{k,j}^2.$$

Therefore one has

$$\frac{z_{k,j}^{(2)}}{z_{k,j}^{(1)}} = \frac{k}{k+1}\left(\frac{1}{M^{2k+1}m^{2k+1}}\right).$$

Since $cmM < 1$, it follows that

$$\frac{z_{k,j}^{(2)}}{z_{k,j}^{(1)}} < c.$$

Hence

$$||I_B f||_{\overline{B^m}} < c||f||_{B^M}.$$

This completes the proof of Lemma A.1.

LEMMA A.2. *If f is harmonic outside $B(p,R)$, then*

$$||f||^2_{\partial B} \leq R||f||_{\overline{B}},$$

where $\overline{B}$ is the region outside of B.

Proof. After expanding

$$f(r,\theta,\psi) = \sum_{k=1}^{\infty}\sum_{m=1}^{2k-1} \frac{c_{k,m}h_{k,m}(\theta,\psi)}{r^{k+1}},$$

we have

$$||f||^2_{\partial B} = \sum_{k=1}^{\infty}\sum_{m=1}^{2k-1} \frac{c^2_{k,m}}{R^{2k}} \leq R\sum_{k=1}^{\infty}\sum_{m=1}^{2k-1} \frac{kc^2_{k,m}}{R^{2k+1}} = R||f||_{\overline{B}}.$$

This completes the proof of Lemma A.2.

LEMMA A.3. *If $f_k, k = 1,2,\ldots,$ are harmonic functions outside $B(\mathbf{p},R)$ and*

$$||f_k||_{\overline{B}} < Yc^k, \qquad c < 1,\ Y \text{ are constants},$$

then there exists a function f such that, at all points $\mathbf{x}$ outside B, f is harmonic and

$$\lim_{k\to\infty}\sum_{j=1}^{k} f_j(\mathbf{x}) = f(\mathbf{x}),$$

$$\lim_{\mathbf{x}\to\infty} f(\mathbf{x}) = 0.$$

Furthermore, the convergence is uniform outside $B^*(\mathbf{p},R^*)$ for any $R^* > R$.

Proof. We assume that $\mathbf{p}$ is at the origin. From Lemma A.2, we have

$$||f_k||^2_{\partial B} < R||f_k||_{\overline{B}} < RYc^k.$$

Hence

$$||f_k||_{\partial B} < \sqrt{RY}(\sqrt{c})^k.$$

Therefore $\{\sum_{i=1}^{k} f_i\}_k$ is a Cauchy sequence in the $||\cdot||_{\partial B}$ norm. Since the L^2 space on ∂B is complete, there exists a function $f \in L^2(\partial B)$ such that

$$\lim_{k\to\infty}\left\|\sum_{i=1}^{k} f_i - f\right\|_{\partial B} = 0.$$

We define f, for any $\mathbf{x}$ outside B, by using

$$f(\mathbf{x}) = \int_{\partial B} P(\mathbf{x},\mathbf{y})f(\mathbf{y})dS_{\mathbf{y}}, \tag{93}$$

where $P(\mathbf{x},\mathbf{y})$ is the Poisson kernel. From Axler, Bourdon, and Ramey [2], we have

$$P(\mathbf{x},\mathbf{y}) = \frac{1}{4\pi R}\frac{|\mathbf{x}|^2 - R^2}{|\mathbf{x}-\mathbf{y}|^3}.$$

Therefore

$$\left| f(\mathbf{x}) - \sum_{i=1}^{k} f_i(\mathbf{x}) \right| = \left| \int_{\partial B} P(\mathbf{x},\mathbf{y}) \left(f(\mathbf{y}) - \sum_{i=1}^{k} f_i(\mathbf{y}) \right) dS_{\mathbf{y}} \right|$$
$$\leq ||P(\mathbf{x},\mathbf{y})||_{\partial B} \cdot \left\| f - \sum_{i=1}^{k} f_i \right\|_{\partial B},$$

where the last inequality comes from the Cauchy–Schwarz inequality We also have a uniform bound on P for all $\mathbf{y} \in \partial B$, when $\mathbf{x}$ is a fixed point strictly outside B,

$$P(\mathbf{x},\mathbf{y}) \leq \frac{1}{4\pi R}\frac{|\mathbf{x}|^2 - R^2}{(|\mathbf{x}| - |\mathbf{y}|)^3} = \frac{1}{4\pi R}\frac{|\mathbf{x}| + R}{(|\mathbf{x}| - R)^2}.$$

Hence

$$\lim_{k\to\infty} \left| f(\mathbf{x}) - \sum_{i=1}^{k} f_i(\mathbf{x}) \right| = 0. \tag{94}$$

Furthermore, if $|\mathbf{x}| \geq R^* > R$, then

$$P(\mathbf{x},\mathbf{y}) \leq \frac{1}{4\pi R}\frac{R^* + R}{(R^* - R)^2}.$$

Thus the convergence in (94) is uniform for $|\mathbf{x}| \geq R^*$.

In this context, f is harmonic because, from (93) and the fact that $P(\mathbf{x},\mathbf{y})$ is harmonic in $\mathbf{x}$ if $\mathbf{y}$ is fixed,

$$\triangle f = \int_{\partial B} \triangle_{\mathbf{x}} P(\mathbf{x},\mathbf{y}) f(\mathbf{y}) dS_{\mathbf{y}} = 0.$$

Since $P(\mathbf{x},\mathbf{y})$ vanishes when $\mathbf{x} \to \infty$, then so does f because of (93). This completes the proof of Lemma A.3.

Proof of Theorem 3.1. Since all the spheres $B_i(\mathbf{x}_i, R_i)$, $i = 1,\ldots,N$, do not intersect and from the remark after the statement of Weiss' sphere theorem, we conclude that $I_i I_j \cdots \phi_k$ is harmonic not only outside $B_i(\mathbf{x}_i, R_i)$, but also outside a smaller sphere $B^*(\mathbf{x}_i, R_i^2/d_{ij})$, where d_{ij} is the distance between $\mathbf{x}_i$ and the closest point on ∂B_j because $I_j \cdots \phi_k$ has singularities only inside B_j. Therefore, we can find constant m, M, c such that

- $m < 1 < M$, $c < 1$, $1 < cMm$,
- $B_i^M(p_i, MR_i)$ do not intersect,
- $I_i \cdots I_j \phi_k$ is harmonic outside $B_i^m(p_i, mR_i)$.

To achieve this we let 2ε be the smallest distance between the surface of any of the N spheres. Let $q = \min_i \frac{R_i+\varepsilon}{R_i}$; then the choice $M = q^{\frac{3}{4}}$, $m = q^{-\frac{1}{4}}$, and $c = m$ will work (for example).

Next, we write

$$\phi = \sum_{j=1}^{N} \Omega_j,$$

where

$$\Omega_j = \phi_j + \sum_{\substack{i=i_1 \\ i_1 \neq j}}^{N} I_j \phi_i + \cdots + \sum_{\substack{i_1,\ldots,i_k=1 \\ i_1 \neq j, i_\ell \neq i_{\ell+1}}}^{N} I_j I_{i_1} I_{i_2} \cdots I_{i_{k-1}} \phi_{i_k} \cdots . \tag{95}$$

From the remarks above we know that Ω_j is harmonic outside $B_j^m(\mathbf{x}_j, mR_j)$.

Our plan is to prove that each term of Ω_j satisfies an estimate of the form given in Lemma A.3. Therefore we must estimate each term in the series. We denote the kth term of (95) as T_k and let

$$Y = \sum_{i=1}^{N} ||\phi_i||_{\overline{B_i^m}}.$$

Then it is obvious that

$$||T_0||_{\overline{B_j^m}} = ||\phi_j||_{\overline{B_j^m}} < Y. \tag{96}$$

To estimate the second term we appeal to Lemma A.1, and we have for $i_1 \neq j$

$$||I_j \phi_{i_1}||_{\overline{B_j^m}} < c||\phi_{i_1}||_{B_j^M} < c||\phi_{i_1}||_{\overline{B_{i_1}^m}}.$$

The second inequality follows since B_j^M is contained in $\overline{B_{i_1}^m}$. Now, we sum the above inequality over i_1 to obtain

$$||T_1||_{\overline{B_j^m}} < c \sum_{\substack{i=i_1 \\ i_1 \neq j}}^{N} ||\phi_{i_1}||_{\overline{B_{i_1}^m}} < cY. \tag{97}$$

Now, we look at the kth term and use Lemma A.1 to obtain the following estimate:

$$||T_k||_{\overline{B_j^m}} < c \sum_{\substack{i_1,\ldots,i_k=1 \\ i_1 \neq j, i_\ell \neq i_{\ell+1}}}^{N} ||I_{i_1} I_{i_2} \cdots I_{i_{k-1}} \phi_{i_k}||_{B_j^M}.$$

Next we use the above estimate and the fact that B_j^M is contained in $\overline{B_{i_1}^m}$ for $i_1 \neq j$ to find

$$||T_k||_{\overline{B_j^m}} < c \sum_{\substack{i_1,\ldots,i_k=1 \\ i_1 \neq j, i_\ell \neq i_{\ell+1}}}^{N} ||I_{i_1} I_{i_2} \cdots I_{i_{k-1}} \phi_{i_k}||_{\overline{B_{i_1}^m}}. \tag{98}$$

Applying Lemma A.1 again, we find

$$||T_k||_{\overline{B_j^m}} < c^2 \sum_{\substack{i_1,\ldots,i_k=1 \\ i_1 \neq j, i_\ell \neq i_{\ell+1}}}^{N} ||I_{i_2} \cdots I_{i_{k-1}} \phi_{i_k}||_{B_{i_1}^M}. \tag{99}$$

Since $i_1 \neq i_2$, it then follows that all $B_{i_1}^M$ are contained in $\overline{B_{i_2}^m}$, and we find from the above inequality

$$||T_k||_{\overline{B_j^m}} < c^2 \sum_{\substack{i_2,\ldots,i_k=1 \\ i_\ell \neq i_{\ell+1}}}^{N} ||I_{i_2} \cdots I_{i_{k-1}} \phi_{i_k}||_{\overline{B_{i_2}^m}}. \tag{100}$$

This is of the same form as (98), so therefore we repeat the same steps as were used to obtain (99) and (100) and thereby obtain the estimate

$$||T_k||_{\overline{B_j^m}} < c^k Y.$$

Next we combine Lemma A.2 and Lemma A.3 to conclude that Ω_j is harmonic and uniformly convergent outside bubble j. It then follows that ϕ is also harmonic and uniformly convergent in the liquid region. The completes our proof of Theorem 3.1.

Appendix B. Proof of Theorem 3.2. We begin with the following formula. Suppose $\mathbf{r} = (x_1, x_2, x_3)$; then we have

(101)
$$(-1)^n \left(\nabla^n \left(\frac{1}{|\mathbf{r}|}\right)\right)_{i_1 \cdots i_n} = \frac{(2n-1)!! x_{i_1} \cdots x_{i_n}}{|\mathbf{r}|^{2n+1}} + \sum_{j=1}^{N_2} \frac{(-1)^j (2n-2j-1)!! A_j}{|\mathbf{r}|^{2n-2j+1}},$$

with $i_1, i_2, \ldots, i_n = 1, 2, 3$; N_2 is the integer part of $\frac{n}{2}$; and

$$A_j = \sum \delta_{k_1 k_2} \cdots \delta_{k_{2j-1} k_{2j}} x_{k_{2j+1}} \cdots x_{k_n},$$

where the sum is over all possible j pairs $(k_1, k_2) \cdots (k_{2j-1}, k_{2j})$ from i_1 to i_n.

This formula can be proven by induction. Some examples of (101) are

$$\left(\nabla \left(\frac{1}{|\mathbf{r}|}\right)\right)_i = -\frac{x_i}{|\mathbf{r}|^3},$$
$$\left(\nabla^2 \left(\frac{1}{|\mathbf{r}|}\right)\right)_{ij} = \frac{3x_i x_j}{|\mathbf{r}|^5} - \frac{\delta_{ij}}{|\mathbf{r}|^3},$$
$$\left(\nabla^3 \left(\frac{1}{|\mathbf{r}|}\right)\right)_{ijk} = \frac{-15 x_i x_j x_k}{|\mathbf{r}|^7} + \frac{3(\delta_{ij} x_k + \delta_{ik} x_j + \delta_{jk} x_i)}{|\mathbf{r}|^5},$$

where i, j, and k run from 1 to 3.

One can use (101) to prove the following:

(102)
$$\frac{(-1)^k}{(2k-1)!!} \nabla^k f \cdot \nabla^k \left(\frac{1}{|\mathbf{r}|}\right) = \nabla^k f \cdot \frac{\mathbf{n}^k}{|\mathbf{r}|^{k+1}},$$

where $k \geq 2$ and

$$\mathbf{n} = \frac{\mathbf{r}}{|\mathbf{r}|}.$$

To prove (102) is straightforward. We first notice, since f is harmonic, that

$$\nabla^k f \cdot \delta_{ij} = 0.$$

Combining this result with (101), we obtain (102). We are now ready to prove Theorem 3.2; without losing the generality, we assume that $\mathbf{p}$ is the origin. According to Weiss's sphere theorem, we have

$$I_B f(\mathbf{r}) = \frac{1}{R} \int_0^{\frac{R^2}{|\mathbf{r}|}} w \nabla f(w\mathbf{n}) \cdot \mathbf{n} dw.$$

Using a Taylor series expansion for $f(\mathbf{r})$, we can rewrite the above expression as

$$I_B f(\mathbf{r}) = \frac{1}{R}\int_0^{\frac{R^2}{|\mathbf{r}|}} \sum_{k=1}^{\infty} \frac{1}{(k-1)!} w^k \nabla^k f(0)\cdot \mathbf{n}^k dw.$$

Integrating term by term, we obtain

$$I_B f(\mathbf{r}) = \sum_{k=1}^{\infty} \frac{R^{2k+1}}{(k-1)!(k+1)|\mathbf{r}|^{k+1}} \nabla^k f(0)\cdot \mathbf{n}^k. \tag{103}$$

Next we combine (102) with (103) to obtain Theorem 3.2. This completes the proof of Theorem 3.2.

Appendix C. Useful formulas. If $g(\mathbf{x})$ is a harmonic function in $B(\mathbf{p}, R)$ and $\mathbf{d}$, $\mathbf{e}$ are constant vectors, then

$$\int_{\partial B} g(\mathbf{x}) ds = 4\pi R^2 g(\mathbf{p}),$$

$$\int_{\partial B} (\mathbf{d}\cdot\mathbf{n}) g(\mathbf{x}) ds = \frac{4\pi R^3}{3} \mathbf{d}\cdot\nabla g(\mathbf{p}),$$

$$\int_{\partial B} (\mathbf{d}\cdot\mathbf{n})(\mathbf{e}\cdot\mathbf{n}) ds = \frac{4\pi}{3} R^2 \mathbf{d}\cdot\mathbf{e},$$

$$\int_{\partial B} I_B g(\mathbf{x}) ds = 0,$$

$$\text{and} \quad \int_{\partial B} (\mathbf{d}\cdot\mathbf{n})\, I_B g(\mathbf{x}) ds = \frac{2\pi R^3}{3} \mathbf{d}\cdot\nabla g(\mathbf{p}).$$

These formulas are established using the orthogonality properties of spherical harmonics. Theorem 3.2 is used in the proof of the last two equations.

Appendix D. Derivative calculations. In this section we shall compute the derivatives of K that appear in the Euler–Lagrange equations. When computing these derivatives, we will not use the expression for K given by (20). Instead we will use the integral form of K, which we rewrite here:

$$K = -\frac{1}{2}\rho_\ell \sum_{j=1}^{N} \int_{S_j} \phi \frac{\partial \phi}{\partial n} ds. \tag{104}$$

We have found it useful, when computing these derivatives, to introduce the operator J_i, which is defined as follows: if we have N spheres $B_1, B_2, \ldots, B_N$ and a function $f(\mathbf{x})$, which is harmonic outside of B_i, then we say that

$$g(\mathbf{x}) = J_i f(\mathbf{x})$$

if

$$\begin{aligned} &\frac{\partial g}{\partial n} = \frac{\partial f}{\partial n} \quad \text{at } \partial B_i, \\ &\frac{\partial g}{\partial n} = 0 \qquad \text{at } \partial B_j \text{ when } j \neq i. \end{aligned} \tag{105}$$

We note that $g(\mathbf{x})$ will be harmonic outside all of the spheres.

The operator can be expressed in terms of the image operator (defined in Theorem 3.1) as follows:

$$J_i(f) = f + \sum_{i_1=1,i_1\neq i}^{N} I_{i_1} f + \cdots + \sum_{i_1,\ldots,i_k=1,i_k\neq i,i_j\neq i_{j+1}}^{N} I_{i_1} I_{i_2} \cdots I_{i_k} f + \cdots. \tag{106}$$

This can be seen by applying Theorem 3.1 with $\phi_i = f$ and $\phi_j = 0$ if $j \neq i$.

It is easy to verify that the solution to (11) is

$$\phi = \sum_{i=1}^{N} J_i \phi_i, \tag{107}$$

where ϕ_i is defined in Theorem 3.1.

One property associated with operator J that we will use, if f and g are harmonic, is

$$\int_S J_i f \frac{\partial g}{\partial n} ds = \int_S \frac{\partial J_i f}{\partial n} g ds = \int_{S_i} \frac{\partial f}{\partial n} g ds, \tag{108}$$

where the first equality is Green's theorem and the second equality follows from the definition of the operator J.

Proof of (22). We have from (104)

$$\begin{aligned} K &= -\frac{\rho_\ell}{2} \sum_{j=1}^{N} \int_{S_j} \phi \frac{\partial \phi}{\partial n} ds \\ &= -\frac{\rho_\ell}{2} \rho_\ell \sum_{j=1}^{N} \int_{S_j} \phi (\dot{R}_j + \mathbf{U}_j \cdot \mathbf{n}) ds. \end{aligned}$$

Thus we have

$$-\frac{2}{\rho_\ell} \frac{\partial K}{\partial \dot{R}_i} = \int_{S_i} \phi ds + \sum_{j=1}^{N} \int_{S_j} \frac{\partial \phi}{\partial \dot{R}_i} \frac{\partial \phi}{\partial n} ds. \tag{109}$$

We will consider the two terms on the right-hand side of (109) separately. One has

$$\int_{S_i} \phi ds = \int_{S_i} (\phi_i + \psi_i + I_i \psi_i) ds.$$

It follows from Appendix C that this becomes

$$\int_{S_i} \phi ds = 4\pi R_i^2 (-R_i \dot{R}_i + \psi_i(\mathbf{x}_i)). \tag{110}$$

Turning to the second term, we have

$$\begin{aligned} \sum_{j=1}^{N} \int_{S_j} \frac{\partial \phi}{\partial \dot{R}_i} \frac{\partial \phi}{\partial n} ds &= \int_S \frac{\partial \phi}{\partial \dot{R}_i} \frac{\partial \phi}{\partial n} ds \\ &= \sum_{j=1}^{N} \int_S \frac{\partial J_j \phi_j}{\partial \dot{R}_i} \frac{\partial \phi}{\partial n} ds, \end{aligned}$$

where we have used (107). Next we observe that $J_j\phi_j$ does not depend on $\dot{R}_i$ unless $i = j$; thus we have

$$\sum_{j=1}^{N}\int_{S_j}\frac{\partial\phi}{\partial\dot{R}_i}\frac{\partial\phi}{\partial n}ds = \int_S \frac{\partial J_i\phi_i}{\partial\dot{R}_i}\frac{\partial\phi}{\partial n}ds.$$

Furthermore, the operator J_i does not depend on $\dot{R}_i$; thus the previous expression becomes

$$\sum_{j=1}^{N}\int_{S_j}\frac{\partial\phi}{\partial\dot{R}_i}\frac{\partial\phi}{\partial n}ds = \int_S J_i\left(\frac{\partial\phi_i}{\partial\dot{R}_i}\right)\frac{\partial\phi}{\partial n}ds. \tag{111}$$

Applying (108), we find

$$\int_S J_i\left(\frac{\partial\phi_i}{\partial\dot{R}_i}\right)\frac{\partial\phi}{\partial n}ds = \int_{S_i}\frac{\partial}{\partial n}\left(\frac{\partial\phi_i}{\partial\dot{R}_i}\right)\phi ds = \int_{S_i}\phi ds. \tag{112}$$

Combining (109), (110), (111), and (112), we find

$$\frac{\partial K}{\partial\dot{R}_i} = 2\pi\rho_\ell(2R_i^3\dot{R} - 2R_i^2\psi_i(\mathbf{x}_i)).$$

Thus (22) is proven. The proof for (23) is similar to that above.

Proof of (24). When calculating $\frac{\partial K}{\partial R_i}$, we notice that R_i enters into K in (104) in three ways:

- the integration region depends on R_i,
- ϕ_i depends on R_i,
- the image potential operator I_i depends on R_i.

Therefore we have

$$\frac{\partial K}{\partial R_i} = \frac{\partial K}{\partial R_i^S} + \frac{\partial K}{\partial R_i^\phi} + \frac{\partial K}{\partial R_i^I},$$

where R_i^S, R_i^ϕ, and R_i^I represent R_i in the integration region, in ϕ_i, and in I_i, respectively.

Step 1. We first assume that ϕ_i and I_i are fixed and consider only the effect of changing the integration region. We have

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^S} = \frac{\partial}{\partial R_i^S}\int_S\phi\frac{\partial\phi}{\partial n}ds = \frac{\partial}{\partial R_i^S}\int_{S_i}\phi\frac{\partial\phi}{\partial n}ds.$$

It follows from the above result and (17) that

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^S} = \frac{\partial}{\partial R_i^S}\int_{S_i}(\phi_i + \psi_i + I_i\psi_i)\frac{\partial\phi}{\partial n}ds.$$

We continue our calculation by applying Theorem 3.2 to expand $I_i\psi_i$ and using a Taylor expansion for ψ_i to obtain

$$\begin{aligned}-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^S} = \frac{\partial}{\partial R_i^S}\int_{S_i}\Bigg[&-\frac{R_i^2\dot{R}_i}{|\mathbf{r}-\mathbf{x}_i|} + \frac{1}{2}R_i^3\nabla_r\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\cdot\mathbf{U}_i\\ &+\psi_i(\mathbf{x}_i) + \mathbf{v}_i(\mathbf{x}_i)\cdot(\mathbf{r}-\mathbf{x}_i) - \frac{1}{2}R_i^3\mathbf{v}_i(\mathbf{x}_i)\cdot\nabla_{\mathbf{r}}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\\ &+(\text{higher order harmonics})\Bigg](\dot{R}_i + \mathbf{U}_i\cdot\mathbf{n})ds.\end{aligned}$$

Evaluating the integrand on S_i ($|\mathbf{r}| = R_i$) and using the orthogonality properties of spherical harmonics, we find

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^S} = \frac{\partial}{\partial R_i^S}\int_{S_i}\Bigg[-\frac{R_i^2\dot{R}_i}{R_i^S} - \frac{R_i^3}{2(R_i^S)^2}\mathbf{U}_i\cdot\mathbf{n} + \psi_i(\mathbf{x}_i) + R_i^S\mathbf{v}_i(\mathbf{x}_i)\cdot\mathbf{n} + \frac{R_i^3}{2(R_i^S)^2}\mathbf{v}_i(\mathbf{x}_i)\cdot\mathbf{n}\Bigg](\dot{R}_i + \mathbf{U}_i\cdot\mathbf{n})ds.$$

The integration over S_i is performed using the results in Appendix C, and we obtain

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^S} = \frac{\partial}{\partial R_i^S}\Bigg[4\pi(R_i^S)^2\left(-\frac{R_i^2\dot{R}_i^2}{R_i^S} + \psi_i(\mathbf{x}_i)\dot{R}_i\right) + \frac{4\pi(R_i^S)^2}{3}\mathbf{U}_i\cdot\left(-\frac{R_i^3\mathbf{U}_i}{2(R_i^S)^2} + R_i^S\mathbf{v}_i(\mathbf{x}_i) + \frac{R_i^3}{2(R_i^S)^2}\mathbf{v}_i(\mathbf{x}_i)\right)\Bigg].$$

Next, we take the derivative of the above expression and evaluate it at $R_i^S = R_i$ to obtain

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^S} = -4\pi R_i^2\dot{R}_i^2 + 8\pi R_i\dot{R}_i\psi_i(\mathbf{x}_i) + 4\pi R_i^2\mathbf{U}_i\cdot\mathbf{v}_i(\mathbf{x}_i). \tag{113}$$

Step 2. We now assume that the integration region and I_i are fixed, and that only R_i in ϕ_i is changing. We need to calculate

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^\phi} = \frac{\partial}{\partial R_i^\phi}\int_S \phi\frac{\partial\phi}{\partial n}ds.$$

Applying (107) and using the fact that only ϕ_i is changing, we have

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^\phi} = \frac{\partial}{\partial R_i^\phi}\int_S J_i(\phi_i)\frac{\partial\phi}{\partial n}ds.$$

In this case neither J_i nor $\frac{\partial\phi}{\partial n}$ depend on R_i^ϕ; thus we may write the above equation as

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^\phi} = \int_S J_i\left(\frac{\partial\phi_i}{\partial R_i^\phi}\right)\frac{\partial\phi}{\partial n}ds.$$

Substituting our expression for ϕ_i given by (13), we have

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^\phi} = \int_S J_i\left(-\frac{2R_i^\phi\dot{R}_i}{|\mathbf{r}-\mathbf{x}_i|} + \frac{3}{2}(R_i^\phi)^2\nabla_r\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\cdot\mathbf{U}_i\right)\frac{\partial\phi}{\partial n}ds.$$

It follows from (108) and (17) that we can write the previous expression as

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^\phi} = \int_{S_i}\frac{\partial}{\partial n}\left(-\frac{2R_i^\phi\dot{R}_i}{|\mathbf{r}-\mathbf{x}_i|} + \frac{3}{2}(R_i^\phi)^2\nabla_r\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\cdot\mathbf{U}_i\right)(\phi_i + \psi_i + I_i\psi_i)ds.$$

Evaluating the normal derivatives at the bubble surface and setting $R_i^\phi = R_i$, we obtain

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^\phi} = \int_{S_i}\left(\frac{2\dot{R}_i}{R_i} + \frac{3\mathbf{U}_i\cdot\mathbf{n}}{R_i}\right)(\phi_i + \psi_i + I_i\psi_i)ds.$$

Next, (13) and the results of Appendix C are used to deduce

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^\phi} = -8\pi R_i^2\dot{R}_i^2 + 8\pi R_i\dot{R}_i\psi_i(\mathbf{x}_i) - 2\pi R_i^2|\mathbf{U}_i|^2 + 6\pi R_i^2\mathbf{U}_i\cdot\mathbf{v}_i(\mathbf{x}_i). \tag{114}$$

Step 3. Finally, we wish to calculate $\frac{\partial K}{\partial R_i}$, where only R_i in the operator I_i is changing. We start with

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^I} = \frac{\partial}{\partial R_i^I}\int_S \phi\frac{\partial\phi}{\partial n}ds.$$

Since $\frac{\partial\phi}{\partial n}$ and the region of integration does not depend on R_i^I, we then have

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^I} = \int_S \frac{\partial\phi}{\partial R_i^I}\frac{\partial\phi}{\partial n}ds. \tag{115}$$

The task at hand then is to calculate $\frac{\partial\phi}{\partial R_i^I}$. This will be done using (14). Some terms of ϕ in (14) have multiple occurrences of I_i. For these terms, we separate each into several terms, so that after the separation, each term only has one changing I_i, denoted by $\tilde{I}_i$. For example, we have

$$\frac{\partial}{\partial R_1^I}I_1I_2I_1I_3I_4I_1\phi_3 = \frac{\partial}{\partial R_1^I}\left(\tilde{I}_1I_2I_1I_3I_4I_1\phi_3 + I_1I_2\tilde{I}_1I_3I_4I_1\phi_3 + I_1I_2I_1I_3I_4\tilde{I}_1\phi_3\right).$$

By doing this, we find

$$\frac{\partial\phi}{\partial R_i^I} = \frac{\partial}{\partial R_i^I}\left(\left(Id + \sum_{j_l\neq j_{l+1}, j_m\neq i} I_{j_1}\cdots I_{j_m}\right)\tilde{I}_i\left(\sum_{i\neq k_1, k_l\neq k_{l+1}} I_{k_1}\cdots I_{k_n}\phi_{k_{n+1}}\right)\right),$$

where Id is the identity operator. From the expressions of J_i and ψ_i in (106) and (16), we obtain

$$\frac{\partial\phi}{\partial R_i^I} = \frac{\partial J_i\tilde{I}_i\psi_i}{\partial R_i^I}.$$

Since J_i does not depend on R_i^I, we can write the previous equation as

$$\frac{\partial\phi}{\partial R_i^I} = J_i\left(\frac{\partial\tilde{I}_i\psi_i}{\partial R_i^I}\right).$$

We use the above equation to rewrite (115) as

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^I} = \int_S J_i\left(\frac{\partial\tilde{I}_i\psi_i}{\partial R_i^I}\right)\frac{\partial\phi}{\partial n}ds.$$

It follows from (108) that

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^I} = \int_{S_i} \phi \frac{\partial}{\partial n}\left(\frac{\partial \tilde{I}_i \psi_i}{\partial R_i^I}\right) ds$$
$$= \int_{S_i} (\phi_i + \psi_i + I_i\psi_i) \frac{\partial}{\partial n}\left(\frac{\partial \tilde{I}_i \psi_i}{\partial R_i^I}\right) ds.$$

If we expand $\tilde{I}_i\psi_i$ using (103), we can show

$$\frac{\partial}{\partial n}\left(\frac{\partial \tilde{I}_i \psi_i}{\partial R_i^I}\right) = W = \sum_{k=1}^{\infty} \frac{-(2k+1)(R_i^I)^{k-2}}{(k-1)!} \nabla^k \psi_i(\mathbf{x}_i)\cdot \mathbf{n}^k.$$

We also expand $I_i\psi_i$ using (103) and expand ψ_i in a Taylor series to obtain

$$-\frac{2}{\rho_\ell}\frac{\partial K}{\partial R_i^I} = \int_{S_i} \Bigg[- R_i\dot{R}_i - \frac{R_i}{2}\mathbf{U}_i\cdot\mathbf{n} + \sum_{k=0}^{\infty} \frac{1}{k!} R_i^k \nabla^k \psi_i(\mathbf{x}_i)\cdot \mathbf{n}^k$$
$$+ \sum_{k=1}^{\infty} \frac{R_i^{2k+1}}{(k-1)!(k+1)R_i^{k+1}} \nabla^k \psi_i(\mathbf{x}_i)\cdot \mathbf{n}^k \Bigg] W ds$$

$$= \int_{S_i} \left(-\frac{R_i}{2}\mathbf{U}_i\cdot\mathbf{n} + \sum_{k=1}^{\infty} \frac{2k+1}{(k+1)!} R_i^k \nabla^k \psi_i(\mathbf{x}_i)\cdot \mathbf{n}^k \right) W ds$$

$$= 2\pi R_i^2 \mathbf{U}_i\cdot \mathbf{v}_i(\mathbf{x}_i) - 6\pi R_i^2 |\mathbf{v}_i(\mathbf{x}_i)|^2 + F, \tag{116}$$

where we have let $R_i^I = R_i$. F contains terms involving $\nabla^k\psi\cdot\nabla^k\psi$ with $k>1$. We have used the orthogonality of spherical harmonics and the results in Appendix C to arrive at (116). Combining all three parts ((113), (114), and (116)), we have

$$\frac{\partial K}{\partial R_i} = 2\pi\rho_\ell \left(3R_i^2\dot{R}_i^2 + \frac{1}{2}R_i^2|\mathbf{U}_i|^2 - 4R_i\dot{R}_i\psi_i(\mathbf{x}_i) - 3R_i^2\mathbf{U}_i\cdot\mathbf{v}_i(\mathbf{x}_i) + \frac{3}{2}R_i^2|\mathbf{v}_i|^2 + F \right),$$

which is (24).

Proof of (25). We first expand the monopole and dipole terms at $\mathbf{x}$ in Laurent series around $\mathbf{y}$:

$$\frac{1}{|\mathbf{r}-\mathbf{x}|} = \sum_{n=0}^{\infty} \frac{1}{n!} \frac{|\mathbf{x}-\mathbf{y}|^{2n+1}}{|\mathbf{r}-\mathbf{y}|^{2n+1}} \nabla_{\mathbf{y}}^n \left(\frac{1}{|\mathbf{x}-\mathbf{y}|}\right)\cdot(\mathbf{r}-\mathbf{y})^n$$
$$= \frac{1}{|\mathbf{r}-\mathbf{y}|} + \frac{(\mathbf{x}-\mathbf{y})\cdot(\mathbf{r}-\mathbf{y})}{|\mathbf{r}-\mathbf{y}|^3} + \cdots,$$
$$\nabla_{\mathbf{r}}\left(\frac{1}{|\mathbf{r}-\mathbf{x}|}\right) = \sum_{n=0}^{\infty} \frac{-(2n+1)}{n!} \frac{|\mathbf{x}-\mathbf{y}|^{2n+1}}{|\mathbf{r}-\mathbf{y}|^{2n+3}} \nabla_{\mathbf{y}}^n \left(\frac{1}{|\mathbf{x}-\mathbf{y}|}\right)\cdot(\mathbf{r}-\mathbf{y})^{n+1}$$
$$+ \frac{1}{(n-1)!} \frac{|\mathbf{x}-\mathbf{y}|^{2n+1}}{|\mathbf{r}-\mathbf{y}|^{2n+1}} \nabla_{\mathbf{y}}^n \left(\frac{1}{|\mathbf{x}-\mathbf{y}|}\right)\cdot(\mathbf{r}-\mathbf{y})^{n-1}$$
$$= \nabla_{\mathbf{r}}\left(\frac{1}{|\mathbf{r}-\mathbf{y}|}\right) + \cdots.$$

We follow the same procedure as in the previous section to calculate $\frac{\partial K}{\partial \mathbf{x}_i}$. If $\mathbf{x}_i^I$, $\mathbf{x}_i^\phi$, and $\mathbf{x}_i^I$ are used to represent $\mathbf{x}_i$ in the integration region, in ϕ_i, and in I_i, respectively, we can make our calculation by using the same arguments as in the previous section and the two Laurent series above. Without writing the details, we obtain

$$\frac{\partial}{\partial \mathbf{x}_i^S}\int_S \phi\frac{\partial \phi}{\partial n}ds = 4\pi R_i^2\dot{R}_i\mathbf{v}_i + \frac{4\pi}{3}R_i^2\dot{R}_i\mathbf{U}_i + \frac{4\pi}{3}R_i^2 + (\nabla\mathbf{v}_i)^T\cdot\mathbf{U}_i,$$

$$\frac{\partial}{\partial \mathbf{x}_i^\phi}\int_S \phi\frac{\partial \phi}{\partial n}ds = -\frac{4\pi}{3}R_i^2\dot{R}_i\mathbf{U}_i + 4\pi R_i^2\dot{R}_i\mathbf{v}_i + 2\pi R_i^3(\nabla\mathbf{v}_i)^T\cdot\mathbf{U}_i,$$

$$\frac{\partial}{\partial \mathbf{x}_i^I}\int_S \phi\frac{\partial \phi}{\partial n}ds = \frac{2\pi}{3}R_i^3(\nabla\mathbf{v}_i)^T\cdot\mathbf{U}_i - 4\pi R_i^3 + (\nabla\mathbf{v}_i)^T\cdot\mathbf{v}_i + G,$$

where $\mathbf{v}_i = \mathbf{v}_i(\mathbf{x}_i)$ and G will have only terms involving $\nabla^k\psi_i(\mathbf{x}_i)\cdot\nabla^{k+1}\psi_i(\mathbf{x}_i)$, with $k > 1$. Adding all three parts together, we have

$$\frac{\partial K}{\partial \mathbf{x}_i} = 2\pi\rho_\ell\left(-2R_i^2\dot{R}_i\mathbf{v}_i + R_i^3(\nabla\mathbf{v}_i)^T\cdot(\mathbf{v}_i - \mathbf{U}_i) + G\right).$$

Appendix E. Energy dissipation and drag force. In this appendix, we will calculate energy dissipation of bubbly flow with a finite number of bubbles. We then calculate the drag force on each bubble.

Energy dissipation. From (72), we have

$$\mathcal{D} = -\mu\int_S \frac{\partial(\nabla\phi\cdot\nabla\phi)}{\partial r}ds.$$

Using (17) in the above expression, we have

$$\mathcal{D} = -\mu\sum_{i=1}^N\int_{S_i}\frac{\partial}{\partial n}\left|\nabla\left(\phi_i + \psi_i + I_i\psi_i\right)\right|^2 ds.$$

Applying Theorem 3.2 and expanding ψ_i, we obtain

$$\begin{aligned}\mathcal{D} =& -\mu\sum_{i=1}^N\int_{S_i}\frac{\partial}{\partial n}\Bigg|\nabla\Bigg(-\frac{R_i^2\dot{R}_i}{|\mathbf{r}-\mathbf{x}_i|} + \frac{1}{2}R_i^3\nabla_{\mathbf{r}}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\cdot\mathbf{U}_i \\ &+ \psi_i(\mathbf{x}_i) + \mathbf{v}_i(\mathbf{x}_i)\cdot(\mathbf{r}-\mathbf{x}_i) - \frac{1}{2}R_i^3\mathbf{v}_i(\mathbf{x}_i)\cdot\nabla_{\mathbf{r}}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right) \\ &+ (\text{higher order harmonics})\Bigg)\Bigg|^2 ds \\ =& -\mu\sum_{i=1}^N\int_{S_i}\frac{\partial}{\partial n}\Bigg|-R_i^2\dot{R}_i\nabla_r\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right) + \frac{1}{2}R_i^3\nabla_{\mathbf{r}}^2\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\cdot(\mathbf{U}_i - \mathbf{v}_i) \\ &+ \mathbf{v}_i + (\text{higher order harmonics})\Bigg|^2 ds.\end{aligned}$$

Since spherical harmonics of different order are orthogonal to each other, we calculate each term in the above equation separately. For the monopole term, we have

$$\begin{aligned}\int_{S_i}\frac{\partial}{\partial n}\left|\nabla\left(-\frac{R_i^2\dot{R}_i}{|\mathbf{r}-\mathbf{x}_i|}\right)\right|^2 ds &= \int_{S_i}\frac{\partial}{\partial n}\left[\frac{R_i^4\dot{R}_i^2}{|\mathbf{r}-\mathbf{x}_i|^4}\right] ds\\ &= \int_{S_i}\frac{-4\dot{R}_i^2}{|\mathbf{r}-\mathbf{x}_i|} ds\\ &= -16\pi R_i\dot{R}_i^2.\end{aligned}$$

A direct calculation from Mathematica shows us that

$$\begin{aligned}&\int_{S_i}\frac{\partial}{\partial n}\left(\frac{\partial^2}{\partial x^2}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\right)^2 ds = -\frac{96\pi}{5R_i^5},\\ &\int_{S_i}\frac{\partial}{\partial n}\left(\frac{\partial^2}{\partial x^2}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\frac{\partial^2}{\partial y^2}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\right) ds = \frac{48\pi}{5R_i^5},\\ &\int_{S_i}\frac{\partial}{\partial n}\left(\frac{\partial^2}{\partial x^2}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\frac{\partial^2}{\partial x\partial y}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\right) ds = 0,\\ &\int_{S_i}\frac{\partial}{\partial n}\left(\frac{\partial^2}{\partial x^2}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\frac{\partial^2}{\partial y\partial z}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\right) ds = 0,\\ &\int_{S_i}\frac{\partial}{\partial n}\left(\frac{\partial^2}{\partial x\partial y}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\frac{\partial^2}{\partial x\partial y}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\right) = -\frac{72\pi}{5R_i^5},\\ &\int_{S_i}\frac{\partial}{\partial n}\left(\frac{\partial^2}{\partial x\partial y}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\frac{\partial^2}{\partial x\partial z}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\right) = 0.\end{aligned}$$

With these results, we can calculate dipole terms in energy dissipation and find

$$\begin{aligned}&\int_{S_i}\frac{\partial}{\partial n}\left|\nabla\left(\frac{1}{2}R_i^3\nabla_{\mathbf{r}}\left(\frac{1}{|\mathbf{r}-\mathbf{x}_i|}\right)\cdot(\mathbf{U}_i-\mathbf{v}_i(\mathbf{x}_i))\right)\right|^2 ds\\ &= -\frac{1}{4}R_i^6\left(\frac{96\pi}{5R_i^5}+\frac{72\pi}{5R_i^5}+\frac{72\pi}{5R_i^5}\right)|\mathbf{U}_i-\mathbf{v}_i(\mathbf{x}_i)|^2\\ &= -12\pi R_i|\mathbf{U}_i-\mathbf{v}_i(\mathbf{x}_i)|^2.\end{aligned}$$

Hence one finds

$$\begin{aligned}\mathcal{D} = \sum_{i=1}^N &\mu\pi R_i\left(16\dot{R}_i^2+12|\mathbf{U}_i-\mathbf{v}_i(\mathbf{x}_i)|^2\right)\\ &+(\text{terms caused by higher order harmonics}).\end{aligned}$$

Drag force. We assume there is no radial oscillation and all bubbles have same radius R. Then

$$\begin{aligned}\mathbf{F}_i &= -\frac{1}{2}\frac{\partial\mathcal{D}}{\partial\mathbf{U}_i} = -6\mu\pi R\frac{\partial}{\partial\mathbf{U}_i}\sum_{j=1}^N|\mathbf{U}_j-\mathbf{v}_j|^2\\ &= -6\mu\pi R\frac{\partial}{\partial\mathbf{U}_i}\sum_{j=1}^N(|\mathbf{U}_j|^2-2\mathbf{U}_j\cdot\mathbf{v}_j(\mathbf{x}_j)+|\mathbf{v}_j(\mathbf{x}_j)|^2)\\ &= -12\mu\pi R\left(\mathbf{U}_i-\frac{\partial}{\partial\mathbf{U}_i}\sum_{j=1}^N\mathbf{U}_j\cdot\mathbf{v}_j(\mathbf{x}_j)+\frac{1}{2}\frac{\partial}{\partial\mathbf{U}_i}\sum_{j=1}^N|\mathbf{v}_j(\mathbf{x}_j)|^2\right).\end{aligned}\tag{117}$$

From the expression for the kinetic energy K in (20), we have, when radial oscillations are absent,

$$\sum_{j=1}^{N} \mathbf{U}_j \cdot \mathbf{v}_j(\mathbf{x}_j) = -\frac{K}{\pi \rho_\ell R^3} + \frac{1}{3}\sum_{j=1}^{N} |\mathbf{U}_j|^2.$$

Hence one finds

$$\frac{\partial}{\partial \mathbf{U}_i}\sum_{j=1}^{N} \mathbf{U}_j \cdot \mathbf{v}_j(\mathbf{x}_j) = -\frac{1}{\pi \rho_\ell R^3}\frac{\partial K}{\partial \mathbf{U}_i} + \frac{2}{3}\mathbf{U}_i.$$

Using (23), we have

$$\frac{\partial}{\partial \mathbf{U}_i}\sum_{j=1}^{N} \mathbf{U}_j \cdot \mathbf{v}_j(\mathbf{x}_j) = 2\mathbf{v}_i(\mathbf{x}_i). \tag{118}$$

Unfortunately we cannot calculate exactly

$$\frac{\partial}{\partial \mathbf{U}_i}\sum_{j=1}^{N} |\mathbf{v}_j(\mathbf{x}_j)|^2,$$

and we will use (14) to provide an approximate calculation. Using the first term in (14), we have

$$\phi \approx \sum_{j=1}^{N} \phi_i,$$

and it follows that

$$\psi_j \approx \sum_{k\neq j, k=1}^{N} \phi_k.$$

With the expression for ϕ_j in (13), we have

$$\frac{\partial \mathbf{v}_j(\mathbf{x}_j)}{\partial \mathbf{U}_i} = \frac{\partial \nabla \psi_j(\mathbf{x}_j)}{\partial \mathbf{U}_i} \approx \begin{cases} \frac{1}{2}R_i^3 \nabla^2 \left(\frac{1}{|\mathbf{x}_i - \mathbf{x}_j|}\right), & i \neq j, \\ 0, & i = j. \end{cases}$$

Therefore we find (with $R_i = R$)

$$\frac{\partial}{\partial \mathbf{U}_i}\sum_{j=1}^{N} |\mathbf{v}_j(\mathbf{x}_j)|^2 = 2\sum_{j=1}^{N} \frac{\partial \mathbf{v}_j(\mathbf{x}_j)}{\partial \mathbf{U}_i} \cdot \mathbf{v}_j(\mathbf{x}_j) = \sum_{j=1, j\neq i}^{N} R^3 \nabla^2 \left(\frac{1}{|\mathbf{x}_i - \mathbf{x}_j|}\right) \cdot \mathbf{v}_j(\mathbf{x}_j). \tag{119}$$

Using (117), (118), and (119), we obtain

$$\mathbf{F}_i \approx -12\pi\mu R(\mathbf{U}_i - 2\mathbf{v}_i(\mathbf{x}_i) - \mathbf{w}_i(\mathbf{x}_i)),$$

where

$$\mathbf{w}_i(\mathbf{r}) = -\sum_{j\neq i} \frac{1}{2} R^3 \nabla^2 \left(\frac{1}{|\mathbf{r} - \mathbf{x}_j|}\right) \cdot \mathbf{v}_j(\mathbf{x}_j).$$

CRITICAL THRESHOLDS IN 2D RESTRICTED EULER–POISSON EQUATIONS*

HAILIANG LIU† AND EITAN TADMOR‡

Abstract. We provide a complete description of the critical threshold phenomenon for the two-dimensional localized Euler–Poisson equations, introduced by the authors in [*Comm. Math. Phys.*, 228 (2002), pp. 435–466]. Here, the questions of global regularity vs. finite-time breakdown for the two-dimensional (2D) restricted Euler–Poisson solutions are classified in terms of precise explicit formulae, describing a remarkable variety of critical threshold surfaces of initial configurations. In particular, it is shown that the 2D critical thresholds depend on the relative sizes of three quantities: the initial density, the initial divergence, and the initial spectral gap, that is, the difference between the two eigenvalues of the 2×2 initial velocity gradient.

Key words. critical thresholds, restricted Euler–Poisson dynamics, spectral gap

1. Introduction and statement of main results.

We are concerned with the critical threshold phenomenon in multidimensional Euler–Poisson equations. In this paper we consider a localized version of the following two-dimensional (2D) Euler–Poisson equations:

$$\partial_t \rho + \nabla \cdot (\rho U) = 0, \quad x \in \mathbb{R}^2, \quad t \in \mathbb{R}^+, \tag{1.1}$$

$$\partial_t (\rho U) + \nabla \cdot (\rho U \otimes U) = -k\rho \nabla \phi, \tag{1.2}$$

$$-\Delta \phi = \rho - c, \quad x \in \mathbb{R}^2, \tag{1.3}$$

which are the usual statements of the conservation of mass, Newton's second law, and the Poisson equation defining, say, the electric field in terms of the charge. Here $k > 0$ is a scaled physical constant, which signifies the property of the underlying repulsive forcing (avoiding the case of an attractive force with $k < 0$), and c denotes the constant "background" state. The unknowns are the local density $\rho = \rho(x,t)$, the velocity field $U = (u,v)(x,t)$, and the potential $\phi = \phi(x,t)$. It follows that, as long as the solution remains smooth, the velocity U solves a forced transport equation

$$\partial_t U + U \cdot \nabla U = F, \quad F = -k\nabla \phi, \tag{1.4}$$

with ϕ being governed by Poisson's equation (1.3).

This hyperbolic-elliptic coupled system (1.1)–(1.3) describes the dynamic behavior of many important physical flows, including charge transport [25], plasma with collision [15], cosmological waves [3], and the expansion of cold ions [13]. Let us men-

tion that the Euler–Poisson equations could also be realized as the semiclassical limit of the Schrödinger–Poisson equation and are found in the "cross section" of Vlasov–Poisson equations. These relations have been the subject of a considerable amount of work in recent years, and we refer to [11, 7] and references therein for further details.

To put our study in the proper perspective we recall a few of the references from the considerable amount of literature available on the behavior of the Euler–Poisson and related problems. Let us mention the local existence in the small H^s-neighborhood of a steady state, e.g., [21, 26, 10]; the global existence of weak solutions with geometrical symmetry [6]; the two-carrier types in one dimension [32]; and the relaxation limit for the weak entropy solution (consult [24] for the isentropic case, and [16] for the isothermal case). Recently, the global existence of time-dependent sheaths with geometric symmetry was established in [14] by studying the Euler–Poisson system (1.1)–(1.3) with $c = e^{-\phi}$, the so-called Boltzmann relation.

For the question of global behavior of strong solutions, however, the choice of the initial data and/or damping forces is decisive. The nonexistence results in the case of attractive forces, $k < 0$, have been obtained by Makino and Perthame [23], and for repulsive forces by Perthame [27]. For research on the singularity formation in the model with diffusion and relaxation, consult [33]. In all these cases, the finite lifespan is due to a *global* condition of large enough initial (generalized) energy, staying outside a critical threshold ball. Using the characteristic-based method, Engelberg [8] gave local conditions for the finite-time loss of smoothness of solutions in Euler–Poisson equations. Global existence due to damping relaxation and with nonzero background can be found in [30, 31, 17]. For the model without damping relaxation the global existence was obtained by Guo [12], assuming that the flow is irrotational. His result applies to H_2-small neighborhoods of constant state.

When dealing with the questions of time regularity for Euler–Poisson equations without damping, one encounters several limitations of the classical stability analysis. Among other issues, we mention that

(i) stability analysis does not tell us how large perturbations can be before losing stability—indeed, the smallness of the initial perturbation is essential to making the energy method work (see, e.g., [12]);

(ii) the steady solution may be only conditionally stable due to the weak dissipation in the system, say, in the one-dimensional (1D) Euler–Poisson equations [9].

In order to address these difficulties, we advocated, in [9], a new notion of critical threshold (CT), which describes the conditional stability of the 1D Euler–Poisson equations, where the answer to the question of global vs. local existence depends on whether the initial configuration crosses an intrinsic $O(1)$ critical threshold. Little or no attention has been paid to this remarkable phenomenon, and our goal is to bridge the gap of previous studies on the behavior in Euler–Poisson solutions, a gap between the regularity of Euler–Poisson solutions "in the small" and their finite-time breakdown "in the large." The CT in the 1D Euler–Poisson system was completely characterized in terms of the relative size of the initial velocity slope and the initial density. Moving to the multidimensional setup, one has first to identify the proper quantities which govern the critical threshold phenomenon. In [19] we have shown that these quantities depend in an essential manner on the *eigenvalues* of the gradient velocity matrix, ∇u. In order to trace the evolution of $M := \nabla U$, we differentiate (1.4), obtaining formally

$$\partial_t M + U \cdot \nabla M + M^2 = -k(\nabla \otimes \nabla)\phi = kR[\rho - c], \tag{1.5}$$

where $R[\ ]$ is the 2×2 Risez matrix operator, defined as

$$R[f] =: \nabla\otimes\nabla\Delta^{-1}[f] = \mathcal{F}^{-1}\left\{\frac{\xi_j\xi_k}{|\xi|^2}\hat{f}(\xi)\right\}_{j,k=1,2}.$$

The above system is complemented by its coupling with the density ρ, which is governed by

$$\partial_t\rho + U\cdot\nabla\rho + \rho trM = 0. \tag{1.6}$$

Passing to the Lagrangian coordinates, that is, using the change of variables $\alpha\mapsto x(\alpha,t)$ with $x(\alpha,t)$ solving

$$\frac{dx}{dt} = U(x,t), \quad x(\alpha,0)=\alpha,$$

Euler–Poisson equations are recast into the coupled system

$$\frac{d}{dt}M + M^2 = kR[\rho - c], \tag{1.7}$$

$$\frac{d}{dt}\rho + \rho trM = 0, \tag{1.8}$$

with d/dt standing for the usual material derivative, $\partial_t + U\cdot\nabla$. It is the global forcing, $kR[\rho-c]$, which presents the main obstacle to studying the CT phenomenon of the multidimensional Euler–Poisson setting.

In this work we focus on the restricted Euler–Poisson (REP) system introduced in [19], which is obtained from (1.7) by restricting attention to the local isotropic trace, $\frac{k}{2}(\rho-c)I_{2\times 2}$, of the global coupling term $kR[\rho-c]$, namely,

$$\frac{d}{dt}M + M^2 = \frac{k}{2}(\rho-c)\cdot I_{2\times 2}, \tag{1.9}$$

$$\frac{d}{dt}\rho + \rho trM = 0. \tag{1.10}$$

We are concerned with the initial value REP problem (1.9), (1.10), subject to initial data

$$(M,\rho)(\cdot,0) = (M_0,\rho_0).$$

We note in passing that the REP system is to the full Euler–Poisson equations what the restricted Euler model is to the full Euler equations; consult [29, 4, 1, 2, 5, 19]. The existence of a critical threshold phenomenon associated with this 2D REP model with zero background, $c=0$, was first identified by us [19]. The current paper provides a precise description of the critical threshold for the 2D REP system (1.9), (1.10), with both zero and nonzero background charges. In particular, we use the so-called spectral dynamics lemma [19, Lemma 3.1] to obtain remarkable explicit formulae for the critical threshold surfaces summarized in the main Theorems 1.1 and 1.2 below.

To state our main results, we introduce two quantities with which we characterize the behavior of the velocity gradient tensor M. These are the trace, $d := trM$ (and we note that in case M coincides with ∇U, then d stands for the divergence, $d = u_x + v_y$), and the nonlinear quantity $\Gamma := (trM)^2 - 4detM$, which serves as an index for the *spectral gap*. Indeed, if $\lambda_i, i=1,2$, are the eigenvalues of M, then

$$\lambda_1 = \frac{1}{2}[d - \sqrt{\Gamma}], \qquad \lambda_2 = \frac{1}{2}[d+\sqrt{\Gamma}],$$

and hence Γ is nothing but the square of the spectral gap $\Gamma = (\lambda_2 - \lambda_1)^2$. We note that when M coincides with ∇U, then $\Gamma = (u_x - v_y)^2 + 4u_y v_x$, and the role of this spectral gap was first identified in the context of the 2D Eikonal equation in [19, Lemma 5.2].

We observe that if $\Gamma < 0$, then the spectral gap is purely imaginary. Otherwise, the spectral gap is real.

THEOREM 1.1 (2D REP with zero background). *Consider the 2D repulsive REP system* (1.9)–(1.10), *with $k > 0$ and with zero background $c = 0$. The solution of the 2D REP remains smooth for all time if and only if the initial data (ρ_0, M_0) lies in one of the following two regions, $(\rho_0, d_0, \Gamma_0) \in S_1 \cup S_2$:*

(i) $(\rho_0, d_0, \Gamma_0) \in S_1$,

$$S_1 := \left\{ (\rho, d, \Gamma) \;\middle|\; \Gamma \le 0 \quad \textit{and} \quad \left\{ \begin{array}{ll} d \ge 0 & \textit{if } \rho = 0, \\ d \textit{ arbitrary} & \textit{if } \rho > 0, \end{array} \right\} \right\}$$

(ii) $(\rho_0, d_0, \Gamma_0) \in S_2$,

$$S_2 := \left\{ (\rho, d, \Gamma) \;\middle|\; \rho > 0,\ \Gamma > 0, \quad \textit{and} \quad d \ge g(\rho, \Gamma) \right\},$$

where

$$g(\rho, \Gamma) := \operatorname{sgn}(\Gamma - 2k\rho) \sqrt{\Gamma - 2k\rho + 2k\rho \ln \left(\frac{2k\rho}{\Gamma} \right)}.$$

THEOREM 1.2 (2D REP with nonzero background). *Consider the 2D repulsive REP system* (1.9)–(1.10), *with $k > 0$ and with nonzero background $c > 0$. The solution of the 2D REP remains smooth for all time if and only if the initial data (ρ_0, M_0) lies in one of the following three regions, $(\rho_0, d_0, \Gamma_0) \in S_1 \cup S_2 \cup S_3$:*

(i) $(\rho_0, d_0, \Gamma_0) \in S_1$,

$$S_1 := \left\{ (\rho, d, \Gamma) \;\middle|\; \Gamma \le 0 \quad \textit{and} \quad \left\{ \begin{array}{ll} d \ge 0 & \textit{if } \rho = 0, \\ d \textit{ arbitrary} & \textit{if } \rho > 0, \end{array} \right\} \right\}$$

(ii) $(\rho_0, d_0, \Gamma_0) \in S_2$,

$$S_2 := \left\{ (\rho, d, \Gamma) \;\middle|\; 0 < \Gamma < \frac{k}{2c}\rho^2 \quad \textit{and} \quad \left\{ \begin{array}{lll} |d| \le g_1(\rho, \Gamma) & \textit{if} & \Gamma < 2k(\rho - c), \\ d \ge g_1(\rho, \Gamma) & \textit{if} & \Gamma \ge 2k(\rho - c), \end{array} \right\} \right\}$$

where

$$g_1(\rho, \Gamma) := \sqrt{\Gamma - 2k \left[c + \sqrt{\rho^2 - 2ck^{-1}\Gamma} + \rho \ln \left(\frac{\rho - \sqrt{\rho^2 - 2ck^{-1}\Gamma}}{2c} \right) \right]},$$

(iii) $(\rho_0, d_0, \Gamma_0) \in S_3$,

$$S_3 := \left\{ (\rho, d, \Gamma) \;\middle|\; \Gamma = \frac{k}{2c}\rho^2, \quad d = g_2(\rho, \Gamma), \quad \rho > 0 \right\},$$

where

$$g_2(\rho) = g_1(\rho, \Gamma)|_{\Gamma = \frac{k}{2c}\rho^2} := \sqrt{-2ck + \frac{k}{2c}\rho^2 + 2k\rho \ln \left(\frac{2c}{\rho} \right)}.$$

Several remarks are in order.

1. The above results show that the global smooth solution is ensured if the *initial* velocity gradient has complex eigenvalues, which applies, for example, for a class of initial configurations with sufficiently large vorticity $|u_{0y}-v_{0x}| \gg 1$. With other initial configurations, however, the finite-time breakdown of solutions may, and actually does, occur unless the initial divergence is above a critical threshold, expressed in terms of the initial density and initial spectral gap. Hence, global regularity depends on whether the initial configuration crosses an intrinsic $\mathcal{O}(1)$ critical threshold.

2. The critical threshold in the 1D Euler–Poisson equations depends on the relative size of the initial velocity slope and the initial density; consult [9]. In contrast to the 1D scenario, the critical threshold presented here depends on three initial quantities: density ρ_0, divergence $\nabla \cdot U_0$, and initial spectral gap $\Gamma_0 = (u_{0x} - v_{0y})^2 + 4u_{0y}v_{0x}$.

3. Theorem 1.1 tells us that the size of the initial subcritical range which gives rise to the regular solution is decreasing as the initial ratio Γ_0/ρ_0 is increasing. In particular, when this ratio is larger than $2k$, then the initial divergence must stay above a positive critical threshold to avoid the finite-time breakdown.

4. From Theorem 1.2 we see that the initial critical range which guarantees global regularity shrinks as the initial ratio Γ_0/ρ_0^2 is increasing in $(-\infty, \frac{k}{2c})$. Finite-time breakdown must occur when this ratio is larger than $\frac{k}{2c}$.

5. The limit $c \downarrow 0$ is a sort of *singular limit*, and hence one cannot recover Theorem 1.1 simply by passing to the limit $c \to 0$ in Theorem 1.2. □

It is well known that a finite-time breakdown is a generic phenomenon for nonlinear hyperbolic convection equations, which is realized by the formation of shock discontinuities. In the context of Euler–Poisson equations, however, there is a delicate balance between the forcing mechanism (governed by a Poisson equation) and the nonlinear focusing (governed by Newton's second law), which supports a critical threshold phenomenon.

In this paper we show how the persistence of the global features of the solutions for REP hinges on a delicate balance between the nonlinear convection and the localized forcing mechanism dictated by the Poisson equation. Here we use these restricted models to demonstrate the ubiquity of *critical thresholds* in the solutions of some of the equations of mathematical physics. This remarkable CT phenomenon has been found in other contexts, such as the scalar convolution model for nonlinear conservation laws [18], a nonlocal model in the nonlinear wave propagation [28], etc. Let us mention in particular the recent study [20], which shows, in the 2D case, how rotation enforces a CT phenomenon through which it prevents finite-time breakdown of nonlinear convection. Let us point out that the approach taken in this paper applies to the 3D case, leading to a closed 4×4 nonlinear system of ODEs governing the time-dynamics of the 3D REP. Identifying the CT phenomenon for such a system, however, is a formidable task which we hope to pursue in a future work.

In this paper we focus our attention on the restricted Euler–Poisson equations, "restricted" in the sense of using the same recipe for localized forcing as in the restricted Euler dynamics [29, 4, 1, 2, 5, 19]. We note in passing that the presence of global forcing in the full 2D Euler–Poisson equation, where $(\rho - c)I_{2\times 2}$ on the right-hand side of (1.9) is restored to the full $R[\rho - c]$ term, should allow for an additional stabilizing effect. We conjecture, therefore, that the full 2D Euler–Poisson equations admit a similar CT phenomenon, and in particular, that they admit global smooth solutions for subcritical initial data. As remarked earlier, the main obstacle in handling

this global case is the lack of an accurate description for the propagation of the Risez transform. Finally, one should not expect the current pressureless model to provide a faithful description of the model with pressure. The addition of a pressure term provides yet an additional mechanism for mixing between different particle paths.

We now conclude this section by outlining the rest of the paper. In section 2 we study the critical threshold for the REP with zero background. The key observation is that the spectral gap is conserved along the particle path. With this property we will be able to reduce the full dynamics on the 2D manifold parameterized by this initial spectral gap. In section 3 we discuss the critical threshold for the REP with nonzero background, where the CT arguments become considerably more involved. We treat the different cases which are indexed by the initial spectral gap.

2. 2D REP with zero background. In this section we prove the existence of the critical threshold of the 2D REP with zero background ($c = 0$)

$$\frac{d}{dt}M + M^2 = \frac{k}{2}\rho I_{2\times 2}, \tag{2.1}$$

$$\frac{d}{dt}\rho + \rho trM = 0. \tag{2.2}$$

This system with initial data (ρ_0, M_0) is well posed in the usual H^s Sobolev spaces for a short time. The global regularity follows from the standard boot-strap argument, once an a priori estimate on $\|M(\cdot)\|_{L^\infty}$ is obtained. First we show that, for the 2D REP (2.1)–(2.2), the velocity gradient tensor is completely controlled by the divergence d and the density ρ.

LEMMA 2.1. *Let M be the solution of the 2D REP; then the boundedness of M depends on the boundedness of trM and ρ; namely, there exists a constant, $Const = Const_T$, such that*

$$\|M(\cdot,t)\|_{L^\infty[0,T]} \le Const_T.\|(trM,\rho)\|_{L^\infty[0,T]}.$$

Proof. For the 2D case the velocity gradient tensor is completely governed by $p := M_{11} - M_{22}$, $q := M_{12} + M_{21}$, $\omega = M_{12} - M_{21}$, and $d = M_{11} + M_{22}$. From the M equation (2.1),

$$\frac{d}{dt}\begin{pmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{pmatrix} + \begin{pmatrix} M_{11}^2 + M_{21}M_{12} & dM_{12} \\ dM_{21} & M_{21}M_{12} + M_{22}^2 \end{pmatrix} = \frac{k}{2}\rho I_{2\times 2},$$

one can obtain

$$\frac{d}{dt}p + pd = 0,$$
$$\frac{d}{dt}q + qd = 0,$$
$$\frac{d}{dt}\omega + \omega d = 0,$$

which, when combined with the mass equation

$$\frac{d}{dt}\rho + \rho d = 0,$$

gives

$$(p, q, \omega) = (p_0, q_0, \omega_0)\rho_0^{-1}\rho.$$

This shows that $|M_{ij}|_{L^\infty}$ are bounded in terms of $|d|_{L^\infty}$ and $|\rho|_{L^\infty}$ as asserted. ∎

This lemma tells us that to show the global regularity it suffices to control the divergence d and the density ρ. Let $\lambda_i, i = 1, 2$, be the eigenvalues of the velocity gradient tensor; then $d = \lambda_1 + \lambda_2$, and the continuity equation (1.10) reads

$$\frac{d}{dt}\rho + \rho(\lambda_1 + \lambda_2) = 0. \tag{2.3}$$

The spectral dynamics lemma [19, Lemma 3.1] tells us that the velocity gradient equation (1.9) yields

$$\frac{d}{dt}\lambda_1 + \lambda_1^2 = \frac{k}{2}\rho, \tag{2.4}$$

$$\frac{d}{dt}\lambda_2 + \lambda_2^2 = \frac{k}{2}\rho. \tag{2.5}$$

Following [19], we consider the difference of the last two equations, which gives for $\eta := \lambda_2 - \lambda_1$

$$\frac{d}{dt}\eta + \eta(\lambda_1 + \lambda_2) = 0.$$

This, combined with the mass equation (2.3) and $trM = \lambda_1 + \lambda_2$, yields

$$\frac{d}{dt}\left(\frac{\eta}{\rho}\right) = 0 \Rightarrow \quad \frac{\eta}{\rho} = \frac{\eta_0(\alpha)}{\rho_0(\alpha)}, \quad \alpha \in \mathbb{R}^2.$$

Set $\beta := \eta_0^2(\alpha)/\rho_0^2(\alpha)$ as a moving parameter with the initial position $\alpha \in \mathbb{R}^2$; one then obtains a closed system for ρ and d:

$$\rho' + \rho d = 0, \quad ' := \frac{d}{dt}, \tag{2.6}$$

$$d' + \frac{d^2 + \beta\rho^2}{2} = k\rho. \tag{2.7}$$

The first is the mass equation; the second is a restatement of summing (2.4), (2.5), $d' + (d^2 + \eta^2)/2 = k\rho$ with $\eta^2 = \beta\rho^2$.

We shall study the dynamics of (ρ, d) parameterized by β. It is easy to see that if the initial eigenvalues are complex, then the eigenvalues remain complex as time evolves. From

$$\beta = \frac{\Gamma_0}{\rho_0^2}, \qquad \Gamma_0 = (\lambda_2(0) - \lambda_1(0))^2,$$

we see that we need to distinguish between two cases, namely, $\beta < 0$, where the initial spectral gap is complex, and $\beta \geq 0$, where the initial spectral gap is real.

2.1. Complex spectral gap. We first study the case $\beta < 0$ when the initial eigenvalues are complex, i.e., $\mathrm{Im}(\lambda_i) \neq 0$.

LEMMA 2.2. *The solution of a 2D REP remains smooth for all time if eigenvalues are initially complex. Moreover, there is a global invariant given by*

$$\frac{d^2 - \beta\rho^2}{\rho} + 2k\ln\rho = Const. \tag{2.8}$$

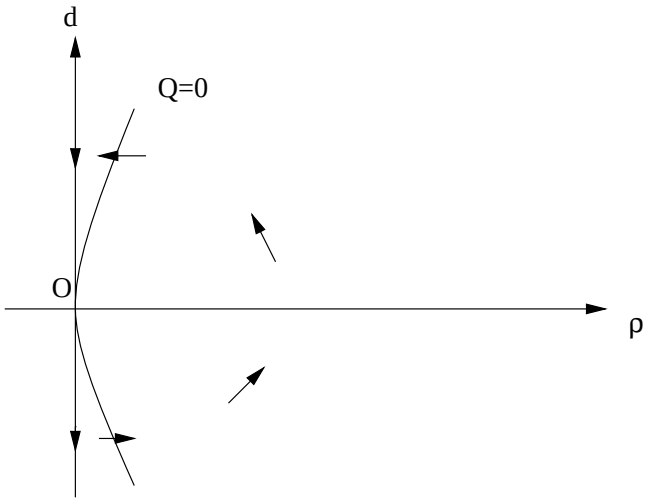

FIG. 2.1. *Zero level set $d' = 0$. Complex spectral gap.*

Proof. To obtain the desired global invariant we set $q := d^2$; then from (2.6)–(2.7) we deduce

$$\frac{dq}{d\rho} = 2d\frac{d'}{\rho'} = -2k + \beta\rho + \frac{q}{\rho}.$$

Integration gives

$$\frac{q}{\rho} - \beta\rho + 2k\ln\rho = Const,$$

which leads to (2.8). The boundedness of d follows at once, since for negative β's,

$$d^2 \le \max_{\rho>0}\left\{Const.\rho - 2k\ln\rho + \beta\rho^2\right\} =: C_1^2.$$

In particular, substitution of the lower bound $d \ge -C_1$ into the mass equation gives

$$\rho' \le C_1\rho,$$

which yields the desired upper bound for the density, $\rho(\cdot,t) \le \rho_0(\alpha)e^{C_1 t}$. □

Remark. More precise information about the large time behavior is available from phase plane analysis. According to (2.7), the zero level set $d' = 0$ is the hyperbola $Q := k\rho - (d^2 + \beta\rho^2)/2 = 0$, with a right branch passing the critical point $(0,0)$ and a left branch located in the left half-plane, $\rho < 0$; see Figure 2.1.

The trajectory on the plane $\rho < 0$ does not affect the solution behavior in the region $\rho > 0$ since $\rho = 0$ is an invariant set governed by

$$\rho \equiv 0, \qquad d' = -\frac{d^2}{2} \to d(t) = \frac{d_0}{1 + \frac{d_0}{2}t}.$$

Note that $(0,0)$ is the only critical point of the autonomous ODE system (2.6), (2.7) on the right half phase plane, and that the vector field in $\{(\rho,d),\ Q < 0, d \ge 0\}$ is

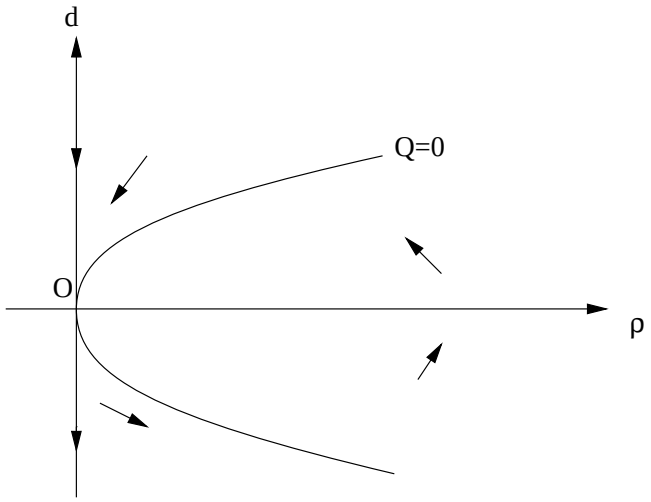

FIG. 2.2. *Zero level set $d' = 0$. Real spectral gap.*

converging to the critical point $(0, 0)$. It follows that for global smoothness it suffices to control the divergence d from below in the region $\{(\rho, d),\ Q < 0, d < 0, \rho > 0\}$ and to control the density from above in the region $\{(\rho, d), Q > 0\}$.

For the former case we have, recalling that $\beta < 0$,

$$\left(\frac{d}{\rho}\right)' = k + \frac{d^2}{2\rho} - \frac{\beta\rho}{2} \geq k,$$

and its integration along a particle path gives

$$d \geq \left(kt + \frac{d_0}{\rho_0}\right)\rho.$$

This shows that the divergence d is bounded from below, and, in particular, it becomes positive for large time since the density is positive. To the upper bound for ρ in the region $Q > 0$, where $d(t) \geq d_0(\alpha)$, we substitute this estimate into the mass equation, yielding

$$\rho' \leq -\rho d_0(\alpha).$$

This clearly gives the upper bound for the density $\rho \leq \rho_0(\alpha)e^{-d_0 t}$.

2.2. Real spectral gap. When $\beta \geq 0$, the initial spectral gap is real, and there are two cases to be considered, as follows.

Subcase 1. $\beta = 0$ when the eigenvalues are equal, i.e., $\lambda_1(0) = \lambda_2(0)$. In this case the zero level set $d' = 0$ becomes a parabola passing through the only critical point $(0, 0)$ (see Figure 2.2), and one can repeat arguments similar to our phase plane analysis in the previous case of distinct real roots. Note that the global invariant (2.8) becomes

$$\frac{d^2}{\rho} + 2k \ln \rho = Const.$$

Subcase 2. $\beta > 0$ when the eigenvalues are initially real.

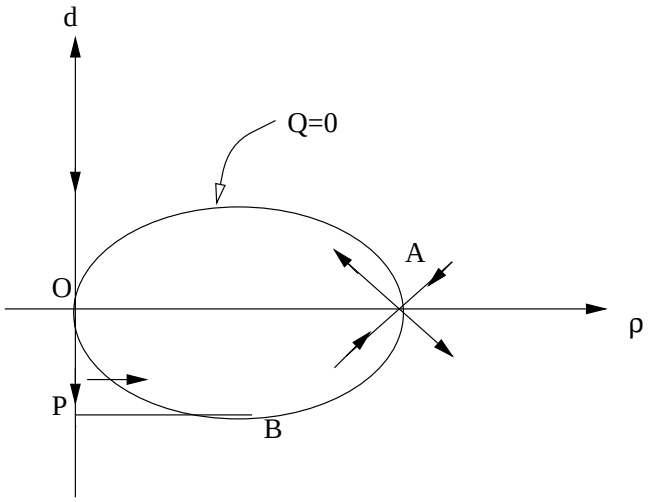

FIG. 2.3. *Critical points in the ρ-d plane. Real spectral gap.*

LEMMA 2.3. *If eigenvalues of ∇U_0 are real, then the solution of 2D REP remains smooth for all time if and only if*

$$\lambda_1(0) + \lambda_2(0) \geq g(\rho_0),$$

where

$$g(\rho) := \operatorname{sgn}\left(\rho - \frac{2k}{\beta}\right)\sqrt{\rho \times \left(F(\rho) - F\left(\frac{2k}{\beta}\right)\right)}, \quad F(\rho) = \beta\rho - 2k\ln\rho.$$

Proof. The system (2.6)–(2.7) has two critical points on the phase plane: $O(0,0)$ and $A(\frac{2k}{\beta}, 0)$; see Figure 2.3.

The coefficient matrix of the linearized system around (ρ^*, d^*) is

$$L(\rho^*, d^*) = \begin{pmatrix} -d^* & -\rho^* \\ k - \beta\rho^* & -d^* \end{pmatrix}.$$

A simple calculation gives the eigenvalues of L,

$$\lambda_\pm = -d^* \pm \sqrt{\rho^*(\beta\rho^* - k)}.$$

At $(0,0)$, we have $\lambda_1 = \lambda_2 = 0$, and hence $(0,0)$ is a nonhyperbolic critical point. Another critical point, $A(\frac{2k}{\beta}, 0)$, is a saddle since $\lambda_{1,2} = \pm\sqrt{\frac{2}{\beta}}k$. We shall use the above facts to construct the critical threshold via the phase plane analysis.

Assume that the seperatrix enters (leaves) A along the line $d = s(\rho - \frac{2k}{\beta})$. Upon substitution into the linearized system around A, i.e.,

$$\rho' = -\frac{2k}{\beta}d, \qquad d' = -k\left(\rho - \frac{2k}{\beta}\right),$$

one can obtain

$$s = \pm\sqrt{\frac{\beta}{2}}.$$

Thus, two seperatrices leave/enter A along the directions

$$\theta_1 = -\text{arctg}\sqrt{\frac{\beta}{2}} \quad \text{and} \quad \theta_2 = \text{arctg}\sqrt{\frac{\beta}{2}}.$$

In the phase plane the zero level set $d' = 0$ is an ellipse (see Figure 2.3),

$$d^2 + \beta\left(\rho - \frac{k}{\beta}\right)^2 = \frac{k^2}{\beta}.$$

Let $\gamma_s(A)$ be the portion of the stable manifold of the system coming into A from $\{d < 0\}$. In order to prove the existence of a critical threshold it suffices to show that $\gamma_s(A)$ can come only from O. Let B be the lowest point of the ellipse with coordinates $(\frac{k}{\beta}, -\frac{k}{\sqrt{\beta}})$, and let $\overline{PB}$ be a horizontal line intersecting with $\rho = 0$ at $(0, -\frac{k}{\sqrt{\beta}})$. According to the vector field inside the ellipse we see that the trajectory $\gamma_s(A)$ can come only from the area OPB by crossing the curve $\overline{OB}$. Note that the vector field on $\overline{PB}$ is going outside OPB and that $\rho = 0$ is invariant. Thus all trajectories in the area OPB originate from O. Therefore $\gamma_s(A)$ can originate only from O (as $t \to -\infty$) and becomes a portion of one unstable manifold of O. By symmetry we can show that the unstable manifold of the system issued from A entering $\{d > 0\}$ will end through the portion $\{d > 0\}$ at O.

Thus the critical curve $g : \mathbb{R}^+ \to \mathbb{R}$ is the one defined as

$$\{(\rho, d),\ d = g(\rho)\} = \gamma_s(A).$$

In order to have a precise formula for g we need to use the global invariant (2.8), i.e.,

$$\frac{d^2 - \beta\rho}{\rho} + 2k\ln\rho = Const.$$

Thus all trajectories can be expressed as

$$d^2 = \rho[C(\alpha) + F(\rho)],$$

with

$$C(\alpha) = \frac{d_0^2}{\rho_0} - F(\rho_0), \qquad F(\rho) := \beta\rho - 2k\ln\rho.$$

Note that $F(\rho)$ is a convex function and $\min_{\rho>0} F = F(\frac{2k}{\beta}) = 2k[1 - \ln(\frac{2k}{\beta})]$. Due to the symmetry, the homoclinic connection is possible when the trajectory passes $(\rho_0, 0)$ with $\rho_0 \le \frac{2k}{\beta}$ and converging to $(0,0)$ as $t \to \pm\infty$; i.e., the initial data must satisfy $0 < \rho_0 < \frac{2k}{\beta}$ and

$$C(\alpha) \le -F\left(\frac{2k}{\beta}\right), \quad \text{i.e.,} \quad \frac{d_0^2}{\rho_0} \le F(\rho_0) - F\left(\frac{2k}{\beta}\right).$$

The seperatrices passing through $(\frac{2k}{\beta}, 0)$ correspond to $C(\alpha) = -F(\frac{2k}{\beta})$. The stable manifold $\gamma_s(A)$ can be written as $d = g(\rho)$ for $0 \le \rho < \infty$, where

$$g(\rho) = \text{sgn}\left(\rho - \frac{2k}{\beta}\right)\sqrt{\rho\left(F(\rho) - F\left(\frac{2k}{\beta}\right)\right)}.$$

It remains to prove that the initial data satisfying $d_0 < g(\rho_0)$ always lead to finite-time breakdown.

First, in the region $\{(\rho, d),\ d < -\sqrt{\rho(F(\rho) - F(\frac{2k}{\beta}))}\}$, there must exist a finite time $T_1 > 0$ such that $\rho(T_1) > \frac{2k}{\beta}$ for $\rho_0 \le \frac{2k}{\beta}$ (take $T_1 = 0$ for $\rho_0 > \frac{2k}{\beta}$) since $\rho' > 0$. Therefore $\rho(t) \ge \rho(T_1)$ for $t \ge T_1$ and

$$\rho' = -\rho d \ge \rho\sqrt{\rho\left(\rho(T_1) - F\left(\frac{2k}{\beta}\right)\right)} \quad \text{for} \quad t \ge T_1.$$

Integration over $[T_1, t]$ gives

$$\sqrt{\rho(t)} \ge \frac{\sqrt{2\rho(T_1)}}{2 - (t - T_1)\sqrt{\rho(T_1)(F(\rho(T_1)) - F(\frac{2k}{\beta}))}}, \qquad t \ge T_1.$$

Thus the solution must become unbounded before the time

$$T_1 + \frac{2}{\sqrt{\rho(T_1)(F(\rho(T_1)) - F(\frac{2k}{\beta}))}}.$$

Second, we consider the trajectories in the region

$$\left\{(\rho, d), \quad \rho > \frac{2k}{\beta}, \quad |d| < \sqrt{\rho\left(F(\rho) - F\left(\frac{2k}{\beta}\right)\right)}\right\}.$$

Note that at finite time the trajectory must enter the subregion $\{(\rho, d),\ d < 0\}$ through the left point $(\rho^*, 0)$ identified as

$$d^2 = \rho[F(\rho) - F(\rho^*)], \qquad \rho \ge \rho^* > \frac{2k}{\beta}.$$

This, combined with the Riccati-type inequality

$$d' < \frac{-d^2}{2},$$

ensures the breakdown at finite time. This completes the confirmation of the curve $d = g(\rho)$ as a critical threshold. □

Proof of Theorem 1.1. It suffices to summarize the above cases, taking

$$\beta = \frac{\Gamma_0}{\rho_0^2}$$

into account. Clearly the cases $\beta < 0$ and $\beta = 0$ correspond to the set

$$\{(\rho_0, M_0), \quad \Gamma_0 \le 0\}.$$

For $\beta > 0$, i.e., $\Gamma_0 > 0$, we rewrite the critical threshold as

$$\begin{aligned} d_0 &= \operatorname{sgn}\left(\rho_0 - \frac{2k}{\beta}\right)\sqrt{\rho_0\left(F(\rho_0) - F\left(\frac{2k}{\beta}\right)\right)} \\ &= \operatorname{sgn}(\Gamma_0 - 2k\rho_0)\sqrt{\Gamma_0 - 2k\rho_0 + 2k\rho_0 \ln\left(\frac{2k\rho_0}{\Gamma_0}\right)}, \end{aligned}$$

where we have used the relation $F(\rho) = \beta\rho - 2k\ln\rho$ and

$$F(\rho_0) = \frac{\Gamma_0}{\rho_0} - 2k\ln\rho_0,$$
$$F\left(\frac{2k}{\beta}\right) = 2k - 2k\ln\left(\frac{2k\rho_0^2}{\Gamma_0}\right).$$

This completes the proof of Theorem 1.1. □

3. 2D REP with nonzero background. This section is devoted to the study of the REP with nonzero background $c > 0$, for which the velocity gradient tensor $M = \nabla U$ solves

$$\frac{d}{dt}M + M^2 = \frac{k}{2}[\rho - c], \tag{3.1}$$

$$\frac{d}{dt}\rho + \rho tr M = 0. \tag{3.2}$$

Again, using the spectral dynamics lemma presented in [19], the spectral dynamics of M is governed by

$$\lambda_1' + \lambda_1^2 = \frac{k}{2}(\rho - c), \quad ' := \frac{d}{dt},$$
$$\lambda_2' + \lambda_2^2 = \frac{k}{2}(\rho - c),$$
$$\rho' + \rho(\lambda_1 + \lambda_2) = 0.$$

As in the zero background case, the difference $\eta := \lambda_2 - \lambda_1$ is proportional to the density along the particle path in the sense that

$$\frac{\eta(t)}{\rho(t)} = \frac{\eta_0(\alpha)}{\rho_0(\alpha)}, \quad \alpha \in \mathbb{R}^2.$$

Further manipulation gives a closed system

$$\rho' = -\rho d, \tag{3.3}$$

$$d' = k(\rho - c) - \frac{d^2 + \beta\rho^2}{2} =: Q, \quad \beta := \frac{\eta_0^2}{\rho_0^2}. \tag{3.4}$$

Once again the dynamics of (3.3), (3.4) is influenced by the choice of β. We proceed to discuss the solution behavior of (3.3), (3.4) by distinguishing two cases:

(1) for $\beta < 0$, the spectral gap is complex;

(2) for $\beta \geq 0$, the spectral gap is real.

3.1. Complex spectral gap. We first discuss the case $\beta < 0$, which corresponds to the case in which the eigenvalues are initially complex.

LEMMA 3.1. *Assume that the eigenvalues are initially complex with* $\mathrm{Im}(\lambda_i(0)) \neq 0$. *Then the solution of* (3.3), (3.4) *remains smooth for all time. Moreover, there is a global invariant in time, given by*

$$V(\rho, d) = \rho^{-1}\left[d^2 - \beta\rho^2 + 2k\rho ln\left(\frac{\rho}{2c}\right) + 2ck\right].$$

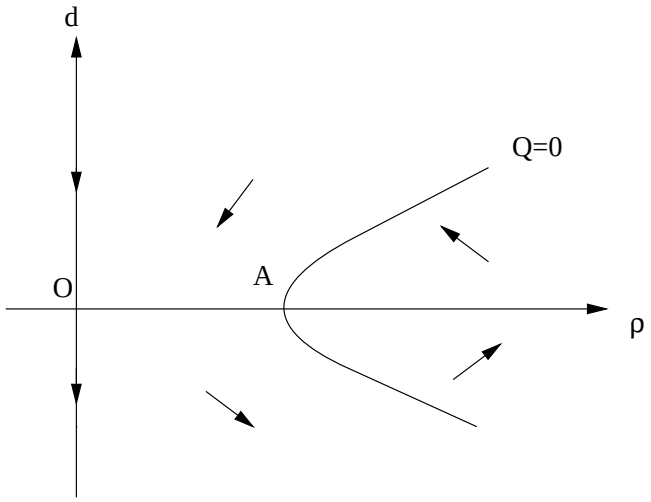

FIG. 3.1. *Zero level set $d' = 0$. Complex spectral gap with nonzero background.*

Proof. A straightforward computation yields $\dot{V} = 0$ along the 2D REP solutions, which implies that the curves $V = Const$ are invariants of the flow. As before, for negative β's we have

$$d^2 \le \max_{\rho>0} \left\{ Const.\rho - 2k\rho \ln\left(\frac{\rho}{2c}\right) - 2ck + \beta\rho^2 \right\} \le C_1^2,$$

and the bounds of d (and hence of ρ) follow. □

Remark. As before, more detailed information is available in this case by a phase plane analysis. If the eigenvalues are initially complex, then one has $\beta = \eta_0^2/\rho_0^2 < 0$. The zero level set $d' = Q = 0$ becomes a hyperbola; see Figure 3.1.

The intersection of its right branch with $d = 0$ is the rest point $A = (\rho^*, 0)$ of the system, where

$$\rho^* = \frac{k}{\beta} + \sqrt{\frac{k^2}{\beta^2} - \frac{2ck}{\beta}}.$$

The coefficient matrix of the linearization around $(\rho^*, 0)$ is

$$L(\rho^*, 0) = \begin{pmatrix} 0 & -\rho^* \\ k - \beta\rho^* & 0 \end{pmatrix}.$$

Its eigenvalues satisfy

$$\lambda^2 = \rho^*(\beta\rho^* - k) = -\rho^*\sqrt{k^2 - 2ck\beta} < 0.$$

Hence such a critical point is a nonhyperbolic equilibrium. The nonlinear effect plays essential roles in the solution behavior. In order to locate the possible critical threshold, we first study the solution around $(\rho^*, 0)$. Setting $n = \rho - \rho^*$, we then have

$$n' = -\rho^* d - nd, \tag{3.5}$$

$$d' = \sqrt{k^2 - 2ck\beta}\, n - \frac{d^2}{2} - \frac{\beta}{2} n^2. \tag{3.6}$$

It is easy to see that the flow governed by the linear part stays on the ellipse

$$\sqrt{k^2 - 2ck\beta}n^2 + \rho^* d^2 = Const.$$

In order to capture the dynamics of the nonlinear system in the neighborhood of the critical point $(n, d) = (0, 0)$, we employ the polar coordinates of the form

$$n = \frac{r\cos\theta}{(k^2 - 2ck\beta)^{1/4}},$$
$$d = \frac{-r\sin\theta}{\sqrt{\rho^*}}.$$

Careful calculation with these polar coordinates yields that (3.5)–(3.6) can be recast into the form

$$r' = R(r, \theta), \tag{3.7}$$
$$\theta' = -\sqrt{\rho^*}(k^2 - 2ck\beta)^{1/4} + \Theta(r, \theta), \tag{3.8}$$

where

$$R(r, \theta) = \frac{r^2\sin\theta}{2\sqrt{\rho^*}}\left[1 + \frac{k\cos^2\theta}{\sqrt{k^2 - 2ck\beta}}\right],$$
$$\Theta(r, \theta) = -\frac{r\cos\theta}{2\sqrt{\rho^*}\sqrt{k^2 - 2ck\beta}}\left[\sqrt{k^2 - 2ck\beta}\sin^2\theta - \beta\rho^*\cos^2\theta\right].$$

When r is sufficiently small, θ' is strictly negative. The pleasant implication of this is that the orbits of system (3.5), (3.6) spiral monotonically in θ around $(\rho^*, 0)$. But the even power of r^2 does not indicate the stability property of the critical point.

Observe that if $(n(t), d(t))$ is a solution, so is $(n(-t), -d(-t))$. Such symmetry implies that there is a center in the neighborhood of $(\rho^*, 0)$.

In order to clarify the global behavior of the flow around such a center, we appeal to the global invariant

$$V(\rho, d) = \rho^{-1}\left[d^2 - \beta\rho^2 + 2k\rho\ln\left(\frac{\rho}{2c}\right) + 2ck\right].$$

We claim that V is positive definite, which serves as a (majorization of) Lyapunov functional. To this end, we consider the function $H(\rho) := -\beta\rho^2 + 2k\rho\ln\left(\frac{\rho}{2c}\right) + 2ck$, which is convex and takes its minimum at $\rho_{\min}$, satisfying

$$\ln\left(\frac{\rho_{\min}}{2c}\right) = -1 + \frac{\beta}{k}\rho_{\min}.$$

Observe that, since $\beta < 0$, the function

$$h(\rho) := 1 - \frac{\beta}{k}\rho + \ln\left(\frac{\rho}{2c}\right)$$

is an increasing function in $\rho > 0$ and $h(\rho_{\min}) = 0$, which, when combined with the fact that $h(\rho^*) \geq 0$, verifies that

$$0 < \rho_{\min} \leq \rho^*, \qquad \rho^* := \beta^{-1}[k - \sqrt{k^2 - 2ck\beta}].$$

Indeed, for ρ^* we have

$$h(\rho^*) = 1 - \frac{\beta}{k}\rho^* + \ln\left(\frac{\rho^*}{2c}\right) = \sqrt{1-2ck^{-1}\beta} - \ln(1+\sqrt{1-2ck^{-1}\beta}) \geq 0.$$

Therefore $H(\rho)$ is nonnegative since

$$H(\rho_{\min}) = \beta\rho_{\min}^2 - 2k\rho_{\min} + 2ck = \beta(\rho_{\min} - \rho^*)(\rho_{\min} - \bar{\rho}^*) \geq 0,$$

where $\bar{\rho}^* = \beta^{-1}[k + \sqrt{k^2 - 2ck\beta}]$.

The invariant curves, $V = Const.$, represent, of course, the bounded periodic orbits containing $(\rho^*, 0)$.

3.2. Real spectral gap. We divide the region $\beta \in [0, \infty)$ into subregions depending on the number of critical points on the phase plane, and then study the solution behavior with β in each subregion. The solution behavior depends strongly on the number of critical points and their stability property.

Let (ρ^*, d^*) be a critical point of the system; then the coefficient matrix of the linearization around (ρ^*, d^*) reads

$$L(\rho^*, d^*) = \begin{pmatrix} -d^* & -\rho^* \\ k - \beta\rho^* & -d^* \end{pmatrix}.$$

Its eigenvalues are given by

$$\lambda = -d^* \pm \sqrt{\rho^*(\beta\rho^* - k)}. \tag{3.9}$$

We now discuss subcases distinguished by the number and type of critical points as β changes.

- $\beta = 0$. Here the zero level set $d' = Q = 0$ is a parabola, $d^2 = 2k(\rho - c)$, intersecting with $d = 0$ at $(\rho^*, d^*) = (c, 0)$. From (3.9) we see that at this point the eigenvalues of L are $\lambda = \pm\sqrt{ck}i$, a pure imaginary number, and the critical point $(c, 0)$ is nonhyperbolic. The stability property of this critical point has to be determined by taking into account the nonlinear effect.
- $0 < \beta < \frac{k}{2c}$. The zero level set $Q = 0$ is an ellipse, located on the right half-plane $\rho > 0$. There are two critical points $(\rho^*, d^*) = (\rho^*, 0)$ with

  $$\rho^* = \frac{k}{\beta} \pm \sqrt{\frac{k^2}{\beta^2} - \frac{2kc}{\beta}}.$$

  The associated eigenvalues of L are

  $$\lambda(\rho_1^*) = \pm\sqrt{\rho_1^*\sqrt{k^2 - 2ck\beta}}i, \qquad \lambda(\rho_2^*) = \pm\sqrt{\rho_2^*\sqrt{k^2 - 2ck\beta}}.$$

  Therefore $(\rho_1^*, 0)$ is a center of the linearized system, and $(\rho_2^*, 0)$ is a saddle; see Figure 3.2.

  Possible bifurcation as β changes from 0 to $\frac{k}{2c}$ may be responsible for the complicated solution structure in this regime.
- $\beta = \frac{k}{2c}$. The zero level set $Q = 0$, i.e.,

  $$d^2 + \beta\left(\rho - \frac{k}{\beta}\right)^2 = 0,$$

  degenerates to a single point $(\rho^*, d^*) = (\frac{k}{\beta}, 0)$, the only critical point with zero eigenvalues.

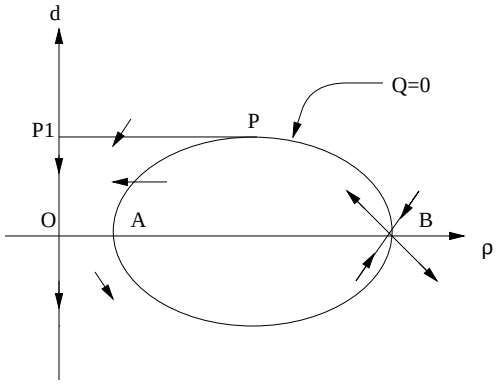

FIG. 3.2. *Critical points in the ρ-d plane. Real spectral gap with nonzero background.*

- $\beta > \frac{k}{2c}$. In this case

$$Q = -\frac{1}{2}\left[d^2 + \beta\left(\rho - \frac{k}{\beta}\right)^2 + 2kc - \frac{k^2}{\beta}\right] \leq \frac{k^2}{2\beta} - kc < 0.$$

There is no critical point at all in the finite phase plane.

The solution behavior distinguished by the above cases is given in the following lemmata.

LEMMA 3.2. *If $\lambda_1(0) = \lambda_2(0)$, then the solution of* (3.3), (3.4) *remains smooth for all time, indicated by the global invariant*

$$\frac{d^2 + 2ck}{\rho} + 2k\ln\rho = Const. \tag{3.10}$$

Proof. The assumption amounts to $\beta = 0$. As discussed above, $(c, 0)$ is the only critical point and the center of the linearized system. In order to find the global invariant we set $R(t) := k(\rho - c)^2 + cd^2$. Along the trajectory $\frac{dx}{dt} = U(x,t)$,

$$\frac{d}{dt}R(t) = 2k(\rho - c)\rho' + 2cdd' = -d[k(\rho - c)^2 + R(t)]. \tag{3.11}$$

From the mass equation it follows that

$$d = -\frac{\rho'}{\rho},$$

which, when inserted into the relation (3.11), gives

$$\frac{dR}{d\rho} = \frac{k(\rho - c)^2}{\rho} + \frac{R}{\rho}.$$

Integration gives

$$\frac{R}{\rho} + \frac{kc^2}{\rho} + 2ck\ln\rho - k\rho = Const,$$

which leads us to the global invariant as asserted in (3.10). This global invariant is compact and ensures that both divergence d and the density ρ remain bounded as time evolves. ∎

We leave the case $0 < \beta < \frac{k}{2c}$ for later and study the critical case $\beta = \frac{k}{2c}$.

LEMMA 3.3. *If $\lambda_2(0) - \lambda_1(0) = \sqrt{\frac{k}{2c}}\rho_0$, then the solution of* (3.3), (3.4) *always develops finite-time breakdown unless the initial data lies within the set*

$$\left\{(\rho, d) \in \mathbb{R}^+ \times \mathbb{R}^+, \quad \frac{d^2 + 2ck}{\rho} - \frac{k}{2c}\rho + 2k\ln\rho = 2k\ln(2c)\right\}.$$

Proof. The given assumption is equivalent to the case $\beta = \frac{k}{2c}$. In this case the divergence always decreases except at the critical point $(2c, 0)$ since

$$d' = -\frac{d^2}{2} - \frac{k(\rho - 2c)^2}{4c} \le 0.$$

In order to clarify the solution behavior, we proceed to obtain the global invariant. Setting $q := d^2$, one then has

$$\frac{dq}{d\rho} = \frac{2dd'}{\rho'} = \frac{q + \beta\rho^2 - 2k(\rho - c)}{\rho}.$$

Solving this equation, we obtain

$$\frac{q}{\rho} = \beta\rho - 2k\ln\rho - \frac{2ck}{\rho} + Const.$$

Therefore we come up with a global invariant

$$\frac{d^2 + 2ck}{\rho} - \beta\rho + 2k\ln\rho = Const. \tag{3.12}$$

The only trajectory converging to the critical point is realized by a half-trajectory converging to $(2c, 0)$ from the first quadrant. For all other trajectories not passing the critical point $(2c, 0)$, the rate d' is strictly negative. The divergence will become negative at finite time even if it is initially positive, which, when combined with the Riccati-type inequality $d' \le -d^2/2$, confirms the finite-time breakdown. ∎

We now look at the case $\beta > \frac{k}{2c}$.

LEMMA 3.4. *Assume that the eigenvalues are initially real and $|\lambda_2(0) - \lambda_1(0)| > \sqrt{\frac{k}{2c}}\rho_0(\alpha)$. Then the solution of* (3.3), (3.4) *always develops finite-time breakdown.*

Proof. The given assumption is nothing but the inequality $\beta > \frac{k}{2c}$. Note that there is no critical point in the finite phase plane; actually Q remains negative for all time. The solution must develop breakdown in finite time. In fact from

$$d' = -\frac{d^2}{2} - \frac{\beta}{2}\left(\rho - \frac{k}{\beta}\right)^2 - \frac{kc}{\beta}\left(\beta - \frac{k}{2c}\right), \tag{3.13}$$

we find that

$$d' \le -\delta \quad \text{with} \quad \delta := \frac{kc}{\beta}\left(\beta - \frac{k}{2c}\right) > 0.$$

This ensures that d must become negative beyond a finite time T_0, say, $T_0 > \max\{\frac{d_0}{\delta}, 0\}$. The $d-$ equation (3.13) also gives

$$d' \le -\frac{d^2}{2},$$

whose integration over $[T_0, t]$ leads to

$$d(t) \le \frac{d(T_0)}{1 - \frac{1}{2}d(T_0)(t - T_0)}.$$

Hence the solution must break down at a finite time before $T_0 - \frac{2}{d(T_0)}$. □

Finally we conclude this subsection by discussing the delicate case $0 < \beta < \frac{k}{2c}$. Set

$$G(\rho, \rho^*, \beta) := \beta(\rho - \rho^*) - 2k \ln\left(\frac{\rho}{\rho^*}\right) - \frac{2ck}{\rho} + \frac{2ck}{\rho^*},$$

with $\rho^* = \beta^{-1}[k \pm \sqrt{k^2 - 2ck\beta}]$ being the ρ-coordinate of the intersection point of the trajectory with the ρ-axis.

LEMMA 3.5. *Assume that the real eigenvalues satisfy* $0 < |\lambda_2(0) - \lambda_1(0)| < \sqrt{\frac{k}{2c}}\rho_0(\alpha)$. *Then for any* $\beta \in (0, \frac{k}{2c})$ *the solutions of* (3.3), (3.4) *remain smooth for all time if and only if*

$$|\lambda_1(0) + \lambda_2(0)| \le \sqrt{\rho_0 G(\rho_0, \rho_2^*, \beta_0)} \quad \textit{for} \quad \rho_0 \le \rho_2^*$$

and

$$\lambda_1(0) + \lambda_2(0) = \sqrt{\rho_0 G(\rho_0, \rho_2^*, \beta_0)} \quad \textit{for} \quad \rho_0 > \rho_2^*.$$

Proof. The assumption tells us that $\beta < \frac{k}{2c}$. In this case there are two critical points in the phase plane, $A = (\rho_1^*, 0)$ and $B = (\rho_2^*, 0)$; see Figure 3.2. B is a saddle whose two manifolds pass, enclosing the critical point A, which is a center of the linearized system. Let $W_s(B)$ denote the stable manifold coming from the region $\{(\rho, d), \rho < \rho_2^*, d < 0\}$, and $W_u(B)$ the unstable manifold entering into $\{(\rho, d), \rho < \rho_2^*, d > 0\}$. To prove the results stated in the theorem it suffices to show that for any $\beta \in (0, \frac{k}{2c})$ such that $W_u(B) \cap W_s(B)$ is not empty, there exists a saddle connection (homoclinic orbit).

This follows from the continuity argument supported by the following facts:

(1) Both $W_u(B)$ and $W_s(B)$ pass through the segment OA, with flow going downward since $d' < 0$ and $\rho' = 0$ on OA; see Figure 3.2

The level curve $d' = 0$ is an ellipse with upper vortex P located at $(\frac{k}{\beta}, 0)$. Let P_1 denote the intersection of the tangent line of the ellipse $Q = 0$ through P with the axis $\rho = 0$. The vector field inside the ellipse shows that $W_u(B)$ must escape the ellipse from the curve $\overline{PA}$. Note that the trajectories on $\overline{PP_1}$ and $\overline{AP}$ enter into the region $PAOP_1$, and the axis $\rho = 0$ is an invariant set. These facts ensure that $W_u(B)$ must enter the region $d < 0$ through OA. Similarly we can show that $W_s(B)$ for $\rho \le \rho_2^*$ must enter the region $d > 0$ through OA.

(2) As β increases in $(0, \frac{k}{2c})$, the point $W_u(B) \cap OA$ moves to the right, and the point $W_s(B) \cap OA$ moves to the left.

We prove the claim for $W_u(B) \cap OA$, and the case for $W_s(B) \cap OA$ follows similarly. The claim follows from the following two observations:

(i) The slope of the unstable manifold $W_u(B, \beta)$ at $(\rho_2^*, 0)$ is $\partial_\rho d|_{\rho=\rho_2^*} = \lambda_-(\rho_2^*, \beta)$, and the eigenvalue $\lambda_-(\rho_2^*, \beta)$ is increasing in β. Indeed,

$$\frac{d\lambda_-(\rho_2^*, \beta)}{d\beta} = -\frac{\beta^2}{k\lambda_-(\rho_2^*, \beta)} \left\{ k + \sqrt{k^2 - 2ck\beta} + \frac{ck\beta}{\sqrt{k^2 - 2ck\beta}} \right\} > 0.$$

(ii) $W_u(B,\beta_1)$ does not intersect with $W_u(B,\beta_2)$ for $\beta_1 \neq \beta_2$. As previously, we can find the global invariant of the system

$$d^2 = \rho\left[\beta\rho - 2k\ln\rho - \frac{2ck}{\rho} + Const\right],$$

from which the left branch of the unstable manifold of B can be explicitly expressed as

$$d = \sqrt{\rho\left[\beta(\rho-\rho_2^*) - 2k\ln\left(\frac{\rho}{\rho_2^*}\right) - \frac{2ck}{\rho} + \frac{2ck}{\rho_2^*}\right]}, \qquad 0<\rho<\rho_2^*.$$

A careful calculation gives

$$\frac{\partial d}{\partial \beta} = \frac{\rho}{2d}(\rho-\rho_2^*) < 0,$$

which ensures the claim (ii).

(3) Let $\rho_u(\beta)$ be the ρ-coordinate of the point $W_u(B,\beta)\cap OA$, and $\rho_s(\beta)$ be the ρ-coordinate of the point $W_s(B,\beta)\cap OA$. We claim

$$\lim_{\beta\to 0+}\rho_u(\beta) < \lim_{\beta\to\frac{k}{2c}-}\rho_s(\beta).$$

In fact, from the expression of seperatrices

$$d^2 = \rho G(\rho,\rho_2^*,\beta), \quad \rho<\rho^*,$$

we find that the ρ-coordinates of points $W_{u/s}(B)\cap OA$ satisfy

$$G(\rho,\rho_2^*,\beta)\equiv 0.$$

Note that

$$\frac{\partial G}{\partial\rho} = \frac{\beta}{\rho^2}(\rho-\rho_1^*)(\rho-\rho_2^*), \qquad \frac{\partial G}{\partial\beta} = \rho-\rho_2^*.$$

Thus we have for $0<\rho<\rho_1^*$

$$\frac{\partial\rho}{\partial\beta} = -\frac{\frac{\partial G}{\partial\beta}}{\frac{\partial G}{\partial\rho}} = \frac{\rho^2}{\beta}(\rho_1^*-\rho) > 0.$$

This confirms the above assertion.

Combining the above observations, we conclude that there exists a $\beta_0\in(0,\frac{k}{2c})$ for which a saddle connection exists. It remains to show that, as β changes in the region $(0,\frac{k}{2c})$, the above saddle connection is preserved. Observe that if $(\rho(t),d(t))$ is a solution, so is $(\rho(-t),-d(-t))$. Such symmetry prevents the occurrence of the possible bifurcation when β changes.

Using the nonlinear terms in the equation and the vector field, we can show for the initial data outside the closed curve—saddle connection—that the solution always develops finite-time breakdown; details are omitted. □

Proof of Theorem 1.2. Summarizing the results stated in the above lemmata, we see that the case $\beta<0$ and $\beta=0$ corresponds to the set

$$S_1 = \left\{(\rho_0,d_0,\Gamma_0)\;\middle|\;\Gamma_0\le 0 \quad\text{and}\quad \left\{\begin{array}{ll} d_0\ge 0 & \text{if } \rho_0=0,\\ d_0 \text{ arbitrary} & \text{if } \rho_0>0,\end{array}\right\}\right\}$$

since $\Gamma_0 = \beta\rho_0^2$. The case $0 < \beta < \frac{k}{2c}$ corresponds to $0 < \Gamma_0 < \frac{k}{2c}\rho_0^2$, and the divergence is required to satisfy the critical threshold condition

$$|d_0| \le \sqrt{\rho_0 G(\rho_0, \rho_2^*, \beta)}, \quad 0 < \rho_0 < \rho_2^*,$$

and $d_0 = \sqrt{\rho_0 G(\rho_0, \rho_2^*, \beta)}$ for $\rho_0 \ge \rho_2^*$. Using $\Gamma_0 = \beta\rho_0^2$ and

$$\rho_2^* = \beta^{-1}[k + \sqrt{k^2 - 2ck\beta}] = \frac{2ck}{k^2 - \sqrt{k^2 - 2ck\beta}} = \frac{2c\rho_0}{\rho_0 - \sqrt{\rho_0^2 - \frac{2c}{k}\Gamma_0}},$$

one has

$$\begin{aligned}
\rho_0 G(\rho_0, \rho_2^*, \beta) &= \rho_0 \left[\beta(\rho_0 - \rho_2^*) - 2k \ln\left(\frac{\rho_0}{\rho_2^*}\right) - \frac{2ck}{\rho_0} + \frac{2ck}{\rho_2^*}\right] \\
&= \Gamma_0 \left(1 - \frac{2c}{\rho_0 - \sqrt{\rho_0^2 - \frac{2c\Gamma_0}{k}}}\right) - 2k\rho_0 \ln\left(\frac{\rho_0 - \sqrt{\rho_0^2 - \frac{2c\Gamma_0}{k}}}{2c}\right) \\
&\quad - 2ck + k\left(\rho_0 - \sqrt{\rho_0^2 - \frac{2c\Gamma_0}{k}}\right) \\
&= \Gamma_0 - 2ck - 2k\sqrt{\rho_0^2 - \frac{2c\Gamma_0}{k}} - 2k\rho_0 \ln\left(\frac{\rho_0 - \sqrt{\rho_0^2 - \frac{2c\Gamma_0}{k}}}{2c}\right),
\end{aligned}$$

which leads to the critical threshold described by the set S_2. The set S_3 can be determined in a similar manner. □

ON EFFECTIVE STOPPING TIME SELECTION FOR VISCO-PLASTIC NONLINEAR BV DIFFUSION FILTERS USED IN IMAGE DENOISING*

I. A. FRIGAARD†, G. NGWA‡, AND O. SCHERZER§

Abstract. We consider denoising applications using nonlinear diffusion filters of BV type. Using the multiple timescales method, an equation is derived that approximates the time evolution of the image noise. Analysis of the corresponding variational inequality leads to an estimate of the timescale over which the noise decays to its local mean, given in terms of the filter parameters. We present a number of computed examples that demonstrate the validity of our stopping time estimate.

1. Introduction. In a diffusion filtering experiment, one attempts to recover an underlying image $U_I(\boldsymbol{x})$ from a noisy image $u_0(\boldsymbol{x}) : \ \boldsymbol{x} \in \Omega \subset \mathbb{R}^2$. This is achieved by taking $u_0(\boldsymbol{x})$ as initial data for a diffusion equation,

$$\frac{\partial u}{\partial t} = \nabla \cdot [D(\boldsymbol{x}, u, \nabla u)\nabla u] : \qquad u(\boldsymbol{x}, 0) = u_0(\boldsymbol{x}), \tag{1.1}$$

and integrating (1.1) over a certain time interval, say $t \in [0, T]$. The final solution $u(\boldsymbol{x}, T)$ is taken to be a reasonable approximation to $U_I(\boldsymbol{x})$. Choice of the diffusivity $D(\boldsymbol{x}, u, \nabla u)$ and selection of T control the effectiveness of the filtering process. In this paper we are interested in diffusion filters D, of the form:

$$D(\boldsymbol{x}, u, \nabla u) = D(\boldsymbol{x}, |\nabla u|) \equiv \mu + \frac{\tau_0}{|\nabla u|}, \tag{1.2}$$

with $\mu > 0$ and $\tau_0 > 0$.

Formally, since $D \to \infty$, where $|\nabla u| \to 0$, in place of (1.1) we generally consider

$$\frac{\partial u}{\partial t} = \nabla \cdot \boldsymbol{\tau}, \tag{1.3}$$

where $\boldsymbol{\tau} = (\tau_x, \tau_y)$:

$$|(\tau_x, \tau_y)| > \tau_0(\boldsymbol{x}) \Longleftrightarrow \begin{cases} \tau_x &= \left[\mu + \dfrac{\tau_0(\boldsymbol{x})}{|\nabla u|}\right] \dfrac{\partial u}{\partial x}, \\ \tau_y &= \left[\mu + \dfrac{\tau_0}{|\nabla u|}\right] \dfrac{\partial u}{\partial y}, \end{cases} \tag{1.4}$$

$$|(\tau_x, \tau_y)| \leq \tau_0 \Longleftrightarrow |\nabla u| = 0. \tag{1.5}$$

We remark here that (1.3)–(1.5) also model an inelastic visco-plastic fluid (a Bingham fluid [17]), of unit density, flowing axially along a cylindrical duct with cross-sectional area Ω. In this analogy, u is the fluid velocity and D represents the effective viscosity of the fluid. The parameters μ and τ_0 are referred to as the plastic viscosity and the yield stress. Various industrial muds, slurries, and pastes are represented fairly well by such rheological models [20], as well as certain porous media flows [15] and the flows of particular types of lava [14]. There is a long and well-established literature concerning the flow of such materials; see, for example, [13, 17, 33, 36, 34, 35, 39, 40, 43, 47, 50, 59, 64, 67, 72, 75, 77, 78] and many others.

The constitutive laws (1.4), (1.5) distinguish between $|\nabla u| = 0$ and $|\nabla u| > 0$. These laws could alternatively be written as

$$\tau \in \partial h(\nabla u),$$

where $\partial h(\mathbf{t})$ is the subgradient of

$$h(\mathbf{t}) := \frac{\mu}{2}|\mathbf{t}|^2 + \tau_0|\mathbf{t}|.$$

However, (1.4) and (1.5) are more physically instructive, since they immediately reveal the key characteristic of Bingham fluids, i.e., that a certain yield stress has to be exceeded in order for a flow to be initiated. The formulation (1.4), (1.5) is the classical formulation commonly used in fluid mechanics applications.

The aim of our study is to develop a *physically* motivated rationale for choosing the stopping time T when using a diffusion filter of type (1.2). We note that for computational ease we will often use a regularized form of (1.3)–(1.5). In this case, we solve (1.1) on Ω, replacing D by D_β:

$$D_\beta \equiv \mu + \frac{\tau_0}{(|\nabla u|^2 + \beta^2)^{1/2}}, \qquad \beta \ll 1. \tag{1.6}$$

Nonlinear diffusion filtering, using either (1.3)–(1.5) or (1.6), has been considered previously by Alvarez and colleagues [2, 3, 4], Catté et al. [21], Perona and Malik [63], and Weickert [76], to name but a few.

In the nonlinear diffusion framework, natural relations exist between biased diffusion and regularization theory via the Euler equation for the regularization functional. The regularization parameter and the diffusion time are analogous if one regards regularization as time-discrete diffusion filtering with a single implicit time step [68, 49, 69, 71]. A popular specific energy functional that arises from unconstrained total variation denoising [1, 22, 25] is

$$\frac{1}{2}\int_\Omega (u(\boldsymbol{x}) - u_0(\boldsymbol{x}))^2 \, d\boldsymbol{x} \; + \; \alpha \int_\Omega |\nabla u(\boldsymbol{x})| \, d\boldsymbol{x}. \tag{1.7}$$

Constrained total variation minimization also leads to a nonlinear diffusion process with a bias term using a time-dependent penalization parameter [68]. Total variation denoising in the continuous and discrete setting has been considered by many authors recently. We give a list which is not at all complete: [11, 12, 18, 22, 23, 24, 26, 27, 28, 31, 32, 37, 38, 44, 45, 46, 48, 51, 52, 53, 54, 55, 58, 60, 61, 62, 63, 66, 70, 71, 73, 74]. The minimizer of (1.7) approximates the solution of the partial differential equation

$$\frac{\partial u}{\partial t} = \nabla \cdot \left(\frac{\nabla u}{|\nabla u|} \right), \tag{1.8}$$

which has been integrated implicitly over one time step, $\Delta t = \alpha$, from the initial condition $u_0(\boldsymbol{x})$. An iterative regularization, consisting of minimizing the functionals

$$\frac{1}{2} \int_\Omega (u(\boldsymbol{x}) - u_{n-1}(\boldsymbol{x}))^2 \, d\boldsymbol{x} \; + \; \alpha \int_\Omega |\nabla u(\boldsymbol{x})| \, d\boldsymbol{x}$$

over $u(\boldsymbol{x})$, and denoting successive minimizers by u_n, will approximate the solution of (1.1) at discrete time points $t_n = n\alpha$, $n = 1, 2, \ldots$. The approximation via implicit time steps is justified by *nonlinear* semigroup theory (see, e.g., [19]). Actually, nonlinear semigroup theory defines the solution of the partial differential equation via implicit time steps. Remarkable properties of the total variation flow equation and bounded variation regularization have been derived recently [7, 9, 8, 10, 16], including analytically calculated solutions. A numerical comparison of denoising with iterative regularization and total variation flow has been given in [65, 66].

Total variation flow and bounded variation regularization are capable of reconstructing blocky data. See [30] for the continuous regularization setting. In [57] it is shown in a discrete setting that bounded variation regularization favors piecewise constant minimizers. For work on this topic in the PDE framework we refer to [7, 9, 8, 10, 16]. It is considered a drawback of the low-shear viscosity regularization (1.6) that it does not recover blocky structures accurately. However, as we have shown in the different context of multiphase Bingham fluid flow [34, 35], this filtering technique is capable of preserving horizontal fluid flow regions, which in the image processing context are data regions of constant grey level intensity. This, to a certain extent, shows that Bingham filtering techniques are capable of preserving essential image details. Since the solution of the Bingham fluid flow equation is in the Sobolev-space H^1 with respect to the space variable, the effect of staircasing, which is sometimes considered a drawback of total variation regularization and total variation flow (see [16, 57]), is limited. Of course, whether or not blocky structures are of interest depends entirely on the image and the application being considered.

The main scope of the paper is to utilize the similarity of (1.1) and Bingham mud flow to derive an asymptotic estimate for the optimal stopping time in problems such as (1.1). The basic idea is to split the solution of (1.1) into low and high frequency components. The high frequency components decay rapidly, and a time can be determined at which they have essentially disappeared. The separation of low and high frequency components as presented below is generally applicable to any sort of diffusion filtering (such as total variation flow) as long as an estimate for the time of disappearance of the high frequency components is available. For the Bingham mud flow counterpart, optimal stopping criteria can be given in terms of the *physical* parameters of the filter. In order to derive the optimal stopping time we adapt results derived by Bristeau for a Bingham fluid flow, described in Glowinski, Lions, and Trémolières [40]. These results are limited to the case $\mu > 0$. However, for

$\mu = 0$, the estimates are still formally applicable and are sharp in predicting the time of disappearance of a highly oscillating piecewise constant function, as we find by a comparison with recent results in [16].

2. Decay in nonlinear diffusion filtering. A key idea behind any form of diffusion filtering is that the decay of high frequency components in the initial data (i.e., the noise) will occur more rapidly than of the underlying image. In a digital image the spatial frequency of the noise is typically the pixel scale, say ϵ, where $\epsilon \ll 1$. We can generally expect that the basic image will be denoised by a diffusion filter only if U_I varies over length-scales larger than ϵ, i.e., unless additional information on U_I is available. For example, if $\Omega = (0,1) \times (0,1)$ and a linear diffusion filter $\tau_0 = 0$ is used, the nth Fourier mode decays like $\mathrm{e}^{-(\mu n \pi)^2 t}$. Frequencies above $n \sim \epsilon^{-1}$ are not present, and hence selection of $\mu \sim \epsilon$ ensures that linear diffusion of the noise occurs on an $O(1)$ timescale. If $T \ll 1$, we expect that the linear diffusion filter will have little effect on the initial image. Including $\tau_0 > 0$ in the filter results in a nonlinear problem, in which the decay of both the noise and underlying image is accelerated.

Suppose that (1.1) is solved numerically, imposing homogeneous Neumann conditions on $\partial\Omega$. Without loss of generality, we may assume that $u_0(\boldsymbol{x})$ has zero mean, and we may thus expect that $\|u\|(t) \to 0$ as $t \to \infty$. (Here and later, $\|\cdot\|$ will denote an L^2 norm over the domain of interest.) Thus, as $t \to \infty$, we have that $\|u_n\| \to \|U_I\|$, where

$$u(\boldsymbol{x}, t) = U_I(\boldsymbol{x}) + u_n(\boldsymbol{x}, t), \tag{2.1}$$

i.e., $u_n(\boldsymbol{x}, t)$ is the noise. Our interest here is to find an (asymptotic) expression for T, in terms of the *physical* parameters of the problem, ϵ, μ, τ_0, and $u_0(\boldsymbol{x})$, that will give an optimal recovered image. Presumably an *optimal* image will be recovered at a time T that is close to the minimum ratio of $\|u_n\|$ to $\|U_I\|$.

An illustrative one-dimensional example is given in Figure 1. An initial image (Figure 1(a)) is perturbed by white noise (Figure 1(b)). Equation (1.1) with Neumann conditions is integrated using a fully implicit finite difference scheme. In Figure 1(c) we show $\|u\|(t)$ and $\|u_n\|(t)$. We see that $\|u_n\|(t)$ exhibits an initial rapid decay followed by a slow increase, as the entire image $u(t)$ decays to its mean. Figures 1(d)–(f) show $u(\boldsymbol{x}, t)$ for two choices of t, close to the minimum of $\|u_n\|(t)$, and for a third choice of t, as $\|u\|(t)$ has begun to decay significantly. It is apparent from Figures 1(d)–(f) that during the initial rapid decay of $\|u_n\|(t)$, the noise in the image is averaged over a local length-scale, and that on a longer timescale this averaging length-scale increases to the entire image.

2.1. Decay estimates for $u(x, t)$. The eventual decay of $\|u\|(t)$ in Figure 1(c) would be expected for a diffusive process with nondegenerate diffusivity, but what is peculiar to the problem with $\tau_0 > 0$ is that $\|u\|(t) \to 0$ in a finite time. This decay is a result of having a finite yield stress: physically there comes a time when the stress everywhere decays below the yield stress, and (see (1.5)) there will be zero *rate of strain* everywhere; i.e., $|\nabla u| = 0$.

From[1] Theorem 3.2 in Appendix 6 of [40], it is well known that if u is the (weak)

[1] Theorem 3.2 in Appendix 6 of [40] is slightly more general and includes a pressure gradient term on the right-hand side of (1.3); i.e., in [40], set $f = 0$, $\beta = b_D$, and $g = \tau_0$ to apply this result.

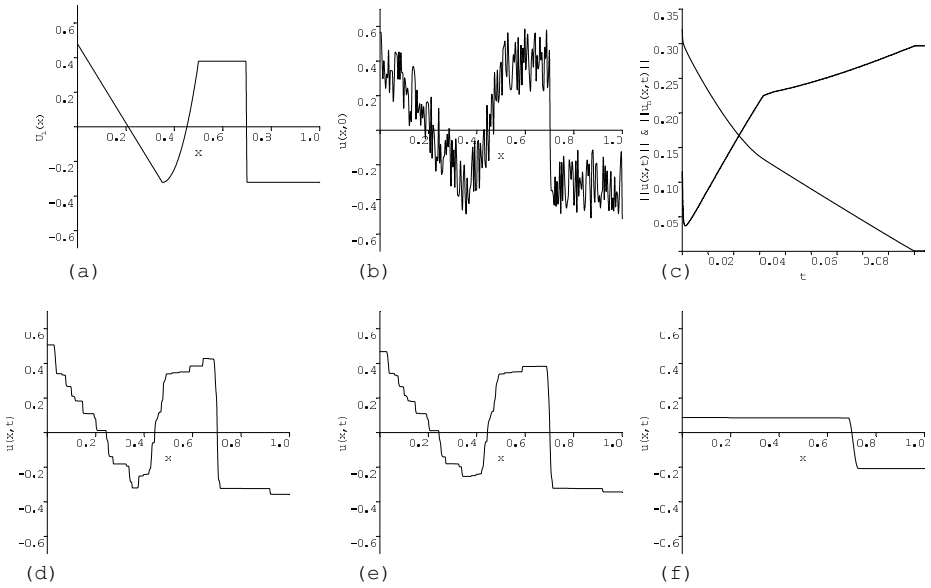

FIG. 1. *One-dimensional example: discretization/pixel-scale* $\epsilon = \Delta x = 1/256$, $\mu = 1/256$, $\tau = 1.0$. (a) $U_I(\boldsymbol{x})$; (b) *initial data,* $u_0(\boldsymbol{x})$, *image plus white noise with maximum amplitude* ± 0.2; (c) $\|u\|(t)$ *and* $\|u_n\|(t)$ *(dashed line);* (d) $u(\boldsymbol{x}, t)$*:* $t = 1.078 \times 10^{-3}$; (e) $u(\boldsymbol{x}, t)$*:* $t = 2.121 \times 10^{-3}$; (f) $u(\boldsymbol{x}, t)$*:* $t = 3.481 \times 10^{-2}$.

solution of the Dirichlet problem corresponding to (1.3)–(1.5), then

$$u(t) = 0 : \qquad t \geq t_0 = \frac{1}{\lambda_0 \mu} \log \left(1 + \lambda_0 \mu \frac{\|u_0\|}{b_D \tau_0} \right), \tag{2.2}$$

where $\lambda_0 > 0$ is the smallest eigenvalue of $-\Delta$ in $V = H_0^1(\Omega)$ and

$$b_D = \inf_{v \in V,\ v \neq 0} \frac{\int_\Omega |\nabla v| \, \mathrm{d}\Omega}{\|v\|} > 0. \tag{2.3}$$

Thus, for $\tau_0 > 0$, decay of $\|u\|(t)$ is no longer exponential, and we expect that $\|u\|(t) \to 0$ in a finite time t_0. For the Neumann problem, we set

$$\hat{V} = \left\{ v \in C^1(\bar{\Omega}) : \ \int_\Omega v \, \mathrm{d}\Omega = 0, \ \ \frac{\partial v}{\partial n} = 0 \text{ on } \partial\Omega \right\}$$

and let V be the closure of $\hat{V}$ with respect to the $H^1(\Omega)$ norm. We then proceed essentially as in [40]; the exact details are not particularly interesting. We have that if u is the weak solution of the Neumann problem corresponding to (1.3)–(1.5), then

$$u = 0 : \qquad t \geq t_0 = \frac{1}{\lambda_0 \mu} \log \left(1 + \lambda_0 \mu \frac{\|u_0\|}{b_N \tau_0} \right), \tag{2.4}$$

where $\lambda_0 > 0$ is the smallest eigenvalue of $-\Delta$ in V and

$$b_N = \inf_{v \in V,\ v \neq 0} \frac{\int_\Omega |\nabla v| \, \mathrm{d}\Omega}{\|v\|} > 0. \tag{2.5}$$

For the example in Figure 1 and associated parameters, we compute $t_0 \approx 0.154$, which

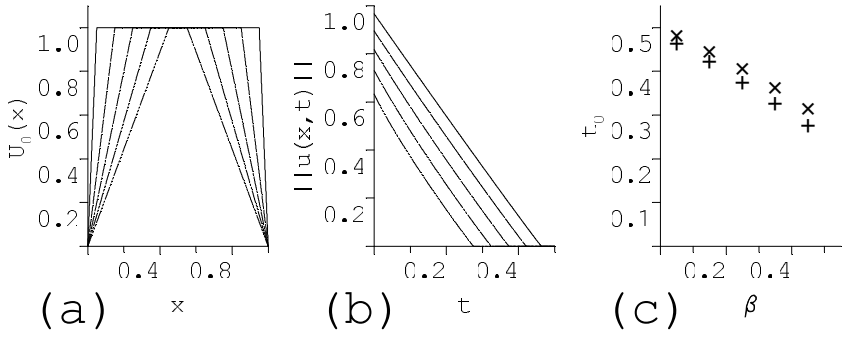

FIG. 2. *Decay of* $\|u\|(t)$ *for different initial conditions* $u(x,0) = u_\beta(x)$, $\Delta x = 0.002$, $\mu = 0.002$, $\tau = 1.0$*:* (a) $u_\beta(x)$, $\beta = 0.05,\ 0.15,\ 0.25,\ 0.35,\ 0.45$*;* (b) $\|u\|(t)$, $\beta = 0.05,\ 0.15,\ 0.25,\ 0.35,\ 0.45$*;* (c) t_0 $(\times)$ *from* (2.2) *compared with computed values* $(+)$.

clearly overestimates the decay shown in Figure 1(c). However, estimates such as (2.2) are not always this poor and will depend on the initial data. In particular, as $u(x,0)$ approaches a minimizer of (2.3), the estimate can be very sharp. As an illustration, we have solved a one-dimensional Dirichlet problem (1.1), for various initial conditions:

$$u(x,0) = u_\beta(x) = \left\{ \begin{array}{ll} \dfrac{x}{\beta}, & 0 \le x < \beta, \\ 1, & \beta \le x < 1-\beta, \\ \dfrac{1-x}{\beta}, & 1-\beta \le x < 1. \end{array} \right\} \tag{2.6}$$

Figure 2(b) shows the decay of $\|u\|(t)$ for the range of initial conditions shown in Figure 2(a). Figure 2(c) shows the difference between the computed decay time and t_0, given by (2.2), as β is varied.

2.2. Local decay estimates for $u_n(x,t)$. Assuming the separation of spatial length-scales between $u_n(\boldsymbol{x},t)$ and $U_I(\boldsymbol{x})$, what we really wish to know is the time interval taken for $u_n(\boldsymbol{x},t)$ to decay to a local mean value. Further, we would like to understand how this decay timescale can be affected by the image $U_I(\boldsymbol{x})$. The estimate we develop is based loosely on the method of multiple scales; e.g., see [42]. Suppose that $\Omega = (0,1)\times(0,1)$ and that, in the neighborhood of an arbitrary $\boldsymbol{x}_0 \in \Omega$, $u_0(\boldsymbol{x})$ is of the form

$$u_0(\boldsymbol{x}) = U_I(\boldsymbol{x}) + u_{n,0}(\tilde{\boldsymbol{x}}): \qquad \tilde{\boldsymbol{x}} = \frac{\boldsymbol{x}-\boldsymbol{x}_0}{\epsilon}, \tag{2.7}$$

where $\epsilon \ll 1$ is the pixel scale, i.e., we assume that the initial image has multiple scales. Consider the forward integration of (1.1) in the neighborhood of $\boldsymbol{x}_0$. Since we expect the high frequency components to decay faster than the low frequency components, we seek a solution of (1.1) of the form

$$u(\boldsymbol{x},t) = U(\boldsymbol{x},t) + u_n(\tilde{\boldsymbol{x}},\tilde{t}), \tag{2.8}$$

where $\tilde{t} = t/\delta$ for some $\delta \ll 1$. The differential operators in (1.1) become

$$\frac{\partial}{\partial t} \to \frac{1}{\delta}\frac{\partial}{\partial \tilde{t}} + \frac{\partial}{\partial t}, \tag{2.9}$$

$$\nabla \to \frac{1}{\epsilon}\tilde{\nabla} + \nabla, \tag{2.10}$$

i.e., with $\tilde{\nabla}$ containing spatial derivatives with respect to the components of $\tilde{\boldsymbol{x}}$. We now make a formal expansion of the right-hand side of (1.1), in terms of ϵ and δ:

$$\begin{aligned}\left[\mu + \frac{\tau_0}{|\nabla u|}\right]\nabla u \to{}& \frac{\mu}{\epsilon}\tilde{\nabla}u_n + \mu\nabla U + \frac{\tau_0}{|\tilde{\nabla}u_n|}\tilde{\nabla}u_n \\ &+ \epsilon\frac{\tau_0}{|\tilde{\nabla}u_n|}\left[\nabla U - \frac{(\nabla U\cdot\tilde{\nabla}u_n)}{|\tilde{\nabla}u_n|^2}\tilde{\nabla}u_n\right] \\ &+ \epsilon^2\frac{\tau_0}{|\tilde{\nabla}u_n|}\left[\frac{3}{2}\frac{(\nabla U\cdot\tilde{\nabla}u_n)^2}{|\tilde{\nabla}u_n|^4} - \frac{1}{2}\frac{|\nabla U|^2}{|\tilde{\nabla}u_n|}\right]\tilde{\nabla}u_n \\ &- \epsilon^2\frac{\tau_0}{|\tilde{\nabla}u_n|}\frac{(\nabla U\cdot\tilde{\nabla}u_n)}{|\tilde{\nabla}u_n|^2}\nabla U + O(\epsilon^3).\end{aligned} \tag{2.11}$$

Substituting into (1.1), we obtain

$$\begin{aligned}\frac{1}{\delta}\frac{\partial u_n}{\partial \tilde{t}} + \frac{\partial U}{\partial t} = {}& \frac{1}{\epsilon^2}\mu\tilde{\nabla}^2 u_n + \frac{1}{\epsilon}\tilde{\nabla}\cdot\left[\frac{\tau_0}{|\tilde{\nabla}u_n|}\tilde{\nabla}u_n\right] + \nabla\cdot(\mu\nabla U) \\ &+ \tilde{\nabla}\cdot\left[\frac{\tau_0}{|\tilde{\nabla}u_n|}\left(\nabla U - \frac{(\nabla U\cdot\tilde{\nabla}u_n)}{|\tilde{\nabla}u_n|^2}\tilde{\nabla}u_n\right)\right] + O(\epsilon).\end{aligned} \tag{2.12}$$

We balance the leading order terms, by setting $\delta = \epsilon^2$, and neglect terms of order ϵ^3:

$$\begin{aligned}\frac{\partial u_n}{\partial \tilde{t}} = {}& \tilde{\nabla}\cdot\left[\left(\mu + \frac{\epsilon\tau_0}{|\tilde{\nabla}u_n|}\right)\tilde{\nabla}u_n\right] + \epsilon^2[\nabla\cdot(\mu\nabla U) - U_t] \\ &+ \epsilon^2\tilde{\nabla}\cdot\left[\frac{\tau_0}{|\tilde{\nabla}u_n|}\left(\nabla U - \frac{(\nabla U\cdot\tilde{\nabla}u_n)}{|\tilde{\nabla}u_n|^2}\tilde{\nabla}u_n\right)\right].\end{aligned} \tag{2.13}$$

Rather than proceeding asymptotically, we simply consider ϵ as a small finite parameter (known from the resolution of the image), which we retain to order ϵ^2 in order to understand the leading order effects of the underlying image U_I.

It is, however, apparent that (2.13) is incomplete, since the limiting behavior as $|\tilde{\nabla}u_n| \to 0$ has been ignored in our formal expansions. In order to have a regular solution to (2.13) (and indeed for our expansions to be valid), it is necessary that $|\tilde{\nabla}u_n| \to 0$ only if $|\nabla U| = 0$. Thus, in place of (2.13) we consider

$$\frac{\partial u_n}{\partial \tilde{t}} = \tilde{\nabla}\cdot[\tilde{\boldsymbol{\tau}} + \epsilon^2\tilde{\boldsymbol{m}}] + \epsilon^2 f, \tag{2.14}$$

where

$$f(\boldsymbol{x}, t) = [\nabla\cdot(\mu\nabla U) - U_t] \tag{2.15}$$

and where we define $\tilde{\boldsymbol{\tau}} = (\tilde{\tau}_x, \tilde{\tau}_y)$:

$$|\tilde{\nabla} u_n| = 0 \Longleftrightarrow |\nabla U| = 0 \quad \text{and} \quad |(\tilde{\tau}_x, \tilde{\tau}_y)| \leq \tilde{\tau}_0, \tag{2.16}$$

$$|\tilde{\nabla} u_n| > 0 \Longleftrightarrow \begin{cases} \tilde{\boldsymbol{\tau}} &= \left[\mu + \dfrac{\epsilon \tau_0}{|\tilde{\nabla} u_n|}\right] \tilde{\nabla} u_n, \\ \tilde{\boldsymbol{m}} &= \dfrac{\tau_0}{|\tilde{\nabla} u_n|} \left[\nabla U - \dfrac{(\nabla U \cdot \tilde{\nabla} u_n)}{|\tilde{\nabla} u_n|^2} \tilde{\nabla} u_n\right]. \end{cases} \tag{2.17}$$

2.2.1. Variational formulation. We return in section 2.2.3 to a physical interpretation of (2.14)–(2.17), but to derive our stopping estimate it is somewhat easier to work with a variational formulation.

We consider $\boldsymbol{x}_0$ to be the corner of a pixel and consider solution of (2.14)–(2.17) in a local domain surrounding $\boldsymbol{x}_0$: $\tilde{\boldsymbol{x}} \in \tilde{\Omega}_k = (-k, k) \times (-k, k)$, where k is numerically of order 1, with initial conditions

$$u_n(\tilde{\boldsymbol{x}}, 0) = u_{n,0}(\tilde{\boldsymbol{x}}). \tag{2.18}$$

It is also necessary to impose boundary conditions on $\partial\tilde{\Omega}_k$, and for this we choose homogeneous Neumann conditions. Equations (2.14)–(2.17) are still diffusive (see section 2.2.3), and the effect of this choice of boundary conditions is that u_n is expected to decay to its mean value over $\tilde{\Omega}_k$. Subtracting any constant value from u_n leaves (2.14)–(2.17) unchanged, and hence we consider only functions of zero mean.

A classical solution to (2.14)–(2.18) will also satisfy the following variational inequality:

$$\begin{aligned} \epsilon^2 f \langle [v - u_n] \rangle \leq & \left\langle \frac{\partial u_n}{\partial \tilde{t}} [v - u_n] \right\rangle + \mu a(u_n, v - u_n) + \epsilon \tau_0 [j(v) - j(u_n)] \\ & + \epsilon^2 \langle \tilde{\boldsymbol{m}} \cdot \nabla (v - u_n) \rangle \\ & \forall v \in V, \qquad u_n(\tilde{\boldsymbol{x}}, 0) = u_{n,0}(\tilde{\boldsymbol{x}}), \end{aligned} \tag{2.19}$$

where

$$\langle v \rangle = \int_{\tilde{\Omega}_k} v \, \mathrm{d}\tilde{x}, \tag{2.20}$$

$$a(u_n, v) = \left\langle \tilde{\nabla} u_n \cdot \tilde{\nabla} v \right\rangle, \tag{2.21}$$

$$j(v) = \left\langle |\tilde{\nabla} v| \right\rangle, \tag{2.22}$$

$$V = \left\{ v \in H^1(\tilde{\Omega}_k) : \int_{\tilde{\Omega}_k} v \, \mathrm{d}\Omega = 0, \quad |\tilde{\nabla} v| = 0 \Rightarrow |\nabla U| = 0 \right\}. \tag{2.23}$$

Note that $\frac{\partial v}{\partial n} = 0$ on $\partial\tilde{\Omega}_k$ is inherent in the above variational formulation. In deriving (2.19), note that f does not vary over the length-scale of $\tilde{\Omega}$. We assume that there exists a solution u_n to (2.19), and that $u_n \in V$, with sufficient regularity for what follows. Existence and uniqueness of solutions to (2.19) and the steady version of (2.19) are interesting problems in their own right. We consider this further in Appendix A. By choosing $v = 0$ and $v = 2u_n$, we see that u_n satisfies

$$\|u_n\| \frac{\mathrm{d}}{\mathrm{d}\tilde{t}} \|u_n\| = \left\langle \frac{\partial u_n}{\partial \tilde{t}} u_n \right\rangle = -\mu a(u_n, u_n) - \epsilon \tau_0 j(u_n) + \epsilon^2 f \langle u_n \rangle. \tag{2.24}$$

Following [39, 40], we bound as follows:

$$\|u_n\| \frac{\mathrm{d}}{\mathrm{d}\tilde{t}} \|u_n\| \leq -\mu\lambda_0 \|u_n\|^2 - b_{N,k}\epsilon\tau_0 \|u_n\| + \epsilon^2|f| \|u_n\|,$$

with λ_0 the least positive eigenvalue of $-\Delta$ over V on $\tilde{\Omega}_k$. Assuming that $\|u_n\| \neq 0$,

$$\frac{\mathrm{d}}{\mathrm{d}\tilde{t}} \|u_n\| \leq -\mu\lambda_0 \|u_n\| - b_{N,k}\epsilon\tau_0 + \epsilon^2|f|. \tag{2.25}$$

Note that $\lambda_0 = \pi^2/k^2$, and by a simple mapping,

$$b_{N,k} \equiv \inf_{v\in V,\ v\neq 0} \frac{\int_{\tilde{\Omega}_k} |\tilde{\nabla} v|\ \mathrm{d}\tilde{\boldsymbol{x}}}{\|v\|_{L^2(\tilde{\Omega}_k)}} = b_N = 2. \tag{2.26}$$

Consider also the steady version of (2.19):

$$\begin{aligned} \mu a(u_n^*, v - u_n^*) + \epsilon\tau_0[j(v) - j(u_n^*)] \geq \epsilon^2 f \langle [v - u_n^*] \rangle - \epsilon^2 \langle \tilde{\boldsymbol{m}} \cdot \nabla(v - u_n^*) \rangle \\ \forall v \in V, \quad u_n^* \in V. \end{aligned} \tag{2.27}$$

Proceeding as for the transient case, we find the bound:

$$0 \leq -\mu\lambda_0 \|u_n^*\|^2 - b_{N,k}\epsilon\tau_0 \|u_n^*\| + \epsilon^2|f| \|u_n^*\|. \tag{2.28}$$

Therefore $u_n^* = 0$ is the unique steady solution (and also a transient solution) if

$$\tau_0 > \frac{\epsilon|f|}{b_{N,k}} \tag{2.29}$$

is satisfied. Returning now to the transient problem and assuming that (2.29) is satisfied, we proceed as in [40, 39]. Applying Gronwall's lemma, we get that

$$\begin{aligned} \|u_n\|(\tilde{t}) &\leq \left[\|u_n\|(0) + \frac{b_{N,k}\epsilon\tau_0 - \epsilon^2|f|}{\lambda_0\mu}\right] \mathrm{e}^{-\lambda_0\mu\tilde{t}} - \frac{b_{N,k}\epsilon\tau_0 - \epsilon^2|f|}{\lambda_0\mu} \\ &\leq 0 \qquad \text{if } \ \lambda_0\mu\tilde{t} \geq \ln\left[1 + \frac{\lambda_0\mu \|u_n\|(0)}{b_{N,k}\epsilon\tau_0 - \epsilon^2|f|}\right]. \end{aligned} \tag{2.30}$$

Returning to the integration of (1.1) over the time variable $t = \epsilon^2\tilde{t}$, we expect that u_n will have decayed to its mean value over $\tilde{\Omega}_k$, after integrating for

$$t \geq t_0 = \frac{\epsilon^2}{\mu\lambda_0} \ln\left[1 + \frac{\lambda_0\mu \|u_n\|(0)}{b_{N,k}\epsilon\tau_0 - \epsilon^2|f|}\right]. \tag{2.31}$$

2.2.2. Relation to total variation filtering. In the total variation denoising case (i.e., $\mu = 0$ and $\tau_0 = 1$) it follows purely formally from (2.25) that

$$\frac{\mathrm{d}}{\mathrm{d}\tilde{t}} \|u_n\| \leq -b_{N,k}\epsilon + \epsilon^2|f|.$$

Thus, by integrating with respect to $\tilde{t}$, it follows that

$$\|u_n\|(\tilde{t}) \leq \|u_n\|(0) + \tilde{t}(-b_{N,k}\epsilon + \epsilon^2|f|).$$

Thus, returning to the integration variable t, we expect $\|u_n\|(\tilde{t}) = 0$ for

$$t \geq t_0 := \frac{\epsilon \|u_n\|(0)}{b_{N,k} - \epsilon|f|} = \frac{\epsilon \|u_n\|(0)}{2 - \epsilon|f|}. \tag{2.32}$$

This above estimate also follows from (2.31) as the leading order term of a Taylor series expansion as $\mu \to 0$. Since we have derived (2.31) in H^1, the estimate (2.32) remains purely formal for total variation denoising.

To evaluate the quality of (2.32) we can rely on a variety of results. In [16] the minimizer u_α of (1.7) has been calculated analytically for given piecewise constant input data in $\mathbb{R}^2$. As a consequence of these calculations a minimal regularization parameter α_* can be calculated such that $u_{\alpha_*} = 0$. For the sake of simplicity of presentation we assume that u_0 is just noise, in which case we have

$$u_0(x) = \sum_{i=1}^{n_p} u_{0,i}\chi_{\Omega_i} = \sum_{i=1}^{n_p} \frac{\epsilon}{4} u_{0,i} \frac{4\epsilon}{\epsilon^2}\chi_{\Omega_i}, \tag{2.33}$$

where Ω_i is a square (pixel) with length ϵ, n_p is the number of pixels (index i), χ_{Ω_i} is an indicator function on Ω_i, and $|u_{0,i}| \leq \rho$ is the noise amplitude. We have introduced (2.33) to be in accordance with [16], and the factor $\frac{4\epsilon}{\epsilon^2}$ is the ratio of the perimeter to the Lebesgue measure of Ω_i. Thus, for a regularization parameter α satisfying $\alpha \geq \epsilon\rho/4$ we have $u_\alpha = 0$. For $\Omega = (0,1) \times (0,1)$, setting $U = 0$, $f = 0$, $\tau_0 = 1$, and $\mu = 0$, it follows from (2.32) that $u_n(t) = 0$ for

$$t \geq t_0 := \frac{\rho\epsilon}{2}.$$

This shows that the regularization parameter of BV-regularization and our estimated stopping time for total variation flow (2.32) differ by a factor of 2. Note, however, that there is a discrepancy between the models: we concentrate on a diffusion framework on a bounded domain, while in [16] a regularization framework on $\mathbb{R}^2$ is considered. Moreover, the estimates in [16] are for piecewise constant functions, while here the estimates are valid for all noise functions. The factor of 2 arises by our defining $b_{N,k}$ over the set of functions of zero mean. If relaxed, the two estimates will coincide. Equivalently, the estimate for $b_{N,k}$ is not optimal in the situation that the total variation flow solution is piecewise constant. Since the total variation flow solution is piecewise constant over time, we could use $b_N = 4$ in this situation, which would yield an estimate analogous to [16].

Finally, we mention that the topic of solvability and exact solution of the total variation flow equation has been addressed in a series of papers [7, 9, 16].

2.2.3. Physical interpretation of (2.14)–(2.17). The underlying image U_I affects u_n at $O(\epsilon^2)$ in two ways in (2.14). The interpretation of f is quite straightforward: as a fluid flow problem, f is an imposed pressure gradient or body force, whereas as a heat/diffusion problem, f is a heat/concentration source term. The second way in which U affects u_n at $O(\epsilon^2)$ in (2.14) is through $\tilde{\boldsymbol{m}}$. We show that $\tilde{\boldsymbol{m}}$ has the effect of introducing an anisotropy into the diffusivity, aligned with the

underlying image. Observe that for $|\tilde{\nabla} u_n| \neq 0$

$$\begin{aligned}\frac{|\tilde{\nabla} u_n|^3}{\tau_0}\tilde{\boldsymbol{m}} &= \nabla U |\tilde{\nabla} u_n|^2 - (\nabla U \cdot \tilde{\nabla} u_n)\tilde{\nabla} u_n \\ &= \begin{pmatrix} -\dfrac{\partial u_n}{\partial \tilde{x}_2}\dfrac{\partial U}{\partial x_2} & \dfrac{\partial u_n}{\partial \tilde{x}_2}\dfrac{\partial U}{\partial x_1} \\ \dfrac{\partial u_n}{\partial \tilde{x}_1}\dfrac{\partial U}{\partial x_2} & -\dfrac{\partial u_n}{\partial \tilde{x}_1}\dfrac{\partial U}{\partial x_1} \end{pmatrix} \begin{pmatrix} \dfrac{\partial u_n}{\partial \tilde{x}_1} \\ \dfrac{\partial u_n}{\partial \tilde{x}_2} \end{pmatrix}.\end{aligned}$$

Together with (2.17), this shows that (2.14) can be rewritten as

$$\frac{\partial u_n}{\partial \tilde{t}} = \tilde{\nabla} \cdot \left[A(\tilde{\nabla} u_n)\tilde{\nabla} u_n \right] + \epsilon^2 f,$$

with

$$A(\tilde{\nabla} u_n) = \left(\mu + \frac{\epsilon\tau_0}{|\tilde{\nabla} u_n|}\right) I + \frac{\epsilon^2\tau_0}{|\tilde{\nabla} u_n|^3} \begin{pmatrix} -\dfrac{\partial u_n}{\partial \tilde{x}_2}\dfrac{\partial U}{\partial x_2} & \dfrac{\partial u_n}{\partial \tilde{x}_2}\dfrac{\partial U}{\partial x_1} \\ \dfrac{\partial u_n}{\partial \tilde{x}_1}\dfrac{\partial U}{\partial x_2} & -\dfrac{\partial u_n}{\partial \tilde{x}_1}\dfrac{\partial U}{\partial x_1} \end{pmatrix}.$$

This shows that (2.14) is an inhomogeneous anisotropic heat equation.

LEMMA 2.1. *Let $|\tilde{\nabla} u_n| \neq 0$. The two eigenvalues of $A(\tilde{\nabla} u_n)$ are given by*

$$\begin{aligned}\lambda_1 &= \left(\mu + \frac{\epsilon\tau_0}{|\tilde{\nabla} u_n|}\right), \\ \lambda_2 &= \left(\mu + \frac{\epsilon\tau_0}{|\tilde{\nabla} u_n|}\right) - \frac{\epsilon^2\tau_0}{|\tilde{\nabla} u_n|^3}\left(\frac{\partial u_n}{\partial \tilde{x}_1}\frac{\partial U}{\partial x_1} + \frac{\partial u_n}{\partial \tilde{x}_2}\frac{\partial U}{\partial x_2}\right).\end{aligned}$$

If $|\nabla U| \neq 0$, then the (right) eigenvectors are given by

$$v_1 = \frac{1}{|\nabla U|}\left(\frac{\partial U}{\partial x_1}, \frac{\partial U}{\partial x_2}\right)^t, \qquad v_2 = \frac{1}{|\tilde{\nabla} u_n|}\left(-\frac{\partial u_n}{\partial \tilde{x}_2}, \frac{\partial u_n}{\partial \tilde{x}_1}\right)^t.$$

Proof.

1. Let us define

$$a = \left(\mu + \frac{\epsilon\tau_0}{|\tilde{\nabla} u_n|}\right) \quad \text{and} \quad c = \frac{\epsilon^2\tau_0}{|\tilde{\nabla} u_n|^3}.$$

Then

$$A(\tilde{\nabla} u_n) = \begin{pmatrix} a - c\dfrac{\partial u_n}{\partial \tilde{x}_2}\dfrac{\partial U}{\partial x_2} & c\dfrac{\partial u_n}{\partial \tilde{x}_2}\dfrac{\partial U}{\partial x_1} \\ c\dfrac{\partial u_n}{\partial \tilde{x}_1}\dfrac{\partial U}{\partial x_2} & a - c\dfrac{\partial u_n}{\partial \tilde{x}_1}\dfrac{\partial U}{\partial x_1} \end{pmatrix}.$$

Now, if λ is an eigenvalue of $A(\tilde{\nabla} u_n)$, we have $\det(\lambda - A(\tilde{\nabla} u_n)) = 0$, which gives the assertion after simple algebra.

2. The first eigenvector is easily calculated from the identity:

$$A(\tilde{\nabla} u_n) = \lambda_1 I + R,$$

with

$$R = \frac{\epsilon^2 \tau_0}{|\tilde{\nabla} u_n|^3} \begin{pmatrix} -\dfrac{\partial u_n}{\partial \tilde{x}_2}\dfrac{\partial U}{\partial x_2} & \dfrac{\partial u_n}{\partial \tilde{x}_2}\dfrac{\partial U}{\partial x_1} \\ \dfrac{\partial u_n}{\partial \tilde{x}_1}\dfrac{\partial U}{\partial x_2} & -\dfrac{\partial u_n}{\partial \tilde{x}_1}\dfrac{\partial U}{\partial x_1} \end{pmatrix}.$$

This shows that the eigenvector according to the first eigenvalue λ_1 must be in the nullspace of R. If $|\nabla U| \neq 0$, ∇U spans the nullspace. The second eigenvector can be calculated by using simple linear algebra.

This shows that the anisotropic diffusion directions are determined from the diffusion directions of the diffused data originating from noise free data.

3. Numerical results. Application of (2.31) and the preceding estimates is not immediate, since it is necessary to estimate $|f|$. Provided that $t_0 \ll 1$, we can consider $|f| = |\nabla(\mu \nabla U) - U_t|$ to be pseudosteady with respect to $\tilde{t}$. To estimate f we might consider deriving the problem satisfied by U in the multiple timescales method. However, due to the nonlinearity, the problem for U does not decouple, and it would be necessary to compute various long-time averages of u_n. We have not derived this problem and instead take a more direct approach. We assume an approximate balance,

$$|U_t| \sim |\nabla(\mu \nabla U)|,$$

for the long-time U-problem. Provided that $\epsilon |\nabla(\mu \nabla U)| \ll 1$, any uniform value $\tau_0 \sim 1$ should dominate the underlying effects of the image. This balance will be met when U_I changes rapidly over a length-scale $\sim [\mu\epsilon]^{1/2} \ll 1$. Consequently, we suggest selecting $\mu \sim \epsilon$ and effectively neglecting the $\epsilon^2 f$ term in the denominator (2.31). Our estimate for the decay timescale of u_n to its local mean over the scale $k\epsilon$ is

$$t \sim T = \frac{\epsilon^2 k^2}{\mu \pi^2} \ln \left[1 + \frac{\pi^2 \mu \left\| u_n \right\| (0)}{2k^2 \epsilon \tau_0} \right], \tag{3.1}$$

which we expect to produce reasonable results, provided that spatial variations in U_I occur over length-scales $\gg [\mu\epsilon]^{1/2}$, i.e., the pixel scale for our choice of μ. We proceed with a number of numerical examples.

In the following examples, we have integrated (1.1) using the regularized form (1.6) of D, with $\beta = 10^{-3}$. A fully implicit fractional steps method is used. Since the derivation of (3.1) is purely formal and mostly heuristic, our first objective is to demonstrate that (3.1) produces a sensible estimate of the stopping time to be used with filters of the form (1.2).

3.1. Example 1. As our first example, we take the image shown in Figure 3, which has been normalized so as to have zero mean and so that $\|U_I\| = 1$. This image is perturbed on each pixel with random white noise of maximum amplitude $\Delta u_{n,\max}$. We fix a base case with parameters $\Delta x = \epsilon = 0.01$, $\mu = 0.01$, $\tau_0 = 1.0$, $\Delta u_{n,\max} = 0.5$, and vary each of μ, τ_0, and $\Delta u_{n,\max}$ in turn. Plotted in Figures 3(b)–(f) is the relative noise level $\|u_n\|(t)/\|u_n\|(0)$ against the time t, normalized with the stopping time estimate (3.1), i.e., t/T. Figures 3(b)–(d) show this decay for varying $\Delta u_{n,\max}$, τ_0, and μ, respectively. Here we have fixed $k = 1$. In Figures 3(e)–(f) we show the variations in the decay of $\|u_n\|(t)/\|u_n\|(0)$ with τ_0 and μ, for $k = 2$; i.e., we wait for the local average to develop over a larger length-scale.

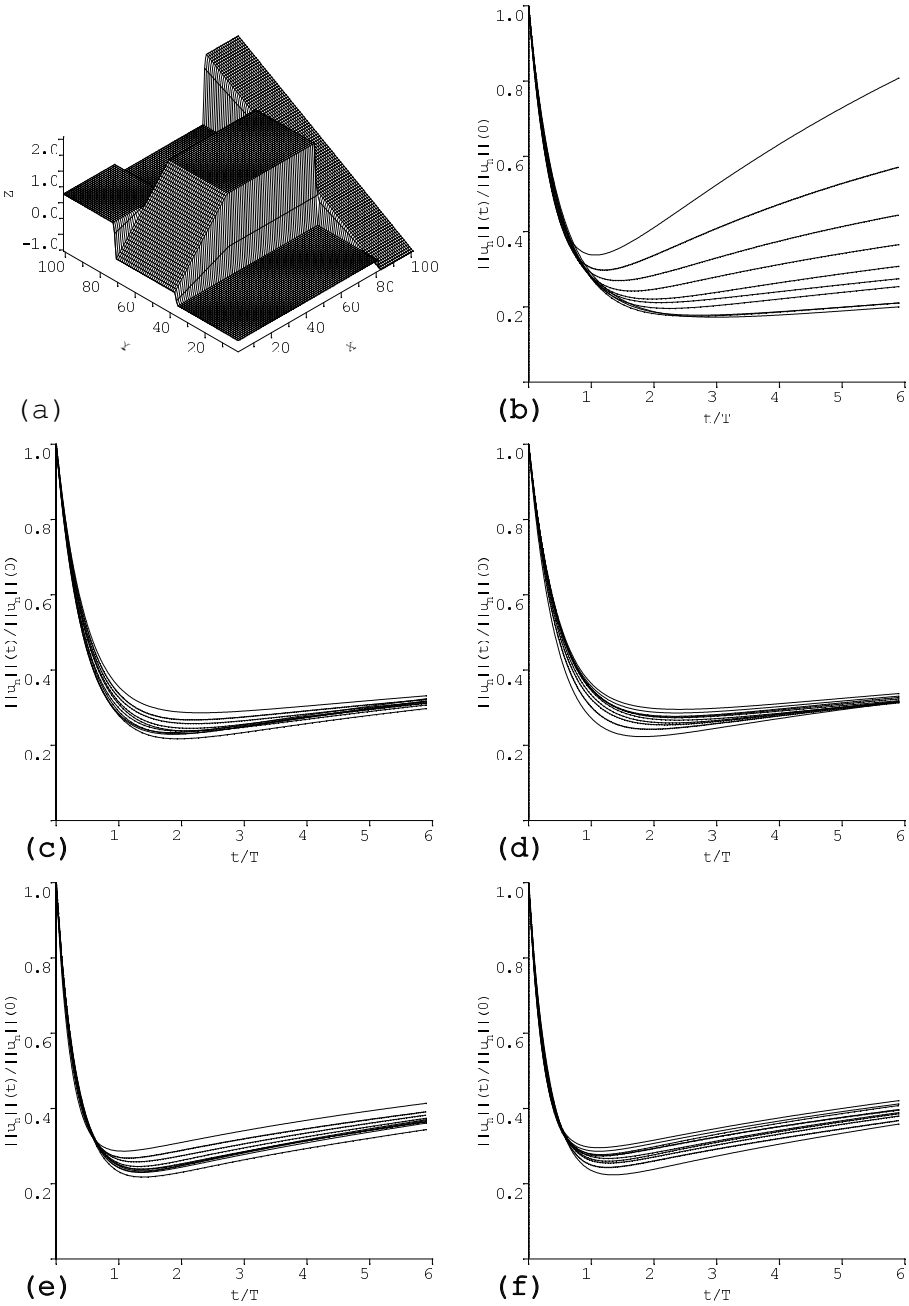

FIG. 3. *Decay of relative noise:* $\|u_n\|(t)/\|u_n\|(0)$ *with* t/T. *Base parameters:* $\Delta x = \epsilon = 0.01$, $\mu = 0.01$, $\tau_0 = 1.0$, $\Delta u_{n,\max} = 0.5$. (a) $U_I(\boldsymbol{x})$; (b) *variations with* $\Delta u_{n,\max} = 0.1,\ 0.2, \ldots,\ 0.9,\ 1.0$, $k = 1$; (c) *variations with* $\tau_0 = 0.1,\ 0.2, \ldots,\ 0.9,\ 1.0$, *initial perturbation of* $U_I(\boldsymbol{x})$ *with white noise of maximum amplitude* $\Delta u_{n,\max} = 0.5$, $k = 1$; (d) *variations with* $\mu = 0.01,\ 0.02, \ldots,\ 0.09,\ 0.1$, $k = 1$; (e) *variations with* $\tau_0 = 0.1,\ 0.2, \ldots,\ 0.9,\ 1.0$, *initial perturbation of* $U_I(\boldsymbol{x})$ *with white noise of maximum amplitude* $\Delta u_{n,\max} = 0.5$, $k = 2$; (f) *variations with* $\mu = 0.01,\ 0.02, \ldots,\ 0.09,\ 0.1$, $k = 2$.

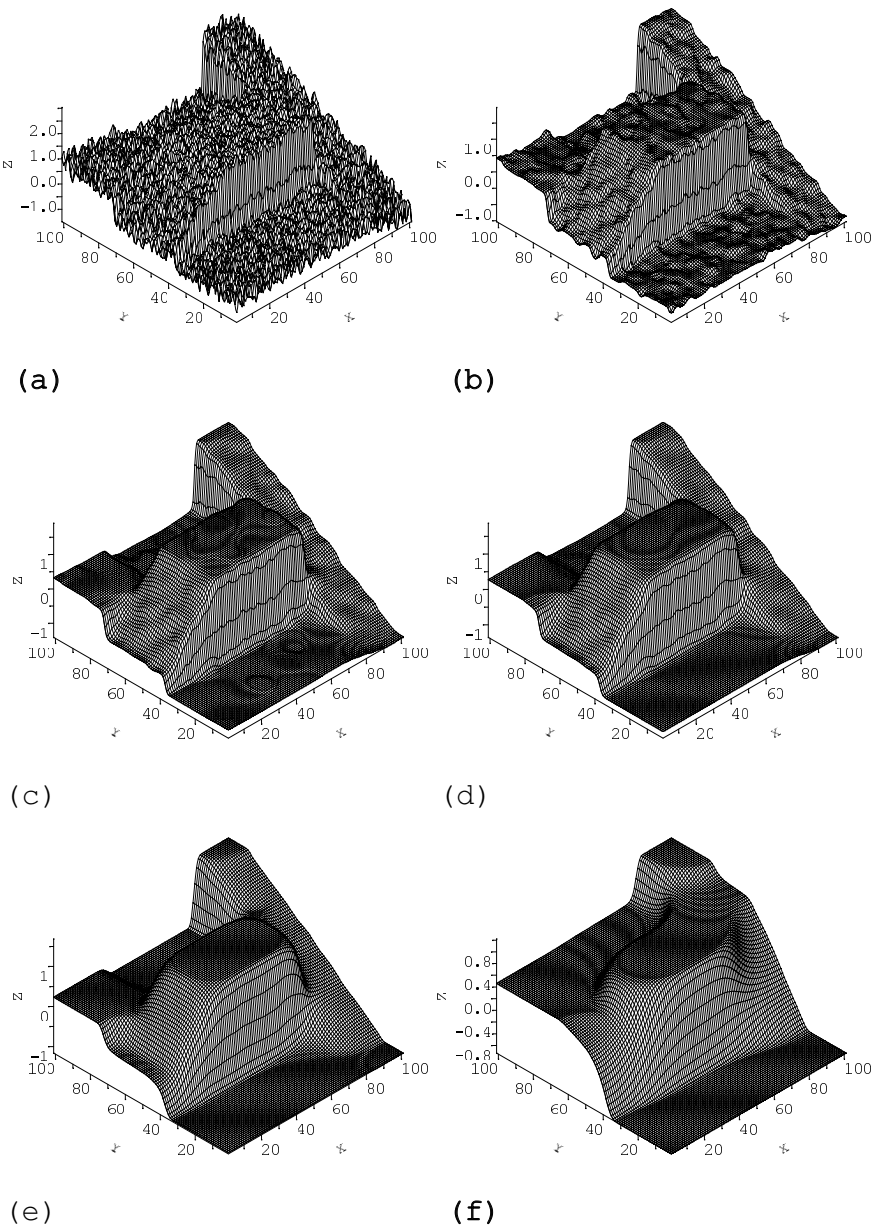

FIG. 4. *Evolution of the image* $u(\boldsymbol{x},t)$ *of Figure* 3(a)*, perturbed with white noise of maximum amplitude* $\pm\Delta u_{n,\max} = 0.5$. (a) $t/T = 0$, (b) $t/T = 1$, (c) $t/T = 2$ *(approximately the minimum of* $\|u_n\|(t)/\|u_n\|(0)$*)*, (d) $t/T = 3$, (e) $t/T = 10$, (f) $t/T = 50$.

The first observation from Figure 3 is that the minimum in $\|u_n\|(t)/\|u_n\|(0)$ is reached for $t/T \sim O(1)$, implying that (3.1) produces a sensible estimate of an appropriate stopping time. For $k = 1$, the minimum is fairly shallow and can be made slightly more extreme by increasing k. Note, however, that we generally do not wish to average the noise over too large a length-scale since the image may then deteriorate. As an example of the evolution of the image, we show in Figure 4 the solution $u(t)$ at different times $t/T = 0,\ 1,\ 2,\ 3,\ 10,\ 50$ for the base case $\Delta x = \epsilon = 0.01$, $\mu = 0.01$, $\tau_0 = 1.0$, $\Delta u_{n,\max} = 0.5$, $k = 2$. The more acceptable recovered images are close to the minimum of $\|u_n\|(t)/\|u_n\|(0)$ (Figures 4(b)–(d)). At larger times, important features of U_I begin to be lost (Figure 4(e)), and for $t \gg T$ the recovered image is very poor (Figure 4(f)).

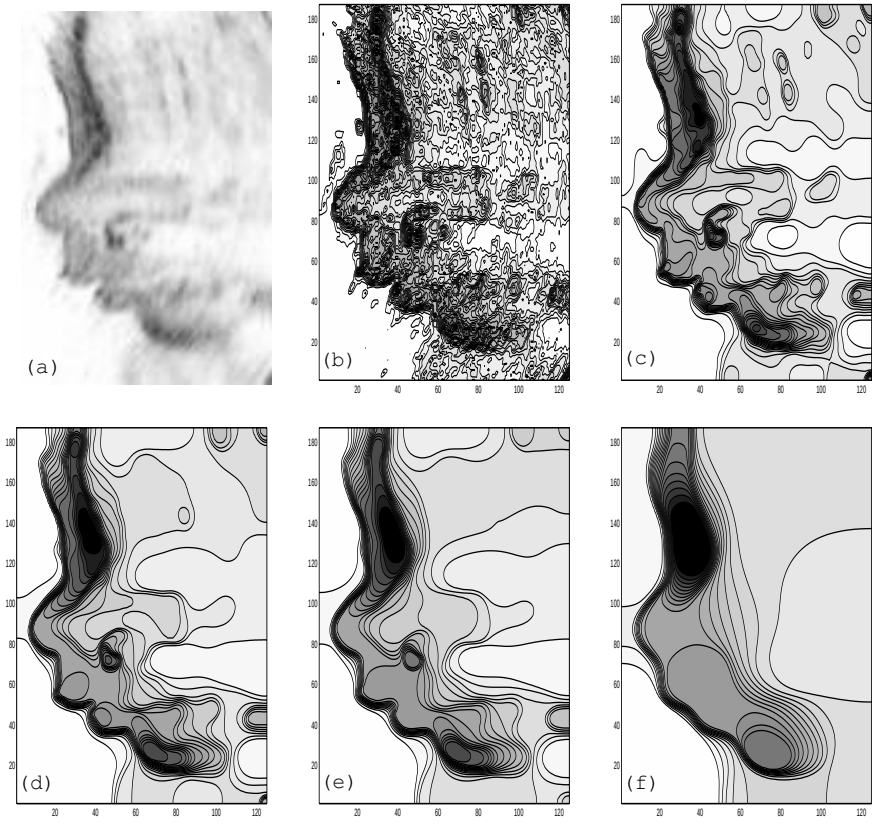

FIG. 5. *Results of applying the diffusion filter to an MR-image;* $\Delta x = \epsilon = 1/124$, $\mu = \epsilon$, $\tau_0 = 1.0$, $k = 2$. (a) *MR-image* $u(\boldsymbol{x}, 0)$, (b) *contour plot of* $u(\boldsymbol{x}, 0)$, (c) $u(\boldsymbol{x}, T)$, (d) $u(\boldsymbol{x}, 2T)$, (e) $u(\boldsymbol{x}, 3T)$, (f) $u(\boldsymbol{x}, 10T)$.

3.2. Example 2. As a second example, we consider an MR-imaged head; see Figure 5(a). Here the initial image is noisy and we can estimate $\|u_n\|(0) \approx 0.2$. For this image, $\Delta x = \epsilon = 1/124$, and we set $\mu = \epsilon$, $\tau_0 = 1.0$, and $k = 2$. Contours of the initial image are shown in Figure 5(b). In Figures 5(c)–(f) the results of applying the diffusion filter with these parameters to the solution $u(\boldsymbol{x}, t)$ at times $t = T,\ 2T,\ 3T,\ 10T$ are shown. On integrating further, the image is effectively

constant by $t \approx 60T$. The contours of the mouth and nose are particularly well-defined for $t \sim T$, but deteriorate rapidly for $t \gg T$.

3.3. Example 3. As a final example, we consider the more complex geometrical image $U_I(\boldsymbol{x})$ in Figure 6(a). This type of image is quite challenging for a diffusion filter due to the fine features, e.g., the edges around the windows, the chair legs, the shadows on the computer screen, etc. In Figure 6(b) we perturb the image with random white noise of maximum amplitude $\pm\Delta u_{n,\max} = 0.1$ and then integrate using $\mu = \epsilon$, $\tau_0 = 1.0$, $k = 2$; here $\Delta x = \epsilon = 1/256$. The recovered image $u(\boldsymbol{x}, t)$ is shown at times $t = T,\ 2T,\ 3T,\ 10T$ in Figures 6(c)–(f). Again for $t = 10T$ many of the fine-scale features of the image are lost, whereas Figures 6(c)–(e) give a reasonable recovered image.

For an image such as $U_I(\boldsymbol{x})$ in Figure 6(a), it is evidently hard to recover fine-scale features when the initial noise level is high, since fine-scale features of the image and noise become indistinguishable. However, the stopping estimate still produces reasonable results, mathematically speaking; it is simply that they are not particularly good aesthetically! In Figure 7 we repeat the numerical experiment of Figure 6, perturbing $U_I(\boldsymbol{x})$ with random white noise of maximum amplitude $\pm\Delta u_{n,\max} = 1.0$, (see Figure 7(a)), and integrating using $\mu = \epsilon$, $\tau_0 = 1.0$, $k = 2$. The recovered image $u(\boldsymbol{x}, t)$ is shown at times $t = T,\ 2T,\ 3T,\ 10T,\ 50T$ in Figures 7(b)–(f). The recovered image is predictably much poorer than in Figure 6. For $t = 50T$ the image has diffused away. Figures 7(c)–(d) are quite reasonable, considering the initial image. (Note that the initial image $u(\boldsymbol{x}, 0)$ is actually much more noisy than it appears in Figure 7(a), since the grey-scale chosen represents only intensities in $[0, 1]$; hence the *salt-and-pepper* look.)

4. Discussion. We have used an analogy between visco-plastic fluid flow and image selective smoothing to determine quantitatively accurate asymptotic stopping time estimates for Bingham diffusion models. The Bingham model is a physical fluid model that, applied to filtering data, is capable of removing the noise locally in a finite time, which, for instance, the Gaussian filtering method ($\tau \to 0$) does not do. The Bingham model is also capable of preserving blocky structure in the original data in the sense that horizontal level lines are preserved as horizontal, although corners are blurred.

There are a number of potential extensions of our work. First, it is important to note that the multiple scales estimate leaves room for the selection of locally varying filter parameters, $\tau_0(\boldsymbol{x})$ and $\mu(\boldsymbol{x})$, which can be chosen within this rational stopping time framework that we have established. This can be used to produce local enhancement of the restored image, particularly in cases where fine-scale features of the image are obscured by noise (e.g., our final example in Figure 7). We have already made some progress in the development of local filtering techniques, which will be reported elsewhere. Second, there are obvious extensions to multidimensional image restoration tasks (e.g., color filtering) wherever Bingham-type filters are used. Third, we mention that the Bingham model is only one of many visco-plastic fluid models. It is of some academic and practical interest to further explore the frontier between non-Newtonian fluid mechanics and image restoration. Currently there are concerns in the image processing community about the use of bounded variation regularization models and their tendency to generate blocky structures (see, e.g., [30, 57]). Recent work of Gousseau and Morel [41] seem to point towards the use of power law models in image denoising, which again have counterparts in fluid mechanics. Filtering methods can be developed for visco-plastic shear-thinning models such as Herschel–Bulkley

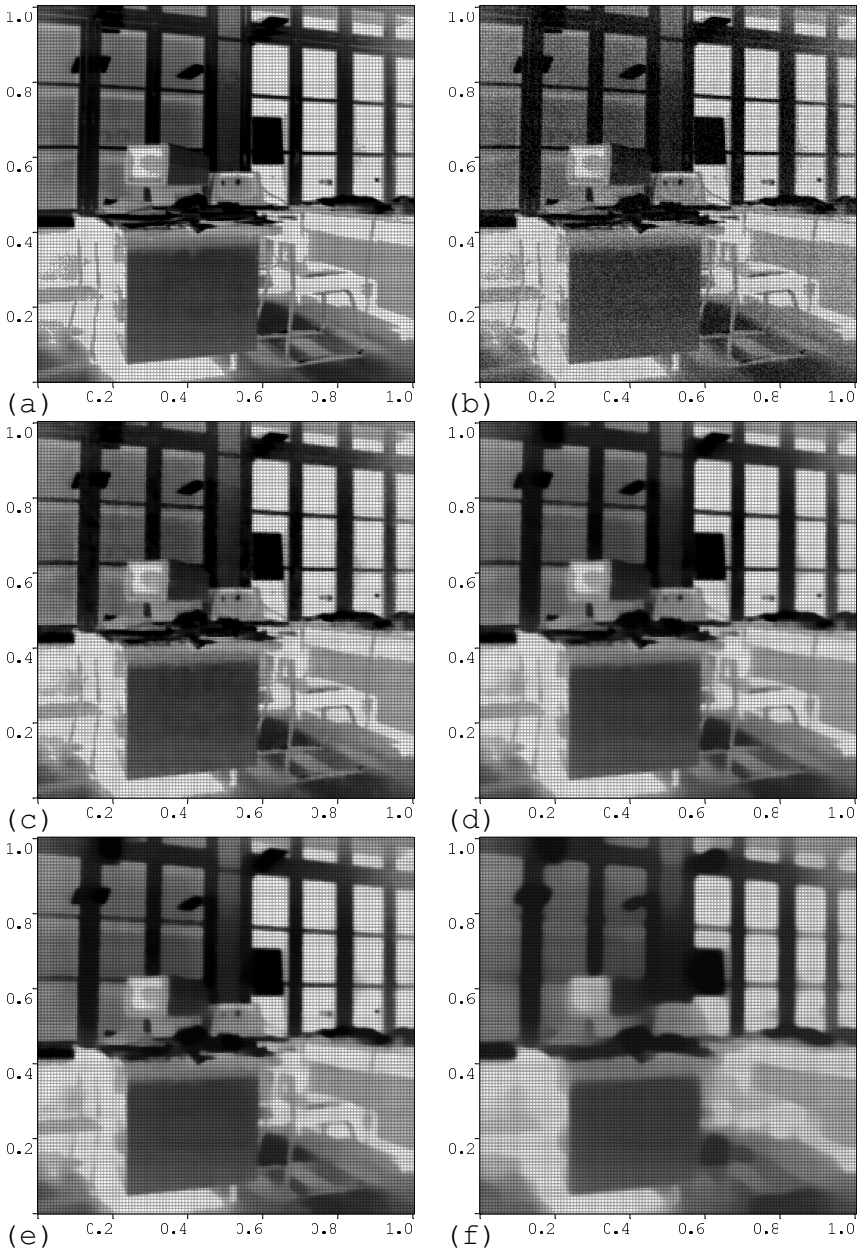

FIG. 6. *Denoising of a more complex geometrical image:* $\Delta x = \epsilon = 1/256$, $\mu = \epsilon$, $\tau_0 = 1.0$, $k = 2$. (a) $U_I(\boldsymbol{x})$, (b) $u(\boldsymbol{x}, 0)$ *after perturbing* $U_I(\boldsymbol{x})$ *with random white noise of maximum amplitude* $\pm\Delta u_{n,\max} = 0.1$, (c) $u(\boldsymbol{x}, T)$, (d) $u(\boldsymbol{x}, 2T)$, (e) $u(\boldsymbol{x}, 3T)$, (f) $u(\boldsymbol{x}, 10T)$.

and Casson fluid models too. The inclusion of visco-elastic (memory) effects is also of extreme practical interest. Our work is progressing in this direction.

Appendix. Weak solutions of (2.14)–(2.17). The differential equation (2.14) has to be understood in a generalized setting. We interpret (2.14) following the concept of nonlinear semigroup theory (see, e.g., [19]) and consider instead a semi-infinite

implicit time-discretized approximation $\hat{u}_n$ for $u_n(\tilde{t})$ at the discrete time samples

$$\tilde{t} = \tilde{t}_i = \tilde{t}_{i-1} + \Delta\tilde{t} \quad (i = 1, \dots), \quad \tilde{t}_0 = 0,$$

via

$$\frac{\hat{u}_n(\tilde{t}+\Delta\tilde{t})-\hat{u}_n(\tilde{t})}{\Delta\tilde{t}} = \tilde{\nabla}\cdot[\tilde{\boldsymbol{\tau}}+\epsilon^2\tilde{\boldsymbol{m}}](\tilde{t}+\Delta\tilde{t})+\epsilon^2 f. \tag{A.1}$$

Note here that in our multiple-timescales approximation, partial derivatives of U, and hence also of f, are considered constant in time and space for the rapid timescale and short length-scale evolution associated with $\hat{u}_n$. The approximation at time $\tilde{t}+\Delta\tilde{t}$ is understood as the minimizer of the functional

$$\begin{aligned}\mathcal{F}(\hat{u}) := \quad \Delta\tilde{t}\Bigg\{ &\frac{\mu}{2}a(\hat{u},\hat{u})+\epsilon\tau_0 j(\hat{u})+\epsilon^2\tau_0\left\langle\frac{\nabla U\cdot\tilde{\nabla}\hat{u}}{|\tilde{\nabla}\hat{u}|}\right\rangle-\epsilon^2\langle f\hat{u}\rangle\Bigg\}\\ &-\tfrac{1}{2}\|\hat{u}_n(\tilde{t})-\hat{u}\|^2\end{aligned}$$

over

$$H^1_{\mathtt{mean}} := \left\{\hat{u}\in H^1 : \int\hat{u}=0\right\}.$$

We consider the variational problem of minimizing $\mathcal{F}$ over the space $H^1_{\mathtt{mean}}$. In contrast to classical solutions for (2.14)–(2.18), we do not have to impose Neumann boundary conditions, since they are inherent in the variational formulation. Note that the space $H^1_{\mathtt{mean}}$ is a Hilbert space with scalar product

$$\langle\nabla u\cdot\nabla v\rangle.$$

Since the functional $\mathcal{F}$ is nonconvex with respect to $\hat{u}$ in general we do not have existence of a minimizer (see, e.g., [29]), and generalized solution concepts have to be employed. There are at least three possible solution concepts:

1. Convexification (see, e.g., [29]). This would be the most attractive concept for numerical purposes: it consists of calculating the convex envelope of the function

$$\mathcal{F}^c(\hat{u}_1,\hat{u}_2)=\Delta\tilde{t}\left\{\frac{\mu}{2}(\hat{u}_1^2+\hat{u}_2^2)+\epsilon\tau_0\sqrt{\hat{u}_1^2+\hat{u}_2^2}+\epsilon^2\tau_0\frac{\nabla U\cdot\hat{u}}{\sqrt{\hat{u}_1^2+\hat{u}_2^2}}\right\}$$

with respect to the variable $(\hat{u}_1,\hat{u}_2)\in\mathbb{R}^2$. Once the convex envelope is calculated, the resulting minimization problem can be solved by solving the first order optimality condition, which is a degenerated elliptic partial differential equation. The difficulty associated with calculation of the convex envelope is the dependence of $\mathcal{F}^c$ on ∇U. Thus the convex envelope is only tractable if we find an analytical expression for the convex envelope in terms of two free parameters (U_1,U_2) representing ∇U.

2. Γ-limits (see, e.g., [5]). That is, we reconsider the functional $\mathcal{F}$:

$$\mathcal{F}^\Gamma(\hat{u}) := \liminf_{\{\{\hat{v}_l,\xi_l\}_{l\in\mathbb{N}}:\hat{v}_l\to u\in H^1_{\mathtt{mean}}(\tilde{\Omega}_k)\text{ and }\xi_l\to 0^+\}}\mathcal{F}_{\xi_l}(\hat{v}_l),$$

with

$$\begin{aligned}\mathcal{F}_\xi(\hat{v}_l) := \quad \Delta\tilde{t}\Bigg\{ &\frac{\mu}{2}a(\hat{v}_l,\hat{v}_l)+\epsilon\tau_0 j(\hat{v}_l)-\epsilon^2\langle f\hat{v}_l\rangle\\ &+\epsilon^2\tau_0\left\langle\frac{\nabla U\cdot\tilde{\nabla}\hat{v}_l}{\sqrt{|\tilde{\nabla}\hat{v}_l|^2+\xi^2}}\right\rangle\Bigg\}+\tfrac{1}{2}\|\hat{u}_n(\tilde{t})-v_e\|^2\end{aligned}$$

As we show below, the modified functional has a minimizer. The modified functional is a reasonable model since, if the original functional $\mathcal{F}$ has a minimizer, it also minimizes $\mathcal{F}^\Gamma$. We remark that for convex functionals the modified functional is identical to the original. We employ Γ^--limits below.

3. Relaxation (see, e.g., [5, 29]). We call a relaxation method a Γ-limit, without additional parameter dependency, i.e., without dependency of the positive sequence $\{\xi_l\}_{l\in\mathbb{N}}$.

In order to simplify the considerations, we abbreviate the functional $\mathcal{F}$ and note that it is of the general form

$$\mathcal{F}(\hat{u}) := \nu_1 a(\hat{u},\hat{u}) + \nu_2 j(\hat{u}) + \nu_3 \left\langle \frac{\nabla U\cdot\tilde{\nabla}\hat{u}}{|\tilde{\nabla}\hat{u}|}\right\rangle - \left\langle \hat{f}\hat{u}\right\rangle + \nu_4\|\hat{u}_n(\tilde{t})-\hat{u}\|^2,$$

with $0<\nu:=(\nu_1,\nu_2,\nu_3,\nu_4)\le\overline{\nu}$.

Accordingly we set

$$\mathcal{F}_\xi(\hat{u}) := \nu_1 a(\hat{u},\hat{u}) + \nu_2 j(\hat{u}) + \nu_3 \left\langle \frac{\nabla U\cdot\tilde{\nabla}\hat{u}}{\sqrt{|\tilde{\nabla}\hat{u}|^2+\xi^2}}\right\rangle - \left\langle \hat{f}\hat{u}\right\rangle + \nu_4\|\hat{u}_n(\tilde{t})-\hat{u}\|^2$$

and define the Γ-limit as above.

LEMMA A.1. *Let $\hat{f}\in(H^1_{\mathtt{mean}})^*$, the dual of $H^1_{\mathtt{mean}}$, and $U\in H^1$. Moreover, let $\tilde{\Omega}_k$ be bounded with Lipschitz boundary. Then the function values $\mathcal{F}^\Gamma(\hat{u})$ are well defined for each $\hat{u}\in H^1_{\mathtt{mean}}$.*

Proof. Under the above assumptions, we have for each $\tilde{u}\in H^1_{\mathtt{mean}}$ and $\xi>0$ that

$$\begin{aligned}\mathcal{F}_\xi(\tilde{u}) &\ge -\overline{\nu}\|\nabla U\|_{L^2} + \nu_1\|\tilde{\nabla}\tilde{u}\|^2_{L^2} - \|\hat{f}\|_{(H^1_{\mathtt{mean}})^*}\|\tilde{\nabla}\tilde{u}\|_{L^2}\\ &\ge -\overline{\nu}\|\nabla U\|_{L^2} - \frac{\|\hat{f}\|^2_{(H^1_{\mathtt{mean}})^*}}{4\nu_1}\,.\end{aligned} \tag{A.2}$$

This shows that for any $\tilde{u}\in H^1_{\mathtt{mean}}$, $\mathcal{F}_\xi(\tilde{u})$ is uniformly bounded from below with respect to ξ. Moreover, $\mathcal{F}_\xi(\tilde{u})$ is uniformly bounded from above since

$$\mathcal{F}_\xi(\tilde{u}) \le \overline{\nu}\|\nabla U\|_{L^2} + C\|\tilde{u}\|^2_{H^1_{\mathtt{mean}}} + \|\hat{f}\|_{(H^1_{\mathtt{mean}})^*}\|\tilde{u}\|_{H^1_{\mathtt{mean}}} + \overline{\nu}\|\tilde{u}\|_{H^1_{\mathtt{mean}}}\sqrt{\mathrm{meas}(\tilde{\Omega}_k)} + C, \tag{A.3}$$

with appropriate $C>0$. Thus for any pair of sequences $\{\hat{v}_l\}_{l\in\mathbb{N}}$ converging weakly to $\hat{u}$, and $\{\xi_l\}_{l\in\mathbb{N}}$ converging to $0+$, the sequence $\{\mathcal{F}_{\xi_l}(\hat{v}_l)\}_{l\in\mathbb{N}}$ is uniformly bounded, and thus its infimum is finite. Taking the infimum over all limits of possible sequences $\{\mathcal{F}_{\xi_l}(\hat{v}_l)\}$ gives the assertion.

THEOREM A.2. *Under the same assumptions as in Lemma* A.1, *$\mathcal{F}^\Gamma$ attains a minimum in $H^1_{\mathtt{mean}}$.*

Proof. From (A.2) it follows that the infimum of $\mathcal{F}^\Gamma$ over $H^1_{\mathtt{mean}}$ is finite. Suppose that $\mathcal{F}^\Gamma$ does not attain a minimum; then there exists a sequence $\{\rho_l\}_{l\in\mathbb{N}}$ satisfying

$$\mathcal{F}^\Gamma(\rho_l)\to\inf\mathcal{F}^\Gamma.$$

By definition, for any ρ_l and any $\delta_l>0$ there exists a pair $(\hat{\rho}_l,\xi_l)$ satisfying

$$|\mathcal{F}^\Gamma(\rho_l)-\mathcal{F}_{\xi_l}(\hat{\rho}_l)|\le\delta_l.$$

Let $\delta_l \to 0$; then

$$\mathcal{F}_{\xi_l}(\hat{\rho}_l) \to \inf \mathcal{F}^\Gamma \,. \tag{A.4}$$

In particular, we have

$$\mathcal{F}_{\xi_l}(\hat{\rho}_l) \le \overline{C} < \infty \quad \text{ for all } l \in \mathbb{N} \,.$$

Thus from the definition of $\mathcal{F}_{\xi_l}$ it follows that

$$\begin{aligned} \overline{\nu}\|\hat{\rho}_l\|^2_{H^1_{\mathtt{mean}}} &\le \left(\overline{C} + \overline{\nu}\|\nabla U\|_{L^2}\right) + \left(\|\hat{f}\|_{(H^1_{\mathtt{mean}})^*} + \overline{\nu}\sqrt{\mathrm{meas}(\tilde{\Omega}_k)}\right)\|\hat{\rho}_l\|_{H^1_{\mathtt{mean}}} \\ &=: C_1 + C_2\|\hat{\rho}_l\|_{H^1_{\mathtt{mean}}}, \end{aligned}$$

which shows that $\{\hat{\rho}_l\}_{l\in\mathbb{N}}$ is uniformly bounded in $H^1_{\mathtt{mean}}$, and therefore it has a weakly convergent subsequence, which again, for simplicity of notation, is denoted by $\{\hat{\rho}_l\}_{l\in\mathbb{N}}$. Let us denote by $\hat{u}$ the weak limit; then by definition of $\mathcal{F}^\Gamma$ we have that

$$\mathcal{F}^\Gamma(\hat{u}) \le \liminf_{l\in\mathbb{N}} \mathcal{F}_{\xi_l}(\hat{\rho}_l),$$

which together with (A.4) shows that

$$\mathcal{F}^\Gamma(\hat{u}) = \inf \mathcal{F}^\Gamma.$$

Acknowledgments. The authors are grateful to two referees for their careful reading of the manuscript, their helpful advice, and bringing to our attention the references [8, 10, 12, 57]. Finally we thank Prof. F. Santosa for encouraging us to include subsection 2.2.2.

SLOWLY COUPLED OSCILLATORS: PHASE DYNAMICS AND SYNCHRONIZATION*

EUGENE M. IZHIKEVICH† AND FRANK C. HOPPENSTEADT‡

Abstract. In this paper we extend the results of Frankel and Kiemel [*SIAM J. Appl. Math*, 53 (1993), pp. 1436–1446] to a network of slowly coupled oscillators. First, we use Malkin's theorem to derive a canonical phase model that describes synchronization properties of a slowly coupled network. Then, we illustrate the result using slowly coupled oscillators (1) near Andronov–Hopf bifurcations, (2) near saddle-node on invariant circle bifurcations, and (3) near relaxation oscillations. We compare and contrast synchronization properties of slowly and weakly coupled oscillators.

Key words. phase model, Andronov–Hopf, saddle-node on invariant circle, Class 1 excitability, relaxation oscillators, Malkin theorem, MATLAB

1. Slowly coupled networks.

In this paper we study synchronization dynamics of a network of $n \geq 2$ coupled oscillators of the form

$$\dot{x}_i = f_i(x_i, s_1, \ldots, s_n), \tag{1.1}$$

$$\dot{s}_i = \varepsilon g_i(x_i, s_i), \tag{1.2}$$

where $x_i \in \mathbb{R}^m$ describes the state of the ith oscillator and $s_i \in \mathbb{R}$ describes how the ith oscillator affects the other oscillators for $i = 1, \ldots, n$. The parameter $\varepsilon \ll 1$ is small reflecting the assumption that the connection variables s_i are "slow." We analyze this system in this section and present several examples in section 2.

Proceeding as in Frankel and Kiemel (1993) we "freeze" the vector of slow variables $s = (s_1, \ldots, s_n) \in \mathbb{R}^n$ and assume that each oscillator described by (1.1) has a $T_i(s)$-periodic solution $x_i = x_i(t, s)$. Substituting this in (1.2) results in the system

$$\dot{s}_i = \varepsilon g_i(x_i(t, s), s_i), \qquad i = 1, \ldots, n,$$

which we can average and obtain a slow system

$$\dot{s}_i = \varepsilon \bar{g}_i(s), \qquad i = 1, \ldots, n, \tag{1.3}$$

where

$$\bar{g}_i(s) = \frac{1}{T_i(s)} \int_0^{T_i(s)} g_i(x_i(t, s), s_i)\, dt$$

is the average of g_i. In this paper we make the following two assumptions:

A1. The system (1.3) has an exponentially stable equilibrium $\bar{s} = (\bar{s}_1, \dots, \bar{s}_n)$.
A2. Each equation (1.1) has an exponentially stable limit cycle attractor $\gamma_i(t) \subset \mathbb{R}^m$ with period $T > 0$ when $s = \bar{s}$.

THEOREM 1.1 (phase model for slowly coupled oscillators). *Consider the slowly coupled system* (1.1), (1.2) *satisfying assumptions* A1 *and* A2 *above. Let* $\tau = \varepsilon t$ *be slow time. Let* $u_i(\tau)$ *be the rescaled deviation of the slow variable* s_i *from the asymptotic value* $\bar{s}_i$*, and let* $\varphi_i(\tau)$ *be the phase deviation of the* i*th oscillator from the natural oscillation* $\gamma_i(t)$*. Then, the phase dynamics and synchronization properties of the slowly coupled system* (1.1), (1.2) *are described by the canonical phase model*

$$\varphi_i' = \sum_{j=1}^{n} \{a_{ij} u_j + H_{ij}(\varphi_j - \varphi_i)\}, \tag{1.4}$$

$$u_i' = \sum_{j=1}^{n} \{b_{ij} u_j + K_{ij}(\varphi_j - \varphi_i)\}, \tag{1.5}$$

where $' = d/d\tau$*, and*

$$\begin{aligned}
a_{ij} &= \frac{1}{T}\int_0^T Q_i(t)^\top \frac{\partial f_i}{\partial s_j}(\gamma_i(t), \bar{s})\, dt,\\
b_{ij} &= \frac{1}{T}\int_0^T \left[P_i(t)^\top \frac{\partial f_i}{\partial s_j}(\gamma_i(t), \bar{s}) + \frac{\partial g_i}{\partial s_j}(\gamma_i(t), \bar{s}_i)\right] dt,\\
H_{ij}(\chi) &= \frac{1}{T}\int_0^T Q_i(t)^\top \frac{\partial f_i}{\partial s_j}(\gamma_i(t), \bar{s}) \int_0^{t+\chi} g_j(\gamma_j(\bar{t}), \bar{s})\, d\bar{t}\, dt,\\
K_{ij}(\chi) &= \frac{1}{T}\int_0^T \left(P_i(t)^\top \frac{\partial f_i}{\partial s_j}(\gamma_i(t), \bar{s}) + \frac{\partial g_i}{\partial s_j}(\gamma_i(t), \bar{s}_i)\right) \int_0^{t+\chi} g_j(\gamma_j(\bar{t}), \bar{s})\, d\bar{t}\, dt,
\end{aligned}$$

where $Q_i(t), P_i(t) \subset \mathbb{R}^m$ *are the unique nontrivial* T*-periodic solutions of the linear adjoint systems*

$$\dot{Q}_i = -\left\{\frac{\partial f_i}{\partial x_i}(\gamma_i(t), \bar{s})\right\}^\top Q_i \quad \textit{and} \quad \dot{P}_i = -\left\{\frac{\partial f_i}{\partial x_i}(\gamma_i(t), \bar{s})\right\}^\top P_i - \left\{\frac{\partial g_i}{\partial x_i}(\gamma_i(t), \bar{s})\right\}^\top \tag{1.6}$$

satisfying the normalization conditions

$$Q_i(t)^\top f_i(\gamma_i(t), \bar{s}) = 1 \qquad \textit{and} \qquad P_i(t)^\top f_i(\gamma_i(t), \bar{s}) = -g_i(\gamma_i(t), \bar{s}) \tag{1.7}$$

for some (and hence all) $t \geq 0$*.*

Remark 1.2. The same result holds when $g_i(x_i, s_i)$ also depend on $s_1, \dots, s_n$.

Remark 1.3. The same result holds for the *slowly and weakly* coupled system

$$\begin{aligned}
\dot{x}_i &= f_i(x_i, s_1, \dots, s_n) + \varepsilon \sum_{j=1}^{n} r_{ij}(x_i, x_j),\\
\dot{s}_i &= \varepsilon g_i(x_i, s_i),
\end{aligned}$$

provided that the term

$$\frac{1}{T}\int_0^T Q_i(t)^\top r_{ij}(\gamma_i(t), \gamma_j(t+\chi))\, dt$$

is added to the function $H_{ij}(\chi)$ and the term

$$\frac{1}{T}\int_0^T P_i(t)^\top r_{ij}(\gamma_i(t),\gamma_j(t+\chi))\,dt$$

is added to the function $K_{ij}(\chi)$.

Remark 1.4. This result not only extends the result of Frankel and Kiemel (1993) to a network of $n \geq 2$ oscillators, but also presents a precise description of all the parameters and functions in the canonical model (1.4), (1.5), which can easily be determined numerically; see Appendix B.

Proof. This result is a corollary to Malkin's theorem, which we restate in Appendix A. Consider the slowly coupled system (1.1), (1.2) in an ε-neighborhood of $\bar{s}$. Let

$$s_i = \bar{s}_i + \varepsilon w_i,$$

so that we can rewrite (1.1), (1.2) in the form (A.1),

$$\dot{x}_i = f_i(x_i,\bar{s}) + \varepsilon\sum_{j=1}^n h_{ij}(x_i,\bar{s})w_j, \tag{1.8}$$

$$\dot{w}_i = g_i(x_i,\bar{s}_i) + \varepsilon p_i(x_i,\bar{s}_i)w_i \tag{1.9}$$

plus higher-order terms in ε, where

$$h_{ij} = \frac{\partial f_i}{\partial s_j} \qquad \text{and} \qquad p_i = \frac{\partial g_i}{\partial s_i}\ .$$

In the rest of the proof we omit $\bar{s}$ for the sake of clarity of notation.

Since (1.8), (1.9) has a "weakly connected" form, it suffices to show that all the conditions of Malkin's theorem are satisfied for each individual oscillator.

Each unperturbed (uncoupled, $\varepsilon = 0$) system

$$\dot{x}_i = f_i(x_i),$$
$$\dot{w}_i = g_i(x_i)$$

has a 2-parameter family of T-periodic solutions

$$x_i(t) = \gamma_i(t+\varphi_i) \qquad \text{and} \qquad w_i(t) = u_i + \int_0^{t+\varphi_i} g_i(\gamma_i(\bar{t}))\,d\bar{t},$$

where φ_i and u_i are independent parameters, $i = 1,\ldots,n$. ($w_i(t)$ is periodic because s_i is at equilibrium and the average of g_i over the limit cycle is assumed to be zero.) Let $Q_i(t)$ and $P_i(t)$ be the unique nontrivial solutions to the adjoint system (1.6), which exist because $\gamma_i(t)$ is a normally hyperbolic attractor (Hoppensteadt and Izhikevich 1997). One can verify that

$$R_i(t) = \begin{pmatrix} Q_i(t) \\ 0 \end{pmatrix} \qquad \text{and} \qquad R_i(t) = \begin{pmatrix} P_i(t) \\ 1 \end{pmatrix}$$

are two independent nontrivial solutions to the adjoint system (A.2),

$$\dot{R}_i = -\begin{pmatrix} \frac{\partial f_i}{\partial x_i}(\gamma_i(t)) & 0 \\ \frac{\partial g_i}{\partial x_i}(\gamma_i(t)) & 0 \end{pmatrix}^\top R_i\ .$$

Equation (A.4) results in

$$\varphi_i' = \frac{1}{T}\int_0^T Q_i(t+\varphi_i)^\top \left\{ \sum_{j=1}^n h_{ij}(\gamma_i(t+\varphi_i)) \left(u_j + \int_0^{t+\varphi_j} g_j(\gamma_j(\bar{t}))\, d\bar{t} \right) \right\} dt$$

$$= \frac{1}{T}\int_0^T Q_i(t)^\top \left\{ \sum_{j=1}^n h_{ij}(\gamma_i(t)) \left(u_j + \int_0^{t+\varphi_j-\varphi_i} g_j(\gamma_j(\bar{t}))\, d\bar{t} \right) \right\} dt$$

and

$$u_i' = \frac{1}{T}\int_0^T P_i(t+\varphi_i)^\top \left\{ \sum_{j=1}^n h_{ij}(\gamma_i(t+\varphi_i)) \left(u_j + \int_0^{t+\varphi_j} g_j(\gamma_j(\bar{t}))\, d\bar{t} \right) \right\}$$

$$+ 1 \cdot \left\{ p_i(\gamma_i(t+\varphi_i)) \left(u_i + \int_0^{t+\varphi_i} g_i(\gamma_i(\bar{t}))\, d\bar{t} \right) \right\} dt$$

$$= \frac{1}{T}\int_0^T P_i(t)^\top \left\{ \sum_{j=1}^n h_{ij}(\gamma_i(t)) \left(u_j + \int_0^{t+\varphi_j-\varphi_i} g_j(\gamma_j(\bar{t}))\, d\bar{t} \right) \right\}$$

$$+ 1 \cdot \left\{ p_i(\gamma_i(t)) \left(u_i + \int_0^{t+\varphi_j-\varphi_i} g_i(\gamma_i(\bar{t}))\, d\bar{t} \right) \right\} dt,$$

which can be written in the form (1.4), (1.5). □

2. Examples. The major challenge in applying Theorem 1.1 is solving the linear adjoint system (1.6). In general, this could be done numerically, as we show in Appendix B. However, there are three important cases when (1.6) can be solved analytically:

- Each oscillator is near an Andronov–Hopf bifurcation.
- Each oscillator is near a saddle-node on invariant circle bifurcation.
- Each oscillator has two time scales (relaxation oscillator).

We consider all three cases below, but first we start with two simple examples.

2.1. Phase oscillators. The system of slowly coupled phase oscillators

$$\dot{\vartheta}_i = 1 + \sum_{j=1}^n c_{ij} s_j, \tag{2.1}$$

$$\dot{s}_i = \varepsilon(\cos\vartheta_i - b s_i) \tag{2.2}$$

illustrates the major steps in Theorem 1.1. When all s_i are not very large, the averaged slow system (1.3) has the form

$$\dot{s}_i = -\varepsilon b s_i.$$

If $b > 0$, $\bar{s} = 0 \in \mathbb{R}^n$ is an exponentially stable equilibrium, and assumption A1 is satisfied. Assumption A2 is also satisfied, since at $\bar{s} = 0$ all phase oscillators, described by $\dot{\vartheta}_i = 1$, have equal period $T = 2\pi$. Let $s_i = \varepsilon w_i$; then system (1.8), (1.9) has the form

$$\dot{\vartheta}_i = 1 + \varepsilon \sum_{j=1}^n c_{ij} w_j,$$

$$\dot{w}_i = \cos\vartheta_i - \varepsilon b w_i.$$

When $\varepsilon = 0$, this system has a family of solutions

$$\vartheta_i(t) = t + \varphi_i \qquad \text{and} \qquad w_i(t) = u_i + \sin(t + \varphi_i).$$

Since $\partial f_i/\partial \vartheta_i = 0$, the adjoint system (1.6) has solutions $Q_i(t) = 1$ and $P_i(t) = -\cos t$, which satisfy the normalization condition (1.7). It is easy to check that

$$\begin{aligned}
a_{ij} &= \frac{1}{T}\int_0^T 1 \cdot c_{ij}\, dt = c_{ij},\\
b_{ij} &= \frac{1}{T}\int_0^T [-\cos t \cdot c_{ij} + 0]\, dt = 0, \qquad i \neq j,\\
b_{ii} &= \frac{1}{T}\int_0^T [-\cos t \cdot c_{ii} - b]\, dt = -b,\\
H_{ij}(\chi) &= \frac{1}{T}\int_0^T \left[1 \cdot c_{ij} \cdot \int_0^{t+\chi} \cos\bar{t}\, d\bar{t}\right] dt = 0,\\
K_{ij}(\chi) &= \frac{1}{T}\int_0^T \left[-\cos t \cdot c_{ij} \int_0^{t+\chi} \cos\bar{t}\, d\bar{t}\right] dt = -\frac{c_{ij}}{2}\sin\chi, \qquad i \neq j,
\end{aligned}$$

and $K_{ii}(0) = 0$, so that the canonical phase model (1.4), (1.5) has the form

$$\begin{aligned}
\varphi_i' &= \sum_{j=1}^n c_{ij} u_j,\\
u_i' &= -bu_i - \frac{1}{2}\sum_{j=1}^n c_{ij}\sin(\varphi_j - \varphi_i).
\end{aligned}$$

It is a simple exercise to check that the same canonical model can be obtained via standard averaging of (2.1), (2.2).

2.2. Frankel and Kiemel's example. As an illustration, Frankel and Kiemel (1993) considered the six-dimensional system

$$\begin{aligned}
\dot{\vartheta}_i &= 1 + s_j(\alpha + \beta r_i \cos\vartheta_i + \gamma r_i^2 \cos^2\vartheta_i),\\
\dot{r}_i &= r_i - r_i^3 + \eta s_j r_i^2 \cos\vartheta_i,\\
\dot{s}_i &= \varepsilon(r_i \cos\vartheta_i - \mu s_i)
\end{aligned}$$

having fast variables in polar coordinates $\mathbb{S}^1 \times \mathbb{R}$ and parameters $\alpha, \beta, \gamma, \eta, \mu \in \mathbb{R}$, and $i, j \in \{1, 2\}$, $i \neq j$. They used a completely different approach to show how the model can be reduced to the planar system

$$\chi' = (-\alpha - \gamma/2)u - \beta\sin\chi, \tag{2.3}$$

$$u' = (\beta/2 - \eta/5 - \mu)u + (\alpha + 3\gamma/4)\sin\chi, \tag{2.4}$$

where

$$\chi = \varphi_2 - \varphi_1 \qquad \text{and} \qquad u = u_2 - u_1 \tag{2.5}$$

and u_i and φ_i have the same meaning as in this paper.

Let us verify Frankel and Kiemel's result using Theorem 1.1. Each uncoupled oscillator has a 2π-periodic solution $(t,1)\in\mathbb{S}^1\times\mathbb{R}$ when $\bar{s}=0$. It is easy to check by differentiating that the adjoint linear systems (1.6),

$$\dot{Q}=-\left\{\begin{array}{cc}0&0\\0&-2\end{array}\right\}^{\top}Q \qquad\text{and}\qquad \dot{P}=-\left\{\begin{array}{cc}0&0\\0&-2\end{array}\right\}^{\top}P-\left\{\begin{array}{cc}-\sin t, & \cos t\end{array}\right\}^{\top},$$

have solutions

$$Q(t)=\left(\begin{array}{c}1\\0\end{array}\right) \qquad\text{and}\qquad P(t)=\left(\begin{array}{c}-\cos t\\ \frac{2}{5}\cos t-\frac{1}{5}\sin t\end{array}\right)$$

satisfying the normalization conditions (1.7). Therefore, the parameters in the canonical model (1.4), (1.5) are (here $i\neq j$)

$$\begin{aligned}
a_{ij}&=\frac{1}{2\pi}\int_0^{2\pi}\left(\begin{array}{c}1\\0\end{array}\right)^{\top}\left(\begin{array}{c}\alpha+\beta\cos t+\gamma\cos^2 t\\ \eta\cos t\end{array}\right)dt=\alpha+\frac{\gamma}{2},\\
b_{ij}&=\frac{1}{2\pi}\int_0^{2\pi}\left(\begin{array}{c}-\cos t\\ \frac{2}{5}\cos t-\frac{1}{5}\sin t\end{array}\right)^{\top}\left(\begin{array}{c}\alpha+\beta\cos t+\gamma\cos^2 t\\ \eta\cos t\end{array}\right)dt=-\frac{\beta}{2}+\frac{\eta}{5},\\
H_{ij}(\chi)&=\frac{1}{2\pi}\int_0^{2\pi}\left(\begin{array}{c}1\\0\end{array}\right)^{\top}\left(\begin{array}{c}\alpha+\beta\cos t+\gamma\cos^2 t\\ \eta\cos t\end{array}\right)\int_0^{t+\chi}\cos\bar{t}\,d\bar{t}\,dt=\frac{\beta}{2}\sin\chi,\\
K_{ij}(\chi)&=\frac{1}{2\pi}\int_0^{2\pi}\left(\begin{array}{c}-\cos t\\ \frac{2}{5}\cos t-\frac{1}{5}\sin t\end{array}\right)^{\top}\left(\begin{array}{c}\alpha+\beta\cos t+\gamma\cos^2 t\\ \eta\cos t\end{array}\right)\int_0^{t+\chi}\cos\bar{t}\,d\bar{t}\,dt\\
&=\left(-\frac{\alpha}{2}-\frac{3}{8}\gamma\right)\sin\chi,
\end{aligned}$$

and

$$a_{ii}=0, \qquad b_{ii}=-\mu, \qquad H_{ii}(0)=0, \qquad\text{and}\qquad K_{ii}(0)=-1/2\ .$$

Using the difference variables (2.5) we arrive exactly at the same model (2.3), (2.4) that Frankel and Kiemel did.

2.3. Andronov–Hopf bifurcation. Next, we derive the canonical phase model for a network of slowly coupled oscillators near an Andronov–Hopf bifurcation. Without loss of generality we may assume that $\bar{s}=0$ and that each oscillator has already been converted into the topological normal form (by a continuous near-identity change of variables; see Hoppensteadt and Izhikevich (1997)). We use complex coordinates for convenience and consider the system

$$\begin{aligned}
&\dot{z}_i=(\mu+\mathrm{i})z_i-z_i|z_i|^2+q_i(z_i,\bar{z}_i,s_1,\ldots,s_n), && z_i\in\mathbb{C},\\
&\dot{s}_i=\varepsilon g_i(z_i,\bar{z}_i,s_i), && s_i\in\mathbb{R},
\end{aligned}$$

where $\mathrm{i}=\sqrt{-1}$ has a different font from the subscript i, $0<\varepsilon\ll\mu\ll 1$ (we assume μ is sufficiently small so that higher-order terms in μ may be neglected) and q_i and g_i are arbitrary smooth functions satisfying

$$q_i(z_i,\bar{z}_i,0,\ldots,0)=0 \qquad\text{and}\qquad g_i(0,0,0)=0.$$

In this case each unperturbed ($\varepsilon=0$) oscillator

$$\dot{z}_i=(\mu+\mathrm{i})z_i-z_i|z_i|^2$$

has a small amplitude limit cycle attractor

$$\gamma_i(t) = \sqrt{\mu}\, e^{\mathrm{i}t} \subset \mathbb{C}$$

with period $T = 2\pi$. We do not need to solve the adjoint linear system (1.6),

$$\dot{Q}_i = -\{\mathrm{i} + \mathcal{O}(\mu)\}^* Q_i \qquad \text{and} \qquad \dot{P}_i = -\{\mathrm{i} + \mathcal{O}(\mu)\}^* P_i - \{\partial g_i/\partial z_i\}^*,$$

since we can find the solutions

$$Q_i(t) = \mathrm{i}e^{\mathrm{i}t}/\sqrt{\mu} \qquad \text{and} \qquad P_i(t) = -\mathrm{i}e^{\mathrm{i}t}\left\{e^{\mathrm{i}t}\partial g_i/\partial z_i + \text{c.c.}\right\}$$

directly from the normalization condition (1.7),

$$Q_i(t)^*\left\{(\mu + \mathrm{i})\gamma_i(t) - \gamma_i(t)|\gamma_i(t)|^2\right\} = Q_i(t)^*\left\{\mathrm{i}\sqrt{\mu}e^{\mathrm{i}t}\right\} = 1$$

and

$$P_i(t)^*\left\{\mathrm{i}\sqrt{\mu}e^{\mathrm{i}t}\right\} = -g_i(\sqrt{\mu}e^{\mathrm{i}t}, 0) = -\left\{\sqrt{\mu}e^{\mathrm{i}t}\partial g_i/\partial z_i + \text{c.c.}\right\},$$

where $Q_i(t), P_i(t) \in \mathbb{C}$, * denotes transposition and complex conjugation, and c.c. means complex-conjugate. Now we can apply Theorem 1.1 to obtain the canonical phase model

$$\begin{aligned}
\varphi_i' &= \sum_{j=1}^{n} \{a_{ij}u_j + c_{ij}\sin(\varphi_j + \psi_{ij} - \varphi_i)\}, \\
u_i' &= \sum_{j=1}^{n} b_{ij}u_j,
\end{aligned}$$

where

$$\begin{aligned}
a_{ij} &= \operatorname{Im}\frac{\partial^2 q_i}{\partial s_j \partial z_i}, \\
b_{ij} &= -\operatorname{Im}\frac{\partial q_i}{\partial s_j}\frac{\partial g_i}{\partial z_i}, \qquad i \neq j, \\
b_{ii} &= -\operatorname{Im}\frac{\partial q_i}{\partial s_i}\frac{\partial g_i}{\partial z_i} + \frac{\partial g_i}{\partial s_i},
\end{aligned}$$

and all derivatives are evaluated at the origin $z = 0$ and $s = 0$. Notice that $P_i = \mathcal{O}(1)$ and $g_i = \mathcal{O}(\sqrt{\mu})$, hence $K_{ij} = \mathcal{O}(\sqrt{\mu})$ is infinitesimal. Let us show that

$$H_{ij}(\chi) = c_{ij}\sin(\psi_{ij} + \chi).$$

First,

$$\begin{aligned}
\int_0^{t+\chi} g_j(\sqrt{\mu}e^{\mathrm{i}\bar{t}}, \sqrt{\mu}e^{-\mathrm{i}\bar{t}}, 0)\, d\bar{t} &= \int_0^{t+\chi} \frac{\partial g_j}{\partial z_j}\sqrt{\mu}e^{\mathrm{i}\bar{t}}d\bar{t} + \text{c.c.} \\
&= \mathrm{i}\sqrt{\mu}\frac{\partial g_j}{\partial z_j}\left(1 - e^{\mathrm{i}(t+\chi)}\right) + \text{c.c.}
\end{aligned}$$

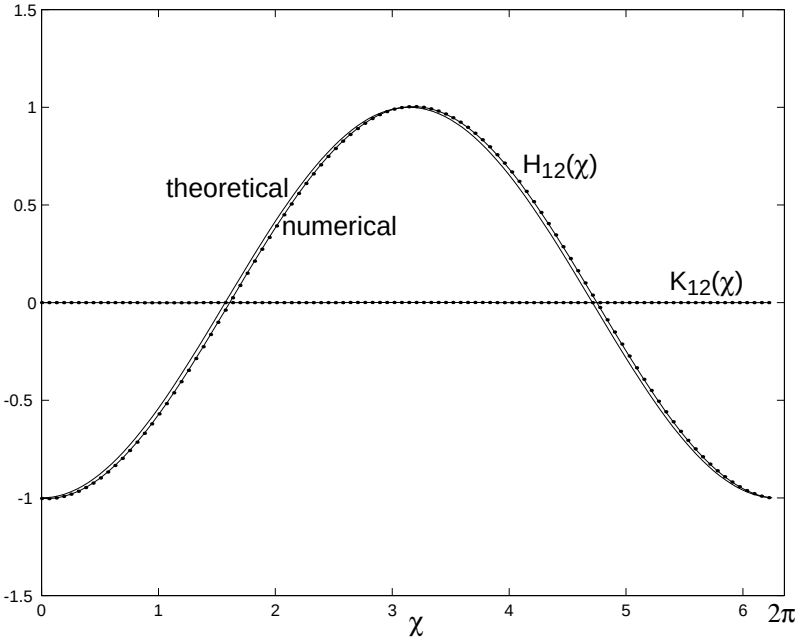

FIG. 2.1. *Numerical (see Appendix* B*) and analytical form of the connection functions for slowly coupled oscillators near an Andronov–Hopf bifurcation. Parameters:* $q_1(z_1, \bar{z}_1, s_1, s_2) = s_2$ *and* $g_1(z_1, \bar{z}_1, s_1) = z_1 + \bar{z}_1 - s_1$, $\mu = 0.01$.

Next,

$$\begin{aligned} H_{ij}(\chi) &= \operatorname{Re} \frac{1}{2\pi} \int_0^{2\pi} \left(\frac{-\mathrm{i} e^{-\mathrm{i}t}}{\sqrt{\mu}} \right) \left(\frac{\partial q_i}{\partial s_j} + \mathcal{O}(\sqrt{\mu}) \right) \left(\mathrm{i}\sqrt{\mu} \frac{\partial g_j}{\partial z_j} \left(1 - e^{\mathrm{i}(t+\chi)} \right) + \text{c.c.} \right) dt \\ &= \operatorname{Re} \frac{1}{2\pi} \int_0^{2\pi} \left(-\frac{\partial q_i}{\partial s_j} \frac{\partial g_j}{\partial z_j} e^{\mathrm{i}\chi} + \text{terms involving } e^{\mathrm{i}t} \right) dt \\ &= -\operatorname{Re} \frac{\partial q_i}{\partial s_j} \frac{\partial g_j}{\partial z_j} e^{\mathrm{i}\chi} = c_{ij} \sin(\psi_{ij} + \chi), \end{aligned}$$

where

$$c_{ij} = \left| \frac{\partial q_i}{\partial s_j} \frac{\partial g_j}{\partial z_j} \right| \qquad \text{and} \qquad \psi_{ij} = \operatorname{Arg} \frac{\partial q_i}{\partial s_j} \frac{\partial g_j}{\partial z_j} - \frac{\pi}{2}.$$

A typical example of the connection function $H_{ij}(\chi)$ is depicted in Figure 2.1. (Because theoretical and numerical curves were obtained using essentially the same formulae, this figure illustrates only the accuracy of the numerical method, and it does not validate the theory.)

Since the connection function $K_{ij}(\chi) = 0$ for all χ, the variables u_i do not depend on the phase variables φ_i. If the matrix (b_{ij}) is stable, all $u_i(t) \to 0$ as $t \to \infty$, and the locking properties of the *slowly* connected network are described by Kuramoto's (1984) system

$$\varphi_i' = \sum_{j=1}^{n} c_{ij} \sin(\varphi_j + \psi_{ij} - \varphi_i),$$

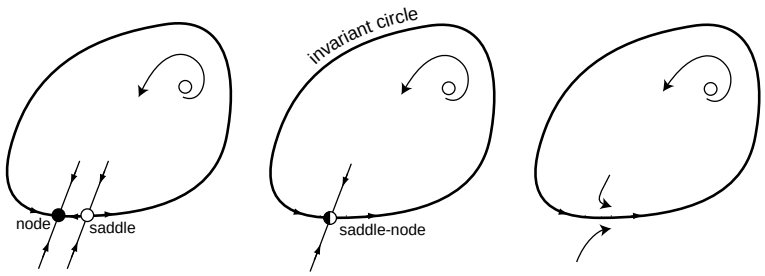

FIG. 2.2. *Saddle-node on invariant circle bifurcation.*

which was originally derived for *weakly* connected networks of Andronov–Hopf oscillators. Notice, though, that the variables u_i may significantly slow down the convergence to a synchronized state if the matrix (b_{ij}) has eigenvalues close to the imaginary axis.

2.4. Saddle-node on invariant circle bifurcation. Now we consider a slowly connected network of oscillators near a saddle-node on invariant circle bifurcation, which is illustrated in Figure 2.2. This bifurcation results in Class 1 excitable systems, i.e., systems able to oscillate with arbitrary small frequency (Hoppensteadt and Izhikevich (1997)). Without loss of generality we assume that $\bar{s} = 0$ and that each oscillator has been restricted to the center manifold and converted to the topological normal form by an appropriate change of variables,

$$\begin{aligned} \dot{y}_i &= \mu + y_i^2 + q_i(y_i, c_1, \ldots, c_n, \mu), \qquad y_i \in \mathbb{R}, \\ \dot{c}_i &= \epsilon g_i(y_i, c_i), \qquad\qquad\qquad\qquad\quad c_i \in \mathbb{R}, \end{aligned}$$

where $\epsilon \ll \sqrt{\mu} \ll 1$ and

$$q_i(y_i, 0, \ldots, 0, \mu) = 0 \qquad \text{and} \qquad g_i(0,0) = 0.$$

Here we consider only a small neighborhood of the origin, since the spike lemma (Lemma 8.1 in Hoppensteadt and Izhikevich (1997)) implies that y_i spends a negligible amount of time outside the small neighborhood; that is, action potentials generated by such a model look instantaneous on the slow time scale of order $1/\sqrt{\mu}$. Now we rescale the variables and parameters,

$$y_i = 2\sqrt{\mu}x_i, \qquad c_i = 2\sqrt{\mu}\{\partial g_i/\partial y_i\}s_i, \qquad \epsilon = 2\sqrt{\mu}\varepsilon, \qquad t_{\text{new}} = 2\sqrt{\mu}t_{\text{old}},$$

to transform the system above into the form

$$\dot{x}_i = 1/4 + x_i^2 + \sum_{j=1}^{n}(c_{ij} + h_{ij}x_i)s_j + \mathcal{O}(\sqrt{\mu}), \tag{2.6}$$

$$\dot{s}_i = \varepsilon\left\{x_i - p_i s_i + \mathcal{O}(\sqrt{\mu})\right\}, \tag{2.7}$$

where

$$\begin{aligned} c_{ij} &= \frac{1}{2}\,\frac{\partial g_i}{\partial y_i}\,\frac{\partial^2 q_i}{\partial c_j \partial \mu}, \\ h_{ij} &= \frac{\partial g_i}{\partial y_i}\,\frac{\partial^2 q_i}{\partial c_j \partial y_i}, \\ p_i &= -\frac{\partial g_i}{\partial c_i}, \end{aligned}$$

and all derivatives are evaluated at the origin. Notice that each unperturbed ($\varepsilon = 0$) oscillator has a limit cycle attractor

$$\gamma_i(t) = \frac{1}{2}\tan\frac{t}{2} \subset \mathbb{R} \cup \{\infty\}$$

with period $T = 2\pi$. From the normalization condition (1.7),

$$Q_i(t)^\top (1/4 + \gamma_i(t)^2) = 1 \qquad \text{and} \qquad P_i(t)^\top (1/4 + \gamma_i(t)^2) = -\gamma_i(t),$$

we can find directly the solutions to the adjoint problem (1.6),

$$Q_i(t) = 2(1 + \cos t) \qquad \text{and} \qquad P_i(t) = -\sin t,$$

and use them in Theorem 1.1 to find all parameters and functions. It is easy to see that

$$\begin{aligned}
a_{ij} &= \frac{1}{2\pi}\int_0^{2\pi} 2(1+\cos t)\ \left(c_{ij} + \frac{h_{ij}}{2}\tan\frac{t}{2}\right)\ dt = 2c_{ij},\\
b_{ij} &= \frac{1}{2\pi}\int_0^{2\pi} -\sin t\ \left(c_{ij} + \frac{h_{ij}}{2}\tan\frac{t}{2}\right)\ dt = -\frac{h_{ij}}{2}, \qquad i \neq j,\\
b_{ii} &= -\frac{h_{ii}}{2} - p_i.
\end{aligned}$$

Next,

$$\int_0^{t+\chi} \frac{1}{2}\tan\frac{\bar{t}}{2}\, d\bar{t} = -\ln\left|\cos\frac{t+\chi}{2}\right|,$$

and

$$\begin{aligned}
H_{ij}(\chi) &= \frac{1}{2\pi}\int_0^{2\pi} 2(1+\cos t)\ \left(c_{ij} + \frac{h_{ij}}{2}\tan\frac{t}{2}\right)\ \left(-\ln\left|\cos\frac{t+\chi}{2}\right|\right)\ dt\\
&= c_{ij}(2\ln 2 - \cos\chi) + \frac{h_{ij}}{2}\sin\chi,\\
K_{ij}(\chi) &= \frac{1}{2\pi}\int_0^{2\pi} -\sin t\ \left(c_{ij} + \frac{h_{ij}}{2}\tan\frac{t}{2}\right)\ \left(-\ln\left|\cos\frac{t+\chi}{2}\right|\right)\ dt\\
&= -\frac{c_{ij}}{2}\sin\chi - \frac{h_{ij}}{4}(2\ln 2 + \cos\chi), \qquad i \neq j,\\
K_{ii}(0) &= -\frac{h_{ii}}{4}(2\ln 2 + 1) - p_i\ \ln 2\ .
\end{aligned}$$

A typical form of the connection function $H_{ij}(\chi)$ and $K_{ij}(\chi)$ is depicted in Figure 2.3.

2.4.1. Two identical oscillators. Let us consider synchronization dynamics of two identical slowly coupled oscillators of the form

$$\begin{aligned}
&\dot{x}_1 = 1/4 + x_1^2 + (c + hx_1)s_2, && \dot{x}_2 = 1/4 + x_2^2 + (c + hx_2)s_1,\\
&\dot{s}_1 = \varepsilon(x_1 - ps_1), && \dot{s}_2 = \varepsilon(x_2 - ps_2)
\end{aligned}$$

with $p > 0$ and arbitrary c and h. The canonical phase model has the form

$$\begin{aligned}
\dot{\varphi}_1 &= 2cu_2 + H(\varphi_2 - \varphi_1),\\
\dot{u}_1 &= -p(u_1 + \ln 2) - \frac{h}{2}(u_1 + u_2) + K(\varphi_2 - \varphi_1),\\
\dot{\varphi}_2 &= 2cu_1 + H(\varphi_1 - \varphi_2),\\
\dot{u}_2 &= -p(u_2 + \ln 2) - \frac{h}{2}(u_1 + u_2) + K(\varphi_1 - \varphi_2),
\end{aligned}$$

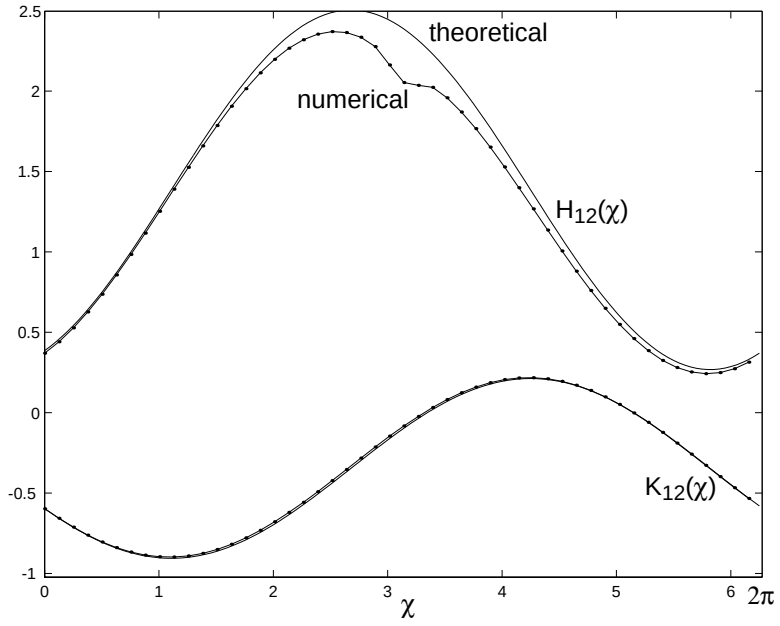

FIG. 2.3. *Numerical (see Appendix* B*) and analytical forms of the connection functions for slowly coupled oscillators near a saddle-node on invariant circle bifurcation. Parameters in* (2.6), (2.7)*:* $c_{12} = h_{12} = p_1 = 1$.

where

$$H(\chi) = c(2\ln 2 - \cos\chi) + \frac{h}{2}\sin\chi \qquad \text{and} \qquad K(\chi) = -\frac{c}{2}\sin\chi - \frac{h}{4}(2\ln 2 + \cos\chi).$$

Let $\chi = \varphi_2 - \varphi_1$ and $u = u_2 - u_1$; then

$$\begin{aligned} \dot{\chi} &= -2cu - h\sin\chi, \\ \dot{u} &= -pu + c\sin\chi. \end{aligned}$$

The in-phase synchronized solution corresponds to the equilibrium $\chi = 0$ and $u = 0$ with the Jacobian matrix

$$L = \begin{pmatrix} -h & -2c \\ c & -p \end{pmatrix}.$$

It is stable when

$$\mathrm{tr}L = -h - p < 0 \qquad \text{and} \qquad \det L = hp + 2c^2 > 0,$$

which is always the case when $h > 0$. (It is an easy exercise to check that the antiphase solution $\chi = \pi$, $u = 0$ is stable when $h < p$ and $hp + 2c^2 < 0$.)

We see that in contrast to weak coupling, which leads to a neutrally stable synchronized state of two Class 1 identical oscillators (Hansel, Mato, and Meunier (1995), Ermentrout (1996), Izhikevich (1999)), slow coupling with $h > 0$ always results in stability of the synchronized state, as we illustrate in Figure 2.4, regardless of the sign of the connection coefficient c. Notice that the convergence to the in-phase synchronized state $\chi = 0$ is oscillatory, as we illustrate in Figure 2.5(a); that is, the oscillators

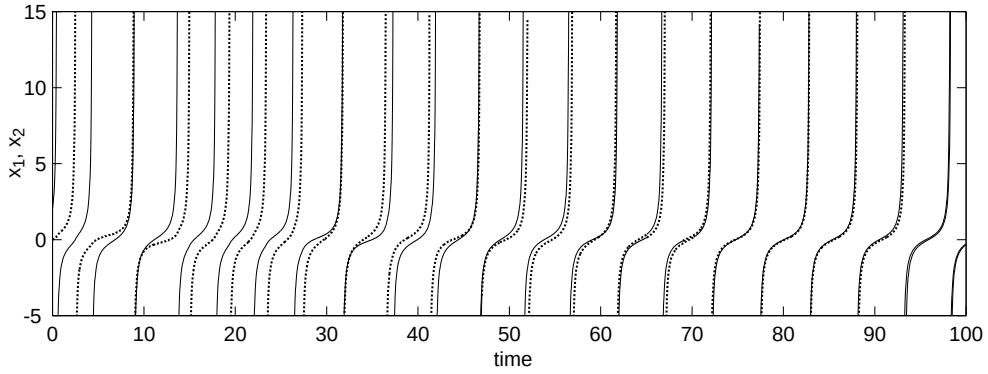

FIG. 2.4. *Synchronization dynamics of two identical oscillators near a saddle-node on invariant circle bifurcation. Parameters:* $c = 5$, $h = p = 1$, *and* $\varepsilon = 0.05$.

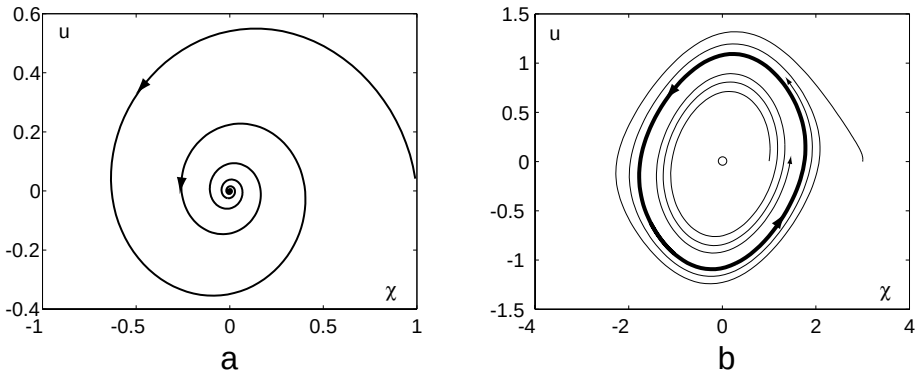

FIG. 2.5. (a) *Convergence to the in-phase synchronized state is oscillatory (parameters as in Figure* 2.4*).* (b) *The phase difference* χ *may oscillate (here* $h = -1.5$*).*

in Figure 2.4 take turns—a prominent feature of slowly connected networks that was discovered by Frankel and Kiemel (1993). If we decrease h past $-p$, a small amplitude limit cycle may appear via a supercritical Andronov–Hopf bifurcation, and the phase difference χ would exhibit sustained oscillations, as shown in Figure 2.5(b).

2.5. Relaxation oscillators. Now we consider a slowly coupled network of relaxation oscillators of the form

$$\begin{aligned} \mu\dot{x}_i &= F_i(x_i, y_i) + q_i(x_i, y_i, s_1, \ldots, s_n), \\ \dot{y}_i &= G_i(x_i, y_i) + r_i(x_i, y_i, s_1, \ldots, s_n), \\ \dot{s}_i &= \varepsilon g_i(x_i, y_i, s_i), \end{aligned}$$

where $\mu \ll 1$, $x_i, y_i, s_i \in \mathbb{R}$, and

$$q_i(x_i, y_i, 0, \ldots, 0) = 0, \quad r_i(x_i, y_i, 0, \ldots, 0) = 0, \qquad \text{and} \qquad g_i(0, 0, 0) = 0.$$

Suppose that each unperturbed ($\varepsilon = 0$, $s = 0$) system

$$\begin{aligned} \mu\dot{x}_i &= F_i(x_i, y_i), \\ \dot{y}_i &= G_i(x_i, y_i) \end{aligned}$$

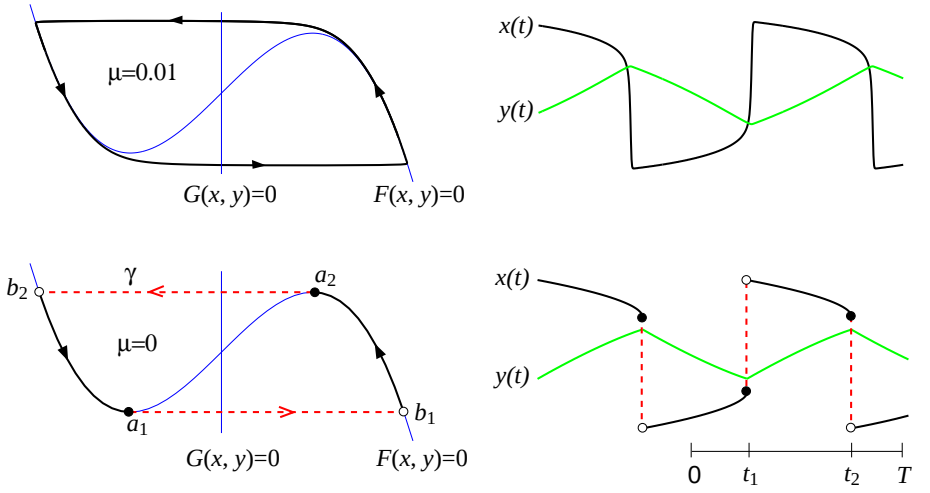

FIG. 2.6. *Top: Nullclines and periodic solution of the van der Pol relaxation oscillator* $\mu\dot{x} = -y + x - x^3/3$, $\dot{y} = x$ *for* $\mu = 0.01$. *Bottom: The periodic solution becomes discontinuous in the limit* $\mu \to 0$. *(Modified from Izhikevich (*2000*)).*

has a relaxation limit cycle attractor with period $T > 0$ converging to $\gamma_i(t) \subset \mathbb{R}^2$ similar to the one depicted in Figure 2.6 in the limit $\mu \to 0$. Such an oscillation $\gamma_i(t)$ has two discontinuities (jumps) at $t = t_1$ and $t = t_2$. Izhikevich (2000) has shown that in this case the solution to the adjoint problem (1.6) converges as $\mu \to 0$ to

$$Q_i(t) = \frac{1}{G_i(\gamma_i(t))}\left(-\frac{\partial G_i}{\partial x_i}(\gamma_i(t))\left(\frac{\partial F_i}{\partial x_i}(\gamma_i(t))\right)^{-1},\ \ 1\right)^{\top} \qquad \text{when } t \neq t_1 \text{ and } t \neq t_2$$

and

$$Q_i(t_k) = \left(c_k\delta(t - t_k),\ \ \frac{1}{G_i(\gamma_i(a_k))}\right)^{\top},$$

where

$$c_k = \left(\frac{\partial F_i}{\partial y_i}(\gamma_i(t))\right)^{-1}\left(\frac{1}{G_i(a_k)} - \frac{1}{G_i(b_k)}\right)$$

and a_k and b_k are the end points of the kth jump, $k = 1, 2$; see Figure 2.6.

Knowing $Q_i(t)$ and $P_i(t)$, one can easily find a_{ij}, b_{ij}, H_{ij}, and K_{ij}. For example,

$$H_{ij}(\chi) = -\frac{1}{T}\int_0^T \frac{\frac{\partial G_i}{\partial x_i}(\gamma_i(t))\left(\frac{\partial F_i}{\partial x_i}(\gamma_i(t))\right)^{-1}\frac{\partial q_i}{\partial s_j}(\gamma_i(t)) - \frac{\partial r_i}{\partial s_j}(\gamma_i(t))}{G_i(\gamma_i(t))}\int_0^{t+\chi} g_j(\gamma_i(\bar{t}))\,d\bar{t}\,dt$$

$$+\frac{1}{T}\sum_{k=1}^{2} c_k^{\top}\frac{\partial q_i}{\partial s_j}(a_k)\int_0^{t_k+\chi} g_j(\gamma_j(\bar{t}))\,d\bar{t}. \tag{2.8}$$

A salient feature of weakly coupled relaxation oscillators is the existence of discontinuities in the connection functions $H_{ij}(\chi)$, which result in many interesting synchronization properties, such as superconvergence, persistence under perturbations of natural frequencies, etc. (see the discussion in Izhikevich (2000)). However, the

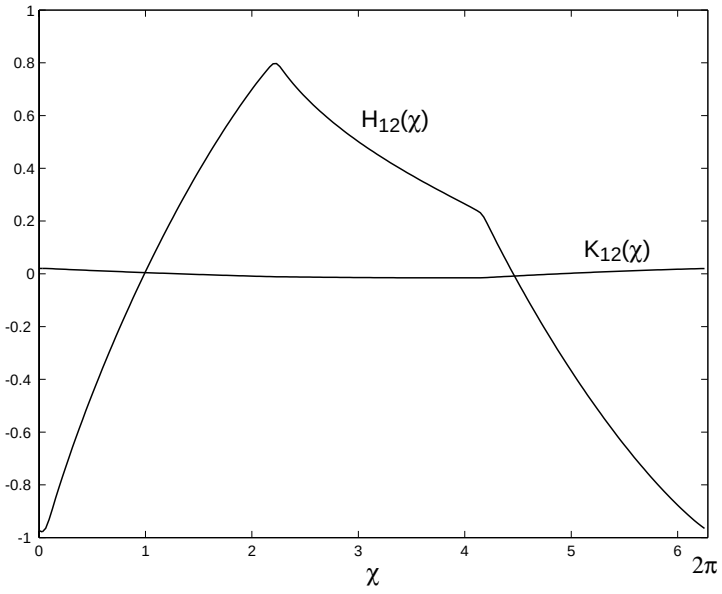

FIG. 2.7. *Numerically found connection functions for slowly coupled Bonhoeffer–van der Pol relaxation oscillators* $\mu\dot{x}_i = x_i - x_i^3/3 - y_i + s_j$, $\dot{y}_i = 0.5 + x_i$, $\dot{s}_i = \varepsilon(x_i - s_i)$, $i = 1, 2$, $j = 2, 1$, $\mu = 0.001$.

connection functions $H_{ij}(\chi)$ (and $K_{ij}(\chi)$) for slowly coupled relaxation oscillators are continuous, as shown in Figure 2.7. Hence, slowly coupled relaxation oscillators do not have those interesting synchronization properties.

3. Discussion. Much research in theoretical neuroscience is devoted to weakly coupled oscillators, as reviewed in Chapter 9 of Hoppensteadt and Izhikevich (1997). Slow connections, however, received less attention despite the fact that slow synaptic transmission is ubiquitous in the brain. Indeed, GABAb and NMDA receptor dynamics occur on the time scale of 150 ms, which are much slower than the period of firing of many neurons, which is often smaller than 10 ms. Purely NMDA synaptic connections have been found in the hippocampus (Isaac, Nicoll, and Malenka (1995)) and in the thalamocortical system (Isaac et al. (1997)). They are often referred to as being "silent synapses" since activation of NMDA receptors requires postsynaptic depolarization. (Most synapses have slow NMDA and fast AMPA glutamate receptors and hence describe slow and weak connections; see Remark 1.3.) Here we speculate that periodically firing neurons connected via NMDA or GABAb receptors could have quite different synchronization properties from the same neurons coupled via fast GABAa or AMPA receptors.

There have been only a few attempts to study rigorously slowly coupled oscillators. Notably, Rinzel and Frankel (1992) and Ermentrout (1994) used averaging to study dynamics of slowly coupled Hodgkin–Huxley-type models. They discovered new regimes that were not seen in weakly coupled networks, such as instabilities of relative phases and network bursting. Bressloff and Coombes (2000) applied similar methods to study integrate-and-fire neurons with slow synapses. The most important contribution was made by Frankel and Kiemel (1993) who showed how two slowly coupled oscillators can be transformed into a canonical phase model by an appropriate change of variables.

In this paper we extend the results of Frankel and Kiemel (1993) to a network of $n \geq 2$ slowly coupled oscillators. We confirm that synchronization properties of such a network are described by a canonical phase model in which each oscillator is represented by a pair of variables φ_i and u_i on a cylindrical phase space. Using Malkin's theorem we can derive an analytical form for all coefficients and all connection functions H_{ij} and K_{ij} for the phase model.

In the second half of the paper we consider a few analytically solvable examples. First, we study oscillators near an Andronov–Hopf bifurcation and show that dynamics of variables u_i do not depend on the phases φ_i. While the variables u_i can slow down the convergence to a synchronized state, they cannot change the stability of that state.

Next, we study synchronization properties of Class 1 oscillators; that is, oscillators that are near a saddle-node on invariant circle bifurcation (Figure 2.2). Such a bifurcation results in periodic activity with arbitrarily small frequency, and it is believed to be involved in excitable properties of neocortical neurons in mammalian brains. It is well known (Hansel, Mato, and Meunier (1995), Ermentrout (1996)) that identical Class 1 oscillators if coupled weakly do not synchronize; more precisely, the synchronized state is neutrally stable for $n = 2$ oscillators and unstable for $n > 2$ oscillators (Izhikevich (1999)) regardless of whether the connections are excitatory or inhibitory. In contrast, *slowly* connected Class 1 oscillators do synchronize for both excitatory and inhibitory connections. We show this analytically using the canonical phase model approach, and then illustrate it numerically in Figure 2.4. Notice that the oscillators take turns, i.e., change order of firing, during the convergence to the synchronized state. This is a salient feature of slowly connected oscillators found by Frankel and Kiemel (1993) that cannot occur in weakly coupled networks of $n = 2$ oscillators.

Finally, we consider slowly coupled relaxation oscillators and show that the connection functions $H_{ij}(\chi)$ and $K_{ij}(\chi)$ are continuous. Therefore, in contrast to *weak* coupling, *slow* coupling of relaxation oscillators does not lead to superstability of the in-phase synchronized solution (Izhikevich (2000)).

Appendix A. Malkin's theorem. Below we provide a general statement of Malkin's theorem (Malkin (1949), (1956)). A one-page proof can be found in (Hoppensteadt and Izhikevich (1997)).

THEOREM A.1 (Malkin). *Consider a T-periodic dynamical system of the form*

$$\dot{X} = F(X,t) + \varepsilon G(X,t,\varepsilon), \qquad X \in \mathbb{R}^m, \tag{A.1}$$

and suppose that the unperturbed system, $\dot{X} = F(X,t)$, has a k-parameter family of T-periodic solutions

$$X(t) = U(t,\alpha),$$

where $\alpha = (\alpha_1, \ldots, \alpha_k)^\top \in \mathbb{R}^k$ is a vector of independent parameters, by which we mean that the rank of the $n \times k$ matrix $D_\alpha U$ is k. Suppose the adjoint linear problem

$$\dot{R}_i = -\left\{DF(U(t,\alpha),t)\right\}^\top R_i \tag{A.2}$$

has exactly k independent T-periodic solutions $R_1(t,\alpha), \ldots, R_k(t,\alpha) \in \mathbb{R}^m$. Let R be the matrix whose columns are these solutions such that

$$R^\top D_\alpha U = I, \tag{A.3}$$

where I is the identity $k \times k$ matrix. Then the perturbed system (A.1) *has a solution of the form*

$$X(t) = U(t, \alpha(\varepsilon t)) + \mathcal{O}(\varepsilon),$$

where

$$\frac{d\alpha}{d\tau} = \frac{1}{T}\int_0^T R(t,\alpha)^\top G(U(t,\alpha),t,0)\,dt, \tag{A.4}$$

where $\tau = \varepsilon t$ is slow time. If (A.4) *has a stable equilibrium, then system* (A.1) *has a T-periodic solution.*

Appendix B. Numerical recipe. A good numerical method to solve the adjoint problem (1.6) was suggested by Williams and Bowtell (1997), and it is available in the Bard Ermentrout software package XPP. Here, for the sake of convenience, we present MATLAB script that uses the same method to determine all parameters and functions of Malkin's theorem.

The following MATLAB program consists of eight separate files, which are available at the first author's website. The user should provide the following parameters and functions:

- The period `T` and an initial point `x0` on the limit cycle $\gamma(t)$ in the file `main.m`.
- The right-hand sides of the fast and slow systems in files `f.m` and `g.m`, respectively.
- The parameters `Np`, `NT`, and `ds` in the file `main.m`, and `dx` and `dy` in the file `Df.m` control the accuracy of the numerical method. They may be changed if necessary.

OPTIMAL CONTROL APPLIED TO COMPETING CHEMOTHERAPEUTIC CELL-KILL STRATEGIES*

K. RENEE FISTER† AND JOHN CARL PANETTA‡

Abstract. Optimal control techniques are used to develop optimal strategies for chemotherapy. In particular, we investigate the qualitative differences between three different cell-kill models: log-kill hypothesis (cell-kill is proportional to mass); Norton–Simon hypothesis (cell-kill is proportional to growth rate); and, E_{max} hypothesis (cell-kill is proportional to a saturable function of mass). For each hypothesis, an optimal drug strategy is characterized that minimizes the cancer mass and the cost (in terms of total amount of drug). The cost of the drug is nonlinearly defined in one objective functional and linearly defined in the other. Existence and uniqueness for the optimal control problems are analyzed. Each of the optimality systems, which consists of the state system coupled with the adjoint system, is characterized. Finally, numerical results show that there are qualitatively different treatment schemes for each model studied. In particular, the log-kill hypothesis requires less drug compared to the Norton–Simon hypothesis to reduce the cancer an equivalent amount over the treatment interval. Therefore, understanding the dynamics of cell-kill for specific treatments is of great importance when developing optimal treatment strategies.

Key words. optimal control, cancer, cell-kill

1. Introduction.

When developing effective treatment strategies, understanding the effects of chemotherapeutic drugs on tumors is of primary importance. Several approaches to modeling chemotherapeutic induced cell-kill (killing of tumor cells) have been developed. One of the early approaches was by Schabel, Skipper, and Wilcox [1] who proposed that cell-kill due to a chemotherapeutic drug was proportional to the tumor population. This hypothesis is based on in vitro studies in the murine leukemia cell-line L1210. It states that for a fixed dose, the reduction of large tumors occurred more rapidly than for smaller tumors. Skipper's concept is referred to as the log-kill mechanism. Norton and Simon [2, 3] find this model to be inconsistent with clinical observations of Hodgkin's disease and acute lymphoblastic leukemia which showed that, in some cases, reduction in large tumors was slower than in histologically similar smaller tumors. Therefore, Norton and Simon hypothesize that the cell-kill is proportional to the growth rate (e.g., exponential, logistic, or Gompertz) of the tumor. A third hypothesis notes that some chemotherapeutic drugs must be metabolized by an enzyme before being activated. This reaction is saturable due to the fixed amount of enzyme. Thus, Holford and Sheiner [4] develop the E_{max} model which describes cell-kill in terms of a saturable function of Michaelis–Menton form.

In this study, we use optimal control theory to evaluate and compare effective treatment strategies for each of these models by developing formal mathematical

criteria to be minimized. These include tumor mass and dose of drug. We give a mathematically detailed development of optimal control forms for the various growth and drug terms that are subject to different objective functionals. We also show therapeutically significant differences between the cell-kill hypotheses and their effect on treatment schedules.

We have previously developed a treatment strategy using optimal control techniques for the use of cell-cycle specific drugs such as Taxol for the reduction of breast and ovarian cancers [5]. The model included a resting phase which made it more realistic in the clinical setting. Among other things, the model showed that treating with repeated shorter periods allows more drug to be given without excess damage to the bone marrow. Similar results were also observed in [6]. Several other models where optimal control methods have been utilized in analyzing effective chemotherapeutic treatments include Swan [7, 8] and Murray [9]. Swan [7, 8] obtained feedback treatment control drug characterizations for cancer models under a quadratic performance criterion. Murray [9] has considered systems of normal and tumor cells under the hypotheses of Gompertzian and logistic growth in which he controls the rate of administration of drugs. Murray has minimized the tumor burden at the end of treatment and, in another application, the toxicity level, defined as the area under the drug concentration curve.

2. The model. Mathematically, the general form of the model under investigation is depicted by the differential equation:

$$\frac{dN}{dt} = rNF(N) - G(N,t), \tag{2.1}$$

where N is the tumor volume, r is the growth rate of the tumor, $F(N)$ is the generalized growth function. For the proposed model, we allow for Gompertzian growth:

$$F(N) = \ln\left(\frac{\Theta}{N}\right). \tag{2.2}$$

The function $G(N,t)$ describes the pharmacokinetic and pharmacodynamic effects of the drug on the system. In this study, we compare three cell-kill strategies. These include the following:

- $G(N) = \delta u(t)N$: Skipper's log-kill (i.e., percentage kill) hypothesis,
- $G(N) = \delta u(t)N/(K+N)$: E_{max} model, and
- $G(N) = \delta u(t)F(N)$: Norton–Simon hypothesis,

where δ is the magnitude of the dose and the control, $u(t)$, describes the time dependent pharmacokinetics of the drug; i.e., $u(t) = 0$ implies no drug effect is present and $u(t) > 0$ implies the amount or strength of the drug effect. We investigated the differences and similarities among the three drug effects via optimal control techniques for ordinary differential equations.

We considered two objective functionals when determining the minimum amount of drug needed to reduce or eliminate the tumor mass. One criterion considered is

$$J_\alpha(u) = \int_0^T \left[a(N - N_d)^2 + bu^2\right]\, dt, \tag{2.3}$$

where the measure of the "closeness" of the tumor mass to the desired tumor density, N_d, and the cost of the control, $u(t)$, are minimized over the class of measurable,

nonnegative controls. Here, a and b are positive weight parameters. The second criterion we considered (previously used by Boldrini and Costa [10] with variations by Murray [11] and Martin and Teo [12]) is

$$J_\beta(u) = aN(T) + b\int_0^T u(t)\,dt, \tag{2.4}$$

in which the tumor burden at the end of treatment (the first term in (2.4)) and the toxicity (the second term in (2.4)), in terms of area under the drug concentration curve, are minimized over the class of measurable, nonnegative controls.

After scaling the models using $\overline{N} = N/\Theta$, $\overline{k} = k/\Theta$, and $\overline{\delta} = \delta/\Theta$ and dropping the bars, we have the following three state equations (which will henceforth be referred to as P1, P2, and P3, respectively), all with the same initial condition of $N(0) = N_0$, where $0 < N_0 < 1$ since the tumor cells have been normalized via the above change of variables:

P1
$$\frac{dN}{dt} = rN\ln\left(\frac{1}{N}\right) - u(t)\delta N,$$

P2
$$\frac{dN}{dt} = rN\ln\left(\frac{1}{N}\right) - u(t)\frac{\delta N}{k+N},$$

P3
$$\frac{dN}{dt} = rN\ln\left(\frac{1}{N}\right)[1 - \delta u(t)].$$

Ultimately, we determine the unique characterization of the optimal control $u(t)$ in the admissible control class,

$$U = \{u \text{ measurable } |0 \le u(t), t \in [0,T]\} \tag{2.5}$$

or

$$V = \{u \text{ measurable } |0 \le u(t) \le M, t \in [0,T]\}, \tag{2.6}$$

such that the objective functionals J_α and J_β are minimized over the class of controls, U and V, respectively.

In sections 3.1–3.3, we consider the existence issues, the characterization of the optimal control, and the uniqueness concept in association with problems P1–P3 such that the objective functional (2.3) involving the nonlinear control term is minimized over the class of controls, U. In sections 4.1–4.2, we discuss the existence of an optimal control and its characterization such that it minimizes the second objective functional (2.4) subject to each of the differential equations represented in P1–P3. Also, in section 5, numerical simulations representing the control situations in relation to the two objective functionals as well as the different cell-kill hypotheses depicted in the differential equations are analyzed.

3. Nonlinear control.

3.1. Existence. First, the existence of the state solution to each of problems P1–P3 given an optimal control in the admissible set, U, is shown. Also, the existence of the optimal control for the state system is analyzed.

THEOREM 3.1. *Given $u \in U$, there exists a bounded solution solving each of the problems* (P1)–(P3).

Proof. We consider the following differential equations in relation to P1, P2, P3, respectively. The state variables $N_1(t)$, $N_2(t)$, and $N_3(t)$ represent supersolutions for problems P1, P2, and P3.

$$\frac{dN_1}{dt} = r, \tag{3.1}$$

$$\frac{dN_2}{dt} = r + u(t)\delta N_2, \tag{3.2}$$

$$\frac{dN_3}{dt} = -rN_3 \ln N_3(1 - u(t)\delta). \tag{3.3}$$

Since $N(t) > 0$ and $\ln \frac{1}{N} \leq \frac{1}{N}$, then equation (3.3) follows from P1.

Using that $0 \leq t \leq T$, we can show that

$$N_1(t) \leq rT + N_0, \tag{3.4}$$

$$N_2(t) \leq (N_0 + rT)e^{\delta \int_0^T u(s)\,ds}, \tag{3.5}$$

$$N_3(t) \leq N_0^{\left(e^{-rt+r\delta \int_0^T u(s)\,ds}\right)}. \tag{3.6}$$

Since $u(t) \in U$, then, along with $N_1(t)$, $N_2(t)$ and $N_3(t)$ are bounded above. Via a maximum principle [13] and standard existence theory for first-order nonlinear differential equations, we obtain the existence of a solution to each of the problems P1–P3. □

Next, the existence of an optimal control for the state system is analyzed. Using the fact that the solution to each state equation is bounded, the existence of an optimal control for each problem can be determined using the theory developed by Fleming and Rishel [14].

THEOREM 3.2. *Given the objective functional, $J_\alpha(u) = \int_0^T \left[a(N - N_d)^2 + bu^2\right] dt$, where*

$$U = \{u \text{ measurable } |0 \leq u(t), t \in [0, T]\} \tag{3.7}$$

and each of the problems P1–P3 *with $N(0) = N_0$, then there exists an optimal control u^* associated with each problem* P1–P3 *such that $\min_{u \in U} J_\alpha(u) = J_\alpha(u^*)$ if the following conditions are met:*

(i) *The class of all initial conditions with a control u in the admissible control set along with each state equation being satisfied is not empty.*

(ii) *The admissible control set U is closed and convex.*

(iii) *Each right-hand side of* P1–P3 *is continuous, is bounded above by a sum of the bounded control and the state, and can be written as a linear function of u with coefficients depending on time and the state.*

(iv) *The integrand of* (2.3) *is convex on U and is bounded below by $-c_2 + c_1|u|^\eta$ with $c_1 > 0$ and $\eta > 1$.*

Proof. Since each problem has a bounded solution for the initial condition, given an optimal control, by Theorem 3.1, then part (i) is established. By definition, U is

closed and convex. To complete part (iii) we first reconsider the right-hand sides of P1–P3 below:

$$f(t,N(t),u(t)) = rN\ln\frac{1}{N} - \delta N u(t),$$
$$g(t,N(t),u(t)) = rN\ln\frac{1}{N} - \frac{\delta N}{k+N}u(t),$$
$$h(t,N(t),u(t)) = rN\ln\frac{1}{N} - \delta rN\ln\frac{1}{N}u(t).$$

We see by the representations of f, g, and h that they are continuous in t, u, and N since $N(t) > 0$. Also, they are each written as a linear function of the control with coefficients depending on time and the state. For the boundedness requirement, we use the bounds in the proof of Theorem 3.1 to obtain the result. Consequently,

$$\begin{aligned}|f(t,N(t),u(t))| &\le \left|rN\ln\frac{1}{N}\right| + |\delta N(t)u(t)|\\ &\le r + \delta|u(t)|(N_0+rT)\\ &\le C_1(1+|u(t)|+|N(t)|),\end{aligned}$$

where C_1 depends on r, d, N_0, and T,

$$\begin{aligned}|g(t,N(t),u(t))| &\le \left|rN\ln\frac{1}{N}\right| + \left|\frac{\delta N(t)}{k+N(t)}u(t)\right|\\ &\le r + \delta|u(t)|\\ &\le r + \delta|u(t)| + |N(t)|,\end{aligned}$$

and

$$\begin{aligned}|h(t,N(t),u(t))| &\le \left|rN\ln\frac{1}{N}\right| + \left|\delta rN(t)\ln\frac{1}{N}u(t)\right|\\ &\le r + \delta r|u(t)|\\ &\le C_2(1+|u(t)|+|N(t)|),\end{aligned}$$

where C_2 depends on r and d. Hence, the right-hand side of each state equation is bounded above by a sum of the control and the state. Lastly, the integrand of the objective functional is convex on U. One can consider the second partial of the integrand of the objective functional with respect to the control and find that it is positive. To obtain the necessary lower bound for the integrand, we see the $a(N-N_d)^2 + bu^2 \ge bu^2 \ge -c + bu^2$ for any $c > 0$. Therefore, part (iv) is complete and so is the proof. □

3.2. Characterization of optimal control. Since an optimal control exists for minimizing the objective functional (2.3) subject to each of the three equations P1–P3 with the initial conditions, the necessary conditions for an optimal control for each problem are determined. For brevity, we derive the conditions using a version of Pontryagin's maximum principle for P3 [15, 16]. Then we give the optimality system, which is the state system coupled with the adjoint system, for each problem.

In order to derive the necessary conditions, we define the Lagrangian associated with $J_\alpha(u)$ subject to P3 as

$$L(N,u,\lambda_3,w_1) = a(N-N_d)^2 + bu^2 + \lambda_3\Big(rN\ln\frac{1}{N}(1-\delta r u(t))\Big) - w_1(t)u(t), \tag{3.8}$$

where $w_1(t) \ge 0$ is a penalty multiplier satisfying $w_1(t)u(t) = 0$ at the optimal u^*.

Similar definitions for hold for $J_\alpha(u)$ subject to P1 and P2.

THEOREM 3.3. *Given an optimal control u^* and solution of the corresponding state equation* (P3)*, there exists an adjoint variable λ_3 satisfying the following:*

$$\frac{d\lambda_3}{dt} = -\frac{\partial L}{\partial N} = -\left[2a(N - N_d) + \lambda_3 r(1 - u\delta)\left[\ln\frac{1}{N} - 1\right]\right] \tag{3.9}$$

with $\lambda_3(T) = 0$. Further, $u^*(t)$ can be represented by

$$u^*(t) = \Big(\frac{-\lambda_3 \delta r N \ln N}{2b}\Big)^+.$$

Proof. The existence of the adjoint solution is found via a maximum principle satisfying [13]. Using the Lagrangian (3.8), we complete the representation for u^* by analyzing the optimality condition $\frac{\partial L}{\partial u} = 0$. Upon some algebraic manipulation, the representation of u^* becomes

$$u^*(t) = \frac{-\lambda_3 \delta r N \ln N + w_1}{2b}.$$

To determine an explicit expression for the optimal control, without w_1, a standard optimality technique is utilized. The optimal control is characterized as

$$u^*(t) = \Big(\frac{-\lambda_3 \delta r N \ln N}{2b}\Big)^+, \tag{3.10}$$

where

$$r^+ = \begin{cases} r & \text{if} \quad r > 0, \\ 0 & \text{if} \quad r \le 0. \end{cases} \tag{3.11}$$

Similarly, we can find the representations for the controls associated with problems P1 and P2 that are subject to J_α. The associated control for P1 is $u^*(t) = \frac{\delta}{2b}(\lambda_1 N)^+$ and the control for P2 is $u^*(t) = \frac{\delta}{2b}(\frac{\lambda_2 N}{k+N})^+$.

Using this explicit representation for the control, the adjoint equation coupled with the state equation and the initial and transversality conditions form the optimality system. The optimality systems associated with each of the state equations and their associated adjoint equations are given below. We note that Optimality System 1 is associated with P1 and its adjoint, Optimality System 2 is associated with P2 and its adjoint, and Optimality System 3 is associated with P3 and its adjoint.

Optimality System 1 (OS1).

$$\begin{aligned} \frac{dN}{dt} &= rN\ln\frac{1}{N} - N\frac{\delta^2}{2b}(\lambda_1 N)^+, \\ \frac{d\lambda_1}{dt} &= -\left[2a(N - N_d) + \lambda_1\left(r\ln\frac{1}{N} - r - \frac{\delta^2}{2b}(\lambda_1 N)^+\right)\right] \end{aligned}$$

with $N(0) = N_0$ and $\lambda_1(T) = 0$.

Optimality System 2 (OS2).

$$\begin{aligned} \frac{dN}{dt} &= rN\ln\frac{1}{N} - \frac{\delta^2}{2b}\frac{N}{k+N}\Big(\frac{\lambda_2 N}{k+N}\Big)^+, \\ \frac{d\lambda_2}{dt} &= -\left[2a(N - N_d) + \lambda_2\left(r\ln\frac{1}{N} - r - \frac{k\delta^2}{2b(k+N)^2}\Big(\frac{\lambda_2 N}{k+N}\Big)^+\right)\right] \end{aligned}$$

with $N(0) = N_0$ and $\lambda_2(T) = 0$.

Optimality System 3 (OS3).

$$\frac{dN}{dt} = rN\ln\frac{1}{N}\Big[1 - \frac{\delta^2 r}{2b}(-\lambda_3 N\ln N)^+\Big],$$
$$\frac{d\lambda_3}{dt} = -\left[2a(N-N_d) + \lambda_3 r\left(1 - \frac{\delta^2 r}{2b}(-\lambda_3 N\ln N)^+\right)\left(\ln\frac{1}{N} - 1\right)\right]$$

with $N(0) = N_0$ and $\lambda_3(T) = 0$.

3.3. Uniqueness. Here, we focus our attention on OS1 and note that similar analysis gives the uniqueness of the OS2 and OS3. The optimal control depends on the adjoint and the state variables. By proving the optimality system has a unique solution, we will argue that the optimal control is unique as well. We recognize that since the tumor mass, $N(t)$, is bounded, then the adjoint equation (3.12) has a bounded right-hand side that is dependent on the final time T. Hence, there exists a $D > 0$, depending on the coefficients of the state equation and the uniform bound for $N(t)$ such that $|\lambda_1(t)| < DT$ on [0,T].

THEOREM 3.4. *For T sufficiently small, the solution to Optimality System* 1 *is unique.*

Proof. We suppose that (N, λ_1) and (M, ψ) are two distinct solutions to OS1. Let $m > 0$ be chosen such that $N = e^{mt}v$, $M = e^{mt}w$, $\lambda_1 = e^{-mt}y$, and $\psi = e^{-mt}z$. Also, we have that $u = \frac{d}{2b}(yv)^+$ and $f = \frac{\delta}{2b}(wz)^+$. Upon substitution of the representations for N, M, λ_1, and ψ into the state and adjoint equations followed by simplification, we obtain the following equations:

$$\frac{dv}{dt} + mv = rv(-mt - \ln v) - \frac{\delta^2}{2b}v(yv)^+,$$
$$\frac{dw}{dt} + mw = rw(-mt - \ln w) - \frac{\delta^2}{2b}w(wz)^+,$$
$$\frac{dy}{dt} - my = -2av + 2ae^{mt}N_d - yr(-mt - \ln v) + ry + \frac{\delta^2}{2b}y(yv)^+,$$
$$\frac{dz}{dt} - mz = -2aw + 2ae^{mt}N_d - zr(-mt - \ln w) + rz + \frac{\delta^2}{2b}z(wz)^+$$

with $v(0) = N_0$, $w(0) = N_0$, $y(T) = 0$, and $z(T) = 0$.

The next step is to subtract the equations corresponding to v, w, y, z. Then each of these differences are multiplied by an appropriate function and are integrated from 0 to T. We obtain the following two equations for the modified state and the adjoint:

$$\frac{1}{2}[v(T) - w(T)]^2 + m\int_0^T (v-w)^2\,dt = mr\int_0^T t(v-w)^2\,dt$$
$$- r\int_0^T [v\ln v - w\ln w](v-w)\,dt$$
$$- \frac{\delta^2}{2b}\int_0^T (v(yv)^+ - w(wz)^+)(v-w)\,dt$$

and

$$\frac{1}{2}[y(0)-z(0)]^2+m\int_0^T(y-z)^2\,dt=2a\int_0^T(v-w)(y-z)\,dt$$
$$+mr\int_0^T t(y-z)^2\,dt+r\int_0^T(y-z)^2\,dt$$
$$+r\int_0^T[y\ln v-z\ln w](y-z)\,dt$$
$$+\frac{\delta^2}{2b}\int_0^T(y(yv)^+-z(wz)^+)(y-z)\,dt.$$

We need to estimate several terms in order to obtain the uniqueness result. For explanation, we include one estimate below where the boundedness of the state variables and Cauchy's inequality are used:

$$\left|\int_0^T(v\ln v-w\ln w)(v-w)\,dt\right|=\left|\int_0^T[v(\ln v-\ln w)+(v-w)\ln w](v-w)\,dt\right|$$
$$=\left|\int_0^T\Big[v\Big(\ln\frac{v}{w}\Big)(v-w)+(v-w)^2\ln w\Big]\,dt\right|$$
$$\le\int_0^T\Big[\frac{v^2}{w}|(v-w)|+|w|(v-w)^2\Big]\,dt$$
$$\le TC_1\int_0^T(v-w)^2\,dt.$$

In the estimate above, C_1 depends on the bounds of the state variables and the coefficients.

To complete this uniqueness proof, we add the two integral equations together and bounds the terms to obtain

$$\frac{1}{2}[v(T)-w(T)]^2+\frac{1}{2}[y(0)-z(0)]^2+m\int_0^T[(v-w)^2+(y-z)^2]\,dt$$
$$\le((mr+C_2)T)\int_0^T[(v-w)^2+(y-z)^2]\,dt,$$

where C_2 depends on the coefficients and the bounds of the state and the adjoint variables.

Since the variable expressions evaluated at the initial and the terminal times are nonnegative, the inequality reduces to

$$(m-mrT-C_2T)\int_0^T\Big[(v-w)^2+(y-z)^2\Big]\,dt\le 0. \tag{3.12}$$

For the optimality system to be unique, we must choose m such that $m>\frac{C_2}{1-r}$ and, thus,

$$m-mrT-C_2T>0.$$

For this choice of m we have that $T<\frac{m}{mr+C_2}$. Moreover, OS1 has a unique solution. Since the characterization of the optimal control directly depends on the state and the adjoint solutions, which are unique, then the optimal control corresponding to OS1 is unique. Similar results give uniqueness for Optimality Systems 2 and 3.

4. Linear control. In this case we still consider the same three differential equations, P1–P3, subject to their initial conditions. However, in this case, we determine the existence and the characterization of an optimal control in the admissible control class, V, such that the objective functional (2.4),

$$J_\beta(u) = aN(T) + b\int_0^T u(t)\,dt, \tag{4.1}$$

is minimized over this class of controls. The goal is to find an optimal control, u^*, such that

$$\min_{0\le u\le M} J(u) = J(u^*).$$

4.1. Existence. In subsection 3.1, we obtain the existence of the state solution for each problem P1–P3 given an optimal control in U. This work can be extended directly because the only change is that $u(t)$ is bounded above by a maximum amount of drug M.

For simpler discussions, we transform the original problems P1–P3 via $x = \ln N$. Consequently, we minimize

$$J_1(u) = ae^{x(T)} + b\int_0^T u(t)\,dt \tag{4.2}$$

over the class of admissible controls, V, subject to each of the three differential equations that correspond to P1, P2, and P3, respectively. We note that $k \neq N_0$ and that the initial condition is $x(0) = \ln N_0$ and is negative since $0 < N_0 < 1$.

$$\frac{dx}{dt} = -rx - u(t)\delta, \tag{4.3}$$

$$\frac{dx}{dt} = -rx - u(t)\frac{\delta}{k+e^x}, \tag{4.4}$$

$$\frac{dx}{dt} = rx(u(t)\delta - 1). \tag{4.5}$$

The theorem for the existence of an optimal control for the appropriate objective functional is stated below. Since the proof involves standard arguments, it is omitted. For further information, see [14].

THEOREM 4.1. *There exists an optimal control in V that minimizes the objective functional $J_1(u)$ subject to* (4.3)*,* (4.4)*, and* (4.5)*, respectively.*

4.2. Characterization of optimal control. Since an optimal control exists, we determine the characterization for each optimal control $u(t)$ associated with each problem (4.3), (4.4), and (4.5) that minimizes $J_1(u)$. We use Pontryagin's maximum principle [17] to obtain the necessary conditions for optimality for each problem.

THEOREM 4.2. *Given an optimal control $u^*(t)$ and a solution, $x(t)$ to* (4.3)*, there exists an adjoint ψ_1 satisfying*

$$\frac{d\psi_1}{dt} = r\psi_1(t),$$
$$\psi_1(T) = ae^{x(T)}.$$

Furthermore,

$$u^*(t) = \begin{cases} M & \text{if} \quad \psi_1(t) > \frac{b}{\delta}, \\ 0 & \text{if} \quad \psi_1(t) < \frac{b}{\delta}. \end{cases} \tag{4.6}$$

Note that this is a problem similar to Swierniak and Duda [18]. We note that $\psi_1(t) = ae^{x(T)-r(T-t)}$ and a singular control could not exist. (A singular control exists when the Hamiltonian is linear in the control and the coefficient of the control is zero for some time interval.) If one were to exist, then $\psi_1(t)$ must equal $\frac{b}{\delta}$ on some interval inclusive to [0,T]. This cannot occur since $\psi_1(t)$ would be constant only for one instant in time. Furthermore, Swierniak and Duda provide conditions for the representation of the control $u^*(t)$ in terms of the model parameters. Please see [18, 19] for complete details.

For problem (4.4), we have the following result.

THEOREM 4.3. *Given an optimal control $u^*(t)$ and corresponding solution $x^*(t)$ to* (4.4)*, there exists an adjoint ψ_2 satisfying*

$$\frac{d\psi_2}{dt} = \psi_2(t)\Big[r - \frac{u(t)\delta e^{x(t)}}{(k+e^{x(t)})^2}\Big], \tag{4.7}$$

$$\psi_2(T) = ae^{x^*(T)}. \tag{4.8}$$

In addition,

$$u^*(t) = \begin{cases} 0 & \text{if} \quad b - \frac{\psi_2(t)\delta}{(k+e^{x^*(t)})} > 0, \\ M & \text{if} \quad b - \frac{\psi_2(t)\delta}{(k+e^{x^*(t)})} < 0. \end{cases} \tag{4.9}$$

Proof. To determine the representation for $u^*(t)$ and the differential equation associated with $\psi_2(t)$, we form the Hamiltonian. We note via Pontryagin's maximum principle [17] that if u^* is an optimal control associated with a corresponding trajectory on $[0,T]$, then there exists $\lambda_0 \geq 0$ and an absolutely continuous function $\lambda : [0,T] \to R$ such that $(\lambda_0, \lambda(t) \neq (0,0))$ for all $t \in [0,T]$ and $\lambda(t)$ satisfies (4.7) and $\lambda(T) = \lambda_0 ae^{x(T)}$. This optimal control minimizes $H = \lambda_0 bu(t) + \lambda(-rx(t) - \frac{u(t)\delta}{(k+e^{x(t)})^2})$ over V. Yet, λ_0 cannot vanish for this problem because, if it did, then $\lambda(T) = 0$ and hence $\lambda(t) = 0$ on $[0,T]$. This contradicts the nontriviality of the multipliers. Therefore, without loss of generality, we let $\lambda_0 = 1$.

Consequently, we consider the following Hamiltonian, where we omit the asterisks for simplicity:

$$H(t, x(t), u(t), \psi_2(t)) = bu(t) + \psi_2(t)\Big(-rx(t) - \frac{u(t)\delta}{(k+e^{x(t)})}\Big).$$

We note that from standard existence theory we obtain the existence of $\psi_2(t)$ solving (4.7) given that $x(t)$ is bounded. The necessary conditions of optimality give that

$$u(t) = \begin{cases} 0 & \text{if} \quad b - \frac{\psi_2(t)\delta}{(k+e^{x^*(t)})} > 0, \\ M & \text{if} \quad b - \frac{\psi_2(t)\delta}{(k+e^{x^*(t)})} < 0, \\ \text{singular} & \text{if} \quad b - \frac{\psi_2(t)\delta}{(k+e^{x^*(t)})} = 0. \end{cases} \tag{4.10}$$

We note that

$$\psi_2(t) = ae^{x(T) - \int_t^T \left[r - \frac{u(t)\delta e^{x(t)}}{(k+e^{x(t)})^2}\right] ds}$$

is always positive on [0,T] since $a > 0$.

We suppose that the control is singular on $(t_0, t_1) \subset [0, T]$, i.e.,

$$b - \frac{\psi_2(t)d}{(k + e^{x(t)})} = 0 \tag{4.11}$$

on that interval. We take the derivative with respect to time of (4.11) and obtain, after simplification,

$$(k + e^{x(t)})\frac{d\psi_2(t)}{dt} - \psi_2(t)e^{x(t)}\frac{dx}{dt} = 0. \tag{4.12}$$

Next, we substitute the right-hand sides of the differential equations for $\psi_2(t)$ and for $x(t)$ associated with problem (4.4) and find that

$$(k + e^{x(t)})\Big[\psi_2(t)\Big(r - \frac{u(t)\delta e^{x(t)}}{(k + e^{x(t)})^2}\Big)\Big] - e^x\psi_2(t)\Big(-rx(t) - \frac{u(t)\delta}{(k + e^{x(t)})}\Big) = 0,$$
$$\psi_2(t)r(k + e^{x(t)} + x(t)e^{x(t)}) = 0.$$

Since $\psi_2(t) > 0$ on [0,T] and $r > 0$, then

$$k + e^{x(t)} + x(t)e^{x(t)} = 0. \tag{4.13}$$

This immediately gives that $x(t)$ is constant.

Since $x(t)$ is constant, then $u(t)$ is constant here. We make note that with the fixed final time that $H(t, x, u, \psi_2)$ is constant [20]. Since $H(t, x, u, \psi_2) = bu + \psi_2\frac{dx}{dt} = bu$ in this case and we are minimizing H, then $u(t) = 0$. However, for this to occur $b - \frac{\psi_2\delta}{(k+e^x)} > 0$, in (4.10), which contradicts our original assumption for the control to be singular. Thus, a singular control does not exist and our control is

$$u^*(t) = \begin{cases} 0 & \text{if} \quad b - \frac{\psi_2(t)\delta}{(k+e^{x^*(t)})} > 0, \\ M & \text{if} \quad b - \frac{\psi_2(t)\delta}{(k+e^{x^*(t)})} < 0. \end{cases} \tag{4.14}$$

□

We now determine the characterization of the optimal control to minimize $J_1(u)$ subject to (4.5).

THEOREM 4.4. *Given an optimal control u^* and a corresponding solution $x^*(t)$ to* (4.5)*, there exists an adjoint $\psi_3(t)$ satisfying*

$$\frac{d\psi_3}{dt} = -\psi_3(t)r(u^*(t)\delta - 1), \tag{4.15}$$

$$\psi_3(T) = ae^{x^*(T)} \tag{4.16}$$

with

$$u^*(t) = \begin{cases} 0 & \textit{if} \quad x(T)e^{x(T)} > \frac{-b}{a\delta r}, \\ M & \textit{if} \quad x(T)e^{x(T)} < \frac{-b}{a\delta r}. \end{cases} \tag{4.17}$$

Proof. To determine the representation for the control, we form the Hamiltonian in a similar fashion as we did in the proof of Theorem 4.3,

$$H(t, x(t), u(t), \psi_3(t)) = bu(t) + \psi_3(t)(rx(t)(u(t)\delta - 1)).$$

As before, a solution to the adjoint exists and is given by

$$\psi_3(t) = ae^{x(T)-r\int_t^T (1-u(s)\delta)\,ds}, \tag{4.18}$$

and a solution to the problem (4.5) is

$$x(t) = x(0)e^{-rt+r\delta\int_0^t u(s)\,ds}. \tag{4.19}$$

Since $x(0) < 0$ and $a > 0$, then $\psi_3(t)x(t) < 0$ on [0,T].

The necessary conditions for optimality give that

$$u(t) = \begin{cases} 0 & \text{if} \quad b + \psi_3(t)\delta r x(t) > 0, \\ M & \text{if} \quad b + \psi_3(t)\delta r x(t) < 0, \\ \text{singular} & \text{if} \quad b + \psi_3(t)\delta r x(t) = 0. \end{cases} \tag{4.20}$$

We see that

$$\begin{aligned} \psi_3(t)x(t) &= (ae^{x(T)-r\int_t^T (1-u(s)\delta)\,ds})(x(0)e^{-rt+r\delta\int_0^t u(s)\,ds}) \\ &= ax(0)e^{x(T)-r(T-t)+r\delta\int_t^T u(s)\,ds-rt+r\delta\int_0^t u(s)\,ds} \\ &= ax(0)e^{x(T)-rT+r\delta\int_0^T u(s)\,ds} \\ &= ax(T)e^{x(T)}. \end{aligned}$$

Hence, $\psi_3(t)x(t)$ is constant on [0,T]. This means that $u^*(t)$ must be either zero, its maximum value—M, or its singular representation on the entire interval [0,T].

Using that $\psi_3(t)x(t)$ is constant and that the Hamiltonian is to be minimized, we can exclude the singular case. If the control is singular, then the Hamiltonian is equal to $-\psi_3(t)x(t)r$. We can see for the case, $u = M$, that $H(t, x(t), u(t), \psi_3(t)) < -\psi_3(t)x(t)r$. Moreover, for the case $u = 0$ we see that the Hamiltonian is bounded strictly above by $\frac{b}{\delta}$, which is the value of the Hamiltonian if the control is singular. Consequently, a singular control will not generate the minimum value for the Hamiltonian.

Therefore, the necessary conditions for optimality are

$$u^*(t) = \begin{cases} 0 & \text{if} \quad x(T)e^{x(T)} > \frac{-b}{a\delta r}, \\ M & \text{if} \quad x(T)e^{x(T)} < \frac{-b}{a\delta r}. \end{cases} \tag{4.21}$$

We simply need to check if the expression $x(T)e^{x(T)}$ is smaller or larger than $\frac{-b}{ar\delta}$. Then this determines the constant control on the interval [0,T]. □

Using the representation of the control in terms of the state and adjoint solutions to the transformed problems (4.3), (4.4), and (4.5), we have the associated Optimality Systems 4, 5, and 6.

Optimality System 4 (OS4).

$$\begin{aligned} \frac{dx}{dt} &= -rx(t) - \delta u^*(t), \\ \frac{d\psi_1}{dt} &= r\psi_1(t), \\ x(0) &= \ln N_0, \text{ and } \psi_1(T) = ae^{x(T)}, \end{aligned}$$

where

$$u^*(t) = \begin{cases} M & \text{if} \quad \psi_1(t) > \frac{b}{\delta}, \\ 0 & \text{if} \quad \psi_1(t) < \frac{b}{\delta}. \end{cases}$$

Optimality System 5 (OS5).

$$\begin{aligned} \frac{dx}{dt} &= -rx(t) - \frac{\delta u^*(t)}{(k + e^{x(t)})}, \\ \frac{d\psi_2}{dt} &= \psi_2\Big[r - \frac{u^*(t)\delta e^{x(t)}}{(k + e^{x(t)})^2}\Big], \\ x(0) &= \ln N_0, \text{ and } \psi_2(T) = ae^{x(T)}, \end{aligned}$$

where

$$u^*(t) = \begin{cases} 0 & \text{if} \quad b - \frac{\psi_2(t)\delta}{(k+e^{x^*(t)})} > 0, \\ M & \text{if} \quad b - \frac{\psi_2(t)\delta}{(k+e^{x^*(t)})} < 0. \end{cases}$$

Optimality System 6 (OS6).

$$\begin{aligned} \frac{dx}{dt} &= rx(t)(u^*(t)\delta - 1), \\ \frac{d\psi_3}{dt} &= -r\psi_3(t)(u^*(t)\delta - 1), \\ x(0) &= \ln N_0, \text{ and } \psi_3(T) = ae^{x(T)}, \end{aligned}$$

where

$$u^*(t) = \begin{cases} 0 & \text{if} \quad x(T)e^{x(T)} > \frac{-b}{a\delta r}, \\ M & \text{if} \quad x(T)e^{x(T)} < \frac{-b}{a\delta r}. \end{cases}$$

5. Numerical results. We obtain numerical solutions to each of the optimality systems using the two-point boundary value solver in Matlab [21, 22].

5.1. OS1–OS3. We observe several interesting differences among the three systems. First, there are significant differences between the optimal solutions of systems OS1–OS3 based on the initial tumor volume. For initial conditions near the carrying capacity (97.5% of carrying capacity), the optimal solutions for OS1 require less treatment to reduce the tumor volume the same amount as in OS2 or OS3 (Figure 5.1(A), (B)). In particular, the optimal solution for OS1 allows for the treatment to be reduced quickly while for OS3 the treatment remains higher for a more extended period. This difference is due to the different cell-kill hypotheses of the three methods. In particular, OS1 hypothesizes that cell-kill is proportional to tumor size, thus larger tumors are effectively reduced by the drug and the optimality scheme can quickly reduce the dose needed to keep the tumor size small over the treatment interval. However, OS3 hypothesizes that cell-kill is proportional to the growth rate, which is small when the tumor is near its carrying capacity. Therefore, the optimality scheme requires more drug for a longer period of time to reduce the tumor an equivalent amount as in OS1.

For initial conditions at half the carrying capacity the differences between the optimal solutions of the three strategies are less significant (Figure 5.1(C), (D)). OS3

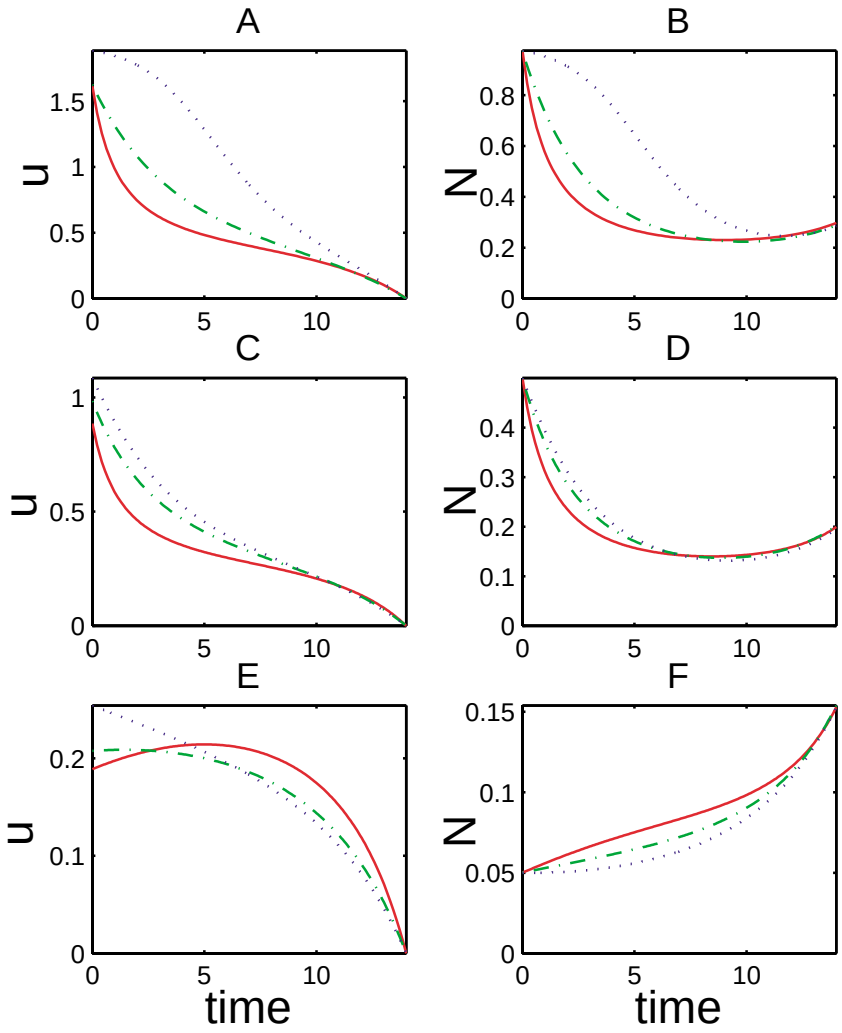

FIG. 5.1. *Comparison of hypotheses OS*1 ——, *OS*2 — - —, *and OS*3 - - -. *The parameters used are given in Table* 5.1. *The left column is the control and the right column is the tumor volume.* A *and* B *represent a large tumor near its carrying capacity (*97.5% *of carrying capacity).* C *and* D *represent a midsized tumor at half its carrying capacity (*50% *of carrying capacity).* E *and* F *represent a small tumor relative to its carrying capacity (*5% *of carrying capacity). In all cases the parameter "δ" was set such that all three methods would have the same tumor volume at the end time "T." The units for time is days.*

still requires more drug early, when the growth rate was slower, to obtain the same overall cell-kill as OS1, but the differences are much smaller.

As for smaller tumors where the initial conditions are much smaller than the carrying capacity (5% of carrying capacity), the optimal solution for OS1 requires more drug later compared to the optimal solution for OS3 to have the same effect on the tumor volume (Figure 5.1(E), (F)). But again, the differences in this case are much less significant compared to tumors near carrying capacity.

We also consider the effects of the weights a, b, and δ in the objective function (2.3). In particular, we fix b and considered how varying a and δ affects results.

TABLE 5.1
Model parameters. All units are nondimensional.

Parameter	OS1	OS2	OS3
r	0.1	0.1	0.1
δ	0.45	0.225	4.0
a	3	3	3
b	1	1	1
N_d	0	0	0
k		0.25	

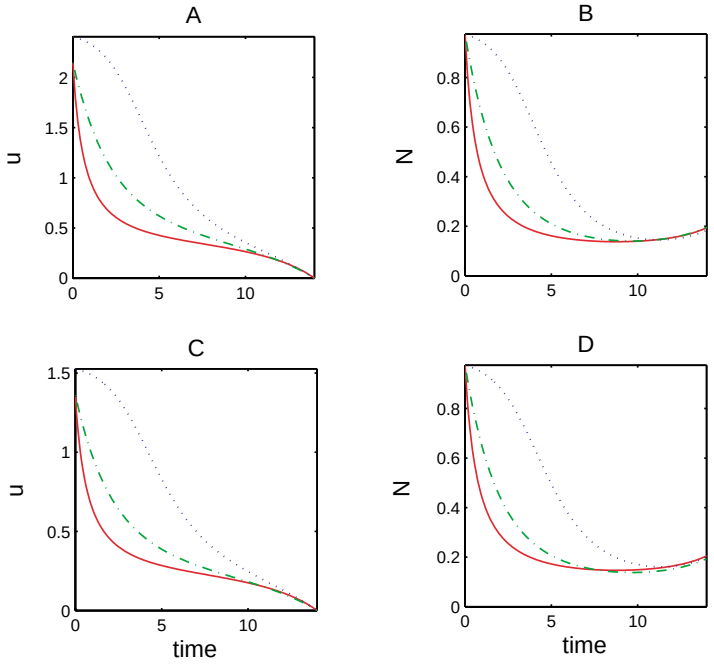

FIG. 5.2. *OS1 ——, OS2 — - —, and OS3 - - -. In* A *and* B *the parameter "a" is larger (*2.5 *times) and the parameter "δ" is smaller (*50%–60%*) compared to* C *and* D*. In all cases the initial condition for the tumor size is* 97.5% *of the carrying capacity and the remaining parameters are given in Table* 5.1*.*

(The remaining parameters are given in Table 5.1.) In general, a smaller a, 2.5 times smaller (i.e., less weight in the objective function on minimizing the tumor volume) requires more drug (or a more effective drug) via an increase in δ (50%–60% increase) to give equivalent results (Figure 5.2). In general, a, b, and δ alter the quantitative but not the qualitative results.

5.2. OS4–OS6. Systems OS4–OS6, with the linear control functional (2.4), give qualitatively different results compared to OS1–OS3. For example, OS4 and OS5 force treatment to be delayed until the later portion of the treatment interval (Figure 5.3). This delay in treatment is due to the choice of the objective functional (2.4), which minimizes N at the end time T. Since (based on the Gompertz growth model) larger tumors grow much slower than smaller ones, it is more advantageous for the tumor to remain larger (and thus slower growing) for the first portion of the treatment

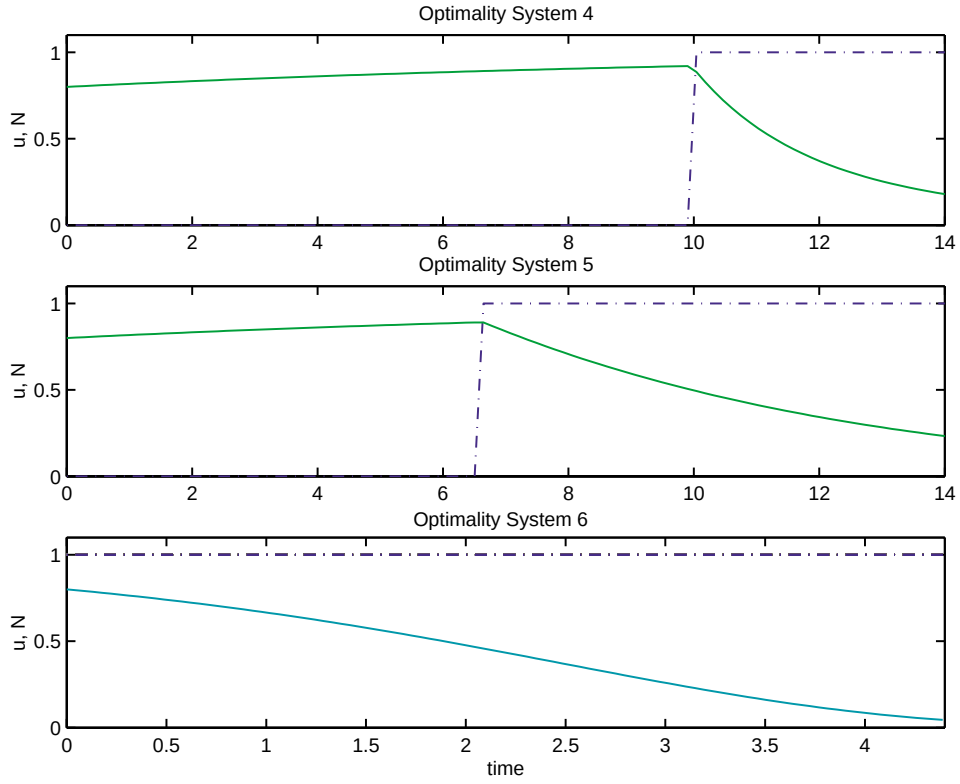

FIG. 5.3. *Tumor volume "N" ——, control "u(t)" — - —. Note that for OS6 the graph shows only the portion where the treatment is "on."*

interval and treat during the remaining portion of the treatment interval. If instead the treatment is given over the first portion of the treatment interval, then the tumor would be able to recover during the second portion of the interval at a much faster rate (since the smaller tumor after treatment has a faster growth rate) and thus not optimize the objective functional (2.4).

OS6 could only determine the length of treatment and not when treatment should be started or stopped due to the end condition being only dependent on the end time T (Figure 5.3). However, there are also some similarities between OS1–OS3 and OS4–OS6. These include OS4, which like OS1 hypothesizes that cell-kill is proportional to the tumor volume and requires drug to be given over a shorter period (3 days) compared to the other two methods (OS5 approximately 7.5 days and OS6 approximately 4.5 days).

6. Conclusions.

Theoretical. There are several important differences in the objective functionals that are minimized over the two classes of controls. For the objective functional with the quadratic control (2.3), the representation for the optimal control involves both the state and the adjoint variables for all time, t. For the second objective functional (2.4), the control is explicitly dependent on the adjoint, which in turn does implicitly depend on the state, for OS4 and OS5. In OS6, the control is dependent only on the final time and the evaluation of the state at the final time.

Within OS1–OS3, the existence, uniqueness, and characterization of the optimal control are easier to obtain because of the nonlinear control. The biological validity of the quadratic cost term has been debated [7]. However, its use in order to incorporate the nonlinear flavor of the problem has given results that are qualitatively significant. For OS4–OS6, an interesting component is the bang-bang structure of the optimal controls. An intriguing difference occurs in OS6 in which the optimal control depends on the length of the treatment. Once this is known, the control will either be given at the maximum or the minimum level. A future problem relating to OS6 could involve the minimization of the time of treatment in conjunction with the minimization of the drug needed.

The mathematical significance of these problems lies in the similarities and differences of the construction of the controls. Basic concepts using a Lagrangian or Hamiltonian are needed in each. Yet, the possibility of singular controls in section 4 required more explorations of the control representations. In this investigation, the strategies employed in both the nonlinear and the linear control settings attempt to qualitatively answer the questions relating to the appropriate drug treatment to impose under the given three hypotheses of cell-kill.

Clinical. The most important clinical question that this study addresses is, When can drug treatment be reduced to reduce toxicity? If the log-kill hypothesis is used, then the optimal control systems suggest that treatment can be given for a shorter period of time relative to the Norton–Simon hypothesis. However, the consequence of choosing the incorrect hypothesis is to either under- or over-treat the patient, causing ineffective reduction of the tumor or toxicity, respectively. Therefore, more studies are needed to determine the specific dynamics of various drugs on tumors relative to these (or other) cell-kill hypotheses.

We also observe qualitatively different treatment strategies based on the use of different objective functionals. These differences show the importance of defining an objective functional that most accurately reflects the toxicities of a particular drug along with the objective of the treatment strategy, e.g., reduce the tumor mass at the end of the treatment interval, reduce the overall tumor burden over the treatment interval, or some other clinically relevant criteria.

ON THE MOTION OF SOLIDS THROUGH AN IDEAL LIQUID: APPROXIMATED EQUATIONS FOR MANY BODY SYSTEMS*

CLODOALDO GROTTA RAGAZZO†

Abstract. The problem of motion of many solids through an unbounded ideal liquid (inviscid and irrotational) is considered. A Lagrangian formulation of the equations of motion leads to a set of ordinary differential equations (ODEs) coupled to an elliptic partial differential equation (PDE) [H. Lamb, *Hydrodynamics*, 6th ed., Dover, New York, 1932]. Here, using a variational approach, an approximated solution for the PDE is presented, and the problem is reduced to the study of a system of ODEs. As a consequence one can get approximate forces and torques due to hydrodynamic interaction of rigid bodies of arbitrary shapes. Some examples are discussed at the end.

Key words. multibody systems, fluid-solid interactions

1. Introduction and main result. This paper is concerned with the motion of solids through an infinite mass of an ideal liquid (inviscid and irrotational). Since the 1800s this problem has been treated in Lagrangian form considering the solids and the liquid as a single system in which dynamics are determined only by their inertia. The equations of motion obtained in this way are given by a set of ordinary differential equations (ODEs) (borne upon the rigid bodies) coupled to an elliptic partial differential equation (PDE) (borne upon the fluid). The fundamental contributions to the subject were given by Kirchhoff, Thomson (Lord Kelvin), and Tait. The book of Lamb [1] contains an excellent presentation of these and related works. A critical discussion on the physical validity of the hypotheses behind this classical approach can be found in the book by Birkhoff [2, paragraph 109].

The problem of motion of solids in ideal liquids has recently received renewed interest, in particular, due to its significance in the study of two phase flows (see, for instance, [3], [4], [5], [6]) and in the study of motion of submerged bodies (see, for instance, [7], [8], [9]). In a few situations of very simple geometry (all bodies are balls) and under the hypothesis of not close approach, some authors were able to approximately solve the elliptic PDE in the equations of motion and to get an explicit set of ODEs for the dynamics of the rigid bodies (see, for instance, [1], [10], [4], [5], [6], [7]). This was particularly important in numerical studies of systems with a great number of bodies (for instance, [4], [6]). In this paper the idea of approximately solving the elliptic part of the problem is extended to systems containing bodies of arbitrary shape. The goal is to obtain an explicit set of ODEs (and/or the Lagrangian function that determines it) for the dynamics of the rigid bodies. This finite set of ODEs depends on geometric parameters, volume, center of volume, and "added-mass" coefficients of each body. In general (except for balls and ellipsoids) these added-mass coefficients are yet to be determined numerically through the solution of an elliptic

PDE. Therefore, the main contribution given here is the reduction of the original coupled ODE-PDE system for the dynamics of rigid bodies in a fluid to a finite system of ODEs with some time-independent parameters. These parameters can be determined by solving a finite number of PDEs only once. Notice that in the original problem at each time step of integration of the ODE, an elliptic PDE has to be solved in a domain that changes according to the motion of the bodies.

The hypotheses assumed in this paper are very restrictive from a physical point of view. A real fluid has viscosity and its dynamic is in most cases very different from that of an inviscid irrotational fluid. A first motivation for this paper was research on the dynamics of ships used as oil floating production storage and offloading (FPSO) units (see, for instance, [11] [12]) carried out by a group of people at the University of São Paulo and PETROBRAS (the Brazilian oil company) under the leadership of J. A. P. Aranha. This group has developed a physical model for the forces and torques (due to current, wind, and waves) acting on a single FPSO under some typical environmental conditions. The hydrodynamic part of the model was developed in two steps. At first expressions for the force and torque functions, depending on a minimal number of unknown parameters, were obtained by means of a theoretical analysis. The guideline for this analysis was a decomposition proposed by Lighthill [13] of the forces acting on the ship into a viscous drag force and an inviscid inertial force (see also [14] and [9]). Then the unknown parameters were determined using either statistical data obtained from similar ships or towing tank experiments. During an offloading operation two ships get close to each other. In this case a new hydrodynamic interaction force between the ships appears. However, in this case not even an estimate of the inviscid potential part of the hydrodynamic interaction functions was available in the literature, at least in a form sufficiently explicit to be used as it was in the single ship case. Therefore, the main motivation for this paper was to come up with such an estimate. Following the general idea of Lighthill's force decomposition the expressions given here provide a starting point for the buildup of more realistic expressions for the force and torque interaction functions. In this context it is clear the importance of having explicit formulas for bodies of arbitrary shape. Of course many terms will have to be incorporated to these interaction functions due to viscous effects as it was in the single ship case. In the end tests and adjustments of the model will have to be done experimentally.

A second more direct application of the results of this paper is to the problem of hydrodynamic interaction between fast oscillating bodies. For instance, consider a system of two bodies inside a fluid. To the first body a fast small amplitude oscillation is imposed. The second one is allowed to move freely. How do they interact? Do they attract or repel each other? These questions were addressed in [15]. There the equations of motion were conveniently averaged and both Theorems 1.2 and 1.4 presented below played an important role. (In the context of the previous paragraph only Theorem 1.2 is relevant.) In this case the fluid flow induced by the fast oscillating body has a small "particle displacement/particle acceleration" ratio, so that the inertial forces are quite relevant (see [2, paragraph 103]). On the other hand eddies are not generated near the bodies (there are no wakes) due to their small fast net displacements. So, eddy formation, the usual major way of body-fluid interaction through viscosity, is not relevant in this case. There may also be the influence of viscosity due to skin friction and of fluid compressibility if the imposed oscillation of the first body is too fast (acoustic effects). However, at least for certain frequency ranges of oscillation, these are second order effects. So, in this context the force and torque expressions given here seem to be the physically most relevant part of the real

hydrodynamic interaction functions.

The hypotheses and notation used in this paper are as follows. Let us consider a system of N bounded rigid bodies whose boundaries are smooth surfaces (or, more precisely, *the boundaries are continuously differentiable*). Each body will be labeled by a Greek letter $\alpha \in \{1, 2, \dots, N\}$. In each body we fix a reference point and a three orthogonal reference frame centered on it. We denote by K_α the reference frame of body α and by $\{\vec{e}_{\alpha 1}, \vec{e}_{\alpha 2}, \vec{e}_{\alpha 3}\}$ its unit vectors. We also consider a space fixed three orthogonal reference frame K and denote by $\{\vec{e}_1, \vec{e}_2, \vec{e}_3\}$ its unit vectors. The configuration of the system is determined by N position vectors $\vec{R}_\alpha$ and N orthogonal transformations T_α, where $\vec{R}_\alpha$ is the position of the reference point of solid α with respect to K and $T_\alpha : K_\alpha \to K$ describes the orientation of body α with respect to K. (T_α is the attitude matrix of body α.) The set of points of body α will be denoted by B_α (sometimes we will just use B_α to refer to the body itself), and the boundary of B_α will be denoted by ∂B_α. The bodies will be supposed to move without collision through an infinite mass of an ideal liquid (inviscid, incompressible) of density ρ which is at rest at infinity. It will be assumed that the motion of the liquid is entirely due to its interaction with the solid, namely there is no external forces acting on the fluid. The fluid flow will be supposed irrotational, and if a body is bounded by a multiply connected surface, then it will be supposed that there is no circulation about any irreducible path on this surface.

We start the study of the dynamics of a system of solids in a fluid by the simplest case of a single body. Let α be the index of this body. Under the above hypothesis it can be shown [1] that the velocity field $\vec{u}$ of the fluid is the gradient of a potential function Φ, $\vec{u} = \nabla\Phi$. For each time t the incompressibility of the liquid implies that the Laplacian of Φ is equal to zero, $\Delta\Phi = 0$. In addition to this equation, it is well known that the following boundary conditions completely determine $\vec{u} = \nabla\Phi$: (1) the components of $\nabla\Phi$ normal to the body surface points are equal to the normal velocity of these points, and (2) the fluid is at rest at infinity. Moreover, these boundary conditions imply that $||\nabla\Phi||$, $\vec{x} \in K$, is of order $1/||\vec{x}||^3$ as $||\vec{x}|| \to \infty$. The time dependence enters parametrically in this elliptic problem. The total kinetic energy of the system solid plus fluid is given by

$$W = \text{kinetic energy of body} + \frac{\rho}{2}\int_{\mathbb{R}^3 - B_\alpha} ||\nabla\Phi||^2,$$

where B_α denotes the set of points of solid α. The position and velocity of each point of B_α are determined by the position vector $\vec{R}_\alpha$, the attitude matrix T_α, the velocity vector $\dot{\vec{R}}_\alpha \stackrel{\text{def}}{=} \vec{V}_\alpha$, and the angular velocity vector $\vec{\Omega}_\alpha$, whose components in the fixed reference frame K are given by

$$\dot{T}_\alpha T_\alpha^\dagger \stackrel{\text{def}}{=} \begin{pmatrix} 0 & -\Omega_{\alpha 3} & \Omega_{\alpha 2} \\ \Omega_{\alpha 3} & 0 & -\Omega_{\alpha 1} \\ -\Omega_{\alpha 2} & \Omega_{\alpha 1} & 0 \end{pmatrix},$$

where $T_\alpha^\dagger$ is the transpose of matrix T_α (which coincides with its inverse because T_α is orthogonal). Since $\nabla\Phi$ is determined by positions and velocities of points in the boundary of B_α, which we denote by ∂B_α, we conclude that the kinetic energy W is completely determined by $\vec{R}_\alpha$, $\vec{V}_\alpha$, T_α, and $\vec{\Omega}_\alpha$. In order to write W explicitly in terms of these positions and velocities it is convenient to represent them in the body reference frame K_α. Using the transformation $T_\alpha : K_\alpha \to K$ we define

$$\vec{r}_\alpha = T_\alpha^{-1}\vec{R}_\alpha, \qquad \vec{v}_\alpha = T_\alpha^{-1}\vec{V}_\alpha, \qquad \vec{\omega}_\alpha = T_\alpha^{-1}\vec{\Omega}_\alpha.$$

Sometimes it will be convenient to denote the components of $\vec{v}_\alpha$ and $\vec{\omega}_\alpha$ in a combined way, so we define

$$c_{\alpha i} = v_{\alpha i}, \qquad c_{\alpha(i+3)} = \omega_{\alpha i}, \qquad i = 1,2,3 \tag{1.1}$$

(we will always use Latin indices i, j, l, k to denote vector components). It is also convenient to use the following decomposition for Φ (see [1, article 118]):

$$\Phi(T_\alpha \vec{x}_\alpha) = \sum_{i=1}^{6} c_{\alpha i}\phi_{\alpha i}(\vec{x}_\alpha), \qquad \vec{x}_\alpha \in K_\alpha,$$

where for $i = 1,2,3$

$$\begin{cases} \Delta\phi_{\alpha i}(\vec{x}_\alpha) = 0 & \text{for} \quad \vec{x}_\alpha \in \mathbb{R}^3 - B_\alpha, \\ \nabla\phi_{\alpha i}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha) = \vec{\mathrm{e}}_{\alpha i}\cdot\vec{n}_\alpha(\vec{x}_\alpha) & \text{for} \quad \vec{x}_\alpha \in \partial B_\alpha, \\ ||\nabla\phi_{\alpha i}(\vec{x}_\alpha)|| \to 0 & \text{as} \quad ||\vec{x}_\alpha|| \to \infty \end{cases} \tag{1.2}$$

($\vec{n}_\alpha(\vec{x}_\alpha) \in K_\alpha$ denotes the unit normal vector at the point $\vec{x}_\alpha \in \partial B_\alpha$ that points out of the body) and for $i = 4,5,6$

$$\begin{cases} \Delta\phi_{\alpha i}(\vec{x}_\alpha) = 0 & \text{for} \quad \vec{x}_\alpha \in \mathbb{R}^3 - B_\alpha, \\ \nabla\phi_{\alpha i}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha) = \vec{\mathrm{e}}_{\alpha(i-3)}\times\vec{x}_\alpha\cdot\vec{n}_\alpha(\vec{x}_\alpha) & \text{for} \quad \vec{x}_\alpha \in \partial B_\alpha, \\ ||\nabla\phi_{\alpha i}(\vec{x}_\alpha)|| \to 0 & \text{as} \quad ||\vec{x}_\alpha|| \to \infty. \end{cases} \tag{1.3}$$

Using the above definitions it is possible to show that the kinetic energy W of the system body plus fluid can be written as

$$W = \frac{1}{2}\left(m_\alpha||\vec{v}_\alpha||^2 + 2m_\alpha\vec{v}_\alpha\cdot(\vec{\omega}_\alpha\times\vec{\tau}_\alpha) + \vec{\omega}_\alpha\cdot I^\alpha\vec{\omega}_\alpha\right) + \frac{1}{2}\sum_{i,j=1}^{6} A_{ij}^\alpha c_{\alpha i}c_{\alpha j}, \tag{1.4}$$

where

m_α is the mass of body α,
$\vec{\tau}_\alpha$ is the position of the center of mass of body α in the reference frame K_α,
I^α is the moment of inertia tensor of body α with respect to the reference frame K_α, and
A_{ij}^α are the added mass coefficients of body α,

$$A_{ij}^\alpha \stackrel{\text{def}}{=} \rho\int_{\mathbb{R}^3 - B_\alpha} \nabla\phi_{\alpha i}\cdot\nabla\phi_{\alpha j}.$$

Finally, using this expression for W and D'Alambert's equation,

$$\frac{d}{dt}\frac{\partial}{\partial\dot{s}_{\alpha i}}W - \frac{\partial}{\partial s_{\alpha i}}W = Q_{\alpha i},$$

where $s_{\alpha i}$ is some generalized coordinate of the body α and $Q_{\alpha i}$ is its related generalized external force, we can write the equations of motion for the dynamics of a single body in a fluid. Notice that the effect of the fluid on the body dynamics is represented by the set of constants A_{ij}^α that depends only on the geometry of solid α. These constants either were already analytically computed for some simple interesting geometries (like ellipsoids; see [1]) or can be numerically estimated with high precision (for instance, with the commercial software "Wamit"; see http://www.wamit.com).

Therefore, in the context of ideal fluids, the problem of the dynamics of a single solid in a fluid reduces to the problem of studying some known set of ODEs. We just remark that by no means is this a trivial task. For instance, it has been proved by Kozlov [16] that even the "free motion" ($Q_{\alpha i} = 0$) of a single rigid body with sufficiently complex geometry leads to a nonintegrable set of ODEs.

Now, let us turn to the problem of motion of several solids through a liquid. As above, the idea is to write the kinetic energy of the system solid plus fluid in terms of generalized coordinates of the solids only. The same arguments as before lead to the following expression [1]:

$$W = \frac{1}{2}\sum_{\alpha=1}^{N}\left[\left(m_\alpha||\vec{v}_\alpha||^2 + 2m_\alpha\vec{v}_\alpha\cdot(\vec{\omega}_\alpha\times\vec{\tau}_\alpha) + \vec{\omega}_\alpha\cdot I^\alpha\vec{\omega}_\alpha\right)\right] + \frac{\rho}{2}\int_S ||\nabla\Phi||^2,$$

where S is the open set of points in $\mathbb{R}^3$ outside $B_1 \cup \ldots \cup B_N$ and

$$\text{(1.5)}\qquad \begin{cases} \Delta\Phi = 0 & \text{for} \quad \vec{x}\in S, \\ \nabla\Phi\cdot\vec{n} = [\vec{V}_\alpha + \vec{\Omega}_\alpha\times(\vec{x}-\vec{R}_\alpha)]\cdot\vec{n} & \text{for} \quad \vec{x}\in\partial B_\alpha, \\ ||\nabla\Phi|| \to 0 & \text{as} \quad ||\vec{x}||\to\infty. \end{cases}$$

Now, in contrast to the case of a single solid, it is not possible to write the integral

$$\text{(1.6)}\qquad \frac{\rho}{2}\int_S ||\nabla\Phi||^2$$

in terms of a set of constants that depend only on the geometry of each body. In fact this integral is a quadratic function of the velocities and angular velocities of each body and also a function of the relative positions and orientations of the bodies. Except for very simple geometries, like two spheres moving on a line of centers ([10, Chapter XI]), the form of this function is unknown. As we already mentioned the goal of this paper is to write this integral approximately and explicitly in the case where the bodies are not close to each other. This approximation will depend on certain geometrical parameters of each body α which are combinations of the added mass coefficients A^α_{ij}; the volume of body α,

$$\eta_\alpha \overset{\text{def}}{=} \int_{B_\alpha} d^3x_\alpha;$$

and the center of volume of body α,

$$\vec{\xi}_\alpha \overset{\text{def}}{=} \int_{B_\alpha}\vec{x}_\alpha d^3x_\alpha.$$

In order to motivate the definition of these geometrical parameters let us present a proposition concerning the solutions of (1.2) and (1.3).

We say that a function $f:\mathbb{R}\to\mathbb{R}$ is of order $1/|x|^n$ or

$$f(x) = \mathcal{O}\left(\frac{1}{|x|^n}\right)$$

if there exist constants C and C' such that

$$|f(x)| < \frac{C'}{|x|^n} \qquad \text{for} \quad |x| > C.$$

PROPOSITION 1.1. *Let $\phi_{\alpha i}$ be the solution of problem* (1.2) *for $i = 1, 2, 3$ and of problem* (1.3) *for $i = 4, 5, 6$. Then the following expansion holds:*

$$\phi_{\alpha i}(\vec{x}_\alpha) = -\frac{1}{4\pi}\frac{1}{||\vec{x}_\alpha||}\left\{\frac{\vec{\lambda}_{\alpha i}\cdot\vec{x}_\alpha}{||\vec{x}_\alpha||^2} + \mathcal{R}(\vec{x}_\alpha)\right\},$$

where

$$\vec{\lambda}_{\alpha i} \stackrel{\text{def}}{=} \left\{\eta_\alpha \vec{e}_{\alpha i} + \frac{1}{\rho}\sum_{j=1}^{3} A_{ij}^{\alpha}\vec{e}_{\alpha j}\right\} \in K_\alpha \qquad \textit{for} \quad i = 1, 2, 3,$$

$$\vec{\lambda}_{\alpha i} \stackrel{\text{def}}{=} \left\{\vec{e}_{\alpha(i-3)} \times \vec{\xi}_\alpha + \frac{1}{\rho}\sum_{j=1}^{3} A_{ij}^{\alpha}\vec{e}_{\alpha j}\right\} \in K_\alpha \qquad \textit{for} \quad i = 4, 5, 6,$$

$$\vec{x}_\alpha = T_\alpha^{-1}(\vec{x} - \vec{R}_\alpha).$$

Moreover, function $\mathcal{R}$ can be expanded in a convergent power series of $\vec{x}_\alpha/||\vec{x}_\alpha||^2$ and

$$|\mathcal{R}(\vec{x}_\alpha)| = \mathcal{O}\left(\frac{1}{||\vec{x}_\alpha||^2}\right).$$

The expansion in this proposition in cases $i = 1, 2, 3$ is essentially given in article 121a of Lamb's book [1]. The expansion in cases $i = 4, 5, 6$ is obtained in a similar way. The proof of the analyticity of $\phi_{\alpha i}$ at infinity can be found, for instance, in Folland's book [18]. Notice that Lamb defines the velocity of the fluid as $-\nabla\phi$ while we use $\nabla\phi$. This explains the difference in sign between the formula above and the one in Lamb's book.

Notice that the geometric parameter $\vec{\lambda}_{\alpha i}$ appearing in Proposition 1.1 is the dipole coefficient of the multipole expansion of $\phi_{\alpha i}$. The main idea in this paper is to use Proposition 1.1 in the following way. Function Φ appearing in (1.5) is unknown but it is well approximated by a sum of solutions of one-body problems $\sum_\alpha \sum_i c_{\alpha i}\phi_{\alpha i}$ if the bodies are sufficiently far apart. Since each $\phi_{\alpha i}$ behaves like a dipole at infinity, the error at the boundary conditions of (1.5) after replacing Φ by its approximation is of order $\mathcal{O}(1/R^3)$, where

$$R \stackrel{\text{def}}{=} \min\{||\vec{R}_\beta - \vec{R}_\alpha|| : \text{for} \quad \alpha \neq \beta,\ \alpha = 1, \dots, N,\ \beta = 1, \dots, N\}.$$

Then a well-known variational principle for (1.5) (see [17, exercise 8.4]) implies that the error in the kinetic energy (1.6) after replacing Φ by its approximation is of order $\mathcal{O}(1/R^6)$. Some further approximations, necessary to obtain more explicit formulas, lead to an error estimate of order $\mathcal{O}(1/R^4)$ for the kinetic energy (1.6). These are the main ideas in the proof of the following theorem.

THEOREM 1.2. *Let us define*

$$\vec{R}_{\alpha\beta} = \vec{R}_\beta - \vec{R}_\alpha \quad \textit{for} \quad \alpha \neq \beta,\ \alpha = 1, \dots, N,\ \beta = 1, \dots, N.$$

For each pair α, β, with $\alpha \neq \beta$, we define a transformation $F^{\alpha\beta} : K_\beta \to K_\alpha$ which depends on T_α, T_β, and $\vec{R}_{\alpha\beta}$, whose 3×3 matrix has the following elements:

$$\begin{aligned} F_{lk}^{\alpha\beta} &= (F^{\alpha\beta}\vec{e}_{\beta k}\cdot\vec{e}_{\alpha l}) \\ &= \frac{1}{4\pi}\frac{1}{||\vec{R}_{\alpha\beta}||^3}\left\{(T_\beta\vec{e}_{\beta k}\cdot T_\alpha\vec{e}_{\alpha l}) - 3\frac{(\vec{e}_{\beta k}\cdot T_\beta^{-1}\vec{R}_{\alpha\beta})(T_\alpha^{-1}\vec{R}_{\alpha\beta}\cdot\vec{e}_{\alpha l})}{||\vec{R}_{\alpha\beta}||^2}\right\} \\ &= F_{kl}^{\beta\alpha} = \mathcal{O}\left(\frac{1}{R^3}\right). \end{aligned}$$

Then

$$\frac{\rho}{2}\int_S ||\nabla\Phi||^2 = \frac{1}{2}\sum_{\alpha=1}^{N}\sum_{i=1}^{6}\sum_{j=1}^{6} A_{ij}^{\alpha} c_{\alpha i} c_{\alpha j} + \frac{\rho}{2}\sum_{\alpha=1}^{N}\sum_{\substack{\beta\neq\alpha\\ \beta=1}}^{N}\sum_{i=1}^{6}\sum_{j=1}^{6}(\vec{\lambda}_{\alpha i}\cdot F^{\alpha\beta}\vec{\lambda}_{\beta j})c_{\alpha i}c_{\beta j} + \mathcal{O}\left(\frac{1}{R^4}\right),$$

where

$$c_{\alpha i} = v_{\alpha i}, \qquad c_{\alpha(i+3)} = \omega_{\alpha i}, \qquad i = 1, 2, 3.$$

The result in Theorem 1.2 can be written in different ways. At first let us represent $\vec{\lambda}_{\alpha i}$ as a column vector with 3 components $\lambda_{\alpha 1 i}, \lambda_{\alpha 2 i}, \lambda_{\alpha 3 i}$ and define a 3×6 matrix λ_α, where the ith column is given by $\vec{\lambda}_{\alpha i}$. We call λ_α the "form matrix." Let us represent $c_{\alpha 1}, \ldots, c_{\alpha 6}$ as a column vector c_α with 6 elements. Notice that $\lambda_\alpha c_\alpha$ is a column vector in K_α with 3 elements. Then the kinetic energy due to the interaction of bodies α and β is given by the quadratic function $(\lambda_\alpha c_\alpha \cdot F^{\alpha\beta}\lambda_\beta c_\beta)$. Notice that matrix $F^{\alpha\beta}$ does not depend on the geometric properties of bodies α and β but just on their relative position and orientation. We call $F^{\alpha\beta}$ the "interaction matrix." It is interesting to write the interaction matrix in a different way. Let $R_{\alpha\beta 1}, R_{\alpha\beta 2}, R_{\alpha\beta 3}$ be the three components of $\vec{R}_{\alpha\beta}$ and $P^{\alpha\beta}$ be the following matrix:

$$P^{\alpha\beta} \stackrel{\text{def}}{=} \frac{1}{||\vec{R}_{\alpha\beta}||^2}\begin{pmatrix} R_{\alpha\beta1}R_{\alpha\beta1} & R_{\alpha\beta1}R_{\alpha\beta2} & R_{\alpha\beta1}R_{\alpha\beta3} \\ R_{\alpha\beta2}R_{\alpha\beta1} & R_{\alpha\beta2}R_{\alpha\beta2} & R_{\alpha\beta2}R_{\alpha\beta3} \\ R_{\alpha\beta3}R_{\alpha\beta1} & R_{\alpha\beta3}R_{\alpha\beta2} & R_{\alpha\beta3}R_{\alpha\beta3} \end{pmatrix}.$$

This matrix defines a transformation $P^{\alpha\beta}: K \to K$ that projects any vector in K on a unit vector with the direction of $\vec{R}_{\alpha\beta}$ ($P^{\alpha\beta}P^{\alpha\beta} = \mathit{identity}$ and $P^{\alpha\beta}\vec{R}_{\alpha\beta} = \vec{R}_{\alpha\beta}$). Let $\mathbb{1}$ be the identity matrix and $G^{\alpha\beta}: K \to K$ be the transformation defined as

$$G^{\alpha\beta} \stackrel{\text{def}}{=} \frac{1}{4\pi||\vec{R}_{\alpha\beta}||^3}[\mathbb{1} - 3P^{\alpha\beta}]. \tag{1.7}$$

Then the interaction matrix can be factorized as

$$F^{\alpha\beta} = T_\alpha^{-1} G^{\alpha\beta} T_\beta, \tag{1.8}$$

where $G^{\alpha\beta}$ depends only on $\vec{R}_{\alpha\beta}$ (notice that $F^{\alpha\beta} = F^{\beta\alpha\dagger}$). As we will see this factorization simplifies a lot the derivation of the equations of motion from the Lagrangian function. Finally, using the form and the interaction matrices we can rewrite the result in Theorem 1.2 as

$$\frac{\rho}{2}\int_S ||\nabla\Phi||^2 = \frac{1}{2}\sum_{\alpha=1}^{N}\sum_{i=1}^{6}\sum_{j=1}^{6} A_{ij}^{\alpha} c_{\alpha i} c_{\alpha j} + \frac{\rho}{2}\sum_{\alpha=1}^{N}\sum_{\substack{\beta\neq\alpha\\ \beta=1}}^{N}(\lambda_\alpha c_\alpha \cdot F^{\alpha\beta}\lambda_\beta c_\beta) + \mathcal{O}\left(\frac{1}{R^4}\right). \tag{1.9}$$

Now, in order to explain the origin of the interaction matrix we differentiate the expansion in Proposition 1.1 to obtain the following proposition. (The symbol ∇

before a function refers to the gradient of the function with respect to the variables in its argument.)

PROPOSITION 1.3. *Let $\phi_{\alpha i}$ be the solution of problem* (1.2) *for $i = 1, 2, 3$ and of problem* (1.3) *for $i = 4, 5, 6$. Suppose that $\vec{x}_\alpha \in \partial B_\beta$, $\beta \neq \alpha$. Then the following expansions hold:*

$$T_\beta^{-1} T_\alpha \nabla \phi_{\alpha i}(\vec{x}_\alpha) = -\vec{f}_i^{\alpha\beta} + \mathcal{O}\left(\frac{1}{R^4}\right)$$

and

$$\phi_{\alpha i}(\vec{x}_\alpha) = \phi_{\alpha i}(T_\alpha^{-1}\vec{R}_{\alpha\beta}) - \vec{f}_i^{\alpha\beta} \cdot \vec{x}_\beta + \mathcal{O}\left(\frac{1}{R^4}\right),$$

where

$$\vec{f}_i^{\alpha\beta} = F^{\beta\alpha}\vec{\lambda}_{\alpha i} = \frac{1}{4\pi}\frac{1}{||\vec{R}_{\alpha\beta}||^5}\left\{||\vec{R}_{\alpha\beta}||^2 T_\beta^{-1} T_\alpha \vec{\lambda}_{\alpha i} - 3(T_\alpha \vec{\lambda}_{\alpha i} \cdot \vec{R}_{\alpha\beta}) T_\beta^{-1}\vec{R}_{\alpha\beta}\right\} \tag{1.10}$$

and

$$\vec{x}_\beta = T_\beta^{-1}(\vec{x} - \vec{R}_\beta) \quad \Rightarrow \quad \vec{x}_\alpha = T_\alpha^{-1}(\vec{R}_{\alpha\beta} + T_\beta \vec{x}_\beta).$$

Proposition 1.3 implies that $-\vec{f}_i^{\alpha\beta} = -F^{\beta\alpha}\vec{\lambda}_{\alpha i} \in K_\beta$ essentially represents the velocity of the fluid at the reference point of body β due to the unit velocity motion of body α in the "direction i," as if the latter were moving in the absence of all other bodies. The vector $\vec{f}_i^{\alpha\beta}$ is nondimensional for $i = 1, 2, 3$, and it has dimension of length for $i = 4, 5, 6$.

Our second main result concerns the problem of motion of a single body, referred as "body α," in $\mathbb{R}^3$ in the presence of N other rigid bodies which are held at rest. If we try to apply the formula in Theorem 1.2 to this problem, we just obtain the kinetic energy for the motion of a single isolated body given in (1.4). This problem requires a better approximation of Φ than that used in the proof of Theorem 1.2. This approximation is presented in section 2. The approximated expression for the kinetic energy in this case is given in the following theorem. The notation follows the one above. In this case $\vec{R}_\beta$, T_β, $\beta = 1, \ldots, N$, do not depend on time.

THEOREM 1.4. *Let us consider a system of $N + 1$ rigid bodies in an ideal irrotational fluid in $\mathbb{R}^3$. The body denoted by the letter α is free to move, but all others with indices $\beta = 1, \ldots, N$ are held at rest. Then*

$$\frac{\rho}{2}\int_S ||\nabla\Phi||^2 = \frac{1}{2}\sum_{i=1}^{6}\sum_{j=1}^{6} c_{\alpha i} c_{\alpha j}(A_{ij}^\alpha + C_{ij}^\alpha) + \mathcal{O}\left(\frac{1}{R^7}\right),$$

where

$$\begin{aligned} C_{ij}^\alpha = C_{ji}^\alpha &= \rho \sum_{\beta=1}^{N}\sum_{k=1}^{3}(\vec{\lambda}_{\beta k} \cdot F^{\beta\alpha}\vec{\lambda}_{\alpha j})(\vec{e}_{\beta k} \cdot F^{\beta\alpha}\vec{\lambda}_{\alpha i}) \\ &= \rho \sum_{\beta=1}^{N}\sum_{k=1}^{3}(\vec{\lambda}_{\beta k} \cdot \vec{f}_j^{\alpha\beta})(\vec{e}_{\beta k} \cdot \vec{f}_i^{\alpha\beta}) \\ &= \mathcal{O}\left(\frac{1}{R^6}\right), \end{aligned}$$

where $F^{\beta\alpha}$ *is defined in Theorem* 1.2 *and* $\vec{f}_i^{\alpha\beta}$ *is defined in* (1.10).

Again the result in Theorem 1.4 can be written in a more concise way. Let $\overline{\lambda}_{\beta\ (3\times3)}$ be the form matrix $\lambda_{\beta\ (3\times6)}$ restricted to its first three first columns. Let $Q : K \to K$ be the transformation defined by

$$Q = \sum_{\beta=1}^{N} G^{\alpha\beta} T_\beta \overline{\lambda}_\beta T_\beta^{-1} G^{\alpha\beta}, \tag{1.11}$$

where $G^{\alpha\beta}$ is defined in (1.7). Notice that Q depends on the position of body α but not on its orientation. These definitions imply that the result in Theorem 1.4 can be written as

$$\frac{\rho}{2}\int_S ||\nabla\Phi||^2 = \frac{1}{2}\left\{\sum_{i=1}^{6}\sum_{j=1}^{6} c_{\alpha i} c_{\alpha j} A_{ij}^{\alpha}\right\} + \frac{\rho}{2}(\lambda_\alpha c_\alpha \cdot T_\alpha^{\dagger} Q T_\alpha \lambda_\alpha c_\alpha) + \mathcal{O}\left(\frac{1}{R^7}\right). \tag{1.12}$$

The rest of this paper is organized as follows. In section 2 we present a variational principle which provides a "good" framework for obtaining approximations for integral (1.6). We then use this variational principle to obtain first approximations for integral (1.6) which, unfortunately, do not provide expressions as explicit and simple as those given in the above theorems. In section 3 we do further approximations to the expressions obtained in section 2 and compute the formulas in Theorems 1.2 and 1.4. In section 4 we obtain the equations of motion for a system of N rigid bodies in the case in which each body has three orthogonal planes of symmetry (like, for instance, a system of ellipsoids). The results in this section indicate how to obtain the equations of motion in the general case. In section 5 we apply Theorem 1.2 to some examples: a system of N spheres, a single sphere moving in a fluid containing other fixed spheres (it could be, for instance, an infinite cubic lattice of identical equally spaced fixed spheres), and a planar system of two bodies. For this last system we also present the equations of motion explicitly. It is interesting to point out that for the problem of two spheres moving on the line of centers, Smereka compared the approximation of Theorem 1.2 to a higher order one, of order $1/R^{12}$, due to Basset (see [6, eqn. (3.26) and Figure 2] and [10, Chapter XI, especially paragraphs 232, 233]). His conclusion was that the agreement between both approximations was very good (the relative error was of order 2/1000) even when the spheres touched. Other applications of Theorems 1.2 and 1.4 can be found in [15].

Finally, it is worth mentioning some words about the important issue of estimating the errors in the first and higher order derivatives of the approximated expressions presented in the above theorems. It is not hard to prove that the function defined by integral (1.6) depends analytically on $\vec{R}_\alpha$ and T_α for $\alpha = 1, \ldots, N$. This proof was essentially presented to me by the late Prof. Daniel Henry. It is a consequence of a general theory developed by himself for the dependence of solutions of elliptic problems on the shape of the domain. (This theory is explained in a book of his which will be published by Cambridge University Press.) This implies that we can differentiate function Φ with respect to $\vec{R}_\alpha$ infinitely many times and that these derivatives satisfy elliptic problems similar to those studied in this paper. In order to estimate the derivatives of the expressions in the above theorems we have to estimate solutions of these new elliptic problems. Though interesting, this problem will not be considered here.

2. The variational principle. Let S be the open set given by $\mathbb{R}^3$ minus the union of B_α, $\alpha = 1, \dots, N$. Let Φ be the solution of problem (1.5) which we write in a simpler way as

$$\begin{cases} \Delta\Phi(\vec{x}) = 0 & \text{for} \quad \vec{x} \in S, \\ \nabla\Phi(\vec{x}) \cdot \vec{n}(\vec{x}) = g(\vec{x}) & \text{for} \quad \vec{x} \in \partial S, \\ ||\nabla\Phi(\vec{x})|| \to 0 & \text{as} \quad ||\vec{x}|| \to \infty. \end{cases}$$

We recall that $\vec{n}$ is the unit normal to ∂S *pointing "inside"* S. We will denote by $\overline{S}$ the closure of S. Using Green's identities it is easy to prove the following theorem (see [17, exercise 8.4]).

THEOREM 2.1. *Let $\theta : \overline{S} \to \mathbb{R}$ be a continuously differentiable function such that the integral of $||\nabla\theta||^2$ over S exists. Then*

$$G(\Phi) \stackrel{\text{def}}{=} \int_S ||\nabla\Phi||^2 \geq -2\int_{\partial S} g\theta - \int_S ||\nabla\theta||^2 \stackrel{\text{def}}{=} F(\theta).$$

Moreover, if $\theta = \Phi + \delta$, then

$$G(\Phi) - F(\theta) = \int_S ||\nabla\delta||^2.$$

Proof. In order to prove the theorem we write $G(\Phi) - F(\Phi + \delta)$ explicitly. Then we use Green's identity to obtain

$$\int_{\partial S} \delta\nabla\Phi \cdot \vec{n} = -\int_S (\nabla\delta \cdot \nabla\Phi),$$
$$\int_{\partial S} \Phi\nabla\Phi \cdot \vec{n} = -\int_S ||\nabla\Phi||^2.$$

With these identities we remove the integrals over the boundary from $G(\Phi) - F(\Phi + \delta)$ and get $G(\Phi) - F(\Phi + \delta) = G(\delta) \geq 0$. Therefore, $F(\theta)$ takes its minimum value when $\theta = \Phi$. □

Notice that if $\Delta\theta = 0$, then using Green's identity again we obtain

$$\left| \int_S ||\nabla\Phi||^2 - F(\theta) \right| = \left| \int_S ||\nabla\delta||^2 \right| = \left| \int_{\partial S} \delta\nabla\delta \cdot \vec{n} \right|, \tag{2.1}$$

which means that the difference $|G(\Phi) - F(\theta)|$ depends quadratically on δ over the boundary ∂S. This enables us to compute the kinetic energy of the fluid with a great precision even if we only know the fluid velocity field approximately. We remark that variational tools similar to the one described above are used to compute capacities in electrostatics (see, for instance, [17]).

In order to prove Theorems 1.2 and 1.4 we use approximations θ_1 and θ_2 that are convenient sums of solutions of one-body problems. At first we restrict attention to θ_1, which is chosen as

$$\theta_1(\vec{x}) = \sum_{\alpha=1}^{N} \sum_{i=1}^{6} c_{\alpha i}\phi_{\alpha i}(\vec{x}_\alpha), \tag{2.2}$$

where $c_{\alpha i}$ is given in (1.1). Notice that θ_1 is harmonic in S, and for each given α it can be decomposed as

$$\begin{aligned}\theta_1(\vec{x}) &= \sum_{i=1}^{6} c_{\alpha i}\phi_{\alpha i}(\vec{x}_\alpha) + \sum_{\substack{\beta\neq\alpha\\ \beta=1}}^{N}\sum_{i=1}^{6} c_{\beta i}\phi_{\beta i}(\vec{x}_\beta)\\ &\stackrel{\text{def}}{=} \sum_{i=1}^{6} c_{\alpha i}\phi_{\alpha i}(\vec{x}_\alpha) + h_\alpha(\vec{x}).\end{aligned}$$

The estimates in Proposition 1.1 imply that for $\vec{x}\in\partial B_\alpha$,

$$h_\alpha(\vec{x}) = \mathcal{O}(1/R^2), \qquad \nabla h_\alpha(\vec{x}) = \mathcal{O}(1/R^3). \tag{2.3}$$

For $\vec{x}\in\partial B_\alpha$, using that

$$\begin{aligned}&\nabla\theta_1(\vec{x}) = \sum_{i=1}^{6} c_{\alpha i}T_\alpha\nabla\phi_{\alpha i}(\vec{x}_\alpha) + \nabla h_\alpha(\vec{x}),\\ &\nabla\phi_{\alpha i}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha) = \vec{\mathrm{e}}_{\alpha i}\cdot\vec{n}_\alpha(\vec{x}_\alpha) \qquad \text{for} \quad i=1,2,3,\\ &\nabla\phi_{\alpha i}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha) = \vec{\mathrm{e}}_{\alpha(i-3)}\times\vec{x}_\alpha\cdot\vec{n}_\alpha(\vec{x}_\alpha) \qquad \text{for} \quad i=4,5,6,\\ &T_\alpha\vec{n}_\alpha(\vec{x}_\alpha) = \vec{n}(\vec{x}),\end{aligned}$$

we obtain

$$\begin{aligned}\nabla\theta_1(\vec{x})\cdot\vec{n}(\vec{x}) &= \sum_{i=1}^{6} c_{\alpha i}[T_\alpha\nabla\phi_{\alpha i}(\vec{x}_\alpha)\cdot\vec{n}(\vec{x})] + \nabla h_\alpha(\vec{x})\cdot\vec{n}(\vec{x})\\ &= \sum_{i=1}^{6} c_{\alpha i}[\nabla\phi_{\alpha i}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha)] + \nabla h_\alpha(\vec{x})\cdot\vec{n}(\vec{x})\\ &= \left[\sum_{i=1}^{3} v_{\alpha i}\vec{\mathrm{e}}_{\alpha i}\cdot\vec{n}_\alpha(\vec{x}_\alpha)\right] + \left[\sum_{i=1}^{3}\omega_{\alpha i}\vec{\mathrm{e}}_{\alpha i}\times\vec{x}_\alpha\cdot\vec{n}_\alpha(\vec{x}_\alpha)\right] + \nabla h_\alpha(\vec{x})\cdot\vec{n}(\vec{x})\\ &= [\vec{v}_\alpha\cdot\vec{n}_\alpha(\vec{x}_\alpha)] + [\omega_\alpha\times\vec{x}_\alpha\cdot\vec{n}_\alpha(\vec{x}_\alpha)] + \nabla h_\alpha(\vec{x})\cdot\vec{n}(\vec{x})\\ &= [\vec{V}_\alpha + \vec{\Omega}_\alpha\times(\vec{x}-\vec{R}_\alpha)]\cdot\vec{n}(\vec{x}) + \nabla h_\alpha(\vec{x})\cdot\vec{n}(\vec{x}).\end{aligned}$$

This and the boundary conditions (1.5) verified by Φ implies that $\delta_1 = \theta_1 - \Phi$ satisfies

$$\begin{cases}\Delta\delta_1(\vec{x}) = 0 & \text{for} \quad \vec{x}\in S,\\ \nabla\delta_1(\vec{x})\cdot\vec{n}(\vec{x}) = \nabla h_\alpha(\vec{x})\cdot\vec{n}(\vec{x}) & \text{for} \quad \vec{x}\in\partial B_\alpha \quad \alpha=1,\dots,N,\\ ||\nabla\delta_1(\vec{x})|| \to 0 & \text{as} \quad ||\vec{x}||\to\infty.\end{cases} \tag{2.4}$$

So, from (2.3) we get that the normal derivative of δ_1 at ∂S is of the order $\mathcal{O}(1/R^3)$.

Now, let θ_2 be given by

$$\theta_2(\vec{x}) = \sum_{i=1}^{6} c_{\alpha i}\phi_{\alpha i}(\vec{x}_\alpha) + \sum_{\beta=1}^{N}\sum_{i=1}^{6}\sum_{j=1}^{3} c_{\alpha i}f_{ij}^{\alpha\beta}\phi_{\beta j}(\vec{x}_\beta), \tag{2.5}$$

where

$$f_{ij}^{\alpha\beta} \stackrel{\text{def}}{=} (\vec{f}_i^{\alpha\beta}\cdot\vec{\mathrm{e}}_{\beta j})$$

and $\vec{f}_i^{\alpha\beta}$ is defined in (1.10). Using Proposition 1.3 and an argument analogous to the one above we obtain that $\delta_2 = \theta_2 - \Phi$ satisfies

$$\text{(2.6)} \qquad \begin{cases} \Delta\delta_2(\vec{x}) = 0 & \text{for} \quad \vec{x} \in S, \\ \nabla\delta_2(\vec{x}) \cdot \vec{n}(\vec{x}) = \mathcal{O}(1/R^4) & \text{for} \quad \vec{x} \in \partial S, \\ ||\nabla\delta_2(\vec{x})|| \to 0 & \text{as} \quad ||\vec{x}|| \to \infty. \end{cases}$$

In order to estimate the difference $|G(\Phi) - F(\theta_l)|$, $l = 1, 2$, using (2.1) it is still necessary to find an upper bound for δ_l on ∂S. This is provided by the lemma below. Its proof is given in the appendix.

LEMMA 2.2. *Suppose that δ is a solution of either problem* (2.4) *or* (2.6) *with $\nabla\delta(\vec{x}) \cdot \vec{n}(\vec{x}) = \mathcal{O}(1/R^k)$ for $\vec{x} \in \partial S$. Then*

$$\max\{|\delta(\vec{x})| : \vec{x} \in \partial S\} = \mathcal{O}(1/R^k).$$

Finally, this lemma, the estimates for $\nabla\delta \cdot \vec{n}$, and (2.1) imply the following theorem.

THEOREM 2.3. *Let θ_1 and θ_2 be the approximations of Φ given in* (2.2) *and* (2.5)*, respectively. Then*

$$\left| \int_S ||\nabla\Phi||^2 + 2\int_{\partial S} \theta_k(\nabla\Phi \cdot \vec{n}) + \int_S ||\nabla\theta_k||^2 \right| = \mathcal{O}(1/R^{4+2k})$$

for $k = 1, 2$.

3. Proofs of Theorems 1.2 and 1.4. In general the functions $\phi_{\alpha i}$ are not known. Thus, it is not easy to directly obtain from Theorem 2.3 expressions that are so explicit as those presented in Theorems 1.2 and 1.4. So, in this section we do some approximations to the integrals in Theorem 2.3 and obtain Theorems 1.2 and 1.4. At first, we will prove Theorem 1.2.

From the definition of $F(\theta)$ in Theorem 2.1 and Green's identity we get

$$\text{(3.1)} \qquad F(\theta) = -2\int_{\partial S} \theta(\nabla\Phi \cdot \vec{n}) - \int_S ||\nabla\theta||^2 = \sum_{\alpha=1}^{N} \int_{\partial B_\alpha} \theta[-2\nabla\Phi \cdot \vec{n} + \nabla\theta \cdot n].$$

Using the definition of θ_1, (2.2), and Proposition 1.3 for $\vec{x} \in \partial B_\alpha$, we get

$$\nabla\theta_1(\vec{x}) \cdot \vec{n}(\vec{x}) = \nabla\Phi(\vec{x}) \cdot \vec{n}(\vec{x}) - \sum_{\substack{\beta=1 \\ \beta\neq\alpha}}^{N} \sum_{i=1}^{6} c_{\beta i} \vec{f}_i^{\beta\alpha} \cdot \vec{n}_\alpha(\vec{x}_\alpha) + \mathcal{O}\left(\frac{1}{R^4}\right).$$

This equation, the definition of θ_1, Proposition 1.3, and

$$\text{(3.2)} \qquad \int_{\partial B_\alpha} [\nabla\phi_{\alpha i}(\vec{x}_\alpha) \cdot \vec{n}_\alpha(\vec{x}_\alpha)] = 0$$

for $i = 1, \ldots, 6$ imply that $F(\theta_1)$ given by (3.1) can be written as

$$\begin{aligned} F(\theta_1) = &- \sum_{\alpha=1}^{N} \sum_{i=1}^{6} \sum_{j=1}^{6} c_{\alpha i} c_{\alpha j} \int_{\partial B_\alpha} \phi_{\alpha j}(\vec{x}_\alpha) \nabla\phi_{\alpha i}(\vec{x}_\alpha) \cdot \vec{n}_\alpha(\vec{x}_\alpha) \\ &+ \sum_{\alpha=1}^{N} \sum_{\substack{\beta=1 \\ \beta\neq\alpha}}^{N} \sum_{i=1}^{6} \sum_{j=1}^{6} c_{\alpha j} c_{\beta i} \left\{ - \int_{\partial B_\alpha} \phi_{\alpha j}(\vec{x}_\alpha) \vec{f}_i^{\beta\alpha} \cdot \vec{n}_\alpha(\vec{x}_\alpha) \right. \\ &\left. + \int_{\partial B_\alpha} (\vec{f}_i^{\beta\alpha} \cdot \vec{x}_\alpha)(\nabla\phi_{\alpha j}(\vec{x}_\alpha) \cdot \vec{n}_\alpha(\vec{x}_\alpha)) \right\} + \mathcal{O}\left(\frac{1}{R^4}\right). \end{aligned}$$

The formula in Theorem 1.2 is a consequence of this equation, Theorem 2.3,

$$-\int_{\partial B_\alpha} \phi_{\alpha j}(\vec{x}_\alpha)\nabla\phi_{\alpha i}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha) = \int_{\mathbb{R}^3-B_\alpha} \nabla\phi_{\alpha i}\cdot\nabla\phi_{\alpha j} = \frac{1}{\rho}A^\alpha_{ij}, \tag{3.3}$$

which is the ij added-mass coefficient of body α, and the following proposition.

PROPOSITION 3.1.

$$-\int_{\partial B_\alpha} \phi_{\alpha j}(\vec{x}_\alpha)\vec{f}_i^{\beta\alpha}\cdot\vec{n}_\alpha(\vec{x}_\alpha) + \int_{\partial B_\alpha}(\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\nabla\phi_{\alpha j}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha)) = (\vec{\lambda}_{\alpha j}\cdot\vec{f}_i^{\beta\alpha}).$$

Proof. Let us consider a large sphere Γ of radius R_Γ centered on B_α. Then using that $\phi_{\alpha j}$ and $\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha$ are harmonic outside B_α from Green's identity, we get

$$\begin{aligned}\int_{\partial B_\alpha} \phi_{\alpha j}(\vec{x}_\alpha)\vec{f}_i^{\beta\alpha}\cdot\vec{n}_\alpha(\vec{x}_\alpha) &+ \int_\Gamma \phi_{\alpha j}(\vec{x}_\alpha)\vec{f}_i^{\beta\alpha}\cdot\vec{n}_\alpha(\vec{x}_\alpha)\\ &= \int_{\partial B_\alpha}(\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\nabla\phi_{\alpha j}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha)) + \int_\Gamma(\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\nabla\phi_{\alpha j}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha)),\end{aligned}$$

which implies

$$\begin{aligned}-\int_{\partial B_\alpha} \phi_{\alpha j}(\vec{x}_\alpha)\vec{f}_i^{\beta\alpha}\cdot\vec{n}_\alpha(\vec{x}_\alpha) &+ \int_{\partial B_\alpha}(\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\nabla\phi_{\alpha j}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha))\\ &= \int_\Gamma \phi_{\alpha j}(\vec{x}_\alpha)\vec{f}_i^{\beta\alpha}\cdot\vec{n}_\alpha(\vec{x}_\alpha) - \int_\Gamma(\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\nabla\phi_{\alpha j}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha)).\end{aligned}$$

Using Proposition 1.1 we obtain

$$\int_\Gamma \phi_{\alpha j}(\vec{x}_\alpha)\vec{f}_i^{\beta\alpha}\cdot\vec{n}_\alpha(\vec{x}_\alpha) = -\frac{1}{4\pi}\int_\Gamma \frac{\vec{\lambda}_{\alpha j}\cdot\vec{x}_\alpha}{||\vec{x}_\alpha||^3}\vec{f}_i^{\beta\alpha}\cdot\vec{n}_\alpha(\vec{x}_\alpha) + \mathcal{O}\left(\frac{1}{R_\Gamma}\right). \tag{3.4}$$

Differentiating the approximation for $\phi_{\alpha j}$ in Proposition 1.1 we obtain

$$\nabla\phi_{\alpha j}(\vec{x}_\alpha) = -\frac{1}{4\pi||\vec{x}_\alpha||^5}\left\{||\vec{x}_\alpha||^2\vec{\lambda}_{\alpha j} - 3(\vec{\lambda}_{\alpha j}\cdot\vec{x}_\alpha)\vec{x}_\alpha\right\} + \mathcal{O}\left(\frac{1}{||\vec{x}_\alpha||^4}\right).$$

Using this approximation we obtain

$$\begin{aligned}\int_\Gamma(\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\nabla\phi_{\alpha j}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha)) = &-\frac{1}{4\pi}\int_\Gamma\frac{\vec{\lambda}_{\alpha j}\cdot\vec{n}_\alpha(\vec{x}_\alpha)}{||\vec{x}_\alpha||^3}\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha\\ &+\frac{3}{4\pi}\int_\Gamma\frac{(\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\vec{\lambda}_{\alpha j}\cdot\vec{x}_\alpha)(\vec{x}_\alpha\cdot\vec{n}_\alpha(\vec{x}_\alpha))}{||\vec{x}_\alpha||^5}\\ &+\mathcal{O}\left(\frac{1}{R_\Gamma}\right).\end{aligned}$$

This equation, equation (3.4), and the fact that for $\vec{x}_\alpha\in\Gamma$, $\vec{n}_\alpha(\vec{x}_\alpha) = -\vec{x}_\alpha/||\vec{x}_\alpha||$ imply that

$$\begin{aligned}\int_\Gamma \phi_{\alpha j}(\vec{x}_\alpha)\vec{f}_i^{\beta\alpha}\cdot\vec{n}_\alpha(\vec{x}_\alpha) &- \int_\Gamma(\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\nabla\phi_{\alpha j}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha))\\ &= -\frac{3}{4\pi}\int_\Gamma\frac{(\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\vec{\lambda}_{\alpha j}\cdot\vec{x}_\alpha)(\vec{x}_\alpha\cdot\vec{n}_\alpha(\vec{x}_\alpha))}{||\vec{x}_\alpha||^5} + \mathcal{O}\left(\frac{1}{R_\Gamma}\right).\end{aligned} \tag{3.5}$$

Using that $\vec{n}_\alpha(\vec{x}_\alpha) = -\vec{x}_\alpha/||\vec{x}_\alpha||$ we obtain

$$\frac{3}{4\pi}\int_\Gamma \frac{(\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\vec{\lambda}_{\alpha j}\cdot\vec{x}_\alpha)(\vec{x}_\alpha\cdot\vec{n}_\alpha(\vec{x}_\alpha))}{||\vec{x}_\alpha||^5} = \frac{3}{4\pi R_\Gamma^3}\int_\Gamma (\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\vec{\lambda}_{\alpha j}\cdot\vec{n}_\alpha(\vec{x}_\alpha)).$$

Using that $(\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)$ and $(\vec{\lambda}_{\alpha j}\cdot\vec{x}_\alpha)$ are harmonic functions in $\mathbb{R}^3$ from Green's identity, we get

$$\frac{3}{4\pi R_\Gamma^3}\int_\Gamma (\vec{f}_i^{\beta\alpha}\cdot\vec{x}_\alpha)(\vec{\lambda}_{\alpha j}\cdot\vec{n}_\alpha(\vec{x}_\alpha)) = -\frac{3}{4\pi R_\Gamma^3}\int_{Ball\ R_\Gamma} (\vec{f}_i^{\beta\alpha}\cdot\vec{\lambda}_{\alpha j}) = -(\vec{f}_i^{\beta\alpha}\cdot\vec{\lambda}_{\alpha j}).$$

Thus, taking the limit as $R_\Gamma \to \infty$ in (3.5), we prove the proposition. □

Now, we turn to the proof of Theorem 1.4. Using (3.1), the definition of θ_2, (2.5), Propositions 1.1 and 1.3, and (3.2) we obtain

$$\begin{aligned} F(\theta_2) = &-\sum_{i=1}^{6}\sum_{j=1}^{6} c_{\alpha i}c_{\alpha j}\int_{\partial B_\alpha}\phi_{\alpha j}(\vec{x}_\alpha)\nabla\phi_{\alpha i}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha) \\ &+\sum_{\beta=1}^{N}\sum_{i=1}^{6}\sum_{j=1}^{6}\sum_{k=1}^{3} c_{\alpha j}c_{\beta i}f_{ik}^{\alpha\beta}\left\{-\int_{\partial B_\alpha}\phi_{\alpha j}(\vec{x}_\alpha)\vec{f}_k^{\beta\alpha}\cdot\vec{n}_\alpha(\vec{x}_\alpha)\right. \\ &\left.+\int_{\partial B_\alpha}(\vec{f}_k^{\beta\alpha}\cdot\vec{x}_\alpha)(\nabla\phi_{\alpha j}(\vec{x}_\alpha)\cdot\vec{n}_\alpha(\vec{x}_\alpha))\right\}+\mathcal{O}\left(\frac{1}{R^7}\right). \end{aligned}$$

This equation, equation (3.3), Proposition 3.1, and Theorem 2.3 imply the formula in Theorem 1.4. The statement $C_{ij}^\alpha = C_{ji}^\alpha$ in Theorem 1.4 is a consequence of (1.12) and the symmetry of matrix Q given in (1.11). (Notice that both $G^{\alpha\beta}$ and $\overline{\lambda}_\beta$ are symmetric.)

4. The equations of motion. Let us consider a system of N rigid bodies such that each body has three orthogonal planes of symmetry. This implies that we can choose each reference frame K_α such that the added mass matrix A_{ij}^α is diagonal. We will assume this choice. In this case all coefficients of the form matrix $\lambda_{\alpha ij}$ are null for $i = 1, 2, 3$ and $j = 4, 5, 6$. So we can restrict the form matrix to its first three columns. To simplify the notation we keep denoting this restricted matrix by λ_α. Notice that λ_α is diagonal: $\lambda_{\alpha ii} = \eta_\alpha + \rho^{-1}A_{ii}^\alpha$, $i = 1, 2, 3$, $\alpha = 1, \dots, N$. Let us write the kinetic energy of the system as

$$W = \sum_{\alpha=1}^{N} W_\alpha + \frac{1}{2}\sum_{\alpha=1}^{N}\sum_{\substack{\beta=1\\ \beta\neq\alpha}}^{N} W_{\alpha\beta}, \tag{4.1}$$

where W_α is the kinetic energy of body α as if it were isolated and $W_{\alpha\beta}$ is the approximation for the kinetic energy of hydrodynamic interaction given in Theorem 1.2,

$$W_{\alpha\beta} = \rho(\lambda_\alpha\vec{v}_\alpha\cdot F^{\alpha\beta}\lambda_\beta\vec{v}_\beta) = W_{\beta\alpha}.$$

The kinetic energy W_α (equation (1.4)) can be written as

$$W_\alpha = \frac{1}{2}\left(\vec{v}_\alpha\cdot b^\alpha\vec{v}_\alpha + 2m_\alpha\vec{v}_\alpha\cdot(\vec{\omega}_\alpha\times\vec{\tau}_\alpha) + \vec{\omega}_\alpha\cdot\xi^\alpha\vec{\omega}_\alpha\right),$$

where b^α and ξ^α are matrices given by

$$
\begin{aligned}
&b^\alpha_{ij} = m_\alpha \delta_{ij} + A^\alpha_{ij}\delta_{ij}, \\
&\xi^\alpha_{ij} = I^\alpha_{ij} + A^\alpha_{(i+3)(j+3)}\delta_{ij} \qquad \text{for} \quad i = 1,2,3,\ j = 1,2,3,
\end{aligned} \tag{4.2}
$$

where $\delta_{ij} = 1$ if $i = j$, otherwise it is zero. In order to find the equations of motion we have to compute

$$
\frac{d}{dt}\nabla_{\vec{V}_\alpha} W - \nabla_{\vec{R}_\alpha} W,
$$
$$
\frac{d}{dt}\nabla_{\dot{\vec{\psi}}_\alpha} W - \nabla_{\psi_\alpha} W
$$

for $\alpha = 1, \dots, N$, where $V_\alpha = \dot{\vec{R}}_\alpha$ and ψ_α is any set of three angles $\psi_{\alpha 1}, \psi_{\alpha 2}, \psi_{\alpha 3}$ that parameterize the attitude matrix T_α. (It can be the Euler angles, for instance.) Due to the decomposition (4.1) of W, the equations of motion are sums of terms of the following types:

$$
\frac{d}{dt}\nabla_{\vec{V}_\alpha} W_\alpha - \nabla_{\vec{R}_\alpha} W_\alpha, \tag{4.3}
$$

$$
\frac{d}{dt}\nabla_{\dot{\vec{\psi}}_\alpha} W_\alpha - \nabla_{\psi_\alpha} W_\alpha, \tag{4.4}
$$

$$
\frac{d}{dt}\nabla_{\vec{V}_\alpha} W_{\alpha\beta} - \nabla_{\vec{R}_\alpha} W_{\alpha\beta}, \tag{4.5}
$$

$$
\frac{d}{dt}\nabla_{\dot{\vec{\psi}}_\alpha} W_{\alpha\beta} - \nabla_{\psi_\alpha} W_{\alpha\beta}, \tag{4.6}
$$

where $\beta \neq \alpha$. There are two main difficulties in computing these derivatives. The first difficulty is the amount of terms that have to be differentiated and that appear in the final equation of motion. In order to partially overcome this problem we define some tensors that allow us to simplify the computations and the final result. The second difficulty is related to the angle parameterization of the attitude matrices. We overcome this problem by using some identities for derivatives of orthogonal matrices that are independent of the particular choice of angle parameterization. We remark that the expressions resulting from (4.3) and (4.4) are well known. They correspond to the equations of motion for an isolated body (Kirchhoff's equations). Here we indicate how to obtain them from the Lagrangian W_α to show how to handle derivatives with respect to angular velocities. Notice that angular velocities do not appear in the particular $W_{\alpha\beta}$ considered in this section, but they do appear in $W_{\alpha\beta}$ for systems of bodies of more complex geometry.

Let us start computing (4.5). Using (1.8), that $\vec{V}_\alpha = T_\alpha \vec{v}_\alpha$, and the identification $T_\alpha^{-1} = T_\alpha^\dagger$, we write

$$
W_{\alpha\beta} = \rho(\vec{V}_\alpha \cdot T_\alpha \lambda_\alpha T_\alpha^\dagger G^{\alpha\beta} T_\beta \lambda_\beta T_\beta^\dagger \vec{V}_\beta). \tag{4.7}
$$

This implies that

$$
\frac{1}{\rho}\nabla_{\vec{V}_\alpha} W_{\alpha\beta} = T_\alpha \lambda_\alpha T_\alpha^\dagger G^{\alpha\beta} T_\beta \lambda_\beta T_\beta^\dagger \vec{V}_\beta
$$

and that

$$\frac{1}{\rho}\frac{d}{dt}\nabla_{\vec{V}_\alpha} W_{\alpha\beta} = \dot{T}_\alpha\lambda_\alpha T_\alpha^\dagger G^{\alpha\beta} T_\beta\lambda_\beta T_\beta^\dagger \vec{V}_\beta + T_\alpha\lambda_\alpha \dot{T}_\alpha^\dagger G^{\alpha\beta} T_\beta\lambda_\beta T_\beta^\dagger \vec{V}_\beta \tag{4.8}$$

$$+ T_\alpha\lambda_\alpha T_\alpha^\dagger G^{\alpha\beta} \dot{T}_\beta\lambda_\beta T_\beta^\dagger \vec{V}_\beta + T_\alpha\lambda_\alpha T_\alpha^\dagger G^{\alpha\beta} T_\beta\lambda_\beta \dot{T}_\beta^\dagger \vec{V}_\beta \tag{4.9}$$

$$+ T_\alpha\lambda_\alpha T_\alpha^\dagger \dot{G}^{\alpha\beta} T_\beta\lambda_\beta T_\beta^\dagger \vec{V}_\beta \tag{4.10}$$

$$+ T_\alpha\lambda_\alpha T_\alpha^\dagger G^{\alpha\beta} T_\beta\lambda_\beta T_\beta^\dagger \dot{\vec{V}}_\beta. \tag{4.11}$$

The time derivatives of the attitude matrices are related to the angular velocities in the following way. Matrix T_α satisfies $T_\alpha T_\alpha^\dagger = \mathbb{1}$. Differentiating this relation we get $\dot{T}_\alpha T_\alpha^\dagger = -T_\alpha \dot{T}_\alpha^\dagger$, which implies that $\dot{T}_\alpha T_\alpha^\dagger$ is antisymmetric. The angular velocities $\vec{\Omega}_\alpha$, $\vec{\omega}_\alpha$ are vectors whose components satisfy

$$\dot{T}_\alpha T_\alpha^\dagger \stackrel{\text{def}}{=} \hat{\Omega}_\alpha = \begin{pmatrix} 0 & -\Omega_{\alpha 3} & \Omega_{\alpha 2} \\ \Omega_{\alpha 3} & 0 & -\Omega_{\alpha 1} \\ -\Omega_{\alpha 2} & \Omega_{\alpha 1} & 0 \end{pmatrix} \tag{4.12}$$

and

$$T_\alpha^\dagger(\dot{T}_\alpha T_\alpha^\dagger)T_\alpha = T_\alpha^\dagger \dot{T}_\alpha \stackrel{\text{def}}{=} \hat{\omega}_\alpha = \begin{pmatrix} 0 & -\omega_{\alpha 3} & \omega_{\alpha 2} \\ \omega_{\alpha 3} & 0 & -\omega_{\alpha 1} \\ -\omega_{\alpha 2} & \omega_{\alpha 1} & 0 \end{pmatrix}. \tag{4.13}$$

Notice that $\hat{\Omega}_\alpha : K \to K$ and $\hat{\omega}_\alpha : K_\alpha \to K_\alpha$ are antisymmetric transformations. For any vector $\vec{U} \in K$ or $\vec{u} \in K_\alpha$ the following identities hold:

$$\dot{T}_\alpha T_\alpha^\dagger \vec{U} = \hat{\Omega}_\alpha \vec{U} = \vec{\Omega}_\alpha \times \vec{U}, \qquad \dot{T}_\alpha^\dagger \dot{T}_\alpha \vec{u} = \hat{\omega}_\alpha \vec{u} = \vec{\omega}_\alpha \times \vec{u}.$$

Sometimes we write $\dot{T}_\alpha^\dagger \dot{T}_\alpha \vec{u} = \hat{\omega}_\alpha \vec{u}$, sometimes $\dot{T}_\alpha^\dagger \dot{T}_\alpha \vec{u} = \vec{\omega}_\alpha \times \vec{u}$. For each $\alpha = 1, \ldots, N$, we write the form matrix in the inertial reference frame K as

$$T_\alpha \lambda_\alpha T_\alpha^\dagger = \Lambda_\alpha. \tag{4.14}$$

With this notation we get that line (4.8) becomes

$$\dot{T}_\alpha\lambda_\alpha T_\alpha^\dagger G^{\alpha\beta} T_\beta\lambda_\beta T_\beta^\dagger \vec{V}_\beta + T_\alpha\lambda_\alpha \dot{T}_\alpha^\dagger G^{\alpha\beta} T_\beta\lambda_\beta T_\beta^\dagger \vec{V}_\beta = [\hat{\Omega}_\alpha\Lambda_\alpha - \Lambda_\alpha\hat{\Omega}_\alpha] G^{\alpha\beta}\Lambda_\beta \vec{V}_\beta \tag{4.15}$$

and line (4.9) becomes

$$T_\alpha\lambda_\alpha T_\alpha^\dagger G^{\alpha\beta} \dot{T}_\beta\lambda_\beta T_\beta^\dagger \vec{V}_\beta + T_\alpha\lambda_\alpha T_\alpha^\dagger G^{\alpha\beta} T_\beta\lambda_\beta \dot{T}_\beta^\dagger \vec{V}_\beta = \Lambda_\alpha G^{\alpha\beta}[\hat{\Omega}_\beta\Lambda_\beta - \Lambda_\beta\hat{\Omega}_\beta]\vec{V}_\beta. \tag{4.16}$$

In order to handle the derivative $\dot{G}^{\alpha\beta}$ we define a tensor $H^{\alpha\beta}$ that with each vector $\vec{U} \in K$ associates a linear transformation $H^{\alpha\beta}(\vec{U})$ in K. The components of $H^{\alpha\beta}$ are

$$H_{ijk}^{\alpha\beta} = \frac{\partial G_{ij}^{\alpha\beta}}{\partial R_{\alpha\beta k}} = -\frac{3}{4\pi||\vec{R}_{\alpha\beta}||^5}\left\{ R_{\alpha\beta k}\delta_{ij} + R_{\alpha\beta i}\delta_{kj} + R_{\alpha\beta j}\delta_{ik} - 5\frac{R_{\alpha\beta i}R_{\alpha\beta j}R_{\alpha\beta k}}{||\vec{R}_{\alpha\beta}||^2}\right\}, \tag{4.17}$$

where i, j, k take values in $1, 2, 3$ and $\delta_{ij} = 1$ if $i = j$, otherwise it is zero. Notice that $H^{\alpha\beta}$ is a totally symmetric tensor. If $\vec{U}$ and $\vec{W}$ are arbitrary vectors in K, then

$$H^{\alpha\beta}(\vec{U})\vec{W} = -\frac{3}{4\pi||\vec{R}_{\alpha\beta}||^5}\Bigg\{\vec{R}_{\alpha\beta}(\vec{U}\cdot\vec{V}) + \vec{U}(\vec{R}_{\alpha\beta}\cdot\vec{V}) + \vec{V}(\vec{R}_{\alpha\beta}\cdot\vec{U}) - 5\frac{\vec{R}_{\alpha\beta}(\vec{R}_{\alpha\beta}\cdot\vec{U})(\vec{R}_{\alpha\beta}\cdot\vec{V})}{||\vec{R}_{\alpha\beta}||^2}\Bigg\}. \tag{4.18}$$

With this definition, after working with each coordinate separately, we get

$$\begin{aligned}\Lambda_\alpha\dot{G}^{\alpha\beta}\Lambda_\beta V_\beta - \nabla_{\vec{R}_{\alpha\beta}}W_{\alpha\beta} \\ = \Lambda_\alpha H^{\alpha\beta}(\Lambda_\beta\vec{V}_\beta)\vec{V}_\beta + [H^{\alpha\beta}(\Lambda_\beta\vec{V}_\beta)\Lambda_\alpha - \Lambda_\alpha H^{\alpha\beta}(\Lambda_\beta\vec{V}_\beta)]\vec{V}_\alpha.\end{aligned} \tag{4.19}$$

Finally, from (4.19), (4.16), (4.15), (4.11), (4.10), (4.9), and (4.8) we get

$$\begin{aligned}&\frac{d}{dt}\nabla_{\vec{V}_\alpha}W_{\alpha\beta} - \nabla_{\vec{R}_\alpha}W_{\alpha\beta} \\ &= \rho[\hat{\Omega}_\alpha\Lambda_\alpha - \Lambda_\alpha\hat{\Omega}_\alpha]G^{\alpha\beta}\Lambda_\beta\vec{V}_\beta + \rho\Lambda_\alpha G^{\alpha\beta}[\hat{\Omega}_\beta\Lambda_\beta - \Lambda_\beta\hat{\Omega}_\beta]\vec{V}_\beta + \rho\Lambda_\alpha G^{\alpha\beta}\Lambda_\beta\dot{\vec{V}}_\beta \\ &+ \rho\Lambda_\alpha H^{\alpha\beta}(\Lambda_\beta\vec{V}_\beta)\vec{V}_\beta + \rho[H^{\alpha\beta}(\Lambda_\beta\vec{V}_\beta)\Lambda_\alpha - \Lambda_\alpha H^{\alpha\beta}(\Lambda_\beta\vec{V}_\beta)]\vec{V}_\alpha.\end{aligned} \tag{4.20}$$

We remark that the force terms in line (4.20) are of order $\mathcal{O}(1/R^4)$ while the terms in the previous line are of order $\mathcal{O}(1/R^3)$.

Let us compute (4.6). Now, we have to differentiate T_α with respect to the angles $\psi_{\alpha i}$, $i = 1, 2, 3$. In the same way we defined the angular velocities Ω_α, (4.12), and ω_α, (4.13), we define vectors $\vec{\Gamma}_{\alpha i}$ and $\vec{\gamma}_{\alpha i}$, $i = 1, 2, 3$, that have components $\Gamma_{\alpha i1}, \Gamma_{\alpha i2}, \Gamma_{\alpha i3}$ and $\gamma_{\alpha i1}, \gamma_{\alpha i2}, \gamma_{\alpha i3}$, respectively, given by

$$\left(\frac{\partial T_\alpha}{\partial\psi_{\alpha i}}\right)T_\alpha^\dagger = \begin{pmatrix} 0 & -\Gamma_{\alpha i3} & \Gamma_{\alpha i2} \\ \Gamma_{\alpha i3} & 0 & -\Gamma_{\alpha i1} \\ -\Gamma_{\alpha i2} & \Gamma_{\alpha i1} & 0 \end{pmatrix} \tag{4.21}$$

and

$$T_\alpha^\dagger\frac{\partial T_\alpha}{\partial\psi_{\alpha i}} = \begin{pmatrix} 0 & -\gamma_{\alpha i3} & \gamma_{\alpha i2} \\ \gamma_{\alpha i3} & 0 & -\gamma_{\alpha i1} \\ -\gamma_{\alpha i2} & \gamma_{\alpha i1} & 0 \end{pmatrix}. \tag{4.22}$$

This definition implies that for any vectors $\vec{U} \in K$, $\vec{u} \in K_\alpha$ the following identities hold:

$$\left(\frac{\partial T_\alpha}{\partial\psi_{\alpha i}}\right)T_\alpha^\dagger\vec{U} = \vec{\Gamma}_{\alpha i}\times\vec{U}, \qquad T_\alpha^\dagger\frac{\partial T_\alpha}{\partial\psi_{\alpha i}}\vec{u} = \vec{\gamma}_{\alpha i}\times\vec{u}.$$

Using that $W_{\alpha\beta}$ does not depend on $\dot{\psi}_{\alpha i}$, the above definition of $\vec{\Gamma}_{\alpha i}$, and some easy vector identities, we get

$$\begin{aligned}\frac{d}{dt}\frac{\partial}{\partial\dot{\psi}_{\alpha i}}W_{\alpha\beta} - \frac{\partial}{\partial\psi_{\alpha i}}W_{\alpha\beta} \\ = \rho(\vec{\Gamma}_{\alpha i}\cdot\{[\vec{V}_\alpha\times\Lambda_\alpha G^{\alpha\beta}\Lambda_\beta\vec{V}_\beta] - [(\Lambda_\alpha\vec{V}_\alpha)\times G^{\alpha\beta}\Lambda_\beta\vec{V}_\beta]\}).\end{aligned}$$

Using the linear independence of $\vec{\Gamma}_{\alpha i}$, $i = 1, 2, 3$, we get

$$\begin{aligned} &\frac{d}{dt}\nabla_{\dot{\psi}_\alpha} W_{\alpha\beta} - \nabla_{\psi_\alpha} W_{\alpha\beta} \\ &\qquad = \rho[\vec{V}_\alpha \times \Lambda_\alpha G^{\alpha\beta}\Lambda_\beta \vec{V}_\beta] - \rho[(\Lambda_\alpha \vec{V}_\alpha) \times G^{\alpha\beta}\Lambda_\beta \vec{V}_\beta]. \end{aligned} \tag{4.23}$$

We remark that the torque on the right-hand side of this equation is of order $\mathcal{O}(1/R^3)$.

The computation of (4.3) uses only arguments similar to those given above. So in this case we just present the final result. Let B^α and Ξ^α be the inertia and moment of inertia matrices given in the inertial reference frame, namely

$$B^\alpha = T_\alpha b^\alpha T_\alpha^\dagger, \qquad \Xi^\alpha = T_\alpha \xi^\alpha T_\alpha^\dagger, \tag{4.24}$$

where b^α and ξ^α were defined in (4.2). Then

$$\begin{aligned} &\frac{d}{dt}\nabla_{\vec{V}_\alpha} W_\alpha - \nabla_{\vec{R}_\alpha} W_\alpha \\ &\qquad = B\dot{\vec{V}}_\alpha + m_\alpha \dot{\vec{\Omega}}_\alpha \times (T_\alpha \vec{\tau}_\alpha) + m_\alpha \vec{\Omega}_\alpha \times [\vec{\Omega}_\alpha \times (T_\alpha \vec{\tau}_\alpha)] \\ &\qquad\quad + [\vec{\Omega}_\alpha \times B\vec{V}_\alpha] - B[\vec{\Omega}_\alpha \times \vec{V}_\alpha]. \end{aligned} \tag{4.25}$$

The computation of (4.4) involves derivatives of W_α with respect to $\dot{\psi}_{\alpha i}$, which did not appear yet. In this case, in order to get a final expression that does not depend on a particular parameterization of T_α we have to use the following identities:

$$\vec{\Gamma}_{\alpha i} \times \vec{\Gamma}_{\alpha j} = \frac{\partial \vec{\Gamma}_{\alpha j}}{\partial \psi_{\alpha i}} - \frac{\partial \vec{\Gamma}_{\alpha i}}{\partial \psi_{\alpha j}}, \tag{4.26}$$

$$\vec{\gamma}_{\alpha i} \times \vec{\gamma}_{\alpha j} = \frac{\partial \vec{\gamma}_{\alpha i}}{\partial \psi_{\alpha j}} - \frac{\partial \vec{\gamma}_{\alpha j}}{\partial \psi_{\alpha i}}, \tag{4.27}$$

and

$$\begin{aligned} \vec{\Omega}_\alpha &= \dot{\psi}_{\alpha 1}\vec{\Gamma}_{\alpha 1} + \dot{\psi}_{\alpha 2}\vec{\Gamma}_{\alpha 2} + \dot{\psi}_{\alpha 3}\vec{\Gamma}_{\alpha 3}, \\ \vec{\omega}_\alpha &= \dot{\psi}_{\alpha 1}\vec{\gamma}_{\alpha 1} + \dot{\psi}_{\alpha 2}\vec{\gamma}_{\alpha 2} + \dot{\psi}_{\alpha 3}\vec{\gamma}_{\alpha 3}. \end{aligned} \tag{4.28}$$

These identities are used in the following way. Let us consider the part of (4.4) given by

$$\frac{d}{dt}\frac{\partial}{\partial \dot{\psi}_{\alpha i}}\frac{\vec{\omega}_\alpha \cdot \xi^\alpha \vec{\omega}_\alpha}{2} - \frac{\partial}{\partial \psi_{\alpha i}}\frac{\vec{\omega}_\alpha \cdot \xi^\alpha \vec{\omega}_\alpha}{2}.$$

Using (4.28) and that ξ^α does not depend on time, we get

$$\frac{d}{dt}\frac{\partial}{\partial \dot{\psi}_{\alpha i}}\frac{\vec{\omega}_\alpha \cdot \xi^\alpha \vec{\omega}_\alpha}{2} = \vec{\gamma}_{\alpha i} \cdot \xi^\alpha \dot{\vec{\omega}}_\alpha + (\xi^\alpha \vec{\omega}_\alpha) \cdot \sum_{j=1}^{3} \dot{\psi}_{\alpha j}\frac{\partial \vec{\gamma}_{\alpha i}}{\partial \psi_{\alpha j}}.$$

Then using (4.27) we get

$$\begin{aligned}
&\frac{d}{dt}\frac{\partial}{\partial\dot{\psi}_{\alpha i}}\frac{\vec{\omega}_\alpha\cdot\xi^\alpha\vec{\omega}_\alpha}{2}-\frac{\partial}{\partial\psi_{\alpha i}}\frac{\vec{\omega}_\alpha\cdot\xi^\alpha\vec{\omega}_\alpha}{2}\\
&\qquad=\vec{\gamma}_{\alpha i}\cdot\xi^\alpha\dot{\vec{\omega}}_\alpha+(\xi^\alpha\vec{\omega}_\alpha)\cdot\sum_{j=1}^{3}\dot{\psi}_{\alpha j}\left[\frac{\partial\vec{\gamma}_{\alpha i}}{\partial\psi_{\alpha j}}-\frac{\partial\vec{\gamma}_{\alpha j}}{\partial\psi_{\alpha i}}\right]\\
&\qquad=\vec{\gamma}_{\alpha i}\cdot\xi^\alpha\dot{\vec{\omega}}_\alpha+(\xi^\alpha\vec{\omega}_\alpha)\cdot\sum_{j=1}^{3}\dot{\psi}_{\alpha j}[\vec{\gamma}_{\alpha i}\times\vec{\gamma}_{\alpha j}]\\
&\qquad=\vec{\gamma}_{\alpha i}\cdot[\xi^\alpha\dot{\vec{\omega}}_\alpha+(\vec{\omega}_\alpha\times\xi^\alpha\vec{\omega}_\alpha)]\\
&\qquad=\vec{\Gamma}_{\alpha i}\cdot[\Xi^\alpha\dot{\vec{\Omega}}_\alpha+(\vec{\Omega}_\alpha\times\Xi^\alpha\vec{\Omega}_\alpha)],
\end{aligned}$$

where in the last line we used that $\vec{\Gamma}_{\alpha i}=T_\alpha\vec{\gamma}_{\alpha i}$ and $\dot{\vec{\Omega}}_\alpha=T_\alpha\dot{\vec{\omega}}_\alpha$. Using these ideas and some well-known vector identities, we obtain

$$\begin{aligned}
&\frac{d}{dt}\nabla_{\dot{\vec{\psi}}_\alpha}W_\alpha-\nabla_{\psi_\alpha}W_\alpha\\
&\qquad=\Xi^\alpha\dot{\vec{\Omega}}_\alpha+m_\alpha(T_\alpha\vec{\tau}_\alpha)\times\dot{\vec{V}}_\alpha+\vec{\Omega}_\alpha\times(\Xi^\alpha\vec{\Omega}_\alpha)+\vec{V}_\alpha\times(B\vec{V}_\alpha).
\end{aligned}\tag{4.29}$$

Equations (4.20), (4.23), (4.25), and (4.29) are given in the inertial reference frame K. It is also possible to write the full system of equations choosing for each equation containing W_α the reference frame K_α. This is the approach taken in the trivial case of a system with only one body, since the attitude matrix disappears from the equations of motion. This advantage is obviously lost when there is more then one body. Nevertheless, it is still interesting to write the equations in the reference frame of each body especially when the bodies are far a way. In this case the attitude matrices appear only in the weak coupling term that corresponds to $W_{\alpha\beta}$. Below, we write equations (4.20), (4.23), (4.25), and (4.29) in the reference frame K_α:

$$\begin{aligned}
&T_\alpha^\dagger\left\{\frac{d}{dt}\nabla_{\vec{V}_\alpha}W_{\alpha\beta}-\nabla_{\vec{R}_\alpha}W_{\alpha\beta}\right\}\\
&\qquad=\rho[\hat{\omega}_\alpha\lambda_\alpha-\lambda_\alpha\hat{\omega}_\alpha]F^{\alpha\beta}\lambda_\beta\vec{v}_\beta+\rho\lambda_\alpha F^{\alpha\beta}\hat{\omega}_\beta\lambda_\beta\vec{v}_\beta\\
&\qquad\quad+\rho\lambda_\alpha F^{\alpha\beta}\lambda_\beta\dot{\vec{v}}_\beta+\rho\lambda_\alpha T_\alpha^\dagger H^{\alpha\beta}(T_\beta\lambda_\beta\vec{v}_\beta)T_\beta\vec{v}_\beta\\
&\qquad\quad+\rho[T_\alpha^\dagger H^{\alpha\beta}(T_\beta\lambda_\beta\vec{v}_\beta)T_\alpha\lambda_\alpha-\lambda_\alpha T_\alpha^\dagger H^{\alpha\beta}(T_\beta\lambda_\beta\vec{v}_\beta)T_\alpha]\vec{v}_\alpha,
\end{aligned}\tag{4.30}$$

$$\begin{aligned}
&T_\alpha^\dagger\left\{\frac{d}{dt}\nabla_{\dot{\psi}_\alpha}W_{\alpha\beta}-\nabla_{\psi_\alpha}W_{\alpha\beta}\right\}\\
&\qquad=\rho[\vec{v}_\alpha\times\lambda_\alpha F^{\alpha\beta}\lambda_\beta\vec{v}_\beta]-\rho[(\lambda_\alpha\vec{v}_\alpha)\times F^{\alpha\beta}\lambda_\beta\vec{v}_\beta],
\end{aligned}\tag{4.31}$$

$$\begin{aligned}
&T_\alpha^\dagger\left\{\frac{d}{dt}\nabla_{\vec{V}_\alpha}W_\alpha-\nabla_{\vec{R}_\alpha}W_\alpha\right\}\\
&\qquad=b^\alpha\dot{\vec{v}}_\alpha+m_\alpha\dot{\vec{\omega}}_\alpha\times\vec{\tau}_\alpha+m_\alpha\vec{\omega}_\alpha\times[\vec{\omega}_\alpha\times\tau_\alpha]+[\vec{\omega}_\alpha\times b^\alpha\vec{v}_\alpha],
\end{aligned}\tag{4.32}$$

$$\begin{aligned}
&T_\alpha^\dagger\left\{\frac{d}{dt}\nabla_{\dot{\vec{\psi}}_\alpha}W_\alpha-\nabla_{\psi_\alpha}W_\alpha\right\}\\
&\qquad=\xi^\alpha\dot{\vec{\omega}}_\alpha+m_\alpha\vec{\tau}_\alpha\times\dot{\vec{v}}_\alpha+m_\alpha\vec{\tau}_\alpha\times(\omega_\alpha\times\vec{v}_\alpha)\\
&\qquad\quad+\vec{\omega}_\alpha\times(\xi^\alpha\vec{\omega}_\alpha)+\vec{v}_\alpha\times(b^\alpha\vec{v}_\alpha).
\end{aligned}\tag{4.33}$$

5. Examples.

5.1. Many balls. The added-mass coefficients for a single ball of radius a_α with respect to its center are $A^\alpha_{ii} = \frac{2}{3}\pi\rho a^3_\alpha$ for $i = 1, 2, 3$, and all the remaining coefficients are zero. The volume of the ball is $\eta_\alpha = \frac{4}{3}\pi a^3_\alpha$, and its center of volume is $\vec{\xi}_\alpha = \vec{0}$. Therefore, $\vec{\lambda}_{\alpha i} = 2\pi a^3_\alpha \vec{e}_{\alpha i}$, $i = 1, 2, 3$, $\vec{\lambda}_{\alpha i} = \vec{0}$, $i = 4, 5, 6$, and $\lambda_\alpha c_\alpha = 2\pi a^3_\alpha \vec{v}_\alpha$. Let us consider a system of N balls of radii a_α, $\alpha = 1, \dots, N$. Then from Theorem 1.2, equations (1.7) and (1.8) the kinetic energy of the system is approximately given by

$$\frac{1}{2}\sum_{\alpha=1}^{N}\left(m_\alpha + \frac{2}{3}\pi a^3_\alpha \rho\right)||\vec{V}_\alpha||^2 + \frac{\rho}{2}\sum_{\alpha=1}^{N}\sum_{\substack{\beta\neq\alpha\\ \beta=1}}^{N}\frac{\pi a^3_\alpha a^3_\beta}{||\vec{R}_{\alpha\beta}||^3}\left\{(\vec{V}_\alpha\cdot\vec{V}_\beta) - 3\frac{(\vec{V}_\alpha\cdot\vec{R}_{\alpha\beta})(\vec{V}_\beta\cdot\vec{R}_{\alpha\beta})}{||\vec{R}_{\alpha\beta}||^2}\right\},$$

where m_α is the mass of ball α. The formulas in this paragraph had been previously obtained in [4] and [6].

5.2. A ball moving in an environment containing many fixed balls. Let us assume that a ball of radius a_α is moving in a fluid of density ρ in $\mathbb{R}^3$ in the presence of N fixed balls of radius b_β, $\beta = 1, \dots, N$, which are not close to each other. Then, from Theorem 1.4, equations (1.11) and (1.12) we get that the kinetic energy of the system is approximately

$$\frac{1}{2}\left(m_\alpha + \frac{2}{3}\pi a^3_\alpha \rho\right)||\vec{V}_\alpha||^2 + \frac{\rho\pi a^6_\alpha}{4}\sum_{\beta=1}^{N}\frac{b^3_\beta}{||\vec{R}_{\alpha\beta}||^6}\left\{||\vec{V}_\alpha||^2 + 3\frac{(\vec{V}_\alpha\cdot\vec{R}_{\alpha\beta})(\vec{V}_\alpha\cdot\vec{R}_{\alpha\beta})}{||\vec{R}_{\alpha\beta}||^2}\right\},$$

where $\vec{R}_{\alpha\beta} = \vec{R}_\beta - \vec{R}_\alpha$ and $\vec{R}_\beta$ is fixed. Notice that using this formula we can get an approximation for the kinetic energy of a ball of radius a moving in a fluid that contains an infinite cubic lattice of fixed equal balls of radius b, provided the lattice spacing is sufficiently larger than a and b. It is easy to check that the infinite sum that appears in this case converges absolutely. This is in contrast to the case of a ball in a box with periodic boundary conditions, where certain sum rules have to be assumed in order to overcome the problem of nonabsolute convergence of an analogous series (see [6]).

5.3. Two bodies moving on a plane. Let us consider a system of two bodies that can freely move on a plane X, Y. For simplicity we will assume that each body is symmetric with respect to two orthogonal lines. We choose the reference point in each body at the intersection of these two lines. In order to make easier the distinction between body labels and coordinate labels, we use α and β to indicate the first and the second body, respectively. Let $\vec{R}_\alpha$, $\vec{R}_\beta$, ψ_α, and ψ_β be the configuration coordinates of the system as shown in Figure 5.1. Notice that

$$T_\alpha(\psi_\alpha) = \begin{pmatrix} \cos\psi_\alpha & -\sin\psi_\alpha \\ \sin\psi_\alpha & \cos\psi_\alpha \end{pmatrix}, \quad T_\beta(\psi_\beta) = \begin{pmatrix} \cos\psi_\beta & -\sin\psi_\beta \\ \sin\psi_\beta & \cos\psi_\beta \end{pmatrix}$$

and $\vec{\omega}_\alpha = \dot{\psi}_\alpha \vec{e}_3$, $\vec{\omega}_\beta = \dot{\psi}_\beta \vec{e}_3$, where $\vec{e}_3$ is a fixed unit vector perpendicular to the plane of motion. The inertia and form coefficients of each body are as follows:

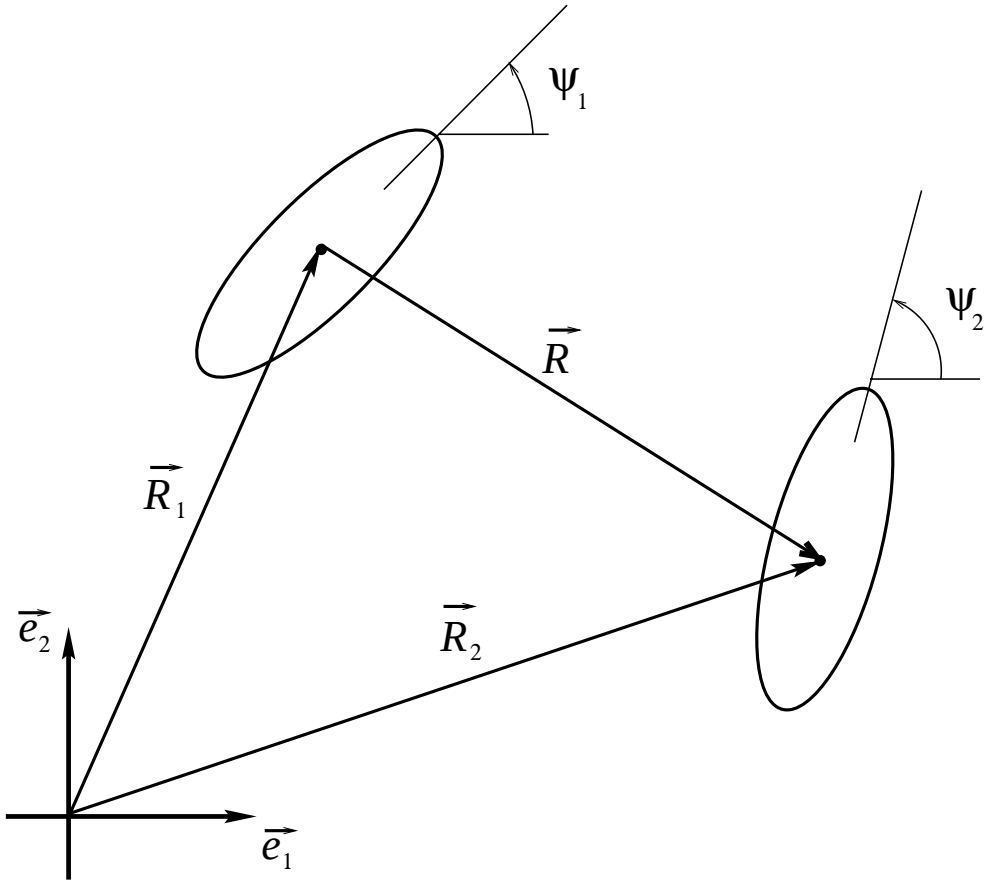

FIG. 5.1. *Diagram showing the coordinates used to describe the two-body system example of section* 5.3.

moment of inertia coefficients: I_{33}^{α} (body 1), I_{33}^{β} (body 2);
added mass matrices:

$$\begin{pmatrix} A_{11}^{\alpha} & 0 & 0 \\ 0 & A_{22}^{\alpha} & 0 \\ 0 & 0 & A_{66}^{\alpha} \end{pmatrix}, \quad \begin{pmatrix} A_{11}^{\beta} & 0 & 0 \\ 0 & A_{22}^{\beta} & 0 \\ 0 & 0 & A_{66}^{\beta} \end{pmatrix};$$

masses: m_{α} and m_{β};
inertia matrices (according to (4.2)):

$$b^{\alpha} = \begin{pmatrix} m_{\alpha} + A_{11}^{\alpha} & 0 \\ 0 & m_{\alpha} + A_{22}^{\alpha} \end{pmatrix}, \quad b^{\beta} = \begin{pmatrix} m_{\beta} + A_{11}^{\beta} & 0 \\ 0 & m_{\beta} + A_{22}^{\beta} \end{pmatrix},$$

and

$$\xi_{33}^{\alpha} = I_{33}^{\alpha} + A_{66}^{\alpha}, \quad \xi_{33}^{\beta} = I_{33}^{\beta} + A_{66}^{\beta};$$

centers of mass: $\vec{\tau}_\alpha \stackrel{\text{def}}{=} \tau_\alpha \vec{e}_{11}$ and $\vec{\tau}_\beta \stackrel{\text{def}}{=} \tau_\beta \vec{e}_{21}$;
volumes: η_α and η_β;
centers of volume: $\vec{\xi}_\alpha = \vec{0}$ and $\vec{\xi}_\beta = \vec{0}$.

For this system the form matrices λ_α and λ_β can be written as 2×2 matrices:

$$\lambda_\alpha = \begin{pmatrix} \eta_\alpha + \rho^{-1} A_{11}^\alpha & 0 \\ 0 & \eta_\alpha + \rho^{-1} A_{22}^\alpha \end{pmatrix}, \quad \lambda_\beta = \begin{pmatrix} \eta_\beta + \rho^{-1} A_{11}^\beta & 0 \\ 0 & \eta_\beta + \rho^{-1} A_{22}^\beta \end{pmatrix}.$$

The interaction matrix $F^{\alpha\beta}$ can be also written as a 2×2 matrix (since our symmetry assumptions imply $F_{16}^{\alpha\beta} = F_{26}^{\alpha\beta} = F_{61}^{\alpha\beta} = F_{62}^{\alpha\beta} = F_{66}^{\alpha\beta} = 0$):

$$\begin{pmatrix} F_{11}^{\alpha\beta} & F_{12}^{\alpha\beta} \\ F_{21}^{\alpha\beta} & F_{22}^{\alpha\beta} \end{pmatrix} = T_\alpha^\dagger G^{\alpha\beta} T_\beta.$$

Defining

$$\vec{R}_\beta - \vec{R}_\alpha \stackrel{\text{def}}{=} \vec{R} = (R_1 \vec{e}_1 + R_2 \vec{e}_2),$$

to simplify the notation, we get from (1.7)

$$G^{\alpha\beta} = \frac{1}{4\pi ||\vec{R}||^3} \left\{ \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} - \frac{3}{||\vec{R}||^2} \begin{pmatrix} R_1 R_1 & R_1 R_2 \\ R_2 R_1 & R_2 R_2 \end{pmatrix} \right\}.$$

It is also convenient to define vectors $\vec{W}_\alpha$ and $\vec{W}_\beta$ in K given by

$$\vec{W}_\alpha \stackrel{\text{def}}{=} T_\alpha \lambda_\alpha \vec{v}_\alpha, \qquad \vec{W}_\beta \stackrel{\text{def}}{=} T_\beta \lambda_\beta \vec{v}_\beta.$$

Then from (4.17) we get

$$H^{\alpha\beta}(\vec{W}_\beta) = -\frac{3}{4\pi ||\vec{R}||^5} \cdot \left\{ \begin{pmatrix} 3W_{\beta 1} R_1 + W_{\beta 2} R_2 & W_{\beta 1} R_2 + W_{\beta 2} R_1 \\ W_{\beta 1} R_2 + W_{\beta 2} R_1 & 3W_{\beta 2} R_2 + W_{\beta 1} R_1 \end{pmatrix} - \frac{5(\vec{R} \cdot \vec{W}_\beta)}{||\vec{R}||^2} \begin{pmatrix} R_1 R_1 & R_1 R_2 \\ R_2 R_1 & R_2 R_2 \end{pmatrix} \right\}.$$

Now, from (4.30) and (4.32) we get the following equation for the velocities of body α written in the reference frame K_α:

$$\begin{aligned}
&b^\alpha \dot{\vec{v}}_\alpha + m_\alpha \tau_\alpha \ddot{\psi}_\alpha \vec{e}_{\alpha 2} - m_\alpha \tau_\alpha \dot{\psi}_\alpha^2 \vec{e}_{\alpha 1} + \dot{\psi}_\alpha \vec{e}_3 \times (b^\alpha \vec{v}_\alpha) \\
&+ (A_{11}^\alpha - A_{22}^\alpha) \dot{\psi}_\alpha \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} F^{\alpha\beta} \lambda_\beta \vec{v}_\beta \qquad (5.1) \\
&+ \rho \dot{\psi}_\beta \lambda_\alpha F^{\alpha\beta} [\vec{e}_3 \times (\lambda_\beta \vec{v}_\beta)] + \rho \lambda_\alpha F^{\alpha\beta} \lambda_\beta \dot{\vec{v}}_\beta \qquad (5.2) \\
&+ \rho \lambda_\alpha T_\alpha^\dagger H^{\alpha\beta}(\vec{W}_\beta) T_\beta \vec{v}_\beta \qquad (5.3) \\
&+ (A_{11}^\alpha - A_{22}^\alpha) \left[H_{12}^{\alpha\beta}(\vec{W}_\beta) \cos(2\psi_\alpha) + \frac{H_{22}^{\alpha\beta}(\vec{W}_\beta) - H_{11}^{\alpha\beta}(\vec{W}_\beta)}{2} \sin(2\psi_\alpha) \right] (\vec{e}_3 \times \vec{v}_\alpha) \\
&= \vec{f}_\alpha, \qquad (5.4)
\end{aligned}$$

where $\vec{f}_\alpha \in K_\alpha$ represents other forces that may act on body α. Notice that the terms in lines (5.1) and (5.2) are of order $\mathcal{O}(1/R^3)$ while those in lines (5.3) and (5.4) are of order $\mathcal{O}(1/R^4)$.

From (4.31) and (4.33) we get the following equations for the angular motion of body α:

$$\begin{aligned} &\xi^{\alpha}_{33}\ddot{\psi}_{\alpha} + m_{\alpha}\tau_{\alpha}\dot{v}_{\alpha 2} + m_{\alpha}\tau_{\alpha}\dot{\psi}_{\alpha}v_{\alpha 1} + (A^{\alpha}_{22} - A^{\alpha}_{11})v_{\alpha 1}v_{\alpha 2} \\ &\quad + (A^{\alpha}_{22} - A^{\alpha}_{11})\vec{v}_{\alpha}\cdot\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} F^{\alpha\beta}\lambda_{\beta}\vec{v}_{\beta} \\ &\quad = n_{\alpha}, \end{aligned} \tag{5.5}$$

where n_α represents other torques that may act in body α. Notice that the term in line (5.5) is of order $\mathcal{O}(1/R^3)$. To get the equations for body β it is enough to change α for β in the equations above.

Appendix. In this appendix we prove Lemma 2.2, namely we show that if δ is a solution of

$$\begin{cases} \Delta\delta(\vec{x}) = 0 & \text{for} \quad \vec{x} \in S, \\ \nabla\delta(\vec{x})\cdot\vec{n}(\vec{x}) = g(\vec{x}) = \mathcal{O}(1/R^k) & \text{for} \quad \vec{x} \in \partial S, \\ ||\nabla\delta(\vec{x})|| \to 0 & \text{as} \quad ||\vec{x}|| \to \infty, \end{cases}$$

then

$$||\delta||_{\partial S\infty} \stackrel{\text{def}}{=} \sup\{|\delta(\vec{x})| : \vec{x} \in \partial S\} = \mathcal{O}\left(\frac{1}{R^k}\right).$$

The proof requires several well-known results that can be found in partial differential equations textbooks. Here we will often refer to the book of Folland [18]. If function g is continuous, then δ is continuous in $\overline{S}$, it is differentiable in S, and its derivative in the direction of the normal to ∂S has a continuous extension to ∂S ([18, Chapter 3A]). Then for $\vec{x} \in S$, the following identity holds (Green's third identity; see the remark below Proposition 3.3 in [18]):

$$\delta(\vec{x}) = -\int_{\partial S}\delta(\vec{y})[\nabla_y\psi(\vec{x},\vec{y})\cdot\vec{n}(\vec{y})]d\sigma(\vec{y}) + \int_{\partial S}[\nabla_y\delta(\vec{y})\cdot\vec{n}(\vec{y})]\psi(\vec{x},\vec{y})d\sigma(\vec{y}), \tag{A.1}$$

where

$$\psi(\vec{x},\vec{y}) = -\frac{1}{4\pi}\frac{1}{||\vec{x}-\vec{y}||}$$

is the Newtonian potential and $d\sigma$ is the element of area on ∂S.

For any $\vec{x} \in \mathbb{R}^3$, there exists $C_1'(\alpha) > 0$, $\alpha = 1, \ldots, N$, such that

$$\int_{\partial B_\alpha}|\psi(\vec{x},\vec{y})|d\sigma(\vec{y}) < C_1'(\alpha).$$

So defining $C_1 = C_1'(1) + \cdots + C_1'(N)$ we obtain that for any $\vec{x} \in \mathbb{R}^3$:

$$\left|\int_{\partial S}[\nabla_y\delta(\vec{y})\cdot\vec{n}(\vec{y})]\psi(\vec{x},\vec{y})d\sigma(\vec{y})\right| = \left|\int_{\partial S} g(y)\psi(\vec{x},\vec{y})d\sigma(\vec{y})\right| \le C_1||g||_{\partial S\infty}. \tag{A.2}$$

Now we need the following result [18, Theorem 3.22].

THEOREM A.1. *Let ∂B be the twice continuously differentiable boundary of a bounded open set B (which may have several components) in R^3 and S be the open*

set of points in $\mathbb{R}^3$ *outside* $B \cup \partial B$. *Let* f *be a real valued continuous function in* ∂B *and* u *be a function in* $B \cup S$ *given by*

$$u(\vec{x}) = \int_S f(\vec{y})[\nabla_y \psi(\vec{x}, \vec{y}) \cdot \vec{n}(\vec{y})] d\sigma(\vec{y}),$$

where $\vec{n}$ *points outside* B. *Then* u *has continuous extensions* u_- *and* u_+ *to* $\overline{B}$ *and* $\overline{S}$, *respectively. Moreover, for* $\vec{x} \in \partial B$,

$$u_-(\vec{x}) = \frac{1}{2} f(\vec{x}) + \int_{\partial B} f(\vec{y})[\nabla_y \psi(\vec{x}, \vec{y}) \cdot \vec{n}(\vec{y})] d\sigma(\vec{y}),$$
$$u_+(\vec{x}) = -\frac{1}{2} f(\vec{x}) + \int_{\partial B} f(\vec{y})[\nabla_y \psi(\vec{x}, \vec{y}) \cdot \vec{n}(\vec{y})] d\sigma(\vec{y}).$$

Let $\vec{x}_*$ be a point in ∂B_α for a particular value of α, such that

$$|\delta(\vec{x}_*)| = ||\delta||_{\partial S \infty}.$$

Then taking $\vec{x} \to \vec{x}_*$, $\vec{x} \in S$, from Theorem A.1 we obtain

$$\delta(\vec{x}) + \int_{\partial S} \delta(\vec{y})[\nabla_y \psi(\vec{x}, \vec{y}) \cdot \vec{n}(\vec{y})] d\sigma(\vec{y}) \to \frac{1}{2}\delta(\vec{x}_*)$$
$$+ \int_{\partial B_\alpha} \delta(\vec{y})[\nabla_y \psi(\vec{x}_*, \vec{y}) \cdot \vec{n}(\vec{y})] d\sigma(\vec{y}) + \sum_{\substack{\beta \neq \alpha \\ \beta = 1}}^{N} \int_{\partial B_\beta} \delta(\vec{y})[\nabla_y \psi(\vec{x}_*, \vec{y}) \cdot \vec{n}(\vec{y})] d\sigma(\vec{y}).$$

(A.3)

If $\vec{y} \in \partial B_\beta$ and $\vec{x}_* \in \partial B_\alpha$, then $||\nabla_y \psi(\vec{x}_*, \vec{y})|| = \mathcal{O}(||\vec{x}_* - \vec{y}||^{-2})$. So there exists $\overline{R} > 0$ and $C_2'(\beta) > 0$ such that for $\beta \neq \alpha$ and $R > \overline{R}$ the following inequality holds:

$$\int_{\partial B_\beta} |[\nabla_y \psi(\vec{x}_*, \vec{y}) \cdot \vec{n}(\vec{y})]| d\sigma(\vec{y}) < \frac{C_2}{R^2}.$$

Defining $C_2 = \sum_{\beta \neq \alpha} C_2'(\beta)$ this implies that for $R > \overline{R}$,

$$\left| \sum_{\substack{\beta \neq \alpha \\ \beta = 1}}^{N} \int_{\partial B_\beta} \delta(\vec{y})[\nabla_y \psi(\vec{x}_*, \vec{y}) \cdot \vec{n}(\vec{y})] d\sigma(\vec{y}) \right| \leq ||\delta||_{\partial S \infty} \frac{C_2}{R^2}. \tag{A.4}$$

Now, taking the limit as $\vec{x} \to \vec{x}_*$, $\vec{x} \in S$, in (A.1) using (A.3) and inequalities (A.2) and (A.4), we get for $R > \overline{R}$

$$|\mathcal{F}(\delta)(\vec{x}_*)| \stackrel{\text{def}}{=} \left| \frac{1}{2}\delta(\vec{x}_*) + \int_{\partial B_\alpha} \delta(\vec{y})[\nabla_y \psi(\vec{x}_*, \vec{y}) \cdot \vec{n}(\vec{y})] d\sigma(\vec{y}) \right|$$
$$\leq ||\delta||_{\partial S \infty} \frac{C_2}{R^2} + C_1 ||g||_{\partial S \infty}. \tag{A.5}$$

From Theorem A.1 with $B = B_\alpha$ we notice that

$$\mathcal{F}(\delta)(\vec{x}_*) = \frac{1}{2}\delta(\vec{x}_*) + \int_{\partial B_\alpha} \delta(\vec{y})[\nabla_y \psi(\vec{x}_*, \vec{y}) \cdot \vec{n}(\vec{y})] d\sigma(\vec{y})$$

is the boundary value of a function δ_- that is harmonic inside the open set B_α. The mapping $\delta \to \mathcal{F}(\delta)$, from the Banach space of continuous functions on ∂B_α with the supremum norm to itself, is a bounded linear bijection (see, for instance, [18, Chapter 3, section E] or [19, section 9.2]). Thus by Banach's inverse theorem (see [20, Chap. 4, section 4, Theorem 3]) the inverse operator of $\mathcal{F}$ is also bounded, namely, there exists a constant C_3 which depends on ∂B_α such that

$$||\delta||_{\partial S\infty} = ||\delta||_{\partial B_\alpha \infty} \leq C_3 \sup_{\vec{x}\in\partial B_\alpha} \left| \frac{1}{2}\delta(\vec{x}) + \int_{\partial B_\alpha} \delta(\vec{y})[\nabla_y \psi(\vec{x},\vec{y})\cdot \vec{n}(\vec{y})]d\sigma(\vec{y}) \right|.$$

From this inequality and inequality (A.5) we obtain

$$||\delta||_{\partial S\infty} \leq ||\delta||_{\partial S\infty} \frac{C_3 C_2}{R^2} + C_1 C_3 ||g||_{\partial S\infty},$$

or using that $||g||_{\partial S\infty} = \mathcal{O}(1/R^k)$,

$$||\delta||_{\partial S\infty} \left(1 - \frac{C_3 C_2}{R^2}\right) \leq \mathcal{O}\left(\frac{1}{R^k}\right),$$

which implies

$$||\delta||_{\partial S\infty} = \mathcal{O}\left(\frac{1}{R^k}\right).$$

Acknowledgments. I am very grateful to J. A. P. Aranha for all his suggestions and for reading the original manuscript. I thank J. Koiller for having suggested some references. I am especially grateful to the late Prof. Daniel Henry to whom this paper is dedicated. He had always helped me in so many different subjects including some of those addressed in the present paper.

A CANARD MECHANISM FOR LOCALIZATION IN SYSTEMS OF GLOBALLY COUPLED OSCILLATORS*

HORACIO G. ROTSTEIN[†‡], NANCY KOPELL[†], ANATOL M. ZHABOTINSKY[‡], AND IRVING R. EPSTEIN[‡]

Abstract. Localization in a discrete system of oscillators refers to the partition of the population into a subset that oscillates at high amplitudes and another that oscillates at much lower amplitudes. Motivated by experimental results on the Belousov–Zhabotinsky reaction, which oscillates in the relaxation regime, we study a mechanism of localization in a discrete system of relaxation oscillators globally coupled via inhibition. The mechanism is based on the canard phenomenon for a single relaxation oscillator: a rapid explosion in the amplitude of the limit cycle as a parameter governing the relative position of the nullclines is varied. Starting from a parameter regime in which each uncoupled oscillator has a large amplitude and no other periodic or other stable solutions, we show that the canard phenomenon can be induced by increasing a global negative feedback parameter γ, with the network then partitioned into low and high amplitude oscillators. For the case in which the oscillators are synchronous within each of the two such populations, we can assign a canard-inducing critical value of γ separately to each of the two clusters; localization occurs when the value for the system is between the critical values of the two clusters. We show that the larger the cluster size, the smaller is the corresponding critical value of γ, implying that it is the smaller cluster that oscillates at large amplitude. The theory shows that the above results come from a kind of self-inhibition of each cluster induced by the local feedback. In the full system, there are also effects of interactions between the clusters, and we present simulations showing that these nonlocal interactions do not destroy the localization created by the self-inhibition.

Key words. canard phenomenon, globally coupled oscillators, relaxation oscillator, localization of oscillations

1. Introduction.

The Belousov–Zhabotinsky (BZ) reaction is the prototype system in nonlinear chemical dynamics [1, 2, 3] (see references therein). In bulk, it is a relaxation oscillator. A wide variety of spatially extended patterns have been found in experiments on this reaction. Along with the experiments, chemically plausible mathematical models have been proposed and studied both analytically and numerically. The results obtained qualitatively reproduce experimental findings. Recently, new patterns have been found as nondiffusive couplings have been experimentally and numerically introduced.

In particular, the existence of localized oscillatory clusters has been reported in [4, 5] for the BZ reaction with global inhibitory feedback. Simulations performed on the Oregonator model [5] and a modified Oregonator model [6] of the BZ reaction, both with global inhibitor feedback, reproduce the experimental findings. However, the mechanism by which localized cluster formation occurs remains unclear from both the mathematical and chemical points of view.

We consider as a cluster a set of "cells" or "chemical points" of the reactor that oscillate synchronously with the same amplitude. In certain cases, depending on some parameter, only two different amplitude regimes of oscillations occur: large amplitude oscillations (LAO) and small amplitude oscillations (SAO). The LAO regime consists of limit cycles whose amplitudes are O(1), i.e., almost equal to the maximum amplitude of the limit cycle for a single uncoupled oscillator, whereas the SAO regime consists of limit cycles whose amplitudes are of order of magnitude $\epsilon \ll 1$. In such cases there is a range of amplitudes that is not observable because they occur in an exponentially small interval of the governing parameter. When the system is divided into two or more clusters and at least one oscillates in an LAO regime and one in an SAO regime, we say that the clusters are localized. Clusters that are in the same amplitude regime may oscillate with a small difference in their amplitudes (compared with the LAO), but we do not refer to that situation as a localization phenomenon. Note that our definition of clusters does not require oscillators in each cluster to be spatially grouped; we disregard spatial structure in this work.

The localized cluster patterns found in the experiments and simulations on the BZ reaction with global inhibitory feedback [4, 5, 6] present two main features that might seem counterintuitive:

1. Two different oscillatory regimes coexist in a system of identical coupled oscillators.
2. The cluster with the largest number of oscillators is always in the SAO regime whereas the smallest clusters are in an LAO regime; one might expect the largest cluster to be oscillating in an LAO regime and suppressing the smaller ones as occurs in other systems, e.g., neural systems with inhibitory synapses, with all-to-all identical coupling. In this latter case, if one cluster has a larger number of cells than the others, the former can suppress the latter.

In this paper we seek to explain the mechanism of localization for globally coupled relaxation oscillators of the FitzHugh–Nagumo (FHN) type, along with the two features mentioned above. The FHN-type models were chosen as simplifications of the Oregonator models. Although they are not precise as descriptions of chemical phenomena, they display the localization phenomenon and are easier to study analytically in order to give some insight into the dynamical mechanisms that produce localized solutions. In addition, they display some of the relevant qualitative features of the modified Oregonator model studied in [6], such as the shape of the nullclines, the fact that the limit cycle is created in a supercritical Hopf bifurcation, and the relaxation nature of the oscillator. In a forthcoming paper we will address the questions related to the mechanism of localization in the modified version of the Oregonator used in [6, 7].

We argue that the mechanism of localization is based on the canard phenomenon that occurs in single relaxation oscillators. The canard phenomenon is a very rapid change in the amplitude of the limit cycle of a relaxation oscillator as the inhibitor nullcline moves with respect to the activator nullcline [11, 12, 13, 14, 15, 16]. It arises in the context of experiments and simulations of nonlinear chemical dynamics [17, 18, 19] and in a two-pool model describing the mechanism of calcium-induced calcium release [20, 21].

The mechanism of localization in oscillatory systems, not of the relaxation type, has been studied in [8, 9, 10] for nonidentical diffusively coupled oscillators. To our knowledge, the mechanism of localization in relaxation-type oscillators has not been analyzed before.

In section 2 we present a general formulation for a class of models of globally coupled oscillators of FHN type that include the modified FHN (MFHN) models studied in this manuscript. For single FHN-type oscillators, the fast variable nullcline is cubic-like and intersects, on its middle branch, the slow variable nullcline, an increasing function. The parameters were chosen such that this intersection is an unstable fixed point. In section 3 we explain the reduction of dimensions strategy, a self-consistent argument that reduces the dimensionality of the mathematical problem by assuming the existence of M clusters, each with a different dynamical behavior (different amplitudes, phases or both). Within each cluster, the oscillators synchronize.

In section 4 we describe the canard phenomenon for a single FHN-type equation and review some results. Following [15], we present a mathematical expression for an asymptotic approximation to the "canard critical value" for the parameter λ, the parameter responsible for the displacement of the slow variable nullcline relative to the fast variable nullcline, as a function of the remaining parameters of the model. When, by increasing or decreasing λ through a critical value λ_c, there is a sudden change (of canard type) in the amplitude of the limit cycle, we say that the canard phenomenon has been induced by changes in λ, and we call λ_c the canard critical value of λ. Strictly speaking, the sudden change in the amplitude of the limit cycle takes place in an exponentially small interval of values of λ; the canard critical value is the limit of the interval as $\epsilon \to 0$.

In section 5 we show that, when there are synchronized (bulk) oscillations for the globally coupled system (only one cluster), the canard phenomenon may be induced by increasing the value of the global feedback parameter γ and keeping λ fixed. In the FHN-type models with global feedback presented here, as well as in the BZ model with global feedback used in [6], the intersection point between nullclines remains fixed as γ is increased. When $\gamma = 0$ (no global feedback) the uncoupled oscillators are in an LAO regime; localization for these models is a consequence of the global coupling. An asymptotic approximation to the critical global feedback value, γ_c, is also calculated as a function of λ and other parameters of the model. These results are the basis of our analysis of the localization phenomenon.

The localization phenomenon for a two-cluster system, in which one cluster is in an LAO regime and the other is in an SAO regime, is analyzed in section 6. The dynamics of the two-cluster globally coupled system is analyzed by studying each cluster separately and considering the other cluster as forcing it. Under specific assumptions, this dynamics is a combination of self-inhibition of each cluster, responsible for creating an interval of values of γ within which a localized solution may exist, and inhibition (forcing) exerted on each cluster by the remaining ones. We show that self-inhibition is stronger the larger the cluster size, which explains why in a localized solution the largest cluster is in an SAO regime. We show that, for the special case of the van der Pol (VDP) equations with global feedback, localization is produced by only the self-inhibition, and the forcing exerted on each cluster by the other does not affect localization. In this paper we analyze only the effect of self-inhibition; however, we present some simulations of other globally coupled FHN systems that support our claim that the localization phenomenon is present with the same features predicted theoretically. In section 7, we relate our results to experiments and simulations.

2. Models. In this paper we study models of the type

$$\begin{cases} v_k' = F(v_k, w_k) - \gamma\ (\langle w \rangle - \bar{w}), \\ w_k' = \epsilon\ G(v_k, w_k; \lambda) \end{cases} \tag{1}$$

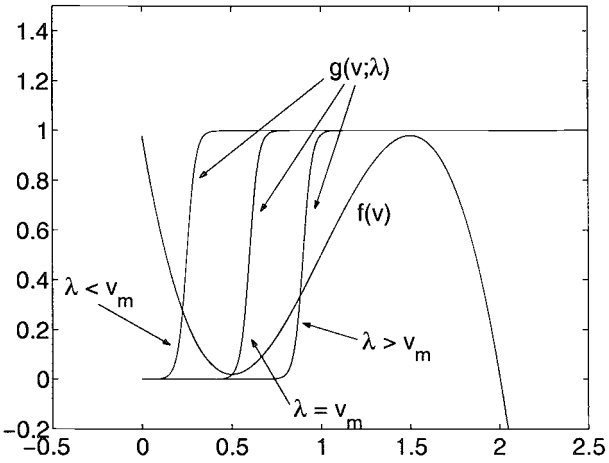

FIG. 1. *Nullclines for a sigmoid version of the FHN model for several values of* $\lambda = \bar{v} - v_{min}$ *(the intersection point between nullclines).*

for $k = 1, \ldots, N$ and $0 < \epsilon \ll 1$. In (1), $F(v, w)$ is such that the zero level curve $F(v, w) = 0$ can be expressed as $w = f(v)$ with $f(v)$ a cubic-like function having one local minimum at (v_m, w_m) and one local maximum at (v_M, w_M) with $v_m < v_M$ and $w_m < w_M$. The function G is a nonincreasing function of w such that the zero level curve $G(v, w; \lambda) = 0$ is an increasing function of v for every λ in a given neighborhood of $\lambda = 0$ and is also a decreasing function of λ for all v in a neighborhood of v_m. We further assume that $F = 0$ and $G = 0$ intersect at $(\bar{v}, \bar{w})$ with $\bar{v} = v_m$ when $\lambda = 0$ and that $(\bar{v}, \bar{w})$ is an unstable fixed point lying on the central branch of f when $\lambda > 0$. The constant γ is the global feedback parameter, and $\langle w \rangle$ is given by

$$\langle w \rangle = \frac{1}{N} \sum_{k=1}^{N} w_k. \tag{2}$$

Note that $(\bar{v}, \bar{w})$ does not depend on γ, as we can see by replacing $\langle w \rangle$ by $\bar{w}$ in (1). In all models considered here, the systems are assumed to be in a relaxation oscillatory regime in the absence of global coupling ($\gamma = 0$). For $\gamma = 0$, changes in the parameter λ alter the position of the w_k nullcline (see Figure 1). When this nullcline moves, the intersection point $(\bar{v}, \bar{w})$ changes. As we will explain in section 4, without loss of generality we can redefine λ such that $\lambda = \bar{v}$. In the literature v is usually referred to as the activator or the "potential" variable and w as the "inhibitor" or the recovery variable.

Some specific systems may be modeled by making simplifying assumptions on (1) and considering $F(v, w) = f(v) - w$ and $G(v, w; \lambda) = g(v; \lambda) - w$, where f is as described before and g is an increasing function of v for every λ in a given neighborhood of $\lambda = 0$ and a decreasing function of λ for all v in a neighborhood of v_m. Examples are

(i) VDP equations in Lienard form

$$f(v) = -v^3 + v^2, \qquad G(v, w; \lambda) = v - \lambda; \tag{3}$$

(ii) the classical FHN equations

$$f(v) = -h\ v^3 + a\ v^2 - b\ v + c, \qquad g(v; \lambda) = \beta\ v - \eta, \tag{4}$$

where h, a, b, c, β, and η are nonnegative constants;

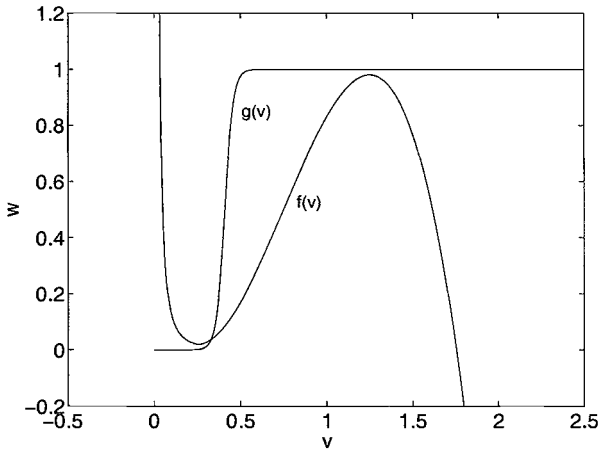

FIG. 2. *Nullclines for the MFHN model for a single oscillator (or equivalently for* $\gamma = 0$*). The values of the parameters used in our simulations are* $h = 1.92$*,* $a = 4.32$*,* $b = 1.8$*,* $c = 0.23$*,* $\beta = 0.41$*,* $\eta = 0.05$*,* $\epsilon = 0.05$*,* $v_m = 0.25$*,* $f(v_m) = 0.02$*,* $\bar{v} = 0.328$*,* $\bar{w} = 0.036092$*. The function* f *was constructed in such a way that the maximum and minimum are close to* 1 *and* 0*, respectively, in the following way:* (i) *we took a cubic function with minimum* 0 *at* $v = 0$ *and maximum* 0.98 *at* $v = 1$*,* (ii) *we shifted it up by* 0.02*,* (iii) *we shifted it to the right by* 0.25*. The function* g*, a sigmoid function, was built in such a way that it crosses* f *at a single point,* $\bar{v}$*, placed to the right of the Hopf bifurcation and such that* $\bar{v} > \lambda_c$ *(beyond the canard critical value for a single oscillator). Note that* g *is very steep and* $\lim_{v\to\pm\infty} = \pm 1$*.*

(iii) the sigmoid FHN equations

$$f(v) = -h\ v^3 + a\ v^2 - b\ v + c, \qquad g(v;\lambda) = \frac{1}{2}\ (\tanh((v-\beta)/\eta) + 1)\,, \tag{5}$$

where h, a, b, c, β, and η are nonnegative constants; and

(iv) the MFHN equations, which we use in our simulations,

$$f(v) = \begin{cases} f_{cub}(v), & v \geq v_m, \\ f_{cub}(v_m)\ v_m^2/v^2, & v \leq v_m, \end{cases}$$
$$g(v;\lambda) = \frac{1}{2}\ (\tanh((v-\beta)/\eta) + 1)\,, \tag{6}$$

and

$$f_{cub} = -h\ v^3 + a\ v^2 - b\ v + c. \tag{7}$$

Here v_m is the minimum of f_{cub}; a, b, c, h, β, η, and ϵ are nonnegative constants. In our simulations we use the following values for the parameters: $h = 1.92$, $a = 4.32$, $b = 1.8$, $c = 0.23$, $\beta = 0.41$, $\eta = 0.05$, and $\epsilon = 0.05$. With those parameters we get $(v_m, w_m) = (0.25, 0.02)$ and $(\bar{v}, \bar{w}) = (0.328, 0.036092)$. We can see the graph of the corresponding nullclines in Figure 2. In (4), (5), and (6) the parameter λ (which was defined as the v-coordinate of the intersection point between the two nullclines of the system) is implicitly defined by other parameters of the model.

The MFHN model is a simplification of the modified version of the Oregonator model used in [6]; it allows an easier qualitative dynamical understanding by reproducing important aspects of the BZ dynamics and keeping some of its features, including

the "N" shape of the nullcline corresponding to the first equation in (1), its asymptotic approach to the w axis, its qualitative behavior as a function of the global feedback parameter, and an inhibitor dynamics described by a sigmoid function rather than a line. The motivation for using the MFHN system instead of more classical versions of the FHN system is that, by changing the global feedback parameter γ, we can find small amplitude limit cycles with smaller amplitude in the v direction than for the FHN equations. This is due to the fact that the activator nullcline is asymptotic to the w axis.

3. Strategy: Reduction of dimension using clusters. We are interested in localized solutions to (1)–(2) for $\gamma \neq 0$, in which two different portions of the system display LAO and SAO, respectively. Toward this end we will analyze the existence, properties, and stability of solutions to models of type (1)–(2) with M different oscillatory behaviors ($M \leq N$). More specifically, we will look for solutions to (1)–(2) in which the system of N oscillators is divided into M different sets, each set containing a fraction α_k, $k = 1, \ldots, M$, of the N oscillators with $\sum_{k=1}^{M} \alpha_k = 1$, and such that all oscillators in a set synchronize and oscillate with the same amplitude.

Since all the oscillators in each set are equivalent, we can write

$$\langle w \rangle = \sum_{j=1}^{M} \alpha_j \, w_j. \tag{8}$$

Bulk oscillations correspond to $M = 1$. Two-phase (phase-locked) oscillations correspond to $M = 2$, as do localized oscillations in which a fraction of the system oscillates with large amplitude and the rest of the system oscillates with small amplitude. $M = 3$ includes three-phase (phase-locked) oscillations and localized oscillations in which a fraction of the system displays two-phase (phase-locked) LAO and the rest of the system oscillates with small amplitude.

In order to consider the influence of the rest of the system on the kth oscillator, we define

$$S_k = \sum_{j=1, j\neq k}^{M} \alpha_j \, w_j \tag{9}$$

for $k = 1, \ldots, M$. Using (9) and (1), we obtain

$$\begin{cases} v_k' = F(v_k, w_k) - \gamma \, \alpha_k \, w_k + \gamma \, \bar{w} - \gamma \, S_k, \\ w_k' = \epsilon \, G(v_k, w_k; \lambda) \end{cases} \tag{10}$$

for $k = 1, \ldots, M$. Note that the last term in the first equation of (10) is the only one depending on w_j, $j = 1, \ldots, M$, $j \neq k$. This term can be seen as a forcing exerted by the rest of the oscillators on the kth one. For $M = 1$ ($S_k = 0$, $\alpha_1 = 1$), (10) is an unforced oscillator with global coupling; it describes bulk oscillations of the whole system. For $M > 1$, the inhibitor nullsurfaces are not dependent on γ or S_k, while the activator nullsurfaces, which are solutions of

$$F(v_k, w_k) - \gamma \, \alpha_k \, w_k + \gamma \, \bar{w} - \gamma \, S_k = 0 \tag{11}$$

for $k = 1, \ldots, M$, vary depending on S_k and γ.

When $F(v, w) = f(v) - w$ in (10) we have FHN-type equations. In this case the activator nullsurfaces are given by

$$w_k = \frac{f(v_k) + \gamma \, \bar{w}}{1 + \gamma \, \alpha_k} - \frac{\gamma}{1 + \gamma \, \alpha_k} \, S_k \tag{12}$$

for $k = 1, \ldots, M$. For each k, the solutions (v_k, w_k) of the FHN-type equations can be considered as living in a three-dimensional space (v_k, w_k, S_k). The activator nullsurfaces vary in the S_k direction. As the system evolves, S_k changes in a periodic fashion. For each value of S_k we can consider the projection of (12) onto the (v_k, w_k) plane. This gives us the possibility of looking at the phase space of the FHN-type equations for each oscillator separately as if it were two-dimensional, with the activator nullcline moving up and down periodically according to S_k, i.e., according to the dynamics of the rest of the $M - 1$ oscillators. The intersection point in the (v_k, w_k) plane between the projections of the inhibitor and activator nullsurfaces becomes a periodic function of t that moves as the w_k nullcline moves. We call the v_k-coordinate of this time-dependent intersection point $\lambda_k = \lambda_k(t)$ for $k = 1, \ldots, M$. Thus, for systems of the form $f(v, w) = f(v) - w$, we can decompose the whole system into M forced subsystems of FHN type, one for each value of k. The forcing exerted on one oscillator depends on the remaining ones.

Stability of a solution to (10) does not automatically imply stability with respect to the full equations (1), since the solution may not be stable to perturbations that destroy the clustering into groups of equivalent oscillators. Hence once a solution has been numerically found for a specific model and value of M, it is desirable to check its stability in the N-array of globally coupled oscillators. We approach this problem numerically. In order to numerically solve system (1) we used the modified Euler method [22] for $N = 100$ with a step size $\Delta t = 0.01$. For $M = 2$ we divided the N oscillators into two sets, each with uniform initial conditions. Once each set of oscillators (with $\alpha_k N$ oscillators belonging to each set, $k = 1, 2$) settled down in a specific limit cycle, we applied a random perturbation of maximum amplitude 0.001 to each variable. We applied the following criterion for stability: if, after the perturbation, each oscillator returns to its original limit cycle and phase difference, then we say that the system is N-stable (numerically stable in an array of N oscillators). Otherwise we say that the system is N-unstable (numerically unstable in an array of N oscillators). We are aware that our definition of stability is not a rigorous one and can be affected by numerical instabilities. Still, it gives us valuable information about the stability of phase and localized clusters for the subset of values of γ for which they exist.

4. Canard phenomenon. In this section we review the canard phenomenon for relaxation oscillators. Consider system (1) for a single oscillator and $\gamma = 0$; i.e.,

$$\begin{cases} v' = F(v, w), \\ w' = \epsilon\, G(v, w; \lambda), \end{cases} \tag{13}$$

where $0 < \epsilon \ll 1$ and where F and G are as described in section 2. We first look at FHN-type models; i.e., $F(v, w) = f(v) - w$ with f as described in section 2. We assume that system (13) is in an oscillatory regime. The nullclines for a sigmoid-type FHN model and a limit cycle corresponding to a chosen set of parameters are shown in Figure 3.

The dynamics of system (13) depends on the value of λ, i.e., on the relative position of the w nullcline with respect to the v nullcline. For the FHN-type equations there exists a Hopf bifurcation point $\lambda_H(\epsilon) \geq v_m$ in a neighborhood of (v_m, w_m) which converges to (v_m, w_m) as $(\epsilon, \lambda) \to (0, 0)$ (see Appendix C and Figure 1). For values of $\lambda < v_H$ system (13) has a steady state as the only attractor, and the system is excitable [1, 3, 23, 24]; i.e., relatively small perturbations (but large enough to exceed a threshold, a curve in phase space, determined by the v nullcline and the parameters of the model) give rise to a large excursion that returns to the attractor. This trajectory

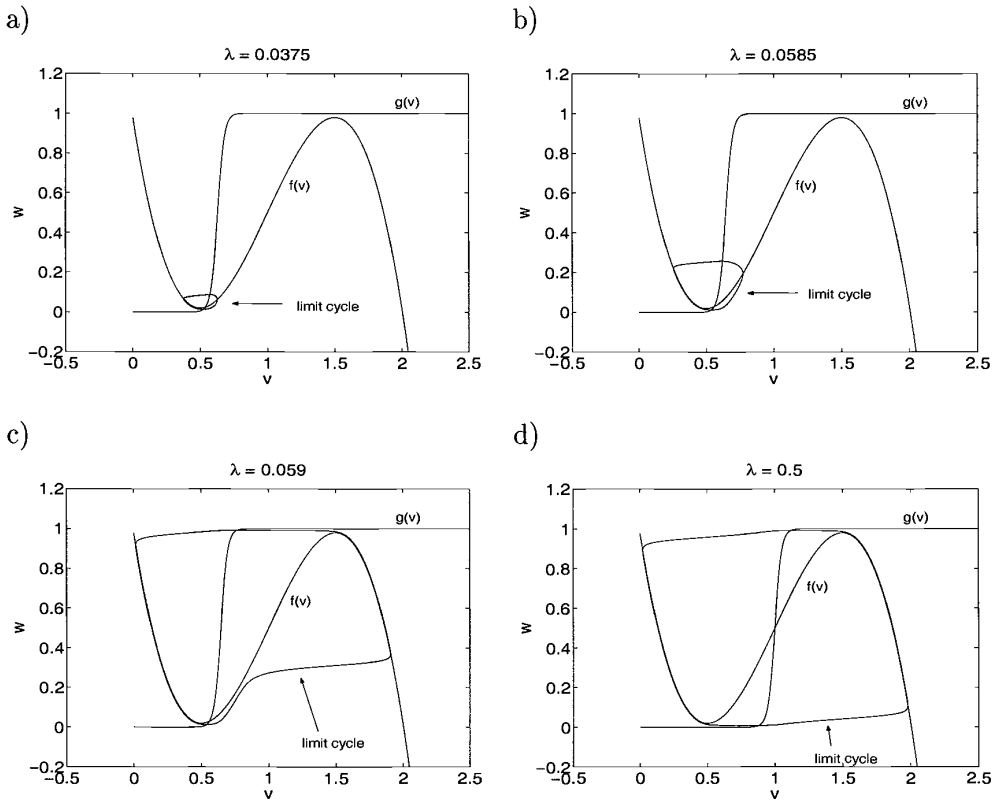

FIG. 3. *Nullclines and limit cycle for a sigmoid version of the FHN model where* $\lambda = \bar{v} - v_{min}$. *The values of the parameters are as in Figure* 2 *and* (a) $\lambda = 0.0375$, (b) $\lambda = 0.0585$, (c) $\lambda = 0.059$, (d) $\lambda = 0.5$.

is usually called an excitation loop, a pulse, or a spike. Subthreshold perturbations return to the stable fixed point with no large excursion. At $\lambda = \lambda_H(\epsilon)$, system (13) undergoes a supercritical Hopf bifurcation. As λ increases, the amplitude of the limit cycle increases slowly for small enough values of λ, part of the trajectory being very close to the unstable branch of the v nullcline for a while, then crossing the unstable branch and moving toward the left branch of the v nullcline, as illustrated in Figure 3(a) and 3(b). At some critical point $\lambda_c(\epsilon) > \lambda_H(\epsilon)$, the trajectory moves toward the right branch of the activator nullcline instead of moving toward the left branch, and the limit cycle expands rapidly (over an exponentially small interval in the parameter λ) becoming a relaxation oscillator [1, 3, 25, 26], as seen in the transition from Figure 3(b) to 3(c). After that, the amplitude of the limit cycle either increases slowly or remains constant as λ is increased, until the oscillator becomes like the one in Figure 3(d). By symmetry, when λ is near the maximum of $w = f(v)$, the same effect is seen in a small neighborhood of the Hopf bifurcation near $\lambda = v_M$. In Figure 4 we can see the amplitude of the limit cycle, given by the maximum and minimum values of v and w ($v_{\min}$, $v_{\max}$, $w_{\min}$, and $w_{\max}$), as a function of λ for the sigmoid version of the FHN equations (5). This rapid change from a "small" amplitude limit cycle to a "large" amplitude limit cycle is known as the canard phenomenon [11, 12, 14, 15, 16, 27]. In this case the canard phenomenon has been induced by changes in λ. Here we concentrate on the canard phenomenon near $v = v_m$.

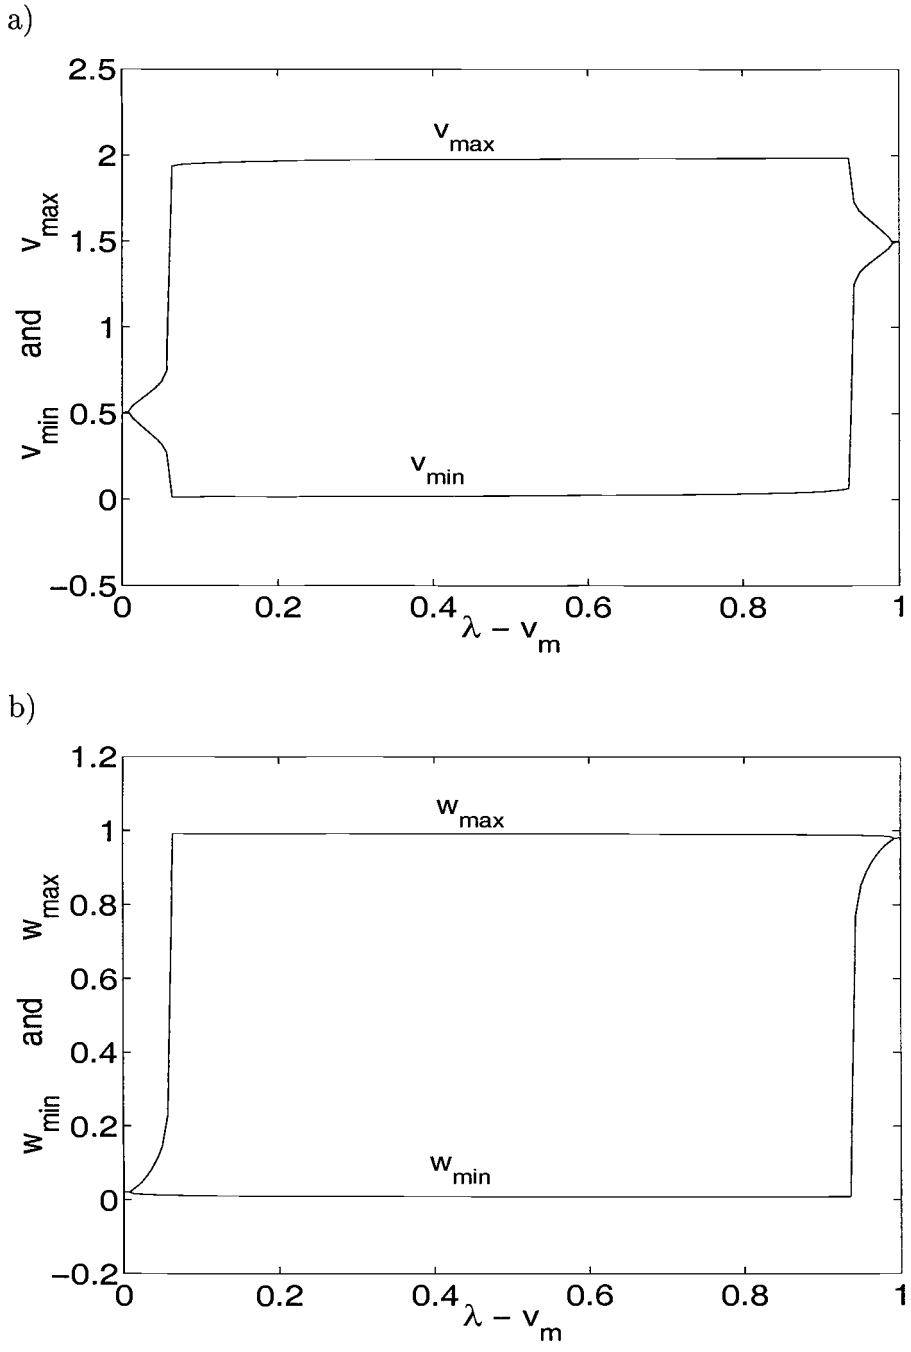

FIG. 4. *Amplitude of the limit cycle as a function of the crossing point between the activator and inhibitor nullclines λ for a single cell FHN oscillator. The values of the parameters are as in Figure* 2. (a) *v-amplitude (v_{min} and v_{max}),* (b) *w-amplitude (w_{min} and w_{max}).*

The canard phenomenon was discovered by Benoit et al. [14] for the VDP oscillator. In their work [14] they show that there exists a critical value $\lambda_c(\epsilon)$ of λ such that for λ in a small neighborhood of λ_c the limit cycle deforms into a curve similar to the one shown in Figure 3(c). While Benoit et al. [14] used nonstandard analysis techniques in their study, Eckhaus [12] and Baer and Emeux [13] used asymptotic techniques. In particular they found expressions for the canard critical value λ_c for VDP-type equations and for a generalization of system (13).

The canard phenomenon for (13) has been also studied by Dumortier and Roussarie [11] and by Krupa and Szmolyan [15, 16]. We follow the latter authors in our approach. In order to present their results, without loss of generality, we take $(v_m, w_m) = (0, 0)$. For $(v, w) = \mathbf{0}$ we assume that $F(\mathbf{0}) = \mathbf{0}$, $\partial F/\partial v(\mathbf{0}) = \mathbf{0}$, $\partial^2 F/\partial v^2(\mathbf{0}) \neq \mathbf{0}$, i.e., (v_m, w_m) is a nondegenerate local minimum (fold point) of the nullcline $F(v, w) = 0$ for λ in a suitable interval. Furthermore, $\partial F/\partial w(\mathbf{0}) \neq \mathbf{0}$. We also assume for $(v, w, \lambda) = \mathbf{0}$ that $G(\mathbf{0}) = \mathbf{0}$, $\partial G/\partial v(\mathbf{0}) \neq \mathbf{0}$, and $\partial G/\partial \lambda(\mathbf{0}) \neq \mathbf{0}$. These conditions defining a canard point (which will be referred to as *canard conditions*) mean that the nullcline $G(v, w, \lambda) = 0$ is transverse to the nullcline $F(v, w) = 0$, and it passes through the fold point with nonzero speed as λ varies. As pointed out above, $\bar{v}$ increases as λ increases (see Figure 1), allowing us to reparametrize λ such that $\lambda = \bar{v}$. For the VDP and FHN equations, these assumptions are satisfied with an appropriate change of variables.

We show in Appendix B that

$$\lambda_c = \Lambda\,\epsilon + |F_w|\,\Upsilon\,\epsilon + \mathcal{O}(\epsilon^{3/2}), \tag{14}$$

where

$$\Upsilon = \frac{G_v}{2\,F_{vv}\,|G_\lambda|}\left(\frac{G_v}{F_{vv}}\right)_v, \qquad \Lambda = -\frac{G_v}{2\,F_{vv}^3\,|G_\lambda|}\,(\,G_v\,F_{vw}\,F_{vv} + G_w\,F_{vv}^2\,), \tag{15}$$

and all the functions are calculated at $\mathbf{0}$. To obtain (14) we used an earlier result by Krupa and Szmolyan [15]. There, the cubic-like function was assumed to have its minimum at $(0, 0)$.

For the VDP equations (3), $\Lambda = 0$ and $\Upsilon = -f'''(0)\,/\,2\,(f''(0))^2 = 3/4$, coinciding with the expression found by Eckhaus [12]. For the classical FHN equations (4), $\Lambda = \beta\,/\,(2\,f''(0)\,|g_\lambda|)$ and $\Upsilon = -\beta\,f'''(0)\,/\,(2\,(f''(0))^3\,|g_\lambda|)$. The expression for the canard critical value becomes

$$\lambda_c = \frac{\beta}{2\,(f''(0))^3\,|g_\lambda(0)|}\,[\,(f''(0))^2 - \beta\,f'''(0)\,]\,\epsilon + \mathcal{O}(\epsilon^{3/2}) = \frac{\beta\,(\,2\,a^2 + 3\,\beta\,h\,)}{8\,a^3\,|g_\lambda(0)|}\,\epsilon + \mathcal{O}(\epsilon^{3/2}). \tag{16}$$

For the general FHN-type equations with $G(v, w; \lambda) = g(v; \lambda) - w$,

$$\lambda_c = \frac{g'(0)}{2\,(f''(0))^3\,|g_\lambda(0)|}\,[\,(f''(0))^2 - f'''(0)\,g'(0) + g''(0)\,f''(0)\,]\epsilon + \mathcal{O}(\epsilon^{3/2})$$

$$= \frac{g'(0)}{8\,a^3\,|g_\lambda(0)|}\,[\,2\,a^2 + 3\,h\,g'(0)\, + a\,g''(0)\,]\epsilon + \mathcal{O}(\epsilon^{3/2}). \tag{17}$$

Note that if the minimum of the activator nullcline $(v_m, f(v_m)) \neq (0, 0)$, a translation of coordinates may be performed without changing the values of the derivatives of f and g.

By construction, f in the MFHN model is a matching of two different functions. The result is continuous but not differentiable at the origin. In order for the theory described in this section to be applicable, F and G must be C^k-functions with $k \geq 3$ (continuous at least up to the third derivative) [16]. In the analysis presented here we consider functions f qualitatively similar to the MFHN function defined above, i.e., satisfying the canard conditions, but C^k with $k \geq 3$. Our numerical simulations with the MFHN function qualitatively agree with the analytical predictions.

5. Canard phenomenon induced by the global feedback parameter in synchronized (bulk) oscillatory systems. In this section we study the influence of the global feedback parameter γ on the amplitude regime (LAO or SAO) of the solution for $M = 1$ (bulk or synchronized oscillations). In what follows, all functions are calculated at $\mathbf{0}$. For $M = 1$, system (1) reads as

$$\begin{cases} v' = F(v,w) - \gamma\ w + \gamma\ \bar{w}, \\ w' = \epsilon\ G(v,w;\lambda). \end{cases} \tag{18}$$

We assume that at $\gamma = 0$, $\lambda_c = \mathcal{O}(\epsilon)$ such that $\lambda_c \neq \mathcal{O}(\epsilon^\nu)$, $\nu > 1$, $\lambda = \mathcal{O}(\epsilon)$ fixed, and $\lambda > \lambda_c$; i.e., the system is in an LAO regime for $\gamma = 0$.

First we explain how to apply the theory developed in section 4 to system (18). In the calculation of the canard critical value we use the fact that in a neighborhood of $(v_m, f(v_m)) = (0,0)$ the v nullcline can be described by a parabolic function (see (48) in Appendix A). Then, by our assumption $\lambda = \mathcal{O}(\epsilon)$ ($\bar{v} = \mathcal{O}(\epsilon)$), it follows that $\gamma\bar{w} = \mathcal{O}(\epsilon^2)$. We can rescale the last term in the first equation in (18) by defining $\bar{w} = \kappa\,\epsilon^2$, getting the following expression for the v nullcline: $\Phi(v,w,\epsilon) := F(v,w) - \gamma\ w + \gamma\ \kappa\,\epsilon^2$. Note that κ is independent of v and that $\Phi(0,0,0) = 0$ as required in [15].

Remark. When the activator nullcline $\Phi = 0$ is ϵ-dependent, the canonical equations (48) are augmented by a term $\epsilon\, h_6(v,w,\epsilon)$ and the expression for the canard critical value has an extra term proportional to $h_{6,v}$ [15].[1] For (18) $h_6 = \gamma\,\epsilon\,\kappa$, so $h_{6,v} = 0$ and the expression for the canard critical value is not affected. The only effect of γ on the canard critical value comes from the term $-\gamma\, w$ in the first equation in (18).

An expression for the canard critical value as a function of the global feedback parameter γ can be calculated as in the calculation for $\gamma = 0$ (see Appendix B) to obtain

$$\lambda_c(\gamma) = \Lambda\,\epsilon + (\,|F_w| + \gamma\,)\,\Upsilon\,\epsilon + \mathcal{O}(\epsilon^{3/2}) = \lambda_c(0) + \gamma\ \Upsilon\ \epsilon + \mathcal{O}(\epsilon^{3/2}). \tag{19}$$

Expressions (19) and (15) imply that, by increasing the value of the global feedback parameter, the value of the canard critical value is increased, provided

$$\left(\frac{G_v}{F_{vv}}\right)_v > 0, \tag{20}$$

since G_v and F_{vv} were assumed to be positive. So, if for $\gamma = 0$ we have $\lambda > \lambda_c(0)$ (the system is in an LAO regime), then the canard phenomenon can be induced by increasing the value of γ without changing the value of λ. The change from LAO to SAO takes place in an interval of values of γ exponentially small in ϵ.

We now compute γ_c, the amount that γ must be increased (in the limit as $\epsilon \to 0$) to induce the canard phenomenon, assuming that the system is in an LAO regime

[1] See the explanation after (53).

when $\gamma = 0$. Taking into account the assumptions made at the beginning of this section on λ and λ_c, the critical value $\gamma_c(\lambda)$ of γ may be calculated as the value of γ that brings $\lambda_c(\gamma)$ to λ, i.e., by replacing γ by γ_c and λ_c by λ, respectively, in (19):

$$\lambda = \lambda_c(0) + \gamma_c(\lambda)\ \Upsilon\ \epsilon + \mathcal{O}(\epsilon^{3/2}). \tag{21}$$

From (14)

$$|F_w|\,\Upsilon\,\epsilon = \lambda_c(0) - \Lambda\,\epsilon + \mathcal{O}(\epsilon^{3/2}). \tag{22}$$

Substituting (22) into (21), multiplied by $|F_w|$, we get

$$|F_w|\,[\,\lambda - \lambda_c(0)\,] = \gamma_c\,[\,\lambda_c(0) - \Lambda\,\epsilon\,] + \mathcal{O}(\epsilon^{3/2}). \tag{23}$$

Note that in the FHN models $|F_w| = \mathcal{O}(1)$, which has been used in the error term in (23). Rearranging terms and using (14), we get

$$\gamma_c(\lambda) = |F_w|\,\frac{\lambda - \lambda_c(0)}{\lambda_c(0) - \Lambda\,\epsilon} + \mathcal{O}\left(\frac{\epsilon^{3/2}}{\lambda_c(0) - \Lambda\,\epsilon}\right) = |F_w|\,\frac{\lambda - \lambda_c(0)}{\lambda_c(0) - \Lambda\,\epsilon} + \mathcal{O}(\epsilon^{1/2}). \tag{24}$$

For the VDP equations (3), $F_w = -1$ and G is independent of w so we have $\Lambda = 0$. Thus from (19)

$$\lambda_c(\gamma) = \lambda_c(0)\ (1 + \gamma) + \mathcal{O}(\epsilon^{3/2}), \tag{25}$$

and

$$\gamma_c(\lambda) = \frac{\lambda - \lambda_c(0)}{\lambda_c(0)} + \mathcal{O}(\epsilon^{1/2}). \tag{26}$$

Note that, since G is independent of w, the nullclines intersect at the same value λ for all $\gamma \geq 0$.

Using (19) and (24), the expressions for λ_c and γ_c for the FHN-type equations with $G(v, w; \lambda) = g(v; \lambda) - w$ are given by

$$\lambda_c(\gamma) = \lambda_c(0) + \frac{\gamma\ g'(0)}{2\ f''(0)\ |g(\lambda)|}\ \left[\frac{g''(0)\ f''(0) - g'(0)\ f'''(0)}{[f''(0)]^2}\right]\ \epsilon + \mathcal{O}(\epsilon^{3/2}) \tag{27}$$

and

$$\gamma_c(\lambda) = \frac{\lambda - \lambda_c(0)}{\lambda_c(0)}\ \left[1 + \frac{g'(0)}{2\ \lambda_c(0)\ f''(0)\ |g_\lambda|}\,\epsilon\right] + \mathcal{O}(\epsilon^{1/2}). \tag{28}$$

In both cases, as γ increases, the canard critical value moves to the right; then there exists a critical value of the global feedback parameter, γ_c, such that for values of γ below (above) γ_c, solutions display LAO (SAO).

As noted above, for the MFHN model used in our simulations, we do not have an expression for the canard critical value as a function of the parameters of the model and γ, but we conjecture on the basis of numerical simulations that the behavior is similar to the smooth case described before. The results of numerical simulations are shown in Figures 5 and 6. In Figure 5 we see the dependence of the amplitude of the limit cycle (represented by the minimum and maximum values of v and w) on γ for the MFHN model. We observe that for $\gamma = \gamma_c$ (in this case $\gamma_c \sim 0.429$), there is a sudden change in both the v- and w-amplitudes of the limit cycle.

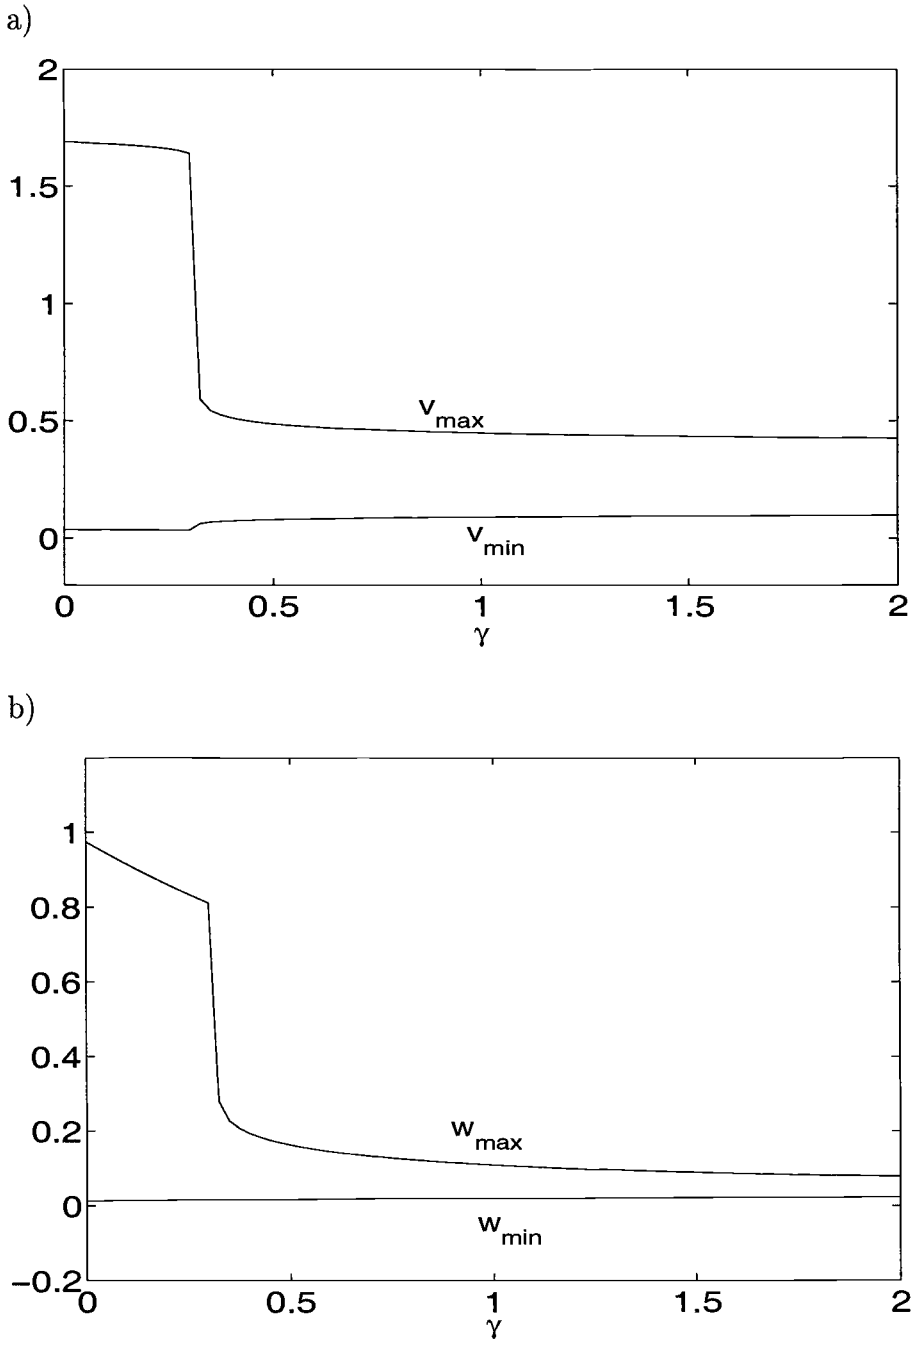

FIG. 5. *Amplitude of the limit cycle for the MFHN oscillator as a function of the global feedback parameter* γ. *The values of the parameters are as in Figure* 2.

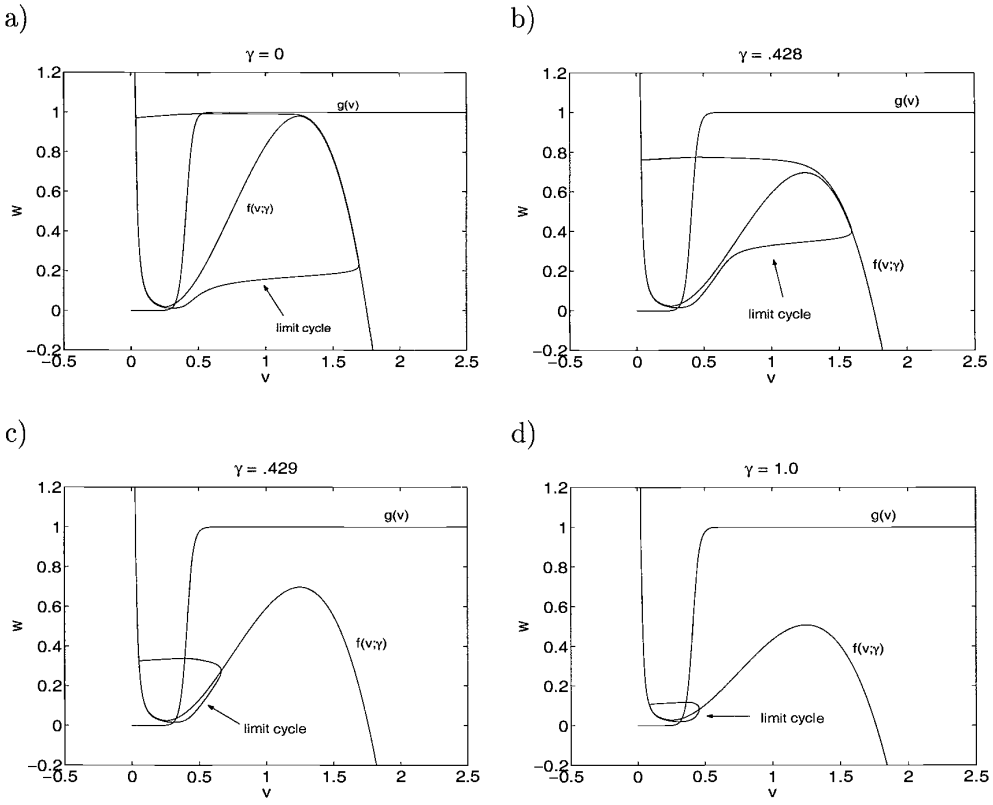

FIG. 6. *Nullclines and phase plane for the MFHN oscillator for various values of* γ. *The function* $f(v;\gamma) = (f(v) + \gamma\,\bar{w})/(1+\gamma)$. *The values of the parameters are as in Figure* 2 *and* (a) $\gamma = 0$, (b) $\gamma = 0.428$, (c) $\gamma = 0.429$, (d) $\gamma = 1$.

In Figure 6 we show the shape of the limit cycle for several values of γ above and below γ_c. For $\gamma = 0$ (Figure 6(a)) the system is in a relaxation oscillation regime. As γ increases, the limit cycle goes through the lower knee of the activator nullcline, comes up along the unstable branch for a while, and then moves rapidly to the right branch of the activator nullcline (Figure 6(b)) if $\gamma < \gamma_c$; if $\gamma > \gamma_c$, the trajectory crosses the unstable branch and moves rapidly to the left branch of the activator nullcline (Figure 6(c)).

Our numerical simulations show that bulk oscillations for the MFHN model are 100-stable for $\gamma \leq 0.39$ and $\gamma \geq 25.0$.

6. Localized solutions. In this section we analyze the existence of localized solutions for a system of globally coupled FHN-type equations, i.e., equations (1)–(2), where $F(v,w) = f(v) - w$. We deal here with the case $M = 2$; this can be easily generalized to larger values of M. In a two-cluster localized solution, some of the oscillators are in an SAO regime while the other oscillators are in an LAO regime.

By applying the reduction of dimensions described in section 3 we reduce the system of N oscillators to a system of two oscillators. The activator nullcline for each oscillator is given by (12) for $k = 1, 2$. The first term in (12) depends only on v_k and the second term is independent of (v_k, w_k) and is the only one depending on w_j, $j = 1, 2$, $j \neq k$. As explained in section 3, we can consider the second term in (12)

as moving the nullcline, whose shape is given by the first term in (12), up and down. We call $\lambda_{k,c}(\gamma)$ and $\gamma_{k,c}(\lambda)$ the canard critical value and the critical global feedback parameter value, respectively, for $k = 1, 2$. Looking at each of the two oscillators separately we can calculate the respective canard critical values as a function of γ and the fraction of oscillators in each cluster, α_k, following the same reasoning leading to (19) and (24) in section 5, where γ is replaced by $\alpha_k\,\gamma$. This yields

$$\lambda_{k,c}(\gamma) = \lambda_c(0) + \alpha_k\,\gamma\ \Upsilon\ \epsilon + \mathcal{O}(\epsilon^{3/2}) \tag{29}$$

and

$$\gamma_{k,c}(\lambda) = \frac{1}{\alpha_k}\,\frac{\lambda - \lambda_c(0)}{\lambda_c(0) - \Lambda\,\epsilon} + \mathcal{O}(\epsilon^{1/2}) \tag{30}$$

for $k = 1, 2$. Thus, for a given γ, the larger α_k the larger the canard critical point for the kth oscillator and the smaller the corresponding $\gamma_{k,c}$, i.e., the less the global feedback needed to get SAO. We can easily calculate

$$\lambda_{1,c}(\gamma) - \lambda_{2,c}(\gamma) = (\alpha_1 - \alpha_2)\,\gamma\ \Upsilon\ \epsilon + \mathcal{O}(\epsilon^{3/2}) \tag{31}$$

and

$$\gamma_{2,c} - \gamma_{1,c} = \frac{\alpha_1 - \alpha_2}{\alpha_1\ \alpha_2}\,\frac{\lambda - \lambda(0)}{\lambda_c(0) - \Lambda\,\epsilon} + \mathcal{O}(\epsilon^{1/2}). \tag{32}$$

For the VDP equations, the value of $\lambda_k(t)$ (see section 3 for the definition of this quantity) does not depend either on k or on t. Let us refer to it as λ. In this case, expression (31) implies that if $\alpha_1 \neq \alpha_2$, then we can find values of the global feedback parameter γ for which λ has a value between $\lambda_{1,c}$ and $\lambda_{2,c}$, thus producing a localized solution. As we can see from (31) and (32) the interval of values of λ and γ for which we can expect a localized solution increases with the difference between the fractions of oscillators in the two clusters. Since $\lambda_k(t)$ is independent of k and t, localization in the VDP model is a consequence only of nonsymmetric self-inhibition, i.e., not a consequence of the forcing that the oscillators exert on one another. Note that the cluster with the larger α_k is the one in the SAO regime, as seen in experiments and simulations on the BZ reaction with global feedback. (In the latter case the LAO regime consisted of two phase locked clusters.) The shape, frequency, and amplitude of each limit cycle (considered separately) in the localized solutions depend, in ways that are not yet fully understood, on γ, on the size of the other oscillator, and possibly on other quantities.

For the FHN-type equations self-inhibition creates intervals of critical values of λ and γ given by (31) and (32), respectively. In contrast to the VDP equations, when $\gamma > 0$, $\lambda_k(t)$ (see section 3 for the definition of this quantity) depends on both k and t. The forcing exerted on each oscillator by the other one changes the value of $\lambda_k(t)$. Thus there are two effects we must consider in understanding how localized solutions arise: self-inhibition and external inhibition or forcing. How external forcing interacts with localization is not yet understood. However, our simulations for the MFHN model show that localization is present as expected and that the numerically determined interval $\gamma_{2,c} - \gamma_{1,c}$ in which there is localization increases as $\alpha_1 - \alpha_2$ increases. In Figure 7 we show the amplitude of the solutions to the MFHN system with $M = 2$ as a function of the global feedback parameter γ for different values

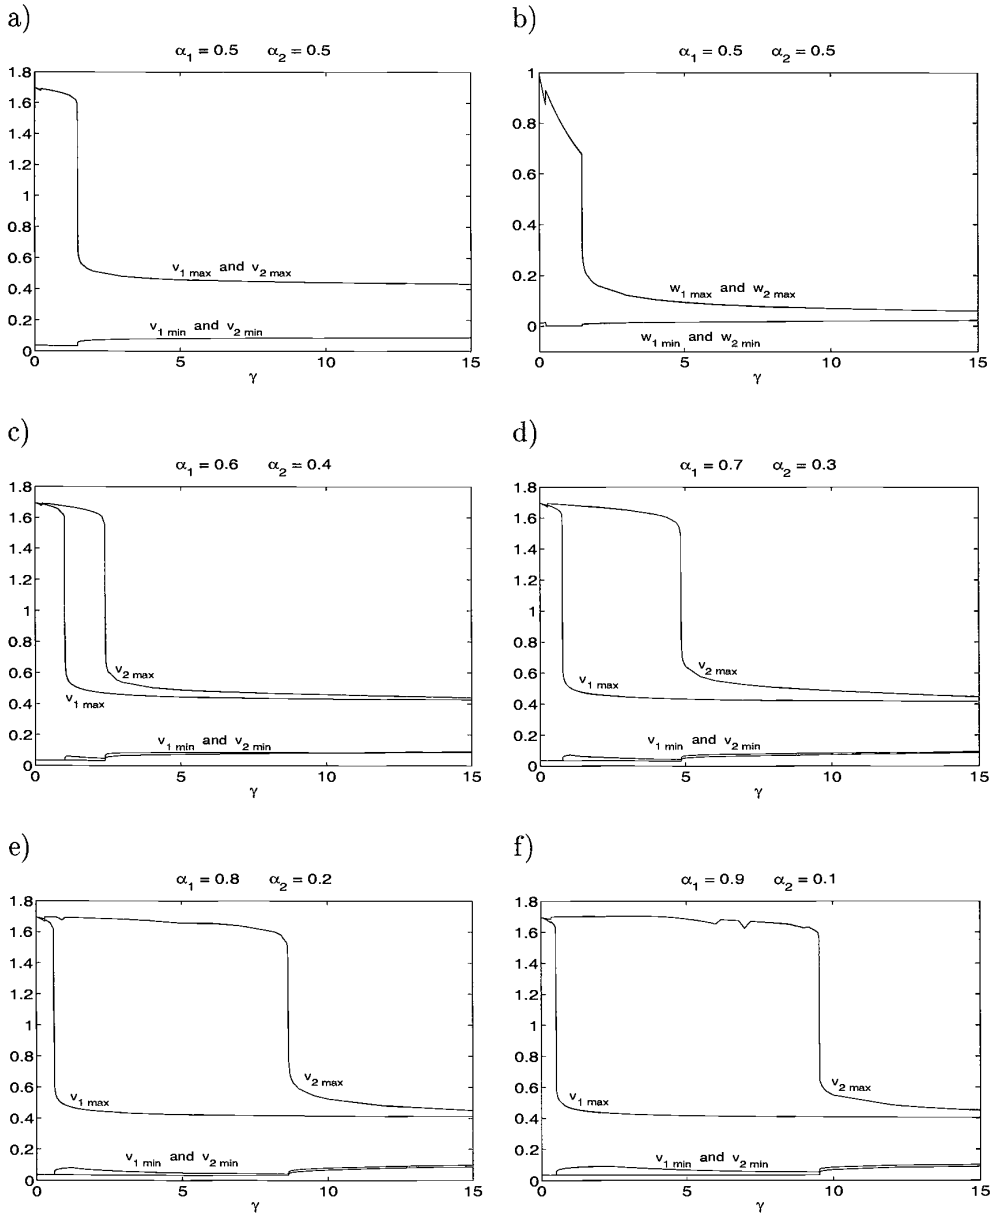

FIG. 7. *Amplitude of the limit cycle for* 2 *globally coupled* ($M = 2$) *MFHN oscillators as a function of the global feedback parameter* γ *and for different values of the fraction of oscillators in each cluster. of α_k, $k = 1, 2$. The amplitude of the oscillatory solutions for v_k is represented as the minimum and maximum values $v_{k,min}$ and $v_{k,max}$, respectively. In Table 1 we present numerical approximations of $\gamma_{1,c}$ and $\gamma_{2,c}$ for different values of α_1 and α_2. For $\alpha_1 = 0.6,\ 0.7$, and 0.8 we found that the localized solutions corresponding to a subset of values of γ included in $(\gamma_{1,c}, \gamma_{2,c})$ are 100-stable.

TABLE 1

Localized solution for the MFHN model. Values of the canard critical values $\gamma_{c,1}$ and $\gamma_{c,2}$ as a function of the fraction of oscillators in each cluster. The values of the parameters are as in Figure 2 with $M = 2$. The intervals of 100-stability, I, are (i) $I = 1.01$ *for* $\alpha_1 = 0.6$, (ii) $I = 0.6$ *for* $\alpha_1 = 0.7$ *and* $I = 0.05$ *for* $\alpha_1 = 0.8$. *For* $\alpha_1 = 0.9$ 100*-stable localized solutions were not found.*

α_1	α_2	$\gamma_{c,1}$	$\gamma_{c,2}$
0.5	0.5	1.47	1.47
0.6	0.4	1.01	2.40
0.7	0.3	0.77	4.85
0.8	0.2	0.6	8.64
0.9	0.1	0.5	9.53

The analysis presented in this section can be generalized for larger values of M, in which case we will have two regimes (LAO and SAO), but in each of the regimes we can have different amplitudes or phases for different clusters.

7. Discussion. In this paper we analyze the mechanism of localization of oscillations for a globally coupled system of relaxation oscillators of FHN type. In addition to localization, these models display the basic features of the modified Oregonator models studied in [6] and [5] to reproduce the experimental results: shape of the nullclines, a limit cycle created in a supercritical Hopf bifurcation, and display of canards among others.

Although the present study is motivated by the BZ reaction, a spatially extended system, experimental evidence suggests that the phenomena studied here, the mechanism of localization or creation of localized clusters, does not depend on diffusion [4, 28]. Based on the results of the simulations presented in [6] and simulations performed by the authors and not presented here, we conjecture that the diffusion plays an important role in spatially grouping together oscillators belonging to the same cluster.

We analyzed the canard phenomenon induced by the global feedback parameter γ for bulk oscillations ($M = 1$), obtaining an expression for the canard critical value λ_c and the critical global feedback parameter γ_c as functions of the parameters of the models considered. We showed that, by increasing the value of the global feedback parameter, the canard phenomenon is induced for a critical value γ_c; i.e., as γ passes γ_c the system rapidly changes from an LAO regime to an SAO regime due to self-inhibition. Our numerical stability calculations show that this limit cycle need not be 100-stable in a neighborhood of γ_c; e.g., for values of γ close enough to γ_c, bulk oscillations lose stability, generating other patterns, among them localized structures. The idea of induction of the canard phenomenon by changing γ is a key to the analysis of localization.

We used the idea of self-inhibition to partially explain the two-cluster localization phenomenon ($M = 2$) for a system of FHN-type equations. We applied the reduction of dimension via clusters, and we analyzed each of the two oscillators separately, considering each as a forcing exerted on the other. By writing the equations for the nullclines of each oscillator, we saw that their dynamics can be understood as a combination of two phenomena: self-inhibition of each oscillator and inhibition (forcing) exerted on each oscillator by the remaining ones. Self-inhibition creates intervals of critical values of λ and γ given by (31) and (32), respectively. The forcing exerted on each oscillator by the other one changes the values of $\lambda_k(t)$. We did not analyze the effect of the forcing exerted on each oscillator by the remaining one, but

we studied this effect numerically, showing that the main features of localization are present; i.e., the larger cluster is in an SAO regime, and the larger the size difference between two clusters the larger the interval of values of γ for which the system has a localized solution, which is 100-stable. Our analysis reveals that for the VDP equations, localization is produced by self-inhibition alone. For systems that are not of FHN type (e.g., the BZ equations [6]), the analysis becomes more complicated.

In experiments on the BZ reaction with global inhibitory feedback [4, 5] as well as in simulations using an Oregonator model [5] and another BZ model [6], localized structures consisted of three clusters, the largest cluster in an SAO regime and two smaller phase-locked clusters in an LAO regime. The mechanism we propose here for FHN-type models does not deal with the multiple clusters in LAO regimes but does explain the counterintuitive inverse relation between amplitude regime and cluster size and sheds light on the role of self-inhibition in the phenomenon of localization.

We conjecture that a similar mechanism is responsible for localization in a modified Oregonator model for the BZ reaction [6] that we study in a forthcoming paper, as well as in the Oregonator model [5]. The canard phenomenon for a single two-dimensional Oregonator model has been studied in [29], although in this case the Hopf bifurcation taking place in a neighborhood of the minimum of the activator nullcline may be subcritical instead of supercritical; then SAO are not possible for a single oscillator, though they might be possible in a globally coupled system. Our preliminary analysis shows that global feedback changes the stability type of the Hopf bifurcation point, thus allowing for SAO.

Appendix A. Calculation of the canonical form. The first step in calculating the canard critical value for system (13) is to transform it into its canonical form. We assume $(v_m, w_m) = 0$.

We first expand the right-hand sides in both equations in (13) in Taylor series:

$$\begin{cases} F(v,w) = -b\ w + a\ v^2 + H_1(v,w), \\ G(v,w,\lambda) = e\ v - c\ \lambda + d\ w + H_2(v,w,\lambda), \end{cases} \tag{33}$$

where

$$a = \frac{1}{2}\frac{\partial^2 F}{\partial v^2}(\mathbf{0}), \qquad b = \left|\frac{\partial F}{\partial w}(\mathbf{0})\right|, \tag{34}$$

$$c = \left|\frac{\partial G}{\partial \lambda}(\mathbf{0})\right|, \qquad d = \frac{\partial G}{\partial w}(\mathbf{0}), \qquad e = \frac{\partial G}{\partial v}(\mathbf{0}), \tag{35}$$

$$H_1(v,w) = \frac{\partial^2 F}{\partial v w}(\mathbf{0})\, v\, w + \frac{1}{6}\frac{\partial^3 F}{\partial v^3}(\mathbf{0})\, v^3 + \mathcal{O}(w^2, v^2 w, v w^2, w^3), \tag{36}$$

$$H_2(v,w,\lambda) = \frac{1}{2}\frac{\partial^2 G}{\partial v^2}(\mathbf{0})\, v^2 + \frac{\partial^2 G}{\partial v \lambda}(\mathbf{0})\, v\, \lambda + \mathcal{O}(w^2, \lambda^2, v\, w, w\lambda). \tag{37}$$

In (34) and (36) $\mathbf{0} = (0,0)$, whereas in (35) and (37) $\mathbf{0} = (0,0,0)$.

Next, we substitute (33) into (13), getting

$$\begin{cases} v' = -b\ w + a\ v^2 + H_1(v,w), \\ w' = \epsilon\,[\, e\ v - c\ \lambda + d\ w + H_2(v,w,\lambda)\,]. \end{cases} \tag{38}$$

Finally, we rescale system (38) by defining

$$V = e^{1/2} b^{1/2} a^{-1}, \quad W = e\, a^{-1}, \quad L = e^{3/2} b^{1/2} a^{-1} c^{-1}, \quad T = e^{-1/2} b^{-1/2}, \tag{39}$$

$$\hat{v} = \frac{v}{V}, \qquad \hat{w} = \frac{w}{W}, \qquad \hat{\lambda} = \frac{\lambda}{L}, \qquad \hat{t} = \frac{t}{T}, \tag{40}$$

$$\hat{H}_1(\hat{v}, \hat{w}) = \frac{T}{V} H_1(V\,\hat{v}, W\,\hat{w})$$

$$= T\,W\,\frac{\partial^2 F}{\partial \hat{v}\hat{w}}(\mathbf{0})\,\hat{v}\,\hat{w} + \frac{1}{6}\,T\,V^2\,\frac{\partial^3 F}{\partial \hat{v}^3}(\mathbf{0})\,\hat{v}^3 + \mathcal{O}(\hat{w}^2, \hat{v}^2\hat{w}, \hat{v}\hat{w}^2, \hat{w}^3)$$

$$= \hat{w}\,\left[T\,W\,\frac{\partial^2 F}{\partial \hat{v}\hat{w}}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w})\right] + \hat{v}^2\,\left[\frac{1}{6} T\,V^2\,\frac{\partial^3 F}{\partial \hat{v}^3}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w})\right], \tag{41}$$

and

$$\hat{H}_2(\hat{v}, \hat{w}, \hat{\lambda}) = \frac{T}{W} H_2(V\,\hat{v}, W\,\hat{w}, L\,\hat{\lambda})$$

$$= \frac{T\,V^2}{2W}\,\frac{\partial^2 G}{\partial \hat{v}^2}(\mathbf{0})\,\hat{v}^2 + \frac{T\,V\,L}{W}\,\frac{\partial^2 G}{\partial \hat{v}\hat{\lambda}}(\mathbf{0})\,\hat{v}\,\hat{\lambda} + \mathcal{O}(\hat{w}^2, \hat{\lambda}^2, \hat{v}\,\hat{w}, \hat{w}\hat{\lambda})$$

$$= \hat{v}\,\left[\frac{T\,V^2}{2\,W}\frac{\partial^2 G}{\partial \hat{v}^2}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w})\right] + \hat{\lambda}\,\left[\frac{T\,V\,L}{W}\frac{\partial^2 G}{\partial \hat{v}\hat{\lambda}}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w}, \hat{\lambda})\right] \tag{42}$$

and substituting (39)–(42) into (38). Calling

$$h_1(\hat{v}, \hat{w}) = -T\,W\frac{\partial^2 F}{\partial \hat{v}\hat{w}}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w}) = b^{-1/2}\,e^{1/2}\,a^{-1}\,\frac{\partial^2 F}{\partial \hat{v}\,\hat{w}}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w}), \tag{43}$$

$$h_2(\hat{v}, \hat{w}) = \frac{1}{6} T\,V^2\,\frac{\partial^3 F}{\partial \hat{v}^3}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w}) = \frac{1}{6}\,e^{1/2}\,b^{1/2}\,a^{-2}\,\frac{\partial^3 F}{\partial \hat{v}^3}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w}), \tag{44}$$

$$h_3(\hat{v}, \hat{w}, \hat{\lambda}) = \frac{T\,V^2}{2\,W}\,\frac{\partial^2 G}{\partial \hat{v}^2}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w}) = \frac{1}{2}\,e^{-1/2}\,b^{1/2}\,a^{-1}\,\frac{\partial^2 G}{\partial \hat{v}^2}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w}), \tag{45}$$

$$\begin{aligned} h_4(\hat{v}, \hat{w}, \hat{\lambda}) &= -\frac{T\,V\,L}{W}\,\frac{\partial^2 G}{\partial \hat{v}\hat{\lambda}}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w}, \hat{\lambda}) \\ &= -e^{1/2}\,a^{-1}\,b^{1/2}\,c^{-1}\,\frac{\partial^2 G}{\partial \hat{v}\hat{\lambda}}(\mathbf{0})\,\hat{v} + \mathcal{O}(\hat{w}, \hat{\lambda}), \end{aligned} \tag{46}$$

$$h_5(\hat{v}, \hat{w}, \hat{\lambda}) = d\,T + \mathcal{O}(\hat{v}, \hat{w}, \hat{\lambda}) = d\,e^{-1/2}\,b^{-1/2} + \mathcal{O}(\hat{v}, \hat{w}, \hat{\lambda}), \tag{47}$$

rearranging terms we get the canonical form

$$\begin{cases} \hat{v}' = -\hat{w} + \hat{v}^2 - \hat{w}\ h_1(\hat{v},\hat{w}) + \hat{v}^2\ h_2(\hat{v},\hat{w}), \\ \hat{w}' = \epsilon\ [\,\hat{v} - \hat{\lambda} + \hat{v}\ h_3(\hat{v},\hat{w},\hat{\lambda}) - \hat{\lambda}\ h_4(\hat{v},\hat{w},\hat{\lambda}) + \hat{w}\ h_5(\hat{v},\hat{w},\hat{\lambda})\,]. \end{cases} \tag{48}$$

Note that in (48) the sign $'$ represents $d/d\,\hat{t}$.

Appendix B. Calculation of the canard critical value. In [16] an expression for $\hat{\lambda_c}$ was found:

$$\hat{\lambda_c} = \frac{-a_1 + 3\ a_2 - 2\ a_3 + 2\ a_5}{8}\ \epsilon + \mathcal{O}(\epsilon^{3/2}), \tag{49}$$

where

$$a_1 = \frac{\partial h_1}{\partial \hat{v}}, \qquad a_2 = \frac{\partial h_2}{\partial \hat{v}}, \qquad a_3 = \frac{\partial h_4}{\partial \hat{v}}, \qquad a_5 = h_5. \tag{50}$$

Substituting (34), (35), and (43)–(47) into (50), we get

$$a_1 = -\frac{2\ G_v^{1/2}\ F_{vw}}{|F_w|^{1/2}\ F_{vv}}, \qquad a_2 = \frac{2\ G_v^{1/2}\ |F_w|^{1/2}\ F_{vvv}}{3\ F_{vv}^2}, \tag{51}$$

$$a_3 = \frac{|F_w|^{1/2}\ G_{vv}}{G_v^{1/2}\ F_{vv}}, \qquad a_5 = \frac{G_w}{G_v^{1/2}\ |F_w|^{1/2}}, \tag{52}$$

where all the functions are calculated at $\mathbf{0}$. The corresponding expression for $\lambda_c = L\,\hat{\lambda_c}$ is

$$\begin{aligned} \lambda_c(\sqrt{\epsilon}) &= -\frac{g_v^{3/2}\ |F_w|^{1/2}}{4\ F_{vv}\ |G_\lambda|}\ [-a_1 + 3\ a_2 - 2\ a_3 + 2\ a_5]\ \epsilon + \mathcal{O}(\epsilon^{3/2}) \\ &= -\frac{G_v}{2\,F_{vv}^3\,|G_\lambda|}[\,G_v\,F_{vw}\,F_{vv} + G_v\,|F_w|\,F_{vvv} \\ &\qquad\qquad - |F_w|\,G_{vv}\,F_{vv} + G_w\,F_{vv}^2\,]\ \epsilon + \mathcal{O}(\epsilon^{3/2}), \end{aligned} \tag{53}$$

where all the functions are calculated at $\mathbf{0}$.

If F were not independent of ϵ, then we would need to add a term $\epsilon\,h_6$ in (48). This would produce an additional $\mathcal{O}(\epsilon)$ term, proportional to dh_6/dv, in the expression for λ_c [15].

Appendix C. Equilibrium point and Hopf bifurcation. Here we present a result by Krupa and Szmolyan [15]. Based on the calculations from appendices A and B, we apply it to system (1) and the examples presented in section 2.

Consider system (1) with $\gamma = 0$ and (v_k, w_k) replaced by (v, w). Call

$$A = -a_1 + 3\,a_2 - 2\,a_3 - 2\,a_5. \tag{54}$$

Assume the following:

(i) The critical manifold $\{(v,w) : F(v,w) = 0\}$ can be written in the form $w = f(v)$, and the function f is cubic-like, i.e., it has precisely two critical points, one nondegenerate minimum and one nondegenerate maximum, each of which satisfies $\partial^2 F/\partial v^2(\mathbf{p}) \neq \mathbf{0}$ and $\partial F/\partial w(\mathbf{p}) \neq \mathbf{0}$. Without loss of generality, the minimum of f can be taken as $(0,0)$.

(ii) For $\epsilon = 0$ the left and right branches of the critical manifold $F(v, w) = 0$ are attracting and the central branch is repelling.

(iii) For $\lambda = 0$ the fold point $(0, 0)$ is a nondegenerate canard point; i.e., it satisfies $\partial G/\partial v(\mathbf{0}) \neq \mathbf{0}$ and $\partial G/\partial \lambda(\mathbf{0}) \neq \mathbf{0}$.

(iv) When $\lambda = 0$, $v' < 0$ for the slow flow on the right branch of f and $v' > 0$ for the slow flow on the central and left branches of f, including the point $(0, 0)$.

Then there exist $\epsilon_0 > 0$ and $\lambda_0 > 0$ such that, for each $0 < \epsilon < \epsilon_0$, $|\lambda| < \lambda_0$, system (1) with $\gamma = 0$ and (v_k, w_k) replaced by (v, w) has precisely one equilibrium point p_e in a neighborhood of the origin which converges to the canard point as $(\epsilon, \lambda) \to (0, 0)$. Moreover, there exists a curve

$$\lambda_H(\sqrt{\epsilon}) = -\frac{a_5}{2}\epsilon + \mathcal{O}(\epsilon^{3/2}) \tag{55}$$

such that p_e is stable (unstable) for $\lambda < \lambda_H$ ($\lambda > \lambda_H$). The equilibrium point p_e loses stability through a supercritical (subcritical) Hopf bifurcation if $A > 0$ ($A < 0$).

The proof is given in [15].

By substituting (51) and (52) into (54) we get

$$A = \frac{2}{|F_w|^{1/2}\,(G_v)^{1/2}\,(F_{vv})^2}\left[G_v\,F_{vv}\,F_{vw} + |F_w|\,G_v\,F_{vvv} - |F_w|\,G_{vv}\,F_{vv} - G_w\,(F_{vv})^2\right]. \tag{56}$$

Note that for the FHN equations (examples (ii) and (iii) in section 2) the condition for a supercritical Hopf bifurcation is equivalent to $3\,h\,g_v + a\,g_{vv} > 2\,a^2$. In particular, for the classical FHN equations (example (ii) in section 2) this becomes $3\,h\,\beta > 2\,a^2$.

By substituting the second equation in (52) into (55) we get

$$\lambda_H(\sqrt{\epsilon}) = -\frac{G_w}{2\,(G_v)^{1/2}\,|F_w|^{1/2}}\epsilon + \mathcal{O}(\epsilon^{3/2}). \tag{57}$$

Note that for the FHN equations $\lambda_H(\sqrt{\epsilon}) = 1\,/\,(G_v)^{1/2}\epsilon + \mathcal{O}(\epsilon^{3/2})$, and for the classical FHN equations $\lambda_H(\sqrt{\epsilon}) = 1\,/\beta^{1/2}\epsilon + \mathcal{O}(\epsilon^{3/2})$.

Acknowledgments. The authors thank Tasso Kaper and Kresimir Josic for helpful comments on the mathematical treatment of the canard phenomenon, Milos Dolnik for useful comments on the BZ reaction, and the canard group at Boston University for the collective learning experience on the mathematics of canards.

LOW MACH NUMBER FLOWS IN TIME-DEPENDENT DOMAINS*

G. ALÌ†

Abstract. We perform a multiple time scale, single space scale analysis of a compressible fluid in a time-dependent domain, when the time variations of the boundary are small with respect to the acoustic velocity. We introduce an average operator with respect to the fast time. The averaged leading order variables satisfy modified incompressible equations, which are coupled to linear acoustic equations with respect to the fast time. We discuss possible initial-boundary data for the asymptotic equations inherited from the initial-boundary data for the compressible equations.

Key words. asymptotic analysis, Euler equations, low Mach number

1. Introduction.

A most remarkable property of the compressible fluid equations is, roughly speaking, their ability to force a solution to remain approximately incompressible when the initial data are approximately incompressible. This is a singular limit result, since the compressible and the incompressible equations are related through a passage to infinite of a characteristic speed. The relationship between compressible and incompressible flows was rigorously stated and proved for isentropic flows in unbounded domains by Klainerman and Majda at the beginning of the eighties [13, 14] and later extended to nonisentropic flows in bounded domains by Schochet [27]. In all these papers, the initial data are "prepared," that is, they are compatible with the limiting incompressible equations. When the data are not prepared, the limit is still valid but it is not uniform for times close to zero, since the initial time derivative fails to be uniformly bounded (cf. [1, 7, 8, 9, 33] and, recently, [25]).

Despite its mathematical subtleties, the physical mechanism of this singular limit is very simple. The smallness of the Mach number constrains the spatial variation of the pressure to stay small at order zero for consistency with the conservation of momentum. Then, the energy equation, written in terms of the pressure, forces the divergence of the fluid velocity to stay close to zero. Finally, if no compression or expansion over the boundary of the domain takes place, the initial density configuration is advected by the flow.

The low Mach number theory plays an important role in many applications, such as in combustion, both in confined and unbounded domains [18, 21], and in astrophysics, in the framework of magnetohydrodynamics, in order to justify the small density fluctuations, called pseudosound, in the solar wind incompressible model [22, 34, 35]. In the context of these physical applications, it is very important to develop numerical schemes that are uniformly valid as the Mach number goes to zero. In the one-dimensional case, by using a multiple scale asymptotic analysis, Klein was able to construct a numerical scheme for compressible flows which retains its validity also at low Mach number regimes [15] (see also the extensive report [16], where, in particular, the issue of asymptotic adaptivity of this scheme with respect to the Mach number is addressed). These results were later extended to the multidimensional case

in [31]. The main point of Klein's asymptotic analysis, later assessed within a systematic mathematical framework in [23] (for unbounded domains), is the introduction of two different length scales corresponding to the large scale motion of the fluid and to small acoustic perturbations. In fact, a simple asymptotic analysis shows that highly oscillating acoustic perturbations show up at the same order as pressure variations become significant [18].

In this paper, we perform a similar analysis, when only a length scale is relevant but two time scales need to be considered. A typical example of this occurrence is a fluid confined in a bounded time-dependent domain, when the time variation of the boundary (the "boundary velocity") is small compared to the acoustic velocity of the fluid. We introduce a slow time t, related to the boundary velocity and therefore to the large scale motion of the fluid, and a fast time $\tau = t/\epsilon$, related to the acoustic speed. The parameter ϵ is proportional to the Mach number. This multiple scale analysis shows that the limiting incompressible variables can be interpreted as averages of the compressible variables with respect to τ. Moreover, they are coupled to linear acoustic equations with respect to the fast time τ. More precisely, we show that at leading order the motion is adiabatic, that is, the leading order pressure $p(t)$ is related to the volume $V(t)$ of the domain by the law $p = cV^{-\gamma}$. Also, the leading order density ρ does not depend on the fast time, and the leading order velocity $\mathbf{u}$ can be split into the averaged part with respect to the fast time and the average-free part, $\mathbf{u} = \bar{\mathbf{u}} + \delta\mathbf{u}$. These variables satisfy the following equations:

$$
\begin{aligned}
&\frac{1}{\rho}(\partial_t + \bar{\mathbf{u}}\cdot\nabla)\rho = -\frac{1}{V}\frac{dV}{dt},\\
&\rho(\partial_t + \bar{\mathbf{u}}\cdot\nabla)\bar{\mathbf{u}} + \nabla\pi = -\nabla\cdot\left(\rho\left\langle\delta\mathbf{u}\otimes\delta\mathbf{u}\right\rangle\right),\\
&\nabla\cdot\bar{\mathbf{u}} = \frac{1}{V}\frac{dV}{dt},
\end{aligned}
\tag{1.1}
$$

where the curled brackets denote average with respect to τ. The "incompressible" pressure π coincides with the averaged second order pressure. Finally, the average-free leading order velocity is coupled to the first order average-free pressure $\delta p^{(1)}$ by the linear acoustic system

$$
\begin{aligned}
&\partial_\tau\delta\mathbf{u} + \frac{1}{\rho}\nabla\delta p^{(1)} = 0,\\
&\partial_\tau\delta p^{(1)} + \gamma p\nabla\cdot\delta\mathbf{u} = 0.
\end{aligned}
\tag{1.2}
$$

The limit equations (1.1) and the acoustic equations (1.2) decouple if no pressure fluctuations appear at order ϵ. In this case, $\delta p^{(1)}$ vanishes as well as $\delta\mathbf{u}$, and (1.1) reduces to the nearly incompressible equations (using the terminology of [22, 34, 35]). The same theory applies if the domain is not moving for compressible flows with typical speed small compared to the acoustic velocity. In this case, we have $dV/dt = 0$ and the system (1.1) reduces to the incompressible system describing a stratified fluid, as found in [27]. An analogous theory can be developed for unbounded domains, obtaining the same set of equations (1.1), (1.2), with $dV/dt = 0$.

The acoustic system (1.2) deserves further comments. Thus far, the problem of high-frequency acoustics has only been addressed for unbounded domains [2, 3, 4, 5, 6, 10, 11, 12, 19, 20, 26, 28, 29], while the moving boundary problem was considered satisfactorily only in a single space dimension (the so-called piston problem) [17, 30, 32]. Here, we address the problem of high-frequency acoustics in more than one space dimension *and* in a closed, variable boundary domain.

The plan of the paper is the following. In section 2, we set the problem and introduce the fundamental equations and initial-boundary conditions. In section 3, we perform a preliminary single scale analysis, following [23]. The details of our asymptotic multiscale analysis are expounded in section 4. In the following two sections, we discuss the initial-boundary conditions for the asymptotic equations inherited from the initial-boundary data for the original compressible equations. In general, it is not possible to assign uniquely initial data for the acoustic equations with respect to the fast time τ. Anyway, at the end of section 6, we are able to produce a simple class of motion for which this problem can be solved. Finally, in section 7, we give an outlook of our results and draw some conclusions. The paper is supplemented by an appendix on weakly nonisentropic flows, that is, flows with constant entropy at order zero, which are produced by constant initial density distributions.

2. The compressible fluid equations. The Euler equations for a compressible fluid are

$$\begin{aligned} &\partial_t \rho + \nabla \cdot (\rho \mathbf{u}) = 0, \\ &\partial_t (\rho \mathbf{u}) + \nabla \cdot (\rho \mathbf{u} \otimes \mathbf{u} + pI) = 0, \\ &\partial_t E + \nabla \cdot [(E+p)\mathbf{u}] = 0, \end{aligned} \tag{2.1}$$

where $E = \rho\left(e + \frac{1}{2}|\mathbf{u}|^2\right)$ is the total energy. The internal energy, e, the pressure, p, and the density, ρ, are related to the entropy, s, and the temperature, T, by

$$de + pd\left(\frac{1}{\rho}\right) = Tds. \tag{2.2}$$

It is useful to write equations (2.1) in nonconservative form:

$$\begin{aligned} &(\partial_t + \mathbf{u} \cdot \nabla)\rho = -\rho \nabla \cdot \mathbf{u}, \\ &\rho(\partial_t + \mathbf{u} \cdot \nabla)\mathbf{u} = -\nabla p, \\ &\rho(\partial_t + \mathbf{u} \cdot \nabla)e = -p \nabla \cdot \mathbf{u}. \end{aligned} \tag{2.3}$$

Equations (2.3) and (2.2) immediately yield the entropy equation

$$(\partial_t + \mathbf{u} \cdot \nabla)s = 0 \tag{2.4}$$

and the identity

$$(\partial_t + \mathbf{u} \cdot \nabla)p = -\rho \left(\left.\frac{\partial p}{\partial \rho}\right|_e + \frac{p}{\rho^2} \left.\frac{\partial p}{\partial e}\right|_\rho \right) \nabla \cdot \mathbf{u}. \equiv -\rho \left.\frac{\partial p}{\partial \rho}\right|_s \nabla \cdot \mathbf{u}. \tag{2.5}$$

In the following, we will assume the existence of an equation of state of the form $s = s(\rho, p)$ and regard (2.1) as a hyperbolic system of partial differential equations for the variables $(\rho, \mathbf{u}, p)$. Using (2.5), we can write the pressure equation

$$\partial_t p + \mathbf{u} \cdot \nabla p + \gamma p \nabla \cdot \mathbf{u} = 0, \tag{2.6}$$

where the adiabatic exponent γ is defined by [24]

$$\gamma = \frac{\rho}{p} \left.\frac{\partial p}{\partial \rho}\right|_s \equiv \frac{\rho}{p} \frac{\partial s / \partial \rho}{\partial s / \partial p}. \tag{2.7}$$

For a perfect fluid satisfying the relation $p = R\rho T$, the adiabatic coefficient is a function of temperature only, that is, γ depends on the ratio $\gamma(p/\rho)$ only. In particular, γ is constant for a polytropic gas. In this case, the equation of state is explicitly given by

$$s = \log\left(p\rho^{-\gamma}\right). \tag{2.8}$$

We consider the equations (2.1), (2.2) on a bounded, time-dependent domain $\Omega_t \in \mathbb{R}^n$. We denote by Ω_0 the domain at the initial time $t = 0$ and describe its evolution by a family of invertible maps $\Phi_t : \mathbb{R}^n \to \mathbb{R}^n$, depending continuously on the time t such that

$$\Omega_t = \Phi_t(\Omega_0) \qquad \text{for all } t.$$

This severe assumption on the domain Ω_t is, nevertheless, general enough to include a moving rigid domain, or a cylinder cut by a fixed surface and a moving surface (piston problem), or a contracting-expanding sphere (star).

In the case of a moving rigid domain, we can choose Φ_t as

$$\Phi_t(\mathbf{x}) = \mathbf{x} + \mathbf{c}(t). \tag{2.9}$$

In the piston model, using the notation $\mathbf{y} = (x^1, x^2, \dots, x^{n-1})$ and $z = x^n$, the time-dependent domain can be written as

$$\Omega_t = \{(\mathbf{y}, z) \in \mathbb{R}^n \,:\, \mathbf{y} \in \Sigma,\ \alpha(\mathbf{y}) \le z \le \beta_t(\mathbf{y})\}, \tag{2.10}$$

where Σ is a bounded set of $\mathbb{R}^{n-1}$, α, β_t are functions defined in Σ, with $\min_\Sigma\{\alpha - \beta_t\} < 0$ for all $t \ge 0$. The piston deformation can be described by

$$\Phi_t(\mathbf{y}, z) = \left(\mathbf{y}, \alpha(\mathbf{y}) + \frac{\beta_t(\mathbf{y}) - \alpha(\mathbf{y})}{\beta_0(\mathbf{y}) - \alpha(\mathbf{y})}(z - \alpha(\mathbf{y}))\right). \tag{2.11}$$

In the star model, we have

$$\Omega_t = \{\mathbf{x} \in \mathbb{R}^3 \,:\, |\mathbf{x}| \le \eta(\hat{\mathbf{x}}, t)\}, \tag{2.12}$$

with $\hat{\mathbf{x}} = \frac{\mathbf{x}}{|\mathbf{x}|}$ and $\eta(\hat{\mathbf{x}}, t) > 0$, $\eta(\hat{\mathbf{x}}, 0) = \eta_0(\hat{\mathbf{x}})$. We can choose

$$\Phi_t(\mathbf{x}) = \begin{cases} \dfrac{\eta(\hat{\mathbf{x}}, t)}{\eta_0(\hat{\mathbf{x}})}\mathbf{x} & \text{if } \mathbf{x} \neq 0, \\ 0 & \text{if } \mathbf{x} = 0. \end{cases} \tag{2.13}$$

The map Φ_t has a geometric meaning and is related neither to the fluid motion nor to the Lagrangian variables. Moreover, Φ_t does not need to be globally unique, since only its restriction to a neighborhood of the boundary $\partial\Omega_0$ characterizes the motion of the domain's boundary $\partial\Omega_t$. In particular, we can use the map Φ_t to define the velocity $\mathbf{u}_\Omega$ of the boundary by

$$\mathbf{u}_\Omega(\mathbf{x}) = \frac{\partial \Phi_t}{\partial t}(\Phi_t^{-1}(\mathbf{x})) \qquad \text{for all } \mathbf{x} \in \partial\Omega_t. \tag{2.14}$$

The aim of this paper is to describe the fluid motion when the velocity of the boundary is small compared to the sound speed. In particular, this requirement is always valid when the boundary is fixed.

To nondimensionalize the equations (2.1), (2.6), we consider reference values for the density, the pressure, the length scale, and the time scale, ρ_{ref}, p_{ref}, l_{ref}, and t_{ref}, respectively. We introduce the rescaled variables

$$\begin{aligned} &\rho' = \frac{\rho}{\rho_{\text{ref}}}, \quad \mathbf{u}' = \frac{\mathbf{u}}{u_{\text{ref}}}, \quad p' = \frac{p}{p_{\text{ref}}}, \\ &\mathbf{x}' = \frac{\mathbf{x}}{l_{\text{ref}}}, \quad t' = \frac{t}{t_{\text{ref}}}, \quad u_{\text{ref}} = \frac{l_{\text{ref}}}{t_{\text{ref}}}. \end{aligned} \tag{2.15}$$

We choose u_{ref} as a typical value of the boundary speed. Some care is required in selecting the "correct" typical velocity. In [32], several choices are checked numerically for a unidimensional piston model. For this simple model, the conclusion is that the most appropriate typical speed is the maximum speed of the piston.

Substituting (2.15) into (2.1), (2.6), we obtain

$$\begin{aligned} &\partial_{t'}\rho' + \nabla' \cdot (\rho' \mathbf{u}') = 0, \\ &\partial_{t'}(\rho' \mathbf{u}') + \nabla' \cdot (\rho' \mathbf{u}' \otimes \mathbf{u}') + \frac{1}{\epsilon^2}\nabla' p' = 0, \\ &\partial_{t'} p' + (\mathbf{u}' \cdot \nabla') p' + \gamma' p' \nabla' \cdot \mathbf{u}' = 0, \end{aligned} \tag{2.16}$$

with $\gamma'(\rho', p') = \gamma(\rho_{\text{ref}}\rho', p_{\text{ref}}p')$, and

$$\epsilon^2 = \frac{u_{\text{ref}}^2}{p_{\text{ref}}/\rho_{\text{ref}}}. \tag{2.17}$$

The parameter ϵ is proportional to the square of the Mach number $M = u_{\text{ref}}/c_{\text{ref}}$, where c_{ref} is the typical sound speed:

$$c_{\text{ref}}^2 = \left.\frac{\partial p}{\partial \rho}\right|_s (\rho_{\text{ref}}, p_{\text{ref}}) \equiv \gamma(\rho_{\text{ref}}, p_{\text{ref}}) \frac{p_{\text{ref}}}{\rho_{\text{ref}}}.$$

Equation (2.16) is defined in the domain $\Omega'_{t'} = \frac{1}{l_{\text{ref}}}\Omega_{t_{\text{ref}}t'}$. We rescale the map Φ_t accordingly as

$$\Phi'_{t'}(\mathbf{x}') = \frac{1}{l_{\text{ref}}} \Phi_{t_{\text{ref}}t'}(l_{\text{ref}}\mathbf{x}'). \tag{2.18}$$

Then we have $\Omega'_{t'} = \Phi'_{t'}(\Omega'_0)$ and

$$\mathbf{u}'_\Omega = \frac{\mathbf{u}_\Omega}{u_{\text{ref}}}. \tag{2.19}$$

It is convenient to drop the primes and rewrite (2.16) as

$$\begin{aligned} &\partial_t \rho + \nabla \cdot \mathbf{m} = 0, \\ &\partial_t \mathbf{m} + \nabla \cdot (\mathbf{m} \otimes \mathbf{u}) + \frac{1}{\epsilon^2}\nabla p = 0, \\ &\frac{1}{\gamma p}(\partial_t + \mathbf{u} \cdot \nabla) p + \nabla \cdot \mathbf{u} = 0, \end{aligned} \tag{2.20}$$

with $\mathbf{m} = \rho\mathbf{u}$.

In conclusion, we consider the system (2.20) on the domain Ω_t with initial data

$$\rho(\mathbf{x}, 0) = \rho_0(\mathbf{x}), \quad \mathbf{u}(\mathbf{x}, 0) = \mathbf{u}_0(\mathbf{x}), \quad p(\mathbf{x}, 0) = p_0(\mathbf{x}) \qquad \text{in} \quad \Omega_0, \tag{2.21}$$

and boundary conditions

$$\mathbf{u}\cdot\mathbf{n}_t = \mathbf{u}_\Omega\cdot\mathbf{n}_t \qquad \text{on} \quad \partial\Omega_t. \tag{2.22}$$

Here, $\mathbf{n}_t$ denotes the outward normal on the boundary $\partial\Omega_t$.

In principle, it is possible to consider more general boundary conditions, by expanding (2.21) as a power series of ϵ. Also, it is possible to consider more general boundary conditions by assuming a given flux rate through the boundary. For simplicity, we will not consider such generalizations in this paper. Moreover, we will restrict our study to a polytropic fluid so that γ is a constant and the equation of state is given by (2.8).

The limit of (2.20) as ϵ tends to zero is a singular limit. There are many ways to approach the study of the limiting behavior of the compressible solutions. Here, we will follow a multiple scale asymptotic approach. Anyway, it is instructive to perform a preliminary single scale asymptotic analysis of this limit. In the following section, we deduce some general properties, which can be recovered just from the boundedness of Ω_t and from the boundary condition (2.22) using a single scale expansion. A detailed account of the appropriate multiple scale asymptotics will be given in the subsequent section 4.

3. Single scale asymptotics. In order to study the basic mechanism of the singular limit in (2.20), we assume that for a polytropic fluid a solution of (2.20) admits a single scale expansion of the form

$$\begin{aligned}
\rho(\mathbf{x},t) &= \rho^{(0)}(\mathbf{x},t) + \epsilon\rho^{(1)}(\mathbf{x},t) + O(\epsilon^2),\\
\mathbf{u}(\mathbf{x},t) &= \mathbf{u}^{(0)}(\mathbf{x},t) + \epsilon\mathbf{u}^{(1)}(\mathbf{x},t) + O(\epsilon^2),\\
p(\mathbf{x},t) &= p^{(0)}(\mathbf{x},t) + \epsilon p^{(1)}(\mathbf{x},t) + \epsilon^2 p^{(2)}(\mathbf{x},t) + O(\epsilon^3).
\end{aligned} \tag{3.1}$$

By using this expansion in (2.20) and equating to zero the coefficient of each power of ϵ, we obtain asymptotic equations for the functions of the expansion at each order. Explicitly, up to order ϵ, we obtain

$$\partial_t\rho^{(0)} + \nabla\cdot\mathbf{m}^{(0)} = 0, \tag{3.2}$$

$$\partial_t\rho^{(1)} + \nabla\cdot\mathbf{m}^{(1)} = 0, \tag{3.3}$$

$$\nabla p^{(0)} = 0, \tag{3.4}$$

$$\nabla p^{(1)} = 0, \tag{3.5}$$

$$\partial_t\mathbf{m}^{(0)} + \nabla\cdot\left(\mathbf{m}^{(0)}\otimes\mathbf{u}^{(0)}\right) + \nabla p^{(2)} = 0, \tag{3.6}$$

$$\frac{1}{\gamma p^{(0)}}\partial_t p^{(0)} + \nabla\cdot\mathbf{u}^{(0)} = 0, \tag{3.7}$$

$$\partial_t\left(\frac{p^{(1)}}{\gamma p^{(0)}}\right) + \nabla\cdot\mathbf{u}^{(1)} = 0. \tag{3.8}$$

Here, we have $\mathbf{m}^{(0)} = \rho^{(0)}\mathbf{u}^{(0)}$, $\mathbf{m}^{(1)} = \rho^{(0)}\mathbf{u}^{(1)} + \rho^{(1)}\mathbf{u}^{(0)}$.

Using (3.4) and (3.5), we can state the following result.

THEOREM 3.1. *If $(\rho,\mathbf{u},p)$ is a solution to* (2.20) *which admits the asymptotic expansion* (3.1)*, then, at the first two orders in ϵ, the pressure p is a function of time:*

$$p = p^{(0)}(t) + \epsilon p^{(1)}(t) + O(\epsilon^2). \tag{3.9}$$

Using the boundary condition (2.22), we can recover the functions $p^{(0)}(t)$ and $p^{(1)}(t)$ from (3.7) and (3.8).

THEOREM 3.2. *If $(\rho, \mathbf{u}, p)$ is a solution to* (2.20), (2.22) *which admits the asymptotic expansion* (3.1), *then $p^{(0)}(t)$ and $p^{(1)}(t)$ are given by*

$$p^{(0)} = C_0 |\Omega_t|^{-\gamma}, \tag{3.10}$$

$$p^{(1)} = C_1 p^{(0)}, \tag{3.11}$$

where $|\Omega_t|$ is the measure of the domain Ω_t and C_0, C_1 are constants.

Proof. We integrate (3.7) and (3.8) over the domain Ω_t. Using Green's formula and the boundary condition (2.22), we find

$$\frac{1}{\gamma p^{(0)}} \frac{dp^{(0)}}{dt} = -\frac{\int_{\partial\Omega_t} \mathbf{u}^{(0)} \cdot \mathbf{n}_t \, dS}{\int_{\Omega_t} dV} = -\frac{1}{|\Omega_t|} \int_{\partial\Omega_t} \mathbf{u}_\Omega \cdot \mathbf{n}_t \, dS, \tag{3.12}$$

$$\frac{d}{dt}\left(\frac{p^{(1)}}{\gamma p^{(0)}}\right) = -\frac{\int_{\partial\Omega_t} \mathbf{u}^{(1)} \cdot \mathbf{n}_t \, dS}{\int_{\Omega_t} dV} = 0. \tag{3.13}$$

The second equation immediately gives (3.11). To evaluate the right-hand side of the first equation, we observe that $\mathbf{u}_\Omega$ can be extended to a differentiable function defined in Ω_t by

$$\mathbf{u}_\Omega(\mathbf{x}) = \partial_t \Phi_t(\Phi_t^{-1}(\mathbf{x})) \qquad \text{for all } \mathbf{x} \in \Omega_t. \tag{3.14}$$

Then we have

$$\begin{aligned}\int_{\partial\Omega_t} \mathbf{u}_\Omega \cdot \mathbf{n}_t \, dS &= \int_{\Omega_t} \nabla \cdot \mathbf{u}_\Omega \, dV = \int_{\Omega_0} \nabla \cdot \frac{\partial \Phi_t}{\partial t} \left|\frac{\partial \Phi_t}{\partial \mathbf{x}_0}\right| dV_0 \\ &= \int_{\Omega_0} \frac{\partial}{\partial t} \left|\frac{\partial \Phi_t}{\partial \mathbf{x}_0}\right| dV_0 = \frac{d}{dt} \int_{\Omega_0} \left|\frac{\partial \Phi_t}{\partial \mathbf{x}_0}\right| dV_0 = \frac{d|\Omega_t|}{dt}.\end{aligned}$$

Here we have used the well-known identity

$$\frac{\partial}{\partial t}\left|\frac{\partial \Phi_t}{\partial \mathbf{x}_0}\right| = \nabla \cdot \frac{\partial \Phi_t}{\partial t}\left|\frac{\partial \Phi_t}{\partial \mathbf{x}_0}\right|.$$

In conclusion, using this result in (3.12), we arrive at the equation

$$\frac{1}{\gamma p^{(0)}} \frac{dp^{(0)}}{dt} = -\frac{1}{|\Omega_t|} \frac{d|\Omega_t|}{dt}, \tag{3.15}$$

which immediately implies (3.10). ∎

As a consequence of Theorem 3.2, since the function $p^{(0)}$ is known in terms of the measure of the domain, (3.7) can be regarded as a constraint for the leading order velocity. In particular, if the domain is fixed, (3.7) reduces to the incompressibility condition.

The dynamics of $\rho^{(0)}$ and $\mathbf{u}^{(0)}$ is ruled by (3.2) and (3.6). Writing them in terms of density, pressure, and velocity, and using Theorem 3.2, we obtain the following result.

THEOREM 3.3. *Under the same assumptions of Theorem* 3.2*, the leading order density and velocity* $(\rho^{(0)}, \mathbf{u}^{(0)})$ *satisfy the system*

$$\begin{aligned} &\frac{1}{\rho^{(0)}}\frac{D\rho^{(0)}}{Dt} = -\frac{1}{|\Omega_t|}\frac{d|\Omega_t|}{dt}, \\ &\rho^{(0)}\frac{D\mathbf{u}^{(0)}}{Dt} + \nabla p^{(2)} = 0, \\ &\nabla\cdot\mathbf{u}^{(0)} = \frac{1}{|\Omega_t|}\frac{d|\Omega_t|}{dt}, \end{aligned} \tag{3.16}$$

where

$$\frac{D}{Dt} = \partial_t + \mathbf{u}^{(0)}\cdot\nabla.$$

From Theorem 3.3, obvious restrictions on the initial data in Ω_0 are

$$\mathbf{u}_0(\mathbf{x}) = \mathbf{u}_0^{(0)}(\mathbf{x}) + O(\epsilon), \qquad p_0(\mathbf{x}) = \text{constant} + O(\epsilon^2), \tag{3.17}$$

with the constraint

$$\nabla\cdot\mathbf{u}_0^{(0)} = \text{constant}. \tag{3.18}$$

Therefore, we expect new effects, which are not described by the single scale theory, to arise when the restriction (3.18) does not hold. In the following section we develop a multiscale analysis which includes an additional time scale related to the acoustic speed.

4. A multiscale analysis. Two time scales arise naturally in the zero Mach number limit of a compressible flow in a bounded domain. They are related to the typical speed of the flow under consideration, u_{ref}, and to the typical acoustic speed, c_{ref}. More precisely, since the domain is bounded, the reference length scale, l_{ref}, can be chosen as the typical size of the domain. Then, we can define the time scales $t_{\text{ref}} = l_{\text{ref}}/u_{\text{ref}}$ and $t_{\text{s}} = l_{\text{ref}}/c_{\text{ref}}$. We recall that the small parameter ϵ is proportional to the ratio between u_{ref} and c_{ref}, that is, between t_{s} and t_{ref}.

In (2.15), we have used t_{ref} to rescale the time according to the relation $t' = t/t_{\text{ref}}$ (here, t is the unscaled time). Since u_{ref} is related to the motion of the domain's boundary (for instance, the piston speed), the rescaled time, t_{ref}, is related to the large scale motion of the fluid (for instance, to flows with speed sufficiently close to the domain's boundary velocity). To describe smaller fluctuations of the flow, due to the propagation of acoustic wave we need to introduce a dependence also on the other time which appears naturally, that is, $t/t_{\text{s}} \sim t'/\epsilon$.

With this motivation we want to express the solution $(\rho, \mathbf{u}, p)$ of (2.20), with initial data (2.21) and boundary condition (2.22), as a series in the powers of ϵ:

$$\begin{aligned} \rho(\mathbf{x},t;\epsilon) &= \rho^{(0)}(\mathbf{x},t,\tau) + \epsilon\rho^{(1)}(\mathbf{x},t,\tau) + \epsilon^2\rho^{(2)}(\mathbf{x},t,\tau) + \cdots, \\ \mathbf{u}(\mathbf{x},t;\epsilon) &= \mathbf{u}^{(0)}(\mathbf{x},t,\tau) + \epsilon\mathbf{u}^{(1)}(\mathbf{x},t,\tau) + \epsilon^2\mathbf{u}^{(2)}(\mathbf{x},t,\tau) + \cdots, \\ p(\mathbf{x},t;\epsilon) &= p^{(0)}(\mathbf{x},t,\tau) + \epsilon p^{(1)}(\mathbf{x},t,\tau) + \epsilon^2 p^{(2)}(\mathbf{x},t,\tau) + \cdots \end{aligned} \tag{4.1}$$

with $\tau = \frac{t}{\epsilon}$. We assume that the expansion (4.1) is uniformly valid in time.

THEOREM 4.1. *The uniform validity of the series* (4.1) *with respect to time for all positive times is equivalent to the sublinearity conditions*

$$\lim_{\tau\to\infty}\frac{1}{\tau}(\rho^{(i)}, \mathbf{u}^{(i)}, p^{(i)})(\mathbf{x},t,\tau) = 0, \qquad i = 0,1,2,\ldots. \tag{4.2}$$

Proof. It suffices to observe that

$$\lim_{\epsilon\to 0}\epsilon w(\mathbf{x},t,\tau)=t\lim_{\epsilon\to 0}\frac{1}{t/\epsilon}w(\mathbf{x},t,t/\epsilon)=t\lim_{\tau\to\infty}\frac{1}{\tau}w(\mathbf{x},t,\tau)$$

for any appropriate function $w(\mathbf{x},t,\tau)$ for all $t>0$. ∎

Recalling the sublinearity condition (4.2), it is natural to introduce for any function $w(\mathbf{x},t,\tau)$ the fast time average

$$\langle w\rangle(\mathbf{x},t)=\lim_{\tau\to\infty}\frac{1}{\tau}\int_0^\tau w(\mathbf{x},t,s)ds.$$

If this limit exists and it is finite, we can write $w(\mathbf{x},t,\tau)=\bar{w}(\mathbf{x},t)+\delta w(\mathbf{x},t,\tau)$, with $\bar{w}=\langle w\rangle$ and $\langle\delta w\rangle=0$. Plugging (4.1) into (2.20) and equating to zero the coefficient of each power of ϵ, we find

$$\partial_\tau\rho^{(0)}=0, \tag{4.3}$$

$$\partial_\tau\rho^{(1)}+\partial_t\rho^{(0)}+\nabla\cdot\mathbf{m}^{(0)}=0, \tag{4.4}$$

$$\partial_\tau\rho^{(2)}+\partial_t\rho^{(1)}+\nabla\cdot\mathbf{m}^{(1)}=0, \tag{4.5}$$

$$\nabla p^{(0)}=0, \tag{4.6}$$

$$\partial_\tau\mathbf{m}^{(0)}+\nabla p^{(1)}=0, \tag{4.7}$$

$$\partial_\tau\mathbf{m}^{(1)}+\partial_t\mathbf{m}^{(0)}+\nabla\cdot(\mathbf{m}^{(0)}\otimes\mathbf{u}^{(0)})+\nabla p^{(2)}=0, \tag{4.8}$$

$$\partial_\tau\mathbf{m}^{(2)}+\partial_t\mathbf{m}^{(1)}+\nabla\cdot(\mathbf{m}^{(0)}\otimes\mathbf{u}^{(1)}+\mathbf{m}^{(1)}\otimes\mathbf{u}^{(0)})+\nabla p^{(3)}=0, \tag{4.9}$$

$$\partial_\tau p^{(0)}=0, \tag{4.10}$$

$$\frac{1}{\gamma p^{(0)}}\partial_\tau p^{(1)}+\frac{1}{\gamma p^{(0)}}\partial_t dp^{(0)}+\nabla\cdot\mathbf{u}^{(0)}=0, \tag{4.11}$$

$$\frac{1}{\gamma p^{(0)}}\partial_\tau p^{(2)}+(\partial_t+\mathbf{u}^{(0)}\cdot\nabla)\left(\frac{p^{(1)}}{\gamma p^{(0)}}\right)+\nabla\cdot\mathbf{u}^{(1)}=0. \tag{4.12}$$

Averaging (4.7) with respect to τ and using the sublinearity condition (4.2), we obtain

$$\nabla\bar{p}^{(1)}=0. \tag{4.13}$$

The following result is a simple consequence of (4.3), (4.6), (4.10), and (4.13).

THEOREM 4.2. *If $(\rho,\mathbf{u},p)$ is a solution to* (2.20) *which admits the asymptotic expansion* (4.1)*, then the density and the pressure have the expansions*

$$\rho=\rho^{(0)}(\mathbf{x},t)+O(\epsilon), \tag{4.14}$$

$$p=p^{(0)}(t)+\epsilon\left[\bar{p}^{(1)}(t)+\delta p^{(1)}(\mathbf{x},t,\tau)\right]+O(\epsilon^2). \tag{4.15}$$

Equations (4.11) and (4.12) convey further information about the leading order and the first order pressure. Averaging (4.11) and (4.12) with respect to τ and using the sublinearity condition (4.2), we obtain

$$\frac{1}{\gamma p^{(0)}}\frac{dp^{(0)}}{dt}+\nabla\cdot\bar{\mathbf{u}}^{(0)}=0, \tag{4.16}$$

$$\frac{d}{dt}\left(\frac{\bar{p}^{(1)}}{\gamma p^{(0)}}\right)+\nabla\cdot\bar{\mathbf{u}}^{(1)}=-\frac{1}{\gamma p^{(0)}}\left\langle\mathbf{u}^{(0)}\cdot\nabla p^{(1)}\right\rangle. \tag{4.17}$$

The next result follows immediately by subtracting (4.13) from (4.7) and (4.16) from (4.11) and recalling (4.14).

THEOREM 4.3. *If $(\rho, \mathbf{u}, p)$ is a solution to* (2.20) *which admits the asymptotic expansion* (4.1)*, then the average-free parts of the first order pressure and of the leading order velocity, $\delta p^{(1)}$ and $\delta \mathbf{u}^{(0)}$, respectively, satisfy the linear acoustic system*

$$\begin{aligned} &\partial_\tau \delta \mathbf{u}^{(0)} + \frac{1}{\rho^{(0)}} \nabla \delta p^{(1)} = 0, \\ &\partial_\tau \delta p^{(1)} + \gamma p^{(0)} \nabla \cdot \delta \mathbf{u}^{(0)} = 0. \end{aligned} \tag{4.18}$$

We can use the acoustic system (4.18) to simplify (4.17). Using the sublinearity condition (4.2), we immediately find

$$\left\langle \mathbf{u}^{(0)} \cdot \nabla p^{(1)} \right\rangle = \left\langle \delta \mathbf{u}^{(0)} \cdot \nabla \delta p^{(1)} \right\rangle = -\frac{\rho^{(0)}}{2} \left\langle \partial_\tau \left| \delta \mathbf{u}^{(0)} \right|^2 \right\rangle = 0, \tag{4.19}$$

and hence the right-hand side of (4.17) vanishes. Now we are ready to prove the analogue of Theorem 3.2.

THEOREM 4.4. *If $(\rho, \mathbf{u}, p)$ is a solution to* (2.20)*,* (2.22) *which admits the asymptotic expansion* (4.1)*, then $p^{(0)}(t)$ and $\bar{p}^{(1)}(t)$ are given by*

$$p^{(0)} = C_0 |\Omega_t|^{-\gamma}, \tag{4.20}$$

$$\bar{p}^{(1)} = C_1 p^{(0)}, \tag{4.21}$$

where $|\Omega_t|$ is the measure of the domain Ω_t and C_0, C_1 are constants.

Proof. The relations (4.20) and (4.21) follow from (4.16), (4.17), and (4.19) as in Theorem 3.2, once we note that

$$\bar{\mathbf{u}}^{(0)} \cdot \mathbf{n}_t = \mathbf{u}_\Omega \cdot \mathbf{n}_t, \qquad \bar{\mathbf{u}}^{(1)} \cdot \mathbf{n}_t = 0 \qquad \text{on } \partial\Omega_t. \tag{4.22}$$

The boundary conditions (4.22) follow from (2.22) after using the expansion (4.1) and averaging with respect to τ. ∎

In the following section we will show that the constants C_0 and C_1 can be recovered by the initial data (2.21) (see Theorem 5.2). As in the single scale analysis, (4.16) can be regarded as a constraint for $\bar{\mathbf{u}}^{(0)}$, which reduces to the incompressibility condition when the domain is not moving. To derive evolution equations for $(\rho^{(0)}, \bar{\mathbf{u}}^{(0)})$, we average (4.4) and (4.8) with respect to τ. Then using the condition (4.2) and recalling that the leading order density is independent of τ, we obtain

$$\partial_t \rho^{(0)} + \nabla \cdot \left(\rho^{(0)} \bar{\mathbf{u}}^{(0)} \right) = 0, \tag{4.23}$$

$$\partial_t \left(\rho^{(0)} \bar{\mathbf{u}}^{(0)} \right) + \nabla \cdot \left(\rho^{(0)} \left\langle \mathbf{u}^{(0)} \otimes \mathbf{u}^{(0)} \right\rangle \right) + \nabla \bar{p}^{(2)} = 0. \tag{4.24}$$

We can rewrite equations (4.23) and (4.24) so that the leading order material derivative $\frac{\bar{D}}{Dt} = \partial_t + \bar{\mathbf{u}}^{(0)} \cdot \nabla$ appears. Also, we can express $\nabla \cdot \bar{\mathbf{u}}^{(0)}$ in terms of $|\Omega_t|$ by using (4.16) and (4.20). The resulting equations are reported in the following statement.

THEOREM 4.5. *Under the same assumptions of Theorem* 4.4*, the averaged leading order density and velocity $(\rho^{(0)}, \bar{\mathbf{u}}^{(0)})$ satisfy the system*

$$\begin{aligned} &\frac{1}{\rho^{(0)}} \frac{\bar{D}\rho^{(0)}}{Dt} = -\frac{1}{|\Omega_t|} \frac{d|\Omega_t|}{dt}, \\ &\rho^{(0)} \frac{\bar{D}\bar{\mathbf{u}}^{(0)}}{Dt} + \nabla \bar{p}^{(2)} = -\nabla \cdot \left(\rho^{(0)} \left\langle \delta \mathbf{u}^{(0)} \otimes \delta \mathbf{u}^{(0)} \right\rangle \right), \\ &\nabla \cdot \bar{\mathbf{u}}^{(0)} = \frac{1}{|\Omega_t|} \frac{d|\Omega_t|}{dt}. \end{aligned} \tag{4.25}$$

Equation (4.25) is the analogue of (3.16). The main difference resides in the coupling of $(\rho^{(0)}, \bar{\mathbf{u}}^{(0)})$ with $\delta\mathbf{u}^{(0)}$ in $(4.25)_2$. In principle, (4.18), (4.20), and (4.25) determine completely $\rho^{(0)}$, $\mathbf{u}^{(0)} = \bar{\mathbf{u}}^{(0)} + \delta\mathbf{u}^{(0)}$, $p^{(1)} = \delta p^{(1)}$, and the average $\bar{p}^{(2)}$. We will discuss the appropriate initial-boundary conditions in the next section.

The next theorem concerns the higher order variables: $\bar{\rho}^{(1)} + \delta\rho^{(1)}$, $\bar{\mathbf{u}}^{(1)} + \delta\mathbf{u}^{(1)}$, and $\delta p^{(2)}$.

THEOREM 4.6. *If $(\rho, \mathbf{u}, p)$ is a solution to* (2.20), (2.21), (2.22) *which admits the asymptotic expansion* (4.1), *then the average-free functions $\delta\rho^{(1)}$, $\delta\mathbf{u}^{(1)}$, and $\delta p^{(2)}$ satisfy the linear acoustic system*

$$
\begin{aligned}
&\partial_\tau \delta\rho^{(1)} = -\nabla\cdot\left(\rho^{(0)}\delta\mathbf{u}^{(0)}\right),\\
&\rho^{(0)}\partial_\tau\delta\mathbf{u}^{(1)} + \nabla\delta p^{(2)} = -\rho^{(1)}\partial_\tau\delta\mathbf{u}^{(0)} - \rho^{(0)}(\partial_t + \mathbf{u}^{(0)}\cdot\nabla)\mathbf{u}^{(0)} - \nabla\bar{p}^{(2)},\\
&\partial_\tau\delta p^{(2)} + \gamma p^{(0)}\nabla\cdot\delta\mathbf{u}^{(1)} = -\gamma p^{(0)}(\partial_t + \mathbf{u}^{(0)}\cdot\nabla)\left(\frac{\delta p^{(1)}}{\gamma p^{(0)}}\right).
\end{aligned}
\tag{4.26}
$$

Moreover, the averaged perturbations $\bar{\rho}^{(1)}$, $\bar{\mathbf{u}}^{(1)}$ satisfy the equations

$$
\partial_t\bar{\rho}^{(1)} + \nabla\cdot\left(\rho^{(0)}\bar{\mathbf{u}}^{(1)} + \bar{\rho}^{(1)}\bar{\mathbf{u}}^{(0)}\right) = 0, \tag{4.27}
$$

$$
\begin{aligned}
\partial_t\left(\rho^{(0)}\bar{\mathbf{u}}^{(1)} + \bar{\rho}^{(1)}\bar{\mathbf{u}}^{(0)}\right) &+ \nabla\cdot\Big\{\bar{\rho}^{(1)}\bar{\mathbf{u}}^{(0)}\otimes\bar{\mathbf{u}}^{(0)}\\
&+ \rho^{(0)}\left(\bar{\mathbf{u}}^{(0)}\otimes\bar{\mathbf{u}}^{(1)} + \bar{\mathbf{u}}^{(1)}\otimes\bar{\mathbf{u}}^{(0)}\right)\Big\} + \nabla\bar{p}^{(3)}\\
= -\nabla\cdot\Big\{\Big\langle\rho^{(1)}\delta\mathbf{u}^{(0)}\otimes\delta\mathbf{u}^{(0)}\Big\rangle &+ \rho^{(0)}\Big\langle\delta\mathbf{u}^{(0)}\otimes\delta\mathbf{u}^{(1)} + \delta\mathbf{u}^{(1)}\otimes\delta\mathbf{u}^{(0)}\Big\rangle\Big\},
\end{aligned}
\tag{4.28}
$$

$$
\nabla\cdot\bar{\mathbf{u}}^{(1)} = 0. \tag{4.29}
$$

Proof. The system (4.26) comes from (4.4), (4.8), and (4.12) after some simple algebra by using (4.14) and (4.23). For the second part of the thesis, we average (4.5) and (4.9) with respect to τ and use the sublinearity condition. The result is

$$
\partial_t\bar{\rho}^{(1)} + \nabla\cdot\bar{\mathbf{m}}^{(1)} = 0, \tag{4.30}
$$

$$
\partial_t\bar{\mathbf{m}}^{(1)} + \nabla\cdot\left\langle\mathbf{m}^{(0)}\otimes\mathbf{u}^{(1)} + \mathbf{m}^{(1)}\otimes\mathbf{u}^{(0)}\right\rangle + \nabla\bar{p}^{(3)} = 0, \tag{4.31}
$$

with $\mathbf{m}^{(0)} = \rho^{(0)}\mathbf{u}^{(0)}$, $\mathbf{m}^{(1)} = \rho^{(0)}\mathbf{u}^{(1)} + \rho^{(1)}\mathbf{u}^{(0)}$. Recalling (4.14), we have

$$
\bar{\mathbf{m}}^{(1)} = \rho^{(0)}\bar{\mathbf{u}}^{(1)} + \bar{\rho}^{(1)}\bar{\mathbf{u}}^{(0)} + \left\langle\delta\rho^{(1)}\delta\mathbf{u}^{(0)}\right\rangle.
$$

We will show in section 6 that

$$
\left\langle\delta\rho^{(1)}\delta\mathbf{u}^{(0)}\right\rangle = 0. \tag{4.32}
$$

After some algebra, (4.30) and (4.31) yield (4.27) and (4.28). Finally, recalling (4.19), equation (4.17) reduces to (4.29) provided $\bar{p}^{(1)} = 0$. The proof of this equality depends on the boundary conditions and will be postponed to the following section (see Theorem 5.2). ∎

The average-free components $(\delta\rho^{(1)}, \delta\mathbf{u}^{(1)}, \delta p^{(2)})$ are coupled with $(\bar{\rho}^{(1)}, \bar{\mathbf{u}}^{(1)})$ through the averaged first order density $\bar{\rho}^{(1)}$ appearing in the right-hand side of $(4.26)_2$. There are two important cases when the two groups of equations (4.26)

and (4.27)–(4.29) decouple. The first case is when the average-free functions $\delta\mathbf{u}^{(0)}$ and $\delta p^{(1)}$ are identically zero. Then, the system (4.25) reduces to (3.16), the right-hand sides of the equations (4.26), (4.27), and (4.28) vanish, and $\delta\rho^{(1)} = 0$. The second case leading to decoupling is induced by a constant initial density distribution, $\rho(\mathbf{x}, 0) = \rho_0$. In this case, the leading order density $\rho^{(0)}$ is inversely proportional to the volume $|\Omega_t|$, the averaged first order density $\bar{\rho}^{(1)}$ vanishes, and the leading order entropy is constant. Since entropy variations appear only at order ϵ, the resulting flow will be called weakly nonisentropic. In the appendix at the end of the paper, we report the main results regarding weakly nonisentropic flows.

5. Initial-boundary conditions. In the previous section, we have shown that a solution of (2.20), which admits the expansion (4.1), takes the form

$$\begin{aligned}
\rho(\mathbf{x}, t; \epsilon) &= \rho^{(0)}(\mathbf{x}, t) + \epsilon \left[\bar{\rho}^{(1)}(\mathbf{x}, t) + \delta\rho^{(1)}(\mathbf{x}, t, \tau)\right] + O(\epsilon^2),\\
\mathbf{u}(\mathbf{x}, t; \epsilon) &= \left[\bar{\mathbf{u}}^{(0)}(\mathbf{x}, t) + \delta\mathbf{u}^{(0)}(\mathbf{x}, t, \tau)\right]\\
&\quad + \epsilon \left[\bar{\mathbf{u}}^{(1)}(\mathbf{x}, t) + \delta\mathbf{u}^{(1)}(\mathbf{x}, t, \tau)\right] + O(\epsilon^2),\\
p(\mathbf{x}, t; \epsilon) &= p^{(0)}(t) + \epsilon \left[\bar{p}^{(1)}(t) + \delta p^{(1)}(\mathbf{x}, t, \tau)\right]\\
&\quad + \epsilon^2 \left[\bar{p}^{(2)}(\mathbf{x}, t) + \delta p^{(2)}(\mathbf{x}, t, \tau)\right] + O(\epsilon^3),
\end{aligned} \tag{5.1}$$

where $p^{(0)}$ and $\bar{p}^{(1)}$ satisfy (4.20) and (4.21), $(\delta\mathbf{u}^{(0)}, \delta p^{(1)})$ satisfy (4.18), and $(\rho^{(0)}, \bar{\mathbf{u}}^{(0)})$ satisfy (4.25). Moreover, we have

$$\left\langle \delta\rho^{(1)} \right\rangle = 0, \qquad \left\langle \delta\mathbf{u}^{(0)} \right\rangle = \left\langle \delta\mathbf{u}^{(1)} \right\rangle = 0, \qquad \left\langle \delta p^{(1)} \right\rangle = \left\langle \delta p^{(2)} \right\rangle = 0. \tag{5.2}$$

In order to determine completely the asymptotic expansion (5.1), we need to assign at each order appropriate initial-boundary conditions which are induced by the initial-boundary conditions (2.21), (2.22) for the original system (2.20), that is,

$$\rho(\mathbf{x}, 0) = \rho_0(\mathbf{x}), \quad \mathbf{u}(\mathbf{x}, 0) = \mathbf{u}_0(\mathbf{x}), \quad p(\mathbf{x}, 0) = p_0(\mathbf{x}) \qquad \text{in} \quad \Omega_0, \tag{5.3}$$

$$\mathbf{u} \cdot \mathbf{n}_t = \mathbf{u}_\Omega \cdot \mathbf{n}_t \qquad \text{on} \quad \partial\Omega_t. \tag{5.4}$$

The theoretical analysis performed in [1, 7, 8, 9, 25, 33] shows that the low Mach number limit for generic data is not uniform in a time interval containing the zero, unless the initial data is compatible with the zero Mach number equations. Therefore, in general we must expect a sort of instantaneous jump from the initial data (5.3) to possibly different initial data adjusted to the asymptotic equations.

In this section, we collect some results which are related to the asymptotic initial-boundary conditions and can be derived immediately from the asymptotic expansion (4.1). First, we discuss the implications of the boundary condition (5.4). Using (5.1) in (5.4) and averaging with respect to τ, we find

$$\bar{\mathbf{u}}^{(0)} \cdot \mathbf{n}_t = \mathbf{u}_\Omega \cdot \mathbf{n}_t, \qquad \bar{\mathbf{u}}^{(1)} \cdot \mathbf{n}_t = 0 \qquad \text{on } \partial\Omega_t. \tag{5.5}$$

In turn, the previous condition implies

$$\delta\mathbf{u}^{(0)} \cdot \mathbf{n}_t = \delta\mathbf{u}^{(1)} \cdot \mathbf{n}_t = 0 \qquad \text{on } \partial\Omega_t. \tag{5.6}$$

Next, we discuss the relationship between the initial data (5.3) for the original system and the initial data for the functions appearing in the asymptotic expansion (5.1). We write $\tau = t/\epsilon$ in the expansion (5.1) and evaluate it at the time $t = 0$. Comparing the result with (5.3), we obtain the following conditions for the density:

$$\rho^{(0)}(\mathbf{x}, 0) = \rho_0(\mathbf{x}), \tag{5.7}$$

$$\bar{\rho}^{(i)}(\mathbf{x}, 0) + \delta\rho^{(i)}(\mathbf{x}, 0, 0) = 0 \qquad \text{for } i = 1, 2, \dots, \tag{5.8}$$

with $\mathbf{x} \in \Omega_0$. The condition (5.7) provides initial data for $\rho^{(0)}$. In the previous section, we have shown that

$$\partial_\tau \rho^{(i)} + \partial_t \rho^{(i-1)} + \nabla \cdot \mathbf{m}^{(i-1)} = 0, \qquad i = 1, 2.$$

It is simple to see that this equation is valid for all integers i. Then, subtracting the averaged equation and using the sublinearity condition (4.2), we obtain

$$\partial_\tau \delta\rho^{(i)} + \nabla \cdot \delta\mathbf{m}^{(i-1)} = 0, \qquad i = 1, 2, \dots. \tag{5.9}$$

Since $\mathbf{m}^{(i-1)}$ is known at this stage, we can integrate (5.9) and recover $\delta\rho^{(i)}$ using the condition $\langle \delta\rho^{(i)} \rangle = 0$. The result is

$$\delta\rho^{(i)}(\mathbf{x}, t, \tau) = \left\langle \nabla \cdot \int_0^\tau \delta\mathbf{m}^{(i-1)}(\mathbf{x}, t, \tau')\, d\tau \right\rangle - \nabla \cdot \int_0^\tau \delta\mathbf{m}^{(i-1)}(\mathbf{x}, t, \tau')\, d\tau, \tag{5.10}$$

which, using (5.8), gives

$$\bar{\rho}^{(i)}(\mathbf{x}, 0) = -\delta\rho^{(i)}(\mathbf{x}, 0, 0) = -\left\langle \nabla \cdot \int_0^\tau \delta\mathbf{m}^{(i-1)}(\mathbf{x}, 0, \tau')\, d\tau \right\rangle \quad \text{for } \mathbf{x} \in \Omega_0. \tag{5.11}$$

In particular, for $i = 1$ we have $\delta\mathbf{m}^{(0)} = \rho^{(0)}\delta\mathbf{u}^{(0)}$, which implies

$$\bar{\rho}^{(1)}(\mathbf{x}, 0) = -\delta\rho^{(1)}(\mathbf{x}, 0, 0) = 0 \qquad \text{for } \mathbf{x} \in \Omega_0. \tag{5.12}$$

Next, comparing the expansion (4.1) for the velocity, written at $t = 0$, and the initial data (5.3), we find

$$\bar{\mathbf{u}}^{(0)}(\mathbf{x}, 0) + \delta\mathbf{u}^{(0)}(\mathbf{x}, 0, 0) = \mathbf{u}_0(\mathbf{x}), \tag{5.13}$$

$$\bar{\mathbf{u}}^{(i)}(\mathbf{x}, 0) + \delta\mathbf{u}^{(i)}(\mathbf{x}, 0, 0) = 0 \qquad \text{for } i = 1, 2, \dots, \tag{5.14}$$

with $\mathbf{x} \in \Omega_0$. Some care is required to determine appropriate initial data for $\bar{\mathbf{u}}^{(i)}$, $i = 0, 1$, since the functions $\bar{\mathbf{u}}^{(0)}(\mathbf{x}, 0)$ and $\bar{\mathbf{u}}^{(1)}(\mathbf{x}, 0)$ must be compatible with $(4.25)_3$ and (4.29). Accordingly, we decompose the initial velocity $\mathbf{u}_0$ as

$$\mathbf{u}_0 = \mathbf{u}_0^* + \nabla\omega^* + \nabla\omega_0. \tag{5.15}$$

In (5.15), $\mathbf{u}_0^*$ is the divergence-free part of $\mathbf{u}_0$ in Ω_0, and ω^* is given by the system

$$\Delta\omega^* = \left(\frac{1}{|\Omega_t|} \frac{d|\Omega_t|}{dt} \right)_{t=0} \qquad \text{in } \Omega_0, \tag{5.16}$$

$$\frac{\partial\omega^*}{\partial\mathbf{n}_0} = 0 \qquad \text{on } \partial\Omega_0. \tag{5.17}$$

Using the decomposition (5.15), the condition (5.13), and the constraint $(4.25)_3$ leads to the reasonable assumption

$$\bar{\mathbf{u}}^{(0)}(\mathbf{x},0) = \mathbf{u}_0^*(\mathbf{x}) + \nabla\omega^*, \qquad \delta\mathbf{u}^{(0)}(\mathbf{x},0,0) = \nabla\omega_0(\mathbf{x}) \qquad \text{in } \Omega_0. \tag{5.18}$$

In the same way, using (4.29), it is simple to see that the condition (5.14) yields

$$\bar{\mathbf{u}}^{(1)}(\mathbf{x},0) = 0, \qquad \delta\mathbf{u}^{(1)}(\mathbf{x},0,0) = 0 \qquad \text{in } \Omega_0. \tag{5.19}$$

Finally, comparing the expansion (4.1) for the pressure, written at $t = 0$, and the initial data (5.3), we find

$$p^{(0)}(0) = p_0(\mathbf{x}), \tag{5.20}$$

$$\bar{p}^{(i)}(\mathbf{x},0) + \delta p^{(i)}(\mathbf{x},0,0) = 0 \qquad \text{for } i = 1,2,\dots, \tag{5.21}$$

with $\mathbf{x} \in \Omega_0$. It is immediately seen that (5.20) is compatible with a constant initial pressure p_0. However, as we will see, general initial data are admissible for p. Then, the condition (5.20) implies that the convergence as ϵ tends to zero cannot be uniform in a neighborhood of $t = 0$ if the initial pressure is not constant in Ω_0.

The functions $p^{(0)}$ and $\bar{p}^{(1)}$ will be determined in terms of $p_0(\mathbf{x})$ by simple physical considerations. We need the following lemma.

LEMMA 5.1. *For any function $a(\mathbf{x},t)$ defined for $\mathbf{x} \in \Omega_t$, $t \geq 0$, we have*

$$\frac{d}{dt}\int_{\Omega_t} a\,dV = \int_{\Omega_t} \partial_t a + \nabla\cdot(a\mathbf{u}^*)\,dV \tag{5.22}$$

for any vector-valued function $\mathbf{u}^*(\mathbf{x},t)$ such that

$$\mathbf{n}_t\cdot\mathbf{u}^* = \mathbf{n}_t\cdot\mathbf{u}_\Omega \qquad \textit{for } \mathbf{x} \in \partial\Omega_t. \tag{5.23}$$

In particular, if

$$\begin{aligned} \partial_t a + \nabla\cdot(a\mathbf{u}^*) &= \nabla\cdot\mathbf{v} \qquad \textit{for } \mathbf{x} \in \Omega_t,\\ \mathbf{n}_t\cdot\mathbf{v} &= 0 \qquad \textit{for } \mathbf{x} \in \partial\Omega_t, \end{aligned}$$

we have

$$\int_{\Omega_t} a\,dV = \int_{\Omega_0} a_0\,dV, \tag{5.24}$$

with $a_0(\mathbf{x}) = a(\mathbf{x},0)$.

Proof. We evaluate the left-hand side of (5.22) as

$$\begin{aligned} \frac{d}{dt}\int_{\Omega_t} a\,dV &= \frac{d}{dt}\int_{\Omega_0} a(\Phi_t(\mathbf{x}_0),t)\left|\frac{\partial\Phi_t}{\partial\mathbf{x}_0}\right| dV_0\\ &= \int_{\Omega_0}\left\{\left(\partial_t + \frac{\partial\Phi_t}{\partial t}\cdot\nabla\right)a + a\nabla\cdot\frac{\partial\Phi_t}{\partial t}\right\}\left|\frac{\partial\Phi_t}{\partial\mathbf{x}_0}\right| dV_0\\ &= \int_{\Omega_t}\left\{\partial_t a + \nabla\cdot(a\mathbf{u}^*) + \nabla\cdot\left[a\left(\frac{\partial\Phi_t}{\partial t} - \mathbf{u}^*\right)\right]\right\} dV\\ &= \int_{\Omega_t}\partial_t a + \nabla\cdot(a\mathbf{u}^*)\,dV + \int_{\partial\Omega_t} a\,\mathbf{n}_t\cdot\left(\frac{\partial\Phi_t}{\partial t} - \mathbf{u}^*\right) dS. \end{aligned}$$

The thesis follows immediately from (2.14) and (5.23). ∎

The following result completes Theorem 4.4.

THEOREM 5.2. *If* $(\rho, \mathbf{u}, p)$ *is a solution to* (2.20), (5.3), (5.4) *which admits the asymptotic expansion* (4.1), *then* $p^{(0)}(t)$ *and* $\bar{p}^{(1)}(t)$ *are given by*

$$p^{(0)}(t) = ||p_0||_{L^{1/\gamma}(\Omega_0)} |\Omega_t|^{-\gamma}, \tag{5.25}$$

$$\bar{p}^{(1)}(t) = 0, \tag{5.26}$$

where $p_0(\mathbf{x})$ *is the initial pressure. Moreover,* $\delta p^{(1)}$ *satisfies the condition*

$$\int_{\Omega_t} \delta p^{(1)} \, dV = 0 \qquad \text{for all } t, \tau \geq 0. \tag{5.27}$$

Proof. Using (2.4), it is possible to show that

$$\partial_t(\rho f(s)) + \nabla \cdot (\rho f(s) \mathbf{u}) = 0$$

for any smooth function f of the entropy s. Then, we can apply Lemma 5.1 with $a = \rho e^{s/\gamma}$, $\mathbf{u}^* = \mathbf{u}$, and $\mathbf{v} = 0$. Recalling (2.8), we obtain

$$\int_{\Omega_t} p^{1/\gamma} \, dV = \int_{\Omega_0} p_0^{1/\gamma} \, dV. \tag{5.28}$$

This equation is valid also when we use the power series expansion of p. At the first two orders in ϵ, we find

$$\int_{\Omega_t} \left[p^{(0)}\right]^{1/\gamma} \, dV = \int_{\Omega_0} p_0^{1/\gamma} \, dV, \tag{5.29}$$

$$\int_{\Omega_t} \frac{1}{\gamma} \left[p^{(0)}\right]^{1/\gamma - 1} \left(\bar{p}^{(1)} + \delta p^{(1)}\right) \, dV = 0. \tag{5.30}$$

Since $p^{(0)}$ and $\bar{p}^{(1)}$ are functions of time only, (5.29) immediately gives (5.25). Equation (5.30) implies

$$\bar{p}^{(1)}(t) = -\frac{1}{|\Omega_t|} \int_{\Omega_t} \delta p^{(1)} \, dV. \tag{5.31}$$

Averaging (5.31) with respect to τ, we obtain (5.26), and (5.31) becomes (5.27). ∎

As a consequence of (5.26), the condition (5.20) implies

$$\delta p^{(1)}(\mathbf{x}, 0, 0) = 0. \tag{5.32}$$

In general, once $\bar{p}^{(i)}$, $i = 2, 3, \ldots$, is given as a result of the evolutionary equations for $\bar{\mathbf{u}}^{(i-2)}$, the condition (5.21) gives the value of $\delta p^{(i)}$ at $t = \tau = 0$ in Ω_0.

In conclusion, we have shown how to assign initial-boundary conditions for all the averaged quantities appearing in the expansion (4.1), namely (5.5), (5.7), (5.12), (5.18), and (5.19). In particular, at the first two orders the pressure is explicitly given by (5.25) and (5.26). We still need to assign appropriate conditions for the average-free functions $\delta \mathbf{u}^{(0)}$, $\delta \mathbf{u}^{(1)}$, $\delta p^{(0)}$, and $\delta p^{(1)}$, depending on the fast time τ and satisfying the acoustic equations (4.18) and (4.26). This problem will be addressed in the following section.

6. The fast acoustic equation. This section is entirely devoted to determining the average-free functions appearing in the expansion (4.1). For simplicity of exposition, we will refer only to $\delta\mathbf{u}^{(0)}$ and $\delta p^{(1)}$, satisfying the system (4.18) and the conditions (5.6), (5.18), and (5.32). The same analysis can be extended to the next orders, since all the systems for $\delta\mathbf{u}^{(i)}$ and $\delta p^{(i+1)}$ share the same differential structure.

The slow time t and the fast time τ are linearly related by the small parameter ϵ. Since the parameter ϵ is arbitrary, it might be meaningful to regard the fast time τ as an independent variable and to assign, for $\tau = 0$, "initial" data depending on t. As a most unfortunate consequence of this approach, arbitrary "initial" data would be compatible with the initial data (5.3). Nevertheless, it is useful to derive a formal representation of the general solution of (4.18). This will be the object of the first part of this section. Subsequently, we will show that it is possible to resolve completely the average-free functions for a relevant class of motion of the domain Ω_t.

We consider the acoustic equation (4.18), supplemented with the boundary condition

$$\delta\mathbf{u}^{(0)} \cdot \mathbf{n}_t = 0 \qquad \text{on } \partial\Omega_t \tag{6.1}$$

and with initial data

$$\delta\mathbf{u}^{(0)}(\mathbf{x}, t, 0) = \nabla\omega_t(\mathbf{x}), \qquad \delta p^{(1)}(\mathbf{x}, t, 0) = \pi_t(\mathbf{x}) \qquad \text{in } \Omega_t, \tag{6.2}$$

consistently with (5.18) and (5.32), that is,

$$\delta\mathbf{u}^{(0)}(\mathbf{x}, 0, 0) = \nabla\omega_0(\mathbf{x}), \qquad \delta p^{(1)}(\mathbf{x}, 0, 0) = \pi_0(\mathbf{x}) = 0 \qquad \text{in } \Omega_0. \tag{6.3}$$

The acoustic system (4.18), (6.1), (6.2) can be replaced by the wave equation

$$\partial_\tau^2 \delta p^{(1)} - c^2 \nabla \cdot \left(r \nabla \delta p^{(1)} \right) = 0, \tag{6.4}$$

where

$$c^2(t) = \frac{\gamma p^{(0)}(t)}{\tilde{\rho}^{(0)}(t)}, \qquad r(\mathbf{x}, t) = \frac{\tilde{\rho}^{(0)}(t)}{\rho^{(0)}(\mathbf{x}, t)}, \qquad \tilde{\rho}^{(0)} = \frac{1}{|\Omega_t|} \int_{\Omega_t} \rho^{(0)}\, dV, \tag{6.5}$$

with boundary condition

$$\frac{\partial \delta p^{(1)}}{\partial \mathbf{n}_t} = 0 \qquad \text{on } \partial\Omega_t \tag{6.6}$$

and initial data

$$\delta p^{(1)}(\mathbf{x}, t, 0) = \pi_t(\mathbf{x}), \qquad \partial_\tau \delta p^{(1)}(\mathbf{x}, t, 0) = -\gamma p^{(0)} \Delta\omega_t(\mathbf{x}) \qquad \text{in } \Omega_t. \tag{6.7}$$

Once we know $\delta p^{(1)}$, the average-free velocity can be recovered from the equation $(4.18)_2$, supported with the condition $\langle \delta\mathbf{u}^{(0)} \rangle = 0$.

The parameter r in (6.4) characterizes the degree of "isentropicity" of the flow, in the sense that when $r = 1$ the flow is weakly nonisentropic. Some properties of weakly nonisentropic flows are reported in the appendix.

The operator $\nabla \cdot r\nabla$, which appears in (6.4), admits a family of eigenfunctions $\{w_j^t\}$ which forms an orthonormal basis of $L^2(\Omega_t)$. They are defined by

$$\begin{aligned} &\nabla \cdot \left(r \nabla w_j^t \right) = -\lambda_j^t w_j^t \qquad \text{in } \Omega_t, \\ &\frac{\partial w_j^t}{\partial \mathbf{n}_t} = 0 \qquad \text{on } \partial\Omega_t, \\ &\left|\left| w_j^t \right|\right|_{L^2(\Omega_t)} = 1. \end{aligned} \tag{6.8}$$

Then, we can express $\delta p^{(1)}$ as

$$\delta p^{(1)}(\mathbf{x},t,\tau)=\sum_j \sigma_j^t(\tau)w_j^t(\mathbf{x}). \tag{6.9}$$

The function σ_j^t for all j and t satisfies the system

$$\left(\frac{d^2}{d\tau^2}+c^2(t)\lambda_j^t\right)\sigma_j^t=0, \tag{6.10}$$

$$\sigma_j^t(0)=\left(\pi_t,w_j^t\right), \qquad \frac{d\sigma_j^t}{d\tau}(0)=-\gamma p^{(0)}\left(\Delta\omega_t,w_j^t\right). \tag{6.11}$$

The eigenvalues λ_j^t are nonnegative for all j and monotonically increasing to infinity as j increases. In particular, the eigenfunction w_0^t associated with the eigenvalue $\lambda_0^t=0$ is

$$w_0^t(\mathbf{x})=|\Omega|^{-1/2}. \tag{6.12}$$

Using (5.27) in (6.9), we get

$$\sigma_0^t(\tau)=0 \qquad \text{for all } t,\tau\geq 0, \tag{6.13}$$

and hence π_t and $\Delta\omega_t$ necessarily satisfy the condition

$$\int_{\Omega_t}\pi_t\,dV=0, \qquad \int_{\Omega_t}\Delta\omega_t\,dV=0. \tag{6.14}$$

The solution of (6.10) for $j>0$ is

$$\sigma_j^t(\tau)=\left(\pi_t,w_j^t\right)\cos\left[c(\lambda_j^t)^{1/2}\tau\right]-\frac{\tilde\rho^{(0)}c\left(\Delta\omega_t,w_j^t\right)}{(\lambda_j^t)^{1/2}}\sin\left[c(\lambda_j^t)^{1/2}\tau\right]. \tag{6.15}$$

Equations (6.9) and (6.15) give a full representation of $\delta p^{(1)}$ in terms of the eigenfunctions w_j^t and the eigenvectors λ_j^t of the operator $\nabla\cdot r\nabla$ in Ω_t. Moreover, using (4.18), (6.2), and (6.9), we find

$$\delta\mathbf{u}^{(0)}(\mathbf{x},t,\tau)=\sum_j S_j^t(\tau)r(\mathbf{x},t)\nabla w_j^t(\mathbf{x}), \tag{6.16}$$

$$S_j^t(\tau)=-\frac{\left(\pi_t,w_j^t\right)}{\tilde\rho^{(0)}c(\lambda_j^t)^{1/2}}\sin\left[c(\lambda_j^t)^{1/2}\tau\right]-\frac{\left(\Delta\omega_t,w_j^t\right)}{\lambda_j^t}\cos\left[c(\lambda_j^t)^{1/2}\tau\right], \tag{6.17}$$

together with the necessary constraint

$$\nabla\omega_t=-\sum_j\left(\Delta\omega_t,w_j^t\right)\frac{r}{\lambda_j^t}\nabla w_j^t. \tag{6.18}$$

Using (5.10), (6.16), and (6.17), it is possible to assess the validity of (4.32).

We conclude this section by showing that the fast acoustics can be completely resolved at least for a class of motion of the boundary $\partial\Omega_t$.

We consider any invertible map $\Phi_t:\Omega_0\to\Omega_t$ which describes the motion of $\partial\Omega_t$. For simplicity, we consider weakly isentropic flows so that $\rho^{(0)}=\rho^{(0)}(t)$. The

following transformation is compatible with the asymptotic analysis presented in this paper:

$$(\mathbf{x}, t, \tau) \to (\mathbf{y}, s, \sigma) = \left(\Psi_t(\mathbf{x}), s(t), \frac{s(t)}{\epsilon} \right) \qquad \text{with } s'(t) \neq 0. \tag{6.19}$$

Here, $\Psi_t : \Omega_t \to \Omega_0$ is the inverse of the map Φ_t, and $s(t)$ is a function to be determined (not the entropy!). After this change of variables the acoustic system (4.18) becomes

$$\begin{aligned} &\partial_\sigma \delta \mathbf{u}^{(0)} + \frac{1}{s' \rho^{(0)}} M \nabla_{\mathbf{y}} \delta p^{(1)} = 0, \\ &s' \partial_\sigma \delta p^{(1)} + \gamma p^{(0)} (M \nabla_{\mathbf{y}}) \cdot \delta \mathbf{u}^{(0)} = 0, \qquad \mathbf{y} \in \Omega_0, \end{aligned} \tag{6.20}$$

where $\nabla_{\mathbf{y}}$ is the gradient operator with respect to $\mathbf{y}$, $M(\mathbf{y}, t)$ is the inverse of the matrix $\partial \Phi_t(\mathbf{y}) / \partial \mathbf{y}$, and t is expressed everywhere as a function of s. The wave equation (6.4) is replaced by

$$\partial_\sigma^2 \delta p^{(1)} - \frac{\gamma p^{(0)}}{(s')^2 \rho^{(0)}} \left| M \nabla_{\mathbf{y}} \right|^2 \delta p^{(1)} = 0. \tag{6.21}$$

We wish to choose $s(t)$ so that the wave speed for (6.21) does not depend on t. This is not possible in general, since the matrix M depends on time as well as on the space variables. Anyway, there is a simple class of motion for which this problem has a solution corresponding to $\Phi_t(\mathbf{y}) = a(t)\mathbf{y} + \mathbf{b}(t)$. In this case we have $M = (1/a)I$. Then, for weakly nonisentropic flows, the choice

$$s'(t) = \text{constant} \cdot \left(\frac{\gamma p^{(0)}(t)}{\rho^{(0)}(t) a^2(t)} \right)^{\frac{1}{2}} \tag{6.22}$$

leads to a wave speed independent of the slow time t. Using (5.25) and (A.2), and noting that $|\Omega_t| / |\Omega_0| = a^n$, it is possible to rewrite the relation (6.22) in terms of $p^{(0)}$:

$$s'(t) = \text{constant} \cdot \left(p^{(0)}(t) \right)^{\frac{\gamma - 1 + 2/n}{2\gamma}}. \tag{6.23}$$

The wave equation (6.21) can be solved by following the method outlined in the first part of this section with initial data (6.3). For the one-dimensional piston problem, this approach leads to equivalent results to the ones obtained in [17].

7. Conclusions. In this paper we have derived the main implications of the ansatz (4.1) in the framework of the low Mach number limit for a compressible flow in a domain with variable boundary. We have shown that the limit incompressible variables are coupled with high-frequency oscillations produced by the motion of the boundary through the equations (4.18), (4.25). Understanding the role of the interplay with fast acoustics has an enormous relevance for the development of numerical schemes capable of dealing with low Mach number phenomena in a bounded domains.

The analysis performed here is not conclusive since the theory presented is not capable of providing a full resolution of high-frequency acoustics, as we have shown in the previous sections. Nevertheless, the representation given by (6.9) and (6.15) gives a first hint for a theoretical comprehension of the acoustic modes generated by the motion of the boundary. In our opinion, the key point is that one fast variable

is not sufficient to describe the sequence of modes produced by a generic motion of the boundary. Thus, we need to extend the theory by including a family of fast variables nonlinearly related to the slow time and to the space variables. The number of independent fast variables for each term of the expansion should increase with the order of the term. This extension, which has a theoretical interest in itself and is a necessary step for the development of efficient numerical schemes for low Mach number flows in bounded domains with moving boundary, is still a work in progress.

Appendix. Weakly nonisentropic flows. In this appendix we collect some results regarding weakly nonisentropic flows resulting from the condition

$$\rho(\mathbf{x},0)=\rho_0=\text{constant}. \tag{A.1}$$

THEOREM A.1. *Let* $(\rho,\mathbf{u},p)$ *be a solution of* (2.20) *which admits the asymptotic expansion* (4.1). *If* (A.1) *holds, the leading order density is a function of time only,* $\rho^{(0)}=\rho^{(0)}(t)$, *given by*

$$\rho^{(0)}(t)=\frac{|\Omega_0|}{|\Omega_t|}\rho_0. \tag{A.2}$$

Moreover,

$$s^{(0)}=\text{constant}, \tag{A.3}$$

where $s^{(0)}$ *is the leading order entropy.*

Proof. Using $(4.25)_1$, we obtain

$$\frac{\bar{D}}{Dt}\left(\rho^{(0)}|\Omega_t|\right)=0.$$

Then, applying Lemma 5.1 with $a=\rho^{(0)}(\rho^{(0)}|\Omega_t|)^{q-1}$, where q is an integer, $\mathbf{u}^*=\bar{\mathbf{u}}^{(0)}$, and $\mathbf{v}=0$, we find

$$\frac{1}{|\Omega_t|}\int_{\Omega_t}\left(\rho^{(0)}|\Omega_t|\right)^q\,dV=(\rho_0|\Omega_0|)^q\qquad\text{for all integers } q,$$

which implies

$$\left|\left|\rho^{(0)}|\Omega_t|-\rho_0|\Omega_0|\right|\right|_{L^q(\Omega_t)}=0\qquad\text{for all integers } q.$$

Thus, we have

$$\left|\left|\rho^{(0)}|\Omega_t|-\rho_0|\Omega_0|\right|\right|_{L^\infty(\Omega_t)}=0,$$

and hence (A.2). Finally, using (4.20) and (A.2) and recalling the equation of state (2.8), we have also (A.3). ∎

THEOREM A.2. *For a weakly nonisentropic flow, the leading order averaged velocity* $\bar{\mathbf{u}}^{(0)}$ *satisfies the system*

$$\begin{aligned}&\frac{\bar{D}\bar{\mathbf{u}}^{(0)}}{Dt}+\nabla\frac{\bar{p}^{(2)}}{\rho^{(0)}}=-\nabla\cdot\left\langle\delta\mathbf{u}^{(0)}\otimes\delta\mathbf{u}^{(0)}\right\rangle,\\&\nabla\cdot\bar{\mathbf{u}}^{(0)}=\frac{1}{|\Omega_t|}\frac{d|\Omega_t|}{dt}.\end{aligned} \tag{A.4}$$

Moreover, the leading order average-free velocity $\delta\mathbf{u}^{(0)}$ *and the first order average-free pressure* $\delta p^{(1)}$ *satisfy system* (4.18)*. In particular, we have*

$$\partial_\tau^2 \delta p^{(1)} - c^2 \Delta \delta p^{(1)} = 0, \tag{A.5}$$

with $c^2 = \gamma p^{(0)}/\rho^{(0)}$.

Proof. Equation (A.4) follows from (4.25) after using Theorem A.1. Equation (A.5) follows from (6.4) after using (A.2). ∎

THEOREM A.3. *For a weakly nonisentropic flow* $(\rho, \mathbf{u}, p)$*, the first order density* $\rho^{(1)} = \bar{\rho}^{(1)} + \delta\rho^{(1)}$ *is given by*

$$\bar{\rho}^{(1)} = 0, \tag{A.6}$$

$$\delta\rho^{(1)} = \frac{\rho^{(0)}}{\gamma p^{(0)}} \delta p^{(1)}. \tag{A.7}$$

Proof. Using (A.2) and (4.18), equation $(4.26)_1$ becomes

$$\partial_\tau \delta p^{(1)} = -\rho^{(0)} \nabla \cdot \delta\mathbf{u}^{(0)} = \partial_\tau \left(\frac{\rho^{(0)}}{\gamma p^{(0)}} \delta p^{(1)} \right).$$

After integrating with respect to τ, we obtain (A.7). Then, recalling the condition $(4.31)_3$, equation $(4.31)_1$ becomes

$$\partial_t \bar{\rho}^{(1)} + \nabla \cdot \left(\bar{\rho}^{(1)} \bar{\mathbf{u}}^{(0)} \right) = -\nabla \cdot \left\langle \delta\rho^{(1)} \delta\mathbf{u}^{(0)} \right\rangle = -\frac{\rho^{(0)}}{\gamma p^{(0)}} \nabla \cdot \left\langle \delta p^{(1)} \delta\mathbf{u}^{(0)} \right\rangle.$$

Using (4.18), we obtain

$$\nabla \cdot \left\langle \delta p^{(1)} \delta\mathbf{u}^{(0)} \right\rangle = -\rho^{(0)} \left\langle \delta\mathbf{u}^{(0)} \cdot \partial_\tau \delta\mathbf{u}^{(0)} \right\rangle - \frac{1}{\gamma p^{(0)}} \left\langle \delta p^{(1)} \partial_\tau \delta p^{(1)} \right\rangle = 0,$$

and hence

$$\partial_t \bar{\rho}^{(1)} + \nabla \cdot \left(\bar{\rho}^{(1)} \bar{\mathbf{u}}^{(0)} \right) = 0.$$

Using $(A.4)_2$, we find

$$\frac{1}{\bar{\rho}^{(1)}} \frac{\bar{D}\bar{\rho}^{(1)}}{Dt} = -\frac{1}{|\Omega_t|} \frac{d|\Omega_t|}{dt}.$$

Finally, proceeding as in Theorem A.1, we arrive at (A.6). ∎

FROZEN PATH APPROXIMATION FOR TURBULENT DIFFUSION AND FRACTIONAL BROWNIAN MOTION IN RANDOM FLOWS*

ALBERT FANNJIANG† AND TOMASZ KOMOROWSKI‡

Abstract. We establish the conditions for the frozen path approximation for turbulent transport in a class of nonmixing Gaussian flows with long-range correlation. We identify the regimes of fractional Brownian motion limit as well as the Brownian motion limit.

Key words. turbulent transport, fractional Brownian motion, Taylor–Kubo formula

AMS subject classifications. Primary, 60F05, 76F05, 76R50; Secondary, 58F25

DOI. 10.1137/S0036139998335293

1. Introduction. The study of turbulent transport is fundamental to understanding of temperature fields as well as pollutant or tracer particles movement in the atmosphere and oceans and solute transport in groundwater flows [1]. For a long time, the Brownian motion (BM) and the heat equation have been the paradigm for describing large-scale turbulent transport since Taylor's works in the 1920s. The wide applicability of the Brownian motion and the related Gaussian processes have much to do with the central limit theorem which is often assumed to be valid over large scales if there is no memory or intermittency effect.

To account for the memory or intermittency effect, anomalous diffusions have been introduced in recent years as phenomenological models within the framework of fractional kinetic equations or continuous-time random walks (see [21], [12], [19], and the references therein). The mechanisms for anomalous behaviors are generally attributed to long waiting times (subdiffusion) or long flights (superdiffusion) or both. The former results in fractional-in-time (hence non-Markovian) differential operators while the latter results in fractional-in-space differential operators. In both cases the underlying processes are non-Gaussian.

In this paper we derive rigorously the fractional Brownian motions (FBMs) as limiting processes of large-scale motions of particles being advected by a family of random flows that are decorrelated both in space and time but in a manner depending on the wave modes of the velocity. This dependence is described in terms of two crucial parameters (α and β) of the flows. Our limit theorem also characterizes the multiple-particle motions in the FBM regime. FBMs are Gaussian but non-Markovian processes and are different from the phenomenological models mentioned above. The FBMs we find in this paper are invariably superdiffusive due to the positive memory effect, while the FBMs we found elsewhere [7] for a different type of flows can be subdiffusive as well as superdiffusive. By varying the parameters we see that the

limiting processes can switch from FBMs to the Brownian motion, and we characterize the boundary of transition precisely.

The FBM regime indicates the breakdown of the central limit theorem, but the Gaussianity persists in the limit and is inherited from that of the velocity field. It is an open problem if one would obtain non-Gaussian limits for non-Gaussian velocity fields, which are beyond the methodology of the paper.

For the particle displacement $\boldsymbol{x}(t)$ in a given random velocity $\mathbf{V}(t,\mathbf{x})$ we consider the general large-scale limit

$$\boldsymbol{x}^{\varepsilon}(t) = \varepsilon \boldsymbol{x}\left(\frac{t}{\varepsilon^{2q}}\right)$$

satisfying the equation

$$d\boldsymbol{x}^{\varepsilon}(t) = \varepsilon^{1-2q}\mathbf{V}(\varepsilon^{-2q}t, \varepsilon^{-p}\boldsymbol{x}^{\varepsilon}(t))dt + \varepsilon^{1-q}\sqrt{2\kappa}d\mathbf{B}(t), \quad p \geq 0, \tag{1.1}$$

for some $q > 0$ (to be determined) as ϵ tends to zero. Here $\mathbf{B}(t)$ is the Brownian motion and κ is the molecular diffusivity. The special case of $p = 0$ and $q = 1$ is the white-noise-in-time limit. The scaling limit with $p = 1$ is the homogenization limit.

We assume that, in addition to incompressibility, the velocity $\mathbf{V}(t,\mathbf{x}), (t,\mathbf{x}) \in \mathbb{R} \times \mathbb{R}^d$, is a zero mean, time-stationary, space-homogeneous, isotropic, Ornstein–Uhlenbeck (thus, Gaussian and Markovian) process with *long-range correlations* (see below). Here the scaling exponent q depends on the correlation functions of the velocity. The scaling limit (1.1) has been studied by Kesten and Papanicolaou [11] in the case of $p = 0$ and Komorowki [13], [14] in the general case of $0 \leq p < 1$ for velocities sufficiently strongly mixing in time, and in this situation the scaling exponent is always $q = 1$, i.e., the *diffusive* scaling, and the limiting process is a Brownian motion with the diffusion coefficients given by the Taylor–Kubo formula [22]

$$D_{ij} = \int_0^{\infty} \{\mathbb{E}[V_i(t,\mathbf{0})V_j(0,\mathbf{0})] + \mathbb{E}[V_j(t,\mathbf{0})V_i(0,\mathbf{0})]\}\, dt. \tag{1.2}$$

To understand how the long-range correlation in velocity fields may change the diffusive scaling, we study the weak coupling limit for Ornstein–Uhlenbeck velocities with long-range correlations in both space and time (thus, nonmixing) defined as follows. We define the family of velocity fields with power-law spectra as follows. Let $(\Omega, \mathcal{V}, P)$ be a probability space of which each element is a velocity field $\mathbf{V}(t,\mathbf{x})$, $(t,\mathbf{x}) \in \mathbb{R} \times \mathbb{R}^d$ satisfying the following properties.

(H1) $\mathbf{V}(t,\mathbf{x})$ is time-stationary, space-homogeneous, and centered, i.e., $\mathbb{E}\mathbf{V}(0,\mathbf{0}) = \mathbf{0}$, and Gaussian. Here $\mathbb{E}$ stands for the expectation with respect to the probability measure P.

(H2) The two-point correlation tensor $\mathbf{R} = [R_{ij}]$ is given by

$$\begin{aligned} R_{ij}(t,\mathbf{x}) &= \mathbb{E}\left[V_i(t,\mathbf{x})V_j(0,\mathbf{0})\right] \\ &= \int_{\mathbb{R}^d} \cos\left(\mathbf{k}\cdot\mathbf{x}\right) \exp\left(-|\mathbf{k}|^{2\beta}t\right) \frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d-1}} \\ &\qquad \times \left(\mathbf{I} - \frac{\mathbf{k}\otimes\mathbf{k}}{|\mathbf{k}|^{d-1}}\right) d\mathbf{k}, \quad \beta \geq 0, \quad d \geq 2, \end{aligned} \tag{1.3}$$

with the spatial spectral density

$$\mathcal{E}(k) = \frac{a(k)}{k^{2\alpha-1}}, \quad \alpha < 1, \tag{1.4}$$

where $a : [0, +\infty) \to \mathbb{R}_+$ is a compactly supported, continuous, nonnegative function. The factor $\mathbf{I} - \mathbf{k} \otimes \mathbf{k}/|\mathbf{k}|^2$ in (1.3) ensures the incompressibility.

Note that for $\alpha < 1$ the instantaneous two-point correlation functions $R_{ij}(0, \mathbf{x})$ decays to zero as $|\mathbf{x}|$ tends to infinity. The velocity is strongly temporally mixing if and only if $\beta = 0$ (see [20]).

We show that the scaling limit is either a Brownian motion or a persistent (i.e., superdiffusive) FBM as stated in the following theorem.

THEOREM 1. *Let the velocity field satisfy properties* (H1)–(H2) *with* $p < 1$.

Case 1. *For* $\alpha + \beta < 1$ *and the scaling exponent*

$$q = 1,$$

the solution $\boldsymbol{x}^\varepsilon(t)$ *converges in distribution, as* ε *tends to zero, to the Brownian motion with the covariance matrix given by the Kubo formula* (1.2) *plus* $\kappa\mathbf{I}$.

Case 2. *For* $1 < \alpha + \beta,\ \alpha + 2\beta < 1 + 1/p$, *and the scaling exponent*

$$q := \frac{\beta}{\alpha + 2\beta - 1}, \tag{1.5}$$

the solution $\boldsymbol{x}^\varepsilon(t)$ *converges in probability, as* ε *tends to zero, to a fractional Brownian motion* $\mathbf{B}_H(t)$ *with covariance given by*

$$Cov(\mathbf{B}_H(t_1), \mathbf{B}_H(t_2)) = \frac{1}{2}\mathbf{D}\left\{|t_1|^{2H} + |t_2|^{2H} - |t_1 - t_2|^{2H}\right\} \tag{1.6}$$

with the coefficients $\mathbf{D}$

$$\mathbf{D} = \int_{\mathbb{R}^d} \frac{e^{-|\mathbf{k}|^{2\beta}} - 1 + |\mathbf{k}|^{2\beta}}{|\mathbf{k}|^{2\alpha+4\beta-1}} \left(\mathbf{I} - \frac{\mathbf{k} \otimes \mathbf{k}}{|\mathbf{k}|^2}\right) \frac{a(0)}{|\mathbf{k}|^{d-1}} d\mathbf{k} \tag{1.7}$$

and the Hurst exponent H,

$$1/2 < H = 1/2 + \frac{\alpha + \beta - 1}{2\beta} < 1. \tag{1.8}$$

The homogenization scaling with $p = 1$ has been considered in [2], [3], [8], [15] and the corresponding scaling exponent q is the same. But the eddy diffusion matrix is no longer given by the Kubo formula.

We also establish the following results, which are very useful for understanding the simultaneous limit of the motion of multiple particles.

THEOREM 2. *Under the same assumptions of Theorem* 1, *the following approximations are valid in the respective regimes in the mean square sense for sufficiently small* ε:

Case 1.

$$\boldsymbol{x}^\varepsilon(t) = \mathbf{W}_\varepsilon(t) + o(1)$$

with

$$\begin{aligned}\mathbf{W}_\varepsilon(t) : = \int_0^t \int_{\mathbb{R}^d} & \frac{|\mathbf{k}|^\beta \mathcal{E}^{\frac{1}{2}}(|\mathbf{k}|)}{(|\mathbf{k}|^{2\beta} + \varepsilon^2)|\mathbf{k}|^{\frac{(d-1)}{2}}} \left(\mathbf{I} - \frac{\mathbf{k} \otimes \mathbf{k}}{|\mathbf{k}|^2}\right)^{\frac{1}{2}} \\ & [\cos(\varepsilon^{-p}\boldsymbol{x}^\varepsilon(s) \cdot \mathbf{k})\mathbf{W}_0(ds, d\mathbf{k}) + \sin(\varepsilon^{-p}\boldsymbol{x}^\varepsilon(s) \cdot \mathbf{k})\mathbf{W}_1(ds, d\mathbf{k})],\end{aligned} \tag{1.9}$$

where $\mathbf{W}_i(dt, d\mathbf{k})$, $i = 0, 1$, *are two independent copies of a d-dimensional space-time white-noise field (see* [16] *for a thorough discussion).*

Case 2.

$$\boldsymbol{x}^\varepsilon(t) = \boldsymbol{x}^\varepsilon(0) + \int_0^t \varepsilon^{1-2q}\mathbf{V}(\varepsilon^{-2q}s, \varepsilon^{-p}\boldsymbol{x}^\varepsilon(0))ds + o(1). \tag{1.10}$$

The surprising feature about the approximation (1.10) is that the "frozen path" approximation is asymptotically exact on the time scale of observation. Thus the multiple-point motion can be easily derived.

The process $\mathbf{W}_\varepsilon(t)$ defined by (1.9) is a continuous martingale with the quadratic variation

$$\langle \mathbf{W}_\varepsilon \rangle_t = t \int_{\mathbb{R}^d} \frac{|\mathbf{k}|^{2\beta}\mathcal{E}(|\mathbf{k}|)}{(|\mathbf{k}|^{2\beta} + \varepsilon^2)^2} \left(\mathbf{I} - \frac{\mathbf{k}\otimes\mathbf{k}}{|\mathbf{k}|^2}\right) \frac{d\mathbf{k}}{|\mathbf{k}|^{d-1}}.$$

Thus we know that $\mathbf{W}_\varepsilon(t)$, $t \geq 0$, is a Brownian motion. It is easy to check that the ratio $\langle \mathbf{W}_\varepsilon \rangle_t / t$ converges to the Kubo formula as ε tends to zero.

Theorem 1 characterizes the limit of one-point motion whereas Theorem 2 enables us to calculate the limit of multiple-point motion with each particle starting from a different point. It is straightforward to check from the corresponding approximations (1.9) and (1.10) that any two particles with a *fixed* initial separation in $\boldsymbol{x}^\varepsilon(0)$ become, in the limit $\varepsilon \to 0$, *independent* Brownian or FBMs for $p > 0$. However, if the initial separation of particles is of order ε^p, then the resulting limit processes are correlated as in the case of $p = 0$ which has been studied in [6]. The proofs of Theorem 1 and 2 use (finite) diagrammatic expansion and are given in sections 4–6.1. In the main text we present the physical explanation of the theorems in terms of the frozen path approximation. The results are shown schematically in Figure 1. In section 7 we provide a scaling argument for the case of $p > 1$ for the fractional Brownian regime.

When an additional infrared cutoff of the size ε^γ is introduced in the velocity spectrum, the results depend on whether the cutoff is *subcritical*, $\gamma < (\alpha + 2\beta - 1)^{-1}$, or *supercritical*, $\gamma > (\alpha + 2\beta - 1)^{-1}$. A supercritical cutoff does not affect the diagram, but a subcritical cutoff does. In particular, the regime of FBM limit disappears, and the limit is always a Brownian motion when the infrared cutoff is subcritical (see [2], [3]). We will not further discuss the effect of infrared cutoff in this paper.

The effect of molecular diffusion on transport may be subtle (see [18], [7]). However, for isotropic flows with monotonically decaying temporal correlation, small molecular diffusivity is negligible and will only affect results perturbatively. So we set $\kappa = 0$ from now on to simplify the presentation.

2. Brownian motion limit. Let us first consider the case of the Brownian motion limit. We express the displacement in the integral form

$$\boldsymbol{x}_\varepsilon(t) = \boldsymbol{x}_\varepsilon(0) + \frac{1}{\varepsilon}\int_0^t \mathbf{V}\left(\frac{t_1}{\varepsilon^2}, \frac{\boldsymbol{x}_\varepsilon(t_1)}{\varepsilon^p}\right) dt_1.$$

Assuming for simplicity that the spatial derivative of the velocity field is uniformly bounded, we know that the frozen path approximation

$$\boldsymbol{x}_\varepsilon(t) \approx \tilde{\boldsymbol{x}}_\varepsilon(t) = \boldsymbol{x}_\varepsilon(0) + \frac{1}{\varepsilon}\int_0^t \mathbf{V}\left(\frac{s}{\varepsilon^2}, \frac{\boldsymbol{x}_\varepsilon(0)}{\varepsilon^p}\right) ds, \quad 0 < t < \tau,$$

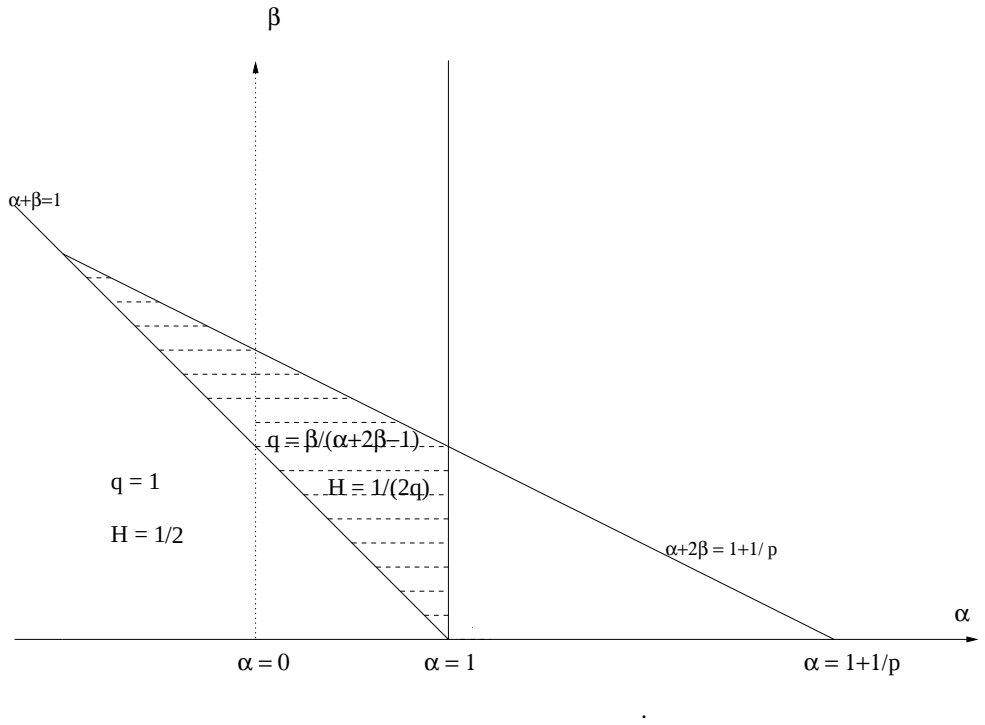

FIG. 1. *Phase diagram with supercritical infrared cutoff.*

is accurate pathwise with an error of $O(\tau^{3/2}\varepsilon^{-1-p})$ on the time scale

$$\varepsilon^2 \ll \tau \ll \varepsilon^{p+1} \tag{2.1}$$

(cf. (3.5)). One then expects that, for small ε, the displacement $\boldsymbol{x}_\varepsilon(t)$ is approximately the sum, $\tilde{\boldsymbol{x}}_\varepsilon(t)$, of t/τ random variables in the form

$$\Delta\tilde{\boldsymbol{x}}^n_\varepsilon(\tau) = \tilde{\boldsymbol{x}}_\varepsilon((n+1)\tau) - \tilde{\boldsymbol{x}}_\varepsilon(n\tau) = \varepsilon \int_{n\tau/\varepsilon^2}^{(n+1)\tau/\varepsilon^2} \mathbf{V}\left(s, \frac{\tilde{\boldsymbol{x}}_\varepsilon(n\tau)}{\varepsilon^p}\right) ds, \quad n = 0, 1, 2, \ldots.$$

Since $\tau \gg \varepsilon^2$, by the central limit theorem for processes with mixing, stationary increments (cf. [20]), the process $\Delta\tilde{\boldsymbol{x}}^n_\varepsilon(t)$,

$$\Delta\tilde{\boldsymbol{x}}^n_\varepsilon(t) = \varepsilon \int_{n\tau/\varepsilon^2}^{(n\tau+t)/\varepsilon^2} \mathbf{V}\left(s, \frac{\tilde{\boldsymbol{x}}_\varepsilon(n\tau)}{\varepsilon^p}\right) ds, \quad 0 < t \le \tau,$$

conditioned on $\tilde{\boldsymbol{x}}_\varepsilon(n\tau)$, is approximately a Brownian motion, starting at 0, with diffusion coefficient given by the Taylor–Kubo formula (1.2). Since $\tau \gg \varepsilon^2$ and the Taylor–Kubo formula converges, $\Delta\tilde{\boldsymbol{x}}^n_\varepsilon$ are nearly uncorrelated for different n and the total error made by the frozen path approximation is $O(\tau\varepsilon^{-1-p})$, which is negligible for $\tau \ll \varepsilon^{1+p}$.

The question is, What is the region in the (α, β) plane where the classical turbulent diffusion theorem, with the Taylor–Kubo formula (1.2), holds? It is easy to find the necessary condition by imposing the convergence of the Taylor–Kubo formula

(1.2). A straightforward calculation

$$\begin{aligned} D^*_{ij} &= \int_0^\infty R_{ij}(t,\mathbf{0})dt \\ &= \int_{\mathbb{R}^d} \left(\delta_{ij} - \frac{k_i k_j}{|\mathbf{k}|^2}\right) \frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d-1}} \int_0^\infty \exp\left(-|\mathbf{k}|^{2\beta} t\right) dt d\mathbf{k} \\ &= \int_{\mathbb{R}^d} \left(\delta_{ij} - \frac{k_i k_j}{|\mathbf{k}|^2}\right) \frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d+2\beta-1}} d\mathbf{k} \end{aligned} \tag{2.2}$$

leads to the condition

$$\alpha + \beta < 1. \tag{2.3}$$

It turns out that (2.3) is also sufficient. In other words, the classical turbulent diffusion theorem holds for this family of Gaussian velocity fields if and only if (2.3) is true (see section 6.1).

Let us see what the frozen path approximation tells us. The covariance of the Gaussian increment $\Delta\tilde{\boldsymbol{x}}^n_\varepsilon(t),\ 0 < t < \tau$ (given by (2.1)), stationary with respect to n, can be expressed as

$$\begin{aligned} & 2\varepsilon^2 \int_0^{t/\varepsilon^2} \int_0^{s_1} R_{ij}(s_1 - s_2, \mathbf{0})\ ds_2\ ds_1 \\ &= 2\varepsilon^2 \int_0^{t/\varepsilon^2} \int_{\mathbb{R}^d} \left(\delta_{ij} - \frac{k_i k_j}{|\mathbf{k}|^2}\right) \frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d+2\beta-1}} (1 - e^{-s_1|\mathbf{k}|^{2\beta}}) d\mathbf{k} ds_1 \\ &= 2\int_0^t \int_{\mathbb{R}^d} \left(\delta_{ij} - \frac{k_i k_j}{|\mathbf{k}|^2}\right) \frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d+2\beta-1}} (1 - e^{-t_1|\mathbf{k}|^{2\beta}/\varepsilon^2}) d\mathbf{k} dt_1 \\ &= 2D^*_{ij} t - 2\int_0^t \int_{\mathbb{R}^d} \left(\delta_{ij} - \frac{k_i k_j}{|\mathbf{k}|^2}\right) \frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d+2\beta-1}} e^{-t_1|\mathbf{k}|^{2\beta}/\varepsilon^2} d\mathbf{k} dt_1 \\ &= 2D^*_{ij} t - 2\int_{\mathbb{R}^d} \left(\delta_{ij} - \frac{k_i k_j}{|\mathbf{k}|^2}\right) \frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d+2\beta-1}} \times \frac{\varepsilon^2}{|\mathbf{k}|^{2\beta}} (1 - e^{-t|\mathbf{k}|^{2\beta}/\varepsilon^2})\, d\mathbf{k} \end{aligned} \tag{2.4}$$

with D^* given by the Taylor–Kubo formula (2.2). The last integral can be estimated by breaking it into two parts: $|\mathbf{k}|^{2\beta} < \varepsilon^2/t$ and $|\mathbf{k}|^{2\beta} \geq \varepsilon^2/t$. The first part has the asymptotic

$$\begin{aligned} & 2t \int_{|\mathbf{k}|^{2\beta} < \varepsilon^2/t} \left(\delta_{ij} - \frac{k_i k_j}{|\mathbf{k}|^2}\right) \frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d+2\beta-1}}\, d\mathbf{k} \\ &\sim |\mathbf{k}|^{2-2\alpha-2\beta} \Big|_0^{(\frac{\varepsilon^2}{t})^{1/(2\beta)}} t \\ &= \varepsilon^{2(1-\alpha-\beta)/\beta} t^{(\alpha+2\beta-1)/\beta}, \end{aligned} \tag{2.5}$$

which, if $\alpha + 2\beta > 1$, gives rise to the *subdiffusive* FBM with the Hurst exponent

$$H = \frac{\alpha + 2\beta - 1}{2\beta} \ < \ 1/2$$

and vanishing coefficient since $\alpha + \beta < 1$. The second part can be estimated by

$$2\int_{|\mathbf{k}|^{2\beta} \geq \varepsilon^2/t} \frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d+2\beta-1}} \times \frac{\varepsilon^2}{|\mathbf{k}|^{2\beta}}\, d\mathbf{k}$$

$$\sim 2\varepsilon^2\left[\left(\frac{\varepsilon^2}{t}\right)^{(1-\alpha-2\beta)/\beta} - K^{2(1-\alpha-2\beta)}\right]$$

$$= 2\varepsilon^{2(1-\alpha-\beta)/\beta}t^{(\alpha+2\beta-1)/\beta} - 2\varepsilon^2 K^{2(1-\alpha-2\beta)}. \tag{2.6}$$

Thus, if $\alpha+2\beta<1$, the second term in (2.6) dominates the first and, if $\alpha+2\beta>1$, the first dominates. But both (2.5) and (2.6) are negligible relative to the leading term $2D^*_{ij}t$.

Therefore, for $\alpha+\beta<1$, the displacement $\boldsymbol{x}_\varepsilon(t)$ behaves like the Brownian motion, with the diffusion coefficient given by the Taylor–Kubo formula (2.2), plus a correction term. When $\alpha+2\beta>1$ the correction term is like a *subdiffusive* FBM.

3. FBM limit. What happens if (2.3) is violated? The divergence of the Taylor–Kubo formula (1.2) suggests a superdiffusive behavior and, consequently, a different scaling limit.

Consider the superdiffusive scaling on the displacement

$$\boldsymbol{x}_\varepsilon(t) = \varepsilon\boldsymbol{x}\left(\frac{t}{\varepsilon^{2q}}\right), \quad q<1. \tag{3.1}$$

The equation of motion becomes

$$\frac{d\boldsymbol{x}_\varepsilon(t)}{dt} = \frac{1}{\varepsilon^{2q-1}}\mathbf{V}\left(\frac{t}{\varepsilon^{2q}}, \frac{\boldsymbol{x}_\varepsilon(t)}{\varepsilon^p}\right), \quad p<1. \tag{3.2}$$

The frozen path argument will show that for

$$\alpha+\beta>1, \quad \alpha<1, \tag{3.3}$$

and

$$q = \frac{\beta}{\alpha+2\beta-1}, \tag{3.4}$$

the solution $\boldsymbol{x}_\varepsilon(t)$ of (3.2) converges to an FBM.

First we note that the frozen path approximation

$$\boldsymbol{x}_\varepsilon(t) \approx \tilde{\boldsymbol{x}}_\varepsilon(t) = \boldsymbol{x}_\varepsilon(0) + \frac{1}{\varepsilon^{2q-1}}\int_0^t \mathbf{V}\left(\frac{t_1}{\varepsilon^{2q}}, \frac{\boldsymbol{x}_\varepsilon(0)}{\varepsilon^p}\right)dt_1$$

is accurate with the error $O(\tau^{1+1/(2q)}\varepsilon^{1-p-2q})$ on the (rescaled) time scale τ,

$$\varepsilon^{2q} \ll \tau \ll \varepsilon^{p+2q-1}, \tag{3.5}$$

provided that the scaling exponent q is the right one (i.e., $\boldsymbol{x}_\varepsilon(t), t>0$ is $O(1)$). The upper limit on τ is imposed in (3.5) because the total error made by the frozen path approximation is then $O(\tau\varepsilon^{1-p-2q})$, which is negligible.

Let us calculate the covariance of the Gaussian increment

$$\Delta\tilde{\boldsymbol{x}}^n_\varepsilon(t) = \varepsilon\int_{n\tau/\varepsilon^{2q}}^{(n\tau+t)/\varepsilon^{2q}} \mathbf{V}\left(s, \frac{\tilde{\boldsymbol{x}}_\varepsilon(n\tau)}{\varepsilon^p}\right)ds, \quad 0<t\le\tau,$$

which is stationary in n. Denoting by $\mathbf{R}_s$ the symmetric part of the covariance matrix $\mathbf{R}$, we have

$$\begin{aligned}
&\mathbb{E}[\Delta\tilde{\mathbf{x}}_\varepsilon^n(t)\otimes\Delta\tilde{\mathbf{x}}_\varepsilon^n(t)]\\
&= 2\varepsilon^2\int_0^{t/\varepsilon^{2q}}\int_0^{s_1}\mathbf{R}_s(s_1-s_2,0)\,ds_1\,ds_2\\
&= 2\varepsilon^2\int_0^{t/\varepsilon^{2q}}\int_{\mathbb{R}^d}\left(\mathbf{I}-\frac{\mathbf{k}\otimes\mathbf{k}}{|\mathbf{k}|^2}\right)\frac{\mathcal{E}(\mathbf{k})}{|\mathbf{k}|^{d+2\beta-1}}(1-e^{-s_1|\mathbf{k}|^{2\beta}})\,ds_1\,d\mathbf{k}\\
&= 2\varepsilon^{2(1-q)}\int_0^t\left(\int_{|\mathbf{k}|^{2\beta}<\varepsilon^{2q}/t_1}+\int_{|\mathbf{k}|^{2\beta}\ge\varepsilon^{2q}/t_1}\right)\\
&\qquad\times\left(\mathbf{I}-\frac{\mathbf{k}\otimes\mathbf{k}}{|\mathbf{k}|^2}\right)\frac{\mathcal{E}(\mathbf{k})}{|\mathbf{k}|^{d+2\beta-1}}(1-e^{-t_1|\mathbf{k}|^{2\beta}/\varepsilon^{2q}})\,d\mathbf{k}\,dt_1.
\end{aligned}$$

The first integral has the order of magnitude

$$\varepsilon^{2(1-q)}\int_0^t\int_{|\mathbf{k}|^{2\beta}<\varepsilon^{2q}/t_1}\frac{\mathcal{E}(\mathbf{k})}{|\mathbf{k}|^{d+2\beta-1}}\times\frac{t_1|\mathbf{k}|^{2\beta}}{\varepsilon^{2q}}\,d\mathbf{k}\,dt_1\sim\varepsilon^{2[1-q(\alpha+2\beta-1)/\beta]}t^{(\alpha+2\beta-1)/\beta}.$$

The second integral has the order of magnitude

$$\varepsilon^{2(1-q)}\int_0^t\int_{|\mathbf{k}|^{2\beta}\ge\varepsilon^{2q}/t_1}\frac{\mathcal{E}(\mathbf{k})}{|\mathbf{k}|^{d+2\beta-1}}\,d\mathbf{k}\,dt_1\sim\varepsilon^{2[1-q(\alpha+2\beta-1)/\beta]}t^{(\alpha+2\beta-1)/\beta}.$$

They are of the same sign so they do not cancel with each other. With (3.4) both terms behave like the FBM of finite, constant coefficients with the Hurst exponent $H=1/(2q)$ on the (rescaled) time scales in the range given by (3.5). In particular, for $p=0$, the FBM limit holds up to order one time as is rigorously proved in [6]. The scaling with (3.4) is *superdiffusive* since $q<1$ for $\alpha+\beta>1$. This is the result of *positive* correlation between successive increments. For the FBM-like behavior to persist up to order one times for $p>0$ the stationary increments at different times must have the right positive correlation. This is proved in section 6.

4. Estimation by diagrammatic method. We now turn to the proof of Theorem 1. We shall only calculate the mean square displacement of the particle. We make use of a spectral representation of the velocity field as follows. Let $\hat{\mathbf{V}}_0(t,d\mathbf{k}),\hat{\mathbf{V}}_1(t,d\mathbf{k})$ be two independent copies of real $\mathbb{R}^d$-valued, Gaussian, random spectral measures with the structure matrix

$$\mathbb{E}[\hat{\mathbf{V}}_i(t,d\mathbf{k})\otimes\hat{\mathbf{V}}_i(0,d\mathbf{k})]=\frac{\mathrm{e}^{-|\mathbf{k}|^{2\beta}t}\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d-1}}\left(\mathbf{I}-\frac{\mathbf{k}\otimes\mathbf{k}}{|\mathbf{k}|^2}\right)d\mathbf{k},\quad i=0,1. \tag{4.1}$$

The modes of the random measure can be intuitively thought of as mutually independent "infinitesimal" Ornstein–Uhlenbeck processes, that is, a stationary solution of a properly understood (e.g., in the sense of generalized functions) stochastic differential equation

$$\begin{aligned}
&d_t\hat{\mathbf{V}}_i(t,d\mathbf{k})\\
&\quad=-|\mathbf{k}|^{2\beta}\hat{\mathbf{V}}_i(t,d\mathbf{k})dt+|\mathbf{k}|^{(2\beta+1-d)/2}\mathcal{E}^{\frac12}(|\mathbf{k}|)\left(\mathbf{I}-\frac{\mathbf{k}\otimes\mathbf{k}}{|\mathbf{k}|^2}\right)\mathbf{W}_i(dt,d\mathbf{k}),\quad i=0,1.
\end{aligned} \tag{4.2}$$

Here $\mathbf{W}_i(dt, d\mathbf{k})$, $i = 0, 1$, are independent $\mathbb{R}^d$-valued, uncorrelated space-time white-noise random measures.

We can write then that

$$\mathbf{V}(t, \mathbf{x}) = \int \hat{\mathbf{V}}(t, \mathbf{x}, d\mathbf{k}), \tag{4.3}$$

with

$$\hat{\mathbf{V}}(t, \mathbf{x}, d\mathbf{k}) := \mathrm{e}^{\mathrm{i}\mathbf{k}\cdot\mathbf{x}}\hat{\mathbf{V}}(t, d\mathbf{k}) \tag{4.4}$$

and $\hat{\mathbf{V}}(t, \cdot)$ a $\mathbb{C}^d$-valued, componentwise Gaussian random measure given by

$$\hat{\mathbf{V}}(t, A) := \frac{1}{2}[\hat{\mathbf{V}}_0(t, A) + \hat{\mathbf{V}}_0(t, -A)] + \frac{\mathrm{i}}{2}[\hat{\mathbf{V}}_1(t, A) - \hat{\mathbf{V}}_1(t, -A)]. \tag{4.5}$$

The velocity field is temporally Markovian because for any Borel set A and $s \le t$

$$\mathbb{E}_s\hat{\mathbf{V}}(t, d\mathbf{k}) = \mathrm{e}^{-|\mathbf{k}|^{2\beta}(t-s)}\hat{\mathbf{V}}(s, d\mathbf{k}). \tag{4.6}$$

Here $\mathbb{E}_s$ denotes the conditional expectation with respect to the history of the random field determined up to time s. Another property of temporal dynamics of the field is its *reversibility*, which can be expressed in the following form. For any $s_1 \ge s_2 \ge \cdots s_n \ge 0$ and functions F, G of appropriate arguments, we have

$$\begin{aligned}&\mathbb{E}\left\{\mathbb{E}_0\left[F(\hat{\mathbf{V}}(s_1, d\mathbf{k}_1), \ldots, \hat{\mathbf{V}}(s_n, d\mathbf{k}_n))\right] G(\hat{\mathbf{V}}(0, d\mathbf{k}_{n+1}))\right\}\\ &= \mathbb{E}\left[F(\hat{\mathbf{V}}(s_1 - s_n, d\mathbf{k}_1), \ldots, \hat{\mathbf{V}}(0, d\mathbf{k}_n))\mathbb{E}_0 G(\hat{\mathbf{V}}(s_n, d\mathbf{k}_{n+1}))\right].\end{aligned} \tag{4.7}$$

As explained in the introduction, the molecular diffusion has only a perturbative effect and will be set to zero to simplify the calculation. The motion of the tracer is then described by

$$\frac{d\boldsymbol{x}(t)}{dt} = \mathbf{V}(t, \varepsilon^{1-p}\boldsymbol{x}(t)). \tag{4.8}$$

Let us set

$$\boldsymbol{x}^\varepsilon(t) = \varepsilon\int_0^{t\varepsilon^{-2q}} \mathbf{V}(s, \varepsilon^{1-p}\boldsymbol{x}(s))ds, \tag{4.9}$$

where $p < 1$ and $\mathbf{x}(t)$ is given by (4.8) and q is to be specified later.

For any $t \ge s$ define $\Delta_n(t, s) := [(s_1, \ldots, s_{n+1}) : t \ge s_1 \ge \cdots \ge s_{n+1} \ge s]$. To compute the mean square displacement of the particle we write

$$\begin{aligned}\mathbb{E}\left[\mathbf{x}_\varepsilon(t) \otimes \mathbf{x}_\varepsilon(t)\right] &= \varepsilon^2\int_0^{t\varepsilon^{-2q}} ds \int_0^s \left\{\mathbb{E}\left[\mathbf{V}(s_1, \varepsilon^{1-p}\mathbf{x}(s_1)) \otimes \mathbf{V}(0, \mathbf{0})\right]\right.\\ &\qquad \left. + \mathbb{E}\left[\mathbf{V}(0, \mathbf{0}) \otimes \mathbf{V}(s_1, \varepsilon^{1-p}\mathbf{x}(s_1))\right]\right\} ds_1\\ &= \sum_{n=0}^{N-1} \mathcal{I}_{n,\varepsilon}(t) + \mathcal{R}_{N,\varepsilon}(t),\end{aligned} \tag{4.10}$$

with $\mathcal{I}_{n,\varepsilon}(t)$ the symmetric part of the matrix

$$\mathcal{I}^0_{n,\varepsilon}(t) := 2\varepsilon^{n(1-p)+2}\int_0^{t\varepsilon^{-2q}} ds \int_{\Delta_n(s,0)}\cdots\int \mathbb{E}\left\{\mathbb{E}_0\left[\mathbf{W}_n(s_1,\ldots,s_{n+1},\mathbf{0})\right] \otimes \mathbf{V}(0,\mathbf{0})\right\} ds_1\cdots ds_{n+1} \tag{4.11}$$

and $\mathcal{R}_{N,\varepsilon}(t)$ the symmetric part of the matrix

$$\begin{aligned}&\mathcal{R}^0_{N,\varepsilon}(t)\\ &= 2\varepsilon^{N(1-p)+2}\int_0^{t\varepsilon^{-2q}} ds \int_{\Delta_N(s,0)}\cdots\int \mathbb{E}\left\{\mathbb{E}_{s_{N+1}}\left[\mathbf{W}_N(s_1,\ldots,s_{N+1},\varepsilon^{1-p}\mathbf{x}(s_{N+1}))\right] \otimes \mathbf{V}(0,\mathbf{0})\right\} ds_1\cdots ds_{N+1},\end{aligned}$$

where $\mathbf{W}_n(\cdot)$ is defined inductively by

$$\mathbf{W}_0(s_1,\mathbf{x}) := \mathbf{V}(s_1,\mathbf{x}), \tag{4.12}$$

$$\mathbf{W}_n(s_1,\ldots,s_{n+1},\mathbf{x}) := \mathbf{V}(s_{n+1},\mathbf{x}) \cdot\nabla\mathbf{W}_{n-1}(s_1,\ldots,s_n,\mathbf{x}) \qquad \text{for } n=1,2,\ldots. \tag{4.13}$$

To estimate both $\mathcal{I}_n$ and the remainder term $\mathcal{R}_{N,\varepsilon}(t)$ we shall deal with expectations of polynomial-like expressions in a Gaussian variable. To calculate the expectation of multiple product of Gaussian random variables, we use Feynman diagrams borrowed from quantum field theory (see, e.g., [9] and [10]). A *Feynman diagram* $\mathcal{F}$ (of order n = number of vertexes and rank r = number of edges) is a graph consisting of a set $B(\mathcal{F})$ of n vertexes and a set $E(\mathcal{F})$ of r edges without common endpoints. So there are r pairs of vertexes, each joined by an edge, and $n-2r$ unpaired vertexes, called *free vertexes*. Let $B(\mathcal{F})$ be a subset of positive integers. An edge whose endpoints are $m,n\in B$ is represented by $\widehat{mn}$ (unless otherwise specified, we always assume $m<n$); an edge includes its endpoints. A diagram $\mathcal{F}$ is said to be *based on* $B(\mathcal{F})$. Denote the set of free vertexes by $A(\mathcal{F})$, so $A(\mathcal{F}) = \mathcal{F}\setminus E(\mathcal{F})$. The diagram is *complete* if $A(\mathcal{F})$ is empty and *incomplete* otherwise. Denote by $\mathcal{G}(B)$ the set of all diagrams based on B, by $\mathcal{G}_c(B)$ the set of all complete diagrams based on B, and by $\mathcal{G}_{\text{in}}(B)$ the set of all incomplete diagrams based on B. A diagram $\mathcal{F}'\in\mathcal{G}_c(B)$ is called a *completion* of $\mathcal{F}\in\mathcal{G}_i(B)$ if $E(\mathcal{F})\subseteq E(\mathcal{F}')$.

Let $\mathbb{Z}_n := \{1,2,3,\ldots,n\}$. For $n\geq 1$ we define inductively a class $\mathfrak{S}_n$ of certain Feynman diagrams based on $\mathbb{Z}_n$ as follows. For $n=1$, $\mathfrak{S}_1$ consists of the trivial diagram $\mathcal{F}$ with vertex 1. Given $\mathfrak{S}_{n-1}$, $\mathfrak{S}_n$ consists of all the *descendants* of $\mathfrak{S}_{n-1}$. A descendant $\mathcal{F}'$ of $\mathcal{F}\in\mathfrak{S}_{n-1}$ is a graph based on $\mathbb{Z}_n$ such that $A(\mathcal{F}')\neq\emptyset$ and

$$\mathcal{F}'_{|n-1} = \mathcal{F}, \tag{4.14}$$

where $\mathcal{F}'_{|n-1}$ is the restriction of $\mathcal{F}'$ to $\mathbb{Z}_{n-1}$ with edges of the type $\widehat{mn}$, $m=1,2,\ldots,n-1$, deleted. We call $\mathcal{F}$ the *predecessor* of $\mathcal{F}'$. The predecessor of any $\mathcal{F}'\in\mathfrak{S}_n$ is clearly unique. For $\mathcal{F}\in\mathfrak{S}_n$ set $A_k(\mathcal{F}) = A(\mathcal{F}_{|k})$, $k=1,2,\ldots,n$.

Adopting the multi-index notation for any $N\in\mathbb{Z}^+$, $\mathbf{n}=(n_1,\ldots,n_{N+1})$, $n_j\in\{1,2,3,\ldots,d\}$, and $|\mathbf{n}| := n_1+n_2+\ldots+n_{N+1}$, we have the following formula.

LEMMA 1. *Let $N\geq 1$ and $s_1\geq s_2\geq\cdots\geq s_{N+1}\geq 0$, $i\in\{1,\ldots,d\}$, $\mathbf{x}\in\mathbb{R}^d$. We have then that*

(4.15)

$$\mathbb{E}_{s_{N+1}} W_{N,i}(s_1,\dots,s_{N+1},\mathbf{x}) = \sum_{\mathbf{n},\mathcal{F}} \int\cdots\int \exp\left\{ \mathrm{i} \sum_{m\in A_N(\mathcal{F})\cup\{N+1\}} \mathbf{k}_m\cdot\mathbf{x} \right\}$$
$$\times\ \mathrm{i}^N \prod_{j=1}^N \left(\sum_{m\in A_j(\mathcal{F})} \mathbf{k}_m \right) \exp\left\{ - \sum_{m\in A_j(\mathcal{F})} |\mathbf{k}_m|^{2\beta}(s_j - s_{j+1}) \right\}$$
$$\times\ C_{\mathbf{n},N} \prod_{\widehat{mm'}\in E(\mathcal{F})} \mathbb{E}\left[\widehat{V}_{n_m}(0,d\mathbf{k}_m)\widehat{V}_{n_{m'}}(0,d\mathbf{k}_{m'}) \right] \prod_{m\in A_N(\mathcal{F})\cup\{N+1\}} \widehat{V}_{n_m}(s_{N+1},d\mathbf{k}_m),$$

where $|C_{\mathbf{n},N}| \le 1$. *The summation extends over all integer valued multi-indices* $\mathbf{n} = (n_1,\dots,n_{N+1})$, $n_1 = i$, *and all Feynman diagrams* $\mathcal{F} \in \mathfrak{S}_N$.

The proof of Lemma 1 is a straightforward moment calculation with jointly Gaussian random variables using spectral representation (4.3)–(4.4). The free vertexes arise from centering and the edges from covariance of each pair. The condition $A(\mathcal{F}') \neq \emptyset$ is due to the gradient operation. The term $C_{\mathbf{n},N}$ contains an $O(1)$ factor like

$$\prod_{\widehat{mm'}\in E(\mathcal{F})} \left[1 - e^{-2|\mathbf{k}_{m'}|^{2\beta}(s_{m'} - s_{N+1})} \right]$$

resulting from replacing the conditional covariance by the covariance of the pairing (cf. [6]).

Using Lemma 1 we can write that

(4.16)
$$\int_0^{t\varepsilon^{-2q}} ds \int_{\Delta_N(s,0)}\cdots\int \mathbb{E}_{s_{N+1}} W_{N,i}(s_1,\dots,s_{N+1},\mathbf{x}) ds_1\cdots ds_{N+1}$$
$$= \sum \int_0^{t\varepsilon^{-2q}} ds \int_0^s ds' \int_{\Delta_{N-1}(s,s')}\cdots\int \varphi_N(\mathbf{k}_1,\dots,\mathbf{k}_N) P_N(\mathbf{x},\mathbf{k}_1,\dots,\mathbf{k}_N;\mathcal{F})$$
$$\times \prod_{\widehat{mm'}\in E(\mathcal{F})} \mathbb{E}\left[\widehat{V}_{n_m}(0,d\mathbf{k}_m)\widehat{V}_{n_{m'}}(0,d\mathbf{k}_{m'}) \right] \prod_{m\in A_N(\mathcal{F})\cup\{N+1\}} \widehat{V}_{n_m}(s',d\mathbf{k}_m)$$

for $i = 1,\dots,d$. Here,

(4.17)
$$\varphi_N(\mathbf{x},\mathbf{k}_1,\dots,\mathbf{k}_N) := \mathrm{i}^N C_{\mathbf{n},N} \prod_{j=1}^N \frac{\sum_{m\in A_j(\mathcal{F})} |\mathbf{k}_m|^{2\beta}}{1 - \exp\left\{ - \sum_{m\in A_j(\mathcal{F})} |\mathbf{k}_m|^{2\beta} t\varepsilon^{-2q}) \right\}} \times \frac{\sum_{m\in A_j(\mathcal{F})} \mathbf{k}_m}{\sum_{m\in A_j(\mathcal{F})} |\mathbf{k}_m|}$$
$$\times \exp\left\{ \mathrm{i} \sum_{m\in A_N(\mathcal{F})\cup\{N+1\}} \mathbf{k}_m\cdot\mathbf{x} \right\}$$
$$\times \int_{\Delta_{N-1}(s,s')}\cdots\int \prod_{j=1}^N \exp\left\{ - \sum_{m\in A_j(\mathcal{F})} |\mathbf{k}_m|^{2\beta}(s_j - s_{j+1}) \right\} ds_1\cdots ds_N$$

and

(4.18)
$$P_N(\mathbf{k}_1,\dots,\mathbf{k}_N;\mathcal{F}) = \prod_{j=1}^{N}\left\{\left(\sum_{m\in A_j(\mathcal{F})}|\mathbf{k}_m|\right)\times\frac{1-\exp\left\{-\sum\limits_{m\in A_j(\mathcal{F})}|\mathbf{k}_m|^{2\beta}t\varepsilon^{-2q}\right\}}{\sum\limits_{m\in A_j(\mathcal{F})}|\mathbf{k}_m|^{2\beta}}\right\}.$$

It is elementary to check that

$$|\varphi_N(\mathbf{x},\mathbf{k}_1,\dots,\mathbf{k}_N)|\le 1. \tag{4.19}$$

To further estimate the expression (4.16) we need to have more refined analysis of the graphs $\mathcal{F}\in\mathfrak{S}_N$. Define

$$r_N(\mathcal{F}) := \max\{m : m\in A_N(\mathcal{F})\}, \tag{4.20}$$
$$a_N(\mathcal{F}) := \min\{m : m\in A_N(\mathcal{F})\}. \tag{4.21}$$

We define $a_k(\mathcal{F}),\ k<N$, as

$$a_{k-1}(\mathcal{F}) = \min\{m : m\in A_{a_k}(\mathcal{F})\}$$

successively unless $a_k=1$. In other words, a_{k-1} is the smallest integer which is the left endpoint of an edge with its right endpoint greater than a_k; cf. (4.14). Below we will use the short-hand notation $a_k := a_k(\mathcal{F})$. Note that $A_N(\mathcal{F})$ and $A_{a_k-1}(\mathcal{F}),\ a_k>1$, are mutually disjoint. Let

$$\mathcal{A}(\mathcal{F}) := A_N(\mathcal{F})\bigcup_{k:\,a_k>1}A_{a_k-1}(\mathcal{F}). \tag{4.22}$$

Observe that any vertex $m\in\mathcal{A}(\mathcal{F})$ cannot be a right endpoint of any edge in $E(\mathcal{F})$. For any $m\in\mathcal{A}(\mathcal{F})$ let m^* be the nearest vertex in $A(\mathcal{F})$ to the right of m, i.e.,

$$m^* := \min[k:\ k\in\mathcal{A}(\mathcal{F}),\, k>m] \tag{4.23}$$

if the relevant set is nonempty; otherwise, set $m^*:=N$. Let

$$q_m := \#\{\widehat{pp'}\in E(\mathcal{F}) : m<p'<m^*\} \tag{4.24}$$

and let $e(\mathcal{F})$, $c(\mathcal{F})$ be the cardinalities of $E(\mathcal{F})$ and $A_N(\mathcal{F})$, respectively. It is easy to see that

$$\sum_{m\in\mathcal{A}} q_m = e(\mathcal{F}), \tag{4.25}$$

and thus

$$\sum_{m\in\mathcal{A}(\mathcal{F})} q_m + e(\mathcal{F}) + c(\mathcal{F}) = N. \tag{4.26}$$

4.1. Estimates for the remainder terms $\mathcal{R}_{N,\varepsilon}(t)$. By the Cauchy–Schwartz inequality we get that

$$
\begin{aligned}
(4.27)\quad & |\mathcal{R}_{N,\varepsilon}(t)|^2 \\
&\le 4\varepsilon^{2N(1-p)}\mathbb{E}|\mathbf{V}(0,\mathbf{0})|^2 \\
&\quad \times \max_{0\le s\le t\varepsilon^{-2}} \mathbb{E}\left|\int_0^s ds' \int_{\Delta_{N-1}(s,s')}\cdots\int \mathbb{E}_{s'}\mathbf{W}_N(s_1,\dots,s_N,s',\varepsilon\mathbf{x}(s'))ds_1\cdots ds_N\right|^2 .
\end{aligned}
$$

The stationarity of the Lagrangian velocity field implies that the right-hand side of (4.27) is equal to

$$
4\varepsilon^{2N(1-p)}\mathbb{E}|\mathbf{V}(0,\mathbf{0})|^2 \max_{0\le s\le t\varepsilon^{-2}} \mathbb{E}\left|\int_0^s ds' \int_{\Delta_N(s',0)}\cdots\int \mathbb{E}_0\mathbf{W}_N(s_1,\dots,s_N,0,\mathbf{0})ds_1\cdots ds_N\right|^2 . \tag{4.28}
$$

Subsequently using (4.16) for the multiple time integration of the conditional expectations in (4.28), we deduce that the above expression is less than or equal to

$$
\begin{aligned}
(4.29)\quad & 4C\varepsilon^{2N(1-p)}t^2\varepsilon^{4(1-2q)}\mathbb{E}\left|\sum_{\mathcal{F},\mathbf{n}}\int\cdots\int \varphi_N(\mathbf{x},\mathbf{k}_1,\dots,\mathbf{k}_N)P_N(\mathbf{k}_1,\dots,\mathbf{k}_N;\mathcal{F})\right. \\
&\left.\times \prod_{\widehat{mm'}\in E(\mathcal{F})} \mathbb{E}\left[\widehat{V}_{n_m}(0,d\mathbf{k}_m)\widehat{V}_{n_{m'}}(0,d\mathbf{k}_{m'})\right] \prod_{m\in A_N(\mathcal{F})\cup\{N+1\}} \widehat{V}_{n_m}(0,d\mathbf{k}_m)\right|^2 .
\end{aligned}
$$

The summation above extends over all Feynman diagrams $\mathcal{F}\in\mathfrak{S}_N$ and multi-indices $\mathbf{n}$.

By introducing an identical copy of the diagram which is supported on $\{N+2, N+2,\dots,2N+2\}$, the expression in (4.29) can be written in the form

$$
\begin{aligned}
& 4C\varepsilon^{2N(1-p)}t^2\varepsilon^{4(1-2q)}\sum\int\dots\int \varphi_N(\mathbf{0},\mathbf{k}_1,\dots,\mathbf{k}_N)\varphi_N(\mathbf{0},\mathbf{k}'_1,\dots,\mathbf{k}'_N) \\
&\qquad\qquad P_N(\mathbf{k}_1,\dots,\mathbf{k}_N;\mathcal{F})P_N(\mathbf{k}'_1,\dots,\mathbf{k}'_N;\mathcal{F}) \\
&\times\left|\prod_{\widehat{mm'}\in E(\mathcal{F})} \mathbb{E}\left[\widehat{V}_{n_m}(0,d\mathbf{k}_m)\widehat{V}_{n_{m'}}(0,d\mathbf{k}_{m'})\right]\right. \\
&\quad\left.\times \prod_{\widehat{mm'}\in E(\mathcal{F})} \mathbb{E}\left[\widehat{V}_{n_m}(0,d\mathbf{k}'_m)\widehat{V}_{n_{m'}}(0,d\mathbf{k}'_{m'})\right]\mathbb{E}\left[\prod_{m\in A^{(2)}(\mathcal{F})}\widehat{V}_{n_m}(0,d\mathbf{k}_m)\right]\right|,
\end{aligned}
$$

where $\mathbf{k}_{N+1+j}:=\mathbf{k}'_j$ and

$$
A^{(2)}(\mathcal{F}) = A_N(\mathcal{F})\cup\{N+1\}\cup\{j+N+1 : j\in A_N(\mathcal{F})\cup\{N+1\}\}. \tag{4.30}
$$

Using the elementary inequality

$$
\frac{1-\mathrm{e}^{-xt/\varepsilon^2}}{x}\le\frac{C}{x+\varepsilon^{2q}/t},\quad t,x>0,
$$

for a constant C independent of ε, x, we conclude that (see (4.18))

$$|P_N(\mathbf{k}_1,\dots,\mathbf{k}_N;\mathcal{F})| \le \prod_{j=1}^{N} \frac{\sum\limits_{m\in A_j(\mathcal{F})} |\mathbf{k}_m|}{\sum\limits_{m\in A_j(\mathcal{F})} |\mathbf{k}_m|^{2\beta} + \varepsilon^{2q}/t}.$$

The expression (4.29) can be now estimated by

$$\begin{aligned}(4.31)\qquad & Ct^2\varepsilon^{4(1-2q)} \sum \int_0^K \cdots \int_0^K Q_N(k_1,\dots,k_N;\mathcal{F})\, Q_N(k'_1,\dots,k'_N;\mathcal{F}) \\ & \times \prod_{\widehat{mm'}\in E(\mathcal{F})} \left[\frac{\delta(k_m - k_{m'})dk_m dk_{m'}}{k_m^{2\alpha-1}} \times \frac{\delta(k'_m - k'_{m'})dk_m dk_{m'}}{{k'_m}^{2\alpha-1}}\right] \\ & \times \prod_{\widehat{mm'}\in E(\mathcal{F}')} \frac{\delta(k_m - k_{m'})dk_m dk_{m'}}{k_m^{2\alpha-1}},\end{aligned}$$

with $k_m = |\mathbf{k}_m|$ and

$$Q_N(k_1,\dots,k_N;\mathcal{F}) := \prod_{j=1}^{N} \frac{\sum\limits_{m\in A_j(\mathcal{F})} k_m}{\sum\limits_{m\in A_j(\mathcal{F})} k_m^{2\beta} + \varepsilon^{2q}/t}.$$

The summation extends over all Feynman diagrams $\mathcal{F} \in \mathfrak{S}_N$ and all complete diagrams $\mathcal{F}'$ made of the vertexes of $A^{(2)}(\mathcal{F})$.

When $2\beta \le 1$, $Q_N(k_1,\dots,k_N;\mathcal{F})$ is bounded. This in turn implies that the expression (4.31) diverges at most at the rate $\varepsilon^{4(1-2q)}$. The estimate (4.27) implies then that $\mathcal{R}_{N,\varepsilon}(t)$ vanishes with $\varepsilon \downarrow 0$ and $N > 2/(1-p)$.

Let us assume therefore that $2\beta > 1$. There exists then a constant C, depending only on t, N, β, and K, such that

$$(4.32)\qquad \frac{\sum\limits_{m\in A_j(\mathcal{F})} k_m}{\sum\limits_{m\in A_j(\mathcal{F})} k_m^{2\beta} + \varepsilon^{2q}/t} \le C\frac{k_{m_j} + \varepsilon^{q/\beta}}{k_{m_j}^{2\beta} + \varepsilon^{2q}} \quad \forall m_j \in A_j(\mathcal{F})$$

and thus

$$(4.33)\qquad Q_N(k_1,\dots,k_N;\mathcal{F}) \le C\prod_{j=1}^{N} \frac{k_{m_j} + \varepsilon^{q/\beta}}{k_{m_j}^{2\beta} + \varepsilon^{2q}}$$

for all $m_j \in A_j(\mathcal{F})$. Hereby we make the following definite choice of m_j: let $m_j := j$ if j is *not* the right endpoint of an edge of the diagram $\mathcal{F}$. Otherwise, let m_j be the closest vertex from $\mathcal{A}(\mathcal{F})$ to the left of j.

Denote by $E'(\mathcal{F})$ the set of the edges of the diagram $\mathcal{F}$ with neither endpoint belonging to $\mathcal{A}(\mathcal{F})$ (see (4.22)) by cardinality of e'. In view of (4.25), (4.26), and the identity

$$(4.34)\qquad e'(\mathcal{F}) + \#[A(\mathcal{F}) \setminus A_N(\mathcal{F})] = e(\mathcal{F}),$$

the expression on the right-hand side of (4.33) can be written as

$$C\prod_{\widehat{mm'}\in E'(\mathcal{F})}\frac{k_m+\varepsilon^{q/\beta}}{k_m^{2\beta}+\varepsilon^{2q}}\times\prod_{m\in\mathcal{A}(\mathcal{F})\setminus A_N(\mathcal{F})}\left(\frac{k_m+\varepsilon^{q/\beta}}{k_m^{2\beta}+\varepsilon^{2q}}\right)^{q_m+1}\times\prod_{m\in A_N(\mathcal{F})}\left(\frac{k_m+\varepsilon^{q/\beta}}{k_m^{2\beta}+\varepsilon^{2q}}\right)^{q_m+1}. \tag{4.35}$$

From (4.31), (4.33), and (4.35) we conclude that

(4.36)

$$|\mathcal{R}_{N,\varepsilon}(t)|^2\le C\varepsilon^{2N(1-p)+4(1-2q)}\sum\prod_{m\in\mathcal{A}(\mathcal{F})\setminus A_N(\mathcal{F})}\left[\int_0^K\left(\frac{k+\varepsilon^{q/\beta}}{k^{2\beta}+\varepsilon^{2q}}\right)^{q_m+1}\frac{dk}{k^{2\alpha-1}}\right]^2\times\left[\int_0^K\frac{(k+\varepsilon^{q/\beta})dk}{(k^{2\beta}+\varepsilon^{2q})k^{2\alpha-1}}\right]^{2e'}\prod_{\widehat{mm'}\in E(\mathcal{F}')}\int_0^K\left(\frac{k+\varepsilon^{q/\beta}}{k^{2\beta}+\varepsilon^{2q}}\right)^{2+q_m+q_{m'}}\frac{dk}{k^{2\alpha-1}}.$$

Here the summation extends over all possible diagrams $\mathcal{F}$, $\mathcal{F}'$ as in (4.31). The meanings of q_m's related to the diagram $\mathcal{F}$ are the same as introduced in the previous section. We adopt also the convention that $q_{N+1}=q_{2N+2}=-1$ and $q_{N+1+m}:=q_m$.

4.2. Estimates for $\mathcal{I}_{n,\varepsilon}(t)$ for $n\ge 1$. The calculation is similar to that for the remainder term carried out in the previous section, so we shall sketch only the main points.

From (4.16) we infer that the i,jth entry of the matrix $\mathcal{I}_{n,\varepsilon}(t)$, given by (4.11), equals

$$2\varepsilon^{n(1-p)+2}\sum\int_0^{t\varepsilon^{-2q}}ds\int\cdots\int\varphi_{n+1}(\mathbf{k}_1,\dots,\mathbf{k}_{n+1})\times P_n(\mathbf{k}_1,\dots,\mathbf{k}_n;\mathcal{F})\left(\sum_{m\in A_{n+1}(\mathcal{F})}|\mathbf{k}_m|^{2\beta}+\varepsilon^{2q}/t\right)^{-1}\times\left|\prod_{\widehat{mm'}\in E(\mathcal{F})}\mathbb{E}\left[\widehat{V}_{l_m}(0,d\mathbf{k}_m)\widehat{V}_{l_{m'}}(0,d\mathbf{k}_{m'})\right]\mathbb{E}\left[\prod_{m\in A_{n+1}(\mathcal{F})\cup\{n+2\}}\widehat{V}_{l_m}(0,d\mathbf{k}_m)\right]\right|. \tag{4.37}$$

Here the summation extends over all multi-indices $\mathbf{l}=(l_1,\dots,l_{n+2})$ such that $l_1=i$, $l_{n+2}=j$, and all Feynman diagrams $\mathcal{F}\in\mathfrak{S}_{n+1}$. Proceeding with the same type of estimates as in the case of the remainder term we conclude that

$$|\mathcal{I}_{n,\varepsilon}(t)|\le Ct\varepsilon^{n(1-p)}\sum\prod_{m\in\mathcal{A}(\mathcal{F})\setminus A_{n+1}(\mathcal{F})}\int_0^K\left(\frac{\varepsilon^{\frac{q}{\beta}}+k}{\varepsilon^{2q}+k^{2\beta}}\right)^{q_m+1}\frac{dk}{k^{2\alpha-1}}\times\left[\int_0^K\frac{(\varepsilon^{\frac{q}{\beta}}+k)dk}{(\varepsilon^{2q}+k^{2\beta})k^{2\alpha-1}}\right]^{e'}\prod_{\widehat{mm'}\in\mathcal{F}'}\int_0^K\frac{(\varepsilon^{\frac{q}{\beta}}+k)^{2+q_m+q_{m'}-r_{m,m'}}}{(\varepsilon^{2q}+k^{2\beta})^{2+q_m+q_{m'}}}\times\frac{dk}{k^{2\alpha-1}}. \tag{4.38}$$

Here the summation extends over all Feynman diagrams $\mathcal{F}\in\mathfrak{S}_{n+1}$ and all complete diagrams $\mathcal{F}'$ made of the vertexes of $A_{n+1}(\mathcal{F})\cup\{n+2\}$; $r_{m,m'}:=\delta_{m,m_{n+1}}+\delta_{m',m_{n+1}}$. Also, we adopt convention $q_{n+2}=-1$.

5. Case 1. $\alpha+\beta<1$, $2p\beta<1$, $0\le p<1$—Brownian motion ($q=1$). We shall give the proof only in the case $2p\beta<1$. Also, for clarity we shall calculate only the asymptotic of the mean square displacement of $\mathbf{x}_\varepsilon(t)$, referring an interested reader to our paper [5], where the proof of the martingale version of our theorem has been laid out for $p=0$. A suitable adaptation of the proof to the case $p\in[0,1)$ and $2p\beta<1$ is possible along the lines of the argument we present below.

After an elementary calculation we deduce that under the assumption $\alpha+\beta<1$

$$\lim_{\varepsilon\downarrow 0}\mathcal{I}_{0,\varepsilon}(t)=\mathbf{D}t$$

with

$$\mathbf{D}=\int_{\mathbb{R}^d}\left(\mathbf{I}-\frac{\mathbf{k}\otimes\mathbf{k}}{|\mathbf{k}|^2}\right)\frac{a(|\mathbf{k}|)}{|\mathbf{k}|^{2\alpha+2\beta-1}}\,\frac{d\mathbf{k}}{|\mathbf{k}|^{d-1}},$$

provided that $q=1$.

Estimates for $\mathcal{R}_{N,\varepsilon}(t)$. We observe that

$$\int_0^K\frac{k+\varepsilon^{1/\beta}}{k^{2\beta}+\varepsilon^2}\,\frac{dk}{k^{2\alpha-1}}\le C, \tag{5.1}$$

$$\int_0^K\left(\frac{\varepsilon^{1/\beta}+k}{\varepsilon^2+k^{2\beta}}\right)^{q_m+1}\frac{dk}{k^{2\alpha-1}}\le C(1+\varepsilon^{\gamma(m)}), \tag{5.2}$$

$$\int_0^K\left(\frac{\varepsilon^{1/\beta}+k}{\varepsilon^2+k^{2\beta}}\right)^{2+q_m+q_{m'}}\frac{dk}{k^{2\alpha-1}}\le C(1+\varepsilon^{\gamma(\widehat{mm'})}), \tag{5.3}$$

with

$$\gamma(m):=\frac{1}{\beta}[2-2\alpha+(q_m+1)(1-2\beta)], \tag{5.4}$$

$$\gamma(\widehat{mm'}):=\frac{1}{\beta}[2-2\alpha+(q_m+q_{m'}+2)(1-2\beta)]. \tag{5.5}$$

We conclude therefore that

$$|\mathcal{R}_{N,\varepsilon}(t)|^2\le C\varepsilon^{\mu}, \tag{5.6}$$

with

$$\mu:=2N(1-p)-4+\kappa, \tag{5.7}$$

$$\kappa:=\frac{1}{\beta}\Big[2f'(2-\alpha-2\beta)+2f''(3-2\alpha-2\beta) +(1-2\beta)\sum{}'(q_m+q_{m'})+2(1-2\beta)\sum{}''q_m\Big], \tag{5.8}$$

where the summation $\sum'$ extends over the edges $\widehat{mm'}$ of the diagram $\mathcal{F}'$ for which $\gamma(\widehat{mm'})<0$ and $\sum''$ extends over the vertexes m of $\mathcal{A}(\mathcal{F})\setminus A_N(\mathcal{F})$, for which $\gamma(m)<0$ (see (5.4), (5.5)) and f',f'' denote the cardinalities of the respective sets of edges and vertexes. Obviously,

$$f'\le c,\quad f''\le e-e', \tag{5.9}$$

with c the cardinality of $A_N(\mathcal{F})$ and e the number of edges of $\mathcal{F}$ (cf. (4.34)). Note that $c + 2e = N$.

Using $\sum'(q_m + q_{m'}) + 2\sum'' q_m \le 2e$ and $2\beta > 1$, we can write that

$$\kappa \ge \frac{2}{\beta}\left[f'(2-\alpha-2\beta) + f''(3-2\alpha-2\beta) + e(1-2\beta)\right]. \tag{5.10}$$

Since $N = c + 2e$ we conclude from (5.9) and (5.10) that

$$\begin{aligned}\mu &\ge -4 + 2N(1-p) + \frac{2}{\beta}\left[f'(2-\alpha-2\beta) + f''(3-2\alpha-2\beta) + e(1-2\beta)\right] \\ &\ge -4 + 2(c-f')(1-p) \\ &\quad + \frac{2}{\beta}\left\{f'[2-\alpha-(1+p)\beta] + f''(3-2\alpha-2\beta) + e(1-2p\beta)\right\} > 0,\end{aligned} \tag{5.11}$$

provided that $2p\beta < 1$ (note that then necessarily $2-\alpha-(1+p)\beta > 0$) and N is sufficiently large.

Estimates for $\mathcal{I}_{n,\varepsilon}(t)$ for $n \ge 1$. Using (5.1)–(5.2) and

$$\int_0^K \frac{(k+\varepsilon^{\frac{1}{\beta}})^{2+q_m+q_{m'}-r_{m,m'}}}{(k^{2\beta}+\varepsilon^2)^{2+q_m+q_{m'}}}\,\frac{dk}{k^{2\alpha-1}} \le C(1+\varepsilon^{\tilde{\gamma}(\widehat{mm'})}),$$

with

$$\tilde{\gamma}(\widehat{mm'}) := \frac{1}{\beta}[2-2\alpha+(q_m+q_{m'}+2)(1-2\beta)-r_{m,m'}], \tag{5.12}$$

we conclude that

$$|\mathcal{I}_{n,\varepsilon}(t)| \le C\varepsilon^{\mu}, \tag{5.13}$$

where $\mu = n(1-p)+\kappa$ and

$$\begin{aligned}\kappa := \frac{1}{\beta}\Big[&2f'(2-\alpha-2\beta) + f''(3-2\alpha-2\beta) \\ &+(1-2\beta)\sum{}'(q_m+q_{m'}) + (1-2\beta)\sum{}'' q_m - 1\Big].\end{aligned}$$

The summation $\sum'$ extends over the edges $\widehat{mm'}$ of the diagram $\mathcal{F}'$ for which $\tilde{\gamma}(\widehat{mm'}) < 0$ and $\sum''$ extends over the vertexes m of $\mathcal{A}(\mathcal{F}) \setminus A_{n+1}(\mathcal{F})$ for which $\gamma(m) < 0$. f', f'' denote the cardinalities of the respective sets of edges and vertexes. Finally, obtain that

$$\begin{aligned}\mu &\ge (c+1-2f'+e)(1-p) \\ &\quad + \frac{1}{\beta}\left[2p\beta + 2f'(2-\alpha-(1+p)\beta) + f''(3-2\alpha-2\beta) + e(1-2p\beta)\right] > 0.\end{aligned}$$

In conclusion, we proved that the utmost left-hand side of (4.10) tends to $\mathbf{D}t$ as $\varepsilon \downarrow 0$, provided that $\alpha + \beta < 1$.

6. Case 2. $1 < \alpha + \beta < 1 + 1/p$, $0 \le p < 1$—FBM. For $\alpha + \beta > 1$, it is straightforward to check that

$$\lim_{\varepsilon \downarrow 0} \mathcal{I}_{0,\varepsilon} = \mathbf{D} t^{2H},$$

provided that $q = \beta/(\alpha + 2\beta - 1)$. Here

$$\mathbf{D} = \int_{\mathbb{R}^d} \frac{e^{-|\mathbf{k}|^{2\beta}} - 1 + |\mathbf{k}|^{2\beta}}{|\mathbf{k}|^{2\alpha+4\beta-1}} \left(\mathbf{I} - \frac{\mathbf{k} \otimes \mathbf{k}}{|\mathbf{k}|^2} \right) \frac{a(0)}{|\mathbf{k}|^{d-1}} d\mathbf{k}$$

and the Hurst exponent H is given by

$$1/2 < H = 1/2 + \frac{\alpha + \beta - 1}{2\beta} < 1.$$

6.1. Case 2a. We assume that

$$3/2 < \alpha + \beta, \quad \alpha + 2\beta < 1 + 1/p, \quad 0 \le p < 1.$$

We shall only carry out the estimates of $\mathcal{R}_{N,\varepsilon}(t)$. One can easily obtain the respective estimates of $\mathcal{I}_{n,\varepsilon}(t)$. These estimates are very similar to the corresponding part of section 5. We use the notation introduced there.

As before we need only to consider the case $2\beta > 1$ (cf. (4.36)). Note that

$$\int_0^K \frac{(\varepsilon^{q/\beta} + k) dk}{(\varepsilon^{2q} + k^{2\beta}) k^{2\alpha-1}} \le C(1 + \varepsilon^{\gamma}),$$

$$\int_0^K \left(\frac{\varepsilon^{q/\beta} + k}{\varepsilon^{2q} + k^{2\beta}} \right)^{q_m+1} \frac{dk}{k^{2\alpha-1}} \le C(1 + \varepsilon^{\gamma(m)}),$$

and

$$\int_0^K \left(\frac{\varepsilon^{q/\beta} + k}{\varepsilon^{2q} + k^{2\beta}} \right)^{2+q_m+q_{m'}} \times \frac{dk}{k^{2\alpha-1}} \le C(1 + \varepsilon^{\gamma(\widehat{mm'})}),$$

with

$$\gamma := \frac{3 - 2\alpha - 2\beta}{\alpha + 2\beta - 1}, \tag{6.1}$$

$$\gamma(m) := \frac{3 - 2\alpha - 2\beta + q_m(1 - 2\beta)}{\alpha + 2\beta - 1}, \tag{6.2}$$

$$\gamma(\widehat{mm'}) := \frac{4 - 2\alpha - 4\beta + (q_m + q_{m'})(1 - 2\beta)}{\alpha + 2\beta - 1} \tag{6.3}$$

(cf. (5.4)–(5.5)).

Estimating the same way as in (5.6)–(5.11) we obtain

$$|\mathcal{R}_{N,\varepsilon}(t)|^2 \le C t^4 \varepsilon^{\mu},$$

with

$$\mu := 2N(1-p) + 4(1-2q) + \kappa, \tag{6.4}$$

$$\kappa := 2(e' + f'')\frac{3-2\alpha-2\beta}{\alpha+2\beta-1}$$

$$+\frac{1}{\alpha+2\beta-1}\left[2f'(2-\alpha-2\beta) + (1-2\beta)\sum{}'(q_m + q_{m'}) + 2(1-2\beta)\sum{}'' q_m\right]$$

(cf. (5.9)). We have

$$\begin{aligned}\mu &\geq 4(1-2q) + 2N(1-p) + 2(e'+f'')\frac{3-2\alpha-2\beta}{\alpha+2\beta-1}\\ &\quad + \frac{2}{\alpha+2\beta-1}\,[f'(2-\alpha-2\beta) + e(1-2\beta)]\\ &\geq 4(1-2q) + 2(c+2e)(1-p) + 2e\frac{3-2\alpha-2\beta}{\alpha+2\beta-1}\\ &\quad + \frac{2}{\alpha+2\beta-1}\,[c(2-\alpha-2\beta) + e(1-2\beta)]\\ &\geq 4(1-2q) + 2Np\,\frac{1+1/p-\alpha-2\beta}{\alpha+2\beta-1} > 0,\end{aligned}$$

provided that N is sufficiently large. This in turn implies that $|\mathcal{R}_{N,\varepsilon}(t)|^2$ vanishes as $\varepsilon \downarrow 0$ for such a choice of N.

6.2. Case 2b. Here we assume that

$$1 < \alpha+\beta < 3/2, \quad \alpha+2\beta < 1 + 1/(2p) + (\alpha+\beta-1)/p, \quad 0 \leq p < 1.$$

In this case one can write κ in (6.4) as

$$\begin{aligned}\kappa &= 2f''\,\frac{3-2\alpha-2\beta}{\alpha+2\beta-1} + \frac{1}{\alpha+2\beta-1}\\ &\quad\times\left[2f'(2-\alpha-2\beta) + (1-2\beta)\sum{}'(q_m+q_{m'}) + 2(1-2\beta)\sum{}'' q_m\right]\end{aligned}$$

and hence

$$\begin{aligned}\mu &\geq 4(1-2q) + 2(c+2e)(1-p)\\ &\quad + 2f''\,\frac{3-2\alpha-2\beta}{\alpha+2\beta-1} + \frac{2}{\alpha+2\beta-1}\,[f'(2-\alpha-2\beta) + e(1-2\beta)]\\ &\geq 4(1-2q) + 2ep\,\frac{(\alpha+\beta-1)/p + 1/(2p) - \alpha - 2\beta}{\alpha+2\beta-1} + 2f''\,\frac{3-2\alpha-2\beta}{\alpha+2\beta-1}\\ &\quad + 2(c-f')(1-p) + 2f'p\,\frac{1+1/p-\alpha-2\beta}{\alpha+2\beta-1} > 0,\end{aligned}$$

provided that N is sufficiently large. This in turn implies that $|\mathcal{R}_{N,\varepsilon}(t)|^2$ vanishes as $\varepsilon \downarrow 0$ for such a choice of N.

7. FBM limit with $p \geq 1$: Heuristics. In this section we give an argument indicating that the FBM limit holds for $p > 1$. The argument is similar to the one given in [8].

Let $\mathbf{U}^\varepsilon(t, \mathbf{x})$ be the Gaussian velocity with energy spectrum given by

$$\mathcal{E}_\varepsilon(k) = \frac{a(\varepsilon^p k)}{k^{2\alpha-1}}. \tag{7.1}$$

Then it follows from the spectral representation of the velocity correlation function that $\mathbf{U}^\varepsilon$ is related to $\mathbf{V}$ via

$$\mathbf{V}\left(\frac{t}{\varepsilon^{2q}}, \frac{\mathbf{x}}{\varepsilon^p}\right) = \varepsilon^{p(1-\alpha)}\mathbf{U}^\varepsilon\left(\frac{t}{\varepsilon^{2(q-p\beta)}}, \mathbf{x}\right).$$

With a unique pair of parameters q, η_ε,

$$q = \beta/(\alpha + 2\beta - 1), \quad \eta_\varepsilon = \varepsilon^{1+p-p(\alpha+2\beta)}, \tag{7.2}$$

the equation of motion can be written as

$$\frac{d\mathbf{x}^\varepsilon(t)}{dt} = \frac{1}{\eta_\varepsilon^{2q-1}}\mathbf{U}^\varepsilon\left(\frac{t}{\eta_\varepsilon^{2q}}, \mathbf{x}^\varepsilon(t)\right). \tag{7.3}$$

Since η_ε must tend to zero we require that

$$\alpha + 2\beta < 1 + \frac{1}{p}. \tag{7.4}$$

Condition (7.4) is also related to the fact that the velocity $\mathbf{U}^\varepsilon$ has increasingly smaller scales as ε tends to zero.

The following physical argument shows that, under the conditions (7.4) and

$$\alpha + \beta > 1,$$

the ultraviolet divergence in $\mathbf{U}^\varepsilon$ has no physical significance. The small-scale velocity associated with high wave number $|\mathbf{k}|$ has the amplitude

$$\left(\int_{c_1|\mathbf{k}| \leq |\mathbf{k}'| \leq c_2|\mathbf{k}|} \mathcal{E}(\mathbf{k}')d|\mathbf{k}'|\right)^{1/2} \sim |\mathbf{k}|^{1-\alpha}, \quad |\mathbf{k}| \gg 1,$$

and the correlation time is of the order $|\mathbf{k}|^{-2\beta}$. Then particles transported by small-scale velocity travel a distance less than or equal to the sum of $t|\mathbf{k}|^{2\beta}$ number uncorrelated random variables of magnitude $|\mathbf{k}|^{1-\alpha}|\mathbf{k}|^{-2\beta}$. Thus, on the time scale $t \sim \eta_\varepsilon^{-2q}$, the displacement caused by high wave number $\mathbf{k}$ is of the order less than or equal to $\sqrt{\eta_\varepsilon^{-2q}|\mathbf{k}|^{2\beta}}|\mathbf{k}|^{1-\alpha-2\beta}$, as suggested by the turbulent diffusion limit theorem for mixing flows [4], which equals $\eta_\varepsilon^{-q}|\mathbf{k}|^{1-\alpha-\beta}$ and is always smaller than η_ε^{-1} (the spatial scale of observation) if $\alpha + \beta > 1$ and $q < 1$ (superdiffusive scaling). With (7.2) the two conditions ($\alpha + \beta > 1$ and $q < 1$) are equivalent. It is clear that for $|\mathbf{k}| = O(1)$ the previous argument is still valid.

Now, if we neglect the high wave numbers in (7.3) the equation becomes

$$d\boldsymbol{x}^\varepsilon(t)/dt = \eta_\varepsilon^{1-2q}\mathbf{V}(t/\eta_\varepsilon^{2q}, \boldsymbol{x}^\varepsilon(t)), \tag{7.5}$$

which has the asymptotic solution

$$\boldsymbol{x}^{\varepsilon}(0) + \eta_{\varepsilon} \int_0^{t/\eta_{\varepsilon}^{2q}} \mathbf{V}(\boldsymbol{x}^{\varepsilon}(0), s) ds \tag{7.6}$$

converging to an FBM (Theorems 1 and 2).

STABILITY AND TRAVELING FRONTS IN LOTKA–VOLTERRA COMPETITION MODELS WITH STAGE STRUCTURE*

J. F. M. AL-OMARI† AND S. A. GOURLEY†

Abstract. This paper is concerned with a delay differential equation model for the interaction between two species, the adult members of which are in competition. The competitive effects are of the Lotka–Volterra kind, and in the absence of competition it is assumed that each species evolves according to the predictions of a simple age-structured model which reduces to a single equation for the total adult population. For each of the two species the model incorporates a time delay which represents the time from birth to maturity of that species. Thus, the time delays appear in the adult recruitment terms.

The dynamics of the model are determined, and global stability results are established for each equilibrium. The equilibria of the model involve the maturation delays. The criteria for global convergence to each equilibrium are sharp and involve these delays.

A reaction-diffusion extension of the model is also studied for the case when only the adult members of each species can diffuse. We prove the existence of a traveling front solution connecting the two boundary equilibria for the case when there is no coexistence equilibrium. This represents invasion by the stronger species of territory previously inhabited only by the weaker. The proof of the existence of such a front uses Wu and Zou's theory for traveling front solutions of delayed reaction-diffusion systems.

Key words. competition, stage structure, time delay, global stability, reaction-diffusion, traveling front

1. Introduction.

This paper is concerned with the following delayed Lotka–Volterra-type model for the adult members of two species U and V in competition,

$$\begin{aligned} \frac{dU(t)}{dt} &= \alpha_u \int_0^\infty f_u(s) e^{-\gamma_u s} U(t-s)\, ds - \beta_u U^2(t) - c_1 U(t) V(t), \\ \frac{dV(t)}{dt} &= \alpha_v \int_0^\infty f_v(s) e^{-\gamma_v s} V(t-s)\, ds - \beta_v V^2(t) - c_2 U(t) V(t) \end{aligned} \tag{1.1}$$

and also with a reaction-diffusion extension thereof. In proposing the system (1.1), it is assumed that competition effects are of the classical Lotka–Volterra kind. It is also assumed that the adult numbers of each species, in the absence of the other species, evolve according to a delay equation of the form

$$\frac{du(t)}{dt} = \alpha \int_0^\infty f(s) e^{-\gamma s} u(t-s)\, ds - \beta u^2(t). \tag{1.2}$$

Equation (1.2) can be regarded as a generalization of the second equation of the system

$$\begin{aligned} u_i'(t) &= \alpha u_m(t) - \gamma u_i(t) - \alpha\, e^{-\gamma\tau} u_m(t-\tau), \\ u_m'(t) &= \alpha\, e^{-\gamma\tau} u_m(t-\tau) - \beta u_m^2(t), \end{aligned} \tag{1.3}$$

which was proposed by Aiello and Freedman [1] as a model of a single species, where u_i denotes the number of sexually immature members of the species and u_m the number of mature adult members. Note that, in system (1.3), the second equation is uncoupled from the first and thus it is sufficient to consider this second equation on its own. The parameter τ in (1.3) measures the time from birth to maturity, and the $e^{-\gamma\tau}$ terms allow for the fact that not all immatures survive to maturity (γ in (1.3) is the death rate of immatures, while β measures deaths of matures). An assumption behind (1.3) is that all individuals take the same amount of time τ to become mature. If we instead allow the possibility that an individual could become mature at any age, and if we denote by $f(s)\,ds$ the probability that the maturation time is between s and $s + ds$ with ds infinitesimal, and $\int_0^\infty f(s)\,ds = 1$, then simple modeling leads to (1.2) as a generalization of the second equation of (1.3). Of course, $f(s)$ will be small when s is small, and when s is large, and it is quite reasonable to take $f(s) = 0$ for all s above some finite value, as we shall do in much of the paper.

Thus, in our model (1.1), we assume that each species on its own grows not according to the logistic equation or delayed logistic equation but according to the predictions of the simple stage structured model (1.2) which is arguably more realistic as a model of a single species. The c_i terms in (1.1) are the competition effects; c_1 and c_2 measure the competitive effect of V on U, and U on V, respectively. Of course, U and V in (1.1) refer only to the *adult* numbers of the two species. Thus, it is assumed that competition occurs only between the adults. Since many species strongly protect their young, we feel this is not too unrealistic an assumption.

Competition systems with time delays have been studied by many authors. For example, Gopalsamy [3] studied the two-species delayed competition system

$$\begin{aligned} du/dt &= u\left(\gamma_1 - a_1 u - b_1 \int_{-T}^{0} K_1(s) v(t+s)\,ds\right), \\ dv/dt &= v\left(\gamma_2 - a_2 \int_{-T}^{0} K_2(s) u(t+s)\,ds - b_2 v\right), \end{aligned}$$

in which the delays are in the interspecies competition terms, and established a result on the global stability of the coexistence equilibrium, showing that when the intraspecies competition is stronger than the interspecies competition, nonconstant oscillatory solutions are not possible.

In the present paper we will show that the global dynamics of our system (1.1) can be completely determined, except in the case when the boundary equilibria $\hat{E}_u$ and $\hat{E}_v$ are both linearly stable. In this case one expects that the outcome of the competition will depend on the initial conditions. For other cases, the possibilities can be enumerated in a similar way to the classical Lotka–Volterra competition model without delay, as described in the book by Murray [6]. If one boundary equilibrium is linearly stable and the other unstable, we show that solutions converge globally to the stable boundary equilibrium. When both boundary equilibria are linearly unstable, we show that solutions converge globally to the coexistence equilibrium. Thus, the conditions for global stability are sharp and can be interpreted ecologically. Furthermore, the conditions involve the maturation delay kernels $f_u(s)$ and $f_v(s)$, and thus the role of these maturation delays can be elucidated. This is important since the comparison approach we adopt in this paper does not always, in other applications, elucidate clearly the role of the time delays and tends rather to furnish conditions which are merely sufficient for convergence and only involve the other parameters of the model.

It is straightforward to show that the solutions of system (1.1), subject to (2.8) below, satisfy $U(t), V(t) > 0$ on $(0, \infty)$. This fact is important for both the modeling and the analysis.

2. Equilibria and their stability. System (1.1) has four equilibria, determined by setting $dU/dt = dV/dt = 0$ in (1.1), and these are

$$E_0 = (0,0), \qquad \hat{E}_u = \left(\frac{\alpha_u}{\beta_u}\int_0^\infty f_u(s)e^{-\gamma_u s}ds, 0\right), \qquad \hat{E}_v = \left(0, \frac{\alpha_v}{\beta_v}\int_0^\infty f_v(s)e^{-\gamma_v s}ds\right),$$

and

$$\hat{E} = (\hat{U}, \hat{V}),$$

where

$$\hat{U} = \frac{\beta_v\alpha_u\int_0^\infty f_u(s)e^{-\gamma_u s}ds - c_1\alpha_v\int_0^\infty f_v(s)e^{-\gamma_v s}ds}{\beta_u\beta_v - c_1c_2}$$

and

$$\hat{V} = \frac{\beta_u\alpha_v\int_0^\infty f_v(s)e^{-\gamma_v s}ds - c_2\alpha_u\int_0^\infty f_u(s)e^{-\gamma_u s}ds}{\beta_u\beta_v - c_1c_2}$$

provided $\hat{U}, \hat{V} > 0$. Of course, the feasibility of the fourth equilibrium $\hat{E}$ depends on the parameters. As we shall show, it is feasible if either (i) the boundary equilibria $\hat{E}_u$ and $\hat{E}_v$ are both linearly unstable, or (ii) the boundary equilibria are both linearly stable.

We will begin by investigating the linearized stability of each equilibrium. Starting with $E_0 = (0,0)$, the linearization of (1.1) about this equilibrium is

$$\begin{aligned} \frac{dU(t)}{dt} &= \alpha_u\int_0^\infty f_u(s)e^{-\gamma_u s}U(t-s)\,ds, \\ \frac{dV(t)}{dt} &= \alpha_v\int_0^\infty f_v(s)e^{-\gamma_v s}V(t-s)\,ds. \end{aligned} \tag{2.1}$$

The characteristic equation resulting from (2.1) is

$$\left(\lambda - \alpha_u\int_0^\infty f_u(s)e^{-s(\gamma_u+\lambda)}ds\right)\left(\lambda - \alpha_v\int_0^\infty f_v(s)e^{-s(\gamma_v+\lambda)}ds\right) = 0,$$

the roots of which are the zeros of the first and the second bracketed factors, and in each of these the existence of a real positive root λ can be seen by plotting against λ the graphs of $y = \lambda$, $y = \alpha_u\int_0^\infty f_u(s)e^{-s(\gamma_u+\lambda)}ds$, and $y = \alpha_v\int_0^\infty f_v(s)e^{-s(\gamma_v+\lambda)}ds$. Therefore, $(0,0)$ is linearly unstable.

The linearization of (1.1) about $\hat{E}_u$ is

$$\begin{aligned} \frac{dU}{dt} &= \alpha_u\int_0^\infty f_u(s)e^{-\gamma_u s}U(t-s)\,ds - 2\alpha_u U(t)\int_0^\infty f_u(s)e^{-\gamma_u s}\,ds \\ &\quad -\frac{c_1\alpha_u}{\beta_u}V(t)\int_0^\infty f_u(s)e^{-\gamma_u s}ds, \\ \frac{dV}{dt} &= \alpha_v\int_0^\infty f_v(s)e^{-\gamma_v s}V(t-s)\,ds - \frac{c_2\alpha_u}{\beta_u}V(t)\int_0^\infty f_u(s)e^{-\gamma_u s}\,ds. \end{aligned} \tag{2.2}$$

The characteristic equation resulting from (2.2) is

$$\left(\lambda + c_2\alpha_u\beta_u^{-1}\int_0^\infty f_u(s)e^{-\gamma_u s}\,ds - \alpha_v\int_0^\infty f_v(s)e^{-s(\gamma_v+\lambda)}ds\right)$$
$$\times\left(\lambda + 2\alpha_u\int_0^\infty f_u(s)e^{-\gamma_u s}\,ds - \alpha_u\int_0^\infty f_u(s)e^{-s(\gamma_u+\lambda)}\,ds\right) = 0.$$

The eigenvalues of the linearization about $\hat{E}_u$ are therefore the roots λ of the equation

$$\lambda + 2\alpha_u\int_0^\infty f_u(s)e^{-\gamma_u s}ds = \alpha_u\int_0^\infty f_u(s)e^{-s(\gamma_u+\lambda)}\,ds \tag{2.3}$$

together with the roots λ of the equation

$$\lambda + c_2\alpha_u\beta_u^{-1}\int_0^\infty f_u(s)e^{-\gamma_u s}\,ds = \alpha_v\int_0^\infty f_v(s)e^{-s(\gamma_v+\lambda)}ds. \tag{2.4}$$

It is not difficult to see that all the roots of (2.3) satisfy $\operatorname{Re}\lambda < 0$. We shall now find the condition which determines that all roots of (2.4) satisfy $\operatorname{Re}\lambda < 0$. Assume, for contradiction, that there exists a root λ^* of (2.4) such that $\operatorname{Re}\lambda^* \geq 0$. Then

$$\begin{aligned}\left|\lambda^* + c_2\alpha_u\beta_u^{-1}\int_0^\infty f_u(s)e^{-\gamma_u s}\,ds\right| &= \left|\alpha_v\int_0^\infty f_v(s)e^{-s(\gamma_v+\lambda)}ds\right| \\ &\leq \alpha_v\int_0^\infty f_v(s)e^{-s\gamma_v}|e^{-s\lambda^*}|ds \\ &= \alpha_v\int_0^\infty f_v(s)e^{-s\gamma_v}e^{-s\operatorname{Re}\lambda^*}ds \\ &\leq \alpha_v\int_0^\infty f_v(s)e^{-s\gamma_v}ds,\end{aligned}$$

since $\operatorname{Re}\lambda^* \geq 0$. This implies that λ^* is in the circle in the complex λ plane centered at $\lambda = -c_2\alpha_u\beta_u^{-1}\int_0^\infty f_u(s)e^{-\gamma_u s}\,ds$ and of radius $\alpha_v\int_0^\infty f_v(s)e^{-s\gamma_v}ds$. Accordingly, we shall have a contradiction if

$$c_2\alpha_u\int_0^\infty f_u(s)e^{-\gamma_u s}\,ds > \beta_u\alpha_v\int_0^\infty f_v(s)e^{-\gamma_v s}ds. \tag{2.5}$$

Therefore, if condition (2.5) holds, then the equilibrium $\hat{E}_u$ is linearly stable.

In a similar way, we can show that $\hat{E}_v$ is linearly stable if

$$c_1\alpha_v\int_0^\infty f_v(s)e^{-\gamma_v s}\,ds > \beta_v\alpha_u\int_0^\infty f_u(s)e^{-\gamma_u s}ds. \tag{2.6}$$

Thus, if (2.5) and (2.6) both hold, then $\hat{E}_u$ and $\hat{E}_v$ are both linearly stable, and the numerators of the components $\hat{U}$, $\hat{V}$ of the equilibrium $\hat{E}$ are both negative. But, at the same time, (2.5) and (2.6) imply that

$$\beta_v < \frac{c_1\alpha_v\int_0^\infty f_v(s)e^{-\gamma_v s}\,ds}{\alpha_u\int_0^\infty f_u(s)e^{-\gamma_u s}ds}, \qquad \beta_u < \frac{c_2\alpha_u\int_0^\infty f_u(s)e^{-\gamma_u s}\,ds}{\alpha_v\int_0^\infty f_v(s)e^{-\gamma_v s}ds}$$

so that $\beta_v\beta_u < c_1c_2$, i.e., the denominators of $\hat{U}, \hat{V}$ are negative too. Thus, under these circumstances, $\hat{U}, \hat{V} > 0$ so that the equilibrium $\hat{E}$ is feasible.

In a similar way, we can see that if (2.5) and (2.6) are both reversed, then the boundary equilibria $\hat{E}_u$ and $\hat{E}_v$ are both linearly unstable and again $\hat{E}$ is feasible under these circumstances. However, if one of the boundary equilibria $\hat{E}_u$, $\hat{E}_v$ is stable and the other unstable, then the coexistence equilibrium $\hat{E}$ is not feasible.

In the next two sections, we shall prove theorems on the global asymptotic stability of the equilibria $\hat{E}_u$, $\hat{E}_v$, and $\hat{E}$ for the case when the kernels $f_u(s)$, $f_v(s)$ have compact support, that is, $f_u(s) = f_v(s) = 0$ for all $s \geq \tau$, for some $\tau > 0$, and normalized such that $\int_0^\tau f_u(s)\,ds = \int_0^\tau f_v(s)\,ds = 1$. In this case the system (1.1) becomes

$$\begin{aligned} \frac{dU(t)}{dt} &= \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}U(t-s)\,ds - \beta_u U^2(t) - c_1 U(t)V(t), \\ \frac{dV(t)}{dt} &= \alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}V(t-s)\,ds - \beta_v V^2(t) - c_2 U(t)V(t). \end{aligned} \tag{2.7}$$

For initial data, we assume that

$$U(t), V(t) \geq 0 \text{ for } -\tau \leq t \leq 0, \quad \text{with} \quad U(0), V(0) > 0. \tag{2.8}$$

Before proceeding, we shall need the following theorem.

THEOREM 1. *Let $u(t)$ be the solution of*

$$\frac{du(t)}{dt} = \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}u(t-s)\,ds - \beta_u u^2(t) - A\,u(t), \tag{2.9}$$

where $u(t) > 0$ for $-\tau \leq t \leq 0$. If

$$0 \leq A < \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds,$$

then $\lim_{t\to\infty} u(t) = \hat{u}$, where

$$\hat{u} = \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - A\right]. \tag{2.10}$$

Proof. Let us first deal with the cases when $u(t)$ is eventually monotonically decreasing or eventually monotonically increasing. In the former case, positivity of solutions immediately yields that $u(t)$ must approach some limit $\hat{u} \geq 0$. This limit must be an equilibrium of (2.9) and is therefore either zero or the value stated. Zero is ruled out since a standard linearized analysis yields that the zero solution of (2.9) is linearly unstable under the stated condition on A.

If $u(t)$ is eventually monotonically increasing, then, when t is sufficiently large, $u(t-s) \leq u(t)$ for all $s \in [0, \tau]$ so that

$$\frac{du(t)}{dt} \leq \alpha_u u(t) \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - \beta_u u^2(t) - A\,u(t)$$

and hence $u(t)$ must be bounded above. Hence $\hat{u} = \lim_{t\to\infty} u(t)$ exists and is an equilibrium of (2.9), and obviously $\hat{u} > 0$ in this case. The conclusion follows immediately.

The remaining case to consider is that in which $u(t)$ is neither eventually monotonically decreasing nor increasing. Of the various possibilities which then arise, we shall treat in detail the case in which $u(t)$ has an infinite sequence of local maxima

$\{t_j\}$, $j = 1, 2, 3, \ldots$, all greater than $\hat{u}$, with $t_j \to \infty$. Other cases can be dealt with similarly. At the times t_j, $u(t_j) > \hat{u}$, $\dot{u}(t_j) = 0$, and $\ddot{u}(t_j) < 0$. We claim that $\sup_{t \geq t_1} u(t) = u(t_k)$ for some integer k. If this is false, it means that after every local maximum $u(t_j)$ there is another that is higher, and therefore that a subsequence of $\{t_j\}$ (still denoted $\{t_j\}$) can be found with the property that $u(t) < u(t_j)$ for all $t_1 \leq t < t_j$ and each j. (The subsequence is generated by including each local maximum that is higher than every one before it.) Then, for each j,

$$\begin{aligned} 0 = \dot{u}(t_j) &= \alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s} u(t_j - s)\, ds - \beta_u u^2(t_j) - A\, u(t_j) \\ &\leq u(t_j) \left(\alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds - \beta_u u(t_j) - A \right) \\ &< u(t_j) \left(\alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds - \beta_u \hat{u} - A \right) \\ &= 0, \end{aligned}$$

which is a contradiction. Thus, $\sup_{t \geq t_1} u(t) = u(t_k)$ for some integer k, and we let $s_1 = t_k$. Now, by applying this same argument to the interval $t \geq t_{k+1}$ we can infer the existence of a t_l ($l > k$) with $\sup_{t \geq t_{k+1}} u(t) = u(t_l)$, and we let $s_2 = t_l$. This process can be continued to generate an infinite sequence $\{s_j\}$ of times such that $s_{j+1} > s_j$, $s_j \to \infty$, $u(t) \leq u(s_j)$ for all $t > s_j$, and $\dot{u}(s_j) = 0$.

Let $y(t) = u(t) - \hat{u}$; then we wish to prove that $y(t) \to 0$ as $t \to \infty$. We have $y(s_j) \geq y(s_{j+1}) > 0$ (since $u(s_j) \geq u(s_{j+1})$ and $u(s_j) > \hat{u}$), and it is now enough to show that $y(s_j) \to 0$ as $j \to \infty$. In terms of y, equation (2.9) becomes, at $t = s_j$,

$$0 = \dot{y}(s_j) = \alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s} y(s_j - s)\, ds - 2\beta_u y(s_j)\hat{u} - \beta_u y^2(s_j) - A y(s_j)$$

so that

$$\begin{aligned} &\alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s} y(s_j - s)\, ds \\ &= 2\beta_u y(s_j)\hat{u} + \beta_u y^2(s_j) + A y(s_j) \\ &= 2\beta_u y(s_j)\hat{u} + \beta_u y^2(s_j) + \left[\alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds - \beta_u \hat{u} \right] y(s_j) \\ &= \beta_u y(s_j)\hat{u} + \beta_u y^2(s_j) + \alpha_u y(s_j) \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds \\ &\geq \left(\alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds + \beta_u \hat{u} \right) y(s_j), \end{aligned}$$

where we have used (2.10). From the sequence $\{s_j\}$ we shall now extract a further subsequence, still denoted $\{s_j\}$, such that $s_j - \tau \geq s_{j-1}$. Then $y(s_j - s) \leq y(s_{j-1})$ for all $s \in [0, \tau]$ and therefore

$$y(s_j) \leq \frac{\alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s} y(s_j - s)\, ds}{\alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds + \beta_u \hat{u}} \leq S\, y(s_{j-1}),$$

where

$$S = \frac{\alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds}{\alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds + \beta_u \hat{u}}.$$

Now, $S < 1$ and S is independent of j. Therefore, $y(s_j) \to 0$ as $j \to \infty$. We conclude that $\lim_{t\to\infty} u(t) = \hat{u}$, and the proof of Theorem 1 is complete.

2.1. Global stability of $\hat{E}_u$. We shall prove a theorem on the global stability of the equilibrium point

$$\hat{E}_u = \left(\frac{\alpha_u}{\beta_u}\int_0^\tau f_u(s)e^{-\gamma_u s}ds, 0\right)$$

of system (2.7), in the situation when the other boundary equilibrium

$$\hat{E}_v = \left(0, \frac{\alpha_v}{\beta_v}\int_0^\tau f_v(s)e^{-\gamma_v s}ds\right)$$

of (2.7) is linearly unstable. This means that the competition between the two species U and V is strong and the species cannot coexist. One of them, in this case the V population, dies out.

In the proof of Theorem 2 below, and in subsequent theorems, we shall use a comparison principle. Comparison principles do not always hold for delay equations; it depends very much on how the delay appears in the equations. For scalar equations, the essential requirement for a comparison principle to hold is that the reaction term be a nondecreasing function of the delayed variable (see, for example, Martin and Smith [5]). The following proposition will be useful and follows easily from the results in [5].

PROPOSITION 1. *Let $v(t)$ be a solution of*

$$\frac{dv(t)}{dt} = \alpha\int_0^\tau f(s)e^{-\gamma s}v(t-s)\,ds - \beta v^2(t) - \lambda v(t), \qquad t > 0,$$

and $u(t)$ some function satisfying

$$\frac{du(t)}{dt} \geq \alpha\int_0^\tau f(s)e^{-\gamma s}u(t-s)\,ds - \beta u^2(t) - \lambda u(t), \qquad t > 0. \tag{2.11}$$

Assume also that $u(s) \geq v(s)$ for all $s \in [-\tau, 0]$. Then $u(t) \geq v(t)$ for all $t > 0$.

Remarks. An analogous result holds with the inequalities reversed, and we shall need this also. In our applications of these comparison results we shall often find that a differential inequality of the form (2.11) holds only for t above some value, say t_1, and not for all $t > 0$. In that case the initial time is simply thought of as t_1 rather than 0, and $u(t) \geq v(t)$ is arranged to hold for $t \leq t_1$ by appropriate definition of $v(t)$ for values of $t \leq t_1$. In the interests of clarity, we shall not always elaborate on this latter point in detail.

THEOREM 2. *Let the initial data satisfy* (2.8)*, and assume that*

$$c_2\alpha_u\int_0^\tau f_u(s)e^{-\gamma_u s}\,ds > \beta_u\alpha_v\int_0^\tau f_v(s)e^{-\gamma_v s}\,ds \tag{2.12}$$

and

$$c_1\alpha_v\int_0^\tau f_v(s)e^{-\gamma_v s}\,ds < \beta_v\alpha_u\int_0^\tau f_u(s)e^{-\gamma_u s}\,ds. \tag{2.13}$$

Then $U(t) \to \frac{\alpha_u}{\beta_u}\int_0^\tau f_u(s)e^{-\gamma_u s}\,ds$ and $V(t) \to 0$ as $t \to \infty$.

Proof. Let $\overline{U} = \limsup_{t\to\infty} U(t)$, $\underline{U} = \liminf_{t\to\infty} U(t)$, $\overline{V} = \limsup_{t\to\infty} V(t)$, and $\underline{V} = \liminf_{t\to\infty} V(t)$. Now, since

$$\begin{aligned}\frac{dU(t)}{dt} &= \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}U(t-s)\,ds - \beta_u U^2(t) - c_1 U(t)V(t)\\ &\le \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}U(t-s)\,ds - \beta_u U^2(t),\end{aligned}$$

we can conclude from this and Theorem 1 that $\overline{U} \le U_B$, where

$$U_B = \frac{\alpha_u}{\beta_u}\int_0^\tau f_u(s)e^{-\gamma_u s}\,ds$$

is the U component of the equilibrium $\hat{E}_u$. By positivity of $V(t)$ we also know that $\underline{V} \ge 0$. To complete the proof it suffices to find two sequences $\{M_m^u\}$, $\{N_m^v\}$ with the properties that $\underline{U} \ge M_m^u$ for each m with $M_m^u \to U_B$ as $m \to \infty$ (so that $\underline{U} \ge U_B$), and $\overline{V} \le N_m^v$ for each m with $N_m^v \to 0$ as $m \to \infty$. As a first step in this process, let $v_1(t)$ satisfy

$$\frac{dv_1(t)}{dt} = \alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}v_1(t-s)\,ds - \beta_v v_1^2(t), \qquad t > 0,$$

with, for $s \le 0$, $v_1(s) \equiv \max\{V(s),\ s \in [-\tau, 0]\} > 0$. Then

$$\lim_{t\to\infty} v_1(t) = \frac{\alpha_v}{\beta_v}\int_0^\tau f_v(s)e^{-\gamma_v s}\,ds.$$

Since $U(t)$ and $V(t)$ are nonnegative,

$$\begin{aligned}\frac{dV(t)}{dt} &= \alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}V(t-s)\,ds - \beta_v V^2(t) - c_2 U(t)V(t)\\ &\le \alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}V(t-s)\,ds - \beta_v V^2(t).\end{aligned}$$

By comparison, $V(t) \le v_1(t)$ and therefore

$$\overline{V} = \limsup_{t\to\infty} V(t) \le \lim_{t\to\infty} v_1(t) = \frac{\alpha_v}{\beta_v}\int_0^\tau f_v(s)e^{-\gamma_v s}\,ds := N_1^v.$$

Let $\varepsilon > 0$ be sufficiently small such that

$$0 < \varepsilon < \frac{\beta_v\alpha_u\int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1\alpha_v\int_0^\tau f_v(s)e^{-\gamma_v s}\,ds}{\beta_v c_1}. \tag{2.14}$$

There exists $t_1 > \tau$ such that $V(t) \le N_1^v + \varepsilon$ for all $t \ge t_1$. For $t > t_1$ let $u_1(t)$ evolve according to

$$\frac{du_1(t)}{dt} = \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}u_1(t-s)\,ds - \beta_u u_1^2(t) - c_1 u_1(t)(N_1^v + \varepsilon),$$

and for $t \in [t_1 - \tau, t_1]$ let

$$u_1(t) \equiv \min\{U(t),\ t \in [t_1 - \tau, t_1]\},$$

which is strictly positive, since $U(t) > 0$ on $(0, \infty)$. It is not necessary to define $u_1(t)$ for $t < t_1 - \tau$ since Proposition 1 is now being applied with initial time t_1 rather than 0.

Since ε satisfies (2.14), Theorem 1 yields that

$$\lim_{t\to\infty} u_1(t) = \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1(N_1^v + \varepsilon)\right].$$

Now, since $N_1^v + \varepsilon \geq V(t)$ for $t \geq t_1$, we have, for such t,

$$\begin{aligned}\frac{dU(t)}{dt} &= \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}U(t-s)\,ds - \beta_u U^2(t) - c_1U(t)V(t)\\ &\geq \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}U(t-s)\,ds - \beta_u U^2(t) - c_1U(t)(N_1^v + \varepsilon).\end{aligned}$$

By comparison, $U(t) \geq u_1(t)$ and therefore

$$\underline{U} = \liminf_{t\to\infty} U(t) \geq \lim_{t\to\infty} u_1(t) = \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1(N_1^v + \varepsilon)\right].$$

Since this is true for any $\varepsilon > 0$ satisfying (2.14), it follows that $\underline{U} \geq M_1^u$, where

$$M_1^u = \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}ds - c_1N_1^v\right].$$

Let $\varepsilon > 0$. There exists $t_2 > 0$ such that $U(t) \geq M_1^u - \varepsilon$ for all $t \geq t_2$. For $t > t_2$ let $v_2(t)$ be the solution of

$$\frac{dv_2(t)}{dt} = \alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}v_2(t-s)\,ds - \beta_v v_2^2(t) - \frac{\beta_u\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds}{\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds}(M_1^u - \varepsilon)v_2$$

with appropriate "initial data" on the interval $[t_2 - \tau, t_2]$. Now

$$\begin{aligned}\frac{dV(t)}{dt} &= \alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}V(t-s)\,ds - \beta_v V^2(t) - c_2U(t)V(t)\\ &\leq \alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}V(t-s)\,ds - \beta_v V^2(t) - \frac{\beta_u\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds}{\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds}(M_1^u - \varepsilon)V(t),\end{aligned}$$

where we have used (2.12). By comparison, $V(t) \leq v_2(t)$. But, by Theorem 1, and using the fact that $M_1^u < (\alpha_u/\beta_u)\int_0^\tau f_u(s)e^{-\gamma_u s}\,ds$,

$$\lim_{t\to\infty} v_2(t) = \frac{1}{\beta_v}\left[\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}ds - \frac{\beta_u\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}ds}{\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}ds}(M_1^u - \varepsilon)\right].$$

Hence

$$\begin{aligned}\overline{V} &= \limsup_{t\to\infty} V(t) \leq \lim_{t\to\infty} v_2(t)\\ &= \frac{1}{\beta_v}\left[\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds - \frac{\beta_u\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds}{\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds}(M_1^u - \varepsilon)\right].\end{aligned}$$

Since ε is arbitrary, we conclude that $\overline{V} \le N_2^v$, where

$$N_2^v = \frac{1}{\beta_v}\left[\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds - \frac{\beta_u\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds}{\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds} M_1^u\right]. \tag{2.15}$$

Now, let $\varepsilon > 0$ be sufficiently small such that the expression given below for $\lim_{t\to\infty} u_2(t)$ is positive. That this is possible follows from the second inequality (2.13) in the hypotheses of Theorem 2, together with the fact that N_2^v satisfies $N_2^v < (\alpha_v/\beta_v)\int_0^\tau f_v(s)e^{-\gamma_v s}\,ds$.

There exists $t_3 > 0$ such that $V(t) \le N_2^v + \varepsilon$ for all $t \ge t_3$. For $t > t_3$ let $u_2(t)$ be a suitable solution of

$$\frac{du_2(t)}{dt} = \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}u_2(t-s)\,ds - \beta_u u_2^2(t) - c_1(N_2^v + \varepsilon)u_2(t).$$

Then, since

$$\begin{aligned}\frac{dU(t)}{dt} &= \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}U(t-s)\,ds - \beta_u U^2(t) - c_1U(t)V(t)\\ &\ge \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}U(t-s)\,ds - \beta_u U^2(t) - c_1(N_2^v + \varepsilon)U(t),\end{aligned}$$

we have $U(t) \ge u_2(t)$. Also

$$\lim_{t\to\infty} u_2(t) = \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1(N_2^v + \varepsilon)\right].$$

Hence

$$\underline{U} \ge \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1(N_2^v + \varepsilon)\right].$$

By the arbitrariness of $\varepsilon > 0$, $\underline{U} \ge M_2^u$, where

$$M_2^u = \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1N_2^v\right]. \tag{2.16}$$

Continuing this process, we obtain two sequences N_m^v, M_m^u, $m = 1, 2, 3, \ldots$, such that, for $m \ge 2$,

$$N_m^v = \frac{1}{\beta_v}\left[\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}ds - \frac{\beta_u\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}ds}{\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}ds} M_{m-1}^u\right] \tag{2.17}$$

and

$$M_m^u = \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}ds - c_1N_m^v\right]. \tag{2.18}$$

Combining these,

$$N_m^v = \frac{c_1\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds}{\beta_v\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds} N_{m-1}^v,$$

which confirms that all the N_m^v are positive. Furthermore, by assumption (2.13), $N_m^v \to 0$ as $m \to \infty$. Hence, by (2.18),

$$\lim_{m\to\infty} M_m^u = \frac{\alpha_u}{\beta_u}\int_0^\tau f_u(s)e^{-\gamma_u s}ds = U_B.$$

Therefore

$$\lim_{t\to\infty} U(t) = U_B$$

and

$$\lim_{t\to\infty} V(t) = 0,$$

which completes the proof of Theorem 2.

The following theorem is an analogue of Theorem 2 for the situation when the equilibrium $\hat{E}_u$ is unstable and $\hat{E}_v$ is asymptotically stable. The proof is similar to that of Theorem 2.

THEOREM 3. *Let the initial data satisfy* (2.8)*, and assume that*

$$c_2\alpha_u\int_0^\tau f_u(s)e^{-\gamma_u s}\,ds < \beta_u\alpha_v\int_0^\tau f_v(s)e^{-\gamma_v s}\,ds$$

and

$$c_1\alpha_v\int_0^\tau f_v(s)e^{-\gamma_v s}\,ds > \beta_v\alpha_u\int_0^\tau f_u(s)e^{-\gamma_u s}\,ds.$$

Then $V(t) \to \frac{\alpha_v}{\beta_v}\int_0^\tau f_v(s)e^{-\gamma_v s}\,ds$ *and* $U(t) \to 0$*, as* $t \to \infty$.

2.2. Global stability of the coexistence state $\hat{E}$. We will prove a theorem on the global stability of the coexistence equilibrium $\hat{E} = (\hat{U}, \hat{V})$ of system (2.7), where

$$\hat{U} = \frac{\beta_v\alpha_u\int_0^\tau f_u(s)e^{-\gamma_u s}ds - c_1\alpha_v\int_0^\tau f_v(s)e^{-\gamma_v s}ds}{\beta_u\beta_v - c_1c_2}$$

and

$$\hat{V} = \frac{\beta_u\alpha_v\int_0^\tau f_v(s)e^{-\gamma_v s}ds - c_2\alpha_u\int_0^\tau f_u(s)e^{-\gamma_u s}ds}{\beta_u\beta_v - c_1c_2}.$$

The hypotheses in Theorem 4 below are those which imply linear instability of both of the boundary equilibria $\hat{E}_u$ and $\hat{E}_v$. In this case the coexistence equilibrium $\hat{E}$ is globally asymptotically stable. The conditions (2.19) and (2.20) below have various ecological interpretations including weak interspecific competition and significant adult mortality. (Recall that deaths rates of *immatures* are measured by γ_u and γ_v, which arise in the conditions in a somewhat different way.)

THEOREM 4. *If the initial data satisfies* (2.8)*, and if the following two conditions hold,*

$$c_2\alpha_u\int_0^\tau f_u(s)e^{-\gamma_u s}\,ds < \beta_u\alpha_v\int_0^\tau f_v(s)e^{-\gamma_v s}ds \tag{2.19}$$

and

$$c_1\alpha_v\int_0^\tau f_v(s)e^{-\gamma_v s}\,ds < \beta_v\alpha_u\int_0^\tau f_u(s)e^{-\gamma_u s}ds, \tag{2.20}$$

then $U(t) \to \hat{U}$ *and* $V(t) \to \hat{V}$ *as* $t \to \infty$.

Proof. Recall that in the proof of Theorem 2 we were able to establish $\overline{U} \le U_B$ and $\underline{V} \ge 0$ in one step, and thereafter we established a sequence of lower bounds M_m^u for $\underline{U}$ and a sequence of upper bounds N_m^v for $\overline{V}$. These sequences approached limits U_B and 0, respectively, establishing our result.

Our approach to proving Theorem 4 is similar, but the situation is more complicated since we are concerned with the coexistence equilibrium. We shall need four sequences, N_m^u, N_m^v, M_m^u, and M_m^v, $m = 1, 2, 3, \ldots$. It is helpful to remember that N_m denotes an upper bound and M_m a lower bound on the limsup and liminf, respectively, as $t \to \infty$, of the variable in the superscript. We shall derive recursion formulae for these bounds and use them to deduce the result.

From positivity of solutions we immediately obtain N_1^u as follows:

$$\frac{dU(t)}{dt} \le \alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s} U(t-s)\, ds - \beta_u U^2(t).$$

Hence

$$\overline{U} = \limsup_{t\to\infty} U(t) \le \frac{\alpha_u}{\beta_u} \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds := N_1^u.$$

In a similar way, we have

$$\overline{V} \le \frac{\alpha_v}{\beta_v} \int_0^\tau f_v(s) e^{-\gamma_v s}\, ds := N_1^v.$$

Let $\varepsilon > 0$ be sufficiently small such that

$$\varepsilon < \frac{\beta_u \alpha_v \int_0^\tau f_v(s) e^{-\gamma_v s}\, ds - c_2 \alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds}{\beta_u c_2}, \tag{2.21}$$

which is possible by (2.19). Let $t_1 > 0$ be such that $U(t) \le N_1^u + \varepsilon$ for all $t \ge t_1$, and for $t > t_1$ let $m_1^v(t)$ be a solution of

$$\frac{dm_1^v(t)}{dt} = \alpha_v \int_0^\tau f_v(s) e^{-\gamma_v s} m_1^v(t-s)\, ds - \beta_v (m_1^v(t))^2 - c_2 (N_1^u + \varepsilon) m_1^v(t)$$

with appropriate initial data on $[t_1 - \tau, t_1]$. Since ε satisfies (2.21), Theorem 1 applies and yields

$$\lim_{t\to\infty} m_1^v(t) = \frac{1}{\beta_v} \left[\alpha_v \int_0^\tau f_v(s) e^{-\gamma_v s} ds - c_2 (N_1^u + \varepsilon) \right].$$

Since $N_1^u + \varepsilon \ge U(t)$ for $t \ge t_1$,

$$\begin{aligned} \frac{dV(t)}{dt} &= \alpha_v \int_0^\tau f_v(s) e^{-\gamma_v s} V(t-s)\, ds - \beta_v V^2(t) - c_2 U(t) V(t) \\ &\ge \alpha_v \int_0^\tau f_v(s) e^{-\gamma_v s} V(t-s)\, ds - \beta_v V^2(t) - c_2 (N_1^u + \varepsilon) V(t) \end{aligned}$$

so that $V(t) \ge m_1^v(t)$, and hence

$$\underline{V} = \liminf_{t\to\infty} V(t) \ge \lim_{t\to\infty} m_1^v(t) = \frac{1}{\beta_v} \left[\alpha_v \int_0^\tau f_v(s) e^{-\gamma_v s}\, ds - c_2 (N_1^u + \varepsilon) \right].$$

This is true for any $\varepsilon > 0$ satisfying (2.21), and hence

$$\underline{V} \geq \frac{1}{\beta_v}\left[\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds - c_2 N_1^u\right] := M_1^v.$$

In exactly the same way, we can show that

$$\underline{U} \geq \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1 N_1^v\right] := M_1^u,$$

and, in doing so, the assumption (2.20) is used.

We shall now show how to find new upper bounds N_2^u, N_2^v in terms of the old lower bounds M_1^v, M_1^u, respectively. New lower bounds are then found from the *new* upper bounds by following the procedure already described. It will then be clear how to proceed from the $(m-1)$th to the mth step in this process.

Let $\varepsilon > 0$. There exists $t_2 > 0$ such that $V(t) \geq M_1^v - \varepsilon$ for all $t \geq t_2$. Then, for $t \geq t_2$,

$$\begin{aligned}\frac{dU(t)}{dt} &= \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}U(t-s)\,ds - \beta_u U^2(t) - c_1 U(t)V(t)\\ &\leq \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}U(t-s)\,ds - \beta_u U^2(t) - c_1(M_1^v - \varepsilon)U(t).\end{aligned}$$

Thus, if for $t > t_2$ we denote by $n_2^u(t)$ the solution of

$$\frac{dn_2^u(t)}{dt} = \alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}n_2^u(t-s)\,ds - \beta_u(n_2^u(t))^2 - c_1(M_1^v - \varepsilon)n_2^u(t)$$

with appropriate initial data, then $U(t) \leq n_2^u(t)$ and thus

$$\overline{U} \leq \lim_{t\to\infty} n_2^u(t) = \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1(M_1^v - \varepsilon)\right].$$

(We have used assumption (2.20) to deduce that $n_2^u(t)$ has this limiting behavior.) Since $\varepsilon > 0$ is arbitrary,

$$\overline{U} \leq \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1 M_1^v\right] := N_2^u.$$

In the same way, and using (2.19), we deduce the following estimate for $\overline{V}$:

$$\overline{V} \leq \frac{1}{\beta_v}\left[\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds - c_2 M_1^u\right] := N_2^v.$$

One now sees that the transition from the $(m-1)$th to the mth step in this iterative process is given by

$$N_m^u = \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1 M_{m-1}^v\right],$$

$$N_m^v = \frac{1}{\beta_v}\left[\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds - c_2 M_{m-1}^u\right],$$

$$M_m^u = \frac{1}{\beta_u}\left[\alpha_u \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1 N_m^v\right],$$
$$M_m^v = \frac{1}{\beta_v}\left[\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds - c_2 N_m^u\right],$$

and, of course,

$$M_m^u \le \underline{U} \le \overline{U} \le N_m^u \quad \text{and} \quad M_m^v \le \underline{V} \le \overline{V} \le N_m^v$$

for each $m = 1, 2, 3, \ldots$. We need to show that M_m^u and N_m^u both approach $\hat{U}$ as $m \to \infty$ and that M_m^v and N_m^v both approach $\hat{V}$.

We see at once that

$$N_m^u = \frac{\alpha_u\beta_v \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds}{\beta_u\beta_v} + \frac{c_1c_2}{\beta_u\beta_v}N_{m-1}^u. \tag{2.22}$$

Note that (2.19) and (2.20) imply that

$$\frac{c_1c_2}{\beta_u\beta_v} < 1.$$

We claim that N_m^u is a monotonically decreasing sequence that is bounded below by $\hat{U}$. The boundedness below by $\hat{U}$ follows immediately from (2.22) by induction. Then, by (2.22), and using (2.20),

$$\begin{aligned}\frac{N_m^u}{N_{m-1}^u} &= \frac{\alpha_u\beta_v \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds}{\beta_u\beta_v N_{m-1}^u} + \frac{c_1c_2}{\beta_u\beta_v}\\ &\le \frac{\alpha_u\beta_v \int_0^\tau f_u(s)e^{-\gamma_u s}\,ds - c_1\alpha_v \int_0^\tau f_v(s)e^{-\gamma_v s}\,ds}{\beta_u\beta_v \hat{U}} + \frac{c_1c_2}{\beta_u\beta_v}\\ &= 1\end{aligned}$$

so that N_m^u is monotonically decreasing. Hence N_m^u converges to a limit which, by (2.22), equals $\hat{U}$.

Of course, convergence of N_m^u implies convergence of M_m^v, and it is easily checked that M_m^v has the limit $\hat{V}$. The analysis for the remaining two sequences is similar. The proof of the theorem is complete.

3. Traveling wave front solutions. In this section we shall explore the existence of a traveling wave front solution of a reaction-diffusion extension of system (1.1) between the two boundary equilibria $\hat{E}_v$ and $\hat{E}_u$, in the situation when V is the weaker competitor and there is no coexistence equilibrium. Ecologically, this situation corresponds to a one-dimensional habitat initially inhabited only by the weaker V species, and then some of the U species are introduced at one end. The U species then invades the domain, driving the V species to extinction. The end result is that the domain is inhabited only by U.

The approach we shall use to prove the existence of such a traveling front is the upper-lower solution technique and the monotone iteration method recently developed by Wu and Zou [9] (in particular, Theorem 3.6 of that paper) for delayed reaction-diffusion systems. To be precise, we shall consider the competitive system

$$\begin{aligned}\frac{\partial U_1(t)}{\partial t} &= d_1\frac{\partial^2 U_1}{\partial x^2} + \alpha_1 e^{-\gamma_1\tau_1}U_1(x,t-\tau_1) - \beta_1 U_1^2(x,t) - c_1U_1(x,t)U_2(x,t),\\ \frac{\partial U_2(t)}{\partial t} &= d_2\frac{\partial^2 U_2}{\partial x^2} + \alpha_2 e^{-\gamma_2\tau_2}U_2(x,t-\tau_2) - \beta_2 U_2^2(x,t) - c_2U_1(x,t)U_2(x,t),\end{aligned} \tag{3.1}$$

where all the parameters are nonnegative constants.

It is well known that the addition of diffusion to a system with time delays can be problematic from the point of view of ecological realism. One expects that in general a time-delayed term would need to become a weighted spatial average involving the diffusivity. However, system (3.1) is realistic in the case when the *immature* members of the species are not moving (the immatures do not explicitly feature in (3.1)). For many species such an assumption is entirely realistic. For example, insects which go through a larval stage do not move, or move hardly at all, during the larval phase, but on becoming adults they can of course travel tremendous distances. In such cases, each individual on reaching adulthood is still at the same location as when it was born, and only on becoming an adult does it start moving.

The situation when the immatures *do* move can be studied by replacing the time delay terms in (3.1) with more complicated delay terms involving integral convolutions in space (see, for example, Al-Omari and Gourley [2]). Of course, the immatures and matures might diffuse at different rates. The methods of Wu and Zou [9] should be applicable to this case also (see, for example, So, Wu, and Zou [7] who treated a scalar delay equation containing such an integral convolution in space). In this paper we shall concentrate on the case when the immatures are immobile.

System (3.1) has four spatially uniform equilibria: $(\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}, 0)$, $(0, \frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2})$, $(0,0)$, and the coexistence equilibrium (if feasible)

$$\left(\frac{\beta_2\alpha_1e^{-\gamma_1\tau_1} - c_1\alpha_2e^{-\gamma_2\tau_2}}{\beta_1\beta_2 - c_1c_2}, \quad \frac{\beta_1\alpha_2e^{-\gamma_2\tau_2} - c_2\alpha_1e^{-\gamma_1\tau_1}}{\beta_1\beta_2 - c_1c_2}\right).$$

The situation of interest here is that in which the equilibrium $(0, \frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2})$ is unstable and when $(\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}, 0)$ is stable, both as solutions of the spatially uniform model. The conditions on the parameters can be extracted as a particular case of Theorem 2 and are

$$c_2\alpha_1e^{-\gamma_1\tau_1} > \beta_1\alpha_2e^{-\gamma_2\tau_2} \quad \text{and} \quad c_1\alpha_2e^{-\gamma_2\tau_2} < \beta_2\alpha_1e^{-\gamma_1\tau_1}. \tag{3.2}$$

Therefore, we assume that (3.2) holds throughout this section. Note that in this case the coexistence equilibrium is not feasible since its components are of opposite sign.

3.1. Wu and Zou's theory. We shall summarize those aspects of the work of Wu and Zou [9] which are relevant here. Applications of their techniques include work by Al-Omari and Gourley [2] on a structured model of a single species, by So and Zou [8] on the diffusive Nicholson's blowflies equation, by Huang and Zou [4] on a cooperative Lotka–Volterra system with delay, and by Wu and Zou themselves [9] on a delayed Fisher equation and a delayed Belousov–Zhabotinskii reaction model.

The theory is for reaction diffusion systems of the form

$$\frac{\partial u(x,t)}{\partial t} = D\frac{\partial^2 u(x,t)}{\partial x^2} + f(u_t(x)), \qquad x \in \mathbf{R},\ t \geq 0, \tag{3.3}$$

with $u \in \mathbf{R}^n$, D a diagonal diffusion matrix with positive entries, $f(\cdot)$ a functional, and its argument $u_t(x)$ the function

$$u_t(x)(s) = u(x, t+s), \qquad s \in [-\tau, 0].$$

This set-up allows more than one time delay. Conversion to traveling wave form, by setting $u(x,t) = \phi(z) \in \mathbf{R}^n$, $z = x + ct$ with $c \geq 0$, yields a system of equations of the form

$$D\phi''(z) - c\phi'(z) + f_c(\phi_z) = \mathbf{0}, \qquad z \in \mathbf{R}, \tag{3.4}$$

where $\phi_z(\zeta) = \phi(\zeta + z)$ and the new functional f_c is defined by $f_c(\psi) = f(\psi^c)$, where $\psi^c(s) := \psi(cs)$, $s \in [-\tau, 0]$. The theory establishes, under certain conditions, existence of a solution of (3.4) satisfying

$$\phi(-\infty) = \mathbf{0}, \qquad \phi(\infty) = \mathbf{K}, \tag{3.5}$$

where $\mathbf{0}$ and $\mathbf{K}$ are equilibria of (3.3).

The theory presumes that there are no other equilibria u with $\mathbf{0} < u < \mathbf{K}$ (here, the ordering is the standard partial ordering in $\mathbf{R}^n$, i.e., $u \le v$ if $u_i \le v_i$, $i = 1, \dots, n$, and $u < v$ if $u \le v$ but $u \ne v$). Actually, this condition is not quite satisfied for us, for reasons which will be explained later. We shall argue, by a detailed examination of its proof, that Wu and Zou's Theorem 3.6 applies nevertheless.

Additionally [9, p. 659], there must exist a matrix $\delta = \operatorname{diag}(\delta_1, \dots, \delta_n)$ with $\delta_i \ge 0$ such that

$$f_c(\phi) - f_c(\psi) + \delta(\phi(0) - \psi(0)) > \mathbf{0} \tag{3.6}$$

for all continuous functions ϕ, ψ such that $\mathbf{0} \le \psi(s) \le \phi(s) \le \mathbf{K}$, $s \in [-c\tau, 0]$. This is called a quasi-monotonicity condition.

The following set is called the *profile set*:

$$\Gamma = \{\phi \in C(\mathbf{R}, \mathbf{R}^n) : \ \phi(z) \text{ is nondecreasing, } \phi(-\infty) = \mathbf{0}, \text{ and } \phi(\infty) = \mathbf{K}\}.$$

Additionally, one must find an *upper solution*, i.e., a function $\overline{\phi}$ that is twice differentiable almost everywhere and satisfies

$$D\overline{\phi}''(z) - c\overline{\phi}'(z) + f_c(\overline{\phi}_z) \le \mathbf{0}.$$

A *lower solution* $\underline{\phi}$ is also required, being a function defined as above but with the inequality reversed. These two functions must be constructed such that

$$\mathbf{0} \le \underline{\phi}(z) \le \overline{\phi}(z) \le \mathbf{K}$$

and such that at least one component of the lower solution is not identically zero. Actually only one component of our lower solution is nonzero, but we shall be arguing that refinements of Wu and Zou's approach (see Remark 4.6 in [9]) lead to their Theorem 3.6 remaining valid.

If all of the above conditions are met, and if the upper solution $\overline{\phi} \in \Gamma$ (the lower solution need not lie in Γ), Theorem 3.6 in [9] guarantees the existence of a solution of (3.4) satisfying (3.5).

3.2. Existence of a traveling wave front. In this section, we will prove the existence of a traveling front solution of (3.1) by using Wu and Zou's theory.

To seek a traveling front solution of system (3.1), set $U_1(x,t) = \phi_1(z)$ and $U_2(x,t) = \phi_2(z)$, where $z = x + ct$ and $c > 0$ is the wave speed. The system (3.1) becomes

$$\begin{aligned} &d_1\phi_1''(z) - c\phi_1'(z) + \alpha_1 e^{-\gamma_1\tau_1}\phi_1(z - c\tau_1) - \beta_1\phi_1^2(z) - c_1\phi_1(z)\phi_2(z) = 0, \\ &d_2\phi_2''(z) - c\phi_2'(z) + \alpha_2 e^{-\gamma_2\tau_2}\phi_2(z - c\tau_2) - \beta_2\phi_2^2(z) - c_2\phi_1(z)\phi_2(z) = 0, \end{aligned} \tag{3.7}$$

which is to be solved subject to

$$\phi_1(-\infty) = 0, \quad \phi_2(-\infty) = \frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}, \quad \phi_1(\infty) = \frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}, \quad \phi_2(\infty) = 0,$$

and also, for ecological realism, $\phi_1(z), \phi_2(z) \geq 0$ for all $z \in (-\infty, \infty)$. The latter is only possible for c exceeding a certain minimum value, as can be seen from the following linearized analysis. As $z \to -\infty$, the first equation of (3.7) becomes, approximately,

$$d_1\phi_1''(z) - c\phi_1'(z) + \alpha_1 e^{-\gamma_1\tau_1}\phi_1(z - c\tau_1) - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\phi_1(z) = 0,$$

and, seeking solutions of this proportional to $\exp(\lambda z)$, one finds that $\Delta_1(\lambda) = 0$, where

$$\Delta_1(\lambda) = \alpha_1 e^{-\gamma_1\tau_1}e^{-\lambda c\tau_1} - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2} - \left(c\lambda - d_1\lambda^2\right). \tag{3.8}$$

Similarly, if we let $z \to \infty$ and approximate the second equation of (3.7) suitably, trial solutions of the form $\exp(\lambda z)$ exist when $\Delta_2(\lambda) = 0$, where

$$\Delta_2(\lambda) = \alpha_2 e^{-\gamma_2\tau_2}e^{-\lambda c\tau_2} - \frac{c_2\alpha_1}{\beta_1}e^{-\gamma_1\tau_1} - \left(c\lambda - d_2\lambda^2\right). \tag{3.9}$$

Since positive and monotone solutions are sought, any decay to zero as $z \to \pm\infty$ must be nonoscillatory. Now, $\Delta_1(\lambda) = 0$ relates to the situation as $z \to -\infty$, so it is necessary that this equation should have at least one real positive root, while $\Delta_2(\lambda) = 0$ should have a real negative root since the latter equation is for $z \to \infty$.

Keeping in mind (3.2), simple graphical arguments show that $\Delta_1(\lambda) = 0$ has no real positive roots if c is very small, but that if c is increased, two real roots appear. We denote by c^* the infimum of the set of values of c for which there are two real positive roots. For any $c > c^*$ the two roots are denoted by $0 < \lambda_1 < \lambda_2$. Furthermore

$$\Delta_1(\lambda) = \begin{cases} > 0 & \text{for} \quad \lambda < \lambda_1, \\ < 0 & \text{for} \quad \lambda \in (\lambda_1, \lambda_2), \\ > 0 & \text{for} \quad \lambda > \lambda_2. \end{cases}$$

The existence of a real negative root (which we shall denote by λ_3) of $\Delta_2(\lambda) = 0$ follows immediately from (3.2) and a graphical argument, without further restriction on c. This equation also has a real positive root λ_4. Furthermore, $\Delta_2(\lambda) > 0$ when $\lambda < \lambda_3$, $\Delta_2(\lambda) < 0$ when $\lambda_3 < \lambda < \lambda_4$, and $\Delta_2(\lambda) > 0$ when $\lambda > \lambda_4$.

We are thus led to conjecture that ecologically relevant traveling fronts exist only for $c > c^*$. Furthermore, note that c^* depends on both of the delays τ_1 and τ_2.

Wu and Zou's theory presumes that the equilibria of the traveling wave equations are $\mathbf{0}$ and $\mathbf{K}$, where $\mathbf{K}$ is a vector with positive components. This is not so in our problem as currently posed but can be made so by the change of variables $\tilde{U}_1 = U_1$ and $\tilde{U}_2 = \frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2} - U_2$ under which the system (3.1) is transformed into

$$\begin{aligned} \frac{\partial\tilde{U}_1(t)}{\partial t} &= d_1\frac{\partial^2\tilde{U}_1}{\partial x^2} + \alpha_1 e^{-\gamma_1\tau_1}\tilde{U}_1(x, t-\tau_1) - \beta_1\tilde{U}_1^2(x,t) - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\tilde{U}_1(x,t) \\ &\quad + c_1\tilde{U}_1(x,t)\tilde{U}_2(x,t), \\ \frac{\partial\tilde{U}_2(t)}{\partial t} &= d_2\frac{\partial^2\tilde{U}_2}{\partial x^2} + \alpha_2 e^{-\gamma_2\tau_2}\tilde{U}_2(x, t-\tau_2) + \beta_2\tilde{U}_2^2(x,t) - 2\alpha_2 e^{-\gamma_2\tau_2}\tilde{U}_2(x,t) \\ &\quad + \frac{c_2\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\tilde{U}_1(x,t) - c_2\tilde{U}_1(x,t)\tilde{U}_2(x,t). \end{aligned} \tag{3.10}$$

The equilibria of interest are now $(0,0)$ and

$$\mathbf{K} := \left(\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}, \frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\right), \tag{3.11}$$

which are unstable and stable, respectively, as solutions of (3.10) to spatially uniform perturbation. We have noted that the coexistence equilibrium is unfeasible, being in either the second or the fourth quadrant of the (U_1, U_2) plane, but in the latter case it is mapped into the open first quadrant of the $(\tilde{U}_1, \tilde{U}_2)$ plane. Fortunately, (3.2) yields that its components are larger than those of $\mathbf{K}$, so that Wu and Zou's results remain applicable. The origin is mapped to $\tilde{U}_1 = 0$, $\tilde{U}_2 = (\alpha_2/\beta_2)e^{-\gamma_2\tau_2}$. This equilibrium lies in $(\mathbf{0}, \mathbf{K})$ according to the meaning of $<$, and thus the assumption that there is no equilibrium u with $\mathbf{0} < u < \mathbf{K}$ does not actually hold. We shall return to this point later. It is not a serious problem and can be dealt with as suggested in Remark 4.6 of [9].

In traveling wave form, system (3.10) becomes (with tildes dropped)

$$\begin{aligned}
&d_1\phi_1''(z) - c\phi_1'(z) + \alpha_1 e^{-\gamma_1\tau_1}\phi_1(z - c\tau_1) - \beta_1\phi_1^2(z) - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\phi_1(z) \\
&\qquad + c_1\phi_1(z)\phi_2(z) = 0, \\
&d_2\phi_2''(z) - c\phi_2'(z) + \alpha_2 e^{-\gamma_2\tau_2}\phi_2(z - c\tau_2) + \beta_2\phi_2^2(z) - 2\alpha_2 e^{-\gamma_2\tau_2}\phi_2(z) + \frac{c_2\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\phi_1 \\
&\qquad - c_2\phi_1(z)\phi_2(z) = 0,
\end{aligned} \tag{3.12}$$

and the boundary conditions are now

$$\begin{aligned}
&\phi_1(-\infty) = 0, \quad \phi_1(\infty) = \frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}, \\
&\phi_2(-\infty) = 0, \quad \phi_2(\infty) = \frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}.
\end{aligned} \tag{3.13}$$

We will prove the following theorem. For ecological relevance the theorem is formulated in terms of the original competition system (3.1). However, for the proof we shall work with the transformed system and its associated traveling wave equations (3.12).

THEOREM 5. *Assume* (3.2) *holds and that* $c > c^*$. *Assume also that*

$$\Delta_2(\lambda_1) \le 2\left(\alpha_2 e^{-\gamma_2\tau_2} - \frac{c_2\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}\right). \tag{3.14}$$

Then there exists a traveling wave front for (3.1) *with speed* c, *connecting the equilibria* $(0, \frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2})$ *and* $(\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}, 0)$.

Remarks. It is inconvenient to have to impose the condition (3.14). We feel that the condition is probably not necessary for Theorem 5 to hold. However, it is needed in our proof. Let us satisfy ourselves that the condition can be satisfied under ecologically realistic circumstances. Note that the right-hand side of (3.14) is negative (by (3.2)), so $\Delta_2(\lambda_1)$ must be negative too. This can certainly be arranged, (for example, by taking d_2 sufficiently small) and then the question is, Under what circumstances will $\Delta_2(\lambda_1)$ be sufficiently negative to satisfy (3.14)? Let us view both sides of (3.14) as functions of c_2 and imagine that c_2 approaches, from above, the critical c_2^* at which (3.2) ceases to hold. Then the right-hand side of (3.14) approaches zero while, noting that λ_1 does not depend on c_2, the left-hand side $\Delta_2(\lambda_1)$ approaches some strictly negative number. Thus, (3.14) is certainly satisfied provided c_2 is not too much greater than the minimum value of c_2 consistent with (3.2).

Proof of Theorem 5. Let $\phi = (\phi_1, \phi_2)$. To prove the theorem we need to show that the quasi-monotonicity condition holds and that upper and lower solutions $\overline{\phi}$ and $\underline{\phi}$ can be found as described in section 3.1, with at least one component of the lower solution not identically zero. (We shall explain later why, in our case, we do not require both components to be nonzero.) For the system (3.12) the functional $f_c(\phi) = (f_{c1}(\phi), f_{c2}(\phi))$ referred to in section 3.1 is given by

$$\begin{aligned} f_{c1}(\phi) &= \alpha_1 e^{-\gamma_1\tau_1}\phi_1(-c\tau_1) - \beta_1\phi_1^2(0) - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\phi_1(0) + c_1\phi_1(0)\phi_2(0), \\ f_{c2}(\phi) &= \alpha_2 e^{-\gamma_2\tau_2}\phi_2(-c\tau_2) + \beta_2\phi_2^2(0) - 2\alpha_2 e^{-\gamma_2\tau_2}\phi_2(0) + \frac{c_2\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\phi_1(0) \\ &\quad - c_2\phi_1(0)\phi_2(0). \end{aligned}$$

Let us verify that this f_c satisfies the quasi-monotonicity condition. Let $\tau = \max\{\tau_1, \tau_2\}$. For any $\phi = (\phi_1, \phi_2)$ and $\psi = (\psi_1, \psi_2) \in C([-c\tau; 0]; \mathbf{R}^2)$, with $\mathbf{0} \le \psi(s) \le \phi(s) \le \mathbf{K}$ for all $s \in [-c\tau, 0]$, we have

$$\begin{aligned} &f_{c1}(\phi) - f_{c1}(\psi) \\ &= \alpha_1 e^{-\gamma_1\tau_1}\phi_1(-c\tau_1) - \beta_1\phi_1^2(0) - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\phi_1(0) + c_1\phi_1(0)\phi_2(0) \\ &\quad - \alpha_1 e^{-\gamma_1\tau_1}\psi_1(-c\tau_1) + \beta_1\psi_1^2(0) + \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\psi_1(0) - c_1\psi_1(0)\psi_2(0) \\ &= \alpha_1 e^{-\gamma_1\tau_1}\phi_1(-c\tau_1) - \alpha_1 e^{-\gamma_1\tau_1}\psi_1(-c\tau_1) - \beta_1\left[\phi_1^2(0) - \psi_1^2(0)\right] \\ &\quad - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\left(\phi_1(0) - \psi_1(0)\right) - c_1\left(\psi_1(0)\psi_2(0) - \phi_1(0)\phi_2(0)\right) \\ &\ge -\beta_1\left(\phi_1(0) - \psi_1(0)\right)\left(\phi_1(0) + \psi_1(0)\right) - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\left(\phi_1(0) - \psi_1(0)\right) \\ &\ge \left[-2\alpha_1 e^{-\gamma_1\tau_1} - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\right]\left(\phi_1(0) - \psi_1(0)\right) \end{aligned}$$

and hence

$$\begin{aligned} &f_{c1}(\phi) - f_{c1}(\psi) + \delta_1\left[\phi_1(0) - \psi_1(0)\right] \\ &\ge \left[-2\alpha_1 e^{-\gamma_1\tau_1} - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2} + \delta_1\right]\left(\phi_1(0) - \psi_1(0)\right) \ge 0 \end{aligned}$$

provided δ_1 is chosen such that

$$\delta_1 \ge 2\alpha_1 e^{-\gamma_1\tau_1} + \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}.$$

Similarly, we have

$$\begin{aligned} f_{c2}(\phi) - f_{c2}(\psi) &= \alpha_2 e^{-\gamma_2\tau_2}\phi_2(-c\tau_2) - \alpha_2 e^{-\gamma_2\tau_2}\psi_2(-c\tau_2) - 2\alpha_2 e^{-\gamma_2\tau_2}\left(\phi_2(0) - \psi_2(0)\right) \\ &\quad + \beta_2\left(\phi_2^2(0) - \psi_2^2(0)\right) + \frac{c_2\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\left(\phi_1(0) - \psi_1(0)\right) - c_2\left(\phi_1(0)\phi_2(0) - \psi_1(0)\psi_2(0)\right) \\ &\ge -2\alpha_2 e^{-\gamma_2\tau_2}\left(\phi_2(0) - \psi_2(0)\right) + \frac{c_2\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\left(\phi_1(0) - \psi_1(0)\right) \\ &\quad + \beta_2\left(\phi_2(0) - \psi_2(0)\right)\left(\phi_2(0) + \psi_2(0)\right) - c_2\left(\phi_1(0)\phi_2(0) - \psi_1(0)\psi_2(0)\right) \\ &= -2\alpha_2 e^{-\gamma_2\tau_2}\left(\phi_2(0) - \psi_2(0)\right) + \beta_2\left(\phi_2(0) - \psi_2(0)\right)\left(\phi_2(0) + \psi_2(0)\right) \\ &\quad + \frac{c_2\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\left(\phi_1(0) - \psi_1(0)\right) - c_2\phi_2(0)\left(\phi_1(0) - \psi_1(0)\right) - c_2\psi_1(0)\left(\phi_2(0) - \psi_2(0)\right) \end{aligned}$$

$$\geq -2\alpha_2 e^{-\gamma_2\tau_2}\left(\phi_2(0)-\psi_2(0)\right)+\beta_2\left(\phi_2(0)-\psi_2(0)\right)\left(\phi_2(0)+\psi_2(0)\right)$$
$$+\frac{c_2\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\left(\phi_1(0)-\psi_1(0)\right)-c_2\frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\left(\phi_1(0)-\psi_1(0)\right)$$
$$-c_2\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}\left(\phi_2(0)-\psi_2(0)\right)$$
$$\geq\left[-2\alpha_2 e^{-\gamma_2\tau_2}-\frac{c_2\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}\right]\left(\phi_2(0)-\psi_2(0)\right).$$

Therefore

$$f_{c2}(\phi)-f_{c2}(\psi)+\delta_2\left[\phi_2(0)-\psi_2(0)\right]$$
$$\geq\left[\delta_2-2\alpha_2 e^{-\gamma_2\tau_2}-\frac{c_2\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}\right]\left(\phi_2(0)-\psi_2(0)\right)\geq 0$$

provided

$$\delta_2\geq 2\alpha_2 e^{-\gamma_2\tau_2}+\frac{c_2\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}.$$

Consequently,

$$f_c(\phi)-f_c(\psi)+\delta\left[\phi(0)-\psi(0)\right]\geq 0,$$

where the matrix δ is given by $\delta=\operatorname{diag}(\delta_1,\delta_2)$. Thus, the quasi-monotonicity condition holds.

Our search for solutions of system (3.12) shall be confined to the profile set

$$\Gamma=\left\{\phi\in C(\mathbf{R},\mathbf{R}^2):\ \begin{array}{l}\text{(i) } \phi \text{ is componentwise nondecreasing in } \mathbf{R},\\ \text{(ii) } \lim\limits_{z\to-\infty}\phi(z)=\mathbf{0} \text{ and } \lim\limits_{z\to\infty}\phi(z)=\mathbf{K}\end{array}\right\},$$

where $\mathbf{K}$ is given by (3.11).

Next, we shall find a pair of upper and lower solutions as required by Wu and Zou's theory. Let $\tau_1,\tau_2>0$, and define

$$\overline{\phi}_1(z)=\min\left\{\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}e^{\lambda_1 z},\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}\right\},$$

$$\overline{\phi}_2(z)=\min\left\{\frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}e^{\lambda_1 z},\frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\right\}.$$

We claim that $\overline{\phi}(z):=(\overline{\phi}_1(z),\overline{\phi}_2(z))^T$ is an upper solution of (3.12) and $\overline{\phi}\in\Gamma$.

Certainly, $\overline{\phi}\in\Gamma$ is clear. We need to verify the two differential inequalities obtained from (3.12) by replacing $=$ by $\leq$, and each needs to be checked separately for $z>0$ and $z<0$. For $\overline{\phi}_1$ we have two cases:

(i) If $z>0$, $\overline{\phi}_1=\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}$, $\overline{\phi}_1(z-c\tau_1)\leq\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}$, and $\overline{\phi}_2(z)=\frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}$. Then

$$d_1\overline{\phi}_1''(z)-c\overline{\phi}_1'(z)+\alpha_1 e^{-\gamma_1\tau_1}\overline{\phi}_1(z-c\tau_1)-\beta_1\overline{\phi}_1^2(z)-\frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\overline{\phi}_1(z)+c_1\overline{\phi}_1(z)\overline{\phi}_2(z)$$
$$\leq\alpha_1 e^{-\gamma_1\tau_1}\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}-\beta_1\frac{\alpha_1^2}{\beta_1^2}e^{-2\gamma_1\tau_1}-\frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}+c_1\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}\frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}$$
$$=0.$$

(ii) If $z<0$, $\overline{\phi}_1=\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}e^{\lambda_1 z}$, $\overline{\phi}_1(z-c\tau_1)=\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}e^{\lambda_1(z-c\tau_1)}$, and $\overline{\phi}_2(z)=\frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}e^{\lambda_1 z}$. Thus

$$\begin{aligned}
&d_1\overline{\phi}_1''(z)-c\overline{\phi}_1'(z)+\alpha_1e^{-\gamma_1\tau_1}\overline{\phi}_1(z-c\tau_1)-\beta_1\overline{\phi}_1^2(z)-\frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\overline{\phi}_1(z)\\
&\quad+c_1\overline{\phi}_1(z)\overline{\phi}_2(z)\\
&=\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}e^{\lambda_1 z}\left\{d_1\lambda_1^2-c\lambda_1+\alpha_1e^{-\gamma_1\tau_1}e^{-\lambda_1 c\tau_1}-\frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\right\}\\
&\quad+\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}e^{2\lambda_1 z}\left\{\frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}-\alpha_1e^{-\gamma_1\tau_1}\right\}\\
&<\frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}e^{\lambda_1 z}\,\Delta_1(\lambda_1)=0,
\end{aligned}$$

where we have used $\Delta_1(\lambda_1)=0$ and $\alpha_1e^{-\gamma_1\tau_1}>\frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}$.

Therefore, we have proved

$$\begin{aligned}
&d_1\overline{\phi}_1''(z)-c\overline{\phi}_1'(z)+\alpha_1e^{-\gamma_1\tau_1}\overline{\phi}_1(z-c\tau_1)-\beta_1\overline{\phi}_1^2(z)-\frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\overline{\phi}_1(z)+c_1\overline{\phi}_1(z)\overline{\phi}_2(z)\\
&\le 0 \text{ (a.e.) on } \mathbf{R}.
\end{aligned}$$

For $\overline{\phi}_2$, again we need to check the cases $z>0$ and $z<0$ separately. The former case is trivial while, for $z<0$, we have

$$\begin{aligned}
&d_2\overline{\phi}_2''(z)-c\overline{\phi}_2'(z)+\alpha_2e^{-\gamma_2\tau_2}\overline{\phi}_2(z-c\tau_2)+\beta_2\overline{\phi}_2^2(z)-2\alpha_2e^{-\gamma_2\tau_2}\overline{\phi}_2(z)\\
&\quad+\frac{c_2\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\overline{\phi}_1(z)-c_2\overline{\phi}_1(z)\overline{\phi}_2(z)\\
&=\frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}e^{\lambda_1 z}\left\{d_2\lambda_1^2-c\lambda_1+\alpha_2e^{-\gamma_2\tau_2}e^{-\lambda_1 c\tau_2}-2\alpha_2e^{-\gamma_2\tau_2}+\frac{c_2\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}\right\}\\
&\quad+\frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}e^{2\lambda_1 z}\underbrace{\left(-\frac{c_2\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}+\alpha_2e^{-\gamma_2\tau_2}\right)}_{<0}\\
&<\frac{\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}e^{\lambda_1 z}\left(\Delta_2(\lambda_1)-2\alpha_2e^{-\gamma_2\tau_2}+\frac{2c_2\alpha_1}{\beta_1}e^{-\gamma_1\tau_1}\right)\\
&\le 0,
\end{aligned}$$

where we have used (3.2) and (3.14). We have shown that $\overline{\phi}=(\overline{\phi}_1,\overline{\phi}_2)$ is an upper solution of (3.12).

Now let us construct a lower solution. Recall that λ_1 and λ_2 are the two real positive roots of $\Delta_1(\lambda)=0$. Now, let $\varepsilon>0$ be sufficiently small such that $\lambda_1<\lambda_1+\varepsilon<\lambda_2$ (so that $\Delta_1(\lambda_1+\varepsilon)<0$) and also such that $\lambda_1+\varepsilon\le 2\lambda_1$. Let $M>1$ be a number to be chosen later. Our candidate for a lower solution is

$$\underline{\phi}_1(z)=\begin{cases}(1-Me^{\varepsilon z})e^{\lambda_1 z}, & z<z_1,\\ 0, & z\ge z_1,\end{cases}\qquad \underline{\phi}_2(z)=0,$$

where $z_1=-(1/\varepsilon)\ln M<0$. Then $\underline{\phi}(z)\ge\mathbf{0}$ for all z. Recall that the lower solution is not required to lie in the profile set Γ.

We must verify that $\underline{\phi}_1$, $\underline{\phi}_2$ satisfy the differential inequalities obtained by replacing $=$ by $\ge$ in (3.12). The second such inequality is trivially satisfied. The first

differential inequality needs to be checked separately for the intervals $z > z_1 + c\tau_1$, $z_1 < z \le z_1 + c\tau_1$, and $z \le z_1$. It trivially holds in the first two of these intervals since in these cases we have $\underline{\phi}_1(z) = \underline{\phi}_1(z - c\tau_1) = 0$ and $\underline{\phi}_1(z) = 0$, $\underline{\phi}_1(z - c\tau_1) \ge 0$, respectively. When $z \le z_1$,

$$\begin{aligned}
&d_1\underline{\phi}_1''(z) - c\underline{\phi}_1'(z) + \alpha_1 e^{-\gamma_1\tau_1}\underline{\phi}_1(z - c\tau_1) - \beta_1\underline{\phi}_1^2(z) \\
&\quad - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\underline{\phi}_1(z) + c_1\underline{\phi}_1(z)\underline{\phi}_2(z) \\
&= e^{\lambda_1 z}\underbrace{\left(d_1\lambda_1^2 - c\lambda_1 + \alpha_1 e^{-\gamma_1\tau_1}e^{-\lambda_1 c\tau_1} - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\right)}_{=\Delta_1(\lambda_1)=0} \\
&\quad - M\,e^{(\lambda_1+\varepsilon)z}\left(d_1(\lambda_1+\varepsilon)^2 - c(\lambda_1+\varepsilon) + \alpha_1 e^{-\gamma_1\tau_1}e^{-(\lambda_1+\varepsilon)c\tau_1} - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\right) \\
&\quad - \beta_1 e^{2\lambda_1 z}(1 - Me^{\varepsilon z})^2 \\
&= -M\,e^{(\lambda_1+\varepsilon)z}\Delta_1(\lambda_1+\varepsilon) - \beta_1 e^{2\lambda_1 z}(1 - Me^{\varepsilon z})^2.
\end{aligned}$$

Now, since $z \le z_1 < 0$, we have $0 \le 1 - Me^{\varepsilon z} < 1$. Also, $2\lambda_1 \ge \lambda_1 + \varepsilon$ so that, since $z < 0$, $e^{2\lambda_1 z} \le e^{(\lambda_1+\varepsilon)z}$. Therefore

$$\begin{aligned}
&d_1\underline{\phi}_1''(z) - c\underline{\phi}_1'(z) + \alpha_1 e^{-\gamma_1\tau_1}\underline{\phi}_1(z - c\tau_1) - \beta_1\underline{\phi}_1^2(z) \\
&\quad - \frac{c_1\alpha_2}{\beta_2}e^{-\gamma_2\tau_2}\underline{\phi}_1(z) + c_1\underline{\phi}_1(z)\underline{\phi}_2(z) \\
&\ge -M\,e^{(\lambda_1+\varepsilon)z}\Delta_1(\lambda_1+\varepsilon) - \beta_1 e^{(\lambda_1+\varepsilon)z} \\
&= Me^{(\lambda_1+\varepsilon)z}\left(\underbrace{-\Delta_1(\lambda_1+\varepsilon)}_{>0} - \frac{\beta_1}{M}\right).
\end{aligned}$$

We now choose M sufficiently large to ensure (a) strict positivity of the right-hand side of the above, and (b) that

$$\sup_{z\in\mathbf{R}}\underline{\phi}_1(z) < \frac{\alpha_1}{\beta_1}e^{-\gamma_1\tau_1},$$

which is easily shown to be possible. We then need to arrange that $\underline{\phi}_1(z) \le \overline{\phi}_1(z)$ for all z, which is not automatically true. But note that $\underline{\phi}_1(z)$ and $\overline{\phi}_1(z)$ have the same exponential decay rate as $z \to -\infty$. Accordingly, we can arrange to have $\underline{\phi}_1(z) \le \overline{\phi}_1(z)$ for all z by replacing our upper solution $\overline{\phi}(z)$ by a leftward shifted translate $\overline{\phi}(z + A)$ thereof, for a suitably large value of $A > 0$. Since our problem is invariant to translations in z, any such translate of $\overline{\phi}$ is still an upper solution and, furthermore, is still in Γ.

We have now established the existence of an upper and a lower solution. We have mentioned that certain hypotheses of Wu and Zou do not quite apply to our problem, namely, the requirement that each component of the lower solution $\underline{\phi}$ be not identically zero and that there be no equilibria u with $\mathbf{0} < u < \mathbf{K}$. But Wu and Zou stress (see Remark 4.6 in [9]) that these very assumptions are required only for the final stage in their proof, i.e., that their solution satisfies $\phi(\infty) = \mathbf{K}$ and that any replacement which also ensures this is perfectly valid. Indeed, their construction of a solution to (3.4) is based on an iterative scheme which starts with the upper solution and

converges to a (nondecreasing) function $\phi(z)$ satisfying (3.4) and $\underline{\phi}(z) \le \phi(z) \le \overline{\phi}(z)$. These facts already imply $\phi(-\infty) = \mathbf{0}$.

In view of the above remarks, Wu and Zou's construction assures us of a solution to (3.12) satisfying $\phi(-\infty) = \mathbf{0}$, and we must now confirm that $\phi(\infty) = \mathbf{K}$ with $\mathbf{K}$ given by (3.11). Indeed (see [9, p. 666]), we can conclude, since $\underline{\phi}_1(z) \not\equiv 0$, that $\lim_{z\to\infty} \phi_1(z) := \phi_1^*$ exists and $\phi_1^* \in (0, \frac{\alpha_1}{\beta_1} e^{-\gamma_1\tau_1}]$. For $\phi_2(z)$, since $\underline{\phi}_2(z) \equiv 0$, we are still assured of the existence of $\lim_{z\to\infty} \phi_2(z) := \phi_2^*$, but we only know that $\phi_2^* \in [0, \frac{\alpha_2}{\beta_2} e^{-\gamma_2\tau_2}]$. However, (ϕ_1^*, ϕ_2^*) must be an equilibrium of (3.10). Thus

$$(\phi_1^*, \phi_2^*) = \left(\frac{\alpha_1}{\beta_1} e^{-\gamma_1\tau_1},\ \frac{\alpha_2}{\beta_2} e^{-\gamma_2\tau_2} \right).$$

The proof of the theorem is complete.

4. Conclusion. For the purely time dependent model studied in sections 1 and 2, it is apparent that the dynamics depends on the values of the four quantities

$$c_2\alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds, \qquad \beta_u\alpha_v \int_0^\tau f_v(s) e^{-\gamma_v s}\, ds, \qquad c_1\alpha_v \int_0^\tau f_v(s) e^{-\gamma_v s}\, ds,$$

and

$$\beta_v\alpha_u \int_0^\tau f_u(s) e^{-\gamma_u s}\, ds.$$

Accordingly, the dynamics depends heavily on the maturation delays as represented by the probability density functions $f_u(s)$ and $f_v(s)$. To see the role of these delays it will be helpful to consider the particular case when $f_u(s) = \delta(s-\tau_u)$ and $f_v(s) = \delta(s-\tau_v)$, so that all members of the U species take time τ_u to mature, and the V species take time τ_v to mature. Then, the criteria for U to win and V to be driven to extinction (Theorem 2) become

$$c_2\alpha_u e^{-\gamma_u\tau_u} > \beta_u\alpha_v e^{-\gamma_v\tau_v} \quad \text{and} \quad c_1\alpha_v e^{-\gamma_v\tau_v} < \beta_v\alpha_u e^{-\gamma_u\tau_u}.$$

These conditions are automatically satisfied if the V species has a long maturation time τ_v, a large immature mortality rate γ_v, or insufficient live births or eggs laid per adult per unit time (this is what α_v represents). Significant *adult* mortality among the V species, as measured by β_v, does not automatically imply extinction of that species. The two species will coexist if

$$c_2\alpha_u e^{-\gamma_u\tau_u} < \beta_u\alpha_v e^{-\gamma_v\tau_v} \quad \text{and} \quad c_1\alpha_v e^{-\gamma_v\tau_v} < \beta_v\alpha_u e^{-\gamma_u\tau_u},$$

and these conditions are satisfied when there is little interspecific competition and/or significant adult mortality in *both* species.

While the conclusions listed above are not counterintuitive, let us emphasize that they explicitly state how the survival or extinction of a species depends on the maturation time for the species, or more generally on a weighted average thereof.

For the reaction-diffusion model, we have proved the existence of a traveling wave front connecting the two boundary equilibria in the situation when the stronger species is sufficiently dominant that there is no possibility of coexistence. In addition to the conditions which one expects to have to impose, based on linearized analysis (i.e., conditions (3.2)), our existence proof requires (3.14) to be satisfied. In practice,

this will happen whenever (i) the diffusivity d_2 of the weaker competitor is relatively small and (ii) the parameter c_2, which measures the competitive pressure exerted by the stronger competitor on the weaker, is not too much greater than the minimum value consistent with (3.2). Smallness of d_2 (i.e., inability to move about quickly) can be interpreted as one of the weaker competitor's weaknesses. The fact that we have to restrict c_2 almost certainly has no ecological interpretation.

We have also calculated the minimum speed c^* implicitly. From simple graphical arguments one easily determines that the circumstances under which the minimum speed will be *reduced* are (i) if one or more of the parameters c_1, α_2, γ_1, or τ_1 is *increased*, or (ii) if one or more of the parameters d_1, α_1, β_2, γ_2, or τ_2 is *decreased*. Of course, one must ensure (3.2) remains satisfied.

Ecologically speaking, invasion of the domain by the dominant species therefore slows down under one or more of the following circumstances: reduction of diffusivity of the dominant species; reduction of the dominant species' reproductive activity; reduction of adult mortality, infant mortality, or maturation time for the weaker species. The invasion speed is also lowered if the weaker species increases its reproductive activity or exerts increased competitive pressure on the stronger, or if the stronger species suffers an increase in infant mortality or its maturation delay.

The minimum speed as determined from the linearized analysis does not depend on d_2 or c_2. Of course, the value of c_2 is important in determining whether conditions are right for colonization by the stronger competitor, driving the weaker to extinction. However, if these conditions are satisfied, then our analysis predicts that the actual invasion speed does not depend on c_2. Also, while the invasion speed depends strongly on the diffusivity d_1 of the stronger competitor, it does not depend at all on the diffusivity d_2 of the weaker.

A HIERARCHY OF MODELS FOR SUPERCONDUCTING THIN FILMS*

S. J. CHAPMAN† AND D. R. HERON†

Abstract. A hierarchy of models for type-II superconducting thin films is presented. Through appropriate asymptotic limits this hierarchy passes from the mesoscopic Ginzburg–Landau model to the London model with isolated vortices as δ-function singularities to vortex-density models and finally to macroscopic critical-state models. At each stage it is found that a key nondimensional parameter is $\Lambda = \lambda^2/dL$, where λ is the penetration depth of the magnetic field, a material parameter, and d and L are a typical thickness and lateral dimension of the film, respectively. The models simplify greatly if this parameter is large or small.

Key words. superconductivity, vortices, thin films, homogenization, critical state

AMS subject classification. 82D55

1. Introduction. The response of a bulk superconducting material to an applied magnetic field is conveniently described by Figure 1, which shows the phase the superconductor adopts as a function of the external magnetic field H_{ext} and the material parameter κ (known as the Ginzburg–Landau parameter), which determines the type of superconducting material; $\kappa < 1/\sqrt{2}$ describes what are known as type-I superconductors, while $\kappa > 1/\sqrt{2}$ describes what are known as type-II superconductors.

For type-I superconductors in sufficiently low magnetic fields the material is in the superconducting state, and the field is excluded from the interior of the sample except in thin boundary layers (this effect is known as the Meissner effect). However, there is a critical magnetic field, H_c, above which the material will revert to the normally conducting (normal) state, and the magnetic field will penetrate it fully.

In type-II superconductors this critical magnetic field splits into a lower critical field, H_{c_1}, and an upper critical field, H_{c_2}. For magnetic fields below H_{c_1} the material is in the superconducting state and the field is excluded from the interior, while for magnetic fields above H_{c_2} the material is in the normal state and the field penetrates it fully. For magnetic fields between H_{c_1} and H_{c_2} a third state exists, known as the "mixed state," in which there is a partial penetration of the magnetic field into the superconducting material, which occurs by means of thin filaments of nonsuperconducting material carrying magnetic flux ("flux tubes") and circled by a vortex of superconducting current (hence these filaments are often referred to as vortices).

A hierarchy of models for bulk type-II superconductors has been derived recently in [6]. The starting point for this hierarchy is the Ginzburg–Landau model, which applies on mesoscopic lengthscales $\sim 0.01\mu m$, and which is generally believed to describe the behavior of superconductors well (at least for low-temperature superconductors not too far from the critical temperature T_c). The Ginzburg–Landau model is quite complicated, and through the asymptotic limit $\kappa \to \infty$ may be simplified to the London model, a linear equation in which the vortices appear as line singularities. These

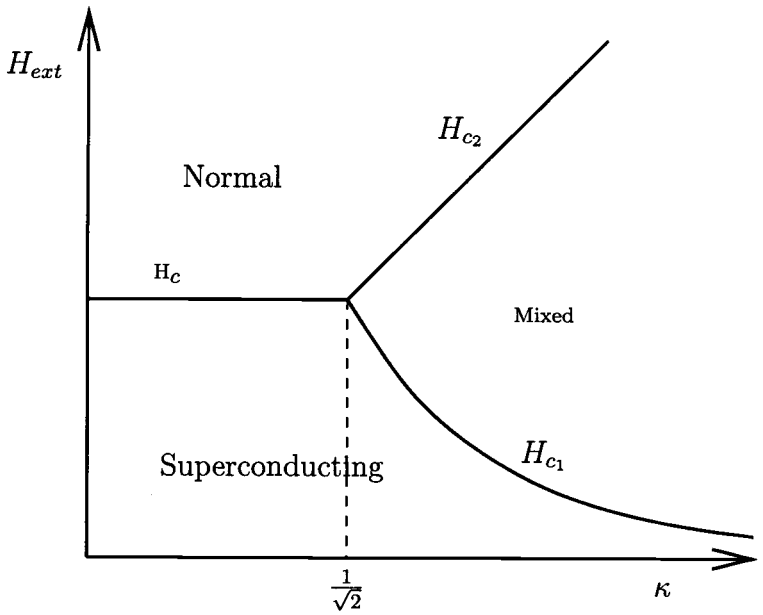

FIG. 1. *The response of a superconducting material as a function of the applied magnetic field H_{ext} and the Ginzburg–Landau parameter κ.*

may then be averaged to produce vortex-density models. Finally, if vortex pinning by inhomogeneities is included in these vortex-density models, so-called critical-state models can be derived.

Here we are interested in the simplifications which arise when the superconducting material comprises a thin film, possibly of varying thickness. Such a situation is very common experimentally and technologically because of the relative ease with which thin films can be manufactured. We will derive a hierarchy of models for superconducting thin films corresponding exactly to those for bulk superconductors. We will find that a key nondimensional parameter is $\Lambda = \lambda_{\text{eff}}/L$, where L is a typical lateral dimension of the film and the effective screening length [24] $\lambda_{\text{eff}} = \lambda^2/d$, where λ is the penetration depth of the magnetic field, a material parameter, and d is a typical thickness of the film. The canonical scaling is for Λ to be of order one as $d/L \to 0$, in which case the problems for the electric current in the film and the magnetic field outside it are coupled. The problem simplifies greatly if Λ is either large or small, since in each case the problems for the electric current and the magnetic field decouple. Many of the models we arrive at are new; our aims are to show where the existing models fit into the general framework and to fill in the gaps. In particular we will find that the thin-film limit of the Ginzburg–Landau model considered in [8] corresponds to the limit $\Lambda \to \infty$, while the thin-film critical-state models studied recently in [29] and [31] correspond to the limit $\Lambda \to 0$.

Before we begin let us first make a note of some of the lengthscales in the problem. There are two material parameters which are lengthscales, both of which appear in the Ginzburg–Landau model. These are λ, the aforementioned penetration depth, which is the typical lengthscale for the decay of magnetic field away from a vortex, and ξ, the coherence length, which is the typical lengthscale for the variation in the number density of superconducting electrons, and is the vortex core radius. The ratio of these

two lengthscales is the Ginzburg–Landau parameter $\kappa = \lambda/\xi$; as we have already said, for type-II superconductors $\kappa > 1/\sqrt{2}$, and the London model corresponds to the limit in which $\kappa \to \infty$. However, we will find that the important parameter in determining the behavior of thin films is not κ but $\kappa_{\text{eff}} = \lambda_{\text{eff}}/\xi = (\lambda/d)\kappa$. Thus when d is small compared to λ, the Ginzburg–Landau parameter is enhanced. The situation is not dissimilar to that of lubrication theory, in which the key parameter is the reduced Reynolds number rather than the Reynolds number itself.

To go with these two material lengths we have three geometrical lengths in the problem. Since we will allow the film to vary in thickness, besides the typical thickness d and lateral dimension L of the film we also have the typical lengthscale for the thickness variations, which we will denote by δ. (We assume that the amplitude of the thickness variations is of the same order as the thickness itself, which is the canonical case.) When pinning through inhomogeneities is introduced we have the typical lengthscale for variation of the pinning potential, which we denote by ε. Finally, we have the typical separation of vortices, which we denote by ν, and which will be determined by the strength of the applied magetic field.

Thus there are seven lengthscales in the problem, and it is the relative sizes of these which will determine which is the relevant thin-film model in any given situation.

In section 2 we introduce the Ginzburg–Landau theory which underpins our hierarchy of models and consider its thin-film limit. In section 3 we consider the London limit $\kappa_{\text{eff}} \to \infty$ of the thin-film Ginzburg–Landau model and show that this is the same as the thin-film limit of the bulk London model. In section 4 we let the separation of vortices $\nu/L \to 0$ and average the thin-film London model to produce a thin-film vortex-density model. We show that this is the same as the thin-film limit of the bulk vortex-density model.

In section 5 we let the lengthscale of the pinning potential $\varepsilon \to 0$ and homogenize the pinning force to produce a thin-film critical-state model. Finally, in section 6, we present our conclusions.

2. Ginzburg–Landau models. The starting point for our discussion of thin-film models of superconductivity is the Ginzburg–Landau equations. In their steady form these equations were written down by Ginzburg and Landau in [17], through the minimization of a phenomenologically developed free-energy functional. Later it was shown by Gor'kov [18] that they could be derived as a limit of the microscopic Bardeen, Cooper, and Schrieffer (BCS) model [2]. Time-dependent versions of the Ginzburg–Landau equations were written down by Schmidt [27], and in 1968 Gor'kov and Éliashberg [19] demonstrated that (1)–(2) could be derived from the BCS model for a superconductor with paramagnetic impurities. These correspond to a gauge-invariant gradient flow of the Ginzburg–Landau energy functional and as such are the simplest time-dependent equations whose solutions evolve to the minimizers of that functional. The dimensionless time-dependent Ginzburg–Landau equations for a superconducting material occupying a region $\Omega \subseteq \mathbb{R}^3$ are

$$\frac{1}{\kappa^2}\frac{\partial \Psi}{\partial t} + \frac{i\Psi\phi}{\kappa} = \left(\frac{1}{\kappa}\nabla - i\boldsymbol{A}\right)^2 \Psi + \Psi\left(1 - |\Psi|^2\right) \text{ in } \Omega, \tag{1}$$

$$-(\operatorname{curl})^2 \boldsymbol{A} - \frac{\sigma}{\kappa^2}\left(\frac{\partial \boldsymbol{A}}{\partial t} + \nabla\phi\right) = \frac{i}{2\kappa}\left(\Psi^*\nabla\Psi - \Psi\nabla\Psi^*\right) + |\Psi|^2\boldsymbol{A} \text{ in } \Omega, \tag{2}$$

where Ψ is the normalized superconducting order parameter, so that $|\Psi|^2$ represents the number density of superconducting electrons, with $|\Psi| = 1$ representing wholly

superconducting material and $\Psi = 0$ representing wholly nonsuperconducting (normal) material; $\boldsymbol{A}$ and ϕ are the magnetic vector potential and electric scalar potential, respectively, which are such that the magnetic field $\boldsymbol{H}$ and electric field $\boldsymbol{E}$ are given by

$$\boldsymbol{H} = \operatorname{curl} \boldsymbol{A}, \tag{3}$$

$$\boldsymbol{E} = -\frac{\partial \boldsymbol{A}}{\partial t} - \nabla \phi. \tag{4}$$

$\boldsymbol{A}$ is determined up to a gradient; once $\boldsymbol{A}$ is given ϕ is determined up to a function of t. The constant σ is a measure of the normal conductivity of the superconducting material (in this nondimensional form σ is the ratio of the timescale for diffusion of magnetic field in the normal state to the timescale for the relaxation of the order parameter), and κ is the Ginzburg–Landau parameter. Length has been scaled with the penetration depth λ, which is the natural lengthscale for variations in the magnetic field. In these units the thermodynamic critical field is given by $H_c = 1/\sqrt{2}$, and the upper and lower critical fields are given by $H_{c_2} = \kappa$ and $H_{c_1} \sim \log(\kappa)/2\kappa$ for large κ, respectively.

The most common boundary conditions on (1)–(2) are the natural conditions

$$\boldsymbol{n} \cdot (\nabla \Psi - i\boldsymbol{A}\Psi) = 0 \qquad \text{on } \partial\Omega \tag{5}$$

and continuity of $\boldsymbol{A}$, $\boldsymbol{H}$, and $\boldsymbol{E}$ across $\partial\Omega$ (assuming that the permeability and permittivity of the region exterior to the superconductor is equal to that of the superconducting material; the modification if this is not the case is easy to make). Equation (5) is applicable when the region adjacent to the superconductor is an insulator, which is the case we will consider henceforth. Note that (5) implies that no supercurrent passes through the boundary, and we assume also that no normal current is applied directly to the superconductor.

Outside Ω we have Maxwell's equations (neglecting displacement current)

$$\operatorname{curl} \boldsymbol{H} = \boldsymbol{J}_{ext}, \tag{6}$$

$$\operatorname{div} \boldsymbol{H} = 0, \tag{7}$$

$$\boldsymbol{H}_t + \operatorname{curl} \boldsymbol{E} = \boldsymbol{0}, \tag{8}$$

$$\operatorname{div} \boldsymbol{E} = 0, \tag{9}$$

where $\boldsymbol{J}_{ext}$ is the externally imposed current which is driving the system. The most commonly considered situation is that in which a uniform magnetic field is applied at infinity, in which case $\boldsymbol{J}_{ext}$ is zero and

$$\boldsymbol{H} \to \boldsymbol{H}_{ext} \text{ as } |\boldsymbol{x}| \to \infty \tag{10}$$

(assuming a bounded superconducting region). The continuities of $\boldsymbol{A}$, $\boldsymbol{H}$, and $\boldsymbol{E}$ are the usual boundary conditions on Maxwell's equations at an interface between two media. Note though that these conditions are not all independent, since, for example, the continuity of the normal component of $\boldsymbol{H}$ arises by taking (7) to hold in a generalized sense everywhere, but this equation is automatic from (3), which, if it holds in a generalized sense, gives continuity of the tangential components of $\boldsymbol{A}$.

Equations (1)–(2) are gauge invariant in the sense that they are invariant under transformations of the form

$$\boldsymbol{A} \to \boldsymbol{A} + \nabla \omega, \qquad \phi \to \phi - \frac{\partial \omega}{\partial t}, \qquad \Psi \to \Psi e^{i\kappa\omega}.$$

We take advantage of this invariance to write the equations in terms of real variables by writing

$$\Psi = fe^{i\chi}, \qquad \boldsymbol{Q} = \boldsymbol{A} - \frac{1}{\kappa}\nabla\chi, \qquad \Phi = \phi + \frac{1}{\kappa}\frac{\partial\chi}{\partial t} \tag{11}$$

to give

$$-\frac{1}{\kappa^2}\frac{\partial f}{\partial t} + \frac{1}{\kappa^2}\nabla^2 f = f^3 - f + f|\boldsymbol{Q}|^2 \quad \text{in } \Omega, \tag{12}$$

$$f^2\Phi + \operatorname{div}(f^2\boldsymbol{Q}) = 0 \quad \text{in } \Omega, \tag{13}$$

$$-(\operatorname{curl})^2\boldsymbol{Q} = \frac{\sigma}{\kappa^2}\left(\frac{\partial\boldsymbol{Q}}{\partial t} + \nabla\Phi\right) + f^2\boldsymbol{Q} \quad \text{in } \Omega, \tag{14}$$

$$\boldsymbol{H} = \operatorname{curl}\boldsymbol{Q}, \tag{15}$$

$$\boldsymbol{E} = -\frac{\partial\boldsymbol{Q}}{\partial t} - \nabla\Phi. \tag{16}$$

The vortex solutions characteristic of type-II superconductors can be illustrated by seeking a solution of the form

$$\Psi = f(r)e^{in\theta}, \tag{17}$$

$$\boldsymbol{A} = A(r)\boldsymbol{e}_\theta \tag{18}$$

on an infinite domain, where n is an integer known as the vortex number, r and θ are polar coordinates, and $\boldsymbol{e}_\theta$ is the unit vector in the azimuthal direction. Substituting into (1)–(2) gives

$$\frac{1}{\kappa^2}\frac{1}{r}\frac{d}{dr}\left(r\frac{df}{dr}\right) - \left(A - \frac{n}{\kappa r}\right)^2 f = f^3 - f, \tag{19}$$

$$\frac{d}{dr}\left(\frac{1}{r}\frac{d}{dr}(rA)\right) = f^2\left(A - \frac{n}{\kappa r}\right), \tag{20}$$

$$f, \quad A \text{ bounded} \quad \text{as } r \to 0, \tag{21}$$

$$f \to 1, \quad A \to 0 \text{ as } r \to \infty. \tag{22}$$

The existence of a solution which necessarily has $f(0) = 0$ has been shown by Berger and Chen [3]. The supercurrent is given by

$$\boldsymbol{J} = -f^2\left(A - \frac{n}{\kappa r}\right)\boldsymbol{e}_\theta, \tag{23}$$

which shows the vortex nature of this solution. The axial magnetic field carried by the vortex is

$$\int_{\mathbb{R}^2} \boldsymbol{H}\cdot\boldsymbol{dS} = \frac{2\pi n}{\kappa}, \tag{24}$$

which is quantized in units of $2\pi/\kappa$, with n the number of flux quanta carried by the vortex. Note that for large values of κ, $f \approx 1$ except in a region of order κ^{-1} from the origin, which is the vortex core.

Since the flux quantum is $O(1/\kappa)$ it is common to rescale magnetic field with $1/\kappa$ when considering vortex solutions. However, when considering the thin-film limit we must first rescale length so that we are working on the lateral dimension of the

sample, L say, which requires a corresponding rescaling of time with L^2/λ^2. The canonical scale for the magnetic field then involves rescaling with $\lambda^2/(L^2\kappa)$ (if we assume that the vortex separation is $O(L)$; see [10], for example), so that $\boldsymbol{Q}$ and $\boldsymbol{J}$ must be rescaled with $\lambda/(L\kappa)$. This gives

$$\frac{\xi^2}{L^2}\left(-\frac{\partial f}{\partial t}+\nabla^2 f\right)=f^3-f+\frac{\xi^2 f|\boldsymbol{Q}|^2}{L^2} \text{ in } \Omega, \tag{25}$$

$$f^2\Phi+\operatorname{div}(f^2\boldsymbol{Q})=0 \text{ in } \Omega, \tag{26}$$

$$-\lambda^2/L^2 \operatorname{curl}\boldsymbol{H}=-\boldsymbol{J}=\frac{\xi^2\sigma}{L^2}\left(\frac{\partial \boldsymbol{Q}}{\partial t}+\nabla\Phi\right)+f^2\boldsymbol{Q} \text{ in } \Omega, \tag{27}$$

$$\boldsymbol{H}=\operatorname{curl}\boldsymbol{Q}, \tag{28}$$

remembering that $\kappa=\lambda/\xi$. Note also the equations

$$\operatorname{div}\boldsymbol{H}=0, \tag{29}$$

$$\operatorname{div}\boldsymbol{J}=0, \tag{30}$$

which follow from (27) and (28) and will prove useful in the thin-film analysis. With these equations we have the boundary conditions

$$\frac{\partial f}{\partial n}=0 \text{ on } \partial\Omega, \tag{31}$$

$$\boldsymbol{Q}\cdot\boldsymbol{n}=0 \text{ on } \partial\Omega, \tag{32}$$

$$\boldsymbol{J}\cdot\boldsymbol{n}=0 \text{ on } \partial\Omega, \tag{33}$$

with $\boldsymbol{H}$ and $\boldsymbol{E}$ continuous across $\partial\Omega$.

2.1. Vortex pinning in the Ginzburg–Landau model. Before we go on to consider the thin-film version of (25)–(33) let us first describe the modifications which can be made to model the pinning of vortices in this framework.

In most technological applications superconductors are required to carry a transport current. The interaction of this current with the current circling a vortex causes the vortex to move. (This is often considered to be the result of the "Lorentz force" on the magnetic flux line carried by the vortex due to the transport current.) The motion of the vortex dissipates energy, leads to an electric field and hence a nonzero resistivity, and is therefore undesirable. In practice attempts are made to "pin" vortices at certain sites in the material in order to impede their motion. It is found that any form of inhomogeneity (for example, impurities, dislocations, or grain boundaries) will help to pin vortices. Such impurities have the effect of impeding locally the ability of the material to become superconducting. A popular way of modeling this inhomogeneity in the Ginzburg–Landau framework is to allow the equilibrium density of superconducting electrons to vary spatially [23, 7]. In the simplest case this leads to

$$\frac{\xi^2}{L^2}\left(-\frac{\partial f}{\partial t}+\nabla^2 f\right)=f^3-a(\boldsymbol{x})f+\frac{\xi^2 f|\boldsymbol{Q}|^2}{L^2} \text{ in } \Omega, \tag{34}$$

$$f^2\Phi+\operatorname{div}(f^2\boldsymbol{Q})=0 \text{ in } \Omega, \tag{35}$$

$$-\lambda^2/L^2 \operatorname{curl}\boldsymbol{H}=-\boldsymbol{J}=\frac{\xi^2\sigma}{L^2}\left(\frac{\partial \boldsymbol{Q}}{\partial t}+\nabla\Phi\right)+f^2\boldsymbol{Q} \text{ in } \Omega, \tag{36}$$

where the equilibrium density of superconducting electrons is denoted by $a(\boldsymbol{x})$. Of course, more generally we may allow the coefficient of $|\Psi|^2\Psi$ as well as λ, ξ, κ, and σ to vary spatially, but we will consider here the case when these parameters are constant.

Numerical simulations of these equations in two dimensions show that the vortices are attracted to minima of a, as we would have hoped [7, 14].

2.2. Thin-film limit of the Ginzburg–Landau model. Let the film be given, here and throughout, by

$$\Omega = \{(x,y,z) : (x,y) \in D, (\zeta - g/2)\epsilon < z < (\zeta + g/2)\epsilon\}, \tag{37}$$

where $D \subset \mathbb{R}^2$ is the projection of the film in the (x,y) plane, $\zeta(x,y)$ is the height of the centersurface of the film, $g(x,y)$ is the film thickness, and $\epsilon = d/L$ is the aspect ratio.

We write $\xi/L = \Xi$ and $\lambda^2/L^2 = \epsilon\Lambda$, since the canonical scaling will turn out to be $\Lambda = O(1)$. Then

$$\Xi^2\left(-\frac{\partial f}{\partial t} + \nabla^2 f\right) = f^3 - a(\boldsymbol{x})f + \Xi^2 f|\boldsymbol{Q}|^2 \text{ in } \Omega, \tag{38}$$

$$f^2\Phi + \operatorname{div}(f^2\boldsymbol{Q}) = 0 \text{ in } \Omega, \tag{39}$$

$$-\epsilon\Lambda \operatorname{curl} \boldsymbol{H} = -\boldsymbol{J} = \Xi^2\sigma\left(\frac{\partial \boldsymbol{Q}}{\partial t} + \nabla\Phi\right) + f^2\boldsymbol{Q} \text{ in } \Omega. \tag{40}$$

We consider first the problem in the film, where we rescale z with ϵ by setting $z = \epsilon Z$. Henceforth for clarity we use $\boldsymbol{h}$ to denote the magnetic field outside the film and $\boldsymbol{H}$ to denote it inside the film. Then

$$\Xi^2\left(-\frac{\partial f}{\partial t} + \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} + \frac{1}{\epsilon^2}\frac{\partial^2 f}{\partial Z^2}\right) = f^3 - f + \Xi^2 f(Q_1^2 + Q_2^2 + Q_3^2) \text{ in } \Omega, \tag{41}$$

$$f^2\Phi + \frac{\partial(f^2Q_1)}{\partial x} + \frac{\partial(f^2Q_2)}{\partial y} + \frac{1}{\epsilon}\frac{\partial(f^2Q_3)}{\partial Z} = 0 \text{ in } \Omega, \tag{42}$$

$$-\epsilon\Lambda\left(\frac{\partial H_3}{\partial y} - \frac{1}{\epsilon}\frac{\partial H_2}{\partial Z}\right) = -J_1 = \Xi^2\sigma\left(\frac{\partial Q_1}{\partial t} + \frac{\partial\Phi}{\partial x}\right) + f^2Q_1 \text{ in } \Omega, \tag{43}$$

$$-\epsilon\Lambda\left(\frac{1}{\epsilon}\frac{\partial H_1}{\partial Z} - \frac{\partial H_3}{\partial x}\right) = -J_2 = \Xi^2\sigma\left(\frac{\partial Q_2}{\partial t} + \frac{\partial\Phi}{\partial y}\right) + f^2Q_2 \text{ in } \Omega, \tag{44}$$

$$-\epsilon\Lambda\left(\frac{\partial H_2}{\partial x} - \frac{\partial H_1}{\partial y}\right) = -J_3 = \Xi^2\sigma\left(\frac{\partial Q_3}{\partial t} + \frac{1}{\epsilon}\frac{\partial\Phi}{\partial Z}\right) + f^2Q_3 \text{ in } \Omega, \tag{45}$$

$$\frac{\partial Q_3}{\partial y} - \frac{1}{\epsilon}\frac{\partial Q_2}{\partial Z} = H_1, \tag{46}$$

$$\frac{1}{\epsilon}\frac{\partial Q_1}{\partial Z} - \frac{\partial Q_3}{\partial x} = H_2, \tag{47}$$

$$\frac{\partial Q_2}{\partial x} - \frac{\partial Q_1}{\partial y} = H_3, \tag{48}$$

$$\frac{\partial H_1}{\partial x} + \frac{\partial H_2}{\partial y} + \frac{1}{\epsilon}\frac{\partial H_3}{\partial Z} = 0, \tag{49}$$

$$\frac{\partial J_1}{\partial x} + \frac{\partial J_2}{\partial y} + \frac{1}{\epsilon}\frac{\partial J_3}{\partial Z} = 0. \tag{50}$$

With these equations we have the boundary conditions on the upper and lower surfaces of the film

$$-\epsilon^2\frac{\partial}{\partial x}(\zeta \pm g/2)\frac{\partial f}{\partial x}(x,y,\zeta\pm g/2) - \epsilon^2\frac{\partial}{\partial y}(\zeta\pm g/2)\frac{\partial f}{\partial y}(x,y,\zeta\pm g/2) + \frac{\partial f}{\partial Z}(x,y,\zeta\pm g/2) = 0 \text{ for } (x,y)\in D, \tag{51}$$

$$-\epsilon\frac{\partial}{\partial x}(\zeta\pm g/2)\,Q_1(x,y,\zeta\pm g/2) - \epsilon\frac{\partial}{\partial y}(\zeta\pm g/2)\,Q_2(x,y,\zeta\pm g/2) + Q_3(x,y,\zeta\pm g/2) = 0 \text{ for } (x,y)\in D, \tag{52}$$

$$-\epsilon\frac{\partial}{\partial x}(\zeta\pm g/2)\,J_1(x,y,\zeta\pm g/2) - \epsilon\frac{\partial}{\partial y}(\zeta\pm g/2)\,J_2(x,y,\zeta\pm g/2) + J_3(x,y,\zeta\pm g/2) = 0 \text{ for } (x,y)\in D, \tag{53}$$

$$\boldsymbol{h}(x,y,z=\epsilon(\zeta\pm g/2)) = \boldsymbol{H}(x,y,Z=\zeta\pm g/2). \tag{54}$$

We formally expand all variables in a power series in ϵ as $\epsilon\to 0$ as

$$\boldsymbol{H} = \boldsymbol{H}^{(0)} + \epsilon\boldsymbol{H}^{(1)} + \cdots,$$

etc. Then at leading order in (41)–(50)

$$\frac{\partial^2 f^{(0)}}{\partial Z^2} = 0 \text{ in } \Omega, \tag{55}$$

$$\frac{\partial((f^{(0)})^2 Q_3^{(0)})}{\partial Z} = 0 \text{ in } \Omega, \tag{56}$$

$$\Lambda\frac{\partial H_2^{(0)}}{\partial Z} = -J_1^{(0)} = \Xi^2\sigma\left(\frac{\partial Q_1^{(0)}}{\partial t} + \frac{\partial\Phi^{(0)}}{\partial x}\right) + (f^{(0)})^2 Q_1^{(0)} \text{ in } \Omega, \tag{57}$$

$$-\Lambda\frac{\partial H_1^{(0)}}{\partial Z} = -J_2^{(0)} = \Xi^2\sigma\left(\frac{\partial Q_2^{(0)}}{\partial t} + \frac{\partial\Phi^{(0)}}{\partial y}\right) + (f^{(0)})^2 Q_2^{(0)} \text{ in } \Omega, \tag{58}$$

$$0 = \frac{\partial\Phi^{(0)}}{\partial Z} \text{ in } \Omega, \tag{59}$$

$$\frac{\partial Q_2^{(0)}}{\partial Z} = 0, \tag{60}$$

$$\frac{\partial Q_1^{(0)}}{\partial Z} = 0, \tag{61}$$

$$\frac{\partial Q_2^{(0)}}{\partial x} - \frac{\partial Q_1^{(0)}}{\partial y} = H_3^{(0)}, \tag{62}$$

$$\frac{\partial H_3^{(0)}}{\partial Z} = 0, \tag{63}$$

$$\frac{\partial J_3^{(0)}}{\partial Z} = 0, \tag{64}$$

with boundary conditions

$$\frac{\partial f^{(0)}}{\partial Z}(x,y,\zeta\pm g/2) = 0 \text{ for } (x,y)\in D, \tag{65}$$

$$Q_3^{(0)}(x,y,\zeta \pm g/2) = 0 \text{ for } (x,y) \in D, \tag{66}$$

$$J_3^{(0)}(x,y,\zeta \pm g/2) = 0 \text{ for } (x,y) \in D, \tag{67}$$

$$\boldsymbol{h}^{(0)}(x,y,z=\pm 0) = \boldsymbol{H}^{(0)}(x,y,Z=\zeta \pm g/2). \tag{68}$$

Equations (55) and (65) give $f^{(0)} = f^{(0)}(x,y,t)$. From (64) and (67) we see that $J_3^{(0)} = 0$. We see from (59)–(61) that $Q_1^{(0)}$, $Q_2^{(0)}$, and $\Phi^{(0)}$ are independent of Z, so that $J_1^{(0)}$ and $J_2^{(0)}$ are independent of Z. Then (57), and (58) may be integrated to give

$$H_1^{(0)} = \frac{ZJ_2^{(0)}}{\Lambda} + a(x,y,t), \tag{69}$$

$$H_2^{(0)} = -\frac{ZJ_1^{(0)}}{\Lambda} + b(x,y,t). \tag{70}$$

Similarly (63) gives

$$H_3^{(0)} = c(x,y,t). \tag{71}$$

Now evaluating on the top and bottom of the film $Z = \zeta \pm g/2$ and using (68) give

$$[\boldsymbol{h}^{(0)}] = \frac{g}{\Lambda}(J_2^{(0)}, -J_1^{(0)}, 0) \quad \text{for} \quad (x,y) \in D, \tag{72}$$

where the square bracket indicates the jump in the quantity enclosed across D. Writing this jump condition in the more usual form gives

$$\left[\boldsymbol{e}_z \wedge \boldsymbol{h}^{(0)}\right] = \frac{g}{\Lambda}\boldsymbol{J}^{(0)} \quad \text{for} \quad (x,y) \in D, \tag{73}$$

$$\left[\boldsymbol{e}_z \cdot \boldsymbol{h}^{(0)}\right] = 0 \quad \text{for} \quad (x,y) \in D, \tag{74}$$

where $\boldsymbol{e}_z$ is the unit vector in the z-direction. Equations (73)–(74) form boundary conditions on the problem for the external magnetic field, which satisfies Maxwell's equations

$$\operatorname{curl} \boldsymbol{h}^{(0)} = \boldsymbol{J}_{ext}^{(0)}, \tag{75}$$

$$\operatorname{div} \boldsymbol{h}^{(0)} = 0, \tag{76}$$

$$\boldsymbol{h}^{(0)} \to \boldsymbol{h}_{ext}^{(0)} \quad \text{as } |\boldsymbol{r}| \to \infty. \tag{77}$$

As we might expect, $\boldsymbol{h}^{(0)}$ is simply the magnetic field generated if the total current in the film were distributed on a sheet, plus the applied (externally generated) magnetic field. We can therefore calculate $\boldsymbol{h}^{(0)}$ once we have found $\boldsymbol{J}^{(0)}$.

Returning to the film, we see from (56) and (66) that $Q_3^{(0)} = 0$. What remains is to find an equation for $f^{(0)}$, $Q_1^{(0)}$, $Q_2^{(0)}$, and $\Phi^{(0)}$. To do this we need to proceed to higher orders in the expansion of (41) and (51).

At first order in (41) and (51) we find

$$\frac{\partial f^{(1)}}{\partial Z} = 0. \tag{78}$$

At second order we find

$$\Xi^2\left(-\frac{\partial f^{(0)}}{\partial t} + \frac{\partial^2 f^{(0)}}{\partial x^2} + \frac{\partial^2 f^{(0)}}{\partial y^2} + \frac{\partial^2 f^{(2)}}{\partial Z^2}\right) = (f^{(0)})^3 - a(\boldsymbol{x})f^{(0)} + \Xi^2 f^{(0)}((Q_1^{(0)})^2 + (Q_2^{(0)})^2) \text{ in } \Omega, \tag{79}$$

with

$$-\frac{\partial}{\partial x}(\zeta \pm g/2)\frac{\partial f^{(0)}}{\partial x}(x,y,\zeta \pm g/2) - \frac{\partial}{\partial y}(\zeta \pm g/2)\frac{\partial f^{(0)}}{\partial y}(x,y,\zeta \pm g/2) + \frac{\partial f^{(2)}}{\partial Z}(x,y,\zeta \pm g/2) = 0 \text{ for } (x,y) \in D. \tag{80}$$

Integrating (79) from $\zeta - g/2$ to $\zeta + g/2$ and using (80) give

$$\Xi^2\left(-\frac{\partial f^{(0)}}{\partial t} + \frac{1}{g}\nabla\cdot\left(g\nabla f^{(0)}\right)\right) = (f^{(0)})^3 - f^{(0)} + \Xi^2 f^{(0)}((Q_1^{(0)})^2 + (Q_2^{(0)})^2) \text{ for } (x,y) \in D. \tag{81}$$

We are still missing an equation for the divergence of $\boldsymbol{Q}^{(0)}$, which should come from (42). Proceeding to next order in this equation gives

$$(f^{(0)})^2\Phi^{(0)} + \frac{\partial((f^{(0)})^2 Q_1^{(0)})}{\partial x} + \frac{\partial((f^{(0)})^2 Q_2^{(0)})}{\partial y} + \frac{\partial((f^{(0)})^2 Q_3^{(1)})}{\partial Z} = 0 \text{ in } \Omega. \tag{82}$$

At next order in the boundary condition (52) we find

$$-\frac{\partial}{\partial x}(\zeta \pm g/2)\, Q_1^{(0)}(x,y,\zeta \pm g/2) - \frac{\partial}{\partial y}(\zeta \pm g/2)\, Q_2^{(0)}(x,y,\zeta \pm g/2) + Q_3^{(1)}(x,y,\zeta \pm g/2) = 0 \text{ for } (x,y) \in D. \tag{83}$$

Now, integrating (82) from $Z = \zeta - g/2$ to $Z = \zeta + g/2$ and using (83) gives

$$(f^{(0)})^2\Phi^{(0)} + \frac{1}{g}\nabla\cdot\left(g(f^{(0)})^2\boldsymbol{Q}^{(0)}\right) = 0 \text{ for } (x,y) \in D. \tag{84}$$

A similar analysis on (50) and (53) gives

$$\nabla\cdot\left(g\boldsymbol{J}^{(0)}\right) = 0. \tag{85}$$

Finally, by continuity of magnetic field at the interface (68) and constancy of H_3 in Z (71), equation (62) becomes

$$\frac{\partial Q_2^{(0)}}{\partial x} - \frac{\partial Q_1^{(0)}}{\partial y} = h_3^{(0)}(x,y,0). \tag{86}$$

Summary. We now have a closed model for the leading-order problem as $\epsilon \to 0$ with Ξ and Λ fixed. Dropping the superscripts for clarity we have

$$\Xi^2\left(-\frac{\partial f}{\partial t} + \frac{1}{g}\nabla\cdot(g\nabla f)\right) = f^3 - a(\boldsymbol{x})f + \Xi^2 f|\boldsymbol{Q}|^2 \quad \text{for} \quad (x,y) \in D, \tag{87}$$

$$f^2\Phi + \frac{1}{g}\nabla\cdot\left(gf^2\boldsymbol{Q}\right) = 0 \quad \text{for} \quad (x,y) \in D, \tag{88}$$

$$\frac{\partial Q_2}{\partial x} - \frac{\partial Q_1}{\partial y} = h_3(x,y,0) \quad \text{for} \quad (x,y) \in D, \tag{89}$$

$$Q_3 = 0, \tag{90}$$

$$\nabla \cdot (g\boldsymbol{J}) = 0, \tag{91}$$

$$\boldsymbol{J} = -\Xi^2\sigma\left(\frac{\partial \boldsymbol{Q}}{\partial t} + \nabla\Phi\right) - f^2\boldsymbol{Q} \quad \text{for} \quad (x,y) \in D, \tag{92}$$

$$J_3 = 0, \tag{93}$$

$$[\boldsymbol{e}_z \wedge \boldsymbol{h}] = \frac{g}{\Lambda}\boldsymbol{J} \quad \text{for} \quad (x,y) \in D, \tag{94}$$

$$[\boldsymbol{e}_z \cdot \boldsymbol{h}] = 0 \quad \text{for} \quad (x,y) \in D, \tag{95}$$

$$\operatorname{curl} \boldsymbol{h} = \boldsymbol{J}_{ext}, \tag{96}$$

$$\operatorname{div} \boldsymbol{h} = 0, \tag{97}$$

$$\boldsymbol{h} \to \boldsymbol{h}_{ext} \quad \text{as} \quad |\boldsymbol{x}| \to \infty. \tag{98}$$

If g is constant, then (87)–(93) are simply the two-dimensional Ginzburg–Landau equations. The big difference in the thin-film case is that h_3 is not related to $\boldsymbol{J}$ through $\boldsymbol{J} = \operatorname{curl}(0,0,h_3)$ but through the exterior problem (94)–(98).

We note that there is an equivalent complex formulation

$$\Xi^2\left(-\frac{\partial\Psi}{\partial t} - i\Psi\phi + \frac{1}{g}(\nabla - i\boldsymbol{A})\cdot g\,(\nabla - i\boldsymbol{A})\,\Psi\right) = \Psi(|\Psi|^2 - a(\boldsymbol{x})) \text{ for } (x,y) \in D, \tag{99}$$

$$\frac{\partial A_2}{\partial x} - \frac{\partial A_1}{\partial y} = h_3(x,y,0) \quad \text{for} \quad (x,y) \in D, \tag{100}$$

$$A_3 = 0, \tag{101}$$

$$[\boldsymbol{e}_z \wedge \boldsymbol{h}] = \frac{g}{\Lambda}\boldsymbol{J} \quad \text{for} \quad (x,y) \in D, \tag{102}$$

$$[\boldsymbol{e}_z \cdot \boldsymbol{h}] = 0 \quad \text{for} \quad (x,y) \in D, \tag{103}$$

$$\nabla \cdot (g\boldsymbol{J}) = 0, \tag{104}$$

$$-\Xi^2\sigma\left(\frac{\partial \boldsymbol{A}}{\partial t} + \nabla\phi\right) + \frac{1}{2}(\Psi^*\nabla\Psi - \Psi\nabla\Psi^*) - |\Psi|^2\boldsymbol{A} = \boldsymbol{J} \quad \text{for} \quad (x,y) \in D, \tag{105}$$

$$J_3 = 0, \tag{106}$$

$$\operatorname{curl} \boldsymbol{h} = \boldsymbol{J}_{ext}, \tag{107}$$

$$\operatorname{div} \boldsymbol{h} = 0, \tag{108}$$

$$\boldsymbol{h} \to \boldsymbol{h}_{ext} \quad \text{as} \quad |\boldsymbol{x}| \to \infty, \tag{109}$$

where

$$\Psi = fe^{i\chi}, \qquad \boldsymbol{Q} = \boldsymbol{A} - \nabla\chi, \qquad \Phi = \phi + \frac{\partial\chi}{\partial t}, \tag{110}$$

and χ is arbitrary. To these equations we must add the boundary conditions (5) (or equivalently (31)–(32)) and (33) on the lateral edges of the film, giving

$$\boldsymbol{\nu} \cdot (\nabla\Psi - i\boldsymbol{A}\Psi) = 0 \qquad \text{on } \partial D, \tag{111}$$

$$\boldsymbol{J} \cdot \boldsymbol{\nu} = 0 \quad \text{on } \partial D, \tag{112}$$

where $\boldsymbol{\nu}$ is the unit outward normal to ∂D.

Before proceeding let us first examine the flow of information in the equations, and in particular whether we have the right number of equations and unknowns. As we have already mentioned, equations (102)–(103) and (107)–(109) form a standard problem in magnetostatics, namely to determine the magnetic field generated by a surface current sheet. Thus these equations determine $\boldsymbol{h}$ if $\boldsymbol{J}$ is given. Having determined $\boldsymbol{h}$, equations (100)–(101) then determine $\boldsymbol{A}$ up to a gradient, which we can fix due to the gauge invariance property (110). With $\boldsymbol{A}$ given, equations (99) and (104) (using (105)) with the boundary conditions (111)–(112) form a closed system for Ψ and ϕ. Finally, the loop is closed by (105), which gives $\boldsymbol{J}$ as a function of Ψ, ϕ, and $\boldsymbol{A}$.

2.2.1. Thin strip geometry. Suppose our thin film is a thin strip of width $2l$, i.e., $D = (x, y) : -l < x < l$, and that $\boldsymbol{J}_{ext}$ and $\boldsymbol{h}_{ext}$ are such that $\boldsymbol{h} = (h_1, 0, h_3)$, $\boldsymbol{J} = (0, J_2, 0)$, with h_1, h_3, and J_2 independent of y. Then we can write the relationship between h_3 and J_2 explicitly using a Hilbert transform as follows. We first write $\boldsymbol{h} = \boldsymbol{h}_{app} + \boldsymbol{h}'$, where $\boldsymbol{h}_{app}$ is the total applied magnetic field (generated by $\boldsymbol{J}_{ext}$ and $\boldsymbol{h}_{ext}$) so that $\boldsymbol{h}'$ satisfies the homogeneous version of (107) and tends to zero at infinity. Then (107) and (108) imply that we can write

$$\boldsymbol{h}' = \nabla w, \tag{113}$$

$$\nabla^2 w = 0, \tag{114}$$

where ∇ is the two-dimensional gradient in x and z, with

$$\left[\frac{\partial w}{\partial x}\right] = \frac{gJ_2}{\Lambda}, \tag{115}$$

$$\left[\frac{\partial w}{\partial z}\right] = 0, \tag{116}$$

$$w \to 0 \quad \text{as } x^2 + z^2 \to \infty. \tag{117}$$

Since the solution to (114)–(117) will be symmetric, so that

$$w(x, z) = -w(x, -z), \tag{118}$$

we may consider the problem in the upper half-plane only, giving

$$\nabla^2 w = 0 \quad \text{in } z > 0, \tag{119}$$

$$\frac{\partial w}{\partial x} = \frac{gJ_2}{2\Lambda} \quad \text{on } z = 0, \tag{120}$$

$$\frac{\partial w}{\partial z} = h_3(x, 0) - h_{app,3}(x, 0) \quad \text{on } z = 0, \tag{121}$$

$$w \to 0 \quad \text{as } x^2 + z^2 \to \infty. \tag{122}$$

Then

$$\left.\frac{\partial w}{\partial z}\right|_{z=0} = \mathcal{H}\left(\left.\frac{\partial w}{\partial x}\right|_{z=0}\right) \equiv \frac{1}{\pi}\int_{-\infty}^{\infty} \frac{1}{\bar{x} - x}\frac{\partial w}{\partial x}(\bar{x}, 0)\, d\bar{x}, \tag{123}$$

so that

$$h_3(x, 0) - h_{app,3}(x, 0) = \frac{1}{\pi}\int_{-l}^{l} \frac{gJ_2(\bar{x})}{2\Lambda(\bar{x} - x)}\, d\bar{x}. \tag{124}$$

This equation replaces (102)–(103) and (107)–(109) in (99)–(112).

2.2.2. The limit $\Lambda \to \infty$ with Ξ fixed. There are three key parameters left in the model, namely Λ, Ξ, and σ. We have so far considered the canonical scaling

in which all the equations remain coupled in the thin-film limit. The thin-film limit of the Ginzburg–Landau equations considered in [8] corresponds to the limit $\Lambda \to \infty$ with Ξ fixed, since they consider the limit $\epsilon \to 0$ with fixed λ, ξ, L, and κ. As $\Lambda \to \infty$ we see from (94) that the current in the film is insufficient to affect the magnetic field at leading order, and the problems for $\boldsymbol{A}$ and Ψ decouple leading to a great simplification. At leading order the applied magnetic field simply passes straight through the film, so that

$$\boldsymbol{h} = \boldsymbol{h}_{app}, \qquad \boldsymbol{A} = (0, xH_{3,app}, 0),$$

where $\boldsymbol{h}_{app}$ is the total applied magnetic field (that generated by the external current plus that imposed at infinity), which is the solution to (107)–(109). Equations (99) and (104) can then be solved for Ψ and ϕ since $\boldsymbol{A}$ is known. Note that the factor Ξ^2 may be removed from these equations by a rescaling of $\boldsymbol{x}$ and $\boldsymbol{A}$, as is done in [8]. The current in the film is then determined from (105). The correction to the magnetic field can then be calculated from (102)–(103) and (107)–(109). Thus in this expansion for large Λ at each stage we have to solve the standard magnetostatics problem of determining the magnetic field due to a known surface current sheet and then a problem for Ψ and ϕ in which $\boldsymbol{A}$ is known.

The numerical solutions in [8] show that vortices are attracted to the minima of $g(x)$, that is, the thin parts of the film. Figure 2 shows a typical calculation, performed on a square film with side of (nondimensional) length 20 ($L = \xi$ is chosen as the unit of length, so dimensionally the side of the square is 20ξ), with applied field perpendicular to the film and of (nondimensional) strength 0.5. In Figure 2(a) the solution for a film of constant thickness is shown. (Contours show the level curves of the modulus of the order parameter.) Ten squares of size $\xi \times \xi$ were then chosen randomly, and the thickness of the film on the squares were reduced to half that of the remaining film; the distribution of the thin regions is shown in Figure 2(b). Figure 2(c) shows the position of the vortices for the variable thickness film with the same magnetic field strength as Figure 2(a). Figure 2(d) shows Figures 2(b) and 2(c) superimposed, so that the position of the vortices can be compared to the position of the thin regions of the film.

Numerical solutions of the time-dependent version of this reduced model are also performed in [1] to study vortex nucleation at boundaries in the presence of applied magnetic fields and currents.

The limit $\Lambda \to 0$ *with* Ξ *fixed.* The alternative limit is $\Lambda \to 0$ with Ξ fixed. In this case, from (94) and (92), we must rescale $\boldsymbol{J}$, $\boldsymbol{Q}$, and Φ with Λ. Then to leading order (89) gives

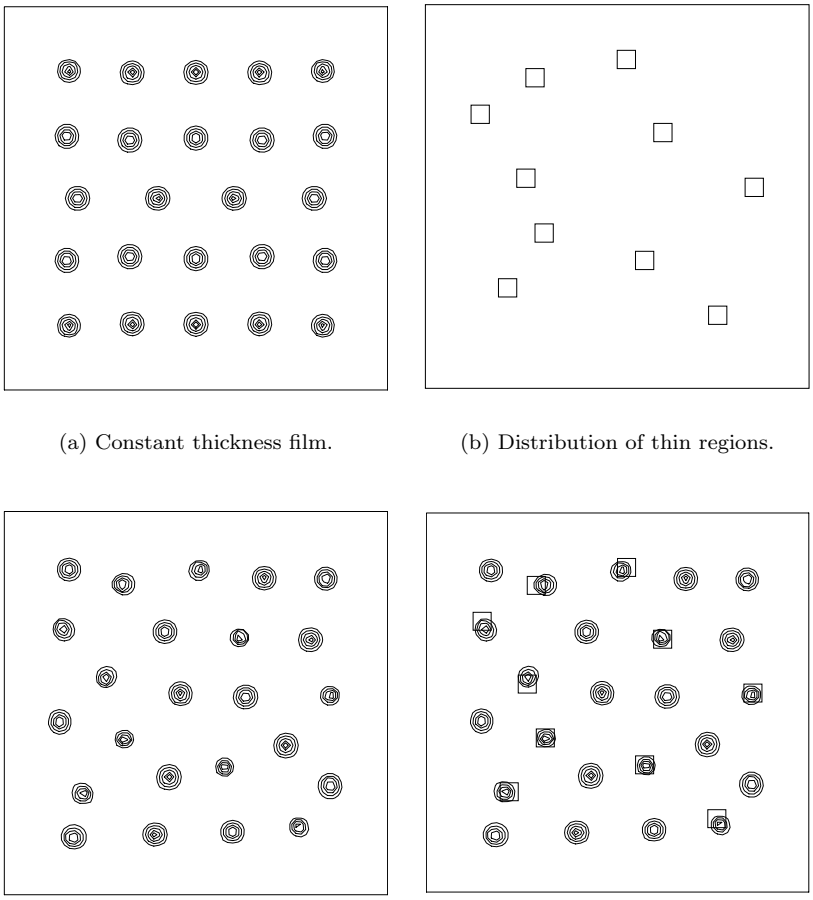
$$h_3(x, y, 0) = 0 \text{ for } (x, y) \in D. \tag{125}$$

Equations (96)–(98) can then be solved with this boundary condition for $\boldsymbol{h}$.

Equation (125) is valid away from vortices. Near each vortex an inner problem must be solved in which length is rescaled with Λ, which couples the problems for $\boldsymbol{h}$ and $\boldsymbol{J}$ together again. The limit $\Lambda \to 0$ will be much more interesting when we go on to consider vortex density models in section 4.

3. London models.

3.1. The London limit of the thin-film Ginzburg–Landau model. From (87) we see that the vortex core radius is of order Ξ in these units. The London model, corresponding to vanishing core radius, therefore corresponds to the limit



(a) Constant thickness film.

(b) Distribution of thin regions.

(c) Variable thickness film.

(d) Figs. 2(b) and 2(c) superimposed.

FIG. 2. *Level curves of the magnitude of the order parameter for superconducting samples having sides equal to* 20 *coherence lengths* [S. J. Chapman, Q. Du, and M. D. Gunzburger, *A model for variable thickness superconducting thin films,* Z. Angew. Math. Phys., 47 (1996), pp. 410–431]. Reprinted with permission.

$\Xi \to 0$. Since we are taking this limit after having let $\epsilon \to 0$ we are in the parameter regime $\epsilon \ll \Xi \ll 1$. We will consider the alternative regime $\Xi \ll \epsilon \ll 1$ in section 3.3.

In the limit $\Xi \to 0$ with Λ fixed we see that (87) implies $f^2 = a(\boldsymbol{x})$ except at vortices. Then from (92) we have

$$\boldsymbol{J} = -a\boldsymbol{Q}, \tag{126}$$

so that (89) gives

$$\boldsymbol{e}_z \cdot \operatorname{curl}\left(\frac{\boldsymbol{J}}{a}\right) + h_3(x, y, 0) = 0 \tag{127}$$

except at vortices.

Suppose there is a vortex at the origin. Near the vortex we rescale $r = (x^2 + y^2)^{1/2} = \Xi R$ and expand

$$f = f^{(0)} + \cdots, \tag{128}$$

$$\boldsymbol{Q} = \frac{1}{\Xi}\boldsymbol{Q}^{(0)} + \cdots. \tag{129}$$

Then at leading order in the core region

$$\boldsymbol{Q}^{(0)} = -\frac{1}{R}\boldsymbol{e}_\theta, \tag{130}$$

$$\frac{\partial^2 f^{(0)}}{\partial R^2} + \frac{1}{R}\frac{\partial f^{(0)}}{\partial R} - \frac{f^{(0)}}{R^2} = (f^{(0)})^3 - a(0)f^{(0)}. \tag{131}$$

Writing

$$f^{(0)} = \sqrt{a(0)}\bar{f}(\rho), \qquad \rho = \sqrt{a(0)}R,$$

as in [12] we find $\bar{f}$ satisfies

$$\bar{f}'' + \frac{\bar{f}'}{\rho} - \frac{\bar{f}}{\rho^2} = \bar{f}^3 - \bar{f}, \tag{132}$$

$$\bar{f}(0) = 0, \tag{133}$$

$$\bar{f} \to 1 \quad \text{as } \rho \to \infty, \tag{134}$$

where $' \equiv d/d\rho$. Hence $\bar{f}$ is simply the solution corresponding to a two-dimensional rectilinear isotropic vortex, whose existence and uniqueness have been shown in [13]. From (130) and (126) we see the matching condition on the outer solution $\boldsymbol{J}$ as a vortex is approached is therefore

$$\boldsymbol{J} \sim \frac{a(0)}{r}\boldsymbol{e}_\theta \text{ as } r \to 0.$$

We may combine this matching condition succinctly with the London equation (127) by writing

$$\boldsymbol{e}_z \cdot \operatorname{curl}\left(\frac{\boldsymbol{J}}{a(\boldsymbol{x})}\right) + h_3(x, y, 0) = 2\pi\delta(\boldsymbol{x}), \tag{135}$$

where $\boldsymbol{x} = (x, y)$ and $\delta(\boldsymbol{x})$ is the two-dimensional Dirac δ-function. Thus we have reduced the nonlinear but regular Ginzburg–Landau equation to a linear but singular London equation. The great advantage of the linearity of (135) is that if we have many vortices located at the positions $\boldsymbol{x}_n$, $n = 0, \ldots, N$, we may simply add up their contributions to the electric current and magnetic field by the principle of superposition to give

$$\boldsymbol{e}_z \cdot \operatorname{curl}\left(\frac{\boldsymbol{J}}{a(\boldsymbol{x})}\right) + h_3(x, y, 0) = 2\pi\sum_{n=0}^{N}\delta(\boldsymbol{x} - \boldsymbol{x}_n). \tag{136}$$

All that remains is to determine a law of motion for each vortex, so that we can determine the evolution of the positions $\boldsymbol{x}_n$. To do this we need to proceed further down the asymptotic expansions. The analysis parallels exactly that in [11, 12, 10].

Asymptotically expanding the solution of (136), (91) in inner coordinates as $r \to 0$ as in [10] we find

$$\boldsymbol{Q} = -\frac{1}{a}\boldsymbol{J} \sim -\frac{1}{\Xi R}\boldsymbol{e}_\theta - \frac{|\log \Xi|}{2(ag)} \begin{pmatrix} (ag)_y \\ -(ag)_x \end{pmatrix} + \cdots, \tag{137}$$

where the second term is evaluated at $r = 0$ (and is therefore constant). Thus the expansion in the inner region must proceed as

$$f = f^{(0)} + \Xi |\log \Xi| f^{(1)} + \cdots, \tag{138}$$

$$\boldsymbol{Q} = \frac{1}{\Xi}\boldsymbol{Q}^{(0)} + |\log \Xi| \boldsymbol{Q}^{(1)} + \cdots, \tag{139}$$

$$\Phi = \frac{|\log \Xi|}{\Xi}\Phi^{(0)} + \cdots, \tag{140}$$

$$\boldsymbol{v} = |\log \Xi| \boldsymbol{v}^{(0)} + \cdots, \tag{141}$$

where $\boldsymbol{v}$ is the velocity of the vortex at the origin. Equating coefficients of $|\log \Xi|$ in (87), (88), (91), and (92) we find

$$\begin{aligned} \boldsymbol{v}^{(0)} \cdot \boldsymbol{e}_r \frac{df^{(0)}}{dR} + \frac{\partial^2 f^{(1)}}{\partial R^2} + \frac{1}{R}\frac{\partial f^{(1)}}{\partial R} - \frac{f^{(1)}}{R^2} + \frac{1}{R^2}\frac{\partial^2 f^{(1)}}{\partial \theta^2} \\ = 3(f^{(0)})^2 f^{(1)} - a(0) f^{(1)} - \frac{2f^{(0)}}{R}\boldsymbol{Q}^{(1)} \cdot \boldsymbol{e}_\theta, \end{aligned} \tag{142}$$

$$\begin{aligned} (f^{(0)})^2 \Phi^{(0)} - \frac{1}{R}\frac{\partial}{\partial \theta}\left(\frac{2f^{(0)} f^{(1)}}{R}\right) \\ + \frac{1}{R}\frac{\partial}{\partial R}\left(R(f^{(0)})^2 \boldsymbol{Q}^{(1)} \cdot \boldsymbol{e}_r\right) + \frac{1}{R}\frac{\partial}{\partial \theta}\left((f^{(0)})^2 \boldsymbol{Q}^{(1)} \cdot \boldsymbol{e}_\theta\right) = 0, \end{aligned} \tag{143}$$

$$\frac{1}{R}\frac{\partial}{\partial R}\left(R\boldsymbol{Q}^{(1)} \cdot \boldsymbol{e}_\theta\right) - \frac{1}{R}\frac{\partial}{\partial \theta}\left(\boldsymbol{Q}^{(1)} \cdot \boldsymbol{e}_r\right) = 0, \tag{144}$$

$$\begin{aligned} -\frac{1}{R}\frac{\partial}{\partial \theta}\left(\frac{2f^{(0)} f^{(1)}}{R}\right) + \frac{1}{R}\frac{\partial}{\partial R}\left(R(f^{(0)})^2 \boldsymbol{Q}^{(0)} \cdot \boldsymbol{e}_r\right) + \frac{1}{R}\frac{\partial}{\partial \theta}\left(R(f^{(0)})^2 \boldsymbol{Q}^{(0)} \cdot \boldsymbol{e}_\theta\right) \\ + \sigma\left(\frac{1}{R}\frac{\partial}{\partial R}\left(R\frac{\partial \Theta^{(0)}}{\partial R}\right) + \frac{1}{R^2}\frac{\partial^2 \Theta^{(0)}}{\partial \theta^2}\right) = 0. \end{aligned} \tag{145}$$

From (144) and (145) we see that

$$(f^{(0)})^2 \Phi^{(0)} = \sigma\left(\frac{1}{R}\frac{\partial}{\partial R}\left(R\frac{\partial \Theta^{(0)}}{\partial R}\right) + \frac{1}{R^2}\frac{\partial^2 \Theta^{(0)}}{\partial \theta^2}\right). \tag{146}$$

As $R \to 0$ we have the boundary condition [11]

$$\Phi^{(0)} \sim -\frac{1}{R}\boldsymbol{v}^{(0)} \cdot \boldsymbol{e}_\theta. \tag{147}$$

From (143) we may write $\boldsymbol{Q}^{(1)}$ in terms of a scalar potential ψ as

$$\boldsymbol{Q}^{(1)} \cdot \boldsymbol{e}_\theta = \frac{1}{R}\frac{\partial \psi}{\partial \theta}, \tag{148}$$

$$\boldsymbol{Q}^{(1)} \cdot \boldsymbol{e}_r = \frac{\partial \psi}{\partial R}. \tag{149}$$

To match with the outer behavior (137) we require

$$\psi \sim \text{constant} \times R\sin(\theta - \alpha)$$

for some constant angle α. Thus we make the ansatz [12]

$$\psi = a(0)^{-1/2}\phi(\rho)\sin(\theta - \alpha), \tag{150}$$

$$\Phi^{(0)} = Ua(0)^{1/2}\eta(\rho)\sin(\theta - \alpha), \tag{151}$$

$$f^{(1)} = F(\rho)\cos(\theta - \alpha), \tag{152}$$

$$\boldsymbol{v}^{(0)} = U(\cos(\theta - \alpha)\boldsymbol{e}_r - \sin(\theta - \alpha)\boldsymbol{e}_\theta) = U(\cos\alpha\boldsymbol{e}_x + \sin\alpha\boldsymbol{e}_y). \tag{153}$$

The system (142), (145), (146) then reduces to

$$\frac{1}{\rho}(\rho F')' - 3\bar{f}^2F + F = -U\bar{f}' - \frac{2\bar{f}\phi}{\rho^2} + \frac{2F}{\rho^2}, \tag{154}$$

$$\frac{1}{\rho}\left(\rho\bar{f}^2\phi'\right)' + \sigma U\left(\eta' + \frac{\eta}{\rho}\right)' - \frac{\bar{f}^2\phi}{\rho^2} + \frac{2\bar{f}F}{\rho^2} = 0, \tag{155}$$

$$\eta'' + \frac{1}{\rho}\eta' - \frac{1}{\rho^2}\eta - \frac{{f^{(0)}}^2\eta}{\sigma} = 0, \tag{156}$$

where $' \equiv d/d\rho$. Equation (147) gives the boundary condition

$$\eta \sim \frac{1}{\rho} \qquad \text{as } \rho \to 0 \tag{157}$$

on (156). Matching with the outer solution gives the second condition:

$$\rho\eta \to 0 \qquad \text{as } \rho \to \infty. \tag{158}$$

This gives a well-posed problem for η, and numerical solutions of (156) with boundary conditions (157) and (158) have been given by Peres and Rubinstein [25].

We consider (154) and (155). Noting that the derivative of the leading-order solution $\bar{f}$ satisfies the homogeneous version of (154) we see that there will be a solution if and only if a certain solvability condition is satisfied. To derive this condition we multiply (154) by $\rho\bar{f}'$, the derivative of (131) by $\rho f^{(1)}$, and subtract to obtain

$$\rho U(\bar{f}')^2 + \left(\rho F'\bar{f}' - \rho F\bar{f}''\right)' = -\frac{2\bar{f}'\bar{f}\phi}{\rho} + \frac{2\bar{f}F}{\rho^2}. \tag{159}$$

Using (155) to eliminate the final F, integrating over $(0, \infty)$ and using the asymptotic behavior of the $\bar{f}$ and $\Theta^{(0)}$ at 0 and ∞ we find

$$\lim_{\rho\to\infty}\left(\phi' + \frac{\phi}{\rho}\right) = -U\beta, \tag{160}$$

where

$$\beta = \int_0^\infty \rho(\bar{f}')^2 d\rho + \int_0^\infty \bar{f}^2\eta d\rho. \tag{161}$$

Hence

$$\lim_{\rho\to\infty}\boldsymbol{Q}^{(1)} = \frac{U\beta}{2}\left(\sin\alpha\boldsymbol{e}_x - \cos\alpha\boldsymbol{e}_y\right). \tag{162}$$

Matching with the outer solution (137) using (153) gives

$$\boldsymbol{v}^{(0)} = -\frac{1}{\beta}\nabla \log(ag), \tag{163}$$

so that to leading order

$$\boldsymbol{v} = -\frac{|\log \Xi|}{\beta}\nabla \log(ag). \tag{164}$$

We see that vortices are attracted to the minima of ag. If we proceed to higher orders we find that the first two terms in the vortex velocity law give

$$\boldsymbol{v} = -\frac{|\log \Xi|}{\beta}\nabla \log(ag) + \frac{2}{\beta a}\boldsymbol{J} \wedge \boldsymbol{e}_z, \tag{165}$$

where $\boldsymbol{J}$ is the regular part of the current density. The second term here becomes dominant either when ag is constant, so that the first term vanishes, or when the background current density $\boldsymbol{J}$ is large, which will be the case when we allow the vortex separation ν/L to tend to zero to arrive at vortex-density models in section 4.[1]

Summary. The leading-order London limit of the thin-film Ginzburg–Landau model is (dropping the superscripts for clarity)

$$\operatorname{curl} \boldsymbol{h} = \boldsymbol{J}_{ext}, \tag{166}$$

$$\operatorname{div} \boldsymbol{h} = 0, \tag{167}$$

with

$$[\boldsymbol{e}_z \wedge \boldsymbol{h}] = \frac{g}{\Lambda}\boldsymbol{J} \quad \text{for} \quad (x, y) \in \Omega, \tag{168}$$

$$[\boldsymbol{e}_z \cdot \boldsymbol{h}] = 0, \tag{169}$$

$$\boldsymbol{h}^{(0)} \to \boldsymbol{h}_{ext} \quad \text{as} \quad |\boldsymbol{r}| \to \infty, \tag{170}$$

for the magnetic field outside the superconductor, and

$$\boldsymbol{e}_z \cdot \operatorname{curl}\left(\frac{\boldsymbol{J}}{a}\right) + h_3(x, y, 0) = 2\pi \sum_n \delta(\boldsymbol{x} - \boldsymbol{x}_n), \tag{171}$$

$$\operatorname{div}(g\boldsymbol{J}) = 0, \tag{172}$$

with

$$\boldsymbol{J} \cdot \boldsymbol{\nu} = 0 \quad \text{on} \quad \partial D, \tag{173}$$

for the electric current inside the superconductor, with the vortices moving according to the law

$$\dot{\boldsymbol{x}}_n = -\frac{|\log \Xi|}{\beta}\nabla \log(ag) + \frac{2}{\beta a}\boldsymbol{J} \wedge \boldsymbol{e}_z. \tag{174}$$

[1] Strictly speaking the law of motion needs to be rederived when the terms in (165) switch order so that the second one dominates, but the analysis proceeds in exactly the same way and (165) still holds.

The key equation here is (171); as we have already said, all the other equations are simply the thin-film versions of Maxwell's equations. We note that there are two source terms in (171) for the current. The first is the sum of δ-functions due to the vortices, as expected. The second is due to the applied magnetic field, which acts as a negative distributed vorticity. This term is due to the Meissner effect, by which a superconductor attempts to exclude a magnetic field from its interior. The current generated by this term in (171) is an attempt to shield the superconductor from the applied field and will result in a lower magnetic field inside the superconductor than the applied field $\boldsymbol{h}_{ext}$.

Note that if we instead consider vortices with negative winding number (corresponding to a magnetic field in the $-\boldsymbol{e}_z$-direction rather than the $\boldsymbol{e}_z$-direction), then (171) and (174) are modified to

$$\boldsymbol{e}_z \cdot \operatorname{curl}\left(\frac{\boldsymbol{J}}{a}\right) + h_3(x,y,0) = -2\pi \sum_n \delta(\boldsymbol{x} - \boldsymbol{x}_n), \tag{175}$$

$$\dot{\boldsymbol{x}}_n = -\frac{|\log \Xi|}{\beta} \nabla \log(ag) - \frac{2}{\beta a} \boldsymbol{J} \wedge \boldsymbol{e}_z. \tag{176}$$

Note also that by writing the equations in terms of the total current in the film $g\boldsymbol{J}$ (rather than the average current $\boldsymbol{J}$) the solution depends only on the product ag. This shows how variations in film thickness play exactly the same role as variations in the equilibrium density of superconducting electrons.

These equations were derived in [10, 21] for the case $a = 1$ and in [16] for the case of a strip geometry $D = (x, y) : -l < x < l$ in the absence of vortices, with $a = g = 1$. In the strip case (166)–(170) may be replaced by

$$h_3(x,0) - h_{app,3}(x,0) = \frac{1}{\pi} \int_{-l}^{l} \frac{g J_2(\bar{x})}{2\Lambda(\bar{x} - x)}\, d\bar{x}, \tag{177}$$

as in section 2.2.1.

The increased Ginzburg–Landau parameter. Note that from (94) the lengthscale for the decay of the magnetic field away from a vortex is Λ, which is the nondimensional version of Pearl's effective screening length for thin films [24]. Thus the London limit we have considered is valid so long as $\Xi \ll \Lambda$. Thus in a thin film the relevant parameter in determining the type of superconductor is not the Ginzburg–Landau parameter κ but the increased Ginzburg–Landau parameter

$$\kappa_{\text{eff}} = \frac{\Lambda}{\Xi} = \frac{\lambda_{\text{eff}}}{\xi} = \frac{\lambda^2}{\xi d} = \frac{\lambda \kappa}{d}.$$

This explains why thin films of even type-I superconducting material develop vortex solutions similar to bulk type-II superconductors once the thickness becomes smaller than the penetration depth, as was first observed by Tinkham [30].

3.2. The bulk London model. Let us now consider the opposite sequence of limits, namely we first let $\Xi \to 0$ keeping λ and ϵ fixed (i.e., we let $\kappa \to \infty$), and then we let $\epsilon \to 0$, that is, we are in the parameter regime $\Xi \ll \epsilon \ll 1$.

We have seen that the vortex cores have vanishingly small radius in the limit $\Xi \to 0$ and (25) gives $f = a(\boldsymbol{x})$ except at these isolated vortex lines. Then from (27)

$$\frac{\lambda^2}{L^2} \operatorname{curl}^2 \boldsymbol{Q} + a\boldsymbol{Q} = \boldsymbol{0}, \tag{178}$$

or, taking the curl,

$$\frac{\lambda^2}{L^2}\mathrm{curl}\left(\frac{1}{a}\mathrm{curl}\boldsymbol{H}\right)+\boldsymbol{H}=\boldsymbol{0}, \tag{179}$$

away from vortices. By matching a local asymptotic analysis of an individual vortex core with this outer expansion away from vortices, as in section 3.1 and as detailed in [11], it may be shown that the presence of vortices leads to δ-function singularities on the right-hand side of (179), so that

$$\frac{\lambda^2}{L^2}\mathrm{curl}\left(\frac{1}{a}\mathrm{curl}\boldsymbol{H}\right)+\boldsymbol{H}=2\pi\sum_n \boldsymbol{\delta}_{\Gamma_n}, \tag{180}$$

where

$$\boldsymbol{\delta}_\Gamma(\boldsymbol{x})=\int_\Gamma \delta(x-\bar{x})\delta(y-\bar{y})\delta(z-\bar{z})\,\boldsymbol{d\bar{x}}. \tag{181}$$

Proceeding to first order in this asymptotic matching and applying a solvability condition gives the law of motion of superconducting vortices as [11, 12]

$$\boldsymbol{v}=\frac{|\log\Xi|}{\beta}C\boldsymbol{n}-\frac{|\log\Xi|}{\beta}\nabla\log a+\frac{2}{a\beta}\boldsymbol{J}\wedge\boldsymbol{t}, \tag{182}$$

where $\boldsymbol{J}$ is the background current, C is the curvature of the vortex line, and β is given by (161) as before.

It has been shown in [10] that (182), (180) imply that vortices must meet the boundary $\partial\Omega$ normally, since if this is not so an infinite current density is produced. (This can also be thought of as an infinite curvature of the vortex and its image, which is clearly incompatible with (182).)

Equations (180), (182) must be coupled with Maxwell's equations (6)–(10) outside the film, along with continuity conditions on $\boldsymbol{H}$ across $\partial\Omega$.

3.3. Thin film of the London equations. As in section 2, we assume that the vortex separation is of the same order as the lateral dimension of the film as $\epsilon\to 0$, that is, the film contains a finite number of vortices in the limit. We write (180) as

$$\boldsymbol{J}=\epsilon\Lambda\,\mathrm{curl}\,\boldsymbol{H}, \tag{183}$$

$$\mathrm{curl}\left(\frac{\boldsymbol{J}}{a}\right)+\boldsymbol{H}=2\pi\sum_n \boldsymbol{\delta}_{\Gamma_n}, \tag{184}$$

where our scaling of $\boldsymbol{J}$, consistent with section 2, is such that terms in (184) are balanced. Of course, in the canonical case both (183) and (184) will be balanced, and it is only when we are considering limiting cases that the scaling of $\boldsymbol{J}$ is important. As in section 2 we will find that the canonical scaling is to have $\Lambda=\lambda^2/dL$ of order one. Since the vortices must meet the upper and lower surfaces of the film normally, they must lie in the z-direction to leading order. Thus the equations to be satisfied are

$$\mathrm{curl}\,\boldsymbol{j}+\boldsymbol{H}=2\pi\sum_n \delta(\boldsymbol{x}-\boldsymbol{x}_n)\boldsymbol{e}_z+\cdots \qquad \text{in } \Omega, \tag{185}$$

$$a\boldsymbol{j}=\Lambda\epsilon\,\mathrm{curl}\,\boldsymbol{H} \qquad \text{in } \Omega, \tag{186}$$

$$\operatorname{div} \boldsymbol{H} = 0 \qquad \text{in } \Omega, \tag{187}$$

$$\operatorname{div} (a\boldsymbol{j}) = 0 \qquad \text{in } \Omega, \tag{188}$$

$$\operatorname{curl} \boldsymbol{h} = \boldsymbol{J}_{ext} \qquad \text{outside } \Omega, \tag{189}$$

$$\operatorname{div} \boldsymbol{h} = 0 \qquad \text{outside } \Omega, \tag{190}$$

with

$$\boldsymbol{h} = \boldsymbol{H} \quad \text{on } \partial\Omega, \tag{191}$$

$$\boldsymbol{j} \cdot \boldsymbol{n} = 0 \quad \text{on } \partial\Omega, \tag{192}$$

and

$$\boldsymbol{h} \to \boldsymbol{h}_{ext} \quad \text{as} \quad |\boldsymbol{r}| \to \infty, \tag{193}$$

where $\boldsymbol{n}$ is the normal to $\partial\Omega$ and we have written $\boldsymbol{J} = a\boldsymbol{j}$.

As usual, we start by considering the problem inside the film. Rescaling $z = \epsilon Z$, equation (185) becomes

$$-\frac{1}{\epsilon}\frac{\partial j_2}{\partial Z} + \frac{\partial j_3}{\partial y} + H_1 = \cdots, \tag{194}$$

$$\frac{1}{\epsilon}\frac{\partial j_1}{\partial Z} - \frac{\partial j_3}{\partial x} + H_2 = \cdots, \tag{195}$$

$$\frac{\partial j_2}{\partial x} - \frac{\partial j_1}{\partial y} + H_3 = 2\pi \sum_n \delta(\hat{\boldsymbol{x}} - \hat{\boldsymbol{x}}_n) + \cdots. \tag{196}$$

We expand all quantities asymptotically in powers of ϵ as

$$\boldsymbol{h} \sim \boldsymbol{h}^{(0)} + \epsilon \boldsymbol{h}^{(1)} + \epsilon^2 \boldsymbol{h}^{(2)} + \cdots, \tag{197}$$

etc. Substituting these expansions into (194)–(196) and equating powers of ϵ gives, at leading order,

$$\frac{\partial j_1^{(0)}}{\partial Z} = \frac{\partial j_2^{(0)}}{\partial Z} = 0, \tag{198}$$

$$\frac{\partial j_2^{(0)}}{\partial x} - \frac{\partial j_1^{(0)}}{\partial y} + H_3^{(0)} = 2\pi \sum_n \delta(\hat{\boldsymbol{x}} - \hat{\boldsymbol{x}}_n). \tag{199}$$

Thus, as before, $j_1^{(0)}$ and $j_2^{(0)}$ are constant in Z. The thin-film analysis of (186)–(193) then proceeds exactly as in section 2.2 to give [10]

$$j_3^{(0)} = 0, \tag{200}$$

$$\left[\boldsymbol{e}_z \wedge \boldsymbol{h}^{(0)}\right] = \frac{ag}{\Lambda}\boldsymbol{j}^{(0)} \quad \text{for} \quad (x, y) \in D, \tag{201}$$

$$\left[\boldsymbol{e}_z \cdot \boldsymbol{h}^{(0)}\right] = 0 \quad \text{for} \quad (x, y) \in D. \tag{202}$$

Similarly the thin-film analysis of (188) gives

$$\operatorname{div} (ag\,\boldsymbol{j}^{(0)}) = 0. \tag{203}$$

Finally we need to determine the law of motion for the vortices. An asymptotic analysis in [10] for constant a matching this outer model with the inner model in the vicinity of the vortex cores gives the law of motion

$$\boldsymbol{v} = \frac{2}{\beta}\boldsymbol{J} \wedge \boldsymbol{e}_z - \frac{|\log \Xi|}{\beta}\nabla \log g. \tag{204}$$

If a variable a is included in this analysis, the result is

$$\boldsymbol{v} = \frac{2}{a\beta}\boldsymbol{J} \wedge \boldsymbol{e}_z - \frac{|\log \Xi|}{\beta}\nabla \log(ag). \tag{205}$$

It is shown in [10] that the motion due to variations in film thickness is consistent with the motion of the vortex under (182) with the curvature it must have if it forms an arc of a circle meeting the upper and lower surfaces of the film normally.

Thus we find that the thin-film version of the London model corresponds exactly to the London limit of the thin-film Ginzburg–Landau model (166)–(174).

3.4. Limiting cases. In the limit $\Lambda \to \infty$ the magnetic field generated by the current in the film gives a negligible contribution to (171), and $h_3(x, y, 0)$ is simply replaced by $h_{app,3}(x, y, 0)$, the third component of the total applied magnetic field. The problem for the electric current is then decoupled from the problem for the magnetic field, which as usual reduces to the standard problem in electromagnetism of calculating the magnetic field due to a current sheet once the electric current has been found.

For Λ small we must rescale the electric current with Λ. Then the current term in (171) is negligible, and this equation reads

$$h_3(x, y, 0) = 2\pi \sum_n \delta(\boldsymbol{x} - \boldsymbol{x}_n) \tag{206}$$

to leading order. Hence the normal component of the magnetic field is zero on $z = 0$, except at the positions of the vortices. Near each vortex an inner problem must be solved, in which length is rescaled with Λ, so that the first term in (171) is relevant again. Thus, effectively, the relevant horizontal lengthscale is no longer L but the effective penetration depth λ_{eff}, and the vortices are completely isolated. This last limit is much more interesting when the vortices are more closely separated, so that the sum of δ-functions can be averaged into a vortex density or vorticity.

4. Vortex-density models. So far we have been considering the limit $\epsilon \to 0$ with the vortex separation of the same order as L, so that there are a finite number of vortices in the film in the limit. In this section we will consider the limit in which $\nu/L \to 0$ where ν is the vortex separation, so that the individual vortices are replaced by a vortex density.

As before we now have two limiting processes ($\epsilon \to 0$ and $\nu/L \to 0$), and we can choose to perform them in either order. We will consider first the vortex-density limit of the thin-film London model, that is, we first let $\epsilon \to 0$ and then let $\nu/L \to 0$, so that $\epsilon \ll \nu/L \ll 1$. In section 4.3 we will consider the alternative regime $\nu/L \ll \epsilon \ll 1$.

4.1. Averaging the thin-film London model. We consider the limit in which the vortex separation $\nu/L \to 0$. In this case it is clear from (171) that both $\boldsymbol{h}$ and $\boldsymbol{J}$ need to be rescaled with L^2/ν^2.

We formally define the vortex density as

$$\omega(\boldsymbol{x}) = \lim_{\eta\to 0} \frac{2\pi\nu^2}{\eta^2 L^2} \int_{|x|<\eta/2,|y|<\eta/2} \sum_i \delta(\boldsymbol{x}' - \boldsymbol{x}_n)\, d\boldsymbol{x}', \tag{207}$$

where the integration is over a square of dimension η, and $\nu/L \ll \eta \ll 1$ as $\nu/L \to 0$, so that the size of the square is tending to zero, but each square contains many vortices. The prefactor ν^2/L^2 ensures that the limit is order one. Now locally averaging (166)–(173) by formally integrating over the same square of side η, we find the electric current inside the superconductor satisfies

$$\boldsymbol{e}_z \cdot \operatorname{curl}\left(\frac{\boldsymbol{J}}{a}\right) + h_3(x,y,0) = \omega, \tag{208}$$

$$\operatorname{div}(g\boldsymbol{J}) = 0, \tag{209}$$

with

$$\boldsymbol{J}\cdot\boldsymbol{\nu} = 0 \quad \text{on} \quad \partial D, \tag{210}$$

while the problem for the magnetic field outside the superconductor,

$$\operatorname{curl}\boldsymbol{h} = \boldsymbol{J}_{ext}, \tag{211}$$

$$\operatorname{div}\boldsymbol{h} = 0, \tag{212}$$

with

$$[\boldsymbol{e}_z \wedge \boldsymbol{h}] = \frac{g}{\Lambda}\boldsymbol{J} \quad \text{for} \quad (x,y) \in D, \tag{213}$$

$$[\boldsymbol{e}_z \cdot \boldsymbol{h}] = 0, \tag{214}$$

$$\boldsymbol{h} \to \boldsymbol{h}_{ext} \quad \text{as} \quad |\boldsymbol{r}| \to \infty, \tag{215}$$

is unchanged. In the strip geometry, with a and g constant, equation (208) was derived by Larkin and Ovchinnikov [22]. As usual, in this geometry (211)–(215) can be replaced by (124). However, we now have another dependent variable, ω, so we need another equation. In passing from isolated vortices to a vortex density we have lost the property of vortex conservation, which is automatic when we are tracking individual vortices. Thus the equation we need to add is a conservation law for the vortices. This law takes the usual form, namely

$$\frac{\partial\omega}{\partial t} + \operatorname{div}(\omega\boldsymbol{v}) = 0, \tag{216}$$

where $\boldsymbol{v}$ is the velocity of the vortices, which is given by (174). Remembering that we have rescaled the electric current with L^2/ν^2, we also now rescale time with $2L^2/\beta\nu^2$ to give

$$\boldsymbol{v} = \frac{1}{a}\boldsymbol{J}\wedge\boldsymbol{e}_z - \frac{\nu^2|\log\Xi|}{2L^2}\nabla\log(ag). \tag{217}$$

Now the pinning effect of variations in ag has been weakened due to the increased current density in the film; if the lengthscale for variations in ag is order L, then the first term is likely to dominate. In section 5 we will consider the case when the

lengthscale ε for variations in a is also small, so that pinning becomes important again.

If we perform the same analysis in a region of vortices with negative winding number, we find $\omega < 0$ and (217) becomes

$$\boldsymbol{v} = -\frac{1}{a}\boldsymbol{J} \wedge \boldsymbol{e}_z - \frac{\nu^2 |\log \Xi|}{2L^2} \nabla \log(ag). \tag{218}$$

We can combine these two results in the single vortex velocity law

$$\boldsymbol{v} = \frac{\operatorname{sign}(\omega)}{a}\boldsymbol{J} \wedge \boldsymbol{e}_z - \frac{\nu^2 |\log \Xi|}{2L^2} \nabla \log(ag). \tag{219}$$

Equation (216) introduces one real characteristic into the model, so that we need to give an extra boundary condition (on ω) whenever this characteristic points into the domain, i.e., whenever $\boldsymbol{v} \cdot \boldsymbol{\nu} < 0$. This condition will typically relate either the magnitude of the vorticity or the flux of vorticity through the boundary to the local current density. In the two-dimensional case it is found that vortices will not be nucleated at the boundary until the current density reaches a critical value. In the thin-film case the details of vortex nucleation will depend on the local shape of the film near the boundary ∂D, and an inner boundary layer problem needs to be solved on a lateral lengthscale of order d, the film thickness. However, it is natural to assume still that vortices will not be nucleated until the current density at the boundary reaches a critical value, J_{nucl} say.

4.2. The bulk vortex-density model. Let us now consider the parameter regime $\nu/L \ll \epsilon \ll 1$; that is, we first consider the limit $\nu/L \to 0$ to obtain the bulk vortex-density model and then consider the thin-film limit of it by letting $\epsilon \to 0$.

In three dimensions a similar formal averaging gives the vortex-density model as [6]

$$\frac{\lambda^2}{L^2} \operatorname{curl} \left(\frac{1}{a} \operatorname{curl} \boldsymbol{H} \right) + \boldsymbol{H} = \boldsymbol{\omega} \quad \text{in } \Omega, \tag{220}$$

$$\operatorname{div} \boldsymbol{H} = 0, \tag{221}$$

with Maxwell's equations (6)–(10) as usual outside Ω, with continuity of $\boldsymbol{H}$ across $\partial\Omega$ and

$$\boldsymbol{J} \cdot \boldsymbol{n} = 0 \quad \text{on } \partial\Omega, \tag{222}$$

where $\boldsymbol{\omega}$ is now a vector vortex density or vorticity given by

$$\boldsymbol{\omega}(\boldsymbol{x}) = \lim_{\eta \to 0} \frac{2\pi\nu^2}{\eta^2 L^2} \int_{|x|<\eta/2, |y|<\eta/2} \sum_i \boldsymbol{\delta}_{\Gamma_n}(\boldsymbol{x}')\, d\boldsymbol{x}'.$$

The law of conservation of vortices in three dimensions is [6, 5]

$$\frac{\partial \boldsymbol{\omega}}{\partial t} + \operatorname{curl} (\boldsymbol{\omega} \wedge \boldsymbol{v}) = 0, \tag{223}$$

where the vortex velocity $\boldsymbol{v}$ is given by

$$\boldsymbol{v} = \frac{1}{a}\boldsymbol{J} \wedge \hat{\boldsymbol{\omega}} + \frac{\nu^2 |\log \Xi|}{2L^2} \left(-\nabla \log a + \operatorname{curl} \hat{\boldsymbol{\omega}} \wedge \hat{\boldsymbol{\omega}} \right), \tag{224}$$

and $\hat{\boldsymbol{\omega}}$ is the unit vector in the direction of $\boldsymbol{\omega}$. The term $\operatorname{curl} \hat{\boldsymbol{\omega}} \wedge \hat{\boldsymbol{\omega}}$ here is just the curvature term rewritten. If the limits $\Xi \to 0$ and $\nu/L \to 0$ are such that $\nu^2 |\log \Xi|/L^2 \to 0$, then the last term is of lower order and can be neglected. In the general three-dimensional situation neglecting the self-induced curvature term leads to the possibility of a short-wavelength large–growth-rate instability on vortex lines if $\boldsymbol{J} \cdot \boldsymbol{\omega} \neq 0$, as shown in [26] and discussed in [6]. However, in the thin-film limit it is safe to neglect the self-induced term since the current will lie in the (x, y)-plane while the vorticity will be normal to it.

As in the thin-film vortex-density model, equation (223) has introduced one real characteristic, and we need to give a boundary condition on $\boldsymbol{\omega}$ whenever $\boldsymbol{v} \cdot \boldsymbol{n} < 0$. Now, an analysis in [15] indicates that on such an inflow boundary either $\boldsymbol{\omega} \cdot \boldsymbol{n} = 0$ (which is the case in the thin-film model and also in the two-dimensional model with axial symmetry) or $\boldsymbol{\omega} \wedge \boldsymbol{n} = \boldsymbol{0}$. In the first case the flux of vorticity through the boundary will be related to the local current density, while in the second no extra condition needs to be given. In a general three-dimensional situation the position of the switch between these two types of behavior is unknown, and a boundary layer calculation may be necessary in its vicinity. However, in our thin film scenario we are fortunate that the top and bottom of the film will have vortices passing through them and be such that $\boldsymbol{\omega} \wedge \boldsymbol{n} = \boldsymbol{0}$ if they are inflow, while we will see that the sides of the film will have $\boldsymbol{\omega} \cdot \boldsymbol{n} = 0$ to leading order, and therefore these are the boundaries through which new vortices will pass.

4.3. Thin film of the vortex-density model. Let us now consider the thin-film limit $\epsilon \to 0$ of the bulk vortex-density model (220)–(224), corresponding to the parameter regime $\nu/L \ll \epsilon \ll 1$. We begin as usual by writing (220) as

$$\operatorname{curl}\left(\frac{\boldsymbol{J}}{a}\right) + \boldsymbol{H} = \boldsymbol{\omega} \quad \text{in } \Omega, \tag{225}$$

$$\boldsymbol{J} = \Lambda\epsilon \operatorname{curl} \boldsymbol{H} \quad \text{in } \Omega. \tag{226}$$

Expanding all quantities in powers of ϵ the analysis proceeds exactly as in section 3.3 giving

$$\operatorname{curl} \boldsymbol{h} = \boldsymbol{J}_{ext}, \tag{227}$$

$$\operatorname{div} \boldsymbol{h} = 0, \tag{228}$$

with

$$[\boldsymbol{e}_z \wedge \boldsymbol{h}] = \frac{g}{\Lambda}\boldsymbol{J} \quad \text{for} \quad (x, y) \in D, \tag{229}$$

$$[\boldsymbol{e}_z \cdot \boldsymbol{h}] = 0, \tag{230}$$

$$\boldsymbol{h} \to \boldsymbol{h}_{ext} \quad \text{as} \quad |\boldsymbol{r}| \to \infty, \tag{231}$$

for the magnetic field outside the superconductor, and

$$\boldsymbol{e}_z \cdot \operatorname{curl}\left(\frac{\boldsymbol{J}}{a}\right) + h_3(x, y, 0) = \omega_3, \tag{232}$$

$$\operatorname{div}(g\boldsymbol{J}) = 0, \tag{233}$$

with

$$\boldsymbol{J} \cdot \boldsymbol{\nu} = 0 \quad \text{on} \quad \partial D, \tag{234}$$

for the electric current inside the superconductor. The only additional work is to check that the three-dimensional vector conservation law (223) reduces to the two-dimensional scalar conservation law (216) in the thin-film limit. To do that we need to show that $\boldsymbol{\omega}$ lies in the z-direction to leading order. Since one of the top or bottom sides of the film is an inflow boundary, and on that inflow boundary $\boldsymbol{\omega} \wedge \boldsymbol{n} = \boldsymbol{0}$, to leading order we must have $\boldsymbol{\omega} \wedge \boldsymbol{e}_z = 0$ there. To be sure that $\omega_1 = \omega_2 = 0$ everywhere we must check that they cannot vary rapidly in z, i.e., they are independent of Z to leading order. Writing (223) in component form in the film gives

$$\frac{\partial \omega_1}{\partial t} + \frac{\partial}{\partial y}(\omega_1 v_2 - \omega_2 v_1) - \frac{1}{\epsilon}\frac{\partial}{\partial Z}(\omega_3 v_1 - \omega_1 v_3) = 0, \tag{235}$$

$$\frac{\partial \omega_2}{\partial t} - \frac{\partial}{\partial x}(\omega_1 v_2 - \omega_2 v_1) + \frac{1}{\epsilon}\frac{\partial}{\partial Z}(\omega_2 v_3 - \omega_3 v_2) = 0, \tag{236}$$

$$\frac{\partial \omega_3}{\partial t} + \frac{\partial}{\partial x}(\omega_3 v_1 - \omega_1 v_3) - \frac{\partial}{\partial y}(\omega_2 v_3 - \omega_3 v_2) = 0, \tag{237}$$

where

$$a v_1 = J_2 \hat{\omega}_3, \tag{238}$$

$$a v_2 = -J_1 \hat{\omega}_3, \tag{239}$$

$$a v_3 = J_1 \hat{\omega}_2 - J_2 \hat{\omega}_1. \tag{240}$$

Thus at leading order in ϵ

$$\omega_3 v_1 - \omega_1 v_3 = \text{ independent of } Z, \tag{241}$$

$$\omega_2 v_3 - \omega_3 v_2 = \text{ independent of } Z. \tag{242}$$

Now (225) implies div $\boldsymbol{\omega} = 0$, which in the film gives ω_3 independent of Z to leading order. Then eliminating $\boldsymbol{v}$ from (241)–(242) gives two equations for ω_1 and ω_2 in terms of ω_3, so that ω_1 and ω_2, and therefore $\boldsymbol{v}$, are also independent of Z to leading order.

Finally (237) then gives

$$\frac{\partial \omega_3}{\partial t} + \frac{\partial}{\partial x}(\omega_3 v_1) + \frac{\partial}{\partial y}(\omega_3 v_2) = 0, \tag{243}$$

as required.

4.4. Limiting cases. In the limit in which $\Lambda \to \infty$, the problem for the electric current becomes

$$\boldsymbol{e}_z \cdot \text{curl}\left(\frac{\boldsymbol{J}}{a}\right) + h_{app,3}(x, y, 0) = \omega, \tag{244}$$

$$\frac{\partial \omega}{\partial t} + \text{div}\,(\omega \boldsymbol{v}) = 0, \tag{245}$$

$$\boldsymbol{v} = \frac{\text{sign}(\omega)}{a} \boldsymbol{J} \wedge \boldsymbol{e}_z, \tag{246}$$

$$\text{div}\,(g\boldsymbol{J}) = 0, \tag{247}$$

with

$$\boldsymbol{J} \cdot \boldsymbol{\nu} = 0 \quad \text{on} \quad \partial\Omega. \tag{248}$$

Once the current has been found, the magnetic field may be found from (211)–(215) in the usual way.

In the limit in which $\Lambda \to 0$, we must scale the electric current with Λ to give

$$\operatorname{curl} \boldsymbol{h} = \boldsymbol{J}_{ext}, \tag{249}$$

$$\operatorname{div} \boldsymbol{h} = 0, \tag{250}$$

with

$$[\boldsymbol{e}_z \wedge \boldsymbol{h}] = g\boldsymbol{J} \quad \text{for} \quad (x, y) \in \Omega, \tag{251}$$

$$[\boldsymbol{e}_z \cdot \boldsymbol{h}] = 0, \tag{252}$$

$$\boldsymbol{h}^{(0)} \to \boldsymbol{h}_{ext} \quad \text{as} \quad |\boldsymbol{r}| \to \infty, \tag{253}$$

$$h_3(x, y, 0) = \omega. \tag{254}$$

The problems for the magnetic field and electric current again simplify, but in this case (249)–(250), (252)–(254) are first solved for the magnetic field, and then (251) is used to determine the current in the superconductor. Having found the current, (216) and (219) are then solved for the vortex density, which in turn feeds into (254). Thus the problems remain coupled in this limit.

However, in taking the limit $\nu/L \to 0$ and $\Lambda \to 0$ there is a constraint on relative magnitudes of these two parameters for the model (216), (219), (249)–(254) to be valid. As we let $\Lambda \to 0$ we are weakening the size of the mean-field current over the local perturbation to this current due to neighboring individual vortices. We have seen that the mean-field current is $O(\Lambda L^2/\nu^2)$, while influence of the current due to a single vortex on its neighbors is $O(L/\nu)$. Thus for the dynamics to be dominated by the mean field as in (219) we need $\nu/L \ll \Lambda$, i.e., $\nu \ll \lambda_{\text{eff}}$. If this is not the case, then the vortex motion will be dominated by local forces and they will form a strong lattice rather than the vortex liquid we are supposing. Note that for bulk superconductors the equivalent condition is $\nu < \lambda^2/L$; the thin film condition is much less stringent since the right-hand side is increased by the aspect ratio L/d.

In the strip geometry (216), (219), (249)–(254) reduce to an interesting singular integral equation. Suppose that $D = (x, y) : -l < x < l$ and that $h_{app,2} = 0$ as usual. In the strip geometry vortex conservation (245) gives

$$\frac{\partial \omega}{\partial t} + \frac{\partial}{\partial x}\left(\frac{J_2|\omega|}{a}\right) = 0, \tag{255}$$

while (124) and (254) give

$$\omega - h_{app,3} = \frac{1}{\pi} \fint_{-l}^{l} \frac{gJ_2(\bar{x})}{2(\bar{x} - x)}\, d\bar{x}, \quad -l < x < l. \tag{256}$$

Hence

$$\frac{\partial}{\partial t}\left(h_{app,3} + \frac{1}{\pi} \fint_{-l}^{l} \frac{gJ_2(\bar{x})}{2(\bar{x} - x)}\, d\bar{x}\right) + \frac{\partial}{\partial x}\left(\frac{J_2}{a}\left|h_{app,3} + \frac{1}{\pi} \fint_{-l}^{l} \frac{gJ_2(\bar{x})}{2(\bar{x} - x)}\, d\bar{x}\right|\right) = 0, \quad -l < x < l. \tag{257}$$

If $l = \infty$, we may invert (256) to give

$$\frac{gJ_2}{2} = \frac{1}{\pi}\int_{-\infty}^{\infty} \frac{\omega(\bar{x}) - h_{app,3}}{x - \bar{x}}\, d\bar{x}, \tag{258}$$

and hence

$$\frac{\partial \omega}{\partial t} + \frac{\partial}{\partial x}\left(\frac{2|\omega|}{ag}\left[\frac{1}{\pi}\int_{-\infty}^{\infty} \frac{\omega(\bar{x}) - h_{app,3}}{x - \bar{x}}\, d\bar{x}\right]\right) = 0. \tag{259}$$

This inversion is not so easy if l is finite, since J_2 depends on h_3 outside the domain D, which cannot be simply written in terms of ω.

5. Critical-state models. So far we have been considering the limit in which the separation of vortices $\nu/L \to 0$ but in which the lengthscale for variations in a, namely ε, remains fixed. Let us now consider the limit in which $\varepsilon/L \to 0$ also, so that the pinning potential is also homogenized. Such a limit will lead to critical state models, in which vortices do not move until the forcing current exceeds a critical value.

5.1. Critical-state limit of the vortex-density thin-film model. Suppose we now allow a in (208)–(217) to vary rapidly. If we look locally near a single vortex which is in the deepest local well and consider the effect of applying a current $\boldsymbol{J}$ to it, we see that if the current is not sufficient to cause the vortex to leave its local well, then it will move up the side of the well until the attraction from the potential balances the applied current (see Figure 3). In this case the vortex will have moved a distance of order ε. Now, if we increase the current $\boldsymbol{J}$, then at some point it will be sufficient to cause the vortex to leave its local well and it will jump into the next well. However, since the vortex was in the deepest local well the current will also be sufficient to cause the vortex to leave the neighboring well. It will continue in this way until it has moved an order-one distance, until either the local well depth has increased, or until the local current density has decreased sufficiently to catch the vortex. Hence, in the limit that $\varepsilon/L \to 0$, we arrive at a stick-slip mobility law: if the local current density is less that a critical value, J_c say (which may be a function of position), then the vortex does not move, while if the local current density is greater than J_c, then the vortex will move but at a reduced speed due to moving through the potential wells. If the distribution of well depth is nonuniform, so that there are a range of depths locally, then it is possible to see how the critical current in this stick-slip model may depend on ω. If we add more and more vortices locally, we have to make use of shallower and shallower wells, thus reducing the critical current required to start some of the vortices moving.

The critical current density in these scalings will be of order $(\nu^2/L\varepsilon)|\log \Xi|$.

We have described the interaction of a single vortex with a rapidly varying potential, which is the case $\varepsilon \ll \nu$. A similar scenario exists in the complementary situation $\nu \ll \varepsilon$ with the single vortex replaced by a "pool" of vorticity, as shown in Figure 4. Applying a forcing term now corresponds to "tilting" the potential, and again there will be a critical current at which the well can no longer hold the pool. In this case it is clear that the critical current will depend on the vortex density.

Thus, after homogenizing the pinning potential the law of motion (219) is modified to be

$$\boldsymbol{v} = \operatorname{sign}(\omega) F(|\boldsymbol{J}|; \boldsymbol{x}, \omega)\hat{\boldsymbol{J}} \wedge \boldsymbol{e}_z, \tag{260}$$

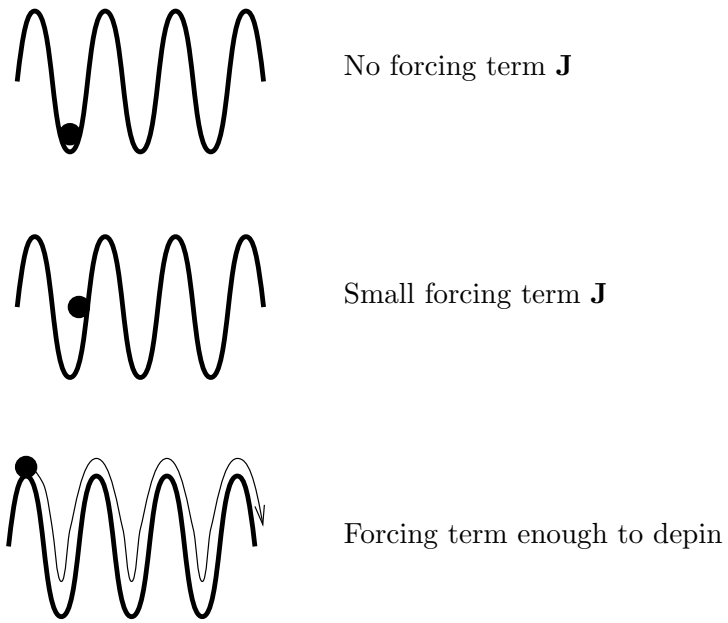


FIG. 3. *Pinning of a single vortex by a rapidly varying pinning potential.*

where $\hat{\boldsymbol{J}}$ is the unit vector in the direction of $\boldsymbol{J}$ and $F(J) = 0$ for $J < J_c(\boldsymbol{x}, \omega)$ (see Figure 5). The value of J_c and the exact form of the velocity law for J above J_c depend on the nature of the pinning potential. We do not delve into the details of this correspondence here, but note that for a single vortex moving in a simple sinusoidal potential with uniform well depth, F approaches zero as $(J - J_c)^{1/2}$. Note also that (208) becomes

$$\boldsymbol{e}_z \cdot \operatorname{curl}\left(\frac{1}{\hat{a}(\boldsymbol{x})}\boldsymbol{J}\right) + h_3(x, y, 0) = \omega, \tag{261}$$

where $\hat{a}$ is the effective equilibrium density of superconducting electrons, which is not simply the local average of a but must be determined through a multiple scales analysis.

Since the critical state corresponds to simply changing the law of motion, the thin-film limit of the bulk critical-state model leads to the same set of equations.

We note that it is quite common in the literature to use a vortex velocity law in which the velocity depends on the electric current via a power law, either with or without a critical current. In [9] a law of this type is used to derive the current-voltage characteristics of thin strips from the underlying vortex velocity law. Even more common (especially when $\Lambda = 0$) is to model the superconductor as a nonlinear conductor by assuming a nonlinear (typically power-law) relationship between the electric field

$$\boldsymbol{E} = \Lambda\frac{\partial \boldsymbol{J}}{\partial t} + \omega \boldsymbol{e}_z \wedge \boldsymbol{v} = \Lambda\frac{\partial \boldsymbol{J}}{\partial t} + |\omega| F(|\boldsymbol{J}|; \boldsymbol{x}, \omega)\hat{\boldsymbol{J}}$$

and the electric current. When $\Lambda = 0$ this corresponds to choosing $F(|\boldsymbol{J}|; \boldsymbol{x}, \omega) \propto |\boldsymbol{J}|^n/|\omega|$. Typically the power chosen is large, $n = 9$ [28] or even $n = 19$ [29]. When n is large these power laws approximate to a stick-slip law of the form (260), but with

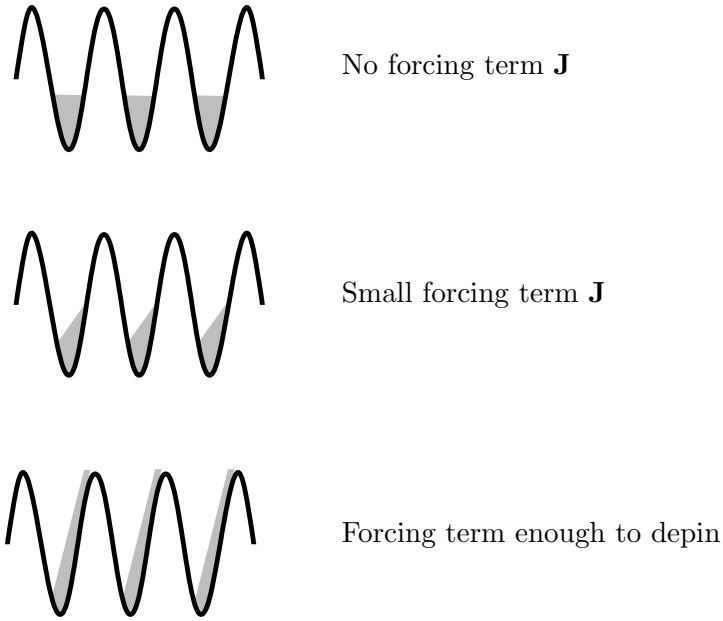

FIG. 4. *Pinning of a vortex pool by a rapidly varying pinning potential.*

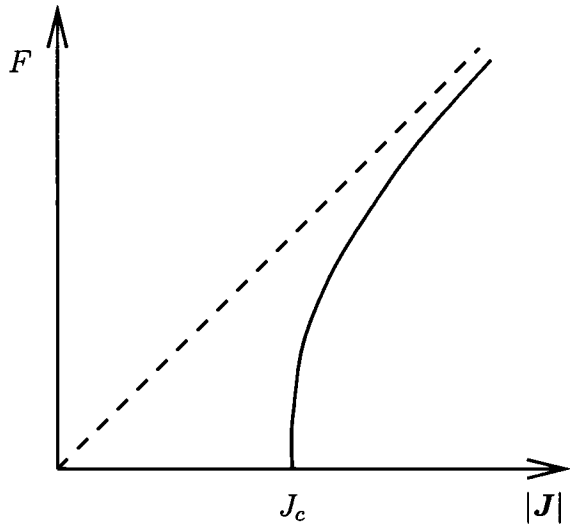

FIG. 5. *Velocity law with stick-slip pinning.*

an infinite vortex mobility once the critical current is exceeded (so that the graph in Figure 5 is vertical). Such an infinite mobility also approximates an arbitrary stick-slip law (260) when the applied magnetic field is slowly varying.

When the mobility of unpinned vortices is infinite the velocity $\boldsymbol{v}$ lies in the direction of $\text{sign}(\omega)\boldsymbol{J} \wedge \boldsymbol{e}_z$, but its magnitude is determined from the constraint that $|\boldsymbol{J}^{(0)}| \leq J_c$, so that

$$\boldsymbol{v} = \text{sign}(\omega) m \boldsymbol{J} \wedge \boldsymbol{e}_z, \tag{262}$$

$$|\boldsymbol{J}| \le J_c \text{ if } \omega \neq 0, \tag{263}$$

$$m \ge 0, \tag{264}$$

$$m\,(|\boldsymbol{J}| - J_c) = 0. \tag{265}$$

These equations are coupled with the law of vortex conservation,

$$\frac{\partial \omega}{\partial t} + \operatorname{div}(\omega \boldsymbol{v}) = 0, \tag{266}$$

and the usual equations for the magnetic field and electric current, namely

$$\operatorname{curl} \boldsymbol{h} = \boldsymbol{J}_{ext}, \tag{267}$$

$$\operatorname{div} \boldsymbol{h} = 0, \tag{268}$$

with

$$[\boldsymbol{e}_z \wedge \boldsymbol{h}] = \frac{g}{\Lambda}\boldsymbol{J} \quad \text{for} \quad (x,y) \in D, \tag{269}$$

$$[\boldsymbol{e}_z \cdot \boldsymbol{h}] = 0, \tag{270}$$

$$\boldsymbol{h} \to \boldsymbol{h}_{ext} \quad \text{as} \quad |\boldsymbol{r}| \to \infty, \tag{271}$$

and

$$\boldsymbol{e}_z \cdot \operatorname{curl}\left(\frac{\boldsymbol{J}}{\hat{a}}\right) + h_3(x,y,0) = \omega, \tag{272}$$

$$\operatorname{div}(g\boldsymbol{J}) = 0, \tag{273}$$

with

$$\boldsymbol{J} \cdot \boldsymbol{\nu} = 0 \quad \text{on} \quad \partial D. \tag{274}$$

However, so far $\omega = 0$ is a solution for all applied magnetic fields. What we are missing is the condition of nucleation of vortices at the boundary ∂D. Vortices will be nucleated once the current reaches the nucleation value J_{nucl}, but if $J_{nucl} < J_c$, they will not move until the current reaches this higher depinning value. Thus in addition to (263) we must also impose

$$|\boldsymbol{J}| \le J_c \quad \text{on } \partial D. \tag{275}$$

Now in three dimensions in regions where $\omega = 0$, taking the curl of (225) shows that $|\boldsymbol{J}|$ takes its maximum value on the boundary. If this is true for the thin-film model (272) also, then we can replace (262)–(265) with

$$\omega \boldsymbol{v} = m\boldsymbol{J} \wedge \boldsymbol{e}_z, \tag{276}$$

$$|\boldsymbol{J}| \le J_c, \qquad m \ge 0, \qquad m\,(|\boldsymbol{J}| - J_c) = 0. \tag{277}$$

Streamfunction formulation. Using (273) we may introduce a streamfunction ψ such that

$$\boldsymbol{J} = \frac{1}{g}\,(\psi_y, -\psi_x, 0)\,. \tag{278}$$

Then $\boldsymbol{v}$ is in the direction of $-\nabla\psi$, so we may set

$$\omega \boldsymbol{v} = -m\nabla\psi, \tag{279}$$

giving

$$\frac{\partial \omega}{\partial t} = \operatorname{div}(m\nabla\psi), \tag{280}$$

$$-\nabla\cdot\left(\frac{1}{\hat{a}g}\nabla\psi\right) + h_3(x,y,0) = \omega, \tag{281}$$

with the constraints

$$|\nabla\psi| \le gJ_c, \qquad m \ge 0, \qquad m\,(|\nabla\psi| - gJ_c) = 0. \tag{282}$$

These equations are coupled to (267)–(271) for Λ order one.

In a virgin sample in an increasing magnetic field there will be a region in the interior, D_1 say, which vortices have not yet reached, and a region around the boundary, $D_2 = D\backslash D_1$ say, in which the current is equal to the critical value.

In a strip $-l < x < l$, with $\hat{a} = 1$ and J_c constant, and with D_1 given by $-s < x < s$, this gives

$$\frac{\partial J_2}{\partial x} + h_3(x,0) = 0 \quad \text{for } |x| < s, \tag{283}$$

$$J_2 = J_c \quad \text{for } -l < x < -s, \tag{284}$$

$$J_2 = -J_c \quad \text{for } s < x < l, \tag{285}$$

with J_2 continuous at $x = \pm s$, and

$$\omega = 0 \quad \text{for } |x| < s, \tag{286}$$

$$\omega = h_3(x,0) \quad \text{for } s < |x| < l, \tag{287}$$

where

$$h_3(x,0) - h_{app,3}(x,0) = \frac{1}{\pi}\int_{-l}^{l} \frac{gJ_2(\bar{x})}{2\Lambda(\bar{x}-x)}\,d\bar{x}. \tag{288}$$

5.2. Limiting cases. As $\Lambda \to \infty$ the problems for the current decouples from the problem for the magnetic field, since, as usual, $h_3(x,y,0)$ in (281) is simply replaced by $h_{app,3}(x,y,0)$. Then we have

$$\frac{\partial \omega}{\partial t} = \operatorname{div}(m\nabla\psi), \tag{289}$$

$$-\nabla\cdot\left(\frac{1}{\hat{a}g}\nabla\psi\right) + h_{app,3} = \omega, \tag{290}$$

with the constraints

$$|\nabla\psi| \le gJ_c, \qquad m \ge 0, \qquad m\,(|\nabla\psi| - gJ_c) = 0. \tag{291}$$

In this limit with $g = 1$ the free-boundary problem (283)–(285) gives

$$J_2 = J_c \quad \text{for } -L < x < -s, \tag{292}$$

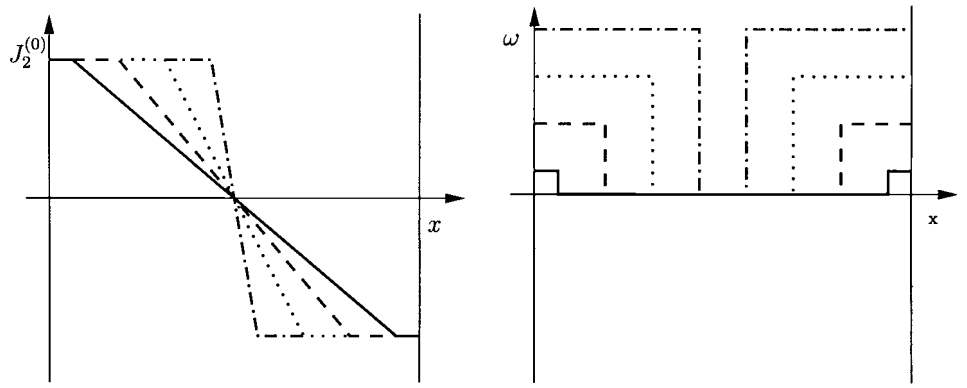
$$J_2 = -h_{app,3}x \quad \text{for } -s < x < s, \tag{293}$$

$$J_2 = -J_c \quad \text{for } s < x < L, \tag{294}$$

$$s = \frac{J_c}{h_{app,3}}, \tag{295}$$

with

$$\omega = 0 \quad \text{for } |x| < s, \tag{296}$$



(a) (b)

FIG. 6. *Solutions of the thin-film critical-state model in a thin strip in the limit* $\Lambda \to \infty$.

$$\omega = h_{app,3}(x, y, 0) \quad \text{for } s < |x| < l. \tag{297}$$

These solutions are plotted in Figure 6 for an increasing applied magnetic field $h_{app,3}$.

For comparison, the corresponding solutions for a two-dimensional critical-state model in a slab are

$$J_2 = J_c \quad \text{for } -L < x < -s, \tag{298}$$

$$J_2 = 0 \quad \text{for } -s < x < s, \tag{299}$$

$$J_2 = -J_c \quad \text{for } s < x < L, \tag{300}$$

$$s = l - \frac{h_{app,3}}{J_c}, \tag{301}$$

with

$$\omega = 0 \quad \text{for } |x| < s, \tag{302}$$

$$\omega = J_c(x - s) \quad \text{for } s < x < l, \tag{303}$$

$$\omega = -J_c(x + s) \quad \text{for } -l < x < -s, \tag{304}$$

which are shown in Figure 7.

In the second limit, $\Lambda \to 0$, we must again scale $\boldsymbol{J}$ with Λ to give

$$\operatorname{curl} \boldsymbol{h} = \boldsymbol{J}_{ext}, \tag{305}$$

$$\operatorname{div} \boldsymbol{h} = 0, \tag{306}$$

with

$$[\boldsymbol{e}_z \wedge \boldsymbol{h}] = (\psi_y, -\psi_x, 0) \quad \text{for} \quad (x, y) \in D, \tag{307}$$

$$[\boldsymbol{e}_z \cdot \boldsymbol{h}] = 0, \tag{308}$$

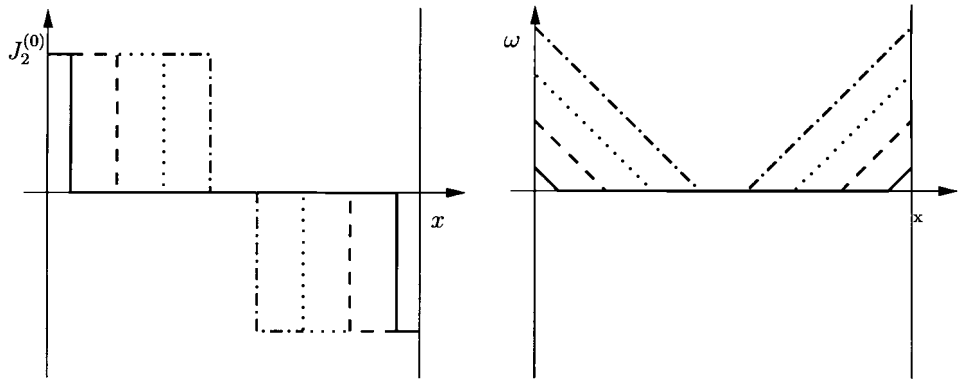
$$\boldsymbol{h} \to \boldsymbol{h}_{ext} \quad \text{as} \quad |\boldsymbol{r}| \to \infty, \tag{309}$$

$$h_3(x, y, 0) = \omega. \tag{310}$$

$$\frac{\partial \omega}{\partial t} = \operatorname{div}(m \nabla \psi), \tag{311}$$

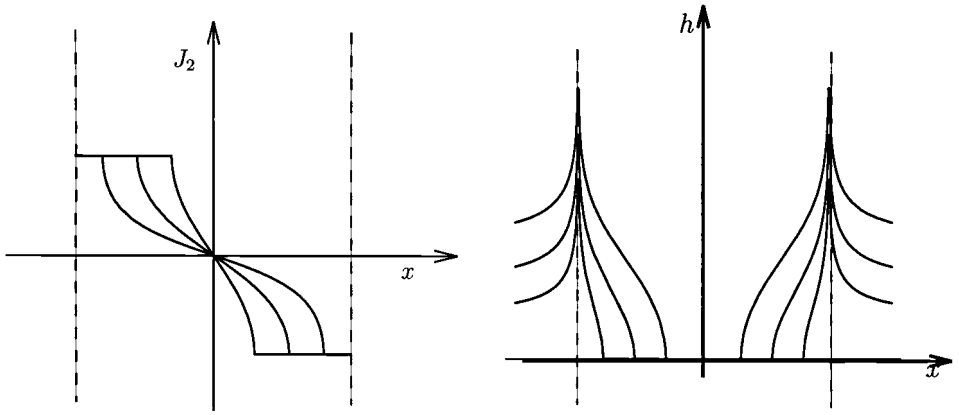
with the constraints

$$|\nabla \psi| \le g J_c, \qquad m \ge 0, \qquad m\,(|\nabla \psi| - g J_c) = 0. \tag{312}$$



(a) (b)

FIG. 7. *Solutions of the two-dimensional critical-state model in a slab.*



(a) (b)

FIG. 8. *Solutions of the thin-film critical-state model in a thin strip in the limit* $\Lambda \to 0$.

In this case with $g = 1$ the free-boundary problem (283)–(285) becomes

$$h_3(x,0) = h_{app,3} + \frac{1}{\pi}\int_{-l}^{l} \frac{J_2(\bar{x})}{2(\bar{x}-x)}\, d\bar{x} = 0 \quad \text{for } |x| < s, \tag{313}$$

$$J_2 = J_c \quad \text{for } -l < x < -s, \tag{314}$$

$$J_2 = -J_c \quad \text{for } s < x < l. \tag{315}$$

This problem has been considered previously in [4, 10, 29, 31]. Solutions are plotted in Figure 8. Note that the magnetic field tends to infinity as $x \to \pm l$; there is an inner region of width Λ in which the problems for $\boldsymbol{J}$ and $\boldsymbol{h}$ are coupled again and which regularizes the magnetic field.

In both [4] and [31] field and current profiles are calculated for superconducting strips in an applied field, with an applied current, and with both an applied field and

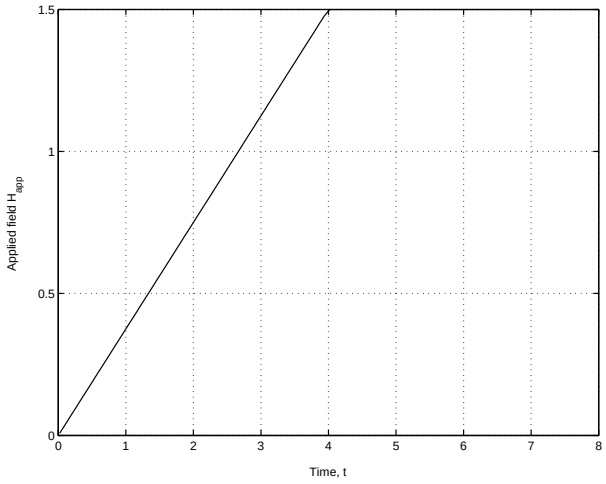


FIG. 9. *Variation of the applied magnetic field with time for the simulations shown in Figures* 10 *and* 11.

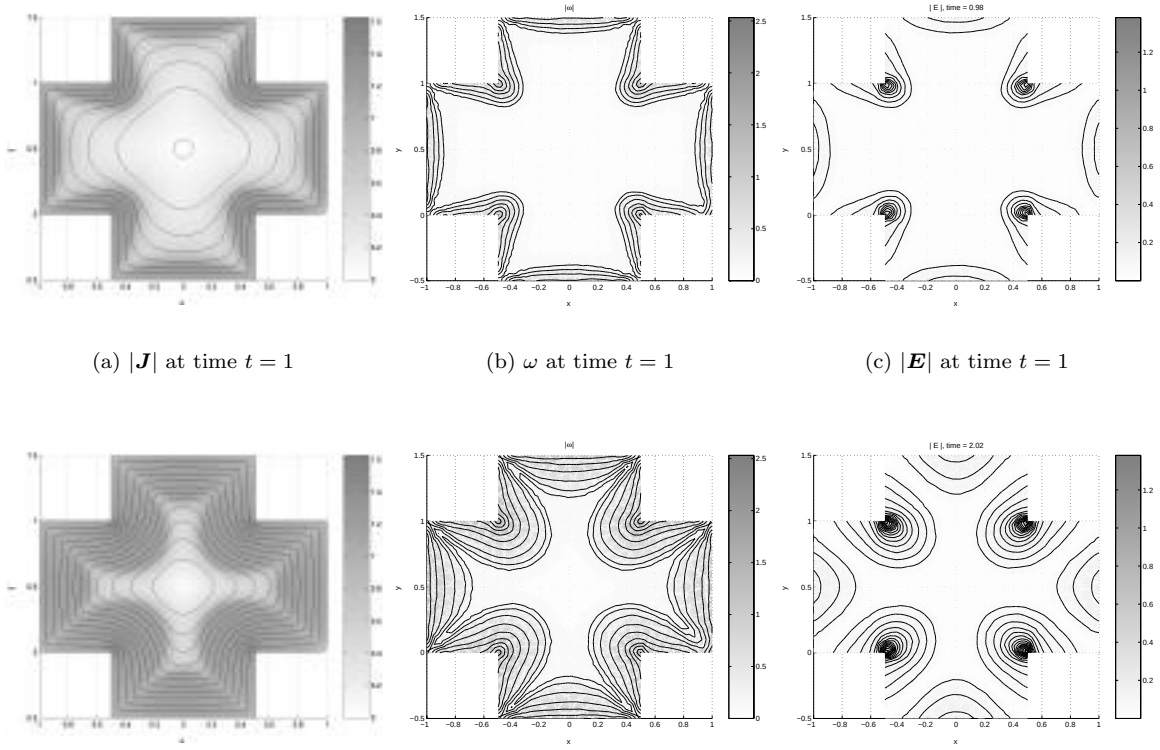
an applied transport current. In [29] the theoretical profiles are compared with experimentally measured profiles of the magnetic field distribution in a superconducting slab in an applied magnetic field, and the agreement is shown to be good. Schuster et al. also consider experimentally the effects of inhomogeneous pinning. If the critical current is lower in the center of a sample than it is at the outside, there can be a sudden jump in the free boundary as the applied magnetic field reaches a critical value. This effect is also examined in [20], where its implications for the flux flow regime under an applied current are considered.

In [29] the profiles of magnetic field distribution on a square film in an applied field are measured experimentally, and in [28] the profiles on a film in the shape of a cross are measured experimentally and calculated theoretically, using a power-law dependence of $\boldsymbol{E}$ on $\boldsymbol{J}$. In [20] field and current distributions for general two-dimensional films are calculated numerically in both the critical state and flux flow regimes (using general vortex velocity laws as well as general nonlinear Ohm's laws), both with an applied magnetic field and a transport current. This work also includes the heating effect of the electric field coupled with an equation for the evolution of temperature, with temperature dependent critical fields and vortex mobilities, but a discussion of this extension is beyond the scope of the present paper.

The solutions for a cross in an increasing applied magnetic field are reproduced in Figure 10. The field is ramped up from zero to 1.5 over 4 time units and then held fixed until the sample reaches steady state, as illustrated in Figure 9. Figure 10 shows the current, vorticity, and electric field at times $t = 1$, 2, 3, and 4. Figure 11 shows the current and vorticity in the steady state which is reached at about $t = 8$ (the electric field is zero in steady state). In Figures 10(a), (d), (g), (j) and 11(a) the shading shows the magnitude of the current density and the lines show the direction of current flow. In the other figures the lines are contour lines of constant ω or $|\boldsymbol{E}|$.

The vortices enter first at the reentrant corners of the cross, and this is where the electric field is largest. In the thermal problem the heating at these points may significantly affect the solution.



(a) $|\boldsymbol{J}|$ at time $t = 1$ (b) ω at time $t = 1$ (c) $|\boldsymbol{E}|$ at time $t = 1$

6. Conclusion. We have developed a hierarchy of models of superconducting thin films, allowing for a spatially varying film thickness and a spatially varying equilibrium density of superconducting electrons.

We began with the Ginzburg–Landau model, where we found that the canonical scaling was to let $\epsilon = d/L \to 0$ with $\Xi = \xi/L$ and $\Lambda = \lambda_{\text{eff}}/L = \lambda^2/dL$ fixed, where λ_{eff} is the effective screening length. This corresponds to letting the Ginzburg–Landau parameter $\kappa = \lambda/\xi$ tend to zero like $\epsilon^{1/2}$. The London limit of this model, in which vortices appear as δ-function singularities, corresponds to the limit in which the increased Ginzburg–Landau parameter $\kappa_{\text{eff}} = \Lambda/\Xi = \lambda\kappa/d \to \infty$, in contrast to bulk superconductors, where it corresponds to the limit $\kappa \to \infty$. This explains why thin films of even type-I superconductors will exhibit vortex solutions when the thickness becomes smaller than the penetration depth.

Following on from the London limit we considered the situation in which the vortex separation tends to zero and the vortices can be averaged to produce a vortex density.

Finally we considered critical state models, in which the pinning potential is homogenized to give stick/slip mobility laws.

In each case we found that a key parameter is $\Lambda = \lambda^2/Ld$. If this parameter is order one, corresponding to a lateral film dimension of the same order as the effective screening length λ_{eff}, then the problems for the electric current in the film and the magnetic field outside it are coupled. If this parameter is large, then the applied magnetic field passes straight through the film to leading order, and the problem for the current inside the film is decoupled. If Λ is small, then the model also simplifies, since then the vorticity in the film determines the magnetic field, which subsequently determines the current in the film.

Our hierarchy contains one or two models which have appeared elsewhere in the literature. The thin-film limit of the Ginzburg–Landau equations was considered in [8], but in the limit $d/L \to 0$ with ξ and λ fixed. Thus the model they obtained corresponds to the limit $\Lambda \to \infty$.

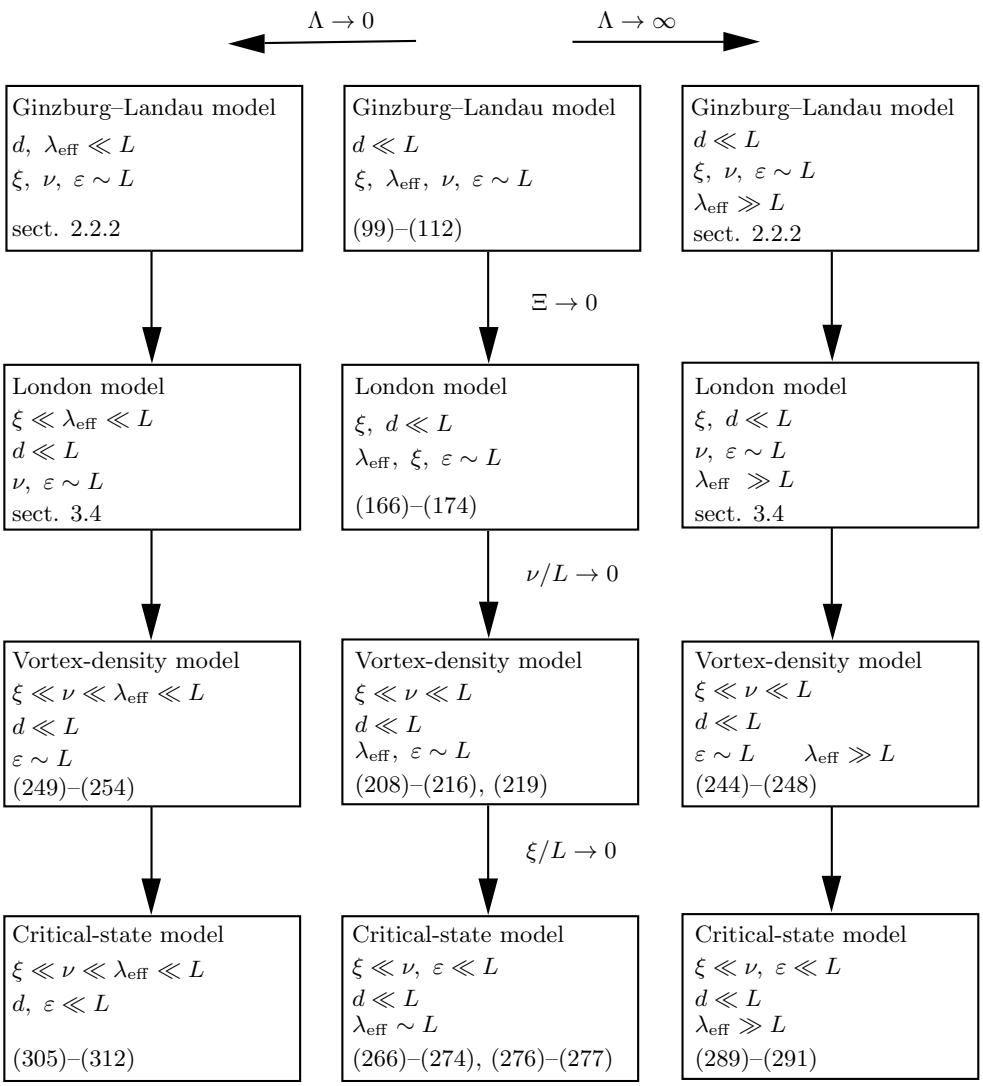

FIG. 12. *The hierarchy of models for superconducting thin films. Recall that* $\Xi = \xi/L$ *and* $\Lambda = \lambda_{\text{eff}}/L$. *Numbers refer to equation numbers in the text. The lengthscales are defined in Table* 1.

The London model for uniform strips in the absence of vortices was considered in [16] and independently for variable thickness films in two lateral dimensions with vortices in [10, 21].

The thin-film critical-state model has been considered in [29] and [31]. However, because they took the thin-film limit of the bulk critical state model, in which λ had already been set to zero, their model corresponds to the $\Lambda \to 0$ limit.

A summary of the hierarchy of models we have derived is shown in Figure 12, with a summary of the definitions of the various lengthscales in Table 1.

Acknowledgments. The first author would like to thank Andrew Grief for many useful discussions, for identifying errors in a preliminary version of this manuscript,

IMAGE SEGMENTATION USING ACTIVE CONTOURS: CALCULUS OF VARIATIONS OR SHAPE GRADIENTS?*

GILLES AUBERT†, MICHEL BARLAUD‡, OLIVIER FAUGERAS§, AND STÉPHANIE JEHAN-BESSON‡

Abstract. We consider the problem of segmenting an image through the minimization of an energy criterion involving region and boundary functionals. We show that one can go from one class to the other by solving Poisson's or Helmholtz's equation with well-chosen boundary conditions. Using this equivalence, we study the case of a large class of region functionals by standard methods of the calculus of variations and derive the corresponding Euler–Lagrange equations. We revisit this problem using the notion of a shape derivative and show that the same equations can be elegantly derived without going through the unnatural step of converting the region integrals into boundary integrals. We also define a larger class of region functionals based on the estimation and comparison to a prototype of the probability density distribution of image features and show how the shape derivative tool allows us to easily compute the corresponding Gâteaux derivatives and Euler–Lagrange equations. Finally we apply this new functional to the problem of regions segmentation in sequences of color images. We briefly describe our numerical scheme and show some experimental results.

Key words. image segmentation, region segmentation, active contours, active regions, image statistics, region functionals, boundary functionals, calculus of variations, shape optimization, shape gradient, Euler–Lagrange equations, Gâteaux derivative, Parzen window estimation, level set methods

1. Introduction.

Many problems in image processing, such as segmentation, tracking, or classification, can be cast in the framework of optimization theory, e.g., as the minimization of some energy measure. The energy is often some combination of region or boundary functionals. The minimization is usually not trivial, and many methods have been developed to reach an optimum which may be only local.

We address here the problem of the optimization of region or boundary functionals with the method of active contours. Active contours have been introduced by Kass, Witkin and Terzopoulos [34] and were originally boundary methods. Snakes [34], balloons [10], or geodesic active contours [4] are driven towards the edges of an image through the minimization of a boundary integral of functions of features depending on edges. Active contours driven by region functionals in addition to boundary functionals have appeared later. Introduced by [11] and [43], they have been further developed in [52, 5, 9, 38, 39, 40, 41, 21, 51] and [31, 33]. In effect, the use of active contours for the optimization of a criterion including both region and boundary functionals appears to be really powerful.

In general, features of the image region to be segmented, tracked, etc., ... are embedded in region functionals while the boundary functional allows smoothness and

regularity of the region boundary. The basic principle is to construct a parabolic partial differential equation (PDE) from the energy criterion, e.g., by computing some sort of Euler–Lagrange equations; this PDE changes the shape of the current curve according to some velocity field which can be thought of as a direction of descent of the energy criterion. Given a closed curve enclosing an initial region one then computes the solution of this PDE for this initial condition. The corresponding family of curves decreases the energy criterion and converges toward a (local) minimum of the criterion hopefully corresponding to the objects to be segmented. To compute such a PDE, several methods have been proposed.

Some authors do not compute the theoretical expression of the velocity field (basically the gradient of the energy criterion) but choose a deformation of the curve that will make the criterion decrease [5, 9] (they compute a direction of descent). Other authors [52, 39, 41] compute the theoretical expression of the velocity vector from the Euler–Lagrange equations. The computation is performed in three main steps. First, region integrals representing region functionals are transformed into boundary integrals using the Green–Riemann theorem. Second, the corresponding Euler–Lagrange equations are derived and used to define a dynamic scheme to evolve the initial region. Another alternative is to keep the region formulation to compute the gradient of the energy criterion with respect to the region boundary instead of reducing region integrals to boundary integrals. In [21], the authors propose computing the derivative of the criterion while taking into account the discontinuities across the contour. In [31, 33] the computation of the evolution equation is achieved through shape derivation principles.

This computation becomes more involved when global information about regions is present in the energy criterion, the so-called region-dependent case. It happens, for example, when statistical features of a region such as, for example, the mean or the variance of the intensity are involved in the minimization. This case has been studied in [6, 7, 20, 21, 31, 33, 51]. In [31, 33] the authors show that the minimization of functionals involving region-dependent features induces additional terms in the evolution equation of the active contour that are important in practice. These additional terms are easily computed thanks to shape derivation tools.

In this article we clarify the relationships between the boundary and region functionals that arise naturally in several image processing tasks. We show in section 3 that one can go from one to the other by solving Poisson's equation with Dirichlet conditions or Helmholtz's equation with Neumann conditions.

We then concentrate on the problem of finding local minima of a large class of region functionals. In section 4 we first transform them into boundary functionals and apply methods from the calculus of variations to compute the corresponding Gâteaux derivatives and construct a velocity field on the region boundary. This field defines a PDE whose solution for a given initial boundary condition defines a one-parameter family of regions which, in practice, converges towards a local minimum of the functional. The problem of the existence and uniqueness of a solution to this PDE is not addressed in this article.

We next change our point of view and rederive the same equations in a simpler and more natural way, i.e., without going through the trouble of turning region integrals into boundary integrals; this is achieved in section 5 by applying shape derivation methods [49, 22]. This line of approach has already been followed in [46] in his work on the estimation of the optical flow.

We then turn in section 6 our attention to a new class of region-based functionals

by considering histograms of image features. The shape derivation tools allow us to easily derive the velocity field that defines the evolution of the region boundary.

Section 7 is devoted to an application of the previous methods to the problem of region segmentation with a given color histogram in a sequence of images. Our experimental results show that the technique indeed has some interesting potentials.

2. Problem statement. In many image processing problems, the issue is to find a set of image regions that minimize a given error criterion. This criterion is often a combination of region and boundary functionals.

A local minimizer for such a criterion including both region and boundary functionals is usually hard to compute. This is mostly due to the fact that the set of image regions, i.e., the set of regular open domains in $\mathbb{R}^n$ (whose boundary is a closed, C^2 manifold), does not have a structure of vector space, preventing us from using in a straightforward fashion gradient descent methods. In order to circumvent this difficulty, calculus of variations and shape optimization techniques can be brought to bear on the problem. The basic idea is to use them in order to derive a PDE that will drive the boundary of an initial region toward a local minimum of the error criterion. The key point is to compute the velocity vector at each point of the boundary at each time instant. In this paper we propose a framework for achieving these goals in a number of practically important cases.

To fix ideas in the two-dimensional case, the evolving boundary, or active contour, is modeled by a parametric curve $\Gamma(s,\tau) = (x_1(s,\tau), x_2(s,\tau))$, where s may be its arc-length and τ is an evolution parameter—the time. The active contour is then driven by the following PDE:

$$\Gamma_\tau \stackrel{def}{=} \frac{\partial \Gamma(s,\tau)}{\partial \tau} = \mathbf{v} \qquad \text{with} \quad \Gamma(\tau = 0) = \Gamma_0, \tag{2.1}$$

where Γ_0 is an initial curve defined by the user and $\mathbf{v}$ the velocity vector of $\Gamma(s,\tau)$. This velocity is the unknown that must be derived from the error criterion so that the solution $\Gamma(.,\tau)$ converges towards a curve achieving a local minimum and thus, hopefully, towards the boundary of the object to segment as $\tau \to \infty$.

2.1. Boundary and region functionals. Let us now define more precisely the region and boundary functionals. Let $\mathcal{U}$ be a class of domains (open, regular bounded sets, i.e., C^2) of $\mathbb{R}^n$ and Ω an element of $\mathcal{U}$ of boundary $\partial\Omega$, which we sometimes denote Γ. A boundary functional, J_b, may be expressed as a boundary integral of some scalar function g of image features:

$$J_b(\partial\Omega) = \int_{\partial\Omega} g(\mathbf{x})\, d\mathbf{a}(\mathbf{x}), \tag{2.2}$$

where $\partial\Omega$ is the boundary of the region and $d\mathbf{a}$ its area element. The derivation of this boundary functional is classical [4, 35] and leads to the following velocity vector:

$$\mathbf{v}_b = [g(\mathbf{x})\kappa - \nabla g(\mathbf{x}) \cdot \mathbf{N}]\, \mathbf{N},$$

where $\mathbf{N}$ is the inward unit normal vector of Γ and κ its mean curvature. The idea is to use a local parametrization of Γ to reduce (2.2) to a standard problem in the calculus of variations.

A region functional, J_r, may be expressed as an integral in a domain Ω of $\mathcal{U}$ of some function f of some region features:

$$J_r(\Omega) = \int_\Omega f(\mathbf{x}, \Omega) d\mathbf{x}. \tag{2.3}$$

In that case, the computation of the velocity vector for (2.1) is not as easy. We propose comparing two main approaches. The first approach is based upon the idea of transforming all functionals into boundary functionals, thereby reducing (through a local parametrization of the boundary) the problem of minimization to a standard problem in the calculus of variations from which the computation of the Gâteaux derivatives follows. The second approach is based upon the use of shape derivation tools. In a sense it is more natural since it keeps the region representation.

Note that the scalar function f in (2.3) is generally region-dependent. This is important since this dependency on the region must be taken into account when searching for a local minimum of the functional, as discussed in later sections.

Also note that we could have added a dependency of g on $\partial\Omega$, i.e., write $g(\mathbf{x}, \partial\Omega)$ in (2.2), to keep the symmetry with the region functional. This is not necessary since the results in section 4.2, in particular Theorem 4.6, do in fact provide an answer for this case.

2.2. Examples of such optimization problems in image processing. An image is represented by its intensity $I(\mathbf{x})$ defined on some region of $\mathbb{R}^n$.

Active contours were originally introduced to search for minima of boundary functionals. In [4, 35], the function g is a function of the magnitude of the image gradient through a strictly decreasing function $\varphi : [0, +\infty[\to \mathbb{R}^+$ such that $\varphi(r) \to 0$ as $r \to +\infty$. Hence $g(\mathbf{x}) = \varphi(|\nabla I(\mathbf{x})|)$. The minimization amounts to the minimization of the length of a curve in a Riemannian space. Local minima are obtained via the steepest descent method.

Region functionals have also been introduced. The region information is embedded in the function f of (2.3). These functionals have been used for many applications such as moving objects detection [38, 40, 30, 32], image segmentation [5, 21, 7, 39, 40, 51], or classification [52, 44, 45, 41]. For example, people have used statistical features such as the mean or the variance of a region Ω:

$$\begin{cases} \mu_\Omega & = \frac{1}{|\Omega|} \int_\Omega I(\mathbf{x}) d\mathbf{x} \quad \text{with} \quad |\Omega| = \int_\Omega d\mathbf{x}, \\ \sigma^2_\Omega & = \frac{1}{|\Omega|} \int_\Omega (I(\mathbf{x}) - \mu_\Omega)^2 d\mathbf{x}. \end{cases}$$

We use these two examples to motivate the introduction of a general region functional

$$J_r(\Omega) = \int_\Omega f(\mathbf{x}, G_1(\Omega), G_2(\Omega), \ldots, G_m(\Omega))\, d\mathbf{x}, \tag{2.4}$$

where the functionals G_i are given by

$$G_i(\Omega) = \int_\Omega H_i(\mathbf{x}, \Omega)\, d\mathbf{x}, \quad i = 1 \ldots m. \tag{2.5}$$

As shown in this equation, the function H_i is itself region-dependent; more precisely,

$$H_i(\mathbf{x}, \Omega) \stackrel{def}{=} H_i(\mathbf{x}, K_{i1}(\Omega), K_{i2}(\Omega), \ldots, K_{il_i}(\Omega)), \tag{2.6}$$

where

$$K_{ij}(\Omega) = \int_\Omega L_{ij}(\mathbf{x})\ d\mathbf{x}, \quad j = 1 \ldots l_i \quad i = 1 \ldots m. \tag{2.7}$$

Note that we have stopped the process at the second level but it could conceivably continue. We have chosen this special case of dependency because it often arises in applications, as shown in the next two sections. The various methods that we develop can be extended in a fairly straightforward fashion to more complicated situations if needed; see, for example, section 6.

2.3. An example involving the mean. Let us choose

$$f(\mathbf{x}, \Omega) = \varrho(I(\mathbf{x}) - \mu_\Omega), \tag{2.8}$$

where $\varrho : \mathbf{R} \to \mathbf{R}^+$ is a positive function of class C^1. f is region-dependent. This is an example where the process described in the previous section stops at the first level:

$$J(\Omega) \;=\; \int_\Omega f(\mathbf{x}, \Omega)\, d\mathbf{x} \;=\; \int_\Omega \varrho(I(\mathbf{x}) \,-\, \mu_\Omega)\, d\mathbf{x} \;=\; \int_\Omega \varrho\left(I(\mathbf{x}) - \frac{G_1(\Omega)}{G_2(\Omega))}\right) d\mathbf{x},$$

where

$$G_1(\Omega) = \int_\Omega H_1(\mathbf{x}, \Omega)\, d\mathbf{x} \quad \text{with} \quad H_1(\mathbf{x}, \Omega) = I(\mathbf{x})\,,$$
$$G_2(\Omega) = \int_\Omega H_2(\mathbf{x}, \Omega)\, d\mathbf{x} \quad \text{with} \quad H_2(\mathbf{x}, \Omega) = 1\,.$$

In this case, the functions H_i, $i = 1, 2$, do not depend on the region Ω, $l_1 = l_2 = 0$, and $K_{ij}(\mathbf{x}) = 0$ for all i, j.

2.4. An example involving the variance. Let us take an example where we stop the process at the second level. Consider the case where the function f is a function of the variance given by

$$f(\mathbf{x}, \Omega) = \varrho(\sigma^2_\Omega). \tag{2.9}$$

$\varrho : \mathbf{R}^+ \to \mathbf{R}^+$ is of class C^1. We write

$$J(\Omega) = \int_\Omega f(\mathbf{x}, \Omega)\, d\mathbf{x} = \int_\Omega \varrho(\sigma^2_\Omega)\, d\mathbf{x} = \int_\Omega \varrho\left(\frac{G_1(\Omega)}{G_2(\Omega))}\right) d\mathbf{x}\,.$$

Therefore we have

$$G_1(\Omega) = \int_\Omega H_1(\mathbf{x}, \Omega)\, d\mathbf{x}\,, \quad H_1(\mathbf{x}, \Omega) = (I(\mathbf{x}) - \mu_\Omega)^2\,,$$
$$G_2(\Omega) = \int_\Omega H_2(\mathbf{x}, \Omega)\, d\mathbf{x}\,, \quad H_2(\mathbf{x}, \Omega) = 1\,,$$

with

$$H_1(\mathbf{x}, \Omega) = \left(I(\mathbf{x}) - \frac{K_{11}}{K_{12}}\right)^2\,, \quad l_1 = 2,$$
$$H_2(\mathbf{x}, \Omega) = 1\,, \quad l_2 = 0\,,$$

and finally

$$K_{11}(\Omega) = \int_\Omega I(\mathbf{x})\, d\mathbf{x}\,, \quad L_{11}(\mathbf{x}) = I(\mathbf{x})\,,$$
$$K_{12}(\Omega) = \int_\Omega d\mathbf{x}\,, \quad L_{12}(\mathbf{x}) = 1\,.$$

3. Expression of region functionals as boundary functionals and vice versa. In this section, we show that a region functional may always be expressed as a boundary functional and vice versa.

3.1. Tranformation of region functionals into boundary functionals. Consider the region functional (2.3); the next proposition shows that, under some reasonable assumptions on the function f, it can always be turned into a boundary functional (2.2).

PROPOSITION 3.1. *Let Ω be a bounded open set with regular boundary $\partial\Omega$. Let $f : \overline{\Omega} \to \mathbb{R}$ be a continuous function and u be the unique solution of Poisson's equation:*

$$\left\{ \begin{array}{rcll} -\Delta u & = & f & in \quad \Omega, \\ u_{|\partial\Omega} & = & 0. & \end{array} \right.$$

We have the following equality:

$$\int_\Omega f(\mathbf{x}, \Omega)\, d\mathbf{x} = \int_{\partial\Omega} \nabla u \cdot \mathbf{N}\, d\mathbf{a}(\mathbf{x}),$$

where $\mathbf{N}$ is the inside pointing unit normal to $\partial\Omega$ and $d\mathbf{a}(\mathbf{x})$ its area element.

Proof. Because of our assumptions, Poisson's equation has a unique classical, i.e., C^2, solution in $\overline{\Omega}$ [2, 25], and we have

$$\int_\Omega f(\mathbf{x}, \Omega)\, d\mathbf{x} = -\int_\Omega \Delta u\, d\mathbf{x} = \int_{\partial\Omega} \nabla u \cdot \mathbf{N}\, d\mathbf{a}(\mathbf{x}),$$

the last equality being a consequence of the Green–Riemann theorem. □

A region functional can always be expressed as a boundary functional, via the solution of Poisson's equation with Dirichlet conditions.

3.2. Tranformation of boundary functionals into region functionals. The converse of Proposition 3.1 is also true. Let us consider the boundary functional (2.2).

PROPOSITION 3.2. *Let Ω be a bounded open set with regular boundary $\partial\Omega$. Let u be the unique solution of Helmholtz's equation:*

$$\left\{ \begin{array}{rcll} -\Delta u + u & = & 0 & in \quad \Omega, \\ \frac{\partial u}{\partial \mathbf{N}}{}_{|\partial\Omega} & = & -g. & \end{array} \right.$$

Then we have the following equality:

$$\int_{\partial\Omega} g(\mathbf{x})\, d\mathbf{a}(\mathbf{x}) = \int_\Omega u(\mathbf{x}, \Omega)\, d\mathbf{x},$$

where $d\mathbf{a}(\mathbf{x})$ is the area element of $\partial\Omega$.

Proof. Because of our assumptions, Helmholtz's equation has a unique classical, i.e., C^2, solution in $\overline{\Omega}$ [42, 13, 14, 15, 16, 17, 18], and we have

$$\int_\Omega u\, d\mathbf{x} = \int_\Omega \Delta u\, d\mathbf{x} = -\int_{\partial\Omega} \nabla u \cdot \mathbf{N}\, d\mathbf{a}(\mathbf{x}),$$

the last equality being a consequence of the Green–Riemann theorem. Therefore

$$\int_\Omega u\, d\mathbf{x} = -\int_{\partial\Omega} \frac{\partial u}{\partial \mathbf{N}}\, d\mathbf{a}(\mathbf{x}) = \int_{\partial\Omega} g(\mathbf{x})\, d\mathbf{a}(\mathbf{x}). \qquad \square$$

A boundary functional can always be expressed as a region functional, via the solution of Helmholtz's equation with Neumann boundary conditions.

4. Computation of the evolution equation using a boundary approach. Originally, the derivation of region functionals has been performed by using the Green–Riemann theorem to transform region functionals into boundary functionals and then by computing the Euler–Lagrange equations. In this section, we recall the principles of the derivation and we explicitly take into account the case of region-dependent features when computing the Gâteaux derivative. Region functionals are transformed into boundary functionals by using Proposition 3.2. The region functional to minimize is (2.3).

The computation of a velocity field for the evolution of the boundary in order to reach a minimum of the error criterion proceeds in three main steps:

1. Tranformation of the region functionals into boundary functionals.
2. Computation of the Gâteaux derivatives of the boundary functionals.
3. Construction of a velocity field for the evolution of the boundary.

The first step can always be performed as it has been proven in Proposition 3.1.

The computation of an optimal velocity field is carried out for region-independent features first, i.e., when the function f does not depend on Ω. We then consider the more general case where f has some region dependency. We derive our results in the two-dimensional case; the generalization to any dimension is tedious but straightforward.

4.1. Region-independent features. In this part, we detail the three steps for region-independent features. We do it for two-dimensional images ($n = 2$) to keep notation simple, but the results hold in any dimension greater than 2.

We parameterize $\partial\Omega$ through the C^2 function $\Gamma : [0,1] \to \mathbb{R}^2$ such that when p varies from 0 to 1 we go once around $\partial\Omega$ counterclockwise. The unit tangent vector to $\partial\Omega$ is the vector $\Gamma'(p)/|\Gamma'(p)|$, where $'$ indicates the derivative with respect to the parameter p. The inside pointing normal $\mathbf{N}$ is the vector $\Gamma'^{\perp}(p)/|\Gamma'(p)|$. The vector $\Gamma'^{\perp}$ is obtained by rotating Γ' by 90 degrees counterclockwise; hence if $\Gamma' = [\Gamma'_1, \Gamma'_2]^T$, $\Gamma'^{\perp} = [-\Gamma'_2, \Gamma'_1]^T$.

4.1.1. Transformation of region functionals into boundary functionals. The following proposition is a straightforward consequence of Proposition 3.1

PROPOSITION 4.1. *If f satisfies the hypotheses of Proposition* 3.1*, the functional* (2.3)*,*

$$J_r(\Omega) = \int_\Omega f(\mathbf{x})\, d\mathbf{x},$$

is equal to

$$\Phi(\Gamma) = \int_0^1 \left(u_{x_2}(\Gamma(p))\Gamma'_1(p) - u_{x_1}(\Gamma(p))\Gamma'_2(p)\right)\, dp \stackrel{def}{=} \int_0^1 \varphi(\Gamma(p), \Gamma'(p))\, dp, \tag{4.1}$$

where $\Gamma = \partial\Omega$ and u is the unique classical solution of

$$\left\{ \begin{array}{rcll} -\Delta u & = & f & in \quad \Omega, \\ u_{|\partial\Omega} & = & 0. & \end{array} \right.$$

Therefore minimizing (2.3) *with respect to Ω is equivalent to minimizing* (4.1) *with respect to Γ.*

Proof. According to Proposition 3.1, we have

$$\int_\Omega f(\mathbf{x})\, d\mathbf{x} = -\int_\Omega \Delta u\, d\mathbf{x} = \int_{\partial\Omega} \nabla u \cdot \mathbf{N}\, d\mathbf{a}(\mathbf{x}),$$

and since $d\mathbf{a}(\mathbf{x}) = |\Gamma'(p)|dp$, the result follows. ∎

4.1.2. Computation of the Gâteaux derivative. According to Proposition 4.1, minimizing (2.3) with respect to Ω is equivalent to minimizing (4.1) with respect to Γ. Thus, we have to compute the Gâteaux derivative of the functional Φ.

THEOREM 4.2. *The Gâteaux derivative in the direction γ of the functional Φ is*

$$\langle \Phi'(\Gamma), \gamma \rangle = -\int_0^1 f(\Gamma(p))\,(\Gamma'^{\perp}(p) \cdot \gamma(p))\,dp.$$

Proof. Let $\gamma : [0,1] \to \mathbf{R}^2$ be a C^2 parametrization of an arbitrary closed curve. The Gâteaux derivative of $\Phi(\Gamma)$ in the direction γ noted $\langle \Phi'(\Gamma), \gamma \rangle >$ is defined by

$$\langle \Phi'(\Gamma), \gamma \rangle = \lim_{\tau \to 0} \frac{\Phi(\Gamma + \tau\gamma) - \Phi(\Gamma)}{\tau}.$$

We have

$$\lim_{\tau \to 0} \frac{\Phi(\Gamma + \tau\gamma) - \Phi(\Gamma)}{\tau} = \int_0^1 (\varphi_\Gamma(\Gamma(p), \Gamma'(p))\gamma(p) + \varphi_{\Gamma'}(\Gamma(p), \Gamma'(p))\gamma'(p))\ dp,$$

where $\varphi_\Gamma = \frac{\partial \varphi}{\partial \Gamma}(\Gamma, \Gamma')$. Integrating by parts, we obtain the following expression for the Gâteaux derivative:

$$\langle \Phi'(\Gamma), \gamma \rangle = \int_0^1 \left(\varphi_\Gamma(\Gamma(p), \Gamma'(p)) - \frac{d}{dp}\varphi_{\Gamma'}(\Gamma(p), \Gamma'(p)) \right) \cdot \gamma(p)\,dp.$$

We then explicitly compute the derivative of φ with respect to Γ using (4.1),

$$\varphi_\Gamma = \nabla u_{x_2}(\Gamma(p))\Gamma_1'(p) - \nabla u_{x_1}(\Gamma(p))\Gamma_2'(p),$$

and with respect to Γ',

$$\varphi_{\Gamma'} = [u_{x_2}, -u_{x_1}]^T.$$

Therefore

$$\frac{d}{dp}\varphi_{\Gamma'} = [\nabla u_{x_2} \cdot \Gamma', -\nabla u_{x_1} \cdot \Gamma']^T.$$

Putting everything together we obtain

$$\varphi_\Gamma - \frac{d}{dp}\varphi_{\Gamma'} = \Delta u \Gamma'^{\perp} = -f\,\Gamma'^{\perp}$$

thanks to Proposition 4.1. ∎

The Euler–Lagrange equations associated with the Gâteaux derivative are thus given by

$$\varphi_\Gamma - \frac{d}{dp}\varphi_{\Gamma'} = -f(\Gamma(p))\Gamma'^{\perp}.$$

An interesting point to note is that the intermediary function u disappears.

4.1.3. Construction of an optimal velocity vector for the evolution of an active contour. In order to find a local extremum of the criterion (4.1), we evolve a curve using the steepest descent method, starting from an initial curve defined by the user. Thus, we obtain the following evolution equation:

$$\frac{\partial \Gamma}{\partial \tau} = f(\Gamma)\mathbf{N} \quad \text{with} \quad \Gamma(\tau = 0) = \Gamma_0. \tag{4.2}$$

This is the classical result [52, 38, 40, 51] when f has no region dependency. Let us now consider the more general case where the function f has some region dependency.

4.2. General case. Let us now derive the evolution equation in the general case. As in the previous case, we follow our three steps.

4.2.1. Transformation of the region functional into a boundary functional. In the following, to simplify the proofs and the notations, we take $m = 1$ and $l_1 = 1$ and drop the indexes. The equations for $m > 1$ and $l_i \geq 1$ are then given without proof.

Because of the form of (2.4)–(2.7), we have to go through three levels of transformations. We start with the first level and the following proposition.

PROPOSITION 4.3. *If L satisfies the assumptions of Proposition* 3.1*, the functional*

$$K(\Omega) = \int_\Omega L(\mathbf{x})\, d\mathbf{x}$$

is equal to

$$\begin{aligned}\Theta(\Gamma) &= \int_0^1 (u_{x_2}(\Gamma(p), L(\Gamma))\Gamma_1'(p) - u_{x_1}(\Gamma(p), L(\Gamma))\Gamma_2'(p))\ dp \\ &\stackrel{def}{=} \int_0^1 \theta(\Gamma(p), \Gamma'(p))\, dp,\end{aligned}$$

where $\Gamma = \partial\Omega$ and u is the unique classical solution of

$$\left\{ \begin{array}{rcll} -\Delta u & = & L & in \quad \Omega, \\ u_{|\partial\Omega} & = & 0. & \end{array} \right.$$

Proof. The proof is identical to that of Proposition 4.1. □

In the same manner, for the second level, we have the following proposition.

PROPOSITION 4.4. *If H satisfies the assumptions of Proposition* 3.1*, the functional*

$$G(\Omega) = \int_\Omega H(\mathbf{x}, K(\Omega))\, d\mathbf{x}$$

with $K(\Omega) = \int_\Omega L(\mathbf{x})d\mathbf{x}$ is equal to

$$\begin{aligned}\Psi(\Gamma) &= \int_0^1 (v_{x_2}(\Gamma(p), \Theta(\Gamma))\Gamma_1'(p) - v_{x_1}(\Gamma(p), \Theta(\Gamma))\Gamma_2'(p))\ dp \\ &\stackrel{def}{=} \int_0^1 \psi(\Gamma(p), \Gamma'(p), \Theta(\Gamma))\, dp,\end{aligned}$$

where $\Gamma = \partial\Omega$ and v is the unique classical solution of

$$\left\{ \begin{array}{rcll} -\Delta v & = & H & in \quad \Omega, \\ v_{|\partial\Omega} & = & 0. & \end{array} \right.$$

Θ is given by Proposition 4.3*.*

Proof. The proof is identical to that of Proposition 4.1. □

We finally reach the third and last level with the following proposition.

PROPOSITION 4.5. *If f satisfies the assumptions of Proposition* 3.1*, the functional*

$$J(\Omega) = \int_\Omega f(\mathbf{x}, G(\Omega))\, d\mathbf{x}\,, \tag{4.3}$$

with $G(\Omega) = \int_\Omega H(\mathbf{x}, K(\Omega))d\mathbf{x}$ *and* $K(\Omega) = \int_\Omega L(\mathbf{x})d\mathbf{x}$*, is equal to*

$$\begin{aligned}\Phi(\Gamma) &= \int_0^1 (w_{x_2}(\Gamma(p), \Psi(\Gamma))\Gamma_1'(p) - w_{x_1}(\Gamma(p), \Psi(\Gamma))\Gamma_2'(p))\, dp \\ &\stackrel{def}{=} \int_0^1 \varphi(\Gamma(p), \Gamma'(p), \Psi(\Gamma))\, dp,\end{aligned} \tag{4.4}$$

where $\Gamma = \partial\Omega$ *and* u *is the unique classical solution of*

$$\begin{cases} -\Delta w &= f \quad in \quad \Omega, \\ w_{|\partial\Omega} &= 0. \end{cases}$$

$\Psi(\Gamma)$ *is given by Proposition* 4.4. *Therefore minimizing* (4.3) *with respect to* Ω *is equivalent to minimizing* (4.4) *with respect to* Γ.

Proof. The proof is identical to that of Proposition 4.1. ∎

4.2.2. Computation of the Gâteaux derivative. According to Proposition 4.5, minimizing (4.3) with respect to Ω is equivalent to minimizing (4.4) with respect to Γ. Thus we compute the Gâteaux derivative of Φ given by (4.4).

THEOREM 4.6. *The Gâteaux derivative in the direction* γ *of the functional* Φ *defined in* (4.4) *is*

$$\begin{aligned}\langle \Phi'(\Gamma), \gamma\rangle = -\int_0^1 [&f(\Gamma(p), \Psi(\Gamma)) + AH(\Gamma(p), \Theta(\Gamma)) \\ &+ ABL(\Gamma(p))]\, q(p)\, dp,\end{aligned}$$

where

$$A = \int_\Omega f_G(x, G(\Omega))\, d\mathbf{x} \quad and \quad B = \int_\Omega H_K(x, K(\Omega))\, d\mathbf{x}$$

with $f_G = \frac{\partial f}{\partial G}$*, and* $q(p) = (\Gamma'^{\perp}(p) \cdot \gamma(p))$.

Proof. The Gâteaux derivative of $\Phi(\Gamma)$ in the direction γ denoted $\langle \Phi'(\Gamma), \gamma\rangle$ is given by

$$\langle \Phi'(\Gamma), \gamma\rangle = \lim_{\tau\to 0} \frac{\Phi(\Gamma + \tau\gamma) - \Phi(\Gamma)}{\tau}.$$

We have

$$\begin{aligned}&\lim_{\tau\to 0} \frac{\Phi(\Gamma + \tau\gamma) - \Phi(\Gamma)}{\tau} \\ &\quad = \int_0^1 (\varphi_\Gamma(\Gamma(p), \Gamma'(p), \Psi(\Gamma))\gamma(p) + \varphi_{\Gamma'}(\Gamma(p), \Gamma'(p), \Psi(\Gamma))\gamma'(p))\, dp \\ &\qquad + \int_0^1 \varphi_\Psi(\Gamma(p), \Gamma'(p), \Psi(\Gamma))\langle \Psi'(\Gamma), \gamma\rangle\, dp,\end{aligned}$$

where $\varphi_\Psi = \frac{\partial \varphi}{\partial \Psi}(\Gamma, \Gamma', \Psi)$. Integrating by parts, we obtain

$$\begin{aligned}\langle \Phi'(\Gamma), \gamma\rangle = &\int_0^1 \left[\varphi_\Gamma - \frac{d}{dp}\varphi_{\Gamma'}\right]\gamma(p)\, dp \\ &+ \int_0^1 \varphi_\Psi(\Gamma(p), \Gamma'(p), \Psi(\Gamma))\langle \Psi'(\Gamma), \gamma\rangle\, dp.\end{aligned} \tag{4.5}$$

According to Theorem 4.2, we obtain $\varphi_\Gamma - \frac{d}{dp}\varphi_{\Gamma'} = -f\,\Gamma'^{\perp}$. The Gâteaux derivative of $\Psi(\Gamma)$ in the direction γ is computed in the same manner and we find

$$\begin{aligned}\langle \Psi'(\Gamma), \gamma\rangle = &- \int_0^1 H(\Gamma(p), \Theta(\Gamma))\, q(p)\, dp \\ &+ \int_0^1 \psi_\Theta(\Gamma(p), \Gamma'(p), \Theta(\Gamma))\langle \Theta'(\Gamma), \gamma\rangle\, dp.\end{aligned}$$

According to Theorem 4.2, the Gâteaux derivative of $\Theta(\Gamma)$ in the direction γ is given by:

$$\langle \Theta'(\Gamma), \gamma\rangle = - \int_0^1 L(\Gamma(p))\, q(p)\, dp.$$

Putting all terms together in (4.5), we find the following expression for the derivative:

$$\begin{aligned}\langle \Phi'(\Gamma), \gamma\rangle = &- \int_0^1 f(\Gamma(p), \Psi(\Gamma))\, q(p)\, dp \\ &- \int_0^1 \varphi_\Psi(\Gamma(p), \Gamma'(p), \Psi(\Gamma))dp \int_0^1 H(\Gamma(p), \Theta(\Gamma))\, q(p)\, dp \\ &- \int_0^1 \varphi_\Psi(\Gamma(p), \Gamma'(p), \Psi(\Gamma))dp \int_0^1 \psi_\Theta(\Gamma(p), \Gamma'(p), \Theta(\Gamma))\, dp \int_0^1 L(\Gamma(p))\, q(p)\, dp.\end{aligned}$$

Using Propositions 4.4 and 4.5, we find that

$$\int_0^1 \varphi_\Psi(\Gamma(p), \Gamma'(p), \Psi(\Gamma))dp = \int_\Omega f_G(\mathbf{x}, G(\Omega))d\mathbf{x} \stackrel{def}{=} A.$$

Similarly, using Propositions 4.3 and 4.4, we obtain

$$\int_0^1 \psi_\Theta(\Gamma(p), \Gamma'(p), \Theta(\Gamma))dp = \int_\Omega H_K(\mathbf{x}, K(\Omega))d\mathbf{x} \stackrel{def}{=} B.$$

The equation of the derivative is obtained:

$$\langle \Phi'(\Gamma), \gamma\rangle = - \int_0^1 \left[f(\Gamma(p), \Psi(\Gamma)) + A\, H(\Gamma(p), \Theta(\Gamma)) + A\, B\, L(\Gamma(p))\right]\, q(p)\, dp. \qquad \square$$

The Euler–Lagrange equations associated with the Gâteaux derivative are given by

$$-\left[f(\Gamma(p), \Psi(\Gamma)) + AH(\Gamma(p), \Theta(\Gamma)) + ABL(\Gamma(p))\right]\Gamma'^{\perp} = 0.$$

Note again that the intermediate functions u, v, and w do not appear in this expression.

We can now state the general theorem for $m > 1$ and $l_i \geq 1$.

THEOREM 4.7. *The Gâteaux derivative in the direction γ of the functional J*

defined in (2.4) *is*

$$\langle \Phi'(\Gamma), \gamma \rangle = -\int_0^1 \left(f(\Gamma(p), G_1(\Gamma), \ldots, G_m(\Gamma)) + \sum_{i=1}^{m} A_i H_i(\Gamma(p), K_{i1}(\Gamma), \ldots, K_{il_i}(\Gamma)) + \sum_{i=1}^{m} A_i \left(\sum_{j=1}^{l_i} B_{ij} L_{ij}(\Gamma(p)) \right) \right) (\Gamma'^{\perp}(p) \cdot \gamma(p))\, dp,$$

where

$$A_i = \int_\Omega f_{G_i}(x, G_1(\Omega), \ldots, G_m(\Omega))\, d\mathbf{x}, \quad i = 1 \ldots m,$$

$$\textit{and} \quad B_{ij} = \int_\Omega H_{iK_{ij}}(x, K_{i1}(\Omega), \ldots, K_{il_i}(\Omega))\, d\mathbf{x}, \quad i = 1 \ldots m, \quad j = 1 \ldots l_i.$$

4.2.3. Construction of an optimal velocity vector for the evolution of an active contour. In the general case, according to Theorem 4.7 the steepest gradient descent method yields the following evolution equation for the active contour:

$$\frac{\partial \Gamma}{\partial \tau} = \left[f(\Gamma) + \sum_{i=1}^{m} A_i H_i(\Gamma) + \sum_{i=1}^{m} A_i \left(\sum_{j=1}^{l_i} B_{ij} L_{ij}(\Gamma) \right) \right] \mathbf{N} \tag{4.6}$$

with $\Gamma(\tau = 0) = \Gamma_0$. Compared with (4.2), some additional terms appear that come from the region dependency of the descriptors.

5. Computation of the derivative using shape derivation tools, or "how to keep a region formulation." In the previous part, region functionals were first transformed into boundary functionals for the computation of the derivative. This step is neither natural nor straightforward. Therefore, we propose another solution based on shape derivation tools [49, 22]. The region formulation is maintained for the computation and this provides a suitable way of obtaining the derivative of the criterion and the evolution equation of an active contour.

We perform three main steps:

1. Introduction of a dynamic scheme. Since the set of all image regions is not a vector space, it is difficult to compute the derivative of the criterion with respect to the domain Ω. To circumvent this problem, we apply a family of transformations T_τ, indexed by a real parameter $\tau \geq 0$, to Ω, and we denote $\Omega(\tau) = T_\tau(\Omega)$. The region functional becomes a function of τ, $J(\tau) \stackrel{def}{=} J(\Omega(\tau))$.
2. Derivation of the criterion based on shape derivation principles. The error criterion $J(\tau)$ is then derived with respect to τ using shape derivation principles.
3. Computation of the evolution equation from the derivative. From the derivative, we deduce the velocity field of the active contour that will make it evolve towards a local minimum of the error criterion.

5.1. Introduction of transformations. As it has already been pointed out, the optimization of the region functional (2.3) is difficult since the set of regular domains (regular open bounded sets) $\mathcal{U}$ of $\mathbb{R}^n$ does not have the structure of a vector space. Variations of a domain must then be defined in some way. Let us consider a reference domain $\Omega \in \mathcal{U}$ and the set $\hat{\mathcal{A}}$ of applications $T : \Omega \to \mathbb{R}^n$, which are at least as regular as homeomorphisms (i.e., one to one with T and T^{-1} continuous). We define

$$\hat{\mathcal{A}} = \left\{T \text{ one to one}, T, T^{-1} \in W^{1,\infty}(\Omega, \mathbb{R}^n)\right\},$$

where

$$W^{1,\infty}(\Omega, \mathbb{R}^n) = \{T : \Omega \to \mathbb{R}^n \text{ such that } T \in L^\infty(\Omega, \mathbb{R}^n) \text{ and } \partial_i T \in L^\infty(\Omega, \mathbb{R}^n),\ i = 1, \ldots, n\}.$$

Given a shape function $F : \mathcal{U} \to \mathbf{R}^+$ for $T \in \hat{\mathcal{A}}$, let us define $\hat{F}(T) = F(T(\Omega))$. The key point is that $W^{1,\infty}(\Omega, \mathbb{R}^n)$ is a Banach space. This allows us to define the notion of derivative with respect to the domain Ω as follows.

DEFINITION 5.1. *F is Gâteaux differentiable with respect to Ω if and only if $\hat{F}$ is Gâteaux differentiable with respect to T.*

In order to compute Gâteaux derivatives with respect to T we introduce a family of deformation $(T(\tau))_{\tau \geq 0}$ such that $T(\tau) \in \hat{\mathcal{A}}$ for $\tau \geq 0$, $T(0) = \mathrm{Id}$, and $T(.) \in C^1([0, A]; W^{1,\infty}(\Omega, \mathbb{R}^n))$, $A > 0$. From a practical point of view, there are many ways to construct such a family. The most famous one is the Hadamard deformation [27].

For a point $\mathbf{x} \in \Omega$, we denote

$$\mathbf{x}(\tau) = T(\tau, \mathbf{x}) \quad \text{with} \quad T(0, \mathbf{x}) = \mathbf{x},$$
$$\Omega(\tau) = T(\tau, \Omega) \quad \text{with} \quad T(0, \Omega) = \Omega.$$

Let us now define the velocity vector field $\mathbf{V}$ corresponding to $T(\tau)$ as

$$\mathbf{V}(\tau, \mathbf{x}) = \frac{\partial T}{\partial \tau}(\tau, \mathbf{x}) \quad \forall \mathbf{x} \in \Omega \ \ \forall \tau \geq 0.$$

5.2. Computation of the derivative using shape derivation tools. We now introduce three main definitions.

DEFINITION 5.2. *The Gâteaux derivative of $J(\Omega) = \int_\Omega f(\mathbf{x}, \Omega) d\mathbf{x}$ in the direction of $\mathbf{V}$, denoted $\langle J'(\Omega), \mathbf{V}\rangle$, is equal to*

$$\langle J'(\Omega), \mathbf{V}\rangle = \lim_{\tau \to 0} \frac{J(\Omega(\tau)) - J(\Omega)}{\tau}.$$

DEFINITION 5.3. *The material derivative of $f(\mathbf{x}, \Omega)$, denoted $f_m(\mathbf{x}, \Omega, \mathbf{V})$, is equal to*

$$f_m(\mathbf{x}, \Omega, \mathbf{V}) = \lim_{\tau \to 0} \frac{f(\mathbf{x}(\tau), \Omega(\tau)) - f(\mathbf{x}, \Omega)}{\tau}.$$

DEFINITION 5.4. *The shape derivative of $f(\mathbf{x}, \Omega)$, denoted $f_s(\mathbf{x}, \Omega, \boldsymbol{V})$, is equal to*

$$f_s(\mathbf{x}, \Omega, \mathbf{V}) = \lim_{\tau \to 0} \frac{f(\mathbf{x}, \Omega(\tau)) - f(\mathbf{x}, \Omega)}{\tau}.$$

5.2.1. Relation between the Gâteaux derivative and the shape derivative. The following theorem gives a relation between the Gâteaux derivative and the shape derivative for the region functional (2.3). The proof can be found in [49, 22], we provide an elementary one here for completeness.

THEOREM 5.5. *The Gâteaux derivative of the functional* $J(\Omega) = \int_\Omega f(\mathbf{x}, \Omega)\, d\mathbf{x}$ *in the direction of* $\mathbf{V}$ *is the following:*

$$\langle J'(\Omega), \mathbf{V}\rangle = \int_\Omega f_s(\mathbf{x}, \Omega, \mathbf{V}) d\mathbf{x} - \int_{\partial\Omega} f(\mathbf{x}, \Omega)(\mathbf{V}(\mathbf{x}) \cdot \boldsymbol{N}(\mathbf{x})) d\mathbf{a}(\mathbf{x}),$$

where $\boldsymbol{N}$ *is the unit inward normal to* $\partial\Omega$ *and* $d\mathbf{a}$ *its area element.*

Proof. As far as the computation of the derivative is concerned, only small deformations are relevant, and we thus consider a first order Taylor expansion of the transformation:

$$\begin{aligned} T(\tau, \mathbf{x}) &= T(0, \mathbf{x}) + \tau \frac{\partial T}{\partial \tau}(0, \mathbf{x}) \\ &= \mathbf{x} + \tau \mathbf{V}(\mathbf{x}), \end{aligned}$$

where $\mathbf{V}(\mathbf{x}) = \frac{\partial T}{\partial \tau}(0, \mathbf{x})$.

We obtain the following expressions for the material and the shape derivatives:

$$\begin{aligned} f_m(\mathbf{x}, \Omega, \mathbf{V}) &= \lim_{\tau \to 0} \frac{f(\mathbf{x} + \tau \mathbf{V}(\mathbf{x}), \Omega + \tau \mathbf{V}) - f(\mathbf{x}, \Omega)}{\tau}, \\ f_s(\mathbf{x}, \Omega, \mathbf{V}) &= \lim_{\tau \to 0} \frac{f(\mathbf{x}, \Omega + \tau \mathbf{V}) - f(\mathbf{x}, \Omega)}{\tau}. \end{aligned}$$

If we assume that $\lim_{\tau \to 0} \nabla f(\mathbf{x}, \Omega + \tau \mathbf{V}) = \nabla f(\mathbf{x}, \Omega)$, we can write

$$f_m(\mathbf{x}, \Omega, \mathbf{V}) = f_s(\mathbf{x}, \Omega, \mathbf{V}) + \nabla f(\mathbf{x}, \Omega) \cdot \mathbf{V}(\mathbf{x}). \tag{5.1}$$

We are now ready for the computation of the Gâteaux derivative of $J(\Omega)$ in the direction of $\mathbf{V}$. We have

$$\frac{J(\Omega(\tau)) - J(\Omega)}{\tau} = \frac{1}{\tau} \left[\int_{\Omega(\tau)} f(\mathbf{x}, \Omega(\tau)) d\mathbf{x} - \int_\Omega f(\mathbf{x}, \Omega) d\mathbf{x} \right]. \tag{5.2}$$

In the first integral, we make the change of variable $\mathbf{x} \to \mathbf{x} + \tau \mathbf{V}(\mathbf{x})$ which yields

$$\int_{\Omega(\tau)} f(\mathbf{x}, \Omega(\tau)) d\mathbf{x} = \int_\Omega f(\mathbf{x} + \tau \mathbf{V}(\mathbf{x}), \Omega + \tau \mathbf{V})| \det J_\tau(\mathbf{x})| d\mathbf{x},$$

where $J_\tau(\mathbf{x})$ is the Jacobian matrix,

$$J_\tau(\mathbf{x}) = \begin{pmatrix} 1 + \tau \frac{\partial V_1}{\partial x_1} & \cdots & \tau \frac{\partial V_1}{\partial x_n} \\ \vdots & \vdots & \vdots \\ \tau \frac{\partial V_n}{\partial x_1} & \cdots & 1 + \tau \frac{\partial V_n}{\partial x_n} \end{pmatrix},$$

$\mathbf{V}(\mathbf{x}) = [V_1(\mathbf{x}), \ldots, V_n(\mathbf{x})]^T$, and $\mathbf{x} = [x_1, \ldots, x_n]^T$. It follows that

$$\det J_\tau(\mathbf{x}) = 1 + \tau \mathrm{div}(\mathbf{V}(\mathbf{x})) + o(\tau).$$

This shows that if τ is small enough, $\det J_\tau(\mathbf{x}) > 0$ and

$$\lim_{\tau\to 0} \frac{\det J_\tau(\mathbf{x}) - 1}{\tau} = \operatorname{div}(\mathbf{V}(\mathbf{x})).$$

Equation (5.2) can now be rewritten as

$$\begin{aligned}\frac{J(\Omega(\tau)) - J(\Omega)}{\tau} &= \int_\Omega \frac{f(\mathbf{x}+\tau\mathbf{V}(\mathbf{x}), \Omega+\tau\mathbf{V}) - f(\mathbf{x},\Omega)}{\tau} \det(J_\tau(\mathbf{x}))d\mathbf{x} \\ &\quad - \int_\Omega f(\mathbf{x},\Omega)\ \frac{\det(J_\tau(\mathbf{x})) - 1}{\tau}\ d\mathbf{x} \stackrel{def}{=} I_1 - I_2.\end{aligned}$$

If τ goes to 0, using (5.1) and Definitions 5.3 and 5.4, we get

$$\begin{aligned}\lim_{\tau\to 0} I_1 &= \int_\Omega f_m(\mathbf{x},\Omega,\mathbf{V})d\mathbf{x} \\ &= \int_\Omega f_s(\mathbf{x},\Omega,\mathbf{V})d\mathbf{x} + \int_\Omega \nabla f(\mathbf{x},\Omega)\cdot\mathbf{V}(\mathbf{x})d\mathbf{x}, \\ \lim_{\tau\to 0} I_2 &= \int_\Omega f(\mathbf{x},\Omega)\operatorname{div}(\mathbf{V}(\mathbf{x}))d\mathbf{x}.\end{aligned}$$

We find that the Gâteaux derivative is given by

$$\begin{aligned}\langle J'(\Omega), \mathbf{V}\rangle &= \int_\Omega f_s(\mathbf{x},\Omega,\mathbf{V})d\mathbf{x} + \int_\Omega (\nabla f(\mathbf{x},\Omega)\cdot\mathbf{V}(\mathbf{x}) + f(\mathbf{x},\Omega)\operatorname{div}(\mathbf{V}(\mathbf{x})))d\mathbf{x} \\ &= \int_\Omega f_s(\mathbf{x},\Omega,\mathbf{V})d\mathbf{x} + \int_\Omega \operatorname{div}(f(\mathbf{x},\Omega)\ \mathbf{V}(\mathbf{x}))d\mathbf{x}.\end{aligned} \tag{5.3}$$

Applying the Green–Riemann theorem in (5.3), we finally obtain

$$\langle J'(\Omega), \mathbf{V}\rangle = \int_\Omega f_s(\mathbf{x},\Omega,\mathbf{V})d\mathbf{x} - \int_{\partial\Omega} f(\mathbf{x},\Omega)(\mathbf{V}(\mathbf{x})\cdot\mathbf{N}(\mathbf{x}))d\mathbf{a}(\mathbf{x}),$$

where $\mathbf{N}$ is the unit inward normal to $\partial\Omega$. □

Note that Theorem 5.5 provides a necessary condition for a domain $\hat{\Omega}$ to be an extremum of $J(\Omega)$:

$$\int_{\hat{\Omega}} f_s(\mathbf{x},\hat{\Omega},\mathbf{V})d\mathbf{x} - \int_{\partial\hat{\Omega}} f(\mathbf{x},\hat{\Omega})(\mathbf{V}(\mathbf{x})\cdot\mathbf{N}(\mathbf{x}))\, d\mathbf{a}(\mathbf{x}) = 0 \quad \forall\mathbf{V}.$$

5.3. Construction of the velocity vector of the active contour from the Gâteaux derivative. We now make good use of the previous tools to derive the velocity vector of the active contour for the same functionals as those which were considered in section 5. As expected we find the same results but in a way which, we feel, is more natural, since we do not have to turn a region integral into a boundary one, and simpler. The evolving region boundary $\partial\Omega$, denoted Γ, is modeled as an active contour: the user defines an initial curve $\Gamma_0 = \partial\Omega_0$ that evolves towards a local minimum of the region functional (2.3) according to a PDE that we will now derive.

5.3.1. Region-independent features. We first consider the simple case where the function f does not depend on Ω, i.e., $f = f(\mathbf{x})$. In that case, the shape derivative f_s is equal to zero and the Gâteaux derivative of J is simply (Theorem 5.5)

$$\langle J'(\Omega), \mathbf{V}\rangle = -\int_{\partial\Omega} f(\mathbf{x})(\mathbf{V}(\mathbf{x})\cdot\boldsymbol{N}(\mathbf{x}))d\mathbf{a}(\mathbf{x}).$$

This leads to the following evolution equation for region-independent descriptors:

$$\frac{\partial \Gamma}{\partial \tau} = f(\Gamma)\mathbf{N}$$

with $\Gamma(\tau = 0) = \Gamma_0$.

We notice that, as expected, the evolution equation is the same as (4.2) in section 4.

5.3.2. General case. Let us now tackle the same general case as in section 4.2, using the functional defined by (2.4)–(2.7). We similarly restrict the computation of the Gâteaux derivative of J to the case $m = 1$ and $l_i = 1$, state the result for $m > 1$ and $l_i \geq 1$, and drop the indexes.

THEOREM 5.6. *The Gâteaux derivative in the direction of* $\mathbf{V}$ *of the functional* J *defined in* (4.3) *is*

$$\langle J'(\Omega), \mathbf{V} \rangle = -\int_\Gamma \left(A\, B\, L(\mathbf{x}) + A\, H(\mathbf{x}, K(\Omega)) + f(\mathbf{x}, \Omega)\right) (\mathbf{V}(\mathbf{x}) \cdot \mathbf{N}(\mathbf{x})) d\mathbf{a}(\mathbf{x}),$$

where

$$A = \int_\Omega f_G(x, G(\Omega))\, d\mathbf{x} \quad \textit{and} \quad B = \int_\Omega H_K(x, K(\Omega))\, d\mathbf{x}.$$

Proof. According to Theorem 5.5, we have

$$\langle J'(\Omega), \mathbf{V} \rangle = \int_\Omega f_s \; d\mathbf{x} - \int_\Gamma f \; (\mathbf{V} \cdot \mathbf{N}) d\mathbf{a}(\mathbf{x}).$$

Let us first compute the shape derivative of f. From the chain rule we get

$$f_s(\mathbf{x}, \Omega, \mathbf{V}) = f_G(\mathbf{x}, G) \langle G'(\Omega), \mathbf{V} \rangle, \tag{5.4}$$

where f_G denotes the partial derivative of the function f with respect to its second argument.

Next we compute the Gâteaux derivative of G in the direction of $\mathbf{V}$. We again apply Theorem 5.5, and we get

$$\langle G'(\Omega), \mathbf{V} \rangle = \int_\Omega H_s \; d\mathbf{x} - \int_\Gamma H \; (\mathbf{V} \cdot \mathbf{N}) d\mathbf{a}(\mathbf{x}).$$

Plugging this into (5.4), we obtain

$$\int_\Omega f_s \, d\mathbf{x} = A \left(\int_\Omega H_s \; d\mathbf{x} - \int_\Gamma H (\mathbf{V} \cdot \mathbf{N}) d\mathbf{a}(\mathbf{x}) \right),$$

where

$$A = \int_\Omega f_G(\mathbf{x}, G(\Omega)) \; d\mathbf{x}.$$

We also compute the shape derivative of H through Theorem 5.5:

$$H_s(\mathbf{x}, \Omega, \mathbf{V}) = H_K(\mathbf{x}, K) \langle K'(\Omega), \mathbf{V} \rangle.$$

We continue with the Gâteaux derivative of K in the direction of $\mathbf{V}$:

$$\langle K'(\Omega), \mathbf{V}\rangle = \int_\Omega L_s \; d\mathbf{x} - \int_\Gamma L(\mathbf{x})(V(\mathbf{x}) \cdot \mathbf{N}(\mathbf{x}))d\mathbf{a}(\mathbf{x}).$$

Since L does not depend on Ω, we obtain $L_s = 0$ and we are done.

Putting all terms together, we obtain the complete expression of the Gâteaux derivative of J:

$$\langle J'(\Omega), \mathbf{V}\rangle = -\int_\Gamma \left(A\,B\,L(\mathbf{x}) + A\,H(\mathbf{x}, K(\Omega)) + f(\mathbf{x}, \Omega)\right)\,(\mathbf{V}(\mathbf{x}) \cdot \mathbf{N}(\mathbf{x}))d\mathbf{a}(\mathbf{x})$$

with $B = \int_\Omega H_K(\mathbf{x}, K)\, d\mathbf{x}$. □

The general case follows easily and is stated in the following theorem.

THEOREM 5.7. *The Gâteaux derivative in the direction of* $\mathbf{V}$ *of the functional* J *defined in* (2.4) *is*

$$\langle J'(\Omega), \mathbf{V}\rangle = -\int_\Gamma \left(\sum_{i=1}^{m} A_i \sum_{j=1}^{l_i}(B_{ij}\, L_{ij}(\mathbf{x})) + \sum_{i=1}^{m}(A_i\, H_i) + f\right)\,(\mathbf{V}(\mathbf{x})) \cdot \mathbf{N}(\mathbf{x})d\mathbf{a}(\mathbf{x}),$$

where

$$A_i = \int_\Omega f_{G_i}(x, G_1(\Omega), \ldots, G_m(\Omega))\, d\mathbf{x}, \quad i = 1 \ldots m,$$

$$\textit{and} \quad B_{ij} = \int_\Omega H_{iK_{ij}}(x, K_{i1}(\Omega), \ldots, K_{il_i}(\Omega))\, d\mathbf{x}, \quad i = 1 \ldots m, \quad j = 1 \ldots l_i.$$

From the Gâteaux derivative of J, we deduce the corresponding evolution equation:

$$\frac{\partial \Gamma}{\partial \tau} = \left[f(\Gamma) + \sum_{i=1}^{m} A_i H_i(\Gamma) + \sum_{i=1}^{m} A_i \left(\sum_{j=1}^{l_i} B_{ij} L_{ij}(\Gamma)\right)\right] \mathbf{N}, \tag{5.5}$$

which, as expected, is identical to (4.6). As far as the final result is concerned, the two methods of computation are equivalent.

5.4. Application. Let us now apply this method to the first example in section 2.3. The function f is given by (2.8). The corresponding functions G_i, H_i are given in section 2.3. We need the terms $A_j, j = 1, 2$:

$$\begin{cases} A_1 &= -\int_\Omega \frac{1}{G_2}\; \varrho'\left(I(\mathbf{x}) - \frac{G_1}{G_2}\right)\, d\mathbf{x} = \frac{-1}{|\Omega|}\int_\Omega \varrho'(I - \mu_\Omega)d\mathbf{x}, \\ A_2 &= \int_\Omega \frac{G_1}{(G_2)^2}\; \varrho'\left(I(\mathbf{x}) - \frac{G_1}{G_2}\right)\, d\mathbf{x} = \frac{\mu_\Omega}{|\Omega|}\int_\Omega \varrho'(I - \mu_\Omega)d\mathbf{x}. \end{cases}$$

Since the terms H_i are not region-dependent, the terms B_{ij} are equal to zero. The velocity vector of the active contour is then the following:

$$\frac{\partial \Gamma(\tau)}{\partial \tau} = \left[\; f - \frac{(I - \mu_\Omega)}{|\Omega|}\int_\Omega \varrho'(I - \mu_\Omega)d\mathbf{x}\;\right]\; \mathbf{N}.$$

In this example, the additional term coming from the region dependency of f is equal to $\frac{(I-\mu_\Omega)}{|\Omega|}\int_\Omega \varrho'(I-\mu_\Omega)d\mathbf{x}$. Note that in the particular case of $\varrho(r) = r^2$, this additional

term is equal to zero [6, 7, 20, 21]. However, in the general case, the additional term is not nul.

Let us apply this method to the second example in section 2.4. The function f is a function of the variance given by (2.9). The corresponding functions G_i, H_i, K_{ij}, and L_{ij} are also given in section 2.4. We need the terms $A_j, j = 1, 2$:

$$\left\{ \begin{array}{rcl} A_1 & = & \int_\Omega \frac{1}{G_2}\ \varrho'\left(\frac{G_1}{G_2}\right) d\mathbf{x} = \varrho'(\sigma^2_\Omega), \\ A_2 & = & -\int_\Omega \frac{G_1}{(G_2)^2}\ \varrho'\left(\frac{G_1}{G_2}\right) d\mathbf{x} = -\sigma^2_\Omega\ \varrho'(\sigma^2_\Omega). \end{array} \right.$$

The terms B_{ij} are given by

$$\left\{ \begin{array}{l} B_{11} = \int_\Omega H_{1K_{11}}(x, K_{11}, K_{12}) = -2\frac{1}{|\Omega|}\int_\Omega (I(\mathbf{x}) - \mu_\Omega) d\mathbf{x} = 0, \\ \\ B_{12} = \int_\Omega H_{1K_{12}}(x, K_{11}, K_{12}) = 2\frac{\mu_\Omega}{|\Omega|}\int_\Omega (I(\mathbf{x}) - \mu_\Omega) d\mathbf{x} = 0. \end{array} \right.$$

We can then compute the velocity vector of the active contour from (5.5) and we find

$$\frac{\partial \Gamma(\tau)}{\partial \tau} = [\ f + \varrho'(\sigma^2_\Omega)\left((I - \mu_\Omega)^2 - \sigma^2_\Omega\right)\ ]\ \mathbf{N}.$$

In this simple example, we notice that the dependency of the function on the region induces an additional term in the evolution equation compared with the evolution equation obtained in the case where the function is region independent (equation (4.2)). This additional term is $\varrho'(\sigma^2_\Omega)\left((I(\mathbf{x}) - \mu_\Omega)^2 - \sigma^2_\Omega\right)$. It must be included in order to reach a true minimum of the criterion as proved in [33].

6. Matching histograms. A natural way of generalizing the use of statistical image features such as the mean and the variance of the intensity for image segmentation is to consider the full probability distribution of the feature of interest within the region, e.g., intensity, color, texture, etc., ... It turns out that in attempting to do so, one is naturally led to extend the criterion (2.4) to the case where the function f depends on a *continuous* family of region criteria. Consider a function $\mathbf{h} : \mathbb{R}^n \to \mathbb{R}^m$ which describes the feature of interest. Suppose we have learnt the probability density function (pdf) of the feature $\mathbf{h}$ within the image region of interest, and let $q(\boldsymbol{\alpha})$ be this pdf. Given a region Ω, we can estimate the pdf of the feature $\mathbf{h}$ through the use of the Parzen method [24]: let $p : \mathbb{R}^m \to \mathbb{R}^+$ be the Parzen window, a smooth positive function whose integral is equal to 1. For the sake of simplicity but without loss of generality, we assume that p is an m-dimensional Gaussian with 0-mean and variance σ^2, we note

$$p(\boldsymbol{\alpha}) = g_\sigma(\boldsymbol{\alpha}) = \frac{1}{(2\pi\sigma^2)^{m/2}} \exp\left(-\frac{|\boldsymbol{\alpha}|^2}{2\sigma^2}\right),$$

and we define

$$\hat{q}(\boldsymbol{\alpha}, \Omega) = \frac{1}{K(\Omega)} \int_\Omega g_\sigma(\mathbf{h}(\mathbf{x}) - \boldsymbol{\alpha})\, d\mathbf{x},$$

where $\mathbf{h}(\mathbf{x})$ is the value of the feature of interest at the point $\mathbf{x}$ of Ω and K is a normalizing constant, in general depending of Ω, such that

$$\int_{\mathbb{R}^m} \hat{q}(\boldsymbol{\alpha}, \Omega)\, d\boldsymbol{\alpha} = 1.$$

Therefore

$$K(\Omega) = \int_{\Omega} \int_{\mathbb{R}^m} g_\sigma(\mathbf{h}(\mathbf{x}) - \boldsymbol{\alpha})\, d\boldsymbol{\alpha}\, d\mathbf{x} = \mid \Omega \mid .$$

We next assume that we have a function $\varphi : \mathbb{R}^+ \times \mathbb{R}^m \to \mathbb{R}^+$ which allows us to compare two pdfs. This function is small if the pdfs are similar and large otherwise. It allows us to introduce the following functional which represents the "distance" between the two histograms:

$$D(\Omega) = \int_{\mathbb{R}^m} \varphi(\hat{q}(\boldsymbol{\alpha}, \Omega), q(\boldsymbol{\alpha}))\, d\boldsymbol{\alpha}. \tag{6.1}$$

The distance can be the square of the L^2 norm when

$$\varphi(\hat{q}(\boldsymbol{\alpha}, \Omega), q(\boldsymbol{\alpha})) = (\hat{q}(\boldsymbol{\alpha}, \Omega) - q(\boldsymbol{\alpha}))^2,$$

or the commonly used Kullback–Leibler divergence when

$$\varphi(\hat{q}(\boldsymbol{\alpha}, \Omega), q(\boldsymbol{\alpha})) = \frac{1}{2}\left(q(\boldsymbol{\alpha}) \log \frac{q(\boldsymbol{\alpha})}{\hat{q}(\boldsymbol{\alpha}, \Omega)} + \hat{q}(\boldsymbol{\alpha}, \Omega) \log \frac{\hat{q}(\boldsymbol{\alpha}, \Omega)}{q(\boldsymbol{\alpha})} \right),$$

or the Hellinger distance when

$$\varphi(\hat{q}(\boldsymbol{\alpha}, \Omega), q(\boldsymbol{\alpha})) = (\sqrt{\hat{q}(\boldsymbol{\alpha}, \Omega)} - \sqrt{q(\boldsymbol{\alpha})})^2 ,$$

or the nonsymmetric chi-2 comparison function when

$$\varphi(\hat{q}(\boldsymbol{\alpha}, \Omega), q(\boldsymbol{\alpha})) = \frac{(\hat{q}(\boldsymbol{\alpha}, \Omega) - q(\boldsymbol{\alpha}))^2}{q(\boldsymbol{\alpha})}.$$

A further generalization of the previous case is to consider second order histograms which describe the probability of having the value $\boldsymbol{\alpha}_1$ at pixel $\mathbf{x}$ and the value $\boldsymbol{\alpha}_2$ at pixel $\mathbf{x} + \boldsymbol{\delta}$, where $\boldsymbol{\delta}$ is a fixed (usually small) vector of $\mathbf{R}^n$. This has been used very much in computer vision for analyzing textures [28, 29]. The corresponding pdf, denoted $q_{\boldsymbol{\delta}}(\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2)$, can be estimated with the same Parzen window technique. We define

$$\hat{q}_{\boldsymbol{\delta}}(\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2, \Omega) = \frac{1}{K_{\boldsymbol{\delta}}(\Omega)} \int_{\Omega} g_\sigma(\mathbf{h}(\mathbf{x}) - \boldsymbol{\alpha}_1) g_\sigma(\mathbf{h}(\mathbf{x} + \boldsymbol{\delta}) - \boldsymbol{\alpha}_2)\, d\mathbf{x}.$$

The normalizing constant $K_{\boldsymbol{\delta}}(\Omega)$ is given by

$$K_{\boldsymbol{\delta}}(\Omega) = \int_{\Omega} \int_{\mathbb{R}^m \times \mathbb{R}^m} g_\sigma(\mathbf{h}(\mathbf{x}) - \boldsymbol{\alpha}_1) g_\sigma(\mathbf{h}(\mathbf{x} + \boldsymbol{\delta}) - \boldsymbol{\alpha}_2)\, d\boldsymbol{\alpha}_1\, d\boldsymbol{\alpha}_2\, d\mathbf{x} = \mid \Omega \mid .$$

We therefore define

$$D_{\boldsymbol{\delta}}(\Omega) = \int_{\mathbb{R}^m \times \mathbb{R}^m} \varphi(\hat{q}_{\boldsymbol{\delta}}(\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2, \Omega), q_{\boldsymbol{\delta}}(\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2))\, d\boldsymbol{\alpha}_1\, d\boldsymbol{\alpha}_2. \tag{6.2}$$

Using the tools developed in section 5, we compute the Gâteaux derivative of the functional D. We have the following theorem.

THEOREM 6.1. *The Gâteaux derivative in the direction* $\mathbf{V}$ *of the functional* D *defined in* (6.1) *is*

$$\langle D'(\Omega), \mathbf{V}\rangle = -\frac{1}{\mid \Omega \mid} \int_\Gamma \Big(\partial_1\varphi(\hat{q}(.,\Omega), q(.)) * g_\sigma(\mathbf{h}(\mathbf{x})) - C(\Omega)\Big)(\mathbf{V}\cdot\mathbf{N})d\mathbf{a}(\mathbf{x}),$$

where $C(\Omega) = \int_{\mathbb{R}^m} \partial_1\varphi(\hat{q}(\boldsymbol{\alpha},\Omega), q(\boldsymbol{\alpha}))\hat{q}(\boldsymbol{\alpha},\Omega)\, d\boldsymbol{\alpha}$.

Proof. By the definition of D we have

$$\langle D'(\Omega), \mathbf{V}\rangle = \int_{\mathbb{R}^m} \langle (\varphi(\hat{q}(\boldsymbol{\alpha},\Omega), q(\boldsymbol{\alpha})))', \mathbf{V}\rangle\, d\boldsymbol{\alpha}.$$

Let us compute the Gâteaux derivative of $\varphi(\hat{q}(\boldsymbol{\alpha},\Omega), q(\boldsymbol{\alpha}))$. We define

$$\varphi(\hat{q}(\boldsymbol{\alpha},\Omega), q(\boldsymbol{\alpha})) = f(G_1(\boldsymbol{\alpha},\Omega), G_2(\Omega)) = \varphi\left(\frac{G_1(\boldsymbol{\alpha},\Omega)}{G_2(\Omega)}, q(\boldsymbol{\alpha})\right),$$

where

$$G_1(\boldsymbol{\alpha},\Omega) = \int_\Omega g_\sigma(\mathbf{h}(\mathbf{x}) - \boldsymbol{\alpha})\, d\mathbf{x} \quad \text{with} \quad H_1(\boldsymbol{\alpha},\mathbf{x}) = g_\sigma(\mathbf{h}(\mathbf{x}) - \boldsymbol{\alpha}),$$
$$G_2(\Omega) = \mid \Omega \mid = \int_\Omega d\mathbf{x}.$$

We obtain

$$\begin{aligned}\langle f', \mathbf{V}\rangle &= f_{G_1}\langle G_1', \mathbf{V}\rangle + f_{G_2}\langle G_2', \mathbf{V}\rangle \\ &= \frac{\partial_1\varphi(\hat{q}(\boldsymbol{\alpha},\Omega), q(\boldsymbol{\alpha}))}{\mid \Omega \mid}\left(\langle G_1', \mathbf{V}\rangle - \hat{q}(\boldsymbol{\alpha},\Omega)\langle G_2', \mathbf{V}\rangle\right)\end{aligned}$$

and, using Theorem 5.5,

$$\langle f', \mathbf{V}\rangle = -\frac{\partial_1\varphi(\hat{q}(\boldsymbol{\alpha},\Omega), q(\boldsymbol{\alpha}))}{\mid \Omega \mid} \int_\Gamma \left(\, g_\sigma(\mathbf{h}(\mathbf{x}) - \boldsymbol{\alpha}) - \hat{q}(\boldsymbol{\alpha},\Omega)\right)(\mathbf{V}\cdot\mathbf{N})d\mathbf{a}(\mathbf{x}).$$

Plugging this result into the expression of $\langle D'(\Omega), \mathbf{V}\rangle$ and swapping the order of integration, we obtain

$$\begin{aligned}\langle D'(\Omega), \mathbf{V}\rangle = -\frac{1}{\mid \Omega \mid} \int_\Gamma \Big(\int_{\mathbb{R}^m} & g_\sigma(\mathbf{h}(\mathbf{x}) - \boldsymbol{\alpha})\partial_1\varphi(\hat{q}(\boldsymbol{\alpha},\Omega), q(\boldsymbol{\alpha}))\, d\boldsymbol{\alpha} \\ & - \int_{\mathbb{R}^m} \partial_1\varphi(\hat{q}(\boldsymbol{\alpha},\Omega), q(\boldsymbol{\alpha}))\hat{q}(\boldsymbol{\alpha},\Omega)\, d\boldsymbol{\alpha}\Big)(\mathbf{V}\cdot\mathbf{N})d\mathbf{a}(\mathbf{x}).\end{aligned}$$

The first integral on the right-hand side is the convolution $\partial_1\varphi(\hat{q}(.,\Omega), q(.)) * g_\sigma$ of the function $\partial_1\varphi(\hat{q}(.,\Omega), q(.)) : \mathbb{R}^m \to \mathbb{R}$ with the function g_σ. The final result is

$$\langle D'(\Omega), \mathbf{V}\rangle \;=\; -\frac{1}{\mid \Omega \mid} \int_\Gamma \Big(\partial_1\varphi(\hat{q}(.,\Omega), q(.)) \,*\, g_\sigma(\mathbf{h}(\mathbf{x})) \,-\, C(\Omega)\Big)(\mathbf{V} \,\cdot\, \mathbf{N})d\mathbf{a}(\mathbf{x}),$$

where $C(\Omega) = \int_{\mathbb{R}^m} \partial_1\varphi(\hat{q}(\boldsymbol{\alpha},\Omega), q(\boldsymbol{\alpha}))\hat{q}(\boldsymbol{\alpha},\Omega)\, d\boldsymbol{\alpha}$. ∎

This solves the question of first order histograms. For second order histograms we have the following theorem.

THEOREM 6.2. *The Gâteaux derivative in the direction* $\mathbf{V}$ *of the functional* $D_{\boldsymbol{\delta}}$ *defined in* (6.2) *is*

$$\langle D'_{\boldsymbol{\delta}}(\Omega), \mathbf{V}\rangle = -\frac{1}{\mid \Omega \mid} \int_\Gamma \Big(\partial_1 \varphi(\hat{q}_{\boldsymbol{\delta}}(.,.,\Omega), q(.,.)) * (g_\sigma \otimes g_\sigma)(\mathbf{h}(\mathbf{x}), \mathbf{h}(\mathbf{x}+\boldsymbol{\delta})) - C_{\boldsymbol{\delta}}(\Omega)\Big)(\mathbf{V}\cdot\mathbf{N}) d\mathbf{a}(\mathbf{x}),$$

where $C_{\boldsymbol{\delta}}(\Omega) = \int_{\mathbb{R}^m \times \mathbb{R}^m} \partial_1 \varphi(\hat{q}_{\boldsymbol{\delta}}(\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2, \Omega), q(\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2)) \hat{q}_{\boldsymbol{\delta}}(\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2, \Omega)\, d\boldsymbol{\alpha}_1\, d\boldsymbol{\alpha}_2$, *and* $g_\sigma \otimes g_\sigma(\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2) = g_\sigma(\boldsymbol{\alpha}_1)\, g_\sigma(\boldsymbol{\alpha}_2)$.

Proof. The proof is identical to that of Theorem 6.1. □

7. Color histograms: Segmentation of regions in video sequences. This work has been motivated by [12, 8] where the tracking algorithms take advantage of statistical color distributions. We propose here to use active contours in order to fit exactly the shape of the object to be segmented. We consider a video sequence where each frame is represented by the color function $\mathbf{h} : \mathbb{R}^2 \to \mathbb{R}^2$. The color space used is (H, V), where H stands for the hue and V for the value.[1] The goal is to segment a reference region, given in the previous image of the sequence, into the current one by minimizing the distance between the reference histogram q of the region in the previous image and the estimated histogram $\hat{q}$ in the current frame. From an initial curve chosen by the user in the current frame, we want to make an active contour evolve towards the region in the current frame whose histogram is closest to the reference histogram of the previous frame.

In order to introduce a competition between the region of interest and the background region, we also consider the complement Ω^c of the region Ω of interest. They share the same boundary, Γ, but with normals pointing in opposite directions. We denote q^c the reference histogram of Ω^c, and we look for the region Ω which minimizes the following criterion:[2]

$$J(\Omega) = D(\Omega) + D(\Omega^c) + \lambda \int_\Gamma ds. \tag{7.1}$$

In this criterion, the first two terms are region functionals while the last one is a boundary functionals. The last one minimizes the curve length and is a regularization term weighted by the positive parameter λ. We have, of course,

$$D(\Omega) = \int_{\mathbb{R}^2} \varphi(\hat{q}(\boldsymbol{\alpha}, \Omega), q(\boldsymbol{\alpha}))\, d\boldsymbol{\alpha},$$
$$D(\Omega^c) = \int_{\mathbb{R}^2} \varphi(\hat{q}(\boldsymbol{\alpha}, \Omega^c), q(\boldsymbol{\alpha}))\, d\boldsymbol{\alpha}.$$

Computation of the Gâteaux derivative. A straightforward application of Theorem 6.1 yields

$$\langle D'(\Omega), \mathbf{V}\rangle = -\frac{1}{\mid \Omega \mid} \int_\Gamma \Big(\partial_1 \varphi(\hat{q}(.,\Omega), q(.)) * g_\sigma(\mathbf{h}(\mathbf{x})) - C(\Omega)\Big)(\mathbf{V}\cdot\mathbf{N}) ds$$

[1] We ignore the saturation to avoid the curse of dimensionality.

[2] The results are even better if we introduce the region area in the criterion by minimizing $D(\Omega)|\Omega| + D(\Omega^c)|\Omega^c| + \lambda \int_\Gamma ds$.

with

$$C(\Omega) = \int_{\mathbb{R}^m} \partial_1\varphi(\hat{q}(\boldsymbol{\alpha},\Omega), q(\boldsymbol{\alpha}))\hat{q}(\boldsymbol{\alpha},\Omega)\, d\boldsymbol{\alpha}\,. \tag{7.2}$$

Similar results hold for Ω^c:

$$\langle D'(\Omega^c), \mathbf{V}\rangle = \frac{1}{\mid \Omega^c \mid} \int_\Gamma \Big(\partial_1\varphi(\hat{q}(.,\Omega^c), q^c(.)) * g_\sigma(\mathbf{h}(\mathbf{x})) - C(\Omega^c)\Big)(\mathbf{V}\cdot\mathbf{N})ds\,,$$

with

$$C(\Omega^c) = \int_{\mathbb{R}^m} \partial_1\varphi(\hat{q}(\boldsymbol{\alpha},\Omega^c), q^c(\boldsymbol{\alpha}))\hat{q}(\boldsymbol{\alpha},\Omega^c)\, d\boldsymbol{\alpha}\,. \tag{7.3}$$

Computation of the evolution equation of an active contour. It is well known that the minimization of the curve length leads to the Euclidean curve shortening flow $\lambda\kappa$ [4, 35]. Then, from the previous derivatives, we can deduce the evolution of an active contour that will evolve towards a minimum of the criterion J_n defined in (7.1). We find the evolution equation

$$\frac{\partial\Gamma(\tau)}{\partial\tau} = F\mathbf{N} \tag{7.4}$$

with

$$\begin{aligned} F = \lambda\kappa &+ \frac{1}{\mid \Omega \mid}\Big(\partial_1\varphi(\hat{q}(.,\Omega), q(.)) * g_\sigma(\mathbf{h}(\mathbf{x})) - C(\Omega)\Big) \\ &- \frac{1}{\mid \Omega^c \mid}\Big(\partial_1\varphi(\hat{q}(.,\Omega^c), q^c(.)) * g_\sigma(\mathbf{h}(\mathbf{x})) - C(\Omega^c)\Big), \end{aligned}$$

where κ is the curvature of Γ and $C(\Omega)$, $C(\Omega^c)$ are given by (7.2) and (7.3), respectively.

Let us take the example of the Hellinger distance, where $\partial_1\varphi(r,\boldsymbol{\alpha}) = (\sqrt{r} - \sqrt{q(\boldsymbol{\alpha})})/\sqrt{r}$. We find for the velocity vector

$$\begin{aligned} F = \lambda\kappa &+ \frac{1}{\mid \Omega \mid}\left(\frac{(\sqrt{\hat{q}(.,\Omega)} - \sqrt{q(.)})}{\sqrt{\hat{q}(.,\Omega)}} * g_\sigma(\mathbf{h}(\mathbf{x})) - C(\Omega)\right) \\ &- \frac{1}{\mid \Omega^c \mid}\left(\frac{(\sqrt{\hat{q}(.,\Omega^c)} - \sqrt{q^c(.)})}{\sqrt{\hat{q}(.,\Omega^c)}} * g_\sigma(\mathbf{h}(\mathbf{x})) - C(\Omega^c)\right). \end{aligned}$$

And for the chi-2 comparison function where $\partial_1\varphi(r,\boldsymbol{\alpha}) = 2(r - q(\boldsymbol{\alpha}))/q(\boldsymbol{\alpha})$, we find

$$\begin{aligned} F = \lambda\kappa &+ \frac{2}{\mid \Omega \mid}\left(\frac{(\hat{q}(.,\Omega) - q(.))}{q(.)} * g_\sigma(\mathbf{h}(\mathbf{x})) - C(\Omega)\right) \\ &- \frac{2}{\mid \Omega^c \mid}\left(\frac{(\hat{q}(.,\Omega^c) - q^c(.))}{q^c(.)} * g_\sigma(\mathbf{h}(\mathbf{x})) - C(\Omega^c)\right). \end{aligned}$$

In the velocity, the convolution term allows us to compare locally the reference histogram to the current histogram.

7.1. Implementation. As far as the numerical implementation is concerned, we can model the active contour with either an explicit parameterization (Lagrangian formulation) or an implicit one (Eulerian formulation). See [23] for an interesting comparison between the two methods. Another interesting review may be found in [36].

Here, we use the level set method approach first proposed by Osher and Sethian [37] and applied this to active contours in [3]. The key idea of the level set method is to introduce an auxiliary function $U(\mathbf{x}, \tau)$ such that $\Gamma(\tau)$ is the zero level set of U. The function U is often chosen to be the signed distance function of $\Gamma(\tau)$ which satisfies

$$\Gamma(\tau) = \{\mathbf{x} \mid U(\mathbf{x}, \tau) = 0\} \quad \text{and} \quad |\nabla U| = 1.$$

This Eulerian formulation presents several advantages [47]. First, the curve U may break or merge as the function U evolves, and topological changes are thus easily handled. Second, the evolving function $U(\mathbf{x}, \tau)$ always remains a function allowing efficient numerical schemes. Third, the geometric properties of the curve, like the curvature κ and the normal vector field $\mathbf{N}$, can be estimated directly from the level set function:

$$\kappa = \operatorname{div}\left(\frac{\nabla U}{|\nabla U|}\right) \quad \text{and} \quad \mathbf{N} = -\frac{\nabla U}{|\nabla U|}.$$

The evolution equation (7.4) then becomes

$$\frac{\partial U(\tau)}{\partial \tau} = F|\nabla U|. \tag{7.5}$$

The velocity function F is computed only on the curve $\Gamma(\tau)$, but we can extend its expression to the whole image domain Ω. To implement the level set method, solutions must be found to circumvent problems coming from the fact that the signed distance function U is not a solution of the PDE (7.5); see [26] for details. In our work, the function U is re-initialized so that it remains a distance function. Details on the re-initialization equation are provided in [1, 19].

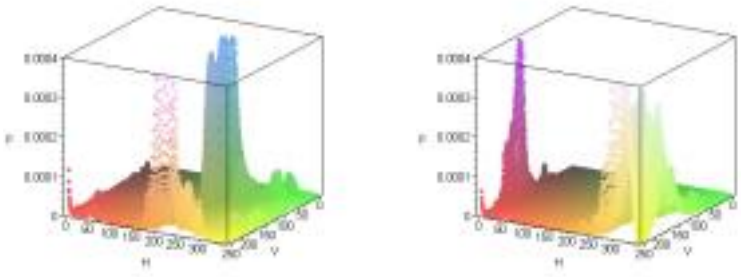
In order to improve numerical efficiency, we compute the equation in a narrow band enclosing the 0 level of the level set function [47, 48]. We also use multiresolution techniques by making the active contour evolve first in a low resolution image. The final contour obtained for this reduced image is then used as an initial curve for the real size image. Another possibility for increasing efficiency would be the use of accurate operator splitting (AOS) schemes [50].

7.2. Experimental results. Experimental results have been obtained on the sequence "Erik" from the European group COST211. Experiments are conducted using the chi-2 comparison function with $\varphi(r, \alpha) = (r - q(\boldsymbol{\alpha}))^2/q(\boldsymbol{\alpha})$ and $\partial_1\varphi(r, \boldsymbol{\alpha}) = 2(r - q(\boldsymbol{\alpha}))/q(\boldsymbol{\alpha})$.

The region of interest is the face. We assume that it has been segmented in the first image as shown in Figure 1(a). The first two reference histograms are computed. The two reference histograms are also given Figure 1(b) for the background reference histogram q^c and Figure 1(c) for the object reference histogram, q. For a given region Ω and for a point $\boldsymbol{\alpha} = [\alpha_1, \alpha_2]^T$, the function $\hat{q}(\boldsymbol{\alpha}, \Omega)$ represents the probability to obtain $H(\mathbf{x}) = \alpha_1$ and $V(\mathbf{x}) = \alpha_2$ for $\mathbf{x}$ belonging to the region Ω.

Then, using the two reference histograms of the previous frame, we make the active contour evolve using (7.4) in the current frame. The initial curve is chosen

a. Reference segmentation



b. Background reference histogram c. Object reference histogram

FIG. 1. *The reference segmentation of the previous frame* (a)*, the corresponding background reference histogram* q^c (b)*, and the corresponding object reference histogram* q (c).

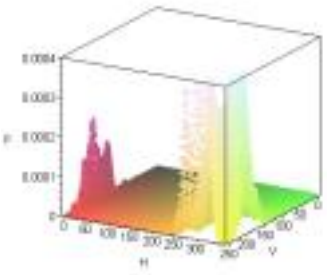
to be a circle. The evolution of the active contour in the current frame is shown in Figure 2. We notice that the final contour in Figure 2(c) nicely describes the region of interest, and the face is accurately segmented. We can also visualize the evolution of the object histogram, $\hat{q}(\boldsymbol{\alpha}, \Omega)$, during the propagation of the active contour. The final object histogram given in Figure 2(d) can be compared to the reference object histogram in Figure 1(c), showing an efficient minimization of the distance between the two histograms.

8. Conclusion. In this article we have clarified the relationships between the boundary and region functionals that arise naturally in several image processing tasks. We have shown that one can go from one to the other by solving Poisson's equation with Dirichlet conditions or Helmholtz's equation with Neumann conditions.

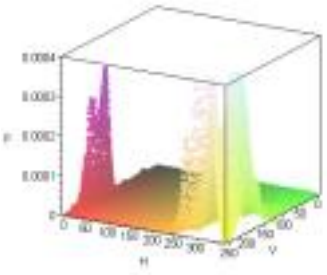
We have then concentrated on the problem of finding local minima of a large class of region functionals. By first transforming them into boundary functionals and applying methods from the calculus of variations we have computed the corresponding Gâteaux derivatives and constructed a velocity field on the region boundary. This field defines a PDE whose solution, for a given initial boundary, generates a one-parameter family of regions which, in practice, converges toward a local minimum of the functional. The problem of the existence and uniqueness of a solution to this PDE has not been addressed.

Changing our point of view, we have then rederived the same equations in a simpler and more natural way, i.e., without going through the trouble of turning region integrals into boundary integrals; this is achieved by applying methods of shape derivation [49, 22].

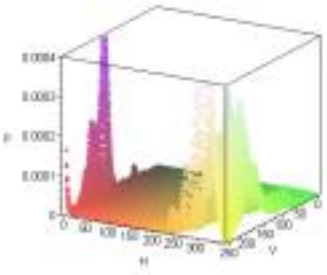
a. Initial contour



b. Initial histogram $\hat{q}(\boldsymbol{\alpha}, \Omega)$



c. Final Contour



d. Final histogram $\hat{q}(\boldsymbol{\alpha}, \Omega)$

FIG. 2. *Evolution of the region histogram* $\hat{q}(\boldsymbol{\alpha}, \Omega)$ *of the current frame during the evolution of the active contour.*

We have then turned our attention to a new class of region-based functionals by considering histograms of image features. The shape derivation tools have allowed us to easily derive the velocity field that defines the evolution of the region boundary.

The final part of the paper has been devoted to an application of the previous methods to the problem of region segmentation with a given color histogram in a sequence of images. Our experimental results show that the technique has indeed some interesting potentials.

Acknowledgments. We thank Rachid Deriche for his helpful comments on an early draft of this document. We also thank Gerardo Hermosillo for providing us with his software package for the robust estimation of image histograms.

PASSIVE LEVITATION IN ALTERNATING MAGNETIC FIELDS*

L. A. ROMERO†

Abstract. In this paper we analyze the stability of a levitated axisymmetric top carrying a system of permanent magnets in an alternating magnetic field. We show that there are stable configurations where the top is stationary, and the alternating magnetic field stabilizes the equilibrium position. We show that one mechanism for achieving stability is to periodically change the coupling between the rotational and translational degrees of freedom.

Key words. Levitron, stability, magnets

1. Introduction.

Earnshaw's theorem states that it is impossible to have stable levitation in a magneto-static or electro-static field. Although the theorem has a very broad scope, there are some very precise conditions that must be met in order for it to apply. In particular, the theorem fails if there are diamagnetic materials present, the levitating body is spinning, or the fields are alternating in time.

The discovery of the Levitron™ [7] demonstrated that it is possible to have stable levitation in a steady magneto-static field. This has led to a renewed interest in the subject of passive magnetic levitation using magneto-static fields [2], [4], [5], [11], [3]. Stable levitation has also been demonstrated using diamagnetic materials. A particular case of this is levitation over a superconducting disc, which can be considered as a diamagnetic material with magnetic permeability of zero.

In this paper we would like to discuss the possibility of achieving passive stable levitation in an alternating magnetic field. Although the fields are varying with time, we still refer to them as being magneto-static, since we assume that they are varying slowly enough that we can ignore the effects of the time varying terms in Maxwell's equations. We say that our system is passive because we prescribe the time variation of the magnetic field ahead of time, rather than adjusting the field in response to the position of the top.

In [10] Paul reviews the work on how small particles can be levitated in an alternating field. This work has demonstrated both theoretically and experimentally how Earnshaw's theorem can be violated in an alternating field. Our paper differs from this work in several respects. Our paper is aimed at trying to design a system on a larger scale, where we have both the flexibility and the necessity of specifying the design of both the levitating body and the supporting magnets.

The theory outlined in [10] applies to point charges in an alternating field. It is very simple and elegant, and has found profound uses in such fields as mass spectrometry. However, if one is going to make an oscillating field (and not spinning) version of the Levitron™, one needs a fuller theory. In particular, we need to take into account

the full (although linearized) rigid body dynamics of the levitated body. When we do this we find that there are two quite distinct methods of stabilizing the top. The first is the mechanism outlined in [10]; the second involves periodically varying the coupling between the rotational and translational modes of the top. In a practical device, one would most likely want to bring both of these mechanisms into play.

We will now describe our proposed setup and the conclusions of the analysis. We assume that there is a system of base magnets that gives a steady magnetic field with axial symmetry about the z axis (the direction of gravity). We also assume that we have a system of axisymmetric magnetic coils that give an axisymmetric periodically varying magnetic field. We suppose that we have an axisymmetric top with an axisymmetric system of magnets attached to it. When the top's axis is pointing in the z direction, and its center of mass is at the origin, we assume that the magnetic force from the steady field exactly balances the force of gravity. We also assume that the time varying force on the top vanishes at this position. In section 7 we will show that it is possible to find configurations of magnets that achieve these conditions. Assuming these conditions are satisfied, we see that there is an equilibrium position where the top is at rest in the time varying field. We then consider the stability of this equilibrium.

The linear stability equations are identical to those used in analyzing the stability of an axisymmetric Levitron™, except the dynamical parameters are time varying and the spin rate is set to zero. In particular, the system can be described by a lateral translational spring constant A, an axial translational spring constant $-2A$, a rotational spring constant $-C$, and a term B that couples the translations to the rotations. All of these terms have both a steady and a time varying component. Due to Earnshaw's theorem, if we set the time varying fields to zero, it is not possible for the system to be stable to both axial and lateral translational perturbations.

The mechanism described in [10] is equivalent to assuming that there is no coupling term B in the equations of motion and the rotational spring constant $-C$ is positive. This gives us a rotationally stable top, but one that at each instant of time sees a negative spring constant for either axial or lateral perturbations. However, by varying the translational spring constant $2A(t)$ at the right amplitude and frequency, it is possible to achieve overall stability in both the axial and lateral directions.

A different mechanism for achieving stability is to keep the translational spring constant A and the rotational spring constant $-C$ steady in time and to periodically vary the coupling term $B(t)$. Our results show that in order to achieve stability, it is necessary that the field varies more rapidly than the natural frequency of the rotational oscillation of the top. Furthermore, there is both an upper and a lower limit to the strength of the time varying coupling term. We cannot achieve stable equilibrium if the coupling is either too big or too small.

We now give a brief outline of the rest of this paper. In section 2 we derive the equations governing the linear stability of the top. In section 3 we discuss how to apply Floquet theory to analyze these equations and give general properties of the stability equations. In section 4 we analyze the case where stabilization is achieved without any coupling between the rotations and translations. In section 5 we consider the case where this coupling is the stabilizing mechanism. In section 6 we discuss the high frequency approximation to the stability equations. In section 7 we discuss how to find configurations that give us the desired dynamical parameters. We give conclusions in section 8.

2. Basic equations. We suppose that there is an equilibrium position where the center of mass of the top is at the origin and its axis of symmetry is pointing in the z direction. We should emphasize that even though the magnetic field is varying with time, we assume that a steady state equilibrium exists. For this to be true, it is necessary that the time varying components of the force and torque vanish at the equilibrium position. Due to symmetry, when the top is placed symmetrically in the field, all components of the force and torque vanish except for the force in the z direction. We must arrange the magnets so that the time varying component of this force vanishes.

We now determine the form of the equations governing the linear stability of this equilibrium. We begin by using simple symmetry arguments to deduce the most general form of the linear stability equations.

In order to orient the axis of symmetry of the top, we assume that the axis is initially pointing in the positive z direction. We orient the body by rotating it about the x axis by θ, then about the y axis by ϕ, and then about the z axis by ψ. Since we are mainly concerned with the linear stability of the system, and we are assuming that the top is axisymmetric, the angle ψ will not appear in the equations of motion.

2.1. Symmetry considerations. For any axisymmetric top with an axisymmetric system of magnets, the energy of the top in a magnetic field can be written as

$$Energy = U(\underline{x}, \underline{d}, t),$$

where $\underline{x} = (x, y, z)$ gives the position of the center of mass of the top and $\underline{d} = (d_x, d_y, d_z)$ is a unit vector pointing in the direction of the axis of symmetry of the top. This very general form for the energy holds as long as the top is axisymmetric and carries with it an axisymmetric system of magnets.

The force and torques can be derived from the potential $U(\underline{x}, \underline{d}, t)$. The forces can be written as

$$\underline{F}(\underline{x}, \underline{d}, t) = -\nabla_x U(\underline{x}, \underline{d}, t). \tag{1}$$

Here ∇_x is the gradient with respect to $\underline{x}$. The torque $\underline{\tau}$ can be computed using the fact that if we rotate our system about the axis $\underline{a}$ by an infinitesimal amount $d\alpha$, the change in energy can be written as

$$dU = -\underline{\tau} \cdot \underline{a} d\alpha.$$

When we rotate our system in this way, the axis $\underline{d}$ changes by the amount $d\alpha \underline{a} \times \underline{d}$. It follows that the change in energy can be written as

$$dU = \nabla_d U(\underline{x}, \underline{d}, t) \cdot (d\alpha \underline{a} \times \underline{d}) = d\alpha \underline{a} \cdot (\underline{d} \times \nabla_d U).$$

Equating the two expressions for dU and requiring that they hold for all values of $\underline{a}$, we conclude that the torque is given by

$$\underline{\tau} = -\underline{d} \times \nabla_d U(\underline{x}, \underline{d}, t). \tag{2}$$

We will also use the fact that

$$\nabla_x^2 U = 0.$$

We are interested in analyzing the stability of an equilibrium position where $\underline{d} = (0, 0, 1)$. For small perturbations to this solution, both θ and ϕ are small, and we

have the approximate expression $(d_x, d_y, d_z) \approx (\phi, -\theta, 1)$. In the linear approximation, the energy U is a quadratic function of x, y, z, θ, and ϕ. In this approximation, the torques τ_x and τ_y are given by

$$\tau_x = -\frac{\partial U}{\partial \theta},$$

$$\tau_y = -\frac{\partial U}{\partial \phi}.$$

We now assume that the top is in an axisymmetric magnetic field with the z axis as the axis of symmetry. Due to the symmetry of our configuration, it is clear that if we reflect both the position and the vector $\underline{d}$ about either the x or y axes, the energy stays the same, as it does for reflections about the plane $x = y$. This implies that

$$U(x, y, z, d_x, d_y, d_z, t) = U(-x, y, z, -d_x, d_y, d_z, t), \tag{3a}$$

$$U(x, y, z, d_x, d_y, d_z, t) = U(x, -y, z, d_x, -d_y, d_z, t), \tag{3b}$$

$$U(x, y, z, d_x, d_y, d_z, t) = U(y, x, z, d_y, d_x, d_z, t). \tag{3c}$$

These symmetry properties must be satisfied by any axisymmetric system. We could write down other symmetry properties, but these suffice to specify the form of the equations of motion.

In the linear approximation these symmetry conditions can be written as

$$U(x, y, z, \theta, \phi, t) = U(-x, y, z, \theta, -\phi, t),$$

$$U(x, y, z, \theta, \phi, t) = U(x, -y, z, -\theta, \phi, t),$$

$$U(x, y, z, \theta, \phi, t) = U(y, x, z, -\phi, \theta, t).$$

These symmetries, along with the fact that the forces and torques are derivable from a potential, imply that the general form for the linearized equations of an axisymmetric top can be written as

$$m\ddot{x} - A(t)x - B(t)\phi = 0,$$

$$m\ddot{y} - A(t)y + B(t)\theta = 0,$$

$$m\ddot{z} + 2A(t)z = 0,$$

$$I_1\ddot{\theta} - C(t)\theta + B(t)y = 0,$$

$$I_1\ddot{\phi} - C(t)\phi - B(t)x = 0.$$

These linearized stability equations depend on the mass m, the moment of inertia I_1, and the dynamical constants A, B, and C. These dynamical constants are given by

$$A(t) = -\frac{1}{2}\frac{\partial F_z}{\partial z} = \frac{\partial F_x}{\partial x} = \frac{\partial F_y}{\partial y},$$

$$B(t) = -\frac{\partial \tau_x}{\partial y} = \frac{\partial \tau_y}{\partial x} = \frac{\partial F_x}{\partial \phi} = -\frac{\partial F_y}{\partial \theta},$$

$$C = \frac{\partial \tau_x}{\partial \theta} = \frac{\partial \tau_y}{\partial \phi}.$$

In these expressions the partial derivatives are to be evaluated at the equilibrium position, which is assumed to be with the top aligned with the axis of symmetry and the center of mass along the axis of symmetry. Note that the dynamical parameters A, B, and C are time dependent due to the time varying nature of the fields.

The dynamical constant A is the translational spring constant. For a steady field, if $B = 0$, then when $A > 0$ we have a stable harmonic oscillator for displacements in the z direction and (due to Earnshaw's theorem) an unstable oscillator in the x and y directions. The constant $-C$ is a torsional spring constant. Finally, the constant B gives the coupling between the rotations and translations. For example, when the top is rotated about the y axis by ϕ, it gives a force in the x direction proportional to $B\phi$, and when the top is displaced in the x direction, there is a torque about the y axis that is proportional to Bx.

Once again we emphasize that this form of the equations holds for any axisymmetric system, no matter how complicated the systems of magnets for either the base or top are. If the top has a single dipole, quadrapole, or octapole on it, and the base consists of a single coil or a single ring magnet, it is possible to find explicit expressions for the constants A, B, and C. Using linear superposition, it is then possible to compute the dynamical constants A, B, and C for arbitrarily complicated systems of magnets on the top and in the base. Alternatively, assuming we have a code that can compute the force and torque on the top when it is placed with an arbitrary position and orientation in an axisymmetric field, we can compute the constants A, B, and C by numerically taking the derivatives of the forces and torques about the equilibrium position.

Given a particular configuration of magnets, the functions $A(t)$, $B(t)$, and $C(t)$ determine the stability properties of the configuration. However, in order to determine if a configuration is in equilibrium, we also need to calculate the lift $L(t)$. In order for this to be a valid configuration, it is necessary that the lift $L(t)$ be independent of time and that it be equal and opposite to the force of gravity on the top.

2.2. Sinusoidally varying fields. In the most general case that we consider in this paper, all of the terms have both a steady and a sinusoidally varying component. We assume that all of the time varying components have the same phase. We will write

$$A(t) = A_0 + A_v \cos(\omega t),$$

$$B(t) = B_0 + B_v \cos(\omega t),$$

$$C(t) = C_0 + C_v \cos(\omega t).$$

We are assuming that the lift $L(t)$ is independent of time.

We will introduce the following dimensionless variables:

$$x = \xi\sqrt{I_1/m},$$

$$y = \chi\sqrt{I_1/m},$$

$$z = \eta\sqrt{I_1/m},$$

$$t = s/\omega.$$

In terms of these dimensionless variables, we get the equations

$$\ddot{\xi} - (\alpha_0 + \alpha_v \cos(s))\xi + (\beta_0 + \beta_v \cos(s))\phi = 0, \tag{4a}$$

$$\ddot{\phi} + (\gamma_0 + \gamma_v \cos(s))\phi + (\beta_0 + \beta_v \cos(s))\xi = 0, \tag{4b}$$

$$\ddot{\eta} + 2(\alpha_0 + \alpha_v \cos(s))\eta = 0. \tag{4c}$$

Here

$$\alpha_0 = \frac{A_0}{m\omega^2},$$

$$\gamma_0 = \frac{-C_0}{I_1\omega^2},$$

$$\beta_0 = \frac{B_0}{\sqrt{mI_1}\omega^2},$$

$$\alpha_v = \frac{A_v}{m\omega^2},$$

$$\gamma_v = \frac{-C_v}{I_1\omega^2},$$

$$\beta_v = \frac{B_v}{\sqrt{mI_1}\omega^2}.$$

Note that the equation for η decouples from those for ξ and ϕ. Furthermore, the equations for χ and θ decouple from the rest of the equations and are almost identical to the equations for ξ and ϕ (and hence we have not bothered to write them down). If the equations for ξ and ϕ are stable, then so will the ones for χ and θ. For this reason we will not carry them along in our analysis.

3. General properties concerning the stability of the equilibrium. The equations (4) can be split up into two independent systems. The equation for η is a second order system that decouples from the rest of the equations. The equations for

ξ and ϕ can be written as a fourth order system of the form

$$\dot{\underline{q}} = R(t)\underline{q}, \tag{5}$$

$$\underline{q} = \begin{pmatrix} \xi \\ \dot{\xi} \\ \phi \\ \dot{\phi} \end{pmatrix},$$

where $R(t)$ is a 4×4 matrix that satisfies $R(t) = R(t + 2\pi)$.

In order to have stability, both the equation for η and (5) must give stability. The equation for η is Mathieu's equation, whose stability properties are well known. In the rest of this section we discuss how to analyze the stability of (5). The arguments we now give are a special case of those given in [8].

In order to analyze the stability of our system of equations we consider the fundamental matrix solution $Q(t)$ satisfying

$$\dot{Q} = R(t)Q,$$

$$Q(0) = I.$$

We define the monodromy matrix Γ as

$$\Gamma = Q(2\pi).$$

The equilibrium with $\underline{q} = 0$ will be stable provided all of the eigenvalues of Γ have magnitudes less than unity. However, since our system is conservative we can at best have neutral stability. This follows since $\mathrm{tr}(R(t)) = 0$. This implies that the Wronskian $Wr(t)$ (the determinant of $Q(t)$) is constant. This follows since the Wronskian satisfies the equation

$$\frac{dWr}{dt} = \mathrm{tr}(R(t))Wr.$$

Since the Wronskian is independent of time, the determinant of $Q(2\pi)$ must be equal to one. This implies that it is not possible to have all of the eigenvalues of Γ have magnitudes less than unity. For this reason we can have only instability or neutral stability.

For given values of the parameters α_0, α_v, etc., it is straightforward to numerically integrate the system of equations and evaluate the eigenvalues of the monodromy matrix Γ. However, if one is going to track (either numerically or with perturbation theory) the curves separating regions of instability from regions of neutral stability, it is helpful to understand some more properties of Γ.

We begin by showing that due to time reversal symmetry, if λ is an eigenvalue of Γ, then so is $1/\lambda$. Suppose we integrate (5) with the initial conditions $\underline{q}(0) = \underline{q}_0$, and after integrating this equation over a single period we end up with the vector $\underline{q}(2\pi) = \underline{q}_1$. If we integrate our differential equations backwards with the initial condition $\underline{q}_1$, we will end up getting back $\underline{q}_0$ at $t = 0$. However, due to the time reversal symmetry of our system, we can get back $\underline{q}_0$ by integrating our equations

forward. In order to do this we need to multiply $\underline{q}_1$ by the matrix

$$J = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}.$$

This has the effect of keeping the values of ξ and ϕ (in the vector $\underline{q}$) the same but changing the signs of their derivatives. If we integrate (5) forward with the initial condition $\underline{q}(0) = J\underline{q}_1$, we will end up with the vector $J\underline{q}_0$ after we have integrated over a single period. This will work for any initial condition $\underline{q}_0$, and hence our monodromy matrix must satisfy

$$\Gamma J \Gamma = J. \tag{6}$$

We will now show that this equation implies that if λ is an eigenvalue of Γ, then so is $1/\lambda$. In order to show this we note that (6) can be written as

$$J\Gamma = \Gamma^{-1} J.$$

Suppose λ is an eigenvalue of Γ with eigenvector $\underline{r}$. This means that $\Gamma\underline{r} = \lambda\underline{r}$, and hence $J\Gamma\underline{r} = \lambda J\underline{r}$. However, using $J\Gamma = \Gamma^{-1}J$, this can be written as $\Gamma^{-1}J\underline{r} = \lambda J\underline{r}$. This implies that λ is an eigenvalue of Γ^{-1} with eigenvector $J\underline{r}$. This is equivalent to saying that $1/\lambda$ is an eigenvalue of Γ.

It follows that the characteristic equation for Γ is a reciprocal equation. That is, it can be written as

$$\det(\lambda I - \Gamma) = \lambda^4 + p(\Gamma)\lambda^3 + q(\Gamma)\lambda^2 + p(\Gamma)\lambda + 1 = 0. \tag{7}$$

Reciprocal equations can be solved by solving equations of half the degree and a quadratic [9]. For fourth order reciprocal equations we use the polynomials $\psi_0 = 1, \psi_1(t) = t$, $\psi_2(t) = t^2 - 2$. These polynomials satisfy

$$\psi_k(x + 1/x) = x^k + 1/x^k.$$

To solve (7) we multiply (7) by $1/\lambda^2$ to get

$$(\lambda^2 + 1/\lambda^2) + p(\Gamma)(\lambda + 1/\lambda) + q(\Gamma) = 0.$$

This can be written as

$$\psi_2(\lambda + 1/\lambda) + p(\Gamma)\psi_1(\lambda + 1/\lambda) + q(\Gamma) = 0.$$

If we make the substitution $z = \lambda + 1/\lambda$, we get the equation

$$z^2 + p(\Gamma)z + q(\Gamma) - 2 = 0, \tag{8}$$

and solving for λ in terms of z we get

$$\lambda^2 - z\lambda + 1 = 0. \tag{9}$$

In order for this last equation to have roots with $\mid \lambda \mid = 1$, it is necessary and sufficient that z be real and satisfy $z^2 < 4$. It follows that a necessary and sufficient

condition that our system is neutrally stable is that all of the roots of (8) be real and have magnitude less than two. These conditions can be written as

$$-4 < p(\Gamma) < 4,$$

$$8 + p(\Gamma)^2 - 4q(\Gamma) > 0,$$

$$2 + 2p(\Gamma) + q(\Gamma) > 0,$$

$$2 - 2p(\Gamma) + q(\Gamma) > 0.$$

It is more useful to express these equations directly in terms of the monodromy matrix. To do this we use

$$p(\Gamma) = -\mathrm{tr}(\Gamma),$$

$$q(\Gamma) = \frac{1}{2}\left(p(\Gamma)^2 - \mathrm{tr}(\Gamma^2)\right).$$

The necessary and sufficient conditions for stability can now be written as

$$Z_1(\Gamma) = 8 + 2\,\mathrm{tr}(\Gamma^2) - \mathrm{tr}(\Gamma)^2 > 0, \tag{10a}$$

$$Z_2(\Gamma) = (2 - \mathrm{tr}(\Gamma))^2 - \mathrm{tr}(\Gamma^2) > 0, \tag{10b}$$

$$Z_3(\Gamma) = (2 + \mathrm{tr}(\Gamma))^2 - \mathrm{tr}(\Gamma^2) > 0, \tag{10c}$$

$$Z_4(\Gamma) = 4 - \mathrm{tr}(\Gamma) > 0, \tag{10d}$$

$$Z_5(\Gamma) = \mathrm{tr}(\Gamma) + 4 > 0. \tag{10e}$$

On the boundary between a region of stability and instability, one of these inequalities is replaced by an equality. For example, numerically it is found that $Z_1(\Gamma) = 0$ is satisfied for the upper bound on β_v and $Z_2(\Gamma) = 0$ for the lower bound on β_v when $\alpha_v = \gamma_v = \beta_0 = 0$ and $\gamma_0 > 0$.

4. Systems with no coupling term $B(t)$. We begin by assuming that both the steady and time varying components of the coupling term $B(t)$ vanish. In this case the equations for ϕ, θ, ξ, χ, and η all decouple from each other. The equations for ϕ and θ imply that the top is rotationally stable provided $\gamma_0 > 0$ and γ_v is not too large. Assuming this is the case, the stability is determined by the condition that the equations

$$\ddot{\xi} - (\alpha_0 + \alpha_v \cos(s))\xi = 0$$

and

$$\ddot{\eta} + 2(\alpha_0 + \alpha_v \cos(s))\eta = 0$$

both give stable solutions. This theory is nearly identical to that presented in [10]. Each one of these equations is a particular case of Mathieu's equation. The theory of Mathieu's equation has been well documented in many different books on nonlinear

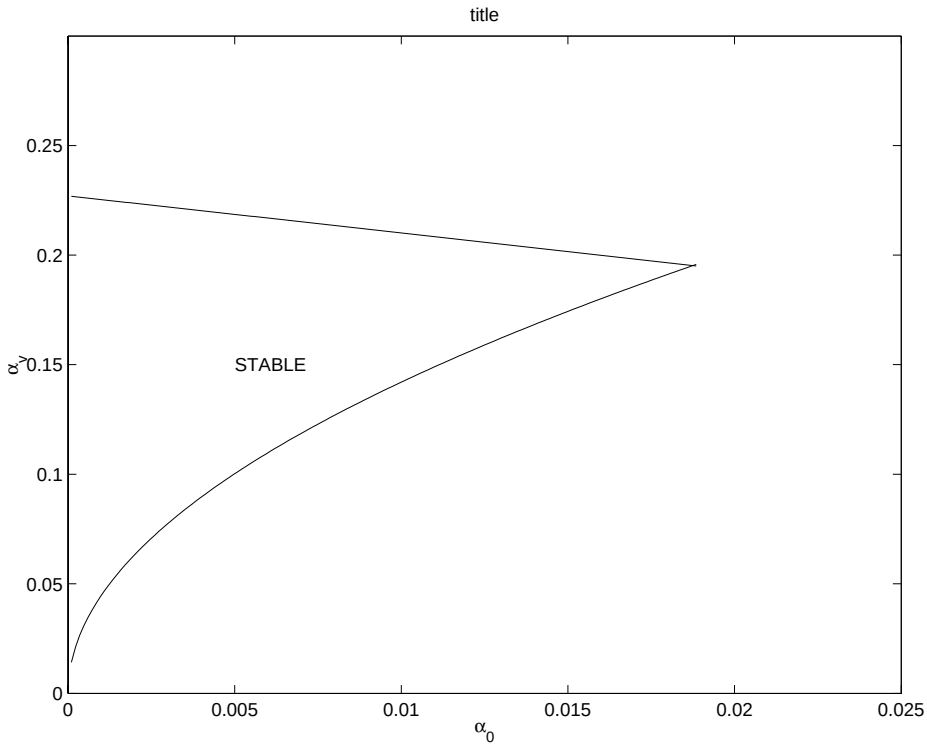

FIG. 1. *This shows the upper and lower values of α_v as a function of α_0 for the case where there is no coupling between the rotational and translational modes.*

oscillations [12], [1]. The only trick here is adjusting the parameters so that both of these equations give stable solutions at the same time. Note that at any instant in time, if we freeze the coefficients, only one of these equations would be stable. However, since the fields are changing with time, we can get overall stability even though the equations with frozen coefficients give instability.

We have numerically integrated these equations to determine the monodromy matrix and the Floquet exponents. Figure 1 shows a plot of the region of stability.

5. Systems stabilized by coupling. We now consider systems where the only time variation is in the coupling term β_v. For simplicity we assume that the steady component β_0 also vanishes. Since the equation for η is decoupled from the rest of the equations, it is clear that we must have $\alpha_0 > 0$ in order to have the top be stable to axial perturbations. Assuming that $\alpha_0 > 0$, the stability of such a system is governed by the equations

$$\ddot{\xi} - \alpha_0 \xi + \beta_v \cos(s)\phi = 0, \tag{11a}$$

$$\ddot{\phi} + \gamma_0 \phi + \beta_v \cos(s)\xi = 0. \tag{11b}$$

Before giving numerical or perturbation results, we will give some intuitive arguments that give the basic features of the numerical calculations.

Suppose that both β_v and α_0 are small. In this case it is reasonable to assume that $\xi(t)$ is changing slowly compared to the driving frequency, and hence $\xi(s)$ can be approximated as a constant in (11b). This implies that we can write

$$\phi(s) = \frac{\xi(s)\beta_v \cos(s)}{1-\gamma_0}.$$

If we substitute this back into the equation for ξ, we get

$$\ddot{\xi} - \alpha_0 \xi + \xi \frac{\beta_v^2}{1-\gamma_0} \cos^2(s) = 0.$$

This can be written as

$$\ddot{\xi} + \left(\frac{\beta_v^2}{2(1-\gamma_0)} - \alpha_0 \right) \xi + \frac{\beta_v^2}{2(1-\gamma_0)} \cos(2s)\xi = 0. \tag{12}$$

This is identical to Mathieu's equation. As long as we are away from regions of parametric resonance we expect that this will be stable provided the steady term in the spring constant is positive. By this we mean that

$$\frac{\beta_v^2}{2(1-\gamma_0)} - \alpha_0 > 0. \tag{13}$$

We see that if we make the coupling term β_v large enough, we can overcome the destabilizing effect of the parameter α_0. However, this is possible only if $\gamma_0 < 1$. However, as the coupling term increases, the steady term approaches 1 and the oscillating term grows. Eventually we are going to reach a point where the system becomes unstable due to parametric excitation.

We can numerically integrate (12) and use Floquet theory to determine regions of stability and instability. Figure 2 shows a plot of the neutral stability region for this equation. We see that the lower limit on stability is well approximated by the curve $\beta_v^2 = 2\alpha_0(1-\gamma_0)$. This lower limit on stability also agrees very well with the lower limit obtained by doing Floquet theory on the full set of equations (11).

The condition $\gamma_0 < 0$ corresponds to having the top be rotationally unstable in the absence of the coupling term β_v. In this case if β_v and α_0 are both small, our system will be unstable due to (11b). In this case it is necessary to stabilize the instability to rotations in a manner similar to the way we stabilized the translational instability. Almost identical arguments show that it is necessary to have

$$\frac{\beta_v^2}{2(1-\alpha_0)} + \gamma_0 > 0 \tag{14}$$

in order to stabilize the rotational instability. This shows that when γ_0 is negative, then even when α_0 is infinitesimally small, there is a minimum value of β_v necessary in order to achieve stability.

We now present numerical results that confirm all of our results based on heuristic reasoning. The only major modification to these results is that the results based on (12) do not do a good job of predicting the upper limit on β_v. In particular, the full numerical calculations show that the upper and lower limits converge towards each other at a finite value of α_0.

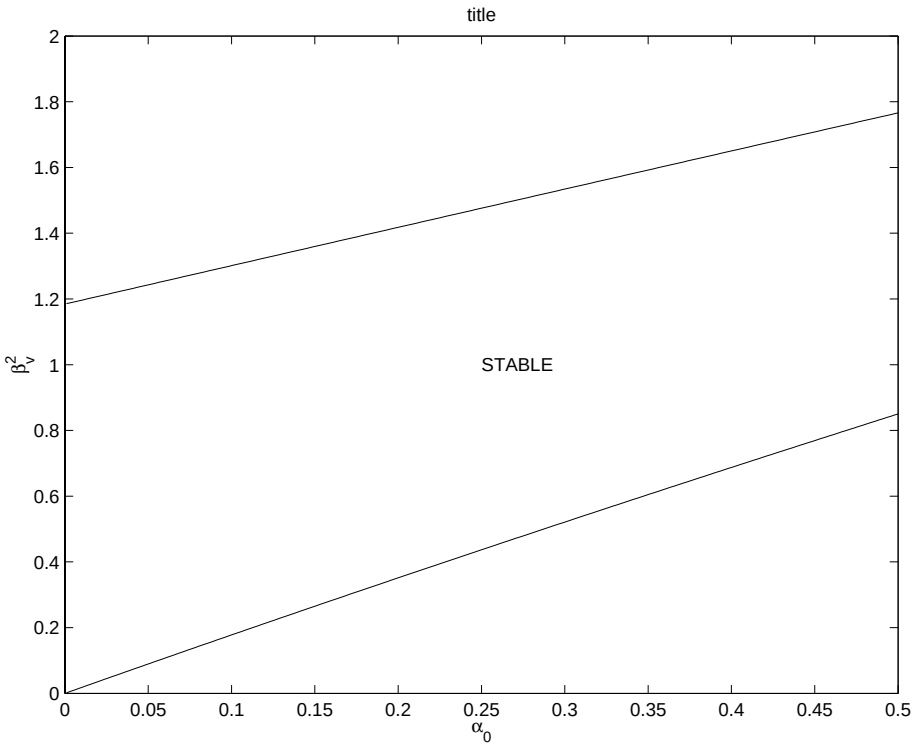

FIG. 2. *This shows the upper and lower values of β_v for stable operation predicted by* (12). *This plot is for $\gamma_0 = .1$.*

Figure 3 shows the bounds on β_v as a function of α_0 when we use the full linearized stability equations (11) to analyze the stability. We see that the upper and lower curves intersect tangentially at a finite value of α_0. As we increase γ_0, the region of stable operation shrinks until it completely vanishes just before $\gamma_0 = 1$.

Figure 4 shows similar plots for negative values of γ_0. Note that when γ_0 is negative the curve for the lower limit on β_v has a kink in it that occurs when $\alpha_0+\gamma_0=0$. The first part of the curve is very well approximated by (14), and the second part of the curve is approximated by (13). As γ_0 gets smaller, the region of stability eventually shrinks to zero.

The "exact" numerical results we present were found by numerically integrating the linearized system of equations with different initial conditions in order to obtain the monodromy matrix. For given values of our parameters this allows us to compute the quantities Z_k in (10). On a surface in parameter space where the system changes stability we must have $Z_k = 0$ for at least one of $k = 1, 2, 3, 4$. If we have a good guess for a point in parameter space satisfying $Z_k = 0$, we can use the secant method to change one parameter until we find a point that exactly satisfies this equation. Using this technique it is possible to map out the regions of stability quite efficiently.

6. The high frequency approximation. The situations we have considered in the last two sections were aimed at isolating two important mechanisms for stabilizing the equilibrium. In particular, both situations assumed that the steady coupling term β_0 was identically zero. Figure 5 shows plots of the upper and lower bounds on β_v

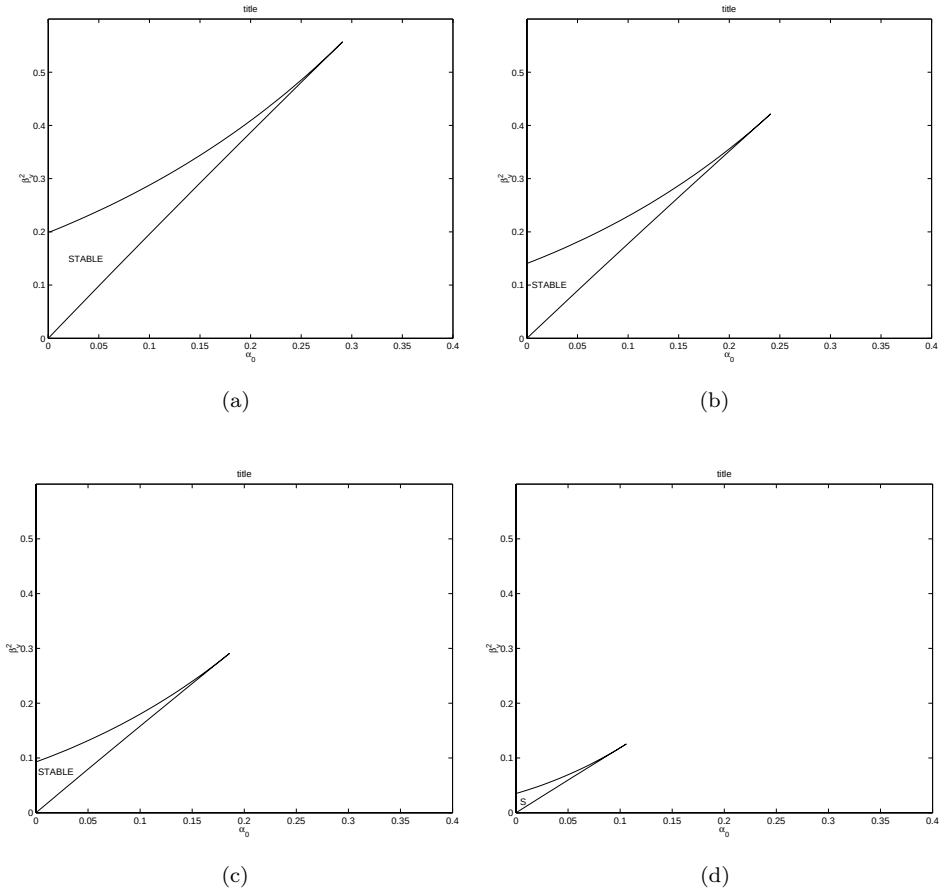

FIG. 3. *This shows the curves for the upper and lower limits to β_v as a function of α_0.* (a) $\gamma_0 = .0$, (b) $\gamma_0 = .1$, (c) $\gamma_0 = .2$, (d) $\gamma_0 = .4$. *Note that as γ_0 gets close to* 1, *the region of stability shrinks to zero.*

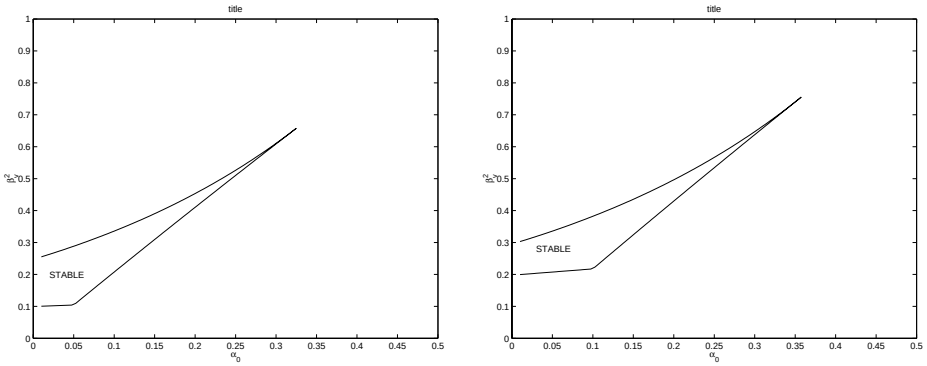
as a function of α_0 when we let the parameter β_0 be nonzero. We see that the lower limit on stability is raised as we increase β_0, and for $\alpha_0 = 0$ the amount it is raised is nearly proportional to $\sqrt{\beta_0}$.

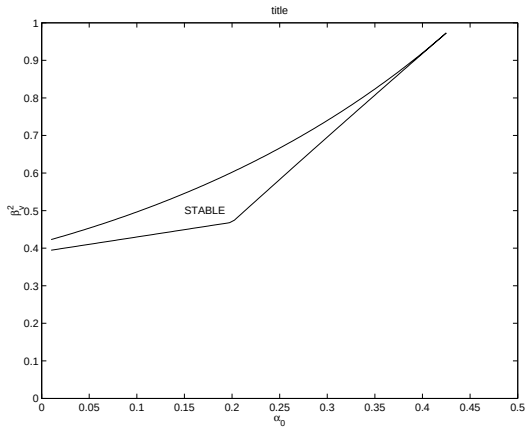
The dependence of our stability curves on β_0 is just one aspect of the stability boundaries that were not explored in the last two sections. In order to understand fully the stability of the equilibrium, we have a six parameter space to explore. The analysis in this section is aimed at attempting to understand the stability boundaries of this space. In order to do this we consider the stability of the equilibrium when all of the dimensionless parameters α_0, β_0, γ_0, α_v, β_v, and γ_v are small. Physically this can be achieved by making the driving frequency ω large.

We can derive the high frequency approximation using the method of averaging. We briefly outline the method of averaging outlined in [6] when applied to linear systems with periodic coefficients. In this special case, we are concerned with systems of the form

$$\dot{\underline{z}} = \epsilon M(t)\underline{z}, \tag{15}$$



(a) (b)



(c)

FIG. 4. *This shows the curves for the upper and lower limits to β_v as a function of α_0.* (a) $\gamma_0 = -.05$, (b) $\gamma_0 = -.1$, (c) $\gamma_0 = -.2$. *Note that the lower bound on β_v follows one branch until $\alpha_0 = -\gamma_0$, then it follows a different branch. As γ_0 decreases, the lower bound on β_v for $\alpha_0 = 0$ is continually raised.*

where ϵ is small and M is a 2π periodic matrix. The method of averaging shows that we can make a change of variable of the form

$$\underline{z} = \underline{\xi} + \left(\epsilon N_1(t) + \epsilon^2 N_2(t) + \cdots + \epsilon^k N_k(t)\right) \underline{\xi},$$

where each $N_i(t)$ is a 2π periodic matrix with zero time average, such that the equation for $\underline{\xi}$ can be written as

$$\dot{\underline{\xi}} = M_{av}\underline{\xi} + O(\epsilon^{k+1}),$$

where M_{av} can be written as

$$M_{av} = \epsilon M_1 + \epsilon^2 M_2 + \cdots + \epsilon^k M_k.$$

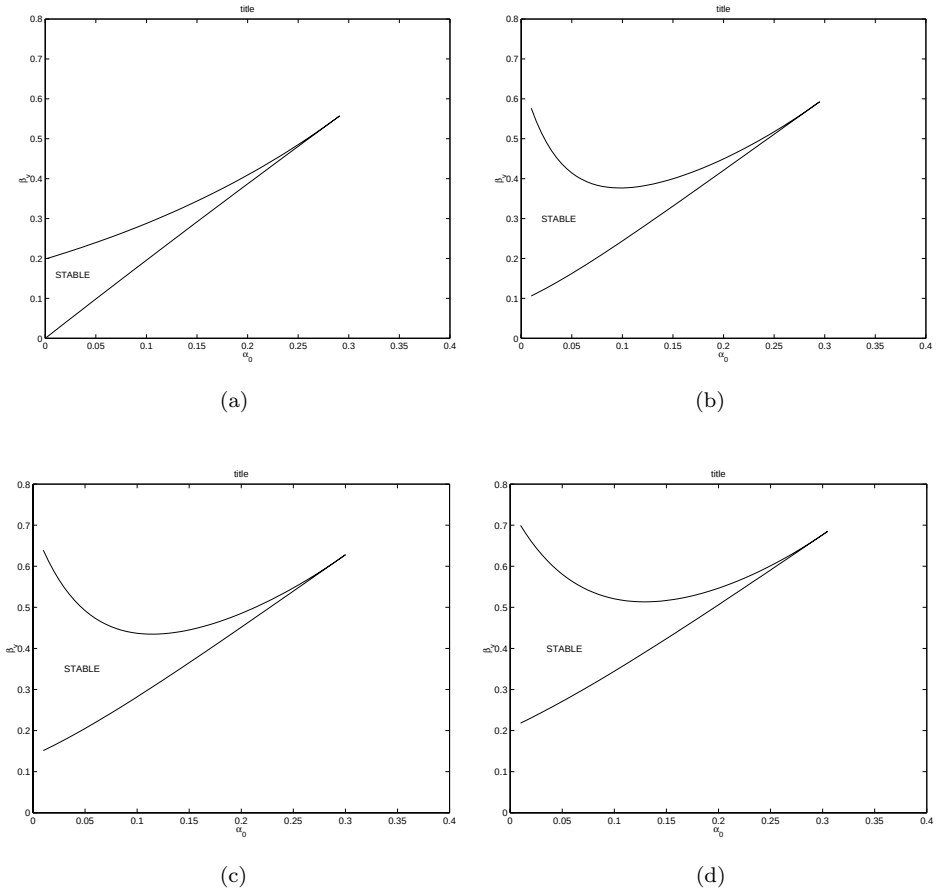


FIG. 5. *This shows the curves for the upper and lower limits to β_v as a function of α_0 with $\gamma_0 = 0$ and different values of β_0.* (a) $\beta_0 = 0$, (b) $\beta_0 = .005$, (c) $\beta_0 = .002$, (d) $\beta_0 = .01$. *Note that increasing β_0 moves the region of neutral stability upwards.*

Here each of the matrices M_j is independent of time. Simple arguments show that the eigenvalues of the matrix M_{av} must agree with the Floquet exponents of the original system (15) to order ϵ^k.

If we carry out this method of averaging, we get

$$M_1 = \langle M(t) \rangle,$$

where

$$\langle f(t) \rangle = \frac{1}{2\pi} \int_0^{2\pi} f(t) dt.$$

The matrix $N_1(t)$ is the unique matrix with $\langle N_1 \rangle = 0$ satisfying

$$\frac{dN_1}{dt} = M(t) - M_1.$$

The matrix M_2 is given by

$$M_2 = \langle M(t)N_1(t) - N_1(t)M_1 \rangle.$$

The matrix $N_2(t)$ is the unique matrix with $\langle N_2 \rangle = 0$ satisfying

$$\frac{dN_2}{dt} = M(t)N_1(t) - N_1(t)M_1 - M_2.$$

The matrix M_3 is given by

$$M_3 = \langle M(t)N_2(t) - N_1(t)M_2 - N_2(t)M_1 \rangle.$$

Assuming that the dimensionless parameters $\alpha(t)$, $\beta(t)$, and $\gamma(t)$ are small, it is possible to apply the method of averaging to our linearized stability equations. We have, in fact, done this. However, we will now present a simpler heuristic analysis that leads to the same results as carrying out this averaging process to third order.

We suppose that the steady parameters α, β, and γ are small compared to the time varying parameters α_v, β_v, and γ_v; we assume that the time varying parameters are themselves small. We will write the solution $\xi(s)$ and $\phi(s)$ as

$$\xi(s) = \xi_0(s) + \xi_1(s),$$

$$\phi(s) = \phi_0(s) + \phi_1(s),$$

where ξ_0 and ϕ_0 are slowly varying and ξ_1 and ϕ_1 are rapidly varying.

Under these assumptions the first two equations in equations (4) imply that the fast components satisfy

$$\ddot{\xi}_1 - \alpha_v \cos(s)\xi_0 + \beta_v \cos(s)\phi_0 = 0, \tag{16}$$

$$\ddot{\phi}_1 + \gamma_v \cos(s)\phi_0 + \beta_v \cos(s)\xi_0 = 0. \tag{17}$$

We can solve these equations to get

$$\xi_1 = \cos(s)\left(-\alpha_v \xi_0 + \beta_v \phi_0\right),$$

$$\phi_1 = \cos(s)\left(\gamma_v \phi_0 + \beta_v \xi_0\right).$$

If we now substitute these expressions into the first two of equations (4) and take the time average, ignoring the time variation of ξ_0 and ϕ_0, we get the averaged equations

$$\ddot{\xi}_0 - \alpha_{eff}\xi_0 + \beta_{eff}\phi_0 = 0,$$

$$\ddot{\phi}_0 + \gamma_{eff} + \beta_{eff}\xi_0 = 0,$$

where

$$\alpha_{eff} = \alpha - \frac{1}{2}\alpha_v^2 - \frac{1}{2}\beta_v^2, \tag{18a}$$

$$\beta_{eff} = \beta - \frac{1}{2}\alpha_v\beta_v + \frac{1}{2}\beta_v\gamma_v, \tag{18b}$$

$$\gamma_{eff} = \gamma + \frac{1}{2}\gamma_v^2 + \frac{1}{2}\beta_v^2. \tag{18c}$$

A necessary and sufficient condition for these averaged equations to have neutrally stable solutions is that the eigenvalues of the matrix

$$K_{eff} = \begin{pmatrix} \alpha_{eff} & -\beta_{eff} \\ -\beta_{eff} & -\gamma_{eff} \end{pmatrix}$$

all be negative. A necessary and sufficient condition for this to be true is that

$$\alpha_{eff} - \gamma_{eff} < 0, \tag{19}$$

$$\alpha_{eff}\gamma_{eff} + \beta_{eff}^2 < 0. \tag{20}$$

These are the necessary and sufficient conditions that the averaged equations yield a neutrally stable equilibrium. One can also obtain these results by carrying out a regular perturbation expansion to find the quantities $Z_k(\Gamma)$ (defined in (10)) assuming that all of the dynamical parameters are small. If we do this, we find that all of the quantities $Z_k(\Gamma)$ are guaranteed to be positive for small values of the dynamical parameters, except for $Z_2(\Gamma)$ and $Z_4(\Gamma)$. The condition $\alpha_{eff} - \gamma_{eff} < 0$ is related to the condition $Z_4(\Gamma) > 0$. In particular, we have

$$Z_4(\Gamma) = 2\pi^2\left(\alpha_v^2 + 2\beta_v^2 + \gamma_v^2 - 2\alpha_0 + 2\gamma_0\right) + \cdots. \tag{21}$$

The requirement that $\alpha_{eff}\gamma_{eff} + \beta_{eff}^2 < 0$ is related to the condition that $Z_2(\Gamma) > 0$. In particular, we have

$$\begin{aligned}\frac{1}{8\pi^4}Z_2(\Gamma) = {} & -4\beta_0^2 + (\beta_v^2 + 2\gamma_0)(\beta_v^2 - 2\alpha_0) + 2\alpha_v^2\gamma_0 \\ & + 4\alpha_v\beta_0\beta_v + \alpha_v^2\gamma_v^2 - 4\beta_0\beta_v\gamma_v - 2\alpha_0\gamma_v^2 + 2\alpha_v\gamma_v\beta_v^2.\end{aligned} \tag{22}$$

The expression for $Z_2(\Gamma)$ is quite complicated, but it contains a considerable amount of information. If we set $\beta_0 = \gamma_v = \alpha_v = 0$, our asymptotic stability conditions imply that

$$Z_4 = 2\pi^2\left(2\beta_v^2 - 2\alpha_0 + 2\gamma_0\right) > 0$$

and

$$Z_2 = 8\pi^4\left(\beta_v^2 + 2\gamma_0\right)\left(\beta_v^2 - 2\alpha_0\right) > 0.$$

In order for the second of these conditions to be satisfied, we must have $\beta_v^2 > 2\alpha_0$. If this is so, and $\gamma_0 > 0$, then the first condition will also be satisfied. In this case, we get the curve for the lower bound on β_v in Figure 3. Note that our high frequency approximation assumes that all of the parameters are small and does not predict the upper limit for β_v. If $\gamma_0 < 0$, then the second condition does not necessarily imply the first and we end up getting a kink in our curve for the lower limit on stability, as in Figure 4. This shows that our asymptotic results agree with the results we previously derived using intuitive arguments.

Suppose we still set $\alpha_v = \gamma_v = \alpha_0 = 0$, but we now let β_0 be nonzero. In this case the condition that $Z_2 = 0$ can be written as

$$-4\beta_0^2 + (\beta_v^2 + 2\gamma_0)\beta_v^2 = 0. \tag{23}$$

If γ_0 is small, this shows that the lower bound on β_v is proportional to the square root of β_0, a result we observed numerically in Figure 5, but had not yet derived. In general, (23) gives a quadratic equation for β_v. Figure 6 shows a plot of $\beta_v(\beta_0)$ for a fixed value of γ_0. It shows both the exact expression obtained by numerically computing the monodromy matrix and the analytical expression obtained by solving (23). We see that there is excellent agreement between these results until β_v gets to be nearly .5, where the high frequency approximation should be expected to break down. Figure 7 shows a similar plot for $\beta_v(\gamma_0)$ and β_0 fixed.

These examples show that although (22) is quite complicated, it contains a considerable amount of information. Furthermore, if we restrict ourselves to simple slices through parameter space, this equation is not so complicated.

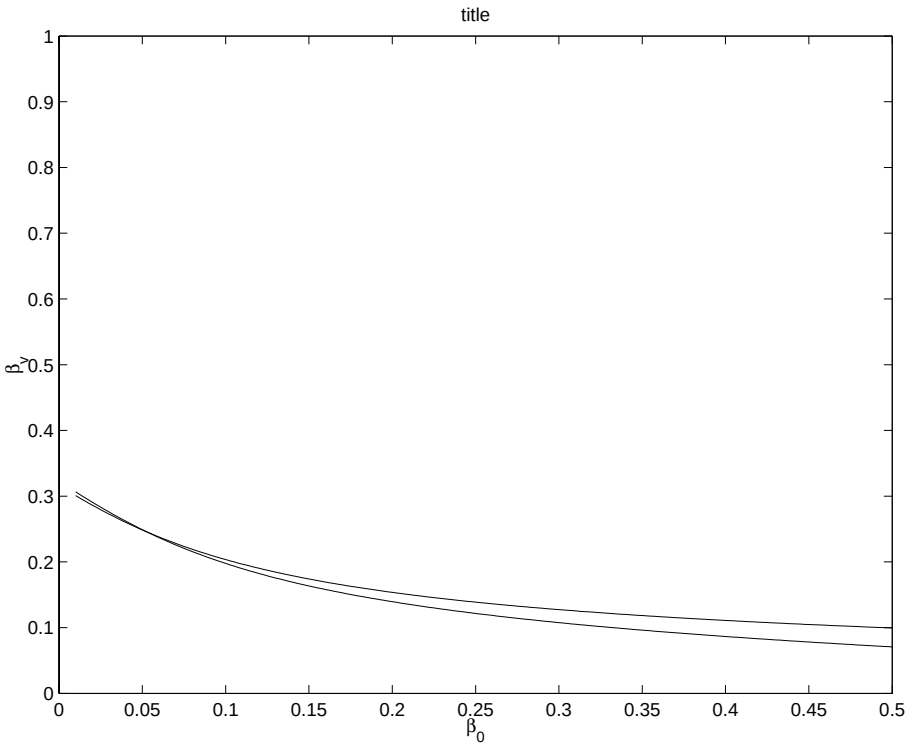

FIG. 6. *This shows the curve for $\beta_v(\beta_0)$ determined by the condition $Z_2 = 0$ ($\alpha_0 = \alpha_v = \gamma_v = 0$, $\gamma_0 = .1$). This gives the lower limit on the value of β_v. The upper curve is found by numerically solving the full set of linearized differential equations. The lower curve is found by using the high frequency approximation. Note that by the time we see significant disagreement between the numerical and asymptotic results, $\beta_v > .5$, which is clearly out of the range of applicability of the high frequency approximation.*

7. Finding real configurations. We will not propose any specific configurations of magnets in this paper. However, we would at least like to explain how one can theoretically find configurations of magnets that yield stable equilibria. We will illustrate the procedure for the case where the only time varying term is B_v and the steady coupling term B_0 is set to zero.

We assume that the top has several systems of axisymmetric multipoles that are, in general, displaced from the center of mass of the top. We assume that each system of magnets on the top can be approximated as a linear combination of dipoles, quadrapoles, and octapoles. It should be pointed out that a ring of finite thickness can be well approximated as a dipole plus an axisymmetric octopole.

We assume that the steady fields are produced by one or more axisymmetric rings of axially magnetized material. These rings in the base can either be approximated as infinitesimally thin rings that have a prescribed magnetization per unit length P_0, or they can be considered as rings of finite thickness that have a prescribed magnetization per unit volume. If we approximate them as being infinitesimally thin, then to actually build such a ring, we prescribe a magnetization per unit volume M_0 and a cross sectional area S for the ring such that SM_0 is equal to P_0.

We assume that the alternating fields are produced by one or more loops of wires that are carrying sinusoidally oscillating currents.

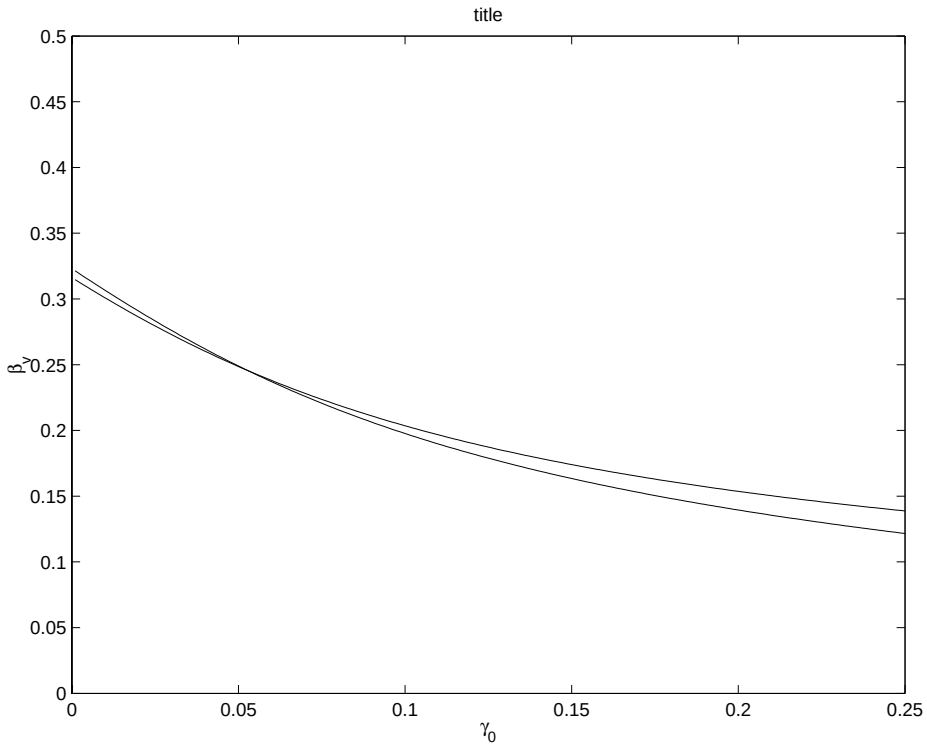

FIG. 7. *This shows the curve for $\beta_v(\gamma_0)$ (for $\alpha_0 = \alpha_v = \gamma_v = 0$ and $\beta_v = .05$) determined by the condition $Z_2 = 0$. This gives the lower limit on the value of β_v. The upper curve (for large values of γ_0) is found by numerically solving the full set of linearized differential equations. The lower curve is found by using the high frequency approximation. Note that the agreement between the numerical and asymptotic results is excellent provided $\gamma_0 < .1$. Beyond this point, the agreement is still quite good, even though we are pushing the limits of the high frequency approximation.*

For a given configuration of magnets it is a straightforward (though tedious) exercise to compute the parameters A, B, C, and L (the lift). We have, in fact, carried out this procedure, but we will just briefly outline it here.

All of the dynamical parameters can be computed if we know the first few terms of the magnetic potential about the equilibrium position of any magnet on the top. In order to find the multidimensional Taylor series, it is only necessary to have the Taylor series on the axis of symmetry. This is because for an axisymmetric field the Taylor series on the axis is sufficient to generate all of the terms in the spherical harmonic expansion of the field. For axisymmetric rings and coils, the Taylor series of the potential on the axis of symmetry is easily computed. This is a very brief outline of how one can compute the dynamical coefficients for quite complicated systems of magnets on the base and the top.

This means that the forward problem of determining whether a given configuration is stable or not can be solved. For a given configuration we can compute both the steady and periodically varying dynamical constants and the lift. If the time varying component of the lift is not zero, or the steady lift term does not balance the force of gravity, then we do not have a good configuration. Assuming these hold, we can compute both the steady and time varying components of the dimensionless

parameters α, β, and γ and use Floquet theory to determine if the configuration is, in fact, stable.

If we could use arbitrarily large values of the magnetization per unit volume M_0, we could easily find configurations of magnets that give stable equilibrium. In order to do this, we could specify the magnets on the top and the positions of four rings in the base. For the given mass and moments of inertia of the top, we determine values of A_0, B_0, C_0, L, and B_v that will give us a stable equilibrium when the center of mass is at the origin. We now determine magnetizations per unit length P_i that give us these values of the dynamical parameters. In order to do this we note that if A_i, B_i, C_i, and L_i are the dynamical parameters coming from the ith ring when it has unit magnetization per unit length, then the total value of A_0 is given by

$$A_0 = \sum P_i A_i.$$

Similar expressions hold for B_0, C_0, and L_0. We see that if we have four rings in the base, we have four linear equations in four unknowns for determining P_i. If the magnetization M_0 is large enough, we are guaranteed of being able to choose a reasonable cross sectional area S_i so that we could actually build the ith ring.

We can carry out a similar procedure for the time varying parameters. Once again, if the current in the coils can be as large as we need, and we have at least four coils, we can find systems of coils such that we get any specified values of the time varying dynamical parameters.

The procedure we have outlined is not quite the one we would want to actually carry out in practice. In practice we would want to wisely position both the magnets on the top and the magnets in the base. Furthermore, we would want to look at several different configurations and choose the one that was the most robust to imperfections in the placement or strengths of the magnets.

8. Conclusions. We believe we have given a comprehensive analysis of the stability of an axisymmetric body in a time periodic magnetic field. We have analyzed the most general configuration possible, taking into account the coupling between the rotational and translational modes of the top. Our analysis applies to any configuration of magnets, as long as they are axisymmetric, and the time varying parts of the field are sinusoidal, and all in phase.

Acknowledgments. The author would like to acknowledge Todd Christenson, Gene Aronson, and Khalid Bou-Rabee for many valuable discussions on this subject.

SPIN STABILIZED MAGNETIC LEVITATION OF HORIZONTAL ROTORS*

L. A. ROMERO†

Abstract. In this paper we present an analysis of a new configuration for achieving spin stabilized magnetic levitation. In the classical configuration, the rotor spins about a vertical axis; the spin stabilizes the lateral instability of the top in the magnetic field. In this new configuration the rotor spins about a horizontal axis; the spin stabilizes the axial instability of the top in the magnetic field.

Key words. Levitron, stability, magnets

1. Introduction. Earnshaw's theorem [9] implies that it is impossible to achieve stable static magnetic levitation in a static magnetic field. However, the discovery of the Levitron™ [7] has shown that it is in fact possible for a spinning top to be in stable equilibrium in a static magnetic field. We refer to this as spin stabilized magnetic levitation. There have been numerous papers analyzing spin stabilized magnetic levitation [1], [2], [6], [10], [5]. In this paper we extend these results by considering the case of a rotor that spins about a horizontal axis. Although no such device has yet been built, a program is currently under way to build one. A sketch of what such a device might look like is given in Figures 1 and 2. As with the classical Levitron™, we anticipate that there will be a high degree of sensitivity in such a device, so that it may take an adept experimentalist to build one. For this reason we believe that it is worth presenting the theory even though there is as yet no experimental justification.

Classically, spin stabilized magnetic levitation devices are axisymmetric. In principle we could achieve a horizontally spinning device using systems of magnets that have no symmetry properties at all. However, we choose to consider systems that have enough symmetry so that equilibrium of forces and torques is guaranteed in all directions except for the vertical. One such situation (depicted in Figure 1) is the following:

- The base magnets have reflectional symmetry about the planes $y = 0$ and $x = 0$.
- The rotor is axisymmetric and has reflectional symmetry about its midplane.
- The rotor is placed with its center of mass at $(0, 0, z_0)$ and its axis of symmetry pointing in the direction $(1, 0, 0)$.

We will show that due to the symmetry of this configuration, there are no forces in the y and x direction when the rotor is placed symmetrically in the field. Similarly,

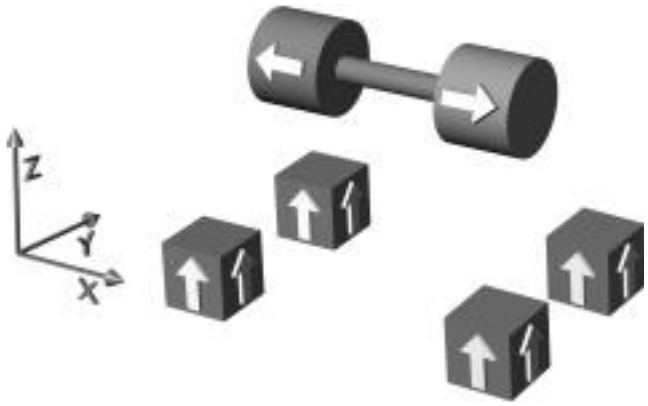

FIG. 1. *This shows a sketch of what a horizontal spin stabilized magnetic levitation device might look like. This particular configuration has an axisymmetric rotor with a system of magnets that has reflectional symmetry about its midplane. The magnets in the base have reflectional symmetry about the planes* $y = 0$ *and* $x = 0$.

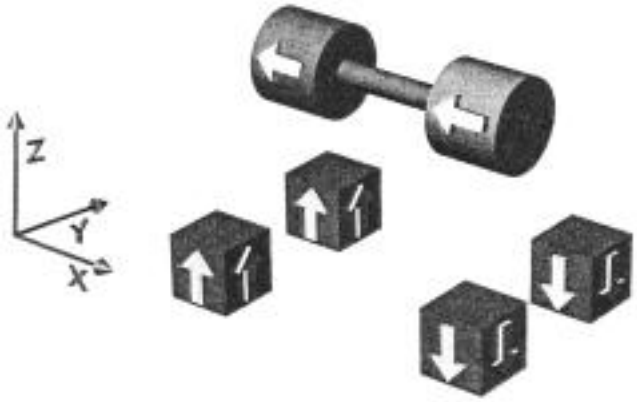

FIG. 2. *This is a schematic of a second type of symmetry for achieving horizontal spin stabilized magnetic levitation. This particular configuration has an axisymmetric rotor with a system of magnets that is antisymmetric about its midplane. The magnets in the base have reflectional symmetry about the plane* $y = 0$ *and are antisymmetric about the plane* $x = 0$.

there are no torques in any direction. Equilibrium in the z direction can be obtained by adjusting the height or weight of the rotor.

A similar situation (depicted in Figure 2) exists when the base magnets are antisymmetric about the plane $x = 0$, and the magnets on the rotor are antisymmetric with respect to reflections about the midplane of the rotor.

Earnshaw's theorem implies that this equilibrium position must be unstable if the rotor is not spinning. When we analyze the stability of a spinning rotor in such a configuration, we find that the equations for perturbations in the y and z directions decouple from the perturbations in the axial (x) direction and from the angular perturbations. This implies that it is not possible for spinning to stabilize the perturbations in the y and z directions. If we are going to stabilize this configuration by spinning the rotor, the rotor must be unstable to perturbations in the axial direction (in the absence of spin). In certain situations we can stabilize the perturbations in

the axial direction by spinning the rotor. As with the vertically spinning systems, there is an upper and lower spin rate for stable equilibrium.

We would like to emphasize that for spin stabilized magnetic levitation of a vertically spinning rotor in an axisymmetric field it is not possible to stabilize the axial direction by spinning. This means that in the absence of spin, the system is stable axially, and unstable laterally. This is exactly the opposite of horizontal spin stabilized systems that we discuss in this paper.

We now give an outline of the rest of this paper. In section 2 we discuss the symmetry properties of these configurations. In section 3 we show that these properties imply that when the rotor is placed symmetrically in the field, all of the forces and torques vanish except for the force in the vertical direction. In section 4 we derive the equations governing the linear stability of the equilibrium. In section 5 we give simple necessary conditions for stability, a simple stability condition similar to the adiabatic approximation made in [1], and a quartic equation that can be solved to determine the upper and lower spin rates. In section 6 we discuss how to compute the dynamical parameters in the linear stability equations for a given configuration of magnets. In section 7 we discuss how to find configurations of magnets that have the desired stability properties. We give our conclusions in section 8.

2. Symmetry properties. We assume that the rotor and its magnets are axisymmetric, that in equilibrium it is aligned with its axis of symmetry in the x direction, and that it spins about the x axis. In equilibrium its center of mass is at $\underline{x} = (0, 0, z_0)$. We consider two different situations:

- Systems where the supporting magnets produce a potential that is antisymmetric with respect to a reflection about the plane $x = 0$ and symmetric with respect to a reflection about the plane $y = 0$. In this case we assume that the magnets on the rotor are antisymmetric with respect to reflections about the midplane.
- Systems where the supporting magnets produce a potential that is symmetric with respect to reflections about the planes $x = 0$ and $y = 0$. In this case we assume that the magnets on the rotor are symmetric with respect to a reflection about the midplane.

We will show that in both of these situations when the center of mass of the rotor is at $y = 0$, $x = 0$ and the axis of symmetry of the rotor is aligned in the x direction, we are guaranteed of having no forces in the y or x direction and no torques on the rotor. By suitably adjusting the weight of the rotor, or the strengths of the magnets, we can make it so that the force in the z direction balances the force of gravity, which we assume points in the z direction.

The first of these symmetries can be constructed by building a rotor with two dipoles on the axis of symmetry, symmetrically located about the midplane, and both pointing in the same direction along the axis of symmetry. In this case a system of supporting magnets having the proper symmetry could consist of magnets in a plane $z =$ constant all pointing in the z direction. In this case any supporting magnet at (x_0, y_0, z_0) would have companion magnets at $(\pm x_0, \pm y_0, z_0)$. The dipole at $(x_0, -y_0, z_0)$ would be in the same direction as the first dipole, and the dipoles at $(-x_0, \pm y_0, z_0)$ would be in the opposite direction. This is just one example of how to achieve this symmetry. More generally we could have the magnets in the base have the dipoles pointing in arbitrary directions as long as their companion magnets have been appropriately reflected.

The second of these symmetries can be constructed by building a rotor with two dipoles on the axis of symmetry, symmetrically placed about the midplane, and pointing in opposite directions along the axis of symmetry. In this case a system of supporting magnets having the proper symmetry could consist of magnets in a plane $z =$ constant all pointing in the z direction. In this case any supporting magnet at (x_0, y_0, z_0) would have companion magnets at $(\pm x_0, \pm y_0, z_0)$. All of the magnets would have their dipoles pointing in the same direction. Once again, this is just one way of achieving systems with this symmetry.

Since the rotor is axisymmetric, the energy of the rotor in an arbitrary magnetic field can be written as

$$Energy = U(\underline{x}, \underline{d}),$$

where $\underline{x} = (x, y, z)$ is the center of mass of the rotor and $\underline{d} = (d_x, d_y, d_z)$ is a unit vector pointing in the direction of the axis of symmetry. The energy satisfies

$$\nabla_x^2 U = 0,$$

where ∇_x^2 is the Laplacian with respect to the variable $\underline{x}$.

The energy of systems where the potential is antisymmetric with respect to reflections about the x axis satisfy the following symmetry properties:

$$U(x, y, z, d_x, d_y, d_z) = U(-x, y, z, d_x, -d_y, -d_z), \tag{1a}$$

$$U(x, y, z, d_x, d_y, d_z) = U(x, -y, z, d_x, -d_y, d_z), \tag{1b}$$

$$U(x, y, z, d_x, d_y, d_z) = -U(x, y, z, -d_x, -d_y, -d_z). \tag{1c}$$

Systems where the potential is symmetric with respect to reflections about the x axis satisfy the identical symmetry properties.

2.1. Examples illustrating the symmetry properties. These symmetry properties become clearer if we consider special cases of such systems. Suppose we have a rotor that has two equal dipoles on the axis of symmetry, each pointing in the direction of the axis of symmetry. We suppose that the magnets are placed symmetrically a distance $\delta/2$ from the center of mass. When the rotor gets displaced and rotated, one of the dipoles will be located at $\underline{x}_+ = \underline{x} + \delta/2\underline{d}$ and the other one at $\underline{x}_- = \underline{x} - \delta/2\underline{d}$. The dipole moment of the magnet at $\underline{x}_+$ will be $\underline{m}_+ = m_0\underline{d}$, and the moment at $\underline{x}_-$ will be $\underline{m}_- = m_0\underline{d}$. The total magnetic energy of the rotor will be

$$U(\underline{x}, \underline{d}) = m_0 \left(\underline{d} \cdot \nabla\phi(\underline{x}_+) + \underline{d} \cdot \nabla\phi(\underline{x}_-) \right).$$

It can be verified that assuming that $\phi(x, y, z)$ is symmetric in y and antisymmetric in x, the energy $U(\underline{x}, \underline{d})$ satisfies the symmetry properties stated in (1). Note that these symmetry properties would hold for more complicated systems, such as rotors having more than one pair of symmetrically placed dipoles or symmetrically placed rings.

An example illustrating the second sort of symmetry comes from a rotor that once again has symmetrically placed dipoles, but in this case the dipoles are equal and opposite to each other. In this case the energy can be written as

$$U(\underline{x},\underline{d}) = m_0\left(\underline{d}\cdot\nabla\phi(\underline{x}_+) - \underline{d}\nabla\phi(\underline{x}_-)\right).$$

Once again it can be verified that if $\phi(x,y,z)$ is symmetric in x and y, then the energy satisfies the symmetry properties (1).

3. Equilibrium. We will now show that assuming our system of magnets and the rotor satisfy the symmetry properties of the last section, we can easily find equilibrium configurations. In particular, we will show that if we place the rotor so that its center of mass is at $(0,0,z_0)$ and its axis of symmetry is pointing in the direction $(1,0,0)$, then there is no torque on the rotor and the only component of force is in the z direction. By appropriately adjusting the weight or the strengths of the magnets, we can make it so that the force of gravity balances this magnetic force.

The force and torque on the rotor can be computed using

$$\underline{F} = -\nabla_x U(\underline{x},\underline{d}),$$

$$\underline{\tau} = -\underline{d}\times\nabla_d U(\underline{x},\underline{d}).$$

Here, ∇_x is the gradient with respect to $\underline{x}$, and ∇_d is the gradient with respect to $\underline{d}$.

We can derive these formulas using generalizations of the derivations for the force and torque on a point dipole [3]. The principle of virtual work tells us that the change in energy when we move the center of mass without rotating it is given by

$$\delta U = -\underline{F}\cdot\delta\underline{r},$$

where $\underline{F}$ is the force on the top and $\delta\underline{r}$ is the change in the center of mass of the top. Since we can write $\delta U = \nabla_x U\cdot\delta\underline{r}$, we see that

$$\nabla_x U\cdot\delta\underline{r} = -\underline{F}\cdot\delta\underline{r}.$$

Since this must hold for all values of $\delta\underline{r}$, we see that

$$\underline{F} = -\nabla_x U.$$

On the other hand, if we rotate the body about the axis $\underline{e}$ by an angle $\delta\theta$, then the principle of virtual work requires that the change in energy is given by

$$\delta U = -\tau\cdot\underline{e}\delta\theta.$$

When we rotate the body about $\underline{e}$ by $\delta\theta$, the change in the unit vector $\underline{d}$ is given by $\delta\underline{d} = \underline{e}\times\underline{d}\delta\theta$. We see that

$$\delta U = \nabla_d U\cdot\delta\underline{d} = \nabla_d U\cdot(\underline{e}\times\underline{d})\delta\theta = (\underline{d}\times\nabla_d U)\cdot\underline{e}\delta\theta.$$

When we equate this expression to the expression from the principle of virtual work, and require that it hold for all values of $\underline{e}$ and θ, we get

$$\underline{\tau} = -\underline{d}\times\nabla_d U.$$

The symmetry properties of the energy show that for both the antisymmetric and symmetric cases we have

$$U(x,0,z,1,0,0) = U(-x,0,z,1,0,0),$$

$$U(0,y,z,1,0,0) = U(0,-y,z,1,0,0).$$

When the rotor is placed symmetrically in the field, the forces F_x and F_y in the x and y directions satisfy

$$F_x(0,0,z,1,0,0) = -\frac{\partial U(0,0,z,1,0,0)}{\partial x} = 0,$$

$$F_y(0,0,z,1,0,0) = -\frac{\partial U(0,0,z,1,0,0)}{\partial y} = 0.$$

To show that the torques vanish, we substitute $x = 0$, $y = 0$ into the symmetry property $U(x,y,z,d_x,d_y,d_z) = U(-x,y,z,d_x,-d_y,-d_z)$ to get

$$U(0,0,z,1,d_y,d_z) = U(0,0,z,1,-d_y,-d_z).$$

This shows that the energy at $x = y = 0$ is an even function of d_y and d_z, and hence the derivatives with respect to d_y and d_z must vanish. Using the fact that $\underline{\tau} = -\underline{d} \times \nabla_d U$ we see that

$$\underline{\tau}(0,0,z,1,0,0) = 0.$$

We see that based on the symmetry of our problem, if we put the rotor so that its center of mass is at $x = y = 0$, so that its axis of symmetry is pointing in the x direction, there will be no forces in the x or y directions and no torques at all.

4. The linearized equations of motion. We describe the kinematics of the rotor in a manner similar to [6]. In our discussion the coordinates (x,y,z) refer to coordinates fixed in space. We assume that the body is axisymmetric with a moment of inertia of I_3 about the axis of symmetry and I_1 about the other two principal axes.

We will orient the body by rotating about the z axis by θ, the y axis by ϕ, and then the x axis by ψ. If the rotor is spinning about the x axis with angular velocity ω_0, then a small perturbation to this state gives approximate angular momenta L_y and L_z of

$$L_y = I_1\dot{\phi} + I_3\omega_0\theta,$$

$$L_z = I_1\dot{\theta} - I_3\omega_0\phi.$$

These formulas can be derived rigorously by expressing the angular momenta in terms of the angular variables and their derivatives and then assuming that θ and ϕ are small. They also have a simple intuitive interpretation. The expression for L_y consists of two terms. The first term is the angular momentum we would get if ω_0 were zero and the body were spinning about the y axis. The second term is the angular momentum we would get if the body kept spinning about the axis of symmetry with angular velocity ω_0 but was slowly tilted by an amount θ about the

x axis. As a result of this tilting some of the angular momentum that was initially in the x direction gets projected onto the y axis. A similar interpretation can be given for the angular momentum in the z direction.

The linearized equations of motion can be written

$$m\ddot{x} = F_x(x, y, z, \theta, \phi),$$

$$m\ddot{y} = F_y(x, y, z, \theta, \phi),$$

$$m\ddot{z} = F_z(x, y, z, \theta, \phi),$$

$$I_1\ddot{\theta} - I_3\omega_0\dot{\phi} = \tau_z(x, y, z, \theta, \phi),$$

$$I_1\ddot{\phi} + I_3\omega_0\dot{\theta} = \tau_y(x, y, z, \theta, \phi).$$

In the linear approximation, the forces and torques are linear functions of (x, y, z, θ, ϕ). In the linear approximation, we have

$$\underline{d} = (d_x, d_y, d_z) = (1, \theta, -\phi).$$

Also, in the linear approximation the forces and torques are derivable from a quadratic potential. The symmetry properties show that many of the terms in the quadratic potential must be missing. For example, the fact that $U(x, y, z, d_x, d_y, d_z) = U(x, -y, z, d_x, -d_y, d_z)$ implies that the Taylor series expansion of the energy cannot have any terms of the form xy, yz, $y\phi$, $x\theta$, $z\theta$, or $\theta\phi$. The fact that $U(x, y, z, d_x, d_y, d_z) = U(-x, y, z, d_x, -d_y, -d_z)$ implies that we cannot have any terms of the form xy, xz, $y\phi$, $y\theta$, $z\phi$, or $z\theta$. Using these symmetry properties we conclude that the linearized equations of motion are of the form

$$m\ddot{y} + A_1 y = 0,$$

$$m\ddot{z} + A_2 z = 0,$$

$$m\ddot{x} - Ax - B\phi = 0,$$

$$I_1\ddot{\theta} - I_3\omega_0\dot{\phi} - C_1\theta = 0,$$

$$I_1\ddot{\phi} + I_3\omega_0\dot{\theta} - C_2\phi - Bx = 0.$$

Note that the equations for y and z decouple from the other equations. This means that in order to have stability we must have A_1 and A_2 both be bigger than zero. In other words, the system would have to be stable to lateral perturbations if the rotor were not spinning. The fact that $\nabla_x^2 U = 0$ (or Earnshaw's theorem) implies that $A_1 + A_2 = A$, and hence the system must be unstable to axial perturbations if the rotor is not spinning.

4.1. The dimensionless equations of motion. We now introduce the dimensionless variables

$$x = \sqrt{I_1/mA}\hat{x},$$

$$t = \sqrt{m/A}\hat{t}.$$

In terms of these dimensionless variables, we get the dimensionless equations (after dropping the hats for notational convenience)

$$\ddot{x} - x - \sqrt{\Lambda}\phi = 0, \tag{2a}$$

$$\ddot{\theta} - \Omega\dot{\phi} - \Gamma_1\theta = 0, \tag{2b}$$

$$\ddot{\phi} + \Omega\dot{\theta} - \Gamma_2\phi - \sqrt{\Lambda}x = 0. \tag{2c}$$

Here we have introduced the dimensionless parameters

$$\Gamma_1 = \frac{mC_1}{I_1 A}, \tag{3}$$

$$\Gamma_2 = \frac{mC_2}{I_1 A}, \tag{4}$$

$$\Lambda = \frac{mB^2}{I_1 A^2}, \tag{5}$$

$$\Omega^2 = \frac{I_3^2\omega_0^2 m}{I_1^2 A}. \tag{6}$$

5. The stability of the equilibrium. We now analyze the stability of the system of equations (2). In the first subsection we compute the characteristic equation governing the stability and give some necessary conditions for stability. In the next subsection we carry out an analysis assuming that Γ_1, Γ_2, and Λ are all large. This analysis gives very simple criteria for stability, and we believe it is similar to making the adiabatic assumption as in [1] (see the discussion in Appendix B). In the next subsection we use results from the theory of polynomials that allow us to predict the exact upper and lower spin rates by solving a quartic equation. This is similar to the procedure carried out in [2] in the analysis of the vertically spinning Levitron™.

5.1. The characteristic equation and its properties. We now assume solutions of the form $e^{i\sigma t}$ in the linearized dynamical equations. This leads to the characteristic polynomial

$$(\sigma^2 + 1)\left((\sigma^2 + \Gamma_1)(\sigma^2 + \Gamma_2) - \Omega^2\sigma^2\right) - \Lambda(\sigma^2 + \Gamma_1) = 0. \tag{7}$$

Expanding this we get

$$G(q,\Omega) = q^3 + q^2\left(1+\Gamma_1+\Gamma_2-\Omega^2\right) + q\left(\Gamma_1+\Gamma_2+\Gamma_1\Gamma_2-\Lambda-\Omega^2\right) + \Gamma_1\Gamma_2 - \Lambda\Gamma_1 = 0, \tag{8}$$

where

$$q = \sigma^2.$$

In order for our system to be stable, all of the roots of (8) must be real and positive. Descarte's theorem [8] implies that for an equation of the form $z^3 + px^2 + qz + r = 0$ to have all real and positive roots, it is necessary that $p < 0$, $q > 0$, and $r < 0$. Furthermore, if all of the roots are real, then these conditions are both necessary and sufficient conditions for all of the roots to be positive. This, along with the condition that $A > 0$ gives us several necessary conditions for stability:

$$\Omega^2 > 1 + \Gamma_1 + \Gamma_2, \tag{9a}$$

$$\Gamma_1 + \Gamma_2 + \Gamma_1\Gamma_2 - \Lambda > \Omega^2, \tag{9b}$$

$$\Lambda\Gamma_1 > \Gamma_1\Gamma_2, \tag{9c}$$

$$\Lambda > 0. \tag{9d}$$

The last of these conditions is the requirement that $A > 0$ in order to have lateral stability. As with the vertically spinning spin stabilized magnetic levitation, we see that there is both an upper and a lower value of Ω for stability.

5.2. Asymptotic stability analysis. We can gain considerable insight into these equations by analyzing their behavior when Γ_1, Γ_2, and Λ are all large. We claim that this is similar to making the adiabatic approximation as in [1]. We elaborate on the connection between our asymptotic stability criterion and the adiabatic approximation in Appendix B.

To be precise, we assume that

$$\Lambda = \lambda/\epsilon^2,$$

$$\Gamma_1 = \gamma_1/\epsilon^2,$$

$$\Gamma_2 = \gamma_2/\epsilon^2,$$

$$\Omega = \omega/\epsilon.$$

If we substitute these expression into (7), multiply by ϵ^4, and set $\epsilon = 0$, we get the equation

$$\sigma^2\gamma_2 = \lambda - \gamma_2.$$

This gives us two roots of our 6th order polynomial. We can have only positive solutions to σ^2 if

$$\gamma_2 > 0$$

and

$$\lambda - \gamma_2 > 0.$$

We get the four other roots by assuming that $\sigma = \hat{\sigma}/\epsilon$. This gives us the equation

$$\hat{\sigma}^2 \left((\hat{\sigma}^2 + \gamma_1)(\hat{\sigma}^2 + \gamma_2) - \Omega^2 \hat{\sigma}^2\right) = 0.$$

After factoring out $\hat{\sigma}^2$ this is the characteristic equation for a spinning rotor in a harmonic potential:

$$(\hat{\sigma}^2 + \gamma_1)(\hat{\sigma}^2 + \gamma_2) - \Omega^2 \hat{\sigma}^2 = 0.$$

A simple application of the quadratic equation shows that in order for this to have all real roots we must have $\Gamma_1 \Gamma_2 > 0$, which along with our previous stability criterion requires that both Γ_1 and Γ_2 be positive. We must also have $\Gamma_1 + \Gamma_2 - \Omega^2 < 0$ and $(\Gamma_1 + \Gamma_2 - \Omega^2)^2 - 4\Gamma_1\Gamma_2 > 0$. By choosing Ω large enough we can satisfy all of these criterion.

We can give a simple interpretation of these stability conditions. If Γ_1, Γ_2, and Λ are large, and the system is not responding too quickly, (2b) implies that

$$\Gamma_2 \phi + \sqrt{\Lambda} x = 0.$$

This is equivalent to saying that as the rotor moves around, it orients itself so that there is no torque on it. This gives us the expression $\phi = -\sqrt{\Lambda} x/\Gamma_2$. When we substitute this into (2a) we get

$$\ddot{x} + x(\Lambda/\Gamma_2 - 1) = 0.$$

We see that this will be a stable harmonic oscillator provided $\Lambda > \Gamma_2$. This is the first of our asymptotic stability conditions. In order to satisfy this condition we must have $\Gamma_2 > 0$, which implies that the rotor would want to flip over in the absence of spin.

Our second criterion is the condition that we are spinning the rotor fast enough that it will not flip over. To analyze this mode we have assumed that σ is of order $1/\epsilon$. In this case, (2a) implies that x is small compared to ϕ. This means that we can solve (2b) and (2c) ignoring x. This is equivalent to considering a rotor spinning in a potential where we ignore the translational energy. This leads to our second stability condition.

The asymptotic analysis we just presented does not predict the existence of an upper spin rate. In order to predict the upper spin rate we once again assume that Γ_1, Γ_2, and Λ are large. We will see that if Ω is too large, the eigenvalues that are of order one will eventually become unstable.

Assuming that σ is order unity and that all of our parameters are large, our eigensystem can be approximated by

$$(\sigma^2 + 1)x + \sqrt{\Lambda}\phi = 0,$$

$$-i\Omega\sigma\phi - \Gamma_1\theta = 0,$$

$$i\sigma\Omega\theta - \Gamma_2\phi - \sqrt{\Lambda}x = 0.$$

These equations are obtained by ignoring the second derivatives of θ and ϕ in (2). They are an extension of the results we have already presented where we ignore all derivatives of these quantities.

These equations imply that

$$(\sigma^2 + 1)\left(\Gamma_1\Gamma_2 - \Omega^2\sigma^2\right) - \Gamma_1\Lambda = 0.$$

This is a quadratic equation for σ^2. We need this equation to have positive real roots. In order for this to be so we must have $\Gamma_1\Gamma_2 > \Omega^2$, $\Lambda > \Gamma_2$, and

$$(z - \Gamma_2)^2 - 4z(\Lambda - \Gamma_2) > 0,$$

where

$$z = \frac{\Omega^2}{\Gamma_1}.$$

This gives a quadratic equation in z whose roots are

$$z_\pm = 2\Lambda - \Gamma_2 \pm \sqrt{(2\Lambda - \Gamma_2)^2 - \Gamma_2^2}. \tag{10}$$

In order to have real roots we must have $z < z_-$ or $z > z_+$. However, if $z > z_+$, we cannot satisfy the other inequalities necessary to have positive real roots. It follows that we must have $\frac{\Omega^2}{\Gamma_1} < z_-$. This is the asymptotic prediction for the upper spin rate. Note that assuming that Γ_1, Γ_2, and Λ are of order $1/\epsilon^2$, this upper limit on the spin rate is also of order $1/\epsilon^2$. On the other hand, the lower spin rate is on the order of $1/\epsilon$. It follows that as we make ϵ smaller, the ratio of the upper and lower spin rate can be made very large.

We will now collect all of our results from the asymptotic stability analysis. Assuming that $\Gamma_1 = \gamma_1/\epsilon$, $\Gamma_2 = \gamma_2/\epsilon$, $\Lambda = \lambda/\epsilon^2$, we see that necessary and sufficient conditions for stability are

$$\Gamma_1 > 0, \tag{11a}$$

$$\Gamma_2 > 0, \tag{11b}$$

$$\Lambda > \Gamma_2, \tag{11c}$$

$$\Omega^2 > \Gamma_1 + \Gamma_2 + 2\sqrt{\Gamma_1\Gamma_2}, \tag{11d}$$

$$\Omega^2 < \Gamma_1 z_-. \tag{11e}$$

Once again we emphasize that if Γ_1, Γ_2, and Λ are order $1/\epsilon^2$, then the lower spin rate is of order $1/\epsilon$ and the upper spin rate is of order $1/\epsilon^2$. This shows that as we keep the ratios of Γ_1, Γ_2, and Λ fixed but let the quantities get large, the ratio of the upper and lower spin rates also gets large.

In the next section we will show that by finding the roots of a fourth order polynomial we can find exact expressions (that must be computed numerically) for the upper and lower spin rates. Figure 3 shows that our asymptotic estimates for the upper and lower spin rates are in fact quite accurate even for moderate values of Γ_1, Γ_2, and Λ.

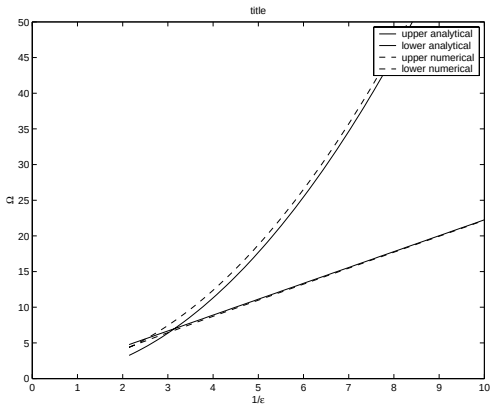

FIG. 3. *This shows the curves for the upper and lower limits on the spin rate* Ω *as a function of* ϵ*, where* $\Gamma_1 = \hat{\Gamma_1}/\epsilon^2$*,* $\Gamma_2 = \hat{\Gamma_2}/\epsilon^2$*, and* $\Lambda = \hat{\Lambda}/\epsilon^2$ *(*$\hat{\Gamma}_1 = 1.$*,* $\hat{\Gamma}_2 = 1.5$*,* $\hat{\Lambda} = 2$*). This figure compares the numerical bounds on the upper and lower spin rate to the asymptotic approximation to these bounds given in* (11).

5.3. Upper and lower bounds on the spin rate. We will now find an exact expression for determining the upper and lower spin rates. In order to do this we first note that in a region of stability we must have $\Lambda\Gamma_1 > \Gamma_1\Gamma_2$. This is both one of our asymptotic stability criteria and one of the conclusions in (9) from Descarte's theorem. This implies that we can never have roots of our characteristic equation $G(q, \Omega) = 0$ (defined in (8)) with $q = 0$. It follows that if Ω_0 is at a boundary of a stability region, then $G(q, \Omega_0)$ must have all real roots, but a small perturbation of Ω will yield complex roots. This implies that on a boundary of a region of stability there must be a root q_0 such that both $G(q_0, \Omega)$ and $G'(q_0, \Omega) = \frac{dG}{dq}$ vanish.

We will write

$$G(q, \Omega) = q^3 + (D - \Omega^2)q^2 + (E - \Omega^2)q + F,$$

where

$$D = 1 + \Gamma_1 + \Gamma_2,$$

$$E = \Gamma_1 + \Gamma_2 + \Gamma_1\Gamma_2 - \Lambda,$$

$$F = \Gamma_1\Gamma_2 - \Lambda\Gamma_1.$$

On the boundary of stability G and G' must have a common root or, equivalently, G must have a multiple root. A necessary and sufficient condition that a polynomial have multiple roots is that the discriminant vanishes. This is equivalent to saying that the resultant of G and G' vanishes. Suppose we have two polynomials

$$g(x) = g_0x^3 + g_1x^2 + g_2x + g_3$$

and

$$h(x) = h_0x^2 + h_1x + h_2.$$

A necessary and sufficient condition that these two polynomials have roots in common is that the resultant vanish. The resultant is the determinant of the following matrix:

$$R = \begin{pmatrix} g_3 & g_2 & g_1 & g_0 & 0 \\ 0 & g_3 & g_2 & g_1 & g_0 \\ h_2 & h_1 & h_0 & 0 & 0 \\ 0 & h_2 & h_1 & h_0 & 0 \\ 0 & 0 & h_2 & h_1 & h_0 \end{pmatrix}.$$

When we substitute the polynomials G and G' into this expression we find (with the help of Mathematica) that the resultant can be written as

$$\psi(\Omega) = \Omega^8 + K_6\Omega^6 + K_4\Omega^4 + K_2\Omega^2 + K_0, \tag{12}$$

$$K_6 = (32 - 16D - 16E + 32F)/8,$$

$$K_4 = (8D^2 - 96E + 32DE + 8E^2 + 144F - 96DF)/8,$$

$$K_2 = (-16D^2E + 96E^2 - 16DE^2 - 144DF + 96D^2F - 144EF)/8,$$

$$K_0 = (8D^2E^2 - 32E^3 - 32D^3F + 144DEF - 216F^2)/8.$$

This is a quartic polynomial in Ω^2. We have shown that on the boundary of stability $\psi(\Omega)$ must vanish, but we have not shown that any root of this equation will yield a value of Ω that is on the boundary of stability. In Appendix A we apply the theory of Hankel matrices [4] to show that the polynomial $G(q, \Omega)$ will have all real roots if and only if $\psi(\Omega) < 0$. We will further show that $G(q, \Omega)$ will have all positive real roots if and only if $\psi(\Omega) < 0$, and all of the inequalities in (9) are satisfied.

If we compute the roots of the polynomial $\psi(\Omega)$, we find that there are roots that do not satisfy the conditions in (9). If we limit ourselves to roots that satisfy the conditions in (9), we find that the roots of $\psi(\Omega)$ do in fact give the upper and lower limits on the spin rates. Figure 3 shows the numerically computed upper and lower spin rates and compares them to the previously derived asymptotic estimates.

6. Computing the dynamical constants. In this section we will explain how, for a given configuration of magnets on the rotor and in the base, one can compute the dynamical constants A_1, A_2, A, B, C_1, C_2, and B that are needed in order to compute the stability of the equilibrium. We also show how to compute the lift L.

For simplicity we will assume that the magnets on the rotor can be approximated by dipoles. We could extend this analysis so that the magnets on the rotor were approximated as a combination of axisymmetric dipoles, quadrapoles, and octopoles. However, that would make some of our results quite tedious. We will begin by analyzing the case where the rotor is in an antisymmetric potential. That is, we assume that the potential $f(x, y, z)$ satisfies

$$f(x, y, z) = f(x, -y, z),$$

$$f(x, y, z) = -f(-x, y, z).$$

We will assume that when the rotor is oriented in its equilibrium position, it has dipoles at $(\pm\delta/2, 0, z_0)$, both of magnitude M_R and both pointing in the direction $(1, 0, 0)$. We will compute the dynamical constants when we have just a single pair of dipoles on the rotor. If we have more than one pair, then the constants can be computed by summing over all the different pairs.

In order to compute the force and torques on the rotor as it gets displaced from its equilibrium, we need to compute the Taylor series (up to the cubic terms) of the magnetic potential about the points $(\pm\delta/2, 0, z_0)$:

$$f(x+\delta/2, y, z_0+z) = \alpha_0 x+\alpha_1 z+\beta_0 xz+\frac{1}{2}\beta_1(2x^2-y^2-z^2)+\frac{1}{2}\beta_2(y^2-z^2)+\Gamma_+(x,y,z),$$

$$\begin{aligned}\Gamma_+(x, y, z_0 + z) = {} & \gamma_0\left(x^3/3 - xy^2/2 - xz^2/2\right) + \gamma_1\left(xy^2/2 - xz^2/2\right) \\ & + \gamma_2(z^3/6 - x^2z/2) + \gamma_3(z^3/6 - y^2z/2) + \cdots.\end{aligned}$$

Around the point $(-\delta/2, 0, z_0)$ we have the Taylor series expansion

$$f(x-\delta/2, y, z_0+z) = \alpha_0 x-\alpha_1 z+\beta_0 xz-\frac{1}{2}\beta_1(2x^2-y^2-z^2)-\frac{1}{2}\beta_2(y^2-z^2)+\Gamma_+(x,y,z),$$

$$\begin{aligned}\Gamma_-(x, y, z_0 + z) = {} & \gamma_0\left(x^3/3 - xy^2/2 - xz^2/2\right) + \gamma_1\left(xy^2/2 - xz^2/2\right) \\ & - \gamma_2(z^3/6 - x^2z/2) - \gamma_3(z^3/6 - y^2z/2) + \cdots.\end{aligned}$$

This is the most general form for the Taylor series (up to cubic terms) of a function $f(x, y, z)$ that is antisymmetric in x and symmetric in y.

The dynamical constants can be computed with the following procedure, which is easily implemented in Mathematica.

- Compute the orientation of the dipole which for small angles is approximated by $\underline{d} = (1 - \theta^2/2 - \phi^2/2, \theta, -\phi)$.
- Set the position of the right dipole to $\underline{x}_+ = \underline{x}_{cm} + \underline{d}\delta/2$ and the dipole moment to $\underline{m}_+ = M_R\underline{d}$.
- Set the position of the left dipole to $\underline{x}_- = \underline{x}_{cm} - \underline{d}\delta/2$ and the dipole moment to $\underline{m}_- = M_R\underline{d}$.
- Compute the magnetic energy $U = \underline{m}_+ \cdot \nabla f(\underline{x}_+) + \underline{m}_- \cdot \nabla f(\underline{x}_-)$.
- Calculate the force $\underline{F} = -\nabla U$.
- Compute the torques, which in the linear approximation can be written as $\tau_z = -\frac{\partial U}{\partial \theta}$ and $\tau_y = -\frac{\partial U}{\partial \phi}$.
- Set $\underline{x}_{cm} = \epsilon(\hat{x}, \hat{y}, \hat{z})$, $\theta = \epsilon\hat{\theta}$, and $\phi = \epsilon\hat{\phi}$.
- Expand the forces and torques up to order ϵ.
- Set the lift L equal to the zeroth order term in the force F_z.
- Set $-A_1$ to the term in F_y that is linearly proportional to y, $-A_2$ to the term in F_z that is linearly proportional to z, and A equal to the term in F_x that is linearly proportional to x. Set B equal to the term in F_x that is linearly proportional to ϕ.
- Set C_1 and C_2 to the terms in τ_z and τ_y that are linearly proportional to θ and ϕ, respectively.

After carrying out this procedure, we arrive at the following expressions for the dynamical constants:

$$L = -2m_0\beta_0, \tag{13}$$

$$A_1 = 2m_0(\gamma_1 - \gamma_0), \tag{14}$$

$$A_2 = -2m_0(\gamma_0 + \gamma_1), \tag{15}$$

$$A = -4m_0\gamma_0, \tag{16}$$

$$B = m_0(2\beta_0 - \gamma_2 d), \tag{17}$$

$$C_1 = 2m_0\alpha_0 + m_0 d\,(4\beta_1 - 2\beta_2) + m_0 d^2(\gamma_0 - \gamma_1)/2, \tag{18}$$

$$C_2 = 2m_0\alpha_0 + m_0 d\,(4\beta_1 + 2\beta_2) + m_0 d^2(\gamma_1 + \gamma_0)/2. \tag{19}$$

If we have several systems of dipoles on the rotor, the dynamical constants are the sum of the dynamical constants for each system of magnets.

It should be pointed out that we get the exact same formula for systems with potentials that are symmetric with respect to reflections about the x axis and whose rotor magnets are also symmetric with respect to reflections about the midplane. In this case we get the same expansion of the field about the point $(\delta/2, 0, z_0)$, but the expansion about $(-\delta/2, 0, 0)$ is exactly opposite that given for the antisymmetric case. If we define our fields using the Taylor expansion about $(\delta/2, 0, 0)$, the dynamical constants have the exact same values as those given for the antisymmetric case.

7. Finding realizable configurations. So far we have discussed how to compute the dynamical constants assuming that we have a given configuration of magnets. We now discuss how one could in fact find a given configuration of magnets that gives the desired dynamical constants. We will present at least one way of going about this for systems that have potentials with reflectional symmetry about the x axis.

We will suppose that the base magnets consist of $4N$ dipoles all pointing in the z direction. The positions of the dipoles are given by

$$\underline{p}_i = (\pm a_i, \pm b_i, c_i), \qquad i = 1, N,$$

and the magnetizations are given by

$$M_i = (0, 0, d_i), \qquad i = 1, N.$$

For each value of i (four symmetrically placed magnets in the base), we can compute the dynamical constants $A_1(i)$, $A_2(i)$, $A(i)$, $B(i)$, $C_1(i)$, $C_2(i)$, and $L(i)$ for $d_i = 1$. The values of the dynamical parameters for the whole system can be obtained by summing over the different sets of magnets multiplied by the strengths of the dipoles. For example,

$$L = \sum_{i=1}^{N} d_i L(i).$$

If we have 6 or more systems of magnets, we can choose the strengths d_i so that we get any desired values of the parameters that we want. This means that in theory we can specify the desired values of A_1, A_2, L, Γ_1, Γ_2, and Λ that we would like, and

thus the values of A, B, C_1, and C_2 that we would like. Once these are known we can determine the dipole strengths of the magnets that give these parameters.

The procedure we have outlined is meant to show that these configurations can be realized in theory. It does not address how to actually find a good configuration. For example, it is possible that the configurations could be very sensitive to small variations in the positions of the magnets or to their strengths. We have carried out some more elaborate forms of this procedure in order to find possible configurations. We do not feel that it is appropriate to give any specific examples until we have analyzed them for their robustness.

8. Conclusions. We have theoretically demonstrated the existence of what is a distinctly different form of spin stabilized magnetic levitation. As with the traditional set up for spin stabilized magnetic levitation, we expect that most configurations will have a high degree of sensitivity to the placement of the magnets. For this reason we believe that it is necessary to come up with some measure of the robustness of a configuration, and to search over a large class of configurations trying to find robust configurations.

Although nobody has ever used spin stabilized magnetic levitation for anything other than a scientific toy, it is possible that this principle could in fact have practical applications. It is hoped that by showing that the classical vertical configuration is not the only possibility, this paper may contribute to the eventual practical use of this principle.

Appendix A. We have shown that on the boundary of a region of stability, we must have $\psi(\Omega) = 0$. In this appendix we will show that the condition $\psi < 0$ is a necessary and sufficient condition for $G(q, \Omega)$ to have all real roots. To do this we apply the method of Hankel matrices presented in [4]. In [4], this method is explained for arbitrary polynomials; to simplify the notation, we will limit ourselves to cubic polynomials. Suppose we have a cubic polynomial of the form

$$a_0 x^3 - a_1 x^2 + a_2 x - a_3.$$

The theory we present allows us to determine the number of real roots of this polynomial.

Suppose (x_0, x_1, x_2) are the roots to this polynomial (which of course we do not know). We begin by computing the Newton polynomials

$$\sigma_k = x_0^k + x_1^k + x_2^k.$$

Even though we do not know the roots to the polynomial, we can compute the Newton polynomials. This follows from the fact that the σ_k's are symmetric polynomials in the variables x_i and hence can be written as polynomials in the coefficients a_j of our polynomial. The theory of how to do this is explained in [8]. We will need to know σ_k up to $k = 4$. We can compute these recursively using

$$\sigma_0 = 3,$$

$$\sigma_1 = a_1,$$

$$\sigma_2 = a_1 \sigma_1 - 2a_2,$$

$$\sigma_3 = a_1\sigma_2 - a_2\sigma_1 + 3a_3,$$

$$\sigma_4 = a_1\sigma_3 - a_2\sigma_2 + a_3\sigma_1.$$

We now form the Hankel matrix:

$$H = \begin{pmatrix} \sigma_0 & \sigma_1 & \sigma_2 \\ \sigma_1 & \sigma_2 & \sigma_3 \\ \sigma_2 & \sigma_3 & \sigma_4 \end{pmatrix}.$$

The number of real roots is equal to $3-2V$, where V is the number of sign changes in the sequence D_0, D_1, D_2, where $D_0 = \sigma_0$,

$$D_1 = \det \begin{pmatrix} \sigma_0 & \sigma_1 \\ \sigma_1 & \sigma_2 \end{pmatrix},$$

and

$$D_2 = \det(H).$$

In order to have all real roots all of the determinants D_0, D_1, and D_2 must be positive. However, for a cubic polynomial, it is not possible to have D_1 be negative while D_2 is positive. This can be shown algebraically, or by noting that if this were the case, then our formula for the number of real roots would yield a negative number of real roots, which is impossible. It follows that a necessary and sufficient condition for our cubic polynomial to have all real roots is that the determinant D_2 is positive.

When we substitute the coefficients from the polynomial $G(q, \Omega)$ into the general expression for D_2, this yields the polynomial $-\psi(\Omega)$. It follows that a necessary and sufficient condition for $G(q, \Omega)$ to have all real roots is that $\psi(\Omega) < 0$.

If a polynomial has all real roots, then a necessary and sufficient condition that all of its roots are positive is that its coefficients alternate in sign. This implies that our system will be stable if and only if both $\psi(\Omega) < 0$ and all of the inequalities in (9) are satisfied.

Appendix B. In this appendix we will discuss the relation between the asymptotic stability analysis made in section 5.2 (assuming Γ_1, Γ_2, and Ω are large) and the adiabatic approximation presented for the vertically spinning Levitron™ in [1]. We will show that these two approaches give the same results, and we will show that the conditions that the dimensionless parameters Γ_1, Γ_2, and Ω be large are equivalent to the conditions stated in [1] for the adiabatic approximation to hold.

Since the adiabatic approximation in [1] is worked out for a point dipole, we will now restrict our analysis to that case. That is, we will assume that our rotor only has a single dipole pointing in the direction of the axis of symmetry. This is an example of one of our two symmetries that we discussed in section 2.

We begin by applying the adiabatic approximation to our problem. Following [1], we argue that assuming that the top is fast we can make the approximation

$$\underline{L} = I_3\omega_0\underline{d}.$$

Here ω_0 is the initial spin of the top, and $\underline{d}$ is the unit vector in the direction of the axis of symmetry. This assumes that we can ignore all components of the angular momentum except for the component about the axis of symmetry of the top. As

pointed out in [1] the fast top approximation holds as long as the spin of the top is large compared to the precession rate of the top.

Under this fast top approximation, the equation for the change in angular momentum can be written as

$$\omega_0 I_3 \dot{\underline{d}} = -m_0 \underline{d} \times \underline{B}.$$

Here m_0 is the dipole moment of the dipole on the rotor. In the adiabatic approximation this equation implies that the quantity

$$\mu_{ad} = \underline{d} \cdot \underline{B} / \mid \underline{B} \mid$$

stays constant. In order for this approximation to hold it is necessary that the rate of change of the vector $\underline{d}$ be large compared to the rate of change of the quantity $\underline{d} \cdot \underline{B} / \mid \underline{B} \mid$.

In the adiabatic approximation, the magnetic energy of the rotor can be written as

$$U_{mag} = -\mu_{ad} \mid \underline{B} \mid .$$

This is equivalent to saying that the top is moving in an effective potential that depends only on the center of mass of the top, not on its orientation. This effective potential is computed by using the magnetic energy $U(\underline{x}, \underline{d}) = -m_0 \underline{d} \cdot \underline{B}$ of the top but using the fact that $\underline{d}$ is always pointing in the direction of the magnetic field. This is clearly equivalent to the approximation made in section 5.2 where we assumed that the rotor always orients itself so that there is no torque on it and then used this to get an effective simple harmonic oscillator for the x component.

We would now like to show that the criteria that our parameters Γ_1, Γ_2, and Ω be large are equivalent to the criteria given in [1] for the adiabatic approximation to hold. We will discuss the scaling properties using the dimensionless linearized equations of motion 2. The precession frequency of the top is given by

$$\Omega_{prec} = \sqrt{\frac{\Gamma_1 \Gamma_2}{\Omega^2}}. \tag{20}$$

This precession frequency is obtained by ignoring the second derivatives of θ and ϕ and the term $\sqrt{\Lambda}$ in (2). The fast top assumption assumes that this precession rate is small compared to the spin rate of the top. This can be written as

$$\Omega \gg \Omega_{prec}. \tag{21}$$

Another condition stated in [1] for the adiabatic approximation to hold is that the bobbing frequency of the top be much less than the precession rate of the top. Physically this means that as the top moves around it can quickly orient itself so that it is aligned with the direction of the magnetic field. In our case the bobbing frequency of the top is obtained by ignoring the term $\sqrt{\Lambda}\phi$ in (2). Since we have made our equations dimensionless by this bobbing frequency, our bobbing frequency is unity. The condition that the precession rate is fast compared to the bobbing frequency can be written as

$$\Omega_{prec} \gg 1. \tag{22}$$

In order to satisfy both of the conditions in (21) and (22), it is clearly necessary that $\Omega \gg 1$. The condition that $\Omega_{prec} \gg 1$ implies that

$$\Gamma_1 \Gamma_2 \gg \Omega^4.$$

Since Ω is large, this implies that the product $\Gamma_1 \Gamma_2$ must be large. In the case of an axisymmetric top considered in [1], this would imply that $\Gamma_1 = \Gamma_2 \gg 1$.
